$$\begin{aligned}\|\mathcal{L}_h f\|^2_{L_h^2, \Delta_h^{\boldsymbol{\mu},0}} &\le \sup\{|\varrho(\mu, \omega_x)|^2,\ |\omega_x \Delta x| \le L/2,\ 0 \le \mu \le 1\} \\ &\quad \times \frac{\Delta v}{|2R|} \sum_{j=0}^{N_v} \sum_{|\boldsymbol{\omega}| \le \mathbf{N}/2} \sum_{|\omega_v'| \le N_v/2} \widehat{f}(\boldsymbol{\omega}) \overline{\widehat{f}(\omega_x, \omega_v')} e^{i(k_v(\omega_v) - k_v(\omega_v'))v_j} \\ &\le \sup\{|\varrho(\mu, \omega_x)|^2,\ |\omega_x \Delta x| \le L/2,\ 0 \le \mu \le 1\} \sum_{|\boldsymbol{\omega}| \le \mathbf{N}/2} |\widehat{f}(\boldsymbol{\omega})|^2 \\ &\le \sup\{|\varrho(\mu, \omega_x)|^2,\ |\omega_x \Delta x| \le L/2,\ 0 \le \mu \le 1\} \|f\|^2_{L_h^2}.\end{aligned}$$

Without loss of generality we can suppose that $L = 2\pi$, $\Delta x = h$, $\xi = \omega_x h$, and $\zeta = \mu - 1/2$. Then we have to prove that

$$\sup\{|\varrho(\zeta,\xi)|,\ |\xi| \leq \pi,\ |\zeta| \leq 1/2\} \leq 1,$$

with

$$\varrho(\zeta,\xi) = \sum_{k=-3/2}^{3/2} \ell_k^3(\zeta) e^{ik\xi},$$

and

$$\ell_k^3(\zeta) = \prod_{\substack{i=-3/2 \\ i\neq k}}^{3/2} \frac{(\zeta - i)}{(k-i)},\ k \in \{-3/2, -1/2, 1/2, 3/2\}.$$

If we set $\theta = 1 - \cos(\xi)$, after some algebra we find

$$|\varrho(\zeta,\theta)|^2 = 1 - \left(\left(\frac{1}{2}\right)^2 - \zeta^2\right)\left(\left(\frac{3}{2}\right)^2 - \zeta^2\right)\theta^2\left[3 + 2\theta\left(\left(\frac{1}{2}\right)^2 - \zeta^2\right)\right]\Big/9,$$

which ends the proof of the estimate (4.2).

Proceeding in the same way, we get

$$\begin{aligned}
\|\tau_{\boldsymbol{\mu},0}\mathcal{H}_h f\|_{L_h^2(\Omega)} &= \|\mathcal{H}_h f\|_{L_h^2,\Delta_h^{\boldsymbol{\mu},0}} \\
&\leq \sup\{|\mathcal{Q}(\mu,\xi,h)|,\ 0 \leq \mu \leq 1,\ |\xi| \leq \pi\}\left(\sum_{|\boldsymbol{\omega}|\leq \mathbf{N}/2} |\widehat{f}(\boldsymbol{\omega})|^2\right)^{1/2} \\
&\leq \sup\{|\mathcal{Q}(\mu,\xi,h)|,\ 0 \leq \mu \leq 1,\ |\xi| \leq \pi\}\|f\|_{L_h^2},
\end{aligned}$$

where

$$\mathcal{Q}(\mu,\xi,h) = \phi_0(\mu h) + \phi_1(\mu h)e^{i\xi} + i\frac{\xi}{h}\psi_0(\mu h) + i\frac{\xi}{h}\psi_1(\mu h)e^{i\xi}$$

and

$$\begin{aligned}
\|\tau_{\boldsymbol{\mu},0}\partial_x\mathcal{H}_h f\|_{L_h^2(\Omega)} &= \|\partial_x\mathcal{H}_h f\|_{L_h^2,\Delta_h^{\boldsymbol{\mu},0}} \\
&\leq \sup\{|\widehat{\mathcal{Q}}(\mu,\xi,h)|,\ 0 \leq \mu \leq 1,\ |\xi| \leq \pi\}\left(\sum_{|\boldsymbol{\omega}|\leq \mathbf{N}/2} |\omega_x|^2|\widehat{f}(\boldsymbol{\omega})|^2\right)^{1/2} \\
&\leq \sup\{|\widehat{\mathcal{Q}}(\mu,\xi,h)|,\ 0 \leq \mu \leq 1,\ |\xi| \leq \pi\}\|\partial_x f\|_{L_h^2},
\end{aligned}$$

where

$$|\widehat{\mathcal{Q}}(\mu,\xi,h)| \cdot |\xi| = |\dot{\mathcal{Q}}(\mu,\xi,h)|,$$

with

$$\dot{\mathcal{Q}}(\mu,\xi,h) = \dot{\phi_0}(\mu h) + \dot{\phi_1}(\mu h)e^{i\xi} + i\xi\dot{\psi_0}(\mu h) + i\xi\dot{\psi_1}(\mu h)e^{i\xi}.$$

Therefore we have to prove that

$$\mathcal{Q}_{\sup} = \sup\{|\mathcal{Q}(\mu,\xi,h)|,\ 0 \le \mu \le 1,\ |\xi| \le \pi\} \le 1$$

and

$$\widehat{\mathcal{Q}}_{\sup} = \sup\{|\widehat{\mathcal{Q}}(\mu,\xi,h)|,\ 0 \le \mu \le 1,\ |\xi| \le \pi\} \le 1.$$

Let us start by $\mathcal{Q}_{\sup}$. First we note that $\mathcal{Q}$ can be rewritten as

$$\mathcal{Q}(\mu,\xi,h) = \mathcal{Q}(\mu,\xi) = (1+2\mu)(1-\mu)^2 + (3-2\mu)\mu^2 e^{i\xi} + i\xi\mu(1-\mu)^2 + i\xi\mu^2(\mu-1)e^{i\xi}.$$

If we take the modulus of $\mathcal{Q}$, after some algebra we get

$$\begin{aligned}|\mathcal{Q}(\mu,\xi)|^2 = 1 - \mu^2(1-\mu)^2 \big\{&2(1-\cos\xi)(3-2\mu)(1+2\mu) - \xi^2(4\mu^2-4\mu+1)\\ &- 2\,\xi^2(1-\cos\xi)\mu(1-\mu) - 2\xi\sin\xi(-4\mu^2+4\mu+1)\big\}.\end{aligned}$$

If we make the change of variable $\nu = \mu - 1/2$, after some algebra we get

$$|\mathcal{Q}(\nu,\xi)|^2 = 1 - \left(\left(\frac{1}{2}\right)^2 - \nu^2\right)^2 \sigma(\nu,\xi),$$

where

$$\sigma(\nu,\xi) = -\nu^2(4\sin(\xi/2) - 2\xi\sin(\xi/2))^2 + 8(1-\cos\xi) - \frac{1}{2}\xi^2(1-\cos\xi) - 4\xi\sin^2\xi.$$

In order to show that $\mathcal{Q}_{\sup} \le 1$ it is enough to show that $\sigma \ge 0$ for all $|\xi| \le \pi,\ |\nu| \le 1/2$. Since σ is a polynomial of degree two with respect to the variable ν whose term in ν^2 is negative, we have to prove that for all ξ such that $|\xi| \le \pi$ the roots of σ are real and of modulus greater than or equal to $1/2$. The roots of σ are

$$\nu_r(\xi) = \pm\sqrt{\frac{-8(1-\cos\xi) + \frac{1}{2}\xi^2(1-\cos\xi) + 4\xi\sin^2\xi}{-\nu^2(4\sin(\xi/2) - 2\xi\sin(\xi/2))^2}}.$$

We must prove that $|\nu_r(\xi)|^2 > \frac{1}{4}$, which is equivalent to showing that $g(\xi) \le 0$, where $g(\xi) = -6(1-\cos\xi) + \xi^2 + 2\xi\sin\xi$. In order to prove that g is negative on $[-\pi,\pi]$, we study the function g. For that we need to derive g three times.

Now, let us show that $\widehat{Q}_{sup} \le 1$. In order to prove that $\widehat{Q}_{sup} \le 1$ it is enough to prove that

$$|\dot{\mathcal{Q}}(\mu,\xi,h)|^2 - |\xi|^2 \le 0 \quad \forall |\xi| \le \pi,\ 0 \le \mu \le 1.$$

In fact $\dot{\mathcal{Q}}(\mu,\xi,h)$ can be recast as

$$\begin{aligned}\dot{\mathcal{Q}}(\mu,\xi,h) &= \dot{\mathcal{Q}}(\mu,\xi)\\ &= 6\mu(\mu-1) + 6\mu(1-\mu)e^{i\xi} + i\xi(1-\mu)(1-3\mu) + i\xi\mu(3\mu-2)e^{i\xi}.\end{aligned}$$

Taking the modulus of $\dot{\mathcal{Q}}$, we get

$$\begin{aligned}|\dot{\mathcal{Q}}(\mu,\xi)|^2 = {}&72\mu^2(1-\mu)^2(1-\cos\xi) + 12\xi\sin\xi\mu(1-\mu)(6\mu^2-6\mu+1)\\ &+ \xi^2(1-6\mu+6\mu^2)^2 + 2(\cos\xi-1)\xi^2\mu(1-\mu)(1-3\mu)(3\mu-2).\end{aligned}$$

If we make the change of variable $\nu = \mu - 1/2$, after some algebra we find

$$|\dot{\mathcal{Q}}(\nu,\xi)|^2 - |\xi|^2 = a(\xi)\nu^4 + b(\xi)\nu^2 + c(\xi),$$

where

$$a(\xi) = \left[12\sin\frac{\xi}{2} - 6\xi\cos\frac{\xi}{2}\right]^2, \quad c(\xi) = \left[\left(3\sin\frac{\xi}{2} - \frac{\xi}{2}\cos\frac{\xi}{2}\right)^2 - \xi^2\right],$$

$$b(\xi) = \left[-2\left(6\sin\frac{\xi}{2} - 2\xi\cos\frac{\xi}{2}\right)^2 + \xi^2\left(1 + \sin^2\frac{\xi}{2}\right)\right].$$

First we note that $|\dot{\mathcal{Q}}(\pm\frac{1}{2},\xi)|^2 - |\xi|^2 = 0$. Consequently $|\dot{\mathcal{Q}}|^2 - |\xi|^2$ can be rewritten as follows:

$$|\dot{\mathcal{Q}}(\nu,\xi)|^2 - |\xi|^2 = \left(\nu^2 - \left(\frac{1}{2}\right)^2\right)(\nu^2 + \beta(\xi)).$$

Let us show that β is positive. By following a classical result on the equation of second degree we get $\beta(\xi) = -4a(\xi)c(\xi)$. It remains to prove that $c(\xi) \leq 0$ for all $|\xi| \leq \pi$. We have $c(\xi) = l_1(\xi)l_2(\xi)$, where

$$l_1(\xi) = 3\sin\frac{\xi}{2} - \frac{\xi}{2}\cos\frac{\xi}{2} - \xi, \quad l_2(\xi) = 3\sin\frac{\xi}{2} - \frac{\xi}{2}\cos\frac{\xi}{2} + \xi.$$

In order to prove that $l_1 l_2$ is negative on $[-\pi,\pi]$, we study the sign of l_1 and l_2. For that we need to compute the derivatives of l_1 and l_2 until the order three. Finally we get

$$|\dot{\mathcal{Q}}(\nu,\xi)|^2 - |\xi|^2 \leq 0, \quad |\nu| \leq 1/2, \quad |\xi| \leq \pi,$$

which ends the proof of the proposition. □

We continue with the following lemma, which gives an estimate of the term (I2).

LEMMA 4.5. *Let $f \in \mathscr{C}_b\left(0,T;\mathscr{C}_b^2(\Omega)\right)$, and then*

$$\begin{aligned}
&\left\|\mathcal{T}_1^{0,0}\circ\mathcal{T}_2^{0,0}\circ\mathcal{T}_1^{0,0}f(t^n) - \mathcal{T}_1^{0,0}\circ\widehat{\mathcal{T}}_2^{0,0}\circ\mathcal{T}_1^{0,0}f(t^n)\right\|_{L_h^2(\Omega)} \\
&\qquad \leq C\Delta t\left(\Delta t^2 + \Delta x^4 + \Delta v^4 + \Delta x^5 + \Delta x\Delta v^4 + \left\|\left(\mathcal{T}_1^{0,0} - \widetilde{\mathcal{T}}_1^{0,0}\right)f(t^n)\right\|_{L_h^2(\Omega)}\right. \\
&\qquad + \left\|\widetilde{\mathcal{T}}_1^{0,0}\left(f(t^n) - f_h(t^n)\right)\right\|_{L_h^2(\Omega)} + \Delta x\left\|\left(\mathcal{T}_1^{1,0} - \widetilde{\mathcal{T}}_1^{1,0}\right)f(t^n)\right\|_{L_h^2(\Omega)} \\
&\qquad \left. + \Delta x\left\|\widetilde{\mathcal{T}}_1^{1,0}\left(f(t^n) - f_h(t^n)\right)\right\|_{L_h^2(\Omega)}\right)
\end{aligned}$$

and

$$\begin{aligned}
&\left\|\nabla\mathcal{T}_1\circ\nabla\mathcal{T}_2\circ\nabla\mathcal{T}_1 f(t^n) - \nabla\mathcal{T}_1\circ\nabla\widehat{\mathcal{T}}_2\circ\nabla\mathcal{T}_1 f(t^n)\right\|_{\mathbb{L}_h^2(\Omega)} \\
&\leq C\Delta t\left(\Delta t^2 + \Delta x^3 + \Delta x^{-1}\Delta v^4 + \Delta v^4 + \Delta x^4 + \Delta x^{-1}\left\|\left(\mathcal{T}_1^{0,0} - \widetilde{\mathcal{T}}_1^{0,0}\right)f(t^n)\right\|_{L_h^2(\Omega)}\right. \\
&+\Delta x^{-1}\left\|\widetilde{\mathcal{T}}_1^{0,0}\left(f(t^n) - f_h(t^n)\right)\right\|_{L_h^2(\Omega)} + \left\|\left(\mathcal{T}_1^{1,0} - \widetilde{\mathcal{T}}_1^{1,0}\right)f(t^n)\right\|_{L_h^2(\Omega)} \\
&\left. + \left\|\widetilde{\mathcal{T}}_1^{1,0}\left(f(t^n) - f_h(t^n)\right)\right\|_{L_h^2(\Omega)}\right).
\end{aligned}$$

Proof. We introduce the characteristic curves $(\widehat{X}(t^n), \widehat{V}(t^n))$ defined by

$$\widehat{X}(t^n, x, v) = x - v\Delta t - \frac{1}{2}\Delta t^2 E_h^{n+1/2}(x - v\Delta t/2),$$
$$\widehat{V}(t^n, x, v) = v - \Delta t E_h^{n+1/2}(x - v\Delta t/2).$$

As has been done in Lemma 4.3 we have

$$\left(\mathcal{T}_1^{0,0} \circ \widehat{\mathcal{T}}_2^{0,0} \circ \mathcal{T}_1^{0,0} f(t^n)\right)_{k,l} = f\left(t^n, \widehat{X}_{k,l}(t^n), \widehat{V}_{k,l}(t^n)\right),$$
$$\left(\nabla\mathcal{T}_1 \circ \nabla\widehat{\mathcal{T}}_2 \circ \nabla\mathcal{T}_1 f(t^n)\right)_{k,l} = \nabla\left(\widehat{X}_{k,l}(t^n), \widehat{V}_{k,l}(t^n)\right) \nabla f\left(t^n, \widehat{X}_{k,l}(t^n), \widehat{V}_{k,l}(t^n)\right).$$

As a consequence we can write

(4.8)
$$\left|\left(\mathcal{T}_1^{0,0} \circ \mathcal{T}_2^{0,0} \circ \mathcal{T}_1^{0,0} f(t^n)\right)_{k,l} - \left(\mathcal{T}_1^{0,0} \circ \widehat{\mathcal{T}}_2^{0,0} \circ \mathcal{T}_1^{0,0} f(t^n)\right)_{k,l}\right|$$
$$\leq \left|\nabla f\left(\widetilde{X}_{k,l}(t^n), \widetilde{V}_{k,l}(t^n)\right)\right| \cdot \left(\left|\widehat{X}_{k,l}(t^n) - \widetilde{X}_{k,l}(t^n)\right| + \left|\widehat{V}_{k,l}(t^n) - \widetilde{V}_{k,l}(t^n)\right|\right)$$

and

(4.9)
$$\left|(\nabla\mathcal{T}_1 \circ \nabla\mathcal{T}_2 \circ \nabla\mathcal{T}_1 f(t^n))_{k,l} - \left(\nabla\mathcal{T}_1 \circ \nabla\widehat{\mathcal{T}}_2 \circ \nabla\mathcal{T}_1 f(t^n)\right)_{k,l}\right|$$
$$\leq \left|\nabla f\left(\widetilde{X}_{k,l}(t^n), \widetilde{V}_{k,l}(t^n)\right)\right| \cdot \left(\left|\nabla\widehat{X}_{k,l}(t^n) - \nabla\widetilde{X}_{k,l}(t^n)\right| + \left|\nabla\widehat{V}_{k,l}(t^n) - \nabla\widetilde{V}_{k,l}(t^n)\right|\right)$$
$$+ \left(\left|\widehat{X}_{k,l}(t^n) - \widetilde{X}_{k,l}(t^n)\right| + \left|\widehat{V}_{k,l}(t^n) - \widetilde{V}_{k,l}(t^n)\right|\right)$$
$$\cdot \left|\nabla^2 f\left(\widetilde{X}_{k,l}(t^n), \widetilde{V}_{k,l}(t^n)\right)\right| \cdot \left|\nabla\left(\widetilde{X}_{k,l}(t^n), \widetilde{V}_{k,l}(t^n)\right)\right|.$$

Let us prove a bound for $|\partial^\alpha \widehat{X}_{k,l}(t^n) - \partial^\alpha \widetilde{X}_{k,l}(t^n)|$ and $|\partial^\alpha \widehat{V}_{k,l}(t^n) - \partial^\alpha \widetilde{V}_{k,l}(t^n)|$. By using the definition of $(\widetilde{X}(t^n), \widetilde{V}(t^n))$ and of $(\widehat{X}(t^n), \widehat{V}(t^n))$ we get

(4.10)
$$\left(\left|\widehat{X}_{k,l}(t^n) - \widetilde{X}_{k,l}(t^n)\right| + \left|\widehat{V}_{k,l}(t^n) - \widetilde{V}_{k,l}(t^n)\right|\right)$$
$$\leq C\Delta t \left\|E_h^{n+1/2}(x) - E(t^{n+1/2}, x)\right\|_{L^\infty}$$
$$\leq C\Delta t \left(\left\|E(t^{n+1/2}, x) - \widetilde{E}(t^{n+1/2}, x)\right\|_{L^\infty} + \left\|\widetilde{E}(t^{n+1/2}, x) - E_h^{n+1/2}(x)\right\|_{L^\infty}\right),$$

$$\left(\left|\partial_x\widehat{X}_{k,l}(t^n) - \partial_x\widetilde{X}_{k,l}(t^n)\right| + \left|\partial_x\widehat{V}_{k,l}(t^n) - \partial_x\widetilde{V}_{k,l}(t^n)\right|\right)$$
$$\leq C\Delta t \left(\left\|\partial_x E(t^{n+1/2}, x) - \partial_x\widetilde{E}(t^{n+1/2}, x)\right\|_{L^\infty}\right.$$
$$\left. + \left\|\partial_x\widetilde{E}(t^{n+1/2}, x) - \partial_x E_h^{n+1/2}(x)\right\|_{L^\infty}\right) \tag{4.11}$$

and

$$\left(\left|\partial_v\widehat{X}_{k,l}(t^n) - \partial_v\widetilde{X}_{k,l}(t^n)\right| + \left|\partial_v\widehat{V}_{k,l}(t^n) - \partial_v\widetilde{V}_{k,l}(t^n)\right|\right)$$
$$\leq C\Delta t^2 \left(\left\|\partial_x E(t^{n+1/2}, x) - \partial_x\widetilde{E}(t^{n+1/2}, x)\right\|_{L^\infty}\right.$$
$$\left. + \left\|\partial_x\widetilde{E}(t^{n+1/2}, x) - \partial_x E_h^{n+1/2}(x)\right\|_{L^\infty}\right), \tag{4.12}$$

where $\widetilde{E}(t^{n+1/2},x)$ and $\partial_x\widetilde{E}(t^{n+1/2},x)$ are solutions of the Poisson problems

$$(\widetilde{\mathrm{P}})\quad\begin{cases}\left(\dfrac{d}{dx}\widetilde{E}\right)(t^{n+1/2},x)=\displaystyle\int_v \mathcal{T}_1 f(t^n,x,v)dv-1=\int_v f(t^n,x-v\Delta t/2,v)dv-1,\\ \displaystyle\int_0^L \widetilde{E}(t^{n+1/2},x)dx=0\end{cases}$$

and

$$(\widetilde{\mathrm{P}}')\quad\begin{cases}\left(\dfrac{d}{dx}\left(\dfrac{d}{dx}\widetilde{E}\right)\right)(t^{n+1/2},x)=\displaystyle\int_v \mathcal{T}_1^{1,0} f(t^n,x,v)dv=\int_v \partial_x f(t^n,x-v\Delta t/2,v)dv,\\ \displaystyle\int_0^L \left(\frac{d}{dx}\widetilde{E}\right)(t^{n+1/2},x)dx=0.\end{cases}$$

First we give an estimate for $\|E(t^{n+1/2},x)-\widetilde{E}(t^{n+1/2},x)\|_{L^\infty}$ and for $\|\partial_x E(t^{n+1/2},x)-\partial_x\widetilde{E}(t^{n+1/2},x)\|_{L^\infty}$. By using the Vlasov equation we get that

$$\begin{aligned}\frac{f(t^{n+1/2},x,v)-f(t^n,x-v\Delta t/2,v)}{\Delta t/2}&=\partial_t f(t^{n+1/2},x,v)+v\partial_x f(t^{n+1/2},x,v)+\mathcal{O}(\Delta t)\\&=-E(t^{n+1/2},x)\partial_v f(t^{n+1/2},x,v)+\mathcal{O}(\Delta t),\end{aligned}$$

and it follows that

(4.13)
$$\begin{aligned}&\left\|E(t^{n+1/2})-\widetilde{E}(t^{n+1/2})\right\|_{L^\infty}\\&\quad=\left\|\int_0^L K(x,y)\left(\int_{-\infty}^{+\infty}[f(t^{n+1/2},y,v)-f(t^n,y-v\Delta t/2,v)]dv\right)dy\right\|_{L^\infty}\\&\quad\le C\Delta t^2.\end{aligned}$$

In the same manner, if we derive the Vlasov equation with respect to the variable x, we get

$$\begin{aligned}\frac{\partial_x f(t^{n+1/2},x,v)-\partial_x f(t^n,x-v\Delta t/2,v)}{\Delta t/2}&=-\partial_x E(t^{n+1/2},x)\partial_v f(t^{n+1/2},x,v)\\&\quad-E(t^{n+1/2},x)\partial_{vx} f(t^{n+1/2},x,v)+\mathcal{O}(\Delta t),\end{aligned}$$

and we find

(4.14)
$$\begin{aligned}&\left\|\partial_x E(t^{n+1/2})-\partial_x\widetilde{E}(t^{n+1/2})\right\|_{L^\infty}\\&\quad=\left\|\int_0^L K(x,y)\left(\int_{-\infty}^{+\infty}[\partial_x f(t^{n+1/2},y,v)-\partial_x f(t^n,y-v\Delta t/2,v)]dv\right)dy\right\|_{L^\infty}\\&\quad\le C\Delta t^2.\end{aligned}$$

Now we estimate the terms $\|E_h^{n+1/2}(x)-\widetilde{E}(t^{n+1/2},x)\|_{L^\infty}$ and $\|\partial_x E_h^{n+1/2}(x)-\partial_x\widetilde{E}(t^{n+1/2},x)\|_{L^\infty}$. Until the end of the proof the following notation is used:

$$\left\|\widetilde{E}(t^{n+1/2})-E_h^{n+1/2}\right\|_\infty=\max_k\left|\widetilde{E}(t^{n+1/2},x_k)-E_h^{n+1/2}(x_k)\right|,$$

$$\left|\widetilde{E}(t^{n+1/2}) - E_h^{n+1/2}\right|_{1,\infty} = \max_k \left|\partial_x \widetilde{E}(t^{n+1/2}, x_k) - \partial_x E_h^{n+1/2}(x_k)\right|,$$

and

$$\|\cdot\|_{1,\infty} = \|\cdot\|_\infty + |\cdot|_{1,\infty}.$$

Suppose that $x = x_k + \theta\Delta x$, with $0 \le \theta \le 1$, and then we get

$$\begin{aligned}
&\left|\widetilde{E}(t^{n+1/2}, x) - E_h^{n+1/2}(x)\right| \le \left|\widetilde{E}(t^{n+1/2}, x) - \phi_0(\theta\Delta x)\widetilde{E}(t^{n+1/2}, x_k)\right.\\
&\left. - \phi_1(\theta\Delta x)\widetilde{E}(t^{n+1/2}, x_{k+1}) - \psi_0(\theta\Delta x)\partial_x\widetilde{E}(t^{n+1/2}, x_k) - \psi_1(\theta\Delta x)\partial_x\widetilde{E}(t^{n+1/2}, x_{k+1})\right|\\
&+ \left|\phi_0(\theta\Delta x)\left(\widetilde{E}(t^{n+1/2}, x_k) - E_h^{n+1/2}(x_k)\right)\right.\\
&+ \phi_1(\theta\Delta x)\left(\widetilde{E}(t^{n+1/2}, x_{k+1}) - E_h^{n+1/2}(x_{k+1})\right)\\
&+\psi_0(\theta\Delta x)\left(\partial_x\widetilde{E}(t^{n+1/2}, x_k) - \partial_x E_h^{n+1/2}(x_k)\right)\\
&\left.+ \psi_1(\theta\Delta x)\left(\partial_x\widetilde{E}(t^{n+1/2}, x_{k+1}) - \partial_x E_h^{n+1/2}(x_{k+1})\right)\right|.
\end{aligned}$$

We deduce that

$$\begin{aligned}
\left\|\widetilde{E}(t^{n+1/2}) - E_h^{n+1/2}\right\|_{L^\infty} \le C\left(\Delta x^4 \left\|\widetilde{E}\right\|_{\mathscr{C}(0,T;\mathscr{C}^4([0,L]))} + \left\|\widetilde{E}(t^{n+1/2}) - E_h^{n+1/2}\right\|_\infty\right.\\
\left. + \Delta x\left|\widetilde{E}(t^{n+1/2}) - E_h^{n+1/2}\right|_{1,\infty}\right).
\end{aligned} \tag{4.15}$$

In the same way we show that

$$\begin{aligned}
\left\|\partial_x\widetilde{E}(t^{n+1/2}) - \partial_x E_h^{n+1/2}\right\|_{L^\infty} \le C\left(\Delta x^4 \left\|\widetilde{E}\right\|_{\mathscr{C}(0,T;\mathscr{C}^4([0,L]))}\right.\\
\left. + \Delta x^{-1}\left\|\widetilde{E}(t^{n+1/2}) - E_h^{n+1/2}\right\|_\infty + \left|\widetilde{E}(t^{n+1/2}) - E_h^{n+1/2}\right|_{1,\infty}\right).
\end{aligned} \tag{4.16}$$

Now we estimate the terms $\|\widetilde{E}(t^{n+1/2}) - E_h^{n+1/2}\|_\infty$ and $|\widetilde{E}(t^{n+1/2}) - E_h^{n+1/2}|_{1,\infty}$. We proceed as follows:

$$\begin{aligned}
&\frac{1}{12\Delta x}\left\{8\left(\widetilde{E}(t^{n+1/2}, x_{k+1}) - \widetilde{E}(t^{n+1/2}, x_{k-1})\right) - \left(\widetilde{E}(t^{n+1/2}, x_{k+2}) - \widetilde{E}(t^{n+1/2}, x_{k-2})\right)\right\}\\
&\qquad = \partial_x\widetilde{E}(t^{n+1/2}, x_k) + \mathcal{O}\left(\Delta x^4\right)\\
&\qquad = -1 + \int_v \mathcal{T}_1^{0,0} f(t^n, x_k, v)dv + \mathcal{O}\left(\Delta x^4\right)\\
&\qquad = -1 + \mathcal{O}\left(\Delta x^4\right) + \mathcal{O}\left(\Delta v^4\right)\\
&\qquad + \frac{\Delta v}{3}\left\{\left(\mathcal{T}_1^{0,0} f(t^n)\right)_{k,0} + \left(\mathcal{T}_1^{0,0} f(t^n)\right)_{k,N_v} + 4\sum_{l,\text{odd}}\left(\mathcal{T}_1^{0,0} f(t^n)\right)_{k,l}\right.\\
&\qquad\qquad \left. + 2\sum_{l,\text{even}}\left(\mathcal{T}_1^{0,0} f(t^n)\right)_{k,l}\right\}.
\end{aligned}$$

If we set $\delta E_k = \widetilde{E}(t^{n+1/2}, x_k) - E_h^{n+1/2}(x_k)$, we get

(4.17)
$$\begin{aligned}
&\frac{1}{12\Delta x}\left\{8\left(\delta E_{k+1} - \delta E_{k-1}\right) - \left(\delta E_{k+2} - \delta E_{k-2}\right)\right\} = \mathcal{O}\left(\Delta x^4\right) + \mathcal{O}\left(\Delta v^4\right) \\
&\quad + \frac{\Delta v}{3}\Bigg\{\left(\mathcal{T}_1^{0,0} f(t^n)\right)_{k,0} - \left(\widetilde{\mathcal{T}}_1^{0,0} f_h(t^n)\right)_{k,0} + \left(\mathcal{T}_1^{0,0} f(t^n)\right)_{k,N_v} - \left(\widetilde{\mathcal{T}}_1^{0,0} f_h(t^n)\right)_{k,N_v} \\
&\qquad + 4\sum_{l,\text{odd}}\left[\left(\mathcal{T}_1^{0,0} f(t^n)\right)_{k,l} - \left(\widetilde{\mathcal{T}}_1^{0,0} f_h(t^n)\right)_{k,l}\right] \\
&\qquad + 2\sum_{l,\text{even}}\left[\left(\mathcal{T}_1^{0,0} f(t^n)\right)_{k,l} - \left(\widetilde{\mathcal{T}}_1^{0,0} f_h(t^n)\right)_{k,l}\right]\Bigg\}.
\end{aligned}$$

By using the periodicity of δE_k we obtain

(4.18)
$$\begin{aligned}
&\frac{1}{12\Delta x}\sum_{k=0}^{N_x}\left|8(\delta E_{k+1} - \delta E_{k-1}) - (\delta E_{k+2} - \delta E_{k-2})\right| \\
&\quad \geq \frac{1}{12\Delta x}\sum_{k=0}^{N_x}\left|8\left|\delta E_{k+1} - \delta E_{k-1}\right| - \left|\delta E_{k+2} - \delta E_{k-2}\right|\right| \\
&\quad \geq \frac{1}{12\Delta x}\left|8\sum_{k=0}^{N_x}\left|\delta E_{k+1} - \delta E_{k-1}\right| - \sum_{k=0}^{N_x}\left|\delta E_{k+2} - \delta E_{k-2}\right|\right| \\
&\quad \geq \frac{1}{12\Delta x}\left\{8\sum_{k=0}^{N_x}\left|\delta E_{k+1} - \delta E_{k-1}\right| - \sum_{k=0}^{N_x}\left|\delta E_{k+2} - \delta E_k\right| - \sum_{k=0}^{N_x}\left|\delta E_k - \delta E_{k-2}\right|\right\} \\
&\quad \geq \frac{1}{2\Delta x}\sum_{k=0}^{N_x}\left|\delta E_{k+1} - \delta E_{k-1}\right|.
\end{aligned}$$

By using (4.17), (4.18), and the Cauchy–Schwarz inequality we obtain

(4.19)
$$\begin{aligned}
&\sum_{k=0}^{N_x}\left|\delta E_{k+1} - \delta E_{k-1}\right| \leq \mathcal{O}\left(\Delta x^4\right) + \mathcal{O}\left(\Delta v^4\right) \\
&\qquad + C\Delta x\Delta v \sum_{(k,l)\in\mathcal{M}_h}\left|\left(\mathcal{T}_1^{0,0} f(t^n)\right)_{k,l} - \left(\widetilde{\mathcal{T}}_1^{0,0} f_h(t^n)\right)_{k,l}\right| \\
&\qquad\quad \leq \mathcal{O}\left(\Delta x^4\right) + \mathcal{O}\left(\Delta v^4\right) + C\left(\left\|\left(\mathcal{T}_1^{0,0} - \widetilde{\mathcal{T}}_1^{0,0}\right) f(t^n)\right\|_{L_h^1(\Omega)}\right. \\
&\qquad\qquad \left. + \left\|\widetilde{\mathcal{T}}_1^{0,0}\left(f(t^n) - f_h(t^n)\right)\right\|_{L_h^1(\Omega)}\right) \\
&\qquad\quad \leq \mathcal{O}\left(\Delta x^4\right) + \mathcal{O}\left(\Delta v^4\right) + C\sqrt{|\Omega|}\left(\left\|\left(\mathcal{T}_1^{0,0} - \widetilde{\mathcal{T}}_1^{0,0}\right) f(t^n)\right\|_{L_h^2(\Omega)}\right. \\
&\qquad\qquad \left. + \left\|\widetilde{\mathcal{T}}_1^{0,0}\left(f(t^n) - f_h(t^n)\right)\right\|_{L_h^2(\Omega)}\right).
\end{aligned}$$

We set $\mathcal{M}$ as a mean value of δE_k

$$\mathcal{M} = \frac{\Delta v}{3L}\left\{\delta E_0 + \delta E_{N_x} + 4\sum_{l,\text{odd}} \delta E_l + 2\sum_{l,\text{even}} \delta E_l\right\},$$

and then

$$\min_k \ \delta E_k \le |\mathcal{M}|.$$

By using a discrete version of the Taylor formula with the integral remainder we get

$$\begin{aligned}\max_k \ \delta E_k &\le \min_k \ \delta E_k + \sum_{k=0}^{N_x} |\delta E_{k+1} - \delta E_{k-1}| \\ &\le |\mathcal{M}| + \sum_{k=0}^{N_x} |\delta E_{k+1} - \delta E_{k-1}|\,. \end{aligned} \tag{4.20}$$

Thanks to the discrete zero-mean electrostatic condition on E_h (see Problem (P_h)) we get

(4.21)

$$\begin{aligned}&\delta E_0 + \delta E_{N_x} + 4\sum_{l,\text{odd}} \delta E_l + 2\sum_{l,\text{even}} \delta E_l \\ &\quad= \widetilde{E}(t^{n+1/2}, x_0) + \widetilde{E}(t^{n+1/2}, x_{N_x}) + 4\sum_{l,\text{odd}} \widetilde{E}(t^{n+1/2}, x_l) + 2\sum_{l,\text{even}} \widetilde{E}(t^{n+1/2}, x_l) \\ &\quad\quad - \left\{E_h^{n+1/2}(x_0) + E_h^{n+1/2}(x_{N_x}) + 4\sum_{l,\text{odd}} E_h^{n+1/2}(x_l) + 2\sum_{l,\text{even}} E_h^{n+1/2}(x_l)\right\} \\ &\quad= \int_0^L \widetilde{E}(t^{n+1/2}, x)dx + \mathcal{O}(\Delta x^4) = \mathcal{O}(\Delta x^4).\end{aligned}$$

Finally, using (4.21) and (4.20) gives

$$|\delta E_k| \le \mathcal{O}(\Delta x^4) + \sum_{k=0}^{N_x} |\delta E_{k+1} - \delta E_{k-1}|\,. \tag{4.22}$$

Thanks to (4.22) and (4.19) we obtain

$$\begin{aligned}\left\|\widetilde{E}(t^{n+1/2}) - E_h^{n+1/2}\right\|_\infty \le C\Bigg(&\Delta x^4 + \Delta v^4 + \left\|\left(\mathcal{T}_1^{0,0} - \widetilde{\mathcal{T}}_1^{0,0}\right) f(t^n)\right\|_{L_h^2(\Omega)} \\ &+ \left\|\widetilde{\mathcal{T}}_1^{0,0}\left(f(t^n) - f_h(t^n)\right)\right\|_{L_h^2(\Omega)}\Bigg).\end{aligned} \tag{4.23}$$

In the same manner we get

$$\begin{aligned}\left|\widetilde{E}(t^{n+1/2}) - E_h^{n+1/2}\right|_{1,\infty} \le C\Bigg(&\Delta x^4 + \Delta v^4 + \left\|\left(\mathcal{T}_1^{1,0} - \widetilde{\mathcal{T}}_1^{1,0}\right) f(t^n)\right\|_{L_h^2(\Omega)} \\ &+ \left\|\widetilde{\mathcal{T}}_1^{1,0}\left(f(t^n) - f_h(t^n)\right)\right\|_{L_h^2(\Omega)}\Bigg).\end{aligned} \tag{4.24}$$

By putting together the estimates (4.8), (4.10), (4.13), (4.15), and (4.23)–(4.24) we obtain the first estimate of Lemma 4.5. Therefore by assembling the estimates (4.9)–(4.16) and (4.23)–(4.24) we get the second estimate of Lemma 4.5. ∎

We continue the proof, with the following proposition which states the H^1-stability of the transport operators.

PROPOSITION 4.6. *Let $f \in \mathscr{C}_b(0,T,\mathscr{C}_b^1(\Omega))$, and then there exists a constant C independent of Δx, Δv, and Δt such that*

$$\left\|\widetilde{\mathcal{T}}_1^{0,0} f(t)\right\|_{L_h^2(\Omega)} \leq \|f(t)\|_{L_h^2(\Omega)}, \tag{4.25}$$

$$\left\|\widetilde{\mathcal{T}}_1^{1,0} f(t)\right\|_{L_h^2(\Omega)} \leq \|\partial_x f(t)\|_{L_h^2(\Omega)}, \tag{4.26}$$

$$\left\|\widetilde{\mathcal{T}}_1^{0,1} f(t)\right\|_{L_h^2(\Omega)} \leq \|\partial_v f(t)\|_{L_h^2(\Omega)} + C\Delta t \|\partial_x f(t)\|_{L_h^2(\Omega)}, \tag{4.27}$$

$$\left\|\widetilde{\mathcal{T}}_2^{0,0} f(t)\right\|_{L_h^2(\Omega)} \leq \|f(t)\|_{L_h^2(\Omega)}, \tag{4.28}$$

$$\left\|\widetilde{\mathcal{T}}_2^{1,0} f(t)\right\|_{L_h^2(\Omega)} \leq \|\partial_x f(t)\|_{L_h^2(\Omega)} + C\Delta t \|\partial_v f(t)\|_{L_h^2(\Omega)}, \tag{4.29}$$

$$\left\|\widetilde{\mathcal{T}}_2^{0,1} f(t)\right\|_{L_h^2(\Omega)} \leq \|\partial_v f(t)\|_{L_h^2(\Omega)}. \tag{4.30}$$

Proof. By using (4.3) we get

$$\left\|\widetilde{\mathcal{T}}_1^{0,0} f\right\|_{L_h^2(\Omega)} = \left\|\mathbb{S}_{v\Delta t/2,0}\mathcal{H}_h f\right\|_{L_h^2(\Omega)} \leq \|f\|_{L_h^2(\Omega)}.$$

From (4.4) it follows that

$$\left\|\widetilde{\mathcal{T}}_1^{1,0} f\right\|_{L_h^2(\Omega)} = \left\|\mathbb{S}_{v\Delta t/2,0}\partial_x\mathcal{H}_h f\right\|_{L_h^2(\Omega)} \leq \|\partial_x f\|_{L_h^2(\Omega)}.$$

Thanks to (4.2) we find that

$$\begin{aligned}\left\|\widetilde{\mathcal{T}}_1^{0,1} f\right\|_{L_h^2(\Omega)} &\leq \left\|\mathbb{S}_{v\Delta t/2,0}\mathcal{L}_h\partial_v f\right\|_{L_h^2(\Omega)} + \frac{\Delta t}{2}\left\|\widetilde{\mathcal{T}}_1^{1,0} f\right\|_{L_h^2(\Omega)} \\ &\leq \|\partial_v f\|_{L_h^2(\Omega)} + C\Delta t \|\partial_x f\|_{L_h^2(\Omega)}.\end{aligned}$$

By using (4.3) we get

$$\left\|\widetilde{\mathcal{T}}_2^{0,0} f\right\|_{L_h^2(\Omega)} = \|\mathbb{S}_{0,\Delta t E_h}\mathcal{H}_h f\|_{L_h^2(\Omega)} \leq \|f\|_{L_h^2(\Omega)},$$

and from (4.6) it follows that

$$\left\|\widetilde{\mathcal{T}}_2^{0,1} f\right\|_{L_h^2(\Omega)} = \|\mathbb{S}_{0,\Delta t E_h}\partial_v\mathcal{H}_h f\|_{L_h^2(\Omega)} \leq \|\partial_v f\|_{L_h^2(\Omega)}.$$

Now let us show that $|E_h^{n+1/2}|_{1,\infty}$ is bounded. To do this, we suppose that $\|\partial_x f_h(t^n)\|_{L_h^2(\Omega)}$

is bounded. Then from Problem (P'_h) we get that

$$\begin{aligned}\sum_{k=0}^{N_x}\left|\partial_x E_h^{n+1/2}(x_{k+1})-\partial_x E_h^{n+1/2}(x_{k-1})\right| &\le 2L + C\Delta x\Delta v\sum_{k,l}\left|\left(\widetilde{\mathcal{T}}_1^{1,0}f_h(t^n)\right)_{k,l}\right| \\ &\le L + C\left\|\widetilde{\mathcal{T}}_1^{1,0}f_h(t^n)\right\|_{L_h^1(\Omega)} \\ &\le L + C\sqrt{|\Omega|}\left\|\widetilde{\mathcal{T}}_1^{1,0}f_h(t^n)\right\|_{L_h^2(\Omega)} \\ &\le C,\end{aligned}$$

and it follows that

$$\begin{aligned}\left|E_h^{n+1/2}\right|_{1,\infty} \le \frac{\Delta v}{3L}\Big|&\partial_x E_h^{n+1/2}(x_0)+\partial_x E_h^{n+1/2}(x_{N_x}) \\ &+4\sum_{l,\mathrm{odd}}\partial_x E_h^{n+1/2}(x_l)+2\sum_{l,\mathrm{even}}\partial_x E_h^{n+1/2}(x_l)\Big| \\ &+\sum_{k=0}^{N_x}\left|\partial_x E_h^{n+1/2}(x_{k+1})-\partial_x E_h^{n+1/2}(x_{k-1})\right| \\ &\le C.\end{aligned}$$

Now let us prove inequality (4.29). By using (4.5) it follows that

$$\begin{aligned}\left\|\widetilde{\mathcal{T}}_2^{1,0}f\right\|_{L_h^2(\Omega)} &\le \left\|\mathbb{S}_{0,\Delta t E_h}\mathcal{L}_h\partial_x f\right\|_{L_h^2(\Omega)} + \frac{\Delta t}{2}\left\|\partial_x E_h^{n+1/2}\right\|_\infty\left\|\widetilde{\mathcal{T}}_2^{0,1}f\right\|_{L_h^2(\Omega)} \\ &\le \|\partial_x f\|_{L_h^2(\Omega)} + C\Delta t\,\|\partial_v f\|_{L_h^2(\Omega)},\end{aligned}$$

which ends the proof of the lemma. ∎

We continue with the following lemma, which gives an estimate of the precision of the approximation of the transport operators.

LEMMA 4.7. *Let $f\in\mathscr{C}_b(0,T;\mathscr{C}_b^4(\Omega))$, and then there exists a constant C independent of Δx, Δv, and Δt such that for $|\alpha|\le 1$ we have*

$$\begin{aligned}\left\|\left(\mathcal{T}_1^\alpha-\widetilde{\mathcal{T}}_1^\alpha\right)f(t)\right\|_{L_h^2(\Omega)} &\le C\Delta x^{4-|\alpha|}\,\|f\|_{\mathscr{C}_b\left(0,T;\mathscr{C}_b^4(\Omega)\right)}, \\ \left\|\left(\widehat{\mathcal{T}}_2^\alpha-\widetilde{\mathcal{T}}_2^\alpha\right)f(t)\right\|_{L_h^2(\Omega)} &\le C\Delta v^{4-|\alpha|}\,\|f\|_{\mathscr{C}_b\left(0,T;\mathscr{C}_b^4(\Omega)\right)}.\end{aligned}$$

Proof. If $f\in\mathscr{C}^{2m}([a,b])$ and $\pi_h f$ is the Hermite polynomial of degree $2m-1$ which interpolates f and its $m-1$ first derivatives at the points a and b, then

$$\left\|f^{(j)}-\pi_h f^{(j)}\right\|_{L^\infty([a,b])} \le \frac{\left\|f^{(2m)}\right\|_{L^\infty([a,b])}}{(2m-j)!2^{2m-[j]}}h^{2m-j},\ 0\le j\le 2m-1,$$

where $[j]=j$ if j is even and $[j]=j+1$ if j is odd. Then we have

$$\begin{aligned}\left\|\left(\mathcal{T}_1^{0,0}-\widetilde{\mathcal{T}}_1^{0,0}\right)f(t)\right\|_{L_h^2(\Omega)} &\le C\left\|\mathbb{S}_{v\Delta t/2,0}\left(f(t)-\mathcal{H}_h f(t)\right)\right\|_{L_h^\infty(\Omega)} \\ &\le C\left\|\mathbb{S}_{v\Delta t/2,0}\left(f(t)-\mathcal{H}_h f(t)\right)\right\|_{L_x^\infty(L_{h,v}^\infty)} \\ &\le C\left\|f(t)-\mathcal{H}_h f(t)\right\|_{L_x^\infty(L_{h,v}^\infty)} \le C\Delta x^4\,\|f\|_{\mathscr{C}_b\left(0,T;\mathscr{C}_b^4(\Omega)\right)},\end{aligned}$$

$$\begin{aligned}
\left\|\left(\mathcal{T}_1^{1,0}-\widetilde{\mathcal{T}}_1^{1,0}\right)f(t)\right\|_{L_h^2(\Omega)} &\leq C\left\|\mathbb{S}_{v\Delta t/2,0}\left(\partial_x f(t)-\partial_x\mathcal{H}_h f(t)\right)\right\|_{L_h^\infty(\Omega)}\\
&\leq C\left\|\mathbb{S}_{v\Delta t/2,0}\left(\partial_x f(t)-\partial_x\mathcal{H}_h f(t)\right)\right\|_{L_x^\infty(L_{h,v}^\infty)}\\
&\leq C\left\|\partial_x f(t)-\partial_x\mathcal{H}_h f(t)\right\|_{L_x^\infty(L_{h,v}^\infty)}\leq C\Delta x^3\left\|f\right\|_{\mathscr{C}_b\left(0,T;\mathscr{C}_b^4(\Omega)\right)},
\end{aligned}$$

$$\begin{aligned}
\left\|\left(\mathcal{T}_1^{0,1}-\widetilde{\mathcal{T}}_1^{0,1}\right)f(t)\right\|_{L_h^2(\Omega)} &\leq C\left\|\mathbb{S}_{v\Delta t/2,0}\left(\partial_v f(t)-\mathcal{L}_h\partial_v f(t)\right)\right\|_{L_h^\infty(\Omega)}\\
&\quad+C\Delta t\left\|\mathbb{S}_{v\Delta t/2,0}\left(\partial_x f(t)-\partial_x\mathcal{H}_h f(t)\right)\right\|_{L_h^\infty(\Omega)}\\
&\leq C\left\|\mathbb{S}_{v\Delta t/2,0}\left(\partial_v f(t)-\mathcal{L}_h\partial_v f(t)\right)\right\|_{L_x^\infty(L_{h,v}^\infty)}\\
&\quad+C\Delta t\left\|\mathbb{S}_{v\Delta t/2,0}\left(\partial_x f(t)-\partial_x\mathcal{H}_h f(t)\right)\right\|_{L_x^\infty(L_{h,v}^\infty)}\\
&\leq C\left\|\partial_v f(t)-\mathcal{L}_h\partial_v f(t)\right\|_{L_x^\infty(L_{h,v}^\infty)}\\
&\quad+C\Delta t\left\|\partial_x f(t)-\partial_x\mathcal{H}_h f(t)\right\|_{L_x^\infty(L_{h,v}^\infty)}\\
&\leq C(\Delta t\Delta x^3+\Delta x^4)\left\|f\right\|_{\mathscr{C}_b\left(0,T;\mathscr{C}_b^4(\Omega)\right)}\\
&\leq C\Delta x^3\left\|f\right\|_{\mathscr{C}_b\left(0,T;\mathscr{C}_b^4(\Omega)\right)},
\end{aligned}$$

$$\begin{aligned}
\left\|\left(\widehat{\mathcal{T}}_2^{0,0}-\widetilde{\mathcal{T}}_2^{0,0}\right)f(t)\right\|_{L_h^2(\Omega)} &\leq C\left\|\mathbb{S}_{0,\Delta tE_h}\left(f(t)-\mathcal{H}_h f(t)\right)\right\|_{L_h^\infty(\Omega)}\\
&\leq C\left\|\mathbb{S}_{0,\Delta tE_h}\left(f(t)-\mathcal{H}_h f(t)\right)\right\|_{L_{h,x}^\infty(L_v^\infty)}\\
&\leq C\left\|f(t)-\mathcal{H}_h f(t)\right\|_{L_{h,x}^\infty(L_v^\infty)}\leq C\Delta v^4\left\|f\right\|_{\mathscr{C}_b\left(0,T;\mathscr{C}_b^4(\Omega)\right)},
\end{aligned}$$

$$\begin{aligned}
\left\|\left(\widehat{\mathcal{T}}_2^{0,1}-\widetilde{\mathcal{T}}_2^{0,1}\right)f(t)\right\|_{L_h^2(\Omega)} &\leq C\left\|\mathbb{S}_{0,\Delta tE_h}\left(\partial_x f(t)-\partial_x\mathcal{H}_h f(t)\right)\right\|_{L_h^\infty(\Omega)}\\
&\leq C\left\|\mathbb{S}_{0,\Delta tE_h}\left(\partial_x f(t)-\partial_x\mathcal{H}_h f(t)\right)\right\|_{L_{h,x}^\infty(L_v^\infty)}\\
&\leq C\left\|\partial_x f(t)-\partial_x\mathcal{H}_h f(t)\right\|_{L_{h,x}^\infty(L_v^\infty)}\leq C\Delta v^3\left\|f\right\|_{\mathscr{C}_b\left(0,T;\mathscr{C}_b^4(\Omega)\right)},
\end{aligned}$$

$$\begin{aligned}
\left\|\left(\widehat{\mathcal{T}}_2^{1,0}-\widetilde{\mathcal{T}}_2^{1,0}\right)f(t)\right\|_{L_h^2(\Omega)} &\leq C\left\|\mathbb{S}_{0,\Delta tE_h}\left(\partial_x f(t)-\mathcal{L}_h\partial_x f(t)\right)\right\|_{L_h^\infty(\Omega)}\\
&\quad+C\Delta t\left\|\partial_x E_h^{n+1/2}\right\|_\infty\left\|\mathbb{S}_{0,\Delta tE_h}\left(\partial_v f(t)-\partial_v\mathcal{H}_h f(t)\right)\right\|_{L_h^\infty(\Omega)}\\
&\leq C\left\|\mathbb{S}_{0,\Delta tE_h}\left(\partial_x f(t)-\mathcal{L}_h\partial_x f(t)\right)\right\|_{L_{h,x}^\infty(L_v^\infty)}\\
&\quad+C\Delta t\left\|\mathbb{S}_{0,\Delta tE_h}\left(\partial_v f(t)-\partial_v\mathcal{H}_h f(t)\right)\right\|_{L_{h,x}^\infty(L_v^\infty)}\\
&\leq C\left\|\partial_x f(t)-\mathcal{L}_h\partial_x f(t)\right\|_{L_{h,x}^\infty(L_v^\infty)}\\
&\quad+C\Delta t\left\|\partial_v f(t)-\partial_v\mathcal{H}_h f(t)\right\|_{L_{h,x}^\infty(L_v^\infty)}\\
&\leq C(\Delta t\Delta v^3+\Delta v^4)\left\|f\right\|_{\mathscr{C}_b\left(0,T;\mathscr{C}_b^4(\Omega)\right)}\\
&\leq C\Delta v^3\left\|f\right\|_{\mathscr{C}_b\left(0,T;\mathscr{C}_b^4(\Omega)\right)}.\qquad\square
\end{aligned}$$

Now let us evaluate the term (I3):

$$\left\|\mathcal{T}_1^\alpha\circ\widehat{\mathcal{T}}_2^\alpha\circ\mathcal{T}_1^\alpha f(t^n)-\widetilde{\mathcal{T}}_1^\alpha\circ\widetilde{\mathcal{T}}_2^\alpha\circ\widetilde{\mathcal{T}}_1^\alpha f(t^n)\right\|_{L_h^2(\Omega)}.$$

LEMMA 4.8. *Let $f \in \mathscr{C}_b(0,T;\mathscr{C}_b^4(\Omega))$, and then*

$$\begin{aligned}
&\left\|\mathcal{T}_1^{0,0}\circ\widehat{\mathcal{T}}_2^{0,0}\circ\mathcal{T}_1^{0,0}f(t^n)-\widetilde{\mathcal{T}}_1^{0,0}\circ\widetilde{\mathcal{T}}_2^{0,0}\circ\widetilde{\mathcal{T}}_1^{0,0}f(t^n)\right\|_{L_h^2(\Omega)}\\
&\quad\le C\Bigg(\Delta x^4+\Delta v^4+\Delta t\Bigg(\Delta t^2+\Delta x^4+\Delta v^4+\Delta x^5+\Delta x\Delta v^4\\
&\quad+\left\|\left(\mathcal{T}_1^{0,0}-\widetilde{\mathcal{T}}_1^{0,0}\right)f(t^n)\right\|_{L_h^2(\Omega)}+\left\|\widetilde{\mathcal{T}}_1^{0,0}\left(f(t^n)-f_h(t^n)\right)\right\|_{L_h^2(\Omega)}\\
&\quad+\Delta x\left\|\left(\mathcal{T}_1^{1,0}-\widetilde{\mathcal{T}}_1^{1,0}\right)f(t^n)\right\|_{L_h^2(\Omega)}+\Delta x\left\|\widetilde{\mathcal{T}}_1^{1,0}\left(f(t^n)-f_h(t^n)\right)\right\|_{L_h^2(\Omega)}\Bigg)\Bigg)
\end{aligned}$$

and

$$\begin{aligned}
&\left\|\nabla\mathcal{T}_1\circ\nabla\widehat{\mathcal{T}}_2\circ\nabla\mathcal{T}_1f(t^n)-\nabla\widetilde{\mathcal{T}}_1\circ\nabla\widetilde{\mathcal{T}}_2\circ\nabla\widetilde{\mathcal{T}}_1f(t^n)\right\|_{\mathbb{L}_h^2(\Omega)}\\
&\quad\le C\Bigg(\Delta x^3+\Delta v^3+\Delta t\Bigg(\Delta t^2+\Delta x^3+\Delta x^{-1}\Delta v^4+\Delta v^4+\Delta x^4\\
&\quad+\left(1+\Delta x^{-1}\right)\left\|\left(\mathcal{T}_1^{0,0}-\widetilde{\mathcal{T}}_1^{0,0}\right)f(t^n)\right\|_{L_h^2(\Omega)}\\
&\quad+\left(1+\Delta x^{-1}\right)\left\|\widetilde{\mathcal{T}}_1^{0,0}\left(f(t^n)-f_h(t^n)\right)\right\|_{L_h^2(\Omega)}\\
&\quad+\left\|\left(\mathcal{T}_1^{1,0}-\widetilde{\mathcal{T}}_1^{1,0}\right)f(t^n)\right\|_{L_h^2(\Omega)}+\left\|\widetilde{\mathcal{T}}_1^{1,0}\left(f(t^n)-f_h(t^n)\right)\right\|_{L_h^2(\Omega)}\Bigg)\Bigg).
\end{aligned}$$

Proof. First we consider the following decomposition:

$$\begin{aligned}
\left\|\mathcal{T}_1^{\alpha}\circ\widehat{\mathcal{T}}_2^{\alpha}\circ\mathcal{T}_1^{\alpha}f(t^n)-\widetilde{\mathcal{T}}_1^{\alpha}\circ\widetilde{\mathcal{T}}_2^{\alpha}\circ\widetilde{\mathcal{T}}_1^{\alpha}f(t^n)\right\|_{L_h^2(\Omega)} &\le \left\|\left(\mathcal{T}_1^{\alpha}-\widetilde{\mathcal{T}}_1^{\alpha}\right)\circ\widehat{\mathcal{T}}_2^{\alpha}\circ\mathcal{T}_1^{\alpha}f(t^n)\right\|_{L_h^2(\Omega)} &(4.31)\\
&+\left\|\widetilde{\mathcal{T}}_1^{\alpha}\circ\left(\widehat{\mathcal{T}}_2^{\alpha}-\widetilde{\mathcal{T}}_2^{\alpha}\right)\circ\mathcal{T}_1^{\alpha}f(t^n)\right\|_{L_h^2(\Omega)} &(4.32)\\
&+\left\|\widetilde{\mathcal{T}}_1^{\alpha}\circ\widetilde{\mathcal{T}}_2^{\alpha}\circ\left(\mathcal{T}_1^{\alpha}-\widetilde{\mathcal{T}}_1^{\alpha}\right)f(t^n)\right\|_{L_h^2(\Omega)}. &(4.33)
\end{aligned}$$

Let us start with the term (4.31). The term (4.31) can be decomposed in the following manner:

$$\begin{aligned}
\left\|\left(\mathcal{T}_1^{\alpha}-\widetilde{\mathcal{T}}_1^{\alpha}\right)\circ\widehat{\mathcal{T}}_2^{\alpha}\circ\mathcal{T}_1^{\alpha}f(t^n)\right\|_{L_h^2(\Omega)} &\le \left\|\left(\mathcal{T}_1^{\alpha}-\widetilde{\mathcal{T}}_1^{\alpha}\right)\circ\mathcal{T}_2^{\alpha}\circ\mathcal{T}_1^{\alpha}f(t^n)\right\|_{L_h^2(\Omega)} &(4.34)\\
&+\left\|\mathcal{T}_1^{\alpha}\circ\left(\widehat{\mathcal{T}}_2^{\alpha}-\mathcal{T}_2^{\alpha}\right)\circ\mathcal{T}_1^{\alpha}f(t^n)\right\|_{L_h^2(\Omega)} &(4.35)\\
&+\left\|\widetilde{\mathcal{T}}_1^{\alpha}\circ\left(\mathcal{T}_2^{\alpha}-\widehat{\mathcal{T}}_2^{\alpha}\right)\circ\mathcal{T}_1^{\alpha}f(t^n)\right\|_{L_h^2(\Omega)}. &(4.36)
\end{aligned}$$

Let us proceed with (4.34):

$$\begin{aligned}\left\|\left(\mathcal{T}_1^\alpha-\widetilde{\mathcal{T}}_1^\alpha\right)\circ\mathcal{T}_2^\alpha\circ\mathcal{T}_1^\alpha f(t^n)\right\|_{L^2_h(\Omega)}&\leq C\Delta x^{4-|\alpha|}\left\|\mathcal{T}_2^{0,0}\circ\mathcal{T}_1^{0,0}f(t^n)\right\|_{\mathscr{C}^4_b(\Omega)}\\&\leq C\left(\|f\|_{\mathscr{C}_b\left(0,T;\mathscr{C}^4_b(\Omega)\right)},\|E\|_{\mathscr{C}^4_b(\Omega)}\right)\Delta x^{4-|\alpha|}\\&\leq C\Delta x^{4-|\alpha|}.\end{aligned}$$

The term (4.35) has already been estimated, and the result is given by Lemma 4.5. Let us evaluate the term (4.36). If we introduce the characteristic curves

$$\begin{aligned}\widetilde{X}^\star(t^n)&=x-v\Delta t+\frac{\Delta t^2}{2}E(t^{n+1/2},x),\\\widetilde{V}^\star(t^n)&=v-\Delta tE(t^{n+1/2},x),\\\widehat{X}^\star(t^n)&=x-v\Delta t+\frac{\Delta t^2}{2}E_h^{n+1/2}(x),\\\widehat{V}^\star(t^n)&=v-\Delta tE_h^{n+1/2}(x),\end{aligned}$$

we get

$$\begin{aligned}\left|\left(\left(\widehat{\mathcal{T}}_2^{0,0}-\mathcal{T}_2^{0,0}\right)\circ\mathcal{T}_1^{0,0}f(t^n)\right)_{k,l}\right|&\leq\left|f\left(t^n,\widehat{X}^\star_{k,l}(t^n),\widehat{V}^\star_{k,l}(t^n)\right)-f\left(t^n,\widetilde{X}^\star_{k,l}(t^n),\widetilde{V}^\star_{k,l}(t^n)\right)\right|\\&\leq C\Delta t\left\|E_h^{n+1/2}-E(t^{n+1/2})\right\|_\infty\|\nabla f\|_{L^\infty(\Omega)}.\end{aligned}$$

We deduce that

$$\left\|\left(\widehat{\mathcal{T}}_2^{0,0}-\mathcal{T}_2^{0,0}\right)\circ\mathcal{T}_1^{0,0}f(t^n)\right\|_{L^2_h(\Omega)}\leq C|\Omega|\Delta t\left\|E_h^{n+1/2}-E(t^{n+1/2})\right\|_\infty,$$

and by using (4.25) we finally get

$$\begin{aligned}\left\|\widetilde{\mathcal{T}}_1^{0,0}\circ\left(\widehat{\mathcal{T}}_2^{0,0}-\mathcal{T}_2^{0,0}\right)\circ\mathcal{T}_1^{0,0}f(t^n)\right\|_{L^2_h(\Omega)}&\leq C|\Omega|\Delta t\left\|E_h^{n+1/2}-E(t^{n+1/2})\right\|_\infty\\&\leq C\Delta t\Big(\Delta t^2+\Delta x^4+\Delta v^4\\&+\left\|\left(\mathcal{T}_1^{0,0}-\widetilde{\mathcal{T}}_1^{0,0}\right)f(t^n)\right\|_{L^2_h(\Omega)}\\&+\left\|\widetilde{\mathcal{T}}_1^{0,0}\left(f(t^n)-f_h(t^n)\right)\right\|_{L^2_h(\Omega)}\Big).\end{aligned}$$

On the other hand we have

$$\begin{aligned}&\left|\left(\left(\nabla\widehat{\mathcal{T}}_2-\nabla\mathcal{T}_2\right)\circ\nabla\mathcal{T}_1f(t^n)\right)_{k,l}\right|\\&\leq\left|\nabla f\left(\widehat{X}^\star_{k,l}(t^n),\widehat{V}^\star_{k,l}(t^n)\right)\right|\cdot\left(\left|\nabla\widehat{X}^\star_{k,l}(t^n)-\nabla\widetilde{X}^\star_{k,l}(t^n)\right|+\left|\nabla\widehat{V}^\star_{k,l}(t^n)-\nabla\widetilde{V}^\star_{k,l}(t^n)\right|\right)\\&+\left|\nabla f\left(\widehat{X}^\star_{k,l}(t^n),\widehat{V}^\star_{k,l}(t^n)\right)-\nabla f\left(\widetilde{X}^\star_{k,l}(t^n),\widetilde{V}^\star_{k,l}(t^n)\right)\right|\cdot\left|\nabla\left(\widetilde{X}^\star_{k,l}(t^n),\widetilde{V}^\star_{k,l}(t^n)\right)\right|\\&\leq\left|\nabla f\left(\widehat{X}^\star_{k,l}(t^n),\widehat{V}^\star_{k,l}(t^n)\right)\right|\cdot\left(\left|\nabla\widehat{X}^\star_{k,l}(t^n)-\nabla\widetilde{X}^\star_{k,l}(t^n)\right|+\left|\nabla\widehat{V}^\star_{k,l}(t^n)-\nabla\widetilde{V}^\star_{k,l}(t^n)\right|\right)\\&+\left(\left|\widehat{X}^\star_{k,l}(t^n)-\widetilde{X}^\star_{k,l}(t^n)\right|+\left|\widehat{V}^\star_{k,l}(t^n)-\widetilde{V}^\star_{k,l}(t^n)\right|\right)\\&\quad\cdot\left|\nabla^2f\left(\widetilde{X}^\star_{k,l}(t^n),\widetilde{V}^\star_{k,l}(t^n)\right)\right|\cdot\left|\nabla\left(\widetilde{X}^\star_{k,l}(t^n),\widetilde{V}^\star_{k,l}(t^n)\right)\right|\end{aligned}$$

$$
\begin{aligned}
&\leq C\left(\|\nabla f\|_{\mathscr{C}_b(0,T;\mathscr{C}_b(\Omega))}, \left\|\nabla^2 f\right\|_{\mathscr{C}_b(0,T;\mathscr{C}_b(\Omega))}, \|\partial_x E\|_{\mathscr{C}_b(0,T;\mathscr{C}_b(\Omega))}\right)\\
&\times\left(\left|\widehat{X}^\star_{k,l}(t^n)-\widetilde{X}^\star_{k,l}(t^n)\right|+\left|\widehat{V}^\star_{k,l}(t^n)-\widetilde{V}^\star_{k,l}(t^n)\right|\right.\\
&\left.+\left|\nabla\widehat{X}^\star_{k,l}(t^n)-\nabla\widetilde{X}^\star_{k,l}(t^n)\right|+\left|\nabla\widehat{V}^\star_{k,l}(t^n)-\nabla\widetilde{V}^\star_{k,l}(t^n)\right|\right)\\
&\leq C\Delta t\left\|E_h^{n+1/2}-E(t^{n+1/2})\right\|_{1,\infty}.
\end{aligned}
$$

From inequalities (4.26), (4.27), (4.29), and (4.30) we find that

$$
\begin{aligned}
\left\|\nabla\widetilde{\mathcal{T}}_1\left(\nabla\widehat{\mathcal{T}}_2-\nabla\mathcal{T}_2\right)\circ\nabla\mathcal{T}_1 f(t^n)\right\|_{\mathbb{L}^2_h(\Omega)} &\leq (1+C\Delta t)\left\|\left(\nabla\widehat{\mathcal{T}}_2-\nabla\mathcal{T}_2\right)\circ\nabla\mathcal{T}_1 f(t^n)\right\|_{\mathbb{L}^2_h(\Omega)}\\
&\leq C|\Omega|\Delta t\left\|E_h^{n+1/2}-E(t^{n+1/2})\right\|_{1,\infty}\\
&\leq C\Delta t\left(\Delta t^2+\Delta x^4+\Delta v^4+\left\|\left(\mathcal{T}_1^{0,0}-\widetilde{\mathcal{T}}_1^{0,0}\right)f(t^n)\right\|_{L^2_h(\Omega)}\right.\\
&+\left\|\widetilde{\mathcal{T}}_1^{0,0}\left(f(t^n)-f_h(t^n)\right)\right\|_{L^2_h(\Omega)}+\left\|\left(\mathcal{T}_1^{1,0}-\widetilde{\mathcal{T}}_1^{1,0}\right)f(t^n)\right\|_{L^2_h(\Omega)}\\
&\left.+\left\|\widetilde{\mathcal{T}}_1^{1,0}\left(f(t^n)-f_h(t^n)\right)\right\|_{L^2_h(\Omega)}\right).
\end{aligned}
$$

Let us continue with the term (4.32). By using (4.25) we get that

$$
\begin{aligned}
\left\|\widetilde{\mathcal{T}}_1^{0,0}\circ\left(\widehat{\mathcal{T}}_2^{0,0}-\widetilde{\mathcal{T}}_2^{0,0}\right)\circ\mathcal{T}_1^{0,0}f(t^n)\right\|_{L^2_h(\Omega)} &\leq \left\|\left(\widehat{\mathcal{T}}_2^{0,0}-\widetilde{\mathcal{T}}_2^{0,0}\right)\circ\mathcal{T}_1^{0,0}f(t^n)\right\|_{L^2_h(\Omega)}\\
&\leq C\Delta v^4\left\|\mathcal{T}_1^{0,0}f(t^n)\right\|_{\mathscr{C}^4_b(\Omega)}\\
&\leq C\Delta v^4\|f\|_{\mathscr{C}\left(0,T;\mathscr{C}^4_b(\Omega)\right)}.
\end{aligned}
$$

By using (4.26) and (4.27) we have

$$
\begin{aligned}
\left\|\nabla\widetilde{\mathcal{T}}_1\circ\left(\nabla\widehat{\mathcal{T}}_2-\nabla\widetilde{\mathcal{T}}_2\right)\circ\nabla\mathcal{T}_1 f(t^n)\right\|_{\mathbb{L}^2_h(\Omega)} &\leq (1+C\Delta t)\left\|\left(\nabla\widehat{\mathcal{T}}_2-\nabla\widetilde{\mathcal{T}}_2\right)\circ\nabla\mathcal{T}_1 f(t^n)\right\|_{\mathbb{L}^2_h(\Omega)}\\
&\leq C\Delta v^3\left\|\mathcal{T}_1^{0,0}f(t^n)\right\|_{\mathscr{C}^4_b(\Omega)}\\
&\leq C\Delta v^3\|f\|_{\mathscr{C}\left(0,T;\mathscr{C}^4_b(\Omega)\right)}.
\end{aligned}
$$

Let us finish with the term (4.33). By using (4.25) and (4.28) we get that

$$
\begin{aligned}
\left\|\widetilde{\mathcal{T}}_1^{0,0}\circ\widetilde{\mathcal{T}}_2^{0,0}\circ\left(\mathcal{T}_1^{0,0}-\widetilde{\mathcal{T}}_1^{0,0}\right)f(t^n)\right\|_{L^2_h(\Omega)} &\leq \left\|\widetilde{\mathcal{T}}_2^{0,0}\circ\left(\mathcal{T}_1^{0,0}-\widetilde{\mathcal{T}}_1^{0,0}\right)f(t^n)\right\|_{L^2_h(\Omega)}\\
&\leq \left\|\left(\mathcal{T}_1^{0,0}-\widetilde{\mathcal{T}}_1^{0,0}\right)f(t^n)\right\|_{L^2_h(\Omega)}\\
&\leq C\Delta x^4\left\|\mathcal{T}_1^{0,0}f(t^n)\right\|_{\mathscr{C}^4_b(\Omega)}\\
&\leq C\Delta x^4\|f\|_{\mathscr{C}\left(0,T;\mathscr{C}^4_b(\Omega)\right)}.
\end{aligned}
$$

By using (4.26), (4.27), (4.29), and (4.30) we get that

$$\begin{aligned}\left\|\nabla\widetilde{\mathcal{T}}_1\circ\nabla\widetilde{\mathcal{T}}_2\circ\left(\nabla\mathcal{T}_1-\nabla\widetilde{\mathcal{T}}_1\right)f(t^n)\right\|_{\mathbb{L}^2_h(\Omega)}&\leq(1+C\Delta t)\left\|\nabla\widetilde{\mathcal{T}}_2\circ\left(\nabla\mathcal{T}_1-\nabla\widetilde{\mathcal{T}}_1\right)f(t^n)\right\|_{\mathbb{L}^2_h(\Omega)}\\&\leq(1+C\Delta t)^2\left\|\left(\nabla\mathcal{T}_1-\nabla\widetilde{\mathcal{T}}_1\right)f(t^n)\right\|_{\mathbb{L}^2_h(\Omega)}\\&\leq C\Delta x^3\left\|f(t^n)\right\|_{\mathscr{C}^4_b(\Omega)}\\&\leq C\Delta x^3\left\|f\right\|_{\mathscr{C}\left(0,T;\mathscr{C}^4_b(\Omega)\right)}.\end{aligned}$$

□

Now let us evaluate the term (I4).

LEMMA 4.9. *Let $f\in\mathscr{C}_b(0,T;\mathscr{C}^1_b(\Omega))$, and then there exists a constant C independent of Δx, Δv, and Δt such that*

$$\left\|\widetilde{\mathcal{T}}_1^{0,0}\circ\widetilde{\mathcal{T}}_2^{0,0}\circ\widetilde{\mathcal{T}}_1^{0,0}(f(t^n)-f_h(t^n))\right\|_{L^2_h(\Omega)}\leq\left\|f(t^n)-f_h(t^n)\right\|_{L^2_h(\Omega)}$$

and

$$\left\|\nabla\widetilde{\mathcal{T}}_1\circ\nabla\widetilde{\mathcal{T}}_2\circ\nabla\widetilde{\mathcal{T}}_1(f(t^n)-f_h(t^n))\right\|_{\mathbb{L}^2_h(\Omega)}\leq(1+C\Delta t)\left\|\nabla f(t^n)-\nabla f_h(t^n)\right\|_{\mathbb{L}^2_h(\Omega)}.$$

Proof. By using (4.25) and (4.28) we get that

$$\begin{aligned}\left\|\widetilde{\mathcal{T}}_1^{0,0}\circ\widetilde{\mathcal{T}}_2^{0,0}\circ\widetilde{\mathcal{T}}_1^{0,0}(f(t^n)-f_h(t^n))\right\|_{L^2_h(\Omega)}&\leq\left\|\widetilde{\mathcal{T}}_2^{0,0}\circ\widetilde{\mathcal{T}}_1^{0,0}(f(t^n)-f_h(t^n))\right\|_{L^2_h(\Omega)}\\&\leq\left\|\widetilde{\mathcal{T}}_1^{0,0}(f(t^n)-f_h(t^n))\right\|_{L^2_h(\Omega)}\\&\leq\left\|f(t^n)-f_h(t^n)\right\|_{L^2_h(\Omega)}.\end{aligned}$$

By using (4.26), (4.27), (4.29), and (4.30) it follows that

$$\begin{aligned}&\left\|\nabla\widetilde{\mathcal{T}}_1\circ\nabla\widetilde{\mathcal{T}}_2\circ\nabla\widetilde{\mathcal{T}}_1(f(t^n)-f_h(t^n))\right\|_{\mathbb{L}^2_h(\Omega)}\\&\qquad\leq(1+C\Delta t)\left\|\nabla\widetilde{\mathcal{T}}_2\circ\nabla\widetilde{\mathcal{T}}_1(f(t^n)-f_h(t^n))\right\|_{\mathbb{L}^2_h(\Omega)}\\&\qquad\leq(1+C\Delta t)^2\left\|\nabla\widetilde{\mathcal{T}}_1(f(t^n)-f_h(t^n))\right\|_{\mathbb{L}^2_h(\Omega)}\\&\qquad\leq(1+C\Delta t)^3\left\|\nabla f(t^n)-\nabla f_h(t^n)\right\|_{\mathbb{L}^2_h(\Omega)}\\&\qquad\leq(1+C\Delta t)\left\|\nabla f(t^n)-\nabla f_h(t^n)\right\|_{\mathbb{L}^2_h(\Omega)}.\end{aligned}$$

□

Proof of Theorem 4.1. By putting together Lemmas 4.3, 4.5, 4.7, 4.8, and 4.9 we obtain

$$\begin{pmatrix}\left\|e_{n+1}\right\|_{L^2_h(\Omega)}\\\left\|\nabla e_{n+1}\right\|_{\mathbb{L}^2_h(\Omega)}\end{pmatrix}=\begin{pmatrix}1+C\Delta t&\Delta t\Delta x\\\Delta t\left(1+\Delta x^{-1}\right)&1+C\Delta t\end{pmatrix}\begin{pmatrix}\left\|e_n\right\|_{L^2_h(\Omega)}\\\left\|\nabla e_n\right\|_{\mathbb{L}^2_h(\Omega)}\end{pmatrix}+\begin{pmatrix}\gamma\\\partial\gamma\end{pmatrix},$$

where

$$\gamma=C\left(\Delta t^3+(1+\Delta t+\Delta x)(\Delta x^4+\Delta v^4)+\Delta x^4+\Delta x^4\right)$$

and

$$\partial\gamma=C\left(\Delta t^3+\Delta x^{-1}(1+\Delta t+\Delta x)(\Delta x^4+\Delta v^4)+\Delta x^3+\Delta x^3\right).$$

The eigenvalues of the matrix

$$\begin{pmatrix} 1+C\Delta t & \Delta t\Delta x \\ \Delta t\left(1+\Delta x^{-1}\right) & 1+C\Delta t \end{pmatrix}$$

are equivalent to $1+\mathcal{O}(\Delta t)$. The formula of recurrence gives

$$\begin{pmatrix} \|e_{n+1}\|_{L_h^2(\Omega)} \\ \|\nabla e_{n+1}\|_{\mathbb{L}_h^2(\Omega)} \end{pmatrix} = \frac{1}{\Delta t}\begin{pmatrix} \gamma \\ \partial\gamma \end{pmatrix} + e^{CT}\begin{pmatrix} \|e_0\|_{L_h^2(\Omega)} \\ \|\nabla e_0\|_{\mathbb{L}_h^2(\Omega)} \end{pmatrix},$$

which is the error estimate of $\partial^\alpha f - \partial^\alpha f_h$ stated in Theorem 4.1, assuming $\|e_0\|_{L_h^2(\Omega)} = \|\nabla e_0\|_{\mathbb{L}_h^2(\Omega)} = 0$. By using the estimates (4.23) and (4.24) and thanks to the error estimate of $\partial^\alpha f - \partial^\alpha f_h$, we find the estimate $\partial^\alpha E - \partial^\alpha E_h$ stated in Theorem 4.1. ∎

ON SINC-BASED METHOD IN COMPUTING EIGENVALUES OF BOUNDARY-VALUE PROBLEMS*

M. H. ANNABY† AND R. M. ASHARABI‡

Abstract. We aim in this paper to give a complete treatment of the error analysis of the use of the sinc method in computing eigenvalues of second order Birkhoff-regular eigenvalue problems. For this task we study truncation and amplitude errors on $\mathbb{C}$ associated with cardinal series representation of band-limited functions as well as those of their derivatives. These results, which seem to be considered for the first time, give us the possibility to establish the error analysis when the eigenvalues are not real or not algebraically simple.

Key words. sinc methods, Birkhoff-regular problems

1. Introduction.

Sinc methods, which are based on the classical sampling theorem of Whittaker, Kotelnikov, and Shannon (WKS), enable solutions to many computational problems. Illustrations are given in [19, 20, 24, 25]. The WKS sampling theorem states that if $f(\mu)$ is entire in μ of exponential type σ, $\sigma > 0$, which belongs to $L^2(\mathbb{R})$ when restricted to $\mathbb{R}$, then $f(\mu)$ can be reconstructed via the cardinal series representation

$$f(\mu) = \sum_{n=-\infty}^{\infty} f\left(\frac{n\pi}{\sigma}\right) \operatorname{sinc}(\sigma\mu - n\pi), \quad \mu \in \mathbb{C}, \tag{1.1}$$

where $\operatorname{sinc} z$ is the function

$$\operatorname{sinc} z = \begin{cases} \dfrac{\sin z}{z}, & z \neq 0, \\ 1, & z = 0, \end{cases} \tag{1.2}$$

and the points $\{n\pi/\sigma\}_{n\in\mathbb{Z}}$ are called the sampling nodes (points). The series (1.1) is absolutely convergent for all $\mu \in \mathbb{C}$, and, moreover, it is uniformly convergent for $\mu \in \mathbb{R}$ and also for all μ on compact subsets of $\mathbb{C}$. The space of all functions f that satisfy the above conditions is the Paley–Wiener space B_σ^2 of band-limited functions with bandwidth σ, i.e., $L^2(\mathbb{R})$-functions whose Fourier transforms vanish on $\{x \in \mathbb{R} : \ |x| > \sigma\}$. Methods based on using the expansion (1.1) are called sinc methods. This paper is devoted to an application of sinc methods, namely, that of computing eigenvalues of second order boundary-value problems as is established in [4, 5, 6, 10, 11]. In such applications, two types of errors appear, namely, truncation and amplitude errors. By the truncation error of $f \in B_\sigma^2$ we mean

$$R_N(\mu) := f(\mu) - f_N(\mu), \quad N \in \mathbb{Z}^+, \quad \mu \in \mathbb{C}, \tag{1.3}$$

†On leave from Department of Mathematics, Faculty of Science, Cairo University, Giza, Egypt (mhannaby@yahoo.com). Current address: Department of Mathematics and Physics, Qatar University, P.O. Box 2713, Doha, Qatar.

‡Department of Mathematics, Faculty of Science, Sana'a University, Yemen (rashad1974@hotmail.com).

where $f_N(\mu)$ is the truncated series

$$f_N(\mu) := \sum_{n=-N}^{N} f\left(\frac{n\pi}{\sigma}\right) \operatorname{sinc}(\sigma\mu - n\pi), \quad \mu \in \mathbb{C}.$$

The amplitude error arises when the exact values $f\left(\frac{n\pi}{\sigma}\right)$, $n \in \mathbb{Z}$, of (1.1) are replaced by approximate ones $\widetilde{f}\left(\frac{n\pi}{\sigma}\right)$, $n \in \mathbb{Z}$. So if the differences $\varepsilon_n := f\left(\frac{n\pi}{\sigma}\right) - \widetilde{f}\left(\frac{n\pi}{\sigma}\right)$ are bounded by a positive number ε, i.e., $|\varepsilon_n| \le \varepsilon$, $\varepsilon > 0$, the amplitude error is defined to be

$$(A_\varepsilon)f(\mu) = \sum_{n=-\infty}^{\infty} \left\{ f\left(\frac{n\pi}{\sigma}\right) - \widetilde{f}\left(\frac{n\pi}{\sigma}\right) \right\} \operatorname{sinc}(\sigma\mu - n\pi), \quad \mu \in \mathbb{C}. \tag{1.4}$$

In [18] it is proved that if $\mu \in \mathbb{R}$, $f(\mu) \in B_\sigma^2$, and $\mu f(\mu) \in L^2(\mathbb{R})$, then for $N \in \mathbb{Z}^+$, $|\mu| < N\pi/\sigma$, one gets

$$|R_N(\mu)| \le \frac{2E}{\pi^2\sqrt{3}} \, \frac{\sigma\sqrt{\sigma}|\sin\sigma\mu|}{N+1} \left(\frac{1}{\sqrt{N\pi - \sigma\mu}} + \frac{1}{\sqrt{N\pi + \sigma\mu}} \right), \tag{1.5}$$

where

$$E := \sqrt{\int_{-\infty}^{\infty} |\mu f(\mu)|^2 dt}. \tag{1.6}$$

Butzer, Splettstösser, and Stens [8] have studied the amplitude error and proved that if $f(\mu) \in B_\sigma^2$ and there is $M_f > 0$ such that

$$|\varepsilon_n| \le |f(n\pi/\sigma)|, \quad n \in \mathbb{Z}, \tag{1.7}$$

$$|f(\mu)| \le M_f \, |\mu|^{-1} \; (|\mu| \ge 1), \quad \mu \in \mathbb{R}, \tag{1.8}$$

hold. We should mention here that condition (1.7) is concluded from [8, p. 20]. Then for $\sigma \ge \pi$, $0 < \varepsilon \le \min\{\pi/\sigma, 1/\sqrt{e}\}$, we have

$$|(A_\varepsilon)f(\mu)| \le \mathcal{A}(\varepsilon) := 4\left(\sqrt{3}e + \sqrt{2}M_f \exp(1/4)\right) \varepsilon \log(1/\varepsilon), \quad \mu \in \mathbb{R}. \tag{1.9}$$

In [4, 5, 6, 7, 10, 11, 12] eigenvalues of particular cases of the second order eigenvalue problem

$$\ell(y) := -y''(x,\mu) + q(x)y(x,\mu) = \mu^2 y(x,\mu), \qquad 0 \le x \le b, \tag{1.10}$$

$$U_1(y) := \alpha_{11}y(0) + \alpha_{12}y'(0) + \beta_{11}y(b) + \beta_{12}y'(b) = 0, \tag{1.11}$$

$$U_2(y) := \alpha_{21}y(0) + \alpha_{22}y'(0) + \beta_{21}y(b) + \beta_{22}y'(b) = 0 \tag{1.12}$$

are computed approximately by the sinc method. Here $q(\cdot) \in L^1(0,b)$, $\mu \in \mathbb{C}$, and $(\alpha_{i1}, \alpha_{i2}, \beta_{i1}, \beta_{i2}) \in \mathbb{C}^4$, $i = 1, 2$, are linearly independent. Some additional details:

1. The self-adjoint eigenvalue problem with a separate type of condition, i.e., when $q(\cdot)$ is an $L^1(0,b)$-real-valued function and

   $$\beta_{11}, \beta_{12}, \alpha_{21}, \alpha_{22} \in \mathbb{R}, \quad \beta_{11} = \beta_{12} = \alpha_{21} = \alpha_{22} = 0, \tag{1.13}$$

   is considered in [4, 10]. The error analysis of the authors of [4, 10] considers only the truncation error, although they should also have considered the amplitude error.

2. The case when $q(\cdot)$ is a real-valued, $L^1(0,b)$ function and

$$\alpha_{11}=\alpha_{22}=1, \beta_{11}=\beta_{22}=-1, \quad \alpha_{ij}=\beta_{ij}=0,\ 1\le i\ne j\ge 2, \tag{1.14}$$

is considered in [6]. The error analysis when eigenvalues are double is not rigorously studied, although almost all eigenvalues of this problem are double; cf., e.g., [14, 17, 21]. When the eigenvalues are simple, only the truncation error is considered, while the amplitude error also arises.

3. The case of a non-self-adjoint eigenvalue problem with a separate type of condition is considered in [5], i.e., when $q \in L^1(0,b)$ is a complex-valued function and

$$\beta_{11}=\beta_{12}=\alpha_{21}=\alpha_{22}=0, \quad \beta_{11},\beta_{12},\alpha_{21},\alpha_{22}\in\mathbb{C}, \tag{1.15}$$

although no error analysis is given in [5].

The aim of this paper is twofold. The first is to derive the method of using the sinc technique in computing eigenvalues of a general Birkhoff-regular second order eigenvalue problem; cf. [2, 21, 22] for definitions. Our second aim is to derive a complete error analysis for the general method, which will also cover the previous omissions. The definition of Birkhoff-regularity is technical [21, section 4.8]. Fortunately Naimark has categorized all regular second order problems as follows.

Case I. $\alpha_{12}\beta_{22}-\alpha_{22}\beta_{12}\ne 0$.

Case II. $\alpha_{12}\beta_{22}-\alpha_{22}\beta_{12}=0, \quad |\alpha_{12}|+|\beta_{12}|>0, \beta_{12}\alpha_{21}+\beta_{21}\alpha_{12}\ne 0$.

Case III. $\alpha_{12}=\beta_{22}=\alpha_{22}=\beta_{12}=0,\ \alpha_{11}\beta_{21}-\beta_{11}\alpha_{21}\ne 0$.

Obviously conditions (1.11)–(1.12) are regular if any of (1.13), (1.14), and (1.15) is fulfilled. Therefore the application of the sinc method to compute the eigenvalues of general regular second order problems will contain all of these cases as special cases. On the other hand, the choice of a regular boundary condition guarantees the existence of a countable set of eigenvalues without finite limit points; cf. [21, p. 64]. The eigenvalues are not necessarily real, and each eigenvalue has algebraic multiplicity which is less than or equals 2. Also the asymptotic behavior of these eigenvalues is given in [21, section 4.8]. Since no error analysis can be established in the general case without error estimates for truncation and amplitude errors on $\mathbb{C}$ for (1.1) and its derivative, we will study truncation and amplitude errors on $\mathbb{C}$ for (1.1) and its derivative. This is the second aim of this paper, and it will be done in the next section. Section 3 is devoted to the numerical computation of the eigenvalues of (1.10)–(1.12) and the associated error analysis. The last section is devoted to giving some new examples exhibiting the technique. In these new examples we study various situations and indicate the effect of the amplitude error, which has been neglected in previous studies. The following complex mean value theorem [15] will be used in what follows. Assume that $f(\mu)$ is holomorphic on an open convex set $\Omega\in\mathbb{C}$. Let a and b be distinct points in Ω and $\Gamma_{a,b}$ be the line joining a and b in Ω. Then there exist $\xi_1,\xi_2\in\Gamma_{a,b}$ such that

$$\Re\left(\frac{f(b)-f(a)}{b-a}\right)=\Re(f'(\xi_1)), \qquad \Im\left(\frac{f(b)-f(a)}{b-a}\right)=\Im(f'(\xi_2)). \tag{1.16}$$

2. Error analysis on $\mathbb{C}$. In this section we establish the error analysis associated with (1.1) on $\mathbb{C}$ which will be needed in what follows. We consider both truncation and amplitude errors. We derive three results. Our first result extends (1.5) to the case of the complex plane. For our second result, we extend a previous

derivation of the derivative sampling theorem to the complex plane $\mathbb{C}$. The last result gave an estimate of the amplitude error of (1.1) and the derivative sampling series on $\mathbb{C}$. Now let $N \in \mathbb{Z}^+$ and Ω_N be the disk

$$\Omega_N := \left\{ \mu \in \mathbb{C} : |\mu| < \frac{N\pi}{\sigma}, \quad N \in \mathbb{Z}^+ \right\}. \tag{2.1}$$

THEOREM 2.1. *Let $N \in \mathbb{Z}^+$, $\mu \in \mathbb{C}$, and $f(\mu) \in B_\sigma^2$. Assume that $\mu f(\mu) \in L^2(\mathbb{R})$ when restricted to $\mathbb{R}$. Then we have*

$$|R_N(\mu)| \le \frac{2E}{\pi^2\sqrt{3}} \frac{\sigma\sqrt{\sigma}|\sin\sigma\mu|}{N+1} \left(\frac{1}{\sqrt{N\pi - \sigma\Re\,\mu}} + \frac{1}{\sqrt{N\pi + \sigma\Re\,\mu}} \right), \quad \mu \in \Omega_N, \tag{2.2}$$

where E is given in (1.6) *above.*

Proof. By applying triangle and Cauchy–Schwarz inequalities to $R_N(\mu)$ (cf. (1.3)), we obtain

$$\begin{aligned} |R_N(\mu)| \le{}& \left(\sum_{n>N} \left| f\left(\frac{n\pi}{\sigma}\right) \right|^2 \right)^{1/2} \left(\sum_{n>N} |\mathrm{sinc}\,(\sigma\mu - n\pi)|^2 \right)^{1/2} \\ &+ \left(\sum_{n<-N} \left| f\left(\frac{n\pi}{\sigma}\right) \right|^2 \right)^{1/2} \left(\sum_{n<-N} |\mathrm{sinc}\,(\sigma\mu - n\pi)|^2 \right)^{1/2}. \end{aligned} \tag{2.3}$$

Since $f(\mu) \in B_\sigma^2$ and $\mu f(\mu) \in L^2(\mathbb{R})$ when restricted to $\mathbb{R}$, then [18, p. 716]

$$\left(\sum_{n>N} \left| f\left(\frac{n\pi}{\sigma}\right) \right|^2 \right)^{1/2} \le \frac{2\sigma^{3/2}E}{\pi^{3/2}\sqrt{3}(N+1)}, \quad \left(\sum_{n<-N} \left| f\left(\frac{n\pi}{\sigma}\right) \right|^2 \right)^{1/2} \le \frac{2\sigma^{3/2}E}{\pi^{3/2}\sqrt{3}(N+1)}. \tag{2.4}$$

Let $\mu := x + iy \in \Omega_N$, $x, y \in \mathbb{R}$. Then

$$\begin{aligned} \sum_{n>N} |\mathrm{sinc}\,(\sigma\mu - n\pi)|^2 &= \sum_{n>N} \frac{|\sin\sigma\mu|^2}{|\sigma\mu - n\pi|^2} \le |\sin\sigma\mu|^2 \sum_{n>N} \frac{1}{(\sigma x - n\pi)^2} \\ &< |\sin\sigma\mu|^2 \int_N^\infty \frac{du}{(\sigma x - u\pi)^2} \le \frac{|\sin\sigma\mu|^2}{\pi(N\pi - \sigma x)}. \end{aligned} \tag{2.5}$$

Similarly

$$\sum_{n<-N} |\mathrm{sinc}\,(\sigma\mu - n\pi)|^2 < \frac{|\sin\sigma\mu|^2}{\pi(N\pi + \sigma x)}, \quad \mu \in \Omega_N. \tag{2.6}$$

By combining (2.3)–(2.6) we obtain (2.2). □

Remark 2.2. Letting $\mu \in \mathbb{R}$ in (2.2) leads to Jagerman estimation (1.5).

In [5] sinc methods are applied to compute eigenvalues for non-self-adjoint eigenvalue problems. However, no error analysis is given. The previous result gives us a chance to compute the error analysis when the eigenvalues are complex. If the eigenvalues are not algebraically simple, estimates (1.5) and (2.2) are not sufficient to compute the error bounds. We need to derive a truncation error estimate of the derivative of sampling series

$$f'(\mu) := \sum_{n=-\infty}^{\infty} f\left(\frac{n\pi}{\sigma}\right) \mathrm{sinc}\,'(\sigma\mu - n\pi), \quad \mu \in \mathbb{C}. \tag{2.7}$$

Series (2.7) converges absolutely on $\mathbb{C}$ and uniformly on $\mathbb{R}$ and on compact subsets of $\mathbb{C}$ [16, p. 52]. Let $N \in \mathbb{Z}^+$ and $R_{1,N}(\mu)$ be

$$R_{1,N}(\mu) := f'(\mu) - f'_N(\mu), \quad f'_N(\mu) := \sum_{n=-N}^{N} f\left(\frac{n\pi}{\sigma}\right) \operatorname{sinc}'(\sigma\mu - n\pi), \quad \mu \in \mathbb{C}. \tag{2.8}$$

THEOREM 2.3. *Let $N \in \mathbb{Z}^+$, $\mu \in \mathbb{C}$, and $f(\mu) \in B^2_\sigma$. Assume that $\mu f(\mu) \in L^2(\mathbb{R})$ when restricted to $\mathbb{R}$. Then we have*

$$\begin{aligned} |R_{1,N}(\mu)| \le{}& \frac{2E}{\pi^2\sqrt{3}} \frac{\sigma^{5/2}|\cos\sigma\mu|}{N+1} \left(\frac{1}{\sqrt{N\pi - \sigma\Re\mu}} + \frac{1}{\sqrt{N\pi + \sigma\Re\mu}}\right) \\ &+ \frac{2E}{3\pi^2} \frac{\sigma^{5/2}\,|\sin\sigma\mu|}{N+1} \left(\frac{1}{(N\pi - \sigma\Re\mu)^{3/2}} + \frac{1}{(N\pi + \sigma\Re\mu)^{3/2}}\right), \quad \mu \in \Omega_N. \end{aligned} \tag{2.9}$$

Proof. From triangle and Cauchy–Schwarz inequalities we obtain, for $\mu \in \Omega_N$,

$$\begin{aligned} |R_{1,N}(\mu)| \le{}& \sigma \left(\sum_{n>N} \left|f\left(\frac{n\pi}{\sigma}\right)\right|^2\right)^{1/2} \left\{\left(\sum_{n>N} \frac{|\cos\sigma\mu|^2}{|\sigma\mu - n\pi|^2}\right)^{1/2} + \left(\sum_{n>N} \frac{|\sin\sigma\mu|^2}{|\sigma\mu - n\pi|^4}\right)^{1/2}\right\} \\ &+ \sigma \left(\sum_{n<-N} \left|f\left(\frac{n\pi}{\sigma}\right)\right|^2\right)^{1/2} \left\{\left(\sum_{n<-N} \frac{|\cos\sigma\mu|^2}{|\sigma\mu - n\pi|^2}\right)^{1/2} \right. \\ &\left. + \left(\sum_{n<-N} \frac{|\sin\sigma\mu|^2}{|\sigma\mu - n\pi|^4}\right)^{1/2}\right\}. \end{aligned} \tag{2.10}$$

Let $\Omega_N \ni \mu := x + iy,\ x, y \in \mathbb{R}$. Then

$$\sum_{n>N} \frac{1}{|\sigma\mu - n\pi|^2} \le \sum_{n>N} \frac{1}{(\sigma x - n\pi)^2} < \int_N^\infty \frac{du}{(\sigma x - u\pi)^2} = \frac{1}{\pi} \frac{1}{N\pi - \sigma x}, \tag{2.11}$$

$$\sum_{n>N} \frac{1}{|\sigma\mu - n\pi|^4} \le \sum_{n>N} \frac{1}{(\sigma x - n\pi)^4} < \int_N^\infty \frac{du}{(\sigma x - u\pi)^4} = \frac{1}{3\pi} \frac{1}{(N\pi - \sigma x)^3}. \tag{2.12}$$

Similarly,

$$\sum_{n<-N} \frac{1}{|\sigma\mu - n\pi|^2} < \frac{1}{\pi} \frac{1}{N\pi + \sigma x}, \quad \sum_{n<-N} \frac{1}{|\sigma\mu - n\pi|^4} < \frac{1}{3\pi} \frac{1}{(N\pi + \sigma x)^3}. \tag{2.13}$$

Substituting from (2.11)–(2.13) and (2.4) in (2.10) completes the proof. ∎

Now we derive estimates for the amplitude error of (1.1) and (2.7) on $\mathbb{C}$. We start with the following two lemmas.

LEMMA 2.4. *Given $p, q > 1$ such that $\frac{1}{p} + \frac{1}{q} = 1$. We have for $r \in \mathbb{N}$*

$$\sum_{n=-\infty}^{\infty} \left(\frac{1}{\pi|n - 1/2|}\right)^{q(r+1)} < p. \tag{2.14}$$

Proof. Obviously

$$\sum_{n=-\infty}^{\infty} \left(\frac{1}{\pi|n - 1/2|}\right)^{q(r+1)} = 2\left(\frac{2}{\pi}\right)^{q(r+1)} + \frac{2}{\pi^{q(r+1)}} \sum_{n=1}^{\infty} \frac{1}{(n + 1/2)^{q(r+1)}}. \tag{2.15}$$

By using the inequalities

$$(2/\pi)^{q(r+1)} < 1, \quad (\pi(n-1/2))^{q(r+1)} \geq (\pi(n-1/2))^q,$$
$$(\pi(n+1/2))^{q(r+1)} \geq (\pi(n+1/2))^q,$$

and Higgins estimate (cf. [16, pp. 114–115])

$$1 + \frac{1}{\pi^q} \sum_{n=1}^{\infty} \left\{ \frac{1}{(n-1/2)^q} + \frac{1}{(n+1/2)^q} \right\} < p \tag{2.16}$$

in (2.15), we obtain (2.14). □

LEMMA 2.5. *Let p, $q > 1$ such that $\frac{1}{p} + \frac{1}{q} = 1$. For $r = 0, 1$, we have*

$$\left(\sum_{n=-\infty}^{\infty} \left| \operatorname{sinc}^{(r)}(\sigma\mu - n\pi) \right|^q \right)^{1/q} < (r+1)\, p\, \sigma^r \exp(\sigma|\Im\mu|), \quad \mu \in \mathbb{C}. \tag{2.17}$$

Proof. The sum in (2.17) is periodic with period π/σ. Indeed,

$$\sum_{n=-\infty}^{\infty} \left| \operatorname{sinc}^{(r)} \left(\sigma \left(\mu + \frac{\pi}{\sigma} \right) - n\pi \right) \right|^q = \sum_{n=-\infty}^{\infty} \left| \operatorname{sinc}^{(r)} (\sigma\mu - (n-1)\pi) \right|^q,$$

$r = 1, 2, \mu \in \mathbb{C}$. By replacing $n-1$ by n, we proved the π/σ-periodicity of the sum of (2.17). Define the strip $\mathcal{S}_\sigma$ to be $\mathcal{S}_\sigma := \{\mu \in \mathbb{C} : |\Re\mu| \leq \pi/2\sigma\}$. From the periodicity of the sum in (2.17), it is sufficient to prove the lemma only on the strip $\mathcal{S}_\sigma$. We distinguish between two cases. Let $r = 0$, $\mathcal{S}_\sigma \ni \mu := x + iy$, $x, y \in \mathbb{R}$.

$$|\operatorname{sinc}(\sigma\mu - n\pi)| \leq \frac{|\sin \sigma\mu|}{|\sigma\mu - n\pi|} \leq \frac{\exp(\sigma|y|)}{|\sigma x - n\pi|}. \tag{2.18}$$

Noting that

$$\operatorname{sinc} \sigma\mu := \frac{1}{2\sigma} \int_{-\sigma}^{\sigma} e^{i\mu\omega} d\omega,$$

then

$$|\operatorname{sinc} \sigma\mu| \leq \exp(\sigma|y|). \tag{2.19}$$

By using (2.18), (2.19), and the fact that $|\sin \sigma\mu| \leq \exp(\sigma|y|)$, we obtain

$$\begin{aligned} &\left(\sum_{n=-\infty}^{\infty} |\operatorname{sinc}(\sigma\mu - n\pi)|^q \right)^{1/q} \\ &\quad \leq \left(1 + \sum_{n=1}^{\infty} \left\{ \frac{1}{(n\pi - \sigma x)^q} + \frac{1}{(n\pi + \sigma x)^q} \right\} \right)^{1/q} \exp(\sigma|y|) \\ &\quad \leq \left(1 + \frac{1}{\pi^q} \sum_{n=1}^{\infty} \left\{ \frac{1}{(n-1/2)^q} + \frac{1}{(n+1/2)^q} \right\} \right)^{1/q} \exp(\sigma|y|), \end{aligned} \tag{2.20}$$

where $\mu \in \mathcal{S}_\sigma$ and we have used the fact that the function $1/2(n\pi - \sigma x)^q + 1/(n\pi + \sigma x)^q$ has a maximum on $[-\pi/2\sigma, \pi/2\sigma]$ at $x := \pm\pi/2\sigma$. Substituting from (2.16) in (2.20) yields (2.17) when $r = 0$. Now we study the case when $r = 1$. For $\mu \in \mathcal{S}_\sigma$ and $n \neq 0$,

we obtain

$$\left|\operatorname{sinc}'(\sigma\mu - n\pi)\right| \le \frac{\sigma|\cos\sigma\mu|}{|\sigma\mu - n\pi|} + \frac{\sigma|\sin\sigma\mu|}{|\sigma\mu - n\pi|^2} \le \frac{\sigma\exp(\sigma|y|)}{|\sigma x - n\pi|} + \frac{\sigma\exp(\sigma|y|)}{|\sigma x - n\pi|^2}. \tag{2.21}$$

Also

$$\operatorname{sinc}'\sigma\mu = \frac{i}{2\sigma}\int_{-\sigma}^{\sigma} \omega\, e^{i\mu\omega} d\omega,$$

and therefore

$$\left|\operatorname{sinc}'\sigma\mu\right| \le \sigma\exp(\sigma|y|). \tag{2.22}$$

By using (2.21) and (2.22), we obtain for $\mu \in \mathcal{S}_\sigma$

$$\begin{aligned}
&\frac{1}{\sigma}\left(\sum_{n=-\infty}^{\infty}\left|\operatorname{sinc}'(\sigma\mu - n\pi)\right|^q\right)^{1/q} \\
&\quad\le \left(\left|\operatorname{sinc}'\sigma\mu\right|^q + \sum_{n\in\mathbb{Z}\setminus\{0\}}\left|\operatorname{sinc}'(\sigma\mu - n\pi)\right|^q\right)^{1/q} \\
&\quad\le \left(1 + \sum_{n\in\mathbb{Z}\setminus\{0\}}\left(\frac{1}{|n\pi - \sigma x|} + \frac{1}{|n\pi - \sigma x|^2}\right)^q\right)^{1/q} \exp(\sigma|y|). \qquad (2.23)
\end{aligned}$$

For $n \in \mathbb{Z}^+$ the functions

$$g_n(x) := \left(\frac{1}{(n\pi - \sigma x)} + \frac{1}{(n\pi - \sigma x)^2}\right)^q + \left(\frac{1}{(n\pi + \sigma x)} + \frac{1}{(n\pi + \sigma x)^2}\right)^q, \quad |x| \le \pi/2\sigma, \tag{2.24}$$

are positive even functions that attain their maximum at $x := \pm\pi/2\sigma$. Therefore by noting that $2/\pi + (2/\pi)^2 > 1$, we obtain

$$\begin{aligned}
&\left(1 + \sum_{n\in\mathbb{Z}\setminus\{0\}}\left(\frac{1}{|n\pi - \sigma x|} + \frac{1}{|n\pi - \sigma x|^2}\right)^q\right)^{1/q} \\
&\quad\le \left(1 + \sum_{n\in\mathbb{Z}\setminus\{0\}}\left(\frac{1}{\pi|n - 1/2|} + \frac{1}{\pi^2|n - 1/2|^2}\right)^q\right)^{1/q} \\
&\quad\le \left(\sum_{n=-\infty}^{\infty}\left(\frac{1}{\pi|n - 1/2|} + \frac{1}{\pi^2|n - 1/2|^2}\right)^q\right)^{1/q}. \qquad (2.25)
\end{aligned}$$

By applying the Minkowsky inequality to (2.25) and blogging in (2.23), we obtain

$$\begin{aligned}
&\left(\sum_{n=-\infty}^{\infty}\left|\operatorname{sinc}'(\sigma\mu - n\pi)\right|^q\right)^{1/q} \\
&\quad\le \sigma\left(\left(\sum_{n=-\infty}^{\infty}\frac{1}{\pi^q|n - 1/2|^q}\right)^{1/q} + \left(\sum_{n=-\infty}^{\infty}\frac{1}{\pi^{2q}|n - 1/2|^{2q}}\right)^{1/q}\right)\exp(\sigma|y|). \qquad (2.26)
\end{aligned}$$

Estimation (2.17) could be obtained by combining (2.14) and (2.26), $r = 1$. ∎

Now we derive an amplitude error estimate which will be used in our investigations.

THEOREM 2.6. *Let $\mu \in \mathbb{C}$. Assume that $f \in B_\sigma^2$ such that* (1.7) *and* (1.8) *hold. Then for $0 < \varepsilon \le \min\{\sigma/\pi, \pi/\sigma, 1/\sqrt{e}\}$ we have*

$$|(A_\varepsilon) f^{(r)}(\mu)| \le (r+1)\sigma^r A(\varepsilon) \exp(\sigma|\Im\mu|), \quad r = 0, 1,\ \mu \in \mathbb{C}. \tag{2.27}$$

Proof. Let $\frac{1}{q} + \frac{1}{p} = 1$, $p > 1$, and $r \in \{0, 1\}$. From the Hölder inequality and (2.17), we obtain

$$\begin{aligned} \left|(A_\varepsilon) f^{(r)}(\mu)\right| &\le \left(\sum_{n=-\infty}^{\infty} \left| \operatorname{sinc}^{(r)}(\sigma\mu - n\pi) \right|^q \right)^{1/q} \left(\sum_{n=-\infty}^{\infty} |\varepsilon_n|^p \right)^{1/p} \\ &\le (r+1)\sigma^r \left(\sum_{n=-\infty}^{\infty} |\varepsilon_n|^p \right)^{1/p} \exp(\sigma|\Im\mu|), \quad \mu \in \mathbb{C}. \end{aligned} \tag{2.28}$$

Let $N_0 := \left[\frac{\sigma}{\pi}\right]$ and $N \in \mathbb{Z}^+$ such that $N \ge N_0$. By applying the Minkowsky inequality, we obtain

$$\left(\sum_{n=-\infty}^{\infty} |\varepsilon_n|^p \right)^{1/p} \le \left(\sum_{|n|\le N} |\varepsilon_n|^p \right)^{1/p} + \left(\sum_{|n|>N} |\varepsilon_n|^p \right)^{1/p}. \tag{2.29}$$

Since $|\varepsilon_n| < \varepsilon$, then

$$\left(\sum_{n=-N}^{N} |\varepsilon_n|^p \right)^{1/p} \le \varepsilon(2N+1)^{1/p}. \tag{2.30}$$

By using (1.7) and (1.8), then for $p \ge 2$, we get

$$\left(\sum_{|n|>N} |\varepsilon_n|^p \right)^{1/p} \le \left(\sum_{|n|>N} \left| f\left(\frac{n\pi}{\sigma}\right) \right|^p \right)^{1/p} \le \sqrt{2} M_f \left(\frac{\sigma}{\pi}\right) N^{(1-p)/p}. \tag{2.31}$$

By combining (2.31), (2.30), and (2.28) we obtain, for $\mu \in \mathbb{C}$,

$$\left|(A_\varepsilon) f^{(r)}(\mu)\right| \le (r+1)\sigma^r p \left(\varepsilon(2N+1)^{1/p} + \sqrt{2} M_f \left(\frac{\sigma}{\pi}\right) N^{(1-p)/p} \right) \exp(\sigma|\Im\mu|). \tag{2.32}$$

The parameters N and p will be chosen suitably to obtain the desired estimate. We distinguish between two cases. When $\sigma \ge \pi$ we take

$$N := \left[\varepsilon^{-1} \left(\frac{\sigma}{\pi}\right)^{\frac{p}{p-1}} \right], \quad p = 4\log(1/\varepsilon). \tag{2.33}$$

Since $\varepsilon \le \{\pi/\sigma, 1/\sqrt{e}\}$, then $(\frac{\sigma}{\pi}) \le \frac{1}{\varepsilon}$ and $N \ge N_0$. Therefore

$$(2N+1)^{1/p} \le \sqrt{3}\, \varepsilon^{-1/p} \left(\frac{\pi}{\sigma}\right)^{\frac{1}{p-1}} \le \sqrt{3} \left(\frac{1}{\varepsilon}\right)^{\frac{2p-1}{p(p-1)}} \le \sqrt{3} \left(\frac{1}{\varepsilon}\right)^{\frac{4}{p}} \le \sqrt{3}\, e, \tag{2.34}$$

where the last inequality comes by taking the logarithm of both sides and using (2.33). Also

$$\left(\frac{\sigma}{\pi}\right) N^{(1-p)/p}) \leq \varepsilon^{\frac{p-1}{p}} = e^{1/4}\varepsilon. \tag{2.35}$$

By substituting from (2.35) and (2.34) in (2.32) and noting that $p = 4\log(1/\varepsilon)$, we obtain (2.27). If $\sigma < \pi$, we choose

$$N := \left[\varepsilon^{-1}\left(\frac{\pi}{\sigma}\right)^{\frac{p}{p-1}}\right]. \tag{2.36}$$

In this case $N_0 = 0$, and we proceed as in the previous case. This ends the proof. □

Remark 2.7. Letting $\mu \in \mathbb{R}$, estimation (2.17) turns out to be

$$\left(\sum_{n=-\infty}^{\infty} \left|\operatorname{sinc}^{(r)}(\sigma\mu - n\pi)\right|^q\right)^{1/q} < (r+1)\, p\, \sigma^r, \quad r = 0, 1, \tag{2.37}$$

leading to the special case obtained by Splettstösser, Stens, and Wilmes [23] when $r = 0$. Also if $\mu \in \mathbb{R}$, then (2.27) becomes

$$|(A_\varepsilon) f^{(r)}(\mu)| \leq (r+1)\sigma^r A(\varepsilon), \quad r = 0, 1. \tag{2.38}$$

In the special case $r = 0$ and $\sigma \geq \pi$ we obtain the result of Butzer, Splettstösser, and Stens (1.9).

3. The scheme and error estimates. In this section we discuss the method and study the error analysis. Let $y_1(\cdot, \mu)$ and $y_2(\cdot, \mu)$ denote the solutions of (1.10) satisfying the following initial conditions:

$$y_j^{(i-1)}(0, \mu) = \delta_{ij}, \qquad i, j = 1, 2, \quad \mu \in \mathbb{C}. \tag{3.1}$$

It is known [13, 21] that $y_i(x, \mu)$ is entire in μ for $x \in [0, b]$, and the eigenvalues of the problem (1.10)–(1.12) are the zeros of the characteristic determinant

$$\Delta(\mu) := \begin{vmatrix} U_1(y_1) & U_1(y_2) \\ U_2(y_1) & U_2(y_2) \end{vmatrix}. \tag{3.2}$$

The characteristic determinant $\Delta(\mu)$ is also an entire function of μ. By using the method of variation of constants we can write $y_1(x, \mu)$ and $y_2(x, \mu)$, respectively, as the solutions of the following Volterra integral equations:

$$y_1(x, \mu) = \cos(\mu x) + (\mathcal{T} y_1)(x, \mu), \qquad y_2(x, \mu) = \frac{\sin(\mu x)}{\mu} + (\mathcal{T} y_2)(x, \mu), \tag{3.3}$$

where $\mathcal{T}$ is the Volterra operator defined by

$$(\mathcal{T} y)(x, \mu) := \int_0^x \frac{\sin \mu(x - t)}{\mu}\, q(t) y(t, \mu) dt; \tag{3.4}$$

cf., e.g., [13, p. 92]. By differentiating (3.3) we obtain

$$y_1'(x, \mu) = -\mu \sin(\mu x) + (\widetilde{\mathcal{T}} y_1)(x, \mu), \qquad y_2'(x, \mu) = \cos(\mu x) + (\widetilde{\mathcal{T}} y_2)(x, \mu), \tag{3.5}$$

where $\widetilde{\mathcal{T}}$ is the Volterra operator defined by

$$(\widetilde{\mathcal{T}}y)(x,\mu) := \int_0^x \cos(\mu(x-t))\, q(t) y(t,\mu) dt; \tag{3.6}$$

see [13, p. 92]. The method of successive approximation yields

$$y_1(x,\mu) = \sum_{n=0}^{\infty} \mathcal{T}^n \cos(\mu x), \quad y_2(x,\mu) = \sum_{n=0}^{\infty} \mathcal{T}^n \frac{\sin(\mu x)}{\mu}, \tag{3.7}$$

where $\mathcal{T}^0$ is the identity operator and the convergence in (3.7) is uniform on $[0,b]$ for any $\mu \in \mathbb{C}$. By differentiating (3.7) we have [3], with uniform convergence on $[0,b]$,

$$y_1'(x,\mu) = -\mu \sin(\mu x) + \sum_{n=0}^{\infty} \widetilde{\mathcal{T}}\mathcal{T}^n \cos(\mu x), \quad y_2'(x,\mu) = \cos(\mu x) + \sum_{n=0}^{\infty} \widetilde{\mathcal{T}}\mathcal{T}^n \frac{\sin(\mu x)}{\mu}. \tag{3.8}$$

For convenience we let

$$\begin{aligned} &C_1 := \alpha_{11}\alpha_{22} - \alpha_{12}\alpha_{21}, \quad && C_2 := \alpha_{11}\beta_{22} - \alpha_{21}\beta_{12}, \quad && C_3 := \alpha_{12}\beta_{22} - \alpha_{22}\beta_{12}, \\ &C_4 := \alpha_{22}\beta_{11} - \alpha_{12}\beta_{21}, \quad && C_5 := \beta_{22}\beta_{11} - \beta_{12}\beta_{21}, \quad && C_6 := \alpha_{11}\beta_{21} - \alpha_{21}\beta_{11}. \end{aligned} \tag{3.9}$$

By substituting from (3.7) and (3.8) in (3.2) we obtain

$$\begin{aligned} \Delta(\mu) = {} & C_1 + C_2 \cos[b\mu] + C_3 \mu \sin[b\mu] + (C_4 + C_5 \cos[b\mu]) \sum_{n=0}^{\infty} \mathcal{T}^n[\cos(\mu x)](b) \\ & + (C_6 + C_5 \mu \sin[b\mu]) \sum_{n=0}^{\infty} \mathcal{T}^n \left[\frac{\sin(\mu x)}{\mu}\right](b) + C_3 \sum_{n=0}^{\infty} \widetilde{\mathcal{T}}\mathcal{T}^n[\cos(\mu x)](b) \\ & + C_2 \sum_{n=0}^{\infty} \widetilde{\mathcal{T}}\mathcal{T}^n \left[\frac{\sin(\mu x)}{\mu}\right](b) + C_5 \sum_{n=0}^{\infty} \mathcal{T}^n \left[\frac{\sin(\mu x)}{\mu}\right](b) \sum_{n=0}^{\infty} \widetilde{\mathcal{T}}\mathcal{T}^n[\cos(\mu x)](b) \\ & + C_5 \sum_{n=0}^{\infty} \mathcal{T}^n[\cos(\mu x)](b) \sum_{n=0}^{\infty} \widetilde{\mathcal{T}}\mathcal{T}^n \left[\frac{\sin(\mu x)}{\mu}\right](b). \end{aligned} \tag{3.10}$$

Let us split $\Delta(\mu)$ into two parts via

$$\Delta(\mu) := \mathcal{K}(\mu) + \mathcal{U}(\mu), \tag{3.11}$$

where $\mathcal{K}(\mu)$ is the known part

$$\begin{aligned} \mathcal{K}(\mu) := {} & C_1 + C_2 \cos[b\mu] + C_3 \mu \sin[b\mu] + (C_4 + C_5 \cos[b\mu]) \sum_{n=0}^{1} \mathcal{T}^n[\cos(\mu x)](b) \\ & + (C_6 + C_5 \mu \sin[b\mu]) \sum_{n=0}^{1} \mathcal{T}^n \left[\frac{\sin(\mu x)}{\mu}\right](b) \\ & + C_3 \sum_{n=0}^{1} \widetilde{\mathcal{T}}\mathcal{T}^n[\cos(\mu x)](b) + C_2 \widetilde{\mathcal{T}} \left[\frac{\sin(\mu x)}{\mu}\right](b) \\ & + C_5 \frac{\sin[b\mu]}{\mu} \sum_{n=0}^{1} \widetilde{\mathcal{T}}\mathcal{T}^n[\cos(\mu x)](b) + C_5 \widetilde{\mathcal{T}} \left[\frac{\sin[x\mu]}{\mu}\right](b) \sum_{n=0}^{1} \mathcal{T}^n[\cos(\mu x)](b) \end{aligned} \tag{3.12}$$

and $\mathcal{U}(\mu)$ is the infinite sum

(3.13)
$$\begin{aligned}\mathcal{U}(\mu) := &\left(C_4 + C_5\cos[b\mu] + C_5\widetilde{\mathcal{T}}\left[\frac{\sin(\mu x)}{\mu}\right](b)\right)\sum_{n=2}^{\infty}\mathcal{T}^n[\cos(\mu x)](b)\\ &+ C_2\sum_{n=1}^{\infty}\widetilde{\mathcal{T}}\mathcal{T}^n\left[\frac{\sin(\mu x)}{\mu}\right](b) + \left(C_3 + C_5\frac{\sin(\mu b)}{\mu}\right)\sum_{n=2}^{\infty}\widetilde{\mathcal{T}}\mathcal{T}^n[\cos(\mu x)](b)\\ &+ \ (C_6 + C_5\mu\sin[b\mu])\sum_{n=2}^{\infty}\mathcal{T}^n\left[\frac{\sin(\mu x)}{\mu}\right](b)\\ &+ C_5\sum_{n=0}^{1}\widetilde{\mathcal{T}}\mathcal{T}^n[\cos(\mu x)](b)\sum_{n=1}^{\infty}\mathcal{T}^n\left[\frac{\sin(\mu x)}{\mu}\right](b)\\ &+ C_5\sum_{n=1}^{\infty}\mathcal{T}^n\left[\frac{\sin(\mu x)}{\mu}\right](b)\sum_{n=2}^{\infty}\widetilde{\mathcal{T}}\mathcal{T}^n[\cos(\mu x)](b)\\ &+ C_5\sum_{n=0}^{1}\mathcal{T}^n[\cos(\mu x)](b)\sum_{n=1}^{\infty}\widetilde{\mathcal{T}}\mathcal{T}^n\left[\frac{\sin(\mu x)}{\mu}\right](b)\\ &+ C_5\sum_{n=2}^{\infty}\mathcal{T}^n[\cos(\mu x)](b)\sum_{n=1}^{\infty}\widetilde{\mathcal{T}}\mathcal{T}^n\left[\frac{\sin(\mu x)}{\mu}\right](b).\end{aligned}$$

The next step is to show that $\mathcal{U}(\mu)$ lies in a Paly–Wiener space B_σ^2 for some $\sigma > 0$. We start with the following introductory estimates.

LEMMA 3.1. *For $n \in \mathbb{N}$ and $\mu \in \mathbb{R}$, we have*

$$\left|\mathcal{T}^n\left[\frac{\sin(\mu x)}{\mu}\right](b)\right| \le \frac{\tau^n}{|\mu|^{n+1}}, \qquad \left|\mathcal{T}^n\big[\cos(\mu x)\big](b)\right| \le \frac{\tau^n}{|\mu|^n}, \tag{3.14}$$

$$\left|\widetilde{\mathcal{T}}\mathcal{T}^n\left[\frac{\sin(\mu x)}{\mu}\right](b)\right| \le \frac{\tau^{n+1}}{|\mu|^{n+1}}, \qquad \left|\widetilde{\mathcal{T}}\mathcal{T}^n\big[\cos(\mu x)\big](b)\right| \le \frac{\tau^{n+1}}{|\mu|^n}, \tag{3.15}$$

where $\tau := \int_0^b |q(t)|dt$.

Proof. We prove the first inequality of (3.14) by induction on n. Assume it holds when $n = m \in \mathbb{N}$, $m \ge 1$. Then

$$\left|\mathcal{T}^{m+1}\left[\frac{\sin(\mu x)}{\mu}\right](b)\right| \le \frac{1}{|\mu|}\int_0^b |q(t)|\left|\mathcal{T}^m\left[\frac{\sin(\mu x)}{\mu}\right](t)\right| dt \le \frac{\tau^{m+1}}{|\mu|^{m+2}}. \tag{3.16}$$

This proves the first inequality of (3.14) for all $n \in N$ since it is obvious when $n = 1$. Similarly, the second inequality of (3.14) holds. By using (3.14) and the definition of $\widetilde{\mathcal{T}}$, we can easily prove (3.15). ∎

THEOREM 3.2. *Assume that $q(\cdot) \in L^1(0,b)$, and then $\mathcal{U}(\mu) \in B_{2b}^2$.*

Proof. Since $\Delta(\mu)$ and $\mathcal{K}(\mu)$ are entire functions in μ, then so is $\mathcal{U}(\mu)$. From Lemma 3.1 above, $\mathcal{U}(\mu) = \mathcal{O}(\frac{1}{|\mu|^2})$ when $|\mu| \to \pm\infty$. Then $S(\mu) \in L^2(\mathbb{R})$. It remains to show that there is a fixed constant $M > 0$ such that

$$|\mathcal{U}(\mu)| \le M\exp(2b|\Im\mu|), \quad \mu \in \mathbb{C}. \tag{3.17}$$

Indeed, for $\mu \in \mathbb{C}$ (see [9]) we have

$$\begin{aligned} &\left|\sum_{n=k}^{\infty} \mathcal{T}^n[\cos(t\mu)](b)\right| \le \left(\sum_{n=k}^{\infty} \frac{\gamma(\mu)^n}{n!}\right) \exp(b|\Im\mu|), \\ &\left|\sum_{n=k}^{\infty} \widetilde{\mathcal{T}}\mathcal{T}^n[\cos(t\mu)](b)\right| \le \tau \left(\sum_{n=k}^{\infty} \frac{\gamma(\mu)^n}{n!}\right) \exp(b|\Im\mu|), \end{aligned} \tag{3.18}$$

where τ is defined above, and

$$\gamma(\mu) := \frac{cb\tau}{1+|\mu|b}, \qquad c := 1.709.$$

Similarly (cf. [3, p. 7])

$$\begin{aligned} &\left|\sum_{n=k}^{\infty} \mathcal{T}^n\left[\frac{\sin(t\mu)}{\mu}\right](b)\right| \le \frac{cb}{1+|\mu|b}\left(\sum_{n=k}^{\infty} \frac{\delta(\mu)^n}{n!}\right) \exp(b|\Im\mu|), \\ &\left|\sum_{n=k}^{\infty} \widetilde{\mathcal{T}}\mathcal{T}^n\left[\frac{\sin(t\mu)}{\mu}\right](b)\right| \le \frac{cb\tau}{1+|\mu|b}\left(\sum_{n=k}^{\infty} \frac{\delta(\mu)^n}{n!}\right) \exp(b|\Im\mu|), \end{aligned} \tag{3.19}$$

where

$$\delta(\mu) := \int_0^b \frac{ct}{1+|\mu|t}|q(t)|dt.$$

By using the inequalities (cf. [9])

$$|\cos b\mu| \le \exp(b|\Im\mu|), \quad |\sin b\mu| \le \frac{c\,b|\mu|}{1+b|\mu|}\ \exp(b|\Im\mu|), \quad \mu \in \mathbb{C}, \tag{3.20}$$

and the fact that $\gamma(\mu)$, $\delta(\mu)$ are bounded functions, we can find $M > 0$ such that (3.17) is satisfied, completing the proof. □

Remark 3.3. In the special case when $C_5 = 0$, $\mathcal{U}(\mu) \in B_b^2$.

The following lemma is necessary for the applicability of Theorem 2.6.

LEMMA 3.4. *Assume that $q(\cdot) \in L^1(0,b)$. Then there exists a positive constant M such that*

$$|\mathcal{U}(\mu)| \le M|\mu|^{-1}, \quad |\mu| \ge 1, \quad \mu \in \mathbb{R}. \tag{3.21}$$

Proof. From the definitions of $\gamma(\mu)$ and $\delta(\mu)$, we obtain

$$\gamma(\mu), \delta(\mu) \le \frac{cb\tau}{1+b|\mu|}, \quad \mu \in \mathbb{C}, \tag{3.22}$$

$$\sum_{n=2}^{\infty} \frac{\gamma(\mu)^n}{n!} \le \gamma(\mu)^2 e^{\gamma(\mu)} \le \gamma(\mu)^2 e^{c\,b\tau}, \quad \mu \in \mathbb{C}. \tag{3.23}$$

Similarly

$$\sum_{n=2}^{\infty} \frac{\delta(\mu)^n}{n!} \le \delta(\mu)^2 e^{c\,b\tau}, \quad \mu \in \mathbb{C}. \tag{3.24}$$

For $\mu \in \mathbb{R}$ and by combining (3.24), (3.23), (3.22), (3.19), and (3.18), we can find a constant M such that

$$|\mathcal{U}(\mu)| \leq \frac{b^2 M}{(1+b|\mu|)^2}, \quad \mu \in \mathbb{R}, \tag{3.25}$$

which is reducible to (3.21) when $|\mu| \geq 1$. □

Applying the WKS sampling theorem to $\mathcal{U}(\mu)$, we obtain, for $\sigma = 2b$,

$$\mathcal{U}(\mu) := \sum_{n=-\infty}^{\infty} \mathcal{U}\left(\frac{n\pi}{2b}\right) \operatorname{sinc}(2b\mu - n\pi), \qquad \mu \in \mathbb{C}. \tag{3.26}$$

Let $N \in \mathbb{Z}^+$ and $\mathcal{U}_N(\mu)$ be the truncated sum of (3.26)

$$\mathcal{U}_N(\mu) := \sum_{n=-N}^{N} \mathcal{U}\left(\frac{n\pi}{2b}\right) \operatorname{sinc}(2b\mu - n\pi), \qquad \mu \in \mathbb{C}. \tag{3.27}$$

The use of $\mathcal{U}_N(\mu)$ produces a truncation error, i.e., $|\mathcal{U}(\mu) - \mathcal{U}_N(\mu)| \leq T_N(\mu)$; cf. Theorem 2.1 above, where $\mu \in \Omega_N$ and

$$T_N(\mu) := \frac{4\sqrt{2}E}{\pi^2\sqrt{3}} \, \frac{b\sqrt{b}\,|\sin 2b\mu|}{N+1} \left(\frac{1}{\sqrt{N\pi - 2b\Im\mu}} + \frac{1}{\sqrt{N\pi + 2b\Im\mu}} \right). \tag{3.28}$$

The samples $\mathcal{U}(n\pi/2b) = \Delta(n\pi/2b) - \mathcal{K}(n\pi/2b)$, $|n| \leq N$, cannot be computed explicitly in the general case. We approximate these samples by solving $4N+2$ initial-value problems defined by (1.10) and (3.1) to obtain the approximate values $\widetilde{\mathcal{U}}(n\pi/2b)$, $|n| \leq N$, i.e., $\widetilde{\mathcal{U}}_N\left(\frac{n\pi}{2b}\right) = \widetilde{\Delta}\left(\frac{n\pi}{2b}\right) - \mathcal{K}\left(\frac{n\pi}{2b}\right)$, and therefore we define $\widetilde{\mathcal{U}}(\mu)$ to be

$$\widetilde{\mathcal{U}}_N(\mu) := \sum_{n=-N}^{N} \widetilde{\mathcal{U}}\left(\frac{n\pi}{2b}\right) \operatorname{sinc}(2b\mu - n\pi). \tag{3.29}$$

For convenience let $A(\varepsilon, \mu) := A(\varepsilon)\exp(\sigma|\Im\mu|)$, where $A(\varepsilon)$ is defined above. Since $\mathcal{U}(\mu)$ satisfies the condition (3.21), then

$$\left|\mathcal{U}_N(\mu) - \widetilde{\mathcal{U}}_N(\mu)\right| \leq A(\varepsilon, \mu), \quad \mu \in \mathbb{C}. \tag{3.30}$$

Now let $\widetilde{\Delta}_N(\mu) := \mathcal{K}(\mu) + \widetilde{\mathcal{U}}_N(\mu)$. From (3.11) and (3.30) we obtain

$$|\Delta(\mu) - \widetilde{\Delta}_N(\mu)| \leq T_N(\mu) + A(\varepsilon, \mu), \quad \mu \in \Omega_N. \tag{3.31}$$

By similar treatment we can get for the derivative of $\Delta(\mu)$

$$|\Delta'(\mu) - \widetilde{\Delta'}_N(\mu)| \leq T_{1,N}(\mu) + 4bA(\varepsilon, \mu) \quad \mu \in \Omega_N. \tag{3.32}$$

Let $(\mu^*)^2$ be an eigenvalue and $(\mu_N)^2$ be its desired approximation, i.e., $\Delta(\mu^*) = 0$ and $\widehat{\Delta}_N(\mu_N) = 0$. From (3.31) we have $|\widetilde{\Delta}_N(\mu^*)| \leq T_N(\mu^*) + A(\varepsilon, \mu^*)$. Let Π_N be the region

$$\mu^* \in \Pi_N := \left\{\mu \in \Omega_N \text{ such that } \left|\widetilde{\Delta}_N(\mu)\right| \leq T_N(\mu) + A(\varepsilon, \mu)\right\}. \tag{3.33}$$

From Π_N we determine an enclosure annulus where μ_N lies in it. We solve the equation $\widetilde{\Delta}_N(\mu) = \pm(T_N(\mu) + A(\varepsilon, \mu))$. Let A_N be the set of all of these solutions. Then $\mu^* \in A_N$. Let $\mu_0, \mu_1 \in \Omega_N$ be

$$\mu_0 := \inf\{|\mu| : \ \mu \in \mathcal{A}_N\}, \quad \mu_1 := \sup\{|\mu| : \ \mu \in \mathcal{A}_N\}. \tag{3.34}$$

The enclosure annulus where μ_N lies is $\mathcal{A}_N := \{\mu \in \Omega_N : \ \mu_0 \le \mu \le \mu_1\}$. If $\mu^* \in \mathbb{R}$, the enclosure annulus becomes an interval I_N. The computation of the error bounds of $|\mu^* - \mu_N|$ depends on whether μ^* is simple or double.

THEOREM 3.5. *Let $(\mu^*)^2$ be a simple eigenvalue of* (1.10)–(1.12). *Then for all $\epsilon > 0$, there exists $N_0 \in \mathbb{N}$ such that for any positive integer N, $N \ge N_0$, there exists μ_N such that $|\mu^* - \mu_N| < \epsilon$. Furthermore, we have the following estimate:*

$$|\mu^* - \mu_N| < \frac{T_N(\mu_N) + A(\varepsilon, \mu_N)}{\inf_{\xi_1, \xi_2 \in \Gamma_{\mu^*, \mu_N}} \sqrt{(\Re\Delta'(\xi_1))^2 + (\Im\Delta'(\xi_2))^2}}. \tag{3.35}$$

Proof. The first part arises from the fact that $\widetilde{\Delta}_N(\mu)$ converges uniformly to $\Delta(\mu)$ on compact subsets of $\mathbb{C}$. By replacing μ by μ_N in (3.31) we obtain

$$|\Delta(\mu_N) - \Delta(\mu^*)| < T_N(\mu_N) + A(\varepsilon, \mu_N), \tag{3.36}$$

where we have used $\widetilde{\Delta}_N(\mu_N) = \Delta(\mu^*) = 0$. From the complex mean value theorem (cf. (1.16)), there exist $\xi_1, \xi_2 \in \Gamma_{\mu^*, \mu_N}$ such that

$$\begin{aligned} |(\overline{\mu_N} - \overline{\mu^*})(\Delta(\mu_N) - \Delta(\mu^*))| &= \big[(\Re\{(\overline{\mu_N} - \overline{\mu^*})(\Delta(\mu_N) - \Delta(\mu^*))\})^2 \\ &\quad + (\Im\{(\overline{\mu_N} - \overline{\mu^*})(\Delta(\mu_N) - \Delta(\mu^*))\})^2\big]^{1/2} \\ &= |\mu_N - \mu^*|^2 \sqrt{(\Re\Delta'(\xi_1))^2 + (\Im\Delta'(\xi_2))^2}. \end{aligned} \tag{3.37}$$

By combining (3.36) and (3.37) we obtain

$$|\mu_N - \mu^*| \sqrt{(\Re\Delta'(\xi_1))^2 + (\Im\Delta'(\xi_2))^2} < T_N(\mu_N) + A(\varepsilon, \mu_N). \tag{3.38}$$

Since μ^* is a simple zero of $\Delta(\mu)$ and N is sufficiently large, then

$$\inf_{\xi_1, \xi_2 \in \Gamma_{\mu^*, \mu_N}} \sqrt{(\Re\Delta'(\xi_1))^2 + (\Im\Delta'(\xi_2))^2} > 0,$$

and hence

$$|\mu^* - \mu_N| < \frac{T_N(\mu_N) + A(\varepsilon, \mu_N)}{\inf_{\xi_1, \xi_2 \in \Gamma_{\mu^*, \mu_N}} \sqrt{(\Re\Delta'(\xi_1))^2 + (\Im\Delta'(\xi_2))^2}},$$

which is (3.35). ∎

Now we estimate the error when $(\mu^*)^2$ is a double zero of $\Delta(\mu)$, i.e., $\Delta(\mu^*) = 0$, $\Delta'(\mu^*) = 0$ and $\Delta''(\mu^*) \ne 0$. In this case estimate (3.35) has no meaning.

THEOREM 3.6. *Let $(\mu^*)^2$ be a double eigenvalue of* (1.10)–(1.12). *Then for all $\epsilon > 0$, there exists $N_0 \in \mathbb{N}$ such that for any positive integer N, $N \ge N_0$, there exists μ_N such that $|\mu^* - \mu_N| < \epsilon$. Furthermore, we have the following estimate:*

$$|\mu^* - \mu_N| < \frac{T_{1,N}(\mu_N) + 4bA(\varepsilon, \mu_N)}{\inf_{\xi_1, \xi_2 \in \Gamma_{\mu^*, \mu_N}} \sqrt{(\Re\Delta''(\xi_1))^2 + (\Im\Delta''(\xi_2))^2}}. \tag{3.39}$$

Proof. The first part arises from the uniform convergence of $\widetilde{\Delta'}_N(\mu)$ to $\Delta'(\mu)$. Since $\widetilde{\Delta'}_N(\mu_N) = \Delta'(\mu^*) = 0$, then

$$|\Delta'(\mu_N) - \Delta'(\mu^*)| \le T_{1,N}(\mu_N) + 4bA(\varepsilon, \mu_N).$$

By similar treatments of (3.37) and using the complex mean value theorem, we obtain

(3.40)
$$|(\mu^* - \mu_N)| \sqrt{(\Re\Delta''(\xi_1))^2 + (\Im\Delta''(\xi_2))^2} < T_{1,N}(\mu_N) + 4bA(\varepsilon, \mu_N), \quad \xi_1, \xi_2 \in \Gamma_{\mu^*,\mu_N}.$$

Since μ^* is a double zero of $\Delta(\mu)$ and N is sufficiently large, then

$$\inf_{\xi_1,\xi_2 \in \Gamma_{\mu^*,\mu_N}} \sqrt{(\Re\Delta''(\xi_1))^2 + (\Im\Delta''(\xi_2))^2} > 0,$$

and hence

$$|\mu^* - \mu_N| < \frac{T_{1,N}(\mu_N) + 4bA(\varepsilon, \mu_N)}{\inf_{\xi_1,\xi_2 \in \Gamma_{\mu^*,\mu_N}} \sqrt{(\Re\Delta''(\xi_1))^2 + (\Im\Delta''(\xi_2))^2}},$$

which is (3.39). ∎

Remark 3.7. Let μ^* be a real and simple eigenvalue. Then the estimate in (3.35) becomes

$$|\mu^* - \mu_N| < \frac{T_N(\mu_N) + A(\varepsilon)}{\inf_{\xi \in I_{\mu^*,\mu_N}} |\Delta'(\xi)|}, \tag{3.41}$$

where $I_{\mu^*,\mu_N} \subset \mathbb{R}$. Also, when μ^* is real and double, the estimate (3.39) turns out to be

$$|\mu^* - \mu_N| < \frac{T_{1,N}(\mu_N) + 4bA(\varepsilon)}{\inf_{\xi \in \Gamma_{\mu^*,\mu_N}} |\Delta''(\xi)|}. \tag{3.42}$$

The authors of [7, 11] established the so-called higher order approximations for the eigenvalues of special cases of (1.10)–(1.12). In these approximations $\mathcal{K}(\mu)$ of (3.12) has more terms. However, the omissions mentioned in the introduction exist here, too. We can do the same in the present situation since if we take more terms in $\mathcal{K}(\mu)$, the remainder will also lie in a Paley–Wiener space. The error analysis will be as established above with better estimates. In [1] the authors established the technique for second order pencils and considered both amplitude and truncation errors. Finally we compute an estimate for the constants E and M which appear in the quantities $T_N(\mu)$, $T_{1,N}(\mu)$, and $\mathcal{A}(\varepsilon, \mu)$. These constants play a major role in the numerical computations, especially to find enclosure annuli and intervals.

LEMMA 3.8. *The constants E and M may be estimated by*

$$\begin{aligned} E \le & \sqrt{2}\rho_1 \sqrt{\int_0^{cb\tau} \left(\frac{f_1(\eta)}{\eta}\right)^2 d\eta} + \sqrt{2}\rho_2 \sqrt{\int_0^{cb\tau} \left(\frac{f_2(\eta)}{\eta}\right)^2 d\eta} \\ & + 2\sqrt{2}c\,\tau |C_5| \sqrt{\int_0^{cb\tau} \left(\frac{f_1(\eta)^2}{\eta}\right)^2 d\eta}, \end{aligned} \tag{3.43}$$

$$M \le \rho_1 f_1(cb\tau) + \rho_2 f_2(cb\tau) + 2\sqrt{2}c\,\tau |C_5| (f_1(cb\tau))^2, \tag{3.44}$$

where

$$f_k(\eta) := \sum_{n\geq k} \frac{\eta^n}{n!}, \quad k = 1, 2,$$

(3.45)
$$\rho_1 := c\,\tau|C_4| + c\,\tau^2|C_3| + (3c\,\tau + 2b\,c^2\,\tau^2)|C_5|, \quad \rho_1 := c\,\tau|C_2| + c\,\tau|C_5| + c\,|C_6|.$$

Proof. By substituting from (3.18)–(3.20) in (3.13), for $\mu \in \mathbb{R}$, we obtain

$$\begin{aligned}|\mathcal{U}(\mu)| \leq{}& (|C_4| + |C_5|) \sum_{n\geq 2} \frac{\gamma(\mu)^n}{n!} + \left(\frac{cb|C_6|}{1+|\mu|b} + c\,|C_5| + |C_2|\gamma(\mu)\right) \sum_{n\geq 2} \frac{\delta(\mu)^n}{n!} \\ &+ \tau|C_3| \sum_{n\geq 2} \frac{\gamma(\mu)^n}{n!} + |C_5|\gamma(\mu) \sum_{n\geq 2} \frac{\delta(\mu)^n}{n!} + 2|C_5|\gamma(\mu) \sum_{n\geq 2} \frac{\gamma(\mu)^n}{n!} \sum_{m\geq 1} \frac{\delta(\mu)^m}{m!} \\ &+ |C_5|\gamma(\mu) \sum_{n\geq 2} \frac{\gamma(\mu)^n}{n!} + 2|C_5|\gamma(\mu)\{1+\gamma(\mu)\} \sum_{n\geq 1} \frac{\delta(\mu)^n}{n!}. \end{aligned} \tag{3.46}$$

Since $0 < \delta(\mu) < \gamma(\mu)$, $\gamma(\mu) < c\,b\tau$, and $|\mu|\,\gamma(\mu) < c\tau$, we have

$$|\mu\,\mathcal{U}(\mu)| \leq \rho_1 \sum_{n\geq 1} \frac{\gamma(\mu)^n}{n!} + \rho_2 \sum_{n\geq 2} \frac{\gamma(\mu)^n}{n!} + 2c\,\tau|C_5| \left(\sum_{n\geq 1} \frac{\gamma(\mu)^n}{n!}\right)^2, \tag{3.47}$$

implying (3.44). From the definitions of E and f_k, inequality (3.47), and the triangle inequality, we obtain

$$E \leq \sqrt{2}\rho_1 \|f_1(\gamma(\mu))\|_2 + \sqrt{2}\rho_2 \|f_2(\gamma(\mu))\|_2 + 2\sqrt{2}c\,\tau|C_5|\;\|f_1(\gamma(\mu))^2\|_2,$$

where

$$\|f_k\|_2 := \sqrt{\int_0^\infty |f_k(\gamma(\mu))|^2 d\mu}.$$

Now we estimate the norm $\|f_k(\gamma(\mu))\|_2$. It is easy to see, from the definition of $\gamma(\mu)$, that

$$\gamma(\mu)^2 = -c\,\tau\,\gamma'(\mu), \quad \text{where} \quad 0 < \mu < \infty.$$

Thus

$$\int_0^\infty |f_k(\gamma(\mu))|^2 d\mu \leq c\tau \int_\infty^0 \frac{f_k(\gamma(\mu))^2}{d(\mu)^2} d[\gamma(\mu)] \leq c\tau \int_0^{cb\tau} \frac{f_k(\eta)^2}{\eta^2} d\eta. \tag{3.48}$$

By substituting from (3.48) in (3.48) one gets (3.43). □

The estimates (3.43) and (3.44) can be simplified with greater bounds. Such simplifications will affect the accuracy of the numerical results.

4. Examples and comparisons. This section includes some new examples illustrating the above method. We derive five examples exhibiting the previous scheme in different situations. The first example is a self-adjoint boundary-value problem

with simple eigenvalues. The second is also self-adjoint but all eigenvalues are double. Then we give two non-self-adjoint examples with double and complex eigenvalues, respectively. The last example is an eigenvalue problem with $q(x) = x^2$. In the following, μ_k denotes the exact eigenvalue, μ_k^* denotes the approximate eigenvalue computed by the method of section 3, and $I_{k,N}$ denotes the enclosure interval. Every example is illustrated with a table where the effect of the amplitude error, which has not been considered in similar studies, is indicated through different choices of the bound ε. We have used *Mathematica* to approximate results to the nearest suitable decimal representations.

Example 4.1. Consider the self-adjoint boundary-value problem

$$-y''(x) + q(x)y(x) = \mu^2 y(x), \quad 0 \le x \le 1, \tag{4.1}$$

$$U_1(y) := y(0) + y'(0) + 2y(1) = 0, \tag{4.2}$$

$$U_2(y) := 2y'(0) + y(1) + y'(1) = 0, \tag{4.3}$$

where

$$q(x) = \begin{cases} 1, & 0 \le x < 1/2, \\ -1, & 1/2 \le x \le 1. \end{cases} \tag{4.4}$$

This problem is a special case of problem (1.10)–(1.12) when $\alpha_{11} = \alpha_{12} = \beta_{21} = 1$, $\alpha_{22} = \beta_{11} = 2$, and $\alpha_{21} = \beta_{12} = 0$. It is obviously self-adjoint. The characteristic determinant is

$$\Delta(\mu) := 4 + 4\cos\sqrt{1+\mu^2} + \sqrt{1+\mu^2}\sin\sqrt{1+\mu^2} + \frac{\sin\sqrt{1+\mu^2}}{\sqrt{1+\mu^2}}. \tag{4.5}$$

The boundary conditions are strongly regular (cf. [21]) and the eigenvalues are simple.

$$N = 20, \quad E = 85.82, \quad M = 338.92$$

μ	μ_k^*	μ_k	$\lvert\mu_k - \mu_k^*\rvert$	$I_{k,N}$, $\varepsilon = 10^{-5}$	$I_{k,N}$, $\varepsilon = 10^{-10}$
μ_1	2.9781814	2.9781881	6.68×10^{-6}	[2.83659, 3.08105]	[2.93715, 3.00631]
μ_2	4.8639142	4.8639061	8.19×10^{-6}	[4.78021, 4.96777]	[4.84235, 4.89277]
μ_3	9.3715736	9.3715761	2.60×10^{-6}	[9.35701, 9.39491]	[9.36730, 9.37526]
μ_4	11.8812419	11.8812150	2.691×10^{-5}	[11.82362, 11.93596]	[11.84949, 11.91175]

Example 4.2. The antiperiodic boundary-value problem

$$y''(x) + y(x) = -\mu^2 y(x), \quad 0 \le x \le 1, \tag{4.6}$$

$$U_1(y) := y(0) + y(1) = 0, \tag{4.7}$$

$$U_2(y) := y'(0) + y'(1) = 0 \tag{4.8}$$

is self-adjoint. Here $q(x) = -1$, $\alpha_{11} = \alpha_{22} = \beta_{22} = \beta_{11} = 1$, and $\beta_{12} = \beta_{21} = \alpha_{21} = \alpha_{12} = 0$. The characteristic determinant is

$$\Delta(\mu) := 4\cos^2\frac{\sqrt{1+\mu^2}}{2}. \tag{4.9}$$

Thus the eigenvalues are $\mu_k^2 = ((2k-1)\pi)^2 - 1,\ k \in \mathbb{Z}$. The eigenvalues are all double from geometric and algebraic points of view.

$$N = 20, \quad E = 19.9980, \quad M = 123.443$$

μ	μ_k^*	μ_k	$\lvert\mu_k^* - \mu_k\rvert$	$I_{k,N}$, $\varepsilon = 10^{-5}$	$I_{k,N}$, $\varepsilon = 10^{-10}$
μ_1	2.9781853	2.9781881	2.85×10^{-6}	[2.52216, 3.28217]	[2.7186, 3.0814]
μ_2	9.3714923	9.3715761	9.51×10^{-6}	[8.9513, 9.6402]	[9.1697, 9.4140]
μ_3	15.6756866	15.6761000	1.79×10^{-5}	[15.2540, 15.9349]	[15.4769, 15.7037]
μ_4	21.9683690	21.9684004	3.14×10^{-5}	[21.5334, 22.2151]	[21.7500, 21.9891]

Example 4.3. The non-self-adjoint problem

$$-y''(x) + q(x)y(x) = \mu^2 y(x), \quad 0 \le x \le 1, \tag{4.10}$$

$$U_1(y) := 2y(0) + y(1) = 0, \tag{4.11}$$

$$U_1(y) := y'(0) + y'(1) = 0 \tag{4.12}$$

is a special case of problem (1.10)–(1.12) when $\alpha_{12} = \alpha_{21} = \beta_{12} = \beta_{21} = 0$, $\beta_{11} = \beta_{22} = \alpha_{22} = 1$, $\alpha_{11} = 2$, and

$$q(x) := \begin{cases} -1, & 0 \le x < 1/2, \\ 0, & 1/2 \le x \le 1. \end{cases} \tag{4.13}$$

Its characteristic determinant is

$$\Delta(\mu) := 3 + 3\cos\sqrt{\mu^2 + 1}. \tag{4.14}$$

Thus the exact eigenvalues are $\mu_k^2 = ((2k-1)\pi)^2 - 1,\ k \in \mathbb{Z}$. Obviously all eigenvalues are algebraically double.

$$N = 20, \quad E = 11.2777, \quad M = 7.8348$$

μ	μ_k^*	μ_k	$\lvert\mu_k - \mu_k^*\rvert$	$I_{k,N}$, $\varepsilon = 10^{-5}$	$I_{k,N}$, $\varepsilon = 10^{-10}$
μ_1	2.9767465	2.9781881	1.44×10^{-3}	[2.8139, 3.0806]	[2.8403, 3.0542]
μ_2	9.3710727	9.3715762	5.03×10^{-4}	[9.2407, 9.44124]	[9.2759, 9.4059]
μ_3	15.6759211	15.676100	1.79×10^{-4}	[15.5485, 15.7380]	[15.5867, 15.6996]
μ_4	21.9684223	21.9684004	2.19×10^{-5}	[21.8358, 22.0251]	[21.8739, 21.9868]

Example 4.4. Consider the non-self-adjoint boundary-value problem

$$y''(x) + (1+i)y(x) = -\mu^2 y(x), \quad 0 \le x \le 1, \tag{4.15}$$

$$U_1(y) := y(0) + y(1) = 0, \tag{4.16}$$

$$U_2(y) := 2y(0) + y(1) = 0. \tag{4.17}$$

In this example we have $\alpha_{12} = \alpha_{22} = \beta_{22} = 0$, $\alpha_{11} = \beta_{12} = \beta_{11} = \beta_{21} = 1$, $\alpha_{21} = 2$, and $g(x) = 1 + i$. The characteristic determinant is

$$\Delta(\mu) := \frac{\sin\sqrt{1 + i + \mu^2}}{\sqrt{1 + i + \mu^2}}, \tag{4.18}$$

The exact eigenvalues are $\mu_k^2 = (k\pi)^2 - 1 - i,\ k \in \mathbb{Z}\backslash\{0\}$. Here also all eigenvalues are simple.

$$N = 20$$

μ	μ_k^*	μ_k	$\lvert\mu_k - \mu_k^*\rvert$
μ_1	2.98407-0.16864i	2.98290-0.16762i	1.55×10^{-3}
μ_2	6.20305-0.08001i	6.20362-0.08060i	8.20×10^{-4}
μ_3	9.37212-0.05375i	9.37173-0.05335i	5.63×10^{-4}
μ_4	12.52658-0.03991i	12.52629-0.03960i	4.30×10^{-4}

Example 4.5. The boundary-value problem

$$-y''(x) + x^2 y(x) = \mu^2 y(x), \quad 0 \le x \le 1, \tag{4.19}$$

$$U_1(y) := y(0) + y'(0) = 0, \tag{4.20}$$

$$U_2(y) := y(1) + y'(1) = 0 \tag{4.21}$$

with the above separate boundary conditions is a special case of problem (1.10)–(1.12) when $\alpha_{11} = \alpha_{12} = \beta_{21} = \beta_{22} = 1$, $\alpha_{21} = \alpha_{22} = \beta_{11} = \beta_{12} = 0$, and $q(x) = x^2$. All eigenvalues are simple.

$$E = 5.832, \quad M = 1.463$$

μ	μ_k^*	μ_k	$\lvert\mu_k - \mu_k^*\rvert$	$I_{k,N}$, $\varepsilon = 10^{-5}$	$I_{k,N}$, $\varepsilon = 10^{-10}$
μ_1	3.2154614	3.2154536	7.82×10^{-6}	[3.21358, 3.21737]	[3.21451, 3.21642]
μ_2	6.3126426	6.3126433	7.93×10^{-7}	[6.31191, 6.31339]	[6.31243, 6.31286]

CONVERGENCE OF THE MASS-TRANSPORT STEEPEST DESCENT SCHEME FOR THE SUBCRITICAL PATLAK–KELLER–SEGEL MODEL*

ADRIEN BLANCHET†, VINCENT CALVEZ‡, AND JOSÉ A. CARRILLO§

Abstract. Variational steepest descent approximation schemes for the modified Patlak–Keller–Segel equation with a logarithmic interaction kernel in any dimension are considered. We prove the convergence of the suitably interpolated in time implicit Euler scheme, defined in terms of the Euclidean Wasserstein distance, associated with this equation for subcritical masses. As a consequence, we recover the recent result about the global in time existence of weak solutions to the modified Patlak–Keller–Segel equation for the logarithmic interaction kernel in any dimension in the subcritical case. Moreover, we show how this method performs numerically in dimension one. In this particular case, this numerical scheme corresponds to a standard implicit Euler method for the pseudoinverse of the cumulative distribution function. We demonstrate its capabilities to reproduce the blow-up of solutions for supercritical masses easily without the need of mesh-refinement.

Key words. Patlak–Keller–Segel model, steepest descent, Wasserstein distance

1. Introduction.

The Patlak–Keller–Segel (PKS) equation is widely used in mathematical biology to model the collective motion of cells which are attracted by a self-emitted chemical substance, the slime mold amoebae *Dictyostelium discoideum* being a prototype organism for this behavior. Moreover, the PKS equation has become a paradigmatic mathematical problem since it shows a concentration-collapse dichotomy: for masses larger than a critical value, solutions aggregate their mass, as delta Diracs, in finite time, while below this critical mass threshold solutions exist globally and disperse, collapsing down to zero. These coexistence of phenomena in this simple-looking mathematical model makes appealing and difficult to develop numerical schemes capable of dealing with both situations.

Historically, the first mathematical models in chemotaxis were introduced in 1953 by Patlak in [40] and in 1970 by Keller and Segel in [33]. Here, we focus on the modified PKS system for the log interaction kernel introduced by Perthame, the second author, and Sharifi tabar in [14]:

$$
\text{(1.1)}\qquad \begin{cases} \dfrac{\partial n}{\partial t}(t,x) = \Delta n(t,x) - \chi \nabla \cdot [n(t,x) \nabla c(t,x)]\,, & t>0\,,\ x \in \mathbb{R}^d, \\ c(t,x) = -\dfrac{1}{d\pi} \displaystyle\int_{\mathbb{R}^d} \log|x-y|\, n(t,y)\, \mathrm{d}y, & t>0\,,\ x \in \mathbb{R}^d, \\ n(0,x) = n_0 \geq 0, & x \in \mathbb{R}^d\,. \end{cases}
$$

Here $(t,x) \mapsto n(t,x)$ represents the cell density, and $(t,x) \mapsto c(t,x)$ is the concentration of chemo-attractant. The constant $\chi > 0$ is the *sensitivity* of the bacteria to the chemo-attractant. Mathematically, it measures the interaction force between cells and hence the strength of the nonlinear coupling. Note that, only in dimension two, the logarithmic kernel is the Poisson kernel, and the system (1.1) corresponds to the variant of the PKS model in the simplified version introduced by Jäger and Luckhaus in [31]. In other dimensions the log kernel has no physical interpretation. However, as we will see below, this is a good "toy model" for studying the competition blow-up phenomenon versus global existence. Initial data are assumed to verify

$$
\text{(1.2)}\qquad (1+|x|^2)\, n_0 \in L^1_+(\mathbb{R}^d) \quad \text{and} \quad n_0 \log n_0 \in L^1(\mathbb{R}^d)\,.
$$

The solutions satisfy the formal conservation of the total mass of the system

$$
\int_{\mathbb{R}^d} n_0(x)\, \mathrm{d}x = \int_{\mathbb{R}^d} n(t,x)\, \mathrm{d}x.
$$

Without loss of generality we assume that the total mass is 1 such that all the parameters of the system are contained in the reduced parameter χ. The center of mass is also conserved as time evolves, and thus we fix it to be zero for the sake of simplicity,

$$
\int_{\mathbb{R}^d} x\, n(t,x)\, \mathrm{d}x = \int_{\mathbb{R}^d} x\, n_0(x)\, \mathrm{d}x = 0.
$$

We first recall that a notion of weak solution n in the space $C^0([0,T); L^1_{\text{weak}}(\mathbb{R}^d))$, with fixed $T > 0$, using the symmetry in x, y for the concentration gradient, was introduced in [42] able to handle measure solutions; see also [41] for an alternative theory. We shall say that n is a weak solution to the system (1.1) if for all test functions $\zeta \in \mathcal{D}(\mathbb{R}^d)$,

$$
\text{(1.3)}\qquad \begin{aligned} \frac{\mathrm{d}}{\mathrm{dt}} \int_{\mathbb{R}^d} \zeta(x)\, n(t,x)\, \mathrm{d}x &= \int_{\mathbb{R}^d} \Delta\zeta(x)\, n(t,x)\, \mathrm{d}x \\ &\quad - \frac{\chi}{2\,d\,\pi} \iint_{\mathbb{R}^d \times \mathbb{R}^d} [\nabla\zeta(x) - \nabla\zeta(y)] \cdot \frac{x-y}{|x-y|^2}\, n(t,s)\, n(t,y)\, \mathrm{d}x\, \mathrm{d}y \end{aligned}
$$

together with $n(t=0) = n_0$ in the distributional sense in $(0,T)$.

As proved in [12, 8, 14], this problem presents the following dichotomy: either solutions blow-up in finite time for the supercritical case $\chi > 2d^2\pi$ or rather solutions exist globally in time and spread in space decaying towards a stationary solution in rescaled variables as $t \to \infty$ in the subcritical case $\chi < 2d^2\pi$.

Global improved weak solutions have been constructed for the system (1.1) in the subcritical case, $\chi < 2d^2\pi$, for $d = 2$ [24, 8] and $d \neq 2$ in [14]; and in the critical case for $d = 2$ in [7]. Very recently, in [25], Dolbeault and Schmeiser investigated the supercritical case in dimension two. Accordingly, the regularization of the logarithmic

kernel produces a defect measure when passing to the limit, accounting for a blow-up phenomenon. In the subcritical case, the proof of global existence of the improved weak solutions relies on the decreasing character of a free energy functional for the PKS equation given by

$$t \mapsto \mathcal{F}[n](t) := \mathcal{S}[n](t) + \mathcal{W}[n](t), \tag{1.4}$$

where $\mathcal{S}[n]$ is the standard Boltzmann's entropy and $\mathcal{W}[n]$ is the interaction energy defined by

$$\mathcal{S}[n](t) := \int_{\mathbb{R}^d} n(t,x) \log n(t,x)\, \mathrm{d}x$$

$$\text{and} \quad \mathcal{W}[n](t) := \frac{\chi}{2d\pi} \iint_{\mathbb{R}^d} n(t,x)\, n(t,y)\, \log|x-y|\, \mathrm{d}x\, \mathrm{d}y.$$

The free energy $\mathcal{F}[n]$ is related to its time derivative, the corresponding Fisher information, in the following way: consider a nonnegative solution $n \in \mathcal{C}^0([0,T), L^1(\mathbb{R}^d))$ of the PKS system (1.1) such that $n(1+|x|^2)$, $n \log n$ are bounded in $L^\infty((0,T), L^1(\mathbb{R}^d))$, $\nabla\sqrt{n} \in L^1((0,T), L^2(\mathbb{R}^d))$, and $\nabla c \in L^\infty((0,T)\times\mathbb{R}^d)$; then

$$\frac{\mathrm{d}}{\mathrm{dt}}\mathcal{F}[n](t) = -\int_{\mathbb{R}^d} n(t,x)\, |\nabla \log n(t,x) - \chi \nabla c(t,x)|^2\, \mathrm{d}x. \tag{1.5}$$

The functional $\mathcal{F}$ structurally belongs to the general class of free energies for interacting particles introduced in [36, 18, 19] and further analyzed in [22, 2]. The functionals treated in those references are of the general form

$$\mathcal{E}[n] := \int_{\mathbb{R}^d} U[n(x)]\, \mathrm{d}x + \int_{\mathbb{R}^d} n(x)\, V(x)\, \mathrm{d}x + \frac{1}{2} \iint_{\mathbb{R}^d\times\mathbb{R}^d} W(x-y)\, n(x)\, n(y)\, \mathrm{d}x\, \mathrm{d}y \tag{1.6}$$

under the basic assumptions that $U : \mathbb{R}^+ \to \mathbb{R}$ is a density of internal energy, $V : \mathbb{R}^d \to \mathbb{R}$ is a convex confinement potential, and $W : \mathbb{R}^d \to \mathbb{R}$ is a symmetric convex interaction potential. The internal energy U should satisfy the following dilation condition, introduced in McCann [36]:

$$\lambda \longmapsto \lambda^d U(\lambda^{-d}) \qquad \text{is convex nonincreasing on } \mathbb{R}^+. \tag{1.7}$$

The most important case of application, as it is for our case, is $U(s) = s \log s$, which identifies the internal energy with Boltzmann's entropy.

Continuity equations where the velocity field is formally derived from the variational derivative of free energy functionals of the type (1.6), given by

$$\frac{\partial \rho}{\partial t} = \operatorname{div}\left(\rho \nabla \frac{\delta \mathcal{E}}{\delta \rho}\right) \qquad \text{in } (0,+\infty)\times\mathbb{R}^d, \tag{1.8}$$

appear in various contexts: the interest for a convex interaction potential energy arose from its use in the modeling of granular flows; see the works of Benedetto and coworkers [5, 6] and of Toscani [44] and Villani [49] and the references therein for the physical background and related mathematical analysis. Nice mathematical and physical reviews are provided in [48, Chapter 5] and [49].

A very powerful theory has been developed in the past decade starting from the seminal paper by McCann [36] where the notion of displacement convexity for

a functional acting on probability measures was introduced. This notion provides functionals of the form (1.6) with a natural convexity structure. However, the interacting kernel W is itself required to be convex. Later, Otto [39] introduced a formal Riemannian structure giving sense to this family of equations (1.8) as the gradient flow of the convex free-energy functional (1.8) with respect to a metric that induces the Euclidean Wasserstein distance for measures. Geodesics in Otto's interpretation correspond to optimal transportation pathways (or *displacement interpolation*),

$$\rho^t = \Big((1-t)\mathrm{Id} + t\nabla\varphi\Big)\#\rho^0,$$

where $T = \nabla\varphi$ is the optimal static transport map between the endpoints ρ^0 and ρ^1.

On the other hand, a steepest descent scheme based on optimal transport of measures was introduced in [32] for the linear Fokker–Planck equation, exhibiting very nice properties. This scheme is now well understood and has been formalized for a large class of degenerate parabolic equations in [1], and in a more abstract setting, by Ambrosio, Gigli, and Savaré [3] with the name of "minimising movement scheme." The idea corresponds to a discrete version of the gradient flow or steepest descent of the free energy under the Wasserstein metric structure; see section 2 below for precise definitions.

In our case, the free-energy functional shows a nonconvex interaction potential, characteristic also of other models in mathematical biology [9, 12] and swarming [43]. To weaken the convexity assumption on the interaction kernel and to find under which conditions stationary states continue to be global attractors of the dynamics are issues of great interest for applications in mathematical biology.

The main results of this work, Theorem 3.4 and Proposition 4.3, show the convergence of the Jordan–Kinderlehrer–Otto steepest descent discrete method [32] using Otto's interpretation of the PKS equation (1.1) as the gradient flow of the free-energy functional for the subcritical case and the exponential convergence towards a unique stationary profile in scaled variables for the subcritical one-dimensional case. The first result recovers the available global existence results in the subcritical cases for the PKS equation in [12, 8, 14]. Moreover, we numerically solve this scheme in the one-dimensional case showing its abilities to capture the blow-up for supercritical cases without the need of mesh-refinement.

The plan of this paper is the following: we first recall in section 2.1 some recent results on free energies and rescaled variables, which allow us to obtain a priori estimates. We recall in section 2.2 notions on optimal transport and on the Wasserstein distance that we will use in section 3 to prove the convergence of the scheme (3.1). The exponential convergence towards a unique equilibrium is shown in the scaled one-dimensional setting in section 4.1. Finally, one-dimensional numerical simulations are given in section 4.2.

2. Preliminaries.

2.1. A priori estimates in the subcritical case. Here, we review some aspects of the PKS model that were already used in [12, 8, 14, 7] as the main tools for the proof of global existence of weak solutions in the subcritical and critical cases.

We will make a fundamental use of the logarithmic Hardy–Littlewood–Sobolev inequality [4, 15]: let f be a nonnegative function in $L^1(\mathbb{R}^d)$ such that $f\log f$ and $f\log(1+|x|^2)$ belong to $L^1(\mathbb{R}^d)$. If

$$\int_{\mathbb{R}^d} f(x)\,\mathrm{d}x = 1,$$

then

$$\int_{\mathbb{R}^d} f(x)\log f(x)\,\mathrm{d}x + d\iint_{\mathbb{R}^d\times\mathbb{R}^d} f(x)f(y)\log|x-y|\,\mathrm{d}x\,\mathrm{d}y \geq -C(d) \tag{2.1}$$

with $C(d) := (1/2)\log\pi + (1/d)\log[\Gamma(d/2)/\Gamma(d)] + (1/2)[\psi(d) - \psi(d/2)]$, where ψ is the logarithmic derivative of the Γ-function. The logarithmic Hardy–Littlewood–Sobolev inequality (2.1) implies that the functional energy (1.4) is bounded from below if $\chi = \chi_c := 2\,d^2\pi$.

Since we will work mainly in the subcritical case $\chi < \chi_c$, it is clearer, although not necessary, to solve the equation in rescaled variables. Let us define the rescaled functions ρ and v by

$$n(t,x) = \frac{1}{R^d(t)}\,\rho\left(\tau(t), \frac{x}{R(t)}\right) \quad \text{and} \quad c(x,t) = v\left(\tau(t), \frac{x}{R(t)}\right) \tag{2.2}$$

with

$$R(t) = \sqrt{1+2t} \quad \text{and} \quad \tau(t) = \log R(t).$$

The rescaled system is

$$\begin{cases} \dfrac{\partial\rho}{\partial t}(t,x) = \Delta\rho(t,x) + \nabla\cdot\{\rho(t,x)\,[x - \chi\nabla v(t,x)]\}\,, & t>0\,,\ x\in\mathbb{R}^d\,, \\ v(t,x) = -\dfrac{1}{d\,\pi}\,\log|\cdot| * \rho(t,x) - \dfrac{1}{d\,\pi}\,\tau(t), & t>0\,,\ x\in\mathbb{R}^d\,, \\ \rho(0,x) = \rho^0 = n_0 \geq 0, & x\in\mathbb{R}^d\,. \end{cases} \tag{2.3}$$

In the rescaled variables, the confinement potential $V(x) = \frac{1}{2}|x|^2$ is added, and the free energy becomes

$$\begin{aligned} \mathcal{G}[\rho] = &\int_{\mathbb{R}^d} \rho(x)\log\rho(x)\,\mathrm{d}x + \frac{1}{2}\int_{\mathbb{R}^d} |x|^2\,\rho(x)\,\mathrm{d}x \\ &+ \frac{\chi}{2\,d\,\pi}\iint_{\mathbb{R}^d\times\mathbb{R}^d} \log|x-y|\,\rho(x)\,\rho(y)\,\mathrm{d}x\,\mathrm{d}y. \end{aligned} \tag{2.4}$$

With the definition (1.3) we shall say that ρ is a weak solution to the system (2.3) if for all test functions $\zeta\in\mathcal{D}(\mathbb{R}^d)$,

$$\begin{aligned} \frac{\mathrm{d}}{\mathrm{d}t}\int_{\mathbb{R}^d}\zeta(x)\,\rho(t,x)\,\mathrm{d}x = &\int_{\mathbb{R}^d}\Delta\zeta(x)\,\rho(t,x)\,\mathrm{d}x - \int_{\mathbb{R}^d}\nabla\zeta(x)\cdot x\,\rho(t,x)\,\mathrm{d}x \\ &- \frac{\chi}{2\,d\,\pi}\iint_{\mathbb{R}^d\times\mathbb{R}^d}[\nabla\zeta(x) - \nabla\zeta(y)]\cdot\frac{x-y}{|x-y|^2}\,\rho(t,x)\,\rho(t,y)\,\mathrm{d}x\,\mathrm{d}y, \end{aligned} \tag{2.5}$$

together with $\rho(t=0) = \rho^0$ in the distributional sense in $(0,T)$. The following lemma extracts enough information from this decreasing free energy to proceed.

LEMMA 2.1 (a priori estimates). *The functional $\mathcal{G}$ is bounded from below on the set*

$$\mathcal{K} := \left\{\rho\in L^1_+(\mathbb{R}^d)\ :\ \int_{\mathbb{R}^d}\rho(t,x) = 1,\ |x|^2\,\rho\in L^1(\mathbb{R}^d),\ \int_{\mathbb{R}^d}\rho(t,x)\,|\log\rho(t,x)|\,\mathrm{d}x < \infty\right\}$$

if and only if $\chi\leq\chi_c$. In addition, if $\chi<\chi_c$, we have on every subset $\{\mathcal{G}\leq C\}$ the following:

(i) *no concentration:* $\int_{\mathbb{R}^d} \rho|\log\rho| \le C$,
(ii) *mass confinement:* $\int_{\mathbb{R}^d} |x|^2\rho \le C$.
As a consequence, every level subset $\{\mathcal{G} \le C\}$ *is equi-integrable.*

Proof. The first use of the logarithmic Hardy–Littlewood–Sobolev inequality (2.1) to bound the free energy $\mathcal{G}$ from below is due to [24]. Rewrite

(2.6)
$$\mathcal{G}[\rho](t) = (1-\theta)\int_{\mathbb{R}^d} \rho(t,x)\,\log\rho(t,x)\,\mathrm{d}x + \frac{1}{2}\int_{\mathbb{R}^d} |x|^2\,\rho(t,x)\,\mathrm{d}x$$
$$+\,\theta d\left[\frac{1}{d}\int_{\mathbb{R}^d} \rho(t,x)\,\log\rho(t,x)\,\mathrm{d}x + \frac{\chi}{2\,d^2\,\pi\,\theta}\iint_{\mathbb{R}^d\times\mathbb{R}^d} \rho(t,x)\,\rho(t,y)\,\log|x-y|\,\mathrm{d}x\,\mathrm{d}y\right].$$

The logarithmic Hardy–Littlewood–Sobolev inequality (2.1) controls the third term if we choose $\theta = \chi/\chi_c$. Because the function $\rho\log\rho$ is negative for small ρ, we need to somehow control the density for large x. We use in fact the confinement potential, i.e., the second momentum of ρ.

LEMMA 2.2 (Carleman's estimates). *For any probability density* $u \in L^1_+(\mathbb{R}^d)$*, if the second moment* $\int_{\mathbb{R}^d} |x|^2\,u(x)\,\mathrm{d}x$ *and the entropy* $\int_{\mathbb{R}^d} u\log u\,\mathrm{d}x$ *are bounded from above, then* $u\log u$ *is uniformly bounded in* $L^1(\mathbb{R}^d)$*, and we have*

$$\int_{\mathbb{R}^d} u(x)\,|\log u(x)|\,\mathrm{d}x \le \int_{\mathbb{R}^d} u(x)\,\left(\log u(x) + \frac{1}{2}|x|^2\right)\,\mathrm{d}x + d\log(4\pi) + \frac{2}{e}\,.$$

Proof. The proof goes as follows. Let $\bar u := u\,\mathbb{1}_{\{u\le 1\}}$ and $m = \int_{\mathbb{R}^d} \bar u(x)\,\mathrm{d}x \le \int_{\mathbb{R}^d} u(x)\,\mathrm{d}x = 1$. Then

$$\int_{\mathbb{R}^d} \bar u(x)\,\left(\log\bar u(x) + \frac{1}{4}|x|^2\right)\,\mathrm{d}x = \int_{\mathbb{R}^d} U(x)\log U(x)\,\mathrm{d}\mu - m\frac{d}{2}\log(4\pi)\,,$$

where $U := \bar u/\mu$, $d\mu(x) = (4\pi)^{-d/2}e^{-|x|^2/4}\,\mathrm{d}x$. The Jensen inequality yields

$$\int_{\mathbb{R}^d} U(x)\,\log U(x)\,\mathrm{d}\mu \ge \left(\int_{\mathbb{R}^d} U(x)\,\mathrm{d}\mu\right)\,\log\left(\int_{\mathbb{R}^d} U(x)\,\mathrm{d}\mu\right) = m\,\log m$$

and

$$\int_{\mathbb{R}^d} \bar u(x)\,\log\bar u(x)\,\mathrm{d}x \ge m\log m - m\frac{d}{2}\log 4\pi - \frac{1}{4}\int_{\mathbb{R}^d} |x|^2\,\bar u(x)\,\mathrm{d}x$$
$$\ge -\frac{1}{e} - \frac{d}{2}\log(4\pi) - \frac{1}{4}\int_{\mathbb{R}^d} |x|^2\,u(x)\,\mathrm{d}x.$$

Using

$$\int_{\mathbb{R}^d} u(x)\,|\log u(x)|\,\mathrm{d}x = \int_{\mathbb{R}^d} u(x)\,\log u(x)\,\mathrm{d}x - 2\int_{\mathbb{R}^d} \bar u(x)\,\log\bar u(x)\,\mathrm{d}x,$$

this completes the proof. ∎

We apply this lemma to obtain the first part of the result from (2.6):

$$\mathcal{G}[\rho](t) \ge (1-\theta)\int_{\mathbb{R}^d} \rho(t,x)\,|\log\rho(t,x)|\,\mathrm{d}x + \frac{\theta}{2}\int_{\mathbb{R}^d} |x|^2\,\rho(t,x)\,\mathrm{d}x + C.$$

On the other hand, the functional $\mathcal{G}[\rho]$ has an interesting scaling property. For a given ρ, let $\rho_\lambda(x) = \lambda^d \rho(\lambda x)$. It is straightforward to check that $\|\rho_\lambda\|_{L^1(\mathbb{R}^d)} = 1$ and

$$\mathcal{G}[\rho_\lambda] = \mathcal{G}[\rho] + d\left(1 - \frac{\chi}{\chi_c}\right)\log\lambda + \frac{\lambda^{-2}-1}{2}\int_{\mathbb{R}^d} |x|^2\,\rho\,\mathrm{d}x.$$

Since $\lambda \mapsto \mathcal{G}[\rho_\lambda]$ is clearly not bounded from below if $\chi > \chi_c$, the proof concludes here. ∎

We shall also state another technical lemma, which will play a major role when passing to the limit in the quadratic interaction contribution.

LEMMA 2.3 (doubling of variables). *Assume $f_i \rightharpoonup f$ in L^1 and that the family $\{f_i\}$ is equi-integrable in the sense of Lemma 2.1; then $f_i \otimes f_i \rightharpoonup f \otimes f$ in $L^1(\mathbb{R}^d \times \mathbb{R}^d)$.*

Proof. Let $\psi(x,y)$ denote any test function in $L^\infty(\mathbb{R}^d \times \mathbb{R}^d)$. For almost every $x \in \mathbb{R}^d$ define

$$\lim \Psi^i(x) := \lim \int_{\mathbb{R}^d} f_i(y)\,\psi(x,y)\,\mathrm{d}y = \int_{\mathbb{R}^d} f(y)\,\psi(x,y)\,\mathrm{d}y =: \Psi(x).$$

Note that for any x, $|\Psi^i(x)|$ and $|\Psi(x)|$ are bounded by $\|\psi\|_{L^\infty}$.

By Egorov's theorem for any $R > 0$ and $\delta > 0$, there exists a measurable set X_δ such that $|X_\delta| < \delta$ and Ψ^i uniformly converges to Ψ in $B_R \setminus X_\delta$. We have

$$\begin{aligned}
&\left|\int_{\mathbb{R}^d} \left[\Psi^i(x)\,f_i(x) - \Psi(x)\,f(x)\right]\,\mathrm{d}x\right| \\
&\quad\le \int_{B_R\setminus X_\delta} \left|\Psi^i(x)\,f_i(x) - \Psi(x)\,f(x)\right|\,\mathrm{d}x + \int_{X_\delta} \left|\Psi^i(x)\,f_i(x) - \Psi(x)\,f(x)\right|\,\mathrm{d}x \\
&\qquad\quad + \int_{B_R^c} \left|\Psi^i(x)\,f_i(x) - \Psi(x)\,f(x)\right|\,\mathrm{d}x \\
&\quad\le \int_{B_R\setminus X_\delta} \left|\Psi^i(x)\,f_i(x) - \Psi(x)\,f(x)\right|\,\mathrm{d}x + \|\psi\| \int_{X_\delta} f_i(x) + f(x)\,\mathrm{d}x \\
&\qquad\quad + \|\psi\|\,\frac{1}{R^2}\int_{B_R^c} |x|^2\,[f_i(x) + f(x)]\,\mathrm{d}x.
\end{aligned}$$

Egorov's theorem and the weak-L^1 convergence of f_i towards f ensures that the first term is as small as desired by choosing i large enough. By the a priori estimates in Lemma 2.1, $\int_{X_\delta} f_i(x)\,\mathrm{d}x$ and $\int_{X_\delta} f(x)\,\mathrm{d}x$ can be made as small as desired by choosing δ small enough; further, the third term can be made as small as desired by choosing R large enough. ∎

2.2. Optimal transport and the Wasserstein distance. We recall some standard results related to optimal transportation and Wasserstein distance that we will use in the remainder of this paper. The interested reader can refer to the books of Villani [48, 50] and the book of Ambrosio, Gigli, and Savaré [3]. A short summary of properties of the Wasserstein distance can be seen in [21].

Let μ and ν be in $\mathcal{P}(\mathbb{R}^d)$ the space of probability measure in $\mathbb{R}^d$, $\mathcal{P}_2(\mathbb{R}^d)$ the subset of probability measures with finite second-momentum, $\mathcal{P}_2^{\mathrm{ac}}(\mathbb{R}^d)$ its subset formed by the absolutely continuous measures with respect to Lebesgue, and T be a measurable map $\mathbb{R}^d \to \mathbb{R}^d$. We say that T *transports* μ onto ν, and we note $\nu = T\#\mu$ if for any measurable set $B \subset \mathbb{R}^d$, $\nu(B) = \mu \circ T^{-1}(B)$. We also say ν is the *push-forward* or *the*

image measure of μ by T; i.e.,

$$\int_{\mathbb{R}^d} \zeta \circ T(x)\, \mathrm{d}\mu(x) = \int_{\mathbb{R}^d} \zeta(y)\, \mathrm{d}\nu(y) \quad \forall \zeta \in \mathcal{C}_b^0(\mathbb{R}^d). \tag{2.7}$$

The Wasserstein distance between μ and ν, d_W can be defined by

$$d_W^2(\mu,\nu) := \inf_{T:\ \nu = T\#\mu} \int_{\mathbb{R}^d} |x - T(x)|^2\, \mathrm{d}\mu(x).$$

By Brenier's theorem [10, 35, 37] (see [48, Theorem 2.32, p. 85] for a review), if μ is absolutely continuous with respect to Lebesgue measure, then there is one measurable plan T such that $\nu = T\#\mu$ and $T = \nabla\varphi$ for some convex function φ. As a consequence,

$$d_W^2(\mu,\nu) = \int_{\mathbb{R}^d} |x - \nabla\varphi(x)|^2\, \mathrm{d}\mu(x). \tag{2.8}$$

The variational problem leading to the definition of the Wasserstein distance can be relaxed to the linear program

$$d_W^2(\mu,\nu) = \inf_{\Pi\in\Gamma} \left\{ \int_{\mathbb{R}^d\times\mathbb{R}^d} |x-y|^2\, \mathrm{d}\Pi(x,y) \right\},$$

where Π runs over the set of transference plans Γ, that is, the set of joint probability measures on $\mathbb{R}^d\times\mathbb{R}^d$ with marginals μ and ν. In fact, the infimum above is a minimum by Kantorovich duality theorems [48, Chapter 1]. The optimal transference plan, in case Brenier's theorem applies, is given by $\Pi_o = (\mathrm{id}_{\mathbb{R}^d} \otimes \nabla\varphi)\#\mu$.

Let us recall a simple consequence of the definition of the Wasserstein distance for controlling averages [21, Corollary 2.4].

LEMMA 2.4 (convergence of averages with d_W). *Given ζ a Lipschitz function with Lipschitz constant L and $\mu,\nu \in \mathcal{P}_2(\mathbb{R}^d)$, then we have*

$$\left| \int_{\mathbb{R}^d} \zeta(x)\, \mathrm{d}\mu - \int_{\mathbb{R}^d} \zeta(x)\, \mathrm{d}\nu \right| \le L\, d_W(\mu,\nu).$$

Proof. Let Π_o be the optimal plan between μ and $\nu \in \mathcal{P}_2(\mathbb{R}^d)$ for d_W. Then

$$\int_{\mathbb{R}^d\times\mathbb{R}^d} |x-y|^2\, \mathrm{d}\Pi_o(x,y) = d_W^2(\mu,\nu),$$

and we can write

$$\int_{\mathbb{R}^d} \zeta(x)\, \mathrm{d}\mu - \int_{\mathbb{R}^d} \zeta(x)\, \mathrm{d}\nu = \int_{\mathbb{R}^d\times\mathbb{R}^d} (\zeta(x) - \zeta(y))\ \mathrm{d}\Pi_o(x,y).$$

Using that ζ is Lipschitz with constant L and estimating by Hölder's inequality, we get

$$\begin{aligned} \left| \int_{\mathbb{R}^d} \zeta(x)\, \mathrm{d}\mu - \int_{\mathbb{R}^d} \zeta(x)\, \mathrm{d}\nu \right| &\le \int_{\mathbb{R}^d\times\mathbb{R}^d} |\zeta(x) - \zeta(y)|\ \mathrm{d}\Pi_o(x,y) \\ &\le L \int_{\mathbb{R}^d\times\mathbb{R}^d} |x-y|\ \mathrm{d}\Pi_o(x,y) \le L\, d_W(\mu,\nu), \end{aligned}$$

giving the assertion. ∎

3. Time discretization. We consider a time-step $\tau > 0$ and an initial datum $\rho^0 \in \mathcal{P}_2^{\mathrm{ac}}(\mathbb{R}^d)$. We introduce the sequence $(\rho_\tau^n)_{n\in\mathbb{N}}$ recursively defined by $\rho_\tau^0 = \rho^0$ and

$$\rho_\tau^{n+1} \in \arg\inf_{\rho\in\mathcal{K}} \left\{ \mathcal{G}[\rho] + \frac{1}{2\,\tau} d_W^2(\rho_\tau^n, \rho) \right\} . \tag{3.1}$$

The Jordan–Kinderlehrer–Otto (JKO) steepest descent scheme can be viewed formally as a time discretization of the abstract gradient flow equation

$$\frac{\partial \rho}{\partial t} = -\text{“}\nabla_W\text{”}\mathcal{G}[\rho] ,$$

where the space $\mathcal{K} \subset \mathcal{P}_2^{\mathrm{ac}}(\mathbb{R}^d)$ is endowed with a formal Riemannian structure compatible with the Wasserstein d_W distance [39]. We refer to [39, 48, 3, 19] for a deeper discussion and rigorous sense of the “∇_W” definition. The next lemma ensures that this discrete scheme is well defined.

LEMMA 3.1 (existence of minimizers). *Let ρ_0 satisfy* (1.2) *and $\chi < \chi_c$; then there recursively exists a minimizer to* (3.1).

Proof. Introduce the function

$$\mathcal{K} \ni \xi \mapsto \mathcal{G}[\xi] + \frac{1}{2\,\tau} d_W^2(\rho_\tau^n, \xi) . \tag{3.2}$$

By the a priori estimates in Lemma 2.1, this function is bounded from below. Consider $(\xi_k)_{k\in\mathbb{N}}$ a minimizing sequence; without loss of generality, we can assume that it satisfies $\mathcal{G}[\xi_k] \le \mathcal{G}[\rho_\tau^n]$ for all $k \in \mathbb{N}$. Proceeding as in Lemma 2.1, we get

$$(1-\theta) \int_{\mathbb{R}^d} \xi_k(x)\, |\log \xi_k(x)|\, \mathrm{d}x + \frac{\theta}{2} \int |x|^2 \xi_k(x) \le \mathcal{G}[\rho_\tau^n] + \theta\, C(d).$$

If $\chi < \chi_c$, then $\theta = \frac{\chi}{\chi_c} < 1$, and this shows that $\xi_k \log \xi_k$ is bounded in $L^1(\mathbb{R}^d)$.

The bound on the second-momentum avoids vanishing, while the $L^1(\mathbb{R}^d)$-bound on $\xi_k \log \xi_k$ avoids concentration: indeed,

$$\int_{\{\xi_k \ge Q\}} \xi_k \, \mathrm{d}x \le \frac{1}{\log Q} \int_{\{\xi_k \ge Q\}} \xi_k \log \xi_k \, \mathrm{d}x \le \frac{1}{\log Q} \int_{\mathbb{R}^d} \xi_k \, |\log \xi_k| \, \mathrm{d}x$$

can be made as small as desired for $Q > 1$ large enough. Hence the family $\{\xi_k\}_{k\in\mathbb{N}}$ verifies the hypotheses in the Dunford–Pettis theorem, and thus there exists a subsequence still denoted $(\xi_k)_{k\in\mathbb{N}}$ which converges weakly L^1 to a density ξ_*.

It remains to prove that this candidate ξ_* realizes in fact a minimum of (3.2). The weak-L^1 lower semicontinuity of the entropy $\mathcal{S}$, the second-momentum, and the Wasserstein distance are well known; see [32, 3] and the references therein. We will prove that the quadratic interaction term is continuous for the weak-L^1 convergence in our situation. We split it into

$$\iint_{\mathbb{R}^d\times\mathbb{R}^d} \xi_k(x)\, \xi_k(y)\, \log|x-y|\, \mathrm{d}x\, \mathrm{d}y = \mathrm{A} + \mathrm{B} + \mathrm{C},$$

with

$$\mathrm{A} := \iint_{|x-y|<\varepsilon} \xi_k(x)\,\xi_k(y)\,\log|x-y|\,\mathrm{d}x\,\mathrm{d}y,$$

$$\mathrm{B} := \iint_{\varepsilon\le|x-y|\le R} \xi_k(x)\,\xi_k(y)\,\log|x-y|\,\mathrm{d}x\,\mathrm{d}y$$

$$\text{and}\quad \mathrm{C} := \iint_{|x-y|>R} \xi_k(x)\,\xi_k(y)\,\log|x-y|\,\mathrm{d}x\,\mathrm{d}y,$$

where $\varepsilon < 1$ and $R > \sqrt{e}$.

Control of $\mathrm{A}(t)$. We use the duality inequality, $ab \le e^a + b\log b - b$:

$$\begin{aligned}
|\mathrm{A}| &\le \iint_{|x-y|<\varepsilon} \xi_k(x)\xi_k(y)\log\frac{1}{|x-y|}\,\mathrm{d}x\,\mathrm{d}y\\
&\le \int\left\{\xi_k(x)\int_{|x-y|<\varepsilon}\alpha^{-1}\xi_k(y)\log(\alpha^{-1}\xi_k(y)) - \alpha^{-1}\xi_k(y) + \exp\left(\alpha\log\frac{1}{|x-y|}\right)\right\}\\
&\le \alpha^{-1}\int \xi_k(y)\log(\alpha^{-1}\xi_k(y))\int_{|x-y|<\varepsilon}\xi_k(x)\,\mathrm{d}x\,\mathrm{d}y + \int\xi_k(x)\,\mathrm{d}x\int_{|z|<\varepsilon}\frac{1}{|z|^\alpha}\,\mathrm{d}z.
\end{aligned}$$

By the $L^1(\mathbb{R}^d)$-bound on $\xi_k\log\xi_k$, $\int_{X_\varepsilon}\xi_k$ is uniformly small on small sets X_ε, and therefore the last term can be made as small as desired uniformly in k by choosing ε small enough and $\alpha < d$.

Control of B. We shall use Lemma 2.3 because $\log|x-y|$ is bounded on the set $\{\varepsilon < |x-y| < R\}$.

Control of C. For $R > \sqrt{e}$, $R \mapsto R^2/\log R$ is an increasing function, so that

$$0 \le \mathrm{C} \le \frac{2\log R}{R^2}\int_{\mathbb{R}^2}|x|^2\,\xi_k(t,x)\,\mathrm{d}x.$$

Because we uniformly bound the second-momentum, this can be made as small as desired while choosing R large enough.

Finally, collecting terms, we get that the difference

$$\left|\iint_{\mathbb{R}^d\times\mathbb{R}^d}\xi_k(x)\,\xi_k(y)\log|x-y|\,\mathrm{d}x\,\mathrm{d}y - \iint_{\mathbb{R}^d\times\mathbb{R}^d}\xi_*(x)\,\xi_*(y)\log|x-y|\,\mathrm{d}x\,\mathrm{d}y\right|$$

can be made as small as desired by choosing ε and δ small enough and r, R, and k large enough. ∎

Remark 3.2 (uniqueness of minimizers). Since the functional $\mathcal{G}[n]$ is not convex, we cannot conclude the uniqueness of minimizers for the discrete scheme, and thus the scheme (3.1) is defined by choosing any element realizing the infimum as ρ_τ^{n+1}. Each choice might in principle give rise to a solution in the limit $\tau \to 0$. It is an open problem to deal with the uniqueness of solutions in the subcritical case.

Now, we define the time interpolation of the discrete scheme as a family of Lipschitz curves $(\rho_\tau)_{\tau>0}$ connecting every pair $\{\rho_\tau^n, \rho_\tau^{n+1}\}$ with a constant speed geodesic in the interval $[n\,\tau, (n+1)\,\tau)$. Accordingly for any $t \in [n\,\tau, (n+1)\,\tau)$ we have

$$d_W\left(\rho_\tau^n, \rho_\tau(t)\right) = \frac{t-n\tau}{\tau}\,d_W\left(\rho_\tau^n, \rho_\tau^{n+1}\right).$$

Obviously $\rho_\tau(n\tau) = \rho_\tau^n$. This is possible due to the Brenier theorem by defining the displacement interpolant

$$\rho_\tau(t) = \left(\frac{(n+1)\tau - t}{\tau} \mathrm{Id} + \frac{t - n\tau}{\tau} \nabla\varphi^n \right) \# \rho_\tau^n$$

with $\nabla\varphi^n$ being the optimal map transporting ρ_τ^n onto ρ_τ^{n+1}.

Remark 3.3 (comparison to literature). Let us point out that once the free energy $\mathcal{G}[n]$ is bounded from below (Lemma 2.1) and the approximation scheme is well defined (Lemma 3.1), then [3, Theorem 11.1.6, pp. 288–289] applies. For the convenience of the reader we give a shorter proof adapted to our problem. Our proof is based on the founding idea of [32] proving the convergence of the ad hoc scheme for the linear Fokker–Planck equation. A nice sketch of the proof of [32] can be found in [48, section 8.4, pp. 256–262].

THEOREM 3.4 (convergence of the scheme as $\tau \to 0$). *Under assumption* (1.2)*, if* $\chi < \chi_c$*, then the family* $(\rho_\tau)_{\tau>0}$ *admits a subsequence converging in* $C^0([0,T]; L^1_{\mathrm{weak}}(\mathbb{R}^d))$ *to a weak solution of* (2.5).

Proof. We proceed in three steps.

Step 1. A priori estimates in space and time: Since ρ_τ^{n+1} minimizes (3.1), we obviously have

$$\mathcal{G}[\rho_\tau^{n+1}] + \frac{1}{2\,\tau} d_W^2(\rho_\tau^n, \rho_\tau^{n+1}) \le \mathcal{G}[\rho_\tau^n] \,.$$

As a consequence we obtain an *energy estimate*

$$\sup_{n\in\mathbb{N}} \mathcal{G}[\rho_\tau^n] \le \mathcal{G}[\rho_\tau^0], \tag{3.3}$$

and a *total square estimate*

$$\frac{1}{2\,\tau} \sum_{n\in\mathbb{N}} d_W^2(\rho_\tau^n, \rho_\tau^{n+1}) \le \mathcal{G}[\rho_\tau^0] - \inf_{n\in\mathbb{N}} \mathcal{G}[\rho_\tau^n] \,. \tag{3.4}$$

The right-hand side is bounded thanks to Lemma 2.1.

From the total square estimate (3.4) we deduce a $\frac{1}{2}$-*Hölder-estimate* in time of $(\rho_\tau)_{\tau\ge0}$: indeed, for any $0 \le m \le n$,

$$d_W(\rho_\tau^m, \rho_\tau^n) \le \sqrt{2\,\tau} \sum_{k=m}^{n-1} \frac{1}{\sqrt{2\,\tau}} d_W(\rho_\tau^k, \rho_\tau^{k+1}) \le \sqrt{2\,\tau}\,\sqrt{(n-m)} \sqrt{\mathcal{G}[\rho_\tau^0] - \inf_{n\in\mathbb{N}} \mathcal{G}[\rho_\tau^n]} \,.$$

As a consequence for any $0 \le s \le t$

$$\begin{aligned}
d_W(\rho_\tau(s), \rho_\tau(t)) &\le d_W\Big(\rho_\tau(s), \rho_\tau^{\left[\frac{s}{\tau}+1\right]\tau}\Big) + d_W\Big(\rho_\tau^{\left[\frac{s}{\tau}+1\right]\tau}, \rho_\tau^{\left[\frac{t}{\tau}\right]\tau}\Big) + d_W\Big(\rho_\tau^{\left[\frac{t}{\tau}\right]\tau}, \rho_\tau(t)\Big) \\
&\le \left(\left[\frac{s}{\tau}+1\right] - \frac{s}{\tau} \right) d_W\Big(\rho_\tau^{\left[\frac{s}{\tau}\right]\tau}, \rho_\tau^{\left[\frac{s}{\tau}+1\right]\tau}\Big) \\
&\quad + \sqrt{2\,\tau \left(\left[\frac{t}{\tau}\right] - \left[\frac{s}{\tau}+1\right] \right) \Big(\mathcal{G}(\rho_\tau^0) - \inf_{n\in\mathbb{N}} \mathcal{G}(\rho_\tau^n) \Big)} \\
&\quad + \left(\frac{t}{\tau} - \left[\frac{t}{\tau}\right] \right) d_W\Big(\rho_\tau^{\left[\frac{t}{\tau}\right]\tau}, \rho_\tau^{\left[\frac{t}{\tau}+1\right]\tau}\Big) \\
&\le \sqrt{6 \left(\mathcal{G}(\rho^0) - \inf_{n\in\mathbb{N}} \mathcal{G}(\rho^n) \right)} \, (t-s)^{\frac{1}{2}} \,.
\end{aligned} \tag{3.5}$$

Step 2. Compactness: By the $\frac{1}{2}$-Hölder-estimate (3.5), ρ_τ is bounded in $\mathcal{P}_2(\mathbb{R}^d)$, so the family $\{\rho_\tau\}_{\tau>0}$ is tight. By the a priori estimates (Lemma 2.1), the family $\{\rho_\tau(t)\}_{\tau>0}$ can neither concentrate nor vanish and the family $\{\rho_\tau(t)\}_{\tau>0}$ is equi-integrable. In the other hand, by the estimate (3.5) the curves $\rho_\tau(t,\cdot)$ are $\frac{1}{2}$-Hölder continuous in time. The Ascoli–Arzelà theorems yield the relative compactness of the family $(\rho_\tau(t,\cdot))_{\tau>0}$.

Finally $\{\rho_\tau\}_{\tau>0}$ is relatively compact in $\mathcal{C}^0([0,T],L^1_{\text{weak}}(\mathbb{R}^d))$ for any $T>0$. As a consequence, for any $T>0$, there exists a subsequence still denoted $(\rho_\tau)_{\tau>0}$ such that $(\rho_\tau)_{\tau>0}$ converges in $\mathcal{C}^0([0,T],L^1_{\text{weak}}(\mathbb{R}^d))$ to a function ρ when τ goes to 0.

Step 3. Approximate Euler–Lagrange equation in weak formulation: *Weak space derivative.* Let ζ be a test function and $\nabla\zeta$ be a smooth vector field with compact support. Let us define $\nabla\varphi_\varepsilon$ with $\varphi_\varepsilon(x) := \frac{|x|^2}{2} + \varepsilon\,\zeta$. For ε small enough $\nabla\varphi_\varepsilon$ is a $\mathcal{C}^\infty$-diffeomorphism and $\operatorname{Det} D^2\varphi_\varepsilon = \operatorname{Det}(\operatorname{Id} + \varepsilon\, D^2\zeta) > 0$. We define $\overline{\rho_\varepsilon}$ to be the push-forward perturbation of ρ_τ^{n+1} by $\nabla\varphi_\varepsilon$:

$$\overline{\rho_\varepsilon} = \nabla\varphi_\varepsilon \# \rho_\tau^{n+1}\ .$$

Changing variables and using (2.7), we have

$$\mathcal{G}[\overline{\rho_\varepsilon}](t) = \int_{\mathbb{R}^d} \log\frac{\rho_\tau^{n+1}(x)}{\operatorname{Det} D^2\varphi_\varepsilon}\rho_\tau^{n+1}(x)\,\mathrm{d}x + \int_{\mathbb{R}^d}\frac{1}{2}|x-\varepsilon\,\nabla\zeta(x)|^2\rho_\tau^{n+1}(x)\,\mathrm{d}x + \iint_{\mathbb{R}^d\times\mathbb{R}^d}\frac{\chi}{2\,d\,\pi}\log|\nabla\varphi_\varepsilon(x)-\nabla\varphi_\varepsilon(y)|\,\rho_\tau^{n+1}(x)\,\rho_\tau^{n+1}(y)\,\mathrm{d}x\,\mathrm{d}y.$$

Alternatively we introduce the optimal map $\nabla\varphi^n$ which transports ρ_τ^n onto ρ_τ^{n+1}. By (2.8)

$$d_W^2(\rho_\tau^n,\rho_\tau^{n+1}) = \int_{\mathbb{R}^d}|x-\nabla\varphi^n(x)|^2\rho_\tau^n(x)\,\mathrm{d}x. \tag{3.6}$$

The map $\nabla\varphi_\varepsilon\circ\nabla\varphi^n$ transports ρ_τ^n on $\overline{\rho_\varepsilon}$. We do not know if this is the optimal map, however, by definition of the Wasserstein distance

$$d_W^2(\rho_\tau^n,\overline{\rho_\varepsilon}) \le \int_{\mathbb{R}^d}\left|x-\nabla\varphi_\varepsilon\circ\nabla\varphi^n(x)\right|^2\rho_\tau^n(x)\,\mathrm{d}x. \tag{3.7}$$

Using the minimizing property of the scheme (3.1) and combining (3.6) and (3.7), we obtain

$$\begin{aligned}0 &\le \frac{1}{2\,\tau}d_W^2(\rho_\tau^n,\overline{\rho_\varepsilon}) + \mathcal{G}[\overline{\rho_\varepsilon}] - \frac{1}{2\,\tau}d_W^2(\rho_\tau^{n+1},\rho_\tau^n) - \mathcal{G}[\rho_\tau^{n+1}]\\ &\le \frac{1}{2\,\tau}\int_{\mathbb{R}^d}\left(|x-\nabla\varphi^n(x)-\varepsilon\,\nabla\zeta\circ\nabla\varphi^n(x)|^2 - |x-\nabla\varphi^n(x)|^2\right)\rho_\tau^n(x)\,\mathrm{d}x\\ &\quad+\frac{1}{2}\int_{\mathbb{R}^d}\left(\left(|x-\varepsilon\nabla\zeta(x)|^2-|x|^2\right) - \log\left[\operatorname{Det}(\operatorname{Id}+\varepsilon\,D^2\zeta)\right]\right)\rho_\tau^{n+1}(x)\,\mathrm{d}x\\ &\quad+\frac{\chi}{2\,d\,\pi}\iint\left(\log\left|x-y+\varepsilon(\nabla\zeta(x)-\nabla\zeta(y))\right| - \log|x-y|\right)\rho_\tau^{n+1}(x)\,\rho_\tau^{n+1}(y)\,\mathrm{d}x\,\mathrm{d}y.\end{aligned}$$

Dividing by ε and letting $\varepsilon>0$ go to zero, we find

$$0 \le \frac{1}{\tau}\int_{\mathbb{R}^d}\left\langle\nabla\varphi^n(x)-x,\nabla\zeta\circ\nabla\varphi^n(x)\right\rangle\rho_\tau^n(x)\,\mathrm{d}x + \int_{\mathbb{R}^d}\left[-\Delta\zeta(x)-x\cdot\nabla\zeta(x)\right]\rho_\tau^{n+1}(x)\,\mathrm{d}x + \frac{\chi}{2\,d\,\pi}\iint_{\mathbb{R}^d\times\mathbb{R}^d}\frac{[\nabla\zeta(x)-\nabla\zeta(y)]\cdot(x-y)}{|x-y|^2}\rho_\tau^{n+1}(x)\,\rho_\tau^{n+1}(y)\,\mathrm{d}x\,\mathrm{d}y.$$

Since we can change ε into $-\varepsilon$ we have in fact

$$\frac{1}{\tau}\int_{\mathbb{R}^d}\left\langle \nabla\varphi^n(x)-x, \nabla\zeta\circ\nabla\varphi^n(x)\right\rangle \rho_\tau^n(x)\,\mathrm{d}x = \int_{\mathbb{R}^d}\left[\Delta\zeta(x)+x\cdot\nabla\zeta(x)\right]\rho_\tau^{n+1}(x)\,\mathrm{d}x$$
$$-\frac{\chi}{2\,d\,\pi}\iint_{\mathbb{R}^d\times\mathbb{R}^d}\frac{[\nabla\zeta(x)-\nabla\zeta(y)]\cdot(x-y)}{|x-y|^2}\rho_\tau^{n+1}(x)\,\rho_\tau^{n+1}(y)\,\mathrm{d}x\,\mathrm{d}y. \tag{3.8}$$

Weak time derivative. Using the Taylor's expansion

$$\zeta(\nabla\varphi^n(x))-\zeta(x)=\left\langle \nabla\varphi^n(x)-x, \nabla\zeta\circ\nabla\varphi^n(x)\right\rangle + O\Big(\left|x-\nabla\varphi^n(x)\right|^2\Big),$$

we can recast the left-hand side of (3.8) as

$$\frac{1}{\tau}\int_{\mathbb{R}^d}\left[\zeta\circ\nabla\varphi^n(x)-\zeta(x)\right]\rho_\tau^n(x)\,\mathrm{d}x + O\left(\frac{1}{\tau}\int_{\mathbb{R}^d}\left|x-\nabla\varphi^n(x)\right|^2\rho_\tau^n(t)\,\mathrm{d}x\right)$$
$$=\frac{1}{\tau}\left(\int_{\mathbb{R}^d}\zeta(x)\rho_\tau^{n+1}(x)\,\mathrm{d}x-\int_{\mathbb{R}^d}\zeta(x)\rho_\tau^n(x)\,\mathrm{d}x\right)+O\left(\frac{1}{\tau}d_W^2\left(\rho_\tau^n,\rho_\tau^{n+1}\right)\right).$$

We multiply (3.8) by τ and eventually obtain

$$\int_{\mathbb{R}^d}\zeta(x)\left[\rho_\tau^{n+1}(x)-\rho_\tau^n(x)\right]\,\mathrm{d}x + O\big(d_W^2\left(\rho_\tau^n,\rho_\tau^{n+1}\right)\big)$$
$$=\tau\int_{\mathbb{R}^d}\left[\Delta\zeta(x)+x\cdot\nabla\zeta(x)-\frac{\chi}{2\,d\,\pi}\int_{\mathbb{R}^d}\frac{[\nabla\zeta(x)-\nabla\zeta(y)]\cdot(x-y)}{|x-y|^2}\rho_\tau^{n+1}(y)\,\mathrm{d}y\right]\rho_\tau^{n+1}(x)\,\mathrm{d}x. \tag{3.9}$$

Let $0\le t_1<t_2$ be fixed times, $m=[t_1/\tau]+1$, and $n=[t_2/\tau]$. By summing (3.9) we have, thanks to the total square estimate (3.4),

$$\int_{\mathbb{R}^d}\zeta(x)\left[\rho_\tau^n(x)-\rho_\tau^m(x)\right]\,\mathrm{d}x+O(\tau)=\sum_{k=m}^{n-1}\tau\int_{\mathbb{R}^d}\left[\Delta\zeta(x)+x\cdot\nabla\zeta(x)\right]\rho_\tau^{k+1}(x)\,\mathrm{d}x$$
$$-\frac{\chi}{2\,d\,\pi}\sum_{k=m}^{n-1}\tau\iint_{\mathbb{R}^d\times\mathbb{R}^d}\frac{[\nabla\zeta(x)-\nabla\zeta(y)]\cdot(x-y)}{|x-y|^2}\rho_\tau^{k+1}(x)\rho_\tau^{k+1}(y)\,\mathrm{d}x\,\mathrm{d}y. \tag{3.10}$$

On the other hand, we can split

$$\int_{\mathbb{R}^d}\zeta(x)\left[\rho_\tau(t_2,x)-\rho_\tau(t_1,x)\right]\,\mathrm{d}x=\int_{\mathbb{R}^d}\zeta(x)\left[\rho_\tau(t_2,x)-\rho_\tau^n(x)\right]\,\mathrm{d}x$$
$$+\int_{\mathbb{R}^d}\zeta(x)\left[\rho_\tau^n(x)-\rho_\tau^m(x)\right]\,\mathrm{d}x+\int_{\mathbb{R}^d}\zeta(x)\left[\rho_\tau^m(x)-\rho_\tau(t_1,x)\right]\,\mathrm{d}x.$$

By Lemma 2.4, we control the bordering averages,

$$\int_{\mathbb{R}^d}\zeta(x)\left|\rho_\tau^m(x)-\rho_\tau(t_1,x)\right|\,\mathrm{d}x\le C\,d_W(\rho_\tau^m,\rho_\tau(t_1,x))\le C\,d_W(\rho_\tau^m,\rho_\tau^{m-1})\le O(\tau^{1/2}).$$

In addition, integrating Lemma 2.4 in time implies for all integers k, $m\le k\le n-1$,

$$\tau\int_{\mathbb{R}^d}\psi(x)\rho_\tau^{k+1}(x)\,\mathrm{d}x=\int_{k\tau}^{(k+1)\tau}\int_{\mathbb{R}^d}\psi(x)\rho_\tau(s,x)\,\mathrm{d}x\,\mathrm{d}s+O(\tau\;d_W(\rho_\tau^k,\rho_\tau^{k+1})),$$

where ψ denotes any bounded test function. Hence we can transform the discrete in time sum (3.10) into a continuous time integration. Finally, the test contributions are bounded in $L^\infty((0,T)\times\mathbb{R}^d)$ so that the bordering time integrands are negligible,

$$\int_{t_1}^{m\tau}\int_{\mathbb{R}^d}[\Delta\zeta(x)+x\cdot\nabla\zeta(x)]\,\rho_\tau(s,x)\,\mathrm{d}x\,\mathrm{d}s$$
$$-\frac{\chi}{2\,d\,\pi}\int_{t_1}^{m\tau}\iint_{\mathbb{R}^d\times\mathbb{R}^d}\frac{[\nabla\zeta(x)-\nabla\zeta(y)]\cdot(x-y)}{|x-y|^2}\rho_\tau(s,y)\rho_\tau(s,x)\,\mathrm{d}y\,\mathrm{d}x\,\mathrm{d}s=O(\tau).$$

Collecting all the terms, we end up with

(3.11)
$$\int_{\mathbb{R}^d}\zeta(x)\,[\rho_\tau(t_2,x)-\rho_\tau(t_1,x)]\,\mathrm{d}x=\int_{t_1}^{t_2}\int_{\mathbb{R}^d}[\Delta\zeta(x)+x\cdot\nabla\zeta(x)]\,\rho_\tau(s,x)\,\mathrm{d}x\,\mathrm{d}s$$
$$-\frac{\chi}{2\,d\,\pi}\int_{t_1}^{t_2}\iint_{\mathbb{R}^d\times\mathbb{R}^d}\frac{[\nabla\zeta(x)-\nabla\zeta(y)]\cdot(x-y)}{|x-y|^2}\rho_\tau(s,y)\,\rho_\tau(s,x)\,\mathrm{d}y\,\mathrm{d}x\,\mathrm{d}s+O(\tau^{1/2}).$$

Step 4. Passing to the limit: The relative compactness of the family of curves $\{\rho_\tau\}_{\tau>0}$ in $\mathcal{C}^0([0,T],L^1_{\mathrm{weak}}(\mathbb{R}^d))$ for any $T>0$ allows us to pass to the limit in the linear parts of (3.11) because $\nabla\zeta$ and $\Delta\zeta$ are bounded in $L^\infty(\mathbb{R}^d)$. The quadratic last term of (3.11), coming from the concave interaction energy, is more difficult to handle. Actually, we shall make another use of the doubling of variables trick: $\rho_\tau\otimes\rho_\tau\rightharpoonup\rho\otimes\rho$, thanks to the equi-integrability, obtained in Lemma 2.3. In addition, recall that the convergence is uniform in time thanks to the Ascoli–Arzelà theorems, and that equi-integrability bounds are also uniform with respect to τ. We can thus pass to the limit when τ goes to zero in (3.11) to obtain for any t_1, t_2

$$\int_{\mathbb{R}^d}\zeta(x)\,[\rho(t_2,x)-\rho(t_1,x)]\,\mathrm{d}x=\int_{t_1}^{t_2}\int_{\mathbb{R}^d}[\Delta\zeta(x)+x\cdot\nabla\zeta(x)]\,\rho(s,x)\,\mathrm{d}x\,\mathrm{d}s$$
$$-\frac{\chi}{2\,d\,\pi}\int_{t_1}^{t_2}\int_{\mathbb{R}^d\times\mathbb{R}^d}\frac{[\nabla\zeta(x)-\nabla\zeta(y)]\cdot(x-y)}{|x-y|^2}\rho(s,y)\rho(s,x)\,\mathrm{d}y\,\mathrm{d}x\,\mathrm{d}s,$$

which is a formulation of the weak solution as defined in (2.5). ∎

Remark 3.5 (original variables). This theorem is true in original variables (1.1) locally in time, when we consider the free energy (1.4) with minor changes; see also [32]. However, the long-time asymptotics are better understood in scaled variables (see the numerical results, section 4.2.1).

Remark 3.6 (comparison to literature). Rigorous convergence of numerical schemes was first obtained by Filbet in [28] in the nonradial case. His approach relies on the entropy and the Gagliardo–Nirenberg–Sobolev inequality. However, in our case as we crucially use the free-energy functional, we are able to prove in Theorem 3.4 the convergence of the JKO scheme for all values $\chi<\chi_c$, where χ_c is known to be optimal. It is worth noticing that the minimizing movement scheme is very expensive numerically in dimension greater than one, at least as a direct implicit discretization detailed in section 4.2. In contrast, the two-dimensional PKS model is much more manageable following [28].

Beyond the optimal threshold, there is another result arguing on this alternative scheme's behalf. Namely, for a given τ the solution $\{\rho_\tau^n\}_n$ is shown to converge towards the unique stationary state, with explicit exponential rate in the one-dimensional case; see Proposition 4.3 in the next section.

Remark 3.7 (nonlinear diffusions). The ongoing work extends to nonlinear diffusions, under suitable assumptions, $\Delta f(n)$ without deeper difficulty. The main point is that the free energy should be bounded from below—this results from a balance between diffusion at high density level (diffusion must be superlinear at infinity above the optimal threshold) and at low density level (basically $f(u) \gtrsim u^\alpha$, where $\alpha > \max(1/2, 1 - 2/d)$ preventing mass from escaping too fast towards infinity); see [13] and [17].

Remark 3.8 (radial case). In the two-dimensional radial case, one can write a closed equation for the mass inside a ball; see [38]. The equation for this radially cumulative function is a local one-dimensional parabolic equation of Burger's type which can be solved in a standard way. As we shall see, we also deal, in dimension one, with the cumulative distribution functions, but this leads to a nonlocal equation. The radial case has already been treated by several authors; see, for instance, [11]. Let us also note that in radial coordinates we lose the gradient flow structure of the equation, which is the basis of the JKO scheme.

4. One-dimensional case. In the case of the real line, consider μ and ν two absolutely continuous measures with respect to the Lebesgue measure, of respective densities f and g. Let $\nabla\varphi$ be the optimal map which transports μ onto ν. In dimension bigger than one, the optimal map is the solution of the following so-called Monge–Ampére equation:

$$f = g \circ \nabla\varphi \operatorname{Det} D^2\varphi,$$

which is fully nonlinear and cannot be solved in general. However, in dimension one it is a increasing rearrangement, as we will discuss below. Let F and G be the cumulative functions of f and g. As the cumulative distribution function is nondecreasing, we can define the pseudoinverse function by

$$V(z) = F^{-1}(z) := \inf\{x \,:\, F(x) \geq z\}.$$

By Brenier's theorem and the definition of the image measure (2.7), we have

$$F(x) = \int_{-\infty}^{x} f(y)\,\mathrm{d}y = \int_{-\infty}^{\varphi'(x)} g(y)\,\mathrm{d}y = G \circ \varphi'(x).$$

Hence, the transport map can be stated explicitly as $\varphi' = G^{-1} \circ F$, and the Wasserstein distance can be expressed in the following more tractable way:

$$d_W^2(\mu, \nu) = \int_0^1 |F^{-1}(w) - G^{-1}(w)|^2\,\mathrm{d}w. \tag{4.1}$$

In fact, $G^{-1} \circ F$ is the optimal map for all convex costs in dimension one [48, Theorem 2.18].

This expression of the one-dimensional Wasserstein distance has been used for nonlinear diffusions and nonlinear nonlocal friction equations in granular media [20, 34, 16] to analyze the long-time asymptotics and the contraction properties with respect to Wasserstein distances of those equations. Moreover, these ideas have first been used in [29, 30] for numerical purposes. Explicit in time numerical schemes for the equations of the inverse distribution function are proposed, keeping the contraction of the Wasserstein distance at the discrete level. Here, we prefer to solve it by an implicit in time Euler scheme since it coincides with the JKO scheme through the

representation (4.1) and since, moreover, the contraction property of the Wasserstein distance is not true due to the lack of convexity of the functional $\mathcal{G}$.

More precisely, let F_n and F_{n+1} be the cumulative distribution functions associated respectively to ρ_τ^n and ρ_τ^{n+1}. By the expression (4.1) of the Wasserstein distance on the real line, the scheme (3.1) can be rewritten in terms of $V_n = F_n^{-1}$ and $V_{n+1} = F_{n+1}^{-1}$ as the gradient flow of the inverse distribution function subject to L^2-metric structure:

$$V_{n+1} \in \arg\inf_{\{W\,:\,(W^{-1})'\in\mathcal{K}\}} \left[\tilde{\mathcal{G}}[W] + \frac{1}{2\,\tau}\|W - V_n\|^2_{L^2(0,1)}\right],$$

where

$$\tilde{\mathcal{G}}[W] := -\int_0^1 \log W'(w)\,\mathrm{d}w + \int_0^1 |W(w)|^2\,\mathrm{d}w + \frac{\chi}{\pi}\int_0^1\int_0^1 \log|W(w) - W(z)|\,\mathrm{d}w\,\mathrm{d}z.$$

Here the metric is Euclidean, and hence the Euler–Lagrange equation associated to this minimization problem is

$$\frac{V_{n+1} - V_n}{\tau} = -\nabla\tilde{\mathcal{G}}[V_{n+1}]\,,$$

where ∇ is the usual gradient operator in $L^2(\mathbb{R})$. This Euler–Lagrange equation can be rewritten as

$$-\frac{V_{n+1}(w) - V_n(w)}{\tau} = \frac{\partial}{\partial w}\left[\left(\frac{\partial V_{n+1}(w)}{\partial w}\right)^{-1}\right] + V_{n+1}(w) + \chi H[V_{n+1}], \tag{4.2}$$

where $\tilde{H}$ is related to the Hilbert transform and is defined by

$$\tilde{H}[V](w) := \frac{1}{\pi}\lim_{\varepsilon\to 0}\int_{|V(w)-V(z)|\geq\varepsilon}\frac{1}{V(w) - V(z)}\,\mathrm{d}z\,.$$

For the sake of simplicity we assume that the space step is constant, equal to h. If we set $V_n^i := V_n(ih)$, for any $i = 0\cdots N$, and $Nh = 1$, the finite difference discretization in space of (4.2) is the following implicit Euler scheme in rescaled variables:

$$\begin{aligned}-\frac{V_{n+1}^i - V_n^i}{\tau} = \frac{1}{V_{n+1}^{i+1} - V_{n+1}^i} - \frac{1}{V_{n+1}^i - V_{n+1}^{i-1}} + V_{n+1}^i \\ + \frac{\chi h}{\pi}\lim_{\varepsilon\to 0}\sum_{j\,:\,|V_{n+1}^i - V_{n+1}^j|\geq\varepsilon}\frac{1}{V_{n+1}^i - V_{n+1}^j}\end{aligned} \tag{4.3}$$

with initial condition $V_0 = \rho_0$. We impose Neumann boundary conditions in the ρ-problem (2.3), i.e., for any n, $\frac{1}{V_n^N - V_n^{N-1}} = 0$ and $\frac{1}{V_n^1 - V_n^0} = 0$, so that the "center of mass" is conserved:

$$\forall n \quad \sum_{i=0}^N V_n^i = 0.$$

The solution at each time-step of the nonlinear system of equations is obtained by an iterative Newton–Raphson procedure.

Remark 4.1 (higher dimensions). A way to extend the previous numerical scheme to higher dimensions is to solve an equivalent L^2 gradient flow for diffeomorphisms proposed in [27]. The price to pay is that one needs to solve a fully nonlinear coupled system of d partial differential equations.

4.1. Exponential convergence in one dimension. Here comes the second main improvement and motivation for this numerical scheme. In addition to convergence as the time step goes to zero, we are able to show that for a fixed $\tau > 0$ the discrete solution converges to a unique steady state as time goes to infinity. First we prove existence of this steady state equilibrium; see Proposition 4.2. Uniqueness and convergence follow from Proposition 4.3.

PROPOSITION 4.2. *Let $(V^i)_i$ be an increasing sequence. The discrete free energy functional defined as*

$$\tilde{\mathcal{G}}_h[V] = -\sum_{i=1}^{N-1} h \log\left(\frac{V^{i+1}-V^i}{h}\right) + \frac{1}{2}\sum_{i=1}^{N} h|V^i|^2 + \frac{\chi}{2\pi}\sum_{i=1}^{N}\sum_{j=1,\ j\neq i}^{N} h^2 \log|V^j - V^i|$$

is coercive and bounded from below if $\chi(1-h) < \chi_c = 2\,\pi$.

Proof. We shall adapt to the discrete setting the so-called logarithmic Hardy–Littlewood–Sobolev (2.1) and Carleman inequalities; see Lemma 2.2.

Step 1. A discrete logarithmic Hardy–Littlewood–Sobolev inequality: we will prove the following discrete logarithmic Hardy–Littlewood–Sobolev inequality:

$$\sum_{i=1}^{N}\sum_{j=1,j\neq i}^{N} h^2 \log|V^j - V^i| \geq (1-h)\sum_{i=1}^{N-1} h \log\left(\frac{V^{i+1}-V^i}{h}\right) + C_h. \tag{4.4}$$

Observe that the space step h modifies the apparent space dimension: the factor $d_h := 1 - h$ replaces $d = 1$ in front of the entropy term. Observe also that the correcting factor d_h is the only admissible one for homogeneity reasons. In fact, when V is multiplied by $\lambda > 0$ (think of $\lambda \to 0$ or $\lambda \to \infty$), then inequality (4.4) is violated if $d_h \neq 1 - h$: the additional term $h(N-1)\big(hN - (1-h)\big)\log\lambda$ comes out, and $hN = d_h$.

The left-hand side in (4.4) can be reorganized as following, where the increasingness of $(V^i)_i$ is crucially used:

$$\begin{aligned}
\sum_{i=1}^{N}\sum_{j=1,j\neq i}^{N} h^2 \log|V^j - V^i| &= \sum_{i=1}^{N}\sum_{j=i+1}^{N} h^2 \log(V^j - V^i) + \sum_{i=1}^{N}\sum_{j=1}^{i-1} h^2 \log(V^i - V^j)\\
&\geq \sum_{i=1}^{N-1}\sum_{j=i+1}^{N} h^2 \log(V^{i+1} - V^i) + \sum_{k=1}^{N-1}\sum_{j=1}^{k} h^2 \log(V^{k+1} - V^j)\\
&\geq \sum_{i=1}^{N-1} h^2 (N-i)\log(V^{i+1} - V^i) + \sum_{k=1}^{N-1} h^2 k \log(V^{k+1} - V^k)\\
&= \sum_{i=1}^{N-1} h(hN)\log(V^{i+1} - V^i)\\
&= d_h \sum_{i=1}^{N-1} h \log\left(\frac{V^{i+1}-V^i}{h}\right) + C_h,
\end{aligned}$$

which proves the discrete logarithmic Hardy–Littlewood–Sobolev inequality (4.4).

Step 2. A discrete Carleman inequality: we shall prove next the following inequality:

$$-\sum_{i=1}^{N-1} h \log\left(\frac{V^{i+1}-V^i}{h}\right) + \frac{1}{2}\sum_{i=1}^{N} h|V_i|^2 \geq C_h. \tag{4.5}$$

Introduce the median of the sequence $(V^i)_i$; that is, select k^0 such that $|V^{k_0}| = \min |V^k|$. Within this choice we have in particular $V^k \le 0$ for $k < k_0$ and $V^k \ge 0$ for $k > k_0$. Thus we obtain

$$
\begin{aligned}
&- \sum_{i=1}^{N-1} h \log\left(\frac{V^{i+1}-V^i}{h}\right) + \frac{1}{2}\sum_{i=1}^{N} h|V^i|^2 \\
&\ge - \sum_{i=1}^{N-1} h \log\left(\frac{V^{i+1}-V^i}{h}\right) + \frac{1}{2}\sum_{i=1, i\neq k_0}^{N} h|V^i|^2 \\
&= -h(N-1)\sum_{i=1}^{k_0-1} \frac{1}{N-1}\log\left((V^{i+1}-V^i)\mathrm{e}^{-\frac{1}{2}|V^i|^2}\right) \\
&\qquad - h(N-1)\sum_{i=k_0}^{N-1} \frac{1}{N-1}\log\left((V^{i+1}-V^i)\mathrm{e}^{-\frac{1}{2}|V^{i+1}|^2}\right) + C_h \\
&\ge -h(N-1)\log\left[\frac{1}{N-1}\left(\sum_{i=1}^{k_0-1}(V^{i+1}-V^i)\mathrm{e}^{-\frac{1}{2}|V^i|^2} + \sum_{i=k_0}^{N-1}(V^{i+1}-V^i)\mathrm{e}^{-\frac{1}{2}|V^{i+1}|^2}\right)\right] + C_h \\
&\ge C_h,
\end{aligned}
$$

thanks to the Jensen inequality and the peculiar choice of k_0. The last minoration step comes from

$$
\begin{aligned}
&\sum_{i=1}^{k_0-1} \mathrm{e}^{-\frac{1}{2}|V^i|^2}(V^{i+1}-V^i) + \sum_{i=k_0}^{N-1} \mathrm{e}^{-\frac{1}{2}|V^{i+1}|^2}(V^{i+1}-V^i) \\
&\le \sum_{i=1}^{k_0-1} \mathrm{e}^{-\frac{1}{2}|V^i|^2}|V^i| + \mathrm{e}^{-\frac{1}{2}|V^{k_0-1}|^2}|V^{k_0}| + \mathrm{e}^{-\frac{1}{2}|V^{k_0+1}|^2}|V^{k_0}| + \sum_{i=k_0}^{N-1} \mathrm{e}^{-\frac{1}{2}|V^{i+1}|^2}|V^{i+1}| \\
&\le C_h,
\end{aligned}
$$

since the function $\mathrm{e}^{-\frac{1}{2}|X|^2}|X|$ is uniformly bounded and $|V^{k_0}| \le \min\{|V^{k_0-1}|, |V^{k_0+1}|\}$.

Step 3. Coercivity of the discrete free energy: as a by-product of discrete logarithmic Hardy–Littlewood–Sobolev and Carleman inequalities we obtain the following coercivity a priori estimate ensuring the existence of a minimizer (which is the stationary state we are looking for). Define $\theta = \frac{\chi(1-h)}{2\pi} < 1$ and deduce from the discrete logarithmic Hardy–Littlewood–Sobolev inequality (4.4) that

$$
\tilde{\mathcal{G}}_h[V] \ge (1-\theta)\left(- \sum_{i=1}^{N-1} h \log\left(\frac{V^{i+1}-V^i}{h}\right)\right) + \frac{1}{2}\sum_{i=1}^{N} h|V^i|^2 + C_h. \tag{4.6}
$$

Then apply the discrete Carleman inequality (4.5) to eventually obtain

$$
\tilde{\mathcal{G}}_h[V] \ge \frac{\theta}{2}\sum_{i=1}^{N} h|V^i|^2 + C_h. \qquad \square
$$

As a by-product we obtain existence of a stationary state realized as a minimizer of the free energy functional. Indeed, it remains to show that a minimizing sequence cannot blow-up in the sense that $V_{i+1} - V_i$ is prevented from vanishing. If so, this would contradict the upper bound obtained above in (4.6).

PROPOSITION 4.3 (convergence in the subcritical case). *Assume that* $\chi(1-h) < \chi_c$. *Then the solution of the numerical scheme* (4.3) *converges to the unique steady state of the problem with exponential rate.*

Proof. First we need the following two characterizations of the unique equilibrium state. The uniqueness will in fact follow from the convergence proof, as we shall see later (Remark 4.4). The discrete function $(V_*^i)_i$ is an equilibrium if and only if

$$\forall i, \quad 0 = \frac{1}{V_*^{i+1} - V_*^i} - \frac{1}{V_*^i - V_*^{i-1}} + V_*^i + \frac{\chi}{\pi} \sum_{j \neq i} h \frac{1}{V_*^i - V_*^j}, \tag{4.7}$$

or equivalently

$$\forall k, \quad (V_*^{k+1} - V_*^k) \left\{ \frac{\chi}{\pi} \sum_{j=0}^{k} \sum_{i=k+1}^{N} h \frac{1}{V_*^i - V_*^j} - \sum_{i=0}^{k} V_*^i \right\} = 1. \tag{4.8}$$

To see that (4.7) and (4.8) are equivalent, rewrite the latter as

$$\forall k, \quad \frac{1}{V_*^{k+1} - V_*^k} = \frac{\chi}{\pi} \sum_{j=0}^{k} \sum_{i=k+1}^{N} h \frac{1}{V_*^i - V_*^j} - \sum_{i=0}^{k} V_*^i$$

and then "derive" the ongoing expression in a discrete way,

$$\begin{aligned} \frac{1}{V_*^{k+1} - V_*^k} - \frac{1}{V_*^k - V_*^{k-1}} &= \frac{\chi}{\pi} \sum_{j=0}^{k} \sum_{i=k+1}^{N} h \frac{1}{V_*^i - V_*^j} - \frac{\chi}{\pi} \sum_{j=0}^{k-1} \sum_{i=k}^{N} h \frac{1}{V_*^i - V_*^j} - V_*^k \\ &= \frac{\chi}{\pi} \sum_{i=k+1}^{N} h \frac{1}{V_*^i - V_*^k} - \frac{\chi}{\pi} \sum_{j=0}^{k-1} h \frac{1}{V_*^k - V_*^j} - V_*^k. \end{aligned}$$

We proceed as computing the time evolution of the L^2-distance between V_n and the stationary state V_*:

$$\begin{aligned} \frac{1}{2\tau} \Big(\|V_{n+1} - V_*\|^2 - \|V_n - V_*\|^2 \Big) &= \frac{1}{2\tau} \sum_i h (V_{n+1}^i - V_n^i)(V_{n+1}^i + V_n^i - 2V_*^i) \\ &= \sum_i h \frac{V_{n+1}^i - V_n^i}{\tau} (V_{n+1}^i - V_*^i) - \frac{1}{2\tau} \sum_i h (V_{n+1}^i - V_n^i)^2. \end{aligned}$$

We then input the evolution equation for $V_{n+1} - V_n$, and obtain, thanks to (4.7),

$$\begin{aligned} \frac{1}{2\tau} \Big(\|V_{n+1} - V_*\|^2 - \|V_n - V_*\|^2 \Big) \leq - \sum_i h \Bigg(& \frac{1}{V^{i+1} - V^i} - \frac{1}{V^i - V^{i-1}} - \frac{1}{V_*^{i+1} - V_*^i} \\ & + \frac{1}{V_*^i - V_*^{i-1}} + V^i - V_*^i + \frac{\chi}{\pi} \sum_{j \neq i} h \frac{1}{V^i - V^j} \\ & - \frac{\chi}{\pi} \sum_{j \neq i} h \frac{1}{V_*^i - V_*^j} \Bigg) (V^i - V_*^i) \\ = A_n + B_n + C_n, \end{aligned}$$

where V stands for V_{n+1} without any ambiguity. We integrate by parts the first (diffusion) contribution, to obtain

$$\begin{aligned} A &= -\sum_i h\left(\frac{1}{V^{i+1}-V^i}-\frac{1}{V^i-V^{i-1}}-\frac{1}{V_*^{i+1}-V_*^i}+\frac{1}{V_*^i-V_*^{i-1}}\right)(V^i-V_*^i)\\ &= \sum_i h\left(\frac{1}{V^{i+1}-V^i}-\frac{1}{V_*^{i+1}-V_*^i}\right)(V^{i+1}-V_*^{i+1}-V^i+V_*^i). \end{aligned}$$

We have carefully used the boundary conditions $\frac{1}{V^N-V^{N-1}}=0$ and $\frac{1}{V^1-V^0}=0$. We can rewrite A using zero-homogeneity of the last expression, namely,

$$A=\sum_i h\gamma\left(\frac{V^{i+1}-V^i}{V_*^{i+1}-V_*^i}\right),$$

where $\gamma(\lambda)=2-\lambda-\lambda^{-1}$ is concave and nonpositive. The second contribution coming from variable rescaling is obvious but crucial, namely,

$$B=-\sum_i h(V^i-V_*^i)^2=-\|V_{n+1}-V_*\|^2.$$

The last (interaction) contribution is more tricky to handle and involves variables doubling, as is known from granular media; see [20]. We have

$$\begin{aligned} C &= -\frac{\chi}{\pi}\sum_i h\left(\sum_{j\neq i} h\frac{1}{V^i-V^j}-\sum_{j\neq i} h\frac{1}{V_*^i-V_*^j}\right)(V^i-V_*^i)\\ &= -\frac{\chi}{2\pi}\sum_{i,j,i\neq j} h^2\left(\frac{1}{V^i-V^j}-\frac{1}{V_*^i-V_*^j}\right)(V^i-V^j-V_*^i+V_*^j)\\ &= -\frac{\chi}{2\pi}\sum_{i,j,i\neq j} h^2\gamma\left(\frac{V^i-V^j}{V_*^i-V_*^j}\right). \end{aligned}$$

Notice that the above expression is symmetric between the two possible choices $i<j$ and $j<i$. We shall also make use of the concavity property of γ as follows:

$$\begin{aligned} C &= -2\frac{\chi}{2\pi}\sum_{j<i} h^2\gamma\left(\sum_{j\le k<i}\frac{V^{k+1}-V^k}{V_*^{k+1}-V_*^k}\cdot\frac{V_*^{k+1}-V_*^k}{V_*^i-V_*^j}\right)\\ &\le -\frac{\chi}{\pi}\sum_{i<j} h^2\sum_{j\le k<i}\gamma\left(\frac{V^{k+1}-V^k}{V_*^{k+1}-V_*^k}\right)\frac{V_*^{k+1}-V_*^k}{V_*^i-V_*^j}\\ &= -\frac{\chi}{\pi}\sum_k h\gamma\left(\frac{V^{k+1}-V^k}{V_*^{k+1}-V_*^k}\right)(V_*^{k+1}-V_*^k)\sum_{j=0}^{k}\sum_{i=k+1}^{N} h\frac{1}{V_*^i-V_*^j}\\ &\le -\sum_k h\gamma\left(\frac{V^{k+1}-V^k}{V_*^{k+1}-V_*^k}\right)(V_*^{k+1}-V_*^k)\left\{\frac{\chi}{\pi}\sum_{j=0}^{k}\sum_{i=k+1}^{N} h\frac{1}{V_*^i-V_*^j}-\sum_{i=0}^{k}V_*^i\right\}, \end{aligned}$$

where we have used the fact that $D_k:=\sum_{i=0}^k V_*^i$ is a nonpositive quantity for all k.

Let us prove this last claim. Indeed, $D_{k+1} - D_{k-1} - 2\,D_k = V_*^{k+1} - V_*^k \geq 0$. Hence, $D_{k+1} - D_k \geq D_{k-1} - D_k$. Since $D_N = 0$ and $D_0 = V_*^0 \leq 0$, there exists k_0 such that $(D_k)_{1\leq k\leq k_0}$ is nondecreasing and $(D_k)_{k_0\leq k\leq N}$ is nonincreasing. As a consequence, $D_k \leq D_0 \leq 0$ for any integer k, $1 \leq k \leq k_0$, and $D_k \leq D_N = 0$ for any integer k, $k_0 + 1 \leq k \leq N$, which proves the assertion.

At this stage we bring in the alternative representation of the stationary solution (4.8), so that $A + C \leq 0$. As a consequence we obtain

$$\frac{1}{2\tau}\Big(\|V_{n+1} - V_*\|^2 - \|V_n - V_*\|^2\Big) \leq -\|V_{n+1} - V_*\|^2. \tag{4.9}$$

We finally get the exponential convergence rate,

$$\|V_n - V_*\|^2 \leq \left(\frac{1}{1+2\tau}\right)^n \|V^0 - V_*\|^2.$$

If τ is small, we can thus approximate $\log(1+2\tau) \approx 2\tau$ and $(\frac{1}{1+2\tau})^n \approx \exp(-2n\tau) \approx \exp(-2t)$. Thus, the bound on the rate, we find, does not depend on the parameter $\chi < \chi_c$. □

Remark 4.4 (uniqueness of the stationary solution). We can deduce a posteriori the uniqueness of the equilibrium. As a matter of fact, let us consider another equilibrium state $\tilde{V}_*$ and set $V_{n+1} = V_n = \tilde{V}_*$ in the above computations. We eventually obtain $\|\tilde{V}_* - V_*\| \leq 0$ from (4.9), which proves the uniqueness.

To complete the picture, we shall prove here that the discrete approximation (4.3) (without the drift term) blows-up in finite time in the supercritical case $(1-h)\chi > \chi_c$, in the sense that the iterations cannot be recursively handled forever. In fact, at some point some increment $V_n^{i+1} - V_n^i$ may vanish, breaking the scheme. We proceed as for the continuous virial method, by computing the evolution of the second-momentum, that is, the L^2-norm of (V_n) in this context. It is shown to vanish eventually in finite time, which is an obstruction.

PROPOSITION 4.5 (blow-up of the discrete solution). *Assume we are in the supercritical case $\chi(1-h) > \chi_c$; then the Keller–Segel steepest descent scheme (without a drift term) blows-up in finite time.*

Proof. We follow exactly the proof of Proposition 4.3, where integration by parts and symmetrization of the "kernel" were already performed.

$$\begin{aligned}
\frac{1}{2\tau}\left(\|V_{n+1}\|^2 - \|V_n\|^2\right) &= \frac{1}{2\tau}\sum_i h(V_{n+1}^i - V_n^i)\left(V_{n+1}^i + V_n^i\right)\\
&= \sum_i h\frac{V_{n+1}^i - V_n^i}{\tau}V_{n+1}^i - \frac{1}{2\tau}\sum_i h\left(V_{n+1}^i - V_n^i\right)^2\\
&\leq \sum_i h\frac{V_{n+1}^i - V_n^i}{\tau}V_{n+1}^i\\
&\leq \sum_i h\left(\frac{1}{V^{i+1} - V^i} - \frac{1}{V^i - V^{i-1}} + \frac{\chi}{\pi}\sum_{j\neq i} h\frac{1}{V^i - V^j}\right)V^i\\
&= A + B,
\end{aligned}$$

where V stands for V_{n+1} without any ambiguity. In fact,

$$A = \sum_i h\,\frac{V^{i+1} - V^i}{V^{i+1} - V^i} = 1,$$

and, doubling the sum,

$$C = -\frac{\chi}{2\pi} \sum_{i,j,i\neq j} h^2 \frac{V^i - V^j}{V^i - V^j}$$
$$= -\frac{\chi h^2}{2\pi} N(N+1) = -\frac{\chi(1-h)}{2\pi} .$$

Thus, in case of $(1-h)\chi > \chi_c$ the second momentum decreases at least linearly in time, ensuring blow-up after a finite time. □

Remark 4.6 (original variables). When coming back in the continuous setting to the original variables $n(t,x)$ by (2.2), we are not able to show even that

$$n(t,x) = n^\infty(t,x) + O_W(1),$$

where n^∞ is the dilatation of the stationary state,

$$n^\infty(t,x) = \frac{1}{1+2t} V_* \left(\frac{x}{\sqrt{1+2t}} \right),$$

and O_W means infinitesimal in the d_W sense. The reason is that the found estimate on the speed of convergence does not depend on the reduced parameter χ, but only on the variable rescaling, and the change of variables restores exactly the factor e^t due to the scaling properties of d_W [48, 21]. This result should be improved as seen from the numerical experiments below, and it is an open problem how to get a faster speed of convergence in the scaled equation leading to a polynomial decay in original variables. In fact, we conjecture that if we fix the center of mass, then the rate of convergence of the solution to the stationary solution in rescaled variables is of order e^{-2t}. This fact coincides with other situations as in nonlinear diffusions in which fixing certain invariants of the equation improves the rate of convergence [23]. Certainly the situation is close to the heat equation for small mass solutions [26].

In the next sections, we will show some numerical experiments for the PKS equation using the scheme (4.3). We begin with the subcritical case $\chi = \pi$ (recall that in dimension one the critical parameter is $\chi_c = 2\pi$) for the not rescaled (section 4.2.1) as opposed to the rescaled (section 4.2.2) system. We next approach the critical parameter, plugging $\chi = 1.8\pi$, and initialize the scheme with a two-peaks density n_0 (resp., sections 4.2.3 and 4.2.4). We then investigate the upper-critical case starting with respectively a single peak (section 4.3.1), two symmetric peaks attracting each other (section 4.3.2), and two asymmetric peaks (section 4.4).

In the following, we assume a uniform in space discretization $w_i = ih$, $i = 0, \ldots, N$, and $Nh = 1$.

4.2. Subcritical case.

4.2.1. Not rescaled case. Starting with the centered initial data,

$$V_0^i = 2 \frac{w_i - 0.5}{[(w_i + 0.01)(1.01 - w_i)]^{1/4}} ,$$

corresponding to a compact supported density n_0, we numerically solve the PKS equation on the time interval $[0, 400]$ with $\chi = \pi$. Figures 4.1 and 4.2 show the evolution of the solution both for the density (Figure 4.2) and its inverse distribution function (Figure 4.1).

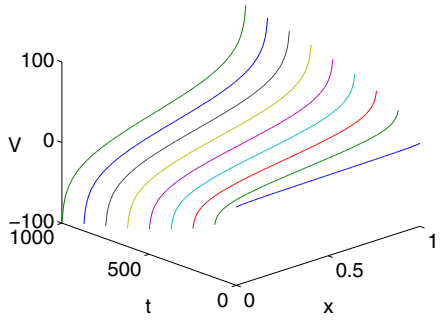

FIG. 4.1. *Inverse cumulative distribution function for $\chi = \pi$. Note that the initial data seems to be flat relative to the very large scale on the V-axis, as opposed to Figure* 4.5.

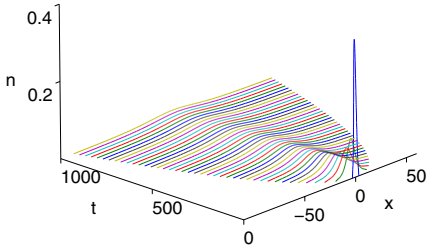

FIG. 4.2. *Cell density n as time evolves, obtained from its inverse cumulative distribution function. According to Figure* 4.1*, the space scale is also very large, and therefore the density seems highly concentrated at $t = 0$.*

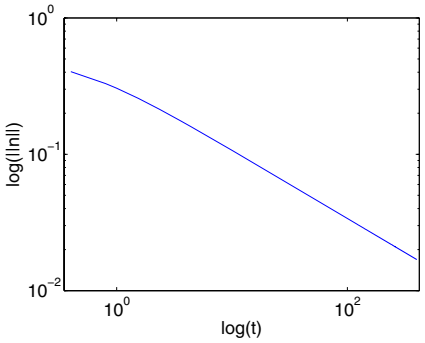

FIG. 4.3. *L^2-norm's evolution for the cell density n, in a* log-log *scale. The decay appears to be polynomial.*

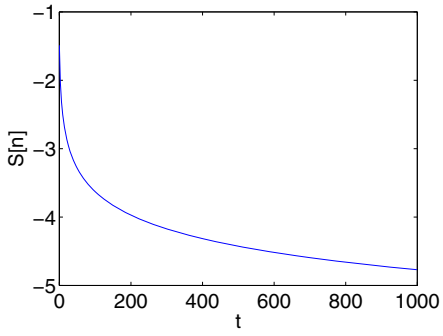

FIG. 4.4. *Evolution of the entropy $\mathcal{S}[n]$ showing slow decay.*

Observe in Figure 4.1 that the branches of the inverse cumulative function V go eventually to $\pm\infty$. This is expected because the support of the cell density spreads as time goes on, and therefore the distribution tails are wider. Recall that in the subcritical regime, the diffusion process dominates. The scheme captures well the collapse down to zero of the cell density and the spreading of the solution. Interestingly, this scheme handles easily with moving density's support (note that finite speed of propagation is a numerical artifact), whereas the reference domain $[0, 1]$ is fixed because we deal with probability densities (mass is conserved).

Moreover, the spreading towards zero seems to be polynomial from Figure 4.3 showing the evolution of the L^2-norm of the cell density in log-log scale. The entropy decay is plotted in Figure 4.4.

4.2.2. Rescaled variables: $\chi = \pi$. Given the compactly supported initial data,

$$V_0^i = 2\,\frac{w_i - 0.5}{\left[(w_i + 0.01)\,(1.01 - w_i)\right]^{1/4}}\,,$$

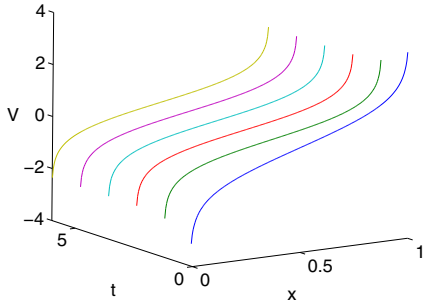

FIG. 4.5. *Fast convergence towards the stationary solution for $\chi = \pi$ and rescaled variables.*

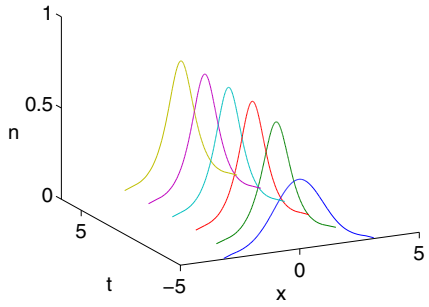

FIG. 4.6. *Evolution of the corresponding cell density n.*

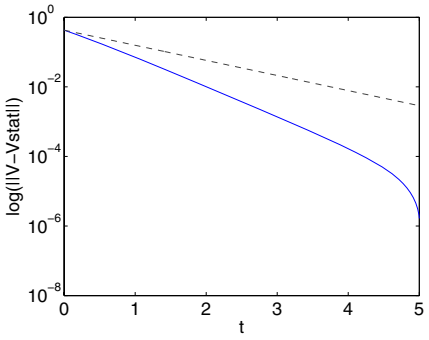

FIG. 4.7. *Wasserstein distance between the density at time t and the final computed density, assumed to be almost the stationary solution. Dashed line: decay rate proved in Proposition* 4.3.

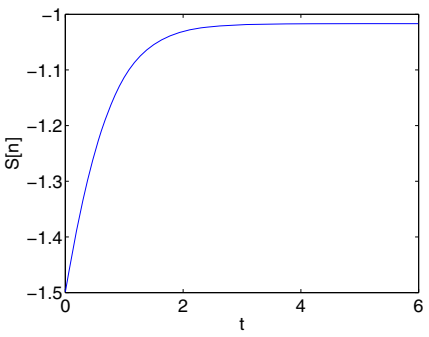

FIG. 4.8. *Evolution of the entropy.*

we solve the PKS equation numerically in rescaled variables on the time interval $[0, 5]$ with $\chi = \pi$ (corresponding results are shown in Figures 4.5 and 4.6, 4.7 and 4.8).

In contrast to previous section 4.2.1, we observe an exponential convergence towards the stationary solution (see Figures 4.5 and 4.7). When computing the Wasserstein distance between the density at time t and the expected stationary solution (last computed time), we find out that the convergence is faster than e^{-t} (Figure 4.7) obtained in Proposition 4.3. This confirms the open problem of trying to find a better decay rate in scaled variables that will eventually lead to a polynomial decay rate towards self-similarity in original variables for subcritical masses.

4.2.3. Rescaled variables: $\chi = 1.8\pi$. Given the compactly supported initial data,

$$V_0^i = 2\,\frac{w_i - 0.5}{\left[(w_i + 0.01)\,(1.01 - w_i)\right]^{1/4}}\,,$$

we numerically solve the PKS equation in rescaled variables on the time interval $[0, 5.5]$ with $\chi = 1.8\pi$. Figures 4.9 and 4.10 show the evolution of the solution.

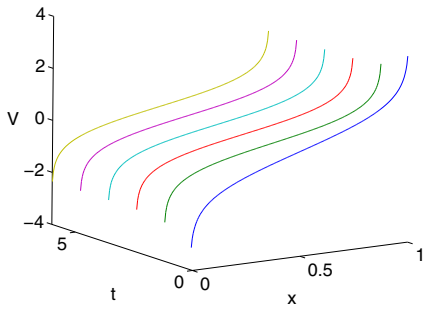

FIG. 4.9. *Cumulative distribution function V for the subcritical case $\chi = 1.8\pi < \chi_c$.*

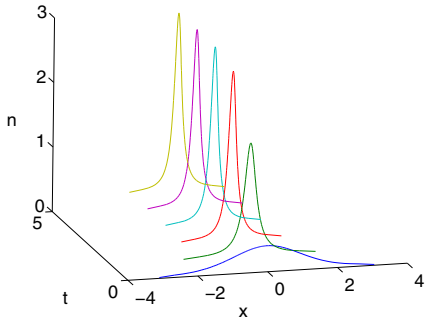

FIG. 4.10. *Evolution of the cell density n.*

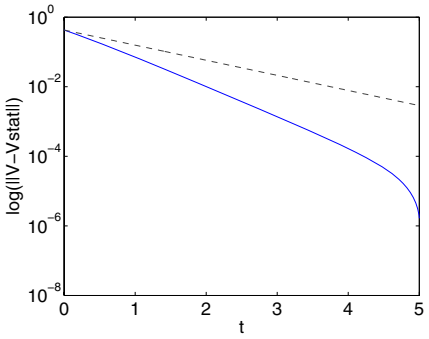

FIG. 4.11. *Wasserstein distance between the density at time t and the final computed density, assumed to be almost the stationary solution. Dashed line: decay rate proved in Proposition* 4.3.

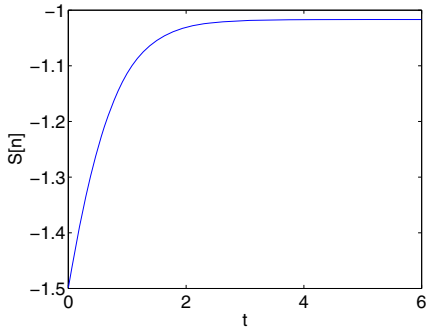

FIG. 4.12. *Evolution of the entropy.*

The initial data is the same as in section 4.2.2, but χ is closer to the critical parameter χ_c. The solution again converges exponentially to the stationary solution (see Figures 4.9 and 4.10). According to Proposition 4.3, the rate of convergence is at least the same as in section 4.2.2; compare Figure 4.11 to Figure 4.7 and the slopes are the same (of order e^{-2t}). On the other hand, the equilibrium state is more concentrated (Figure 4.10), corresponding to a flat plateau in Figure 4.9, as we expect it converges to a Dirac mass. The entropy seems to converge; see Figure 4.12.

4.2.4. Two-peaks initial data. Initialize with the centered cumulative distribution function,

$$V_0^i = \frac{\exp\left[10\ (w_i - 0.5)\right] - 1}{\left[(w_i + 0.01)\,(1.01 - w_i)\right]^{1/4}}\ ,$$

corresponding to a two-peaks-like density with compact support. We numerically solve the PKS equation in rescaled variables on the time interval $[0, 5]$ with $\chi = \pi$.

Whereas the parameter χ is the same as in section 4.2.2, the initial data is qualitatively different. The two peaks diffuse, eventually merging and finally converging to the stationary solution with exponential speed (see Figures 4.13 and 4.14). Let

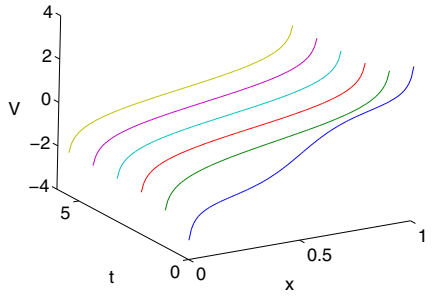

FIG. 4.13. *Cumulative distribution function V for $\chi = \pi$ and a two-peaks initial condition.*

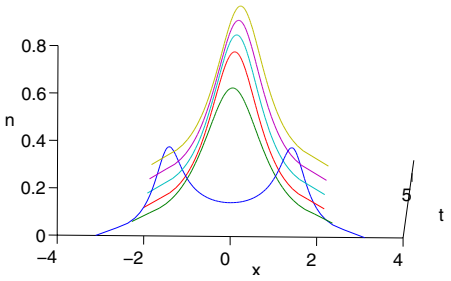

FIG. 4.14. *Cell density n.*

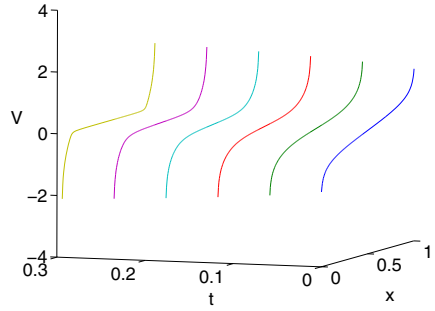

FIG. 4.15. *Cumulative distribution function V for $\chi > \chi_c$. The solution blows-up exhibiting a plateau in finite time.*

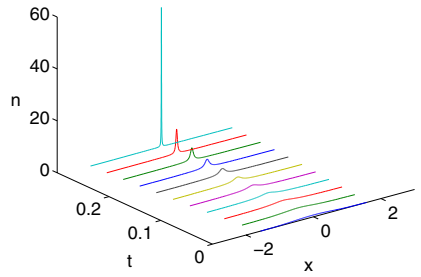

FIG. 4.16. *Cell density n. We observe blow-up in finite time.*

us mention finally that the numerical scheme does not preserve the exact value of the critical mass. The scheme does not preserve the law of evolution of the second moment. However, with the same initial data as in the first two subsections, the numerical critical mass is situated between 1.973π and 1.974π.

4.3. Supercritical case.

4.3.1. Single-peak initial data. Given the compactly supported initial data,

$$V_0^i = 2\,\frac{w_i - 0.5}{\left[(w_i + 0.01)\,(1.01 - w_i)\right]^{1/4}}\,,$$

we numerically solve the PKS equation in original variables on the time interval $[0, 0.32]$ with $\chi = (5/2)\,\pi$. Note that in the upper-critical case, the variables' rescaling seems to play no role.

The solution blows-up in finite time (either a flat portion or a highly concentrated region appears; see, resp., Figures 4.15 and 4.16). Visualized in Wasserstein distance (namely, the square root of the second-momentum), the convergence to the Dirac mass located at zero seems to be linear in time (see Figure 4.17), as it should be from the theoretical viewpoint. However, the computed distance does not reach zero in finite

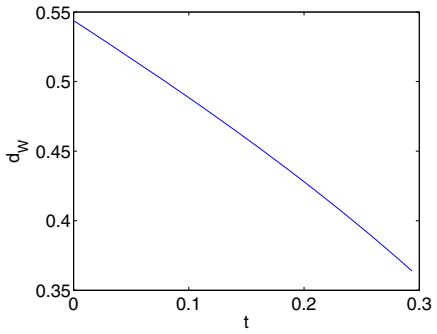

FIG. 4.17. *Wasserstein distance to the Dirac mass at zero δ_0. Blow-up occurs previously, and part of the mass has not yet reached zero at this time.*

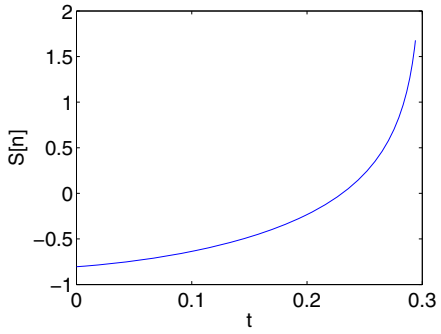

FIG. 4.18. *The variation of the entropy $\mathcal{S}[n]$ seems to blow-up.*

time. This is not surprising, because when blow-up occurs, part of the mass is still away from the blow-up point (here, zero). In order to see some vanishing distance, one can normalize the process in the following away: localize the Wasserstein distance in the transport variable (L^2-distance for the cumulative distribution function), to capture only the final plateau. This plateau is known a priori because it is entirely determined by the ratio χ_c/χ. However, this does not provide any new insight into what happens after blow-up, and it is known from theoretical works that the behavior depends highly upon the regularization procedure [46, 47, 25].

Interestingly, numerics are able to track the blow-up phenomenon quite precisely, without mesh refinement. Indeed, if the space step is even uniform, the number of space points at the density level adapts to the highly concentrated (blow-up) regions, corresponding to plateaus (compare Figure 4.15 and Figure 4.16). This is the counterpart of the "moving support" observed in section 4.2.1. The evolution of the entropy is plotted in Figure 4.18.

4.3.2. Two symmetric peaks: Case $\chi = 3\,\pi$. Given the compactly supported initial data,

$$V_0^i = \frac{\exp\left[10\ (w_i - 0.5)\right] - 1}{\left[(w_i + 0.01)\,(1.01 - w_i)\right]^{1/4}}\ ,$$

we numerically solve the PKS equation in original variables on the time interval $[0, 1.3]$ with $\chi = 3\,\pi$.

The factor χ is supercritical but is less than $2\,\chi_c$. Then, according to the conjectures in [45, 46, 47], there should be only one blow-up point. The density first diffuses (see Figure 4.20) and then concentrates in a delta Dirac (see Figures 4.19 and 4.21).

4.3.3. Two symmetric peaks: Case $\chi = 5\,\pi$. Starting with the centered cumulative distribution function,

$$V_0^i = \frac{\exp\left[10\ (w_i - 0.5)\right] - 1}{\left[(w_i + 0.01)\,(1.01 - w_i)\right]^{1/4}}\ ,$$

corresponding to a two-peaks-like initial density, we numerically solve the PKS equation in original variables on the time interval $[0, 0.45]$ with $\chi = 5\,\pi$.

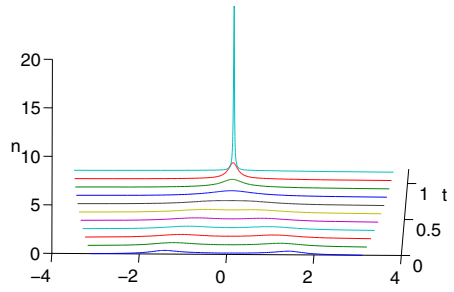

FIG. 4.19. *Cell density n for $\chi = 3\pi$ and two initial peaks.*

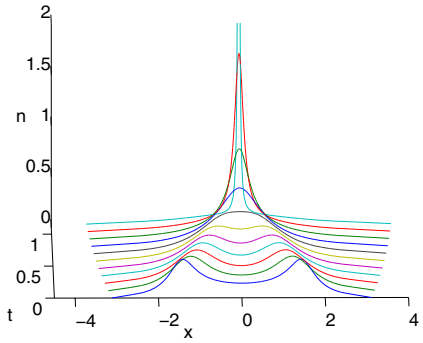

FIG. 4.20. *Zoom of Figure 4.19. Because both peaks do not contain enough mass to blow-up far from each other, they first merge, and then the solution blows-up.*

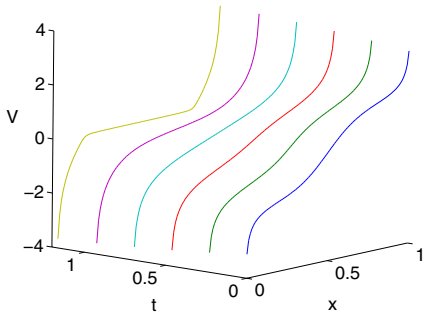

FIG. 4.21. *Cumulative function distribution function V for $\chi = 3\pi$ and two initial plateaus (that is, density peaks). The solution flattens into a single plateau.*

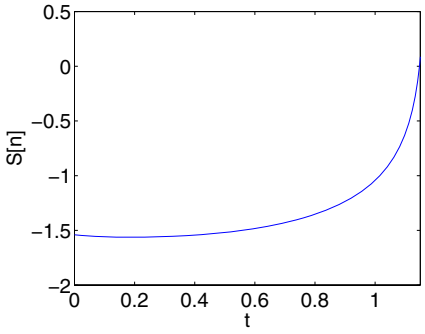

FIG. 4.22. *Evolution of the entropy.*

The initial condition is the same as in section 4.3.2, but χ is now bigger than $2\,\chi_c$. The blow-up occurs in two different points (see Figures 4.23 and 4.24). The entropy seems to blow-up; see Figure 4.22.

4.4. Two asymmetric peaks. Given the compactly supported initial data,

$$V_0^i = \frac{\exp\left[10\ (w_i - 0.45)\right] - 1}{\left[(w_i + 0.01)\,(1.01 - w_i)\right]^{1/4}}\ ,$$

we numerically solve the PKS equation in original variables on the time interval $[0, 1.1]$ with $\chi = 3\,\pi$. Note that the initial density is not centered, but it has no effect because Proposition 4.3 does not hold in this case.

When the parameter is between the critical parameter χ_c and twice the critical parameter $2\,\chi_c$, if the peaks are asymmetric, the blow-up occurs at the center of mass which is closer to the highest peak. The peaks diffuses, and then the density blows-up at the center of mass (see Figures 4.25 and 4.26).

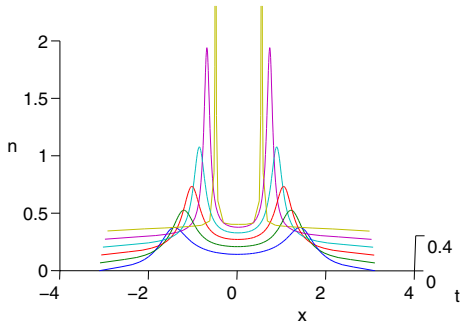

FIG. 4.23. *Cell density n for two initial peaks and $\chi = 5\pi$. In contrast to the previous section 4.3.2, each peak contains enough mass to blow-up itself.*

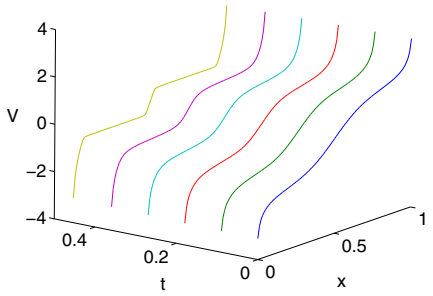

FIG. 4.24. *Cumulative distribution function V. Two distinct plateaus may appear when χ is above twice the critical parameters χ_c.*

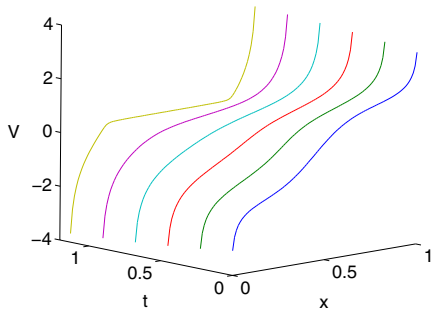

FIG. 4.25. *Cumulative distribution function V when $\chi \in (\chi_c, 2\,\chi_c)$ and initial data is a two-peaks-like density.*

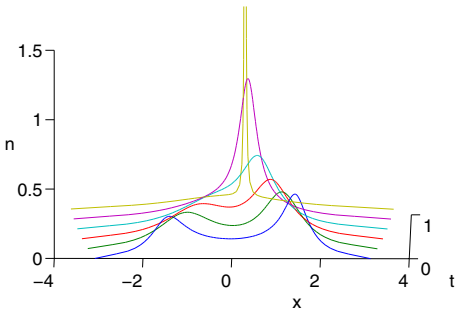

FIG. 4.26. *Evolution of the cell density n.*

ADAPTIVE MULTIPRECISION PATH TRACKING*

DANIEL J. BATES†, JONATHAN D. HAUENSTEIN‡, ANDREW J. SOMMESE‡, AND CHARLES W. WAMPLER II§

Abstract. This article treats numerical methods for tracking an implicitly defined path. The numerical precision required to successfully track such a path is difficult to predict a priori, and indeed it may change dramatically through the course of the path. In current practice, one must either choose a conservatively large numerical precision at the outset or rerun paths multiple times in successively higher precision until success is achieved. To avoid unnecessary computational cost, it would be preferable to adaptively adjust the precision as the tracking proceeds in response to the local conditioning of the path. We present an algorithm that can be set to either reactively adjust precision in response to step failure or proactively set the precision using error estimates. We then test the relative merits of reactive and proactive adaptation on several examples arising as homotopies for solving systems of polynomial equations.

DOI. 10.1137/060658862

1. Introduction.

Path tracking is the task of tracing out a one-real-dimensional solution curve described implicitly by a system of equations, typically n equations in $n+1$ variables, given an initial point on, or close to, the path. This can arise in many ways, but our motivation is the solution of systems of polynomials via homotopy continuation (see [1, 9, 10, 13, 14, 21]). In this method, to find the isolated solutions of the system $f(z) = 0$ for given polynomials $f : \mathbb{C}^n \to \mathbb{C}^n$, one constructs a homotopy, $H(z,t)$, $H : \mathbb{C}^n \times \mathbb{C} \to \mathbb{C}^n$ such that $H(z,0) = f(z)$ is the target system to be solved, while $H(z,1)$ is a starting system whose isolated solutions are known. There is a well-developed theory on how to construct such homotopies to guarantee, with probability one, that every isolated solution of $f(z) = 0$ is the endpoint in the limit as $t \to 0$ of at least one smooth path $z_i(t)$, where $H(z_i(t),t) = 0$ on $t \in (0,1]$ and where $z_i(1)$, $i = 1, 2, \ldots$, are the known isolated solutions of $H(z,1) = 0$. Similar constructions arise in other contexts, where the existence of a path leading to the desired solutions may or may not be guaranteed. Even when there is no guarantee, experience shows that in some application domains, continuation techniques yield solutions more reliably than Newton's method, especially when good initial guesses are not available. While in our applications the path is just a means of arriving at the endpoint, in other applications one may desire to accurately trace out the path itself, such as when plotting the response of a mathematical model as one of its parameters

is varied.

The most common path tracking algorithms are predictor-corrector methods: from an approximate solution point on the path, a predictor gives a new approximate point a given step size along the path, then a corrector brings this new point closer to the path. For example, one may use an Euler predictor, which steps ahead along the tangent to the path, or a higher order predictor that uses one or more recent points and possibly derivatives of the homotopy function at them to extrapolate to the predicted point. Typically, the prediction is then used as the initial point for correction by Newton's method. Since the solution set is one-dimensional, an extra constraint is introduced to isolate the target of the correction. For general homotopies, a useful constraint is to find where the solution path intersects the hyperplane normal to the last computed tangent direction. In the more restrictive setting of polynomial systems, the homotopy can be designed such that the paths advance monotonically with t, that is, there are no turning points, in which case it is acceptable (and simpler) to perform corrections by holding t fixed. The adaptive precision algorithm we discuss here is compatible with any of these prediction and correction schemes.

For good results, the predictor step size must be chosen appropriately. Too large a step size may result in a prediction outside the zone of convergence of the corrector, while too small a step size means progress is slow and computationally costly. Consequently, it has long been recognized that adaptive control of the step size is crucial for obtaining good reliability without undue computational cost.

While step size control is well established, less attention has been paid to efficient handling of precision. With wider availability of software packages for higher precision arithmetic, along with faster computers to execute the software, it becomes interesting to consider how adjustable precision might be deployed to improve the performance of path tracking algorithms. The issue at stake is analogous to step size control: without enough precision, path tracking might fail, but the use of excessive precision is inefficient. To address this trade-off, this paper proposes an algorithm that dynamically adjusts the number of digits used in computations according to the evolution of the numerical conditioning of the homotopy function.

In our primary application of interest, the solution of polynomial systems, there are several factors driving the need for higher precision. It is well known that high degree polynomials often lead to ill-conditioned problems. When treating polynomial systems in several variables, the total degree of the system, being the product of the degrees of the individual equations, quickly becomes large even for low degree polynomials, which can also lead to ill-conditioning. Thus, one driving force is the desire to solve larger systems of higher total degree.

A second motivation is that our systems often have some, or possibly many, singular solutions, and thus, the solution paths leading to these solutions are necessarily ill-conditioned near the end. While endgame methods exist for enhancing the accuracy with which such endpoints can be estimated, for singularities of high enough multiplicity, more precision is required.

A third motivation is that many polynomial systems from applications come with natural parameters. These systems with the parameters included typically have exact coefficients, which are relatively small integers. For "general values" of the parameters the structure of the solution set of the systems are the same [15], i.e., the number of multiplicity k points for $k = 1, 2, 3, \ldots$ remains constant. If the coefficients of the polynomials are computed to sufficient accuracy using the given choice of parameter values, the solutions of the system will typically have a clean structure for multiple

points, i.e., they will not have a cluster of solutions near each other unless the points computed more precisely converge to the same point. Here it is important that the coefficients are computed accurately as functions of the parameters. For example, in section 5.5, the polynomial system has coefficients computed accurately to 308 digits. The coefficients are polynomial functions of certain lengths, e.g., offsets and link lengths, and of cosines and sines of what are called twist angles. If only eight digits are used for the coefficients, as printed in the table in [14], then the algebraic relationships that should exist between the coefficients fail to hold to more than eight digits. For example, some coefficients depend on $\cos\alpha$ and $\sin\alpha$, where α is a twist angle, and when these are rounded to eight digits, the algebraic relation $\cos^2(\alpha)+\sin^2(\alpha) = 1$ no longer holds at higher precision. The effect of this is that the multiple points, e.g., the ones of multiplicity 24, form clusters that do not come together as precision is increased.

Finally, although the homotopy constructions guarantee, with probability one, that no path passes exactly through a singularity before reaching its endpoint, there is always a chance that a near-singular condition can be encountered. To obtain the highest reliability possible, we need to detect this and allocate sufficient digits to successfully track past such obstructions.

The paper is organized as follows. In section 2, we review the behavior of Newton's method in floating point, revealing how its accuracy and convergence properties depend on precision. In section 3, we discuss path tracking with adaptive step size control and identify how it fails when precision is insufficient. This leads, in section 4, to a novel technique for path tracking using adaptive precision. This new adaptive precision path tracking algorithm has been implemented in a software package, Bertini [2], currently under development by the authors. Several examples are presented in section 5 to illustrate the usefulness of adaptive precision. Section 6 contains a brief discussion of the value of adaptive precision in the presence of endgames. Finally, in section 7, a few related ideas that would make interesting studies are discussed.

2. Background: Newton's method. The core numerical process in the path tracker is the corrector, which in our case is Newton's method. A good predictor speeds up the path tracker by allowing a large step while still supplying an initial guess within the convergence region of the corrector. However, it is the loss of convergence that causes path tracking to fail. In exact arithmetic, as long as the path remains nonsingular, there must be a region surrounding the path within which Newton's method converges quadratically. With a small enough step Δt in t, we can be assured of advancing along the path, although possibly very slowly. This holds even if we use only a zeroth order predictor, i.e., if the point from the last value t_k is used to initialize the corrector for the new value $t_{k+1} = t_k + \Delta t$. In contrast, in inexact floating point arithmetic, the convergence region can disappear, thus halting the path tracker. Short of this, an unacceptably slow linear rate of convergence might dominate, causing the step size to plummet. It can also happen that the corrector appears to converge, judging by a diminishing corrector step, but since the limit point is a zero of the inexactly evaluated function, it may be further than the desired tolerance away from the exact root. Consequently, success requires enough precision to produce a convergence region and to ensure that the limit point is within the prescribed tolerance of the exact root.

Due to these considerations, an analysis of Newton's method in floating point is of interest and will help us derive rules for setting the precision used in our path tracker. The following analysis resembles that of [22]. Let $F(z) : \mathbb{C}^n \to \mathbb{C}^n$ be continuously differentiable, and denote its Jacobian matrix of partial derivatives as $J(z)$. To solve

$F(z) = 0$ by Newton's method given an initial guess z_0, one iteratively updates z_i, $i = 1, 2, \ldots$, as

$$\begin{aligned} &\text{Solve } J(z_i)\Delta z_i = -F(z_i) \text{ for } \Delta z_i, \\ &z_{i+1} = z_i + \Delta z_i. \end{aligned} \tag{1}$$

In the following analysis, we will assume a submultiplicative matrix norm, i.e., one that satisfies $\|AB\| \leq \|A\|\|B\|$. In particular, the 2-norm suffices. When we apply the formulas, we may save computation by using other norms with an adjustment factor. For example, for an $n \times n$ matrix A, $\|A\|_2 \leq \sqrt{n}\|A\|_p$ for $p = 1$ or $p = \infty$.

Suppose that we work in floating point with unit roundoff u. In other words, if we compute with a mantissa of b bits in binary or with P digits in decimal, $u = 2^{-b} = 10^{-P}$. We may consider evaluating the residuals $F(z_i)$ in higher precision, say $\bar{u} \leq u$, before rounding back to working precision u to compute the Newton correction. Let $\hat{F}(z)$ be the floating point output of the procedure that evaluates $F(z)$. We assume that there exists a function ψ depending on z, u, and $\bar{u}$ such that the error $e(z) = \hat{F}(z) - F(z)$ obeys

$$\|e(z)\| \leq u\|F(z)\| + \psi(z, u, \bar{u}). \tag{2}$$

By definition, at a solution point z_*, we have $F(z_*) = 0$, so it is clear that the function ψ drives the final error. To determine ψ, one must examine the function F and the program that implements it. We will give approximations to ψ later for the systems we treat.

In solving (1) for the correction Δz_i, there is error in evaluating $J(z_i)$ and in solving the linear system. Both errors can be absorbed into an error matrix E_i such that the computed correction is

$$\Delta z_i = (J(z_i) + E_i)^{-1}(F(z_i) + e(z_i)). \tag{3}$$

We assume this error is bounded by

$$\|E_i\| \leq \mathcal{E}\,(u\|J(z_i)\| + \phi(z_i, u)) \tag{4}$$

for some constant $\mathcal{E} > 1$ and positive function ϕ. We expect the first term because of roundoff of the Jacobian, whereas ϕ accounts for errors in evaluating J that do not vanish even when J does. The constant $\mathcal{E}$ accounts for the subsequent growth in the error during the linear solve.

For simplicity of notation, let $v = z_i$ be the current guess, $\bar{v} = z_{i+1}$ the new guess after a single iteration, and v_* the solution point near v. Also, let's use the shorthand notation $F = F(v)$, $J = J(v)$, $J_* = J(v_*)$, $\Delta = \|v - v_*\|$, and $\bar{\Delta} = \|\bar{v} - v_*\|$. In the next paragraph, we will establish a bound on $\bar{\Delta}$ in terms of Δ. Whenever $\bar{\Delta} < \Delta$, the Newton step successfully reduces the error in the estimate of the root v_*.

Since $F(v_*) = 0$, the Taylor series of $F(z)$ at v_* gives

$$F(z) = J_* \cdot (z - v_*) + H.O.T.,$$

where the higher order terms, $H.O.T.$, are quadratic or higher in $z - v_*$. Similarly,

$$J(z) = J_* + H.O.T.,$$

where the higher order terms are linear in $z - v_*$. Consequently, in a ball $B = \{z : \|z - v_*\| \leq R\}$ centered at v_* with $v \in B$, there exist positive constants α and β such that

$$\|F(z)\| \leq \|J_*\|\|z - v_*\| + \alpha\|z - v_*\|^2, \tag{5}$$

$$\|F(z) - J_*(z - v_*)\| \leq \alpha\|z - v_*\|^2, \tag{6}$$

$$\|J_*\| \leq \|J\| + \beta\|z - v_*\|, \qquad \|J - J_*\| \leq \beta\|z - v_*\|. \tag{7}$$

From these, we may conclude that

$$\|F(z)\| \leq \|J\|\Delta + (\alpha + \beta)\Delta^2. \tag{8}$$

In Newton's method, we solve

$$(J + E)d = -(F(v) + e) \tag{9}$$

for d and take the step

$$\bar{v} = v + d + \varepsilon, \tag{10}$$

where ε is the error in forming the sum. The standard model of round-off error in floating point addition [26] gives

$$\|\varepsilon\| \leq u(\|v\| + \|d\|) \leq u(\Delta + \|v_*\| + \|d\|), \tag{11}$$

so subtracting v_* from both sides of (10), we have

$$\bar{\Delta} \leq \|v - v_* + d\| + u(\Delta + \|v_*\| + \|d\|). \tag{12}$$

If J is nonsingular and $\|J^{-1}\|\|E\| < 1$, then $(J + E)$ is nonsingular, the Newton step is well defined, and

$$\|(J + E)^{-1}\| \leq K\|J^{-1}\|, \qquad K = \frac{1}{1 - \|J^{-1}\|\|E\|}. \tag{13}$$

Accordingly, from (9) we have

$$\|d\| \leq K\|J^{-1}\|(\|F\| + \|e\|). \tag{14}$$

Also, after adding $(J + E)(v - v_*)$ to both sides of (9) and simplifying using (5)–(8), (13), we have

$$\|v - v_* + d\| \leq K\|J^{-1}\|(\|E\|\Delta + (\alpha + \beta)\Delta^2 + \|e\|). \tag{15}$$

Substituting from (14), (15) into (12) and using (2), (4), (8), we obtain the bound

$$\begin{aligned}\bar{\Delta} &\leq K\|J^{-1}\|(1 + u)^2(\alpha + \beta)\Delta^2 \\ &\quad + (K\|J^{-1}\|\,[(2 + \mathcal{E} + u)u\|J\| + \mathcal{E}\phi] + u)\Delta + K\|J^{-1}\|(1 + u)\psi + u\|v_*\|.\end{aligned} \tag{16}$$

This relation holds as long as $\|J^{-1}\|\|E\| < 1$, so that the linear solve in the Newton step is well defined, and v is in the ball B, so that (5)–(7) hold.

If $\bar{\Delta} < \Delta$, the Newton step reduces the error in the approximation of the root. In exact arithmetic, we have $u = \phi = \psi = 0$ and $K = 1$, so $\bar{\Delta} \leq \|J^{-1}\|(\alpha + \beta)\Delta^2$. The error contracts if the initial guess is accurate enough so that $\Delta < 1/(\|J^{-1}\|(\alpha + \beta))$. If we also have $\Delta < 1/(\|J_*^{-1}\|(\alpha + \beta))$, it is clear that all subsequent iterates are nonsingular and contractive, from which one has the well-known result that Newton's method converges quadratically to a nonsingular solution for a sufficiently accurate initial guess. One sees that the more singular the Jacobian is at the root, the slower the convergence and the smaller the convergence zone.

In floating point arithmetic, we cannot expect the error to converge to zero. From (16), one may expect the error to contract until

$$\Delta \approx (1 + u)K\|J^{-1}\|\psi + u\|v_*\| \approx K\|J_*^{-1}\|\psi + u\|v_*\|. \tag{17}$$

The second term is the error inherent in representing v_* in floating point. The first term depends on the accuracy, ψ, with which the function is evaluated. This can be reduced by using higher precision, $\bar{u}$, in the function evaluation per (2). The precision of the Jacobian and the linear solve do not affect the final error.

On the other hand, the precision of the Jacobian and the linear solve do affect convergence. Without enough precision, $\|J^{-1}\|\|E\|$ may approach or surpass 1, which means that the linear solve may fail due to singularity or may yield such an inaccurate step that the error diverges. Notice that $\|J^{-1}\|\|E\| = u\|J^{-1}\|\|J\| + \|J^{-1}\|\phi = u\kappa + \|J^{-1}\|\phi$, where $\kappa = \text{cond}(J)$. The first term, $u\kappa$, reflects the well-known result that in solving a linear system, floating point roundoff is magnified by the condition number of the matrix.

3. Step length control and failure. To produce an improved path tracking algorithm, it is useful to first examine a standard predictor-corrector algorithm to see why adaptive step size control generally succeeds when conditioning is mild and why it may fail when conditioning is adverse.

A simple and effective approach for step size control is to adjust the step size up or down according to the success or failure of a complete prediction-correction cycle. Suppose the homotopy function $H(z, t) = 0$ defines a one-dimensional nonsingular path $z(t)$. We are given a start point approximately on the path, $z_0 \approx z(t_0)$, an ending value of t, and a tolerance to which points on the path are to be found. Then, in brief, a predictor-corrector path tracker with adaptive step size control may be constructed as follows.

Initialize Select: an initial step size, s; the number of corrector iterations allowed per step, $N \geq 1$; the step adjustment factor, $a \in (0, 1)$; the step expansion integer, $M \geq 1$; and a minimum step size $s_{\min}$.

Predict Estimate a new point near the path whose distance from the current point is the step size s.

Correct Iteratively improve the new path point, constraining its distance from the prior path point. Allow at most N iterations to reach the specified tolerance.

On success If the tolerance is achieved:

- Update the current path point to be the newly found path point.
- If we have reached the final value of t, exit with *success*.
- If there have been M successes in a row, expand the step size to $s = s/a$.

On failure If the tolerance is not achieved:

- Cut the step size to $s = as$.
- If $s < s_{\min}$, exit with *failure*.

Loop Go back to **Predict**.

The key is to allow only a small number of iterations in the corrector, typically only $N = 2$ or $N = 3$. This forces the prediction to stay within a good convergence region surrounding the path. If a large number of iterations is allowed, a bad prediction might ultimately converge, but it may wander first and become attracted to a completely different path in the homotopy. Keeping N small, the step size adaptation slows down to negotiate sharp turns in the path and accelerates whenever the path is relatively straight. Properly implemented, this results in a robust and efficient path tracking algorithm.

We can be a bit more precise. Let us do so by specifically considering an Euler predictor with a Newton corrector. Both of these derive from the linearized local model of the path. The Taylor series at (z_1, t_1) is

$$H(z_1 + \Delta z, t_1 + \Delta t) = H(z_1, t_1) + \frac{\partial H}{\partial z}(z_1, t_1)\Delta z + \frac{\partial H}{\partial t}(z_1, t_1)\Delta t + H.O.T., \tag{18}$$

where the higher order terms, $H.O.T.$, are quadratic or higher in $(\Delta z, \Delta t)$. Ignoring the higher order terms and setting $H(z_1 + \Delta z, t_1 + \Delta t) = 0$, one has the basic Euler predictor and Newton corrector relations. These are a system of n equations in $n + 1$ unknowns; as long as the combined matrix $[\partial H/\partial z \ \partial H/\partial t]$ is rank n, there is a well-defined tangent direction and tracking may proceed. The predictor adds a constraint on the length of the step along the tangent, whereas corrector steps are constrained to move transverse to the tangent. The extra constraints are particularly simple in the case where $\partial H/\partial z$ is rank n, for then the path progresses monotonically in t, and the step can be controlled via the advance of t. Accordingly, one has a linear system to be solved for Δz:

$$\left[\frac{\partial H}{\partial z}(z_1, t_1)\right] \Delta z = -\left(H(z_1, t_1) + \frac{\partial H}{\partial t}(z_1, t_1)\Delta t\right). \tag{19}$$

For prediction, we set $\Delta t = s$, the current step size, and for correction, we set $\Delta t = 0$.

Since the neglected terms are quadratic, the prediction error is order $\mathcal{O}(s^2)$. Thus, in the case of a failed step, cutting the step size from s to as reduces the prediction error by a factor of a^2. In this way, cuts in the step size quickly reduce the prediction error until it is within the convergence region of the corrector. With a kth order predictor, the prediction error scales as a^{k+1}, potentially allowing larger step sizes. In any case, the adaptive approach quickly settles to a step size s just small enough so that the corrector converges, while the next larger step of s/a fails. With $a = 1/2$ and $M = 5$, the step size adapts to within a factor of 2 of its optimum, with an approximate overhead of 20% spent checking if a larger step size is feasible.

Failure of path tracking with an adaptive step size can be understood from the discussion of Newton's method in section 2. For small enough initial error and exact arithmetic, the Newton corrector gives quadratic convergence to a nonsingular root. Near a singularity, $\|J_*^{-1}\|$ is large, which can lead to a small quadratic convergence zone and a slower rate of quadratic convergence. Inexact arithmetic can further shrink the convergence zone, degrade the convergence rate from quadratic to linear, and introduce error into the final answer. From these considerations, we see that there are two ways for the adaptive step size path tracker to halt prematurely near a singularity.

1. The predictor is limited to a tiny step size to keep the initial guess within the convergence zone of the corrector. If this is too small, we may exceed the total computational cost allotted for the path.
2. The path may approach a point where the final error of the corrector is larger than the requested path tracking tolerance.

The first mode of failure can occur even with infinite precision, but degradation of the convergence properties with too low a precision increases the occurrence of this failure. The second mode of failure is entirely a consequence of lack of precision. By allocating enough precision, we can eliminate the second mode of failure and reduce the occurrence of the first mode. It is important to note that in some applications there is flexibility in the definition of the homotopy, which can be used to enlarge convergence zones and thereby speed up path tracking. For example, rescaling of the equations and variables can sometimes help. However, such maneuvers are beyond the scope of this paper, which concentrates only on tracking the path of a given homotopy.

4. Adaptive precision. The use of high precision can largely eliminate both types of path tracking failure identified above. However, high precision arithmetic is expensive, so it must be employed judiciously. One might be tempted to ratchet precision up or down in response to step failures as in the adaptive step size algorithm. This presents the difficulty that there is just one stimulus, step failure, and two possible responses, cut the step size or increase precision. In the following paragraphs, we outline two possible approaches for adapting both step size and precision.

Both our "reactive" adaptation algorithm and our "proactive" one are encompassed in the same flowchart, Figure 1. One may see that the heart of the method is still the adaptive step size tracker described in section 3. In the diagram, P is the number of digits of precision and $P_{\max}$ is the largest precision we allow. The step size of the tracker is Δt, and $\varepsilon(P)$ is a lower limit for it, depending on P, as discussed further below. The magnitude of the most recent Newton step in the corrector is $\|d\|$ and $10^{-\tau}$ is the accuracy to which we wish to track the path. The final value of t to which we wish to track is t_{f}. Limits on P and on the total number of steps guarantee that the algorithm always terminates, declaring failure if too much computation has occurred before reaching t_{f}.

The algorithm as presented in Figure 1 assumes that the final value t_{f} can be reached without encountering an exact singularity. The homotopies used for solving polynomial systems are constructed such that, with probability one, no singularities will occur until possibly at the end, say $t = t^*$, where the homotopy function $H(z, t^*) = F(z)$ is the target system. In this situation, one should not use the corrector at $t = t^*$. Instead, one may predict the endpoint from values of t near t^* and accept the predictions as accurate when two successive ones agree to the desired precision. Both the prediction to t^* and the prediction to the next point on the path near t^* benefit from the use of a more sophisticated predictor than Euler's method, accounting for the possible existence of a singularity at the endpoint. For example, endgames that estimate the winding number of the root and use it to compute a fractional power series can be very effective [16, 18]. Such endgames still use a path tracker to approach t^*. In this paper, the endgame itself is out of scope: we discuss only the tracking algorithm and consider the final value $t_{\mathrm{f}} \neq t^*$ to be the last point on the path required by the endgame.

4.1. Reactive adaptation. Reactive adaptation changes precision in response to the observed behavior of the tracking process. In particular, if path tracking fails at a given precision, one may try again at a higher precision. The simplest approach is to run the entire path in a fixed precision with adaptive reruns. That is, if the path tracking fails, one reruns it in successively higher precision until the whole path is tracked successfully or until limits in computing resources force termination. The advantage of this approach is that adaptation is completely external to the core path tracking routine. Thus, this strategy can be applied to any path tracker that enables requests

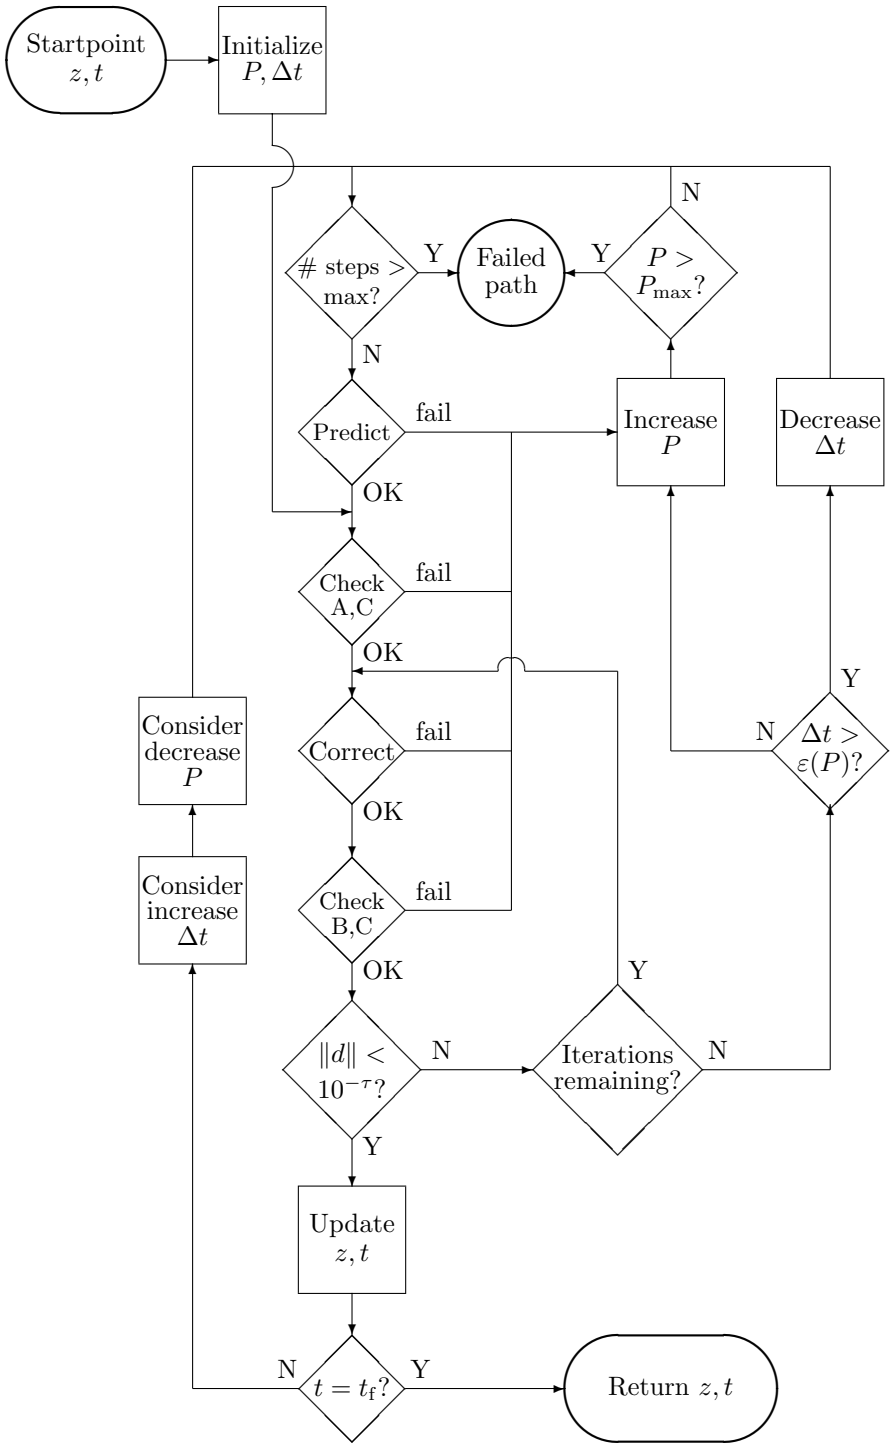

FIG. 1. *Adaptive precision path tracker with proactive precision checks. The purely reactive algorithm skips all checks of conditions A, B, and C. The purely proactive approach sets* $\varepsilon(P) \equiv 0$.

for higher precision. For example, in the polynomial domain, the package PHC [23] offers multiple precision, although the precision must be set when calling the program.

The path rerun strategy has two main disadvantages. First, when too low a precision is specified, the tracker wastes computation near the point of failure before giving up and initiating a rerun in higher precision. Second, and more important, the whole path is computed in high precision when it may be needed only in a small section of the path, often near the end in the approach to a singular solution.

A slightly more sophisticated treatment avoids recomputing the segment of the path leading up to the failure point. Upon failure at one precision, higher precision is initiated from the last successfully computed point on the path. In this approach, the adaptive step size module may still waste time cutting the step size before finally triggering a needed increase in precision. Moreover, the minimum step size needs to be set appropriately so that the precision is increased correctly. Once the precision has been increased, it may take many steps before the step size is increased again to a reasonable size. There is also a theoretical possibility that even though more precision is needed to accurately track the path, the tracking module may wander instead of failing, jumping to another solution path in the homotopy.

Figure 1 presents a flowchart that encompasses both the reactive adaptation method just described and the proactive one of the following section. For the reactive method, the checks labeled A, B, and C are skipped. There are three branches where the reactive method increases the precision, P: the prediction or correction steps may fail or the step size, Δt, may become too small. Failure in the predictor or corrector steps means that the linear solve of (19) has aborted early due to singularity. Using the magnitude of the largest entry in J as $\|J\|$, Gaussian elimination with row pivoting may declare such a failure when the magnitude of the largest available pivot is smaller than $u\mathcal{E}\|J\|$, for then the answer is meaningless.

The check for a step size that is too small is to compare Δt to $\varepsilon(P)$, a predetermined minimum step size for each level of precision. It is important to note that making $\varepsilon(P)$ too large may cause a runaway condition where precision is rapidly increased to its maximum, thus causing the path to declare failure. Setting it too small will result in temporary stalling of the path, wasting computation until the precision increase is finally triggered and wasting more computation afterwards as the algorithm has by then adopted an unnecessarily small step size. Our settings for $\varepsilon(P)$ are given in section 5.1. We determined by experimentation that values of $\varepsilon(P) = 10^{a-P}$ for $2 \le a \le 4$ seem to work well.

A path may have a difficult spot somewhere other than near the end of the path. Approaching this spot, the step size will decrease and the precision may increase. After passing the difficulty, the algorithm needs a means of readjusting back to a larger step size and smaller precision. For the box "Consider increase Δt," we use the criterion of the classic step size control method of section 3, that is, we increase Δt if several successive steps have succeeded. It is not clear at this time how to implement decreases in precision in a purely reactive manner. In contrast, the proactive approach of the following section gives a clear signal for when precision can be decreased.

4.2. Proactive adaptation. Instead of waiting for the adaptive step size method to fail before initiating higher precision, we propose to proactively monitor the conditioning of the homotopy to judge the level of precision needed at each step. In this way, the computational burden of higher precision is incurred only as needed, adjusting up and down as the tracker proceeds. If done properly, this avoids the computational cost incurred in the reactive approach of unnecessarily cutting the step

size when lack of precision is the root cause. Of course, monitoring the numerical properties of the homotopy introduces a new computational burden of its own. We will explore whether the trade-off is advantageous with respect to total computation, but even if the trade-off is in favor of the reactive approach, the proactive approach could still be preferable to avoid wandering due to lack of precision.

To decide how much precision is needed, we turn to the analysis of Newton's method from section 2. We wish to ensure that the achievable accuracy is within the specified tolerance and that convergence is fast enough.

In what follows, we need to evaluate $\|J\|$ and $\|J^{-1}\|$. These do not need to be very accurate, as we will always include safety margins in the formulas that use them. $\|J\|$ is readily available in the max norm, i.e., the matrix norm induced by the infinity norm for vectors. $\|J^{-1}\|$ is more difficult, as we do not wish to compute the full inverse of the matrix. This issue has been widely studied in terms of estimating the condition number $\kappa = \|J\|\|J^{-1}\|$. A relatively inexpensive method, suggested in [25] and elsewhere, is to choose a unit vector b at random and solve $Jy = b$ for y. Then we use the estimate $\|J^{-1}\| \approx \|y\|$. Although this underestimates $\|J^{-1}\|$, tests of matrices up to size 10×10 show the approximation to be reliably within a factor of 10 of the true value, which is easily absorbed into our safety margins.

One requirement is that $\|J^{-1}\|\|E\|$ should be small enough to ensure that the error-perturbed Jacobian is nonsingular. Minimally, we require $\|J^{-1}\|\|E\| < 1$, but by requiring it to be a bit smaller, say $\|J^{-1}\|\|E\| < 10^{-\sigma_1}$ for some $\sigma_1 \geq 1$, we force $K \approx 1$, as defined in (13). This removes the growth of K as one possible source of failure. Suppose that the error function ϕ in (4) is of the form $\phi = \Phi u$. Then our first rule is to require

$$\|J^{-1}\|\mathcal{E}\left(\|J\| + \Phi\right) u < 10^{-\sigma_1}. \tag{20}$$

Using P decimal digits of arithmetic results in precision $u = 10^{-P}$, so we may restate this rule as

$$P > \sigma_1 + \log_{10}[\|J^{-1}\|\mathcal{E}\left(\|J\| + \Phi\right)]. \tag{A}$$

A second requirement is that the corrector must converge within N iterations, where we keep N small as in the usual adaptive step size algorithm, typically 2 or 3. Let us say that the tolerance for convergence is $\Delta = \|v - v_*\| < 10^{-\tau}$. Recall that in each step of Newton's method, we compute d and take the step $\bar{v} = v + d$. The best estimate available of the accuracy is $\Delta \approx \|d\|$, so we declare success when $\|d\| < 10^{-\tau}$. Suppose that after $i < N$ iterations this is not yet satisfied. We still have $N - i$ iterations to meet the tolerance, and we would like to be sure that a lack of precision does not prevent success. Pessimistically, we assume that the linear factor in Δ in (16) dominates the quadratic one and that the rate of convergence does not improve with subsequent iterations. We force $K \approx 1$, and we have $u \ll 1$. Including the same safety margin as before, 10^{σ_1}, the requirement becomes

$$\left[10^{\sigma_1}\|J^{-1}\|\left((2+\mathcal{E})u\|J\| + \mathcal{E}\phi\right) + u\right]^{N-i}\|d\| < 10^{-\tau}. \tag{21}$$

As before, let's assume $\phi = \Phi u$. Taking logarithms, the number of decimal digits of precision must satisfy

$$P > \sigma_1 + \log_{10}\left[\|J^{-1}\|\left((2+\mathcal{E})\|J\| + \mathcal{E}\Phi\right) + 1\right] + (\tau + \log_{10}\|d\|)/(N-i). \tag{B}$$

Since we apply this formula only when the tolerance is not yet satisfied, we have $\|d\| > 10^{-\tau}$, or equivalently, $\tau + \log_{10}\|d\| > 0$. This implies that between corrector

iterations, requirement B is always more stringent than A. However, we still use A outside the corrector, because $\|d\|$ is not then available.

Our third requirement is that the precision must be high enough to ensure that the final accuracy of the corrector is within the tolerance at full convergence. For this, (17) is binding, so including a safety margin of $10^{-\sigma_2}$ and using the norm of the current approximate solution, $\|v\|$, as the best available estimate of $\|v_*\|$, we require

$$\|J^{-1}\|\psi + u\|v\| < 10^{-\tau-\sigma_2}. \tag{22}$$

Suppose the error in evaluating the homotopy function is given by $\psi = \Psi\bar{u}$. If the function is evaluated in the same precision as the rest of the calculations, i.e., $\bar{u} = u$, we have the requirement

$$P > \sigma_2 + \tau + \log_{10}(\|J^{-1}\|\Psi + \|v\|). \tag{C}$$

If instead we evaluate the function to higher precision, say $\bar{u} = 10^{-P'} < u = 10^{-P}$, we have the dual criteria

$$P > \sigma_2 + \tau + \log_{10}\|v\|, \qquad P' > \sigma_2 + \tau + \log_{10}\|J^{-1}\| + \log_{10}\Psi. \tag{C$'$}$$

The effect of adding the two errors is absorbed into the safety factor σ_2.

Conditions A, B, and C (or C$'$) allow one to adjust the precision as necessary without waiting for the adaptive step size to fail. If necessary, the precision can even be increased between corrector iterations. An algorithm using these criteria is described by the flowchart in Figure 1. With the proactive checks in place, it is no longer useful to trigger reactive increases in precision due a to small step size. Accordingly, we may remove the step size check, which is equivalent to setting $\varepsilon(P) \equiv 0$.

Unlike in the reactive method, the proactive method has a clear signal for when it is safe to decrease precision after passing a locally ill-conditioned point on the path. In the "Consider decrease P" box of Figure 1, one may safely do so if the checks of criteria A, B, and C in the last tracking step indicate that a lower precision would have sufficed.

4.3. Error estimates. To use the foregoing procedures, we need the function evaluation error, ψ, and the errors contributing to E, namely, $\mathcal{E}$ and ϕ. There is a trade-off between using rigorously safe bounds for highest reliability or using less stringent figures reflecting typical behavior to avoid the overuse of high precision. Rough figures are acceptable as this is just a means of setting the precision.

While ψ and ϕ concern the errors in evaluating the function and its Jacobian, the factor $\mathcal{E}$ concerns the stability of the linear solve. Roundoff errors can accumulate through each stage of elimination. When Gaussian elimination with partial pivoting is used, the worst-case error bound grows as $\mathcal{E} = 2^n$ for solving an $n \times n$ system [3]. However, as indicated in [3], $\mathcal{E}$ rarely exceeds n with the average case around $n^{\frac{2}{3}}$ or $n^{\frac{1}{2}}$. Setting $\mathcal{E} = n^2$ should therefore be sufficient for almost all cases.

It is important to note that the error in the function depends on the error in its parameters. For example, consider the simple function $f(x) = x^2 - 1/3$. If this is rounded off to $g(x) = x^2 - 0.333$ before we use high precision to solve $g(x) = 0$, we will obtain an accurate value of $\sqrt{0.333}$ but we will never get an accurate value of $1/\sqrt{3}$. Although this is an obvious observation, it can easily be forgotten in passing a homotopy function from some application to the adaptive precision path tracking algorithm. If coefficients in the function are frozen at fixed precision, the algorithm

tracks the solutions of the frozen function, not the exact problem that was intended. Whether the difference is significant depends on the nature of the application and the sensitivity of the function.

In the remainder of this section, we discuss how to obtain error estimates for several classes of functions.

4.3.1. General functions. A user of the path tracker will not usually wish to expend a lot of effort in developing error bounds, so an automated error analysis is desirable. A rigorous and automated way of establishing error bounds for almost any continuous function is to use interval arithmetic. Software packages such as IntBis [5], IntLab [20], Alias [12], and MPFI [19] provide interval evaluation for any real-valued function composed from a wide range of continuous elementary functions and arithmetic operations. Among these packages IntLab and MPFI currently support multiple precision, although IntLab's multiple precision is slow while MPFI does not support complex arithmetic. While a relatively efficient complex multiprecision interval arithmetic could be built on top of MPFI, it is beyond our scope to pursue this.

One could go further and employ interval techniques to obtain a path tracker with fully rigorous step size control, as in [6], guaranteeing that path crossing never occurs. However, this can be expensive, due partially to the cost of interval arithmetic but more significantly due to the cost of overconservative error bounds, which slow the algorithm's progress by driving the step size smaller than necessary. Still, when rigorous results are desired, it may be worth the computational cost. The method of [6] does not explicitly include adaptive precision, so something along the lines discussed here could be useful in modifying that approach.

Since our main area of interest is in systems of polynomial equations, we devote the rest of this article to that important subclass.

4.3.2. Straight-line polynomials. Suppose $f : \mathbb{C}^n \to \mathbb{C}$ is a polynomial whose terms are indexed by the set $\mathcal{I}$, that is,

$$f(z) = f(z_1, \ldots, z_n) = \sum_{i \in \mathcal{I}} c_i z_1^{d_{1i}} \cdots z_n^{d_{ni}}. \tag{23}$$

We wish to estimate the error in evaluating $f(z)$ using floating point arithmetic with unit roundoff $\bar{u}$. Evaluating the fully expanded form of a polynomial, that is, evaluating each term of (23) and then summing, is not the most efficient approach in terms of operation counts. For example, to evaluate a dense polynomial in one variable, e.g., $f(x) = c_0x^3 + c_1x^2 + c_2x + c_3$, Horner's rule, $f(x) = (((c_0x) + c_1)x + c_2)x + c_3$, uses the fewest multiplications. See [6, section 4.6] for more discussion. Different evaluation procedures can result in different floating point roundoff errors as well, for example, in floating point arithmetic distributivity, $a(b + c) = ab + ac$, and associativity, $(a + b) + c = a + (b + c)$, do not hold exactly [6, section 4.2].

Suppose the program to evaluate $f(z)$ has been parsed into a straight-line program, that is, a sequence of unary and binary operations free of branches or loops. Then we may approximate errors by accumulating their effects across successive operations. Interval analysis by circular arithmetic [4] is a convenient method for this. Let $\langle a, r\rangle$, $a \in \mathbb{C}$, $r \in \mathbb{R}^+$, denote the closed disk in the complex plane with center a and radius r. For two disks A_1, A_2 and an operation "$\circ$," let

$$A_1 \circ A_2 = \{x_1 \circ x_2 | x_1 \in A_1, x_2 \in A_2\}.$$

We are interested in the cases when "$\circ$" is addition or multiplication. Then one may confirm the inclusions [4]

$$\begin{aligned} \langle a_1, r_1\rangle + \langle a_2, r_2\rangle &= \langle a_1 + a_2, r_1 + r_2\rangle, \\ \langle a_1, r_1\rangle \times \langle a_2, r_2\rangle &\subset \langle a_1 a_2, |a_1| r_2 + |a_2| r_1 + r_1 r_2\rangle. \end{aligned} \tag{24}$$

This shows that if a_1 and a_2 are the computed values of the operands whose exact values lie in the respective disks, then the true sum or product must lie within the disks on the right-hand side of these relations. However, when we evaluate $a_1 \circ a_2$ in floating point, roundoff error must be taken into consideration. By appropriately increasing the radius of the output disk, we can guarantee that it still contains the exact answer. Since the roundoff for any point in the disk is bounded by $|x|u$ where $|x|$ is the largest magnitude of any point in the disk, we have

$$\begin{aligned} \langle a_1, r_1\rangle + \langle a_2, r_2\rangle &\subset \langle a_1 + a_2, r_1 + r_2 + (|a_1 + a_2| + r_1 + r_2)u\rangle, \\ \langle a_1, r_1\rangle \times \langle a_2, r_2\rangle &\subset \langle a_1 a_2, \rho + (\rho + |a_1 a_2|)u\rangle, \\ \text{where } \rho &= |a_1| r_2 + |a_2| r_1 + r_1 r_2. \end{aligned} \tag{25}$$

These relations can be used to bound the accumulated floating point error in the straight-line evaluation of a polynomial. In computing the radius in either of these formulas in floating point, one should consistently use upward rounding to be sure of obtaining inclusion.

To apply proactive adaptation based on criteria A, B, and C (or C′), we would like to develop a linearized model of how the error depends on precision. That is, we would like to express the evaluation error $\psi(z, u)$ as $\psi(z, u) \le \Psi(z)u + H.O.T.$, where the higher order terms depend on quadratic and higher powers of u. To this end, suppose that the error radii of all the initial data are expressed in terms of the unit roundoff. For example, the exact number $2{+}3i$ is $\langle 2{+}3i, 0u\rangle$, whereas the floating point representation $(1/3)_{\text{fp}}$ of $1/3$ is inexact: $(1/3) \in \langle (1/3)_{\text{fp}}, (1/3)_{\text{fp}} u\rangle$. Applying (25) to each operation of the straight-line program and keeping u as an indeterminant, the result after each operation is a disk of the form $\langle a, r(u)\rangle$, where $a \in \mathbb{C}$ and $r(u)$ is a polynomial in u with nonnegative real coefficients. At the end of the computation, one obtains a disk $f(z) \in \langle \hat{f}(z), r_1(z)u + r_2(z)u^2 + H.O.T.\rangle$, where $\hat{f}(z)$ is the floating point evaluation of $f(z)$, and r_1 and r_2 are numeric coefficients. For a given unit roundoff u_0, if $r_2 u_0 \ll r_1$, then the linear term dominates the quadratic one and presumably all higher powers of u as well. Then we may safely use $\psi(z, u) \approx r_1(z)u$, i.e., $\Psi = r_1(z)$, in the adaptive precision routines.

The foregoing methodology computes the function value and the error bound simultaneously. Unfortunately, the error bound is at least as expensive to compute as the function value, which may be an unacceptable computational burden. A less burdensome approach is to compute an error bound over a region and update this only when the path tracking algorithm leaves that region. To do so, we again just apply (25), but we begin with a disk for each coordinate z_i of z, say $z_i \in \langle a_i, \rho_i\rangle$, $\rho_i \in \mathbb{R}^+$, $i = 1, \ldots, n$. The method proceeds as above, with the only difference being that the radii of the results of each operation have a constant coefficient. At the end, we have a disk $\langle \hat{f}(z), r_0(z, \rho) + r_1(z, \rho)u + r_2(z, \rho)u^2 + H.O.T.\rangle$ that contains all possible values that the polynomial may take on the region defined by the initial disks.

Throughout this section, we have spoken only of how to bound the roundoff error in function evaluation. It should be clear that the same approach applies to bound the

errors in the entries of the Jacobian matrix, since each of these is also a polynomial. After estimating the error in each entry, one may estimate the error $\phi(z,u)$ in (4) using the relations $\|A\|_2 \leq \sqrt{n}\,\|A\|_p$ for $p=1$ or $p=\infty$.

4.3.3. Approximations for expanded polynomials. To avoid program complexity and save computation time, it is preferable not to perform a complete interval analysis of errors. In many cases a rough analysis is sufficient and easily derived. This is indeed possible for the case of expanded polynomials.

Referring to (23), we denote the degree of the ith term as $d_i = \sum_{j=1}^{n} d_{ji}$. If the coefficient c_i is represented in floating point with unit roundoff $\bar{u}$, then the error in the floating point evaluation of the ith term is $\bar{u}(d_i+1)|c_i||z_1|^{d_{1i}}\cdots|z_n|^{d_{ni}}$, ignoring quadratic and higher terms in $\bar{u}$. (If c_i has an exact floating point representation, such as if it is an integer of magnitude smaller than $1/\bar{u}$, then a slightly smaller bound applies: $\bar{u}d_i|c_i||z_1|^{d_{1i}}\cdots|z_n|^{d_{ni}}$.) Summing the terms and rounding off to working precision u gives the error between the computed value $\hat{f}(z)$ and the true $f(z)$ of

$$e(z) = |\hat{f}(z) - f(z)| \leq u|f(z)| + \bar{u}\sum_{i\in\mathcal{I}}(d_i+1)|c_i||z_1|^{d_{1i}}\cdots|z_n|^{d_{ni}}. \tag{26}$$

Thus, comparing to (2), we have

$$\psi(z,\bar{u}) = \bar{u}\sum_{i\in\mathcal{I}}(d_i+1)|c_i||z_1|^{d_{1i}}\cdots|z_n|^{d_{ni}}. \tag{27}$$

Equation (27) is as computationally expensive to evaluate as $f(z)$. However, this cost is usually small compared to evaluating the Jacobian matrix and solving for the Newton correction. Even so, one might prefer to replace $\psi(z,\bar{u})$ with an upper bound that is cheaper to compute. Suppose $D = \max_{i\in\mathcal{I}} d_i$ and $|z|_\infty = \max_{j\in[1,n]}|z_j|$. Then clearly

$$\psi(z,\bar{u}) \leq \bar{u}|z|_\infty^D \sum_{i\in\mathcal{I}}(d_i+1)|c_i| = \bar{u}|z|_\infty^D S, \tag{28}$$

where S is the sum indicated in the intermediate expression. Since S does not depend on z, it can be computed once at the beginning of the path tracking algorithm.

For a system of polynomials, $F:\mathbb{C}^n\to\mathbb{C}^m$, we obtain an error estimate for each polynomial in the system, i.e., $\psi_j(z,\bar{u})$, $j=1,\ldots,m$. Then the 2-norm error of the system is simply $\psi(z,\bar{u}) = \|[\psi_j(z,\bar{u})]\|_2$, which if we use (28) becomes

$$\psi(z,\bar{u}) = \bar{u}|z|_\infty^D(S_1^2+\cdots+S_m^2)^{1/2},$$

where S_j is the sum appearing in (28) applied to the jth polynomial.

At first glance, it may seem that errors could be reduced by simply scaling the functions, and thereby scaling their coefficients, by some small factor. But $\|J_*^{-1}\|$ will scale oppositely, so the error predicted by (17) is unchanged.

4.3.4. Homogeneous polynomials. Homogeneous polynomials, in which every term has the same degree $D = d_i$, $i\in\mathcal{I}$, are a special case. Some problems are naturally homogeneous, but for those that are not, it is often convenient and numerically advantageous to homogenize the equations before solving the system. Any inhomogeneous polynomial $f(z_1,\ldots,z_n)$ can be easily homogenized to obtain a related function $F(x_0,x_1,\ldots,x_n)$, with

$$F(1,x_1,\ldots,x_n) = f(x_1,\ldots,x_n).$$

If f is as in (23), then

$$F(x) = \sum_{i \in \mathcal{I}} c_i x_0^{D-d_i} x_1^{d_{1i}} \cdots x_n^{d_{ni}}, \tag{29}$$

where D and d_i are as above. Hence, for any solution z_* of $f(z) = 0$ there is a corresponding solution $x_* = (1, z_*)$ of $F(x) = 0$.

One advantage of homogenization is that we can rescale any solution x_* of $F(x) = 0$ to make $\|x_*\| = 1$, which often helps numerical conditioning. More precisely, since $F(\lambda x) = \lambda^D F(x)$, we have that if $F(x) = 0$, then also $F(\lambda x) = 0$. Consequently, the solution set of a system of homogeneous polynomials can be said to lie in projective space $\mathbb{P}^n$, the set of lines through the origin in $\mathbb{C}^{n+1}$. (Similarly, the solutions of multihomogeneous polynomials lie in a product of projective spaces; see [21].) To numerically solve for a point $x_* \in \mathbb{P}^n$, we intersect the corresponding line in $\mathbb{C}^{n+1}$ with an inhomogeneous hyperplane $a^T x - 1 = 0$, where $a \in \mathbb{C}^{n+1}$ can be chosen arbitrarily excepting a such that $a^T x_* = 0$. In other words, $a^T x - 1 = 0$ defines a $\mathbb{C}^n$ patch on $\mathbb{P}^n$, and $a^T x = 0$ is the hyperplane at infinity for that patch. In practice, we may choose a at random, with a zero probability of picking it such that the one-real-dimensional homotopy path intersects the hyperplane at infinity. However, during path tracking, if $\|x\|$ should grow, one may reassign $a = x'/\|x\|_2$, where x' denotes the complex conjugate of x, so that the new representative of the same projective point is $x/\|x\|_2$. In this way, the magnitudes of both a and x can be kept near 1 throughout the homotopy without changing the underlying path in projective space.

Suppose we use homogenization to force each homogenized coordinate x_i, $i = 0, 1, \ldots, n$, to lie in a unit disk at the origin: $x_i \in \langle 0, 1 \rangle$. Then we may obtain in one initial computation an error bound that will hold throughout the entire path tracking procedure by applying the method of section 4.3.2. Similarly, since $\|x\|_\infty \leq 1$, (28) becomes

$$\psi(x, u) \leq u(D+1) \sum_{i \in \mathcal{I}} |c_i|, \tag{30}$$

or just $uD \sum_{i \in \mathcal{I}} |c_i|$ if the coefficients are exact. Similarly, the derivatives have an approximate error bound of

$$\phi(x, u) \approx uD(D+1) \sum_{i \in \mathcal{I}} |c_i|. \tag{31}$$

The downside is that this bound may be overly conservative.

The effect of homogenization on the interpretation of the desired tolerance should be noted. The homogeneous coordinates $x = [x_0, x_1, \ldots, x_n] \in \mathbb{P}^n$ correspond to dehomogenized coordinates $z = (z_1, \ldots, z_n) = (x_1/x_0, \ldots, x_n/x_0)$. Suppose each coordinate of x is computed to accuracy $\epsilon \ll 1$ and consider what this implies about the accuracy of z. Dehomogenization of the result approximates z_i as $\hat{z}_i = (x_i + \delta_i)/(x_0 + \delta_0)$, where $|\delta_i| \leq \epsilon$, $i = 0, \ldots, n$. If $\|z\|_\infty < 1$, our homogenization will compute it with $|x_0| \approx 1$ and so $|\hat{z}_i - z_i| \approx \delta_i + \delta_0 \leq 2\epsilon$. On the other hand, if $\|z\|_\infty > 1$, the largest coordinate of x, say x_k will be computed with magnitude 1, and dehomogenization gives $|\hat{z}_k - z_k| \approx |z_k|\delta_i + |z_k|^2\delta_0 \leq (|z_k| + |z_k|^2)\epsilon$. So small solutions are found to absolute error 2ϵ, whereas large ones are found to absolute error $\epsilon\|z\|_\infty^2$. This implies a total loss of precision for $\|z\|_\infty \geq 1/\epsilon$, as one must expect since $[\epsilon, 1] \in \mathbb{P}$ and $[0, 1] \in \mathbb{P}$ become indistinguishable to accuracy ϵ, yet they dehomogenize to $1/\epsilon$ and ∞, respectively.

5. Computational results. This section contains a brief discussion of the implementation details for multiprecision arithmetic and for evaluating the rules for adapting precision. We then discuss the application of the adaptive precision methods to several polynomial systems.

5.1. Implementation details. Bertini [2] is a software package for computation in numerical algebraic geometry currently under development by the authors. Bertini is written in the C programming language and makes use of straight-line programs for the representation, evaluation, and differentiation of polynomials. All the examples discussed here were run on an Opteron 250 processor running Linux, using a version of Bertini similar to the beta release.

The adaptation rules, A, B, and C (or C$'$), leave some implementation choices open. For the runs reported here, we chose to evaluate function residuals to the same precision as the computation of Newton corrections, so rule C applied, not rule C$'$. Also, in rules A and B, we chose to use $\mathcal{E} = n^2$, where n is the number of variables, which is somewhat conservative for typical cases but underestimates the worst pathological cases. (See section 4.3 for more on this issue.) The rules require formulas for evaluating the error bounds $\psi(x,u) = \Psi u$ and $\phi(x,u) = \Phi u$. These are problem dependent, so we report our choices for each of the example problems below. Also, since the size of the first step is problem and path dependent, Bertini automatically adjusts this based on the results of the Euler prediction of the first step rather than relying on the user to provide an appropriate size.

To adaptively change precision, Bertini relies on the open source MPFR library for multiprecision support. Bertini has data types and functions for double precision (based on the IEEE double standard) and higher precision (using MPFR). Although the program would be simpler if MPFR data types and functions were used exclusively, the standard double precision types and functions in C are more efficient, so Bertini uses these whenever the adaptation rules indicate that double precision is sufficient. Additional details regarding the use of multiple precision may be found on the Bertini website. Since the use of adaptive precision variables is highly implementation-specific, no other details are described here.

MPFR requires the addition of precision to the mantissa in packets of 32 bits. Since the discussion of the examples below involves both binary and decimal digits, Table 1 provides the conversion between the two for selected levels of precision.

The reactive adaptation method requires a minimum step size, $\varepsilon(P)$, for each level of precision, P. The values we used in our experiments are shown in Table 2.

5.2. Numerical error for a Wilkinson polynomial. Before testing adaptive precision in a path tracking application, let's consider Newton's method applied to a Wilkinson polynomial and compare its results to the predictions of our error analysis. The kth Wilkinson polynomial, $w_k(z)$, is defined as $w_k(z) = \prod_{i=1}^{k}(z-k)$, and we report here on the specific case of $k = 11$. To solve $w_{11}(z) = 0$ numerically, we use straight-line programs to evaluate $w_{11}(z)$ and $J(z) = w'_{11}(z)$ and apply Newton's method. Let us consider two different straight-line programs for $w_{11}(z)$:

- the product form $f_1(z) = (z-1)(z-2)\cdots(z-11)$ evaluated left to right as written;
- the expanded form $f_2(z) = z^{11} - 66z^{10} + 1925z^9 - \cdots - 150917976z^2 + 120543840z - 39916800$, where powers of z are formed by multiplication, then the terms are summed from left to right.

In the expanded form, the coefficient of largest magnitude is that of the quadratic term, which is large, but still small enough to be represented exactly in double precision. (For large enough k, an error analysis in double precision would have to include roundoff error in the coefficients.)

Consider Newton's method in the vicinity of the root $z = 7$. For $z \in \langle 7, .1\rangle$ with exact coefficients, error analysis of the product form gives

$$f_1(\langle 7, .1\rangle) \in \langle 0, 2682 + 52492u + 488015u^2\rangle,$$

while the expanded form gives

$$f_2(\langle 7, .1\rangle) \in \langle 0, 1.2 \times 10^{11} + 9.4 \times 10^{12}u + 2.6 \times 10^{13}u^2\rangle.$$

In both cases, the quadratic term in u is negligible for all u under consideration. Now, the Jacobian at $z = 7$ is $J(7) = 17280$, so (17) predicts that Newton's method will converge to $\Delta \approx (7 + \Psi/17000)u$, where $\Psi = 53000$ for the product form and $\Psi = 9.4 \times 10^{12}$ for the expanded form. For double precision, $u \approx 2.2 \times 10^{-16}$, so we have $\Delta \approx 2.2 \times 10^{-15}$ for the product form and $\Delta \approx 1.2 \times 10^{-7}$ for the expanded form. As Newton's method converges towards the root, the bound Ψ may improve. For example, consider the tighter disk $z \in \langle 7, 1 \times 10^{-7}\rangle$ for which the error analysis gives

$$f_1(\langle 7, 1 \times 10^{-7}\rangle) \in \langle 0, 0.00173 + 0.035u + 0.33u^2\rangle,$$

while the expanded form gives

$$f_2(\langle 7, 1 \times 10^{-7}\rangle) \in \langle 0, 1.2 \times 10^{5} + 8.7 \times 10^{12}u + 2.3 \times 10^{13}u^2\rangle.$$

Due to the fact that $z = 7$ has an exact representation in floating point (this will not be the case for the roots of most polynomials one would solve numerically!), a better estimate of the final error for Newton's method is in this case just $\Delta \approx u\Psi/17000$. One finds that as the disk tightens around $z = 7$, $\Psi \to 0$ for the product form, and so we expect Newton's method to converge to the exact root. In contrast, for the expanded form of $w_{11}(z)$, Ψ remains at 8.7×10^{12}, implying that one cannot expect a final answer better than $\Delta \approx 1.1 \times 10^{-7}$ using double precision.

This is a good estimate of the behavior one observes by running Newton's method with initial guesses in the vicinity of $z = 7$. Using the product form to evaluate the polynomial and starting with an initial guess of $z = 7.03 + 0.07i$, one obtains errors $|z_i - 7|$ in the first five iterates of 1.96×10^{-3}, 1.42×10^{-6}, 7.36×10^{-13}, 1.54×10^{-25}, 0, at

TABLE 3
Estimates of Ψ and Φ for the Chebyshev problems of varying degrees.

n	Ψ	Φ
10	54	230
50	520,000	$1.4{\cdot}10^{7}$
100	$1.3{\cdot}10^{10}$	$7.2{\cdot}10^{11}$
150	$2.3{\cdot}10^{14}$	$2.0{\cdot}10^{16}$

which point the exact root has been found. For the expanded form and the same initial guess, the errors are 1.96×10^{-3}, 1.41×10^{-6}, 4.22×10^{-10}, 2.40×10^{-9}, 2.43×10^{-10}. The iterates dither around the exact root, staying within $|z_i - 7| < 3.6 \times 10^{-9}$ for $3 \leq i \leq 50$. This is somewhat better than the predicted residual of 1×10^{-7}, which is not surprising because the estimate of Ψ is conservative.

5.3. High degree Chebyshev polynomials. To illustrate our method's applicability to high degree polynomials, let's consider the Chebyshev polynomials, which have been studied extensively and are known to have many interesting properties [3]. There is one Chebyshev polynomial in each degree, and scaled so that the leading coefficient is 1; they may be defined recursively by

$$\begin{aligned} T_0(x) &:= 2, \\ T_1(x) &:= x, \text{ and} \\ T_i(x) &:= xT_{i-1}(x) - T_{i-2}(x)/4 \quad \text{for } i \geq 2. \end{aligned}$$

The roots of $T_{n+1}(x)$ are all nonsingular and given by

$$\cos\left(\frac{(2n+1-2k)\,\pi}{2n+2}\right)$$

for $k = 0, 1, \ldots, n$.

Several of these polynomials, with degrees ranging from 10 to 150, were solved using Bertini. The systems were run with a linear homotopy with a total-degree start system and without homogenizing. Bounds on Φ and Ψ were set using the method of section 4.3.2 and are displayed in Table 3. Since the solutions of the Chebyshev polynomials are known to be nonsingular, the paths were tracked to $t_{\mathrm{f}} = 0$ using basic homotopy continuation with a tolerance of 10^{-8}, i.e., $\tau = 8$, and both safety digits set to 1.

With this setup, double precision is sufficient for path tracking with $n = 10$. This allows for the demonstration of the current cost of higher precision relative to double precision as shown in Table 4. Notably, increasing from double precision (52 bits) to 64-bit multiple precision increases the computational time by a factor of 13.3, while increasing from 64 bits to 1024 bits causes only a factor of 3.8 increase. This clearly shows the high computational cost to make the first move from double precision to higher precision.

Table 5 compares the computational times of fixed precision with those of proactive and reactive adaptive precision. For fixed precision, we report the time for the minimum precision that successfully tracked all paths. For $n = 10$, which runs successfully in double precision, one can see in the proactive run time the overhead cost of checking conditions A, B, and C to see if an increase in precision is needed. Since higher precision is not needed for $n = 10$, the proactive method is the worst performer.

TABLE 4
Average time, in seconds, of 10 *runs of the Chebyshev polynomial of degree* 10 *with* $\tau = 8$, *for different levels of fixed precision.*

Double (52 bits)	64 bits	96 bits	128 bits	256 bits	512 bits	1024 bits
2.447	32.616	35.456	35.829	50.330	73.009	124.401

TABLE 5
Average time of 10 *runs of Chebyshev polynomials of degree* n *with* $\tau = 8$, *in seconds.*

n	Minimum fixed precision		Proactive	Reactive
10	52 bits	2.447	2.937	2.447
50	96 bits	1698.350	797.064	319.251
100	128 bits	9763.147	9739.978	3730.438
150	192 bits	32709.488	28944.029	21121.190

For larger n, however, increases in precision are needed, so both adaptive methods outperform fixed precision. As n increases, so does the fraction of the path which must be tracked in higher precision, so relative differences in the times decrease. However, since one does not know a priori how much fixed precision is needed, the real cost of a fixed precision rerun strategy would be much higher.

In these runs, the reactive method uses less time than the proactive approach. This is because the proactive error bounds are conservative, causing an increase in precision somewhat earlier than the reactive method. The high cost of leaving double precision outweighs any savings in avoiding failed steps, thus giving the reactive method the advantage.

5.4. A problem from chemistry. To illustrate the effect of tightening the tracking tolerance (i.e., increasing τ) on adaptive precision path tracking, we will consider a polynomial system coming from chemistry. To determine chemical equilibria, one may pass from a set of reaction and conservation equations to polynomials, as described in [13, 21]. One such polynomial system, discussed in [17], is the following:

$$f = \begin{bmatrix} 14z_1^2 + 6z_1z_2 + 5z_1 - 72z_2^2 - 18z_2 - 850z_3 + 0.000000002 \\ 0.5z_1z_2^2 + 0.01z_1z_2 + 0.13z_2^2 + 0.04z_2 - 40000 \\ 0.03z_1z_3 + 0.04z_3 - 850 \end{bmatrix}.$$

Bertini homogenized this system using one variable group and found the solutions by using a linear homotopy with a compatible total-degree start system, that is, one whose polynomials have degrees 2, 3, and 2, respectively. The solution set of this system consists of eight nonsingular finite solutions and a multiplicity-4 solution at infinity.

Using the method of section 4.3.2, the error bounds were set to $\Psi = 120{,}030$ and $\Phi = 240{,}008$. Both safety digits were set to 1. To exhibit the effect of adaptive precision tracking for tighter tolerances, the paths were tracked from $t = 1$ to $t_{\mathrm{f}} = 10^{-30}$ using $\tau = 8$ and $\tau = 14$. Each setting was run with 10 different choices of random numbers, and the average run time for the entire system is provided in Table 6.

With $\tau = 8$, the paths leading to the infinite solution started to fail around $t = 10^{-7}$ when using double precision due to the inadequacy of double precision to complete the linear algebra calculations. With $\tau = 14$, in each of the ten tests performed, one of the paths leading to the infinite solution failed before $t = 0.9$ when using double precision due to Newton iterations not converging to the required

TABLE 6
Average time of 10 *runs of the chemical system, in seconds.*

τ	Minimum fixed precision		Proactive	Reactive
8	96 bits	6.018	1.565	0.368
14	128 bits	203.67	198.67	86.68

tolerance. By rerunning the system with increased (fixed) precision, the path tracking completed successfully.

Both the proactive and reactive methods tracked all of the paths successfully in both tolerances. With $\tau = 8$, both methods started tracking all of the paths in double precision. For the paths in which precision needed to be increased, this first occurred around $t = 10^{-2}$ and $t = 10^{-7}$ for the proactive and reactive method, respectively. With $\tau = 14$, the proactive method increased precision immediately and started tracking all paths in 96-bit precision, while the reactive method was able to start tracking in double precision. These differences of when the precision was increased directly caused the difference in average tracking time between the proactive and reactive method.

5.5. A multivariate system from robotics. When using homotopy continuation methods to solve polynomial systems, one should always make use of an endgame. The purpose of the following example is to compare how the adaptive precision tracking methods of this paper perform when solving a typical, nonpathological example by simple tracking and with the added power of an endgame. In particular, the fractional power series endgame of [18] was employed in solving the following polynomial system [14], an inverse kinematics problem for a general six-revolute serial-link robot.

$$f = \begin{bmatrix} x_1^2 + x_2^2 - 1 \\ x_3^2 + x_4^2 - 1 \\ x_5^2 + x_6^2 - 1 \\ x_7^2 + x_8^2 - 1 \\ -0.24915068x_1x_3 + 1.6091354x_1x_4 + 0.27942343x_2x_3 + 1.4348016x_2x_4 \\ + 0.40026384x_5x_8 - 0.80052768x_6x_7 + 0.074052388x_1 - 0.083050031x_2 - 0.38615961x_3 \\ - 0.75526603x_4 + 0.50420168x_5 - 1.0916287x_6 + 0.40026384x_8 + 0.04920729 \\ 0.12501635x_1x_3 - 0.68660736x_1x_4 - 0.11922812x_2x_3 - 0.71994047x_2x_4 \\ - 0.43241927x_5x_7 - 0.86483855x_6x_8 - 0.03715727x_1 + 0.035436896x_2 + 0.085383482x_3 \\ - 0.039251967x_5 - 0.43241927x_7 + 0.013873010 \\ -0.63555007x_1x_3 - 0.11571992x_1x_4 - 0.66640448x_2x_3 + 0.11036211x_2x_4 \\ + 0.29070203x_5x_7 + 1.2587767x_5x_8 - 0.62938836x_6x_7 + 0.58140406x_6x_8 \\ + 0.19594662x_1 - 1.2280342x_2 - 0.079034221x_4 + 0.026387877x_5 - 0.057131430x_6 \\ - 1.1628081x_7 + 1.2587767x_8 + 2.162575 \\ 1.4894773x_1x_3 + 0.23062341x_1x_4 + 1.3281073x_2x_3 - 0.25864503x_2x_4 + 1.1651720x_5x_7 \\ - 0.26908494x_5x_8 + 0.53816987x_6x_7 + 0.58258598x_6x_8 - 0.20816985x_1 + 2.6868320x_2 \\ - 0.69910317x_3 + 0.35744413x_4 + 1.2499117x_5 + 1.4677360x_6 + 1.1651720x_7 \\ + 1.1076340x_8 - 0.69686809 \end{bmatrix}.$$

The exact formulation of this problem includes nonalgebraic functions as coefficients, which Bertini does not currently accept. As a result, the coefficients were calculated in 1024-bit precision, available at [2], with the first 8 digits matching the coefficients given above. Using a homotopy similar to that of section 5.4, there are

TABLE 7
Average time of 10 *runs of the IPP system for the two tests, in seconds.*

	Minimum fixed precision		Proactive	Reactive
Test 1	192 bits	300.169	85.404	176.591
Test 2	96 bits	196.143	47.393	37.630

256 paths, 32 leading to finite regular solutions, 64 leading to thirty-two multiplicity-2 infinite solutions, 64 leading to four multiplicity-16 infinite solutions, and 96 leading to four multiplicity-24 infinite solutions. Even though this problem is 2-homogeneous with the variable groups $\{x_1, x_2, x_5, x_6\}$ and $\{x_3, x_4, x_7, x_8\}$, this was not used. Not taking advantage of the special structure of the system makes it a bit more representative of systems that come up in practice, where, even taking account of all special structure, the number of singular solutions greatly outnumbers the actual physical solutions, as in [24].

We ran this system using two different endgames: the first tracking until the path stabilizes and the second using a power series endgame. In both cases, a geometric series of sample values for t was set: $t = 10^{-k}$ for $k = 1, 2, \ldots$. The paths were tracked between the sample points with a tolerance of 10^{-6}, and sample points for the endgame were refined to full precision. The endgame stops when successive predictions of the endpoint at $t = 0$ agree to within 10^{-12}. In the first test, the prediction to $t = 0$ is taken as just the current path point, whereas in the second test, a fractional power series was used following the method in [18]. In both tests, using the method of section 4.3.2, we set Φ to 14.5 and Ψ to 42.2, and both safety digits to 1. The average times are provided in Table 7. One observes a marked reduction in run time using the more advanced endgame.

In both tests, the proactive adaptive precision tracking used higher precision and larger step size than the reactive method to track between the sample points. In the first test, the proactive method was faster since taking fewer steps in higher precision was advantageous over taking more steps in lower precision utilized by the reactive method. In the second test, fewer sample points were needed to generate an accurate prediction, which kept the tracking sufficiently far away from the endpoints that have high multiplicity. In this case, the reactive method was faster since taking more steps in lower precision was advantageous over using higher precision with fewer steps utilized by the proactive method.

6. Discussion regarding singular endgames. Multiple precision becomes necessary when numerical stability is poor, such as at a point having a near-singular Jacobian matrix. In the case of an exact singularity at the end of a continuation path, an endgame based on fractional power (Puiseux) series or Cauchy integration [18, 21] can increase the accuracy that can be obtained at a given precision, thereby reducing the computational burden of higher precision, especially in cases where a double precision endgame suffices. For the endgame to succeed, the homotopy path must be sampled in an "endgame operating zone" inside the branchpoint closest to the endpoint but before the path becomes too ill-conditioned at the end [18, 21]. Without enough precision, this operating zone is empty. Adaptive precision tracking will ensure that enough precision is allocated to succeed. Likewise, endgames based on deflating the system to derive a related nonsingular one [8] may need higher than double precision to make a correct decision regarding the rank of the Jacobian at each stage of deflation. The method of [11] may lower the precision needed to make a correct rank decision, but there is no guarantee that double precision, or any

prespecified precision, will suffice. So while either type of endgame can help reduce computation and sometimes can avoid higher precision, ultimately an adaptive precision method is needed to ensure success in difficult cases. Among the causes leading to difficult cases, the most common are high degree polynomials, badly scaled functions, endpoints having high multiplicity, and a tight tolerance on the final accuracy.

7. Conclusion. We have presented an adaptive precision predictor-corrector path tracking algorithm that automatically allocates enough precision to allow convergence of Newton's method in the corrector phase. The adaptation can be driven reactively in response to failures in convergence or proactively using rules based on a numerical analysis of Newton's coupled to bounds established on the floating point error incurred in evaluating the homotopy function. The reactive approach is simpler in that no error bound is required and no computation time is spent evaluating the adaptation rules. It does, however, require the careful setting of the minimum step size, $\varepsilon(P)$, to ensure that the need for higher precision is triggered appropriately. We determined good settings for $\varepsilon(P)$ by experimentation.

The proactive approach requires an error bound. Floating point errors depend not only on the mathematical function being evaluated but also on the sequence of operations used, for example, $a(b+c)$ and $ab+ac$ may have different errors. We provide rough formulas for polynomials evaluated in expanded form, based on just the degree and the size of the coefficients, and we give a more precise method using circular arithmetic, a form of interval analysis, to bound the error in any straight-line polynomial function. To apply the proactive approach to nonpolynomial systems, one must extend the interval analysis to handle whatever new elementary functions arise, such as trigonometric functions and the like. Although we have not carried this out in our experiments, there appears to be no fundamental barrier to such extensions of the approach.

In focusing on Newton's method in the corrector phase, we have neglected the prediction phase. While the corrector dominates the convergence to the path, we recognize that a careful study of predictor methods is certainly warranted. The use of different predictor schemes, e.g., Adams–Bashforth rather than Euler, is well worth considering. Moreover, step size control in the current algorithm is entirely reactive, i.e., based on the history of success and failure of the predictor-corrector steps. A careful analysis of the predictor might be combined with the convergence criteria of the corrector to proactively determine a safe step size, possibly making decisions balancing the computational cost of a small step size against that of higher precision. Along this line, the method presented in [6] presents a rigorous step size control algorithm based on interval arithmetic, but it does not consider adaptive precision. Instead, if not enough precision is used, the safe step size goes to zero. An approach like ours may remove this mode of failure. The main intent of [6] is to prevent path crossing when two or more paths in the homotopy pass close to each other. We have not addressed this important issue here.

In conclusion, the adaptive precision approach presented here appears to be highly effective for tracking numerically difficult homotopy paths. Open questions remain about prediction methods and step size control, and additional work is needed to extend the error analysis to nonpolynomial functions. While our error analysis goes far in explaining the conditions that drive an increase in precision, at present the conservative nature of the bounds causes the proactive method to increase precision earlier than necessary. Due to the high cost of leaving double precision, the reactive method, which uses double precision as long as possible, takes less computational time than

the proactive method in all our standard tracking experiments. When endgames are utilized and the tracking between the sample points needs to be completed in precision higher than double, the reactive method may become slower than the proactive method due to the increased number of steps needed to track between the sample points.

Acknowledgment. We would like to thank the referees for their insightful comments, which have resulted in this being a much better article.

AN OPTIMAL ADAPTIVE FINITE ELEMENT METHOD FOR THE STOKES PROBLEM*

YAROSLAV KONDRATYUK† AND ROB STEVENSON‡

Abstract. A new adaptive finite element method for solving the Stokes equations is developed, which is shown to converge with the best possible rate. The method consists of 3 nested loops. The outermost loop consists of an adaptive finite element method for solving the pressure from the (elliptic) Schur complement system that arises by eliminating the velocity. Each of the arising finite element problems is a Stokes-type problem, with the pressure being sought in the current trial space and the divergence-free constraint being reduced to orthogonality of the divergence to this trial space. Such a problem is still continuous in the velocity field. In the middle loop, its solution is approximated using the Uzawa scheme. In the innermost loop, the solution of the elliptic system for the velocity field that has to be solved in each Uzawa iteration is approximated by an adaptive finite element method.

Key words. adaptive finite element method, convergence rates, computational complexity, a posteriori error estimators, Uzawa iteration, Stokes equations

1. Introduction.

Often the solution of a boundary value problem exhibits singularities, e.g., due to a nonsmooth boundary. Then, because of the lacking (Sobolev) smoothness of the solution, finite element methods based on quasi-uniform partitions converge with a rate smaller than allowed by the polynomial degrees used in the finite element spaces. This can be repaired when suitable refinements are made near those singularities. The optimal distribution of the size of elements as a function of the distance to a singularity depends on the strength of the singularity, which is generally unknown.

With adaptive finite element methods (AFEMs), a sequence of nested partitions is created, where, when creating the next partition, the decision of where to refine is made on the basis of an a posteriori estimator of the error in the current finite element approximation. Although they had been used successfully for more than 25 years, in more than one space dimension, even for second order *elliptic* equations, their convergence was not shown before the works of Dörfler [Dör96] and that of Morin, Nochetto, and Siebert [MNS00]. Convergence alone, however, does not show that the use of an adaptive method for a solution that has singularities improves upon, or even competes with, that of a nonadaptive one. Recently, after the derivation of such a result by Binev, Dahmen, and DeVore [BDD04] for an AFEM extended with a so-called coarsening or derefinement routine, in [Ste07] we could prove that standard AFEMs converge with the best possible rate in linear complexity.

In this paper, as a model *saddle point problem*, we consider the Stokes equations

$$\begin{cases} -\triangle \mathbf{u} + \nabla p = \mathbf{f} & \text{on } \Omega \subset \mathbf{R}^d, \\ \qquad \text{div}\mathbf{u} = 0 & \text{on } \Omega, \\ \qquad\quad \mathbf{u} = 0 & \text{on } \partial\Omega. \end{cases}$$

(Although, in this introduction, we write equations in strong form, actually we always mean the corresponding variational formulations.) In [DDU02], Dahlke, Dahmen, and Urban analyzed an adaptive wavelet method for solving these equations. The starting point was the application of the Uzawa iteration on the continuous level, i.e., given some p_0, compute for $j = 0, 1, \ldots$

$$\left\{ \begin{array}{ll} -\triangle \mathbf{u}_{j+1} = \mathbf{f} - \nabla p_j & \text{on } \Omega \\ \qquad\quad \mathbf{u} = 0 & \text{on } \partial\Omega \end{array} \right\}, \quad p_{j+1} = p_j - \text{div}\mathbf{u}_j.$$

Of course, this iteration cannot be performed exactly, and in each iteration the solution of the elliptic system was approximated using an adaptive wavelet method within decreasing tolerances as the iteration proceeds. Convergence was shown, and by the inclusion of coarsening steps, even optimal rates and linear complexity were demonstrated. Since no Galerkin discretizations were formed from the mixed problem, the so-called LBB stability for the discrete problem was not required.

In [BMN02], Bänsch, Morin, and Nochetto studied the above solution method with the adaptive wavelet method replaced by an AFEM. They proved convergence, and despite the fact that they did not include coarsening, in numerical experiments they observed optimal rates, at least when the elliptic problems were solved not too accurately. When prescribing an a priori tolerance of the form γ^j in the jth iteration, it was necessary to take γ in the range $[\approx .95, 1)$. By the addition of coarsening to this method, in [Kon06] optimal computational complexity was demonstrated.

When starting this work, our aim was to prove optimal computational complexity of basically the method from [BMN02], i.e., without coarsening. For a reason that will be indicated later (in Remark 6.6), we did not succeed in doing this. Instead, we prove this result for a somewhat more complicated algorithm involving an additional outer loop, without coarsening though. Below we briefly describe the loops of our algorithm starting from the outermost one.

The pressure p can be found as the solution of the Schur complement equation that one obtains by eliminating the velocity $\mathbf{u}$ from the Stokes equations. This equation is *elliptic*, with corresponding energy norm equivalent to the $L_2(\Omega)$-norm. Given a finite element space $\mathbb{P}_{\sigma_i}$, where σ_i denotes the underlying finite element partition, the best approximation from this space to p with respect to this energy norm is the Galerkin solution $p_i \in \mathbb{P}_{\sigma_i}$. With Q_{σ_i} denoting the $L_2(\Omega)$-orthogonal projection onto $\mathbb{P}_{\sigma_i}$, this p_i can be shown to be the unique solution of

$$\begin{cases} -\triangle \mathbf{u}^{(i)} + \nabla p_i = \mathbf{f} & \text{on } \Omega, \\ Q_{\sigma_i}\text{div}\mathbf{u}^{(i)} = 0 & \text{on } \Omega, \\ \qquad\quad \mathbf{u}^{(i)} = 0 & \text{on } \partial\Omega, \end{cases}$$

i.e., the Stokes equations in which the divergence-free condition has been relaxed. We refer to this system as the reduced Stokes equations.

Concerning the velocity, this is still a problem posed over an infinite-dimensional space. Inside the inner loops, a sufficiently accurate approximate solution will be

determined, which here again is denoted as $(\mathbf{u}^{(i)}, p_i)$. We will have that $p_i \in \mathbb{P}_{\sigma_i}$, while $\mathbf{u}^{(i)}$ is from a finite element space $\mathbb{V}_{\tau_i}$ with respect to a partition τ_i that is a refinement of σ_i. It will be shown that the energy norm of $p - p_i$ is equivalent to the *a posteriori error estimator* $\|\mathrm{div}\mathbf{u}^{(i)}\|_{L_2(\Omega)}$, and that for any refinement σ_{i+1} of σ_i, the energy norm of $p_{i+1} - p_i$ is equivalent to $\|Q_{\sigma_{i+1}}\mathrm{div}\mathbf{u}^{(i)}\|_{L_2(\Omega)}$. Now following along the lines of [Dör96, MNS00] for Poisson-type problems, by selecting σ_{i+1} such that for some $\theta \in (0, 1]$, $\|Q_{\sigma_{i+1}}\mathrm{div}\mathbf{u}^{(i)}\|_{L_2(\Omega)} \geq \theta\|\mathrm{div}\mathbf{u}^{(i)}\|_{L_2(\Omega)}$ (the "bulk criterion"), the so-called saturation property is guaranteed, and a linearly convergent sequence $(p_i)_i$ towards p is obtained. Moreover, by taking θ to be small enough, and σ_{i+1} with quasi-minimal cardinality, following along the lines of [Ste07] convergence of the $p_i \in \mathbb{P}_{\sigma_i}$ towards p with the optimal rate is shown.

Compared to the adaptive methods for Poisson-type problems, a complication is that to find such a σ_{i+1}, it is generally not sufficient to search it within the set of partitions that can be created by refining each element of σ_i some fixed number of times. On the other hand, by considering finite element spaces such that $\mathrm{div}\mathbb{V}_{\tau_i} \subseteq \mathbb{P}_{\tau_i}$, we know that we never have to subdivide elements that are in τ_i. To determine σ_{i+1} with the required properties we apply an adaptive tree algorithm developed by Binev and DeVore in [BD04].

For solving the reduced Stokes problem for given i, i.e., fixed σ_i, we follow the approach from [BMN02] for the full Stokes problem. That is, we apply Uzawa, where the pressure update then reads as $p_{j+1}^{(i)} = p_j^{(i)} - Q_{\sigma_i}\mathrm{div}\mathbf{u}_j^{(i)}$. Each of the inner elliptic systems $-\triangle\mathbf{u}_{j+1}^{(i)} = \mathbf{f} - \nabla p_j^{(i)}$ on Ω, $\mathbf{u} = 0$ on $\partial\Omega$ is solved with a standard AFEM producing increasingly more refined partitions, with σ_i being the initial partition for the first call. Already having optimal control over $\#\sigma_i$, we are now able to prove also optimal rates of the velocity approximations towards $\mathbf{u}$. Note that other than in [BMN02], we have two different partitions underlying pressure and velocity approximations, with the latter being always a refinement of the first. Throughout the algorithm, both partitions become increasingly more refined, i.e., no derefinements are made.

This paper is organized as follows: In section 2, we recall some properties of the Stokes problem. In section 3, we define the finite element spaces that we will use. We give some properties of a procedure for refining partitions, which is a generalization to arbitrary space dimensions of the newest vertex bisection method in two space dimensions. An overview of the solution method will be given in section 4. In section 5, a posteriori error estimators are derived for the various problems that occur in our solution method. In section 6, the adaptive refinement routines for pressure and velocity partitions are given. In section 7, we give the detailed description of the adaptive method in the simplified situation that the right-hand side $\mathbf{f}$ is piecewise polynomial with respect to the initial partition. We prove convergence with the optimal rates. In this section, we assume that the arising finite-dimensional linear systems are solved exactly, ignoring the question of computational complexity. In section 8, we give the method for general right-hand sides, and replace the direct solvers by iterative solution methods, with which we end up with a method of optimal computational complexity. Finally, in section 9, we present numerical results, and compare them with those obtained with the method from [BMN02]. As we will see, in this example both methods give similar results.

In this paper, by $C \lesssim D$ we will mean that C can be bounded by a multiple of D, independently of parameters which C and D may depend on. Obviously, $C \gtrsim D$ is defined as $D \lesssim C$, and $C \eqsim D$ as $C \lesssim D$ and $C \gtrsim D$.

2. Stokes problem. Let Ω be a polygonal domain in $\mathbf{R}^d$. We consider the Stokes problem in variational form: With

$$\mathbb{V} := H^1_0(\Omega)^d, \quad \mathbb{P} := L_{2,0}(\Omega) := \left\{ q \in L_2(\Omega) : \int_\Omega q = 0 \right\},$$

and given an $\mathbf{f} \in \mathbb{V}'$, throughout this paper $\mathbf{u} \in \mathbb{V}$ (the velocity) and $p \in \mathbb{P}$ (the pressure) will denote the solutions of

$$\boxed{a(\mathbf{u},\mathbf{v}) + b(\mathbf{v},p) + b(\mathbf{u},q) = \mathbf{f}(\mathbf{v}) \quad (\mathbf{v} \in \mathbb{V},\, q \in \mathbb{P}),} \tag{2.1}$$

where $a : \mathbb{V} \times \mathbb{V} \to \mathbf{R}$, $b : \mathbb{V} \times \mathbb{P} \to \mathbf{R}$ are defined by

$$a(\mathbf{w},\mathbf{v}) := \int_\Omega \nabla\mathbf{w} : \nabla\mathbf{v}, \quad b(\mathbf{v},q) := -\int_\Omega q\, \mathrm{div}\mathbf{v}.$$

It is well known that

$$\|\mathbf{v}\|_{\mathbb{V}} := a(\mathbf{v},\mathbf{v})^{\frac{1}{2}} \eqsim \|\mathbf{v}\|_{H^1(\Omega)^d} \quad (\mathbf{v} \in \mathbb{V}),$$

b is bounded, and

$$\beta := \inf_{0\neq q\in\mathbb{P}} \sup_{0\neq \mathbf{v}\in\mathbb{V}} \frac{b(\mathbf{v},q)}{\|\mathbf{v}\|_{\mathbb{V}}\|q\|_{L_2(\Omega)}} > 0. \tag{2.2}$$

As a consequence, the Stokes problem is well-posed, meaning that

$$\|\mathbf{w}\|_{\mathbb{V}} + \|r\|_{L_2(\Omega)} \eqsim \sup_{0\neq(\mathbf{v},q)\in\mathbb{V}\times\mathbb{P}} \frac{a(\mathbf{w},\mathbf{v}) + b(\mathbf{v},r) + b(\mathbf{w},q)}{\|\mathbf{v}\|_{\mathbb{V}} + \|q\|_{L_2(\Omega)}} \quad (\mathbf{w} \in \mathbb{V},\, r \in \mathbb{P}). \tag{2.3}$$

Remark 2.1. Since $a(\cdot,\cdot)$ is elliptic on the whole of $\mathbb{V}$ instead of only on the space of the divergence-free velocities, clearly the Stokes problem (2.1) with $\mathbb{P}$ replaced by any subspace is also well-posed, uniformly in the choice of such a subspace.

Defining $A : \mathbb{V} \to \mathbb{V}'$, $B : \mathbb{V} \to \mathbb{P}'$, and $B' : \mathbb{P} \to \mathbb{V}'$ by $(A\mathbf{v})(\mathbf{w}) = a(\mathbf{v},\mathbf{w})$, $(B\mathbf{v})(q) = b(\mathbf{v},q) = (B'q)(\mathbf{v})$, problem (2.1) can be equivalently written as

$$\begin{bmatrix} A & B' \\ B & 0 \end{bmatrix} \begin{bmatrix} \mathbf{u} \\ p \end{bmatrix} = \begin{bmatrix} \mathbf{f} \\ 0 \end{bmatrix},$$

and, with the Schur complement $S := BA^{-1}B'$, p is also uniquely determined by

$$Sp = BA^{-1}f.$$

LEMMA 2.2. *$(Sq)(q) = \sup_{0\neq\mathbf{v}\in\mathbb{V}} \frac{b(\mathbf{v},q)^2}{a(\mathbf{v},\mathbf{v})}$ and $\|q\|_{\mathbb{P}} := (Sq)(q)^{\frac{1}{2}} \eqsim \|q\|_{L_2(\Omega)}$ $(q \in \mathbb{P})$.*

Proof. With $\langle\cdot,\cdot\rangle = \langle\cdot,\cdot\rangle_{H^1(\Omega)^d}$ (or $\langle\cdot,\cdot\rangle = a(\cdot,\cdot)$), let $R : \mathbb{V} \to \mathbb{V}'$ be the mapping such that $\mathbf{g}(\mathbf{v}) = \langle\mathbf{v}, R\mathbf{g}\rangle$ $(\mathbf{v} \in \mathbb{V},\, \mathbf{g} \in \mathbb{V}')$. Writing $\tilde{B}' = RB'$, $\tilde{A} = RA$, we have

$$\sup_{0\neq\mathbf{v}\in\mathbb{V}} \frac{b(\mathbf{v},q)^2}{a(\mathbf{v},\mathbf{v})} = \sup_{0\neq\mathbf{v}\in\mathbb{V}} \frac{(B'q)(\mathbf{v})^2}{(A\mathbf{v})(\mathbf{v})} = \sup_{0\neq\mathbf{v}\in\mathbb{V}} \frac{\langle\mathbf{v},\tilde{B}'q\rangle^2}{\langle\mathbf{v},\tilde{A}\mathbf{v}\rangle} = \sup_{0\neq\mathbf{w}\in\mathbb{V}} \frac{\langle\mathbf{w},\tilde{A}^{-\frac{1}{2}}\tilde{B}'q\rangle^2}{\langle\mathbf{w},\mathbf{w}\rangle}$$
$$= \langle\tilde{A}^{-\frac{1}{2}}\tilde{B}'q, \tilde{A}^{-\frac{1}{2}}\tilde{B}'q\rangle = \langle A^{-1}B'q, RB'q\rangle = (Sq)(q) \quad (q \in \mathbb{P}).$$

The second statement follows from the ellipticity of a, the boundedness of b, and (2.2). ∎

For $\mathbf{g} \in \mathbb{V}'$, we set $\|\mathbf{g}\|_{\mathbb{V}'} = \sup_{0\neq\mathbf{v}\in\mathbb{V}} \frac{|\mathbf{g}(\mathbf{v})|}{\|\mathbf{v}\|_{\mathbb{V}}}$. Equipped with norms $\|\cdot\|_{\mathbb{V}}$ and $\|\cdot\|_{\mathbb{V}'}$, respectively, $A : \mathbb{V} \to \mathbb{V}'$ is an isomorphism.

Functions $\mathbf{g} \in L_2(\Omega)^d$ will be interpreted as functionals by means of $\mathbf{g}(\mathbf{v}) := \int_\Omega \mathbf{g}\cdot\mathbf{v}$.

3. Finite element approximation. Given some fixed $m \in \mathbf{N}_{>0}$, and partitions τ and σ of $\bar{\Omega}$ into essentially disjoint (closed) d-simplices, we will search approximations for $\mathbf{u}$ and p from the finite element spaces

$$\mathbb{V}_\tau := \mathbb{V} \cap \prod_{T\in\tau} P_m(T)^d \quad \text{and} \quad \mathbb{P}_\sigma := \mathbb{P} \cap \prod_{T\in\sigma} P_{m-1}(T),$$

respectively. For doing so, furthermore we will approximate the right-hand side $\mathbf{f}$ by functions from

$$\mathbb{V}_\tau^* := \prod_{T\in\tau} P_{m-1}(T)^d.$$

At any moment in our algorithm we will have that $\tau \supseteq \sigma$, meaning that $\tau = \sigma$ or that it is a proper refinement of σ. Note that $(\mathbb{V}_\tau, \mathbb{P}_\tau)$ is *not* an LBB stable pair.

Sometimes we will view $\mathbb{V}$ and $\mathbb{P}$ formally as finite element spaces corresponding to the infinitely fine partition ∞, and denote them as $\mathbb{V}_\infty$ and $\mathbb{P}_\infty$, respectively.

Remark 3.1. The fact that the approximate pressure is a piecewise polynomial of degree not larger than $m-1$ will be used only in the forthcoming Proposition 5.2. It is most likely that also there higher degree polynomials can be permitted at the expense of having a more complicated refinement rule for the velocity partitions (it will be needed to create more interior vertices; cf. Figure 5.1). On the other hand, at least for our analysis, it will be essential that $\mathbb{P}_\tau \supseteq \mathrm{div}\mathbb{V}_\tau$ (cf. Remark 6.1).

We will exclusively consider partitions that can be created by a certain recursive *bisection* procedure starting from some fixed conforming initial partition τ_0. The procedure we consider is a generalization to any space dimension of the well-known newest vertex bisection rule in two space dimensions (cf. [Mit89]). Here we recall a few properties of this generalized newest vertex bisection method that are relevant for the current exposition, and we refer to [Ste06] for a complete description of the method.

The way of bisecting any simplex in any partition that can be created by the method is uniquely determined. It depends only on a local numbering of the vertices of the simplices in the initial partition τ_0. As a consequence, any partition can be represented by a subtree of the infinite binary master tree $\mathcal{T}_*$ having as roots the simplices of τ_0, and in which the parent–child relation corresponds to the unique bisection of the parent. The partitions that can be created are *uniformly shape regular*, dependent only on τ_0.

For applying a posteriori error estimators, we will need the partitions τ underlying the velocity approximation spaces $\mathbb{V}_\tau$ to be conforming. So in the following,

$$\tau, \tau', \tilde{\tau}, \textit{ etc., will always denote } \text{conforming } \textit{partitions}.$$

Bisecting one or more simplices in a conforming partition τ generally results in a nonconforming partition ϱ. Conformity has to be restored by (recursively) bisecting any simplex $T \in \varrho$ that contains a vertex v of a $T' \in \varrho$ that does not coincide with any vertex of T (such a v is called a hanging vertex). This process, called completion, results into the smallest conforming refinement of ϱ.

Our adaptive method will be of the following form:

`for` $j := 1$ `to` M
`do` *create some, possibly nonconforming refinement* ϱ_j *of* τ_{j-1}
complete ϱ_j *to its smallest conforming refinement* τ_j
`endfor`

As we will see, we will be able to bound $\sum_{j=1}^{M} \#\varrho_j - \#\tau_{j-1}$. Because of the additional bisections made in the completion steps, however, generally $\#\tau_M - \#\tau_0$ will be larger. The following crucial result shows that these additional bisections inflate the total number of simplices by at most an absolute constant factor. It is valid with a proper local numbering of the vertices of the simplices in the initial partition τ_0, which we will assume in the following. In two dimensions such a numbering exists for any conforming partition. In more than two dimensions, it always exists after some initial refinement that inflates the number of simplices by not more than a constant factor.

THEOREM 3.2 (see [Ste06], generalizes upon [BDD04, Theorem 2.4] for $d = 2$).

$$\#\tau_M - \#\tau_0 \lesssim \sum_{j=1}^{M} \#\varrho_j - \#\tau_{j-1},$$

dependent only on τ_0, and in particular thus independent of M.

Remark 3.3. Note that this result in particular implies that any descendant ϱ of τ_0 has a conforming refinement τ with $\#\tau \lesssim \#\varrho$, dependent only on τ_0 and d.

We end this section by introducing some more notation. The smallest partition that is a refinement of partitions ϱ_1 and ϱ_2, i.e., their smallest common refinement, will be denoted as $\varrho_1 \cup \varrho_2$. For a partition τ (thus a conforming one), E_τ will denote the set of all internal $(d-1)$-dimensional hyperfaces in τ. For $T \in \tau$, $\mathcal{F}_\tau(T)$ denotes the union of T and the set of its neighbors in τ, i.e., those simplices that share a $(d-1)$-dimensional hyperface with T.

4. Overview of the solution method. For a partition σ_i, we consider the Galerkin problem of finding $p^{(i)} \in \mathbb{P}_{\sigma_i}$ such that

$$(Sp^{(i)})(q) = (BA^{-1}\mathbf{f})(q) \quad (q \in \mathbb{P}_{\sigma_i}).$$

With $\mathbf{u}^{(i)} := A^{-1}(\mathbf{f} - B'p^{(i)})$, this problem is equivalent to the semidiscrete problem of finding $(\mathbf{u}^{(i)}, p^{(i)}) \in \mathbb{V} \times \mathbb{P}_{\sigma_i}$ such that

$$a(\mathbf{u}^{(i)}, \mathbf{v}) + b(\mathbf{v}, p^{(i)}) + b(\mathbf{u}^{(i)}, q) = \mathbf{f}(\mathbf{v}) \quad (\mathbf{v} \in \mathbb{V},\ q \in \mathbb{P}_{\sigma_i}). \tag{4.1}$$

Since this is just the Stokes problem in which the divergence-free constraint has been relaxed, we will refer to this problem as the *reduced Stokes problem*. The solution $p^{(i)}$ *is the best approximation to p from $\mathbb{P}_{\sigma_i}$ with respect to $\|\cdot\|_{\mathbb{P}}$*, and by creating a suitable *adaptively refined* sequence of partitions $\tau_0 =: \sigma_0 \subset \sigma_1 \subset \cdots$, a convergent sequence $(p^{(i)})_i$ towards p is obtained.

The reduced Stokes problem, however, cannot be solved exactly. With the Riesz operator $R_{\sigma_i} : \mathbb{P}' \to \mathbb{P}_i$ being defined by $g(q) = \langle q, R_{\sigma_i} g\rangle_{L_2(\Omega)}$ $(q \in \mathbb{P}_{\sigma_i})$, it can be written as $R_{\sigma_i} Sp^{(i)} = R_{\sigma_i} BA^{-1}\mathbf{f}$. Equipping $\mathbb{P}_{\sigma_i}$ with $\langle\cdot,\cdot\rangle_{L_2(\Omega)}$, the operator $R_{\sigma_i} S : \mathbb{P}_{\sigma_i} \to \mathbb{P}_{\sigma_i}$ is symmetric, bounded, and positive definite, with a spectrum in $[\beta^2, 1]$ (cf. [NP04]). So to solve the reduced Stokes problem approximately, we may apply Richardson's iteration:

$$p_{j+1}^{(i)} = p_j^{(i)} - (R_{\sigma_i} Sp_j^{(i)} - R_{\sigma_i} BA^{-1}\mathbf{f}) \quad (j = 0, 1, \dots).$$

With $Q_{\sigma_i} : \mathbb{P} \to \mathbb{P}_{\sigma_i}$ denoting the $L_2(\Omega)$-orthogonal projector onto $\mathbb{P}_{\sigma_i}$, we have $R_{\sigma_i} B = -Q_{\sigma_i}\mathrm{div}$. Writing $\mathbf{u}_j^{(i)} := A^{-1}(\mathbf{f} - B'p_j^{(i)})$, we arrive at the equivalent formulation

$$\begin{cases} a(\mathbf{u}_j^{(i)}, \mathbf{v}) \;=\; \mathbf{f}(\mathbf{v}) - b(\mathbf{v}, p_j^{(i)}) \quad (\mathbf{v} \in \mathbb{V}), \\ \qquad p_{j+1}^{(i)} \;=\; p_j^{(i)} - Q_{\sigma_i}\mathrm{div}\mathbf{u}_j^{(i)}, \end{cases} \tag{4.2}$$

known as the Uzawa iteration. The properties of $R_{\sigma_i}S$ show that

$$\|p^{(i)} - p^{(i)}_{j+1}\|_{L_2(\Omega)} \leq [1-\beta^2]\|p^{(i)} - p^{(i)}_j\|_{L_2(\Omega)}. \tag{4.3}$$

Also the Uzawa iteration for solving the reduced Stokes problem cannot be performed exactly since it involves solving an elliptic problem posed over $\mathbb{V}$. To solve this problem approximately, we will again consider Galerkin approximations: Given a partition $\tau^{(i)}_{j,k}$, let $\mathbf{u}^{(i)}_{j,k} \in \mathbb{V}_{\tau^{(i)}_{j,k}}$ be the solution of

$$a(\mathbf{u}^{(i)}_{j,k}, \mathbf{v}) = \mathbf{f}(\mathbf{v}) - b(\mathbf{v}, p^{(i)}_j) \quad (\mathbf{v} \in \mathbb{V}_{\tau^{(i)}_{j,k}}). \tag{4.4}$$

It is the best approximation to $\mathbf{u}^{(i)}_j$ from $\mathbb{V}_{\tau^{(i)}_{j,k}}$ with respect to $\|\cdot\|_{\mathbb{V}}$, and by creating a suitable *adaptively refined* sequence of partitions $\sigma_i \subseteq \tau^{(i)}_{j,0} \subset \tau^{(i)}_{j,1} \subset \cdots$, a convergent sequence $(\mathbf{u}^{(i)}_{j,k})_k$ towards $\mathbf{u}^{(i)}_j$ is obtained. To guarantee that $\mathbf{u}^{(i)}_{j,k+1}$ is indeed a better approximation than $\mathbf{u}^{(i)}_{j,k}$, we will require that $\mathbf{f} \in \mathbb{V}'$ be sufficiently well approximated by a vector field from $\mathbb{V}^*_{\tau^{(i)}_{j,k}}$. To implement the latter requirement, instead of working with $\mathbf{f}$, we will replace it by suitable piecewise polynomial vector fields of degree $m-1$, which should become increasingly more accurate when the iterations proceed.

Finally, instead of solving the finite-dimensional linear systems (4.4) exactly, in order to obtain a method of (quasi-)optimal computational complexity, we will use approximate solutions obtained by employing optimal iterative solvers.

In order to stop each of the nested loops in time, as well as for both Galerkin problems, to create adaptively refined partitions such that the corresponding approximations converge towards the solution, and such that these partitions have quasi-optimal cardinalities, we need *a posteriori error estimators*, which will be discussed in the next section. On the one hand, stopping a loop in time means that it should not stop too early in order to guarantee convergence of the overall process. On the other hand, the iterations should not proceed too long in order to control both the cardinalities of the partitions, which grow by the refinements, and the computational complexity.

In view of our solution method, we fix some notation. Throughout this paper, given some $r \in \mathbb{P}$, where we have in mind an approximation to p, and a partition τ, $\mathbf{u}^r_\tau \in \mathbb{V}_\tau$ will denote the solution of the (discretized) elliptic problem

$$\boxed{a(\mathbf{u}^r_\tau, \mathbf{v}_\tau) = \mathbf{f}(\mathbf{v}_\tau) - b(\mathbf{v}_\tau, r) \quad (\mathbf{v}_\tau \in \mathbb{V}_\tau).} \tag{4.5}$$

As a special case of (4.5), $\mathbf{u}^r = \mathbf{u}^r_\infty \in \mathbb{V}$ thus denotes the solution of

$$a(\mathbf{u}^r, \mathbf{v}) = \mathbf{f}(\mathbf{v}) - b(\mathbf{v}, r) \quad (\mathbf{v} \in \mathbb{V}). \tag{4.6}$$

So the subscript τ in the notation $\mathbf{u}^r_\tau$ refers to its membership of the finite element space $\mathbb{V}_\tau$, whereas the superscript r in the notation $\mathbf{u}^r_\tau$ and $\mathbf{u}^r$ refers to their dependence on the approximate pressure r on the right-hand side. Note that $\mathbf{u} = \mathbf{u}^p$. Often we will consider (4.5) and (4.6) for $r = r_\sigma \in \mathbb{P}_\sigma$ for some $\sigma \subseteq \tau$ giving rise to the notation $\mathbf{u}^{r_\sigma}_\tau$ and $\mathbf{u}^{r_\sigma}$.

Given a partition σ, $(\mathbf{u}^{p_\sigma}, p_\sigma) \in \mathbb{V} \times \mathbb{P}_\sigma$ will denote the solution of the reduced Stokes problem

$$\boxed{a(\mathbf{u}^{p_\sigma}, \mathbf{v}) + b(\mathbf{v}, p_\sigma) + b(\mathbf{u}^{p_\sigma}, q_\sigma) = \mathbf{f}(\mathbf{v}) \quad (\mathbf{v} \in \mathbb{V},\, q_\sigma \in \mathbb{P}_\sigma).}$$

Note that $a(\mathbf{u}^{p_\sigma}, \mathbf{v}) = \mathbf{f}(\mathbf{v}) - b(\mathbf{v}, p_\sigma)$ $(\mathbf{v} \in \mathbb{V})$ so that the notation $\mathbf{u}^{p_\sigma}$ is consistent with (4.6).

5. A posteriori error estimators.

5.1. A posteriori error estimator for the inner elliptic problem. For a given right-hand side $\mathbf{f}$ and partitions $\tau \supseteq \sigma$ and $r_\sigma \in \mathbb{P}_\sigma$, we study an a posteriori error estimator for $\|\mathbf{u}^{r_\sigma} - \mathbf{u}_\tau^{r_\sigma}\|_{\mathbb{V}}$. Since even the Galerkin problem (4.5) will be solved only inexactly, whenever possible we even estimate $\|\mathbf{u}^{r_\sigma} - \mathbf{w}_\tau\|_{\mathbb{V}}$ for some general $\mathbf{w}_\tau \in \mathbb{V}_\tau$.

For $T \in \tau$, we set the local error indicator

$$\begin{aligned}&\eta_T(\mathbf{f}, r_\sigma, \mathbf{w}_\tau)\\ &\quad := \operatorname{diam}(T)^2 \|\mathbf{f} - \nabla r_\sigma + \triangle \mathbf{w}_\tau\|^2_{L_2(T)^d} + \operatorname{diam}(T) \|[\![r_\sigma \mathbf{n} - \nabla \mathbf{w}_\tau \cdot \mathbf{n}]\!]_{\partial T}\|^2_{L_2(\partial T)^d},\end{aligned}$$

where $[\![\cdot]\!]_{\partial T}$ denotes the jump of its argument over ∂T in the direction of $\mathbf{n}$, being a unit vector normal to ∂T. This jump is defined to be zero over $\partial\Omega$. We set the elliptic error estimator

$$\mathcal{E}^{\mathrm{E}}(\tau, \mathbf{f}, r_\sigma, \mathbf{w}_\tau) := \left[\sum_{T\in\tau} \eta_T(\mathbf{f}, r_\sigma, \mathbf{w}_\tau)\right]^{\frac{1}{2}}.$$

Note that the definition of the error estimator requires $\mathbf{f} \in L_2(\Omega)^d$, which we therefore assume here.

In Proposition 5.1 below, for $\tau' \supseteq \tau$ it is shown that the sum of the local error indicators corresponding to the simplices that were refined when creating τ' from τ, or those that have nonempty intersection with such simplices, is an *upper bound* for $\|\mathbf{u}_{\tau'}^{r_\sigma} - \mathbf{u}_\tau^{r_\sigma}\|^2_{\mathbb{V}}$. Substituting $\tau' = \infty$, it generalizes the known upper bound for $\|\mathbf{u}^{r_\sigma} - \mathbf{u}_\tau^{r_\sigma}\|_{\mathbb{V}}$ [BMN02, Lemma 5.1, eq. (5.4)], [Ver96]. Since our generalization is not so difficult to derive, we refer to the extended preprint version [KS07] of this work for a proof.

PROPOSITION 5.1. *Let $\tau' \supseteq \tau \supseteq \sigma$ be partitions, and let $r_\sigma \in \mathbb{P}_\sigma$, $\mathbf{f} \in L_2(\Omega)^d$, and*

$$\overline{F} = \overline{F}(\tau, \tau') := \{T \in \tau : T \cap \tilde{T} \neq \emptyset \text{ for some } \tilde{T} \in \tau \text{ that has been refined in } \tau'\}.$$

Then we have

$$\|\mathbf{u}_{\tau'}^{r_\sigma} - \mathbf{u}_\tau^{r_\sigma}\|_{\mathbb{V}} \leq C_1 \left[\sum_{T\in\overline{F}} \eta_T(\mathbf{f}, r_\sigma, \mathbf{u}_\tau^{r_\sigma})\right]^{\frac{1}{2}}$$

for some absolute constant $C_1 > 0$. Note that $\#\overline{F} \lesssim \#\tau' - \#\tau$.

In particular, by taking $\tau' = \infty$, we have $\|\mathbf{u}^{r_\sigma} - \mathbf{u}_\tau^{r_\sigma}\|_{\mathbb{V}} \leq C_1 \mathcal{E}^{\mathrm{E}}(\tau, \mathbf{f}, r_\sigma, \mathbf{u}_\tau^{r_\sigma})$.

Next we study whether the error estimator also provides a *lower bound* for the error $\|\mathbf{u}^{r_\sigma} - \mathbf{u}_\tau^{r_\sigma}\|_{\mathbb{V}}$ and, when τ' is a sufficient refinement of τ, for $\|\mathbf{u}_{\tau'}^{r_\sigma} - \mathbf{u}_\tau^{r_\sigma}\|_{\mathbb{V}}$. In order to derive such estimates, for the time being we further restrict the type of right-hand sides to piecewise polynomials of degree $m-1$ with respect to τ. We will call $\tau' \supset \tau$ *a full refinement with respect to $T \in \tau$*, when

> *all $\tilde{T} \in \mathcal{F}_\tau(T)$, as well as all $(d-1)$-dimensional hyperfaces of T, contain a vertex of τ' in their interiors.*

See Figure 5.1 for an illustration of the case $d = 2$. The following proposition was shown in [BMN02, Lemma 5.3]. (Actually, a somewhat stronger condition on the

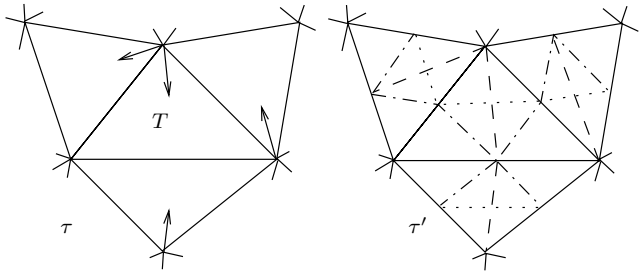

FIG. 5.1. *A refinement τ' of τ, which is a full refinement with respect to a triangle $T \in \tau$. The arrows in τ emanate from the newest vertices.*

refinement was imposed there, but not used; a more general $\mathbf{f}$ was considered at the expense of an additional "oscillation" term in the expression; and, finally, there our general $\mathbf{w}_\tau \in \mathbb{V}_\tau$ reads as $\mathbf{u}_\tau^{r_\sigma}$, whose additional property of being the solution of (4.5) was not used though.)

PROPOSITION 5.2. *Let $\tau \supseteq \sigma$ be partitions, let $r_\sigma \in \mathbb{P}_\sigma$, and let us assume that $\mathbf{f} \in \mathbb{V}_\tau^*$. Let $\tau' \supset \tau$ be a full refinement of τ with respect to $T \in \tau$. Then for any $\mathbf{w}_\tau \in \mathbb{V}_\tau$, we have*

$$\eta_T(\mathbf{f}, r_\sigma, \mathbf{w}_\tau) \lesssim \sum_{\tilde{T} \in \mathcal{F}_\tau(T)} |\mathbf{u}_{\tau'}^{r_\sigma} - \mathbf{w}_\tau|^2_{H^1(\tilde{T})^d}.$$

As a straightforward consequence we have the following.

COROLLARY 5.3. *In the situation of Proposition* 5.2, *let $\tau' \supseteq \tau$ be a full refinement of τ with respect to all T from some $\underline{F} \subset \tau$. Then*

$$c_2 \left[\sum_{T \in \underline{F}} \eta_T(\mathbf{f}, r_\sigma, \mathbf{w}_\tau) \right]^{\frac{1}{2}} \leq \|\mathbf{u}_{\tau'}^{r_\sigma} - \mathbf{w}_\tau\|_{\mathbb{V}}$$

for some absolute constant $c_2 > 0$. In particular, we have

$$c_2 \mathcal{E}^{\mathrm{E}}(\tau, \mathbf{f}, r_\sigma, \mathbf{w}_\tau) \leq \|\mathbf{u}^{r_\sigma} - \mathbf{w}_\tau\|_{\mathbb{V}}. \tag{5.1}$$

Finally in this subsection, we investigate the stability of the elliptic error estimator.

PROPOSITION 5.4. *Let $\tau \supseteq \sigma$ be partitions, and let $r_\sigma \in \mathbb{P}_\sigma$, $\mathbf{f} \in L_2(\Omega)^d$, and $\mathbf{v}_\tau, \mathbf{w}_\tau \in \mathbb{V}_\tau$. Then*

$$c_2 |\mathcal{E}^{\mathrm{E}}(\tau, \mathbf{f}, r_\sigma, \mathbf{v}_\tau) - \mathcal{E}^{\mathrm{E}}(\tau, \mathbf{f}, r_\sigma, \mathbf{w}_\tau)| \leq \|\mathbf{v}_\tau - \mathbf{w}_\tau\|_{\mathbb{V}}.$$

Proof. For $\mathbf{g} \in L_2(\Omega)^d$, $q_\sigma \in \mathbb{P}_\sigma$, by two applications of the triangle inequality in the form $\big|\|\cdot\| - \|\cdot\|\big|^2 \leq \|\cdot - \cdot\|^2$, first for vectors and then for functions, we have

$$|\mathcal{E}^{\mathrm{E}}(\tau, \mathbf{f}, r_\sigma, \mathbf{v}_\tau) - \mathcal{E}^{\mathrm{E}}(\tau, \mathbf{g}, q_\sigma, \mathbf{w}_\tau)| \leq \mathcal{E}^{\mathrm{E}}(\tau, \mathbf{f} - \mathbf{g}, r_\sigma - q_\sigma, \mathbf{v}_\tau - \mathbf{w}_\tau).$$

By substituting $\mathbf{g} = \mathbf{f}$ and $q_\sigma = r_\sigma$, and by applying (5.1), the proof is completed. ∎

5.2. A posteriori error estimator for the (reduced) Stokes problem. For given $\mathbf{f} \in L_2(\Omega)^d$ and partitions $\tau \supseteq \sigma$ and ϱ, where we think of either $\varrho = \infty$ (full Stokes) or $\varrho = \sigma$ (reduced Stokes), $r_\sigma \in \mathbb{P}_\sigma$ being an approximation for p_ϱ, we study an a posteriori error estimator for $\|\mathbf{u}^{p_\varrho} - \mathbf{u}_\tau^{r_\sigma}\|_{\mathbb{V}} + \|p_\varrho - r_\sigma\|_{\mathbb{P}}$, or whenever possible, for this quantity with $\mathbf{u}_\tau^{r_\sigma}$ replaced by a general $\mathbf{w}_\tau \in \mathbb{V}_\tau$. We set the estimator

$$\mathcal{E}^{\mathrm{S}}(\varrho, \tau, \mathbf{f}, r_\sigma, \mathbf{w}_\tau) := \mathcal{E}^{\mathrm{E}}(\tau, \mathbf{f}, r_\sigma, \mathbf{w}_\tau) + \|Q_\varrho \mathrm{div} \mathbf{w}_\tau\|_{L_2(\Omega)}.$$

PROPOSITION 5.5. *For partitions $\tau \supseteq \sigma$ and ϱ, $r_\sigma \in \mathbb{P}_\sigma$, and $\mathbf{f} \in L_2(\Omega)^d$, we have*

$$\|\mathbf{u}^{p_\varrho} - \mathbf{u}_\tau^{r_\sigma}\|_{\mathbb{V}} + \|p_\varrho - r_\sigma\|_{\mathbb{P}} \leq C_3 \mathcal{E}^{\mathrm{S}}(\varrho, \tau, \mathbf{f}, r_\sigma, \mathbf{u}_\tau^{r_\sigma})$$

for some absolute constant $C_3 > 0$.

The proof given in [Ver96] (cf. [BMN02, Lemma 4.1]) for $\varrho = \infty$ easily generalizes to $\varrho \subsetneq \infty$. More details can be found in [KS07].

The first statement of the following proposition was shown in [Ver96] (cf. [BMN02, Lemma 4.3]) for the case $\varrho = \infty$, but the proof generalizes immediately to general partitions ϱ. The second statement follows easily by using $Q_\varrho \mathrm{div} \mathbf{u}^{p_\varrho} = 0$.

PROPOSITION 5.6. *Let $\tau \supseteq \sigma$ and ϱ be partitions, let $r_\sigma \in \mathbb{P}_\sigma$ and $\mathbf{w}_\tau \in \mathbb{V}_\tau$, and let us assume that $\mathbf{f} \in \mathbb{V}_\tau^*$. Then*

$$\eta_T(\mathbf{f}, r_\sigma, \mathbf{w}_\tau) \lesssim \sum_{\tilde{T} \in \mathcal{F}_\tau(T)} \left[|\mathbf{u}^{p_\varrho} - \mathbf{w}_\tau|^2_{H^1(\tilde{T})^d} + \|p_\varrho - r_\sigma\|^2_{L_2(\tilde{T})^d} \right] \quad (T \in \tau)$$

and

$$c_4 \mathcal{E}^{\mathrm{S}}(\varrho, \tau, \mathbf{f}, r_\sigma, \mathbf{w}_\tau) \leq \|\mathbf{u}^{p_\varrho} - \mathbf{w}_\tau\|_{\mathbb{V}} + \|p_\varrho - r_\sigma\|_{\mathbb{P}}$$

for some absolute constant $c_4 > 0$.

The last result in this subsection provides an a posteriori error estimator for the outer elliptic problem.

PROPOSITION 5.7. *For a partition ϱ, and for $r \in \mathbb{P}$, we have*

$$c_6 \|Q_\varrho \mathrm{div} \mathbf{u}^r\|_{L_2(\Omega)} \leq \|p_\varrho - r\|_{\mathbb{P}} \leq C_5 \|Q_\varrho \mathrm{div} \mathbf{u}^r\|_{L_2(\Omega)}$$

for some absolute constants $C_5, c_6 > 0$.

Proof. Use $\sup_{0 \neq \mathbf{v} \in \mathbb{V}} \frac{b(\mathbf{v}, p_\varrho - r)}{\|\mathbf{v}\|_{\mathbb{V}}} = \sup_{0 \neq \mathbf{v} \in \mathbb{V}} \frac{a(\mathbf{u}^r - \mathbf{u}^{p_\varrho}, \mathbf{v})}{\|\mathbf{v}\|_{\mathbb{V}}} = \|\mathbf{u}^{p_\varrho} - \mathbf{u}^r\|_{\mathbb{V}}$, and thus

$$\beta \leq \frac{\|\mathbf{u}^{p_\varrho} - \mathbf{u}^r\|_{\mathbb{V}}}{\|p_\varrho - r\|_{\mathbb{P}}} \leq 1, \tag{5.2}$$

and

$$\begin{aligned} &\|p_\varrho - r\|_{\mathbb{P}} + \|\mathbf{u}^{p_\varrho} - \mathbf{u}^r\|_{\mathbb{V}} \\ &\eqsim \sup_{0 \neq (\mathbf{v}, q_\varrho) \in \mathbb{V} \times \mathbb{P}_\varrho} \frac{a(\mathbf{u}^{p_\varrho} - \mathbf{u}^r, \mathbf{v}) + b(\mathbf{v}, p_\varrho - r) + b(\mathbf{u}^{p_\varrho} - \mathbf{u}^r, q_\varrho)}{\|\mathbf{v}\|_{\mathbb{V}} + \|q_\varrho\|_{\mathbb{P}}} \\ &= \|Q_\varrho \mathrm{div} \mathbf{u}^r\|_{L_2(\Omega)}. \qquad \square \end{aligned}$$

Clearly, the evaluation of this estimator $\|Q_\varrho \mathrm{div} \mathbf{u}^r\|_{L_2(\Omega)}$ is not feasible, and so later $\mathbf{u}^r$ will be replaced by an approximation.

6. Adaptive refinements resulting in error reduction. For both elliptic problems $Sp = BA^{-1}f$ and $a(\mathbf{u}^r, \mathbf{v}) = \mathbf{f}(\mathbf{v}) - b(\mathbf{v}, r)$ $(\mathbf{v} \in \mathbb{V})$, the latter for some given $r \in \mathbb{P}$, we construct adaptive refinement routines based on the a posteriori error estimators. Given (approximate) Galerkin solutions from $\mathbb{P}_\sigma$ or $\mathbb{V}_\tau$, respectively, they produce refinements $\tilde{\sigma} \supset \sigma$ or $\tilde{\tau} \supset \tau$ such that the Galerkin solutions with respect to these partitions have strictly smaller errors. Moreover, we will give bounds on the number of refined simplices which eventually will lead to the conclusion that our adaptive Stokes solver generates quasi-optimal partitions.

6.1. Adaptive pressure refinements. With C_5, c_6 being the constants from Proposition 5.7, for some absolute constants

$$d \in \left(1 - \frac{c_6^2}{C_5^2}, 1\right], \quad \theta \in \left(0, \left[1 - \frac{1 - c_6^2/C_5^2}{d}\right]^{\frac{1}{2}}\right), \quad D \geq 1, \tag{6.1}$$

we assume that we have the following routine available. We think of its argument $\mathbf{w}$ as being an approximation to $\mathbf{u}^{r_\sigma}$, where r_σ is some approximation to p from $\mathbb{P}_\sigma$.

REFpres$[\sigma, \mathbf{w}] \to \tilde{\sigma}$
% σ is a partition and $\mathbf{w} \in \mathbb{V}$.
Select a partition $\tilde{\sigma} \supseteq \sigma$ with

$$\|Q_{\tilde{\sigma}} \mathrm{div}\mathbf{w}\|_{L_2(\Omega)} \geq \theta \|\mathrm{div}\mathbf{w}\|_{L_2(\Omega)}, \tag{6.2}$$

such that

$$\#\tilde{\sigma} - \#\sigma \leq D(\#\breve{\sigma} - \#\sigma)$$

for any $\breve{\sigma} \supseteq \sigma$ with

$$\|Q_{\breve{\sigma}} \mathrm{div}\mathbf{w}\|_{L_2(\Omega)} \geq \sqrt{1 - d(1 - \theta^2)} \|\mathrm{div}\mathbf{w}\|_{L_2(\Omega)}. \tag{6.3}$$

Remark 6.1. Eventually, we will make calls $\tilde{\sigma} := \mathbf{REFpres}[\sigma, \mathbf{w}]$ only for the argument $\mathbf{w}$ from $\mathbb{V}_\tau$ for some $\tau \supseteq \sigma$. Since then $\mathrm{div}\mathbf{w} \in \mathbb{P}_\tau$, in those cases we may always assume that $\sigma \subseteq \tilde{\sigma} \subseteq \tau$. The fact that the partition underlying the pressure approximation is always contained in or equal to that underlying the velocity approximation will be essential for the forthcoming adaptive refinement routine for reducing the error in the inner elliptic problem.

The benefit of **REFpres** can be seen from the following two lemmas.

LEMMA 6.2. *Let σ be a partition, and let $r_\sigma \in \mathbb{P}_\sigma$. Then for $\tilde{\sigma} = \mathbf{REFpres}[\sigma, \mathbf{u}^{r_\sigma}]$, we have*

$$\|p - p_{\tilde{\sigma}}\|_{\mathbb{P}} \leq \left[1 - \tfrac{c_6^2 \theta^2}{C_5^2}\right]^{\frac{1}{2}} \|p - r_\sigma\|_{\mathbb{P}}.$$

Moreover,

$$\#\tilde{\sigma} - \#\sigma \leq D[\#\bar{\sigma} - \#\tau_0]$$

for any *partition $\bar{\sigma}$ for which*

$$\inf_{q_{\bar{\sigma}} \in \mathbb{P}_{\bar{\sigma}}} \|p - q_{\bar{\sigma}}\|_{\mathbb{P}} \leq \left[1 - \tfrac{C_5^2}{c_6^2}(1 - d(1 - \theta^2))\right]^{\frac{1}{2}} \|p - r_\sigma\|_{\mathbb{P}}. \tag{6.4}$$

(Note that (6.1) implies that $\frac{C_5^2}{c_6^2}(1 - d(1 - \theta^2)) < 1$.)

Proof. Recall that $p_{\tilde\sigma}$ denotes the solution of a reduced Stokes problem, i.e., it is the best approximation to p from $\mathbb{P}_{\tilde\sigma}$ with respect to $\|\cdot\|_{\mathbb{P}}$. Therefore, the first statement follows from

$$\|p-r_\sigma\|_{\mathbb{P}}^2=\|p-p_{\tilde\sigma}\|_{\mathbb{P}}^2+\|p_{\tilde\sigma}-r_\sigma\|_{\mathbb{P}}^2$$

and $\|p_{\tilde\sigma}-r_\sigma\|_{\mathbb{P}}\ge c_6\|Q_{\tilde\sigma}\mathrm{div}\mathbf{u}^{r_\sigma}\|_{L_2(\Omega)}\ge c_6\theta\|\mathrm{div}\mathbf{u}^{r_\sigma}\|_{L_2(\Omega)}\ge\frac{c_6\theta}{C_5}\|p-r_\sigma\|_{\mathbb{P}}$ by Proposition 5.7.

For a $\bar\sigma$ satisfying (6.4), let $\breve\sigma=\sigma\cup\bar\sigma$. Then from $\|p-p_{\breve\sigma}\|_{\mathbb{P}}\le\inf_{q_{\bar\sigma}\in\mathbb{P}_{\bar\sigma}}\|p-q_{\bar\sigma}\|_{\mathbb{P}}$ and Proposition 5.7, with $\lambda:=\frac{C_5^2}{c_6^2}(1-d(1-\theta^2))$ we have

$$\begin{aligned}C_5^2\|Q_{\breve\sigma}\mathrm{div}\mathbf{u}^{r_\sigma}\|_{L_2(\Omega)}^2&\ge\|p_{\breve\sigma}-r_\sigma\|_{\mathbb{P}}^2=\|p-r_\sigma\|_{\mathbb{P}}^2-\|p-p_{\breve\sigma}\|_{\mathbb{P}}^2\\&\ge\lambda\|p-r_\sigma\|_{\mathbb{P}}^2\ge\lambda c_6^2\|\mathrm{div}\mathbf{u}^{r_\sigma}\|_{L_2(\Omega)}^2.\end{aligned}$$

Noting that $\frac{\lambda c_6^2}{C_5^2}=1-d(1-\theta^2)$, by construction of $\tilde\sigma$, we conclude that

$$\#\tilde\sigma-\#\sigma\le D[\#\breve\sigma-\#\sigma]\le D[\#\bar\sigma-\#\tau_0].\qquad\square$$

Now we generalize Lemma 6.2 to the practical relevant situation in which only an approximation to $\mathbf{u}^{r_\sigma}$ is available.

LEMMA 6.3. *Let $\omega\in(0,\theta)$ be a constant, let σ be a partition, let $r_\sigma\in\mathbb{P}_\sigma$, and let $\mathbf{w}\in\mathbb{V}$ with*

$$\|\mathrm{div}\mathbf{u}^{r_\sigma}-\mathrm{div}\mathbf{w}\|_{L_2(\Omega)}\le\omega\|\mathrm{div}\mathbf{w}\|_{L_2(\Omega)}.$$

Then for $\tilde\sigma=\mathbf{REFpres}[\sigma,\mathbf{w}]$, we have

$$\|p-p_{\tilde\sigma}\|_{\mathbb{P}}\le\big[1-\tfrac{c_6^2(\theta-\omega)^2}{C_5^2(1+\omega)^2}\big]^{\frac12}\|p-r_\sigma\|_{\mathbb{P}}.$$

Moreover, if ω is sufficiently small such that $\frac{\omega+\sqrt{1-d(1-\theta^2)}}{1-\omega}<\frac{c_6}{C_5}$, then

$$\#\tilde\sigma-\#\sigma\le D[\#\bar\sigma-\#\tau_0]$$

for any *partition $\bar\sigma$ for which, with $\xi:=\big[1-\big(\frac{\omega+\sqrt{1-d(1-\theta^2)}}{1-\omega}\frac{C_5}{c_6}\big)^2\big]^{\frac12}$,*

$$\inf_{q_{\bar\sigma}\in\mathbb{P}_{\bar\sigma}}\|p-q_{\bar\sigma}\|_{\mathbb{P}}\le\xi\|p-r_\sigma\|_{\mathbb{P}}.\tag{6.5}$$

Proof. The proof is similar to that of Lemma 6.2. For the first part use that

$$\|Q_{\tilde\sigma}\mathrm{div}\mathbf{u}^{r_\sigma}\|_{L_2(\Omega)}\ge\|Q_{\tilde\sigma}\mathrm{div}\mathbf{w}\|_{L_2(\Omega)}-\omega\|\mathrm{div}\mathbf{w}\|_{L_2(\Omega)}\ge\tfrac{\theta-\omega}{1+\omega}\|\mathrm{div}\mathbf{u}^{r_\sigma}\|_{L_2(\Omega)},$$

and, for the second part, with any $\bar\sigma$ satisfying (6.5) and $\breve\sigma=\sigma\cup\bar\sigma$, that

$$\begin{aligned}&C_5[\|Q_{\breve\sigma}\mathrm{div}\mathbf{w}\|_{L_2(\Omega)}+\omega\|\mathrm{div}\mathbf{w}\|_{L_2(\Omega)}]\ge C_5\|Q_{\breve\sigma}\mathrm{div}\mathbf{u}^{r_\sigma}\|_{L_2(\Omega)}\ge\|p_{\breve\sigma}-r_\sigma\|_{\mathbb{P}}\\&=\big[\|p-r_\sigma\|_{\mathbb{P}}^2-\|p-p_{\breve\sigma}\|_{\mathbb{P}}^2\big]^{\frac12}\ge\sqrt{1-\xi^2}\|p-r_\sigma\|_{\mathbb{P}}\ge c_6\sqrt{1-\xi^2}\|\mathrm{div}\mathbf{u}^{r_\sigma}\|_{L_2(\Omega)}\\&\ge(1-\omega)c_6\sqrt{1-\xi^2}\|\mathrm{div}\mathbf{w}\|_{L_2(\Omega)},\end{aligned}$$

or, equivalently, $\|Q_{\breve\sigma}\mathrm{div}\mathbf{w}\|_{L_2(\Omega)}\ge\sqrt{1-d(1-\theta^2)}\|\mathrm{div}\mathbf{w}\|_{L_2(\Omega)}$. $\square$

As mentioned previously, we will make calls $\tilde{\sigma} := \mathbf{REFpres}[\sigma, \mathbf{w}]$ only for the argument $\mathbf{w}$ from $\mathbb{V}_\tau$ for some $\tau \supseteq \sigma$, so that $\mathrm{div}\mathbf{w} \in \mathbb{P}_\tau$. Obviously, if **REFpres** is implemented as the selection for some $\theta \in (0, c_6/C_5)$ of the *smallest* partition $\tilde{\sigma} \supseteq \sigma$ such that (6.2) is valid, it satisfies its requirements with $d = 1 = D$. Yet, at least a naive implementation of this algorithm would require computing $\|Q_{\breve{\sigma}}\mathrm{div}\mathbf{w}\|_{L_2(\Omega)}$ for all partitions $\sigma \subsetneq \breve{\sigma} \subsetneq \tau$, which is prohibitively expensive.

Recalling that any partition corresponds to a subtree of the infinite binary master tree $\mathcal{T}_*$ that is determined by the initial partition τ_0, alternatively one may apply an adaptive tree approximation algorithm from [BD04]. Note that (6.2) and (6.3) are equivalent to $\|(I-Q_{\tilde{\sigma}})\mathrm{div}\mathbf{w}\|_{L_2(\Omega)} \leq \sqrt{1-\theta^2}\,\|\mathrm{div}\mathbf{w}\|_{L_2(\Omega)}$ and $\|(I-Q_{\breve{\sigma}})\mathrm{div}\mathbf{w}\|_{L_2(\Omega)} \leq \sqrt{d}\sqrt{1-\theta^2}\,\|\mathrm{div}\mathbf{w}\|_{L_2(\Omega)}$, respectively. Prescribing a $\theta \in (0, c_6/C_5)$, a call of the *thresholding second algorithm* starting with initial partition σ, "error functional" $e(T) = \inf_{q\in P_{m-1}(T)} \|(\mathrm{div}\mathbf{w})|_T - q\|^2_{L_2(T)}$ $(T \in \mathcal{T}_*)$, and tolerance $(1-\theta^2)\|\mathrm{div}\mathbf{w}\|^2_{L_2(\Omega)}$ fulfills the requirements on **REFpres** for any given $d < 1$ and $D := D(d) < \infty$, independent of σ, and thus for d, θ, D as in (6.1). This was demonstrated to the authors by Binev [Bin07], using the properties of $\mathcal{T}_*$ being a binary tree and $e(T) \geq e(T_1) + e(T_2)$ whenever $T_1 \cup T_2 = T$. (The proof of [BD04, Corollary 5.4] shows the properties mentioned in **REFpres** for some specific constants $d < 1 < D$ that might not fulfill the conditions from (6.1).) After precomputing the values $e(T)$ for any simplex T from any partition $\sigma \subsetneq \breve{\sigma} \subsetneq \tau$, which can be done in $\mathcal{O}(\#\tau)$ operations, this algorithm produces $\tilde{\sigma}$ as in (6.2) in $\mathcal{O}(\#\tilde{\sigma})$ additional operations. With this implementation of **REFpres** we thus have that for $\sigma \subseteq \tau$ and $\mathbf{w} \in \mathbb{V}_\tau$, the call $\mathbf{REFpres}[\sigma, \mathbf{w}]$ takes $\mathcal{O}(\#\tau)$ operations.

6.2. Adaptive velocity refinements. For some *fixed*

$$\zeta \in \left(0, \frac{c_2}{C_1}\right),$$

we will make use of the following routine to determine a suitable adaptive refinement for an update of the velocity:

$\mathbf{REFvel}[\tau, \mathbf{g}, r_\sigma, \mathbf{w}_\tau] \to \tilde{\tau}$
% τ is a partition, $\mathbf{g} \in L_2(\Omega)^d$, $r_\sigma \in \mathbb{P}_\sigma$ for some $\sigma \subseteq \tau$, and $\mathbf{w}_\tau \in \mathbb{V}_\tau$.
Select a set $\underline{F} \subset \tau$ with, up to some absolute factor, minimal cardinality *such that*

$$\sum_{T\in\underline{F}} \eta_T(\mathbf{g}, r_\sigma, \mathbf{w}_\tau) \geq \zeta^2\, \mathcal{E}^{\mathrm{E}}(\tau, \mathbf{g}, r_\sigma, \mathbf{w}_\tau)^2. \tag{6.6}$$

Construct the smallest $\tilde{\tau} \supset \tau$ which is a full refinement with respect to all $T \in \underline{F}$.

The next lemma will show the benefit of **REFvel**. It applies under the (unrealistic) assumptions that $\mathbf{f} \in \mathbb{V}^*_\tau$ and that the Galerkin problems are solved exactly. In Lemma 8.2, inexact Galerkin solutions will be allowed, and the given right-hand side $\mathbf{f} \in \mathbb{V}'$ will be replaced by approximations from $\mathbb{V}^*_\tau$ and $\mathbb{V}^*_{\tilde{\tau}}$, respectively.

Note that when $\mathbf{f} \in \mathbb{V}^*_\tau$, the computation of all $\eta_T(\mathbf{f}, r_\tau, \mathbf{w}_\tau)$ $(T \in \tau)$ can be done in $\mathcal{O}(\#\tau)$ operations. By doing an *approximate* sorting of the $\eta_T(\mathbf{f}_\tau, r_\tau, \mathbf{w}_\tau)$ by their values, $\mathbf{REFvel}[\tau, \mathbf{f}, \cdot, \cdot]$ can be implemented in $\mathcal{O}(\#\tau)$ operations (cf. [Ste07]).

LEMMA 6.4. *Let $\tau \supseteq \sigma$ be partitions, let $\mathbf{f} \in \mathbb{V}^*_\tau$, and let $r_\sigma \in \mathbb{P}_\sigma$. Then for $\tilde{\tau} = \mathbf{REFvel}[\tau, \mathbf{f}, r_\sigma, \mathbf{u}^{r_\sigma}_\tau]$, we have*

$$\|\mathbf{u}^{r_\sigma} - \mathbf{u}^{r_\sigma}_{\tilde{\tau}}\|_{\mathbb{V}} \leq \left[1 - \tfrac{c_2^2\zeta^2}{C_1^2}\right]^{\frac{1}{2}} \|\mathbf{u}^{r_\sigma} - \mathbf{u}^{r_\sigma}_{\tau}\|_{\mathbb{V}}.$$

Moreover, if $\zeta < \frac{c_2}{C_1}$*, and, for some absolute constant* $\vartheta > 0$*,*

$$\|\mathbf{u}^{r_\sigma} - \mathbf{u}_\tau^{r_\sigma}\|_{\mathbb{V}} \geq \vartheta \|\mathbf{u} - \mathbf{u}^{r_\sigma}\|_{\mathbb{V}}, \tag{6.7}$$

then for the set of marked simplices $\underline{F}$ *inside* **REFvel***, we have*

$$\#\underline{F} \lesssim \#\bar{\tau} + \#\bar{\sigma} + \#\sigma \tag{6.8}$$

for any partitions $\bar{\tau}$ *and* $\bar{\sigma}$ *for which*

$$\inf_{\mathbf{v}_{\bar{\tau}} \in \mathbb{V}_{\bar{\tau}}} \|\mathbf{u} - \mathbf{v}_{\bar{\tau}}\|_{\mathbb{V}} \leq \tfrac{1}{3}\big[1 - \tfrac{C_1^2\zeta^2}{c_2^2}\big]^{\frac{1}{2}} \|\mathbf{u}^{r_\sigma} - \mathbf{u}_\tau^{r_\sigma}\|_{\mathbb{V}}, \tag{6.9}$$

$$\inf_{q_{\bar{\sigma}} \in \mathbb{P}_{\bar{\sigma}}} \|p - q_{\bar{\sigma}}\|_{\mathbb{V}} \leq \tfrac{1}{3}\big[1 - \tfrac{C_1^2\zeta^2}{c_2^2}\big]^{\frac{1}{2}} \|\mathbf{u}^{r_\sigma} - \mathbf{u}_\tau^{r_\sigma}\|_{\mathbb{V}}. \tag{6.10}$$

Remark 6.5. Note that the bound on $\#\underline{F}$ in terms of $\mathbf{u}$ and p (via $\bar{\tau}$ and $\bar{\sigma}$) and σ can be shown only when (the variational formulation of) $-\triangle \mathbf{u}^{r_\sigma} = \mathbf{f} - \nabla r^\sigma$ is *solved not too accurately*, a restriction imposed by (6.7). This will be enforced by a timely stopping of the AFEM for solving this elliptic problem guided by a posteriori error estimators (cf. (7.20)). By assuming that $\mathbf{u}$ and p are in certain approximation classes, i.e., that these functions *can* be approximated with certain rates by finite element functions with respect to the *best partitions*, later we will derive quasi-optimal bounds for $\#\bar{\tau}$ and $\#\bar{\sigma}$, as well as for $\#\sigma$ via Lemma 6.3, and so in the end on $\#\underline{F}$. Without imposing (6.7), we would arrive at a similar bound on $\#\underline{F}$ only when we would assume that all approximations $\mathbf{u}^{r_\sigma}$ to $\mathbf{u}$ corresponding to all approximate pressures r_σ that are created in the adaptive method are similarly easy to approximate as $\mathbf{u}$ itself, which is an unverifiable assumption.

Proof. The first statement follows from

$$\|\mathbf{u}^{r_\sigma} - \mathbf{u}_\tau^{r_\sigma}\|_{\mathbb{V}}^2 = \|\mathbf{u}^{r_\sigma} - \mathbf{u}_{\tilde{\tau}}^{r_\sigma}\|_{\mathbb{V}}^2 + \|\mathbf{u}_{\tilde{\tau}}^{r_\sigma} - \mathbf{u}_\tau^{r_\sigma}\|_{\mathbb{V}}^2,$$

and $\|\mathbf{u}_{\tilde{\tau}}^{r_\sigma} - \mathbf{u}_\tau^{r_\sigma}\|_{\mathbb{V}} \geq c_2\zeta\mathcal{E}^{\mathrm{E}}(\tau, \mathbf{f}, r_\sigma, \mathbf{u}_\tau^{r_\sigma}) \geq \frac{c_2\zeta}{C_1}\|\mathbf{u}^{r_\sigma} - \mathbf{u}_\tau^{r_\sigma}\|_{\mathbb{V}}$ by Corollary 5.3 and Proposition 5.1.

Let $\hat{\tau}$ be a partition for which

$$\inf_{\mathbf{v}_{\hat{\tau}} \in \mathbb{V}_{\hat{\tau}}} \|\mathbf{u}^{r_\sigma} - \mathbf{v}_{\hat{\tau}}\|_{\mathbb{V}} \leq \big[1 - \tfrac{C_1^2\zeta^2}{c_2^2}\big]^{\frac{1}{2}} \|\mathbf{u}^{r_\sigma} - \mathbf{u}_\tau^{r_\sigma}\|_{\mathbb{V}}, \tag{6.11}$$

and let $\breve{\tau} = \tau \cup \hat{\tau}$. Then with $\overline{F} = \overline{F}(\tau, \breve{\tau})$ from Proposition 5.1, we have

$$\begin{aligned} C_1^2 \sum_{T \in \overline{F}} \eta_T(\mathbf{f}, r_\sigma, \mathbf{u}_\tau^{r_\sigma}) &\geq \|\mathbf{u}_{\breve{\tau}}^{r_\sigma} - \mathbf{u}_\tau^{r_\sigma}\|_{\mathbb{V}}^2 = \|\mathbf{u}^{r_\sigma} - \mathbf{u}_\tau^{r_\sigma}\|_{\mathbb{V}}^2 - \|\mathbf{u}^{r_\sigma} - \mathbf{u}_{\breve{\tau}}^{r_\sigma}\|_{\mathbb{V}}^2 \\ &\geq \tfrac{C_1^2\zeta^2}{c_2^2}\|\mathbf{u}^{r_\sigma} - \mathbf{u}_\tau^{r_\sigma}\|_{\mathbb{V}}^2 \geq C_1^2\zeta^2\mathcal{E}^{\mathrm{E}}(\tau, \mathbf{f}, r_\sigma, \mathbf{u}_\tau^{r_\sigma})^2. \end{aligned}$$

By construction of $\underline{F}$, we infer that

$$\#\underline{F} \lesssim \overline{F} \lesssim \#\breve{\tau} - \#\tau \leq \#\hat{\tau} - \#\tau_0. \tag{6.12}$$

It remains to bound $\#\hat{\tau} - \#\tau_0$ for a $\hat{\tau}$ as in (6.11). With $\bar{\sigma}$ as in (6.10), we write $\mathbf{u}^{r_\sigma} = (\mathbf{u}^{r_\sigma} - \mathbf{u}^{p_{\bar{\sigma}}}) + (\mathbf{u}^{p_{\bar{\sigma}}} - \mathbf{u}) + \mathbf{u}$ and approximate each of the three terms within

tolerance $\frac{1}{3}\big[1-\frac{C_1^2\zeta^2}{c_2^2}\big]^{\frac{1}{2}}$ with finite element functions (the second one with zero). From (5.2), we have

$$\|\mathbf{u}-\mathbf{u}^{p_{\bar\sigma}}\|_{\mathbb{V}} \le \|p-p_{\bar\sigma}\|_{\mathbb{P}} \le \tfrac{1}{3}\big[1-\tfrac{C_1^2\zeta^2}{c_2^2}\big]^{\frac{1}{2}}\|\mathbf{u}^{r_\sigma}-\mathbf{u}_\tau^{r_\sigma}\|_{\mathbb{V}}.$$

The vector field $\mathbf{w}=\mathbf{u}^{r_\sigma}-\mathbf{u}^{p_{\bar\sigma}}$ solves

$$a(\mathbf{w},\mathbf{v}) = -b(\mathbf{v}, r_\sigma - p_{\bar\sigma}) \quad (\mathbf{v}\in\mathbb{V}).$$

With $\hat\sigma=\sigma\cup\bar\sigma$, the error in its best approximation $\mathbf{w}_{\hat\sigma}$ from $\mathbb{V}_{\hat\sigma}$ can be bounded by

$$\begin{aligned}\|\mathbf{w}-\mathbf{w}_{\hat\sigma}\|_{\mathbb{V}} \le \|\mathbf{w}\|_{\mathbb{V}} &\le \|\mathbf{u}^{r_\sigma}-\mathbf{u}\|_{\mathbb{V}} + \|\mathbf{u}-\mathbf{u}^{p_{\bar\sigma}}\|_{\mathbb{V}}\\ &\le \left(\vartheta^{-1}+\frac{1}{3}\left[1-\frac{C_1^2\zeta^2}{c_2^2}\right]^{\frac{1}{2}}\right)\|\mathbf{u}^{r_\sigma}-\mathbf{u}_\tau^{r_\sigma}\|_{\mathbb{V}}.\end{aligned}$$

With $\hat\sigma_0=\hat\sigma$, for $k=1,2,\dots$ let $\hat\sigma_k\supset\hat\sigma_{k-1}$ be the smallest partition that is a full refinement with respect to all $T\in\hat\sigma_{k-1}$. Then using the fact that $r_\sigma-p_{\bar\sigma}\in\mathbb{P}_{\hat\sigma_0}$, as in the first part of this lemma, now with $\zeta=1$, we have $\|\mathbf{w}-\mathbf{w}_{\hat\sigma_k}\|_{\mathbb{V}} \le \big[1-\frac{C_1^2}{c_2^2}\big]^{\frac{k}{2}}\|\mathbf{w}-\mathbf{w}_{\hat\sigma}\|_{\mathbb{V}}$, where $\mathbf{w}_{\hat\sigma_k}$ denotes the best approximation to $\mathbf{w}$ from $\mathbb{V}_{\sigma_k}$. With k being the smallest integer with $\big[1-\frac{C_1^2}{c_2^2}\big]^{\frac{k}{2}}\big(\vartheta^{-1}+\frac{1}{3}\big[1-\frac{C_1^2\zeta^2}{c_2^2}\big]^{\frac{1}{2}}\big) \le \frac{1}{3}\big[1-\frac{C_1^2\zeta^2}{c_2^2}\big]^{\frac{1}{2}}$, we conclude that

$$\begin{aligned}\inf_{\mathbf{v}_{\bar\tau}\in\mathbb{V}_{\bar\tau}}\|\mathbf{u}^{r_\sigma}-(\mathbf{v}_{\bar\tau}+\mathbf{w}_{\hat\sigma_k})\|_{\mathbb{V}} &\le \|\mathbf{u}^{r_\sigma}-\mathbf{u}^{p_{\bar\sigma}}-\mathbf{w}_{\hat\sigma_k}\|_{\mathbb{V}} + \|\mathbf{u}^{p_{\bar\sigma}}-\mathbf{u}\|_{\mathbb{V}} + \inf_{\mathbf{v}_{\bar\tau}\in\mathbb{V}_{\bar\tau}}\|\mathbf{u}-\mathbf{v}_{\bar\tau}\|_{\mathbb{V}}\\ &\le \big[1-\tfrac{C_1^2\zeta^2}{c_2^2}\big]^{\frac{1}{2}}\|\mathbf{u}^{r_\sigma}-\mathbf{u}_\tau^{r_\sigma}\|_{\mathbb{V}}.\end{aligned}$$

Since $\mathbf{v}_{\bar\tau}+\mathbf{w}_{\hat\sigma_k}\in\mathbb{V}_{\bar\tau\cup\hat\sigma_k}$, and $\#(\bar\tau\cup\hat\sigma_k)-\#\tau_0 \lesssim \#\bar\tau+\#\bar\sigma+\#\sigma$ (dependent on k and thus on ϑ), in view of (6.11) and (6.12) the proof is complete. ∎

Remark 6.6. If in (6.7) $\vartheta > \big[1-\frac{C_1^2\zeta^2}{c_2^2}\big]^{-\frac{1}{2}}$, then by a simplification of the above proof, instead of (6.8), one obtains that

$$\#\underline{F} \lesssim \#\bar\tau - \#\tau_0$$

for any $\bar\tau$ with

$$\inf_{\mathbf{v}_{\bar\tau}\in\mathbb{V}_{\bar\tau}}\|\mathbf{u}-\mathbf{v}_{\bar\tau}\|_{\mathbb{V}} \le \big(\big[1-\tfrac{C_1^2\zeta^2}{c_2^2}\big]^{\frac{1}{2}}-\vartheta^{-1}\big)\|\mathbf{u}^{r_\sigma}-\mathbf{u}_\tau^{r_\sigma}\|_{\mathbb{V}},$$

which bound on $\#\underline{F}$ is in particular independent of the pressure p. It is, however, not clear whether under the condition $\|\mathbf{u}^{r_\sigma}-\mathbf{u}_\tau^{r_\sigma}\|_{\mathbb{V}} \ge \vartheta\|\mathbf{u}-\mathbf{u}^{r_\sigma}\|_{\mathbb{V}}$ for such ϑ the inner elliptic problem is solved with sufficient accuracy to obtain a convergent inexact Uzawa algorithm for solving the reduced Stokes problem of finding $(\mathbf{u}^{p_\sigma}, p_\sigma)$. Knowing that $\#\sigma$ is controlled in our outermost loop that produces Galerkin approximations to p, Lemma 6.4 provides a way to avoid the condition that $\vartheta > \big[1-\frac{C_1^2\zeta^2}{c_2^2}\big]^{-\frac{1}{2}}$. This point is the exact reason why we did not succeed in proving quasi-optimality of the Uzawa iteration for solving the full Stokes problem, i.e., without our outermost loop. Indeed, with that method there is no separate control over the partitions that underlie the pressure approximations.

7. An adaptive method for the Stokes problem in an idealized setting. For $s > 0$, we define the approximation class

$$\mathcal{A}^s_{\mathbb{V}} = \{\mathbf{v} \in \mathbb{V} : |\mathbf{v}|_{\mathcal{A}^s_{\mathbb{V}}} := \sup_{\varepsilon>0} \varepsilon \inf_{\{\tau:\inf_{\mathbf{v}_\tau\in\mathbb{V}_\tau}\|\mathbf{v}-\mathbf{v}_\tau\|_{\mathbb{V}}\le\varepsilon\}} [\#\tau - \#\tau_0]^s < \infty\}$$

and equip it with norm $\|\mathbf{v}\|_{\mathcal{A}^s_{\mathbb{V}}} := \|\mathbf{v}\|_{\mathbb{V}} + |\mathbf{v}|_{\mathcal{A}^s_{\mathbb{V}}}$. So $\mathcal{A}^s_{\mathbb{V}}$ is the class of vector fields that *can* be approximated within any given tolerance $\varepsilon > 0$ by a $\mathbf{v}_\tau \in \mathbb{V}_\tau$ for *some* partition τ with $\#\tau - \#\tau_0 \lesssim \varepsilon^{-1/s}|\mathbf{u}|^{1/s}_{\mathcal{A}^s_{\mathbb{V}}}$. Similarly, we define

$$\mathcal{A}^s_{\mathbb{P}} = \{q \in \mathbb{P} : |q|_{\mathcal{A}^s_{\mathbb{P}}} := \sup_{\varepsilon>0} \varepsilon \inf_{\{\sigma:\inf_{q_\sigma\in\mathbb{P}_\sigma}\|q-q_\sigma\|_{\mathbb{P}}\le\varepsilon\}} [\#\sigma - \#\tau_0]^s < \infty\}$$

and equip it with norm $\|q\|_{\mathcal{A}^s_{\mathbb{P}}} := \|q\|_{\mathbb{P}} + |q|_{\mathcal{A}^s_{\mathbb{P}}}$.

Because of the polynomial degrees of our approximations, only for $s \le m/d$ can membership of $\mathbf{u} \in \mathcal{A}^s_{\mathbb{V}}$ or $p \in \mathcal{A}^s_{\mathbb{P}}$ be enforced by imposing suitable smoothness conditions on $\mathbf{u}$ or p, respectively. These smoothness conditions, however, are much milder than requiring that $\mathbf{u} \in H^{1+sd}(\Omega)^d$ or $p \in H^{sd}(\Omega)$, which would be needed when only uniformly refined partitions were considered. The approximation classes can be (nearly) characterized as certain Besov spaces (see [BDDP02] for details). In any case for $d = 2$, polygonal domains, and sufficiently smooth $\mathbf{f}$, it is known (see [Dah99]) that $\mathbf{u}$ and p have sufficient Besov smoothness so that they are in $\mathcal{A}^s_{\mathbb{V}}$ or $\mathcal{A}^s_{\mathbb{P}}$ for any $s < m/d$, and thus also in the presence of reentrant corners.

The results derived in section 6.2 concerning adaptive velocity refinements were valid under the assumption that $\mathbf{f}$ was piecewise polynomial of degree $m-1$ with respect to the current partition. In order to make our exposition not too complicated, *in this section we will assume that* $\mathbf{f}$ *is piecewise polynomial of degree* $m-1$ *with respect to any partition that we encounter, i.e., that is in* $\mathbb{V}^*_{\tau_0}$. In the next section, we will remove this restriction. Furthermore, *in this section we assume that the arising finite-dimensional linear systems are solved exactly*, i.e., we do not care about the computational cost. In the next section, by applying iterative solvers, we will show quasi-optimal computational complexity.

The following algorithm is an implementation of the solution method that was announced in section 4 with the simplifications mentioned above. Note that the `do`-loop in the algorithm actually consists of 3 nested loops over i, j, and k. The loop over i concerns an adaptive method for solving p from the Schur complement equation. The loop over j concerns the Uzawa method for solving p^{σ_i} from the reduced Stokes problem. Finally, the loop over k concerns an adaptive finite element method for approximating the solution $\mathbf{u}^{p_j^{(i)}} \in \mathbb{V}$ of $a(\mathbf{u}^{p_j^{(i)}}, \mathbf{v}) = \mathbf{f}(\mathbf{v}) - b(\mathbf{v}, p_j^{(i)})$ $(\mathbf{v} \in \mathbb{V})$. We have formulated these loops as one loop to deal efficiently with the complicated stopping criteria. For example, the innermost one stops when either $\mathcal{E}^{\mathrm{E}}(\cdots) \le \alpha\mathcal{E}^{\mathrm{S}}(\sigma_i, \dots)$ or $\mathcal{E}^{\mathrm{S}}(\sigma_i, \dots) \le \kappa\mathcal{E}^{\mathrm{S}}(\infty, \dots)$ or $\mathcal{E}^{\mathrm{S}}(\infty, \dots) \le \varepsilon$, i.e., when either

$$\|\mathbf{u}^{p_j^{(i)}} - \mathbf{u}^{(i)}_{j,k}\|_{\mathbb{V}} \le C_1\alpha c_4^{-1}[\|p_{\sigma_i} - p_j^{(i)}\|_{\mathbb{P}} + \|\mathbf{u}^{p_{\sigma_i}} - \mathbf{u}^{(i)}_{j,k}\|_{\mathbb{V}}] \quad \text{or}$$

$$\|p^{\sigma_i} - p_j^{(i)}\|_{\mathbb{P}} + \|\mathbf{u}^{p_{\sigma_i}} - \mathbf{u}^{(i)}_{j,k}\|_{\mathbb{V}} \le C_3\kappa c_4^{-1}[\|p - p_j^{(i)}\|_{\mathbb{P}} + \|\mathbf{u} - \mathbf{u}^{(i)}_{j,k}\|_{\mathbb{V}}] \quad \text{or}$$

$$\|p - p_j^{(i)}\|_{\mathbb{P}} + \|\mathbf{u} - \mathbf{u}^{(i)}_{j,k}\|_{\mathbb{V}} \le \varepsilon.$$

STOKESSOLVE$_0[f,\varepsilon] \to [\sigma_j^{(i)}, p_j^{(i)}, \tau_{j,k}^{(i)}, \mathbf{u}_{j,k}^{(i)}]$
% For this preliminary version of the adaptive solver it is assumed
% that $f \in \mathbb{V}_{\tau_0}^*$.
% Let the parameter ζ *from* **REFvel** *satisfy* $\zeta \in (0, \frac{c_2}{C_1})$, *and* θ *from* **REFpres**
% satisfy $\theta \in (0, [1 - \frac{1-c_6^2/C_5^2}{d}]^{\frac{1}{2}})$. *For some* $\omega \in (0,\theta)$ *small enough such that*

`enddo`

THEOREM 7.1. (I) *Let* $\mathbf{f} \in \mathbb{V}_{\tau_0}^*$. *Then* $[\sigma_j^{(i)}, p_j^{(i)}, \tau_{j,k}^{(i)}, \mathbf{u}_{j,k}^{(i)}] := \mathbf{STOKESSOLVE}_0[f,\varepsilon]$ *terminates, and* $\|\mathbf{u} - \mathbf{u}_{j,k}^{(i)}\|_{\mathbb{V}} + \|p - p_j^{(i)}\|_{\mathbb{P}} \le \varepsilon$. (II) *If, for some* $s > 0$, $p \in \mathcal{A}_{\mathbb{P}}^{\mathbf{s}}$, *then* $\#\sigma_j^{(i)} - \#\tau_0 \lesssim \varepsilon^{-1/s}|p|_{\mathcal{A}_{\mathbb{P}}^{\mathbf{s}}}^{1/s}$, *dependent only on* τ_0, *and on* s *when it tends to* 0 *or infinity. If, in addition, for some* $\tilde{s} > 0$, $\mathbf{u} \in \mathcal{A}_{\mathbb{V}}^{\tilde{\mathbf{s}}}$, *then with* $\bar{s} = \min(s, \tilde{s})$, $\#\tau_{j,k}^{(i)} - \#\tau_0 \lesssim \varepsilon^{-1/\bar{s}}(\|p\|_{\mathcal{A}_{\mathbb{P}}^{\bar{\mathbf{s}}}}^{1/\bar{s}} + \|\mathbf{u}\|_{\mathcal{A}_{\mathbb{V}}^{\bar{\mathbf{s}}}}^{1/\bar{s}})$, *dependent only on* τ_0, *and on* $\bar{s}$ *when it tends to* 0 *or infinity.*

Remark 7.2. In view of the assumptions, note that generally $\#\sigma_j^{(i)} - \#\tau_0$ is at most a constant multiple larger than this expression for the *best partition* $\sigma_j^{(i)}$ giving rise to such an error in the pressure. Similarly, generally $\#\tau_{j,k}^{(i)} - \#\tau_0$ is at most a constant multiple larger than this expression for the *best partition* $\tau_{j,k}^{(i)}$ on which p and $\mathbf{u}$ can be approximated by piecewise polynomials of degree $m-1$, or continuous piecewise polynomials of degree m with errors less than or equal to ε in $\|\cdot\|_{\mathbb{P}}$ or $\|\cdot\|_{\mathbb{V}}$, respectively.

Proof. (I) Given i and j, $\underline{k} = \underline{k}(i,j)$ will denote the maximum value attained by k for those i and j. Given an i, $\underline{j} = \underline{j}(i)$ will denote the maximum value attained by j for that i, and $\underline{\underline{k}} = \underline{\underline{k}}(i) := \underline{k}(i, \underline{j}(i))$ is the the maximum value attained by k for that i. Finally, $\underline{\underline{i}}$ will denote the maximum value attained by i.

At the moment $C_3\mathcal{E}^{\mathrm{S}}(\infty,\tau^{(i)}_{j,k},\mathbf{f},p^{(i)}_j,\mathbf{u}^{(i)}_{j,k})\le\varepsilon$ is passed, i.e., the loop over i, and thus the algorithm terminates, then, by definition $(i,j,k)=(\underline{i},\underline{j}(\underline{i}),\underline{\underline{k}}(\underline{i}))$, and we have $\|\mathbf{u}-\mathbf{u}^{(\underline{i})}_{\underline{j},\underline{\underline{k}}}\|_{\mathbb{V}}+\|p-p^{(\underline{i})}_{\underline{j}}\|_{\mathbb{P}}\le\varepsilon$ by Proposition 5.5. Next, we show that indeed the loop over i terminates. In doing so, we first assume that each inner loop over j terminates, which will be shown afterwards.

The inequality $\mathcal{E}^{\mathrm{S}}(\sigma_i,\tau^{(i)}_{j,k},\mathbf{f},p^{(i)}_j,\mathbf{u}^{(i)}_{j,k})\le\kappa\mathcal{E}^{\mathrm{S}}(\infty,\tau^{(i)}_{j,k},\mathbf{f},p^{(i)}_j,\mathbf{u}^{(i)}_{j,k})$ is equivalent to $\mathcal{E}^{\mathrm{E}}(\tau^{(i)}_{j,k},\mathbf{f},p^{(i)}_j,\mathbf{u}^{(i)}_{j,k})\le(1-\kappa)^{-1}(\kappa\|\mathrm{div}\mathbf{u}^{(i)}_{j,k}\|_{L_2(\Omega)}-\|Q_{\sigma_i}\mathrm{div}\mathbf{u}^{(i)}_{j,k}\|_{L_2(\Omega)})$. So at the moment that this test is passed, i.e., a loop over j terminates, then by definition $(j,k)=(\underline{j}(i),\underline{\underline{k}}(i))$, and by Propositions 5.1, 5.6, and 5.5,

$$C_1^{-1}\|\mathbf{u}^{p^{(i)}_{\underline{j}}}-\mathbf{u}^{(i)}_{\underline{j},\underline{\underline{k}}}\|_{\mathbb{V}}\le\mathcal{E}^{\mathrm{E}}(\tau^{(i)}_{\underline{j},\underline{\underline{k}}},\mathbf{f},p^{(i)}_{\underline{j}},\mathbf{u}^{(i)}_{\underline{j},\underline{\underline{k}}})\le\tfrac{\kappa}{1-\kappa}\|\mathrm{div}\mathbf{u}^{(i)}_{\underline{j},\underline{\underline{k}}}\|_{L_2(\Omega)},\tag{7.1}$$

$$C_1^{-1}\|\mathbf{u}^{p^{(i)}_{\underline{j}}}-\mathbf{u}^{(i)}_{\underline{j},\underline{\underline{k}}}\|_{\mathbb{V}}\le\kappa c_4^{-1}(\|\mathbf{u}-\mathbf{u}^{(i)}_{\underline{j},\underline{\underline{k}}}\|_{\mathbb{V}}+\|p-p^{(i)}_{\underline{j}}\|_{\mathbb{P}}),\tag{7.2}$$

$$C_3^{-1}\|p_{\sigma_i}-p^{(i)}_{\underline{j}}\|_{\mathbb{P}}\le\kappa c_4^{-1}(\|\mathbf{u}-\mathbf{u}^{(i)}_{\underline{j},\underline{\underline{k}}}\|_{\mathbb{V}}+\|p-p^{(i)}_{\underline{j}}\|_{\mathbb{P}}).\tag{7.3}$$

Furthermore, by (7.2), $\kappa\le c_4C_1^{-1}$, and (5.2), we have

$$\begin{aligned}\boxed{\|\mathbf{u}-\mathbf{u}^{(i)}_{\underline{j},\underline{\underline{k}}}\|_{\mathbb{V}}}&\le\|\mathbf{u}-\mathbf{u}^{p^{(i)}_{\underline{j}}}\|_{\mathbb{V}}+\tfrac{\kappa C_1}{c_4-\kappa C_1}(\|\mathbf{u}-\mathbf{u}^{p^{(i)}_{\underline{j}}}\|_{\mathbb{V}}+\|p-p^{(i)}_{\underline{j}}\|_{\mathbb{P}})\\&\le\boxed{\tfrac{c_4+\kappa C_1}{c_4-\kappa C_1}\|p-p^{(i)}_{\underline{j}}\|_{\mathbb{P}}},\end{aligned}\tag{7.4}$$

and so by (7.3),

$$\|p_{\sigma_i}-p^{(i)}_{\underline{j}}\|_{\mathbb{P}}\le\tfrac{2\kappa C_3}{c_4-\kappa C_1}\|p-p^{(i)}_{\underline{j}}\|_{\mathbb{P}}.\tag{7.5}$$

By (7.1), by $\|\mathrm{div}\cdot\|_{L_2(\Omega)}\le\|\cdot\|_{\mathbb{V}}$ on $\mathbb{V}$, and by $C_1\frac{\kappa}{1-\kappa}\le\omega$, Lemma 6.3 shows that for the output σ_{i+1} of the routine **REFpres** called subsequently, it holds that

$$\|p-p_{\sigma_{i+1}}\|_{\mathbb{P}}\le\big[1-\tfrac{c_6^2(\theta-\omega)^2}{C_5^2(1+\omega)^2}\big]^{\frac12}\|p-p^{(i)}_{\underline{j}}\|_{\mathbb{P}}.\tag{7.6}$$

Furthermore, since $\frac{\omega+\sqrt{1-d(1-\theta^2)}}{1-\omega}<\frac{c_6}{C_5}$ and in view of the definition of $\mathcal{A}^s_{\mathbb{P}}$, we have that

$$\#\sigma_{i+1}-\#\sigma_i\lesssim\|p-p^{(i)}_{\underline{j}}\|_{\mathbb{P}}^{-1/s}|p|^{1/s}_{\mathcal{A}^s_{\mathbb{P}}},\tag{7.7}$$

which will be used in the second part of the proof. Concerning (7.6), it is not $p_{\sigma_{i+1}}$ that is computed in the next loop over j, but instead its approximation $p^{(i+1)}_{\underline{j}(i+1)}$. Combining (7.5), with i reading as $i+1$, together with (7.6) shows that with $\rho_1:=[1-\frac{2\kappa C_3}{c_4-\kappa C_1}]^{-1}[1-\frac{c_6^2(\theta-\omega)^2}{c_5^2(1+\omega)^2}]^{\frac12}<1$,

$$\boxed{\|p-p^{(i+1)}_{\underline{j}(i+1)}\|_{\mathbb{P}}\le\rho_1\|p-p^{(i)}_{\underline{j}(i)}\|_{\mathbb{P}}.}\tag{7.8}$$

Since $c_4\mathcal{E}^{\mathrm{S}}(\infty,\tau^{(i)}_{\underline{j},\underline{\underline{k}}},\mathbf{f},p^{(i)}_{\underline{j}},\mathbf{u}^{(i)}_{\underline{j},\underline{\underline{k}}})\le\|\mathbf{u}-\mathbf{u}^{(i)}_{\underline{j},\underline{\underline{k}}}\|_{\mathbb{V}}+\|p-p^{(i)}_{\underline{j}}\|_{\mathbb{P}}$, together (7.8) and (7.4) show that indeed the loop over i, and thus the algorithm, terminates once we have

shown that each loop over j does, which is shown next. In doing so, we first assume that each inner loop over k terminates, which will be shown afterwards.

At the moment $\mathcal{E}^{\mathrm{E}}(\tau_{j,k}^{(i)},\mathbf{f},p_j^{(i)},\mathbf{u}_{j,k}^{(i)}) \leq \alpha\mathcal{E}^{\mathrm{S}}(\sigma_i,\tau_{j,k}^{(i)},\mathbf{f},p_j^{(i)},\mathbf{u}_{j,k}^{(i)})$ is passed, i.e., a loop over k terminates, then by definition $k=\underline{k}(i,j)$, and

$$\|\mathbf{u}^{p_j^{(i)}}-\mathbf{u}_{j,\underline{k}}^{(i)}\|_{\mathbb{V}} \leq \alpha C_1 c_4^{-1}(\|p_{\sigma_i}-p_j^{(i)}\|_{\mathbb{P}}+\|\mathbf{u}^{\sigma_i}-\mathbf{u}_{j,\underline{k}}^{(i)}\|_{\mathbb{V}}). \tag{7.9}$$

Estimating $\|\mathbf{u}^{\sigma_i}-\mathbf{u}_{j,\underline{k}}^{(i)}\|_{\mathbb{V}} \leq \|\mathbf{u}^{\sigma_i}-\mathbf{u}^{p_j^{(i)}}\|_{\mathbb{V}}+\|\mathbf{u}^{p_j^{(i)}}-\mathbf{u}_{j,\underline{k}}^{(i)}\|_{\mathbb{V}}$, and applying (7.9) and $\|\mathbf{u}^{\sigma_i}-\mathbf{u}^{p_j^{(i)}}\|_{\mathbb{V}} \leq \|p_{\sigma_i}-p_j^{(i)}\|_{\mathbb{P}}$ ((5.2)), we obtain that

$$\|\mathbf{u}^{\sigma_i}-\mathbf{u}_{j,\underline{k}}^{(i)}\|_{\mathbb{V}} \leq \tfrac{c_4+\alpha C_1}{c_4-\alpha C_1}\|p_{\sigma_i}-p_j^{(i)}\|_{\mathbb{P}} \tag{7.10}$$

and, by substituting this in (7.9), that

$$\boxed{\|\mathbf{u}^{p_j^{(i)}}-\mathbf{u}_{j,\underline{k}}^{(i)}\|_{\mathbb{V}} \leq \tfrac{2\alpha C_1}{c_4-\alpha C_1}\|p_{\sigma_i}-p_j^{(i)}\|_{\mathbb{P}}.} \tag{7.11}$$

For $p_{j+1}^{(i)} := p_j^{(i)}-Q_{\sigma_i}\mathrm{div}\mathbf{u}_{j,\underline{k}}^{(i)}$ that is evaluated subsequently, from $\|\mathrm{div}\cdot\|_{L_2(\Omega)} \leq \|\cdot\|_{\mathbb{V}}$, (7.11), and the statement (4.3) concerning convergence of the exact Uzawa iteration, with $\rho_2 := 1-\beta^2+\frac{2\alpha C_1}{c_4-\alpha C_1} < 1$, we have

$$\boxed{\|p_{\sigma_i}-p_{j+1}^{(i)}\|_{\mathbb{P}} \leq \rho_2\|p_{\sigma_i}-p_j^{(i)}\|_{\mathbb{P}}.} \tag{7.12}$$

Since $c_4\mathcal{E}^{\mathrm{S}}(\sigma_i,\tau_{j,\underline{k}}^{(i)},\mathbf{f},p_j^{(i)},\mathbf{u}_{j,\underline{k}}^{(i)}) \leq \|\mathbf{u}^{\sigma_i}-\mathbf{u}_{j,\underline{k}}^{(i)}\|_{\mathbb{V}}+\|p_{\sigma_i}-p_j^{(i)}\|_{\mathbb{P}}$, together (7.11) and (7.12) show that indeed each loop over j terminates by either $\mathcal{E}^{\mathrm{S}}(\sigma_i,\tau_{j,k}^{(i)},\mathbf{f},p_j^{(i)},\mathbf{u}_{j,k}^{(i)}) \leq \kappa\mathcal{E}^{\mathrm{S}}(\infty,\tau_{j,k}^{(i)},\mathbf{f},p_j^{(i)},\mathbf{u}_{j,k}^{(i)})$ or $C_3\mathcal{E}^{\mathrm{S}}(\infty,\tau_{j,k}^{(i)},\mathbf{f},p_j^{(i)},\mathbf{u}_{j,k}^{(i)}) \leq \varepsilon$ once we have shown that each loop over k terminates, which is shown next.

With $\rho_3 := [1-\frac{c_2^2\zeta^2}{C_1^2}]^{\frac{1}{2}} < 1$, Lemma 6.4 shows that

$$\boxed{\|\mathbf{u}^{p_j^{(i)}}-\mathbf{u}_{j,k+1}^{(i)}\|_{\mathbb{V}} \leq \rho_3\|\mathbf{u}^{p_j^{(i)}}-\mathbf{u}_{j,k}^{(i)}\|_{\mathbb{V}}.} \tag{7.13}$$

Since $c_2\mathcal{E}^{\mathrm{E}}(\tau_{j,k}^{(i)},\mathbf{f},p_j^{(i)},\mathbf{u}_{j,k}^{(i)}) \leq \|\mathbf{u}^{p_j^{(i)}}-\mathbf{u}_{j,k}^{(i)}\|_{\mathbb{V}}$, from (7.13) we conclude that indeed each loop over k terminates by either $\mathcal{E}^{\mathrm{E}}(\tau_{j,k}^{(i)},\mathbf{f},p_j^{(i)},\mathbf{u}_{j,k}^{(i)}) \leq \alpha\mathcal{E}^{\mathrm{S}}(\sigma_i,\tau_{j,k}^{(i)},\mathbf{f},p_j^{(i)},\mathbf{u}_{j,k}^{(i)})$ or $\mathcal{E}^{\mathrm{S}}(\sigma_i,\tau_{j,k}^{(i)},\mathbf{f},p_j^{(i)},\mathbf{u}_{j,k}^{(i)}) \leq \kappa\mathcal{E}^{\mathrm{S}}(\infty,\tau_{j,k}^{(i)},\mathbf{f},p_j^{(i)},\mathbf{u}_{j,k}^{(i)})$ or $C_3\mathcal{E}^{\mathrm{S}}(\infty,\tau_{j,k}^{(i)},\mathbf{f},p_j^{(i)},\mathbf{u}_{j,k}^{(i)}) \leq \varepsilon$. With this, part (I) of the theorem is proved.

Before starting with the second part, we collect some estimates for $\|p-p_{\underline{j}(0)}^{(0)}\|_{\mathbb{P}}$, $\|p_{\sigma_i}-p_0^{(i)}\|_{\mathbb{P}}$, and $\|\mathbf{u}^{p_j^{(i)}}-\mathbf{u}_{j,0}^{(i)}\|_{\mathbb{V}}$, i.e., the initial values for the recursions (7.8), (7.12), and (7.13) over i, j, and k, respectively.

From (7.5) we infer that

$$\|p-p_{\underline{j}(0)}^{(0)}\|_{\mathbb{P}} \leq [1-\tfrac{2\kappa C_3}{c_4-\kappa C_1}]^{-1}\|p-p_{\tau_0}\|_{\mathbb{P}} \leq [1-\tfrac{2\kappa C_3}{c_4-\kappa C_1}]^{-1}\|p\|_{\mathbb{P}}. \tag{7.14}$$

For $j=0$ and $i=0$, we have that

$$\|p_{\sigma_0}-p_0^{(0)}\|_{\mathbb{P}} \leq \|p_{\sigma_0}-p\|_{\mathbb{P}}+\|p\|_{\mathbb{P}} \leq 2\|p\|_{\mathbb{P}} \tag{7.15}$$

and, for $j=0$ and $i>0$, that

$$\|p_{\sigma_i}-p_0^{(i)}\|_{\mathbb{P}}=\|p_{\sigma_i}-p_{\underline{j}(i-1)}^{(i-1)}\|_{\mathbb{P}}\le\|p_{\sigma_i}-p\|_{\mathbb{P}}+\|p-p_{\underline{j}(i-1)}^{(i-1)}\|_{\mathbb{P}}$$

$$\le\big(\big[1-\tfrac{c_6^2(\theta-\omega)^2}{C_5^2(1+\omega)^2}\big]^{\frac12}+1\big)\|p-p_{\underline{j}(i-1)}^{(i-1)}\|_{\mathbb{P}} \tag{7.16}$$

by (7.6).

For $k=j=i=0$, we have

$$\|\mathbf{u}^{p_0^{(0)}}-\mathbf{u}_{0,0}^{(0)}\|_{\mathbb{V}}\le\|\mathbf{u}^{p_0^{(0)}}\|_{\mathbb{V}}=\|\mathbf{f}\|_{\mathbb{V}'}. \tag{7.17}$$

For $k=j=0$ and $i>0$, we have $p_0^{(i)}=p_{\underline{j}(i-1)}^{(i-1)}$ and $\tau_{0,0}^{(i)}=\tau_{\underline{j}(i-1),\underline{\underline{k}}(i-1)}^{(i-1)}$, and so

$$\|\mathbf{u}^{p_0^{(i)}}-\mathbf{u}_{0,0}^{(i)}\|_{\mathbb{V}}=\|\mathbf{u}^{p_{\underline{j}(i-1)}^{(i-1)}}-\mathbf{u}_{\underline{j}(i-1),\underline{\underline{k}}(i-1)}^{(i-1)}\|_{\mathbb{V}}\le\tfrac{2C_1\kappa}{c_4-\kappa C_1}\|p-p_{\underline{j}(i-1)}^{(i-1)}\|_{\mathbb{P}} \tag{7.18}$$

by (7.2) and (7.4). For $k=0$ and $j>0$, we have

$$\|\mathbf{u}^{p_j^{(i)}}-\mathbf{u}_{j,0}^{(i)}\|_{\mathbb{V}}\le\|\mathbf{u}^{p_j^{(i)}}-\mathbf{u}_{j-1,\underline{k}(j-1)}^{(i)}\|_{\mathbb{V}}$$

$$\le\|\mathbf{u}^{p_j^{(i)}}-\mathbf{u}^{p_{j-1}^{(i)}}\|_{\mathbb{V}}+\|\mathbf{u}^{p_{j-1}^{(i)}}-\mathbf{u}_{j-1,\underline{k}(j-1)}^{(i)}\|_{\mathbb{V}}.$$

Now using that

$$\|\mathbf{u}^{p_j^{(i)}}-\mathbf{u}^{p_{j-1}^{(i)}}\|_{\mathbb{V}}\le\|p_j^{(i)}-p_{j-1}^{(i)}\|_{\mathbb{P}}\le\|\mathbf{u}^{\sigma_i}-\mathbf{u}_{j-1,\underline{k}(j-1)}^{(i)}\|_{\mathbb{V}}$$

$$\le\|\mathbf{u}^{\sigma_i}-\mathbf{u}^{p_{j-1}^{(i)}}\|_{\mathbb{V}}+\|\mathbf{u}^{p_{j-1}^{(i)}}-\mathbf{u}_{j-1,\underline{k}(j-1)}^{(i)}\|_{\mathbb{V}}$$

$$\le\|p_{\sigma_i}-p_{j-1}^{(i)}\|_{\mathbb{P}}+\|\mathbf{u}^{p_{j-1}^{(i)}}-\mathbf{u}_{j-1,\underline{k}(j-1)}^{(i)}\|_{\mathbb{V}}$$

by (5.2) and

$$\|\mathbf{u}^{p_{j-1}^{(i)}}-\mathbf{u}_{j-1,\underline{k}(j-1)}^{(i)}\|_{\mathbb{V}}\le\tfrac{2\alpha C_1}{c_4-\alpha C_1}\|p_{\sigma_i}-p_{j-1}^{(i)}\|_{\mathbb{P}}$$

by (7.11), we find that

$$\|\mathbf{u}^{p_j^{(i)}}-\mathbf{u}_{j,0}^{(i)}\|_{\mathbb{V}}\le\big(1+\tfrac{4\alpha C_1}{c_4-\alpha C_1}\big)\|p_{\sigma_i}-p_{j-1}^{(i)}\|_{\mathbb{P}}. \tag{7.19}$$

(II) At the moment of a call $\sigma_{i+1}:=\mathbf{REFpres}[\sigma_i,\mathbf{u}_{\underline{j},\underline{\underline{k}}}^{(i)}]$, we have

$$\|p-p_{\underline{j}}^{(i)}\|_{\mathbb{P}}\ge c_4\mathcal{E}^{\mathrm{S}}(\infty,\tau_{\underline{j},\underline{\underline{k}}}^{(i)},\mathbf{f},p_{\underline{j}}^{(i)},\mathbf{u}_{\underline{j},\underline{\underline{k}}}^{(i)})>c_4C_3^{-1}\varepsilon,$$

so that in view of (7.7) and (7.8), we have

$$\#\sigma_{\underline{i}}-\#\tau_0\le\sum_{i=0}^{\underline{i}}\#\sigma_i-\#\sigma_{i-1}\lesssim\varepsilon^{-1/s}|p|_{\mathcal{A}_{\mathbb{P}}^s}^{1/s}.$$

At the moment of a call $\tau_{j,k+1}^{(i)}:=\mathbf{REFvel}[\tau_{j,k}^{(i)},\mathbf{f},p_j^{(i)},\mathbf{u}_{j,k}^{(i)}]$, we have

$$\|\mathbf{u}^{p_j^{(i)}}-\mathbf{u}_{j,k}^{(i)}\|_{\mathbb{V}}>c_2\mathcal{E}^{\mathrm{E}}(\tau_{j,k}^{(i)},\mathbf{f},p_j^{(i)},\mathbf{u}_{j,k}^{(i)})>c_2\alpha\mathcal{E}^{\mathrm{S}}(\sigma_i,\tau_{j,k}^{(i)},\mathbf{f},p_j^{(i)},\mathbf{u}_{j,k}^{(i)})$$

$$>c_2\alpha\kappa\mathcal{E}^{\mathrm{S}}(\infty,\tau_{j,k}^{(i)},\mathbf{f},p_j^{(i)},\mathbf{u}_{j,k}^{(i)})\ge c_2\alpha\kappa C_3^{-1}\|\mathbf{u}-\mathbf{u}_{j,k}^{(i)}\|_{\mathbb{V}}, \tag{7.20}$$

where for the first time in this proof we use the fact that the innermost iteration is stopped in time. In view of the definitions of $\mathcal{A}_{\mathbb{P}}^{\bar{s}}$ and $\mathcal{A}_{\mathbb{V}}^{\bar{s}}$, Lemma 6.4 now shows that the set of marked simplices $\underline{F}_{i,j,k} = \underline{F}$ inside $\mathbf{REFvel}[\tau_{j,k}^{(i)}, \mathbf{f}, p_j^{(i)}, \mathbf{u}_{j,k}^{(i)}]$ satisfies

$$\#\underline{F}_{i,j,k} \lesssim \|\mathbf{u}^{p_j^{(i)}} - \mathbf{u}_{j,k}^{(i)}\|_{\mathbb{V}}^{-1/\bar{s}}(|\mathbf{u}|_{\mathcal{A}_{\mathbb{V}}^{\bar{s}}}^{1/\bar{s}} + |p|_{\mathcal{A}_{\mathbb{P}}^{\bar{s}}}^{1/\bar{s}}) + \#\sigma_i - \#\tau_0 + \#\tau_0. \tag{7.21}$$

From $\|\mathbf{u}^{p_j^{(i)}} - \mathbf{u}_{j,k}^{(i)}\|_{\mathbb{V}} \le \|\mathbf{u}^{p_j^{(i)}}\|_{\mathbb{V}} \lesssim \|\mathbf{u}\|_{\mathbb{V}} + \|p\|_{\mathbb{P}}$, we have

$$\#\tau_0 \lesssim 1 \lesssim \|\mathbf{u}^{p_j^{(i)}} - \mathbf{u}_{j,k}^{(i)}\|_{\mathbb{V}}^{-1/\bar{s}}(\|\mathbf{u}\|_{\mathbb{V}}^{1/\bar{s}} + \|p\|_{\mathbb{P}}^{1/\bar{s}}).$$

For $i > 0$, we have $\#\sigma_i - \#\tau_0 \lesssim \|p - p_{\underline{j}(i-1)}^{(i-1)}\|_{\mathbb{P}}^{-1/\bar{s}}|p|_{\mathcal{A}_{\mathbb{P}}^{\bar{s}}}^{1/\bar{s}}$ by (7.7). By (7.18), (7.16), and (7.19), and the decrease of $\|p_{\sigma_i} - p_j^{(i)}\|_{\mathbb{P}}$ and $\|\mathbf{u}^{p_j^{(i)}} - \mathbf{u}_{j,k}^{(i)}\|_{\mathbb{V}}$ as a function of j or k, respectively, we have

$$\begin{aligned}\|p - p_{\underline{j}(i-1)}^{(i-1)}\|_{\mathbb{P}} &\gtrsim \begin{cases} \|\mathbf{u}^{p_0^{(i)}} - \mathbf{u}_{0,0}^{(i)}\|_{\mathbb{V}} \\ \|p_{\sigma_i} - p_0^{(i)}\|_{\mathbb{P}} \ge \|p_{\sigma_i} - p_{j-1}^{(i)}\|_{\mathbb{P}} \gtrsim \|\mathbf{u}^{p_j^{(i)}} - \mathbf{u}_{j,0}^{(i)}\|_{\mathbb{V}} \quad (j > 0) \end{cases} \\ &\gtrsim \|\mathbf{u}^{p_j^{(i)}} - \mathbf{u}_{j,k}^{(i)}\|_{\mathbb{V}}\end{aligned}$$

uniformly in i, j, k. We conclude that

$$\#\underline{F}_{i,j,k} \lesssim \|\mathbf{u}^{p_j^{(i)}} - \mathbf{u}_{j,k}^{(i)}\|_{\mathbb{V}}^{-1/\bar{s}}(\|\mathbf{u}\|_{\mathcal{A}_{\mathbb{V}}^{\bar{s}}}^{1/\bar{s}} + \|p\|_{\mathcal{A}_{\mathbb{P}}^{\bar{s}}}^{1/\bar{s}}),$$

and so, by Theorem 3.2 and (7.13),

$$\begin{aligned}\#\tau_{\underline{j}(\underline{i}),\underline{k}(\underline{i})}^{(\underline{i})} - \tau_0 &\lesssim (\|\mathbf{u}\|_{\mathcal{A}_{\mathbb{V}}^{\bar{s}}}^{1/\bar{s}} + \|p\|_{\mathcal{A}_{\mathbb{P}}^{\bar{s}}}^{1/\bar{s}}) \sum_{i=0}^{\underline{i}} \sum_{j=0}^{\underline{j}(i)} \sum_{k=0}^{\underline{k}(j)-1} \|\mathbf{u}^{p_j^{(i)}} - \mathbf{u}_{j,k}^{(i)}\|_{\mathbb{V}}^{-1/\bar{s}} \\ &\lesssim (\|\mathbf{u}\|_{\mathcal{A}_{\mathbb{V}}^{\bar{s}}}^{1/\bar{s}} + |p|_{\mathcal{A}_{\mathbb{P}}^{\bar{s}}}^{1/\bar{s}}) \sum_{i=0}^{\underline{i}} \sum_{j=0}^{\underline{j}(i)} \|\mathbf{u}^{p_j^{(i)}} - \mathbf{u}_{j,\underline{k}(j)-1}^{(i)}\|_{\mathbb{V}}^{-1/\bar{s}}.\end{aligned}$$

We will bound this expression by using the fact that each of the three nested iterations is stopped in time.

For any i and j, by the definition of $\underline{k}$, we have

$$\begin{aligned}\mathcal{E}^{\mathrm{E}}(\tau_{j,\underline{k}-1}^{(i)}, \mathbf{f}, p_j^{(i)}, \mathbf{u}_{j,\underline{k}-1}^{(i)}) &> \alpha\mathcal{E}^{\mathrm{S}}(\sigma_i, \tau_{j,\underline{k}-1}^{(i)}, \mathbf{f}, p_j^{(i)}, \mathbf{u}_{j,\underline{k}-1}^{(i)}) \\ &> \alpha\kappa\mathcal{E}^{\mathrm{S}}(\infty, \tau_{j,\underline{k}-1}^{(i)}, \mathbf{f}, p_j^{(i)}, \mathbf{u}_{j,\underline{k}-1}^{(i)}) > \alpha\kappa C_3^{-1}\varepsilon,\end{aligned}$$

or

$$\begin{aligned}\|\mathbf{u}^{p_j^{(i)}} - \mathbf{u}_{j,\underline{k}-1}^{(i)}\|_{\mathbb{V}} &\gtrsim \|\mathbf{u}^{\sigma_i} - \mathbf{u}_{j,\underline{k}-1}^{(i)}\|_{\mathbb{V}} + \|p_{\sigma_i} - p_j^{(i)}\|_{\mathbb{P}} \\ &\gtrsim \|\mathbf{u} - \mathbf{u}_{j,\underline{k}-1}^{(i)}\|_{\mathbb{V}} + \|p - p_j^{(i)}\|_{\mathbb{P}} \gtrsim \varepsilon.\end{aligned}$$

Similarly, for any i, by the definition of $\underline{j}$, we have

$$\mathcal{E}^{\mathrm{S}}(\sigma_i, \tau_{\underline{j}-1,\underline{k}}^{(i)}, \mathbf{f}, p_{\underline{j}-1}^{(i)}, \mathbf{u}_{\underline{j}-1,\underline{k}}^{(i)}) > \kappa\mathcal{E}^{\mathrm{S}}(\infty, \tau_{\underline{j}-1,\underline{k}}^{(i)}, \mathbf{f}, p_{\underline{j}-1}^{(i)}, \mathbf{u}_{\underline{j}-1,\underline{k}}^{(i)}) > \kappa C_3^{-1}\varepsilon,$$

or

$$\|p_{\sigma_i}-p^{(i)}_{\underline{j}-1}\|_{\mathbb{P}}\eqsim\|\mathbf{u}^{\sigma_i}-\mathbf{u}^{(i)}_{\underline{j}-1,\underline{k}}\|_{\mathbb{V}}+\|p_{\sigma_i}-p^{(i)}_{\underline{j}-1}\|_{\mathbb{P}}\gtrsim\|\mathbf{u}-\mathbf{u}^{(i)}_{\underline{j}-1,\underline{k}}\|_{\mathbb{V}}+\|p-p^{(i)}_{\underline{j}-1}\|_{\mathbb{P}}\gtrsim\varepsilon,$$

where for "$\eqsim$" we used (7.10). Finally, by the definition of $\underline{i}$, we have

$$\mathcal{E}^{\mathrm{S}}(\infty,\tau^{(\underline{i}-1)}_{\underline{j},\underline{\underline{k}}},\mathbf{f},p^{(\underline{i}-1)}_{\underline{j}},\mathbf{u}^{(\underline{i}-1)}_{\underline{j},\underline{\underline{k}}})>C_3^{-1}\varepsilon,$$

or

$$\|p-p^{(\underline{i}-1)}_{\underline{j}}\|_{\mathbb{P}}\eqsim\|\mathbf{u}-\mathbf{u}^{(\underline{i}-1)}_{\underline{j},\underline{\underline{k}}}\|_{\mathbb{V}}+\|p-p^{(\underline{i}-1)}_{\underline{j}}\|_{\mathbb{P}}\gtrsim\varepsilon,$$

where for "$\eqsim$" we used (7.4). By using in addition (7.12) and (7.8), we find that

$$\begin{aligned}
&\sum_{i=0}^{\underline{i}}\sum_{j=0}^{\underline{j}(i)}\|\mathbf{u}^{p^{(i)}_j}-\mathbf{u}^{(i)}_{j,\underline{k}(j)-1}\|_{\mathbb{V}}^{-1/\bar{s}}\\
&\lesssim\sum_{i=0}^{\underline{i}}\sum_{j=0}^{\underline{j}(i)-1}\|p_{\sigma_i}-p^{(i)}_j\|_{\mathbb{P}}^{-1/\bar{s}}+\sum_{i=0}^{\underline{i}-1}\|p-p^{(i)}_{\underline{j}(i)}\|_{\mathbb{P}}^{-1/\bar{s}}+\varepsilon^{-1/\bar{s}}\\
&\lesssim\sum_{i=0}^{\underline{i}}\|p_{\sigma_i}-p^{(i)}_{\underline{j}(i)-1}\|_{\mathbb{P}}^{-1/\bar{s}}+\|p-p^{(\underline{i}-1)}_{\underline{j}(\underline{i}-1)}\|_{\mathbb{P}}^{-1/\bar{s}}+\varepsilon^{-1/\bar{s}}\\
&\lesssim\sum_{i=0}^{\underline{i}-1}\|p-p^{(i)}_{\underline{j}(i)-1}\|_{\mathbb{P}}^{-1/\bar{s}}+\|p_{\sigma_{\underline{i}}}-p^{(\underline{i})}_{\underline{j}(\underline{i})-1}\|_{\mathbb{P}}^{-1/\bar{s}}+\varepsilon^{-1/\bar{s}}\\
&\lesssim\sum_{i=0}^{\underline{i}-1}\|p-p^{(i)}_{\underline{j}(i)}\|_{\mathbb{P}}^{-1/\bar{s}}+\varepsilon^{-1/\bar{s}}\lesssim\varepsilon^{-1/\bar{s}},
\end{aligned}$$

which completes the proof of the theorem. ∎

8. A practical adaptive method for the Stokes problem. In the previous section, we assumed that with respect to any current partition τ, the right-hand side $\mathbf{f}$ was in $\mathbb{V}^*_\tau$. This led to the severe limitation of $\mathbf{f}$ being in $\mathbb{V}^*_{\tau_0}$. In the practical method, given a general right-hand side $\mathbf{f}$ and any current partition τ, $\mathbf{f}$ is going to be *replaced* by a sufficiently accurate approximation from $\mathbb{V}^*_\tau$ or, when such an approximation does not exist, by an approximation from $\mathbb{V}^*_{\tau'}$ for some $\tau'\supset\tau$. We assume the availability of the following routine, **RHS**.

RHS$[\tau,\eta]\to[\tau',\mathbf{f}_{\tau'}]$
% $\eta>0$. The output consists of an $\mathbf{f}_{\tau'}\in\mathbb{V}^*_{\tau'}$, where $\tau'=\tau$, or, if necessary,
% $\tau'\supset\tau$, such that $\|\mathbf{f}-\mathbf{f}_{\tau'}\|_{\mathbb{V}'}\le\eta$.

Assuming that $p\in\mathcal{A}^s_{\mathbb{P}}$ and $\mathbf{u}\in\mathcal{A}^{\tilde{s}}_{\mathbb{V}}$ for some $s,\tilde{s}>0$, the cost of approximating the right-hand side $\mathbf{f}$ using **RHS** will generally not dominate the other cost of our practical adaptive method only then when there is some constant $c_{\mathbf{f}}$ such that, with $\bar{s}=\max(s,\tilde{s})$, for any $\eta>0$ and any partition τ, for $[\tau',\cdot]:=\mathbf{RHS}[\tau,\eta]$, it holds that

$$\#\tau'-\#\tau\le c_{\mathbf{f}}^{1/\bar{s}}\eta^{-1/\bar{s}},$$

and the number of arithmetic operations required by the call is $\mathcal{O}(\#\tau')$. We will call such an **RHS** $\bar{s}$-*optimal* with constant $c_{\mathbf{f}}$. Obviously, given $\bar{s}$, such a routine can exist only when $\mathbf{f} \in \mathcal{A}^{\bar{s}}_{\mathbb{V}'}$, defined by

$$\mathcal{A}^{\bar{s}}_{\mathbb{V}'} = \{\mathbf{g} \in \mathbb{V}' : \sup_{\varepsilon>0} \varepsilon \inf_{\{\tau:\inf_{\mathbf{g}_\tau \in \mathbb{V}^*_\tau} \|\mathbf{g}-\mathbf{g}_\tau\|_{\mathbb{V}'} \le \varepsilon\}} [\#\tau - \#\tau_0]^{\bar{s}} < \infty\}.$$

Knowing that $\mathbf{f} \in \mathcal{A}^{\bar{s}}_{\mathbb{V}'}$ is a different thing than knowing how to *construct* suitable approximations. If $\bar{s} \in [1/d, (m+1)/d]$ and $\mathbf{f} \in H^{\bar{s}d-1}(\Omega)^d$, then $\mathbf{f} \in \mathcal{A}^{\bar{s}}_{\mathbb{V}'}$, and $\mathbf{f}_{\tau'}$ constructed as the best approximation from $\mathbb{V}^*_{\tau'}$ to $\mathbf{f}$ with respect to $L_2(\Omega)^d$ using (the smallest common refinement of the input partition and) uniform refined partitions τ' are known to converge at the required rate. For general $\mathbf{f} \in \bar{\mathcal{A}}^{\bar{s}}_{\mathbb{V}'}$, however, a realization of a suitable routine **RHS** has to depend on $\mathbf{f}$ at hand.

The maximal values of s, $\tilde{s}$, and $\bar{s}$ for which membership $p \in \mathcal{A}^s_{\mathbb{P}}$, $\mathbf{u} \in \mathcal{A}^{\tilde{s}}_{\mathbb{V}}$, and $\mathbf{f} \in \mathcal{A}^{\bar{s}}_{\mathbb{V}'}$ can be expected are m/d, m/d, and $(m+1)/d$, respectively. Therefore, usually one can expect that asymptotically calls of **RHS** will not give rise to refinements.

Remark 8.1. Instead of replacing $\mathbf{f}$ by a piecewise polynomial approximation both for setting up the Galerkin system for the inner elliptic problem and for computing the a posteriori error estimators, one may work with the original $\mathbf{f}$. In that case, generally one commits quadrature errors, which one may view as a consequence of an implicit replacement of $\mathbf{f}$ by a piecewise polynomial approximation. This approach, however, is restricted to $\mathbf{f} \in L_2(\Omega)^d$, since otherwise the error estimators are not defined.

Since we are going to consider modified right-hand sides, we introduce the following notation: Given $r \in \mathbb{P}$, $\mathbf{g} \in \mathbb{V}'$, and a partition τ, $\mathbf{u}^{r,\mathbf{g}}_\tau \in \mathbb{V}_\tau$ will denote the solution of the Galerkin problem

$$\boxed{a(\mathbf{u}^{r,\mathbf{g}}_\tau, \mathbf{v}_\tau) = \mathbf{g}(\mathbf{v}_\tau) - b(\mathbf{v}_\tau, r) \quad (\mathbf{v}_\tau \in \mathbb{V}_\tau).} \tag{8.1}$$

So in view of the notation introduced in (4.5), we have $\mathbf{u}^{r,\mathbf{f}}_\tau = \mathbf{u}^r_\tau$. Note that $\|\mathbf{u}^r_\tau - \mathbf{u}^{r,\mathbf{g}}_\tau\|_{\mathbb{V}} \le \|\mathbf{f}-\mathbf{g}\|_{\mathbb{V}}$.

In the previous section, we solved the arising Galerkin systems exactly. When aiming at a method of optimal computational complexity we cannot afford this. Therefore, we assume that we have an iterative solver of optimal type available:

GALSOLVE$[\tau, \mathbf{f}_\tau, r_\tau, \mathbf{w}^{(0)}_\tau, \eta] \to \bar{\mathbf{w}}_\tau$
% τ is a partition, $\mathbf{f}_\tau \in \mathbb{V}^*_\tau$, $r_\sigma \in \mathbb{P}_\sigma$ for some $\sigma \supseteq \tau$, $\mathbf{w}^{(0)}_\tau \in \mathbb{V}_\tau$, the latter being an
% initial approximation for an iterative solver, and $\eta > 0$.
% The output $\bar{\mathbf{w}}_\tau \in \mathbb{V}_\tau$ satisfies

$$\|\mathbf{u}^{r_\sigma,\mathbf{f}_\tau}_\tau - \bar{\mathbf{w}}_\tau\|_{\mathbb{V}} \le \eta.$$

% The call requires $\lesssim \max\{1, \log(\eta^{-1}\|\mathbf{u}^{r_\sigma,\mathbf{f}_\tau}_\tau - \mathbf{w}^{(0)}_\tau\|_{\mathbb{V}})\}\#\tau$ arithmetic operations.

Additive or multiplicative multigrid methods with local smoothing are known to be of this type [WC06].

In Lemma 6.4, the adaptive refinement routine **REFvel** was analyzed. For a call $\tilde{\tau} = \mathbf{REFvel}[\tau, \mathbf{f}, r_\sigma, \mathbf{u}^{r_\sigma}_\tau]$, it was shown that $\|\mathbf{u}^{r_\sigma} - \mathbf{u}^{r_\sigma}_{\tilde{\tau}}\|_{\mathbb{V}}$ was strictly smaller than $\|\mathbf{u}^{r_\sigma} - \mathbf{u}^{r_\sigma}_\tau\|_{\mathbb{V}}$, and for $\mathbf{u}^{r_\sigma}_\tau$ not too close to $\mathbf{u}^{r_\sigma}$, a bound for the number of marked simplices inside the call was given. In the following lemma, these results are extended to the situation in which we work with approximations to $\mathbf{f}$, and where we have only inexact Galerkin solutions available.

LEMMA 8.2. *There exist constants* $\chi_1 = \chi_1(\zeta, C_1, c_2) > 0$ *and* $\lambda = \lambda(\chi_1, C_1, c_2) \in (0, \frac{1}{3}\big[1 - \frac{C_1^2\zeta^2}{c_2^2}\big]^{\frac{1}{2}}]$ *such that if for* $\mathbf{f} \in \mathbb{V}'$, *partitions* $\tau \supseteq \sigma$, $r_\sigma \in \mathbb{P}_\sigma$, $\mathbf{f}_\tau \in \mathbb{V}_\tau^*$, $\mathbf{w}_\tau \in \mathbb{V}_\tau$,

$$\|\mathbf{f} - \mathbf{f}_\tau\|_{\mathbb{V}'} + \|\mathbf{u}_\tau^{r_\sigma, \mathbf{f}_\tau} - \mathbf{w}_\tau\|_{\mathbb{V}} \leq \chi_1 \mathcal{E}(\tau, \mathbf{f}_\tau, r_\sigma, \mathbf{w}_\tau) \tag{8.2}$$

and, for some absolute constant $\vartheta > 0$,

$$\|\mathbf{u}^{r_\sigma} - \mathbf{w}_\tau\|_{\mathbb{V}} \geq \vartheta \|\mathbf{u} - \mathbf{u}^{r_\sigma}\|_{\mathbb{V}},$$

then the set of marked simplices $\underline{F}$ *inside the call* $\tilde{\tau} := \mathbf{REFvel}[\tau, \mathbf{f}_\tau, r_\sigma, \mathbf{w}_\tau]$ *satisfies*

$$\#\underline{F} \lesssim \#\bar{\tau} + \#\bar{\sigma} + \#\sigma$$

for any partitions $\bar{\tau}$ *and* $\bar{\sigma}$ *for which*

$$\inf_{\mathbf{v}_{\bar{\tau}} \in \mathbb{V}_{\bar{\tau}}} \|\mathbf{u} - \mathbf{v}_{\bar{\tau}}\|_{\mathbb{V}} \leq \lambda \|\mathbf{u}^{r_\sigma} - \mathbf{w}_\tau\|_{\mathbb{V}}, \quad \inf_{q_{\bar{\sigma}} \in \mathbb{P}_{\bar{\sigma}}} \|p - q_{\bar{\sigma}}\|_{\mathbb{V}} \leq \lambda \|\mathbf{u}^{r_\sigma} - \mathbf{w}_\tau\|_{\mathbb{V}}. \tag{8.3}$$

Furthermore, given a

$$\mu \in \big(\big[1 - \tfrac{c_2^2\zeta^2}{C_1^2}\big]^{\frac{1}{2}}, 1\big),$$

there exists an $\chi_2 = \chi_2(\mu, \zeta, C_1, c_2) > 0$, *such that if* (5.2) *is valid with* χ_1 *reading as* χ_2, *and for* $\tau' \supseteq \tilde{\tau}$, $\mathbf{f}_{\tau'} \in \mathbb{V}'$, *and* $\mathbf{w}_{\tau'} \in \mathbb{V}_{\tau'}$,

$$\|\mathbf{f} - \mathbf{f}_{\tau'}\|_{\mathbb{V}'} + \|\mathbf{u}_{\tau'}^{r_\sigma, \mathbf{f}_{\tau'}} - \mathbf{w}_{\tau'}\|_{\mathbb{V}} \leq \chi_2 \mathcal{E}^{\mathrm{E}}(\tau, \mathbf{f}_\tau, r_\sigma, \mathbf{w}_\tau),$$

then

$$\|\mathbf{u}^{r_\sigma} - \mathbf{w}_{\tau'}\|_{\mathbb{V}} \leq \mu \|\mathbf{u}^{r_\sigma} - \mathbf{w}_\tau\|_{\mathbb{V}}.$$

Proof. Following along the lines of [Ste07, proof of Lemma 6.1], for suitable constants χ_1 and λ, one can show that $\#\underline{F} \lesssim \#\hat{\tau} - \#\tau_0$ for any partition $\hat{\tau}$ with $\inf_{\mathbf{v}_{\hat{\tau}} \in \mathbb{V}_{\hat{\tau}}} \|\mathbf{u}^{r_\sigma} - \mathbf{v}_{\hat{\tau}}\|_{\mathbb{V}} \leq \lambda \|\mathbf{u}^{r_\sigma} - \mathbf{w}_\tau\|_{\mathbb{V}}$. Then, following the proof of Lemma 6.4, we infer that $\#\hat{\tau} - \#\tau_0 \leq \#\bar{\tau} + \#\bar{\sigma} + \#\sigma$, with $\bar{\tau}$ and $\#\bar{\sigma}$ from (8.3).

The second statement can be proven as in [Ste07, Lemma 6.2]. ∎

Now we are ready to formulate our practical adaptive Stokes solver, **STOKESSOLVE**.

STOKESSOLVE$[f, \varepsilon] \to [\sigma_j^{(i)}, p_j^{(i)}, \tau_{j,k}^{(i)}, \mathbf{w}_{j,k}^{(i)}]$

% Let the parameter ζ *from* **REFvel** *satisfy* $\zeta \in (0, \frac{c_2}{C_1})$, *and let* θ *from* **REFpres**

% satisfy $\theta \in (0, [1 - \frac{1 - c_6^2/C_5^2}{d}]^{\frac{1}{2}})$. *Let* $\kappa, \beta, \alpha, \chi > 0$ *be sufficiently small constants.*

$\sigma_0 := \tau_{0,0}^{(0)} := \tau_0$, $p_0^{(0)} := 0$, $\mathbf{w}_{0,0}^{(0)} := 0$, $\delta \eqsim \|\mathbf{f}\|_{\mathbb{V}'}$, $i := j := k := 0$

`do` $[\mathbf{f}_{j,k}^{(i)}, \tau_{j,k}^{(i)}] := \mathbf{RHS}[\delta/2, \tau_{j,k}^{(i)}]$

  $\mathbf{w}_{j,k}^{(i)} := \mathbf{GALSOLVE}[\tau_{j,k}^{(i)}, \mathbf{f}_{j,k}^{(i)}, p_j^{(i)}, \mathbf{w}_{j,k}^{(i)}, \delta/2]$

  `if` $C_3\mathcal{E}^{\mathrm{S}}(\infty, \tau_{j,k}^{(i)}, \mathbf{f}_{j,k}^{(i)}, p_j^{(i)}, \mathbf{w}_{j,k}^{(i)}) + (1 + C_3(2c_2^{-1} + 1))\delta/2 \leq \varepsilon$ `then stop`

  `elseif` $\mathcal{E}^{\mathrm{S}}(\sigma_i, \tau_{j,k}^{(i)}, \mathbf{f}_{j,k}^{(i)}, p_j^{(i)}, \mathbf{w}_{j,k}^{(i)}) + \delta \leq \kappa\mathcal{E}^{\mathrm{S}}(\infty, \tau_{j,k}^{(i)}, \mathbf{f}_{j,k}^{(i)}, p_j^{(i)}, \mathbf{w}_{j,k}^{(i)})$ `then`

    $\sigma_{i+1} := \mathbf{REFpres}[\sigma_i, \mathbf{w}_{j,k}^{(i)}]$

    $p_0^{(i+1)} := p_j^{(i)}$, $\tau_{0,0}^{(i+1)} := \tau_{j,k}^{(i)}$, $\mathbf{w}_{0,0}^{(i+1)} := \mathbf{w}_{j,k}^{(i)}$

$\delta := \beta(\mathcal{E}^{\mathrm{S}}(\infty, \tau_{j,k}^{(i)}, \mathbf{f}_{j,k}^{(i)}, p_j^{(i)}, \mathbf{w}_{j,k}^{(i)}) + \delta)$
$i{+}{+},\ j := k := 0$
elseif $\mathcal{E}^{\mathrm{E}}(\tau_{j,k}^{(i)}, \mathbf{f}_{j,k}^{(i)}, p_j^{(i)}, \mathbf{w}_{j,k}^{(i)}) + \delta \leq \alpha \mathcal{E}^{\mathrm{S}}(\sigma_i, \tau_{j,k}^{(i)}, \mathbf{f}_{j,k}^{(i)}, p_j^{(i)}, \mathbf{w}_{j,k}^{(i)})$ **then**
$p_{j+1}^{(i)} := p_j^{(i)} - Q_{\sigma_i} \mathrm{div} \mathbf{w}_{j,k}^{(i)}$
$\tau_{j+1,0}^{(i)} := \tau_{j,k}^{(i)},\ \mathbf{w}_{j+1,0}^{(i)} := \mathbf{w}_{j,k}^{(i)}$
$\delta := \beta(\mathcal{E}^{\mathrm{S}}(\sigma_i, \tau_{j,k}^{(i)}, \mathbf{f}_{j,k}^{(i)}, p_j^{(i)}, \mathbf{w}_{j,k}^{(i)}) + \delta)$
$j{+}{+},\ k := 0$
elseif $\delta \leq \chi \mathcal{E}^{\mathrm{E}}(\tau_{j,k}^{(i)}, \mathbf{f}_{j,k}^{(i)}, , p_j^{(i)}, \mathbf{w}_{j,k}^{(i)})$
$\tau_{j,k+1}^{(i)} := \mathbf{REFvel}[\tau_{j,k}^{(i)}, \mathbf{f}_{j,k}^{(i)}, p_j^{(i)}, \mathbf{w}_{j,k}^{(i)}],\ \mathbf{w}_{j,k+1}^{(i)} := \mathbf{w}_{j,k}^{(i)}$
$\delta := \beta(\mathcal{E}^{\mathrm{E}}(\tau_{j,k}^{(i)}, \mathbf{f}_{j,k}^{(i)}, p_j^{(i)}, \mathbf{w}_{j,k}^{(i)}) + \delta)$
$k{+}{+}$
else $\delta := \delta/2$
endif
enddo

Compared to the preliminary version $\mathbf{STOKESSOLVE}_0$, in **STOKESSOLVE** the exact solution $\mathbf{u}_{j,k}^{(i)}$ of the inner elliptic problem is replaced by an approximate one, $\mathbf{w}_{j,k}^{(i)}$, which is moreover computed using an approximation $\mathbf{f}_{j,k}^{(i)} \in \mathbb{V}_{\tau_{j,k}^{(i)}}^{*}$ of the right-hand side $\mathbf{f} \in \mathbb{V}'$. As a consequence, the results on the a posteriori error estimators from section 5 cannot be applied directly. Using the stability of the problems defining $\mathbf{u}$ and p with respect to perturbations in $\mathbf{f}$, and the stability of the error estimator $\mathcal{E}^{\mathrm{E}}$ demonstrated in Proposition 5.4, for sufficiently small α and κ, stopping by either $\mathcal{E}^{\mathrm{E}}(\cdots)+\delta \leq \alpha \mathcal{E}^{\mathrm{S}}(\sigma_i, \dots)$, $\mathcal{E}^{\mathrm{S}}(\sigma_i, \dots)+\delta \leq \kappa \mathcal{E}^{\mathrm{S}}(\infty, \dots)$ or $\mathcal{E}^{\mathrm{S}}(\infty, \dots)+(1+C_3(2c_2^{-1}+1))\delta/2 \leq \varepsilon$ means that

$$\|\mathbf{u}^{p_j^{(i)}} - \mathbf{w}_{j,k}^{(i)}\|_{\mathbb{V}} \leq D_1(\alpha)[\|p_{\sigma_i} - p_j^{(i)}\|_{\mathbb{P}} + \|\mathbf{u}^{p_{\sigma_i}} - \mathbf{w}_{j,k}^{(i)}\|_{\mathbb{V}}],$$
$$\|p^{\sigma_i} - p_j^{(i)}\|_{\mathbb{P}} + \|\mathbf{u}^{p_{\sigma_i}} - \mathbf{w}_{j,k}^{(i)}\|_{\mathbb{V}} \leq D_2(\kappa)[\|p - p_j^{(i)}\|_{\mathbb{P}} + \|\mathbf{u} - \mathbf{w}_{j,k}^{(i)}\|_{\mathbb{V}}], \quad \text{or}$$
$$\|p - p_j^{(i)}\|_{\mathbb{P}} + \|\mathbf{u} - \mathbf{w}_{j,k}^{(i)}\|_{\mathbb{V}} \leq \varepsilon,$$

respectively, with $D_1(\alpha), D_2(\kappa) > 0$ being some constants that tend to zero when α or κ tend to zero.

Since the tolerance $\delta/2$ for the approximations for the right-hand side and for the approximate solution of the inner Galerkin problem decreases until $\delta \leq \chi \mathcal{E}^{\mathrm{E}}(\cdots)$, where, for β small enough, the next δ respects the same bound, the second part of Lemma 8.2 shows that for each i and j, $\mathbf{w}_{j,k}^{(i)}$ converges linearly towards $\mathbf{u}^{p_j^{(i)}}$. Here, we silently assumed that by halving δ, at some point $\delta \leq \chi \mathcal{E}^{\mathrm{E}}(\cdots)$ is valid. This, however, is not necessarily true since $\mathcal{E}^{\mathrm{E}}(\cdots)$ changes as well. For example, think of the (unlikely) situation in which we have reached a partition on which $\mathbf{u}^{p_j^{(i)}}$ can be represented exactly. Yet, in that case we have also linear convergence of $\mathbf{w}_{j,k}^{(i)}$ towards $\mathbf{u}^{p_j^{(i)}}$. Indeed, if during the process of halving δ it remains larger than $\chi \mathcal{E}^{\mathrm{E}}(\cdots)$, then $\chi \mathcal{E}^{\mathrm{E}}(\cdots) + \delta$, being up to some constant factor an upper bound for $\|\mathbf{u}^{p_j^{(i)}} - \mathbf{w}_{j,k}^{(i)}\|_{\mathbb{V}}$, decreases linearly.

Based on these observations, similarly as in the proof of part (I) of Theorem 8.3, for sufficiently small κ and α, one shows convergence of **STOKESSOLVE**, with

$\|p-p_j^{(i)}\|_{\mathbb{P}}+\|\mathbf{u}-\mathbf{w}_{j,k}^{(i)}\|_{\mathbb{V}}\le\varepsilon$ at termination.

When **REFvel** is called, from $\delta\le\chi\mathcal{E}^{\mathrm{E}}(\cdots)$ for sufficiently small χ, $\mathcal{E}^{\mathrm{E}}(\cdots)+\delta>\alpha\mathcal{E}^{\mathrm{S}}(\sigma_i,\cdots)$ and $\mathcal{E}^{\mathrm{S}}(\sigma_i,\cdots)+\delta>\kappa\mathcal{E}^{\mathrm{S}}(\infty,\cdots)$, we have

$$\|\mathbf{u}^{p_j^{(i)}}-\mathbf{w}_{j,k}^{(i)}\|_{\mathbb{V}}\gtrsim\mathcal{E}^{\mathrm{E}}(\cdots)-\delta\gtrsim\mathcal{E}^{\mathrm{E}}(\cdots)+\delta\gtrsim\mathcal{E}^{\mathrm{S}}(\sigma_i,\dots)+\delta\gtrsim\mathcal{E}^{\mathrm{S}}(\infty,\dots)+\delta\gtrsim\|\mathbf{u}-\mathbf{w}_{j,k}^{(i)}\|_{\mathbb{V}},$$

meaning that we may apply the first part of Lemma 8.2 to bound the cardinality of the set $\underline{F}_{i,j,k}$ of marked simplices. Assuming that $p\in\mathcal{A}_{\mathbb{P}}^{\bar{s}}$ and $\mathbf{u}\in\mathcal{A}_{\mathbb{V}}^{\bar{s}}$, as in (7.21) we find

$$\#\underline{F}_{i,j,k}\lesssim\|\mathbf{u}^{p_j^{(i)}}-\mathbf{w}_{j,k}^{(i)}\|_{\mathbb{V}}^{-1/\bar{s}}(|\mathbf{u}|_{\mathcal{A}_{\mathbb{V}}^{\bar{s}}}^{1/\bar{s}}+|p|_{\mathcal{A}_{\mathbb{P}}^{\bar{s}}}^{1/\bar{s}})+\#\sigma_i-\#\tau_0+\#\tau_0.$$

Other than in **STOKESSOLVE**$_0$, in **STOKESSOLVE** refinements can also be made by calls $[\mathbf{f}_{j,k}^{(i)},\tau_{j,k}^{(i)}]:=\mathbf{RHS}[\delta/2,\tilde{\tau}_{j,k}^{(i)}]$. Assuming that **RHS** $\bar{s}$-optimal with constant $c_{\mathbf{f}}$, then $\#\tau_{j,k}^{(i)}-\#\tilde{\tau}_{j,k}^{(i)}\le c_{\mathbf{f}}^{-1/\bar{s}}(\delta/2)^{-1/\bar{s}}$. Using the fact that such a call can be made only when

$$\delta\gtrsim\mathcal{E}^{\mathrm{E}}(\cdots)+\delta\gtrsim\mathcal{E}^{\mathrm{S}}(\sigma_i,\dots)+\delta\gtrsim\mathcal{E}^{\mathrm{S}}(\infty,\dots)+\delta\gtrsim\varepsilon,$$

by applying similar techniques to those in the proof of Theorem 7.1 one can prove that **STOKESSOLVE** outputs quasi-optimal partitions.

Finally, one can prove that **STOKESSOLVE** is of quasi-optimal computational complexity. The main point is that with a call $\mathbf{GALSOLVE}[\tau_{j,k}^{(i)},p_j^{(i)},\mathbf{f}_{j,k}^{(i)},\mathbf{w}_{j,k}^{(i)},\delta/2]$, it holds that $\|\mathbf{u}^{p_j^{(i)},\mathbf{f}_{j,k}^{(i)}}-\mathbf{w}_{j,k}^{(i)}\|_{\mathbb{V}}\lesssim\delta/2$, so that the error has to be reduced by a constant factor only.

Along the lines indicated above, we end up with the following theorem. We have chosen not to include a full proof, since this would require another level of technicalities on top of those from the proof of Theorem 7.1.

THEOREM 8.3. (I) $[\sigma_j^{(i)},p_j^{(i)},\tau_{j,k}^{(i)},\mathbf{w}_{j,k}^{(i)}]:=\mathbf{STOKESSOLVE}[f,\varepsilon]$ *terminates, and* $\|\mathbf{u}-\mathbf{w}_{j,k}^{(i)}\|_{\mathbb{V}}+\|p-p_j^{(i)}\|_{\mathbb{P}}\le\varepsilon$. (II) *If, for some* $s>0$, $p\in\mathcal{A}_{\mathbb{P}}^{s}$, *then* $\#\sigma_j^{(i)}-\#\tau_0\lesssim\varepsilon^{-1/s}|p|_{\mathcal{A}_{\mathbb{P}}^{s}}^{1/s}$, *dependent only on* τ_0, *and on* s *when it tends to* 0 *or infinity. If, in addition, for some* $\tilde{s}>0$, $\mathbf{u}\in\mathcal{A}_{\mathbb{V}}^{\tilde{s}}$ *and, with* $\bar{s}=\min(s,\tilde{s})$, **RHS** *is* $\bar{s}$*-optimal with constant* $c_{\mathbf{f}}$, *then* $\#\tau_{j,k}^{(i)}-\#\tau_0\lesssim\varepsilon^{-1/\bar{s}}(\|p\|_{\mathcal{A}_{\mathbb{P}}^{\bar{s}}}^{1/\bar{s}}+\|\mathbf{u}\|_{\mathcal{A}_{\mathbb{V}}^{\bar{s}}}^{1/\bar{s}}+c_{vcf}^{1/\bar{s}})$, *dependent only on* τ_0, *and on* $\bar{s}$ *when it tends to* 0 *or infinity. Moreover, when* $\varepsilon\lesssim\|\mathbf{f}\|_{\mathbb{V}'}$, *the number of arithmetic operations and storage locations required by the call is also bounded by a multiple of* $\varepsilon^{-1/\bar{s}}(\|p\|_{\mathcal{A}_{\mathbb{P}}^{\bar{s}}}^{1/\bar{s}}+\|\mathbf{u}\|_{\mathcal{A}_{\mathbb{V}}^{\bar{s}}}^{1/\bar{s}}+c_{vcf}^{1/\bar{s}})$.

9. Numerical experiment. We consider $d=2$, the L-shaped domain $\Omega=(0,1)^2\backslash(\frac{1}{2},1)^2$, $\mathbf{f}:\mathbf{x}\mapsto 25(4\mathbf{x}_2-1,1-4\mathbf{x}_1)$, and $m=1$, i.e., continuous piecewise linear approximation for the velocity, piecewise constant approximation for the pressure, and an initial partition into 24 triangles.

The "bulk chasing" parameters θ and ζ inside **REFpres** or **REFvel** were chosen to be 0.7 and $\sqrt{0.3}$, respectively. Since $\mathbf{f}$ is smooth, we followed the approach discussed in Remark 8.1 and skipped the calls of **RHS**. Furthermore, instead of solving each arising finite-dimensional linear system within tolerance $\delta/2$, for the first value of $\delta/2$ obtained by successively halving that is less than $\chi\mathcal{E}^{\mathrm{E}}(\tau_{j,k}^{(i)},\mathbf{f}_{j,k,}^{(i)},p_j^{(i)},\mathbf{w}_{j,k}^{(i)})$, we always approximately solved it by 3 multigrid iterations with local smoothing (cf. [WC06])

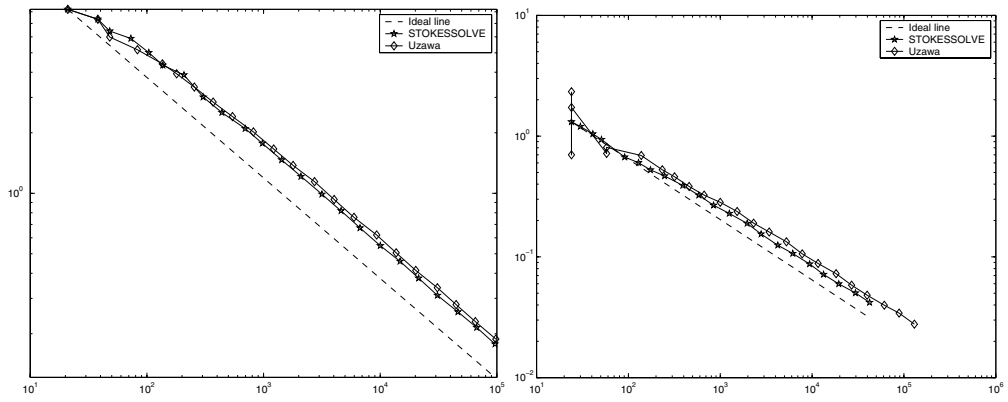

FIG. 9.1. *Estimated Stokes error* (left) *and estimated pressure error* (right) *vs. cardinality underlying partition.*

starting with the previously computed approximate velocity. The parameters κ and α are chosen to be 0.88 and 0.9, respectively.

For comparison, we also implemented the adaptive Uzawa method for solving the full Stokes problem, i.e., **STOKESSOLVE** without the outermost loop over i, i.e., without the part starting from the first `elseif` statement until the second one, and all remaining occurrences of σ_i replaced by ∞. In particular the pressure update $p_{j+1}^{(i)} := p_j^{(i)} + Q_{\sigma_i}\mathrm{div}\mathbf{w}_{j,k}^{(i)}$ then reads $p_{j+1} := p_j + \mathrm{div}\mathbf{w}_{j,k}$. This is the algorithm studied in [BMN02], apart from the replacement of a priori prescribed tolerances by a posteriori ones.

In Figure 9.1 (left), we plotted the full Stokes error estimator $\mathcal{E}^{\mathrm{S}}(\infty, \tau_{\underline{\underline{j}},\underline{\underline{k}}}^{(i)}, \mathbf{f}, p_{\underline{\underline{j}}}^{(i)}, \mathbf{w}_{\underline{\underline{j}},\underline{\underline{k}}}^{(i)})$ vs. $\#\tau_{\underline{\underline{j}},\underline{\underline{k}}}^{(i)}$ (or $\mathcal{E}^{\mathrm{S}}(\infty, \tau_{j,\underline{k}}, \mathbf{f}, p_j, \mathbf{w}_{j,\underline{k}})$ vs. $\#\tau_{j,\underline{k}}$). Ignoring the fact that generally $\mathbf{w}_{\underline{\underline{j}},\underline{\underline{k}}}^{(i)} \neq \mathbf{u}_{\tau_{\underline{\underline{j}},\underline{\underline{k}}}^{(i)}}^{p_{\underline{\underline{j}}}^{(i)}}$ (or $\mathbf{w}_{j,\underline{k}} \neq \mathbf{u}_{\tau_{j,\underline{k}}}^{p_j}$), modulo a constant factor this estimator is an upper bound for $\|\mathbf{u}-\mathbf{w}_{\underline{\underline{j}},\underline{\underline{k}}}^{(i)}\|_{\mathbb{V}} + \|p-p_{\underline{\underline{j}}}^{(i)}\|_{\mathbb{P}}$ (or $\|\mathbf{u}-\mathbf{w}_{j,\underline{k}}\|_{\mathbb{V}} + \|p-p_j\|_{\mathbb{P}}$). (For $\mathbf{f} \in \mathbb{V}^*_{\tau_{\underline{\underline{j}},\underline{\underline{k}}}^{(i)}}$ (or $\mathbf{f} \in \mathbb{V}^*_{\tau_{j,\underline{k}}}$), it would also be a lower bound.) In Figure 9.1 (right), we plotted the pressure error estimator $\|\mathrm{div}\mathbf{w}_{\underline{\underline{j}},\underline{\underline{k}}}^{(i)}\|_{L_2(\Omega)}$ vs. $\#\sigma_i$ (or $\|\mathrm{div}\mathbf{w}_{j,\underline{k}}\|_{L_2(\Omega)}$ vs. $\#\tau_{j,0}$). Ignoring the fact that generally $\mathbf{w}_{\underline{\underline{j}},\underline{\underline{k}}}^{(i)} \neq \mathbf{u}^{p_{\underline{\underline{j}}}^{(i)}}$ (or $\mathbf{w}_{j,\underline{k}} \neq \mathbf{u}^{p_j}$), this estimator is equivalent to $\|p-p_{\underline{\underline{j}}}^{(i)}\|_{\mathbb{P}}$ (or $\|p-p_j\|_{\mathbb{P}}$). As predicted by the theory, the approximations produced by **STOKESSOLVE** converge with the best possible rates. In this example, we observe that the same is true for the adaptive Uzawa method.

Our implementation is partly written in C and, for our convenience, partly in MATLAB, making use of the PDE toolbox. This toolbox was modified such that it performs newest vertex bisection. Due to the data structures used in the MATLAB part, our code is not of optimal computational complexity; the time needed for a call of **REFvel** is not proportional to the cardinality of its output partition. Subtracting the times spent for this routine, we observed computing times that are proportional to the cardinality of the final partition.

In Figure 9.2 we show two partitions σ_i that were produced by **STOKESSOLVE**. Note that these partitions are nonconforming. In Figure 9.3 we give two partitions $\tau_{j,k}^{(i)}$. Finally, in Figure 9.4 plots of p and $\mathbf{u}$ are given.

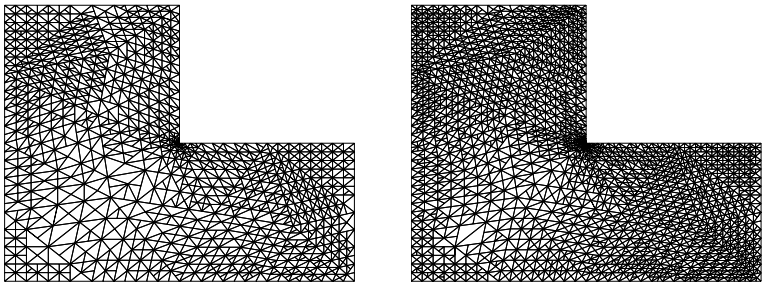

FIG. 9.2. *Pressure partitions with* 1965 *or* 4235 *triangles.*

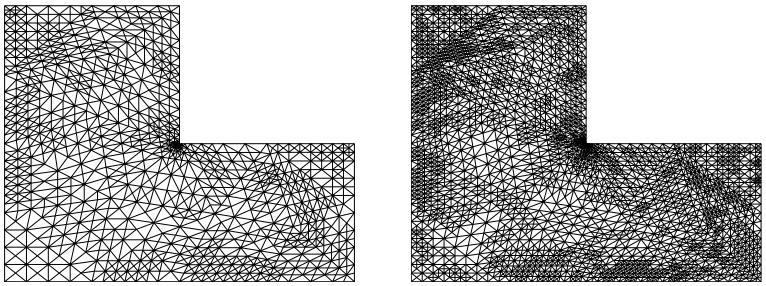

FIG. 9.3. *Velocity partitions with* 1842 *or* 6126 *triangles.*

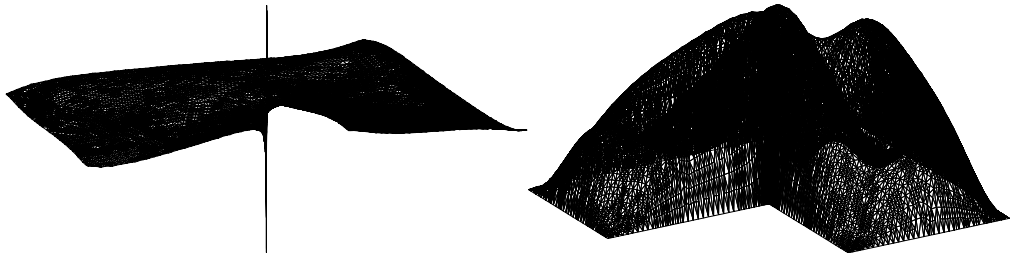

FIG. 9.4. *Pressure* p *and the norm* $|\mathbf{u}|$ *of the velocity.*

Acknowledgments. The authors are indebted to Dr. Haijun Wu (Nanjing University, China) for making available to us his code implementing multigrid on locally refined partitions. We thank Dr. Peter Binev (University of South Carolina, USA) for proving a new estimate for an adaptive tree algorithm that we needed for the **REFpres** routine.

DISCONTINUOUS GALERKIN METHODS FOR FRIEDRICHS' SYSTEMS. PART III. MULTIFIELD THEORIES WITH PARTIAL COERCIVITY*

ALEXANDRE ERN† AND JEAN-LUC GUERMOND‡

Abstract. This paper is the third and last part of a work attempting to give a unified analysis of discontinuous Galerkin methods. The purpose of this paper is to extend the framework that has been developed in Part II for two-field Friedrichs' systems associated with second-order PDEs. We now consider two-field Friedrichs' systems with partial L^2-coercivity and three-field Friedrichs' systems with an even weaker L^2-coercivity hypothesis. In particular, this work generalizes the discontinuous Galerkin methods of Part II to compressible and incompressible linear continuum mechanics. We also show how the stabilizing parameters of the method must be set when the two-field Friedrichs' system is composed of terms that may be of different magnitude, thus accounting, for instance, for advection–diffusion equations at high Péclet numbers.

Key words. Friedrichs' systems, finite elements, partial differential equations, discontinuous Galerkin method

1. Introduction.

The framework of Friedrichs' systems [21] is well adapted to the analysis of first-order PDEs for it accommodates many types of PDEs in a unified setting and systematically handles various types of boundary conditions. Friedrichs' systems were initially developed to deal with change of type in transonic flows, but the theory developed by Friedrichs turned out to give a "unified treatment" of PDEs that goes beyond the elliptic/hyperbolic/parabolic divide. The key ingredient of the theory is that the sum of the operator associated with the PDE and its formal adjoint is L^2-coercive (implying that the coefficients of the PDE satisfy symmetry properties).

As shown in Part I of this work [15], approximating Friedrichs' systems using discontinuous Galerkin (DG) methods is somewhat natural, and the setting of Friedrichs' systems lends itself nicely to analysis. Actually this observation is not new, and the analysis of DG approximations of Friedrichs' systems had been initiated in the 1970s by Lesaint and Raviart [25, 26] and further pursued by Johnson, Nävert, and Pitkäranta [24], but for some reason research remained focused for many years on hyperbolic equations. Meanwhile the development of DG methods for solving elliptic equations followed a different route and has been essentially based on the early work of Nitsche on boundary-penalty methods [27] and the use of interior penalties (IP) to weakly enforce continuity conditions imposed on the solution or its derivatives across the interfaces between adjoining elements; see Douglas and Dupont [12], Baker [4], Wheeler [29], Arnold [1], Bassi and Rebay [5], and Cockburn and Shu [11]. All these approaches have been recast into a single framework amenable to a unified error analysis in Arnold et al. [2] for the Poisson problem.

In Part I [15] we reunited the two above diverging viewpoints by showing that the theory of Friedrichs' systems is a proper setting to analyze DG methods irrespective of the type of the PDE: The DG analysis of a transport equation and that of the Laplace equation are identical when all the components of the unknown are given equal attention. Sometimes, however, the unknown, say z, possesses a two-field structure, $z = (z^\sigma, z^u)$, and the σ-component can be eliminated to yield a system of second-order PDEs for the u-component. (We have in mind here the Maxwell equations, the mixed form of the Laplace equation, or the mixed form of the linear elasticity equations.) This situation, which gives more weight to one component of the unknown, say the u-component, has been analyzed in Part II [16]. Therein we developed a theory of two-field Friedrichs' systems and analyzed two-field DG methods for which z^σ can be locally eliminated on each mesh cell.

The goal of the third and last part of this work is to extend the analysis of Part II in three directions by weakening the assumption of L^2-coercivity on which the theory of the two-field Friedrichs' systems is based. First, the L^2-coercivity is assumed to hold only on the σ-component of the field $z = (z^\sigma, z^u)$. Examples include advection–diffusion equations and compressible linear continuum mechanics problems. Second, further weakening of the partial coercivity framework is done by introducing a three-field theory of Friedrichs' systems. This framework encompasses incompressible linear continuum mechanics, e.g., Stokes and Oseen flows. Third, the two-field DG method is revisited by performing a singular perturbation analysis. The goal of this third extension is to determine how the stabilizing parameters of the method must be set when the elliptic-like PDE associated with the two-field Friedrichs' system under scrutiny is composed of a second-order term and a first-order term that may be of different magnitude. The situation covered by this theory is that of advection–diffusion equations at high Péclet numbers. The recurrent theme of the present paper is to construct robust multifield DG methods that can efficiently handle type changes (elliptic/hyperbolic, compressible/incompressible, etc.) and are such that one subfield of the unknown, say z^σ, can be eliminated on each mesh element.

This paper is organized as follows. Section 2 sets the notation and briefly reviews the main results obtained in Parts I and II. This section can be skipped by readers who are familiar with the material. Section 3 treats two-field Friedrichs' systems for which L^2-coercivity holds only on the σ-component. The key difference with Part II is that a Poincaré-like inequality must be invoked to transfer the L^2-stability from z^σ to z^u. Section 4 deals with three-field Friedrichs' systems where the partial coercivity framework is further weakened. In both cases, the well-posedness of the Friedrichs' systems is established and the convergence of their DG approximation is analyzed under general design conditions. Finally, section 5 presents a singular perturbation analysis relevant to second-order PDEs where first- and second-order terms are not of the same magnitude. Sections 3, 4, and 5 are independent and can be read separately. The theme of section 4 is robustness with respect to the compressible/incompressible-type change and that of section 5 is robustness with respect to the elliptic/hyperbolic-type change.

2. DG approximation of Friedrichs' systems. The objective of this section is to set the notation and briefly restate the main results of Parts I and II. The reader familiar with this material can jump to section 3.

2.1. One-field Friedrichs' systems. Let Ω be a bounded, open, and connected Lipschitz domain in $\mathbb{R}^d$. Let m be a positive integer and set $L = [L^2(\Omega)]^m$ with inner product $(\cdot,\cdot)_L$. The two ingredients to build a Friedrichs' system are an operator

$K \in \mathcal{L}(L;L)$ and a family $\{\mathcal{A}^k\}_{1\le k\le d}$ of d functions on Ω with values in $\mathbb{R}^{m,m}$ such that

(A1) $\quad \forall k \in \{1,\dots,d\},\ \mathcal{A}^k \in [L^\infty(\Omega)]^{m,m} \quad \text{and} \quad \sum_{k=1}^d \partial_k \mathcal{A}^k \in [L^\infty(\Omega)]^{m,m},$

(A2) $\quad \forall k \in \{1,\dots,d\},\ \mathcal{A}^k = (\mathcal{A}^k)^t$ a.e. in Ω,

(A3) $\quad \exists \mu_0 > 0, \quad \forall z \in L, \quad ((K + K^* - \nabla\cdot A)z, z)_L \ge 2\mu_0 \|z\|_L^2,$

where K^* is the adjoint of K in $\mathcal{L}(L;L)$ and $\nabla\cdot A \in \mathcal{L}(L;L)$ is defined such that $\nabla\cdot A(z) = (\sum_{k=1}^d \partial_k \mathcal{A}^k)z$ for all $z \in L$.

Let $\mathfrak{D}(\Omega)$ denote the space of $\mathfrak{C}^\infty$ functions that are compactly supported in Ω. A function z in L is said to have an A-weak derivative in L if the linear form $[\mathfrak{D}(\Omega)]^m \ni \phi \longmapsto -\int_\Omega \sum_{k=1}^d z^t \partial_k(\mathcal{A}^k\phi) \in \mathbb{R}$ is bounded on L. In this case, the function in L that can be associated with the above linear form by means of the Riesz representation theorem is denoted by Az. The so-called graph space $W = \{z \in L;\ Az \in L\}$ is endowed with a Hilbert structure when equipped with the scalar product $(z,y)_L + (Az, Ay)_L$. Define the operators $A \in \mathcal{L}(W;L)$ and $\tilde{A} \in \mathcal{L}(W;L)$ by

$$Az = \sum_{k=1}^d \mathcal{A}^k \partial_k z, \qquad \tilde{A}z = -\sum_{k=1}^d \partial_k(\mathcal{A}^k z), \tag{2.1}$$

and set $T = K + A$, $\tilde{T} = K^* + \tilde{A}$. $\tilde{A}$ and $\tilde{T}$ are the formal adjoints of A and T, respectively. Assumption (A3), which implies that $T + \tilde{T}$ is L-coercive on L, is the full L^2-coercivity property alluded to in section 1.

Let $f \in L$ and consider the PDE system $Tz = f$. An important question we are facing now is to equip this problem with proper boundary conditions. The key idea underlying the theory of Friedrichs' systems is that boundary conditions can be enforced by making use of a boundary operator $M \in \mathcal{L}(W;W')$ such that

(M1) $\quad \forall z \in W,\ \langle Mz, z\rangle_{W',W} \ge 0,$

(M2) $\quad W = \mathrm{Ker}(D - M) + \mathrm{Ker}(D + M),$

where $D \in \mathcal{L}(W;W')$ is defined by

$$\forall (z,y) \in W \times W, \quad \langle Dz, y\rangle_{W',W} = (Az, y)_L - (z, \tilde{A}y)_L. \tag{2.2}$$

Observe that (2.2) is just an integration-by-parts formula and that D is self-adjoint by construction. It is shown in [17] that by setting $V = \mathrm{Ker}(D - M)$ and $V^* = \mathrm{Ker}(D + M^*)$, where M^* is the adjoint operator of M, the following problems are well-posed:

$$\text{Seek } z \in V \text{ such that } Tz = f. \qquad \text{Seek } z^* \in V^* \text{ such that } \tilde{T}z^* = f. \tag{2.3}$$

The key idea sustaining the entire DG theory developed in Parts I, II, and hereafter is that it is possible to enforce boundary conditions weakly by introducing the following bilinear forms on $W \times W$,

$$a(z,y) = (Tz, y)_L + \tfrac{1}{2}\langle (M - D)z, y\rangle_{W',W}, \tag{2.4}$$

$$a^*(z,y) = (\tilde{T}z, y)_L + \tfrac{1}{2}\langle (M^* + D)z, y\rangle_{W',W}, \tag{2.5}$$

and by reformulating (2.3) as follows:

$$\text{Seek } z \in W \text{ such that } a(z,y) = (f,y)_L \quad \forall y \in W. \tag{2.6}$$

$$\text{Seek } z^* \in W \text{ such that } a^*(z^*,y) = (f,y)_L \quad \forall y \in W. \tag{2.7}$$

The key well-posedness result established in Part I is the following.

THEOREM 2.1. *Assume* (A1)–(A3) *and* (M1)–(M2). *Then there are unique solutions to* (2.6) *and* (2.7) *and these solutions solve* (2.3).

We finish this section by giving local representations of the operators D and M. Let $n = (n_1, \ldots, n_d)^t$ be the unit outward normal to $\partial\Omega$. Whenever the fields $\{\mathcal{A}^k\}_{1\le k\le d}$ are sufficiently smooth for the field $\mathcal{D} = \sum_{k=1}^d n_k \mathcal{A}^k : \partial\Omega \longrightarrow \mathbb{R}^{m,m}$ to be meaningful at the boundary, the following representation of D holds:

$$\langle Dz, y\rangle_{W',W} = \int_{\partial\Omega} y^t \mathcal{D} z \tag{2.8}$$

for every smooth function z and y. Likewise, we henceforth assume that there is a field $\mathcal{M} : \partial\Omega \longrightarrow \mathbb{R}^{m,m}$ such that following representation of M holds for every smooth function z and y:

$$\langle Mz, y\rangle_{W',W} = \int_{\partial\Omega} y^t \mathcal{M} z. \tag{2.9}$$

2.2. Two-field Friedrichs' systems. We now briefly recall the two-field theory developed in Part II. Elliptic-like PDEs in mixed form lead to Friedrichs' systems with the following 2×2 structure: There are two positive integers m_σ and m_u such that $m = m_\sigma + m_u$ and $L = L_\sigma \times L_u$, where $L_\sigma = [L^2(\Omega)]^{m_\sigma}$ and $L_u = [L^2(\Omega)]^{m_u}$, yielding the decomposition $v = (v^\sigma, v^u)$ for all $v \in L$. With obvious notation this leads to the following block decompositions

$$K = \left[\begin{array}{c:c} K^{\sigma\sigma} & K^{\sigma u} \\ \hdashline K^{u\sigma} & K^{uu} \end{array}\right], \qquad \mathcal{A}^k = \left[\begin{array}{c:c} \mathcal{A}^{\sigma\sigma,k} & \mathcal{B}^k \\ \hdashline (\mathcal{B}^k)^t & \mathcal{C}^k \end{array}\right], \tag{2.10}$$

where for all $k \in \{1, \ldots, d\}$, $\mathcal{B}^k$ is an $m_\sigma \times m_u$ matrix field and $\mathcal{C}^k$ an $m_u \times m_u$ matrix field. Assume now that the block $K^{\sigma\sigma}$ has a local representation, i.e., there is $\mathcal{K}^{\sigma\sigma} \in [L^\infty(\Omega)]^{m_\sigma, m_\sigma}$ such that $K^{\sigma\sigma} y^\sigma = \mathcal{K}^{\sigma\sigma} y^\sigma$ for all $y^\sigma \in L_\sigma$ (this localization hypothesis is needed to locally eliminate the σ-component in the two-field DG method described below). The two key hypotheses on which the two-field theory is based are

$$\forall k \in \{1, \ldots, d\}, \quad \mathcal{A}^{\sigma\sigma,k} = 0, \tag{A4}$$

$$\exists k_0 > 0, \quad \mathcal{K}^{\sigma\sigma} \ge k_0 \mathcal{I}_{m_\sigma}, \tag{A5}$$

where $\mathcal{I}_{m_\sigma}$ is the identity matrix in $\mathbb{R}^{m_\sigma, m_\sigma}$. Assumptions (A4)–(A5) allow us to eliminate the σ-component of z in the PDE system $Tz = f$ leading to an elliptic-like PDE for the u-component. Furthermore, assumption (A4) yields

$$\mathcal{D} = \left[\begin{array}{c:c} 0 & \mathcal{D}^{\sigma u} \\ \hdashline \mathcal{D}^{u\sigma} & \mathcal{D}^{uu} \end{array}\right], \tag{2.11}$$

with $\mathcal{D}^{\sigma u} = \sum_{k=1}^d n_k \mathcal{B}^k$, $\mathcal{D}^{u\sigma} = (\mathcal{D}^{\sigma u})^t$, and $\mathcal{D}^{uu} = \sum_{k=1}^d n_k \mathcal{C}^k$.

Henceforth, boundary conditions are enforced by taking

$$\mathcal{M} = \left[\begin{array}{c|c} 0 & -\alpha\mathcal{D}^{\sigma u} \\ \hline \alpha\mathcal{D}^{u\sigma} & \mathcal{M}^{uu} \end{array}\right], \tag{2.12}$$

where $\mathcal{M}^{uu} \in \mathbb{R}^{m_u,m_u}$ is positive and $\alpha \in \{-1,+1\}$. The choice $\alpha = +1$ leads to the Dirichlet boundary condition $z^u \in \mathrm{Ker}(\mathcal{D}^{\sigma u}) \cap \mathrm{Ker}(\mathcal{M}^{uu} - \mathcal{D}^{uu})$. The choice $\alpha = -1$ yields the Robin-type boundary condition $2\mathcal{D}^{u\sigma}z^\sigma + (\mathcal{D}^{uu} - \mathcal{M}^{uu})z^u = 0$; the boundary condition is of Neumann-type if $\mathcal{M}^{uu} = \mathcal{D}^{uu}$, provided $\mathcal{D}^{uu}$ is positive. In practice (see the examples in sections 3.3 and 3.4), $\mathrm{Ker}(\mathcal{D}^{\sigma u}) = \{0\}$, so that the Dirichlet boundary condition amounts to $z^u = 0$, while the Robin-type boundary condition is enforced by taking $\mathcal{M}^{uu} = |\mathcal{D}^{uu}|$.

It will prove convenient in what follows to define the operators $B = \sum_{k=1}^d \mathcal{B}^k\partial_k$, $B^\dagger = \sum_{k=1}^d [\mathcal{B}^k]^t\partial_k$, and $C = \sum_{k=1}^d \mathcal{C}^k\partial_k$.

2.3. The discrete setting. Let $\{\mathcal{T}_h\}_{h>0}$ be a family of meshes of Ω. To simplify, we assume that the meshes are affine and that Ω is a polyhedron. For all $K \in \mathcal{T}_h$, $n_K = (n_{K,1},\ldots,n_{K,d})^t$ denotes the unit outward normal to K and h_K is the diameter of K. We set $h = \max_{K\in\mathcal{T}_h} h_K$ and we denote by $\mathfrak{h}$ the piecewise constant function such that for all $K \in \mathcal{T}_h$, $\mathfrak{h}|_K = h_K$. Henceforth, the notation $\xi \lesssim \zeta$ means that there is a positive c, *independent of* h, such that $\xi \le c\zeta$.

We denote by $\mathcal{F}_h^{\mathrm{i}}$ the set of mesh interfaces, i.e., $F \in \mathcal{F}_h^{\mathrm{i}}$ if F is a $(d-1)$-manifold and there are $K_1(F)$ and $K_2(F) \in \mathcal{T}_h$ such that $F = K_1(F) \cap K_2(F)$. For $F \in \mathcal{F}_h^{\mathrm{i}}$, we set $\mathcal{T}(F) = K_1(F) \cup K_2(F)$. We denote by $\mathcal{F}_h^\partial$ the set of the faces that separate the mesh from the exterior of Ω, i.e., $F \in \mathcal{F}_h^\partial$ if F is a $(d-1)$-manifold and there is $K(F) \in \mathcal{T}_h$ such that $F = K(F) \cap \partial\Omega$. For $F \in \mathcal{F}_h^\partial$, we set $\mathcal{T}(F) = K(F)$. For all $F \in \mathcal{F}_h^{\mathrm{i}}$, n_F is the unit normal vector on F pointing from $K_1(F)$ to $K_2(F)$, and for all $F \in \mathcal{F}_h^\partial$, n_F is the unit normal vector on F pointing outside Ω. Finally, we set $\mathcal{F}_h = \mathcal{F}_h^{\mathrm{i}} \cup \mathcal{F}_h^\partial$ and for all $F \in \mathcal{F}_h$, h_F denotes the diameter of F. The sole assumption we make on the matching of element faces is that for all $F \in \mathcal{F}_h$, $\max_{K\in\mathcal{T}(F)} h_K \lesssim h_F$. This assumption implies, in particular, that the mesh family $\{\mathcal{T}_h\}_{h>0}$ is shape-regular.

For any measurable subset E of Ω, $(\cdot,\cdot)_{L,E}$ denotes the usual scalar product in $[L^2(E)]^m$. For ease of notation, we define the operators B_h, $B_h^\dagger$, and C_h as the elementwise versions of B, $B^\dagger$, and C, respectively; for instance, for v smooth enough, $(B_hv)|_K = \sum_{k=1}^d \mathcal{B}^k\partial_k(v|_K)$ for all $K \in \mathcal{T}_h$.

Let p be a *nonnegative* integer and consider the DG finite element space

$$W_h = [P_{h,p}]^m, \qquad P_{h,p} = \{v_h \in L^2(\Omega);\, \forall K \in \mathcal{T}_h,\, v_h|_K \in \mathbb{P}_p\}, \tag{2.13}$$

$\mathbb{P}_p$ denoting the vector space of polynomials with real coefficients and with total degree less than or equal to p. Observe that the usual inverse and trace inverse inequalities hold in W_h. For a function v that admits a possibly two-valued trace on mesh interfaces, we define the jump and mean-value of v on $F \in \mathcal{F}_h^{\mathrm{i}}$ as

$$[\![v]\!] = v^1 - v^2, \qquad \{v\} = \tfrac{1}{2}(v^1 + v^2), \tag{2.14}$$

where $v^\gamma(x) = \lim_{y\to x} v(y)|_{K_\gamma(F)}$, $\gamma \in \{1,2\}$. The field $\mathcal{D}$ is extended to $\mathcal{F}_h$ by setting for all $K \in \mathcal{T}_h$, $\mathcal{D} = \sum_{k=1}^d n_{K,k}\mathcal{A}^k$ a.e. on ∂K. Observe that $\mathcal{D}$ is two-valued on $\mathcal{F}_h^{\mathrm{i}}$ with $\{\mathcal{D}\} = 0$ on $\mathcal{F}_h^{\mathrm{i}}$ and that $|\mathcal{D}|$ is well-defined and single-valued since $\mathcal{D}$ is symmetric. We also define $\mathcal{D}_F = \sum_{k=1}^d n_{F,k}\mathcal{A}^k$.

To write a DG method starting from (2.6), we introduce three families of boundary and interface operators: $\{M_F\}_{\mathcal{F}_h^\partial}$, $\{S_F\}_{\mathcal{F}_h^{\mathrm{i}}}$, and $\{R_F\}_{\mathcal{F}_h}$. For all $F \in \mathcal{F}_h^\partial$, the role

of the operator $M_F \in \mathcal{L}([L^2(F)]^m;[L^2(F)]^m)$ is to weakly enforce the boundary conditions on F. For all $F \in \mathcal{F}_h^{\mathrm{i}}$, the role of the operator $S_F \in \mathcal{L}([L^2(F)]^m;[L^2(F)]^m)$ is to penalize the jump of the discrete unknowns across F. For all $F \in \mathcal{F}_h$, the operator $R_F \in \mathcal{L}([L^2(\mathcal{F}_h)]^m;[L^2(F)]^m)$ is user-defined so as to facilitate the implementation of the method. The default option is to take $R_F \equiv 0$ in general for the one-field approach, but a nonzero choice must be made if, when using the multifield approach, one insists on obtaining an IP-like method; cf. Part II. The reader can take $R_F \equiv 0$ in a first reading. The design of the above operators depends on whether the one-field, two-field, or three-field approach is used.

Let $W(h) = W_h + [H^1(\Omega)]^m$ and define on $W(h) \times W(h)$ the DG bilinear form

(2.15)
$$a_h(z,y) = \sum_{K\in\mathcal{T}_h} (Tz,y)_{L,K} + \sum_{F\in\mathcal{F}_h^\partial} \tfrac{1}{2}(M_F(z) - \mathcal{D}z, y)_{L,F} - \sum_{F\in\mathcal{F}_h^{\mathrm{i}}} 2(\{\mathcal{D}z\},\{y\})_{L,F} + \sum_{F\in\mathcal{F}_h^{\mathrm{i}}} (S_F([\![z]\!]),[\![y]\!])_{L,F} + \sum_{F\in\mathcal{F}_h} (R_F([\![z]\!]),[\![y]\!])_{L,F}.$$

The first and second terms on the right-hand side are the discrete counterparts of (2.4). The third term is a consistency term; it is zero whenever z is smooth and it is meant to guarantee the L-coercivity of a_h (recall that (A3) and (M1) imply that a is L-coercive). The discrete counterpart of (2.6) is formulated as follows:

$$\text{Seek } z_h \in W_h \text{ such that } a_h(z_h,y_h) = (f,y_h)_L \quad \forall y_h \in W_h. \tag{2.16}$$

Problem (2.16) can be equivalently reformulated in local form by introducing the notion of flux: Seek $z_h \in W_h$ such that for all $K \in \mathcal{T}_h$ and for all $y \in [\mathbb{P}_p(K)]^m$,

$$(Kz_h,y)_{L,K} + (z_h,\tilde{A}y)_{L,K} + (\phi_{\partial K}(z_h),y)_{L,\partial K} = (f,y)_{L,K}, \tag{2.17}$$

where the element fluxes are defined on a face $F \subset \partial K$ by

$$\phi_{\partial K}(z)|_F = \begin{cases} \frac{1}{2}\mathcal{D}_F z + \frac{1}{2}M_F(z) + R_F(z) & \text{if } F \in \mathcal{F}_h^\partial, \\ n_F{\cdot}n_K(\mathcal{D}_F\{z\} + S_F([\![z]\!]) + R_F([\![z]\!])) & \text{if } F \in \mathcal{F}_h^{\mathrm{i}}. \end{cases} \tag{2.18}$$

2.4. One-field DG approximation. For the one-field DG method, the operators $\{R_F\}_{\mathcal{F}_h}$ are generally set to zero and the operators $\{M_F\}_{\mathcal{F}_h^\partial}$ and $\{S_F\}_{\mathcal{F}_h^{\mathrm{i}}}$ are designed as follows: For all $v,w \in [L^2(F)]^m$,

(DG1A) $$\mathrm{Ker}(\mathcal{M}-\mathcal{D}) \subset \mathrm{Ker}(M_F - \mathcal{D}),$$

(DG1B) $$(M_F(v),v)_{L,F} \geq 0,$$

(DG1C) $$|(M_F(v) - \mathcal{D}v, w)_{L,F}| \lesssim |v|_{M,F}\|w\|_{L,F},$$

(DG1D) $$|(M_F(v) + \mathcal{D}v, w)_{L,F}| \lesssim \|v\|_{L,F}|w|_{M,F},$$

(DG1E) $$S_F = (S_F)^* \text{ and } |\mathcal{D}| \lesssim S_F \lesssim \mathcal{I}_m,$$

where $|v|_{M,F}^2 = (M_F(v),v)_{L,F}$, $\mathcal{I}_m$ is the identity matrix in $\mathbb{R}^{m,m}$, and $(S_F)^*$ is the adjoint operator of S_F. Assumption (DG1A) is a consistency assumption meaning that for all $F \in \mathcal{F}_h^\partial$ and for all $v \in [L^2(F)]^m$, $\mathcal{M}v = \mathcal{D}v$ implies $M_F(v) = \mathcal{D}v$. Design conditions for $\{S_F\}_{\mathcal{F}_h^{\mathrm{i}}}$ slightly more general than (DG1E) are stated in Part I.

To formulate the convergence result, we equip $W(h)$ with the following norms:

$$\|y\|_{h,A}^2 = \|y\|_L^2 + |y|_J^2 + |y|_M^2 + \sum_{K\in\mathcal{T}_h} h_K \|Ay\|_{L,K}^2, \tag{2.19}$$

$$\|y\|_{h,\frac{1}{2}}^2 = \|y\|_{h,A}^2 + \sum_{K\in\mathcal{T}_h} [h_K^{-1}\|y\|_{L,K}^2 + \|y\|_{L,\partial K}^2], \tag{2.20}$$

with $|y|_J^2 = \sum_{F\in\mathcal{F}_h^{\mathrm{i}}} |[\![y]\!]|_{J,F}^2$, $|y|_{J,F}^2 = (S_F([\![y]\!]),[\![y]\!])_{L,F}$, and $|y|_M^2 = \sum_{F\in\mathcal{F}_h^{\partial}} |y|_{M,F}^2$.

The main convergence result derived in Part I is the following.

THEOREM 2.2. *Assume* (DG1A)–(DG1E) *and* $\mathcal{A}^k \in [\mathfrak{C}^{0,\frac{1}{2}}(K)]^{m,m}$ *for all* $K\in\mathcal{T}_h$ *and all* $1\le k\le d$. *Let* $z\in[H^1(\Omega)]^m\cap V$ *solve* (2.6) *and let* z_h *solve* (2.16). *Then*

$$\|z-z_h\|_{h,A} \lesssim \inf_{y_h\in W_h} \|z-y_h\|_{h,\frac{1}{2}}. \tag{2.21}$$

Theorem 2.2 yields $(p+\frac{1}{2})$-order convergence in the L-norm and p-order convergence in the broken graph norm if the mesh family is quasi-uniform and the exact solution is in the broken Sobolev space $[H^{p+1}(\mathcal{T}_h)]^m$.

2.5. Two-field DG approximation. Let $p_u>0$ be a *positive* integer and take $p_\sigma\in\mathbb{N}$ such that $p_u-1\le p_\sigma$. Define the finite element spaces

$$\Sigma_h = [P_{h,p_\sigma}]^{m_\sigma}, \qquad U_h = [P_{h,p_u}]^{m_u}, \qquad W_h = \Sigma_h\times U_h. \tag{2.22}$$

The bilinear form a_h is still defined by (2.15) and the discrete problem is still (2.16).

The design of the operators $\{M_F\}_{F\in\mathcal{F}_h^{\partial}}$, $\{S_F\}_{F\in\mathcal{F}_h^{\mathrm{i}}}$, and $\{R_F\}_{F\in\mathcal{F}_h^{\partial}}$ for the two-field DG approximation hinges on the requirement that we be able to locally eliminate the discrete component z_h^σ. To this purpose, these operators are designed such that

(DG2A) $$M_F = \left[\begin{array}{c|c} 0 & -\alpha\mathcal{D}^{\sigma u} \\ \hline \alpha\mathcal{D}^{u\sigma} & M_F^{uu}\end{array}\right],\ \alpha\in\{-1,+1\}, \quad S_F = \left[\begin{array}{c|c} 0 & 0 \\ \hline 0 & S_F^{uu}\end{array}\right], \quad R_F = \left[\begin{array}{c|c} 0 & 0 \\ \hline 0 & R_F^{uu}\end{array}\right];$$

(DG2B) if $\alpha=+1$, $$\begin{cases} M_F^{uu} = (M_F^{uu})^* \quad\text{and}\quad \mathrm{Ker}(\mathcal{D}^{\sigma u})\subset\mathrm{Ker}(M_F^{uu}-\mathcal{D}^{uu}),\\ h_F^{-1}(\mathcal{D}^{u\sigma}\mathcal{D}^{\sigma u})^{\frac{1}{2}} + h_F|\mathcal{D}^{uu}| \lesssim M_F^{uu} \lesssim h_F^{-1}\mathcal{I}_{m_u};\end{cases}$$

(DG2C) if $\alpha=-1$, $M_F^{uu}(v) = \mathcal{M}^{uu}v$ and $|\mathcal{D}^{uu}|\lesssim\mathcal{M}^{uu}\lesssim\mathcal{I}_{m_u}$;

(DG2D) $S_F^{uu} = (S_F^{uu})^*$ and $h_F^{-1}(\mathcal{D}^{u\sigma}\mathcal{D}^{\sigma u})^{\frac{1}{2}} + h_F|\mathcal{D}^{uu}| \lesssim S_F^{uu} \lesssim h_F^{-1}\mathcal{I}_{m_u}$.

Furthermore, letting $|y^u|_J^2 = \sum_{F\in\mathcal{F}_h^{\mathrm{i}}} |y^u|_{J,F}^2$ and $|y^u|_M^2 = \sum_{F\in\mathcal{F}_h^{\partial}} |y^u|_{M,F}^2$, where

$$|y^u|_{J,F}^2 = (S_F^{uu}([\![y^u]\!]),[\![y^u]\!])_{L_u,F}, \qquad |y^u|_{M,F}^2 = (M_F^{uu}(y^u),y^u)_{L_u,F}, \tag{2.23}$$

the user-dependent operator R_F^{uu} must be designed such that for all $z_h^u\in U_h$ and all $(z^u,y_h^u)\in U(h)\times U_h$,

(DG2E) $$\sum_{F\in\mathcal{F}_h} (R_F^{uu}([\![z_h^u]\!]),[\![z_h^u]\!])_{L_u,F} \ge -\frac{1}{4}(|z_h^u|_J^2 + |z_h^u|_M^2),$$

(DG2F) $$\sum_{F\in\mathcal{F}_h} (R_F^{uu}([\![z^u]\!]),[\![y_h^u]\!])_{L_u,F} \lesssim (|z^u|_J + |z^u|_M)(|y_h^u|_J + |y_h^u|_M).$$

Owing to (DG2A), the σ-component of the element fluxes defined by (2.18) does not depend on z_h^σ, thus allowing for the local elimination of z_h^σ. Design conditions slightly more general than (DG2A)–(DG2D) are stated in Part II. Furthermore, assumptions (DG2A)–(DG2C) imply the consistency condition $\mathrm{Ker}(\mathcal{M}-\mathcal{D}) \subset \mathrm{Ker}(M_F-\mathcal{D})$ and the adjoint-consistency condition $\mathrm{Ker}(\mathcal{M}^t+\mathcal{D}) \subset \mathrm{Ker}(M_F^*+\mathcal{D})$. Indeed, both conditions are evident if $\alpha=-1$ since (DG2A) and (DG2C) imply $M_F=\mathcal{M}$. If $\alpha=+1$, the consistency condition directly results from (DG2B), while the adjoint-consistency condition results from the fact that if $z \in \mathrm{Ker}(\mathcal{M}^t+\mathcal{D})$, $\mathcal{D}^{\sigma u} z^u = 0$ and using (DG2B) yields $(\mathcal{M}^{uu})^t z^u = -\mathcal{D}^{uu} z^u = -M_F^{uu}(z^u) = -(M_F^{uu})^*(z^u)$. Finally, we observe that the second part of assumption (DG2C) imposes a condition on the way the Robin–Neumann boundary condition is enforced rather than on the DG setting; in practice, $\mathcal{M}^{uu} = |\mathcal{D}^{uu}|$ (see section 3.3.2) so that (DG2C) holds.

Equip $W(h)$ with the following norms:

$$\|y\|_{h,B}^2 = \|y\|_L^2 + |y^u|_J^2 + |y^u|_M^2 + \|B_h y^u\|_{L_\sigma}^2, \tag{2.24}$$

$$\|y\|_{h,1}^2 = \|y\|_{h,B}^2 + \sum_{K\in\mathcal{T}_h} [h_K^{-2}\|z^u\|_{L_u,K}^2 + h_K^{-1}\|z^u\|_{L_u,\partial K}^2 + h_K\|z^\sigma\|_{L_\sigma,\partial K}^2], \tag{2.25}$$

$$\|y\|_{h,1^+}^2 = \|y\|_{h,1}^2 + \sum_{K\in\mathcal{T}_h} [h_K^2\|y^\sigma\|_{[H^1(K)]^{m_\sigma}}^2 + h_K\|y^\sigma\|_{L_\sigma,\partial K}^2]. \tag{2.26}$$

The main convergence result proved in Part II is the following.

THEOREM 2.3. *Assume* (DG2A)–(DG2F) *and* $\mathcal{B}^k \in [\mathfrak{C}^{0,1}(K)]^{m_\sigma,m_u}$ *for all* $K\in\mathcal{T}_h$ *and* $1\le k\le d$. *Let* $z\in[H^1(\Omega)]^m\cap V$ *solve* (2.6) *and let* z_h *solve* (2.16). *Then*

$$\|z-z_h\|_{h,B} \lesssim \inf_{y_h\in W_h} \|z-y_h\|_{h,1}. \tag{2.27}$$

Moreover, if for every $y^u\in L_u$, *the solution* $\psi\in V^*$ *to the dual problem* $\tilde{T}\psi=(0,y^u)$ *is such that* $\|\psi^u\|_{[H^2(\Omega)]^{m_u}} + \|\psi^\sigma\|_{[H^1(\Omega)]^{m_\sigma}} \lesssim \|y^u\|_{L_u}$, *then*

$$\|z^u-z_h^u\|_{L_u} \lesssim h \inf_{y_h\in W_h} \|z-y_h\|_{h,1^+}. \tag{2.28}$$

If the exact solution is in $[H^{p_u}(\mathcal{T}_h)]^{m_\sigma}\times[H^{p_u+1}(\mathcal{T}_h)]^{m_u}$, Theorem 2.3 yields p_u-order convergence in the L_σ-norm for the σ-component, (p_u+1)-order convergence in the L_u-norm for the u-component, and p_u-order convergence in the broken graph norm for the u-component.

3. Two-field theory with L_σ-coercivity only. The goal of this section is to weaken assumption (A3), so as to be able to account for two-field Friedrichs' systems with no L_u-coercivity on the u-component. The model problems we have in mind are advection–diffusion equations with no zero-order term, i.e., no reaction (see section 3.3), and compressible linear continuum mechanics (see section 3.4).

3.1. Two-field Friedrichs' systems with L_σ-coercivity only. We assume

$$\text{(A3A)} \qquad \forall z\in L,\quad ((K+K^*-\nabla\cdot A)z,z)_L \gtrsim \|z^\sigma\|_{L_\sigma}^2,$$

$$\text{(A3B}') \qquad K^{\sigma u} = (K^{u\sigma})^* = 0 \text{ and the fields } \mathcal{B}^k \text{ are constant over } \Omega,$$

$$\text{(A3B}'') \qquad \forall z\in V\cup V^*,\quad \|z^u\|_{L_u} \lesssim a(z,z)^{\frac12} + \|Bz^u\|_{L_\sigma}.$$

Observe that (A3B″) is meaningful since a is L_σ-coercive on W. Indeed, the definition of D and assumptions (M1) and (A3A) yield, for all $z \in W$,

$$a(z,z) = \tfrac{1}{2}[(Tz,z)_L + (z,\tilde{T}z)_L] + \tfrac{1}{2}\langle Mz,z\rangle_{W',W} \gtrsim \|z^\sigma\|_{L_\sigma}^2. \tag{3.1}$$

Moreover, T (resp., T^*) is L_σ-coercive on V (resp., V^*).

THEOREM 3.1. *The conclusions of Theorem* 2.1 *still hold if assumption* (A3) *is replaced by assumptions* (A3A)–(A3B′)–(A3B″).

Proof. (1) Let us first prove that $T : V \to L$ is an isomorphism by using the so-called Banach–Nečas–Babuška (BNB) theorem, which states that the bijectivity of $T \in \mathcal{L}(V;L)$ is equivalent to the following conditions [14, p. 85]:

$$\forall z \in V, \quad \sup_{y\in L\setminus\{0\}} \frac{(Tz,y)_L}{\|y\|_L} = \|Tz\|_L \gtrsim \|z\|_W, \tag{3.2}$$

$$\forall y \in L, \quad ((Tz,y)_L = 0 \ \forall z \in V) \implies (y = 0). \tag{3.3}$$

Recall that the graph norm is $\|z\|_W = \|z\|_L + \|Az\|_L$ with $\|z\|_L = \|z^\sigma\|_{L_\sigma} + \|z^u\|_{L_u}$ and $\|Az\|_L = \|Bz^u\|_{L_\sigma} + \|B^\dagger z^\sigma + Cz^u\|_{L_u}$.

(1a) Proof of (3.2). Let $z \in V$. Owing to (A3B′), $Bz^u = (Tz)^\sigma - \mathcal{K}^{\sigma\sigma} z^\sigma$. Hence, $\|Bz^u\|_{L_\sigma} \lesssim \|z^\sigma\|_{L_\sigma} + \|Tz\|_L$. Then, since $a(z,z) = (Tz,z)_L$, (A3B″) implies

$$\|z^u\|_{L_u} \lesssim (Tz,z)_L^{\frac{1}{2}} + c(\|z^\sigma\|_{L_\sigma} + \|Tz\|_L) \lesssim \gamma\|z^u\|_{L_u} + (\|z^\sigma\|_{L_\sigma} + \|Tz\|_L),$$

where $\gamma > 0$ can be chosen as small as needed. Hence, $\|z^u\|_{L_u} \lesssim \|z^\sigma\|_{L_\sigma} + \|Tz\|_L$. Combining this result with the L_σ-coercivity of T on V yields

$$\|z^\sigma\|_{L_\sigma}^2 \lesssim \frac{(Tz,z)_L}{\|z\|_L}(\|z^\sigma\|_{L_\sigma} + \|z^u\|_{L_u}) \lesssim \|Tz\|_L(\|z^\sigma\|_{L_\sigma} + \|Tz\|_L),$$

whence $\|z^\sigma\|_{L_\sigma} \lesssim \|Tz\|_L$. Collecting the above bounds leads to $\|z\|_L \lesssim \|Tz\|_L$, and hence $\|z\|_W = \|z\|_L + \|Az\|_L \lesssim \|z\|_L + \|Tz\|_L \lesssim \|Tz\|_L$.

(1b) Proof of (3.3). Assume that $y \in L$ is such that $(Tz,y)_L = 0$ for all $z \in V$. Following the same arguments as in the proof of [15, Theorem 2.5] in Part I or Corollary 5.8 in [14], we infer that $y \in V^*$ and $\tilde{T}y = 0$. The L_σ-coercivity of $\tilde{T}$ on V^* yields $y^\sigma = 0$. Proceeding as above using (A3B′) leads to $\|z^u\|_{L_u} \lesssim \|z^\sigma\|_{L_\sigma} + \|\tilde{T}z\|_L$ for all $z \in V^*$. Applying this estimate to y yields $y^u = 0$. Hence, $y = 0$.

(2) Since $T : V \to L$ is an isomorphism and $V = \mathrm{Ker}(D - M)$, a solution to (2.6) is readily constructed by setting $z = T^{-1}f$. To prove uniqueness, let us prove that the only solution to (2.6) with $f = 0$ is $z = 0$. Since a is L_σ-coercive on W, $z^\sigma = 0$. In addition, taking $y \in [\mathfrak{D}(\Omega)]^m$ in (2.6) yields $Tz = 0$ in L and $z \in V$. Hence, the bound $\|Bz^u\|_{L_\sigma} \lesssim \|z^\sigma\|_{L_\sigma} + \|Tz\|_L$ implies $Bz^u = 0$ and owing to (A3B″), $z^u = 0$.

(3) Proceed similarly to prove that problem (2.7) is well-posed. ∎

3.2. Two-field DG approximation with L_σ-coercivity only. Consider the two-field DG method introduced in section 2.5 and assume that conditions (DG2A)–(DG2F) are fulfilled. The objective of this section is to analyze the convergence of the two-field DG approximation in the framework of the partial coercivity assumptions (A3A), (A3B′), and (A3B″). The discrete counterpart of assumption (A3B″) is

$$\forall z_h \in W_h, \quad \|z_h^u\|_{L_u} \lesssim a_h(z_h,z_h)^{\frac{1}{2}} + \|B_h z_h^u\|_{L_\sigma}. \tag{3.4}$$

Recall that the norm $\|\cdot\|_{h,B}$ is defined by (2.24).

LEMMA 3.2. *Assume* (A3A)–(A3B′), (3.4), *and* (DG2A)–(DG2F). *Then*

$$\forall z_h \in W_h, \qquad \|z_h\|_{h,B} \lesssim \sup_{y_h \in W_h\setminus\{0\}} \frac{a_h(z_h,y_h)}{\|y_h\|_{h,B}}. \tag{3.5}$$

Proof. Let $z_h \in W_h$. Owing to the definition of a_h, (DG2A), (DG2E), and (A3A),

$$\|z_h^\sigma\|_{L_\sigma}^2 + |z_h^u|_J^2 + |z_h^u|_M^2 \lesssim a_h(z_h,z_h). \tag{3.6}$$

Set $\varpi_h = (B_h z_h^u, 0)$ and observe that $\varpi_h \in W_h$ since the fields $\mathcal{B}^k$ are constant over Ω and $p_u - 1 \le p_\sigma$. Moreover,

$$\begin{aligned}\|B_h z_h^u\|_{L_\sigma}^2 &= a_h(z_h,\varpi_h) - (\mathcal{K}^{\sigma\sigma} z_h^\sigma, B_h z_h^u)_{L_\sigma} - \sum_{F\in\mathcal{F}_h^\partial} \tfrac{\alpha+1}{2} (\mathcal{D}^{\sigma u} z_h^u, B_h z_h^u)_{L_{\sigma},F} \\ &\quad + \sum_{F\in\mathcal{F}_h^{\mathrm{i}}} 2(\{\mathcal{D}^{\sigma u} z_h^u\}, \{B_h z_h^u\})_{L_\sigma,F} := a_h(z_h,\varpi_h) + R_1 + R_2 + R_3.\end{aligned}$$

Clearly, $|R_1| \lesssim \|z_h^\sigma\|_{L_\sigma}^2 + \gamma \|B_h z_h^u\|_{L_\sigma}^2$, where $\gamma > 0$ can be chosen as small as needed. If $\alpha = +1$, use (DG2B) and a trace inverse inequality to infer

$$|R_2| \lesssim \sum_{F\in\mathcal{F}_h^\partial} h_F^{\frac12} |z_h^u|_{M,F} h_F^{-\frac12} \|B_h z_h^u\|_{L_\sigma,\mathcal{T}(F)} \lesssim |z_h^u|_M^2 + \gamma \|B_h z_h^u\|_{L_\sigma}^2,$$

while if $\alpha = -1$, $R_2 = 0$. Finally, using $\{\mathcal{D}^{\sigma u}\} = 0$ and (DG2D) leads to $|R_3| \lesssim |z_h^u|_J^2 + \gamma \|B_h z_h^u\|_{L_\sigma}^2$. Collecting the above bounds yields

$$\|B_h z_h^u\|_{L_\sigma}^2 \lesssim a_h(z_h,\varpi_h) + a_h(z_h,z_h),$$

and owing to (3.4) and (3.6), it is inferred that $\|z_h\|_{h,B}^2 \lesssim a_h(z_h,\varpi_h) + a_h(z_h,z_h)$. Conclude using the fact that $\|\varpi_h\|_{h,B} = \|B_h z_h^u\|_{L_\sigma} \lesssim \|z_h\|_{h,B}$. ∎

It is now straightforward to verify the following convergence result.

THEOREM 3.3. *The statement of Theorem* 2.3 *remains valid under the assumptions of Lemma* 3.2.

3.3. Example 1: Advection–diffusion. Let $f \in L^2(\Omega)$ and let $\beta \in [L^\infty(\Omega)]^d$ with $\nabla\cdot\beta \in L^\infty(\Omega)$. Let $\mu \in L^\infty(\Omega)$ and let $\kappa = (\kappa_{kl})_{1\le k,l\le d}$ be a symmetric positive definite tensor-valued field defined on Ω whose lowest eigenvalue is uniformly bounded away from zero. Consider the PDE $-\nabla\cdot(\kappa\nabla u) + \beta\cdot\nabla u + \mu u = f$ in mixed form

$$\begin{cases} \kappa^{-1}\sigma + \nabla u = 0, \\ \mu u + \nabla\cdot\sigma + \beta\cdot\nabla u = f. \end{cases} \tag{3.7}$$

Letting $m = d+1$, $m_\sigma = d$, and $m_u = 1$, the mixed formulation (3.7) fits the two-field framework by setting, for all $z \in L$ and for all $k \in \{1,\dots,d\}$,

$$K(z) = \left[\begin{array}{c:c} \kappa^{-1} & 0 \\ \hdashline 0 & \mu \end{array}\right] z, \qquad \mathcal{A}^k = \left[\begin{array}{c:c} 0 & e^k \\ \hdashline (e^k)^t & \beta^k \end{array}\right], \tag{3.8}$$

where e^k is the kth vector in the canonical basis of $\mathbb{R}^d$, and β^k is the kth component of β. Clearly, hypotheses (A1), (A2), (A4), and (A5) hold. We further assume that

$$\inf_\Omega \operatorname{ess}(\mu - \tfrac12 \nabla\cdot\beta) \ge 0 \tag{3.9}$$

so that (A3) does not hold, but (A3A) holds instead with μ_0 equal to the reciprocal of the largest eigenvalue of κ. This situation covers, in particular, the Laplace/Poisson equation where $\mu = 0$ and $\beta = 0$.

The graph space is $W = H(\mathrm{div};\Omega) \times H^1(\Omega)$ and the boundary operator D is such that for all $z, y \in W$,

$$\langle Dz, y\rangle_{W',W} = \langle z^\sigma \cdot n, y^u\rangle_{-\frac{1}{2},\frac{1}{2}} + \langle y^\sigma \cdot n, z^u\rangle_{-\frac{1}{2},\frac{1}{2}} + \int_{\partial\Omega} (\beta\cdot n) z^u y^u, \tag{3.10}$$

where $\langle , \rangle_{-\frac{1}{2},\frac{1}{2}}$ denotes the duality pairing between $H^{-\frac{1}{2}}(\partial\Omega)$ and $H^{\frac{1}{2}}(\partial\Omega)$. Dirichlet boundary conditions can be enforced by setting

$$\langle Mz, y\rangle_{W',W} = \langle z^\sigma \cdot n, y^u\rangle_{-\frac{1}{2},\frac{1}{2}} - \langle y^\sigma \cdot n, z^u\rangle_{-\frac{1}{2},\frac{1}{2}}, \tag{3.11}$$

yielding $V = H(\mathrm{div};\Omega)\times H^1_0(\Omega)$. Furthermore, mixed Robin–Neumann boundary conditions can be enforced by setting

$$\langle Mz, y\rangle_{W',W} = -\langle z^\sigma \cdot n, y^u\rangle_{-\frac{1}{2},\frac{1}{2}} + \langle y^\sigma \cdot n, z^u\rangle_{-\frac{1}{2},\frac{1}{2}} + \int_{\partial\Omega} (2\varrho + \beta\cdot n) z^u y^u, \tag{3.12}$$

where $\varrho \in L^\infty(\partial\Omega)$ is such that $2\varrho + \beta\cdot n \geq 0$ a.e. on $\partial\Omega$. Then $V = \{z \in W;\, z^\sigma\cdot n - \varrho z^u|_{\partial\Omega} = 0\}$ and $V^* = \{z \in W;\, z^\sigma\cdot n + (\varrho + \beta\cdot n) z^u|_{\partial\Omega} = 0\}$. In terms of boundary fields, (3.10), (3.11), (3.12), respectively, yield

$$\mathcal{D} = \left[\begin{array}{c:c} 0 & n \\ \hdashline n^t & \beta\cdot n \end{array}\right], \qquad \mathcal{M} = \left[\begin{array}{c:c} 0 & -n \\ \hdashline n^t & 0 \end{array}\right], \qquad \mathcal{M} = \left[\begin{array}{c:c} 0 & n \\ \hdashline -n^t & 2\varrho + \beta\cdot n \end{array}\right]. \tag{3.13}$$

Observe that $\mathrm{Ker}(\mathcal{D}^{\sigma u}) = \{0\}$. Furthermore, a possible choice for the mixed Robin–Neumann boundary condition is $\varrho = -\min(\beta\cdot n, 0)$ (or, equivalently, $\mathcal{M}^{uu} = |\beta\cdot n| = |\mathcal{D}^{uu}|$), yielding the usual Robin (inflow) condition $(z^\sigma + \beta z^u)\cdot n = 0$ on $\partial\Omega^- = \{x \in \partial\Omega;\, \beta(x)\cdot n(x) < 0\}$ and the usual Neumann (outflow) condition $z^\sigma\cdot n = 0$ on $\partial\Omega\backslash\partial\Omega^-$.

3.3.1. Well-posedness. Let us verify that the advection–diffusion equation equipped with the above boundary conditions fits the theoretical framework analyzed in section 3.1.

PROPOSITION 3.4. *Assumptions* (A3A), (A3B′), *and* (A3B″) *hold for Dirichlet boundary conditions and for mixed Robin–Neumann boundary conditions, provided either* $\mu - \frac{1}{2}\nabla\cdot\beta \neq 0$ *or* $\varrho + \frac{1}{2}\beta\cdot n \neq 0$ *(this means that either* $\mu - \frac{1}{2}\nabla\cdot\beta$ *or* $\varrho + \frac{1}{2}\beta\cdot n$ *is uniformly bounded away from zero on a measurable subset of* Ω *or of* $\partial\Omega$*, respectively, of nonzero measure).*

Proof. Assumptions (A3A) and (A3B′) are evident. Observe also that $Bz^u = \nabla z^u$.

(1) For Dirichlet boundary conditions, (A3B″) directly results from the Poincaré inequality since $z \in V = V^*$ implies $z^u \in H^1_0(\Omega)$ so that $\|z^u\|_{L_u} \lesssim \|\nabla z^u\|_{L_\sigma}$.

(2) For mixed Robin–Neumann boundary conditions, observe that for all $z \in W$,

$$a(z,z) \geq \int_\Omega (\mu - \tfrac{1}{2}\nabla\cdot\beta)(z^u)^2 + \int_{\partial\Omega} (\varrho + \tfrac{1}{2}\beta\cdot n)(z^u)^2. \tag{3.14}$$

We apply Lemma 3.5 below; it is a simple variant of the Petree–Tartar lemma (the proof is omitted for brevity). Take $X = H^1(\Omega)$, $Y = [L^2(\Omega)]^d$, $Z = L^2(\Omega)$, $Fx = \nabla x$, $Gx = x$, and $\Phi(x) = \|(\mu - \frac{1}{2}\nabla\cdot\beta)^{\frac{1}{2}} x\|_{L^2(\Omega)} + \|(\varrho + \frac{1}{2}\beta\cdot n)^{\frac{1}{2}} x\|_{L^2(\partial\Omega)}$. Properties (i) and (iii) are evident. Property (ii) results from the fact that if $\|Fx\|_Y + \Phi(x) = 0$,

then x is constant (since Ω is connected) and $\Phi(x) = 0$ implies that $x = 0$ since $\mu - \frac{1}{2}\nabla\cdot\beta \neq 0$ or $\varrho + \frac{1}{2}\beta\cdot n \neq 0$. Moreover, Φ is continuous since for all $x, y \in X$, $|\Phi(x) - \Phi(y)| \leq \Phi(x - y) \lesssim \|x - y\|_X$. Hence, Lemma 3.5 yields $\|z^u\|_{L_u} \lesssim \Phi(z^u) + \|\nabla z^u\|_{L_\sigma}$, whence (A3B$''$) follows owing to (3.14). ∎

LEMMA 3.5. *Let X, Y, Z be Banach spaces, let $F \in \mathcal{L}(X;Y)$, and let $G \in \mathcal{L}(X;Z)$. Let $\Phi : X \to \mathbb{R}_+$ be a continuous functional. Assume that*

(i) *G is compact;*

(ii) *for all $x \in X$, $(\|Fx\|_Y + \Phi(x) = 0) \Rightarrow (x = 0)$;*

(iii) *there is $\gamma_1 > 0$ such that for all $x \in X$, $\gamma_1\|x\|_X \leq \|Fx\|_Y + \|Gx\|_Z$.*

Then there is $\gamma_2 > 0$ such that for all $x \in X$, $\gamma_2\|x\|_X \leq \|Fx\|_Y + \Phi(x)$.

Remark 3.1. When mixed Robin–Neumann boundary conditions are enforced and $\mu - \frac{1}{2}\nabla\cdot\beta = 0$ and $2\varrho + \beta\cdot n = 0$, (A3B$''$) no longer holds and the analysis proceeds as follows. If $\mu \neq 0$ or $\varrho \neq 0$, it is easily verified that T is injective on V and that $\tilde{T}$ is injective on V^*. The injectivity of T on V combined with Lemma 3.5 easily yields (3.2), while the injectivity of $\tilde{T}$ on V^* yields (3.3); thus well-posedness holds. If $\mu = \nabla\cdot\beta = 0$ and $\varrho = \beta\cdot n = 0$, then T is no longer injective on V, the compatibility condition $\langle f\rangle_\Omega = 0$ must be imposed on the data, and the solution u is subjected to the constraint $\langle u\rangle_\Omega = 0$ (here, for a function $\phi \in L^2(\Omega)$, $\langle\phi\rangle_\Omega := \frac{1}{|\Omega|}\int_\Omega \phi$, where $|\Omega|$ denotes the measure of Ω). Hence, we modify (3.7) as follows:

$$\begin{cases} \kappa^{-1}\sigma + \nabla u = 0, \\ \nabla\cdot\sigma + \beta\cdot\nabla u + \langle u\rangle_\Omega = f, \end{cases} \tag{3.15}$$

equipped with the boundary condition $\sigma\cdot n|_{\partial\Omega} = 0$. Since $\langle\nabla\cdot\sigma + \beta\cdot\nabla u\rangle_\Omega = \langle f\rangle_\Omega = 0$, the second PDE implies $\langle u\rangle_\Omega = 0$, i.e., (3.15) is equivalent to (3.7) together with $\langle u\rangle_\Omega = 0$. Moreover, for all $z \in W$, $a(z,z) \geq |\Omega|\langle z^u\rangle_\Omega^2$, so that (A3B$''$) results from the fact that for all $\phi \in H^1(\Omega)$, $\|\phi\|_{L_u} \lesssim \langle\phi\rangle_\Omega + \|\nabla\phi\|_{L_\sigma}$.

3.3.2. Two-field DG approximation. When Dirichlet boundary conditions are enforced, let $\eta_1 > 0$, $\eta_2 > 0$ (these parameters can vary from face to face), and set

$$M_F^{uu}(v) = \eta_1 h_F^{-1} v, \qquad S_F^{uu}(v) = \eta_2 h_F^{-1} v, \qquad R_F^{uu} \equiv 0. \tag{3.16}$$

Since $\mathcal{D}^{u\sigma}\mathcal{D}^{\sigma u} = 1$ and $\mathcal{D}^{uu} = \beta\cdot n$, properties (DG2A)–(DG2F) hold. Many other choices can be considered for M_F^{uu}, S_F^{uu}, and R_F^{uu}; see Part II [16] for details.

PROPOSITION 3.6. *Property* (3.4) *holds.*

Proof. The proof is a direct consequence of the fact that for all $v_h \in U_h$,

$$\|v_h\|_{L_u}^2 \lesssim \sum_{K\in\mathcal{T}_h} \|\nabla v_h\|_{L_\sigma,K}^2 + \sum_{F\in\mathcal{F}_h^{\mathrm{i}}} h_F^{-1}\|[\![v_h]\!]\|_{L_u,F}^2 + \sum_{F\in\mathcal{F}_h^{\partial}} h_F^{-1}\|v_h\|_{L_u,F}^2.$$

See [1, 6] or [14, p. 134] for the proof. ∎

When mixed Robin–Neumann boundary conditions are enforced, (DG2C) holds for $M_F^{uu}(v) = \mathcal{M}^{uu}v = (2\varrho + \beta\cdot n)v$, provided $\varrho \geq -\min(\beta\cdot n, 0)$, while S_F^{uu} can be chosen as in (3.16).

PROPOSITION 3.7. *Assume that either $\mu - \frac{1}{2}\nabla\cdot\beta \neq 0$ or $\varrho + \frac{1}{2}\beta\cdot n \neq 0$ and that Ω is such that $H^{\frac{3}{2}+\epsilon}$-elliptic regularity holds, $\epsilon > 0$. Then property* (3.4) *holds.*

Proof. Let v_h be an arbitrary function in U_h. Let $\psi \in H^1(\Omega)$ solve

$$(\mu - \tfrac{1}{2}\nabla\cdot\beta)\psi - \Delta\psi = v_h, \qquad \partial_n\psi|_{\partial\Omega} = -(\rho + \tfrac{1}{2}\beta\cdot n)\psi.$$

This problem is well-posed (proceed as in the proof of Proposition 3.4), and the $H^{\frac{3}{2}+\epsilon}$-elliptic regularity hypothesis means that $\|\psi\|_{H^{\frac{3}{2}+\epsilon}} \lesssim \|v_h\|_{L_u}$. Testing with v_h yields

$$\begin{aligned}\|v_h\|_{L_u}^2 &= ((\mu - \tfrac{1}{2}\nabla\cdot\beta)\psi, v_h)_{L_u} + \sum_{K\in\mathcal{T}_h} (\nabla\psi, \nabla v_h)_{L_\sigma,K} \\ &\quad - \sum_{F\in\mathcal{F}_h^{\mathrm{i}}} \int_F 2\nabla\psi\cdot\{nv_h\} + \sum_{F\in\mathcal{F}_h^{\partial}} \int_F (\varrho + \tfrac{1}{2}\beta\cdot n)\psi v_h \\ &\lesssim \|\psi\|_{H^{\frac{3}{2}+\epsilon}} \Big(\|(\mu - \tfrac{1}{2}\nabla\cdot\beta)^{\frac{1}{2}} v_h\|_{L_u} + \Big(\sum_{K\in\mathcal{T}_h} \|\nabla v_h\|_{L_\sigma,K}^2 \Big)^{\frac{1}{2}} + |v_h|_J \\ &\qquad + \|(\varrho + \tfrac{1}{2}\beta\cdot n)^{\frac{1}{2}} v_h\|_{L_u,\partial\Omega} \Big).\end{aligned}$$

The conclusion follows readily. ∎

3.4. Example 2: Compressible linear continuum mechanics. Let $\beta \in [L^\infty(\Omega)]^d$ with $\nabla\cdot\beta \in L^\infty(\Omega)$, let λ, $\delta \in L^\infty(\Omega)$, and let $f \in [L^2(\Omega)]^d$. Consider the set of PDEs

$$\begin{cases} \sigma - \frac{1}{d+\delta}\mathrm{tr}(\sigma)\mathcal{I}_d - \frac{1}{2}(\nabla u + (\nabla u)^t) = 0, \\ -\frac{1}{2}\nabla\cdot(\sigma + \sigma^t) + \beta\cdot\nabla u + \lambda u = f, \end{cases} \tag{3.17}$$

where σ is $\mathbb{R}^{d,d}$-valued and u is $\mathbb{R}^d$-valued. Assuming $\delta \neq 0$, the first equation in (3.17) implies $\sigma = \frac{1}{2}(\nabla u + (\nabla u)^t) + \delta^{-1}(\nabla\cdot u)\mathcal{I}_d$. Equations (3.17) are a linearized version of the compressible Navier–Stokes equations and model also linear continuum mechanics (when $\lambda = 0$ and $\beta = 0$). In the context of linear continuum mechanics these equations are usually referred to as the displacement-stress formulation. The tensor field σ with values in $\mathbb{R}^{d,d}$ can be identified with the vector field $\overline{\sigma}$ with values in $\mathbb{R}^{d^2}$ by setting $\overline{\sigma}_{[ij]} = \sigma_{ij}$ with $1 \le i,j \le d$ and $[ij] := d(j-1)+i$. To alleviate the notation, we henceforth use the same symbol for both fields.

Set $m = d^2 + d$, $m_\sigma = d^2$, and $m_u = d$. The mixed formulation (3.17) fits in the framework of two-field Friedrichs' systems by setting, for all $z \in L$ and for all $k \in \{1,\dots,d\}$,

$$K(z) = \left[\begin{array}{c:c} \mathcal{I}_{d^2} - \frac{1}{d+\delta}\mathcal{Z} & 0 \\ \hdashline 0 & \lambda\mathcal{I}_d \end{array}\right] z, \qquad \mathcal{A}^k = \left[\begin{array}{c:c} 0 & \mathcal{E}^k \\ \hdashline (\mathcal{E}^k)^t & \mathcal{C}^k \end{array}\right], \tag{3.18}$$

where $\mathcal{Z} \in \mathbb{R}^{d^2,d^2}$ is such that $\mathcal{Z}_{[ij][kl]} = \delta_{ij}\delta_{kl}$ with $1 \le i,j,k,l \le d$, and for all $k \in \{1,\dots,d\}$, $\mathcal{C}^k = \beta^k\mathcal{I}_d \in \mathbb{R}^{d,d}$ and $\mathcal{E}^k \in \mathbb{R}^{d^2,d}$ is such that $\mathcal{E}^k_{[ij],l} = -\frac{1}{2}(\delta_{ik}\delta_{jl} + \delta_{il}\delta_{jk})$ with $1 \le i,j,l \le d$; here, the δ's are Kronecker symbols. Clearly, hypotheses (A1), (A2), and (A4) hold. We further assume that

$$\lambda_0 := \inf_\Omega \mathrm{ess}(\lambda - \tfrac{1}{2}\nabla\cdot\beta) \ge 0, \qquad \delta_0 := \inf_\Omega \mathrm{ess}\,\delta > 0. \tag{3.19}$$

Then observing that

$$\begin{aligned}\mathcal{K}^{\sigma\sigma}\sigma\cdot\sigma = (\sigma - \tfrac{1}{d+\delta}\mathrm{tr}(\sigma)\mathcal{I}_d) : \sigma &= \tfrac{\delta}{d+\delta}\|\sigma\|^2 + \tfrac{d}{d+\delta}\|\sigma - \tfrac{1}{d}\mathrm{tr}(\sigma)\mathcal{I}_d\|^2 \\ &= \tfrac{\delta}{(d+\delta)^2}|\mathrm{tr}(\sigma)|^2 + \|\sigma - \tfrac{1}{d+\delta}\mathrm{tr}(\sigma)\mathcal{I}_d\|^2,\end{aligned} \tag{3.20}$$

where $\|\cdot\|$ is the Frobenius norm, we deduce that (A5) also holds. The incompressible limit $\delta_0 = 0$ is treated in sections 3.5 and 4.3. Note that (A3) does not hold ((A3) would hold if $\lambda_0 > 0$. The case $\lambda_0 \geq 0$ covers the usual compressible solid mechanics problems for which $\lambda = 0$ and $\beta = 0$.

The graph space is $W = H_\sigma \times [H^1(\Omega)]^d$ with $H_\sigma = \{\sigma \in [L^2(\Omega)]^{d,d};\ \nabla\cdot(\sigma+\sigma^t) \in [L^2(\Omega)]^d\}$ and the boundary operator D is such that for all $z, y \in W$ with $z = (\sigma, u)$ and $y = (\tau, v)$,

$$\langle Dz, y\rangle_{W',W} = -\langle \tfrac{1}{2}(\tau+\tau^t)\cdot n, u\rangle_{-\frac{1}{2},\frac{1}{2}} - \langle \tfrac{1}{2}(\sigma+\sigma^t)\cdot n, v\rangle_{-\frac{1}{2},\frac{1}{2}} + \int_{\partial\Omega} (\beta\cdot n)uv, \tag{3.21}$$

where $\langle , \rangle_{-\frac{1}{2},\frac{1}{2}}$ denotes the duality pairing between $[H^{-\frac{1}{2}}(\partial\Omega)]^d$ and $[H^{\frac{1}{2}}(\partial\Omega)]^d$. An homogeneous Dirichlet boundary condition on the u-component is obtained by setting

$$\langle Mz, y\rangle_{W',W} = \langle \tfrac{1}{2}(\tau+\tau^t)\cdot n, u\rangle_{-\frac{1}{2},\frac{1}{2}} - \langle \tfrac{1}{2}(\sigma+\sigma^t)\cdot n, v\rangle_{-\frac{1}{2},\frac{1}{2}}, \tag{3.22}$$

yielding $V = V^* = H_\sigma \times [H^1_0(\Omega)]^d$. Similarly, a mixed Robin–Neumann boundary condition is obtained by setting

$$\langle Mz, y\rangle_{W',W} = -\langle \tfrac{1}{2}(\tau+\tau^t)\cdot n, u\rangle_{-\frac{1}{2},\frac{1}{2}} + \langle \tfrac{1}{2}(\sigma+\sigma^t)\cdot n, v\rangle_{-\frac{1}{2},\frac{1}{2}} + \int_{\partial\Omega} (2\varrho+\beta\cdot n)uv, \tag{3.23}$$

where $\varrho \in L^\infty(\partial\Omega)$ is such that $2\varrho + \beta\cdot n \geq 0$ a.e. on $\partial\Omega$. Then $V = \{(\sigma, u) \in W;\ \frac{1}{2}(\sigma+\sigma^t)\cdot n - \varrho u|_{\partial\Omega} = 0\}$ and $V^* = \{(\sigma, u) \in W;\ \frac{1}{2}(\sigma+\sigma^t)\cdot n + (\varrho+\beta\cdot n)u|_{\partial\Omega} = 0\}$. A standard choice is $\varrho = -\min(\beta\cdot n, 0)$.

In terms of boundary fields, letting $\mathcal{N} = \sum_{k=1}^d n_k \mathcal{E}^k \in \mathbb{R}^{d^2,d}$, (3.21), (3.22), and (3.23), respectively, yields

$$\mathcal{D} = \left[\begin{array}{c:c} 0 & \mathcal{N} \\ \hdashline \mathcal{N}^t & (\beta\cdot n)\mathcal{I}_d \end{array}\right], \quad \mathcal{M} = \left[\begin{array}{c:c} 0 & -\mathcal{N} \\ \hdashline \mathcal{N}^t & 0 \end{array}\right], \quad \mathcal{M} = \left[\begin{array}{c:c} 0 & \mathcal{N} \\ \hdashline -\mathcal{N}^t & (2\varrho+\beta\cdot n)\mathcal{I}_d \end{array}\right]. \tag{3.24}$$

Observe that $\mathrm{Ker}(\mathcal{D}^{\sigma u}) = \{0\}$ and that $\mathcal{M}^{uu} = |\mathcal{D}^{uu}|$ in the Robin–Neumann case, provided $\varrho = -\min(\beta\cdot n, 0)$.

3.4.1. Well-posedness. For the sake of brevity, we restrict ourselves to homogeneous Dirichlet boundary conditions. The case of mixed Robin–Neumann boundary conditions can be treated by proceeding as in section 3.3.1.

PROPOSITION 3.8. *Assume $\lambda_0 = 0$ and $\delta_0 > 0$ and that Dirichlet boundary conditions are enforced. Then assumptions* (A3A)*,* (A3B′)*, and* (A3B″) *hold.*

Proof. Assumptions (A3A)–(A3B′) are evident. Moreover, since Dirichlet boundary conditions are enforced on the u-component, $z \in V = V^*$ implies $z^u \in [H^1_0(\Omega)]^d$; hence, (A3B″) results from Korn's first inequality. ∎

3.4.2. Two-field DG approximation. We assume again for simplicity that homogeneous Dirichlet boundary conditions are enforced. Let $\eta_1 > 0$, $\eta_2 > 0$ (these parameters can vary from face to face), and

$$M_F^{uu}(v) = \eta_1 h_F^{-1} v, \qquad S_F^{uu}(v) = \eta_2 h_F^{-1} v, \qquad R_F^{uu} \equiv 0. \tag{3.25}$$

Since $\mathcal{D}^{u\sigma}\mathcal{D}^{\sigma u} = \frac{1}{2}(\mathcal{I}_d + n\otimes n)$ and $\mathcal{D}^{uu} = (\beta\cdot n)\mathcal{I}_d$, properties (DG2A)–(DG2D) hold. Many other choices can be considered for M_F^{uu}, S_F^{uu}, and R_F^{uu}.

PROPOSITION 3.9. *Property* (3.4) *holds.*

Proof. The proof is a direct consequence of the fact that for all $v_h \in U_h$,

$$\|v_h\|_{L_u}^2 \lesssim \sum_{K\in\mathcal{T}_h} \|\nabla v_h + (\nabla v_h)^t\|_{L_\sigma,K}^2 + \sum_{F\in\mathcal{F}_h^{\mathrm{i}}} h_F^{-1}\|[\![v_h]\!]\|_{L_u,F}^2 + \sum_{F\in\mathcal{F}_h^{\partial}} h_F^{-1}\|v_h\|_{L_u,F}^2.$$

See [7, 13] for a proof. ∎

3.5. Remarks on the incompressible limit. The above analysis is not uniform with respect to the compressibility factor δ, i.e., the analysis fails as $\delta \to 0$; this is the well-known locking phenomenon. The origin of the problem is that the operator $K^{\sigma\sigma}$ is not invertible at the limit $\delta = 0$; indeed, since $K^{\sigma\sigma}\sigma = \sigma - \frac{1}{d+\delta}\mathrm{tr}(\sigma)\mathcal{I}_d$, it is clear that $K^{\sigma\sigma}\sigma = 0$ when $\delta = 0$ and σ is proportional to the identity. In other words, it is our insisting on eliminating σ that is responsible for locking (i.e., the primal formulation locks).

Actually the above two-field DG approximation is robust with respect to δ if one *abandons* the idea of eliminating σ; in other words, the mixed formulation is robust. This fact has already been recognized in Franca and Stenberg [20] using the GaLS technique, and this is also true for conforming mixed approximations; see Brezzi and Fortin [8] and Schwab and Suri [28]. (A DG method (IP) where σ is eliminated and which does not lock for small δ is analyzed in Hansbo and Larson [23]. This method, though, yields a linear system with a condition number that grows unboundedly as $\delta \to 0$.)

Let us now substantiate the above claim. Since it is not more difficult to analyze the general case, let us forget problem (3.17) and let us deal with the general DG approximation (2.16). We now weaken the L_σ-coercivity requirement used in section 3.1 as follows. We replace (A3A) by the following: Assume that there exists an operator $\pi \in \mathcal{L}(L_\sigma, L_\sigma)$ such that

$$(\text{A3A}') \qquad \forall z \in L, \qquad ((K + K^* - \nabla\cdot A)z, z)_L \gtrsim \|\mathcal{K}^{\sigma\sigma}z^\sigma\|_{L_\sigma}^2 + \|\pi z^\sigma\|_{L_\sigma}^2.$$

We also modify (DG2A) as follows:

$$(\text{DG2A}') \qquad M_F = \left[\begin{array}{c|c} 0 & -\alpha\mathcal{D}^{\sigma u} \\ \hline \alpha\mathcal{D}^{u\sigma} & M_F^{uu} \end{array}\right],\ \alpha\in\{-1,+1\}, \quad S_F = \left[\begin{array}{c|c} S_F^{\sigma\sigma} & 0 \\ \hline 0 & S_F^{uu} \end{array}\right], \quad R_F \equiv 0,$$

where $S_F^{\sigma\sigma}$ is defined by

$$(\text{DG2A}'') \qquad (S_F^{\sigma\sigma}(z^\sigma), y^\sigma)_{L_\sigma,F} = \eta h_F (z^\sigma - \pi z^\sigma, y^\sigma - \pi y^\sigma)_{L_\sigma,F},$$

with user-dependent parameter $\eta > 0$. Note that owing to the presence of $S_F^{\sigma\sigma}$, z_h^σ can no longer be locally eliminated. We introduce the notation $|z^\sigma|_{J'}^2 := \sum_{F\in\mathcal{F}_h^{\mathrm{i}}} |z^\sigma|_{J',F}^2$, $|z^\sigma|_{J',F}^2 = (S_F^{\sigma\sigma}([\![z^\sigma]\!]), [\![z^\sigma]\!])_{L_\sigma,F}$, and we redefine the $\|\cdot\|_{h,B}$ discrete norm as

$$\|y\|_{h,B}^2 := \|y\|_L^2 + |y^u|_J^2 + |y^\sigma|_{J'}^2 + |y^u|_M^2 + \|B_h y^u\|_{L_\sigma}^2. \tag{3.26}$$

To ascertain control over $z_h^\sigma - \pi z_h^\sigma$ we make the two following assumptions:

$$\forall z_h^\sigma \in \Sigma_h, \quad \|z_h^\sigma - \pi z_h^\sigma\|_{L_\sigma}^2 \lesssim \|\pi z_h^\sigma\|_{L_\sigma}^2 + |z_h^\sigma|_{J'}^2 + \left(\sup_{0\neq v_h^u\in U_h} \frac{\mathbb{B}_h(z_h^\sigma, v_h^u)}{\|(0, v_h^u)\|_{h,B}}\right)^2, \tag{3.27}$$

$$\forall z_h^u \in U_h, \quad \|C_h z_h^u\|_{L_u} \lesssim \|B_h z_h^u\|_{L_\sigma} + \|z_h^u\|_{L_u}, \tag{3.28}$$

where $\mathbb{B}_h(z_h^\sigma, v_h^u) := a_h((z_h^\sigma, 0), (0, v_h^u))$, i.e.,

$$\mathbb{B}_h(z_h^\sigma, v_h^u) := (B_h^\dagger z_h^\sigma, v_h^u)_{L_u} - 2\sum_{F\in\mathcal{F}_h^{\rm i}} (\{\mathcal{D}^{u\sigma} z_h^\sigma\}, \{v_h^u\})_{L_u,F} + \tfrac{\alpha-1}{2}\sum_{F\in\mathcal{F}_h^{\partial}} (\mathcal{D}^{u\sigma} z_h^\sigma, v_h^u)_{L_u,F}. \tag{3.29}$$

THEOREM 3.10. *The statement of Theorem* 2.3 *remains true under the assumptions* (A3A′)–(A3B′), (DG2A′)–(DG2A″), (DG2B)–(DG2F), *and* (3.4), (3.27), *and* (3.28).

Proof. We just sketch the proof since most of the arguments will be repeated with more details in section 4.2. Let us prove the inf-sup inequality

$$\forall z_h \in W_h, \qquad \|z_h\|_{h,B} \lesssim \sup_{y_h\in W_h\setminus\{0\}} \frac{a_h(z_h, y_h)}{\|y_h\|_{h,B}}. \tag{3.30}$$

Let $z_h \in W_h$ and define $\mathbb{S} := \sup_{y_h\in W_h\setminus\{0\}} \frac{a_h(z_h,y_h)}{\|y_h\|_{h,B}}$. Owing to the definition of a_h, (DG2A′)–(DG2A″), and (A3A′),

$$\|\mathcal{K}^{\sigma\sigma} z_h^\sigma\|_{L_\sigma}^2 + \|\pi z_h^\sigma\|_{L_\sigma}^2 + |z_h^u|_J^2 + |z_h^\sigma|_{J'}^2 + |z_h^u|_M^2 \lesssim a_h(z_h, z_h) \lesssim \mathbb{S}\,\|z_h\|_{h,B}.$$

Set $\varpi_h = (B_h z_h^u, 0)$ and observe that $\varpi_h \in W_h$ since the fields $\mathcal{B}^k$ are constant over Ω (see (A3B′)) and $p_u - 1 \le p_\sigma$. Then

$$\|B_h z_h^u\|_{L_\sigma}^2 = a_h(z_h, \varpi_h) - (\mathcal{K}^{\sigma\sigma} z_h^\sigma, B_h z_h^u)_{L_\sigma} - \sum_{F\in\mathcal{F}_h^{\partial}} \tfrac{\alpha+1}{2} (\mathcal{D}^{\sigma u} z_h^u, B_h z_h^u)_{L_\sigma,F} + \sum_{F\in\mathcal{F}_h^{\rm i}} 2(\{\mathcal{D}^{\sigma u} z_h^u\}, \{B_h z_h^u\})_{L_\sigma,F} - (S_F^{\sigma\sigma}(z_h^\sigma), B_h z_h^u)_{L_\sigma,F}.$$

Proceeding as in the proof of Lemma 3.2 and observing that $\|\varpi_h\|_{h,B} \lesssim \|B_h z_h^u\|_{L_\sigma} + |B_h z_h^u|_{J'} \lesssim \|z_h\|_{h,B}$, we infer

$$\|B_h z_h^u\|_{L_\sigma}^2 \lesssim a_h(z_h, \varpi_h) + a_h(z_h, z_h) \lesssim \mathbb{S}\,\|z_h\|_{h,B}.$$

Using (3.4) then yields $\|z_h^u\|_{L_u}^2 \lesssim \mathbb{S}\,\|z_h\|_{h,B}$. Finally, to control $\|z_h^\sigma - \pi z_h^\sigma\|_{L_\sigma}$, observe that $\mathbb{B}_h(z_h^\sigma, v_h^u) = a_h(z_h, (0, v_h^u)) - a_h(0, z_h^u), (0, v_h^u))$ and using (3.27)–(3.28) proceed as in the proof of Lemma 4.2, step (4c). This yields $\|z_h^\sigma - \pi z_h^\sigma\|_{L_\sigma}^2 \lesssim \mathbb{S}\,\|z_h\|_{h,B}$. The rest of the proof is standard. ∎

Coming back to our compressible linear elasticity problem (3.17), observe that the above analysis applies by setting $\pi\sigma = \sigma - \frac{1}{d}\mathrm{tr}(\sigma)\mathcal{I}_d$. Inequality (A3A′) holds *uniformly* with respect to δ, as can be seen by taking the mean of the two equations in (3.20). Assumption (3.28) results from Korn's second inequality. A proof for (3.27) is given in the proof of Proposition 4.5. In conclusion, the present two-field DG formulation is robust with respect to δ. However, owing to the presence of the stabilization operator $S_F^{\sigma\sigma}$ which penalizes the jumps of $\mathrm{tr}(\sigma_h)$, σ_h cannot be eliminated locally. This motivates the introduction of a new scalar variable (the pressure) whose jumps will be penalized instead of those of $\mathrm{tr}(\sigma_h)$.

4. Three-field theory. The goal of this section is to weaken even further the set of hypotheses (A3A), (A3B′), and (A3B″). We have in mind the linear elasticity equations, and we want to come up with a method which is robust in the incompressible limit and for which the σ-component can be eliminated locally. To this purpose, we introduce a three-field theory of Friedrichs' systems and adapt the DG approximation to this setting. Thus, we assume that z can be decomposed into three fields, z^σ, z^p, and z^u, and we have in mind to locally eliminate z^σ.

4.1. Three-field Friedrichs' systems. We now assume that $L = L_\sigma \times L_p \times L_u$, where $L_\sigma = [L^2(\Omega)]^{m_\sigma}$, $L_p = [L^2(\Omega)]^{m_p}$, and $L_u = [L^2(\Omega)]^{m_u}$, with $m = m_\sigma + m_p + m_u$. We also assume that the operator K and the matrices $\mathcal{A}^k$, $1 \le k \le d$, admit the following 3×3 structure:

$$K = \left[\begin{array}{c:c:c} K^{\sigma\sigma} & K^{\sigma p} & 0 \\ \hdashline K^{p\sigma} & K^{pp} & 0 \\ \hdashline 0 & 0 & K^{uu} \end{array}\right] \qquad \text{and} \qquad \mathcal{A}^k = \left[\begin{array}{c:c:c} 0 & 0 & \mathcal{B}^k \\ \hdashline 0 & 0 & 0 \\ \hdashline [\mathcal{B}^k]^t & 0 & \mathcal{C}^k \end{array}\right]. \tag{4.1}$$

We assume that the block $K^{\sigma\sigma}$ has a local representation, i.e., there is $\mathcal{K}^{\sigma\sigma} \in [L^\infty(\Omega)]^{m_\sigma, m_\sigma}$ such that $K^{\sigma\sigma}(y^\sigma) = \mathcal{K}^{\sigma\sigma} y^\sigma$ for all $y^\sigma \in L_\sigma$ (this local representation is needed in the three-field DG method described below to locally eliminate the discrete σ-component). We denote by K^σ (resp., K^p) the canonical projection of K onto L_σ (resp., L_p). Finally, we assume that there exists $\pi \in \mathcal{L}(L_\sigma; L_\sigma)$ such that

(A3C) $$\forall z \in L, \quad ((K + K^* - \nabla\cdot A)z, z)_L \gtrsim \|\pi z^\sigma\|_{L_\sigma}^2 + \|K^\sigma z\|_{L_\sigma}^2 + \|K^p z\|_{L_p}^2,$$

(A3D) $$\forall z \in V \cup V^*, \quad \|z^u\|_{L_u} \lesssim a(z,z)^{\frac12} + \|Bz^u\|_{L_\sigma},$$

(A3E) $$\forall z \in W, \quad \|Cz^u\|_{L_u} \lesssim \|z^u\|_{L_u} + \|Bz^u\|_{L_\sigma},$$

(A3F) $$\forall z \in V \cup V^*, \quad \|z^\sigma - \pi z^\sigma\|_{L_\sigma} \lesssim \|\pi z^\sigma\|_{L_\sigma} + \|B^\dagger z^\sigma\|_{L_u},$$

(A3G) $$\forall z \in L, \quad \|z^p\|_{L_p}^2 \lesssim ((K + K^* - \nabla\cdot A)z, z)_L + \|K^{pp} z^p\|_{L_p}^2,$$

(A3H) $$\forall k \in \{1, \dots, k\}, \quad \mathcal{B}^k \text{ is constant over } \Omega,$$

and that (A3C) and (A3G) also hold when K^σ, K^p, and K^{pp} are substituted by the corresponding terms in K^*, say $K^{*\sigma}$, K^{*p}, and K^{*pp}.

THEOREM 4.1. *The conclusions of Theorem* 2.1 *still hold if assumption* (A3) *is replaced by assumptions* (A3C)–(A3H).

Proof. The proof, which is similar to that of Theorem 3.1, is only sketched. We only prove that $T : V \longrightarrow L$ is an isomorphism, since the rest of the proof is unchanged or goes along the same lines.

(1) Proof of (3.2). Let $z \in V$. Recall that $(Tz, z)_L = a(z,z) \ge ((K + K^* - \nabla\cdot A)z, z)_L$. Hence, property (A3C) implies

$$\|K^p z\|_{L_p} + \|K^\sigma z\|_{L_\sigma} + \|\pi z^\sigma\|_{L_\sigma} \lesssim (Tz, z)_L^{\frac12}.$$

Since $Bz^u + K^\sigma z = (Tz)^\sigma$, we infer $\|Bz^u\|_{L_\sigma} \lesssim \|Tz\|_L + (Tz, z)_L^{\frac12}$. Then, owing to (A3D)–(A3E),

$$\|z^u\|_{L_u} + \|Cz^u\|_{L_u} \lesssim \|Tz\|_L + (Tz, z)_L^{\frac12}.$$

Now we use (A3F), the above bounds, and the fact that $B^\dagger z^\sigma = (Tz)^u - Cz^u - K^{uu} z^u$ to deduce

$$\|z^\sigma - \pi z^\sigma\|_{L_\sigma} \lesssim \|B^\dagger z^\sigma\|_{L_u} + (Tz, z)_L^{\frac12} \lesssim \|Tz\|_L + (Tz, z)_L^{\frac12},$$

and the same bound holds for $\|z^\sigma\|_{L_\sigma}$ by the triangle inequality. To derive a bound on $\|z^p\|_{L_p}$ we use the fact that $K^p z = (Tz)^p$ to infer

$$\|K^{pp} z^p\|_{L_p} \le \|K^p z\|_{L_p} + \|K^{p\sigma} z^\sigma\|_{L_p} \lesssim \|Tz\|_L + \|z^\sigma\|_{L_\sigma}.$$

Hence, (A3G) and the above bounds yield $\|z^p\|_{L_p} \lesssim \|Tz\|_L + (Tz,z)_L^{\frac12}$. Combining the previous estimates yields $\|z\|_L \lesssim \|Tz\|_L + (Tz,z)_L^{\frac12}$ and we conclude as usual.

(2) Proof of (3.3). Assume that $y \in L$ is such that $(Tz,y)_L = 0$ for all $z \in V$. Then $y \in V^*$ and $\tilde T y = 0$. Hence (A3C) implies $\pi y^\sigma = 0$ and $K^{*\sigma} y = 0$. Then, observing that $0 = (\tilde T y)^\sigma = K^{*\sigma} y - B y^u$ since the fields $\mathcal{B}^k$ are constant, we infer $By^u = 0$. Then (A3D) and (A3E) yield $y^u = 0$ and $Cy^u = 0$. Using $0 = (\tilde T y)^u$ and the fact that the fields $\mathcal{B}^k$ are constant, we then infer $B^\dagger y^\sigma = 0$ so that (A3F) implies $y^\sigma - \pi y^\sigma = 0$, and hence $y^\sigma = 0$. Finally, since $0 = (\tilde T y)^p = K^{*pp} y^p$, using (A3G) we infer $y^p = 0$, thus completing the proof. ∎

4.2. Three-field DG approximation. We analyze in this section a DG method to approximate the three-field Friedrichs' systems introduced in section 4.1. We assume that hypotheses (A3C)–(A3H) hold so that the continuous problem is well-posed.

Let $p_u > 0$ be a *positive* integer and let p_σ and p_p be such that

$$p_u - 1 \le p_\sigma \le p_u + 1, \qquad p_\sigma \le p_p. \tag{4.2}$$

Consider the finite elements spaces

$$\Sigma_h = [P_{h,p_\sigma}]^{m_\sigma}, \quad P_h = [P_{h,p_p}]^{m_p}, \quad U_h = [P_{h,p_u}]^{m_u}, \quad W_h = \Sigma_h \times P_h \times U_h. \tag{4.3}$$

Consider the discrete problem (2.16) with the bilinear form still defined by (2.15).

The key property of the three-field DG approximation developed hereafter is that the operators M_F and S_F are designed in such a way that the discrete σ-component can be locally eliminated. We consider either Dirichlet boundary conditions or mixed Robin–Neumann boundary conditions enforced by setting $\mathcal{M}^{uu} = |\mathcal{D}^{uu}|$; see sections 3.3 and 3.4. The design conditions of the three-field DG method are the following:

(DG3A) $$M_F = \left[\begin{array}{c|c|c} 0 & 0 & -\alpha\mathcal{D}^{\sigma u} \\ \hline 0 & 0 & 0 \\ \hline \alpha\mathcal{D}^{u\sigma} & 0 & M_F^{uu} \end{array}\right], \quad S_F = \left[\begin{array}{c|c|c} 0 & 0 & 0 \\ \hline 0 & S_F^{pp} & 0 \\ \hline 0 & 0 & S_F^{uu} \end{array}\right], \quad R_F = \left[\begin{array}{c|c|c} 0 & 0 & 0 \\ \hline 0 & 0 & 0 \\ \hline 0 & 0 & R_F^{uu} \end{array}\right];$$

(DG3B) $$\text{if } \alpha = +1, \begin{cases} M_F^{uu} = (M_F^{uu})^* \quad \text{and} \quad \operatorname{Ker}(\mathcal{D}^{\sigma u}) \subset \operatorname{Ker}(M_F^{uu} - \mathcal{D}^{uu}), \\ h_F^{-1}(\mathcal{D}^{u\sigma}\mathcal{D}^{\sigma u})^{\frac12} + h_F^{-1}|\mathcal{D}^{uu}| \lesssim M_F^{uu} \lesssim h_F^{-1}\mathcal{I}_{m_u}; \end{cases}$$

(DG3C) $$\text{if } \alpha = -1,\ M_F^{uu}(v) = \mathcal{M}^{uu} v;$$

(DG3D) $$S_F^{uu} = (S_F^{uu})^*, \text{ and } h_F^{-1}(\mathcal{D}^{u\sigma}\mathcal{D}^{\sigma u})^{\frac12} + h_F^{-1}|\mathcal{D}^{uu}| \lesssim S_F^{uu} \lesssim h_F^{-1}\mathcal{I}_{m_u};$$

(DG3E) $$S_F^{pp} = (S_F^{pp})^*, \quad \text{and} \quad h_F \mathcal{I}_{m_p} \lesssim S_F^{pp} \lesssim h_F \mathcal{I}_{m_p},$$

where $\alpha \in \{-1,+1\}$ in the definition of M_F in (DG3A).

Our aim is to control the approximation error in the norm $\|\cdot\|_{h,B}$ defined by

$$\|y\|_{h,B}^2 = \|y\|_L^2 + |y^u|_M^2 + |y^u|_{J^u}^2 + |y^p|_{J^p}^2 + \|B_h y^u\|_{L_\sigma}^2, \tag{4.4}$$

with $|y^u|_{J^u}^2 = \sum_{F\in\mathcal{F}_h^{\mathrm{i}}} |y^u|_{J^u,F}^2$, $|y^p|_{J^p}^2 = \sum_{F\in\mathcal{F}_h^{\mathrm{i}}} |y^p|_{J^p,F}^2$, $|y^u|_M^2 = \sum_{F\in\mathcal{F}_h^{\partial}} |y^u|_{M,F}^2$,

$$|y^u|_{J^u,F}^2 = (S_F^{uu}(\llbracket y^u \rrbracket), \llbracket y^u \rrbracket)_{L_u,F}, \quad |y^p|_{J^p,F}^2 = (S_F^{pp}(\llbracket y^p \rrbracket), \llbracket y^p \rrbracket)_{L_p,F}, \tag{4.5}$$

$$|y^u|_{M,F}^2 = (M_F^{uu}(y^u), y^u)_{L_u,F}. \tag{4.6}$$

The user-dependent operator R_F^{uu} must be designed so that for all $z_h^u \in U_h$ and all $(z^u, y_h^u) \in U(h)\times U_h$,

$$\text{(DG3F)} \qquad \sum_{F\in\mathcal{F}_h} (R_F^{uu}([\![z_h^u]\!]), [\![z_h^u]\!])_{L_u,F} \geq -\frac{1}{4}(|z_h^u|_{J^u}^2 + |z_h^u|_M^2),$$

$$\text{(DG3G)} \qquad \sum_{F\in\mathcal{F}_h} (R_F^{uu}([\![z^u]\!]), [\![y_h^u]\!])_{L_u,F} \lesssim (|z^u|_{J^u} + |z^u|_M)(|y_h^u|_{J^u} + |y_h^u|_M).$$

The discrete counterpart of assumption (A3D) is still (3.4), while the discrete counterpart of assumption (A3F) is the following: For all $z_h^\sigma \in \Sigma_h$,

$$\|z_h^\sigma - \pi z_h^\sigma\|_{L_\sigma}^2 \lesssim \|\pi z_h^\sigma\|_{L_\sigma}^2 + \sum_{F\in\mathcal{F}_h^{\mathrm{i}}} h_F \|[\![z_h^\sigma - \pi z_h^\sigma]\!]\|_{L_\sigma,F}^2 + \left(\sup_{0\neq v_h^u\in U_h} \frac{\mathbb{B}_h(z_h^\sigma, v_h^u)}{\|(0,0,v_h^u)\|_{h,B}}\right)^2, \tag{4.7}$$

where $\mathbb{B}_h(z_h^\sigma, v_h^u)$ is defined by (3.29). Finally, the discrete counterpart of assumption (A3E) is

$$\forall z_h^u \in U_h, \qquad \|C_h z_h^u\|_{L_u} \lesssim \|B_h z_h^u\|_{L_\sigma} + \|z_h^u\|_{L_u}. \tag{4.8}$$

Since the jumps of the σ-component are not controlled in the three-field DG method (so as to eliminate this component locally), stability must come from the control on the jumps of the p-component. The link between the jumps of the σ- and p-components is provided by the equation for the p-component. This motivates the following additional assumptions:

$$\forall z_h \in W_h, \quad K^p z_h \in P_h, \tag{4.9}$$

$$\forall z_h \in W_h, \quad \forall F \in \mathcal{F}_h^{\mathrm{i}}, \quad \|[\![z_h^\sigma - \pi z_h^\sigma]\!]\|_{L_\sigma,F} \lesssim \|[\![K^p z_h]\!]\|_{L_p,F} + \|[\![z_h^p]\!]\|_{L_p,F}. \tag{4.10}$$

LEMMA 4.2. *Assume that* (A3C)–(A3H) *and the discrete assumptions* (DG3A)–(DG3G), (3.4), (4.2), (4.7), (4.8), (4.9), *and* (4.10) *hold. Then the following holds:*

$$\forall z_h \in W_h, \qquad \|z_h\|_{h,B} \lesssim \sup_{y_h\in W_h\setminus\{0\}} \frac{a_h(z_h, y_h)}{\|y_h\|_{h,B}}. \tag{4.11}$$

Proof. Let $z_h \in W_h$ and set $\mathbb{S} = \sup_{y_h\in W_h\setminus\{0\}} \frac{a_h(z_h,y_h)}{\|y_h\|_{h,B}}$.

(1) Owing to the definition of a_h, (DG3A), (DG3F), and (A3C),

$$\|K^\sigma z_h\|_{L_\sigma}^2 + \|K^p z_h\|_{L_p}^2 + |\pi z_h^\sigma|_{L_\sigma}^2 + |z_h^u|_M^2 + |z_h^u|_{J^u}^2 + |z_h^p|_{J^p}^2 \lesssim a_h(z_h, z_h) \leq \mathbb{S}\,\|z_h\|_{h,B}. \tag{4.12}$$

(2) Control on z_h^u, $C_h z_h^u$, and $B_h z_h^u$. Set $y_h = (B_h z_h^u, 0, 0)$ and observe that $y_h \in W_h$ owing to (A3H) and the fact that $p_u - 1 \leq p_\sigma$. Moreover, $\|y_h\|_{h,B} \lesssim \|z_h\|_{h,B}$. Furthermore,

$$\|B_h z_h^u\|_{L_\sigma}^2 = a_h(z_h, y_h) - (K^\sigma z_h, B_h z_h^u)_{L_\sigma} - \tfrac{\alpha+1}{2} \sum_{F\in\mathcal{F}_h^\partial} (\mathcal{D}^{\sigma u} z_h^u, B_h z_h^u)_{L_\sigma,F} + \sum_{F\in\mathcal{F}_h^{\mathrm{i}}} 2(\{\mathcal{D}^{\sigma u} z_h^u\}, \{B_h z_h^u\})_{L_\sigma,F} := T_1 + T_2 + T_3 + T_4.$$

Clearly, $|T_1| \lesssim \mathbb{S}\,\|z_h\|_{h,B}$ and owing to (4.12),

$$|T_2| \lesssim \|K^\sigma z_h\|_{L_\sigma}\|B_h z_h^u\|_{L_\sigma} \lesssim \mathbb{S}\,\|z_h\|_{h,B} + \gamma\|B_h z_h^u\|_{L_\sigma}^2,$$

where $\gamma > 0$ can be chosen as small as needed. Similarly, using (DG3B), $\{\mathcal{D}^{\sigma u}\} = 0$, (DG3D), and a trace inverse inequality leads to

$$|T_3| + |T_4| \lesssim (|z_h^u|_M + |z_h^u|_{J^u})\|B_h z_h^u\|_{L_\sigma} \lesssim \mathbb{S}\,\|z_h\|_{h,B} + \gamma\|B_h z_h^u\|_{L_\sigma}^2.$$

Collecting the above bounds and choosing the γ's small enough, it is inferred that $\|B_h z_h^u\|_{L_\sigma}^2 \lesssim \mathbb{S}\,\|z_h\|_{h,B}$. Then, owing to (3.4), (4.8), and (4.12), this in turn implies

$$\|z_h^u\|_{L_u}^2 + \|C_h z_h^u\|_{L_u}^2 + \|B_h z_h^u\|_{L_\sigma}^2 \lesssim \mathbb{S}\,\|z_h\|_{h,B}. \tag{4.13}$$

(3) Control on z_h^σ. It remains to control $z_h^\sigma - \pi z_h^\sigma$. The idea is to use (4.7) by estimating the three terms on the right-hand side, say R_1–R_3.

(3a) Clearly, $R_1 \lesssim \mathbb{S}\,\|z_h\|_{h,B}$.

(3b) To control R_2, use (4.10) and the fact that $\|[\![K^p z_h]\!]\|_{L_p,F} \lesssim h_F^{-1/2}\|K^p z_h\|_{L_p,\mathcal{T}(F)}$ owing to a trace inverse inequality (which can be used by (4.9)) to infer

$$\|[\![z_h^\sigma - \pi z_h^\sigma]\!]\|_{L\sigma,F}^2 \lesssim h_F^{-1}\|K^p z_h\|_{L_p,\mathcal{T}(F)}^2 + h_F^{-1}|z_h^p|_{J^p,F}^2.$$

Hence, owing to the estimates for $\|K^p z_h\|_{L_p}$ and $|z_h^p|_{J^p,F}$ resulting from step (1), $R_2 \lesssim \mathbb{S}\,\|z_h\|_{h,B}$.

(3c) For R_3, observe that $\mathbb{B}_h(z_h^\sigma, v_h^u) = a_h(z_h,(0,0,v_h^u)) - a_h((0,0,z_h^u),(0,0,v_h^u))$ and that for all $v_h^u \in U_h$, the following holds:

$$a_h((0,0,z_h^u),(0,0,v_h^u)) \lesssim \mathbb{A}_h := (\mathbb{S}\,\|z_h\|_{h,B})^{\frac{1}{2}}\|(0,0,v_h^u)\|_{h,B}. \tag{4.14}$$

Indeed,

$$\begin{aligned} a_h((0,0,z_h^u),(0,0,v_h^u)) &= (K^{uu}z_h^u, v_h^u)_{L_u} + (C_h z_h^u, v_h^u)_{L_u} \\ &+ \sum_{F\in\mathcal{F}_h^\partial} \tfrac{1}{2}(M_F^{uu}(z_h^u) - \mathcal{D}^{uu}z_h^u, v_h^u)_{L_u,F} - \sum_{F\in\mathcal{F}_h^{\mathrm{i}}} 2(\{\mathcal{D}^{uu}z_h^u\},\{v_h^u\})_{L_u,F} \\ &+ \sum_{F\in\mathcal{F}_h^{\mathrm{i}}} ((S_F^{uu}+R_F^{uu})([\![z_h^u]\!]),[\![v_h^u]\!])_{L_u,F} := T_1+T_2+T_3+T_4+T_5. \end{aligned}$$

Using (4.13) yields $|T_1| + |T_2| \lesssim \mathbb{A}_h$, while (4.12) together with (DG3G) readily yields $|T_5| \lesssim \mathbb{A}_h$. Since $\{\mathcal{D}^{uu}\} = 0$, using (DG3D) and a trace inverse inequality leads to

$$|T_4| \lesssim \sum_{F\in\mathcal{F}_h^{\mathrm{i}}} h_F^{\frac{1}{2}}|z_h^u|_{J^u,F}h_F^{-\frac{1}{2}}\|v_h^u\|_{L_u,\mathcal{T}(F)} \lesssim \mathbb{A}_h.$$

Finally, to control T_3, we proceed similarly using (DG3B) if $\alpha = +1$ to infer $|T_3| \lesssim |z_h^u|_M(|v_h^u|_M + \|v_h^u\|_{L_u}) \lesssim \mathbb{A}_h$, while if $\alpha = -1$, we use (DG3C) and the assumption $\mathcal{M}^{uu} = |\mathcal{D}^{uu}|$ to infer $|T_3| \lesssim |z_h^u|_M|v_h^u|_M \lesssim \mathbb{A}_h$. Collecting the bounds for T_1–T_5 yields (4.14), whence the bound $R_3 \lesssim \mathbb{S}^2 + \mathbb{S}\,\|z_h\|_{h,B}$ is readily inferred.

(3d) Collecting the bounds for R_1–R_3 yields

$$\|z_h^\sigma - \pi z_h^\sigma\|_{L_\sigma}^2 \le R_1 + R_2 + R_3 \lesssim \mathbb{S}^2 + \mathbb{S}\,\|z_h\|_{h,B}. \tag{4.15}$$

The same bound is inferred for $\|z_h^\sigma\|_{L_\sigma}^2$ by the triangle inequality.

(4) Control on z_h^p. Using (A3G), the fact that $K^{pp}z_h^p = K^p z_h - K^{p\sigma}z_h^\sigma$, and the derived bounds on $\|K^p z_h\|_{L_p}$ and $\|z_h^\sigma\|_{L_\sigma}$ leads to

$$\|z_h^p\|_{L_p}^2 \lesssim a_h(z_h,z_h) + \|K^p z_h\|_{L_p}^2 + \|K^{p\sigma}z_h^\sigma\|_{L_p}^2 \lesssim \mathbb{S}^2 + \mathbb{S}\,\|z_h\|_{h,B}. \tag{4.16}$$

(5) Conclusion. Collecting the above bounds yields $\|z_h\|_{h,B}^2 \lesssim \mathbb{S}^2 + \mathbb{S}\,\|z_h\|_{h,B}$, whence (4.11) readily follows. ∎

Remark 4.1. Assumption (DG3D) (resp., (DG3B)) requires a stronger control on $|\mathcal{D}^{uu}|$ with respect to (DG2D) (resp., (DG2B)). This stronger control is needed to prove (4.14) in step (3c) of the above proof. This is not really a restriction, since in practice $|\mathcal{D}^{uu}| \lesssim (\mathcal{D}^{u\sigma}\mathcal{D}^{\sigma u})^{\frac{1}{2}}$ so that $h_F^{-1}(\mathcal{D}^{u\sigma}\mathcal{D}^{\sigma u})^{\frac{1}{2}} \lesssim S_F^{uu}$ already yields $h_F^{-1}|\mathcal{D}^{uu}| \lesssim S_F^{uu}$ (see the examples in sections 3.3 and 3.4).

It is now straightforward to verify the following convergence result.

THEOREM 4.3. *The statement of Theorem* 2.3 *remains valid under the assumptions of Lemma* 4.2.

4.3. Example: Linear continuum mechanics. Let us consider again problem (3.17) in section 3.4 and let us introduce a third field $p := -\frac{1}{d+\delta}\mathrm{tr}(\sigma)$ so that (3.17) can be recast into

$$\begin{cases} \sigma + p\mathcal{I}_d - \frac{1}{2}(\nabla u + (\nabla u)^t) = 0, \\ \mathrm{tr}(\sigma) + (d+\delta)p = 0, \\ -\frac{1}{2}\nabla\cdot(\sigma+\sigma^t) + \beta\cdot\nabla u + \lambda u = f; \end{cases} \tag{4.17}$$

p is often referred to as the pressure. This type of problem arises in the modeling of non-Newtonian fluids. (4.17) is the limit of the so-called upper convected Maxwell model for small relaxation times; see Fortin and Pierre [19], Fortin, Guénette, and Pierre [18], and Schwab and Suri [28]. Although three-field models may not be easy to implement or may lead to increased computational costs, they appear to be more robust for high Weissenberg numbers; see Baaijens for a review on this question [3].

Instead of (3.19), we now assume that

$$\lambda_0 \geq 0, \qquad \delta_0 = 0. \tag{4.18}$$

This setting covers incompressible materials (i.e., $\lambda = 0$, $\beta = 0$, and $\delta = 0$) and incompressible fluid flows. For the sake of simplicity, we henceforth restrict ourselves to homogeneous Dirichlet boundary conditions, i.e., $\alpha = 1$. Then the pressure is defined up to a constant, and to avoid this arbitrariness, we choose the representative of the pressure which is of zero mean, i.e., $\langle p\rangle_\Omega = 0$. Accordingly, we modify slightly the equations as follows:

$$\begin{cases} \sigma + p\mathcal{I}_d - \frac{1}{2}(\nabla u + (\nabla u)^t) = 0, \\ \mathrm{tr}(\sigma) + (d+\delta)p + \langle p\rangle_\Omega = 0, \\ -\frac{1}{2}\nabla\cdot(\sigma+\sigma^t) + \beta\cdot\nabla u + \lambda u = f. \end{cases} \tag{4.19}$$

Note that by taking the trace of the first equation and integrating over Ω, we obtain $\langle \mathrm{tr}(\sigma) + dp\rangle_\Omega = \langle \nabla\cdot u\rangle_\Omega = 0$ for homogeneous Dirichlet boundary conditions on u. Accounting for the second equation in (4.19) yields $\langle \mathrm{tr}(\sigma)\rangle_\Omega = \langle p\rangle_\Omega = 0$. Hence, we are really solving (4.17) with $\langle p\rangle_\Omega = 0$. Note that K is self-adjoint and that K^{pp} is the only nonlocal block in the operator K.

4.3.1. Well-posedness. Define $\pi \in \mathcal{L}(L_\sigma; L_\sigma)$ such that for all $\sigma \in L_\sigma$,

$$\pi\sigma = \sigma - \tfrac{1}{d}(\mathrm{tr}(\sigma) - \langle \mathrm{tr}(\sigma)\rangle_\Omega)\mathcal{I}_d. \tag{4.20}$$

PROPOSITION 4.4. *Assumptions* (A3C)–(A3H) *hold.*

Proof. Let us first prove (A3C). A straightforward calculation yields, for all $z = (\sigma, p, 0) \in W$,

$$\begin{aligned}(Kz, z)_L &= \|\sigma + p\mathcal{I}_d\|_{L_\sigma}^2 + \delta\|p\|_{L_p}^2 + \langle p\rangle_\Omega^2 \\ &= \tfrac{d}{d+\delta}\|\sigma - \tfrac{1}{d}\mathrm{tr}(\sigma)\mathcal{I}_d\|_{L_\sigma}^2 + \tfrac{1}{d+\delta}\|\mathrm{tr}(\sigma) + (d+\delta)p\|_{L_p}^2 + \tfrac{\delta}{d+\delta}\|\sigma\|_{L_\sigma}^2 + \langle p\rangle_\Omega^2.\end{aligned}$$

Hence, taking the mean of the two above equations and using triangle inequalities,

$$\gamma(Kz, z)_L \geq \|\pi\sigma\|_{L_\sigma}^2 + \|K^\sigma z\|_{L_\sigma}^2 + \|K^p z\|_{L_p}^2 + \langle p\rangle_\Omega^2,$$

with γ independent of δ_0. Since K is self-adjoint, $\lambda_0 \geq 0$, and the fields $\mathcal{B}^k$ are constant over Ω, it is inferred that for all $z = (\sigma, p, u) \in W$,

$$\tfrac{1}{2}((K + K^* - \nabla\cdot A)z, z)_L \geq (K(\sigma, p, 0), (\sigma, p, 0))_L.$$

This proves (A3C). Assumption (A3D) is a simple consequence of Korn's first inequality since $V = V^* = H_\sigma \times L^2(\Omega) \times [H_0^1(\Omega)]^d$. Assumption (A3E) results from Korn's second inequality. Let us prove (A3F). Let $z \in V$ be such that $\sigma \neq \pi\sigma$; then $\mathrm{tr}(\sigma - \pi\sigma) \neq 0$. Since $\mathrm{tr}(\sigma - \pi\sigma) = \mathrm{tr}(\sigma) - \langle \mathrm{tr}(\sigma)\rangle_\Omega \in L_0^2(\Omega)$, there is $0 \neq v \in [H_0^1(\Omega)]^d$ such that $\nabla\cdot v = \mathrm{tr}(\sigma - \pi\sigma)$ and $\|v\|_{[H^1(\Omega)]^d} \lesssim \|\sigma - \pi\sigma\|_{L_\sigma}$. Since $\langle \nabla\cdot v\rangle_\Omega = 0$, we have $Bv - \pi Bv = \sigma - \pi\sigma$. Hence,

$$\begin{aligned}\|\sigma - \pi\sigma\|_{L_\sigma} &\lesssim \tfrac{1}{\|v\|_{[H^1(\Omega)]^d}}(Bv - \pi Bv, \sigma - \pi\sigma)_{L_\sigma} \lesssim \tfrac{1}{\|v\|_{[H^1(\Omega)]^d}}(Bv, \sigma - \pi\sigma)_{L_\sigma} \\ &\lesssim \|\pi\sigma\|_{L_\sigma} + \tfrac{1}{\|v\|_{[H^1(\Omega)]^d}}(Bv, \sigma)_{L_\sigma} \lesssim \|\pi\sigma\|_{L_\sigma} + \|B^\dagger\sigma\|_{L_u},\end{aligned}$$

whence (A3F). To prove (A3G), observe that $\|z^p\|_{L_p} \lesssim \|K^{pp}z^p\|_{L_p} + \langle p\rangle_\Omega$ and that $\langle p\rangle_\Omega \lesssim (Kz, z)_L^{1/2}$. Finally, assumption (A3H) is evident. ∎

4.3.2. Three-field DG approximation. Let $\eta_1 > 0$, $\eta_2 > 0$, $\eta_3 > 0$ (these parameters can vary from face to face) and

$$M_F^{uu}(v) = \eta_1 h_F^{-1} v, \qquad S_F^{uu}(v) = \eta_2 h_F^{-1} v, \qquad S_F^{pp}(q) = \eta_3 h_F q, \qquad R_F^{uu} \equiv 0. \tag{4.21}$$

Clearly, assumptions (DG3B)–(DG3G) hold. Other choices can be considered for M_F^{uu}, S_F^{uu}, and S_F^{pp}; see, e.g., [10, 9] for a similar DG method to approximate the Stokes and the Oseen equations.

PROPOSITION 4.5. *The discrete assumptions* (3.4)*,* (4.7)*,* (4.8)*,* (4.9)*, and* (4.10) *hold.*

Proof. The discrete Poincaré inequality (3.4) has already been shown to hold in section 3.4. Furthermore, assumptions (4.8), (4.9), and (4.10) are evident. It remains to prove (4.7). Let $z_h \in W_h$ be such that $z_h^\sigma \neq \pi z_h^\sigma$. Proceeding as in the proof of (A3E) in Proposition 4.4, there is $0 \neq v \in [H_0^1(\Omega)]^d$ such that $\nabla\cdot v = \mathrm{tr}(z_h^\sigma - \pi z_h^\sigma)$, $\|v\|_{[H^1(\Omega)]^d} \lesssim \|z_h^\sigma - \pi z_h^\sigma\|_{L_\sigma}$, and

$$\|z_h^\sigma - \pi z_h^\sigma\|_{L_\sigma} \lesssim \|\pi z_h^\sigma\|_{L_\sigma} + \tfrac{1}{\|v\|_{[H^1(\Omega)]^d}}(Bv, z_h^\sigma)_{L_\sigma}.$$

Since $v \in [H_0^1(\Omega)]^d$, integration by parts yields

$$(Bv, z_h^\sigma \pi z_h^\sigma)_{L_\sigma} = -(v, B_h^\dagger z_h^\sigma)_{L_u} + 2 \sum_{F \in \mathcal{F}_h^{\mathrm{i}}} (\{\mathcal{D}^{u\sigma} z_h^\sigma\}, v)_{L_u,F}.$$

Let v_h be the L_u-orthogonal projection of v onto U_h. Then

$$\begin{aligned}(Bv, z_h^\sigma)_{L_\sigma} = & -(v - v_h, B_h^\dagger z_h^\sigma)_{L_u} + 2 \sum_{F \in \mathcal{F}_h^{\mathrm{i}}} (\{\mathcal{D}^{u\sigma} z_h^\sigma\}, \{v - v_h\})_{L_u,F} \\ & -(v_h, B_h^\dagger z_h^\sigma)_{L_u} + 2 \sum_{F \in \mathcal{F}_h^{\mathrm{i}}} (\{\mathcal{D}^{u\sigma} z_h^\sigma\}, \{v_h\})_{L_u,F} := T_1 + T_2 + T_3 + T_4.\end{aligned}$$

By construction, $T_1 = 0$ and by definition $T_3 + T_4 = -\mathbb{B}_h(z_h^\sigma, v_h)$. Moreover, adding and subtracting πz_h^σ in T_2, using trace and inverse inequalities and the facts that $p_\sigma \le p_u + 1$ and $\|v - v_h\|_{L_u,\partial K} \lesssim h_K^{\frac{1}{2}} \|v\|_{[H^1(K)]^d}$ for all $K \in \mathcal{T}_h$, leads to

$$|T_2| \lesssim \left(\|\pi z_h^\sigma\|_{L_\sigma}^2 + \sum_{F \in \mathcal{F}_h^{\mathrm{i}}} h_F \|[\![z_h^\sigma - \pi z_h^\sigma]\!]\|_{L_\sigma,F}^2 \right)^{\frac{1}{2}} \|v\|_{[H^1(\Omega)]^d},$$

whence (4.7). ∎

5. Singular perturbation analysis. The situation we want to analyze in this section is that of two-field Friedrichs' systems where the off-diagonal term $\mathcal{B}^k$ coupling the σ- and u-components and the diagonal term $\mathcal{C}^k$ may have different magnitude. The model situation we have in mind is that of an elliptic/hyperbolic-type change. We show that this situation is properly accounted for by appropriately defining (tuning) the stabilizing parameters controlling the interface jumps of z_h^u.

To avoid irrelevant technicalities, we henceforth assume that (A1)–(A5) hold, i.e., full L-coercivity holds. Hypothesis (A3) can be replaced by the weaker hypotheses introduced in section 3, but these developments are omitted for brevity. The singular perturbation analysis for the three-field DG approximation will be reported elsewhere.

5.1. The setting. Let $1 \ge \epsilon > 0$ be a positive real number. The setting of section 2.2 is modified by considering the following two-field structure:

$$K = \left[\begin{array}{c|c} K^{\sigma\sigma} & K^{\sigma u} \\ \hline K^{u\sigma} & K^{uu} \end{array}\right], \qquad \mathcal{A}^k = \left[\begin{array}{c|c} 0 & \epsilon^{\frac{1}{2}} \mathcal{B}^k \\ \hline \epsilon^{\frac{1}{2}} [\mathcal{B}^k]^t & \mathcal{C}^k \end{array}\right], \tag{5.1}$$

where it is assumed that all the blocks of the operator K as well as the fields $\mathcal{B}^k$ and $\mathcal{C}^k$ are independent of the parameter ϵ.

Owing to (5.1), the definitions (2.11) and (2.12) are now replaced by

$$\mathcal{D} = \left[\begin{array}{c|c} 0 & \epsilon^{\frac{1}{2}} \mathcal{D}^{\sigma u} \\ \hline \epsilon^{\frac{1}{2}} \mathcal{D}^{u\sigma} & \mathcal{D}^{uu} \end{array}\right], \qquad \mathcal{M} = \left[\begin{array}{c|c} 0 & -\alpha\epsilon^{\frac{1}{2}} \mathcal{D}^{\sigma u} \\ \hline \alpha\epsilon^{\frac{1}{2}} \mathcal{D}^{u\sigma} & \mathcal{M}^{uu} \end{array}\right]. \tag{5.2}$$

The discrete problem we consider is (2.16) with the bilinear form a_h still defined by (2.15). As in section 2.5, we assume that p_u is a *positive* integer and that $p_u - 1 \le p_\sigma \le p_u$.

Henceforth the notation $\xi \lesssim \zeta$ now means that there is a positive c, *independent of h and ϵ*, such that $\xi \le c\zeta$.

5.2. Design of the boundary and jump operators. To avoid unnecessary technicalities we assume that the user-dependent operator R_F^{uu} is zero. Everything that is said hereafter extends to IP-like methods provided the assumptions (DG2E)–(DG2F) are localized. The details are left to the reader. To account for the presence of ϵ, we modify the design conditions (DG2A)–(DG2D) for the operators M_F and S_F as follows:

(DG2$_\epsilon$A) $$M_F = \left[\begin{array}{c:c} 0 & -\alpha\epsilon^{\frac12}\mathcal{D}^{\sigma u} \\ \hdashline \alpha\epsilon^{\frac12}\mathcal{D}^{u\sigma} & M_F^{uu} \end{array}\right],\ \alpha\in\{-1,+1\},\qquad S_F = \left[\begin{array}{c:c} 0 & 0 \\ \hdashline 0 & S_F^{uu} \end{array}\right];$$

(DG2$_\epsilon$B) $$\text{if } \alpha=+1,\ \begin{cases} M_F^{uu} = (M_F^{uu})^* \quad\text{and}\quad \mathrm{Ker}(\mathcal{D}^{\sigma u})\subset\mathrm{Ker}(M_F^{uu}-\mathcal{D}^{uu}),\\ \epsilon(\mathcal{D}^{u\sigma}\mathcal{D}^{\sigma u})^{\frac12} + h_F|\mathcal{D}^{uu}| \lesssim h_F M_F^{uu} \lesssim \theta_F\mathcal{I}_{m_u}; \end{cases}$$

(DG2$_\epsilon$C) $$\text{if } \alpha=-1,\ M_F^{uu}(v) = \mathcal{M}^{uu}v \text{ and } |\mathcal{D}^{uu}| \lesssim \mathcal{M}^{uu} \lesssim \mathcal{I}_{m_u};$$

(DG2$_\epsilon$D) $$S_F^{uu} = (S_F^{uu})^* \text{ and } \epsilon(\mathcal{D}^{u\sigma}\mathcal{D}^{\sigma u})^{\frac12} + h_F|\mathcal{D}^{uu}| \lesssim h_F S_F^{uu} \lesssim \theta_F\mathcal{I}_{m_u},$$

where we have set

$$\theta_S = \max(\epsilon, h_S)\qquad \forall S\in\mathcal{F}_h\cup\mathcal{T}_h. \tag{5.3}$$

If $\epsilon \ll h$, (DG2$_\epsilon$D) amounts to $|\mathcal{D}^{uu}| \lesssim S_F^{uu} \lesssim \mathcal{I}_{m_u}$, that is, assumption (DG1E) for one-field Friedrichs' systems is recovered for the (uu)-blocks. If $\epsilon\sim 1$, (DG2$_\epsilon$D) leads to assumption (DG2D) for two-field Friedrichs' systems concerning the control on $(\mathcal{D}^{u\sigma}\mathcal{D}^{\sigma u})^{\frac12}$ and leads to a slightly stronger control on $\mathcal{D}^{uu}$, namely, $|\mathcal{D}^{uu}| \lesssim M_F^{uu}$. The reason for this difference is that in the present analysis, we aim at obtaining a sharper convergence result for the u-component.

5.3. Convergence analysis. For all $z\in W(h)$, we introduce the following norms:

$$\|z\|_{h\epsilon,A}^2 = \|z\|_L^2 + |z^u|_J^2 + |z^u|_M^2 + \|\epsilon^{\frac12}B_h z^u\|_{L_\sigma}^2 + \|\mathfrak{h}^{\frac12}C_h z^u\|_{L_u}^2, \tag{5.4}$$

$$\|z\|_{h\epsilon,1}^2 = \|z\|_{h\epsilon,A}^2 + \sum_{K\in\mathcal{T}_h}[\theta_K h_K^{-1}(h_K^{-1}\|z^u\|_{L_u,K}^2 + \|z^u\|_{L_u,\partial K}^2) + h_K\|z^\sigma\|_{L_\sigma,\partial K}^2]. \tag{5.5}$$

We denote by $\mathcal{T}_h^+$ the set of mesh cells K such that $h_K\ge\epsilon$. We also denote by $\mathcal{F}_h^{i+}$ the set of faces F such that $\max_{K\in\mathcal{T}(F)}h_K\ge\epsilon$; observe that $h_F\gtrsim\epsilon$ whenever $F\in\mathcal{F}_h^{i+}$. The same definition applies for $\mathcal{F}_h^{\partial+}$.

LEMMA 5.1. *Assume $\mathcal{B}^k\in[\mathfrak{C}^{0,1}(K)]^{m_\sigma,m_u}$ and $\mathcal{C}^k\in[\mathfrak{C}^{0,\frac12}(K)]^{m_u,m_u}$ for all $K\in\mathcal{T}_h$ and all $1\le k\le d$, and that*

$$\forall z_h\in W_h,\quad \|C_h z_h^u\|_{L_u} \lesssim \|B_h z_h^u\|_{L_\sigma} + \|z_h^u\|_{L_u}. \tag{5.6}$$

Then

$$\forall z_h\in W_h,\qquad \|z_h\|_{h\epsilon,A} \lesssim \sup_{y_h\in W_h\setminus\{0\}}\frac{a_h(z_h,y_h)}{\|y_h\|_{h\epsilon,A}}. \tag{5.7}$$

Proof. Let $z_h\in W_h$ and set $\mathbb{S} = \sup_{y_h\in W_h\setminus\{0\}}\frac{a_h(z_h,y_h)}{\|y_h\|_{h\epsilon,A}}$.

(1) Using the definition of a_h together with (DG2$_\epsilon$A) and (A3) yields

$$\|z_h\|_L^2 + |z_h^u|_J^2 + |z_h^u|_M^2 \lesssim a_h(z_h,z_h) \le \mathbb{S}\,\|z_h\|_{h\epsilon,A}. \tag{5.8}$$

(2) Define the field π_h^σ such that for all $K \in \mathcal{T}_h$, $\pi_h^\sigma|_K = \sum_{k=1}^d \epsilon^{\frac{1}{2}} \overline{\mathcal{B}_K^k} \partial_k z_h^u$, where $\overline{\mathcal{B}_K^k}$ denotes the mean-value of $\mathcal{B}^k$ over K. Owing to the regularity of the $\mathcal{B}^k$'s, a standard inverse inequality, and the fact that $\epsilon \le 1$,

$$\|(\pi_h^\sigma, 0)\|_{h\epsilon,A} = \|\pi_h^\sigma\|_{L_\sigma} \lesssim \|\epsilon^{\frac{1}{2}} B_h z_h^u\|_{L_\sigma} + \epsilon^{\frac{1}{2}} \|z_h^u\|_{L_u} \lesssim \|z_h\|_{h\epsilon,A}. \tag{5.9}$$

From the definition of a_h and (DG2_ϵA), it follows that

$$\begin{aligned}\|\epsilon^{\frac{1}{2}} B_h z_h^u\|_{L_\sigma}^2 = a_h(z_h, (\pi_h^\sigma, 0)) + (\epsilon^{\frac{1}{2}} B_h z_h^u, \epsilon^{\frac{1}{2}} B_h z_h^u - \pi_h^\sigma)_{L_\sigma} \\ - (K^{\sigma\sigma} z_h^\sigma + K^{\sigma u} z_h^u, \pi_h^\sigma)_{L_\sigma} + \sum_{F\in\mathcal{F}_h^\partial} \tfrac{\alpha+1}{2} \epsilon^{\frac{1}{2}} (\mathcal{D}^{\sigma u} z_h^u, \pi_h^\sigma)_{L_\sigma,F} \\ + \sum_{F\in\mathcal{F}_h^{\mathrm{i}}} 2\epsilon^{\frac{1}{2}} (\{\mathcal{D}^{\sigma u} z_h^u\}, \{\pi_h^\sigma\})_{L_\sigma,F}.\end{aligned}$$

Then proceeding as in the proof of [16, lemma 5.5] in Part II yields

$$\|\epsilon^{\frac{1}{2}} B_h z_h^u\|_{L_\sigma}^2 \lesssim \mathbb{S} \|z_h\|_{h\epsilon,A}. \tag{5.10}$$

(3) Let $\overline{\mathcal{C}_K^k}$ denote the mean-value of $\mathcal{C}^k$ over K and define the field π_h^u such that $\pi_h^u|_K = \sum_{k=1}^d h_K \overline{\mathcal{C}_K^k} \partial_k z_h^u$ if $h_K \ge \epsilon$, and $\pi_h^u|_K = 0$ otherwise. Owing to the regularity of the $\mathcal{C}^k$'s and a standard inverse inequality,

$$h_K^{-\frac{1}{2}} \|\pi_h^u\|_{L_u,K} \lesssim h_K^{\frac{1}{2}} \|C_h z_h^u\|_{L_u,K} + \|z_h^u\|_{L_u,K}, \tag{5.11}$$

whence it is inferred, using inverse inequalities, the fact that $h_K \ge \epsilon$ in the support of π_h^u, and the upper bounds in (DG2_ϵB)–(DG2_ϵD), that $\|(0, \pi_h^u)\|_{h\epsilon,A} \lesssim \|z_h\|_{h\epsilon,A}$. Set $\mathtt{C} = \sum_{K\in\mathcal{T}_h^+} h_K \|C_h z_h^u\|_{L_u,K}^2$. From the definition of a_h, it follows that

$$\begin{aligned}\mathtt{C} = a_h(z_h, (0, \pi_h^u)) - (K^{u\sigma} z_h^\sigma + K^{uu} z_h^u, \pi_h^u)_{L_u} \\ - \sum_{K\in\mathcal{T}_h^+} (\epsilon^{\frac{1}{2}} B_h^\dagger z_h^\sigma, \pi_h^u)_{L_u,K} + \sum_{K\in\mathcal{T}_h^+} (C_h z_h^u, h_K C_h z_h^u - \pi_h^u)_{L_u,K} \\ - \sum_{F\in\mathcal{F}_h^{\partial+}} \tfrac{\alpha-1}{2} \epsilon^{\frac{1}{2}} (\mathcal{D}^{u\sigma} z_h^\sigma, \pi_h^u)_{L_u,F} - \sum_{F\in\mathcal{F}_h^{\partial+}} \tfrac{1}{2} (M_F^{uu}(z_h^u) - \mathcal{D}^{uu} z_h^u, \pi_h^u)_{L_u,F} \\ + \sum_{F\in\mathcal{F}_h^{i+}} 2\epsilon^{\frac{1}{2}} (\{\mathcal{D}^{u\sigma} z_h^\sigma\}, \{\pi_h^u\})_{L_u,F} + \sum_{F\in\mathcal{F}_h^{i+}} 2(\{\mathcal{D}^{uu} z_h^u\}, \{\pi_h^u\})_{L_u,F} \\ - \sum_{F\in\mathcal{F}_h^{i+}} (S_F^{uu}([\![z_h^u]\!]), [\![\pi_h^u]\!])_{L_u,F} = a_h(z_h, (0, \pi_h^u)) + R_1 + \cdots + R_8.\end{aligned}$$

Let us estimate the remainder terms R_i, $1 \le i \le 8$, on the right-hand side. Clearly, $|R_1| \lesssim \|z_h\|_L \|\pi_h^u\|_{L_u}$. Furthermore, using an inverse inequality and the fact that $\epsilon \le h_K$ for $K \in \mathcal{T}_h^+$,

$$|R_2| \lesssim \sum_{K\in\mathcal{T}_h^+} \epsilon^{\frac{1}{2}} h_K^{-1} \|z_h^\sigma\|_{L_\sigma,K} \|\pi_h^u\|_{L_u,K} \lesssim \sum_{K\in\mathcal{T}_h^+} \|z_h^\sigma\|_{L_\sigma,K} h_K^{-\frac{1}{2}} \|\pi_h^u\|_{L_u,K},$$

and $|R_3| \lesssim \sum_{K\in\mathcal{T}_h^+} h_K^{\frac12}\|C_h z_h^u\|_{L_u,K}\|z_h^u\|_{L_u,K}$. If $\alpha = +1$, then $R_4 = 0$, while if $\alpha = -1$, then

$$\begin{aligned}|R_4| &\lesssim \sum_{F\in\mathcal{F}_h^{\partial+}} \epsilon^{\frac12} h_F^{-\frac12}\|z_h^\sigma\|_{L_\sigma,\mathcal{T}(F)} h_F^{-\frac12}\|\pi_h^u\|_{L_u,\mathcal{T}(F)}\\ &\lesssim \sum_{F\in\mathcal{F}_h^{\partial+}} \|z_h^\sigma\|_{L_\sigma,\mathcal{T}(F)} h_F^{-\frac12}\|\pi_h^u\|_{L_u,\mathcal{T}(F)}.\end{aligned}$$

Moreover, since $|\mathcal{D}^{uu}| \lesssim M_F^{uu} \lesssim \mathcal{I}_{m_u}$ for all $F \in \mathcal{F}_h^{\partial+}$ in both cases for α,

$$|R_5| \lesssim \sum_{F\in\mathcal{F}_h^{\partial+}} |z_h^u|_{M,F}(|\pi_h^u|_{M,F} + \|\pi_h^u\|_{L_u,F}) \lesssim \sum_{F\in\mathcal{F}_h^{\partial+}} |z_h^u|_{M,F} h_F^{-\frac12}\|\pi_h^u\|_{L_u,\mathcal{T}(F)}.$$

Similarly,

$$|R_6| + |R_7| \lesssim \sum_{F\in\mathcal{F}_h^{i+}} (\|z_h^\sigma\|_{L_\sigma,\mathcal{T}(F)} + |z_h^u|_{J,F}) h_F^{-\frac12}\|\pi_h^u\|_{L_u,\mathcal{T}(F)},$$

and $|R_8| \le \sum_{F\in\mathcal{F}_h^{i+}} |z_h^u|_{J,F}|\pi_h^u|_{J,F} \lesssim \sum_{F\in\mathcal{F}_h^{i+}} |z_h^u|_{J,F} h_F^{-\frac12}\|\pi_h^u\|_{L_u,\mathcal{T}(F)}$. Collecting the above bounds and using (5.8) and (5.11), we deduce $|R_1|+\cdots+|R_8| \lesssim \gamma\mathfrak{C} + a_h(z_h,z_h)$, where γ can be chosen as small as needed. Hence, $\mathfrak{C} \lesssim \mathbb{S}\,\|z_h\|_{h\epsilon,A}$, and using (5.6) and (5.10) leads to the same bound for $\|\mathfrak{h}^{\frac12} C_h z^u\|_{L_u}^2$.

(4) Collecting the above bounds yields $\|z_h\|_{h\epsilon,A}^2 \lesssim \mathbb{S}\,\|z_h\|_{h\epsilon,A}$ and hence (5.7). ∎

LEMMA 5.2. *The following holds:*

$$\forall (z,y_h) \in W(h)\times W_h, \quad a_h(z,y_h) \lesssim \|z\|_{h\epsilon,1}\|y_h\|_{h\epsilon,A}. \tag{5.12}$$

Proof. Use integration by parts to infer

$$\begin{aligned}a_h(z,y_h) = &\sum_{K\in\mathcal{T}_h} (z,\tilde{T}y_h)_{L,K} + \sum_{F\in\mathcal{F}_h^\partial} \tfrac12 (M_F(z) + \mathcal{D}z, y_h)_{L,F}\\ &+ \sum_{F\in\mathcal{F}_h^{\mathrm{i}}} \tfrac12 (\llbracket \mathcal{D}z\rrbracket, \llbracket y_h\rrbracket)_{L,F} + \sum_{F\in\mathcal{F}_h^{\mathrm{i}}} (S_F^{uu}(\llbracket z^u\rrbracket), \llbracket y_h^u\rrbracket)_{L_u,F}.\end{aligned}$$

Let R_1 to R_4 be the four terms on the right-hand side. Observe that

$$\begin{aligned}(z,\tilde{T}y_h)_{L,K} &\lesssim \|z\|_{L,K}\|y_h\|_{L,K} + \|z^\sigma\|_{L_\sigma,K}\epsilon^{\frac12}\|B_h y_h^u\|_{L_\sigma,K}\\ &\quad + \|z^u\|_{L_u,K}\epsilon^{\frac12}\|B_h^\dagger y_h^\sigma\|_{L_u,K} + \|z^u\|_{L_u,K}\|C_h y_h^u\|_{L_u,K}\\ &\lesssim \|z\|_{L,K}\|y_h\|_{L,K} + \|z^\sigma\|_{L_\sigma,K}\epsilon^{\frac12}\|B_h y_h^u\|_{L_\sigma,K}\\ &\quad + \epsilon^{\frac12} h_K^{-1}\|z^u\|_{L_u,K}\|y_h^\sigma\|_{L_\sigma,K} + h_K^{-\frac12}\|z^u\|_{L_u,K} h_K^{\frac12}\|C_h y_h^u\|_{L_u,K}.\end{aligned}$$

Hence, $|R_1| \lesssim \|z\|_{h\epsilon,1}\|y_h\|_{h\epsilon,A}$. Furthermore, if $\alpha = +1$,

$$\begin{aligned}|R_2| &\le \sum_{F\in\mathcal{F}_h^\partial} [|\epsilon^{\frac12}(\mathcal{D}^{u\sigma}z^\sigma, y_h^u)_{L_u,F}| + \tfrac12 |(M_F^{uu}(z^u) + \mathcal{D}^{uu}z^u, y_h^u)_{L_u,F}|]\\ &\lesssim \sum_{F\in\mathcal{F}_h^\partial} [\|z^\sigma\|_{L_\sigma,F} h_F^{\frac12}|y_h^u|_{M,F} + \theta_F^{\frac12} h_F^{-\frac12}\|z^u\|_{L_u,F}|y_h^u|_{M,F}],\end{aligned}$$

while if $\alpha = -1$, $|R_2| \lesssim \sum_{F\in\mathcal{F}_h^\partial}[\epsilon^{\frac12}\|z^u\|_{L_u,F}h_F^{-\frac12}\|y_h^\sigma\|_{L_\sigma,\mathcal{T}(F)} + \|z^u\|_{L_u,F}|y_h^u|_{M,F}]$. Hence, in both cases, $|R_2| \lesssim \|z\|_{h\epsilon,1}\|y_h\|_{h\epsilon,A}$. Similarly,

$$\epsilon^{\frac12}([\![\mathcal{D}^{\sigma u}z^u]\!],[\![y_h^\sigma]\!])_{L_\sigma,F} \lesssim \epsilon^{\frac12}\|\{z^u\}\|_{L_u,F}h_F^{-\frac12}\|y_h^\sigma\|_{L_\sigma,\mathcal{T}(F)},$$
$$\epsilon^{\frac12}([\![\mathcal{D}^{u\sigma}z^\sigma]\!],[\![y_h^u]\!])_{L_u,F} \lesssim \|\{z^\sigma\}\|_{L_\sigma,F}h_F^{\frac12}|y_h^u|_{J,F},$$
$$([\![\mathcal{D}^{uu}z^u]\!],[\![y_h^u]\!])_{L_u,F} \lesssim \|\{z^u\}\|_{L_u,F}|y_h^u|_{J,F}.$$

Hence, $|R_3| \lesssim \|z\|_{h\epsilon,1}\|y_h\|_{h\epsilon,A}$. Finally, it is clear that $\sum_{F\in\mathcal{F}_h^{\mathrm{i}}}(S_F^{uu}([\![z^u]\!]),[\![y_h^u]\!])_{L_u,F} \le \|z\|_{h\epsilon,1}\|y_h\|_{h\epsilon,A}$, thereby completing the proof. ∎

It is now straightforward to derive the following result.

THEOREM 5.3. *Keep the hypotheses of Lemma* 5.1. *Assume that* $z \in [H^1(\Omega)]^m$. *Then*

$$\|z - z_h\|_{h\epsilon,A} \lesssim \inf_{y_h\in W_h}\|z - y_h\|_{h\epsilon,1}. \tag{5.13}$$

In particular, if $z \in [H^{p_u+1}(\Omega)]^m$,

$$\|z - z_h\|_{h\epsilon,A} \lesssim \theta^{\frac12}h^{p_u}\|z\|_{[H^{p_u+1}(\Omega)]^m}. \tag{5.14}$$

The convergence estimate in Theorem 5.3 is consistent with that from the two-field DG theory when $1 \sim \epsilon \ge h$, and it degenerates into that from the one-field theory for the u-component when $h \ge \epsilon$. Indeed, if $1 \sim \epsilon \ge h$,

$$\|z^u - z_h^u\|_{L_u} + \|B_h(z^u - z_h^u)\|_{L_\sigma} \lesssim h^{p_u}\|z\|_{[H^{p_u+1}(\Omega)]^m}, \tag{5.15}$$

and the L_u-norm error estimate can be improved if elliptic regularity holds, while if $h \ge \epsilon$,

$$\|z^u - z_h^u\|_{L_u} + \|\mathfrak{h}^{\frac12}C_h(z^u - z_h^u)\|_{L_u} \lesssim h^{p_u+\frac12}\|z\|_{[H^{p_u+1}(\Omega)]^m}. \tag{5.16}$$

Remark 5.1. A similar result to that of Theorem 5.3 has been proved in Gopalakrishnan and Kanschat [22, Thm. 5.1] for the advection–diffusion equation (5.17).

5.4. Example: Advection dominated advection–diffusion. Consider the advection–diffusion equation introduced in section 3.3 with a diffusion coefficient $\epsilon > 0$. The PDE $-\epsilon\Delta u + \beta\cdot\nabla u + \mu u = f$ in mixed form becomes

$$\begin{cases} \sigma + \epsilon^{\frac12}\nabla u = 0, \\ \mu u + \epsilon^{\frac12}\nabla\cdot\sigma + \beta\cdot\nabla u = f, \end{cases} \tag{5.17}$$

so that the off-diagonal blocks of $\mathcal{A}^k$ in (3.8) are rescaled by $\epsilon^{\frac12}$, while the operator K is unchanged.

In the case of a Dirichlet boundary condition, the boundary and interface operators can be redesigned to fit the above analysis by modifying (3.16) as follows:

$$M_F^{uu}(v) = \eta_1(|\beta\cdot n_F| + \epsilon h_F^{-1})v, \qquad S_F^{uu}(v) = \eta_2(|\beta\cdot n_F| + \epsilon h_F^{-1})v, \tag{5.18}$$

where n_F is a unit normal vector to F and $\eta_1 > 0$, $\eta_2 > 0$ (these two parameters can vary from face to face). It is easily verified that properties (DG2_ϵB) and (DG2_ϵD) hold.

Assuming $\varrho \ge -\min(\beta\cdot n, 0)$, mixed Robin–Neumann boundary conditions can be enforced by redesigning the boundary and interface operators as follows:

$$M_F^{uu}(v) = (2\varrho + \beta\cdot n)v, \qquad S_F^{uu}(v) = \eta_2(|\beta\cdot n_F| + \epsilon h_F^{-1})v. \tag{5.19}$$

Again, it is easily verified that properties (DG2_ϵC) and (DG2_ϵD) hold.

6. Conclusion. We have analyzed various DG methods in Parts I, II, and III. We have attempted to give a unified analysis for all of these methods. Following the seminal ideas of Lesaint and Raviart [25, 26], we have shown that the framework of symmetric positive Friedrichs' systems is the natural setting for this theory insofar as boundary conditions can be enforced weakly for all of these systems. The first building block of the theory is the bilinear form (2.4) along with the weak formulation (2.6). All the DG methods that we have analyzed can be put into the unified bilinear form (2.15) and the unified formulation (2.16). The differences between all of these methods reside solely in the design of the boundary and interface operators.

The method described in Part I is the most robust in the sense that it is essentially independent of the type of the PDE (which is the main argument for our working with Friedrichs' systems). The price for robustness is the slightly suboptimal convergence rate $\mathcal{O}(h^{p+/2})$ in the L^2-norm. In Part II, two components of the unknown are identified, say (z^σ, z^u), and the generic DG method is set so that the z^σ unknown can be locally eliminated on each mesh cell. The underlying model is that of elliptic equations. Compared to the method of Part I, the convergence rate in the L^2-norm for the z^u unknown is now optimal, i.e., $\mathcal{O}(h^{p+1})$, the downside being a slight loss of robustness with respect to type change, which is addressed in Part III, section 5. Part III revisits the results of Part II in two aspects: (i) weakening of the L^2-coercivity assumption on which Part II is based; (ii) questions regarding robustness with respect to type change.

DISCONTINUOUS GALERKIN METHODS FOR ANISOTROPIC SEMIDEFINITE DIFFUSION WITH ADVECTION*

DANIELE A. DI PIETRO†‡, ALEXANDRE ERN†, AND JEAN-LUC GUERMOND§

Abstract. We construct and analyze a discontinuous Galerkin method to solve advection-diffusion-reaction PDEs with anisotropic and semidefinite diffusion. The method is designed to automatically detect the so-called elliptic/hyperbolic interface on fitted meshes. The key idea is to use consistent weighted average and jump operators. Optimal estimates in the broken graph norm are proven. These are consistent with well-known results when the problem is either hyperbolic or uniformly elliptic. The theoretical results are supported by numerical evidence.

Key words. discontinuous Galerkin, advection-diffusion-reaction, discontinuous coefficients, anisotropic diffusion, coupled elliptic-hyperbolic, weighted averages

1. Introduction.

Discontinuous Galerkin (DG) methods were originally introduced to solve transport equations in [23, 24, 25] and later extended to problems involving second-order elliptic operators in [1, 4, 26]. For many years, the development and analysis of DG methods have followed two somewhat parallel routes according to the hyperbolic or elliptic nature of the problem at hand. A unifying viewpoint has recently been proposed in a series of papers [10, 11, 13], where the authors rely on the Friedrichs framework originally proposed in [17] to perform an abstract analysis valid for a variety of (linear) PDE systems.

The goal of the present work is to merge even further the hyperbolic and elliptic points of view by considering advection-diffusion-reaction problems with discontinuous, anisotropic, and semidefinite diffusivity (or, using the terminology from [22], scalar-valued second-order PDEs with nonnegative characteristic form). One major difficulty associated with this class of problems is that only the conservative flux is continuous and, at variance with uniformly elliptic problems, the scalar field can be discontinuous across hyperbolic/elliptic interfaces (see (2.4) for the definition of these interfaces). The literature in numerical analysis dedicated to this topic is scarce. This issue has been investigated in one space dimension by Gastaldi and Quarteroni in [18], where interface conditions are derived using asymptotic analysis. In [22], Houston, Schwab, and Süli propose and analyze a DG method for PDEs with nonnegative characteristic form in higher space dimensions. They treat hyperbolic/elliptic interfaces in a numerical example at the end of the paper (see [22, section 6.4]). Another example can be found in [14]. Both proposed techniques are ad hoc in the sense that they require removing a priori some penalty terms at the hyperbolic/elliptic interface. Our

objective is to go beyond [14, 18, 22] by proposing a DG method that automatically detects the so-called hyperbolic/elliptic interface under the mild assumption that the mesh fits the discontinuities of the diffusion tensor.

The material is organized as follows. We introduce the model problem in section 2. It is a multidimensional scalar-valued second-order PDE with nonnegative characteristic from. We derive the multidimensional counterpart of the one-dimensional interface condition introduced in [18]. We reformulate the problem as a symmetric Friedrichs system (in the spirit of [10, 13, 17]) by identifying appropriate interface and boundary operators. A well-posedness result is proven under some assumptions. In section 3 we focus our attention on the discrete problem. We propose a DG approximation based on the weak formulation of the continuous problem with boundary and interface conditions enforced weakly. The discrete bilinear form is designed so that the correct interface conditions are automatically enforced on fitted meshes without identifying a priori the hyperbolic/elliptic interfaces. The basic requirements on the bilinear form are that it be strongly consistent, continuous, and (in the spirit of Friedrichs) L^2-coercive. The convergence of the method is proven in section 4, and the main results are stated in Theorems 4.5 and 4.7. The error estimates are optimal in the broken graph norm and compatible with those presented in [10, 11] when the problem is either hyperbolic or uniformly elliptic. Implementation issues are addressed in section 5, and variants of the method are discussed. Section 6 is devoted to numerical experiments illustrating the performance of the proposed method. Concluding remarks are contained in section 7.

2. The continuous problem. In this section we introduce the model problem, and we recast it as a first-order PDE system endowed with a Friedrichs-like structure. We then derive a weak formulation where boundary and interface conditions are enforced naturally. This formulation will be the starting point for the design of the DG method constructed in section 3.

2.1. The PDE setting. Let $\Omega \subset \mathbb{R}^d$ be a bounded, open, and connected Lipschitz domain with boundary $\partial\Omega$ and outward normal n. The problem investigated in the present work consists of the following scalar-valued PDE:

$$\nabla\cdot(-\nu\nabla u + \beta u) + \mu u = f, \tag{2.1}$$

with data $f \in L^2(\Omega)$. Boundary conditions are specified later in this section. The following assumptions are made on the coefficients:

(i) $\nu \in [L^\infty(\Omega)]^{d,d}$ is a symmetric positive *semi*definite tensor field, meaning that for all $r \in \mathbb{R}^d$ and for a.e. (almost every) $x \in \Omega$, $r^t\nu(x)r \geq 0$;

(ii) $\beta \in [\mathfrak{C}^1(\overline{\Omega})]^d$ and $\mu \in L^\infty(\Omega)$;

(iii) there is some $\mu_0 > 0$ so that $\mu + \frac{1}{2}\nabla\cdot\beta \geq \mu_0$ for a.e. $x \in \Omega$.

Throughout the rest of this work, the symbols $\lesssim$ and $\gtrsim$ are used for inequalities that hold up to a real positive multiplicative constant that is independent of ν (and discretization parameters like the meshsize) but may depend on β and μ (and regularity parameters of the mesh family considered later on).

We finally assume that the field ν is discontinuous and that we know the location of the discontinuities. More precisely, we assume that we are given a partition of Ω into Lipschitz connected subdomains $P_\Omega \stackrel{\text{def}}{=} \{\Omega_i\}_{i=1}^N$ so that the following holds:

(iv) ν is piecewise constant on the partition P_Ω, and the problem is normalized so that $\|\nu\|_{[L^\infty(\Omega)]^{d,d}} \leq 1$.

We introduce the symbol Γ to denote the union of the inner boundaries of the subdomains Ω_i, i.e.,

$$\Gamma \stackrel{\text{def}}{=} \{x \in \Omega;\ \exists i_1, i_2 \in \{1, \dots, N\},\ i_1 \neq i_2,\ x \in \partial\Omega_{i_1} \cap \partial\Omega_{i_2}\}. \tag{2.2}$$

The unit outward normals to Ω_{i_1} and Ω_{i_2} are denoted by n_{i_1} and n_{i_2}. For a.e. $x \in \Gamma$, the two indices i_1, i_2 are chosen such that $(n^t\nu n)(x)|_{\Omega_{i_1}} \geq (n^t\nu n)(x)|_{\Omega_{i_2}}$. We also denote by n the two-valued field on Γ such that, for $x \in \partial\Omega_{i_1} \cap \partial\Omega_{i_2}$, $n(x) = \{n_{i_1}, n_{i_2}\}$.

For every two-valued function φ on Γ, we denote by φ_1 the value of φ which is defined on the side of Ω_{i_1} and by φ_2 the value of φ which is defined on the side of Ω_{i_2}. For example, when applying this convention to the normal vector n, we have $n_1 = n_{i_1}$ and $n_2 = n_{i_2}$. Mean values and jumps across Γ are defined as follows:

$$\{\varphi\} \stackrel{\text{def}}{=} \tfrac{1}{2}(\varphi_1 + \varphi_2), \qquad [\![\varphi]\!] \stackrel{\text{def}}{=} \varphi_1 - \varphi_2. \tag{2.3}$$

2.2. The interface/transmission conditions. Since we are not requiring that ν be uniformly positive definite, the mathematical nature of the PDE can change over the domain. To account for this, we define the subset $I \subset \Gamma$ that we subsequently refer to as the elliptic/hyperbolic interface:

$$I \stackrel{\text{def}}{=} \{x \in \Gamma;\ (n^t\nu n)(x)|_{\Omega_{i_1}} > 0 \ \text{ and } \ (n^t\nu n)(x)|_{\Omega_{i_2}} = 0\}. \tag{2.4}$$

For any x in I, we refer to Ω_{i_1} as the elliptic side of I at x, and we refer to Ω_{i_2} as the hyperbolic side of I at x. Note that the terms elliptic and hyperbolic are not volumic properties but interface properties. Ω_{i_1} being the elliptic side of I at x does not mean that the diffusivity is positive definite in Ω_{i_1}. The diffusivity may not be positive definite in Ω_{i_1}, but still have a nonzero component in the normal direction at x and vice versa for the hyperbolic side. We now define

$$\Omega^\dagger \stackrel{\text{def}}{=} \Omega \setminus I, \qquad I^+ \stackrel{\text{def}}{=} \{x \in I;\ \beta{\cdot}n_1 > 0\}, \qquad I^- \stackrel{\text{def}}{=} \{x \in I;\ \beta{\cdot}n_1 < 0\}. \tag{2.5}$$

I^+ (resp., I^-) is the subset of I where the advection field flows from the elliptic side to the hyperbolic side (resp., hyperbolic side to the elliptic side). The reader is referred to Figures 2(a)–2(b) for examples illustrating these definitions.

Let $\kappa \stackrel{\text{def}}{=} \nu^{1/2}$. The assumptions on ν imply that κ is bounded and positive semidefinite. We now rewrite (2.1) in mixed form by introducing the auxiliary unknown σ so that

$$\begin{cases} \sigma + \kappa\nabla u = 0 & \text{in } \Omega^\dagger, \\ \nabla{\cdot}(\kappa\sigma + \beta u) + \mu u = f & \text{in } \Omega, \end{cases} \tag{2.6}$$

and we require the following continuity property to hold:

$$[\![u]\!] = 0 \quad \text{on } I^+. \tag{INT1}$$

Observe that σ is defined in $\Omega^\dagger$ only. Indeed, u may be discontinuous across I, in which case $\kappa\nabla u$ cannot be defined in the distributional sense, since the product of a discontinuous function and a distribution is not legitimate within the standard distribution theory. Note also that (INT1) demands that u be continuous only on the portion of I where the advection field flows from the elliptic to the hyperbolic side.

The above formulation implies the following formal property:

$$\{(\kappa\sigma + \beta u)\cdot n\} = 0 \quad \text{on } \Gamma, \tag{INT2}$$

since the second equation in (2.6) is expected to hold in the whole domain Ω. Similarly, the first equation in (2.6) formally implies that

$$[\![u]\!] = 0 \quad \text{across } \Gamma \setminus I. \tag{2.7}$$

Finally by combining (INT1)–(INT2) on I^+ and using Lemma 2.1 together with the continuity of β, we observe that (INT1) amounts to enforcing

$$n_1^t \kappa_1 \nabla u_1 = 0 \quad \text{on } I^+. \tag{2.8}$$

LEMMA 2.1. *Let ν be a $d\times d$ positive semidefinite matrix; then*

$$\forall r \in \mathbb{R}^d, \quad (\nu r = 0) \Leftrightarrow (r^t \nu r = 0).$$

This simple lemma will be frequently invoked in the paper.

2.3. Asymptotic justification. In one space dimension, (INT1)–(INT2) are the interface conditions derived by Gastaldi and Quarteroni in [18], and these are the transmission conditions used in [8, 14]. These conditions are deduced by considering the following regularized problem supplemented with suitable boundary conditions:

$$(-\nu u_\epsilon' + \beta u_\epsilon)' + \mu u_\epsilon - \epsilon u_\epsilon'' = f.$$

Under the hypothesis that β is a nonzero constant, it can be proved that, as $\epsilon \to 0$, u_ϵ converges in $L^2(\Omega)$ to the so-called viscosity solution of (2.6) which satisfies (INT1)–(INT2).

As an example, consider $\Omega = (0,1)$ partitioned into $\Omega_1 \stackrel{\text{def}}{=} (0, \frac{1}{3})$, $\Omega_2 \stackrel{\text{def}}{=} (\frac{1}{3}, \frac{2}{3})$, $\Omega_3 \stackrel{\text{def}}{=} (\frac{2}{3}, 1)$. Take $f = 0$, $\mu = 0$, $\beta = 1$, and set $\nu|_{\Omega_1 \cup \Omega_3} = 1$ and $\nu|_{\Omega_2} = 0$. The viscosity solution of (2.6) corresponding to the Dirichlet boundary conditions $u(0) = 1$, $u(1) = 0$ is

$$u|_{\Omega_1} = 1, \quad u|_{\Omega_2} = 1, \quad u|_{\Omega_3} = 1 - e^{(x-1)}. \tag{2.9}$$

It can be verified that this solution satisfies (INT1)–(INT2), so that u is continuous at $x = \frac{1}{3}$ and discontinuous at $x = \frac{2}{3}$.

Let us mention at this point that there is a theoretical difficulty in the above regularization process if the advection field is zero and $\mu = 0$. In this case, the limit solution can be shown to be

$$u|_{\Omega_1} = 1, \quad u|_{\Omega_2} = 2 - 3x, \quad u|_{\Omega_3} = 0. \tag{2.10}$$

Comparing (2.10) with (2.9), we conclude that the limit process $\lim_{\epsilon \to 0,\, \beta \to 0}$ is not uniform.

We hereafter assume that in higher space dimensions (INT1)–(INT2) can be obtained by means of a regularization process and that there is no ambiguity on the limit, provided $\mu + \frac{1}{2}\nabla\cdot\beta \geq \mu_0 > 0$. The goal of the present paper is not to justify (INT1)–(INT2) but to show that these conditions yield a well-posed problem which we propose to approximate using a DG method.

2.4. The functional setting. We now reformulate the above problem in an appropriate functional setting. To this end, we set

$$L_u \stackrel{\text{def}}{=} L^2(\Omega), \quad L_\sigma \stackrel{\text{def}}{=} [L^2(\Omega^\dagger)]^d, \quad L \stackrel{\text{def}}{=} L_\sigma \times L_u,$$

so that $L = \{(z^\sigma, z^u);\ z^\sigma \in L_\sigma,\ z^u \in L_u\}$. L is a Hilbert space when equipped with the product norm. We define the so-called graph space:

$$W \stackrel{\text{def}}{=} \{z \in L;\ \kappa\nabla z^u \in L_\sigma,\ \nabla\cdot(\kappa z^\sigma + \beta z^u) \in L_u\},$$

where all the derivatives are understood in the weak sense. Then we consider the following operators:

$$\begin{aligned} &K : L \ni z \mapsto (z^\sigma, \mu z^u) \in L,\\ &A : W \ni z \mapsto (\kappa\nabla z^u, \nabla\cdot\Phi(z)) \in L,\\ &\tilde{A} : W \ni z \mapsto (-\kappa\nabla z^u, (\nabla\cdot\beta)z^u - \nabla\cdot\Phi(z)) \in L, \end{aligned}$$

where, for all $y \in W$, $\Phi(y) \stackrel{\text{def}}{=} \kappa y^\sigma + \beta y^u$. A and $\tilde{A} \in \mathcal{L}(W; L)$ are formal adjoints of each other. W is clearly a Hilbert space when equipped with the following norm:

$$\|y\|_W^2 \stackrel{\text{def}}{=} \|y\|_L^2 + \|Ay\|_L^2.$$

Moreover, K and A are bounded operators; i.e., $K \in \mathcal{L}(L; L)$ and $A \in \mathcal{L}(W; L)$. We refer to W as the graph space of A, and the norm of W is called the graph norm. Note that functions in W satisfy (INT2) but not necessarily (INT1).

2.5. Boundary operators. Following [10, 13], we consider the operator $D : W \longrightarrow W'$ defined by

$$\langle Dz, y\rangle_{W',W} \stackrel{\text{def}}{=} (Az, y)_L - (z, \tilde{A}y)_L. \tag{2.11}$$

Clearly $D \in \mathcal{L}(W; W')$, and D is a boundary operator in the following sense.

LEMMA 2.2. *The following holds:*

$$\langle Dz, y\rangle_{W',W} = \int_{\partial\Omega} [\Phi(z)\cdot n y^u + \Phi(y)\cdot n z^u - (\beta\cdot n) z^u y^u] - \int_I (\beta\cdot n_1)[\![z^u]\!][\![y^u]\!] \tag{2.12}$$

for all $(z, y) \in W \times W$ smooth enough for the integrals to make sense.

Proof. Integrating by parts over $\Omega^\dagger$ in (2.11) yields

$$\begin{aligned} \langle Dz, y\rangle_{W',W} = \int_I 2\left\{z^u n^t \kappa y^\sigma + y^u n^t \kappa z^\sigma + (\beta\cdot n) z^u y^u\right\} \\ + \int_{\partial\Omega} \left[z^u n^t \kappa y^\sigma + y^u n^t \kappa z^\sigma + (\beta\cdot n) z^u y^u\right]. \end{aligned}$$

We conclude using the fact that on I, $n_1^t \kappa_1 z_1^\sigma = -\beta\cdot n_1 [\![z^u]\!]$ and $n_2^t \kappa_2 = 0$, so that $2\{z^u n^t \kappa y^\sigma + y^u n^t \kappa z^\sigma + \beta\cdot n z^u y^u\} = -(\beta\cdot n_1)[\![y^u]\!] z_1^u - (\beta\cdot n_1)[\![z^u]\!] y_1^u + (\beta\cdot n_1) y_1^u z_1^u + (\beta\cdot n_2) y_2^u z_2^u = -(\beta\cdot n_1)[\![z^u]\!][\![y^u]\!]$. ∎

In other words, if z and y are smooth enough, D admits the following integral representation:

$$\langle Dz, y\rangle_{W',W} = \int_{\partial\Omega} y^t \mathcal{D} z - \int_I (\beta\cdot n_1)[\![z^u]\!][\![y^u]\!], \quad \text{where} \quad \mathcal{D} \stackrel{\text{def}}{=} \left[\begin{array}{c:c} 0 & \kappa n \\ \hdashline (\kappa n)^t & \beta\cdot n \end{array}\right]. \tag{2.13}$$

When the traces of z and y are not in $L^2(\partial\Omega \cup I)$, the above integrals have to be understood in some duality sense that we do not try to identify here.

Let $\alpha \in \{-1, +1\}$. Still following [10, 13], we assume that there is a second boundary operator $M \in \mathcal{L}(W; W')$ such that we have the following:

(i) M is monotone, meaning that $\langle My, y\rangle_{W',W} \geq 0$ for all $y \in W$.

(ii) Letting

$$V \stackrel{\text{def}}{=} \operatorname{Ker}(M - D), \qquad V^* \stackrel{\text{def}}{=} \operatorname{Ker}(M^* + D), \tag{2.14}$$

where M^* is the adjoint of M, the following holds:

$$D(V)^\perp = V^*, \qquad D(V^*)^\perp = V, \tag{2.15}$$

where, for all $E \subset W'$, $E^\perp$ denotes the polar set of E; i.e., $E^\perp$ is composed of those linear forms on W that vanish on E.

(iii) If $(z, y) \in W \times W$ are smooth enough for the integrals to make sense, M admits the following integral representation:

$$\langle Mz, y\rangle_{W',W} = \int_{\partial\Omega} y^t \mathcal{M} z + \int_I |\beta{\cdot}n| [\![z^u]\!][\![y^u]\!], \quad \text{where} \quad \mathcal{M} \stackrel{\text{def}}{=} \left[\begin{array}{c:c} 0 & -\alpha\kappa n \\ \hdashline \alpha(\kappa n)^t & |\beta{\cdot}n| \end{array}\right]. \tag{2.16}$$

The above hypotheses essentially assert the existence of surjective trace operators on I and $\partial\Omega$. The purpose of the operator M is to impose boundary conditions and to enforce (INT1). The choice $\alpha = +1$ (resp., $\alpha = -1$) is used to enforce Dirichlet (resp., Neumann) boundary conditions. Indeed, one can verify that if $z \in W$ is smooth enough, then

(i) if $\alpha = +1$,

$$\{z \in V\} \iff \{[\![z^u]\!]|_{I^+} = 0 \text{ and } z^u|_{\{x\in\partial\Omega;\ \kappa n\neq 0 \text{ or } \beta\cdot n<0\}} = 0\}, \tag{2.17}$$

$$\{z \in V^*\} \iff \{[\![z^u]\!]|_{I^-} = 0 \text{ and } z^u|_{\{x\in\partial\Omega;\ \kappa n\neq 0 \text{ or } \beta\cdot n>0\}} = 0\}; \tag{2.18}$$

(ii) if $\alpha = -1$,

$$\{z \in V\} \iff \{[\![z^u]\!]|_{I^+} = 0 \text{ and } \Phi(z){\cdot}n = \tfrac{1}{2}(\beta{\cdot}n + |\beta{\cdot}n|)z^u\}, \tag{2.19}$$

$$\{z \in V^*\} \iff \{[\![z^u]\!]|_{I^-} = 0 \text{ and } \Phi(z){\cdot}n = \tfrac{1}{2}(\beta{\cdot}n - |\beta{\cdot}n|)z^u\}. \tag{2.20}$$

For instance, taking $\alpha = +1$, if $z \in V$ is smooth enough, then for all $y \in W$, $\langle (M - D)z, y\rangle_{W',W} = 0$, so that if y is smooth enough,

$$-\int_{\partial\Omega} [(n^t \kappa y^\sigma) z^u + (\beta{\cdot}n)^- y^u z^u] + \int_{I^+} (\beta{\cdot}n_1)[\![y^u]\!][\![z^u]\!] = 0, \tag{2.21}$$

whence (2.17) is inferred.

2.6. Well-posedness. Let $a_0 \in \mathcal{L}(W \times L; \mathbb{R})$, $a_0^* \in \mathcal{L}(W \times L; \mathbb{R})$ be defined by

$$a_0(z, y) \stackrel{\text{def}}{=} (Kz, y)_L + (Az, y)_L \qquad \forall (z, y) \in W \times L, \tag{2.22}$$

$$a_0^*(z, y) \stackrel{\text{def}}{=} (Kz, y)_L + (\tilde{A}z, y)_L \qquad \forall (z, y) \in W \times L. \tag{2.23}$$

LEMMA 2.3 (L-coercivity). *a_0 and a_0^* are L-coercive on V and V^*, respectively, in the following sense:*

(2.24)
$$\forall y \in V, \quad a_0(y,y) \geq \|y^\sigma\|_{L_\sigma}^2 + \mu_0\|y^u\|_{L_u}^2 + \tfrac{1}{2}\|[\![y^u]\!]\|_{L^2(|\beta\cdot n|;I)}^2 + \tfrac{1}{2}\|y^u\|_{L^2(|\beta\cdot n|;\partial\Omega)}^2,$$

(2.25)
$$\forall y \in V^*, \quad a_0^*(y,y) \geq \|y^\sigma\|_{L_\sigma}^2 + \mu_0\|y^u\|_{L_u}^2 + \tfrac{1}{2}\|[\![y^u]\!]\|_{L^2(|\beta\cdot n|;I)}^2 + \tfrac{1}{2}\|y^u\|_{L^2(|\beta\cdot n|;\partial\Omega)}^2.$$

Proof. Using the definition of D and V, we infer, for all $y \in V$,

$$\begin{aligned}((K+A)y,y)_L &= ((K+\tfrac{1}{2}(A+\tilde{A}))y,y)_L + (\tfrac{1}{2}(A-\tilde{A})y,y)_L \\ &= \|y^\sigma\|_{L_\sigma}^2 + ((\mu + \tfrac{1}{2}\nabla\cdot\beta)y^u, y^u)_{L_u} + \tfrac{1}{2}\langle My, y\rangle_{W',W}.\end{aligned}$$

The desired result then follows from the construction of M. Proceed similarly to prove (2.25). ∎

Consider the following problem: For $f \in L_u$,

$$\text{(2.26)} \qquad \begin{cases}\text{find } z \in V \text{ such that, } \forall y \in L,\\ a_0(z,y) = (f, y^u)_{L_u}.\end{cases}$$

PROPOSITION 2.4. *Assume that there is an $M \in \mathcal{L}(W;W')$ satisfying* (2.15). *Then, problem* (2.26) *is well-posed.*

Proof. See the appendix. ∎

Remark 2.1. Note that the boundary and interface conditions in problem (2.26) are strongly enforced by requiring the solution to be a member of V.

Having in mind that boundary conditions are weakly enforced in DG methods, we introduce the following bilinear form:

$$\text{(2.27)} \qquad a(z,y) \stackrel{\text{def}}{=} a_0(z,y) + \tfrac{1}{2}\langle (M-D)z, y\rangle_{W',W} \qquad \forall (z,y) \in W \times W.$$

Clearly, all the terms above are well defined and $a \in \mathcal{L}(W \times W; \mathbb{R})$.

LEMMA 2.5 (L-coercivity). *a is L-coercive on W.*

Proof. Clearly for all $y \in W$,

$$\begin{aligned}a(y,y) &= ((K+A)y,y)_L + \tfrac{1}{2}\langle (M-D)y,y\rangle_{W',W} \\ &= ((K+\tfrac{1}{2}(A+\tilde{A}))y,y)_L + \tfrac{1}{2}((A-\tilde{A})y,y)_L + \tfrac{1}{2}\langle (M-D)y,y\rangle_{W',W} \\ &\geq \|y^\sigma\|_{L_\sigma}^2 + \mu_0\|y^u\|_{L_u}^2 + \tfrac{1}{2}\|[\![y^u]\!]\|_{L^2(|\beta\cdot n|;I)}^2 + \tfrac{1}{2}\|y^u\|_{L^2(|\beta\cdot n|;\partial\Omega)}^2;\end{aligned}$$

that is to say, a is L-coercive. ∎

We henceforth consider the following reformulation of problem (2.26): For $f \in L_u$,

$$\text{(2.28)} \qquad \begin{cases}\text{find } z \in W \text{ such that, } \forall y \in W,\\ a(z,y) = (f, y^u)_{L_u}.\end{cases}$$

PROPOSITION 2.6 (well-posedness). *Assume that there is an $M \in \mathcal{L}(W;W')$ satisfying* (2.15). *Then, problem* (2.28) *is well-posed, and the solutions to* (2.26) *and* (2.28) *coincide.*

Proof. The unique solution to (2.26) solves (2.28). Moreover, coercivity (see Lemma 2.5) immediately implies that the solution to (2.28) is unique. ∎

3. The discrete problem. The goal of this section is to construct a DG approximation of the model problem (2.28). After introducing the DG setting in section 3.1, we explain in detail in section 3.2 how the DG bilinear form a_h (see (3.17)) is constructed.

3.1. The discrete setting. Let $\{\mathcal{T}_h\}_{h>0}$ be a family of affine meshes of Ω compatible with the partition P_Ω, which, for simplicity, is supposed to be composed of polyhedra. The elements are not necessarily simplices, and the interfaces are not required to match. We denote by $\mathcal{F}_h^i$ the set of element interfaces, i.e., $F \in \mathcal{F}_h^i$ if F is a $(d-1)$-manifold and there are $T_1, T_2 \in \mathcal{T}_h$ such that $F = \partial T_1 \cap \partial T_2$. The set of the faces that separate the mesh from the exterior of Ω is denoted by $\mathcal{F}_h^\partial$; i.e., $F \in \mathcal{F}_h^\partial$ if F is a $(d-1)$-manifold and there is a $T \in \mathcal{T}_h$ such that $F = \partial T \cap \partial\Omega$. The set of all the faces is denoted by $\mathcal{F}_h$; i.e., $\mathcal{F}_h \stackrel{\text{def}}{=} \mathcal{F}_h^i \cup \mathcal{F}_h^\partial$. Moreover, for every face $F \in \mathcal{F}_h$ we introduce the set $\mathcal{T}_h(F) \stackrel{\text{def}}{=} \{T \in \mathcal{T}_h;\ F \subset \partial T\}$. The diameters of $T \in \mathcal{T}_h$ and $F \in \mathcal{F}_h$ are denoted by h_T and h_F, respectively. Without loss of generality, we assume that $h \le 1$.

For every nonnegative integer p, we define

$$P_{h,p} \stackrel{\text{def}}{=} \{v_h \in L^2(\Omega);\ \forall T \in \mathcal{T}_h,\ v_h|_T \in \mathbb{P}_p(T)\}, \tag{3.1}$$

where $\mathbb{P}_p(T)$ denotes the set of d-variate polynomials of total degree at most p on T. The mesh family $\{\mathcal{T}_h\}_{h>0}$ is assumed regular in the sense that

$$h_T \lesssim h_F, \quad F \subset \partial T, \tag{3.2}$$

$$\|\nabla v_h\|_{[L^2(T)]^d} \lesssim h_T^{-1} \|v_h\|_{L^2(T)} \quad \forall T \in \mathcal{T}_h,\ \forall v_h \in P_{h,p}, \tag{3.3}$$

$$\|v_h\|_{L^2(F)} \lesssim h_F^{-1/2} \|v_h\|_{L^2(\mathcal{T}_h(F))} \quad \forall F \in \mathcal{F}_h,\ \forall v_h \in P_{h,p}. \tag{3.4}$$

Let p_u and p_σ be two nonnegative integers such that $p_u - 1 \le p_\sigma \le p_u$, and define the following spaces:

$$\Sigma_h = [P_{h,p_\sigma}]^d, \qquad U_h = P_{h,p_u}, \qquad W_h = \Sigma_h \times U_h.$$

Observe that the inverse and trace inequalities (3.3) and (3.4) are local and that they can be applied componentwise to the functions in Σ_h. Let $H^s(\mathcal{T}_h) \stackrel{\text{def}}{=} \{v \in L^2(\Omega);\ v \in H^s(T)\ \forall T \in \mathcal{T}_h\}$ be equipped with the usual broken Sobolev norm denoted by $\|\cdot\|_{H^s(\mathcal{T}_h)}$, and define

$$W(h) \stackrel{\text{def}}{=} W \cap [H^1(\mathcal{T}_h)]^{d+1} + W_h.$$

According to the assumptions listed in section 2.1 and since $\{\mathcal{T}_h\}_{h>0}$ is compatible with the partition P_Ω, we have that

$$\nu \in [P_{h,0}]^{d,d} \quad \text{and} \quad \kappa \in [P_{h,0}]^{d,d}. \tag{3.5}$$

Remark 3.1. (i) The hypotheses on ν could be slightly weakened by assuming that ν is Lipschitz in each subdomain, but to avoid unnecessary technicalities we restrict ourselves to piecewise constant diffusivity. (ii) The mesh being compatible with the partition P_Ω means that the meshes fit the discontinuities of the diffusivity.

3.2. Design of the DG bilinear form. We now construct a discrete DG counterpart of the bilinear form a defined in (2.27) under the following constraints: (i) The discrete bilinear form should satisfy a discrete version of Lemma 2.5 (L-coercivity) and be strongly consistent. (ii) It should not require that the elliptic-hyperbolic interface I be identified a priori. (Since computers work in finite precision arithmetic, it may happen in practice that $n^t\nu n$ takes small values instead of being exactly zero, so that I is possibly difficult to identify.) (iii) It should include stabilizing terms suitable to weakly enforcing boundary and interface conditions.

3.2.1. Step 0: Discrete analogue of a. We start by localizing the volume and boundary/interface integrals in (2.27) and by deriving a discrete counterpart of the operator M defined by (2.16).

The localization of a_0 and D does not pose any problem and is done by splitting the volume and boundary/interface integrals over the mesh elements and faces. Now let us now focus our attention on the discretization of M.

We first construct a discrete counterpart of the boundary integral over $\partial\Omega$ in (2.16). To this end, we take inspiration from [11, 12] and we proceed as follows. For every $F \in \mathcal{F}_h^\partial$ we define the operator $M_F \in \mathcal{L}([L^2(F)]^{d+1}; [L^2(F)]^{d+1})$ such that, for all $(z, y) \in W(h) \times W(h)$,

$$(M_F(z), y)_{L,F} \stackrel{\text{def}}{=} -\alpha(z^u, \kappa y^\sigma \cdot n)_{L_u,F} + \alpha(\kappa z^\sigma \cdot n, y^u)_{L_u,F} + (M_F^{uu}(z^u), y^u)_{L_u,F},$$

where the boundary operator $M_F^{uu} \in \mathcal{L}(L^2(F); L^2(F))$ is defined by

$$M_F^{uu}(y^u) \stackrel{\text{def}}{=} \left(|\beta\cdot n| + \tfrac{1}{2}(\alpha+1)\lambda^2 h_F^{-1}\right) y^u, \tag{3.6}$$

and we have set $\lambda \stackrel{\text{def}}{=} \sqrt{n^t\nu n}$. Observe that M_F satisfies the following consistency conditions:

$$\mathrm{Ker}(\mathcal{M} - \mathcal{D}) \subset \mathrm{Ker}(M_F - \mathcal{D}), \qquad \mathrm{Ker}(\mathcal{M} + \mathcal{D}) \subset \mathrm{Ker}(M_F + \mathcal{D}). \tag{3.7}$$

Since M_F^{uu} is nonnegative, we define

$$|y^u|_{M,F}^2 \stackrel{\text{def}}{=} (M_F^{uu}(y^u), y^u)_{L_u,F}, \qquad |y^u|_M^2 \stackrel{\text{def}}{=} \textstyle\sum_{F\in\mathcal{F}_h^\partial} |y^u|_{M,F}^2.$$

The $|\cdot|_M$-seminorm will be used to measure the error due to the weak enforcement of boundary conditions.

Second, we construct a discrete counterpart of the boundary integral over the interface I in (2.16). To this end we extend the definition of λ to interior faces. For every $F \in \mathcal{F}_h^i$, the two-valued field $\lambda|_F = \{\lambda_1, \lambda_2\}$ is defined by

$$\lambda_i \stackrel{\text{def}}{=} \sqrt{n_i^t \nu n_i}, \quad i \in \{1, 2\}. \tag{3.8}$$

Recall that the indexing is defined such that $\lambda_1 \geq \lambda_2$. A discrete counterpart of the manifold I is defined by

$$\mathcal{I}_h \stackrel{\text{def}}{=} \{F \in \mathcal{F}_h^i;\ \lambda_1 > 0 \text{ and } \lambda_2 = 0\}.$$

To avoid unnecessary extra technicalities we suppose for the time being that the sign of $\beta\cdot n$ is constant on every interface F in $\mathcal{F}_h^i$. Then we identify two subsets of $\mathcal{I}_h$, say $\mathcal{I}_h^\pm$, representing the discrete versions of $I^\pm$. The boundary integral over the interface

I in (2.16) is then discretized by splitting it over $\mathcal{I}_h$. The sets $\mathcal{I}_h, \mathcal{I}_h^{\pm}$ and the above assumption on the sign of $\beta{\cdot}n$ are introduced solely to explicate the design of the DG bilinear form. These sets are not required in the final definition (3.17).

Combining all the steps above, we obtain the discrete bilinear form $a_h^{(0)}$ such that, for all $(z,y) \in W(h) \times W(h)$,

$$\begin{aligned} a_h^{(0)}(z,y) \stackrel{\text{def}}{=} & \sum_{T\in\mathcal{T}_h} [(Kz,y)_{L,T} + (Az,y)_{L,T}] + \tfrac{1}{2} \sum_{F\in\mathcal{F}_h^\partial} ((M_F - \mathcal{D})z, y)_{L,F} \\ & + \sum_{F\in\mathcal{I}_h^+} ((\beta{\cdot}n_1)[\![z^u]\!], [\![y^u]\!])_{L_u,F}. \end{aligned} \tag{3.9}$$

3.2.2. Step 1: *L*-coercivity and consistency. The bilinear form $a_h^{(0)}$ is not appropriate since it does not satisfy the design criteria (i) (L-coercivity) and (ii) (the interface $\mathcal{I}_h^+$ is explicitly identified), as stated in the introduction of section 3.2.

To remedy the above two problems, we introduce weighted averages. Let $\Gamma_h \stackrel{\text{def}}{=} \bigcup_{F\in\mathcal{F}_h^i} F$, and let ω be a two-valued weight function such that $[L^2(\Gamma_h)]^2 \ni \omega = (\omega_1, \omega_2)$ with $\omega_1 + \omega_2 = 1$ for a.e. $x \in \Gamma_h$. For all $y \in W(h)$ and every $F \in \mathcal{F}_h^i$, we define the weighted average and weighted jump of y^u across F as follows:

$$\{y^u\}_\omega \stackrel{\text{def}}{=} \omega_1 y_1^u + \omega_2 y_2^u, \qquad [\![y^u]\!]_\omega \stackrel{\text{def}}{=} 2(\omega_2 y_1^u - \omega_1 y_2^u), \tag{3.10}$$

where, for a.e. $x \in F$, $y_i^u(x) = \lim_{y\to x} y^u(y)|_{T_i}$, $i \in \{1,2\}$. We adopt similar definitions for $\{\Phi(y){\cdot}n\}_\omega$ and $[\![\Phi(y){\cdot}n]\!]_\omega$. To alleviate notation we set $\{\cdot\} \stackrel{\text{def}}{=} \{\cdot\}_{(\frac12,\frac12)}$ and $[\![\cdot]\!] \stackrel{\text{def}}{=} [\![\cdot]\!]_{(\frac12,\frac12)}$. The following algebraic formula will be used repeatedly in the rest of the paper:

$$\{ab\} = \{a\}\{b\}_\omega + \tfrac14 [\![a]\!]_\omega [\![b]\!]. \tag{3.11}$$

LEMMA 3.1. *The following integration by parts formula holds:*

$$\sum_{T\in\mathcal{T}_h} [(Az,y)_{L,T} - (z,\tilde{A}y)_{L,T}] = \sum_{F\in\mathcal{F}_h^\partial} (\mathcal{D}z,y)_{L,F} + \sum_{F\in\mathcal{F}_h^i} 2\left[\chi_{F,\omega}(z,y) + \chi_{F,\omega}(y,z)\right], \tag{3.12}$$

where

$$\chi_{F,\omega}(z,y) \stackrel{\text{def}}{=} (\{\Phi(z){\cdot}n\}, \{y^u\}_\omega)_{L_u,F} + \left([\![z^u]\!], \frac14 [\![\Phi(y){\cdot}n]\!]_\omega - \frac{\beta{\cdot}n_1}{2}\{y^u\}\right)_{L_u,F}. \tag{3.13}$$

Proof. Indeed, let *LHS* be the left-hand side of (3.12), and observe that

$$LHS = \sum_{F\in\mathcal{F}_h^\partial} (\mathcal{D}z,y)_{L,F} + 2\sum_{F\in\mathcal{F}_h^i} \int_F \left[\{\Phi(z){\cdot}n y^u\} + \{\Phi(y){\cdot}n z^u\} - \{(\beta{\cdot}n) z^u y^u\}\right].$$

Apply (3.11) to the averages involving $\Phi(z)$ and $\Phi(y)$, and observe that $\{(\beta{\cdot}n)z^u y^u\} = \frac{\beta{\cdot}n_1}{2}[\![z^u]\!]\{y^u\} + \frac{\beta{\cdot}n_1}{2}[\![y^u]\!]\{z^u\}$. ∎

Applying (3.12) in (3.9), we infer that

$$\begin{aligned} a_h^{(0)}(y,y) = & \sum_{T\in\mathcal{T}_h} (K + \tfrac12(A+\tilde{A})y, y)_{L,T} + \tfrac12 \sum_{F\in\mathcal{F}_h^\partial} (M_F(y), y)_{L,F} \\ & + \sum_{F\in\mathcal{I}_h^+} (|\beta{\cdot}n|[\![y^u]\!], [\![y^u]\!])_{L_u,F} + 2\sum_{F\in\mathcal{F}_h^i} \chi_{F,\omega}(y,y). \end{aligned}$$

This expression suggests that the following bilinear form can be considered in order to restore L-coercivity:

$$\hat{a}_h^{(1)}(z,y) \stackrel{\text{def}}{=} a_h^{(0)}(z,y) - 2\sum_{F\in\mathcal{F}_h^i} \chi_{F,\omega}(z,y). \tag{3.14}$$

Let us now examine the consistency of the new bilinear form $\hat{a}_h^{(1)}$. Let $z \in V \cap W(h)$ and let $y_h \in W_h$. Since $a_h^{(0)}$ is consistent, we just have to verify the consistency of the sum involving $\chi_{F,\omega}(z,y)$. For all $F \in \mathcal{F}_h^i \setminus \mathcal{I}_h$, it is clear that $\chi_{F,\omega}(z,y_h) = 0$ owing to (INT1)–(INT2). Let us now consider a face F in $\mathcal{I}_h$. From this point on, we design ω so that

$$\forall F \in \mathcal{I}_h,\ \forall x \in F, \quad \omega(x) = (1,0). \tag{3.15}$$

This implies that $\{y_h^u\}_\omega = y_h^u|_{T_1}$ and, since $z \in V$ and $F \in \mathcal{I}_h$,

$$\frac{1}{4}[\![\Phi(y_h)\cdot n]\!]_\omega - \frac{\beta\cdot n_1}{2}\{y_h^u\} = \frac{\beta\cdot n_1}{2} y_h^u|_{T_2(F)} - \frac{\beta\cdot n_1}{2}\{y_h^u\} = -\frac{\beta\cdot n_1}{4}[\![y_h^u]\!].$$

Thus, the following simplification occurs:

$$\begin{aligned} -2\chi_{F,\omega}(z,y_h) &= -2(\{\Phi(z)\cdot n\}, y_h^u|_{T_1(F)})_{L_u,F} + \left(\frac{\beta\cdot n_1}{2}[\![z^u]\!], [\![y_h^u]\!]\right)_{L_u,F} \\ &= \left(\frac{\beta\cdot n_1}{2}[\![z^u]\!], [\![y_h^u]\!]\right)_{L_u,F}. \end{aligned}$$

In this form it is now clear that $\chi_{F,\omega}(z,y_h) \neq 0$ over $\mathcal{I}_h$ (actually over $\mathcal{I}_h^-$ only); i.e., $\hat{a}_h^{(1)}$ is not consistent. To make the bilinear form consistent, we remove the trouble-making term by defining the new bilinear form

$$\begin{aligned} a_h^{(1)}(z,y) &\stackrel{\text{def}}{=} \hat{a}_h^{(1)}(z,y) - \sum_{F\in\mathcal{I}_h}\left(\frac{\beta\cdot n_1}{2}[\![z^u]\!], [\![y^u]\!]\right)_{L_u,F} \\ &= \sum_{T\in\mathcal{T}_h}[(Kz,y)_{L,T} + (Az,y)_{L,T}] + \frac{1}{2}\sum_{F\in\mathcal{F}_h^\partial}((M_F - \mathcal{D})z,y)_{L,F} \\ &\quad - 2\sum_{F\in\mathcal{F}_h^i}\chi_{F,\omega}(z,y) + \sum_{F\in\mathcal{I}_h}\left(\frac{|\beta\cdot n|}{2}[\![z^u]\!], [\![y^u]\!]\right)_{L_u,F}. \end{aligned} \tag{3.16}$$

Then, the above arguments imply that $a_h^{(1)}$ is strongly consistent and satisfies the following coercivity property: For all $y \in W(h)$,

$$a_h^{(1)}(y,y) \geq \|y^\sigma\|_{L_\sigma}^2 + \mu_0\|y^u\|_{L_u}^2 + \tfrac{1}{2}|y^u|_M^2 + \tfrac{1}{2}\|[\![y^u]\!]\|_{L^2(|\beta\cdot n|;\mathcal{I}_h)}^2.$$

3.2.3. Step 2: Elimination of $\mathcal{I}_h$ and stability. Note that $a_h^{(1)}$ is not yet satisfactory since it still requires $\mathcal{I}_h$ be explicitly identified by the user, thus violating our design constraint (ii).

The key idea to eliminate any reference to $\mathcal{I}_h$ in (3.16) is to observe that the bilinear form $(|\beta\cdot n|[\![z^u]\!], [\![y^u]\!])_{L_u,F}$ is positive and consistent on every face which is not in $\mathcal{I}_h$. In other words, L-coercivity and consistency are preserved by extending the sum over $\mathcal{I}_h$ to $\mathcal{F}_h^i$. We thus replace $a_h^{(1)}$ by

(3.17)
$$
\begin{aligned}
a_h(z,y) \stackrel{\text{def}}{=} & \sum_{T\in\mathcal{T}_h} \left[(Kz,y)_{L,T} + (Az,y)_{L,T}\right] + \frac{1}{2}\sum_{F\in\mathcal{F}_h^\partial} (M_F(z)-\mathcal{D}z,y)_{L,F} \\
& - 2\sum_{F\in\mathcal{F}_h^i} \left[\left(\{\Phi(z)\cdot n\}, \{y^u\}_\omega\right)_{L_u,F} + \left([\![z^u]\!], \frac{1}{4}[\![\Phi(y)\cdot n]\!]_\omega - \frac{\beta\cdot n_1}{2}\{y^u\}\right)_{L_u,F}\right] \\
& + \sum_{F\in\mathcal{F}_h^i} (S_F([\![z^u]\!]), [\![y^u]\!])_{L,F},
\end{aligned}
$$

where the interface operator $S_F \in \mathcal{L}(L^2(F);L^2(F))$ is defined for all $F\in\mathcal{F}_h^i$ by

$$
S_F(v) \stackrel{\text{def}}{=} \left(\frac{|\beta\cdot n|}{2} + \frac{\lambda_2^2}{h_F}\right) v. \tag{3.18}
$$

Observe that λ_2 is by definition the minimum of λ_1 and λ_2. Hence, automatically

$$
S_F(v) = \frac{|\beta\cdot n|}{2} v \qquad \forall F\in\mathcal{I}_h. \tag{3.19}
$$

Finally, to avoid any reference to $\mathcal{I}_h$ in the definition of the weighting function ω while satisfying condition (3.15), we define ω as follows:

$$
\omega \stackrel{\text{def}}{=} \begin{cases} (\frac{\lambda_1}{2\{\lambda\}}, \frac{\lambda_2}{2\{\lambda\}}) & \text{if } \lambda_1 > 0, \\ (\frac{1}{2},\frac{1}{2}) & \text{otherwise.} \end{cases} \tag{3.20}
$$

Although other expressions for ω are possible, this one is simple and yields robust error estimates. A similar choice is made in [6, 15].

The discrete problem is now formulated as follows:

$$
\begin{cases} \text{Seek } z_h\in W_h \text{ such that} \\ a_h(z_h,y_h) = (f,y_h^u)_{L_u} \quad \forall y_h\in W_h. \end{cases} \tag{3.21}
$$

Observe that the σ-component of the unknown can be eliminated locally since the jumps of this quantity across element interfaces are not penalized; see, e.g., [11, section 4.4].

Remark 3.2. The use of weights in DG methods has been highlighted in several articles (see, e.g., [16, 20, 19, 21]). Although some of the above references point out that using weights may yield higher accuracy, they do not connect the weights with the coefficients of the problem. The weight/diffusivity dependence has recently been investigated in [6, 15], where the authors show that the use of a particular weighted average improves the stability of the numerical scheme in problems with high diffusivity contrasts, the diffusivity being still positive definite. In the present case, resorting to weighted average and jump operators is required for the method to select the proper interface conditions automatically, i.e., the design constraint (ii).

4. Convergence analysis. In this section we carry out the convergence analysis of the discrete problem (3.21). The main results are Theorems 4.5 and 4.7.

4.1. Basic convergence estimates. For all $y\in W(h)$ we introduce the following seminorm:

$$
|y^u|_{J,F}^2 \stackrel{\text{def}}{=} (S_F([\![y^u]\!]), [\![y^u]\!])_{L_u,F}, \qquad |y^u|_J^2 \stackrel{\text{def}}{=} \sum_{F\in\mathcal{F}_h^i} |y^u|_{J,F}^2. \tag{4.1}
$$

The space $W(h)$ is equipped with the following discrete norm:

$$\|y\|_{h,\kappa}^2 \stackrel{\text{def}}{=} \|y\|_L^2 + |y^u|_J^2 + |y^u|_M^2 + \sum_{T\in\mathcal{T}_h} \|\kappa\nabla y^u\|_{L_\sigma,T}^2. \tag{4.2}$$

The following two lemmata follow from the design procedure outlined in section 3.2.

LEMMA 4.1 (consistency). *Let z solve* (2.6) *and z_h solve* (3.21). *Assume, moreover, that $z \in [H^1(\mathcal{T}_h)]^{d+1}$. Then,*

$$\forall y_h \in W_h, \quad a_h(z - z_h, y_h) = 0.$$

LEMMA 4.2 (L-coercivity). *For all h and for all y in $W(h)$,*

$$a_h(y,y) \gtrsim \|y\|_L^2 + |y^u|_J^2 + |y^u|_M^2.$$

In order to estimate the L^2-norm of the diffusive derivative $\kappa\nabla z^u$ we need the following result.

LEMMA 4.3 (stability). *The following bound holds:*

$$\forall z_h \in W_h, \quad \|z_h\|_{h,\kappa} \lesssim \sup_{y_h\in W_h\setminus\{0\}} \frac{a_h(z_h,y_h)}{\|y_h\|_{h,\kappa}}.$$

Proof. Let $z_h \in W_h$ and set $\mathbb{S} \stackrel{\text{def}}{=} \sup_{y_h\in W_h\setminus\{0\}} \frac{a_h(z_h,y_h)}{\|y_h\|_{h,\kappa}}$.

(1) Owing to Lemma 4.2,

$$\|z_h\|_L^2 + |z_h^u|_J^2 + |z_h^u|_M^2 \lesssim a_h(z_h,z_h) \lesssim \mathbb{S}\|z_h\|_{h,\kappa}. \tag{4.3}$$

(2) Control of $\mathtt{B} \stackrel{\text{def}}{=} \sum_{T\in\mathcal{T}_h} \|\kappa\nabla z_h^u\|_{L_\sigma,T}^2$. Let $\pi_h^\sigma \in \Sigma_h$ be the field such that, for all $T \in \mathcal{T}_h$, $\pi_h^\sigma|_T \stackrel{\text{def}}{=} \kappa\nabla z_h^u|_T$. From the definition of a_h it follows that

$$\begin{aligned}\mathtt{B} = a_h(z_h,(\pi_h^\sigma,0)) - (z_h^\sigma,\pi_h^\sigma)_{L_\sigma} + \sum_{F\in\mathcal{F}_h^\partial} \frac{1+\alpha}{2}(\kappa n z_h^u, \pi_h^\sigma)_{L_\sigma,F} \\ + \frac{1}{2}\sum_{F\in\mathcal{F}_h^i} (\llbracket z_h^u\rrbracket, \llbracket n^t\kappa\pi_h^\sigma\rrbracket_\omega)_{L_u,F}.\end{aligned}$$

Let R_i, $i \in \{1,2,3\}$ denote the last three terms in the right-hand side. The first term is bounded from above as follows:

$$|R_1| \le \|z_h^\sigma\|_{L_\sigma}\|\pi_h^\sigma\|_{L_\sigma} \lesssim \|z_h^\sigma\|_{L_\sigma}^2 + \gamma\mathtt{B},$$

where γ can be chosen as small as needed.

The second term vanishes if $\alpha = -1$. If $\alpha = +1$, use trace inequality (3.4) together with (3.6) to get

$$|R_2| \lesssim \sum_{F\in\mathcal{F}_h^\partial} h_F^{-\frac12} |(n^t\nu n z_h^u, z_h^u)_{L_u,F}|^{\frac12} \|\pi_h^\sigma\|_{L_\sigma,\mathcal{T}_h(F)} \lesssim \sum_{F\in\mathcal{F}_h^\partial} |z_h^u|_{M,F}\|\pi_h^\sigma\|_{L_\sigma,\mathcal{T}_h(F)}.$$

Consequently, $|R_2| \lesssim |z_h^u|_M^2 + \gamma\mathtt{B}$. According to (3.20), for all $\mathcal{F}_h^i \ni F = \partial T_1 \cap \partial T_2$,

$$\|\llbracket n^t\kappa\pi_h^\sigma\rrbracket_\omega\|_{L_u,F} = \frac{\lambda_1\lambda_2}{\{\lambda\}}\|\llbracket (n^t\kappa/\lambda)\pi_h^\sigma\rrbracket\|_{L_u,F} \lesssim h_F^{-\frac12}\frac{\lambda_1\lambda_2}{\{\lambda\}}\|\pi_h^\sigma\|_{L_\sigma,\mathcal{T}_h(F)}.$$

Using the above relation together with (3.18) yields

$$|R_3| \lesssim \sum_{F\in\mathcal{F}_h^i} \frac{\lambda_1}{\{\lambda\}} \left(\frac{\lambda_2^2}{h_F}\|[\![z_h^u]\!]\|_{L_u,F}^2\right)^{\frac12} \|\pi_h^\sigma\|_{L_\sigma,\mathcal{T}_h(F)} \lesssim |z_h^u|_J^2 + \gamma\mathsf{B}.$$

The above bounds with $\gamma = \frac16$ together with Lemma 4.2 give

$$\tfrac12 \sum_{T\in\mathcal{T}_h} \|\kappa\nabla z_h^\sigma\|_{L_\sigma,T}^2 \lesssim a_h(z_h,(\pi_h^\sigma,0)) + a_h(z_h,z_h) \lesssim \mathbb{S}\|z_h\|_{h,\kappa}, \tag{4.4}$$

where we used the fact that, by definition, $\|(\pi_h^\sigma,0)\|_{h,\kappa} = \|\pi_h^\sigma\|_{L_\sigma} \le \|z_h\|_{h,\kappa}$. Observe that, owing to the choice of the weight function ω, the above estimate is robust with respect to the possible discontinuity and anisotropy of ν.

(3) Equations (4.3)–(4.4) yield $\|z_h\|_{h,\kappa}^2 \lesssim \mathbb{S}\|z_h\|_{h,\kappa}$, i.e., the desired result. ∎

Let us now introduce

$$W_h^\perp \overset{\text{def}}{=} \{y\in W(h);\ \forall w_h\in W_h,\ (y,w_h)_L = 0\}. \tag{4.5}$$

Moreover, we define the following norm on $W(h)$:

$$[\![y]\!]^2 \overset{\text{def}}{=} \|y\|_{h,\kappa}^2 + \sum_{T\in\mathcal{T}_h}\left[\frac{\mathfrak{h}_T}{h_T^2}\|y^u\|_{L_u,T}^2 + h_T\|y^\sigma\|_{L_\sigma,\partial T}^2 + \sum_{F\subset\partial T}\frac{\mathfrak{h}_F}{h_F}\|y^u\|_{L_u,F}^2\right], \tag{4.6}$$

where, for all $T\in\mathcal{T}_h$ and for all $F\in\mathcal{F}_h$, we have defined

$$\mathfrak{h}_T \overset{\text{def}}{=} \max(\|\nu\|_{[L^\infty(T)]^{d,d}}, h_T), \quad \mathfrak{h}_F \overset{\text{def}}{=} \begin{cases}\max(\lambda_1^2,h_F) & \text{if } F\in\mathcal{F}_h^i,\\ \max(\lambda^2,h_F) & \text{if } F\in\mathcal{F}_h^\partial.\end{cases} \tag{4.7}$$

The last property needed to prove convergence is stated in the following.

LEMMA 4.4 (continuity). *The following holds:*

$$\forall (z,y_h)\in W_h^\perp\times W_h,\quad a_h(z,y_h) \lesssim [\![z]\!]\|y_h\|_{h,\kappa}.$$

Proof. Let $(z,y_h)\in W_h^\perp\times W_h$. Using the integration by parts formula (3.12), we obtain

$$\begin{aligned} a_h(z,y_h) = {}& \sum_{T\in\mathcal{T}_h}(z,(K+\tilde A)y_h)_{L,T} + 2\sum_{F\in\mathcal{F}_h^i}\chi_{F,\omega}(y_h,z)\\ &+ \tfrac12\sum_{F\in\mathcal{F}_h^\partial}(M_F(z)+\mathcal{D}z,y_h)_{L,F} + \sum_{F\in\mathcal{F}_h^i}(S_F([\![z^u]\!]),[\![y_h^u]\!])_{L_u,F}. \end{aligned} \tag{4.8}$$

We now derive bounds for the four terms in the right-hand side, say $R_1,\dots,R_4$. For the first one we have

$$\begin{aligned} &(z,(K+\tilde A)y_h)_{L,T}\\ &\quad = (z^\sigma, y_h^\sigma - \kappa\nabla y_h^u)_{L_\sigma,T} + (z^u, \mu y_h^u - \nabla\cdot(\kappa y_h^\sigma) - \overline{\beta}\cdot\nabla y_h^u - (\beta-\overline{\beta})\cdot\nabla y_h^u)_{L_u,T}, \end{aligned}$$

where, for all $T\in\mathcal{T}_h$, $\overline{\beta}|_T$ is the mean value of the field β over T. Observe that, since $\kappa\nabla y_h^u\in\Sigma_h$, $\overline{\beta}\cdot\nabla y_h^u\in U_h$, and $z\in W_h^\perp$, $(z^\sigma,\kappa\nabla y_h^u)_{L_\sigma}=0$ and $(z^u,\overline{\beta}\cdot\nabla y_h^u)_{L_u}=0$. As a result,

$$|R_1| \lesssim \|z\|_L \|y_h\|_L + \sum_{T\in\mathcal{T}_h} \left[\|z^u\|_{L_u,T} h_T^{-1} \|\kappa y_h^\sigma\|_{L_\sigma,T} + (z^u, (\beta-\overline{\beta})\cdot\nabla y_h^u)_{L_u,T}\right]$$
$$\lesssim \|z\|_L \|y_h\|_L + \sum_{T\in\mathcal{T}_h} \left[\frac{\mathfrak{h}_T^{\frac{1}{2}}}{h_T} \|z^u\|_{L_u,T} \|y_h^\sigma\|_{L_\sigma,T} + \|\beta\|_{[\mathfrak{C}^1(\Omega)]^d} \|y_h^u\|_{L_u,T} \|z^u\|_{L_u,T}\right],$$

and, therefore, $|R_1| \lesssim [\![z]\!] \|y_h\|_L$. The second term R_2 can be simplified as follows:

$$R_2 = 2 \sum_{F\in\mathcal{F}_h^i} \left[(\{z^u\}_\omega, \{n^t \kappa y_h^\sigma\})_{L_u,F} + \frac{1}{4} ([\![n^t \kappa z^\sigma]\!]_\omega, [\![y_h^u]\!])_{L_u,F} + \left(\frac{\beta\cdot n_1}{2} \{z^u\}, [\![y_h^u]\!]\right)_{L_u,F}\right].$$

Let $R_{2,i}$, $i = 1, 2, 3$, be the addends of R_2. Using the definition of the weight function ω, (3.20), together with the inverse trace inequality (3.4) and definition (4.7), we infer

$$|R_{2,1}| \lesssim \sum_{F\in\mathcal{F}_h^i} \mathfrak{h}_F^{\frac{1}{2}} h_F^{-\frac{1}{2}} \left(\|z_1^u\|_{L_u,F} + \|z_2^u\|_{L_u,F}\right) \|y_h^\sigma\|_{L_\sigma,\mathcal{T}_h(F)},$$
$$|R_{2,2}| \lesssim \sum_{F\in\mathcal{F}_h^i} \frac{\lambda_1}{\{\lambda\}} h_F^{\frac{1}{2}} \left(\|z_1^\sigma\|_{L_\sigma,F} + \|z_2^\sigma\|_{L_\sigma,F}\right) \lambda_2 h_F^{-\frac{1}{2}} \|[\![y_h^u]\!]\|_{L_u,F}$$
$$\lesssim \sum_{F\in\mathcal{F}_h^i} h_F^{\frac{1}{2}} \left(\|z_1^\sigma\|_{L_\sigma,F} + \|z_2^\sigma\|_{L_\sigma,F}\right) |y_h^u|_{J,F},$$
$$|R_{2,3}| \lesssim \left(\|z_1^u\|_{L_u,F} + \|z_2^u\|_{L_u,F}\right) |y_h^u|_{J,F} \lesssim \mathfrak{h}_F^{\frac{1}{2}} h_F^{-\frac{1}{2}} \left(\|z_1^u\|_{L_u,F} + \|z_2^u\|_{L_u,F}\right) |y_h^u|_{J,F}.$$

Therefore, $|R_2| \lesssim [\![z]\!] \|y_h\|_L$. The third term is expanded as follows:

$$|R_3| = \sum_{F\in\mathcal{F}_h^\partial} \left[\frac{1-\alpha}{2} (z^u, n^t \kappa y_h^\sigma)_{L_u,F} + \frac{1+\alpha}{2} (n^t \kappa z^\sigma, y_h^u)_{L_u,F} + \frac{1}{2} ((M_F^{uu} + \beta\cdot n) z^u, y_h^u)_{L_u,F}\right].$$

Let $R_{3,i}$, $i = 1, \ldots, 3$, be the addends of R_3. If $\alpha = -1$, then $R_{3,2} = 0$, and using (4.7) and (3.4), we infer that

$$|R_{3,1}| \lesssim \sum_{F\in\mathcal{F}_h^\partial} \lambda h_F^{-\frac{1}{2}} \|z^u\|_{L_u,F} \|y_h^\sigma\|_{L_\sigma,\mathcal{T}_h(F)} \lesssim \sum_{F\in\mathcal{F}_h^\partial} \mathfrak{h}_F^{\frac{1}{2}} h_F^{-\frac{1}{2}} \|z^u\|_{L_u,F} \|y_h^\sigma\|_{L_\sigma,\mathcal{T}_h(F)},$$

whereas, if $\alpha = +1$, then $R_{3,1} = 0$, and (3.18) implies that

$$|R_{3,2}| \lesssim \sum_{F\in\mathcal{F}_h^\partial} h_F^{\frac{1}{2}} \|z^\sigma\|_{L_\sigma,F} \lambda h_F^{-\frac{1}{2}} \|y_h^u\|_{L_u,F} \lesssim \sum_{F\in\mathcal{F}_h^\partial} h_F^{\frac{1}{2}} \|z^\sigma\|_{L_\sigma,F} |y_h^u|_{M,F}.$$

Finally, (3.18) yields $|R_{3,3}| \lesssim |z^u|_M |y_h^u|_M$. Therefore, $|R_3| \lesssim [\![z]\!] \|y_h\|_L$. For the fourth term we immediately have $|R_4| \le |z^u|_J |y_h^u|_J$. The desired result is obtained by collecting the above bounds. ∎

Let π_h be the L^2-projection onto W_h. Upon collecting the above results (consistency, stability, and continuity) and observing that $z - \pi_h z \in W_h^\perp$, the second Strang lemma immediately yields the following convergence result.

THEOREM 4.5 (convergence). *Let z solve* (2.28) *and z_h solve* (3.21). *Assume that $z \in [H^1(\mathcal{T}_h)]^{d+1}$. Then,*

$$\|z - z_h\|_{h,\kappa} \lesssim [\![z - \pi_h z]\!].$$

Owing to the regularity of the mesh family $\{\mathcal{T}_h\}_{h>0}$, the following interpolation property holds: For all $z \in [H^{r_\sigma}(\mathcal{T}_h)]^d \times H^{r_u}(\mathcal{T}_h)$,

$$\begin{aligned}|\!|\!| z - \pi_h z |\!|\!| \lesssim & \left(\sum_{T\in\mathcal{T}_h} h_T^{2s_\sigma} \|z^\sigma\|^2_{[H^{s_\sigma}(T)]^d} + \mathfrak{h}_T h_T^{2s_u-2} \|z^u\|^2_{H^{s_u}(T)} \right)^{\frac12} \\ & + \left(\sum_{F\in\mathcal{F}_h} \mathfrak{h}_F h_F^{2s_u-2} \|z^u\|^2_{H^{s_u}(\mathcal{T}_h(F))} \right)^{\frac12}, \end{aligned} \tag{4.9}$$

where $s_\sigma \overset{\text{def}}{=} \min(r_\sigma, p_\sigma+1)$ and $s_u \overset{\text{def}}{=} \min(r_u, p_u+1)$. Since $p_u - 1 \le p_\sigma$ and provided $(r_\sigma, r_u) \ge (p_\sigma+1, p_u+1)$, the above interpolation error is of order h^{p_u}, i.e.,

$$|\!|\!| z - \pi_h z |\!|\!| \lesssim h^{p_u} \|z\|_{[H^{p_\sigma+1}(\mathcal{T}_h)]^d \times H^{p_u+1}(\mathcal{T}_h)}. \tag{4.10}$$

Remark 4.1. The above estimate is optimal for the $\|\cdot\|_{h,\kappa}$-norm but yields suboptimal convergence in the L^2-norm. If $p_\sigma = p_u - 1$, the error estimate is optimal in the L^2-norm for z_h^σ but is still suboptimal for the L^2-norm of z_h^u. From a theoretical viewpoint, it is optimal to set $\Sigma_h = [P_{h,p_u-1}]^d$, i.e., to work with different approximation orders for the σ- and u-components. However, working with equal-order approximation may be more convenient for implementation purposes.

Remark 4.2 (positive definite diffusivity). If the diffusivity is such that $\nu \ge \nu_0 \mathcal{I}_d$ with $\nu_0 = \mathcal{O}(1)$, the estimate (4.10) can be improved using a duality argument. More precisely, consider the mapping $L_u \ni y^u \longmapsto \psi \in V^*$ defined by

$$(K + \tilde{A})\psi = (0, y^u),$$

and assume that the following bound holds:

$$\|\psi^u\|_{H^2(\mathcal{T}_h)} + \|\psi^\sigma\|_{[H^1(\mathcal{T}_h)]^d} \lesssim \|y^u\|_{L_u}. \tag{4.11}$$

Adapting the reasoning in [11, section 5.3], if $r_u \ge p_u + 1$ and $p_u \ge 1$, it can be proved that

$$\|z - z_h\|_{L_u} \lesssim h^{p_u+1} \|z\|_{[H^{p_\sigma+1}(\mathcal{T}_h)]^d \times H^{p_u+1}(\mathcal{T}_h)}.$$

4.2. Improved convergence estimates. Owing to the definition of the $\|\cdot\|_{h,\kappa}$-norm, the convergence result of Theorem 4.5 does not contain an estimate involving the advective derivative. Such an estimate can be obtained, assuming that

$$\kappa \text{ is scalar-valued}, \tag{4.12}$$

and we still admit that κ may vanish over a portion of the domain. Define the following new discrete norm on $W(h)$:

$$\|y\|^2_{h,\kappa,\beta} \overset{\text{def}}{=} \|y\|^2_{h,\kappa} + \|y^u\|^2_{h,\beta} \quad \text{with} \quad \|y^u\|^2_{h,\beta} \overset{\text{def}}{=} \sum_{T\in\mathcal{T}_h} h_T \|\beta\cdot\nabla y^u\|^2_{L_u,T}. \tag{4.13}$$

LEMMA 4.6. *Assume that κ satisfies* (4.12). *Then the following bound holds:*

$$\forall z_h \in W_h, \quad \|z_h\|_{h,\kappa,\beta} \lesssim \sup_{y_h \in W_h\setminus\{0\}} \frac{a_h(z_h, y_h)}{\|y_h\|_{h,\kappa,\beta}}.$$

Proof. Let $z_h \in W_h$ and set $\mathbb{S} \overset{\text{def}}{=} \sup_{y_h \in W_h \setminus \{0\}} \frac{a_h(z_h, y_h)}{\|y_h\|_{h,\kappa,\beta}}$.

(1) Proceeding as in Lemma 4.3 and observing that $\|(\pi_h^\sigma, 0)\|_{h,\kappa,\beta} = \|(\pi_h^\sigma, 0)\|_{h,\kappa}$, we conclude that

$$\|z_h\|_{h,\kappa}^2 \lesssim \mathbb{S}\|z_h\|_{h,\kappa,\beta}. \tag{4.14}$$

(2) We define the field $W_h \ni \pi_h \overset{\text{def}}{=} (0, \pi_h^u)$ in such a way that, for all $T \in \mathcal{T}_h$, $\pi_h^u|_T = h_T \overline{\beta}\cdot\nabla z_h^u$, where $\overline{\beta}$ is the mean of β over T. Using (3.3) together with the regularity of β and the fact that $h_T \le 1$, for all $T \in \mathcal{T}_h$, we have

$$\begin{aligned} h_T^{-\frac{1}{2}}\|\pi_h^u\|_{L_u,T} &\le h_T^{\frac{1}{2}}\|(\overline{\beta} - \beta)\cdot\nabla z_h^u\|_{L_u,T} + h_T^{\frac{1}{2}}\|\beta\cdot\nabla z_h^u\|_{L_u,T} \\ &\le h_T^{\frac{1}{2}}\|\beta\|_{[\mathfrak{C}^1(\Omega)]^d}\|z_h^u\|_{L_u,T} + h_T^{\frac{1}{2}}\|\beta\cdot\nabla z_h^u\|_{L_u,T}. \end{aligned} \tag{4.15}$$

(i) We first show that $\|\pi_h\|_{h,\kappa,\beta} \lesssim \|z_h\|_{h,\kappa,\beta}$. According to the above bound, it is clear that $\|\pi_h^u\|_{L_u} \lesssim \|z_h\|_{h,\kappa,\beta}$. Commuting the operators $\kappa\nabla$ and $\overline{\beta}\cdot\nabla$ and applying the inverse inequality (3.3), we infer that

$$\sum_{T\in\mathcal{T}_h}\|\kappa\nabla\pi_h^u\|_{L_u,T}^2 = \sum_{T\in\mathcal{T}_h} h_T^2\|\overline{\beta}\cdot\nabla(\kappa\nabla z_h^u)\|_{L_u,T}^2 \lesssim \sum_{T\in\mathcal{T}_h}\|\kappa\nabla z_h^u\|_{L_\sigma,T}^2.$$

Moreover, the regularity of β and again (3.3) yield

$$\begin{aligned} \|\pi_h^u\|_{h,\beta}^2 &\lesssim \sum_{T\in\mathcal{T}_h} h_T^3\left[\|\partial_{\overline{\beta}}(\beta\cdot\nabla z_h^u)\|_{L_u,T} + \|\partial_{\overline{\beta}}\beta\|_{[L^\infty(T)]^d}h_T^{-1}\|z_h^u\|_{L_u,T}\right]^2 \\ &\lesssim \sum_{T\in\mathcal{T}_h} h_T\left[\|\beta\cdot\nabla z_h^u\|_{L_u,T} + \|z_h^u\|_{L_u,T}\right]^2. \end{aligned}$$

The term $|\pi_h^u|_J$ is treated as follows:

$$|\pi_h^u|_J^2 \lesssim \sum_{F\in\mathcal{F}_h^i}\||\beta\cdot n|^{\frac{1}{2}}[\![\pi_h^u]\!]\|_{L_u,F}^2 + \sum_{F\in\mathcal{F}_h^i}\|\lambda_2 h_F^{-\frac{1}{2}}[\![\pi_h^u]\!]\|_{L_u,F}^2 \overset{\text{def}}{=} R_1 + R_2.$$

Using (3.4) together with (4.15), we immediately conclude that

$$|R_1| \lesssim \sum_{F\in\mathcal{F}_h^i} h_F^{-1}\|\pi_h^u\|_{L_u,\mathcal{T}_h(F)}^2 \lesssim \|z_h\|_{h,\kappa,\beta}^2.$$

The second term is zero if $\lambda_2 = 0$. On the other hand, by definition, if $\lambda_2 > 0$, then $\lambda_1 > 0$; i.e., κ is nonzero on both sides of the considered element interface. We proceed using the trace inequality (3.4) together with assumption (4.12) (i.e., $\kappa_1 = \lambda_1 I$, $\kappa_2 = \lambda_2 I$, and $\lambda_1 \ge \lambda_2$), to get

$$|R_2| \lesssim \sum_{F\in\mathcal{F}_h^i}\frac{\lambda_2^2}{h_F}h_F\|\overline{\beta}\cdot\nabla z_h^u\|_{L_u,\mathcal{T}_h(F)}^2 \lesssim \sum_{F\in\mathcal{F}_h^i}\lambda_2^2\|\nabla z_h^u\|_{L_\sigma,\mathcal{T}_h(F)}^2 \le \sum_{F\in\mathcal{F}_h^i}\|\kappa\nabla z_h^u\|_{L_\sigma,\mathcal{T}_h(F)}^2,$$

whence $|\pi_h^u|_J \lesssim \|z_h\|_{h,\kappa,\beta}$. In a similar way we can prove that $|\pi_h^u|_M \lesssim \|z_h\|_{h,\kappa,\beta}$.

(ii) Estimate for $\|z_h^u\|_{h,\beta}$. Integrating by parts only the diffusive terms and setting $\tilde{\mu} \stackrel{\text{def}}{=} \mu + \nabla\cdot\beta$, we obtain

$$\begin{aligned}\|z_h^u\|_{h,\beta}^2 = a_h(z_h,\pi_h)&\\ &+ \sum_{T\in\mathcal{T}_h}\left[h_T(\beta\cdot\nabla z_h^u, (\beta-\overline{\beta})\cdot\nabla z_h^u)_{L_u,T} + (z_h^\sigma, \kappa\nabla\pi_h^u)_{L_\sigma,T} - (\tilde{\mu} z_h^u, \pi_h^u)_{L_u,T}\right]\\ &+ 2\sum_{F\in\mathcal{F}_h^i}\left[-\frac{1}{4}([\![n^t\kappa z_h^\sigma]\!]_\omega, [\![\pi_h^u]\!])_{L_u,F} + \left(\frac{\beta\cdot n_1}{2}[\![z_h^u]\!], \{\pi_h^u\}\right)_{L_u,F}\right]\\ &- \frac{1}{2}\sum_{F\in\mathcal{F}_h^\partial}\left[(1+\alpha)(n^t\kappa z_h^\sigma, \pi_h^u)_{L_u,F} + ((M_F^{uu}-\beta\cdot n)z_h^u, \pi_h^u)_{L_u,F}\right]\\ &- \sum_{F\in\mathcal{F}_h^i}(S_F([\![z_h^u]\!]), [\![\pi_h^u]\!])_{L_u,F}.\end{aligned}$$

Let R_i, $i=1,\dots,9$, be the nine terms in the right-hand side, and observe that

$$|R_1| \lesssim \mathbb{S}\|\pi_h\|_{h,\kappa,\beta} \lesssim \mathbb{S}\|z_h\|_{h,\kappa,\beta}.$$

Furthermore,

$$|R_2| \lesssim \sum_{T\in\mathcal{T}_h} h_T\|\beta\cdot\nabla z_h^u\|_{L_u,T}\|\overline{\beta}-\beta\|_{[L^\infty(T)]^d} h_T^{-1}\|z_h^u\|_{L_u,T} \lesssim \gamma\|z_h^u\|_{h,\beta}^2 + \|z_h\|_{h,\kappa}^2.$$

Moreover,

$$|R_3| + |R_4| + |R_5| + |R_7| + |R_9| \lesssim \|z_h\|_{h,\kappa}\|\pi_h\|_{h,\kappa,\beta} \lesssim \mathbb{S}^{\frac{1}{2}}\|z_h\|_{h,\kappa,\beta}^{\frac{3}{2}},$$
$$|R_6| \lesssim \|z_h\|_{h,\kappa}\|z_h\|_{h,\kappa,\beta} \lesssim \mathbb{S}^{\frac{1}{2}}\|z_h\|_{h,\kappa,\beta}^{\frac{3}{2}},$$

and $|R_8| \lesssim \|z_h\|_{h,\kappa}(\|\pi_h\|_{h,\kappa,\beta} + \|z_h\|_{h,\kappa,\beta}) \lesssim \mathbb{S}^{\frac{1}{2}}\|z_h\|_{h,\kappa,\beta}^{\frac{3}{2}}$. Hence,

$$\|z_h^u\|_{h,\beta}^2 \lesssim \mathbb{S}\|z_h\|_{h,\kappa,\beta} + \mathbb{S}^{\frac{1}{2}}\|z_h\|_{h,\kappa,\beta}^{\frac{3}{2}},$$

whence it follows, using (4.14), that $\|z_h^u\|_{h,\beta}^2 \lesssim \mathbb{S}^2$. ∎

By using Lemma 4.6 and proceeding as usual, we infer the next result.

THEOREM 4.7 (convergence). *Let z solve (2.28) and z_h solve (3.21). Assume that $z \in [H^1(\mathcal{T}_h)]^{d+1}$ and that κ satisfies (4.12). Then,*

$$\|z - z_h\|_{h,\kappa,\beta} \lesssim [\![z - \pi_h z]\!].$$

Remark 4.3 (purely hyperbolic case). A special situation is obtained when the diffusivity is identically zero over the entire domain, since, for all $T\in\mathcal{T}_h$ and for all $F\in\mathcal{F}_h$, $\mathfrak{h}_T = h_T$ and $\mathfrak{h}_F = h_F$. In such a case it is readily seen that

$$\|z^u - z_h^u\|_{L_u} + \|z^u - z_h^u\|_{h,\beta} \lesssim h^{p_u+\frac{1}{2}}\|z^u\|_{H^{p_u+1}(\mathcal{T}_h)}, \tag{4.16}$$

which is exactly the estimate for the problem investigated in [10, section 3.1].

5. Implementation issues. In this section we discuss important implementation aspects of the method. We show how it can be interpreted in terms of so-called numerical fluxes so as to compare it with other known approximation techniques that are defined in these terms in the literature. We also present two variants of the method that yield substantial computational savings.

5.1. Flux formulation. The notion of (numerical) fluxes is widely used by engineers. This concept originally introduced in the context of finite volume methods, naturally extends to DG methods. The link between DG methods and the concept of flux has been explored in [3] for the Laplace equation and in [11] for more general cases. A number of methods have originally been presented in terms of fluxes, and it is therefore interesting to recast our formulation in this framework so as to facilitate comparisons. To this purpose, let us define

$$\phi^u_{\partial T}(z^\sigma, z^u)|_F \stackrel{\text{def}}{=} \begin{cases} \frac{1+\alpha}{2} n^t \kappa z^\sigma + \frac{1}{2}(\beta\cdot n) z^u + \frac{1}{2} M^{uu}_F z^u & \text{if } F \in \mathcal{F}_h^\partial, \\ n_T^t \{\kappa z^\sigma\}_{\overline{\omega}} + (\beta\cdot n_T)\{z^u\} + (n_T\cdot n_F) S_F([\![z^u]\!]) & \text{if } F \in \mathcal{F}_h^i, \end{cases} \tag{5.1}$$

$$\phi^\sigma_{\partial T}(z^u)|_F \stackrel{\text{def}}{=} \begin{cases} \frac{1-\alpha}{2}(\kappa n)^t z^u & \text{if } F \in \mathcal{F}_h^\partial, \\ (\kappa n)^t|_T \{z^u\}_\omega & \text{if } F \in \mathcal{F}_h^i, \end{cases} \tag{5.2}$$

where $\overline{\omega} \stackrel{\text{def}}{=} (1,1) - \omega$ and n_T is the outward normal to the element T. It is possible to prove (see [11, section 4.3] for the details) that the discrete problem (3.21) can be equivalently reformulated in terms of the following local problems:

$$\begin{cases} \text{Seek } z_h \in W_h \text{ such that, } \forall T \in \mathcal{T}_h \text{ and } \forall q \in [\mathbb{P}_{p_\sigma}(T)]^d \times \mathbb{P}_{p_u}(T), \\ (z_h, (K + \tilde{A})q)_{L,T} + (\phi_{\partial T}(z_h), q)_{L,\partial T} = (f, q^u)_{L_u,T}. \end{cases}$$

The above form is known as the flux formulation of (3.21). Observe that the above flux definitions lead to the use of harmonic averages of the normal component of the diffusion tensor at mesh interfaces; see (3.20). Harmonic averaging of the diffusion matrix has been considered for dual-mixed formulations, e.g., in [2].

5.2. Interior penalty (IP) variant. In this section we discuss a variant of the method designed in section 3.2 which reduces the size of the local problems to be solved to eliminate the σ-component of the unknown. The advantages of such a variant are that it is easier to implement and that the associated matrix pattern is sparser. To this purpose we introduce the lifting operator defined as follows: For all $F \in \mathcal{F}_h$ and for all $\varphi \in L^2(F)$, $r_{F,\kappa}(\varphi) \in \Sigma_h$ is defined by

$$\forall \tau_h \in \Sigma_h, \quad (r_{F,\kappa}(\varphi), \tau_h)_{L_\sigma} \stackrel{\text{def}}{=} \begin{cases} \frac{\alpha+1}{2}(\varphi n, \kappa\tau_h)_{L_\sigma,F} & \text{if } F \in \mathcal{F}_h^\partial, \\ (\varphi n_1, \{\kappa\tau_h\}_{\overline{\omega}})_{L_\sigma,F} & \text{if } F \in \mathcal{F}_h^i. \end{cases} \tag{5.3}$$

Moreover, we let $R_\kappa(\varphi) \stackrel{\text{def}}{=} \sum_{F\in\mathcal{F}_h} r_{F,\kappa}(\varphi)$. Observe that, unlike in [3], the lifting operator depends on the diffusivity. Moreover, for a given face $F \in \mathcal{F}_h$, it is clear that $\text{supp}(r_{F,\kappa}(\varphi)) = \mathcal{T}_h(F)$. In what follows we shall extend the definition of the jump operator to boundary faces by setting

$$[\![y^u]\!] \stackrel{\text{def}}{=} y^u \quad \forall F \in \mathcal{F}_h^\partial, \ \forall y \in W(h).$$

The following result holds.

LEMMA 5.1. *For all $F \in \mathcal{F}_h$ and for all $v_h \in U_h$,*

$$\|r_{F,\kappa}([\![v_h]\!])\|_{L_\sigma} \lesssim \begin{cases} \lambda h_F^{-\frac{1}{2}} \|v_h\|_{L_u,F} & \text{if } F \in \mathcal{F}_h^\partial, \\ \lambda_2 h_F^{-\frac{1}{2}} \|[\![v_h]\!]\|_{L_u,F} & \text{if } F \in \mathcal{F}_h^i. \end{cases}$$

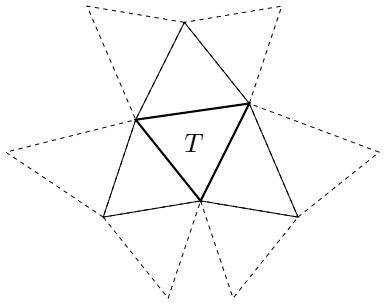

FIG. 1. *Elimination of the σ-component on element T. Stencil for the IP variant of the method (solid lines) and for the LDG variant (solid and dashed lines).*

Proof. Let $F \in \mathcal{F}_h^i$. Then, using (5.3), (3.20), and (3.4), we have that

$$\|r_{F,\kappa}(\llbracket v_h \rrbracket)\|_{L_\sigma}^2 = (\llbracket v_h \rrbracket n_1, \{\kappa r_{F,\kappa}(\llbracket v_h \rrbracket)\}_{\overline{\omega}})_{L_\sigma,F} \lesssim \|\llbracket v_h \rrbracket\|_{L_u,F} \frac{\lambda_1\lambda_2}{2\{\lambda\}} h_F^{-\frac{1}{2}} \|r_{F,\kappa}(\llbracket v_h \rrbracket)\|_{L_\sigma},$$

from which the assertion follows readily. The proof is carried out similarly for $F \in \mathcal{F}_h^\partial$. ∎

Proceeding in a way similar to that in [3, section 3.2] and using the fact that, owing to assumption (3.5), $\kappa\tau_h$ is in Σ_h for all $\tau_h \in \Sigma_h$, it is possible to prove that, for all $(\sigma, u) \in W(h)$ such that $\sigma = \kappa\nabla u - R_\kappa(\llbracket u \rrbracket)$ and for all $(0, v) \in W(h)$,

$$\begin{aligned} a_h((\sigma,u),(0,v)) = &\sum_{T\in\mathcal{T}_h} [(\kappa\nabla u - R_\kappa(\llbracket u\rrbracket), \kappa\nabla v - R_\kappa(\llbracket v\rrbracket))_{L_\sigma,T} + (\mu u, v)_{L_u,T}] \\ &- \sum_{T\in\mathcal{T}_h} (u, \beta\cdot\nabla v)_{L_u,T} + \sum_{F\in\mathcal{F}_h^\partial} \tfrac{1}{2}(M_F^{uu}(u) + (\beta\cdot n)u, v)_{L_u,F} \\ &+ \sum_{F\in\mathcal{F}_h^i} ((\beta\cdot n_1)\{u\}, \llbracket v\rrbracket)_{L_u,F} + \sum_{F\in\mathcal{F}_h^i} (S_F(\llbracket u\rrbracket), \llbracket v\rrbracket)_{L_u,F}. \end{aligned} \tag{5.4}$$

Notice that σ does not appear in the expression on the right-hand side; i.e., we have found a decoupled problem for the sole primal unknown u. The expression (5.4) will henceforth be referred to as the *LDG (local discontinuous Galerkin) variant* of the discrete bilinear form because of the similarity with the method for convection-diffusion systems proposed in [7].

One can verify that, when the basis functions are defined in such a way that their support is restricted to one element of the triangulation, the stencil resulting from (5.4) is composed of all the elements shown in Figure 1 (solid and dashed lines). But by having a closer look at (5.4), one realizes that the only term involving the dashed elements in Figure 1 is the following:

$$\sum_{T\in\mathcal{T}_h} (R_\kappa(\llbracket u\rrbracket), R_\kappa(\llbracket v\rrbracket))_{L_\sigma,T} \stackrel{\text{def}}{=} -\rho_h(u,v).$$

Hence, in order to reduce the stencil, it seems reasonable to consider the following perturbation of a_h:

$$a_h^{\text{IP}}(z,y) \stackrel{\text{def}}{=} a_h(z,y) + \rho_h(z^u, y^u). \tag{5.5}$$

Let us define the following seminorm:

$$|y^u|^2_{\mathrm{LDG}} \stackrel{\mathrm{def}}{=} \frac{\alpha+1}{2}\sum_{F\in\mathcal{F}_h^\partial}\|\lambda h_F^{-\frac{1}{2}} y^u\|^2_{L_u,F} + \sum_{F\in\mathcal{F}_h^i}\|\lambda_2 h_F^{-\frac{1}{2}}[\![y^u]\!]\|^2_{L_u,F} \quad \forall y\in W(h). \tag{5.6}$$

The following lemma is crucial to accommodating the proofs of Lemmata 4.2–4.4 to the new bilinear form a_h^{IP}.

LEMMA 5.2. *The following properties, uniform in h, hold:*

(i) *For all $(z,y_h)\in(V\cap W(h))\times W_h$ we have*

$$\forall y_h\in W_h,\quad \rho_h(z^u,y_h^u)=0.$$

(ii) *For all y in $W(h)$,*

$$\rho_h(y^u,y^u)\le CN_F|y^u|^2_{\mathrm{LDG}},$$

N_F being the maximum number of faces of one mesh element and C a positive parameter depending only on the mesh geometry and on the polynomial order of approximation.

(iii) *For all $(z,y_h)\in W_h^\perp\times W_h$,*

$$\rho_h(z,y_h)\lesssim |z^u|_{\mathrm{LDG}}|y_h^u|_{\mathrm{LDG}}. \tag{5.7}$$

Proof. (i) We know that $[\![z^u]\!]=0$, and consequently $r_{F,\kappa}([\![z^u]\!])=0$, on all $F\in\mathcal{F}_h\setminus\mathcal{I}_h^-$. On the other hand, let $\mathcal{I}_h^-\ni F=\partial T_1\cap\partial T_2$ and $\tau_h\in\Sigma_h$. Then, since $n^t\kappa|_{T_2}=0$ entails $\lambda_2=0$,

$$n_1^t\{\kappa\tau_h\}_{\overline{\omega}} = \frac{\lambda_2}{2\{\lambda\}}n_1^t\cdot\kappa\tau_h|_{T_1}+\frac{\lambda_1}{2\{\lambda\}}n_1^t\cdot\kappa\tau_h|_{T_2}=0,$$

i.e., $r_{F,\kappa}([\![z^u]\!])=0$, which gives the desired result.

(ii) The second point can be proved as follows. Observe that

$$\|R_\kappa([\![y^u]\!])\|^2_{L_\sigma}\le\sum_{F\in\mathcal{F}_h}\sum_{F'\in\mathcal{F}_h}\|r_{F,\kappa}([\![y^u]\!])\|_{L_\sigma}\|r_{F',\kappa}([\![y^u]\!])\|_{L_\sigma}.$$

Let $\mathcal{F}_h^i\ni F=\partial T_1\cap\partial T_2$. Since $\mathrm{supp}(r_{F,\kappa}([\![y^u]\!]))=T_1\cup T_2$, only a few products on the right-hand side are nonzero. In particular, the nonzero products are those for which $F'\in\Delta_F$, where $\Delta_F\stackrel{\mathrm{def}}{=}\{F'\in\mathcal{F}_h;\ F'\subset\partial T_1 \text{ or } F'\subset\partial T_2\}$. Therefore, the only terms involving F are

$$\sum_{F'\in\Delta_F}\|r_{F,\kappa}([\![y^u]\!])\|_{L_\sigma}\|r_{F',\kappa}([\![y^u]\!])\|_{L_\sigma}\le\tfrac{1}{2}\sum_{F'\in\Delta_F}\left(\|r_{F,\kappa}([\![y^u]\!])\|^2_{L_\sigma}+\|r_{F',\kappa}([\![y^u]\!])\|^2_{L_\sigma}\right).$$

We realize that $\|r_{F,\kappa}([\![y^u]\!])\|^2_{L_\sigma}$ is added at most N_F times. The desired result follows by repeating this argument for the other faces and using Lemma 5.1.

(iii) Deriving (5.7) is a simple application of Lemma 5.1. ∎

Modifying Lemmata 4.2–4.4 so as to hold for a_h^{IP} instead of a_h is now simple in view of the above result. However, observe that, according to the second point of Lemma 5.2, in order to preserve the L-coercivity, (3.6) and (3.18) should be modified as follows:

$$M_F^{uu}(v)\stackrel{\mathrm{def}}{=}\left(\frac{|\beta\cdot n|}{2}+N_F\eta\frac{\alpha+1}{2}\frac{\lambda^2}{h_F}\right)v,\qquad S_F(v)\stackrel{\mathrm{def}}{=}\left(\frac{|\beta\cdot n|}{2}+N_F\eta\frac{\lambda_2^2}{h_F}\right)v, \tag{5.8}$$

where the multiplicative factor η must be strictly greater than the constant C appearing in (5.7). The term ρ_h that has been added to simplify the elimination of the σ-component is thus counterbalanced by adding "more stabilization." The resulting method is termed the *IP variant* because of the similarity with the IP method proposed in [1, 4]. The method recently proposed in [15] also belongs to this class, although some modifications are introduced in the definition of the penalty parameter.

5.3. BRMPS variant. The parameter C in (5.7), and, consequently, η in (5.8), is possibly difficult to estimate in practical applications. To avoid this difficulty, we consider the following alternative expression for the boundary and interface operators:

$$M_F^{uu}(v) \stackrel{\text{def}}{=} \frac{|\beta\cdot n|}{2}v + N_F\eta r_{F,\kappa}(v), \qquad S_F(v) \stackrel{\text{def}}{=} \frac{|\beta\cdot n|}{2}v + N_F\eta\{r_{F,\kappa}(v)\}_{\overline{\omega}}. \tag{5.9}$$

A closer look at the proof of the second point of Lemma 5.2 shows that it is sufficient to take $\eta > 1$ to preserve L-coercivity. Owing to the similarities with the approach first presented in [5], the resulting numerical method is termed the *BRMPS variant* (after the initials of the authors of [5]).

6. Numerical results. In this section we evaluate the performance of the proposed method on two test cases. The simulations are done using the BRMPS variant discussed in section 5.3. In both test cases, we assume that the exact solution is smooth enough elementwise.

6.1. Convergence. In order to assess the theoretical convergence estimates, we consider the problem described in Figure 2(a). Here (r,θ) denote the standard cylindrical coordinates with the angle θ measured in the anticlockwise sense starting from the positive x-axis. The domain is taken to be $(-1,1)^2 \setminus [-0.5,0.5]^2$, while the coefficients are set to

$$\kappa = \begin{cases} \pi & \text{if } 0 < \theta < \pi, \\ 0 & \text{if } \pi < \theta < 2\pi, \end{cases} \qquad \beta = \frac{e_\theta}{r}, \qquad \mu = 10^{-3},$$

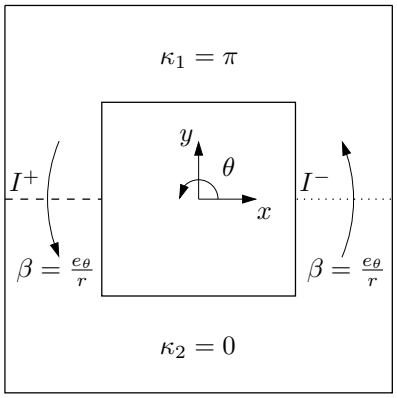
where e_θ is the unit azimuthal vector. The exact solution for a suitable right-hand side f is

$$u = \begin{cases} (\theta-\pi)^2 & \text{if } 0 \le \theta \le \pi, \\ 3\pi(\theta-\pi) & \text{if } \pi < \theta < 2\pi. \end{cases}$$

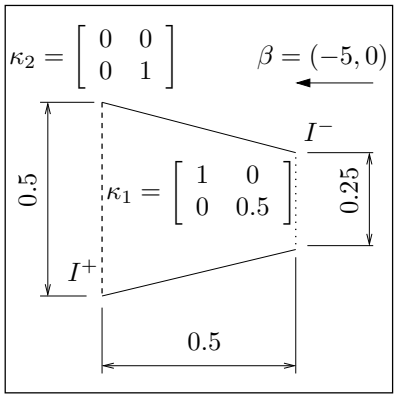
Observe that, although piecewise polynomial in θ, the above solution does *not* belong to the discrete space U_h since we are solving the problem in Cartesian coordinates. Moreover, according to the interface condition (INT1), the solution is continuous across I^+, while only (INT2) is verified on I^-. We introduce the following norm:

$$\|u\|_{h,\text{BRMPS}}^2 \stackrel{\text{def}}{=} \|u\|_{L_u}^2 + |u|_J^2 + |u|_M^2 + \sum_{T\in\mathcal{T}_h} \|\kappa\nabla u\|_{L_\sigma,T}^2.$$

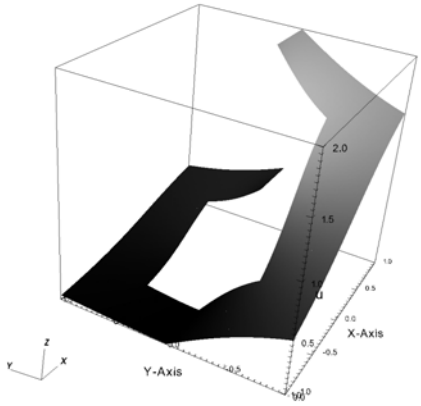
Let (σ_h, u_h) solve the discrete problem associated with the BRMPS variant. Then, observing that $\sigma_h = \kappa\nabla u_h + R([\![u_h]\!])$, it can be proved that $\|u-u_h\|_{h,\text{BRMPS}}$ is equivalent to $\|(\sigma,u)-(\sigma_h,u_h)\|_{h,\kappa}$. Coherently with the desire to avoid the additional cost coming from the computation of σ_h, $\|u-u_h\|_{h,\text{BRMPS}}$ was reported in Table 1. The convergence results confirm the sharpness of the estimates derived in sections 4.1 and 4.2. The L^2-norm is also reported for completeness, showing that convergence at order p_u+1 can be expected.



(a) Description of the test case of section 6.1.



(b) Description of the test case of section 6.2.



(c) Exact solution of the test case of section 6.1.

FIG. 2. *Problem setting for the numerical test cases. I^+ and I^- are plotted as dashed and dotted lines, respectively.*

6.2. Strongly anisotropic diffusivity. To demonstrate the behavior of the method in the presence of strongly anisotropic diffusivity we consider the test of Figure 2(b). The domain $\Omega = (0,1)^2$ is partitioned into two subdomains where the diffusivity takes different values; it is positive definite in one region and positive semidefinite in the other region. The advection field is $\beta = (-5,0)^t$, and the reaction coefficient is $\mu = 1$. The solution is discontinuous across the interface $I^- = \{x = 0.75; 0.375 \leq y \leq 0.625\}$. The solutions obtained for different polynomial degrees are displayed in Figure 3, showing that the predicted behavior is captured accurately.

7. Conclusion. In this work we developed and analyzed a DG method to approximate advection-diffusion-reaction equations with discontinuous, anisotropic, and semidefinite diffusivity. The proposed method is capable of treating in a robust fashion the semidefinite diffusivity case owing to our design of the boundary and penalty terms and provided the mesh fits the discontinuities of the diffusivity field. This is

achieved by resorting to weighted average and jump operators. The convergence analysis yields estimates that are uniform with respect to the diffusivity. The theoretical results are supported by numerical evidence.

Appendix. Proof of Proposition 2.4.

Proof. According to the so-called Banach–Nečas–Babuška (BNB) theorem (see, e.g., [9, section 2.1.3]), the statement amounts to proving that the following conditions hold:

$$\text{(BNB1)} \qquad \forall z \in V, \quad \sup_{y \in L\setminus\{0\}} \frac{a_0(z,y)}{\|y\|_L} \gtrsim \|z\|_V,$$

$$\text{(BNB2)} \qquad \forall z \in V, \quad (\forall y \in L, \quad a_0(z,y) = 0) \Longrightarrow (y = 0).$$

(i) Let us prove (BNB1). Let $z \in V$, and set $\mathbb{S} \overset{\text{def}}{=} \sup_{y\in L\setminus\{0\}} \frac{a_0(z,y)}{\|y\|_L}$. Using the definition of the L^2-norm, we deduce

$$\mathbb{S} \gtrsim \sup_{y\in L\setminus\{0\}} \frac{(Az,y)_L}{\|y\|_L} - \|z\|_L \gtrsim \|Az\|_L - \|z\|_L.$$

Then Lemma 2.3 gives

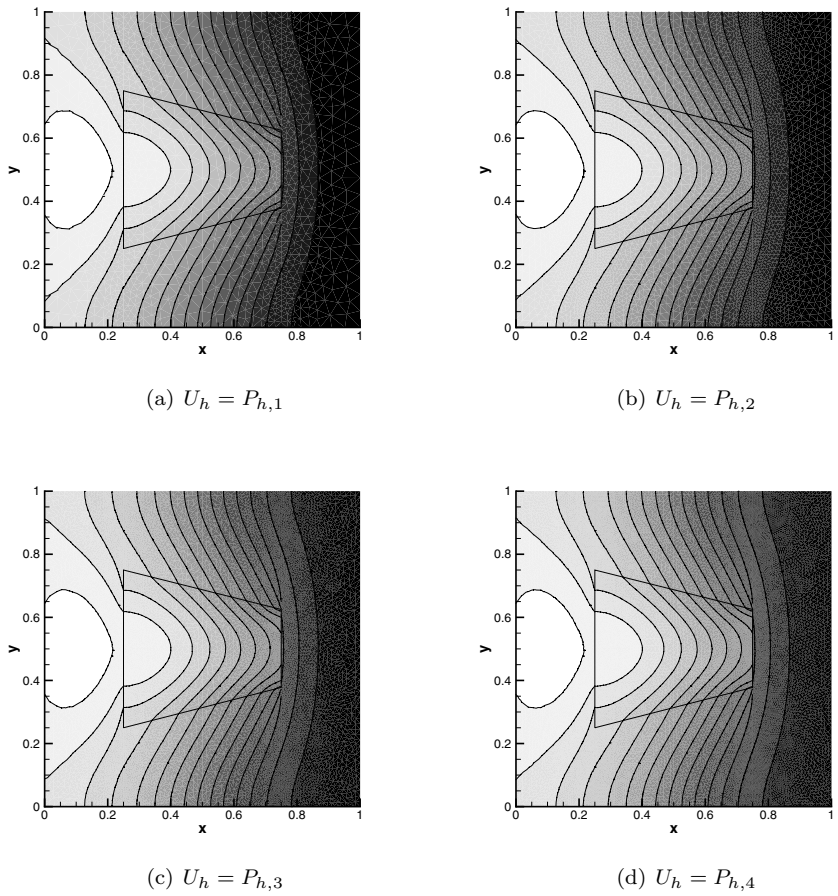
$$\|z\|_L \lesssim \frac{a_0(z,z)}{\|z\|_L} \lesssim \mathbb{S} \Longrightarrow \|z\|_L + \|Az\|_L \lesssim \mathbb{S},$$

i.e., $\|z\|_V \lesssim \mathbb{S}$, which proves (BNB1).

(ii) Let us prove (BNB2). Let $y \in L$ be such that

$$\text{(A.1)} \qquad a_0(z,y) = 0 \quad \forall z \in V.$$

Let us prove that y is necessarily zero.



(a) $U_h = P_{h,1}$ (b) $U_h = P_{h,2}$

(c) $U_h = P_{h,3}$ (d) $U_h = P_{h,4}$

FIG. 3. *Numerical results for the test case of section* 6.2.

(1) Let $\Omega_i \in P_\Omega$, take $z = (z^\sigma, 0)$ with $z^\sigma \in [\mathcal{D}(\Omega_i)]^d$, and observe that z is a member of V. Then using z to test (A.1), we obtain

$$a_0((z^\sigma, 0), y) = \langle y^\sigma - \kappa \nabla y^u, z^\sigma \rangle_{[\mathcal{D}(\Omega_i)]^d} = 0 \quad \forall z^\sigma \in [\mathcal{D}(\Omega_i)]^d,$$

meaning that $y^\sigma - \kappa \nabla y^u = 0$ in Ω_i, i.e., $\kappa \nabla y^u|_{\Omega_i} \in L^2(\Omega_i)$. Now let us prove that y^u is continuous across $\Gamma \setminus I$. Let x be a point in $\Gamma \setminus I$. Let Ω_i and Ω_j be the two subdomains that are on each side of the interface $\Gamma \setminus I$ at x. We assume that x is an interior point of $\overline{\Omega_i} \cap \overline{\Omega_j}$; i.e., all the points in a small neighborhood of x, say $\mathcal{V}$, belong to either $\overline{\Omega_i}$ or $\overline{\Omega_j}$. Up to a Lipschitz map, we can assume that the restriction of Γ to $\mathcal{V}$ is a hyperplane. We choose a local Cartesian coordinate system $(x_1, \ldots, x_d)$ so that the two normals n_1, n_2 are aligned with the x_1-axis. The neighborhood $\mathcal{V}$ can be chosen small enough so that $\mathcal{V} \cap I = \emptyset$. κ being piecewise constant, this means that $\kappa \cdot n_1$ is uniformly bounded away from zero in $\mathcal{V}$; in other words, the component κ_{11} is uniformly bounded away from zero in $\mathcal{V}$.

Let $\psi \in \mathcal{D}(\mathcal{V})$ and define the d-vector field $\tilde{\sigma}$ by $\tilde{\sigma}_1 = \frac{1}{\kappa_{11}}\psi$, and $\tilde{\sigma}_l = 0$ for $l > 1$. Then $\kappa\tilde{\sigma} = (1, \frac{\kappa_{21}}{\kappa_{11}}, \ldots, \frac{\kappa_{d1}}{\kappa_{11}})\psi$. Observe that $\tilde{\sigma} \in L_\sigma$ and $\nabla \cdot (\kappa\tilde{\sigma}) \in L^2(\Omega)$; in other

words, the pair $(\tilde{\sigma}, 0)$ is in V. By testing (A.1) with $(\tilde{\sigma}, 0)$, we obtain

$$\begin{aligned} 0 &= \int_{\mathcal{V}} [\tilde{\sigma}\cdot y^{\sigma} + \nabla\cdot(\kappa\tilde{\sigma}) y^{u}] \\ &= -\langle \psi, \partial_{x_1} y^{u}\rangle_{\mathfrak{D}(\Omega)} + \int_{\mathcal{V}} \psi \frac{1}{\kappa_{11}} (y_1^{\sigma} - \kappa_{12}\partial_{x_2} y^{u} - \cdots - \kappa_{1d}\partial_{x_d} y^{u}), \end{aligned}$$

where we used that $\kappa_{12}\partial_{x_2} y^{u}, \ldots, \kappa_{1d}\partial_{x_d} y^{u}$ are in $L^2(\mathcal{V})$ from the first part of the argument. A standard distribution argument implies

$$\partial_{x_1} y^{u} = \frac{1}{\kappa_{11}} (y_1^{\sigma} - \kappa_{12}\partial_{x_2} y^{u} - \cdots - \kappa_{1d}\partial_{x_d} y^{u}) \in L^2(\mathcal{V}).$$

Then we conclude that $\partial_{x_1} y^{u} \in L^2(\mathcal{V})$; i.e., y^{u} is continuous across Γ in a neighborhood of x. Using a standard argument together with x being an interior point of $\overline{\Omega_i} \cap \overline{\Omega_j}$, we infer that $\kappa\nabla y^{u}$ is in L_{σ}.

(2) Use $z = (0, z^{u})$ with $z^{u} \in \mathfrak{D}(\Omega)$ as a test function in (2.22), and observe that again z is a member of V. A distributional argument gives

$$\langle (\mu + \nabla\cdot\beta) y^{u} - \nabla\cdot(\kappa y^{\sigma} + \beta y^{u}), z^{u}\rangle_{\mathfrak{D}(\Omega)} = 0.$$

Owing to the regularity assumptions on μ and β listed in section 2.1, we conclude that $\nabla\cdot(\kappa y^{\sigma} + \beta y^{u}) \in L^2(\Omega)$, i.e., y is a member of W and

$$(K + \tilde{A}) y = 0.$$

(3) We then deduce that, for all $z \in V$,

$$\langle Dz, y\rangle_{W',W} = ((K + A) z, y)_L - ((K + \tilde{A}) y, z)_L = 0;$$

i.e., y is a member of $D(V)^{\perp} = V^*$. In conclusion, $a_0^*(y, w) = 0$ for all $w \in L$ and $y \in V^*$. Finally, the L-coercivity of a_0^* (see Lemma 2.3) implies that $y = 0$. ∎

LOCAL REGULARIZATION FOR THE NONLINEAR INVERSE AUTOCONVOLUTION PROBLEM*

ZHEWEI DAI† AND PATRICIA K. LAMM‡

Abstract. We develop a local regularization theory for the nonlinear inverse autoconvolution problem. Unlike classical regularization techniques such as Tikhonov regularization, this theory provides regularization methods that preserve the causal nature of the autoconvolution problem, allowing for fast sequential numerical solution ($\mathcal{O}(rN^2 - r^2N)$ flops, where $r \ll N$ for the method discussed in this paper as applied to the nonlinear problem; in comparison, the cost for Tikhonov regularization applied to a general *linear* problem is $\mathcal{O}(N^3)$ flops). We prove the convergence of the regularized solutions to the true solution as the noise level in the data shrinks to zero and supply convergence rates for the cases of both L_2 and continuous data. We propose several regularization methods and provide a theoretical basis for their convergence; of note is that this class of methods does not require an initial guess of the unknown solution. Our numerical results confirm the effectiveness of the methods, with results comparing favorably to numerical examples found in the literature for the autoconvolution problem (e.g., [G. Fleischer, R. Gorenflo, and B. Hofmann, *ZAMM Z. Angew. Math. Mech.*, 79 (1999), pp. 149–159] for examples using Tikhonov regularization with total variation constraints and [J. Janno, *Inverse Problems*, 16 (2000), pp. 333–348] for examples using the method of Lavrent'ev); this especially seems to be true when it comes to the recovery of sharp features in the unknown solution. We also show the effectiveness of our method in cases not covered by the theory.

Key words. local regularization of inverse problems, nonlinear Volterra problem, numerical methods, inverse autoconvolution problem

1. Introduction.

In this paper we develop a local regularization theory for the inverse autoconvolution problem of finding $\bar{x} \in L_2(0,T)$ solving

$$G(x) = f, \tag{1.1}$$

where G is the nonlinear Volterra operator given by

$$G(x)(t) = \int_0^t x(t-s)\,x(s)\,ds, \quad \text{a.e. } t \in (0,T), \tag{1.2}$$

and where $f \in \mathit{Range}(G) \subseteq L_2(0,T)$. Without loss of generality we will henceforth let $T = 1$.

Autoconvolution has been of interest to scientists for decades because of its applications in various fields. It arises in stochastics, where the density function of a continuous random variable V is reconstructed after observing the density function of the random variable $S = V_1 + V_2$, where V_1 and V_2 are identically and independently distributed random variables of V [14]. Another application of autoconvolution occurs in spectroscopy. Baumeister presents in [1] a reference list of physically motivated papers concerning this class of problems. He also discusses in detail the mathematical

model of deconvolution of "appearance potential"(AP) spectra to investigate electronic properties of solids in their surface region. In this context, the density of unoccupied states in the surface region of a solid is recovered from the measured AP-spectrum data.

Properties of the autoconvolution problem have been explored extensively in [12, 13, 11, 14] (to name just a few of the references in this area) and include analysis of the ill-posedness of the problem due to the lack of continuous dependence of solutions $\bar{x}$ on data f. Indeed, for $D(G) \equiv \{x \in L_2(0,1),\ x(t) \geq 0,\ \text{a.e. } t \in (0,1)\}$, the operator $G : D(G) \subset L_2(0,1) \mapsto L_2(0,1)$ is such that the inverse autoconvolution operator G^{-1} is discontinuous at every point f in the range of G; i.e., the autoconvolution equation is locally ill-posed at every point x in $D(G)$. Degrees of ill-posedness for the autoconvolution equation are discussed in [13, 14]. In short, we expect a correlation between the degree of ill-posedness and both the smoothness of the solution $\bar{x}$ and the behavior of $\bar{x}$ at 0.

Various regularization methods have been studied for the autoconvolution equation. One can utilize the Tikhonov regularization theory for nonlinear inverse problems, since the autoconvolution operator G is continuous and weakly closed on $D(G)$ and G has a compact Fréchet derivative at all $x \in L_2(0,1)$ satisfying assumptions needed to guarantee stability in the nonlinear Tikhonov theory [9, 14, 30]. However, as is well known in the case of the linear Volterra problem, classical regularization methods such as Tikhonov regularization have inherent disadvantages in solving Volterra problems; indeed, the use of Tikhonov regularization transforms problems that are structurally causal in nature into noncausal or full-domain problems (see, e.g., [21] for a discussion of these difficulties). Causal-based methods have advantages because they are sequential in nature, and we will see in section 5.1 that the cost of the local regularization algorithm discussed in that section is $\mathcal{O}(rN^2 - r^2N)$, where $r \ll N$, while the cost for Tikhonov regularization on a general *linear* problem is $\mathcal{O}(N^3)$.

In addition, source conditions needed for convergence rates for Tikhonov regularization as applied to the nonlinear problem (1.1) require that $\bar{x} - x^\star = G'(\bar{x})^\star w$ for some $w \in L_2(0,1)$ [10], where $x^\star$ is an initial guess for $\bar{x}$ and $\bar{x}$ is the true solution of (1.1). It is not hard to show that the source condition requires that $x^\star(1) = \bar{x}(1)$; since $x^\star$ is part of the Tikhonov algorithm, the method then requires knowledge of the value of the unknown solution $\bar{x}$ at $t = 1$.

In the late 1960s, Beck developed a regularization scheme for the discretized inverse heat conduction problem (IHCP), a linear Volterra inverse problem, which retains the causal nature of the original problem [2]. Because of its sequential formulation, the numerical implementation of the Beck method is also more efficient than classical regularization methods. In the mid-1990s, the second author established the theoretical basis for the convergence of the sequential local regularization method, and Beck's approach was generalized to a wide class of linear first-kind Volterra problems [17, 18, 19]. While Beck's method was an approach developed to handle a finite-dimensional approximation of the IHCP, the current theory of local regularization methods can be placed in both finite- and infinite-dimensional settings. In addition, the theory has been extended more recently to nonlinear Volterra problems [29] of the Hammerstein type,

$$\int_0^t k(t-s)g(x(s),s)\,ds = f(t), \quad \text{a.e. } t \in (0,T). \tag{1.3}$$

In [24], the special structure of this equation was coupled with the linear convergence

theory so that local regularization was used to solve

$$\int_0^t k(t-s)v(s)\,ds = f(t), \quad \text{a.e. } t \in (0,T),$$

for v, and then u, was recovered as a solution of the nonlinear problem $v(t) = g(u(t), t)$ for all $t \in [0,1]$. More recently in [26] this work has been modified so that the nonlinear equation (1.3) need only be solved on an initial (small) interval $[0,\varepsilon]$; then for $t > \varepsilon$, the solution x is stably recovered explicitly and sequentially from a local regularization equation which is an extension of the method found in [24].

In [15, 16], Janno applied the Lavrent'ev regularization method to the autoconvolution equation and provided both theoretical convergence estimates and numerical examples. The advantage of the Lavrent'ev method is that it preserves the causal nature of Volterra problems and therefore leads to a fast sequential method. The drawback for the method is that it requires and depends on an initial guess $x^\star$ of the true solution $\bar{x}$, and it must be that $x^\star(0) = \bar{x}(0)$, which means that $\bar{x}(0)$ must be known in advance (or at least computed using regularized differentiation of noisy data; we note that in section 5 we propose an algorithm which approximates $\bar{x}(0)$ in exactly the same way). The performance of both the Lavrent'ev and Tikhonov methods seems fairly dependent on the choice of the initial guess $x^\star$ and of its closeness to $\bar{x}$.

In this paper, we develop a local regularization theory for the nonlinear autoconvolution problem of finding $x \in D(G) \subset L_2(0,1)$ solving (1.1) with G given by (1.2). The result is an effective regularization method which essentially preserves the causal nature of the problem and does not require an initial guess of the true solution (such as is needed for the Lavrent'ev and Tikhonov methods).

2. The regularized autoconvolution equation. We will first motivate the equation which will become the basis for our regularized approximation of the true solution $\bar{x}$ of (1.1). We assume that our data and solution are available on an extended interval $[0, 1+\bar{R}]$ for some small $\bar{R} \in (0,1]$ and note that this can always be accomplished by simply decreasing the size of our original interval slightly. Thus, for any $0 < R < \bar{R}$, $\bar{x}$ solves

$$\int_0^{t+\rho} x(t+\rho-s)\,x(s)\,ds = f(t+\rho), \quad \text{a.e. } t \in (0,1),\ \rho \in (0,R).$$

We split the integral at ρ and t and then change the variable of integration to obtain

$$2\int_0^\rho x(t+\rho-s)\,x(s)\,ds + \int_\rho^t x(t+\rho-s)\,x(s)\,ds = f(t+\rho) \tag{2.1}$$

for a.e. $t \in (0,1), \rho \in (0,R)$. In order to consolidate the local future information introduced by the variable ρ, we follow the idea of local regularization in the case of the linear Volterra problem (see, e.g., [17, 18]) and integrate both sides of (2.1) with respect to a suitable measure $\eta = \eta(\rho) > 0$ (which we will clarify later) on $[0,R]$, leading to the equation

$$\begin{aligned} 2\int_0^R \int_0^\rho x(t+\rho-s)\,x(s)\,ds\,d\eta(\rho) + \int_0^R \int_\rho^t x(t+\rho-s)\,x(s)\,ds\,d\eta(\rho) \\ = \int_0^R f(t+\rho)\,d\eta(\rho), \quad \text{a.e. } t \in (0,1). \end{aligned} \tag{2.2}$$

Note that $\bar{x}$ still satisfies (2.2) exactly.

In reality, instead of having the exact data f, we have access only to some approximation f^δ to f. Because of the local ill-posedness of the original problem (1.1), some form of regularization is needed when the perturbed data f^δ are used in place of the "ideal" data f. The results of regularization differ depending on the smoothness of the perturbed data, so we will investigate the properties of our method using data f^δ in two different spaces $\mathcal{F}$ of functions defined on $[0, 1+\bar{R}]$. Our assumption regarding data will be as follows.

DEFINITION 2.1. *We will say the data f^δ satisfy the* $\mathcal{F}$-data assumption *if $f^\delta \in \mathcal{F}$ and*

$$\|f^\delta - f\|_{\mathcal{F}} \leq \delta \tag{2.3}$$

for some $\delta > 0$, where either $\mathcal{F} = C[0, 1+\bar{R}]$ or $\mathcal{F} = L_2(0, 1+\bar{R})$.

Returning then to local regularization in the presence of perturbed data f^δ, the method is suggested by the idea of momentarily holding x constant on a small local interval $[t, t+R]$; i.e., we replace $x(t+\rho-s)$ by $x(t)$ in the first term of (2.2) for values of ρ, s such that $\rho - s \in [0, R]$. Here the length of this local interval R serves as the regularization parameter. We then obtain the regularization equation

$$\alpha_R(x)x + F_R(x) = f_R^\delta, \tag{2.4}$$

where, for a.e. $t \in (0,1)$,

$$\alpha_R(x) \equiv 2\int_0^R \int_0^\rho x(s)\, ds\, d\eta(\rho), \tag{2.5}$$

$$F_R(x)(t) \equiv \int_0^R \int_\rho^t x(t+\rho-s)\, x(s)\, ds\, d\eta(\rho), \tag{2.6}$$

$$f_R^\delta(t) \equiv \int_0^R f^\delta(t+\rho)\, d\eta(\rho). \tag{2.7}$$

The R-dependent measure η is defined via

$$\int_0^R g(\rho)\, d\eta(\rho) \equiv \int_0^R g(\rho)\, \omega(\rho, R)\, d\rho, \quad g \in L_2(0,R), \tag{2.8}$$

where the family $\{\omega(\cdot, R) \in L_\infty(0,R)\}_{R\in(0,\bar{R}]}$ is assumed to be such that there exist $\underline{\omega}$, $\bar{\omega} > 0$ independent of R so that

$$0 < \underline{\omega} \leq \omega(\rho, R) \leq \bar{\omega}, \quad \text{a.e. } \rho \in (0, R], \tag{2.9}$$

for all R sufficiently small. It follows then that for any real $m \geq 0$ there exist constants $K(m) > 0$ independent of R so that

$$\frac{\int_0^R \rho^m\, d\eta(\rho)}{\int_0^R \rho\, d\eta(\rho)} \leq K(m) R^{m-1} \tag{2.10}$$

for all $R > 0$ sufficiently small. We note that this class of measures is a special case of the measures discussed in previous papers on local regularization for linear Volterra problems (see, e.g., [5, 6, 7, 17, 18, 19, 20, 22, 23, 25, 27, 28, 31]) and that the discrete

measures discussed in these references are not suitable for use in (2.7) in the case of $f^\delta \in L_2(0, 1+R)$.

Our main results involving the well-posedness of (2.4) and the convergence of the solution x of (2.4) to the true solution $\bar{x}$ of the original autoconvolution equation will be given in the next section. First we will introduce some additional spaces and norms, which will facilitate further analysis below of the operator F_R, as well as the theory given in section 3.

We will define a new R-dependent topology on $L_2(0,1)$ via

$$\langle x, y\rangle_{\sigma,R} \equiv \frac{\mathcal{C}^2 - 1}{R}\int_0^R e^{-2\sigma t}x(t)\,y(t)\,dt + \int_0^1 e^{-2\sigma t}x(t)\,y(t)\,dt, \tag{2.11}$$

where $\sigma > 0$ and $\mathcal{C} > 1$, with further conditions on these constants to be specified later. We will designate by $\|\cdot\|_{\sigma,R}$ the usual norm associated with this inner product and let $L_2^{\sigma,R}(0,1)$ denote the space $L_2(0,1)$ coupled with this R-dependent topology. The closed ball in $L_2^{\sigma,R}(0,1)$ centered at x_0 with radius r will be defined by

$$\mathcal{B}(x_0, r) = \{z \in L_2^{\sigma,R}(0,1),\ \|z - x_0\|_{\sigma,R} \le r\}. \tag{2.12}$$

The following lemma provides a technical estimate useful in the theory which follows.

LEMMA 2.2. *Let $g \in L_\infty(0,1)$. Then for σ, $\mathcal{C}$ defined above and $R \in (0, \bar{R}]$,*

$$\|g\|_{\sigma,R} \le \mathcal{C}\|g\|_\infty. \tag{2.13}$$

Proof. For any $T \in (0,1]$, $\int_0^T e^{-2\sigma t}|g(t)|^2\,dt \le T\|g\|_\infty^2$ so that

$$\|g\|_{\sigma,R}^2 \le \left(\frac{\mathcal{C}^2-1}{R}R + 1\right)\|g\|_\infty^2. \qquad \square$$

LEMMA 2.3. *The operator $F_R : L_2^{\sigma,R}(0,1) \to L_2^{\sigma,R}(0,1)$ as defined in (2.6) is Fréchet differentiable with*

$$F_R'(x)(h)(t) = 2\int_0^R \int_\rho^t x(t+\rho-s)\,h(s)\,ds\,d\eta(\rho), \quad \text{a.e. } t \in (0,1), \tag{2.14}$$

for $h \in L_2^{\sigma,R}(0,1)$. Further, F_R' is uniformly Lipschitz in $L_2^{\sigma,R}(0,1)$ for all $R > 0$ sufficiently small; i.e., there exists some constant $k > 0$ such that

$$\|F_R'(x_1) - F_R'(x_2)\| \le k\|x_1 - x_2\|_{\sigma,R}$$

for $x_1, x_2 \in L_2^{\sigma,R}(0,1)$, where $\|\cdot\|$ denotes the usual $\mathcal{L}(L_2^{\sigma,R}(0,1))$ operator norm.

Proof. Standard arguments (e.g., see [8]) give (2.14). To show the Lipschitz condition, we let $x_1, x_2, h \in L_2^{\sigma,R}(0,1)$ and define

$$g(t;R) \equiv 2\int_0^R \int_\rho^t (x_1(t+\rho-s) - x_2(t+\rho-s))h(s)\,ds\,d\eta(\rho), \quad \text{a.e. } t \in (0,1).$$

Then

$$\begin{aligned}
&|g(t;R)| \\
&\le 2\int_0^R \left(\int_\rho^t e^{2\sigma\tau}e^{-2\sigma\tau}(x_1(\tau) - x_2(\tau))^2\,d\tau\right)^{1/2}\left(\int_\rho^t e^{2\sigma s}e^{-2\sigma s}h^2(s)\,ds\right)^{1/2} d\eta(\rho) \\
&\le 2e^{2\sigma}\,\|x_1 - x_2\|_{\sigma,R}\,\|h\|_{\sigma,R}\int_0^R d\eta(\rho)
\end{aligned}$$

for a.e. $t \in (0,1)$. It follows then from Lemma 2.2 that

$$\|F_R'(x_1) - F_R'(x_2)\| \le \left(2\,\mathcal{C}e^{2\sigma}\int_0^R d\eta(\rho)\right)\|x_1 - x_2\|_{\sigma,R}. \qquad \square$$

LEMMA 2.4. *Let $v, v_1, v_2 \in \mathcal{B}(0,r) \subseteq L_2^{\sigma,R}(0,1)$ and $x \in L_2^{\sigma,R}(0,1)$. Then the remainder*

$$\mathcal{R}_R(x,v) \equiv F_R(x+v) - F_R(x) - F_R'(x)v \tag{2.15}$$

of the Fréchet derivative $F_R'(x)$ satisfies

$$\|\mathcal{R}_R(x,v)\|_{\sigma,R} \le e^{2\sigma}\int_0^R d\eta(\rho)\,\|v\|_{\sigma,R}^2 \tag{2.16}$$

and

$$\begin{aligned}\|\mathcal{R}_R(x,v_1) - \mathcal{R}_R(x,v_2)\|_{\sigma,R} \\ \le 2\,e^{2\sigma}\int_0^R d\eta(\rho)\,\max\{\|v_1\|_{\sigma,R},\,\|v_2\|_{\sigma,R}\}\,\|v_1 - v_2\|_{\sigma,R}\end{aligned} \tag{2.17}$$

for all $R > 0$ sufficiently small.

Proof. As in Lemma 1 of [16] and Lemma 2.2 of [8], we may write

$$\mathcal{R}_R(x,v) = \int_0^1 (F_R'(x+tv) - F_R'(x))\,v\,dt,$$

$$\mathcal{R}_R(x,v_1) - \mathcal{R}_R(x,v_2) = \int_0^1 (F_R'(x+tv_1+(1-t)v_2) - F_R'(x))(v_1 - v_2)\,dt$$

and then apply the results of Lemma 2.3. $\square$

3. Convergence and well-posedness results. Our main convergence results are stated below. They are immediate consequences of Theorem 3.7 and Corollary 3.8, respectively, which are proved at the end of this section.

THEOREM 3.1. *Assume f^δ satisfies the $\mathcal{F}$-data assumption, and let $\tau_{\text{data}} = 1/2$ if $\mathcal{F} = C[0, 1+\bar{R}]$ and $\tau_{\text{data}} = 2/5$ if $\mathcal{F} = L_2(0, 1+\bar{R})$. Let the measure η be given satisfying* (2.8)–(2.9).

Then there exist $\bar{C} > 0$ and $\kappa_1 > 0$ independent of R such that, if the true solution $\bar{x} \in W^{2,\infty}[0, 1+\bar{R}]$ of the autoconvolution equation is positive and satisfies

$$\bar{x}(0) > \bar{C}\,\|\bar{x}'\|_\infty, \tag{3.1}$$

then, for $R = R(\delta) > 0$ selected satisfying

$$\kappa_1 \delta^{\tau_{\text{data}}} \le R(\delta) \le c\,\delta^p \tag{3.2}$$

for any $c > 0$ and $p \in (0, \tau_{\text{data}}]$ ($c \ge \kappa_1$ if $p = \tau_{\text{data}}$) as $\delta \to 0$, it follows that there is a unique solution $x^\delta_{R(\delta)}$ of the regularization equation (2.4) *associated with data f^δ which depends continuously on $f^\delta \in \mathcal{F}$ and which satisfies*

$$\|x^\delta_{R(\delta)} - \bar{x}\|_{L_2(0,1)} = \mathcal{O}(\delta^p) \tag{3.3}$$

as $\delta \to 0$, with an optimal rate obtained for $p = \tau_{\text{data}}$. Thus the optimal convergence rate for continuous data is $\mathcal{O}(\delta^{1/2})$, and the optimal convergence rate for L_2 data is $\mathcal{O}(\delta^{2/5})$.

Proof. Let $\kappa_1 = k_1^{-\tau_{\text{data}}}$, where k_1 is defined in the proof of Theorem 3.7 below. Then assumption (3.2) becomes $\delta \leq k_1 R^{1/(\tau_{\text{data}})}$, and with this assumption Theorem 3.7 gives

$$\|x_R^\delta - \bar{x}\|_{\sigma,R} \leq \hat{C} R$$

for all $R > 0$ sufficiently small. Since

$$\|x_R^\delta - \bar{x}\|_{L_2(0,1)}^2 \leq e^{2\sigma} \int_0^1 e^{-2\sigma t} |x_\delta^R - \bar{x}|^2 \, dx \leq e^{2\sigma} \|x_R^\delta - \bar{x}\|_{\sigma,R}^2,$$

the result follows. ∎

Condition (3.1) is an a priori condition or source condition on the true solution $\bar{x}$, a sufficient condition needed to obtain the convergence rate (3.3) in theory. We note that Example 2 in section 6 below illustrates that this a priori condition is evidently *not* always needed in practice. The particular nature of this a priori condition reflects the fact that the ill-posedness of the original problem increases as $\bar{x}(0)$ approaches zero; thus if $\bar{x}$ is such that $\bar{x}(0)$ is close to zero, the a priori condition says that convergence is assured provided $\bar{x}$ is relatively "flat." To further explore this restriction, note that, for any $y \in W^{1,\infty}(0, 1 + \bar{R})$,

$$\frac{\int_0^R y(t+\rho)\, d\eta(\rho)}{\int_0^R d\eta(\rho)} = y(t)\left(1 + \mathcal{O}(R\,\|y'\|_\infty)\right), \quad \text{a.e. } t \in (0,1),$$

so that the degree to which, for a given value of $R > 0$, the measure is able to recover information about y depends to a large extent on the size of $\|y'\|_\infty$; i.e., flat functions y are handled better under a local averaging process than are functions y with a lot of local variation. Thus, for very ill-posed autoconvolution problems, the source condition says that a method based on local averaging will perform better if the true solution $\bar{x}$ is relatively flat. It is worth noting that a condition like this arises in other areas associated with local regularization; for example, in [4], where a discrepancy principle is developed for the determination of the appropriate value of $R \in (0, \bar{R}]$ in the case of linear Volterra problems, one needs to have the true data f satisfy a similar condition on $\|f'\|_\infty$, a condition which is less restrictive if the value of $\bar{R}$ is small and more restrictive if $\bar{R}$ is relatively large.

As the next corollary shows, we may dispense with the source condition (3.1) entirely if we have knowledge of the actual value of $\bar{x}(0) > 0$ (or an approximation $\hat{x}(0; R)$ to it, as is discussed in Remark 3.3 below) and make use of this information in the construction of our measure η. The proof of this result follows immediately from Corollary 3.8.

COROLLARY 3.2. *Let $\bar{x} \in W^{2,\infty}[0, 1 + \bar{R}]$ be positive. Assume that the perturbed data f^δ satisfy the $\mathcal{F}$-data assumption, and let $\tau_{\text{data}} = 1/2$ if $\mathcal{F} = C[0, 1 + \bar{R}]$ and $\tau_{\text{data}} = 2/5$ if $\mathcal{F} = L_2(0, 1 + \bar{R})$. Assume that the measure η satisfies* (2.8)–(2.9) *with $\bar{\omega}$, $\underline{\omega}$ in* (2.9) *satisfying*

$$\frac{\bar{\omega}}{\underline{\omega}} \leq \tilde{K}\, \bar{x}(0) \tag{3.4}$$

for all $R > 0$ sufficiently small, where $\tilde{K}$ is independent of R and $\bar{x}$.

Then there exists $\kappa_1 > 0$ independent of R such that, if $R = R(\delta) > 0$ is selected satisfying

$$\kappa_1 \delta^{\tau_{\text{data}}} \le R(\delta) \le c\,\delta^p$$

for any $c > 0$ and $p \in (0, \tau_{\text{data}}]$ ($c \ge \kappa_1$ if $p = \tau_{\text{data}}$) as $\delta \to 0$, it follows that there is a unique solution $x^\delta_{R(\delta)}$ of the regularization equation (2.4) associated with data f^δ which depends continuously on $f^\delta \in \mathcal{F}$ and which satisfies

$$\|x^\delta_{R(\delta)} - \bar{x}\|_{L_2(0,1)} = \mathcal{O}(\delta^p)$$

as $\delta \to 0$, with the optimal rate obtained for $p = \tau_{\text{data}}$. Thus the optimal convergence rate for continuous data is $\mathcal{O}(\delta^{1/2})$, and the optimal convergence rate for L_2 data is $\mathcal{O}(\delta^{2/5})$.

Remark 3.3. Despite the presence of $\bar{x}(0)$ in condition (3.4) of Corollary 3.2, it is not necessary to know $\bar{x}(0)$ exactly in order to have such a condition hold. It is enough to have some basic information about the size of $\bar{x}$ and to have an approximation $\hat{x}(0;R)$ of $\bar{x}(0)$ satisfying

$$|\bar{x}(0) - \hat{x}(0;R)| = \mathcal{O}(R) \tag{3.5}$$

as $R \to 0$. (In the next section we will show that an $\mathcal{O}(R)$ approximation to $\bar{x}(0)$ is easily found.) For example, in the case where it is known that $\bar{x}(0) > 1$, then for $\hat{R}$ sufficiently small we have $1 < \hat{x}(0,\hat{R}) < (\hat{x}(0,\hat{R}))^2$, and we may define

$$\underline{\omega} = \hat{x}(0,\hat{R}), \quad \bar{\omega} = (\hat{x}(0;\hat{R}))^2.$$

Then

$$\frac{\bar{\omega}}{\underline{\omega}} = \hat{x}(0,\hat{R}) \le 2\bar{x}(0)$$

for $\hat{R}$ sufficiently small, so that (3.4) holds with $\tilde{K} = 2$. Once $\bar{\omega}$ and $\underline{\omega}$ have been specified, one can always find a suitable R-dependent family of measures η satisfying (2.8)–(2.9) using these choices of constants; for example, let η be given by (2.8) where $\omega(\cdot;R)$ is the line on $[0,R]$ joining $(0,\underline{\omega})$ to $(R,\bar{\omega})$.

To begin the arguments needed to prove the main convergence results given above, we first rewrite (2.2) using similar notation to that used in (2.4). That is, the solution $\bar{x}$ of the original autoconvolution equation satisfies

$$\alpha_R(\bar{x})\bar{x} + F_R(\bar{x}) = f_R + \epsilon_R, \tag{3.6}$$

where

$$\epsilon_R(t) \equiv 2\int_0^R \int_0^\rho (\bar{x}(t) - \bar{x}(t+\rho-s))\,\bar{x}(s)\,ds\,d\eta(\rho), \quad \text{a.e. } t \in (0,1), \tag{3.7}$$

$\alpha_R(\bar{x})$ and $F_R(\bar{x})$ are defined as in (2.5)–(2.6), here using $\bar{x}$ instead of x, and f_R is defined as in (2.7) using f instead of f^δ.

For $h \in L_2^{\sigma,R}(0,1)$ we define bounded linear operators in $L_2^{\sigma,R}(0,1)$:

$$B_R(\bar{x})(h)(t) \equiv 2\int_0^R \int_0^t \bar{x}(t+\rho-s)\,h(s)\,ds\,d\eta(\rho), \tag{3.8}$$

$$D_R(\bar{x})(h)(t) \equiv 2\int_0^R \int_0^\rho \bar{x}(t+\rho-s)\,h(s)\,ds\,d\eta(\rho) \tag{3.9}$$

for a.e. $t \in (0,1)$ and note that

$$F_R'(\bar{x})(h)(t) = B_R(\bar{x})(h)(t) - D_R(\bar{x})(h)(t), \quad \text{a.e. } t \in (0,1). \tag{3.10}$$

We may then use the expansion of $F_R(x)$ in (2.4) to write

$$\alpha_R(x)x + F_R(\bar{x}) + F_R'(\bar{x})(x-\bar{x}) + \mathcal{R}_R(\bar{x}, x-\bar{x}) = f_R^\delta. \tag{3.11}$$

Combining (3.6) and (3.10) with (3.11), we obtain

$$\begin{aligned}(\alpha_R(\bar{x})I + B_R(\bar{x}))(x-\bar{x}) = f_R^\delta - f_R - \epsilon_R - \mathcal{R}_R(\bar{x}, x-\bar{x}) \\ + D_R(\bar{x})(x-\bar{x}) + (\alpha_R(\bar{x}) - \alpha_R(x))x,\end{aligned} \tag{3.12}$$

where I is the identity operator on $L_2^{\sigma,R}(0,1)$. Let us further denote for $v \in L_2^{\sigma,R}(0,1)$ that

$$E_R(\bar{x}, v) = D_R(\bar{x})(v) - \alpha_R(v)\,\bar{x}, \tag{3.13}$$

where we note that $v \to E_R(\bar{x}, v)$ is linear. Then (3.12) becomes

$$\begin{aligned}(\alpha_R(\bar{x})I + B_R(\bar{x}))(x-\bar{x}) = f_R^\delta - f_R - \epsilon_R - \mathcal{R}_R(\bar{x}, x-\bar{x}) \\ + E_R(\bar{x}, x-\bar{x}) + (\alpha_R(x) - \alpha_R(\bar{x}))(\bar{x}-x).\end{aligned} \tag{3.14}$$

The following two lemmas will be used to establish the invertibility of the operator $(\alpha_R(\bar{x})I + B_R(\bar{x})) \in \mathcal{L}(L_2^{\sigma,R}(0,1))$.

LEMMA 3.4. *If $\bar{x} \in W^{2,\infty}[0, 1+\bar{R}]$ and $\bar{x}(t) > 0$ for $t \in [0, 1+\bar{R}]$, then there exists $\sigma_0 > 0$ independent of $R > 0$ such that the operator $B_R(\bar{x})$ is accretive in $L_2^{\sigma,R}(0,1)$ for $\sigma \geq \sigma_0$; i.e.,*

$$\langle B_R(\bar{x})v, v\rangle_{\sigma,R} \geq 0 \qquad \textit{for any} \quad v \in L_2^{\sigma,R}(0,1),$$

where B_R is defined using a measure η satisfying (2.8)–(2.9).

Proof. Following the ideas of [16], only now with R-dependent quantities, we make the definition for $t \in [0,1]$, $a_R(t) \equiv 2\int_0^R \bar{x}(t+\rho)\,d\eta(\rho)$, so that we may write, for $h \in L_2^{\sigma,R}(0,1)$,

$$B_R(\bar{x})(h)(t) = \int_0^t a_R(t-s)h(s)\,ds, \quad \text{a.e. } t \in (0,1). \tag{3.15}$$

For all σ sufficiently large, we will first show that the operator $B_R^\sigma(\bar{x})$ is accretive in $L_2(0,1)$, where $B_R^\sigma(\bar{x})$ is defined as in (3.15) except that the kernel $a_R(t)$ for B_R is replaced by $a_R[\sigma](t) = e^{-\sigma t}a_R(t)$. Defining

$$A_0 = \min_{t\in[0,1+\bar{R}]} \bar{x}(t) > 0, \qquad A_1 = \|\bar{x}'\|_{L^\infty[0,1+\bar{R}]}, \qquad A_2 = \|\bar{x}''\|_{L^\infty[0,1+\bar{R}]},$$

then

$$\min_{t\in[0,1]} a_R(t) \geq 2\,A_0 \int_0^R d\eta(\rho),$$

$$\|a_R'\|_{L^\infty[0,1]} \leq 2\,A_1 \int_0^R d\eta(\rho),$$

$$\|a_R''\|_{L^\infty[0,1]} \leq 2\,A_2 \int_0^R d\eta(\rho),$$

and, for a.e. $t \in (0,1)$,

$$a_R[\sigma](t) \ge e^{-\sigma t}\left(2\,A_0\int_0^R d\eta(\rho)\right),$$

$$a_R'[\sigma](t) \le e^{-\sigma t}\,2\,(-\sigma A_0 + A_1)\int_0^R d\eta(\rho),$$

$$a_R''[\sigma](t) \ge e^{-\sigma t}\,2\,(\sigma^2 A_0 - 2\sigma A_1 - A_2)\int_0^R d\eta(\rho).$$

For $\sigma \ge \sigma_0$, where

$$\sigma_0 \ge \frac{A_1 + \sqrt{A_1^2 + A_0 A_2}}{A_0} \qquad \text{(independent of } R\text{)},$$

we then have from the positivity of η that

$$a_R[\sigma](t) \ge 0, \qquad a_R[\sigma]'(t) \le 0, \qquad a_R[\sigma]''(t) \ge 0$$

for a.e. $t \in (0,1)$.

Therefore, the kernel $a_R[\sigma](\cdot)$ is nonnegative, nonincreasing, and convex. Using Lemma 2 of [16] for $\sigma \ge \sigma_0$, we have $B_R^\sigma(\bar{x})$ accretive on $L_2(0,1)$, from which it follows that $B_R(\bar{x})$ is accretive in $L_2(0,1)$ with a weighted $e^{-2\sigma t}$ norm. A similar statement may be made for $B_R(\bar{x})$ using a weighted $L_2(0,R)$ norm, from which it follows that $B_R(\bar{x})$ is accretive in $L_2^{\sigma,R}(0,1)$ for all $\sigma \ge \sigma_0$. ∎

LEMMA 3.5. *Let $\bar{x} \in C^1[0, 1+\bar{R}]$ satisfy $\bar{x}(0) > 0$, and assume that the measure η satisfies* (2.8)–(2.9). *Then for $R > 0$ sufficiently small we have $\alpha_R(\bar{x}) > 0$ and*

$$\frac{1}{\alpha_R(\bar{x})} \le \frac{1}{\bar{x}(0)\int_0^R \rho\, d\eta(\rho)}. \tag{3.16}$$

Proof. We can write

$$\alpha_R(\bar{x}) = 2\,\bar{x}(0)\int_0^R \rho\, d\eta(\rho)\;[1 + h(R)]\,,$$

where

$$h(R) = \frac{1}{\bar{x}(0)\int_0^R \rho\, d\eta(\rho)}\int_0^R\int_0^\rho s\,\bar{x}'(\xi(s))\,ds\,d\eta(\rho)$$

for some $\xi(s) \in [0,R]$. But

$$|h(R)| \le \frac{1}{\bar{x}(0)\int_0^R \rho\, d\eta(\rho)}\,\|\bar{x}'\|_\infty \int_0^R \frac{\rho^2}{2}\,d\eta(\rho) \le \frac{\|\bar{x}'\|_\infty K(2)}{2\,\bar{x}(0)}R,$$

where $K(2)$ is defined in (2.10), so it follows that

$$\frac{1}{\alpha_R(\bar{x})} = \frac{1}{2\,\bar{x}(0)\int_0^R \rho\, d\eta(\rho)}\,(1 + \mathcal{O}(R)) \quad \text{as } R \to 0. \qquad ∎$$

As a consequence of Lemmas 3.4 and 3.5, we have that if $\bar{x} \in W^{2,\infty}[0, 1+\bar{R}]$ with $\bar{x}(0) > 0$, then $\alpha_R(\bar{x}) > 0$ and $(\alpha_R(\bar{x})I + B_R(\bar{x}))^{-1} \in \mathcal{L}(L_2^{\sigma,R}(0,1))$ for all $R > 0$ sufficiently small; in addition, we have the following estimate (see [33]):

$$\|(\alpha_R(\bar{x})I + B_R(\bar{x}))^{-1}\| \leq \frac{1}{\alpha_R(\bar{x})} \tag{3.17}$$

for $\|\cdot\|$ the $\mathcal{L}(L_2^{\sigma,R}(0,1))$ operator norm and for $\sigma \geq \sigma_0$, where $\sigma_0 > 0$ is independent of R.

We are now ready to rewrite our regularized equation (2.4) as

$$x = H_R\, x, \tag{3.18}$$

where, from (3.14), $H_R : L_2^{\sigma,R}(0,1) \mapsto L_2^{\sigma,R}(0,1)$ is given by

$$\begin{aligned} H_R\, x = (\alpha_R(\bar{x})I + B_R(\bar{x}))^{-1}[f_R^\delta - f_R - \epsilon_R - \mathcal{R}_R(\bar{x}, x-\bar{x}) \\ + E_R(\bar{x}, x-\bar{x}) + (\alpha_R(x) - \alpha_R(\bar{x}))(\bar{x}-x)] + \bar{x}. \end{aligned} \tag{3.19}$$

In the next lemma we bound relevant quantities on the right-hand side of (3.19).

LEMMA 3.6. *Let $\bar{x} \in C^1[0, 1+\bar{R}]$ satisfy $\bar{x}(0) > 0$, let f^δ satisfy the $\mathcal{F}$-data assumption, assume the measure η satisfies* (2.8)–(2.9), *and let $\sigma > 0$. Let $x_1, x_2 \in L_2^{\sigma,R}(0,1)$. Then*

$$\|f_R^\delta - f_R\|_{\sigma,R} \leq \begin{cases} \delta\, \mathcal{C}\, \bar{\omega}\, R & \text{if } \mathcal{F} = C[0, 1+\bar{R}], \\ \delta\, \mathcal{C}\, \bar{\omega}\, R^{1/2} & \text{if } \mathcal{F} = L_2(0, 1+\bar{R}), \end{cases} \tag{3.20}$$

$$\|E_R(\bar{x}, x_1 - x_2)\|_{\sigma,R} \leq \mathcal{C}\, \frac{2e^{\sigma,R}}{\sqrt{3}} \|\bar{x}'\|_\infty \|x_1 - x_2\|_{\sigma,R} \int_0^R \rho^{3/2}\, d\eta(\rho), \tag{3.21}$$

$$\|\epsilon_R\|_{\sigma,R} \leq 2\, \mathcal{C} \sqrt{\frac{2}{3}} \|\bar{x}'\|_\infty \left(\bar{x}(0) \int_0^R \rho^2\, d\eta(\rho) + \frac{\|\bar{x}'\|_\infty}{\sqrt{3}} \int_0^R \rho^3\, d\eta(\rho) \right), \tag{3.22}$$

and

$$|\alpha_R(x_1) - \alpha_R(x_2)| \leq 2\, e^{\sigma R} \sqrt{\frac{R}{\mathcal{C}^2 - 1}}\, \|x_1 - x_2\|_{\sigma,R} \int_0^R \rho^{1/2}\, d\eta(\rho). \tag{3.23}$$

Proof. The bounds in (3.20)–(3.22) each follow from applications of Lemma 2.2 using obvious choices of the function $g = g(\cdot; R)$. Inequality (3.20) is straightforward in the case of $f^\delta \in C[0, 1+\bar{R}]$ since

$$\begin{aligned} |f_R^\delta(t) - f_R(t)| &= \left| \int_0^R (f^\delta(t+\rho) - f(t+\rho))\, \omega(\rho; R)\, d\rho \right| \\ &\leq \delta\, \bar{\omega}\, R. \end{aligned}$$

For the case of $f^\delta \in L_2(0, 1+\bar{R}]$ we observe that $f_R^\delta - f_R \in L_\infty(0,1)$ since

$$\begin{aligned} |f_R^\delta(t) - f_R(t)| &\leq \left(\int_0^R |f^\delta(t+\rho) - f(t+\rho)|^2 d\rho \right)^{1/2} \left(\int_0^R |\omega(\rho; R)|^2 d\rho \right)^{1/2} \\ &\leq \|f^\delta - f\|_{L_2(0,1+\bar{R})}\, \bar{\omega}\, R^{1/2} \end{aligned}$$

for a.e. $t \in (0, 1+\bar{R})$. The result then follows from Lemma 2.2.

For (3.21) we use the fact that, for a.e. $t \in (0,1)$,

$$\begin{aligned}
&|E_R(\bar{x}, x_1 - x_2)(t)| \\
&\le 2\int_0^R \int_0^\rho |\bar{x}(t+\rho-s) - \bar{x}(t)|\, |x_1(s) - x_2(s)|\, ds\, d\eta(\rho) \\
&\le 2\|\bar{x}'\|_\infty \int_0^R \left(\int_0^\rho (\rho - s)^2\, ds\right)^{1/2} \left(\int_0^\rho e^{2\sigma s} e^{-2\sigma s} |x_1(s) - x_2(s)|^2\, ds\right)^{1/2} d\eta(\rho).
\end{aligned}$$

For (3.22) we observe that, for some $\xi \in (0, R)$,

$$\begin{aligned}
|\epsilon_R(t)| &\le 2\|\bar{x}'\|_\infty \int_0^R \left(\int_0^\rho (\rho - s)^2\, ds\right)^{1/2} \left(\int_0^\rho \left(\bar{x}(0)\, ds + \bar{x}'(\xi)\, s\right)^2\, ds\right)^{1/2} d\eta(\rho) \\
&\le 2\|\bar{x}'\|_\infty \int_0^R \left[\frac{\rho^3}{3} 2\left(\bar{x}(0)^2\, \rho + \|\bar{x}'\|_\infty^2\, \frac{\rho^3}{3}\right)\right]^{1/2} d\eta(\rho) \\
&\le 2\|\bar{x}'\|_\infty \int_0^R \sqrt{\frac{2}{3}}\, \rho^{3/2} \left(\bar{x}(0)\rho^{1/2} + \|\bar{x}'\|_\infty \frac{\rho^{3/2}}{\sqrt{3}}\right) d\eta(\rho)
\end{aligned}$$

for a.e. $t \in (0,1)$, from which the bound in (3.22) follows.

Finally, by using the fact that

$$\begin{aligned}
|\alpha_R(x_1) - \alpha_R(x_2)| &\le 2\int_0^R \left|\int_0^\rho (x_1(s) - x_2(s))\, ds\right| d\eta(\rho) \\
&\le 2\, e^{\sigma R} \left(\int_0^R e^{-2\sigma t} |x_1(t) - x_2(t)|^2\, dt\right)^{1/2} \int_0^R \rho^{1/2} d\eta(\rho),
\end{aligned}$$

the estimate in (3.23) is obtained. ∎

We are now ready to state our main convergence results which are given below in Theorem 3.7 and Corollary 3.8.

THEOREM 3.7. *Assume that f^δ satisfies the $\mathcal{F}$-data condition, and let $\tau_{\text{data}} = 1/2$ in the case of $\mathcal{F} = C[0, 1+\bar{R}]$ and $\tau_{\text{data}} = 2/5$ in the case of $\mathcal{F} = L_2(0, 1+\bar{R})$. Assume that the measure $\eta(\rho) > 0$ satisfies (2.8)–(2.9) and that the autoconvolution problem (1.1) has a positive solution $\bar{x} \in W^{2,\infty}[0, 1+\bar{R}]$ satisfying*

$$\bar{x}(0) > 9\, b^2\, e^{2\sigma}\, \|\bar{x}'\|_\infty \tag{3.24}$$

for $\sigma \ge \sigma_0$ and $b \ge 2\bar{\omega}/\underline{\omega}$, where $\bar{\omega}, \underline{\omega}$ are given in (2.8). Then for any $\mathcal{C} \in (1, 9/8]$ there exist constants $k_1 > 0$ and $\hat{C} = \hat{C}(\mathcal{C}) > 0$ independent of R such that, if $\delta = \delta(R) > 0$ satisfies

$$\delta \le k_1 R^{1/\tau_{\text{data}}}, \tag{3.25}$$

then for all $R > 0$ sufficiently small the regularized equation (3.18) has a unique solution $x_R^\delta \in L_2^{\sigma,R}(0,1)$ satisfying

$$\|x_R^\delta - \bar{x}\|_{\sigma,R}^2 \le \hat{C}^2 R^2,$$

where $\|\cdot\|_{\sigma,R}$ *is defined from* (2.11) *using the value of* $\mathcal{C}$ *given above. Further,* $x_R^\delta \in L_2^{\sigma,R}(0,1)$ *depends continuously on* $f^\delta \in \mathcal{F}$ *for all* $R > 0$ *sufficiently small.*

Proof. We will apply the contraction mapping principle to the regularized equation (3.18) in the ball $\mathcal{B}(\bar{x}, \hat{C}R)$. From Lemmas 2.4, 3.5, and 3.6 and inequality (3.17) we have

$$\begin{aligned}
\|H_R x - \bar{x}\|_{\sigma,R} &\le \frac{1}{\alpha(\bar{x})}\|f_R^\delta - f_R\|_{\sigma,R} + \frac{1}{\alpha(\bar{x})}\|\mathcal{R}_R(\bar{x}, x-\bar{x})\|_{\sigma,R} + \frac{1}{\alpha(\bar{x})}\|\epsilon_R\|_{\sigma,R} \\
&\quad + \frac{1}{\alpha(\bar{x})}\|E_R(\bar{x}, x-\bar{x})\|_{\sigma,R} + \frac{|\alpha_R(x) - \alpha_R(\bar{x})|}{\alpha_R(\bar{x})}\|x-\bar{x}\|_{\sigma,R} \\
&\le \frac{\delta\,\mathcal{C}}{\bar{x}(0)}\,\frac{2\bar{\omega}}{\underline{\omega}}\,R^p + \frac{e^{2\sigma}}{\bar{x}(0)}\,\frac{2\bar{\omega}}{\underline{\omega}}\,R^{-1}\,\|x-\bar{x}\|_{\sigma,R}^2 \\
&\quad + 2\,\mathcal{C}\sqrt{\frac{2}{3}}\,\|\bar{x}'\|_\infty\left(\frac{2\bar{\omega}}{3\underline{\omega}}\,R + \frac{\|\bar{x}'\|_\infty}{\sqrt{3}\,\bar{x}(0)}\,K(3)\,R^2\right) \\
&\quad + \frac{2\,\mathcal{C}\,\|\bar{x}'\|_\infty\,e^{\sigma R}}{\sqrt{3}\,\bar{x}(0)}\,K(\tfrac{3}{2})\,R^{1/2}\,\|x-\bar{x}\|_{\sigma,R} \\
&\quad + \frac{2\,e^{\sigma R}}{\bar{x}(0)}\,K(\tfrac{1}{2})\,R^{-1/2}\,\|x-\bar{x}\|_{\sigma,R}^2\,\sqrt{\frac{R}{\mathcal{C}^2-1}}
\end{aligned}$$

for $\sigma \ge \sigma_0$, where $p = -1$ for $\mathcal{F} = C[0, 1+\bar{R}]$ and $p = -3/2$ for $\mathcal{F} = L_2(0, 1+\bar{R})$. Using assumption (3.25) and the fact that $\|x-\bar{x}\|_{\sigma,R} \le \hat{C}R$, we have

$$\begin{aligned}
\|H_R x - \bar{x}\|_{\sigma,R} &\le \frac{k_1\mathcal{C}}{\bar{x}(0)}\,\frac{2\bar{\omega}}{\underline{\omega}}R + \frac{e^{2\sigma}}{\bar{x}(0)}\,\frac{2\bar{\omega}}{\underline{\omega}}\,\hat{C}^2R + 2\mathcal{C}\sqrt{\frac{2}{3}}\,\|\bar{x}'\|_\infty\,\frac{2\bar{\omega}}{3\underline{\omega}}\,R \\
&\quad + \frac{2\sqrt{2}\,\mathcal{C}\|\bar{x}'\|_\infty^2}{3\bar{x}(0)}\,K(3)R^2 + \frac{2\,\mathcal{C}\,\|\bar{x}'\|_\infty e^{\sigma R}}{\sqrt{3}\,\bar{x}(0)}\,K(\tfrac{3}{2})\,\hat{C}R^{\frac{3}{2}} + \frac{2\,e^{\sigma R}\,K(\frac{1}{2})}{\bar{x}(0)}\,\frac{\hat{C}^2R^2}{\sqrt{\mathcal{C}^2-1}}.
\end{aligned}$$

Therefore to have $\|H_R x - \bar{x}\|_{\sigma,R} \le \hat{C}R$ for some $\hat{C} > 0$ and all $R > 0$ sufficiently small, a sufficient condition is that

$$\frac{1}{\bar{x}(0)}\,b\,k_1\,\mathcal{C} + \|\bar{x}'\|_\infty\,b\,\mathcal{C} + \frac{e^{2\sigma}}{\bar{x}(0)}\,b\,\hat{C}^2 < \hat{C}. \tag{3.26}$$

If we let

$$k_1 = \|\bar{x}'\|_\infty\,\bar{x}(0), \tag{3.27}$$

then (3.26) becomes

$$L(\hat{C}) \equiv \frac{e^{2\sigma}\,b}{\bar{x}(0)}\,\hat{C}^2 - \hat{C} + 2\,b\,\mathcal{C}\,\|\bar{x}'\|_\infty < 0. \tag{3.28}$$

It is not hard to see that $L(\hat{C}) = 0$ has two distinct positive solutions $0 < \hat{C}_1 < \hat{C}_2$ by assumption (3.24) when $\mathcal{C} \in (1, 9/8]$. Then for $\hat{C}$ satisfying $\hat{C}_1 < \hat{C} < \hat{C}_2$ we have $L(\hat{C}) < 0$, and thus $\|H_R x - \bar{x}\|_{\sigma,R} \le \hat{C}R$ for all $R > 0$ sufficiently small.

To further demonstrate that H_R is a contraction on $\mathcal{B}(\bar{x}, \hat{C}R)$, we let $x_1, x_2 \in \mathcal{B}(\bar{x}, \hat{C}R)$ and note that

$$
\begin{aligned}
(3.29)\quad & \|H_R\, x_1 - H_R\, x_2\|_{\sigma,R} \\
&= \| \left(\alpha_R(\bar{x})I + B_R(\bar{x})\right)^{-1} \{\mathcal{R}_R(\bar{x}, x_2 - \bar{x}) - \mathcal{R}_R(\bar{x}, x_1 - \bar{x}) + E_R(\bar{x}, x_1 - x_2) \\
&\qquad - [(\alpha_R(x_1) - \alpha_R(\bar{x}))(x_1 - \bar{x}) - (\alpha_R(x_2) - \alpha_R(\bar{x}))(x_2 - \bar{x})]\,\} \|_{\sigma,R} \\
&\le T_R(x_1, x_2),
\end{aligned}
$$

where

$$
\begin{aligned}
T_R(x_1, x_2) \equiv & \frac{1}{\alpha_R(\bar{x})} \|\mathcal{R}_R(\bar{x}, x_2 - \bar{x}) - \mathcal{R}_R(\bar{x}, x_1 - \bar{x})\|_{\sigma,R} \\
& + \frac{1}{\alpha_R(\bar{x})} \|E_R(\bar{x}, x_1 - x_2)\|_{\sigma,R} \\
& + \frac{1}{\alpha_R(\bar{x})} \|(\alpha_R(x_1) - \alpha_R(\bar{x}))(x_1 - \bar{x}) - (\alpha_R(x_2) - \alpha_R(\bar{x}))(x_2 - \bar{x})\|_{\sigma,R}.
\end{aligned}
$$

Since

$$
\begin{aligned}
& \frac{1}{\alpha_R(\bar{x})} \|(\alpha_R(x_1) - \alpha_R(\bar{x}))(x_1 - \bar{x}) - (\alpha_R(x_2) - \alpha_R(\bar{x}))(x_2 - \bar{x})\|_{\sigma,R} \\
&= \frac{1}{\alpha_R(\bar{x})} \|(\alpha_R(x_1) - \alpha_R(x_2))(x_1 - \bar{x}) + (\alpha_R(x_2) - \alpha_R(\bar{x}))(x_1 - x_2)\|_{\sigma,R} \\
&\le \frac{|\alpha_R(x_1) - \alpha_R(x_2)|}{\alpha(\bar{x})} \|x_1 - \bar{x}\|_{\sigma,R} + \frac{|\alpha_R(x_2) - \alpha_R(\bar{x})|}{\alpha(\bar{x})} \|x_1 - x_2\|_{\sigma,R} \\
&\le \frac{2e^{\sigma R} \int_0^R \rho^{\frac{1}{2}}\, d\eta(\rho)}{\bar{x}(0) \int_0^R \rho\, d\eta(\rho)} \sqrt{\frac{R}{\mathcal{C}^2 - 1}}\ \{\|x_1 - x_2\|_{\sigma,R} \|x_1 - \bar{x}\|_{\sigma,R} + \|x_2 - \bar{x}\|_{\sigma,R}\, \|x_1 - x_2\|_{\sigma,R}\} \\
&\le \frac{4e^{\sigma R} K(\frac{1}{2}) \hat{C} R}{\bar{x}(0)\sqrt{\mathcal{C}^2 - 1}} \|x_1 - x_2\|_{\sigma,R},
\end{aligned}
$$

we have

$$
\begin{aligned}
T_R(x_1, x_2) \le & \left[\frac{2e^{2\sigma}}{\bar{x}(0)}\, \frac{2\bar{\omega}}{\underline{\omega}}\, \hat{C}\right] \|x_1 - x_2\|_{\sigma,R} \\
& + \left[\frac{2\,\mathcal{C}\, \|\bar{x}'\|_\infty e^{\sigma R}}{\sqrt{3}\bar{x}(0)}\, K\left(\frac{3}{2}\right) R^{\frac{1}{2}} + \frac{4e^{\sigma R} K(\frac{1}{2}) \hat{C} R}{\bar{x}(0)\sqrt{\mathcal{C}^2 - 1}}\right] \|x_1 - x_2\|_{\sigma,R}.
\end{aligned}
$$

Thus if we require that

$$
(3.30)\qquad \hat{C} < \frac{\bar{x}(0)}{2\, e^{2\sigma}\, b},
$$

it follows that

$$
\hat{C} < \frac{\bar{x}(0)}{2e^{2\sigma}}\, \frac{\underline{\omega}}{2\bar{\omega}}
$$

and, for $R > 0$ sufficiently small,

$$\|H_R\, x_1 - H_R\, x_2\|_{\sigma,R} \le T_R(x_1, x_2) \le q\, \|x_1 - x_2\|_{\sigma,R}$$

for any $x_1, x_2 \in \mathcal{B}(\bar{x}, \hat{C}R)$ with some $q < 1$. Further we note that $\frac{\hat{C}_1+\hat{C}_2}{2} = \frac{\bar{x}(0)}{2\, e^{2\sigma}\, b}$, and therefore our regularized equation (3.18) has a unique solution x_R^δ in $\mathcal{B}(\bar{x}, \hat{C}R)$ for $\hat{C}$ satisfying $\hat{C}_1 < \hat{C} < \frac{\bar{x}(0)}{2\, e^{2\sigma}\, b}$.

Finally, fix $R > 0$ sufficiently small, and let $f_1^\delta, f_2^\delta \in \mathcal{F}$ satisfy

$$\|f_i^\delta - f\|_{\mathcal{F}} \le \delta \le k_1 R^{1/\tau_{\rm data}}, \quad i = 1, 2,$$

for the value of k_1 given in (3.27), where $\mathcal{F}$ is either $C[0, 1+\bar{R}]$ or $L_2(0, 1+\bar{R})$. Let $\hat{C}$, $\mathcal{C}$, σ, and q be as specified above, and let $f_{R,i}^\delta$ and $H_{R,i}$ be defined for $i = 1, 2$ as in (2.7) and (3.19), respectively, using f_i^δ instead of f^δ as data. Then for $i = 1, 2$ there exists a unique solution $x_{R,i}^\delta \in \mathcal{B}(\bar{x}, \hat{C}R) \subset L_2^{\sigma,R}(0,1)$ of the equation $x = H_{R,i}x$. Further,

$$\begin{aligned}
\|x_{R,1}^\delta - x_{R,2}^\delta\|_{\sigma,R} &= \|H_{R,1}x_{R,1}^\delta - H_{R,2}x_{R,2}^\delta\|_{\sigma,R} \\
&= \| \left(\alpha_R(\bar{x})I + B_R(\bar{x})\right)^{-1} \{ \left(f_{R,1}^\delta - f_{R,2}^\delta\right) \\
&\qquad + \mathcal{R}_R(\bar{x}, x_{R,2}^\delta - \bar{x}) - \mathcal{R}_R(\bar{x}, x_{R,1}^\delta - \bar{x}) + E_R(\bar{x}, x_{R,1}^\delta - x_{R,2}^\delta) \\
&\qquad - [(\alpha_R(x_{R,1}^\delta) - \alpha_R(\bar{x}))(x_{R,1}^\delta - \bar{x}) - (\alpha_R(x_{R,2}^\delta) - \alpha_R(\bar{x}))(x_{R,2}^\delta - \bar{x})] \} \|_{\sigma,R} \\
&\le \frac{1}{\alpha_R(\bar{x})} \|f_{R,1}^\delta - f_{R,2}^\delta\|_{\sigma,R} + T_R(x_{R,1}^\delta, x_{R,2}^\delta) \\
&\le \frac{\mathcal{C}\, \|f_1^\delta - f_2^\delta\|_{\mathcal{F}}}{\bar{x}(0)} \frac{2\bar{\omega}}{\underline{\omega}} R^p + q \|x_{R,1}^\delta - x_{R,2}^\delta\|_{\sigma,R},
\end{aligned}$$

where $p = -1$ in the case of $\mathcal{F} = C[0, 1+\bar{R}]$ and $p = -3/2$ in the case of $\mathcal{F} = L_2(0, 1+\bar{R})$ and where we have used arguments such as those needed to verify (3.20) in the first term above. Therefore

$$\|x_{R,1}^\delta - x_{R,2}^\delta\|_{\sigma,R} \le \frac{\mathcal{C}\, b}{(1-q)\bar{x}(0)}\, R^p\, \|f_1^\delta - f_2^\delta\|_{\mathcal{F}},$$

and continuous dependence of solutions on data is obtained for the regularized equation (3.18). ∎

COROLLARY 3.8. *Assume that the autoconvolution problem* (1.1) *has a positive solution* $\bar{x} \in W^{2,\infty}[0, 1+\bar{R}]$ *and that the measure* η *satisfies* (2.8)–(2.9) *with constants* $\bar{\omega}$, $\underline{\omega}$ *in* (2.9) *satisfying* (3.4) *for all* $R > 0$ *sufficiently small, where* $\tilde{K}$ *is independent of* R *and* $\bar{x}$. *Let* f^δ *satisfy the* $\mathcal{F}$*-data condition, and let* $\tau_{\rm data} = 1/2$ *in the case of* $\mathcal{F} = C[0, 1+\bar{R}]$ *and* $\tau_{\rm data} = 2/5$ *in the case of* $\mathcal{F} = L_2(0, 1+\bar{R})$.

Then there exist constants $k_1, \hat{C} > 0$ *independent of* R *such that, if* $\delta = \delta(R) > 0$ *satisfies*

$$\delta \le k_1 R^{1/\tau_{\rm data}}, \tag{3.31}$$

then for all $R > 0$ *sufficiently small the regularized equation* (3.18) *has a unique solution* $x_R^\delta \in L_2^{\sigma,R}(0,1)$ *satisfying*

$$\|x_R^\delta - \bar{x}\|_{\sigma,R}^2 \le \hat{C}^2 R^2,$$

where $\|\cdot\|_{\sigma,R}$ *is defined from* (2.11) *using the value of* $\mathcal{C} = \sqrt{2}$. *Further,* $x_R^\delta \in L_2^{\sigma,R}(0,1)$ *depends continuously on* $f^\delta \in \mathcal{F}$ *for all* $R > 0$ *sufficiently small.*

Proof. Let $\mathcal{C} = \sqrt{2}$, and define $\tilde{b} = 2\tilde{K}$, where $\tilde{K}$, given by (3.4), is independent of R and $\bar{x}$. We observe that without loss of generality we may assume that $\bar{x}$ satisfies

$$\bar{x}(0)\|\bar{x}'\|_\infty < \frac{\sqrt{2}\, e^{-2\sigma}}{16\,\tilde{b}^2}, \tag{3.32}$$

because if this does not already hold, we may rescale (1.1) via division by some $\kappa^2 > 1$ to obtain a new equation with data f/κ^2 and solution $\bar{y} = \bar{x}/\kappa$, where $\bar{y}$ satisfies (3.32). Note that a similar rescaling of η will not change the value of $\tilde{K}$, i.e., of $\tilde{b}$.

The proof of the corollary follows the proof of Theorem 3.7 with only a few changes. First we note that, if we let $b = \tilde{b}\bar{x}(0)$, then $b \geq 2\bar{\omega}/\underline{\omega}$, and (3.26) still holds from the proof of Theorem 3.7. Writing (3.26) in terms of $\tilde{b}$, we then have the following sufficient condition ensuring that $\|H_R x - \bar{x}\|_{\sigma,R} < \hat{C}R$ for some $\hat{C} > 0$:

$$k_1\tilde{b}\,\mathcal{C} + \|\bar{x}'\|_\infty\,\bar{x}(0)\,\tilde{b}\,\mathcal{C} + e^{2\sigma}\,\tilde{b}\,\hat{C}^2 < \hat{C}. \tag{3.33}$$

Defining k_1 as in (3.27), the inequality in (3.33) now becomes

$$L(\hat{C}) = e^{2\sigma}\,\tilde{b}\,\hat{C}^2 - \hat{C} + 2\|\bar{x}'\|_\infty\,\bar{x}(0)\,\tilde{b}\,\mathcal{C} < 0.$$

Under condition (3.32) the quadratic L has two distinct positive roots $0 < \hat{C}_1 < \hat{C}_2$ so that we may pick $\hat{C} \in (\hat{C}_1, \hat{C}_2)$ to guarantee that $L(\hat{C}) < 0$.

The remainder of the proof of Theorem 3.7 carries over without change; we note only that the new condition (3.30) on $\hat{C}$ in that proof creates no difficulty because here our roots $\hat{C}_1$ and $\hat{C}_2$ satisfy $\frac{\hat{C}_1+\hat{C}_2}{2} = \frac{1}{2e^{2\sigma}\tilde{b}} = \frac{\bar{x}(0)}{2e^{2\sigma}b}$ as needed for the proof of Theorem 3.7. ∎

4. Discretization. In this section, we will consider a discretized version of the regularized equation (2.4), which leads to a stable method on the interval $[0,1]$; the resulting method is nonlinear and nonsequential on the initial small interval $[0,R]$ but sequential and linear on the larger interval $[R,1]$.

We will consider a collocation-based discretization of (2.4) where, for simplicity, we will assume that the measure η is given by the Lebesgue measure, i.e.,

$$\int_0^R g(\rho)\,d\eta(\rho) = \int_0^R g(\rho)\,d\rho, \tag{4.1}$$

and note that condition (2.9) is satisfied in this case. Indeed our numerical results were so good using this simple measure that there seemed little need to construct a weighted measure based on an approximate value of $\bar{x}(0)$ as was discussed as a possibility in Remark 3.3.

Let $N = 1, 2, 3, \ldots$, and define

$$t_i = i\Delta t, \quad i = 0, 1, \ldots, N, \quad \Delta t = 1/N.$$

We will also let $R = r\Delta t$, where $r \in \{1, 2, \ldots, N\}$ is fixed ($r \ll N$, in general).

For $i = 2, 3, \ldots, N$, let $\chi_i(t)$ be the indicator function on the interval $(t_{i-1}, t_i]$ and $\chi_1(t)$ the indicator function on the interval $[t_0, t_1]$, and define the approximation

space of piecewise constant functions on $[0,1]$ by $\mathcal{S}_N = \text{span}\{\,\chi_i,\, i = 1,2,\ldots,N\}$. We then seek $x \in \mathcal{S}_N$ satisfying the collocation equations

$$2\int_0^R \int_0^\rho x(s)\,ds\,d\rho\,x(t_i) + \int_0^R \int_\rho^{t_i} x(t_i+\rho-s)\,x(s)\,ds\,d\rho = \int_0^R f^\delta(t_i+\rho)\,d\rho \tag{4.2}$$

for $i = 1,2,\ldots,N$. We will use the rectangular quadrature rule to approximate integrals on $[0,R]$, i.e.,

$$\int_0^R g(\rho)\,d\rho \approx \Delta t \sum_{j=0}^{r-1} g(t_j),$$

and incorporate this approximation directly into (4.2). Looking at each term in (4.2) we then make the following replacements:

$$\int_0^R f^\delta(t_i+\rho)\,d\rho \approx \Delta t \sum_{q=0}^{r-1} f^\delta(t_{i+q}),$$

and, letting $x(t) = \sum_{p=1}^N c_p \chi_p(t)$ for $t \in [0,1]$, we have

$$\begin{aligned} 2\int_0^R \int_0^\rho x(s)\,ds\,d\rho\,x(t_i) &\approx 2\Delta t \left(\int_0^0 x(s)\,ds + \int_0^{t_1} x(s)\,ds + \cdots + \int_0^{t_{r-1}} x(s)\,ds \right) c_i \\ &= 2\,(\Delta t)^2 \left(\sum_{l=1}^{r-1} \sum_{m=1}^{l} c_m \right) c_i, \end{aligned}$$

where we notice that the coefficient of c_i involves only $c_1, c_2, \ldots, c_{r-1}$. The second term of the left-hand side of (4.2) is more complicated, and, depending on the value of i in relation to r, we come to different forms for the term. In general, for any fixed $i = 1,2,\ldots,N$, we have

$$\int_0^R \int_\rho^{t_i} x(t_i+\rho-s)\,x(s)\,ds\,d\rho \approx \Delta t \sum_{j=0}^{r-1} \int_{t_j}^{t_i} x(t_{i+j}-s)x(s)\,ds. \tag{4.3}$$

Further investigation of (4.3) leads us to the following cases:

- If $i < r-1$, then

$$\begin{aligned} &\int_0^R \int_\rho^{t_i} x(t_i+\rho-s)\,x(s)\,ds\,d\rho \\ &\quad\approx (\Delta t)^2 \left[\sum_{m=1}^{i} \sum_{l=m}^{i} c_l\,c_{i+m-l} - \sum_{m=i+1}^{r-1} \sum_{l=i+1}^{m} c_l\,c_{i+1+m-l} \right], \end{aligned}$$

  which is nonlinear in c_i and involves all values of $c_1, c_2, \ldots, c_{r-1}$.
- If $i = r-1$, then

$$\int_0^R \int_\rho^{t_i} x(t_i+\rho-s)\,x(s)\,ds\,d\rho \approx (\Delta t)^2 \sum_{m=1}^{i} \sum_{l=m}^{i} c_l\,c_{i+m-l},$$

  which is also nonlinear in c_i and involves all values of $c_1, c_2, \ldots, c_{r-1}$.

- If $i \geq r$, then

$$\int_0^R \int_\rho^{t_i} x(t_i + \rho - s)\, x(s)\, ds\, d\rho \approx (\Delta t)^2 \sum_{m=1}^{r} \sum_{l=m}^{i} c_l\, c_{i+m-l}.$$

With this result, we notice that, specifically for $i = r$, (4.3) is quadratic in c_r once $c_1, c_2, \ldots, c_{r-1}$ are found. Even better, for $i > r$, (4.3) is linear in c_i once $c_1, c_2, \ldots, c_r$ are found.

Therefore, to determine the values for c_i, $i = 1, 2, \ldots, N$, we solve the following N equations:

- For $i = 1, 2, \ldots, r-2$, we have the first $r-2$ equations.

$$\left(2(\Delta t)^2 \sum_{l=1}^{r-1} \sum_{m=1}^{l} c_m\right) c_i$$

$$+ (\Delta t)^2 \left[\sum_{m=1}^{i} \sum_{l=m}^{i} c_l\, c_{i+m-l} - \sum_{m=i+1}^{r-1} \sum_{l=i+1}^{m} c_l\, c_{i+1+m-l}\right] = \Delta t \sum_{q=0}^{r+1} f^\delta(t_{i+q}).$$

Note that all values of $c_1, c_2, \ldots, c_{r-1}$ are involved in any of these $r-2$ equations.

- For $i = r-1$, we have the $(r-1)$th equation.

$$\left(2\,(\Delta t)^2 \sum_{l=1}^{r-1} \sum_{m=1}^{l} c_m\right) c_i + (\Delta t)^2 \sum_{m=1}^{i} \sum_{l=m}^{i} c_l\, c_{i+m-l} = \Delta t \sum_{q=0}^{r+1} f^\delta(t_{i+q}).$$

Note that all values of $c_1, c_2, \ldots, c_{r-1}$ are also involved in this $(r-1)$th equation. Since we now have $r-1$ equations with $r-1$ unknowns, we are ready to solve $c_1, c_2, \ldots, c_{r-1}$. We would expect the procedure to this point to be computationally intensive since we are basically solving a system of nonlinear equations for $c_1, c_2, \ldots, c_{r-1}$.

- Once $c_1, c_2, \ldots, c_{r-1}$ are found, we can solve for $c_r, \ldots, c_N$ sequentially by

$$\left(2\,(\Delta t)^2 \sum_{l=1}^{r-1} \sum_{m=1}^{l} c_m\right) c_i + (\Delta t)^2 \sum_{m=1}^{r} \sum_{l=m}^{i} c_l\, c_{i+m-l} = \Delta t \sum_{q=0}^{r+1} f^\delta(t_{i+q}) \tag{4.4}$$

for $i = r, r+1, \ldots, N$. As noted before, we still have to solve a nonlinear equation for c_r since the rth equation is quadratic in c_r. However, once $c_1, c_2, \ldots, c_r$ have already been determined, the remaining $N-r$ equations can be sequentially solved quickly since the ith equation is linear in c_i for $i > r$.

Before turning to numerical examples for this discretization, we first examine whether the method can be modified slightly on $[0, R]$ so that the resulting numerical algorithm avoids the difficulties seen above for obtaining c_i when $i = 1, \ldots, r$.

5. Alternate methods on $[0, R]$. As we have just seen, a standard discretization of the regularization method associated with Theorem 3.1 leads to a sequential numerical method for recovering $x(t)$ for $R < t \leq 1$. Unfortunately, for the $x(t)$ values on the interval $0 \leq t \leq R$, we have to solve a nonsequential nonlinear system of equations which can be numerically expensive. This disadvantage motivates us to

look for cheaper alternatives to recover x on the interval $0 \leq t \leq R$. In this section, we will propose some alternative methods and give a theoretical basis for them.

In what follows we will show that, for any function x_R sufficiently close to $\bar{x}$ on $[0, R]$, we may find a unique $\hat{x}_R^\delta \in L_2(0,1)$ for which

$$\hat{x}_R^\delta(t) = x_R(t), \quad t \in [0, R],$$

and such that $\hat{x}_R^\delta$ satisfies (2.4) on the restricted interval $(R, 1]$. That is, $\hat{x}_R^\delta \in L_2(0,1)$ satisfies

$$\alpha_R(x)\, x(t) + F_R(x)(t) = f_R^\delta(t), \quad t \in (R, 1]. \tag{5.1}$$

Further, we will see that, under suitable conditions on the true solution $\bar{x}$ and the choice of $R = R(\delta)$, the function $\hat{x}_R^\delta$ is a good approximation of $\bar{x}$ for δ small. The advantage to this new approach is that we are free to find easier ways of determining an approximation x_R to $\bar{x}$ on $[0, R]$ than that obtained by solving (2.4) on the interval $[0, R]$.

THEOREM 5.1. *Assume that f^δ satisfies the $\mathcal{F}$-data condition, and let $\tau_{\text{data}} = 1/2$ in the case of $\mathcal{F} = C[0, 1+\bar{R}]$ and $\tau_{\text{data}} = 2/5$ in the case of $\mathcal{F} = L_2(0, 1+\bar{R})$. Assume that the measure η is given satisfying* (2.8)–(2.9) *and that the autoconvolution problem* (1.1) *has a positive solution $\bar{x} \in W^{2,\infty}[0, 1+\bar{R}]$ satisfying*

$$\bar{x}(0) > 13\, b^2\, e^{2\sigma}\, \|\bar{x}'\|_\infty \tag{5.2}$$

for $\sigma \geq \sigma_0$ and $b \geq 2\bar{\omega}/\underline{\omega}$, where $\bar{\omega}$, $\underline{\omega}$ are given in (2.9). *Assume further that $\{x_R\}_{R \in (0, \bar{R}]}$ is any family of $L_\infty(0, R)$ functions satisfying*

$$\sup_{t \in [0,R]} |x_R(t) - \bar{x}(t)| \leq \tilde{C} R \tag{5.3}$$

for $\tilde{C} > 0$ satisfying

$$\tilde{C} \leq b\, \|\bar{x}'\|_\infty. \tag{5.4}$$

Then there exist constants $k_1 > 0$ and $\hat{C} > 0$, all independent of R, such that, if $\delta = \delta(R) > 0$ satisfies

$$\delta \leq k_1 R^{1/\tau_{\text{data}}}, \tag{5.5}$$

then for all $R > 0$ sufficiently small there exists a unique $\hat{x}_R^\delta \in L_2(0,1)$, with $\hat{x}_R^\delta = x_R(t)$, $t \in (0, R]$, with $\hat{x}_R^\delta$ satisfying (2.4) *for $t \in (R, 1]$ and for which*

$$\|\hat{x}_R^\delta - \bar{x}\|_{\sigma,R}^2 \leq \hat{C}^2 R^2,$$

where $\|\cdot\|_{\sigma,R}$ is defined from (2.11) *using $\mathcal{C} \in (1, \frac{13}{12}]$. Finally, if $x_R \in L_\infty(0, R)$ depends continuously on data $f^\delta \in \mathcal{F}$, then so does $\hat{x}_R^\delta \in L_2^{\sigma,R}(0,1)$ for all $R > 0$ sufficiently small.*

Proof. To begin, let $\hat{C} < \frac{\bar{x}(0)}{2\, e^{2\sigma}\, b}$, and define a new ball around $\bar{x}$ by

$$\hat{\mathcal{B}}_R(\bar{x}) \equiv \{x \in L_2^{\sigma,R}(0,1) : x|_{\,[0,R]} = x_R|_{\,[0,R]}, \|x - \bar{x}\|_{\sigma,R} \leq \hat{C} R\}, \tag{5.6}$$

noting that $\hat{\mathcal{B}}_R(\bar{x}) \subseteq \mathcal{B}(\bar{x}, \hat{C}R)$, where $\mathcal{B}(\bar{x}, \hat{C}R)$ was fundamental to the proof of Theorem 3.7.

Defining the new operator $\bar{H}_R$ via

$$\bar{H}_R(x)(t) = \begin{cases} x(t) & \text{if } t \in [0, R], \\ H_R x(t) & \text{if } t \in (R, 1], \end{cases}$$

where H_R was defined in (3.19), we will use the contraction mapping theorem to show that the operator $\bar{H}_R(x)$ has a fixed point in the ball $\hat{\mathcal{B}}_R(\bar{x})$. Let $x \in \hat{\mathcal{B}}_R(\bar{x})$. Then since $H_R x = x = x_R$ on $[0, R]$ and

$$\int_0^R e^{-2\sigma t} \left(x_R(t) - \bar{x}(t)\right)^2 \, dt \le \tilde{C}^2 R^3 \tag{5.7}$$

we have

$$\begin{aligned} \|\bar{H}_R x - \bar{x}\|_{\sigma,R}^2 &\le \tilde{C}^2 R^3 \left(\frac{\mathcal{C}^2 - 1}{R} + 1\right) + \int_R^1 e^{-2\sigma t} \left(H_R x(t) - \bar{x}(t)\right)^2 \, dt \\ &\le \tilde{C}^2 R^2 \left(\mathcal{C}^2 - (1 - R)\right) + \|H_R(x) - \bar{x}\|_{\sigma,R}^2 \\ &\le (\tilde{C}\mathcal{C}R)^2 + \|H_R(x) - \bar{x}\|_{\sigma,R}^2 \end{aligned}$$

for $R > 0$ sufficiently small. Using the proof of Theorem 3.7 (in particular, inequality (3.26)), we find that a sufficient condition for $\|\bar{H}_R x - \bar{x}\|_{\sigma,R} \le \hat{C}R$ is that

$$\tilde{C}\mathcal{C} + \frac{1}{\bar{x}(0)} \, k_1 b \, \mathcal{C} + \|\bar{x}'\|_\infty \, b \, \mathcal{C} + \frac{e^{2\sigma}}{\bar{x}(0)} \, b \, \hat{C}^2 < \hat{C}, \tag{5.8}$$

so that, letting k_1 be defined by (3.27) and using condition (5.4) on $\tilde{C}$, we find that inequality (5.8) holds if

$$L(\hat{C}) \equiv \frac{e^{2\sigma} \, b}{\bar{x}(0)} \, \hat{C}^2 - \hat{C} + 3 \, b \, \|\bar{x}'\|_\infty \, \mathcal{C} < 0.$$

In fact, L has two distinct positive real roots $0 < \hat{C}_1 < \hat{C}_2$ under assumption (5.2) and $\mathcal{C} \in (1, \frac{13}{12}]$. Thus any value of $\hat{C}$ in the interval $(\hat{C}_1, (\hat{C}_1 + \hat{C}_2)/2)$ will give $L(\hat{C}) < 0$ and also ensure that $\hat{C} < \frac{\bar{x}(0)}{2 \, e^{2\sigma} \, b}$ as prescribed at the beginning of the proof. Thus $\bar{H}_R$ takes $\hat{\mathcal{B}}_R(\bar{x})$ into itself.

Let $x_1, x_2 \in \hat{\mathcal{B}}_R(\bar{x})$. Then

$$\begin{aligned} \|\bar{H}_R(x_1) - \bar{H}_R(x_2)\|_{\sigma,R}^2 &= 0 + \int_R^1 e^{-2\sigma t} \left(H_R(x_1)(t) - H_R(x_2)(t)\right)^2 dt \\ &\le \|H_R(x_1) - H_R(x_2)\|_{\sigma,R}^2, \end{aligned}$$

and thus from the proof of Theorem 3.7 we have that the conditions already placed on $\hat{C}$ are sufficient for $\bar{H}_R$ to be a contraction in the ball $\hat{\mathcal{B}}_R(\bar{x})$.

Finally, we refine our definition of $\hat{C}$ further to ensure that the ball $\hat{\mathcal{B}}_R(\bar{x})$ is nonempty. We note from (5.4) and (5.2) that

$$\tilde{C} \le \frac{\bar{x}(0)}{13 \, b \, e^{2\sigma}} = \frac{2}{13} \frac{\hat{C}_1 + \hat{C}_2}{2},$$

so that, if we further restrict $\hat{C}$ to lie in the (nonempty) intersection of the intervals $(\frac{2}{13}(\hat{C}_1+\hat{C}_2)/2, (\hat{C}_1+\hat{C}_2)/2)$ and $(\hat{C}_1, (\hat{C}_1+\hat{C}_2)/2)$, we have that

$$\tilde{C} \leq \hat{C}.$$

Thus if we define $\hat{x}_R \in L_2^{\sigma,R}(0,1)$ via

$$\hat{x}_R = \begin{cases} x_R(t) & \text{if } t \in [0,R], \\ \bar{x}(t) & \text{if } t \in (R,1], \end{cases}$$

we have from (5.7) that

$$\|\hat{x}_R - \bar{x}\|_{\sigma,R}^2 \leq \hat{C}^2 R^2 \left(\mathcal{C}^2 - 1 + R\right) + 0 \leq \hat{C}^2 R^2 \tag{5.9}$$

for $R > 0$ sufficiently small. Thus $\hat{x}_R \in \hat{\mathcal{B}}_R(\bar{x})$.

Continuous dependence of $\hat{x}_R^\delta$ on data f^δ follows arguments similar to those in Theorem 3.7. ∎

As in Corollary 3.8 we may dispense with condition (5.2) provided that we have access to an appropriate approximation $\hat{x}(0;R)$ of $\bar{x}(0)$ and that we make use of this information in the construction of our measure η. See Remark 3.3 for more information on the construction of such a measure.

COROLLARY 5.2. *Assume that f^δ satisfies the $\mathcal{F}$-data condition, and let $\tau_{\text{data}} = 1/2$ in the case of $\mathcal{F} = C[0,1+\bar{R}]$ and $\tau_{\text{data}} = 2/5$ in the case of $\mathcal{F} = L_2(0,1+\bar{R})$. Let the solution $\bar{x} \in W^{2,\infty}[0,1+\bar{R}]$ of (1.1) be positive. Assume that the measure η satisfies (2.8)–(2.9) with $\bar{\omega}$, $\underline{\omega}$ in (2.9) satisfying (3.4) for all $R > 0$ sufficiently small, where $\tilde{K}$ is independent of R and $\bar{x}$. Assume further that $\{x_R\}_{R\in(0,\bar{R}]}$ is any family of $L_\infty(0,1)$ functions satisfying*

$$\sup_{t\in[0,R]} |x_R(t) - \bar{x}(t)| \leq \tilde{C}R \tag{5.10}$$

for some $\tilde{C} > 0$.

Then there exist constants $k_1 > 0$ and $\hat{C} > 0$, all independent of R, such that, if $\delta = \delta(R) > 0$ satisfies

$$\delta \leq k_1 R^{1/\tau_{\text{data}}}, \tag{5.11}$$

then there exists a unique $\hat{x}_R^\delta \in L_2(0,1)$, with $\hat{x}_R^\delta = x_R(t)$, $t \in (0,R]$, with $\hat{x}_R^\delta$ satisfying (2.4) for $t \in (R,1]$ and for which

$$\|\hat{x}_R^\delta - \bar{x}\|_{\sigma,R}^2 \leq \hat{C}^2 R^2,$$

where $\|\cdot\|_{\sigma,R}$ is defined from (2.11) using $\mathcal{C} = \sqrt{2}$ and $\sigma \geq \sigma_0$. Finally, if it is known that $x_R \in L_\infty(0,R)$ depends continuously on data $f^\delta \in \mathcal{F}$, then so does $\hat{x}_R^\delta \in L_2^{\sigma,R}(0,1)$ for all $R > 0$ sufficiently small.

Proof. Define b satisfying both $b \geq 2\bar{\omega}/\underline{\omega}$ and $\tilde{C} \leq b\|\bar{x}'\|_\infty$, and let $\tilde{b} = b/\bar{x}(0)$. As in Corollary 3.8 we may assume without loss of generality that the original equation (1.1) has been rescaled so that

$$\|\bar{x}'\|_\infty \bar{x}(0) < \frac{\sqrt{2}\, e^{-2\sigma}}{24\,\tilde{b}^2}. \tag{5.12}$$

Then following the proof of Theorem 5.1 a sufficient condition for $\|\bar{H}_R x - \bar{x}\|_{\sigma,R} < \hat{C}R$ is that

$$L(\hat{C}) \equiv e^{2\sigma}\,\tilde{b}\,\hat{C}^2 - \hat{C} + 3\,\|\bar{x}'\|_\infty \bar{x}(0)\,\tilde{b}\,\mathcal{C} < 0,$$

so for $\mathcal{C} = \sqrt{2}$ and under the rescaling in (5.12) we have that L has two distinct positive roots $0 < \hat{C}_1 < \hat{C}_2$. The remainder of the proof of Theorem 5.1 then carries over exactly as before, with the exception that we now have from (5.12)

$$\tilde{C} \le \tilde{b}\|\bar{x}'\|_\infty \bar{x}(0) < \frac{\sqrt{2}}{12}\frac{1}{2e^{2\sigma}\tilde{b}} = \frac{\sqrt{2}}{12}\left(\frac{\hat{C}_1 + \hat{C}_2}{2}\right),$$

so that the arguments in the proof of Theorem 5.1 remain valid if we select $\hat{C}$ in the (nonempty) intersection of the intervals $(\frac{\sqrt{2}}{12}(\hat{C}_1+\hat{C}_2)/2,\ (\hat{C}_1+\hat{C}_2)/2)$ and $(\hat{C}_1,\ (\hat{C}_1+\hat{C}_2)/2)$. ∎

Remark 5.3. The results of Theorem 5.1 and Corollary 5.2 indicate that, as before, under the a priori conditions on $R = R(\delta)$ that

$$(\delta/k_1)^{\tau_{\text{data}}} \le R(\delta) \le c\,\delta^p$$

for any $c > 0$ and $p \in (0, \tau_{\text{data}}]$ ($c \ge k_1^{-\tau_{\text{data}}}$ if $p = \tau_{\text{data}}$) as $\delta \to 0$, we obtain

$$\|x^\delta_{R(\delta)} - \bar{x}\|_{L_2(0,1)} = \mathcal{O}\left(\delta^p\right) \ \text{ as } \ \delta \to 0,$$

with an optimal rate obtained for $p = \tau_{\text{data}}$. Thus the optimal convergence rate for continuous data is $\mathcal{O}(\delta^{1/2})$, and the optimal convergence rate for L_2 data is $\mathcal{O}(\delta^{2/5})$.

As mentioned earlier, Theorem 5.1 and Corollary 5.2 provide us the freedom of finding easier ways of determining an approximation x_R to $\bar{x}$ on $[0, R]$ than that obtained by solving the local regularization equation (2.4) on the interval $[0, R]$. One way to find such an x_R (and to find an $\mathcal{O}(R)$ approximation $\hat{x}(0; R)$ of $\bar{x}(0)$, which is of particular use in Corollaries 3.8 and 5.2 via Remark 3.3) is by a standard discretization of the unregularized problem

$$G(x)(t) = \int_0^t x(t-s)x(s)\,ds = f^\delta(t), \quad t \in [0, R] \tag{5.13}$$

(with noisy data f^δ), on the interval $[0, R]$. As is well known, coarse discretization is a form of regularization; however, the ill-posedness of (5.13) can lead to significant errors in $x_R(t)$ for large t, even more so when the discretization step size is small. It is for this reason that the standard discretization will be used only on a small interval of length R.

We will describe here one simple discretization of (5.13) which is suitable for use with Theorem 5.1 and Corollary 5.2. Let $K = K(R) \ge 1$ be an integer, and partition the interval $[0, R]$ into K equal-length subintervals; i.e., let

$$t_i = i\Delta t, \quad i = 0, 1, \ldots, K, \quad \Delta t = R/K.$$

Defining $\chi_i(t)$ as in the last section (only now for $i = 1, 2, \ldots, K$), we define $\mathcal{S}_K = \text{span}\{\,\chi_i,\ i = 1, 2, \ldots, K\}$ and seek $x_R \in \mathcal{S}_K$, i.e.,

$$x_R(t) = \sum_{l=1}^{K} c_l\,\chi_l(t), \tag{5.14}$$

satisfying the collocation equations

$$G(x)(t_i) = \int_0^{t_i} x(t_i - s)x(s)ds = f^\delta(t_i), \quad i = 1, 2, \ldots, K. \tag{5.15}$$

Therefore,

$$\sum_{\gamma=1}^{i} \int_{t_{\gamma-1}}^{t_\gamma} \left[\sum_{l=1}^{K} c_l\, \chi_l(t_i - s)\right] \left[\sum_{p=1}^{K} c_p\, \chi_p(s)\right] ds = f^\delta(t_i), \quad i = 1, 2, \ldots, K,$$

or

$$\sum_{\gamma=1}^{i} c_{i-\gamma+1}\, c_\gamma = \frac{f^\delta(t_i)}{\Delta t}, \quad i = 1, 2, \ldots, K. \tag{5.16}$$

The collocation equations (5.16) allow us to explicitly solve for c_i, $i = 1, 2, \ldots, K$, provided that $f^\delta(t_1) > 0$. That is,

$$c_1 = \sqrt{\frac{f^\delta(t_1)}{\Delta t}}, \tag{5.17}$$

and if $c_1, \ldots, c_{i-1}$ have been found already, c_i is determined by

$$c_i = \frac{\frac{f^\delta(t_i)}{\Delta t} - (c_{i-1}c_2 + \cdots + c_2 c_{i-1})}{2c_1}, \tag{5.18}$$

and therefore $c_2, c_3, \ldots, c_K$ can be found uniquely, explicitly, and sequentially from (5.18).

The following result is proved using standard techniques (see the details in [8]). If the constant $\tilde{C}$ in (5.21) is not too large (a condition needed for Theorem 5.1 only, not for Corollary 5.2), it follows that the collocation-based approximation x_R is suitable for use in methods based on Theorem 5.1 or Corollary 5.2. That is, we may use x_R as an approximation for $\bar{x}$ on $[0, R]$ and then use the local regularization equation (2.4) to find an approximation for $\bar{x}$ on $[R, 1]$. We note that the condition $K = K(R) \le \tilde{M}$ for all $R > 0$ sufficiently small is not a serious constraint as we generally expect $K \ge 1$ to be a fixed integer so that the step size $\Delta t = R/K$ decreases as $R \to 0$. However, not surprisingly since we are now dealing with a discretization of the original problem, we do need pointwise values of f^δ on $[0, R]$, and we require that they be within $\mathcal{O}(R^2)$ of the corresponding values of f on that interval.

COROLLARY 5.4. *Assume the autoconvolution problem* (1.1) *has a positive solution* $\bar{x} \in C^1[0, 1]$. *Let* $x_R = \sum_{l=1}^{K} c_l\, \chi_l(t)$ *be the unique solution of the discrete autoconvolution equation* (5.15) *on the interval* $[0, R]$, *where the constants* c_i, $i = 1, 2, \ldots, K$, *are specified in* (5.17) *and* (5.18) *and* $K = K(R) \ge 1$ *is an integer. Then if there exists a constant* $\tilde{M} > 0$, *such that* $K = K(R) \le \tilde{M}$ *uniformly in* R *and* f^δ *is piecewise continuous on* $[0, R]$ *with*

$$|f^\delta(t) - f(t)| \le \delta \le k_1 R^2, \qquad t \in [0, R], \tag{5.19}$$

convergence of $x_R(t)$ *to the true solution* $\bar{x}(t)$ *for* $t \in [0, R]$ *occurs at the collocation points as* $R \to 0$, *i.e.,*

$$|x_R(t_i) - \bar{x}(t_i)| \sim \mathcal{O}(R) \quad \text{for } i = 1, 2, \ldots, K \tag{5.20}$$

for R sufficiently small. Further, we have a constant $\tilde{C}$ depending on $\bar{x}$ but independent of R such that

$$|x_R(t) - \bar{x}(t)| \le \tilde{C}R \tag{5.21}$$

for R sufficiently small and all $t \in [0, R]$.

Remark 5.5. It is worth noting that the results of Theorem 5.1 are improved if we require that x_R be an $\mathcal{O}(R^p)$ approximation to $\bar{x}$ on $[0, R]$ for some $p > 1$ [8]. This result is of use, for example, if we know both $\bar{x}(0)$ and $\bar{x}'(0)$ so that we form an $\mathcal{O}(R^2)$ approximation of $\bar{x}$ on $[0, R]$ via $x_R(t) = \bar{x}(0) + \bar{x}'(0)t$. However, as can be seen in [8], such approximations on $[0, R]$ actually perform worse (locally) in numerical examples than do approximations based on the simple $\mathcal{O}(R)$ collocation-based discretization of (5.13) given above. The reason for this is likely due to the fact that the approximation based on a Taylor expansion does not make good use of all of the available data f^δ on $[0, R]$, as does the collocation-based discretization.

5.1. Operation count for the alternative method. If we let $r = K$ in (5.17)–(5.18), then the cost of computing $c_1, c_2, \ldots, c_r$ from (5.17)–(5.18) is $\mathcal{O}(r^2/2)$ flops. The remaining steps in the alternative approach require the sequential solution of (4.4) for $c_{r+1}, \ldots c_N$. We can rewrite (4.4) for c_i as

$$(D_1 + D_2)c_i + D_3(i) = D_4(i), \quad i = r + 1, \ldots, N,$$

where D_j, $j = 1, \ldots, 4$, are constants which are independent of i in the case of D_1 and D_2,

$$D_1 = \left(2 \sum_{l=1}^{r-1} \sum_{m=1}^{l} c_m \right), \quad D_2 = 2 \sum_{m=1}^{r} c_m,$$

$$D_3(i) = \sum_{m=1}^{r} \sum_{l=m+1}^{i-1} c_l \, c_{i+m-l}, \quad D_4(i) = \frac{1}{\Delta t} \sum_{q=0}^{r+1} f^\delta(t_{i+q}).$$

The computation of D_1 and D_2 require one-time costs of order $\mathcal{O}(r)$ flops each, while the cost of $D_3(i)$ and $D_4(i)$ are $\mathcal{O}(2ir - r^2 - 3r)$ and $\mathcal{O}(r)$ flops, respectively, computations which are done for $i = r + 1$ to $i = N$. Thus the total cost of the alternative method described in this section (assuming $r \ll N$) is $\mathcal{O}(rN^2 - r^2N)$.

Operation counts for the Lavrent'ev method are likely to be similar to those found above (i.e., $\mathcal{O}(cN^2)$ for some constant $c > 0$); however, fairly accurate knowledge of the value of $\bar{x}(0)$ is of importance if one is to make use of this method; in addition, one requires an initial guess $x^\star$ for implementation of Lavrent'ev. For comparison with methods which do not preserve the causal nature of the nonlinear autoconvolution problem, we have been unable to find operation counts for Tikhonov regularization applied to this nonlinear problem (and of course there are many different approaches—methods using Newton or Levenberg–Marquardt, descent methods such as steepest descent, etc.—that one might take to solve the nonlinear Tikhonov problem). Without a suitable comparison, we will simply note that cost for a direct implementation of Tikhonov regularization on a general *linear* problem is $\mathcal{O}(N^3)$ flops [10]. Some actual computational costs (in seconds) are provided in Examples 3 and 4 below.

6. Numerical results. The examples in this section provide evidence of the effectiveness of the local regularization methods applied to the autoconvolution equation. The local regularization methods have advantages over existing methods in that they do not require an initial guess $x^\star$ and they maintain the causal nature of the problem at least for the majority of the domain, leading to very rapid solution methods. One drawback, of course, is that the theory requires that true solutions $\bar{x}$ should not cross the t-axis. However, as Examples 3 and 4 below illustrate, the method appears to perform perfectly well in this situation.

Henceforth we will refer to *method* 1 as the collocation-based discretization derived in section 4 for the local regularization equation (2.4), i.e., a discretization of the continuous local regularization method which is rigorously justified by Theorem 3.7. Recall that method 1 requires solving nonsequential nonlinear equations for $c_1, \dots, c_r$ and sequential linear equations for $c_{r+1}, \dots, c_N$.

In contrast, *method* 2 will refer to the method of determining $c_1, \dots, c_r$ via (5.17)–(5.18) (where we set $K = r$) and $c_{r+1}, \dots, c_N$ via (4.4). In method 2, all coefficients are found using a procedure that is fully sequential and linear in the unknown coefficient at each step. This algorithm is a discretization of the continuous local regularization method which is rigorously justified by Theorem 5.1. It is interesting to note in our numerical examples below that the fully sequential linear method 2, which is significantly easier to implement and considerably faster in terms of computational times, actually performs as well as the (slower) partly nonlinear method 1.

In order for easy comparison with numerical tests in the literature for existing methods (a Tikhonov regularization approach using total variation constraints in [11] and a Lavrent'ev approach in [16]), we demonstrate the recovery of both a continuous $\bar{x}$ and a discontinuous $\bar{x}$ using methods 1 and 2 above. We select our true solution $\bar{x}$ ahead of time and then generate the data function f by integration: $f(t) = \int_0^t \bar{x}(t-s)\bar{x}(s)\,ds$ for $t \in [0,1]$. The perturbed data f^δ was then produced by adding uniformly distributed noise from the interval $[-\delta f(t), \delta f(t)]$ to the discrete values of $f(t)$ for $t = t_i$, where $i = 1, 2, \dots, N$. Each example within the same noise level δ was found using the same sampled data f^δ.

In the figures below, we display the recovered solution against the true solution $\bar{x}$, first without any special regularization (except for that due to discretization alone) and then with regularization using methods 1 and 2. In all figures presented below, the true solution $\bar{x}$ is plotted as a dashed line, while the solid line expresses the approximate solution computed according to the specified method. The regularized solutions end before reaching $t = 1$ in Examples 1 and 2 because we have chosen not to extend our data past the interval $[0,1]$ in those examples; to have regularized solutions on all of $[0,1]$, one needs to make use of data f^δ on $[0, 1+R]$.

6.1. Example 1: Continuous true solution $\bar{x}$. The true solution in this example is a continuous function $\bar{x}(t) = 1 - 3(t-1/2)^2$, $0 \le t \le 1$, with the true data then given by $f(t) = \frac{3}{10}t^5 - \frac{3}{2}t^4 + t^3 + \frac{3}{4}t^2 + \frac{1}{16}t$ for $0 \le t \le 1$. For Figures 6.1–6.3, we use relative noise level $\delta = 10^{-3}$, $N = 100$, and $r = 4$ for the regularized problems. In Figure 6.1, we show the unregularized numerical solution, while, in Figures 6.2–6.3, we show the regularized solution using methods 1 and 2 as introduced in the last section.

For Figures 6.4–6.6, we repeat the above example using a larger relative noise level $\delta = 10^{-2}$, $N = 100$, and $r = 4$ for method 1 and $r = 6$ for method 2. (We selected the value of r small, which gave the best results in each case visually.)

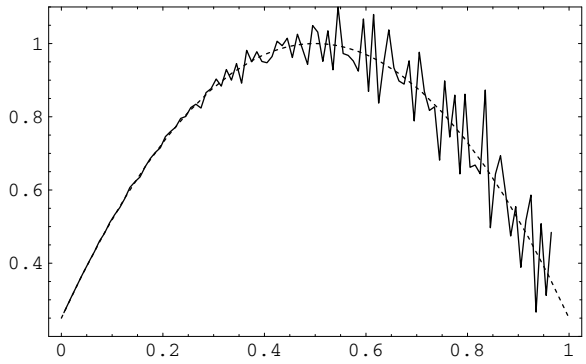

FIG. 6.1. *Example* 1. *Solution without regularization,* $\delta = 10^{-3}$, $N = 100$.

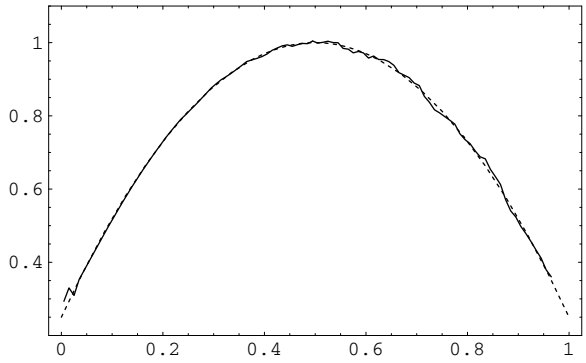

FIG. 6.2. *Example* 1. *Solution obtained by method* 1, $\delta = 10^{-3}$, $N = 100$, $r = 4$.

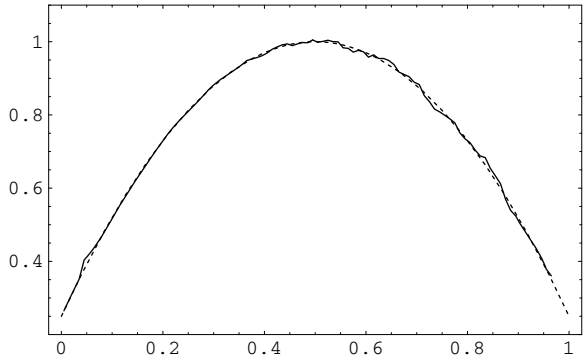

FIG. 6.3. *Example* 1. *Solution obtained by method* 2, $\delta = 10^{-3}$, $N = 100$, $r = 4$.

6.2. Example 2: Discontinuous true solution $\bar{x}$. In this example, we will use a step function as our true solution; $\bar{x}$ and true data f are given by

$$\bar{x}(t) = \begin{cases} 0.5 & \text{if } t \in [0, 0.5], \\ 0.25 & \text{if } t \in (0.5, 0.8], \\ 0.75 & \text{if } t \in (0.8, 1], \end{cases} \qquad f(t) = \begin{cases} 0.25t & \text{if } t \in [0, 0.5], \\ 0.125 & \text{if } t \in (0.5, 0.8], \\ 0.5t - 0.275 & \text{if } t \in (0.8, 1]. \end{cases}$$

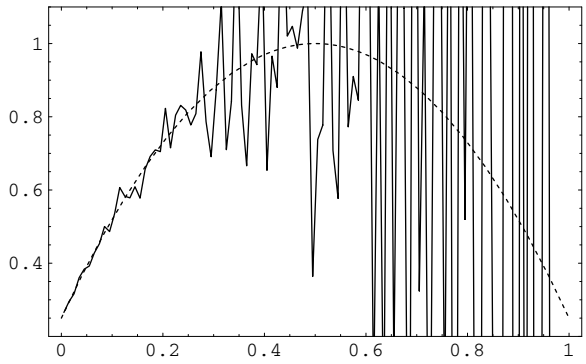

FIG. 6.4. *Example* 1. *Solution without regularization,* $\delta = 10^{-2}$, $N = 100$.

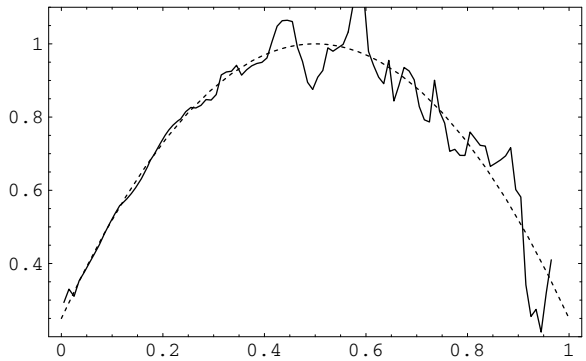

FIG. 6.5. *Example* 1. *Solution obtained by method* 1, $\delta = 10^{-2}$, $N = 100$, $r = 4$.

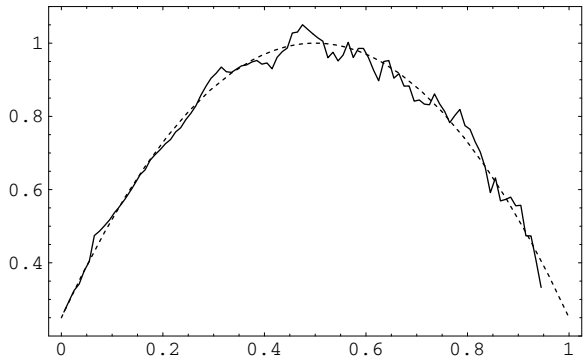

FIG. 6.6. *Example* 1. *Solution obtained by method* 2, $\delta = 10^{-2}$, $N = 100$, $r = 6$.

For all of the figures shown in this example, we use relative noise level $\delta = 10^{-3}$, $N = 200$, and $r = 4$ for the regularized problem. In Figure 6.7, we show the solution without any special regularization, while Figures 6.8–6.9 show the regularized solution using methods 1 and 2. The results for both methods are much better than was presented in [11, 16]. It is worth noting that the true solution $\bar{x}$ here does not satisfy the assumptions of Theorem 3.7 (which are only sufficient conditions for convergence anyway).

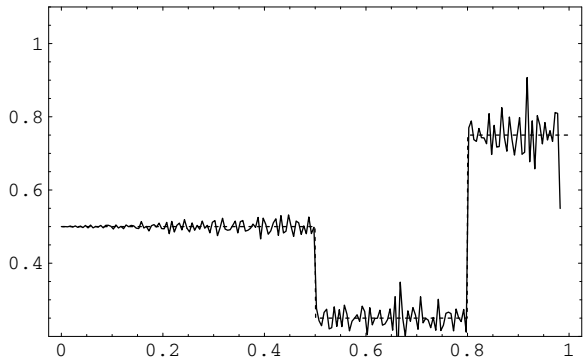

FIG. 6.7. *Example* 2. *Solution without regularization,* $\delta = 10^{-3}$, $N = 200$.

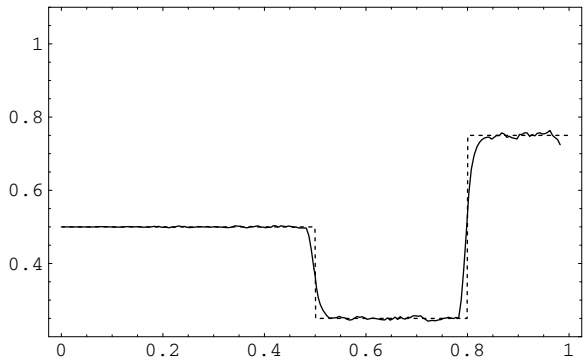

FIG. 6.8. *Example* 2. *Solution obtained by method* 1, $\delta = 10^{-3}$, $N = 200$, $r = 4$.

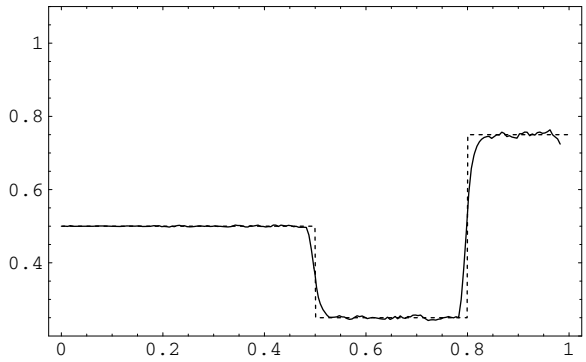

FIG. 6.9. *Example* 2. *Solution obtained by method* 2, $\delta = 10^{-3}$, $N = 200$, $r = 4$.

For comparison with local regularization, we show in Figure 6.10 the results of Tikhonov regularization and Lavrent'ev regularization applied to this same problem. In each case, regularization parameters were selected as those providing the best visual fit between approximate and true solutions. For our implementation of Lavrent'ev, the true value of $\bar{x}(0)$ was incorporated into the approximating equation, and the regularization parameter $\alpha = .01555$ was used. For Tikhonov regularization, we used the parameter $\alpha = 10^{-22}$ with a starting guess of $x(t) = \sqrt{f^{\delta}(t_1)/\Delta t}$; for more

information about our implementation of the nonlinear Tikhonov scheme, refer to Example 3 below.

6.3. Example 3: Nonpositive true solution $\bar{x}$. Although the theory developed here requires that $\bar{x}$ be strictly positive (resp., strictly negative), in practice the numerical methods developed in this paper can still be applied to situations where the unknown $\bar{x}$ crosses the t-axis. We illustrate with an example where the true solution is given by $\bar{x}(t) = \sin 8t + (1/4)$, $0 \le t \le 1$, and the associated true data are $f(t) = \frac{5}{80}(1 + t - \cos 8t + \sin 8t) - \frac{1}{2}t \cos 8t$, $0 \le t \le 1$. We use a relative noise level $\delta = .01$ and $N = 100$ and in Figures 6.11–6.12 show the results of no regularization as well as those for Tikhonov regularization, Lavrent'ev regularization, and local regularization, all applied to the same data f^δ.

In the case of local regularization we use method 2 and $r = 7$ and in so doing make use of data on the extended interval $[0, 1.07]$; for a fair comparison, we also allow Tikhonov regularization to make use of the same extended interval for its computations; however, only the results on $[0, 1]$ are displayed for both methods. We note that the Lavrent'ev method is solved sequentially without the use of future data, so additional data past the interval $[0, 1]$ do not change its result. For the Tikhonov

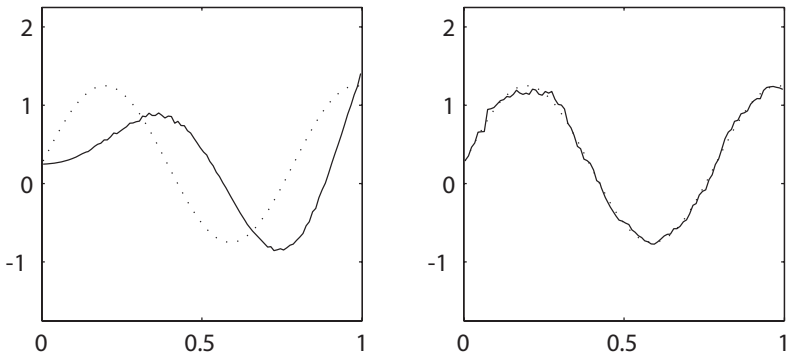

FIG. 6.12. *Example* 3, *continued. Left: Lavrent'ev method (computing time* 0.01 *sec). Right: Local regularization (method* 2*) with* $r = 7$ *(*0.01 *sec).*

and Lavrent'ev methods we use the regularization parameters $\alpha = 10^{-6}$ and $\alpha = 0.4$, respectively, incorporating the true value of $\bar{x}(0)$ into the Lavrent'ev approximating equation. Minimization of the nonlinear Tikhonov regularization functional (with regularization term $\alpha\|x\|^2$) is accomplished in these examples using the MATLAB function `fminunc` with the initial guess provided by the constant function $x(t) = c_1$, where c_1 is the first value of the approximation found in method 2 for local regularization, i.e., $c_1 = \sqrt{f^\delta(t_1)/\Delta t}$. The regularization parameters used for all methods are the best ones found by visual comparison with the true solution.

We note that Lavrent'ev provides a shifted approximation; decreasing α does reduce the shift but at the same time causes large distortions in the shape of the solution. The fact that the Tikhonov method gives a smoother solution than local regularization can be expected due to the global versus local smoothing associated with the two methods. The computing time for Lavrent'ev and local regularization is about the same as that for the unregularized solution (0.01 sec on a 2.21 GHz dual core machine), while Tikhonov regularization requires 166 times that much computing time (1.66 sec).

6.4. Example 4: Nonpositive true solution $\bar{x}$. In this example we take the true $\bar{x}$ from Example 1 above and shift it down so that it crosses the t-axis in two places. That is, we use $\bar{x}(t) = (1/2) - 3(t - 1/2)^2$ for $0 \le t \le 1$, with true data $f(t) = \frac{3}{10}t^5 - \frac{3}{2}t^4 + 2t^3 - \frac{3}{4}t^2 + \frac{1}{16}t$ for $0 \le t \le 1$. In this example we use a relative noise level $\delta = .015$ and $N = 200$, and in Figures 6.13–6.14 we again show the results of no regularization, Tikhonov regularization, Lavrent'ev regularization, and local regularization for the same data f^δ.

The true data f is graphed in Figure 6.15. The difference between the data f in Example 3 (Figure 6.16) and the data f in Figure 6.15 for this example is important in understanding the difference between the way Tikhonov regularization and local regularization perform in this particular case. Note that here the true data f (graphed in Figure 6.15) is nearly zero for the first third to half of the interval. This means that, with even small amounts of added error, the signal-to-noise ratio is likely to be so small as to make the solution unrecoverable if only the data from the first third of the interval are used. Now Tikhonov regularization uses all of the data to compute its regularized approximation, while local regularization constructs a sequential method making use of future data only on the interval $[t, t + r\Delta t]$ to compute the value of the

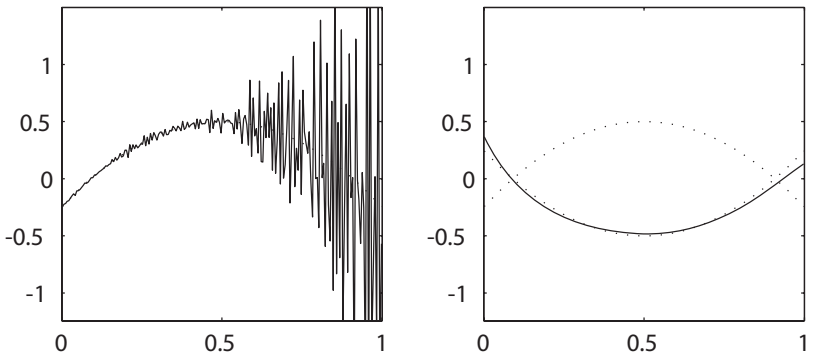

FIG. 6.13. *Example* 4 *with the nonpositive true solution,* $\delta = 1.5 \times 10^{-2}$*, and* $N = 200$*. Left: Unregularized solution (computing time:* 0.003 *sec). FIG. 6.16. *Example* 3. *True data* f.

approximate solution at t. Thus r will need to be large enough to allow for meaningful information about the data to be obtained in the case of local regularization. In this case, a value of $r = 65$ (nearly 1/3 of the interval) is used in order to get good results with local regularization. In contrast, the data in Example 3 do not exhibit this same difficulty with small signal-to-noise data ratios over large regions, so a small value of r ($r = 7$) is acceptable for that example. Fortunately, the need for large r can be determined by a simple inspection of the given (perturbed) data f^δ prior to use of the local regularization method.

Note further that the Lavrent'ev approximation, also found sequentially, uses no future data information in order to compute the value of the approximation at the current time t. Thus Lavrent'ev can be expected to fail badly in situations where the signal-to-noise ratio is small over large regions of the domain.

As in Example 3, we allow Tikhonov regularization to make use of the same extended data set as that for local regularization, i.e., of data on the interval $[0, 1.325]$. Although the starting value for Tikhonov is the constant function $x(t) = c_1$, where now $c_1 = -\sqrt{f^\delta(t_1)/\Delta t}$ (since $\bar{x}(0) < 0$ in this case), Tikhonov regularization actually finds the negative solution $-\bar{x}$ for this problem. (Recall that there are two solutions $\bar{x}$ and $-\bar{x}$ for every autoconvolution problem; by specifying a positive or negative starting value for each method, we are giving some indication of which of the two solutions to find.)

As expected from the data, Lavrent'ev performs quite poorly in this example. It is possible that the approximation is that for the negative solution of the autoconvolution equation, although the results are not very convincing. On the other hand, local regularization performs quite well provided r is large enough to get a meaningful local sample of the data. We note that for $r \leq 58$ the local regularization approximation blows up at about $t = 1/3$, while acceptable results are found for a large range of values of $r \geq 59$. Thus, a simple inspection of the noisy data is very important in order to obtain information about the smallest of r, which is likely to gain any meaningful information from data on an interval of length $[t, t + r\Delta t]$.

It is worth observing that, with the large value of r used in this example ($r = 65$), the computing time (.03 sec) for local regularization becomes about 10 times that for the unregularized problem and for Lavrent'ev regularization (.003 sec each); on the other hand, the computing time for Tikhonov regularization (at 5.43 sec) is about 180 times that of local regularization. Such differences in computational times

become important if discrepancy principles are to be used in the determination of the correct regularization parameters, since such methods require repeated solution of the approximation for different choices of the parameters.

7. Selection of the regularization parameter. One of the most commonly asked questions with regard to the local regularization methods is how one picks the regularization parameter r (or R in the continuous version of the regularized equation). This question has been answered for the linear convolution problem with the development of a modified discrepancy principle [3, 4] but remains an open problem (other than the need for minimal values of r in some cases, as discussed in Example 4 above) for nonlinear problems, including the nonlinear autoconvolution equation under study here.

The *discrepancy principle* is one of the most successful criteria in determining the regularization parameter α for the method of Tikhonov regularization. To summarize the discrepancy principle on the Hilbert space F, we assume that the perturbed data f^δ have an absolute noise level $\hat{\delta}$, i.e., $\|f^\delta - f\|_F \leq \hat{\delta}$. The Tikhonov theory states that for every choice of $\alpha > 0$ the unique solution u_α^δ of the Tikhonov problem (see, e.g., [10]) associated with the perturbed data f^δ is such that the discrepancy

$$\delta_d \equiv \|\mathcal{A}u_\alpha^\delta - f^\delta\|_F$$

is monotone in α; here $\mathcal{A}$ denotes a linear integral operator. The discrepancy principle is then used to pick α so

$$\delta_d = \tau\hat{\delta},$$

with $\tau \geq 1$ some constant. In practice, τ is often picked as $\sqrt{2}$. Development of the discrepancy principle for Tikhonov regularization of nonlinear operator equations can be found in [30, 32].

In the following, we use the discrepancy principle to select an "optimal" r for a given relative noise level δ and fixed discretization parameter N. Method 2 is used for all numerical experiments that follow. For local regularization the discrepancy δ_d is not exactly a monotone increasing function of the regularization parameter r. Therefore, we modified the principle to select the smallest $r > 0$ for which the discrepancy δ_d exceeds the absolute data noise $\hat{\delta}$.

7.1. Example 1a: A repeat of Example 1, now using the discrepancy principle to select r. In Table 7.1 we illustrate how the modified discrepancy principle can be used to determine r for the two numerical tests (associated with the two different noise levels $\delta = 10^{-3}$ and $\delta = 10^{-2}$) from Example 1 in the last section. We

r	$\hat{\delta}$	δ_d
2	0.00133155	0.00113062
• 3	0.0013285	0.00202835
4	0.00131227	0.00308485

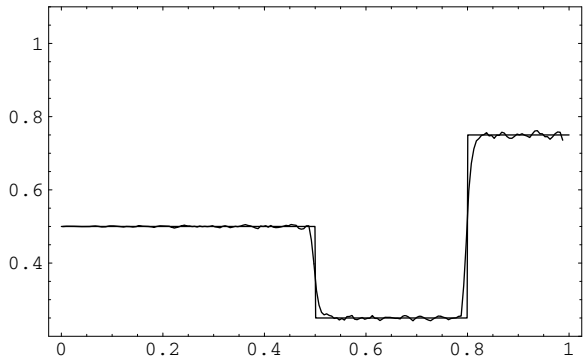

FIG. 7.2. *Example* 2a. *Solution obtained for Example* 2 *using method* 2 *with* $\delta = 10^{-3}$, $N = 200$, $r = 3$. *For comparison, see Figure* 6.9.

see that $r = 5$ is selected for the case of $\delta = 10^{-3}$, while $r = 13$ is selected for the case of $\delta = 10^{-2}$. As expected, the suggested value of r increases as the noise level in the data increases. We show in Figure 7.1 the outcome when using the predicted $r = 13$ at noise level of $\delta = .01$; indeed, in comparing with Figure 6.6 (where $r = 6$ was used), the relative root-mean-square (rms) error of the reconstructed x is 0.0258251 with $r = 13$, which is just about half of the rms error (0.0502236) using $r = 6$, when the same set of noisy data is used. We note also that the predicted $r = 13$ gives $R = 1.3 \times 10^{-1}$, a value which might be seen as more in line with the suggestion made by Theorem 3.1 than the values of R used in Example 1.

7.2. Example 2a: A repeat of Example 2, now using the discrepancy principle to select r. We show in Table 7.2 the results of applying the modified discrepancy principle to Example 2 of the last section; here the value $r = 3$ is selected by the principle, and the associated numerical solution is shown in Figure 7.2. While

Figure 7.2 looks quite similar to Figure 6.9 (where $r = 4$ was used), we can quantitatively conclude that $r = 3$ is a better choice since the relative rms error is 0.072, which is slightly better than the rms error (0.086) in the case of $r = 4$ when the same set of noisy data is used.

Other examples of the use of the modified discrepancy principle for the local regularization of the autoconvolution problem can be found in [8].

8. Conclusion. In this paper we have developed a local regularization theory for the autoconvolution equation, an ill-posed nonlinear Volterra problem. Several local regularization methods have been established, all of which provide stable solutions for the autoconvolution problem. The methods also preserve the causal nature of the autoconvolution equation, allowing for numerically fast sequential solution.

Using the underlying idea of local regularization, we formulated the local regularized equation for the autoconvolution problem and proved the convergence of the solution produced by this regularized equation to the true solution of the autoconvolution equation as the noise level in the data shrinks to zero. The convergence rate of $\mathcal{O}(\delta^{2/5})$ that we obtain for L_2 data is not as good as that $\mathcal{O}(\delta^{1/2})$ obtained by Tikhonov regularization and Lavrent'ev regularization. Only with continuous data are we able to reach the $\mathcal{O}(\delta^{1/2})$ rate of these methods. However, in contrast to these other methods, the theory for local regularization does not rely on an a priori guess for the value of the true solution or of the solution's value at $t = 0$, although a source condition does require a particular relationship between $\bar{x}(0)$ and $\|\bar{x}'\|_\infty$. The theory for both the local regularization and the Lavrent'ev methods requires a positive true solution $\bar{x}$, a condition not needed for Tikhonov regularization. However, as was shown in Examples 3 and 4, local regularization still performs quite well in numerical testing with nonpositive $\bar{x}$ provided a simple inspection of the noisy data has been made in order to determine a minimal suitable value of the local regularization parameter.

We have also presented two discretization algorithms which illustrate the theory developed in this paper; one algorithm involves the solution of nonsequential nonlinear equations on $[0, R]$; the second algorithm is an improvement in both speed and ease of implementation in that the approximate solution can be determined in a (linear) sequential manner for the entire interval $[0, 1]$. The cost for the second algorithm is $\mathcal{O}(rN^2 - r^2N)$, where $r \ll N$, so that it is of the order of the cost of solving the autoconvolution problem without any regularization whatsoever.

Finally, we have shown numerical results which provide evidence that the local regularization methods developed in this work compare favorably to the other numerical methods for the autoconvolution equation in the literature [11, 16], especially in capturing sharp features in the solution. In fact, the numerical results confirm the effectiveness of local regularization methods even in cases not completely falling under the assumptions of the general theory we developed here. Numerical examples also seem to confirm the feasibility of a modified discrepancy principle for the selection of the regularization parameter r. The theoretical analysis of this principle is currently under study.

Acknowledgments. Part of the research was completed while both authors were at the Institute for Pure and Applied Mathematics (IPAM) at UCLA. We thank IPAM for providing the financial support and hospitable environment conducive to productive research. We also thank the referees for helpful comments which improved the exposition of this paper.

ASYMPTOTIC HIGH-ORDER SCHEMES FOR 2 × 2 DISSIPATIVE HYPERBOLIC SYSTEMS*

DENISE AREGBA-DRIOLLET†, MAYA BRIANI‡, AND ROBERTO NATALINI§

Abstract. We investigate finite difference schemes which approximate 2 × 2 one-dimensional linear dissipative hyperbolic systems. We show that it is possible to introduce some suitable modifications in standard upwinding schemes, which keep into account the long-time behavior of the solutions, to yield numerical approximations which are increasingly accurate for large times when computing small perturbations of stable asymptotic states, respectively, around stationary solutions and in the diffusion (Chapman–Enskog) limit.

Key words. finite difference methods, dissipative hyperbolic problems, asymptotic behavior, asymptotic high-order schemes, Chapman–Enskog expansion

AMS subject classifications. 65M12, 35L65

DOI. 10.1137/060678373

1. Introduction.

Let us consider a one-dimensional 2 × 2 linear system with real coefficients

$$\begin{cases} u_t + \alpha u_x + \beta v_x = 0, \\ v_t + \gamma u_x + \delta v_x = \zeta u - \eta v \end{cases} \tag{1}$$

for $x \in \mathbb{R}$ and $t > 0$, with the initial conditions

$$u(x,0) = u_0(x),\ v(x,0) = v_0(x) \quad \text{for } x \in \mathbb{R}. \tag{2}$$

We assume that the system is strictly hyperbolic: The eigenvalues of the matrix $A = \begin{pmatrix} \alpha & \beta \\ \gamma & \delta \end{pmatrix}$,

$$\lambda_\pm = \frac{1}{2}\left[(\alpha+\delta) \pm \sqrt{(\alpha-\delta)^2 + 4\beta\gamma}\right],$$

are real and distinct, which is simply equivalent to the condition

$$(\alpha-\delta)^2 + 4\beta\gamma > 0. \tag{3}$$

Clearly, according to the general theory of linear hyperbolic problems (see, for instance, [16]) for every initial datum in some suitable functional class, there exists a

corresponding global solution in the same class. However, the stability of this solution, i.e., its global boundedness in time, is more involved, and mostly connected to the behavior of the equilibrium problem, when the source term vanishes, namely, the problem restricted on the manifold $v = \frac{\zeta}{\eta}u$, with u solving

$$u_t + \alpha^* u_x = 0 \tag{4}$$

for $\alpha^* = \alpha + \frac{\zeta}{\eta}\beta$. It is well known that a necessary and sufficient stability condition for problem (1) is given by the so-called subcharacteristic condition; see [17, 12]: The coefficient η is positive, and the speed of the equilibrium problem has to be bounded by the speeds of problem (1), i.e.,

$$\eta > 0, \qquad \lambda_- \le \alpha^* \le \lambda_+. \tag{5}$$

This simple example is a useful prototype for more general nonlinear relaxation systems which arise in various contexts; see again [17, 12] for examples and references. Recently, in [9, 2], a quite complete theory of global existence and of the asymptotic behavior of smooth solutions for this type of systems was developed, actually in a nonlinear and fully multidimensional framework. This theory, which in the case of our special example will be briefly summarized in section 2, needs for an extra assumption the so-called Shizuta–Kawashima condition [15, 9], which guarantees a sufficient coupling between the source and the advection terms. In the present example this condition is just equivalent to imposing the strict inequalities in (5). Roughly speaking, under these assumptions, it is possible to prove that, for every perturbation of a given stationary solution to problem (1), the corresponding solution decays in the L^p-norm to its unperturbed state as $\mathcal{O}(t^{-\frac{1}{2}(1-\frac{1}{p})})$ for $p \in [1, \infty]$. Moreover, when the asymptotic state is given by a constant state, it is possible to compare this perturbed solution with the solution $\hat{u}$ of the Chapman–Enskog expansion, which in the present case is given by

$$\hat{u}_t + \alpha^* \hat{u}_x = \nu \hat{u}_{xx}, \tag{6}$$

with $\nu = \frac{\beta}{\eta^2}[\gamma\eta - \frac{\beta}{\eta}\zeta^2 - (\alpha - \delta)\zeta]$. Notice that the strict subcharacteristic inequalities are equivalent to the condition $\nu > 0$. So (6) enjoys well-posedness of the Cauchy problem, and, again under the previous assumptions, it is actually possible to prove that the difference between u and the diffusive profile $\hat{u}$ decays in the L^p-norm as $\mathcal{O}(t^{-\frac{1}{2}(2-\frac{1}{p})})$ for $p \in [1, \infty]$, so a factor $\frac{1}{2}$ better than the simple decay to the steady state. Clearly, if the Shizuta–Kawashima condition is violated, no decay is in general expected, as follows easily, for instance, in the case $\beta = 0$.

In this paper, numerical approximations related to these asymptotic results will be introduced and discussed. Following the ideas in [5], where the case of a scalar hyperbolic equation was considered, we are looking for *asymptotic high-order* (AHO) schemes, i.e., schemes which are high-order accurate, with respect to the local truncation error, when restricted to every element of a given family of stable asymptotic states. Here we show that, for 2×2 dissipative hyperbolic systems, it is possible to introduce AHO schemes which are compatible with the behavior predicted by the qualitative analysis, respectively, for the long-time asymptotic and in the Chapman–Enskog regimes. The main idea we are going to apply is to modify standard upwinding schemes to keep into account the long-time behavior of the solutions. In section 3, we present some results of convergence and error estimates for general upwinding finite difference schemes for systems of the form (1), under the strict subcharacteristic

condition. Even if these results can be proven for more general weakly coupled systems (see, for instance, [12]), we prefer to present a precise statement to make the paper self-contained. Section 4 contains the description of our new schemes, which are AHO, respectively, around the perturbation of general steady states and in the diffusion limit. CFL estimates are presented to guarantee the monotonicity of these schemes. Some numerical tests are presented and discussed in section 5 to show the better performance of our schemes with respect to the usual pointwise approximation of the source term and even with the classical upwinding of the source proposed by Roe in 1986 [14]. In particular, we show by numerical tests that the L^∞ global error of our main diffusive adapted AHO2p-scheme decays as $\mathcal{O}(1/t)$, in agreement with the decay given by inequality (28), for a given fixed space step, against the decay as $\mathcal{O}(1/\sqrt{t})$ of the other schemes.

Let us notice that our schemes can be in principle extended to most of the dissipative nonlinear hyperbolic systems arising in applications (see examples reported in [9, 2]), even if the computation of the form of the schemes could be not trivial. Notice that the AHO modifications occur mainly in the pointwise discretization of the source term and do not require the explicit knowledge of the asymptotic solution. However, stability analysis should be much more involved in the general case, and so this problem will be addressed in a future paper.

Finally, let us remark that our approach is somewhat related to the ideas motivating the so-called well-balanced schemes; see, for instance, [1, 7, 10, 3, 13], and the book [4], which, however, are more relevant on different time scales and contexts, as, for instance, for inhomogeneous source terms.

2. Analytical backgrounds. Let us consider system (1), which first will be rewritten in a vector form, by setting $U = (u, v)$ and

$$A = \begin{pmatrix} \alpha & \beta \\ \gamma & \delta \end{pmatrix}, \qquad B = \begin{pmatrix} 0 & 0 \\ \zeta & -\eta \end{pmatrix}.$$

System (1) reads now

$$U_t + AU_x = BU. \tag{7}$$

The first-order system (7) is said to be in conservative-dissipative form (CD form) if the matrix A is symmetric and the coefficient ζ, in the matrix B, vanishes. Our first goal is to reduce every 2×2 system, which verifies some suitable assumptions, to the CD form, to enter the framework in [2].

PROPOSITION 2.1. *Let $\eta > 0$, and assume the strict subcharacteristic condition*

$$\lambda_- < \alpha^* < \lambda_+. \tag{8}$$

Then there exists a nonsingular linear change of variable such that system (1) *can be set in the CD form.*

Proof. First let us remark that, by an elementary computation, condition (8) is equivalent to the single inequality

$$\beta \left[\gamma\eta - \frac{\beta}{\eta}\zeta^2 - (\alpha - \delta)\zeta \right] > 0. \tag{9}$$

Let us introduce the following change of variable:

$$\begin{pmatrix} \tilde{u} \\ \tilde{v} \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ q & r \end{pmatrix} \begin{pmatrix} u \\ v \end{pmatrix},$$

with $q = -\frac{\zeta}{\eta} r$ and r given by

$$r = \left[\beta\eta \left(\gamma\eta - \frac{\beta}{\eta}\zeta^2 - (\alpha - \delta)\zeta \right)^{-1} \right]^{1/2}.$$

By condition (9), this quantity is well-defined, real, and positive. The new unknowns $(\tilde{u}, \tilde{v})$ solve the system

$$\begin{cases} \tilde{u}_t + (\alpha + \frac{\zeta}{\eta}\beta)\tilde{u}_x + \frac{\beta}{r}\tilde{v}_x = 0, \\ \\ \tilde{v}_t + \frac{\beta}{r}\tilde{u}_x + (\delta - \frac{\zeta}{\eta}\beta)\tilde{v}_x = -\eta\tilde{v}, \end{cases} \tag{10}$$

which is in CD form. □

Therefore, according to the previous result, from now on and without loss of generality, we shall restrict our attention to the following model problem:

$$\begin{cases} u_t + au_x + bv_x = 0, \\ \\ v_t + bu_x + cv_x = -dv, \end{cases} \tag{11}$$

where the constants a, b, c, and d are real, $b \neq 0$, and $d > 0$.

We want to obtain some estimates for the L^1-, L^∞- norms and total variation, so we need to diagonalize the system. First let us rewrite system (11) in the vector form (7), with

$$A = \begin{pmatrix} a & b \\ b & c \end{pmatrix}, \qquad B = -\begin{pmatrix} 0 & 0 \\ 0 & d \end{pmatrix}.$$

Now we can diagonalize the matrix A:

$$A = R\Lambda R^{-1},$$

where $\Lambda = \mathrm{diag}(\lambda_1, \lambda_2)$ and $R = (r^{(1)}, r^{(2)})$ is the column matrix of right eigenvectors, i.e., $Ar^{(i)} = \lambda_i r^{(i)}$, $i = 1, 2$. Introducing the notation

$$\mathrm{w} = R^{-1}U, \tag{12}$$

problem (11) becomes

$$\begin{cases} \mathrm{w}_t + \Lambda \mathrm{w}_x = \tilde{B}\mathrm{w}, \\ \\ \mathrm{w}(x, 0) = \mathrm{w}^0(x) = R^{-1}\mathrm{u}^0(x), \end{cases} \tag{13}$$

where $\tilde{B} = R^{-1}BR$.

If we choose the matrix of the diagonalization of the system (7) as

$$R = \begin{pmatrix} 1 & 1 \\ -\dfrac{(a - \lambda_1)}{b} & \dfrac{(\lambda_2 - a)}{b} \end{pmatrix}, \tag{14}$$

the corresponding source term is then given by

$$\tilde{B} = \frac{d}{\lambda_2 - \lambda_1} \begin{pmatrix} -(a - \lambda_1) & (\lambda_2 - a) \\ (a - \lambda_1) & -(\lambda_2 - a) \end{pmatrix}. \tag{15}$$

Now we can prove the main result about monotonicity and L^1-contraction properties of system (11). Let us set

$$L = L(\lambda) = \max_{i=1,2} |\lambda_i|.$$

For any given vectors $C, D \in \mathbb{R}^2$, set $C \leq D$ if $c_i \leq d_i$ $(i = 1, 2)$; if $C \leq D$, let us denote the corresponding interval by $[C, D]$. Also, for each interval $I = (x_1, x_2) \subseteq \mathbb{R}$, we set $\tau = (x_2 - x_1)/2L$.

PROPOSITION 2.2. *Let* w *and* $\tilde{\mathrm{w}}$ *be two weak solutions of the Cauchy problem* (13) *in* $\mathbb{R} \times (0, T)$ $(T > 0)$ *for the initial data* w^0 *and* $\tilde{\mathrm{w}}^0$*, respectively. Let* $[C, D] \subseteq \mathbb{R}^2$ *be an interval with nonempty interior such that* w, $\tilde{\mathrm{w}} \in [C, D]$*. If the matrix* B *is given by* (15)*, then for each interval* $(x_1, x_2) \subseteq \mathbb{R}$ *and for all* $t \in (0, \min(\tau, T))$ *we have*

$$\sum_{i=1,2} \int_{x_1+tL}^{x_2-tL} [w_i - \tilde{w}_i]_+ dx \leq \sum_{i=1,2} \int_{x_1}^{x_2} [w_i^0 - \tilde{w}_i^0]_+ dx. \tag{16}$$

Proof. Define $\mathrm{v} = \mathrm{w} - \tilde{\mathrm{w}}$. We multiply the i component of the system (13) by the Heaviside function $H(v_i)$, where $v_i = w_i - \tilde{w}_i$, $i \in \{1, 2\}$, and we add both equations. We get

$$\sum_{i=1}^{2} \partial_t [v_i]_+ + \sum_{i=1}^{2} \lambda_i \partial_x [v_i]_+ = \sum_{i,j \in \{1,2\}} \tilde{b}_{ij} H(v_i) v_j, \tag{17}$$

where we used the relations $H(\mathrm{v})\mathrm{v} = [\mathrm{v}]_+$ and $H(\mathrm{v})\partial_\cdot \mathrm{v} = \partial_\cdot [\mathrm{v}]_+$. We have

$$\sum_{i,j \in \{1,2\}} \tilde{b}_{ij} H(v_i) v_j \leq \sum_{i \in \{1,2\}} \tilde{b}_{ii} [v_i]_+ + \sum_{i \in \{1,2\}} \sum_{j \neq i} \tilde{b}_{ij} [v_j]_+ \tag{18}$$

$$= \sum_{i \in \{1,2\}} \left(\tilde{b}_{ii} + \sum_{j \neq i} \tilde{b}_{ji} \right) [v_i]_+. \tag{19}$$

By considering (15), we can therefore conclude that the right-hand side of (17) is nonpositive. Then we argue as in [8] and obtain the desired inequality. ∎

Clearly, from Proposition 2.2 we can easily deduce, by standard arguments, L^1- and L^∞-estimates, as well as obvious comparison properties of solutions, and, as the system (11) is linear, the same estimates hold for the derivatives of solutions. More precisely we use the following result in what follows.

COROLLARY 2.3. *Let* $\mathrm{w}^0 \in C^m(\mathbb{R})$ *such that*

$$\frac{d^k \mathrm{w}^0}{dx^k} \in L^1(\mathbb{R}) \cap L^\infty(\mathbb{R}) \quad \textit{for } 0 \leq k \leq m. \tag{20}$$

Then the Cauchy problem (13) *has a unique solution* $\mathrm{w} \in C^0([0, +\infty[, L^1(\mathbb{R}))$*, and there exists a constant* $K > 0$*, not depending on* w^0*, such that for* $0 \leq k \leq m$*,* $p = 1$*, and* $p = \infty$*,*

$$\|\partial_x^k \mathrm{w}(., t)\|_p \leq K \left\| \frac{d^k \mathrm{w}^0}{dx^k} \right\|_p, \quad \|\partial_t \mathrm{w}(., t)\|_p \leq K \left(\left\| \frac{d\mathrm{w}^0}{dx} \right\|_p + \|\mathrm{w}^0\|_p \right). \tag{21}$$

Let us also notice that for system (11) it is possible to prove an energy inequality, as in [9], but in the present framework this estimate is not immediately relevant.

Now we are in position to investigate the asymptotic behavior of solutions to problem (11). Here we refer to the results in [9, 2] about the Cauchy problem for a general $n \times n$ hyperbolic symmetrizable one-dimensional system of balance laws

$$U_t + f(U)_x = g(U), \tag{22}$$

with the initial condition

$$U(x,0) = U_0(x), \tag{23}$$

where $U = (u_1, u_2) \in \Omega \subseteq \mathbb{R}^{n_1} \times \mathbb{R}^{n_2}$, with $n_1 + n_2 = n$. It is also assumed that there are n_1 conservation laws in the system, namely, that we can take

$$g(U) = \begin{pmatrix} 0 \\ q(U) \end{pmatrix}, \quad \text{with } q(U) \in \mathbb{R}^{n_2}. \tag{24}$$

In [9], a general framework of sufficient conditions was proposed which guarantee the global existence in time of smooth solutions, by showing that dissipation, at least for small data, can prevent shock formation. Actually, for the systems which are endowed with a strictly convex entropy function $\mathcal{E} = \mathcal{E}(U)$, a first natural assumption is the *entropy dissipation condition* (see [6]); namely, for every U, $\overline{U} \in \Omega$, with $g(\overline{U}) = 0$,

$$\big(\mathcal{E}'(U) - \mathcal{E}'(\overline{U})\big) \cdot g(U) \le 0.$$

Unfortunately, it is easy to see that this condition is too weak to prevent the formation of singularities. A quite natural supplementary condition can be imposed to entropy dissipative systems, following the approach first proposed by Kawashima [11] and Shizuta and Kawashima [15], which for system (22) reads

$$\text{Ker } Dg(\overline{U}) \cap \{\text{eigenspaces of } Df(\overline{U})\} = \{0\} \tag{25}$$

for every $\overline{U} \in \Omega$, with $g(\overline{U}) = 0$. It is possible to prove that this condition, which is satisfied in many interesting examples, is also sufficient to establish a result of global existence for small perturbations of equilibrium constant states; see [9]. Clearly also system (11) fits this framework. In fact the system is entropy dissipative for the entropy function $\mathcal{E}(u,v) = \frac{1}{2}(u^2 + v^2)$ if and only if $d > 0$, and condition (25) is satisfied if $b \neq 0$. Therefore we can apply all of the results proved in [2] about the asymptotic behavior of dissipative hyperbolic systems to system (11). Here we just state two main results of time decay. More details and proofs are contained in [2]. For $s > 0$, set $E_s = \max\{\|U(0)\|_{L^1}, \|U(0)\|_{H^s}\}$.

THEOREM 2.4. *Let $(u(t), v(t))$ be a smooth global solution to problem (11)–(2), with $b \neq 0$ and $d > 0$. Let $p \in [1, \infty]$. The following decay estimate holds for some positive constant $C > 0$:*

$$\|D^\beta(u(t), v(t))\|_{L^p} \le C \min\Big\{1, t^{-\frac{1}{2}(1-\frac{1}{p})-|\beta|/2}\Big\} E_{|\beta|+2}. \tag{26}$$

For the dissipative part $v(t)$, we have a more precise estimate for some positive constant $C > 0$:

$$\|D^\beta v(t)\|_{L^p} \le C \min\Big\{1, t^{-\frac{1}{2}(1-\frac{1}{p})-1/2-|\beta|/2}\Big\} E_{|\beta|+2}. \tag{27}$$

Another interesting result concerns the convergence to the Chapman–Enskog expansion of problem (11), which is given by the parabolic equation (6).

THEOREM 2.5. *Let $\hat{u}$ be the solution of problem* (6)*, with $\alpha^* = a$ and $\nu = \frac{b^2}{d}$, and the initial condition given by* (2)*. Under the assumptions of Theorem* 2.4*, we have the following more accurate decay estimate for some positive constant $C > 0$:*

$$\|D^\beta(u(t) - \hat{u}(t))\|_{L^p} \le C \min\left\{1, t^{-\frac{1}{2}(1-\frac{1}{p})-|\beta|/2-1/2}\right\} E_{|\beta|+2}. \tag{28}$$

3. Numerical approximation. Here we introduce and discuss general finite difference approximations for system (11), and we prove some convergence properties and error estimates.

3.1. Construction of the schemes. We approximate the differential part following the direction of the characteristic velocities, so first we study the methods for the system in diagonal form (13) obtained by the choice (14). We denote by $\mathrm{w} = (w^1, w^2)$ the exact solution.

We denote by h the uniform mesh length and by $x_l = l\,h$ the spatial grid points for all $l \in \mathbb{Z}$. The time levels t_n, with $t_0 = 0$, are also spaced uniformly with mesh length $\Delta t = t_{n+1} - t_n$ for $n \in \mathbb{N}$. We denote by δ the CFL ratio $\delta = \Delta t/h$, which is taken constant through the paper.

We consider the Cauchy problem (13). The initial data w^0 is supposed to be smooth and is approximated by its node values. The approximate solution $W_l^n = (w_{l,n}^1, w_{l,n}^2)^T$ is given by

$$\begin{aligned} &\frac{W_l^{n+1} - W_l^n}{\Delta t} + \frac{\Lambda}{2h}\left(W_{l+1}^n - W_{l-1}^n\right) - \frac{\tilde{Q}}{2h}\left(W_{l+1}^n - 2W_l^n + W_{l-1}^n\right) \\ &= \tilde{\mathcal{B}}_{-1} W_{l-1}^n + \tilde{\mathcal{B}}_0 W_l^n + \tilde{\mathcal{B}}_1 W_{l+1}^n, \quad l \in \mathbb{Z},\ n \in \mathbb{N}, \\ &W_l^0 = \mathrm{w}^0(x_l), \quad l \in \mathbb{Z}, \end{aligned} \tag{29}$$

where $\tilde{Q} = \mathrm{diag}(\tilde{q}_1, \tilde{q}_2)$ is the diagonal matrix of the artificial diffusion terms $\tilde{q}_i \ge 0$ ($i \in \{1, 2\}$), and $\tilde{\mathcal{B}}_{-1} = (\tilde{\beta}_{ij}^{-1})_{i,j=1,2}$, $\tilde{\mathcal{B}}_0 = (\tilde{\beta}_{ij}^0)_{i,j=1,2}$, and $\tilde{\mathcal{B}}_1 = (\tilde{\beta}_{ij}^1)_{i,j=1,2}$ are 2×2 constant matrices that define the source approximation. Those matrices may depend on h.

We set

$$W_\Delta^n(x) = W_l^n \quad \text{if } x \in [x_l, x_{l+1}[$$

and

$$W_\Delta(x,t) = W_\Delta^n(x) \quad \text{if } t \in [t_n, t_{n+1}[.$$

The scheme (29) can be seen as a linear function

$$W_\Delta^{n+1} = \mathbf{S}_{\Delta t}(W_\Delta^n). \tag{30}$$

More precisely we have

$$w_{l,n+1}^i = S^i(W_{l-1}^n, W_l^n, W_{l+1}^n), \quad i \in \{1, 2\}, \quad l \in \mathbb{Z}, \tag{31}$$

with

$$\begin{aligned} S^i(W_{l-1}^n, W_l^n, W_{l+1}^n) &= \alpha_{-1}^i w_{l-1,n}^i + \alpha_0^i w_{l,n}^i + \alpha_1^i w_{l+1,n}^i \\ &+ \Delta t \sum_{j \in \{1,2\}} \left(\tilde{\beta}_{ij}^{-1} w_{l-1,n}^j + \tilde{\beta}_{ij}^0 w_{l,n}^j + \tilde{\beta}_{ij}^1 w_{l+1,n}^j\right), \end{aligned} \tag{32}$$

where, for all $i \in \{1,2\}$,

$$\alpha_{-1}^i = \frac{\delta}{2}\lambda_i + \frac{\delta}{2}\tilde{q}_i, \quad \alpha_0^i = 1 - \delta\tilde{q}_i, \quad \alpha_1^i = -\frac{\delta}{2}\lambda_i + \frac{\delta}{2}\tilde{q}_i \,. \tag{33}$$

For any function ψ defined on $\mathbb{R}$ with values in $\mathbb{R}^2$, we set

$$\overline{\psi}(x) = (\psi(x-h), \psi(x), \psi(x+h)). \tag{34}$$

The function $\mathbf{S}_{\Delta t}$ is then defined by

$$\mathbf{S}_{\Delta t}(\psi)(x) = \left(S^1(\overline{\psi}(x)), S^2(\overline{\psi}(x))\right). \tag{35}$$

3.2. Convergence for smooth data. We assume that the scheme satisfies the two following properties:

1. *Consistency.* The scheme (29) is consistent with problem (13), i.e.,

$$\tilde{\mathcal{B}}_{-1} + \tilde{\mathcal{B}}_0 + \tilde{\mathcal{B}}_1 = \tilde{B} + h\tilde{C}, \tag{36}$$

   where $\tilde{C} = (\tilde{c}_{ij})_{i,j=1,2}$ is a 2×2 constant matrix not depending on h and Δt.
2. *Monotonicity.* For all $i \in \{1,2\}$, the operators S^i, defined in (31), are monotone nondecreasing in all of their components, i.e.,

$$\tilde{\beta}_{ij}^{-1}, \tilde{\beta}_{ij}^0, \tilde{\beta}_{ij}^1 \geq 0 \quad \forall\, i \neq j, \tag{37}$$

$$A_{i,0} = 1 - \delta\tilde{q}_i + \Delta t\tilde{\beta}_{ii}^0 \geq 0 \quad \forall\ i \in \{1,2\}, \tag{38}$$

$$\begin{cases} A_{i,-1} = \dfrac{\delta\lambda_i}{2} + \dfrac{\delta\tilde{q}_i}{2} + \Delta t\tilde{\beta}_{ii}^{-1} \geq 0, \\ \\ A_{i,1} = -\dfrac{\delta\lambda_i}{2} + \dfrac{\delta\tilde{q}_i}{2} + \Delta t\tilde{\beta}_{ii}^1 \geq 0 \end{cases} \quad \forall\ i \in \{1,2\}. \tag{39}$$

For $t \geq 0$ and $x \in \mathbb{R}$, by using the notation (34) for w, the local truncation error $T(x,t)$ is defined by

$$T(x,t) = \frac{\mathrm{w}(x, t+\Delta t) - \mathbf{S}_{\Delta t}\mathrm{w}(.,t)(x)}{\Delta t},$$

which can also be written

$$T^i(x,t) = \frac{w^i(x,t+\Delta t) - S^i(\overline{\mathrm{w}}(x,t))}{\Delta t}, \quad i \in \{1,2\}.$$

It is obtained straightforwardly by Taylor expansions:

$$\begin{aligned} T^i(x,t) \;=\; & \frac{\Delta t}{2}\partial_{tt}w^i(x,t+\theta_i\Delta t) - h\frac{\tilde{q}_i}{2}\partial_{xx}w^i(x,t) - h\sum_{j\in\{1,2\}}\tilde{c}_{ij}w^j(x,t) \\ & -h\sum_{j\in\{1,2\}}(\tilde{\beta}_{ij}^1 - \tilde{\beta}_{ij}^{-1})\partial_x w^j(x,t) + \mathcal{O}(h^2). \end{aligned} \tag{40}$$

In this formula, $\theta_i \in [0,1]$, and the last term depends on the spatial derivatives of w, up to third order.

In view of proving convergence, we need the discrete truncation error, which is defined as

$$T_\Delta(x,t) = T(x_l,t) \quad \text{for} \quad x \in [x_l, x_{l+1}[.$$

The scheme is first-order in the following sense.

PROPOSITION 3.1 (accuracy for smooth data). *Consider a smooth initial datum* w^0 *such that*

$$\frac{d^k \mathrm{w}^0}{dx^k} \in L^1(\mathbb{R}) \cap L^\infty(\mathbb{R}) \quad for \;\; 0 \le k \le 4. \tag{41}$$

Then the discrete local truncation error $T_\Delta(x,t)$ *for the scheme* (29) *satisfies*

$$\sum_{i\in\{1,2\}} \left[\|T^i_\Delta(.,t)\|_1 + \|T^i_\Delta(.,t)\|_\infty \right] \le C(\Delta t + h). \tag{42}$$

Here

$$C \le C_1 \sup_{0\le k\le 4} \left(\left\| \frac{d^k \mathrm{w}^0}{dx^k} \right\|_1 + \left\| \frac{d^k \mathrm{w}^0}{dx^k} \right\|_\infty \right), \tag{43}$$

and C_1 *is a uniform constant.*

Proof. We can express $\partial_{tt}\mathrm{w}$ as a linear function of w, $\partial_x \mathrm{w}$, $\partial_{xx}\mathrm{w}$. As a consequence, there exists a constant C_0,

$$C_0 \le C_0' \sup_{k\le 3} \sup_{t\in[0,+\infty[} (\|\partial_x^k \mathrm{w}(.,t)\|_1 + \|\partial_x^k \mathrm{w}(.,t)\|_\infty),$$

such that

$$\sum_{i\in\{1,2\}} \left[\|T^i(.,t)\|_1 + \|T^i(.,t)\|_\infty \right] \le C_0(\Delta t + h). \tag{44}$$

Moreover, it is easy to see that for $p = 1$ or $p = \infty$

$$\|T^i(.,t) - T^i_\Delta(.,t)\|_p \le h \|\partial_x T^i(.,t)\|_p, \quad i \in \{1,2\},$$

which, with Corollary 2.3, gives the estimate (42). ∎

We prove now that the scheme is stable.

PROPOSITION 3.2 (L^1 stability). *For the matrix* $\tilde{C}$ *defined in* (36), *we introduce the quantity*

$$\tilde{\gamma} = \left[\sup_{i\in\{1,2\}} \left\{ \tilde{c}_{ii} + \sum_{j\neq i} \tilde{c}_{ji} \right\} \right]_+ . \tag{45}$$

Under the monotonicity assumptions (37)–(39), *the scheme* (29) *is* L^1*-stable: For all* $W^0_\Delta \in L^1(\mathbb{R})$ *it holds that*

$$\|W^n_\Delta\|_1 \le e^{\tilde{\gamma} h t_n} \|W^0_\Delta\|_1 \quad \forall n \ge 1. \tag{46}$$

Proof. The norm of W_Δ^{n+1} can be written as

$$\|W_\Delta^{n+1}\|_1 = h \sum_{i=1,2} \sum_{l\in\mathbb{Z}} \left| w_{l,n}^i - \delta \frac{\lambda_i}{2}(w_{l+1,n}^i - w_{l-1,n}^i) + \delta \frac{\tilde{q}_i}{2}(w_{l+1,n}^i - 2w_{l,n}^i + w_{l-1,n}^i) \right.$$

$$\left. + \Delta t \sum_{j=1,2} \left(\tilde{\beta}_{ij}^{-1} w_{l-1,n}^j + \tilde{\beta}_{ij}^0 w_{l,n}^j + \tilde{\beta}_{ij}^1 w_{l+1,n}^j \right) \right| \tag{47}$$

$$\leq h \sum_{i=1,2} \sum_{l\in\mathbb{Z}} |w_{l,n}^i| A_i.$$

Here A_i is defined by

$$A_i = |A_{i,0}| + |A_{i,-1}| + |A_{i,1}| + \Delta t \sum_{j\neq i} (|\tilde{\beta}_{ji}^{-1}| + |\tilde{\beta}_{ji}^0| + |\tilde{\beta}_{ji}^1|),$$

with quantities $A_{i,k}$ defined in (37)–(39). By those assumptions and by the definition of $\tilde{C}$ we obtain that

$$A_i \leq 1 + \tilde{\gamma} h \, \Delta t.$$

Hence

$$\|W_\Delta^{n+1}\|_1 \leq (1 + \tilde{\gamma} h \, \Delta t) \|W_\Delta^n\|_1,$$

and this gives (46). ∎

We have also a uniform bound for the scheme.

PROPOSITION 3.3 (L^∞ stability). *Under the monotonicity assumptions* (37)–(39)*, the scheme* (29) *is L^∞-stable: For all $W_\Delta^0 \in L^\infty(\mathbb{R})$ it holds that*

$$\|W_\Delta^n\|_\infty \leq (1 + \tilde{\gamma} h \, \Delta t) \|W_\Delta^{n-1}\|_\infty \leq e^{\tilde{\gamma} h t_n} \|W_\Delta^0\|_\infty \quad \forall n \geq 1. \tag{48}$$

The proof is similar to the one of Proposition (3.2), so we omit it.

We have proved consistency and stability, so we have convergence.

THEOREM 3.4. *Let* w^0 *be a smooth initial datum satisfying* (41)*. We suppose that the monotonicity assumptions* (37)–(39) *are verified and that $\delta = \Delta t/h$ is fixed.*

For all $T > 0$ the scheme (29) *converges in $L^\infty([0,T], L^1(\mathbb{R}) \cap L^\infty(\mathbb{R}))$ towards the solution of the Cauchy problem* (13)*: There exists $h_0(T) > 0$ such that for all $h < h_0(T)$*

$$\sup_{t\in[0,T]} (\|W_\Delta(.,t) - \mathrm{w}(.,t)\|_1 + \|W_\Delta(.,t) - \mathrm{w}(.,t)\|_\infty) \leq (2T+1)\, C\, (\Delta t + h), \tag{49}$$

where C is defined in (43)*.*

Proof. Let us fix $t \in [0,T]$. There exists an integer n such that $t_n \leq t < t_{n+1}$. We set

$$\mathrm{w}_\Delta(x,t) = \mathrm{w}(x_l, t) \quad \text{for} \quad x \in [x_l, x_{l+1}[.$$

For $p = 1$ and $p = \infty$, we have

$$\begin{aligned} \|W_\Delta(.,t) - \mathrm{w}(.,t)\|_p \leq{}& \|W_\Delta^n - \mathrm{w}_\Delta(.,t_n)\|_p \\ &+ \|\mathrm{w}_\Delta(.,t_n) - \mathrm{w}(.,t_n)\|_p \\ &+ \|\mathrm{w}(.,t_n) - \mathrm{w}(.,t)\|_p \,. \end{aligned} \tag{50}$$

The two last terms of this inequality are easily estimated:

$$\|\mathrm{w}_\Delta(.,t_n) - \mathrm{w}(.,t_n)\|_p + \|\mathrm{w}(.,t_n) - \mathrm{w}(.,t)\|_p \le C(h+\Delta t).$$

In order to study the other term, we introduce the following notation:

$$V_\Delta^m = \mathrm{w}_\Delta(.,t_m), \quad m = 0,\dots,n.$$

We have

$$\begin{aligned}\|W_\Delta^n - \mathrm{w}_\Delta(.,t_n)\|_p \le{}& \|\mathbf{S}_{\Delta t}^{n-1}\mathbf{S}_{\Delta t}(V_\Delta^0) - \mathbf{S}_{\Delta t}^{n-1}(V_\Delta^1)\|_p \\ &+ \|\mathbf{S}_{\Delta t}^{n-2}\mathbf{S}_{\Delta t}(V_\Delta^1) - \mathbf{S}_{\Delta t}^{n-2}(V_\Delta^2)\|_p \\ &+ \cdots \\ &+ \|\mathbf{S}_{\Delta t}(V_\Delta^{n-1}) - V_\Delta^n\|_p\ .\end{aligned}$$

By L^p stability,

$$\begin{aligned}\|W_\Delta^n - \mathrm{w}_\Delta(.,t_n)\|_p \le{}& \|\mathbf{S}_{\Delta t}(V_\Delta^0) - V_\Delta^1\|_p e^{\tilde\gamma h t_{n-1}} \\ &+ \|\mathbf{S}_{\Delta t}(V_\Delta^1) - V_\Delta^2\|_p e^{\tilde\gamma h t_{n-2}} \\ &+ \cdots \\ &+ \|\mathbf{S}_{\Delta t}(V_\Delta^{n-1}) - V_\Delta^n\|_p\ .\end{aligned} \tag{51}$$

We then sum over $p \in \{1,\infty\}$. We may apply the consistency result (42) to each term in the right-hand side:

$$V_\Delta^{j+1}(x) - \mathbf{S}_{\Delta t}(V_\Delta^j)(x) = \Delta t T_\Delta(x,t_j), \quad j = 0,\dots,n-1.$$

Summing up all of the terms gives

$$\|W_\Delta^n - \mathrm{w}_\Delta(.,t_n)\|_1 + \|W_\Delta^n - \mathrm{w}(.,t_n)\|_\infty \le \Delta t C(\Delta t + h)\frac{e^{\tilde\gamma h T}-1}{e^{\tilde\gamma h \Delta t}-1}\,.$$

As δ is constant we have

$$\lim_{h\to 0} \Delta t \frac{e^{\tilde\gamma h T}-1}{e^{\tilde\gamma h \Delta t}-1} = T,$$

which ends the proof. ∎

Notice that, if $\tilde\gamma = 0$, the scheme is L^1 contracting, and we have for all h and Δt

$$\sup_{t\in[0,T]} \left(\|W_\Delta(.,t) - \mathrm{w}(.,t)\|_1 + \|W_\Delta(.,t) - \mathrm{w}(.,t)\|_\infty\right) \le (T+1)\ C\ (\Delta t + h).$$

4. Asymptotic high-order schemes. In this section, we study the discretization of the source term, defined by coefficients $\tilde{\mathcal{B}}_{-1,0,1}$ introduced in (13), to present some schemes which are increasingly accurate for large times, with respect to the asymptotic behavior of solutions. This property of accuracy is required in order to get better results for large time simulations when computing perturbations of nonconstant stable states. Actually, given a stable solution z (or a family of stable solutions), we say that a scheme is *asymptotic high-order* of order q (AHOq) with respect to this stable state if the scheme is accurate of order q when restricted to this solution; see [5].

4.1. The construction of an AHO4 scheme for stationary solutions. Here we consider the case of a perturbation of a generic stationary solution. Let us first develop the formula (40) for a smooth solution w:

$$
\begin{aligned}
T(x,t) &= \frac{\Lambda}{2h}\left(\frac{h^3}{3}\partial_x^3 \mathrm{w}(x,t) + \mathcal{O}(h^5)\right)\\
&-\frac{\tilde{Q}}{2h}\left(h^2\partial_x^2 \mathrm{w}(x,t) + \frac{h^4}{12}\partial_x^4 \mathrm{w}(x,t) + \mathcal{O}(h^6)\right)\\
&-h\tilde{C}\mathrm{w}(x,t) - h\left(\tilde{\mathcal{B}}_1 - \tilde{\mathcal{B}}_{-1}\right)\partial_x \mathrm{w}(x,t) - \frac{h^2}{2}\left(\tilde{\mathcal{B}}_1 + \tilde{\mathcal{B}}_{-1}\right)\partial_x^2 \mathrm{w}(x,t)\\
&-\frac{h^3}{6}\left(\tilde{\mathcal{B}}_1 - \tilde{\mathcal{B}}_{-1}\right)\partial_x^3 \mathrm{w}(x,t) + \mathcal{O}(h^4) + \Delta t\int_0^1 (1-\theta)\partial_t^2 \mathrm{w}(x,t+\theta\Delta t)d\theta.
\end{aligned}
\tag{52}
$$

The terms $\mathcal{O}(h^k)$ involve only spatial derivatives of w. Let us now consider the stationary solution z, namely, the solution of problem

$$
\Lambda\partial_x \mathrm{z} = \tilde{B}\mathrm{z}. \tag{53}
$$

First, we remark that if $\lambda_1\lambda_2 = 0$, i.e., $ac - b^2 = 0$, then all of the stationary solutions are constant with respect to x. Hence for such solutions

$$
T(x,t) = -h\tilde{C}\mathrm{z}.
$$

Any scheme with $\tilde{C} = 0$ is an AHO-∞ scheme. In the following we suppose that

$$
ac - b^2 \neq 0. \tag{54}
$$

For smooth data we get

$$
\partial_x^k \mathrm{z} = (\Lambda^{-1}\tilde{B})^k \mathrm{z}. \tag{55}
$$

We compute the local truncation error (52) on this particular solution. It does not depend on t anymore, and we denote it by $T_{stat}(x)$:

$$
\begin{aligned}
T_{stat}(x) = \quad & -\frac{h}{2}\left(\tilde{Q}(\Lambda^{-1}\tilde{B})^2 + 2\tilde{C} + 2\big(\tilde{\mathcal{B}}_1 - \tilde{\mathcal{B}}_{-1}\big)(\Lambda^{-1}\tilde{B})\right)\mathrm{z}(x)\\
& -\frac{h^2}{6}\left(-\tilde{B} + 3\big(\tilde{\mathcal{B}}_1 + \tilde{\mathcal{B}}_{-1}\big)\right)(\Lambda^{-1}\tilde{B})^2\mathrm{z}(x)\\
& -\frac{h^3}{24}\left(\tilde{Q}(\Lambda^{-1}\tilde{B}) + 4\big(\tilde{\mathcal{B}}_1 - \tilde{\mathcal{B}}_{-1}\big)\right)(\Lambda^{-1}\tilde{B})^3\mathrm{z}(x) + \mathcal{O}(h^4).
\end{aligned}
\tag{56}
$$

Example 1 (pointwise approximation of the source term (AHO1-UP)). Fixing, for the differential terms, the upwind approximation $\tilde{Q} = \mathrm{diag}(|\lambda_1|, |\lambda_2|)$, the basic scheme gives a first-order approximation even on the stationary solution:

$$
\tilde{B}_{up}^{-1} = \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix}, \quad \tilde{B}_{up}^{0} = \begin{bmatrix} \tilde{b}_{11} & \tilde{b}_{12} \\ \tilde{b}_{21} & \tilde{b}_{22} \end{bmatrix}, \quad \tilde{B}_{up}^{1} = \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix}. \tag{57}
$$

Example 2 (upwinding of the source term (AHO2-ROE) [14]). An improvement on the previous example is given by a second-order upwinding scheme:

$$\tilde{B}^{-1}_{roe} = \frac{1}{2}\begin{bmatrix} H(\lambda_1)\tilde{b}_{11} & H(\lambda_1)\tilde{b}_{12} \\ H(\lambda_2)\tilde{b}_{21} & H(\lambda_2)\tilde{b}_{22} \end{bmatrix}, \quad \tilde{B}^{0}_{roe} = \frac{1}{2}\begin{bmatrix} \tilde{b}_{11} & \tilde{b}_{12} \\ \tilde{b}_{21} & \tilde{b}_{22} \end{bmatrix},$$
$$\tilde{B}^{1}_{roe} = \frac{1}{2}\begin{bmatrix} (1-H(\lambda_1))\tilde{b}_{11} & (1-H(\lambda_1))\tilde{b}_{12} \\ (1-H(\lambda_2))\tilde{b}_{21} & (1-H(\lambda_2))\tilde{b}_{22} \end{bmatrix}, \tag{58}$$

where $H(\cdot)$ is the Heaviside function and where, as above, $\tilde{Q} = \mathrm{diag}(|\lambda_1|, |\lambda_2|)$.

A more accurate scheme is given by our AHO4 scheme, which is fourth-order on the stationary solution, as soon as all terms between round brackets in (56) vanish. The AHO4 coefficients $\tilde{\mathcal{B}}_{-1}$, $\tilde{\mathcal{B}}_0$, $\tilde{\mathcal{B}}_1$ are then uniquely defined by

$$\begin{cases} \tilde{\mathcal{B}}_{-1} = \tilde{B}/6 + \tilde{Q}\Lambda^{-1}\tilde{B}/8, \\ \tilde{\mathcal{B}}_0 = 2\tilde{B}/3 - h\tilde{Q}(\Lambda^{-1}\tilde{B})^2/4, \\ \tilde{\mathcal{B}}_1 = \tilde{B}/6 - \tilde{Q}\Lambda^{-1}\tilde{B}/8, \end{cases} \tag{59}$$

or equivalently

$$\tilde{\mathcal{B}}^{-1}_{aho} = \frac{1}{8}\begin{bmatrix} \tilde{b}_{11}\big(4/3 + \tilde{q}_1/\lambda_1\big) & \tilde{b}_{12}\big(4/3 + \tilde{q}_1/\lambda_1\big) \\ \tilde{b}_{21}\big(4/3 + \tilde{q}_2/\lambda_2\big) & \tilde{b}_{22}\big(4/3 + \tilde{q}_2/\lambda_2\big) \end{bmatrix},$$

$$\tilde{\mathcal{B}}^{0}_{aho} = \frac{2}{3}\begin{bmatrix} \tilde{b}_{11} & \tilde{b}_{12} \\ \tilde{b}_{21} & \tilde{b}_{22} \end{bmatrix} + \frac{adh}{4\lambda_1^2\lambda_2^2}\begin{bmatrix} \lambda_2\tilde{q}_1\tilde{b}_{11} & \lambda_2\tilde{q}_1\tilde{b}_{12} \\ \lambda_1\tilde{q}_2\tilde{b}_{21} & \lambda_1\tilde{q}_2\tilde{b}_{22} \end{bmatrix},$$

$$\tilde{\mathcal{B}}^{1}_{aho} = \frac{1}{8}\begin{bmatrix} \tilde{b}_{11}\big(4/3 - \tilde{q}_1/\lambda_1\big) & \tilde{b}_{12}\big(4/3 - \tilde{q}_1/\lambda_1\big) \\ \tilde{b}_{21}\big(4/3 - \tilde{q}_2/\lambda_2\big) & \tilde{b}_{22}\big(4/3 - \tilde{q}_2/\lambda_2\big) \end{bmatrix}.$$

The scheme is of fourth order for long times, as expressed in the following proposition.

PROPOSITION 4.1 (asymptotic high order). *Let* z *be a smooth stationary solution of system* (13). *Let* w_0 *be a small and smooth perturbation of* z.

Then for any compact set $K \subset \mathbb{R}$ *there exists a constant* $C_4(K)$ *such that the local truncation error* $T(x,t)$ *of the scheme* (13)–(59) *satisfies*

$$\|T(.,t)\|_{L^\infty(K)} \le C_4(K)\min\left(\Delta t + h, h^4 + \frac{1}{\Delta t\sqrt{t}}\right). \tag{60}$$

Proof. This result is an easy consequence of the uniform boundedness property (48) and of Theorem 2.4: There exists a constant $C > 0$ such that for all $t > 0$

$$\|\mathrm{w}(.,t) - \mathrm{z}\|_\infty \le \frac{C}{\sqrt{t}}.$$

Hence, using the notation (34) for w and z, we can write

$$\|T(.,t)\|_{L^\infty(K)} \le \frac{\|\mathrm{w}(.,t+\Delta t) - \mathrm{z}\|_\infty}{\Delta t} + \|T_{stat}\|_{L^\infty(K)} + \frac{\|S_{\Delta t}(\overline{Z} - \overline{W})\|_\infty}{\Delta t}.$$

Here we have to consider $\|T_{stat}\|_{L^\infty(K)}$ because the stationary solutions are not uniformly bounded in general. So, we find

$$\|T(.,t)\|_{L^\infty(K)} \leq \frac{C}{\Delta t\sqrt{t+\Delta t}} + C'h^4 + \frac{C}{\Delta t\sqrt{t}}.$$

To conclude, it is enough to use the consistency result (44) in the proof of Proposition 3.1. ∎

We address now the problem of the monotonicity of our schemes. Clearly the schemes AHO1-UP, given by (57), and AHO2-ROE, given by (58), are easily seen to be monotone under the standard upwind CFL condition. For the scheme AHO4 we have the following result.

PROPOSITION 4.2 (monotonicity). *The scheme* (13) *coupled with* (59) *satisfies the monotonicity requirements* (37)–(39) *under the following assumptions:*

$$h < \min_{1\leq i\leq 2} \frac{3|\lambda_i|}{|\tilde{b}_{ii}|}, \tag{61}$$

$$h \leq \left|\frac{2\lambda_1\lambda_2}{ad}\right| \quad if \quad \min(a\lambda_1, a\lambda_2) < 0, \tag{62}$$

$$1 + h\,\frac{|\tilde{b}_{ii}|}{3(4|\lambda_i| + h|\tilde{b}_{ii}|)} \leq \frac{\tilde{q}_i}{|\lambda_i|} \leq \frac{4}{3}, \quad i = 1,2, \tag{63}$$

and

$$\frac{\Delta t}{h} \leq \min_{1\leq i\leq 2} \left(\tilde{q}_i + h|\tilde{b}_{ii}|\left(\frac{adh\tilde{q}_i}{4\lambda_1\lambda_2\lambda_i} + \frac{2}{3}\right)\right)^{-1}. \tag{64}$$

Moreover these conditions are not empty.

Proof. We recall that for system (13) we have $\tilde{b}_{11}, \tilde{b}_{22} < 0$ and $\tilde{b}_{12}, \tilde{b}_{21} > 0$ and that $\lambda_1\lambda_2 \neq 0$.

We begin with condition (39). It can be written as

$$\begin{cases} \dfrac{\lambda_i}{2h} + \dfrac{\tilde{b}_{ii}}{6} + \dfrac{\tilde{q}_i}{\lambda_i}\left(\dfrac{\lambda_i}{2h} + \dfrac{\tilde{b}_{ii}}{8}\right) \geq 0, \\ -\dfrac{\lambda_i}{2h} + \dfrac{\tilde{b}_{ii}}{6} + \dfrac{\tilde{q}_i}{\lambda_i}\left(\dfrac{\lambda_i}{2h} - \dfrac{\tilde{b}_{ii}}{8}\right) \geq 0, \end{cases} \quad i = 1,2. \tag{65}$$

Adding those inequalities shows that necessarily $\tilde{q}_i > 0$. Let us denote

$$r_i = \frac{|\lambda_i|}{2h}, \quad s_i = -\frac{\tilde{b}_{ii}}{2}, \quad \alpha_i = \frac{\tilde{q}_i}{|\lambda_i|}.$$

Conditions (65) read as

$$\begin{cases} r_i - \dfrac{s_i}{3} + \alpha_i\left(r_i - \dfrac{s_i}{4}\right) \geq 0, \\ -r_i - \dfrac{s_i}{3} + \alpha_i\left(r_i + \dfrac{s_i}{4}\right) \geq 0, \end{cases} \quad i = 1,2.$$

Condition (61) ensures that $r_i > \frac{s_i}{3} > \frac{s_i}{4}$, so that we have to verify that

$$\alpha_i \geq \frac{r_i + s_i/3}{r_i + s_i/4}, \quad i = 1,2,$$

which also is written

$$1 + h\,\frac{|\tilde{b}_{ii}|}{3(4|\lambda_i| + h|\tilde{b}_{ii}|)} \leq \frac{q_i}{|\lambda_i|}, \quad i = 1, 2. \tag{66}$$

Consequently, under the assumptions of the proposition, condition (39) is satisfied. Condition (37) is satisfied if and only if

$$\begin{cases} \dfrac{4}{3} \pm \dfrac{\tilde{q}_i}{\lambda_i} \geq 0, \\ \dfrac{2}{3} + \dfrac{adh}{4|\lambda_i|\lambda_j}\dfrac{\tilde{q}_i}{|\lambda_i|} \geq 0, \end{cases} \qquad i = 1, 2, \quad j \neq i. \tag{67}$$

The first inequality is ensured by assumption (63). If $a\lambda_j$ is nonnegative, the second inequality is satisfied. Otherwise, we have to ensure that

$$h \leq \frac{8|\lambda_i\lambda_j|}{3|a|d}\,\frac{|\lambda_i|}{\tilde{q}_i}.$$

As $\frac{\tilde{q}_i}{|\lambda_i|} \leq \frac{4}{3}$, assumption (62) implies that this inequality is satisfied. It remains to verify that (38) holds. Let us denote

$$\mathcal{A}_i = \frac{2}{3} + \frac{adh}{4\lambda_1\lambda_2}\frac{\tilde{q}_i}{\lambda_i}.$$

This quantity is nonnegative, and (38) can be written as

$$1 - \frac{\Delta t}{h}\left(\tilde{q}_i - h\tilde{b}_{ii}\mathcal{A}_i\right) \geq 0, \quad i = 1, 2.$$

Taking into account the facts that $\tilde{q}_i > 0$ and $\tilde{b}_{ii} < 0$, this is equivalent to the CFL restriction (64). To end the proof we remark that the sign properties ensure that the conditions (61)–(64) are not empty. ∎

4.2. An AHO scheme for the diffusion limit. In this section we construct a numerical scheme for system (11) which is high-order accurate with respect to the parabolic asymptotic problem (6). The numerical error decays in time faster than the error of other schemes.

We consider for simplicity only the case $c = -a$, looking at the adimensional problem satisfied by $U(x, b^{-1}t)$:

$$\begin{cases} u_t + \tilde{a}u_x + v_x = 0, \\ \\ v_t + u_x - \tilde{a}v_x = -\tilde{d}v, \end{cases} \tag{68}$$

where $\tilde{a} = a/b$ and $\tilde{d} = b^{-1}d$. The Chapman–Enskog limit of system (68) is given by

$$\begin{cases} \hat{u}_t + \tilde{a}\hat{u}_x = \frac{1}{\tilde{d}}\hat{u}_{xx}, \\ \\ \hat{v} = -\frac{1}{\tilde{d}}\hat{u}_x. \end{cases} \tag{69}$$

Let $U_j^n = (u_j^n, v_j^n)$ be the numerical approximation of the analytical solution $U = (u, v)$ to problem (68). Let us consider the following finite difference approximation:

$$\begin{aligned} &\frac{U_j^{n+1} - U_j^n}{\Delta t} + \frac{A}{2h}\left(U_{j+1}^n - U_{j-1}^n\right) - \frac{R\tilde{Q}R^{-1}}{2h}\left(U_{j+1}^n - 2U_j^n + U_{j-1}^n\right) \\ &\quad = R\tilde{\mathcal{B}}_{-1}R^{-1}U_{j-1}^n + R\tilde{\mathcal{B}}_0R^{-1}U_j^n + R\tilde{\mathcal{B}}_1R^{-1}U_{j+1}^n. \end{aligned} \tag{70}$$

Let $\pm\lambda = \pm\sqrt{1+\tilde{a}^2}$ be the eigenvalues of matrix A and

$$R = \begin{pmatrix} 1 & 1 \\ -(\tilde{a}+\lambda) & \lambda - \tilde{a} \end{pmatrix}.$$

Taking

$$\tilde{Q} = \begin{pmatrix} \lambda & 0 \\ 0 & \lambda \end{pmatrix},$$

we have that

$$Q = R\tilde{Q}R^{-1} = \tilde{Q}.$$

We set also

$$C = R\tilde{C}R^{-1}, \quad \mathcal{B}_k = R\tilde{\mathcal{B}}_kR^{-1}, \quad k = -1, 0, 1.$$

By Taylor expansion, the numerical approximation (70) is consistent with system

$$U_t + AU_x - BU = h\left[\frac{Q}{2}U_{xx} + (\mathcal{B}_1 - \mathcal{B}_{-1})U_x + CU\right] + \mathcal{O}(h^2 + \Delta t). \tag{71}$$

Going into details, for different schemes, the Chapman–Enskog limit of system (71) gives the following:

- For the source term pointwise approximation (AHO1-UP), given by (57), we have

$$\mathcal{B}_1 - \mathcal{B}_{-1} = 0, \quad C = 0,$$

$$\begin{cases} \hat{u}_t + \tilde{a}\hat{u}_x = \left(\frac{1}{d} + \frac{h\lambda}{2}\right)\hat{u}_{xx}, \\ \hat{v} = -\frac{1}{d}\hat{u}_x. \end{cases} \tag{72}$$

- For the upwinding of the source term (AHO2-ROE), given by (58), we have

$$\mathcal{B}_1 - \mathcal{B}_{-1} = \frac{\tilde{d}}{2\lambda}\begin{pmatrix} 0 & 1 \\ 0 & -\tilde{a} \end{pmatrix}, \quad C = 0,$$

$$\begin{cases} \hat{u}_t + \tilde{a}\hat{u}_x = \left(\frac{1}{d} + h\frac{\lambda}{2} - h\frac{1}{2\lambda}\right)\hat{u}_{xx}, \\ \hat{v} = -\frac{1}{d}\hat{u}_x. \end{cases} \tag{73}$$

- For the asymptotic high-order (AHO4) given by (59), we have

$$\mathcal{B}_1 - \mathcal{B}_{-1} = \frac{\tilde{d}}{4\lambda}\begin{pmatrix} 0 & 1 \\ 0 & -\tilde{a} \end{pmatrix}, \quad C = \frac{\tilde{a}\tilde{d}^2}{4\lambda^3}\begin{pmatrix} 0 & 1 \\ 0 & -\tilde{a} \end{pmatrix},$$

(74)
$$\begin{cases} \hat{u}_t + \tilde{a}\left(1 + h\frac{\tilde{a}\tilde{d}}{\left(4\lambda^3 + h\tilde{a}^2\tilde{d}\right)}\right)\hat{u}_x = \left[\frac{4\lambda^3}{\tilde{d}\left(4\lambda^3 + h\tilde{a}^2\tilde{d}\right)} + h\frac{\lambda}{2} - h\frac{\lambda^2}{\left(4\lambda^3 + h\tilde{a}^2\tilde{d}\right)}\right]\hat{u}_{xx}, \\ \hat{v} = -\frac{4\lambda^3}{\tilde{d}\left(4\lambda^3 + h\tilde{a}^2\tilde{d}\right)}\hat{u}_x. \end{cases}$$

Notice that for all schemes the consistency with the parabolic system (69) is of order $\mathcal{O}(h)$. In all cases, the diffusive term has a perturbation of order $\mathcal{O}(h)$. In particular, the pointwise approximation is the most diffusive one. Moreover, we observe that the AHO4 approximation has a perturbation of order $\mathcal{O}(h)$ also on the drift term.

According to this discussion, it is worth looking for a scheme which is at least of order $\mathcal{O}(h^2)$ with respect to the parabolic problem (69). Consider system (71) with $Q = \tilde{Q} = \mathrm{diag}(q, q)$,

(75)
$$\begin{cases} u_t + \tilde{a}u_x + v_x = h\left[\frac{q}{2}u_{xx} + (\beta_{11}^1 - \beta_{11}^{-1})u_x + (\beta_{12}^1 - \beta_{12}^{-1})v_x + c_{11}u + c_{12}v\right] \\ \qquad\qquad + \mathcal{O}(h^2 + \Delta t), \\ v_t + u_x - \tilde{a}v_x + \tilde{d}v = h\left[\frac{q}{2}v_{xx} + (\beta_{21}^1 - \beta_{21}^{-1})u_x + (\beta_{22}^1 - \beta_{22}^{-1})v_x + c_{21}u + c_{22}v\right] \\ \qquad\qquad + \mathcal{O}(h^2 + \Delta t). \end{cases}$$

Assuming enough regularity on the data, the decay properties of the solution stated in Theorem 2.5 allow us to consider, when t goes to $+\infty$, the following reduced system:

(76)
$$\begin{cases} u_t + \tilde{a}u_x + v_x = h\left[\frac{q}{2}u_{xx} + (\beta_{11}^1 - \beta_{11}^{-1})u_x + (\beta_{12}^1 - \beta_{12}^{-1})v_x + c_{11}u + c_{12}v\right], \\ u_x + \tilde{d}v = h\left[(\beta_{21}^1 - \beta_{21}^{-1})u_x + c_{21}u + c_{22}v\right]. \end{cases}$$

Then, by choosing $c_{11} = c_{21} = 0$ and setting $\gamma_{ij} = \beta_{ij}^1 - \beta_{ij}^{-1}$, $i, j = 1, 2$, from the second equation, we have

$$v_x = \frac{1 - h\gamma_{21}}{-\tilde{d} + hc_{22}}u_{xx}.$$

By replacing this expression in the first equation and neglecting second-order terms, we get

$$u_t + \left[\tilde{a} - h\left(\gamma_{11} - c_{12}\frac{1 - h\gamma_{21}}{\tilde{d} - hc_{22}}\right)\right]u_x = \left[\frac{1 - h\gamma_{21}}{\tilde{d} - hc_{22}}(1 - h\gamma_{12}) + h\frac{q}{2}\right]u_{xx} + \mathcal{O}(h^2 + \Delta t).$$

We now look for coefficients $c_\cdot$ and $\gamma_\cdot$ such that the drift and the diffusion terms are equal to $\tilde{a}$ and $1/\tilde{d}$, respectively.

- Studying the drift term, we have

$$\tilde{a}' = \tilde{a} + h\left(c_{12}\frac{1-h\gamma_{21}}{\tilde{d}-hc_{22}} - \gamma_{11}\right) = \tilde{a} + h\frac{c_{12}(1-h\gamma_{21}) - \gamma_{11}(\tilde{d}-hc_{22})}{\tilde{d}-hc_{22}}. \tag{77}$$

  Then, to have $c_\cdot$ and $\gamma_\cdot$ independent of h, we choose

$$c_{12} = \gamma_{11}\tilde{d}, \quad c_{22} = \gamma_{21}\tilde{d}.$$

- Studying the diffusion term, we have

$$\tilde{d}' = \frac{1-h\gamma_{21}}{\tilde{d}-hc_{22}}(1-h\gamma_{12}) + h\frac{q}{2} = \frac{2(1-h\gamma_{21})(1-h\gamma_{12}) + hq(\tilde{d}-hc_{22})}{2(\tilde{d}-hc_{22})}. \tag{78}$$

  We then write

$$\tilde{d}' = \frac{1}{\tilde{d}} + \tilde{d}'',$$

  and, therefore,

$$\tilde{d}'' = \frac{h(-2\tilde{d}(\gamma_{12}+\gamma_{21}) + 2c_{22} + \tilde{d}^2 q) + h^2(2\tilde{d}\gamma_{21}\gamma_{12} - \tilde{d}qc_{22})}{2\tilde{d}(\tilde{d}-hc_{22})}.$$

  For $c_{22} = \gamma_{21}\tilde{d}$, we obtain that $\tilde{d}'' = 0$ if

$$\gamma_{12} = \frac{\tilde{d}q}{2}.$$

To summarize, a class of finite different schemes of the form (70), consistently of order $\mathcal{O}(h^2 + \Delta t)$ with respect the asymptotic problem (69), is defined by selecting

$$c_{11} = c_{21} = 0, \quad c_{12} = \gamma_{11}\tilde{d}, \quad c_{22} = \gamma_{21}\tilde{d}, \quad \gamma_{12} = \frac{\tilde{d}q}{2}. \tag{79}$$

There are still some parameters to define, which will be chosen to guarantee the monotonicity properties of the scheme. Let us focus on the particular case $q = \lambda$ (upwind approximation for the first-order derivatives), which arises if we look for the minimal artificial diffusion in the scheme.

PROPOSITION 4.3 (monotonicity for the AHO2p scheme). *Let $q = \lambda$, and set $a_\pm = \lambda \pm \tilde{a}$. The scheme* (29) *with coefficients $\tilde{\mathcal{B}}_{-1}$, $\tilde{\mathcal{B}}_0$, $\tilde{\mathcal{B}}_1$ defined by*

$$\tilde{\mathcal{B}}_0 = \frac{\tilde{d}}{4\lambda}\begin{pmatrix} -2a_+(\lambda^2+1) & a_- \\ a_+ & -2a_-(\lambda^2+1) \end{pmatrix},$$

$$\tilde{\mathcal{B}}_{\pm 1} = \tfrac{1}{2}\left(\tilde{B} - \tilde{\mathcal{B}}_0 \pm \tilde{\Gamma} + h\tilde{C}\right), \tag{80}$$

$$\tilde{\Gamma} = \tfrac{\tilde{d}q}{2}\begin{pmatrix} -a_+ & 0 \\ 0 & a_- \end{pmatrix}, \quad \tilde{C} = \tfrac{\tilde{d}^2 q}{4\lambda}\begin{pmatrix} a_+ & -a_- \\ -a_+ & a_-, \end{pmatrix}$$

satisfies the monotonicity assumptions (37)–(39) *under the conditions:*

$$h < \frac{4}{\tilde{d}}, \quad \Delta t \le \frac{2\lambda h}{2\lambda^2 + h\tilde{d}(\lambda+\tilde{a})(\lambda^2+1)}. \tag{81}$$

Proof. Let us consider system (68) in diagonal form

$$\begin{cases} w_t - \lambda w_x = \frac{\tilde{d}}{2\lambda}\left[-(\tilde{a}+\lambda)w + (\lambda-\tilde{a})z\right], \\ \\ z_t + \lambda z_x = \frac{\tilde{d}}{2\lambda}\left[(\tilde{a}+\lambda)w - (\lambda-\tilde{a})z\right] \end{cases} \tag{82}$$

and the general numerical finite difference approximation (29). Starting from relations (79), we then construct the AHO2p coefficients $\tilde{\mathcal{B}}_{-1}$, $\tilde{\mathcal{B}}_0$, $\tilde{\mathcal{B}}_1$ (80) to satisfy conditions (37)–(39).

First of all, we look at condition (37). We have to prove that

$$\tilde{\beta}_{ij}^k \geq 0 \quad \text{for} \quad i \neq j.$$

Clearly, from consistency (36) and setting $\tilde{\Gamma} = \tilde{\mathcal{B}}_1 - \tilde{\mathcal{B}}_{-1}$, we have

$$\tilde{\mathcal{B}}_{\pm 1} = \frac{1}{2}\left(\tilde{B} - \tilde{\mathcal{B}}_0 \pm \tilde{\Gamma} + h\tilde{C}\right). \tag{83}$$

Since h goes to 0, in practice we have to impose that

$$\tilde{\beta}_{ij} - |\tilde{\gamma}_{ij}| > \tilde{\beta}_{ij}^0 \geq 0 \quad \text{for} \quad i \neq j. \tag{84}$$

By setting $a_\pm = \lambda \pm \tilde{a}$, we can write

$$\tilde{B} = -\frac{\tilde{d}}{2\lambda}\begin{pmatrix} a_+ & -a_- \\ -a_+ & a_- \end{pmatrix}.$$

So, to verify the inequalities (84), it is enough to show that

$$\frac{\tilde{d}}{2\lambda}a_- > |\tilde{\gamma}_{12}|, \qquad \frac{\tilde{d}}{2\lambda}a_+ > |\tilde{\gamma}_{21}|, \tag{85}$$

taking then the off-diagonal values of $\tilde{\mathcal{B}}_0$ small enough, for instance,

$$\tilde{\beta}_{ij}^0 = \frac{1}{2}\left(\tilde{\beta}_{ij} - |\tilde{\gamma}_{ij}|\right) \text{ for } i \neq j. \tag{86}$$

Now we can compute $\tilde{\Gamma}$. We have

$$\tilde{\Gamma} = R^{-1}\Gamma R = \frac{1}{2\lambda}\begin{pmatrix} a_- & -1 \\ a_+ & 1 \end{pmatrix}\begin{pmatrix} \gamma_{11} & \gamma_{12} \\ \gamma_{21} & \gamma_{22} \end{pmatrix}\begin{pmatrix} 1 & 1 \\ -a_+ & a_- \end{pmatrix}$$

$$= \frac{1}{2\lambda}\begin{pmatrix} a_-(\gamma_{11} - a_+\gamma_{12}) - (\gamma_{21} - a_+\gamma_{22}) & a_-(\gamma_{11} + a_-\gamma_{12}) - (\gamma_{21} + a_-\gamma_{22}) \\ \\ a_+(\gamma_{11} - a_+\gamma_{12}) + (\gamma_{21} - a_+\gamma_{22}) & a_+(\gamma_{11} + a_-\gamma_{12}) + (\gamma_{21} + a_-\gamma_{22}) \end{pmatrix}.$$

So inequalities (85) read now

$$\begin{aligned} \tilde{d}a_- &> \left|a_-(\gamma_{11} + a_-\gamma_{12}) - (\gamma_{21} + a_-\gamma_{22})\right|, \\ \tilde{d}a_+ &> \left|a_+(\gamma_{11} - a_+\gamma_{12}) + (\gamma_{21} - a_+\gamma_{22})\right|. \end{aligned} \tag{87}$$

The best we can do is to put to 0 the right-hand side in both inequalities, which gives, recalling that $\gamma_{12} = \frac{\tilde{d}q}{2}$,

$$-a_-(\gamma_{11} - \gamma_{22}) + \gamma_{21} = a_-^2 \frac{\tilde{d}q}{2},$$

$$a_+(\gamma_{11} - \gamma_{22}) + \gamma_{21} = a_+^2 \frac{\tilde{d}q}{2}.$$

By solving the linear system, we find

$$\gamma_{11} - \gamma_{22} = \tilde{d}q\tilde{a}, \qquad \gamma_{21} = \frac{\tilde{d}q}{2} = \gamma_{12}. \tag{88}$$

We can quantify the influence of the matrix $\tilde{C}$ in the monotonicity. Let us just consider the parabolic case. It is clear that, since the limit $h \to 0$ is relevant, we can start from conditions (88). Now we have that

$$\tilde{C} = R^{-1}CR = \frac{\tilde{d}}{2\lambda} \begin{pmatrix} a_- & -1 \\ a_+ & 1 \end{pmatrix} \begin{pmatrix} 0 & \gamma_{11} \\ 0 & \gamma_{21} \end{pmatrix} \begin{pmatrix} 1 & 1 \\ -a_+ & a_- \end{pmatrix}$$

$$= \frac{\tilde{d}}{2\lambda} \begin{pmatrix} -a_+a_-\gamma_{11} + a_+\gamma_{21} & a_-^2\gamma_{11} - a_-\gamma_{21} \\ -a_+^2\gamma_{11} - a_+\gamma_{21} & a_+a_-\gamma_{11} + a_-\gamma_{21} \end{pmatrix}.$$

Then inequalities (84) can be refined to

$$\tilde{\beta}_{ij} - |\tilde{\gamma}_{ij}| + h\tilde{c}_{ij} > \tilde{\beta}^0_{ij} \geq 0 \quad \text{for} \quad i \neq j. \tag{89}$$

Using conditions (88), we need to verify both

$$1 + \frac{h}{2\lambda}(a_-\gamma_{11} - \gamma_{21}) > 0 \quad \text{and} \quad 1 - \frac{h}{2\lambda}(a_+\gamma_{11} + \gamma_{21}) > 0, \tag{90}$$

which are equivalent to

$$1 - \frac{h}{4\lambda}\tilde{d}q \pm \frac{h}{2\lambda}a_\mp\gamma_{11} > 0. \tag{91}$$

So the optimal choice is given by

$$\gamma_{11} = 0, \qquad \gamma_{22} = -\tilde{d}q\tilde{a}, \qquad \gamma_{21} = \gamma_{12} = \frac{\tilde{d}q}{2}, \tag{92}$$

with the restriction on the space step

$$h < \frac{4\lambda}{\tilde{d}q}. \tag{93}$$

To summarize, up to now we have defined

$$\Gamma = \frac{\tilde{d}q}{2} \begin{pmatrix} 0 & 1 \\ 1 & -2\tilde{a} \end{pmatrix}, \quad C = \begin{pmatrix} 0 & 0 \\ 0 & \gamma_{21}\tilde{d}, \end{pmatrix}.$$

From these two relations we obtain in diagonal variables $\tilde{\Gamma}$ and $\tilde{C}$ defined by (80).

To complete the construction of the scheme and the study of monotonicity, we need to verify conditions (38) and (39). In this case, they are given by

$$1 - \frac{\Delta t}{h} q + \Delta t \tilde{\beta}^0_{ii} \geq 0, \quad i = 1, 2, \tag{94}$$

$$\frac{\lambda}{2h} + \frac{q}{2h} + \tilde{\beta}^{-1}_{ii} \geq 0, \qquad -\frac{\lambda}{2h} + \frac{q}{2h} + \tilde{\beta}^{1}_{ii} \geq 0, \quad i = 1, 2. \tag{95}$$

From (83), we have

$$\tilde{\beta}^{-1}_{11} = \frac{1}{2}\left(\tilde{\beta}_{11} - \tilde{\beta}^0_{11} - \tilde{\gamma}_{11} + h\tilde{c}_{11}\right) = \frac{\tilde{d}}{4} a_+ \left(q - \frac{1}{\lambda}\right) - \frac{\tilde{\beta}^0_{11}}{2},$$

$$\tilde{\beta}^{-1}_{22} = \frac{1}{2}\left(\tilde{\beta}_{22} - \tilde{\beta}^0_{22} - \tilde{\gamma}_{22} + h\tilde{c}_{22}\right) = -\frac{\tilde{d}}{4} a_- \left(q + \frac{1}{\lambda}\right) - \frac{\tilde{\beta}^0_{22}}{2},$$

$$\tilde{\beta}^{1}_{11} = \frac{1}{2}\left(\tilde{\beta}_{11} - \tilde{\beta}^0_{11} + \tilde{\gamma}_{11} + h\tilde{c}_{11}\right) = -\frac{\tilde{d}}{4} a_+ \left(q + \frac{1}{\lambda}\right) - \frac{\tilde{\beta}^0_{11}}{2},$$

$$\tilde{\beta}^{1}_{22} = \frac{1}{2}\left(\tilde{\beta}_{22} - \tilde{\beta}^0_{22} + \tilde{\gamma}_{22} + h\tilde{c}_{22}\right) = \frac{\tilde{d}}{4} a_- \left(q - \frac{1}{\lambda}\right) - \frac{\tilde{\beta}^0_{22}}{2}.$$

From (95), the coefficient $\tilde{\beta}^0_{11}$ has to verify the relations

$$\begin{aligned} &\frac{1}{h}(q + \lambda) + \frac{\tilde{d}}{2} a_+ \left(q - \frac{1}{\lambda}\right) - \tilde{\beta}^0_{11} \geq 0, \\ &\frac{1}{h}(q - \lambda) - \frac{\tilde{d}}{2} a_+ \left(q + \frac{1}{\lambda}\right) - \tilde{\beta}^0_{11} \geq 0, \end{aligned} \tag{96}$$

and $\tilde{\beta}^0_{22}$

$$\begin{aligned} &\frac{1}{h}(q + \lambda) - \frac{\tilde{d}}{2} a_- \left(q + \frac{1}{\lambda}\right) - \tilde{\beta}^0_{22} \geq 0, \\ &\frac{1}{h}(q - \lambda) + \frac{\tilde{d}}{2} a_- \left(q - \frac{1}{\lambda}\right) - \tilde{\beta}^0_{22} \geq 0. \end{aligned} \tag{97}$$

For $q = \lambda$, a good choice for $\tilde{\beta}^0_{11}$ and $\tilde{\beta}^0_{22}$ should be given by

$$\tilde{\beta}^0_{11} = -\frac{\tilde{d}}{2} a_+ \left(\frac{\lambda^2 + 1}{\lambda}\right), \quad \tilde{\beta}^0_{22} = -\frac{\tilde{d}}{2} a_- \left(\frac{\lambda^2 + 1}{\lambda}\right). \tag{98}$$

Substituting these two expressions in condition (94), we get the following restriction on the time step Δt:

$$\begin{aligned} &1 - \frac{\Delta t}{h}\lambda - \frac{\Delta t}{2}\tilde{d} a_+ \left(\frac{\lambda^2 + 1}{\lambda}\right) \geq 0, \\ &1 - \frac{\Delta t}{h}\lambda - \frac{\Delta t}{2}\tilde{d} a_- \left(\frac{\lambda^2 + 1}{\lambda}\right) \geq 0. \end{aligned} \tag{99}$$

Therefore,

$$\Delta t \leq \frac{2\lambda h}{2\lambda^2 + h\tilde{d}a_+(\lambda^2+1)}. \tag{100}$$

To conclude, from relations (86) and (98) we get the AHO2p coefficients $\tilde{\mathcal{B}}_{-1}$, $\tilde{\mathcal{B}}_0$, $\tilde{\mathcal{B}}_1$ defined by (80), under the monotonicity assumptions (93) with $q = \lambda$ and (100). ∎

5. Numerical tests. In this section our aim is to show how, for large time simulations, AHO schemes give better numerical results than standard approximations. Therefore, we focus our attention on the numerical error as a function of time: For all tests, we fix the grid steps $h = \mathcal{O}(10^{-2})$ and Δt satisfying the CFL conditions, and we plot the error as the time $t = n\Delta t$ increases.

For all schemes under consideration we set $\tilde{Q} = \mathrm{diag}(|\lambda_1|, |\lambda_2|)$. The reference solution is obtained by the Roe-type scheme AHO2-ROE (58), with $h = \mathcal{O}(10^{-3})$.

5.1. Test n.1. Let us consider system (11) around the stationary and time-asymptotic stable solutions given by

$$u = u_0 - bv_0 e^{px}/a, \quad v = v_0 e^{px} \tag{101}$$

for some constants u_0, v_0 and for $p = -ad/(ac - b^2)$.

First, we compare the AHO4 scheme, with the standard first-order pointwise upwind scheme (57), which is actually just an AHO1-UP scheme, and with the AHO2-ROE scheme (58). The parameters in the test are $a = 1$, $c = -a$, $b = 1$, and $d = 5$. In Figure 1, we plot the l^∞-error for the problem as a function of time. Remark that, even if the total time of simulation is $T = 5$, this interval is divided into eight subintervals to plot the error curve.

In Figures 1(a) and 1(b) we have the evolution of the error, when the initial data are taken to be the stationary solution. In this case all of the schemes do not exactly preserve this stable state, but anyway AHO schemes show a better accuracy, which is proportional to their formal asymptotic order. In Figures 1(c) and 1(d) we show the evolution of the error when the initial data are given by small, compactly supported perturbations of the stationary solutions. In that case, the errors evolve in time, and the AHO2-ROE and the AHO4 improve clearly their accuracy for large times. Moreover, we show that the AHO4 scheme gives a good approximation also at intermediate times, when the perturbation is still present in the solution. In Figure 2, we plot the solution U as obtained by the AHO4 scheme at time $T = 2.5$ (see the bottom of Figure 2). To see the properties of the AHO4 scheme, we plot, at the top of these plots, the pointwise difference between the approximate solutions, given by schemes AHO1-UP, AHO2-ROE, and AHO4, and the reference solution, which is obtained by the Roe-type scheme AHO2-ROE (58), with $h = \mathcal{O}(10^{-3})$. Again, the AHO4 scheme is better performing.

5.2. Test n.2. Let us consider for system (11) the constant equilibrium state $u = 1$ and $v = 0$. The parameters in the test are again $a = 1$, $c = -a$, $b = 1$, and $d = 5$. We consider a small, compactly supported perturbation of this constant solution as the initial data, and we expect a diffusive behavior of the solution near the corresponding solution of problem (69). Actually what we look for is always a better approximation of the hyperbolic problem, but, to obtain that, we need to force the high-order consistency with the main terms in the asymptotic behavior, which are given by the diffusive expansion.

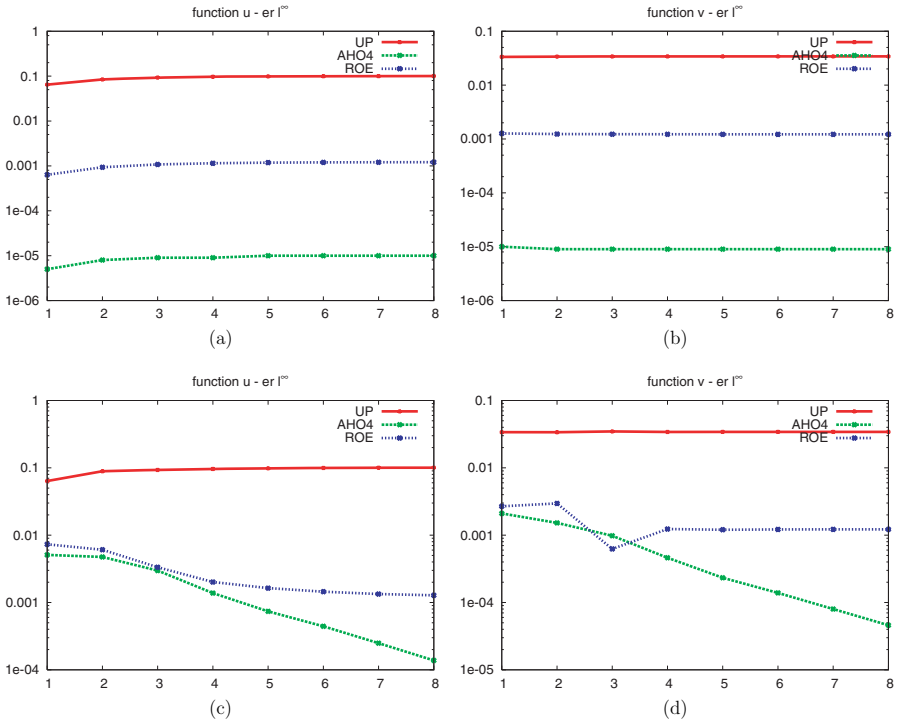

FIG. 1. *Test n.*1. (a)–(b) *Evolution of the* l^∞*-error, when the initial data are taken to be the stationary solutions* (101). (c)–(d) *Evolution of the error, when the initial data are given by a small, compactly supported perturbation of a stationary solution.*

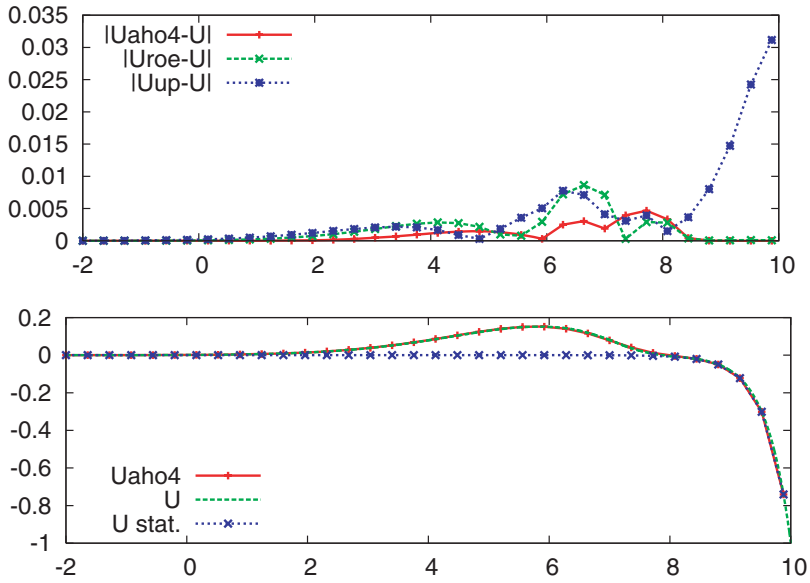

FIG. 2. *Test n.*1. *Bottom: Plot of the solution U as obtained by the AHO*4 *scheme at time* $T = 2.5$*, starting from a small perturbation of the stationary solution. Top: Pointwise difference between the approximates solutions given, respectively, by schemes AHO*1*-UP, AHO*2*-ROE, and AHO*4 *and the reference solution.*

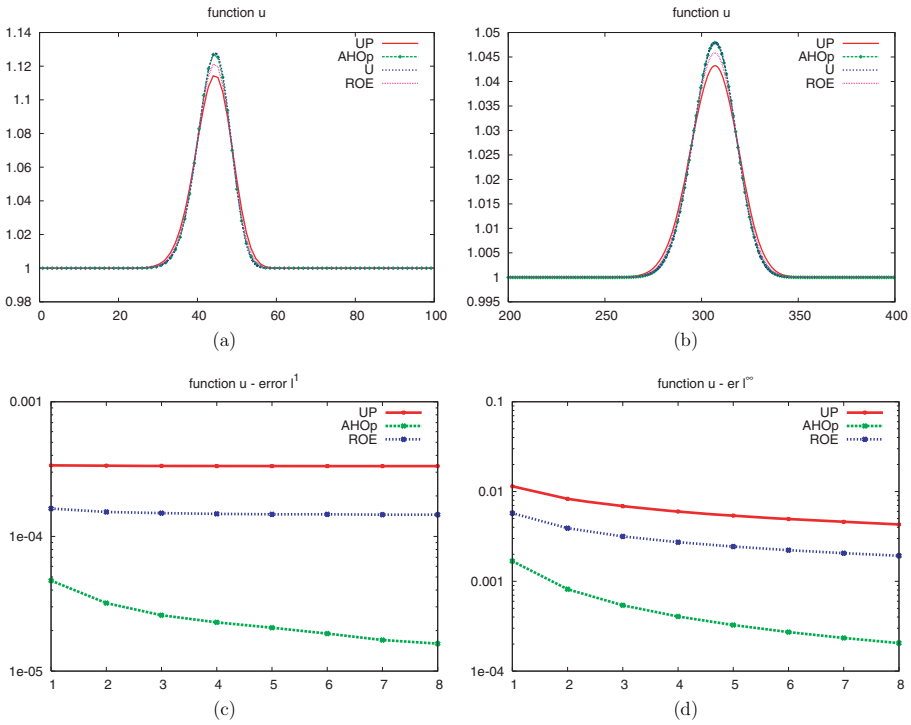

FIG. 3. *Test n.*2. (a)–(b) *Plot of different approximations of the function* u *at times* $T = 43$ *and* $T = 350$. (c)–(d) *Time evolution of the* l^1*- and* l^∞*-errors for the different approximations.*

More specifically, here we compare the AHO2p scheme (80) with the standard first-order pointwise upwind scheme (57) and with the AHO2-ROE scheme (58). The reference solution is always obtained by the AHO2-ROE scheme with $h = \mathcal{O}(10^{-3})$.

In Figures 3(a) and 3(b), we plot the different approximations of the function u at times $T = 43$ and $T = 350$. In Figures 3(c) and 3(d), we plot, respectively, the l^1- and l^∞-errors as a function of time. Again, even if the total time of simulation is $T = 350$, this interval is divided into eight subintervals to plot the error curve.

The numerical results show a clear better performance of the AHO2p scheme, in particular, for large times, as expected by our asymptotic analysis. To end, in Figure 4 we compare all of the considered schemes with the solution of the diffusion limit problem (69).

Actually this better performance is not surprising and can be explained in terms of a better time decay of the error for the AHO2p scheme. We denote by $\hat{u}^P$ the analytical solution of the parabolic problem (69) and by u^H the solution of (68). From Theorem 2.5, we know that

$$\|(\hat{u}^P - u^H)(t)\|_{L^\infty} \leq Ct^{-1} \tag{102}$$

for a positive constant C.

By construction, for large time, the scheme AHO2p closely follows the parabolic asymptotic problem (69), and so we expect that the same decay property (102) should then hold for the error function, namely,

$$e(t) = \|(U^h_{AHO2p} - u^H)(t)\|_{L^\infty} \leq Ct^{-1}, \tag{103}$$

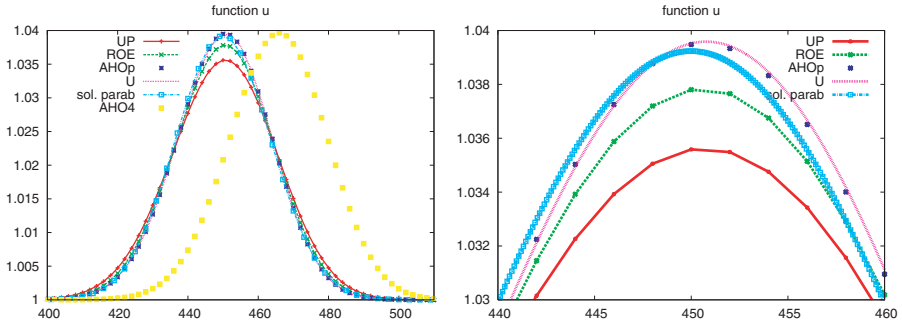

FIG. 4. *Test n.2.* (a) *Different approximations of the u component, against the reference solution of the hyperbolic problem* (11) *and of the parabolic problem* (69). (b) *Zoom on the top of the solution, to magnify the different performances.*

TABLE 1

Evaluation of constants γ and C for relation (104)*, where the solution u is given, first by the approximation of $\hat{u}^P$ computed by Crank–Nicolson scheme with a fine grid and then, respectively, by the schemes AHO2p* (80)*, AHO1-UP* (57)*, and AHO2-ROE* 58.

	$\|(u-u^H)(t)\|_{L^\infty} = Ct^{-\gamma}$	
u	γ	C
$\hat{u}^P$	0.942868	0.385312
AHO2p	0.934315	0.050421
UP	0.480781	0.071943
ROE	0.497644	0.035540

where U^h_{AHO2p} is the numerical solution of (68) obtained with the AHO2p scheme (80).

Then we look, from numerical tests, for a constant C and an exponent of decay γ which best fit the equality

$$e(t) = \|(u^H - U^h)(t)\|_{L^\infty} = Ct^{-\gamma} \tag{104}$$

for different numerical approximations U^h.

Using two instants of time t_1 and t_2, to evaluate γ, we have the following estimate:

$$\gamma \approx \frac{\ln\left[e(t_1)/e(t_2)\right]}{\ln[t_2/t_1]},$$

and C is estimated by

$$C \approx t_1^\gamma e(t_1) \approx t_2^\gamma e(t_2).$$

In Table 1, we show the values obtained for different schemes, where u^H is our reference solution of (68), always obtained by the AHO2-ROE scheme with a fine grid, say, the $h = \mathcal{O}(10^{-3})$, and where the solution $\hat{u}^P$ of (69) has been computed by the Crank–Nicolson scheme with the same fine grid. The table shows that the AHO2p scheme, unlike all of the other schemes, closely follows the theoretical time decay behavior of the analytical solution.

Acknowledgment. We thank warmly Bernard Hanouzet, in particular, for some useful discussions and his sometimes irritating questions, which as usual have been decisive to develop the scheme AHO2p.

A NUMERICAL SCHEME FOR THE PORE-SCALE SIMULATION OF CRYSTAL DISSOLUTION AND PRECIPITATION IN POROUS MEDIA*

V. M. DEVIGNE†‡, I. S. POP§, C. J. VAN DUIJN§, AND T. CLOPEAU†

Abstract. In this paper we analyze a numerical scheme for a dissolution and precipitation model in porous media. We focus here on the chemistry, which is modeled by a parabolic problem that is coupled through the boundary conditions to an ordinary differential inclusion defined on the boundary. We use a regularization approach for constructing a semi-implicit scheme that is stable and convergent. For dealing with the emerging time discrete nonlinear problems, we propose a simple fixed-point iterative procedure. The paper is concluded by numerical results.

Key words. dissolution, precipitation, porous media, convergence, linearization, coupled system, differential inclusion

1. Introduction.

In this paper we consider a pore-scale model for the dissolution and precipitation of crystals in a porous medium. This model is studied in [7] and represents the pore-scale analogue of the macroscopic (core-scale) model proposed in [17]. The particularity of the model is in the description of the precipitation processes taking place on the surface of the grains Γ_G, involving a multivalued function. Models of similar type are analyzed in a homogenization context in [23, 5, 12, 13, 24].

Without going into details, we briefly recall the background of the model. A fluid in which cations and anions are dissolved occupies the pores of a porous medium. The boundary of the void space consists of two disjoint parts: the surface of the porous skeleton (the grains), named from now on the *internal boundary*, and the external part, which is the outer boundary of the domain. Under certain conditions, the ions transported by the fluid can precipitate and form a crystalline solid, which is attached to the internal boundary and thus is immobile. The reverse reaction of dissolution is also possible.

The model proposed in [7] consists of several components: the Stokes flow in the pores, the transport of dissolved ions by convection and diffusion, and dissolution/precipitation reactions on the surface of the porous skeleton (grains). It is assumed that the flow geometry as well as the fluid properties are not affected by

the chemical processes. Therefore the flow component can be completely decoupled from the remaining part of the model. This situation appears, for example, if the crystal size is negligible when compared to the typical grain size or the pore scale. We mention [25] for a preliminary investigation of the case where dissolution and precipitation lead to changes in the pore space.

Another simplification follows by considering the total electric charge in the fluid. This is a linear combination of the concentrations of the ions and can be determined by solving a linear parabolic problem that depends only on the flow and not on the chemistry. Therefore once the fluid flow is determined, the total charge can be decoupled from the chemistry (see [6] for details).

Our main interest is focused on the chemistry, this being the challenging part of the model. Here we investigate an appropriate numerical scheme for the dissolution and precipitation component of the model in [7]. The present work is closely related to [11]. The numerical scheme proposed there also involves a special treatment of the diffusion on the grain boundary. The coupled system is solved by iterating between the equations in the pores and on the solid matrix.

Numerical methods for the macroscale equations modeling the dissolution and precipitation in porous media are considered in [1, 8, 9, 21, 22]. The time stepping is performed by various first order implicit schemes, and finite elements or finite volumes are employed for the spatial discretization. For the upscaled version of the present model, a numerical algorithm for computing traveling wave solutions is proposed in [17].

We denote the flow domain by $\Omega \subset \mathbb{R}^d$ $(d > 1)$, which is assumed to be open, connected, and bounded. Further, the boundary $\partial\Omega$ is assumed to be Lipschitz continuous. It consists of two disjoint parts: an internal and an external one. The internal boundary Γ_G is the surface of the grains, and the external boundary Γ_D is the outer boundary of the domain. Let $\vec{\nu}$ denote the outer normal to $\partial\Omega$ and $T > 0$ be a fixed but arbitrarily chosen value of time. For X being Ω, Γ_G, or Γ_D, and any $0 < t \leq T$, we define

$$X^t = (0, t] \times X.$$

To simplify the presentation, we assume that the initial data are compatible in the sense of [6, 17]. Essentially this means that initially the system is in equilibrium. Moreover, the boundary data are assumed such that the total charge remains constant in time and space. In this way, and after an appropriate scaling, the model can be reduced to

$$\begin{cases} \partial_t u + \nabla \cdot (\vec{q}u - D\nabla u) = 0 & \text{in } \Omega^T, \\ -D\vec{\nu} \cdot \nabla u = \varepsilon\tilde{n}\partial_t v & \text{on } \Gamma_G^T, \\ u = 0 & \text{on } \Gamma_D^T, \\ u = u_I & \text{in } \Omega, \text{ for } t = 0, \end{cases} \tag{1.1}$$

for the ion transport and

$$\begin{cases} \partial_t v = D_a(r(u) - w) & \text{on } \Gamma_G^T, \\ w \in H(v) & \text{on } \Gamma_G^T, \\ v = v_I & \text{on } \Gamma_G, \text{ for } t = 0, \end{cases} \tag{1.2}$$

for the precipitation and dissolution. Here u denotes the cation concentration and is defined in the entire void space Ω, whereas v stands for the concentration of the

precipitate, which is defined only on the interior boundary Γ_G. These two concentrations, together with w modeling the actual value of the dissolution rate, are the unknown quantities.

In the above $\vec{q}$ is the divergence-free fluid velocity, which is assumed to be known and to have a zero trace along the internal grain boundary Γ_G:

$$\vec{q} \in [H^1(\Omega)]^d, \qquad \nabla \cdot \vec{q} = 0 \text{ in } \Omega, \qquad \vec{q} = \vec{0} \text{ on } \Gamma_G. \tag{1.3}$$

By $H^1(\Omega)$ we mean the space of functions defined on Ω and having L^2 generalized derivatives. To avoid unnecessary technical complications we also assume that the fluid velocity $\vec{q}$ is essentially bounded, $\vec{q} \in [L^\infty(\Omega)]^d$, and define

$$M_q = \|\vec{q}\|_{\infty,\Omega} < \infty. \tag{1.4}$$

For the Stokes model with homogeneous Dirichlet boundary conditions, the essential boundedness of $\vec{q}$ holds if, for example, the domain is polygonal (see [16] or [20]).

The above equations are employing several functions, which are model-specific. Here we assume them to be given. By r we denote the precipitation rate. Assuming mass action kinetics, with $[\cdot]_+$ denoting the nonnegative cut,

$$[u]_+ = \begin{cases} 0 & \text{if } u < 0, \\ u & \text{if } u > 0, \end{cases} \tag{1.5}$$

the precipitation rate is defined by

$$r(u) = [u]_+^{\tilde{m}} [(\tilde{m}u - c)/\tilde{n}]_+^{\tilde{n}}, \tag{1.6}$$

where $\tilde{m}$ and $\tilde{n}$ are the valences of the cation and the anion, respectively. As mentioned before, the total negative charge c is assumed to be known and constant in time and space. In a generalized framework, r satisfies the following:

(A_r) (i) $r : \mathbb{R} \to [0, \infty)$ is locally Lipschitz in $\mathbb{R}$;
(ii) there exists a unique $u_* \geq 0$, such that

$$r(u) = \begin{cases} 0 \qquad \text{for} \quad u \leq u_*, \\ \text{strictly increasing for } u > u_* \text{ with } r(\infty) = \infty. \end{cases}$$

Remark 1.1. In this setting, a unique u^* exists for which $r(u^*) = 1$. If $u = u^*$ for all t and x, then the system is in equilibrium: No precipitation or dissolution occurs, since the precipitation rate is balanced by the dissolution rate regardless of the presence or absence of crystals.

In (1.2_2), H stands for the Heaviside graph,

$$H(v) = \begin{cases} \{0\} & \text{if } v < 0, \\ [0,1] & \text{if } v = 0, \\ \{1\} & \text{if } v > 0. \end{cases}$$

This implies that the dissolution rate is constant (scaled to 1) in the presence of crystals, i.e., for $v > 0$ somewhere on Γ_G. In the absence of crystals ($v = 0$), the overall rate is either zero, if $r(u) \leq 1$, or positive. In the first case we have $u < u^*$, and we speak about an undersaturated fluid since there are not sufficient ions for an effective

gain in the precipitate. This second situation is appearing in the oversaturated regime, when $u > u^*$. Then we take $w = 1$, and the overall rate is $r(u) - 1 > 0$. Following the detailed discussion in [6], this can be summarized as

$$w = \begin{cases} 0 & \text{if } v < 0, \\ \min\{r(u), 1\} & \text{if } v = 0, \\ 1 & \text{if } v > 0. \end{cases} \tag{1.7}$$

Finally, D in (1.1)–(1.2) denotes the diffusion coefficient. D_a represents the ratio of the characteristic precipitation/dissolution time scale and the characteristic transport time scale—the Damköhler number. Both D and D_a are assumed to be of moderate order $O(1)$. By ε we mean the ratio of the characteristic pore scale and the reference (macroscopic) length scale. In an appropriate scaling (see Remark 1.2 of [7]), this gives

$$\varepsilon \operatorname{meas}(\Gamma_G) \approx \operatorname{meas}(\Omega). \tag{1.8}$$

This balance is natural for a porous medium, where $\operatorname{meas}(\Gamma_G)$ denotes the total surface of the porous skeleton and $\operatorname{meas}(\Omega)$ the total void volume. Throughout this paper we keep the value of ε fixed. However, the convergence results are uniform with respect to ε and thus also for arbitrarily small values of ε.

The present setting is a simplification of the dissolution/precipitation model in [7]. However, the main difficulties that are associated with that model are still present here: The system (1.1)–(1.2) consists of a parabolic equation that is coupled through the boundary conditions to a differential inclusion defined on a lower-dimensional manifold. For ease of presentation we have considered here only the case of homogeneous Dirichlet boundary conditions on the external boundary Γ_D, but the results can be extended to more general cases. With $H^1_{0,\Gamma_D}(\Omega)$ being the subspace of $H^1(\Omega)$ functions having a zero trace on the external boundary Γ_D, for the initial data we assume the following:

(A_D) The initial data are assumed essentially bounded and nonnegative. Further, $u_I \in H^1_{0,\Gamma_D}(\Omega)$ and $v_I \in L^2(\Gamma_G)$.

Due to the occurrence of the multivalued dissolution rate, classical solutions do not exist, except for some particular cases. For defining a weak solution we consider the following sets:

$$\begin{aligned} \mathcal{U} &:= \{u \in L^2(0,T; H^1_{0,\Gamma_D}(\Omega)) : \partial_t u \in L^2(0,T; H^{-1}(\Omega))\}, \\ \mathcal{V} &:= \{v \in H^1(0,T; L^2(\Gamma_G))\}, \\ \mathcal{W} &:= \{w \in L^\infty(\Gamma_G^T), : 0 \le w \le 1\}, \end{aligned}$$

where by $H^{-1}(\Omega)$ we mean the dual of $H^1_{0,\Gamma_D}(\Omega)$. Here we have used standard notations in the functional analysis. In what follows $(\cdot,\cdot)_X$ stands for the usual scalar product in a Hilbert space X, or the duality pairing between H^{-1} and H^1. With $t \in (0,T]$, by $(\cdot,\cdot)_{X^t}$ we mean the integration in time of $(\cdot,\cdot)_X$ on $(0,t)$.

DEFINITION 1.1. *A triple $(u,v,w) \in \mathcal{U} \times \mathcal{V} \times \mathcal{W}$ is called a weak solution of* (1.1) *and* (1.2) *if $\{u(0), v(0)\} = \{u_I, v_I\}$ and if*

$$(\partial_t u, \varphi)_{\Omega^T} + D(\nabla u, \nabla \varphi)_{\Omega^T} - (\vec{q} u, \nabla \varphi)_{\Omega^T} = -\varepsilon \tilde{n} (\partial_t v, \varphi)_{\Gamma_G^T}, \tag{1.9}$$

$$(\partial_t v, \theta)_{\Gamma_G^T} = D_a (r(u) - w, \theta)_{\Gamma_G^T}, \tag{1.10}$$

$$w \in H(v) \quad \text{a.e. in } \Gamma_G^T$$

for all $(\varphi,\theta)\in L^2(0,T;H^1_{0,\Gamma_D}(\Omega))\times L^2(\Gamma_G^T)$.

In the above definition the initial condition should be understood in the sense of L^2 functions. This makes sense since $\mathcal{U}\subset C([0,T];L^2(\Omega))$ and $\mathcal{V}\subset C([0,T];L^2(\Gamma_G))$ (see, for example, [31] or [36]). The existence of a weak solution is proven in [7, Theorem 2.21]. Moreover, with

$$M_u := \max\{\|u_I\|_{\infty,\Omega}, u^*\}, \tag{1.11}$$

$$M_v := \max\{\|v_I\|_{\infty,\Omega}, 1\}, \quad C_v := \frac{r(M_u)D_a}{M_v}, \tag{1.12}$$

a weak solution satisfies

$$\begin{aligned} 0\le u\le M_u &\quad \text{a.e. in } \Omega^T,\\ 0\le v(t,\cdot)\le M_v e^{C_v t} &\quad \text{for all } t\in[0,T] \text{ and a.e. on } \Gamma_G,\\ 0\le w\le 1 &\quad \text{a.e. on } \Gamma_G^T, \end{aligned} \tag{1.13}$$

and

$$\begin{aligned} \|u(t)\|_\Omega^2 + \|\nabla u\|_{\Omega^T}^2 + \|\partial_t u\|^2_{L^2(0,T;H^{-1}(\Omega))}&\\ + \varepsilon\|v(t)\|^2_{\Gamma_G} + \varepsilon\|\partial_t v\|^2_{\Gamma_G^T} \le C& \end{aligned} \tag{1.14}$$

for all $0\le t\le T$. Here $C>0$ is a constant not depending on u, v, w, or ε. The proof is based on regularization arguments and provides a solution for which, in addition, we have

$$w = r(u) \qquad \text{a.e. in } \{v=0\}\cap\Gamma_G^T.$$

This is in good agreement with the definition in (1.7).

Finally we mention that (1.1) and (1.2) have a unique weak solution, as proven in [26].

2. The time discrete numerical scheme. In this section we analyze a semi-implicit numerical scheme for the system (1.1)–(1.2). To overcome the difficulties that are due to the multivalued dissolution rate, we approximate the Heaviside graph by

$$H_\delta(v) := \begin{cases} 0 & \text{if } v\le 0,\\ v/\delta & \text{if } v\in(0,\delta),\\ 1 & \text{if } v\ge\delta, \end{cases} \tag{2.1}$$

where $\delta>0$ is a small regularization parameter.

Next we consider a time stepping that is implicit in u and explicit in v. Though possible here as well, an implicit discretization of v would involve an additional nonlinearity in v without bringing any significant improvement of the results.

With $N\in\mathbb{N}$, $\tau = T/N$, and $t_n = n\tau$ $(n=0,\dots,N)$, the approximation pair (u^n,v^n) of $(u(t_n),v(t_n))$ is the solution of the following problem.

Problem P^n_δ. Given u^{n-1} and v^{n-1} compute $u^n\in H^1_{0,\Gamma_D}(\Omega)$ and $v^n\in L^2(\Gamma_G)$ such that

$$\begin{aligned} (u^n-u^{n-1},\phi)_\Omega + \tau D(\nabla u^n,\nabla\phi)_\Omega - \tau(\vec{q}u^n,\nabla\phi)_\Omega&\\ + \epsilon\tilde{n}(v^n-v^{n-1},\phi)_{\Gamma_G} = 0,& \end{aligned} \tag{2.2}$$

$$(v^n,\theta)_{\Gamma_G} = (v^{n-1},\theta)_{\Gamma_G} + \tau D_a(r(u^n) - H_\delta(v^{n-1}),\theta)_{\Gamma_G} \tag{2.3}$$

for all $\phi \in H^1_{0,\Gamma_D}(\Omega)$ and $\theta \in L^2(\Gamma_G)$.

Here $n = 1, \ldots, N$, while $u^0 = u_I$ and $v^0 = v_I$. For consistency with the original setting, in (2.3) we approximate the dissolution rate $w(t_n)$ by

$$w^n := H_\delta(v^n). \tag{2.4}$$

To simplify the notations, we have given up the subscript δ for the solution triple (u^n, v^n, w^n).

Remark 2.1. As we will see later, for guaranteeing the stability of the scheme the regularization parameter δ should be chosen such that $\delta \geq \tau D_a$. This is the only restriction that is related to the explicit discretization of v. Further, the convergence result is obtained under the assumption that the ratio τ/δ approaches 0 as $\tau \searrow 0$. This happens, for example, if $\delta = O(\tau^\alpha)$, with some $\alpha \in (0, 1)$, which is consistent with the previous restriction. To simplify the presentation, from now on we assume $\delta = D_a\sqrt{\tau}$. Then the stability condition $\delta \geq \tau D_a$ is ensured whenever $\tau \leq 1$, which is a mild restriction.

Due to the explicit discretization of v, the ion transport equation in Problem P^n_δ can be decoupled from the time discrete precipitation/dissolution equation. Replacing the Γ_G-scalar product in (2.2) by the last term in (2.3), we end up with an elliptic problem having a nonlinear boundary condition on Γ_G. Specifically, given u^{n-1} and v^{n-1}, we seek for $u^n \in H^1_{0,\Gamma_D}(\Omega)$ such that

$$\begin{aligned}(u^n - u^{n-1}, \phi)_\Omega + \tau D(\nabla u^n, \nabla\phi)_\Omega - \tau(\vec{q}u^n, \nabla\phi)_\Omega \\ + \tau\epsilon\tilde{n}D_a(r(u^n) - H_\delta(v^{n-1}), \theta)_{\Gamma_G} = 0\end{aligned}$$

for all $\phi \in H^1_{0,\Gamma_D}(\Omega)$. Since r is monotone and Lipschitz, standard monotonicity methods provide the existence and uniqueness for the above problem (see, e.g., [34, Chapter 10]). Alternatively, a contraction argument is described in section 3. This writing is used there as the starting point for constructing a linear iterative scheme for solving Problem P^n_δ. The fixed-point approach proving the convergence of the iteration procedure discussed in section 3 can also be employed for the existence and uniqueness of a u^n solving the nonlinear problem above. Having u^n, v^n can be determined straightforwardly from (2.3). In this way we obtain the following.

LEMMA 2.2. *Problem P^n_δ has a unique solution pair (u^n, v^n).*

2.1. Stability in L^∞. All of the estimates in this section should be interpreted in the a.e. sense. As follows from (1.13), the concentrations u and v as well as the dissolution rate w are nonnegative and bounded. Here we prove similar results for the time discrete concentrations u^n and v^n. The bounds for w^n follow straightforwardly from (2.4).

LEMMA 2.3. *Assume $\tau \leq 1$ and that u^{n-1} and v^{n-1} are nonnegative. Then u^n and v^n are nonnegative as well.*

Proof. We start with the estimate in v^n. With $[\cdot]_-$ denoting the nonpositive cut (see also (1.5)), we test (2.3) with $\theta := [v^n]_-$ and obtain

$$\|[v^n]_-\|^2_{\Gamma_G} = \tau D_a\left(r(u^n), [v^n]_-\right)_{\Gamma_G} + \left(v^{n-1} - \tau D_a H_\delta(v^{n-1}), [v^n]_-\right)_{\Gamma_G}.$$

In view of (A_r), the first term on the right is nonpositive. Further, since $v^{n-1} \geq 0$ and $\delta = D_a\sqrt{\tau}$, by the construction of H_δ we have

$$v^{n-1} - \tau D_a H_\delta(v^{n-1}) \geq v^{n-1}(1 - \tau D_a/\delta) \geq 0$$

a.e. on Γ_G. Hence the second term on the right is nonpositive as well. This yields

$$\|[v^n]_-\|^2_{\Gamma_G} \le 0,$$

implying the assertion for v^n.

For proving that u^n is nonnegative we proceed in a similar manner. Testing (2.2) with $\phi := [u^n]_-$ gives

$$\|[u^n]_-\|^2_\Omega + \tau D\,\|\nabla[u^n]_-\|^2_\Omega - \tau\,(\vec{q}u^n, \nabla[u^n]_-)_\Omega + \epsilon\tilde{n}\left(v^n - v^{n-1}, [u^n]_-\right)_{\Gamma_G} = (u^{n-1}, [u^n]_-)_\Omega. \tag{2.5}$$

The first two terms in the above are nonnegative, whereas the third one vanishes. This follows from

$$\begin{aligned}(\vec{q}u^n, \nabla[u^n]_-)_\Omega &= \tfrac{1}{2}(\vec{q}, \nabla[u^n]^2_-)_\Omega \\ &= \tfrac{1}{2}(\vec{\nu}\cdot\vec{q}, [u^n]^2_-)_{\Gamma_D\cup\Gamma_G} - \tfrac{1}{2}(\nabla\cdot\vec{q}, [u^n]^2_-)_\Omega\end{aligned}$$

and the boundary conditions on $\partial\Omega$, since $\nabla\cdot\vec{q} = 0$ in Ω.

Further, since $[u^n]_- \le 0$ a.e. and it belongs to $H^1_{0,\Gamma_D}(\Omega)$, its trace $[u^n]_-|_{\Gamma_G}$ is a nonpositive $L^2(\Gamma_G)$ function. Testing (2.3) with $[u^n]_-|_{\Gamma_G}$ gives

$$\begin{aligned}(v^n - v^{n-1}, [u^n]_-)_{\Gamma_G} &= \tau D_a(r(u^n) - H_\delta(v^{n-1}), [u^n]_-)_{\Gamma_G} \\ &= -\tau D_a(H_\delta(v^{n-1}), [u^n]_-)_{\Gamma_G} \ge 0,\end{aligned}$$

where we have used (A_r) and the positivity of H_δ.

Finally, the term on the right in (2.5) is nonpositive, since $u^{n-1} \ge 0$. In this way we obtain $[u^n]_- = 0$ a.e. in Ω, implying the result. ∎

Now we turn our attention to the upper bounds for u^n and v^n. First, with M_u defined in (1.11) we have the following.

LEMMA 2.4. *If $u^{n-1} \le M_u$, then the same holds for u^n.*

Proof. We test (2.2) with $\phi := [u^n - M_u]_+$, the nonnegative part of $u^n - M_u$. This gives

$$\begin{aligned}&\|[u^n - M_u]_+\|^2_\Omega + \tau D\|\nabla[u^n - M_u]_+\|^2_\Omega - \tau(\vec{q}u^n, \nabla[u^n - M_u]_+)_\Omega \\ &\quad = (u^{n-1} - M_u, [u^n - M_u]_+)_\Omega - \epsilon\tilde{n}(v^n - v^{n-1}, [u^n - M_u]_+)_{\Gamma_G}.\end{aligned}$$

Arguing as in the proof of Lemma 2.3, we first observe that the convection term vanishes. Further, since $u^{n-1} \le M_u$, the first term on the right is nonpositive. Finally, for the last term we have

$$(v^n - v^{n-1}, [u^n - M_u]_+)_{\Gamma_G} = \tau D_a(r(u^n) - H_\delta(v^{n-1}), [u^n - M_u]_+)_{\Gamma_G}.$$

By the definition of M_u, whenever $u^n \ge M_u$ we have $r(u^n) \ge 1 \ge H_\delta(v^{n-1})$. This implies the positivity of the above scalar product. We are therefore left with

$$\|[u^n - M_u]_+\|^2_\Omega + \tau D\|\nabla[u^n - M_u]_+\|^2_\Omega \le 0,$$

implying that $u^n \le M_u$. ∎

Remark 2.5. Since for the initial data we assume $0 \le u_I \le M_u$ and $0 \le v_I$, Lemmas 2.3 and 2.4 show that $0 \le u^n \le M_u$ and $0 \le v^n$ for all $n = 0, \dots, N$.

Upper estimates for v^n can be obtained as for u^n.

LEMMA 2.6. *With M_v and C_v defined in* (1.12), *assume that* $v^{n-1} \le M_v e^{C_v(n-1)\tau}$. *Then* $v^n \le M_v e^{C_v n\tau}$.

Proof. Testing (2.3) with $\theta := [v^n - M_v e^{C_v n\tau}]_+$ gives

$$\begin{aligned}(2.6)\qquad \|[v^n - M_v e^{C_v n\tau}]_+\|^2_{\Gamma_G} &= (v^{n-1} - M_v e^{C_v(n-1)\tau}, [v^n - M_v e^{C_v n\tau}]_+)_{\Gamma_G} \\ &\quad + M_v(e^{C_v(n-1)\tau} - e^{C_v n\tau}, [v^n - M_v e^{C_v n\tau}]_+)_{\Gamma_G} \\ &\quad + \tau D_a(r(u^n) - H_\delta(v^{n-1}), [v^n - M_v e^{C_v n\tau}]_+)_{\Gamma_G}.\end{aligned}$$

We denote the terms on the right by I_1, I_2, and I_3. We first notice that the assumption on v^{n-1} implies $I_1 \le 0$. Further, since $0 \le u^n \le M_u$, $H_\delta(v^{n-1}) \ge 0$, and due to the monotonicity of r we obtain

$$I_3 \le \tau D_a(r(M_u), [v^n - M_v e^{C_v n\tau}]_+)_{\Gamma_G}.$$

Recalling (1.12), this gives

$$I_2 + I_3 \le M_v(\tau C_v + e^{C_v(n-1)\tau}(1 - e^{\tau C_v}), [v^n - M_v e^{Cn\tau}]_+)_{\Gamma_G} \le 0.$$

Here we have used the elementary inequality $e^x \ge 1 + x$, as well as $e^{C_v(n-1)\tau} \ge 1$. In this way (2.6) becomes

$$\|[v^n - M_v e^{C_v n\tau}]_+\|^2_{\Gamma_G} \le 0,$$

implying the upper bounds for v^n. ∎

Remark 2.7. As before, since $v_I \le M_v$, it follows that $v^n \le M_v e^{Cn\tau}$ for all $n = 1, \dots, N$.

Remark 2.8. The essential bounds provided by Lemmas 2.3, 2.4, and 2.6 are uniform in δ, whereas τ appears only in the upper bounds for v^n. But for any $0 \le n \le N$ one has $n\tau = t_n \le T$, and we have $v^n \le M_v e^{C_v t_n} \le M_v e^{C_v T}$, which is τ-independent as well.

2.2. A priori estimates. We continue the analysis of the numerical scheme (2.2)–(2.3) by giving some energy estimates for the sequence of time discrete concentrations $\{(u^n, v^n),\ n = 0, \dots, N\}$. We start with the estimates in v, which are depending on meas(Γ_G).

LEMMA 2.9. *For any $n \ge 1$ we have*

$$(2.7)\qquad \left\|v^n - v^{n-1}\right\|_{\Gamma_G} \le \tau D_a\ r(M_u)\ meas(\Gamma_G)^{1/2} \qquad \text{and}$$

$$(2.8)\qquad \|v^n\|_{\Gamma_G} \le \|v_I\|_{\Gamma_G} + n\tau D_a\ r(M_u)\ meas(\Gamma_G)^{1/2}.$$

Proof. Testing (2.3) with $\theta := [v^n - v^{n-1}] \in L^2(\Gamma_G)$ and applying Cauchy's inequality gives

$$(2.9)\qquad \|v^n - v^{n-1}\|^2_{\Gamma_G} \le \tau D_a \|r(u^n) - H_\delta(v^{n-1})\|_{\Gamma_G} \|v^n - v^{n-1}\|_{\Gamma_G}.$$

The essential bounds on u^n and v^n, together with the assumptions on r and H_δ, imply $-1 \le r(u^n) - H_\delta(v^{n-1}) \le r(M_u)$. By (1.11) we have $r(M_u) \ge 1$, implying the first estimates.

In a similar manner, by taking $\theta := v^n \in L^2(\Gamma_G)$ in (2.3) and applying the Cauchy inequality we obtain

$$(2.10)\qquad \|v^n\|^2_{\Gamma_G} \le \|v^{n-1}\|_{\Gamma_G} \|v^n\|_{\Gamma_G} + \tau D_a\ r(M_u)\ \text{meas}(\Gamma_G)^{1/2} \|v^n\|_{\Gamma_G}.$$

By dividing by $\|v^n\|_{\Gamma_G}$ and applying the inequality backward we immediately obtain the estimate (2.8). □

Remark 2.10. Notice that the estimates in Lemma 2.9 are δ-independent. Next, for $n \leq N$, the term on the right in (2.8) is bounded uniformly in τ as well. Finally, due to (1.8) we can replace meas(Γ_G) by C/ϵ, where C does not depend on δ, τ, or ϵ.

Now we proceed by the estimates for u.

LEMMA 2.11. *Assume $\tau \leq \tau_0$, with $\tau_0 > 0$ a fixed value that will be given below. For the time discrete solute concentrations we have*

$$\tau \sum_{n=1}^{N} \|\nabla u^n\|_\Omega^2 \leq C, \tag{2.11}$$

$$\sum_{n=1}^{N} \|u^n - u^{n-1}\|_\Omega^2 \leq C\sqrt{\tau}, \tag{2.12}$$

$$\tau \sum_{n=1}^{N} \|\nabla(u^n - u^{n-1})\|_\Omega^2 \leq C\sqrt{\tau}, \tag{2.13}$$

$$\sum_{n=1}^{N} \|u^n - u^{n-1}\|_{\Gamma_G}^2 \leq C. \tag{2.14}$$

Here C is a constant that does not depend on δ and τ.

Proof. We start by testing (2.2) with $\phi = u^n$. This gives

$$\begin{aligned}(u^n - u^{n-1}, u^n)_\Omega + \tau D\|\nabla u^n\|_\Omega^2 \\ + \tau(\vec{q}u^n, \nabla u^n)_\Omega + \varepsilon\tilde{n}(v^n - v^{n-1}, u^n)_{\Gamma_G} = 0.\end{aligned} \tag{2.15}$$

We denote the terms on the right by $T_1, \ldots, T_4$. We have

$$T_1 = \frac{1}{2}(\|u^n\|_\Omega^2 - \|u^{n-1}\|_\Omega^2 + \|u^n - u^{n-1}\|_\Omega^2).$$

Furthermore, T_2 is nonnegative, and T_3 vanishes as argued in the proof of Lemma 2.3.

Before estimating the last term we notice the existence of positive constants C_1 and C_2 such that

$$\|\varphi\|_{\Gamma_G}^2 \leq C_1\|\varphi\|_\Omega^2 + C_2\|\varphi\|_\Omega\|\nabla\varphi\|_\Omega \tag{2.16}$$

for all $\varphi \in H^1_{0,\Gamma_D}(\Omega)$. This can be obtained by following the proof of the trace theorem (e.g., see [10, Theorem 1.5.1.10]). By the inequality of means

$$ab \leq \frac{1}{4\rho}a^2 + \rho b^2 \qquad \text{for all } a, b, \text{ and } \rho > 0, \tag{2.17}$$

we get

$$\|\varphi\|_{\Gamma_G}^2 \leq \left(C_1 + \frac{C_2^2}{4\rho}\right)\|\varphi\|_\Omega^2 + \rho\|\nabla\varphi\|_\Omega^2. \tag{2.18}$$

Here $\rho > 0$ can be taken arbitrarily small.

With $M := \varepsilon\tilde{n} D_a \; r(M_u) \; \mathrm{meas}(\Gamma_G)^{1/2}$, we use (2.7) to estimate T_4:

$$|T_4| \leq \tau M \|u^n\|_{\Gamma_G} \leq \frac{\tau M^2}{4} + \tau \|u^n\|^2_{\Gamma_G}.$$

Now we use (2.18) with $\rho = D/2$ and obtain

$$|T_4| \leq \frac{\tau M^2}{4} + \tau \left(C_1 + \frac{C_2^2}{2D} \right) \|u^n\|^2_\Omega + \frac{\tau D}{2} \|\nabla u^n\|^2_\Omega.$$

Using the estimates above into (2.15), summing for $n = 1, \ldots, N$, and multiplying the result by 2 yields

$$\|u^N\|^2_\Omega + \sum_{n=1}^{N} \|u^n - u^{n-1}\|^2_\Omega + \tau D \sum_{n=1}^{N} \|\nabla u^n\|^2_\Omega \leq \|u_I\|^2_\Omega + \frac{TM^2}{2} + C,$$

where $C = T\big(C_1 + C_2^2/(2D)\big) M_u^2 \; \mathrm{meas}(\Omega)$. This estimate follows by the essential bounds on u^n. An alternative proof can be given based on the discrete Gronwall lemma. In this way we have proven (2.11). Notice that we have also obtained

$$\sum_{n=1}^{N} \|u^n - u^{n-1}\|^2_\Omega \leq C,$$

which is not as good as (2.12).

To proceed with (2.12) and (2.13) we notice that, since $u_I \in H^1_{0,\Gamma_D}$, $u^n - u^{n-1}$ is a H^1_{0,Γ_D} function for all $n \geq 1$. Testing (2.2) with $u^n - u^{n-1}$ gives

$$\begin{aligned} (2.19) \qquad & \|u^n - u^{n-1}\|^2_\Omega + \tau D (\nabla u^n, \nabla (u^n - u^{n-1}))_\Omega \\ & - \tau (\vec{q} u^n, \nabla (u^n - u^{n-1}))_\Omega + \epsilon \tilde{n} \left(v^n - v^{n-1}, u^n - u^{n-1} \right)_\Omega = 0. \end{aligned}$$

Denoting the terms in the above by $I_1, \ldots, I_4$, we have

$$I_2 = \frac{\tau D}{2} (\|\nabla u^n\|^2_\Omega - \|\nabla u^{n-1}\|^2_\Omega + \|\nabla (u^n - u^{n-1})\|^2_\Omega).$$

Recalling (1.4), the inequality of means gives

$$\begin{aligned} |I_3| &= \tau (\nabla \cdot (\vec{q} u^n), u^n - u^{n-1})_\Omega \leq \tau M_q \|\nabla u^n\|_\Omega \|u^n - u^{n-1}\|_\Omega \\ &\leq \frac{1}{2} \|u^n - u^{n-1}\|^2_\Omega + \frac{\tau^2 M_q^2}{2} \|\nabla u^n\|^2_\Omega. \end{aligned}$$

With M defined above, for I_4 we use the estimate (2.7) and obtain

$$|I_4| \leq \varepsilon \tilde{n} \|v^n - v^{n-1}\|_{\Gamma_G} \|u^n - u^{n-1}\|_{\Gamma_G} \leq \frac{(\tau M)^2}{4\mu_1} + \mu_1 \|u^n - u^{n-1}\|^2_{\Gamma_G},$$

where $\mu_1 > 0$ will be chosen below. Now we can take $\rho = \tau D/(4\mu_1)$ into (2.18) to obtain

$$|I_4| \leq \frac{(\tau M)^2}{4\mu_1} + \mu_1 \left(C_1 + \frac{\mu_1 C_2^2}{\tau D} \right) \|u^n - u^{n-1}\|^2_\Omega + \frac{\tau D}{4} \|\nabla (u^n - u^{n-1})\|^2_\Omega.$$

Using the above estimates into (2.19), taking $\mu_1 = \sqrt{\tau D}/(2C_2)$, multiplying the result by 2, and summing up for $n = 1, \dots, N$, (2.11) gives

$$\left(\frac{1}{2} - \frac{C_1\sqrt{\tau D}}{C_2}\right) \sum_{n=1}^{N} \|u^n - u^{n-1}\|_\Omega^2 + \frac{\tau D}{2} \sum_{n=1}^{N} \|\nabla(u^n - u^{n-1})\|_\Omega^2$$
$$\leq \tau D \|\nabla u_I\|_\Omega^2 + \frac{TM^2C_2}{\sqrt{D}}\tau^{1/2} + \tau C.$$

For $\tau_0 := C_2^2/(16C_1^2D)$ and $\tau \leq \tau_0$, since $u_I \in H^1_{0,\Gamma_D}$, the inequality above immediately implies (2.12) and (2.13).

Finally, using (2.18) with $\rho = \tau^{1/2}$, (2.14) is a direct consequence of (2.12) and (2.13). ∎

Remark 2.12. As in Remark 2.10, if the medium is ϵ-periodic, the constant C in Lemma 2.11 does not depend on ϵ. To see this we recall (1.8), and Lemma 3 of [12], saying that there exists a constant $C > 0$, independent of ε, such that

$$\varepsilon \|\varphi\|_{\Gamma_G}^2 \leq C\left(\|\varphi\|_\Omega^2 + \varepsilon^2 \|\nabla\varphi\|_\Omega^2\right)$$

for all $\varphi \in H^1(\Omega)$. Then the boundary term in (2.19) yields a constant C which does not depend on ε as well.

2.3. Convergence. In this part we proceed by proving the convergence of the numerical scheme defined in (2.2)–(2.3) to a weak solution of the system (1.1)–(1.2), as given in Definition 1.1. The multivalued dissolution rate hinders us in obtaining useful error estimates. Therefore convergence will be achieved by compactness arguments. In doing so we mainly follow the ideas in [7].

By considering the sequence of time discrete triples $\{(u^n, v^n, w^n), n = 1, \dots, N\}$ solving Problem P_δ^n, where w^n is defined in (2.4), we construct an approximation of the solution of (1.1) and (1.2) for all times $t \in [0, T]$. Specifically, define for any $n = 1, \dots, N$ and $t \in (t_{n-1}, t_n]$

$$Z^\tau(t) := z^n \frac{(t - t_{n-1})}{\tau} + z^{n-1} \frac{(t_n - t)}{\tau}, \tag{2.20}$$

where (z, Z) stands for (u, U) or (v, V), and define

$$W^\tau(t) := H_\delta(V^\tau(t)). \tag{2.21}$$

Notice that U_τ, V_τ, and W_τ depend not only on τ but also on the regularization parameter δ.

For the time continuous triple $\{U^\tau, V^\tau, W^\tau)\}$ we can use the uniform L^∞ bounds, as well as the a priori estimates in Lemmas 2.9 and 2.11, to derive δ-independent estimates that are similar to those for the solution defined in Definition 1.1 (see [7]).

LEMMA 2.13. *Assume $\delta \geq \tau D_a$. Then for (U^τ, V^τ, W^τ) we have*

$$0 \leq U^\tau \leq M_u \quad \textit{a.e. in } \Omega^T, \tag{2.22}$$

$$0 \leq V^\tau \leq M_v e^{CT},\ 0 \leq W^\tau \leq 1 \quad \textit{a.e. in } \Gamma_G^T, \tag{2.23}$$

$$\|U^\tau(t)\|_\Omega + \|V^\tau(t)\|_{\Gamma_G}^2 \leq C \quad \textit{for all } 0 \leq t \leq T, \tag{2.24}$$

$$\|\partial_t U^\tau\|^2_{L^2(0,T;H^{-1}(\Omega))} + \|\nabla U^\tau\|^2_{\Omega^T} + \|\partial_t V^\tau\|^2_{\Gamma_G^T} \leq C. \tag{2.25}$$

Here $C > 0$ is a constant that does not depend on τ or δ.

Proof. The essential bounds in (2.22) and (2.23) are a direct consequence of Lemmas 2.3, 2.4, and 2.6 and (2.4). The same holds for (2.24), for which we employ the stability estimates in Lemmas 2.9 and 2.11.

To proceed with the gradient estimates in (2.25) we notice that

$$\begin{aligned}\int_0^T \|\nabla U^\tau(t)\|_\Omega^2 dt &\le 2\sum_{n=1}^N \tau \|\nabla u^{n-1}\|_\Omega^2 \\ &\quad + \int_{t_{n-1}}^{t_n} 2\frac{(t-t_{n-1})^2}{\tau^2}\|\nabla(u^n - u^{n-1})\|_\Omega^2 dt \\ &\le 2\tau \sum_{n=1}^N \|\nabla u^{n-1}\|_\Omega^2 + \frac{2\tau}{3}\sum_{n=1}^N \|\nabla(u^n - u^{n-1})\|_\Omega^2 \le C.\end{aligned}$$

Here we have used the estimate in (2.11) and (2.13).

The estimate on $\partial_t V^\tau$ follows by (2.7):

$$\int_0^T \|\partial_t V^\tau(t)\|_{\Gamma_G}^2 dt = \sum_{n=1}^N \int_{t_{n-1}}^{t_n} \left\| \frac{v^n - v^{n-1}}{\tau} \right\|_{\Gamma_G}^2 dt \le CN\tau = CT.$$

Finally, for estimating $\partial_t U^\tau$ we notice that

$$(\partial_t U^\tau(t), \phi) = \left(\frac{u^n - u^{n-1}}{\tau}, \phi \right)$$

for all $\phi \in H^1_{0,\Gamma_D}(\Omega)$ and all $t \in (t_{n-1}, t_n]$. By (2.2) this gives

$$\begin{aligned}|(\partial_t U^\tau, \phi)| &\le D\ \|\nabla u^n\|_\Omega\ \|\nabla\phi\|_\Omega + M_q\ \|\nabla u^n\|_\Omega\ \|\phi\|_\Omega \\ &\quad + \frac{\epsilon\tilde{n}}{\tau}\left\|v^n - v^{n-1}\right\|_{\Gamma_G}\ \|\phi\|_{\Gamma_G}.\end{aligned}$$

By using the trace theorem we obtain

$$\begin{aligned}|(\partial_t U^\tau, \phi)| &\le (D + M_q)\|\nabla u^n\|_\Omega \|\phi\|_{H^1(\Omega)} \\ &\quad + C(\Omega)\frac{\epsilon\tilde{n}}{\tau}\|v^n - v^{n-1}\|_{\Gamma_G}\|\phi\|_{H^1(\Omega)}\end{aligned} \tag{2.26}$$

for any $\phi \in H^1_{0,\Gamma_D}(\Omega)$. This implies that

$$\|\partial_t U^\tau(t)\|_{H^{-1}(\Omega)} \le C\left(\|\nabla u^n\|_\Omega + \frac{\epsilon\tilde{n}}{\tau}\|v^n - v^{n-1}\|_{\Gamma_G} \right) \tag{2.27}$$

for all $t \in (t_{n-1}, t_n]$, and the remaining part is a direct consequence of the L^∞ and stability estimates. ∎

Remark 2.14. *For an ϵ-periodic medium, the estimates in Lemma* 2.13 *can be made ϵ-independent. This follows from Remarks* 2.10 *and* 2.12. *In this case the estimates* (2.24) *and* (2.25) *become*

$$\begin{aligned}&\|U^\tau(t)\|_\Omega + \|\partial_t U^\tau\|^2_{L^2(0,T;H^{-1}(\Omega))} + \|\nabla U^\tau\|^2_{\Omega^T} \\ &\quad + \epsilon\left(\|V^\tau(t)\|^2_{\Gamma_G} + \|\partial_t V^\tau\|^2_{\Gamma_G^T} \right) \le C\end{aligned}$$

for all $0 \le t \le T$*, where* C *does not depend on* τ*,* δ*, or* ε*.*

Having the τ and δ uniform estimates in Lemma 2.13, we can proceed by sending τ and δ to 0. For any $\tau > 0$ and $\delta = \sqrt{\tau} D_a \ge \tau D_a$ we have $(U^\tau, V^\tau, W^\tau) \in \mathcal{U} \times \mathcal{V} \times L^\infty(\Gamma_G^T)$. Obviously $\tau \searrow 0$ implies the same for δ, as well as for the ratio τ/δ. Compactness arguments give the existence of a triple $(u, v, w) \in \mathcal{U} \times \mathcal{V} \times L^\infty(\Gamma_G^T)$ and a subsequence $\tau \searrow 0$ such that

(a) $U^\tau \to u$ weakly in $L^2((0,T); H^1_{0,\Gamma_D}(\Omega))$,
(b) $\partial_t U^\tau \to \partial_t u$ weakly in $L^2((0,T); H^{-1}(\Omega))$,
(c) $V^\tau \to v$ weakly in $L^2((0,T); L^2(\Gamma_G))$,
(d) $\partial_t V^\tau \to \partial_t v$ weakly in $L^2((0,T); L^2(\Gamma_G))$,
(e) $W^\tau \to w$ weak star in $L^\infty(\Gamma_G^T)$.

It remains to show that the limit triple (u, v, w) solves (1.1)–(1.2) weakly. By the uniqueness of the solution, this would actually imply that, along any sequence $\tau \searrow 0$, the approximating triple (U^τ, V^τ, W^τ) converges to (u, v, w). This result is proven in the following.

THEOREM 2.15. *The limit triple* (u, v, w) *is the weak solution of* (1.1)–(1.2) *in the sense of Definition* 1.1*. Moreover, for the dissolution rate we have*

$$w = r(u) \qquad \text{a.e. in } \{v = 0\} \cap \Gamma_G^T,$$

meaning that w *satisfies* (1.7).

Proof. By the weak convergence, all of the estimates stated in Lemma 2.13 hold for the limit triple (u, v, w). Furthermore, for any $t \in (t_{n-1}, t_n]$, by (2.2) we have

$$\begin{aligned}(\partial_t U^\tau(t), \phi)_\Omega + D(\nabla U^\tau(t), \nabla\phi)_\Omega \\ + (\nabla \cdot (\vec{q} U^\tau(t)), \phi)_\Omega + \epsilon\tilde{n}(\partial_t V^\tau(t), \phi)_{\Gamma_G} \\ = D(\nabla(U^\tau(t) - u^n), \nabla\phi)_\Omega + (\nabla \cdot (\vec{q}(U^\tau(t) - u^n)), \phi)_\Omega\end{aligned} \tag{2.28}$$

for all $\phi \in H^1_{0,\Gamma_D}(\Omega)$. Denoting the terms on the right by $I_1(t)$ and $I_2(t)$, taking $\phi \in L^2(0,T; H^1_{0,\Gamma_D}(\Omega))$, and integrating (2.28) in time gives

$$\begin{aligned}(\partial_t U^\tau, \phi)_{\Omega^T} + D(\nabla U^\tau, \nabla\phi)_{\Omega^T} \\ + (\nabla \cdot (\vec{q}\, U^\tau), \phi)_{\Omega^T} + \epsilon\tilde{n}(\partial_t V^\tau, \phi)_{\Gamma_G^T} \\ = \sum_{n=1}^{N} \int_{t_{n-1}}^{t^n} I_1(t) + I_2(t) dt.\end{aligned} \tag{2.29}$$

The definition (2.20) of U^τ implies for almost all $0 \le t \le T$

$$|I_1(t)| \le D \frac{t_n - t}{\tau} \|\nabla(u^n - u^{n-1})\|_\Omega \|\nabla\phi\|_\Omega \tag{2.30}$$

and

$$|I_2(t)| \le M_q \frac{t_n - t}{\tau} \|u^n - u^{n-1}\|_\Omega \|\nabla\phi\|_\Omega. \tag{2.31}$$

In (2.31) we have integrated by parts and used the essential bounds (1.4) on $\vec{q}$. Now

we can proceed by estimating the terms on the right in (2.29). For I_1 we get

$$\begin{aligned}\left|\sum_{n=1}^{N}\int_{t_{n-1}}^{t^n} I_1(t)dt\right| &\le \sum_{n=1}^{N}\int_{t_{n-1}}^{t^n}\frac{t_n-t}{\tau}D\|\nabla(u^n-u^{n-1})\|_\Omega\|\nabla\phi(t)\|_\Omega dt\\ &\le \sum_{n=1}^{N}\left(\frac{\tau}{3}D^2\|\nabla(u^n-u^{n-1})\|_\Omega^2\right)^{\frac{1}{2}}\left(\int_{t_{n-1}}^{t^n}\|\nabla\phi(t)\|_\Omega^2 dt\right)^{\frac{1}{2}}\\ &\le \frac{1}{2\sqrt{3}}\tau^{\frac{1}{4}}\int_0^T\|\nabla\phi(t)\|_\Omega^2 dt+\frac{\tau^{\frac{3}{4}}}{2\sqrt{3}}\sum_{n=1}^{N}D^2\|\nabla(u^n-u^{n-1})\|_\Omega^2\\ &\le \frac{1}{2\sqrt{3}}\left(\int_0^T\|\nabla\phi(t)\|_\Omega^2 dt+C\right)\tau^{\frac{1}{4}}.\end{aligned}$$

In the above we have used the inequality of means (2.17) with $\rho=\tau^{1/4}$, as well as the estimates (2.12) and (2.13). In a similar manner, for I_2 we get

$$\left|\sum_{n=1}^{N}\int_{t_{n-1}}^{t^n} I_1(t)dt\right| \le \left(\frac{1}{2\sqrt{3}}\int_0^T\|\nabla\phi(t)\|_\Omega^2 dt+C\tau^{\frac{1}{2}}\right)\tau^{\frac{1}{4}}.$$

Letting $\tau\searrow 0$, the weak convergence of U^τ and V^τ as well as the estimates above imply that u and v satisfy (1.9).

For the dissolution-precipitation equation (1.10) we start by analyzing the behavior of U^τ on Γ_G^T. The a priori estimates, together with Lemma 9 and Corollary 4 of [31], imply

$$U^\tau\to u \quad \text{strongly in} \quad C([0,T];H^{-s}(\Omega))\cap L^2(0,T;H^s(\Omega))$$

for any $s\in(0,1)$. Then the trace theorem (see, for example, Satz 8.7 of [36]) gives

$$U^\tau\to u \quad \text{strongly in} \quad L^2(\Gamma_G^T).$$

Taking into account the Lipschitz continuity of r, this yields

$$r(U^\tau)\to r(u) \quad \text{strongly in} \quad L^2(\Gamma_G^T).$$

Further we proceed as for (1.9). For any $t_{n-1}<t\le t_n$ and $\theta\in L^2(\Gamma_G)$ we rewrite (2.3) as

$$\begin{aligned}(\partial_t V^\tau(t),\theta)_{\Gamma_G} &= D_a(r(U^\tau(t))-W^\tau(t),\theta)_{\Gamma_G}\\ &\quad + D_a(r(u^n)-r(U^\tau(t)),\theta)_{\Gamma_G}\\ &\quad + D_a(W^\tau(t)-H_\delta(v^{n-1}),\theta)_{\Gamma_G}.\end{aligned}\tag{2.32}$$

Denoting the last two terms on the right by $I_3(t)$ and $I_4(t)$, with $\theta\in L^2(\Gamma_G^T)$, we integrate (2.32) in time and obtain

$$\begin{aligned}(\partial_t V^\tau,\theta)_{\Gamma_G^T} &= D_a(r(U^\tau)-W^\tau,\theta)_{\Gamma_G^T}\\ &\quad +\sum_{n=1}^{N}\int_{t_{n-1}}^{t^n} I_3(t)+I_4(t)dt.\end{aligned}\tag{2.33}$$

For almost all $0 \le t \le T$, since r and H_δ are Lipschitz, we use the definition of V^τ and W^τ in (2.20) and (2.21) to obtain

$$|I_3(t)| \le D_a L_r \, \frac{(t_n - t)}{\tau} \|u^n - u^{n-1}\|_{\Gamma_G} \|\theta\|_{\Gamma_G} \tag{2.34}$$

and

$$|I_4(t)| \le \frac{D_a}{\delta} \, \frac{(t_n - t)}{\tau} \|v^n - v^{n-1}\|_{\Gamma_G} \|\theta\|_{\Gamma_G}, \tag{2.35}$$

respectively. Using the estimate in (2.14), the first sum in (2.33) is bounded by

$$\begin{aligned}
\left| \sum_{n=1}^{N} \int_{t_{n-1}}^{t^n} I_3(t) dt \right| &\le D_a L_r \sum_{n=1}^{N} \int_{t_{n-1}}^{t^n} \frac{t_n - t}{\tau} \|u^n - u^{n-1}\|_{\Gamma_G} \|\theta(t)\|_{\Gamma_G} dt \\
&\le D_a L_r \sum_{n=1}^{N} \left(\frac{\tau}{3} \|u^n - u^{n-1}\|^2_{\Gamma_G} \right)^{\frac{1}{2}} \left(\int_{t_{n-1}}^{t^n} \|\theta(t)\|^2_{\Gamma_G} dt \right)^{\frac{1}{2}} \\
&\le \frac{D_a L_r}{2\sqrt{3}} \left(\|\theta\|^2_{\Gamma_G^T} + \sum_{n=1}^{N} \|u^n - u^{n-1}\|^2_{\Gamma_G} \right) \tau^{\frac{1}{2}} \\
&\le \frac{D_a L_r}{2\sqrt{3}} \left(\|\theta\|^2_{\Gamma_G^T} + C \right) \tau^{\frac{1}{2}}.
\end{aligned}$$

In the above we have use the inequality of means (2.17) with $\rho = \tau^{1/2}$. Similarly, for the last sum in (2.33), by (2.7) we get

$$\begin{aligned}
\left| \sum_{n=1}^{N} \int_{t_{n-1}}^{t^n} I_4(t) dt \right| &\le \frac{D_a}{\delta} \sum_{n=1}^{N} \int_{t_{n-1}}^{t^n} \frac{t_n - t}{\tau} \|v^n - v^{n-1}\|_{\Gamma_G} \|\theta(t)\|_{\Gamma_G} dt \\
&\le \frac{D_a}{\delta} \sum_{n=1}^{N} \left(\frac{\tau}{3} \|v^n - v^{n-1}\|^2_{\Gamma_G} \right)^{\frac{1}{2}} \left(\int_{t_{n-1}}^{t^n} \|\theta(t)\|^2_{\Gamma_G} dt \right)^{\frac{1}{2}} \\
&\le \frac{1}{2\sqrt{3}} \left(\tau {D_a}^2 \|\theta\|^2_{\Gamma_G^T} + \sum_{n=1}^{N} \|v^n - v^{n-1})\|^2_{\Gamma_G} \right) \frac{1}{\delta} \\
&\le \frac{{D_a}^2}{2\sqrt{3}} \left(\|\theta\|^2_{\Gamma_G^T} + r(M_u)^2 \, \mathrm{meas}(\Gamma_G) \right) \frac{\tau}{\delta}.
\end{aligned}$$

We now let $\tau \searrow 0$. Since $\delta = \sqrt{\tau} D_a$, the above estimates together with the weak convergence of $\partial_t V^\tau$, the strong convergence of $r(U^\tau)$, and the weak-star convergence of W^τ imply that u, v, and w satisfy (1.10_1).

It remains only to show that the dissolution rate satisfies (1.10_2). To this aim we improve the previously stated weak $L^2(\Gamma_G^T)$ convergence of V^τ to a strong one, implying also a pointwise convergence a.e. This is done by employing the Riesz–Fréchet–Kolmogorov compactness criterion, requiring estimates on translations in time and space.

We first notice that V^τ is bounded uniformly in $L^2(\Gamma_G^T)$. Moreover, by (2.7) it immediately follows that, as $h \searrow 0$, the time translations of V^τ converge to 0 in $L^2(\Gamma_G^{T-h})$, and the convergence is uniform with respect to τ. So we only have

to consider estimates for translations in space. To avoid an excess of technicalities, these are proven in a simplified setting: Decomposing $x \in \mathbb{R}^n$ into $x = (y, x_n)$, with $y \in \mathbb{R}^{n-1}$, we assume Γ_G to be open and bounded in the hyperplane $\{x_n = 0\}$. The proof for general (compact and Lipschitz) boundaries follows similarly and involves a finite number of homeomorphisms, mapping Ω locally inside the half-space $\{x_n > 0\}$.

Given a $\zeta \in \mathbb{R}^{n-1}$, we consider an arbitrary $\gamma \subset \Gamma_G$ such that $y + \zeta \in \Omega$ for any $y \in \gamma$. With Δ_ζ denoting the translation operator

$$\Delta_\zeta f(y) = f(y) - f(y + \zeta)$$

and fixing a $t \in (t_{n-1}, t_n]$ $(0 < n \leq N)$ and a $y \in \gamma$, by (2.20) we get

$$\Delta_\zeta V^\tau(t, y) = \Delta_\zeta v^{n-1}(y) + (t - t_{n-1}) D_a \big[\Delta_\zeta r(u^n)(y, x_n) - \Delta_\zeta H_\delta(v^{n-1})(y)\big].$$

Since $\delta = \sqrt{\tau} D_a$ and because r is Lipschitz continuous, this yields

$$\big|\Delta_\zeta V^\tau(t, y)\big| \leq \big|\Delta_\zeta v^{n-1}(y)\big| + D_a L_r (t - t_{n-1}) \big|\Delta_\zeta u^n(y)\big|.$$

Continuing the argument for $t = t_{n-1}, \ldots, t_1$ we obtain

$$\big|\Delta_\zeta V^\tau(t, y)\big| \leq \big|\Delta_\zeta v_I(y)\big| + \tau D_a L_r \sum_{p=1}^{n} \big|\Delta_\zeta u^p(y)\big|.$$

Since $n\tau \leq T$, standard arithmetic inequalities as well as integration over γ yield

$$\|\Delta_\zeta V^\tau(t, \cdot)\|^2_{L^2(\gamma)} \leq 2\|\Delta_\zeta v_I\|^2_{L^2(\gamma)} + 2\tau T D_a^2 L_r^2 \sum_{p=1}^{N} \|\Delta_\zeta u^p\|^2_{L^2(\gamma)}.$$

With $\bar{U}^\tau$ denoting the piecewise constant time interpolation of the time discrete approximations $\{u^n, n = 1, \ldots, N\}$,

$$\bar{U}^\tau(t) = u^n \qquad \text{whenever} \qquad t_{n-1} < t \leq t_n,$$

the inequality above becomes

$$\|\Delta_\zeta V^\tau(t, \cdot)\|^2_{L^2(\gamma)} \leq 2\|\Delta_\zeta v_I\|^2_{L^2(\gamma)} + 2T D_a^2 L_r^2 \|\Delta_\zeta \bar{U}^\tau\|^2_{L^2(\gamma^T)}. \tag{2.36}$$

Since v_I is L^2, the first term on the right vanishes as $|\zeta| \to 0$. It remains only to deal with the last term. In doing so we notice that

$$(\bar{U}^\tau - U^\tau)(t) = \frac{t_n - t}{\tau}(u^n - u^{n-1}).$$

By the estimates in (2.14), this gives

$$\big\|\bar{U}^\tau - U^\tau\big\|^2_{L^2(\Gamma_G^T)} = \sum_{n=1}^{N} \int_{t_{n-1}}^{t_n} \frac{(t_n - t)^2}{\tau^2} \|u^n - u^{n-1}\|^2_{L^2(\Gamma_G)} dt \leq C\tau.$$

Since $U^\tau \to u$ strongly in $L^2(\Gamma_G^T)$ along a sequence $\tau \searrow 0$, the same follows for $\bar{U}^\tau$. Therefore the last term in (2.36) approaches 0 uniformly with respect to τ (see also Corollary IV.26 in [2] and its converse).

Once the strong $L^2(\Gamma_G^T)$ convergence $V^\tau \to v$ is proven, we can proceed as follows. For almost every pair $(t,x) \in \Gamma_G^T$ we have either $v(t,x) > 0$ or $v(t,x) = 0$. In the first case and with $\mu := v(t,x)/2 > 0$, the pointwise convergence of V^τ to v yields the existence of a $\tau_\mu > 0$ so that $V^\tau(t,x) > \mu$ for all $\tau < \tau_\mu$. Then for any $\tau \le \min\{\tau_\mu, (\mu/D_a)^2\}$ we have $W^\tau(t,x) = 1$, implying $w(t,x) = 1$. For the second case we let $S_0 = \{v = 0\}$. Since $\partial_t v \in L^2(\Gamma_G^T)$, it follows that $\partial_t v = 0$ a.e. in the interior of S_0, and therefore $w = r(u)$ with $0 \le w \le 1$ there. □

Remark 2.16. Notice that in the proof of Theorem 2.15 we have improved the convergence of V^τ stated before. Specifically, we have shown that $V^\tau \to v$ not only weakly but also strongly in $L^2((0,T); L^2(\Gamma_G))$.

Remark 2.17. Besides the convergence of the numerical scheme, Theorem 2.15 also provides an alternative existence proof for a weak solution of (1.1)–(1.2). In [7] this is obtained by fixed-point arguments, whereas here the solution is the limit of a time discrete approximating sequence.

Remark 2.18. In this section we have considered only the time discretization of the system (1.1)–(1.2). For performing the numerical calculations that are presented in section 5, we have employed piecewise linear finite elements on Ω, whereas the crystal concentration is determined at the nodes located on Γ_G. Since the solutions of the time discrete problems are sufficiently regular, the convergence of the fully discrete scheme can be proven by standard techniques (see, e.g., [35]). In the case of convection-dominated regimes, numerical instabilities may occur as the result of the lacking maximum principle for the standard finite element method discretization. Such situations require appropriate stabilization techniques, as proposed, for example, in the book [14] or more recent works [3, 15, 19].

3. A fixed-point iteration for the time discrete problems. In this section we analyze a linear iteration scheme for solving the nonlinear time discrete Problem P_δ^n. The nonlinearity appears in the boundary condition (2.3). Numerical experiments based on a Newton-type iteration led to instabilities in the form of negative concentrations or to a precipitation in the undersaturated regime ($u \le u^*$). Moreover, there is no guarantee of convergence, unless the time stepping is not small enough. Here we discuss an alternative fixed-point approach that provides stable results. Moreover, the scheme converges linearly in H^1, regardless of the initial iteration or of the parameters ε, τ, and δ.

Assume u^{n-1} and v^{n-1} to be given and to satisfy the bounds in Lemmas 2.3, 2.4, and 2.6. To construct the iteration scheme we proceed as discussed in the beginning of section 2 and decouple the ion transport equation from the dissolution/precipitation equation on the boundary. Using (2.3), (2.2) can be rewritten as

$$(u^n - u^{n-1}, \phi)_\Omega + \tau D(\nabla u^n, \nabla\phi)_\Omega - \tau(\vec{q}u^n, \nabla\phi)_\Omega + \tau\epsilon\tilde{n}D_a(r(u^n) - H_\delta(v^{n-1}), \theta)_{\Gamma_G} = 0 \tag{3.1}$$

for all $\phi \in H^1_{0,\Gamma_D}(\Omega)$. This is a scalar elliptic equation with nonlinear boundary conditions on Γ_G. We first construct a sequence $\{u^{n,i}, i \ge 0\}$ approximating the solution u^n of (3.1). Once this is computed, we use (2.3) for determining v^n directly.

Let L_r be the Lipschitz constant of the precipitation rate r on the interval $[0, M_u]$. With

$$\mathcal{K} := \{u \in H^1_{0,\Gamma_D}(\Omega) / \ 0 \le u \le M_u \text{ a.e. in } \Omega\}, \tag{3.2}$$

and for a given $u^{n,i-1} \in \mathcal{K}$, we define $u^{n,i}$ as the solution of the linear elliptic equation

$$
\begin{aligned}
(u^{n,i} - u^{n-1}, \phi)_\Omega + \tau D(\nabla u^{n,i}, \nabla\phi)_\Omega - \tau(\vec{q}u^{n,i}, \nabla\phi)_\Omega \\
= \tau\epsilon\tilde{n}D_a L_r(u^{n,i-1} - u^{n,i}, \phi)_{\Gamma_G} \\
-\tau\epsilon\tilde{n}D_a(r(u^{n,i-1}) - H_\delta(v^{n-1}), \theta)_{\Gamma_G}
\end{aligned} \tag{3.3}
$$

for all $\phi \in H^1_{0,\Gamma_D}(\Omega)$. The starting point of the iteration can be chosen arbitrarily in $\mathcal{K}$. However, a good initial guess is $u^{n,0} = u^{n-1}$.

Comparing the above to (3.1), disregarding the superscripts $i-1$ and i, the only difference is in the appearance of the first term on the right in (3.3). In the case of convergence, this term vanishes, so $u^{n,i}$ approaches u^n. Before making this sentence more precise we mention that the above construction is common in the analysis of nonlinear elliptic problems, in particular when sub- or supersolutions are sought (see, e.g., [34, p. 96]). In [29], this approach is placed in a fixed-point context, for approximating the solution of an elliptic problem with a nonlinear and possibly unbounded source term (see also [37]). The same ideas are followed in [32, 28], where similar schemes are considered for the implicit discretization of a degenerate (fast diffusion) problem in both conformal and mixed formulation. We also mention here [33] for a related work on nonlinear elliptic equations.

Since (3.3) defines a fixed-point iteration, only a linear convergence rate is to be expected. This drawback is compensated by the stability of the approximation sequence, as well as its guaranteed convergence. These statements are made precise below.

LEMMA 3.1. *Assume* $0 \le u^{n,i-1} \le M_u$ *a.e. on* Ω. *Then* $u^{n,i}$ *solving* (3.3) *satisfies the same bounds.*

Proof. This can be shown by following the ideas used in proving Lemmas 2.3 and 2.4. We omit the details here. □

Starting the iteration with $u^{n,0} \in \mathcal{K}$, a straightforward mathematical induction argument shows the stability of the entire sequence $\{u^{n,i}, i \ge 0\}$. To prove the convergence of the scheme we let

$$
e^{n,i} := u^n - u^{n,i} \tag{3.4}
$$

denote the error at iteration i and define the H^1-equivalent norm

$$
|||f|||^2 := \|f\|^2_\Omega + \tau D\|\nabla f\|^2_\Omega + \zeta\|f\|^2_{\Gamma_G}. \tag{3.5}
$$

Here f is any function in $H^1_{0,\Gamma_D}(\Omega)$, and the constant $\zeta > 0$ is defined as

$$
\zeta := \frac{\tau}{2}\epsilon\tilde{n}D_a L_r. \tag{3.6}
$$

Notice that if τ is reasonably small, $\zeta < 1$.

The lemma below shows that the iteration error defined in (3.4) is a contraction in the norm (3.5).

LEMMA 3.2. *For* $\tau < 2/(\epsilon\tilde{n}D_a L_r)$, *an* i*-independent constant* $0 < \gamma < 1$ *exists such that*

$$
|||e^{n,i}|||^2 \le \gamma|||e^{n,i-1}|||^2,
$$

provided $u^{n,i-1}$ *satisfies the bounds in Lemma* 3.1.

Proof. With ζ given above, we start by adding $2\zeta(u^n,\phi)_{\Gamma_G}$ on both sides of (2.2). Subtracting (3.3) from the resulting equation gives

$$\begin{aligned}\left(e^{n,i},\phi\right)_\Omega + \tau D\left(\nabla e^{n,i},\nabla\phi\right)_\Omega - \tau\left(qe^{n,i},\nabla\phi\right)_\Omega + 2\zeta\left(e^{n,i},\phi\right)_{\Gamma_G}\\ = 2\zeta\left(e^{n,i-1},\phi\right)_{\Gamma_G} + \tau\epsilon\tilde{n}D_a\left(r(u^n) - r(u^{n,i-1}),\phi\right)_{\Gamma_G}.\end{aligned}$$

Since $\nabla\cdot q = 0$ and $e^{n,i}$ has a zero trace on Γ_D, taking $\phi = e^{n,i}$ into the above yields

$$\begin{aligned}&\|e^{n,i}\|_\Omega^2 + \tau D\|\nabla e^{n,i}\|_\Omega^2 + 2\zeta\|e^{n,i}\|_{\Gamma_G}^2\\ &\quad\le \tau\epsilon\tilde{n}D_a\|L_r e^{n,i-1} - \left(r(u^n) - r(u^{n,i-1})\right)\|_{\Gamma_G}\|e^{n,i}\|_{\Gamma_G}\\ &\quad\le 2\zeta\|e^{n,i-1}\|_{\Gamma_G}\|e^{n,i}\|_{\Gamma_G}.\end{aligned}$$

We then immediately get

$$|||e^{n,i}|||^2 \le \zeta\|e^{n,i-1}\|_{\Gamma_G}^2 = \zeta(1-\alpha)\|e^{n,i-1}\|_{\Gamma_G}^2 + \zeta\alpha\|e^{n,i-1}\|_{\Gamma_G}^2, \tag{3.7}$$

where $|||\cdot|||$ is introduced in (3.5) and α is an arbitrary constant in $(0,1)$ to be chosen below.

Using the trace estimate (2.16) and the inequality of means, for any $\beta > 0$ we have

$$\|e^{n,i-1}\|_{\Gamma_G}^2 \le \left(C_1 + \frac{C_2^2}{4\beta}\right)\|e^{n,i-1}\|_\Omega^2 + \beta\|\nabla e^{n,i-1}\|_\Omega^2.$$

By using this in (3.7) and taking $\alpha\in(0,1)$, $\beta>0$, and $\gamma>0$ satisfying the constraints

$$\begin{aligned}\zeta\alpha\left(C_1 + \frac{C_2^2}{4\beta}\right) &\le \gamma,\\ \zeta\alpha\beta &\le \tau D\gamma,\\ \zeta(1-\alpha) &\le \gamma,\end{aligned} \tag{3.8}$$

we obtain

$$\begin{aligned}|||e^{n,i}|||^2 &\le (1-\alpha)\zeta\|e^{n,i-1}\|_{\Gamma_G}^2 + \alpha\beta\zeta\|\nabla e^{n,i-1}\|_\Omega^2\\ &\quad + \alpha\zeta\left(C_1 + \frac{C_2^2}{4\beta}\right)\|e^{n,i-1}\|_\Omega^2 \le \gamma|||e^{n,i-1}|||^2.\end{aligned} \tag{3.9}$$

With

$$\beta = \frac{\tau D}{2}\left(C_1 + \sqrt{C_1^2 + \frac{C_2^2}{\tau D}}\right) \quad\text{and}\quad \alpha = \left(1 + \frac{C_1}{2} + \frac{1}{2}\sqrt{C_1^2 + \frac{C_2^2}{\tau D}}\right)^{-1},$$

the restrictions on α and β are fulfilled. Further, this choice also gives identical lower bounds for γ in (3.8), for which we can now take

$$\gamma = \zeta\left(C_1 + \sqrt{C_1^2 + \frac{C_2^2}{\tau D}}\right)\left(2 + C_1 + \sqrt{C_1^2 + \frac{C_2^2}{\tau D}}\right)^{-1}. \tag{3.10}$$

By the assumptions on τ we have $\gamma < 1$, and hence the iteration error is contractive in the norm defined in (3.5). ∎

Remark 3.3. The iteration (3.3) defines an operator $\mathcal{T} : \mathcal{K} \to \mathcal{K}$. Following the steps in the proof of Lemma 3.2, we can show that $\mathcal{T}$ is a contraction with respect to the norm defined in (3.5). Therefore $\mathcal{T}$ has a unique fixed point, yielding the existence and uniqueness of a solution for the nonlinear equation (3.1). This immediately implies the existence and uniqueness of a solution for Problem P_δ^n, as stated in Lemma 2.2.

Lemma 3.2 implies the linear convergence in H^1 of the iteration sequence $\{u^{n,i}, i \geq 0\}$. Moreover, its limit is the solution u^n of (3.1).

THEOREM 3.4. *With $u^{n,0} \in H^1_{0,\Gamma_D}(\Omega)$ bounded essentially by 0 and M_u, if $\tau < 2/(\epsilon\tilde{n}D_aL_r)$, the iteration* (3.3) *is convergent. Specifically, for all $i > 0$ we have*

$$|||e^{n,i}|||^2 \leq \gamma^i |||e^{n,0}|||^2.$$

Remark 3.5. The contraction constant γ in the above is bounded from above by $\zeta = \tau\epsilon\tilde{n}D_aL_r/2$. Notice that the first term in the H^1-equivalent norm in (3.5) does not depend on τ. As $\tau \searrow 0$, γ approaches 0, implying a fast convergence of the iteration at least in the L^2 sense. In the numerical computations presented in the following section, 3–4 iterations were enough for obtaining a good numerical approximation of the time discrete solution.

As stated in Theorem 3.4, convergence is achieved as $i \to \infty$. In practice we stop this procedure after a finite (small) number of iterations. This means that at each time step we are adding an iteration error to the time discrete approximation. This error depends on the number of iterations performed per time step, as well as on the initial iteration error. As mentioned before, the solution at the previous time step can be used for initiating the iteration. In the remaining part of this section we show that by this choice the total error is vanishing as $\tau \searrow 0$.

To make this statement rigorous we assume that i iterations are performed at each time step n. The computed solution $\tilde{u}^n = u^{n,i}$ will be only an approximation of u^n, the solution of (3.1). Let now $\tilde{e}^n$ denote the error at the time step n:

$$\tilde{e}^n := u^n - \tilde{u}^n.$$

Based on the stability estimates in Lemma 2.11, we can estimate the total error that is accumulated in the numerical approximation of the time discrete sequence $\{u^n, n = 1, \ldots, N\}$.

LEMMA 3.6. *Assume that, for each $n = 1, \ldots, N$, i iterations* (3.3) *are performed by starting with $u^{n,0} = \tilde{u}^{n-1} = u^{n-1,i}$. We have*

$$\sum_{n=1}^{N} |||\tilde{e}^n||| \leq C\frac{\gamma^{i/2}}{\tau^{1/4}}.$$

Remark 3.7. Since $\gamma = O(\tau)$, the total error vanishes as $\tau \searrow 0$.

Proof. With $u^{n,0} = \tilde{u}^{n-1}$, the initial error at the time step n is given by

$$e^{n,0} = u^n - \tilde{u}^{n-1} = u^n - u^{n-1} + \tilde{e}^{n-1}.$$

By Theorem 3.4 the error at the time step n can be estimated as

$$|||\tilde{e}^n||| \leq \gamma^{i/2}|||e^{n,0}||| \leq \gamma^{i/2}\left(|||u^n - u^{n-1}||| + |||\tilde{e}^{n-1}|||\right).$$

Repeating this estimates inductively for $n = 1, \dots, N$, since $\tilde{e}^0 = 0$ we obtain

$$|||\tilde{e}^n||| \le \sum_{k=1}^{n} \gamma^{(n+1-k)i/2} |||u^k - u^{k-1}|||. \tag{3.11}$$

Adding the above for $n = 1$ up to N gives

$$\sum_{n=1}^{N} |||\tilde{e}^n||| \le \frac{\gamma^{i/2}}{1-\gamma^{i/2}} \sum_{k=1}^{N} \left(1 - \gamma^{(N+1-k)i/2}\right) |||u^k - u^{k-1}|||.$$

By the definition of γ in (3.10), if τ is small enough, the fraction in the above can be bounded by $C\gamma^{i/2}$ for some constant $C > 0$. Now the proof can be completed straightforwardly by applying the stability estimates in Lemma 2.11. ∎

4. Numerical results. In this section we present some numerical simulations obtained for the undersaturated regime, when only dissolution is possible. Extensive numerical results for both dissolution and precipitation, and for high or low Damköhler numbers, will be presented in a forthcoming paper. All of the computations are implemented in the research software *SciFEM* (Scilab finite element method [38]; see also [4]).

Here we consider a two-dimensional domain Ω, obtained by removing the disc $B_R(0,0)$ of radius $R = 1/4$ and centered in the origin form the square $(-1/2, 1/2)^2$. The impermeable grain is represented by the disc, and flow takes place around the grain, from the left boundary to the right one. The present experiments are similar to those presented in [7], where a simple geometry—a two-dimensional strip—has been considered. There the occurrence of a dissolution front has been investigated both analytically and numerically. After a waiting time t^*, the front started moving in the flow direction. As we will see below, the present computations reveal similar features.

We have used the following parameters and rate function:

$$D = 1,\ D_a = 1,\ \varepsilon = 1,\ \tilde{m} = \tilde{n} = 1.0, \text{ and } r(u,c) = \frac{10}{9}[u]_+[u - 0.1]_+.$$

This gives $u_* = 0.1$ and $u^* = 1.0$. The initial and (external) boundary conditions are

$$\begin{aligned} v_I &= 0.1 && \text{on } \Gamma_G, \\ u_I &= 1.0 && \text{in } \Omega, \\ u &= u_* && \text{if } x = -1/2, t > 0, \\ \partial_\nu u &= 0 && \text{on } \partial\Omega \backslash \{\Gamma_G \cup \{x = -1/2\}\}. \end{aligned}$$

With the data above, the system is initially in equilibrium: No precipitation or dissolution is taking place. This equilibrium is perturbed by injecting an undersaturated fluid at the inflow boundary $x = -1/2$. We start with a uniformly distributed layer of precipitate. As resulting from the L^∞ estimates, only dissolution is possible.

The fluid velocity $\vec{q}$ is determined by solving numerically the Stokes system

$$\begin{cases} \mu \triangle \vec{q} = \nabla p & \text{in } \Omega, \\ \nabla \cdot \vec{q} = 0 & \text{in } \Omega, \end{cases}$$

where $\mu = 0.01$. At both the in- and outflow boundaries $x = \pm 1/2$ we take $\vec{q} = (2, 0)$. On the upper and lower boundaries $y = \pm 1/2$ we take $q_y = 0$, and $\partial_y q_x = 0$. For

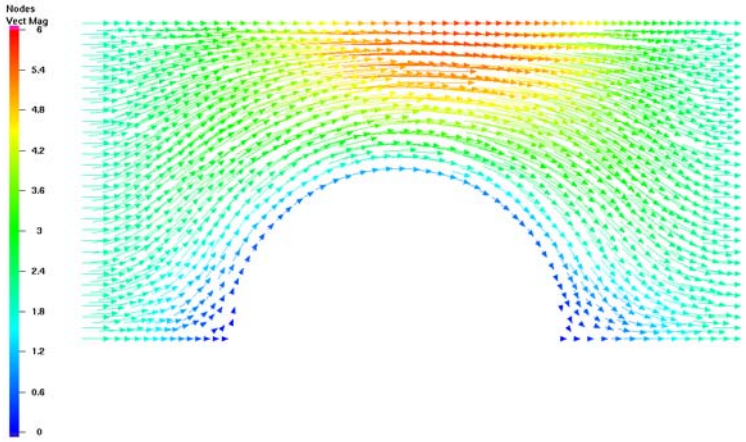

FIG. 1. *The computed velocity field* $\vec{q}$.

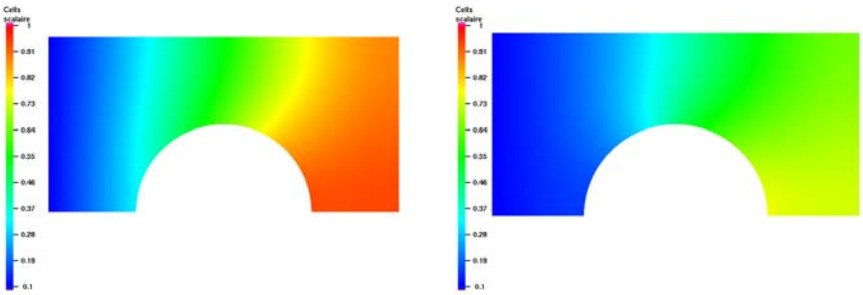

FIG. 2. *Concentration of the cation* u *at* $t_1 = 0.1$ *(left) and* $t_2 = 0.2$ *(right).*

symmetry reasons, the computations are restricted to the upper half of the domain. The numerical approximation of $\vec{q}$ is obtained by employing the bubble stabilized finite element method proposed in [30] (see also [18]). The computed velocity field is presented in Figure 1.

For computing the cation concentration u and the precipitate concentration v we have applied the scheme (2.2)–(2.3) with a fixed time step $\tau = 10^{-4}$ and the regularization parameter $\delta = 10^{-4}$. As mentioned in the appendix of [6] (see also Theorem 2.15), we set $w = \min\{r(u), 1\}$ whenever $v = 0$. The emerging nonlinear time discrete problems are solved by the linearization (3.3), with $u^{n,0} = u^{n-1}$. The procedure is stopped once the maximal difference between two successive iterations is reduced below 10^{-3}. In our experiments 3–4 iterates were sufficient to fulfill this stopping criterion. We have used piecewise linear finite elements for the spatial discretization of the time discrete problems in Ω. The crystal concentration is determined at the corresponding nodes on Γ_G. In this specific example the Peclet number is moderate, so no special stabilizing techniques were needed.

The computations are performed up to $T = 0.4$. Figure 2 displays the cation

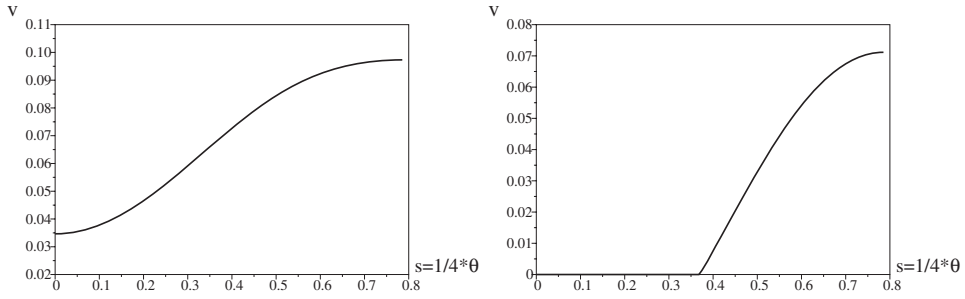

FIG. 3. *Concentration of the precipitate v at $t_1 = 0.1$ (left) and $t_2 = 0.2$ (right) as a function of the arc length.*

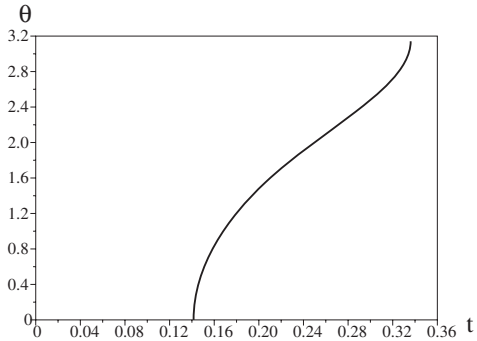

FIG. 4. *The position of the dissolution front as a function of time: At $t^* \approx 0.1415$ precipitate is present everywhere on the grain boundary; after $\tilde{t} \approx 0.3359$ the entire precipitate has been dissolved.*

concentration u at two different times $t_1 = 0.1$ and $t_2 = 0.2$. As expected, u is higher at the outflow than at the inflow and stays bounded by u_* and u^*. This excludes the possibility of precipitation. Moreover, the amount of cations is decreasing in time. Figure 3 displays the precipitate concentration v as a function of the arc length $s = R\theta$. Here $R = 1/4$, while θ is the angle between the radii through the leftmost point $(-R, 0)$ through the location of interest on Γ_G. Notice that v is monotone with respect to s. A major difference can be noticed in the v profiles for $t_1 = 0.1$ and $t_2 = 0.2$. In the former case we have $v > 0$ for any s, and thus precipitate is present everywhere. For t_2 we identify two different regions on Γ_G. In the left one the precipitate has been completely dissolved, whereas crystals can be found everywhere in the region on the right. This shows the occurrence of a dissolution front, located at the free boundary separating the two regions on Γ_G. At t_2 the dissolution front is located close to $(0, R)$, the upper point of Γ_G.

The evolution of the dissolution front is presented in Figure 4, where the angle θ is given as a function of time. Up to $t^* \approx 0.1415$, the precipitate is present everywhere on the grain surface Γ_G. For any time between t^* and $\tilde{t} \approx 0.3359$ the dissolution front moves towards the rightmost point on Γ_G, $(R, 0)$. After $\tilde{t}$ the entire precipitate has been dissolved. Notice the fast movement of the free boundary as t is greater than but close to the waiting time t^*. This is due to the fact that the grain boundary Γ_G is nearly transversal to the flow. Since the inflow boundary conditions for u and $\vec{q}$ are constant, a minimal variation of u in the vertical direction can be expected. This implies a similar behavior for v if s (or θ) is close to 0, and therefore the complete dissolution along this region occurs nearly simultaneously.

5. Conclusion. We have analyzed a numerical scheme for the time discretization of (1.1)–(1.2). This is a simplification of the pore-scale model for crystal dissolution and precipitation in porous media. The main difficulties associated with the model, a parabolic problem that is coupled through the boundary to a differential inclusion, are still present in this setting.

The numerical scheme is implicit in u and explicit in v. A regularization step is employed for dealing with the multivalued dissolution rate. We prove the stability of the scheme in both L^∞ as well as energy norms. Further, compactness arguments are used for showing that the scheme is convergent.

A fixed-point iteration is proposed for solving the nonlinear time discrete problems. This linearization is stable and converges linearly, regardless of the discretization parameters and the starting point.

Acknowledgments. We thank Prof. A. Mikelić (Lyon) and the members of the Applied Analysis group in Eindhoven for their suggestions.

CONVEXITY-PRESERVING PIECEWISE RATIONAL QUARTIC INTERPOLATION*

XULI HAN†

Abstract. A family of piecewise rational quartic interpolants is given. Identified uniquely by the value of a tension parameter λ_i, each interpolant of the family can be C^2 spline without solving a linear or nonlinear system of consistency equations for the derivative values at the knots. The interpolant can preserve the local convexity/concavity properties of the given data. A proper choice of λ_i to guarantee shape preservation is given. A convergence analysis establishes an error bound in terms of λ_i and shows that $O(h^3)$ accuracy is obtained for C^2 continuity. Several examples are supplied to support the practical value of the method.

Key words. rational interpolation, tension spline, convexity-preserving

1. Introduction.

In industrial design and manufacturing it is often required to generate a smooth function passing through a given set of data which preserves certain shape properties of the data such as positivity, monotonicity, or convexity, that is, a smooth shape-preserving interpolant.

Different polynomial methods have received attention in the study of shape-preserving interpolation. Some necessary and sufficient conditions for shape-preserving properties have been discussed. For brevity, the reader is referred to [1, 2, 3, 4]. These methods have a common feature in that no additional knots need be supplied. In contrast, the papers [5, 6, 7, 8] discussed the methods by adding one or two additional knots on the subinterval so that the monotonicity and convexity of the data are preserved.

Some rational spline methods have been presented for shape-preserving interpolation. In the papers [9, 10], a piecewise rational quadratic function was developed which produces a monotonic interpolant to monotonic data. In the papers [11, 12, 13, 14, 15], shape-preserving interpolations to convex data were shown. The given rational interpolants are C^1 continuous. For C^2 continuity, the solution of the consistency equations is concerned; see [10, 11, 12, 13, 14, 15]. For some tension methods, such as those mentioned in [15], the proper choice of the tension parameter to guarantee shape preservation is still an unsettled question.

This paper presents a piecewise rational quartic interpolant that preserves local convexity/concavity properties of the given data and is of C^2 continuity without solving a system of consistency equations for the derivative values at the knots.

The present paper is organized as follows. In section 2, the piecewise expression of the rational quartic interpolant is described and the C^2 continuity is shown. The shape-preserving properties are shown and the proper tension values are given in section 3. In section 4, error estimates are shown. Some numerical examples are given in section 5, and conclusions are given in section 6.

2. Piecewise rational quartic interpolant. Let (x_i, f_i) be given real data and d_i be chosen derivative values at knots x_i, $i = 1, 2, \ldots, n$, where $a = x_1 < x_2 < \cdots < x_n = b$ is a partition of the interval $[a, b]$. We put

$$h_i = x_{i+1} - x_i, \quad \Delta_i = (f_{i+1} - f_i)/h_i, \quad A_i = \Delta_i - d_i, \quad B_i = d_{i+1} - \Delta_i$$

for $i = 1, 2, \ldots, n-1$.

For $[x_i, x_{i+1}]$, $i = 1, 2, \ldots, n-1$, we construct the interpolant

$$\begin{aligned} s(x) &= (1-t)f_i + tf_{i+1} \\ &\quad - \frac{h_i(1-t)t}{Q_i(t)}\big[(1-t)^2 A_i + \lambda_i(1-t)tA_iB_i + t^2 B_i\big], \end{aligned} \tag{1}$$

where $t = (x - x_i)/h_i$, λ_i are tension parameters, and

$$Q_i(t) = (1-t)^2 + \lambda_i(1-t)t\big[(1-t)B_i + tA_i\big] + t^2. \tag{2}$$

In the following section, we will suggest the choice of λ_i for the subinterval.

Clearly the interpolatory properties $s(x_i) = f_i, s(x_{i+1}) = f_{i+1}$ hold. Further,

$$\lim_{\lambda_i \to \infty} s(x) = (1-t)f_i + tf_{i+1} - \frac{h_i(1-t)tA_iB_i}{(1-t)B_i + tA_i}. \tag{3}$$

This form is the interpolant given in [12], where it was shown that the form (3) is also a special form given in [11].

THEOREM 1. *For any given d_i, $i = 2, 3, \ldots, n-1$, $s(x) \in C^1[a, b]$. If*

$$d_i = \frac{1}{h_{i-1} + h_i}(h_{i-1}\Delta_i + h_i\Delta_{i-1}), \ i = 2, 3, \ldots, n-1, \tag{4}$$

then $s(x) \in C^2[a, b]$.

Proof. For $[x_i, x_{i+1}], i = 1, 2, \ldots, n-1$, after much manipulation, the derivatives $s'(x), s''(x)$ are

$$s'(x) = \Delta_i - \frac{1}{Q_i^2(t)} \sum_{j=0}^{6} (1-t)^{6-j} t^j \bar{A}_{ij}, \tag{5}$$

$$s''(x) = \frac{1}{h_i Q_i^3(t)} \sum_{j=0}^{8} (1-t)^{8-j} t^j \bar{B}_{ij}, \tag{6}$$

where $\bar{A}_{i0} = A_i$, $\bar{A}_{i6} = -B_i$, $\bar{A}_{i1} = 2\lambda_i A_i B_i$, $\bar{A}_{i5} = -2\lambda_i A_i B_i$,

$$\begin{aligned} \bar{A}_{i2} &= A_i B_i^2 \lambda_i^2 + A_i(B_i - A_i)\lambda_i - 2A_i + 3B_i, \\ \bar{A}_{i3} &= 2(B_i^2 - A_i^2)\lambda_i - 4A_i + 4B_i, \\ \bar{A}_{i4} &= -A_i^2 B_i \lambda_i^2 - (A_i - B_i)B_i\lambda_i - 3A_i + 2B_i, \end{aligned}$$

and $\bar{B}_{i0} = 2A_i$, $\bar{B}_{i8} = 2B_i$,

$$\begin{aligned} \bar{B}_{i1} &= 6A_i^2\lambda_i + 10A_i - 6B_i, \\ \bar{B}_{i2} &= 6A_i^2 B_i \lambda_i^2 + 6(A_iB_i + 2A_i^2 - B_i^2)\lambda_i + 26A_i - 18B_i, \\ \bar{B}_{i3} &= 2A_i^2 B_i^2 \lambda_i^3 + 2(7A_i^2 B_i + A_i B_i^2 - A_i^3 - B_i^3)\lambda_i^2 \\ &\quad + 2(16A_iB_i + A_i^2 - 8B_i^2)\lambda_i + 30A_i - 18B_i, \end{aligned}$$

$$\begin{aligned}
\bar{B}_{i4} &= 4A_i^2B_i^2\lambda_i^3 + 2(5A_i^2B_i + 5A_iB_i^2 - 2A_i^3 - 2B_i^3)\lambda_i^2 \\
&\quad + 2(26A_iB_i - 7A_i^2 - 7B_i^2)\lambda_i + 6A_i + 6B_i, \\
\bar{B}_{i5} &= 2A_i^2B_i^2\lambda_i^3 + 2(A_i^2B_i + 7A_iB_i^2 - A_i^3 - B_i^3)\lambda_i^2 \\
&\quad + 2(16A_iB_i - 8A_i^2 + B_i^2)\lambda_i - 18A_i + 30B_i, \\
\bar{B}_{i6} &= 6A_iB_i^2\lambda_i^2 + 6(A_iB_i - A_i^2 + 2B_i^2)\lambda_i - 18A_i + 26B_i, \\
\bar{B}_{i7} &= 6B_i^2\lambda_i - 6A_i + 10B_i.
\end{aligned}$$

From (5) we have

$$s'(x_i^+) = d_i,\ s'(x_{i+1}^-) = d_{i+1}.$$

These imply $s(x) \in C^1[a,b]$.

From (4) and (6) we have

$$s''(x_i^+) = \frac{2A_i}{h_i} = \frac{2}{h_{i-1}+h_i}(\Delta_i - \Delta_{i-1}),\ \ s''(x_{i+1}^-) = \frac{2B_i}{h_i} = \frac{2}{h_i+h_{i+1}}(\Delta_{i+1} - \Delta_i).$$

These imply $s(x) \in C^2[a,b]$. □

Based on Theorem 1, the interpolant (1) can be C^2 continuous without solving a system of consistency equations for the derivative values at the knots. Actually, the derivatives given by (4) are widely used; see [9, 12]. In [11] and [14], it has been shown that the limits of the derivatives at the knots are given by (4).

3. Shape-preserving properties. At first, we establish some properties of $s(x)$ on strictly convex/concave sets of data.

THEOREM 2. *For $x \in [x_i, x_{i+1}]$, $i = 1, 2, \ldots, n-1$, if $A_i > 0, B_i > 0$, then $s''(x) > 0$ when*

$$\lambda_i \geq \max\left\{\frac{A_i}{B_i^2}, \frac{B_i}{A_i^2}\right\}; \tag{7}$$

if $A_i < 0, B_i < 0$, then $s''(x) < 0$ when

$$\lambda_i \leq \min\left\{\frac{A_i}{B_i^2}, \frac{B_i}{A_i^2}\right\}. \tag{8}$$

Proof. From (6), the expression of $s''(x)$ can be reduced to the following form:

$$s''(x) = \frac{1}{h_iQ_i^3(t)}\sum_{j=0}^{6}(1-t)^{6-j}t^jB_{ij}, \tag{9}$$

where $B_{i0} = 2A_i$, $B_{i6} = 2B_i$,

$$\begin{aligned}
B_{i1} &= 6A_i^2\lambda_i + 6A_i - 6B_i, \\
B_{i2} &= 6A_i^2B_i\lambda_i^2 + 6(A_i - B_i)B_i\lambda_i + 12A_i - 6B_i, \\
B_{i3} &= 2A_i^2B_i^2\lambda_i^3 + 2(A_i^2B_i + A_iB_i^2 - A_i^3 - B_i^3)\lambda_i^2 + 4(5A_iB_i - A_i^2 - B_i^2)\lambda_i, \\
B_{i4} &= 6A_iB_i^2\lambda_i^2 + 6A_i(B_i - A_i)\lambda_i - 6A_i + 12B_i, \\
B_{i5} &= 6B_i^2\lambda_i - 6A_i + 6B_i.
\end{aligned}$$

If $A_i > 0, B_i > 0, \lambda_i \geq \max\{A_i/B_i^2, B_i/A_i^2\}$, and $A_i \leq B_i$, then

$$\lambda_i \geq \max\left\{\frac{A_i}{B_i^2}, \frac{B_i}{A_i^2}\right\} = \frac{B_i}{A_i^2} \geq \frac{1}{A_i} \geq \frac{1}{B_i} \geq \frac{A_i}{B_i^2}.$$

Since $B_{i0} = 2A_i, B_{i6} = 2B_i$,

$$\begin{aligned}
B_{i1} &= 6(A_i^2\lambda_i - B_i) + 6A_i, \quad B_{i5} = 6(B_i^2\lambda_i - A_i) + 6B_i,\\
B_{i2} &= 6B_i(A_i^2\lambda_i - B_i)\lambda_i + 6(A_i\lambda_i - 1)B_i + 12A_i,\\
B_{i3} &= 2(A_i^2\lambda_i - B_i)B_i^2\lambda_i^2 + 2A_i^2(B_i - A_i)\lambda_i^2\\
&\quad + 2(A_iB_i\lambda_i + 8A_i - 2B_i)B_i\lambda_i + 4A_i(B_i - A_i)\lambda_i,\\
&= 2(A_i^2\lambda_i - B_i)B_i^2\lambda_i^2 + 2A_i^2(B_i - A_i)\lambda_i^2\\
&\quad + \frac{2B_i}{A_i}[(A_i^2\lambda_i - B_i)B_i + 8A_i^2 + B_i^2 - 2A_iB_i]\lambda_i + 4A_i(B_i - A_i)\lambda_i,\\
B_{i4} &= 6A_i(B_i^2\lambda_i - A_i)\lambda_i + 6A_i(B_i\lambda_i - 1) + 12B_i,
\end{aligned}$$

we can see that $B_{ij} > 0$, $j = 0, 1, \ldots, 6$, and then $s''(x) > 0$.

In the same way, we can show that $s''(x) > 0$ when $A_i > 0$, $B_i > 0$, $\lambda_i \geq \max\{A_i/B_i^2, B_i/A_i^2\}$, and $A_i > B_i$. The proof for the case $A_i < 0$, $B_i < 0$ is similar. □

At the end knots x_1, x_n, if we set derivative values

$$d_1 = \Delta_1 - \frac{h_1}{h_1 + h_2}(\Delta_2 - \Delta_1), \quad d_n = \Delta_{n-1} + \frac{h_{n-1}}{h_{n-2} + h_{n-1}}(\Delta_{n-1} - \Delta_{n-2}), \tag{10}$$

then

$$A_1 = \frac{h_1}{h_1 + h_2}(\Delta_2 - \Delta_1), \quad B_{n-1} = \frac{h_{n-1}}{h_{n-2} + h_{n-1}}(\Delta_{n-1} - \Delta_{n-2}).$$

From (4) we have

$$A_i = \frac{h_i}{h_{i-1} + h_i}(\Delta_i - \Delta_{i-1}), \quad B_{i-1} = \frac{h_{i-1}}{h_{i-1} + h_i}(\Delta_i - \Delta_{i-1})$$

for $i = 2, 3, \ldots, n-1$. Therefore, if we take d_i as defined by (4) and (10), then the given interpolant is convexity-preserving when the λ_i satisfy (7) or (8). For $x \in [x_i, x_{i+1}]$, when the differences Δ_k $(k = i-1, i, i+1)$ satisfy the inequalities $\Delta_{i-1} < \Delta_i < \Delta_{i+1}$ or $\Delta_{i-1} > \Delta_i > \Delta_{i+1}$, the interpolant is convexity-preserving.

Remark. If $A_iB_i > 0$, then $s(x)$ is also monotonicity-preserving for $x \in [x_i, x_{i+1}]$ when λ_i is large enough. In fact, (5) can be written as

$$s'(x) = \frac{1}{Q_i^2(t)}\sum_{j=0}^{6}(1-t)^{6-j}t^jA_{ij},$$

where $A_{i0} = d_i$, $A_{i6} = d_{i+1}$,

$$\begin{aligned}
A_{i1} &= 2B_id_i\lambda_i + 2\Delta_i, \quad A_{i5} = 2A_id_{i+1}\lambda_i + 2\Delta_i,\\
A_{i2} &= B_i^2d_i\lambda_i^2 + [2(A_i + B_i)\Delta_i + A_i^2 - A_iB_i]\lambda_i + 3\Delta_i + 2A_i - 3B_i,\\
A_{i3} &= 2A_iB_i\Delta_i\lambda_i^2 + 2[(A_i + B_i)\Delta_i + A_i^2 - B_i^2]\lambda_i + 4\Delta_i + 4A_i - 4B_i,
\end{aligned}$$

$$A_{i4} = A_i^2 d_{i+1}\lambda_i^2 + [2(A_i + B_i)\Delta_i + A_iB_i - B_i^2]\lambda_i + 3\Delta_i + 3A_i - 2B_i.$$

Therefore, if we choose λ_i so that $sgn(\lambda_i) = sgn(A_i)$, then $sgn(A_{ij}) = sgn(d_i)(j = 0, 1, 2)$, $sgn(A_{i3}) = sgn(\Delta_i)$, $sgn(A_{ij}) = sgn(d_{i+1})$ $(j = 4, 5, 6)$ when λ_i is large enough.

Now we give an inflection property that is satisfied by the curve.

THEOREM 3. *For $i = 1, 2, \ldots, n-1$, if $A_iB_i < 0$, then for $x \in [x_i, x_{i+1}]$, the curve $s(x)$ has exactly one inflection in $[x_i + 0.4573h_i,\ x_{i+1} - 0.4573h_i]$ when $\lambda_i = 0$.*

Proof. Let $A_iB_i < 0$, $\lambda_i = 0$. For $x \in [x_i, x_{i+1}]$, from (9) we have $s''(x) = 0$ when $t = (x - x_i)/h_i$ satisfies

$$\begin{aligned}&[(1-t)^6 + 3(1-t)^5 t + 6(1-t)^4 t^2 - 3(1-t)^2 t^4 - 3(1-t)t^5]A_i\\ &= [3(1-t)^5 t + 3(1-t)^4 t^2 - 6(1-t)^2 t^4 - 3(1-t)t^5 - t^6]B_i.\end{aligned}$$

If we write

$$g(t) = -3(1-t)^5 t - 3(1-t)^4 t^2 + 6(1-t)^2 t^4 + 3(1-t)t^5 + t^6,$$

then $s''(x) = 0$ can be written as $g(t) = g(1-t)|A_i/B_i|$. Thus, we have

$$\begin{aligned}g'(t) &= 3(8t^5 - 20t^4 + 24t^3 - 16t^2 + 8t - 1),\\ g''(t) &= 24[(5t^2 - 5t + 4)(1-t)t + 1],\end{aligned}$$

where the derivatives represent differentiation with respect to t. Obviously, for $t \in [0, 1]$, $g''(t) > 0$ and then $g'(t)$ has only one zero point $t = \underline{t} \approx 0.170013$. Thus, $g(t)$ is decreasing for $t \in [0, \underline{t}]$ and increasing for $t \in [\underline{t}, 1]$. Further $g(0) = 0, g(t^*) = 0, g(t) < 0$ for $t \in (0, t^*)$ and $g(t) > 0$ for $t \in (t^*, 1]$, where $t^* \approx 0.457312$. Symmetrically, $g(1-t) > 0$ for $t \in [0, 1-t^*), g(1-t) < 0$ for $t \in (1-t^*, 1)$, and $g(1-t)$ is deceasing for $t \in [0, 1-t^*]$.

For $t \in [0, 1]$, since $g(t^*) = 0$, $g(1-t^*)|A_i/B_i| > 0$, and $g(1-t^*) > 0$, $g(t^*)|A_i/B_i| = 0$, we can know that $g(t) = g(1-t)|A_i/B_i|$ holds only for one point in $[0.4573, 1 - 0.4573]$. ∎

When $A_iB_i < 0$, we also want to set $\lambda_i = 0$ based on the denominator of $s(x)$. Thus, $Q_i(t) = (1-t)^2 + t^2 \geq 1/2$.

The remaining case we need to discuss is $A_iB_i = 0$. When $A_i = B_i = 0$, $s(x)$ is linear interpolant to (x_i, f_i) and (x_{i+1}, f_{i+1}).

THEOREM 4. *If $A_i \neq 0, B_i = 0$ or $A_i = 0, B_i \neq 0$, then when $sgn(\lambda_i) = sgn(A_i + B_i)$, we have*

$$\lim_{\lambda_i \to \infty} s(x) = (1-t)f_i + tf_{i+1} \tag{11}$$

for $x \in [x_i, x_{i+1}]$, $t = (x - x_i)/h_i$.

Proof. Let $A_i \neq 0, B_i = 0$. Then, for $x \in [x_i, x_{i+1}]$,

$$s(x) = (1-t)f_i + tf_{i+1} - \frac{h_i(1-t)^3 t A_i}{Q_i(t)}.$$

Obviously,

$$\Big|\frac{(1-t)^3 t A_i}{Q_i(t)}\Big| \leq \frac{(1-t)^3 t|A_i|}{(1-t)^3 + (1-t)t^2\lambda_i A_i} \leq \frac{1-t}{2}\sqrt{\frac{A_i}{\lambda_i}}.$$

From this we obtain (11). In the same way, we can obtain (11) when $A_i = 0, B_i \neq 0$. ∎

According to (4), $A_i = 0$ implies $\Delta_{i-1} = \Delta_i$ and $B_i = 0$ implies $\Delta_i = \Delta_{i+1}$. In these cases, we can choose the tension parameter λ_i so that the interpolant (1) approximates the linear interpolant.

Based on Theorems 2, 3, and 4, we give a proper choice of the tension parameter as follows:

$$\lambda_i = \begin{cases} A_i/B_i^2 + B_i/A_i^2 & \text{for } A_iB_i > 0, \\ (A_i + B_i)c_i & \text{for } A_iB_i = 0, \\ 0 & \text{for } A_iB_i < 0, \end{cases} \tag{12}$$

where $c_i > 0$ could be left as user input.

By (12), we can treat data sets for all cases. Often a data set will not be globally convex/concave, but instead switches back and forth between convexity and concavity. Thus, expression (12) is practical.

4. Convergence analysis. Let $f(x)$ be a given function with which $s(x)$ is compared. We have $f(x_i) = f_i$ and write $f_i' = f'(x_i)$, $i = 1, 2, \ldots, n$,

$$\|f^{(r)}\|_{i,j} = \max_{x_i \le x \le x_j} |f^{(r)}(x)|, \quad \delta_i = \min_{x_{i-1} \le x \le x_{i+2}} |f^{(2)}(x)|$$

for all possible r, i, j.

THEOREM 5. *Let $f \in C^4[a, b]$. For $x \in [x_i, x_{i+1}], i = 1, 2, \ldots, n-1$, if $\lambda_i A_i \ge 0$, $\lambda_i B_i \ge 0$, then*

$$\begin{aligned} |f(x) - s(x)| \le{}& \frac{h_i^4}{384}\|f^{(4)}\|_{i,i+1} + \frac{h_i}{4}\max\{|f_i' - d_i|, |f_{i+1}' - d_{i+1}|\} \\ &+ \frac{h_i}{2 + \min\{\lambda_i A_i, \lambda_i B_i\}}|A_i - B_i|\left[\frac{\sqrt{3}}{18} + \frac{1}{16}|\lambda_i(A_i - B_i)|\right]. \end{aligned} \tag{13}$$

Proof. For $x \in [x_i, x_{i+1}]$, $i = 1, 2, \ldots, n-1$, let $t = (x - x_i)/h_i$ and

$$H_3(x) = (1-t)f_i + tf_{i+1} - h_i(1-t)t[(1-t)A_i + tB_i].$$

After some manipulations, we obtain

$$s(x) = H_3(x) + \frac{h_i(1-t)^2t^2}{Q_i(t)}(A_i - B_i)[2t - 1 + \lambda_i(1-t)t(A_i - B_i)].$$

By $f_i' = f'(x_i)$, $i = 1, 2, \ldots, n$, let

$$H_3^*(x) = (1-t)f_i + tf_{i+1} - h_i(1-t)t[(1-t)(\Delta_i - f_i') + t(f_{i+1}' - \Delta_i)].$$

Since $H_3^*(x)$ is the cubic Hermite interpolant to $f(x)$, we have

$$|f(x) - H_3^*(x)| \le \frac{h_i^4}{384}\|f^{(4)}\|_{i,i+1}.$$

It is easy to see that

$$|H_3^*(x) - H_3(x)| \le \frac{h_i}{4}\max\{|f_i' - d_i|, |f_{i+1}' - d_{i+1}|\},$$

$$Q_i(t) = (1-t)^2 + \lambda_i(1-t)t[(1-t)B_i + tA_i] + t^2$$
$$\geq (1-t)t(2 + \min\{\lambda_i A_i, \lambda_i B_i\}),$$

and $|(1-t)t(2t-1)| \leq \sqrt{3}/18$. From these, we obtain (13). ∎

THEOREM 6. *Let $f \in C^4[a,b]$, and let d_i be given by (4) and (10). For $x \in [x_i, x_{i+1}]$, $i = 1, 2, \ldots, n-1$, if $\lambda_i(\Delta_i - \Delta_{i-1}) \geq 0, \lambda_i(\Delta_{i+1} - \Delta_i) \geq 0$, then*

$$|f(x) - s(x)| \leq \frac{h_1^4}{384}\|f^{(4)}\|_{1,2} + \frac{h_1^2}{24}(h_1 + h_2)\|f^{(3)}\|_{1,3} \tag{14}$$

for $x \in [x_1, x_2]$,

$$\begin{aligned} |f(x) - s(x)| \leq{}& \frac{h_i^4}{384}\|f^{(4)}\|_{i,i+1} + \frac{h_i^2}{24}\max\{h_{i-1}, h_{i+1}\}\|f^{(3)}\|_{i-1,i+1} \\ &+ \frac{h_i^2(h_{i-1} + h_i + h_{i+1})}{18(4 + h_i\delta_i|\lambda_i|)}\|f^{(3)}\|_{i-1,i+2}\left[\frac{\sqrt{3}}{3}\right. \\ &\left. + \frac{h_i}{16}(h_{i-1} + h_i + h_{i+1})|\lambda_i|\|f^{(3)}\|_{i-1,i+2}\right] \end{aligned} \tag{15}$$

for $x \in [x_i, x_{i+1}]$, $i = 2, 3, \ldots, n-2$, and

$$|f(x) - s(x)| \leq \frac{h_{n-1}^4}{384}\|f^{(4)}\|_{n-1,n} + \frac{h_{n-1}^2}{24}(h_{n-2} + h_{n-1})\|f^{(3)}\|_{n-2,n} \tag{16}$$

for $x \in [x_{n-1}, x_n]$.

Proof. For (4) and (10), by using a Peano kernel analysis, it can be shown that

$$\begin{aligned} &f_1' - d_1 = \frac{1}{6}h_1(h_1 + h_2)f^{(3)}(\xi_1), \quad \xi_1 \in (x_1, x_3), \\ &f_n' - d_n = \frac{1}{6}h_{n-1}(h_{n-2} + h_{n-1})f^{(3)}(\xi_n), \quad \xi_n \in (x_{n-2}, x_n), \\ &d_1 + d_2 - 2\Delta_1 = 0, \quad d_{n-1} + d_n - 2\Delta_{n-1} = 0, \\ &d_i - f_i' = \frac{1}{6}h_{i-1}h_i f^{(3)}(\xi_i), \quad \xi_i \in (x_{i-1}, x_{i+1}), \\ &d_i + d_{i+1} - 2\Delta_i = \frac{1}{6}h_i(h_{i-1} + h_i + h_{i+1})f^{(3)}(\eta_i), \quad \eta_i \in (x_{i-1}, x_{i+2}), \\ &\Delta_i - \Delta_{i-1} = \frac{1}{2}(h_{i-1} + h_i)f^{(2)}(\zeta_i), \quad \zeta_i \in (x_{i-1}, x_{i+1}), \end{aligned}$$

for $i = 2, 3, \ldots, n-1$. From these, (13), and $A_i = h_i(\Delta_i - \Delta_{i-1})/(h_{i-1} + h_i)$, $B_i = h_i(\Delta_{i+1} - \Delta_i)/(h_i + h_{i+1})$, $A_i - B_i = 2\Delta_i - d_i - d_{i+1}$, it is easy to obtain (14), (15), and (16). ∎

It can be seen from Theorem 6 that $f(x) - s(x) = O(h^3)$ for $x \in [x_1, x_n]$, where $h = \max_{1 \leq i \leq n-1} h_i$.

5. Numerical results. Numerical experiments are conducted by using (4), (10), and the values of λ_i given by (12). Since the influence of c_i in (12) is little, we give the experimental results by taking $c_i = 1$. The algorithm is easy to implement and fast to compute.

We first consider two sets of data to show the convexity-preserving property. The first set of data may be found in [12], and the interpolation curve is shown in Figure 1.

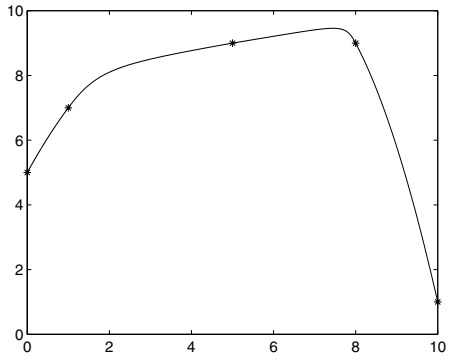

FIG. 1. *Curve on strictly convex data.*

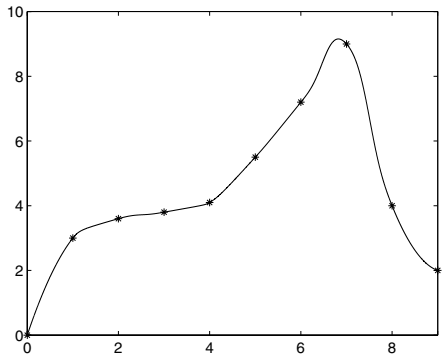

FIG. 2. *Curve on nonstrictly convex data.*

The second set of data may be found in [14], and the interpolation curve is shown in Figure 2. We conclude from the figures that the given method appears to produce visually pleasing curves.

We next consider two sets of data to show the order of convergence of the interpolation method. The first set of data is the set of the points of the curve $f_1(x) = 2\exp(-(x-1.5)^2)$, $0 \le x \le 3$. The second set of data is the set of the points of the curve $f_2(x) = \cos^2 x$, $0 \le x \le \pi/2$. The knots x_i of two examples are taken to be equally spaced. Figures 3 and 4 show the interpolation curves for $n = 10$ for the first and second sets, respectively. The errors are evaluated by $e = \max_i |f(\bar{x}_i) - s(\bar{x}_i)|$ for $\bar{x}_i = x_1 + i(x_n - x_1)10^{-4}, i = 0, 1, \ldots, 10^4$. Table 1 shows the interpolation errors with $n = 11$, 101, 1001, respectively. The errors confirm the expected convergence rates.

6. Conclusions. An explicit representation of a piecewise rational quartic interpolant has been developed, which can preserve the local convexity/concavity of the interpolation data. The given interpolant can be C^2 continuous without solving a linear or nonlinear system of consistency equations for the derivative values at the knots. For C^2 methods that concern the solution of the consistency equations, see [6, 10, 11, 12, 14, 15]. The given interpolant contains a parameter, λ_i, which serves as a tension factor. The proper choice of λ_i to guarantee shape preservation is given.

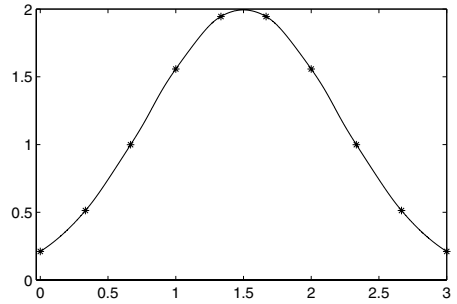

FIG. 3. *Interpolation curve for* $f_1(x)$.

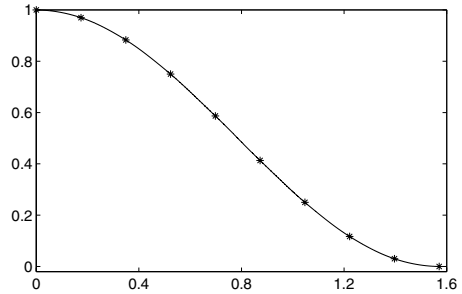

FIG. 4. *Interpolation curve for* $f_2(x)$.

TABLE 1
Interpolation errors for $f_1(x)$ *and* $f_2(x)$.

n	11	101	1001
$f_1(x)$	7.15900×10^{-3}	6.03609×10^{-6}	6.87149×10^{-9}
$f_2(x)$	9.88001×10^{-4}	9.94430×10^{-7}	9.92200×10^{-10}

A large value of λ_i will give approximately the interpolant in [12] or the special form in [11]. For C^2 interpolation, the interpolant has $O(h^3)$ convergence. Numerical examples indicate that the method produces visually pleasing curves.

Acknowledgment. The author thanks the referees for their valuable advice.

NEW QUADRATURE FORMULAS FROM CONFORMAL MAPS*

NICHOLAS HALE† AND LLOYD N. TREFETHEN†

Abstract. Gauss and Clenshaw–Curtis quadrature, like Legendre and Chebyshev spectral methods, make use of grids strongly clustered at boundaries. From the viewpoint of polynomial approximation this seems necessary and indeed in certain respects optimal. Nevertheless such methods may "waste" a factor of $\pi/2$ with respect to each space dimension. We propose new nonpolynomial quadrature methods that avoid this effect by conformally mapping the usual ellipse of convergence to an infinite strip or another approximately straight-sided domain. The new methods are compared with related ideas of Bakhvalov, Kosloff and Tal-Ezer, Rokhlin and Alpert, and others. An advantage of the conformal mapping approach is that it leads to theorems guaranteeing geometric rates of convergence for analytic integrands. For example, one of the formulas presented is proved to converge 50% faster than Gauss quadrature for functions analytic in an ε-neighborhood of $[-1, 1]$.

Key words. Gauss quadrature, Clenshaw–Curtis quadrature, spectral methods, conformal mapping

AMS subject classifications. 65D32, 30C20

1. Introduction. The Gauss and Clenshaw–Curtis quadrature formulas, as well as other related numerical methods for integration of nonperiodic functions or spectral solution of nonperiodic ODEs or PDEs, all cluster the grid points near the boundaries. Indeed, for any convergent numerical method derived from polynomial interpolation in the grid points, the clustering will be asymptotically the same: on $[-1, 1]$, n points will be distributed with density $\sim n/(\pi\sqrt{1-x^2})$ as $n \to \infty$ [36, Thm. 12.7].

It is well known that this clustering may cause problems. The high density of points near the boundaries may necessitate very small time steps in an explicit time-stepping spectral method or make the matrices involved in implicit time-stepping terribly ill conditioned [12, 49]. At the same time the low density of points in the middle of the domain may force one to use more points than "ought" to be needed to resolve the solution. Compared with equally spaced grids, these clustered grids have $\pi/2$ times coarser spacing in the middle, implying that, for many calculations, n must be about $\pi/2$ times larger than one might expect. In a three-dimensional calculation, a discretization may need $(\pi/2)^3 \approx 4$ times as many grid points as one would like. Such a factor may have a large impact on the cost of linear algebra operations.

In this article we focus on this $\pi/2$ problem and mainly on quadrature, not spectral, methods. The problem arises in purest form if we consider the integral from -1 to 1 of a function f analytic in a narrow strip about the real axis. If f is periodic, we can use the trapezoid rule and get geometric convergence, i.e., convergence at a rate e^{-Cn} for some $C > 0$. If f is not periodic, the trapezoid rule loses its speed, but Gauss quadrature still converges geometrically. However, the constant C is $\pi/2$ times smaller, and thus the convergence rate is $\pi/2$ times slower.

Various authors have proposed methods for countering this effect. We shall suggest a new approach based on conformal mapping, which leads to formulas that

†Oxford University Computing Laboratory, Wolfson Bldg., Parks Rd., Oxford OX1 3QD, UK (nich@comlab.ox.ac.uk, LNT@comlab.ox.ac.uk).

converge more quickly than Gauss quadrature for many integrands. The practical performance of our methods is not much different from that of other methods in the literature, such as those of Alpert [3] and Kosloff and Tal-Ezer [33] (see section 5). Nevertheless, the conformal mapping idea has advantages. First, it is conceptually clear, simple, and flexible, explaining in a precise way the nature of the $\pi/2$ effect and exactly what improvements may be possible for integrands analytic in specified domains. Second, it leads immediately to theorems on geometric convergence rates for analytic integrands. In the existing literature of related methods, it is hard to find such theorems. An additional advantage, which we shall not discuss further, is that the conformal mapping approach connects these simple quadrature problems to more complicated problems where conformal maps have also proved useful, such as the double exponential quadrature formula and Tee's adaptive rational spectral methods [22, 38, 43, 44, 46, 47, 48].

An outline of the article is as follows. In section 2 we present the conformal transplantation idea. We apply it in section 3 to the particular case of a map to an infinite strip and in section 4 to a simpler variant that may be equally useful in practice. Related work is surveyed in section 5, and theorems about geometric convergence rates are presented in section 6. The Clenshaw–Curtis variant of our formulas is considered in section 7, and we close in section 8 with a summary discussion. The appendix includes a 14-line FFT-based MATLAB code that runs in less than a second for n as high as 10^5 yet usually delivers more accurate integrals than the Gauss rule for each value of n.

2. Transplanted quadrature formulas. Let f be an analytic function on $[-1,1]$ whose integral

$$I = I(f) = \int_{-1}^{1} f(x)\,dx \tag{2.1}$$

we seek to calculate. A general interval $[a,b]$ can be handled by a linear change of variables. All of the methods we shall consider approximate I by sums

$$I_n = I_n(f) = \sum_{k=1}^{n} w_k f(x_k) \tag{2.2}$$

defined by *nodes* $\{x_k\}$ and *weights* $\{w_k\}$. *Polynomial methods* of this kind are based on the following principle: given nodes $\{x_k\}$, the weights $\{w_k\}$ are chosen so that I_n is equal to the integral of the unique degree $n-1$ polynomial interpolant through the data points. In particular, Newton–Cotes quadrature is obtained from equally spaced nodes, Gauss quadrature from the roots of the Legendre polynomial P_n, and Clenshaw–Curtis quadrature from the Chebyshev points $x_k = \cos((k-1)\pi/(n-1))$. Any polynomial method that converges as $n \to \infty$ for all analytic f must have its nodes distributed asymptotically with density $\sim n/(\pi\sqrt{1-x^2})$ as $n \to \infty$. The Gauss and Clenshaw–Curtis formulas have this property and converge for any continuous f. The Newton–Cotes formulas do not and diverge in general even if f is analytic [5, 36, 41].

The standard theorems about convergence of polynomial methods for analytic functions assume that the integrand is analytic in an elliptical region. For any $\rho > 1$, let us define E_ρ to be the open set in the complex plane bounded by the ellipse with foci ± 1 with semiminor and semimajor axis lengths summing to ρ. This ellipse can also be described as the image of the circle of radius ρ about the origin under the

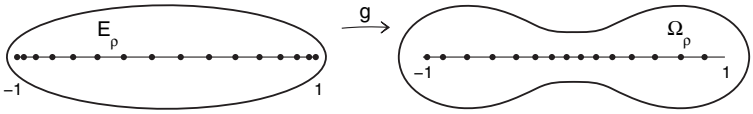

FIG. 2.1. *A transplanted quadrature formula* (2.6) *is defined by an analytic function* g *that maps the elliptical region* E_ρ *into a region* Ω_ρ *containing* $[-1,1]$. *In this illustration the map is* $g(s) = 0.5s + 0.2s^3 + 0.3s^5$ *with* $\rho = 1.4$. *The dots show Gauss points* $x_k \in E_\rho$ *for* $n = 16$ *and their images* $\tilde{x}_k \in \Omega_\rho$.

map $w = (z + z^{-1})/2$. The general idea of the following convergence theorem goes back to Bernstein in 1919 [8], but such results do not appear in many textbooks or monographs, and there is not much uniformity in the constants that one finds on the right-hand side [25, p. 114]. The particular result presented here is due to Rabinowitz [42, eq. (18)]; see also [11, Thm. 90] and [50, Thm. 4.5].

THEOREM 2.1. *If* f *is analytic in* E_ρ, *with* $|f(z)| \le M$ *for some* $\rho > 1$, *then Gauss quadrature converges geometrically with the bound*

$$|I_n - I| \le \frac{64M}{15(1-\rho^{-2})\rho^{2n}} \qquad (n \ge 0). \tag{2.3}$$

When we don't care about constants, we may simply note that Theorem 2.1 ensures geometric convergence at the rate $O(\rho^{-2n})$ as $n \to \infty$.

To experts in approximation theory, the assumption of analyticity in an elliptical region is so familiar as to seem almost beyond question. Nevertheless, the appearance of ellipses in this analysis is driven not by the quadrature formula (2.2) per se but by the decision to derive weights from polynomial interpolation. If we do not insist on polynomials, ellipses cease to have any special status.

We have already observed from the uneven distribution of Gauss and Clenshaw–Curtis nodes that there may be a reason to move beyond polynomials. Here is another argument based on the shape of E_ρ. From an applications point of view, the assumption that f is analytic in E_ρ is unbalanced, for it permits f to be "less analytic" near the ends of the interval, where the ellipse is narrow, than in the middle, where it is wide. Specifically, the Taylor series of f at a point $x \approx \pm 1$ is allowed to have more rapidly increasing coefficients than are permitted at a point $x \approx 0$. This nonuniform analyticity condition leads to Theorem 2.1 and related results for other polynomial quadrature formulas, but it has no intrinsic justification. Further consequences of the same nonuniformity reverberate throughout the field of polynomial approximation theory—for example, in the book by Ditzian and Totik [17]. Of course, there are applications where the functions of interest do have less smoothness near the boundary than in the interior, such as fluid mechanics problems with boundary layers. Even here, however, there is no reason to expect that an ellipse should be exactly the right region to consider. Weak boundary layers might benefit from less grid clustering at boundaries and strong ones from even more.

Our plan is to derive new quadrature formulas (2.2) for $[-1,1]$ by conformally mapping E_ρ to a region Ω_ρ that has straighter sides. We describe the procedure first in general terms; see Figure 2.1.

Let Ω_ρ be an open set in $\mathbb{C}$ containing $[-1,1]$ inside of which the function f is analytic. Let g be an analytic function in E_ρ satisfying

$$g(E_\rho) \subseteq \Omega_\rho, \qquad g(-1) = -1, \quad g(1) = 1. \tag{2.4}$$

Then $g([-1,1])$ is an analytic curve in Ω_ρ, parametrized by $s \in [-1,1]$, that connects -1 to 1. By Cauchy's theorem for analytic functions, the integral of f over this curve is the same as the integral of f over $[-1,1]$ itself. Thus (2.1) can be rewritten

$$I(f) = \int_{-1}^{1} g'(s)\, f(g(s))\, ds. \tag{2.5}$$

If we apply (2.2) to this integral in the s variable, we obtain

$$I_n(\, g' \cdot (f \circ g)) = \sum_{k=1}^{n} w_k\, g'(x_k)\, f(g(x_k)),$$

which can be rewritten in the form (2.2) as

$$\boxed{\tilde{I}_n = \tilde{I}_n(f) = \sum_{k=1}^{n} \tilde{w}_k\, f(\tilde{x}_k), \quad \tilde{w}_k = w_k\, g'(x_k), \quad \tilde{x}_k = g(x_k).} \tag{2.6}$$

TRANSPLANTED QUADRATURE FORMULA

In this article we generally speak of g as a conformal map, which is defined as an analytic function with nonvanishing derivative that maps one region bijectively onto another. In fact, for the theorems we present, g does not actually have to be conformal, merely analytic. Nor does g have to map $[-1,1]$ into itself; it could take complex values. For the formulas of practical interest, however, these extra conditions will usually be satisfied, and if they are, then we have the additional properties that the nodes $\tilde{x}_k$ are real and the weights $\tilde{w}_k$ are real and positive. In some applications to spectral methods, not considered here, conformality is genuinely required.

The following theorem on the convergence of transplanted Gauss quadrature is a corollary of Theorem 2.1.

THEOREM 2.2. *Let f be analytic in a region Ω_ρ containing $[-1,1]$ with $|f(z)| \le M$ for some $\rho > 1$, and let a transplanted Gauss quadrature formula* (2.6) *be defined by some map g satisfying* (2.4). *Then*

$$|\tilde{I}_n - I\,| \le \frac{64 M \gamma}{15(1-\rho^{-2})\rho^{2n}} \qquad (n \ge 0),$$

where $\gamma = \sup_{s \in E_\rho} |g'(s)| \le \infty$.

If $\gamma = \infty$ in this estimate, we can shrink ρ a little bit to make it finite. Thus transplanted Gauss quadrature always converges geometrically if f is analytic on $[-1,1]$.

3. Map to an infinite strip. We now turn to particular choices of the map g that may be useful in practice. Since our aim is to make the sides of Ω_ρ straighter than those of E_ρ, we begin by taking this notion as far as possible and considering the map g that takes E_ρ to an infinite strip Ω_ρ symmetric about the real axis with $g(\pm 1) = \pm 1$ and the ends of the ellipse mapping to $\pm\infty$ (Figure 3.1). These conditions determine g fully. The half-width a of Ω_ρ is not adjustable but is determined by the value of ρ ((3.5) below).

The map of the ellipse to the strip can be constructed in three steps (Figure 3.2). Let F_s denote the upper half of E_ρ, with distinguished boundary points $s_A = 0$, $s_B = 1$, and $s_C = (\rho + \rho^{-1})/2$ (the right end point of E_ρ). The function $u = \sin^{-1} s$ maps F_s to the rectangle F_u of width π and height $\log \rho$ with corresponding boundary

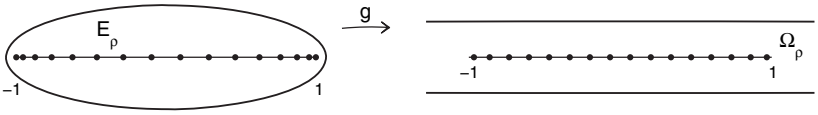

FIG. 3.1. *One choice of Ω_ρ is an infinite strip, shown here again for $\rho = 1.4$. The semiminor axis length of E_ρ is $\sim (\rho - 1)$, whereas the half-width of Ω_ρ is $\sim (2/\pi)(\rho - 1)$, reflecting the $\pi/2$ times weaker analyticity requirement of the transplanted quadrature formula. Note how the Gauss nodes in E_ρ map to nodes in Ω_ρ that are so close to equally spaced that they appear almost exactly even. For more on this spacing see Figure* 5.2.

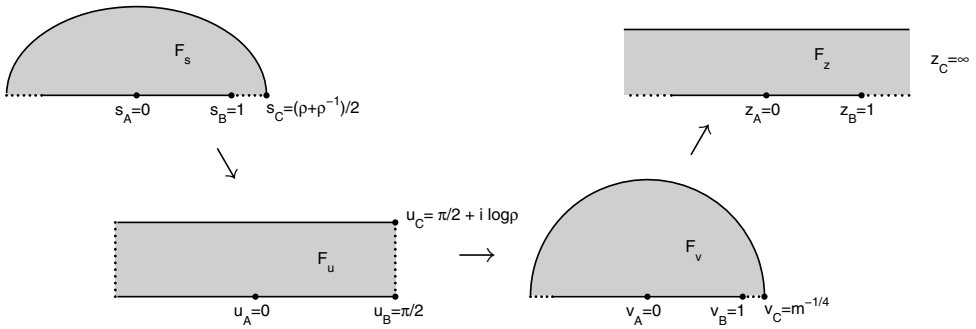

FIG. 3.2. *Construction of the strip map in three steps $s \to u \to v \to z$. The upper half of each region is shown. A large value of ρ has been used for clarity ($\rho = 2.3$), since, as ρ decreases to* 1*, the segment from v_B to v_C shrinks exponentially.*

points $u_A = 0$, $u_B = \pi/2$, and $u_C = \pi/2 + i \log \rho$. We now map F_u to a half-disk by a Jacobi elliptic sine function sn with parameter m [1, 16, 20]. Specifically, $v = \mathrm{sn}(2Ku/\pi \,|\, m)$ maps F_u to the upper half-disk F_v about the origin of radius $m^{-1/4}$, with $v_A = 0$, $v_B = 1$, and $v_C = m^{-1/4}$. Here, following standard notation, the parameter m with $0 < m < 1$ is chosen such that the associated elliptic integrals K' and K satisfy $K'/K = 4 \log(\rho)/\pi$. Given ρ, the appropriate value of m can be calculated by the rapidly convergent series expression given in [24]:

$$m^{1/4} = 2\sum_{j=1}^{\infty} \rho^{-4(j-\frac{1}{2})^2} \Big/ \left(1 + 2\sum_{j=1}^{\infty} \rho^{-4j^2}\right). \tag{3.1}$$

Finally $z = \tanh^{-1}(m^{1/4}v)/\tanh^{-1}(m^{1/4})$ maps F_v to F_z, the upper half of an infinite strip about the real axis with $z_A = 0$, $z_B = 1$, and $z_C = +\infty$. By combining the steps, we have the ellipse $\to$ strip map

$$g(s) = \tanh^{-1}\left(m^{1/4}\,\mathrm{sn}\left(\frac{2K}{\pi \sin^{-1}(s) \,|\, m}\right)\right) \Big/ \tanh^{-1}(m^{1/4}) \,. \tag{3.2}$$

The same formula is valid also below the real axis (by the Schwarz reflection principle), and thus g as given by (3.2) maps all of E_ρ to all of Ω_ρ. For the transplanted quadrature formula (2.6) we also require the derivative of the map function, which for $s \in (-1, 1)$ is given by

$$g'(s) = \frac{2Km^{1/4}}{\pi\sqrt{1-s^2}} \frac{\mathrm{cn}(\omega|m)\,\mathrm{dn}(\omega|m)}{(1 - m^{1/2}\,\mathrm{sn}^2(\omega|m))} \Big/ \tanh^{-1}(m^{1/4}), \tag{3.3}$$

where $\omega = 2K \sin^{-1}(s)/\pi$. For the end points $s = \pm 1$, with the aid of L'Hopital's rule

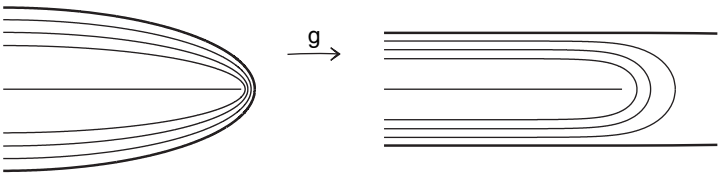

FIG. 3.3. *Though g maps E_ρ to the unbounded strip Ω_ρ, it maps smaller ellipses within E_ρ to regions that hug the interval $[-1,1]$ closely. Because of this property, f does not have to be analytic far down the strip for transplanted Gauss quadrature to be effective. Also, since the subregions have nearly straight sides, a value of ρ chosen for the strip of a particular half-width will also be effective for integrands whose true regions of analyticity are narrower.*

one can derive the formula

$$g'(\pm 1) = 4K^2\pi^{-2}m^{1/4}(1+m^{1/2}) \Big/ \tanh^{-1}(m^{1/4}) \,, \tag{3.4}$$

which we shall need for the Clenshaw–Curtis variant in section 7.

The half-width a of Ω_ρ is

$$a = \frac{\pi}{4\tanh^{-1}(m^{1/4})} < \frac{2}{\pi}(\rho-1), \tag{3.5}$$

with $a \sim (2/\pi)(\rho-1)$ as $\rho \to 1$ (we have verified this inequality numerically, and no doubt it could be proved analytically). The half-width of E_ρ in the same limit is $\sim(\rho-1)$. Thus the transplanted formula needs only $2/\pi$ times as wide a strip of analyticity to achieve the same convergence rate, as is confirmed by the following theorem. Further convergence results for this method are given in section 6.

THEOREM 3.1. *Let f be analytic in the strip Ω_ρ about $\mathbb{R}$ of half-width $(2/\pi)(\rho-1)$ for some $\rho > 1$. Let f be integrated by the transplanted Gauss quadrature formula* (2.6) *associated with the map* (3.2) *from E_ρ to Ω_ρ. Then, for any $\tilde\rho < \rho$,*

$$\tilde I_n - I = O(\tilde\rho^{-2n}) \qquad (n \to \infty). \tag{3.6}$$

Proof. The inequality (3.5) implies that $f(x)$ is analytic in the strip of half-width a, and therefore $f(g(s))$ is analytic in E_ρ. The constant γ of Theorem 2.2 is infinite for this map g, so we do not quite get $O(\rho^{-2n})$ convergence, and for this reason we have not assumed that f is bounded either. For any $\tilde\rho < \rho$, however, Theorem 2.1 still applies to the integrand $g'(s)f(g(s))$ of (2.5), which will be analytic and bounded in this smaller ellipse. This implies (3.6). ∎

To make our domain narrower in the imaginary direction by a factor of $2/\pi$, we have lengthened it in the real direction by a factor of ∞! This may seem a dubious improvement, and, indeed, it is a very strong condition that f must be analytic throughout an infinite strip. However, this is not a serious issue in practice because if we consider slightly smaller $\tilde\rho$-ellipses within E_ρ, we find that they map under g to domains about $[-1,1]$ that are much shorter. Thus little is lost if f is analytic near $[-1,1]$ but not very far down the real axis. Figure 3.3 illustrates this effect.

Let us see how strip-transplanted Gauss quadrature performs in practice. We do not normally recommend tuning ρ to the integrand at hand, for we are hardly likely to beat adaptive quadrature methods at their own game. Instead the aim is to derive a fixed family of formulas that perform well, if not quite optimally, and with this in mind we start by fixing the value $\rho = 1.4$ arbitrarily, as in Figures 2.1–3.1. Figure 3.4 shows

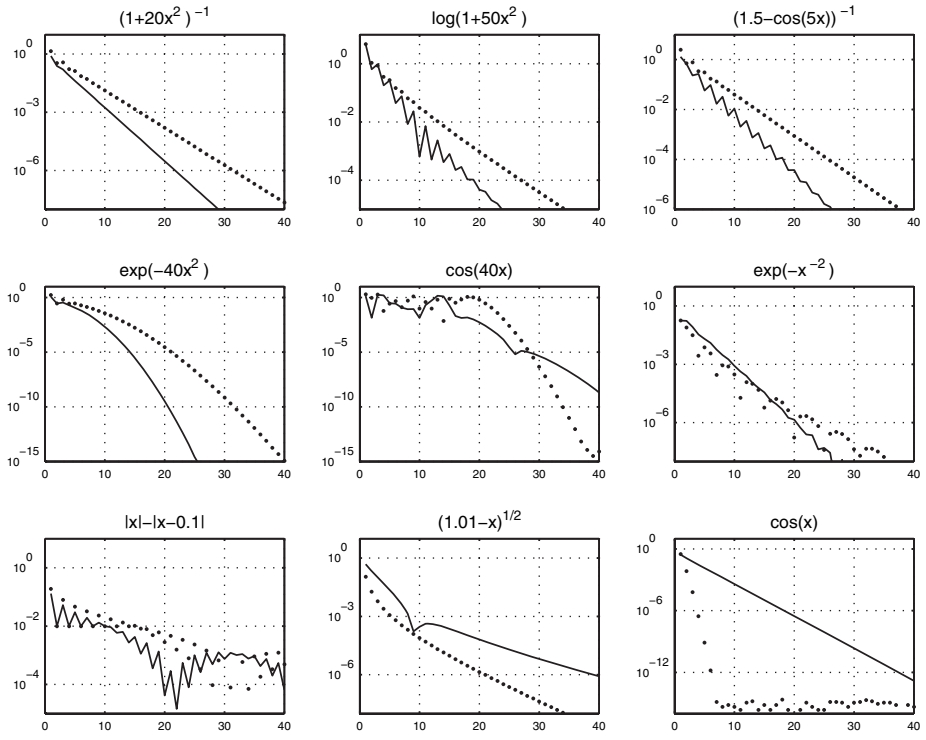

FIG. 3.4. *Comparison of Gauss quadrature (dots) against Gauss quadrature transplanted to an infinite strip (solid line) for nine integrands on* $[-1,1]$*, with* $\rho = 1.4$*. In a number of cases the transplanted formulas converge about* 1.4 *times faster.*

that, for many integrands, the result is a clear improvement over Gauss quadrature. (For this relatively large value of ρ, the improvement factor is about 1.42 rather than $\pi/2 \approx 1.57$.) This occurs, for example, for the first three integrands, which have poles or branch points close to $[-1,1]$ in the complex plane. A similar speedup is observed for the fourth function $\exp(-40x^2)$, which has no singularities but grows very rapidly as x moves away from the real axis. For the fifth function $\cos(40x)$, the transplanted quadrature formula begins to converge sooner than the untransplanted one since it resolves the oscillations sooner; once the error falls below 10^{-5}, the untransplanted formula overtakes it because the function is entire. The sixth integrand $\exp(-x^{-2})$ is C^∞ but not analytic; here we see comparable performance of the two methods. The same is observed for $|x| - |x - 0.1|$, which is continuous but not differentiable. For the eighth integrand $\sqrt{1.01 - x}$, the untransplanted Gauss rule wins because of its weaker analyticity requirement near ± 1. Finally, for the entire function $\cos(x)$, the transplanted rule loses by a substantial factor because it is stuck at the particular convergence rate $O(\rho^{-2n})$, with $\rho = 1.4$, since g is singular at the end points of this ellipse. The standard Gauss formula, by contrast, is not tied to any particular ellipse of analyticity and thus does very well in a case like this where the integrand is analytic and not too large in a sizable region around $[-1,1]$.

In fact, the convergence rate for the transplanted Gauss formula applied to $\cos(x)$ in Figure 3.4 has rather little to do with $\cos(x)$—the rate would be almost exactly the same for the integrand $f(x) = 1$! In general, nonpolynomial quadrature formulas do not integrate constants exactly. This perhaps startling property can be removed

by a scaling adjustment to our formula (2.6), whereby we multiply the weights $\tilde{w}_k$ by a constant so as to make them sum to 2. Since the transplanted quadrature formula integrates the constant function with exponential accuracy, the adjustment factor will be exponentially close to 1, and there will be no effect on the asymptotic convergence rates of Theorem 3.6 or Theorems 6.1 and 6.2 to follow. As a practical matter, the adjustment sometimes improves the behavior of our formulas slightly, and perhaps it is worth making.[1]

To implement the transplanted formula (2.6), we need to be able to compute g and g'. The following MATLAB code segment does this for the strip map (3.2). The standard MATLAB functions `ellipke` and `ellipj` used here to compute Jacobi elliptic functions are restricted to real arguments; for the complex values needed in Figures 3.1 and 3.3, we replaced `ellipj` by the function `ellipjc` from Driscoll's Schwarz–Christoffel Toolbox [19]. The function `gauss`, from [49], computes Gauss quadrature nodes and weights.

```
f = @(x) 1./(1+20*x.^2);                % change this for other integrands
[s,w] = gauss(n);                       % Gauss nodes and weights
[g,gprime] = strip(s);                  % g and g'
In = (w.*gprime')*f(g);                 % the integral

function [g,gprime] = strip(s)          % change this for a different map g
rho = 1.4;                              % this can be adjusted
num = 0; den = 0;
for j = 1:round(.5+sqrt(10/log(rho)))   % given rho, find m
  num = num + rho^(-4*(j-.5)^2);
  den = den + rho^(-4*j^2);
end
m4 = 2*num/(1+2*den); m = m4^4;         % m^{1/4} and m
K = ellipke(m);                         % Jacobi elliptic parameter
u = asin(s);
[sn,cn,dn] = ellipj(2*K*u/pi,m);        % Jacobi eliptic function
duds = 1./sqrt(1-s.^2);
dvdu = (2*K/pi)*cn.*dn;
dgdv = (m4./(1-m4.^2*sn.^2))/atanh(m4);
g = atanh(m4*sn)/atanh(m4);             % g
gprime = dgdv.*dvdu.*duds;              % g'
```

If ρ is close to 1 (smaller than about 1.1), the code just given suffers from numerical instability. The appendix outlines what can be done in such cases and offers an elementary map slightly different from (3.2) that as a practical matter may be superior.

4. A simpler conformal map. We now put aside the infinite strip and consider another idea for selecting the function g. Suppose we set out to cancel the clustering of Gauss or Clenshaw–Curtis points exactly. The function $g(s) = (2/\pi)\sin^{-1}(s)$ would achieve this, and the factor $2/\pi$ makes it plain that the result would be a grid denser by that factor in the middle of the interval. This choice of g would be useless, however, because $\sin^{-1}(s)$ has singularities at ± 1, so we would have no ellipse of analyticity at all for the transplanted integrand.

[1] Relatedly, one of the anonymous referees of this paper as originally submitted for publication pointed out that our transplanted n-point formulas, unlike polynomial methods, could in theory have arbitrarily large errors even for functions with a bounded kth derivative for any $k > 0$.

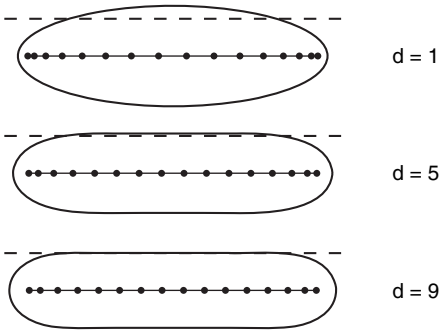

FIG. 4.1. *"Sausages" Ω_ρ corresponding to the maps* (4.1), (4.2), *and* (4.3), *with* $\rho = 1.4$. *The dashed line in each image marks the target height* $(2/\pi)(\rho - 1)$.

Instead we propose taking the terms through degree d of the Taylor series

$$\sin^{-1} s = s + \frac{1}{6}s^3 + \frac{3}{40}s^5 + \frac{5}{112}s^7 + \frac{35}{1152}s^9 + \cdots$$

and then normalizing so that $g(\pm 1) = \pm 1$ as required by (2.4). Taking $d = 1$, 5, or 9 gives the following choices, respectively:

$$g(s) = s, \tag{4.1}$$

$$g(s) = \frac{1}{149}(120s + 20s^3 + 9s^5), \tag{4.2}$$

$$g(s) = \frac{1}{53089}(40320s + 6720s^3 + 3024s^5 + 1800s^7 + 1225s^9). \tag{4.3}$$

Figure 4.1 shows the corresponding "sausage domains" Ω_ρ for $\rho = 1.4$.[2]

To implement transplanted Gauss quadrature of degree d (odd), we can replace the function `strip` in the code above by the following function `sausage`. The line with the `cumprod` command computes the Taylor series coefficients of $\sin^{-1}(x)$.

```
function [g,gprime] = sausage(s)
d = 9;                                          % this can be adjusted
c = zeros(1,d+1);
c(d:-2:1) = [1 cumprod(1:2:d-2)./cumprod(2:2:d-1)]./(1:2:d);
c = c/sum(c); g = polyval(c,s);
cp = c(1:d).*(d:-1:1); gprime = polyval(cp,s);
```

Figure 4.2 shows the performance of this method with $d = 9$ for various integrands. On the whole the convergence is much like that with the strip map, though somewhat slower for the first few examples and faster for the last few. With $f(x) = \cos x$, for example, we do much better now since g has no singularity to limit the convergence rate. Although it is entire, however, g still grows rapidly away from $[-1, 1]$, and that is why this map still does not match untransplanted Gauss quadrature for $\cos(x)$.

In section 6 we give a theorem that establishes that Gauss quadrature transplanted by (4.3) is 30% faster than standard Gauss quadrature for functions analytic in an ε-neighborhood of $[-1, 1]$.

[2]Previous authors have investigated the conformal mapping of a "bratwurst," but their maps concern exteriors rather than interiors and the applications are different [32].

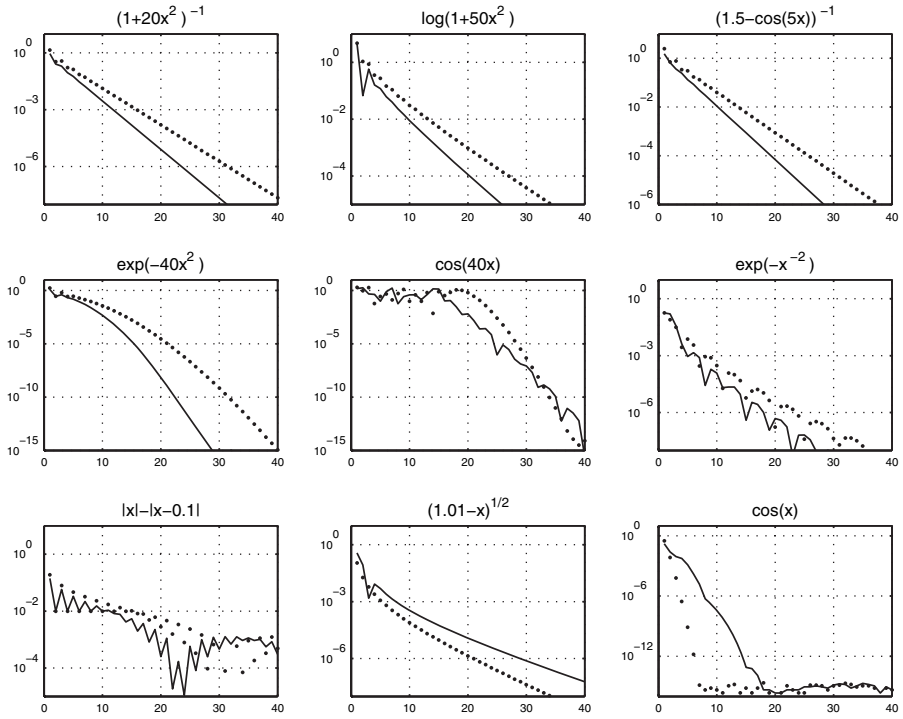

FIG. 4.2. *Comparison of Gauss quadrature (dots) against transplanted Gauss quadrature for the degree* 9 *polynomial* (4.3) *(solid line), for the same nine integrands as in Figure* 3.4. *Again in many cases the transplanted formulas converge faster.*

5. Related work. A number of ideas have been proposed over the years for combating the $\pi/2$ problem, for both quadrature and spectral methods, which might be classified as follows: (i) end point corrections, (ii) alternatives to polynomials, (iii) transplantation. Here is a brief summary of some of these developments.

The end point corrections idea starts from the observation that the trapezoid rule would achieve the ideal convergence rate if only the integrand were periodic. Accordingly, one might make some adjustments at the boundaries to achieve this effect, at least up to a prescribed order. The Euler–Maclaurin formula suggests one approach: one can add to the quadrature formula certain linear combinations of odd-order derivatives of the integrand at the end points, chosen to annihilate the error up to any prescribed power of the grid size. To get a quadrature rule based on function values only (i.e., without derivatives), one can then replace these terms by one-sided finite difference approximations of the appropriate orders. The resulting quadrature rules are known as *Gregory's formulas* [11, 30, 35], and they are effective up to medium orders of accuracy, at which point they encounter the difficulties caused by exponentially large coefficients of alternating signs. An improvement on Gregory formulas capable of achieving exponential convergence has been proposed by Alpert [3], building upon ideas of Kapur and Rokhlin [31]. Alpert's method goes beyond the equispaced grid to include a small number of extra Gauss-like nodes near the end points, now with weights guaranteed to be positive. High-precision computations are required in advance to obtain the nodes and weights, but once they are known the method is highly effective.

By alternatives to polynomials we mean the explicit construction of orthogonal bases that are nonpolynomial and have more uniform behavior over the interval of interest. An important set of functions in this connection is the *prolate spheroidal wave functions*, which were introduced in the 1960s by Slepian and Pollak [45]. These functions have excellent resolution properties, and more recent authors have shown their power for a variety of computational applications [9, 10, 13, 53]. In this literature, rather than derive theorems about convergence for functions analytic in specified domains as we are about to do, it is customary to quantify the matter of resolution by considering applications to band-limited functions.

Finally there is the transplantation idea, the basis of the present article. A notable contribution in this area is a forty-year-old theoretical paper by Bakhvalov [4]. What is the optimal family of quadrature formulas, Bakhvalov asks, for the set of functions analytic and bounded by M in a given complex region Ω containing $[-1,1]$? His first step is to transplant the problem by a conformal map g to an ellipse E_ρ. This is very close to what we have done but with a difference. In the ellipse, the new quadrature problem has a weight g'. Since his aim is to investigate optimal formulas, Bakhvalov now considers the Gauss formulas associated with this weight, which he shows are in a sense optimal. By contrast we have used the unweighted Gauss formula, including g' instead as part of the integrand. We presume that this simpler procedure does not hurt the convergence rate much in practice, but we have not investigated this matter. Bakhvalov's paper is full of interesting ideas, and it has led to subsequent developments in the theoretical quadrature literature by Petras [40] and other authors [23, 28, 34]. So far as we are aware, however, this collection of publications has not been concerned with the $\pi/2$ phenomenon, nor with particular choices of Ω, and does not propose actual quadrature formulas for numerical use.

A more practically oriented transplantation idea was introduced in the spectral methods literature by Kosloff and Tal-Ezer in 1993 [33]. Like the conformal maps proposed in the last section, the Kosloff–Tal-Ezer map is derived from the inverse sine function. Their transformation is

$$g(s) = \frac{\sin^{-1}(\alpha s)}{\sin^{-1}(\alpha)} \tag{5.1}$$

for a value of α slightly less than 1. Various methods for choosing α are considered both in their original paper and in various subsequent works by other authors [2, 7, 15, 18, 29, 37].

The Kosloff–Tal-Ezer map is quite different from those of sections 3 and 4 in original concept but rather similar in practice. These authors, and their successors, do not consider g as a conformal map, and they do not present theorems about geometric rates of convergence for analytic functions. Nevertheless the function (5.1) has the familiar effect of mapping E_ρ to a region with straighter sides, with the usual consequence that the nodes are distributed more evenly in the interior and clustered less near ± 1. To investigate a Kosloff–Tal-Ezer map in the framework established in this paper, we might begin by setting $\rho = 1.4$ and drawing a plot analogous to those of Figures 2.1, 3.1, and 4.1. The largest choice of α for which g will be analytic in E_ρ is $\alpha = 2/(\rho + \rho^{-1}) \approx 0.9459$. Figure 5.1 shows the result.[3]

The node spacings for the various transformations we have considered are shown (for $n = 24$) in Figure 5.2.

[3]In [29] Hesthaven, Dinesen, and Lynov consider a spectral method with $\alpha = \cos(1/2) \approx 0.88$, corresponding to $\rho \approx 1.69$. In most other spectral methods papers that make use of the Kosloff–Tal-Ezer mapping, α is chosen to increase toward 1 as n increases.

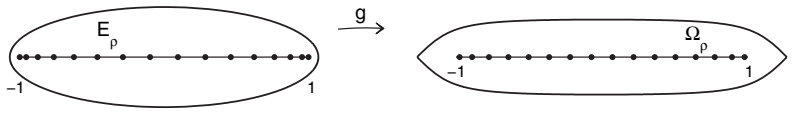

FIG. 5.1. *The Kosloff–Tal-Ezer map* (5.1) *for* $\rho = 1.4$ *and* $\alpha = 2/(\rho + \rho^{-1}) \approx 0.9459$. *For the given choice of* ρ, *this is the largest possible* α *for which* g *is analytic in* E_ρ.

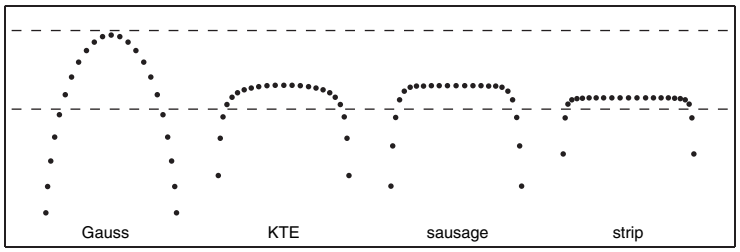

FIG. 5.2. *Comparison of node spacings with* $n = 24$ *for Gauss quadrature, the Kosloff–Tal-Ezer (KTE) map* (5.1) *with* $\rho = 1.4$ *and* $\alpha = 2/(\rho + \rho^{-1})$, *the polynomial* (4.3) *of degree* 9, *and the strip map* (3.2) *with* $\rho = 1.4$. *Dots appear at horizontal positions* $(x_j + x_{j+1})/2$ *and vertical positions* $(x_{j+1} - x_j)/2$. *The dashed lines correspond to equally spaced points and the same times* $\pi/2$.

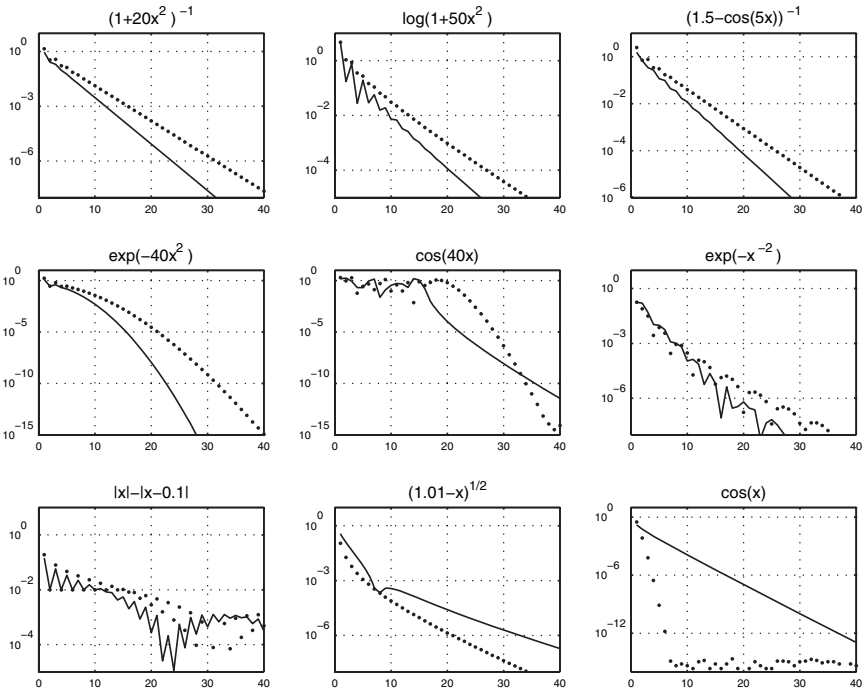

FIG. 5.3. *Another comparison of Gauss (dots) and transplanted Gauss (solid line) quadrature for the integrands of Figures* 3.4 *and* 4.2, *now for the Kosloff–Tal-Ezer map* (5.1) *with* $\rho = 1.4$ *and* $\alpha = 2/(\rho + \rho^{-1}) \approx 0.9459$.

If we apply the Kosloff–Tal-Ezer map to the same nine test integrands as before, we get the curves shown in Figure 5.3. These results are good. Nevertheless, the strip-transplanted formula of Figure 3.4 does better for the first four functions, and

the sausage-transplanted formula of Figure 4.2 does as well or better for the last five. There are parameters in all of these methods that might be tuned to enhance their performance, so one cannot draw fine judgments from these simple experiments. The proper lesson is that all of these methods are capable of outperforming Gauss quadrature by 20%–50% for many integrands. Let us now make this observation more precise.

6. Convergence theorems for analytic integrands. An advantage of the conformal mapping point of view is that it leads readily to convergence theorems for analytic integrands. The trick is to decide which analyticity assumptions and conformal maps g to consider, for the number of possibilities is unlimited. Rather than explore this terrain thoroughly, we shall offer a few representative choices. Our class of integrands will be as follows. For any $\varepsilon > 0$:

$$\mathcal{A}(\varepsilon) = \text{set of functions analytic in the open } \varepsilon\text{-neighborhood of } [-1,1]. \tag{6.1}$$

Now the ellipse with foci ± 1 whose semiminor axis length is ε has parameter $\rho = \varepsilon + \sqrt{1+\varepsilon^2} = 1 + \varepsilon + O(\varepsilon^2)$. Since $\rho > 1+\varepsilon$, any $f \in \mathcal{A}(\varepsilon)$ is bounded in the ellipse $E_{1+\varepsilon}$, and thus by Theorem 2.1, Gauss quadrature will achieve $I_n - I = O((1+\varepsilon)^{-2n})$ as $n \to \infty$ for any $f \in \mathcal{A}(\varepsilon)$. On the other hand, since $\rho \sim 1+\varepsilon$ as $\varepsilon \to 0$, it will do no better than this in general as $\varepsilon \to 0$. By contrast, the methods of the last three sections, with the parameters used there, converge at least 40%, 30%, and 30% faster, respectively.

THEOREM 6.1. *Let the transplanted Gauss quadrature formula* (2.6) *be applied to a function $f \in \mathcal{A}(\varepsilon)$. The following statements pertain to the limit $n \to \infty$:*

For the strip map (3.2) *with $\rho = 1.4$, for any $\varepsilon \le 0.24$: $\tilde{I}_n - I = O((1+1.4\varepsilon)^{-2n})$.*

For the polynomial (4.3) *with $d = 9$, for any $\varepsilon \le 0.8$: $\tilde{I}_n - I = O((1+1.3\varepsilon)^{-2n})$.*

For the KTE map (5.1) *with $\rho = 1.4$, for any $\varepsilon \le 0.3$: $\tilde{I}_n - I = O((1+1.3\varepsilon)^{-2n})$.*

Proof. Consider, for example, the first assertion, that the map (3.2) with $\rho = 1.4$ has convergence rate $O((1+1.4\varepsilon)^{-2n})$. By Theorem 2.1, this conclusion will be valid if for all $\varepsilon \le 0.24$ the function g is analytic in the elliptical region $E_{1+1.4\varepsilon}$ and maps the ellipse of parameter $1+1.4\varepsilon$ into the open ε-neighborhood of $[-1,1]$. We know that g is analytic throughout $E_{1.4}$, so the first condition holds since $1 + (1.4)(0.24) < 1.4$. The second condition can be verified numerically by plotting the image of the ellipse and the boundary of the ε-neighborhood for various ε and verifying that the first is inside the second; of course, we have chosen parameters in the theorem to make this true. ∎

The speedups of Theorem 6.1 are not particularly close to the limiting value of $\pi/2$ that can be achieved as $\varepsilon \to 0$. We now give another result that comes closer to this limit. This time we modify the Gauss quadrature estimate $O((1+\varepsilon)^{-2n})$ by improving the exponent rather than the factor multiplying ε.

THEOREM 6.2. *Let the transplanted Gauss quadrature formula* (2.6) *be applied to a function $f \in \mathcal{A}(\varepsilon)$ for any $\varepsilon \le 0.05$. For the strip map* (3.2) *with $\rho = 1.1$, $\tilde{I}_n - I = O((1+\varepsilon)^{-3n})$ as $n \to \infty$.*

The proof is as before, combining Theorem 2.1 with a numerical verification for the particular map g. Similarly, it can be shown that one gets $\tilde{I}_n - I = O((1+\varepsilon)^{-2.7n})$ for $\varepsilon \le 0.1$ for the strip map (3.2) with $\rho = 1.4$, the higher-degree analogue of the polynomial (4.3) with $d = 17$, or the KTE map (5.1) with $\rho = 1.2$, and $\tilde{I}_n - I = O((1+\varepsilon)^{-2.5n})$ for $\varepsilon \le 0.3$ for the strip map (3.2) with $\rho = 1.5$, the polynomial (4.3) with $d = 9$, or the KTE map (5.1) with $\rho = 1.4$.

7. Clenshaw–Curtis variant. Among polynomial quadrature methods, Gauss quadrature is optimal from the point of view of degree of polynomials integrated exactly, namely, $2n-1$ for the formula (2.2). It also has an elegant convergence theory for analytic integrands, as represented by Theorem 2.1 and the further theorems we have derived from it. Thus it is natural that, in the experiments of this paper until now, we have considered Gauss quadrature and its transplanted alternatives.

Gauss quadrature has the disadvantage, however, that it takes $O(n^2)$ work and memory to compute Gauss nodes and weights by the standard algorithm of Golub and Welsch [27]. In some applications this is not an issue, because either n is small or the nodes and weights are precomputed. In others, it is troublesome indeed. Certainly one would rarely use a Gauss quadrature formula with thousands of points.

An easy alternative is Clenshaw–Curtis quadrature, which is readily implemented via the fast Fourier transform in $O(n \log n)$ operations [14, 26]; now there is no problem if n is 10^4 or 10^5 [6, 50]. All of the conformal transplantation ideas discussed in this article can be applied to Clenshaw–Curtis as well as Gauss formulas, with comparable effect: a speedup for many integrands by a factor approaching $\pi/2$. A Clenshaw–Curtis code segment for $(n+1)$-point integration of f over $[-1,1]$ can be written like this [50]:

```
s = cos((0:n)'*pi/n);
[g,gprime] = strip(s);
fx = f(g).*gprime/(2*n);
h = real(fft(fx([1:n+1 n:-1:2])));
a = [h(1); h(2:n)+h(2*n:-1:n+2); h(n+1)];
w = 0*a'; w(1:2:end) = 2./(1-(0:2:n).^2);
In = w*a;
```

One's first expectation is that Clenshaw–Curtis convergence rates should generally be about half those of Gauss, for both the pure and the transplanted variants. For example, the n-point Clenshaw–Curtis formula exactly integrates polynomials only up to degree n, not $2n-1$, and similarly, a result like Theorem 2.1 holds with $O(\rho^{-2n})$ reduced to $O(\rho^{-n})$. Thus one might expect that a transplanted Clenshaw–Curtis formula should converge about $2 \times 2/\pi = 4/\pi$ times more slowly than untransplanted Gauss quadrature.

In actuality, however, Clenshaw–Curtis formulas are often about as accurate as Gauss, for the values of n of interest, despite what the standard theorems might lead one to expect. This effect was observed by O'Hara and Smith in the 1960s [39] and has recently been investigated further [21, 50, 52]. We find the same happy surprise with transplanted Clenshaw–Curtis quadrature. We shall make no attempt to add more to the theoretical discussion of this effect but just present two computational illustrations. The first is Figure 7.1, another repetition of Figure 3.4 but now comparing pure Gauss quadrature against strip-transplanted Clenshaw–Curtis, again for $\rho = 1.4$. The latter does very well—about as well as transplanted Gauss. Indeed it is only for the function $\exp(-40x^2)$ where we have lost much in moving from transplanted Gauss to transplanted Clenshaw–Curtis: the convergence rate starts out as before but then cuts abruptly in half at an error level of about 10^{-5}. This kink in the Clenshaw–Curtis convergence curve for analytic functions is explained in [21, 50, 52].

Our second example is a complicated function $f(x)$ on $[-1,1]$ considered in [51], defined by the initial conditions $f = \beta = \sin(10x)$ followed by 15 steps of the iteration $\beta = 3(1-2\beta^4)/4$, $f = f+\beta$. (In [51] the initial condition is $\sin(\pi x)$, but we change this to $\sin(10x)$ to break the periodicity.) Figure 7.2 illustrates f and the convergence of

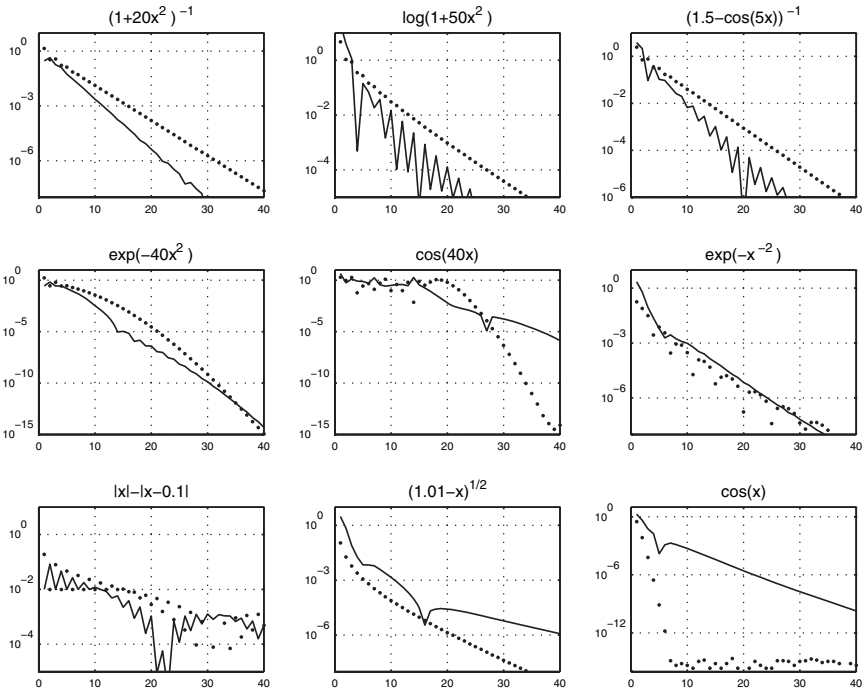

FIG. 7.1. *Another repetition of Figure* 3.4 *but with the solid curve corresponding now to strip-transplanted Clenshaw–Curtis rather than Gauss quadrature. The results are much the same as in Figure* 3.4*, the main exception being* $\exp(-40x^2)$*, where we now see a convergence rate that cuts in half at around* $n = 14$*. Evidently transplanted Clenshaw–Curtis quadrature, quite apart from its much greater speed of implementation, is often more accurate than Gauss quadrature as well.*

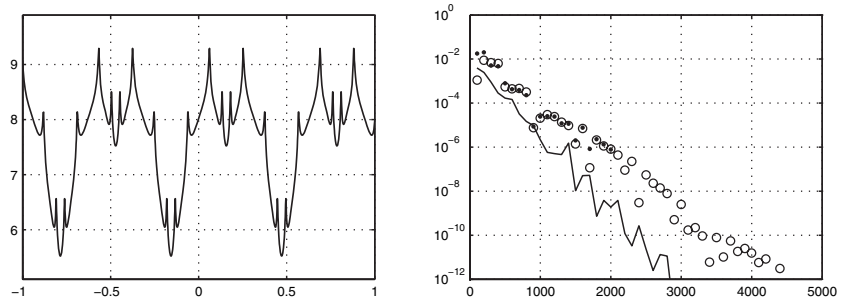

FIG. 7.2. *On the left, the function* $f(x)$ *adapted from* [51]*. On the right, convergence of Gauss (dots), Clenshaw–Curtis (circles), and strip-transplanted Clenshaw–Curtis formulas (solid line) with* $\rho = 1.1$ *for this function. Data are plotted corresponding to values of* n *equal to multiples of* 100 *(up to* $n = 2000$ *for Gauss quadrature). There is no significant difference between the Gauss and Clenshaw–Curtis formulas, and the transplanted formula beats them both by about* 50%*, as one would expect for Gauss quadrature from Theorem* 6.2*.*

quadrature formulas to $I \approx 15.3198135546173$. Strip-transplanted Clenshaw–Curtis quadrature with $\rho = 1.1$ beats untransplanted Clenshaw–Curtis, which is more or less the same as Gauss. This function f is entire, but it is very ill behaved outside a small region surrounding $[-1, 1]$, as illustrated in Figure 7.3. For example, the maximum value of $|f(z)|$ for $\operatorname{Im} z = 0.004$ is about 9.5, for $\operatorname{Im} z = 0.006$ it is about 3236, for $\operatorname{Im} z = 0.008$ it is about 10^{41}, and for $\operatorname{Im} z = 0.01$ it is about 10^{263}.

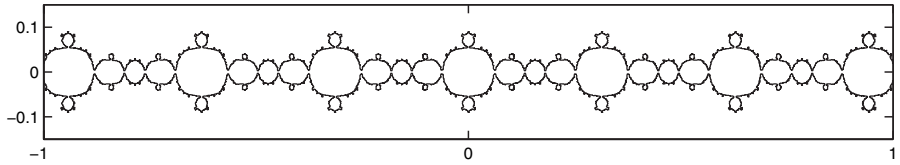

FIG. 7.3. *Although entire, the function f of Figure* 7.2 *is ill-behaved away from a strip of width about* 0.003 *surrounding* $[-1,1]$. *This plot shows the region around* $[-1,1]$ *in which* $|f(x)| < 1000$. *The boundary has a fractal structure* 15 *levels deep.*

8. Discussion. The idea of transforming the integrand in a numerical quadrature rule is an old one. What is new in this paper has been to choose transformations based on explicit conformal maps and to thereby derive specific quadrature formulas that often converge faster than Gauss quadrature. Numerical experiments justifying this claim were presented in sections 3–5 and 7 and theorems in sections 3 and 6. The theorems apply to analytic integrands f, but experiments show that the modified formulas often outperform Gauss quadrature for nonanalytic integrands, too.

All of the methods we have discussed contain adjustable parameters, notably ρ for (3.2), the degree d for the maps of section 4, and α for (5.1). Rather than try to optimize these values, we have taken somewhat arbitrary fixed choices such as $\rho = 1.4$ or 1.1 and $d = 9$ or 17, which are enough to deliver fairly robust quadrature improvements by 30%–50%. These figures could be increased closer to the 57% associated with the ratio $\pi/2$ by decreasing ρ and increasing d and α, perhaps in a fashion dependent on the number of grid points n, and, in some applications, such adjustments may be worthwhile. There is a literature on how to choose α for the application of the Kosloff–Tal-Ezer map (5.1) to spectral methods [2, 15, 18, 29, 37]. Preliminary experiments show that the speedups we have described for quadrature appear equally for spectral methods, and we hope to give details in a later publication. For spectral methods there is the additional consideration that the diminished clustering near ± 1 permits larger time steps or faster iterative matrix solves, making the choice of effective parameters a more complicated matter.

To compute a single integral, or a small number of integrals, one would normally use an adaptive quadrature program, and we do not recommend Gauss or Clenshaw–Curtis formulas, or their transplanted improvements, for such applications. Indeed, even for the complicated integrand of Figure 7.2, transplanted Clenshaw–Curtis quadrature is less than ten times faster than MATLAB's general-purpose adaptive codes `quad` and `quadl`. Rather, the potential practical relevance of the methods investigated in this paper is to situations where large numbers of integrals are embedded inside a bigger computation. We close with an artificial example of a multidimensional integral. Suppose we compute

$$\int_{-1}^{1}\int_{-1}^{1}\int_{-1}^{1}\int_{-1}^{1} \cos(100(w+x+y+z))\,dw\,dx\,dy\,dz = \left(\frac{\sin(100)}{50}\right)^4 \approx 1.05\times 10^{-8}$$

numerically by a quadrature formula applied in four dimensions, exploiting none of the symmetries or simple structure of this particular integrand. To get three digits of relative accuracy, Gauss quadrature requires $63^4 = 15{,}752{,}961$ points, whereas strip-transplanted Gauss quadrature with $\rho = 1.4$ needs $52^4 = 7{,}311{,}616$ points.

Appendix. Computation of the strip transformation in extreme cases and a MATLAB code. Figure 3.2 shows how the conformal map g of (3.2) from the ρ-ellipse E_ρ to the infinite strip Ω_ρ can be constructed in three steps: ellipse$\to$periodic strip$\to$disk$\to$infinite strip, with the middle step involving a Jacobi elliptic function. All of this is mathematically straightforward, but, when ρ is smaller than about 1.1, it is numerically troublesome. The problem is that the right end of the periodic strip gets mapped in the disk domain to the interval $[1, m^{-1/4}]$, and this interval shrinks exponentially as ρ decreases to 1 (similarly at the left end). For example, $\rho = 1.4, 1.2, 1.1$ correspond to $m^{-1/4} \approx 1.0026, 1.0000053, 1.000000000023$, and for $\rho = 1.05$ one calculates $m^{-1/4} = 1$ on a computer to machine precision. This "crowding phenomenon" is a familiar challenge in numerical conformal mapping, making it impossible to compute g accurately unless the computation is reformulated [20].

It would be possible to consider systematically the development of an algorithm to evaluate g to as close to machine precision as possible. Rather than attempt this, we propose a method that works very well for our quadrature application and is much simpler. When ρ is small, the two ends of the rectangle$\to$strip map of Figure 3.2 are exponentially decoupled from one another. In fact, for ρ less than about 1.2, the map near one end of the rectangle is indistinguishable in 16-digit arithmetic from what it would be if the rectangle were a semi-infinite strip. By following this line of reasoning, after quite of bit of algebra, one is led to consider the function g defined by $u = \sin^{-1} s$, $\tau = \pi/\log\rho$, and

$$g(s) = C\left[\log(1+e^{-\tau(\pi/2+u)}) - \log(1+e^{-\tau(\pi/2-u)}) + \left(\frac{1}{2} + \frac{1}{e^{\tau\pi}+1}\right)\tau u\right], \tag{A.1}$$

where the constant C is fixed so that $g(\pm 1) = \pm 1$. To 16-digit precision, for $\rho < 1.2$, this function is the same as the strip map (3.2); and it is numerically reliable down to about $\rho = 1.02$, which is closer to 1 than one would ever need to go in practice. For $s \in (-1, 1)$ the derivative is

$$g'(s) = \frac{-\tau C}{\sqrt{1-s^2}}\left[\frac{1}{e^{\tau(\pi/2+u)}+1} + \frac{1}{e^{\tau(\pi/2-u)}+1} - \left(\frac{1}{2} + \frac{1}{e^{\tau\pi}+1}\right)\right], \tag{A.2}$$

and at the end points we have

$$g'(\pm 1) = \frac{C\tau^2}{4}\tanh^2\left(\frac{\tau\pi}{2}\right). \tag{A.3}$$

Notice how much more elementary (A.1)–(A.2) are than (3.1)–(3.4). In principle g is not analytic in the ellipse, having branch points at $s = \pm 1$. The singularities are so weak, however, that for $\rho < 1.2$ they are undetectable in 16-digit arithmetic.

Although the map (A.1) was derived as an approximation to the ideal (3.2) for small values of ρ, it is surprisingly effective even for larger values of ρ. If (3.2) is replaced by (A.1) in the experiments of Figure 3.4, for example, it makes no difference.

The following terse code combines all of the elements we have discussed, implementing the Clenshaw–Curtis quadrature formula for the modified strip transformation (A.1). Since such a code will be especially useful for large n, the listing gives a value of ρ close to 1. If this code is applied to the function of Figure 7.2 with $n = 1800$, it gets the right answer to 15 digits in about 0.01 seconds on a 2006 workstation. (With $n = 10^6$ it gets the same answer in 5 seconds.) Untransformed Gauss quadrature with $n = 1800$ achieves 11 digits of accuracy and takes far longer.

COUPLING DISCONTINUOUS GALERKIN AND MIXED FINITE ELEMENT DISCRETIZATIONS USING MORTAR FINITE ELEMENTS*

VIVETTE GIRAULT†, SHUYU SUN‡, MARY F. WHEELER§, AND IVAN YOTOV¶

Abstract. Discontinuous Galerkin (DG) and mixed finite element (MFE) methods are two popular methods that possess local mass conservation. In this paper we investigate DG-DG and DG-MFE domain decomposition couplings using mortar finite elements to impose weak continuity of fluxes and pressures on the interface. The subdomain grids need not match, and the mortar grid may be much coarser, giving a two-scale method. Convergence results in terms of the fine subdomain scale h and the coarse mortar scale H are established for both types of couplings. In addition, a nonoverlapping parallel domain decomposition algorithm is developed, which reduces the coupled system to an interface mortar problem. The properties of the interface operator are analyzed.

Key words. discontinuous Galerkin, mixed finite element, flow in porous media, mortar finite element, interface problem

1. Introduction.

In modeling of flow and reactive transport in porous media, it is important to employ algorithms that preserve mathematical properties of physical systems, such as local mass conservation and continuity of fluxes. In addition, geological media such as aquifers and petroleum reservoirs exhibit a high level of spatial variability at a multiplicity of scales, from the size of individual grains or pores to facies, stratigraphic, and hydrologic units, up to sizes of formations. Two methods that are well-suited to subsurface modeling are the mixed finite element (MFE) and discontinuous Galerkin (DG) methods. Common features of these methods are local conservation of mass and accurate treatment of rough coefficients and grids.

MFE and related methods have been very popular in the porous media modeling community. They provide accurate approximation for both the pressure and the velocity. A number of approaches have been developed to eliminate the velocity and reduce the MFE method to a cell-centered or face-centered algebraic pressure system with a substantially smaller dimension; see, e.g., [40, 8, 6]. For single phase flow, the reduced system in most cases is symmetric and positive definite, allowing for the use

of efficient solvers. These reduction techniques, however, apply in most cases to low order MFE methods on relatively structured grids and may lead to deterioration in the accuracy on highly irregular or unstructured grids.

DG methods are finite element methods that use discontinuous approximations. Examples of these schemes include the Bassi–Rebay method [9], the local discontinuous Galerkin (LDG) [3, 21] methods, the Oden–Babuška–Baumann (OBB-DG) [32] method, and interior penalty Galerkin methods [23, 38, 45]. DG methods are of particular interest for multiscale problems because they (1) support local approximations of high order and are capable of delivering exponential rates of convergence, (2) are robust and nonoscillatory in the presence of high gradients, and (3) are implementable on unstructured and even nonmatching grids and can thus treat highly heterogeneous porous media. On the negative side, because of the number of unknowns, DG solvers can be expensive.

Nonoverlapping domain decomposition is a useful approach for spatial coupling and/or decoupling. A subsurface flow example is the multiblock mortar MFE methodology described in [4, 34, 35, 44]. The governing equations hold locally on the subdomains, and physically driven matching conditions are imposed on block interfaces in a numerically stable and accurate way by using mortar finite element spaces. References on the mortar approach for other discretizations include [12, 11, 46, 10] for conforming Galerkin and [24] for finite volume elements. Domain decomposition solvers and preconditioners for mortar discretizations have been developed in [28, 2, 1, 27, 33].

Some computational advantages of the multiblock approach are as follows: (1) *Multiphysics:* different physical processes/mathematical models in different parts of the domain may be coupled in a single simulation; (2) *multinumerics:* different numerical techniques may be employed on different subdomains; (3) *multiscale resolution and adaptivity:* highly refined regions or fine-scale models may be coupled with more coarsely discretized regions, and dynamic grid adaptivity may be performed locally on each block; (4) *multidomains:* highly irregular domains may be described as unions of more regular and locally discretized subdomains with the possibility of having interfaces with nonmatching grids; and (5) *parallelism:* the approach leads to domain decomposition algorithms with near-optimal computational load balance and minimal communication overhead.

Couplings of DG and MFE methods have been previously studied in the literature. In [37], a DG-MFE coupling is introduced, which uses two Lagrange multipliers to impose continuity of fluxes and pressures. A method for coupling LDG and MFE is developed in [20] by choosing appropriate numerical fluxes on interface edges.

In [5], a multiscale mortar mixed finite element method was introduced for modeling Darcy flow. There, the continuity of the flux is imposed via mortar finite elements on a coarse grid scale, while the equations in the coarse elements (or subdomains) are discretized on a fine grid scale.

In this paper we develop mortar couplings of DG with DG or MFE methods, using possibly different scales in the mortar and subdomain grids. Such couplings allow for (1) the flexibility of applying DG to subdomains where general grids are required for treating pinchouts, discrete faults and fractures, and highly variable full permeability tensors; (2) developing a mortar domain decomposition parallel DG solver via reduction to an interface problem and employing conjugate gradient or GMRES for its solution; efficient interface preconditioners such as balancing could be developed [30, 22, 33]; (3) applying the MFE method, which has substantially fewer unknowns than DG, in regions with relatively smooth or structured grids; and (4) achieving model reduction through multiscale approximations.

We study mortar couplings of type DG-DG and DG-MFE, based on four different DG formulations, the OBB-DG [32], the nonsymmetric interior penalty Galerkin (NIPG) [39], the symmetric interior penalty Galerkin (SIPG) [7, 45, 43, 42], and the incomplete interior penalty Galerkin (IIPG) [43, 23, 42]. The mortar variable has a meaning of pressure, and it is used as a Lagrange multiplier to impose weak continuity of normal velocities and subdomain pressures on the interface. This is achieved via a Robin-type matching condition, which involves a flux jump term and a penalized pressure jump term. Our approach differs from the one in [37], where two Lagrange multipliers are used and the method cannot be reduced to an interface problem.

The paper is organized as follows. In the next section we introduce the model problem and set up some notation. In section 3 we develop and analyze DG-DG mortar couplings. In particular, we establish equivalence between the DG weak formulation and the partial differential equation, existence and uniqueness for the discrete solution, and convergence estimates. The error estimates are derived in terms of h and H, the discretization parameters for the subdomain and mortar spaces, respectively. We also develop a parallel nonoverlapping domain decomposition algorithm for the solution of the algebraic system based on a reduction of the algebraic system to an interface mortar problem. Similar results are obtained in section 4 for DG-MFE mortar couplings. We end with some conclusions in section 5.

2. Problem statement and notation.

2.1. Model equations. Let the domain be $\Omega = \Omega_1 \cup \Omega_2 \cup \Gamma_{12} \subset \mathbb{R}^d$, $d = 1$, 2, or 3. Although for simplicity we present only the method for two subdomains, our results easily extend to geometrically nonconforming domain decompositions with a finite number of subdomains. Similarly, our results can be generalized to more general boundary conditions than (2.2) below, such as Dirichlet or mixed Dirichlet–Neumann boundary conditions. We consider the following equation, which can be used to model a single-phase flow process in porous media:

$$-\nabla \cdot \mathbf{K}\nabla p = f \quad \text{in } \Omega, \tag{2.1}$$

$$-\mathbf{K}\nabla p \cdot \mathbf{n} = g \quad \text{on } \partial\Omega. \tag{2.2}$$

The above system can also be written in a mixed form:

$$\begin{aligned} \mathbf{u} &= -\mathbf{K}\nabla p \quad \text{in}\, \Omega, \\ \nabla \cdot \mathbf{u} &= f \quad \text{in}\, \Omega, \\ \mathbf{u} \cdot \mathbf{n} &= g \quad \text{on}\, \partial\Omega. \end{aligned}$$

Here $\mathbf{n}$ denotes the unit outward normal vector to $\partial\Omega$. We assume that the data f belong to $L^2(\Omega)$ and g belong to $L^2(\partial\Omega)$ and they both satisfy the compatibility condition

$$\int_\Omega f dx = \int_{\partial\Omega} g d\sigma. \tag{2.3}$$

With (2.3), system (2.1)–(2.2) defines p uniquely up to an additive constant. The conductivity $\mathbf{K}$ is assumed to be uniformly symmetric positive definite and bounded from above. In Ω_1, we use a DG formulation; in Ω_2, we use either a DG or a mixed formulation, with the matching on the interface being achieved by a multiplier.

Throughout the paper we will use the following standard notation. For $D \subset \mathbb{R}^d$, we denote the norm in the Hilbert space $H^s(D)$ by $\|\cdot\|_{s,D}$. Consequently, $\|\cdot\|_{0,D}$ will

denote the norm in $L^2(D)$. We may omit the subscript D if $D = \Omega$. We denote by C a generic positive constant, independent of h and H, that may not have the same value at different occurrences. In addition, we denote by ϵ a fixed positive constant that may be chosen arbitrarily small.

Let $\mathcal{E}_h(\Omega_i)$ be a nondegenerate partition of Ω_i, $i = 1, 2$, composed of line segments if $d = 1$, triangles or quadrilaterals if $d = 2$, or tetrahedra, prisms, or hexahedra if $d = 3$. If MFE discretization is used in Ω_2, we consider only affine elements there. The partitions do not need to match on the interface Γ_{12}. If SIPG, NIPG, or IIPG is used in Ω_i, we allow $\mathcal{E}_h(\Omega_i)$ to be nonconforming by refining the mesh in some of the elements. Let $\mathcal{E}_h(\Omega) = \mathcal{E}_h(\Omega_1) \cup \mathcal{E}_h(\Omega_2)$.

Here h is the maximum element diameter for the mesh. The nondegeneracy requirement (also called regularity) is that the element is convex and that there exists $\rho > 0$ such that, if h_j is the diameter of $E_j \in \mathcal{E}_h(\Omega)$, each of the subtriangles (for $d = 2$) or subtetrahedra (for $d = 3$) of element E_j contains a ball of radius ρh_j in its interior. If E_j is a triangle (or a tetrahedron), then its subtriangles (or subtetrahedra) coincide with E_j. The set of all interior points ($d = 1$), edges ($d = 2$), or faces ($d = 3$) within $\mathcal{E}_h(\Omega_i)$ is denoted by $\Gamma_h(\Omega_i)$. Let $\Gamma_h(\Omega) = \Gamma_h(\Omega_1) \cup \Gamma_h(\Omega_2)$. On each element face $\gamma \in \Gamma_h(\Omega)$, a unit normal vector $\mathbf{n}$ is chosen once and for all. This could be done by numbering the elements of $\mathcal{E}_h(\Omega_i)$ and directing $\mathbf{n}$ from E_k to E_l if E_k and E_l are adjacent and $k < l$. On $\partial\Omega$, the normal vector $\mathbf{n}$ coincides with the outward unit normal vector $\mathbf{n}_{\partial\Omega}$. On Γ_{12}, the unit normal vector $\mathbf{n}$ is chosen as $\mathbf{n} = \mathbf{n}_{\partial\Omega_1} = -\mathbf{n}_{\partial\Omega_2}$. On Γ_{12}, we introduce a mortar finite element partition Γ_H, where H is the maximum diameter of mortar elements. We allow for Γ_H to be different from the traces of the subdomain grids on Γ_{12}.

Let E_i and E_j be two adjacent elements in $\mathcal{E}_h(\Omega)$, with $i < j$, and let $\gamma = \partial E_i \cap \partial E_j \in \Gamma_h(\Omega)$; then $\mathbf{n}$ is exterior to E_i. We denote the average and jump on γ for an elementwise smooth function ϕ by, respectively,

$$\{\phi\} := \frac{1}{2}((\phi|_{E_i})|_\gamma + (\phi|_{E_j})|_\gamma), \qquad [\phi] := (\phi|_{E_i})|_\gamma - (\phi|_{E_j})|_\gamma .$$

The following functional spaces will be used in weak formulations of our problem:

$$X(\Omega_i) := \left\{q \in L^2(\Omega_i) : \forall E \in \mathcal{E}_h(\Omega_i),\, q|_E \in H^s(E)\right\}, \quad s > \frac{3}{2}, \quad i = 1 \text{ and } 2,$$
$$\mathbf{V}_0(\Omega_2) := \{\mathbf{v} \in H(\mathrm{div}; \Omega_2) : \mathbf{v} \cdot \mathbf{n} = 0 \text{ on } \partial\Omega_2 \setminus \Gamma_{12}\},$$
$$W(\Omega_2) := L^2(\Omega_2), \quad \Lambda := H^{\frac{1}{2}}(\Gamma_{12}).$$

Here $\mathbf{v}\cdot\mathbf{n}$ is defined in a weak sense, i.e., in the dual of $H_{00}^{\frac{1}{2}}(\partial\Omega_2\setminus\Gamma_{12})$, where $H_{00}^{\frac{1}{2}}(D)$ is the interpolation space between $L^2(D)$ and $H_0^1(D)$ [29]. The space $X(\Omega_i)$ is equipped with the norm

$$\|\!|\!| \cdot |\!|\!|_{s,\Omega_i} = \left(\sum_{E\in\mathcal{E}_h(\Omega_i)} \|\cdot\|_{s,E}^2\right)^{\frac{1}{2}}. \tag{2.4}$$

For the DG discretization we will use the finite element spaces

$$X_h(\Omega_i) := \left\{q_h \in L^2(\Omega_i) : \forall E \in \mathcal{E}_h(\Omega_i),\, q_h|_E \in \mathbb{P}_r(E)\right\}, \quad i = 1, 2, \quad r \geq 1.$$

For the MFE discretization in Ω_2 we will use any of the usual mixed spaces, including the Raviart–Thomas–Nedelec (RTN) spaces [36, 31], Brezzi–Douglas–Marini (BDM) spaces [16], Brezzi–Douglas–Fortin–Marini (BDFM) spaces [15], Brezzi–Douglas–

Duràn–Fortin (BDDF) spaces [14], or Chen–Douglas (CD) spaces [18]. We denote these spaces by $\mathbf{V}_h(\Omega_2) \times W_h(\Omega_2)$, where $\mathbf{V}_h(\Omega_2) \times W_h(\Omega_2) \subset H(\mathrm{div};\Omega_2) \times L^2(\Omega_2)$. To enforce the boundary condition on $\partial\Omega_2 \setminus \Gamma_{12}$, we set

$$\mathbf{V}_{h,0}(\Omega_2) = \mathbf{V}_h(\Omega_2) \cap \mathbf{V}_0(\Omega_2).$$

On an element E, the restriction of $\mathbf{V}_h(\Omega_2)$ is denoted by $\mathbf{V}_h(E)$. We assume that the velocity space $\mathbf{V}_h(E)$ contains $(\mathbb{P}_m(E))^d$, $m \geq 0$, with normal components on each edge (face) in $\mathbb{P}_m(\gamma)$ and that the pressure space $W_h(E)$ contains $\mathbb{P}_l(E)$. In all cases $l = m$ or $l = m-1$, when $m \geq 1$.

On the interface we will use a mortar finite element space to approximate the pressure and impose weakly the continuity of flux and pressure:

$$\Lambda_H := \left\{ \mu_H \in L^2(\Gamma_{12}) : \forall \tau \in \Gamma_H,\, \mu_H|_\tau \in \mathbb{P}_{\bar{r}}(\tau) \right\}, \quad \bar{r} \geq 1.$$

In the above, r, m, and $\bar{r}$ are possibly different constants. We note that all results in this paper hold if Λ_H is replaced by its continuous version

$$\Lambda_H^c := \left\{ \mu_H \in C^0(\Gamma_{12}) : \forall \tau \in \Gamma_H,\, \mu_H|_\tau \in \mathbb{P}_{\bar{r}}(\tau) \right\}, \quad \bar{r} \geq 1.$$

3. Coupling DG with DG using a mortar space. From now on, we assume that the tensor $\mathbf{K}$ is sufficiently smooth in each element, so that the trace $\mathbf{K}\nabla p \cdot \mathbf{n}$ is well-defined on element faces. In this section we consider coupled schemes involving DG discretizations in both Ω_1 and Ω_2 and matching conditions on the interface imposed through a mortar finite element space.

3.1. Weak formulation. We define bilinear forms and linear functionals for the DG scheme in Ω_i, $i = 1, 2$:

(3.1)
$$\begin{aligned} B_i(p,q) := & \sum_{E \in \mathcal{E}_h(\Omega_i)} \int_E \mathbf{K}\nabla p \cdot \nabla q \, dx - \sum_{\gamma \in \Gamma_h(\Omega_i)} \int_\gamma \{\mathbf{K}\nabla p \cdot \mathbf{n}\} [q] \, d\sigma \\ & - s_{\mathrm{form}} \sum_{\gamma \in \Gamma_h(\Omega_i)} \int_\gamma \{\mathbf{K}\nabla q \cdot \mathbf{n}\} [p] \, d\sigma - \int_{\Gamma_{12}} \mathbf{K}\nabla p \cdot \mathbf{n}_{\partial\Omega_i} q|_{\Omega_i} \, d\sigma \\ & - \bar{s}_{\mathrm{form}} \int_{\Gamma_{12}} \mathbf{K}\nabla q \cdot \mathbf{n}_{\partial\Omega_i} p|_{\Omega_i} \, d\sigma + \sum_{\gamma \in \Gamma_h(\Omega_i)} \frac{\sigma_\gamma}{h_\gamma} \int_\gamma [p] [q] \, d\sigma + \sum_{\tau \in \Gamma_H} \frac{\sigma_\tau}{H_\tau} \int_\tau p|_{\Omega_i} q|_{\Omega_i} d\sigma, \end{aligned}$$

(3.2)
$$L_i(q;\lambda) := \int_{\Omega_i} f\, q \, dx - \int_{\partial\Omega_i \setminus \Gamma_{12}} g\, q \, d\sigma - \bar{s}_{\mathrm{form}} \int_{\Gamma_{12}} \mathbf{K}\nabla q \cdot \mathbf{n}_{\partial\Omega_i} \lambda \, d\sigma + \sum_{\tau \in \Gamma_H} \frac{\sigma_\tau}{H_\tau} \int_\tau q|_{\Omega_i} \, \lambda \, d\sigma.$$

Here $s_{\mathrm{form}} = -1$ for NIPG or OBB-DG, $s_{\mathrm{form}} = 1$ for SIPG, and $s_{\mathrm{form}} = 0$ for IIPG. The penalty parameter is a discrete positive function that takes the constant value σ_γ on an interior element face γ and σ_τ on a mortar element τ. We let $\sigma_\gamma \equiv 0$ for OBB-DG and assume that $0 < \sigma_\gamma^0 \leq \sigma_\gamma \leq \sigma_\gamma^1$ for SIPG, NIPG, and IIPG. For all methods we assume that $0 < \sigma_\tau^0 \leq \sigma_\tau \leq \sigma_\tau^1$. We will also show solvability for all schemes if $\sigma_\tau \equiv 0$, assuming that condition (A.1) holds for either $X_h(\Omega_1)$ or $X_h(\Omega_2)$, but will provide no convergence analysis in this case.

We take $\bar{s}_{\mathrm{form}} = -1$ for all methods. This leads to an easy control of the terms involving integrals on Γ_{12}. The choices 0 or 1 for $\bar{s}_{\mathrm{form}}$ are also possible. However,

in these cases, the weights in the last terms of $B_i(\cdot,\cdot)$ and $L_i(\cdot;\cdot)$ must be modified. More details are given in Remarks 3.1 and 3.3.

The weak formulation is: Find $p \in L^2(\Omega)$ with $p|_{\Omega_i} \in X(\Omega_i)$ for $i = 1, 2$, and $\lambda \in \Lambda$ such that

$$B_i(p,q) = L_i(q;\lambda) \quad \forall\, q \in X(\Omega_i), \quad i = 1,\, 2, \tag{3.3}$$

$$-\int_{\Gamma_{12}} [\mathbf{K}\nabla p \cdot \mathbf{n}]\, \mu d\sigma + \sum_{\tau\in\Gamma_H} \frac{\sigma_\tau}{H_\tau} \int_\tau \sum_{i=1,2} (p|_{\Omega_i} - \lambda)\mu d\sigma = 0 \quad \forall \mu \in \Lambda. \tag{3.4}$$

3.2. Equivalence. We next show that any solution of the mortar DG weak formulation satisfies the original problem. It is easy to check that the converse is true, provided the solution of the original problem is sufficiently smooth.

THEOREM 3.1. *If (p,λ) is a solution of* (3.3)–(3.4)*, then p satisfies* (2.1)–(2.2) *in the sense of distributions.*

Proof. We first consider the domain Ω_1. For any fixed $E \in \mathcal{E}_h(\Omega_1)$, by taking $q \in C_0^\infty(E)$ in (3.3), we easily see that (2.1) holds within E. We next consider two adjacent elements $E_1 \subset \Omega_1$ and $E_2 \subset \Omega_1$ with an interface γ. By letting $q \in H_0^2(E_1 \cup \gamma \cup E_2)$ in (3.3), we have

$$\begin{aligned}
&\int_{E_1} \mathbf{K}\nabla p \cdot \nabla q dx + \int_{E_2} \mathbf{K}\nabla p \cdot \nabla q dx - s_{\text{form}} \int_\gamma \{\mathbf{K}\nabla q \cdot \mathbf{n}\}\, [p]\, d\sigma \\
&= \int_{E_1\cup E_2} f q dx = -\int_{E_1} \nabla\cdot(\mathbf{K}\nabla p) q dx - \int_{E_2} \nabla\cdot(\mathbf{K}\nabla p) q dx \\
&= \sum_{i=1,2} \left(\int_{E_i} \mathbf{K}\nabla p \cdot \nabla q dx - \int_{\partial E_i} \mathbf{K}\nabla p \cdot \mathbf{n}_{\partial E_i} q d\sigma \right),
\end{aligned}$$

where we have used the fact that $-\nabla\cdot(\mathbf{K}\nabla p) = f$ in E for all $E \in \mathcal{E}_h(\Omega_1)$. Therefore

$$s_{\text{form}} \int_\gamma \{\mathbf{K}\nabla q \cdot \mathbf{n}\}\, [p]\, d\sigma = \int_\gamma [\mathbf{K}\nabla p \cdot \mathbf{n}]\, q d\sigma. \tag{3.5}$$

For OBB-DG, NIPG, and SIPG, we have $s_{\text{form}} \neq 0$, and we can choose $q \in H_0^2(E_1 \cup \gamma \cup E_2)$ such that q is zero on γ and $\{\mathbf{K}\nabla q \cdot \mathbf{n}\}$ is arbitrary in $H_{00}^{\frac{1}{2}}(\gamma)$. Then (3.5) implies that $[p] = 0$ on γ. When running over all interior faces of Ω_1, this means that p belongs to $H^1(\Omega_1)$. In turn, we can choose $q \in H_0^2(E_1 \cup \gamma \cup E_2)$ such that $q|_\gamma$ is arbitrary in $H_0^{\frac{3}{2}}(\gamma)$; then (3.5) implies that the jump $[\mathbf{K}\nabla p \cdot \mathbf{n}] = 0$ on γ. Thus $\mathbf{K}\nabla p$ belongs to $H(\text{div};\Omega_1)$, and, therefore, the interior equation $-\nabla\cdot\mathbf{K}\nabla p = f$ holds globally in Ω_1. The same conclusion holds in Ω_2.

If $s_{\text{form}} = 0$ (i.e., if we use IIPG), then (3.5) directly implies that $[\mathbf{K}\nabla p \cdot \mathbf{n}] = 0$ on γ. Next, by choosing for $i = 1, 2$, q in (3.3) such that $q|_{E_i} \in H^2(E_i)$ with q and $\nabla q \cdot \mathbf{n}$ both zero on $\partial(E_i) \setminus \gamma$, q arbitrary on $H_0^{\frac{3}{2}}(\gamma)$, and $q = 0$ elsewhere, we see that (3.3) reduces to

$$\frac{\sigma_\gamma}{h_\gamma} \int_\gamma [p]\, [q]\, d\sigma = 0,$$

which implies that $[p] = 0$ on γ. Then we conclude as above that p belongs to $H^1(\Omega_1)$ and (2.1) is satisfied in Ω_1 for the four DG versions. Clearly, the same result is true in Ω_2.

Now, by substituting this information into (3.3) with $i = 1, 2$, we obtain that p and λ satisfy for any $q \in X(\Omega_i)$

$$\begin{aligned}\int_{\Gamma_{12}} \mathbf{K}\nabla q \cdot \mathbf{n}_{\partial\Omega_i} p|_{\Omega_i}\, d\sigma + \sum_{\tau\in\Gamma_H} \frac{\sigma_\tau}{H_\tau}\int_\tau (pq)|_{\Omega_i}\, d\sigma = \sum_{\tau\in\Gamma_H} \frac{\sigma_\tau}{H_\tau}\int_\tau q|_{\Omega_i}\,\lambda\, d\sigma \\ - \int_{\partial\Omega_i\setminus\Gamma_{12}} (g + \mathbf{K}\nabla p\cdot\mathbf{n}_{\partial\Omega_i}) q\, d\sigma + \int_{\Gamma_{12}} \mathbf{K}\nabla q\cdot\mathbf{n}_{\partial\Omega_i}\lambda\, d\sigma.\end{aligned} \tag{3.6}$$

To recover the boundary condition (2.2), let E be an element of $\mathcal{E}_h(\Omega_i)$ adjacent to $\partial\Omega_i \setminus \Gamma_{12}$, and $\gamma = \partial E \cap (\partial\Omega_i \setminus \Gamma_{12})$. By taking $q|_{\Omega_i\setminus\overline{E}} = 0$ and $q|_E \in H^2(E)$ with $q = 0$ and $\nabla q\cdot\mathbf{n} = 0$ on $\partial E\setminus\gamma$, (3.6) reduces to

$$-\int_\gamma \mathbf{K}\nabla p\cdot\mathbf{n}\, q\, d\sigma = \int_\gamma g\, q\, d\sigma.$$

Since the trace of q is arbitrary in $H_0^{\frac{3}{2}}(\gamma)$, we conclude that $-\mathbf{K}\nabla p\cdot\mathbf{n} = g$ on γ. Therefore (2.2) is satisfied on $\partial\Omega_i\setminus\Gamma_{12}$, and (3.6) becomes

$$\begin{aligned}\int_{\Gamma_{12}} \mathbf{K}\nabla q \cdot \mathbf{n}_{\partial\Omega_i} p|_{\Omega_i}\, d\sigma + \sum_{\tau\in\Gamma_H} \frac{\sigma_\tau}{H_\tau}\int_\tau (pq)|_{\Omega_i}\, d\sigma = \sum_{\tau\in\Gamma_H} \frac{\sigma_\tau}{H_\tau}\int_\tau q|_{\Omega_i}\,\lambda\, d\sigma \\ + \int_{\Gamma_{12}} \mathbf{K}\nabla q\cdot\mathbf{n}_{\partial\Omega_i}\lambda\, d\sigma.\end{aligned} \tag{3.7}$$

Finally, we turn to the interface Γ_{12}. For $i = 1, 2$, let E be an element of $\mathcal{E}_h(\Omega_i)$ adjacent to Γ_{12}, and $\gamma = \partial E \cap \Gamma_{12}$. By taking $q|_{\Omega_i\setminus\overline{E}} = 0$ and $q|_E \in H^2(E)$ with $q = 0$ and $\nabla q\cdot\mathbf{n} = 0$ on $\partial E\setminus\gamma$, (3.7) becomes

$$\sum_{\tau\in\Gamma_H,\tau\cap\gamma\neq\emptyset} \left(\int_\tau \mathbf{K}\nabla q\cdot\mathbf{n}_{\partial\mathbf{\Omega_i}}(p|_{\Omega_i} - \lambda) d\sigma + \frac{\sigma_\tau}{H_\tau}\int_\tau (p|_{\Omega_i} - \lambda) q|_{\Omega_i}\, d\sigma\right) = 0.$$

By choosing $\mathbf{K}\nabla q\cdot\mathbf{n}$ and q arbitrarily in the interior of γ, we show that $p|_{\Omega_i} = \lambda$ on γ, and consequently for $i = 1, 2$, $p|_{\Omega_i} = \lambda$ on Γ_{12}. This implies in particular that $p \in H^1(\Omega)$. The matching condition (3.4) now becomes $-\int_{\Gamma_{12}} [\mathbf{K}\nabla p\cdot\mathbf{n}]\,\mu d\sigma = 0$, which implies that $\mathbf{K}\nabla p\cdot\mathbf{n}$ is continuous across Γ_{12}. Thus we have (2.1) over the entire domain Ω. ∎

3.3. Discretization. The mortar DG-DG finite element scheme is as follows: Find $(p_h|_{\Omega_1}, p_h|_{\Omega_2}, \lambda_H) \in X_h(\Omega_1)\times X_h(\Omega_2)\times\Lambda_H$ such that

$$B_i(p_h, q_h) = L_i(q_h;\lambda_H) \quad \forall\, q_h \in X_h(\Omega_i), \quad i = 1,\, 2, \tag{3.8}$$

$$\int_{\Gamma_{12}} [\mathbf{K}\nabla p_h\cdot\mathbf{n}]\,\mu_H d\sigma = \sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\int_\tau \sum_{i=1}^{2}(p_h|_{\Omega_i} - \lambda_H)\mu_H d\sigma \quad \forall\mu_H \in \Lambda_H. \tag{3.9}$$

In the analysis we shall use the following inequalities, which hold if the penalty parameter σ_γ^0 is chosen to be sufficiently large.

LEMMA 3.1. *For $i = 1, 2$, let $\mathcal{E}_h(\Omega_i)$ be nondegenerate. Then, with each γ in $\Gamma_h(\Omega_i)$, we can associate a positive number σ_γ such that the following inequality holds for all $q_h \in X_h(\Omega_i)$ and all $q \in X(\Omega_i)$:*

$$\left|\sum_{\gamma\in\Gamma_h(\Omega_i)}\int_\gamma \{\mathbf{K}\nabla q_h\cdot\mathbf{n}\}\,[q]\, d\sigma\right| \le \frac{1}{8}\|\mathbf{K}^{\frac{1}{2}}\nabla q_h\|_{0,\Omega_i}^2 + \frac{1}{8}\sum_{\gamma\in\Gamma_h(\Omega_i)}\frac{\sigma_\gamma}{h_\gamma}\int_\gamma [q]^2\, d\sigma. \tag{3.10}$$

Proof. For each E in $\mathcal{E}_h(\Omega_i)$, let $\lambda_E^{\max}$ (resp., $\lambda_E^{\min}$) denote the maximum (resp., minimum) of the eigenvalues of $\mathbf{K}$ on E. By assumption, $\lambda_E^{\max} \le k_{\max}$ and $\lambda_E^{\min} \ge k_{\min} > 0$, with $k_{\max}$ and $k_{\min}$ independent of h and E. Let $\gamma = \partial E_1 \cap \partial E_2$ belong to $\Gamma_h(\Omega_i)$, and let us expand

$$\|\{\mathbf{K}\nabla q_h \cdot \mathbf{n}\}\|_{0,\gamma} \le \frac{1}{2} \sum_{j=1,2} \|\mathbf{K}\nabla q_h|_{E_j}\|_{0,\gamma} \le \frac{1}{2} \sum_{j=1,2} \lambda_{E_j}^{\max} \|\nabla q_h|_{E_j}\|_{0,\gamma}.$$

By reverting to the reference element $\hat{E}$, and using the equivalence of norms on a finite-dimensional space on $\hat{E}$, there exists a constant $\hat{c}$, independent of h, such that

$$\begin{aligned} \|\{\mathbf{K}\nabla q_h \cdot \mathbf{n}\}\|_{0,\gamma} &\le \frac{\hat{c}}{2} \sum_{j=1,2} \lambda_{E_j}^{\max} \left(\frac{|\gamma|}{|E_j|}\right)^{\frac{1}{2}} \|\nabla q_h\|_{0,E_j} \\ &\le \frac{\hat{c}}{2} \sum_{j=1,2} \frac{\lambda_{E_j}^{\max}}{\sqrt{\lambda_{E_j}^{\min}}} \left(\frac{|\gamma|}{|E_j|}\right)^{\frac{1}{2}} \|\mathbf{K}^{\frac{1}{2}}\nabla q_h\|_{0,E_j}. \end{aligned} \tag{3.11}$$

Therefore

$$\left| \sum_{\gamma \in \Gamma_h(\Omega_i)} \int_\gamma \big\{\mathbf{K}\nabla q_h \cdot \mathbf{n}\big\}[q] d\sigma \right| \le \frac{\hat{c}}{2} \sum_{\gamma \in \Gamma_h(\Omega_i)} \sum_{j=1,2} \frac{\lambda_{E_j}^{\max}}{\sqrt{\lambda_{E_j}^{\min}}} \left(\frac{|\gamma|}{|E_j|}\right)^{\frac{1}{2}} \|\mathbf{K}^{\frac{1}{2}}\nabla q_h\|_{0,E_j} \|[q]\|_{0,\gamma}.$$

By applying Young's inequality with parameter $\epsilon > 0$, this becomes

$$\begin{aligned} \left| \sum_{\gamma \in \Gamma_h(\Omega_i)} \int_\gamma \big\{\mathbf{K}\nabla q_h \cdot \mathbf{n}\big\}[q] d\sigma \right| &\le \frac{\epsilon}{4} \sum_{\gamma \in \Gamma_h(\Omega_i)} \sum_{j=1,2} \|\mathbf{K}^{\frac{1}{2}}\nabla q_h\|_{0,E_j}^2 \\ &+ \frac{\hat{c}^2}{4\epsilon} \sum_{\gamma \in \Gamma_h(\Omega_i)} \sum_{j=1,2} \frac{(\lambda_{E_j}^{\max})^2}{\lambda_{E_j}^{\min}} \frac{|\gamma|}{|E_j|} \|[q]\|_{0,\gamma}^2. \end{aligned} \tag{3.12}$$

It is easy to see that in the first sum an element E is counted at most L times, where L is a fixed number that depends on the type of elements used; for instance, $L = 4$ in the case of tetrahedra. Therefore, by choosing $\epsilon = \frac{1}{2L}$, we can take

$$\sigma_\gamma = 4L\hat{c}^2 \sum_{j=1,2} \frac{|\gamma| h_\gamma}{|E_j|} \frac{(\lambda_{E_j}^{\max})^2}{\lambda_{E_j}^{\min}}, \tag{3.13}$$

a quantity that is bounded above and below independently of h, owing to the nondegeneracy of the mesh. With this choice, (3.12) implies (3.10). ∎

We next analyze the solvability of the system (3.8)–(3.9). This is a square finite-dimensional system, and existence is equivalent to uniqueness. Let $f = 0$ and $g = 0$. Take $q_h = p_h$ in (3.8), and sum over the two subdomains Ω_1 and Ω_2 to obtain

$$\begin{aligned} &\sum_{E \in \mathcal{E}_h(\Omega)} \int_E \mathbf{K}\nabla p_h \cdot \nabla p_h dx - (1 + s_{\text{form}}) \sum_{\gamma \in \Gamma_h(\Omega)} \int_\gamma \{\mathbf{K}\nabla p_h \cdot \mathbf{n}\} [p_h] \, d\sigma \\ &+ \sum_{\gamma \in \Gamma_h(\Omega)} \frac{\sigma_\gamma}{h_\gamma} \int_\gamma [p_h]^2 \, d\sigma + \sum_{\tau \in \Gamma_H} \frac{\sigma_\tau}{H_\tau} \int_\tau \sum_{i=1}^{2} p_h|_{\Omega_i}^2 \, d\sigma \\ &= \int_{\Gamma_{12}} [\mathbf{K}\nabla p_h \cdot \mathbf{n}] \, \lambda_H d\sigma + \sum_{\tau \in \Gamma_H} \frac{\sigma_\tau}{H_\tau} \int_\tau \sum_{i=1}^{2} p_h|_{\Omega_i} \, \lambda_H d\sigma. \end{aligned} \tag{3.14}$$

Summation of (3.14) and (3.9) with $\mu_H = \lambda_H$ leads to

$$\begin{aligned}(3.15)\qquad &\|\mathbf{K}^{\frac{1}{2}}\nabla p_h\|_{0,\Omega}^2 - (1+s_{\text{form}})\sum_{\gamma\in\Gamma_h(\Omega)}\int_\gamma \{\mathbf{K}\nabla p_h\cdot\mathbf{n}\}\,[p_h]\,d\sigma\\ &+\sum_{\gamma\in\Gamma_h(\Omega)}\frac{\sigma_\gamma}{h_\gamma}\int_\gamma [p_h]^2\,d\sigma+\sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\int_\tau\sum_{i=1}^{2}\left(p_h|_{\Omega_i}-\lambda_H\right)^2 d\sigma=0.\end{aligned}$$

First consider the case $0<\sigma_\tau^0\le\sigma_\tau\le\sigma_\tau^1$. For OBB-DG and NIPG, we have

$$(3.16)\quad \|\mathbf{K}^{\frac{1}{2}}\nabla p_h\|_{0,\Omega}^2+\sum_{\gamma\in\Gamma_h(\Omega)}\frac{\sigma_\gamma}{h_\gamma}\int_\gamma [p_h]^2\,d\sigma+\sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\int_\tau\sum_{i=1}^{2}\left(p_h|_{\Omega_i}-\lambda_H\right)^2 d\sigma=0.$$

Since $\mathbf{K}$ is positive definite in Ω, the above equation implies that $\nabla p_h=0$ in each $E\in\mathcal{E}_h(\Omega)$ and $p_h|_{\Omega_i}=\lambda_H$ on Γ_{12}, i.e., p_h is continuous across Γ_{12}. For NIPG, we see, in addition, that p_h is continuous in Ω_1 and Ω_2; therefore p_h is a constant over the entire domain Ω, and λ_H is the same constant on Γ_{12}.

For OBB-DG and $i=1,2$, (3.8) now implies that

$$(3.17)\qquad \sum_{\gamma\in\Gamma_h(\Omega_i)}\int_\gamma\{\mathbf{K}\nabla q_h\cdot\mathbf{n}\}\,[p_h]\,d\sigma=0.$$

Let $\gamma\in\Gamma_h(\Omega_i)$, and let $\gamma\subset\partial E$, $E\in\mathcal{E}_h(\Omega_i)$. If $r\ge 2$, we can construct q_h such that $q_h|_{\Omega\setminus\overline{E}}=0$, $q_h|_E\in\mathbb{P}_r$, $\int_\gamma\mathbf{K}\nabla q_h\cdot\mathbf{n}d\sigma=1$, and $\int_{\gamma'}\mathbf{K}\nabla q_h\cdot\mathbf{n}d\sigma=0$ for $\gamma'\subset\partial E\setminus\gamma$ (see [39]). Equation (3.17) implies that $[p_h]=0$ on γ. Hence p_h is continuous in Ω_i, $i=1$ and 2, and therefore p_h is a constant over the entire domain Ω and λ_H is the same constant on Γ_{12}.

For SIPG and IIPG, assuming that σ_γ^0 is sufficiently large, we employ the inequality (3.10) in Ω_1 and Ω_2 with $q_h=q=p_h$ and conclude from (3.15) that

$$(3.18)\qquad 0\ge\frac{1}{2}\|\mathbf{K}^{\frac{1}{2}}\nabla p_h\|_{0,\Omega}^2+\frac{1}{2}\sum_{\gamma\in\Gamma_h(\Omega)}\frac{\sigma_\gamma}{h_\gamma}\int_\gamma[p_h]^2\,d\sigma+\sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\int_\tau\sum_{i=1}^{2}\left(p_h|_{\Omega_i}-\lambda_H\right)^2 d\sigma.$$

We then conclude that p_h is a constant over the entire Ω and λ_H is the same constant on Γ_{12}.

Let us now consider the case $\sigma_\tau=0$; we see from (3.8), using (3.17), (3.16), or (3.18), that for all schemes we have

$$(3.19)\qquad \int_{\Gamma_{12}}\mathbf{K}\nabla q_h|_{\Omega_i}\cdot\mathbf{n}_{\partial\Omega_i}(p_h|_{\Omega_i}-\lambda_H)d\sigma=0,\quad i=1\text{ and }2.$$

If the mortar compatibility condition (A.1) is satisfied for $X_h(\Omega_1)$, we have $\lambda_H=p_h|_{\Omega_1}$ from (3.19) with $i=1$. Since λ_H and $p_h|_{\Omega_2}$ are both constants, we further conclude, from (3.19) with $i=2$, that $p_h|_{\Omega_1}$, $p_h|_{\Omega_2}$, and λ_H must be the same constant. This concludes the argument for $\sigma_\tau=0$.

We have shown for all schemes that the null space of the linear system (3.8)–(3.9) is the constant vector. Owing to the compatibility condition (2.3), the right-hand side for $q_h=1$ is $\int_\Omega f\,dx-\int_{\partial\Omega}g\,d\sigma=0$. Hence the solution exists and is unique up to an additive constant. We therefore have proved the following solvability theorem.

THEOREM 3.2. *For OBB-DG, we assume that $r \geq 2$. For SIPG and IIPG, we assume that σ_γ^0 is sufficiently large. We make no assumption for NIPG. Then the scheme* (3.8)–(3.9) *possesses a solution (p_h, λ_H) unique up to an additive constant that is the same for p_h and λ_H. The same conclusion holds if $\sigma_\tau = 0$, assuming that the compatibility condition* (A.1) *holds for either $i = 1$ or 2.*

3.4. Convergence of the DG-DG schemes. Now, we use an interpolant $\hat{p}$ of p that has particular properties on the elements adjacent to the interface Γ_{12}. On the other elements E, we take $\hat{p}$ to be the interpolant constructed in [39] in the case of OBB-DG or simply take $\hat{p}$ to be the $L^2(E)$-projection of p for the DG methods with interior penalties. More precisely, $\hat{p}|_{\Omega_i} \in X_h(\Omega_i)$, $i = 1, 2$, for all $E \in \mathcal{E}_h(\Omega)$, $\hat{p}|_E$ is exact on $\mathbb{P}_r$, and for all E adjacent to Γ_{12}

$$\int_\gamma \mathbf{K}\nabla\hat{p}\cdot\mathbf{n} = \int_\gamma \mathbf{K}\nabla p\cdot\mathbf{n} \quad \forall\gamma \subset \partial E \cap \Gamma_{12}. \tag{3.20}$$

In the case where $r \geq 2$ such an interpolant is constructed in [39]. In fact, that interpolant satisfies (3.20) on all element sides $\gamma \subset \partial E$. In the case where $r = 1$, we augment (3.20) with the conditions

$$\int_{\gamma_i} \mathbf{K}\nabla\hat{p}\cdot\mathbf{n}d\sigma = \int_{\gamma_i} \mathbf{K}\nabla p\cdot\mathbf{n}d\sigma, \quad \gamma_i \subset \partial E \setminus \Gamma_{12},\ i = 1, \ldots, d-k, \tag{3.21}$$

$$\int_E \hat{p}dx = \int_E p dx, \tag{3.22}$$

where k is the number of sides that E shares with Γ_{12}. Note that condition (3.21) is empty if $k = d$. It is easy to see that, if $\mathbf{K}$ is a constant on E, (3.20)–(3.22) define $\hat{p}$ uniquely and that $\hat{p}$ is exact for linears. If $\mathbf{K}$ is not a constant on E, an extension similar to the one in [39] can be used. In all cases, $\hat{p}$ has optimal approximation properties, namely, on each $E \in \mathcal{E}_h(\Omega)$,

$$|p - \hat{p}|_{k,E} \leq C h_E^{r+1-k}|p|_{r+1,E}, \quad k = 0,\ 1,\ 2. \tag{3.23}$$

Note that, for $\gamma \subset \partial E$, the trace inequality [7] $|\phi|_{k,\gamma} \leq C(h_E^{\frac{1}{2}}|\phi|_{k+1,E} + h_E^{-\frac{1}{2}}|\phi|_{k,E})$ implies that

$$|p - \hat{p}|_{k,\gamma} \leq C h_E^{r+\frac{1}{2}-k}|p|_{r+1,E}, \quad k = 0,\ 1. \tag{3.24}$$

More generally, we have the following lemma.

LEMMA 3.2. *Let $\mathcal{E}_h(\Omega_i)$, $i = 1, 2$, be nondegenerate. Then there exists a constant C, independent of h, such that for all p in $H^s(\Omega_i)$, $s > \frac{3}{2}$,*

$$\left(\sum_{\gamma\in\Gamma_h(\Omega_i)} h_\gamma \| \{\mathbf{K}\nabla(p - \hat{p})\cdot\mathbf{n}\} \|_{0,\gamma}^2 \right)^{\frac{1}{2}} \leq C\, h^{\mu-1}|p|_{\mu,\Omega_i}, \quad \mu = \min(r+1, s). \tag{3.25}$$

Proof. Consider a side γ adjacent to an element E. The result follows by switching to the reference element, applying a trace theorem, and using (3.23):

$$\begin{aligned} h_\gamma \|\mathbf{K}\nabla(p - \hat{p})|_E\cdot\mathbf{n}\|_{0,\gamma}^2 &\leq C\frac{h_\gamma|\gamma|}{|E|}(\lambda_E^{\max})^2 \left(|p - \hat{p}|_{1,E}^2 + h_E^{2(s-1)}|p - \hat{p}|_{s,E}^2 \right) \\ &\leq C\, h_E^{2(\mu-1)}|p|_{\mu,E}^2. \qquad \square \end{aligned}$$

THEOREM 3.3. *Let p be a solution of (2.1)–(2.2). Let (p_h, λ_H) be a solution of (3.8)–(3.9). We assume that $p \in H^s(\Omega)$ for some real number $s > \frac{3}{2}$ and that σ_γ^0 is sufficiently large for SIPG and IIPG. Then there exists a constant C, independent of h and H, such that*

$$\begin{aligned}&\left\|\mathbf{K}^{\frac{1}{2}}\nabla\left(p_h-p\right)\right\|_{0,\Omega}+\sqrt{\sum_{\gamma\in\Gamma_h(\Omega)}\frac{\sigma_\gamma}{h_\gamma}\left\|[p_h]\right\|_{0,\gamma}^2}+\sqrt{\sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\sum_{i=1,2}\left\|p_h|_{\Omega_i}-\lambda_H\right\|_{0,\tau}^2}\\&\leq C\left(h^{\mu-1}\left(\frac{H}{h}\right)^{\frac{1}{2}}+H^{\bar{\mu}-\frac{1}{2}}\right),\quad \mu=\min\left(r+1,s\right),\ \bar{\mu}=\min\left(\bar{r}+1,s-\frac{1}{2}\right).\end{aligned}$$

Proof. Since by assumption p is smooth enough, we let $\bar{p} \in \Lambda_H$ be the continuous nodal interpolant of p and define

$$\eta := \lambda_H - p, \quad \eta^I := p - \bar{p}, \quad \eta^A := \lambda_H - \bar{p} = \eta + \eta^I.$$

Define

$$\xi := p_h - p, \quad \xi^I := p - \hat{p}, \quad \xi^A := p_h - \hat{p} = \xi + \xi^I.$$

The interpolant $\bar{p}$ satisfies [19]

$$|p - \bar{p}|_{k,\Gamma_{12}} \leq C H^{\bar{\mu}-k} |p|_{\bar{\mu}+1/2,\Omega_i},\ 0 \leq k \leq 1, \tag{3.26}$$

where the bound for fractional k is obtained by interpolation between $L^2(\Gamma_{12})$ and $H^1(\Gamma_{12})$.

By subtracting the weak formulation (3.3) from the finite element scheme (3.8) and choosing $q_h = \xi^A$, we obtain

$$B_i(\xi^A, \xi^A) = L_i(\xi^A; \lambda_H) - L_i(\xi^A; p) + B_i(\xi^I, \xi^A), \quad i = 1, 2.$$

Summation over the two subdomains leads to

$$\begin{aligned}\sum_{i=1}^{2} B_i(\xi^A, \xi^A) &= \sum_{i=1}^{2}\big(B_i(\xi^I, \xi^A) + L_i(\xi^A; \lambda_H) - L_i(\xi^A; p)\big)\\&= \sum_{i=1}^{2} B_i(\xi^I, \xi^A) + \int_{\Gamma_{12}} \left[\mathbf{K}\nabla\xi^A \cdot \mathbf{n}\right] \eta d\sigma + \sum_{i=1}^{2}\sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\int_\tau \xi^A|_{\Omega_i}\,\eta d\sigma.\end{aligned} \tag{3.27}$$

Similarly, by subtracting (3.4) from (3.9), with $\mu = \mu_H = \eta^A$, and noting that p and $\mathbf{K}\nabla p \cdot \mathbf{n}$ are continuous across the interface Γ_{12}, we obtain

$$\begin{aligned}&\int_{\Gamma_{12}} \left[\mathbf{K}\nabla\xi^A \cdot \mathbf{n}\right] \eta^A d\sigma - \sum_{i=1,2}\sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\int_\tau (\xi^A|_{\Omega_i} - \eta^A)\eta^A d\sigma\\&= \int_{\Gamma_{12}} \left[\mathbf{K}\nabla\xi^I \cdot \mathbf{n}\right] \eta^A d\sigma - \sum_{i=1,2}\sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\int_\tau (\xi^I|_{\Omega_i} - \eta^I)\eta^A d\sigma.\end{aligned} \tag{3.28}$$

Summing (3.27) and (3.28) results in

(3.29)

$$\sum_{i=1}^{2} B_i(\xi^A,\xi^A) - \sum_{i=1,2}\sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\int_\tau \xi^A\big|_{\Omega_i}\eta^A d\sigma - \sum_{i=1,2}\sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\int_\tau (\xi^A\big|_{\Omega_i}-\eta^A)\eta^A d\sigma$$
$$= \sum_{i=1}^{2} B_i(\xi^I,\xi^A) - \int_{\Gamma_{12}}\left[\mathbf{K}\nabla\xi^A\cdot\mathbf{n}\right]\eta^I d\sigma + \int_{\Gamma_{12}}\left[\mathbf{K}\nabla\xi^I\cdot\mathbf{n}\right]\eta^A d\sigma$$
$$- \sum_{i=1,2}\sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\int_\tau \xi^A\big|_{\Omega_i}\eta^I d\sigma - \sum_{i=1,2}\sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\int_\tau (\xi^I\big|_{\Omega_i}-\eta^I)\eta^A d\sigma.$$

We expand the first term on the left-hand side of (3.29):

$$\sum_{i=1}^{2} B_i(\xi^A,\xi^A) = \|\mathbf{K}^{\frac{1}{2}}\nabla\xi^A\|_{0,\Omega}^2 - (1+s_{\text{form}})\sum_{\gamma\in\Gamma_h(\Omega)}\int_\gamma\left\{\mathbf{K}\nabla\xi^A\cdot\mathbf{n}\right\}\left[\xi^A\right]d\sigma$$
$$+\sum_{\gamma\in\Gamma_h(\Omega)}\frac{\sigma_\gamma}{h_\gamma}\int_\gamma\left[\xi^A\right]^2 d\sigma + \sum_{i=1,2}\sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\int_\tau \xi^A\big|_{\Omega_i}^2 d\sigma.$$

We denote by L_{ErrEqu} and R_{ErrEqu} the left-hand and right-hand sides of (3.29), respectively. An algebraic manipulation yields

$$L_{\text{ErrEqu}} = \|\mathbf{K}^{\frac{1}{2}}\nabla\xi^A\|_{0,\Omega}^2 - (1+s_{\text{form}})\sum_{\gamma\in\Gamma_h(\Omega)}\int_\gamma\left\{\mathbf{K}\nabla\xi^A\cdot\mathbf{n}\right\}\left[\xi^A\right]d\sigma$$
$$+\sum_{\gamma\in\Gamma_h(\Omega)}\frac{\sigma_\gamma}{h_\gamma}\int_\gamma\left[\xi^A\right]^2 d\sigma + \sum_{i=1,2}\sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\int_\tau\left(\xi^A\big|_{\Omega_i}-\eta^A\right)^2 d\sigma.$$

For NIPG and OBB-DG, the second term in L_{ErrEqu} vanishes, leaving only the coercive terms. For SIPG and IIPG, we employ the inequality (3.10) with $q_h = q = \xi^A$ to conclude that

$$L_{\text{ErrEqu}} \geq \frac{1}{2}\|\mathbf{K}^{\frac{1}{2}}\nabla\xi^A\|_{0,\Omega}^2 + \frac{1}{2}\sum_{\gamma\in\Gamma_h(\Omega)}\frac{\sigma_\gamma}{h_\gamma}\int_\gamma\left[\xi^A\right]^2 d\sigma$$
$$+\frac{1}{2}\sum_{i=1,2}\sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\int_\tau\left(\xi^A\big|_{\Omega_i}-\eta^A\right)^2 d\sigma.$$

We now consider the right-hand side of (3.29). By expanding its first term as

$$\sum_{i=1}^{2} B_i(\xi^I,\xi^A) = \sum_{E\in\mathcal{E}_h(\Omega)}\int_E \mathbf{K}\nabla\xi^I\cdot\nabla\xi^A dx - \sum_{\gamma\in\Gamma_h(\Omega)}\int_\gamma\left\{\mathbf{K}\nabla\xi^I\cdot\mathbf{n}\right\}\left[\xi^A\right]d\sigma$$
$$- s_{\text{form}}\sum_{\gamma\in\Gamma_h(\Omega)}\int_\gamma\left\{\mathbf{K}\nabla\xi^A\cdot\mathbf{n}\right\}\left[\xi^I\right]d\sigma - \int_{\Gamma_{12}}\left[\mathbf{K}\nabla\xi^I\cdot\mathbf{n}\xi^A\right]d\sigma$$
$$+\int_{\Gamma_{12}}\left[\mathbf{K}\nabla\xi^A\cdot\mathbf{n}\xi^I\right]d\sigma + \sum_{\gamma\in\Gamma_h(\Omega)}\frac{\sigma_\gamma}{h_\gamma}\int_\gamma\left[\xi^I\right]\left[\xi^A\right]d\sigma + \sum_{i=1,2}\sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\int_\tau(\xi^I\xi^A)|_{\Omega_i}d\sigma$$

and using the fact that η^I and η^A are uniquely defined on Γ_{12}, we have

$$\begin{aligned}
R_{\text{ErrEqu}} &= \sum_{E\in\mathcal{E}_h(\Omega)}\int_E \mathbf{K}\nabla\xi^I\cdot\nabla\xi^A dx - \sum_{\gamma\in\Gamma_h(\Omega)}\int_\gamma \left\{\mathbf{K}\nabla\xi^I\cdot\mathbf{n}\right\}\left[\xi^A\right]d\sigma \\
&- s_{\text{form}}\sum_{\gamma\in\Gamma_h(\Omega)}\int_\gamma \left\{\mathbf{K}\nabla\xi^A\cdot\mathbf{n}\right\}\left[\xi^I\right]d\sigma + \sum_{\gamma\in\Gamma_h(\Omega)}\frac{\sigma_\gamma}{h_\gamma}\int_\gamma\left[\xi^I\right]\left[\xi^A\right]d\sigma \\
&- \sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\int_\tau\sum_{i=1,2}(\xi^I|_{\Omega_i}-\eta^I)(\xi^A|_{\Omega_i}-\eta^A)d\sigma \\
&- \int_{\Gamma_{12}}\left[\mathbf{K}\nabla\xi^A\cdot\mathbf{n}(\eta^I-\xi^I)\right]d\sigma + \int_{\Gamma_{12}}\left[\mathbf{K}\nabla\xi^I\cdot\mathbf{n}(\eta^A-\xi^A)\right]d\sigma =: \sum_{i=1}^7 T_i.
\end{aligned}$$

We now bound each term T_i of R_{ErrEqu}. We first bound T_2 for NIPG, SIPG, and IIPG:

$$|T_2| \le \epsilon\sum_{\gamma\in\Gamma_h(\Omega)}\frac{\sigma_\gamma}{h_\gamma}\int_\gamma\left[\xi^A\right]^2 d\sigma + Ch^{2\mu-2}.$$

For OBB-DG we use an argument from [39] and the property (3.20) of $\hat{p}$, which holds for all element sides. On each side $\gamma=\partial E_1\cap\partial E_2$, let $c_\gamma = c_\gamma^1 - c_\gamma^2$, where c_γ^i is the mean value of ξ^A on E_i. We have

$$\begin{aligned}
|T_2| &= \left|\sum_{\gamma\in\Gamma_h(\Omega)}\int_\gamma\left\{\mathbf{K}\nabla\xi^I\cdot\mathbf{n}\right\}\left(\left[\xi^A\right]-c_\gamma\right)d\sigma\right| \\
&\le \sum_{\gamma\in\Gamma_h(\Omega)}\left(\frac{\tilde{\epsilon}}{h_\gamma}\|[\xi^A]-c_\gamma\|_{0,\gamma}^2 + Ch_\gamma\|\{\mathbf{K}\nabla\xi^I\cdot\mathbf{n}\}\|_{0,\gamma}^2\right) \le \epsilon|\!|\!|\mathbf{K}^{\frac12}\nabla\xi^A|\!|\!|_{0,\Omega}^2 + Ch^{2\mu-2},
\end{aligned}$$

where we used the fact that

$$\|[\xi^A]-c_\gamma\|_{0,\gamma} \le \|\xi^A|_{E_1}-c_\gamma^1\|_{0,\gamma} + \|\xi^A|_{E_2}-c_\gamma^2\|_{0,\gamma} \le Ch_\gamma^{\frac12}(|\xi^A|_{1,E_1}+|\xi^A|_{1,E_2}).$$

We continue with bounds on the rest of the terms T_i of R_{ErrEqu} for all methods:

$$\begin{aligned}
|T_1| &\le \epsilon|\!|\!|\mathbf{K}^{\frac12}\nabla\xi^A|\!|\!|_{0,\Omega}^2 + C|\!|\!|\mathbf{K}^{\frac12}\nabla\xi^I|\!|\!|_{0,\Omega}^2 \le \epsilon|\!|\!|\mathbf{K}^{\frac12}\nabla\xi^A|\!|\!|_{0,\Omega}^2 + Ch^{2\mu-2}, \\
|T_3| &\le \tilde{\epsilon}\sum_{\gamma\in\Gamma_h(\Omega)}h_\gamma\int_\gamma\left\{\mathbf{K}\nabla\xi^A\cdot\mathbf{n}\right\}^2 d\sigma + C\sum_{\gamma\in\Gamma_h(\Omega)}\frac{1}{h_\gamma}\int_\gamma\left[\xi^I\right]^2 d\sigma \\
&\le \epsilon|\!|\!|\mathbf{K}^{\frac12}\nabla\xi^A|\!|\!|_{0,\Omega}^2 + Ch^{2\mu-2}, \\
|T_4| &\le \epsilon\sum_{\gamma\in\Gamma_h(\Omega)}\frac{\sigma_\gamma}{h_\gamma}\int_\gamma\left[\xi^A\right]^2 d\sigma + Ch^{2\mu-2}, \\
|T_5| &\le \epsilon\sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\int_\tau\sum_{i=1,2}\left(\xi^A|_{\Omega_i}-\eta^A\right)^2 d\sigma + C\sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\int_\tau\sum_{i=1,2}\xi^I|_{\Omega_i}^2\, d\sigma \\
&\quad + C\sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\int_\tau\sum_{i=1,2}\left(\eta^I\right)^2 d\sigma \\
&\le \epsilon\sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\int_\tau\sum_{i=1,2}\left(\xi^A|_{\Omega_i}-\eta^A\right)^2 d\sigma + Ch^{2\mu-1}H^{-1} + CH^{2\bar{\mu}}H^{-1} \\
&\le \epsilon\sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\int_\tau\sum_{i=1,2}\left(\xi^A|_{\Omega_i}-\eta^A\right)^2 d\sigma + Ch^{2\mu-2} + CH^{2\bar{\mu}-1}.
\end{aligned}$$

To handle term T_6, we use the special properties (3.20)–(3.22) of the interpolant $\hat{p}$ on the interface Γ_{12}. We define

$$T_{6,i} := -\int_{\Gamma_{12}} \mathbf{K}\nabla\xi^A \cdot \mathbf{n}_{\partial\Omega_i}(\eta^I - \xi^I)\big|_{\Omega_i}\, d\sigma, \quad i = 1, 2.$$

Obviously, we have $T_6 = T_{6,1} + T_{6,2}$. We bound $T_{6,1}$, suppressing the subscript $\partial\Omega_1$ for simplicity; the bound for $T_{6,2}$ is similar. By using the same argument as for bounding T_3, it is easy to see that

$$|T_{6,1}| \le T_A + T_B + \tilde{\epsilon}\|\mathbf{K}^{\frac{1}{2}}\nabla\xi^A\|^2_{0,\Omega_1} + Ch^{2\mu-2},$$

where

$$T_A := \int_{\Gamma_{12}} \left|\mathbf{K}\nabla\xi^I \cdot \mathbf{n}\eta^I\right| d\sigma, \quad T_B := \int_{\Gamma_{12}} \left|\mathbf{K}\nabla\xi \cdot \mathbf{n}\eta^I\right| d\sigma.$$

To bound term T_A, let $P_{h,1}$ be the L^2-projection onto the space of piecewise constants on $\mathcal{E}_h(\Omega_1) \cap \Gamma_{12}$, use (3.20), and revert to the reference element to recover the $H^{\frac{1}{2}}$ norm in the second factor below; this gives

$$\begin{aligned} T_A &= \int_{\Gamma_{12}} \left|\mathbf{K}\nabla(p - \hat{p}) \cdot \mathbf{n}(\eta^I - P_{h,1}\eta^I)\right| d\sigma \\ &\le C\left(\sum_{\gamma\in\Gamma_{12}} h_\gamma \|\mathbf{K}\nabla(p - \hat{p}) \cdot \mathbf{n}\|^2_{0,\gamma}\right)^{\frac{1}{2}} \left(\sum_{\gamma\in\Gamma_{12}} \left\|\eta^I\right\|^2_{\frac{1}{2},\gamma}\right)^{\frac{1}{2}}. \end{aligned}$$

Then we apply (3.25) to the first factor and (3.26) with $k = \frac{1}{2}$ to the second factor; this gives

$$T_A \le Ch^{\mu-1}|p|_{\mu,\Omega_1} H^{\bar{\mu}-\frac{1}{2}}|p|_{\bar{\mu}+\frac{1}{2},\Omega_1} \le Ch^{2\mu-2} + CH^{2\bar{\mu}-1}.$$

To bound term T_B, we first subtract (3.3) from (3.8) and take the test function to be a piecewise constant on $\mathcal{E}_h(\Omega_1)$, to obtain the discrete mass balance equation

$$\begin{aligned} &-\sum_{\gamma\in\Gamma_h(\Omega_1)} \int_\gamma \{\mathbf{K}\nabla(p_h - p) \cdot \mathbf{n}\}\,[q]\, d\sigma - \int_{\Gamma_{12}} \mathbf{K}\nabla(p_h - p) \cdot \mathbf{n}q|_{\Omega_1} d\sigma \\ &+\sum_{\gamma\in\Gamma_h(\Omega_1)} \frac{\sigma_\gamma}{h_\gamma} \int_\gamma [p_h]\,[q]\, d\sigma + \sum_{\tau\in\Gamma_H} \frac{\sigma_\tau}{H_\tau} \int_\tau \left(p_h|_{\Omega_1} - \lambda_H\right) q d\sigma = 0. \end{aligned} \tag{3.30}$$

Let $\tilde{\eta}^I = P_1(\eta^I)$, where $P_1 \in \mathcal{L}(H^{\frac{1}{2}}(\Gamma_{12}); H^1(\Omega_1))$ is an extension operator, and let $\mathcal{Q}_h$ be the L^2-projection onto the space of piecewise constants on $\mathcal{E}_h(\Omega_1)$. Using (3.30) and the continuity of the trace of $\tilde{\eta}^I$ across interior interfaces, the term T_B has the following expression:

$$\begin{aligned} &\int_{\Gamma_{12}} \mathbf{K}\nabla\xi \cdot \mathbf{n}\eta^I d\sigma \\ &= \sum_{\gamma\in\Gamma_h(\Omega_1)} \int_\gamma \{\mathbf{K}\nabla(p_h - p) \cdot \mathbf{n}\}\left[\tilde{\eta}^I\right] d\sigma + \int_{\Gamma_{12}} \mathbf{K}\nabla(p_h - p) \cdot \mathbf{n}\tilde{\eta}^I d\sigma \\ &= \sum_{\gamma\in\Gamma_h(\Omega_1)} \int_\gamma \{\mathbf{K}\nabla(p_h - p) \cdot \mathbf{n}\}\left[\tilde{\eta}^I - \mathcal{Q}_h\tilde{\eta}^I\right] d\sigma + \int_{\Gamma_{12}} \mathbf{K}\nabla(p_h - p) \cdot \mathbf{n}(\tilde{\eta}^I - \mathcal{Q}_h\tilde{\eta}^I) d\sigma \\ &\quad + \sum_{\gamma\in\Gamma_h(\Omega_1)} \frac{\sigma_\gamma}{h_\gamma} \int_\gamma [p_h]\left[\mathcal{Q}_h\tilde{\eta}^I\right] d\sigma + \sum_{\tau\in\Gamma_H} \frac{\sigma_\tau}{H_\tau} \int_\tau \left(p_h|_{\Omega_1} - \lambda_H\right) \mathcal{Q}_h\tilde{\eta}^I d\sigma =: \sum_{i=1}^4 T_{B,i}. \end{aligned}$$

To bound the first term, observe that, by mapping to the reference element, using a trace theorem and the regularity of $\mathcal{E}_h(\Omega_1)$, we have on any segment γ adjacent to an element E

$$\|\tilde{\eta}^I - \mathcal{Q}_h\tilde{\eta}^I\|_{0,\gamma} \le Ch_\gamma^{\frac{1}{2}}|\tilde{\eta}^I|_{1,E}.$$

Applying the continuity of the extension operator P_1 gives

$$|T_{B,1}| \le C\left(\sum_{\gamma\in\Gamma_h(\Omega_1)} h_\gamma\|\mathbf{K}\nabla(p_h-p)\|_{0,\gamma}^2\right)^{\frac{1}{2}} \|\eta^I\|_{\frac{1}{2},\Gamma_{12}}.$$

For the first factor we write $p_h - p = \xi^A + \xi^I$ and apply (3.11), (3.25), and (3.26), thus deriving

$$\begin{aligned}|T_{B,1}| &\le CH^{\bar{\mu}-\frac{1}{2}}|p|_{\bar{\mu}+\frac{1}{2},\Omega_1}\left(h^{\mu-1}|p|_{\mu,\Omega_1} + \|\mathbf{K}^{\frac{1}{2}}\nabla\xi^A\|_{0,\Omega_1}\right)\\ &\le \epsilon\|\mathbf{K}^{\frac{1}{2}}\nabla\xi^A\|_{0,\Omega_1}^2 + C(h^{2\mu-2}+H^{2\bar{\mu}-1}),\end{aligned}$$

with a similar bound for $|T_{B,2}|$. The remaining terms are bounded as follows:

$$|T_{B,3}| = \left|\sum_{\gamma\in\Gamma_h(\Omega_1)}\frac{\sigma_\gamma}{h_\gamma}\int_\gamma [p_h]\left[\mathcal{Q}_h\tilde{\eta}^I - \tilde{\eta}^I\right]d\sigma\right| \le \epsilon\sum_{\gamma\in\Gamma_h(\Omega_1)}\frac{\sigma_\gamma}{h_\gamma}\|[p_h]\|_{0,\gamma}^2 + CH^{2\bar{\mu}-1},$$

$$\begin{aligned}|T_{B,4}| &\le \left|\sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\int_\tau\left(p_h|_{\Omega_1}-\lambda_H\right)\left(\mathcal{Q}_h\tilde{\eta}^I-\tilde{\eta}^I\right)d\sigma\right| + \left|\sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\int_\tau\left(p_h|_{\Omega_1}-\lambda_H\right)\tilde{\eta}^I d\sigma\right|\\ &\le \epsilon\sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\left\|p_h|_{\Omega_1}-\lambda_H\right\|_{0,\tau}^2 + C(H^{2\bar{\mu}-2}h + H^{2\bar{\mu}-1}).\end{aligned}$$

By combining the results for T_A and $T_{B,i}$, we obtain

$$\begin{aligned}|T_{6,1}| \le \epsilon\|\mathbf{K}^{\frac{1}{2}}\nabla\xi^A\|_{0,\Omega_1}^2 &+ \epsilon\sum_{\gamma\in\Gamma_h(\Omega_1)}\frac{\sigma_\gamma}{h_\gamma}\|[p_h]\|_{0,\gamma}^2 + \epsilon\sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\left\|\xi^A|_{\Omega_1}-\eta^A\right\|_{0,\tau}^2\\ &+ C(h^{2\mu-2}+H^{2\bar{\mu}-1}),\end{aligned}$$

where we have also used (3.24) and (3.26). The last term T_7 can be bounded as follows:

$$\begin{aligned}|T_7| &\le \left(\sum_{i=1,2}\sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\|\xi^A|_{\Omega_i}-\eta^A\|_{0,\tau}^2\right)^{\frac{1}{2}}\left(\sum_{i=1,2}\sum_{\tau\in\Gamma_H}\frac{H_\tau}{\sigma_\tau}\|\mathbf{K}\nabla\xi^I|_{\Omega_i}\cdot\mathbf{n}\|_{0,\tau}^2\right)^{\frac{1}{2}}\\ &\le \epsilon\sum_{i=1,2}\sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\|\,\xi^A\big|_{\Omega_i}-\eta^A\|_{0,\tau}^2 + Ch^{2\mu-3}H.\end{aligned}$$

Thus

$$\begin{aligned}\|\mathbf{K}^{\frac{1}{2}}\nabla\xi^A\|_{0,\Omega_1}^2 &+ \sum_{\gamma\in\Gamma_h(\Omega)}\frac{\sigma_\gamma}{h_\gamma}\left\|\left[\xi^A\right]\right\|_{0,\gamma}^2 + \sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\sum_{i=1,2}\left\|\xi^A|_{\Omega_i}-\eta^A\right\|_{0,\tau}^2\\ &\le Ch^{2\mu-2}\left(\frac{H}{h}\right) + CH^{2\bar{\mu}-1}.\end{aligned}$$

The proof is completed by using the triangle inequality. ∎

Remark 3.1. It is also possible to choose $\bar{s}_{\text{form}} = 0$ or 1, independently of s_{form}. For example, taking $\bar{s}_{\text{form}} = 1$ in SIPG preserves the symmetry of the method. These choices, however, require fine-scale related weights in the interface penalty terms of $B_i(\cdot,\cdot)$ and $L_i(\cdot;\cdot)$, in order to control the terms involving integrals on Γ_{12}. More precisely, the last terms of $B_i(\cdot,\cdot)$ and $L_i(\cdot;\cdot)$ in (3.8)–(3.9) need to be replaced by

$$\sum_{\gamma\in\Gamma_{h,i}} \frac{\sigma_\gamma}{h_\gamma}\int_\gamma p_h|_{\Omega_i} q_h|_{\Omega_i} d\sigma \quad \text{and} \quad \sum_{\gamma\in\Gamma_{h,i}} \frac{\sigma_\gamma}{h_\gamma}\int_\gamma q_h|_{\Omega_i}\lambda_H\, d\sigma, \tag{3.31}$$

respectively. Here $\Gamma_{h,i}$ denotes the trace of $\mathcal{E}_h(\Omega_i)$ on Γ_{12}. Similarly, the interface pressure continuity term in (3.4) should be replaced by

$$\sum_{i=1,2}\sum_{\gamma\in\Gamma_{h,i}} \frac{\sigma_\gamma}{h_\gamma}\int_\gamma (p_h|_{\Omega_i} - \lambda_H)\mu_H d\sigma.$$

Then the terms involving integrals on Γ_{12} can be controlled by the terms in (3.31) and $|\!|\!| \cdot |\!|\!|_{0,\Omega_i}$, via the inequality, for all $q_h \in X_h(\Omega_i)$ and all $\mu \in L^2(\Gamma_{12})$,

$$\left|\int_{\Gamma_{12}} \mathbf{K}\nabla q_h\cdot\mathbf{n}\,\mu d\sigma\right| \le \frac{1}{8}|\!|\!|\mathbf{K}^{\frac{1}{2}}\nabla q_h|\!|\!|^2_{0,\Omega_i} + \frac{1}{8}\sum_{\gamma\in\Gamma_{h,i}}\frac{\sigma_\gamma}{h_\gamma}\int_\gamma \mu^2 d\sigma, \tag{3.32}$$

assuming the weights σ_γ are sufficiently large. Note that (3.32) can be shown in a way similar to (3.10). It can then be seen that all modified mortar DG methods are well-posed; i.e., Theorem 3.2 holds for $\bar{s}_{\text{form}} = 0$, 1, or -1. Moreover, under the assumptions of Theorem 3.3, following its argument, we can show that there exists a constant C, independent of h and H, such that

$$|\!|\!|\mathbf{K}^{\frac{1}{2}}\nabla\left(p_h - p\right)|\!|\!|_{0,\Omega} + \sqrt{\sum_{\gamma\in\Gamma_h(\Omega)}\frac{\sigma_\gamma}{h_\gamma}\left\|[p_h]\right\|^2_{0,\gamma}} + \sqrt{\sum_{i=1,2}\sum_{\gamma\in\Gamma_{h,i}}\frac{\sigma_\gamma}{h_\gamma}\left\|p_h|_{\Omega_i} - \lambda_H\right\|^2_{0,\gamma}}$$
$$\le C\left(h^{\mu-1} + H^{\bar{\mu}-\frac{1}{2}}\left(\frac{H}{h}\right)^{\frac{1}{2}}\right), \quad \mu = \min\left(r+1, s\right),\ \bar{\mu} = \min\left(\bar{r}+1, s-\frac{1}{2}\right).$$

Note that, if $H = O(h)$, the above bound and the estimate from Theorem 3.3 provide the same (optimal) asymptotic convergence. However, in the multiscale case $H = O(h^\alpha)$, $0 < \alpha < 1$, the bound from Theorem 3.3 is better.

3.5. The interface operator and the reduced problem. In the following we present a nonoverlapping domain decomposition algorithm, which involves the reduction of the coupled system to an interface problem in the mortar space. We are motivated by the algorithms developed in [26, 4].

Let us split $L_i(q,\lambda)$ into a sum of two terms:

$$L_i(q;\lambda) = l_i(q) + b_i(\lambda, q),$$

where

$$l_i(q) := \int_{\Omega_i} fq dx - \int_{\partial\Omega_i\setminus\Gamma_{12}} gq d\sigma, \tag{3.33}$$

$$\begin{aligned} b_i(\lambda,q) &:= -\bar{s}_{\text{form}}\int_{\Gamma_{12}}\mathbf{K}\nabla q\cdot\mathbf{n}_{\partial\Omega_i}\lambda d\sigma + \sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\int_\tau q|_{\Omega_i}\lambda\, d\sigma \\ &:= \int_{\Gamma_{12}}\mathbf{K}\nabla q\cdot\mathbf{n}_{\partial\Omega_i}\lambda d\sigma + \sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\int_\tau q|_{\Omega_i}\lambda\, d\sigma, \end{aligned} \tag{3.34}$$

since we take $\bar{s}_{\text{form}} = -1$. We comment on the choices $\bar{s}_{\text{form}} = 0$ or 1 in Remark 3.3.

Define a bilinear form $d_H : L^2(\Gamma_{12}) \times L^2(\Gamma_{12}) \mapsto \mathbb{R}$ for $\lambda, \mu \in L^2(\Gamma_{12})$ by

(3.35)
$$d_H(\lambda,\mu) := \sum_{i=1}^{2}\left(\int_{\Gamma_{12}} \mathbf{K}\,\nabla p_h^*(\lambda)|_{\Omega_i}\cdot \mathbf{n}_{\partial\Omega_i}\mu d\sigma - \sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\int_\tau (p_h^*(\lambda)|_{\Omega_i}-\lambda)\mu d\sigma\right),$$

where $p_h^*(\lambda)|_{\Omega_i} \in X_h(\Omega_i)$, $i = 1, 2$, is the solution of

$$B_i\left(p_h^*(\lambda), q_h\right) = b_i\left(\lambda, q_h\right), \quad q_h \in X_h(\Omega_i),\ i = 1 \text{ and } 2. \tag{3.36}$$

Define a linear functional $g_H : L^2(\Gamma_{12}) \mapsto \mathbb{R}$ by

$$g_H(\mu) := -\sum_{i=1}^{2}\left(\int_{\Gamma_{12}} \mathbf{K}\,\nabla \bar{p}_h|_{\Omega_i}\cdot \mathbf{n}_{\partial\Omega_i}\mu d\sigma - \sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\int_\tau \bar{p}_h|_{\Omega_i}\mu d\sigma\right),$$

where $\bar{p}_h|_{\Omega_i} \in X_h(\Omega_i)$, $i = 1, 2$, solves

$$B_i\left(\bar{p}_h, q_h\right) = l_i\left(q_h\right), \quad q_h \in X_h(\Omega_i),\ i = 1 \text{ and } 2.$$

It is easy to see that the solution (p_h, λ_H) of the DG-DG scheme (3.8)–(3.9) satisfies

$$d_H\left(\lambda_H, \mu_H\right) = g_H\left(\mu_H\right), \quad \mu_H \in \Lambda_H, \tag{3.37}$$

with

$$p_h = p_h^*(\lambda_H) + \bar{p}_h.$$

We now analyze the properties of the bilinear form $d_H(\cdot,\cdot)$ for the various DG schemes. We first let $q_h = p_h^*(\mu)$ in (3.36) for some $\mu \in L^2(\Gamma_{12})$ to obtain

$$B_i\left(p_h^*(\lambda), p_h^*(\mu)\right) = b_i\left(\lambda, p_h^*(\mu)\right), \quad i = 1 \text{ and } 2. \tag{3.38}$$

By using (3.35), (3.34), and (3.38), we have

(3.39)
$$\begin{aligned} d_H\left(\lambda,\mu\right) &= \sum_{i=1}^{2} b_i(\mu, p_h^*(\lambda)) - 2\sum_{i=1}^{2}\sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\int_\tau p_h^*(\lambda)|_{\Omega_i}\mu\, d\sigma + 2\sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\int_\tau \lambda\mu d\sigma \\ &= \sum_{i=1}^{2} B_i\left(p_h^*(\mu), p_h^*(\lambda)\right) - 2\sum_{i=1}^{2}\sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\int_\tau p_h^*(\lambda)|_{\Omega_i}\mu\, d\sigma + 2\sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\int_\tau \lambda\mu d\sigma. \end{aligned}$$

Note that the above representation implies that the interface bilinear form $d_H(\cdot,\cdot)$ is nonsymmetric for all DG versions.

To show coercivity, using (3.39) and (3.1), we obtain

$$\begin{aligned} d_H\left(\lambda,\lambda\right) &= \|\mathbf{K}^{\frac{1}{2}}\nabla p_h^*(\lambda)\|_{0,\Omega}^2 - (1+s_{\text{form}})\sum_{\gamma\in\Gamma_h(\Omega)}\int_\gamma \{\mathbf{K}\nabla p_h^*(\lambda)\cdot\mathbf{n}\}\left[p_h^*(\lambda)\right] d\sigma \\ &\quad + \sum_{\gamma\in\Gamma_h(\Omega)}\frac{\sigma_\gamma}{h_\gamma}\int_\gamma \left[p_h^*(\lambda)\right]^2 d\sigma + \sum_{i=1,2}\sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\int_\tau \left(p_h^*(\lambda)|_{\Omega_i}-\lambda\right)^2 d\sigma \\ &\geq \frac{1}{2}\|\mathbf{K}^{\frac{1}{2}}\nabla p_h^*(\lambda)\|_{0,\Omega}^2 + \frac{1}{2}\sum_{\gamma\in\Gamma_h(\Omega)}\frac{\sigma_\gamma}{h_\gamma}\int_\gamma \left[p_h^*(\lambda)\right]^2 d\sigma \\ &\quad + \sum_{i=1,2}\sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\int_\tau \left(p_h^*(\lambda)|_{\Omega_i}-\lambda\right)^2 d\sigma, \end{aligned} \tag{3.40}$$

where we have used (3.10) for the inequality when $s_{\text{form}} = 0$ or 1. Therefore the interface bilinear form $d_H(\cdot,\cdot)$ is positive semidefinite on $L^2(\Gamma_{12})$. The argument in the solvability Theorem 3.2 implies that $d_H(\lambda,\lambda) = 0$ only if λ = constant. We summarize our results below.

THEOREM 3.4. *Let the assumptions of Theorem* 3.2 *hold. For all DG versions, the interface bilinear form $d_H(\cdot,\cdot)$ is nonsymmetric and positive semidefinite on $L^2(\Gamma_{12})$, with the kernel consisting of the constant functions.*

Remark 3.2. If the Dirichlet boundary condition is imposed on a part of $\partial\Omega$, Γ_D, such that $|\Gamma_D| > 0$, then $d_H(\cdot,\cdot)$ is positive definite on $L^2(\Gamma_{12})$.

Remark 3.3. For a general choice of $\bar{s}_{\text{form}}$, coercivity of $d_H(\cdot,\cdot)$ can be shown for all modified schemes introduced in Remark 3.1, by using inequality (3.32). Recall that taking $\bar{s}_{\text{form}} = 1$ in SIPG gives symmetric forms $B_i(\cdot,\cdot)$. It is easy to see that in this case $d_H(\cdot,\cdot)$ is also symmetric. In particular, by using (3.35) and (3.34) with modified penalty terms and (3.38), we obtain

$$\begin{aligned} d_H(\lambda,\mu) &= -\sum_{i=1}^{2}\left(b_i(\mu,p_h^*(\lambda)) + \sum_{\gamma\in\Gamma_{h,i}}\frac{\sigma_\gamma}{h_\gamma}\int_\gamma \lambda\mu d\sigma\right) \\ &= -\sum_{i=1}^{2}\left(B_i(p_h^*(\mu),p_h^*(\lambda)) + \sum_{\gamma\in\Gamma_{h,i}}\frac{\sigma_\gamma}{h_\gamma}\int_\gamma \lambda\mu d\sigma\right) = d_H(\mu,\lambda). \end{aligned}$$

Therefore in this case the conjugate gradient method can be employed for solving (3.37).

4. Coupling DG with MFE using a mortar space.

4.1. Weak formulation. We now consider the case where DG formulation is used in Ω_1 and a mixed formulation is used in Ω_2, the matching at the interface being achieved by a mortar multiplier. Recall that $W(\Omega_2) = L^2(\Omega_2)$, $\Lambda = H^{\frac{1}{2}}(\Gamma_{12})$, and $B_i(\cdot,\cdot)$ and $L_i(\cdot;\cdot)$ are defined in (3.1) and (3.2), respectively. In this section, we use only the definitions in Ω_1 and drop the subscripts for simplicity. That is, we denote $B_1(\cdot,\cdot)$ and $L_1(\cdot;\cdot)$ simply by $B(\cdot,\cdot)$ and $L(\cdot;\cdot)$, respectively.

Let $\mathbf{u}_g$ be the restriction to Ω_2 of an extension of g satisfying $\mathbf{u}_g \in H(\text{div};\Omega)$ and $\mathbf{u}_g\cdot\mathbf{n} = g$ on $\partial\Omega$. The coupled DG-mixed weak formulation is as follows: Find $p \in L^2(\Omega)$, such that $p|_{\Omega_1} \in X(\Omega_1)$, $p|_{\Omega_2} \in W(\Omega_2)$, $\mathbf{u} \in \mathbf{V}_0(\Omega_2) + \mathbf{u}_g$, and $\lambda \in \Lambda$ such that

$$B(p,q) = L(q;\lambda) \quad \forall q \in X(\Omega_1), \tag{4.1}$$

$$\int_{\Omega_2}\mathbf{K}^{-1}\mathbf{u}\cdot\mathbf{v}dx - \int_{\Omega_2} p\,\nabla\cdot\mathbf{v}dx = -\int_{\Gamma_{12}}\mathbf{v}\cdot\mathbf{n}_{\partial\Omega_2}\lambda d\sigma \quad \forall\,\mathbf{v}\in\mathbf{V}_0(\Omega_2), \tag{4.2}$$

$$\int_{\Omega_2}\nabla\cdot\mathbf{u}\,q\,dx = \int_{\Omega_2} f\,q\,dx \quad \forall\,q\in W(\Omega_2), \tag{4.3}$$

$$-\int_{\Gamma_{12}}(\mathbf{K}\nabla p|_{\Omega_1}\cdot\mathbf{n} + \mathbf{u}\cdot\mathbf{n})\mu d\sigma + \sum_{\tau\in\Gamma_H}\int_\tau\frac{\sigma_\tau}{H_\tau}(p|_{\Omega_1}-\lambda)\mu d\sigma = 0 \quad \forall\mu\in\Lambda. \tag{4.4}$$

As in section 3, we take $\bar{s}_{\text{form}} = -1$. The choices $\bar{s}_{\text{form}} = 0$ or 1 are discussed in Remarks 4.2 and 4.4.

4.2. Equivalence.

THEOREM 4.1. *If $(\mathbf{u},p,\lambda)$ is a solution of* (4.1)–(4.4)*, then p satisfies* (2.1)–(2.2) *in the sense of distributions. Conversely, if p is a sufficiently smooth solution of* (2.1)–(2.2)*, then there exists $\mathbf{u}$ and λ such that $(\mathbf{u},p,\lambda)$ solves* (4.1)–(4.4)*.*

Proof. By using the same arguments as in the DG-DG case, we conclude that $p|_{\Omega_1} \in H^1(\Omega_1)$ satisfies (2.1) in Ω_1 and (2.2) on $\partial\Omega_1 \setminus \Gamma_{12}$ and that $p|_{\Omega_1} = \lambda$ on Γ_{12}.

We now take $\mathbf{v} \in (C_0^\infty(\Omega_2))^d$, and (4.2) becomes

$$\int_{\Omega_2} \mathbf{K}^{-1}\mathbf{u} \cdot \mathbf{v} dx - \int_{\Omega_2} p\nabla \cdot \mathbf{v} dx = 0,$$

which implies that $\mathbf{u} = -\mathbf{K}\nabla p$ in Ω_2. With $q \in C_0^\infty(\Omega_2)$, (4.3) implies that $\nabla \cdot \mathbf{u} = f$ in Ω_2. Hence (2.1) is satisfied in Ω_2. We have forced that $\mathbf{u} \cdot \mathbf{n} = g$ on $\partial\Omega_2 \setminus \Gamma_{12}$, which results in the satisfaction of (2.2) on $\partial\Omega_2 \setminus \Gamma_{12}$.

By taking $\mathbf{v} \in \left(H^1(\Omega_2)\right)^d$, with $\mathbf{v} = 0$ on $\partial\Omega_2 \setminus \Gamma_{12}$, (4.2) becomes

$$\begin{aligned} -\int_{\Gamma_{12}} \mathbf{v} \cdot \mathbf{n}_{\partial\Omega_2} \lambda d\sigma &= -\int_{\Omega_2} \nabla p \cdot \mathbf{v} dx - \int_{\Omega_2} p\nabla \cdot \mathbf{v} dx \\ &= -\int_{\partial\Omega_2} \mathbf{v} \cdot \mathbf{n}_{\partial\Omega_2} p d\sigma = -\int_{\Gamma_{12}} \mathbf{v} \cdot \mathbf{n}_{\partial\Omega_2} p d\sigma. \end{aligned}$$

Since the trace of $\mathbf{v}$ can be arbitrarily chosen in $H_{00}^{\frac{1}{2}}(\Gamma_{12})^d$, we conclude that $p|_{\Omega_2} = \lambda$ on Γ_{12}. Hence p has the same trace on both sides of Γ_{12}, and therefore p belongs to $H^1(\Omega)$.

Finally, on Γ_{12}, (4.4) gives $-\mathbf{K}\nabla p|_{\Omega_1} \cdot \mathbf{n} = \mathbf{u} \cdot \mathbf{n} = -\mathbf{K}\nabla p|_{\Omega_2} \cdot \mathbf{n}$; that is, $\mathbf{K}\nabla p \cdot \mathbf{n}$ has the same trace on both sides of Γ_{12}. Therefore (2.1) is satisfied in the entire domain Ω. ∎

4.3. Discretization. We recall that the DG and MFE approximation spaces were introduced in section 2. Let $\Pi_h \in \mathcal{L}(H^1(\Omega_2)^d; \mathbf{V}_h(\Omega_2))$ be the standard MFE interpolation operator satisfying on any $E \in \mathcal{E}_h(\Omega_2)$ [17]

$$\int_E \nabla \cdot (\mathbf{u} - \Pi_h\mathbf{u})\, q_h \, dx = 0 \quad \forall\, q_h \in W_h(E), \tag{4.5}$$

$$\int_\gamma (\mathbf{u} - \Pi_h\mathbf{u}) \cdot \mathbf{n}\ \mathbf{v}_h \cdot \mathbf{n}\, d\sigma \quad \forall\, \mathbf{v}_h \in \mathbf{V}_h(E), \quad \forall \gamma \in \partial E, \tag{4.6}$$

$$\|\Pi_h\mathbf{u}\|_{H(\mathrm{div};E)} \le C\|\mathbf{u}\|_{1,E}, \tag{4.7}$$

$$\|\mathbf{u} - \Pi_h\mathbf{u}\|_{0,E} \le Ch^{m+1}|\mathbf{u}|_{m+1,E}. \tag{4.8}$$

These properties imply that for all MFE spaces under consideration [17]

$$\nabla \cdot \mathbf{V}_{h,0}(\Omega_2) = W_h(\Omega_2). \tag{4.9}$$

More precisely, we have the following inf-sup condition.

LEMMA 4.1. *Let $\mathcal{E}_h(\Omega_2)$ be nondegenerate. For any p_h in $W_h(\Omega_2)$, there exists $\mathbf{v}_h$ in $\mathbf{V}_{h,0}(\Omega_2)$ such that*

$$\nabla \cdot \mathbf{v}_h = p_h \quad \text{in } \Omega_2$$

and a constant C independent of $\mathbf{v}_h$, p_h, and h such that

$$\|\mathbf{v}_h\|_{H(\mathrm{div};\Omega_2)} + \|\mathbf{v}_h \cdot \mathbf{n}\|_{0,\Gamma_{12}} \le C\|p_h\|_{0,\Omega_2}. \tag{4.10}$$

Proof. First, we extend p_h by a constant function in Ω_1 so that its mean value is zero in Ω. Let $\tilde{p}_h$ denote the extended function. Then

$$\|\tilde{p}_h\|_{0,\Omega} \le C\|p_h\|_{0,\Omega_2}.$$

As $\tilde{p}_h$ has mean value zero in Ω, there exists $\mathbf{v}$ in $H_0^1(\Omega)^d$ such that (cf. [25])

$$\nabla \cdot \mathbf{v} = \tilde{p}_h \quad \text{in } \Omega$$

and

$$|\mathbf{v}|_{1,\Omega} \leq C\|\tilde{p}_h\|_{0,\Omega} \leq C\|p_h\|_{0,\Omega_2}. \tag{4.11}$$

Take $\mathbf{v}_h = \Pi_h \mathbf{v}$. Then we easily derive from (4.5)–(4.7) and the regularity of $\mathbf{v}$ that the restriction of $\mathbf{v}_h$ to Ω_2 belongs to $\mathbf{V}_{h,0}(\Omega_2)$ and satisfies (4.10). ∎

Let $\mathbf{u}_{h,g}$ be an adequate approximation of $\mathbf{u}_g$ in $\mathbf{V}_h(\Omega_2)$. The finite element mortar DG-MFE discretization is to find $(p_h|_{\Omega_1}, p_h|_{\Omega_2}, \mathbf{u}_h, \lambda_H)$ in $X_h(\Omega_1)\times W_h(\Omega_2)\times (\mathbf{V}_{h,0}(\Omega_2)+\mathbf{u}_{h,g})\times \Lambda_H$ such that the following equations hold for all $(q_h|_{\Omega_1}, q_h|_{\Omega_2}, \mathbf{v}_h, \mu_H)$ in $X_h(\Omega_1)\times W_h(\Omega_2)\times \mathbf{V}_{h,0}(\Omega_2)\times \Lambda_H$:

$$B(p_h, q_h) = L(q_h; \lambda_H), \tag{4.12}$$

$$\int_{\Omega_2} \mathbf{K}^{-1}\mathbf{u}_h \cdot \mathbf{v}_h dx = \int_{\Omega_2} p_h \nabla \cdot \mathbf{v}_h dx - \int_{\Gamma_{12}} \mathbf{v}_h \cdot \mathbf{n}_{\partial\Omega_2} \lambda_H d\sigma, \tag{4.13}$$

$$\int_{\Omega_2} \nabla \cdot \mathbf{u}_h q_h dx = \int_{\Omega_2} f q_h dx, \tag{4.14}$$

$$\int_{\Gamma_{12}} \mathbf{u}_h \cdot \mathbf{n} \mu_H d\sigma = -\int_{\Gamma_{12}} \mathbf{K}\nabla p_h|_{\Omega_1} \cdot \mathbf{n}\mu_H d\sigma + \sum_{\tau\in\Gamma_H} \frac{\sigma_\tau}{H_\tau} \int_\tau (p_h|_{\Omega_1} - \lambda_H)\mu_H d\sigma. \tag{4.15}$$

Note that both $\mathbf{u}_g$ and $\mathbf{u}_{h,g}$ are introduced only for theoretical reasons and in practice we need only to approximate g.

We now address the existence and uniqueness of the solution of the above system. This is a square finite-dimensional system, and existence is equivalent to uniqueness. Let $f = 0$ and $\mathbf{u}_{h,g} = \mathbf{0}$. By taking $q_h = p_h$ in (4.12), we have

$$\begin{aligned} &\sum_{E\in\mathcal{E}_h(\Omega_1)} \int_E \mathbf{K}\nabla p_h \cdot \nabla p_h dx - (1+s_{\text{form}}) \sum_{\gamma\in\Gamma_h(\Omega_1)} \int_\gamma \{\mathbf{K}\nabla p_h \cdot \mathbf{n}\}\,[p_h]\,d\sigma \\ &+ \sum_{\gamma\in\Gamma_h(\Omega_1)} \frac{\sigma_\gamma}{h_\gamma} \int_\gamma [p_h]^2\, d\sigma + \sum_{\tau\in\Gamma_H} \frac{\sigma_\tau}{H_\tau} \int_\tau p_h|_{\Omega_1}^2 d\sigma \\ &= \int_{\Gamma_{12}} \mathbf{K}\nabla p_h|_{\Omega_1} \cdot \mathbf{n}\lambda_H d\sigma + \sum_{\tau\in\Gamma_H} \frac{\sigma_\tau}{H_\tau} \int_\tau p_h|_{\Omega_1}\lambda_H d\sigma. \end{aligned} \tag{4.16}$$

By taking $\mathbf{v}_h = \mathbf{u}_h$ in (4.13) and $q_h = p_h$ in (4.14), we have

$$\int_{\Omega_2} \mathbf{K}^{-1}\mathbf{u}_h \cdot \mathbf{u}_h dx = -\int_{\Gamma_{12}} \mathbf{u}_h \cdot \mathbf{n}_{\partial\Omega_2} \lambda_H d\sigma = \int_{\Gamma_{12}} \mathbf{u}_h \cdot \mathbf{n}\lambda_H d\sigma. \tag{4.17}$$

By taking $\mu_H = \lambda_H$ in (4.15), we obtain

$$\int_{\Gamma_{12}} \mathbf{u}_h \cdot \mathbf{n}\lambda_H d\sigma = -\int_{\Gamma_{12}} \mathbf{K}\nabla p_h|_{\Omega_1} \cdot \mathbf{n}\lambda_H d\sigma + \sum_{\tau\in\Gamma_H} \frac{\sigma_\tau}{H_\tau} \int_\tau (p_h|_{\Omega_1} - \lambda_H)\lambda_H d\sigma. \tag{4.18}$$

Summation of (4.16), (4.17), and (4.18) leads to

$$\begin{aligned} &|\!|\!|\mathbf{K}^{\frac{1}{2}}\nabla p_h|\!|\!|_{0,\Omega_1}^2 - (1+s_{\text{form}}) \sum_{\gamma\in\Gamma_h(\Omega_1)} \int_\gamma \{\mathbf{K}\nabla p_h \cdot \mathbf{n}\}\,[p_h]\,d\sigma + \|\mathbf{K}^{-\frac{1}{2}}\mathbf{u}_h\|_{0,\Omega_2}^2 \\ &+ \sum_{\gamma\in\Gamma_h(\Omega_1)} \frac{\sigma_\gamma}{h_\gamma} \int_\gamma [p_h]^2\, d\sigma + \sum_{\tau\in\Gamma_H} \frac{\sigma_\tau}{H_\tau} \int_\tau (p_h|_{\Omega_1} - \lambda_H)^2 d\sigma = 0. \end{aligned} \tag{4.19}$$

First consider the case $0 < \sigma_\tau^0 \leq \sigma_\tau \leq \sigma_\tau^1$. As in section 3.3, we easily derive from (4.19) that for OBB-DG and NIPG, $\mathbf{u}_h = \mathbf{0}$ in Ω_2, p_h is a constant in Ω_1 and λ_H is the same constant on Γ_{12}. The same conclusion holds for SIPG and IIPG, by applying inequality (3.10).

Now as $\mathbf{u}_h$ is zero, (4.13) becomes

$$\forall \mathbf{v}_h \in \mathbf{V}_{h,0}(\Omega_2)\,, \int_{\Omega_2} p_h \nabla \cdot \mathbf{v}_h dx = \int_{\Gamma_{12}} \mathbf{v}_h \cdot \mathbf{n}_{\partial\Omega_2} \lambda_H d\sigma. \tag{4.20}$$

Let $\overline{p_h}$ denote the mean value of p_h in Ω_2: $\overline{p_h} = \frac{1}{|\Omega_2|}\int_{\Omega_2} p_h dx$. Then (4.20) implies that for all $\mathbf{v}_h$ in $\mathbf{V}_{h,0}(\Omega_2)$, with $\mathbf{v}_h \cdot \mathbf{n} = 0$ on $\partial\Omega_2$,

$$\int_{\Omega_2} (p_h - \overline{p_h}) \nabla \cdot \mathbf{v}_h dx = 0.$$

As $p_h - \overline{p_h}$ belongs to $W_h(\Omega_2)$ and has mean value zero, the argument of Lemma 4.1 implies that there exists $\mathbf{v}_h$ in $\mathbf{V}_h(\Omega_2)$, with $\mathbf{v}_h \cdot \mathbf{n} = 0$ on $\partial\Omega_2$, such that

$$\int_{\Omega_2} (p_h - \overline{p_h}) \nabla \cdot \mathbf{v}_h dx = \|p_h - \overline{p_h}\|_{0,\Omega_2}^2.$$

Therefore p_h is also constant in Ω_2, and (4.20) implies that

$$\forall \mathbf{v}_h \in \mathbf{V}_{h,0}(\Omega_2)\,, \int_{\Gamma_{12}} \mathbf{v}_h \cdot \mathbf{n} (\lambda_H - p_h|_{\Omega_2}) d\sigma = 0. \tag{4.21}$$

Since λ_H is constant and coincides with the trace of p_h coming from Ω_1, we infer from (4.21) that it also coincides with the trace of p_h coming from Ω_2. Thus p_h is constant in Ω.

There remains the case $\sigma_\tau = 0$. With the information we have so far, (4.12) implies that

$$\int_{\Gamma_{12}} \mathbf{K} \nabla q_h|_{\Omega_1} \cdot \mathbf{n} (\lambda_H - p_h|_{\Omega_1}) d\sigma = 0. \tag{4.22}$$

If the mortar compatibility condition (A.2) is satisfied, since p_h is constant in Ω_2, (4.21) implies that $\lambda_H = p_h|_{\Omega_2}$. Thus, λ_H is constant, and (4.22) implies readily that p_h has the same trace on both sides of Γ_{12}. If the mortar compatibility condition (A.1) holds, as p_h is constant in Ω_1, then (4.22) implies that $\lambda_H = p_h|_{\Omega_1}$. Hence λ_H is constant, and (4.21) implies again that $\lambda_H = p_h|_{\Omega_2}$; therefore p_h is constant in Ω.

We have shown for all schemes that $\mathbf{u}_h$ is unique and that the null space of the linear system (4.12)–(4.15) for p_h and λ_H is the constant vector. The compatibility condition (2.3) implies that the right-hand side is orthogonal to the null space, and therefore the solution exists and is unique up to an additive constant for p_h and λ_H. We have proved the following solvability theorem.

THEOREM 4.2. *For OBB-DG, we assume that $r \geq 2$. For SIPG and IIPG, we assume that σ_γ^0 is sufficiently large. No assumption is needed for NIPG. Then the scheme* (4.12)–(4.15) *possesses a solution $(p_h, \mathbf{u}_h, \lambda_H)$ unique up to an additive constant that is the same for p_h and λ_H. The same conclusion holds if $\sigma_\tau = 0$, assuming that either the compatibility condition* (A.1) *for $i = 1$ or* (A.2) *holds.*

4.4. Convergence. We define the interpolant $\hat{p}$ of p such that $\hat{p}$ in Ω_2 is the L^2-projection and $\hat{p}$ in Ω_1 is defined as in the previous section. Then, on any $E \in \mathcal{E}_h(\Omega_2)$, $\hat{p}$ satisfies

$$\|p - \hat{p}\|_{0,E} \leq C h_E^{l+1} |p|_{l+1,E}. \tag{4.23}$$

For $\bar{p}$, we take again the continuous nodal interpolant of p in Λ_H. Now we choose $\mathbf{u}_{h,g}$. On any $\gamma \subset \partial E \cap (\partial\Omega_2 \setminus \Gamma_{12})$, considering that $\mathbf{u} \cdot \mathbf{n} = g$, we define $P_h g$ by

$$P_h g = (\Pi_h \mathbf{u} \cdot \mathbf{n})|_\gamma.$$

Since, by construction, $(\Pi_h \mathbf{u} \cdot \mathbf{n})|_\gamma$ does not depend on the interior values of $\mathbf{u}$, $P_h g$ depends only on g. Then we can take for $\mathbf{u}_{h,g}$ any function in $\mathbf{V}_h(\Omega_2)$ such that $\mathbf{u}_{h,g} = P_h g$ on $\partial\Omega_2 \setminus \Gamma_{12}$. All results derived below are independent of this choice and depend only on $P_h g$. To prove the convergence theorem below, we need the following trace inequality. The proof is a variant of those derived by Brenner in [13]; see also [41]. It is stated in Ω_1, but it is valid in any connected Lipschitz domain.

THEOREM 4.3. *Let $\mathcal{E}_h(\Omega_1)$ be nondegenerate, and let Γ be any portion of $\partial\Omega_1$ with positive measure. Assume that $0 < \sigma_\gamma^0 \leq \sigma_\gamma \leq \sigma_\gamma^1$. Then there exists a constant C, independent of h such that, for all functions q_h in $X_h(\Omega_1)$, the following trace inequality holds:*

$$\int_{\Gamma_{12}} q_h^2 d\sigma \leq C \left(\|\mathbf{K}^{\frac{1}{2}} \nabla q_h\|_{0,\Omega_1}^2 + \sum_{\gamma \in \Gamma_h(\Omega_1)} \frac{\sigma_\gamma}{h_\gamma} \int_\gamma [q_h]^2 \, d\sigma + \left| \int_\Gamma q_h \, d\sigma \right|^2 \right). \tag{4.24}$$

We proceed with the convergence analysis of the coupled DG-MFE methods. We consider only the cases of NIPG, SIPG, or IIPG, since Theorem 4.3 does not apply in the case of OBB-DG. We comment on that case in Remark 4.1.

THEOREM 4.4. *Let $\mathcal{E}_h(\Omega_i)$ $i = 1, 2$, be nondegenerate. Let $p \in H^s(\Omega)$, $s \geq 2$, be a solution of (2.1)–(2.2), and let $\mathbf{u} = -\mathbf{K}\nabla p$. Let $(p_h, \mathbf{u}_h, \lambda_H)$ be a solution of (4.12)–(4.15), where NIPG, SIPG, or IIPG is used in (4.12). We assume that σ_γ^0 is sufficiently large for SIPG and IIPG. Then there exists a constant C, independent of h and H, such that*

$$\|\mathbf{K}^{\frac{1}{2}} \nabla (p_h - p)\|_{0,\Omega_1} + \sqrt{\sum_{\gamma \in \Gamma_h(\Omega_1)} \frac{\sigma_\gamma}{h_\gamma} \|[p_h]\|_{0,\gamma}^2} + \left\| \mathbf{K}^{-\frac{1}{2}} (\mathbf{u}_h - \mathbf{u}) \right\|_{0,\Omega_2}$$
$$+ \sqrt{\sum_{\tau \in \Gamma_H} \frac{\sigma_\tau}{H_\tau} \left\| p_h|_{\Omega_1} - \lambda_H \right\|_{0,\tau}^2} \leq C \left(h^{\mu-1} \left(\frac{H}{h} \right)^{\frac{1}{2}} + H^{\bar{\mu} - \frac{1}{2}} + h^\nu \right),$$

where $\mu = \min(r+1, s)$, $\bar{\mu} = \min\left(\bar{r}+1, s - \frac{1}{2}\right)$, and $\nu = \min\left(m+1, s - \frac{3}{2}\right)$.

Proof. In addition to the error variables η, η^I, η^A, ξ, ξ^I, and ξ^A introduced in section 3.4, we define

$$\chi := \mathbf{u}_h - \mathbf{u}, \quad \chi^I := \mathbf{u} - \Pi_h \mathbf{u}, \quad \chi^A := \mathbf{u}_h - \Pi_h \mathbf{u} = \chi + \chi^I,$$

and observe that, owing to the choice of $\mathbf{u}_{h,g}$, χ^A belongs to $\mathbf{V}_{h,0}(\Omega_2)$. By subtracting the weak formulation (4.1) from the finite element scheme (4.12), and choosing $q_h = \xi^A$, we obtain

$$\begin{aligned} B(\xi^A, \xi^A) &= B(\xi^I, \xi^A) + L(\xi^A; \lambda_H) - L(\xi^A; p) \\ &= B(\xi^I, \xi^A) + \int_{\Gamma_{12}} \mathbf{K}\nabla \xi^A|_{\Omega_1} \cdot \mathbf{n} \eta \, d\sigma + \sum_{\tau \in \Gamma_H} \frac{\sigma_\tau}{H_\tau} \int_\tau \xi^A|_{\Omega_1} \eta \, d\sigma. \end{aligned} \tag{4.25}$$

By subtracting from the mixed finite element scheme (4.13)–(4.14) the corresponding weak formulation (4.2)–(4.3), we obtain the error equations for all $(\mathbf{v}_h, q_h)$ in $\mathbf{V}_{h,0}(\Omega_2) \times W_h(\Omega_2)$:

$$\int_{\Omega_2} \mathbf{K}^{-1}\chi \cdot \mathbf{v}_h \, dx = \int_{\Omega_2} \xi^A \, \nabla \cdot \mathbf{v}_h \, dx - \int_{\Gamma_{12}} \mathbf{v}_h \cdot \mathbf{n}_{\partial\Omega_2} \eta d\sigma, \tag{4.26}$$

$$\int_{\Omega_2} \nabla \cdot \chi^A \, q_h \, dx = 0, \tag{4.27}$$

where we have used the properties (4.9) and (4.5). Note that (4.27) and (4.9) imply that

$$\nabla \cdot \chi^A = 0. \tag{4.28}$$

By taking $\mathbf{v}_h = \chi^A$ in the equations above and noting that $\mathbf{n} = -\mathbf{n}_{\partial\Omega_2}$, we have

$$\int_{\Omega_2} \mathbf{K}^{-1}\chi \cdot \chi^A dx - \int_{\Gamma_{12}} \chi^A \cdot \mathbf{n} \, \eta \, d\sigma = 0. \tag{4.29}$$

Similarly, by subtracting the matching condition (4.4) from its finite element formulation (4.15), and taking $\mu_H = \eta^A$, we obtain

$$\int_{\Gamma_{12}} \chi \cdot \mathbf{n} \eta^A d\sigma = -\int_{\Gamma_{12}} \mathbf{K}\nabla\xi|_{\Omega_1} \cdot \mathbf{n}\eta^A d\sigma + \sum_{\tau \in \Gamma_H} \frac{\sigma_\tau}{H_\tau} \int_\tau (\xi|_{\Omega_1} - \eta)\eta^A d\sigma. \tag{4.30}$$

Summation of (4.25), (4.29), and (4.30) yields

$$\begin{aligned} B(\xi^A, \xi^A) &+ \int_{\Omega_2} \mathbf{K}^{-1}\chi \cdot \chi^A dx - \int_{\Gamma_{12}} \chi^A \cdot \mathbf{n}\eta d\sigma + \int_{\Gamma_{12}} \chi \cdot \mathbf{n}\eta^A d\sigma \\ &= B(\xi^I, \xi^A) + \int_{\Gamma_{12}} \mathbf{K}\nabla\xi^A|_{\Omega_1} \cdot \mathbf{n}\eta d\sigma + \sum_{\tau \in \Gamma_H} \frac{\sigma_\tau}{H_\tau} \int_\tau \xi^A\big|_{\Omega_1} \eta d\sigma \\ &\quad - \int_{\Gamma_{12}} \mathbf{K}\nabla\xi|_{\Omega_1} \cdot \mathbf{n}\eta^A d\sigma + \sum_{\tau \in \Gamma_H} \frac{\sigma_\tau}{H_\tau} \int_\tau (\xi|_{\Omega_1} - \eta)\eta^A d\sigma. \end{aligned}$$

Rearranging terms results in

$$\begin{aligned} &B(\xi^A, \xi^A) + \|\mathbf{K}^{-\frac{1}{2}}\chi^A\|^2_{0,\Omega_2} + \sum_{\tau \subset \Gamma_H} \frac{\sigma_\tau}{H_\tau} \int_\tau (\xi^A\big|_{\Omega_1} - \eta^A)^2 d\sigma - \sum_{\tau \in \Gamma_H} \frac{\sigma_\tau}{H_\tau} \int_\tau (\xi^A\big|_{\Omega_1})^2 d\sigma \\ &= B(\xi^I, \xi^A) - \int_{\Gamma_{12}} \mathbf{K}\nabla\xi^A|_{\Omega_1} \cdot \mathbf{n}\eta^I d\sigma - \sum_{\tau \in \Gamma_H} \frac{\sigma_\tau}{H_\tau} \int_\tau \xi^A\big|_{\Omega_1} \eta^I d\sigma \\ &\quad - \sum_{\tau \in \Gamma_H} \frac{\sigma_\tau}{H_\tau} \int_\tau (\xi^I\big|_{\Omega_1} - \eta^I)\eta^A d\sigma + \int_{\Gamma_{12}} \mathbf{K}\nabla\xi^I\big|_{\Omega_1} \cdot \mathbf{n}\eta^A d\sigma \\ &\quad + \int_{\Omega_2} \mathbf{K}^{-1}\chi^I \cdot \chi^A dx - \int_{\Gamma_{12}} \chi^A \cdot \mathbf{n}\eta^I d\sigma + \int_{\Gamma_{12}} \chi^I \cdot \mathbf{n}\eta^A d\sigma. \end{aligned} \tag{4.31}$$

We denote by L_{ErrEqu} the left-hand side of (4.31) and apply an algebraic manipulation to obtain

$$\begin{aligned} L_{\mathrm{ErrEqu}} &= \|\mathbf{K}^{\frac{1}{2}}\nabla\xi^A\|^2_{0,\Omega_1} - (1 + s_{\mathrm{form}}) \sum_{\gamma \in \Gamma_h(\Omega_1)} \int_\gamma \left\{\mathbf{K}\nabla\xi^A \cdot \mathbf{n}\right\} \left[\xi^A\right] d\sigma \\ &\quad + \sum_{\gamma \in \Gamma_h(\Omega_1)} \frac{\sigma_\gamma}{h_\gamma} \int_\gamma \left[\xi^A\right]^2 d\sigma + \|\mathbf{K}^{-\frac{1}{2}}\chi^A\|^2_{0,\Omega_2} + \sum_{\tau \in \Gamma_H} \frac{\sigma_\tau}{H_\tau} \int_\tau (\xi^A\big|_{\Omega_1} - \eta^A)^2 d\sigma. \end{aligned}$$

For NIPG and OBB-DG, the second term in L_{ErrEqu} vanishes, leaving only the coercive terms. For SIPG and IIPG, we employ the inequality (3.10) with $q_h = q = \xi^A$ to conclude that

$$L_{\text{ErrEqu}} \geq \frac{3}{4}\|\mathbf{K}^{\frac{1}{2}}\nabla\xi^A\|^2_{0,\Omega_1} + \frac{3}{4}\sum_{\gamma\in\Gamma_h(\Omega_1)}\frac{\sigma_\gamma}{h_\gamma}\int_\gamma \left[\xi^A\right]^2 d\sigma + \left\|\mathbf{K}^{-\frac{1}{2}}\chi^A\right\|^2_{0,\Omega_2} + \sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\int_\tau \left(\xi^A|_{\Omega_1} - \eta^A\right)^2 d\sigma.$$

We now consider the right-hand side of (4.31), which is denoted by R_{ErrEqu}. By expanding the first term as

$$\begin{aligned} B(\xi^I,\xi^A) &= \sum_{E\in\mathcal{E}_h(\Omega_1)}\int_E \mathbf{K}\nabla\xi^I\cdot\nabla\xi^A dx - \sum_{\gamma\in\Gamma_h(\Omega_1)}\int_\gamma \left\{\mathbf{K}\nabla\xi^I\cdot\mathbf{n}\right\}\left[\xi^A\right] d\sigma \\ &- s_{\text{form}}\sum_{\gamma\in\Gamma_h(\Omega_1)}\int_\gamma \left\{\mathbf{K}\nabla\xi^A\cdot\mathbf{n}\right\}\left[\xi^I\right] d\sigma - \int_{\Gamma_{12}}\mathbf{K}\nabla\xi^I|_{\Omega_1}\cdot\mathbf{n}\xi^A|_{\Omega_1} d\sigma \\ &+ \int_{\Gamma_{12}}\mathbf{K}\nabla\xi^A|_{\Omega_1}\cdot\mathbf{n}\xi^I|_{\Omega_1} d\sigma + \sum_{\gamma\in\Gamma_h(\Omega_1)}\frac{\sigma_\gamma}{h_\gamma}\int_\gamma\left[\xi^I\right]\left[\xi^A\right] d\sigma + \sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\int_\tau \xi^I|_{\Omega_1}\xi^A|_{\Omega_1} d\sigma, \end{aligned}$$

we have

$$\begin{aligned} R_{\text{ErrEqu}} &= \sum_{E\in\mathcal{E}_h(\Omega_1)}\int_E \mathbf{K}\nabla\xi^I\cdot\nabla\xi^A dx - \sum_{\gamma\in\Gamma_h(\Omega_1)}\int_\gamma \left\{\mathbf{K}\nabla\xi^I\cdot\mathbf{n}\right\}\left[\xi^A\right] d\sigma \\ &- s_{\text{form}}\sum_{\gamma\in\Gamma_h(\Omega_1)}\int_\gamma \left\{\mathbf{K}\nabla\xi^A\cdot\mathbf{n}\right\}\left[\xi^I\right] d\sigma + \sum_{\gamma\in\Gamma_h(\Omega_1)}\frac{\sigma_\gamma}{h_\gamma}\int_\gamma\left[\xi^I\right]\left[\xi^A\right] d\sigma \\ &+ \sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\int_\tau (\xi^I|_{\Omega_1} - \eta^I)(\xi^A|_{\Omega_1} - \eta^A) d\sigma \\ &+ \int_{\Omega_2}\mathbf{K}^{-1}\chi^I\cdot\chi^A dx - \int_{\Gamma_{12}}\chi^A\cdot\mathbf{n}\eta^I d\sigma + \int_{\Gamma_{12}}\chi^I\cdot\mathbf{n}\eta^A d\sigma \\ &- \int_{\Gamma_{12}}\mathbf{K}\nabla\xi^A|_{\Omega_1}\cdot\mathbf{n}\left(\eta^I - \xi^I|_{\Omega_1}\right) d\sigma + \int_{\Gamma_{12}}\mathbf{K}\nabla\xi^I|_{\Omega_1}\cdot\mathbf{n}\left(\eta^A - \xi^A|_{\Omega_1}\right) d\sigma =: \sum_{i=1}^{10} T_i. \end{aligned}$$

We now bound each term in R_{ErrEqu}. We skip terms T_1–T_5 because they have the same bounds as in the proof of Theorem 3.3. Next, (4.8) implies that

$$|T_6| \leq \epsilon\left\|\mathbf{K}^{-\frac{1}{2}}\chi^A\right\|^2_{0,\Omega_2} + C\left\|\mathbf{K}^{-\frac{1}{2}}\chi^I\right\|^2_{0,\Omega_2} \leq \epsilon\left\|\mathbf{K}^{-\frac{1}{2}}\chi^A\right\|^2_{0,\Omega_2} + Ch^{2\nu}.$$

To bound term T_7, let $\tilde{\eta}^I = P_2(\eta^I)$, where $P_2 \in \mathcal{L}(H^{\frac{1}{2}}(\Gamma_{12}); H^1(\Omega_2))$ is the analogue of P_1. By considering that $\chi^A\cdot\mathbf{n}$ vanishes on $\partial\Omega_2\setminus\Gamma_{12}$, we can write

$$|T_7| \leq \left|\int_{\partial\Omega_2}(\chi^A\cdot\mathbf{n})\tilde{\eta}^I d\sigma\right| \leq \|\chi^A\cdot\mathbf{n}\|_{-\frac{1}{2},\partial\Omega_2}\|\tilde{\eta}^I\|_{\frac{1}{2},\partial\Omega_2} \leq C\left\|\chi^A\right\|_{H(\text{div};\Omega_2)}\left\|\eta^I\right\|_{\frac{1}{2},\Gamma_{12}}.$$

Then, by using (4.28) and (3.26), we obtain

$$|T_7| \leq \epsilon\left\|\mathbf{K}^{-\frac{1}{2}}\chi^A\right\|^2_{0,\Omega_2} + CH^{2\bar{\mu}-1}.$$

To estimate T_8, we split it into

$$\int_{\Gamma_{12}} (\chi^I \cdot \mathbf{n})\eta^A d\sigma = \int_{\Gamma_{12}} (\chi^I \cdot \mathbf{n})(\eta^A - \xi^A) d\sigma + \int_{\Gamma_{12}} (\chi^I \cdot \mathbf{n})\xi^A d\sigma,$$

and we consider first the last term. Let $\overline{\xi^A} = \frac{1}{|\Gamma_{12}|}\int_{\Gamma_{12}} \xi^A d\sigma$. The approximation property (4.6) of Π_h implies that

$$\int_{\Gamma_{12}} (\chi^I \cdot \mathbf{n})\xi^A d\sigma = \int_{\Gamma_{12}} (\chi^I \cdot \mathbf{n})(\xi^A - \overline{\xi^A}) d\sigma.$$

As $\xi^A - \overline{\xi^A}$ has mean value zero on Γ_{12} and $\overline{\xi^A}$ is a constant, the trace Theorem 4.3 yields:

$$\left| \int_{\Gamma_{12}} (\chi^I \cdot \mathbf{n})\xi^A d\sigma \right| \leq C \|\chi^I \cdot \mathbf{n}\|_{0,\Gamma_{12}} \left(|\!|\!| \mathbf{K}^{\frac{1}{2}} \nabla \xi^A |\!|\!|^2_{0,\Omega_1} + \sum_{\gamma \in \Gamma_h(\Omega_1)} \frac{\sigma_\gamma}{h_\gamma} \|[\xi^A]\|^2_{0,\gamma} \right)^{\frac{1}{2}}.$$

As far as the first term is concerned, we write

$$\left| \int_{\Gamma_{12}} (\chi^I \cdot \mathbf{n})(\eta^A - \xi^A) d\sigma \right| \leq \left(\sum_{\tau \in \Gamma_H} \frac{\sigma_\tau}{H_\tau} \|\eta^A - \xi^A\|^2_{0,\tau} \right)^{\frac{1}{2}} \left(\sum_{\tau \in \Gamma_H} \frac{H_\tau}{\sigma_\tau} \|\chi^I \cdot \mathbf{n}\|^2_{0,\tau} \right)^{\frac{1}{2}}.$$

By collecting these inequalities and using the approximation properties of Π_h, we derive:

$$|T_8| \leq \epsilon \sum_{\gamma \in \Gamma_h(\Omega_1)} \frac{\sigma_\gamma}{h_\gamma} \int_\gamma \left[\xi^A\right]^2 d\sigma + \epsilon |\!|\!| \mathbf{K}^{\frac{1}{2}} \nabla \xi^A |\!|\!|^2_{\Omega_1} + \epsilon \sum_{\tau \in \Gamma_H} \frac{\sigma_\tau}{H_\tau} \int_\tau \left(\xi^A\big|_{\Omega_1} - \eta^A \right)^2 d\sigma + C h^{2\nu}.$$

Term T_9 can be bounded by using the argument for $T_{6,1}$ in Theorem 3.3:

$$|T_9| \leq \epsilon |\!|\!| \mathbf{K}^{\frac{1}{2}} \nabla \xi^A |\!|\!|^2_{0,\Omega_1} + \epsilon \sum_{\gamma \in \Gamma_h(\Omega_1)} \frac{\sigma_\gamma}{h_\gamma} \|[p_h]\|^2_{0,\gamma} + \epsilon \sum_{\tau \in \Gamma_H} \frac{\sigma_\tau}{H_\tau} \left\| \xi^A\big|_{\Omega_1} - \eta^A \right\|^2_{0,\tau} + C(h^{2\mu-2} + H^{2\bar{\mu}-1}).$$

The estimate of the last term is the same as for T_7 in Theorem 3.3:

$$|T_{10}| \leq \epsilon \sum_{\tau \in \Gamma_H} \frac{\sigma_\tau}{H_\tau} \left\| \eta^A - \xi^A|_{\Omega_1} \right\|^2_{0,\tau} + C h^{2\mu-3} H.$$

Finally, we combine all terms to conclude that

$$|\!|\!| \mathbf{K}^{\frac{1}{2}} \nabla \xi^A |\!|\!|^2_{0,\Omega_1} + \sum_{\gamma \in \Gamma_h(\Omega_1)} \frac{\sigma_\gamma}{h_\gamma} \left\| \left[\xi^A\right] \right\|^2_{0,\gamma} + \left\| \mathbf{K}^{-\frac{1}{2}} \chi^A \right\|^2_{0,\Omega_2} + \sum_{\tau \in \Gamma_H} \frac{\sigma_\tau}{H_\tau} \left\| \xi^A\big|_{\Omega_1} - \eta^A \right\|^2_{0,\tau} \leq C \left(h^{2\mu-2} \left(\frac{H}{h} \right) + H^{2\bar{\mu}-1} + h^{2\nu} \right).$$

An application of the triangle inequality completes the proof. ∎

Remark 4.1. The difficulty in coupling OBB-DG with MFE in the above proof lies in the estimate of term T_8. The term is bounded by using the special trace inequality

from Theorem 4.3, which involves penalized jump terms on interior edges (faces). An alternative approach to handle T_8 is to construct a special MFE interpolant $\tilde{\Pi}\mathbf{u}$ satisfying

$$\forall \mu_H \in \Lambda_H\,, \int_{\Gamma_{12}} (\mathbf{u} - \tilde{\Pi}\mathbf{u}) \cdot \mathbf{n} \mu_H \, d\sigma = 0.$$

This can be done by assuming a specific relation between the mortar grid and the MFE grid. Due to lack of space, we do not pursue this approach further here.

Remark 4.2. The cases $\bar{s}_{\text{form}} = 0$ or 1 can be treated as in Remark 3.1. It can be shown for the modified DG-MFE methods that, under the assumptions of Theorem 4.4, there exists a constant C, independent of h and H, such that

$$\begin{aligned}
&\left|\!\left|\!\left| \mathbf{K}^{\frac{1}{2}} \nabla (p_h - p) \right|\!\right|\!\right|_{\Omega_1} + \sqrt{\sum_{\gamma \in \Gamma_h(\Omega_1)} \frac{\sigma_\gamma}{h_\gamma} \left\| [p_h] \right\|_{0,\gamma}^2} + \left\| \mathbf{K}^{-\frac{1}{2}} (\mathbf{u}_h - \mathbf{u}) \right\|_{0,\Omega_2} \\
&\quad + \sqrt{\sum_{\gamma \in \Gamma_h(\Omega_1)} \frac{\sigma_\gamma}{h_\gamma} \left\| p_h|_{\Omega_1} - \lambda_H \right\|_{0,\gamma}^2} \le C \left(h^{\mu-1} + H^{\bar{\mu}-\frac{1}{2}} \left(\frac{H}{h} \right)^{\frac{1}{2}} + h^{\nu} \right), \\
&\qquad \|p_h - p\|_{0,\Omega_2} \le C \left(h^{\mu-1} + H^{\bar{\mu}-\frac{1}{2}} \left(\frac{H}{h} \right)^{\frac{1}{2}} + h^{\nu} + h^{\bar{\nu}} \right),
\end{aligned}$$

where $\mu = \min(r+1, s)$, $\bar{\mu} = \min\left(\bar{r}+1, s-\frac{1}{2}\right)$, $\nu = \min\left(m+1, s-\frac{3}{2}\right)$, and $\bar{\nu} = \min(l+1, s)$.

4.4.1. Convergence for the MFE pressure. To estimate the error on the pressure computed by the MFE method in Ω_2, we start again with the error equation (4.26). By virtue of the inf-sup condition in Lemma 4.1, we can choose in (4.26) $\mathbf{v}_h \in \mathbf{V}_{h,0}(\Omega_2)$ such that

$$\int_{\Omega_2} (p_h - \hat{p}) \nabla \cdot \mathbf{v}_h \, dx = \|p_h - \hat{p}\|_{0,\Omega_2}^2,$$

$$\|\mathbf{v}_h\|_{H(\text{div};\Omega_2)} + \|\mathbf{v}_h \cdot \mathbf{n}\|_{0,\Gamma_{12}} \le C \|p_h - \hat{p}\|_{0,\Omega_2}.$$

Therefore,

$$\|p_h - \hat{p}\|_{0,\Omega_2} \le C \left(\|\mathbf{K}^{-\frac{1}{2}} (\mathbf{u}_h - \mathbf{u})\|_{0,\Omega_2} + \|\lambda_H - p\|_{0,\Gamma_{12}} \right).$$

The first term on the right is bounded in Theorem 4.4. For the second term on the right, we have

$$\|\lambda_H - p\|_{0,\Gamma_{12}} \le \|\lambda_H - p_h|_{\Omega_1}\|_{0,\Gamma_{12}} + \|p_h|_{\Omega_1} - p\|_{0,\Gamma_{12}}.$$

The first term on right above is bounded in Theorem 4.4. Finally, by choosing the undetermined coefficient in p_h such that $\int_{\Gamma_{12}} (p - p_h|_{\Omega_1}) \, d\sigma = 0$, and applying Theorem 4.3, the last term above can be controlled by terms bounded in Theorem 4.4.

Thus, by using a triangle inequality and (4.23), we derive the following theorem.

THEOREM 4.5. *Let the assumptions of Theorem* 4.4 *hold, and let* $\int_{\Gamma_{12}} (p - p_h) \, d\sigma = 0$. *Then there exists a constant* C*, independent of* h *and* H*, such that*

$$\|p_h - p\|_{0,\Omega_2} \le C \left(h^{\mu-1} \left(\frac{H}{h} \right)^{\frac{1}{2}} + H^{\bar{\mu}-\frac{1}{2}} + h^{\nu} + h^{\bar{\nu}} \right),$$

where $\mu = \min(r+1, s)$, $\bar{\mu} = \min\left(\bar{r}+1, s-\frac{1}{2}\right)$, $\nu = \min\left(m+1, s-\frac{3}{2}\right)$, *and* $\bar{\nu} = \min(l+1, s)$.

Remark 4.3. When Ω is decomposed into several subdomains, then the last step in the proof of Theorem 4.5 involves the estimate of $p - p_h$ over the union of several interfaces, say, $\Gamma = \cup_{1\le i\le \ell}\Gamma_i$. The statement of Theorem 4.3 can be extended to this case. Therefore, it suffices to choose the undetermined constant in p_h such that $\int_\Gamma (p_h - p)d\sigma = 0$.

4.5. The interface operator and the reduced problem. Recall the definition of $l_i(\cdot)$ and $b_i(\cdot,\cdot)$ in (3.33) and (3.34), respectively. We now define a bilinear form $d_H : L^2(\Gamma_{12}) \times L^2(\Gamma_{12}) \mapsto \mathbb{R}$ for $\lambda, \mu \in L^2(\Gamma_{12})$ by $d_H(\lambda,\mu) := \sum_{i=1}^2 d_{H,i}(\lambda,\mu)$:

$$d_{H,1}(\lambda,\mu) := \int_{\Gamma_{12}} \mathbf{K}\,\nabla p_h^*(\lambda)|_{\Omega_1}\cdot \mathbf{n}_{\partial\Omega_1}\mu d\sigma - \sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\int_\tau (p_h^*(\lambda)|_{\Omega_1} - \lambda)\mu d\sigma,$$

$$d_{H,2}(\lambda,\mu) := -\int_{\Gamma_{12}} \mathbf{u}_h^*(\lambda)|_{\Omega_2}\cdot \mathbf{n}_{\partial\Omega_2}\mu d\sigma,$$

where $p_h^*(\lambda) \in X_h(\Omega_1)$ is the solution of

$$B_1\left(p_h^*(\lambda), q_h\right) = b_1\left(\lambda, q_h\right) \quad \forall q_h \in X_h(\Omega_1) \tag{4.32}$$

and $\mathbf{u}_h^*(\lambda)$ is the first component of the solution $(\mathbf{u}_h^*(\lambda), p_h^*(\lambda)) \in \mathbf{V}_{h,0}(\Omega_2)\times W_h(\Omega_2)$ of

(4.33)

$$\int_{\Omega_2}\mathbf{K}^{-1}\mathbf{u}_h^*(\lambda)\cdot\mathbf{v}_h dx = \int_{\Omega_2} p_h^*(\lambda)\nabla\cdot\mathbf{v}_h dx - \int_{\Gamma_{12}}\mathbf{v}_h\cdot\mathbf{n}_{\partial\Omega_2}\lambda d\sigma \quad \forall \mathbf{v}_h\in\mathbf{V}_{h,0}(\Omega_2),$$

$$\int_{\Omega_2}\nabla\cdot\mathbf{u}_h^*(\lambda) q_h dx = 0 \quad \forall q_h \in W_h(\Omega_2).$$

Define a linear functional $g_H : L^2(\Gamma_{12}) \mapsto \mathbb{R}$ by $g_H(\mu) := \sum_{i=1}^2 g_{H,i}(\mu)$:

$$g_{H,1}(\mu) := -\int_{\Gamma_{12}} \mathbf{K}\,\nabla\bar{p}_h|_{\Omega_1}\cdot\mathbf{n}_{\partial\Omega_1}\mu d\sigma + \sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\int_\tau \bar{p}_h|_{\Omega_1}\mu d\sigma,$$

$$g_{H,2}(\mu) := \int_{\Gamma_{12}}\bar{\mathbf{u}}_h|_{\Omega_2}\cdot\mathbf{n}_{\partial\Omega_2}\mu d\sigma,$$

where $\bar{p}_h \in X_h(\Omega_1)$ solves

$$B_1\left(\bar{p}_h, q_h\right) = l_1\left(q_h\right) \quad \forall q_h \in W_h(\Omega_1)$$

and $\bar{\mathbf{u}}_h$ is the first component of the solution $(\bar{\mathbf{u}}_h, \bar{p}_h) \in (\mathbf{V}_{h,0}(\Omega_2) + \mathbf{u}_{h,g})\times W_h(\Omega_2)$ of

$$\int_{\Omega_2}\mathbf{K}^{-1}\bar{\mathbf{u}}_h\cdot\mathbf{v}_h dx = \int_{\Omega_2}\bar{p}_h\nabla\cdot\mathbf{v}_h dx \quad \forall\mathbf{v}_h\in\mathbf{V}_{h,0}(\Omega_2),$$

$$\int_{\Omega_2}\nabla\cdot\bar{\mathbf{u}}_h\, q_h dx = \int_{\Omega_2} f\, q_h\, dx \quad \forall q_h\in W_h(\Omega_2).$$

It is easy to see that the solution $(p_h, \mathbf{u}_h, \lambda_H)$ of the DG-MFE scheme (4.12)–(4.15) satisfies

$$d_H\left(\lambda_H, \mu_H\right) = g_H\left(\mu_H\right), \quad \mu_H \in \lambda_H,$$

with

$$p_h = p_h^*(\lambda_H) + \bar{p}_h \quad \text{on } \Omega_1 \text{ and } \Omega_2; \qquad \mathbf{u}_h = \mathbf{u}_h^*(\lambda_H) + \bar{\mathbf{u}}_h \quad \text{on } \Omega_2.$$

We now analyze the properties of the bilinear form $d_H(\cdot,\cdot)$ for the various DG-MFE schemes. By taking $q_h = p_h^*(\mu)$ in (4.32) and $\mathbf{v}_h = \mathbf{u}_h^*(\mu)$ in (4.33) for some $\mu \in L^2(\Gamma_{12})$, we obtain

$$B_1\left(p_h^*(\lambda), p_h^*(\mu)\right) = b_1\left(\lambda, p_h^*(\mu)\right) \tag{4.34}$$

and

$$\int_{\Omega_2} \mathbf{K}^{-1}\mathbf{u}_h^*(\lambda)\cdot\mathbf{u}_h^*(\mu)\,dx = -\int_{\Gamma_{12}} \mathbf{u}_h^*(\mu)\cdot\mathbf{n}_{\partial\Omega_2}\lambda\,d\sigma. \tag{4.35}$$

By using (3.34), (4.34), and (4.35), we have the following representation of $d_H(\cdot,\cdot)$:

$$\begin{aligned} d_H(\lambda,\mu) &= b_1(\mu, p_h^*(\lambda)) - 2\sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\int_\tau p_h^*(\lambda)|_{\Omega_1}\mu\,d\sigma \\ &\quad + \sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\int_\tau \lambda\,\mu\,d\sigma - \int_{\Gamma_{12}} \mathbf{u}_h^*(\lambda)|_{\Omega_2}\cdot\mathbf{n}_{\partial\Omega_2}\mu\,d\sigma \\ &= B_1(p_h^*(\mu), p_h^*(\lambda)) - 2\sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\int_\tau p_h^*(\lambda)|_{\Omega_1}\mu\,d\sigma \\ &\quad + \sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\int_\tau \lambda\,\mu\,d\sigma + \int_{\Omega_2}\mathbf{K}^{-1}\mathbf{u}_h^*(\mu)\mathbf{u}_h^*(\lambda)\,dx. \end{aligned}$$

By an argument similar to that used in proving (3.40), using the above representation and (3.1), we obtain

$$\begin{aligned} d_H(\lambda,\lambda) &\geq \frac{3}{4}\|\mathbf{K}^{\frac{1}{2}}\nabla p_h^*(\lambda)\|_{\Omega_1}^2 + \frac{3}{4}\sum_{\gamma\in\Gamma_h(\Omega_1)}\frac{\sigma_\gamma}{h_\gamma}\int_\gamma \left[p_h^*(\lambda)\right]^2 d\sigma \\ &\quad + \sum_{\tau\in\Gamma_H}\frac{\sigma_\tau}{H_\tau}\int_\tau \left(p_h^*(\lambda)|_{\Omega_1} - \lambda\right)^2 d\sigma + \|\mathbf{K}^{-\frac{1}{2}}\mathbf{u}_h^*(\lambda)\|_{0,\Omega_2}^2, \end{aligned}$$

implying that $d_H(\cdot,\cdot)$ is positive semidefinite on $L^2(\Gamma_{12})$. The argument in the solvability Theorem 4.2 implies that the kernel of $d_H(\cdot,\cdot)$ consists of the constant functions. We have obtained the following result.

THEOREM 4.6. *Let the assumptions of Theorem* 4.2 *hold. For all four versions of coupled DG-MFE methods, the interface bilinear form $d_H(\cdot,\cdot)$ is nonsymmetric and positive semidefinite on $L^2(\Gamma_{12})$, with the kernel consisting of the constant functions.*

Remark 4.4. In the case of $\bar{s}_{\text{form}} = 0$ or 1, coercivity of $d_H(\cdot,\cdot)$ can be shown for all modified DG-MFE schemes introduced in Remark 4.2, by using inequality (3.32). It is easy to see that $d_H(\cdot,\cdot)$ is symmetric for SIPG with $\bar{s}_{\text{form}} = 1$.

5. Discussion and conclusions. We have developed a multiscale formulation for coupling DG with DG and DG with MFE using mortar spaces. The method is based on imposing weak continuity of flux and pressure via a Robin-type matching condition with a penalized pressure jump. Although the formulations described in this paper are for two subdomains, the results can be extended to geometrically nonconforming domain decompositions with a finite number of subdomains.

Our mortar formulation can be viewed as a two-level domain decomposition solver via reduction to an interface problem. By choosing the special case of continuous approximating functions in the subdomains, this approach allows the coupling of

continuous Galerkin (CG) with DG, CG with MFE, and CG with CG. The latter represents a new mortar domain decomposition algorithm for CG.

Appendix A. Mortar compatibility conditions. Here we define the mortar compatibility conditions needed for solvability of the methods with $\sigma_\tau = 0$.

DEFINITION (mortar compatibility conditions). *We say that a DG space $X_h(\Omega_i)$ is compatible with a mortar space Λ_H if, for any $\mu_H \in \Lambda_H$,*

$$\int_{\Gamma_{12}} \mathbf{K}\nabla q_h \cdot \mathbf{n}\, \mu_H d\sigma = 0 \quad \forall q_h \in X_h(\Omega_i) \;\Rightarrow \mu_H = 0. \tag{A.1}$$

We say that the MFE space $\mathbf{V}_{h,0}(\Omega_2)$ is compatible with the mortar space Λ_H if, for any $\mu_H \in \Lambda_H$,

$$\int_{\Gamma_{12}} \mathbf{v}_h \cdot \mathbf{n}\, \mu_H d\sigma = 0 \quad \forall \mathbf{v}_h \in \mathbf{V}_{h,0}(\Omega_2) \;\Rightarrow \mu_H = 0. \tag{A.2}$$

Note that (A.1) is imposed only if $\sigma_\tau = 0$. For DG-MFE methods, either (A.1) or (A.2) is needed. For matching meshes, one can choose Γ_H to be the trace of the subdomain grids. In this case a sufficient condition for (A.1) is $r \geq \bar{r} + 1$, and a sufficient condition for (A.2) is $m \geq \bar{r}$. For nonmatching meshes, if a compatibility condition is needed, it is imposed only on one of the subdomains, allowing flexibility for the mesh and the finite element space in the other subdomain.

The compatibility condition (A.2) limits the richness of the mortar space. It has been studied in [47, 4, 33], and it has been shown to hold for very general nonmatching configurations of mortar and subdomain grids and spaces.

Below, we give some examples of spaces on nonmatching meshes satisfying the compatibility condition (A.1) for $d = 2$. For simplicity we assume that $\mathbf{K}$ is a constant tensor in each element.

PROPOSITION A.1. *Let $\mathbf{K}$ be constant in each element. Assume that $d = 2$, $r = 2$, and each element of Γ_H contains at least two element faces from $\mathcal{E}_h(\Omega_1) \cap \Gamma_{12}$. Then the DG space $X_h(\Omega_1)$ and the mortar space Λ_H with $\bar{r} = 2$ or $\bar{r} = 3$ satisfy* (A.1).

Proof. Consider a mortar element $\tau \in \Gamma_H$, and assume that $\tau \supset \gamma_1 \cup \gamma_2$, where γ_1 and γ_2 are the edges of two distinct elements $E_1 \subset \mathcal{E}_h(\Omega_1)$ and $E_2 \subset \mathcal{E}_h(\Omega_1)$. Since $\mathbf{K}$ is nonsingular (because $\mathbf{K}$ is positive definite), $\mathbf{Kn}$ is not zero. Noting that $\mathbf{K}\nabla q_h \cdot \mathbf{n} = \nabla q_h \cdot \mathbf{Kn}$ (because $\mathbf{K}$ is symmetric) and q_h ranges over $\mathbb{P}_2(\gamma_i)$, we conclude that $\mathbf{K}\nabla q_h \cdot \mathbf{n}$ ranges over $\mathbb{P}_1(\gamma_i)$.

First let us consider $\bar{r} = 2$ for Λ_H and take $\mu_H \in \mathbb{P}_2(\tau)$. The orthogonality condition in (A.1) yields

$$\int_{\gamma_i} p_1 \mu_H d\sigma = 0 \quad \forall p_1 \in \mathbb{P}_1(\gamma_i)\,,\; i = 1, 2.$$

In particular, $\int_{\gamma_1} \mu_H d\sigma = \int_{\gamma_2} \mu_H d\sigma = 0$. Therefore, μ_H has a root inside γ_1, say, α_1, and a root inside γ_2, say, α_2. Therefore $\mu_H = C(x - \alpha_1)(x - \alpha_2)$. By choosing $p_1 = (x - \alpha_1)$ in γ_1, we have $\int_{\gamma_1} C(x - \alpha_1)^2(x - \alpha_2) d\sigma = 0$. Since $(x - \alpha_2)$ cannot change sign in γ_1, we must have $C = 0$; consequently $\mu_H = 0$, and (A.1) holds.

We now let $\bar{r} = 3$ and take $\mu_H \in \mathbb{P}_3(\tau)$. Then, as before, we have two distinct roots $\alpha_1 \in \gamma_1$ and $\alpha_2 \in \gamma_2$. Since $\mu_H \in \mathbb{P}_3(\tau)$, we know that μ_H has another real root, say, α_3, and then $\mu_H = C(x - \alpha_1)(x - \alpha_2)(x - \alpha_3)$. By taking $p_1 = (x - \alpha_1)$

in γ_1, we have $\int_{\gamma_1} C(x-\alpha_1)^2(x-\alpha_2)(x-\alpha_3)d\sigma = 0$. Since $(x-\alpha_2)$ cannot change sign in γ_1, we must have either $C=0$ or $\alpha_3 \in \gamma_1$. By taking $p_1 = (x-\alpha_2)$ in γ_2, we conclude similarly that either $C=0$ or $\alpha_3 \in \gamma_2$. As γ_1 and γ_2 are disjoint, we must have $C=0$; consequently $\mu_H = 0$, and (A.1) holds. ∎

STABILITY ANALYSIS OF THE GURTIN–MACCAMY MODEL*

D. BREDA†, M. IANNELLI‡, S. MASET§, AND R. VERMIGLIO†

Abstract. In this paper we propose a numerical scheme to investigate the stability of steady states of the nonlinear Gurtin–MacCamy system, which is a basic model in population dynamics. In fact the analysis of stability is usually performed by the study of transcendental characteristic equations that are too difficult to approach by analytical methods. The method is based on the discretization of the infinitesimal generator associated to the semigroup of the solution operator by using pseudospectral differencing techniques. The method computes the rightmost characteristic roots, and it is shown to converge with spectral accuracy behavior.

Key words. age-structured population, asymptotic stability, characteristic roots, eigenvalue problem

1. Introduction.

The nonlinear Gurtin–MacCamy model represents a milestone in the study of the dynamics of an age-structured population (see the original work [11]), and the qualitative analysis of its solutions is of central interest. Within this context, the investigation of the behavior of the solutions near an equilibrium requires two important steps: the determination of the steady state solutions and the stability analysis of the linearized system. In both cases the numerical methods represent powerful tools for a complete analysis. In particular, it is known that stability of steady states is governed by transcendental characteristic equations that are not easy to solve analytically. Thus efficient numerical methods to compute the characteristic roots allow one to explore the behavior of the models determining asymptotic stability. Moreover, we are interested in examining the displacement of the characteristic roots versus some significant parameter, in order to observe the possible crossing of the imaginary axis from the left to the right implying Hopf bifurcations and the existence of periodic solutions.

Within the framework described above, several papers have been devoted to the analysis of population models based on specific interactions between different ages. In particular adults-juveniles competition and cannibalism have been investigated [5], [6], [7], [8], [12], by both performing local stability analysis and simulating the solutions by special numerical methods [13], [14].

Numerical approaches for the computation of characteristic roots of linear autonomous delay differential equations have been recently proposed (see [10], [2], [3]). They are based on the discretization of either the solution operator or the infinitesimal generator relevant to the semigroup associated to the original equation. Since the spectrum of the infinitesimal generator consists of the characteristic roots and

the spectrum of the solution operator is related to the characteristic roots by an exponential transformation, such roots can be computed as the eigenvalues of suitable matrices approximating the infinitesimal generator or the solution operator. In a recent paper [1], this technique has been proposed to analyze the stability properties for age-structured population models. Actually, the population model considered in [1] is a particular case of the Gurtin–MacCamy problem, because nonlinear effects are supposed to influence fertility only. The full problem is mathematically more complex, and the numerical method set up in [1] must be adapted and implemented to cover the full case.

Here we propose a general numerical approach for determining the asymptotic stability of solutions of a rather general linear problem which includes, as a particular case, the full Gurtin–MacCamy model linearized at a stationary solution. As a worked example, we consider a general age-structured logistic model and analyze its stability by showing Hopf bifurcation and the existence of periodic solutions.

2. The Gurtin–MacCamy model: Stationary solutions and stability analysis. Let us consider a general nonlinear Gurtin–MacCamy model, describing the dynamics of an age-structured population, here represented by its age density $p(a,t)$ at the age a and time t:

$$\frac{\partial p}{\partial t}(a,t)+\frac{\partial p}{\partial a}(a,t)+\mu(a,S(t))p(a,t)=0,\ a\in[0,a_\dagger],\ t\geq 0, \tag{2.1}$$

$$p(0,t)=\int_0^{a_\dagger}\beta(a,S(t))p(a,t)da,\ t\geq 0, \tag{2.2}$$

$$S(t)=\int_0^{a_\dagger}\gamma(a)p(a,t)da,\ t\geq 0, \tag{2.3}$$

where $\gamma(t)=(\gamma_1(t),\dots,\gamma_n(t))^T\in\mathbb{R}^n$ and then $S(t)=(S_1(t),\dots,S_n(t))^T\in\mathbb{R}^n$, with

$$S_i(t)=\int_0^{a_\dagger}\gamma_i(a)p(a,t)da,\ t\geq 0.$$

The n variables $S_i(t)$, $i=1,\dots,n$, are called *sizes* and represent different ways of weighting the age distribution. Note that both *fertility* β and *mortality* μ depend on the age and on the sizes. We will assume that the functions

$$\begin{aligned}&\beta:[0,a_\dagger]\times\mathbb{R}^n\to\mathbb{R},\\&\mu:[0,a_\dagger]\times\mathbb{R}^n\to\mathbb{R},\\&\gamma_i:[0,a_\dagger]\to\mathbb{R}\quad(i=1,\dots,n)\end{aligned}$$

are measurable and satisfy the following general conditions:

$$0\leq\beta(a,x)\leq\beta_+\ \text{a.e. in}\ [0,a_\dagger]\times\mathbb{R}^n,$$

$$0\leq\gamma_i(a)\leq\gamma_+\ \text{a.e. in}\ [0,a_\dagger],$$

$$0\leq\mu(a,x)=\mu_0(a)+\mathcal{M}(a,x)\quad\text{a.e. in}\ [0,a_\dagger]\times\mathbb{R}^n,$$

where $\mu_0(a)$ satisfies

$$\mu_0(\cdot)\in L^1_{loc}([0,a_\dagger)),\mu_0(a)\geq 0\quad\text{a.e. in}\ [0,a_\dagger],$$

$$\int_0^{a_\dagger}\mu_0(\sigma)d\sigma=+\infty,$$

and

$$\mathcal{M}(a,0) = 0 \quad \text{a.e. in } [0,a_\dagger].$$

Moreover, we assume that $\beta, \mathcal{M}$ are locally Lipschitz with respect to the second argument. These assumptions ensure that an initial condition

$$p(a,0) = p_0(a),\ a \in [0,a_\dagger],$$

uniquely fixes a solution for (2.1), (2.2), and (2.3).

A stationary solution $p^*(a)$ of the model (2.1), (2.2), and (2.3) satisfies the following equations:

$$\frac{d}{da}p^*(a) + \mu(a,S^*)p^*(a) = 0,\ a \in [0,a_\dagger], \tag{2.4}$$

$$p^*(0) = \int_0^{a_\dagger} \beta(a,S^*)p^*(a)da,$$

$$S^* = \int_0^{a_\dagger} \gamma(a)p^*(a)da.$$

By defining the function (*survival probability* at S^*)

$$\Pi(a,S^*) = \exp\left(-\int_0^a \mu(\sigma,S^*)d\sigma\right),\ a \in [0,a_\dagger], \tag{2.5}$$

a solution of (2.4) is given by

$$p^*(a) = p^*(0)\Pi(a,S^*),\ a \in [0,a_\dagger], \tag{2.6}$$

and so it is completely described by the values $p^*(0)$ and S^*. Besides the trivial stationary solution $p^*(a) = 0$, $a \in [0,a_\dagger]$, nontrivial solutions are given by positive S^* satisfying

$$1 = \int_0^{a_\dagger} \beta(a,S^*)\Pi(a,S^*)da \tag{2.7}$$

and

$$\frac{S_1^*}{\int_0^{a_\dagger} \gamma_1(a)\Pi(a,S^*)da} = \frac{S_2^*}{\int_0^{a_\dagger} \gamma_2(a)\Pi(a,S^*)da} = \cdots = \frac{S_n^*}{\int_0^{a_\dagger} \gamma_n(a)\Pi(a,S^*)da}, \tag{2.8}$$

i.e., a nonlinear algebraic system of n equations in the n unknowns S_i^*, $i = 1,\dots,n$. The value $p^*(0)$ is then given by

$$p^*(0) = \frac{S_i^*}{\int_0^{a_\dagger} \gamma_i(a)\Pi(a,S^*)da},\ i = 1,\dots,n.$$

To investigate the stability of a stationary solution p^*, we linearize the model (2.1), (2.2), and (2.3) around p^*, and we get for the function $u = p - p^*$ the following linear equations:

$$\frac{\partial u}{\partial t}(a,t) + \frac{\partial u}{\partial a}(a,t) + \mu(a,S^*)u(a,t) + p^*(a)\frac{\partial \mu}{\partial S}(a,S^*)U(t) = 0, \tag{2.9}$$

$$u(0,t) = \int_0^{a_\dagger} \beta(a,S^*)u(a,t)da + \int_0^{a_\dagger} p^*(a)\frac{\partial \beta}{\partial S}(a,S^*)U(t)da, \tag{2.10}$$

$$U(t) = (U_1(t),\dots,U_n(t))^T,\ U_i(t) = \int_0^{a_\dagger} \gamma_i(a)u(a,t)da, \tag{2.11}$$

where we used the notation $\frac{\partial f}{\partial X}(a,X)$, with $X = (x_1,\dots,x_n)^T$ for the row-vector gradient $(\frac{\partial f}{\partial x_1}(a,X),\dots,\frac{\partial f}{\partial x_n}(a,X))$ and

$$\frac{\partial f}{\partial X}(a,X)Y = \sum_{i=1}^{n} \frac{\partial f}{\partial x_i}(a,X)Y_i.$$

We note that, by setting

$$u(a,t) = \Pi(a,S^*)v(a,t),\ a \in [0,a_\dagger],\ t \geq 0,$$

where $\Pi(a,S^*)$ is the survival probability defined in (2.5), from (2.9), (2.10), and (2.11) we get the following simplified equations for the function v:

$$\frac{\partial v}{\partial t}(a,t) + \frac{\partial v}{\partial a}(a,t) + p^*(0)\frac{\partial \mu}{\partial S}(a,S^*)V(t) = 0, \tag{2.12}$$

$$v(0,t) = \int_0^{a_\dagger} \beta(a,S^*)\Pi(a,S^*)v(a,t)da + \int_0^{a_\dagger} p^*(a)\frac{\partial \beta}{\partial S}(a,S^*)V(t)da, \tag{2.13}$$

$$V(t) = (V_1(t),\dots,V_n(t))^T,\ V_i(t) = \int_0^{a_\dagger} \gamma_i(a)\Pi(a,S^*)v(a,t)da. \tag{2.14}$$

It is important to observe that the zero solution of (2.9), (2.10), and (2.11) is asymptotically stable if and only if the zero solution of (2.12), (2.13), and (2.14) is asymptotically stable. Hence, the stability analysis of the linearized model can be equivalently performed with the equations for the function v.

3. Abstract formulation and characteristic equation. We are interested in studying the stability of the steady states by analyzing the stability of the zero solution of the linearized model (2.12), (2.13), and (2.14). In order to present and develop a numerical approach we rewrite the general model as an abstract evolution equation, and we derive the characteristic equation. This last step is essential to introduce the numerical approach in the next section.

In order to present our numerical method in a more general setting, we enlarge our attention to complex-valued functions, and we consider the Banach space $X = L^1([0,a_\dagger],\mathbb{C})$. Then, by introducing the linear bounded functional $K_0 : X \to \mathbb{C}$ and the linear bounded operator $\mathcal{H} : X \to X$ of finite rank, i.e.,

$$\operatorname{ran}(\mathcal{H}) = \operatorname{span}\{h_1,\dots,h_n\} \tag{3.1}$$

for some $h_i \in X$, $i = 1,\dots,n$, we propose to consider the following general linear equation:

$$\frac{\partial v}{\partial t}(a,t) + \frac{\partial v}{\partial a}(a,t) + (\mathcal{H}v(\cdot,t))(a) = 0,\ a \in [0,a_\dagger],\ t \geq 0, \tag{3.2}$$

with boundary condition

$$v(0,t) = K_0 v(\cdot,t),\ t \geq 0. \tag{3.3}$$

Observe that (3.1) implies that

$$(\mathcal{H}\varphi)(a) = H(a)K\varphi = \sum_{i=1}^{n} h_i(a)K_i\varphi,\ \varphi \in X, \tag{3.4}$$

where $H(a) = (h_1(a), \dots, h_n(a))$ and $K\varphi = (K_1\varphi, \dots, K_n\varphi)^T$, with $K_i : X \to \mathbb{C}, i = 1, \dots, n$, suitable linear bounded functionals.

The model (3.2) is a generalized version of problem (2.12), (2.13), (2.14), which fits into it by choosing the linear functionals K_0, K in (3.3) and (3.4), respectively, as follows:

$$K_0\varphi = \int_0^{a_\dagger} k_0(s)\varphi(s)ds,\ \varphi \in X, \tag{3.5}$$

with kernel $k_0 \in L^\infty([0, a_\dagger], \mathbb{C})$ given by

$$k_0(a) = \Pi(a, S^*)\left(\beta(a, S^*) + \sum_{i=1}^{n} \gamma_i(a) \int_0^{a_\dagger} p^*(s) \frac{\partial \beta}{\partial S_i}(s, S^*)\, ds\right),$$

$$K\varphi = \int_0^{a_\dagger} k(s)\varphi(s)ds = \left(\int_0^{a_\dagger} k_1(s)\varphi(s)ds, \dots, \int_0^{a_\dagger} k_n(s)\varphi(s)ds\right),\ \varphi \in X, \tag{3.6}$$

with a vector kernel $k(a) = (k_1(a), \dots, k_n(a))^T$, $k_i \in L^\infty([0, a_\dagger], \mathbb{C})$ for $i = 1, \dots, n$ given by

$$k(a) = \Pi(a, S^*)\gamma(a),$$

and

$$H(a) = p^*(0)\frac{\partial \mu}{\partial S}(a, S^*).$$

Problem (3.2) can be restated as the following abstract evolution equation on the state space X:

$$\frac{d}{dt}U(t) = \mathcal{A}U(t),\ t \geq 0,$$

where $\mathcal{A} : \mathrm{dom}(\mathcal{A}) \subseteq X \to X$ is the unbounded linear operator given by

$$\mathcal{A}\varphi = -\varphi' - \mathcal{H}\varphi,\ \varphi \in \mathrm{dom}(\mathcal{A}), \tag{3.7}$$

with domain

$$\mathrm{dom}(\mathcal{A}) = \{\varphi \in X \mid \varphi' \in X \text{ and } \varphi(0) = K_0\varphi\}. \tag{3.8}$$

Observe that $\mathcal{A}$ in (3.7) is the infinitesimal generator of the C_0-semigroup of the solution operators $\{T(t)\}_{t\geq 0}$ defined by

$$T(t)\varphi = v(\cdot, t),\ \varphi \in X,$$

where $v(a, t)$ is the solution of (3.2) fulfilling the initial condition

$$v(a, 0) = \varphi(a),\ a \in [0, a_\dagger]$$

(see [9]). It can be shown that such a semigroup is eventually compact, and so the spectrum of the infinitesimal generator $\mathcal{A}$ consists of eigenvalues only.

The asymptotic stability of the zero solution of (3.2) is determined by analyzing the position in the complex plane of the eigenvalues of the infinitesimal generator $\mathcal{A}$ defined in (3.7) and (3.8). In particular the (hyperbolic) asymptotic stability holds if and only if all of the eigenvalues lie in the left half-plane $\Re(z) < 0$. Now we show that the eigenvalues of $\mathcal{A}$ satisfy a characteristic equation.

Let $\lambda \in \mathbb{C}$ and $\varphi \in D(\mathcal{A})$. The condition

$$\mathcal{A}\varphi = \lambda\varphi$$

means

$$\begin{cases} \varphi'(a) = -\lambda\varphi(a) - H(a)K\varphi, \ a \in [0, a_\dagger], \\ \varphi(0) = K_0\varphi. \end{cases} \tag{3.9}$$

By defining $x_0 = K_0\varphi$, $x = K\varphi$, and

$$\hat{H}(a,\lambda) = \int_0^a e^{-\lambda(a-s)} H(s)ds, \ a \in [0, a_\dagger], \tag{3.10}$$

we can equivalently rewrite (3.9) as

$$\varphi(a) = e^{-\lambda a}x_0 - \hat{H}(a,\lambda)x, \ a \in [0, a_\dagger].$$

Hence λ is eigenvalue of $\mathcal{A}$ if and only if there exists a nonzero solution $\overline{x} = \left(x_0, x^T\right)^T \in \mathbb{C}^{n+1}$ of the system

$$\begin{cases} x_0 = K_0 e^{-\lambda \cdot} x_0 - K_0 \hat{H}(\cdot,\lambda)x, \\ x = K e^{-\lambda \cdot} x_0 - K \hat{H}(\cdot,\lambda)x. \end{cases}$$

By introducing the matrix

$$\overline{A}(\lambda) = \begin{pmatrix} K_0 e^{-\lambda \cdot} & -K_0 \hat{H}(\cdot,\lambda) \\ K e^{-\lambda \cdot} & -K \hat{H}(\cdot,\lambda) \end{pmatrix} \in \mathbb{C}^{(n+1)\times(n+1)}, \tag{3.11}$$

we can conclude that λ is an eigenvalue of $\mathcal{A}$ if and only if

$$\det\left(I_{n+1} - \overline{A}(\lambda)\right) = 0, \tag{3.12}$$

which represents the characteristic equation for (3.2). We note that, since the entries of $\overline{A}(\lambda)$ are entire functions, the roots of (3.12) are a discrete set of the complex plane, and any right half-plane contains only a finite number of roots.

These characteristic roots are the eigenvalues of the infinitesimal generator $\mathcal{A}$ and can be approximated by the eigenvalues of a suitable matrix which is a discrete approximation of $\mathcal{A}$. For this task the pseudospectral technique guarantees a highly accurate discretization, and recently it has been proposed to investigate the behavior of solutions for different classes of mathematical models [2], [3]. In particular, this method has been applied to the Gurtin–MacCamy equation (2.1), (2.2), and (2.3) in the special case of the nonlinearity restricted to the fertility rate [1]. In order to treat a nonlinear mortality rate the method has to be extended and improved. Such a discretization technique is presented in the next section.

4. The numerical approach. We construct a discrete approximation of the infinitesimal generator $\mathcal{A}$ defined in (3.7) and in (3.8), under the assumption that H is continuous.

For a given positive integer N, let Ω_N be the mesh of Chebyshev extremal nodes on $[0, a_\dagger]$:

$$\Omega_N = \left\{ \theta_i = \frac{a_\dagger}{2} \cos\left(\frac{N-i}{N}\pi \right) + \frac{a_\dagger}{2},\ i = 0, \dots, N \right\}.$$

We replace the continuous space X by the space $X_N = (\mathbb{C})^{\Omega_N \setminus \{0\}} \cong \mathbb{C}^N$ of the discrete functions defined on $\Omega_N \setminus \{0\}$; i.e., any $\varphi \in X$ is discretized into the N-vector $y = (y_1, \dots, y_N)^T \in X_N$ of components $y_i = \varphi(\theta_i) \in \mathbb{C}$, $i = 1, \dots, N$.

Now we replace the operator $\mathcal{A}$ by the finite-dimensional linear operator $\mathcal{A}_N : X_N \to X_N$ given by

$$\mathcal{A}_N y = -z,\ y \in X_N,$$

where

$$\begin{aligned} z_i &= \varphi_N'(\theta_i) + (\mathcal{H}\varphi_N)(\theta_i) \\ &= \varphi_N'(\theta_i) + H(\theta_i) K \varphi_N,\ i = 1, \dots, N, \end{aligned}$$

and φ_N is the N-degree polynomial interpolating the values y_i at the nodes θ_i, $i = 1, \dots, N$, and such that

$$\varphi_N(0) = K_0 \varphi_N. \tag{4.1}$$

By using the representation

$$\varphi_N(a) = \sum_{i=0}^{N} l_{N,i}(a) y_i,\ a \in [0, a_\dagger],$$

where $y_0 = \varphi_N(0)$ and $l_{N,i}$ are the Lagrange coefficients relevant to the nodes θ_i, $i = 0, 1, \dots, N$, we obtain

$$z_i = \sum_{j=0}^{N} \left(l_{N,j}'(\theta_i) + H(\theta_i) K l_{N,j} \right) y_j,\ i = 1, \dots, N,$$

and, by the condition (4.1),

$$y_0 = \sum_{i=1}^{N} (1 - K_0 l_{N,0})^{-1} K_0 l_{N,i} y_i.$$

For K_0 defined in (3.5), we have that $(1 - K_0 l_{N,0})^{-1} \to 1$ for $N \to \infty$, since $\int_0^{a_\dagger} |l_{N,0}(s)| ds \to 0$ for $N \to \infty$. Moreover we remark that, if the functionals K_0, K are given by (3.5) and (3.6), respectively, and the integrals cannot be exactly computed, we approximate them by the Clenshaw–Curtis formula, which uses Chebyshev extremal points as quadrature nodes (see, for instance, [15]). Hence, in the case of kernels k_0, k which are piecewise smooth, it is advisable to use a piecewise polynomial φ_N as now explained. Moreover the use of piecewise polynomials is necessary when H is piecewise continuous. Assume there exist $0 = a_0 < a_1 < \cdots < a_d = a_\dagger$ such

that the kernels k_0 and k and the function H are smooth on each interval $[a_l, a_{l+1}]$, $l = 0, \dots, d-1$. We choose the mesh

$$\Omega_N = \bigcup_{l=1}^{d} \Omega_N^{(l)}$$

on the interval $[0, a_\dagger]$, where $\Omega_N^{(l)}$ is the mesh of Chebyshev extremal nodes $\theta_i^{(l)}, i = 0, \dots, N$, on $[a_{l-1}, a_l]$, and consider the space $X_N = (\mathbb{C})^{\Omega_N \setminus \{0\}} \cong \mathbb{C}^{dN}$ of the discrete functions defined on the mesh $\Omega_N \setminus \{0\}$; i.e., any $\varphi \in X$ is discretized into the dN-vector

$$y = \left(y_1^{(1)}, \dots, y_N^{(1)}, y_1^{(2)}, \dots, y_N^{(2)}, \dots, y_1^{(d)}, \dots, y_N^{(d)}\right)^T \in X_N$$

of components $y_i^{(l)} = \varphi(\theta_i^{(l)}) \in \mathbb{C}$, $i = 1, \dots, N$, $l = 1, \dots, d$. Note that $y_N^{(l-1)} = \varphi(a_{l-1})$ for $l = 2, \dots, d$.

Given a vector $y \in X_N$, the piecewise polynomial φ_N is then defined by the following conditions:

1. φ_N is continuous;
2. φ_N is an N-degree polynomial on every interval $[a_{l-1}, a_l]$, $l = 1, \dots, d$;
3. $\varphi_N(\theta_i^{(l)}) = y_i^{(l)}$, $i = 1, \dots, N, l = 1, \dots, d$.

The details of the discrete operator $\mathcal{A}_N$ can be easily obtained by proceeding as described above. For simplicity in this paper we do not consider the piecewise polynomial case, since it can be treated by similar arguments.

5. Convergence analysis. As a first step we derive the discrete analogous of the characteristic equation (3.12).

For $\lambda \in \mathbb{C}$ and $\overline{x} = (x_0, x^T)^T \in \mathbb{C}^{n+1}$, where $x_0 \in \mathbb{C}$ and $x \in \mathbb{C}^n$, let $y(\cdot; \lambda, \overline{x})$ be the solution of the initial value problem

$$\begin{cases} y'(a; \lambda, \overline{x}) = -\lambda y(a; \lambda, \overline{x}) - H(a)x, \ a \in [0, a_\dagger], \\ y(0; \lambda, \overline{x}) = x_0. \end{cases} \tag{5.1}$$

It follows that

$$y(a; \lambda, \overline{x}) = e^{-\lambda a} x_0 - \hat{H}(a, \lambda)x, \ a \in [0, a_\dagger],$$

where $\hat{H}(a, \lambda)$ is defined in (3.10). Let us observe that the matrix $\overline{A}(\lambda)$ given in (3.11) is such that

$$\overline{A}(\lambda)\overline{x} = \overline{K} y(\cdot; \lambda, \overline{x}), \ \overline{x} \in \mathbb{C}^{n+1}, \tag{5.2}$$

where $\overline{K}\varphi$ denotes $(K_0\varphi, (K\varphi)^T)^T \in \mathbb{C}^{n+1}$. Moreover let $p_N(\cdot; \lambda, \overline{x})$ be the N-degree collocation polynomial relevant to the nodes in Ω_N for the initial value problem (5.1); i.e., it satisfies

$$\begin{cases} p_N'(\theta_i; \lambda, \overline{x}) = -\lambda p_N(\theta_i; \lambda, \overline{x}) - H(\theta_i)x, \ i = 1, \dots, N, \\ p_N(0; \lambda, \overline{x}) = x_0. \end{cases} \tag{5.3}$$

Similarly to (5.2) we introduce the matrix $\overline{A}_N(\lambda)$ given by

$$\overline{A}_N(\lambda)\overline{x} = \overline{K} p_N(\cdot; \lambda, \overline{x}), \ \overline{x} \in \mathbb{C}^{n+1}. \tag{5.4}$$

Then we get that λ is an eigenvalue of $\mathcal{A}_N$ if and only if

$$\det\left(I_{n+1} - \overline{A}_N(\lambda)\right) = 0, \tag{5.5}$$

which is the discrete characteristic equation.

The order of convergence depends on the smoothness properties of the function $H : [0, a_\dagger] \to \mathbb{C}^n$ in (3.4). So we do the following assumption.

ASSUMPTION 5.1. *Assume that the ran$(\mathcal{H}) \subseteq C^\infty([0, a_\dagger])$, i.e., the function $H : [0, a_\dagger] \to \mathbb{C}^n$ in* (3.4)*, is of class C^∞ and, moreover, that derivatives of H satisfy the following bounds:*

$$\left\|H^{(k)}\right\|_1 := \sum_{i=1}^{n} \left\|h_i^{(k)}\right\|_\infty \leq \beta D^k,\ k = 0, 1, \ldots, \tag{5.6}$$

where $\|\cdot\|_\infty$ is the maximum norm and β and D are positive constants.

Let us denote by $B(\lambda, \rho)$ the closed ball in $\mathbb{C}$ of center λ and radius ρ. In the next lemma we give an upper bound of the error of the collocation polynomial $p_N(\cdot; \lambda, \overline{x})$ for (5.1).

LEMMA 5.2. *Let $\overline{\lambda} \in \mathbb{C}$ and $\rho_0 > 0$. Under Assumption* 5.1*, there exists $N_0 \in \mathbb{N}$ such that for $N \geq N_0$, $\lambda \in B(\overline{\lambda}, \rho_0)$, and $\overline{x} \in \mathbb{C}^{n+1}$ the collocation polynomial $p_N(\cdot; \lambda, \overline{x})$ for* (5.1) *and based on Ω_N exists and is unique. Moreover*

$$\|p_N(\cdot; \lambda, \overline{x}) - y(\cdot; \lambda, \overline{x})\|_\infty \leq \frac{C_0}{\sqrt{N}} \left(\frac{C_1}{N}\right)^N \|\overline{x}\|_\infty$$

holds, where $C_0 = C_0(\overline{\lambda}, \rho_0)$ and $C_1 = C_1(\overline{\lambda}, \rho_0)$ are constants independent of N.

Proof. Let $\mathcal{C}$ be the subspace $C([0, a_\dagger], \mathbb{C})$ of X endowed with the maximum norm $\|\cdot\|_\infty$, and let $\|\cdot\|$ be the induced operator norm. We introduce the integral Volterra operator $V : \mathcal{C} \to \mathcal{C}$ as

$$(V\varphi)(a) = -\int_0^a \varphi(s)ds,\ \varphi \in \mathcal{C},\ a \in [0, a_\dagger],$$

and the Lagrange interpolation operator $L_{N-1} : \mathcal{C} \to \mathcal{C}$ relevant to the nodes in $\Omega_N \setminus \{0\}$.

We can rewrite (5.1) and its collocation equations (5.3) as the equations on the subspace $\mathcal{C}$

$$y = x_0 + \lambda V y + VHx \tag{5.7}$$

and

$$p_N = x_0 + \lambda V L_{N-1} p_N + V L_{N-1} Hx, \tag{5.8}$$

respectively, where $y = y(\cdot; \lambda, \overline{x})$, $p_N = p_N(\cdot; \lambda, \overline{x})$, and x_0 denotes the function of $\mathcal{C}$ of constant value x_0. By subtracting (5.7) from (5.8) and setting $e_N = p_N - y$ we get for e_N the following equation:

$$e_N = \lambda V L_{N-1} e_N + V r_N, \tag{5.9}$$

where

$$r_N = (L_{N-1} - I)(\lambda y + Hx). \tag{5.10}$$

It can be directly shown that e_N is a solution of (5.9) if and only if $e_N = V\hat{e}_N$, where $\hat{e}_N$ satisfies

$$\hat{e}_N = \lambda L_{N-1} V \hat{e}_N + r_N.$$

Since $I - \lambda V$ is invertible and, by the known estimate for the Lagrange interpolation at Chebyshev nodes, $\|(L_{N-1} - I)V\| \to 0$ as $N \to \infty$, it follows that, for sufficiently large N (and independently of $\lambda \in B(\overline{\lambda}, \rho_0)$), the operator $I - \lambda L_{N-1} V$ is invertible, and

$$\left\|(I - \lambda L_{N-1} V)^{-1}\right\| \leq 2 \left\|(I - \lambda V)^{-1}\right\|$$

holds. Hence $e_N = V(I - \lambda L_{N-1} V)^{-1} r_N$ is the unique solution of (5.9), and

$$\|e_N\|_\infty \leq 2\|V\|\|(I - \lambda V)^{-1}\|\|r_N\|_\infty$$

holds.

The function r_N in (5.10) is the error of the Lagrange interpolation relevant to the nodes in Ω_N of $y' = -\lambda y - Hx$. By (5.6) we get

$$\left\|y^{(k+1)}\right\|_\infty \leq |\lambda| \left\|y^{(k)}\right\|_\infty + \beta D^k \left\|\overline{x}\right\|_\infty, \ k = 0, 1, 2, \ldots,$$

and

$$\|y\|_\infty \leq \alpha(\lambda) \left\|\overline{x}\right\|_\infty,$$

where

$$\alpha(\lambda) = \max\left\{1, e^{-\Re(\lambda) a_\dagger}\right\} (1 + \beta a_\dagger).$$

Hence we can conclude that

$$\left\|y^{(k)}\right\|_\infty \leq \alpha(\lambda) E(\lambda)^k \left\|\overline{x}\right\|_\infty, \ k = 0, 1, 2, \ldots,$$

where

$$E(\lambda) = \max\left\{|\lambda| + \frac{\beta}{\alpha(\lambda)}, D\right\}.$$

Thus

$$\|r_N\|_\infty \leq \alpha(\lambda) E(\lambda) \frac{(E(\lambda) a_\dagger)^N}{N!} \left\|\overline{x}\right\|_\infty,$$

and by the Stirling formula the thesis follows. □

The above result is stated under Assumption 5.1, but we note that, under less regularity hypotheses such as $H : [0, a_\dagger] \to \mathbb{C}^n$ in (3.4) of class C^m, $m \geq 1$, by standard interpolation results, we get that

$$\|p_N(\cdot; \lambda, \overline{x}) - y(\cdot; \lambda, \overline{x})\|_\infty \leq \frac{C(\lambda)}{N^m} \left\|\overline{x}\right\|_\infty,$$

where $C(\lambda)$ is independent of N.

In our remark at the end of section 4 we have seen that, when the functionals K_0, K are given by (3.5) and (3.6) and the integrals cannot be exactly computed, they are approximated by the Clenshaw–Curtis formula. So we assume that the integral functionals K_0 and K in (3.5) and (3.6) are replaced by suitable functionals $K_{0,N}$ and K_N, respectively (with $K_{0,N} = K_0$ and $K_N = K$ when the integrals are exactly computed). Moreover we set

$$\overline{K}_N\varphi = (K_{0,N}\varphi, (K_N\varphi)^T)^T \in \mathbb{C}^{n+1} \tag{5.11}$$

and do the following assumption that is fulfilled by Clenshaw–Curtis formulas.

ASSUMPTION 5.3. *We assume that the sequence* $\left\{\overline{K}_N\right\}$ *of functionals in* (5.11) *satisfies*

$$\sup_{N\in\mathbb{N}} \left\|\overline{K}_N\right\| < +\infty,$$

where

$$\left\|\overline{K}_N\right\| = \sup_{\varphi\in C([0,a_\dagger],\mathbb{C})} \frac{\left\|\overline{K}_N\varphi\right\|_\infty}{\|\varphi\|_\infty}.$$

Now let us set the following notation relevant to the continuous and discrete characteristic equations (3.12) and (5.5), respectively:

$$d(\lambda) = \det\left(I_{n+1} - \overline{A}(\lambda)\right),$$
$$d_N(\lambda) = \det\left(I_{n+1} - \overline{A}_N(\lambda)\right),$$

with $\overline{A}(\lambda)$ and $\overline{A}_N(\lambda)$ defined in (3.11) and (5.4), respectively. The next two lemmas are necessary steps to state the final theorem of convergence.

LEMMA 5.4. *Let* $\overline{\lambda} \in \mathbb{C}$ *and* $\rho_0 > 0$. *Under Assumptions* 5.1 *and* 5.3, *there exists* $N_0 \in \mathbb{N}$ *such that for* $N \geq N_0$ *and* $\lambda \in B(\overline{\lambda}, \rho_0)$ *we have*

$$|d_N(\lambda) - d(\lambda)| \leq C_2\left(\varepsilon_N + \frac{1}{\sqrt{N}}\left(\frac{C_1}{N}\right)^N\right),$$

where

$$\varepsilon_N = \sup_{\substack{\lambda\in B(\overline{\lambda},\rho_0)\\ \overline{x}\in\mathbb{C}^{n+1}}} \frac{\left\|\overline{K}_N\left(y(\cdot;\lambda,\overline{x})\right) - \overline{K}\left(y(\cdot;\lambda,\overline{x})\right)\right\|_\infty}{\|\overline{x}\|_\infty},$$

$C_1 = C_1(\overline{\lambda}, \rho_0)$ *as defined in Lemma* 5.2, *and* $C_2 = C_2(\overline{\lambda}, \rho_0)$ *is a constant independent of* N.

Proof. By Lemma 5.2 we have

$$\begin{aligned}\left\|\overline{A}_N(\lambda)\overline{x} - \overline{A}(\lambda)\overline{x}\right\|_\infty &\leq \left\|\overline{K}_N\left(p_N(\cdot;\lambda,\overline{x})\right) - \overline{K}_N\left(y(\cdot;\lambda,\overline{x})\right)\right\|_\infty \\ &\quad + \left\|\overline{K}_N\left(y(\cdot;\lambda,\overline{x})\right) - \overline{K}\left(y(\cdot;\lambda,\overline{x})\right)\right\|_\infty \\ &\leq \left(\sup_{N\in\mathbb{N}}\|\overline{K}_N\|\frac{C_0}{\sqrt{N}}\left(\frac{C_1}{N}\right)^N + \varepsilon_N\right)\|\overline{x}\|_\infty\end{aligned}$$

for $N \geq N_0$ and $\lambda \in B(\overline{\lambda}, \rho_0)$.

Since the derivative of $\det(A)$ with respect to $A \in \mathbb{C}^{(n+1)(n+1)}$ is continuous, the assertion follows. ∎

LEMMA 5.5. *If the function $d(\lambda)$ has a zero $\overline{\lambda} \in \mathbb{C}$ with multiplicity ν, then there exists $\rho_1 > 0$ such that for $\lambda \in B(\overline{\lambda}, \rho_1) \setminus \{\overline{\lambda}\}$*

$$|d(\lambda)| > C_3 \left\|\lambda - \overline{\lambda}\right\|^{\nu},$$

where $C_3 = C_3(\overline{\lambda}, \rho_1)$.

Proof. By expanding $d(\lambda)$ around $\overline{\lambda}$ and taking into account the multiplicity ν we obtain

$$d(\lambda) = \frac{d^{(\nu)}(\overline{\lambda})}{\nu!}(\lambda - \overline{\lambda})^{\nu} + O\left(\left\|\lambda - \overline{\lambda}\right\|^{\nu+1}\right),$$

with $d^{(\nu)}(\overline{\lambda}) \neq 0$. The result follows. ∎

We are now able to state the convergence result.

THEOREM 5.6 (convergence). *Under Assumptions* 5.1 *and* 5.3, *if the function $d(\lambda)$ has a zero $\overline{\lambda} \in \mathbb{C}$ with multiplicity ν and if*

$$\left(\frac{C_2}{C_3}\right)^{1/\nu} \left(\varepsilon_N + \frac{1}{\sqrt{N}}\left(\frac{C_1}{N}\right)^{N}\right)^{1/\nu} \leq \rho_1$$

for $N \geq N_0$, where C_3 and ρ_1 are defined in Lemma 5.5 *and N_0, C_1, and C_2 are defined in Lemma* 5.4, *with $\rho_0 = \rho_1$, then the function $d_N(\lambda)$ has ν zeros λ_i, $i = 1, \ldots, \nu$, (taking into account multiplicities) such that*

$$\max_{1 \leq i \leq \nu} |\overline{\lambda} - \lambda_i| \leq \left(\frac{C_2}{C_3}\right)^{1/\nu} \left(\varepsilon_N + \frac{1}{\sqrt{N}}\left(\frac{C_1}{N}\right)^{N}\right)^{1/\nu}. \tag{5.12}$$

Proof. Let

$$\rho_N = \left(\frac{C_2}{C_3}\right)^{1/\nu} \left(\varepsilon_N + \frac{1}{\sqrt{N}}\left(\frac{C_1}{N}\right)^{N}\right)^{1/\nu}.$$

Since $\rho_N \leq \rho_1 = \rho_0$, Lemmas 5.4 and 5.5 yield

$$|d(\lambda)| > |d_N(\lambda) - d(\lambda)|$$

for $\left|\lambda - \overline{\lambda}\right| = \rho_N$. Hence, by Rouché's theorem [4, section 5, Theorem 3.8], d and d_N have exactly the same number of zeros counted with their multiplicities in $B(\overline{\lambda}, \rho_N)$. ∎

It is important to point out that the spectral accuracy of the collocation error stated in Lemma 5.2 under Assumption 5.1 is preserved in the behavior of the convergence error (5.12) in Theorem 5.6, if the functionals K_0, K are given by (3.5) and (3.6) and the integrals in (3.5) and (3.6) can be exactly computed, i.e., $\varepsilon_N = 0$. On the other hand, we also maintain the spectral accuracy in the convergence if we make the further assumptions that:

1. the kernels k_0 and k in (3.5) and (3.6) are of class C^{∞} and there exist constants $c, F > 0$ such that

$$\max_{i=0,1,\ldots,n} \left\|k_i^{(q)}\right\|_{\infty} \leq cF^q, \ q = 0, 1, 2, \ldots;$$

2. a simple interpolatory quadrature rule based on $N+1$ distinct nodes is used for the integrals in (3.5) and (3.6).

Finally, we observe that if the quadrature error is independent of N, i.e., $\varepsilon_N \leq$ TOL (e.g., machine precision), the error bound (5.12) in Theorem 5.6 is still valid with ε_N replaced by TOL, and thus spectral accuracy holds down to the tolerance TOL.

6. A case study: Logistic population growth. Here we consider the particular case of the Gurtin–MacCamy model endowed with a general form of the logistic mechanism designed to include the role of age structure. Namely, in system (2.1), (2.2), and (2.3) we adopt the following specific form of the vital rates:

$$\beta(a, S(t)) = R_0 \beta_0(a) e^{-S(t)}, \tag{6.1}$$

$$\mu(a, S(t)) = \mu_0(a) + m(a)\frac{S(t)}{1+S(t)}, \tag{6.2}$$

where we assume that the occupation of the niche is described through a single size

$$S(t) = \int_0^{a_\dagger} \gamma(a) p(a,t) da.$$

Moreover we assume the following specific form for the functions above:

$$\beta_0(a) = \frac{\alpha+1}{a_\dagger}, \tag{6.3}$$

$$\mu_0(a) = \frac{\alpha}{(a_\dagger - a)}, \tag{6.4}$$

$$m(a) = m_0 \chi_{[a_1,a_2]}(a), \tag{6.5}$$

$$\gamma(a) = \gamma_1 e^{-\delta_1 a} + \gamma_2 e^{\delta_2 (a - a_\dagger)}. \tag{6.6}$$

With the assumptions above we assume a simple intrinsic maternity function. We allow selection of the age interval $[a_1, a_2]$ and the intensity m_0 relative to the impact of the logistic effect on the survival probability, and, by the four parameters in $\gamma(a)$, we allow a weighted selection of adults and juveniles.

By these specific assumptions, as we have seen in (2.6), (2.7), and (2.8), a stationary solution is given by

$$p^*(a) = \frac{S^* \left(a_\dagger - a\right)^\alpha e^{-\frac{m_0 S^* M(a)}{1+S^*}}}{\int_0^{a_\dagger} \gamma(\sigma) \left(a_\dagger - \sigma\right)^\alpha e^{-\frac{m_0 S^* M(\sigma)}{1+S^*}} d\sigma}, \ a \in [0, a_\dagger],$$

where

$$M(a) = \begin{cases} 0 & \text{for } a < a_1, \\ a - a_1 & \text{for } a_1 \leq a \leq a_2, \\ a_2 - a_1 & \text{for } a > a_2, \end{cases}$$

and $S^* > 0$ is the (unique) positive solution to the equation

$$(\alpha+1) R_0 e^{-x} \int_0^1 (1-\sigma)^\alpha e^{-\frac{x M(a_\dagger \sigma)}{1+x}} d\sigma = 1, \tag{6.7}$$

which exists if and only if $R_0 > 1$. In fact the left-hand side of (6.7) is a decreasing function of x with value R_0 at $x = 0$ and vanishing as $x \to +\infty$.

When we linearize the model at such a stationary solution p^* we obtain (3.2) with the following specific kernels:

$$k_0(a) = R_0 \frac{\alpha+1}{a_\dagger}\left(1-\frac{a}{a_\dagger}\right)^\alpha e^{-S^*\left(1+\frac{m_0 M(a)}{1+S^*}\right)}\left(1-\int_0^{a_\dagger} p^*(s)ds\gamma(a)\right), \tag{6.8}$$

$$k(a) = \gamma(a)\left(1-\frac{a}{a_\dagger}\right)^\alpha e^{-\frac{m_0 S^* M(a)}{1+S^*}}, \tag{6.9}$$

and

$$H(a) = \frac{p^*(0)m_0\chi_{[a_1,a_2]}(a)}{(1+S^*)^2}. \tag{6.10}$$

The next section is devoted to describing some simulations showing stability and bifurcations.

7. Numerical exploration of the logistic model. In this section we apply the numerical method developed in this work to the logistic model presented in the previous section for the values reported in Table 7.1. In particular, we consider R_0 as a parameter of nominal value $R_0 = 1$, and then we increase its value above one analyzing the asymptotic behavior of the nontrivial equilibrium. This latter is computed by using a standard zero-finder routine as applied to (6.7). We observe that the functions (6.8), (6.9), and (6.10) are clearly piecewise defined because of the discontinuity of the function m in a_1 and a_2. Figure 7.1 shows part of the rightmost characteristic roots of the nominal system. Results are obtained with $N = 200$, and hence high accuracy is ensured as it turns out from the following convergence analysis.

The convergence behavior can be analyzed by comparing approximated and exact characteristic roots for increasing N. In the case of the rightmost one, i.e., $\lambda = 0$, convergence is so fast that we get accuracy to machine precision already with $N = 1$. This is due to the error constant C_1 in Lemma 5.2 and Theorem 5.6, which is proportional to $|\lambda| = 0$. Therefore, to better show the spectral accuracy typical of this approach, we follow the convergence of the first five rightmost roots (computed with $N = 200$ and assumed to be exact to the first 11 digits). Results are shown in Figure 7.2 for the nominal system for $N = 1, 2, \ldots, 50$, from which it can be seen that the convergence is faster for smaller $|\lambda|$.

The characteristic roots of the logistic model clearly depend on R_0. The variation of the spectrum is shown in Figure 7.3 (only for the nonnegative imaginary part, the negative one being symmetric) when R_0 increases from 1 to 20 with variable steps in order to capture the main features of this analysis. Moreover, for better clarity, only the first five righmost roots are considered, the behavior of the others being qualitatively similar. These roots are marked with $\circ$ for the nominal value $R_0 = 1$, while they are marked with $\bullet$ for greater values.

As R_0 is increased, the imaginary roots move from the right to the left, turning back to the right towards the imaginary axis. For the real root, i.e., the zero eigenvalue for $R_0 = 1$, when R_0 is increased, it moves leftward as the complex ones do. In the

Values of the parameters in (6.1)–(6.6).

Parameter	R_0	α	a_1	a_2	$a_\dagger$	m	γ_1	δ_1	γ_2	δ_2
Value	1	1	0.6	0.85	1	0.3	0.2	0.5	7	4

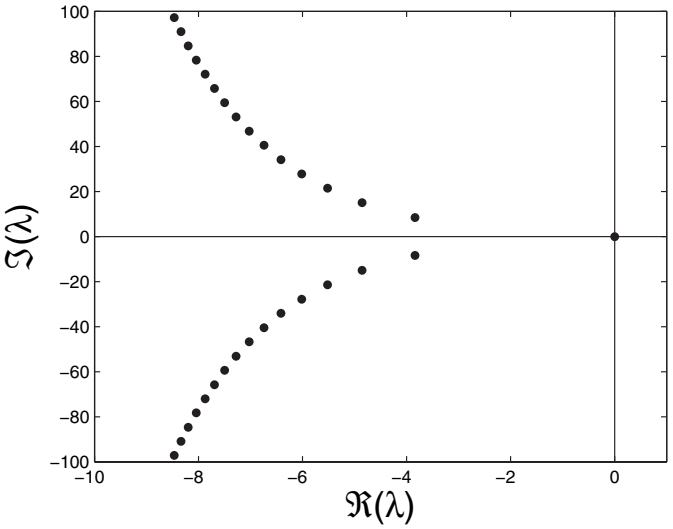

FIG. 7.1. *Partial characteristic spectrum for the logistic model with* $R_0 = 1$ *(*$N = 200$*).*

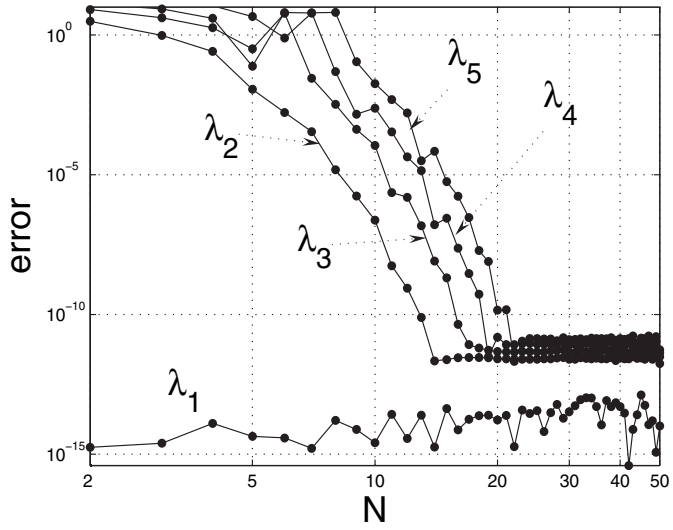

FIG. 7.2. *Absolute error analysis with respect to the first five rightmost roots of the logistic model with* $R_0 = 1$ *for varying* N*.*

meanwhile, a second real root is coming rightward from $-\infty$. At $R_0 = R_{0,1} \simeq 1.493$, these two real roots collapse and then split into a complex-conjugate pair. This latter moves rightward to the imaginary axis for increasing R_0 above $R_{0,1}$ as all the other complex branches. In particular, when $R_0 = R_{0,2} \simeq 11.903$, a Hopf bifurcation occurs.

This analysis can be performed similarly for other models by choosing different functions (6.8), (6.9), and (6.10), i.e., basically for different choices of the vital rates and of the sizes. In such a way, this numerical method represents a fast and reliable tool to investigate the dynamics of the Gurtin–MacCamy model as treated here and without the need of computing the solution.

ON STABILITY OF STAGGERED SCHEMES*

AMY L. BAUER†, RAPHAËL LOUBÈRE‡, AND BURTON WENDROFF§

Abstract. This paper investigates the theoretical stability bound of a Lagrangian staggered scheme used to solve hydrodynamics equations. We present the two-dimensional (2D) wave equation as a possible model for this study and, by using the numerical radius of the amplification matrix, we prove that the family of schemes defined with two time-centering parameters is limited by a non-classical stability bound limit defined with an analytical curve. We further show that 2D numerical experiments agree with this theoretical result.

Key words. staggered schemes, stability, wave equations, Euler equations

DOI. 10.1137/060660151

1. Introduction.

The concept of stability was first introduced in the seminal paper [1] of Courant, Friedrichs, and Lewy in 1928 where they discussed finite-difference methods for solving partial differential equations. Amazingly in the very same paper they studied one of the first staggered numerical schemes for the one-dimensional (1D) wave equation $v_t = cw_x, w_t = cv_x$, which was further developed in 1967 by Richtmyer and Morton in [6] and cast in its "modern" form as:

$$\frac{v_j^{n+1} - v_j^n}{\Delta t} = c\,\frac{w_{j+1/2}^n - w_{j-1/2}^n}{\Delta x}, \quad \frac{w_{j-1/2}^{n+1} - w_{j-1/2}^n}{\Delta t} = c\,\frac{v_j^{n+1} - v_{j-1}^{n+1}}{\Delta x}.$$

By considering these works as the genesis for numerical analysis and computational fluid dynamics, one would expect the stability of staggered numerical schemes to be at present well understood. However, this is far from being the case. Although staggered schemes have since been widely employed computationally, not much is known analytically about the stability of staggered schemes.

The use of staggered schemes also dates back to the inception of Los Alamos National Laboratory where the "calculation of certain time-dependent fluid flows played an important part in the wartime work of the laboratory" (preface to the first edition of [6]). Staggered schemes have frequently been used to solve the compressible fluid dynamics equations in their Lagrangian formulation. In this case, a staggered spatial placement of variables is used, where the position and velocity are defined at grid points and density, internal energy, and the pressure are defined at cell centers. Since this time, other Lagrangian hydrodynamics staggered numerical codes have been de-

veloped around the globe, but again little advancement has been made towards a deeper understanding and analytical proof of the stability of such schemes.

Some years ago, Shashkov proposed a simple problem for the purpose of testing the stability of Lagrangian hydrodynamics codes. The initial data are given as zero velocity, constant pressure, and constant density. One then computes the total kinetic energy, which should be zero for all time. Caramana recently tried this problem with his two-dimensional (2D) staggered grid Lagrangian code and discovered that it was unstable for certain mesh ratios that "folklore" indicated should be otherwise—the instability manifested itself as an explosive growth of kinetic energy. The surprise here is not that a 1D symmetry-preserving 2D code could be unstable for 1D data; the surprise lies in the contradiction of the folklore.

The precise numerical scheme we are referring to and which is the focus of our investigation is the staggered-grid predictor-corrector compatible Lagrangian hydrodynamics scheme. We refer the reader to [3], [4] for the details of this scheme which we omit here. Briefly, there are two parameters α and β such that, if $\alpha = \beta = 1/2$, the scheme resembles a time-centered (Crank–Nicolson) scheme, while if $\alpha = \beta = 1$, it looks like backward Euler. For the Courant–Friedrichs–Lewy (CFL) condition CFL $= 1$, the scheme is stable for $\alpha = \beta = 1/2$. However, for $\alpha = 1$, $\beta = 1/2$ the scheme is unstable for CFL > 0.71, indicating that, as α increases, the CFL limit decreases. Bauer et al. then created a 1D problem by using the same data; they seed their 1D staggered-grid predictor-corrector compatible hydrodynamics Lagrangian code with a small random perturbation of the pressure. Moreover, they created the multidimension version of the problem and ran their 2D and Caramana's 3D code as well. They observed the same phenomenon in 1D, 2D, and 3D [3]. The stability limit was conjectured to be CFL $= 1/(2\sqrt{\alpha\beta})$, and numerical tests using the full nonlinear equations show that this is true provided $\alpha \geq 1/2$ and $\beta \geq 1/2$ [3].

We prove the above conjecture in 2D, which contains 1D as a special case. Of course, there is no possibility of doing this for the full nonlinear problem—the Euler equations. Ultimately, one applies a von Neumann analysis to the linearized system. Bauer et al. [3] almost succeeded in doing this theoretical analysis in 1D, resorting to numerical sampling only at the very end of the proof. We have succeeded in 2D, by using the numerical radius of the amplification matrix as a tool, an idea apparently first applied in [2]. This proof is the goal of this paper, which is articulated as follows: First we present the Lagrangian coordinates and justify the use of the wave equation as a possible linear model for the Euler equations in 1D and 2D; second, we introduce the notation; third, we show that the staggered implicit scheme is unconditionally stable for $\alpha \geq 1/2$, $\beta \geq 1/2$; fourth, we show that the predictor-corrector staggered scheme is stable for $\alpha \geq 1/2$, $\beta \geq 1/2$, and CFL $\leq 1/(2\sqrt{\alpha\beta})$. In a paragraph we show on a specific 1D example that the schemes for $\alpha < 1/2$ or $\beta < 1/2$ cannot be stable as some Fourier components are amplified. Finally, we show 2D numerical results for the wave and Euler equations using a compatible Lagrangian hydrodynamics code.

2. Lagrangian coordinates and wave equation models.

2.1. 1D. The hydrodynamic equations in 1D Lagrangian coordinates, expressed in mass variables m, are

$$\frac{du}{dt} = -\frac{\partial p}{\partial m}, \qquad \frac{d\tau}{dt} = \frac{\partial u}{\partial m}, \qquad \frac{de}{dt} = -p\frac{\partial u}{\partial m},$$

where u is the velocity, τ is the specific volume, e is the specific internal energy, and $p = p(\tau, e)$ is the pressure.

Total energy E and entropy S are conserved:

$$\begin{aligned}\frac{dE}{dt} &= \frac{1}{2}\frac{du^2}{dt} + \frac{de}{dt} \\ &= -u\frac{\partial p}{\partial m} - p\frac{\partial u}{\partial m} = -\frac{\partial pu}{\partial m},\end{aligned}$$

and

$$T\,\frac{dS}{dt} = \frac{de}{dt} + p\frac{d\tau}{dt} = 0.$$

Therefore for smooth flows the exact differential equations for u, p are

$$\begin{aligned}\frac{du}{dt} &= -\frac{\partial p}{\partial m}, \\ \frac{dp}{dt} &= \frac{dp}{d\tau}\frac{d\tau}{dt} + \frac{dp}{de}\frac{de}{dt} = \left(\frac{dp}{d\tau} - p\frac{dp}{de}\right)\frac{\partial u}{\partial m},\end{aligned}$$

and taking the coefficients p, $\frac{dp}{d\tau}$, and $\frac{dp}{de}$ to be constant yields a linear system with constant coefficients. Now assume that $\frac{dp}{d\tau} < 0$ and $\frac{dp}{de} > 0$. As

$$c = \sqrt{\left|\frac{dp}{d\tau}\right| + p\frac{dp}{de}}$$

is the sound speed, the linearization of the system with constant coefficients is obtained by freezing the sound speed; that is, c is assumed to be constant in space and time. Consequently, the resulting system is just the wave equation

$$\begin{aligned}\frac{du}{dt} &= -\frac{\partial p}{\partial m}, \\ \frac{dp}{dt} &= -c^2\frac{\partial u}{\partial m}.\end{aligned}$$

By using the new variables $u = u'/c$ and $dm/c = -da$ and dropping the prime notation, this linearized system can be written as

$$\frac{du}{dt} = \frac{\partial p}{\partial a}, \tag{2.1}$$

$$\frac{dp}{dt} = \frac{\partial u}{\partial a}. \tag{2.2}$$

2.2. 2D. The same linearized reduction can be performed for Lagrangian coordinates in 2D, but it is not quite as straightforward. In 2D the Euler equation system

is

$$\begin{aligned}
\rho\frac{du}{dt} &= -\frac{\partial p}{\partial x},\\
\rho\frac{dv}{dt} &= -\frac{\partial p}{\partial y},\\
\rho\frac{d\tau}{dt} &= \frac{\partial u}{\partial x}+\frac{\partial v}{\partial y},\\
\rho\frac{de}{dt} &= -p\left(\frac{\partial u}{\partial x}+\frac{\partial v}{\partial y}\right),\\
\frac{dx}{dt} &= u,\\
\frac{dy}{dt} &= v.
\end{aligned}$$

By following [7], [8] we make the change of variables:

$$\begin{aligned}
x &= x(a,b,t),\\
y &= y(a,b,t),
\end{aligned}$$

with the choice

$$\begin{aligned}
a &= x(a,b,0),\\
b &= y(a,b,0).
\end{aligned}$$

The Jacobian matrix of the transformation $(x,y)\leftrightarrow(a,b)$ is given by

$$\mathbf{J}=\begin{pmatrix} \frac{\partial x}{\partial a} & \frac{\partial x}{\partial b}\\ \frac{\partial y}{\partial a} & \frac{\partial y}{\partial b}\end{pmatrix},$$

the determinant of which is the Jacobian

$$J=\frac{\partial x}{\partial a}\frac{\partial y}{\partial b}-\frac{\partial y}{\partial a}\frac{\partial x}{\partial b}.$$

For the two velocity equations we now have

$$\begin{aligned}
J\rho\frac{du}{dt} &= \frac{\partial y}{\partial a}\frac{\partial p}{\partial b}-\frac{\partial y}{\partial b}\frac{\partial p}{\partial a},\\
J\rho\frac{dv}{dt} &= \frac{\partial x}{\partial b}\frac{\partial p}{\partial a}-\frac{\partial x}{\partial a}\frac{\partial p}{\partial b}.
\end{aligned}$$

But then, by starting the linearization by freezing the entries of the Jacobian, we obtain

$$\begin{aligned}
J\rho\frac{d}{dt}\left(u\frac{\partial x}{\partial a}+v\frac{\partial y}{\partial a}\right) &= -J\frac{\partial p}{\partial a},\\
J\rho\frac{d}{dt}\left(u\frac{\partial x}{\partial b}+v\frac{\partial y}{\partial b}\right) &= -J\frac{\partial p}{\partial b}.
\end{aligned}$$

Thus, by letting

$$\begin{aligned}
u' &= u\frac{\partial x}{\partial a}+v\frac{\partial y}{\partial a},\\
v' &= u\frac{\partial x}{\partial b}+v\frac{\partial y}{\partial b},
\end{aligned}$$

we obtain

$$\rho\frac{du'}{dt} = -\frac{\partial p}{\partial a},$$
$$\rho\frac{dv'}{dt} = -\frac{\partial p}{\partial b}.$$

We next need to evaluate $\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y}$ in the energy equation. First,

$$Ju = \frac{\partial y}{\partial b}u' - \frac{\partial y}{\partial a}v',$$
$$-Jv = \frac{\partial x}{\partial b}u' - \frac{\partial x}{\partial a}v'.$$

Then taking the derivative of u and v yields

$$J^2\frac{\partial u}{\partial x} = \frac{\partial y}{\partial b}\left(\frac{\partial y}{\partial b}\frac{\partial u'}{\partial a} - \frac{\partial y}{\partial a}\frac{\partial u'}{\partial b}\right) - \frac{\partial y}{\partial a}\left(\frac{\partial y}{\partial b}\frac{\partial v'}{\partial a} - \frac{\partial y}{\partial a}\frac{\partial v'}{\partial b}\right),$$
$$J^2\frac{\partial v}{\partial y} = \frac{\partial x}{\partial b}\left(\frac{\partial x}{\partial b}\frac{\partial u'}{\partial a} - \frac{\partial x}{\partial a}\frac{\partial u'}{\partial b}\right) - \frac{\partial x}{\partial a}\left(\frac{\partial x}{\partial b}\frac{\partial v'}{\partial a} - \frac{\partial x}{\partial a}\frac{\partial v'}{\partial b}\right).$$

Summing the previous equations gives

$$J^2\frac{\partial u}{\partial x} + J^2\frac{\partial v}{\partial y} = \left(\left(\frac{\partial x}{\partial b}\right)^2 + \left(\frac{\partial y}{\partial b}\right)^2\right)\frac{\partial u'}{\partial a} - \left(\frac{\partial x}{\partial a}\frac{\partial x}{\partial b} + \frac{\partial y}{\partial a}\frac{\partial y}{\partial b}\right)\frac{\partial u'}{\partial b}$$
$$- \left(\frac{\partial x}{\partial a}\frac{\partial x}{\partial b} + \frac{\partial y}{\partial a}\frac{\partial y}{\partial b}\right)\frac{\partial v'}{\partial a} + \left(\left(\frac{\partial x}{\partial a}\right)^2 + \left(\frac{\partial y}{\partial a}\right)^2\right)\frac{\partial v'}{\partial b},$$

and in order to cancel the cross terms, we are forced to assume here that

$$\frac{\partial x}{\partial a}\frac{\partial x}{\partial b} + \frac{\partial y}{\partial a}\frac{\partial y}{\partial b} = 0, \tag{2.3}$$

so that

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = d_1\frac{\partial u'}{\partial a} + d_2\frac{\partial v'}{\partial b},$$
$$d_1 = \frac{1}{J^2}\left(\left(\frac{\partial x}{\partial b}\right)^2 + \left(\frac{\partial y}{\partial b}\right)^2\right),$$
$$d_2 = \frac{1}{J^2}\left(\left(\frac{\partial x}{\partial a}\right)^2 + \left(\frac{\partial y}{\partial a}\right)^2\right).$$

So

$$\rho\frac{du'}{dt} = -\frac{\partial p}{\partial a},$$
$$\rho\frac{dv'}{dt} = -\frac{\partial p}{\partial b},$$
$$\rho\frac{d\tau}{dt} = d_1\frac{\partial u'}{\partial a} + d_2\frac{\partial v'}{\partial b},$$
$$\rho\frac{de}{dt} = -p\left(d_1\frac{\partial u'}{\partial a} + d_2\frac{\partial v'}{\partial b}\right).$$

Now ρ can be scaled into a, b, and as before, a simple substitution yields

$$\begin{aligned}\frac{du'}{dt} &= -\frac{\partial p}{\partial a},\\ \frac{dv'}{dt} &= -\frac{\partial p}{\partial b},\\ \frac{dp}{dt} &= -c^2\left(d_1\frac{\partial u'}{\partial a} + d_2\frac{\partial v'}{\partial b}\right).\end{aligned}$$

Finally, returning to (u, v, a, b), set

$$\begin{aligned} u &= -c\sqrt{d_1}u', & v &= -c\sqrt{d_2}v',\\ a &= c\sqrt{d_1}\,\widetilde{a}, & b &= c\sqrt{d_2}\,\widetilde{b},\end{aligned}$$

to obtain the 2D wave equation as a model:

$$\frac{du}{dt} = \frac{\partial p}{\partial \widetilde{a}}, \qquad \frac{dv}{dt} = \frac{\partial p}{\partial \widetilde{b}}, \qquad \frac{dp}{dt} = \frac{\partial u}{\partial \widetilde{a}} + \frac{\partial v}{\partial \widetilde{b}}. \tag{2.4}$$

However, this formulation critically depends on (2.3), so ultimately we present this as only a potential model.[1]

3. Notation. This section defines the notation that will be used throughout the rest of this paper.

The standard inner product on a complex vector space of dimension N is $\langle \mathbf{f}, \mathbf{g}\rangle = \sum_{i=1}^{N} f_i\,\bar{g}_i$ for two complex vectors $\mathbf{f} = (f_i)_{i=1,\dots,N}$ and $\mathbf{g} = (g_i)_{i=1,\dots,N}$.

Time. We will assume equal time steps; that is, the temporal interval $[0, T > 0]$ is discretized into equal intervals $[t_n, t_{n+1}]$, with $t_{n+1} = t_n + \Delta t$.

Space. In 2D we define uniform rectangles with vertices $x_{i,j}$, $y_{i,j}$, where $x_{i+1,j} = x_{i,j} + \Delta x$ and $y_{i,j+1} = y_{i,j} + \Delta y$. Nodal quantities are indexed by (i, j), while cell quantities are indexed by $(i + \frac{1}{2}, j + \frac{1}{2})$.

Discretization. The ratio of time step to space step in each dimension is given by $\lambda_x = \frac{\Delta t}{\Delta x}$, $\lambda_y = \frac{\Delta t}{\Delta y}$.

Hence, any quantity P at some point (i, j) at time t_n is represented as $P^n_{i,j}$. Similarly, any cell-based quantity C at time t_{n+1} is represented as $C^{n+1}_{i+\frac{1}{2},j+\frac{1}{2}}$.

For any variable w defined at two time levels $t_{n+1} > t_n$ on a point or in a cell, we define its interpolated value at an intermediate time $n + \kappa$ as:

$$w^{n+\kappa} = \kappa w^{n+1} + (1-\kappa)\,w^n, \qquad 0 \le \kappa \le 1.$$

We further define a vector $\mathbf{w} = (\mathbf{u}, \mathbf{v}, \mathbf{p})^t$ and $\mathbf{w}^{\alpha,\beta} = (\mathbf{u}^{n+\alpha}, \mathbf{v}^{n+\alpha}, \mathbf{p}^{n+\beta})^t$, where

$$\mathbf{u} = \{u_{i,j} : \ \forall\,(i,j)\}, \quad \mathbf{v} = \{v_{i,j} : \ \forall\,(i,j)\}, \quad \text{and} \quad \mathbf{p} = \left\{p_{i+\frac{1}{2},j+\frac{1}{2}} : \ \forall\,(i,j)\right\}.$$

[1] The Jacobian matrix $\mathbf{J}$ contains information relating to the volume, shape, and orientation of an element after the transformation $(a, b) \to (x, y)$. $\mathbf{\Lambda} = \mathbf{J}^{\mathrm{T}}\mathbf{J}$ is the associated metric tensor:

$$\mathbf{\Lambda} = \begin{pmatrix} \lambda_{11} & \lambda_{21} \\ \lambda_{12} & \lambda_{22} \end{pmatrix} = \begin{pmatrix} \left(\frac{\partial x}{\partial a}\right)^2 + \left(\frac{\partial x}{\partial b}\right)^2 & \frac{\partial x}{\partial a}\frac{\partial x}{\partial b} + \frac{\partial y}{\partial a}\frac{\partial y}{\partial b} \\ \frac{\partial x}{\partial a}\frac{\partial x}{\partial b} + \frac{\partial y}{\partial a}\frac{\partial y}{\partial b} & \left(\frac{\partial y}{\partial a}\right)^2 + \left(\frac{\partial y}{\partial b}\right)^2 \end{pmatrix},$$

$\mathbf{\Lambda}$ is a symmetric matrix, and moreover the constraint (2.3) states that $\lambda_{12} = 0$: The metric tensor $\mathbf{\Lambda}$ is diagonal, meaning that the implied system of coordinates is orthogonal.

Boundary conditions. We assume throughout that all sums exist and that Fourier transforms can be taken. Also, in the usual way, it is supposed that effectively there are no boundaries and therefore that indices can be shifted in a sum without changing its value. For example, for all integers k

$$\sum_i u_{i,j}\ p_{i+\frac{1}{2},j} = \sum_i u_{i+k,j}\ p_{i+\frac{1}{2}+k,j}.$$

Operators. There are two sets of data: nodal quantities and cell quantities. Consider the operator Q_x that maps cell data to nodal data given by

$$(Q_x p)_{i,j} = \frac{1}{2}\left(p_{i+\frac{1}{2},j+\frac{1}{2}} + p_{i+\frac{1}{2},j-\frac{1}{2}} - p_{i-\frac{1}{2},j+\frac{1}{2}} - p_{i-\frac{1}{2},j-\frac{1}{2}}\right).$$

By using the usual scalar product in both nodal and cell spaces, the adjoint Q_x^* maps nodal data to cell data and is defined by

$$\begin{aligned}\langle Q_x^* u, p\rangle = \langle u, Q_x p\rangle &= \frac{1}{2}\sum u_{i,j}\left(p_{i+\frac{1}{2},j+\frac{1}{2}} + p_{i+\frac{1}{2},j-\frac{1}{2}} - p_{i-\frac{1}{2},j+\frac{1}{2}} - p_{i-\frac{1}{2},j-\frac{1}{2}}\right)\\ &= \frac{1}{2}\sum p_{i+\frac{1}{2},j+\frac{1}{2}}\Big(u_{i,j} + u_{i,j+1} - u_{i+1,j} - u_{i+1,j+1}\Big);\end{aligned}$$

that is,

$$(Q_x^* u)_{i+\frac{1}{2},j+\frac{1}{2}} = \frac{1}{2}\Big(u_{i,j} + u_{i,j+1} - u_{i+1,j} - u_{i+1,j+1}\Big).$$

Similar definitions exist for Q_y and Q_y^*.

The notation for a staggered scheme on a rectangular grid for the 2D wave equation is depicted in Figure 3.1, where p is defined at the center of each cell and u and v are defined at nodes. For this scheme p has fractional indices, whereas u and v have integer indices. Moreover, one defines interpolated values at each midedge point; for example, for a midedge point defined with indices $i+\frac{1}{2}, j+1$ one has $p_{i+\frac{1}{2},j+1} = \frac{1}{2}(p_{i+\frac{1}{2},j+\frac{3}{2}} + p_{i+\frac{1}{2},j-\frac{1}{2}})$ and $u_{i+\frac{1}{2},j+1} = \frac{1}{2}(u_{i,j+1} + u_{i+1,j+1})$, whereas for a midedge point $i, j+\frac{1}{2}$ one has $p_{i,j+\frac{1}{2}} = \frac{1}{2}(p_{i+\frac{1}{2},j+\frac{1}{2}} + p_{i+\frac{3}{2},j+\frac{1}{2}})$ and $u_{i,j+\frac{1}{2}} = \frac{1}{2}(u_{i,j+1} + u_{i+1,j})$.

By using this notation, a fully implicit staggered scheme applied to system (2.4) can be written as

$$\begin{aligned} u_{i,j}^{n+1} &= u_{i,j}^n + \lambda_x\left(p_{i+\frac{1}{2},j}^{n+\alpha} - p_{i-\frac{1}{2},j}^{n+\alpha}\right),\\ v_{i,j}^{n+1} &= v_{i,j}^n + \lambda_y\left(p_{i,j+\frac{1}{2}}^{n+\alpha} - p_{i,j-\frac{1}{2}}^{n+\alpha}\right),\\ p_{i+\frac{1}{2},j+\frac{1}{2}}^{n+1} &= p_{i+\frac{1}{2},j+\frac{1}{2}}^n + \lambda_x\left(u_{i+1,j+\frac{1}{2}}^{n+\beta} - u_{i,j+\frac{1}{2}}^{n+\beta}\right) + \lambda_y\left(v_{i+\frac{1}{2},j+1}^{n+\beta} - v_{i+\frac{1}{2},j}^{n+\beta}\right).\end{aligned} \tag{3.1}$$

The difference operator is given by the matrix

$$\mathbf{M} = \begin{pmatrix} 0 & 0 & Q_x \\ 0 & 0 & Q_y \\ -Q_x^* & -Q_y^* & 0 \end{pmatrix},$$

together with

$$\mathbf{\Lambda} = \begin{pmatrix} \lambda_x & 0 & 0 \\ 0 & \lambda_y & 0 \\ 0 & 0 & 1 \end{pmatrix}.$$

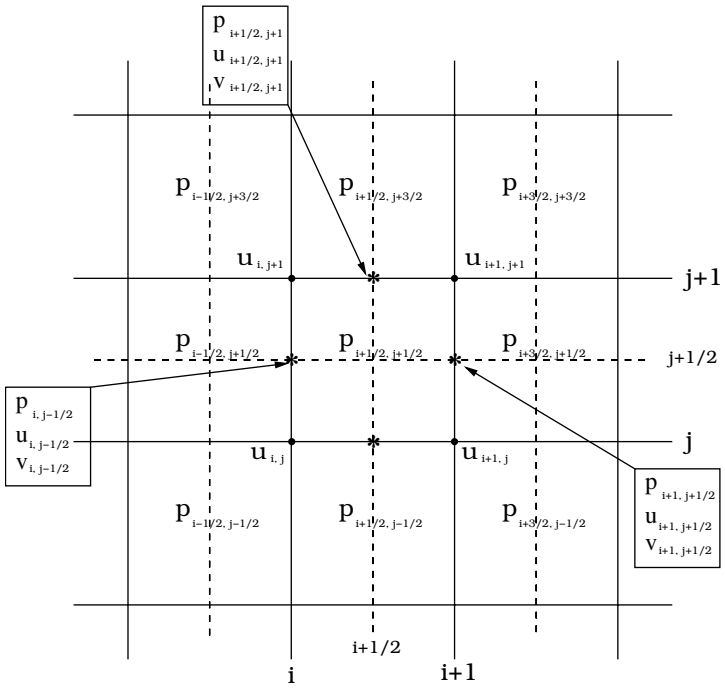

FIG. 3.1. *Rectangular staggered scheme. p is defined at cell centers with fractional indices: $p_{i+\frac{1}{2},j+\frac{1}{2}}$, whereas u, v are defined at nodes with integer indices: $u_{i,j}$. Moreover u, v, p are interpolated at each midedge point $*$. For example, $p_{i+\frac{1}{2},j+1} = \frac{1}{2}(p_{i+\frac{1}{2},j+\frac{3}{2}} + p_{i+\frac{1}{2},j-\frac{1}{2}})$ and $u_{i+\frac{1}{2},j+1} = \frac{1}{2}(u_{i,j+1} + u_{i+1,j+1})$, and similarly for v.*

Thus, the implicit difference scheme (3.1) has the form

$$\mathbf{w}^{n+1} = \mathbf{w}^n + \mathbf{\Lambda M \Lambda w}^{\alpha,\beta}.$$

THEOREM 3.1. *The staggered implicit scheme is stable for any λ_x, λ_y if $\alpha \geq \frac{1}{2}$ and $\beta \geq \frac{1}{2}$.*

Proof. Throughout the proofs, all sums are taken over both indices i and j. Applying the energy method yields

$$H(\alpha,\beta) = \sum \left(u_{i,j}^{n+1} - u_{i,j}^n\right) u_{i,j}^{n+\beta} + \sum \left(v_{i,j}^{n+1} - v_{i,j}^n\right) v_{i,j}^{n+\beta} + \sum \left(p_{i+\frac{1}{2},j+\frac{1}{2}}^{n+1} - p_{i+\frac{1}{2},j+\frac{1}{2}}^n\right) p_{i+\frac{1}{2},j+\frac{1}{2}}^{n+\alpha} = 0.$$

This follows from the fact that

$$\mathbf{M}^* = -\mathbf{M}$$

and therefore for real $\mathbf{w}$

$$\langle \mathbf{Mw}, \mathbf{w} \rangle = 0\,.$$

Now let us define $U(\beta), V(\beta), P(\alpha)$ such that $H(\alpha,\beta) = U(\beta) + V(\beta) + P(\alpha)$ and

$$\begin{aligned}
U(\beta) &= \sum \left(u_{i,j}^{n+1} - u_{i,j}^{n}\right) u_{i,j}^{n+\beta} \\
&= \beta \sum \left(u_{i,j}^{n+1}\right)^2 - (1-\beta) \sum \left(u_{i,j}^{n}\right)^2 - (2\beta - 1) \sum \left(u_{i,j}^{n+1} u_{i,j}^{n}\right), \\
V(\beta) &= \sum \left(v_{i,j}^{n+1} - v_{i,j}^{n}\right) v_{i,j}^{n+\beta} \\
&= \beta \sum \left(v_{i,j}^{n+1}\right)^2 - (1-\beta) \sum \left(v_{i,j}^{n}\right)^2 - (2\beta - 1) \sum \left(v_{i,j}^{n+1} v_{i,j}^{n}\right), \\
P(\alpha) &= \sum \left(p_{i+\frac{1}{2},j+\frac{1}{2}}^{n+1} - p_{i+\frac{1}{2},j+\frac{1}{2}}^{n}\right) p_{i+\frac{1}{2},j+\frac{1}{2}}^{n+\alpha} \\
&= \alpha \sum \left(p_{i+\frac{1}{2},j+\frac{1}{2}}^{n+1}\right)^2 - (1-\alpha) \sum \left(p_{i+\frac{1}{2},j+\frac{1}{2}}^{n}\right)^2 \\
&\quad - (2\alpha - 1) \sum \left(p_{i+\frac{1}{2},j+\frac{1}{2}}^{n+1} p_{i+\frac{1}{2},j+\frac{1}{2}}^{n}\right).
\end{aligned}$$

We detail the steps in the proof by using U and comment that the steps in the proof for V and P are similarly obtained.

Differentiating U with respect to β gives

$$U'(\beta) = \sum \left(u_{i,j}^{n+1}\right)^2 + \sum \left(u_{i,j}^{n}\right)^2 - 2 \sum \left(u_{i,j}^{n+1} u_{i,j}^{n}\right).$$

Then by the Schwarz inequality

$$U'(\beta) > 0$$

($U' = 0$ only in the trivial case that the initial data are constant). Since

$$U\left(\frac{1}{2}\right) = \frac{1}{2}\left(\sum \left(u_{i,j}^{n+1}\right)^2 - \sum \left(u_{i,j}^{n}\right)^2\right),$$

it follows that for $\beta \geq \frac{1}{2}$

$$U(\beta) \geq \frac{1}{2}\left(\sum \left(u_{i,j}^{n+1}\right)^2 - \sum \left(u_{i,j}^{n}\right)^2\right),$$

while for $\beta < \frac{1}{2}$

$$U(\beta) < \frac{1}{2}\left(\sum \left(u_{i,j}^{n+1}\right)^2 - \sum \left(u_{i,j}^{n}\right)^2\right).$$

By applying the same reasoning to V and P we see that for $\beta \geq \frac{1}{2}$ and $\alpha \geq \frac{1}{2}$

$$\begin{aligned}
\sum \left(\left(u_{i,j}^{n+1}\right)^2 - \left(u_{i,j}^{n}\right)^2\right) + \sum \left(\left(v_{i,j}^{n+1}\right)^2 - \left(v_{i,j}^{n}\right)^2\right) \\
+ \sum \left(\left(p_{i+\frac{1}{2},j+\frac{1}{2}}^{n+1}\right)^2 - \left(p_{i+\frac{1}{2},j+\frac{1}{2}}^{n}\right)^2\right) \leq 0;
\end{aligned}$$

that is, we have stability because

$$\begin{aligned}
\sum \left(u_{i,j}^{n+1}\right)^2 + \sum \left(v_{i,j}^{n+1}\right)^2 + \sum \left(p_{i+\frac{1}{2},j+\frac{1}{2}}^{n+1}\right)^2 \\
\leq \sum \left(u_{i,j}^{n}\right)^2 + \sum \left(v_{i,j}^{n}\right)^2 + \sum \left(p_{i+\frac{1}{2},j+\frac{1}{2}}^{n}\right)^2. \qquad \square
\end{aligned}$$

4. Rectangular predictor-corrector scheme. The predictor-corrector scheme in 2D [4] for the wave equation can now be described.

Predictor step.

$$\begin{aligned}
\widetilde{u}_{i,j}^{n+1} &= u_{i,j}^{n} + \lambda_x \left(Q_x p^n\right)_{i,j}, \\
\widetilde{v}_{i,j}^{n+1} &= v_{i,j}^{n} + \lambda_y \left(Q_y p^n\right)_{i,j}, \\
\widetilde{p}_{i+\frac{1}{2},j+\frac{1}{2}}^{n+1} &= p_{i+\frac{1}{2},j+\frac{1}{2}}^{n} - \lambda_x \left(Q_x^* u^{n+\beta}\right)_{i+\frac{1}{2},j+\frac{1}{2}} - \lambda_y \left(Q_y^* v^{n+\beta}\right)_{i+\frac{1}{2},j+\frac{1}{2}};
\end{aligned}$$

recall that $w^{n+\beta} = \beta \widetilde{w}^{\,n+1} + (1-\beta) w^n$ for $w = u, v$.

Corrector step.

$$\begin{aligned}
u_{i,j}^{n+1} &= u_{i,j}^{n} + \lambda_x \left(Q_x p^{n+\alpha}\right)_{i,j}, \\
v_{i,j}^{n+1} &= v_{i,j}^{n} + \lambda_y \left(Q_y p^{n+\alpha}\right)_{i,j}, \\
p_{i+\frac{1}{2},j+\frac{1}{2}}^{n+1} &= p_{i+\frac{1}{2},j+\frac{1}{2}}^{n} - \lambda_x \left(Q_x^* u^{n+\beta}\right)_{i+\frac{1}{2},j+\frac{1}{2}} - \lambda_y \left(Q_y^* v^{n+\beta}\right)_{i+\frac{1}{2},j+\frac{1}{2}};
\end{aligned}$$

recall that $p^{n+\alpha} = \alpha \widetilde{p}^{\,n+1} + (1-\alpha) p^n$ and now $w^{n+\beta} = \beta w^{n+1} + (1-\beta) w^n$ for $w = u, v$.

By substituting the equation resulting from the predictor step into the corrector step, we obtain the following difference scheme:

$$\mathbf{w}^{n+1} = \mathbf{S}\mathbf{w}^n.$$

Rather than write this out in terms of the difference operators, we immediately move to the Fourier transforms of the variables and operators.

The Fourier transform employs a substitution of variables; for instance, for p we have

$$p_{i+\frac{1}{2},j+\frac{1}{2}}^{n} \longmapsto p_0 e^{\theta(n\Delta t) + \mathrm{i}\left(2\delta\left((i+\frac{1}{2})\Delta x\right) + 2\gamma\left((j+\frac{1}{2})\Delta y\right)\right)},$$

where θ is complex and δ, γ are real. After factoring we obtain:

$$\begin{aligned}
\left(\widehat{Q}_x p\right)_{i,j} &= p_0 e^{\theta(n\Delta t) + \mathrm{i}(2\delta(i\Delta x) + 2\gamma(j\Delta y))} \frac{1}{2} \left(2\mathrm{i}\sin(\delta\Delta x)\right) \left(e^{\mathrm{i}\gamma\Delta y} + e^{-\mathrm{i}\gamma\Delta y}\right) \\
&= p_0 e^{\theta(n\Delta t) + \mathrm{i}(2\delta(i\Delta x) + 2\gamma(j\Delta y))} \left(2\mathrm{i}\sin(\delta\Delta x)\cos(\gamma\Delta y)\right),
\end{aligned}$$

with $\mathrm{i} = \sqrt{-1}$. Then if one denotes $\xi = \delta\Delta x$, and $\eta = \gamma\Delta y$, the dimensionless wave numbers in the x and y directions, respectively, on an uniform mesh, the Fourier transforms of the operator Q_x, Q_y are

$$\left(\widehat{Q}_x p\right)_{i,j} = p_0 e^{\theta(n\Delta t) + 2\mathrm{i}(i\xi + j\eta)} \left(2\mathrm{i}\sin\xi\cos\eta\right), \tag{4.1}$$

$$\left(\widehat{Q}_y p\right)_{i,j} = p_0 e^{\theta(n\Delta t) + 2\mathrm{i}(i\xi + j\eta)} \left(2\mathrm{i}\cos\xi\sin\eta\right). \tag{4.2}$$

The same formulas can be similarly obtained for Q^*.

By setting

$$\Phi_x = 2\lambda_x \sin\xi\cos\eta \quad \text{and} \quad \Phi_y = 2\lambda_y \sin\eta\cos\xi,$$

and dropping the hat notation, we obtain

$$\mathbf{S} = \begin{pmatrix} 1-\alpha\Phi_x^2 & -\alpha\Phi_x\Phi_y & \mathrm{i}\Phi_x\left(1-\alpha\beta(\Phi_x^2+\Phi_y^2)\right) \\ -\alpha\Phi_x\Phi_y & 1-\alpha\Phi_y^2 & \mathrm{i}\Phi_y\left(1-\alpha\beta\left(\Phi_x^2+\Phi_y^2\right)\right) \\ \mathrm{i}\Phi_x\left(1-\alpha\beta(\Phi_x^2+\Phi_y^2)\right) & \mathrm{i}\Phi_y\left(1-\alpha\beta(\Phi_x^2+\Phi_y^2)\right) & 1+\alpha\beta^2(\Phi_x^2+\Phi_y^2)^2-\beta\left(\Phi_x^2+\Phi_y^2\right) \end{pmatrix}.$$

The Lax–Richtmyer stability theory [6] tells us that we must show that the amplification factor $\mathbf{S}$ has uniformly bounded powers. First, observe that $\mathbf{S}\mathbf{S}^* \neq \mathbf{S}^*\mathbf{S}$, so it is not sufficient to show that the eigenvalues of $\mathbf{S}$ are less than 1. We shall show instead that the numerical radius of $\mathbf{S}$ is bounded by 1, since this implies that the powers of $\mathbf{S}$ are uniformly bounded by 2. A survey of results about the numerical radius is given in [5] along with a direct proof that, if the numerical radius is bounded by one, the powers are bounded by 2. We remark that the Kreiss matrix theorem implies a weaker result, namely, that the powers are bounded by a constant that depends on the size of the matrix [6]. The numerical radius was apparently first used as a stability analysis tool in [2], and here we use the basic ideas of that work.

We henceforth use the same symbols for grid functions and their Fourier transforms, realizing that this is an abuse of the notation, but hoping that no confusion will occur. The numerical radius of $\mathbf{S}$, denoted $R(\mathbf{S})$, is

$$R(\mathbf{S}) = \sup_{\mathbf{w}} |\langle \mathbf{S}\mathbf{w}, \mathbf{w}\rangle|, \quad \text{with} \quad \langle \mathbf{w}, \mathbf{w}\rangle = 1.$$

The matrix $\mathbf{S}$ can be split into real and imaginary parts as

$$\mathbf{S} = \mathbf{A} + \mathrm{i}\mathbf{B},$$

where

$$\mathbf{A} = \begin{pmatrix} 1-\alpha\Phi_x^2 & -\alpha\Phi_x\Phi_y & 0 \\ -\alpha\Phi_x\Phi_y & 1-\alpha\Phi_y^2 & 0 \\ 0 & 0 & 1+\alpha\beta^2(\Phi_x^2+\Phi_y^2)^2-\beta\left(\Phi_x^2+\Phi_y^2\right) \end{pmatrix},$$

$$\mathbf{B} = \left(1-\alpha\beta(\Phi_x^2+\Phi_y^2)\right)\begin{pmatrix} 0 & 0 & \Phi_x \\ 0 & 0 & \Phi_y \\ \Phi_x & \Phi_y & 0 \end{pmatrix}.$$

Now let

$$r = \langle \mathbf{A}\mathbf{w}, \mathbf{w}\rangle, \quad j = \langle \mathbf{B}\mathbf{w}, \mathbf{w}\rangle.$$

Since $\mathbf{A}$ and $\mathbf{B}$ are real and symmetric, r and j are real. Then

$$|\langle \mathbf{S}\mathbf{w}, \mathbf{w}\rangle|^2 = |\langle \mathbf{A}\mathbf{w}, \mathbf{w}\rangle + \mathrm{i}\langle \mathbf{B}\mathbf{w}, \mathbf{w}\rangle|^2 = |r+\mathrm{i}j|^2 = r^2+j^2.$$

THEOREM 4.1. *The* 2D *staggered rectangular scheme is stable if* $\alpha \geq \frac{1}{2}$, $\beta \geq \frac{1}{2}$, *and* $4\alpha\beta\max(\lambda_x^2, \lambda_y^2) \leq 1$.

Proof. Suppose that $\alpha \geq \frac{1}{2}$, $\beta \geq \frac{1}{2}$, and $4\alpha\beta\max(\lambda_x^2, \lambda_y^2) \leq 1$. Let

$$\overline{\mathrm{x}} = \sqrt{\alpha\beta}\,\Phi_x, \quad \overline{\mathrm{y}} = \sqrt{\alpha\beta}\,\Phi_y.$$

First note that

$$z^2 = \overline{\mathrm{x}}^2 + \overline{\mathrm{y}}^2 \leq 1,$$

since

$$\begin{aligned} z^2 = \overline{\mathrm{x}}^2 + \overline{\mathrm{y}}^2 &= \alpha\beta\left(\Phi_x^2 + \Phi_y^2\right) \\ &= \alpha\beta\left(4\lambda_x^2 \sin^2\xi\cos^2\eta + 4\lambda_y^2 \sin^2\eta\cos^2\xi\right) \\ &\le \underbrace{4\alpha\beta\max\left(\lambda_x^2, \lambda_y^2\right)}_{\le 1}\left[(\cos\eta\sin\xi)^2 + (\cos\xi\sin\eta)^2\right] \\ &\le (\cos\eta\sin\xi)^2 + (\cos\xi\sin\eta)^2 \le 1. \end{aligned}$$

Recall that $|\mathbf{u}|^2 + |\mathbf{v}|^2 + |\mathbf{p}|^2 = 1$, and note that

$$|\overline{\mathrm{x}}u + \overline{\mathrm{y}}v|^2 \le \left(1 - |p|^2\right)\left(\overline{\mathrm{x}}^2 + \overline{\mathrm{y}}^2\right), \tag{4.3}$$

since

$$\begin{aligned} |\overline{\mathrm{x}}u + \overline{\mathrm{y}}v|^2 = \left(\overline{\mathrm{x}}u + \overline{\mathrm{y}}v\right)\left(\overline{\mathrm{x}}\overline{u} + \overline{\mathrm{y}}\overline{v}\right) &= \overline{\mathrm{x}}^2 u\overline{u} + \overline{\mathrm{y}}^2 v\overline{v} + \overline{\mathrm{x}}\overline{\mathrm{y}}\left(\overline{u}v + \overline{v}u\right) \\ &\le \overline{\mathrm{x}}^2 u\overline{u} + \overline{\mathrm{y}}^2 v\overline{v} + \overline{\mathrm{x}}^2|v|^2 + \overline{\mathrm{y}}^2|u|^2 \\ &= \left(|u|^2 + |v|^2\right)\left(\overline{\mathrm{x}}^2 + \overline{\mathrm{y}}^2\right) \\ &\le \left(1 - |p|^2\right)\left(\overline{\mathrm{x}}^2 + \overline{\mathrm{y}}^2\right). \end{aligned} \tag{4.4}$$

Also, by setting

$$\overline{\mathrm{a}} = 1/\alpha, \quad \overline{\mathrm{b}} = 1/\beta,$$

we have that $\overline{\mathrm{a}}, \overline{\mathrm{b}}$ are positive and bounded by 2. Then

$$\begin{aligned} r &= 1 - \overline{\mathrm{b}}|\overline{\mathrm{x}}u + \overline{\mathrm{y}}v|^2 - \overline{\mathrm{a}}\left(\overline{\mathrm{x}}^2 + \overline{\mathrm{y}}^2\right)|p|^2 + \overline{\mathrm{a}}\left(\overline{\mathrm{x}}^2 + \overline{\mathrm{y}}^2\right)^2|p|^2, \\ j &= 2\sqrt{\overline{\mathrm{a}}\overline{\mathrm{b}}}\,\mathcal{R}\left(\overline{p}\left(\overline{\mathrm{x}}u + \overline{\mathrm{y}}v\right)\right)\left(1 - \left(\overline{\mathrm{x}}^2 + \overline{\mathrm{y}}^2\right)\right), \end{aligned}$$

where $\mathcal{R}(q)$ is the real part of q, and

$$\begin{aligned} r^2 &= \left(1 - \overline{\mathrm{b}}|\overline{\mathrm{x}}u + \overline{\mathrm{y}}v|^2 - \overline{\mathrm{a}}z^2\left(1 - z^2\right)|p|^2\right)^2, \\ j^2 &\le 4\overline{\mathrm{a}}\overline{\mathrm{b}}\left(1 - z^2\right)^2|p|^2|\overline{\mathrm{x}}u + \overline{\mathrm{y}}v|^2. \end{aligned}$$

Now set

$$|\overline{\mathrm{x}}u + \overline{\mathrm{y}}v|^2 = z^2\left(1 - |p|^2\right)\gamma.$$

By (4.3), $0 \le \gamma \le 1$. We thus have that

$$\begin{aligned} r^2 &= \left(1 - \gamma\overline{\mathrm{b}}z^2\left(1 - |p|^2\right) - \overline{\mathrm{a}}z^2\left(1 - z^2\right)|p|^2\right)^2, \\ j^2 &\le 4\overline{\mathrm{a}}\left(\gamma\overline{\mathrm{b}}\right)z^2\left(1 - z^2\right)^2|p|^2\left(1 - |p|^2\right). \end{aligned}$$

Also note that, for all $0 \le p \le 1$,

$$|p|^2\left(1 - |p|^2\right) \le \frac{1}{4}.$$

Since $\gamma\overline{\mathrm{b}}$ has the same range as $\overline{\mathrm{b}}$, we can replace $\gamma\overline{\mathrm{b}}$ by $\overline{\mathrm{b}}$. What we need to show then is that

$$g\left(z, p, \overline{\mathrm{a}}, \overline{\mathrm{b}}\right) = \left[1 - \overline{\mathrm{b}}z^2\left(1 - |p|^2\right) - \overline{\mathrm{a}}z^2\left(1 - z^2\right)|p|^2\right]^2 + \overline{\mathrm{a}}\overline{\mathrm{b}}z^2\left(1 - z^2\right)^2 \le 1$$

for $0 \le \overline{\mathrm{a}}, \overline{\mathrm{b}} \le 2$, and $0 \le z, p \le 1$.

LEMMA 4.2. *The function* $g(z,p,\bar{\mathrm{a}},\bar{\mathrm{b}}) \le 1$ *for* $0 \le \bar{\mathrm{a}},\bar{\mathrm{b}} \le 2$, *and* $0 \le z,p \le 1$.
Proof: Let

$$q = |p|^2, \quad t = z^2.$$

Then

$$g = \left[1 - \bar{\mathrm{b}}t\,(1-q) - \bar{\mathrm{a}}t\,(1-t)\,q\right]^2 + \bar{\mathrm{a}}\bar{\mathrm{b}}t\,(1-t)^2\,.$$

We first show that $g \le 1$ on the boundary of the (t,q) domain. Consider the t boundary values:

$$g\,(t=0) = 1,$$

and since $\bar{\mathrm{b}}(1-q) \le 2$,

$$g\,(t=1) \le 1.$$

For the q boundary values:

$$\begin{aligned} g\,(q=0) - 1 = \bar{\mathrm{b}}t\left[-2 + \bar{\mathrm{b}}t + \bar{\mathrm{a}}\,(1-t)^2\right] &\le \bar{\mathrm{b}}t\Big[-2 + \bar{\mathrm{b}}t + \bar{\mathrm{a}}\,(1-t)\Big] \\ &\le \bar{\mathrm{b}}t\Big[-2 + 2\,(t+1-t)\Big] = 0, \end{aligned}$$

while

$$g\,(q=1) - 1 = \bar{\mathrm{a}}t\,(1-t)\left[-2 + \bar{\mathrm{a}}t\,(1-t) + \bar{\mathrm{b}}\,(1-t)\right] \le \left[-2 + \bar{\mathrm{a}}t + \bar{\mathrm{b}}\,(1-t)\right] \le 0.$$

To finish the proof, we need only to show that, for each fixed t, g (a quadratic function in q) does not have a maximum for $0 < q < 1$. This is achieved by showing that either $\frac{\partial g}{\partial q}(q=1) \ge 0$, in which case g is either monotone nondecreasing or has a minimum in $0 < q < 1$, or that $\frac{\partial g}{\partial q}(q=0) \le 0$ and $\frac{\partial g}{\partial q}(q=1) \le 0$, in which case g is monotone nonincreasing in $0 < q < 1$. We proceed as follows:

$$\frac{\partial g}{\partial q} = 2\kappa\big[1 - \bar{\mathrm{b}}t + \kappa q\big],$$

where

$$\kappa = \bar{\mathrm{b}}t - \bar{\mathrm{a}}t + \bar{\mathrm{a}}t^2.$$

Note that

$$1 - \bar{\mathrm{b}}t + \kappa = 1 - \bar{\mathrm{a}}t(1-t) \ge 1 - \bar{\mathrm{a}}\frac{1}{4} \ge \frac{1}{2}. \tag{4.5}$$

- Case $\bar{\mathrm{a}} \le \bar{\mathrm{b}}$ $(\alpha \ge \beta)$:[2] In this case $\kappa \ge 0$, so by (4.5)

$$\frac{\partial g}{\partial q}\,(q=1) = 2\kappa\left(1 - \bar{\mathrm{b}}t + \kappa\right) \ge 2\kappa\,\frac{1}{2} \ge 0.$$

- Case $\bar{\mathrm{a}} \ge \bar{\mathrm{b}}$ $(\alpha \le \beta)$: Then $\kappa \le 0$ if $t \le t_0 = 1 - \frac{\bar{\mathrm{b}}}{\bar{\mathrm{a}}}$, and $\kappa \ge 0$ if $t \ge t_0$.
  - If $t \ge t_0$ $(k \ge 0)$. Then as in the case above, $\frac{\partial g}{\partial q}(q=1) > 0$.
  - If $t \le t_0$ $(k \le 0)$. Then by (4.5), both $\frac{\partial g}{\partial q}(q=1) < 0$ and $\frac{\partial g}{\partial q}(q=0) < 0$.

Thus ends the proof of the lemma and completes the proof of the theorem. ∎

[2] This case is the most important, since for the compatible Lagrangian hydrodynamics scheme applied to the Euler equations one must necessarily have $\beta = \frac{1}{2}$ for the scheme to conserve total energy.

5. Instability for $\alpha < 1/2$ or $\beta < 1/2$. Both the fully implicit and the predictor-corrector schemes are unstable if either $\alpha < 1/2$ or $\beta < 1/2$, for any mesh ratios. We just need to show this in 1D for the special case of $p = u$, for then the schemes are being applied to $\frac{du}{dt} = \frac{\partial u}{\partial x}$, with one set of difference equations used to advance u at half-integer indexes $i + 1/2$ and a different set at integer indexes i. Instability occurs if some Fourier component is amplified. So by setting $\Phi_y = 0$ in the amplification factor $\mathbf{S}$ for the predictor-corrector factor, we need only to show first that $|1 - \alpha\Phi_x^2 + \mathrm{i}\Phi_x(1 - \alpha\beta(\Phi_x^2))| > 1$ if $\alpha < 1/2$. This is clearly the case if $|\Phi_x|$ is positive and sufficiently small since

$$\left|1 - \alpha\Phi_x^2 + \mathrm{i}\Phi_x\left(1 - \alpha\beta(\Phi_x^2)\right)\right|^2 = 1 + \Phi_x^2 \underbrace{(1 - 2\alpha)}_{>0} + \underbrace{\Phi_x^4\ \alpha^2\beta^2\ \left(\frac{1}{\beta^2} + \Phi_x^2 - \frac{2}{\alpha\beta}\right)}_{\sim o(\Phi_x^4)}.$$

A similar argument works for the second row of $\mathbf{S}$ if $\beta < 1/2$. The fully implicit scheme yields to the same kind of analysis; we omit the details.

6. Numerical results. We solve the simple problem already described in [3] where, on a unit domain using a quadrangular mesh of 100×100, velocity is set to zero, density and sound speed are set to unity by using a perfect equation of state with γ, the ratio of specific heats, equal to $5/3$ and reflective boundary conditions.

Since for this problem no velocity should develop, simulations are run for a very large number of time cycles, typically 10^5, and with varying values for the CFL number $\lambda = \lambda_x = \lambda_y$ and parameters α, β. A sensitive gauge of instability is to keep track of the total kinetic energy $K^\lambda(t^n) = \frac{1}{2}\sum[(u_{i,j}^n)^2 + (v_{i,j}^n)^2]$ for a given CFL number λ at a given time t_n. Since the density and domain size are scaled to unity, this number should remain at the square of machine precision, about 10^{-28}–10^{-30} in our case. For an unstable scheme, it is observed that $K^\lambda(t^n)$ grows by several orders of magnitude long before the 10^5 cycle limit is reached. In this way, one can accurately identify the stability boundary in the CFL number and α space for a given β.

2D wave equations. We solve the 2D wave equations with the rectangular predictor-corrector scheme. From Theorem 4.1 we have that

$$4\alpha\beta \max\left(\lambda_x^2, \lambda_y^2\right) \le 1 \quad \Longrightarrow \quad \lambda \le \frac{1}{2\sqrt{\alpha\beta}},$$

provided that $\lambda = \lambda_x = \lambda_y$. Thus, the maximum CFL number achievable, denoted $\mathrm{CFL}_{\max}$, therefore depends on α and β and is described by the following function:

$$\mathrm{CFL}_{\max} = \mathrm{CFL}_{\max}(\alpha, \beta) = \frac{1}{2\sqrt{\alpha\beta}}. \tag{6.1}$$

In Figure 6.1, we plot the maximal CFL as a function of α for a sample of five β values: $\beta = \{0.5, 0.6, 0.75, 0.9, 1.0\}$. The maximum CFL numbers obtained numerically with the code for a pair of α, β are superimposed; $+$ for $\beta = 0.5$, $*$ for $\beta = 0.6$, $\square$ for $\beta = 0.75$, $\blacksquare$ for $\beta = 0.9$, and $\circ$ for $\beta = 1.0$. As expected they perfectly match the theoretical CFL limit (6.1) given by Theorem 4.1.

2D Euler equations. We present the results obtained with our 2D Lagrangian predictor-corrector code for the Euler equations by using Lagrangian coordinates. In this context (see [3], for example) the conservation of total energy is ensured provided that $\beta = \frac{1}{2}$. In Figure 6.2, we plot seven data points (symbol $+$) obtained by the code which represent the maximum CFL number that can be used for a given α for which

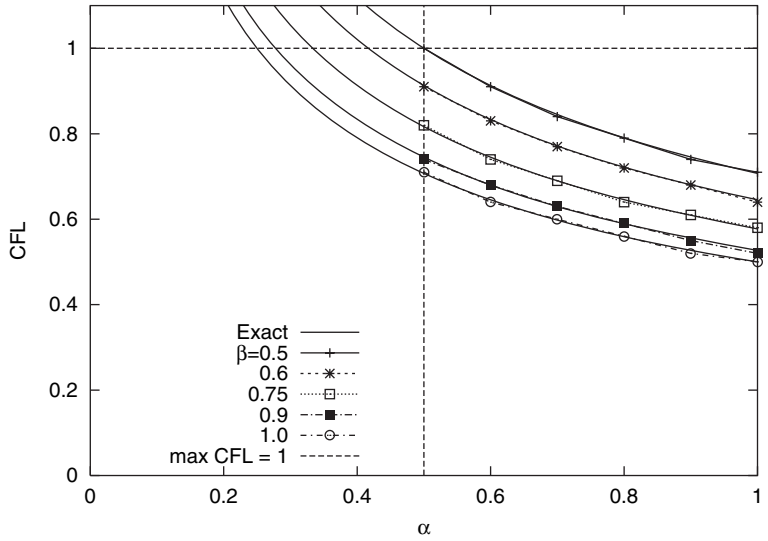

FIG. 6.1. 2D *wave equations—maximum CFL number* λ *as a function of* α *(*β *fixed) for the kinetic energy to remain on the order of machine precision for the test case. The vertical dashed line is the* $\alpha = 1/2$ *limit, and the horizontal one is the CFL* $= 1$ *limit. The theorem predicts the continuous thick lines, and the code produces the data:* $+$ *for* $\beta = 0.5$, $*$ *for* $\beta = 0.6$, $\square$ *for* $\beta = 0.75$, $\blacksquare$ *for* $\beta = 0.9$, *and* $\circ$ *for* $\beta = 1.0$. *Any scheme defined by a value* $\alpha \geq 1/2$ *and* $\beta \geq 1/2$ *is stable with the following CFL number:* $\lambda \leq 1/(2\sqrt{\alpha\beta})$.

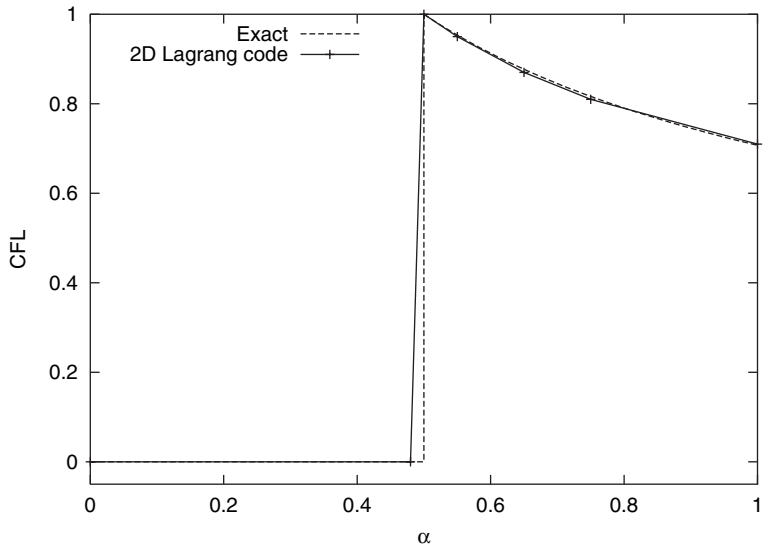

FIG. 6.2. *Hydrodynamics equations—maximum CFL number* λ *as a function of* α *(*$\beta = 1/2$*) for the kinetic energy to remain on the order of machine precision for the test case. The theorem predicts the continuous line; the* 2*D code produces the dashed line. Any scheme defined by a value* $\alpha \geq 1/2$ *is stable with the CFL number* $\lambda \leq 1/\sqrt{2\alpha}$ *and is unstable otherwise.*

numerical stability is preserved. The exact function CFL (dashed line) predicted by (6.1) is superimposed.[3] We can easily see that any scheme defined by a value $\alpha \geq 1/2$ is stable with the CFL number $\lambda \leq 1/\sqrt{2\alpha}$ and is unstable otherwise. We comment that for $\alpha = 1/2$ one exactly reaches the maximum CFL number $\lambda = 1$. The scheme with $\alpha = \beta = 1/2$ is the only staggered predictor-corrector scheme that reaches the maximum CFL number. Therefore the choice of using this scheme in several Lagrangian simulation codes, at least for this "optimal stability reason," seems justified. The results of our simulations perfectly match the predicted curve; this is also true of our 1D and 3D codes.

7. Conclusion. We have proposed the 2D wave equation as a linear constant coefficient model for 2D Lagrangian hydrodynamics, and we have established a sufficient stability condition for the standard staggered-grid numerical scheme. The 1D case is concurrently obtained as a special case of the 2D analysis.

This stability boundary has been tested with the 2D compatible Lagrangian hydrodynamics scheme for the wave equations and the Euler equations in Lagrangian coordinates. The numerical results fit the theoretical curve, showing that

- the general belief that for such numerical schemes "the more implicit, the more stable" is not always true,
- the classical choice made by several generations of Lagrangian code developers to use the $\alpha = \beta = 1/2$ scheme is reasonable as it leads to optimal stability results (at least for the artificial test case presented).

For the Euler equations these numerical results have been obtained in 1D, 2D, and 3D.

Acknowledgment. The authors thank Misha Shashkov for many fruitful discussions.

WELL-BALANCED HIGH ORDER EXTENSIONS OF GODUNOV'S METHOD FOR SEMILINEAR BALANCE LAWS*

MANUEL CASTRO†, JOSÉ M. GALLARDO†, JUAN A. LÓPEZ-GARCÍA†, AND CARLOS PARÉS†

Abstract. This paper is concerned with the development of well-balanced high order numerical schemes for systems of balance laws with a linear flux function, whose coefficients may be variable. First, well-balanced first order numerical schemes are obtained based on the use of exact solvers of Riemann problems that include both the flux and the source terms. Godunov's methods so obtained are extended to higher order schemes by using a technique of reconstruction of states. The main contribution of this paper is to introduce a reconstruction technique that preserves the well-balanced property of Godunov's methods. Some numerical experiments are presented to verify in practice the properties of the developed numerical schemes.

1. Introduction.

This paper is concerned with the numerical approximation of Cauchy problems for one-dimensional semilinear strictly hyperbolic systems of the form

$$W_t + A(\sigma)W_x = G(\sigma, W)\sigma_x, \quad x \in \mathbb{R},\ t > 0. \tag{1.1}$$

Here $W(x,t) \in \Omega \subset \mathbb{R}^N$ is the vector of unknowns; $\sigma(x)$ is a known function; $A(\sigma)$ is a smooth matrix-valued function; $G(\sigma, W)$ is also a smooth function from $\mathbb{R} \times \Omega$ to $\mathbb{R}^N$. The matrix $A(\sigma)$ is supposed to have N different real nonvanishing eigenvalues. Notice that systems of the form

$$W_t + A(x)W_x = G(x, W), \quad x \in \mathbb{R},\ t > 0,$$

can be considered as a particular case of (1.1).

The problems to be considered are thus systems of balance laws with a linear flux function, whose coefficients may be variable. Systems of this kind frequently arise in computational fluid dynamics, when models involving chemical reactions, external forces, or geometrical source terms are linearized; they also appear in relaxation systems (see [19] for some examples).

Besides the interest by itself of solving system (1.1), the development of numerical schemes with good properties for this kind of system may be helpful in the design of numerical methods for the more general case of a system of balance laws:

$$W_t + F(\sigma, W)_x = G(\sigma, W)\sigma_x, \quad x \in \mathbb{R},\ t > 0. \tag{1.2}$$

In fact, the numerical difficulties due to the presence of a source term are similar in both cases, but considering a linear flux function makes easier the development and analysis of methods based on exact Riemann solvers. Nevertheless, the numerical schemes developed here can be extended to the more general case (1.2) by replacing, if necessary, the exact Riemann solver by an approximate one, provided that stationary solutions of the system can be exactly calculated.

A first numerical difficulty in solving (1.1) is related to stiff and singular source terms: In some problems the source term is concentrated over a very small region (even at a single point), or, due to the structure of the solutions, it acts only on a small region, where it can be very large. Appropriate fractional step methods, in which the problem is split into two subproblems (one related to the conservation law and the other one to the source term) can correctly handle these situations. Nevertheless, a second difficulty arises when solving steady-state solutions or solutions close to equilibrium. In this case, if the numerical source term does not balance the flux term in an adequate manner, the numerical solutions may exhibit nonphysical oscillations. In general, it is not easy to solve this difficulty with numerical methods based on a fractional step approach (see [19]).

The development and analysis of well-balanced numerical schemes for systems of balance laws is a very active front of research, and there is a huge amount of recent literature devoted to this topic. An important part of this literature is concerned with the approximation of shallow water systems with geometrical source terms. We refer to [5], [30], and the references therein for a review on the subject. In particular, the well-balanced properties of high order numerical schemes for shallow water systems have been studied in [6], [24], [25], [29], and [33].

The goal of this paper is to develop high order well-balanced numerical schemes for systems of the form (1.1). The idea is to consider finite volume methods based on the use of exact solvers of Riemann problems that include both the flux and the source terms. To do this, by following a technique introduced in [16] for the Euler equation in a nozzle, σ is interpreted as an artificial unknown of the system, whose value is fixed by the initial condition. Then (1.1) is rewritten under the form

$$\widetilde{W}_t + \widetilde{A}(\widetilde{W})\widetilde{W}_x = 0, \quad x \in \mathbb{R},\ t > 0, \tag{1.3}$$

where $\widetilde{W} = [W, \sigma]^T$. Once the system has been rewritten under this form, well-balanced first order numerical schemes are obtained by considering piecewise constant approximations of the solutions and applying Godunov's method. This approach has been also pursued in [1], [2], [7], [13], [14], [9], [15], [17].

When (1.1) is written under the form (1.3), a new linearly degenerate characteristic field is added to the system, whose corresponding eigenvalue is zero. Therefore, when one of the eigenvalues of $A(\sigma)$ vanishes, the system loses the strictly hyperbolic character: The problem becomes *resonant*, and the Riemann problems may not have a unique solution. This difficulty will not be considered here.

The organization of the article is as follows: In section 2 we consider the easier particular case

$$W_t + AW_x = CW\sigma_x, \quad x \in \mathbb{R},\ t > 0,$$

A and C being two given matrices. The solution of the Riemann problems of the system is discussed, and the expression of the corresponding Godunov's method is obtained, which is a particular case of path-conservative numerical scheme for (1.1), as

defined in [27]. In this reference, the general writing of a high order numerical scheme based on the use of a reconstruction operator and a first order path-conservative numerical scheme has also been presented. In section 3, we adapt this general methodology to problem (1.3) in order to obtain high order extensions of Godunov's methods.

Standard reconstruction operators do not preserve, in general, the well-balanced property of Godunov's methods. The main contribution of this paper is introduced in section 4: We present a technique to modify a standard reconstruction operator to solve this difficulty. The idea is to use, in the reconstruction procedure, the information given by the characteristic curves of the linearly degenerate field associated to the null eigenvalue. These curves, as will be seen, are related both to the stationary contact discontinuities and to the regular stationary solutions of (1.3).

In section 5 we consider first the extension of the numerical schemes developed to systems of the form

$$W_t + AW_x = G(W)\sigma_x, \quad x \in \mathbb{R},\ t > 0,$$

and, next, to the more general case (1.1).

Finally, in section 6 the numerical schemes are applied to some test cases.

2. Linear case: Godunov's method. We consider the system

$$W_t + AW_x = CW\sigma_x, \tag{2.1}$$

where $W \in \mathbb{R}^N$, $A, C \in \mathcal{M}_N(\mathbb{R})$, and $\sigma(x)$ is a known function. This system can be interpreted as a linear system of conservation laws with a source term.

Assume that the system is strictly hyperbolic, that is, the matrix A has N real distinct eigenvalues $\lambda_1 < \cdots < \lambda_N$, and let $R_1, \ldots, R_N$ be the associated eigenvectors.

Notice that systems of the form

$$W_t + AW_x = CW$$

can be considered as a particular case of (2.1), corresponding to the choice $\sigma(x) = x$.

If we add to system (2.1) the equation

$$\sigma_t = 0,$$

we obtain the following quasi-linear system in nonconservative form:

$$\widetilde{W}_t + \widetilde{\mathcal{A}}(\widetilde{W})\widetilde{W}_x = 0, \tag{2.2}$$

where

$$\widetilde{W} = \begin{bmatrix} W \\ \sigma \end{bmatrix}, \quad \widetilde{\mathcal{A}}(\widetilde{W}) = \begin{bmatrix} A & -CW \\ 0 & 0 \end{bmatrix}.$$

Assume that the eigenvalues λ_i of the matrix A satisfy $\lambda_i \neq 0,\ i = 1, \ldots, N$. Then, for every $\widetilde{W}$, $\widetilde{\mathcal{A}}(\widetilde{W})$ has $N+1$ real distinct eigenvalues $\lambda_1, \ldots, \lambda_N, \lambda_{N+1} = 0$, with associated eigenvectors $\widetilde{R}_1(\widetilde{W}), \ldots, \widetilde{R}_N(\widetilde{W}), \widetilde{R}_{N+1}(\widetilde{W})$ given by

$$\widetilde{R}_i(\widetilde{W}) = \begin{bmatrix} R_i \\ 0 \end{bmatrix}, \quad i = 1, \ldots, N; \qquad \widetilde{R}_{N+1}(\widetilde{W}) = \begin{bmatrix} A^{-1}CW \\ 1 \end{bmatrix}.$$

By assumption, the first N fields are linearly degenerate. Since λ_{N+1} is constant, the additional field is linearly degenerate as well. The integral curves of the characteristic fields are those of the ODE systems

$$\frac{d\widetilde{W}}{ds}(s) = \widetilde{R}_i(\widetilde{W}(s)), \quad i = 1, \ldots, N+1.$$

The solutions of these systems corresponding to initial conditions

$$\widetilde{W}(0) = \begin{bmatrix} W_i \\ \sigma_i \end{bmatrix}, \quad i = 1, \dots, N+1,$$

are, respectively,

$$\widetilde{W}(s) = \begin{bmatrix} sR_i + W_i \\ \sigma_i \end{bmatrix}, \quad i = 1, \dots, N,$$

and

$$\widetilde{W}(s) = \begin{bmatrix} e^{A^{-1}Cs} W_{N+1} \\ s + \sigma_{N+1} \end{bmatrix}, \quad i = N+1. \tag{2.3}$$

As all of the characteristic fields are linearly degenerate, the simple waves of the system are contact discontinuities linking two states belonging to the same integral curve of one of the characteristic fields. Moreover, these contact discontinuities propagate at speed λ_i if they are related to the ith characteristic field, for $i = 1, \dots, N$, or they are stationary if related to the $(N+1)$th characteristic field.

Let us consider now the Riemann problem

$$\begin{cases} \widetilde{W}_t + \widetilde{\mathcal{A}}(\widetilde{W})\widetilde{W}_x = 0, \\ \widetilde{W}(x,0) = \begin{cases} \widetilde{W}_L & \text{if } x < 0, \\ \widetilde{W}_R & \text{if } x > 0. \end{cases} \end{cases} \tag{2.4}$$

A general nonconservative theory of quasi-linear Riemann problems has been presented in [8]. We give hereafter a result of the existence and uniqueness of the solution for our particular case, whose constructive proof will play a central role in the development of the numerical schemes.

PROPOSITION 2.1. *For $[\![\sigma]\!] = \sigma_R - \sigma_L$ small enough, the Riemann problem* (2.4) *has a unique solution consisting of at most $N+2$ intermediate states linked by contact discontinuities.*

Proof. Let I be the maximum value of i for which $\lambda_i < 0$. If all of the eigenvalues are positive, we take $I = 0$, and if they are all negative, $I = N$.

Let us consider first the case $0 < I < N$. The structure of the solution must be as follows:

$$\widetilde{W}(x,t) = \begin{cases} \widetilde{W}_0 = \widetilde{W}_L & \text{if } \ x < \lambda_1 t, \\ \widetilde{W}_1 & \text{if } \ \lambda_1 t < x < \lambda_2 t, \\ \vdots & \\ \widetilde{W}_{I-1} & \text{if } \ \lambda_{I-1} t < x < \lambda_I t, \\ \widetilde{W}_I^- & \text{if } \ \lambda_I t < x < 0, \\ \widetilde{W}_I^+ & \text{if } \ 0 < x < \lambda_{I+1} t, \\ \widetilde{W}_{I+1} & \text{if } \ \lambda_{I+1} t < x < \lambda_{I+2} t, \\ \vdots & \\ \widetilde{W}_{N-1} & \text{if } \ \lambda_{N-1} t < x < \lambda_N t, \\ \widetilde{W}_N = \widetilde{W}_R & \text{if } \ \lambda_N t < x, \end{cases} \tag{2.5}$$

where the following apply:

1. The states $\widetilde{W}_i$, $i = 1, \dots, I-1$, and $\widetilde{W}_I^-$ must have the form

$$\widetilde{W}_i = \begin{bmatrix} W_L + \sum_{j=1}^{i} s_j R_j \\ \sigma_L \end{bmatrix}, \quad i = 1, \dots, I-1,$$
$$\widetilde{W}_I^- = \begin{bmatrix} W_I^- \\ \sigma_I^- \end{bmatrix} = \begin{bmatrix} W_L + \sum_{j=1}^{I} s_j R_j \\ \sigma_L \end{bmatrix}$$

for some $s_1, \dots, s_I \in \mathbb{R}$.

2. The states $\widetilde{W}_I^-$ and $\widetilde{W}_I^+$ must verify

$$\widetilde{W}_I^+ = \begin{bmatrix} W_I^+ \\ \sigma_I^+ \end{bmatrix} = \begin{bmatrix} e^{A^{-1}Cs_*} W_I^- \\ \sigma_I^- + s_* \end{bmatrix} = \begin{bmatrix} e^{A^{-1}Cs_*} \left(W_L + \sum_{j=1}^{I} s_j R_j \right) \\ \sigma_L + s_* \end{bmatrix}$$

for some $s_* \in \mathbb{R}$.

3. Finally, the states $\widetilde{W}_i$, $i = I+1, \dots, N$, must have the form

$$\widetilde{W}_i = \begin{bmatrix} W_I^+ + \sum_{j=I+1}^{i} s_j R_j \\ \sigma_I^+ \end{bmatrix}, \quad i = I+1, \dots, N,$$

for some $s_{I+1}, \dots, s_N \in \mathbb{R}$. In particular,

$$\widetilde{W}_N = \begin{bmatrix} W_I^+ + \sum_{j=I+1}^{N} s_j R_j \\ \sigma_I^+ \end{bmatrix} = \begin{bmatrix} W_R \\ \sigma_R \end{bmatrix},$$

and thus

$$s_* = \sigma_R - \sigma_L = [\![\sigma]\!],$$
$$W_I^+ = e^{A^{-1}C[\![\sigma]\!]} \left(W_L + \sum_{j=1}^{I} s_j R_j \right) = W_R - \sum_{j=I+1}^{N} s_j R_j.$$

Therefore, to find the solution of the Riemann problem, the values of $s_1, \dots, s_N$ have to be determined so that the following identity holds:

$$W_R - e^{A^{-1}C[\![\sigma]\!]} W_L = e^{A^{-1}C[\![\sigma]\!]} \sum_{j=1}^{I} s_j R_j + \sum_{j=I+1}^{N} s_j R_j. \tag{2.6}$$

Observe that (2.6) is an $N \times N$ linear system for the unknowns $s_1, \dots, s_N$. When $[\![\sigma]\!] = 0$ this system reduces to

$$W_R - W_L = \sum_{j=1}^{N} s_j R_j,$$

whose solution is given by the coordinates of $[\![W]\!] = W_R - W_L$ in the basis of eigenvectors R_j. Consequently, by continuity, system (2.6) has also a unique solution $s_1, \dots, s_N$ for small values of $[\![\sigma]\!]$.

The cases $I = 0$ and $I = N$ are similar. Notice that, in these situations, system (2.6) has always a unique solution: For $I = 0$ (respectively, $I = N$), $\{s_1, \dots, s_N\}$ are the coordinates of $W_R - e^{A^{-1}C[\![\sigma]\!]} W_L$ (respectively, $e^{-A^{-1}C[\![\sigma]\!]} W_R - W_L$) in the basis $\{R_1, \dots, R_N\}$. ∎

The hypothesis of smallness of $\sigma_R - \sigma_L$ cannot be removed in general: Consider, for instance, the particular case corresponding to

$$A = \begin{bmatrix} -1 & 0 \\ 0 & 1 \end{bmatrix}, \quad C = \begin{bmatrix} 1 & 2 \\ 1 & 2 \end{bmatrix}.$$

Given $[\![\sigma]\!] = \sigma_R - \sigma_L$, the linear system (2.6) is written in this case as follows:

$$e^{A^{-1}C[\![\sigma]\!]}(W_L + s_1 R_1) = W_R + s_2 R_2,$$

where $R_1 = [1, 0]^T$ and $R_2 = [0, 1]^T$. A straightforward calculation shows that

$$e^{A^{-1}C[\![\sigma]\!]} = \begin{bmatrix} 2 - e^{[\![\sigma]\!]} & 2(1 - e^{[\![\sigma]\!]}) \\ e^{[\![\sigma]\!]} - 1 & 2e^{[\![\sigma]\!]} - 1 \end{bmatrix}.$$

Therefore, the linear system can be expressed as follows:

$$\begin{cases} (2 - e^{[\![\sigma]\!]})s_1 = w_1^R - 2(1 - e^{[\![\sigma]\!]})w_2^L - (2 - e^{[\![\sigma]\!]})w_1^L, \\ (e^{[\![\sigma]\!]} - 1)s_1 + s_2 = -(2e^{[\![\sigma]\!]} - 1)w_2^L - (e^{[\![\sigma]\!]} - 1)w_1^L, \end{cases}$$

where

$$W_L = \begin{bmatrix} w_1^L \\ w_2^L \end{bmatrix}, \quad W_R = \begin{bmatrix} w_1^R \\ w_2^R \end{bmatrix}.$$

Now this system has a unique solution if $[\![\sigma]\!] < \log(2)$. But when $[\![\sigma]\!] = \log(2)$, there is no solution if

$$w_1^R + 2w_2^L \neq 0.$$

Otherwise, it has infinitely many solutions.

However, in some particular cases the conclusion of Proposition 2.1 holds for arbitrary values of $[\![\sigma]\!]$.

COROLLARY 2.2. *The Riemann problem* (2.4) *has always a unique solution if one of the following conditions holds:*

(i) *All of the eigenvalues of A have the same sign.*

(ii) *The matrix C is diagonalizable and commutes with A.*

Proof. If (i) holds, then $I = 0$ or $I = N$ in the proof of Proposition 2.1, and (2.6) has always a unique solution. Notice that this is always the case for $N = 1$.

If (ii) holds, we have

$$Ae^{A^{-1}C[\![\sigma]\!]} = e^{A^{-1}C[\![\sigma]\!]}A,$$

and then

$$Ae^{A^{-1}C[\![\sigma]\!]}R_j = e^{A^{-1}C[\![\sigma]\!]}AR_j = \lambda_j e^{A^{-1}C[\![\sigma]\!]}R_j;$$

that is, $e^{A^{-1}C[\![\sigma]\!]}R_j$ is an eigenvector of A associated to λ_j. Therefore,

$$e^{A^{-1}C[\![\sigma]\!]}R_j = \beta_j R_j, \quad j = 1, \ldots, N,$$

for some $\beta_j \neq 0$. If α_j are the coordinates of $W_R - e^{A^{-1}C[\![\sigma]\!]}W_L$ in the basis composed by the eigenvectors R_j, that is,

$$W_R - e^{A^{-1}C[\![\sigma]\!]}W_L = \sum_{j=1}^{N} \alpha_j R_j,$$

the unique solution of (2.6) is given by

$$\begin{cases} s_j = \dfrac{\alpha_j}{\beta_j} & \text{for } \ j = 1, \dots, I, \\ s_j = \alpha_j & \text{for } \ j = I+1, \dots, N. \end{cases} \qquad \square$$

Remark 2.3. Notice that, in every case, the following equalities hold:

$$W_I^- - W_L = \sum_{j=1}^{I} s_j R_j, \quad W_R - W_I^+ = \sum_{j=I+1}^{N} s_j R_j.$$

Remark 2.4. The solutions of the Riemann problem found in Proposition 2.1 are not solutions in the distributional sense, as the product $CW\sigma_x$ doesn't make sense as a distribution when both W and σ are discontinuous. Nevertheless, the theory developed by Dal Maso, LeFloch, and Murat in [8] can be used to give a weaker sense to this nonconservative product as Borel measures. See also [18].

Once the Riemann problem has been analyzed, we study the application of Godunov's method to Cauchy's problem consisting of system (2.1) with initial condition $W(x,0) = W_0(x),\ x \in \mathbb{R}$, or equivalently, system (2.2) with initial condition $\widetilde{W}(x,0) = \widetilde{W}_0(x),\ x \in \mathbb{R}$, where

$$\widetilde{W}_0 = \begin{bmatrix} W_0 \\ \sigma \end{bmatrix}.$$

For the discretization of the system, computing cells $I_i = [x_{i-1/2}, x_{i+1/2}]$ are considered. For simplicity, we suppose that these cells have constant size Δx and that $x_{i+\frac{1}{2}} = i\Delta x$. Define $x_i = (i - 1/2)\Delta x$, the center of the cell I_i. Let Δt be the constant time step, and define $t^n = n\Delta t$.

We denote by $\widetilde{W}_i^n$ the approximation of the cell averages of the exact solution provided by the numerical scheme:

$$\widetilde{W}_i^n = \begin{bmatrix} W_i^n \\ \sigma_i^n \end{bmatrix} \cong \frac{1}{\Delta x} \int_{x_{i-1/2}}^{x_{i+1/2}} \widetilde{W}(x, t^n)\, dx.$$

In particular, at time $t = 0$ we consider

$$\widetilde{W}_i^0 = \begin{bmatrix} W_i^0 \\ \sigma_i \end{bmatrix},$$

where

$$W_i^0 = \frac{1}{\Delta x} \int_{x_{i-1/2}}^{x_{i+1/2}} W_0(x)\, dx, \quad \sigma_i = \frac{1}{\Delta x} \int_{x_{i-1/2}}^{x_{i+1/2}} \sigma(x)\, dx.$$

Suppose that the averages $\widetilde{W}_i^n$ at time $t = t^n$ are known. As is usual in Godunov's methods, to advance in time we consider the Riemann problems

$$\begin{cases} \widetilde{W}_t^{i+1/2} + \widetilde{\mathcal{A}}(\widetilde{W}^{i+1/2})\widetilde{W}_x^{i+1/2} = 0, \\ \widetilde{W}^{i+1/2}(x,0) = \begin{cases} \widetilde{W}_i^n & \text{if } x < 0, \\ \widetilde{W}_{i+1}^n & \text{if } x > 0, \end{cases} \end{cases} \tag{2.7}$$

and we approximate the solution at time t^{n+1} by

$$\begin{aligned} \widetilde{W}_i^{n+1} = \frac{1}{\Delta x}\Bigg(& \int_{x_{i-1/2}}^{x_i} \widetilde{W}^{i-1/2}(x - x_{i-1/2}, \Delta t)\, dx \\ & + \int_{x_i}^{x_{i+1/2}} \widetilde{W}^{i+1/2}(x - x_{i+1/2}, \Delta t)\, dx \Bigg). \end{aligned} \tag{2.8}$$

If a CFL 1/2 condition is assumed and the $(N+1)$th components are dropped, some easy calculations allow us to write the numerical scheme as follows:

$$W_i^{n+1} = W_i^n + \frac{\Delta t}{\Delta x}\left(A\big(W_{i-1/2}^{n,+} - W_i^n\big) + A(W_i^n - W_{i+1/2}^{n,-})\big)\right), \tag{2.9}$$

or, equivalently,

$$W_i^{n+1} = W_i^n + \frac{\Delta t}{\Delta x} A\big(W_{i-1/2}^{n,+} - W_{i+1/2}^{n,-}\big), \tag{2.10}$$

where $W_{i+1/2}^{n,\pm}$ are the limits of the solution of problem (2.7) to the left and to the right of $x = 0$.

Finally, by making use of the equalities in Remark 2.3, the numerical scheme can also be written as follows:

$$W_i^{n+1} = W_i^n + \frac{\Delta t}{\Delta x}\big(F_{i-1/2}^+ - F_{i+1/2}^-\big), \tag{2.11}$$

with

$$F_{i+1/2}^- = A\sum_{j=1}^{I} s_j^{i+1/2} R_j, \quad F_{i+1/2}^+ = -A\sum_{j=I+1}^{N} s_j^{i+1/2} R_j,$$

I being the maximum value of i for which $\lambda_i < 0$, and $s_j^{i+1/2}$, $j = 1, \ldots, N$, the solutions of

$$W_{i+1}^n - e^{A^{-1}C(\sigma_{i+1} - \sigma_i)} W_i^n = e^{A^{-1}C(\sigma_{i+1} - \sigma_i)} \sum_{j=1}^{I} s_j^{i+1/2} R_j + \sum_{j=I+1}^{N} s_j^{i+1/2} R_j. \tag{2.12}$$

Remark 2.5.

1. In practice, a CFL 1 condition can be used, as it ensures the stability of the scheme.
2. This numerical scheme is path-conservative in the sense defined in [27]. Consequently, it is consistent in the usual sense for regular solutions.
3. In [23] a convergence result of Lax–Wendroff type has been proved for Godunov's methods in the context of a more general class of hyperbolic nonconservative systems.

4. In the case $N = 1$ Godunov's method studied here is the particular case of the well-balanced numerical scheme introduced in [9] corresponding to a linear flux function. This is also a particular case of Godunov's method for scalar balance laws studied in [15], where the convergence of the numerical method has been proved.
5. The Goldstein–Taylor model of the Boltzmann equations (see [20]) is the particular case of (2.1) corresponding to the choice

$$W = \begin{bmatrix} v \\ u \end{bmatrix}, \quad \sigma(x) = x,$$
$$A = \frac{1}{\varepsilon}\begin{bmatrix} -1 & 0 \\ 0 & 1 \end{bmatrix}, \quad C = \frac{1}{\varepsilon}\begin{bmatrix} -1 & 1 \\ 1 & -1 \end{bmatrix}.$$

In this case, it can be shown that Godunov's method (2.10) coincides with the well-balanced numerical scheme introduced in [11].

3. High order extensions. The goal of this section is to construct high order extensions of Godunov's methods introduced in section 2, based on the use of a reconstruction operator of order s, i.e., an operator that associates to a given sequence $\{\widetilde{W}_i\}$ two new sequences $\{\widetilde{W}^-_{i+1/2}\}$ and $\{\widetilde{W}^+_{i+1/2}\}$ in such a way that, whenever

$$\widetilde{W}_i = \frac{1}{\Delta x}\int_{I_i} \widetilde{W}(x)\,dx \quad \forall\, i \in \mathbb{Z}$$

for some smooth function $\widetilde{W}$, then

$$\widetilde{W}^{\pm}_{i+1/2} = \widetilde{W}(x_{i+1/2}) + O\left(\Delta x^s\right) \quad \forall\, i \in \mathbb{Z}.$$

We follow [6] or [27] to construct a semidiscrete high order extension of Godunov's methods. Let us introduce some notation:

$$\widetilde{W}_i(t) = \begin{bmatrix} W_i(t) \\ \sigma_i \end{bmatrix}$$

is the approximation given by the numerical scheme of the average of the solution $\widetilde{W}$ at the ith cell at time t;

$$\widetilde{W}^{\pm}_{i+1/2}(t) = \begin{bmatrix} W^{\pm}_{i+1/2}(t) \\ \sigma^{\pm}_{i+1/2}(t) \end{bmatrix}$$

are the reconstructed states at the intercells associated to the sequence $\{\widetilde{W}_i(t)\}$;

$$\widetilde{W}^{\pm}_{i+1/2,0}(t) = \begin{bmatrix} W^{\pm}_{i+1/2,0}(t) \\ \sigma^{\pm}_{i+1/2}(t) \end{bmatrix}$$

represent the limits to the left and to the right of $x = 0$ of the solution of the Riemann problem (2.7) with initial data $\widetilde{W}^{\pm}_{i+1/2}(t)$; finally,

$$\widetilde{P}^t_i = \begin{bmatrix} P^t_i \\ p^t_{N+1,i} \end{bmatrix} = \begin{bmatrix} p^t_{1,i} \\ \vdots \\ p^t_{N,i} \\ p^t_{N+1,i} \end{bmatrix}$$

is a function defined at the ith cell with values in $\mathbb{R}^{N+1}$, satisfying

$$\lim_{x\to x^+_{i-1/2}} \widetilde{P}^t_i(x) = \widetilde{W}^+_{i-1/2}(t), \qquad \lim_{x\to x^-_{i+1/2}} \widetilde{P}^t_i(x) = \widetilde{W}^-_{i+1/2}(t).$$

In practice, the definition of the reconstruction operator gives the natural choice of the functions $\widetilde{P}^t_i$, as the usual procedure is the following: Given a sequence $\{\widetilde{W}_i\}$ of values at the cells, an approximation function is calculated at every cell I_i by using the values $\widetilde{W}_j$ in a stencil,

$$\widetilde{P}_i(x; \widetilde{W}_{i-l}, \dots, \widetilde{W}_{i+r}),$$

with l, r being two natural numbers. The reconstructions $\widetilde{W}^{\pm}_{i+1/2}$ are then calculated by taking the limits of these functions at the intercells. These approximations functions are usually calculated by means of interpolation or approximation techniques. The natural choice of $\widetilde{P}^t_i$ is thus

$$\widetilde{P}^t_i(x) = \widetilde{P}_i(x; \widetilde{W}_{i-l}(t), \dots, \widetilde{W}_{i+r}(t)).$$

With this notation, the general expression of a semidiscrete numerical scheme proposed here is the following:

$$W_i' = \frac{1}{\Delta x}\left(A W^+_{i-1/2,0}(t) - A W^-_{i+1/2,0}(t) + \int_{x_{i-1/2}}^{x_{i+1/2}} C P^t_i(x) \frac{d}{dx} p^t_{N+1,i}(x)\, dx \right). \tag{3.1}$$

The following result can be shown (see [27]).

THEOREM 3.1. *Let us suppose that the reconstruction operator is of order s and that, given the sequence defined by*

$$\widetilde{W}_i = \frac{1}{\Delta x} \int_{I_i} \widetilde{W}(x)\, dx,$$

for any smooth function $\widetilde{W}$, the following approximation properties are satisfied:

$$\widetilde{P}_i(x; \widetilde{W}_{i-l}, \dots, \widetilde{W}_{i+r}) = \widetilde{W}(x) + O\left(\Delta x^{s_1}\right) \quad \forall\, x \in I_i,$$
$$\frac{d}{dx}\widetilde{P}_i(x; \widetilde{W}_{i-l}, \dots, \widetilde{W}_{i+r}) = \widetilde{W}'(x) + O\left(\Delta x^{s_2}\right) \quad \forall\, x \in I_i.$$

Then (3.1) *is of order at least $\bar{s} = \min(s, s_1 + 1, s_2 + 1)$.*

Remark 3.2. While in the case of a system of conservation laws, i.e., if $C = 0$, the numerical scheme is obviously independent of the function $\widetilde{P}^t_i$ chosen at the cells, this is not the case in the presence of source terms. As a consequence, while the numerical scheme has order s for systems of conservation laws, when $C \neq 0$ the order depends on the choice of the functions $\widetilde{P}^t_i$. For the usual reconstruction techniques one has $s_2 < s_1 \leqslant s$, and the order of (3.1) is thus $s_2 + 1$ for nonconservative systems and s for systems of conservation laws. Therefore a loss of accuracy can be observed when a technique of reconstruction is applied to a nonconservative problem. This effect has been detected and verified numerically in [6].

4. Well-balanced high order extensions. Well-balancing is related to the numerical approximation of equilibria, i.e., steady-state solutions, which are in turn related to the family of integral curves of the $(N+1)$th characteristic field (2.3):

$$\Gamma_{W^*} = \{[X(\sigma, W^*), \sigma]^T,\ \sigma \in \mathbb{R}\}, \quad W^* \in \mathbb{R}^N,$$

where

$$X(\sigma, W^*) = e^{A^{-1}C\sigma} W^*.$$

In effect, the stationary solutions of (2.2) always take values on a curve of this family. To see this, consider first a discontinuous stationary solution of the form

$$\widetilde{W}(x,t) = \begin{cases} \widetilde{W}_L & \text{if } x < 0, \\ \widetilde{W}_R & \text{if } x > 0. \end{cases}$$

By taking into account the proof of Proposition 2.1, such a solution is possible only if there exists W^* such that both states $\widetilde{W}_L$ and $\widetilde{W}_R$ belong to Γ_{W^*}.

Next, if $\widetilde{W}(x) = [W(x), \sigma(x)]^T$ is a regular stationary solution, then

$$\widetilde{A}(\widetilde{W}(x))\widetilde{W}'(x) = 0 \quad \forall\, x.$$

If $\widetilde{W}'(x) \neq 0$ for every x, $\widetilde{W}'(x)$ is an eigenvector of the matrix $\widetilde{A}(\widetilde{W}(x))$ associated to the eigenvalue 0; i.e., the function can be interpreted as a parameterization of an arc of an integral curve of the $(N+1)$th characteristic field. As a consequence, there exists W^* such that

$$W(x) = X(\sigma(x), W^*) \quad \forall\, x.$$

The following definition of a well-balanced numerical scheme can be introduced (see [26], [27]).

DEFINITION 4.1. *A numerical scheme is said to be* exactly well-balanced *for an integral curve Γ_{W^*} if it exactly solves every stationary solution taking values in this curve. The scheme is said to be exactly well-balanced if it is exactly well-balanced for every integral curve Γ_{W^*}.*

By using (2.10) and the proof of Proposition 2.1, the following result can be easily proved.

PROPOSITION 4.2. *Godunov's method* (2.8) *is exactly well-balanced.*

The definition of well-balanced numerical schemes can be extended to semidiscrete numerical schemes such as those introduced in the previous section.

DEFINITION 4.3. *A semidiscrete numerical method* (3.1) *is said to be* exactly well-balanced *for an integral curve Γ_{W^*} if, given a stationary solution $\widetilde{W}(x) = [W(x), \sigma(x)]^T$ taking values on this curve, the vector $\{W_i\}$ defined by*

$$W_i = \frac{1}{\Delta x} \int_{x_{i-1/2}}^{x_{i+1/2}} W(x)\, dx \quad \forall\, i \tag{4.1}$$

is a critical point of the system of differential equations defined by (3.1).

We introduce also the definition of well-balanced reconstruction operators. Let us suppose that the reconstructions are calculated on the basis of some approximation functions at the cells:

$$\widetilde{P}_i(x; \widetilde{W}_{i-l}, \ldots, \widetilde{W}_{i+r}).$$

DEFINITION 4.4. *The reconstruction operator is said to be* well-balanced *for an integral curve Γ_{W^*} if, given a stationary solution $\widetilde{W}(x) = [W(x), \sigma(x)]^T$ taking values*

on this curve, the approximation functions corresponding to the cell averages of $\widetilde{W}(x)$ *satisfy*

$$\widetilde{P}_i(x;\widetilde{W}_{i-l},\dots,\widetilde{W}_{i+r}) \in \Gamma_{W^*} \quad \forall\, x \in [x_{i-1/2}, x_{i+1/2}].$$

PROPOSITION 4.5. *If the reconstruction operator is well-balanced for a curve* Γ_{W^*}*, the numerical scheme* (3.1) *is exactly well-balanced for* Γ_{W^*}*.*

Proof. Let us apply the numerical scheme to the initial condition $\{W_i\}$ given by (4.1), $\widetilde{W}(x)$ being a stationary solution taking values on Γ_{W^*}. Due to the well-balanced character of the reconstruction operator, we have that, for every i,

$$x \in [x_{i-1/2}, x_{i+1/2}] \mapsto \widetilde{P}_i^0(x)$$

is a parameterization of an arc of an integral curve. Therefore,

$$\int_{x_{i-1/2}}^{x_{i+1/2}} CP_i^0(x)\frac{d}{dx}p_{N+1,i}^0(x)\,dx = A\big(W_{i+1/2}^-(0) - W_{i-1/2}^+(0)\big).$$

As a consequence, at time $t = 0$ the right-hand side of (3.1) reduces to

$$\frac{1}{\Delta x}\left(A\big(W_{i-1/2,0}^+(0) - W_{i-1/2}^+(0)\big) - A\big(W_{i+1/2,0}^-(0) - W_{i+1/2}^-(0)\big)\right).$$

Finally, as $W_{i+1/2}^{\pm}(0)$ belong to the same integral curve of the $(N+1)$th characteristic field, the solution of the corresponding Riemann problem is a stationary discontinuity. Then

$$W_{i-1/2,0}^+(0) = W_{i-1/2}^+(0), \quad W_{i+1/2,0}^-(0) = W_{i+1/2}^-(0).$$

Thus, the right-hand side of (3.1) vanishes, as we wanted to prove. ∎

Let us remark that the usual reconstruction operators are based on standard interpolation techniques, as polynomial interpolation: This is the case of essentially nonoscillatory (ENO) or weighted ENO (WENO) reconstructions, for instance. But in this case, there is not any particular reason to expect the operator to be well-balanced for a given integral curve Γ_{W^*}, except for the trivial case $W^* = 0$: Notice that the expression of the integral curve involves exponential terms that cannot be exactly approached by means of polynomial interpolators.

We propose here a strategy to obtain well-balanced reconstructions based on a modification of a standard reconstruction operator in $\mathbb{R}^N$ of order s

$$Q_i(x; W_{i-l},\dots,W_{i+r}). \tag{4.2}$$

The only requirement for (4.2) is that it has to be exact for the null function, i.e.,

$$Q_i(x;0,\dots,0) = 0 \quad \forall\, x.$$

Given a sequence $\{\widetilde{W}_i = [W_i, \sigma_i]^T\}$ of values at the cells, the reconstruction function $\widetilde{P}_i$ corresponding to the ith cell, I_i, is calculated as follows:

1. Look for W_i^* such that

$$W_i = \frac{1}{\Delta x}\int_{x_{i-1/2}}^{x_{i+1/2}} X(\sigma(x), W_i^*)\,dx. \tag{4.3}$$

2. For $j = i-l, \dots, i+r$, define V_j by

$$V_j = W_j - \frac{1}{\Delta x}\int_{x_{j-1/2}}^{x_{j+1/2}} X(\sigma(x), W_i^*)\, dx.$$

3. Set

$$Q_i(x) = Q_i(x; V_{i-l}, \dots, V_{i+r}), \quad x \in I_i. \tag{4.4}$$

4. Finally, define

$$\widetilde{P}_i(x) = \begin{bmatrix} X(\sigma(x), W_i^*) + Q_i(x) \\ \sigma(x) \end{bmatrix}, \quad x \in I_i. \tag{4.5}$$

5. The reconstructions at the intercells are thus given by

$$\widetilde{W}_{i-1/2}^{+} = \begin{bmatrix} X(\sigma(x_{i-1/2}), W_i^*) + Q_i(x_{i-1/2}) \\ \sigma(x_{i-1/2}) \end{bmatrix}, \tag{4.6}$$

$$\widetilde{W}_{i+1/2}^{-} = \begin{bmatrix} X(\sigma(x_{i+1/2}), W_i^*) + Q_i(x_{i+1/2}) \\ \sigma(x_{i+1/2}) \end{bmatrix}. \tag{4.7}$$

Notice that, following this construction, P_i is not a polynomial: It is the sum of the polynomial Q_i and the stationary solution $X(\sigma(x_{i+1/2}), W_i^*)$ whose average is W_i.

PROPOSITION 4.6. *The reconstruction operator given by* (4.6)–(4.7) *is well-balanced and of order* s.

Proof. Let us consider a vector $\{\widetilde{W}_i\}$ defined by (4.1) where $\widetilde{W}(x)$ is a stationary solution taking values on Γ_{W^*}, for some W^*. In this case, the solution of (4.3) is $W_i^* = W^*$ for every i. Moreover,

$$V_j = 0, \quad j = i-l, \dots, i+r,$$

and thus $Q_i \equiv 0$. Therefore,

$$\widetilde{P}_i(x) = [X(\sigma(x); W^*), \sigma(x)]^T \in \Gamma_{W^*} \quad \forall\, x,$$

and the reconstruction operator is well-balanced.

Next, let us suppose that the values W_i are the averages at the cells of a smooth function W and that σ and, consequently, $X(\sigma(x), W^*)$ are also smooth. Then, by construction:

$$\begin{aligned} Q_i(x_{i+1/2}) &= W(x_{i+1/2}) - X(x_{i+1/2}, W_i^*) + O(\Delta x^s), \\ Q_i(x_{i-1/2}) &= W(x_{i-1/2}) - X(x_{i-1/2}, W_i^*) + O(\Delta x^s). \end{aligned}$$

From these equalities and the definition of the functions $\widetilde{P}_i$, it can be easily deduced that the reconstruction operator is of order s. ∎

By making use of the definition of the functions $\widetilde{P}_i$, a reformulation of the well-balanced high order numerical scheme (3.1) can be given that makes appear explicitly the stationary solutions and the operator Q used in the reconstructions of states:

$$\begin{aligned} W_i' = \frac{1}{\Delta x}\Big(& A\big(W_{i-1/2,0}^{+}(t) - X(\sigma(x_{i-1/2}), W_i^*(t))\big) \\ & -A\big(W_{i+1/2,0}^{-}(t) - X(\sigma(x_{i+1/2}), W_i^*(t))\big) + \int_{x_{i-1/2}}^{x_{i+1/2}} CQ_i^t(x)\sigma_x(x)\, dx\Big). \end{aligned} \tag{4.8}$$

Remark 4.7.

1. Notice that problems (4.3) to be solved at the cells are linear:

$$\left(\frac{1}{\Delta x}\int_{x_{i-1/2}}^{x_{i+1/2}} e^{A^{-1}C\sigma(x)}\,dx\right)W_i^*(t) = W_i(t),$$

but the coefficients of the matrix can be difficult to calculate. The matrix of this linear system is regular if Δx is small enough, as its limit as Δx tends to 0 is

$$e^{A^{-1}C\sigma(x_i)},$$

which is regular.

2. Let us suppose that the following approximation hypotheses hold:

$$Q_i(x; V_{i-l}, \dots, V_{i+r}) = V(x) + O\left(\Delta x^{s_1}\right) \quad \forall\, x \in I_i,$$
$$\frac{d}{dx}Q_i(x; V_{i-l}, \dots, V_{i+r}) = V'(x) + O\left(\Delta x^{s_2}\right) \quad \forall\, x \in I_i,$$

for any given sequence defined by

$$V_i = \frac{1}{\Delta x}\int_{I_i} V(x)\,dx,$$

V being any smooth function. Then, if σ is smooth enough, it can be easily shown that the approximation functions $\widetilde{P}_i$ satisfy the hypotheses of Theorem 3.1.

3. If the integrals appearing in (4.8) are approached by a quadrature formula which is exact for the null function, the numerical scheme is still exactly well-balanced.

4. If the cell averages $\{W_i\}$ at time $t = 0$ are calculated by means of a quadrature formula, the introduced strategy still produces a well-balanced reconstruction operator if the integral in (4.3) is approached by using this same quadrature formula.

5. Extensions to more general problems.

5.1. Linear conservation laws with nonlinear source terms. We consider now the case of systems of the form

$$W_t + AW_x = G(W)\sigma_x, \tag{5.1}$$

where G is a smooth function from $\mathbb{R}^N$ to $\mathbb{R}$. The system can still be written under the form (2.2), with

$$\widetilde{\mathcal{A}}(\widetilde{W}) = \begin{bmatrix} A & -G(W) \\ 0 & 0 \end{bmatrix}.$$

Again, the system is strictly hyperbolic if A has N real distinct nonvanishing eigenvalues.

The main difference with the linear case comes from the expression of the integral curves of the $(N+1)$th characteristic field associated to the null eigenvalue. In this case, these integral curves are those of the autonomous ODE system

$$\frac{dW}{d\sigma} = A^{-1}G(W).$$

Let us denote by $X(\sigma; W^*)$ the maximal solution of this system with initial condition

$$W(0) = W^* \tag{5.2}$$

and by Γ_{W^*} the corresponding curve in $\mathbb{R}^{N+1}$.

The solution of the Riemann problem is again constructed as in the proof of Proposition 2.1, but now the following nonlinear system has to be solved: Find $s_1,\dots,$ s_N such that

$$X\left([\![\sigma]\!], W_L + \sum_{j=1}^{I} s_j R_j\right) = W_R - \sum_{j=I+1}^{N} s_j R_j, \tag{5.3}$$

where I denotes the last index of a negative eigenvalue. The Riemann problem has then a unique solution composed by $N+1$ contact discontinuities if and only if this nonlinear system has a unique solution $\{s_1,\dots,s_N\}$. In this case, the solution is still given by (2.5), with

$$\widetilde{W_0^+} = \begin{bmatrix} X\big([\![\sigma]\!], W_L + \sum_{j=1}^{I} s_j R_j\big) \\ \sigma_R \end{bmatrix}.$$

Obviously, the solution of the nonlinear equation (5.3) can be hard or even impossible to calculate in an explicit way. Nevertheless, it is easier to solve if all of the eigenvalues have the same sign, i.e., if $I=0$ or $I=N$.

Godunov's method can still be written under any of the forms (2.9), (2.10), or (2.11), by just replacing the linear equation (2.12) by the nonlinear one (5.3).

By using the notations of section 3, the expression of a high order extension is now

$$W_i' = \frac{1}{\Delta x}\left(AW^+_{i-1/2,0}(t) - AW^-_{i+1/2,0}(t) + \int_{x_{i-1/2}}^{x_{i+1/2}} G(P_i^t(x))\frac{d}{dx}p^t_{N+1,i}(x)\,dx\right),$$

and the expression of the well-balanced high order extension is as follows:

$$\begin{aligned} W_i' = \frac{1}{\Delta x}\Bigg(& A\big(W^+_{i-1/2,0}(t) - X(\sigma(x_{i-1/2}), W_i^*(t))\big) \\ & - A\big(W^-_{i+1/2,0}(t) - X(\sigma(x_{i+1/2}), W_i^*(t))\big) \\ & + \int_{x_{i-1/2}}^{x_{i+1/2}} \big(G(P_i^t(x)) - G(X(\sigma, W_i^*))\big)\sigma_x(x)\,dx\Bigg). \end{aligned}$$

The main difficulty to apply such a numerical scheme comes from the calculation of the reconstruction operator: On the one hand, the calculation of $X(\sigma; W)$ can be very difficult; on the other hand, even if it is possible to calculate these functions, the equation (4.3) is now nonlinear, and it can be difficult to solve.

5.2. Linear problems with nonconstant coefficients. We finally consider systems of the form

$$W_t + A(\sigma)W_x = G(\sigma, W)\sigma_x;$$

i.e., the coefficients of the matrix A and the function G are allowed to depend on σ and thus on x.

This system is strictly hyperbolic if the eigenvalues of $A(\sigma)$ are real, distinct, and different from zero. In this case, the integral curves of the characteristic field related to the eigenvalue zero are the solutions of the ODE system

$$\frac{dW}{d\sigma} = A(\sigma)^{-1}G(\sigma, W).$$

With the notation used in the previous subsection, the nonlinear systems to be solved in order to calculate the solution of the Riemann problem are again (5.3). Once more, these systems can be very difficult to solve.

The expression of Godunov's method is now

$$W_i^{n+1} = W_i^n + \frac{\Delta t}{\Delta x} A(\sigma_i)\big(W_{i-1/2}^{n,+} - W_{i+1/2}^{n,-}\big).$$

The general expression (3.1) of a high order extension can be written in this case as follows:

$$W_i' = \frac{1}{\Delta x}\Bigg(A(\sigma_{i-1/2}^+)W_{i-1/2,0}^+(t) - A(\sigma_{i+1/2}^-)W_{i+1/2,0}^-(t) + \int_{x_{i-1/2}}^{x_{i+1/2}} \widetilde{G}(\widetilde{P}_i^t(x))\frac{d}{dx}p_{N+1,i}^t(x)\,dx\Bigg),$$

where

$$\widetilde{G}(\widetilde{W}) = G(\sigma, W) + A'(\sigma)W,$$

where $A'(\sigma)$ represents the derivative of $A(\sigma)$. Finally, the well-balanced high order extension should be written as follows:

$$W_i' = \frac{1}{\Delta x}\Bigg(A(\sigma(x_{i-1/2}))\big(W_{i-1/2,0}^+(t) - X(\sigma(x_{i-1/2}), W_i^*(t))\big) - A(\sigma(x_{i+1/2}))\big(W_{i+1/2,0}^-(t) - X(\sigma(x_{i+1/2}), W_i^*(t))\big) + \int_{x_{i-1/2}}^{x_{i+1/2}} \big(\widetilde{G}(\widetilde{P}_i^t(x)) - \widetilde{G}(X(\sigma(x), W_i^*(t)))\big)\sigma_x(x)\,dx\Bigg).$$

Again, (4.3) can be difficult or even impossible to solve.

6. Numerical tests.

6.1. A linear scalar problem. Let us begin by considering an easy scalar problem, in order to illustrate the methodology introduced in previous sections. We consider the linear balance law

$$\begin{cases} w_t + \lambda w_x = cw, \\ w(x,0) = w_0(x), \end{cases} \tag{6.1}$$

with $\lambda > 0$. First, the problem is reformulated as follows:

$$\begin{cases} \widetilde{w}_t + \widetilde{A}(\widetilde{w})\widetilde{w}_x = 0, \\ \widetilde{w}(x_0) = \widetilde{w}_0(x), \end{cases} \tag{6.2}$$

where

$$\widetilde{w} = \begin{bmatrix} w \\ \sigma \end{bmatrix}, \quad \widetilde{A}(\widetilde{w}) = \begin{bmatrix} \lambda & -cw \\ 0 & 0 \end{bmatrix}, \quad \widetilde{w}_0(x) = \begin{bmatrix} w_0(x) \\ x \end{bmatrix}, \quad \sigma(x) = x.$$

System (6.2) is strictly hyperbolic: The matrix has two real eigenvalues λ and 0, with associated eigenvectors

$$r_1 = \begin{bmatrix} 1 \\ 0 \end{bmatrix}, \quad r_2 = \begin{bmatrix} \lambda^{-1}cw \\ 1 \end{bmatrix}.$$

The integral curves of the second characteristic field are given by

$$w = ke^{\lambda^{-1}c\sigma}, \quad \sigma \in \mathbb{R},$$

where k is an arbitrary constant.

A major advantage of reformulating the problem as a quasi-linear system comes from the fact that the solutions of Riemann problems for (6.2) are self-similar and they consist of constant states linked by simple waves, which is not the case for (6.1).

After some straightforward calculations, Godunov's method (2.10) for this particular case can be written as follows:

$$w_i^{n+1} = w_i^n + \frac{\Delta t}{\Delta x}\lambda\big(w_{i-1}^n e^{\lambda^{-1}c\Delta x} - w_i^n\big),$$

which can also be reformulated in the following form:

$$w_i^{n+1} = w_i^n + \frac{\Delta t}{\Delta x}\lambda(w_{i-1}^n - w_i^n) + \frac{\Delta t}{\Delta x}\lambda\big(e^{\lambda^{-1}c\Delta x} - 1\big)w_{i-1}^n. \tag{6.3}$$

Notice that the second addend on the right-hand side is a consistent approximation of the source term, as

$$\lambda\big(e^{\lambda^{-1}c\Delta x} - 1\big) = c\Delta x + \mathcal{O}(\Delta x^2).$$

The numerical treatment of the source term in (6.3) can be interpreted as an approximation by means of a sum of Dirac masses, as was done in [11] and [10]: Once the approximations at time t^n have been obtained, the source term $cw(x, t^n)$ is approximated by the measure

$$\sum_i \lambda\big(e^{\lambda^{-1}c\Delta x} - 1\big)w_{i-1}^n \delta_{x=x_{i+1/2}},$$

and every Dirac mass in the above sum is taken into account in the Riemann problem solved at the corresponding intercells.

The wave-propagation algorithm proposed in [3] to approximate quasi-steady solutions of balance laws is based on a similar approach: At every intercell, a Riemann problem is considered where the source term is approached by a delta function. For instance, in this easy example, a Riemann problem would be considered at the intercell $x_{i+1/2}$ for an equation of the form

$$w_t + \lambda w_x = cw_{i+1/2}^n \delta_{x=x_{i+1/2}}\Delta x,$$

where $w_{i+1/2}^n$ is an average of w_i^n and w_{i+1}^n to be chosen. The numerical scheme (6.3) can thus be interpreted as the particular case of the wave-propagation algorithm corresponding to the choice

$$w_{i+1/2}^n = \frac{\lambda}{c\Delta x}\big(e^{\lambda^{-1}c\Delta x} - 1\big)w_i^n.$$

This choice, given by the solution of the Riemann problem for the nonconservative system (6.2), ensures the well-balanced character of the numerical scheme for every stationary solution.

If, instead, the choice

$$w_{i+1/2}^n = \frac{1}{2}\left(w_i^n + w_{i+1}^n\right)$$

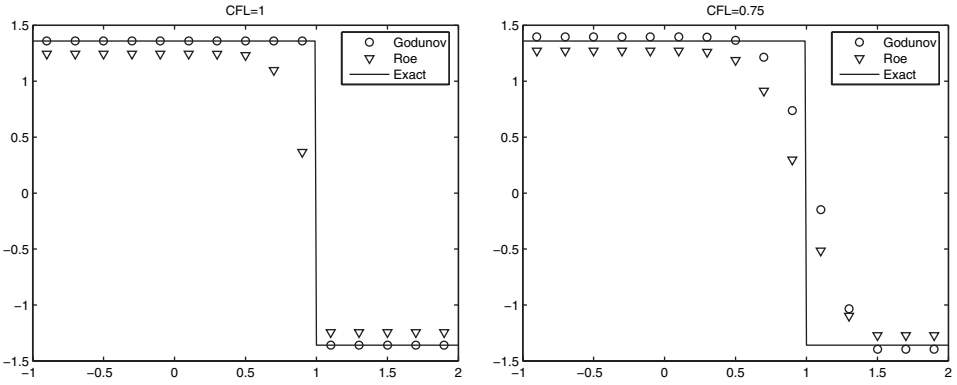

FIG. 1. *Solution of problem* (6.1) *at time* $t = 1$ *with initial condition* (6.5). *Left: CFL* $= 1$*; right: CFL* $= 0.75$.

is done, the following wave-propagation algorithm is obtained:

$$w_i^{n+1} = w_i^n + \lambda \frac{\Delta t}{\Delta x} \left(w_{i-1}^n - w_i^n \right) + \Delta t c \frac{w_{i-1}^n + w_i^n}{2}. \tag{6.4}$$

This is the classical scheme upwinding the source term (see [28] or [4]). It can also be obtained by applying to system (6.2) a generalized Roe's method of the family introduced by Toumi in [31]. This family of methods is based on the choice of a family of paths which, in the particular case of (6.4), is the family of segments: See [26] for details. In what follows, the numerical scheme (6.4) will be referred to as Roe's method. The general results shown in [26] allow one to prove that this Roe's method is not exactly well-balanced but it solves the stationary solutions up to second order.

In order to compare the numerical schemes (6.3) and (6.4), we consider (6.1) on the interval $-1 < x < 2$ with $\lambda = 1$ and $c = 1$. We consider the Riemann problem corresponding to the initial condition

$$w(x,0) = \begin{cases} 0.5 & \text{if } x < 0, \\ -0.5 & \text{if } x > 0. \end{cases} \tag{6.5}$$

In Figure 1 we compare the numerical results obtained with both numerical schemes by using $\Delta x = 0.2$ and CFL $= 1$. Observe that Godunov's method (6.3) gives the exact solution, even if the Riemann problems solved at the intercells are not associated to the PDE in (6.1) but to an approximation of it, due to the artificial piecewise constant approximation of the identity function performed. On the other hand, the numerical scheme (6.4) correctly approximates the location of the discontinuity, but the exponential growth of the states at both sides cannot be captured. The error in the approximation of these states increases with time. Nevertheless, the solutions provided by (6.4) converge to the exact solution as Δx tends to 0.

For CFL $= 0.75$, (6.3) still gives a better approximation of the growth of the states at both sides of the discontinuity; see Figure 1.

To test the well-balanced property of the numerical schemes, we consider the stationary solution $w(x) = e^x$ as the initial condition on the interval $[-3, 3]$: As expected, Godunov's method is exact, while Roe's method solves the stationary solution with order 2 (see Table 1).

TABLE 1
Error in L^1 norm for Roe's scheme (6.4) *and Godunov's scheme* (6.3) *with initial condition* $w(x,0) = e^x$ *at time* $t = 2$. *CFL* $= 0.9$, $c = \lambda = 1$.

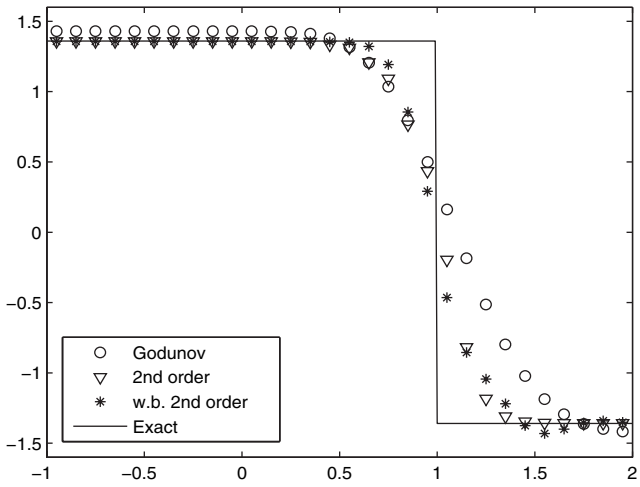

FIG. 2. *Solution of problem* (6.1) *at time* $t = 1$ *with initial condition* (6.5). *CFL* $= 0.75$.

By following section 3, the form of a high order extension of (6.3) is as follows:

$$w_i' = \frac{1}{\Delta x}\left(\lambda w^-_{i-1/2}(t)e^{\lambda^{-1}c[\sigma^t_{i+1/2}]} - \lambda w^-_{i+1/2}(t) + c\int_{x_{i-1/2}}^{x_{i+1/2}} p^t_{1,i}(x)\frac{d}{dx}p^t_{2,i}(x)\,dx\right).$$

Notice that, as $\sigma_i = x_i$ for every i, if the approximation functions are exact for polynomials of degree 1, the numerical scheme reduces to

$$w_i' = \frac{1}{\Delta x}\left(\lambda w^-_{i-1/2}(t) - \lambda w^-_{i+1/2}(t) + c\int_{x_{i-1/2}}^{x_{i+1/2}} p^t_{1,i}(x)\,dx\right). \tag{6.6}$$

We consider again the Riemann problem (6.5), and we apply a second order extension of Godunov's method based on a monotone upstream-centered schemes for conservation laws (MUSCL) reconstruction with a *minmod* slope limiter (see [32]). The discretization in time is performed with an explicit Runge–Kutta TVD second order method (see [12]). In Figure 2 we compare the results obtained for CFL $= 0.75$ with those corresponding to Godunov's method.

Unlike Godunov's method, this higher order extension is not exactly well-balanced. The errors and computed order corresponding to the stationary solution $w(x) = e^x$ as initial data on the interval $[-3, 3]$ are shown in Table 2. As expected, the solution is approximated with the order of the numerical scheme.

To obtain a well-balanced second order extension of (6.3), the techniques developed in section 4 can be applied: The form of a well-balanced high order extension

(4.8) applied to the particular case (6.1) is as follows:

$$w_i' = \frac{1}{\Delta x}\left(\lambda\big(w^-_{i-1/2}(t) - e^{\lambda^{-1}cx_{i-1/2}}w^*_i(t)\big) - \lambda\big(w^-_{i+1/2}(t) - e^{\lambda^{-1}cx_{i+1/2}}w^*_i(t)\big) + c\int_{x_{i-1/2}}^{x_{i+1/2}} q^t_i(x)\,dx\right), \tag{6.7}$$

where

$$w^*_i(t) = \frac{c\lambda^{-1}\Delta x}{e^{\lambda^{-1}cx_{i+1/2}} - e^{\lambda^{-1}cx_{i-1/2}}}w_i(t),$$
$$q^t_i = q_i(\cdot; v_{i-l}(t), \dots, v_{i+r}(t)),$$

q_i being the approximation functions of a reconstruction operator in $\mathbb{R}$, and

$$v_j(t) = w_j(t) - \frac{\lambda}{c\Delta x}\big(e^{\lambda^{-1}c(j+1/2)\Delta x} - e^{\lambda^{-1}c(j-1/2)\Delta x}\big)w^*_i(t), \quad j = i-l, \dots, i+r.$$

Finally,

$$w^+_{i+1/2}(t) = q^t_{i+1}(x_{i+1/2}) + e^{\lambda^{-1}cx_{i+1/2}}w^*_{i+1}(t),$$
$$w^-_{i+1/2}(t) = q^t_i(x_{i+1/2}) + e^{\lambda^{-1}cx_{i+1/2}}w^*_i(t).$$

Again, MUSCL reconstructions and an explicit Runge–Kutta TVD method for the discretization in time are considered. In Figure 2 we compare the results obtained for the considered Riemann problem above for CFL $= 0.75$ with Godunov's method, its second order extension, and the well-balanced second order extension. As can be seen, the results obtained with both second order numerical schemes are similar.

Table 3 shows the committed errors solving the stationary solution $w(x) = e^x$ on the interval $[-3, 3]$ with the well-balanced second order method. As expected, the solution is exactly calculated.

Finally, we include a test to verify the second order accuracy of the schemes for time-dependent solutions. We solve (6.1) with $w_0(x) = e^{-10x^2}$ on the interval $[-3, 3]$. In Table 4 we show the L^1 errors and the order obtained with the schemes (6.6) and (6.7).

TABLE 4
Error in L^1 norm for the schemes (6.6) and (6.7) with initial condition $w(x,0) = e^{-10x^2}$ at time $t = 1$. CFL $= 0.9$, $c = \lambda = 1$.

No. cells	L^1 error (sch. (6.6))	Order (sch. (6.6))	L^1 error (sch. (6.7))	Order (sch. (6.7))
100	2.246E-02	-	2.260E-02	-
200	6.273E-03	1.84	6.310E-03	1.84
400	1.626E-03	1.94	1.635E-03	1.94
800	4.131E-04	1.97	4.154E-04	1.97

6.2. A linear scalar problem with a singular source term. In the previous paragraph, it has been shown that numerical results obtained with Roe's scheme (6.4) are worse than those obtained with Godunov's method (6.3) but that, nevertheless, they converge to the right solution of problem (6.1) as Δx tends to 0. In this example, we show that the convergence of Roe's scheme may fail when $\sigma(x)$ is discontinuous.

We consider the scalar equation

$$\begin{cases} w_t + 2w_x = w\sigma'(x), \\ w(x,0) = w_0(x), \end{cases} \tag{6.8}$$

with $\lambda > 0$,

$$\sigma(x) = \begin{cases} -1 & \text{if } x < 0, \\ 1 & \text{if } x > 0, \end{cases}$$

and

$$w_0(x) = \begin{cases} 0.5 & \text{if } x < 0, \\ -0.5 & \text{if } x > 0. \end{cases} \tag{6.9}$$

Godunov's method (2.10) can be expressed now as follows:

$$w_i^{n+1} = w_i^n + \frac{\Delta t}{\Delta x}\lambda\big(w_{i-1}^n e^{\lambda^{-1}c(\sigma_i - \sigma_{i-1})} - w_i^n\big),$$

while Roe's method upwinding the source term is given by

$$w_i^{n+1} = w_i^n + \lambda\frac{\Delta t}{\Delta x}\left(w_{i-1}^n - w_i^n\right) + c\frac{\Delta t}{\Delta x}\frac{w_{i-1}^n + w_i^n}{2}(\sigma_i - \sigma_{i-1}). \tag{6.10}$$

We have solved problem (6.8) with initial condition (6.9) on the interval $-1 < x < 1$ with $\Delta x = 0.02$ and CFL $= 1$. The results obtained at time $t = 0.4$ have been represented in Figure 3. While Godunov's method gives again the exact solution, Roe's method (6.10) produces an incorrect intermediate state between the discontinuities. Table 5 shows the errors in L^∞ norm for CFL $= 1$ and decreasing values of Δx. In fact, in this case the solutions provided by (6.10) converge to a function which is a solution of (6.8) corresponding to a different definition of the nonconservative product. More precisely, it is a solution of the problem if the family of segments is chosen as the family of paths.

6.3. A relaxation system. We consider the following relaxation system (see [21]):

$$\begin{cases} u_t + v_x = 0, \\ v_t + au_x = \frac{1}{\varepsilon}(f(u) - v), \end{cases} \tag{6.11}$$

with $a > 0$ and $f(u) = \sqrt{a}u$.

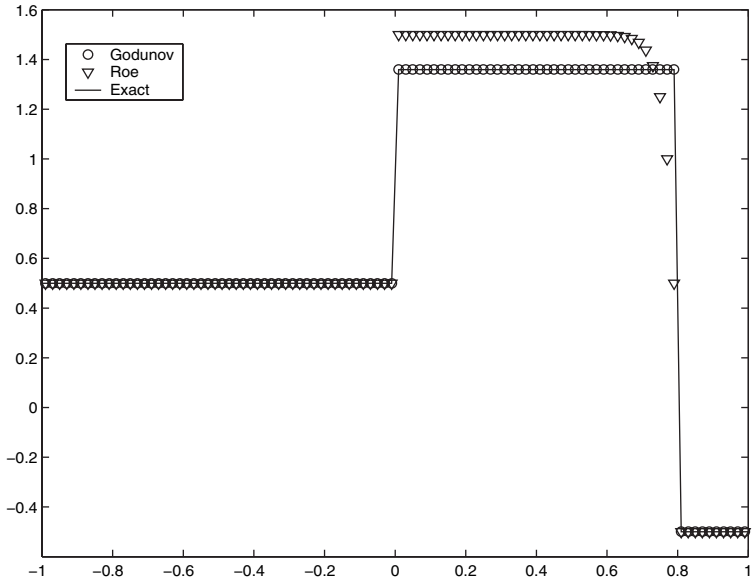

FIG. 3. *Solution of problem* (6.8) *with initial condition* (6.9) *at time* $t = 0.4$.

TABLE 5
Errors in L^∞ *norm for Roe's method* (6.10).

Δx	Roe L^∞ errors
0.2	0.13891
0.05	0.14086
0.02	0.14086
0.005	0.14086
0.002	0.14086

This system can be expressed under the formulation (5.1) with

$$W = \begin{bmatrix} u \\ v \end{bmatrix}, \quad A = \begin{bmatrix} 0 & 1 \\ a & 0 \end{bmatrix}, \quad G(W) = \begin{bmatrix} 0 \\ (f(u) - v)/\varepsilon \end{bmatrix}, \quad \sigma(x) = x.$$

The eigenvalues of the system are $\lambda_1 = -\sqrt{a}$, $\lambda_2 = \sqrt{a}$, and $\lambda_3 = 0$, with associated eigenvectors $R_1 = [1, -\sqrt{a}, 0]^T$, $R_2 = [1, \sqrt{a}, 0]^T$, and $R_3 = [(f(u) - v)/(\varepsilon a), 0, 1]^T$.

The integral curves associated to the zero eigenvalue are of the form

$$v = \overline{v}, \quad u = \frac{v}{\sqrt{a}} + Ce^{\frac{\sigma}{\varepsilon\sqrt{a}}},$$

where $\overline{v}$ and C are real constants.

Godunov's method (2.10) can be written as

$$u_i^{n+1} = u_i^n + \frac{\Delta t}{\Delta x}\big(- \sqrt{a}\ s_{2,i+1/2}^n + \sqrt{a}\ s_{1,i-1/2}^n\big),$$
$$v_i^{n+1} = v_i^n + \frac{\Delta t}{\Delta x}\big(- a\ s_{2,i-1/2}^n - a\ s_{1,i+1/2}^n\big),$$

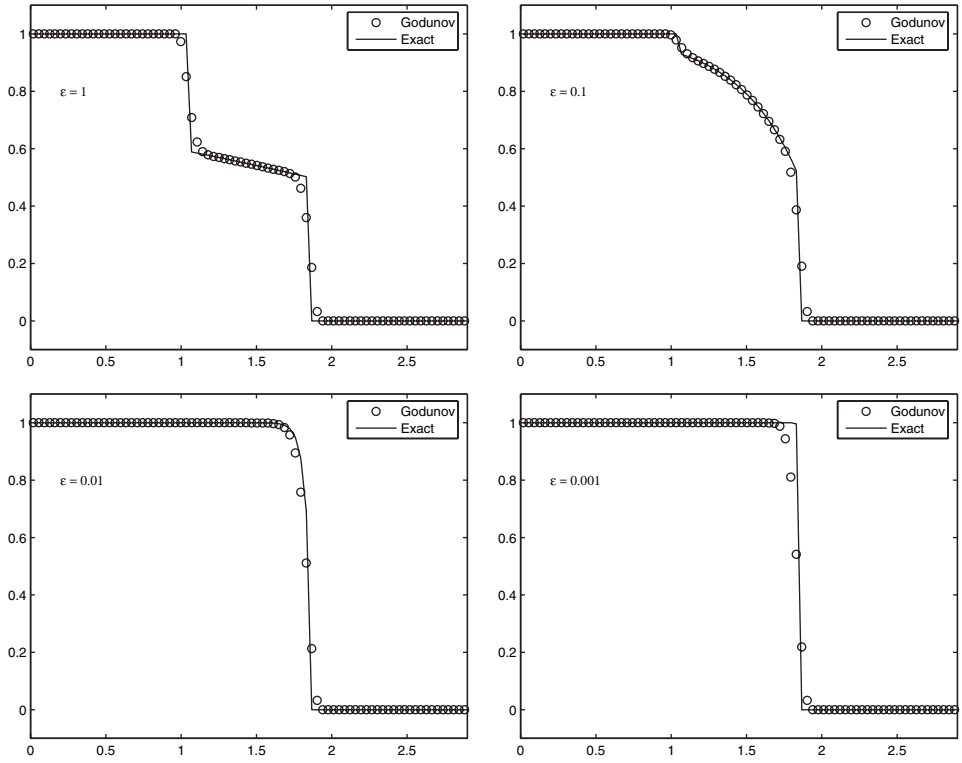

FIG. 4. *Solution u of problem* (6.11) *with initial condition* (6.12) *at time $t = 0.2$. CFL $= 0.9$,* 80 *grid cells.*

where $s^n_{1,i+1/2}$ and $s^n_{2,i+1/2}$ are given by, respectively,

$$s^n_{1,i+1/2} = \frac{1}{2}\left(u^n_{i+1} - \frac{v^n_{i+1}}{\sqrt{a}} e^{-\frac{\Delta x}{\varepsilon\sqrt{a}}}\right) - \frac{1}{2}\left(u^n_i - \frac{v^n_i}{\sqrt{a}}\right),$$

$$s^n_{2,i+1/2} = s^n_{1,i+1/2} - \frac{v^n_i - v^n_{i+1}}{\sqrt{a}}.$$

We consider a test proposed in [21] on the interval $[0, 2.9]$ with the following initial conditions:

$$u(x,0) = \begin{cases} 1 & \text{if } x < 2.9/2, \\ 0 & \text{if } x \geq 2.9/2, \end{cases}$$
$$v(x,0) = 0, \quad x \in [0, 2.9]. \tag{6.12}$$

In Figure 4 we plot the solution at time $t = 0.2$ for different values of the parameter ε. In [21] a finite volume method based on a splitting procedure, called the NM-scheme, was proposed. Numerical results shown there are more diffusive than those obtained here due to the small CFL number required to guarantee stability of the NM-scheme.

6.4. A linearized shallow water system. We consider the system obtained by linearization of the shallow water equations around a steady state $[h_0(x), q_0(x)]^T$

(see [3]):

$$\frac{\partial W}{\partial t} + \frac{\partial}{\partial x}(A(x)W) = G(x)W, \tag{6.13}$$

where $W = [h, q]^T$ represents the perturbation to the steady state and whose components correspond to the fluid depth and discharge, respectively. $A(x)$ and $G(x)$ are given by, respectively,

$$A(x) = \begin{bmatrix} 0 & 1 \\ -\dfrac{q_0(x)^2}{h_0(x)^2} + gh_0(x) & 2\dfrac{q_0(x)}{h_0(x)} \end{bmatrix}, \quad G(x) = \begin{bmatrix} 0 & 0 \\ gH'(x) & 0 \end{bmatrix},$$

where $H(x)$ is the bottom topography and g is the gravity acceleration.

The eigenvalues of the matrix A are $\lambda_1(x) = q_0/h_0 - \sqrt{gh_0}$ and $\lambda_2(x) = q_0/h_0 + \sqrt{gh_0}$; $R_1 = [1, \lambda_1]^T$ and $R_2 = [1, \lambda_2]^T$ are associated eigenvectors. We will assume in what follows that the flow is subcritical, i.e., $\lambda_1(x) < 0 < \lambda_2(x)$ for every x.

Some calculations yield that the stationary solutions of (6.13) are of the form

$$X(x, W^*) = \begin{bmatrix} h \\ q \end{bmatrix} = \begin{bmatrix} \dfrac{C_1 h_0^3 - q_0 h_0 q}{-q_0^2 + g h_0^3} \\ C_2 \end{bmatrix}, \tag{6.14}$$

C_1, C_2 being two arbitrary constants.

The expression of Godunov's method (2.10) is as follows:

$$W_i^{n+1} = W_i^n + \frac{\Delta t}{\Delta x} A(x_i)\big(- s_{2,i-1/2}^n R_{1,i} - s_{1,i+1/2}^n R_{2,i}\big), \tag{6.15}$$

where $s_{1,i+1/2}^n$ and $s_{2,i+1/2}^n$ are given by, respectively,

$$s_{1,i+1/2}^n = \frac{q_{i+1}^n - q_i^n - \lambda_{2,i+1}\beta_{i+1/2}^n}{\lambda_{1,i} - \alpha_{i+1/2}\lambda_{2,i+1}},$$
$$s_{2,i+1/2}^n = \beta_{i+1/2}^n - \alpha\ s_{1,i+1/2}^n,$$

with

$$\alpha_{i+1/2} = c_{i+1}(a_i + b_i\lambda_{1,i}) - d_{i+1}\lambda_{1,i},$$
$$\beta_{i+1/2}^n = h_{i+1}^n - c_{i+1}(a_i h_i^n + b_i q_i^n) + d_{i+1} q_i^n,$$
$$a_i = \frac{-q_{0,i}^2 + g h_{0,i}^3}{h_{0,i}^3},$$
$$b_i = \frac{q_{0,i}}{h_{0,i}^2},$$
$$c_i = \frac{1}{a_i},$$
$$d_i = \frac{q_{0,i} h_{0,i}}{-q_{0,i}^2 + g h_{0,i}^3}.$$

By following [3], we consider the depth function

$$H(x) = \begin{cases} -0.25\big(\cos(\pi(x - 0.5)/0.1) + 1\big) & \text{if } |x - 0.5| < 0.1, \\ 0 & \text{otherwise,} \end{cases} \tag{6.16}$$

TABLE 6

and consider the steady state corresponding to $q_0 = 0.15$ everywhere and $h_0 = 1$ away from the hump defined in (6.16). The value of g has been fixed to 1.

Table 6 shows that method (6.15) is well-balanced for the stationary solution (6.14) corresponding to $C_1 = C_2 = 1$ on the interval $[0, 0.8]$ (see Figure 5).

Now let us apply a well-balanced high order scheme. In this case, the expression of the scheme is the following:

$$
\begin{aligned}
W_i' = \frac{1}{\Delta x}\Bigg(& A(x_{i-1/2})\big(W^+_{i-1/2,0}(t) - X(x_{i-1/2}, W_i^*(t))\big) \\
& -A(x_{i+1/2})\big(W^-_{i+1/2,0}(t) - X(x_{i+1/2}, W_i^*(t))\big) \\
& + \int_{x_{i-1/2}}^{x_{i+1/2}} G(x) Q_i^t(x)\, dx\Bigg),
\end{aligned} \tag{6.17}
$$

where

$$
\begin{aligned}
W^+_{i+1/2,0} &= W_{i+1} - s_{2,i+1/2} R_{2,i+1/2}, \\
W^-_{i+1/2,0} &= W_i + s_{1,i+1/2} R_{1,i+1/2},
\end{aligned}
$$

with

$$
\begin{aligned}
s_{1,i+1/2} &= \frac{q_{i+1} - q_i - \lambda_{2,i+1/2}(h_{i+1} - h_i)}{\lambda_{1,i+1/2} - \lambda_{2,i+1/2}}, \\
s_{2,i+1/2} &= h_{i+1} - h_i - s_{1,i+1/2},
\end{aligned}
$$

TABLE 7

Error in L^1 norm for the third order well-balanced method (6.17) *with initial condition* (6.14) *and $C_1 = C_2 = 1$ at time $t = 1$. CFL $= 1$.*

No. cells	L^1 error h	L^1 error q
75	1.9123E-14	2.0211E-14
150	3.3747E-14	3.9726E-14
300	7.3356E-14	7.7903E-14
600	1.4558E-13	1.5481E-14

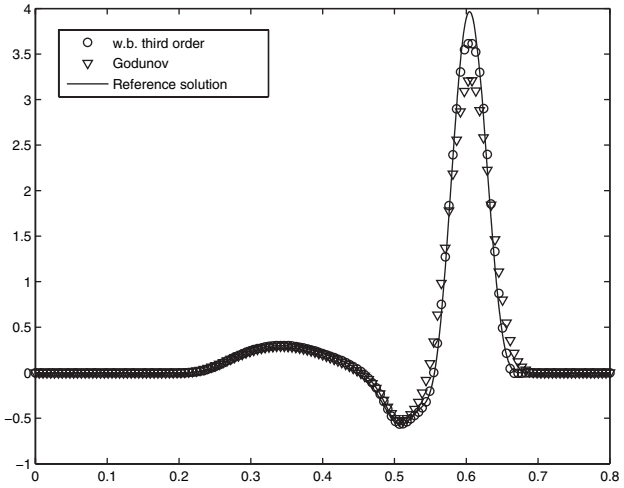

FIG. 6. *Solution of problem* (6.13) *with initial condition* (6.18) *at time $t = 0.3$. CFL $= 0.9$, 150 grid cells. The reference solution has been obtained with scheme* (6.17) *and* 1000 *grid cells.*

and, for any t, $W_i^*(t)$ is calculated so that the average of the stationary solution $X(x, W_i^*(t))$ at the ith cell coincides with $W_i(t)$. In practice, the averages are approximated by means of a quadrature rule with order at least that of the reconstruction operator.

We consider the third order reconstruction operator based on hyperbolas introduced in [22]. The time discretization is performed with a third order TVD explicit Runge–Kutta method (see [12]). Table 7 shows the committed errors solving the stationary solution (6.14) corresponding to $C_1 = C_2 = 1$.

Finally, in Figure 6 we compare the schemes (6.15) and (6.17) for the following initial perturbation proposed in [3]:

$$
\begin{aligned}
h(x,0) &= \begin{cases} \big(1 - \cos(2\pi(x-0.2)/0.15)\big)^2 & \text{if } 0.2 < x < 0.35, \\ 0 & \text{otherwise,} \end{cases} \\
q(x,0) &= (q_0/h_0 + \sqrt{gh_0})h(x,0).
\end{aligned}
\tag{6.18}
$$

The numerical solutions are compared with a reference solution obtained with a finer mesh. Notice the improved resolution obtained with the third order numerical scheme. Results are similar to those shown in [3].

MOLLIFIED IMPULSE METHODS FOR HIGHLY OSCILLATORY DIFFERENTIAL EQUATIONS*

J. M. SANZ-SERNA†

Abstract. We introduce a family of impulselike methods for the integration of highly oscillatory second-order differential equations whose forces can be split into a fast part and a slow part. Methods of this family are specified by two weight functions ϕ, ψ; one is used to average positions and the other to mollify the force. When the fast forces are conservative and $\phi = \psi$, the methods here coincide with the mollified impulse methods introduced by García-Archilla, Sanz-Serna, and Skeel. On the other hand, the methods here extend to nonlinear situations a well-known class of exponential integrators introduced by Hairer and Lubich for cases of linear fast forces. A convergence analysis is presented that provides insight into the role played by the processes of mollification and averaging in avoiding order reduction. A simple condition on the weight functions is shown to be both necessary and sufficient to avoid order reduction.

Key words. impulse methods, highly oscillatory problem, Fourier analysis

1. Introduction.

We consider numerical methods for the integration of multiple-time-scale problems of the form

$$M\frac{d^2}{dt^2}q = f(q) + g(q), \tag{1}$$

where M is a symmetric positive-definite mass matrix and the forces are split into a *soft* or *slow* part g that does not contribute any fast modes to the solution and a *strong* or *fast* part f such that the *reduced* problem

$$M\frac{d^2}{dt^2}q = f(q)$$

possesses highly oscillatory modes (and possibly slow modes as well). These problems arise in many situations including molecular dynamics, astronomy, and the time integration of partial differential equations describing wave phenomena. The fast/slow splitting is of interest in situations where the computational cost of integrating the reduced system is much smaller than that of integrating the full system. For instance, in an N-body problem, the evaluation of the fast force is cheaper than that of the slow force if the former is composed only of next-neighbor interactions and the latter includes interactions between all particles. A second example is provided by cases where the reduced problem can be solved analytically with a cost that is independent (or almost independent) of the step length. In such situations the aim is to sample the slow forces as sparingly as possible and, certainly, at a rate that is not determined by the periods of the fast motions, i.e., by the stiffness of the reduced problem.

*Received by the editors February 2, 2007; accepted for publication (in revised form) October 29, 2007; published electronically March 5, 2008. This research was supported by DGI-MCYT under project MTM2004-07194 cofinanced by FEDER funds.

†Departamento de Matemática Aplicada, Universidad de Valladolid, 47011 Valladolid, Spain (sanzsern@mac.uva.es, http://hermite.mac.cie.uva.es/sanzserna).

The impulse method was devised to cater to these situations. The time stepping of the impulse method intersperses evaluations of the slow forces at intervals of length h with integrations of the reduced system that are taken to be exact, either because an analytic integration is feasible or because, in a multiple time-step approach [7], [8], [17], a numerical integration is performed with a time step much smaller than h. Unfortunately, the impulse method, which is formally of second-order accuracy, leads only to errors that behave $O(h^2)$ if h is small as compared with the smallest period of the reduced system. An alternative family of methods, the mollified impulse methods, was introduced in [5]; there is one mollified impulse method for each choice of a so-called weight function. Proved in [5] is the fact that, for several choices of weight functions, the mollified impulse method yields errors in q that behave as $O(h^2)$, where the implied constant is independent of the size of the fast forces and depends only on the energy of the solution and on bounds for g and its derivatives. It is then possible to apply the mollified impulse methods with a given time step h to faster and faster problems without impairing the accuracy. This is feasible because, for a given oscillation amplitude, the energy grows with the frequency; therefore, in solutions of limited energy, fast oscillations are present with small amplitudes and need not be accurately resolved. In conclusion, for problems with fast oscillations, the scenario here is then similar to that found in the development of stiff solvers [3], [12] for problems with fast rates of decay: Good stiff solvers perform satisfactorily with step lengths independent of the stiffness of the problem and determined only by the smoothness of the solution, and this is possible because they need not accurately resolve fast components. As in the (nonoscillatory) stiff situation [3], [12], methods for highly oscillatory problems have a conventional order that is brought out in simulations where the step length h is small when compared to the stiffness of the problem and a *stiff order* that manifests itself in the cases where h is not small. In general the stiff order is smaller than the conventional order, and one speaks of an *order reduction*.

In this paper we reconsider the ideas behind the mollified impulse method. In section 2 we introduce a large family of methods, the (ϕ, ψ)-methods, which extends in two ways the family in [5]. In the first place, (ϕ, ψ)-methods are specified by *two* independent weight functions: one, ψ, that defines the so-called mollification and one, ϕ, that is employed in an averaging. On the other hand, our description here of the mollification process depends on the Alekseev–Groebner formula [11] and applies to cases where the fast forces are nonconservative. This should be compared with the methods in [5] that depend on one weight function and apply only to conservative fast forces (Hamiltonian reduced problems). In section 3, it is shown that, if ϕ and ψ are taken to coincide and the reduced problem is Hamiltonian, the family of methods considered here coincides with the mollified methods of [5].

When the fast forces are linear, the reduced problem may in principle be integrated analytically, and we show in section 4 that the (ϕ, ψ)-method can be implemented in terms of two *filters* defined in terms of the Fourier transforms of the weights ϕ and ψ. In this case of linear fast forces, the family of (ϕ, ψ)-methods essentially mimics a by now well known family of exponential integrators first described by Hairer and Lubich [9] (see also, among others, [2] and Chapter XIII in the monograph [10]; an error analysis has been provided in [6]). The relation between weights and filters is explored in further detail in section 7, where filters are characterized via a classical Fourier analysis result of Paley and Wiener.

Sections 5 and 6 contain an analysis of the accuracy of (ϕ, ψ)-methods as applied to problems with linear fast forces. The approach here resembles in a way that in [5], because it is based on the weight functions rather than on the corresponding filters.

The analysis here is then completely different from those in the convergence proofs presented in [6] and (for a particular model problem with only one fast frequency) in Chapter XIII of [10]; both proofs are carried out in terms of the filters. We show how a study in terms of weights makes it possible to identify in a natural way simple conditions on the methods that are both necessary and sufficient to ensure that no order reduction takes place. Essentially, no order reduction is equivalent to the requirement that the translation of the weight function are a basis set for a consistent interpolation scheme. On the other hand, our analysis differs from that in [5] in a number of points that we believe to be of some importance. We cater here to weight functions of arbitrary bounded support; in [5] the support had to be contained in $[-1, 1]$. Our analysis applies to cases where the mollification filter ψ is different from the averaging filter ϕ; this not only means that more methods are covered but also tells apart the effects of the averaging from those of the mollifier. We finally mention that section XIV.2.4 of [10] presents an analysis for the long-average mollified impulse method that covers fast forces more general than those considered by us.

Extensive numerical experiments based on the new methods will be provided in a forthcoming paper.

2. Description of the methods. For numerical work, we rewrite the system (1) in the first-order format

$$\frac{d}{dt}p = f(q) + g(q), \qquad \frac{d}{dt}q = M^{-1}p, \tag{2}$$

with the reduced version

$$\frac{d}{dt}p = f(q), \qquad \frac{d}{dt}q = M^{-1}p. \tag{3}$$

If we denote by P_n and Q_n the numerical approximations to the true solution values of the momenta $p_n = p(t_n)$ and coordinates $q_n = q(t_n)$, respectively, at the step point $t_n = nh$, a step $n \to n + 1$ of any of the methods considered in this paper may be fit into the following composition or split-step pattern.

Kick. Compute an approximation $\bar{G}_n$ to the value of the slow force $g(q_n)$, and then set $P_n^+ = P_n + \frac{h}{2}\bar{G}_n$.

Oscillation. Use the h-flow of the reduced problem (3) to advance from (P_n^+, Q_n) to (P_{n+1}^-, Q_{n+1}). In other words, (P_{n+1}^-, Q_{n+1}) is obtained by integrating, over a time interval of length h, the system (3) with initial conditions (P_n^+, Q_n).

Kick. Set $P_{n+1} = P_{n+1}^- + \frac{h}{2}\bar{G}_{n+1}$.

Of course, the force $\bar{G}_{n+1}$ at the second kick of the current step coincides with the force at the first kick of the next step, so that the methods essentially consist of a sequence of oscillations $(P_n^+, Q_n) \to (P_{n+1}^-, Q_{n+1})$ followed by kicks $P_{n+1}^- = P_{n+1}^+ + h\bar{G}_{n+1}$; it is not necessary to compute the vector P_{n+1} unless output at t_{n+1} is required.

Different methods within the class considered here differ in the way in which the forces $\bar{G}_n$ are computed. The simplest and earliest choice, that of the original impulse method, is given by $\bar{G}_n = g(Q_n)$ and, unfortunately, suffers from an order reduction in p from 2 to 0 and in q from 2 to 1 in the stiff oscillatory situations considered here [5]. An improvement that may ensure (stiff) order 1 in p and (stiff) order 2 in q was presented in [5]. The family of mollified impulse methods introduced there have

$$\bar{G}_n = \mathcal{M}(Q_n, h)g(\mathcal{A}(Q_n, h)), \tag{4}$$

where, given Q_n and h, $\mathcal{A}(Q_n, h)$ represents an average of values of q and $\mathcal{M}$ is a so-called mollifier matrix. The use of $\mathcal{A}$ avoids [5] the dangers associated with sampling at grid points a quickly varying $g(q(t))$, and the role of $\mathcal{M}$ is to mimic the way in which extra external forces contribute to build up the momentum in highly oscillatory problems (see the analysis and counterexamples in sections 5 and 6 below).

As discussed in [5], there is much freedom within the class of mollified impulse methods, both in how $\mathcal{M}$ and $\mathcal{A}$ may be mathematically specified and in the analytic or numerical technique employed to actually compute them. Here we add to this freedom by further enlarging the class of possible choices in (4).

Before we proceed, we need some notation. We denote by $\mathcal{P}(p, q, t)$, $\mathcal{Q}(p, q, t)$ the flow of the reduced system (3), so that $p(t) = \mathcal{P}(p_0, q_0, t)$, $q(t) = \mathcal{Q}(p_0, q_0, t)$ is the value at time t of the solution of (3) with initial conditions $p(0) = p_0$, $q(0) = q_0$. Thus $P_{n+1}^- = \mathcal{P}(P_n^+, Q_n, h)$, and $Q_{n+1} = \mathcal{Q}(P_n^+, Q_n, h)$. For compactness, it is useful to combine P_n and Q_n into a single vector $Y_n = (P_n, Q_n)$ and similarly write $y(t) = (p(t), q(t))$, $\mathcal{Y} = (\mathcal{P}, \mathcal{Q})$, etc. If d represents the number of degrees of freedom in the problem, we will also use the $(2d) \times (2d)$ Jacobian matrix $\mathcal{Y}'(\alpha, t)$ of $\mathcal{Y}(\alpha, t)$ with respect to its argument α, which can be found by integrating the variational equation

$$\frac{\partial}{\partial t}\mathcal{Y}'(\alpha, t) = \begin{bmatrix} 0 & f'(\mathcal{Q}(\alpha, t)) \\ M^{-1} & 0 \end{bmatrix} \mathcal{Y}'(\alpha, t), \tag{5}$$

with initial condition $\mathcal{Y}'(\alpha, 0) = I_{2d}$. It is clear that $\mathcal{Y}'$ possesses a natural block structure corresponding to the partition of y:

$$\mathcal{Y}' = \begin{bmatrix} \mathcal{P}_p & \mathcal{P}_q \\ \mathcal{Q}_p & \mathcal{Q}_q \end{bmatrix}.$$

Each of the methods considered here is defined by two *weight* functions. For the purpose of this paper, a weight function is a bounded, integrable real-valued function $\chi(t)$ that is assumed to be even $\chi(-t) \equiv \chi(t)$ and to satisfy

$$\int_{-\infty}^{\infty} \chi(s) ds = 1. \tag{6}$$

(Note that we do not require $\chi \geq 0$.)

We may now describe the new methods. As in [5], to construct $\mathcal{A}$, we start by choosing a weight function ϕ and then define

$$\mathcal{A}(Q_n, h) = \frac{1}{h} \int_{-\infty}^{\infty} q^*(t) \phi\left(\frac{t}{h}\right) dt = \int_{-\infty}^{\infty} q^*(hs) \phi(s)\, ds, \tag{7}$$

where $q^*(t)$ is obtained by solving the reduced problem (3) with initial conditions $q = Q_n$, $p = 0$, i.e., $q^*(t) = \mathcal{Q}(0, Q_n, t)$. Since q^* is an even function of t, the integrals in (7) are in practice replaced by twice their value over $(0, \infty)$.

To define the mollifier, we choose a second weight function ψ, and, at each time step, we find a matrix-valued function Y' of the independent variable t

$$Y'(t) = \begin{bmatrix} P_p(t) & P_q(t) \\ Q_p(t) & Q_q(t) \end{bmatrix}$$

by integrating the variational problem ($q^*(t)$ is as above)

$$\frac{d}{dt}Y' = \begin{bmatrix} 0 & f'(q^*(t)) \\ M^{-1} & 0 \end{bmatrix} Y', \tag{8}$$

with initial condition $Y'(0) = I_{2d}$, and then set

$$\mathcal{M}(Q_n, h) = \frac{1}{h}\int_{-\infty}^{\infty} R(t)\psi\left(\frac{t}{h}\right)\,dt = \int_{-\infty}^{\infty} R(hs)\psi(s)\,ds, \tag{9}$$

where $R(t)$ is the upper left $d \times d$ block of the inverse matrix $Y'(t)^{-1}$, i.e.,

$$R(t) = [I_d, 0_d]Y'(t)^{-1}[I_d, 0_d]^T.$$

Note that q^*, Y', R depend on Q_n, but this dependence is not reflected in the notation, and that again, in practice, the required integrals may be replaced by twice their value over $(0, \infty)$. (Reversing the sign of t in (8) shows that the $(1, 1)$ and $(2, 2)$ diagonal blocks of $Y'(t)$ are even functions of t, while the off-diagonal blocks are odd functions of t. The inverse $Y'(t)^{-1}$ inherits this odd/even structure, and therefore $R(t)$ is even.)

To sum up, for any pair of weight functions ϕ and ψ, we have introduced a numerical scheme, to be referred to as the (ϕ, ψ)-*method*, that uses the kick/oscillation/kick structure with kicking forces $\bar{G}_n$ given by (4) and $\mathcal{A}$ and $\mathcal{M}$ defined in (7) and (9). We will stretch somehow the notation and understand that (δ, ψ), with δ the standard Dirac function, refers to a method with mollification but no averaging; (ϕ, δ) refers to a method with averaging but no mollification, and (δ, δ) is the original impulse method. All methods are symmetric or time-reversible [16], [10] and therefore convergent of the second order (in nonstiff situations). Furthermore, since individual kicks and oscillations preserve volume in phase space, all methods are volume-preserving.

The methods require at each step two integrations of the reduced problem: one to carry out the oscillation $(P_n^+, Q_n) \to (P_{n+1}^-, Q_{n+1})$ and one to compute the auxiliary $q^*(t)$ that features in (7) and (9). Furthermore the latter is to be carried out in tandem with the integration of the variational problem (8); see [5]. In some applications (see section 4 below) these integrations may be performed analytically, and in other cases one has to resort to a numerical technique with a small time step. If numerical integration is used, the weight functions ϕ and ψ have to possess bounded support so that the auxiliary problems are integrated only over a bounded time interval. The integrals in (7) and (9) can be computed along the integrations for q^* and Y' if one appends extra unknown functions b, c that evolve in time according to $db/dt = \phi(t/h)q^*(t)$ and $dc/dt = \psi(t/h)R(t)$; cf. [5].

We end this section by presenting the motivation for the definition of the mollifier. The original impulse method can be expressed [18] in terms of the Dirac delta function as an exact integration of the approximation

$$\frac{d^2}{dt^2}q = f(q) + \sum_n \delta\left(\frac{t - t_n}{h}\right) g(Q_n),$$

and the idea behind the mollification is to employ less abrupt versions [5]

$$\frac{d^2}{dt^2}q = f(q) + \sum_n \psi\left(\frac{t - t_n}{h}\right) G_n^*, \tag{10}$$

where G_n^* is the force $g(\mathcal{A}(Q_n, h))$ to be mollified.

In order to incorporate the forces $\psi((t-t_n)/h)G_n^*$ into the solution of the reduced problem, we use here the Alekseev–Groebner (AG)/nonlinear variation of constants formula [11] as distinct from the approach used in section 5 of [5], which is limited

to the case where the reduced system is Hamiltonian. According to the AG formula, solutions of (2) can be expressed in terms of the reduced flow $\mathcal{Y}$ as

$$y(t_b) = \mathcal{Y}(y(t_a), t_b - t_a) + \int_{t_a}^{t_b} \mathcal{Y}'(y(s), t_b - s) \begin{bmatrix} g(y(s)) \\ 0 \end{bmatrix} ds.$$

Assume then that, at the step $n-1 \to n$, we have performed the corresponding oscillation and we wish to additionally incorporate the effect of $\psi((t-t_n)/h)G_n^*$, acting while $t \le t_n$. (The effect of the force acting in the interval $t \ge t_n$ is incorporated at the first kick of the next step in a symmetric way.) We set $t_b = t_n$ and let $t_a \downarrow -\infty$, to conclude that

$$\left(\int_{-\infty}^{t_n} \mathcal{Y}'(y(s), t_n - s) \psi \left(\frac{s - t_n}{h} \right) ds \right) \begin{bmatrix} G_n^* \\ 0 \end{bmatrix} \tag{11}$$

is the change in solution caused by the extra force. Therefore, the extra momentum is

$$\left(\int_{-\infty}^{t_n} \mathcal{P}_p(y(s), t_n - s) \psi \left(\frac{s - t_n}{h} \right) ds \right) G_n^*,$$

and we would like to add this expression to P_n^- to obtain P_n. There are two difficulties to be tackled. The first stems from the fact that (11) contains the solution $y(t)$ being sought; it is readily circumvented by using an approximation to $y(t)$. The second is that present in (11) is a *family* of Jacobian matrices, one for each vector $y(s)$, so that, in principle, we may fear that, for each s, in order to find $\mathcal{Y}'(y(s), t_n - s)$ we would have to solve a different initial value problem for (5). However, differentiation of the identity $\mathcal{Y}(\mathcal{Y}(\alpha, t), -t) \equiv \alpha$ (group property of the flow) yields for the corresponding Jacobian matrices the well-known relation

$$\mathcal{Y}'(\mathcal{Y}(\alpha, t), -t) = \mathcal{Y}'(\alpha, t)^{-1}. \tag{12}$$

We then approximate the unknown $y(s)$ by $\mathcal{Y}((0, Q_n), s - t_n)$, use the relation (12) with $\alpha = (0, Q_n)$, $t = s - t_n$), and rewrite (11) as

$$\left(\int_{-\infty}^{t_n} \mathcal{Y}'((0, Q_n), s - t_n)^{-1} \psi \left(\frac{s - t_n}{h} \right) ds \right) \begin{bmatrix} G_n^* \\ 0 \end{bmatrix},$$

an expression that, after shifting the integration variable and multiplying by 2 to account for the effect of ψG_n^* acting while $t \ge t_n$, leads to (9).

3. Conservative fast forces. When the fast forces are conservative, $f(q) = -\nabla W(q)$, with W a scalar potential function, the system (3) is Hamiltonian [16], [10], [14], and the symmetries associated with Hamiltonian flows allow a simplification of the mollification procedure. The key observation is as follows.

LEMMA 1. *Assume that the reduced problem* (3) *is Hamiltonian. Then*

$$\mathcal{Y}'(\alpha, t)^{-1} = J^{-1} \mathcal{Y}'(\alpha, t)^T J,$$

where J is the matrix that defines the canonical symplectic form of the Hamiltonian formalism. In particular, the upper left block of the inverse of $\mathcal{Y}'(\alpha, t)$ coincides with $\mathcal{Q}_q(\alpha, t)^T$ (transposed lower right block).

Proof. Due to the symplecticness of Hamiltonian flows, $K = \mathcal{Y}'(\alpha, t)$ satisfies the relation $K^T J K = J$, or $K^{-1} = J^{-1} K^T J$. ∎

After this result, in the Hamiltonian case, the matrix R averaged in (9) can be found without inverting the $(2d) \times (2d)$ Jacobian Y'; instead we set

$$R(t) = Q_q(t)^T, \tag{13}$$

with Q_q found from solving

$$\frac{d}{dt}\begin{bmatrix} Q_p(t) \\ Q_q(t) \end{bmatrix} = \begin{bmatrix} 0 & f'(q^*(t)) \\ M^{-1} & 0 \end{bmatrix} \begin{bmatrix} Q_p(t) \\ Q_q(t) \end{bmatrix},$$

with initial condition $Q_p(t) = 0_d$, $Q_q(t) = I_d$. The left upper and lower blocks of Y' have been discarded from the variational equation (8) as they are not coupled to the lower right block Q_q to be used in (13).

The mollified impulse method was conceived by Skeel [5] in a context where much relevance was attached to the symplectic character [16], [10], [14] of the numerical schemes considered, and, for this reason, the paper [5] deals only with the case of conservative fast forces. In [5] the weight function ϕ may be freely chosen, but the mollifier is determined by

$$\mathcal{M}(Q_n, h) = \mathcal{A}'(Q_n, h)^T \tag{14}$$

(a prime denotes differentiation with respect to Q), a choice that ensures that, whenever the force g is conservative with $g(q) = -\nabla U(q)$, the force $\bar{G}_n$ used in the kicks is itself conservative as the negative gradient of the averaged potential $U(\mathcal{A}(Q_{n+1}, h))$. In the present work, fast forces need not be conservative, and there are two weight functions ϕ and ψ to be chosen. Nevertheless, if the fast forces are conservative and if ψ is chosen to coincide with ϕ, the (ϕ, ϕ)-methods defined here coincide with the methods introduced in [5]: Differentiating the average of q^* and transposing as in (14) is equivalent to averaging the transposed of the corresponding Jacobian as in (9) and (13).

4. Linear fast forces. We now address the case where the fast forces are linear: $f(q) = -Sq$, with S a stiffness matrix. We do not assume S to be symmetric, but, in order to deal with oscillatory problems, we suppose that $M^{-1/2} S M^{-1/2}$ possesses only real nonnegative eigenvalues and can be diagonalized. The material below would remain valid even if the conditions on S may be relaxed considerably; for instance, $M^{-1/2} S M^{-1/2}$ could be allowed to have complex eigenvalues close to the positive real axis. An abstract situation where S is the generator of a cosine operator [1] in a Banach space could also be catered to, but we will not concern ourselves with such extensions.

Under the hypothesis above, there exists a unique (in general, nonsymmetric) matrix Ω such that $\Omega^2 = M^{-1/2} S M^{-1/2}$ and all eigenvalues of Ω are nonnegative; the solution flow of the reduced problem is given in terms of Ω by $y(t) = \mathcal{R}(t) y(0)$, where $\mathcal{R}(t)$ is the rotation matrix

$$\mathcal{R}(t) = \begin{bmatrix} M^{1/2} \cos t\Omega \, M^{-1/2} & -M^{1/2} \Omega \sin t\Omega \, M^{1/2} \\ M^{-1/2} \Omega^{-1} \sin t\Omega \; M^{-1/2} & M^{-1/2} \cos t\Omega \, M^{1/2} \end{bmatrix}$$

or, in the spirit of the theory of cosine operators [1],

$$\mathcal{R}(t) = \begin{bmatrix} M^{1/2} C(t) M^{-1/2} & M^{1/2} \frac{d}{dt} C(t) M^{1/2} \\ M^{-1/2} \int_0^t C(s) ds \; M^{-1/2} & M^{-1/2} C(t) M^{1/2} \end{bmatrix},$$

with $C(t) = \cos t\Omega$. The second formula for $\mathcal{R}$ possesses the merit of deemphasizing the dependence of the material presented here on special properties of the trigonometric functions; the occurrence of the derivative and the integral is a direct consequence of the fact that p is essentially the time derivative of q. The upper left block of $\mathcal{R}(t)$ is bounded by a constant, and therefore the lower left block possesses an estimate of the form $O(t)$; the analysis below is based on these facts. On the other hand, from the group properties of the flow, $\mathcal{R}(t)\mathcal{R}(s) = \mathcal{R}(t+s)$, so that, in particular, $\mathcal{R}(-t)$ is the inverse of $\mathcal{R}(t)$; these properties are not contingent on trigonometric identities and will also be crucial below. It is perhaps of some interest to point out that, in agreement with section 3, if the problem is Hamiltonian, then Ω is symmetric and the upper left block of $\mathcal{R}(-t)$ coincides with the transpose of the lower right block of $\mathcal{R}(t)$.

The definition (7) now yields, since $\mathcal{R}(t)^{-1} = \mathcal{R}(-t)$,

$$\begin{aligned}\mathcal{A}(Q_n, h) &= M^{-1/2}\left(\frac{1}{h}\int_{-\infty}^{\infty}\cos t\Omega\,\phi\left(\frac{t}{h}\right)\,dt\right)M^{1/2}\,Q_n \\ &= M^{-1/2}\left(\int_{-\infty}^{\infty}\cos sh\Omega\,\phi(s)\,ds\right)M^{1/2}\,Q_n,\end{aligned}$$

an expression that, after introducing the Fourier transform of the even function ϕ

$$\hat{\phi}(\omega) = \int_{-\infty}^{\infty}\exp(-i\omega t)\phi(t)\,dt = \int_{-\infty}^{\infty}\cos\omega t\phi(t)\,dt, \tag{15}$$

can be rewritten as

$$\mathcal{A}(Q_n, h) = \mathcal{A}_h Q_n = \left(M^{-1/2}\hat{\phi}(h\Omega)M^{1/2}\right)Q_n.$$

Similarly, (9) now reads

$$\begin{aligned}\mathcal{M}_h &= M^{-1/2}\left(\frac{1}{h}\int_{-\infty}^{\infty}\cos t\Omega\,\psi\left(\frac{t}{h}\right)\,dt\right)M^{1/2} \\ &= M^{-1/2}\left(\int_{-\infty}^{\infty}\cos sh\Omega\,\psi(s)\,ds\right)M^{1/2}\end{aligned}$$

or

$$\mathcal{M}_h = M^{-1/2}\hat{\psi}(h\Omega)M^{1/2},$$

with

$$\hat{\psi}(\omega) = \int_{-\infty}^{\infty}\exp(-i\omega t)\psi(t)\,dt = \int_{-\infty}^{\infty}\cos\omega t\psi(t)\,dt, \tag{16}$$

and we conclude that the kicking force is given by

$$\bar{G}_n = M^{-1/2}\hat{\psi}(h\Omega)M^{1/2}g\left(M^{-1/2}\hat{\phi}(h\Omega)M^{1/2}Q_n\right). \tag{17}$$

For cases of linear fast forces where the stiffness matrix S is symmetric, a number of recent contributions starting from [9] have considered a family of kick-oscillate-kick algorithms whose kicking force includes *four* independent filtering functions (see

Chapter XIII of [10], [6], and references therein). If the attention is restricted to symmetric (time reversible) methods within that family, then the number of independent filters is reduced to two and the format for the kicking force is precisely (17) (see section 7).

Some final remarks: The real filter functions $\hat{\phi}$, $\hat{\psi}$ are even. Since weight functions are assumed throughout to satisfy the normalizing condition (6), we have $\hat{\phi}(0) = \hat{\psi}(0) = 1$. Furthermore the integrability of the weights implies that $\hat{\phi}$ and $\hat{\psi}$ are continuous, vanish at ∞, and possess the estimates $\|\hat{\phi}\|_\infty \leq \|\phi\|_1$, $\|\hat{\psi}\|_\infty \leq \|\psi\|_1$. If in particular ϕ or ψ are nonnegative, then $\|\hat{\phi}\|_\infty = 1$ or $\|\hat{\psi}\|_\infty = 1$. When ϕ or ψ are the Dirac function, then the Fourier transform is the unit function and the average or mollification filters become the identity, as they should.

5. Analysis: Mollification. Throughout this section and the next, we assume that the mass matrix M is the identity. What follows may easily be extended to the case $M \neq I$ (but the formulas soon become cluttered with powers of M); alternatively, a problem with $M \neq I$ may be reduced to the case $M = I$ by a linear change of variables [5]. Similarly, we assume that the stiffness matrix S is symmetric and positive-semidefinite, so that, in the Euclidean norm, $\|\cos t\Omega\| \leq 1$; again the analysis below may be easily extended to cover the more relaxed hypotheses on S considered in section 4, but this brings a bound for $\|\cos t\Omega\|$ as an additional constant in many of the formulas.

The analysis begins with the following result, which is Lemma 3 of [5] (but there is a square root missing from some formulas in that paper). To simplify the writing, we denote by $\bar{g}(\cdot) = \mathcal{M}_h g(\mathcal{A}_h \cdot)$ the function that provides the kicking force and furthermore set $\bar{g}_n = \bar{g}(q_n)$. Similarly we set $g^*(\cdot) = g(\mathcal{A}_h \cdot)$ and $g^*_n = g^*(q_n)$. Furthermore we denote by L_0, L_1, and L_2 a bound for g, a Lipschitz constant for g, and a Lipschitz constant for the derivative of g, respectively, when they exist; it follows from the boundedness of the filters that, if g is Lipschitz continuous, $\bar{g}$ and g^* are then also Lipschitz continuous with constants $\bar{L}_1 = \|\psi\|_1 L_1 \|\phi\|_1$ and $L^* = L_1 \|\phi\|_1$, respectively.

THEOREM 1. *Assume that the problem* (2) *with linear fast forces satisfies the hypotheses above, with g Lipschitz continuous, and is solved with $P_0 = p(0)$ and $Q_0 = q(0)$ by means of a (ϕ, ψ)-method (ϕ and/or ψ may be taken to be δ). Then the global error satisfies*

$$\|Q_n - q_n\| \leq \cosh(t_n \sqrt{\bar{L}_1}) \cdot \max_{1 \leq j \leq n} \|\sigma_{q,j}\|$$

and

$$\|P_n - p_n\| \leq \|\sigma_{p,n}\| + \bar{L}_1 t_n \cosh(t_n \sqrt{\bar{L}_1}) \cdot \max_{1 \leq j \leq n} \|\sigma_{q,j}\|,$$

where $\sigma_{p,n}$ $\sigma_{q,n}$ are the quadrature errors

$$\begin{bmatrix} \sigma_{p,n} \\ \sigma_{q,n} \end{bmatrix} = \sum_{j=0}^{n} h 1_j \begin{bmatrix} \cos(t_n - t_j)\Omega \\ \Omega^{-1} \sin(t_n - t_j)\Omega \end{bmatrix} \bar{g}_j - \int_0^{t_n} \begin{bmatrix} \cos(t_n - t)\Omega \\ \Omega^{-1} \sin(t_n - t)\Omega \end{bmatrix} g(q(t))\, dt \tag{18}$$

(1_j is defined to be 1 except for $1_0 = 1_n = 1/2$).

This theorem, based on a Gronwall lemma argument, provides a basic stability result for all of the methods in the class considered in this paper. To be noted is

the fact that the truncation error perpetrated at each step does not explicitly feature in the global error bound; instead the stepwise truncation errors up to t_n have been compounded into a single quadrature error σ_n. Integrated forms of the truncation error may lead to sharper error bounds than a stepwise approach whenever error cancellations are to be expected. This is an old theme in the analysis of numerical methods that, for ordinary differential equations, goes back at least to Spijker's thesis (see the discussion in [15]).

If $\bar{g}_n = g(Q_n)$ (original impulse method), σ coincides with the error in the trapezoidal quadrature rule. In the highly oscillatory scenario considered here where $h\Omega$ is not assumed to be small, the function $\cos(t_n - t)\Omega$ has an unbounded first derivative, and one cannot expect to derive $O(h)$ error bounds for σ_p that are uniform in Ω. A counterexample is provided by the case of a scalar harmonic oscillator of frequency ω subject to a constant external force g with $h\omega = 2\pi$ (the situation presented in [5] to prove that the global error—not the quadrature error—of the impulse method has stiff order 0 in the p variables). In the p component, the integral in (18) vanishes, while the trapezoidal quadrature rule takes the $O(1)$ value $t_n g$. For the q component the situation is not as bad: $\Omega^{-1}\sin(t_n - t)\Omega$ has a bounded first derivative, and standard theory leads to $O(h)$ error bounds for σ_q and hence for $Q_n - q_n$ in the application of the original impulse method to stiff oscillatory situations.

The proof of the next lemma essentially reverses the construction of the mollifier in section 2: There we incorporated into the kicking force $\bar{G}_n$ the "distributed" force $\psi((t - t_n)/h)G_n^*$ (see (10)) by way of the mollification matrix; we now recover the distributed force from the mollification matrix. The meaning of the lemma is clear: While the impulse method approximates the oscillatory integral in (18) by interpolation of the whole integrand, mollified methods interpolate only the soft force $g(q(t))$. This is precisely the idea behind Filon-type methods for the quadrature of oscillatory functions; see, e.g., [13].

LEMMA 2. *The quadrature error* (18) *may be rewritten as*

$$\begin{bmatrix} \sigma_{p,n} \\ \sigma_{q,n} \end{bmatrix} = \int_{-\infty}^{\infty} \begin{bmatrix} \cos(t_n - t)\Omega \\ \Omega^{-1}\sin(t_n - t)\Omega \end{bmatrix} \sum_{j=0}^{n} 1_j \psi\left(\frac{t - t_j}{h}\right) g_j^*\, dt - \int_0^{t_n} \begin{bmatrix} \cos(t_n - t)\Omega \\ \Omega^{-1}\sin(t_n - t)\Omega \end{bmatrix} g(q(t))\, dt. \tag{19}$$

Furthermore, for a mollified method (ϕ, ψ) (ϕ may be the Dirac function) in which ψ has bounded support and vanishes for $|\ t\ | > \mu > 0$, the quadrature error is of the form

$$\begin{bmatrix} \sigma_{p,n} \\ \sigma_{q,n} \end{bmatrix} = \int_0^{t_n} \begin{bmatrix} \cos(t_n - t)\Omega \\ \Omega^{-1}\sin(t_n - t)\Omega \end{bmatrix} I(t)\, dt + \beta_n, \tag{20}$$

where $I(t)$ is the interpolation error

$$I(t) = \left(\sum_{j=0}^{n} \psi\left(\frac{t - t_j}{h}\right) g_j^*\right) - g(q(t)) \tag{21}$$

and β_n represents boundary effects and can be estimated as

$$\|\beta_n\| \le 2\mu(1 + t_n^2)^{1/2}\|\psi\|_1 L_0 h.$$

Proof. By the definition of the mollifier and since the integral of $\sin(t_j - t)\Omega\psi((t - t_j)/h)$ vanishes, the jth term T_j of the sum in (18) can be written as

$$\begin{aligned} h1_j\mathcal{R}(t_n - t_j) &\begin{bmatrix} \hat{\psi}(h\Omega)g_j^* \\ 0 \end{bmatrix} \\ &= 1_j \int_{-\infty}^{\infty} \mathcal{R}(t_n - t_j) \begin{bmatrix} \cos(t_j - t)\Omega \\ \Omega^{-1}\sin(t_j - t)\Omega \end{bmatrix} \psi\left(\frac{t - t_j}{h}\right) g_j^*\, dt \\ &= 1_j \int_{-\infty}^{\infty} \begin{bmatrix} \cos(t_n - t)\Omega \\ \Omega^{-1}\sin(t_n - t)\Omega \end{bmatrix} \psi\left(\frac{t - t_j}{h}\right) g_j^*. \end{aligned}$$

Away from the boundary, when j is such that $0 \le t_j - \mu h$, $t_j + \mu h \le t_n$, the last integral may be taken between the limits 0 and t_n and incorporated into the integral in (18). There are at most 2μ boundary values of j (μ near 0 and μ near t_n). For those values, the corresponding term T_j is incorporated only in part to the integral. The lemma follows after noticing that each T_j can be bounded by $h(1 + t_n^2)^{1/2}\|\psi\|_1 L_0$. ∎

After Theorem 1 and Lemma 2, global error estimates depend on bounds for the interpolation error (21), and we now turn to these. It is well known that a minimum requirement for any linear interpolation scheme is that it reproduces with no error the constant functions:

$$\sum_{j=-\infty}^{\infty} \psi(t - j) \equiv 1, \tag{22}$$

a condition that was featured in [5]. We recall from the standard theory behind the Poisson summation formula that the 1-periodic function

$$\Psi(t) = \sum_{j=-\infty}^{\infty} \psi(t - j)$$

(the sum is well defined if ψ has bounded support) has a Fourier series

$$\Psi(t) = \sum_n c_n \exp(i2\pi nt)$$

whose coefficients are values of the Fourier transform of ψ:

$$c_n = \int_0^1 \exp(-i2\pi nt)\Psi(t)\, dt = \int_{-\infty}^{\infty} \exp(-i2\pi nt)\psi(t)\, dt = \hat{\psi}(2\pi n).$$

Therefore (22) is equivalent to the condition

$$\hat{\psi}(2\pi n) = 0, \quad n = \pm 1, \pm 2, \ldots \tag{23}$$

that appears in the analysis of [10], [6]. We now prove that these conditions are essentially necessary and sufficient to achieve stiff order of convergence 1.

THEOREM 2. *With the hypotheses of Theorem* 1, *assume that* g *has a bounded derivative and that the weight function* ψ *has bounded support and satisfies* (22) *or* (23) *(*ϕ *may be the Dirac function). Then the global error possesses a bound*

$$\|P_n - p_n\| + \|Q_n - q_n\| \le Ch,$$

where the constant C depends on ψ, ϕ, t_n, L_0, and L_1 and also on a bound E for the reduced energy of the true solution

$$E = \max_{-\mu h \le t \le t_n + \mu h} \left(\frac{1}{2}\|p(t)\|^2 + \frac{1}{2}\|\Omega q(t)\|^2 \right).$$

Conversely, if the (ψ, ϕ)-method, where ψ is boundedly supported and ϕ may be δ, possesses a global error bound of this form, then (22) *and* (23) *hold true.*

Proof. Consider a method such that $\hat{\psi}(2k\pi) \neq 0$ for $k \neq 0$ an integer. In the case of a scalar harmonic oscillator with frequency $\omega = 2k\pi/h$ forced by a constant g, the global errors can be found explicitly, and $P_n - p_n$ turns out to possess an $O(1)$ behavior as $h \to 0$.

Let us next derive the error bound when $\phi = \delta$. It is standard to show (by approximating $m(t)$ by a constant) that, when interpolating a function m, the interpolation error

$$\left(\sum_{j=\infty}^{\infty} \psi\left(\frac{t - t_j}{h} \right) m(t_j) \right) - m(t)$$

can be bounded by $K_\psi K_1 h$, where K_ψ depends only on ψ and K_1 is a bound for the derivative $(d/dt)m(t)$. In our situation, where $m(t) = g(q(t))$ and $(d/dt)m(t) = g'p$, this yields an upper bound of the form $K_\psi L_1 \sqrt{E} h$ for the interpolation error in (21) for t away from the boundary $\mu h \le t \le t_n - \mu h$. The remaining intervals $0 \le t \le \mu h$ and $t_n - \mu h \le t \le t_n$ have length $O(h)$, and in them $I(t)$ is bounded. This, along with Lemma 2 and Theorem 1, yields the error bound for the global error.

The effect of an averaging operation with $\phi \neq \delta$ is to perturb the interpolation by bringing in approximate values $g_n^* = g(\mathcal{A}_h q_n)$ for the function values $g_n = g(q_n)$. Since $(I - \mathcal{A}_h)(h\Omega)^{-1}$ can be bounded independently of h and Ω (see the proof of (28) below), the differences $g_n^* - g_n$ are $O(h)$, with the implied constant depending on L_1, ϕ, and a bound for $\|\Omega q_n\|$. Then a global error bound $O(h^2)$ also holds in the presence of averaging. ∎

6. Analysis: Averaging. In this section we prove that, for suitable averaging operators, the (ϕ, ψ)-method yields $O(h^2)$ errors in q uniformly in the stiffness of the problem. After Theorem 2, we consider only situations where ψ is of bounded support and (22) holds.

The analysis begins by observing that, from the Alekseev–Groebner variation of constants formula:

$$p(t) = \mathcal{P}(p(0), q(0)) + \int_0^t \cos s\Omega \, g(q(s))\, ds,$$

and

$$q(t) = \mathcal{Q}(p(0), q(0)) + \int_0^t \Omega^{-1} \sin s\Omega \, g(q(s))\, ds,$$

or, after integration by parts,

$$q(t) = \mathcal{Q}(p(0), q(0)) + \int_0^t \cos s\Omega \int_s^t g(q(u))\, du\, ds.$$

Thus, there is one quadrature of the force to build up the momentum and *two* in the evolution of q. In numerical methods, global errors are built up from local errors in a way analogous to that in which forcing terms build up the true solution. We showed in section 5 how the global error for p and q is obtained after one quadrature, and we shall presently show how the global error for q may be obtained by two quadratures. To avoid order reduction, each of these quadratures has to employ a weight function, and this essentially explains why methods that include mollification but no averaging cannot achieve stiff order 2 in q.

Led by the preceding insight, the idea now is to integrate by parts in (19) (note that (20) is of no use because the boundary terms β_n are $O(h)$). The analysis is straightforward except for problems with the boundary, and to soften these we proceed as follows. The functions $\psi((t-t_j)/h)$, $0 \le j \le n$, do not add up to 1 near the boundaries of the interval $I_n = [0, t_n]$ (this is because, for t_j near the boundary, $\psi((t-t_j)/h)$ "spreads" out of I_n, and, correspondingly, there are basis functions $\psi((t-t_j)/h)$, with $t_j < 0$ or $t_j > t_n$, that "intrude" into I_n). For fixed h and t_n, a system of $n+1$ functions λ_j with the partition of unity property

$$\sum_{j=0}^{n} \lambda_j(t) = 1, \quad 0 \le t \le t_n,$$

is easily constructed by setting, for $0 \le t \le t_n$,

$$\begin{aligned}
\lambda_0(t) &= \psi\left(\frac{t-t_0}{h}\right), \\
\lambda_j(t) &= \psi\left(\frac{t-t_j}{h}\right) + \psi\left(\frac{-t-t_j}{h}\right), \quad 0 < j < \mu, \\
\lambda_j(t) &= \psi\left(\frac{t-t_j}{h}\right), \qquad \mu \le j \le n-\mu, \\
\lambda_j(t) &= \psi\left(\frac{t-t_j}{h}\right) + \psi\left(\frac{-t+2t_n-t_j}{h}\right), \quad n-\mu < j < n, \\
\lambda_n(t) &= \psi\left(\frac{t-t_n}{h}\right).
\end{aligned}$$

(Near the boundaries the basis function $\psi((t-t_j)/h)$ have been "reflected" about 0 or t_n to compensate for the functions with $j = -1, -2, \ldots$ or $j = n+1, n+2, \ldots$ missing from the new basis.) The introduction of this corrected set of basis functions makes it possible to extend to the common interval $0 \le t \le t_n$ the integrals in (19).

LEMMA 3. *If ψ is of bounded support as in Lemma 2, the quadrature error $\sigma_{q,n}$ satisfies*

$$\begin{aligned}
\sigma_{q,n} = &\int_0^{t_n} \Omega^{-1} \sin(t_n - t)\Omega \sum_{j=0}^{n} \lambda_j(t) g_j^* \, dt \\
&- \int_0^{t_n} \Omega^{-1} \sin(t_n - t)\Omega \, g(q(t)) \, dt + \beta_n^*,
\end{aligned} \tag{24}$$

where β_n^* represent boundary contributions, with

$$\|\beta_n^*\| \le 2\mu^2 \|\psi\|_1 L_0 h^2,$$

so that, after integration by parts,

$$\sigma_{q,n} = \int_0^{t_n} \cos(t_n - t)\Omega\, I^*(t)\, dt + \beta_n^*,$$

with I^* equal to the integrated interpolation error

$$I^*(t) = \int_0^t \left[\left(\sum_{j=0}^{n} \lambda_j(s) g_j^* \right) - g(q(ts)) \right] ds. \tag{25}$$

Proof. The q-component of the first integral in (19) differs from the first integral in (24) only because of the contributions of values of j in the summation corresponding to t_j near the boundary. For $0 \le j < \mu$ there is a difference

$$1_j \int_{t_j - \mu h}^{0} \Omega^{-1} \sin(t_n - t)\Omega\ \psi\left(\frac{t - t_j}{h}\right) g_j^*\, dt$$
$$-1_j \int_{0}^{\mu h - t_j} \Omega^{-1} \sin(t_n - t)\Omega\ \psi\left(\frac{-t - t_j}{h}\right) g_j^*\, dt$$

or

$$1_j \int_{t_j - \mu h}^{0} \left[\Omega^{-1} \sin(t_n - t)\Omega - \Omega^{-1} \sin(t_n + t)\Omega\right]\ \psi\left(\frac{t - t_j}{h}\right) g_j^*\, dt,$$

whose Euclidean norm is $\le 2\mu h \times (h/2)\|\psi\|_1 \times L_0$ (note that $\Omega^{-1}\sin(t_n - t)\Omega$ is Lipschitz continuous in t with Lipschitz constant 1 so that the term in square brackets has norm $\le 2\mu h$). The estimate for β_n^* follows readily by summing over the contributions of j near the boundary at 0 and by treating in a similar way the boundary at t_n. ∎

In particular, at $t = t_n$,

$$I^*(t_n) = \sum_{j=0}^{n} h 1_j g_j^* - \int_0^{t_n} g(q(s))\, ds, \tag{26}$$

and we find once more the trapezoidal quadrature rule. For methods without averaging, $g_n^* = g(q_n)$ and second-order accuracy cannot be achieved in stiff cases where g oscillates with periods of the order of h. A simple counterexample is as follows. We take $d = 2$ and (the subindex refers to the components of the vectors)

$$\frac{d^2}{dt^2} q_{(1)} = -\omega^2 q_{(1)}, \quad \frac{d^2}{dt^2} q_{(2)} = -q_{(1)}; \tag{27}$$

the force $-\omega^2 q_{(1)}$ driving the first component is taken to be fast, and the force $q_{(1)}$ driving the second component is taken to be soft. We focus on the initial data $q_{(1)}(0) = \omega^{-1}$, $q_{(2)}(0) = \omega^{-3}$, $p_{(1)}(0) = 0$, $p_{(2)}(0) = 0$, leading to the solution $q_{(1)}(t) = \omega^{-1}\cos\omega t$, $q_{(2)}(t) = \omega^{-3}\cos\omega t$, that has reduced energy bounded independently of $\omega \ge 1$. If $h\omega = 2\pi$, then, in (26), the integral vanishes, while the value of the quadrature rule is the $O(h)$ vector $[0, \omega^{-1}t_n]$. Computation of the actual global error shows that in this instance $Q_n - q_n$ is also $O(h)$ and not $O(h^2)$.

The next and last lemma is relevant in understanding why averaging works: While g_j^* is only an $O(h)$ approximation to the true value $g(q(t_j))$ of the function being integrated in (25) or (26), hg_j^* provides a higher-order approximation to the integral

of $g(q(t))$ in the neighborhood of t_j. Note that below we use, without loss of generality, the same upper bound μ for the supports of ϕ and ψ.

LEMMA 4. *Under the hypotheses of Theorem* 2*, the following estimate holds:*

$$\|q(t) - \mathcal{A}_h q_j\| \leq (\mid t - t_j \mid + \|\phi\|_1)\sqrt{2E}\, h, \quad -\mu h \leq t \leq t_n + \mu h, \tag{28}$$

so that, in particular,

$$\|g_j - g_j^*\| = \|g(q(t_j)) - g(\mathcal{A}_h q(t_j))\| \leq L_1 \|\phi\|_1 \sqrt{2E}\, h.$$

Furthermore, if g possesses a Lipschitz continuous derivative and ϕ is boundedly supported with $\phi = 0$ for $\mid t \mid > \mu > 0$, then

$$h g_j^* = \int_{t_j - \mu h}^{t_j + \mu h} \phi\left(\frac{t - t_j}{h}\right) g(q(t))\, dt + h r_j, \tag{29}$$

where r_j can be estimated as

$$\|r_j\| \leq \|\phi\|_1 \left[L_2(\mu + \|\phi\|_1)^2 E + \frac{1}{2}\mu^2 L_0 L_1 \right] h^2.$$

Proof. To bound $q(t) - \mathcal{A}_h q_j$, add and subtract q_j. Then $q(t) - q_j$ may be written as the integral of p, and $(I - \mathcal{A}_h)q_j$ is given, by the definition of $\mathcal{A}_h$, as an integral involving the expression $(1 - \cos t\Omega)q_j$, which can be bounded by $\|h\Omega q_j\|$.

Next, by expanding g around $\mathcal{A}_h q_j$ we get

$$g(q(t)) = g_j^* + J_j[q(t) - \mathcal{A}_h q_j] + d_j, \quad t_j - \mu h \leq t \leq t_j + \mu h,$$

where J_j is the relevant Jacobian and the residual d_j may be bounded, according to (28) as $(1/2)L_2[(\mu + \|\phi\|_1)\sqrt{2E}\, h]^2$. Integration yields

$$-r_j = J_j \frac{1}{h} \int_{t_j - \mu h}^{t_j + \mu h} \phi\left(\frac{t - t_j}{h}\right) [q(t) - \mathcal{A}_h q_j]\, dt + e_j,$$

where the integrated residual e_j is bounded by $\|\phi\|_1$ times the bound for d_j. We are therefore left with the task of estimating the last integral. We note that, by the definition of averaging,

$$\frac{1}{h} \int_{t_j - \mu h}^{t_j + \mu h} \phi\left(\frac{t - t_j}{h}\right) \mathcal{A}_h q_j\, dt = \mathcal{A}_h q_j = \frac{1}{h} \int_{t_j - \mu h}^{t_j + \mu h} \phi\left(\frac{t - t_j}{h}\right) \cos(t - t_j)\Omega\, q_j dt,$$

while, by using the form of the true flow,

$$\frac{1}{h}\int_{t_j-\mu h}^{t_j+\mu h}\phi\left(\frac{t-t_j}{h}\right)q(t)\,dt = \frac{1}{h}\int_{t_j-\mu h}^{t_j+\mu h}\phi\left(\frac{t-t_j}{h}\right)[\cos(t-t_j)\Omega q_j+\sin(t-t_j)\Omega p_j+\Delta_j]\,dt, \tag{30}$$

where $\Delta_j=\Delta_j(t)$ is the integral contribution from the variation of constant formula

$$\Delta_j(t)=\int_{t_j}^{t}\Omega^{-1}\sin(t-s)\Omega\, g(q(s))\,ds.$$

In (30) the integral of the sine term vanishes by symmetry and that of the cosine term is cancelled with the same contribution from $\mathcal{A}_h$. This leaves us the term with Δ_j, and we note that, for $t_j-\mu h\le t\le t_j+\mu h$,

$$\|\Delta_j\|\le\int_{t_j}^{t}\mid t-s\mid L_0\,ds\le\frac{1}{2}\mu^2L_0h^2.$$

After combining all of these estimates, we obtain the bound being sought. ∎

Equipped with (29), we return to (25). Away from the integration limits, the integral of $\lambda_j(s)$ is h so that the jth term in the summation matches, except for an $O(h^3)$ residual, the integral of $\phi((s-t_j)/h)g(q(s))$. Therefore it is appropriate to impose the condition

$$\sum_{j=-\infty}^{\infty}\phi(t-j)\equiv 1, \tag{31}$$

as this would ensure that, except for boundary effects, the sum matches the whole integral. This leads us to the next theorem, where, for completeness, we refer to the equivalent formulation

$$\hat{\phi}(2\pi n)=0,\quad n=\pm1,\pm2,\ldots \tag{32}$$

of the last condition.

THEOREM 3. *With the hypotheses of Theorem* 1*, assume that g has a bounded, Lipschitz continuous derivative and that the weight functions ϕ and ψ have bounded support and satisfy* (22)–(23) *and* (31)–(32)*. Then the global error possesses a bound*

$$h\|P_n-p_n\|+\|Q_n-q_n\|\le Ch^2,$$

where the constant C depends on ψ, ϕ, t_n, L_0, L_1, L_2, and E.

Conversely, if the (ψ,ϕ)-method with boundedly supported ϕ and ψ possesses a bound of this form, then (22)–(23) *and* (31)–(32) *hold.*

Proof. The necessity of the condition for ϕ is proved by considering the counterexample (27).

To prove the bound we construct a set of interpolation basis functions κ_j, $j=0,1,\ldots,n$, by applying to the functions $\phi((t-t_j)/h)$ the construction that was used to derive the λ_j's from the $\psi((t-t_j)/h)$'s. Then, the κ_j's add to 1 and

$$I^*(t)=\sum_{j=0}^{n}\left[\int_0^t\lambda_j(s)g_j^*\,ds-\int_0^t\kappa(s)g(q(ts))\,ds\right].$$

If k is the largest j such that $t_j \le t$, we split I^* as $I^* = I_1^* + I_2^*$, with

$$I_1^* = \sum_{j=0}^{n} \left[\int_0^{t_k} \lambda_j(s) g_j^* \, ds - \int_0^{t_k} \kappa(s) g(q(ts)) \, ds \right],$$
$$I_2^* = \sum_{j=0}^{n} \left(\int_{t_k}^{t} \lambda_j(s) \right) g_j^* - \int_{t_k}^{t} g(q(s)) \, ds.$$

Both expressions being subtracted in I_2^* can be approximated with $O(h^2)$ errors by $(t - t_k)g_k$. For I_1^*, and as noted above, if t_j is away from the integration limits, the jth term in the sum is $O(h^3)$. For $j < \mu$, the term is only $O(h^2)$, because there κ_j does not quite match $\phi((t - t_j)/h)$. The terms with t_j near t can be dealt with in a similar way. ∎

7. Filters and weights. As discussed in section 4, when applied to cases with linear fast forces, the methods in this paper can be specified and implemented in terms of the two filter functions $\hat{\phi}$ and $\hat{\psi}$ in (17). However, both the implementation of the methods in nonlinear cases and the analysis in sections 5 and 6 require the weight functions themselves ϕ and ψ. Let us then address the question of whether given two real, even filter functions there exist corresponding weight functions that generate them as in (15)–(16). We furthermore recall that weights are assumed to be bounded and that the interest should be restricted to weights with bounded support if one is to compute numerically the averaging and mollifier operators.

The answer to our question is well known in Fourier analysis: According to a classical result by Paley and Wiener, a square integrable function $\hat{\chi}(\omega)$ of the real variable ω is the Fourier transform of a square integrable function χ supported in $[-\nu, \nu]$, $\nu > 0$, if and only if $\hat{\chi}$ can be extended to a holomorphic function of ω in the whole complex plane such that for all complex ω

$$| \hat{\chi}(\omega) | \le C \exp(\nu \, | \, \omega \, |).$$

For given ν, the space of all such $\hat{\chi}$ of *exponential type* is referred to as the Paley–Wiener space $PW_{[-\nu,\nu]}$. Hence any reversible method for linear fast forces of the family considered in [10], [6] for which the filter functions belong to some $PW_{[-\nu,\nu]}$ space can be extended to a (ϕ, ψ)-method applicable to nonlinear fast forces simply by taking as weights the inverse Fourier transforms of the filters. An example will be provided at the end of this section.

From the classical theorems of Weierstraß and Hadamard, it is well known that entire functions (functions holomorphic in the whole complex plane) are not determined by their zeros. However, a result by Titchmarsh (see, e.g., [4]) implies that any function $\hat{\chi}$ in $PW_{[-\nu,\nu]}$ can be expressed in terms of its infinitely many zeros ω_n as

$$\hat{\chi}(\omega) = \hat{\chi}(0) \prod_n \left(1 - \frac{\omega}{\omega_n} \right);$$

for the optimal convergence of the numerical method, $\hat{\chi}(0) = 1$ and the set of zeros must at least contain all nonzero even multiples of π. In this sense, the choice called *short* in [5],

$$\hat{\chi}_s(\omega) = \prod_{k=1} \left(1 - \frac{\omega^2}{4k^2\pi^2} \right) = \frac{\sin(\omega/2)}{\omega/2},$$

appears as a *minimal* filter: Filters of all potentially useful (ϕ, ψ)-methods can be obtained by multiplying $\hat{\chi}_s$ by suitable factors that bring in additional zeros. The corresponding weight function χ_s equals 1 for $-1/2 \le t \le 1/2$ and vanishes elsewhere. Obviously, no weight function may have support smaller than $[-1/2, 1/2]$ if its translations are to add to 1 (see (22), (31)).

Two other weight functions were explicitly discussed in [5]. The *long* weight χ_l, with value $1/2$ for $-1 \le t \le 1$ and 0 elsewhere, is a dilation of the short weight: $\chi_l(t) = (1/2)\chi_s(t/2)$. The *linear* weight function is the convolution of the short weight with itself, $\chi_{lin} = \chi_s * \chi_s$; it is the well-known hat basis function for piecewise linear interpolation with $\chi_{lin}(0) = 1$ and $\chi_{lin}(t) = 0$ for $| t | \ge 1$. The filter functions are, respectively, given by $\hat{\chi}_l(\omega) = \hat{\chi}_s(2\omega)$ (zeros at $k\pi$, $k \ne 0$) and $\hat{\chi}_{lin}(\omega) = \hat{\chi}_s(\omega)^2$ (double zeros at $2k\pi$, $k \ne 0$). Of course, convolution of the weights means product of the filters, and dilations translate into rescalings of ω.

The way to further generalizations by using convolutions and dilations is clear; these generalizations include the spline weights $\chi_s * \cdots * \chi_s$ (or $\chi_l * \cdots * \chi_l$) obtained by iterating the convolution of χ_s (or χ_l) with itself; the filters are the powers of $\hat{\chi}_s$ (or $\hat{\chi}_l$). More factors in the convolution mean higher-order zeros in the filter, and hopefully a better filtering, at the price of a longer support that entails higher computational work. The uncertainty principle implies that there is a limit on how much one can simultaneously concentrate near $t = 0$ the mass of χ and near $\omega = 0$ the mass of $\hat{\chi}$: Thus low computational cost and the drastic suppression of high frequencies are contradictory goals.

It is not our purpose here to settle the question as to the best choice of weight functions. We feel that the answer would very much depend both on the problem being solved and on the relation between the computational costs of integrating the reduced problem and of sampling the soft forces.

We shall finish the paper by presenting an example that illustrates how methods for linear fast forces based on filters can be extended to nonlinear fast forces by using weights. Grimm and Hochbruck have suggested [6] the filters $\omega^{-1} \sin \omega$ for the average and $\omega^{-2} \sin^2 \omega$ for the mollifier. These functions have exponential type 1 and 2, respectively, and, via the Paley–Wiener theorem, the method introduced in [6] can be extended to nonlinear fast forces by the (ϕ, ψ)-method that uses as weights the corresponding inverse Fourier transforms with supports $[-1, 1]$ and $[-2, 2]$. In fact, the weights are readily seen to be $\phi = \chi_l$ and $\psi = \chi_l * \chi_l$.

For a numerical test of this method, we use the nonlinear fast forces problem in section 4 of [5] and consider a system consisting of two unit point masses in the plane. The first mass is attached to one end of a (potentially strong) spring of unit length with stiffness ω^2 (in the experiments $0 \le \omega^2 \le 900$). The other end of this spring is fixed at the origin. The second mass is attached to the first through a (soft) spring of unit length and stiffness $1/2$. Initially the first mass is at $(1, 0)$ and the second at $(2, 0)$ so that the potential energy of the system is 0. The corresponding initial velocities are $(\sqrt{2}/4, \sqrt{2}/4)$ and $(-\sqrt{2}/4, \sqrt{2}/4)$, and the integration takes place for $0 \le t \le 16$, with step lengths $h = 1/2$ and $h = 1/4$.

Numerical results are presented for the $(\chi_l, \chi_l * \chi_l)$-method and, for comparison, also for the original impulse (δ, δ)-method and for the short filter (χ_s, χ_s)-method of [5]. The figure plots as a function of ω, $0 \le \omega \le 30$, the maximum over $0 \le t \le 16$ of the Euclidean norm of the error in the 4-dimensional vector of positions of the masses. For small values of ω the first spring is not really strong, and $(\chi_l, \chi_l * \chi_l)$ performs worse than the other two methods. For ω larger than, say, 10, the results of the original impulse method are clearly inferior to those of the methods that use

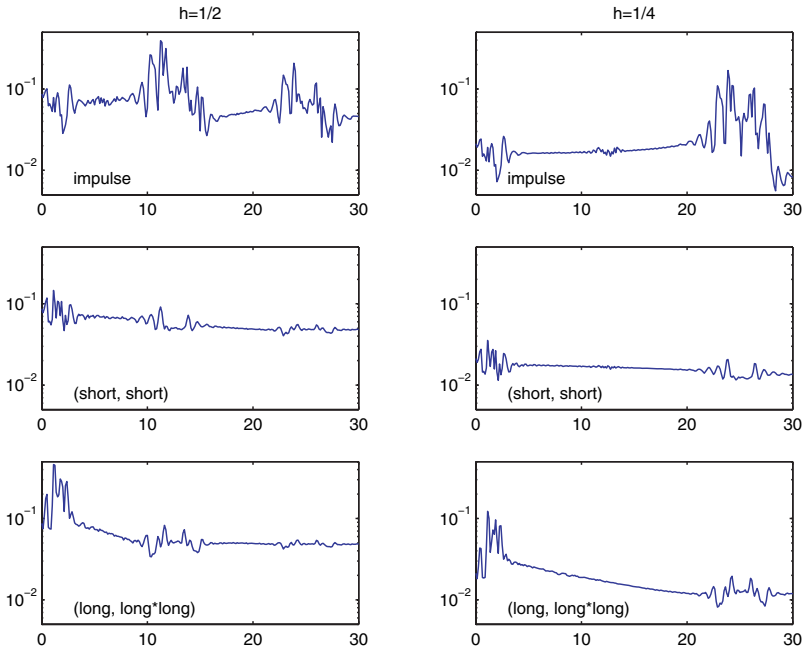

FIG. 7.1. *Two spring nonlinear problem: error in positions against* ω.

averaging and mollification. For the (χ_s, χ_s)-method the maximum over ω of the error is 0.1461 when $h = 1/2$ and 0.0354 when $h = 1/4$; for $(\chi_l, \chi_l * \chi_l)$ the corresponding figures are 0.4618 and 0.1227; thus both methods show in this nonlinear problem an $O(h^2)$ error behavior (as that ensured by Theorem 3 for the linear case). For the impulse method halving h brings down the error from 0.3931 to 0.1686, so that an order reduction manifests itself. In Figure 7.1 it is apparent that the order reduction is more pronounced if the attention is restricted to ω larger than, say, 20: Near $\omega = 8\pi$ the errors for $h = 1/4$ are hardly smaller than those for $h = 1/2$.

Acknowledgments. The author is thankful to D. Cohen, A. G. García, A. Iserles, Ch. Lubich, R. D. Skeel, and A. M. Stuart for their comments on the manuscript.

A SPECTRAL VISCOSITY METHOD BASED ON HERMITE FUNCTIONS FOR NONLINEAR CONSERVATION LAWS*

JULIÁN AGUIRRE† AND JUDITH RIVAS†

Abstract. We consider the approximation by a spectral method of the solution of the Cauchy problem for a scalar conservation law in one dimension posed in the whole real line. We analyze a spectral viscosity method in which the orthogonal basis considered is the one of Hermite functions. We prove the convergence of the approximate solution to the unique entropy solution of the problem by using compensated compactness arguments.

Key words. hyperbolic conservation laws, Hermite functions, spectral methods, spectral viscosity, compensated compactness

1. Introduction.

We consider the Cauchy problem for a genuinely nonlinear scalar conservation law in one space dimension posed in the whole real line:

$$\begin{cases} \dfrac{\partial u}{\partial t} + \dfrac{\partial f(u)}{\partial x} = 0, & x \in \mathbb{R}, t > 0, \\ u(x,0) = \varphi(x), & x \in \mathbb{R}, \end{cases} \tag{1.1}$$

where $f \in C^1$ is a smooth nonlinear function and $\varphi \in L^\infty(\mathbb{R})$. It is well known that, in general, there are no classical solutions to this problem. Moreover, weak solutions are not unique. To isolate the physically relevant solution, one has to impose the entropy condition

$$\frac{\partial U(u)}{\partial t} + \frac{\partial F(u)}{\partial x} \le 0 \tag{1.2}$$

in the sense of distributions, for all entropy pairs (U, F), with $U \in C^2$ convex and $F'(u) = U'(u)f'(u)$; see [7], [11].

Our aim is to approximate the unique entropy solution of (1.1), that is, the only weak solution verifying (1.2), by means of a spectral viscosity method based on Hermite functions.

The idea of a spectral method [8] is to approximate the solution of a PDE by a truncated series of the form $\sum_{k=0}^{N} \tilde{u}_k(t)\phi_k(x)$, where $\{\phi_k\}$ is an orthogonal basis of some Hilbert space. When applied to a hyperbolic conservation law, the spectral method must be supplied with an appropriate amount of artificial viscosity to avoid the possible instabilities that can appear due to the nonsmoothness of the exact solution. The so-called spectral viscosity method was first introduced in [21] and then developed in [15], [14], and [12] among others.

On the other hand, numerical methods such as finite differences, finite elements, or Fourier spectral methods always assume a finite domain of computation. When

dealing with a problem posed in an unbounded domain, the usual techniques to avoid this difficulty are the following:

(i) choose a large bounded computational domain and impose artificial boundary conditions;

(ii) assume the solution is periodic;

(iii) make a change of variables transforming the original domain into a bounded one.

Our approach respects the unboundedness of the domain considering as orthogonal basis for the spectral method the one consisting of Hermite functions.

The use of Hermite functions for the approximation of solutions of partial differential equations posed in the whole real line was proposed by Funaro and Kavian [6] and developed in [16], [13] for the case of viscous scalar conservation laws, in [5] for the Fokker–Planck equation, and in [9] for the Dirac equation.

One of the advantages of spectral methods is that they enjoy spectral accuracy; this is, if the function to be approximated is very regular, the approximation converges faster than any negative power of N. They are, therefore, very appropriate in the case of elliptic and parabolic equations thanks to the regularization properties of these operators. However, solutions of hyperbolic nonlinear problems may develop discontinuities in finite time, as mentioned before, leading to at most first order accurate spectral approximations. In [18], a postprocessing technique has been developed to enhance the convergence rate of the approximations, at least in points not too close to the shock.

The paper is organized as follows. In section 2 we describe the elements involved in the definition of our spectral method and recall the basic properties that will be needed in what follows. In section 3 we describe the method. Section 4 is devoted to finding a priori estimates for the approximate solutions that will be used in section 5 to prove the convergence of the method by compensated compactness arguments, supplemented by an L^∞ uniform boundedness assumption on the numerical solution. Finally, in section 6, we present some numerical experiments

2. Preliminaries. In this section we will describe the elements that take part in our spectral method as well as the basic properties that will be used in the proof of convergence.

As we have mentioned, we will consider the Hermite functions as an orthogonal basis. These functions are defined as

$$h_k(x) = e^{-x^2} H_k(x), \quad k = 0, 1, 2 \ldots,$$

where H_k is the Hermite polynomial of degree k and leading coefficient 2^k, the solution of the second order differential equation

$$y'' - 2xy' + 2ky = 0. \tag{2.1}$$

From the properties of Hermite polynomials [20], it follows that

$$h_k'(x) = -h_{k+1}(x), \quad k = 0, 1, 2 \ldots. \tag{2.2}$$

Hermite functions satisfy an orthogonality relation with respect to the weight function $w(x) = e^{x^2}$:

$$\int_{-\infty}^{\infty} h_n(x) h_m(x)\, w(x) dx = \delta_{m,n} 2^n n! \sqrt{\pi} \quad \forall\, n, m = 0, 1, 2, \ldots. \tag{2.3}$$

Hence, they form an orthogonal basis of the weighted L^2 space

$$L^2_w = \left\{ \varphi \colon \mathbb{R} \to \mathbb{R} \ \text{ measurable } \quad \Big| \quad \int_{-\infty}^{\infty} \Big| \varphi(x)|^2 \, w(x) dx < \infty \right\}.$$

We shall denote the norm in this space by

$$\|\varphi\|_{0,w} = \left(\int_{-\infty}^{\infty} |\varphi(x)|^2 \, w(x) dx \right)^{1/2}.$$

The weighted Sobolev spaces associated to L^2_w are

$$H^k_w = \left\{ \varphi \colon \mathbb{R} \to \mathbb{R} \quad | \quad \varphi, \varphi', \dots, \varphi^{(k)} \in L^2_w \right\}, \quad k = 0, 1, 2, \dots.$$

In [6] one can find a characterization of the functions of H^1_w that we recover in the following proposition, as well as some inequalities regarding the norms of functions in this space.

PROPOSITION 1. *Let $\varphi \in L^2_w$. $\varphi \in H^1_w$ if and only if $w^{1/2}\varphi \in H^1(\mathbb{R})$ and $x\varphi \in L^2_w$. Besides,*

$$\|(w^{1/2}\varphi)'\|_{L^2} \le \|\varphi'\|_{0,w}, \tag{2.4}$$

$$\|\varphi\|_{0,w} \le \|\varphi'\|_{0,w}, \tag{2.5}$$

$$\|x\varphi\|_{0,w} \le \|\varphi'\|_{0,w}. \tag{2.6}$$

Inequality (2.5), analogous to Poincare's one in bounded domains, implies that $\|\varphi^{(k)}\|_{0,w}$ is equivalent to the usual norm $\sum_{j=0}^{k} \|\varphi^{(j)}\|_{0,w}$ on H^k_w. Therefore, we define the norm in H^k_w as

$$\|\varphi\|_{k,w} = \|\varphi^{(k)}\|_{0,w}.$$

For noninteger $s > 0$, H^s_w is defined by interpolation, and, for $s < 0$, H^s_w is the dual of H^{-s}_w.

Since Hermite functions form an orthogonal basis of L^2_w, any $\varphi \in L^2_w$ can be expressed in a unique way as a Fourier–Hermite series of the form

$$\varphi(x) = \sum_{k=0}^{\infty} \widehat{\varphi}_k h_k(x), \qquad \text{where} \qquad \widehat{\varphi}_k = \frac{1}{\sqrt{\pi}\, 2^k \, k!} \int_{-\infty}^{\infty} \varphi(x) h_k(x) w(x) dx.$$

If we denote by V_N the subspace of L^2_w generated by the first $N+1$ Hermite functions, $h_0, h_1, \dots, h_N$, given $\varphi \in L^2_w$, its best approximation in the L^2_w norm by functions of V_N is the orthogonal or spectral projection, that is,

$$\pi_N \varphi(x) = \sum_{k=0}^{N} \widehat{\varphi}_k h_k(x).$$

From the definition of the operator π_N, one has

$$\|\pi_N \varphi\|_{0,w} \le \|\varphi\|_{0,w} \quad \forall \varphi \in L^2_w.$$

Besides, the following estimate for the weighted Sobolev norms of the error of the approximation of φ by $\pi_N \varphi$ is given in [6].

PROPOSITION 2. *Let $0 \le \mu \le \sigma$. There exists a positive constant C, independent of N, such that, for all $\varphi \in H_w^\sigma$,*

$$\|\varphi - \pi_N \varphi\|_{\mu,w} \le C N^{\frac{\mu-\sigma}{2}} \|\varphi\|_{\sigma,w}. \tag{2.7}$$

In practice, the spectral projection $\pi_N\varphi$ is of limited value since it is difficult to compute accurately. There is another way of approximating a continuous function $\varphi \in L_w^2$ by an element of V_N. Let $z_0, z_1, \ldots, z_N$ be the zeros of H_{N+1}, which are all real and distinct. Given $\varphi \in C(\mathbb{R}) \cap L_w^2$, its Nth pseudospectral projection is the unique function $I_N\varphi \in V_N$ such that

$$I_N\varphi(z_j) = \varphi(z_j), \quad j = 0, 1, \ldots, N.$$

If $I_N\varphi(x) = \sum_{k=0}^N \tilde{\varphi}_k h_k(x)$, the kth coefficient $\tilde{\varphi}_k$ is the result of approximating the exact Fourier–Hermite coefficient $\widehat{\varphi}_k$ by means of a Gaussian quadrature formula. More precisely,

$$\tilde{\varphi}_k = \sum_{j=0}^N w_{k,j}\varphi(z_j), \quad \text{where } w_{k,j} = \frac{2^{N-k} N! h_k(z_j)}{(N+1)k!(h_N(z_j))^2}. \tag{2.8}$$

In [1], the following estimate for the weighted Sobolev norms of the error of the pseudospectral projection is given.

PROPOSITION 3. *Let $\sigma \ge 1$ and $0 \le \mu \le \sigma$. There exists a positive constant C, independent of N, such that, for all $\varphi \in H_w^\sigma$,*

$$\|\varphi - I_N\varphi\|_{\mu,w} \le C N^{\frac{1}{6}+\frac{\mu-\sigma}{2}} \|\varphi\|_{\sigma,w}. \tag{2.9}$$

Finally, we introduce a differential operator which will play the role of the Laplacian in the usual viscosity spectral methods. Given $\varphi \in H_w^2$,

$$\mathcal{L}\varphi(x) = -e^{-x^2}\left(e^{x^2}\varphi'(x)\right)' = -(\varphi''(x) + 2x\varphi'(x)).$$

From (2.1) and the definition of Hermite functions it follows that the eigenfunctions of $\mathcal{L}$ are the Hermite functions h_k with eigenvalues $\lambda_k = 2(k+1)$; that is,

$$\mathcal{L}h_k(x) = 2(k+1)h_k(x), \quad k = 0, 1, 2, \ldots.$$

In [3] it is proved that $\mathcal{L}$ is a positive definite self-adjoint operator with compact inverse in L_w^2 that generates an analytic semigroup of contractions $\{e^{-t\mathcal{L}}\}$.

3. The Hermite spectral and pseudospectral viscosity methods. It is well known that the entropy solution of (1.1) can be obtained as the limit when ϵ tends to 0 of the solution of the parabolic problem obtained when one introduces in the right-hand side of (1.1) a vanishing viscosity term of the form ϵu_{xx}. Based on this fact, Tadmor defined the spectral viscosity approximation of the entropy solution u as a truncated Fourier series that is the solution of the approximated problem

$$\begin{cases} \dfrac{\partial u_N}{\partial t} + P_N \dfrac{\partial f(u_N)}{\partial x} = \epsilon_N \dfrac{\partial}{\partial x}\left(Q_{m_N} \dfrac{\partial u_N}{\partial x}\right), & x \in I, t > 0, \\ u_N(x,0) = P_N u(x,0), & x \in I, \end{cases}$$

where P_N stands for the Fourier spectral or pseudospectral projection. Since the exponentials e^{ikx} are eigenfunctions of the Laplacian, the term on the right-hand side can be easily implemented. However, when one takes the Hermite functions as an orthogonal basis, the Laplacian is not an appropriate way to introduce the artificial viscosity in the numerical scheme.

By using the properties of the operator $\mathcal{L}$ as well as compensated compactness arguments similar to those to be used in the proof of convergence in section 5, one can prove the following result about the entropy solution of (1.1).

THEOREM 1. *Let $f \in C^1$ be a nonlinear function such that $f'(0) = 0$, $\varphi \in L^2_w \cap L^\infty(\mathbb{R})$ and u_ϵ the solution of*

$$\begin{cases} \dfrac{\partial u_\epsilon}{\partial t} + \dfrac{\partial f(u_\epsilon)}{\partial x} + \epsilon \mathcal{L} u_\epsilon = 0, & x \in \mathbb{R},\ t > 0, \\ u_\epsilon(x,0) = \varphi(x), & x \in \mathbb{R}. \end{cases}$$

Then, for any $p \geq 1$ and any $\Omega \subset \mathbb{R} \times (0,\infty)$ open and bounded, u_ϵ converges in $L^p(\Omega)$ to the unique entropy solution of (1.1) *when ϵ tends to* 0.

By taking this into account, we define the spectral (or pseudospectral) viscosity approximation to the unique entropy solution of (1.1) as $u_N(x,t) = \sum_{k=0}^N \widetilde{u}_k(t)\, h_k(x)$ such that

$$\begin{cases} \dfrac{\partial u_N}{\partial t} + \dfrac{\partial}{\partial x}\left(P_{N-1} f(u_N)\right) + \epsilon_N \mathcal{L}(Q_{m_N} u_N) = 0, & x \in \mathbb{R},\ t \in (0,T), \\ u_N(x,0) = P_N \varphi(x), & x \in \mathbb{R}. \end{cases}$$

P_N stands for π_N in the spectral viscosity approximation and for I_N in the pseudospectral one. Q_{m_N} is a viscosity operator which modifies only the high modes of the Fourier–Hermite expansion, that is,

$$Q_{m_N}\left(\sum_{k=0}^N \widehat{\varphi}_k\, h_k(x)\right) = \sum_{k=0}^N \hat{q}_k\, \widehat{\varphi}_k\, h_k(x), \tag{3.1}$$

where

$$\begin{cases} \hat{q}_k = 0 & \text{if } k \leq m_N, \\ 1 - \dfrac{m_N}{k} \leq \hat{q}_k \leq 1 & \text{if } k > m_N, \end{cases} \tag{3.2}$$

$m_N < N$ being a positive integer that tends to ∞ with N. Finally, ϵ_N is a positive parameter depending on N that will tend to 0 as N tends to infinity.

We will give conditions on m_N and ϵ_N to ensure the convergence of u_N to the unique entropy solution of (1.1).

4. A priori estimates. In this section we will find two kinds of a priori estimates, following the lines of [14]. The first kind of estimate is related to the viscosity operator Q_{m_N}, while the second one is concerned with the approximate solution u_N.

LEMMA 1. *Let R be a linear operator defined in V_N in the following way:*

$$R\left(\sum_{k=0}^N \widehat{\varphi}_k\, h_k(x)\right) = \sum_{k=0}^N \hat{r}_k\, \widehat{\varphi}_k\, h_k(x),$$

where $\hat{r}_0, \ldots, \hat{r}_N$ are real numbers. Then, for all $\varphi \in V_N$,

$$\|R\varphi\|_{1,w}^2 \leq 2\left(\sum_{k=0}^{N} \hat{r}_k^2(k+1)\right)\|\varphi\|_{0,w}^2 .$$

Proof. Let $\varphi(x) = \sum_{k=0}^{N} \widehat{\varphi}_k h_k(x)$. From (2.2), $(R\varphi)'(x) = -\sum_{k=0}^{N} \hat{r}_k\, \widehat{\varphi}_k\, h_{k+1}(x)$, so that, by taking norms and recalling (2.3), one has

$$\begin{aligned}\|R\varphi\|_{1,w}^2 &= \sum_{k=0}^{N} \hat{r}_k^2\, \widehat{\varphi}_k^2\, 2^{k+1}(k+1)!\,\sqrt{\pi} \\ &\leq 2\left(\sum_{k=0}^{N} \hat{r}_k^2(k+1)\right)\left(\sum_{k=0}^{N} \widehat{\varphi}_k^2\, 2^k\, k!\,\sqrt{\pi}\right) \\ &= 2\left(\sum_{k=0}^{N} \hat{r}_k^2\,(k+1)\right)\|\varphi\|_{0,w}{}^2. \qquad \square\end{aligned}$$

By using this result we can now bound the norm of the derivative of a function of V_N by the sum of the H_w^1 norms of its high frequencies modified by Q_{m_N} and the L_w^2 norm of the function itself, multiplied by a constant that grows with N.

LEMMA 2. *Let Q_{m_N} be defined as in* (3.1), (3.2). *Then there exist positive constants C_1 and C_2, independent of N, such that*

$$\|\varphi\|_{1,w}^2 \leq C_1\,\|Q_{m_N}\varphi\|_{1,w}^2 + C_2 m_N^2\,\|\varphi\|_{0,w}^2 \quad \forall \varphi \in V_N.$$

Proof. Let $\varphi(x) = \sum_{k=0}^{N} \widehat{\varphi}_k h_k(x)$, and let $R_{m_N} = I - Q_{m_N}$, where I is the identity operator. Then

$$\|\varphi\|_{1,w}^2 \leq C\left(\|Q_{m_N}\varphi\|_{1,w}^2 + \|R_{m_N}\varphi\|_{1,w}^2\right).$$

We split φ in dyadic parts $\varphi(x) = \sum_{k=0}^{m_N} \widehat{\varphi}_k\, h_k(x) + \sum_{j=1}^{J} \varphi^j(x)$, where

$$\varphi^j(x) = \sum_{k>2^{j-1}m_N}^{2^j m_N} \widehat{\varphi}_k\, h_k(x), \qquad j = 1, \ldots, J.$$

Here $J = [\log_2 \frac{N}{m_N}] + 1$ and $\widehat{\varphi}_k = 0$ for $k = N+1, \ldots, 2^J m_N$.

From the orthogonality relation (2.3), one has

$$\|R_{m_N}\varphi\|_{1,w}^2 = \left\|R_{m_N}\sum_{k=0}^{m_N} \widehat{\varphi}_k\, h_k\right\|_{1,w}^2 + \sum_{j=1}^{J} \left\|R_{m_N}\varphi^j\right\|_{1,w}^2 . \tag{4.1}$$

We bound each summand by using the result obtained in Lemma 1. Since $\hat{q}_k = 0$ for $k \leq m_N$,

$$\begin{aligned}\left\|R_{m_N}\sum_{k=0}^{m_N} \widehat{\varphi}_k\, h_k\right\|_{1,w}^2 &\leq 2\left(\sum_{k=0}^{m_N}(1-\hat{q}_k)^2(k+1)\right)\left\|\sum_{k=0}^{m_N} \widehat{\varphi}_k\, h_k\right\|_{0,w}^2 \\ &\leq C m_N^2 \left\|\sum_{k=0}^{m_N} \widehat{\varphi}_k\, h_k\right\|_{0,w}^2 .\end{aligned}$$

For the terms in the summatory, since $\hat{q}_k \geq 1 - \frac{m_N}{k}$, we get, for any $j = 1, \ldots, J$,

$$\begin{aligned}
\left\|R_{m_N}\varphi^j\right\|_{1,w}^2 &\leq C\left(\sum_{k>2^{j-1}m_N}^{2^j m_N}(1-\hat{q}_k)^2(k+1)\right)\left\|\varphi^j\right\|_{0,w}^2 \\
&\leq Cm_N^2\sum_{k>2^{j-1}m_N}^{2^j m_N}\frac{1}{k}\left\|\varphi^j\right\|_{0,w}^2 \\
&\leq Cm_N^2\frac{1}{2^{j-1}m_N}(2^j m_N - 2^{j-1}m_N)\left\|\varphi^j\right\|_{0,w}^2 \\
&= Cm_N^2\left\|\varphi^j\right\|_{0,w}^2.
\end{aligned}$$

Hence,

$$\begin{aligned}
\|R_{m_N}\varphi\|_{1,w}^2 &\leq Cm_N^2\left(\left\|\sum_{k=0}^{m_N}\widehat{\varphi}_k\,h_k\right\|_{0,w}^2 + \sum_{j=1}^{J}\left\|\varphi^j\right\|_{0,w}^2\right) \\
&\leq Cm_N^2\left\|\varphi\right\|_{0,w}^2,
\end{aligned}$$

and by substituting in (4.1) we get the desired result. □

Now we will find some a priori estimates for the solution of the approximate problem u_N. We will use the following notation for norms in $\mathbb{R}\times[0,T]$, where $T>0$:

$$\|\varphi\|_{k,w,T}^2 = \int_0^T \|\varphi(\cdot,t)\|_{k,w}^2\,dt \quad \forall\varphi\in L^2(\mathbb{R},H_w^k).$$

There are some differences between the spectral and the pseudospectral cases; therefore we will distinguish both cases. We start with the spectral approximation.

LEMMA 3. *Let $f\in C^2(\mathbb{R})$ be such that $f'(0)=0$, $\varphi\in L_w^2$, $T>0$, $m_N=[O(N^\beta)]$, $\epsilon_N = O(N^{-\theta})$, with $0<2\beta<\theta<1/2$, Q_{m_N} given by (3.1), (3.2), and $u_N\colon[0,T]\to V_N$ the solution of*

$$\text{(4.2)}\qquad \begin{cases} \dfrac{\partial u_N}{\partial t} + \dfrac{\partial}{\partial x}\left(\pi_{N-1}f(u_N)\right) + \epsilon_N\mathcal{L}(Q_{m_N}u_N) = 0, & x\in\mathbb{R},\ t\in(0,T), \\ u_N(x,0) = \pi_N\varphi(x), & x\in\mathbb{R}. \end{cases}$$

Let us assume that there exists a positive constant c, independent of N, such that

$$\text{(4.3)}\qquad \|(1+|x|)u_N\|_{L^\infty(\mathbb{R}\times(0,T))}\leq c.$$

Then there exist positive constants k and $C(T)$, independent of N, such that

$$\text{(4.4)}\qquad \|u_N(\cdot,t)\|_{0,w}\leq e^{kt}\|u_N(\cdot,0)\|_{0,w}\quad\forall\,t\in(0,T),$$

$$\text{(4.5)}\qquad \|Q_{m_N}u_N\|_{1,w,T}\leq\frac{C(T)}{\sqrt{\epsilon_N}},$$

$$\text{(4.6)}\qquad \|u_N\|_{1,w,T}\leq\frac{C(T)}{\sqrt{\epsilon_N}}.$$

Proof. We multiply (4.2) by u_N and integrate in space with respect to the weight $w(x)$ to yield

$$\begin{aligned}\int_{-\infty}^{\infty} \frac{\partial u_N}{\partial t} u_N\, w\, dx + \int_{-\infty}^{\infty} \frac{\partial}{\partial x}\left(\pi_{N-1} f(u_N)\right) u_N\, w\, dx \\ - \epsilon_N \int_{-\infty}^{\infty} e^{-x^2} \frac{\partial}{\partial x}\left(e^{x^2} \frac{\partial}{\partial x}(Q_{m_N} u_N)\right) u_N\, w\, dx = 0.\end{aligned} \tag{4.7}$$

By taking into account that $\frac{d}{dx}\pi_{N-1} = \pi_N \frac{d}{dx}$ and the orthogonality of Hermite functions, we get

$$\int_{-\infty}^{\infty} \frac{\partial}{\partial x}\left(\pi_{N-1} f(u_N)\right) u_N\, w\, dx = \int_{-\infty}^{\infty} \frac{\partial}{\partial x}\left(f(u_N)\right) u_N\, w\, dx.$$

Let F be a primitive of $uf'(u)$ such that $F(0) = 0$. Then by integrating by parts above

$$\int_{-\infty}^{\infty} \frac{\partial}{\partial x}\left(f(u_N)\right) u_N\, w\, dx = \int_{-\infty}^{\infty} \frac{\partial}{\partial x}\left(F(u_N)\right)\, w\, dx = -\int_{-\infty}^{\infty} 2x\, F(u_N)\, w\, dx.$$

From the mean value theorem, for each (x,t) there exists η_N between 0 and u_N such that

$$F(u_N) = F'(\eta_N)\, u_N = \eta_N\, f'(\eta_N) u_N.$$

By using again the mean value theorem, this time with f', for each (x,t) there exists ξ_N between 0 and η_N such that

$$F(u_N) = \eta_N\, \left(f'(\eta_N) - f'(0)\right)\, u_N = \eta_N\, f''(\xi_N)\, \eta_N\, u_N = f''(\xi_N)\, \eta_N^2\, u_N$$

and hence

$$\begin{aligned}\left|\int_{-\infty}^{\infty} 2x\, F(u_N)\, w\, dx\right| &= \left|\int_{-\infty}^{\infty} 2x\, \eta_N^2\, f''(\xi_N)\, u_N\, w\, dx\right| \\ &\le \|2\,|x|\, u_N\|_{L^\infty(\mathbb{R}\times(0,T))} \sup_{|\xi|\le c} |f''(\xi)|\, \|\eta_N(\cdot,t)\|_{0,w}^2 \\ &\le k\, \|u_N(\cdot,t)\|_{0,w}^2\,.\end{aligned} \tag{4.8}$$

In the third integral in (4.7) we integrate by parts to yield

$$-\epsilon_N \int_{-\infty}^{\infty} e^{-x^2} \frac{\partial}{\partial x}\left(e^{x^2} \frac{\partial}{\partial x}\left(Q_{m_N} u_N\right)\right) u_N\, w\, dx = \epsilon_N \int_{-\infty}^{\infty} \frac{\partial}{\partial x}\left(Q_{m_N} u_N\right) \frac{\partial u_N}{\partial x}\, w\, dx.$$

Let $u_N(x,t) = \sum_{k=0}^{N} \widetilde{u}_k(t) h_k(x)$. From the definition of Q_{m_N} and the orthogonality of Hermite functions,

$$\begin{aligned}\int_{-\infty}^{\infty} \frac{\partial}{\partial x}\left(Q_{m_N} u_N\right) \frac{\partial u_N}{\partial x}\, w\, dx &= \sum_{k=0}^{N} \widehat{q}_k \left(\widetilde{u}_k(t)\right)^2 \|h_{k+1}\|_{0,w}^2 \\ &\ge \sum_{k=0}^{N} \widehat{q}_k^2 \left(\widetilde{u}_k(t)\right)^2 \|h_{k+1}\|_{0,w}^2 \\ &= \left\| \frac{\partial}{\partial x}(Q_{m_N} u_N)(\cdot,t)\right\|_{0,w}^2.\end{aligned} \tag{4.9}$$

By substituting (4.8) and (4.9) in (4.7), we get

$$\frac{1}{2}\frac{d}{dt}\left\|u_N(\cdot,t)\right\|_{0,w}^2+\epsilon_N\left\|\frac{\partial}{\partial x}(Q_{m_N}u_N)(\cdot,t)\right\|_{0,w}^2\leq k\left\|u_N(\cdot,t)\right\|_{0,w}^2. \tag{4.10}$$

In particular, $\frac{d}{dt}\|u_N(\cdot,t)\|_{0,w}^2\leq 2k\|u_N(\cdot,t)\|_{0,w}^2$; hence

$$\left\|u_N(\cdot,t)\right\|_{0,w}^2\leq e^{2kt}\left\|u_N(\cdot,0)\right\|_{0,w}^2,$$

and (4.4) follows. Besides, by integrating (4.10) in time between 0 and T,

$$\begin{aligned}\left\|u_N(\cdot,T)\right\|_{0,w}^2+2\epsilon_N\left\|\frac{\partial}{\partial x}(Q_{m_N}u_N)\right\|_{0,w,T}^2&\leq\left\|u_N(\cdot,0)\right\|_{0,w}^2+2k\int_0^T\left\|u_N(\cdot,t)\right\|_{0,w}^2\,dt\\ &\leq C(T)\left\|u_N(\cdot,0)\right\|_{0,w}^2.\end{aligned} \tag{4.11}$$

Since $u_N(x,0)=\pi_N\varphi(x)$ and $\varphi\in L^2_w$, we know that $\|u_N(\cdot,t)\|_{0,w}\leq\|\varphi\|_{0,w}$. Therefore, from (4.11) one deduces the estimate (4.5). Finally, by Lemma 2 one can obtain

$$\begin{aligned}\left\|\frac{\partial u_N}{\partial x}\right\|_{0,w,T}^2&\leq C\left\|\frac{\partial}{\partial x}(Q_{m_N}u_N)\right\|_{0,w,T}^2+Cm_N^2\int_0^T\left\|u_N(\cdot,t)\right\|_{0,w}^2\,dt\\ &\leq\frac{C(T)}{\epsilon_N}+C(T)m_N^2\\ &\leq C(T)\frac{1+\epsilon_N m_N^2}{\epsilon_N}.\end{aligned}$$

The inequality $2\beta<\theta$ implies that $\epsilon_N m_N^2=o(1)$ and, hence, the estimate (4.6) is verified. □

In the case of the pseudospectral approximation, more restrictive conditions must be imposed due to the fact that the approximation properties of I_N are not as good as those of π_N.

LEMMA 4. *Let $f\in C^2(\mathbb{R})$ be such that $f'(0)=0$, $\varphi\in H^1_w$, $T>0$, $m_N=[O(N^\beta]$, $\epsilon_N=O(N^{-\theta})$, with $0<2\beta<\theta<1/3$, Q_{m_N} given by (3.1), (3.2), and $u_N\colon[0,T]\to V_N$ the solution of*

$$\begin{cases}\dfrac{\partial u_N}{\partial t}+\dfrac{\partial}{\partial x}\left(I_{N-1}f(u_N)\right)+\epsilon_N\mathcal{L}(Q_{m_N}u_N)=0, & x\in\mathbb{R},\ t\in(0,T),\\ u_N(x,0)=I_N\varphi(x), & x\in\mathbb{R}.\end{cases} \tag{4.12}$$

Let us assume that there exists a positive constant c, independent of N, such that

$$\|(1+|x|)u_N\|_{L^\infty(\mathbb{R}\times(0,T))}\leq c. \tag{4.13}$$

Then there exist positive constants k and $C(T)$, independent of N, such that

$$\|u_N(\cdot,t)\|_{0,w}\leq e^{kt}\|u_N(\cdot,0)\|_{0,w}\quad\forall\,t\in(0,T), \tag{4.14}$$

$$\|Q_{m_N}u_N\|_{1,w,T}\leq\frac{C(T)}{\sqrt{\epsilon_N}}, \tag{4.15}$$

$$\|u_N\|_{1,w,T}\leq\frac{C(T)}{\sqrt{\epsilon_N}}. \tag{4.16}$$

Proof. Since the proof of these results is very similar to the one of Lemma 3, we will detail only the steps that present some difference. By multiplying (4.12) by u_N and integrating in space with respect to w, we get

$$\begin{aligned}\int_{-\infty}^{\infty} \frac{\partial u_N}{\partial t} u_N\, w\, dx + \int_{-\infty}^{\infty} \frac{\partial}{\partial x}\left(I_{N-1} f(u_N)\right) u_N\, w\, dx \\ - \epsilon_N \int_{-\infty}^{\infty} e^{-x^2} \frac{\partial}{\partial x}\left(e^{x^2} \frac{\partial}{\partial x}(Q_{m_N} u_N)\right) u_N\, w\, dx = 0.\end{aligned} \tag{4.17}$$

While the first and third integrals are rewritten and bounded as in Lemma 3, the second integral needs a different analysis, since $\frac{d}{dx} I_{N-1} \neq I_N \frac{d}{dx}$. We decompose this integral as follows:

$$\begin{aligned}\int_{-\infty}^{\infty} \frac{\partial}{\partial x}\left(I_{N-1} f(u_N)\right) u_N\, w\, dx = \int_{-\infty}^{\infty} \frac{\partial}{\partial x}\left(f(u_N)\right) u_N\, w\, dx \\ - \int_{-\infty}^{\infty} \frac{\partial}{\partial x}\left((I - I_{N-1}) f(u_N)\right) u_N\, w\, dx.\end{aligned}$$

The first summand is bounded as for u_N:

$$\left| \int_{-\infty}^{\infty} \frac{\partial}{\partial x}\left(f(u_N)\right) u_N\, w\, dx \right| \leq C \left\| u_N(\cdot, t) \right\|_{0,w}^2. \tag{4.18}$$

In the second term, we integrate by parts:

$$-\int_{-\infty}^{\infty} \frac{\partial}{\partial x}\left((I - I_{N-1}) f(u_N)\right) u_N\, w\, dx = \int_{-\infty}^{\infty} (I - I_{N-1}) f(u_N) \left(\frac{\partial u_N}{\partial x} + 2\, x\, u_N\right) w\, dx.$$

By the Cauchy–Schwartz inequality, followed by (2.9) and (2.6), one can deduce that

$$\begin{aligned}&\left| \int_{-\infty}^{\infty} \frac{\partial}{\partial x}\left((I - I_{N-1}) f(u_N)\right) u_N\, w\, dx \right| \\ &\quad \leq \left\| (I - I_{N-1}) f(u_N(\cdot, t)) \right\|_{0,w} \left\| 2\, x\, u_N(\cdot, t) + \frac{\partial u_N}{\partial x}(\cdot, t) \right\|_{0,w} \\ &\quad \leq C\, N^{-1/3} \left\| \frac{\partial}{\partial x}\left(f(u_N(\cdot, t))\right) \right\|_{0,w} \left\| \frac{\partial u_N}{\partial x}(\cdot, t) \right\|_{0,w} \\ &\quad \leq C\, N^{-1/3} \left\| \frac{\partial u_N}{\partial x}(\cdot, t) \right\|_{0,w}^2,\end{aligned}$$

where one has to take into account that $|f'(u_N)| \leq C$ due to the uniform boundedness assumed in (4.13).

Finally, we apply the estimate in Lemma 2 and obtain

$$\begin{aligned}&\left| \int_{-\infty}^{\infty} \frac{\partial}{\partial x}\left((I - I_{N-1}) f(u_N)\right) u_N\, w\, dx \right| \\ &\quad \leq C\, N^{-1/3} \left(\left\| \frac{\partial}{\partial x}(Q_{m_N} u_N)(\cdot, t) \right\|_{0,w}^2 + m_N^2 \left\| u_N(\cdot, t) \right\|_{0,w}^2 \right).\end{aligned} \tag{4.19}$$

By substituting (4.18) and (4.19) in (4.17) we obtain

$$\begin{aligned}\frac{1}{2} \frac{d}{dt} \left\| u_N(\cdot, t) \right\|_{0,w}^2 + \left(\epsilon_N - C\, N^{-1/3}\right) \left\| \frac{\partial}{\partial x}(Q_{m_N} u_N)(\cdot, t) \right\|_{0,w}^2 \\ \leq C \left(1 + N^{-1/3} m_N^2\right) \left\| u_N(\cdot, t) \right\|_{0,w}.\end{aligned}$$

Since $\epsilon_N = O(N^{-\theta})$ with $\theta < 1/3$ and $m_N = [O(N^{\beta})]$ with $2\beta < \theta$, $\epsilon_N - CN^{-1/3} = O(\epsilon_N)$ and $N^{-1/3}m_N^2 = o(1)$, so that

$$\frac{1}{2}\frac{d}{dt}\,\|u_N(\cdot,t)\|_{0,w}^2 + C\,\epsilon_N \Big\| \frac{\partial}{\partial x}(Q_{m_N}u_N)(\cdot,t)\Big\|_{0,w}^2 \le C\,\|u_N(\cdot,t)\|_{0,w}^2\,.$$

By arguing as in Lemma 3, we get (4.14) as well as

$$\epsilon_N \Big\| \frac{\partial}{\partial x}(Q_{m_N}u_N)\Big\|_{0,w,T} \le C(T)\,\|u_N(\cdot,0)\|_{0,w}^2\,.$$

By recalling that $\varphi \in H_w^1$, we use (2.9) to deduce that

$$\|u_N(\cdot,0)\|_{0,w}^2 = \|I_N\varphi\|_{0,w}^2 \le \|\varphi\|_{0,w}^2 + C\,N^{-1/3}\,\|\varphi\|_{1,w}^2 \le C\,\|\varphi\|_{1,w}^2\,,$$

and inequalities (4.15) and (4.16) are satisfied. □

The uniform boundedness hypothesis on $\{u_N\}$ is common in spectral viscosity approximations as can be seen in [21], [15], [14], although in some cases it is deduced from the approximate equation itself, as in [2]. In (4.3) and (4.13) an L^∞ bound for xu_N is also imposed. The factor x is related to the weight $2x = w'w^{-1}$. Another consequence of the presence of the weight is the more involved arguments needed to deduce the a priori estimates of Lemmas 3 and 4, compared with the case of Fourier or Legendre approximations, where the basis functions are orthogonal in the unweighted L^2 space.

5. Convergence to the unique entropy solution. In the proof of convergence of u_N to the unique entropy solution of (1.1), we will make use of compensated compactness arguments [4], [10], [19], in which the estimates just proved in the previous section will be determinant. Since both the spectral and the pseudospectral cases are analogous, we will detail only the proof of convergence of the first one and state the result for the pseudospectral case under the more restrictive conditions mentioned earlier.

The proof that, for any entropy pair (U,F) associated to (1.1), $\{\frac{\partial u_N}{\partial t} + \frac{\partial f(u_N)}{\partial x}\}$ and $\{\frac{\partial U(u_N)}{\partial t} + \frac{\partial F(u_N)}{\partial x}\}$ satisfy the hypothesis of Murat's lemma will be split into several lemmas.

LEMMA 5. *Under the hypothesis of Lemma* 3 *the sequence* $\{\epsilon_N \mathcal{L}(Q_{m_N}u_N)\}_{N\in\mathbb{N}}$ *tends to* 0 *in* $H^{-1}_{\mathrm{loc}}(\mathbb{R}\times(0,T))$.

Proof. From the definition of $\mathcal{L}$,

$$\mathcal{L}(Q_{m_N}u_N) = 2Q_{m_N}u_N - \frac{\partial}{\partial x}(2xQ_{m_N}u_N) - \frac{\partial}{\partial x}\left(\frac{\partial}{\partial x}(Q_{m_N}u_N)\right).$$

Let $K \subset \mathbb{R}\times(0,T)$ be compact. Since $0 \le \widehat{q}_k \le 1$ for $k = 0,\dots,N$, and by taking into account the estimate (4.4),

$$\|2Q_{m_N}u_N\|_{L^2(K)} \le 2\|Q_{m_N}u_N\|_{0,w,T} \le 2\|u_N\|_{0,w,T} \le C(T)\|\varphi\|_{0,w}.$$

By using now property (2.6) and estimate (4.5), we get

$$\|2xQ_{m_N}u_N\|_{L^2(K)} \le 2\|xQ_{m_N}u_N\|_{0,w,T} \le 2\|Q_{m_N}u_N\|_{1,w,T} \le \frac{C(T)}{\sqrt{\epsilon_N}}.$$

Finally, by applying again estimate (4.5) we can deduce that

$$\left\| \frac{\partial}{\partial x}(Q_{m_N} u_N) \right\|_{L^2(K)} \leq \|Q_{m_N} u_N\|_{1,w,T} \leq \frac{C(T)}{\sqrt{\epsilon_N}}.$$

Hence, $\epsilon_N \mathcal{L}(Q_{m_N} u_N)$ is the sum of a function tending to 0 in $L^2(K)$ and the derivatives of two functions also tending to 0 in $L^2(K)$, K being any compact subset, and, therefore, $\epsilon_N \mathcal{L}(Q_{m_N} u_N)$ tends to 0 in $H^{-1}_{\text{loc}}(\mathbb{R} \times (0,T))$. ∎

LEMMA 6. *Under the same hypothesis of Lemma* 3, $\{\frac{\partial}{\partial x}((I - \pi_{N-1}) f(u_N))\}_{N \in \mathbb{N}}$ *tends to* 0 *in* $H^{-1}_{\text{loc}}(\mathbb{R} \times (0,T))$.

Proof. Let $K \subset \mathbb{R} \times (0,T)$ be compact. From (2.7) we have

$$\|(I - \pi_{N-1}) f(u_N)\|_{L^2(K)} \leq \|(I - \pi_{N-1}) f(u_N)\|_{0,w,T} \leq C N^{-1/2} \|f(u_N)\|_{1,w,T}.$$

Without loss of generality, we can suppose that $f(0) = 0$. The uniform boundedness of u_N together with the continuity of f' allows us to deduce that if $C = \max_{|\xi| \leq c} |f'(\xi)|$, then $|f(u_N)| \leq C|u_N|$, so that, by (4.6), we obtain

$$\|(I - \pi_{N-1}) f(u_N)\|_{L^2(K)} \leq C N^{-1/2} \|u_N\|_{1,w,T} \leq \frac{C(T)}{\sqrt{N \epsilon_N}},$$

and $\frac{\partial}{\partial x}((I - \pi_{N-1}) f(u_N))$ is the derivative of a function that tends to 0 in $L^2_{\text{loc}}(\mathbb{R} \times (0,T))$, since $\epsilon_N = O(N^{-\theta})$ with $\theta < 1/2$. Therefore, the result follows. ∎

LEMMA 7. *Let* $U \in C^2(\mathbb{R})$ *be an entropy function of* (1.1)*, and assume that the hypotheses of Lemma* 3 *are satisfied. Then* $\epsilon_N U'(u_N) \mathcal{L}(Q_{m_N} u_N)$ *can be written as the sum of two terms, one of them tending to* 0 *in* $H^{-1}_{\text{loc}}(\mathbb{R} \times (0,T))$ *and the other one bounded in* $L^1(\mathbb{R} \times (0,T))$.

Proof. From the definition of $\mathcal{L}$, we can write

$$\epsilon_N U'(u_N) \mathcal{L}(Q_{m_N} u_N) = -\epsilon_N U'(u_N) \left(\frac{\partial^2}{\partial x^2}(Q_{m_N} u_N) + 2x \frac{\partial}{\partial x}(Q_{m_N} u_N) \right) = I + II,$$

where

$$I = \epsilon_N \left(2U'(u_N) Q_{m_N} u_N - \frac{\partial}{\partial x} \left(2x U'(u_N) Q_{m_N} u_N \right) - \frac{\partial}{\partial x} \left(U'(u_N) \frac{\partial}{\partial x}(Q_{m_N} u_N) \right) \right),$$

$$II = \epsilon_N U''(u_N) \frac{\partial u_N}{\partial x} \left(2x Q_{m_N} u_N + \frac{\partial}{\partial x}(Q_{m_N} u_N) \right).$$

U' is continuous and u_N uniformly bounded in L^∞ so that there exists a constant $C > 0$, independent of N, such that $|U'(u_N)| \leq C$. By arguing as in Lemma 5, $2U'(u_N) Q_{m_N} u_N$, $2xU'(u_N) Q_{m_N} u_N$, and $U'(u_N) \frac{\partial}{\partial x}(Q_{m_N} u_N)$ tend to 0 in $L^2_{\text{loc}}(\mathbb{R} \times (0,T))$, and hence I tends to 0 in $H^{-1}_{\text{loc}}(\mathbb{R} \times (0,T))$.

On the other hand, U'' is also continuous; therefore, by the Cauchy–Schwartz inequality, followed by property (2.6) and estimates (4.5) and (4.6), we get

$$\begin{aligned}
\|II\|_{L^1(\mathbb{R} \times (0,T))} &= \epsilon_N \left\| U''(u_N) \frac{\partial u_N}{\partial x} \left(2x Q_{m_N} u_N + \frac{\partial}{\partial x}(Q_{m_N} u_N) \right) \right\|_{L^1(\mathbb{R} \times (0,T))} \\
&\leq C \epsilon_N \left\| \frac{\partial u_N}{\partial x} \right\|_{L^2(\mathbb{R} \times (0,T))} \left\| 2x Q_{m_N} u_N + \frac{\partial}{\partial x}(Q_{m_N} u_N) \right\|_{L^2(\mathbb{R} \times (0,T))} \\
&\leq C \epsilon_N \|u_N\|_{1,w,T} \|Q_{m_N} u_N\|_{1,w,T} \\
&\leq C(T);
\end{aligned}$$

that is, II is bounded in $L^1(\mathbb{R} \times (0,T))$. ∎

LEMMA 8. *Let $U \in C^2(\mathbb{R})$ be an entropy function of (1.1), and assume that the hypotheses of Lemma 3 are satisfied. Then $U'(u_N)\frac{\partial}{\partial x}((I-\pi_{N-1})f(u_N))$ can be written as the sum of two terms, one of them tending to 0 in $H^{-1}_{\mathrm{loc}}(\mathbb{R}\times(0,T))$ and the other one bounded in $L^1(\mathbb{R}\times(0,T))$.*

Proof. We write $U'(u_N)\frac{\partial}{\partial x}((I-\pi_{N-1})f(u_N))$ as a difference in the following way:

$$U'(u_N)\frac{\partial}{\partial x}\left((I-\pi_{N-1})f(u_N)\right) = \frac{\partial}{\partial x}\left(U'(u_N)(I-\pi_{N-1})f(u_N)\right) - U''(u_N)\frac{\partial u_N}{\partial x}\left((I-\pi_{N-1})f(u_N)\right).$$

The first term is the derivative of a function that tends to 0 in $L^2(\mathbb{R}\times(0,T))$ since, by arguing as in Lemma 6,

$$\begin{aligned}\|U'(u_N)(I-\pi_{N-1})f(u_N)\|_{L^2(\mathbb{R}\times(0,T))} &\le C\|(I-\pi_{N-1})f(u_N)\|_{0,w,T}\\ &\le \frac{C(T)}{\sqrt{N\epsilon_N}}.\end{aligned}$$

Therefore, $\frac{\partial}{\partial x}\left(U'(u_N)(I-\pi_{N-1})f(u_N)\right)$ tends to 0 in $H^{-1}_{\mathrm{loc}}(\mathbb{R}\times(0,T))$.

To bound the L^1 norm of the second term we use the Cauchy–Schwartz inequality, followed by (2.7) and the estimates obtained in Lemma 3, yielding

$$\begin{aligned}&\left\|U''(u_N)\frac{\partial u_N}{\partial x}\left((I-\pi_{N-1})f(u_N)\right)\right\|_{L^1(\mathbb{R}\times(0,T))}\\ &\le C\left\|\frac{\partial u_N}{\partial x}\right\|_{L^2(\mathbb{R}\times(0,T))}\left\|(I-\pi_{N-1})f(u_N)\right\|_{L^2(\mathbb{R}\times(0,T))}\\ &\le C\|u_N\|_{1,w,T}N^{-1/2}\|u_N\|_{1,w,T}\\ &\le \frac{C(T)}{N^{1/2}\epsilon_N}.\end{aligned}$$

By recalling that $\epsilon_N = O(N^{-\theta})$ with $\theta < 1/2$, the result follows. ∎

We are now ready to prove the convergence of u_N, by making use of Murat's and Tartar's lemmas.

THEOREM 2. *Let $f \in C^2(\mathbb{R})$ be a nonlinear function such that $f'(0) = 0$, $\varphi \in L^2_w \cap L^\infty(\mathbb{R})$, $m_N = [O(N^\beta)]$, $\epsilon_N = O(N^{-\theta})$, with $0 < 2\beta < \theta < 1/2$, and assume that, for a given $T > 0$, the solution u_N of (4.2) verifies the uniform bound (4.3). Then $\{u_N\}$ converges in $L^p(\Omega)$ to the unique entropy solution of (1.1) for any $\Omega \subset \mathbb{R}\times[0,T]$ open and bounded and any $p \ge 1$.*

Proof. The uniform boundedness of $\{u_N\}$ in $L^\infty(\mathbb{R}\times(0,T))$ ensures that there exists a subsequence that we will still denote by $\{u_N\}$, which converges in the weak-* topology of L^∞. Let u be its limit. We will prove that u is the unique entropy solution of (1.1), and we will also show that the whole sequence tends to u in $L^p(\Omega)$ for every $p \ge 1$ and every $\Omega \subset \mathbb{R}\times(0,T)$ open and bounded.

Let (U,F) be an entropy pair associated to (1.1). We first prove that $\frac{\partial u_N}{\partial t} + \frac{\partial f(u_N)}{\partial x}$ and $\frac{\partial U(u_N)}{\partial t} + \frac{\partial F(u_N)}{\partial x}$ are in a compact set of $H^{-1}_{\mathrm{loc}}(\mathbb{R}\times(0,T))$. From (4.2), we can write

$$\begin{aligned}\frac{\partial u_N}{\partial t} + \frac{\partial f(u_N)}{\partial x} &= \frac{\partial u_N}{\partial t} + \frac{\partial}{\partial x}\left(\pi_{N-1}f(u_N)\right) + \frac{\partial}{\partial x}\left((I-\pi_{N-1})f(u_N)\right)\\ &= -\epsilon_N\mathcal{L}(Q_{m_N}u_N) + \frac{\partial}{\partial x}\left((I-\pi_{N-1})f(u_N)\right). \qquad (5.1)\end{aligned}$$

We have shown in Lemmas 5 and 6 that both summands in the right-hand side tend to 0 in $H^{-1}_{\mathrm{loc}}(\mathbb{R}\times(0,T))$, and therefore $\frac{\partial u_N}{\partial t} + \frac{\partial f(u_N)}{\partial x}$ is in a compact set of this space.

On the other hand, since $F'(u) = f'(u)U'(u)$,

$$\begin{aligned}\frac{\partial U(u_N)}{\partial t} + \frac{\partial F(u_N)}{\partial x} &= U'(u_N)\frac{\partial u_N}{\partial t} + F'(u_N)\frac{\partial u_N}{\partial x}\\ &= -\epsilon_N U'(u_N)\mathcal{L}(Q_{m_N}u_N) + U'(u_N)\frac{\partial}{\partial x}\left((I-\pi_{N-1})f(u_N)\right).\end{aligned}$$

From Lemmas 7 and 8 it follows that $\frac{\partial U(u_N)}{\partial t} + \frac{\partial F(u_N)}{\partial x}$ is the sum of two terms, one of them being in a compact set of $H^{-1}_{\mathrm{loc}}(\mathbb{R}\times(0,T))$ and the other one being bounded in the set of measures $\mathcal{M}(\mathbb{R}\times(0,T))$. Besides, $\frac{\partial U(u_N)}{\partial t} + \frac{\partial F(u_N)}{\partial x}$ is in $W^{-1,p}_{\mathrm{loc}}(\mathbb{R}\times(0,T))$ for any $p>2$, since U and F are continuous and u_N uniformly bounded in $L^\infty(\mathbb{R}\times(0,T))$. Therefore, by Murat's lemma, $\frac{\partial U(u_N)}{\partial t} + \frac{\partial F(u_N)}{\partial x}$ is in a compact set of $H^{-1}_{\mathrm{loc}}(\mathbb{R}\times(0,T))$.

We apply now Tartar's div-culr lemma [22] to conclude that u is in fact a weak solution of (1.1). Let us now turn to the analysis of the entropy condition.

$$\begin{aligned}\frac{\partial U(u_N)}{\partial t} + \frac{\partial F(u_N)}{\partial x} &= \epsilon_N e^{-x^2}\frac{\partial}{\partial x}\left(e^{x^2}U'(u_N)\frac{\partial}{\partial x}(Q_{m_N}u_N)\right)\\ &\quad -\epsilon_N U''(u_N)\frac{\partial u_N}{\partial x}\frac{\partial}{\partial x}(Q_{m_N}u_N)\\ &\quad +\frac{\partial}{\partial x}\left(U'(u_N)(I-\pi_{N-1})f(u_N)\right)\\ &\quad -U''(u_N)\frac{\partial u_N}{\partial x}\left((I-\pi_{N-1})f(u_N)\right).\end{aligned}$$

We multiply this equality by a nonnegative function test $\phi \in C^1_0(\mathbb{R}\times(0,T))$ and integrate by parts to obtain

$$\begin{aligned}&\int_0^\infty\int_{-\infty}^\infty \left(U(u_N)\frac{\partial\phi}{\partial t} + F(u_N)\frac{\partial\phi}{\partial x}\right)dx\,dt\\ &= \epsilon_N\int_0^\infty\int_{-\infty}^\infty U'(u_N)\frac{\partial}{\partial x}(Q_{m_N}u_N)\left(-2x\phi + \frac{\partial\phi}{\partial x}\right)dx\,dt\\ &\quad +\epsilon_N\int_0^\infty\int_{-\infty}^\infty U''(u_N)\frac{\partial u_N}{\partial x}\frac{\partial}{\partial x}(Q_{m_N}u_N)\phi\,dx\,dt\\ &\quad +\int_0^\infty\int_{-\infty}^\infty U'(u_N)\left((I-\pi_{N-1})f(u_N)\right)\frac{\partial\phi}{\partial x}\,dx\,dt\\ &\quad +\int_0^\infty\int_{-\infty}^\infty U''(u_N)\frac{\partial u_N}{\partial x}\left((I-\pi_{N-1})f(u_N)\right)\phi\,dx\,dt.\end{aligned}$$

Estimates (4.5) and (4.6) and property (2.7) imply that the first, third, and fourth integrals on the right-hand side tend to 0 when N tends to infinity. Besides, if $R_{m_N} = I - Q_{m_N}$, then

$$\frac{\partial u_N}{\partial x}\frac{\partial}{\partial x}(Q_{m_N}u_N) = \left(\frac{\partial u_N}{\partial x}\right)^2 - \frac{\partial u_N}{\partial x}\frac{\partial}{\partial x}(R_{m_N}u_N),$$

and, by taking into account the estimate obtained in the proof of Lemma 2 for $\|R_{m_N}\varphi\|_{1,w}$ and the bound (4.6), we have

$$\begin{aligned}\left\|\frac{\partial u_N}{\partial x}\frac{\partial}{\partial x}(R_{m_N}u_N)\right\|_{L^1(\mathbb{R}\times(0,T))} &\le \left\|\frac{\partial u_N}{\partial x}\right\|_{0,w,T}\left\|\frac{\partial}{\partial x}(R_{m_N}u_N)\right\|_{0,w,T}\\ &\le C(T)m_N\epsilon_N^{-1/2}\|\varphi\|_{0,w}.\end{aligned}$$

By taking this into account, we split the second integral in the right-hand side above into two terms, and we deduce that

$$\lim_{N\to\infty} \epsilon_N \int_0^\infty \int_{-\infty}^\infty U''(u_N)\frac{\partial u_N}{\partial x}\frac{\partial}{\partial x}(R_{m_N}u_N)\phi\,dx\,dt = 0,$$

while

$$\epsilon_N \int_0^\infty \int_{-\infty}^\infty U''(u_N)\left(\frac{\partial u_N}{\partial x}\right)^2 \phi \geq 0,$$

thanks to the convexity of U. We have proved, therefore, that u verifies the entropy condition. The uniqueness of the entropy solution allows us to assure that not only a subsequence but the whole sequence $\{u_N\}$ converges to u and, by recalling results about Young measures, the convergence in $L^p(\Omega)$ for any $p \geq 1$ and any $\Omega \subset \mathbb{R}\times(0,T)$ open and bounded is also fulfilled. ∎

The same convergence result is obtained for the pseudspectral viscosity approximation, under the more restrictive conditions of Lemma 4.

THEOREM 3. *Let $f \in C^2(\mathbb{R})$ be a nonlinear function such that $f'(0) = 0$, $\varphi \in H^1_w$, $m_N = [O(N^\beta)]$, $\epsilon_N = O(N^{-\theta})$, with $0 < 2\beta < \theta < 1/3$, and assume that, given $T > 0$, the solution u_N of (4.12) verifies (4.13). Then $\{u_N\}$ converges in $L^p(\Omega)$ to the unique entropy solution of (1.1) for any $\Omega \subset \mathbb{R}\times[0,T]$ open and bounded and any $p \geq 1$.*

6. Numerical experiments. In this section we present the numerical results obtained when applying our spectral viscosity method to Burgers' equation with initial condition $u(x,0) = h_0(x)$, that is, to the Cauchy problem

$$\begin{cases} \dfrac{\partial u}{\partial t} + \dfrac{\partial}{\partial x}\left(\dfrac{u^2}{2}\right) = 0, & x \in \mathbb{R}, t > 0, \\ u(x,0) = e^{-x^2}, & x \in \mathbb{R}. \end{cases} \tag{6.1}$$

The solution to this problem presents a shock at time $T^* = (e/2)^{1/2} \sim 1.1658$. All of the numerical results presented in this section have been recorded at time $t = 1.5 > T^*$.

Although we have proved the convergence of the spectral and pseudospectral viscosity methods, the implementation of the spectral one is expensive since the Fourier–Hermite coefficients defined as an integral must be approximated sufficiently accurately. Because of this, we will consider only the pseudospectral case. Hence our approximation $u_N(x,t) = \sum_{k=0}^N \widetilde{u}_k(t)h_k(x)$ will be the solution of

$$\begin{cases} \dfrac{\partial u_N}{\partial t} + \dfrac{1}{2}\dfrac{\partial}{\partial x}\left(I_{N-1}u_N^2\right) + \epsilon_N \mathcal{L}\left(Q_{m_N}u_N\right) = 0, \\ u_N(x,0) = I_N\varphi(x) = e^{-x^2}. \end{cases} \tag{6.2}$$

As stated in (2.8), the coefficients of the pseudospectral projection are obtained by a Gaussian quadrature formula, whose weights have been computed for different values of N by using *Mathematica*® and stored, so that there is no need to compute them each time the method is applied. To obtain the values of u_N^2 at the nodes z_j, we have used Clenshaw's formula [17] that gives an efficient and stable algorithm to compute the values of sums of the form $\sum_{k=0}^N \hat{\varphi}_k h_k(x)$. Besides, from (2.2), one has $(\sum_{k=0}^{N-1} \hat{\varphi}_k h_k(x))' = -\sum_{k=1}^N \hat{\varphi}_{k-1} h_k(x)$. Therfore, the coefficients of $\frac{\partial}{\partial x}(I_{N-1}u_N^2)$ are a nonlinear combination of those of u_N.

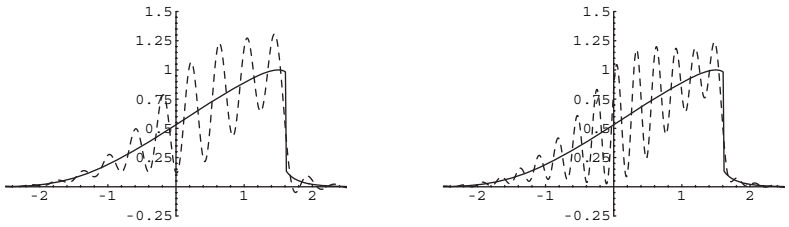

FIG. 6.1. *Graphs of the exact solution of Burgers' equation (solid line) and of the pseudospectral approximation without viscosity (dashed line), with* $N = 129$ *and* $N = 257$.

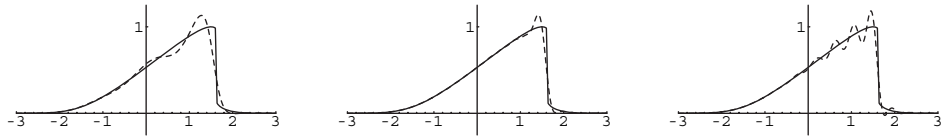

FIG. 6.2. *Graphs of the exact solution of Burgers' equation (solid line) and the viscosity pseudospectral approximation (dashed line) at time* $t = 1.5$, *for* $N = 257$, $\epsilon_N = 0.5N^{-0.33}$, *and* $m_N = [5N^{0.16}]$, *by taking* $\widehat{q}_k = \widehat{q}_k^1$, $\widehat{q}_k = \widehat{q}_k^2$, *and* $\widehat{q}_k = \widehat{q}_k^3$, *respectively, for* $k > m_N$.

On the other hand, from the definition of Q_{m_N} and the fact that h_k is an eigenfunction of $\mathcal{L}$, the coefficients of the viscosity term are obtained by multiplying those of u_N by $2(k+1)\hat{q}_k$.

Hence, the coefficients $\widetilde{u}_k(t)$, $k = 0, \ldots, N$, are the solution of a nonlinear system of ordinary differential equations that has been solved by using a fourth order Runge–Kutta method with an adaptive time step.

In Figure 6.1 we show the result of approximating u by a Hermite pseudospectral method without viscosity ($\epsilon_N = 0$) for $N = 129$ and $N = 257$. The appearance of instabilities prevents the convergence of the approximation.

The viscosity introduced by the numerical scheme (6.2) depends on the parameters ϵ_N and m_N and the operator Q_{m_N}. Convergence is ensured if

$$\epsilon_N = O(N^{-\theta}), \quad 0 < \theta < 1/3, \tag{6.3}$$

$$m_N = [O(N^{\beta})], \quad 0 < \beta < \theta/2, \tag{6.4}$$

$$1 - \frac{m_N}{k} \leq \hat{q}_k \leq 1, \quad m_N < k \leq N. \tag{6.5}$$

The bigger the coefficients $\hat{q}_k$ and ϵ_N are, the stronger the viscosity introduced is, while high values of m_N mean less viscosity since fewer coefficients are present in the viscosity term. Too much viscosity yields a worse resolution of the shock, but too little viscosity allows more oscillations that can lead to lack of convergence. By taking this into account, we have chosen $\epsilon_N = 0.5N^{-0.33}$ and $m_N = [5N^{0.16}]$, so that conditions (6.3) and (6.4) are satisfied but viscosity is not too strong.

In Figure 6.2 we show the results obtained, for $N = 257$ and $t = 1.5$, with different operators Q_{m_N} that verify in any case that $\hat{q}_N = 1$.

The first figure corresponds to taking

$$\widehat{q}_k^1 = \frac{N}{N - m_N}\left(1 - \frac{m_N}{k}\right) \quad \text{for} \quad k > m_N$$

which satisfies (6.5). The approximate solution presents few oscillations, but the shock is not very well approximated.

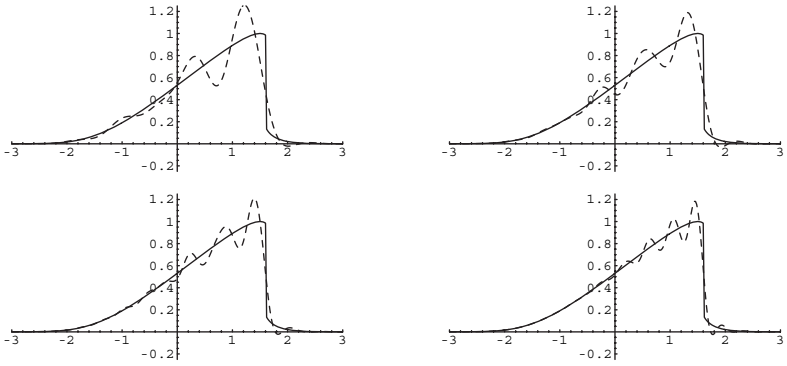

FIG. 6.3. *Graphs of the exact solution to Burgers' equation (solid line) and of the pseudospectral viscosity approximation (dashed line), by taking* $\widehat{q}_k = \widehat{q}_k^3$, $\epsilon_N = 0.5N^{-0.33}$, *and* $m_N = [5N^{0.16}]$, *for* $N = 33$, $N = 65$, $N = 129$, *and* $N = 257$.

In the second figure we present the solution obtained when

$$\widehat{q}_k^2 = \frac{k - m_N}{N - m_N} \quad \text{for } k > m_N,$$

which corresponds to coefficients laying on the straight line that joins the points $(m_N, 0)$ and $(N, 1)$, in a similar fashion as in one of the examples presented in [15]. The resulting approximation is more accurate near the shock, and there are very few oscillations.

Finally, we have taken

$$\widehat{q}_k^3 = \exp\left(-\left(\frac{k - N}{k - m_N}\right)^2\right) \quad \text{for} \quad k > m_N,$$

since in [15] the author suggests that coefficients that can be written as $\hat{q}_k = q(k/N)$, with $q \in C^\infty$, may lead to better results. This approximation is more accurate near the discontinuity, at the expense of more oscillations all over the domain.

In the three cases, the results can be slightly improved by properly choosing ϵ_N and m_N, but the third viscosity operator considered gives the best resolution of the shock.

The approximations obtained with this last operator for different values of N are shown in Figure 6.3. The improvement in the resolution of the shock when N increases is clear. However, the overshoot near the discontinuity does not decrease, and oscillations are present all along the domain. These are the main features of the so-called Gibbs phenomenon that appears when a nonregular function is approximated by its spectral or pseudospectral projection. Associated to this Gibbs phenomenon there is also a poor pointwise convergence rate even at points far away from the discontinuity.

In [18], a filter has been developed to enhance the convergence rate of the spectral projection of nonsmooth functions of L_w^2. Given $\varphi \in L_w^2$, the new approximation is defined as

$$\mathcal{F}^{\theta,p}[\pi_N \varphi](x) = \pi_p F^{N,\theta,x}(x),$$

where $F^{N,\theta,x}$ is a localization of the Nth spectral projection of φ:

$$F^{N,\theta,x}(y) = \pi_N \varphi(y) \rho\left(\frac{x - y}{\theta}\right).$$

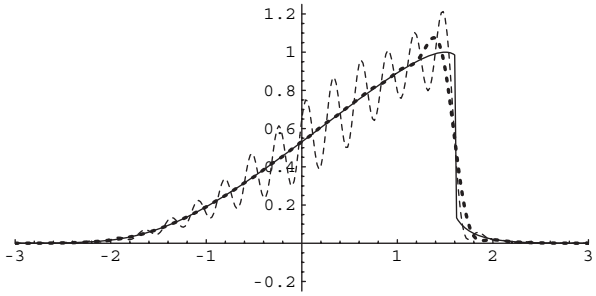

FIG. 6.4. *Graphs of the solution of Burgers' equation (solid line) and its pseudospectral viscosity approximation before filtering (dashed line) and after filtering (dotted line).*

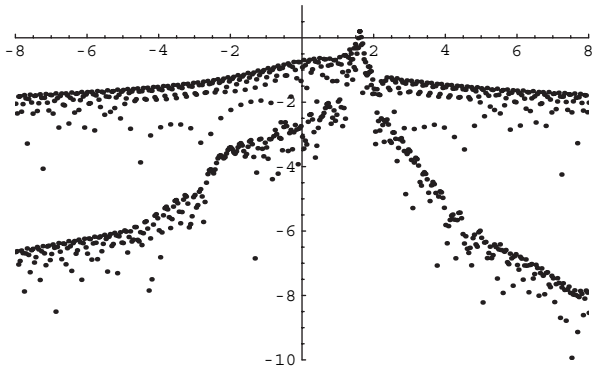

FIG. 6.5. *Logarithms of the errors multiplied by $w^{1/2}$ for the pseudospectral viscosity approximation of the solution of Burgers' equation before filtering and after filtering.*

ρ is an even smooth function with compact support, θ is a positive number, and p is an integer that will typically be taken as $p = [O(N^\alpha)]$.

If φ is piecewise C^∞ and has a jump discontinuity at $x_0 \in \mathbb{R}$, it is proven in [18] that for $\rho \in C^m$, $\alpha = \frac{1}{2} - \frac{1}{3m+1}$, and $|x - x_0| > \theta$ one has

$$e^{x^2/2} \left| \varphi(x) - \mathcal{F}^{\theta,p}[\pi_N \varphi](x) \right| = O(N^\gamma), \qquad \text{with } \gamma = -\frac{m}{4} + \frac{m}{3m+1}.$$

Spectral convergence is thus recovered, away from the discontinuity, by choosing $\rho \in C^\infty$ and $p = [O(\sqrt{N})]$.

When this filtering procedure is applied to the pseudospectral viscosity approximation, smaller artificial viscosity can be allowed. Although more oscillations will appear, the shock will be better resolved, and it is the task of the filter to diminish the oscillatory behavior and improve the convergence rate away from the discontinuity.

From the definition of $\tilde{q}_k^3$, increasing m_N makes almost no difference in the amount of viscosity introduced. Therefore we have modified only the parameter ϵ_N.

In Figure 6.4 we present the pseudospectral approximation u_N, with $\tilde{q}_k = \tilde{q}_k^3$, $m_N = [5N^{0.16}]$, and $\epsilon_N = 0.05N^{0.33}$, as well as the filtered approximation $\mathcal{F}^{\theta,p}[u_N]$ with parameters $p = [5\sqrt{N}]$, $\rho(x) = \exp(-\frac{5x^2}{1-x^2})\chi_{[-1,1]}(x)$, and $\theta = 0.9$, for $N = 257$. Figure 6.5 corresponds to the graphs of the logarithms of

$$e^{x^2/2}|u(x,t) - u_{257}(x,t)| \quad \text{and} \quad e^{x^2/2}|u(x,t) - \mathcal{F}^{\theta,p}[u_{257}](x,t)|.$$

The postprocessed solution gives a clear improvement in the convergence rate at points not too close to the discontinuity. However, the resolution of the shock is quite poor, and a better postprocessing technique should be developed in order to retain the good properties of the viscosity approximation near discontinuities.

NEW SOLUTION AND ANALYTICAL TECHNIQUES OF THE IMPLICIT NUMERICAL METHOD FOR THE ANOMALOUS SUBDIFFUSION EQUATION*

P. ZHUANG†, F. LIU‡, V. ANH§, AND I. TURNER§

Abstract. A physical-mathematical approach to anomalous diffusion is based on a generalized diffusion equation containing derivatives of fractional order. In this paper, an anomalous subdiffusion equation (ASub-DE) is considered. A new implicit numerical method (INM) and two solution techniques for improving the order of convergence of the INM for solving the ASub-DE are proposed. The stability and convergence of the INM are investigated by the energy method. Some numerical examples are given. The numerical results demonstrate the effectiveness of theoretical analysis. These methods and supporting theoretical results can also be applied to other fractional integro-differential equations and higher-dimensional problems.

Key words. anomalous subdiffusion equation, implicit numerical method, stability, convergence, fractional integro-differential equation

1. Introduction.

Fractional differential equations have attracted considerable interest because of their ability to model many phenomena, for example, in fractal media, mathematical biology, chemistry, statistical mechanics, and biochemistry due to anomalous diffusion effects in constrained environments. A physical-mathematical approach to anomalous diffusion may be based on generalized partial differential equations containing derivatives of fractional order in space, or time, or space-time [1, 2]. These fractional diffusion equations can be derived asymptotically from basic random walk models or from generalized master equations. Anomalous diffusion, known since Richardson's treatise on turbulent diffusion in 1926, is ubiquitous in physical and biological systems where trapping and binding of particles can occur. In particular, the trapping of Brownian particles by static traps randomly distributed over either a Euclidean or a disordered substrate is a fundamental problem of nonequilibrium statistical mechanics and chemistry with a very wide range of applications [3]. Fractional kinetic equations have proved particularly useful in the context of anomalous subdiffusion [1]. The mean square displacement of the particles from the original starting site is no longer linear in time but verifies a generalized Fick's second law. Subdiffusive motion is characterized by an asymptotic long-time behavior of the mean square displacement of the form

$$\langle x^2(t)\rangle \sim \frac{2K_\gamma}{\Gamma(1+\gamma)}t^\gamma, \quad t \to \infty, \tag{1.1}$$

where γ (with $0 < \gamma < 1$) is the anomalous diffusion exponent and K_γ is the generalized diffusion coefficient. Ordinary (or Brownian) diffusion corresponds to $\gamma = 1$ with $K_1 = D$ (the ordinary diffusion coefficient).

Subdiffusive motion is particularly important in the context of complex systems such as glassy and disordered materials, in which pathways are constrained for geometric or energetic reasons. For anomalous subdiffusive random walkers, the continuum description via the ordinary diffusion equation is replaced by the fractional diffusion equation. It has been suggested that the probability density function $u(x,t)$ that describes anomalous subdiffusion particles follows the anomalous subdiffusion equation (ASub-DE) [1, 3, 4, 5]:

$$\frac{\partial u}{\partial t} = \frac{\partial^{1-\gamma}}{\partial t^{1-\gamma}}\left[K_\gamma \frac{\partial^2 u}{\partial x^2}\right], \quad 0 \le x \le a, \quad 0 < t \le T, \tag{1.2}$$

where $u(x,t)$ is the probability density that the particle that started at 0 at time 0 is at x at time t and $\frac{\partial^{1-\gamma} u}{\partial t^{1-\gamma}}$ denotes the Riemann–Liouville fractional derivative of order $1-\gamma$ defined by

$$\frac{\partial^{1-\gamma}}{\partial t^{1-\gamma}} u(x,t) = \frac{1}{\Gamma(\gamma)} \frac{\partial}{\partial t} \int_0^t \frac{u(x,\eta)}{(t-\eta)^{1-\gamma}} d\eta, \tag{1.3}$$

with $0 \le \gamma \le 1$. For $\gamma = 1$ one recovers the identity operator and for $\gamma = 0$ the ordinary first-order derivative. The integro-differential nature of the Riemann–Liouville fractional operator according to (1.3) ensures the non-Markovian nature of the subdiffusive process defined by (1.2). Equation (1.2) can be rewritten as the following equivalent time fractional diffusion equation:

$$\frac{\partial^\gamma}{\partial t^\gamma} u(x,t) - \frac{t^{-\gamma}}{\Gamma(1-\gamma)} u_0(x) = K_\gamma \frac{\partial^2}{\partial x^2} u(x,t), \tag{1.4}$$

where $u_0(x)$ is the initial value.

Anomalous subdiffusion equations have been widely studied. Schneider and Wyss [6] considered the following time fractional diffusion and wave equations:

$$\frac{\partial^\gamma u(\mathbf{x},t)}{\partial t^\gamma} = \frac{\partial^2 u(\mathbf{x},t)}{\partial \mathbf{x}^2}, \quad 0 < \gamma \le 2. \tag{1.5}$$

They derived the corresponding Green functions in closed form for arbitrary space dimensions in terms of Fox functions. Huang and Liu [7] considered the time fractional diffusion equation in n-dimensional whole space and half-space. They investigated the explicit relationships between the problems in whole space with the corresponding problems in half-space by the Fourier–Laplace transform. Mainardi [8] derived the fundamental solutions for the fractional diffusion-wave equation. Anh and Leonenko [9] presented spectral analysis of the fractional kinetic equation with random data; Gorenflo, Iskenderov, and Luchko [10] investigated mappings between solutions of fractional diffusion-wave equations; Kilbas, Saigo, and Saxena [11] presented solutions of Volterra integro-differential equations with kernels given in the form of generalized Mittag–Leffler functions.

Different numerical methods for solving the space, or time, or space-time fractional partial differential equations have been proposed. Liu et al. [12, 13] transformed the space fractional partial differential equation into a system of ordinary differential

equations (method of lines) that was then solved by using backward differentiation formulas. McLean, Sloan, and Thomée [14] considered time discretization via a Laplace transformation of an inhomogeneous integro-differential equation of parabolic type. The method is combined with a finite element discretization in the spatial variables to yield a fully discrete method. McLean, Mustrapha, and Thomee [15] also proposed numerical methods for some fractional differential equations and gave a convergence and stability analysis. Roop [16] investigated the numerical approximation of the variational solution to the fractional advection dispersion equation. Meerschaert and Tadjeran [17] examined finite difference approximations for fractional advection-dispersion flow equations. Shen and Liu [18] proposed an explicit finite difference approximation for the space fractional diffusion equation and gave an error analysis. Liu et al. [19] discussed an approximation of the Lévy–Feller advection-dispersion process by a random walk and finite difference method. Zhang, Liu, and Anh [20] proposed a numerical approximation for the Lévy–Feller fractional diffusion equation. They used the finite difference method to discretize the integro-differential equation and gave an analysis of stability and convergence in the L_1-norm. Liu et al. [21] derived an analysis of a discrete non-Markovian random walk approximation for the time fractional diffusion equation. Zhuang and Liu [22] analyzed an implicit difference approximation for the time fractional diffusion equation, and the stability and convergence of the method were also discussed. Liu et al. [23] also discussed the stability and convergence of the difference methods for the space-time fractional advection-diffusion equation. Lin and Liu [24] proposed the high order (2–6) approximations of the fractional ordinary differential equation and discussed the consistency, convergence, and stability of these fractional high order methods.

There have been some attempts on deriving numerical methods and analysis techniques for the ASub-DE (1.2). Cao, Burrage, and Abdullah [25] presented a variable coefficient fractional derivative approximation scheme and used embedding techniques to develop a variable step-size implementation for solving time fractional differential equations. They gave a stability and order analysis for a fractional Euler method and a fractional trapezoidal method. Yuste and Acedo [4] proposed an explicit finite difference method and a new von Neumann-type stability analysis for the ASub-DE (1.2). Langlands and Henry [5] also investigated this problem and proposed an implicit numerical scheme (L1 approximation). However, effective numerical methods and supporting error analyses for the ASub-DE (1.2) are still limited. The main purpose of this paper is to solve and analyze this problem by introducing an implicit numerical method and new solution techniques.

In section 2, an implicit numerical method (INM) is proposed. In sections 3 and 4, stability and convergence analyses are given for the INM. In section 5, two solution techniques to improve the order of convergence are presented. Finally, some numerical results are given in section 6 to evaluate the method.

2. An implicit numerical method for the ASub-DE. In this section, we construct a new implicit numerical method for the ASub-DE

$$\frac{\partial u}{\partial t} = \frac{\partial^{1-\gamma}}{\partial t^{1-\gamma}}\left[K_\gamma \frac{\partial^2 u}{\partial x^2} + f(x,t)\right], \quad 0 \le x \le a,\ 0 < t \le T, \tag{2.1}$$

with initial and boundary conditions:

$$u(x,0) = \phi(x), \quad 0 \le x \le a, \tag{2.2}$$

$$u(0,t) = \varphi_1(t), \quad u(a,t) = \varphi_2(t), \quad 0 \le t \le T, \tag{2.3}$$

where $0 < \gamma < 1$.

Yuste and Acedo [4] combined the forward time centered space (FTCS) method, which is well known for the numerical integration of ordinary diffusion equations, with the Grünwald–Letnikov discretization of the Riemann–Liouville derivative to obtain an explicit FTCS scheme for the ASub-DE (1.2). However, they did not give the convergence analysis and pointed out that this is not such an easy task when implicit methods are considered. Langlands and Henry [5] proposed an implicit numerical scheme (L1 approximation) for the ASub-DE (1.2) and discussed the accuracy and stability of this scheme. However, the global accuracy of the implicit numerical scheme has not been derived, and it seems that the unconditional stability for all γ in the range $0 < \gamma \leq 1$ has not been established.

Let $\Omega = [0, a] \times [0, T]$. We define the function space

$$G(\Omega) = \left\{ w(x,t) | \frac{\partial^2 w}{\partial x^2} \in C^2(\Omega) \text{ and } \frac{\partial^5 w}{\partial x^4 \partial t} \in C(\Omega) \right\}.$$

In this paper, we suppose the continuous problem (2.1)–(2.3) has a smooth solution $u(x,t) \in G(\Omega)$.

Define $t_k = k\tau, k = 0, 1, 2, \ldots, n, x_i = ih, i = 0, 1, 2, \ldots, m$, where $\tau = \frac{T}{n}$ and $h = \frac{a}{m}$ are the space and time step sizes, respectively. For convenience, we introduce the following notations:

$$Lu(x,t) = K_\gamma \frac{\partial^2 u(x,t)}{\partial x^2},$$
$$\delta_x^2 u(x,t) = u(x+h,t) - 2u(x,t) + u(x-h,t),$$

and

$$b_j = (j+1)^\gamma - j^\gamma, \quad j = 0, 1, 2, \ldots, n. \tag{2.4}$$

By integrating both sides of (2.1), we obtain

$$\begin{aligned} u(x_i, t_{k+1}) &= u(x_i, t_k) + \frac{1}{\Gamma(\gamma)} \int_0^{t_{k+1}} \frac{Lu(x_i,\eta) + f(x_i,\eta)}{(t_{k+1} - \eta)^{1-\gamma}} d\eta \\ &\quad - \frac{1}{\Gamma(\gamma)} \int_0^{t_k} \frac{Lu(x_i,\eta) + f(x_i,\eta)}{(t_k - \eta)^{1-\gamma}} d\eta \\ &= u(x_i, t_k) + \frac{1}{\Gamma(\gamma)} \int_0^{\tau} \frac{Lu(x_i,\eta) + f(x_i,\eta)}{(t_{k+1} - \eta)^{1-\gamma}} d\eta \\ &\quad + \frac{1}{\Gamma(\gamma)} \int_0^{t_k} \frac{Lv(x_i,\eta) + g(x_i,\eta)}{(t_k - \eta)^{1-\gamma}} d\eta, \end{aligned} \tag{2.5}$$

where $v(x,t) = u(x, t+\tau) - u(x,t)$ and $g(x,t) = f(x, t+\tau) - f(x,t)$. By letting

$$I_1 = \frac{1}{\Gamma(\gamma)} \int_0^{\tau} \frac{Lu(x_i,\eta) + f(x_i,\eta)}{(t_{k+1} - \eta)^{1-\gamma}} d\eta$$

and

$$I_2 = \frac{1}{\Gamma(\gamma)} \int_0^{t_k} \frac{Lv(x_i,\eta) + g(x_i,\eta)}{(t_k - \eta)^{1-\gamma}} d\eta,$$

(2.5) can be written as

$$u(x_i, t_{k+1}) = u(x_i, t_k) + I_1 + I_2.$$

For I_1, we can use the following approximation:

$$\begin{aligned} I_1 &= \frac{1}{\Gamma(\gamma)} \int_0^\tau \frac{Lu(x_i,\tau) + f(x_i,\tau)}{(t_{k+1}-\eta)^{1-\gamma}} d\eta + R_{11} \\ &= \frac{\tau^\gamma}{\Gamma(\gamma+1)} \left[(k+1)^\gamma - k^\gamma\right] \left[Lu(x_i,\tau) + f(x_i,\tau)\right] + R_{11} \\ &= \frac{\tau^\gamma}{\Gamma(\gamma+1)} b_k \left[K_\gamma \frac{1}{h^2} \delta_x^2 u(x_i,\tau) + R_{12} + f(x_i,\tau)\right] + R_{11} \\ &= \frac{\tau^\gamma}{\Gamma(\gamma+1)} b_k \left[K_\gamma \frac{1}{h^2} \delta_x^2 u(x_i,\tau) + f(x_i,\tau)\right] + R_1, \end{aligned}$$

where

$$\begin{aligned} R_{11} &= \frac{1}{\Gamma(\gamma)} \int_0^\tau \frac{Lu(x_i,\eta) - Lu(x_i,\tau) + f(x_i,\eta) - f(x_i,\tau)}{(t_{k+1}-\eta)^{1-\gamma}} d\eta, \\ R_{12} &= K_\gamma \left[\frac{\partial^2 u(x_i,\tau)}{\partial x^2} - \frac{1}{h^2} \delta_x^2 u(x_i,\tau)\right], \end{aligned}$$

and $R_1 = \frac{b_k \tau^\gamma}{\Gamma(\gamma+1)} R_{12} + R_{11}$. By noting that

$$\begin{aligned} Lu(x_i,\eta) + f(x_i,\eta) &= K_\gamma \frac{\partial^2 u(x_i,\eta)}{\partial x^2} + f(x_i,\eta) \\ &= K_\gamma \frac{\partial^2 u(x_i,\tau)}{\partial x^2} + f(x_i,\tau) + \left[K_\gamma \frac{\partial^3 u(x_i,\xi_1)}{\partial x^2 \partial t} + \frac{\partial f(x_i,\xi_1)}{\partial t}\right](\eta - \tau), \end{aligned}$$

where $0 \le \eta \le \xi_1 \le \tau$, we obtain

$$|R_{11}| \le C_1 \tau \frac{1}{\Gamma(\gamma)} \int_0^\tau \frac{1}{(t_{k+1}-\eta)^{1-\gamma}} d\eta \le \frac{C_1 \tau^{1+\gamma}}{\Gamma(\gamma+1)} b_k.$$

Again, it is apparent that

$$|R_{12}| \le C_2 h^2.$$

Hence, we have $|R_1| \le C b_k \tau^\gamma (\tau + h^2)$.

As for I_2, we can obtain the following approximation:

$$\begin{aligned} I_2 &= \frac{1}{\Gamma(\gamma)} \sum_{j=0}^{k-1} \int_{t_j}^{t_{j+1}} \frac{Lv(x_i,\eta) + g(x_i,\eta)}{(t_k-\eta)^{1-\gamma}} d\eta \\ &= \frac{1}{\Gamma(\gamma)} \sum_{j=0}^{k-1} \int_{t_j}^{t_{j+1}} \frac{Lv(x_i,t_{j+1}) + g(x_i,t_{j+1})}{(t_k-\eta)^{1-\gamma}} d\eta + R_{21} \\ &= \frac{\tau^\gamma}{\Gamma(\gamma+1)} \sum_{j=0}^{k-1} b_{k-j-1} \left[Lv(x_i,t_{j+1}) + g(x_i,t_{j+1})\right] + R_{21} \\ &= \frac{\tau^\gamma}{\Gamma(\gamma+1)} \sum_{j=0}^{k-1} b_{k-j-1} \left[L_h v(x_i,t_{j+1}) + g(x_i,t_{j+1})\right] + R_{22} + R_{21}, \end{aligned}$$

where

$$R_{21} = \frac{1}{\Gamma(\gamma)} \sum_{j=0}^{k-1} \int_{t_j}^{t_{j+1}} \frac{Lv(x_i,\eta) - Lv(x_i,t_{j+1}) + g(x_i,\eta) - g(x_i,t_{j+1})}{(t_k-\eta)^{1-\gamma}} d\eta,$$

$$R_{22} = \frac{\tau^\gamma}{\Gamma(\gamma+1)} \sum_{j=0}^{k-1} b_{k-j-1} \left[Lv(x_i,t_{j+1}) - L_h v(x_i,t_{j+1}) \right],$$

and $L_h u(x_i,t_j) = K_\gamma \frac{1}{h^2} \delta_x^2 u(x_i,t_j)$.

LEMMA 2.1. *Let $u(x,t) \in G(\Omega)$ be the solution of (2.1)–(2.3). Then we have*

(1) $|R_{21}| \le C\tau^2$;

(2) $|R_{22}| \le C\tau h^2$.

Proof. (1) When $t_j \le \eta \le t_{j+1}$, we have

$$\begin{aligned} Lv(x_i,\eta+\tau) + g(x_i,\eta+\tau) &= K_\gamma \frac{\partial^2 v(x_i,\eta+\tau)}{\partial x^2} + g(x_i,\eta+\tau) \\ &= K_\gamma \frac{\partial^2 v(x_i,t_{j+2})}{\partial x^2} + g(x_i,t_{j+2}) \\ &\quad + K_\gamma \frac{\partial^3 v(x_i,\widetilde{\eta}_1)}{\partial x^2 \partial t}(\eta - t_{j+1}) + \frac{\partial g(x_i,\widetilde{\eta}_1)}{\partial t}(\eta - t_{j+1}), \end{aligned}$$

where $\eta+\tau \le \widetilde{\eta}_1 \le t_{j+2}$.

Again,

$$\frac{\partial^3 v(x_i,\widetilde{\eta}_1)}{\partial x^2 \partial t} = \frac{\partial^3 u(x_i,\widetilde{\eta}_1+\tau)}{\partial x^2 \partial t} - \frac{\partial^3 u(x_i,\widetilde{\eta}_1)}{\partial x^2 \partial t} = \frac{\partial^4 u(x_i,\widetilde{\eta}_2)}{\partial x^2 \partial t^2}\tau,$$

$$\frac{\partial g(x_i,\widetilde{\eta}_1)}{\partial t} = \frac{\partial f(x_i,\widetilde{\eta}_1+\tau)}{\partial t} - \frac{\partial f(x_i,\widetilde{\eta}_1)}{\partial t} = \frac{\partial^2 f(x_i,\widetilde{\eta}_3)}{\partial t^2}\tau,$$

where $\widetilde{\eta}_1 \le \widetilde{\eta}_2, \widetilde{\eta}_3 \le \widetilde{\eta}_1 + \tau$. Consequently,

$$|Lu(x_i,\eta+\tau) - Lu(x_i,\eta) - [Lu(x_i,t_{j+2}) - Lu(x_i,t_{j+1})]\,| \le C_3\tau^2.$$

Thus, we have

$$|R_{21}| \le C_3\tau^2 \frac{1}{\Gamma(\gamma)} \int_0^{t_k} \frac{d\eta}{(t_k-\eta)^{1-\gamma}} \le C\tau^2.$$

(2) By using Taylor's formula, we obtain

$$\begin{aligned} Lv(x_i,t_{j+1}) &= L_h v(x_i,t_{j+1}) + \frac{h^2}{12}\frac{\partial^4 v(\xi_2,t_{j+1})}{\partial x^4} \\ &= L_h v(x_i,t_{j+1}) + \frac{h^2}{12}\left[\frac{\partial^4 u(\xi_2,t_{j+2})}{\partial x^4} - \frac{\partial^4 u(\xi_2,t_{j+1})}{\partial x^4}\right] \\ &= L_h v(x_i,t_{j+1}) + \frac{h^2\tau}{12}\frac{\partial^5 u(\xi_2,\widetilde{\eta}_4)}{\partial x^4 \partial t}, \\ &|Lv(x_i,t_{j+1}) - L_h v(x_i,t_{j+1})| \le C_3\tau h^2 \tau. \end{aligned}$$

Thus, we have

$$|R_{22}| \le C_3\tau h^2 \frac{\tau^\gamma}{\Gamma(\gamma+1)} \sum_{j=0}^{k-1} b_{k-j+1} \le C\tau h^2. \qquad \square$$

From the above results, we obtain

$$\begin{aligned} u(x_i,t_{k+1}) &= u(x_i,t_k) + r_1 b_k \delta_x^2 u(x_i,\tau) + r_2 b_k f(x_i,\tau) \\ &\quad + r_1 \sum_{j=0}^{k-1} b_{k-j-1} \left[\delta_x^2 u(x_i,t_{j+2}) - \delta_x^2 u(x_i,t_{j+1})\right] \\ &\quad + r_2 \sum_{j=0}^{k-1} b_{k-j-1} \left[f(x_i,t_{j+2}) - f(x_i,t_{j+1})\right] + R_i^{k+1}, \end{aligned}$$

where $r_1 = K_\gamma \frac{\tau^\gamma}{\Gamma(\gamma+1)h^2}, r_2 = \frac{\tau^\gamma}{\Gamma(\gamma+1)}$, and

$$|R_i^{k+1}| \le C(b_k\tau^\gamma + \tau)(\tau + h^2). \tag{2.6}$$

LEMMA 2.2. *The coefficients $b_k (k = 0, 1, 2, \ldots)$ defined by (2.4) satisfy:*
(1) $b_0 = 1, b_k > 0, k = 0, 1, 2, \ldots$;
(2) $b_k > b_{k+1}, k = 0, 1, 2, \ldots$;
(3) *there exists a positive constant $C > 0$ such that*

$$\tau \le C b_k \tau^\gamma, \quad k = 1, 2, \ldots.$$

Proof. Let $\psi_1(x) = x^\gamma$ and $\psi_2(x) = (x+1)^\gamma - x^\gamma$. For $x > 0$, it can be seen that $\psi_1(x)$ is monotone increasing and $\psi_2(x)$ is monotone decreasing. Thus, (1) and (2) in Lemma 2.2 hold.

For (3) in Lemma 2.2, by using

$$\lim_{n\to\infty} \frac{n^{\gamma-1}}{b_n} = \lim_{n\to\infty} \frac{n^{-1}}{(1+n^{-1})^\gamma - 1} = \frac{1}{\gamma},$$

we have

$$\frac{n^{\gamma-1}}{b_n} \le C_1,$$

or

$$n^{-1} \le C_1 b_n n^{-\gamma} \le C_1 b_k n^{-\gamma}.$$

Thus, from $\tau = \frac{T}{n}$, the inequality (3) can be obtained. ∎

Let $\mathbf{R}^k = (R_1^k, R_2^k, \ldots, R_{m-1}^k)^T$. By applying Lemma 2.2 with (2.6), we obtain the following lemma.

LEMMA 2.3. *Suppose that $\|\mathbf{R}^k\|_2 = \sqrt{\sum_{i=1}^{m-1} |R_i^k|^2}$. If $u(x,t) \in G(\Omega)$ is the solution of (2.1)–(2.3), then we have*

$$\|\mathbf{R}^{k+1}\|_2 \le C b_k \tau^\gamma (\tau + h^2).$$

Let u_i^k be the numerical approximation to $u(x_i,t_k)$, $f_i^k = f(x_i,t_k)$, and introduce the following notations:

$$\delta_x^2 u_i^k = u_{i+1}^k - 2u_i^k + u_{i-1}^k, \quad \Delta_x u_i^k = u_{i+1}^k - u_i^k. \tag{2.7}$$

We obtain the following implicit difference scheme:

$$\begin{aligned} u_i^{k+1} &= u_i^k + r_1 b_k \delta_x^2 u_i^1 + r_2 b_k f_i^1 \\ &\quad + r_1 \sum_{j=0}^{k-1} b_{k-j-1} \left[\delta_x^2 u_i^{j+2} - \delta_x^2 u_i^{j+1}\right] + r_2 \sum_{j=0}^{k-1} b_{k-j-1} \left[f_i^{j+2} - f_i^{j+1}\right]. \end{aligned}$$

The INM can be rewritten in the following form:

$$
\begin{aligned}
u_i^{k+1} = u_i^k + r_1\delta_x^2 u_i^{k+1} + r_1\sum_{j=0}^{k-1}(b_{j+1}-b_j)\delta_x^2 u_i^{k-j} \\
+ r_2 f_i^{k+1} + r_2\sum_{j=0}^{k-1}(b_{j+1}-b_j) f_i^{k-j},
\end{aligned} \tag{2.8}
$$

for $i = 1, 2, \ldots, m-1, k = 0, 1, 2, \ldots, n-1$.

The initial and boundary conditions are

$$
\begin{aligned}
&u_i^0 = \phi(ih), \quad i = 0, 1, 2, \ldots, m, \\
&u_0^k = \varphi_1(k\tau), \quad u_m^k = \varphi_2(k\tau), \quad k = 1, 2, \ldots, n.
\end{aligned} \tag{2.9}
$$

Equations (2.8) and (2.9) can be rewritten as the following matrix form:

$$
\begin{cases}
A\mathbf{u}^1 = \mathbf{u}^0 + r_1\mathbf{v}^1 + r_2\mathbf{f}^{\mathbf{1}}, \\
A\mathbf{u}^{k+1} = \mathbf{u}^k + r_1\mathbf{v}^{k+1} + r_1\mathbf{w}^{k+1} + r_2\mathbf{g}^{\mathbf{k+1}}, k > 0, \\
\mathbf{u}^0 = \mathbf{\Phi},
\end{cases} \tag{2.10}
$$

where

$$
A = \begin{bmatrix}
1+2r_1 & -r_1 & 0 & \cdots & 0 & 0 \\
-r_1 & 1+2r_1 & -r_1 & \cdots & 0 & 0 \\
0 & -r_1 & 1+2r_1 & \cdots & 0 & 0 \\
\cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\
0 & 0 & 0 & \ldots & 1+2r_1 & -r_1 \\
0 & 0 & 0 & \ldots & -r_1 & 1+2r_1
\end{bmatrix}, \tag{2.11}
$$

$$
\mathbf{u}^k = \begin{bmatrix} u_1^k \\ u_2^k \\ \vdots \\ u_{m-2}^k \\ u_{m-1}^k \end{bmatrix}, \quad
\mathbf{f}^k = \begin{bmatrix} f_1^k \\ f_2^k \\ \vdots \\ f_{m-2}^k \\ f_{m-1}^k \end{bmatrix}, \quad
\mathbf{v}^{k+1} = \begin{bmatrix} u_0^{k+1} \\ 0 \\ \vdots \\ 0 \\ u_m^{k+1} \end{bmatrix}, \quad
\mathbf{\Phi} = \begin{bmatrix} \phi_1 \\ \phi_2 \\ \vdots \\ \phi_{m-2} \\ \phi_{m-1} \end{bmatrix}, \tag{2.12}
$$

and $\mathbf{w}^{k+1} = \sum_{j=0}^{k-1}(b_{j+1}-b_j)\delta_x^2\mathbf{u}^{k-j}$, $\mathbf{g}^{k+1} = \mathbf{f}^{k+1} + \sum_{j=0}^{k-1}(b_{j+1}-b_j)\mathbf{f}^{k-j}$, $\phi_i = \phi(ih)$.

In (2.11) we see that the matrix A is strictly diagonally dominant with positive diagonal terms and nonpositive off-diagonal terms. Hence, the following theorem can be obtained.

THEOREM 2.4. *The discretization matrix A is invertible. Furthermore, the system* (2.8) *and* (2.9) *has a unique solution.*

3. Stability of the INM. For $\mathbf{u} = (u_1, u_2, \ldots, u_{m-1})^T, \mathbf{v} = (v_1, v_2, \ldots, v_{m-1})^T$, we define

$$
(\mathbf{u}, \mathbf{v}) = \sum_{j=1}^{m-1} u_j v_j h, \ \|\mathbf{u}\|_2 = \sqrt{(\mathbf{u}, \mathbf{u})} = \left(\sum_{j=1}^{m-1} u_j^2 h\right)^{\frac{1}{2}}. \tag{3.1}
$$

We suppose that $\widetilde{u}_i^k, \ i = 0, 1, 2, \ldots, m; \ j = 0, 1, 2, \ldots, n$ is the approximate solution of (2.8) and (2.9). The rounding error $\varepsilon_i^k = \widetilde{u}_i^k - u_i^k$ satisfies

$$
\varepsilon_i^{k+1} = \varepsilon_i^k + r_1\delta_x^2\varepsilon_i^{k+1} + r_1\sum_{j=0}^{k-1}(b_{j+1}-b_j)\delta_x^2\varepsilon_i^{k-j} \tag{3.2}
$$

and

$$\varepsilon_0^k = 0, \quad \varepsilon_m^k = 0, \quad k = 1, 2, \ldots, n. \tag{3.3}$$

Let $\mathbf{E}^k = (\varepsilon_1^k, \varepsilon_2^k, \ldots, \varepsilon_{m-1}^k)^T$. By multiplying (3.2) by $h\varepsilon_i^{k+1}$ and summing i from 1 to $m-1$, we obtain

$$\begin{aligned}
\|\mathbf{E}^{k+1}\|_2^2 &= (\mathbf{E}^{k+1}, \mathbf{E}^k) + r_1(\delta_x^2\mathbf{E}^{k+1}, \mathbf{E}^{k+1}) + r_1\sum_{j=0}^{k-1}(b_{j+1}-b_j)(\delta_x^2\mathbf{E}^{k-j}, \mathbf{E}^{k+1}) \\
&= (\mathbf{E}^{k+1}, \mathbf{E}^k) - r_1[(\varepsilon_1^{k+1})^2 h + \|\Delta_x\mathbf{E}^{k+1}\|_2^2] \\
&\quad + r_1\sum_{j=0}^{k-1}(b_{j+1}-b_j)[-\varepsilon_1^{k-j}\varepsilon_1^{k+1}h - (\Delta_x\mathbf{E}^{k-j}, \Delta_x\mathbf{E}^{k+1})] \\
&\le \frac{1}{2}[\|\mathbf{E}^{k+1}\|_2^2 + \|\mathbf{E}^k\|_2^2] - r_1|\varepsilon_1^{k+1}|^2 h - r_1\|\Delta_x\mathbf{E}^{k+1}\|_2^2 \\
&\quad + \frac{r_1}{2}\sum_{j=0}^{k-1}(b_j - b_{j+1})[|\varepsilon_1^{k+1}|^2 h + |\varepsilon_1^{k-j}|^2 h] \\
&\quad + \frac{r_1}{2}\sum_{j=0}^{k-1}(b_j - b_{j+1})[\|\Delta_x\mathbf{E}^{k-j}\|_2^2 + \|\Delta_x\mathbf{E}^{k+1}\|_2^2].
\end{aligned}$$

By noting that $\sum_{j=0}^{k-1}(b_j - b_{j+1}) = b_0 - b_k = 1 - b_k$ and $b_k > 0$, we have

$$\begin{aligned}
\|\mathbf{E}^{k+1}\|_2^2 &\le \frac{1}{2}[\|\mathbf{E^{k+1}}\|_2^2 + \|\mathbf{E^k}\|_2^2] - \frac{r_1}{2}(1+b_k)[|\varepsilon_1^{k+1}|^2 h + \|\Delta_x\mathbf{E}^{k+1}\|_2^2] \\
&\quad + \frac{r_1}{2}\sum_{j=0}^{k-1}(b_j - b_{j+1})(|\varepsilon_1^{k-j}|^2 h + \|\Delta_x\mathbf{E}^{k-j}\|_2^2) \\
&\le \frac{1}{2}[\|\mathbf{E^{k+1}}\|_2^2 + \|\mathbf{E^k}\|_2^2] - \frac{r_1}{2}[|\varepsilon_1^{k+1}|^2 h + \|\Delta_x\mathbf{E}^{k+1}\|_2^2] \\
&\quad + \frac{r_1}{2}\sum_{j=0}^{k-1}(b_j - b_{j+1})(|\varepsilon_1^{k-j}|^2 h + \|\Delta_x\mathbf{E}^{k-j}\|_2^2),
\end{aligned}$$

i.e.,

$$\begin{aligned}
&\|\mathbf{E}^{k+1}\|_2^2 + r_1\sum_{j=0}^{k} b_j\{|\varepsilon_1^{k+1-j}|^2 h + \|\Delta_x\mathbf{E}^{k+1-j}\|_2^2\} \\
&\qquad \le \|\mathbf{E}^k\|_2^2 + r_1\sum_{j=0}^{k-1} b_j\{|\varepsilon_1^{k-j}|^2 h + \|\Delta_x\mathbf{E}^{k-j}\|_2^2\}.
\end{aligned} \tag{3.4}$$

By defining the energy norm $\|\mathbf{E}^k\|_E^2 = \|\mathbf{E}^k\|_2^2 + r_1\sum_{j=0}^{k-1} b_j\{|\varepsilon_1^{k-j}|^2 h + \|\Delta_x\mathbf{E}^{k-j}\|_2^2\}$, we have

$$\|\mathbf{E}^{k+1}\|_2^2 \le \|\mathbf{E}^{k+1}\|_E^2 \le \|\mathbf{E}^k\|_E^2 \le \cdots \le \|\mathbf{E}^1\|_E^2.$$

Because $\varepsilon_i^1 = \varepsilon_i^0 + r_1\delta_x^2\varepsilon_i^1$, we obtain

$$\begin{aligned}
\|\mathbf{E}^1\|_2^2 &= (\mathbf{E}^1, \mathbf{E}^0) + r_1(\delta_x^2\mathbf{E}^1, \mathbf{E}^1) \\
&= (\mathbf{E}^1, \mathbf{E}^0) - r_1[(\varepsilon_1^1)^2 h + \|\Delta_x\mathbf{E}^1\|_2^2] \\
&\le \tfrac{1}{2}[\|\mathbf{E}^1\|_2^2 + \|\mathbf{E}^0\|_2^2] - r_1|\varepsilon_1^1|^2 h - r_1\|\Delta_x\mathbf{E}^1\|_2^2,
\end{aligned}$$

i.e.,

$$\|\mathbf{E}^1\|_E^2 = \|\mathbf{E}^1\|_2^2 + r_1 \sum_{j=0}^{k} b_j \{|\varepsilon_1^{1-j}|^2 h + \|\Delta_x \mathbf{E}^{1-j}\|_2^2\} \le \|\mathbf{E}^0\|_2^2, \tag{3.5}$$

so that $\|\mathbf{E}^{k+1}\|_2^2 \le \|\mathbf{E}^0\|_2^2$.

Hence, the following theorem of stability is obtained.

THEOREM 3.1. *The fractional implicit numerical method defined by* (2.8) *is unconditionally stable.*

4. Convergence of the INM. In this section, we discuss the convergence of the INM. Let $u(x_i, t_k), i = 0, 1, 2, \ldots, m; k = 0, 1, 2, \ldots, n$ be the exact solution of the ASub-DE (2.1)–(2.3) at mesh point (x_i, t_k). Suppose that $u(x, t)$ is the solution of (2.1)–(2.3) and $u(x, t) \in G(\Omega)$.

Define

$$\eta_i^k = u(x_i, t_k) - u_i^k, \quad i = 0, 1, 2, \ldots, m; \quad k = 0, 1, 2, \ldots, n$$

and $\mathbf{Y}^k = (\eta_1^k, \eta_2^k, \ldots, \eta_{m-1}^k)^T$. By using $u_i^k = u(x_i, t_k) - \eta_i^k$, substitution into (2.8) leads to

$$\eta_i^{k+1} = \eta_i^k + r_1 \delta_x^2 \eta_i^{k+1} + r_1 \sum_{j=0}^{k-1} (b_{j+1} - b_j) \delta_x^2 \eta_i^{k-j} + R_i^{k+1}, \tag{4.1}$$

where $i = 1, 2, \ldots, m-1; k = 0, 1, 2, \ldots, n-1$, and

$$\eta_i^0 = 0, \quad i = 0, 1, \ldots, m,$$
$$\eta_0^k = \eta_m^k = 0, \quad k = 0, 1, \ldots, n.$$

By multiplying (4.1) by $h\eta_i^{k+1}$ and summing i from 1 to $m-1$, we obtain

$$\begin{aligned} \|\mathbf{Y}^{k+1}\|_2^2 &= (\mathbf{Y}^{k+1}, \mathbf{Y}^k) + r_1 (\delta_x^2 \mathbf{Y}^{k+1}, \mathbf{Y}^{k+1}) \\ &\quad + r_1 \sum_{j=0}^{k-1} (b_{j+1} - b_j)(\delta_x^2 \mathbf{Y}^{k-j}, \mathbf{Y}^{k+1}) + (\mathbf{R}^{k+1}, \mathbf{Y}^{k+1}). \end{aligned} \tag{4.2}$$

For $j = 0, 1, \ldots, k+1$, we have

$$(\delta_x^2 \mathbf{Y}^j, \mathbf{Y}^{k+1}) = -\eta_1^j \eta_1^{k+1} - (\Delta_x \mathbf{Y}^j, \Delta_x \mathbf{Y}^{k+1}).$$

By using $|v \cdot w| \le \sigma v^2 + \frac{1}{4\sigma} w^2$, $\sigma > 0$, we obtain

$$(\mathbf{Y}^{k+1}, \mathbf{Y}^j) \le \frac{1}{2} \left[\|\mathbf{Y}^{k+1}\|^2 + \|\mathbf{Y}^j\|^2 \right], \tag{4.3}$$

$$\eta_1^{k+1} \eta_1^j \le \frac{1}{2} \left[|\eta_1^{k+1}|^2 + |\eta_1^j|^2 \right], \tag{4.4}$$

and

$$|(\mathbf{R}^{k+1}, \mathbf{Y}^{k+1})| \le \frac{r_1 h^2 b_k}{a^2} \|\mathbf{Y}^{k+1}\|_2^2 + \frac{a^2}{4 r_1 h^2 b_k} \|\mathbf{R}^{k+1}\|_2^2. \tag{4.5}$$

Noting that $\sum_{j=0}^{k-1}(b_j - b_{j+1}) = b_0 - b_k = 1 - b_k$ and $b_k > 0$, similarly to the proof of the stability, we have

$$\begin{aligned}\|\mathbf{Y}^{k+1}\|_2^2 \le{}& \frac{1}{2}[\|\mathbf{Y}^{\mathbf{k+1}}\|_2^2 + \|\mathbf{Y}^k\|_2^2] - \frac{r_1}{2}(1+b_k)[|\eta_1^{k+1}|^2 h + \|\Delta_x \mathbf{Y}^{k+1}\|_2^2] \\ &+ \frac{r_1}{2}\sum_{j=0}^{k-1}(b_j - b_{j+1})(|\eta_1^{k-j}|^2 h + \|\Delta_x \mathbf{Y}^{k-j}\|_2^2) \\ &+ \frac{r_1 h^2 b_k}{a^2}\|\mathbf{Y}^{k+1}\|_2^2 + \frac{a^2}{4r_1 h^2 b_k}\|\mathbf{R}^{k+1}\|_2^2.\end{aligned} \tag{4.6}$$

LEMMA 4.1. *Given* $\|\mathbf{Y}^k\|_\infty = \max_{1\le i\le m-1}|\eta_i^k|$, *then*

$$\|\mathbf{Y}^k\|_2^2 \le a\|\mathbf{Y}^k\|_\infty^2 \le \frac{a^2}{2h^2}\left[h|\eta_1^k|^2 + \|\Delta_x \mathbf{Y}^k\|_2^2\right].$$

Proof. The first inequality is apparent.
For the second inequality, let $|\eta_{i_0}^k| = \max_{1\le i\le m-1}|\eta_i^k|$, and then

$$\eta_{i_0}^k = \eta_1^k + \sum_{j=1}^{i_0-1}\Delta_x \eta_j^k, \quad \eta_{i_0}^k = -\sum_{j=i_0}^{m-1}\Delta_x \eta_j^k.$$

Thus

$$2|\eta_{i_0}^k| \le |\eta_1^k| + \sum_{j=1}^{m-1}|\Delta_x \eta_j^k|.$$

By using the Cauchy–Schwarz inequality, we have

$$\begin{aligned}4|\eta_{i_0}^k|^2 &\le 2m\left[|\eta_1^k| + \sum_{j=1}^{m-1}|\Delta_x \eta_j^k|\right]^2 \\ &\le \frac{2a}{h^2}\left[h|\eta_1^k|^2 + \|\Delta_x \mathbf{Y}^k\|_2^2\right].\end{aligned}$$

Therefore,

$$\|\mathbf{Y}^k\|_\infty^2 \le \frac{a}{2h^2}\left[h|\eta_1^k|^2 + \|\Delta_x \mathbf{Y}^k\|_2^2\right]. \qquad \square$$

By applying Lemma 4.1, we have

$$\frac{r_1 h^2 b_k}{a^2}\|\mathbf{Y}^{k+1}\|_2^2 \le \frac{r_1 h^2 b_k}{a^2}\cdot a\|\mathbf{Y}^{k+1}\|_\infty^2 \le \frac{b_k}{2}r_1\left[|\eta_1^{k+1}|^2 h + \|\Delta_x \mathbf{Y}^{k+1}\|_2^2\right]. \tag{4.7}$$

Hence, from (4.6) and (4.7), we have

$$\begin{aligned}\|\mathbf{Y}^{k+1}\|_2^2 \le{}& \frac{1}{2}[\|\mathbf{Y}^{k+1}\|_2^2 + \|\mathbf{Y}^{\mathbf{k}}\|_2^2] - \frac{r_1}{2}[|\eta_1^{k+1}|^2 h + \|\Delta_x \mathbf{Y}^{k+1}\|_2^2] \\ &+ \frac{r_1}{2}\sum_{j=0}^{k-1}(b_j - b_{j+1})(|\eta_1^{k-j}|^2 h + \|\Delta_x \mathbf{Y}^{k-j}\|_2^2) + \frac{a^2}{4r_1 h^2 b_k}\|\mathbf{R}^{k+1}\|_2^2.\end{aligned}$$

Let $\rho_k = \|\mathbf{Y}^k\|_2^2 + r_1 \sum_{j=0}^{k-1} b_j \{|\eta_1^{k-j}|^2 h + \|\Delta_x \mathbf{Y}^{k-j}\|_2^2\}$, and then

$$\rho_{k+1} \le \rho_k + \frac{a^2}{4r_1 h^2 b_k} \|\mathbf{R}^{k+1}\|_2^2, \tag{4.8}$$

$$\rho_0 = 0. \tag{4.9}$$

According to Lemma 2.3, and $r_1 = K_r \frac{\tau^\gamma}{\Gamma(\gamma+1)h^2}$, we have

$$\rho_{k+1} \le \rho_k + C b_k \tau^\gamma (\tau + h^2)^2. \tag{4.10}$$

Hence, we obtain

$$\rho_{k+1} \le C \sum_{j=0}^{k} b_j \tau^\gamma (\tau + h^2)^2. \tag{4.11}$$

By noting that $\sum_{j=0}^{k} b_j \tau^\gamma = (k+1)^\gamma \tau^\gamma \le T^\gamma$ and $\|\mathbf{Y}^{k+1}\|_2^2 \le \rho_{k+1}$, we have

$$\|\mathbf{Y}^{k+1}\|_2^2 \le C T^\gamma (\tau + h^2)^2.$$

Consequently, the following theorem of convergence is obtained.

THEOREM 4.2. *Let $u(x,t) \in G(\Omega)$ be the solution of (2.1)–(2.3). Then the fractional implicit difference scheme defined by (2.8) is convergent, and there exists a positive constant $C > 0$ such that*

$$\|\mathbf{Y}^{k+1}\|_2 \le C(\tau + h^2), \quad k = 0, 1, 2, \ldots, n-1. \tag{4.12}$$

5. Improving the order of convergence of the INM. In this section, we propose two techniques to improve the rate of convergence of the INM.

5.1. The extrapolation method (EM). According to Theorem 4.2, we know that the INM converges at the rate $O(\tau + h^2)$. In order to improve the order of convergence, we apply the INM on a (coarse) grid $\Delta t = \tau$ and then on a finer grid of size $\tau/2$ with the same Δx. The extrapolated solution is then computed from $u(x_i, t) \approx 2u_i^{2k}(\tau/2) - u_i^k(\tau)$, $i = 1, 2, \ldots, m-1$, where $t = t_k$ on the coarse grid, while $t = t_{2k}$ on the fine grid. Here $u_i^k(\tau)$ and $u_i^{2k}(\tau/2)$ are numerical solutions on the coarse grid and the fine grid, respectively. Thus, the extrapolation method can be used to obtain a solution with convergence order $O(\tau^2 + h^2)$.

5.2. Improved difference scheme (IDS). We use a technique of increasing the order of local truncation error to obtain an IDS. By integrating both sides of (2.1) for t, we obtain

$$u(x_i, t_{k+1}) = u(x_i, 0) + \frac{1}{\Gamma(\gamma)} \int_0^{t_{k+1}} \frac{K_\gamma \frac{\partial^2 u(x_i,\eta)}{\partial x^2} + f(x_i, \eta)}{(t_{k+1} - \eta)^{1-\gamma}} d\eta,$$

or

$$u(x_i, t_{k+1}) = u(x_i, 0) + \frac{1}{\Gamma(\gamma)} \sum_{j=0}^{k} \int_{t_j}^{t_{j+1}} \frac{K_\gamma \frac{\partial^2 u(x_i,\eta)}{\partial x^2} + f(x_i, \eta)}{(t_{k+1} - \eta)^{1-\gamma}} d\eta.$$

LEMMA 5.1. *If the function $v(x,t)$ is sufficiently smooth, then*

$$v(x_i, \eta) = \frac{(t_{j+1} - \eta) v(x_i, t_j) + (\eta - t_j) v(x_i, t_{j+1})}{\tau} + O(\tau^2). \tag{5.1}$$

Proof. The estimate (5.1) can be obtained from the following formulas:

$$v(x_i,t_j)=v(x_i,\eta)+\frac{\partial v(x_i,\eta)}{\partial t}(t_j-\eta)+\frac{1}{2}\frac{\partial^2 v(x_i,\xi_1)}{\partial t}(t_j-\eta)^2,$$

$$v(x_i,t_{j+1})=v(x_i,\eta)+\frac{\partial v(x_i,\eta)}{\partial t}(t_{j+1}-\eta)+\frac{1}{2}\frac{\partial^2 v(x_i,\xi_2)}{\partial t}(t_{j+1}-\eta)^2,$$

where $t_j\le\xi_1\le\eta\le\xi_2\le t_{j+1}$. ∎

By applying Lemma 5.1, we have

$$\begin{aligned}u(x_i,t_{k+1})=u(x_i,0)&+r_1\sum_{j=0}^{k}\left[c_j^{(1)}\delta_x^2u(x_i,t_{k-j+1})+c_j^{(2)}\delta_x^2u(x_i,t_{k-j})\right]\\&+r_2\sum_{j=0}^{k}\left[c_j^{(1)}f(x_i,t_{k-j+1})+c_j^{(2)}f(x_i,t_{k-j})\right]+R_i^{k+1},\end{aligned}\tag{5.2}$$

where $r_1=\frac{K_\gamma\tau^\gamma}{\Gamma(\gamma+1)h^2}$, $r_2=\frac{\tau^\gamma}{\Gamma(\gamma+1)}$, and

$$c_j^{(1)}=(j+1)^\gamma-\frac{1}{\gamma+1}\left[(j+1)^{\gamma+1}-j^{\gamma+1}\right],\tag{5.3}$$

$$c_j^{(2)}=\frac{1}{\gamma+1}\left[(j+1)^{\gamma+1}-j^{\gamma+1}\right]-j^\gamma,\tag{5.4}$$

$$|R_i^{k+1}|\le Ct_{k+1}^{\gamma+1}(\tau^2+h^2).\tag{5.5}$$

Thus, we obtain the following improved difference scheme:

$$u_i^{k+1}=u_i^0+r_1\sum_{j=0}^{k}\left[c_j^{(1)}\delta_x^2u_i^{k-j+1}+c_j^{(2)}\delta_x^2u_i^{k-j}\right]+r_2\sum_{j=0}^{k}\left[c_j^{(1)}f_i^{k-j+1}+c_j^{(2)}f_i^{k-j}\right].$$

6. Numerical results. In order to demonstrate the effectiveness of our theoretical analysis, two examples are now presented. To simplify the computation, (2.8) is rewritten as

$$\begin{aligned}u_i^{l+1}-u_i^l=r_1\delta_x^2u_i^{l+1}&+r_1\sum_{j=0}^{l-1}(b_{j+1}-b_j)\delta_x^2u_i^{l-j}\\&+r_2f_i^{l+1}+r_2\sum_{j=0}^{l-1}(b_{j+1}-b_j)f_i^{l-j}.\end{aligned}\tag{6.1}$$

By summing l from 0 to $k-1$, we obtain

$$u_i^k=u_i^0+r_1\sum_{j=0}^{k-1}b_j\delta_x^2u_i^{k-j}+r_2\sum_{j=0}^{k-1}b_jf_i^{k-j},$$

where $i=1,2,\dots,m-1$; $k=1,2,\dots,n$.

Example 1. Consider the following ASub-DE:

$$\frac{\partial u(x,t)}{\partial t}=\frac{\partial^{1-\gamma}}{\partial t^{1-\gamma}}\left[0.5\Gamma(\gamma+3)\frac{\partial^2u(x,t)}{\partial x^2}+0.5\Gamma(\gamma+3)(t^2-t^{2+\gamma})e^x\right],\tag{6.2}$$

TABLE 6.1
The error $\|\mathbf{Y}^n\|_2$ for the INM, EM, and IDS and the effect of the grid size reduction at time $t = 1.0$ ($\gamma = 0.9$).

Δx	Δt	INM	EM	IDS
$\frac{1}{10}$	$\frac{1}{10}$	1.4252E-2	3.5158E-4	3.5663E-5
$\frac{1}{15}$	$\frac{1}{15}$	9.6200E-3	1.6191E-4	8.4894E-6
$\frac{1}{20}$	$\frac{1}{20}$	7.2613E-3	1.2173E-4	8.1641E-6
$\frac{1}{25}$	$\frac{1}{25}$	5.8285E-3	1.1443E-4	6.4540E-6

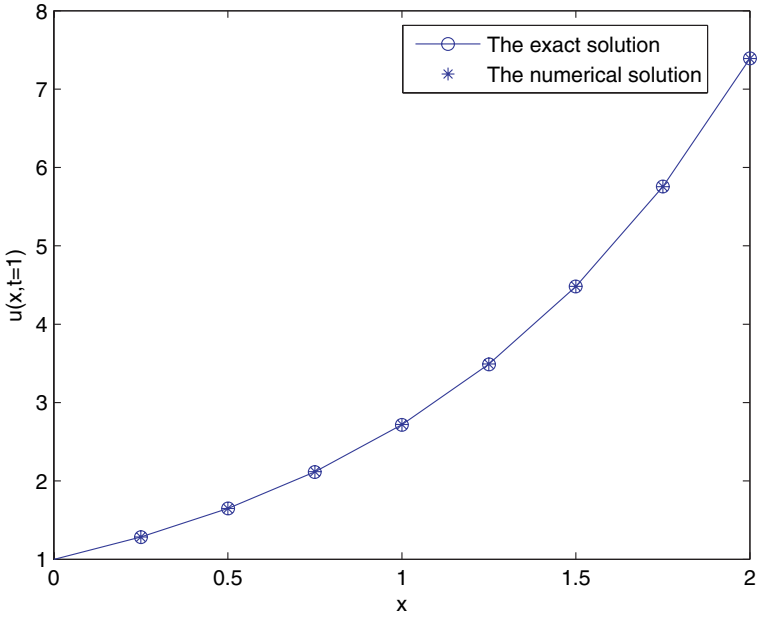

FIG. 6.1. *The comparison of the exact solution and the numerical solution (INM) when $\gamma = 0.9$ and $t = 1$.*

with the boundary and initial conditions

$$u(0,t) = t^{2+\gamma}, \quad u(1,t) = et^{2+\gamma}, \quad u(x,0) = 0. \tag{6.3}$$

The exact solution of (6.2) and (6.3) is $u(x,t) = t^{2+\gamma}e^x$, which can be obtained by evaluating the fractional derivative formula [26, 27].

Table 6.1 shows the numerical errors at $t = 1$ between the exact solution and the numerical solution obtained by the INM, the EM, and the IDS. From Table 6.1, all three methods are in excellent agreement with the exact solution, and the convergence order of the EM and IDS is improved significantly.

A comparison of the exact solution and the numerical solution by using INM with various time and space steps for ASub-DE at $t = 1.0$ and $\gamma = 0.9$ is shown in Figure 6.1. It is apparent that the numerical solution (INM) is in excellent agreement with the exact solution.

Example 2. Consider the following ASub-DE:

$$\frac{\partial u(x,t)}{\partial t} = \frac{\partial^{1-\gamma}}{\partial t^{1-\gamma}}\left[\frac{\partial^2 u(x,t)}{\partial x^2}\right], \tag{6.4}$$

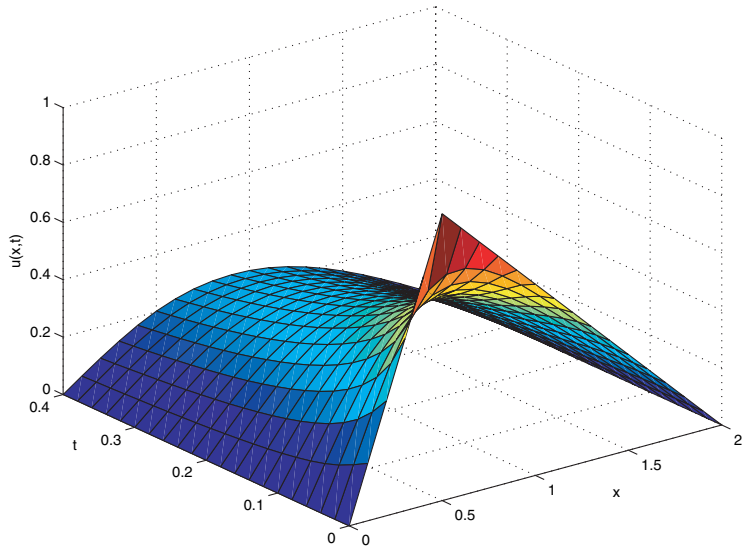

FIG. 6.2. *The numerical approximation when* $\gamma = 0.8$.

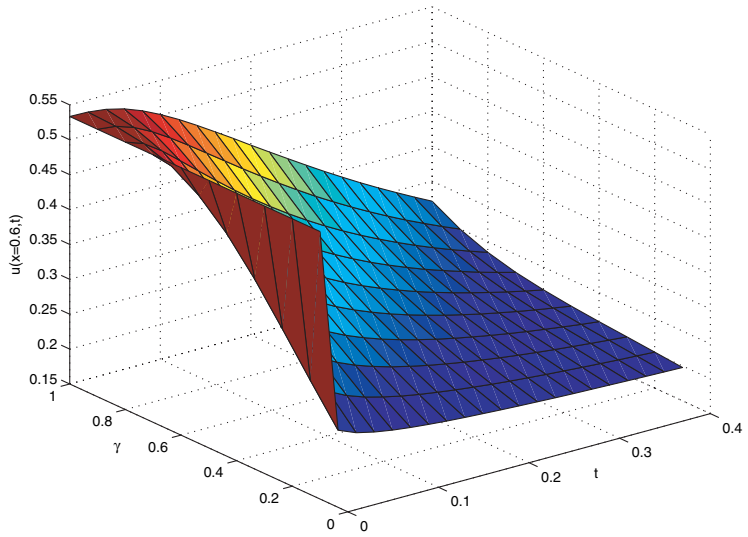

FIG. 6.3. *The numerical approximation* $u(x,t)$ *for various* γ *when* $x = 0.6$.

with initial and boundary conditions

$$u(x,0) = \begin{cases} 2x, & 0 \le x \le 0.5, \\ \frac{4-2x}{3}, & 0.5 \le x \le 2, \end{cases}$$
$$u(0,t) = u(2,t) = 0, \quad 0 \le t \le 0.4.$$

The evolution results for the INM when $\gamma = 0.8$, $0 \le t \le 0.4$, $0 \le x \le 2$, $0.1 \le \gamma \le 1$, $0 \le t \le 0.4$, $x = 0.6$, and $0.1 \le \gamma \le 1$, $t = 0.4$, $0 \le x \le 2$ are shown in Figures 6.2, 6.3, and 6.4, respectively. Figures 6.2–6.4 show that the system exhibits subdiffusion behaviors. From Figure 6.4, it can be seen that the solution continuously depends on the time fractional derivative.

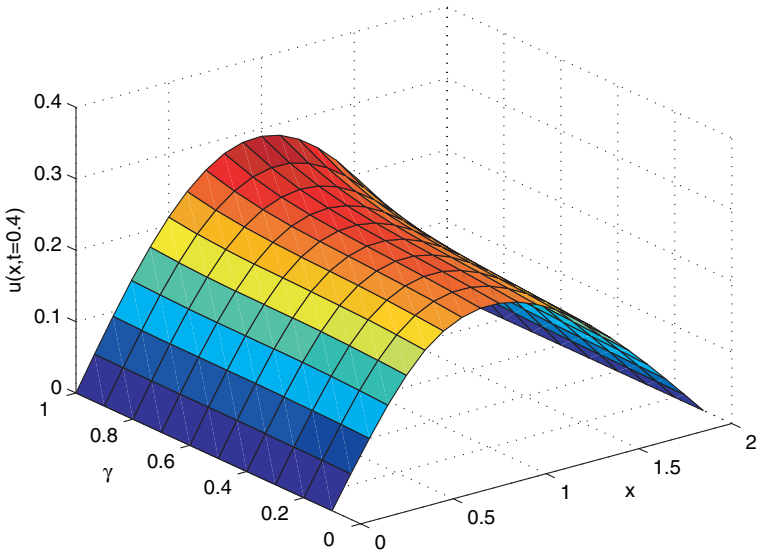

FIG. 6.4. *The numerical approximation $u(x,t)$ for various γ when $t = 0.4$.*

7. Conclusions. In this paper, an INM for the fractional subdiffusion equation in a bounded domain has been described and demonstrated. We prove that the INM is unconditionally stable and convergent. Two techniques to improve the convergence rate are presented. Both the EM and the IDS techniques provide computationally effective tools for simulating the behavior of the solution of the ASub-DE. These methods and analytical techniques can also be extended to any fractional integro-differential equations and higher-dimensional problems.

STABLE AND CONVERGENT UNSYMMETRIC MESHLESS COLLOCATION METHODS*

LEEVAN LING† AND ROBERT SCHABACK‡

Abstract. In the theoretical part of this paper, we introduce a simplified proof technique for error bounds and convergence of a variation of Kansa's well-known unsymmetric meshless collocation method. For a numerical implementation of the convergent variation, a previously proposed greedy technique is coupled with linear optimization. This algorithm allows a fully adaptive on-the-fly data-dependent meshless selection of test and trial spaces. The new method satisfies the assumptions of the background theory, and numerical experiments demonstrate its stability.

Key words. Kansa's method, convergence, error bounds, linear optimization

1. Introduction.

A general framework for solving PDE problems in strong or weak form by kernel-based meshless methods was outlined in [13]. It writes the PDE problem as uncountably many simultaneous scalar equations

$$\lambda(u) = f_\lambda \in \mathbb{R} \quad \text{for all} \quad \lambda \in \Lambda. \tag{1.1}$$

We call Λ the *test set*, because applying all functionals λ from Λ to a function u tests whether the function u solves the given problem. If several differential or boundary operators are involved, we simply put everything into a single set Λ of functionals of various types.

Testing can be done in *strong* and *weak* forms. For testing in *strong form*, the set Λ consists of infinitely many linear real-valued functionals λ that usually take the form of point evaluations of functions or their derivatives at points inside a domain or on some boundary or interface layer.

Testing in *weak* form uses functionals

$$\lambda_{v,a}(u) := a(u, v),$$

which evaluate bilinear forms $a(.,.)$ after inserting a *test function* v. These bilinear forms may contain derivatives, and they always require an integration.

No matter how testing is done, we call (1.1) a *generalized interpolation problem*, and we assume it to be solvable by a function u^* that generates the data via $f_\lambda := \lambda(u^*)$ for all $\lambda \in \Lambda$.

To make generalized interpolation problems numerically accessible, we have to *discretize* them. Discretization on the *trial* side is done by choosing a finite-dimensional *trial space* $\mathcal{U}$ of functions which can approximate the exact solution u^* well. It will be the space of functions from which the numerical solution u will be constructed, and

we assume it to be spanned by a basis $\{u_1, \ldots, u_m\}$ as

$$u := \sum_{j=1}^{m} \alpha_j u_j \ \in \mathcal{U} := \mathrm{span}\{u_1, \ldots, u_m\}. \tag{1.2}$$

Discretization on the *test* side just consists in replacing the infinite set Λ by some finite unstructured subset $\Lambda_n := \{\lambda_1, \ldots, \lambda_n\}$. The space spanned by these functionals can be called the *test space*.

Then the discretized problem reads as

$$\lambda_i(u) = \sum_{j=1}^{m} \alpha_j \lambda_i(u_j) = f_{\lambda_i} = \lambda_i(u^*), \quad 1 \le i \le n, \tag{1.3}$$

when written as an unsymmetric system of linear equations for a function u of the trial space $\mathcal{U}$. In most cases, the system will have $n \ge m$, but it is always a hard problem to study the matrix with entries $\lambda_i(u_j)$, e.g., to assert that it has rank m.

Weak formulations use functionals of the form $\lambda_i(u) := a_i(u, v_i)$, with certain bilinear forms a_i and *test functions* $v_1, \ldots, v_n$ such that the discretized problem takes the familiar form

$$\lambda_i(u) = a_i(u, v_i) = \sum_{j=1}^{m} \alpha_j a_i(u_j, v_i) = f_{\lambda_i} = \lambda_i(u^*), \quad 1 \le i \le n,$$

of meshless Petrov–Galerkin schemes [1]. If trial functions u_j and test functions v_i coincide, and if there is only a single bilinear form involved, this reduces to the well-known Galerkin method. It has a strong built-in connection of test functionals to trial functions and yields a linear system with a positive semidefinite symmetric Gramian matrix. This makes it easy to handle, and it forms the core of the finite element method and some of its generalizations. However, for unsymmetric weak Petrov–Galerkin schemes, the theoretical and numerical analysis is rather hard [15].

To make problems in strong formulation symmetric, the connection between test functionals and trial functions must be established differently. To get a truly meshless technique and to allow very general problems, the connection is made via a symmetric positive definite *kernel* $\Phi : \mathbb{R}^d \times \mathbb{R}^d \to \mathbb{R}$ if the underlying problem is posed for functions of d variables on a domain $\Omega \subset \mathbb{R}^d$. It takes the discretized set Λ_m of test functionals and defines the trial functions in (1.2) as $u_j := \lambda_j^y \Phi(\cdot, y)$ for $1 \le j \le m$, where the superscript of λ indicates the variable of Φ on which the functional operates. Then the collocation matrix (1.3) is symmetric with entries $\lambda_i(u_j) = \lambda_i^x \lambda_j^y \Phi(x, y)$ for $1 \le i, j \le n$. This *symmetric collocation* technique dates back to [17] and has a solid mathematical basis [3, 4]. Like in the standard (non-Petrov) Galerkin scheme, the trial and test functions or functionals are closely related in order to maintain symmetry.

But this paper will deal with *unsymmetric meshless collocation*. By following an early idea of Kansa [8, 9] used by many authors afterwards (see an overview in [5]), one takes a set $X_m := \{x_1, \ldots, x_m\} \subset \mathbb{R}^d$ of m scattered points and uses a kernel Φ to define the trial space $\mathcal{U}$ spanned by the trial functions

$$u_j = \Phi(\cdot, x_j) = \lambda_{\delta_{x_j}}^y \Phi(\cdot, y), \quad 1 \le j \le m, \tag{1.4}$$

associated to simple point evaluation functionals $\lambda_{\delta_{x_j}}$. Often, but not necessarily, the points x_j are irregularly placed within Ω. Since they determine the trial functions in

(1.4), we can call them *trial centers*. The resulting unsymmetric collocation matrix has the entries

$$\lambda_i(u_j) = \lambda_i^y \Phi(y, x_j), \quad 1 \le i \le n, \quad 1 \le j \le m,$$

and can be singular in exceptional cases [6]. Consequently, there are very limited mathematical results on this technique, though it gives very good results in plenty of applications in science and engineering.

To overcome these solvability problems, one has to modify the setting. To get solvability and error bounds, there should at least be a unique solution to the modified discretized system that converges to the true solution if the discretization is refined. The first question requires that, if $n \gg m$ test functionals are fixed and are linearly independent, the system has rank m, if the trial functions are chosen properly. This was proven in [11], while the earlier paper [13] contained an asymptotic analysis for sufficiently many test functionals and trial functions. By a rather complicated and abstract machinery, a fairly general theory leading to error bounds and convergence results for the unsymmetric meshless collocation method was finally provided in [14].

This paper is independent of the theory in [14] and will prove a much more elementary convergence result for a variation of meshless unsymmetric collocation. Furthermore, since [14] does not focus on numerical techniques, we show how certain algorithms allow one to satisfy the requirements needed for convergence, in the context of both this paper and [14]. In particular, we combine an adaptive greedy method with linear programming, and some numerical examples show that our new adaptive on-the-fly algorithm works stably in spite of large condition numbers.

2. Well-posed problems. We now go back to the infinite problem (1.1) and proceed to define a variation of the unsymmetric collocation technique that will have a convergence proof. To this end, we have to fix the mathematical background.

The problem (1.1) is posed in a Hilbert space $\mathcal{U}$ via a test set $\Lambda \subset \mathcal{U}^*$ of continuous linear functionals on $\mathcal{U}$. The functionals can clearly be normalized to satisfy $\|\lambda\|_{\mathcal{U}^*} = 1$ for all $\lambda \in \Lambda$. The specific solution to our problem is called u^* from now on. This way, we assume solvability within the Hilbert space $\mathcal{U}$, even if the space $\mathcal{U}$ is smaller than the "existence space," i.e., the space in which minimal assumptions guarantee the existence of a solution by mathematical analysis. For instance, a Poisson problem on a domain $\Omega \subset \mathbb{R}^d$ can be stated in Sobolev "existence" space $W_2^1(\Omega)$ in weak formulation, but we can also take a Hilbert space $\mathcal{U}$ of at least twice differentiable functions and pose the Poisson problem there in strong form, by using the data from a smooth function $u^* \in \mathcal{U}$. Note that standard regularity theory [10] allows this, if the data and the domain are smooth. The above general framework allows both settings, if applied in weak form, since the given data always are of the form $\lambda(u^*),\ \lambda \in \Lambda$, for a specific function $u^* \in \mathcal{U}$. But here we want to stick to problems posed in strong form, and we assume sufficient additional regularity.

Furthermore, we need the problem to be *well-posed*, and this is expressed by the requirement that

$$\|u\|_\Lambda := \sup_{\lambda \in \Lambda} |\lambda(u)| \tag{2.1}$$

is a norm on $\mathcal{U}$. This definition will always provide a seminorm without further assumptions, but we get a norm if we can prove unique solvability by additional analytic arguments like a maximum principle. Note that this norm will be weaker

than the norm in $\mathcal{U}$ because of

$$\|u\|_\Lambda \le \|u\|_{\mathcal{U}} \quad \text{for all} \quad u \in \mathcal{U} \tag{2.2}$$

following from

$$|\lambda(u)| \le \|\lambda\|_{\mathcal{U}^*}\|u\|_{\mathcal{U}} = \|u\|_{\mathcal{U}} \quad \text{for all} \quad u \in \mathcal{U},\ \lambda \in \Lambda,$$

and normalization of the test functionals. The well-posedness of the problem is often alternatively expressed in the form

$$\|u\|_A \le C_A\|u\|_\Lambda \le C_A\|u\|_{\mathcal{U}} \quad \text{for all} \quad u \in \mathcal{U}, \tag{2.3}$$

where $\mathcal{U}_A$ with norm $\|.\|_A$ is a data-independent function space like $\mathcal{U}$ but with a weaker norm. This also means that $\mathcal{U}$ is continuously embedded in $\mathcal{U}_A$. The upshot here is that the space $\mathcal{U}_A$ and its norm should not be dependent on the test set Λ anymore. We call (2.3) the basic *analytic a priori inequality* for well-posedness of the problem in the space $\mathcal{U}_A$. The condition (2.3) looks rather abstract, but it can be explained by the following.

Example 2.1. Let a Poisson problem in two dimensions be given in strong form as

$$\begin{aligned} \Delta u &= f \quad && \text{in } \Omega, \\ u &= \varphi \quad && \text{on } \partial\Omega, \end{aligned}$$

with f continuous in $\overline{\Omega}$ and φ continuous on $\partial\Omega$. Furthermore, let Ω be a bounded domain in $\mathbb{R}^2$. The domain should allow the standard maximum principle and admit the standard a priori inequality

$$\|u\|_{W^2(\Omega)} \le C_A\|\Delta u\|_{L_2(\Omega)}$$

for all u in $W_0^2(\Omega)$ (see [10, p. 66, eq. (6.8)]). Since we are in two dimensions, there is a Sobolev embedding inequality

$$\|u\|_{\infty,\Omega} \le C_S\|u\|_{W^2(\Omega)}$$

for all $u \in W^2(\Omega)$. We pose a strong problem by taking the test set Λ to consist of all functionals

$$\begin{aligned} u &\mapsto (\Delta u)(x), \quad && x \in \overline{\Omega}, \\ u &\mapsto u(y), && y \in \partial\Omega. \end{aligned}$$

We consider the space $\mathcal{U} = C^2(\overline{\Omega})$ of functions on $\overline{\Omega}$. For all functions $u \in \mathcal{U}$ we define

$$\begin{aligned} \|u\|_\Lambda &:= \max(\|\Delta u\|_{\infty,\Omega}, \|u\|_{\infty,\partial\Omega}), \\ \|u\|_{\mathcal{U}} &:= 2 \cdot \max_{|\alpha|\le 2} \|D^\alpha u\|_{\infty,\overline{\Omega}} \end{aligned}$$

to get $\|u\|_\Lambda \le \|u\|_{\mathcal{U}}$. Let there be a $W^2(\Omega)$-regular true solution u^*, and assume that we have an approximate solution $v \in \mathcal{U} = C^2(\overline{\Omega})$, with

$$\begin{aligned} \Delta v &\approx f \quad && \text{in } \Omega, \\ v &\approx \quad && \varphi \text{ on } \partial\Omega \end{aligned}$$

such that Δv is still continuous in $\overline{\Omega}$ and v is continuous on $\partial\Omega$. Let w be the solution of

$$\begin{aligned} \Delta w &= 0 && \text{in } \Omega, \\ w &= v - \varphi && \text{on } \partial\Omega. \end{aligned}$$

Then, by the maximum principle, we have

$$\|w\|_{\infty,\Omega} \le \|w\|_{\infty,\partial\Omega} = \|v - \varphi\|_{\infty,\partial\Omega},$$

and we get the error bound

$$\|u^* - v\|_{\infty,\Omega} \le \|u^* - v + w\|_{\infty,\Omega} + \|w\|_{\infty,\Omega} \le \|u^* - v + w\|_{\infty,\Omega} + \|v - \varphi\|_{\infty,\partial\Omega}.$$

The function $u^* - v + w$ has vanishing boundary values and thus lies in $W_0^2(\Omega)$. With the Sobolev embedding inequality we then get

$$\begin{aligned} \|u^* - v + w\|_{\infty,\Omega} &\le C_S \|u^* - v + w\|_{W^2(\Omega)} \\ &\le C_S C_A \|\Delta(u^* - v + w)\|_{L_2(\Omega)} \\ &= C_S C_A \|\Delta(u^* - v)\|_{L_2(\Omega)} \\ &= C_S C_A \|f - \Delta v\|_{L_2(\Omega)} \\ &\le C_S C_A \sqrt{vol(\Omega)} \|f - \Delta v\|_{\infty,\Omega} \end{aligned}$$

and finally

$$\begin{aligned} \|u^* - v\|_{\infty,\Omega} &\le \|v - \varphi\|_{\infty,\partial\Omega} + C_S C_A \sqrt{vol(\Omega)} \|f - \Delta v\|_{\infty,\Omega} \\ &\le \left(1 + C_S C_A \sqrt{vol(\Omega)}\right) \max(\|v - \varphi\|_{\infty,\partial\Omega}, \|f - \Delta v\|_{\infty,\Omega}) \\ &= \left(1 + C_S C_A \sqrt{vol(\Omega)}\right) \|v - u^*\|_\Lambda. \end{aligned}$$

Under the above assumptions, there is a constant C, independent of $u^* \in W^2(\Omega)$ and $v \in C^2(\Omega)$, such that the following holds:

$$\|v - u^*\|_{\infty,\Omega} \le C \|v - u^*\|_\Lambda.$$

This altogether proves (2.3) for $\mathcal{U}_A = C(\overline{\Omega})$ with norm $\|.\|_A = \|.\|_\infty$.

Note that our assumption of well-posedness replaces standard assumptions such as uniform ellipticity of the underlying differential operator. Thus we can handle much more general situations.

3. Approximation in trial spaces. Now let $\mathcal{U}_\epsilon$ be a subspace of $\mathcal{U}$ such that for all $u \in \mathcal{U}$ there is some approximation $v_{u,\epsilon} \in \mathcal{U}_\epsilon$, with

$$\|u - v_{u,\epsilon}\|_\Lambda \le \epsilon \|u\|_{\mathcal{U}} \quad \text{for all} \quad u \in \mathcal{U}, \tag{3.1}$$

with a small number $\epsilon > 0$. This is satisfied for subspaces that come from a sequence of subspaces getting dense in $\mathcal{U}$, e.g., for Kansa-type trial spaces with sufficiently dense trial centers. One will, however, need a little more regularity in $\mathcal{U}$ than the regularity to define $\|u\|_\Lambda$ to get such a bound. Let us explain how to derive (3.1) in special cases. Details and proof techniques are in the recent book [16].

Example 3.1. Take a smooth positive definite radial basis function ϕ, and define a translation-invariant kernel Φ on $\mathbb{R}^d$ via

$$\Phi(x - y) := \phi(\|x - y\|_2), \quad x, y \in \mathbb{R}^d.$$

Its smoothness is measured via Fourier transforms and a positive real number β satisfying

$$\hat{\Phi}(\omega) \leq C(1+\|\omega\|_2)^{-d-\beta} \quad \text{for all} \quad \omega \in \mathbb{R}^d.$$

Then there is a unique "native" Hilbert space $\mathcal{U}$ isomorphic to $W^{(d+\beta)/2}(\mathbb{R}^d)$ in which Φ is a reproducing kernel. Now take a large set X of scattered centers in a bounded domain $\Omega \subset \mathbb{R}^d$ such that the *fill distance* or *mesh norm*

$$h := \sup_{y\in\Omega} \min_{x\in X} \|x-y\|_2$$

is small. For each $u \in \mathcal{U}$ consider the standard interpolant $s_{u,X}$ based on translates $\Phi(\cdot - x_j)$ with respect to the data in X. Then there is a pointwise error bound

$$|(D^\alpha u)(x) - (D^\alpha s_{u,X})(x)| \leq C_\alpha h^{\beta/2-|\alpha|}\|u\|_{\mathcal{U}} \quad \text{for all} \quad u \in \mathcal{U},\ x \in \Omega,\ 0 \leq |\alpha| < \beta/2,$$

where C is a constant depending only on $\mathcal{U}$ and the domain but not on X, x, h, α, and u. We apply this for all functionals $\lambda \in \Lambda$ if they are in strong form, i.e., evaluations of operators acting on u and evaluated at a point, like $\mu(u) := D^\alpha_x u := (D^\alpha u)(x)$. Then it is clear that (3.1) holds, provided that regularity of the solution and smoothness of the kernel are good enough to guarantee $\beta/2 - |\alpha| > 0$ for all occurring derivative orders $|\alpha|$ in the strong functionals of the test set Λ.

Again, our assumptions are much more general than in standard theories, because we just require a reasonably good approximation of the true solution by the trial space, no matter how it is defined.

4. Convergence. Now we describe the basic convergence argument, but we start in a rather abstract setting and do not even specify whether we apply weak or strong testing or how we do the numerical calculations. By using the subspace $\mathcal{U}_\epsilon \subset \mathcal{U}$ provided by the previous section, we would like to construct a function $v_\epsilon \in \mathcal{U}_\epsilon$ that solves

$$v_\epsilon = \arg\min_{v\in\mathcal{U}_\epsilon} \|v-u^*\|_\Lambda = \arg\min_{v\in\mathcal{U}_\epsilon} \sup_{\lambda\in\Lambda} |\lambda(v)-\lambda(u^*)| \tag{4.1}$$

over all $v \in \mathcal{U}_\epsilon$. We do not know whether the minimum is attained or how to calculate it, but we know that there is a function $v^*_\epsilon \in \mathcal{U}_\epsilon$, with

$$\|v^*_\epsilon - u^*\|_\Lambda \leq 2\|v_{u^*,\epsilon} - u^*\|_\Lambda \leq 2\epsilon\|u^*\|_{\mathcal{U}}, \tag{4.2}$$

which is sufficient for our purpose. Though almost trivial, we state the following.

THEOREM 4.1. *Let $\mathcal{U}$ be a normed linear space with norm $\|.\|_{\mathcal{U}}$, dual space $\mathcal{U}^*$, and dual unit sphere $\mathcal{U}^*_1 := \{\lambda \in \mathcal{U}^* : \|\lambda\|_{\mathcal{U}^*} = 1\}$. Let a test set $\Lambda \subset \mathcal{U}^*_1$ be given such that $\|.\|_\Lambda$ is defined on $\mathcal{U}$ with* (2.1) *and* (2.2)*. Assume further that the general interpolation problem* (1.1) *is well-posed, i.e., that $\|.\|_\Lambda$ is a norm. Let $\{\mathcal{U}_\epsilon\}_\epsilon$ be a scale of subspaces of $\mathcal{U}$ for $\epsilon \to 0$ such that for all $u \in \mathcal{U}$ there is a $v_{u,\epsilon} \in \mathcal{U}_\epsilon$ with* (3.1)*. For all $\epsilon \to 0$, take a function v^*_ϵ satisfying* (4.2)*. Then the error bound* (4.2) *holds, and there is convergence $\|v^*_\epsilon - u^*\|_\Lambda \to 0$. If well-posedness holds via* (2.3) *for a space $\mathcal{U}_A$, then the convergence and the error bound can both be rewritten in terms of $\|.\|_A$. The same results hold for solutions v_ϵ of* (4.1)*.*

Note that convergence rates of the approximation in $\mathcal{U}_\epsilon$ spaces carry over to convergence rates of the approximate solutions v^*_ϵ, precisely as in the finite element method (FEM) case. In other words, the rate of convergence of the approximate solutions is exactly the one of the best approximation in $\mathcal{U}_\epsilon$ with respect to the norm $\|.\|_\Lambda$ to functions in $\mathcal{U}$. Details can be worked out along the lines of the above examples.

5. Abstract greedy adaptive algorithm. Now we want to set Theorem 4.1 to work. For ϵ fixed, we want to show how (4.2) can be solved. The space $\mathcal{U}_\epsilon$ will be a standard finite-dimensional Kansa trial space along the lines of section 3. Following the previous section, we have to solve the semi-infinite linear optimization problem P_Λ defined by

$$\begin{aligned} &\textbf{Minimize} \quad \eta \text{ such that (s.t.)} \\ &\lambda(v) - \lambda(u^*) \le \eta \qquad \text{for all } \lambda \in \Lambda, \\ &-\lambda(v) + \lambda(u^*) \le \eta \qquad \text{for all } \lambda \in \Lambda, \\ &v \in \mathcal{U}_\epsilon, \\ &\eta \in \mathbb{R} \end{aligned} \tag{5.1}$$

to obtain the solution v_ϵ in (4.1) or at least a suboptimal function v_ϵ^* satisfying (4.2). But we want to *discretize* the test side of this optimization problem, replacing Λ above by a finite subset $\Lambda_n := \{\lambda_1, \dots, \lambda_n\}$ to get a standard finite-dimensional linear optimization problem P_{Λ_n}.

To this end, we define the following abstract *greedy adaptive* algorithm:

- For $n := 0$ define $v_0 := 0$ and $\Lambda_0 := \emptyset$.
- 1. If $\|v_n - u^*\|_\Lambda = 0$ holds, stop.
  2. Else take $\lambda_{n+1} \in \Lambda$, with

$$\frac{2}{3}\|v_n - u^*\|_\Lambda \le |\lambda_{n+1}(v_n - u^*)| \le \|v_n - u^*\|_\Lambda, \tag{5.2}$$

  and set $\Lambda_{n+1} = \Lambda_n \cup \{\lambda_{n+1}\}$.
  3. Solve the finite-dimensional linear optimization problem $P_{\Lambda_{n+1}}$ by a function $v_{n+1} \in \mathcal{U}_\epsilon$.
  4. Set $n \Leftarrow n + 1$, and repeat.

We now show how close this algorithm comes to solving (4.1) or (5.1) with the optimal value

$$\eta^* = \min_{v \in \mathcal{U}_\epsilon} \|v - u^*\|_\Lambda = \min_{v \in \mathcal{U}_\epsilon} \sup_{\lambda \in \Lambda} |\lambda(v) - \lambda(u^*)|.$$

THEOREM 5.1. *If the algorithm is finite, then $u^* \in \mathcal{U}_\epsilon$ holds, and the true solution of the problem is reached in a finite number of steps. Otherwise,*

$$\eta^* \le \|v_n - u^*\|_\Lambda \le 2\|v_n - u^*\|_{\Lambda_n} =: 2\eta_n \le 2\eta^*$$

holds for infinitely many n. After a finite number of steps, the sufficient criterion

$$\|v_n - u^*\|_\Lambda \le 2\eta_n \tag{5.3}$$

for v_n being a solution of (4.2) *is satisfied.*

Proof. The first statement is trivial. If the algorithm generates an infinite sequence with $\|v_n - u^*\|_\Lambda > 0$, we renormalize and get convergence of a subsequence to

$$\frac{v_n - u^*}{\|v_n - u^*\|_\Lambda} \to w \in \mathcal{U}_\epsilon,$$

with $\|w\|_\Lambda = 1$, because $\mathcal{U}_\epsilon$ and u^* span a finite-dimensional space. By our selection rule,

$$\|v_n - u^*\|_\Lambda \ge \|v_n - u^*\|_{\Lambda_{n+1}} \ge |\lambda_{n+1}(v_n - u^*)| \ge \frac{2}{3}\|v_n - u^*\|_\Lambda$$

and

$$\begin{aligned}\|w\|_{\Lambda_{n+1}} &\geq \left\| \frac{v_n - u^*}{\|v_n - u^*\|_\Lambda} \right\|_{\Lambda_{n+1}} - \left\| w - \frac{v_n - u^*}{\|v_n - u^*\|_\Lambda} \right\|_{\Lambda_{n+1}} \\ &\geq \frac{2}{3} - \left\| w - \frac{v_n - u^*}{\|v_n - u^*\|_\Lambda} \right\|_\Lambda \\ &\geq \frac{1}{2}\end{aligned}$$

for sufficiently large n from our subsequence. Similarly,

$$\begin{aligned}\frac{\eta_n}{\|v_n - u^*\|_\Lambda} &= \frac{\|v_n - u^*\|_{\Lambda_n}}{\|v_n - u^*\|_\Lambda} \\ &\geq \|w\|_{\Lambda_n} - \left\| w - \frac{v_n - u^*}{\|v_n - u^*\|_\Lambda} \right\|_{\Lambda_n} \\ &\geq \|w\|_{\Lambda_n} - \left\| w - \frac{v_n - u^*}{\|v_n - u^*\|_\Lambda} \right\|_\Lambda\end{aligned}$$

implies that we have

$$\frac{\eta_n}{\|v_n - u^*\|_\Lambda} \geq \frac{1}{2}$$

and

$$\frac{1}{2}\|v_n - u^*\|_\Lambda \leq \eta_n \leq \|v_n - u^*\|_\Lambda$$

for infinitely many sufficiently large n from our subsequence. Since

$$0 \leq \eta_1 \leq \cdots \leq \eta_n \leq \lim_{j\to\infty} \eta_j =: \tilde{\eta} \leq \eta^* := \inf_{v\in\mathcal{U}_\epsilon} \|v - u^*\|_\Lambda < \infty,$$

we can conclude that

$$\eta^* \leq \|v_n - u^*\|_\Lambda \leq 2\eta_n \leq 2\tilde{\eta} \leq 2\eta^*$$

holds for sufficiently large n of a subsequence. If (5.3) holds, the above inequality is satisfied. Then we have (4.2) due to

$$\|v_n - u^*\|_\Lambda \leq 2\eta^* \leq 2\|v_{u^*,\epsilon} - u^*\|_\Lambda \leq 2\epsilon\|u^*\|_{\mathcal{U}}. \qquad \square$$

Note that the criterion (5.3) is rather close to being numerically available.

Theorem 5.1 shows that the selection of useful finite subsets Λ_n can be done by an adaptive greedy method, by taking sequences of finite linear programs, checking their solutions on the remaining test functionals, and taking in those functionals where large errors occur. The next sections will address the implementation of the above abstract algorithm.

6. Linear optimization. With the theoretical background of the previous section, we now proceed towards the implementation of a greedy adaptive on-the-fly variant of a linear optimization algorithm, but we have to postpone adaptivity to the next section. Assume that we have a selection $\Lambda_n := \{\lambda_1, \ldots, \lambda_n\}$ of test functionals

and a selection $\mathcal{U}_m := \text{ span } \{u_1, \ldots, u_m\}$ of a space of trial functions such that the linear optimization problem, i.e., the discretized version of (5.1), reads as

$$\begin{aligned} &\textbf{Minimize} \quad \eta \text{ s.t.} \\ \sum_{k=1}^{m} \alpha_k \lambda_j(u_k) - \lambda_j(u^*) &\le \eta, \quad 1 \le j \le n, \\ -\sum_{k=1}^{m} \alpha_k \lambda_j(u_k) + \lambda_j(u^*) &\le \eta, \quad 1 \le j \le n, \\ \alpha_k &\in \mathbb{R}, \quad 1 \le k \le m, \\ \eta &\in \mathbb{R}. \end{aligned}$$

This is a linear discrete Chebyshev approximation problem of the form

$$\begin{aligned} &\textbf{Minimize} \quad \eta \text{ s.t.} \\ Ax - b &\le \eta \cdot \mathbf{1}, \\ -Ax + b &\le \eta \cdot \mathbf{1} \end{aligned}$$

written out componentwise with a matrix $A \in \mathbb{R}^{n \times m}$, $m \le n$, and vectors $b \in \mathbb{R}^n$ and $\mathbf{1} \in \mathbb{R}^n$. We explicitly reformulate the standard reduction to a dual problem in canonical form [2] because we want to add adaptivity later. First, we rewrite the constraints as

$$\begin{pmatrix} A & -\mathbf{1} \\ -A & -\mathbf{1} \end{pmatrix} \cdot \begin{pmatrix} x \\ \eta \end{pmatrix} \le \begin{pmatrix} b \\ -b \end{pmatrix}$$

and the objective function as

$$-\eta = (\mathbf{0}, -1) \cdot \begin{pmatrix} x \\ \eta \end{pmatrix}$$

to be *maximized*. The standard dual of such a problem is

$$\begin{aligned} &\textbf{Minimize } (u^T, v^T) \cdot \begin{pmatrix} b \\ -b \end{pmatrix} \text{ s.t.} \\ &\begin{pmatrix} A^T & -A^T \\ -\mathbf{1}^T & -\mathbf{1}^T \end{pmatrix} \cdot \begin{pmatrix} u \\ v \end{pmatrix} = \begin{pmatrix} \mathbf{0} \\ -1 \end{pmatrix}, \\ &u, v \ge 0 \end{aligned}$$

or, equivalently,

$$\begin{aligned} &\textbf{Minimize } b^T(u - v) \text{ s.t.} \\ A^T(u - v) &= 0, \\ \mathbf{1}^T(u + v) &= 1, \\ u, v &\ge 0. \end{aligned} \tag{6.1}$$

Since the original problem is solvable, the weak and strong duality theorems hold. In addition, the complementary slackness conditions at the optimal primal and dual solutions, denoted by x^*, η^*, u^*, v^*, will be satisfied. They are

$$\begin{aligned} u_j^* \cdot (Ax^* - b - \eta^* \cdot \mathbf{1})_j &= 0, \\ v_j^* \cdot (-Ax^* + b - \eta^* \cdot \mathbf{1})_j &= 0, \end{aligned}$$

while the factors are nonnegative. The upshot is that there are *active* indices j which can be grouped into two sets

$$\begin{array}{lllll} j \in J^+ & \text{if} & u_j^* > 0 & \text{and} & (Ax^* - b)_j = \eta, \\ j \in J^- & \text{if} & v_j^* > 0 & \text{and} & (Ax^* - b)_j = -\eta. \end{array}$$

If $\eta > 0$, these index sets are disjoint. This implies that the index sets are related to the signs of the nonzero components of w^*, if there are no degenerations.

We work with the revised simplex method based on (6.1). This means that (except for the startup phase, which is postponed here) we always keep the inverse C of a $(m+2) \times (m+2)$ matrix

$$C^{-1} = B := \begin{pmatrix} A_s^T & 0 \\ \mathbf{1}^T & 0 \\ b_s^T & -1 \end{pmatrix},$$

with a sign vector $s \in \{-1, +1\}^{m+1}$ such that B contains a nonsingular selection of $m+1$ columns of

$$\mathcal{B} := \begin{pmatrix} A^T & -A^T & 0 \\ \mathbf{1}^T & \mathbf{1}^T & 1 \\ b^T & -b^T & -1 \end{pmatrix}$$

with the appropriate signs. In addition, one must store the numbers of the selected columns of $\mathcal{B}$ or, equivalently, the numbers of the selected test functionals. We call the selection of $m+1$ signs and functionals occurring in B the *dual basis*. The current dual vertex is a vector $w_s \in \mathbb{R}^{m+1}$ such that

$$\begin{array}{rcl} A_s^T w_s & = & 0, \\ \mathbf{1}^T w_s & = & 1. \end{array} \tag{6.2}$$

This means that

$$\begin{pmatrix} A_s^T & 0 \\ \mathbf{1}^T & 0 \\ b_s^T & -1 \end{pmatrix} \cdot \begin{pmatrix} w_s \\ b_s^T w_s \end{pmatrix} = \begin{pmatrix} 0 \\ 1 \\ 0 \end{pmatrix} \text{ and } \begin{pmatrix} w_s \\ b_s^T w_s \end{pmatrix} = C \cdot \begin{pmatrix} 0 \\ 1 \\ 0 \end{pmatrix}$$

hold. Thus the dual vertex and the value of the dual objective function can be read off the penultimate column of the matrix C. The corresponding primal vertex is described by

$$\begin{pmatrix} A_s & \mathbf{1} & b_s \\ 0 & 0 & -1 \end{pmatrix} \cdot \begin{pmatrix} x_s \\ -\eta \\ -1 \end{pmatrix} = \begin{pmatrix} 0 \\ 1 \end{pmatrix} \text{ or } \begin{pmatrix} x_s \\ -\eta \\ -1 \end{pmatrix} = C^T \cdot \begin{pmatrix} 0 \\ 1 \end{pmatrix} \tag{6.3}$$

and can be read off the last column of C^T which is the last row of C.

The revised simplex method based on (6.1) already is an on-the-fly technique, provided that new columns of the constraint matrix are successively added, while the rows are fixed [2]. For the original problem, this means that new test functionals are introduced, while the trial space is fixed. So there are no problems when adding new test functionals to a solver running as a revised simplex method for the dual problem (6.1). We shall explain this in detail in the following section. The actual calculation matrix C (i.e., the inverse of a square part B of the full data matrix $\mathcal{B}$) will be of constant size for a fixed trial space.

For completeness and later use, let us describe the on-the-fly recipe. In theory, the standard full simplex tableau is the matrix $C \cdot \mathcal{B}$ which is of the form

$$\begin{pmatrix} S_+ & S_- & w_s \\ z_+^T & z_-^T & b_s^T w_s \end{pmatrix}$$

due to the factorization

$$\begin{pmatrix} A_s^T & 0 \\ \mathbf{1}^T & 0 \\ b_s^T & -1 \end{pmatrix} \cdot \begin{pmatrix} S_+ & S_- & w_s \\ z_+^T & z_-^T & b_s^T w_s \end{pmatrix} = \begin{pmatrix} A^T & -A^T & 0 \\ \mathbf{1}^T & \mathbf{1}^T & 1 \\ b^T & -b^T & 0 \end{pmatrix}. \tag{6.4}$$

Note that this tableau is never stored. The crucial row for the simplex method is the final one, containing the vectors

$$z_+^T = b_s S_+ - b^T, \quad z_-^T = b_s S_- + b^T.$$

It is representable as $e_{n+2}^T C\mathcal{B}$, but we know that $e_{n+2}^T C$ contains the primal data $(x_s^T, -\eta, -1)$. This means that

$$(z_+^T, z_-^T, b_s^T w_s) = (x_s^T, -\eta, -1) \cdot \begin{pmatrix} A^T & -A^T & 0 \\ \mathbf{1}^T & \mathbf{1}^T & 1 \\ b^T & -b^T & 0 \end{pmatrix}$$

holds; i.e.,

$$\begin{aligned} Ax_s - b - \eta\mathbf{1} &= z_+, \\ -Ax_s + b - \eta\mathbf{1} &= z_-, \\ -\eta &= b_s^T w_s. \end{aligned} \tag{6.5}$$

The tableau is optimal iff all components of the z vectors are nonpositive. This means $\|Ax_s - b\|_\infty \le \eta$, as expected.

7. Adaptive linear optimization. We now know that we have to look for a test functional $\lambda \in \Lambda$ with a large positive value of

$$|\lambda(U_m)^T \cdot x_s - f_\lambda| - \eta,$$

with $(\lambda(u_1), \dots, \lambda(u_m)) =: \lambda(U_m)^T$. This can be done without storing any matrix data, and the search for a good test functional can be made on an extremely large set of test functionals. Going for the largest possible value can be called a "greedy" strategy. This is the common choice in linear optimization, and it has been used favorably [11] also in meshless adaptive PDE solvers based on unsymmetric collocation. But note that (5.2) is satisfied only if we make sure that our new functional λ has the property

$$|\lambda(U_m)^T \cdot x_s - f_\lambda| \ge \frac{2}{3} \sup_{\mu \in \Lambda} |\mu(U_m)^T \cdot x_s - f_\mu|;$$

i.e., it suffices to find a reasonably good suboptimal functional to make our error bounds and convergence results valid.

Once we have such a functional, we generate the corresponding column of $\mathcal{B}$, multiply it by C, and get the corresponding column of the full tableau. We have to

make sure that the coresponding entry of z_- or z_+ is positive. In view of (6.5) we go for the left-hand part of $\mathcal{B}$, if

$$\lambda(U_m)^T \cdot x_s - f_\lambda - \eta$$

is positive. This sign information must be stored together with the identification or index for λ. Up to this point, we have found the column of the pivot for the next step of the simplex algorithm. The pivot row is now generated in the standard way, by comparing entries of the pivot column to the final column of the tableau, which is the penultimate column of C. Such a pivot row must exist, because otherwise our discrete linear optimization would be unsolvable. This determines a Gauss–Jordan transformation, which is carried out on C and *not* on the tableau. In fact, since the standard Gauss–Jordan transformation can be written as multiplication of the tableau from the left by an $(m+2) \times (m+2)$ matrix J, we can use (6.4) to see that we need only to multiply C^{-1} with J^{-1} from the right. This means that we can update C by forming $J \cdot C$. This finishes the step of the revised simplex method.

The above algorithm runs on a fixed trial space and can handle extremely large amounts of test functionals. It does not need to arrive at a full minimum, in particular if the current value of $\eta = -b_s^T w_s$ is too large to be tolerated for the given problem. Note that for any intermediate situation we have the inequality

$$\eta \le \inf_{u \in U_m} \sup_{\lambda \in \Lambda} |\lambda(u) - f_\lambda|. \tag{7.1}$$

This follows from the weak duality theorem in linear optimization. In fact, if u is any function from the trial space with coefficient vector $x \in \mathbb{R}^m$ in the basis $u_1, \ldots, u_m$, we have $(A_s x - b_s)^T w_s = -b_s^T w_s = \eta$ and find

$$\eta \le \|w_s\|_1 \|A_s x - b_s\|_\infty = \|A_s x - b_s\|_\infty \le \sup_{\lambda \in \Lambda} |\lambda(u) - f_\lambda|$$

because $A_s x - b_s$ is a signed collection of values $\lambda(u) - f_\lambda$ with those functionals λ which constitute the actual rows of A_s.

In (7.1) one would finally get equality if the revised simplex algorithm is carried out indefinitely with $\mathcal{U}_m$ fixed. But if η is at some stage already rather large to be tolerated, it does not make sense to work all of the way towards a full optimization with respect to all test functionals, because η will increase all of the time. It is more advisable to enlarge the trial space to make smaller values of η possible at all. This is to be investigated in the next section.

8. Adaptivity of trial spaces. We focus now on a situation where there are no new test functionals to be introduced while the error level η is still too large. This calls for an enlargement of the trial space. Adding a new trial function means adding a column to A, and at this point we do not assume anything about that choice. One can use radial basis functions of any shape or scale, finite elements, or singular functions to cope with boundary singularities. However, adding a column to A means adding a row to A^T, and consequently the actual vertex solution of the dual problem (6.1) cannot be used any more. A complete restart should be avoided. We thus look for an on-the-fly technique that makes use of the current optimal vertex of (6.1) while adding a new row to A^T and which continues effectively.

We first comment on the selection of a new row a^T of A^T. The current dual vector w_s has the property $A_s w_s = 0$, and a^T would be useless if $a^T w_s = 0$. This quantity

has the form

$$a^T w_s = \sum_{j=1}^{n} w_j s_j \lambda_j(u)$$

if a comes out of a new trial function u, where λ_j and s_j are the functionals and signs of the current dual basis. In this way, one can ask for an "optimal" new trial function u that maximizes this quantity under some normalization of u, e.g., $\|u\|_\Lambda := \sup_{\lambda\in\Lambda} |\lambda(u)| = 1$. In the following, we assume only $a^T w_s \neq 0$ and denote our new trial function by u_{m+1}.

At this point, one could restart the whole process, by using the above test functionals first before introducing others. This would mean a new startup of the whole algorithm.

To avoid a restart, we have to produce a new enlarged version of the square matrices B and C. But then we also need an additional column. This means that we have to add another test functional, too. But since we already have a good mechanism for finding good test functionals, we add the zero functional as a dummy that will be eliminated in the next simplex step. The enlarged B matrix will be

$$B' := \begin{pmatrix} A_s^T & 0 & 0 \\ a^T & 0 & 0 \\ \mathbf{1}^T & 1 & 0 \\ b_s^T & 0 & -1 \end{pmatrix},$$

which is nonsingular because $a^T w_s \neq 0$, and $A_s^T w_s = 0$ ensures that a^T is not a linear combination of the rows of A_s^T. The inverse C of B has the form

$$\begin{pmatrix} C_s & w_s & 0 \\ b_s^T C_s & b_s^T w_s & -1 \end{pmatrix},$$

with

$$\begin{aligned} A_s C_s &= I, \\ \mathbf{1}^T C_s &= 0^T. \end{aligned}$$

Then the inverse of B' is

$$\begin{pmatrix} C_s' & \alpha \cdot w_s & 0 & 0 \\ z^T & -\alpha & 1 & 0 \\ b_s^T C_s' & \alpha \cdot b_s^T w_s & 0 & -1 \end{pmatrix},$$

with

$$\begin{aligned} \alpha &= \frac{1}{a^T w_s}, \\ z^T &= -\alpha a^T C_s, \\ C_s' &= C_s + w_s z^T. \end{aligned}$$

This is an easy $\mathcal{O}(m^2)$ recipe to upgrade C.

Inspection of the new matrix C' via (6.3) shows that the new value of η will be zero and that the old primal coefficients are the same, the new coefficient being $\alpha b_s^T w_s$. If u and u' are the old and new primal solutions, respectively, written as trial functions, then

$$\lambda(u') = \lambda(u) + \alpha b_s^T w_s \lambda(u_{m+1})$$

can be used as a simplified technique for evaluating new test functionals on the new solution, if the $\lambda(u)$ were stored.

By looking at the system (6.2) and using Cramer's rule, we see that

$$|\det B'| = \left|\det \begin{pmatrix} A_s^T \\ a^T \end{pmatrix}\right| = \left|\det \begin{pmatrix} A_s^T \\ \mathbf{1}^T \end{pmatrix}\right| \cdot |a^T w_s| = |\det B| \cdot |a^T w_s|.$$

This gives a hint to stabilize the full process. One can keep track of the determinant of B and select a (or, equivalently, the new trial function) such that $|\det B'|$ is as close to 1 as possible. This strategy was quite successful in the adaptive greedy method of [11].

We also suggest the method of [11] for startup. It will make a selection of n test functionals $\lambda_1, \ldots, \lambda_n$ and n trial functions $u_1, \ldots, u_n$ to provide exact generalized interpolation for a function u from the trial space. The inverse $\tilde{C}$ of the $n \times n$ matrix $\tilde{A} = (\lambda_j(u_k))$ will be available when the algorithm of [11] stops.

We then find another functional λ_{n+1} such that $\lambda_{n+1}(u) \neq f_{\lambda_{n+1}}$ and define the $(n+1) \times n$ matrix $A = (\lambda_j(u_k))$ of the standard form of this paper. Then $A^T = (\tilde{A}^T, z)$ is known, where z is the vector with components $\lambda_{n+1}(u_j)$. With $v := \tilde{C}^T z$ we have $\tilde{A}^T v - z = 0$, and $w := (v^T, -1)^T$ is in the nullspace of A^T. From this vector, we derive a sign vector s by taking the signs of its components, and we renormalize the vector to generate a vector w_s of nonnegative components such that $\|w_s\|_1 = 1$ and $A_s^T w_s = 0$. This means that the signs of the components of w now occur as signs associated to columns of A_s^T and that we can write $A_s^T = (\tilde{A}^T, z) \cdot D_s$ with a diagonal matrix D_s carrying the signs in its diagonal. This way, we get the system (6.2). By using the sign vector, we can form b_s and have the matrix B that we need.

To get $C = B^{-1}$ cheaply, it suffices to get the inverse of

$$\begin{pmatrix} A_s^T \\ \mathbf{1}^T \end{pmatrix} = \begin{pmatrix} (\tilde{A}^T, z) \\ s^T \end{pmatrix} \cdot D_s$$

cheaply. This can be done at $\mathcal{O}(n^2)$ cost from the inverse $\tilde{C}$ of the $n \times n$ matrix $\tilde{A}$ in the standard rank-one update way.

9. Numerical demonstrations. In this section, we show some numerical examples that demonstrate the efficiency of our proposed algorithm. In all presented examples, we have used the multiquadric kernel

$$\Phi_c(x, y) = \sqrt{1 + \frac{||x - y||^2}{c^2}},$$

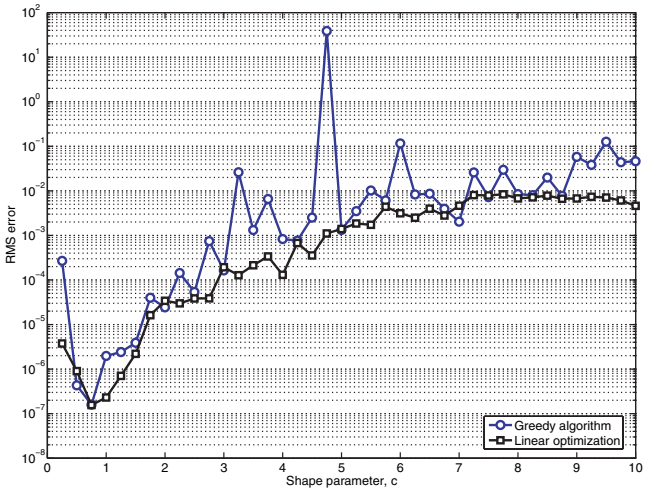
where $x, y \in \mathbb{R}^2$ and $c > 0$ is the *scaling parameter*. As a test equation, we solve the Poisson problem with Dirichlet boundary conditions on $\Omega = [-1, 1]^2$, i.e.,

$$\begin{aligned} \triangle u(x) &= f(x) \quad \text{for } x \in \Omega \subset \mathbb{R}^d, \\ u(x) &= \varphi(x) \quad \text{for } x \in \partial\Omega. \end{aligned} \tag{9.1}$$

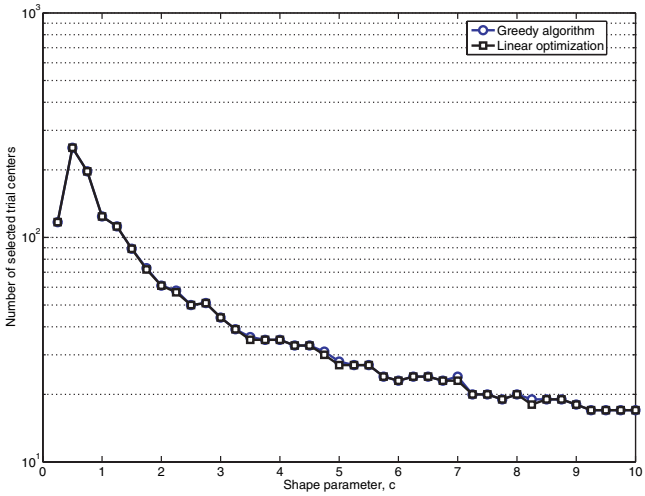
The functions f and φ in (9.1) are generated by the exact solution

$$u^*(x, y) = \frac{1}{2} \log\left((x-2)^2 + (x-2)^2\right).$$

First, the test problem is run on $\Omega = [-1, 1]^2$ with different shape parameters c in order to demonstrate the performance of the adaptive greedy scheme in [11] and the proposed adaptive greedy linear optimization scheme of this paper. The number of trial functions and test functionals offered to the algorithms for selection are $M = 8822$ and $N = 2129$, respectively, but note that the algorithms select much smaller subsets adaptively. In Figure 9.1(a), the root mean square (RMS) errors of both schemes are given. Most of the tested c values are unusual for the original radial basis functions (RBF) collocation method, since in the



(a) *Error profile.*



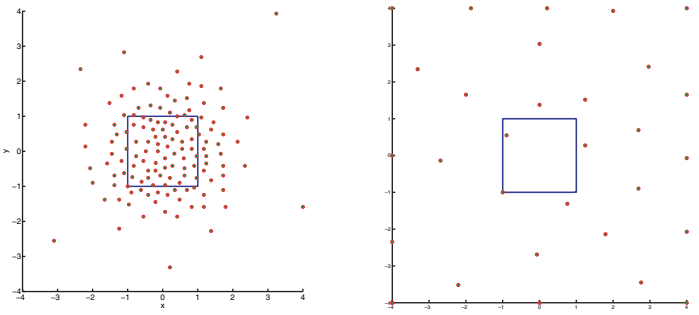
(b) *Degrees of freedom.*

FIG. 9.1. *Solving a Poisson equation with the multiquadric (MQ) kernel on a square domain: Error profile and degrees of freedom as a function of shape parameter c.*

standard setup the shape parameters are usually chosen to have roughly the same order as the mesh norm of the test functionals in order to circumvent the problem of ill-conditioning [7].

It turns out that the new linear optimization scheme is more stable in comparison to the adaptive greedy scheme. In particular, when $c = 4.75$, the adaptive greedy scheme fails to provide an acceptable solution, whereas the new linear optimization scheme performs reasonably well. We observe, from Figure 9.1(a), that there is an optimal shape parameter value of $c = 0.75$ for this particular example,

Furthermore, we show the number m of selected trial centers in Figure 9.1(b). Recall that the new adaptive linear optimization scheme uses the selected m trial centers and finally performs an ℓ^∞ fit to *all* $N \gg m$ available test functionals. In



(a) $c = 1$. (b) $c = 5$.

FIG. 9.2. *Solving a Poisson equation with the MQ kernel on a square domain: Selected trial centers for different shape parameters c.*

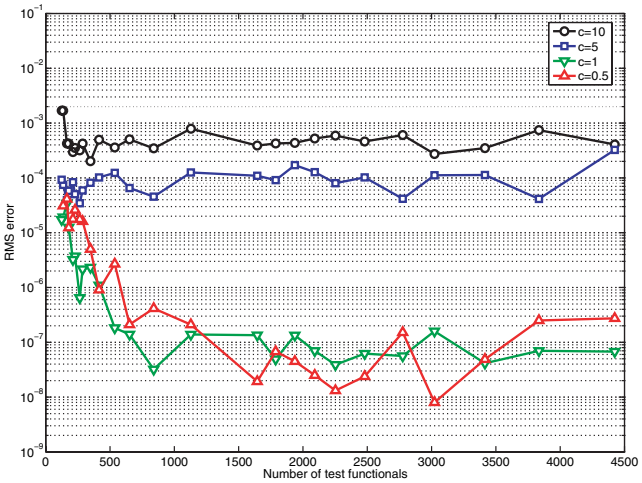


FIG. 9.3. *Solving a Poisson equation with the MQ kernel on an L-shaped domain: Error profile as a function of numbers of test functionals.*

contrast, the original adaptive greedy scheme of [11] calculates an exact interpolation by using the selected m trial functions and $m = n \ll N$ selected test functionals.

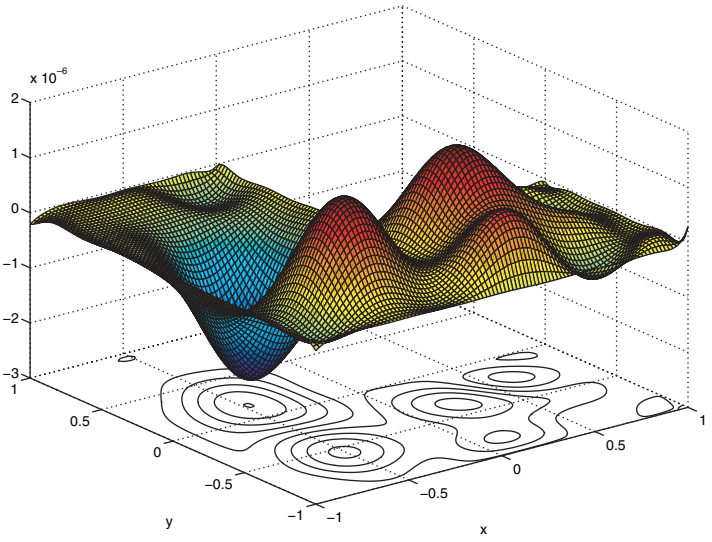
When the shape parameter c increases, the number of trial centers decreases. Moreover, the distributions of the selected trial centers change. As shown in Figure 9.2, in which we show the trial center distributions of two cases when $c = 1$ and $c = 5$, the adaptive algorithm tends to select trial centers away from the domain when the shape parameter is large.

Our next test demonstrates the effect of increasing the number of offered test functionals. This test is run on an L-shaped domain

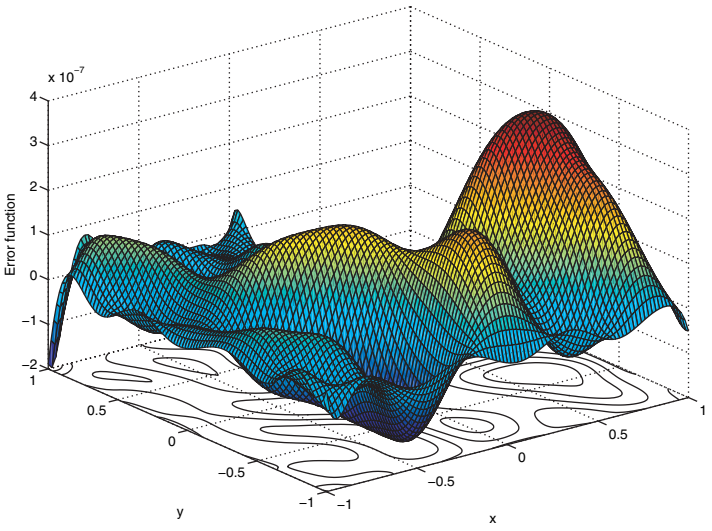
$$\Omega = \{(x, y) : \ -1 \le x, y \le 1, \, \mathrm{sign}(x) + \mathrm{sign}(y) \le 0\}.$$

For all runs, the trial space is adaptively selected from a fixed set of $M = 34692$ trial functions. Four shape parameters $c = 0.5$, $c = 1$, $c = 5$, and $c = 10$ are tested.

Figure 9.3 shows the corresponding RMS errors versus different numbers of test functionals. In all cases, large numbers of test functionals have no significant influence



(a) *Adaptive greedy.*



(b) *Linear optimization.*

FIG. 9.4. *Solving a Poisson equation with the MQ kernel on an L-shaped domain: Error functions.*

on the error. This is in line with our theory, since the error is dominated by the approximation properties of the trial space alone. Enlarging the set of test functionals will stabilize the algorithm. In fact, the error profiles for all tested c values remain stable even though the nonsquare background matrix increases in size, which usually causes ill-conditioning in the original formulation.

Last, Figures 9.4(a) and 9.4(b) show typical error functions of the adaptive greedy method and the proposed linear optimization method, respectively. Since the adaptive

greedy method solves the selected small square submatrix system in the sense of exact interpolation, its error function shows clear peaks. In contrast, the linear optimization method handles the overdetermined system with the selected trial functions and *all* test functionals in such a way that the maximal error in the differential equation and the boundary values is minimized on very many points. Thus the error profile usually is smaller in magnitude and more oscillatory with less obvious peaks.

10. Conclusion. On the theoretical side, we prove that the unsymmetric meshless collocation method, if carried out with smooth kernel-based trial functions and sufficiently many test functionals, converges at the same rate as interpolation of the solution. In particular, trial spaces formed by multiquadrics and Gaussian basis would result in exponential convergence [12] if the solution is analytic. However, from the computational point of view, exponential convergence is difficult to observe under double precision computation. Our proof techniques are much simpler than those of [14] because we focus on minimizing the maximum of the residuals via semi-infinite linear optimization.

On the practical side, we couple the previously proposed greedy technique of [11] with linear optimization to provide a fully adaptive on-the-fly data-dependent method guaranteeing solvability and fitting seamlessly into our theory. Numerical results show that the proposed coupled method is very stable, even though serious ill conditioning of the resultant systems must be expected.

In terms of computational cost, the saving of meshing the domain has shifted to solving the linear optimization problem. The complexity of the linear optimization may be by no means trivial. Interested readers are encouraged to employ the greedy algorithm with least-squares optimization despite the lack of theoretical results.

AN A POSTERIORI–A PRIORI ANALYSIS OF MULTISCALE OPERATOR SPLITTING*

D. ESTEP†, V. GINTING‡, D. ROPP§, J. N. SHADID¶, AND S. TAVENER‡

Abstract. In this paper, we analyze a multiscale operator splitting method for solving systems of ordinary differential equations such as those that result upon space discretization of a reaction-diffusion equation. Our goal is to analyze and accurately estimate the error of the numerical solution, including the effects of any instabilities that can result from multiscale operator splitting. We present both an a priori error analysis and a new type of hybrid a priori–a posteriori error analysis for an operator splitting discontinuous Galerkin finite element method. Both analyses clearly distinguish between the effects of the operator splitting and the discretization of each component of the decomposed problem. The hybrid analysis has the form of a computable a posteriori leading order expression and a provably higher order a priori expression. The hybrid analysis takes into account the fact that the adjoint problems for the original problem and a multiscale operator splitting discretization differ in significant ways. In particular, this provides the means to monitor global instabilities that can arise from operator splitting.

1. Introduction.

Operator decomposition is perhaps the most widely used technique for solving multiscale, multiphysics problems. The general approach is to decompose a model into components involving simpler physics over a relatively limited range of scales, and then to seek the solution of the entire system by using numerical solutions of the individual components. This approach has many appealing aspects. For example, it capitalizes on the significant progress that has been made on the stable, accurate, and efficient solution of a broad spectrum of single-physics problems. It provides an avenue to use highly evolved legacy codes to tackle multiphysics problems. It also provides a natural way to tackle problems encompassing multiple time and length scales.

The classic example of operator decomposition is *operator splitting* for reaction-diffusion equations. The generic picture is a relatively fast, destabilizing reaction component interacting with a relatively slow, stabilizing diffusion component. Accuracy considerations dictate the use of relatively small steps to integrate the reaction component. On the other hand, stability considerations over moderate to long time

intervals suggest the use of implicit, dissipative numerical methods for integrating diffusion problems. Such methods are expensive to use per step, but relatively large steps can be used on a purely dissipative problem. If the reaction and diffusion components are integrated together, then the small steps required for accurate resolution of the reaction lead to an expensive computation.

In a multiscale operator splitting approach, the reaction and diffusion components are integrated independently inside each time interval of a discretization of time and "synchronized" in some fashion only at the nodes of the interval. The reaction component is often integrated by using significantly smaller substeps (e.g., 10^{-5} smaller is not uncommon) than those used to integrate the diffusion component, which can lead to a tremendous computational savings.

However, operator decomposition presents an entirely new set of accuracy and stability issues, some obvious, some subtle, and all difficult to correct. In the case of operator splitting, the instantaneous interaction between reaction and diffusion is discretized and this has a strong effect on accuracy and stability, even if each component is solved exactly. For example, consider the instability observed in the Brusselator problem [28, 27].

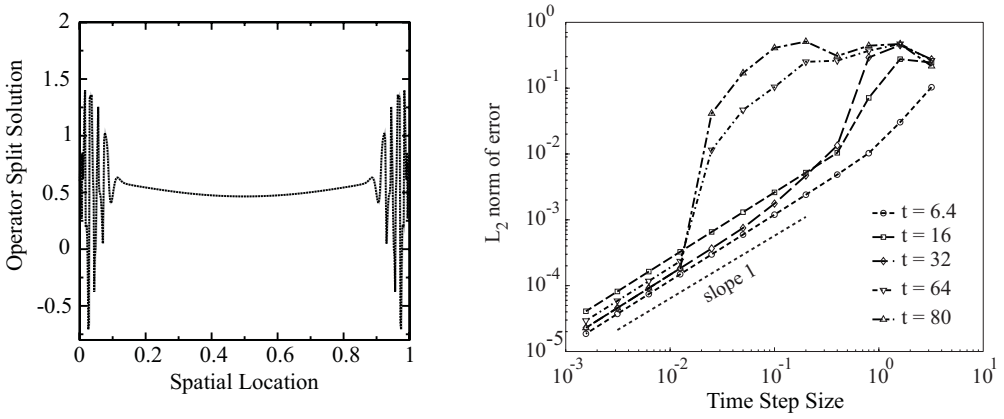

FIG. 1.1. *The left-hand plot illustrates typical instability that can arise from multiscale operator splitting applied to the Brusselator problem. Solution is shown at time* 80. *On the right, we show plots of the error in the* L_2 *norm versus time step size at different times.*

Example 1.1. We illustrate the instability of operator splitting applied to the Brusselator problem in Figure 1.1. We apply a standard first order splitting scheme to a space discretization of the Brusselator model with 500 discrete points (see (6.6) in section 6 with $\alpha = .6$, $\beta = 2$, $k_1 = k_2 = .025$). We integrate using the trapezoidal rule with time step of .2 for the diffusion and backward Euler with time step of .004 for the reaction. On the left of Figure 1.1, we show a numerical solution that exhibits nonphysical oscillations that developed after some time. On the right, we show plots of the error versus time steps at different times. There is a critical time step above which the instability develops. Moreover, changing the space discretization does not improve the accuracy. In [25, 28], it is demonstrated that a finer spatial discretization for a constant time step size leads to significantly more error in the long time solution. The observed instability is a direct consequence of the operator splitting, which in effect separates the stabilizing effect of the diffusion component from the destabilizing reaction component.

Beginning with the classic work of Marchuk and Strang, there is a highly developed literature devoted to a priori convergence analysis of operator splitting for reaction-diffusion equations; see, for example, [32, 23, 5, 20, 31, 34, 8] and the references therein. Almost all of the classic literature assumes that the time steps for the reaction and diffusion components are comparably sized, though Dawson and Wheeler consider multiscale operator splitting for convection-reaction-diffusion problems in [5]. There are also studies of stability properties of various operator splitting procedures; see, for example, [21].

All of the existing convergence analysis is carried out under assumptions that, if strictly enforced, would prevent instabilities arising from the operator splitting discretization. However, enforcing such requirements presents serious problems on both theoretical and practical grounds. This provides the motivation to seek an a posteriori error analysis that devises a computational basis for detecting and correcting instabilities and inaccuracies arising from operator splitting as a particular computation proceeds.

To simplify the presentation, we consider a simple example of operator splitting applied to a model system of ordinary differential equations of the following form: find $y \in \mathbb{R}^l$, $l \geq 1$, such that

$$\begin{cases} \dot{y} = Ay(t) + F(y(t)), & 0 < t \leq T, \\ y(0) = y_0, \end{cases} \tag{1.1}$$

where A is an $l \times l$ constant matrix representing a "diffusion component" and $F(y) = (F_1(y), F_2(y), \ldots, F_l(y))^\top$ is a vector of nonlinear functions representing a "reaction component."

Example 1.2. Such a system arises after semidiscretization of a reaction-diffusion governed by the initial boundary value problem,

$$\begin{cases} \dfrac{\partial u}{\partial t} = \epsilon \, \Delta u + f(u), & x \in \Omega, 0 < t, \\ \text{suitable boundary conditions}, & x \in \partial\Omega, 0 < t, \\ u(\cdot, 0) = u_0(\cdot), \end{cases} \tag{1.2}$$

where $\Omega \subset \mathbb{R}^d$ is a spatial domain. For example, using a continuous, piecewise linear finite element method for a Dirichlet problem with N_e elements, we obtain the initial value problem (1.1). The unknown y consists of the vector of nodal values of the finite element solution with dimension $N_e - 1$, and A is a symmetric negative definite sparse matrix.

Our results extend in a straightforward way to different operator splitting schemes and differential equations with a nonlinear diffusion component, e.g., $\dot{y} = F_D(y) + F_R(y)$, albeit at the cost of complicated notation. Formally, our approach also extends directly to reaction-diffusion problems (1.2) where the splitting is carried out at the continuous differential equation level followed by the discretization independently for each component. A technical issue is dealing with the finite-dimensional representation of the reaction component, which is an ordinary differential equation in a Banach space when the reaction is decoupled from the diffusion.

Our main goal is to derive a computable a posteriori expression that *accurately* estimates the error in a specified quantity of interest computed from a multiscale operator splitting approximate solution of (1.1). The a posteriori analysis is based on duality, adjoint operators, and variational analysis [14, 15, 13, 10, 11, 17, 24, 29].

To deal with operator splitting, we distinguish the effects of operator splitting from the effects of numerical discretization of the components. The latter can be treated with the standard a posteriori analysis. Estimating the error arising from operator splitting requires a new approach.

A main technical issue is the definition of a suitable adjoint problem. The standard approach in error analysis is to form an implicit equation for the error, linearize this problem around an average of the true and approximate solutions using the integral mean value theorem, and then employ the unique adjoint to this linearized error equation [17]. This approach generally works for implicit discretizations, for which the differential operator and its discretization are close in some sense. This approach generally fails or requires significant modification for other discretizations, e.g., explicit, multistep, and implicit/explicit schemes. Indeed, the solution operator for many classes of numerical schemes is associated with *different* adjoint operators than the solution operator for the original problem. This is particularly true for operator decomposition methods, which are generally associated with radically different adjoint operators than the forward problem (see below and [2, 18]). This is one important reason, perhaps unrecognized, why previous a posteriori analyses of evolution problems have focused on fully implicit time integration methods.

Because an adjoint problem carries the global stability information about the quantity of interest computed from the solution, accounting for the differences between adjoint problems associated with the original problem and a numerical discretization is critical for obtaining accurate error estimates. In the estimate derived below, this difference takes the form of "residuals" between certain adjoint operators associated with the fully coupled problem and an analytic operator split version. A practical difficulty with such a result is that solving the adjoint for the fully coupled problem poses the same multiphysics challenges as solving the original forward problem. We therefore develop a new hybrid a priori–a posteriori estimate that combines a computable leading order expression obtained using a posteriori arguments with a provably higher order bound obtained using a priori convergence result.

The rest of the paper is organized as follows. In section 2, we formulate the analytic operator splitting procedure for (1.1) and conduct a preliminary investigation of the instability in operator splitting using an illuminating "blow up" problem. We present a multiscale operator splitting Galerkin finite element method for (1.1) in section 3. We begin the analysis by presenting the results of an a priori convergence analysis of the finite element method in section 4. The main result of the a posteriori analysis of the operator splitting finite element method is presented in section 5, followed by several numerical examples in section 6. In section 7, we give the details of proof of the a priori result. Finally, in section 8, we present a conclusion.

2. Analytic operator splitting. In this section, we define an *analytic* operator splitting version of (1.1). We first discretize $[0,T]$ into $0 = t_0 < t_1 < t_2 < \cdots < t_N = T$ with *diffusion* time steps $\{\Delta t_n\}_{n=1}^N$, $\Delta t_n = t_n - t_{n-1}$, and $\Delta t = \max_{1\le n\le N}(\Delta t_n)$.

For the first discretization, we introduce a theoretical discretization in which each component is solved exactly. We define a piecewise continuous approximate solution

$$\tilde{y}(t) = \frac{t_n - t}{\Delta t_n}\,\tilde{y}_{n-1} + \frac{t - t_{n-1}}{\Delta t_n}\,\tilde{y}_n, \quad t_{n-1} \le t \le t_n, \tag{2.1}$$

with nodal values $\tilde{y}_n$ obtained from the following procedure.

ALGORITHM 2.1 (analytic operator splitting).

- *Set* $\tilde{y}_0 = y_0$.
- *For* $n = 1$ *to* N
  - *Compute* $y^r(t_n^-)$ *satisfying the reaction component*

$$\begin{cases} \dot{y}^r = f(y^r(t)), \quad t_{n-1} < t \le t_n, \\ y^r(t_{n-1}^+) = \tilde{y}_{n-1}. \end{cases} \tag{2.2}$$

  - *Compute* $y^d(t_n^-)$ *satisfying the diffusion component*

$$\begin{cases} \dot{y}^d = Ay^d(t), \quad t_{n-1} < t \le t_n, \\ y^d(t_{n-1}^+) = y^r(t_n^-). \end{cases} \tag{2.3}$$

  - *Set* $\tilde{y}_n = y^d(t_n^-)$.

  end for

Example 2.2. To provide motivation, we consider a problem in which the reaction component exhibits finite time blow up when undamped by the diffusion component. The problem is

$$\begin{cases} \dot{y} + \lambda y = y^2, \qquad t > 0, \\ y(0) = y_0 \in \mathbb{R}, \end{cases} \tag{2.4}$$

which has the exact solution

$$y(t) = \frac{\lambda y_0}{y_0 - (y_0 - \lambda)\, e^{\lambda t}} \tag{2.5}$$

when $\lambda \neq 0$. The exact solution exists for all time and tends to zero as $t \to \infty$ when $\lambda > y_0$. On the other hand, there is finite time blow up if $\lambda < y_0$.

Applying the analytic operator splitting (2.2), (2.3) to (2.4), the solutions of the two components and the true solution are

$$y^r(t) = \frac{y_{n-1}^{d-}}{1 - y_{n-1}^{d-}(t - t_{n-1})}, \quad y^d(t) = e^{-\lambda(t-t_{n-1})}\, y_n^{r-}, \quad \tilde{y}_n = \frac{e^{-\lambda \Delta t_n}\, \tilde{y}_{n-1}}{1 - \Delta t_n\, \tilde{y}_{n-1}}$$

when the reaction component is defined. We see that splitting off the smoothing effect provided by instantaneous interaction with the diffusion component means that the reaction component can blow up in finite time.

The different behavior of the reaction and diffusion components introduces a difference in scales. Consider $\lambda = 2$ with initial condition $y_0 = 1$, so $y(t) = 2/(1+e^{2t})$. This solution has an *asymptotic* decay rate proportional to e^{-2t}, i.e., an *asymptotic* decay time scale of $1/2$. This same asymptotic behavior is observed for any $y_0 < 2$. The solution to the diffusion equation, $y^d(t) = e^{-2(t-t_{n-1})} y_n^{r-}$, has a fixed decay rate proportional to $e^{-2(t-t_{n-1})}$, i.e., a fixed decay time scale $\tau_D = 1/2$. However, the solution to the reaction equation, $y^r(t) = y_{n-1}^{d-}/(1 - y_{n-1}^{d-}(t - t_{n-1}))$, becomes unbounded at $t = t_{n-1} + 1/y_{n-1}^{d-}$ for all $y_{n-1}^{d-} > 0$, and has a doubling time equal to $t_{n-1} + 1/(2y_{n-1}^{d-})$, suggesting a reaction time scale $\tau_R = 1/y_{n-1}^{d-}$. If $y_{n-1}^{d-} \ll 1$, $\tau_R > \tau_D$. If $y_{n-1}^{d-} \approx \lambda$, $\tau_R \approx \tau_D$, but the reaction time scale is not constant and decreases rapidly as the reaction progresses independently undamped by diffusion. Operator splitting has created two uncoupled problems with very different stability properties and with very different time scales. Furthermore, the time scales are not clearly separated nor do they remain in constant proportion. The time scale τ_D is

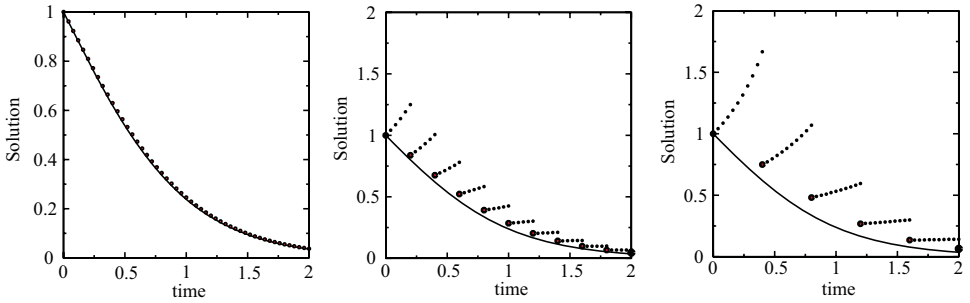

FIG. 2.1. *Plots of the solution $\tilde{y}$ and the true solution. Left: $N = 50$, $M = 1$. Middle: $N = 10$, $M = 5$. Right: $N = 5$, $M = 10$. The nodal values of $\tilde{y}$ are denoted by the larger points, while the smaller points denote node values of the reaction components on the mesh used for the reaction.*

related to the time scale of the coupled process in the limit of small solutions, but the time scale τ_R is completely unrelated.

On the left side of Figure 2.1, we plot the true solution and the nodal values of the approximation $\tilde{y}$ for $N = 50$ diffusion steps and $M = 1$ reaction step per diffusion step. The approximation is reasonably accurate.

Next, we increase the diffusion step by choosing $N = 10$ and, in order to maintain the same resolution, we correspondingly increase to $M = 5$. In Figure 2.1, we plot $\tilde{y}$, the reaction component y^r, and the true solution.

The node values of $\tilde{y}$ are relatively close to those of y. The subsequent nodal values of the reaction component solution y^r inside each step move away from the true solution. This large departure is somewhat counteracted by application of the diffusion operator. The multiscale reaction components exhibit significant growth inside each diffusion step, which severely affects accuracy.

If we increase the diffusion step by taking $N = 5$ and maintain resolution in the reaction component by taking $M = 10$, the approximation becomes even less accurate. In Figure 2.1, we plot $\tilde{y}$, the reaction component y^r, and the true solution. If we increase the diffusion step further, then the reaction component actually blows up inside a diffusion step.

3. A multiscale operator splitting finite element method. We first discretize $[0, T]$ into $0 = t_0 < t_1 < t_2 < \cdots < t_N = T$ with *diffusion* time steps $\{\Delta t_n\}_{n=1}^N$, $\Delta t_n = t_n - t_{n-1}$, and $\Delta t = \max_{1\le n\le N}(\Delta t_n)$. For each diffusion step, we choose a (small) time step $\Delta s_n = \Delta t_n / M_n$ with $\Delta s = \max_{1\le n\le N}(\Delta s_n)$, and the nodes $t_{n-1} = s_{0,n} < s_{1,n} < \cdots < s_{M_n,n} = t_n$ (see Figure 3.1). We associate the time intervals $I_n = [t_{n-1}, t_n]$ and $I_{m,n} = [s_{m-1,n}, s_{m,n}]$ with these discretizations.

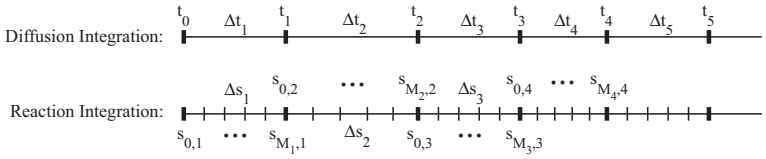

FIG. 3.1. *Discretization of time used for multiscale operator splitting.*

We observe that an operator splitting discretization is actually a consistent discretization of the analytic operator split problem, that is, a consistent discretization

of (2.2) followed by a consistent discretization of (2.3). Since the a posteriori analysis is based on the framework of variational formulation and adjoint problems, we formulate the discretization as a discontinuous Galerkin (dG) finite element method in time [7, 6, 13, 16, 17].

The variational formulation of (1.1) reads, for $n = 1, \ldots, N$, find $y^d \in C^1(I_n)$ such that

$$\begin{cases} \displaystyle\int_{I_n} (\dot{y^d}, v)\, dt = \int_{I_n} (Ay^d, v)\, dt \quad \text{for all } v \in C^1(I_n), \\ y^d(t_{n-1}^+) = y^r(t_n^-), \end{cases} \tag{3.1}$$

where $y^r \in C^1(I_n)$ satisfies

$$\begin{cases} \displaystyle\int_{I_n} (\dot{y^r}, w)\, dt = \int_{I_n} (F(y^r), w)\, dt \quad \text{for all } w \in C^1(I_n), \\ y^r(t_{n-1}^+) = \tilde{y}_{n-1}, \end{cases} \tag{3.2}$$

and we set $\tilde{y}_n = y_n^{d-}$. The finite element approximate solutions are sought in piecewise polynomial spaces,

$$\mathcal{V}^{(q_d)} = \left\{ U : U|_{I_n} \in \mathcal{P}^{(q_d)}(I_n), 1 \le n \le N \right\},$$

$$\mathcal{V}^{(q_r)}(I_n) = \left\{ U : U|_{I_{m,n}} \in \mathcal{P}^{(q_r)}(I_{m,n}), 1 \le m \le M_n \right\}$$

for $n = 1, \ldots, N$, and $I_n = [t_{n-1}, t_n]$ and $I_{m,n} = [s_{m-1,n}, s_{m,n}]$. $\mathcal{P}^{(q_d)}(I_n)$ denotes the space of polynomials in $\mathbb{R}^l$ of degree q_d on I_n. A similar definition holds for $\mathcal{P}^{(q_r)}(I_{m,n})$. We let $U_n^{+,-}$ denote the left- and right-hand limits of U at t_n and $[U]_n = U_n^+ - U_n^-$ the jump value of U at t_n.

Let $\tilde{Y}(t)$ be the piecewise continuous finite element approximation of the operator splitting with

$$\tilde{Y}(t) = \frac{t_n - t}{\Delta t_n}\, \tilde{Y}_{n-1} + \frac{t - t_{n-1}}{\Delta t_n}\, \tilde{Y}_n, \quad t_{n-1} \le t \le t_n.$$

The nodal values $\tilde{Y}_n$ are obtained from the following procedure.

ALGORITHM 3.1 (multiscale operator splitting finite element method).

- *Set* $\tilde{Y}_0 = y_0$.
- *For* $n = 1$ *to* N
  - *Set* $Y_{0,n}^{r-} = \tilde{Y}_{n-1}$.
  - *For* $m = 1$ *to* M_n *compute* $Y^r|_{I_{m,n}} \in \mathcal{P}^{(q_r)}(I_{m,n})$ *satisfying*

$$\int_{I_{m,n}} \left(\dot{Y^r}, W \right) dt + \left([Y^r]_{m-1,n}, W_{m-1}^+ \right) = \int_{I_{m,n}} (F(Y^r), W)\, dt \quad \textit{for all } W \in \mathcal{P}^{(q_r)}(I_{m,n}). \tag{3.3}$$

  end for
  - *Set* $Y_{n-1}^{d-} = Y_{M_n,n}^{r-}$.

– *Compute* $Y^d|_{I_n} \in \mathcal{P}^{(q_d)}(I_n)$ *satisfying*

$$\int_{I_n} (\dot{Y^d}, V)\,dt + \left([Y^d]_{n-1}, V_{n-1}^+\right) = \int_{I_n} (AY^d, V)\,dt \quad \textit{for all } V \in \mathcal{P}^{(q_d)}(I_n). \tag{3.4}$$

– *Set* $\tilde{Y}_n = Y_n^{d-}$.

end for

In general, the dG method using polynomials of degree q converges with order up to $q+1$ at all points t, while its nodal values from the left converge with order up to $2q+1$ under certain conditions; see [11, 13].

Example 3.2. For $q_r = q_d = 0$,

$$\int_{I_{m,n}} F(Y^r)\,dt \to F(Y_{m-1,n}^{r-})\,\Delta s_n, \quad \int_{I_n} AY^d\,dt \to AY_n^{d-}\,\Delta t_n.$$

The dG approximations for the two components are

$$Y_{m,n}^{r-} = Y_{m-1,n}^{r-} + F(Y_{m-1,n}^{r-})\,\Delta s_n, \quad Y_n^{d-} = Y_{n-1}^{d-} + AY_n^{d-}\,\Delta t_n.$$

The former is equivalent to the forward Euler scheme, while the latter is equivalent to the backward Euler scheme.

By employing quadrature formulas to evaluate the integrals in (3.3) and (3.4), many popular finite difference schemes can be described using this variational framework; see [7, 6, 16, 17]. Using quadrature requires a straightforward extension of the a posteriori analysis presented below. The results also extend easily to higher order dG methods as well as the continuous Galerkin (cG) method [15, 17].

Example 3.3. We can use the dG $q_d = 0$ for the diffusion component and the cG $q_r = 1$ implemented with the trapezoidal rule to obtain the reaction component approximation

$$Y_{m,n}^r = Y_{m-1,n}^r + \frac{1}{2}\,\Delta s_n\,\left(F(Y_{m-1,n}^r) + F(Y_{m,n}^r)\right),$$

which is equivalent to the Crank–Nicolson scheme.

4. An a priori convergence analysis. In this section, we carry out an a priori convergence analysis for the multiscale operator splitting dG finite element method. We require this convergence result for the hybrid a posteriori–a priori error analysis. The convergence analysis uses familiar tools from standard results for difference schemes. However, we carry out the analysis in an unusual way by using the analytic operator split problem (2.2) and (2.3) directly.

The goal is to estimate the global error $(y - \tilde{Y}) = (y - \tilde{y}) + (\tilde{y} - \tilde{Y})$, which we decompose as the sum of the error due to the analytical operator splitting and the error due to the numerical discretization of the components of the problem. We give estimates of these two errors in Theorems 4.2 and 4.4, respectively, and combine these in Theorem 4.5.

For $y \in \mathbb{R}^l$, we define the Euclidean norm as $|y|^2 = \sum_{i=1}^l |y_i|^2$.

4.1. A priori error analysis of analytic operator splitting. With $y_n = y(t_n)$, we write the Taylor expansion of $y(t)$ solving (1.1) around t_{n-1} as

$$y(t) = y_{n-1} + (t-t_{n-1})\,(Ay_{n-1} + F(y_{n-1})) + \frac{1}{2}\,(t-t_{n-1})^2\,(A + F'(y_{n-1}))(Ay_{n-1} + F(y_{n-1})) + \mathbf{O}(\Delta t_n^3), \tag{4.1}$$

where $F'(y)$ denotes the Jacobian of $F(y)$. Similarly,

$$y_n^{r-} = y_{n-1}^{r+} + \Delta t_n\,F(y_{n-1}^{r+}) + \frac{1}{2}\,\Delta t_n^2\,F'(y_{n-1}^{r+})\,F(y_{n-1}^{r+}) + \mathbf{O}(\Delta t_n^3)$$

and

$$y_n^{d-} = \left(I + \Delta t_n\,A + \frac{1}{2}\,\Delta t_n^2\,A^2 + \mathbf{O}(\Delta t_n^3)\right)\,y_{n-1}^{d+}.$$

Since $y_{n-1}^{d+} = y_n^{r-}$, $y_{n-1}^{r+} = \tilde{y}_{n-1}$, and $\tilde{y}_n = y_n^{d-}$, we have

$$\tilde{y}_n = \tilde{y}_{n-1} + \Delta t_n\,(A\tilde{y}_{n-1} + F(\tilde{y}_{n-1})) + \frac{1}{2}\,\Delta t_n^2\,\left(A^2\tilde{y}_{n-1} + 2AF(\tilde{y}_{n-1}) + F'(\tilde{y}_{n-1})\,F(\tilde{y}_{n-1})\right) + \mathbf{O}(\Delta t_n^3). \tag{4.2}$$

Furthermore, substitution of (4.2) in (2.1) yields a representation of $\tilde{y}(t)$ with $t_{n-1} \le t \le t_n$:

$$\tilde{y}(t) = \tilde{y}_{n-1} + (t-t_{n-1})\,(A\tilde{y}_{n-1} + F(\tilde{y}_{n-1})) + \frac{1}{2}\,\Delta t_n\,(t-t_{n-1})\,\left(A^2\tilde{y}_{n-1} + F'(\tilde{y}_{n-1})\,F(\tilde{y}_{n-1}) + 2AF(\tilde{y}_{n-1})\right) + \mathbf{O}(\Delta t_n^3). \tag{4.3}$$

LEMMA 4.1. *In the case of* $\tilde{y}_{n-1} = y_{n-1}$,

$$|y_n - \tilde{y}_n| \approx \mathbf{O}(\Delta t_n^2) \quad \textit{and} \quad \int_{I_n} |y(t) - \tilde{y}(t)|\,dt \approx \mathbf{O}(\Delta t_n^3).$$

Proof. With $\tilde{y}_{n-1} = y_{n-1}$, (4.2) yields

$$y_n - \tilde{y}_n = \frac{1}{2}\Delta t_n^2\Big(F'(y_{n-1})Ay_{n-1} - AF(y_{n-1})\Big) + \mathbf{O}(\Delta t_n^3),$$

from which we get the first part of the lemma. Moreover, subtraction of (4.3) from (4.1) with $\tilde{y}_{n-1} = y_{n-1}$ yields

$$y(t) - \tilde{y}(t) = \frac{1}{2}(t-t_{n-1})^2\,(A + F'(y_{n-1}))(Ay_{n-1} + F(y_{n-1})) - \frac{1}{2}\,\Delta t_n\,(t-t_{n-1})\,\left(A^2y_{n-1} + F'(y_{n-1})\,F(y_{n-1}) + 2AF(y_{n-1})\right) + \mathbf{O}(\Delta t_n^3),$$

and the second estimate in the lemma results from integration over I_n. ∎

THEOREM 4.2 (global analytic operator splitting error). *Let y be the solution of* (1.1) *and let $\tilde{y}$ be the solution of the analytical operator splitting* (2.2) *and* (2.3). *Then* $|y_N - \tilde{y}_N| \approx \mathbf{O}(\Delta t)$.

Remark 4.1. If we use higher order splitting, analogous analysis yields a higher order accuracy.

Proof. Subtraction of (4.3) from (4.1) gives

$$\begin{aligned} y_n - \tilde{y}_n &= (y_{n-1} - \tilde{y}_{n-1}) + \Delta t_n \left(F(y_{n-1}) - F(\tilde{y}_{n-1}) + A(y_{n-1} - \tilde{y}_{n-1})\right) + \mathbf{O}(\Delta t_n^2) \\ &\leq C\,|y_{n-1} - \tilde{y}_{n-1}| + \mathbf{O}(\Delta t_n^2), \end{aligned}$$

where C is a generic constant independent of Δt. Summing,

$$|y_N - \tilde{y}_N| \leq C \sum_{n=1}^{N} \mathbf{O}(\Delta t_n^2) \leq C\,\Delta t. \qquad \square$$

Example 4.3. We consider the blow up example in section 2. Assuming a uniform diffusion time step, induction yields

$$\tilde{y}_N = \frac{y_0\, e^{-\lambda t_N}\,(1 - e^{-\lambda \Delta t})}{(1 - e^{-\lambda \Delta t}) - y_0\,\Delta t\,(1 - e^{-\lambda t_N})}.$$

Using (2.5), we obtain an estimate of the analytic operator splitting error

$$|y_N - \tilde{y}_N| = \frac{\left(1 - e^{-2t_N}\right)\,\left(2\Delta t - (1 - e^{-2\Delta t})\right)}{(1 + e^{2t_N})\,((1 - e^{-2\Delta t}) - (1 - e^{-2t_N})\,\Delta t)} \leq C\Delta t.$$

Table 4.1 shows the error versus the time step.

TABLE 4.1
Analytic operator splitting errors at $T = 2.0$ for the blow up example in section 2.

Δt	Error	Order
0.050000	0.00185	1.102
0.025000	0.00089	1.048
0.012500	0.00044	1.023
0.006250	0.00021	1.011
0.003125	0.00010	1.005

4.2. Analysis of the multiscale operator splitting dG finite element method. We now turn to the analysis of the numerical solution of the multiscale operator splitting problem (2.3) and (2.2). The unusual feature of this problem is the numerical solution of an alternating sequence of diffusion and reaction components. The analysis is carried out using the analogue of the standard local error analysis for a finite difference scheme. For each component solve on each interval, we decompose the error as a sum of the error in the initial condition inherited from the previous component solve and the error of the numerical solution of the component assuming exact initial conditions on the current interval. We describe the main results below and give the detailed proof in section 7.

THEOREM 4.4 (numerical discretization error). *Let $\tilde{y}$ be the solution of analytic operator splitting and let $\tilde{Y}$ be the multiscale operator splitting dG finite element solution, which approximates $\tilde{y}$. Assume that there exists a positive constant L such that $|F(u) - F(v)| \leq L\,|u - v|$ for all u, v. Then for $q_d = 0, 1$ and $q_r = 0, 1$,*

$$|\tilde{y}_N - \tilde{Y}_N| \approx \mathbf{O}(\Delta t^{q_d+1}) + \mathbf{O}(\Delta s^{q_r+1}). \tag{4.4}$$

Proof. We set $e = \tilde{y} - \tilde{Y}$ and write

$$e_n = \tilde{y}_n - \tilde{Y}_n = y_n^{d-} - Y_n^{d-} = (y_n^{d-} - X_n^-) + (X_n^- - Y_n^{d-}) = \theta_n^- + \zeta_n^-, \tag{4.5}$$

where X and θ are defined in Lemma 7.5. Subtracting (3.4) from (7.6) yields

$$\int_{I_n} (\dot{\zeta}, V)\, dt - \int_{I_n} (A\zeta, V)\, dt + (\zeta_{n-1}^+, V_{n-1}^+) = (e_n^{r-}, V_{n-1}^+)$$

for all $V \in \mathcal{P}^{(q_d)}(I_n)$, where $e_n^{r-} = y_n^{r-} - Y_n^{r-}$. Now, $\zeta \in \mathcal{V}^{(q_d)}$. Arguing as in the proof of Lemma 7.1, we find

$$|\zeta_n^-| \le \exp(8C_A \Delta t_n)\, |e_n^{r-}|,$$

where $C_A = |A|$. By Lemma 7.2, this inequality together with (4.5) and Lemma 7.5 give the recursive relation

$$|e_n| \le C\left(\Delta t_n^{q_d+2} + \exp(\tau_n)\Delta s_n^{q_r+1}\, \Delta t_n + \exp(2\tau_n)\, |e_{n-1}|\right),$$

where $\tau_n = C\Delta t_n$. From this recursive inequality, we have

$$|e_N| \le C\, \Delta t^{q_d+1} \sum_{n=1}^{N} \exp(2(n-1)\tau_n)\Delta t_n + C\, \Delta s^{q_r+1} \sum_{n=1}^{N} \exp((2n-1)\tau_n)\, \Delta t_n,$$

yielding the desired result. ∎

Combining Theorems 4.2 and 4.4 we have the following global a priori error bound.

THEOREM 4.5 (global a priori error bound). *Let $\tilde{Y}$ be a multiscale operator splitting dG finite element solution. Assume that there exists a positive constant L such that $|F(u) - F(v)| \le L\,|u - v|$ for all u, v. Then for $q_d = 0, 1$ and $q_r = 0, 1$, there exists constants C_1, C_2, C_3 such that*

$$|y_N - \tilde{Y}_N| \le C_1 \Delta t + C_2 \Delta t^{q_d+1} + C_3 \Delta s^{q_r+1}.$$

5. An a posteriori–a priori analysis. We now turn to the hybrid a posteriori–a priori analysis of the multiscale operator splitting dG finite element method. As mentioned in section 1, the analysis differs from the standard a posteriori analysis for an evolution problem in several ways. Mainly, we have to account for the fact that different adjoint operators are associated with the fully coupled problem (1.1) and the analytic operator split version (2.2)–(2.3). The difference between these adjoints provides the means to estimate the effects of operator splitting on the stability properties of a quantity of interest computed from a solution.

5.1. Defining adjoint problems. To define adjoint operators for the forward problems, we seek analogues of the classic representation formula involving the Green's function of a linear elliptic problem. In order to obtain unique adjoint problems from this condition, we use linearization. We assume that $y = 0$ is a steady state solution of (1.1), which can be achieved by assuming that

$$\textit{Homogeneity assumption:} \quad F(0) = 0,$$

and we linearize in a region around 0. In terms of applications to reaction-diffusion problems, there are mathematical reasons for making the homogeneity assumption [30], and it is satisfied in a great many cases. We can modify the analysis to allow for linearization around any other constant steady state solution and more generally around any known function of time. The selection of a suitable "point" for linearization requires some insight into the behavior of the solution being approximated. We illustrate below in the bistable example presented in section 6.

On time interval (t_{n-1}, t_n), we consider the linearized problem

$$\begin{cases} \dot{y} = A\, y(t) + \overline{F'(y)}\, y(t), & t_{n-1} < t \le t_n, \\ y(t_{n-1}) = y_{n-1}, \end{cases}$$

where $\overline{F'(y)}$ is a matrix whose ijth entry is expressed as

$$\overline{F'(y)}_{ij} = \int_0^1 \frac{\partial F_i(sy)}{\partial y_j}\, ds.$$

We note that $\overline{F'(y)}y = F(y)$ because $F(0) = 0$. The generalized Green's function φ satisfies the adjoint problem

$$\begin{cases} -\dot{\varphi} = A^\top \varphi(t) + \overline{F'(y)}^\top \varphi(t), & t_n > t \ge t_{n-1}, \\ \varphi(t_n) = \psi_n, \end{cases} \tag{5.1}$$

where ψ_n determines the quantity of interest $(y(t_n), \psi_n)$, and $A^\top$ and $\overline{F'(y)}^\top$ denote the transpose of A and $\overline{F'(y)}$, respectively.

Remark 5.1. The analysis extends to cover quantities of interest of the form $\int_0^T (y, \psi)\, dt$ in a straightforward way.

We choose $\psi_n = \varphi(t_n^+)$, which couples the local adjoint problems (5.1) to form a global adjoint problem. This definition yields a simple representation of the solution value over one time step. Taking the Euclidean inner product of (5.1) with y and integrating over I_n gives

$$\begin{aligned} 0 &= \int_{I_n} \left(-\dot{\varphi} - A^\top \varphi(t) - \overline{F'(y)}^\top \varphi(t), y \right) dt \\ &= -\int_{I_n} \frac{d}{dt}(\varphi, y)\, dt + \int_{I_n} (\dot{y} - Ay - \overline{F'(y)}y, \varphi) dt. \end{aligned} \tag{5.2}$$

The second term on the right-hand side vanishes by (1.1), and thus integrating the first term yields

$$(y_n, \psi_n) = (y_{n-1}, \varphi_{n-1}). \tag{5.3}$$

Using the analogous approach for each component of the analytic operator splitting (2.2) and (2.3), we define the two adjoint problems for $n = 1, \ldots, N$,

$$\begin{cases} -\dot{\varphi^r} = \overline{F'(y^r)}^\top \varphi^r(t), & t_n > t \ge t_{n-1}, \\ \varphi^r(t_n^-) = \psi_n^r, \end{cases} \tag{5.4}$$

$$\begin{cases} -\dot{\varphi^d} = A^\top \varphi^d(t), & t_n > t \ge t_{n-1}, \\ \varphi^d(t_n^-) = \psi_n^d. \end{cases} \tag{5.5}$$

Note that (5.4) is linearized around y^r. We obtain the following representations for the component solutions:

$$(y_n^{r-}, \psi_n^r) = (y_{n-1}^{r+}, \varphi_{n-1}^{r+}) = (\tilde{y}_{n-1}, \varphi_{n-1}^{r+}), \tag{5.6}$$

$$(y_n^{d-}, \psi_n^d) = (y_{n-1}^{d+}, \varphi_{n-1}^{d+}) = (y_n^{r-}, \varphi_{n-1}^{d+}). \tag{5.7}$$

5.2. A local representation of the analytic operator splitting error. As with the a priori analysis, we begin with the decomposition

$$y - \tilde{Y} = (y - \tilde{y}) + (\tilde{y} - \tilde{Y}). \tag{5.8}$$

In order to construct a representation of the nodal value $y_n - \tilde{y}_n$, where $\tilde{y}_n = y_n^{d-}$, it is natural to set $\psi_n^r = \varphi_{n-1}^{d+}$. Thus, taken together, the adjoint components (5.4)–(5.5) are analogous to an analytic operator split version of the adjoint problem (5.1), except that the linearization is taken around y^r instead of y. Note that the adjoint component problems (5.4)–(5.5) are solved "in the reverse order," which mirrors the fact that the adjoint of a composition of linear transformations is equal to the composition of the adjoints of the transformations computed in reverse order.

Now we combine (5.6) and (5.7) to get

$$(\tilde{y}_n, \psi_n^d) = (y_n^{d-}, \psi_n^d) = (\tilde{y}_{n-1}, \varphi_{n-1}^{r+}). \tag{5.9}$$

To obtain a representation of the local error of operator splitting, we assume that the adjoint problems (5.1) and (5.5) and (5.4) have the same data $\psi_n^d = \psi_n$ at time t_n. Using (5.3) and (5.9) we obtain the error representation

$$(y_n - \tilde{y}_n, \psi_n) = (y_{n-1}, \varphi_{n-1}) - (\tilde{y}_{n-1}, \varphi_{n-1}^{r+}). \tag{5.10}$$

At this point, it is convenient to change notation and introduce the solution operators of the various adjoint problems. Let $\Phi_n(y)$ be the solution operator for the full adjoint problem (5.1) so $\Phi_n(y)\psi_n = \varphi_{n-1}$. For a problem of the form (1.1),

$$\Phi_n(y) = \exp\left(\Delta t_n A^\top + \int_{I_n} \overline{F'(y)}^\top \, dt\right).$$

Similarly, we set $\Phi_n^r(y^r)$ and Φ_n^d to be the solution operators for (5.4) and (5.5), respectively, so

$$\Phi_n^r(y^r)\varphi_n^{r-} = \varphi_{n-1}^{r+} \quad \text{and} \quad \Phi_n^d \psi_n^d = \varphi_{n-1}^{d+}.$$

For (1.1),

$$\Phi_n^r(y^r) = \exp\left(\int_{I_n} \overline{F'(y^r)}^\top \, dt\right) \quad \text{and} \quad \Phi_n^d = \exp\left(\Delta t_n A^\top\right).$$

Under the assumptions above, $\varphi_{n-1}^{r+} = \Phi_n^r(y^r)\Phi_n^d\psi_n$, and (5.10) reads

$$(y_n - \tilde{y}_n, \psi_n) = (y_{n-1}, \Phi_n(y)\psi_n) - (\tilde{y}_{n-1}, \Phi_n^r(y^r)\Phi_n^d\psi_n).$$

To conduct a local analysis, we assume that the forward problems have the correct data $\tilde{y}_{n-1} = y_{n-1}$. Thus, we obtain the following.

THEOREM 5.1 (local analytical splitting error). *The splitting error over a single diffusion time step is represented by*

$$(y_n - \tilde{y}_n, \psi_n) = (\tilde{y}_{n-1}, \Delta\Phi_n \, \psi_n), \tag{5.11}$$

with $\Delta\Phi_n = \Phi_n(y) - \Phi_n^r(y^r)\Phi_n^d$.

We note that the first term on the right-hand side of (5.11) includes the effects associated with the linearization of the nonlinear reaction function around y and y^r, respectively. The goal now is to use (5.11) to derive a computable estimate.

5.3. An error representation for the multiscale operator splitting dG finite element solution. We now derive the error estimate for the numerical discretization of the analytic operator splitting. Let ϑ^d define the adjoint solution associated with (3.4) (diffusion component) satisfying

$$\begin{cases} -\dot{\vartheta^d} = A^\top \vartheta^d(t), & t_n > t \geq t_{n-1}, \\ \vartheta^d(t_n^-) = \psi_n. \end{cases}$$

Furthermore, let ϑ^r define the adjoint solution associated with (3.3) (reaction component) satisfying

$$\begin{cases} -\dot{\vartheta^r} = (\hat{F}'(y^r, Y^r))^\top \vartheta^r(t), & s_{m,n} > t \geq s_{m-1,n}, \\ \vartheta^r(s_{m,n}) = \psi^r_{m,n} \end{cases}$$

for $m = M_n, \ldots, 1$, with $\psi^r_{M_n,n} = \vartheta^{d+}_{n-1}$ and $\psi^r_{m,n} = \vartheta^r_{m,n}$ for $m < M_n$. Thus ϑ^r is continuous across the internal reaction time nodes $s_{m,n}$, $m = 1, \ldots, M_n - 1$. Here $\hat{F}'(y^r, Y^r)$ is the Jacobian matrix linearized along the trajectory $zy^r + (1-z)Y^r$, with entries

$$\hat{F}'_{ij} = \int_0^1 \frac{\partial F_i}{\partial y_j}(zy^r + (1-z)Y^r)\, dz.$$

We set $e^d = y^d - Y^d$ and $e^r = y^r - Y^r$. Obviously on time interval I_n,

$$\int_{I_n} (e^d, \dot{\vartheta^d} + A^\top \vartheta^d)\, dt = 0 \quad \text{and} \quad \int_{I_n} (\dot{y^d} - Ay^d, \vartheta^d)\, dt = 0.$$

Using integration by parts

$$\int_{I_n} (e^d, \dot{\vartheta^d})\, dt = (e^{d-}_n, \psi_n) - (e^{d+}_{n-1}, \vartheta^{d+}_{n-1}) - \int_{I_n} (\dot{e^d}, \vartheta^d)\, dt,$$

we obtain

$$(e^{d-}_n, \psi_n) = (e^{d+}_{n-1}, \vartheta^{d+}_{n-1}) - \int_{I_n} (\dot{Y^d} - AY^d, \vartheta^d)\, dt.$$

Furthermore, taking $V = \Pi\vartheta^d \in \mathcal{V}^{(q_d)}$ in (3.4) and using the fact that $e^{d+}_{n-1} = e^{r-}_{M_n,n} - [Y^d]_{n-1}$ yields

$$(e^{d-}_n, \psi_n) = (e^{r-}_n, \vartheta^{d+}_{n-1}) - \int_{I_n} (\dot{Y^d} - AY^d, \vartheta^d - \Pi\vartheta^d)\, dt - ([Y^d]_{n-1}, \vartheta^{d+}_{n-1} - \Pi\vartheta^{d+}_{n-1}).$$

To get a representation for e^{r-}_n, we use similar arguments to obtain

$$0 = \sum_{m=1}^{M_n} \left((e^{r-}_{m,n}, \vartheta^{r-}_{m,n}) - (e^{r+}_{m-1,n}, \vartheta^{r+}_{m-1,n}) - \int_{I_{m,n}} (\dot{e^r} - (\hat{F}'(y^r, Y^r))e^r, \vartheta^r)\, dt \right).$$

Since $(\hat{F}'(y^r, Y^r))e^r = F(y^r) - F(Y^r)$, and y^r satisfies (2.2), this reduces to

$$0 = \sum_{m=1}^{M_n} \left((e^{r-}_{m,n}, \vartheta^{r-}_{m,n}) - (e^{r+}_{m-1,n}, \vartheta^{r+}_{m-1,n}) + \int_{I_{m,n}} (\dot{Y}^r - F(Y^r), \vartheta^r)\, dt \right).$$

Taking $V = \Pi\vartheta^r \in \mathcal{V}^{(q_r)}(I_n)$ in (3.3), we then have

$$0 = \sum_{m=1}^{M_n} (e^{r-}_{m,n}, \vartheta^{r-}_{m,n}) - (e^{r-}_{m-1,n}, \vartheta^{r+}_{m-1,n}) + \int_{I_{m,n}} (\dot{Y}^r - F(Y^r), \vartheta^r - \Pi\vartheta^r)\, dt + ([Y^r]_{m-1,n}, \vartheta^{r+}_{m-1,n} - \Pi\vartheta^{r+}_{m-1,n}).$$

Now since $\vartheta^{r-}_{m,n} = \vartheta^{r+}_{m,n}$, $e^{r-}_{0,n} = \tilde{y}_{n-1} - \tilde{Y}_{n-1}$, we get

$$(e^{r-}_{M_n,n}, \vartheta^{d+}_{n-1}) = (\tilde{y}_{n-1} - \tilde{Y}_{n-1}, \vartheta^{r+}_{0,n}) - \sum_{m=1}^{M_n} \left(\int_{I_{m,n}} (\dot{Y}^r - f(Y^r), \vartheta^r - \Pi\vartheta^r)\, dt + ([Y^r]_{m-1,n}, \vartheta^{r+}_{m-1,n} - \Pi\vartheta^{r+}_{m-1,n}) \right).$$

Note that $e^{d-}_n = \tilde{y}_n - \tilde{Y}_n$, and thus we can combine all these representations into the following result.

THEOREM 5.2 (local discretization error). *The discretization error over a single diffusion step is represented by*

$$(\tilde{y}_n - \tilde{Y}_n, \psi_n) = (\tilde{y}_{n-1} - \tilde{Y}_{n-1}, \vartheta^{r+}_{0,n}) - \sum_{m=1}^{M_n} \left(\int_{I_{m,n}} (\dot{Y}^r - F(Y^r), \vartheta^r - \Pi\vartheta^r)\, dt + ([Y^r]_{m-1,n}, \vartheta^{r+}_{m-1,n} - \Pi\vartheta^{r+}_{m-1,n}) \right) - \int_{I_n} (\dot{Y}^d - AY^d, \vartheta^d - \Pi\vartheta^d)\, dt - ([Y^d]_{n-1}, \vartheta^{d+}_{n-1} - \Pi\vartheta^{d+}_{n-1}). \tag{5.12}$$

5.4. A computable error representation. In light of (5.12) and (5.11), which represent the errors over a single diffusion step, and using $\tilde{y}_{n-1} = y_{n-1}$, we obtain the recursive relation

$$(y_n - \tilde{Y}_n, \psi_n) = (y_{n-1} - \tilde{Y}_{n-1}, \vartheta^{r+}_{0,n}) + (y_{n-1}, \Delta\Phi_n\, \psi_n) - \sum_{m=1}^{M_n} \left(\int_{I_{m,n}} (\dot{Y}^r - F(Y^r), \vartheta^r - \Pi\vartheta^r)\, dt + ([Y^r]_{m-1,n}, \vartheta^{r+}_{m-1,n} - \Pi\vartheta^{r+}_{m-1,n}) \right) - \int_{I_n} (\dot{Y}^d - AY^d, \vartheta^d - \Pi\vartheta^d)\, dt - ([Y^d]_{n-1}, \vartheta^{d+}_{n-1} - \Pi\vartheta^{d+}_{n-1}). \tag{5.13}$$

Undoing (5.13) after choosing the adjoint data $\psi_{n-1} = \vartheta^{r+}_{0,n}$ for $n = 2, \ldots, N-1$ and summing the resulting expressions up to N yields the following result.

THEOREM 5.3. *Given an adjoint data ψ_N, the operator splitting error at the final time can be represented as*

$$
\begin{aligned}
(y_N - \tilde{Y}_N, \psi_N) &= \sum_{n=1}^{N} (y_{n-1}, \Delta\Phi_n\, \psi_n) \\
&- \sum_{n=1}^{N} \sum_{m=1}^{M_n} \left(\int_{I_{m,n}} \left(\dot{Y^r} - F(Y^r), \vartheta^r - \Pi\vartheta^r \right) dt + \left([Y^r]_{m-1,n}, \vartheta^{r+}_{m-1,n} - \Pi\vartheta^{r+}_{m-1,n} \right) \right) \\
&- \sum_{n=1}^{N} \left(\int_{I_n} \left(\dot{Y^d} - AY^d, \vartheta^d - \Pi\vartheta^d \right) dt + \left([Y^d]_{n-1}, \vartheta^{d+}_{n-1} - \Pi\vartheta^{d+}_{n-1} \right) \right) \\
&= \tilde{Q}_1 + Q_2 + Q_3,
\end{aligned} \tag{5.14}
$$

where $\psi_{n-1} = \vartheta^{r+}_{0,n}$ for $n = 2, \ldots, N-1$.

$\tilde{Q}_1$ represents the accumulated effects of operator splitting measured using the *adjoint residual* $\Delta\Phi_n\, \psi_n$ weighted by the solution values y_{n-1}. Note that if y tends to zero as time passes, then the accumulated effects of operator splitting decrease correspondingly. On the other hand, if y is increasing, then the effects of operator splitting also increase. The quantities Q_2 and Q_3 are typical a posteriori error representations for the dG finite element approximate solutions of the component problems and are computable up to the linearization of the error equation (which typically does not cause difficulty [17, 9].) Note that we expect the dG approximations to be much closer to the analytic operator split solutions, $\mathbf{O}(\Delta s^{q_r+1})$ and $\mathbf{O}(\Delta t^{q_d+1})$, respectively, than to the solution of the full problem.

Unfortunately, $\tilde{Q}_1$ contains quantities that are not computable, namely, the exact solution of the fully coupled problem (1.1) and the associated adjoint operator. Even if we have the true solution, we cannot expect to solve the adjoint of the full problem since this nominally presents the same difficulties as the original forward problem. We now decompose $\tilde{Q}_1$ into a computable leading order expression and a remainder that is provably higher order. As a first step,

$$
\begin{aligned}
(y_N - \tilde{Y}_N, \psi_N) &= \sum_{n=1}^{N} \left(\tilde{Y}_{n-1}, \Delta\Phi_n\, \psi_n \right) + Q_2 + Q_3 + \sum_{n=1}^{N} \left(y_{n-1} - \tilde{Y}_{n-1}, \Delta\Phi_n\, \psi_n \right) \\
&= Q_1 + Q_2 + Q_3 + Q_4,
\end{aligned} \tag{5.15}
$$

where Q_2 and Q_3 are the same as for (5.14), and the new expression Q_1 does not depend directly on the solution values. Next, we derive a computable estimate for the factor $\Delta\Phi_n\, \psi_n$ in Q_1 and then use asymptotic analysis to prove that after substituting the estimate the remainders from Q_1 as well as from Q_4 are higher order.

Example 5.4. To motivate (5.15) as a natural representation, we consider the blow up example in section 2 once again. Since there is no numerical solution involved, the expressions Q_2 and Q_3 drop out. The adjoint associated with the blow up problem is

$$
\varphi(t) = \Phi_n(t)\, \psi_n, \quad t_n > t \geq t_{n-1}, \quad \Phi_n(t) = \frac{y_{n-1} - (y_{n-1} - \lambda)e^{\lambda(t-t_{n-1})}}{y_{n-1} - (y_{n-1} - \lambda)e^{\lambda\Delta t_n}}.
$$

Since the diffusion component is linear, the associated adjoint is readily seen to be

$$
\varphi^d(t) = \Phi^d_n(t)\, \psi^d_n, \quad t_n > t \geq t_{n-1}, \quad \Phi^d_n(t) = e^{\lambda(t-t_n)}.
$$

For the reaction component, the associated adjoint is

$$\varphi(t) = \Phi_n^r(t)\,\psi_n, \quad t_n > t \geq t_{n-1}, \quad \Phi_n^r(t) = \frac{1 - y_{n-1}^{d-}(t - t_{n-1})}{1 - y_{n-1}^{d-}\Delta t_n}$$

for $t \in I_n$. At the final time level t_N, (5.15) reads

$$y_N - \tilde{y}_N = \sum_{n=1}^{N} y_{n-1}^{d-}\,\Delta\Phi_n(t_{n-1})\,\psi_n + \sum_{n=1}^{N} \left(y_{n-1} - y_{n-1}^{d-}\right)\,\Delta\Phi_n(t_{n-1})\psi_n,$$

where $\psi_N = 1$ and $\psi_n = \Phi_{n+1}^r(t_n)\,\Phi_{n+1}^d(t_n)\,\psi_{n+1}$ for $1 \leq n < N$.

Table 5.1 illustrates the performance of the a posteriori error representation. We use $\lambda = 0.9$ and initial condition $y_0 = 1$. The column with title "order" shows the computed order of convergence of Q_4 to zero.

TABLE 5.1
Operator splitting estimated errors at $T = 2.0$ for blow up example in section 2.

Δt	Exact	Q_1	Q_4	Order
1/80	−0.176863	−0.183464	0.006600	2.176
1/160	−0.085044	−0.086602	0.001557	2.083
1/320	−0.041723	−0.042101	0.000378	2.040
1/640	−0.020667	−0.020760	0.000093	2.020
1/1280	−0.010285	−0.010309	0.000023	2.010

This example suggests that

$$\Delta\Phi_n = \Phi_n(y) - \Phi_n^r(y^r)\Phi_n^d \approx \mathbf{O}(\Delta t_n^2). \tag{5.16}$$

If this is true, then Q_4 is $\mathbf{O}(\Delta t^{q_d+2})$ and can be ignored in the asymptotic limit when computing an estimate.

It helps to decompose (5.16) into two separate quantities,

$$\Phi_n(y) - \Phi_n^r(y^r)\Phi_n^d = \left(\Phi_n(y) - \Phi_n^r(y)\Phi_n^d\right) + \left((\Phi_n^r(y) - \Phi_n^r(y^r))\;\Phi_n^d\right) = E_1 + E_2.$$

E_1 measures the splitting error around the true solution, while E_2 measures the effect of switching the linearization from around the true solution y to around y^r in the nonlinear reaction.

We next derive an asymptotic representation for E_1.

LEMMA 5.5. *$E_1 = \overline{E}_1 + \mathbf{O}(\Delta t_n^3)$, with*

$$\overline{E}_1 = \frac{1}{2}\Delta t_n \left(A^\top R(\tilde{y}) - R(\tilde{y})\,A^\top\right) \quad \textit{and} \quad R(y) = \int_{I_n} \overline{F'(y)}^\top\, dt.$$

Proof. Using the expansion $\exp(B) = \sum_{i=0}^{\infty} \frac{1}{i!} B^i$ for a square matrix B, E_1 can be expressed as

$$E_1 = \frac{1}{2}\left(\Delta t_n A^\top\, R(y) - R(y)\,\Delta t_n A^\top\right) + \mathbf{O}(\Delta t_n^3). \tag{5.17}$$

E_1 can be approximated by the first term in (5.17) up to $\mathbf{O}(\Delta t_n^3)$. For practical reasons, the dependence on y has to be avoided. A natural candidate to replace y is the operator splitting solution $\tilde{y}$, which is approximated to high order by the operator

splitting dG finite element method. By adding and subtracting appropriate terms, we write

(5.18)
$$E_1 \approx \frac{1}{2}\Delta t_n \left(A^\top R(\tilde{y}) - R(\tilde{y})\, A^\top\right) + \frac{1}{2}\Delta t_n A^\top \left(R(y) - R(\tilde{y})\right) + \frac{1}{2}\Delta t_n (R(\tilde{y}) - R(y))\, A^\top.$$

It is obvious that the first term is computable. The task is to demonstrate that the remaining terms in (5.18) are higher order. Specifically, we show that

$$\left(\tilde{Y}_{n-1}, A^\top \left(R(y) - R(\tilde{y})\right) \psi_n\right) \approx \mathbf{O}(\Delta t_n^2) \tag{5.19}$$

and

$$\left(\tilde{Y}_{n-1}, (R(\tilde{y}) - R(y))\, A^\top \psi_n\right) \approx \mathbf{O}(\Delta t_n^2). \tag{5.20}$$

For (5.19), we may write

$$\begin{aligned}\left(\tilde{Y}_{n-1}, A^\top (R(y) - R(\tilde{y}))\psi_n\right) &= \left(A\tilde{Y}_{n-1}, (R(y) - R(\tilde{y}))\psi_n\right) \\ &\le |A|_{l_\infty} |\tilde{Y}_{n-1}|_{l_\infty} |R(y) - R(\tilde{y})|_{l_1} |\psi_n|_{l_1},\end{aligned}$$

where we have used the usual vector norms and the corresponding subordinate matrix norms. In particular, since $R(y)$ involves the matrix transpose,

$$|R(y) - R(\tilde{y})|_{l_1} = \max_{1\le i\le l} \sum_{j=1}^{l} \left| \int_{I_n} (\overline{F'}_{ij}(y) - \overline{F'}_{ij}(\tilde{y}))\, dt \right| \le C \int_{I_n} |y - \tilde{y}|\, dt,$$

where we have used the Lipschitz continuity of $\overline{F'}_{ij}$. By Lemma 4.1 this yields (5.19). Similar arguments hold for (5.20) and the proof is complete. ∎

Next, we seek an approximate estimate for E_2 that does not depend on the unknown solution y.

LEMMA 5.6. *Assume that* $\frac{\partial F_i}{\partial y_j}$ *and* $\frac{\partial^2 F_i}{\partial y_j \partial y_k}$ *are Lipschitz continuous. Then* $E_2 = \overline{E}_2 + \mathbf{O}(\Delta t_n^3)$, *with* $\overline{E}_2 = \left(\Phi_n^r(\tilde{y}) - \Phi_n^r(y^r)\right) \Phi_n^d$.

Proof. We write

$$E_2 = \left(\Phi_n^r(\tilde{y}) - \Phi_n^r(y^r)\right) \Phi_n^d + \left(\Phi_n^r(y) - \Phi_n^r(\tilde{y})\right) \Phi_n^d.$$

We want to show that

$$\left(\Phi_n^r(y) - \Phi_n^r(\tilde{y})\right) \Phi_n^d \approx \mathbf{O}(\Delta t_n^3).$$

This requires estimating the difference between the solution operators of the reaction component adjoints corresponding to linearization around y and $\tilde{y}$. The solution operator $\Phi_n^r(y)$ is associated with the problem

$$\begin{cases} -\dot{\omega} = \overline{F'(y)}^\top \omega(t), & t_n > t \ge t_{n-1}, \\ \omega(t_n) = \Phi_n^d \psi_n, \end{cases} \tag{5.21}$$

while the solution operator $\Phi_n^r(\tilde{y})$ is associated with

$$\begin{cases} -\dot{\tilde{\omega}} = \overline{F'(\tilde{y})}^\top \tilde{\omega}(t), & t_n > t \ge t_{n-1}, \\ \tilde{\omega}(t_n) = \Phi_n^d \psi_n. \end{cases} \tag{5.22}$$

We expect that if $\tilde{y}$ closely approximates y, then the solutions of these differential equations are close as well. In fact, Lemma 4.1 implies that $|y_n - \tilde{y}_n| \approx \mathbf{O}(\Delta t_n^2)$ for $\tilde{y}_{n-1} = y_{n-1}$.

Using a Taylor expansion, we write

$$\begin{aligned}\omega(t_{n-1}) &= \omega(t_n) - \Delta t_n \frac{d\omega(t_n)}{dt} + \frac{1}{2}\Delta t_n^2 \frac{d^2\omega(t_n)}{dt^2} + \mathbf{O}(\Delta t_n^3) \\ &= \left(I + \Delta t_n \overline{F'(y_n)}^\top - \frac{1}{2}\Delta t_n^2 \left(\frac{d\overline{F'(y_n)}^\top}{dt} + [\overline{F'(y_n)}^\top]^2 \right) \right) \Phi_n^d \psi_n + \mathbf{O}(\Delta t_n^3).\end{aligned}$$

Similarly,

$$\tilde{\omega}(t_{n-1}) = \left(I + \Delta t_n \overline{F'(\tilde{y_n})}^\top - \frac{1}{2}\Delta t_n^2 \left(\frac{d\overline{F'(\tilde{y_n})}^\top}{dt} + [\overline{F'(\tilde{y_n})}^\top]^2 \right) \right) \Phi_n^d \psi_n + \mathbf{O}(\Delta t_n^3).$$

In these two expansions, we have applied the initial condition $\omega(t_n) = \tilde{\omega}(t_n) = \Phi_n^d \psi_n$. Taking the difference between the expansions,

$$\begin{aligned}&\omega(t_{n-1}) - \tilde{\omega}(t_{n-1}) \\ &= \left(\Delta t_n (\overline{F'(y_n)}^\top - \overline{F'(\tilde{y}_n)}^\top) + \frac{1}{2}\Delta t_n^2 \frac{d}{dt} \left(\overline{F'(\tilde{y}_n)}^\top - \overline{F'(y_n)}^\top \right) \right. \\ &\qquad \left. + \frac{1}{2}\Delta t_n^2 \left(\left[\overline{F'(\tilde{y_n})}^\top \right]^2 - \left[\overline{F'(y_n)}^\top \right]^2 \right) \right) \Phi_n^d \psi_n + \mathbf{O}(\Delta t_n^3).\end{aligned} \tag{5.23}$$

Now, we show that $\overline{F'(y_n)}^\top - \overline{F'(\tilde{y}_n)}^\top$ is $\mathbf{O}(\Delta t_n^2)$, and that $([\overline{F'(\tilde{y_n})}^\top]^2 - [\overline{F'(y_n)}^\top]^2)$ and $d/dt(\overline{F'(\tilde{y}_n)}^\top - \overline{F'(y_n)}^\top)$ are at least $\mathbf{O}(\Delta t_n)$. In elemental form, we may write

$$\overline{F'(y_n)}_{ij} - \overline{F'(\tilde{y}_n)}_{ij} = \int_0^1 \left(\frac{\partial F_i(sy_n)}{\partial y_j} - \frac{\partial F_i(s\tilde{y}_n)}{\partial y_j} \right) ds \leq C|y_n - \tilde{y}_n| \approx \mathbf{O}(\Delta t_n^2),$$

where we have used the assumption that $\partial F_i(y)/\partial y_j$ is Lipschitz continuous. Moreover, we may write

$$\begin{aligned}\left([\overline{F'(\tilde{y_n})}^\top]^2 - [\overline{F'(y_n)}]^2 \right) &= \left(\overline{F'(\tilde{y_n})}^\top - \overline{F'(y_n)}^\top \right) \overline{F'(\tilde{y_n})}^\top \\ &\quad + \overline{F'(y_n)} \left(\overline{F'(\tilde{y_n})}^\top - \overline{F'(y_n)}^\top \right).\end{aligned}$$

Arguing as above shows this term is $\mathbf{O}(\Delta t_n^2)$, and thus the contribution of the third term in (5.23) is $\mathbf{O}(\Delta t_n^4)$. The same conclusion about the second term in (5.23) follows using the assumption that $\frac{\partial^2 F_i}{\partial y_j \partial y_k}$ is Lipschitz continuous. This finally leads to the conclusion that $\omega(t_{n-1}) - \tilde{\omega}(t_{n-1}) = \mathbf{O}(\Delta t_n^3)$. ∎

Finally, Lemmas 5.5 and 5.6 involve $\tilde{y}$ and y^r, which we do not have in practice. We use the same kinds of arguments to replace them by the approximations $\tilde{Y}$ and Y^r at the cost of further higher order expressions. The result is contained in Theorem 5.7.

THEOREM 5.7 (computable a posteriori error estimate). *A computable error representation for the multiscale operator splitting dG finite element method is*

$$
\begin{aligned}
(y_N - \tilde{Y}_N, \psi_N) &= \sum_{n=1}^{N} (\tilde{Y}_{n-1}, (\overline{E}_1 + \overline{E}_2)\psi_n) \\
&- \sum_{n=1}^{N} \sum_{m=1}^{M_n} \left(\int_{I_{m,n}} (\dot{Y^r} - F(Y^r), \vartheta^r - \Pi\vartheta^r)\, dt + ([Y^r]_{m-1,n}, \vartheta^{r+}_{m-1,n} - \Pi\vartheta^{r+}_{m-1,n}) \right) \\
&- \sum_{n=1}^{N} \left(\int_{I_n} (\dot{Y^d} - AY^d, \vartheta^d - \Pi\vartheta^d)\, dt + ([Y^d]_{n-1}, \vartheta^{d+}_{n-1} - \Pi\vartheta^{d+}_{n-1}) \right) \\
&+ \mathbf{O}(\Delta t^{q_d+2}) + \mathbf{O}(\Delta t\, \Delta s^{q_r+1}),
\end{aligned}
$$

where

$$
\overline{E}_1 = \frac{1}{2}\Delta t_n \left(A^\top R(\tilde{Y}) - R(\tilde{Y})\, A^\top \right) \quad \textit{and} \quad \overline{E}_2 = \left(\Phi^r_n(\tilde{Y}) - \Phi^r_n(Y^r) \right) \Phi^d_n.
$$

We have finally obtained the hybrid a posteriori–a priori error estimate, where the leading order expressions are computable and the remainder is provably higher order. Recall that the term $\overline{E}_1$ is a matrix that consists of the diffusion matrix $A^\top$ and the Jacobian of the nonlinear reaction, $R(\tilde{Y}) = \int_{I_n} \overline{F'(\tilde{Y})} dt$. These are computable and do not require the solution of an adjoint problem. On the other hand, the term E_2 involves the computation of three adjoint solutions, namely, one adjoint solution of the diffusion component and the adjoint solutions of the reaction components linearized about $\tilde{Y}$ and Y^r, respectively.

5.5. Remark on the definition of the adjoint problem. The homogeneity assumption $F(y) = 0$ implies that $y = 0$ is a steady state solution of (1.1). We can also define adjoint problems using other steady state solutions or a given function of time. We illustrate by assuming that c is a vector such that

$$
\textit{General homogeneity assumption:} \quad F(c) = 0.
$$

We define the variable $z = y - c$ and set

$$
\overline{F'(z)} = \int_0^1 F'(sz + c)\, ds,
$$

so that $\overline{F'(z)}z = F(y) - F(c) = F(y)$. We can define a differential equation governing z,

$$
\dot{z} = A\, z(t) + F(y) + Ac = A\, z(t) + \overline{F'(z)}\, z(t) + Ac. \tag{5.24}
$$

The associated generalized Green's function φ satisfies the adjoint differential equation

$$
-\dot{\varphi} = A^\top \varphi(t) + \overline{F'(z)}^\top \varphi(t). \tag{5.25}
$$

Arguing as in section 5.1 yields

$$
\begin{aligned}
0 &= \int_{I_n} \left(-\dot{\varphi} - A^\top \varphi(t) - (\overline{f'}(z))^\top \varphi(t), z \right) dt \\
&= -\int_{I_n} \frac{d}{dt}(\varphi, z)\, dt + \int_{I_n} (\dot{z} - Az - \overline{F'(z)}z - Ac, \varphi) dt + \int_{I_n} (Ac, \varphi) dt.
\end{aligned} \tag{5.26}
$$

The second term on the right-hand side vanishes by (5.24), and thus integrating the first term yields

$$(z_n, \psi_n) = (z_{n-1}, \varphi_{n-1}) + \int_{I_n} (Ac, \varphi) dt. \tag{5.27}$$

Using the analogous approach for each component of the analytic operator splitting (2.2) and (2.3), we define, respectively, $z^r = y^r - c$ and $z^d = y^d - c$, and the associated differential equations

$$\dot{z^r} = F(y^r) = \overline{F'(z^r)} z^r, \quad \dot{z^d} = Az^d + Ac.$$

To these differential equations, we define the respective adjoint problems

$$-\dot{\varphi^r} = \overline{F'(z^r)}^\top \varphi^r(t), \quad -\dot{\varphi^d} = A^\top \varphi^d(t).$$

Again, arguing as in section 5.1, we obtain the following representations for the component solutions:

$$(z_n^{r-}, \psi_n^r) = (z_{n-1}^{r+}, \varphi_{n-1}^{r+}),$$
$$(z_n^{d-}, \psi_n^d) = (z_{n-1}^{d+}, \varphi_{n-1}^{d+}) + \int_{I_n} \left(Ac, \varphi^d\right) dt.$$

Next we can follow the analysis in section 5.2 to get an error representation analogous to Theorem 5.1.

THEOREM 5.8. *Let c be a vector such that $F(c) = 0$. Then the splitting error over a single diffusion time step can be represented by*

$$(y_n - \tilde{y}_n, \psi_n) = (\tilde{y}_{n-1} - c, \Delta\Phi_n \psi_n) + \int_{I_n} \left(Ac, \varphi - \varphi^d\right) dt$$

with $\Delta\Phi_n = \Phi_n(y) - \Phi_n^r(y^r)\Phi_n^d$.

We note that when $c = 0$, the original error representation in Theorem 5.1 is recovered. Also, we showed above that the first term involving $\Delta\Phi_n \psi_n$ can be cast into expressions that are computable. Similar analysis can be carried out for the last term involving $\varphi - \varphi^d$. To see this, we write

$$\varphi - \varphi^d = (\varphi - \omega) + (\omega - \tilde{\omega}) + (\tilde{\omega} - \varphi^d), \tag{5.28}$$

where ω and $\tilde{\omega}$ are the functions governed by differential equations (5.21) and (5.22). Using the expansion of φ and ω gives

$$\begin{aligned} \varphi(t) - \omega(t) &= (t_n - t)\, A^\top \psi_n - \Delta t_n\, A^\top \psi_n + \mathbf{O}\left((t_n - t)^2 + \Delta t_n^2\right) \\ &= (t_{n-1} - t)\, A^\top \psi_n + \mathbf{O}\left((t_n - t)^2 + \Delta t_n^2\right), \end{aligned} \tag{5.29}$$

from which we obtain

$$\int_{I_n} (Ac, \varphi - \omega)\, dt = -\frac{1}{2}\Delta t_n^2 \left(Ac, A^\top \psi_n\right) + \mathbf{O}(\Delta t_n^3). \tag{5.30}$$

Using a similar argument to that in the proof of Lemma 5.6, we can deduce that

$$\int_{I_n} (Ac, \omega - \tilde{\omega})\, dt = \mathbf{O}(\Delta t_n^3). \tag{5.31}$$

Finally, the function $\tilde{\omega}$ is actually computed in the error estimator and thus we may write

$$\int_{I_n} \left(Ac, \varphi - \varphi^d\right)\, dt = -\frac{1}{2}\Delta t_n^2 \left(Ac, A^\top \psi_n\right) + \int_{I_n} \left(Ac, \tilde{\omega} - \varphi^d\right)\, dt + \mathbf{O}(\Delta t_n^3). \tag{5.32}$$

We note that in this setting, the rest of the error estimator components remains as before.

6. Numerical examples. In this section, we present several numerical examples that show the performance of the error estimates. All of these problems originate as reaction-diffusion initial boundary value problems. Unless otherwise noted, we use a continuous, piecewise linear Galerkin finite element method with N_e elements to discretize space. All forward problems are solved using the lowest order, piecewise constant dG method, which is equivalent to backward Euler scheme, while the adjoint solutions are computed using a second order, piecewise linear, cG method, which is equivalent to the Crank–Nicolson scheme.

6.1. Assessment of the operator splitting exact error. To gain some insights into the splitting procedure, we solve a nonlinear initial boundary value problem described in (1.2) with the following specification:

$$f(x,u) = \frac{u^2}{\sin(\pi x)}, \quad u_d = 0, \quad u_0(x) = \sin(\pi x).$$

After spatial discretization, the vector of initial conditions g has entries $g_j = \sin(\pi x_j)$ $= \sin(j\pi/N_e)$, while using the trapezoidal rule to approximate the integrals involving the forcing terms gives

$$F_i(y) \approx \frac{1}{2}\left(0 + \frac{y_i^2}{\sin(\pi x_i)}\right) + \frac{1}{2}\left(\frac{y_i^2}{\sin(\pi x_i)} + 0\right) = \frac{y_i^2}{\sin(\pi x_i)}. \tag{6.1}$$

The eigenvalues of the matrix A are

$$\lambda_i = \frac{2k}{h^2} - \frac{2k}{h^2}\cos(i\pi/N_e), \tag{6.2}$$

with the associated eigenvectors V_i whose entries are

$$V_{ij} = \sin(ij\pi/N_e). \tag{6.3}$$

We note that $g = V_1$ and assume that the exact solution of (1.1) has entries

$$y(t) = \xi(t) V_1, \tag{6.4}$$

where $\xi(t)$ is a scalar function to be determined later and V_1 is the eigenvector of matrix D associated with the eigenvalue λ_1. Consequently, we have

$$F_i(y) = F_i(\xi V_1) = \frac{(\xi V_{1i})^2}{\sin(\pi x_i)} = \xi^2 V_{1i}, \tag{6.5}$$

using the fact that $V_{1i} = \sin(i\pi/N_e) = \sin(\pi x_i)$. Substitution of (6.5) and (6.4) into (1.1) yields the ordinary differential equation (noting that $AV_1 = \lambda_1 V_1$)

$$\dot{\xi}(t) + \lambda_1\, \xi(t) = \xi^2(t),$$

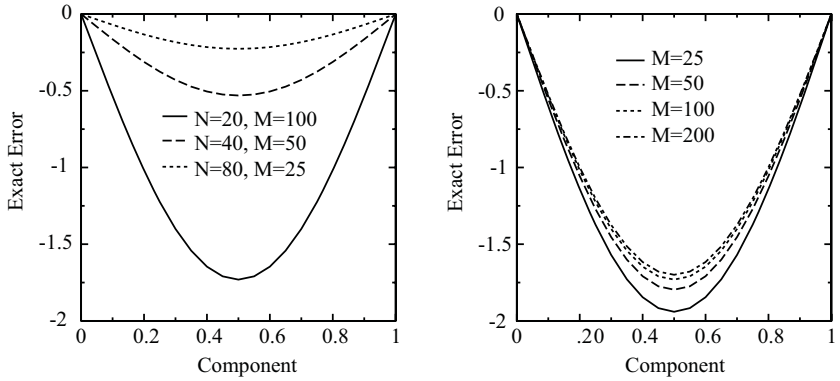

FIG. 6.1. *Comparison of exact errors at $T = 2$ against spatial location: reaction time step is kept constant (left), diffusion time step is kept constant (right).*

with $\xi_i(0) = 1$. This has the analytical solution

$$\xi(t) = \frac{\lambda_1}{1 - (1 - \lambda_1)e^{\lambda_1 t}}.$$

Figure 6.1 shows exact errors of the splitting procedure for this problem. The plot on the left shows the exact error at $T = 2$ plotted against the spatial location while the reaction time step is kept constant. This demonstrates that the error behaves like $\mathbf{O}(\Delta t)$. The plot on the right shows the exact error at $T = 2$ while the diffusion time step is kept constant. As the reaction time step is decreased, the error also decreases until it reaches a condition where the dominating error comes from the diffusion time step. After this, there is no improvement in accuracy. This result confirms the a priori analysis established in the previous section that the error in the operator splitting is dominated by the component that is of $\mathbf{O}(\Delta t)$.

6.2. Performance of the a posteriori error representation. The main purpose of the next four examples is to test the accuracy of the computable parts of the hybrid a posteriori–a priori error estimate where we drop the uncomputable higher order terms. Since we do not have true solutions for most of these problems, we approximate exact errors by computing the difference between the operator splitting solution with numerical solution of the fully coupled problems computed on a very fine mesh. We refer to this approximated error as the "error."

The first three examples fall into the category of stable diffusion interacting with unstable reaction. The reaction components in the three examples present a range of instability. The last example is radically different in that it represents competition between stable reaction and diffusion components.

6.2.1. A blow up problem. The first example is the "blow up" problem obtained from

$$\begin{cases} \dfrac{\partial u}{\partial t} - 0.05\,\dfrac{\partial^2 u}{\partial x^2} = u^2, & x \in (0,1), t > 0, \\ u(0,t) = u(1,t) = 0, & t > 0, \\ u(x,0) = 4x(1-x), & x \in (0,1). \end{cases}$$

TABLE 6.1
Operator splitting error estimate for the blow up problem at $T = 1$, reaction time step $= 10^{-3}$.

Δt	M	Exact error (%)	Effectivity
10^{-1}	100	11.07	1.0286
10^{-2}	10	1.35	1.0067
10^{-3}	1	0.45	1.0020

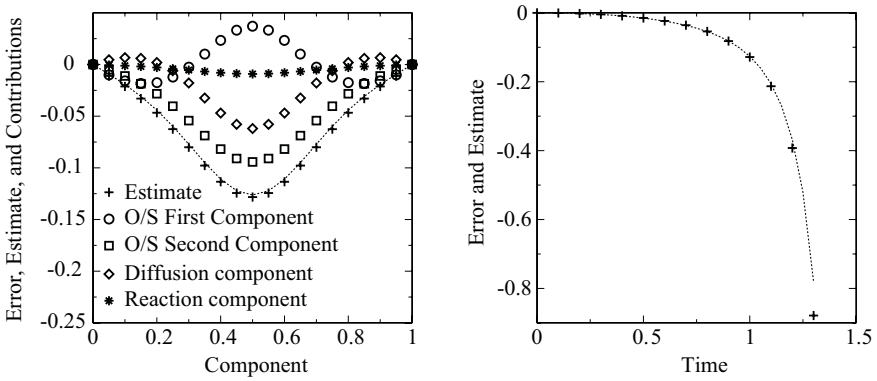

FIG. 6.2. *Blow up results: Comparison of errors against the spatial location (left), time history of errors at the midpoint location (right). The dotted line is the exact error and the + is the estimated error.*

As mentioned in section 2, the solution of the reaction component exhibits finite time blow up when undamped by the diffusion component. This is perhaps the most extreme form of instability. For this computation, we use 20 spatial finite elements. Table 6.1 shows the effectivity index of the error estimate computed at the final time $T = 1$. In this computation, we keep the reaction time step constant and varied the diffusion time step and number of reaction time steps.

Figure 6.2 shows a comparison of the errors computed using $\Delta t = 0.05$ and $M = 50$ reaction time steps. The left plot in Figure 6.2 compares the errors at $T = 1$ plotted against the spatial location. In this plot, we plot each of the expressions contributing to the overall estimate. In the plot on the right, the time history up to $T = 1.3$ of the error at the midpoint location is shown.

6.2.2. Chemical dynamics: The Brusselator problem. The Brusselator problem is represented by a coupled set of equations first introduced by Prigogine and Lefever [26] as a model of chemical dynamics:

$$
\begin{cases}
\dfrac{\partial u_1}{\partial t} - k_1 \dfrac{\partial^2 u_1}{\partial x^2} = \alpha - (\beta + 1)u_1 + u_1^2 u_2, & x \in (0,1), t > 0, \\
\dfrac{\partial u_2}{\partial t} - k_2 \dfrac{\partial^2 u_2}{\partial x^2} = \beta u_1 - u_1^2 u_2, & x \in (0,1), t > 0, \\
u_1(0,t) = u_1(1,t) = \alpha,\ u_2(0,t) = u_2(1,t) = \beta/\alpha, & t > 0, \\
u_1(x,0) = u_{1,0}(x),\ u_2(x,0) = u_{2,0}(x), & x \in (0,1),
\end{cases}
\tag{6.6}
$$

where u_1 and u_2 are the concentration of species 1 and 2, respectively. We use $\alpha = 2$, $\beta = 5.45$, $k_1 = 0.008$, $k_2 = 0.004$ and initial conditions $u_1(x,0) = \alpha + 0.1\sin(\pi x)$

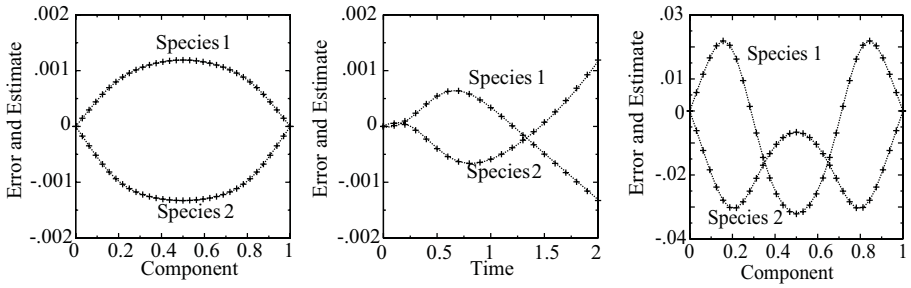

FIG. 6.3. *Brusselator results. Left: comparison of errors against the spatial location at $T = 2$. Middle: time history of errors at the midpoint location on $[0, 2]$. Right: comparison of errors against the spatial location at $T = 40$. The dotted line is the exact error and the + is the estimated error.*

and $u_2(x, 0) = \beta/\alpha + 0.1\sin(\pi x)$, which yields an oscillatory solution. In this case, the reaction is very mildly unstable, with at most a polynomial rate accumulation of perturbations as time passes. We use a 32 node spatial finite element discretization, resulting in an ordinary differential equation system with dimension 62. We note that in original form, the reaction terms do not satisfy the requirement $F(0) = 0$. Instead, we use a vector c as discussed in section 5.5 with $c_i = \alpha$ for $i = 1, \ldots, N_e - 1$ and $c_i = \beta/\alpha$ for $i = N_e, \ldots, 2N_e - 2$, so that $F(c) = 0$.

Figure 6.3 compares the errors computed using $\Delta t = 0.01$ and $M = 10$ reaction time steps to the hybrid a posteriori error estimates. We show results for $[0, 2]$ when the solution is still in a transient stage, and at $T = 40$ when the solution has become periodic. All the results show that the exact and estimated errors are in remarkable agreement.

6.2.3. Chaotic dynamics: The Lorenz problem. In this example, we treat the chaotic Lorenz equations as a reaction component of a reaction-diffusion problem:

$$
\begin{cases}
\dfrac{\partial u_1}{\partial t} - 0.5\,\dfrac{\partial^2 u_1}{\partial x^2} = 10(u_2 - u_1), & x \in (0,1), t > 0, \\
\dfrac{\partial u_2}{\partial t} - 0.5\,\dfrac{\partial^2 u_2}{\partial x^2} = u_1(28 - u_3) - u_2, & x \in (0,1), t > 0, \\
\dfrac{\partial u_3}{\partial t} - 0.5\,\dfrac{\partial^2 u_3}{\partial x^2} = u_1 u_2 - \dfrac{8}{3}u_3, & x \in (0,1), t > 0, \\
u_i(0,t) = u_i(1,t) = 0, & t > 0, i = 1,2,3, \\
u_i(x,0) = .1\sin(\pi x), & x \in (0,1), i = 1,2,3.
\end{cases}
\tag{6.7}
$$

The chaotic nature of the Lorenz equations implies that errors accumulate locally at an exponential rate in an average sense, placing this instability between that of the blow up and the Brusselator problems. Here, we use 20 spatial finite elements, resulting in a system of ordinary differential equations with dimension 57. Figure 6.4 shows typical error estimates for the three species. Across the top row, we compare estimates and errors at the final time $T = 2$ using $\Delta t = 5 \times 10^{-3}$ and $M = 10$ reaction time steps. We show the time history at the midpoint across the bottom row. Again the figures show good agreement between exact and estimated errors.

We illustrate the accuracy at a longer time of $T = 16$ in Figure 6.5.

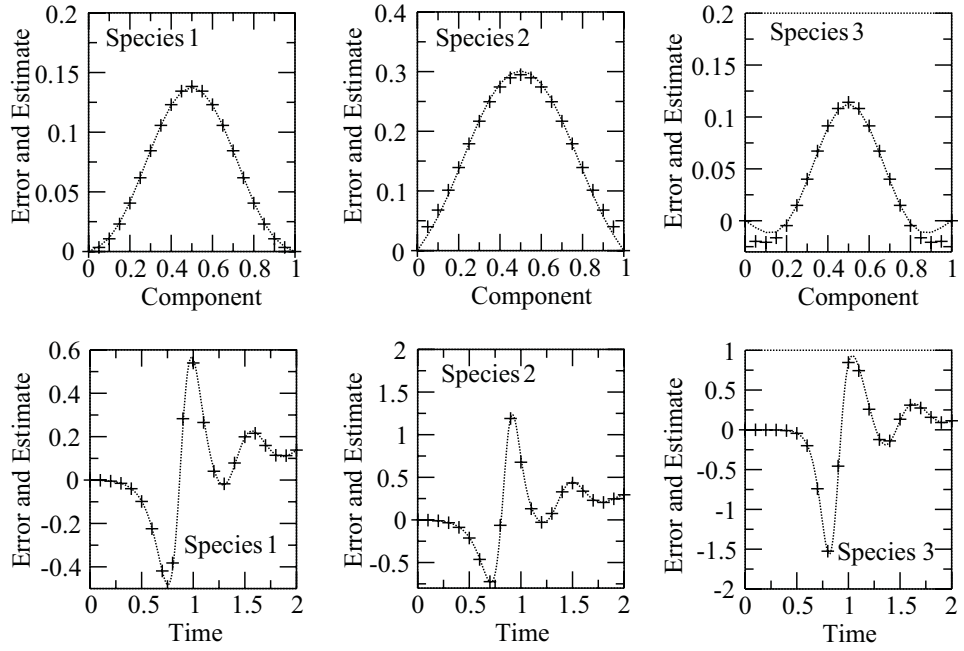

FIG. 6.4. *Lorenz results. Top row: comparison of errors against the spatial location. Bottom row: time history of errors at the midpoint location. The dotted line is the exact error and the + is the estimated error.*

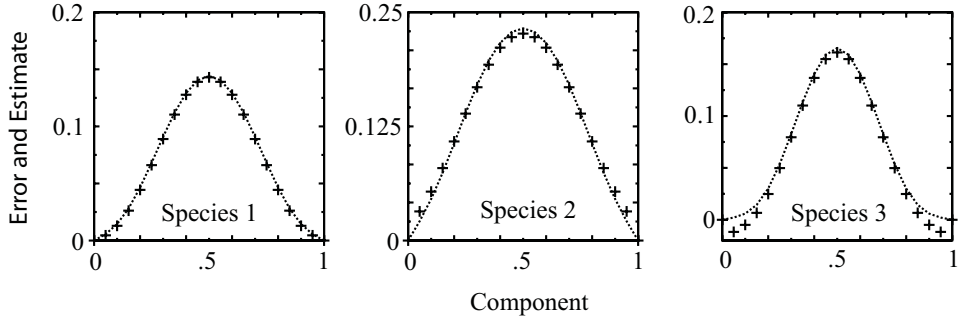

FIG. 6.5. *Accuracy of the error estimate for the Lorenz problem at time $T = 16$. The dotted line is the exact error and the + is the estimated error.*

6.2.4. The bistable problem. The bistable problem,

$$\begin{cases} \dfrac{\partial u}{\partial t} - \epsilon \dfrac{\partial^2 u}{\partial x^2} = u - u^3, & x \in (0,1), t > 0, \\ u_x(0,t) = u_x(1,t) = 0, & t > 0, \\ u(x,0) = u_0(x), & x \in (0,1), \end{cases} \tag{6.8}$$

is a well-studied example of nonlinear relaxation to equilibrium in the presence of competing stable steady states [3, 19, 1, 12, 17]. The stable steady states are $u = 1$ and $u = -1$, while $u = 0$ is an unstable steady state. Here, both the diffusion and the

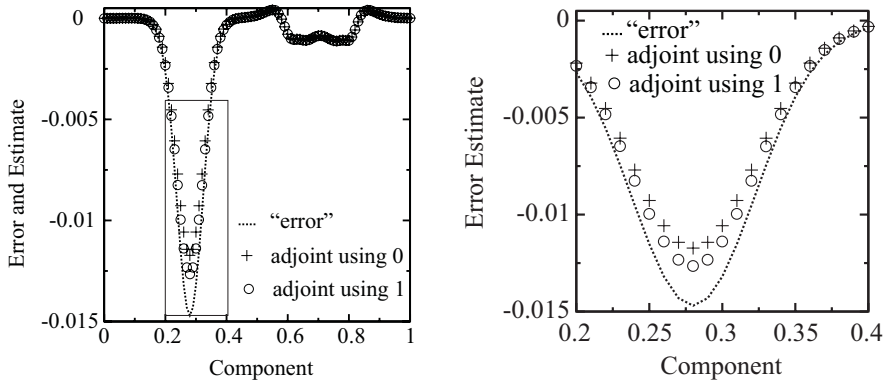

FIG. 6.6. *Bistable problem error estimate at $T = 41$; the right plot is the zoomed view of the boxed portion on the left plot.*

reaction are stabilizing, while instability arises because of the competition between these two components. Nonequilibrium solutions are characterized by long periods of "metastability" during which the solution is nearly stationary over periods of time on the order of $\exp(1/\epsilon)$ that are punctuated by rapid transients. The spatial profile of a metastable solution consists of narrow layers between regions where the solution has values of 1 and -1. We emphasize that the interaction between reaction and diffusion is very delicate in a metastable solution, and it is by no means clear that operator splitting is a reasonable approach.

For the computation we use 100 spatial finite elements. We compute the solution until final time level $T = 41$. Figure 6.6 shows comparison of the error. Here, we use $c = 0$ and $c = 1$ as the linearization points. The figure shows an observable improvement when computing the error using $c = 1$ than when using $c = 0$. Note that the solution eventually converges to 1.

7. Details of the a priori analysis. The following section contains the sequence of lemmas required for the proof of Theorem 4.4.

Lemma 7.1 determines the error in the numerical solution of the reaction component arising from errors in the initial conditions.

LEMMA 7.1. *Let $Z \in \mathcal{V}^{(q_r)}(I_n)$ satisfy*

$$\int_{I_{m,n}} (\dot{Z}, W)\, dt - \int_{I_{m,n}} (F(Z), W)\, dt + (Z^+_{m-1,n}, W^+_{m-1}) = (Z^-_{m-1,n}, W^+_{m-1}) \tag{7.1}$$

for all $W \in \mathcal{P}^{(q_r)}(I_{m,n})$, $m = 1, 2, \ldots, M_n$, and $Z^-_{0,n} = y^{r+}_{n-1}$. With $\xi = Z - Y^r$,

$$|\xi^-_{M_n,n}|^2 \le \exp(16L\Delta t_n)\, |\tilde{y}_{n-1} - \tilde{Y}_{n-1}|^2.$$

Proof. By construction, $\xi \in \mathcal{V}^{(q_r)}(I_n)$. It is obvious that for $q_r = 0, 1$,

$$\int_{I_{m,n}} |\xi|^2\, dt \le 2\Delta s_n\, |\xi^-_{m,n}|^2 + \frac{2}{3}\, \Delta s_n^3\, |\dot{\xi}|^2_{I_{m,n}}. \tag{7.2}$$

Subtracting (3.3) from (7.1) yields

$$\int_{I_{m,n}} (\dot{\xi}, W)\, dt - \int_{I_{m,n}} (F(Z) - F(Y^r), W)\, dt + (\xi^+_{m-1,n}, W^+_{m-1}) = (\xi^-_{m-1,n}, W^+_{m-1}) \tag{7.3}$$

for every $W \in \mathcal{P}^{(q_r)}(I_{m,n})$. Setting $W = (t - s_{m-1,n})\dot{\xi}$ in (7.3) and estimating yields

$$\frac{1}{2}\Delta s_n^2 |\dot{\xi}|^2_{I_{m,n}} \leq \frac{\epsilon^2}{2} L^2 \Delta s_n \int_{I_{m,n}} |\xi|^2 \, dt + \frac{1}{2\epsilon^2} \Delta s_n^2 \, |\dot{\xi}|^2_{I_{m,n}}$$

for some $\epsilon > 0$. Thus,

$$\Delta s_n^2 |\dot{\xi}|^2_{I_{m,n}} \leq C_\epsilon \, L^2 \Delta s_n \int_{I_{m,n}} |\xi|^2 \, dt, \tag{7.4}$$

where $C_\epsilon = \epsilon^4/(\epsilon^2 - 1)$. Substitution of (7.4) into (7.2) gives

$$\left(1 - \frac{2}{3} C_\epsilon \Delta s_n^2 L^2\right) \int_{I_{m,n}} |\xi|^2 \, dt \leq 2\Delta s_n \, |\xi^-_{m,n}|^2,$$

from which we obtain

$$\int_{I_{m,n}} |\xi|^2 \, dt \leq 4\Delta s_n \, |\xi^-_{m,n}|^2, \tag{7.5}$$

provided $1 - \frac{2}{3} C_\epsilon \Delta s_n^2 L^2 > 1/2$. Next, we choose $W = \xi$ in (7.3) and use the Lipschitz continuity of F to get

$$\frac{1}{2}|\xi^-_{m,n}|^2 + \frac{1}{2}|\xi^+_{m-1,n}|^2 \leq L \int_{I_{m,n}} |\xi|^2 \, dt + |\xi^-_{m-1,n}| \, |\xi^+_{m-1,n}|.$$

This gives

$$|\xi^-_{m,n}|^2 \leq |\xi^-_{m-1,n}|^2 + 2L \int_{I_{m,n}} |\xi|^2 \, dt.$$

Using (7.5), this implies

$$|\xi^-_{m,n}|^2 \leq \frac{1}{1 - 8\Delta s_n L} \, |\xi^-_{m-1,n}|^2 \leq \exp(16\Delta s_n L) \, |\xi^-_{m-1,n}|^2,$$

provided $1 - 8\Delta s_n L > 1/2$. Applying this recursive relation M_n times yields the desired result. ∎

Lemma 7.2 determines the error in the numerical solution of the reaction component due to discretization and the inherited initial conditions.

LEMMA 7.2. *Let y^r be the solution of analytical reaction component and let Y^r be the dG numerical solution approximating y^r. For $n = 1, \ldots, N$,*

$$|y^{r-}_n - Y^{r-}_{M,n}| \leq C \, \Delta t_n \, \Delta s_n^{q_r+1} + \exp(8L\Delta t_n) \, |\tilde{y}_{n-1} - \tilde{Y}_{n-1}|.$$

Proof. We write

$$y^{r-}_n - Y^{r-}_{M,n} = (y^{r-}_n - Z^-_{M,n}) + (Z^-_{M,n} - Y^{r-}_{M,n}),$$

where $Z \in \mathcal{V}^{(q_r)}(I_n)$ is defined as in Lemma 7.1. Moreover, it has been established (cf. Delfour and Dubean [6], Johnson [22], and Estep [13]) that

$$|y^{r-}_n - Z^-_{M,n}| \leq C \, \Delta t_n \, \Delta s_n^{q_r+1}.$$

Using Lemma 7.1, the proof is complete. ∎

We also use the following result from Delfour, Hager, and Trochu [7].

LEMMA 7.3. *Let $w \in H^1(I_n)$ satisfying $\dot{w} + A^\top w = 0$ in I_n. Then there exists a constant C independent of $s \in I_n$, such that $\|w\|_{r+1,n} \le C|w(s)|$, where the norm $\|\cdot\|_{r,n}$ is associated with the Sobolev space*

$$H^r(I_n) = \left\{ w : \|w\|_{r,n}^2 = \sum_{i=0}^{r} \left\| \frac{d^i w}{dt^i} \right\|_{L^2(I_n)}^2 < \infty \right\}.$$

Lemma 7.4 bounds the residual to a linear constant coefficient differential equation when its exact solution is projected into a piecewise polynomial space.

LEMMA 7.4. *Let $\Pi : L^2(I_n) \to \mathcal{P}^{(q)}(I_n)$ denote an interpolation operator. Let w be as defined in Lemma 7.3, and $\Pi w \in \mathcal{P}^q(I_n)$, $q \ge 1$, its interpolation function. Then there is a positive constant C such that for all $s \in I_n$,*

$$\left\| \frac{d}{dt}\Pi w + A^\top \Pi w \right\|_{L^2(I_n)} \le C\, \Delta t_n^q\, |w(s)|.$$

Proof. Since w in Lemma 7.3 is homogeneous, the interpolation property (cf. Strang and Fix [33] and Ciarlet [4]) and Lemma 7.3 imply that for $t_{n-1} \le s \le t_n$,

$$\begin{aligned} \left\| \frac{d}{dt}\Pi w + A^\top \Pi w \right\| &= \left\| \frac{d}{dt}(\Pi w - w) + A^\top (\Pi w - w) \right\| \\ &\le C\, \|w - \Pi w\|_{1,n} \le C\, \Delta t_n^q\, \|w\|_{q+1,n} \le C\, \Delta t_n^q\, |w(s)|. \end{aligned}$$ ∎

Lemma 7.5 bounds the error in the numerical solution to a constant coefficient differential equation.

LEMMA 7.5. *Let $X \in \mathcal{P}^{q_d}(I_n)$ satisfy*

$$\int_{I_n} (\dot{X}, V)\, dt - \int_{I_n} (AX, V)\, dt + (X_{n-1}^+, V_{n-1}^+) = (y_n^{r-}, V_{n-1}^+) \tag{7.6}$$

for all $V \in \mathcal{P}^{q_d}(I_n)$, where $X_{n-1}^- = y^{r-}{}_n$. With $\theta = y^d - X$, $|\theta_n^-| \le C\, \Delta t_n^{q_d+2}$ for $q_d = 0, 1$.

Proof. Obviously y^d defined in (2.3) satisfies (7.6). Let $U \in \mathcal{P}^{q_d}(I_n)$ satisfy

$$\int_{I_n} (\dot{U}, V)\, dt - \int_{I_n} (Ay^d, V)\, dt + (U_{n-1}^+, V_{n-1}^+) = (y_n^{r-}, V_{n-1}^+) \quad \text{for all } V \in \mathcal{P}^{q_d}(I_n). \tag{7.7}$$

For sufficiently small Δt_n, the following estimate holds (see [13]):

$$|\theta|_{I_n} \le |y^d - U|_{I_n} + |U - X|_{I_n} \le C\Delta t_n^{q_d+1} |y^{(q_d+1)}|_{I_n} + C\Delta t_n^{q_d+3/2} |y^{(q_d+1)}|_{I_n}. \tag{7.8}$$

Subtracting (7.6) from the variational formulation of y^d gives

$$\int_{I_n} (\dot{\theta}, V)\, dt - \int_{I_n} (A\theta, V)\, dt + (\theta_{n-1}^+, V_{n-1}^+) = 0. \tag{7.9}$$

Integration by parts gives

$$(\theta_n^-, V_n^-) = \int_{I_n} (\theta, \dot{V} + A^\top V)\, dt. \tag{7.10}$$

For $q_d = 0$, we choose $V = V_n^- = \theta_n^-$ in (7.9) and use (7.8) to get $|\theta_n^-| \leq C\Delta t_n^2$. For $q_d = 1$, we choose $V = \Pi w$ in (7.9), with w defined as in Lemma 7.3, and $w(t_n) = \theta_n^-$. Then using (7.8) and Lemma 7.4,

$$|\theta_n^-|^2 \leq \int_{I_n} |\theta|\, |\dot{\Pi w} + A^\top \Pi w|\, dt \leq C\Delta t_n^3 \sqrt{\Delta t_n}\, |\theta_n^-|, \tag{7.11}$$

which gives the desired estimate. □

8. Conclusion. In this paper, we derive both an a priori convergence estimate and a hybrid a posteriori–a priori estimate for the multiscale operator splitting discontinuous Galerkin finite element method for a system of ordinary differential equations. The system of equations is assumed to have a form that typically arises from space discretization of a reaction-diffusion problem. The a priori analysis uses the fact that an operator splitting approximation is a consistent approximation of an analytic operator splitting problem. The a posteriori analysis takes into account the fact that the original problem and an analytic operator split version are associated with different adjoint problems. The differences in the adjoints provides the means to accurately understand the effects of operator splitting on the stability properties of a quantity of interest computed from the solution. To produce a computable a posteriori estimate of the error, we manipulate the original a posteriori error representation to obtain a computable expression plus uncomputable quantities that are provably higher order in an asymptotic sense. We conclude with some examples that demonstrate the accuracy of the computable parts of the hybrid a posteriori–a priori estimate.

Our results can be extended in a straightforward way to differential equations with a more general nonlinear form, higher order splitting schemes, and different time finite element methods. The results also extend formally, and rigorously for the most part, to operator splitting finite element schemes for reaction-diffusion problems where the splitting occurs at the partial differential equation level. We will pursue the complete extension to the latter in future work.

The general approach to analyzing operator splitting can be used to analyze operator decomposition in a wide variety of settings; see, e.g., [2, 18].

HIGH FREQUENCY INDUCED INSTABILITY IN NYSTRÖM METHODS FOR THE VAN DER POL EQUATION*

S. W. SCHOOMBIE† AND E. MARÉ‡

Abstract. In this paper several Nyström methods for the van der Pol equation are considered. In an earlier study by Cai, Aoyagi, and Abe it was shown that the second order Nyström, or leapfrog, method fails to approximate the limit cycle of the van der Pol equation, exhibiting a periodic modulation of the amplitude and sporadic high frequency noise instead. Cai et al. did a linear analysis and concluded that the spurious behavior was due to the interaction of the main part of the solution with a high frequency computational mode. In this paper we also apply a third and fourth order Nyström method to the van der Pol equation. Numerical experiments show that in these cases the high frequency mode causes blowup after some time. The onset of the instability can be delayed by decreasing the time step. We also improve on their analysis of the second order scheme by doing a nonlinear analysis, to wit a discrete multiple scales analysis. By this means we are able to explain the spurious behavior of this system completely.

Key words. van der Pol equation, spurious solutions, Nyström, leapfrog, multiple scales, discrete approximation, difference equations

1. Introduction.

The van der Pol equation

$$\frac{d^2x}{dt^2} - \epsilon(1-x^2)\frac{dx}{dt} + \omega^2 x = 0, \tag{1.1}$$

with

$$0 < \epsilon \ll 1, \tag{1.2}$$

was first formulated by van der Pol [12] in 1922 in the context of electronic circuits in vacuum tubes.

This equation is well known to have an unstable equilibrium at the origin of its phase plane, surrounded by a stable limit cycle. It is a standard classroom exercise to find an approximate analytic expression for the solution of the equation, using a multiple scales method [3, 6], namely,

$$x = \frac{2\cos(\omega t + \phi)}{\sqrt{1 + (4/a_0^2 - 1)e^{-\epsilon t}}} + O(\epsilon), \tag{1.3}$$

where a_0 is the initial amplitude.

Thus the limit cycle has a period which is very near to $2\pi/\omega$ and an amplitude which is very near to 2. To find the limit cycle more precisely, the van der Pol equation needs to be solved numerically. Various approaches have been used for this purpose.

These include extrapolation-based methods with step size control [2], Runge–Kutta Nyström methods [2], the implicit Adams method of order up to twelve, and Gear's method for stiff equations [4], among others.

That care must be taken when designing a high order finite difference method for the van der Pol equation was shown by Cai, Aoyagi, and Abe [1]. They considered a second order Nyström method which showed a peculiar type of spurious behavior. Its solution periodically approaches the correct limit cycle, but then moves away from it again. They essentially used a linear analysis to explain this phenomenon, ascribing the spurious behavior to a spurious mode which interferes with the numerical solution.

We investigated this phenomenon further by also applying third and fourth order Nyström methods to the van der Pol equation. In these cases we found that the solution behaved reasonably well for some time, after which there was rapid growth of a high frequency mode, followed by blowup. By decreasing the time step the onset of this nonlinear instability may be delayed.

To analyze this type of instability, we considered only the simplest case, namely, the second order Nyström, or leapfrog, method used by Cai et al. [1]. We felt that their linear analysis provides only part of the explanation, and that a nonlinear analysis would give a more complete picture. This paper attempts to do just that. We use a discrete version of the multiple scales technique mentioned above to analyze the difference equation, and finally show that the full explanation is to be found in the phase plane.

In section 2 we will briefly review the difference scheme considered by Cai et al. [1] and demonstrate the nature of its spurious behavior, as well as show the behavior of the third and fourth order Nyström schemes.

In sections 3 and 4 we then proceed with a nonlinear analysis to explain the observed phenomena in the case of the second order scheme. The results of the nonlinear analysis is then related to some numerical results in section 5. Section 6 contains some conclusive remarks.

2. Nyström time discretizations. Following [1], we rewrite (1.1) as a system of two first order equations, namely,

$$\frac{dx}{dt} = y, \tag{2.1}$$

$$\frac{dy}{dt} = \epsilon(1 - x^2)y - \omega^2 x. \tag{2.2}$$

To discretize these equations, we introduce the time step τ, the finite difference approximations $x^n \approx x(n\tau)$ and $y^n \approx y(n\tau)$, and the shift operators E and E^{-1}, defined for any sequence x^n by

$$Ex^n = x^{n+1} \quad \text{and} \quad E^{-1}x^n = x^{n-1}. \tag{2.3}$$

Finally, we define the central divided difference operator

$$\delta = (E - E^{-1})/(2\tau). \tag{2.4}$$

2.1. Second order Nyström discretization (leapfrog). Following Cai et al. [1], we first discretize the system (2.1), (2.2) by means of a second order Nyström method:

$$\delta x^n = y^n, \tag{2.5}$$

$$\delta y^n = \epsilon(1 - (x^n)^2)y^n - \omega^2 x^n. \tag{2.6}$$

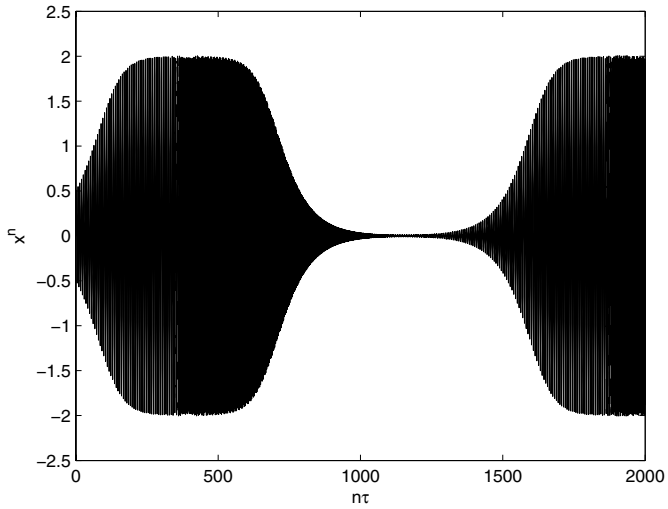

FIG. 1. *Results when running the difference system* (2.5), (2.6) *with* $\epsilon = 0.025$, $\omega = 1$, $\tau = 0.2$, *and* $x^0 = 0$, $y^0 = 0.5$.

This discretization is often referred to as a leapfrog method.

The system of difference equations (2.5), (2.6) can easily be seen to be equivalent to a single fourth order difference equation,

$$(E^2 - 2 + E^{-2})x^n/(4\tau^2) - \epsilon(1 - (x^n)^2)(E - E^{-1})x^n/(2\tau) + \omega^2 x^n = 0. \tag{2.7}$$

Using the following notation for the forward and backward divided difference operators, respectively,

$$\Delta = (E - 1)/\tau, \quad \nabla = (1 - E^{-1})/\tau, \tag{2.8}$$

we can rewrite (2.7) in the more concise form

$$\left[\Delta\nabla + \frac{\tau^2}{4}\Delta^2\nabla^2\right] x^n - \epsilon(1 - (x^n)^2)\delta x^n + \omega^2 x^n = 0. \tag{2.9}$$

To compute a numerical solution from (2.5) and (2.6), we need to specify initial values x^0 and y^0. Values for x^1 and y^1 are also required, and these are calculated by means of a second order Runge–Kutta starter with time increment τ. Figure 1 shows the result of such a computation with $\epsilon = 0.025$, $\omega = 1$, $\tau = 0.2$, and $x^0 = 0$, $y^0 = 0.5$. Initially everything seems to go well, and the solution approaches the limit cycle with its amplitude at around 2 and remains with it for a while. However, after some time it leaves the limit cycle and eventually returns to it again. What seems to be a periodic amplitude modulation is imposed, which is quite spurious.

Cai et al. [1] showed that this spurious behavior is due to the presence of a high frequency computational mode. They performed a linear stability analysis and showed that the computational mode starts growing when the amplitude of the numerical solution reaches a value of about $\sqrt{0.8}$.

The onset of the growth of the high frequency mode can be delayed by decreasing the time step, as shown in Figure 2, where the time step was decreased to $\tau = 0.1$.

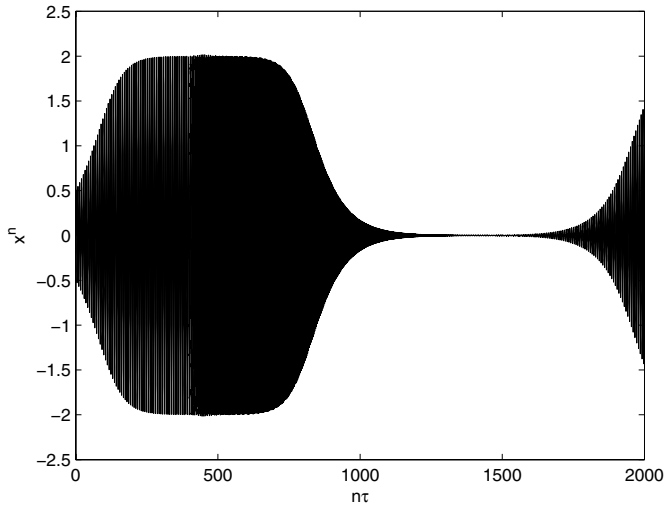

FIG. 2. *Results when running the difference system* (2.5), (2.6) *with* $\epsilon = 0.025$, $\omega = 1$, $\tau = 0.1$, *and* $x^0 = 0$, $y^0 = 0.5$.

2.2. Third order Nyström time discretization. The order of convergence of the numerical method can be increased by using a higher order Nyström discretization. For a third order scheme the discretization of the system becomes

$$\delta x^n = \frac{1}{6}[7y^n - 2y^{n-1} + y^{n-2}], \tag{2.10}$$

$$\delta y^n = \frac{1}{6}[7f(x^n, y^n) - 2f(x^{n-1}, y^{n-1}) + f(x^{n-2}, y^{n-2})], \tag{2.11}$$

where

$$f(x, y) = \epsilon(1 - x^2)y - \omega^2 x. \tag{2.12}$$

This time we need to supply two extra initial values, namely, for both $n = 1$ and $n = 2$. Because of the increased order of this method we used a fourth order Runge–Kutta method to calculate these initial values.

Using the same parameters as in Figure 1, we find that the numerical solution does not stay finite though spuriously modulated as with the leapfrog discretization, but that it suddenly blows up. The reason for this instability is the same, however: a sudden growth of a high frequency mode. The result is shown in Figure 3.

Since this is a convergent method, like the leapfrog method above, the onset of the instability can again be delayed by using a smaller time step. In order to reach the limit cycle before the high frequency mode grows significantly, we found that a time step of at most $\tau = 0.05$ has to be used.

Thus, although a higher order method is used, a much smaller time step is required in order to find the limit cycle numerically. The high frequency induced (HFI) instability observed here enforces an upper limit to the time step.

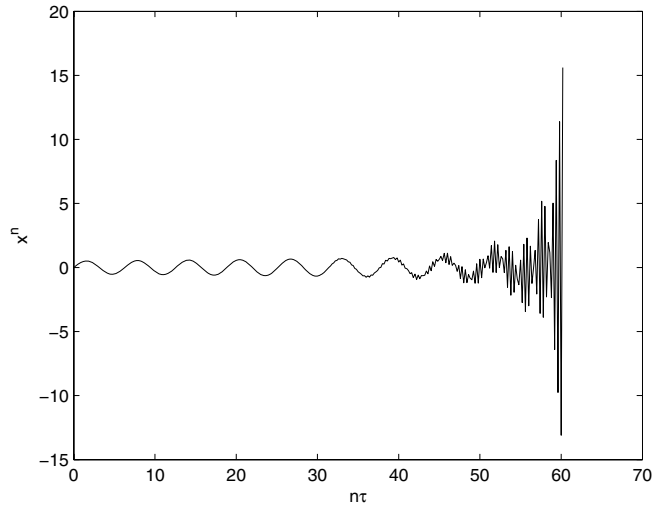

FIG. 3. *Results when running the difference system* (2.10), (2.11) *with* $\epsilon = 0.025$, $\omega = 1$, $\tau = 0.2$, *and* $x^0 = 0$, $y^0 = 0.5$.

2.3. Fourth order Nyström time discretization. Applying the fourth order Nyström discretization to the system (2.1), (2.2), we get

$$\delta x^n = \frac{1}{6}[8y^n - 5y^{n-1} + 4y^{n-2} - y^{n-3}], \tag{2.13}$$

$$\delta y^n = \frac{1}{6}[8f(x^n, y^n) - 5f(x^{n-1}, y^{n-1}) + 4f(x^{n-2}, y^{n-2}) - f(x^{n-3}, y^{n-3})] \tag{2.14}$$

with f as in (2.12).

The three extra initial values are again computed with a fourth order Runge–Kutta method. The results are similar to those of the third order method, except that the high frequency mode now appears much sooner, again leading to blowup. Figure 4 shows what happens when $\tau = 0.05$, and it turns out that the limit cycle can be reached fairly accurately only for time steps lower than about $\tau = 0.01$. Thus the upper bound for the time step is even lower than before.

Having observed the havoc caused by the high frequency spurious mode, the next thing to be attempted is an analysis of this phenomenon. This is done in the next section for the leapfrog case.

3. A discrete multiple scales analysis. Since the behavior of the leapfrog time discretization is the most complicated (the others simply blow up), and since this is also the simplest difference scheme, we shall attempt an analysis of this case only.

Since the spurious behavior of (2.9) consists of an amplitude modulation, a multiple scales analysis would seem to be an appropriate tool to investigate it.

To perform a multiple scales analysis of (2.9) we shall work in direct analogy with the well-known continuous multiple scales analysis performed for the van der Pol equation, e.g., [6]. We shall use two discrete time scales, namely,

$$T_p = \epsilon^p n\tau, \quad p = 0, 1, \tag{3.1}$$

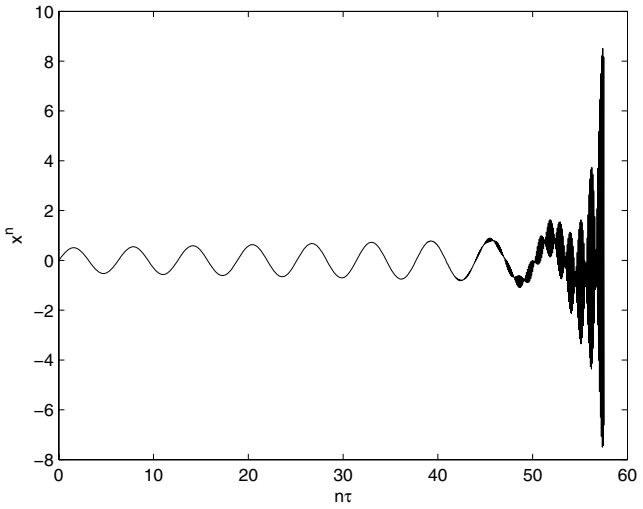

FIG. 4. *Results when running the difference system* (2.13), (2.14) *with* $\epsilon = 0.025$, $\omega = 1$, $\tau = 0.05$, *and* $x^0 = 0$, $y^0 = 0.5$.

and consider the expansion [9]

$$x^n = x_0(T_0, T_1) + \epsilon x_1(T_0, T_1) + O(\epsilon^2). \tag{3.2}$$

We shall also use partial shift operators E_{T_p} which we define as

$$E_{T_p} f(\ldots, T_p, \ldots) := f(\ldots, T_p + \epsilon^p \tau, \ldots) \tag{3.3}$$

in analogy with the temporal shift operator in (2.3). Using the partial shift operator (3.3) above we also define partial divided difference operators for T_p, namely,

$$\Delta_{T_p} := (E_{T_p} - 1)/(\epsilon^p \tau), \quad \nabla_{T_p} := (1 - E_{T_p}^{-1})/(\epsilon^p \tau). \tag{3.4}$$

The analogue of the central difference operator δ, defined in (2.4), follows similarly:

$$\delta_{T_p} \equiv (\Delta_{T_p} + \nabla_{T_p})/2. \tag{3.5}$$

Following Schoombie [9, 10] we note the following discrete multiple scales expansion of the differential approximations Δ and ∇ given in (2.8), namely,

$$\Delta = \Delta_{T_0} + \epsilon\, \Delta_{T_1} E_{T_0}, \quad \nabla = \nabla_{T_0} + \epsilon \nabla_{T_1} E_{T_0}^{-1}. \tag{3.6}$$

By making use of the definition of δ in (2.4) and substitution of (3.6) therein, we also obtain that

$$\delta = \delta_{T_0} + \epsilon/2(\Delta_{T_1} E_{T_0} + \nabla_{T_1} E_{T_0}^{-1}). \tag{3.7}$$

The equations above are essentially the discrete analogues of the chain rule for differentiation as used in a normal continuous multiple scales analysis.

We now proceed with our discrete multiple scales analysis. We substitute (3.6) into (2.9). Note the expansion of the first operator in (2.9):

$$\begin{aligned}&\Delta\nabla + (\tau^2/4)\Delta^2\nabla^2\\ &= \Delta_{T_0}\nabla_{T_0} + (\tau^2/4)\Delta_{T_0}^2\nabla_{T_0}^2\\ &+ \epsilon(\Delta_{T_0}\Delta_{T_1} + \nabla_{T_0}\nabla_{T_1} + (\tau^2/2)\Delta_{T_0}^2\nabla_{T_0}\Delta_{T_1} + (\tau^2/2)\nabla_{T_0}^2\Delta_{T_0}\nabla_{T_1}).\end{aligned} \tag{3.8}$$

We proceed by collecting terms with equal powers of ϵ. In this way we generate a set of equations given by

$$Lx_0 = 0, \tag{3.9}$$

relevant to $O(1)$, and for $O(\epsilon)$,

$$Lx_1(T_0, T_1) = R(T_0, T_1), \tag{3.10}$$

where the difference operator L is defined by

$$Lu(T_0, T_1) = (\Delta_{T_0}\nabla_{T_0} + (\tau^2/4)\Delta_{T_0}^2\nabla_{T_0}^2)u(T_0, T_1) + \omega^2 u(T_0, T_1) \tag{3.11}$$

for any discrete variable $u(T_0, T_1)$, and where

$$\begin{aligned}R(T_0, T_1) = &-(\Delta_{T_0}\Delta_{T_1} + \nabla_{T_0}\nabla_{T_1} + (\tau^2/2)\Delta_{T_0}^2\nabla_{T_0}\Delta_{T_1} + (\tau^2/2)\nabla_{T_0}^2\Delta_{T_0}\nabla_{T_1})x_0\\ &+ \beta(1 - x_0^2)\delta_{T_0}x_0.\end{aligned} \tag{3.12}$$

It is easy to see that any real-valued solution of (3.9) must be of the form

$$x_0(T_0, T_1) = a(T_1)e^{i\Omega n\tau/2} + (-1)^n b(T_1)e^{i\Omega n\tau/2} + \text{c.c.}, \tag{3.13}$$

where c.c. denotes the complex conjugate, and where

$$\cos(\Omega\tau) = 1 - 2\omega^2\tau^2. \tag{3.14}$$

The second term in (3.13) represents the computational wave considered by Cai et al. [1], the presence of which causes spurious behavior.

If we substitute this expression for x_0 into the right-hand side of (3.10), we eventually find that (neglecting $O(\epsilon^2)$ terms)

$$\begin{aligned}\frac{\tau}{i}R(T_0, T_1) = &\{-\sin(\Omega\tau)\delta_{T_1}a + \sin(\Omega\tau/2)(a - a|a|^2 + 3b^2\bar{a} - 2a|b|^2)\}e^{i\Omega n\tau/2}\\ &+ \{-\sin(\Omega\tau)\delta_{T_1}b + \sin(\Omega\tau/2)(-b + b|b|^2 - 3a^2\bar{b} + 2b|a|^2)\}(-1)^n e^{i\Omega n\tau/2}\\ &+ \sin(\Omega\tau/2)(-a^3 + ab^2)e^{3i\Omega n\tau/2}\\ &+ \sin(\Omega\tau/2)(b^3 - a^2b)(-1)^n e^{3i\Omega n\tau/2} + \text{c.c.},\end{aligned} \tag{3.15}$$

where the bar indicates the complex conjugate.

To ensure a bounded solution for x_1, we need to remove secular terms, which is done by requiring that the coefficients of both $e^{i\Omega n\tau/2}$ and $(-1)^n e^{i\Omega n\tau/2}$ be equated to zero. This leads to the two ordinary differential equations

$$a' = r(a - a|a|^2 + 3b^2\bar{a} - 2a|b|^2), \tag{3.16}$$

$$b' = -r(b - b|b|^2 + 3a^2\bar{b} - 2b|a|^2), \tag{3.17}$$

where

$$r = \frac{1}{2\cos(\Omega\tau/2)}, \tag{3.18}$$

and we have noted from the definition of δ_{T_1} that we can write

$$\delta_{T_1} = (E_{T_1} - E_{T_1}^{-1})/(2\epsilon\tau) = \partial_{T_1} + O(\epsilon^2). \tag{3.19}$$

Next we put

$$a = \frac{1}{2}\alpha(T_1)e^{i\theta(T_1)}, \quad b = \frac{1}{2}\beta(T_1)e^{i\phi(T_1)}, \tag{3.20}$$

where α and β are real and nonnegative, and θ and ϕ are real. This enables us to write x_0 in the real form

$$x_0(T_0, T_1) = \alpha\cos(\Omega n\tau/2 + \theta) + (-1)^n\beta\cos(\Omega n\tau/2 + \phi). \tag{3.21}$$

When we put (3.20) into (3.16) and (3.17), and separate real and imaginary parts, we finally obtain the following coupled system of nonlinear ordinary differential equations:

$$\alpha' = r\alpha(1 - \alpha^2/4 - \beta^2/2) + \frac{3}{4}r\alpha\beta^2\cos(2\phi - 2\theta), \tag{3.22}$$

$$\beta' = -r\beta(1 - \beta^2/4 - \alpha^2/2) - \frac{3}{4}r\beta\alpha^2\cos(2\phi - 2\theta), \tag{3.23}$$

$$\theta' = \frac{3}{4}r\beta^2\sin(2\phi - 2\theta), \tag{3.24}$$

$$\phi' = \frac{3}{4}r\alpha^2\sin(2\phi - 2\theta). \tag{3.25}$$

4. Amplitude dynamics. The system (3.22) through (3.25) can be reduced to three equations by introducing the variable $\gamma = \cos(2\phi - 2\theta)$:

$$\alpha' = r\alpha(1 - \alpha^2/4 - \beta^2/2) + \frac{3}{4}r\alpha\beta^2\gamma, \tag{4.1}$$

$$\beta' = -r\beta(1 - \beta^2/4 - \alpha^2/2) - \frac{3}{4}r\beta\alpha^2\gamma, \tag{4.2}$$

$$\gamma' = \frac{3}{2}r(\beta^2 - \alpha^2)(1 - \gamma^2). \tag{4.3}$$

As far as the orbits of this system are concerned, we will be interested only in the orbits within the region $\alpha \geq 0$, $\beta \geq 0$, $-1 \leq \gamma \leq 1$.

First consider the orbits for which the projections on the $\alpha\beta$-plane are along the α-axis (i.e., $\beta = 0$). For these the system (4.1)–(4.3) reduces to the two equations

$$\alpha' = r\alpha(1 - \alpha^2/4), \tag{4.4}$$

$$\gamma' = -(3/2)r\alpha^2(1 - \gamma^2). \tag{4.5}$$

Equation (4.4) has the solution

$$\alpha = \frac{2}{\sqrt{1 + (4/\alpha_0^2 - 1)e^{-2rT_1}}} = \frac{2}{\sqrt{1 + (4/\alpha_0^2 - 1)e^{-2r\epsilon n\tau}}}, \tag{4.6}$$

where

$$\alpha(0) = \alpha_0, \tag{4.7}$$

which is very close to the amplitude in (1.3), since $2r = 1 + O(\tau^2)$ from (3.18).

Equation (4.5) shows that if $|\gamma(0)| < 1$, γ will decrease monotonically and eventually approach the limiting value of $\gamma = -1$. This orbit therefore ends at the unstable equilibrium point $(2, 0, -1)$.

For the rest of the orbits in the quarter cylinder, it is convenient to transform to cylindrical coordinates, i.e., the coordinates (R, Θ, γ), where

$$\alpha = R\cos\Theta, \tag{4.8}$$

$$\beta = R\sin\Theta. \tag{4.9}$$

In terms of these coordinates, the system (4.1)–(4.3) then becomes

$$R' = rR(1 - R^2/4)\cos(2\Theta), \tag{4.10}$$

$$\Theta' = -r\left[1 - \frac{3}{8}R^2(1-\gamma)\right]\sin(2\Theta), \tag{4.11}$$

$$\gamma' = -\frac{3}{2}rR^2(1-\gamma^2)\cos(2\Theta). \tag{4.12}$$

This system can be solved analytically. First we eliminate Θ by dividing (4.12) by (4.10) to get the differential equation

$$\frac{d\gamma}{dR} = -\frac{3}{2}\frac{R(1-\gamma^2)}{1 - R^2/4}. \tag{4.13}$$

This can easily be solved by separation of variables to give the following relationship between γ and R:

$$\gamma = \frac{C(1 - R^2/4)^6 - 1}{C(1 - R^2/4)^6 + 1}, \tag{4.14}$$

where C is a constant defined by

$$C = \frac{(1+\gamma_0)}{(1-\gamma_0)(1 - R_0^2/4)^6}, \tag{4.15}$$

which is positive since $-1 < \gamma_0 = \gamma(0) < 1$. We note that in the limit if $R \to 2$, then $\gamma \to -1$.

Note that (4.14) defines a family of nonintersecting surfaces, which are all tangent to the curve

$$R = 2, \quad \gamma = -1, \quad 0 \le \Theta \le \pi/2.$$

Figure 5 shows some of these surfaces.

If we now substitute the relationship (4.14) into (4.10) and (4.11), we get the system

$$R' = rR(1 - R^2/4)\cos(2\Theta), \tag{4.16}$$

$$\Theta' = -r\left[1 - \frac{3R^2}{4[C(1 - R^2/4)^6 + 1]}\right]\sin(2\Theta). \tag{4.17}$$

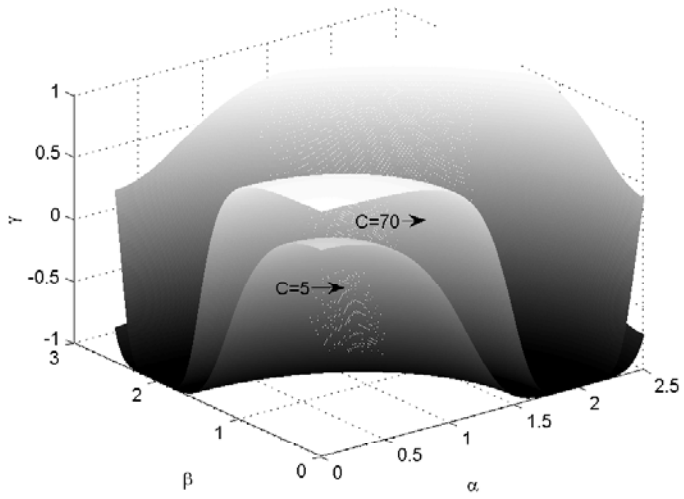

FIG. 5. *Two of the surfaces defined by* (4.14)*, namely, for* $C = 5$ *and for* $C = 70$.

This system describes the projection on the $\alpha\beta$-plane of all orbits intersecting the circle arc

$$R = R_0, \quad 0 \le \Theta \le \pi/2, \quad \gamma = \gamma_0, \tag{4.18}$$

defining C in (4.15).

Since we are primarily interested in the interaction of α and β (and therefore that of R and Θ), this dynamical system is of particular interest to us, and it is worthwhile to examine its dynamics in some detail.

In the quadrant $0 \le \Theta \le \pi/2$ the system has the equilibrium points

$$(R, \Theta) = (0, 0), \ \ (2, 0), \ \ (2, \pi/2),$$

as well as the point where $\Theta = \pi/4$ and

$$3R^2 = 4[C(1 - R^2/4)^6 + 1]. \tag{4.19}$$

If we put $u = 1 - R^2/4$, where $u \le 1$, (4.19) can be written in the simpler form

$$Cu^6 = 2 - 3u. \tag{4.20}$$

As can be seen clearly from Figure 6, the curve representing the left-hand side of (4.20) and the line representing the right-hand side have two real intersections for each value of C, namely, $u_1 > 0$ and $u_2 < 0$. This corresponds to two equilibrium points $(R_1, \pi/4)$ and $(R_2, \pi/4)$, such that $R_1 < 2$ and $R_2 > 2$. Clearly, if $C \to 0$, then $u_1 \to 2/3$ and $R_1 \to 2/\sqrt{3}$, while $u_2 \to -\infty$ and $R_2 \to \infty$. Also, if $C \to \infty$, then both $u_1, u_2 \to 0$ and $R_1, R_2 \to 2$. Thus

$$2/\sqrt{3} \le R_1 \le 2, \quad 2 \le R_2 < \infty, \tag{4.21}$$

with the equalities achieved when $\gamma_0 = -1$ (so that $C = 0$) and $\gamma_0 = 1$ (so that $C = \infty$), respectively.

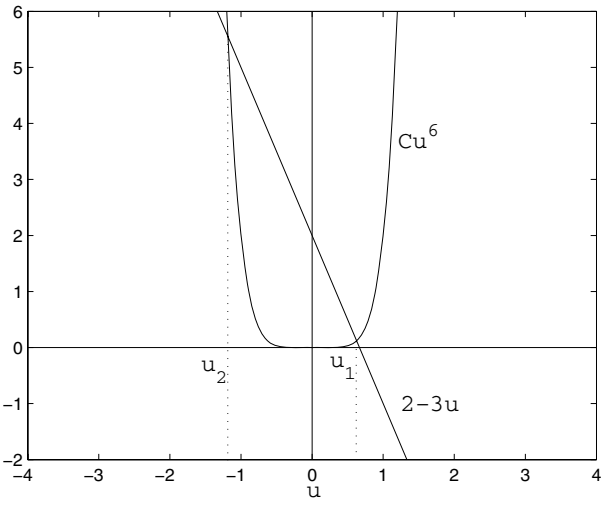

FIG. 6. *The two real solutions* $u_2 < 0$ *and* $u_1 > 0$ *of* (4.20)*, shown here for* $C = 2$.

The points $(R, \Theta) = (0, 0), (2, 0)$, and $(2, \pi/2)$ are easily seen to be saddle points. We shall show that the remaining two equilibrium points of the projected system are both surrounded by closed orbits, and are therefore centers.

It is also easy to see that the lines $\Theta = 0$ and $\Theta = \pi/2$ are orbits, directed away from and towards the origin, respectively, as well as the circle segment $R = 2$, $0 \le \Theta \le \pi/2$, in a counterclockwise direction.

The rest of the orbits can be found from the differential equation

$$\frac{du}{d\Theta} = \frac{2u(1-u)(Cu^6+1)\cot(2\Theta)}{Cu^6+1-3(1-u)}, \tag{4.22}$$

obtained by dividing (4.16) by (4.17) and putting

$$u = 1 - R^2/4.$$

Integrating this by separation of variables yields the orbit equation

$$\ln(\sin 2\Theta) = \ln\frac{u}{1-u} - \frac{1}{2}\ln\left(\frac{Cu^6}{1+Cu^6}\right) + \text{ constant}, \tag{4.23}$$

or

$$L\sqrt{1+Cu^6} = u^2(1-u)\sin(2\Theta), \tag{4.24}$$

where L is a constant which is nonnegative for orbits in the region under consideration. (Note that (4.24) is also true for $C = 0$, i.e., $\gamma = -1$. According to (4.12) these are planar orbits.)

To investigate the nature of these orbits, we first note that (4.22) shows that for $u < 1$ and $C > 0$,

$$\frac{du}{d\Theta} = 0 \text{ when } \Theta = \pi/4. \tag{4.25}$$

The extremes of u are therefore on the line $\Theta = \pi/4$ and are defined by

$$u^2(1-u) = L\sqrt{1+Cu^6} \tag{4.26}$$

or, equivalently, are given by those zeros of the polynomial

$$f(u) = (L^2C-1)u^6 + 2u^5 - u^4 + L^2 \tag{4.27}$$

which are less than one. Now since

$$f'(u) = 2u^3[3(L^2C-1)u^2 + 5u - 2], \tag{4.28}$$

the critical points of f are at $u = 0$ and $u = u_\pm$, where

$$u_\pm = \frac{-5 \pm \sqrt{1+24L^2C}}{6(L^2C-1)}. \tag{4.29}$$

For all $L \geq 0$, u_+ is always a local minimum, with

$$0 \leq u_+ = \frac{4}{(5+\sqrt{1+24L^2C})} \leq 2/3 < 1. \tag{4.30}$$

On the other hand, when $L^2C > 1$, u_- is a local minimum with

$$u_- = \frac{5+\sqrt{1+24L^2C}}{6(1-L^2C)} < 0, \tag{4.31}$$

while if $L^2C < 1$, u_- is a local maximum and $u_- > 1$.

Thus the nature of f, and therefore of its zeros, depends very much on whether $L^2C > 1$ or $L^2C < 1$. If $L^2C < 1$, i.e., for $0 < L < 1/\sqrt{C}$, the graph of f is as in Figure 7.

There is then always one and only one negative zero, signifying a single extreme value for u and hence an open orbit in the region $R > 2$. There are no positive zeros at all, unless $L \leq L_1$, where L_1 is that value of L for which f is tangent to the horizontal axis at u_+ (see Figure 7(b)). For $L < L_1$ there are two positive zeros of f less than one (Figure 7(a)), signifying two extremes in u in the region $R < 2$, and thus a closed orbit. When $L > L_1$, the function f is positive for all positive u (Figure 7(c)), and hence for all $R < 2$. Since this also implies that $\sin(2\Theta) > 1$, there are no orbits in this region for these values of L. Hence all orbits inside the quarter circle $R < 2$, $0 < \Theta < \pi/2$ are closed. However, there are open orbits in the region $R > 2$ for the entire range of values of L between 0 and $1/\sqrt{C}$.

When $L^2C > 1$, i.e., $L > 1/\sqrt{C}$, the graph of f is as in Figure 8.

There are no positive zeros of f less than one at all, and negative zeros only if $L < L_2$, where L_2 is that value of L for which f is tangent to the horizontal axis at u_- (Figure 8(b)). If $1/\sqrt{C} < L < L_2$, there are two negative zeros, signifying closed orbits in the region $R > 2$ (Figure 8(a)). For $L > L_2$, the function f is positive for all u (Figure 8(c)), which means that there are no orbits at all for these values of L.

To find L_1 and L_2, we return to (4.26). The function f will be tangent to the horizontal axis when the functions $f_1 = u^2(1-u)$ and $f_2 = L\sqrt{1+Cu^6}$ are tangent to each other. If we suppose that the tangent point is at $u = \nu$, corresponding to $L = L^*$, then ν and L^* may be found by solving the two equations

$$\nu^2(1-\nu) = L^*\sqrt{1+C\nu^6}, \tag{4.32}$$

$$2\nu - 3\nu^2 = \frac{3CL^*\nu^5}{\sqrt{1+C\nu^6}}, \tag{4.33}$$

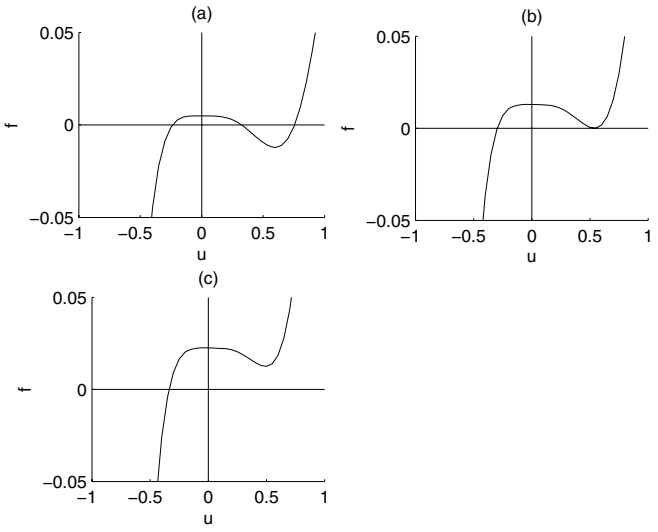

FIG. 7. *The function f as defined in* (4.27) *for* $C = 16$ *and for* (a) $L = 0.07 < L_1$, (b) $L = 0.1135 = L_1$, *and* (c) $L = 0.15 > L_1$. *In all three cases* $L^2C < 1$.

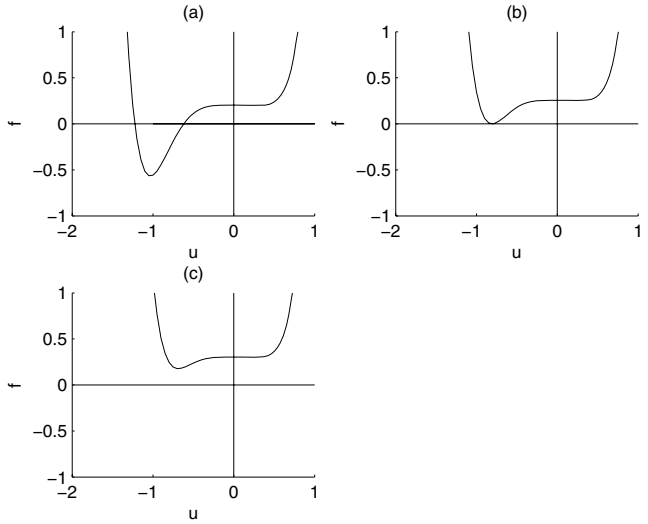

FIG. 8. *The function f as defined in* (4.27) *for* $C = 16$ *and for* (a) $L = 0.4 < L_2$, (b) $L = 0.5055 = L_2$, *and* (c) $L = 0.55 > L_2$. *In all three cases* $L^2C > 1$.

from which we find, by eliminating L^*, that ν satisfies

$$2 - 3\nu = C\nu^6, \tag{4.34}$$

which is just (4.20). Thus $\nu = u_1, u_2$ and $L^* = L_1, L_2$, respectively, and the tangent points are the centers $(R, \Theta) = (R_i, \pi/4)$, $i = 1, 2$, of the projected system. Also

$$L_i = \frac{(u_i)^2\sqrt{1 - u_i}}{\sqrt{3}}. \tag{4.35}$$

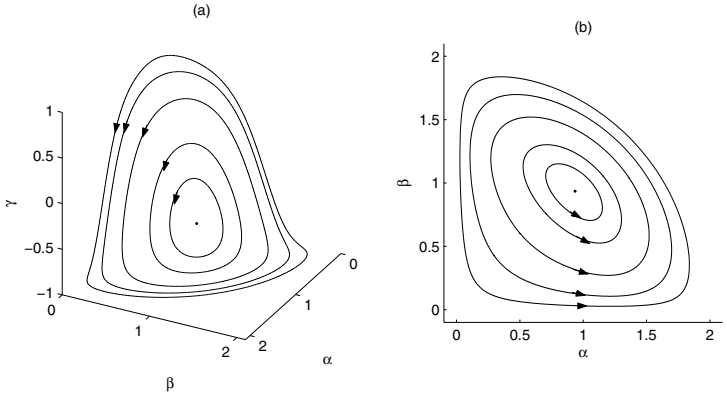

FIG. 9. *Three-dimensional phase diagram* (a) *as well as its projection* (b) *on the* $\alpha\beta$*-plane for* $C = 10$.

Thus the orbits may be classified as follows:

- $L = 0$: The saddle points $(R, \Theta) = (0, 0), (2, 0), (2, \pi/2)$, and the orbit $R = 2$, $0 < \Theta < \pi/2$. (Note that from (4.15), whenever $R = 2$, $\gamma = -1$, so that these saddle points will correspond to the unstable equilibrium points $(\alpha, \beta, \gamma) = (0, 0, (C-1)/(C+1)), (0, 2, -1), (2, 0, -1)$ of the three-dimensional system (4.1)–(4.3).)
- $0 < L < L_1$: Closed orbits for $R < 2$, open orbits for $R > 2$.
- $L = L_1$: Center at $R = R_1, \Theta = \pi/4$ and an open orbit in the region $R > 2$.
- $L_1 < L \leq 1/\sqrt{C}$: Only open orbits in the region $R > 2$.
- $1/\sqrt{C} < L < L_2$: Only closed orbits in the region $R > 2$.
- $L = L_2$: Center at $R = R_2$, $\Theta = \pi/4$.
- $L > L_2$: No orbits.

From (4.22) we can also see that $\frac{d\Theta}{du}$ will be zero if $Cu^6 + 3u - 2 = 0$ or $u = u_1, u_2$. Then the extreme values of Θ on the orbit are given by

$$\sin 2\Theta_e = L/L_i, \quad i = 1, 2, \tag{4.36}$$

i.e.,

$$\Theta_{\max} = \pi/2 - \frac{1}{2}\arcsin(L/L_i), \tag{4.37}$$

$$\Theta_{\min} = \frac{1}{2}\arcsin(L/L_i). \tag{4.38}$$

A typical phase diagram, both in three-dimensional phase space and as projected on the $\alpha\beta$-plane, is shown in Figure 9 for $C = 10$.

5. Application to the leapfrog method. Having studied the dynamics of the amplitudes of the two interacting waves in general, we can now relate it to the actual numerical results obtained when solving (2.5) and (2.6). It should be remembered that the values of y^1 and x^1 must be found by using some one-step method like the Euler method or one of the Runge–Kutta methods before the leapfrog method can start. Because of this, the computational wave is present from the outset, as we will demonstrate below.

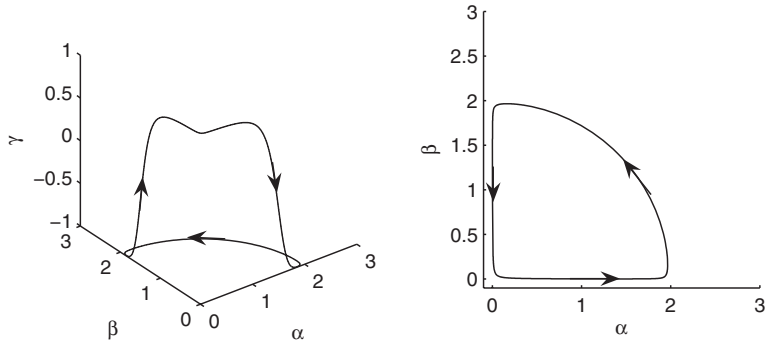

FIG. 10. *Orbit in three dimensions, and projected on the $\alpha\beta$-plane, for an Euler starter and $\tau = 0.2$, $\epsilon = 0.025$, $\omega = 1$, $x^0 = 0$, $y^0 = 0.5$.*

To find the initial amplitudes $\alpha(0) = \alpha_0$ and $\beta(0) = \beta_0$, as well as the initial phase angles θ_0 and ϕ_0 (and hence also γ_0), we put

$$x^n = \alpha_0 \cos\left(\frac{\Omega n\tau}{2} + \theta_0\right) + (-1)^n \beta_0 \cos\left(\frac{\Omega n\tau}{2} + \phi_0\right) \tag{5.1}$$

for $n = 0, 1, 2$, and 3. (Here we assume that ϵ is small enough so that the functions depending on T_1, i.e., α, β, θ, and ϕ, do not change significantly over three time steps.) Note that x^0 and y^0 are the given initial conditions, and x^1, x^2, and x^3 depend on the actual starter scheme used. By solving for $\alpha_0 \cos\theta_0$, $\alpha_0 \sin\theta_0$, $\beta_0 \cos\phi_0$, and $\beta_0 \sin\phi_0$ first, we need only solve a linear algebraic system. Eventually we can then find R_0, Θ_0, and γ_0, and hence the orbit parameters C and L.

For $\tau = 0.2$, $\epsilon = 0.025$, $\omega = 1$, $x^0 = 0$, $y^0 = 0.5$, and an Euler starter, the initial amplitudes and phases were

$$\alpha_0 = 0.5089, \tag{5.2}$$

$$\beta_0 = 0.0040, \tag{5.3}$$

$$\theta_0 = -1.5718 \text{ radians}, \tag{5.4}$$

$$\phi_0 = -1.4428 \text{ radians}. \tag{5.5}$$

Thus the computational wave has a small but significant amplitude β_0 initially. The initial orbit polar coordinates are then

$$R_0 = 0.5089, \tag{5.6}$$

$$\Theta_0 = 0.0079 \text{ radians}, \tag{5.7}$$

$$\gamma_0 = 0.9669, \tag{5.8}$$

from which the orbital parameters of this numerical solution can be calculated as $C = 88.8002$ and $L = 0.00011453$. The resulting orbit and its projection in the $\alpha\beta$-plane are shown in Figure 10.

We also used both a second order and a fourth order Runge–Kutta starter. The initial phases and amplitudes for these are given in Table 1.

The corresponding orbits are shown in Figures 11 and 12.

When comparing Figures 10, 11, and 12, we note that the projection of the orbit on the $\alpha\beta$-plane looks virtually the same in all three cases, but that the full

TABLE 1
Orbital parameters for different starter schemes.

Starter	α_0	β_0	θ_0	ϕ_0	R_0	Θ_0	γ_0	C	L
2nd order RK	0.5038	0.00117	−1.5715	1.2499	0.5038	0.0023	0.8019	13.4768	0.000083
4th order RK	0.5038	0.00132	−1.5722	1.0015	0.5038	0.0026	0.4215	3.6407	0.000160

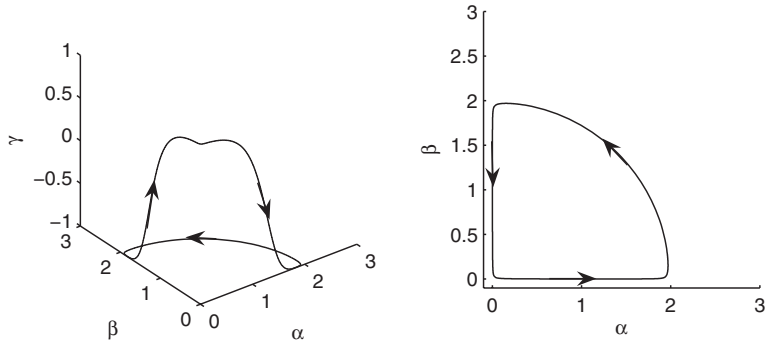

FIG. 11. *Orbit in three dimensions, and projected on the $\alpha\beta$-plane, for a second order Runge–Kutta starter and $\tau = 0.2$, $\epsilon = 0.025$, $\omega = 1$, $x^0 = 0$, $y^0 = 0.5$.*

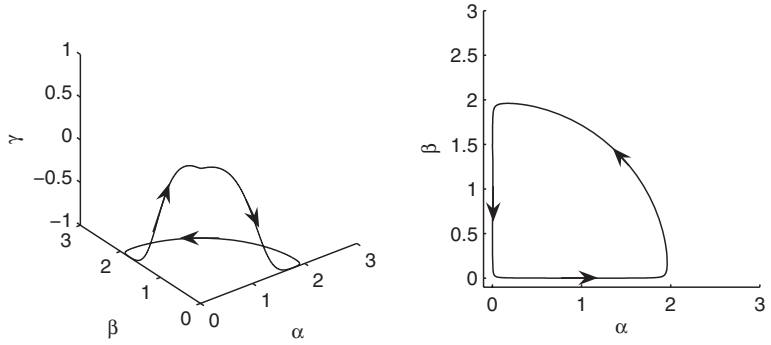

FIG. 12. *Orbit in three dimensions, and projected on the $\alpha\beta$-plane, for a fourth order Runge–Kutta starter and $\tau = 0.2$, $\epsilon = 0.025$, $\omega = 1$, $x^0 = 0$, $y^0 = 0.5$.*

three-dimensional orbit varies significantly. The more inaccurate the starter scheme is, the more variation there seems to be in γ, and hence in the phase angles θ and ϕ.

From the actual orbits it is easy to find the point where the computational wave starts to grow. Cai et al. [1] calculated that this happens when $\alpha = \sqrt{0.8} = 0.8944$. Our nonlinear analysis allows us to be more precise by finding the lowest point of a particular orbit. In fact, we can already see that the computational wave is initially damped, until the damping eventually becomes an amplification. In Table 2 we list, for each of the three starter schemes and the parameter values and initial conditions as before, the point $\alpha = \alpha_1^*$, where the amplitude β of the computational wave reaches a minimum value of β^*. At this point the computational wave starts growing, albeit very slowly at first. We also list the point $\alpha = \alpha_2^*$ where the amplitude β first exceeds the value of 0.01.

TABLE 2

The point $\alpha = \alpha_1^*$ on the orbit where β reaches its minimum β^*, together with the value α_2^* of α, where β first exceeds 0.01 for the three different starter schemes, and $\tau = 0.2$, $\epsilon = 0.025$, $\omega = 1$, $x^0 = 0$, $y^0 = 0.5$.

Starter	α_1^*	α_2^*	β^*
Euler	1.4450	1.8866	0.000996
2nd order RK	1.2507	1.9043	0.000465
4th order RK	1.1065	1.8655	0.000713

We see that α_1^* is sensitive for the particular starter scheme used, whereas α_2^* does not vary very much. From Table 1 we see that C decreases with the accuracy of the initial values x^1 and y^1. It is worthwhile to note at this point that if $C = 0$ (and therefore $\gamma = -1$ throughout), then if we consider an orbit close to $\beta = 0$, by putting $\beta = \epsilon \ll 1$, then (4.2) becomes

$$\epsilon' = r\epsilon(5\alpha^2/4 - 1), \tag{5.9}$$

showing that α_1^* would take on the value of $\sqrt{0.8}$ predicted by Cai et al. Their value is therefore a limiting value. In practice, growth of the computational wave starts a bit later. In practical terms, for the type of accuracy expected from a second order method and a time step of 0.2, the computational wave will start to cause trouble only when its amplitude becomes larger than about 0.01, i.e., about 0.5% of the limit circle amplitude. This does not happen before the solution gets very close to the limit cycle, i.e., at about $\alpha = 1.9$. Up to then the effect of β in (3.22) and (3.24) is negligible, so that the phase angle θ is virtually constant, and the amplitude of the solution is given by (4.6), which is as near to the analytic solution as can be expected from a second order method. In other words, the numerical solution is quite sound and useful until it very nearly reaches the limit cycle.

We may also note from the phase diagram in Figure 9 that when we start with initial conditions which leads to an initial amplitude larger than that of the limit cycle, the open orbits in the region $R > 2$ imply eventual blowup. To test this, we used the parameter values we used before, but changed the initial values to $x^0 = 5$, $y^0 = 0$. With a second order Runge–Kutta starter, the numerical results are shown in Figure 13.

The computational wave is clearly seen to become significantly large quite early, causing a blowup of the solution at about 50 time units. The orbit parameters for these parameter values and initial conditions turn out to be $C = 3.1070 \times 10^{-6}$ and $L = 5.2642$. For this low value of C, closed orbits in the region $R > 2$ start only at about $L = 567$, so that this orbit is definitely open. Figure 14 shows this orbit, both in three dimensions and projected on the $\alpha\beta$-plane. The point on this orbit where β is a minimum is at $\alpha = \alpha_1^* = 6.82$. Since the initial point on this orbit is further along, the computational wave is amplified from the very start, where it already has an amplitude of 0.08. Thus, for these particular initial conditions, the numerical solution is useless.

Finally (4.12) implies that there is another set of planar orbits besides $\gamma = -1$, namely, those on the plane $\gamma = 1$ ($C = \infty$). Then, according to (4.11), $\Theta' < 0$ on $(0, \pi/2)$, and hence β, monotonically decreases for all orbits on this plane. Thus the computational wave will cause no problems as long as $\gamma = 1$ (i.e., $\theta = \phi$). Unfortunately these orbits are structurally unstable. The smallest deviation from $\gamma = 1$ will move the solution to one of the other C-surfaces, and hence lead to growth of β.

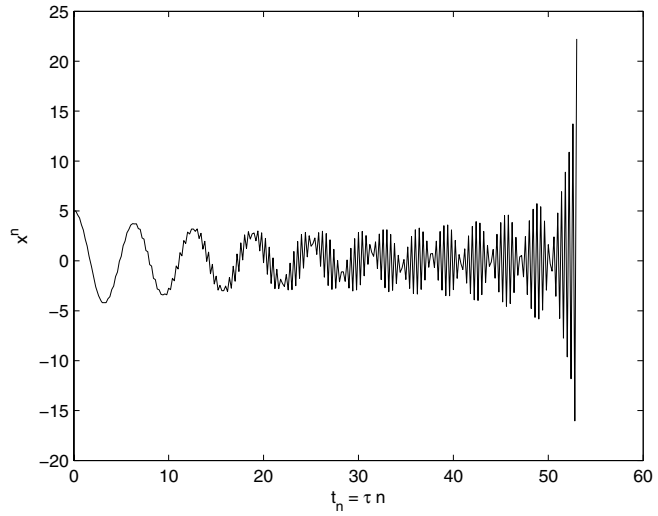

FIG. 13. *Results when running the difference system* (2.5), (2.6) *with* $\epsilon = 0.025$, $\tau = 0.2$, *and* $x^0 = 5$, $y^0 = 0$.

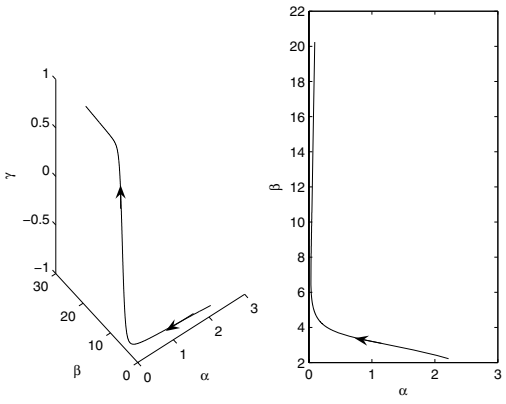

FIG. 14. *Orbit in three dimensions, and projected on the* $\alpha\beta$*-plane, for a second order Runge–Kutta starter and* $\tau = 0.2$, $\epsilon = 0.025$, $\omega = 1$, $x^0 = 5$, $y^0 = 0$.

6. Discussion. In this paper we demonstrated that attempts to calculate the solution of the van der Pol equation by means of several Nyström methods of different orders lead to nonlinear instabilities caused by sudden growth of a high frequency mode. This high frequency induced (HFI) instability can be delayed simply by decreasing the time step. Thus it is always possible to calculate the limit cycle accurately, provided a small enough time step is used. Time step restrictions get more severe as the order of the method is increased.

As far as the analysis is concerned, we first improved upon the work done by Cai et al. [1], in the sense that by doing a full nonlinear analysis of the amplitude dynamics of the second order Nyström difference scheme (2.5), we were able to fully explain the observed spurious amplitude modulation imposed by it, and also to assess the extent to which this scheme could still be useful as a second order numerical method.

We also demonstrated the use of a discrete multiple scales technique combined with a phase plane analysis to analyze such a nonlinear difference scheme. These techniques will certainly also be applicable to other numerical methods for the van der Pol and other nonlinear differential equations, and indeed to nonlinear models which are discrete to start with.

The fact that leapfrog time discretizations could cause spurious behavior has been known for some time [7, 8, 11], and Sanz-Serna [7] and Sanz-Serna and Vadillo [8] did a phase plane analysis in some simpler cases. Of course, in the case of (2.5) the problem is much more complicated, since it is not the behavior of the solution itself which needs to be analyzed (as in the cases studied by Sanz-Serna and his coworkers), but rather that of its amplitude, which makes it necessary to use a discrete multiple scales method first.

In a case such as Duffing's equation, which models oscillations but does not have a limit cycle, we found that the HFI instabilities were less severe, in the sense that it seems to be totally absent in the case of the second order Nyström scheme, although still present in the case of the higher order methods.

We also observed HFI instability where Nyström methods were applied to other cases where limit cycles occurred in the dynamics of the solutions. One such case was a predator-prey system described in [5, Chapter 3, section 3.3]. An analysis of these and other cases is currently under way and will be discussed in forthcoming papers.

ON THE ERROR IN QR INTEGRATION*

LUCA DIECI† AND ERIK S. VAN VLECK‡

Abstract. An important change of variables for a linear time varying system $\dot{x} = A(t)x,\ t \geq 0$, is that induced by the QR-factorization of the underlying fundamental matrix solution: $X = QR$, with Q orthogonal and R upper triangular (with positive diagonal). To find this change of variable, one needs to solve a nonlinear matrix differential equation for Q. Practically, this means finding a numerical approximation to Q by using some appropriate discretization scheme, whereby one attempts to control the local error during the integration. Our contribution in this work is to obtain global error bounds for the numerically computed Q. These bounds depend on the local error tolerance used to integrate for Q, and on structural properties of the problem itself, but not on the length of the interval over which we integrate. This is particularly important, since—in principle—Q may need to be found on the half-line $t \geq 0$.

Key words. QR methods, orthogonal integration, Lyapunov exponents, integral separation

Notation. An $(n \times n)$ real matrix X is indicated by $X \in \mathbb{R}^{n\times n}$. $\mathrm{diag}(X)$ is the matrix comprising the diagonal part of X, the rest being all 0's; $\mathrm{upp}(X)$ is the matrix comprising the upper triangular part of X, the rest being all 0's; and $\mathrm{low}(X)$ is the matrix comprising the strictly lower triangular part of X, the rest being all 0's. The default norm we consider is the 2-norm of vectors and the induced norm for matrices.

1. Introduction.

Consider the homogeneous nonautonomous linear differential equation

$$\dot{x}(t) = A(t)x(t),\ t \geq 0, \tag{1.1}$$

where A is a bounded function taking values in $\mathbb{R}^{n\times n}$. Equation (1.1) appears pervasively in the study of dynamical systems. For example, it is the equation we end up with when we study variation with respect to the initial conditions, or parameters, of a nonlinear system. Therefore, it is the problem we have to face when we do general stability analyses for trajectories of a dynamical system, e.g., for periodic or for chaotic trajectories. Moreover, (1.1) is also the problem at hand during a Newton process to solve general nonlinear differential systems, a process often advocated for solving boundary value problems. Alas, in spite of its apparent simplicity, numerical investigation of (1.1) is extremely hard, since the solution structure depends on the fundamental matrix solution. Unquestionably, the problem is certainly conceptually and computationally simpler if A happened to be triangular. For this reason, techniques which find an orthogonal change of variable to triangular structure have been studied by several researchers for a long time; e.g., see [6, 12, 18]. Our own interest in these techniques originates with methods to approximate Lyapunov exponents of

dynamical systems, a feat which is greatly simplified when the system is brought in upper triangular structure; e.g., see [13, 8, 9].

Of course, the factor Q which performs the change of variables has to be found numerically, and this itself is not easy since Q satisfies a nonlinear matrix differential equation. Thus, to find Q, one must approximate the solution of this nonlinear matrix equation in some appropriate way. In practice, this means that we will control the local errors while approximating Q, a fact which generally does not guarantee that Q will be approximated accurately, i.e., that the global error in our approximation will stay small. Our contribution in this work is to provide accurate bounds on the *global* error when finding Q: Our bounds will depend on the *local* error tolerance and on the coefficient function A, but not on the length of the interval over which we approximate Q. Our result is somewhat atypical and is important. It is atypical because, even though Q lies in a compact space, usually one does not obtain accurate global error bounds (on arbitrarily long intervals) except for contractive problems, and our problem is not contractive. It is important, because—used in conjunction with standard techniques to approximate Lyapunov exponents—it can be used to obtain global error bounds on the computed Lyapunov exponents of a linear time varying system, as well as global errors on other spectral quantities.

The way we will obtain global error bounds for the computed Q is in itself interesting and apparently new. Our main idea is to combine two types of error analyses: A backward error analysis guaranteeing that the computed Q factor gives a transformation to nearly triangular form, and a forward error analysis guaranteeing that for this nearly triangular problem there is a near-the-identity orthogonal transformation reducing it further to a triangular structure. Combining these two ingredients, we will obtain the sought result. Oversimplifying it, let us sketch the basic idea which has guided us:

- We want to express $X = QR$, Q orthogonal, R upper triangular with positive diagonal.
  - If we had Q, then R would satisfy a triangular system $\dot{R} = \widetilde{B}R$.
  - Suppose that instead of Q we compute (*backward error result*) an orthogonal Q_c, which gives $X = Q_c\widehat{R}$, with $\dot{\widehat{R}} = (B + F)\widehat{R}$, with B triangular and F of small norm (F not triangular).
  - Suppose also that we write $\widehat{R} = VU$, with V orthogonal and U upper triangular with positive diagonal. Then we have $X = Q_cVU$, and so, by uniqueness, $R = U$ and $Q_cV = Q$.
- If we now show that $V \approx I$ (*forward error result*), then we will infer that $Q_c \approx Q$ (*global error result*).

An outline of the paper is as follows. In the remainder of this introduction we review the basic change of variables $X = QR$ and the differential equations satisfied by Q and R. In section 2 we recall the key backward error statement which we proved in [10]. In section 3 we give in a concise way the global error statement result, and in section 4 we give details of a systematic way to obtain sharp bounds on the quantities appearing in the error bound. In section 5 we illustrate our results in an example. Conclusions are in section 6, which include a remark on the modifications needed to handle the case in which we only have a "reduced" QR-factorization, that is, when X comprises only a subset of columns of the fundamental matrix solution.

We now consider the differential equations governing the evolution of the Q and R factors in the QR-factorization of X. Presently, X is a fundamental matrix solution

for (1.1): $\dot{X} = A(t)X$, $X(0) = X_0$ invertible. Let $X_0 = Q_0R_0$ be the unique QR-factorization of X_0 with the diagonal of R_0 being positive.

Differentiating the relation $X = QR$ one obtains $\dot{Q}R + Q\dot{R} = A(t)QR$, and multiplying by Q^T on the left we obtain the equation for R:

$$\dot{R} = \widetilde{B}(t)R\ , \quad R(0) = R_0, \tag{1.2}$$

where we have set

$$\widetilde{B}(t) := Q^T(t)A(t)Q(t) - Q^T(t)\dot{Q}(t). \tag{1.3}$$

Let us formally set $S := Q^T\dot{Q}$. Since R has to be upper triangular, we must have $\widetilde{B}$ upper triangular, which leads to

$$\dot{Q} = QS(Q, A(t)),\ \ t \geq 0, \tag{1.4}$$

where

$$S(Q(t), A(t))_{ij} = \begin{cases} (Q^T(t)A(t)Q(t))_{ij}, & i > j, \\ 0, & i = j, \\ -(Q^T(t)A(t)Q(t))_{ji}, & i < j. \end{cases} \tag{1.5}$$

In particular, we notice that if Q is known, then R satisfies (1.2), and we also notice that S is linear in A. Furthermore, in light of (1.5), for the entries of $\widetilde{B}$ we have $\widetilde{B}_{ij} = \left(Q^TAQ\right)_{ij} + \left(Q^TAQ\right)_{ji}$ for $i < j$ and $\widetilde{B}_{ii} = \left(Q^TAQ\right)_{ii}$, that is, $\widetilde{B} = \mathrm{upp}(Q^TAQ) + (\mathrm{low}(Q^TAQ))^T$.

The above derivation of the equations for the QR-factorization of X has been obtained many times before, and specific attention has been paid in recent years to techniques which maintain orthogonality while approximating the factor Q. A sample of relevant references includes [2, 3, 14, 12, 7, 16]. We are not going to review these works in detail, because the precise way in which the approximation for Q is obtained is not relevant to our main scope here, which is to derive global error bounds for the obtained approximations to Q. What is relevant is that the obtained approximations be orthogonal at the grid-points found during numerical integration of (1.4), a fact which the schemes proposed in the above cited works do achieve.

2. Background. Suppose we are seeking the factorization $X(t_k) = Q(t_k)R(t_k)$, $k = 0, 1, 2, \ldots$. In other words, we are looking for the change of variables, the factor Q in the QR-factorization of X, at the grid-points $0 = t_0 < t_1 < \cdots$. Practically, the grid-points $\{t_k\}$ may have been found during numerical integration of (1.4) by any of the schemes in the previously cited works. Alternatively, we can always think of indirectly having found approximations to Q by directly seeking the QR-factorization of $X(t_k)$ as follows. Write

$$X(t_k) = \Phi(t_k, t_{k-1}) \ldots \Phi(t_2, t_1)\Phi(t_1, 0)X_0, \tag{2.1}$$

where

$$\dot{\Phi}(t, t_{j-1}) = A(t)\Phi(t, t_{j-1}),\ \Phi(t_{j-1}, t_{j-1}) = I, \quad t_{j-1} \leq t \leq t_j,\ j = 1, 2, \ldots, k. \tag{2.2}$$

Then, for $j = 1, 2, \ldots, k$, recursively consider (*discrete QR technique*)

$$\begin{aligned} &\dot{\Psi}(t, t_{j-1}) = A(t)\Psi(t, t_{j-1}),\ \ \Psi(t_{j-1}, t_{j-1}) = Q(t_{j-1}), \\ &\text{and factor } \Psi(t_j, t_{j-1}) = Q(t_j)R(t_j, t_{j-1}), \end{aligned} \tag{2.3}$$

where $Q(t_j)$ are orthogonal and $R(t_j, t_{j-1})$ are upper triangular with positive diagonal. So, we have the QR-factorization of $X(t_k)$,

$$X(t_k) = Q(t_k)R(t_k, t_{k-1}) \dots R(t_2, t_1)R(t_1, t_0)R(t_0). \tag{2.4}$$

If we adopt this point of view, the error we commit in finding Q is inherited from the error we do when approximating the transition matrices $\Phi(t_j, t_{j-1})$, $j = 1, 2, \dots, k$.

Notice that taking this point of view, we have expressed $R(t_k)$ as the product of local triangular transition matrices:

$$R(t_k) = R(t_k, t_{k-1}) \cdots R(t_2, t_1)R(t_1, t_0),$$

where each of these triangular transition matrices is the same as the solution of

$$\dot{R}(t, t_{j-1}) = \widetilde{B}(t)R(t, t_{j-1}),\ R(t_{j-1}, t_{j-1}) = I, \quad t_{j-1} \le t \le t_j,\ j = 1, 2, \dots, k,$$

where $\widetilde{B}$ is given in (1.3).

Now, we cannot hope to be able to obtain the exact factors $Q(t_k)$ (and $R(t_k)$). Still, let us assume that the obtained numerical approximations to the $Q(t_k)$'s, call them Q_k's, are orthogonal. The key fact, which we proved in [10], is the following: "By using either direct integration of (1.4) or having indirectly approximated Q via the discrete QR technique, with a numerical realization of the change of variables $X = QR$, we are obtaining a numerical approximation to $X(t_k)$, call it X_k, and to the triangular transition matrices $R(t_k, t_{k-1})$, call these R_k, so that we have

$$X_k = Q_k R_k R_{k-1} \dots R_2 R_1 R(t_0)\,,\ \ k = 1, 2, \dots, \tag{2.5}$$

and at the same time

$$X_k = Q(t_k)[R(t_k, t_{k-1}) + E_k] \dots [R(t_2, t_1) + E_2][R(t_1, t_0) + E_1]R(t_0)\,,\ \ k = 1, 2, \dots, \tag{2.6}$$

where $Q(t_k)$ is the exact Q-factor at t_k and the triangular transitions $R(t_j, t_{j-1})$ are also the exact ones. Moreover, the factors E_j, $j = 1, \dots, k$, are bounded in norm by the local error committed during integration of the relevant differential equations; see Theorems 3.1 and 3.16."

We will henceforth simply write

$$\|E_j\| \ \le\ \eta,\ \ j = 1, 2, \dots, \tag{2.7}$$

and stress that η is computable, in fact controllable, in terms of local error tolerances.

Furthermore, close inspection of the error terms E_j, $j = 1, \dots, k$, $k = 1, 2, \dots$, allowed us to obtain a backward error result, which we summarize below. For details, we refer to the original work (see [10, Theorem 3.12]); here we are content with a useful rephrasing of this result.

SUMMARY 2.1. *With a numerical realization of the QR change of variables, either having directly integrated* (1.4) *or indirectly through the numerical realization of the discrete QR technique, we do not obtain the exact transformation to the triangular form* (1.2)–(1.3)*, but rather find an orthogonal change of variable to the perturbed triangular system*

$$\dot{\widehat{R}} = \big(B(t) + F(t)\big)\widehat{R},\ \ t \ge 0, \tag{2.8}$$

where B is the piecewise constant (and triangular) function given by

$$B(t) := \frac{1}{t_{j+1}-t_j}\log\big(R(t_{j+1},t_j)\big), \quad t_j \le t < t_{j+1}, \tag{2.9}$$

and F is bounded as

$$\sup_{t\ge 0}\|F\| \le c\eta + O(\eta^2) =: \delta. \tag{2.10}$$

For the sake of completeness, we remark that in (2.10) the bounds on the norm of F are obtained locally, on each subinterval $[t_{j-1},t_j]$, $j=1,2,\dots$, so that one really has $\sup_{t_{j-1}\le t\le t_j}\|F\| \le c_j\eta + O(\eta^2)$, and the main contribution to the magnification factor c_j is given by the departure from normality of the exact triangular transition factors $R(t_j,t_{j-1})$. Indeed, at first order in $\mathtt{TOL}$, we have

$$\sup_{t_{j-1}\le t\le t_j}\|F\| \;\approx\; \mathtt{TOL}(1+\kappa_{j-1}h_{j-1}),\;\; h_{j-1}=t_j-t_{j-1}, \tag{2.11}$$

where $\mathtt{TOL}$ is the local error for the obtained approximation to the transition matrix, and κ_{j-1} is the departure from normality of $R(t_j,t_{j-1})$. In any case, we stress once more that the bounds on the norm of F are computable.

Remark 2.1. In order to obtain (2.10), in [10], we needed to have a certain condition satisfied; see [10, Assumption 3.5]. This amounted to the requirement that

$$\mathtt{TOL}\left[\min\left(1,\min_{1\le i\le n}\exp\left(\int_{t_{j-1}}^{t_j}B_{ii}(s)ds\right)\right)\right]^{-1} < 1.$$

In practice, this means that one may need to have the stepsizes $h_j := t_j - t_{j-1}$, $j=1,2,\dots$, sufficiently small.

3. Global error bounds for Q. Next, consider the unperturbed and perturbed triangular systems

$$\dot R = B(t)R,\; R(0)=R_0 \qquad \text{and} \qquad \dot{\widehat R} = [B(t)+F(t)]\widehat R,\; \widehat R(0)=R_0, \tag{3.1}$$

where we can assume that $\sup_{t\ge0}\|F(t)\|\le\delta$.

In [11], we proved (see Lemma 3.1 below) that there is an orthogonal change of variables, close to the identity, taking the perturbed triangular system to triangular form. The proof we gave used global (and fairly crude) norm estimates and proceeded as follows.

First, write $R = R_D + R_U$, where $R_D = \mathrm{diag}(R)$ and $R_U = \mathrm{upp}(R)$, so that $R = (I + R_U R_D^{-1})R_D =: ZR_D$. Accordingly, we have the unperturbed and perturbed diagonal systems

$$\dot R_D = D(t)R_D,\;\; \dot{\widehat R}_D = [D(t)+E(t)]\widehat R_D, \tag{3.2}$$

where $D(t)=\mathrm{diag}(B(t))$, $E = Z^{-1}FZ$, and $\widehat R = Z\widehat R_D$. Define

$$\mathrm{cond}(Z) = \sup_{t\ge0}\|Z(t)\|\cdot\|Z^{-1}(t)\|, \tag{3.3}$$

and assume that $\mathrm{cond}(Z)$ is bounded. In other words, we are assuming that Z is a Lyapunov transformation; e.g., this is certainly the case if the triangular system $\dot R = BR$ is integrally separated. This last assertion follows from [8, Theorem 5.1].

Recall that R is an *integrally separated* fundamental matrix solution if there exist $a > 0$ and $d \geq 1$ such that

$$\frac{||R(t)e_i||}{||R(s)e_i||} \cdot \frac{||R(s)e_{i+1}||}{||R(t)e_{i+1}||} \geq de^{a(t-s)} \tag{3.4}$$

for all $t, s,\ t \geq s \geq 0$, and $i = 1, 2, \ldots, n-1$. We also recall that integral separation is a generic property for linear systems (see [19]) and is a necessary and sufficient condition for stability of the Lyapunov exponents when they are distinct [1].

Next, let $\omega := \sup_{t\geq 0} \|E(t)\|$, and observe that

$$\omega \ \leq \ \sup_{t\geq 0} \|F\| \ \mathrm{cond}(Z) \ \leq \ \delta \ \mathrm{cond}(Z). \tag{3.5}$$

We make note here that the integral separation constants used in Lemmas 3.1 and 4.1 below are the integral separation constants for the piecewise constant upper triangular system that results from (2.4); see (2.9). That is, we write

$$R(t_{j+1}, t_j) = e^{(t_{j+1}-t_j)B(t)}, \quad t_j \leq t < t_{j+1},$$

where in fact

$$B(t) := \frac{1}{t_{j+1} - t_j} \log\big(R(t_{j+1}, t_j)\big), \quad t_j \leq t < t_{j+1}.$$

This piecewise constant triangular system produces the same upper triangular fundamental matrix solution as the exact upper triangular system when evaluated at mesh-points. Therefore,

$$\int_{t_j}^{t_{j+1}} B_{ii}(\tau)d\tau = \int_{t_j}^{t_{j+1}} \widetilde{B}_{ii}(\tau)d\tau, \tag{3.6}$$

where B denotes the piecewise constant triangular coefficient matrix function and $\widetilde{B}$ the exact triangular coefficient matrix function of (1.3). Thus, if $\widetilde{B}$ has integral separation with constants $\widetilde{a} > 0$ and $\widetilde{d} \geq 0$ so that for $t \geq s$ (take logarithms in (3.4))

$$\int_s^t \big(\widetilde{B}_{ii}(\tau) - \widetilde{B}_{i+1,i+1}(\tau)\big)d\tau \geq \widetilde{a}(t-s) - \widetilde{d} \tag{3.7}$$

for $i = 1, \ldots, n-1$, then for $t_{j-1} < s < t_j$ and $t_k < t < t_{k+1}$,

$$\begin{aligned} &\int_s^t \big(B_{ii}(\tau) - B_{i+1,i+1}(\tau)\big)d\tau = \int_s^t \big(\widetilde{B}_{ii}(\tau) - \widetilde{B}_{i+1,i+1}(\tau)\big)d\tau \\ &+\int_s^{t_j} \big[(B_{ii}(\tau) - \widetilde{B}_{ii}(\tau)) - (B_{i+1,i+1}(\tau) - \widetilde{B}_{i+1,i+1}(\tau))\big]d\tau \\ &+\int_{t_k}^t \big[(B_{ii}(\tau) - \widetilde{B}_{ii}(\tau)) - (B_{i+1,i+1}(\tau) - \widetilde{B}_{i+1,i+1}(\tau))\big]d\tau \geq a(t-s) - d, \end{aligned} \tag{3.8}$$

where $a = \widetilde{a}$, $d \leq \widetilde{d} + 4M_{i,i+1}h_{max}$, $M_{i,i+1} = \sup_{t\geq 0} |B_{ii}(t) - B_{i+1,i+1}(t)|$, and $h_{max} = \sup_j (t_{j+1} - t_j)$. In other words, the problem with B also has integral separation with constants $a > 0$ and $d \geq 0$.

Then the following result shows the existence of a near identity orthogonal change of variables which brings the perturbed diagonal system to upper triangular, provided

that ω is small enough. We proved this result in [11] under the assumption of integral separation of both unperturbed and perturbed triangular systems.

LEMMA 3.1 (see [11]). *Let* $\sup_{t\geq 0}\|B(t)\| = M$, *and let* a *and* d *be as defined in* (3.4). *Let* $\widehat{Q}$ *be the orthogonal factor in the QR-factorization of* $\widehat{R}_D$.

If $\omega < \omega_+(\alpha, K, M)$, *then* $|\widehat{Q}_{ij}(t)| \leq \overline{\rho}$ *for* $i \neq j$ *and all* $t \geq 0$. *Here,* $\overline{\rho} = \beta \cdot \omega$, $\beta = \alpha K$, $\alpha > 1$, $K = e^d/a$, *and*

$$\omega_+(\alpha, K, M) := \left(\sqrt{a_1^2 + 4(\alpha-1)a_2} - a_1\right)/(2a_2), \tag{3.9}$$

where $a_2 = n^2\beta^2[M\beta + 2]$ *and* $a_1 = n\beta[2M\beta + 1]$.

As an immediate consequence we have the following.

COROLLARY 3.1. *If* $\omega < \omega_+(\alpha, K, M)$ *and* $(n-1)\overline{\rho}^2 \leq 1$, *then* $\|\widehat{Q}(t) - I\| \leq \rho \equiv (n-1)(\overline{\rho} + \overline{\rho}^2)$ *and* $\|\widehat{Q}(t) - I\|_F \leq \rho_F \equiv \overline{\rho}\sqrt{2(n^2-n)}$, *where* $\|\cdot\|_F$ *is the Frobenius norm.*

Perhaps surprisingly, we already have all the ingredients to obtain global error bounds on $Q_k - Q(t_k)$.

First of all, let us look again at (2.6). In the notation of Corollary 3.1, if $\omega < \omega_+(\alpha, K, M)$, then (2.6) can be rewritten as

$$X_k = Q(t_k)Z(t_k)\widehat{Q}(t_k)U(t_k), \tag{3.10}$$

where $U(t_k)$ is upper triangular with positive diagonal elements, and $\|\widehat{Q}(t_k) - I\| \leq \rho$.

Next, let $\widehat{Z} \equiv Z(t_k)$ and $\widehat{Q} \equiv \widehat{Q}(t_k)$. Then

$$\widehat{Z}\widehat{Q} = \widehat{Z}(I + \Delta\widehat{Q}) = \widehat{Z} + \widehat{Z}\Delta\widehat{Q} =: \widehat{Z} + \Delta\widehat{Z}, \tag{3.11}$$

where $\|\Delta\widehat{Z}\| \leq \|\widehat{Z}\| \cdot \|\Delta\widehat{Q}\| \leq \|\widehat{Z}\|\rho$.

THEOREM 3.2. *With the previous notation, assume that*

1. $\omega < \omega_+(\alpha, K, M)$,
2. $\mathrm{cond}(Z)\rho < 1/2$, *and*
3. $\|\widehat{Q}(t_k) - I\| \leq \rho$.

Then we have

$$\|Q_k - Q(t_k)\| \leq \epsilon := \frac{3\mathrm{cond}(Z)\rho}{1 - 2\mathrm{cond}(Z)\rho},\ k = 0, 1, 2\ldots. \tag{3.12}$$

Proof. By the perturbation theory for the QR-factorization (e.g., see [22, Theorem 3.1]),

$$\widehat{Z} + \Delta\widehat{Z} = (I + W)(\widehat{Z} + G), \tag{3.13}$$

where $I + W$ is orthogonal, $\widehat{Z} + G$ is upper triangular with positive diagonal elements, and

$$\|W\| \leq \frac{3\|\widehat{Z}^{-1}\| \cdot \|\Delta\widehat{Z}\|}{1 - 2\|\widehat{Z}^{-1}\| \cdot \|\Delta\widehat{Z}\|}. \tag{3.14}$$

Thus, (3.10) may be written as

$$X_k = Q(t_k)(I + W)(\widehat{Z} + G)U(t_k), \tag{3.15}$$

and by the uniqueness of the QR-factorization, from (2.5), $Q_k = Q(t_k)(I + W)$ and therefore

$$\|Q_k - Q(t_k)\| = \|Q^T(t_k)Q_k - I\| = \|W\| \le \epsilon. \qquad \square \tag{3.16}$$

It is possible to improve the perturbation bounds on the QR-factors of nearby matrices; see, e.g., [5, 4] and the references therein. However, the real drawback of the global error bound in (3.12) is actually due to the fact that we have used a global transformation (via Z) to diagonal form and are thus penalized by $\mathrm{cond}(Z)$. The optimal situation of course is if $Z = I$, which occurs for instance when the upper triangular problem is in fact diagonal. In this case, we can take $\omega = \delta$ in (3.5).

However, aside from this case of $Z = I$, it is probably best to avoid altogether the diagonalizing transformation Z and tackle directly the perturbed triangular problem in (3.1), thereby attempting to bring directly $\widehat{R}$ to triangular form via an orthogonal near-the-identity transformation and obtain sharper estimates. This is what we do in the next section.

4. Handling the triangular term directly. Let us consider the perturbed triangular problem (3.1), rewritten here again as

$$\dot{\widehat{R}} = [B(t) + F(t)]\widehat{R}, \;\; t \ge 0, \;\; \widehat{R}(0) = R_0, \tag{4.1}$$

with $\sup_{t\ge 0} \|F(t)\| \le \omega$. Recall that B has upper triangular structure, and ω is small. We have $\omega = \delta$ here (see (2.10)), but we chose to use ω to unify the notation to Lemma 3.1.

Below, we show that there exists an orthogonal change of variables to the upper triangular structure, that is, a change of variables $\widehat{R} = \widehat{Q}U$ with $\widehat{Q}$ orthogonal and U upper triangular with positive diagonal, such that $\widehat{Q}$ remains, under reasonable conditions, a small perturbation of the identity given the initial condition $\widehat{Q}(0) = \widehat{Q}_0 = I$. The proof of the lemma below uses a similar technique to that used to prove Lemma 3.1 (see [11]), but much more careful estimates are now employed. In the simplest sense, Lemma 4.1 is a componentwise version of Lemma 3.1 but for a perturbed triangular system as opposed to a perturbed diagonal system. In order to obtain bounds on the entries of $\widehat{Q}$, we assume bounds on the entries of B and assume integral separation constants for both consecutive and nonconsecutive diagonal diagonal elements of B. Our bounds will be of the type $|\widehat{Q}_{ij}(t)| \le \rho_{ij}$, $i \ne j$, with $\rho_{ij} = \alpha_{ij}K_{ij}\omega$; see below. The key to obtaining this result is that the α_{ij} in this bound may be found recursively starting from $|i - j| = n - 1$ down to $|i - j| = 1$ with, for instance, $\alpha_{1,n} = \alpha_{n,1} = 2$.

LEMMA 4.1. *Consider the problem* (4.1) *and write* $B(t)+F(t) = D(t)+T(t)+F(t)$ *for all* t, *where* $D = \mathrm{diag}(B)$ *and* $T = \mathrm{upp}(B)$. *Also, let* $\sup_{t\ge 0} \|F(t)\| \le \omega$. *Then there exists an orthogonal change of variables* $\widehat{Q}$, *with* $\widehat{Q}(0) = I$, *which bring* $B + F$ *to upper triangular structure* $C := \widehat{Q}^T[B + F]\widehat{Q} - \widehat{Q}^T\dot{\widehat{Q}}$.

Moreover, let $|D_{ii}(t)| \le \kappa_{ii}$ *for* $i = 1, \ldots, n$, *let* $|T_{ij}(t)| \le \kappa_{ij}$ *for* $i < j$ *for all* $t \ge 0$, *and let* K_{ij} *be such that for all* $t \ge 0$,

$$K_{ij} \ge \int_0^t e^{-\int_\tau^t (D_{ii}(r) - D_{jj}(r))dr} d\tau, \;\; i < j, \;\; \text{and} \;\; K_{ij} = K_{ji}, \;\; i > j. \tag{4.2}$$

For $|i - j| = n - 1, |i - j| = n - 2, \ldots, |i - j| = 1$, *choose* α_{ij} *such that*

$$\alpha_{ij} > 1 + \sum_{k=j+1}^{n} \kappa_{jk}K_{ik}\alpha_{ik} + \sum_{k=1}^{i-1} K_{jk}\alpha_{jk}\kappa_{ki} \quad \text{for } i < j, \tag{4.3}$$

and let $\alpha_{ij} = \alpha_{ji}$, $i > j$.

Set

$$\omega_+^{(ij)} := \left(\sqrt{(a_1^{(ij)})^2 - 4a_0^{(ij)}a_2^{(ij)}} - a_1^{(ij)}\right)/(2a_2^{(ij)}),\ \ \omega_+ := \min_{i,j}\omega_+^{(ij)}, \tag{4.4}$$

where $a_0^{(ij)}, a_1^{(ij)}, a_2^{(ij)}$ *are defined in* (4.17).

If $\omega < \omega_+(\{\alpha_{ij}\},\{K_{ij}\},\{\kappa_{ij}\})$, *then* $|\widehat{Q}_{ij}(t)| \le \rho_{ij}$ *for* $i \ne j$ *and all* $t \ge 0$, *where* $\rho_{ij} = \alpha_{ij}K_{ij}\cdot\omega$.

Proof. Recall (see (1.4)) that $\widehat{Q}$ must satisfy $\dot{\widehat{Q}} = \widehat{Q}S(\widehat{Q}, B+F)$. So, for $i<j$ we have

$$\begin{aligned}\dot{\widehat{Q}}_{ij} &= -\widehat{Q}_{ij}[D_{ii}-D_{jj}] + \left(\widehat{Q}_{ij}[D_{ii}-D_{jj}] + e_i^T(\widehat{Q}[S(\widehat{Q},D)+S(\widehat{Q},T)+S(\widehat{Q},F)])e_j\right)\\ &=: -\widehat{Q}_{ij}[D_{ii}-D_{jj}] + q_{ij}(t,\widehat{Q},\omega)\end{aligned} \tag{4.5}$$

and a similar formula for $i>j$. We want to show that if the conditions of the theorem are satisfied and $\widehat{Q}(0)=I$, then $|\widehat{Q}_{ij}(t)| \le \rho_{ij}$ for all $i\ne j$ and $t\ge 0$. The proof involves applying [15, Theorem IV.2.1].

Using the nonlinear variation of constants formula, we have for $\widehat{Q}(0)=I$ and $i<j$

$$\widehat{Q}_{ij}(t) = \int_0^t e^{-\int_\tau^t (D_{ii}(r)-D_{jj}(r))dr} q_{ij}(\tau,\widehat{Q}(\tau),\omega)d\tau. \tag{4.6}$$

Thus, $\sup_t|\widehat{Q}_{ij}(t)| \le K_{ij}\sup_t|q_{ij}(t,\widehat{Q}(t),\omega)|$. We have

$$\begin{aligned}|q_{ij}(t,\widehat{Q},\omega)| &\le |q_{ij}(t,\widehat{Q},\omega) - q_{ij}(t,I,\omega)| + |q_{ij}(t,I,\omega)|\\ &\le \eta(\{\rho_{kl}\},\omega)\rho_{ij} + N(\omega),\end{aligned} \tag{4.7}$$

where since $S(I,D)=S(I,T)=0$ and $S(I,F)=F_L-F_L^T$, where $F_L=\mathrm{low}(F)$, $N(\omega)\le\omega$. To bound $\eta(\{\rho_{kl}\},\omega)$ write

$$\begin{aligned}q_{ij}(t,\widehat{Q},\omega) &= q_{ij}^D(t,\widehat{Q},\omega) + q_{ij}^T(t,\widehat{Q},\omega) + q_{ij}^F(t,\widehat{Q},\omega)\\ &:= \left(\widehat{Q}_{ij}[D_{ii}-D_{jj}] + e_i^T\widehat{Q}S(\widehat{Q},D)e_j\right) + e_i^T\widehat{Q}S(\widehat{Q},T)e_j + e_i^T\widehat{Q}S(\widehat{Q},F)e_j\end{aligned} \tag{4.8}$$

and consider the case in which $i<j$ (the case $i>j$ is similar).

For $q_{ij}^D(t,\widehat{Q},\omega)$ we have, from (A.3) using the notation $\beta_{ij}=\alpha_{ij}K_{ij}$,

$$\begin{aligned}&|q_{ij}^D(t,\widehat{Q},\omega) - q_{ij}^D(t,I,\omega)|\\ &\quad\le \kappa_{ii}\left[\rho_{ij}\left(\rho_{ij}^2 + 2\sum_{k=j+1}^n \rho_{ik}^2\right)\right] + \kappa_{jj}\left[\rho_{ij}\sum_{k=1,k\ne j}^n \rho_{jk}^2 + 2\sum_{k=j+1}^n \rho_{ik}\rho_{jk}\right]\\ &\qquad + \sum_{l\ne i,j}\kappa_{ll}\left[\rho_{lj}\left(\sum_{k=1}^{j-1}\rho_{ik}\rho_{lk} + \sum_{k=j+1}^n \rho_{ik}\rho_{lk}\right)\right]\end{aligned}$$

$$
\begin{aligned}
&\le \kappa_{ii}\left[\rho_{ij}\left(\rho_{ij}^2+2\sum_{k=j+1}^{n}\rho_{ik}^2\right)\right]+\kappa_{jj}\left[\rho_{ij}\sum_{k=1,k\neq j}^{n}\rho_{jk}^2+2\sum_{k=j+1}^{n}\rho_{ik}\rho_{jk}\right]\\
&\quad+\sum_{l\neq i,j}\kappa_{ll}\left[\rho_{lj}\left(\rho_{li}+\rho_{il}+\sum_{k=1,k\neq i,j,l}^{n}\rho_{ik}\rho_{lk}\right)\right]\\
&=\rho_{ij}\left\{\omega^2\left[\kappa_{ii}\left(\beta_{ij}^2+2\sum_{k=j+1}^{n}\beta_{ik}^2\right)+\kappa_{jj}\sum_{k=1,k\neq j}^{n}\beta_{jk}^2+\sum_{l\neq i,j}\kappa_{ll}\frac{\beta_{lj}}{\beta_{ij}}\sum_{k=1,k\neq i,j,l}^{n}\beta_{ik}\beta_{lk}\right]\right.\\
&\quad\left.+\omega\left[\frac{2\kappa_{jj}}{\beta_{ij}}\sum_{k=j+1}^{n}\beta_{ik}\beta_{jk}+\sum_{l\neq i,j}\kappa_{ll}\frac{\beta_{lj}}{\beta_{ij}}(\beta_{li}+\beta_{il})\right]\right\}\\
&=:\rho_{ij}\eta_{ij}^{D}=:\rho_{ij}\big(\omega^2\eta_{ij}^{D,2}+\omega\eta_{ij}^{D,1}\big).
\end{aligned}
\tag{4.9}
$$

Next, we obtain, using (A.4) and again $\beta_{ij}=\alpha_{ij}K_{ij}$,

$$
\begin{aligned}
|q_{ij}^T(t,\widehat{Q},\omega)-q_{ij}^T(t,I,\omega)|&\le\sum_{m=j+1}^{n}\kappa_{jm}\rho_{im}+\sum_{l=1}^{i-1}\rho_{jl}\kappa_{li}+\sum_{l=1,l\neq j}^{n}\sum_{m=l+1,m\neq i}^{n}\rho_{jl}\kappa_{lm}\rho_{im}\\
&\quad+\sum_{k=1,k\neq i}^{j-1}\rho_{ik}\sum_{l=1}^{n}\sum_{m=l+1}^{n}\rho_{jl}\kappa_{lm}\rho_{km}+\sum_{k=j+1}^{n}\rho_{ik}\sum_{l=1}^{n}\sum_{m=l+1}^{n}\rho_{kl}\kappa_{lm}\rho_{jm}\\
&\le\sum_{m=j+1}^{n}\kappa_{jm}\rho_{im}+\sum_{l=1}^{i-1}\rho_{jl}\kappa_{li}+\sum_{l=1,l\neq j}^{n}\sum_{m=l+1,m\neq i}^{n}\rho_{jl}\kappa_{lm}\rho_{im}\\
&\quad+\sum_{k=1,k\neq i}^{j-1}\rho_{ik}\left[\sum_{m=j+1}^{n}\kappa_{jm}\rho_{km}+\sum_{l=1}^{k-1}\rho_{jl}\kappa_{lk}+\sum_{l=1,l\neq j}^{n}\sum_{m=l+1,m\neq k}^{n}\rho_{jl}\kappa_{lm}\rho_{km}\right]\\
&\quad+\sum_{k=j+1}^{n}\rho_{ik}\left[\sum_{m=k+1}^{n}\kappa_{km}\rho_{jm}+\sum_{l=1}^{j-1}\rho_{kl}\kappa_{lj}+\sum_{l=1,l\neq k}^{n}\sum_{m=l+1,m\neq j}^{n}\rho_{kl}\kappa_{lm}\rho_{jm}\right]\\
&=\rho_{ij}\left\{\omega^2\left[\sum_{k=1,k\neq i}^{j-1}\frac{\beta_{ik}}{\beta_{ij}}\sum_{l=1,l\neq j}^{n}\sum_{m=l+1,m\neq k}^{n}\beta_{jl}\beta_{km}\kappa_{lm}\right.\right.\\
&\quad\left.+\sum_{k=j+1}^{n}\frac{\beta_{ik}}{\beta_{ij}}\sum_{l=1,l\neq k}^{n}\sum_{m=l+1,m\neq j}^{n}\beta_{kl}\beta_{jm}\kappa_{lm}\right]\\
&\quad+\omega\left[\sum_{l=1,l\neq j}^{n}\sum_{m=l+1,m\neq i}^{n}\frac{\beta_{jl}\beta_{im}\kappa_{lm}}{\beta_{ij}}+\sum_{k=1,k\neq i}^{j-1}\frac{\beta_{ik}}{\beta_{ij}}\left(\sum_{m=j+1}^{n}\kappa_{jm}\beta_{km}+\sum_{l=1}^{k-1}\beta_{jl}\kappa_{lk}\right)\right.\\
&\quad\left.\left.+\sum_{k=j+1}^{n}\frac{\beta_{ik}}{\beta_{ij}}\left(\sum_{m=k+1}^{n}\kappa_{km}\beta_{jm}+\sum_{l=1}^{j-1}\beta_{kl}\kappa_{lj}\right)\right]+1\left[\sum_{m=j+1}^{n}\kappa_{jm}\frac{\beta_{im}}{\beta_{ij}}+\sum_{l=1}^{i-1}\kappa_{li}\frac{\beta_{jl}}{\beta_{ij}}\right]\right\}\\
&=:\rho_{ij}\eta_{ij}^{T}=:\rho_{ij}\eta_{ij}^{T,2}\omega^2+\eta_{ij}^{T,1}\omega+\eta_{ij}^{T,0}.
\end{aligned}
\tag{4.10}
$$

Then, using the fact that $0<\widehat{Q}_{jj}\le 1$, and so $1-\widehat{Q}_{jj}\le 1-\widehat{Q}_{jj}^2=\sum_{k=1,k\neq j}^{n}\widehat{Q}_{jk}^2$,

we obtain from (A.5)

$$
\begin{aligned}
&|q_{ij}^F(t,\widehat{Q},\omega) - q_{ij}^F(t,I,\omega)| \\
&\le \omega\left[\sum_{k\neq j,k=1}^{n}\rho_{jk}^2 + \sum_{k\neq i,k=1}^{n}\rho_{ik}^2 + \sum_{(l,m)\neq(j,i),l,m=1}^{n}\rho_{lj}\rho_{mi} + \sum_{k=1,k\neq i,j}^{n}\rho_{ik}\right] \\
&= \rho_{ij}\left\{\omega^2\left[\sum_{k\neq j,k=1}^{n}\frac{\beta_{jk}^2}{\beta_{ij}} + \sum_{k\neq i,k=1}^{n}\frac{\beta_{ik}^2}{\beta_{ij}} + \sum_{(l,m)\neq(j,i),l,m=1}^{n}\frac{\beta_{lj}\beta_{mi}}{\beta_{ij}}\right] + \omega\sum_{k=1,k\neq i,j}^{n}\frac{\beta_{ik}}{\beta_{ij}}\right\} \\
&=: \rho_{ij}\eta_{ij}^F =: \rho_{ij}\big(\omega^2\eta_{ij}^{F,2} + \omega\eta_{ij}^{F,1}\big),
\end{aligned}
\tag{4.11}
$$

where $\beta_{ij} = \alpha_{ij}K_{ij}$.

So, we have, using (4.7), (4.8), (4.9), (4.10), and (4.11),

$$\eta_{ij}(\{\rho_{kl}\},\omega) \le \eta_{ij}^D + \eta_{ij}^T + \eta_{ij}^F, \tag{4.12}$$

and finally from (4.7) we obtain

$$\sup_t |\widehat{Q}_{ij}(t)| \le K_{ij}\big(N(\omega) + \eta_{ij}(\{\rho_{kl}\},\omega)\rho_{ij}\big).$$

Since $N(\omega) \le \omega$, Theorem IV.2.1 of [15] may be applied if

$$K_{ij}[(\eta_{ij}^D + \eta_{ij}^T + \eta_{ij}^F)\rho_{ij} + \omega] \ < \ \rho_{ij}, \tag{4.13}$$

or

$$1 > K_{ij}(\eta_{ij}^D + \eta_{ij}^T + \eta_{ij}^F) + 1/\alpha_{ij}, \tag{4.14}$$

or equivalently

$$0 > \alpha_{ij}K_{ij}(\eta_{ij}^D + \eta_{ij}^T + \eta_{ij}^F) + (1 - \alpha_{ij}). \tag{4.15}$$

Then we need to have

$$
\begin{aligned}
0 > {}& \alpha_{ij}K_{ij}(\eta_{ij}^{D,2} + \eta_{ij}^{T,2} + \eta_{ij}^{F,2})\omega^2 + \alpha_{ij}K_{ij}(\eta_{ij}^{D,1} + \eta_{ij}^{T,1} + \eta_{ij}^{F,1})\omega \\
&+ [\alpha_{ij}K_{ij}\eta_{ij}^{T,0} + 1 - \alpha_{ij}],
\end{aligned}
\tag{4.16}
$$

which we rewrite as

$$f(\omega) := a_2^{(ij)}\omega^2 + a_1^{(ij)}\omega + a_0^{(ij)} < 0, \tag{4.17}$$

where in particular

$$a_0^{(ij)} = 1 - \alpha_{ij} + \sum_{l=1}^{i-1}\kappa_{li}\alpha_{jl}K_{jl} + \sum_{m=j+1}^{n}\kappa_{jm}\alpha_{im}K_{im}. \tag{4.18}$$

We notice that $a_1^{(ij)} > 0$, $a_2^{(ij)} > 0$. Since $f'(\omega) > 0$ for $\omega > 0$, we need to have $a_0^{(ij)} < 0$ in order to be sure that there are values of ω satisfying $f(\omega) < 0$. This is guaranteed by (4.3).

Thus, if $\omega < \omega_+$ with ω_+ given in (3.9), then $|\widehat{Q}_{ij}(t)| \le \rho_{ij} \equiv \alpha_{ij}K_{ij}\omega$ for $i \neq j$ and $t \ge 0$. ∎

What one expects from Lemma 4.1 are $\rho_{ij} \equiv \alpha_{ij} K_{ij} \omega$, where ρ_{ij} are smaller for $|i-j|$ large than for $|i-j|$ small, e.g., $|i-j| = 1$. This is due in part to the sharper bounds obtained by employing $K_{ji} \equiv K_{ij} = e^{d_{ij}}/a_{ij}$ for $i < j$, where for $t \geq s$

$$\int_s^t \big(B_{ii}(\tau) - B_{jj}(\tau)\big) d\tau \geq a_{ij}(t-s) - d_{ij},$$

as opposed to

$$\int_s^t \big(B_{ii}(\tau) - B_{jj}(\tau)\big) d\tau \geq \left[\sum_{k=i}^{j-1} a_{k,k+1}\right](t-s) - \sum_{k=i}^{j-1} d_{k,k+1},$$

essentially avoiding the use of a triangular inequality. It is also, due to the form of the recursion, possible to determine the α_{ij} in (4.3) in which we choose $\alpha_{1,n} = \alpha_{n,1} > 1$, then determine α_{ij} for $|i-j| = n-2$, etc. There is the potential for the α_{ij} to become large as $|i-j| \downarrow 1$, depending on the size of the off-diagonal elements of B characterized by κ_{ij} and the strength of the integral separation between diagonal elements as characterized by K_{ij}.

The bound on the perturbation F that allows for application of Lemma 4.1 is given in (4.4) using (4.17) with $a_0^{(ij)}$ given in (4.18). The coefficients $a_1^{(ij)}, a_2^{(ij)}$ may be obtained from (4.9), (4.10), and (4.11), which give for $\beta_{ij} := \alpha_{ij} K_{ij}$

$$\begin{aligned}
a_1^{(ij)} &:= \beta_{ij}(\eta_{ij}^{D,1} + \eta_{ij}^{T,1} + \eta_{ij}^{F,1}) \\
&= \left[2\kappa_{jj} \sum_{k=j+1}^{n} \beta_{ik}\beta_{jk} + \sum_{l\neq i,j} \kappa_{ll}\beta_{lj}(\beta_{li} + \beta_{il})\right] \\
&\quad + \left[\sum_{l=1,l\neq j}^{n} \sum_{m=l+1,m\neq i}^{n} \beta_{jl}\beta_{im}\kappa_{lm} + \sum_{k=1,k\neq i}^{j-1} \beta_{ik}\left(\sum_{m=j+1}^{n} \kappa_{jm}\beta_{km} + \sum_{l=1}^{k-1} \beta_{jl}\kappa_{lk}\right)\right. \\
&\quad \left. + \sum_{k=j+1}^{n} \beta_{ik}\left(\sum_{m=k+1}^{n} \kappa_{km}\beta_{jm} + \sum_{l=1}^{j-1} \beta_{kl}\kappa_{lj}\right)\right] + \sum_{k=1,k\neq i,j}^{n} \beta_{ik}
\end{aligned} \tag{4.19}$$

and

$$\begin{aligned}
a_2^{(ij)} &:= \beta_{ij}(\eta_{ij}^{D,2} + \eta_{ij}^{T,2} + \eta_{ij}^{F,2}) \\
&= \left[\beta_{ij}\left\{\kappa_{ii}\left(\beta_{ij}^2 + 2\sum_{k=j+1}^{n} \beta_{ik}^2\right) + \kappa_{jj} \sum_{k=1,k\neq j}^{n} \beta_{jk}^2\right\} + \sum_{l\neq i,j} \kappa_{ll}\beta_{lj} \sum_{k=1,k\neq i,j,l}^{n} \beta_{ik}\beta_{lk}\right] \\
&\quad + \left[\sum_{k=1,k\neq i}^{j-1} \beta_{ik} \sum_{l=1,l\neq j}^{n} \sum_{m=l+1,m\neq k}^{n} \beta_{jl}\beta_{km}\kappa_{lm}\right. \\
&\quad \left. + \sum_{k=j+1}^{n} \beta_{ik} \sum_{l=1,l\neq k}^{n} \sum_{m=l+1,m\neq j}^{n} \beta_{kl}\beta_{jm}\kappa_{lm}\right] \\
&\quad + \left[\sum_{k\neq j,k=1}^{n} \beta_{jk}^2 + \sum_{k\neq i,k=1}^{n} \beta_{ik}^2 + \sum_{(l,m)\neq(j,i),l,m=1}^{n} \beta_{lj}\beta_{mi}\right].
\end{aligned} \tag{4.20}$$

The following theorem shows that C obtained from Lemma 4.1 is a small perturbation of the piecewise constant upper triangular B and that C may be interpreted as upper triangularizing a perturbation of A in which the perturbation is not in general small.

THEOREM 4.2. *Let $\widetilde{B}$ be the upper triangular matrix function obtained for the exact Q: $\widetilde{B} = Q^T AQ - S(Q,A)$. If we write the piecewise constant upper triangular B as $B = \widetilde{B} + \widetilde{F}$, then the upper triangular C that results from having only approximated Q satisfies for $\overline{Q} = Q\widehat{Q}$*

$$\begin{aligned} C &= \overline{Q}^T[A+G]\overline{Q} - S(\overline{Q}, A+G) \\ &= \widetilde{B} + \mathrm{upp}[\overline{Q}^T(A+G)\overline{Q} - Q^TAQ] + (\mathrm{low}[\overline{Q}^T(A+G)\overline{Q} - Q^TAQ])^T \\ &= B + \mathrm{upp}[-\widetilde{F} + \overline{Q}^T(A+G)\overline{Q} - Q^TAQ] + (\mathrm{low}[-\widetilde{F} + \overline{Q}^T(A+G)\overline{Q} - Q^TAQ])^T, \end{aligned} \tag{4.21}$$

where $G = Q[\widetilde{F} + F - S(Q,A)]Q^T$.

Moreover, if Lemma 4.1 holds, then C is an $O(\widetilde{\rho})$ perturbation of B and C is an $O(\widetilde{\rho}) + O(\|\widetilde{F}\|)$ perturbation of $\widetilde{B}$ for $\widetilde{\rho} = \max_{i\neq j}\rho_{ij}$.

Proof. We have

$$\begin{aligned} C &= \widehat{Q}^T[B+F]\widehat{Q} - S(\widehat{Q}, B+F) = \widehat{Q}^T[\widetilde{B}+\widetilde{F}+F]\widehat{Q} - S(\widehat{Q}, \widetilde{B}+\widetilde{F}+F) \\ &= \overline{Q}^T[A+G]\overline{Q} - S(\overline{Q}, A+G) = \mathrm{upp}[\overline{Q}^T(A+G)\overline{Q}] + (\mathrm{low}[\overline{Q}^T(A+G)\overline{Q}])^T \\ &= \widetilde{B} + \mathrm{upp}[\overline{Q}^T(A+G)\overline{Q} - Q^TAQ] + (\mathrm{low}[\overline{Q}^T(A+G)\overline{Q} - Q^TAQ])^T \\ &= B - \widetilde{F} + \mathrm{upp}[\overline{Q}^T(A+G)\overline{Q} - Q^TAQ] + (\mathrm{low}[\overline{Q}^T(A+G)\overline{Q} - Q^TAQ])^T \\ &= B + \mathrm{upp}[-\widetilde{F} + \overline{Q}^T(A+G)\overline{Q} - Q^TAQ] + (\mathrm{low}[\overline{Q}^T(A+G)\overline{Q} - Q^TAQ])^T \\ &= B + \mathrm{upp}[-\widetilde{F} + \overline{Q}^T(A+G)\overline{Q} - Q^TAQ] + (\mathrm{low}[-\widetilde{F} + \overline{Q}^T(A+G)\overline{Q} - Q^TAQ])^T, \end{aligned} \tag{4.22}$$

where we have used that $\mathrm{upp}[\widetilde{F}] = \widetilde{F}$ and $\mathrm{low}[\widetilde{F}] = 0$. We now show that C is a small perturbation of B.

Since $\overline{Q}^T G\overline{Q} = \widehat{Q}^T[\widetilde{F}+F]\widehat{Q} - \widehat{Q}^T S(Q,A)\widehat{Q}$, we have

$$\widehat{Q}^T\widetilde{F}\widehat{Q} = \widetilde{F} + (\widehat{Q}^T - I)\widetilde{F} + \widetilde{F}(\widehat{Q} - I) + (\widehat{Q}^T - I)\widetilde{F}(\widehat{Q} - I)$$

and

$$\widehat{Q}^T S(Q,A)\widehat{Q} = S(Q,A) + (\widehat{Q}^T - I)S(Q,A) + S(Q,A)(\widehat{Q} - I) + (\widehat{Q}^T - I)S(Q,A)(\widehat{Q} - I).$$

Since $\mathrm{upp}[S(Q,A)] + (\mathrm{low}[S(Q,A)])^T = 0$, we then obtain (i), and (ii) follows from (4.22) and the definition of G. ∎

Notice that although C results from having upper triangularized $A+G$, in general G is not small. We conclude this section with a few important remarks.

Remarks 4.1.

(a) While Lemma 3.1 (see Lemma 3.1 of [11]) together with Theorem 3.2 of [11] are in a sense analogous to a classical Bauer–Fike theorem by employing a diagonalizing transformation, Lemma 4.1 together with (4.21) may obtain sharper bounds by avoiding the use of a diagonalizing transformation.

(b) We note here that if the original problem with coefficient matrix function A is integrally separated, then (see, e.g., [1, 20, 21, 8, 9]) the $\widetilde{B}$ problem is integrally separated, and hence so is the B problem. Besides the bound on F, δ, and the measure of integral separation, the K_{ij}, the bounds obtained depend on the $\kappa_{ij} = \sup_t |B_{ij}(t)|$ for $i \le j$.

(c) An important point to make here is that we can view the exact solution as a perturbation of the computed solution as opposed to the computed solution being a perturbation of the exact solution. The bound on the norm of the perturbation, δ, is the same in either case, but by considering the exact solution as a perturbation of the computed solution, the quantities employed to bound the error, e.g., K_{ij} and κ_{ij}, may be obtained from the computed solution.

4.1. Simplified bounds and approximations. Next, we derive somewhat simplified bounds on $\|\widehat{Q}(t) - I\|$ by first taking the largest of the ρ_{ij}, then using $\rho_k = \sup_{k=|i-j|} \rho_{ij}$ and $\kappa = \sup_{i,j} \kappa_{ij} = \sup_{i,j} |B_{ij}(t)|$. In addition, we determine an asymptotic approximation for ω_+. Note that we have $\rho_{ij} = \rho_{ji}$ for $i \neq j$, so the bounds we obtain on $\|\widehat{Q}(t) - I\|$ are identical in the 1-, 2-, and ∞-norms.

COROLLARY 4.1. *In the notation of Lemma* 4.1, *let* $\delta \equiv \omega < \omega_+(\{\alpha_{ij}\}, \{K_{ij}\}, \{\kappa_{ij}\})$. *Let* $\widetilde{\rho} = \max_{i \neq j} \rho_{ij}$, *and assume that* $(n-1)(\widetilde{\rho} + \widetilde{\rho}^2) \le 1$. *Then,* $\|\widehat{Q}(t) - I\| \le \rho \equiv (n-1)(\widetilde{\rho} + \widetilde{\rho}^2)$ *and* $\|\widehat{Q}(t) - I\|_F \le \rho_F \equiv \sqrt{2(n^2 - n)}\widetilde{\rho}$ *for all* $t \ge 0$. *Moreover, for* $k = 0, 1, 2, \ldots$, $\|Q_k - Q(t_k)\| \le \rho$.

We next prove a corollary that gives a more computable bound on the error in the approximate Q while taking into account the variation in ρ_{ij} as a function of i and j. Let $\rho_k = \sup_{k=|i-j|} \rho_{ij}$, $K_k = \sup_{k=|i-j|} K_{ij}$, and $\alpha_k = \sup_{k=|i-j|} \alpha_{ij}$, and assume that $\kappa = \sup_{i,j} \kappa_{ij}$.

COROLLARY 4.2. *If the assumptions of Lemma* 4.1 *are satisfied,* $K_{n-1} \le K_{n-2} \le \cdots \le K_1$, *and* $\sum_{k=1}^{n-1} \rho_k + \rho_k^2 \le 1$, *then* $\rho_j \le \alpha_j K_j \omega$, $\|\widehat{Q}(t) - I\|_F \le (2\sum_{k=1}^{n-1}(n-k)\rho_k^2 + \sum_{i=1}^{n}(\sum_{k=1}^{i-1}\rho_k^2 + \sum_{i=1}^{n-i}\rho_k^2)^2)^{1/2}$, *and*

$$\|\widehat{Q}(t) - I\| \le \begin{cases} 2\displaystyle\sum_{k=1}^{(n-1)/2} (\rho_k + \rho_k^2), & n \text{ odd}, \\ 2\displaystyle\sum_{k=1}^{(n-2)/2} (\rho_k + \rho_k^2) + (\rho_{n/2} + \rho_{n/2}^2), & n \text{ even}, \end{cases} \tag{4.23}$$

where $\alpha_{n-1} > 1$ *and*

$$\alpha_j > 1 + (n-j-1)\kappa K_{j+1}\big(1 + (n-j-2)\kappa K_{j+2}(1 + \cdots (1 + \kappa K_{n-1}\alpha_{n-1}))\cdots\big) \tag{4.24}$$

for $j = n-2, \ldots, 1$.

Proof. The proof involves recursively applying the condition (4.3) for $i < j$ and $k = |i-j| = n-1, \ldots, 1$. This means we can choose α_k so that

$$\begin{aligned} &\alpha_{n-1} > 1, \ \ \alpha_{n-2} > 1 + \kappa K_{n-1}\alpha_{n-1} > \alpha_{n-1}, \\ &\alpha_{n-3} > 1 + 2\kappa K_{n-2}\alpha_{n-2} > \alpha_{n-2}, \ldots \end{aligned} \tag{4.25}$$

or in general

$$\alpha_{j-1} > 1 + (n-j)\kappa K_j \alpha_j > \alpha_j, \ \ j = n-1, \ldots, 1. \tag{4.26}$$

The result then follows by recalling that $\rho_j \leq \alpha_j K_j \omega$ and obtaining the bounds on the matrix norms in a straightforward fashion using

$$\|\widehat{Q}(t) - I\| \leq \sqrt{\|\widehat{Q}(t) - I\|_1 \|\widehat{Q}(t) - I\|_\infty}. \qquad \square$$

In spite of their appearances, Corollaries 4.1 and 3.1 are very different, even if in Corollary 3.1 we happen to have $\omega = \delta$ (as when $Z = I$). Moreover, the factors ω_+, as well as ρ, are different in these two contexts; notice the use of $\bar{\rho}$ in Corollary 3.1 versus the use of $\widetilde{\rho}$ in Corollary 4.1.

To estimate ω_+, we reason as follows. An asymptotic analysis of the terms in (4.20), (4.19), and (4.18) that contribute to a_2, a_1, and a_0 in (4.16) and (4.17) which determine ω_+ in (4.4) suggest that

$$a_2 \approx (3\kappa_D + \kappa)\alpha_1^3 K_1^3, \;\; a_1 \approx (2\kappa_D + \kappa)\alpha_1^2 K_1^2, \;\; a_0 \approx 1 - \alpha_1 + 2\kappa\alpha_2 K_2 < 0, \tag{4.27}$$

where $\kappa_D = \sup_{i,t} |B_{ii}(t)|$.

These coefficients were determined by first observing that the dominant term for $a_2 \equiv \beta_{ij}(\eta_{ij}^{D,2} + \eta_{ij}^{T,2} + \eta_{ij}^{F,2})$ in (4.20), where $\beta_{ij} = \alpha_{ij} K_{ij}$, is proportional to $\alpha_1^3 K_1^3$. Then in (4.20) we obtain the term $3\kappa_D$ from $\kappa_{ii}\beta_{ij}^3 + \kappa_{jj}\beta_{ij}(\beta_{j,j-1} + \beta_{j,j+1})$ when $j = i+1$ and the term κ is obtained from $\beta_{ik}\beta_{jl}\beta_{km}\kappa_{lm}$ when $k = i+1, l = j-1, m = i+2$, and $j = i+2$. There are no terms in $\eta_{ij}^{F,2}$ proportional to $\alpha_1^3 K_1^3$. To determine the dominant terms in a_1 observe that the term $2\kappa_D$ is obtained from $\kappa_{ll}\beta_{lj}(\beta_{li} + \beta_{il})$ in (4.19) when $l = j-1 = i+1$ and the term κ is obtained from $\beta_{jl}\beta_{im}\kappa_{lm}$ in (4.19) when $l = j-1$, $m = i+1$, and $j = i+1$. The dominant terms in $\eta_{ij}^{F,1}$ are not proportional to $\alpha_1^2 K_1^2$. The approximation of a_0 is found by considering (4.18) when $j = i+1$.

Using the form for ω_+ in (4.4) and the approximation $\sqrt{1+x} \approx 1 + \frac{x}{2}$, we have $\omega_+ \approx -\frac{a_0}{a_1} \approx C[(2\kappa_D + \kappa)\alpha_1^2 K_1^2]^{-1}$, where $C \approx -a_0$.

Notice that the ρ_{ij} we have when treating the triangular term directly appears to decrease as $|i-j|$ grows. There is an accumulation for $|i-j|$ small, but it looks friendlier than the accumulation to find $\mathrm{cond}(Z)$ when using the diagonalizing transformation. Indeed, it is interesting to compare the bounds one obtains with the two different approaches: (i) using the diagonalizing transformation Z, and (ii) working directly with the triangular system. We do this below on a two-dimensional system.

4.2. Comparison for two-dimensional systems. Here we compare the two global error bounds obtained by the two different approaches we examined: (i) using the diagonalizing transformation Z (see section 3), and (ii) dealing directly with the triangular coefficient matrix function (call this the *triangular approach*) for a two-dimensional system. That is, we have $B = \left(\begin{smallmatrix} D_{11} & T_{12} \\ 0 & D_{22} \end{smallmatrix}\right)$.

Of course, a bound on the error in Q using the diagonalizing transformation approach is given by (3.12), while with the triangular approach it is given in Corollary 4.1. The interesting thing is to see what bounds we need for ω in the two cases.

We assume $|D_{ii}(t)| \leq M$ for $i = 1, 2$ and $|T_{12}(t)| \leq \kappa_{12}$ for all t and use the bound $||Z(t)||_F, ||Z^{-1}(t)||_F \leq \sqrt{2 + \kappa_{12}^2 K^2}$, where $K = e^d/a$ (see Lemma 3.1).

Then we have a bound $|\sin(\theta(t))| \leq \rho := 2K\omega$, where (i) $|\sin(\theta(t))| = |\widehat{Q}_{12}(t)|$ and $\omega = \delta \mathrm{cond}(Z)$ with the diagonalizing transformation approach, and (ii) $|\sin(\theta(t))| = |\widehat{Q}_{12}(t)|$ and $\omega = \delta$ with the triangular approach, provided that in these two cases we have

$$\text{(i)} \quad \omega < \omega_+^D := \frac{\sqrt{1 + 4MK} - 1}{2K(2MK + 1)} \cdot \frac{1}{\mathrm{cond}(Z)} \tag{4.28}$$

and

$$\text{(ii)} \quad \omega < \omega_+^T \equiv \frac{\sqrt{1+4M/(K\kappa_{12}^2)}-1}{8MK/\kappa_{12}}, \tag{4.29}$$

respectively.

Since for $x > 0$, $1 + x/2 - x^2/8 \le \sqrt{1+x} \le 1 + x/2$, using $\mathrm{cond}(Z) \le 2 + K^2\kappa_{12}^2$, we have

$$\frac{M(1-MK)}{(2MK+1)\mathrm{cond}(Z)} < \omega_+^D < \frac{M}{(2MK+1)\mathrm{cond}(Z)} < \frac{1}{2K\mathrm{cond}(Z)} \tag{4.30}$$

and

$$\begin{aligned} \frac{1}{4K^2\kappa_{12}}\left[1-\frac{M}{K\kappa_{12}^2}\right] &= \frac{1-M/(K\kappa_{12}^2)}{4K^2\kappa_{12}} < \omega_+^T < \frac{M/(K\kappa_{12}^2)}{4MK/\kappa_{12}} \\ &= \frac{1}{4K^2\kappa_{12}} \le \frac{1}{4K\sqrt{\mathrm{cond}(Z)-2}}. \end{aligned} \tag{4.31}$$

Quite clearly, the triangular approach gives much improved bounds.

4.3. Bounding the K_{ij}'s. In light of Remark 4.1(c), besides the size of the perturbation of B, the quantities needed to apply Lemma 4.1, the κ_{ij}'s that measure the nonnormality and the K_{ij}'s that measure the integral separation, can be obtained from the computed solution. To this end we consider now how to obtain bounds for the K_{ij}'s. We consider two approaches.

The first approach follows ideas developed in [8] using Steklov averages; see also Adrianova [1, Lemma 5.4.1]. In particular, for $i < j$ set

$$p(t) := B_{ii}(t) - B_{jj}(t)$$

and for some $H > 0$ consider finding the quantities $c(H)$ (positive) and M:

$$c(H) = \inf_t \frac{1}{H}\int_t^{t+H} p(r)dr > 0, \quad M = \inf_t p(t). \tag{4.32}$$

We have the following result.

LEMMA 4.3. *For $a := c(H) > 0$, and a positive integer N, let*

$$d := \left\{\sum_{k=1}^{N}(c(H) - c(H/2^k))\cdot(H/2^k)\right\} + (c(H) - M)\cdot(H/2^N) \ge 0.$$

Then, for $t \ge s$, we have

$$\int_s^t p(r)dr \ge a(t-s) - d. \tag{4.33}$$

Proof. That $d \ge 0$ follows from

$$c(H) \ge c(H/2) \ge c(H/4) \ge \cdots \ge c(H/2^N) \ge M.$$

If $t - s = jH$ for some positive integer j, then

$$\int_s^t p(r)dr \ge c(H)\cdot(t-s) \ge a(t-s) - d$$

since $d \geq 0$. Otherwise, $t-s = jH + (t-s-jH)$ with $0 < (t-s-jH) < H$, and for $\gamma_k \in \{0,1\}$ we can write

$$t-s-jH = \left\{ H \sum_{k=1}^{N} \gamma_k / 2^k \right\} + x,$$

where $0 \leq x < H/2^N$.

$$\begin{aligned}\int_s^t p(r)dr &\geq jH \cdot c(H) + \left\{ H \sum_{k=1}^{N} \gamma_k 2^k \cdot c(H/2^k) \right\} + x \cdot M \\ &= c(H) \cdot (t-s) + (jH - (t-s))c(H) + \left\{ H \sum_{k=1}^{N} \gamma_k / 2^k \cdot c(H/2^k) \right\} + x \cdot M \\ &\geq a(t-s) - d. \qquad \square\end{aligned}$$

(4.34)

Recalling (4.2), based on the above lemma, we may use

$$K_{ij} = e^d / a.$$

Of course, the K_{ij}'s are still functions of H: $K_{ij}(H)$. The idea now is to use for K_{ij} the minimum value of $K_{ij}(H)$ subject to maintaining $c(H) > 0$.

We also develop an alternative approach that is a simplification of Lemmas 4.1 and 4.2 of [17]. This alternative approach may yield better bounds on the K_{ij}'s.

As before, for all t, let $p(t) = B_{ii}(t) - B_{jj}(t)$, $i < j$. Consider a discretization of the interval $[0,T]$:

$$0 = t_0 < t_1 < \cdots < t_N = T.$$

LEMMA 4.4. *Let $\epsilon > 0$ be given. There exists $a_k > 0$ and $d_k \geq 0$ such that for $t_k \leq s \leq t_{k+1}$,*

$$\int_s^{t_{k+1}} p(r)dr \geq a_k(t_{k+1} - s) - d_k, \tag{4.35}$$

where for $h_k = t_{k+1} - t_k$ and for

$$Y_k = \min_{t_k \leq s \leq t_{k+1}} \frac{1}{t_{k+1} - s} \int_s^{t_{k+1}} p(r)dr, \tag{4.36}$$

$$a_k = \begin{cases} \epsilon h_k^{-1}, & h_k Y_k < \epsilon, \\ Y_k, & h_k Y_k \geq \epsilon, \end{cases} \qquad d_k = \begin{cases} \epsilon - h_k Y_k, & h_k Y_k < \epsilon, \\ 0, & h_k Y_k \geq \epsilon, \end{cases} \tag{4.37}$$

and

$$\int_0^T e^{-\int_s^T p(r)dr} ds \leq \sum_{k=0, d_k=0}^{N-1} e^{-\left[\sum_{l=k+1}^{N-1} X_l\right]} \frac{(1 - e^{-Y_k h_k})}{Y_k} + \frac{(e^\epsilon - 1)}{\epsilon} \tag{4.38}$$

$$\times \sum_{k=0, a_k = \epsilon h_k^{-1}}^{N-1} e^{-\left[\sum_{l=k+1}^{N-1} X_l\right]} h_k e^{-h_k Y_k} =: K(T), \tag{4.39}$$

where

$$X_k = \int_{t_k}^{t_{k+1}} p(r)dr.$$

Proof. If $h_k Y_k < \epsilon$, then for $a_k = \epsilon/h_k$, $d_k = \epsilon - h_k Y_k \geq 0$, and $s \in [t_k, t_{k+1}]$,

$$\int_s^{t_{k+1}} p(r)dr \geq (t_{k+1}-s)Y_k = (t_{k+1}-s)\left[\frac{\epsilon}{h_k} - \frac{(\epsilon - h_k Y_k)}{h_k}\right] \geq \frac{\epsilon}{h_k}(t_{k+1}-s) - (\epsilon - h_k Y_k). \tag{4.40}$$

If $h_k Y_k \geq \epsilon$, then for $a_k = Y_k$, $d_k = 0$, and $s \in [t_k, t_{k+1}]$,

$$\int_s^{t_{k+1}} p(r)dr \geq (t_{k+1} - s)Y_k = a_k(t_{k+1} - s). \tag{4.41}$$

The proof of (4.38) is then a direct consequence of the estimate

$$\begin{aligned}
\int_0^T e^{-\int_s^T p(r)dr} ds &= \sum_{k=0}^{N-1} \int_{t_k}^{t_{k+1}} e^{-\int_s^T p(r)dr} ds \\
&= \sum_{k=0}^{N-1} \int_{t_k}^{t_{k+1}} e^{-\left[\int_s^{t_{k+1}} p(r)dr + \sum_{l=k+1}^{N-1} \int_{t_l}^{t_{l+1}} p(r)dr\right]} ds \\
&\leq \sum_{k=0}^{N-1} e^{-\left[\sum_{l=k+1}^{N-1} X_l\right]} \int_{t_k}^{t_{k+1}} e^{-a_k(t_{k+1}-s)+d_k} ds \\
&= \sum_{k=0}^{N-1} e^{-\left[\sum_{l=k+1}^{N-1} X_l\right]} \frac{e^{d_k}}{a_k}(1 - e^{-a_k h_k}). \qquad \square
\end{aligned}$$

Observe that the bounds (4.38) can be used to obtain bounds on the K_{ij}'s in (4.2) by setting $K_{ij} = \sup_k K(t_k)$.

5. Example. Here we illustrate our results, in particular the effectiveness of the bounds on the error in the orthogonal matrix function Q, in the following example, also considered in [11]. We report only on the improved bounds obtained when handling directly the triangular term.

Let $B(t) = D(t) + U(t)$ be the upper triangular matrix function with

$$D(t) = \mathrm{diag}(D_{11}(t), D_{22}(t), D_{33}(t), D_{44}(t)), \tag{5.1}$$

where we take $D_{11}(t) = 10 + \sin(t)$, $D_{22}(t) = \zeta\cos(t)$, $D_{33}(t) = \lambda - \zeta\cos(t)$, $D_{44}(t) = -10 + \sin(t)$, $\zeta > 0$, and

$$U(t) = \kappa \begin{pmatrix} 0 & \cos(t) & \sin(t) & \cos(t) \\ 0 & 0 & \cos(t) & \sin(t) \\ 0 & 0 & 0 & \cos(t) \\ 0 & 0 & 0 & 0 \end{pmatrix}. \tag{5.2}$$

The parameter κ changes the degree to which there is nonnormality in the upper triangular part, and the parameters λ and ζ determine the degree of integral separation in the system. For simplicity, in our experiments below we fix $\lambda = -5$, and all computations refer to this case.

Form the matrix function

$$A(t) = Q(t)B(t)Q^T(t) + \dot{Q}(t)Q^T(t),$$

TABLE 5.1

Error in the approximate Q varying the degree of nonnormality and integral separation, method, and tolerance.

where

$$Q(t) = \mathrm{diag}(1, Q_\beta(t), 1) \cdot \mathrm{diag}(Q_\eta(t), Q_\eta(t))$$

and

$$Q_\gamma(t) = \begin{pmatrix} \cos(\gamma t) & \sin(\gamma t) \\ -\sin(\gamma t) & \cos(\gamma t) \end{pmatrix}, \ \eta = 1, \ \beta = \sqrt{2}.$$

Results for this problem were obtained using the code LESLIS, which we developed (see www.math.gatech.edu/∼dieci and www.math.ku.edu/∼evanvleck).

In particular, we employ the continuous QR method (Cont QR in Table 5.1) using the projected fifth order scheme (IPAR(8)=0 in LESLIS) with local error control on the orthogonal factor Q (IPAR(10)=1 in LESLIS), and the discrete QR method (Disc QR in Table 5.1) with a fifth order scheme (IPAR(8)=4 in LESLIS), with local error control on the Lyapunov exponents (IPAR(10)=0 in LESLIS). TOL is the value of the local error tolerance, and we used TOL = 1.E-6 throughout. Before reporting on the results, we remark that (see (2.11)) we expect to have ω to be about the same as TOL. In other words, the bound on the norm of the perturbation term F in Lemma 4.1 is essentially TOL. In Table 5.1 we tabulate the actual error for different methods and varying κ and ζ values. We report on the error in Q in the two norm (the largest singular value of the error) at grid-points. Exponential notation is used throughout.

We further compare the actual error with the error bounds obtained in the previous sections. Although the quantities needed to determine the bounds, $\rho_{ij} = \alpha_{ij} K_{ij} \omega$, on $|\widehat{Q}_{ij}(t)|$, in particular the α_{ij}, are somewhat difficult to give in closed form, the recursion (4.3) is straightforward to code. Likewise, the formula for ω_+, given by (4.4) with (4.18), (4.19), and (4.20), are functions of the K_{ij}, the measure of integral separation, and the κ_{ij}, the measure of nonnormality. For this problem, we have $\kappa_{11} = \kappa_{44} = 11$, $\kappa_{22} = \zeta$, $\kappa_{33} = |\lambda| + \zeta$, and $\kappa_{ij} = \kappa$ for $i < j$.

We have, for $\lambda = -5$ and $\zeta < \sqrt{24}$, $K_{12} = K_{24} = 1/(10 - \sqrt{1+\zeta^2})$, $K_{13} = 1/(15 - \sqrt{1+\zeta^2})$, $K_{34} = 1/(5 - \sqrt{1+\zeta^2})$, and $K_{14} = 1/20$. If $\zeta < 5/2$, then $K_{23} = 1/(5 - 2\zeta)$. We next focus on determining bounds on K_{23} using Lemmas 4.3 and 4.4 when $\zeta \geq 5/2$.

TABLE 5.2
Bounds on K_{23} obtained using Lemmas 4.3 and 4.4.

K_{23} bounds for $T = 10^4$, $\lambda = -5$, and $\zeta = 4$.

N	K_{23} w/ Lemma 4.3	K_{23} w/ Lemma 4.4 ($h = \pi/2^N, \epsilon = 10^{-8}$)

6	3.8E4	3.8E1

We have $p(t) := D_{22}(t) - D_{33}(t) = 5 + 2\zeta\cos(t)$. To employ Lemma 4.3 we have

$$K_{23}(H) = \frac{e^{d(H)}}{c(H)}, \quad d(H) = 4\zeta\left\{H/2^{N+1} + \sum_{k=1}^{N}\sin(H/2^{k+1}) - \sin(H/2)\right\} \tag{5.3}$$

for H sufficiently large so that $c(H) \equiv 5 - 4\zeta\sin(H/2)/H > 0$. For different values of N we can determine, at least approximately, optimal values of H. When using Lemma 4.4, and in the notation used there, we set $h \equiv h_k = \pi/2^N$ for integer $N \geq 0$. When $p(t)$ is decreasing, $Y_k = 5 + 2\zeta\cos(t_{k+1})$, and when $p(t)$ is increasing, $Y_k = 5 + 2\zeta[\sin(t_{k+1}) - \sin(t_k)]/h$.

In Table 5.2 we tabulate bounds on K_{23} found using Lemmas 4.3 and 4.4 for different values of N. In the case of Lemma 4.3, N refers to discretization of the Steklov window length as in (5.3), while in the case of Lemma 4.4, N refers to the fineness of the discretization of $[0, T]$ ($h = \pi/2^N$). We will use the best of the bounds found to determine bounds on the error in Q.

By Corollary 4.2 we have $\|Q(t_k) - Q_k\| \approx 2\rho_1 + \rho_2$, and we recall that $\rho_i \leq \alpha_i K_i \omega$, $i = 1, 2$. For convenience, in Table 5.3 we report on the estimates for ρ_1 and ρ_2 obtained by using these bounds and those for α_i, K_i, $i = 1, 2$, for different values of κ and ζ.

At this point, we make an important observation: *If we use $\omega =$ `TOL` in the expressions obtained for ρ_1 and ρ_2 in Table* 5.3*, and use $2\rho_1 + \rho_2$ as a measure of the true global error, then we observe that the observed true global error is always below the theoretical estimate.* This is actually an important fact, since it is not easy to know exactly the value of ω. At the same time, this is not entirely rigorous, since we can use $2\rho_1 + \rho_2$ as a measure of the global error only if $\omega < \omega_+$. For this reason, we also estimated ω_+ using the approximations to a_2, a_1, a_0 in (4.27).

For the example we are considering, $\kappa_D := \sup_{i,t}|B_{ii}(t)| = 11$. In the last column of Table 5.3 we record this estimated value of $[(2\kappa_D + \kappa)\alpha_1^2 K_1^2]^{-1}$, which serves as the estimate of ω_+ (see the discussion after (4.27)).

Now, by comparison of the true errors obtained in Table 5.1, using the estimates for ω_+ from Table 5.3, and still adopting the rationale that $\omega =$ `TOL`, we see that the results for $\kappa = 0$, $\kappa = 1$, or $\kappa = 10$ and $\zeta \neq 4$ in Table 5.3 validate that $\omega < \omega_+$. To further corroborate this fact, we notice that for these value of κ, the error bounds obtained are in good agreement with the actual errors observed and recorded in Tables 5.1 and 5.3. For $\kappa = 10^2$ or $\kappa = 10$ and $\zeta = 4$ the bounds obtained do not appear to be sharp, in the sense that it becomes increasingly difficult to satisfy the hypothesis $\omega < \omega^+$ that is necessary to apply Lemma 4.1 and Corollary 4.2.

TABLE 5.3
Bound on the error in Q is dominated by $\rho_1 = \alpha_1 K_1 \omega$.

Bounds obtained for the example with $\lambda = -5$.

6. Conclusions and consequences. We have provided a global error analysis for the factor Q in the change of variables $X = QR$ of a fundamental matrix solution for a nonautonomous linear system. Our basic technique consists of a combination of backward and forward error analyses, and this is seemingly a new approach in the context of numerical integration.

Several comments are in order.

(1) Among the noteworthy consequences of a global error analysis for Q, probably the most important one is that it becomes simple to obtain global error statements for all quantities which derive from the simplified triangular structure of the linear system, e.g., error bounds on the Lyapunov exponents and/or the Sacker–Sell spectrum.

(2) We have made our analysis for the entire fundamental matrix solution, although at times one is interested in computing the QR-factorization of only a few of the columns of the fundamental matrix solution: *reduced* QR-factorization. However, dealing with this case is—in principle—simple, since as a consequence of the combined backward and forward error analyses for all k we have

$$\begin{aligned} Q_k &= Q(t_k)\widetilde{Q}(t_k), \\ &\quad R_k R_{k-1} \dots R_2 R_1 R(t_0) \\ &= \widetilde{Q}^T(t_k)[R(t_k,t_{k-1}) + E_k] \dots [R(t_2,t_1) + E_2][R(t_1,t_0) + E_1]R(t_0) \\ &\equiv \widetilde{R}(t_k,t_{k-1}) \dots \widetilde{R}(t_2,t_1)\widetilde{R}(t_1,t_0)R(t_0). \end{aligned} \tag{6.1}$$

Thus, multiplying by $\left(\begin{smallmatrix} I & 0 \\ 0 & 0 \end{smallmatrix}\right)$, one obtains backward error statements and subsequent forward error estimates for the case of the reduced QR-factorization, obtaining bounds which cannot be worse than the bounds obtained on the full Q.

(3) We remark that in this work we made use of the assumption of integral separation for the linear system. This is reasonable, since this is the generic case. However, it would be interesting to obtain direct bounds also removing this assumption, in a similar way to [11, Theorem 4.3].

(4) For the general case of integration of a matrix equation of the form

$$\dot{y} = f(t,y), \;\; y(t_0) = y_0 \;\text{ orthogonal}$$

we note that in order for the solution to remain orthogonal $y^T\dot{y}$ must be skew-symmetric; hence $f(t,y) = y\ s(t,y)$, where $s(t,y)$ is skew-symmetric. Obtaining a result similar in flavor to Lemma 4.1 would require determining a splitting

$$\dot{y} = yL + y[s(t,y) - L], \;\; y(t_0) = I,$$

where L is such that $y[s(t,y) - L]$ remains small enough for $y(t) \approx I$. In the specific case considered here the splitting was motivated by integral separation, a natural property for linear nonautonomous differential equations $\dot{x} = A(t)x$, and we took advantage of the fact that the skew-symmetric matrix function $S(Q,A)$ is linear in A.

Appendix. Here we derive some technical expressions that are useful in proving Lemma 4.1. In particular, we derive expressions relative to $q_{ij}^D(t,\widehat{Q},\omega)$, $q_{ij}^T(t,\widehat{Q},\omega)$, and $q_{ij}^F(t,\widehat{Q},\omega)$ in (4.8) that are useful in obtaining the bounds (4.9), (4.10), (4.11) in the proof of Lemma 4.1.

First, consider $q_{ij}^D(t,\widehat{Q},\omega)$. We have, writing $\widehat{Q}(t) = [\widehat{Q}_1(t)|\cdots|\widehat{Q}_n(t)]$,

$$\begin{aligned}
&q_{ij}^D(t,\widehat{Q},\omega) - q_{ij}^D(t,I,\omega)\\
&= q_{ij}^D(t,\widehat{Q},\omega) = \widehat{Q}_{ij}[D_{ii} - D_{jj}] + \left[-\sum_{k=1}^{j-1} \widehat{Q}_{ik}\widehat{Q}_k^T + \sum_{k=j+1}^{n} \widehat{Q}_{ik}\widehat{Q}_k^T \right] D\widehat{Q}_j\\
&= \widehat{Q}_{ij}[D_{ii} - D_{jj}] + \sum_{l=1}^{n} D_{ll}\left[\widehat{Q}_{lj} \cdot \left\{ -\sum_{k=1}^{j-1} \widehat{Q}_{ik}\widehat{Q}_{lk} + \sum_{k=j+1}^{n} \widehat{Q}_{ik}\widehat{Q}_{lk} \right\} \right]\\
&= D_{ii}\left[\widehat{Q}_{ij} \cdot \left\{ 1 - \sum_{k=1}^{j-1} \widehat{Q}_{ik}^2 + \sum_{k=j+1}^{n} \widehat{Q}_{ik}^2 \right\} \right]\\
&\quad + D_{jj}\left[-\widehat{Q}_{ij} + \widehat{Q}_{jj} \cdot \left\{ -\sum_{k=1}^{j-1} \widehat{Q}_{ik}\widehat{Q}_{jk} + \sum_{k=j+1}^{n} \widehat{Q}_{ik}\widehat{Q}_{jk} \right\} \right]\\
&\quad + \sum_{l\neq i,j} D_{ll}\left[\widehat{Q}_{lj} \cdot \left\{ -\sum_{k=1}^{j-1} \widehat{Q}_{ik}\widehat{Q}_{lk} + \sum_{k=j+1}^{n} \widehat{Q}_{ik}\widehat{Q}_{lk} \right\} \right].
\end{aligned} \tag{A.1}$$

By orthogonality we have

$$1 = \sum_{k=1}^{n} \widehat{Q}_{ik}^2 \quad \text{and} \quad \widehat{Q}_{ij}\widehat{Q}_{jj} = -\sum_{k\neq j} \widehat{Q}_{ik}\widehat{Q}_{jk}, \tag{A.2}$$

so for $i < j$,

$$\begin{aligned}
q_{ij}^D(t,\widehat{Q},\omega) &= D_{ii}\left[\widehat{Q}_{ij} \left(\widehat{Q}_{ij}^2 + 2\sum_{k=j+1}^{n} \widehat{Q}_{ik}^2 \right) \right]\\
&\quad + D_{jj}\left[-\widehat{Q}_{ij}(1 - \widehat{Q}_{jj}^2) + 2\widehat{Q}_{jj} \sum_{k=j+1}^{n} \widehat{Q}_{ik}\widehat{Q}_{jk} \right]\\
&\quad + \sum_{l\neq i,j} D_{ll}\left[\widehat{Q}_{lj} \left(-\sum_{k=1}^{j-1} \widehat{Q}_{ik}\widehat{Q}_{lk} + \sum_{k=j+1}^{n} \widehat{Q}_{ik}\widehat{Q}_{lk} \right) \right].
\end{aligned} \tag{A.3}$$

Next, consider the term $q_{ij}^T(t,\widehat{Q},\omega)$. We have for $i<j$ (and similarly for $i>j$)

$$\begin{aligned}
q_{ij}^T(t,\widehat{Q},\omega) - q_{ij}^T(t,I,\omega) &= q_{ij}^T(t,\widehat{Q},\omega) = \sum_{k=1}^{n} \widehat{Q}_{ik}(S(\widehat{Q},T))_{kj} \\
&= -\sum_{k=1}^{j-1} \widehat{Q}_{ik}(\widehat{Q}_j^T T \widehat{Q}_k) + \sum_{k=j+1}^{n} \widehat{Q}_{ik}(\widehat{Q}_k^T T \widehat{Q}_j) \\
&= -\sum_{k=1}^{j-1} \widehat{Q}_{ik} \sum_{l=1}^{n}\sum_{m=l+1}^{n} \widehat{Q}_{jl} T_{lm} \widehat{Q}_{km} + \sum_{k=j+1}^{n} \widehat{Q}_{ik} \sum_{l=1}^{n}\sum_{m=l+1}^{n} \widehat{Q}_{kl} T_{lm} \widehat{Q}_{jm} \\
&= -\widehat{Q}_{ii} \sum_{l=1}^{n}\sum_{m=l+1}^{n} \widehat{Q}_{jl} T_{lm} \widehat{Q}_{im} \\
&\quad - \sum_{k=1,k\neq i}^{j-1} \widehat{Q}_{ik} \sum_{l=1}^{n}\sum_{m=l+1}^{n} \widehat{Q}_{jl} T_{lm} \widehat{Q}_{km} + \sum_{k=j+1}^{n} \widehat{Q}_{ik} \sum_{l=1}^{n}\sum_{m=l+1}^{n} \widehat{Q}_{kl} T_{lm} \widehat{Q}_{jm} \\
&= -\widehat{Q}_{ii}\left[\widehat{Q}_{jj} \sum_{m=j+1}^{n} T_{jm} \widehat{Q}_{im} + \widehat{Q}_{ii} \sum_{l=1}^{i-1} \widehat{Q}_{jl} T_{li} + \sum_{l=1,l\neq j}^{n}\sum_{m=l+1,m\neq i}^{n} \widehat{Q}_{jl} T_{lm} \widehat{Q}_{im} \right] \\
&\quad - \sum_{k=1,k\neq i}^{j-1} \widehat{Q}_{ik} \sum_{l=1}^{n}\sum_{m=l+1}^{n} \widehat{Q}_{jl} T_{lm} \widehat{Q}_{km} + \sum_{k=j+1}^{n} \widehat{Q}_{ik} \sum_{l=1}^{n}\sum_{m=l+1}^{n} \widehat{Q}_{kl} T_{lm} \widehat{Q}_{jm}.
\end{aligned} \tag{A.4}$$

Finally, consider the term $q_{ij}^F(t,\widehat{Q},\omega)$. Using (1.5), we have for $i<j$ (and similarly for $i>j$)

$$\begin{aligned}
q_{ij}^F(t,\widehat{Q},\omega) - q_{ij}^F(t,I,\omega) &= [\widehat{Q}S(\widehat{Q},F) - S(I,F)]_{ij} \\
&= -\sum_{k=1}^{j-1} \widehat{Q}_{ik} S(\widehat{Q},F)_{jk} + \sum_{k=j+1}^{n} \widehat{Q}_{ik} S(\widehat{Q},F)_{kj} + F_{ji} \\
&= F_{ji}\left(1 - \widehat{Q}_{jj} + \sum_{k\neq i,k=1}^{n} \widehat{Q}_{ik}^2 \widehat{Q}_{jj}\right) \\
&\quad - \widehat{Q}_{ii} \sum_{(l,m)\neq(j,i),l,m=1}^{n} \widehat{Q}_{lj} F_{lm} \widehat{Q}_{mi} + \sum_{k=1,k\neq i}^{n} \widehat{Q}_{ik} S(\widehat{Q},F)_{kj}.
\end{aligned} \tag{A.5}$$

A LOCALLY DIVERGENCE-FREE INTERIOR PENALTY METHOD FOR TWO-DIMENSIONAL CURL-CURL PROBLEMS*

SUSANNE C. BRENNER†, FENGYAN LI‡, AND LI-YENG SUNG§

Abstract. An interior penalty method for certain two-dimensional curl-curl problems is investigated in this paper. This method computes the divergence-free part of the solution using locally divergence-free discontinuous P_1 vector fields on graded meshes. It has optimal order convergence (up to an arbitrarily small ϵ) for the source problem and the eigenproblem. Results of numerical experiments that corroborate the theoretical results are also presented.

Key words. curl-curl problem, Maxwell eigenproblem, locally divergence-free, interior penalty methods, graded meshes

1. Introduction.

Let $\Omega \subset \mathbb{R}^2$ be a bounded polygonal domain. Consider the following weak curl-curl problem: Find $\boldsymbol{u} \in H_0(\mathrm{curl};\Omega)$ such that

$$(\nabla \times \boldsymbol{u}, \nabla \times \boldsymbol{v}) + \alpha(\boldsymbol{u}, \boldsymbol{v}) = (\boldsymbol{f}, \boldsymbol{v}) \qquad \forall\, \boldsymbol{v} \in H_0(\mathrm{curl};\Omega), \tag{1.1}$$

where α is a constant, $(\cdot,\cdot)$ denotes the inner product of $L_2(\Omega)$ (or $[L_2(\Omega)]^2$),

$$H(\mathrm{curl};\Omega) = \left\{ \boldsymbol{v} = \begin{bmatrix} v_1 \\ v_2 \end{bmatrix} \in [L_2(\Omega)]^2 : \nabla \times \boldsymbol{v} = \frac{\partial v_2}{\partial x_1} - \frac{\partial v_1}{\partial x_2} \in L_2(\Omega) \right\},$$

and

$$H_0(\mathrm{curl};\Omega) = \left\{ \boldsymbol{v} = \begin{bmatrix} v_1 \\ v_2 \end{bmatrix} \in H(\mathrm{curl};\Omega) : \boldsymbol{n} \times \boldsymbol{v} = n_1 v_2 - n_2 v_1 = 0 \text{ on } \partial\Omega \right\},$$

with $\boldsymbol{n} = \left[\begin{smallmatrix} n_1 \\ n_2 \end{smallmatrix}\right]$ the unit outer normal on $\partial\Omega$.

The curl-curl problem (1.1) is related to electromagnetic problems. For $\alpha \leq 0$, it is the weak form of the time-harmonic (frequency-domain) Maxwell equations. For $\alpha > 0$, it is related to the spatial problems appearing in implicit semidiscretizations of the time-dependent (time-domain) Maxwell equations.

It is well known [24, 25, 5] that H^1 conforming nodal finite element methods can lead to a wrong solution of (1.1) if Ω is not convex. Many alternative approaches have been developed which include $H(\mathrm{curl};\Omega)$ conforming edge element methods [41, 42, 13,

33, 38, 40], H^1 conforming nodal finite element methods with weighted regularization [27, 29], the singular complement/field method [32, 5], and interior penalty methods [43, 36, 37, 35, 34].

In this paper we take a different approach. By the Helmholtz decomposition, the solution $\boldsymbol{u} \in H_0(\mathrm{curl};\Omega)$ of (1.1) can be written uniquely as

$$\boldsymbol{u} = \mathring{\boldsymbol{u}} + \nabla\phi, \tag{1.2}$$

where $\mathring{\boldsymbol{u}} \in H_0(\mathrm{curl};\Omega) \cap H(\mathrm{div}^0;\Omega)$, $\phi \in H_0^1(\Omega)$,

$$H(\mathrm{div}^0;\Omega) = \left\{ \boldsymbol{v} = \begin{bmatrix} v_1 \\ v_2 \end{bmatrix} \in [L_2(\Omega)]^2 : \nabla\cdot\boldsymbol{v} = \frac{\partial v_1}{\partial x_1} + \frac{\partial v_2}{\partial x_2} = 0 \right\}.$$

It is easy to see that ϕ satisfies

$$\alpha(\nabla\phi, \nabla\psi) = (\boldsymbol{f}, \nabla\psi) \qquad \forall\, \psi \in H_0^1(\Omega). \tag{1.3}$$

Since the Poisson problem (1.3) (when $\alpha \neq 0$) can be solved by many standard methods under the assumption that $\boldsymbol{f} \in H(\mathrm{div};\Omega)$, we will focus on the divergence-free part $\mathring{\boldsymbol{u}}$, which satisfies

$$(\nabla\times\mathring{\boldsymbol{u}}, \nabla\times\boldsymbol{v}) + \alpha(\mathring{\boldsymbol{u}}, \boldsymbol{v}) = (\boldsymbol{f}, \boldsymbol{v}) \qquad \forall\, \boldsymbol{v} \in H_0(\mathrm{curl};\Omega) \cap H(\mathrm{div}^0;\Omega). \tag{1.4}$$

We shall refer to (1.4) as the weak form of the reduced curl-curl problem and assume in the case where $\alpha \leq 0$ that (1.4) has a unique solution (i.e., $-\alpha$ is not a Maxwell eigenvalue). Note that the strong form of the reduced curl-curl problem is given by

$$\nabla\times(\nabla\times\mathring{\boldsymbol{u}}) + \alpha\mathring{\boldsymbol{u}} = Q\boldsymbol{f}, \tag{1.5}$$

where $Q : [L_2(\Omega)]^2 \longrightarrow H(\mathrm{div}^0;\Omega)$ is the orthogonal projection.

Remark 1.1. The strong form (1.5) and the well-posedness of (1.4) imply immediately

$$\|\nabla\times\mathring{\boldsymbol{u}}\|_{H^1(\Omega)} \leq C_{\Omega,\alpha}\|Q\boldsymbol{f}\|_{L_2(\Omega)} \leq C_{\Omega,\alpha}\|\boldsymbol{f}\|_{L_2(\Omega)}. \tag{1.6}$$

Here and below we use C (with or without subscripts) to denote a generic positive constant that can take different values at different occurrences.

The advantage of working with (1.4) is that it behaves like an elliptic problem, unlike the full curl-curl problem (1.1). In particular, the solution $\mathring{\boldsymbol{u}}$ of (1.4) enjoys elliptic regularity under the assumption that $\boldsymbol{f} \in L_2(\Omega)$, which greatly simplifies the duality argument needed for the analysis.

In [15] we developed a numerical scheme (in the case where $\alpha \leq 0$) for (1.4) using locally divergence-free Crouzeix–Raviart nonconforming P_1 vector fields [30]. In this paper we investigate an interior penalty method that avoids the difficulties involved in the construction of local bases for locally divergence-free Crouzeix–Raviart vector fields at the cost of a larger number of unknowns. These two methods are very closely related, which simplifies the analysis of the new scheme.

Since the solution operator of the interior penalty method converges uniformly to the solution operator of (1.4) with respect to the norm $\|\cdot\|_{L_2(\Omega)}$, the classical spectral approximation theory [7] implies that we can also apply the interior penalty method

to the following Maxwell eigenproblem: Find $(\lambda, \mathring{\boldsymbol{u}}) \in \mathbb{R} \times H_0(\mathrm{curl};\Omega) \cap H(\mathrm{div}^0;\Omega)$ such that

$$(\nabla \times \mathring{\boldsymbol{u}}, \nabla \times \boldsymbol{v}) = \lambda(\mathring{\boldsymbol{u}}, \boldsymbol{v}) \qquad \forall\, \boldsymbol{v} \in H_0(\mathrm{curl};\Omega) \cap H(\mathrm{div}^0;\Omega). \tag{1.7}$$

In particular, the spectral approximation based on our interior penalty method is free of spurious eigenvalues.

The rest of the paper is organized as follows. We introduce the finite element space and graded meshes in section 2. The interior penalty method and some preliminary estimates are presented in section 3. The convergence analysis for the source problem (1.1) is carried out in section 4. Application to the eigenproblem (1.7) is discussed in section 5, followed by numerical results in section 6, and we end with some concluding remarks in section 7.

2. Finite element spaces and graded meshes. In this section we will introduce discontinuous finite element spaces defined on meshes graded around the corners $c_1, \ldots, c_L$ of Ω.

We assume that the triangulation $\mathcal{T}_h$ of Ω satisfies the following condition:

$$h_T \approx h\Phi_\mu(T) \qquad \forall\, T \in \mathcal{T}_h, \tag{2.1}$$

where $h_T = \mathrm{diam}\, T$, h is a mesh parameter proportional to $\max_{T\in\mathcal{T}_h} h_T$, and $\mu = (\mu_1, \ldots, \mu_L)$ is the vector containing the grading parameters. The constants in the equivalence (2.1) are independent of h and depend in general on the minimum angle of the mesh. The weight $\Phi_\mu(T)$ is defined by

$$\Phi_\mu(T) = \Pi_{\ell=1}^{L} |c_\ell - c_{_T}|^{1-\mu_\ell}, \tag{2.2}$$

where $c_{_T}$ is the center of T. Note that

$$h_T \le Ch. \tag{2.3}$$

The choices of the grading parameters are dictated by the singularities [6, 28, 26] of the solution $\mathring{\boldsymbol{u}}$ of (1.4). In order to recover optimal convergence rates in both the energy norm and the L_2 norm (cf. [15]), we take

$$\begin{aligned} &\mu_\ell = 1 && \text{if} \quad \omega_\ell \le \frac{\pi}{2}, \\ &\mu_\ell < \frac{\pi}{2\omega_\ell} && \text{if} \quad \omega_\ell > \frac{\pi}{2}, \end{aligned} \tag{2.4}$$

where ω_ℓ is the interior angle at the corner c_ℓ. The construction of $\mathcal{T}_h$ satisfying (2.1) can be found, for example, in [31, 4, 1, 14]. Note that $\mathcal{T}_h$ can be constructed so that it satisfies a minimum angle condition for any fixed choice of the grading parameters.

Remark 2.1. The choice of the grading parameters in (2.4) indicates that grading is needed at any corner where the angle is larger than $\pi/2$. This is different from problems involving the Laplace operator where grading is only needed at reentrant corners and is due to the fact that the singularities of the curl-curl operator are one order worse than the singularities of the Laplace operator.

The finite element space V_h is defined by

$$V_h = \{\boldsymbol{v} \in [L_2(\Omega)]^2 : \boldsymbol{v}_{_T} = \boldsymbol{v}\big|_{_T} \in [P_1(T)]^2 \text{ and } \nabla \cdot \boldsymbol{v}_{_T} = 0\ \forall\, T \in \mathcal{T}_h\}.$$

For any $s > \frac{1}{2}$ there is a natural weak interpolation operator $\Pi_T : [H^s(T)]^2 \longrightarrow [P_1(T)]^2$ defined by

$$(\Pi_T \boldsymbol{\zeta})(m_{e_i}) = \frac{1}{|e_i|}\int_{e_i} \boldsymbol{\zeta}\, ds \quad \text{for} \quad i = 1, 2, 3, \tag{2.5}$$

where m_{e_i} is the midpoint of the edge e_i of T and $|e|$ denotes the length of an edge e.

It follows immediately from (2.5), the midpoint rule, and Green's theorem that

$$\int_T \nabla \times (\Pi_T \boldsymbol{\zeta}) dx = \int_T \nabla \times \boldsymbol{\zeta}\, dx \qquad \forall\, \boldsymbol{\zeta} \in [H^s(T)]^2, \tag{2.6}$$

$$\int_T \nabla \cdot (\Pi_T \boldsymbol{\zeta}) dx = \int_T \nabla \cdot \boldsymbol{\zeta}\, dx \qquad \forall\, \boldsymbol{\zeta} \in [H^s(T)]^2. \tag{2.7}$$

Furthermore, given $s \in (1/2, 2]$, we have the following interpolation error estimates [30]:

$$\|\boldsymbol{\zeta} - \Pi_T \boldsymbol{\zeta}\|_{L_2(T)} + h_T^{\min(s,1)} |\boldsymbol{\zeta} - \Pi_T \boldsymbol{\zeta}|_{H^{\min(s,1)}(T)} \le C_T h_T^s |\boldsymbol{\zeta}|_{H^s(T)} \tag{2.8}$$

for all $\boldsymbol{\zeta} \in [H^s(T)]^2$, where the positive constant C_T depends on the minimum angle of T (and also on s when s is close to $1/2$).

Since the solution $\mathring{\boldsymbol{u}}$ of the reduced curl-curl problem belongs to $[H^s(\Omega)]^2$ for some $s > \frac{1}{2}$ (cf. [40]), we can define a global interpolant of $\mathring{\boldsymbol{u}}$ by

$$(\Pi_h \mathring{\boldsymbol{u}})_T = \Pi_T \mathring{\boldsymbol{u}}_T \qquad \forall\, T \in \mathcal{T}_h,$$

where $\mathring{\boldsymbol{u}}_T = \mathring{\boldsymbol{u}}\big|_T$. It follows from (2.7) and $\nabla \cdot \mathring{\boldsymbol{u}} = 0$ that $\Pi_h \mathring{\boldsymbol{u}} \in V_h$.

Remark 2.2. Note that $\Pi_h \mathring{\boldsymbol{u}}$ is the same interpolation operator used in [15] and $\Pi_h \mathring{\boldsymbol{u}}$ belongs to the space of locally divergence-free Crouzeix–Raviart nonconforming P_1 vector fields [30].

Since the vector fields in V_h are discontinuous, their jumps across the edges of $\mathcal{T}_h$ play an important role in the development of interior penalty methods. We will denote by $\mathcal{E}_h$ (resp., $\mathcal{E}_h^i$) the set of the edges (resp., interior edges) of $\mathcal{T}_h$. Let $e \in \mathcal{E}_h^i$ be shared by the two triangles $T_1, T_2 \in \mathcal{T}_h$ (cf. Figure 2.1) and let $\boldsymbol{n}_1$ (resp., $\boldsymbol{n}_2$) be the unit normal of e pointing towards the outside of T_1 (resp., T_2). We define, on e,

$$[\![\boldsymbol{n} \times \boldsymbol{v}]\!] = \boldsymbol{n}_1 \times \boldsymbol{v}_{T_1}\big|_e + \boldsymbol{n}_2 \times \boldsymbol{v}_{T_2}\big|_e, \tag{2.9a}$$

$$[\![\boldsymbol{n} \cdot \boldsymbol{v}]\!] = \boldsymbol{n}_1 \cdot \boldsymbol{v}_{T_1}\big|_e + \boldsymbol{n}_2 \cdot \boldsymbol{v}_{T_2}\big|_e. \tag{2.9b}$$

For an edge e along $\partial\Omega$, we take $\boldsymbol{n}_e$ to be the unit normal of e pointing towards the outside of Ω and define

$$[\![\boldsymbol{n} \times \boldsymbol{v}]\!] = \boldsymbol{n}_e \times \boldsymbol{v}\big|_e. \tag{2.10}$$

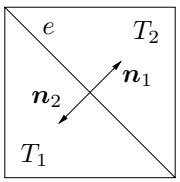

FIG. 2.1. *Triangles and normals in the definitions of* $[\![\boldsymbol{n} \times \boldsymbol{v}]\!]$ *and* $[\![\boldsymbol{n} \cdot \boldsymbol{v}]\!]$.

We will also denote the piecewise defined curl and div operators by $\nabla_h\times$ and $\nabla_h\cdot$, i.e.,

$$(\nabla_h \times \boldsymbol{v})\big|_T = \nabla \times \boldsymbol{v}_T \quad \text{and} \quad (\nabla_h \cdot \boldsymbol{v})\big|_T = \nabla \cdot \boldsymbol{v}_T.$$

3. Discretization and preliminary error estimates. In this section we present the interior penalty method for the reduced curl-curl problem and some preliminary estimates.

The discrete problem is to find $\mathring{\boldsymbol{u}}_h \in V_h$ such that

$$a_h(\mathring{\boldsymbol{u}}_h, \boldsymbol{v}) = (\boldsymbol{f}, \boldsymbol{v}) \qquad \forall\, \boldsymbol{v} \in\ V_h, \tag{3.1}$$

where

$$\begin{aligned} a_h(\boldsymbol{w}, \boldsymbol{v}) = {} & (\nabla_h \times \boldsymbol{w}, \nabla_h \times \boldsymbol{v}) + \alpha(\boldsymbol{w}, \boldsymbol{v}) \\ & + \sum_{e\in\mathcal{E}_h} \frac{[\Phi_\mu(e)]^2}{|e|} \int_e [\![\boldsymbol{n} \times \boldsymbol{w}]\!][\![\boldsymbol{n} \times \boldsymbol{v}]\!]\, ds \\ & + \sum_{e\in\mathcal{E}_h^i} \frac{[\Phi_\mu(e)]^2}{|e|} \int_e [\![\boldsymbol{n} \cdot \boldsymbol{w}]\!][\![\boldsymbol{n} \cdot \boldsymbol{v}]\!]\, ds \\ & + h^{-2} \sum_{e\in\mathcal{E}_h} \frac{1}{|e|} \int_e \big(\Pi_e^0[\![\boldsymbol{n} \times \boldsymbol{w}]\!]\big)\big(\Pi_e^0[\![\boldsymbol{n} \times \boldsymbol{v}]\!]\big)\, ds \\ & + h^{-2} \sum_{e\in\mathcal{E}_h^i} \frac{1}{|e|} \int_e \big(\Pi_e^0[\![\boldsymbol{n} \cdot \boldsymbol{w}]\!]\big)\big(\Pi_e^0[\![\boldsymbol{n} \cdot \boldsymbol{v}]\!]\big)\, ds, \end{aligned} \tag{3.2}$$

where Π_e^0 is the orthogonal projection from $L_2(e)$ onto $P_0(e)$ (the space of constant functions on e). The weight $\Phi_\mu(e)$ in (3.2) is defined by

$$\Phi_\mu(e) = \Pi_{\ell=1}^L |c_\ell - m_e|^{1-\mu_\ell},$$

where m_e is the midpoint of e.

Remark 3.1. The weight $\Phi_\mu(e)$ is closely related to the weight $\Phi_\mu(T)$ in (2.2). In fact, we have

$$\Phi_\mu(e) \approx \Phi_\mu(T) \qquad \text{if} \quad e \subset \partial T, \tag{3.3}$$

where the constants in the equivalence are independent of h and depend in general on the minimum angle of the mesh. The inclusion of $\Phi_\mu(e)$ in (3.2) is crucial for the derivation of optimal convergence rates on graded meshes.

Remark 3.2. The weak problem (1.4) for the reduced curl-curl problem can be written as

$$a_h(\mathring{\boldsymbol{u}}, \boldsymbol{v}) = (\boldsymbol{f}, \boldsymbol{v}) \qquad \forall\, \boldsymbol{v} \in H_0(\mathrm{curl};\Omega) \cap H(\mathrm{div}^0;\Omega).$$

Remark 3.3. For nonconforming Crouzeix–Raviart P_1 vector fields $\boldsymbol{w}$ and $\boldsymbol{v}$, we have

$$\begin{aligned} a_h(\boldsymbol{w},\boldsymbol{v}) &= (\nabla_h\times\boldsymbol{w},\nabla_h\times\boldsymbol{v})+\alpha(\boldsymbol{w},\boldsymbol{v}) \\ &\quad+\sum_{e\in\mathcal{E}_h}\frac{[\Phi_\mu(e)]^2}{|e|}\int_e[\![\boldsymbol{n}\times\boldsymbol{w}]\!][\![\boldsymbol{n}\times\boldsymbol{v}]\!]\,ds \\ &\quad+\sum_{e\in\mathcal{E}_h^i}\frac{[\Phi_\mu(e)]^2}{|e|}\int_e[\![\boldsymbol{n}\cdot\boldsymbol{w}]\!][\![\boldsymbol{n}\cdot\boldsymbol{v}]\!]\,ds, \end{aligned}$$

which is the variational form used in [15]. The two additional sums in (3.2) compensate for the lack of weak continuity for the vector fields in V_h.

Remark 3.4. The weak overpenalization causes the discrete system to become more ill-conditioned. For example, the condition number grows at the rate of $O(h^{-4})$ on quasi-uniform meshes. However, there exists a simple block-diagonal preconditioner that can reduce the growth of the condition number to $O(h^{-2})$ on quasi-uniform meshes and $O(h^{-2}(1+|\ln h|)$ on graded meshes [16, 17].

Let the mesh-dependent energy norm $\|\cdot\|_h$ be defined by

$$\begin{aligned} \|\boldsymbol{v}\|_h^2 &= \|\nabla_h\times\boldsymbol{v}\|_{L_2(\Omega)}^2+\|\boldsymbol{v}\|_{L_2(\Omega)}^2 \\ &\quad+\sum_{e\in\mathcal{E}_h}\frac{[\Phi_\mu(e)]^2}{|e|}\|[\![\boldsymbol{n}\times\boldsymbol{v}]\!]\|_{L_2(e)}^2+\sum_{e\in\mathcal{E}_h^i}\frac{[\Phi_\mu(e)]^2}{|e|}\|[\![\boldsymbol{n}\cdot\boldsymbol{v}]\!]\|_{L_2(e)}^2 \\ &\quad+h^{-2}\left(\sum_{e\in\mathcal{E}_h}\frac{1}{|e|}\|\Pi_e^0[\![\boldsymbol{n}\times\boldsymbol{v}]\!]\|_{L_2(e)}^2+\sum_{e\in\mathcal{E}_h^i}\frac{1}{|e|}\|\Pi_e^0[\![\boldsymbol{n}\cdot\boldsymbol{v}]\!]\|_{L_2(e)}^2\right). \end{aligned} \tag{3.4}$$

Note that

$$\|\boldsymbol{v}\|_{L_2(\Omega)}\le\|\boldsymbol{v}\|_h\qquad\forall\,\boldsymbol{v}\in H_0(\mathrm{curl};\Omega)\cap H(\mathrm{div}^0;\Omega)+V_h, \tag{3.5}$$

and from (3.2) and (3.4),

$$|a_h(\boldsymbol{w},\boldsymbol{v})|\le(|\alpha|+1)\|\boldsymbol{w}\|_h\|\boldsymbol{v}\|_h\qquad\forall\,\boldsymbol{w},\boldsymbol{v}\in[H_0(\mathrm{curl};\Omega)\cap H(\mathrm{div}^0;\Omega)]+V_h. \tag{3.6}$$

For $\alpha>0$, $a_h(\cdot,\cdot)$ is coercive with respect to $\|\cdot\|_h$, i.e.,

$$a_h(\boldsymbol{v},\boldsymbol{v})\ge\min(1,\alpha)\|\boldsymbol{v}\|_h^2\qquad\forall\,\boldsymbol{v}\in H_0(\mathrm{curl};\Omega)\cap H(\mathrm{div}^0;\Omega)+V_h. \tag{3.7}$$

In this case the discrete problem is well-posed and we have the following abstract error estimate.

LEMMA 3.5. *Let α be positive, $\beta=\min(1,\alpha)$, $\mathring{\boldsymbol{u}}$ be the solution of* (1.4)*, and $\mathring{\boldsymbol{u}}_h$ satisfy* (3.1)*. It holds that*

$$\|\mathring{\boldsymbol{u}}-\mathring{\boldsymbol{u}}_h\|_h\le\Big(\frac{1+\alpha+\beta}{\beta}\Big)\inf_{\boldsymbol{v}\in V_h}\|\mathring{\boldsymbol{u}}-\boldsymbol{v}\|_h+\frac{1}{\beta}\sup_{\boldsymbol{w}\in V_h\setminus\{\boldsymbol{0}\}}\frac{a_h(\mathring{\boldsymbol{u}}-\mathring{\boldsymbol{u}}_h,\boldsymbol{w})}{\|\boldsymbol{w}\|_h}. \tag{3.8}$$

Proof. Let $\boldsymbol{v} \in V_h$ be arbitrary. It follows from (3.6), (3.7), and the triangle inequality that

$$\begin{aligned}\|\mathring{\boldsymbol{u}} - \mathring{\boldsymbol{u}}_h\|_h &\leq \|\mathring{\boldsymbol{u}} - \boldsymbol{v}\|_h + \|\boldsymbol{v} - \mathring{\boldsymbol{u}}_h\|_h \\ &\leq \|\mathring{\boldsymbol{u}} - \boldsymbol{v}\|_h + \frac{1}{\beta} \sup_{\boldsymbol{w}\in V_h\setminus\{\boldsymbol{0}\}} \frac{a_h(\boldsymbol{v} - \mathring{\boldsymbol{u}}_h, \boldsymbol{w})}{\|\boldsymbol{w}\|_h} \\ &\leq \Big(\frac{1+\alpha+\beta}{\beta}\Big)\|\mathring{\boldsymbol{u}} - \boldsymbol{v}\|_h + \frac{1}{\beta} \sup_{\boldsymbol{w}\in V_h\setminus\{\boldsymbol{0}\}} \frac{a_h(\mathring{\boldsymbol{u}} - \mathring{\boldsymbol{u}}_h, \boldsymbol{w})}{\|\boldsymbol{w}\|_h},\end{aligned}$$

which implies (3.8). ∎

For $\alpha \leq 0$, the following Gårding (in)equality holds:

$$a_h(\boldsymbol{v},\boldsymbol{v}) + (|\alpha|+1)(\boldsymbol{v},\boldsymbol{v}) = \|\boldsymbol{v}\|_h^2 \qquad \forall\, \boldsymbol{v} \in [H_0(\mathrm{curl};\Omega)\cap H(\mathrm{div}^0;\Omega)] + V_h. \tag{3.9}$$

In this case the discrete problem is indefinite and the following lemma provides an abstract error estimate for the scheme (3.1) under the assumption that it has a solution.

LEMMA 3.6. *Let* $\mathring{\boldsymbol{u}} \in H_0(\mathrm{curl};\Omega)\cap H(\mathrm{div}^0;\Omega)$ *satisfy* (1.4) *and let* $\mathring{\boldsymbol{u}}_h$ *be a solution of* (3.1). *It holds that*

$$\begin{aligned}\|\mathring{\boldsymbol{u}} - \mathring{\boldsymbol{u}}_h\|_h \leq (2|\alpha|+3) \inf_{\boldsymbol{v}\in V_h} \|\mathring{\boldsymbol{u}} - \boldsymbol{v}\|_h + \sup_{\boldsymbol{w}\in V_h\setminus\{\boldsymbol{0}\}} \frac{a_h(\mathring{\boldsymbol{u}} - \mathring{\boldsymbol{u}}_h, \boldsymbol{w})}{\|\boldsymbol{w}\|_h} \\ + (|\alpha|+1)\|\mathring{\boldsymbol{u}} - \mathring{\boldsymbol{u}}_h\|_{L_2(\Omega)}.\end{aligned} \tag{3.10}$$

Proof. It follows from (3.5) and (3.9) that, for $\boldsymbol{v} \in V_h \setminus \{\boldsymbol{0}\}$,

$$\begin{aligned}\|\boldsymbol{v}\|_h &\leq \frac{a_h(\boldsymbol{v},\boldsymbol{v})}{\|\boldsymbol{v}\|_h} + (|\alpha|+1)\frac{(\boldsymbol{v},\boldsymbol{v})}{\|\boldsymbol{v}\|_h} \\ &\leq \sup_{\boldsymbol{w}\in V_h\setminus\{\boldsymbol{0}\}} \frac{a_h(\boldsymbol{v},\boldsymbol{w})}{\|\boldsymbol{w}\|_h} + (|\alpha|+1)\|\boldsymbol{v}\|_{L_2(\Omega)}.\end{aligned} \tag{3.11}$$

Let $\boldsymbol{v} \in V_h$ be arbitrary. We find, using (3.5), (3.6), (3.11), and the triangle inequality,

$$\begin{aligned}\|\mathring{\boldsymbol{u}} - \mathring{\boldsymbol{u}}_h\|_h &\leq \|\mathring{\boldsymbol{u}} - \boldsymbol{v}\|_h + \|\boldsymbol{v} - \mathring{\boldsymbol{u}}_h\|_h \\ &\leq \|\mathring{\boldsymbol{u}} - \boldsymbol{v}\|_h + \sup_{\boldsymbol{w}\in V_h\setminus\{\boldsymbol{0}\}} \frac{a_h(\boldsymbol{v} - \mathring{\boldsymbol{u}}_h, \boldsymbol{w})}{\|\boldsymbol{w}\|_h} + (|\alpha|+1)\|\boldsymbol{v} - \mathring{\boldsymbol{u}}_h\|_{L_2(\Omega)} \\ &\leq (2|\alpha|+3)\|\mathring{\boldsymbol{u}} - \boldsymbol{v}\|_h + \sup_{\boldsymbol{w}\in V_h\setminus\{\boldsymbol{0}\}} \frac{a_h(\mathring{\boldsymbol{u}} - \mathring{\boldsymbol{u}}_h, \boldsymbol{w})}{\|\boldsymbol{w}\|_h} + (|\alpha|+1)\|\mathring{\boldsymbol{u}} - \mathring{\boldsymbol{u}}_h\|_{L_2(\Omega)},\end{aligned}$$

which implies (3.10). ∎

From here on we consider α to be fixed and drop the dependence on α in our estimates.

Remark 3.7. The first term on the right-hand side of (3.8) and (3.10) measures the approximation property of V_h with respect to the norm $\|\cdot\|_h$. The second term

measures the consistency error. The third term on the right-hand side of (3.10) addresses the indefiniteness of the reduced curl-curl problem when $\alpha \leq 0$.

As mentioned in Remark 2.2, the interpolation operator Π_h is also the one used in [15]. Therefore in our analysis we can use the following two results from that paper (cf. Lemmas 5.1 and 5.2 of [15]), which were obtained using (2.4), (2.8), and a representation of $\mathring{\boldsymbol{u}}$ as the sum of a regular part and a singular part.

LEMMA 3.8. *Let $\mathring{\boldsymbol{u}} \in H_0(\mathrm{curl};\Omega) \cap H(\mathrm{div}^0;\Omega)$ be the solution of (1.4). We have the following interpolation error estimate:*

$$\|\mathring{\boldsymbol{u}} - \Pi_h \mathring{\boldsymbol{u}}\|_{L_2(\Omega)} \leq C_\epsilon h^{2-\epsilon} \|\boldsymbol{f}\|_{L_2(\Omega)} \qquad \text{for any} \quad \epsilon > 0. \tag{3.12}$$

LEMMA 3.9. *Let $\mathring{\boldsymbol{u}} \in H_0(\mathrm{curl};\Omega) \cap H(\mathrm{div}^0;\Omega)$ be the solution of (1.4). We have the following interpolation error estimate:*

$$\sum_{e\in\mathcal{E}_h} \frac{[\Phi_\mu(e)]^2}{|e|} \|[\![\mathring{\boldsymbol{u}} - \Pi_h \mathring{\boldsymbol{u}}]\!]\|^2_{L_2(e)} \leq C_\epsilon h^{2-\epsilon} \|\boldsymbol{f}\|^2_{L_2(\Omega)} \tag{3.13}$$

for any $\epsilon > 0$, where $[\![\mathring{\boldsymbol{u}} - \Pi_h \mathring{\boldsymbol{u}}]\!]$ is the jump of $\mathring{\boldsymbol{u}} - \Pi_h \boldsymbol{u}$ across the interior edges of $\mathcal{T}_h$ and $[\![\mathring{\boldsymbol{u}} - \Pi_h \mathring{\boldsymbol{u}}]\!] = \mathring{\boldsymbol{u}} - \Pi_h \mathring{\boldsymbol{u}}$ on the boundary edges of $\mathcal{T}_h$.

LEMMA 3.10. *It holds that*

$$\sum_{e\in\mathcal{E}_h} |e|\,[\Phi_\mu(e)]^{-2} \|\eta - \bar{\eta}_{T_e}\|^2_{L_2(e)} \leq Ch^2 |\eta|^2_{H^1(\Omega)} \qquad \forall\, \eta \in H^1(\Omega),$$

where

$$\bar{\eta}_{T_e} = \frac{1}{|T_e|} \int_{T_e} \eta \, dx \tag{3.14}$$

is the mean of η over T_e, one of the triangles in $\mathcal{T}_h$ that has e as an edge.

Proof. This is the consequence of (2.1), (3.3), the trace theorem (with scaling), and a standard interpolation error estimate [22, 18]:

$$\begin{aligned}
&\sum_{e\in\mathcal{E}_h} |e|\,[\Phi_\mu(e)]^{-2} \|\eta - \bar{\eta}_{T_e}\|^2_{L_2(e)} \\
&\qquad \leq C \sum_{e\in\mathcal{E}_h} [\Phi_\mu(T)]^{-2} \big(\|\eta - \bar{\eta}_{T_e}\|^2_{L_2(T_e)} + h_T^2 |\eta - \bar{\eta}_{T_e}|^2_{H^1(T_e)} \big) \\
&\qquad \leq C \sum_{e\in\mathcal{E}_h} [\Phi_\mu(T)]^{-2} h_T^2 |\eta|^2_{H^1(T_e)} \leq Ch^2 |\eta|^2_{H^1(\Omega)}. \qquad \square
\end{aligned}$$

Recall that Q is the L_2 orthogonal projection operator onto $H(\mathrm{div}^0;\Omega)$. The following result will be useful in addressing the consistency error caused by the appearance of Q in (1.5).

LEMMA 3.11. *The following estimate holds:*

$$\|\boldsymbol{v} - Q\boldsymbol{v}\|_{L_2(\Omega)} \leq Ch \|\boldsymbol{v}\|_h \quad \forall\, \boldsymbol{v} \in [H_0(\mathrm{curl};\Omega) \cap H(\mathrm{div}^0;\Omega)] + V_h. \tag{3.15}$$

Proof. Let $\boldsymbol{v} \in [H_0(\mathrm{curl};\Omega) \cap H(\mathrm{div}^0;\Omega)] + V_h$ be arbitrary. Since $\boldsymbol{v} - Q\boldsymbol{v}$ belongs to $\nabla H_0^1(\Omega)$, the orthogonal complement of $H(\mathrm{div}^0;\Omega)$ in $[L_2(\Omega)]^2$, we have, by duality,

$$\|\boldsymbol{v} - Q\boldsymbol{v}\|_{L_2(\Omega)} = \sup_{\eta\in H_0^1(\Omega)\setminus\{0\}} \frac{(\boldsymbol{v} - Q\boldsymbol{v}, \nabla\eta)}{\|\nabla\eta\|_{L_2(\Omega)}} = \sup_{\eta\in H_0^1(\Omega)\setminus\{0\}} \frac{(\boldsymbol{v}, \nabla\eta)}{\|\nabla\eta\|_{L_2(\Omega)}}. \tag{3.16}$$

Let $\eta \in H_0^1(\Omega)$ be arbitrary. Since $\nabla \cdot \boldsymbol{v} = 0$ on each triangle $T \in \mathcal{T}_h$, we find, using integration by parts and the fact that $\eta\big|_{\partial\Omega} = 0$,

$$(\boldsymbol{v}, \nabla\eta) = \sum_{e\in\mathcal{E}_h^i} \int_e (\eta - \bar{\eta}_{T_e}) [\![\boldsymbol{n}\cdot\boldsymbol{v}]\!]\, ds + \sum_{e\in\mathcal{E}_h^i} \int_e \bar{\eta}_{T_e} \big(\Pi_e^0 [\![\boldsymbol{n}\cdot\boldsymbol{v}]\!]\big)\, ds = S_1 + S_2, \tag{3.17}$$

where $\bar{\eta}_{T_e}$ is defined in (3.14).

By the Cauchy–Schwarz inequality, (3.4), and Lemma 3.10, we have

$$\begin{aligned} S_1 &\le \left[\sum_{e\in\mathcal{E}_h^i} |e|[\Phi_\mu(e)]^{-2} \|\eta - \bar{\eta}_{T_e}\|_{L_2(e)}^2\right]^{1/2} \left[\sum_{e\in\mathcal{E}_h^i} \frac{[\Phi_\mu(e)]^2}{|e|} \|[\![\boldsymbol{n}\cdot\boldsymbol{v}]\!]\|_{L_2(e)}^2\right]^{1/2} \\ &\le Ch\|\nabla\eta\|_{L_2(\Omega)} \|\boldsymbol{v}\|_h. \end{aligned} \tag{3.18}$$

On the other hand, from (3.4), the Cauchy–Schwarz inequality, and a Poincaré–Friedrichs inequality, we find

$$\begin{aligned} S_2 &\le \sum_{e\in\mathcal{E}_h^i} \big(|e|^{1/2} \|\bar{\eta}_{T_e}\|_{L_2(e)}\big) \big(|e|^{-1/2} \|\Pi_e^0 [\![\boldsymbol{n}\cdot\boldsymbol{v}]\!]\|_{L_2(e)}\big) \\ &\le Ch \left[\sum_{e\in\mathcal{E}_h^i} \|\bar{\eta}_{T_e}\|_{L_2(T_e)}^2\right]^{1/2} \left[h^{-2} \sum_{e\in\mathcal{E}_h^i} \frac{1}{|e|} \|\Pi_e^0 [\![\boldsymbol{n}\cdot\boldsymbol{v}]\!]\|_{L_2(e)}^2\right]^{1/2} \qquad (3.19) \\ &\le Ch\|\eta\|_{L_2(\Omega)} \|\boldsymbol{v}\|_h \le Ch\|\nabla\eta\|_{L_2(\Omega)} \|\boldsymbol{v}\|_h. \end{aligned}$$

Here we have also used the simple fact that, if e is an edge of a triangle T, then

$$|e|\, \|q\|_{L_2(e)}^2 \le C_T \|q\|_{L_2(T)}^2 \quad \text{for any constant function } q, \tag{3.20}$$

where the positive constant C_T depends only on the shape regularity of T.

The estimate (3.15) follows from (3.16)–(3.19). ∎

4. Convergence analysis. We begin with three lemmas that provide estimates to the three terms on the right-hand side of (3.8) and (3.10).

LEMMA 4.1. *Let $\mathring{\boldsymbol{u}} \in H_0(\mathrm{curl};\Omega) \cap H(\mathrm{div}^0;\Omega)$ be the solution of (1.4). It holds that*

$$\inf_{\boldsymbol{v}\in V_h} \|\mathring{\boldsymbol{u}} - \boldsymbol{v}\|_h \le \|\mathring{\boldsymbol{u}} - \Pi_h\mathring{\boldsymbol{u}}\|_h \le C_\epsilon h^{1-\epsilon} \|\boldsymbol{f}\|_{L_2(\Omega)} \tag{4.1}$$

for any $\epsilon > 0$.

Proof. Since $\Pi_e^0 [\![\boldsymbol{n}\times(\mathring{\boldsymbol{u}} - \Pi_h\mathring{\boldsymbol{u}})]\!] = 0$ for all $e \in \mathcal{E}_h$ and $\Pi_e^0 [\![\boldsymbol{n}\cdot(\mathring{\boldsymbol{u}} - \Pi_h\mathring{\boldsymbol{u}})]\!] = 0$ for all $e \in \mathcal{E}_h^i$, we have

$$\begin{aligned} \|\mathring{\boldsymbol{u}} - \Pi_h\mathring{\boldsymbol{u}}\|_h^2 &= \|\nabla_h \times (\mathring{\boldsymbol{u}} - \Pi_h\mathring{\boldsymbol{u}})\|_{L_2(\Omega)}^2 + \|\mathring{\boldsymbol{u}} - \Pi_h\mathring{\boldsymbol{u}}\|_{L_2(\Omega)}^2 \\ &\quad + \sum_{e\in\mathcal{E}_h} \frac{[\Phi_\mu(e)]^2}{|e|} \|[\![\boldsymbol{n}\times(\mathring{\boldsymbol{u}} - \Pi_h\mathring{\boldsymbol{u}})]\!]\|_{L_2(e)}^2 \qquad (4.2) \\ &\quad + \sum_{e\in\mathcal{E}_h^i} \frac{[\Phi_\mu(e)]^2}{|e|} \|[\![\boldsymbol{n}\cdot(\mathring{\boldsymbol{u}} - \Pi_h\mathring{\boldsymbol{u}})]\!]\|_{L_2(e)}^2. \end{aligned}$$

The second term on the right-hand side of (4.2) has been estimated in Lemma 3.8, and the third and fourth terms can be estimated using Lemma 3.9. Therefore it only remains to estimate the first term.

Observe that (2.6) implies

$$\nabla_h \times (\Pi_h \mathring{\boldsymbol{u}}) = \Pi_h^0(\nabla \times \mathring{\boldsymbol{u}}), \tag{4.3}$$

where Π_h^0 is the orthogonal projection from $L_2(\Omega)$ onto the space of piecewise constant functions with respect to $\mathcal{T}_h$. It then follows from (1.6), (2.3), (4.3), and a standard interpolation error estimate [22, 18] that

$$\begin{aligned}\|\nabla_h \times (\mathring{\boldsymbol{u}} - \Pi_h \mathring{\boldsymbol{u}})\|_{L_2(\Omega)}^2 &= \|\nabla \times \mathring{\boldsymbol{u}} - \Pi_h^0(\nabla \times \mathring{\boldsymbol{u}})\|_{L_2(\Omega)}^2 \\ &\le Ch^2 |\nabla \times \mathring{\boldsymbol{u}}|_{H^1(\Omega)}^2 \le Ch^2 \|\boldsymbol{f}\|_{L_2(\Omega)}^2.\end{aligned} \tag{4.4}$$

The estimate (4.1) follows from (4.2), (4.4), and Lemmas 3.8 and 3.9. ∎

LEMMA 4.2. *Let $\mathring{\boldsymbol{u}} \in H_0(\mathrm{curl};\Omega) \cap H(\mathrm{div}^0;\Omega)$ be the solution of (1.4) and let $\mathring{\boldsymbol{u}}_h \in V_h$ satisfy (3.1). It holds that*

$$\sup_{\boldsymbol{w} \in V_h \setminus \{\boldsymbol{0}\}} \frac{a_h(\mathring{\boldsymbol{u}} - \mathring{\boldsymbol{u}}_h, \boldsymbol{w})}{\|\boldsymbol{w}\|_h} \le Ch \|\boldsymbol{f}\|_{L_2(\Omega)}. \tag{4.5}$$

Proof. Let $\boldsymbol{w} \in V_h$ be arbitrary. Using integration by parts, the discrete problem (3.1), the strong form of the reduced curl-curl problem (1.5), and the fact that $\nabla_h \cdot \boldsymbol{w} = 0$, we find

$$\begin{aligned}a_h(\mathring{\boldsymbol{u}} - \mathring{\boldsymbol{u}}_h, \boldsymbol{w}) &= a_h(\mathring{\boldsymbol{u}}, \boldsymbol{w}) - (\boldsymbol{f}, \boldsymbol{w}) \\ &= (Q\boldsymbol{f} - \boldsymbol{f}, \boldsymbol{w}) + \sum_{T \in \mathcal{T}_h} \int_{\partial T} (\nabla \times \mathring{\boldsymbol{u}})(\boldsymbol{n}_T \times \boldsymbol{w}_T)\, ds,\end{aligned} \tag{4.6}$$

where $w_T = w\big|_T$ and $\boldsymbol{n}_T$ is the unit outer normal along ∂T. We see from (4.6) that there are two sources for the inconsistency of the scheme defined by (3.1), namely the projection Q that appears in (1.5) and the discontinuity of the vector fields in V_h.

Equation (4.6) can be rewritten as

$$\begin{aligned}a_h(\mathring{\boldsymbol{u}} - \mathring{\boldsymbol{u}}_h, \boldsymbol{w}) &= (\boldsymbol{f}, Q\boldsymbol{w} - \boldsymbol{w}) + \sum_{e \in \mathcal{E}_h} \int_e (\nabla \times \mathring{\boldsymbol{u}}) [\![\boldsymbol{n} \times \boldsymbol{w}]\!]\, ds \\ &= (\boldsymbol{f}, Q\boldsymbol{w} - \boldsymbol{w}) + \sum_{e \in \mathcal{E}_h} \int_e (\nabla \times \mathring{\boldsymbol{u}} - \overline{(\nabla \times \mathring{\boldsymbol{u}})}_{T_e}) [\![\boldsymbol{n} \times \boldsymbol{w}]\!]\, ds \\ &\quad + \sum_{e \in \mathcal{E}_h} \int_e \overline{(\nabla \times \mathring{\boldsymbol{u}})}_{T_e} (\Pi_e^0 [\![\boldsymbol{n} \times \boldsymbol{w}]\!])\, ds,\end{aligned} \tag{4.7}$$

where $\overline{(\nabla \times \mathring{\boldsymbol{u}})}_{T_e}$ is the mean of $\nabla \times \mathring{\boldsymbol{u}}$ on one of the triangles $\mathcal{T}_e \in \mathcal{T}_h$ that has e as an edge. The first two terms on the right-hand side of (4.7) satisfy the estimate

$$(\boldsymbol{f}, Q\boldsymbol{w} - \boldsymbol{w}) + \sum_{e \in \mathcal{E}_h} \int_e (\nabla \times \mathring{\boldsymbol{u}} - \overline{(\nabla \times \mathring{\boldsymbol{u}})}_{T_e}) [\![\boldsymbol{n} \times \boldsymbol{w}]\!]\, ds \le Ch \|\boldsymbol{f}\|_{L_2(\Omega)} \|\boldsymbol{w}\|_h. \tag{4.8}$$

The derivation of (4.8), which is based on Lemmas 3.10 and 3.11 and (1.6), can be found in the proof of Lemma 6.2 in [15].

Using the Cauchy–Schwarz inequality, (1.6), (3.4), and (3.20), the third term on the right-hand side of (4.7) can be estimated as follows:

$$\sum_{e\in\mathcal{E}_h}\int_e \overline{(\nabla\times\mathring{\boldsymbol{u}})}_{T_e}\big(\Pi_e^0[\![\boldsymbol{n}\times\boldsymbol{w}]\!]\big)\,ds$$

(4.9)

$$\begin{aligned}
&\le \sum_{e\in\mathcal{E}_h}\big(|e|^{1/2}\|\overline{(\nabla\times\mathring{\boldsymbol{u}})}_{T_e}\|_{L_2(e)}\big)\big(|e|^{-1/2}\|\Pi_e^0[\![\boldsymbol{n}\times\boldsymbol{w}]\!]\|_{L_2(e)}\big)\\
&\le Ch\left(\sum_{e\in\mathcal{E}_h}\|\overline{(\nabla\times\mathring{\boldsymbol{u}})}_{T_e}\|^2_{L_2(T_e)}\right)^{1/2}\left(h^{-2}\sum_{e\in\mathcal{E}_h}\frac{1}{|e|}\|\Pi_e^0[\![\boldsymbol{n}\times\boldsymbol{w}]\!]\|^2_{L_2(e)}\right)^{1/2}\\
&\le Ch\|\nabla\times\mathring{\boldsymbol{u}}\|_{L_2(\Omega)}\|\boldsymbol{w}\|_h \le Ch\|\boldsymbol{f}\|_{L_2(\Omega)}\|\boldsymbol{w}\|_h.
\end{aligned}$$

The estimate (4.5) follows from (4.7)–(4.9). ∎

LEMMA 4.3. *Let $\mathring{\boldsymbol{u}}\in H_0(\mathrm{curl};\Omega)\cap H(\mathrm{div}^0;\Omega)$ be the solution of (1.4) and let $\mathring{\boldsymbol{u}}_h\in V_h$ satisfy (3.1). It holds that*

$$\|\mathring{\boldsymbol{u}}-\mathring{\boldsymbol{u}}_h\|_{L_2(\Omega)}\le C_\epsilon\big(h^{2-\epsilon}\|\boldsymbol{f}\|_{L_2(\Omega)}+h^{1-\epsilon}\|\mathring{\boldsymbol{u}}-\mathring{\boldsymbol{u}}_h\|_h\big) \tag{4.10}$$

for any $\epsilon>0$.

Proof. We use a duality argument. Let $\mathring{\boldsymbol{z}}\in H_0(\mathrm{curl};\Omega)\cap H(\mathrm{div}^0;\Omega)$ satisfy the reduced curl-curl problem

$$a_h(\boldsymbol{v},\mathring{\boldsymbol{z}})=(\boldsymbol{v},\mathring{\boldsymbol{u}}-\mathring{\boldsymbol{u}}_h)\qquad\forall\,\boldsymbol{v}\in H_0(\mathrm{curl};\Omega)\cap H(\mathrm{div}^0;\Omega). \tag{4.11}$$

The strong form of (4.11) is

$$\nabla\times(\nabla\times\mathring{\boldsymbol{z}})+\alpha\mathring{\boldsymbol{z}}=Q(\mathring{\boldsymbol{u}}-\mathring{\boldsymbol{u}}_h), \tag{4.12}$$

and we have the following analogue of (1.6):

$$\|\nabla\times\mathring{\boldsymbol{z}}\|_{H^1(\Omega)}\le C_\Omega\|\mathring{\boldsymbol{u}}-\mathring{\boldsymbol{u}}_h\|_{L_2(\Omega)}. \tag{4.13}$$

It follows from (4.12) and integration by parts that

$$a_h(\mathring{\boldsymbol{u}}_h,\mathring{\boldsymbol{z}})=(\mathring{\boldsymbol{u}}_h,Q(\mathring{\boldsymbol{u}}-\mathring{\boldsymbol{u}}_h))+\sum_{e\in\mathcal{E}_h}\int_e(\nabla\times\mathring{\boldsymbol{z}})[\![\boldsymbol{n}\times\mathring{\boldsymbol{u}}_h]\!]\,ds. \tag{4.14}$$

From (4.11) and (4.14), we have

$$\begin{aligned}
\|\mathring{\boldsymbol{u}}-\mathring{\boldsymbol{u}}_h\|^2_{L_2(\Omega)}&=(\mathring{\boldsymbol{u}},\mathring{\boldsymbol{u}}-\mathring{\boldsymbol{u}}_h)-(\mathring{\boldsymbol{u}}_h,\mathring{\boldsymbol{u}}-\mathring{\boldsymbol{u}}_h)\\
&=a_h(\mathring{\boldsymbol{u}}-\mathring{\boldsymbol{u}}_h,\mathring{\boldsymbol{z}})+a_h(\mathring{\boldsymbol{u}}_h,\mathring{\boldsymbol{z}})-(\mathring{\boldsymbol{u}}_h,\mathring{\boldsymbol{u}}-\mathring{\boldsymbol{u}}_h)\\
&=a_h(\mathring{\boldsymbol{u}}-\mathring{\boldsymbol{u}}_h,\mathring{\boldsymbol{z}})-(\mathring{\boldsymbol{u}}_h,(I-Q)(\mathring{\boldsymbol{u}}-\mathring{\boldsymbol{u}}_h))\\
&\quad+\sum_{e\in\mathcal{E}_h}\int_e(\nabla\times\mathring{\boldsymbol{z}})[\![\boldsymbol{n}\times\mathring{\boldsymbol{u}}_h]\!]\,ds.
\end{aligned} \tag{4.15}$$

We will estimate the three terms on the right-hand side of (4.15) separately.

Using (4.7) and the fact that $[\![\boldsymbol{n}\times(\Pi_h\mathring{\boldsymbol{z}})]\!]$ vanishes at the midpoints of all $e\in\mathcal{E}_h$, we can rewrite the first term as

$$\begin{aligned} a_h(\mathring{\boldsymbol{u}}-\mathring{\boldsymbol{u}}_h,\mathring{\boldsymbol{z}}) &= a_h(\mathring{\boldsymbol{u}}-\mathring{\boldsymbol{u}}_h,\mathring{\boldsymbol{z}}-\Pi_h\mathring{\boldsymbol{z}})+a_h(\mathring{\boldsymbol{u}}-\mathring{\boldsymbol{u}}_h,\Pi_h\mathring{\boldsymbol{z}}) \\ &= a_h(\mathring{\boldsymbol{u}}-\mathring{\boldsymbol{u}}_h,\mathring{\boldsymbol{z}}-\Pi_h\mathring{\boldsymbol{z}})+(\boldsymbol{f},Q\Pi_h\mathring{\boldsymbol{z}}-\Pi_h\mathring{\boldsymbol{z}}) \\ &\quad+\sum_{e\in\mathcal{E}_h}\int_e(\nabla\times\mathring{\boldsymbol{u}}-\overline{(\nabla\times\mathring{\boldsymbol{u}})}_{T_e})[\![\boldsymbol{n}\times(\Pi_h\mathring{\boldsymbol{z}})]\!]\,ds, \end{aligned} \tag{4.16}$$

where $\overline{(\nabla\times\mathring{\boldsymbol{u}})}_{T_e}$ is the mean of $\nabla\times\mathring{\boldsymbol{u}}$ on one of the triangles $T_e\in\mathcal{T}_h$ that has e as an edge. Using the expression (4.16), the following estimate was obtained in the proof of Lemma 6.5 of [15]:

$$a_h(\mathring{\boldsymbol{u}}-\mathring{\boldsymbol{u}}_h,\mathring{\boldsymbol{z}})\le C_\epsilon\big(h^{2-\epsilon}\|\boldsymbol{f}\|_{L_2(\Omega)}+h^{1-\epsilon}\|\mathring{\boldsymbol{u}}-\mathring{\boldsymbol{u}}_h\|_h\big)\|\mathring{\boldsymbol{u}}-\mathring{\boldsymbol{u}}_h\|_{L_2(\Omega)}. \tag{4.17}$$

Since $(I-Q)\mathring{\boldsymbol{u}}=\boldsymbol{0}$, the second term on the right-hand side of (4.15) can be estimated by Lemma 3.11:

$$\begin{aligned} -\big(\mathring{\boldsymbol{u}}_h,(I-Q)(\mathring{\boldsymbol{u}}-\mathring{\boldsymbol{u}}_h)\big) &= \big(\mathring{\boldsymbol{u}}-\mathring{\boldsymbol{u}}_h,(I-Q)(\mathring{\boldsymbol{u}}-\mathring{\boldsymbol{u}}_h)\big) \\ &\le C\|\mathring{\boldsymbol{u}}-\mathring{\boldsymbol{u}}_h\|_{L_2(\Omega)}\big(h\|\mathring{\boldsymbol{u}}-\mathring{\boldsymbol{u}}_h\|_h\big). \end{aligned} \tag{4.18}$$

Finally we estimate the third term on the right-hand side of (4.15). We have

$$\begin{aligned} \sum_{e\in\mathcal{E}_h}\int_e(\nabla\times\mathring{\boldsymbol{z}})[\![\boldsymbol{n}\times\mathring{\boldsymbol{u}}_h]\!]\,ds &= \sum_{e\in\mathcal{E}_h}\int_e\big(\nabla\times\mathring{\boldsymbol{z}}-\overline{(\nabla\times\mathring{\boldsymbol{z}})}_{T_e}\big)[\![\boldsymbol{n}\times\mathring{\boldsymbol{u}}_h]\!]\,ds \\ &\quad+\sum_{e\in\mathcal{E}_h}\int_e\overline{(\nabla\times\mathring{\boldsymbol{z}})}_{T_e}\big(\Pi_e^0[\![\boldsymbol{n}\times\mathring{\boldsymbol{u}}_h]\!]\big)\,ds, \end{aligned} \tag{4.19}$$

where $\overline{(\nabla\times\mathring{\boldsymbol{z}})}_{T_e}$ is the mean of $\nabla\times\mathring{\boldsymbol{z}}$ on a triangle $T_e\in\mathcal{T}_h$ that has e as an edge. The following estimate can be found in the proof of Lemma 6.5 of [15]:

$$\sum_{e\in\mathcal{E}_h}\int_e\big(\nabla\times\mathring{\boldsymbol{z}}-\overline{(\nabla\times\mathring{\boldsymbol{z}})}_{T_e}\big)[\![\boldsymbol{n}\times\mathring{\boldsymbol{u}}_h]\!]\,ds\le Ch\|\mathring{\boldsymbol{u}}-\mathring{\boldsymbol{u}}_h\|_{L_2(\Omega)}\|\mathring{\boldsymbol{u}}-\mathring{\boldsymbol{u}}_h\|_h. \tag{4.20}$$

On the other hand, we obtain, by the Cauchy–Schwarz inequality, (3.4), (3.20), and (4.13),

$$\begin{aligned} &\sum_{e\in\mathcal{E}_h}\int_e\overline{(\nabla\times\mathring{\boldsymbol{z}})}_{T_e}\big(\Pi_e^0[\![\boldsymbol{n}\times\mathring{\boldsymbol{u}}_h]\!]\big)\,ds \\ &\quad=\sum_{e\in\mathcal{E}_h}\int_e\overline{(\nabla\times\mathring{\boldsymbol{z}})}_{T_e}\big(\Pi_e^0[\![\boldsymbol{n}\times(\mathring{\boldsymbol{u}}_h-\mathring{\boldsymbol{u}})]\!]\big)\,ds \\ &\quad\le Ch\|\nabla\times\mathring{\boldsymbol{z}}\|_{L_2(\Omega)}\|\mathring{\boldsymbol{u}}-\mathring{\boldsymbol{u}}_h\|_h\le Ch\|\mathring{\boldsymbol{u}}-\mathring{\boldsymbol{u}}_h\|_{L_2(\Omega)}\|\mathring{\boldsymbol{u}}-\mathring{\boldsymbol{u}}_h\|_h. \end{aligned} \tag{4.21}$$

The estimate (4.10) follows from (4.15) and (4.17)–(4.21). ∎

In the case where $\alpha>0$, the following theorem is an immediate consequence of Lemmas 3.5, 4.1, 4.2, and 4.3.

THEOREM 4.4. *Let α be positive. The following estimates hold for the solution $\mathring{\boldsymbol{u}}_h$ of* (3.1):

$$\|\mathring{\boldsymbol{u}} - \mathring{\boldsymbol{u}}_h\|_h \leq C_\epsilon h^{1-\epsilon} \|\boldsymbol{f}\|_{L_2(\Omega)} \qquad \text{for any} \quad \epsilon > 0, \tag{4.22}$$

$$\|\mathring{\boldsymbol{u}} - \mathring{\boldsymbol{u}}_h\|_{L_2(\Omega)} \leq C_\epsilon h^{2-\epsilon} \|\boldsymbol{f}\|_{L_2(\Omega)} \qquad \text{for any} \quad \epsilon > 0. \tag{4.23}$$

In the case where $\alpha \leq 0$, we have the following convergence theorem for the scheme (3.1).

THEOREM 4.5. *Assume that $-\alpha \geq 0$ is not a Maxwell eigenvalue. There exists a positive number h_* such that the discrete problem* (3.1) *is uniquely solvable for all $h \leq h_*$, in which case the following discretization error estimates are valid:*

$$\|\mathring{\boldsymbol{u}} - \mathring{\boldsymbol{u}}_h\|_h \leq C_\epsilon h^{1-\epsilon} \|\boldsymbol{f}\|_{L_2(\Omega)} \qquad \text{for any} \quad \epsilon > 0, \tag{4.24}$$

$$\|\mathring{\boldsymbol{u}} - \mathring{\boldsymbol{u}}_h\|_{L_2(\Omega)} \leq C_\epsilon h^{2-\epsilon} \|\boldsymbol{f}\|_{L_2(\Omega)} \qquad \text{for any} \quad \epsilon > 0. \tag{4.25}$$

Proof. We follow the approach of Schatz [44] for indefinite problems. Assuming $\mathring{\boldsymbol{u}}_h$ satisfies (3.1), it follows from (3.10) and Lemmas 4.1–4.3 that

$$\|\mathring{\boldsymbol{u}} - \mathring{\boldsymbol{u}}_h\|_h \leq C_\epsilon h^{1-\epsilon} \big(\|\boldsymbol{f}\|_{L_2(\Omega)} + \|\mathring{\boldsymbol{u}} - \mathring{\boldsymbol{u}}_h\|_h \big) \quad \text{for any} \quad \epsilon > 0. \tag{4.26}$$

By choosing an $\epsilon_* > 0$, we deduce from (4.26) that, for $h \leq h_* = 1/(2C_{\epsilon_*})^{1/(1-\epsilon_*)}$,

$$\begin{aligned} \|\mathring{\boldsymbol{u}} - \mathring{\boldsymbol{u}}_h\|_h &\leq C_{\epsilon_*} h^{1-\epsilon_*} \big(\|\boldsymbol{f}\|_{L_2(\Omega)} + \|\mathring{\boldsymbol{u}} - \mathring{\boldsymbol{u}}_h\|_h \big) \\ &\leq C_{\epsilon_*} h^{1-\epsilon_*} \|\boldsymbol{f}\|_{L_2(\Omega)} + C_{\epsilon_*} h_*^{1-\epsilon_*} \|\mathring{\boldsymbol{u}} - \mathring{\boldsymbol{u}}_h\|_h \\ &\leq C_{\epsilon_*} h^{1-\epsilon_*} \|\boldsymbol{f}\|_{L_2(\Omega)} + \frac{1}{2} \|\mathring{\boldsymbol{u}} - \mathring{\boldsymbol{u}}_h\|_h, \end{aligned}$$

and hence

$$\|\mathring{\boldsymbol{u}} - \mathring{\boldsymbol{u}}_h\|_h \leq 2C_{\epsilon_*} h^{1-\epsilon_*} \|\boldsymbol{f}\|_{L_2(\Omega)}. \tag{4.27}$$

Therefore, any solution $\mathring{\boldsymbol{z}}_h \in V_h$ of the homogeneous discrete problem

$$a_h(\mathring{\boldsymbol{z}}_h, \boldsymbol{v}) = 0 \qquad \forall\, \boldsymbol{v} \in V_h, \tag{4.28}$$

which corresponds to the special case where $\boldsymbol{f} = \boldsymbol{0} = \mathring{\boldsymbol{z}}$, will satisfy the following special case of (4.27):

$$\|\mathring{\boldsymbol{z}}_h\|_h \leq 0.$$

Hence the only solution of (4.28) is the trivial solution and the discrete problem (3.1) is uniquely solvable for $h \leq h_*$.

The energy error estimate (4.24) now follows from (4.26) and (4.27), and the L_2 error estimate (4.25) follows from Lemma 4.3 and (4.24). ∎

5. Application to the Maxwell eigenproblem. Given any $\boldsymbol{f} \in [L_2(\Omega)]^2$, we define $T\boldsymbol{f} \in H_0(\mathrm{curl};\Omega) \cap H(\mathrm{div}^0;\Omega)$ by the condition that

$$(\nabla \times (T\boldsymbol{f}), \nabla \times \boldsymbol{v}) + (T\boldsymbol{f}, \boldsymbol{v}) = (\boldsymbol{f}, \boldsymbol{v}) \qquad \forall\, \boldsymbol{v} \in H_0(\mathrm{curl};\Omega) \cap H(\mathrm{div}^0;\Omega). \tag{5.1}$$

Clearly T is a bounded linear operator from $[L_2(\Omega)]^2$ into $H_0(\mathrm{curl};\Omega) \cap H(\mathrm{div}^0;\Omega)$. Since $H_0(\mathrm{curl};\Omega) \cap H(\mathrm{div}^0;\Omega)$ is a compact subspace of $[L_2(\Omega)]^2$ (cf. [23]), the operator $T : [L_2(\Omega)]^2 \longrightarrow [L_2(\Omega)]^2$ is symmetric, positive, and compact. Moreover, $(\lambda, \mathring{\boldsymbol{u}})$ satisfy the Maxwell eigenproblem (1.7) if and only if

$$T\mathring{\boldsymbol{u}} = \frac{1}{1+\lambda}\mathring{\boldsymbol{u}}. \tag{5.2}$$

Similarly, let $T_h\boldsymbol{f} \in V_h$ be defined by the condition

$$a_{h,1}(T_h\boldsymbol{f}, \boldsymbol{v}) = (\boldsymbol{f}, \boldsymbol{v}) \qquad \forall\, \boldsymbol{v} \in V_h, \tag{5.3}$$

where $a_{h,1}(\cdot,\cdot)$ is the bilinear form $a_h(\cdot,\cdot)$ in (3.2) with $\alpha = 1$; then

$$T_h\mathring{\boldsymbol{u}}_h = \frac{1}{1+\lambda_h}\mathring{\boldsymbol{u}}_h \tag{5.4}$$

is equivalent to

$$a_{h,0}(\mathring{\boldsymbol{u}}_h, \boldsymbol{v}) = \lambda_h(\mathring{\boldsymbol{u}}_h, \boldsymbol{v}) \qquad \forall\, \boldsymbol{v} \in V_h, \tag{5.5}$$

where $a_{h,0}(\cdot,\cdot)$ is the bilinear form $a_h(\cdot,\cdot)$ in (3.2) with $\alpha = 0$.

From Theorem 4.4 we have

$$\|(T - T_h)\boldsymbol{f}\|_{L_2(\Omega)} \le C_\epsilon h^{2-\epsilon}\|\boldsymbol{f}\|_{L_2(\Omega)} \tag{5.6}$$

for all $\boldsymbol{f} \in [L_2(\Omega)]^2$ and

$$\|(T - T_h)\boldsymbol{f}\|_h \le C_\epsilon h^{1-\epsilon}\|\boldsymbol{f}\|_{L_2(\Omega)} \le C_\epsilon h^{1-\epsilon}\|\boldsymbol{f}\|_h \tag{5.7}$$

for all $\boldsymbol{f} \in H_0(\mathrm{curl};\Omega) \cap H(\mathrm{div}^0;\Omega) + V_h$. Thus the symmetric finite rank operator T_h converges uniformly to the symmetric positive compact operator T as $h \downarrow 0$, which implies that the classical theory of spectral approximation [39, 7] can be applied to the approximation of the eigenvalues and eigenfunctions of T by the eigenvalues and eigenfunctions of T_h. Hence we have the following result through the connections between (1.7) and (5.2) and between (5.5) and (5.4).

THEOREM 5.1. *Let $0 \le \lambda_1 \le \lambda_2 \le \cdots$ be the eigenvalues of (1.7), let $\lambda = \lambda_j = \lambda_{j+1} = \cdots = \lambda_{j+m-1}$ be an eigenvalue with multiplicity m, and let $V_\lambda \subset H_0(\mathrm{curl};\Omega) \cap H(\mathrm{div}^0;\Omega)$ be the corresponding m-dimensional eigenspace. Let $\lambda_{h,1} \le \lambda_{h,2} \le \cdots$ be the eigenvalues of (5.5). Then, as $h \downarrow 0$, we have*

$$|\lambda_{h,\ell} - \lambda| \le C_{\lambda,\epsilon}h^{2-\epsilon}, \qquad \ell = j, \ldots, j+m-1. \tag{5.8}$$

Furthermore, if $V_{h,\lambda} \subset V_h$ is the space spanned by the eigenfunctions corresponding to $\lambda_{h,j}, \ldots, \lambda_{h,j+m-1}$, then the gap between V_λ and $V_{h,\lambda}$ goes to zero at the rate of $C_\epsilon h^{2-\epsilon}$ in the L_2 norm and at the rate of $C_\epsilon h^{1-\epsilon}$ in the norm $\|\cdot\|_h$.

Proof. Let E_λ (resp., $E_{h,\lambda}$) be the L_2 orthogonal projection onto V_λ (resp., $V_{h,\lambda}$). It follows from (5.6) and (5.7) and the classical theory of spectral approximation of compact operators [39, 7] that

$$\|(E_\lambda - E_{h,\lambda})\boldsymbol{w}\|_{L_2(\Omega)} \leq C_\epsilon h^{2-\epsilon}\|\boldsymbol{w}\|_{L_2(\Omega)} \tag{5.9}$$

for all $\boldsymbol{w} \in [L_2(\Omega)]^2$ and

$$\|(E_\lambda - E_{h,\lambda})\boldsymbol{w}\|_h \leq C_\epsilon h^{1-\epsilon}\|\boldsymbol{w}\|_h \tag{5.10}$$

for all $\boldsymbol{w} \in H_0(\mathrm{curl};\Omega) \cap H(\mathrm{div}^0;\Omega) + V_h$.

Let $\boldsymbol{x} \in V_{h,\lambda}$ be a unit eigenfunction of $\lambda_{h,\ell}$ for some ℓ between j and $j+m-1$. Then we have

$$(T_h\boldsymbol{x},\boldsymbol{x}) = \mu_{h,\ell} \quad \text{and} \quad \|\boldsymbol{x}\|_{L_2(\Omega)} = 1, \tag{5.11}$$

where (cf. (5.4))

$$\mu_{h,\ell} = (1+\lambda_{h,\ell})^{-1}. \tag{5.12}$$

Let $\hat{\boldsymbol{x}} = E_\lambda\boldsymbol{x}$ and $\hat{\boldsymbol{y}} = \hat{\boldsymbol{x}} - \boldsymbol{x}$. Then $\hat{\boldsymbol{x}}$ and $\hat{\boldsymbol{y}}$ are orthogonal with respect to both the L_2 inner product and the inner product $(T\cdot,\cdot)$, and the estimate (5.9) implies that

$$\|\hat{\boldsymbol{y}}\|_{L_2(\Omega)} = \|(E_\lambda - E_{h,\lambda})\boldsymbol{x}\|_{L_2(\Omega)} \leq C_\epsilon h^{2-\epsilon}. \tag{5.13}$$

In particular, it follows from Pythagoras' theorem with respect to the L_2 inner product that

$$1 - \|\hat{\boldsymbol{x}}\|^2_{L_2(\Omega)} = \|\boldsymbol{x}\|^2_{L_2(\Omega)} - \|\hat{\boldsymbol{x}}\|^2_{L_2(\Omega)} = \|\hat{\boldsymbol{y}}\|^2_{L_2(\Omega)} \leq C_\epsilon h^{4-\epsilon}. \tag{5.14}$$

Let $\hat{\boldsymbol{e}} = \hat{\boldsymbol{x}}/\|\hat{\boldsymbol{x}}\|_{L_2(\Omega)}$. Then $\hat{\boldsymbol{e}}$ is a unit eigenfunction of T corresponding to the eigenvalue (cf. (5.2))

$$\mu = (1+\lambda)^{-1}, \tag{5.15}$$

and we have

$$|\mu - \mu_{h,\ell}| = \big|(T\hat{\boldsymbol{e}},\hat{\boldsymbol{e}}) - (T_h\boldsymbol{x},\boldsymbol{x})\big| \leq \big|((T-T_h)\boldsymbol{x},\boldsymbol{x})\big| + \big|(T\hat{\boldsymbol{e}},\hat{\boldsymbol{e}}) - (T\boldsymbol{x},\boldsymbol{x})\big|. \tag{5.16}$$

From (5.6) we have

$$\big|((T-T_h)\boldsymbol{x},\boldsymbol{x})\big| \leq C_\epsilon h^{2-\epsilon}, \tag{5.17}$$

and it follows from Pythagoras' theorem with respect to the inner product $(T\cdot,\cdot)$ that

$$\begin{aligned}\big|(T\hat{\boldsymbol{e}},\hat{\boldsymbol{e}}) - (T\boldsymbol{x},\boldsymbol{x})\big| &= \big|(T\hat{\boldsymbol{e}},\hat{\boldsymbol{e}}) - (T\hat{\boldsymbol{x}},\hat{\boldsymbol{x}}) - (T\hat{\boldsymbol{y}},\hat{\boldsymbol{y}})\big| \\ &\leq (1 - \|\hat{\boldsymbol{x}}\|^2_{L_2(\Omega)})(T\hat{\boldsymbol{e}},\hat{\boldsymbol{e}}) + (T\hat{\boldsymbol{y}},\hat{\boldsymbol{y}}).\end{aligned} \tag{5.18}$$

Combining (5.13), (5.14), and (5.18), we find

$$\big|(T\hat{\boldsymbol{e}},\hat{\boldsymbol{e}}) - (T\boldsymbol{x},\boldsymbol{x})\big| \leq C_\epsilon h^{4-\epsilon},$$

which, together with (5.16) and (5.17), implies

$$|\mu - \mu_{h,\ell}| \le C_\epsilon h^{2-\epsilon}. \tag{5.19}$$

The estimate (5.8) follows from (5.12), (5.15), and (5.19).

Recall that the gap $\hat{\delta}(M,N)$ between two subspaces M and N of a normed linear space $(X, \|\cdot\|_X)$ is defined by (cf. [39])

$$\hat{\delta}(M,N) = \max(\delta(M,N), \delta(N,M)),$$

where

$$\delta(M,N) = \sup_{\substack{x\in M \\ \|x\|_X=1}} \inf_{y\in N} \|x-y\|_X.$$

Therefore the statements about the gap between V_λ and $V_{h,\lambda}$ follow immediately from (5.9) and (5.10). ∎

Remark 5.2. The compactness of the solution operator T and the existence of the uniform estimates (5.6) and (5.7) greatly simplify the analysis of the Maxwell eigenproblem. These ingredients are absent from Maxwell spectral approximations based on the full curl-curl problem and hence their justifications are much more involved [10, 11, 8, 20, 21, 9, 19, 12].

6. Numerical results. In this section, we report a series of numerical examples that corroborate our theoretical results. Besides the L_2 error $\|\mathring{\boldsymbol{u}} - \mathring{\boldsymbol{u}}_h\|_{L_2(\Omega)}$ and the energy error $\|\mathring{\boldsymbol{u}} - \mathring{\boldsymbol{u}}_h\|_h$, we also report the errors measured in the seminorm $|\cdot|_{\mathrm{curl}}$ defined by

$$|\boldsymbol{v}|_{\mathrm{curl}} = \|\nabla_h \times \boldsymbol{v}\|_{L_2(\Omega)}.$$

6.1. Source problems. We first demonstrate the performance of our scheme for the source problems where we take α to be $-k^2$ for all the computations in this subsection.

In the first experiment, we check the convergence behavior of our numerical scheme (3.1) on the square $(0, 0.5)^2$ with uniform meshes, where the exact solution is

$$\mathring{\boldsymbol{u}} = [y(y-0.5)\sin(ky), x(x-0.5)\cos(kx)] \tag{6.1}$$

for $k = 0$, 1, and 10. The results tabulated in Table 6.1 confirm the estimates (4.24) and (4.25). Observe also that, as expected, finer meshes are needed for computing satisfactory approximate solutions when the wave numbers become larger.

Since our numerical scheme is designed for solving the reduced curl-curl problem (1.5), its performance should not be affected by the addition to the right-hand side of a gradient term ∇G where $G \in H_0^1(\Omega)$. This is demonstrated by our second experiment. Here we add ∇G with

$$G(x,y) = xy(x-0.5)(y-0.5)\sin(x+y) \tag{6.2}$$

to the right-hand side

$$\boldsymbol{f} = \nabla \times (\nabla \times \mathring{\boldsymbol{u}}) - \mathring{\boldsymbol{u}} \tag{6.3}$$

of the problem in the first experiment (with $k = 1$) and compare their performance. The results are reported in Table 6.2.

TABLE 6.3

Loss of convergence without the last two stabilizing terms in the scheme (3.1)*. The computation is on the square* $(0,0.5)^2$ *with uniform meshes and the exact solution* $\mathring{\boldsymbol{u}}$ *is given by* (6.1) *with* $k=1$.

h	$\frac{\|\mathring{\boldsymbol{u}}-\mathring{\boldsymbol{u}}_h\|_{L_2(\Omega)}}{\|\mathring{\boldsymbol{u}}\|_{L_2(\Omega)}}$	Order	$\frac{\|\mathring{\boldsymbol{u}}-\mathring{\boldsymbol{u}}_h\|_{\mathrm{curl}}}{\|\mathring{\boldsymbol{u}}\|_{\mathrm{curl}}}$	Order
1/10	5.17E−00	—	2.61E−01	—
1/20	4.91E−00	0.22	1.71E−01	0.61
1/40	4.78E−00	0.04	1.33E−01	0.37
1/80	4.69E−00	0.03	1.20E−01	0.15

Note that the scheme (3.1) differs from the one proposed in [15] because of the last two stabilizing terms. In the third experiment, we show that these two terms are necessary for the convergence of our method due to the lack of continuity of the approximating vectors across the element interfaces. See Table 6.3 for the numerical evidence.

TABLE 6.4

Convergence of the scheme (3.1) *with graded meshes on the L-shaped domain* $(-0.5,0.5)^2 \setminus [0,0.5]^2$ *with* $k=1$ *and exact solution* $\mathring{\boldsymbol{u}}$ *given by* (6.4).

h	$\frac{\|\mathring{\boldsymbol{u}}-\mathring{\boldsymbol{u}}_h\|_{L_2(\Omega)}}{\|\mathring{\boldsymbol{u}}\|_{L_2(\Omega)}}$	Order	$\frac{\|\mathring{\boldsymbol{u}}-\mathring{\boldsymbol{u}}_h\|_h}{\|\mathring{\boldsymbol{u}}\|_h}$	Order	$\frac{\lvert\mathring{\boldsymbol{u}}-\mathring{\boldsymbol{u}}_h\rvert_{\mathrm{curl}}}{\lvert\mathring{\boldsymbol{u}}\rvert_{\mathrm{curl}}}$	Order
1/4	1.77E+02	—	2.20E+01	—	9.13E−00	—
1/8	4.22E+01	2.07	7.76E−00	1.50	4.52E−00	1.02
1/16	3.42E−00	3.63	2.24E−00	1.79	7.86E−01	2.52
1/32	7.10E−01	2.27	1.09E−00	1.04	4.27E−01	0.88
1/64	1.77E−01	2.01	5.53E−01	0.98	2.34E−01	0.86

The last example in this subsection demonstrates the convergence behavior of our scheme on the L-shaped domain $(-0.5,0.5)^2 \setminus [0,0.5]^2$ with corners $(0.5,0)$, $(0,0)$, $(0,0.5)$, $(-0.5,0.5)$, $(-0.5,-0.5)$, and $(0.5,-0.5)$. We take $k=1$ and the exact solution is chosen to be

$$\mathring{\boldsymbol{u}} = \nabla \times \Big(r^{2/3} \cos\Big(\frac{2}{3}\theta - \frac{\pi}{3}\Big)\phi(r/0.5)\Big), \tag{6.4}$$

where (r,θ) are the polar coordinates at the origin and the cutoff function is given by

$$\phi(r) = \begin{cases} 1, & r \le 0.25, \\ -16(r-0.75)^3 & \\ \quad \times\big[5+15(r-0.75)+12(r-0.75)^2\big], & 0.25 \le r \le 0.75, \\ 0, & r \ge 0.75. \end{cases}$$

The meshes are graded around the reentrant corner with the grading parameter equal to 1/3. The results are tabulated in Table 6.4 and they agree with the estimates (4.24) and (4.25).

6.2. Maxwell eigenproblem. In this subsection, we report the numerical results for the Maxwell eigenproblem.

In the first experiment, the computation is carried out on the square domain $(0,\pi)^2$ with uniform meshes. In this case, the exact eigenvalues are r^2+s^2, $r,s = 0,1,2,3,4,\ldots$ with $r^2+s^2 \neq 0$. For instance, the first ten eigenvalues are 1, 1, 2, 4, 4, 5, 5, 8, 9, 9. In Figure 6.1, we plot the first twenty numerical eigenvalues versus the parameter $n=\pi/h$. The symbol "o" on the right side denotes the exact eigenvalue, and "(2)" indicates that the multiplicity of the eigenvalue is 2. All the numerical approximations converge at a second order rate. To save space, only the first five numerical eigenvalues are included in Table 6.5. Furthermore, there is no spurious eigenvalue in our results.

In the second experiment, we compute the eigenvalues for the L-shaped domain $(-0.5,0.5)^2 \setminus [0,0.5]^2$ and the meshes are graded around the reentrant corner with the grading parameter equal to 1/3. Table 6.6 contains the first five numerical eigenvalues, which show second order convergence of our method. This agrees with our analysis. In this case the "exact eigenvalues" are derived from numerical results of Dauge, which can be found at http://perso.univ-rennes1.fr/monique.dauge/core/index.html. In Figure 6.2, we plot the first ten numerical eigenvalues versus the parameter $n = 1/(2h)$. Again, there is no spurious eigenvalue.

7. Concluding remarks. We have analyzed an interior penalty method with weak overpenalization for the two-dimensional reduced curl-curl problem and the Maxwell eigenproblem. This method is inconsistent but stable without the need of tuning any penalty parameter. We expect other discontinuous Galerkin schemes will be discovered along this line. An advantage of this new approach is that fast solvers for the resulting schemes can be constructed using techniques developed for elliptic problems.

The scheme developed in this paper can be extended to three-dimensional domains. In the case of uniform meshes, our two-dimensional analysis can be easily generalized to establish convergence at a suboptimal rate. It is likely that quasi-optimal convergence rates can be recovered using graded meshes, which is of course much more complicated in three dimensions [2, 3]. This will be one of the topics of our ongoing research.

Acknowledgment. Part of the research in this paper was carried out while the first and third authors were visiting the Humboldt Universität zu Berlin, and they would like to thank the members of the Institut für Mathematik for their hospitality.

ON FINITE ELEMENT METHODS FOR FULLY NONLINEAR ELLIPTIC EQUATIONS OF SECOND ORDER*

KLAUS BÖHMER†

Dedicated to my highly esteemed teacher and friend, Prof. Dr. Karl Nickel, on the occasion of his 80th birthday

Abstract. For the first time, we present for the general case of fully nonlinear elliptic differential equations of second order a nonstandard C^1 finite element method (FEM). We consider, throughout the paper, two cases in parallel: For convex, bounded, polyhedral domains in $\mathbf{R}^n$, or for C^2 bounded domains in $\mathbf{R}^2$, we prove stability and convergence for the corresponding conforming or nonconforming C^1 FEM, respectively. The results for equations and systems of orders 2 and $2m$ and quadrature approximations appear elsewhere. The classical theory of discretization methods is applied to the differential operator or the combined differential and the boundary operator. The consistency error for satisfied or violated boundary conditions on polyhedral or curved domains has to be estimated. The stability has to be proved in an unusual way. This is the hard core of the paper. Essential tools are linearization, a compactness argument, the interplay between the weak and strong form of the linearized operator, and a new regularity result for solutions of finite element equations. An essential basis for our proofs are Davydov's results for C^1 FEs on polyhedral domains in $\mathbf{R}^n$ or of local degree 5 for C^2 domains in $\mathbf{R}^2$. Better convergence and extensions to $\mathbf{R}^n$ for C^2 domains are to be expected from his forthcoming results on curved domains. Our proof for the second case in $\mathbf{R}^n$, includes the first essentially as a special case. The method applies to quasi-linear elliptic problems not in divergence form as well. A discrete Newton method is shown to converge locally quadratically, essentially independently of the actual grid size by the mesh independence principle.

Key words. conforming, nonconforming finite element method, $\mathbf{R}^n$, variational crimes, fully nonlinear elliptic differential equations, order 2, C^1 finite elements, quasi-linear elliptic equations not in divergence form, stability, convergence, regularity for finite element solutions, discrete Newton method, locally quadratic convergence

1. Introduction.

We present a finite element method (FEM) for the general case of fully nonlinear elliptic differential equations of second order in $\mathbf{R}^n, n \geq 2$. To the knowledge of many specialists, consulted by the author, this seems to be the first such paper. The generalization to equations and systems of orders 2 and $2m$ and quadrature approximations is to appear elsewhere; see Böhmer [11]. Here we give a short summary of the main ideas behind the formulation and the proofs for our "nonstandard" FEM. The standard approaches for FEMs do not work; see below. So we proceed as follows:

- Our FEM for general fully nonlinear elliptic differential equations requires a bounded, convex, polyhedral or a C^2 domain in $\mathbf{R}^n$ with conforming and nonconforming C^1 FEs. Both cases are presented in parallel.
- Only FEMs for strong, not for weak, forms make sense. This requires FEs in C^1, satisfying and violating Dirichlet boundary conditions on polyhedral and C^2 domains.

- The classical theory of discretization methods has to be applied to the differential operator and, on C^2 domains, to the differential and the boundary operator.
- The most difficult claim, the stability of the nonlinear operator, is proved via the stability of the linearized operator, with coinciding strong and weak bilinear FE forms. Compact perturbation and a new regularity result for FE solutions of weak linear FE equations lift the "weak stability" back to the "strong stability."
- For computations the weak linear forms, coinciding with the strong forms, are used. Thus the many known powerful numerical methods apply for our FEM as well.
- The mesh independence principle (MIP) guarantees a quadratically convergent solution process via the Newton method for the highly nonlinear systems of equations.

Our FEM is a natural translation of the nonstandard situation for fully nonlinear elliptic differential equations, including quasi-linear equations not in divergence form; we abbreviate this as *nondivergent quasi-linear equations.* As for fully nonlinear equations, weak forms are not possible. The solution has to be determined from the original strong form with derivatives up to second order. This situation is directly translated into our strong form of a FEM; see section 2 for more details. This FEM, based upon the classical discretization theory, strongly differs from the earlier approaches.

Difference methods for viscosity solutions are studied by Crandall and Lions [23], Crandall et al. [25], and Kuo and Trudinger [41] with discrete maximum principles.

For FEMs, there are several papers with results for the Monge–Ampère equations in $\mathbf{R}^2$ or modifications. Oliker and Prussner [44] prove, by convexity arguments, that their sequences converge monotonically to the solution. Fulton [34] studies multigrid solutions as models of nonlinear balance equations in meteorology. Dean and Glowinski [32, 33] reformulate it as a problem of calculus of variations involving the biharmonic (or a related) operator. A reinterpretation as saddle-point problem for a well-chosen augmented Lagrangian functional leads to iterative methods such as that of Uzawa, Douglas, and Rachford, applicable to the related Pucci equation.

These FE approaches are based upon either combinations of the special properties of a specific problem with the proposed numerical method or upon maximum and/or monotonicity arguments. But none of them seems to be applicable nor has any been applied to the general fully nonlinear elliptic differential equations (and systems) as treated in this paper. This seems to indicate the need for new ideas.

2. Main ideas and results for the new FEM: An extended summary. We propose an approach totally different from those in the above papers. As mentioned, a major part of the analysis for fully nonlinear differential equations is based upon the strong form of these equations; see, e.g., Gilbarg and Trudinger [35], Showalter [49], and Taylor [54, 55, 56]. This motivates a FEM, based upon the strong form of the differential equation. For proving existence, uniqueness, and related results for the exact solution, e.g., monotonicity, maximum principles, and the Schauder fixed point theorem are needed. We avoid this, but employ, as for many other numerical approaches, these results as the basis for our method.

We simplify the presentation by considering only FEMs for second order equations; see Böhmer [11] for the general case. We prove convergence in the framework of general discretization theory, based upon consistency and stability (see, e.g., Stetter

[51]), in a first step fitted to the present problem. We need the strong form for the FEM and (see below) a convex, bounded (and we assume additionally) polyhedral Ω or an $\Omega \in C^2$; both cases are discussed here. The strong form requires C^1 FEs for an L^2 evaluation of the differential equation. For a polyhedral Ω, (trivial) boundary conditions are satisfied exactly; curved domains cause violated boundary conditions.

The second step is the proof of consistency. For polyhedral Ω and their conforming FEs this is a straightforward consequence of a vanishing interpolation error for a continuous differential operator.

For smooth $\Omega \in C^2$, requiring nonconforming FEs, consistency is more complicated. The earlier approaches (see, e.g., Lenoir [42] and Brenner and Scott [13] for linear problems) do not seem to be applicable to the fully nonlinear problems. So other nonstandard, not surprisingly similarly complicated considerations are necessary. The clue is an operator with two components, the differential and the boundary operator. This requires a more complicated version of the general discretization theory. Specifically, we have to carefully introduce the necessary projectors and spaces for including the violated differential operator *and* the boundary conditions into the classical discretization theory. Then the "classical consistency error" for the differential and the boundary operator can be estimated in a simple proof; see (6.29) and Theorem 7.1 below. Essentially we split this error into the FE error for a conforming FEM on an $\Omega_c^h \approx \Omega$ and its complementary *geometric error,* due to $\partial\Omega \neq \partial\Omega_c^h$, according to a new idea of Tiihonen [57].

The most difficult part is the proof of stability. We did not see a direct possibility for the strong form. So we combine linearization with regularity of FE solutions. This is another difference of our FEM to the standard methods and those in the previous papers. Stability is first proved for the linearized weak form. Unfortunately, we lose the powerful machinery of weak bilinear forms and their FEMs, *unless* we find a kind of *connection* between the two forms. This is achieved by Proposition 8.2 and Lemma 8.5. The first shows coinciding weak and strong FE bilinear forms in our case. The latter states, similarly to the exact solution of a "smooth" linear elliptic problem, a new regularity and stability result for our FE solutions. This and the available existence, uniqueness, and regularity results require a convex, bounded, polyhedral Ω or an $\Omega \in C^2$, implying satisfied or violated boundary conditions for our FEM. Generalizing our earlier compact perturbation techniques (see Böhmer and Sassmannshausen [12] and Böhmer [9, 8]) to satisfied or violated boundary conditions allows lifting the stability from coercive to general elliptic bilinear forms. A combination of these results lifts the weak back to the strong stability and allows the proof of convergence.

We do need convex, bounded (polyhedral) or smooth $\Omega \in C^2$ for existence, convergence, and the regularity lemma, Lemma 8.5. The smooth $\Omega \in C^2$ requires and allows the extension operator in Theorem 4.5. We require FEs in C^1, since for FEs in C^0 we did not see a possibility to handle the interior variational crimes. The standard interplay between the weak and strong form is impossible for fully nonlinear problems and *excludes, e.g., discontinuous Galerkin methods.* Thus we choose the unusual C^1 FEs, conforming and nonconforming for polyhedral and C^2 domains, respectively. Davydov [27] has proved the complete approximation results on bounded, polyhedral Ω in R^n. For $\Omega \in C^2$ we need the new "stable splitting" of C^1 FEs into interior and boundary elements. Presently, these results are available for modified Argyris piecewise polynomials of degree 5 on polygonal $\Omega^h \approx \Omega \subset \mathbf{R}^2$. This restricts, for $\Omega \in C^2$, the order of convergence of our FEM to 2. Davydov is extending his results

to higher degrees and $\mathbf{R}^n$. Our proof is formulated for including these extensions as well.

The FE equations have to be set up. They are solved numerically by a quadratically converging discrete Newton method. Its local quadratic convergence is guaranteed by the MIP; see Allgower and Böhmer [2, 3], Allgower et al. [4], and section 9. It starts with a good approximation, e.g., obtained by a continuation method. Again linear problems are essential to solve the highly nonlinear systems of equations. As a welcome consequence of our coinciding weak and strong FE bilinear forms, the standard solution techniques for weak linear problems are applicable to the fully nonlinear equations as well. However, the standard C^0 FEs have to be replaced by C^1 FEs.

With the notation introduced below, let G be a uniformly elliptic operator on Ω; see (3.8), (3.10). Homogeneous Dirichlet conditions are obtained by the standard techniques. Violated boundary conditions for the nonconforming FEM below will play a dominant role. The exact solution, u_0, is determined by the differential equation and the boundary condition in the trace sense:

$$\begin{aligned} u_0 \in \mathcal{U} := H^2(\Omega): \quad & G(u_0)(x) := G^w(x, u_0(x), Du_0(x), D^2u_0(x)) = 0 \quad \forall x \in \Omega \\ & \iff (G(u_0), v)_{L^2(\Omega)} = 0 \quad \forall v \in L^2(\Omega) = (L^2(\Omega))', \\ & \text{and } u_0|_{\partial\Omega} = 0 \iff (u_0|_{\partial\Omega}, v_b)_{L^2(\partial\Omega)} = 0 \quad \forall v_b \in L^2(\partial\Omega), \end{aligned} \tag{2.1}$$

with $G^w : \Omega' \times \mathbf{R} \times \mathbf{R}^n \times \mathbf{R}^{n^2} \to \mathbf{R}$, $\overline{\Omega}$, $\overline{\Omega_c^h} \subset \Omega'$ (see (3.6)), and so $G(u^h)(x) := G^w(x, u^h(x), Du^h(x), D^2u^h(x))$ is defined as well. Since $H^{3/2}(\partial\Omega)$ is dense in $L^2(\partial\Omega)$ testing with only for all $v_b \in L^2(\partial\Omega)$ is correct. For a systematic study of the differential and the boundary operator, we abbreviate (2.1) into an equivalent form, determining

$$\begin{aligned} & u_0 \in \mathcal{U}: \quad 0 = F(u_0) := (G(u_0)|_\Omega = 0, u_0|_{\partial\Omega} = 0) \\ \iff & (G(u_0), v)_{L^2(\Omega)} + (u_0|_{\partial\Omega}, v_b)_{L^2(\partial\Omega)} = 0 \quad \forall v \in L^2(\Omega), \quad v_b \in L^2(\partial\Omega). \end{aligned} \tag{2.2}$$

We introduce the C^1 FE spaces of local degree d in $\mathbf{R}^n$, the $\mathcal{S}_d^1(\mathcal{T}_c^h)$, for polyhedral, and $d \geq 5$ for C^2 domains. For a unified notation we assume that they are defined on a triangulation $\mathcal{T}_c^h$ of the original Ω, a polyhedral Ω^h, or a curved $\Omega_c^h \approx \Omega$, with the same notation $\mathcal{T}_c^h, \Omega_c^h$ for all cases; cf. section 4 for $S^h \subset \mathcal{S}_d^1(\mathcal{T}_c^h)$:

$$\mathcal{U}^h := S^h \subset \mathcal{S}_d^1(\mathcal{T}_c^h) \text{ and } \mathcal{U}_0^h := \mathcal{V}^h := \{u^h \in S^h : u^h|_{\partial\Omega_c^h} = 0\} \subset \mathcal{U}^h \neq \mathcal{V}^h. \tag{2.3}$$

For convex polyhedral Ω, the conforming FE solution, $u_0^h \in \mathcal{U}_0^h$, is determined by testing only the differential equation w.r.t. $v^h \in \mathcal{V}^h$, again in the L^2 sense:

$$u_0^h \in \mathcal{U}_0^h = \mathcal{V}^h \text{ s.t. } (G(u_0^h), v^h)_{L^2(\Omega_c^h)} = 0 \quad \forall v^h \in \mathcal{V}^h. \tag{2.4}$$

For smooth $\Omega \in C^2$ we have to test both operators. So the FE solution satisfies

$$u_0^h \in \mathcal{U}^h \text{ s.t. } (G(u_0^h), v^h)_{L^2(\Omega_c^h)} = 0 \quad \forall v^h \in \mathcal{V}^h, \text{ and } u_0^h|_{\partial\Omega_c^h} = 0, \text{ and so } u_0^h \in \mathcal{V}^h; \tag{2.5}$$

see Theorem 8.1. The FEM (cf. (2.2)) determines $u_0^h \in \mathcal{U}^h$ and defines F^h s.t.

$$(G(u_0^h), v^h)_{L^2(\Omega_c^h)} + (u_0^h|_{\partial\Omega_c^h}, v_b^h)_{L^2(\partial\Omega_c^h)} = 0 \quad \forall v^h \in \mathcal{V}^h, \quad v_b^h \in \mathcal{V}_b^h \Leftrightarrow 0 = F^h(u_0^h), \tag{2.6}$$

with $\mathcal{V}_b^h := \{u^h|_{\partial\Omega_c^h} : u^h \in \mathcal{U}^h\}$. For $\Omega \in C^2$, comparing u_0^h and u_0 requires extension operators, e.g., $E_c : H^2(\Omega) \to H^2(\Omega \cup \Omega_c^h)$.

Our FEM transforms $F(u_0) = 0$ in (2.2) into $F^h(u_0^h) = 0$ in (2.6). It is a classical discretization method in the sense of, e.g., Stetter [51]. Related approaches for general discretization methods are discussed in Stummel [52, 53], Vainikko [59], Keller [40], Reinhardt [46], Zeidler [62, 63, 64], and Böhmer [7, 9, 8]. Here Theorems 1.2.3–1.2.5 in Stetter [51] provide the tools for showing convergence if consistency and stability can be proved. Thus sections 4–8 are the core of this paper.

For our unusual FEM, we summarize the main ideas. We mainly formulate the results for the nonconforming FEM for $\Omega \in C^2$. The corresponding reduction to the conforming FEs for polyhedral Ω is obvious.

1. *The FEMs, transforming* (2.1) *into* (2.4)*, and* (2.2) *into* (2.6)*, are general discretization methods:*

- The existence, uniqueness, and regularity results for the original problems in section 3 are the basic results for a general discretization method.
- The fully nonlinear elliptic problem (2.1), (2.2) is approximated by the *strong* form (2.4), (2.6), requiring FEs in C^1. For (2.4) identical ansatz and test functions, $\mathcal{U}_0^h = \mathcal{V}^h$, are possible. For (2.6) we choose as ansatz functions $\mathcal{U}^h = S^h$ and test the differential operator with $v^h \in \mathcal{V}^h = S^h \cap H_0^1(\Omega_c^h)$ and the boundary operator with the restrictions to the boundary, $v_b^h \in \mathcal{V}_b^h = S^h|_{\partial\Omega_c^h}$; see (2.3) and section 4 for the relevant extension results in Theorem 4.5.
- The FEM is a general linear discretization method; cf. sections 5 and 6.
- In subsections 5.1–5.3 and 6.1–6.3 we reformulate the FEM, introduce the necessary projectors, and verify the required conditions. Thus the FEMs are convergent if they are stable and consistent; see Theorem 5.1.
- For a "smooth" problem our FEM is consistent; see (5.15) and Theorem 7.1.

2. *Stability for the nonlinear* strong *equation* (2.6) *is the most difficult problem; cf. section* 8*:*

- The nonlinear stability is a consequence of the stability for the *linearized strong* problem; see (2.7) and Theorem 8.1. For given u_0^h and f, ϕ, determine the FE solution u_1^h from

$$u_1^h \in \mathcal{U}^h \text{ s.t. } (F^h)'(u_0^h)u_1^h = \big(G'(u_0^h)u_1^h, u_1^h|_{\partial\Omega_c^h}\big) = (f, \phi). \tag{2.7}$$

  For this linearized problem, two FEMs complement each other; see below:
- The first component of the linearized *strong* and *weak* bilinear forms coincide:

$$(G'(u_0^h)u^h,\ v^h)_{L^2(\Omega_c^h)} = \langle G'(u_0^h)u^h,\ v^h\rangle \quad \forall\ u^h \in \mathcal{U}^h, \quad v^h \in \mathcal{V}^h, \tag{2.8}$$

  with $\langle\cdot,\cdot\rangle = \langle\cdot,\cdot\rangle_{H^{-1}(\Omega_c^h)\times H^1(\Omega_c^h)}$; see Proposition 8.2.
- For (extended) $(f, \phi) \in H^{-1}(\Omega_c^h) \times H^{1/2}(\partial\Omega_c^h)$, the linearized *weak* problem

$$(F^h)'(u_0^h)u_1^h = (f, \phi) \Leftrightarrow \langle G'(u_0^h)u_1^h - f, v^h\rangle + ((u_1^h - \phi)|_{\partial\Omega_c^h}, v_b^h)_{L^2(\partial\Omega_c^h)} = 0$$

  for all $v^h \in \mathcal{V}^h, v_b^h \in \mathcal{V}_b^h$ is stable, essentially if u_0 is an isolated solution of $F(u_0) = 0$ with boundedly invertible $F'(u_0)$. This is a consequence of the discussion at the end of section 3 and the compactness arguments in Theorem 8.4.
- By Lemma 8.5 the regularity results for the exact solution of a linear elliptic problem are valid for the corresponding FE solutions. In the *weak linearized*

problem, $(F^h)'(u_0^h)u_1^h = (f,\phi) \in H^{-1}(\Omega_c^h) \times H^{1/2}(\partial\Omega_c^h)$, we determine $u_1^h \in \mathcal{U}^h$ for the smooth $(f,\phi) \in L^2(\Omega_c^h) \times H^{3/2}(\partial\Omega_c^h)$; see (2.6), (2.8). The stability of the *weak* problem implies the stability of the *strong* problem

$$(G'(u_0^h)u_1^h - f, v^h)_{L^2(\Omega_c^h)} + ((u_1^h - \phi)|_{\partial\Omega_c^h}, v_b^h)_{L^2(\partial\Omega_c^h)} = 0 \quad \forall v^h \in \mathcal{V}^h, \quad v_b^h \in \mathcal{V}_b^h.$$

This allows estimates for discrete solutions w.r.t. a piecewise H^2-norm instead of the usual H^1-norm. This requires smooth coefficients, necessary for good convergence, and a convex, bounded (polyhedral) domain or $\Omega \in C^2$.

3. *Summary: Essentially simultaneously with a unique* u_0*, the FE solutions* u_0^h *of* (2.4)*,* (2.5)*, and* (2.6) *uniquely exist, for small enough* h*, and converge; see* (2.9) *and Theorems* 5.1 *and* 8.7*.*

4. *Setting up the FE equations* (2.5) *and solving them; see section* 9*:*

- Setting up the nonlinear system (2.5) is formulated in (9.1).
- As a consequence of **1.**, **2.**, the MIP is valid. So the Newton method for the discrete equation (2.5), with a good enough initial guess $u_1^h = P^h u_1$, e.g., obtained by a continuation method, converges quadratically to u_0^h equally well as the Newton–Kantorovich method, started in u_1, for the original problem (2.1); see Theorem 9.1 and (2.10).
- The linearization of G is elliptic. Thus the efficient solvers for linear elliptic problems in weak form (see (2.7)) can be applied in the continuation and Newton processes, replacing C^0 FEs by C^1 FEs. Results of Davydov [28] and Davydov and Stevenson [30] for Ω^h allow extensions to nested sequences of triangulations $\mathcal{T}_1^h \sqsubset \mathcal{T}_2^h \sqsubset \cdots$, hence even multiresolution techniques.

We formulate the convergence of the FE and the discrete Newton method: Let (2.1), for smooth enough G and Ω, have a smooth isolated solution $u_0 \in H^\ell(\Omega)$ with bounded $(F'(u_0))^{-1}$ and choose FEs of local degree d in C^1 with $0 \le \ell - 1 \le d$; cf. (4.9). Then the discrete solutions u_0^h of (2.5) converge as (see Theorem 8.7)

$$\|E_c u_0 - u_0^h\|_{H^2(\Omega_c^h)}^h \le C h^{\min\{\ell-2,p\}} \|u_0\|_{H^\ell(\Omega)} \quad \text{for large enough } \ell,\ d. \tag{2.9}$$

For convex, bounded, polyhedral domains all results are known in $\mathbf{R}^n$ (cf. [27]), and we get $p = \ell - 2$. For $\Omega \in C^2$ we obtain $p = 2$ for polyhedral Ω^h and $p > 2$ for curved Ω_c^h. Davydov has fully proved the case $\mathbf{R}^2, d = 5, p = 2$ and is working on higher $\mathbf{R}^n, p > 2$. The proofs in this paper are based upon these generalizations.

The Newton method for the discrete problem (2.6) has the form (2.10) and converges locally quadratically; see Theorem 9.1:

$$\begin{aligned} &u_{\nu+1}^h \in \mathcal{U}^h : \ (F^h)'(u_\nu^h)(u_{\nu+1}^h - u_\nu^h) = -F^h(u_\nu^h) \\ &\implies \|u_{\nu+1}^h - u_\nu^h\|_{H^2(\Omega_c^h)}^h \le C(\|u_\nu^h - u_{\nu-1}^h\|_{H^2(\Omega_c^h)}^h)^2. \end{aligned} \tag{2.10}$$

Finally, we indicate, but do not explicitly formulate, two further extensions. In section 8 the linearized weak problem turns out to be a compact perturbation of a coercive bilinear form. Hence, the usual Fredholm alternative results apply. The above FEM can easily be extended to parameter dependent problems and for studying bifurcation scenarios. Some general results prove the convergence of the bifurcation characteristics of the discrete FEM to those of the original problem, starting with Brezzi, Rappaz, and Raviart in [14, 15, 16], and, e.g., Böhmer [7, 9, 8] and Cliff, Spence, and Tavener [21]. Extensions of these results to convergence of the characteristics of center manifolds for the discrete FEM to those for the original problem are, for the first time, studied in Böhmer [9, 11].

3. Fully nonlinear and general quasi-linear elliptic equations. We introduce the standard notations for derivatives

$$(3.1)\ \partial^i u = \frac{\partial u}{\partial x_i},\ Du = (\partial^i u)_{i=1}^n,\ D^2u = (\partial^i\partial^j u)_{i,j=1}^n,\ \partial^0 u := u, (-1)_{j>0} := 1,\ j = 0,$$

and $:= -1$ for $j \geq 1$. We formulate the conditions for the domain and introduce four Hilbert spaces with $\mathcal{W}_0$ for trivial Dirichlet boundary conditions:

$$(3.2)\quad \Omega \text{ is an (open) bounded domain in } \mathbf{R}^n \text{ with Lipschitz continuous } \partial\Omega \text{ and}$$
$$\mathcal{U} := H^2(\Omega) \subset \mathcal{W} := H^1(\Omega) \subset \mathcal{V} := L^2(\Omega) = \mathcal{V}', \mathcal{V}_D := H^{3/2}(\partial\Omega), \mathcal{W}_D := H^{1/2}(\partial\Omega),$$
$$\mathcal{W}_0 := H_0^1(\Omega) := \{v \in H^1(\Omega) : v = 0 \text{ on } \partial\Omega\},\ \mathcal{U}_0 := \mathcal{W}_0 \cap \mathcal{U}, \mathcal{W}' := H^{-1}(\Omega),$$

with the standard Sobolev norms, seminorms, inner products for $\mathcal{U}, \mathcal{W}, \mathcal{V}$, and Sobolev–Sloboditskii norms for $\mathcal{V}_D, \mathcal{W}_D$; cf. Hackbusch [37] and Oden and Reddy [43].

For a quasi-linear elliptic equation in divergence form a weak conforming FEM determines the FE solution $u_0^h \in \mathcal{V}^h = \mathcal{U}_0^h$ as

$$(3.3)\ \langle Gu_0^h, v^h\rangle_{\mathcal{W}'\times\mathcal{W}} := \int_\Omega \sum_{j=0}^n a_j(x, u_0^h, Du_0^h)\partial^j v^h dx = \langle f, v^h\rangle_{\mathcal{W}'\times\mathcal{W}} \quad \forall v^h \in \mathcal{V}^h.$$

For a general quasi-linear or a fully nonlinear G a weak form is impossible:

$$(3.4)\qquad u_0 \in \mathcal{U}_0 :\ Gu_0 - f = \sum_{i,j=0}^n a_{i,j}(\cdot, u_0, Du_0)\partial^i\partial^j u_0 - f(\cdot) = 0 \in \mathcal{V},\ \text{or}$$

$$(3.5)\qquad u_0 \in \mathcal{U}_0 :\ G(u_0) = G(\cdot, u_0(\cdot), Du_0(\cdot), D^2u_0(\cdot)) = 0 \in \mathcal{V}.$$

Consequently, a weak form of a FEM is impossible, thus motivating our FEM.

The general theory of discretization methods used in this paper can be applied if the original problem has two properties: It admits a locally unique solution u_0, strongly related to the stability, and u_0 is smooth enough, implying the consistency and good enough convergence of our method. So we list some results for fully nonlinear elliptic equations, based upon rather technical conditions, summarizing, e.g., Gilbarg and Trudinger [35], Chen and Wu [18], and Skrypnik [50]. We assume (3.2) for $\Omega \subset \mathbf{R}^n$, a slightly larger open $\Omega' \subset \mathbf{R}^n$ with $\overline{\Omega} \subset \Omega'$, $\overline{\Omega_c^h} \subset \Omega'$, where Ω_c^h indicates later approximations for Ω for the $u^h \in \mathcal{U}^h$. A real valued function G^w is defined s.t.

$$(3.6)\ G^w : w = (x, z, p, r) \in \mathcal{D}(G^w) = \Omega' \times \Gamma \to \mathbf{R}, \Gamma \subset \mathbf{R} \times \mathbf{R}^n \times \mathbf{R}^{n^2}, \Omega', \Gamma \text{ open}.$$

We consider the strong elliptic BVP (cf. (2.1), (3.5), (3.6)), often with $\phi = 0$ and

$$(3.7)\quad w(x) := w_u(x) := (x, u(x), Du(x), D^2u(x)), \quad u \to G(u) := G^w(w_u) \text{ for}$$
$$u \in \mathcal{D}(G) := \{u \in \mathcal{U} : w_u(x) \in \mathcal{D}(G^w) \quad \forall x \in \Omega \text{ and } G^w(u) \in \mathcal{V}\},$$
$$(3.8)\qquad \text{the solution satisfies } u_0 \in \mathcal{D}(G) :\ G(u_0) = 0 \text{ on } \Omega, \quad u_0 = \phi \text{ on } \partial\Omega.$$

Ellipticity is defined by the linear $G'(u_0)$ in $w_0 := w_{u_0}$ applied to u with $u, u_0 \in \mathcal{D}(G)$:

$$(3.9)\qquad G'(u_0)u = \frac{\partial G^w}{\partial z}(w_0)u + \sum_{i=1}^n \frac{\partial G^w}{\partial p_i}(w_0)\partial^i u + \sum_{i,j=1}^n \frac{\partial G^w}{\partial r_{ij}}(w_0)\partial^i\partial^j u.$$

This will be important below for the local uniqueness and stability. The operator G is called *uniformly elliptic* in $u_0 \in \mathcal{D}(G)$ and all of $\mathcal{D}(G)$ if its linearization $G'(u)$ is uniformly elliptic for $u = u_0$ and for all $u \in \mathcal{D}(G)$, respectively. In the first case its principal part, $a_p(u, v)$ (see (3.11)), satisfies, for $0 < \lambda < \Lambda$, and $w_0 = w_{u_0}$ in (3.7),

$$0 < \lambda|\vartheta|^2 \le -\sum_{i,j=1}^{n} \frac{\partial G^w}{\partial r_{ij}}(w_0)\vartheta^i\vartheta^j \le \Lambda|\vartheta|^2 \quad \forall 0 \ne \vartheta = (\vartheta_1, \dots, \vartheta_n) \in \mathbf{R}^n, \tag{3.10}$$

sometimes only for a.e. $x \in \Omega$ in $w_0(x)$. For fully nonlinear second order elliptic equations this implies the $\mathcal{W}$-coercivity of the bilinear form induced by the principal part, $a_p(u, v)$ of $G'(u_0)$. By choosing $\vartheta^i = \partial^i u(x)$, integrating over Ω, and using partial integration we obtain, with the equivalence in $\mathcal{W}_0$ of the energy norm $(\sum_{i,j=1}^n \|\partial^i u\|_{\mathcal{V}}^2)^{1/2}$ and $\|\cdot\|_{H^1(\Omega)}$ and again with $0 < \lambda_1 < \Lambda_1 \in \mathbf{R}$,

(3.11)

$$\lambda_1\|u\|_{H^1(\Omega)}^2 \le a_p(u, u) := \int_\Omega \sum_{i,j=1}^{n} \frac{\partial G^w}{\partial r_{ij}}(w)\partial^i u\partial^j u dx \ \le \Lambda_1\|u\|_{H^1(\Omega)}^2 \quad \forall u \in \mathcal{W}_0.$$

Therefore we chose the Hilbert space setting, $\mathcal{W} = H^1(\Omega)$. A Banach space setting, $W^{1,p}(\Omega)$, might be appropriate if in addition to (3.10) some monotonicity conditions would be considered. Furthermore, since $W^{2,p}(\Omega)$ is continuously embedded into $H^2(\Omega)$, for $p \ge 2$, our new FEM even works for fully nonlinear equations in $W^{2,p}(\Omega)$, e.g., $G(u) = (\Delta u)^p + f(u)$; however, it yields only discrete $H^2(\Omega)$ estimates.

We formulate some of the most important examples.

EXAMPLE 3.1 (Monge–Ampère equation). *This is, in particular for* $n = 2$,

$$0 = G(u) := \det D^2u - f(x, u, Du) = u_{xx}u_{yy} - u_{xy}^2 - f(x, u, Du) \quad \textit{for } n = 2. \tag{3.12}$$

This fully nonlinear $G(u)$ is uniformly elliptic in u_0 for a symmetric strictly positive matrix $r = D^2u_0$ in Ω, hence for a function $u_0 \in C^2(\Omega)$, strictly convex for all $x \in \Omega$ on a convex Ω. With $\det(D^2u) > 0$, uniformly convex solutions are possible only for positive f [35, pp. 441ff.]. For partially nonelliptic generalizations, see [35, pp. 467ff.] and Courant and Hilbert [22, p. 324]. According to Haltiner, Kasahara, and Fulton the leading term in the balance equation in dynamical meteorology has the form (3.12) [38, 39, 34]. In Westcott [60] it is related to geometric optics.

Among the many applications in geometry we mention the following equation.

Equation for a surface with prescribed Gauss curvature $K = K(x)$ at x. It is closely related to the Monge–Ampère equation. Equation (3.12) has to be modified as

$$G(u) := \det D^2u - K(1 + |Du|^2)^{(n+2)/2} = 0, \quad K(x) > 0. \tag{3.13}$$

The existence of surfaces with prescribed Gauss curvature is known for appropriate given curvature, K. Specific properties would become more flexibly available via our FEMs than by finite difference methods, e.g., by Crandall and Lions [24]: Our FEM allows C^1 FEs on quasi-uniform grids and yields, for convex polyhedral Ω or the forthcoming better boundary approximations, higher orders of convergence than the difference methods in [24], which are defined only on equidistant grids. □

To guarantee existence and uniqueness results we have to impose *growth conditions*. We distinguish the cases $n = 2$ and $n \ge 2$, evaluate the following derivatives in

$w=(x,z,p,r)\in\mathcal{D}(G^w), x\in\partial\Omega$, and require, for $G^w_x, G^w_z, G^w_p, G^w_r$ (see (3.9), (3.10)),

$$\begin{aligned}&\text{for } n=2: |G^w_z(w)|, |G^w_p(w)|\le\lambda\mu,\\ &\qquad |G^w_x(w)|\le\mu\lambda(1+|p|+|r|) \text{ and}\end{aligned}\tag{3.14}$$

$$\begin{aligned}&\text{for } n\ge 2: |G^w_z(w)|, |G^w_p(w)|, |G^w_{rx}(w)|, |G^w_{px}(w)|, |G^w_{zx}(w)|\le\lambda\mu,\\ &\qquad |G^w_x(w)|, |G^w_{xx}(w)|\le\mu\lambda(1+|p|+|r|).\end{aligned}\tag{3.15}$$

The nonnegative $\lambda=\lambda(\cdot)$ and $\Lambda=\Lambda(\cdot), \mu=\mu(\cdot)$ in (3.10), (3.14)–(3.15) depend upon $|z|$ and have to be nonincreasing and nondecreasing in $z\in[0,\infty)$, respectively.

THEOREM 3.1 (see [35, Theorem 17.12]). *Assume* $n=2,\ \partial\Omega\in C^3,\ \phi\in C^3(\overline{\Omega})$; *see* (3.8). *Let* G *satisfy the conditions* (3.10), (3.14), *and* $G^w_z\le 0$ *in* Γ; *see* (3.6). *Then the classical Dirichlet problem* (3.8) *has a unique solution* $u_0\in C^{2,\alpha}(\overline{\Omega})$ *for all* $0<\alpha<1$.

THEOREM 3.2 (see [35, Theorem 17.17]). *Assume* $n\ge 2, \phi\in C(\partial\Omega)$. *Let* Ω *satisfy an exterior sphere condition for every* $\xi\in\partial\Omega$ *and* G *satisfy the conditions* (3.10), (3.15), *and* $G^w\in C^2(\Gamma)$ *is concave (or convex) w.r.t.* (z,p,r), *nonincreasing w.r.t.* z. *Then the classical Dirichlet problem* (3.8) *has a unique solution* $u_0\in C^2(\Omega)\cap C(\overline{\Omega})$.

Remark 3.1. Ω satisfies an exterior sphere condition, for every $\xi\in\partial\Omega$, if there exists a ball $B=B_R(y)\subset\mathbf{R}^n$ s.t. $\overline{B}\cap\overline{\Omega}=\{\xi\}$. Mind the difference in these theorems. For $n=2$ a $\partial\Omega\in C^3$ implies the global $u_0\in C^{2,\alpha}(\overline{\Omega})$ for all $0<\alpha<1$, in contrast to the interior estimate $u_0\in C^2(\Omega)\cap C(\overline{\Omega})$ for $n\ge 2$ and no condition for $\partial\Omega$.

More detailed results for the above special cases in Example 3.1 are presented in [35] and Skrypnik [50]. Reference [50] requires for the Monge–Ampère equation (3.12) on $\Omega=B_R(0)\subset\mathbf{R}^2$ with center 0 functions ϕ,ψ,f_0 s.t.

$$(u_0-\phi)|_{\partial B_R(0)}=0,\ \psi: B_R(0)\subset\mathbf{R}^2\to\mathbf{R}_+,\ f_0:\mathbf{R}^2\to\mathbf{R}_+,\ m:=\max_{x\in B_R(0)}\phi(x),$$

$$f(x,u,p)\le\psi(\|x\|^2)f_0(\|p\|^2)\quad \text{for } x,p,s\in\mathbf{R}^2,\quad \mathbf{R}\ni u\le m \text{ and let}\tag{3.16}$$

$$\int_{B_R(0)}\psi(\|x\|^2)dx\le\int_{\mathbf{R}^2}\inf_{\|s-p\|^2<M_H}1/f_0(\|s\|^2)ds,$$

where M_H is the lower winding of $(u_0-\phi)|_{\partial B_R(0)}=0$. Finally, let $\partial^1\partial^1 u(x)>0$:

$$H^4_+(\Omega):=\{u\in H^4(\Omega): \det D^2u(x)>0, \partial^1\partial^1u(x)>0\quad\forall x\in\overline{B_R(0)}\}.$$

THEOREM 3.3 (regular solutions [50, Theorem 3.2.3]). *Let* (3.16) *be satisfied and* $f\in C^{2,\gamma}(\Omega), \phi\in C^{4,\gamma}(\partial\Omega)$. *Then* (3.12) *has at least one solution in* $H^4_+(\Omega)$.

Regularity results for $u\in C^{k,\gamma}(\Omega), k\ge 2$, can be deduced from Chen and Wu [18, Chapter 7] and are extended in Böhmer [10].

Existence and uniqueness results are obtained by methods, usually independent of linearization. However, we assume additionally a locally unique solution u_0 in (2.2), with boundedly invertible Fréchet derivative, similarly for G on convex polyhedral Ω:

$$F:\mathcal{U}\to\mathcal{V}\times\mathcal{V}_D,\quad \text{locally } \exists_1 u_0: F(u_0)=(0,\phi),\quad (F'(u_0))^{-1}\in\mathcal{L}(\mathcal{V}\times\mathcal{V}_D,\mathcal{U}).\tag{3.17}$$

We defend this condition by the close relation to the numerically necessary condition of a (locally) well-conditioned problem $F(u)=0$. For an existing locally unique solution the Fréchet differentiability is satisfied for many practically relevant problems. By the Taylor formula, a boundedly invertible $F'(u_0)\in\mathcal{L}(\mathcal{U},\mathcal{V}\times\mathcal{V}_D)$ is very

probable but not necessarily satisfied. But there will be exceptions. For our numerical approach we detect this *exceptional case,* e.g., the discrete Newton method below. The *convergence* for our numerical method *is not proved.* Unless $F'(u_0) \in \mathcal{L}(\mathcal{U}, \mathcal{V} \times \mathcal{V}_D)$ is (nearly) singular, $(F^h)'(u_0^h)$ is stable; see Theorem 8.6. If (3.17) would be violated, small perturbations of an original parameter dependent problem would usually have a bifurcation point and numerical methods for bifurcation would have to be applied.

4. Smooth FEs and extension theorems. We have emphasized above that the proof of the "strong stability" will require

(4.1) a bounded either convex polyhedral Ω with conforming FEs or

(4.2) $\Omega \in C^2$, with a polyhedral or curved $\Omega_c^h \approx \Omega$ with nonconforming FEs.

We give a short summary of the Davydov results in [27]: C^1 FEs, defined on polyhedral domains Ω, are conforming, satisfying the boundary conditions. All necessary approximation theoretic results are known for $n \geq 2, d \geq 2^n + 1$. For $\Omega \in C^2$, C^1 FEs on polyhedral or curved approximating domains $\Omega_c^h \approx \Omega$ usually are nonconforming by violating the boundary conditions. The results are proved for modified Argyris FEs in $\mathbf{R}^2$ on Ω_c^h. We indicate the forthcoming generalization of [27] to curved approximations of Ω, allowing higher accuracy, and to $\mathbf{R}^n$. These FEs are split into the sum of FEs vanishing and living on the boundary. For comparing an original function and its interpolating FE we need extension operators from Ω and Ω_c^h to $\Omega' \supset \Omega_c^h \cup \Omega$.

4.1. Smooth FEs on polyhedral and curved domains. Fully nonlinear weak forms are impossible. So the FEs u^h fit to our discrete equations (2.5), (2.6) if $G(u^h) \in L^2(\Omega_c^h)$, hence for $u^h \in C^1(\Omega_c^h)$. In fact, the standard FEs $u^h \in C(\Omega_c^h)$, with $G(u^h) \in L^2(\mathcal{T}_c^h)$, would imply interior variational crimes by the nondifferentiability of the $u^h \notin H^2(\Omega_c^h)$ between neighboring simplices $T \in \mathcal{T}_c^h$. The interplay of strong and weak forms, impossible for fully nonlinear operators, seemed to leave no other choice than FEs in C^1.

We combine the Davydov results [27] with a new idea of Tiihonen [57]. He decomposes, for linear sample problems, the error for FEMs by introducing an auxiliary problem defined in a polyhedral $\Omega^h \approx \Omega$ for a *smooth* domain. Then a standard FEM on Ω^h with known error estimates is combined with the "geometric part of the error", caused by $\Omega^h \approx \Omega$. We generalize his approach to our equations; see Theorem 4.4.

Let $\mathcal{T}^h$ be a simplicial subdivision or triangulation of a polyhedral Ω, or a polyhedral approximation $\overline{\Omega^h} := \cup_{T \in \mathcal{T}^h} \overline{T} \approx \overline{\Omega} \in C^2$. In the final $\mathcal{T}_c^h$ we maintain all "interior" facets of $\mathcal{T}^h$ with at most one boundary point. As boundary facets (see Figure 4.1), we choose either plane ∂T or curved facets ∂T_c, approximating $\partial\Omega$, e.g., between P_i and P_e. Finally, let $\overline{\Omega_c^h} := \cup_{T \in \mathcal{T}_c^h} \overline{T} \approx \overline{\Omega}$ with $h := \max_{T \in \mathcal{T}_c^h} \{\text{diam } T\}$. $\mathcal{T}_c^h$ satisfies the standard conditions; see [27]: It is a finite set of nondegenerate open pairwise disjoint n-simplices s.t. $\Omega \approx \Omega_c^h$. Each facet of a simplex $T \in \mathcal{T}_c^h$ either is a common face of, in $\mathbf{R}^2$ exactly two, for $\mathbf{R}^n, n > 2$, only few simplices in $\mathcal{T}_c^h$ or it approximates, as plane or curved surface, a part of $\partial\Omega$. We use the unifying notations Ω_c^h and $\mathcal{T}_c^h$ and $\mathcal{S}_d^1(\mathcal{T}_c^h)$, $\mathbf{R}^n$ for all cases.

For any $d \geq 0$, we consider FEs, $S_d(\mathcal{T}_c^h)$, and $S_d^1(\mathcal{T}_c^h)$, the spaces of all[1] piecewise polynomial functions of total degree $\leq d$ w.r.t. $\mathcal{T}_c^h$ of n variables, s.t.

$$(4.3)\quad s \in S_d(\mathcal{T}_c^h) \iff s|_T \in \Pi_d^n \quad \forall T \in \mathcal{T}_c^h \text{ and } S_d^1(\mathcal{T}_c^h) = S_d(\mathcal{T}_c^h) \cap C^1(\Omega^h).$$

[1] We do not want to overformalize the notation and have chosen $h \in H \subset \mathbf{R}, \inf_{h \in H} h = 0$.

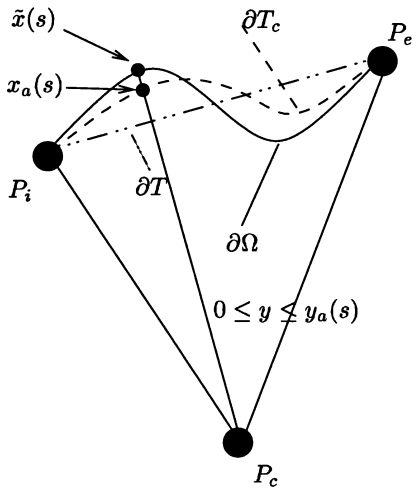

FIG. 4.1. *Approximation of the* $\partial\Omega$.

We need $d \ge 2^n + 1, n \ge 2$, and so $d \ge 5$ in $\mathbf{R}^2$ and $d \ge 9$ in $\mathbf{R}^3$ for $S^1_d(\mathcal{T}^h_c)$.

Davydov uses *quasi-uniform* and *nondegenerate* FEs, the *shape regularity constant* $\omega_{\mathcal{T}^h_c}$ with $1/\omega_{\mathcal{T}^h_c} := \min_{T\in\mathcal{T}^h} \operatorname{diam} B_T/\operatorname{diam} T \ge \chi > 0$, where B_T is the largest ball in $\overline{T}$. The *star,* $\operatorname{star}(v)$, of a vertex, v, of $\mathcal{T}^h_c$ is the union of all n-simplices $\overline{T} \in \mathcal{T}^h_c$ attached to v. We set $\operatorname{star}^1(v) := \operatorname{star}(v)$ and define $\operatorname{star}^\gamma(v)$, $\gamma \ge 2$, recursively as the union of the stars of all vertices of $\mathcal{T}^h_c$ contained in $\operatorname{star}^{\gamma-1}(v)$.

The $\mathcal{S}^1_d(\mathcal{T}^h_c) \not\subset H^k(\Omega^h_c), 1 < k-1$, are subsets of the broken Sobolev spaces, $H^k(\mathcal{T}^h_c)$. We choose three *sequences of linear FE subspaces*

$$\mathcal{U}^h = \mathcal{W}^h = S^h \subset \mathcal{S}^1_d(\mathcal{T}^h_c) \supset \mathcal{V}^h = S^h_0 \subset \mathcal{S}^1_d(\mathcal{T}^h_c) \cap H^1_0(\Omega^h_c), \text{ with } d \ge 2^n + 1$$

(4.4) and $\|u^h\|_{\mathcal{U}^h} := \|u^h\|_{H^2(\mathcal{T}^h_c)}, \quad \|w^h\|_{\mathcal{W}^h} := \|w^h\|_{H^1(\mathcal{T}^h_c)}, \quad \|v^h\|_{\mathcal{V}^h} := \|v^h\|_{L^2(\mathcal{T}^h_c)}.$

The $\|u^h\|_{\mathcal{U}^h}$, $\|w^h\|_{\mathcal{W}^h}$ are nonequivalent norms for $h \to 0$, essential for convergence.

4.2. Inverse and error estimates for polyhedral Ω in $\mathbf{R}^n$. For polyhedral Ω and the FEMs below we choose the subspaces $\mathcal{U}^h = \mathcal{V}^h = S^h_0$ of $\mathcal{S}^1_d(\mathcal{T}^h_c)$, exactly vanishing on $\partial\Omega^h_c$. For this case and its conforming FEs we need only the "inverse" and "error estimates"; cf. Theorems 4.1 and 4.2 with (4.5) and (4.11). They are proved in [27] for polyhedral $\Omega \subset \mathbf{R}^n, n \ge 2, d \ge 2^n + 1$, or polyhedral approximations $\Omega^h_c \approx \Omega$.

THEOREM 4.1. *For* $0 \le k < \mu \le d$, *we have*

$$|s|_{H^\mu(T)} \le \frac{K}{(\operatorname{diam} T)^{\mu-k}} |s|_{H^k(T)} \quad \forall s \in S_d(\mathcal{T}^h_c), \quad T \in \mathcal{T}^h_c. \tag{4.5}$$

The constant K *depends only on* $n, d, \omega_{\mathcal{T}^h_c}$. *For a quasi-uniform triangulation* $\mathcal{T}^h_c$ *the* $|s|_{H^j(T)}, j = \mu, k$, *can be replaced by* $|s|_{H^j(\mathcal{T}^h_c)}$.

We introduce a *stable and local basis* for S^h and its dual basis for $S^{h'}$:

$$\mathcal{S}_d(\mathcal{T}^h_c) \supset \mathcal{S}^1_d(\mathcal{T}^h_c) \supset S^h := \operatorname{span}[s^1, \dots, s^N] \text{ and } S^{h'} := \operatorname{span}[\lambda^1, \dots, \lambda^N]. \tag{4.6}$$

This means, for each $s^k, k = 1, \dots, N$, there exist a set $E_k \subset \Omega^h_c$ and a vertex v_k, s.t.

$$\operatorname{supp} s^k \subset E_k, \text{ with a vertex } v_k, \text{ and } E_k \subset \operatorname{star}^\gamma(v_k), \text{ and with} \tag{4.7}$$

$$\|s^k\|_{L_\infty(\Omega^h_c)} \le C_1, \text{ and } |\lambda^k s| \le C_2 \|s\|_{L_\infty(E_k)} \ \ \forall s \in S^h, \ \lambda^k \text{ in (4.6)}, \tag{4.8}$$

for some C_1, C_2 and γ; see (3.1)–(3.4) and (3.13) in [27]. Hence, after renorming the s^μ, the norms

$$\|(c_\mu)_{\mu=1}^N\|_p \text{ and } \Big\|\sum_{\mu=1}^N c_\mu s^\mu\Big\|_p \quad \forall 1 \le p \le \infty \text{ are equivalent.}$$

This property is important for stable interpolations. It is proved for $S_d^1(\mathcal{T}_c^h)$ and subspaces $S^h \subset S_d^1(\mathcal{T}_c^h)$ if $d \ge 2^n + 1$ in Davydov [28, 27] and the references therein; for FE subspaces, see, e.g., [13]. Generalizing (4.3), let the S^h satisfy the global property

$$\Pi_{\ell-1}^n \subset S^h \subset S_d(\mathcal{T}_c^h) \quad \text{for some } 0 \le \ell - 1 \le d. \tag{4.9}$$

THEOREM 4.2. *Under the conditions* (4.6)–(4.9)*, there exists a linear operator* $I^h : L_1(\Omega_c^h) \to S^h$*, s.t. for any* $T \in \mathcal{T}_c^h$*,* $0 \le |\alpha| \le \ell - 1$*,* $u \in L_1(\Omega_c^h)$ *with* $|u|_{H^\ell(\Omega_T^\gamma)} < \infty$*,*

$$\|D^\alpha(u - I^h u)\|_{L^2(T)} \le K h_T^{\ell-|\alpha|} |u|_{H^\ell(\Omega_T^\gamma)}, \text{ with } \Omega_T^\gamma := \cup_{v\in T} \mathrm{star}^{2\gamma-1}(v), \tag{4.10}$$

with the Lipschitz constant $L_{\partial\Omega_c^h}$ *of* $\partial\Omega_c^h$ *and* $K = K(n, d, \omega_{\mathcal{T}_c^h}, \gamma, C_1, C_2, L_{\partial\Omega_c^h})$*. If* $u \in H^\ell(\Omega_c^h)$*, then for all* $0 \le |\alpha|, k \le \ell - 1$*,*

$$\|D^\alpha(u - I^h u)\|_{L^2(\Omega_c^h)} \le K h^{\ell-|\alpha|} |u|_{H^\ell(\Omega_c^h)} \Rightarrow \lim_{h\to 0} \|I^h u\|_{H^k(\mathcal{T}_c^h)} = \|u\|_{H^k(\Omega_c^h)}, \tag{4.11}$$

$$\|u - I^h u\|_{H^k(\mathcal{T}_c^h)} \le K h^{\ell-k} |u|_{H^\ell(\Omega_c^h)} \quad \textit{and} \tag{4.12}$$

$$\|u - I^h u\|_{H^k(\partial\Omega_c^h)} \le K h^{\ell-k-1/2} |u|_{H^\ell(\Omega_c^h)} \Longrightarrow \lim_{h\to 0} \|I^h u\|_{H^k(\partial\Omega_c^h)} = \|u\|_{H^k(\partial\Omega_c^h)},$$

with the broken boundary norm, $\|u^h\|_{H^k(\partial\Omega_c^h)} = \|u^h\|_{H^k(\partial\mathcal{T}_c^h)}$*; cf. the trace theorem.*

4.3. Stable splitting of $S^h = S_0^h \oplus S_b^h$ for $\Omega \in C^2$. The S^h and $S^{h'}$, constructed for an $\Omega_c^h \approx \Omega$, and their above local stable basis for S^h have to be determined in a special way. They have to allow a stable splitting for the FEs, S_0^h, vanishing on $\partial\Omega_c^h$, and the complementary set, S_b^h, with two local stable bases and their duals satisfying

$$\begin{aligned} &S_d^1(\mathcal{T}_c^h) \supset \mathrm{span}\{s^1, \dots, s^N\} = S^h = S_0^h \cup S_b^h, S_0^h \cap S_b^h = \{0\}, \text{ with} \\ &S_0^h = \mathrm{span}\{s^1, \dots, s^{N_0}\}, \quad S_b^h = \mathrm{span}\{s^{1+N_0}, \dots, s^N\}, \quad N_0 + N_b = N. \end{aligned} \tag{4.13}$$

Analogously we obtain, with $\lambda^i s^j = \delta_{i,j}$, for the dual bases

$$\begin{aligned} &\mathrm{span}\{\lambda^1, \dots, \lambda^{N_0}, \lambda^{1+N_0}, \dots, \lambda^N\} = S^{h'} = S_0^{h'} \cup S_b^{h'}, \quad S_0^{h'} \cap S_b^{h'} = \{0\}, \text{ s.t. for} \\ &i = 1, \dots, N: \quad s^j \in S_0^h, \quad j = 1, \dots, N_0: \ \lambda^i s^j = \begin{cases} 1 & \text{if } i = j, \\ 0 & \text{otherwise} \end{cases} \text{ and} \\ &s_b^j = s^{j+N_0} \in S_b^h, \quad \lambda_b^j = \lambda^{j+N_0}, \quad j = 1, \dots, N_b: \quad \lambda^i s_b^j = \begin{cases} 1 & \text{if } j + N_0 = i, \\ 0 & \text{otherwise.} \end{cases} \end{aligned} \tag{4.14}$$

We apply, for simplicity, the following interpolation operators, I^h, only to functions

$$\lambda^i, \quad i = 1, \dots, N, \text{ are defined, e.g., for } f \in C^{k_0}(\Omega_c^h). \tag{4.15}$$

Otherwise averaged Taylor polynomials or extension theorems could be used; see [27].

The above I^h (cf. (4.11)) and the new I_b^h have the form

$$(4.16)\, I^h, I_b^h : C^2(\Omega_c^h) \to S^h,\ I^h(f) = \sum_{i=1}^{N} \lambda^i(f) s^i \in S^h,\ I_b^h(f) = \sum_{i=1+N_0}^{N} \lambda^i(f) s^i \in S_b^h.$$

A stable splitting with the properties in Theorem 4.4 is possible only if S^h satisfies certain unexpected conditions. For the usual Argyris FEs in $\mathcal{S}_5^1(\mathcal{T}_c^h)$, the standard continuous second derivatives in all vertices are required for S^h only for interior vertices. So the chosen degree, smoothness properties, and interpolation conditions at $\partial\Omega_c^h$ are related; cf. the subtle discussion for the modified Argyris FEs in [27].

Presently, the following results are fully proved in [27] only for modified Argyris FEs in $\mathbf{R}^2$ on a polygonal $\Omega_c^h \approx \Omega$ with $\operatorname{dist}(\partial\Omega_c^h, \partial\Omega) \le Ch^2$. This restricts, for $\Omega \in C^2$, the convergence of our FEM to the order $p = 2$. Davydov is generalizing these results to FEs $\mathcal{S}_d^1(\mathcal{T}_c^h)$ on piecewise conical $\partial\Omega_c^h \approx \partial\Omega$. This allows FEMs of order $p > 2$ for $\Omega \in C^p$, probably even in $\mathbf{R}^n, n \ge 2$.

THEOREM 4.3. *Let $\partial\Omega \in C^p, p \ge 2$. Then the polyhedral Ω^h with $p = 2$ and piecewise curved approximation Ω_c^h for Ω with $p > 2$ yield*

$$(4.17)\ \operatorname{dist}\{\partial\Omega, \partial\Omega_c^h\} \le Ch^2 \|\partial\Omega\|_{C^p} \text{ and } \operatorname{dist}\{\partial\Omega, \partial\Omega_c^h\} \le Ch^p \|\partial\Omega\|_{C^p},\ \textit{respectively.}$$

THEOREM 4.4. *We assume $n \ge 2, d \ge 2^n + 1$, $\partial\Omega \in C^p, 2 \le p \le 5$ and choose the piecewise polyhedral, $p = 2$, or conical $\partial\Omega_c^h \approx \partial\Omega, 2 < p \le 5$ from Theorem 4.3. Davydov [27] proves and remarks for $n = 2, d = 5, p = 2$ and $n \ge 2, d \ge 2^n - 1$:*

1. *There exists a subspace S^h of $\mathcal{S}_d^1(\mathcal{T}_c^h)$ in $\mathbf{R}^n$ with a stable splitting of a local stable basis in (4.6)–(4.9) into two complementary stable subbases in (4.13), (4.14).*

2. *The above* interpolation operators $I : C^{k_0}(\Omega_c^h) \to S$ *and* $I_b : C^{k_0}(\Omega_c^h) \to S_b$ *(see (4.15) and (4.16)) have the following properties.*

   a. *If $f|_{\partial\Omega_c^h} = 0$, then $I(f) \in S_0$.*

   b. *For $f \in C^{k_0}(\Omega_c^h)$ and $\ell \le d + 1$, let $H^\ell(\Omega_c^h) \subset C^{k_0}(\Omega_c^h)$. Then*

$$(4.18)\ \|D^\alpha(f - I(f))\|_{L_2(\Omega_c^h)} \le Kh^{\ell-|\alpha|} |f|_{H^\ell(\Omega_c^h)} 0 \quad \forall 0 \le |\alpha| \le \ell - 1;\ \textit{moreover,}$$
$$I_b(f)|_{\partial\Omega_c^h} = I(f)|_{\partial\Omega_c^h} \text{ and } \|D^\alpha(f - I_b(f))\|_{L_p(\partial\Omega_c^h)} \le Kh^{\ell-|\alpha|-1/2} |f|_{H^\ell(\Omega_c^h)}.$$

The constant K depends only on p, $\omega_{\mathcal{T}_c^h}$, and the Lipschitz constant $L_{\partial\Omega_c^h}$.

3. *Restricting $u^h \in S^h$ to the boundary $\partial\Omega_c^h$ yields*

$$(4.19)\quad u^h \in S^h \text{ satisfies } u^h|_{\Omega_c^h} = 0 \Longleftrightarrow (u^h|_{\Omega_c^h}, v^h|_{\Omega_c^h})_{L^2(\partial\Omega_c^h)} = 0 \quad \forall v^h \in S_b^h.$$

Davydov [27] states in his Remark 5.2 that 1.–3. remain correct for $n = 2$, some curved $\partial\Omega_c^h \approx \partial\Omega, 2 < p \le 5$, and modified S^h.

The convergence proofs of our FEM below are formulated on the basis of the results in Theorem 4.4. So future updates of our FEM are straightforward by these general results, based upon Theorem 5.1 and Remark 5.2 of [27].

4.4. An extension theorem and error estimates for $\Omega \in C^2$. The preceding FE spaces are defined on $\Omega_c^h \ne \Omega$. Similarly to Crouzeix and Raviart [26], Ciarlet [19], Lenoir [42], and Bernadou [5, 6], we apply extension operators, E_c (see Theorem 4.5), to the original functions. Then Theorem 4.6 correctly formulates error estimates as $\|E_c u - P^h u\|_{H^\ell(\Omega_c^h)}$. Correspondingly, the boundary conditions $B_D u = u|_{\partial\Omega} = 0$ are violated into $B_D^h u = (E_c u)|_{\partial\Omega_c^h} = \mathcal{O}(h^p)$ and for $\Omega \in C^p$, with $p = 2$ for polygonal Ω^h and $p > 2$ for curved Ω_c^h.

Different types of extension operators are studied in the literature; see, e.g., Gilbarg and Trudinger [35, pp. 136ff.], Zeidler [63, pp. 305ff.], and Brenner and Scott [13, p. 31]. Treves [58] proves Theorem 26.A.3 for functions in $u \in C^k(\overline{\Omega})$ and extends it continuously to $u \in W^{k,p}(\Omega), 1 \le p < \infty$, in Corollary 26.A.1, yielding (4.20), (4.21). This technique can obviously be extended to show (4.22).

THEOREM 4.5 (extension operator). *Let $\Omega \in C^k$, Ω_c^h, $\Omega_0 \supset \overline{(\Omega \cup \Omega_c^h)}$, and $k \in \mathbf{N}$ be given. Then there exist a linear bounded extension $E_c : H^k(\Omega) \to H^k(\Omega \cup \Omega_c^h) \to H_0^k(\Omega_0)$ and a constant, $C = C(k, \Omega, \Omega_c^h, \Omega_0)$, s.t.*

$$E_c u|_\Omega = u \text{ on } \Omega \text{ and } \|E_c u\|_{H^k(\Omega \cup \Omega_c^h)} \le C \|u\|_{H^k(\Omega)} \quad \forall u \in H^k(\Omega). \tag{4.20}$$

The traces of the partials of u and $E_c u \in H^k(\Omega \cup \Omega_c^h)$ to the boundary $\partial\Omega$ coincide:

$$H^{k-|\beta|-1/2}(\partial\Omega) \ni \partial^\beta (u - E_c u)|_{\partial\Omega} = 0 \quad \forall |\beta| \le k, \forall u \in H^k(\Omega) \tag{4.21}$$

$$\Longrightarrow \|\partial^\beta \big(E_c u(x)\big) - E_c\big(\partial^\beta u(x)\big)\|_{L^2(\Omega \cup \Omega_c^h)} \le Ch \|u\|_{H^{|\beta|}(\Omega)} = 0 \quad \forall u \in H_0^k(\Omega). \tag{4.22}$$

THEOREM 4.6 (interpolation errors). *Under the conditions* (4.6)–(4.9)*, those of Theorems* 4.4 and 4.5*, and for Ω piecewise in $C^p, 2 \le p \le 5$, a positive constant $K = K(n, d, \omega_{\mathcal{T}_c^h}, \gamma, C := C_1 C_2, L_{\partial\Omega^h})$ exists, s.t. for $u \in H^\ell(\Omega)$, and $0 \le s \le \ell - 1$ (cf.* (4.9), (4.15)*), we obtain for the operator*

$$P^h = I^h E_c : \quad \|E_c u - P^h u\|_{H^s(\mathcal{T}_c^h)} \le C\ h^{\ell - s} |u|_{H^\ell(\Omega)}, \text{ and } \|P^h u\|_{H^s(\mathcal{T}_c^h)} \le C \|u\|_{H^\ell(\Omega)}$$

$$\|E_c u - P^h u\|_{H^s(\partial\Omega_c^h)} \le C\ h^{\ell - s - 1/2} |u|_{H^\ell(\Omega)}, \text{ and } \|P^h u\|_{H^s(\partial\Omega_c^h)} \le C \|u\|_{H^\ell(\Omega)}. \tag{4.23}$$

The $\mathcal{U}^h$ approximate the $H^s(\Omega), \ell \ge s$, and $H^s(\partial\Omega)$, $\ell \ge s + 1/2$, e.g., in the sense that

$$dist(E_c u, \mathcal{U}^h) := \inf_{u^h \in \mathcal{U}^h} ||E_c u - u^h||_{H^s(\mathcal{T}_c^h)} \to 0 \quad \forall u \in H^s(\Omega) \quad \text{for } h \to 0. \tag{4.24}$$

5. An abstract convergence theorem. We want to apply the general theory of discretization methods, e.g., in Stetter [51, Definition 1.1.2] and Böhmer [9, 10], with its standard "consistency and stability implies convergence" result to our FEM, here the *conforming and the nonconforming FEMs* in the next section. We formulated the new FEM for second order equations with trivial Dirichlet boundary conditions; see (2.6). We use the notations in (3.1), (3.6), and (3.7). Let (3.8) have a locally unique solution (see section 3) with boundedly invertible derivative $G'(u_0)$.

We recall that our program for proving convergence requires several steps, summarized in section 2, **1.**–**4.**: Until now we have worked through the first two bullets of **1.**, and we turn, in this and the next section, to the last three bullets of **1.**.

The *conforming FEs,* defined on a triangulation with straight edges, $\mathcal{T}^h$, require

$$\Omega \text{ convex, bounded and polyhedral with } \overline{\Omega} = \cup_{T \in \mathcal{T}^h} \overline{T}. \tag{5.1}$$

In section 6 we will return to *nonconforming FEs,* defined on $\Omega \in C^2$. This yields the more complicated case of violated differential and boundary equations.

5.1. The original problem and its discretization. We need the following spaces:

$$\mathcal{U} = H^2 \subset \mathcal{V} = \mathcal{V}' = L^2, \quad \mathcal{U}_0 = \mathcal{U} \cap H_0^1 \text{ all defined on } \Omega. \tag{5.2}$$

G and its exact solution u_0 satisfy

$$G : \mathcal{D}(G) \subset \mathcal{U} \to \mathcal{V} \text{ and } G(u_0) = 0 \in \mathcal{V} \Longleftrightarrow (G(u_0), v)_{\mathcal{V}} = 0 \quad \forall v \in \mathcal{V}. \tag{5.3}$$

We choose the discrete G^h for G as in (2.4). The *sequences of approximating subspaces* $\mathcal{U}^h = \mathcal{V}^h = S_0^h$ in (4.4), defined on the original Ω by (5.1), satisfy the boundary conditions on the exact boundary. This FEM is a so-called *conforming Petrov–Galerkin method.* It yields the standard "consistency and stability implies convergence" result. More precisely we need

$$\{\mathcal{U}^h, \mathcal{V}^h, P^h, Q^h, G^h\}_{h\in H}, \text{ with } \inf\{0 < h \in H\} = 0, \quad \mathcal{S}_d^1(\mathcal{T}^h) \supset \mathcal{U}^h = \mathcal{V}^h = S_0^h. \tag{5.4}$$

For these spaces with identical elements we require (asymptotically) *nonequivalent norms and scalar products,* defined as those of the original spaces (cf. (5.2)), e.g.,

$$\|u^h\|_{\mathcal{U}^h} := \|u^h\|_{\mathcal{U}}, \quad \|v^h\|_{\mathcal{V}^h} := \|v^h\|_{\mathcal{V}}. \tag{5.5}$$

By Theorems 4.2 and 4.6 these sequences *approximate the Banach spaces* $\mathcal{U}, \mathcal{V}$.

For the final FE version of (2.4) we need $G^w, w_{u^h}(x), \mathcal{D}(G^w)$ in (3.6), (3.8), (5.3):

$$\mathcal{D}(G^h) := \{u^h \in \mathcal{U}^h : w_{u^h}(x) \in \mathcal{D}(G^w) \quad \forall x \in \Omega, G(u^h) \in \mathcal{V}\}. \tag{5.6}$$

Then we define the FE solution $u_0^h \in \mathcal{U}^h \subset \mathcal{U}$ s.t.

$$G^h : \mathcal{D}(G^h) \to \mathcal{V}^h, \text{ and } G^h(u_0^h) = 0 \Longleftrightarrow (G(u_0^h), v^h)_{\mathcal{V}} = 0 \quad \forall v^h \in \mathcal{V}^h \subset \mathcal{V}. \tag{5.7}$$

5.2. The necessary projectors. Hence, we introduce *sequences* of projectors, $\{P^h, Q^h\}_{h\in H}$, as appropriate tools for our FEM. The P^h have to satisfy

$$P^h \in \mathcal{L}(\mathcal{U}, \mathcal{U}^h) : \ \forall u \in \mathcal{U} \ \lim_{h\to 0} \|P^h u\|_{\mathcal{U}^h} = \|u\|_{\mathcal{U}}, \text{ we choose } P^h u := I^h u. \tag{5.8}$$

Instead of interpolating values of functions or derivatives as I^h in (4.10), the P^h may be based upon some kind of quasi- or averaging-interpolation or best approximation operator, sometimes called Clément interpolation; cf., e.g., Clément [20], de Boor [31], Scott and Zhang [48], and Davydov [27].

More delicate than P^h are the projectors to the image spaces, the $Q^h \in \mathcal{L}(\mathcal{V}, \mathcal{V}^{h'})$, motivated by G^h. We test $G(u_0) = 0$ and $G^h(u_0^h) = 0$ as in (5.3) and in (5.7). We keep the concepts for the original and the discrete problem as close as possible and use the function spaces and norms in (5.2), (5.4), (5.5). In (5.3) and (5.7) we have satisfied the differential equation and its discrete counterpart by testing with $\mathcal{V}$ and $\mathcal{V}^h$. We define (see (4.20)–(4.22) and Theorem 4.6), for all $f \in \mathcal{V}$,[2]

$$Q^h \in \mathcal{L}(\mathcal{V}, \mathcal{V}^{h'}) : \ \langle Q^h f - f, v^h\rangle_{(\mathcal{V}^{h'}\cup\mathcal{V})\times\mathcal{V}^h} = 0 \quad \forall v^h \in \mathcal{V}^h; \ \lim_{h\to 0} \|Q^h f\|_{\mathcal{V}^{h'}} = \|f\|_{\mathcal{V}}. \tag{5.9}$$

The last limit is obtained as a consequence of (4.11). By (4.13), (4.14) with $\mathcal{V}^h \neq \mathcal{V}^{h'}$ it makes sense that for a function, e.g., $f \in \mathcal{V}$ or $G(u^h) \notin \mathcal{V}^h$, the $Q^h f \in \mathcal{V}^{h'}$ is not a function. We did not identify $\mathcal{V}^h \neq \mathcal{V}^{h'}$ for emphasizing this situation more clearly.

The choice of P^h, Q^h, for the given $\mathcal{U}^h, \mathcal{V}^h$, and problem (5.3) certainly is not unique. The combination $\mathcal{U}, \mathcal{V}, \mathcal{U}^h, \mathcal{V}^h, P^h, Q^h, G^h$ should be chosen appropriately to yield classical consistency (see below) with the highest possible order; see (5.13).

[2]Systematically we use the following identification: For $\mathcal{U} \subset \mathcal{V} = \mathcal{V}'$, for all $u \in \mathcal{U}$, for all $v \in \mathcal{V} \subset \mathcal{U}'$, and the corresponding discrete terms, we obtain $(u, v)_{\mathcal{V}} = \langle u, v\rangle_{\mathcal{U}\times\mathcal{U}'} = \langle u, v\rangle_{\mathcal{U}'\times\mathcal{U}}$, similarly for $\mathcal{V}_D \subset \mathcal{V}_b = \mathcal{V}_b' \subset \mathcal{V}_D', \ldots$, and $\mathcal{W} \subset \mathcal{V} = \mathcal{V}' \subset \mathcal{W}'$ below. This is applied for the following projectors $Q^h, \ldots$ as well.

$$\begin{array}{ccccc} \mathcal{U} & \xrightarrow{G} & \mathcal{V} & \overset{tested\ by}{\longleftrightarrow} & \mathcal{V}=\mathcal{V}' \\ P^h\big\downarrow & \Phi^h\big\downarrow & Q^h\big\downarrow & & \\ \mathcal{U}^h & \xrightarrow{G^h} & \mathcal{V}^{h'} & \overset{tested\ by}{\longleftrightarrow} & \mathcal{V}^h\neq\mathcal{V}^{h'} \end{array}$$

FIG. 5.1. *Conforming FEMs for fully nonlinear problems.*

5.3. Projectors and discretization. For the nonlinear operator, $G : \mathcal{D}(G) \subset \mathcal{U} \to \mathcal{V}$, in (5.3), the previously introduced projectors P^h, Q^h allow a shorthand notation of the corresponding discrete operator, $G^h : \mathcal{D}(G^h) \subset \mathcal{U}^h \to \mathcal{V}^{h'}$; see (5.7). So we determine the exact solution $u_0^h \in \mathcal{U}^h$ s.t.

$$\langle G(u_0^h), v^h\rangle_{\mathcal{V}^{h'}\times\mathcal{V}^h} = 0 \quad \forall v^h \in \mathcal{V}^h \Longleftrightarrow G^h(u_0^h) = 0 \text{ with } G^h := Q^h G|_{\mathcal{U}^h}. \tag{5.10}$$

This brings about a mapping

$$\mathcal{D}(\Phi^h) := \{G \text{ in (5.3)}\} \text{ and } \Phi^h \text{ defined by } \Phi^h(G) := G^h := Q^h G|_{\mathcal{U}^h} \text{ in (5.10)}. \tag{5.11}$$

This Φ^h is even linear s.t.

$$\Phi^h(c_1G^1 + c_2G^2) = c_1\Phi^h(G^1) + c_2\Phi^h(G^2) \quad \forall c_1, c_2 \in \mathbf{R},\ \forall G^1, G^2 \in \mathcal{D}(\Phi^h). \tag{5.12}$$

Linearity is essential for the MIP in section 9, allowing the proof of a quadratically convergent discrete Newton method.

Our modification of Stetter [51] and Vainikko [59] emphasizes the testing with the $\mathcal{V},\ \mathcal{V}^h$: Summarizing yields Figure 5.1 with uniformly bounded P^h, Q^h.

A method is called *convergent* and *convergent of order k* if the solutions u_0 and u_0^h of $Gu_0 = 0$ and $G^h u_0^h = 0$ in (6.5) and (5.10), satisfy[3]

$$\|u_0^h - P^h u_0\|_{\mathcal{U}^h} \to 0 \text{ and } \|u_0^h - P^h u_0\|_{\mathcal{U}^h} = \mathcal{O}(h^k) \text{ for } h \to 0, \text{ respectively.}$$

These $\mathcal{O}(h^k)$ are usually estimated by $Ch^k\|u_0\|_{H^{k'}(\Omega)}$ with appropriate k, k'.

For convergence, we need the *classical consistency errors* for general u (see (5.3)):

$$\|G^h P^h u - Q^h G u\|_{\mathcal{V}^{h'}} \quad \text{for } u_0 : \|G^h P^h u_0 - Q^h G u_0\|_{\mathcal{V}^{h'}} = \|Q^h G P^h u_0\|_{\mathcal{V}^{h'}}, \tag{5.13}$$

where these residuals can be used for adaptive methods. A discretization method for $G(u) = 0$ is called *consistent* and *consistent of order k* in u, if, respectively,

$$\|Q^h G P^h u - Q^h G u\|_{\mathcal{V}^{h'}} \to 0 \text{ and } \|Q^h G P^h u - Q^h G u\|_{\mathcal{V}^{h'}} = \mathcal{O}(h^k) \text{ for } h \to 0. \tag{5.14}$$

Our conforming FEM is consistent for a continuous or Lipschitz continuous G, e.g.,

$$\|Q^h G P^h u - Q^h G u\|_{\mathcal{V}^{h'}} \le \|Q^h\|_{\mathcal{V}^{h'}\hookleftarrow\mathcal{V}} L \|P^h u - u\|_{\mathcal{U}}. \tag{5.15}$$

For the *stability,* we start with a fixed sequence $\{u^h \in \mathcal{D}(G^h)\}_{h\in H}$. Assume there exist constants, $h_0, r, S \in \mathbf{R}_+$, *independent of h,* s.t., *uniformly* for all $h \in H, h < h_0$,

$$\forall\ u_i^h \in B_r(u^h) \subset \mathcal{D}(G^h), \quad i = 1, 2, \Longrightarrow \|u_1^h - u_2^h\|_{\mathcal{U}^h} \le S\|G^h(u_1^h) - G^h(u_2^h)\|_{\mathcal{V}^{h'}}, \tag{5.16}$$

[3] Although we could use $\|u_0^h - u_0\|_{\mathcal{U}}$ in our case, we use the notation $\|u_0^h - P^h u_0\|_{\mathcal{U}^h}$, applicable to the nonconforming case below.

with $B_r(u^h) = \{v^h \in \mathcal{U}^h : \|v^h - u^h\|_{\mathcal{U}^h} < r\}$, similarly for $B_r(u)$. We always assume $B_r(u), B_r(u^h) \subset \mathcal{D}(G)$. G^h is called *stable in the sequence* $\{u^h\}_{h\in H}$ or for short *stable in* u^h, and the S and r are called *stability bound and stability threshold,* respectively. Often we choose $u^h := P^h u_0$. Combining Theorems 1.2.3 and 1.2.4 in Stetter [51] we get the following.

THEOREM 5.1. *Let the original problem* (5.3) *have the exact solution* $u_0 \in \mathcal{U}$. *Let its discretization* $G^h = Q^h G|_{\mathcal{U}^h} : \mathcal{U}^h \to \mathcal{V}^{h'}$ *in* (5.10) *satisfy the following:*

1. *The projectors* P^h *and* $Q^h_{c,\Pi}$ *are (equi-)bounded and satisfy* (5.8) *and* (5.9).
2. $G^h : \mathcal{U}^h \to \mathcal{V}^{h'}$ *is defined and continuous in* $B_r(P^h u_0),\ r > 0, h$*-independent.*
3. G^h *is consistent with* G *in* $P^h u_0$.
4. G^h *is stable for* $P^h u_0$.

Then the discrete problem $G^h(u^h) = 0$ *possesses a unique solution* $u^h_0 \in \mathcal{U}^h$ *near* u_0 *for all sufficiently small* $h \in H$, *and* u^h_0 *converges to* u_0. *If* G^h *is consistent and consistent of order* p, *then* u^h_0 *converges and converges of order* p, *respectively:*

$$\|u^h_0 - P^h u_0\|_{\mathcal{U}^h} \le S\|Q^h G P^h u_0\|_{\mathcal{V}^{h'}} \to 0 \text{ and } \|u^h_0 - P^h u_0\|_{\mathcal{U}^h} \le \mathcal{O}(h^p). \tag{5.17}$$

We will discuss the significance of the conditions 1.–4. in Remark 6.1 below.

6. An abstract convergence theorem for nonconforming FEs. Now we return to *nonconforming FEs.* So we require

$$\Omega \in C^2 \text{ and a triangulation, } \mathcal{T}^h_c, \text{ with curved edges, s.t. } \overline{\Omega} = \cup_{T\in\mathcal{T}^h_c}\overline{T}. \tag{6.1}$$

Again, the first two paragraphs in section 5 remain valid. The $\mathcal{U}, \mathcal{W}, \mathcal{V} = \mathcal{V}'$, defined on the original Ω, now are approximated by *sequences of nonconforming subspaces* $\mathcal{U}^h, \mathcal{W}^h, \mathcal{V}^h$, defined on the approximate Ω^h_c. This implies *violated boundary conditions* on the exact boundary; cf. (6.2). The FEM changes into a so-called *nonconforming Petrov–Galerkin method,* requiring a more complicated treatment than in section 5.

6.1. The original problem and its nonconforming discretization. We need (cf. (5.2))

$$\begin{aligned}&\mathcal{U} = H^2 \subset \mathcal{W} = H^1 \subset \mathcal{V} = \mathcal{V}' = L^2 \subset \mathcal{W}' = H^{-1},\ \mathcal{W}_0 = H^1_0 \text{ all defined on } \Omega \text{ versus}\\ &\mathcal{U}_c = H^2 \subset \mathcal{W}_c = H^1 \subset \mathcal{V}_c = L^2 \subset \mathcal{W}'_c = H^{-1},\ \mathcal{W}_{c,0} = H^1_0 \text{ all defined on } \Omega^h_c.\end{aligned} \tag{6.2}$$

We have indicated above that the realization of the differential equation *and* the boundary condition and their violation is a deciding step of this method. Hence, the discretization method has to care about both aspects. This is achieved by the new operator F with the differential operator and the boundary operator as its two components; see (2.1), (2.2). The boundary operator, B_D, maps, by the trace theorem,

$$B_D : \mathcal{U} \to \mathcal{V}_D := H^{3/2}(\partial\Omega) = B_D\mathcal{U}, B_D u := u|_{\partial\Omega}, \quad \mathcal{V}_D \subset \mathcal{V}'_b = \mathcal{V}_b := L^2(\partial\Omega). \tag{6.3}$$

We consider here mainly trivial Dirichlet conditions. Thus we have to characterize

$$u|_{\partial\Omega} = 0 \Leftrightarrow \langle v', u|_{\partial\Omega}\rangle_{\mathcal{V}'_D\times\mathcal{V}_D} = 0 \quad \forall v' \in \mathcal{V}'_D \Leftrightarrow (u|_{\partial\Omega}, v)_{L^2(\partial\Omega)} = 0 \quad \forall v \in \mathcal{V}_b \tag{6.4}$$

for $u \in \mathcal{U}$, with $\mathcal{V}_D = H^{3/2}(\partial\Omega) \hookrightarrow \mathcal{V}_b = \mathcal{V}'_b \hookrightarrow \mathcal{V}'_D$, a dense (compact) embedding.

The transformation from nontrivial to trivial Dirichlet conditions will be combined in Theorems 7.1, 8.4, and 8.7 obtaining stability and convergence for the inhomogeneous case as well.

$F = (G, B_D)$ is called *elliptic* simultaneously with G. F and its Fréchet derivative $F'(u)$ map $\mathcal{U}$ into and onto, respectively, the Cartesian product $\mathcal{V} \times \mathcal{V}_D$:

$$F := (F_1, F_2) := (G, B_D) : \mathcal{U} \to \mathcal{V}_\Pi := \mathcal{V} \times \mathcal{V}_D \subset \hat{\mathcal{V}}_\Pi := \mathcal{V} \times \mathcal{V}_b = \hat{\mathcal{V}}_\Pi'; \tag{6.5}$$

see (3.7). Since $\mathcal{V}_D$ is dense in $\mathcal{V}_b$, the exact solution u_0 is hence characterized by

$$\begin{aligned} F(u_0) = 0 \in \mathcal{V}_\Pi &\Longleftrightarrow (F(u_0), v_\Pi)_{\hat{\mathcal{V}}_\Pi} = 0 \quad \forall v_\Pi := (v, v_b) \in \hat{\mathcal{V}}_\Pi \\ &\Longleftrightarrow (G(u_0), v)_{\mathcal{V}} = 0 \ \forall v \in \mathcal{V}, \text{ and } (B_D u_0, v_b)_{\mathcal{V}_b} = 0 \quad \forall v_b \in \mathcal{V}_b, \\ \text{abbreviated } &\Longleftrightarrow (G(u_0), v)_{\mathcal{V}} + (B_D u_0, v_b)_{\mathcal{V}_b} = 0 \quad \forall v \in \mathcal{V}, \quad v_b \in \mathcal{V}_b. \end{aligned} \tag{6.6}$$

For the standard weak form for $F'(u)$ in section 8, we need (cf. (6.3), (6.4))

$$\begin{aligned} &B_D : \mathcal{W} \to \mathcal{W}_D := H^{1/2}(\partial\Omega) = B_D \mathcal{W}, \quad u \to B_D u = u|_{\partial\Omega}, \text{ with} \\ &u \in \mathcal{W} \text{ and } B_D u = 0 \Longleftrightarrow (u|_{\partial\Omega}, v)_{L^2(\partial\Omega)} = 0 \quad \forall v \in \mathcal{V}_b \text{ dense in } \mathcal{W}_D'. \end{aligned} \tag{6.7}$$

$B_D : \mathcal{U} \to \mathcal{V}_D$ and $B_D : \mathcal{W} \to \mathcal{W}_D$ are continuous w.r.t. the corresponding Sobolev–Sloboditskii norms [37, 43]. Similarly to (6.2), we introduce

$$\begin{aligned} &\mathcal{V}_{c,D} := H^{3/2}(\partial\Omega_c^h) \subset \mathcal{W}_{c,D} := H^{1/2}(\partial\Omega_c^h) \subset \mathcal{V}_{c,b} := L^2(\partial\Omega_c^h) \text{ and} \\ &B_{c,D} : \mathcal{U}_c \to \mathcal{V}_{c,D}, u_c \to B_{c,D} u_c := u_c|_{\partial\Omega_c^h}; \text{ similarly, } B_{c,D} : \mathcal{W}_c \to \mathcal{W}_{c,D}. \end{aligned} \tag{6.8}$$

To apply the general discretization theory [51, 10], we introduce the discrete F^h for F, the corresponding projectors $P^h \in \mathcal{L}(\mathcal{U}, \mathcal{U}^h)$, and $Q_\Pi^h \in \mathcal{L}(\mathcal{V}_\Pi, \mathcal{V}_\Pi^{h'})$, $Q_{c,\Pi}^h \in \mathcal{L}(\mathcal{V}_{c,\Pi}, \mathcal{V}_\Pi^{h'})$; see (6.26). This yields the standard "consistency and stability implies convergence" result, (6.1); mind $S_0^h = S^h \cap H_0^1(\mathcal{T}_c^h)$:

$$\mathcal{S}_d^1(\mathcal{T}_c^h) \supset \mathcal{U}^h = \mathcal{W}^h = S^h = S_0^h \oplus S_b^h, \quad \mathcal{V}^h = S_0^h, \quad \mathcal{V}_D^h = \mathcal{W}_D^h = \mathcal{V}_b^h := S_b^h|_{\partial\Omega_c^h}. \tag{6.9}$$

Again these spaces require *nonequivalent norms and scalar products.* With the norms of the original spaces, now defined on Ω_c^h and $\partial\Omega_c^h$ (cf. (6.2), (6.8)), let

$$\begin{aligned} &\|u^h\|_{\mathcal{U}^h} := \|u^h\|_{\mathcal{U}_c}, \quad \|w^h\|_{\mathcal{W}^h} := \|w^h\|_{\mathcal{W}_c}, \quad \|v^h\|_{\mathcal{V}^h} := \|v^h\|_{\mathcal{V}_c}, \quad \|u^h|_{\partial\Omega_c^h}\|_{\mathcal{V}_D^h} \\ &:= \|u^h|_{\partial\Omega_c^h}\|_{\mathcal{V}_{c,D}}, \quad \|w^h|_{\partial\Omega_c^h}\|_{\mathcal{W}_D^h} := \|w^h|_{\partial\Omega_c^h}\|_{\mathcal{W}_{c,D}}, \quad \|v^h|_{\partial\Omega_c^h}\|_{\mathcal{V}_b^h} := \|v^h|_{\partial\Omega_c^h}\|_{\mathcal{V}_{c,b}}. \end{aligned} \tag{6.10}$$

By Theorems 4.2 and 4.6 these sequences *approximate the Banach spaces* $E_c\mathcal{U}, E_c\mathcal{W}$, $E_c\mathcal{V}, E_c\mathcal{V}_D, E_c\mathcal{W}_D, E_c\mathcal{V}_b$ defined on Ω_c^h and $\partial\Omega_c^h$ w.r.t. the corresponding norms. The $u^h \in S^h$, and $v^h \in \mathcal{V}_b^h$, violate the original boundary conditions.

The product operator $F : \mathcal{U} \to \mathcal{V} \times \mathcal{V}_D$ and the corresponding $F^h : \mathcal{U}^h \to \mathcal{V}^{h'} \times \mathcal{V}_D^h$ cause some unpleasant technicalities in the definition of Q_Π^h, $Q_{c,\Pi}^h$, compared to section 5. Subsequently, the consistency theory becomes relatively simple again; see Figure 6.1 and section 7. These technicalities are not surprising compared to some other approaches for violated boundary conditions, e.g., in Lenoir [42] and Bernadou [5, 6]. The unavoidable complications are piled up in section 8.

The terms u^h, $G(u^h)$, and $u^h|_{\partial\Omega_c^h}$ are, by (3.7), defined on Ω_c^h and $\partial\Omega_c^h$ instead of the original Ω and $\partial\Omega$. Thus we start updating the preliminary FE version (2.6). With $G^w, \mathcal{D}(G^w), w_{u^h}(x)$ in (3.6), (3.7), (3.8), and $\mathcal{U}^h$ in (4.4), let

$$\mathcal{D}(G^h) := \{u^h \in \mathcal{U}^h : w_{u^h}(x) \in \mathcal{D}(G^w) \quad \forall x \in \Omega \cup \Omega_c^h, G(u^h) := G^w(w_{u^h}) \in \mathcal{V}_c\}. \tag{6.11}$$

This extended definition of G^w was the reason for introducing the Ω' in (3.6).

We replace the differential equation $G(u_0) = 0 \in \mathcal{V}, u_0 \in \mathcal{D}(G)$, in (6.5) by the FE equations in equivalent formulations; see (2.5), (2.6), (6.5): Define (cf. (6.10))

$$\text{(6.12) the sequence } F_1^h(u_0^h) = G^h(u_0^h) = 0 \Longleftrightarrow (G(u_0^h), v^h)_{\mathcal{V}_c} = 0 \quad \forall v^h \in \mathcal{V}^h \subset \mathcal{V}_c.$$

Similarly, the boundary conditions (6.4) are tested (see the equivalence (4.19)) as

$$\text{(6.13)} \quad u^h \in \mathcal{U}^h : F_2^h(u^h) = B_D^h u^h = u^h|_{\partial\Omega_c^h} = 0 \in \mathcal{V}_D^h \Leftrightarrow (v_b^h, u^h)_{\mathcal{V}_b^h} = 0 \quad \forall v_b^h \in S_b^h,$$

essentially with S_b^h dense in $\mathcal{V}'_{c,D}$. Consequently we introduce (cf. F in (6.5))

$$F^h = (F_1^h, F_2^h) = (G^h, B_D^h) \text{ with } \mathcal{D}(F^h) := \mathcal{D}(G^h). \tag{6.14}$$

6.2. The nonconforming projectors. Again, projectors represent an appropriate tool for $F^h = (F_1^h, F_2^h)$. They have to handle the discrepancy between u^h, $G(u^h)$, and $u^h|_{\partial\Omega_c^h}$, by (3.7), defined on Ω_c^h and $\partial\Omega_c^h$ instead of the original Ω and $\partial\Omega$. We combine the extension operator E_c introduced in Theorem 4.5 with inverse estimates and the estimates for interpolation errors on Ω in Theorems 4.1–4.6. The *sequence* of P^h has to satisfy

$$P^h \in \mathcal{L}(\mathcal{U},\mathcal{U}^h) : \ \forall u \in \mathcal{U} \ \lim_{h\to 0} \|P^h u\|_{\mathcal{U}^h} = \|u\|_{\mathcal{U}}, \text{ we choose } P^h u := I^h E_c u. \tag{6.15}$$

E_c is unnecessary for the Argyris FEs but possibly needed for other schemes.

Again more delicate than P^h are the projectors on the product space, $Q_\Pi^h \in \mathcal{L}(\mathcal{V}_\Pi, \mathcal{V}_\Pi^{h'})$. They live on the original and discrete image spaces, listed in (6.16)–(6.18), with their duals, scalar products, and pairings; cf. (6.5), (6.6). For the reader's convenience, we summarize and introduce the spaces defined on Ω and Ω_c^h; cf. (4.13), (4.14), Theorem 4.4, (6.2), (6.4), (6.9), (6.12), (6.13). We mark functions and functionals, according to their definition, by obvious indices. For functions defined on Ω_c^h we use $_c$, for $\partial\Omega$ we use $_b$, for $\partial\Omega_c^h$ we use $_{c,b}$, for the images of B_D on $\partial\Omega_c^h$ we use $_{c,D}$, and on the product of domain and boundary on Ω and Ω_c^h we use $_\Pi$ or $_{c,\Pi}$:

$$\begin{aligned} &\mathcal{V}_\Pi := \mathcal{V} \times \mathcal{V}_D \subset \hat{\mathcal{V}}_\Pi := \mathcal{V} \times \mathcal{V}_b, \text{ with } \mathcal{U} = H^2(\Omega), \mathcal{V} = L^2(\Omega) = \mathcal{V}', \\ &\mathcal{V}_b = L^2(\partial\Omega) = \mathcal{V}_b' \supset \mathcal{V}_D = B_B\mathcal{U} = H^{3/2}(\partial\Omega), \text{ defined on } \Omega, \text{ with} \\ &\big((u,u_b),(v,v_b)\big)_{\mathcal{V}_\Pi} := (u,v)_{\mathcal{V}} + (u_b,v_b)_{\mathcal{V}_D}, \ \big((u,u_b),(v,v_b)\big)_{\hat{\mathcal{V}}_\Pi} := (u,v)_{\mathcal{V}} + (u_b,v_b)_{\mathcal{V}_b}. \end{aligned} \tag{6.16}$$

Similarly, we define the spaces and scalar products on the curved approximations

$$\mathcal{V}_c = L^2(\Omega_c^h), \quad \mathcal{V}_{c,D} = B_B\mathcal{U}_c = H^{3/2}(\partial\Omega_c^h), \quad \mathcal{V}_{c,\Pi}, \mathcal{V}_{c,b}, \dots, \text{ defined on } \Omega_c. \tag{6.17}$$

Correspondingly, the discrete analog spaces and their scalar products are

$$\begin{aligned} &\mathcal{V}_\Pi^h := \mathcal{V}^h \times \mathcal{V}_D^h := S_0^h \times S_b^h|_{\partial\Omega_c^h}, \ \mathcal{V}^{h'} \neq \mathcal{V}^h, \ \mathcal{V}_\Pi^{h'} = \mathcal{V}^{h'} \times \mathcal{V}_D^h := S_0^{h'} \times S_b^h|_{\partial\Omega_c^h} \neq \mathcal{V}_\Pi^h, \\ &\hat{\mathcal{V}}_\Pi^h := \mathcal{V}^h \times \mathcal{V}_b^h, \quad \langle (u^{h'},u_b^h),(v^h,v_b^h)\rangle_{\mathcal{V}_\Pi^{h'}\times\mathcal{V}_\Pi^h} := \langle u^{h'},v^h\rangle_{\mathcal{V}^{h'}\times\mathcal{V}^h} + (u_b^h,v_b^h)_{\mathcal{V}_D^h}. \end{aligned} \tag{6.18}$$

In (6.6), (6.12) and (6.4), (6.13) we have satisfied the differential equation and boundary condition or their discrete counterparts by testing with $\mathcal{V}$ and $\mathcal{V}_b$ or (see the equivalence (4.19)) with $\mathcal{V}^h$ and $\mathcal{V}_b^h$. The two components (6.6), (6.4) and (6.12), (6.13) of F and F^h, defined on Ω and Ω_c^h, respectively, are now combined with the

extension operator E_c in (4.20) for motivating the appropriate definitions of the projection operators. For the discrete spaces $\mathcal{V}^{h'} \neq \mathcal{V}^h$ and $\mathcal{V}_b^{h'} = \mathcal{V}_b^h$ the FE equations always are tested with $v^h \in \mathcal{V}^h$ and $v_b^h \in \mathcal{V}_b^h$, but we use for the boundary condition the equivalence (6.13). Thus corresponding to the product spaces $\mathcal{V}_\Pi$ and $\mathcal{V}_{c,\Pi}$ we have to introduce two projectors $Q_\Pi^h := (Q^h, Q_b^h) \in \mathcal{L}(\mathcal{V}_\Pi, \mathcal{V}_\Pi^{h'})$ and $Q_{c,\Pi}^h := (Q_c^h, Q_{c,b}^h) \in \mathcal{L}(\mathcal{V}_{c,\Pi}, \mathcal{V}_\Pi^{h'})$. We start with the component of the differential operator, (6.12) (mind $\mathcal{V} = \mathcal{V}', \mathcal{V}_b = \mathcal{V}_b'$), and define (see (4.20)–(4.22) and Theorem 4.6)

$$(6.19)\quad Q^h \in \mathcal{L}(\mathcal{V}, \mathcal{V}^{h'}) \text{ for } f \in \mathcal{V} \text{ by } \langle Q^h f, v^h\rangle_{\mathcal{V}^{h'}\times\mathcal{V}^h} - (E_c f, v^h)_{\mathcal{V}_c} = 0 \quad \forall v^h \in \mathcal{V}^h.$$

The approximate domains require

$$Q_c^h \in \mathcal{L}(\mathcal{V}_c, \mathcal{V}^{h'}) \text{ for } f_c \in \mathcal{V}_c:\ \langle Q_c^h f_c, v^h\rangle_{\mathcal{V}^{h'}\times\mathcal{V}^h} - (f_c, v^h)_{\mathcal{V}_c} = 0 \quad \forall v^h \in \mathcal{V}^h.$$

Both projectors yield the norm limits, the last limit as a consequence of (4.11):

$$(6.20)\qquad \lim_{h\to 0} \|Q^h f\|_{\mathcal{V}^{h'}} = \|f\|_{\mathcal{V}}, \text{ and } \lim_{h\to 0} \|Q_c^h f_c\|_{\mathcal{V}^{h'}} = \lim_{h\to 0} \|f_c\|_{\mathcal{V}_c}.$$

Since the S_0^h and $S_0^{h'}$ form a pair of dual spaces (see Theorem 4.4), we alternatively formulate corresponding projectors (see Theorem 4.6) and use them, e.g., in (8.31):

$$(6.21)\qquad Q_d^h \in \mathcal{L}(\mathcal{V}, \mathcal{V}^h), \text{ by } f \in \mathcal{V}:\ Q_d^h f := \sum_{j=1}^{m_0} \langle Q^h f, s^j\rangle_{\mathcal{V}^{h'}\times\mathcal{V}^h} s^j \in \mathcal{V}^h$$

$$\text{again with } \lim_{h\to 0} \|Q_d^h f\|_{\mathcal{V}^h} = \|f\|_{\mathcal{V}};\ \text{similarly, e.g., } \lim_{h\to 0} \|Q_{c,d}^h f_c\|_{\mathcal{V}^h} = \lim_{h\to 0} \|f_c\|_{\mathcal{V}_c}.$$

We turn to the projectors for the traces on the boundary. We always have to recall that the $u_b \in \mathcal{V}_D$ and $u_b^h \in \mathcal{V}_b^h \subset \mathcal{V}_b$ have the forms $u_b = u|_{\partial\Omega}, u \in \mathcal{U}$ and $u_b^h = u^h|_{\partial\Omega_c^h}, u^h \in \mathcal{V}^h$, respectively. It suffices testing vanishing boundary conditions w.r.t. the L^2 scalar product $(\cdot,\cdot)_{\mathcal{V}_{c,b}}$. This and the dense embeddings $\mathcal{V}_D \subset \mathcal{V}_b$ and $\mathcal{V}_{c,D} \subset \mathcal{V}_{c,b}$ motivate the following projectors:

$$(6.22)\quad Q_b^h \in \mathcal{L}(\mathcal{V}_D, \mathcal{V}_D^h) \quad \text{for } u_b := u|_{\partial\Omega} \in \mathcal{V}_D \subset \mathcal{V}_b : (Q_b^h u_b - (E_c u)|_{\partial\Omega_c^h}, v_b^h)_{\mathcal{V}_{c,b}} = 0,$$
$$Q_{c,b}^h \in \mathcal{L}(\mathcal{V}_{c,D}, \mathcal{V}_D^h), \quad u_{c,b} := u|_{\partial\Omega_c^h} \in \mathcal{V}_{c,D} : (Q_{c,b}^h u_{c,b} - u_{c,b}, v_b^h)_{\mathcal{V}_{c,b}} = 0 \quad \forall v_b^h \in \mathcal{V}_b^h,$$

and by (6.9) we obtain for all $v_b^h \in \mathcal{V}_b^h = \mathcal{V}_D^h$ that $v_b^h = v^h|_{\partial\Omega_c^h}$ for an appropriate $v^h \in \mathcal{V}^h$ and $v_b^h = Q_{c,b}^h v^h|_{\partial\Omega_c^h}$. The convergence results along $\partial\Omega_c^h$ in (4.12), (4.19), and Theorems 4.4 and 4.6 imply the limits of the boundary norms

$$(6.23)\qquad \lim_{h\to 0} \|Q_{c,b}^h u_{c,b}\|_{\mathcal{V}_D^h} = \lim_{h\to 0} \|u_{c,b}\|_{\mathcal{V}_{c,D}}, \quad \lim_{h\to 0} \|Q_b^h u_b\|_{\mathcal{V}_D^h} = \lim_{h\to 0} \|u_b\|_{\mathcal{V}_D}.$$

We summarize the product projectors and norms in (6.19)–(6.23) obtaining

$$(6.24)\qquad Q_\Pi^h := (Q^h, Q_b^h) \in \mathcal{L}\big(\mathcal{V}\times\mathcal{V}_D, \mathcal{V}^{h'}\times\mathcal{V}_D^h\big) = \mathcal{L}\big(\mathcal{V}_\Pi, \mathcal{V}_\Pi^{h'}\big),$$
$$Q_{d,\Pi}^h := (Q_d^h, Q_b^h) \in \mathcal{L}\big(\mathcal{V}_\Pi, \mathcal{V}_\Pi^h\big), \text{with } \|(f, u|_{\partial\Omega})\|_{\mathcal{V}_\Pi} = \|f\|_{\mathcal{V}} + \|u|_{\partial\Omega}\|_{\mathcal{V}_D}, \text{ and}$$
$$\lim_{h\to 0} \|Q_\Pi^h (f, u|_{\partial\Omega})\|_{\mathcal{V}_\Pi^{h'}} = \lim_{h\to 0} \|Q_{d,\Pi}^h (f, u|_{\partial\Omega})\|_{\mathcal{V}_\Pi^h} = \|(f, u|_{\partial\Omega})\|_{\mathcal{V}_\Pi}.$$

The approximate domains yield

$$(6.25)\qquad Q_{c,\Pi}^h := (Q_c^h, Q_{c,b}^h) \in \mathcal{L}\big(\mathcal{V}_c\times\mathcal{V}_{c,D}, \mathcal{V}_\Pi^{h'}\big) = \mathcal{L}\big(\mathcal{V}_{c,\Pi}, \mathcal{V}_\Pi^{h'}\big),$$
$$\lim_{h\to 0} \|Q_{c,\Pi}^h (f_c, E_c u|_{\partial\Omega_c^h})\|_{\mathcal{V}_\Pi^{h'}} = \lim_{h\to 0} \|(f_c, E_c u|_{\partial\Omega_c^h})\|_{\mathcal{V}_{c,\Pi}}.$$

Again, the choice of $P^h, Q_\Pi^h, Q_{c,\Pi}^h, \ldots$ is not unique.

$$\begin{array}{ccccc} \mathcal{U} & \xrightarrow{F} & \mathcal{V}_\Pi = \mathcal{V}\times\mathcal{V}_D & \overset{tested\ by}{\longleftrightarrow} & \hat{\mathcal{V}}_\Pi = \mathcal{V}\times\mathcal{V}_b, \text{ cf. (6.6)} \\ P^h\big\downarrow & \Phi^h\big\downarrow & Q^h_\Pi\big\downarrow & & \\ \mathcal{U}^h & \xrightarrow{F^h} & \mathcal{V}^{h'}_\Pi = \mathcal{V}^{h'}\times\mathcal{V}^h_D & \overset{tested\ by}{\longleftrightarrow} & \hat{\mathcal{V}}^h_\Pi = \mathcal{V}^h\times\mathcal{V}^h_b, \text{ cf. (6.26)} \end{array}$$

FIG. 6.1. *Nonconforming FEMs for fully nonlinear problems.*

6.3. Nonconforming projectors and discretization. We need only a few changes compared to subsection 5.3. The operator, spaces, and projectors there, $G:\mathcal{D}(G)\subset\mathcal{U}\to\mathcal{V}, Q^h$, have to be replaced by the product terms, $F=(F_1,F_2)=(G,B_D):\mathcal{D}(F)\subset\mathcal{U}\to\mathcal{V}_\Pi=\mathcal{V}\times\mathcal{V}_D$, $Q^h_\Pi, Q^h_{c,\Pi}$. Again we obtain a short definition of the corresponding discrete operator, $F^h:\mathcal{U}^h\to\mathcal{V}^{h'}\times\mathcal{V}^h_b$, and a linear mapping, Φ^h; see (6.11), (6.12) and (6.4), (6.13), (6.16)–(6.18), (6.24), (5.11). We finally get

$$F^h(u^h)=(G^h(u^h),u^h|_{\partial\Omega^h_c})=(Q^h_cG(u^h),Q^h_{c,b}u^h|_{\partial\Omega^h_c}). \tag{6.26}$$

We determine the approximate solution u^h_0 from

$$\begin{aligned} &u^h_0\in\mathcal{U}^h \text{ s.t. } F^h(u^h_0)=0\Longleftrightarrow(F(u^h_0),v^h_\Pi)_{\mathcal{V}_{c,\Pi}}=0\quad\forall v^h_\Pi=(v^h,v^h_b)\in\mathcal{V}^h_\Pi \\ &\Longleftrightarrow(G(u^h_0),v^h)_{\mathcal{V}^h}+(u^h_0,v^h_b)_{\mathcal{V}^h_b}=0\quad\forall v^h\in S^h_0=\mathcal{V}^h\subset\mathcal{V}_c\quad\forall v^h_b\in S^h_b=\mathcal{V}^h_b. \end{aligned} \tag{6.27}$$

By (6.26), (6.27) the new FEM is defined for the $F=(G,B_D)$ in (6.5) (cf. (6.8)) as

$$\mathcal{D}(\Phi^h):=\{F=(G,B_D)\}:\Phi^h(F):=F^h=Q^h_{c,\Pi}F|_{\mathcal{U}^h}=(Q^h_cG|_{\mathcal{U}^h},Q^h_{c,b}B_{c,D}|_{\mathcal{U}^h}). \tag{6.28}$$

We have thus defined a *nonconforming Petrov–Galerkin method applicable* to every F in (6.5). With uniformly bounded $P^h, Q^h_\Pi, Q^h_{c,\Pi}$ we modify the above Figure 5.1 into Figure 6.1 We reformulate only the not quite trivial consistency:

$$\|F^hP^hu-Q^h_\Pi Fu\|_{\mathcal{V}^{h'}_\Pi}=\|\big((Q^h_cG(P^hu)-Q^hG(u)),(P^hu|_{\partial\Omega^h_c}-E_cu|_{\partial\Omega^h_c})\big)\|_{\mathcal{V}^{h'}_\Pi}. \tag{6.29}$$

Remark 6.1. 1. With the above changes, *convergence, consistency, stability, and the results in Theorem* 5.1 remain valid.

2. Stetter [51] requires for his theory linear bounded operators P^h and $Q^h_{c,\Pi}:=(Q^h_c,Q^h_{c,b})$ in (6.15) and (6.24). But in fact he does need only equicontinuous operators and the limits of the norms listed above; see also (6.19), (6.23). The convergence properties in (6.9) are not required here, since usually 3. is impossible without them.

3. Condition 2. is correct if F or G are continuous in $B_r(P^hu_0)$ or $B_r(u_0)$.

4. The consistency, 3., will be verified in Theorem 7.1. Due to the careful preparations this is a relatively simple proof.

5. Then 4. is the only missing and hard condition in Theorem 5.1. In our approach the stability of the linearized problem and its regularity are the essential tools for the proof of stability; see Theorem 8.1. This makes sense only if the original F is continuously differentiable. Then F is Lipschitz continuous as well.

7. Consistency for the nonconforming FEM. Verifying the conditions of Theorem 5.1 we start with the easier consistency. Similarly to the Ciarlet, Raviart, Lenoir, and Bernadou approaches (see [26, 19, 42, 5, 6]) we have already and will furthermore use the extension operator, E_c (cf. Theorem 4.5). It allows estimates of

the interpolation errors on Ω and $\partial\Omega$, as in (4.23),(4.24), and thus are essential for the following proof.

THEOREM 7.1. *We require the conditions for Theorems* 4.2, 4.4, *mind* Ω *in* $C^p, 2 \le p \le 5$, *an exact solution* $u_0 \in H^\ell(\Omega), \ell > 2$, *a Lipschitz continuous* G^w *in* (3.6) *with a global constant* L,

$$G^w(\cdot) \in C_L\big(\ \overline{(\Omega_c^h \cup \Omega) \times \Gamma'}\ \big) \text{ with } \overline{(\Omega_c^h \cup \Omega) \times \Gamma'} := \{(x,z,p,r) : \tag{7.1}$$
$$x \in \overline{\Omega_c^h \cup \Omega}, (z,p,r) = \big((E_c u)(x), D(E_c u)(x), D^2(E_c u)(x)\big) \text{ with } u \in \overline{B_{r,H^2(\Omega)}(u_0)}\}\big],$$

and $d \ge n^2 + 1$. *Then* F^h *is consistent with* F *in* $P^h u_0$ *and*

$$\|F^h P^h u_0 - Q_\Pi^h F u_0\|_{\mathcal{V}_\Pi^{h\prime}} = \|\big(Q_c^h G(P^h u_0), -E_c u_0|_{\partial\Omega_c^h}\big)\|_{\mathcal{V}_\Pi^{h\prime}} \tag{7.2}$$
$$\le CLh^{\min\{\ell-2,p\}}\|u_0\|_{H^\ell(\Omega)}.$$

Remark 7.1. $d \ge n^2 + 1$ (see Theorem 4.4), and ℓ are related by (4.9). For inhomogeneous boundary conditions as in (6.3), the estimate (7.2) remains valid.

Proof. We estimate the first component in (7.2) with (6.19), L in (7.1), $G(u_0) \equiv 0$, and (4.23):

$$\|Q_c^h G(P^h u_0) - Q^h G(u_0)\|_{\mathcal{V}^{h\prime}} = \|Q_c^h G(P^h u_0) - 0\|_{\mathcal{V}^{h\prime}} \tag{7.3}$$
$$\le \|Q_c^h G(P^h u_0) - Q_c^h G(E_c u_0)\|_{\mathcal{V}^{h\prime}} + \|Q_c^h G(E_c u_0)\|_{\mathcal{V}^{h\prime}}$$
$$\le CL\|P^h u_0 - E_c u_0\|_{\mathcal{U}^h} + \|Q_c^h G(E_c u_0)\|_{\mathcal{V}^{h\prime}} \text{ by (4.18)}$$
$$\le CLh^{\ell-2}\|u_0\|_{H^\ell(\Omega)} + \|Q_c^h G(E_c u_0)\|_{\mathcal{V}^{h\prime}}.$$

We test $Q_c^h G(E_c u_0) - Q^h G(u_0)$ with $v^h \in \mathcal{V}^h$, combine it with (3.6), (6.19), and get

$$\big|\langle Q_c^h G(E_c u_0), v^h\rangle_{\mathcal{V}^{h\prime}\times\mathcal{V}^h}\big| = \Big|\int_{\Omega_c^h} \big[G(E_c u_0)(x)\big] v^h(x)dx\Big| \quad \forall v^h \in \mathcal{V}^h \tag{7.4}$$
$$\le \Big|\int_{\Omega_c^h} \big[G(E_c u_0)(x)\big] v^h(x)dx - \int_\Omega \big[0 \equiv G(u_0)(x)\big] E_c v^h(x)dx\Big|$$
$$\le \int_{\Omega_c^h\setminus\Omega} \Big|G(E_c u_0)(x) v^h(x)\Big|dx, \text{ since } \Big(\int_{\Omega_c^h} - \int_\Omega\Big)\Big|_{\Omega_c^h\cap\Omega} = 0,$$

where $G(E_c u_0), v^h \in L^2(\Omega_c^h)$ are well defined; cf. (6.11). By $\big[0 \equiv G(u_0)(x)\big] E_c v^h(x)$, we do not need to explicitly define the extension $E_c v^h$. Now (7.1) and $u_0 \in H^\ell(\Omega)$, $\ell > 2$, imply $|G(E_c u_0)(x)| \le CL\|u_0\|_{H^\ell(\Omega)}$. This is combined with $\operatorname{dist}(\Omega_c^h, \Omega) \le C' h^p$ (cf. (4.17)) and the bounded $S_{\partial\Omega} :=$ surface $(\partial\Omega) < \infty$ yielding

$$G(E_c u_0)(x) \text{ satisfies } G(E_c u_0) \equiv 0 \text{ in } \Omega \Longrightarrow \|G(E_c u_0)\|_{L^2(\Omega_c^h\setminus\Omega)} \tag{7.5}$$
$$\le CL\|u_0\|_{H^\ell(\Omega)}\|1\|_{L^2(\Omega_c^h\setminus\Omega)} \le CL\|u_0\|_{H^\ell(\Omega)} S_{\partial\Omega} C' h^p \le C^* h^p \|u_0\|_{H^\ell(\Omega)}.$$

We combine (7.3), (7.4), (7.5) with the Cauchy–Schwarz inequality

$$\|Q_c^h G(P^h u_0)\|_{\mathcal{V}^h} \le CLh^{\ell-2}\|u_0\|_{H^\ell(\Omega)} + \|Q_c^h G(E_c u_0)\|_{\mathcal{V}^h} \tag{7.6}$$
$$\le CLh^{\ell-2}\|u_0\|_{H^\ell(\Omega)} + C'' h^p \|u_0\|_{H^\ell(\Omega)} \le \hat{C} h^{\min\{\ell-2,p\}}\|u_0\|_{H^\ell(\Omega)};$$

thus we have estimated the first component in (7.2).

To simplify estimating the second component in (7.2), we assume $n < 2(\ell - 1)$. Then the Sobolev embedding theorem implies the compact embedding of $H^\ell(\Omega)$ into

$C^1(\overline{\Omega})$. Then $u_0 \in H^\ell(\Omega) \cap H^1_0(\Omega)$ implies $C(\partial\Omega) \ni u_0|_{\partial\Omega} \equiv 0$. Now choose any $P \in \partial\Omega^h_c$, a ray through $P \perp \partial\Omega^h_c$, the intersection point, P_b of this ray with $\partial\Omega$, and the directional derivative $\partial_P E_c u_0$ of $E_c u_0$ from P_b to P. Then

$$|E_c u_0(P)| = \Big|0 + \int_{P_b}^{P} \partial_P E_c u_0\Big| \le \|u_0\|_{H^\ell(\Omega)} C' h^p.$$

So we obtain for the second component in (7.2)

$$\|E_c u_0\|_{L^2(\partial\Omega^h_c)} \le C'' h^p \|u_0\|_{H^\ell(\Omega)}.$$

For inhomogeneous boundary conditions (cf. (6.3)), we employ the extension of ϕ, necessarily here $\phi \in H^{\ell-1/2}(\partial\Omega)$, to $\phi \in H^\ell(\Omega)$; we still have $G(u_0) = 0$, and so (7.3), (7.4) remain correct. Boundary conditions for the exact and the discrete problem are $(u_0 - \phi)|_{\partial\Omega} \equiv 0$ and $(u^h_0 - P^h\phi)|_{\partial\Omega^h_c} \equiv 0$ with $P^h\phi$ extended to Ω. We replace the exact boundary conditions by $(u_0 - P^h\phi)|_{\partial\Omega} \equiv 0$. Then the error estimates in Theorem 4.6 and the stability results for linear elliptic operators w.r.t. the right-hand side $(f, \phi) \in \mathcal{V} \times \mathcal{V}_D$, e.g., in Hackbusch [37, Theorem 9.1.16], yield again (7.2). ∎

8. Stability for the linearized operator and convergence. Fortunately, there is a standard result strongly simplifying the proof of stability; see, e.g., Stetter [51, Theorem 1.2.5], Stummel [52, 53], and Keller [40]: We need a simple corollary of Stetter's theorem, Theorem 1.2.5. It replaces the condition of a continuous and differentiable discretization, F^h, in $B_r(u^h)$ by the continuous differentiability in $B_r(u^h)$. This slightly enforced condition is usually satisfied by the equations considered here. It is even simplified in our case, since $F \in C^1(B_r(u))$ implies $F^h \in C^1(B_{r-\delta}(P^h u))$ with a small $\delta > 0$ for $h_0 > h \in H$.

THEOREM 8.1. *Let the nonlinear F be continuously differentiable in $B_r(u)$, and let the sequence of linearized $(F^h)'$ be stable at $P^h u$, satisfying*

$$\|\big((F^h)'(P^h u)\big)^{-1}\|_{\mathcal{U}^h \hookleftarrow \mathcal{V}^{h'}_\Pi} \le S \ \text{uniformly} \quad \forall h \in H, \quad h_0 > h. \tag{8.1}$$

Then the nonlinear F^h is stable at $P^h u$ as well with stability bound and threshold, $2S$ and $r_0 = r/(2S)$, respectively.

According to section 2, **3.**, Theorems 5.1, 7.1, and 8.1 and Remark 6.1 show that the only missing claim for convergence is the stability for the linearized operator for $u^h = P^h u$, here $u = u_0$. So we have to elaborate the program in section 2 in **3.** We indicate only the conforming FEM on convex polyhedral domains in (4.1) and mainly discuss the nonconforming FEM on C^2 domains in (4.2). For the conforming FEs it suffices to discuss the differential operator G. Then the boundary operators, B_D, the extension, E_c, and all the product machinery, in particular in subsections 8.3 and 8.4, can be avoided. This would considerably simplify the proofs, presented here only for the nonconforming FEMs. The interested reader easily can verify this claim. For our $F(u)$ with $F'(u_1)u = (G'(u_1)u, u|_{\partial\Omega})$ the linearization of G is essential. Thus a major part of the following discussion is concerned with $G'(u_1)$. We obtain the claimed stability, $\|\big((F^h)'(u^h_1)|_{\mathcal{U}^h \to \mathcal{V}^{h'}_\Pi}\big)^{-1}\|_{\mathcal{V}^{h'}_\Pi \hookleftarrow \mathcal{U}^h} \le C$, by the end of this section.

8.1. The linearized operator. We start with G assuming a continuously differentiable operator G or its defining function G^w; see (3.7), (3.8). Here we sometimes integrate the boundary conditions into the spaces $\mathcal{U}_0, \mathcal{W}_0$ and $\mathcal{U}^h_0, \mathcal{W}^h_0$. In the literature the same notation $G'(u_0) : \mathcal{U} \to \mathcal{V}$ and $G'(u_0) : \mathcal{W} \to \mathcal{W}'$ is used for the strong

and weak forms of the linearized operators, $G'_s(u_0) = G'(u_0)$ and $G'(u_0)$, respectively. For a smooth enough situation, the strong form is just the restriction of the weak form, and so $G'(u_0)|_{\mathcal{U}} = G'_s(u_0) : \mathcal{U} \to \mathcal{V}$ under the condition (8.2). The proofs in this section fundamentally depend upon a systematic interplay between these strong and weak forms of the linearized operators. To avoid misunderstandings, it is necessary to distinguish at least the strong and weak bilinear forms as $a_s(\cdot,\cdot)$ and $a(\cdot,\cdot)$. Later on, we even use the notations $A = G'(u_0), A_s = G'_s(u_0)$ and A^h, A^h_s for the weak and strong linear operators. Correspondingly, we formulate two different FEMs for the linearized problem. To its strong form, $a_s(\cdot,\cdot)$, we apply the FEM (6.12), (8.7), to its weak form, $a(\cdot,\cdot)$, the standard FEM; see (8.8) below. We will see that for the linear case both bilinear forms coincide, and so $a_s(u^h, v^h) = a(u^h, v^h)$ for all $u^h \in \mathcal{U}^h = \mathcal{W}^h \supset \mathcal{U}^h_0 = \mathcal{V}^h \ni v^h$; see (8.6) and Proposition 8.2.

We called the original nonlinear problem G *uniformly elliptic* in u_0 if its derivative $G'(u_0)u$ in (3.9) satisfies (3.10). In contrast to G, it is possible to transform the linearization in (3.9) into the standard weak form. We start with the strong operator $G'(u_0) : \mathcal{U} \to \mathcal{V}$ (see (3.2)) and introduce new coefficients a_{ij}. This yields the *strong bilinear form* $a_s(\cdot,\cdot)$ and conditions for the partials of G^w; see (3.2), (3.6), (3.7):

$$
\begin{aligned}
(8.2)\qquad & G'(u_0) : \mathcal{U} \to \mathcal{V} \text{ and } a_s(u,v) := (G'(u_0)u, v)_{\mathcal{V}} \quad \forall u \in \mathcal{U}, v \in \mathcal{V} \text{ with} \\
& G'(u_0)u = \sum_{i,j=0}^{n} (-1)_{j>0} \partial^j (a_{ij} \partial^i\ u) \text{ and } w_0(\cdot) = (\cdot, u_0(\cdot), Du_0(\cdot), D^2u_0(\cdot)) : \\
& a_{ij} = a_{ij}(u_0) = \frac{\partial G^w}{\partial r_{ij}}(w_0) \text{ for } i,j \geq 1, \quad a_{00} = a_{00}(u_0) = \frac{\partial G^w}{\partial z}(w_0), \\
& a_{i0} = a_{i0}(u_0) = \frac{\partial G^w}{\partial p_i}(w_0) + \sum_{j=1}^{n} \partial^j \frac{\partial G^w}{\partial r_{ij}}(w_0), \quad a_{0i} = 0 \text{ for } i \geq 1; \\
& \text{this strong form } G'(u_0) \text{ is bounded if } a_{ij} = a_{ij}(w_0(\cdot)) \in W^{1-\delta_{0j},\infty}(\Omega).
\end{aligned}
$$

Partial integration or the Green's formula now combined with $v \in \mathcal{W} \cap H^1_0(\Omega)$ yields the (standard) weak problem or the *coinciding bounded weak and strong bilinear form,* $a(\cdot,\cdot) : \mathcal{W} \times \mathcal{W} \to \mathbf{R}$, and the induced weak, $G'(u_0) : \mathcal{W} \to \mathcal{W}'$ (see (3.2), (3.3)), as

$$
\begin{aligned}
(8.3)\qquad & a(u,v) := \int_\Omega \sum_{i,j=0}^{n} a_{ij} \partial^i u \partial^j v dx\ =: \langle G'(u_0)u, v\rangle_{\mathcal{W}' \times \mathcal{W}} \quad \forall u \in \mathcal{W},\ \forall v \in \mathcal{W}_0, \\
& a(\cdot,\cdot), G'(u_0) \text{ bounded for } a_{ij} = a_{ij}(u_0) = a_{ij}(w_0(\cdot)) \in L^\infty(\Omega) \text{ for } i,j = 0,\dots,n, \\
& \text{and with } a_s(u,v) = a(u,v) \quad \forall u \in \mathcal{U},\ \forall v \in \mathcal{W}_0.
\end{aligned}
$$

The principal part $a_p(u,v)$ of $a(u,v)$ is $\mathcal{W}_0$-*coercive*, by (3.10), and, since $\|u\|_{H^1_0(\Omega)}$ and $\|u\|_{\mathcal{W}}$ are equivalent norms on $\mathcal{W}_0$,

$$
(8.4)\qquad a_p(u,u) \geq \lambda \int_\Omega \sum_{i=1}^{n} (\partial^i u)^2 dx = \lambda \|u\|^2_{H^1_0(\Omega)} \geq \alpha \|u\|^2_{\mathcal{W}} \quad \forall u \in \mathcal{W}_0.
$$

The original $a(u,v)$, inducing $A = G'(u_0)$, is the sum of $a_p(u,v)$, inducing B, and its complement $c(u,v)$, inducing C, a compact perturbation of $A = B + C$, with $A, B, C \in \mathcal{L}(\mathcal{W}, \mathcal{W}')$:

$$
(8.5)\qquad a(u,v) = a_p(u,v) + c(u,v) = \langle G'(u_0)u, v\rangle_{\mathcal{W}' \times \mathcal{W}} = \langle (B+C)u, v\rangle_{\mathcal{W}' \times \mathcal{W}}.
$$

B is boundedly invertible on $\mathcal{W}_0$ by (8.4). Thus $G'(u_0)$ satisfies the *Fredholm alternative* on $\mathcal{W}_0$. This compact perturbation $C \in \mathcal{L}(\mathcal{W}, \mathcal{W}')$ will play a dominant role for the following stability results.

In addition to the above approximating spaces (see (3.1), (4.4)), we need for $\mathcal{W}_0$

$$\mathcal{U}^h = \mathcal{W}^h \supset \mathcal{V}^h \text{ and } \mathcal{U}_0^h = \mathcal{W}_0^h := \mathcal{V}^h = \mathcal{U}^h \cap H_0^1(\Omega_c^h) \quad \text{for } \mathcal{U}_0 \subset \mathcal{W}_0, \tag{8.6}$$

again with the corresponding nonequivalent norms $\|\cdot\|_{\mathcal{U}^h}, \|\cdot\|_{\mathcal{W}^h}, \|\cdot\|_{\mathcal{V}^h}$.

We want to contrast the two different FEMs for the linear problem. We start with (6.12) and then turn to the standard FEM based upon the *weak bilinear form* $a(\cdot,\cdot)$. In both cases we have to determine $u_1^h \in \mathcal{U}_0^h$ and $u_1^h \in \mathcal{W}_0^h$ s.t.

$$\begin{aligned} u_1^h \in \mathcal{U}_0^h : a_s(u_1^h, v^h) &= \big(G'(P^h u_0)u_1^h, v^h\big)_{\mathcal{V}_c} := \Big(\sum_{i,j=0}^n (-1)_{j>0}\partial^j(a_{ij}(P^h u_0)\partial^i\ u_1^h), v^h\Big)_{\mathcal{V}_c} \\ &= (E_c f, v^h)_{\mathcal{V}_c} \quad \forall v^h \in \mathcal{V}^h, \ \text{ with } f \in \mathcal{V}, a_{ij} \in W^{1-\delta_{0j},\infty}(\Omega); \text{ see (8.2).} \end{aligned} \tag{8.7}$$

Similarly as G^w we assume the $a_{ij}(P^h u_0)$ to be well defined on the extended $\Omega \cup \Omega_c^h$. The standard FEM for the *weak bilinear form* $a(\cdot,\cdot)$ with its solution $u_1^h \in \mathcal{W}_0^h$ is

$$\begin{aligned} u_1^h \in \mathcal{W}_0^h : a(u_1^h, v^h) &= \int_{\Omega_c^h} \sum_{i,j=0}^n a_{ij}(P^h u_0)\partial^i u_1^h \partial^j v^h dx \ = \langle G'(P^h u_0)u_1^h, v^h\rangle_{\mathcal{W}_c' \times \mathcal{W}_c} \\ &= \langle E_c f, v^h\rangle_{\mathcal{W}_c' \times \mathcal{W}_c} \text{ or } = \langle E_c f, v^h\rangle_{\mathcal{V}_c} \text{ for } f \in \mathcal{V} \ \ \forall v^h \in \mathcal{W}_0^h, \text{ with } a_{ij} \in L^\infty(\Omega). \end{aligned} \tag{8.8}$$

As in (6.12) for G, we use here the same notation for the discrete $a_s(u^h, v^h), a(u^h, v^h)$ and the original $a_s(u,v), a(u,v)$. These bilinear forms are, for small enough h, simultaneously bounded and elliptic. Equations (8.7), (8.8) can and will be similarly reinterpreted by using the above projectors and defining new ones.

8.2. Weak and strong linear operators coincide on $\mathcal{U}^h \times \mathcal{V}^h$. The techniques in this and subsection 8.4 are strongly related to the standard approach in spectral methods for collocation (see Canuto et al. [17]) and to regularity for difference equations; see, e.g., Hackbusch [37, Theorem 9.2.26].

PROPOSITION 8.2. *Choose the above $\mathcal{U}^h, \dots, \subset \mathcal{S}_d^1(\mathcal{T}_c^h)$ in (8.6) for $d \geq 2^n + 1$ as approximating spaces for $\mathcal{U}, \dots$, and let $a_{ij} \in W^{1-\delta_{0j},\infty}(\Omega)$. Then for all $u^h \in \mathcal{U}^h, v^h \in \mathcal{V}^h$,*

$$\begin{aligned} a_s(u^h, v^h) &= (G'(P^h u_0)u^h, v^h)_{\mathcal{V}_c} \\ = a(u^h, v^h) &= \langle G'(P^h u_0)u^h, v^h\rangle_{\mathcal{W}_c' \times \mathcal{W}_c} \quad \forall u^h \in \mathcal{U}^h = \mathcal{W}^h, \quad v^h \in \mathcal{V}^h = \mathcal{U}_0^h. \end{aligned} \tag{8.9}$$

Proof. We apply partial integration for every $T \in \mathcal{T}_c^h$ with $\overline{\Omega_c^h} = \cup_{T \in \mathcal{T}_c^h} \overline{T}$. We use the notations $\nu = \nu_T$ for the outer unit normal vector of T and B_a and u for the boundary operator, induced by $A = G'(u_0)$; see, e.g., [37]:

$$B_a\ u = \sum_{i,j=1}^n \nu_j a_{ij}\partial^i\ u + \sum_{j=1}^n \nu_j a_{0j}\ u, \text{ e.g., } B_a\ u = \partial u/\partial\nu \quad \text{for } A_s u = -\Delta u. \tag{8.10}$$

All ∂T have a *positive orientation* w.r.t. T. Hence in (8.12) every interior edge $e \in \overline{T}$ will be obtained twice in opposite directions. Edges $e \subset \partial\Omega_c^h$ will appear once. Let $\nu = \nu_T$ be one of the normal vectors for an interior edge $e \subset \overline{T_r}$. It is oppositely

oriented for neighboring $T_r\ , T_l \in \mathcal{T}_c^h$ with $e \subset \overline{T_r} \cap \overline{T_l}$ and ν the outer normal[4] for $e \subset \partial\Omega_c^h$. To consider the transition from a triangle T_l to its neighboring T_r, we introduce the restriction of v to $\overline{T_l}, \overline{T_r}, \partial\Omega_c^h$ and the standard notation; see [61]:

$$v_l = v|_{\overline{T_l}}, \quad v_r = v|_{\overline{T_r}}, \quad [v] := v_l|_e - v_r|_e, \quad \text{and } \{v\} := (v_l|_e + v_r|_e)/2, \tag{8.11}$$

for the corresponding jumps and arithmetic means of v across an interior e, and

$$[v] := \{v\} := v|_{\partial\Omega_c^h} \text{ along } e \in \partial\Omega_c^h, \quad \text{and} \quad v \ \text{ arbitrary in } \ \mathbf{R}^n \backslash \Omega_c^h.$$

The next transformation via the n-dimensional Green's formula is the deciding reason for the of C^1 FEs. Only for this choice do the following jump contributions, the $\big[B_a u^h\big] = 0$, vanish (the $[v^h]$ vanish already for C FEs v^h):

$$\begin{aligned} a(u^h, v^h) = \langle G'(E_c u_0) u^h, v^h \rangle_{\mathcal{W}_c' \times \mathcal{W}_c} \ &= \ \sum_{T \in \mathcal{T}_c^h} \Big(\int_T \sum_{i,j=0}^{n} a_{ij} \partial^i \ u^h \partial^j \ v^h dx \Big) \\ &= \sum_{T \in \mathcal{T}_c^h} \Big(\int_T \sum_{i,j=0}^{n} (-1)_{j>0} \partial^j (a_{ij} \partial^i \ u^h) v^h dx \Big) + \int_{\partial\Omega_c^h} v_l^h B_a u^h \, ds \\ + \sum_{e \in \mathcal{T}_c^h \backslash \partial\Omega_c^h} \int_e \big(\{v^h\} \big[B_a u^h\big] + [v^h] \{B_a u^h\} \big) ds &= \int_{\Omega_c^h} (G'(E_c u_0)_s \ u^h) v^h dx \end{aligned} \tag{8.12}$$

$$= a_s(u^h, v^h) \text{ since } u^h \in \mathcal{U}^h \subset C^1(\Omega_c^h), v^h \in \mathcal{V}^h \subset H_0^1(\Omega_c^h); \text{ hence,}$$
$$a(u^h, v^h) = a_s(u^h, v^h) \quad \forall u^h \in \mathcal{U}^h, v^h \in \mathcal{V}^h.$$

Discontinuous Galerkin methods would certainly be possible for $a(u^h, v^h)$. But they would violate the necessary $a(u^h, v^h) = a_s(u^h, v^h)$ by their penalty terms. ∎

8.3. Stability of the weak linear operator. The previous subsections play the role of preparing this stability proof. We essentially had confined the discussion there to the differential equation and indicated the boundary conditions either by the index $_0$ or using $v^h \in \mathcal{V}^h$. Instead of the previous strong and weak forms, $A_s : \mathcal{U} \to \mathcal{V}$ and $A : \mathcal{W} \to \mathcal{W}'$ (see (6.2), (6.5)–(6.7)), we need their two component versions:

$$\begin{aligned} &A_{\mathcal{U}} := (A_s, B_D) : \mathcal{U} \to \mathcal{V} \times \mathcal{V}_D \subset \hat{\mathcal{V}}_\Pi = \mathcal{V} \times \mathcal{V}_b, \ A_{\mathcal{U}} \in \mathcal{L}(\mathcal{U}, \mathcal{V} \times \mathcal{V}_D) \text{ and} \\ &A_{\mathcal{W}} := (A, B_D) : \mathcal{W} \to \mathcal{W}' \times \mathcal{W}_D \subset \mathcal{W}_\Pi' = \mathcal{W}' \times \mathcal{V}_b, \ A_{\mathcal{W}} \in \mathcal{L}(\mathcal{W}, \mathcal{W}' \times \mathcal{W}_D). \end{aligned} \tag{8.13}$$

With the dense (compact) embedding $\mathcal{W}_D \hookrightarrow \mathcal{V}_b = L^2(\partial\Omega)$ we test the $\mathcal{W}' \times \mathcal{W}_D \subset \mathcal{W}_\Pi'$ by the following $\mathcal{W}_\Pi$. We emphasize that the stable splitting $S^h = S_0^h + S_b^h$ in Theorem 4.4 plays a dominant role. We choose (cf. (4.18), (4.19), (6.16)–(6.18))

$$\begin{aligned} &\mathcal{W} \times \mathcal{W}_D \subset \mathcal{W}_\Pi := \mathcal{W} \times \mathcal{V}_b \neq \mathcal{W}_\Pi' = \mathcal{W}' \times \mathcal{V}_b, \text{ with } \mathcal{V}_b \supset \mathcal{W}_D \text{ and} \\ &\qquad \langle (u', u_b), (v, v_b) \rangle_{\mathcal{W}_\Pi' \times \mathcal{W}_\Pi} := \langle u', v \rangle_{\mathcal{W}' \times \mathcal{W}} + (u_b, v_b)_{\mathcal{V}_b}, \text{ and on} \\ &\Omega_c^h \text{ the } \mathcal{W}_{c,\Pi} = \mathcal{W}_c \times \mathcal{V}_{c,b} \neq \mathcal{W}_{c,\Pi}' \text{ with } \langle (u', u_b), (v, v_b) \rangle_{\mathcal{W}_{c,\Pi}' \times \mathcal{W}_{c,\Pi}}. \end{aligned} \tag{8.14}$$

The discrete counterparts are the

$$\begin{aligned} &\mathcal{W}_\Pi^h = \mathcal{W}^h \times \mathcal{V}_b^h := S^h \times S_b^h|_{\partial\Omega_c^h} \neq \mathcal{V}_\Pi^h, \quad \mathcal{W}_\Pi^{h'} := \mathcal{W}^{h'} \times \mathcal{V}_b^h := S^{h'} \times S_b^h|_{\partial\Omega_c^h} \neq \mathcal{V}_\Pi^{h'}, \\ &\text{and } \langle (u^{h'}, u_b^h), (v^h, v_b^h) \rangle_{\mathcal{W}_\Pi^{h'} \times \mathcal{W}_\Pi^h} := \langle u^{h'}, v^h \rangle_{\mathcal{W}^{h'} \times \mathcal{W}^h} + (u_b^h, v_b^h)_{\mathcal{V}_b^h}. \end{aligned} \tag{8.15}$$

[4]We will use the notation $e \in \partial\Omega_c^h$, although mostly $e \subset \partial\Omega_c^h$; similarly, $e \in \mathcal{T}_c^h \setminus \partial\Omega_c^h$.

$$\begin{array}{ccccc} \mathcal{W} & \xrightarrow{A_{\mathcal{W}}} & \mathcal{W}'_\Pi = \mathcal{W}' \times \mathcal{W}_D & \overset{tested\ by}{\longleftrightarrow} & \mathcal{W}_\Pi = \mathcal{W} \times \mathcal{V}_b \\ P^h \big\downarrow & \Phi^h_{\mathcal{W}} \big\downarrow & Q^{h'}_\Pi \big\downarrow & & \\ \mathcal{W}^h & \xrightarrow{A^h_{\mathcal{W}}} & \mathcal{W}^{h'}_\Pi = \mathcal{W}^{h'} \times \mathcal{W}^h_D & \overset{tested\ by}{\longleftrightarrow} & \mathcal{W}^h_\Pi = \mathcal{W}^h \times \mathcal{V}^h_b \end{array}$$

FIG. 8.1. *Nonconforming FEMs for linear problems.*

The exact and discrete linear boundary conditions remain nearly unchanged, except replacing $\mathcal{V}_D$ by $\mathcal{W}_D$, and so they can be treated as in (6.4), (6.13); see (6.22), (6.23).

For the weak differential operator, we introduce a modified Ritz operator. The above extension operator E_c in Theorem 4.5 is continuously extended to $f \in H^k(\Omega), k < 0$. We define the projectors, $Q^{h'}, Q^{h'}_c$, and so on, indicating the weak form by the exponent $^{h'}$, in contrast to the strong projectors Q^h and so on with the exponent ^{h} in (6.24); cf. (4.11), (4.12), (4.18), (4.19):

(8.16)

$$\begin{aligned} &Q^{h'} \in \mathcal{L}(\mathcal{W}', \mathcal{W}^{h'}) \quad \text{for } f \in \mathcal{W}' \text{ by } \langle Q^{h'} f, v^h\rangle_{\mathcal{W}^{h'}\times\mathcal{W}^h} - \langle (E_c f), v^h\rangle_{\mathcal{W}'_c\times\mathcal{W}_c} = 0, \\ &Q^{h'}_c \in \mathcal{L}(\mathcal{W}'_c, \mathcal{W}^{h'}) : f_c \in \mathcal{W}'_c : \ \langle Q^{h'}_c f_c, v^h\rangle_{\mathcal{W}^{h'}\times\mathcal{W}^h} - \langle f_c, v^h\rangle_{\mathcal{W}'_c\times\mathcal{W}_c} = 0 \quad \forall v^h \in \mathcal{W}^h. \end{aligned}$$

This allows formulating the product projectors, and we obtain

$$Q^{h'}_\Pi := (Q^{h'}, Q^h_b) \in \mathcal{L}\big(\mathcal{W}'_\Pi, \mathcal{W}^{h'}_\Pi\big), \quad Q^{h'}_{c,\Pi} := (Q^{h'}_c, Q^h_{c,b}) \in \mathcal{L}\big(\mathcal{W}'_{c,\Pi}, \mathcal{W}^{h'}_\Pi\big). \tag{8.17}$$

For both types of projectors we obtain the necessary norm limits:

$$\begin{aligned} &\lim_{h\to 0} \|Q^{h'} f\|_{\mathcal{W}^{h'}} = \|f\|_{\mathcal{W}'}, \text{and } \lim_{h\to 0} \|Q^{h'}_c f_c\|_{\mathcal{W}^{h'}} = \lim_{h\to 0} \|f_c\|_{\mathcal{W}'_c} = \lim_{h\to 0} \|E_c f_c\|_{\mathcal{W}'}, \\ &\lim_{h\to 0} \|Q^{h'}_\Pi (f, u_1|_{\partial\Omega})\|_{\mathcal{W}^{h'}_\Pi} = \|(f, u_1|_{\partial\Omega})\|_{\mathcal{W}'_\Pi}, \text{ and } \lim_{h\to 0} \|Q^{h'}_{c,\Pi}(f_c, (E_c u)|_{\partial\Omega^h_c})\|_{\mathcal{W}^{h'}_\Pi} \\ &\qquad = \lim_{h\to 0} \|(f_c, (E_c u)|_{\partial\Omega^h_c})\|_{\mathcal{W}'_{c,\Pi}} = \lim_{h\to 0} \|(E_c f_c, (E_c u)|_{\partial\Omega})\|_{\mathcal{W}'_\Pi}. \end{aligned} \tag{8.18}$$

Similarly to the above $F^h = Q^h_{c,\Pi} F|_{\mathcal{U}^h}$ we use the projectors for reformulating (8.7) and (8.8) (cf. (8.13)) for $a_{ij} \in C_L(\Omega \cup \Omega^h_c)$. For the strong $A_{\mathcal{U}}$ and $A^h_{\mathcal{U}}$ we get

$$A^h_{\mathcal{U}} = Q^h_{c,\Pi} A_{\mathcal{U}}|_{\mathcal{U}^h} : u^h_0 \in \mathcal{U}^h : A^h_{\mathcal{U}} u^h_0 = Q^h_{c,\Pi}(A_s u^h_0, u^h_0|_{\partial\Omega^h_c}) = Q^h_\Pi(f, \phi). \tag{8.19}$$

Similarly, the weak linear operators $A_{\mathcal{W}}$ and $A^h_{\mathcal{W}}$ yield, for $(f, \phi) \in \mathcal{W}'_\Pi$,

$$A^h_{\mathcal{W}} = Q^{h'}_{c,\Pi} A_{\mathcal{W}}|_{\mathcal{W}^h} : u^h_0 \in \mathcal{W}^h : A^h_{\mathcal{W}} u^h_0 = Q^{h'}_{c,\Pi}(A u^h_0, u^h_0|_{\partial\Omega^h_c}) = Q^{h'}_\Pi(f, \phi). \tag{8.20}$$

We summarize the new situation with uniformly bounded $A^h, P^h, Q^{h'}_{c,\Pi}$ in Figure 8.1. For proving the stability for $A^h_{\mathcal{W}}$ in Theorem 8.4 assume the principal part induces the ($\mathcal{W}_0$-coercive) operator B; cf. (8.5). We use the notations

$$A_{\mathcal{W}} = (A, B_D),\ B_{\mathcal{W}} = (B, B_D),\ C_{\mathcal{W}} = (C, B_D),\ C \text{ compact},\ A^h_{\mathcal{W}}, B^h_{\mathcal{W}}, C^h_{\mathcal{W}}. \tag{8.21}$$

THEOREM 8.3 (stability and convergence for the principal part). *Assume* (8.3), *the ellipticity* (8.4), *the approximate spaces in* (8.6) *with the norm limits in* (8.18) *and* (6.24), *and* $B_{\mathcal{W}}$ *and* $B^h_{\mathcal{W}}$ *as in* (8.13), (8.20). *Then* $B_{\mathcal{W}}$ *is boundedly invertible,*

and $B^h_{\mathcal{W}}$ is stable. Then unique solutions u_1 of $B_{\mathcal{W}}u_1 = (f,\phi) \in \mathcal{W}'_\Pi$ and u_1^h of $B^h_{\mathcal{W}}u_1^h = Q^{h'}_\Pi(f,\phi) \in \mathcal{W}^{h'}_\Pi$ exist and u_1^h converge s.t. $\|u_1^h - E_c u_1\|_{\mathcal{W}^h} \to 0$ for $h \to 0$.

Proof. Equation (8.3) shows that $a_p^h(u^h, v^h)$ is bounded on $\mathcal{W}^h$. The ellipticity condition (8.4) implies with the usual arguments (cf. (8.4)) that

$$a_p^h(u^h,u^h) \geq \lambda \int_{\Omega_c^h} \sum_{i=1}^n (\partial^i u^h)^2 dx = \lambda \|u^h\|^2_{H^1_0(\Omega_c^h)} \geq \alpha \|u^h\|^2_{\mathcal{W}^h} \quad \forall u^h \in \mathcal{W}^h_0, \tag{8.22}$$

hence the stability of $B^h_{\mathcal{W}}$ in $\mathcal{W}^h_0$. We reduce the inhomogeneous problem

$$B^h_{\mathcal{W}}u_1^h = Q^{h'}_\Pi(f,\phi) = (Q^{h'}f \in \mathcal{W}^{h'}, Q_b^h\phi \in \mathcal{V}_b^h) \in \mathcal{W}^{h'}_\Pi$$

to $\mathcal{W}^h_0$: As usual, we determine $u_2^h \in \mathcal{W}^h$ with $(u_2^h - Q_b^h\phi)|_{\partial\Omega_c^h} = 0 \in \mathcal{V}_b^h$. Then

$$B^h_{\mathcal{W}}(u_1^h - u_2^h) = (Q^{h'}f - B^h u_2^h \in \mathcal{W}^{h'}, 0|_{\partial\Omega_c^h} \in \mathcal{V}_b^h) \in \mathcal{W}^{h'}_\Pi.$$

This guarantees, by (8.22) and Theorems 5.1 and 7.1, the stability, consistency, and hence existence of the unique discrete solution $u_1^h - u_2^h$ and its convergence to the corresponding exact solution $u_1 - u_2$, and hence of u_1^h as well. ∎

THEOREM 8.4 (stability of $A^h_{\mathcal{W}} = (A = G'(u_0), B_D)^h \in \mathcal{L}(\mathcal{W}^h, \mathcal{W}^{h'} \times \mathcal{V}_b^h)$). *Under the conditions of Theorem* 8.3*, assume a boundedly invertible $A_{\mathcal{W}}$ in* (8.13)*. Then $A^h_{\mathcal{W}}$ in* (8.20) *is stable.*

Proof. This is a generalization to nonconforming FEMs of the Böhmer and Sassmannshausen results (see [47, 9, 8]) for conforming FEMs. For an arbitrary $u \in \mathcal{W}$ choose $v_w := C_{\mathcal{W}}u \in \mathcal{W}'_\Pi = \mathcal{W}' \times \mathcal{W}_D$. By assumption, unique exact and discrete solutions, $\hat{u}$ and $\hat{u}^h$, exist for the equations

$$B_{\mathcal{W}}\hat{u} = v_w \text{ and } B^h_{\mathcal{W}}\hat{u}^h = Q^{h'}_{c,\Pi}B_{\mathcal{W}}|_{\mathcal{W}^h}\hat{u}^h = Q^{h'}_\Pi B_{\mathcal{W}}\hat{u} = Q^{h'}_\Pi v_w \in \mathcal{W}^{h'}_\Pi. \tag{8.23}$$

With the notations

$$T_w := B^{-1}_{\mathcal{W}} \in \mathcal{L}(\mathcal{W}'_\Pi, \mathcal{W}) \text{ and } T_w^h := (B^h_{\mathcal{W}})^{-1}Q^{h'}_\Pi \in \mathcal{L}(\mathcal{W}'_\Pi, \mathcal{W}^h).$$

Theorem 8.3 implies that

$$\|E_c\hat{u} - \hat{u}^h\|_{\mathcal{W}^h} \;=\; \|(E_cT_w - T_w^h)C_{\mathcal{W}}u\|_{\mathcal{W}^h} \to 0 \quad \text{for } h \to 0 \text{ and } \forall u \in \mathcal{W}.$$

Since, by assumption, $C_{\mathcal{W}}$ is compact and $(E_cT_w - T_w^h)$ are equibounded, this implies

$$\|(E_cT_w - T_w^h)C_{\mathcal{W}}\|_{\mathcal{W}\hookleftarrow\mathcal{W}} \to 0 \quad \text{for } h \to 0. \tag{8.24}$$

Now let $u^h \in \mathcal{W}^h \subset \mathcal{W}_c$. Because $A_{\mathcal{W}}$ has been extended to yield

$$A_{\mathcal{W}} : \mathcal{W}_c \to \mathcal{W}'_{c,\Pi} = \mathcal{W}'_c \times \mathcal{W}_{c,D} \text{ still boundedly invertible with } \mathcal{W}^h \subset \mathcal{W}_c, \tag{8.25}$$

we can estimate

$$\begin{aligned}\|u^h\|_{\mathcal{W}^h} &\leq \|A^{-1}_{\mathcal{W}}\|_{\mathcal{W}^h\hookleftarrow\mathcal{W}'_{c,\Pi}}\|A_{\mathcal{W}}u^h\|_{\mathcal{W}'_{c,\Pi}} = \|A^{-1}_{\mathcal{W}}\|_{\mathcal{W}^h\hookleftarrow\mathcal{W}'_{c,\Pi}}\|B_{\mathcal{W}}(I + T_wC_{\mathcal{W}})u^h\|_{\mathcal{W}'_{c,\Pi}} \\ &\leq \|A^{-1}_{\mathcal{W}}\|_{\mathcal{W}^h\hookleftarrow\mathcal{W}'_{c,\Pi}}\|B_{\mathcal{W}}\|_{\mathcal{W}'_{c,\Pi}\hookleftarrow\mathcal{W}^h}\|(I + T_wC_{\mathcal{W}})u^h\|_{\mathcal{W}^h}; \text{ hence,} \\ \|(I + T_wC_{\mathcal{W}})u^h\|_{\mathcal{W}^h} &\geq (\|A^{-1}_{\mathcal{W}}\|_{\mathcal{W}^h\hookleftarrow\mathcal{W}'_{c,\Pi}}\|B_{\mathcal{W}}\|_{\mathcal{W}'_{c,\Pi}\hookleftarrow\mathcal{W}^h})^{-1}\|u^h\|_{\mathcal{W}^h}.\end{aligned} \tag{8.26}$$

The $Q^{h'}_{\Pi} B_{\mathcal{W}} u$ is defined for every $u \in \mathcal{W}$. We apply the stability of $B^h_{\mathcal{W}}$ to $w^h := B^h_{\mathcal{W}} u^h$:

$$\|u^h\|_{\mathcal{W}^h} \leq \|(B^h_{\mathcal{W}})^{-1}\|_{\mathcal{W}^h \hookleftarrow \mathcal{W}^{h'}_{\Pi}} \cdot \|w^h\|_{\mathcal{W}^{h'}_{\Pi}}.$$

Furthermore

$$\begin{aligned}\|(I + T^h_w C_{\mathcal{W}})u^h\|_{\mathcal{W}^h} &= \|(B^h_{\mathcal{W}})^{-1} B^h_{\mathcal{W}}(I + T^h_w C_{\mathcal{W}})u^h\|_{\mathcal{W}^h} \\ &\leq \|(B^h_{\mathcal{W}})^{-1}\|_{\mathcal{W}^h \hookleftarrow \mathcal{W}^{h'}_{\Pi}} \|B^h_{\mathcal{W}}(I + T^h_w C_{\mathcal{W}})u^h\|_{\mathcal{W}^{h'}_{\Pi}}\end{aligned}$$

implies

$$\|B^h_{\mathcal{W}}(I + T^h_w C_{\mathcal{W}})u^h\|_{\mathcal{W}^{h'}_{\Pi}} \geq \frac{1}{\|(B^h_{\mathcal{W}})^{-1}\|_{\mathcal{W}^h \hookleftarrow \mathcal{W}^{h'}_{\Pi}}} \cdot \|(I + T^h_w C_{\mathcal{W}})u^h\|_{\mathcal{W}^h}. \tag{8.27}$$

We combine (8.23)–(8.27) and use the fact that $A_{\mathcal{W}}, B_{\mathcal{W}}, C_{\mathcal{W}}$ are extended to $\mathcal{W}^h$, s.t. $Q^{h'}_{c,\Pi} A_{\mathcal{W}} u^h$ is well defined for estimating

$$\begin{aligned}\|A^h_{\mathcal{W}} u^h\|_{\mathcal{W}^{h'}_{\Pi}} &= \|Q^{h'}_{c,\Pi} A_{\mathcal{W}}|_{\mathcal{W}^h} u^h\|_{\mathcal{W}^{h'}_{\Pi}} = \|Q^{h'}_{c,\Pi} A_{\mathcal{W}} u^h\|_{\mathcal{W}^{h'}_{\Pi}} \quad \forall u^h \in \mathcal{W}^h \\ &= \|Q^{h'}_{c,\Pi} B_{\mathcal{W}}(I + T_w C_{\mathcal{W}})u^h\|_{\mathcal{W}^{h'}_{\Pi}} \overset{(8.23)}{=} \|B^h_{\mathcal{W}}(I + T_w C_{\mathcal{W}})u^h\|_{\mathcal{W}^{h'}_{\Pi}} \\ &\geq \|B^h_{\mathcal{W}}(I + T^h_w C_{\mathcal{W}})u^h\|_{\mathcal{W}^{h'}} - \|B^h_{\mathcal{W}}(E_c T_w - T^h_w) C_{\mathcal{W}} u^h\|_{\mathcal{W}^{h'}_{\Pi}} \\ &\overset{(8.27)}{\geq} \|(I + T^h_w C_{\mathcal{W}})u^h\|_{\mathcal{W}^h} / \|(B^h_{\mathcal{W}})^{-1}\|_{\mathcal{W}^h \hookleftarrow \mathcal{W}^{h'}_{\Pi}} - \|B^h_{\mathcal{W}}(E_c T_w - T^h_w) C_{\mathcal{W}} u^h\|_{\mathcal{W}^{h'}_{\Pi}} \\ &\geq (\|(I + T_w C_{\mathcal{W}})u^h\|_{\mathcal{W}^h} - \|(E_c T_w - T^h_w) C_{\mathcal{W}} u^h\|_{\mathcal{W}^h}) / \|(B^h_{\mathcal{W}})^{-1}\|_{\mathcal{W}^h \hookleftarrow \mathcal{W}^{h'}_{\Pi}} \\ &\quad - \|B^h_{\mathcal{W}}(E_c T_w - T^h_w) C_{\mathcal{W}}\|_{\mathcal{W}^{h'}_{\Pi} \hookleftarrow \mathcal{W}^h} \|u^h\|_{\mathcal{W}^h} \\ &\overset{(8.26)}{\geq} \Big(\frac{1}{(\|A^{-1}_{\mathcal{W}}\|_{\mathcal{W}^h \hookleftarrow \mathcal{W}'_{c,\Pi}} \|B^h_{\mathcal{W}}\|_{\mathcal{W}^{h'}_{\Pi} \hookleftarrow \mathcal{W}^h} \|(B^h_{\mathcal{W}})^{-1}\|_{\mathcal{W}^h \hookleftarrow \mathcal{W}^{h'}_{\Pi}})} \\ &\quad - \mathcal{O}(\|(E_c T_w - T^h_w) C_{\mathcal{W}}\|_{\mathcal{W}^{h'}_{\Pi} \hookleftarrow \mathcal{W}^h}) \Big) \|u^h\|_{\mathcal{W}^h}.\end{aligned}$$

The last estimate shows the following: The $\|A^{-1}_{\mathcal{W}}\|_{\mathcal{W}^h \hookleftarrow \mathcal{W}'_{c,\Pi}}$ is the deciding factor if $B^h_{\mathcal{W}}$ has a moderate condition number. Because of (8.24) and the stability of $(B^h_{\mathcal{W}})_{h \in H}$ there exists a positive constant K, independent of h, such that for all $h \leq h_0$,

$$\|A^h_{\mathcal{W}} u^h\|_{\mathcal{W}^h} = \|Q^{h'}_{c,\Pi} A_{\mathcal{W}} u^h\|_{\mathcal{W}^h} \geq K \|u^h\|_{\mathcal{W}^h} \quad \forall u^h \in \mathcal{W}^h.$$

This and $\dim \mathcal{W}^h < \infty$ show that $Q^{h'}_{c,\Pi} A_{\mathcal{W}}|_{\mathcal{W}^h}$ is invertible for $h \leq h_0$. Moreover, we obtain $\|(Q^{h'}_{c,\Pi} A_{\mathcal{W}}|_{\mathcal{W}^h})^{-1}\|_{\mathcal{W}^h \hookleftarrow \mathcal{W}^{h'}} \leq 1/K$; i.e., $A^h_{\mathcal{W}}|_{\mathcal{W}^h}$ for all $h \in H$ is stable. □

8.4. Regularity for FE solutions. Our next task is lifting the preceding stability result w.r.t. the weak forms back to the strong form. This is achieved by the regularity for FE solutions in this subsection. Until now, *regularity results for the solutions of FEMs* seem to be known only as oscillation results in the sense of De Giorgi, Nash, and Moser; see Aguilera and Caffarelli [1]. They are not applicable to our problem of stability. Here we need, for the solution of a FEM applied to a differential equation of order 2, results analogous to those for the exact solution. These are estimates of the $H^2(\Omega)$ instead of the usual $H^1(\Omega)$ norm for a right-hand

side in $L^2(\Omega) \times H^{3/2}(\Omega)$ instead of the usual $H^{-1}(\Omega) \times H^{1/2}(\Omega)$. To the author's knowledge, the following type of lemma was not known for FEMs. It is a transformation to our FEM of Hackbusch's regularity result [37, Theorem 9.2.26] for difference methods. We employ inverse and interpolation error estimates (4.5), (4.11), (4.23), valid under the conditions of Theorems 4.1, 4.2, and 4.6. The lemma is based upon a regularity result for the exact solution u_1 of the corresponding linear problem $A_{\mathcal{W}}u_1 = (f,\phi) \in \mathcal{V} \times \mathcal{V}_D \subset \hat{\mathcal{V}}_\Pi, u_1 \in \mathcal{W}_0$. Indeed, known regularity results, e.g., in Hackbusch [37, Theorems 9.1.22, 9.1.16], show that, for a convex bounded or smooth domain and smooth coefficients, the restriction $A_{\mathcal{U}} = A_{\mathcal{W}}|_{\mathcal{U}} \in \mathcal{L}(\mathcal{U}, \mathcal{V} \times \mathcal{V}_D)$ is boundedly invertible for a boundedly invertible $A_{\mathcal{W}} \in \mathcal{L}(\mathcal{W}, \mathcal{W}' \times \mathcal{W}_D)$; hence we assume

$$\Omega \text{ convex bounded, polyhedral or } \Omega \in C^2, \tag{8.28}$$
$$(A_{\mathcal{W}})^{-1} \in \mathcal{L}(\mathcal{W}' \times \mathcal{W}_D, \mathcal{W}), \quad a_{i,j} \in W^{1-\delta_{j0},\infty}(\Omega) \quad \forall 0 \le i,j \le n.$$

LEMMA 8.5 (regularity of solutions of FEMs). *We assume the bounded elliptic $A_{\mathcal{W}} \in \mathcal{L}(\mathcal{W}, \mathcal{W}' \times \mathcal{W}_D)$ and $A_{\mathcal{U}} \in \mathcal{L}(\mathcal{U}, \mathcal{V} \times \mathcal{V}_D)$ to be boundedly invertible, e.g., by* (8.28). *Choose the above FEs,* (8.19) *and* (8.20), *of local degree $d \ge 2$, on a quasi-uniform triangulation; see* (4.4), (8.6). *Then $A^h_{\mathcal{W}}$ is regular w.r.t. stability and convergence; hence, there exist unique solutions u_1 for $A_{\mathcal{W}}u_1 = (f,\phi)$, u_1^h, and a $C' > 0$, independent of h, s.t. (see* (4.11), (4.23)*)*

(8.29)
$$A^h_{\mathcal{W}}u_1^h = Q^{h'}_{c,\Pi}(f,\phi), \quad (f,\phi) \in \mathcal{V} \times \mathcal{V}_D \implies \|u_1^h\|_{\mathcal{U}^h} \le C'(\|f\|_{\mathcal{V}} + \|\phi\|_{\mathcal{V}_D}) \quad \textit{with}$$
$$\|E_c u_1 - u_1^h\|_{\mathcal{U}^h} \le C'(\|E_c u_1 - P^h u_1\|_{\mathcal{U}^h} + \|E_c\phi - P^h u_1\|_{\mathcal{V}_D^h}). \tag{8.30}$$

$A_{\mathcal{W}} \in \mathcal{L}(\mathcal{W}, \mathcal{W}'_\Pi)$ and $A_{\mathcal{U}} \in \mathcal{L}(\mathcal{U}, \hat{\mathcal{V}}_\Pi)$ simultaneously satisfy the Fredholm alternative.

Remark 8.1. Hence, the FE error in the strong norm $\|E_c u_1 - u_1^h\|_{\mathcal{U}^h}$ is estimated by the interpolation errors of u_1 in $\mathcal{U}^h$ and $\mathcal{V}_D^h$. The FE spaces considered here need a quasi-uniform triangulation guaranteeing inverse estimates in the global form, $\|v^h\|^h_{H^j(\Omega_c^h)} \le C\ h^{l-j}\|v^h\|^h_{H^l(\Omega_c^h)}$; see (4.5). If inverse estimates will be available for $\mathcal{S}^1_d(\mathcal{T}_c^h)$ on nondegenerate triangulations, e.g., by applying the techniques in Graham, Hackbusch, and Sauter [36], the lemma remains valid for this case. Under the conditions of the lemma, (8.29) even holds for noninvertible $A_{\mathcal{W}}$ with $\|(f,\phi)\|_{\hat{\mathcal{V}}_\Pi}$ replaced by $\|(f,\phi)\|_{\hat{\mathcal{V}}_\Pi} + \|u_1\|_{\mathcal{W}}$; see [37].

For Figure 8.2 and the following proof we contrast the strong and weak operators $A_{\mathcal{U}} \in \mathcal{L}(\mathcal{U} \cup \mathcal{U}_c, \hat{\mathcal{V}}_\Pi)$ and $A_{\mathcal{W}} \in \mathcal{L}(\mathcal{W} \cup \mathcal{W}_c, \mathcal{W}'_\Pi)$, extended as in (8.25); see (6.16)–(6.18), (8.14), (8.15) with the FE versions in (6.24), (8.17). The horizontal arrows in the first line of Figure 8.2 indicate compact embeddings and in the second line the decreasingly weaker norms in the spaces $\mathcal{U}^h = \mathcal{W}^h$ and $\hat{\mathcal{V}}_\Pi^h \subset \mathcal{W}_\Pi^{h'}$. The $\longrightarrow$ between $\mathcal{W}, \hat{\mathcal{V}}_\Pi$ are missing, since only $\mathcal{W} \longrightarrow \mathcal{V}$ would be appropriate.

Proof. For a boundedly invertible $A_{\mathcal{W}} \in \mathcal{L}(\mathcal{W}, \mathcal{W}'_\Pi)$, Theorem 8.4 implies the stability and thus the bounded invertibility of $A^h_{\mathcal{W}} = Q^{h'}_{c,\Pi}A_{\mathcal{W}}|_{\mathcal{W}^h} \in \mathcal{L}(\mathcal{W}^h, \mathcal{W}_\Pi^{h'})$. This yields with the consistency in Theorem 7.1 the existence of a discrete solution u_1^h for $A^h_{\mathcal{W}}u_1^h = Q^{h'}_\Pi(f,\phi) \in \mathcal{W}_\Pi^{h'}$ by Theorem 5.1. The solution $u_1^h \in \mathcal{W}^h$ for $(f,\phi) \in \mathcal{W}'_\Pi$ satisfies the estimate $\|u_1^h\|_{\mathcal{W}^h} \le C\|(f,\phi)\|_{\mathcal{W}'_\Pi}$. Now we use the same technique as in the proof of Theorem 8.3 for reducing the inhomogeneous to trivial Dirichlet boundary conditions. We have assumed $\phi \in \mathcal{V}_D = H^{3/2}(\partial\Omega)$ as a restriction of $\phi \in \mathcal{V} = H^2(\Omega)$.

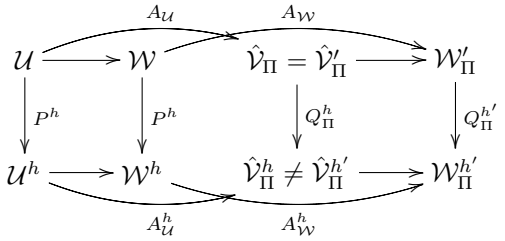

FIG. 8.2. *Strong and weak FEMs for linear problems.*

This is possible by combining Theorem 4.5 with Zeidler [64, p. 1030]. The last lines of the proof of Theorem 7.1 can then be updated to obtain the (8.29), (8.30) results for $\phi \not\equiv 0$ if they are correct for $\phi \equiv 0$. So we restrict the discussion for the remaining proof to trivial Dirichlet boundary conditions.

We find for $P^h = I^h E_c$, $A_{\mathcal{U}}$, and the $v^h_\Pi = (v^h, 0) \in \hat{\mathcal{V}}^h_\Pi$ (cf. (8.25), (6.16)–(6.18))

$$P^h A^{-1}_{\mathcal{U}} : \mathcal{V}^h_\Pi \subset \mathcal{V}_{c,\Pi} \to \mathcal{U}^h \text{ or } P^h A^{-1}_{\mathcal{U}} v^h_\Pi \text{ is well defined } \ \forall v^h_\Pi = (v^h, 0) \in \hat{\mathcal{V}}^h_\Pi.$$

$\mathcal{V}^h \subset C^1(\ \overline{\Omega^h_c}\ ) \subset C^\gamma(\ \overline{\Omega^h_c}\ )$ for a $0 < \gamma < 1$ implies that $A^{-1}_{\mathcal{U}} v^h_\Pi \in C^{2,\gamma}(\ \overline{\Omega^h_c}\ )$ by standard regularity results, e.g., [63, Chapter 6.3, Problem 6.8, p. 259] and so the $P^h A^{-1}_{\mathcal{U}} v^h_\Pi$ is well defined for all $v^h_\Pi = (v^h, 0 \in \hat{\mathcal{V}}^h_\Pi$. Alternatively, we choose interpolation via the Bramble–Hilbert lemma. Thus $P^h A^{-1}_{\mathcal{U}} v^h_\Pi$ is well defined for derivatives up to second order for P^h in (4.14), e.g., for the Argyris FEs. Higher derivatives defining P^h require quasi interpolants as, e.g., in Theorem 4.2, Scott and Zhang [48], and Davydov [27].

For the estimate in (8.35) we need the embedding $I_{WU} : \mathcal{W}^h \to \mathcal{U}^h$, the bounded transformation (cf. (6.21)), and [27]:

(8.31)
$$I^h_{\mathcal{V}^0} : \mathcal{V}^{h',0}_\Pi := \mathcal{V}^{h'} \times \{0\} \subset \mathcal{V}^{h'}_\Pi \to \mathcal{V}^0_{c,\Pi} := \mathcal{V}_c \times \{0\} \subset \mathcal{V}_{c,\Pi},\ (v^{h'}, 0) \to (Q^h_d v^{h'}, 0).$$

We assumed a smooth $(f \in \mathcal{V}, \phi \equiv 0) \in \hat{\mathcal{V}}_\Pi$. By (6.22) and $\phi \equiv 0$ we restrict the discussion to $u^h \in \mathcal{W}^h \cap S^h_0 = \mathcal{U}^h_0 = \mathcal{W}^h_0 = \mathcal{V}^h$. For the equalities between weak and strong problems we use special spaces and (6.16)–(6.19), (8.9), (8.14)–(8.18):

$$\forall u^h, v^h \in \mathcal{U}^h_0 = \mathcal{W}^h_0 = \mathcal{V}^h,\ \forall v^h_\Pi := (v^h, 0) \in \hat{\mathcal{V}}^{h,0}_\Pi := \mathcal{V}^h \times \{0\},\ \hat{\mathcal{V}}^{h',0}_\Pi,\ \hat{\mathcal{W}}^{h,0}_\Pi,\ \mathcal{W}^{h',0}_\Pi.$$

We find for $f \in \mathcal{V}$ and the definition of A, A_s in $\Omega \cup \Omega^h_c$ that

$$\langle A^h_{\mathcal{W}} u^h, v^h_\Pi \rangle_{\mathcal{W}^{h',0}_\Pi \times \mathcal{W}^{h,0}_\Pi} = \langle A u^h, v^h \rangle_{\mathcal{W}'_c \times \mathcal{W}_c} = (A_s u^h, v^h)_{\mathcal{V}_c} = \langle A^h_{\mathcal{U}} u^h, v^h_\Pi \rangle_{\mathcal{V}^{h',0}_\Pi \times \mathcal{V}^{h,0}_\Pi} \text{ and}$$

$$(E_c f, v^h)_{\mathcal{V}_c} = \langle Q^{h',0}_\Pi (E_c f, 0), v^h_\Pi \rangle_{\mathcal{W}^{h',0}_\Pi \times \mathcal{W}^{h,0}_\Pi} = \langle Q^{h,0}_\Pi (E_c f, 0), v^h_\Pi \rangle_{\mathcal{V}^{h',0}_\Pi \times \mathcal{V}^{h,0}_\Pi}. \tag{8.32}$$

This implies coinciding weak and strong bilinear forms, since for all $v^h \in \mathcal{V}^h$

$$\langle A^h_{\mathcal{W}} u^h_1, v^h_\Pi \rangle_{\mathcal{W}^{h',0}_\Pi \times \mathcal{W}^{h,0}_\Pi} = (A_s u^h_1, v^h)_{\mathcal{V}_c} = \langle A^h_{\mathcal{U}} u^h_1, v^h_\Pi \rangle_{\mathcal{V}^{h',0}_\Pi \times \mathcal{V}^{h,0}_\Pi} = (E_c f, v^h)_{\mathcal{V}_c}. \tag{8.33}$$

Hence, a weak solution u^h_1 solves the strong problem as well:

$$A^h_{\mathcal{W}} u^h_1 = Q^{h',0}_\Pi (f, 0), \quad (f, 0) \in \mathcal{V}^0_\Pi := \mathcal{V} \times \{0\} \Longrightarrow A^h_{\mathcal{U}} u^h_1 = Q^{h,0}_\Pi (f, 0). \tag{8.34}$$

For proving stability and consistency for the strong form, we start with the identity

$$(A^h_{\mathcal{U}})^{-1}_{\mathcal{U}^h_0 \hookleftarrow \mathcal{V}^{h',0}_{\Pi}} = \big[P^h_{\mathcal{U}^h_0 \hookleftarrow \mathcal{U}_{c,0}}(A^{-1}_{\mathcal{U}})_{\mathcal{U}_{c,0} \hookleftarrow \mathcal{V}^0_{c,\Pi}} - (I_{WU})_{\mathcal{U}^h_0 \hookleftarrow \mathcal{W}^h_0} (A^h_{\mathcal{U}})^{-1}_{\mathcal{W}^h_0 \hookleftarrow \mathcal{W}^{h',0}_{\Pi}} [(A^h_{\mathcal{U}} P^h - Q^h_{c,\Pi} A_{\mathcal{U}})]_{\mathcal{W}^{h',0}_{\Pi} \hookleftarrow \mathcal{U}_{c,0}} (A^{-1}_{\mathcal{U}})_{\mathcal{U}_{c,0} \hookleftarrow \mathcal{V}^0_{c,\Pi}}\big] I_{\mathcal{V}^0_{c,\Pi}, \mathcal{V}^{h',0}_{\Pi}}. \tag{8.35}$$

The inverse and the error estimates (4.5) and (4.11), (4.23), the approximation property (4.23), for the local degree $d \geq 2$, show the three inequalities

$$\|I_{WU}\|_{\mathcal{U}^h_0 \hookleftarrow \mathcal{W}^h_0} \leq C_1 h^{-1},\ \|P^h\|_{\mathcal{U}^h_0 \hookleftarrow \mathcal{U}_{c,0}} \leq C_2,\ \|P^h u_1 - E_c u_1\|_{\mathcal{W}^h} \leq C_3 h \|u_1\|_{\mathcal{U}}. \tag{8.36}$$

With (4.23), the solution of $A_{\mathcal{U}} u_1 = (f, 0) \in \mathcal{V}_{\Pi}$, equal weak and strong bilinear forms, $a_{i,j}$ (cf. (8.2)), defined in $\Omega \cup \Omega^h_c$, and the special $v^h_{\Pi} = (v^h, 0) \in \mathcal{V}^{h,0}_{\Pi}$, we get by (4.22)

$$\begin{aligned}
|\langle A^h_{\mathcal{U}} P^h u_1 - Q^h_{\Pi} A_{\mathcal{U}} u_1, v^h_{\Pi} \rangle_{\mathcal{W}^{h',0}_{\Pi} \times \mathcal{W}^{h,0}_{\Pi}}| &= |(A_s P^h u_1 - Q^h f, v^h)_{\mathcal{V}_c}| \\
&= |(A_s P^h u_1 - E_c f, v^h)_{\mathcal{V}_c}| = |(A_s P^h u_1 - E_c A_s u_1, v^h)_{\mathcal{V}_c}| \\
&= \Big| \Big(\sum_{i,j=0}^{n} a_{ij} (\partial^i\ P^h u_1 -\ E_c \partial^i u_1), \partial^j v^h \Big)_{\mathcal{V}_c} \Big| + Ch \|u_1\|_{\mathcal{U}} \|v^h\|_{\mathcal{W}^h} \\
&\leq (C_3 + C) h \|u_1\|_{\mathcal{U}} \|v^h\|_{\mathcal{W}^h} \quad \forall v^h_{\Pi} = (v^h, 0) \in \mathcal{V}^{h,0}_{\Pi}.
\end{aligned}$$

With (8.34), this consistency, and the stability of $A^h_{\mathcal{W}}$, the $\|(A^h_{\mathcal{W}})^{-1}_{\mathcal{W}^h_0 \hookleftarrow \mathcal{W}^{h',0}_{\Pi}}\| \leq C_4$, we estimate the first term in (8.35):

$$\begin{aligned}
&\|(A^h_{\mathcal{U}})^{-1}_{\mathcal{W}^h_0 \hookleftarrow \mathcal{W}^{h',0}_{\Pi}} [(A^h_{\mathcal{U}} P^h - Q^h_{c,\Pi} A_{\mathcal{U}})]_{\mathcal{W}^{h',0}_{\Pi} \hookleftarrow \mathcal{U}_{c,0}}\|_{\mathcal{W}^h_0 \hookleftarrow \mathcal{U}_{c,0}} \\
&= \|(A^h_{\mathcal{W}})^{-1}_{\mathcal{W}^h_0 \hookleftarrow \mathcal{W}^{h',0}_{\Pi}} [(A^h_{\mathcal{U}} P^h - Q^h_{c,\Pi} A_{\mathcal{U}})]_{\mathcal{W}^{h',0}_{\Pi} \hookleftarrow \mathcal{U}_{c,0}}\|_{\mathcal{W}^h_0 \hookleftarrow \mathcal{U}_{c,0}} \\
&\leq C_4 \|(A^h_{\mathcal{U}} P^h - Q^h_{\Pi} A_{\mathcal{U}})\|_{\mathcal{W}^{h',0}_{\Pi} \hookleftarrow \mathcal{U}_{c,0}} \\
&\leq C_4 \sup_{0 \neq u \in \mathcal{U}_{c,0}} \sup_{0 \neq v^h \in \mathcal{W}^h_0} \frac{|\langle A^h_{\mathcal{U}} P^h u - A_{\mathcal{U}} u, v^h_{\Pi} \rangle_{\mathcal{W}^{h',0}_{\Pi} \times \mathcal{W}^{h,0}_{\Pi}}|}{\|v^h\|_{\mathcal{W}^h} \|u\|_{\mathcal{U}}} \leq C_3 C_4 h.
\end{aligned}$$

With (8.36), (8.35) and a boundedly invertible $\|(A^{-1}_{\mathcal{U}}\|_{\mathcal{U}_{c,0} \hookleftarrow \mathcal{V}^0_{c,\Pi}} \leq C_5$ and a bound for $\|I_{\mathcal{V}^0_{c,\Pi}, \mathcal{V}^{h',0}_{\Pi}}\|_{\mathcal{V}^0_{c,\Pi} \hookleftarrow \mathcal{V}^{h',0}_{\Pi}} \leq C_6$, this yields the stability of $A^h_{\mathcal{U}} : \mathcal{U}^h_0 \to \mathcal{V}^{h',0}_{\Pi}$, since

$$\begin{aligned}
\|(A^h_{\mathcal{U}})^{-1}\|_{\mathcal{U}^h_0 \hookleftarrow \mathcal{V}^{h',0}_{\Pi}} &\leq \big[\|P^h\|_{\mathcal{U}^h_0 \hookleftarrow \mathcal{U}_{c,0}} \|(A^{-1}_{\mathcal{U}})\|_{\mathcal{U}_{c,0} \hookleftarrow \mathcal{V}^0_{c,\Pi}} + \|(I_{WU})_{\mathcal{U}^h_0 \hookleftarrow \mathcal{W}^h_0}\| \\
&\|(A^h_{\mathcal{U}})^{-1}_{\mathcal{W}^h_0 \hookleftarrow \mathcal{W}^{h',0}_{\Pi}} [(A^h_{\mathcal{U}} P^h - Q^h_{c,\Pi} A_{\mathcal{U}})]_{\mathcal{W}^{h',0}_{\Pi} \hookleftarrow \mathcal{U}_{c,0}}\|_{\mathcal{W}^h_0 \hookleftarrow \mathcal{U}_{c,0}} \|A^{-1}_{\mathcal{U}}\|_{\mathcal{U}_{c,0} \hookleftarrow \mathcal{V}^0_{c,\Pi}}\big], \\
\|I_{\mathcal{V}^0_{c,\Pi}, \mathcal{V}^{h',0}_{\Pi}}\|_{\mathcal{V}^0_{c,\Pi} \hookleftarrow \mathcal{V}^{h',0}_{\Pi}} &\leq \big[C_2 C_5 + C_1 h^{-1} C_3 C_4 h C_5\big] C_6 \leq C.
\end{aligned}$$

The combination of these inequalities yields the claim, since

$$\|u^h_1\|_{\mathcal{U}^h} = \|(A^h_{\mathcal{U}})^{-1} Q^h_{\Pi}(f, 0)\|_{\mathcal{U}^h} \leq \|(A^h_{\mathcal{U}})^{-1}\|_{\mathcal{U}^h_0 \hookleftarrow \mathcal{V}^{h',0}_{\Pi}} \|Q^h_{\Pi}\|_{\mathcal{V}^{h',0}_{\Pi} \hookleftarrow \mathcal{V}^0_{\Pi}} \|f\|_{\mathcal{V}} \leq C \|f\|_{\mathcal{V}}.$$

The convergence in (8.30) is, by Theorem 5.1, an immediate consequence of the stability in (8.29) and the consistency in Theorem 7.1. ∎

8.5. Stability for the strong linear operator and convergence. Combining Theorem 8.4, Proposition 8.2, and Lemma 8.5 we obtain the following.

THEOREM 8.6. *For the linearized operator* $A_s = G'(u_0) \in \mathcal{L}(\mathcal{U}, \mathcal{V})$ *in* (8.2)*, assume* (3.10)*, for the domain* (8.28)*, a quasi-uniform* $\mathcal{S}^1_d(\mathcal{T}^h), d \geq 2^n + 1$ *(see* (4.4)*), and let the corresponding* $A_s \in \mathcal{L}(\mathcal{U}_0, \mathcal{V})$ *and, hence,* $A_{\mathcal{U}} := (A_s, B_D) \in \mathcal{L}(\mathcal{U}, \mathcal{V} \times \mathcal{V}_D)$ *be boundedly invertible. Then the conforming FEM* (8.7) *for the linear* $A^h_s u^h_1 = Q^h A_s|_{\mathcal{U}_0} u^h_1 = Q^h f, f \in \mathcal{V}$*, and the nonconforming FEM* (8.19)*,* $A^h_{\mathcal{U}} u^h_1 = Q^h_{c,\Pi} A_{\mathcal{U}} u^h_1 = Q^h_\Pi(f, \phi)$*,* $(f, \phi) \in \mathcal{V} \times \mathcal{V}_D$*, are stable as well.*

We discussed the relation between the bounded invertibility of $A_s = G'(u_0) \in \mathcal{L}(\mathcal{U}_0, \mathcal{V})$ and $A_{\mathcal{U}} = (A_s, B_D) \in \mathcal{L}(\mathcal{U}, \mathcal{V} \times \mathcal{V}_D)$ and the existence of a locally unique solution of $G(u_0) = 0$ and $F(u_0) = 0$ already at the end of section 3.

Proof. The boundedness of the strong $A_{\mathcal{U}} := (A_s, B_D) \in \mathcal{L}(\mathcal{U}, \mathcal{V} \times \mathcal{V}_D)$ and its weak counterpart $A_{\mathcal{W}} \in \mathcal{L}(\mathcal{W}, \mathcal{W}' \times \mathcal{W}_D)$ under the conditions in (8.28), (8.2), (8.3) is straightforward. We want to show that the bounded invertibility of $A_{\mathcal{U}}$ implies that of $A_{\mathcal{W}} \in \mathcal{L}(\mathcal{W}, \mathcal{W}' \times \mathcal{W}_D)$ as well. Indeed, by (8.2)–(8.3), the corresponding $G'(u_0) \in \mathcal{L}(\mathcal{U}, \mathcal{V}')$ induces a strong bounded bilinear form, by Proposition 8.2 simultaneously a $\mathcal{W}$-elliptic bilinear form, and thus finally $A_{\mathcal{W}} \in \mathcal{L}(\mathcal{W}, \mathcal{W}' \times \mathcal{W}_D)$. Thus the Fredholm alternative applies: If $A_{\mathcal{W}} \in \mathcal{L}(\mathcal{W}, \mathcal{W}' \times \mathcal{W}_D)$ would not be boundedly invertible, each of the infinitely many solutions of $A_{\mathcal{W}} u_1 = (f, \phi) \in \mathcal{V} \times \mathcal{V}_D$ for appropriate (f, ϕ) would be $u_1 \in \mathcal{U}$ by (8.28) and the well-known regularity results; see, e.g., Hackbusch [37, Chapter 9]. So $A_{\mathcal{U}}$ could not be boundedly invertible either.

Now we apply Theorem 8.4 to guarantee the stability for the strong form: The bounded invertibility of $Q^{h'}_\Pi A_{\mathcal{W}}|_{\mathcal{W}^h} \in \mathcal{L}(\mathcal{W}^h, \mathcal{W}^{h'}_\Pi)$ and Lemma 8.5 guarantee the stability of $Q^h_\pi A_{\mathcal{U}}|_{\mathcal{U}^h} \in \mathcal{L}(\mathcal{U}^h, \mathcal{V}^h_\Pi)$ and thus the claim. ∎

Theorems 5.1, 7.1, and 8.1 and the last section combined with the last proof show that we have proved stability and convergence for the FEM in (6.26) if G is continuously differentiable near a locally unique solution u_0 with boundedly invertible $F'(u_0)$. This is guaranteed, again in the interplay between weak and strong form of the derivative, e.g., with $B_{r,\mathcal{W}}(u_0)$ the ball w.r.t. $\|u - u_0\|_{\mathcal{W}} < r$, by

$$\begin{aligned} &a_{ij}(w(\cdot)) \in C^{1-\delta_{0j},\infty}(B_{r,\mathcal{W}}(u_0)) \text{ and } a_{ij}(w(\cdot)) \in C^{1-\delta_{0j},\infty}(B_{r,\mathcal{U}}(u_0)), \\ &\text{yield } C(B_{r,\mathcal{W}}(u_0)) \ni A = G'(\cdot) : \mathcal{W} \to \mathcal{W}' \text{ and } C(B_{r,\mathcal{U}}(u_0)) \ni A_s = G'(\cdot) : \mathcal{U} \to \mathcal{V}', \end{aligned} \tag{8.37}$$

where $i, j = 0, \ldots, n$, $a_{ij}(w(\cdot))$ are defined in (3.7). Alternatively, we might require $a_{ij}(\cdot) \in C^{1-\delta_{0j}}(\mathcal{D}(G^w))$, with $w, w_0 \in \mathcal{D}(G^w)$ as in (3.6).

THEOREM 8.7. *Let the nonlinear elliptic problem in* (6.6)*,* $G(u_0) = 0, u_0 \in \mathcal{U}_0$*, or* $F(u_0) = (G, B_D)(u_0) = 0, u_0 \in \mathcal{U}$*, have an isolated solution, with boundedly invertible* $G'(u_0) : \mathcal{U}_0 \to \mathcal{V}$*, or* $F'(u_0) : \mathcal{U} \to \hat{\mathcal{V}}_\Pi$*, let* G *be continuously differentiable in* $B_r(u_0)$*, e.g., by* (8.37)*, and let the domain satisfy* (8.28)*. Choose* $\mathcal{U}^h = \mathcal{S}^1_d(\mathcal{T}^h_c), d \geq 2^n + 1$ *(see* (4.4)*), on a quasi-uniform triangulation. Then the conforming FEM* (5.10) *is*

$$G^h = Q^h_c G|_{\mathcal{U}^h_0} : \mathcal{U}^h_0 \to \mathcal{V}^{h'}, \quad u^h_0 \in \mathcal{D}(G^h) \subset \mathcal{U}^h_0 \text{ s.t. } G^h u^h_0 = 0.$$

The nonconforming FEM (6.26) *is*

$$F^h = Q^h_{c,\Pi} F|_{\mathcal{U}^h} : \mathcal{U}^h \to \mathcal{V}^{h'} \times \mathcal{V}^h_b, \quad u^h_0 \in \mathcal{D}(F^h) \subset \mathcal{U}^h \text{ s.t. } F^h u^h_0 = 0.$$

Both methods are stable in $P^h u_0$*, consistent, and convergent. Both have, for small enough* h*, a unique solution* u^h_0 *near* u_0*. We obtain (cf.* (7.2)*), for* $u_0 \in H^\ell(\Omega)$*,* $\ell > 2$*, for the conforming and nonconforming FEM, for polyhedral and* C^2 *domains,*

$$\|P^h u_0 - u^h_0\|_{\mathcal{U}^h} \leq C h^{\ell-2} \|u_0\|_{H^\ell(\Omega)} \text{ and } \leq C h^{\min\{\ell-2,p\}} \|u_0\|_{H^\ell(\Omega)}, \tag{8.38}$$

respectively, with $p = 2$ *for polyhedral* Ω^h *and* $p > 2$ *for polyhedral or curved* $\Omega_c^h \approx \Omega \in C^2$. $F'(u_0) \in \mathcal{L}(\mathcal{W}, \mathcal{W}' \times \mathcal{W}_D)$ *and* $F'(u_0) \in \mathcal{L}(\mathcal{U}, \mathcal{V} \times \mathcal{V}_D)$ *simultaneously satisfy the Fredholm alternative.*

Remark 8.2. 1. For the above F (see (3.8), (3.10), (8.2)), ℓ and d are related by (4.9). With the ellipticity assumption (3.10), the previous (8.2), (8.3), (8.28) are implied by (8.37), except Ω convex polyhedral or $\in C^2$. The latter are necessary for the regularity and the extension operators.

2. For quadrature approximations, exactly reproducing polynomials of degree $< k$ with $k > 2(d-1) > d > 2$, the solution $\tilde{u}_0^h$ of an approximate $\tilde{F}^h(\tilde{u}_0^h) = 0$ satisfies the same estimate as in (8.38); see Böhmer [11].

9. Numerical solution of the FE equations with Newton's method. We have indicated this problem for the (highly) nonlinear system (cf. (2.2), (2.6)) already in section 2, **4.**: We have to determine the FE $u_0^h \in \mathcal{U}^h \subset C^1(\Omega_c^h)$ s.t.

$$\langle F^h(u_0^h), v_\Pi^h \rangle = 0 \Longleftrightarrow (G(u_0^h), v^h)_{\mathcal{V}_c} = 0 \quad \forall v^h \in \mathcal{V}^h, (u_0^h, v_b^h)_{\mathcal{V}_{c,b}} = 0 \quad \forall v_b^h \in \mathcal{V}_b^h. \tag{9.1}$$

In this context again *local and stable bases* and *stable splittings* $S^h = S_0^h + S_b^h$ are important; see Theorems 4.2 and 4.4. We insert $u_0^h = \sum_{\mu=1}^m c_\mu s^\mu$ into (9.1) and test $G(u_0^h)$ with $v^h = s^j, j = 1, \dots, m_0$, and the boundary term with $v_b^h = s_b^i = s^{i+m_0}, i = 1, \dots, m - m_0$. So we obtain a nonlinear system of m equations for the m unknowns $c_\mu, \mu = 1, \dots, m$. For computing the terms in (9.1) results of Davydov [28] and Davydov and Stevenson [30], with multiresolution techniques quadrature [11], have to be used.

Equation (9.1) is solved by the well-known continuation and Newton methods. We formulate the discrete Newton method and its quadratic convergence via the less-known mesh independence principle (MIP). Both methods require the solution of the corresponding *linearized sparse FE equations,* with the defect or residuum, $F^h(u_\nu^h), u_\nu^h \approx u_0^h$. The $u^h|_{\partial\Omega_c^h} = 0$ and Proposition 8.2 allow the standard efficient solvers with FEs in $C^0(\Omega^h)$ replaced by $C^1(\Omega_c^h)$. Efficient strategies combining continuation with the MIP on different discretization levels have been studied in Allgower and Böhmer [2, 3]. Presently, multiresolution techniques are available for polyhedral Ω in $\mathbf{R}^n$ and $d \geq 2^n + 1$; see Davydov's papers, e.g., [28, 29, 30]. For $\Omega \in C^2$ and the necessary Ω_c^h for general $\mathcal{S}_d^1(\mathcal{T}_c^h)$ this is still open.

For specific cases, not discussed here, (9.1) represents a *sparse nonlinear system.*

The MIP, the Newton–Kantorowich method, and the convergence of our FEM require a unique solution u_0, s.t. $F'(u_0)$ is boundedly invertible. So we assume

$$F(u_0) = 0 \text{ with } F'(\cdot) \in C_L(B_r(u_0)), \quad (F'(u_0))^{-1} \in \mathcal{L}(\mathcal{V}, \mathcal{U}). \tag{9.2}$$

Starting near $u_0^h \approx u_0$, we apply Newton's method to F^h. By Theorem 8.6, the $(F^h(u_i^h))' : \mathcal{U}^h \to \mathcal{V}^h$ are equiboundedly invertible; hence

$$u_{i+1}^h := u_i^h - (F^h(u_i^h)')^{-1} F^h(u_i^h), \quad i = 1, \dots, \text{ is well defined.} \tag{9.3}$$

In addition to (9.2), the MIP (see Allgower and Böhmer [2, 3] and Allgower et al. [4]) requires a linear FEM; cf. (5.12). Then the Newton method converges quadratically; cf. Theorem 9.1.

Equation (8.38) shows that for $u_0 \in \mathcal{U}_s = H^\ell(\Omega), \ell > 2$ (see (8.38)), the FEM converges of orders $p' = \ell - 2 > 0$ and $p' := \min\{\ell - 2, p\} > 0$. Then, with the above

projectors $P^h = I^h E_c : \mathcal{U} \to \mathcal{U}^h$, $Q^h_\Pi : \hat{\mathcal{V}}_\Pi \to \mathcal{V}^{h'}_\Pi$ (see (6.15), (6.24)), we impose the condition

$$F|_{\mathcal{U}_s} : \mathcal{D}(F) \cap (\mathcal{U}_s := H^\ell(\Omega)) \to H^{\ell-2}(\Omega). \tag{9.4}$$

THEOREM 9.1 (MIP; see [2, 4]). *In addition to the conditions in Theorem* 8.7 *with convergence in* (8.38) *of order* $p' = \ell - 2 > 0$ *or* $p' = \min\{\ell-2, p\} > 0$ *we assume* (9.2), (9.4). *Start the Newton processes for* F, *by omitting all exponents* ^{h} *in* (9.3), *and for* F^h *with the sufficiently good starting values* $u_1 \in B_r(u_0) \cap \mathcal{D}(F) \cap \mathcal{U}_s$ *and* $u^h_1 := P^h u_1$. *Then, for* $h \le h_0 = (\min\{r, (SCL)^{-1}\}/(2Sc_0))^{1/p'}$ *(cf. the following proof), both Newton methods converge quadratically to* u_0 *and* u^h_0, *respectively, and*

$$\begin{aligned}
&\|u^h_{\nu+1} - u^h_\nu\|_{\mathcal{U}^h} \le C(\|u^h_\nu - u^h_{\nu-1}\|_{\mathcal{U}^h})^2 \text{ and}\\
&\|u^h_i - P^h u_i\|_{\mathcal{U}^h} \le Ch^{p'}\|u_i\|_{\mathcal{U}_s}, \quad i = 1, \dots,\\
&\|F^h(u^h_i) - Q^h_\Pi F(u_i)\|_{\mathcal{V}} \le Ch^{p'}\|u_i\|_{\mathcal{U}_s}, \quad i = 1, \dots,\\
&\|(u^h_i - u^h_0) - (P^h(u_i - u_0))\|_{\mathcal{U}^h} \le Ch^{p'}\|u_i\|_{\mathcal{U}_s}, \quad i = 1, \dots.
\end{aligned} \tag{9.5}$$

Under these conditions there exists $\overline{h} = \overline{h}(\epsilon, u_0)$ *s.t. for all* $h \in (0, \overline{h}]$

$$\big|\min\{i \ge 1 : \|u^h_i - P^h u_0\|_{\mathcal{U}^h} < \epsilon\} - \min\{i \ge 1 : \|u_i - u_0\|_{\mathcal{U}} < \epsilon\}\big| \le 1. \tag{9.6}$$

This last result is the reason for the notation as MIP and our remark concerning the essential h independence of the convergence.

Proof. We have to show that the conditions in [4] are satisfied. By section 6, $P^h = I^h E_c \in \mathcal{L}(\mathcal{U}, \mathcal{U}^h)$, $Q^h_\Pi \in \mathcal{L}(\hat{\mathcal{V}}_\Pi = \hat{\mathcal{V}}'_\Pi,\ \mathcal{V}^{h'}_\Pi \ne \mathcal{V}^h_\Pi)$ are bounded and linear, and $F^h = Q^h_{c,\Pi} F|_{\mathcal{U}^h} : \mathcal{D}(F^h) = \mathcal{D}(F) \cap \mathcal{U}^h \to \mathcal{V}^{h'}_\Pi$. As a consequence of (9.4) and $\mathcal{U}^h$, we obtain the uniform Lipschitz continuity of our $(F^h)'$:

$$\|(F^h)'(u^h) - (F^h)'(v^h)\|_{\mathcal{V}^h_\Pi \leftarrow \mathcal{U}^h} = \|Q^h_{c,\Pi}(F'(u^h) - F'(v^h))\|_{\mathcal{V}^h_\Pi \leftarrow \mathcal{U}^h} \le CL\|u^h - v^h\|_{\mathcal{U}^h}$$

for all $u^h, v^h \in B_r(P^h u_0)$. As a consequence of $F'(\cdot) \in C_L(B_r(u_0))$ and the isolated solution u_0 of $F(u) = 0$ with boundedly invertible $F'(u_0)$ we obtain stability of $(F^h(u^h))'$, and hence $\|((F^h)'(u^h))^{-1}\|_{\mathcal{U}^h \leftarrow \mathcal{V}^h_\Pi} \le S$ for all $u^h \in B_{r/2}(P^h u_0)$ with a slightly reduced $r/2$; see Theorem 8.1. Finally we need the *consistent differentiability*

$$\begin{aligned}
&\forall u, v \in B_r(u_0) \cap \mathcal{U}_s : \quad \|Q^h_\Pi F(u) - Q^h_{c,\Pi} F(P^h u)\|_{\mathcal{V}^h_\Pi} \le Ch^{p'}\|u\|_{\mathcal{U}_s} \le c_0 h^{p'},\\
&\text{and } \|Q^h_\Pi F'(u)v - Q^h_{c,\Pi} F'(P^h u)P^h v\|_{\mathcal{V}^h_\Pi} \le Ch^{p'}(1 + \|u\|_{\mathcal{U}_s})\|v\|_{\mathcal{U}_s} \le c_1 h^{p'}\|v\|_{\mathcal{U}_s},
\end{aligned} \tag{9.7}$$

an immediate consequence of $F'(\cdot) \in C_L(B_r(u_0))$ and of (9.4).

For (9.6), the only missing conditions (see (3.25) in [4]) require the existence of a constant $\delta > 0$ s.t.

$$\liminf_{h>0} \|P^h u\|_{\mathcal{U}^h} \ge \delta\|u\|_{\mathcal{U}} \quad \forall u \in \mathcal{U}_s.$$

This is an immediate consequence of (4.11). ∎

Acknowledgments. I want to thank the two referees. They have very constructively helped to improve the original version of this paper. Prof. Wolfgang Hackbusch and Prof. Oleg Davydov helped with stimulating discussions. Davydov introduced me to his stable local bases for the $\mathcal{S}^1_d(\mathcal{T}^h_c)$ splines on polygonal domains. It was an exciting joint process extending his and my results as the necessary tools in his [27] for the formulation and proofs of my paper.

OPTIMAL CONVERGENCE OF THE ORIGINAL DG METHOD FOR THE TRANSPORT-REACTION EQUATION ON SPECIAL MESHES*

BERNARDO COCKBURN†, BO DONG†, AND JOHNNY GUZMÁN†

Abstract. We show that the approximation given by the original discontinuous Galerkin method for the transport-reaction equation in d space dimensions is optimal provided the meshes are suitably chosen: the L^2-norm of the error is of order $k+1$ when the method uses polynomials of degree k. These meshes are not necessarily conforming and do not satisfy any uniformity condition; they are required only to be made of simplexes, each of which has a unique *outflow* face. We also find a new, element-by-element postprocessing of the derivative in the direction of the flow which superconverges with order $k+1$.

Key words. discontinuous Galerkin methods, transport-reaction equation, error estimates

DOI. 10.1137/060677215

1. Introduction.

We show that the original discontinuous Galerkin (DG) [15, 13] method can approximate in an *optimal* fashion the solution of the convection-reaction problem

$$\boldsymbol{\beta}\cdot\nabla u + c\,u = f \quad \text{in } \Omega, \tag{1.1a}$$

$$u = g \quad \text{on } \Gamma^-. \tag{1.1b}$$

Here $\Omega \subset R^d$ is a polyhedral domain, $\Gamma^- := \{x \in \partial\Omega : \boldsymbol{\beta}\cdot\boldsymbol{n}(x) < 0\}$, and $\boldsymbol{n}(x)$ is the outward unit normal at the point $x \in \partial\Omega$. The functions f and g are smooth, $\boldsymbol{\beta}$ is a nonzero constant unit vector, and c is a bounded function. Indeed, if u_h denotes the approximation given by the DG method using polynomials of degree k, we prove that, for a *special* class of triangulations $\mathcal{T}_h$, we have

$$\|\,u-u_h\,\|_{L^2(\mathcal{T}_h)} + \|\,\mathsf{P}(\partial_{\boldsymbol{\beta}}u) - \partial_{\boldsymbol{\beta},h}u_h\,\|_{L^2(\mathcal{T}_h)} \le C\,|\,u\,|_{H^{k+1}(\mathcal{T}_h)}\,h^{k+1},$$

where $\partial_{\boldsymbol{\beta}} := \boldsymbol{\beta}\cdot\nabla$, P is the L^2-projection into the finite element space, and $\partial_{\boldsymbol{\beta},h}u_h$ is an approximation to $\partial_{\boldsymbol{\beta}}\,u$ obtained by using an element-by-element postprocessing of u_h. Note that the above approximation result is optimal for the quantity $\|\,u-u_h\,\|_{L^2(\mathcal{T}_h)}$ in the order of convergence in h as well as in the regularity of the exact solution; the estimate of the quantity $\|\,\mathsf{P}(\partial_{\boldsymbol{\beta}}u) - \partial_{\boldsymbol{\beta},h}u_h\,\|_{L^2(\mathcal{T}_h)}$ is clearly a superconvergence result. This has to be contrasted with the estimate for general triangulations

$$\|\,u-u_h\,\|_{L^2(\mathcal{T}_h)} + h^{1/2}\,\|\,\partial_{\boldsymbol{\beta}}u - \partial_{\boldsymbol{\beta}}u_h\,\|_{L^2(\mathcal{T}_h)} \le\ C\,|\,u\,|_{H^{k+1}(\mathcal{T}_h)}\,h^{k+1/2},$$

which follows from results obtained back in 1986 in [12].

†School of Mathematics, University of Minnesota, Vincent Hall, Minneapolis, MN 55455 (cockburn@math.umn.edu, bdong@dam.brown.edu, guzma033@umn.edu). The first author's research was supported in part by National Science Foundation grant DMS-0411254 and by the University of Minnesota Supercomputing Institute. The third author's research was supported by an NSF Mathematical Science Postdoctoral Research Fellowship (DMS-0503050).

The mechanisms that induce the loss of $h^{1/2}$ in the order of convergence of the L^2-norm of the error are not very well known yet. In 1988, it was shown [16] that, in the two-dimensional case, the estimate

$$\| u - u_h \|_{L^2(\mathcal{T}_h)} \leq C \, | u |_{H^{k+2}(\mathcal{T}_h)} \, h^{k+1}$$

holds for conforming triangulations obtained by using slabs of parallelograms divided into two triangles always in the same way. The triangles were chosen so that their sides are uniformly not aligned with the convection direction $\boldsymbol{\beta}$, that is, so that they satisfy what we could call the *transversality* condition

$$|\boldsymbol{\beta} \cdot \boldsymbol{n}_K| \geq \gamma > 0 \quad \text{on } \partial K \quad \text{for all } K \in \mathcal{T}_h, \tag{1.2}$$

where $\boldsymbol{n}_K$ is the outward unit normal of the simplex K and γ is a fixed constant. In 1991, the rate of convergence of $h^{k+1/2}$ for $\| u - u_h \|_{L^2(\mathcal{T}_h)}$ was shown to be sharp in [14]; a rigorous proof was given for the case $k = 0$, and convincing numerical evidence was shown for the case $k = 1$, also in the two-dimensional case. As the reader might expect, in those numerical experiments, triangulations violating the transversality condition played a central role which led the author to conjecture that this condition "*may be a natural condition under which to seek improved estimates.*" However, a consequence of our main result is that improved estimates can be obtained even if the transversality condition is not satisfied in *any* triangle. Indeed, our improved estimates hold for triangulations $\mathcal{T}_h$ made of simplexes K satisfying the following simple *flow* conditions with respect to $\boldsymbol{\beta}$:

(1.3a) Each simplex K has a unique *outflow* face with respect to $\boldsymbol{\beta}$, e_K^+.

(1.3b) Each interior face e_K^+ is included in an *inflow* face with respect to $\boldsymbol{\beta}$ of another simplex.

We say that the face e of the simplex K is an outflow (inflow) face with respect to $\boldsymbol{\beta}$ if $\boldsymbol{\beta} \cdot \boldsymbol{n}_K|_e > (<)\ 0$. We say that a face is interior if it is not included in $\partial\Omega$. Note that the second condition allows the triangulation to be nonconforming. In two dimensions, this means that hanging nodes in a simplex K are allowed provided they are *not* in its outflow edge; an example of such a triangulation is given in Figure 1.1. Note that this triangulation is not uniform or translation invariant. In the appendix, we show how to construct triangulations satisfying the flow conditions in any number of space dimensions.

As usual, the families of triangulations we consider also satisfy the classical assumption of shape regularity (see [6]); namely, there is a constant $\sigma > 0$ such that

$$\text{for each simplex } K \in \mathcal{T}_h : h_K / \rho_K \geq \sigma, \tag{1.4}$$

where h_K denotes the diameter of the simplex K and ρ_K the diameter of the biggest ball included in K.

The main idea behind the devising of these meshes, and the associated analysis giving rise to optimal error estimates, is a suitable adaptation to the convection-reaction equation under consideration of the projection $(\boldsymbol{\Pi}, \mathbb{P})$ recently introduced for the analysis of superconvergent DG methods for second-order elliptic problems in [7]. The first component of such projection, $\boldsymbol{\Pi}$, was previously used in the analysis of the so-called minimal-dissipation local discontinuous Galerikin method for convection-diffusion problems. Here, we use the second component, $\mathbb{P}$, to render the analysis

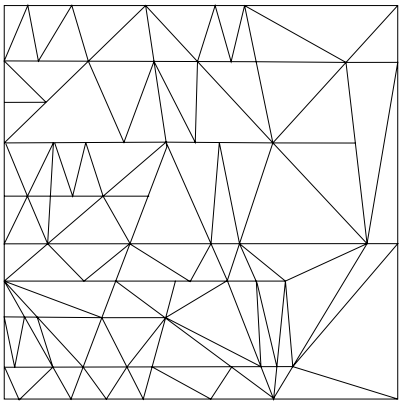

FIG. 1.1. *A triangulation satisfying the flow conditions with* $\boldsymbol{\beta} = (1, 0)$.

of error in u not only extremely simple and optimal but also capable of handling nonconforming meshes that are not uniform in any way.

Let us emphasize that the role of the special meshes for the construction of the approximation $\partial_{\boldsymbol{\beta},h} u_h$ to the directional derivative $\partial_{\boldsymbol{\beta}} u$ is *not* essential for two reasons. The first is that such an approximation can be defined on any mesh of simplexes. The second is that, for the general meshes considered in [12], we can still obtain the estimate

$$\| \mathsf{P}(\partial_{\boldsymbol{\beta}} u) - \partial_{\boldsymbol{\beta},h} u_h \|_{L^2(\mathcal{T}_h)} \leq C \, | \, u \, |_{H^{k+1}(\mathcal{T}_h)} \, h^{k+1/2},$$

which shows that even in this case, $\partial_{\boldsymbol{\beta},h} u_h$ is a better approximation than $\partial_{\boldsymbol{\beta}} u_h$. Postprocessings similar to the one giving rise to $\partial_{\boldsymbol{\beta},h} u_h$ have been used before in the context of flow through porous media [4], in the context of the Navier–Stokes equations [8], and in the context of linear elastic incompressible materials [9]. In all the above-mentioned references, they have been used to construct exactly divergence-free approximations to the velocity or exactly divergence-free stresses.

It is interesting to note that, when the triangulations $\mathcal{T}_h$ satisfy the flow conditions (1.3) with respect to $\boldsymbol{\beta}$ *and* with respect to $-\boldsymbol{\beta}$, the case in which the triangulation consists of tubes aligned with $\boldsymbol{\beta}$, we can obtain error estimates of the numerical trace $\widehat{u}_h$ in *each* outflow face e, namely,

$$\|\mathsf{P}_\partial u - \widehat{u}_h\|_{H^{-s}(e)} \leq \mathsf{C}(c, s) h^{k+s+1} | \, u \, |_{H^{k+1}(\Omega_e)}$$

for $s \in [0, k]$, where P_∂ is the L^2-projection into the space of polynomials of degree at most k on each face, Ω_e is a suitably chosen subset of $\mathcal{T}_h$, and $c \in W^{s,\infty}(\Omega_e)$. In particular, this implies that the average of $\widehat{u}_h$ on the face e converges to the average of u on that face with order $2\,k+1$. This is the only result of this type in the current available scientific literature, to the knowledge of the authors.

Finally, we extend our results in two directions. First, we consider approximations that are polynomials of different degrees on different elements. With the condition that the degrees of polynomials are nonincreasing in the direction of $\boldsymbol{\beta}$, we show that the estimates of approximations of u and $\partial_{\boldsymbol{\beta},h} u_h$ still hold. Then we consider the

singularly perturbed problem in $\Omega \subset \mathbb{R}^2$,

$$-\epsilon \Delta u + \boldsymbol{\beta} \cdot \nabla u + cu = f \quad \text{in } \Omega,$$

$$u = g \quad \text{on } \partial\Omega,$$

where $0 < \epsilon \ll 1$ is a constant, and we prove optimal *local* error estimates for $\epsilon \leq h^2$ on quasi-uniform meshes. We also show that internal numerical layers have width $\max(h, \epsilon^{1/2})$ on triangulations $\mathcal{T}_h$ that satisfy the flow conditions (1.3) with respect to both $\boldsymbol{\beta}$ and $-\boldsymbol{\beta}$. This improves the best known result of $h^{1/2}$; see [11]. A similar result for the streamline-diffusion method is contained in [17].

The paper is organized as follows. In section 2 we state and prove our main results. In section 3, we extend our results to variable-degree versions of the method; we show the results for the singularly perturbed problem. Our theoretical results are verified in section 4 by numerical experiments. We end in section 5 with some concluding remarks.

2. The main results.

2.1. The DG method. Suppose we have a family of triangulations $\{\mathcal{T}_h\}$ of Ω satisfying the flow conditions (1.3). To each triangulation $\mathcal{T}_h$, we associate the number $h = \sup_{K \in \mathcal{T}_h} h_K$, where $h_K = diam(K)$, and the finite-dimensional space V_h^k, which is composed of functions that are polynomials of degree at most k on each simplex $K \in \mathcal{T}_h$.

The DG approximation $u_h \in V_h^k$ of the solution of (1.1) satisfies

$$B(u_h, v_h) = (f, v_h)_{\mathcal{T}_h} - \langle g, v_h \, \boldsymbol{\beta} \cdot \boldsymbol{n} \rangle_{\Gamma^-} \quad \text{for all } v_h \in V_h^k, \tag{2.1a}$$

where

$$B(w, v) = -(w, \partial_{\boldsymbol{\beta}} v)_{\mathcal{T}_h} + \langle \widehat{w}, v \, \boldsymbol{\beta} \cdot \boldsymbol{n} \rangle_{\partial \mathcal{T}_h \setminus \Gamma^-} + (c\, w, v)_{\mathcal{T}_h} \tag{2.1b}$$

for any w, v in $H^1(\mathcal{T}_h)$. Note that we need only to define the numerical trace $\widehat{w}$ on faces that are not parallel to the direction $\boldsymbol{\beta}$ and do not belong to the inflow part of the boundary Γ^-. Therefore, the numerical trace of a function w on a simplex K for such faces e is given by

$$\widehat{w} := w^-, \tag{2.1c}$$

where $w^{\pm}(z) = \lim_{\delta \downarrow 0} w(z \pm \delta \boldsymbol{\beta})$, where $z \in e$. We are using the notation

$$(\boldsymbol{\sigma}, \boldsymbol{v})_{\mathcal{T}_h} := \sum_{K \in \mathcal{T}_h} \int_K \boldsymbol{\sigma}(x) \cdot \boldsymbol{v}(x)\, dx, \qquad (\zeta, \omega)_{\mathcal{T}_h} := \sum_{K \in \mathcal{T}_h} \int_K \zeta(x)\, \omega(x)\, dx,$$

$$\langle \zeta, \boldsymbol{v} \cdot \boldsymbol{n} \rangle_{\partial \mathcal{T}_h} := \sum_{K \in \mathcal{T}_h} \int_{\partial K} \zeta(\gamma)\, \boldsymbol{v}(\gamma) \cdot \boldsymbol{n}\, d\gamma$$

for any functions $\boldsymbol{\sigma}, \boldsymbol{v}$ in $\boldsymbol{H}^1(\mathcal{T}_h) := [H^1(\mathcal{T}_h)]^d$ and ζ, ω in $H^1(\mathcal{T}_h)$. The outward normal unit vector to ∂K is denoted by $\boldsymbol{n}$.

Notice that the exact solution u of (1.1) also satisfies the weak formulation (2.1), so we have the error equation

$$B(u - u_h, v_h) = 0 \qquad \text{for all } v_h \in V_h^k. \tag{2.2}$$

2.2. The approximation of u. To state our result on the approximation of u, we need to introduce a special projection, $\mathbb{P}$, defined on triangulations $\mathcal{T}_h$ satisfying the flow condition (1.3a). The function $\mathbb{P}u \in V_h^k$ restricted to $K \in \mathcal{T}_h$ is given by

$$(\mathbb{P}u - u, v)_K = 0 \qquad \text{for all } v \in \mathcal{P}^{k-1}(K), \tag{2.3a}$$

$$\langle \mathbb{P}u - u, w \rangle_{e_K^+} = 0 \qquad \text{for all } w \in \mathcal{P}^k(e_K^+), \tag{2.3b}$$

where $\mathcal{P}^\ell(D)$ stands for the space of polynomials of total degree at most ℓ defined on the set D.

The following lemma was proved in [7].

LEMMA 2.1. *If the triangulation $\mathcal{T}_h$ satisfies the flow condition* (1.3a)*, the projection $\mathbb{P}$ given by* (2.3) *is well defined. Moreover, if the triangulation $\mathcal{T}_h$ is shape-regular (see* (1.4)*), then, on each simplex $K \in \mathcal{T}_h$, we have*

$$\|\mathbb{P}u - u\|_{L^2(K)} \le Ch^{k+1} |\, u \,|_{H^{k+1}(K)}, \tag{2.4}$$

where C depends only on k and the shape regularity constant σ.

Now we can state our first error estimate.

THEOREM 2.2. *If $\mathcal{T}_h$ satisfies the flow conditions* (1.3) *and the shape-regularity condition* (1.4)*, then for $h^{1/2} \| c \|_{L^\infty(\Omega)}$ small enough, the error between u_h given by the discontinuous Galerkin method* (2.1) *and the exact solution u of the equations* (1.1) *is bounded as follows:*

$$\|\mathbb{P}u - u_h\|_{L^2(\mathcal{T}_h)} \le C \|c(u - \mathbb{P}u)\|_{L^2(\mathcal{T}_h)},$$

where C depends on $\| c \|_{L^\infty(\Omega)}$ and the diameter of Ω. In particular, if $c \equiv 0$, then

$$u_h = \mathbb{P}u.$$

Note that, after a straightforward application of the triangle inequality, we get

$$\|u - u_h\|_{L^2(\mathcal{T}_h)} \le \|u - \mathbb{P}u\|_{L^2(\mathcal{T}_h)} + C \|c(u - \mathbb{P}u)\|_{L^2(\mathcal{T}_h)},$$

and, if we assume the shape-regularity condition (1.4) on the triangulation $\mathcal{T}_h$, by the approximation property of the projection $\mathbb{P}$, (2.4), we obtain that

$$\| u - u_h \|_{L^2(\mathcal{T}_h)} \le C \, | \, u \, |_{H^{k+1}(\mathcal{T}_h)} \, h^{k+1}$$

whenever $u \in H^{k+1}(\mathcal{T}_h)$, as claimed in the introduction. Let us prove the above theorem.

Proof. Set $\mathbb{E} = u_h - \mathbb{P}u$. By the error equation (2.2), we have that for all $v \in V_h^k$,

$$B(\mathbb{E}, v) = B(u - \mathbb{P}u, v) = \sum_{i=1}^{3} T_i,$$

where, by definition of the bilinear form $B(\cdot, \cdot)$, (2.1b),

$$T_1 := - (u - \mathbb{P}u, \partial_{\boldsymbol{\beta}} v)_{\mathcal{T}_h},$$

$$T_2 := \langle u - \widehat{\mathbb{P}u}, v \, \boldsymbol{\beta} \cdot \boldsymbol{n} \rangle_{\partial \mathcal{T}_h \setminus \Gamma^-},$$

$$T_3 := (c \, (u - \mathbb{P}u), v)_{\mathcal{T}_h}.$$

Now, by the definition of the projection $\mathbb{P}$, (2.3a),

$$T_1 = 0.$$

Moreover,

$$\begin{aligned} T_2 =& \langle u - \widehat{\mathbb{P}u}, v\,\boldsymbol{\beta}\cdot\boldsymbol{n}\rangle_{\partial\mathcal{T}_h\setminus\Gamma^-} \\ =& \sum_{K\in\mathcal{T}_h} \langle u - \widehat{\mathbb{P}u}, v\,\boldsymbol{\beta}\cdot\boldsymbol{n}\rangle_{\partial K\setminus\Gamma^-} \\ =& \sum_{K\in\mathcal{T}_h} \langle u - \widehat{\mathbb{P}u}, (v^- - v^+)\,\boldsymbol{\beta}\cdot\boldsymbol{n}\rangle_{e_K^+} \\ =& \sum_{K\in\mathcal{T}_h} \langle u - \mathbb{P}u, (v^- - v^+)\,\boldsymbol{\beta}\cdot\boldsymbol{n}\rangle_{e_K^+} \end{aligned}$$

by the definition of the numerical trace $\widehat{\mathbb{P}\,u}$, (2.1c). But, since by the second flow condition (1.3b), $(v^- - v^+)|_{e_K^+} \in \mathcal{P}^k(e_K^+)$, we can conclude that

$$T_2 = 0,$$

by the definition of the projection $\mathbb{P}$, (2.3b). Therefore, we have that

$$B(\mathbb{E}, v) = (c(u - \mathbb{P}u), v)_{\mathcal{T}_h} \quad \text{for all } v \in V_h^k.$$

We claim that this implies

$$\|\mathbb{E}\|_{L^2(\mathcal{T}_h)} \le C\|c\,(u - \mathbb{P}u)\|_{L^2(\mathcal{T}_h)}$$

for $h^{1/2}\,\|\,c\,\|_{L^\infty(\Omega)}$ small enough. This claim is a straightforward consequence of the stability result Theorem 2.1 in [12], which implies that the DG approximation u_h defined by (2.1) satisfies the inequality

$$\|\,u_h\,\|_{L^2(\Omega)} \le C\left(\|\,f\,\|_{L^2(\Omega)} + \|\,\sqrt{|\boldsymbol{\beta}\cdot\boldsymbol{n}|}\,g\,\|_{L^2(\Gamma^-)}\right)$$

for $h^{1/2}\,\|\,c\,\|_{L^\infty(\Omega)}$ small enough. The claim follows by replacing u_h by $\mathbb{E}$, f by $c\,(u - \mathbb{P}u)$, and g by 0. Let us emphasize the fact that although this stability result was obtained for the two-dimensional case and conforming triangulations, it can be easily extended to multidimensional cases and nonconforming triangulations. This completes the proof. □

2.3. Postprocessing: The approximation to $\partial_{\boldsymbol{\beta}}\boldsymbol{u}$. Next we show how to postprocess u_h in order to get a superconvergent approximation of $\partial_{\boldsymbol{\beta}}u$. To this end, for each simplex K we define $\boldsymbol{q}_h \in \boldsymbol{\mathcal{P}}^k(K) + \boldsymbol{x}\,\mathcal{P}^k(K)$ to be the solution of

$$(\boldsymbol{q}_h - \boldsymbol{\beta}u_h, \boldsymbol{v})_K = 0 \qquad \text{for all } \boldsymbol{v} \in \boldsymbol{\mathcal{P}}^{k-1}(K), \tag{2.5a}$$

$$\langle(\boldsymbol{q}_h - \boldsymbol{\beta}\lambda_h)\cdot\boldsymbol{n}, w\rangle_e = 0 \qquad \text{for all } w \in \mathcal{P}^k(e), \text{ for all faces } e \text{ of } K, \tag{2.5b}$$

where $\lambda_h = \mathsf{P}_\partial g$ on Γ^- and $\lambda_h = \widehat{u}_h$ otherwise; here $\boldsymbol{\mathcal{P}}^k(K) := [\mathcal{P}^k(K)]^d$. The existence and uniqueness of $\boldsymbol{q}_h$ are well known; see, for example, [5]. We then define

$$\partial_{\boldsymbol{\beta},h} u_h := \nabla \cdot \boldsymbol{q}_h \qquad \text{in } \mathcal{T}_h.$$

We can now state the error estimate between $\partial_{\boldsymbol{\beta},h} u_h$ and $\partial_{\boldsymbol{\beta}} u$.

THEOREM 2.3. *If $\mathcal{T}_h$ is an* arbitrary *triangulation of Ω, then*

$$\|\partial_{\boldsymbol{\beta},h} u_h - \mathsf{P}(\partial_{\boldsymbol{\beta}} u)\|_{L^2(\mathcal{T}_h)} \le C \|c(u - u_h)\|_{L^2(\mathcal{T}_h)}.$$

In particular, if $c \equiv 0$, then

$$\partial_{\boldsymbol{\beta},h} u_h = \mathsf{P}(\partial_{\boldsymbol{\beta}} u).$$

Here P is the L^2-projection into V_h^k.

We can thus see that, if we use the estimates for arbitrary triangulations $\mathcal{T}_h$ obtained in [12], which assume the shape-regularity condition (1.4), we obtain

$$\| \mathsf{P}(\partial_{\boldsymbol{\beta}} u) - \partial_{\boldsymbol{\beta},h} u_h \|_{L^2(\mathcal{T}_h)} \le C \, | \, u \, |_{H^{k+1}(\mathcal{T}_h)} \, h^{k+1/2},$$

and if we assume that $\mathcal{T}_h$ satisfies the flow conditions (1.3), we obtain, by Theorem 2.2,

$$\| \mathsf{P}(\partial_{\boldsymbol{\beta}} u) - \partial_{\boldsymbol{\beta},h} u_h \|_{L^2(\mathcal{T}_h)} \le C \, | \, u \, |_{H^{k+1}(\mathcal{T}_h)} \, h^{k+1},$$

as claimed in the introduction. This implies that, if u is smooth enough, the quantity $\| \partial_{\boldsymbol{\beta}} u - \partial_{\boldsymbol{\beta},h} u_h \|_{L^2(\mathcal{T}_h)}$ is of order $h^{k+1/2}$ for arbitrary meshes and of order h^{k+1} for the special meshes under consideration.

Proof. For $v \in V_h^k$ we have

$$\begin{aligned}
(\partial_{\boldsymbol{\beta},h} u_h - \mathsf{P}(\partial_{\boldsymbol{\beta}} u), v)_{\mathcal{T}_h} &= (\nabla \cdot \boldsymbol{q}_h - \partial_{\boldsymbol{\beta}} u, v)_{\mathcal{T}_h} \\
&= -(\boldsymbol{q}_h, \nabla v)_{\mathcal{T}_h} + \langle \boldsymbol{q}_h \cdot \boldsymbol{n}, v \rangle_{\partial \mathcal{T}_h} - (\partial_{\boldsymbol{\beta}} u, v)_{\mathcal{T}_h} \\
&= -(\boldsymbol{q}_h, \nabla v)_{\mathcal{T}_h} + \langle \boldsymbol{q}_h \cdot \boldsymbol{n}, v \rangle_{\partial \mathcal{T}_h} - (f, v)_{\mathcal{T}_h} + (c\, u, v)_{\mathcal{T}_h},
\end{aligned}$$

by the definition of the exact solution u of (1.1a). By the definition of $\boldsymbol{q}_h$, (2.5),

$$\begin{aligned}
(\partial_{\boldsymbol{\beta},h} u_h - \mathsf{P}(\partial_{\boldsymbol{\beta}} u), v)_{\mathcal{T}_h} &= -(u_h, \partial_{\boldsymbol{\beta}} v)_{\mathcal{T}_h} + \langle \widehat{u}_h, v\, \boldsymbol{\beta} \cdot \boldsymbol{n} \rangle_{\mathcal{T}_h \setminus \Gamma^-} + \langle g, v \boldsymbol{\beta} \cdot \boldsymbol{n} \rangle_{\Gamma^-} \\
&\quad - (f, v)_{\mathcal{T}_h} + (c\, u, v)_{\mathcal{T}_h} \\
&= (c\,(u - u_h), v)_{\mathcal{T}_h},
\end{aligned}$$

by the definition of the approximate solution u_h, (2.1). The proof is complete once we take $v = \partial_{\boldsymbol{\beta},h} u_h - \mathsf{P}(\partial_{\boldsymbol{\beta}} u)$. ∎

2.4. The approximation of the numerical trace $\widehat{u}_h$ on outflow faces. To state the approximation result, let us introduce some notation. We are going to use the negative-order norm

$$\| \gamma \|_{H^{-s}(e)} := \sup_{\varphi \in \mathcal{C}^\infty(e)} \frac{\langle \gamma, \varphi \rangle_e}{\| \varphi \|_{H^s(e)}}, \tag{2.6}$$

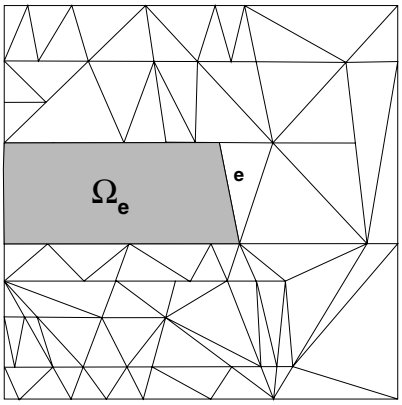

FIG. 2.1. *An example of the set* Ω_e *for* $\boldsymbol{\beta} = (1, 0)$.

where e is the outflow face of the simplex $K \in \mathcal{T}_h$. To this face, we associate the subset of $\mathcal{T}_h$ defined by

$$\Omega_e := \{K' \in \mathcal{T}_h : \text{for all } x \in K', x + \boldsymbol{\beta} t \text{ lies on } e \text{ for some } t \geq 0\}.$$

An example is displayed in Figure 2.1.

THEOREM 2.4. *Let* $\mathcal{T}_h$ *be a triangulation of* Ω *satisfying the shape-regularity condition* (1.4) *and the flow conditions* (1.3)*, with respect to* $\boldsymbol{\beta}$ *and* $-\boldsymbol{\beta}$*. Then on any outflow face* e

$$\|\mathsf{P}_\partial u - \widehat{u}_h\|_{H^{-s}(e)} \leq \mathsf{C}(c, s)\, h^{k+s+1} |\, u \,|_{H^{k+1}(\Omega_e)}$$

for $s \in [0, k]$*, where* $\mathsf{C}(c, s) := C(\|c\|_{W^{\max\{s,0\},\infty}(\Omega_e)}, \Omega_e)\, \|c\|^2_{L^\infty(\Omega_e)} / |\, \boldsymbol{\beta} \cdot \boldsymbol{n}_e \,|$*. In particular, if* $c \equiv 0$*, then*

$$\mathsf{P}_\partial u = \widehat{u}_h.$$

Note that if the triangulation $\mathcal{T}_h$ satisfies the flow conditions (1.3) with respect to $\boldsymbol{\beta}$ and $-\boldsymbol{\beta}$, then each of its simplexes K has exactly one outflow face e_K^+ and one inflow face e_K^-. Moreover, the outflow face e_K^+ lies on $\partial\Omega \setminus \Gamma^-$ or coincides with an inflow face, and e_K^- lies on Γ^- or coincides with an outflow face.

This result implies, in particular, that the average of the numerical trace $\widehat{u}_h$ on each outflow face e converges to the average of the exact solution u on that face with order $2k + 1$ for general c and with order $2k + 2$ in the case $c = 0$. To see this, let us begin by noting that if $\Upsilon \in H^{k+1}(e)$, we have that

$$\begin{aligned}\langle \widehat{u}_h - u, \Upsilon \rangle_e &= \langle \widehat{u}_h - \mathsf{P}_\partial u, \Upsilon \rangle_e + \langle \mathsf{P}_\partial u - u, \Upsilon \rangle_e \\ &= \langle \widehat{u}_h - \mathsf{P}_\partial u, \Upsilon \rangle_e + \langle \mathsf{P}_\partial u - u, \Upsilon - \mathsf{P}_\partial \Upsilon \rangle_e,\end{aligned}$$

and so

$$\begin{aligned}|\,\langle \widehat{u}_h - u, \Upsilon\rangle_e\,| &\le \|\,\widehat{u}_h - \mathsf{P}_\partial u\,\|_{H^{-k}(e)}\,\|\,\Upsilon\,\|_{H^k(e)}\\ &\quad + \|\,\mathsf{P}_\partial u - u\,\|_{L^2(e)}\,\|\,\Upsilon - \mathsf{P}_\partial\Upsilon\,\|_{L^2(e)}\\ &\le C\,h^{2\,k+1},\end{aligned}$$

where

$$C = \mathsf{C}(c,s)\,|\,u\,|_{H^k(\Omega_e)}\,\|\,\Upsilon\,\|_{H^{k+1}(e)} + C\,h\,|\,u\,|_{H^{k+1}(e)}\,|\,\Upsilon\,|_{H^{k+1}(e)}.$$

The claim follows by simply taking $\Upsilon = 1$.

Let us emphasize that the order of convergence of the approximation of linear functionals of the form $\langle u\,,\,\Upsilon\rangle_{\partial\Omega\setminus\Gamma^-}$ can be proven to be of order $2\,k+1$; see [1] for the case $c=0$ and $\Upsilon = 1$. This result holds for functions Υ that are independent of the mesh; as a consequence, Υ cannot be taken to have support in a single element face. To the knowledge of the authors, Theorem 2.4 is the only result that allows this.

Next, we give a proof of the result. To do that, we need to introduce some notation. We begin by introducing the so-called corresponding dual problem, namely,

$$-\boldsymbol{\beta}\cdot\nabla\psi + c\,\psi = 0 \qquad \text{in } \Omega_e, \tag{2.7a}$$

$$\psi = \varphi/\boldsymbol{\beta}\cdot\boldsymbol{n} \qquad \text{on } e. \tag{2.7b}$$

We are also going to use two auxiliary projections. We set $\mathbb{P}^+ := \mathbb{P}$, which is defined in (2.3), and we let $\mathbb{P}^-$ be the projection which satisfies (2.3a) and imposes (2.3b) on e_K^- instead of e_K^+.

We are now ready to prove Theorem 2.4.

Proof. To prove this result, we begin by noting that

$$\langle \mathsf{P}_\partial u - \widehat{u}_h, \varphi\rangle_e = \langle \mathsf{P}_\partial u - \widehat{u}_h, \psi\boldsymbol{\beta}\cdot\boldsymbol{n}\rangle_e,$$

by the boundary condition of the dual problem, (2.7b), and that

$$\langle \mathsf{P}_\partial u - \widehat{u}_h, \varphi\rangle_e = \langle \mathsf{P}_\partial u - \widehat{u}_h, \psi\boldsymbol{\beta}\cdot\boldsymbol{n}\rangle_{\partial\Omega_e\setminus\Gamma^-},$$

by our assumptions on the triangulation $\mathcal{T}_h$. Then

$$\begin{aligned}\langle \mathsf{P}_\partial u - \widehat{u}_h, \varphi\rangle_e &= \langle \mathsf{P}_\partial u - \widehat{u}_h, (\psi - \mathbb{P}^-\psi)\,\boldsymbol{\beta}\cdot\boldsymbol{n}\rangle_{\partial\Omega_e\setminus\Gamma^-}\\ &\quad + \langle \mathsf{P}_\partial u - \widehat{u}_h, \mathbb{P}^-\psi\,\boldsymbol{\beta}\cdot\boldsymbol{n}\rangle_{\partial\Omega_e\setminus\Gamma^-}.\end{aligned}$$

Since we can rewrite the error equation (2.2) in terms of the projections $\mathbb{P}^+$ and P_∂ as

$$-(\mathbb{P}^+u - u_h, \partial_{\boldsymbol{\beta}} v)_{\Omega_e} + \langle \mathsf{P}_\partial u - \widehat{u}_h, v\,\boldsymbol{\beta}\cdot\boldsymbol{n}\rangle_{\partial\Omega_e\setminus\Gamma^-} + (c\,(u-u_h), v)_{\Omega_e} = 0,$$

taking $v := \mathbb{P}^- \psi$, we get that

$$\begin{aligned}
\langle \mathsf{P}_\partial u - \widehat{u}_h, \varphi \rangle_e = \; & \langle \mathsf{P}_\partial u - \widehat{u}_h, (\psi - \mathbb{P}^- \psi)\, \boldsymbol{\beta} \cdot \boldsymbol{n} \rangle_{\partial \Omega_e \setminus \Gamma^-} \\
& + (\mathbb{P}^+ u - u_h, \partial_{\boldsymbol{\beta}} \mathbb{P}^- \psi)_{\Omega_e} \\
& - (c\,(u - u_h), \mathbb{P}^- \psi)_{\Omega_e} \\
= \; & \langle \mathsf{P}_\partial u - \widehat{u}_h, (\psi - \mathbb{P}^- \psi)\, \boldsymbol{\beta} \cdot \boldsymbol{n} \rangle_{\partial \Omega_e \setminus \Gamma^-} \\
& + (\mathbb{P}^+ u - u_h, \partial_{\boldsymbol{\beta}} \mathbb{P}^- \psi)_{\Omega_e} \\
& - (c\,(\mathbb{P}^+ u - u_h), \mathbb{P}^- \psi)_{\Omega_e} \\
& - (c\,(u - \mathbb{P}^+ u), \mathbb{P}^- \psi)_{\Omega_e}.
\end{aligned}$$

Hence, by the dual equation (2.7a), we can write

$$\langle \mathsf{P}_\partial u - \widehat{u}_h, \varphi \rangle_e = \sum_{i=1}^{4} T_i,$$

where

$$\begin{aligned}
T_1 := \; & \langle \mathsf{P}_\partial u - \widehat{u}_h, (\psi - \mathbb{P}^- \psi)\, \boldsymbol{\beta} \cdot \boldsymbol{n} \rangle_{\partial \Omega_e \setminus \Gamma^-}, \\
T_2 := \; & (\mathbb{P}^+ u - u_h, \partial_{\boldsymbol{\beta}} (\mathbb{P}^- \psi - \psi))_{\Omega_e}, \\
T_3 := \; & - (c\,(\mathbb{P}^+ u - u_h), \mathbb{P}^- \psi - \psi)_{\Omega_e}, \\
T_4 := \; & - (c\,(u - \mathbb{P}^+ u), \mathbb{P}^- \psi)_{\Omega_e}.
\end{aligned}$$

Let us estimate the terms $T_i, i = 1, 2, 3, 4$. We begin by showing that $T_1 + T_2 = 0$. After a simple integration by parts, we get that

$$\begin{aligned}
T_2 = & - \langle \mathbb{P}^+ u - u_h, (\psi - \mathbb{P}^- \psi)\, \boldsymbol{\beta} \cdot \boldsymbol{n} \rangle_{\partial \Omega_e} + (\partial_{\boldsymbol{\beta}} (\mathbb{P}^+ u - u_h), \psi - \mathbb{P}^- \psi)_{\Omega_e} \\
= & - \langle \mathbb{P}^+ u - u_h, (\psi - \mathbb{P}^- \psi)\, \boldsymbol{\beta} \cdot \boldsymbol{n} \rangle_{\partial \Omega_e}
\end{aligned}$$

by the orthogonality property of the projection $\mathbb{P}^-$, (2.3a). Hence,

$$\begin{aligned}
T_1 + T_2 = & \langle \mathsf{P}_\partial u - \widehat{u}_h, (\psi - \mathbb{P}^- \psi)\, \boldsymbol{\beta} \cdot \boldsymbol{n} \rangle_{\partial \Omega_e \setminus \Gamma^-} - \langle \mathbb{P}^+ u - u_h, (\psi - \mathbb{P}^- \psi)\, \boldsymbol{\beta} \cdot \boldsymbol{n} \rangle_{\partial \Omega_e} \\
= & \; 0
\end{aligned}$$

since, by the definition of $\mathbb{P}^+$ and $\widehat{u}_h$, we have that $\mathsf{P}_\partial u = \mathbb{P}^+ u$ and $\widehat{u}_h = u_h$ on any outflow face, and since, by the definition of $\mathbb{P}^-$, we have that

$$\langle \omega, (\psi - \mathbb{P}^- \psi)\, \boldsymbol{\beta} \cdot \boldsymbol{n} \rangle_{\tilde{e}} = 0 \quad \text{for all } \omega \in \mathcal{P}^k(\tilde{e})$$

on any inflow face $\tilde{e}$.

It remains to estimate T_3 and T_4. To do this, we are going to use the following stability estimate for the solution ψ of the dual problem (2.7):

$$|\psi|_{H^s(\Omega_e)} \le C\|\varphi\|_{H^s(e)}/\boldsymbol{\beta}\cdot\boldsymbol{n}, \tag{2.8}$$

where $C = C(\|c\|_{W^{\max\{s,0\},\infty}(\Omega_e)}, \Omega_e)$. It follows from the expression

$$\psi(x) = \varphi(x_0)e^{-\int_0^t c(x_0-\tau\boldsymbol{\beta}))d\tau}/\boldsymbol{\beta}\cdot\boldsymbol{n},$$

where $x = x_0 - \boldsymbol{\beta}\, t \in \Omega_e$ for some $t \ge 0$ and $x_0 \in e$, by successive differentiation.

The estimate of T_3 follows after a straightforward application of the Cauchy–Schwarz inequality, the estimate of Theorem 2.2, the approximation property of the projection $\mathbb{P}^-$, (2.4), and the stability estimate (2.8). Indeed, we easily get that

$$T_3 \le \mathsf{C}(c,s)\, h^{k+s+1}|\, u\,|_{H^{k+1}(\Omega_e)}\|\varphi\|_{H^s(e)}$$

for $s \in [0, k+1]$. Let us estimate T_4. If we denote by P^{k-1} the L^2-projection onto V_h^{k-1}, we have that

$$\begin{aligned} T_4 &= (c\,(u-\mathbb{P}^+u), \psi - \mathbb{P}^-\psi)_{\Omega_e} - (u-\mathbb{P}^+u, c\psi)_{\Omega_e} \\ &= (c\,(u-\mathbb{P}^+u), \psi - \mathbb{P}^-\psi)_{\Omega_e} - (u-\mathbb{P}^+u, c\psi - \mathsf{P}^{k-1}c\psi)_{\Omega_e}, \end{aligned}$$

by the orthogonality property of the projection $\mathbb{P}^+$, (2.3a). Then we get

$$T_4 \le\ \mathsf{C}(c,s)\, h^{k+s+1}\|\varphi\|_{H^s(e)}|\, u\,|_{H^{k+1}(\Omega_e)}$$

for $s \in [0,k]$, by the approximation properties of the projections $\mathbb{P}^+$, $\mathbb{P}^-$, and P^{k-1} and the stability estimate (2.8). This completes the proof. ∎

3. Extensions.

3.1. The variable-degree DG method. The variable-degree DG approximation u_h belongs to the finite dimensional space $V_h^{\boldsymbol{k}}$ which is given by

$$V_h^{\boldsymbol{k}} = \{v \in L^2(\Omega), v|_K \in \mathcal{P}^{k(K)}(K) \quad \text{for all } K \in \mathcal{T}_h\},$$

where $\boldsymbol{k} = \{k(K) \text{ for all } K \in \mathcal{T}_h\}$.

The definition of $\mathbb{P}$ can easily be generalized for the variable-degree space. We define $\mathbb{P}u \in V_h^{\boldsymbol{k}}$ using the definition of the previous section but with the space $\mathcal{P}^{k-1}(K)$ replaced with $\mathcal{P}^{k(K)-1}(K)$ and the space $\mathcal{P}^k(e_K^+)$ replaced with $\mathcal{P}^{k(K)}(e_K^+)$.

We need to impose a condition on the space $V_h^{\boldsymbol{k}}$:

$$k(K) \ge k(K') \text{ whenever } e_K^+ \subseteq e_{K'}^-. \tag{3.1}$$

The following result can be proven in the same way as Theorem 2.2.

THEOREM 3.1. *Let $u_h \in V_h^{\boldsymbol{k}}$ be the variable degree DG approximation given by* (2.1) *with V_h^k replaced with $V_h^{\boldsymbol{k}}$. If $\mathcal{T}_h$ satisfies the flow conditions* (1.3) *with respect to β and the shape-regularity condition* (1.4)*, and $V_h^{\boldsymbol{k}}$ satisfies the condition of the polynomial degrees* (3.1)*, then the results of Theorem* 2.2 *hold for the variable-degree DG method.*

3.2. Singularly perturbed problem. We present local error estimates of a DG method for the following singular perturbed problem in $\Omega \subset \mathbb{R}^2$:

$$-\epsilon \triangle u + \boldsymbol{\beta} \cdot \nabla u + c\, u = f \quad \text{in } \Omega, \tag{3.2a}$$

$$u = g \quad \text{on } \partial\Omega. \tag{3.2b}$$

We use the interior penalty method to discretize the viscosity term $-\epsilon\triangle u$; see [2] and [10]. Any other DG method which is consistent and stable could be used to discretize this term; see [3].

Thus, the DG approximation $u_h \in V_h^k$, where $k \geq 1$, of (3.2) solves

$$\epsilon A(u_h, v_h) + B(u_h, v_h) = F(v_h) \quad \text{for all } v_h \in V_h^k, \tag{3.3}$$

where

$$A(\omega, v) = (\nabla\omega, \nabla v)_{\mathcal{T}_h} - \sum_{e\in\mathcal{E}_h} \Big(\langle \{\!\{\nabla\omega\}\!\}, [\![v]\!] \rangle_e + \langle \{\!\{\nabla v\}\!\}, [\![\omega]\!] \rangle_e - \frac{\eta}{h} \langle [\![\omega]\!], [\![v]\!] \rangle_e \Big),$$

$$F(v) = (f, v)_{\mathcal{T}_h} + \langle g, v\boldsymbol{\beta}\cdot\boldsymbol{n}\rangle_{\partial\Omega} + \epsilon \langle \nabla v \cdot \boldsymbol{n}, g\rangle_{\partial\Omega} - \epsilon \frac{\eta}{h} \langle g, v\rangle_{\partial\Omega}.$$

The set $\mathcal{E}_h$ is the collection of edges of the triangulation $\mathcal{T}_h$. The parameter η is large enough in order to ensure stability.

The average $\{\!\{\cdot\}\!\}$ and jump $[\![\cdot]\!]$ operators are defined as follows: For an interior edge e, we set

$$\{\!\{\boldsymbol{q}\}\!\} = \frac{1}{2}(\boldsymbol{q}_1 + \boldsymbol{q}_2), \qquad [\![\boldsymbol{q}]\!] = \boldsymbol{q}_1 \cdot \boldsymbol{n}_1 + \boldsymbol{q}_2 \cdot \boldsymbol{n}_2,$$

$$\{\!\{\varphi\}\!\} = \frac{1}{2}(\varphi_1 + \varphi_2), \qquad [\![\varphi]\!] = \varphi_1\boldsymbol{n}_1 + \varphi_2\boldsymbol{n}_2,$$

where $e = K_1 \cap K_2$, $\boldsymbol{q}_i = \boldsymbol{q}|_{K_i}$, $\varphi_i = \varphi|_{K_i}$, and $\boldsymbol{n}_i$ is the exterior unit normal to K_i, $i = 1, 2$. For a boundary edge e, we set

$$\{\!\{\boldsymbol{q}\}\!\} = \boldsymbol{q}, \quad [\![\varphi]\!] = \varphi\boldsymbol{n},$$

where $\boldsymbol{n}$ is the outward unit normal. The quantities $[\![\boldsymbol{q}]\!]$ and $\{\!\{\varphi\}\!\}$ on boundary edges are not required, so they are left undefined.

In order to state the result, we need to introduce a proper weight function. For simplicity we assume $\boldsymbol{\beta} = (1, 0)$. Accordingly, we set, for fixed x_0, y_1, and y_2,

$$\Omega_0 = \big((-\infty, x_0] \times [y_1, y_2]\big) \cap \Omega,$$

and construct a function ω satisfying

$$C_1 \leq \omega(x, y) \leq C_2 \qquad \text{for } (x, y) \in \Omega_0,$$

$$|\omega(x, y)| \leq C_2 e^{-(x-x_0)/M\rho} \qquad \text{for } x \geq x_0 + h,$$

$$|\omega(x, y)| \leq C_2 e^{-(y-y_2)/M\sigma} \qquad \text{for } y \geq y_2 + h,$$

$$|\omega(x, y)| \leq C_2 e^{-(y_1-y)/M\sigma} \qquad \text{for } y \leq y_1 - h.$$

Here $\rho \geq 0$, $\sigma \geq 0$ are parameters that will depend on the mesh size h and ϵ. We say that ρ is the size of the upwind layer and σ is the size of the crosswind layer. The positive constants C_1, C_2, and M are fixed.

THEOREM 3.2. *Assume that $\epsilon \leq h$ and that the triangulation $\mathcal{T}_h$ is quasi-uniform; that is, assume that there is a parameter $\kappa > 0$ such that*

$$\max_{K\in\mathcal{T}_h}\{h_K\} \leq \kappa \min_{K\in\mathcal{T}_h}\{h_K\}.$$

If $\mathcal{T}_h$ satisfies the flow conditions (1.3) *with respect to $\boldsymbol{\beta}$. Then the error between u_h given by* (3.3) *and u given by* (3.2) *is*

$$\|\omega(u-u_h)\|_{L^2(\mathcal{T}_h)} \leq C\bigg(\left(1+\frac{\epsilon^{1/2}}{h}\right)\|\omega(u-\mathbb{P}u)\|_{L^2(\mathcal{T}_h)} + \epsilon^{1/2}\|\omega\nabla(u-\mathbb{P}u)\|_{L^2(\mathcal{T}_h)}$$

$$+ h\epsilon^{1/2}\|\omega D^2(u-\mathbb{P}u)\|_{L^2(\mathcal{T}_h)}\bigg),$$

where ω is given above with $\rho = \log(\frac{1}{h})h$, $\sigma = h^{1/2}$, and M is a sufficiently large fixed constant. Moreover, if $\mathcal{T}_h$ also satisfies the flow conditions (1.3) *with respect to $-\boldsymbol{\beta}$, then we can choose $\sigma = \max(\epsilon^{1/2}, h)$.*

From this result, we immediately get optimal weighted error estimates if $\epsilon \leq h^2$. The size of the crosswind layer σ is typically $\sigma = h^{1/2}$ for general triangulations; see [11]. However, we see that the size of the crosswind layer is reduced to $\sigma = h$ if the flow conditions (1.3) for both $\boldsymbol{\beta}$ and $-\boldsymbol{\beta}$ are satisfied. This is exactly the result that was obtained for the streamline-diffusion method in [17]. However, in [17] the following almost-uniform condition on the mesh was imposed: two adjacent elements K and K' that share an edge that is not aligned with $\boldsymbol{\beta}$ must satisfy

$$|h_{\boldsymbol{\beta},K} - h_{\boldsymbol{\beta},K'}| \leq Ch_{\boldsymbol{\beta}}^2,$$

where $h_{\boldsymbol{\beta},K}$ is the length of the edge of K that is parallel to $\boldsymbol{\beta}$ and $h_{\boldsymbol{\beta}} = \max_K h_{\boldsymbol{\beta},K}$; see the inequality (3.8) in [17]. In contrast, in our results, we assume only quasi uniformity. Moreover, our results also hold for high-order elements.

The proof of Theorem 3.2 is very similar to the proof of the local estimates given in [11]. However, instead of using the L^2-projection, one must use the projections $\mathbb{P} = \mathbb{P}^+$ and $\mathbb{P}^-$ used in this paper.

4. Numerical results. In this section we present numerical experiments which validate our theoretical results. The domain is $\Omega = (-.5, .5) \times (-.5, .5)$. The coefficients are $\boldsymbol{\beta} \equiv (1, 0)$ and $c \equiv 1$. We choose the right-hand side f so that the solution is $u(x, y) = (x + 1/2)\sin(x)\sin(y)$.

We start with a uniform mesh of size h which satisfies the flow condition with respect to $\boldsymbol{\beta}$; see Figure 4.1, left. We then perturb the coordinates of the interior nodes randomly by at most $\frac{2h}{5}$ in such a way that the resulting mesh is *no longer uniform but still satisfies the flow condition with respect to $\boldsymbol{\beta}$*; see Figure 4.1, right. A mesh ℓ is a perturbation of a uniform mesh of size $h = \frac{1}{2^\ell}$.

In Table 4.1 we display the error and orders of convergence for approximate solutions using polynomials of degree $k = 0, 1, 2$. We see that order $k + 1$ is observed for $\|u - u_h\|_{L^2(\Omega)}$ and $\|\partial_{\boldsymbol{\beta}}u - \partial_{\boldsymbol{\beta},h}u_h\|_{L^2(\Omega)}$ as the theory predicts. Moreover, we see that $\max_{e\in\mathcal{E}_h} |\text{avg}_e(u - \widehat{u}_h)|$ converges with order $2k + 1$ as expected.

FIG. 4.1. *Meshes satisfying the flow condition with respect to* $\boldsymbol{\beta} = (1, 0)$*: Uniform mesh* ($h = \frac{1}{2^3}$) *(left) and its nonuniform perturbation* ($\ell = 3$) *(right).*

5. Concluding remarks. This paper contains the first instance in which the approximation error $\| u - u_h \|_{L^2(\mathcal{T}_h)}$, where u is the solution of the transport-reaction equation and u_h is given by the original DG method, is proven to be optimal in the mesh size h *and* in the regularity of the exact solution. Unexpectedly, this happens with meshes whose main feature is to be, roughly speaking, *aligned* with the flow.

The fact that the direction of the flow $\boldsymbol{\beta}$ is a constant and the use of simplexes to define the triangulations $\mathcal{T}_h$ seem to play a major role in the result. The case of variable $\boldsymbol{\beta}$ and simplexes with curved boundaries is the subject of ongoing research.

Appendix. The construction of triangulations satisfying the flow conditions. Let us show that it is always possible to construct a triangulation of the domain $\Omega \subset \mathbb{R}^d$ satisfying the flow conditions (1.3).

We can do this as follows. First, we triangulate the inflow border of Ω, Γ^-, by using $(d-1)$-dimensional simplexes T; let $\Gamma_h^- := \{T\}$ be such a triangulation. Next, for each T, we construct the d-dimensional *prism*

$$\mathcal{T}_T := (T \oplus \{\lambda\, \boldsymbol{\beta} : \lambda \in \mathbb{R}\}) \cap \Omega,$$

which we are going to triangulate by using conforming d-dimensional simplexes. Note that the triangulations of the prisms are completely independent of each other since no conformity between them is required thanks to the flow conditions (1.3).

To triangulate the prism $\mathcal{T}_T$, we have only to show that, if T and T' are two $(d-1)$-dimensional simplexes whose vertices are on the border of $\mathcal{T}_T$, we can triangulate the convex hull of T and T', $CH(T, T')$, by using exactly d d-dimensional simplexes, each of which has one inflow face and one outflow face. Those simplexes are $CH(T_{i-1}, T_i)$, $i = 1, \ldots, d$, where the $(d-1)$-dimensional simplexes T_i, $i = 0, \ldots, d$, are constructed in such a way that $T_0 := T$, $T_d := T'$, and, assuming that T is an inflow face, that T_{i-1} is the only inflow face of the simplex $CH(T_{i-1}, T_i)$ and T_i is the only outflow face of the simplex $CH(T_{i-1}, T_i)$.

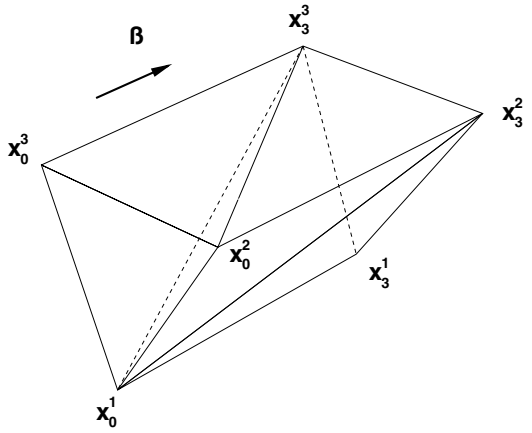

FIG. A.1. *Detail of the construction of a three-dimensional triangulation satisfying the flow conditions.*

If we identify the $(d-1)$-dimensional simplex T_i with its set of vertices, $\{\boldsymbol{x}_i^j\}_{j=1}^d$,

it is not difficult to see that we can take

$$T_0 \equiv \{\boldsymbol{x}_0^1, \boldsymbol{x}_0^2, \ldots, \boldsymbol{x}_0^{d-2}, \boldsymbol{x}_0^{d-1}, \boldsymbol{x}_0^d\},$$

$$T_1 \equiv \{\boldsymbol{x}_0^1, \boldsymbol{x}_0^2, \ldots, \boldsymbol{x}_0^{d-2}, \boldsymbol{x}_0^{d-1}, \boldsymbol{x}_d^d\},$$

$$T_2 \equiv \{\boldsymbol{x}_0^1, \boldsymbol{x}_0^2, \ldots, \boldsymbol{x}_0^{d-2}, \boldsymbol{x}_d^{d-1}, \boldsymbol{x}_d^d\},$$

$$T_3 \equiv \{\boldsymbol{x}_0^1, \boldsymbol{x}_0^2, \ldots, \boldsymbol{x}_d^{d-2}, \boldsymbol{x}_d^{d-1}, \boldsymbol{x}_d^d\},$$

$$\ldots$$

$$T_d \equiv \{\boldsymbol{x}_d^1, \boldsymbol{x}_d^2, \ldots, \boldsymbol{x}_d^{d-2}, \boldsymbol{x}_d^{d-1}, \boldsymbol{x}_d^d\},$$

respectively. An example of this construction is illustrated in Figure A.1.

IMPLICIT RUNGE–KUTTA METHODS FOR LIPSCHITZ CONTINUOUS ORDINARY DIFFERENTIAL EQUATIONS*

XIAOJUN CHEN† AND SAYED MAHMOUD‡

Abstract. Implicit Runge–Kutta (IRK) methods for solving the nonsmooth ordinary differential equation (ODE) involve a system of nonsmooth equations. We show superlinear convergence of the slanting Newton method for solving the system of nonsmooth equations. We prove the slanting differentiability and give a slanting function for the involved function. We develop a new code based on the slanting Newton method and the IRK method for nonsmooth ODEs arising from structural oscillation and pounding. We show that the new code is efficient for solving a nonsmooth ODE model for the collapse of the Tacoma Narrows suspension bridge and simulating 13 different earthquakes.

Key words. implicit Runge–Kutta method, slanting Newton method, nonsmooth equations, ordinary differential equation

DOI. 10.1137/070688699

1. Introduction.

Let $D \subset R^n$ be a domain, $p : D \to R^n$ be a continuously differentiable function, and $f : D \to R^n$ be a continuous function. The function f is not necessarily differentiable.

We consider the following system of nonsmooth ordinary differential equations of the first order:

$$\begin{aligned} &\frac{dp(u)}{dt} = f(u), \qquad t \geq 0, \\ &u(0) = u_0, \end{aligned} \tag{1.1}$$

where $u \in R^n$. Here smoothness refers to continuous differentiability. It is known that if f is Lipschitz continuous, then (1.1) has a unique solution in a certain interval $[0, T]$ [9]. Moreover, it is shown in [2] that f is Lipschitz continuous if and only if f is slantly differentiable. A slanting Newton method can be defined in appropriate function spaces. The concept of slanting differentiability of f means that f has a slanting function f^o such that

$$f(u + \triangle u) - f(u) - f^o(u + \triangle u)\triangle u = o(\|\triangle u\|).$$

This property ensures that the slanting Newton method

$$u^{k+1} = u^k - f^o(u^k)^{-1} f(u^k)$$

has a superlinear convergence rate [2].

Note that, though the function f is nonsmooth, the solution of (1.1) may be smooth (continuously differentiable). See the example of the collapse of the Tacoma

Narrows suspension bridge in section 4. In this paper, we consider numerical solution of the nonsmooth ODEs (1.1).

One step of an s-stage implicit Runge–Kutta (IRK) method for solving (1.1) has the following version [8].

IRK method. Given a step size h, a coefficient matrix $A \in R^{s\times s}$, and a weight vector $b \in R^s$, let $U_0 = u_0$. For $k \geq 0$ do the following.

Step 1. Solve the $s \times n$-dimensional system of nonlinear equations

$$H(x) := \begin{pmatrix} p(x_1) - p(U_k) - h\sum_{j=1}^{s} a_{1j} f(x_j) \\ \vdots \\ p(x_s) - p(U_k) - h\sum_{j=1}^{s} a_{sj} f(x_j) \end{pmatrix} = 0 \tag{1.2}$$

to get a solution $x^k = (x_1^k, x_2^k, \ldots, x_s^k)^T \in R^{s\times n}$.

Step 2. Solve the n-dimensional system of nonlinear equations

$$\tilde{H}(U) := p(U) - p(U_k) - h\sum_{j=1}^{s} b_j f(x_j^k) = 0, \tag{1.3}$$

and let the solution be U_{k+1}.

A practical IRK method can be defined, by choosing appropriate matrix A and vector b, such as coefficients of Gauss, Radau IA & IIA, Lobatto IIIA, Burrage, etc. [1, 8]. Recently, much attention has been paid to choosing A, b such that the IRK method has the best properties in some sense of stability [5]. Moreover, Jay [8] showed that for various choices of A, b the use of inexact simplified Newton methods is efficient for solving the system of nonlinear equations (1.2) under the condition that H is continuously differentiable. In this paper, we focus our attention on how to solve the system of nonlinear equations (1.2) efficiently when f is not differentiable. Such nonsmooth problems arise from mathematical models of structural pounding earthquake and structural oscillations [7, 10, 11, 14]. We apply the slanting Newton method [2,6] to solve (1.2). In section 2, we show that H is slantly differentiable if f is piecewise continuously differentiable. Moreover, we give a simple method to compute a slanting function for H. In section 3, we discuss the convergence order of IRK methods for nonsmooth ODEs. In section 4, we illustrate the slanting Newton method by using a simple model for the collapse of the Tacoma Narrows suspension bridge [14]. Furthermore, we develop a code based on the slanting Newton method and the IRK method for nonsmooth ODEs arising from structural oscillation and pounding. A suite of 27 ground motion records from 12 different earthquakes and a record from the Kobe earthquake are used to show that the code is efficient for simulation of a structural pounding earthquake. All data used in the numerical experiments were taken from the PEER Strong Motion Database [15].

2. Slanting Newton iterations for IRK methods. Let X and Y be Banach spaces and D be an open domain in X. Let $L(X, Y)$ denote the set of all bounded linear operators on X into Y.

DEFINITION 2.1 (see [2]). *A function $H : D \subset X \to Y$ is said to be slantly differentiable at $x \in D$ if there exists a mapping $H^o : D \to L(X, Y)$ such that the*

family $\{H^o(x+\triangle x)\}$ *of bounded linear operators is uniformly bounded in the operator norm for* h *sufficiently small and*

$$\lim_{\triangle x\to 0}\frac{H(x+\triangle x)-H(x)-H^o(x+\triangle x)\triangle x}{\|\triangle x\|}=0.$$

The function H^o *is called a slanting function for* H *at* x.

DEFINITION 2.2 (see [2, 4]). *A function* $H: X\to Y$ *is said to be Lipschitz continuous at* x *if there is a constant* K *such that for all sufficiently small* $\triangle x$

$$\|H(x+\triangle x)-H(x)\|\le K\|\triangle x\|.$$

LEMMA 2.1 (see [2]). *A function* $H: X\to Y$ *is slantly differentiable at* x *if and only if* H *is Lipschitz continuous at* x.

LEMMA 2.2 (see [2]). *Suppose that* H *is slantly differentiable at a solution* x^* *of* $H(x)=0$. *Let* H^o *be a slanting function for* H *at* x^* *and* $\|H^o(x)^{-1}\|\le\Gamma$ *in a neighborhood* $\mathcal{N}$ *of* x^*, *where* Γ *is a positive constant. Then the iterative sequence* $\{x^m\}$ *generated by the slanting Newton method*

$$x^{m+1}=x^m-H^o(x^m)^{-1}H(x^m) \tag{2.1}$$

superlinearly converges to x^* *in a neighborhood of* x^*.

DEFINITION 2.3 (see [12]). *We say* $f: R^n\to R^n$ *is piecewise continuously differentiable if it is continuous and there is a finite collection of continuously differentiable functions* $\phi_l: R^n\to R, l\in\mathcal{L}:=\{1,2,\dots,L\}$, *such that*

$$f_i(u)\in\{\phi_l(u),\ l\in\mathcal{L}\},\ \textit{for any } u\in R^n,\quad i\in\{1,2,\dots,n\}.$$

Such a collection is called a representation for f *on* R^n.

THEOREM 2.1. *The function* $H: R^{s\times n}\to R^{s\times n}$ *defined in* (1.2) *is slantly differentiable at any point* $x\in R^{s\times n}$ *if* f *is piecewise continuously differentiable.*

Proof. We first show that, for a fixed point $\bar u\in R^n$ and a fixed index $i\in\{1,2,\dots,n\}$, f_i is Lipschitz continuous at $\bar u\in R^n$. Let $\mathcal{I}$ and $\mathcal{J}$ be two index sets defined by

$$\mathcal{I}=\{l\,|\,f_i(\bar u)=\phi_l(\bar u),\ l\in\mathcal{L}\}$$

and

$$\mathcal{J}=\{i\,|\,f_i(\bar u)\ne\phi_l(\bar u),\ l\in\mathcal{L}\},$$

respectively. Since $\mathcal{J}$ is a finite set, we have

$$r=\min_{l\in\mathcal{J}}\|\phi_l(\bar u)-f_i(\bar u)\|>0. \tag{2.2}$$

Since f_i is continuous in R^n, there are positive constants δ_0 and $\alpha<1$ such that if $\|u-\bar u\|<\delta_0$, then

$$\|f_i(u)-f_i(\bar u)\|\le\alpha r. \tag{2.3}$$

Furthermore, since every $\phi_l, l\in\mathcal{L}$, is continuously differentiable, there are positive constants K_l, δ_l such that if $\|u-\bar u\|<\delta_l$, then

$$\|\phi_l(u)-\phi_l(\bar u)\|\le K_l\|u-\bar u\|,\quad l\in\mathcal{L}. \tag{2.4}$$

Let

$$K = \max_{l\in\mathcal{L}} K_l \quad \text{and} \quad \delta = \min\left\{\delta_0, \frac{1-\alpha}{K}r, \min_{l\in\mathcal{L}}\delta_l\right\}.$$

For any u satisfying $\|u-\bar{u}\| < \delta$, if $f_i(u) = \phi_l(u), l \in \mathcal{I}$, then we have

$$\|f_i(u) - f_i(\bar{u})\| = \|\phi_l(u) - \phi_l(\bar{u})\| \le K\|u-\bar{u}\|.$$

Otherwise, if $f_i(u) = \phi_j(u), j \in \mathcal{J}$, we apply (2.2)–(2.4) and obtain

$$\begin{aligned}\alpha r &\ge \|f_i(u) - f_i(\bar{u})\| \\ &= \|\phi_j(u) - f_i(\bar{u})\| \\ &\ge \|\phi_j(\bar{u}) - f_i(\bar{u})\| - \|\phi_j(u) - \phi_j(\bar{u})\| \\ &\ge r - K\|u-\bar{u}\| > \alpha r,\end{aligned}$$

which implies that there is no $j \in \mathcal{J}$ such that $f_i(u) = \phi_j(u), j \in \mathcal{J}$. Hence

$$\|f_i(u) - f_i(\bar{u})\| \le K\|u-\bar{u}\|. \tag{2.5}$$

Now we show that H is Lipschitz continuous at a point $x^* = (x_1^*, \ldots, x_s^*) \in R^{s\times n}$ for the norm $\|\cdot\|_\infty$.

Note that p is continuously differentiable in R^n, and the point $\bar{u} \in R^n$, the index $i \in \{1, 2, \ldots, n\}$, and the norm in (2.2)–(2.5) are arbitrarily chosen. Without loss of generality, we may assume that there are a constant K and a neighborhood $\mathcal{N}^* := \mathcal{N}_1^* \times \mathcal{N}_2^* \ldots \mathcal{N}_s^*$ of x^* such that, for any $x \in \mathcal{N}^*$,

$$\|f(x_i) - f(x_i^*)\|_\infty \le K\|x_i - x_i^*\|_\infty$$

and

$$\|p(x_i) - p(x_i^*)\|_\infty \le K\|x_i - x_i^*\|_\infty, \quad i = 1, 2 \ldots, s.$$

Therefore, by the definition of H, we find

$$\begin{aligned}\|H(x) - H(x^*)\|_\infty &\le \max_{1\le i\le s}\|p(x_i) - p(x_i^*)\|_\infty + h\|A\|_\infty s \max_{1\le i\le s}\|f(x_i) - f(x_i^*)\|_\infty \\ &\le \max_{1\le i\le s} K\|x_i - x_i^*\|_\infty + hs\|A\|_\infty \max_{1\le i\le s} K\|x_i - x_i^*\|_\infty \\ &\le (1 + hs\|A\|_\infty)K \max_{1\le i\le s}\|x_i - x_i^*\|_\infty \\ &\le (1 + hs\|A\|_\infty)K\|x - x^*\|_\infty.\end{aligned}$$

By Lemma 2.1, H is slantly differentiable at x^*. □

THEOREM 2.2. *Let $f^o \in R^{n\times n}$ be a slanting function for f at x_i^*, $i = 1, 2, \ldots, s$. Then*

$$H^o(x) = \operatorname{diag}(p'(x_1), \ldots, p'(x_s)) - h(A \otimes I_n)\operatorname{diag}(f^o(x_1), \ldots, f^o(x_s)) \tag{2.6}$$

is a slanting function for H at x^*, where diag *denotes block diagonal, $I_n \in R^{n\times n}$ is the identity matrix, and the symbol $\otimes$ denotes the tensor product.*

Proof. Since p is continuously differentiable and f^o is a slanting function for f at x_i^*, $i = 1, 2, \ldots, s$, we have that, if $\|x - x^*\|$ is sufficiently small,

$$p(x_i) - p(x_i^*) = p'(x_i)(x_i - x_i^*) + o(\|x_i - x_i^*\|), \quad i = 1, 2, \ldots s,$$

and

$$f(x_i) - f(x_i^*) = f^o(x_i)(x_i - x_i^*) + o(\|x_i - x_i^*\|), \quad i = 1, 2, \ldots, s.$$

Therefore, we get

$$\begin{aligned}
&H(x) - H(x^*) \\
&= \begin{pmatrix} p(x_1) - p(x_1^*) \\ \vdots \\ p(x_s) - p(x_s^*) \end{pmatrix} - h \begin{pmatrix} \sum_{j=1}^{s} a_{1j}(f(x_j) - f(x_j^*)) \\ \vdots \\ \sum_{j=1}^{s} a_{sj}(f(x_j) - f(x_j^*)) \end{pmatrix} \\
&= \begin{pmatrix} p'(x_1)(x_1 - x_1^*) + o(\|x_1 - x_1^*\|) \\ \vdots \\ p'(x_s)(x_s - x_s^*) + o(\|x_s - x_s^*\|) \end{pmatrix} - h \begin{pmatrix} \sum_{j=1}^{s} a_{1j}(f^o(x_j)(x_j - x_j^*) + o(\|x_j - x_j^*\|)) \\ \vdots \\ \sum_{j=1}^{s} a_{sj}(f^o(x_j)(x_j - x_j^*) + o(\|x_j - x_j^*\|)) \end{pmatrix} \\
&= \begin{pmatrix} p'(x_1) & & \\ & \ddots & \\ & & p'(x_s) \end{pmatrix} \begin{pmatrix} x_1 - x_1^* \\ \vdots \\ x_s - x_s^* \end{pmatrix} - h \begin{pmatrix} a_{11}f^o(x_1) & \ldots & a_{1s}f^o(x_s) \\ \vdots & & \vdots \\ a_{s1}f^o(x_1) & \ldots & a_{ss}f^o(x_s) \end{pmatrix} \begin{pmatrix} x_1 - x_1^* \\ \vdots \\ x_s - x_s^* \end{pmatrix} \\
&\qquad + o(\|x - x^*\|) \\
&= (\mathrm{diag}(p'(x_1), \ldots, p'(x_s)) - h(A \otimes I_n)\mathrm{diag}(f^o(x_1), \ldots, f^o(x_s)))(x - x^*) + o(\|x - x^*\|).
\end{aligned}$$

Hence H^o defined in (2.6) is a slanting function for H at x^*. ∎

Now we consider how to compute a slanting function f^o for a piecewise continuously differentiable function f. From Theorem 2.1, f is a locally Lipschitzian function. By the Rademacher theorem, f is differentiable almost everywhere. Hence, we can define the Clarke generalized Jacobian [3]

$$\partial f(y) = \mathrm{co}\{ \lim_{\substack{y^k \to y \\ y^k \in D_f}} f'(y^k)\},$$

where the symbol co denotes the convex hull and D_f is the set of points where f is differentiable. In [2], it is shown that any single valued selection of $\partial f(y)$ is a slanting function of f at y. Furthermore, from Lemma 2 in [12], if f_i is differentiable at y, then there exists ϕ_l in the representation for f such that

$$f_i(y) = \phi_l(y) \quad \text{and} \quad f_i'(y) = \phi_l'(y).$$

Therefore, we can define a slanting function of f as

$$(f^o(y))_i = \phi_l'(y), \qquad \text{where } f_i(y) = \phi_l(y).$$

For such a slanting function, by Theorems 2.1 and 2.2 and Lemma 2.1, we can easily obtain the following corollary.

COROLLARY 2.1. *Let x^* be a solution of $H(x) = 0$. If f is piecewise continuously differentiable, and $p'(x_i^*)$, $i = 1, 2, \ldots, s$, are nonsingular, then for small h the slanting Newton method* (2.1) *is well defined and superlinearly converges to x^*.*

Proof. By the continuity of p' and the nonsingularity of $p'(x_1^*)$, there are a positive constant γ_1 and a neighborhood $\mathcal{N}_1$ of x^* such that, for any $x \in \mathcal{N}_1$, $p'(x_i)$ are all nonsingular and $\|p'(x_i)^{-1}\|_\infty \le \gamma_1$, $i = 1, 2, \ldots, s$. Moreover, by the locally Lipschitzian continuity of f, there are a positive constant γ_2 and a neighborhood $\mathcal{N}_2$ of x^* such that, for any $x \in \mathcal{N}_2$, $\|f^o(x_i)\|_\infty \le \gamma_2$, $i = 1, 2, \ldots, s$. Let

$$B = h\mathrm{diag}(p'(x_1)^{-1}, \ldots, p'(x_s)^{-1})(A \otimes I)\mathrm{diag}(f^o(x_1), \ldots, f^o(x_s)),$$

$$\gamma = s\gamma_1\gamma_2\|A\|_\infty,$$

and $\mathcal{N} = \mathcal{N}_1 \cap \mathcal{N}_2$. Then, for $h \le \lambda/\gamma$ ($\lambda < 1$) and $x \in \mathcal{N}$, we have

$$\|B\|_\infty \le \lambda < 1.$$

Hence, for $h \le \lambda/\gamma$ ($\lambda < 1$) and $x \in \mathcal{N}$, $H^o(x)$ is nonsingular and

$$\begin{aligned}\|H^o(x)^{-1}\| &= \|\mathrm{diag}(p'(x_i)^{-1})(I - B)\|_\infty \\ &\le \|\mathrm{diag}(p'(x_i)^{-1})\|_\infty \|I + B + B^2 + \cdots\|_\infty \\ &\le \frac{\gamma}{1-\lambda} \\ &=: \Gamma.\end{aligned}$$

By Lemma 2.2, the slanting Newton method (2.1) is well defined and superlinearly converges to x^*. ∎

Remark 2.1. When H is continuously differentiable, Jay [8] suggested to use the simplified Newton method

$$x^{m+1} = x^m - H'(x^0)^{-1}H(x^m) \tag{2.7}$$

for solving the system of nonlinear equations in IRK methods. If x^0 is sufficiently close to a solution x^* of $H(x) = 0$,

$$\Phi(x) := x - H'(x^0)^{-1}H(x)$$

is locally contractive in a neighborhood of x^* containing x^0. By using the contractive property, Jay proved the convergence of an inexact simplified Newton method. Note that, when H is continuously differentiable, $H'(x)$ is a slanting function $H^o(x)$ for H. However, if H is not differentiable at x^*,

$$\Psi(x) := x - H^o(x^0)^{-1}H(x)$$

is not locally contractive in any neighborhood of x^* containing x^0. For example,

$$H(x) = \begin{cases} x^2 - 1, & x \ge 1, \\ 1 - x, & x < 1. \end{cases}$$

The function H is not differentiable at the solution $x^* = 1$ of $H(x) = 0$. It is easy to get a slanting function for H:

$$H^o(x) = \begin{cases} 2x, & x \ge 1, \\ -1, & x < 1. \end{cases}$$

For $x^0 < 1$ and $x \ge 1$,

$$|\Psi(x) - \Psi(x^*)| = |x - H^o(x^0)^{-1}H(x) - x^*| = |x + (x^2 - 1) - 1| = |x + 2||x - x^*| > |x - x^*|.$$

For $x^0 \geq 1$ and $0 < x < 1$,

$$|\Psi(x) - \Psi(x^*)| = |x - H^o(x^0)^{-1}H(x) - x^*|$$
$$= \left|x - \frac{1-x}{2x^0} - 1\right| = \left|1 + \frac{1}{2x^0}\right| |x - x^*| > |x - x^*|.$$

Therefore, the simplified Newton method cannot be applied to solve (1.2) when H is not differentiable.

Remark 2.2. Analysis in this section can be easily generalized to the system of nonautonomous ordinary differential equations

$$\begin{aligned} &\frac{dp(t,u)}{dt} = f(t,u), \qquad t \geq 0, \\ &u(0) = u_0. \end{aligned} \tag{2.8}$$

3. Convergence order of IRK methods. We have tested various IRK methods with the slanting Newton method and the bisection method on numerous problems in structural oscillation and pounding. From our numerical experiments, we observe that the order of the IRK methods for Lipschitz continuous ODEs can be preserved if there are finite discontinuous times, and we can find these discontinuous times sufficiently accurately. However, in many cases the order of convergence may drop to one. In theory, we can show that the order of convergence is at least one for the Lipschitz continuous ODEs under mild conditions. This is done for the solution $u(t)$ to (1.1) in a fixed interval $[0, T]$ with the number n of steps chosen such that $t_n = nh = T$. Let

$$e_k(h) = U_k - u(t_k), \qquad k = 0, 1, \ldots, n,$$

and

$$E(h) = \max_{k=0,\ldots,n} \|e_k(h)\|.$$

We assume that the IRK method is well defined; that is, for any U_k there are x^k, U_{k+1} such that $H(x^k) = 0$ and $\tilde{H}(U_{k+1}) = 0$. For simplicity, we consider $p(u) = u$. Let

$$G(x,U) := \begin{pmatrix} x_1 - U - h\sum_{j=1}^{s} a_{1j} f(x_j) \\ \vdots \\ x_s - U - h\sum_{j=1}^{s} a_{sj} f(x_j) \end{pmatrix}.$$

Since f is Lipschitz continuous, the function G is Lipschitz continuous. By the Rademacher theorem, G is differentiable almost everywhere. Hence we can define the Clarke generalized Jacobian [3]

$$\partial G(x,U) = [\pi_x \partial G(x,U), \pi_U \partial G(x,U)],$$

where $\pi_x \partial G(x,U)$ signifies the set of all $(s \times n) \times (s \times n)$ matrices M such that, for some $(s \times n) \times n$ matrix N, the $(s \times n) \times (s \times n + n)$ matrix $[M, N]$ belongs to $\partial G(x,U)$.

For small h, $\pi_x \partial G(x^k, U_k)$ is of maximal rank; i.e., every matrix M in $\pi_x \partial G(x^k, U_k)$ is nonsingular. By the implicit function theorem for Lipschitz continuous function in [3], there exist a neighborhood $\mathcal{U}_k$ of U_k and a Lispchitz function $\psi_k(\cdot; h) : \mathcal{U}_k \to R^{s\times n}$ such that $x^k = \psi_k(U_k; h)$ and, for every $U \in \mathcal{U}_k$, $G(\psi_k(U; h), U) = 0$. Therefore, we have

$$U_{k+1} = U_k + h\sum_{j=1}^{s} b_j f((\psi_k(U_k; h))_j) =: U_k + h\phi_k(U_k; h). \tag{3.1}$$

Obviously $\phi_k(\cdot; h) : R^n \to R^n$ is a locally Lipschitz continuous function.

THEOREM 3.1. *Suppose that there are positive constants K_1 and K_2 such that*

$$\|\phi_k(u(t_k); h) - \phi_k(U_k; h)\| \le K_1\|u(t_k) - U_k\| \tag{3.2}$$

and

$$\|\phi_k(u(t_k); h) - u'(t_k)\| \le K_2 h. \tag{3.3}$$

Then there is a constant $\alpha > 0$ such that

$$E(h) \le \alpha h.$$

Proof. By the Lipschitz continuity of f, u' is Lipschitz continuous. This implies that there is a constant $K_3 > 0$ such that

$$\left\| \frac{u(t_k + h) - u(t_k)}{h} - u'(t_k) \right\| \le K_3 h. \tag{3.4}$$

By (3.1), we have

$$e_{k+1} - e_k = U_{k+1} - U_k - (u(t_{k+1}) - u(t_k)) = h\left(\phi_k(U_k; h) - \frac{u(t_k + h) - u(t_k)}{h}\right).$$

Hence from (3.2)–(3.4), we obtain

$$\begin{aligned}\|e_{k+1}\| &\le (1 + hK_1)\|e_k\| + (K_2 + K_3)h^2 \\ &= (1 + hK_1)^{k+1}\|e_0\| + \frac{K_2 + K_3}{K_1}\left(K_1 h\sum_{j=0}^{k}(1 + K_1 h)^j\right)h,\end{aligned}$$

which, together with $\|e_0\| = 0$, implies that

$$E(h) \le \frac{K_2 + K_3}{K_1}(e^{K_1 T} - 1)h. \qquad \square$$

If $s = 1$, $a_{11} = 0$, and $b_1 = 1$, then $\psi_k(U_k; h) = U_k$, $\phi_k(U_k; h) = f(U_k)$, and (3.1) reduces to the Euler method which has convergence order one. Obviously, (3.2) and (3.3) hold for $\phi_k(U_k; h) = f(U_k)$ and $\phi_k(u(t_k); h) = f(u(t_k))$. Theorem 3.1 shows that the IRK methods for Lispchitz continuous ODEs have convergence order one as the Euler method if $u'(t)$ is not differentiable at some points in the interval $[t_k, t_{k+1}]$ for some k. It is worth noting that the implicit RK methods are numerically stable but require more computational time to solve a system of nonsmooth equations at each step, while explicit methods are faster but may cause a numerical stability problem for stiff ODEs. It will be interesting to study a hybrid method that takes advantage of both implicit and explicit RK methods for solving Lipschitz continuous ODEs.

4. Numerical experiment. Jay [8] developed a code based on 3-stage IRK methods for the numerical solution of (1.1) where f is continuously differentiable. To solve (1.1) where f is not differentiable, we developed a new code based on the slanting Newton method and Jay's code. In our code, the function f can be defined by a finite collection of continuously differentiable functions $\{\phi_l, l \in \mathcal{L}\}$. See Definition 2.3 and Theorem 2.1. The set of points where f is not differentiable is

$$\mathcal{S}_f = \{u \in D \,|\, \phi_i(u) - \phi_j(u) = 0, \phi_i'(u) - \phi_j'(u) \neq 0, i, j \in \mathcal{L}\}.$$

If a point in $\mathcal{S}_f$ is contained within an integration interval, then the order of the IRK method may drop to one. If we can compute exactly the discontinuity times, then the order of the IRK method can be preserved. See the example in subsection 4.1. In our code, a root-finding process is used to find the discontinuities in time. We tested the new code by using many nondifferentiable ODEs. Numerical results show that the new code is efficient. In this section, we report numerical results of IRK methods with the 2-stage Burrage coefficient [1]

$$A = \begin{pmatrix} 1/4 & 0 \\ 1/2 & 1/4 \end{pmatrix} \quad \text{and} \quad b = \begin{pmatrix} 1/2 \\ 1/2 \end{pmatrix},$$

the 2-stage Radau IA coefficient [13]

$$A = \begin{pmatrix} 1/4 & -1/4 \\ 1/4 & 5/12 \end{pmatrix} \quad \text{and} \quad b = \begin{pmatrix} 1/4 \\ 3/4 \end{pmatrix},$$

the 2-stage Radau IIA coefficient [13]

$$A = \begin{pmatrix} 5/12 & -1/12 \\ 3/4 & 1/4 \end{pmatrix} \quad \text{and} \quad b = \begin{pmatrix} 3/4 \\ 1/4 \end{pmatrix},$$

and the 3-stage Lobatto IIIA coefficient [8]

$$A = \begin{pmatrix} 0 & 0 & 0 \\ 5/24 & 1/3 & -1/24 \\ 1/6 & 2/3 & 1/6 \end{pmatrix} \quad \text{and} \quad b = \begin{pmatrix} 1/6 \\ 2/3 \\ 1/6 \end{pmatrix}$$

for solving a nondifferentiable ODE model for the collapse of the Tacoma Narrows suspension bridge and simulating 13 different earthquakes with a suite of 28 ground motion records.

4.1. Bridge collapse. The collapse of the Tacoma Narrows suspension bridge in 1940 left many open questions about the collapse. Lazer and McKenna [10] contend that the nonlinear effects were the main factors leading to the large oscillations of the bridge. The following ODE is a simple version of their model [14]:

$$m\ddot{u} + q(u) = g(t), \qquad u(0) = 0, \quad \dot{u}(0) = \gamma > 0, \tag{4.1}$$

where

$$q(u) = \begin{cases} \alpha u, & u \geq 0, \\ \beta u, & u < 0. \end{cases}$$

Here m is the mass of the section of the roadway, g is the applied force, q is an upward restoring force when $u \geq 0$ and a downward restoring force when $u < 0$, and α and

β are Hooke's constants for the tension and compression, respectively. Note that the function $q(u)$ can be written as

$$q(u) = \alpha \max(0, u) - \beta \max(0, -u).$$

It is shown in [6] that the mapping $\max(0, \cdot) : L^q(\Omega) \to L^p(\Omega)$, with $1 \le p < q \le \infty$, is slantly differentiable on $L^q(\Omega)$ and

$$G(u)(t) = \begin{cases} 1, & u(t) > 0, \\ 0, & u(t) < 0, \\ \delta, & u(t) = 0, \end{cases}$$

is a slanting function for the mapping $\max(0, \cdot)$, where δ is a fixed arbitrary number. By the linear combination [2], the function $q : L^q(\Omega) \to L^p(\Omega)$, with $1 \le p < q \le \infty$, is slantly differentiable on $L^q(\Omega)$ and

$$q^o(u)(t) = \begin{cases} \alpha, & u(t) > 0, \\ \beta, & u(t) < 0, \\ \delta, & u(t) = 0, \end{cases}$$

is a slanting function for q. Furthermore, this problem can be equivalently written as (2.8), by resetting

$$u = \begin{pmatrix} u_1 \\ u_2 \end{pmatrix}, \qquad p(u) = \begin{pmatrix} u_1 \\ mu_2 \end{pmatrix}, \quad \text{and} \quad f(t, u) = \begin{pmatrix} u_2 + \gamma \\ g(t) - q(u_1) \end{pmatrix}.$$

Hence, we can apply the IRK method with the slanting Newton method to obtain numerical solution $U^k, k \ge 0$, of this problem. Moreover, if $q(U^k)q(U^{k-1}) < 0$, then there may be a $\tilde{t} \in [t_{k-1}, t_k]$ such that $q(u(\tilde{t})) = 0$. We used the bisection method to find the discontinuity time $\tilde{t}$ and recomputed U^k by the IRK method with $\tilde{t}$ and $\tilde{h} = \tilde{t} - t_{k-1}$.

For $\alpha = 4, \beta = 1, \gamma = 1$, and $g(t) = \sin 4t$ (Example 1, pp. 264 in [14]), the exact solution in the interval $[0, 3\pi]$ is

$$u^*(t) = \begin{cases} (\frac{2}{3} - \frac{1}{6}\cos 2t)\sin 2t, & 0 \le t \le \frac{\pi}{2}, \\ (\frac{7}{5} - \frac{4}{15}\sin t \cos 2t)\cos t, & \frac{\pi}{2} \le t \le \frac{3\pi}{2}, \\ (-\frac{11}{15} - \frac{1}{6}\cos 2t)\sin 2t, & \frac{3\pi}{2} \le t \le 2\pi, \\ (-\frac{23}{15} - \frac{4}{15}\cos t \cos 2t)\sin t, & 2\pi \le t \le 3\pi, \end{cases}$$

which is twice continuously differentiable in $[0, 3\pi]$.

We chose step sizes

$$h_l = \frac{3\pi}{N_l}, \quad N_l = 100 \times 2^l, \quad l = 0, \ldots, 6,$$

so that

$$\log h_{l-1} - \log h_l = \log 2, \quad l = 1, \ldots, 6.$$

We obtain approximate solutions $\{U^k\}_{k=0}^{N_l}$, $l = 0, \ldots, 6$.

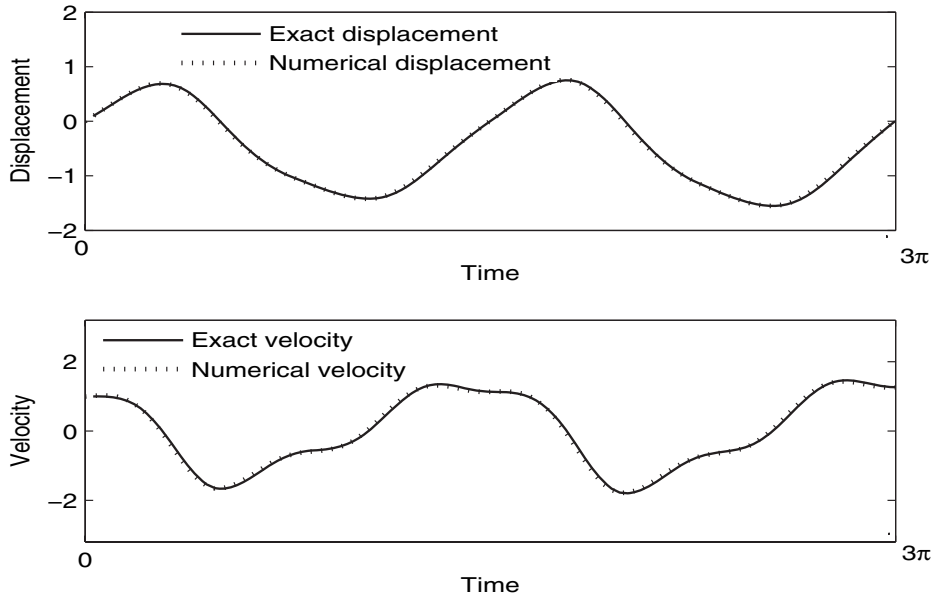

FIG. 4.1. *Exact solution and numerical solution for the collapse of the Tacoma Narrows suspension bridge.*

Figure 4.1 shows what the exact solution and the velocity look like and the numerical solution obtained by the IRK method with the Radau IA and $h_l = \frac{3\pi}{100}$. Figure 4.2 shows the error of the approximate solution

$$\|U_{N_l} - u^*(t_{N_l})\|_2, \quad l = 0, \ldots, 6,$$

at the end point $t_{N_l} = 3\pi$ to compare the 2-stage Burrage, Radau IA, and Radau IIA coefficients. The logarithmic scale is used for the step sizes and errors so that the order of convergence can be seen clearly, when $\|U_{N_l} - u^*(t_{N_l})\|_2 = O(h^l)$. Figure 4.2 shows that the IRK method has order two of convergence for this nonsmooth ODE.

4.2. Seismic pounding. We consider the following nonlinear model of seismic pounding between two adjacent structures called $B1$ and $B2$.

For $i = 1, 2$, let m_i be the masses, r_i be the viscous damping coefficients and k_i be the initial stiffness for $B1$ and $B2$, respectively. The coupling equation of motion for two adjacent buildings subjected to horizontal ground motion $\ddot{u}_g$ has the following version [7, 11]:

$$\begin{array}{rcl} m_1\ddot{u}_1 + r_1\dot{u}_1 + k_1u_1 + q(u_1, u_2, \dot{u}_1, \dot{u}_2) & = & -m_1\ddot{u}_g, \\ m_2\ddot{u}_2 + r_2\dot{u}_2 + k_2u_2 - q(u_1, u_2, \dot{u}_1, \dot{u}_2) & = & -m_2\ddot{u}_g, \end{array} \tag{4.2}$$

where q is the pounding force

$$q(u_1, u_2, \dot{u}_1, \dot{u}_2) = \begin{cases} \alpha(u_1 - u_2 - d)^\gamma + \beta(\dot{u}_1 - \dot{u}_2) & \text{if } u_1 - u_2 > d,\ \dot{u}_1 - \dot{u}_2 > 0, \\ \alpha(u_1 - u_2 - d)^\gamma & \text{if } u_1 - u_2 > d,\ \dot{u}_1 - \dot{u}_2 \le 0, \\ 0 & \text{if } u_1 - u_2 \le d. \end{cases}$$

Here d is the initial separation distance between $B1$ and $B2$, and $\alpha > 0$, $\beta > 0$, and $\gamma > 1$ are fixed parameters.

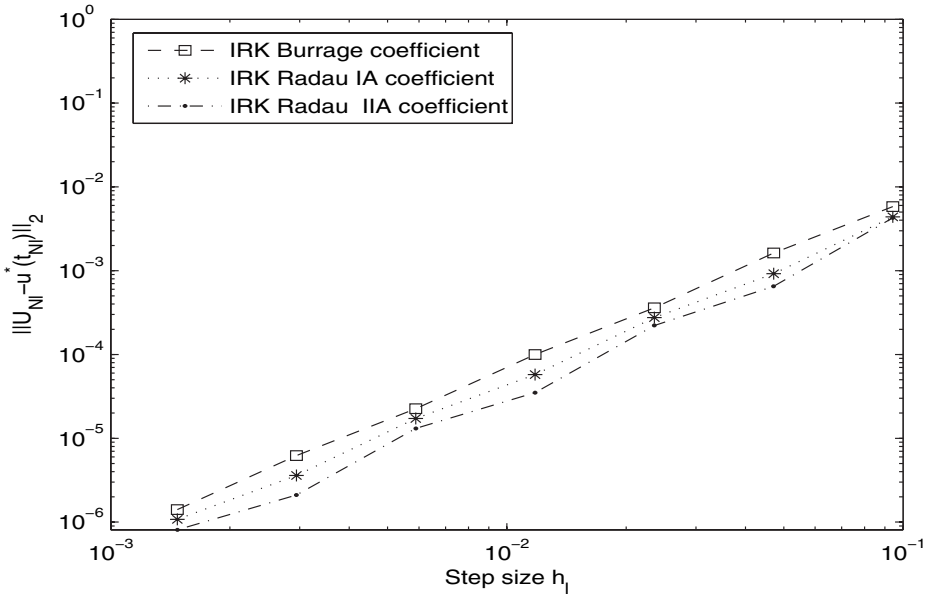

FIG. 4.2. *Error at $t_{N_l} = 3\pi$ of the IRK method with Burrage and Radau coefficients and various step sizes h_l for the collapse of the Tacoma Narrows suspension bridge.*

The ordinary differential equation (4.2) is equivalent to the following system:

$$\begin{aligned} \dot{u}_1 &= u_3, \\ \dot{u}_2 &= u_4, \\ m_1\dot{u}_3 &= -r_1u_3 - k_1u_1 - q(u_1,u_2,u_3,u_4) - m_1\ddot{u}_g, \\ m_2\dot{u}_4 &= -r_2u_4 - k_2u_2 + q(u_1,u_2,u_3,u_4) - m_2\ddot{u}_g. \end{aligned} \tag{4.3}$$

Let us denote

$$u = \begin{pmatrix} u_1 \\ u_2 \\ u_3 \\ u_4 \end{pmatrix}, \quad p(u) = \begin{pmatrix} u_1 \\ u_2 \\ m_1u_3 \\ m_2u_4 \end{pmatrix}, \quad \text{and} \quad f(t,u) = \begin{pmatrix} u_3 \\ u_4 \\ -r_1u_3 - k_1u_1 - q(u) - m_1\ddot{u}_g \\ -r_2u_4 - k_2u_2 + q(u) - m_2\ddot{u}_g \end{pmatrix}.$$

Together with the initial condition $u(0) = 0$, we obtain a system of nonsmooth ordinary differentiable equations (2.8).

We choose

$$m_1 = m_2 = 7.8,\ r_1 = 16.34,\ r_2 = 8.17,\ k_1 = 3421.5,\ k_2 = 855.4,$$
$$\alpha = 25000,\ \gamma = 3/2,\ d = 0.5,\ T = 10.$$

Table 4.1 reports numerical results of the use of a suite of 27 ground motion records with different peak ground accelerations (PGA) from 12 different earthquakes and difference parameters β. The values

$$e(h_1) = ||U^{h_1}(T) - U^{h_4}(T)||_2 \quad \text{and} \quad e(h_3) = ||U^{h_3}(T) - U^{h_4}(T)||_2$$

show the difference of numerical solutions at the end point, for approximate solutions U^{h_l}, with different step sizes

$$h_1 = 2 \times 10^{-3}, \quad h_3 = 2 \times 10^{-4}, \quad h_4 = 10^{-4}.$$

Figure 4.3 reports numerical results of the 3-stage Lobatto IIIA coefficient with parameter $\beta = 112$ in a simulation of the 1995 Great Hanshin earthquake, commonly referred to as the Kobe earthquake. The exact solution of this problem is unknown. In the first subplot, we show the difference of simulation solutions at end point $T = 20$:

$$\|U^{h_l}(T) - U^{h_5}(T)\|_2, \quad l = 0, \ldots, 4,$$

where

$$h_l = \frac{20}{N_l}, \quad N_l = 1000 \times 2^l, \quad l = 0, \ldots, 5.$$

We use a logarithmic scale for the step sizes and the difference. The 3-stage Lobatto IIIA method seems to maintain its fourth order of convergence for this problem. The remainder of Figure 4.3 uses step size $h = 0.002$, which shows the displacement u_1, u_2 and the force q for the first 20 seconds of the earthquake. Moreover, we enlarge the plot around the maximum force in the first 10 seconds and the following 10 seconds to show what the pounding force looks like.

All of the ground motion records used in the numerical experiments were taken from the PEER Strong Motion Database [15]. The numerical experiments were performed by using MATLAB 7.0 on a Dell PC with 2 MB memory and 800 MHz.

5. Conclusion. Systems of slantly differentiable ODEs arise from many applications in earthquake engineering and structural dynamics. We proposed IRK methods

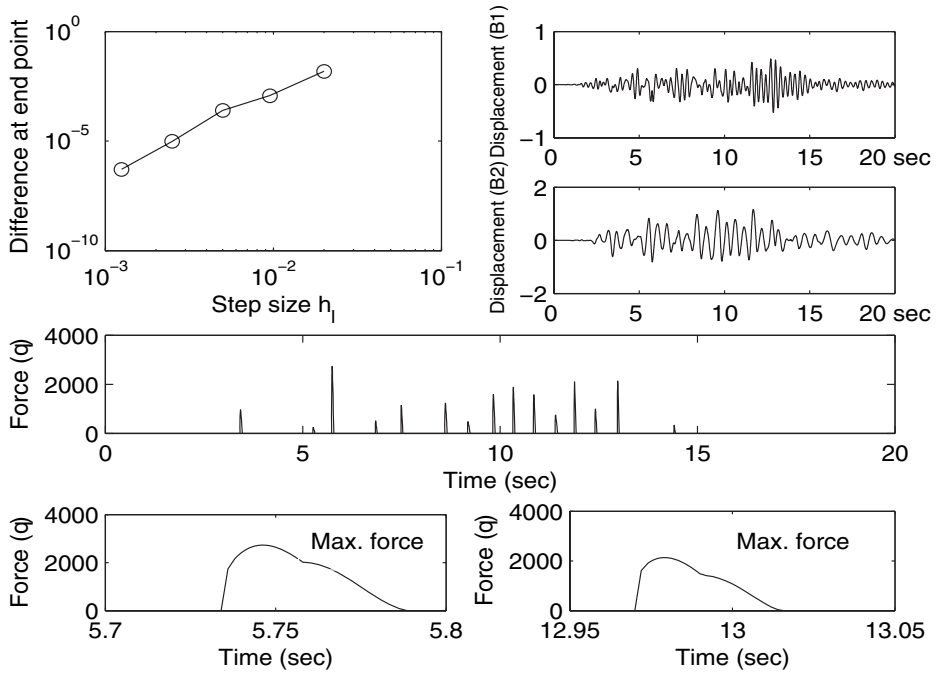

FIG. 4.3. *Difference of simulation solutions. Displacement u_1, u_2, force q, and maximum force during the first* 10 *seconds and the following* 10 *seconds.*

with the slanting Newton method to solve the system of nonsmooth ODEs. We studied the slanting differentiability of the nonsmooth functions involved in the ODEs and proved the superlinear convergence of the slanting Newton method for solving the system of nonsmooth equations in the IRK method. Moreover, we developed a code for nonsmooth ODEs based on Jay's code [8] and the analysis in section 2. Numerical experiments show that the code is efficient. In section 4, we reported some numerical results for the collapse of the Tacoma Narrows suspension bridge and simulating 13 different earthquakes.

Acknowledgments. The authors are grateful to Professor Robert Russell and two anonymous referees for their many helpful comments.

NATURAL SUPERCONVERGENCE POINTS IN THREE-DIMENSIONAL FINITE ELEMENTS*

RUNCHANG LIN† AND ZHIMIN ZHANG‡

Abstract. A systematic and analytic process is conducted to identify natural superconvergence points of high degree polynomial C^0 finite elements in a three-dimensional setting. This identification is based upon explicitly constructing an orthogonal decomposition of local finite element spaces. Derivative and function value superconvergence points are investigated for both the Poisson and the Laplace equations. Superconvergence results are reported for hexahedral, pentahedral, and tetrahedral elements up to certain degrees.

Key words. finite element methods, natural superconvergence, hexahedral, pentahedral (triangular prism), tetrahedral elements polynomial

1. Introduction.

In this paper, we study *natural superconvergence* points of the finite element (FE) approximation u_h to the Poisson equation

$$\begin{cases} -\Delta u = f & \text{in} \quad \Omega, \\ u = g & \text{on} \quad \partial\Omega, \end{cases} \tag{1.1}$$

where $\Omega \subset \mathbb{R}^3$ is an open bounded domain with Lipschitz boundary $\partial\Omega$ and f and g are sufficiently smooth given functions. When $f \equiv 0$, the Poisson equation (1.1) reduces to the Laplace equation.

Superconvergence for FE methods has been a research topic for about 35 years. For the literature, the reader is referred to [1, 2, 4, 9, 10, 14, 15, 16, 22, 26, 27] and references therein. Here, by "natural superconvergence," we mean that the superconvergence points are obtained without employing any postprocessing in FE solutions. The authors are aware that many superconvergence results can be obtained from postprocessing or recovery techniques. Nevertheless, our investigation is limited to the natural superconvergence in this paper. Moreover, *natural superconvergence* is abbreviated as *superconvergence* when no confusion arises.

Superconvergence points for the three-dimensional (3D) tensor-product FE can be determined from one-dimensional (1D) and/or two-dimensional (2D) results by the tensor-product technique. When the element is not tensor-product due to either geometry or construction, the problem becomes tricky. In [6] Brandts and Křížek surveyed techniques and typical difficulties of superconvergence problems in 3D FEs. Three different methods were reviewed, namely, the *element orthogonality analysis* introduced by Chen [9], Zhu and Lin [26], et al.; the *symmetry theory* due to Schatz, Sloan, and Wahlbin [19]; and *computer-based methods* proposed by Babuška et al. [5].

Following the reasoning of computer-based methods, Zhang [23, 24] proposed an analytic approach to locate derivative superconvergence points for some 2D rectangular and 3D hexahedral elements. In this paper, we systematically extend this analytic approach to identify superconvergence points for 3D higher order FEs of different geometries, including pentahedral (triangular prism) and tetrahedral elements. Specifically, Lagrangian and Serendipity elements of both a hexahedron and a pentahedron are considered; two patterns of tetrahedral elements are also investigated. Superconvergence results for function values and derivatives are provided for elements up to certain degrees. The reader is referred to [25] as a supplement for computational aspects. To the best of our knowledge, many results in this paper are reported for the first time in the literature.

The article is organized as follows. Section 2 contains some preliminaries. Hierarchic shape functions for the elements considered in this paper are constructed in section 3. In section 4, we introduce a decomposition of the FE spaces, which provides us a way to specify the polynomial spaces needed in locating superconvergence points. The structures of the spaces are illustrated in section 5. Section 6 is devoted to presenting the main superconvergence results in different elements. Some concluding remarks are made in the last section.

2. Preliminaries.

2.1. Master cell and reference cell. Consider superconvergence near $\boldsymbol{x}^0 \in \Omega$. We assume that the local FE triangulation is based on a uniform hexahedral mesh (which may be further decomposed into pentahedral or tetrahedral elements) near $\boldsymbol{x}^0$. Without loss of generality, we may assume that the point $\boldsymbol{x}^0$ is the center of one cell in the mesh, which is referred to as the *master cell*. Denote a cell centered at $\boldsymbol{x} = (x_1, x_2, x_3) \in \Omega$ with side $2l$ by

$$c(\boldsymbol{x}, l) = \{\boldsymbol{y} = (y_1, y_2, y_3) \in \Omega \mid |y_i - x_i| \le l,\ i = 1, 2, 3\}.$$

The master cell is hence $c(\boldsymbol{x}^0, h)$, where h is the *mesh parameter*. Let $\Omega_1 = c(\boldsymbol{x}^0, H)$ and $\Omega_0 = c(\boldsymbol{x}^0, 2H) \subset\subset \Omega$ with $H = h^\delta$, $0 < 3\delta/2 < 1$.

Using the reference element technique, the study in the master cell $c(\boldsymbol{x}^0, h)$ can be equivalently conducted in the *reference cell* $K = [-1, 1]^3$. In this context, we will use (x_1, x_2, x_3) for the standard Euclidean coordinates in the master cell (or physical domain Ω), and use (ξ, η, ζ) for those in the reference cell.

2.2. Function spaces. In this paper, we use standard notation for Lebesgue and Sobolev spaces and the corresponding norms.

We denote by Π_n the space of polynomials in three variables with degree not exceeding n. Associated with a particular partition of the reference cell K, we denote by $\Pi_n^w(K)$ ($\Pi_n^\pi(K)$, respectively) the set of *piecewise continuous* (*periodic piecewise continuous*, respectively) polynomials of degree not greater than n. Here, we say a function f is *periodic with respect to* K, or simply *periodic*, if $f(1, \eta, \zeta) = f(-1, \eta, \zeta)$, $f(\xi, 1, \zeta) = f(\xi, -1, \zeta)$, and $f(\xi, \eta, 1) = f(\xi, \eta, -1)$ for any $\xi, \eta, \zeta \in [-1, 1]$. Functions *periodic with respect to the master cell* can be analogously defined. These functions can be periodically extended to Ω_0, which are referred to as *$2h$-periodic functions*.

Let $\mathcal{H}_{n+1}$ be the space of *homogeneous harmonic polynomials* in three variables of degree $n+1$. For $\boldsymbol{x} \in \mathbb{R}^3$, denote its Euclidean norm by $|\boldsymbol{x}|$. It is proved in [3, p. 76] that every $p \in \Pi_{n+1} \backslash \Pi_n$ can be expressed as $p = p_1 + |\boldsymbol{x}|^2 p_2$ with $p_1 \in \mathcal{H}_{n+1}$ and $p_2 \in \Pi_{n-1} \backslash \Pi_{n-2}$. We have the following proposition [3].

PROPOSITION 2.1. *For $n \ge 1$, the space $\mathcal{H}_{n+1}$ has dimension* $\dim \mathcal{H}_{n+1} = 2n+3$.

Furthermore, with help of the *Kelvin transform*, we can find an explicit basis of $\mathcal{H}_{n+1}$. For the detailed approach, see [3, p. 92].

We denote by V_n the polynomial FE space of degree n, and by V_n^π the collection of $2h$-periodic functions in V_n. We denote also by $V_n(K)$ and $V_n^\pi(K)$ the corresponding FE spaces on K.

2.3. Auxiliary functions. The following auxiliary functions will be used later. Let P_k be the *Legendre polynomial* of degree k on $[-1,1]$. Define

$$\phi_k(x) = \int_{-1}^{x} P_{k-1}(t)\ \mathrm{d}t, \quad k = 2,3,\ldots. \tag{2.1}$$

We define also

$$\begin{aligned} \tilde{\phi}_2 &= \phi_2 + \frac{1}{3}, \\ \tilde{\phi}_k &= \phi_k \quad \forall k = 3,4,\ldots. \end{aligned} \tag{2.2}$$

Note that ϕ_k and $\tilde{\phi}_k$ are polynomials of degree k for $k \geq 2$.

2.4. Residue estimates. Let u be the weak solution of (1.1), and u_h be the FE approximation of u in V_n. It follows that

$$a(u - u_h, v) = 0 \qquad \forall v \in V_n^{comp}, \tag{2.3}$$

where V_n^{comp} is the collection of functions in V_n with compact support in Ω, and the bilinear form $a(\cdot,\cdot)$ is defined as

$$a(v,w) = \int_\Omega \nabla v \cdot \nabla w\ \mathrm{d}\Omega.$$

Under various conditions given in [20], the following L_∞ estimates of $u - u_h$ and its derivatives are obtained.

LEMMA 2.2. *Let u and u_h be the weak solution of* (1.1) *and its FE approximation, respectively. Assume that $s \geq 0$ and $1 \leq q \leq \infty$. Then there exists a constant C independent of u, u_h, h, H, and $\boldsymbol{x}^0$ such that*

$$\|u - u_h\|_{L_\infty(\Omega_1)} \leq C \left(\ln \frac{H}{h}\right)^{\bar{n}} \min_{v \in V_n} \|u - v\|_{L_\infty(\Omega_0)} + \ CH^{-s-3/q} \|u - u_h\|_{W_q^{-s}(\Omega_0)}.$$

Here $\bar{n} = 1$ if $n = 1$, and $\bar{n} = 0$ otherwise.

LEMMA 2.3. *Under the same hypotheses as in Lemma* 2.2, *there exists a constant C independent of u, u_h, h, H, and $\boldsymbol{x}^0$ such that*

$$\begin{aligned} \|u - u_h\|_{W_\infty^1(\Omega_1)} \leq C \min_{v \in V_n} \left(|u - v|_{W_\infty^1(\Omega_0)} + H^{-1}\|u - v\|_{L_\infty(\Omega_0)}\right) \\ + \ CH^{-1-s-\frac{3}{q}} \|u - u_h\|_{W_q^{-s}(\Omega_0)}. \end{aligned}$$

The proofs of Lemmas 2.2 and 2.3 can be found in [20].

For $n \geq 1$, we assume that

$$\|u - u_h\|_{L_\infty(\Omega_0)} \leq Ch^{n+1-L}, \tag{2.4}$$

with $L \geq 0$ and $L + 3\delta/2 < 1$. This assumption implies that pollution effects from outside of the domain Ω_0 have been properly controlled and the error loss is of order h^L. Moreover, for $n > 1$, we assume that

$$\|u - u_h\|_{W_\infty^{-1}(\Omega_0)} \leq Ch^{n+2-\Lambda}, \tag{2.5}$$

with $\Lambda \geq 0$ and $\Lambda + \delta < 1$.

The following theorems are analogous to the 2D results in [5] and [18]. We refer the reader also to [22].

THEOREM 2.4. *Assume that the FE mesh over Ω is locally translation invariant on Ω_0 and (2.4) holds. Then, for $n \geq 1$, we have*

$$\frac{\partial}{\partial x_i}(u - u_h)(\boldsymbol{x}) = \frac{\partial \psi}{\partial x_i}(\boldsymbol{x}) + R_{x_i}(\boldsymbol{x}), \qquad i = 1, 2, 3, \quad \boldsymbol{x} \in \Omega_1,$$

where

$$\|R_{x_i}\|_{L_\infty(\Omega_1)} \leq Ch^n \left(h^\delta + h^{1-L-\frac{3}{2}\delta}\right).$$

Here, ψ is the periodic extension of a piecewisely defined polynomial of degree $n+1$, which is periodic with respect to the master cell.

Proof. Let Q be the $n+1$st order Taylor expansion of u at $\boldsymbol{x}_0$. By approximation theory one has

$$\|u - Q\|_{W_\infty^s(\Omega_0)} \leq CH^{n+2-s}, \qquad 0 \leq s \leq n+2. \tag{2.6}$$

Let $N_h Q$ be the *Neumann projection* of Q into $V_n(\Omega_0)$ in the sense that

$$a(Q - N_h Q, v) = 0 \quad \forall v \in V_n(\Omega_0), \quad \text{and} \quad \int_{\Omega_0} (Q - N_h Q)\, \mathrm{d}\Omega = 0. \tag{2.7}$$

Let $R_Q = (u - u_h) - (Q - N_h Q)$. From (2.3) and (2.7) one has

$$a(R_Q, v) = 0 \qquad \forall v \in V_n^{comp}(\Omega_0).$$

By Lemma 2.3 with $s = 0$ and $q = 2$, it follows that, for $i = 1, 2$, and 3,

$$\begin{aligned} \left\| \frac{\partial R_Q}{\partial x_i} \right\|_{L_\infty(\Omega_1)} \leq C \min_{v \in V_n(\Omega_0)} & |(u - Q) - v|_{W_\infty^1(\Omega_0)} \\ & + H^{-1}\|(u - Q) - v\|_{L_\infty(\Omega_0)}) + CH^{-5/2}\|R_Q\|_{L_2(\Omega_0)}. \end{aligned} \tag{2.8}$$

Let $v \in V_n(\Omega_0)$ be the interpolation of $u - Q$. By approximation theory and (2.6) with $s = n + 1$,

$$|(u - Q) - v|_{W_\infty^1(\Omega_0)} \leq Ch^n \|u - Q\|_{W_\infty^{n+1}(\Omega_0)} \leq Ch^n H. \tag{2.9}$$

Similarly,

$$H^{-1}\|(u - Q) - v\|_{L_\infty(\Omega_0)} \leq Ch^{n+1}. \tag{2.10}$$

Recalling (2.4), one has

$$\|u - u_h\|_{L_2(\Omega_0)} \leq CH\|u - u_h\|_{L_\infty(\Omega_0)} \leq CHh^{n+1-L}. \tag{2.11}$$

It follows, by the standard L_2 estimate, that

$$\begin{aligned}\|Q - N_h Q\|_{L_2(\Omega_0)} &\le Ch^{n+1}\|Q\|_{W_2^{n+1}(\Omega_0)} \\ &\le Ch^{n+1}H^{3/2}\|Q\|_{W_\infty^{n+1}(\Omega_0)} \le CH^{3/2}h^{n+1-L}.\end{aligned} \tag{2.12}$$

Hence, from (2.8)–(2.12), one gets

$$\left\| \frac{\partial R_Q}{\partial x_i} \right\|_{L_\infty(\Omega_1)} \le Ch^n(H + H^{-3/2}h^{1-L} + H^{-1}h^{1-L}). \tag{2.13}$$

Let $\rho = Q - I_h Q$, where $I_h Q$ is an interpolation of Q in $V_n(\Omega_0)$. Since, as indicated in [5], $I_h Q$ is translation invariant by $2h$, it can be shown that ρ is $2h$-periodic; cf. [5, 22]. Set $\psi = \rho - N_h^\pi \rho$, where $N_h^\pi \rho$ is the Neumann projection of ρ into $V_n^\pi(\Omega_0)$; i.e., $N_h^\pi \rho$ is the $2h$-periodic version of $N_h \rho$. It follows immediately from (2.7) that

$$a(\psi, v) = 0 \qquad \forall v \in V_n^{comp}(\Omega_0). \tag{2.14}$$

Rewrite $Q - N_h Q = \psi + [Q - N_h Q - \psi]$. From (2.7) and (2.14), one gets

$$a(Q - N_h Q - \psi, v) = 0 \qquad \forall v \in V_n^{comp}(\Omega_0).$$

Notice that $v = Q - N_h Q - \psi = I_h Q + N_h^\pi \rho - N_h Q \in V_n(\Omega_0)$. It follows from Lemma 2.3 with $s = 0, q = 2$ that

$$\begin{aligned}\|Q - N_h Q - \psi\|_{W_\infty^1(\Omega_1)} &\le CH^{-5/2}\|Q - N_h Q - \psi\|_{L_2(\Omega_0)} \\ &\le CH^{-5/2}\left(\|Q - N_h Q\|_{L_2(\Omega_0)} + \|\psi\|_{L_2(\Omega_0)}\right).\end{aligned} \tag{2.15}$$

Another application of the L_2 estimate gives

$$\|Q - N_h Q\|_{L_2(\Omega_0)} \le Ch^{n+1-L}H^{3/2}. \tag{2.16}$$

By a duality argument (see, e.g., [8]),

$$\begin{aligned}\|\psi\|_{L_2(\Omega_0)} &\le Ch\|\rho\|_{W_2^1(\Omega_0)} \le Ch^{n+1}\|Q\|_{W_2^{n+1}(\Omega_0)} \\ &\le Ch^{n+1}H^{3/2}\|Q\|_{W_\infty^{n+1}(\Omega_0)} \le Ch^{n+1-L}H^{3/2}.\end{aligned} \tag{2.17}$$

From (2.15)–(2.17), one concludes that

$$\|Q - N_h Q - \psi\|_{W_\infty^1(\Omega_1)} \le Ch^{n+1-L}H^{-1}. \tag{2.18}$$

Finally, set $R = (u - u_h) - \psi$ and $R_{x_i} = \partial R/\partial x_i$, $i = 1, 2, 3$. From (2.13) and (2.18), one gets

$$\|R_{x_i}\|_{L_\infty(\Omega_1)} \le Ch^n(H + H^{-3/2}h^{1-L} + H^{-1}h^{1-L}).$$

Note that $H = h^\delta < 1$, and the desired result follows. ∎

THEOREM 2.5. *Assume that the FE mesh on Ω is locally translation invariant over Ω_0. Assume also that* (2.5) *holds. Then, for $n > 1$, we have*

$$(u - u_h)(\boldsymbol{x}) = \psi(\boldsymbol{x}) + R(\boldsymbol{x}), \quad \boldsymbol{x} \in \Omega_1,$$

where

$$\|R\|_{L_\infty(\Omega_1)} \le Ch^{n+1}\left(h^\delta + h^{1-\Lambda-\delta}\right),$$

and ψ is as described in Theorem 2.4.

Proof. Define N_hQ, R_Q, and R as in Theorem 2.4. By Lemma 2.2 with $q = \infty, s = 1$,

$$\|R_Q\|_{L_\infty(\Omega_1)} \le C \min_{v\in V_n(\Omega_0)} \|(u-Q)-v\|_{L_\infty(\Omega_0)} + CH^{-1}\|R_Q\|_{W_\infty^{-1}(\Omega_0)}. \tag{2.19}$$

Let $v \in V_n(\Omega_0)$ be the interpolation of $u - Q$. From (2.6) with $s = n + 1$, one gets

$$\|(u-Q)-v\|_{L_\infty(\Omega_0)} \le Ch^{n+1}\|u-Q\|_{W_\infty^{n+1}(\Omega_0)} \le Ch^{n+1}H. \tag{2.20}$$

By assumption (2.5)

$$\|R_Q\|_{W_\infty^{-1}(\Omega_0)} \le \|u-u_h\|_{W_\infty^{-1}(\Omega_0)} + \|Q-N_hQ\|_{W_\infty^{-1}(\Omega_0)} \le Ch^{n+2-\Lambda}. \tag{2.21}$$

Combining (2.19)–(2.21) yields

$$\|R_Q\|_{L_\infty(\Omega_1)} \le Ch^{n+1}H + CH^{-1}h^{n+2-\Lambda}. \tag{2.22}$$

Since $Q - N_hQ - \psi \in V_n(\Omega_0)$, from Lemma 2.2,

$$\begin{aligned}\|Q-N_hQ-\psi\|_{L_\infty(\Omega_1)} &\le CH^{-1}\|Q-N_hQ-\psi\|_{W_\infty^{-1}(\Omega_0)}\\ &\le CH^{-1}\left(\|Q-N_hQ\|_{W_\infty^{-1}(\Omega_0)} + \|\psi\|_{W_\infty^{-1}(\Omega_0)}\right).\end{aligned} \tag{2.23}$$

By assumption (2.5)

$$\|Q-N_hQ\|_{W_\infty^{-1}(\Omega_0)} \le Ch^{n+2-\Lambda}. \tag{2.24}$$

By a duality argument,

$$\|\psi\|_{W_\infty^{-1}(\Omega_0)} \le \|\rho\|_{W_\infty^{-1}(\Omega_0)} \le Ch^{n+2}\|Q\|_{W_\infty^{n+1}(\Omega_0)} \le Ch^{n+2-\Lambda}. \tag{2.25}$$

Therefore, (2.23)–(2.25) give

$$\|Q-N_hQ-\psi\|_{L_\infty(\Omega_1)} \le CH^{-1}h^{n+2-\Lambda}. \tag{2.26}$$

From (2.22) and (2.26), one gets

$$\|R\|_{L_\infty(\Omega_1)} \le Ch^{n+1}(H + H^{-1}h^{1-\Lambda}), \tag{2.27}$$

which completes the proof of the theorem. □

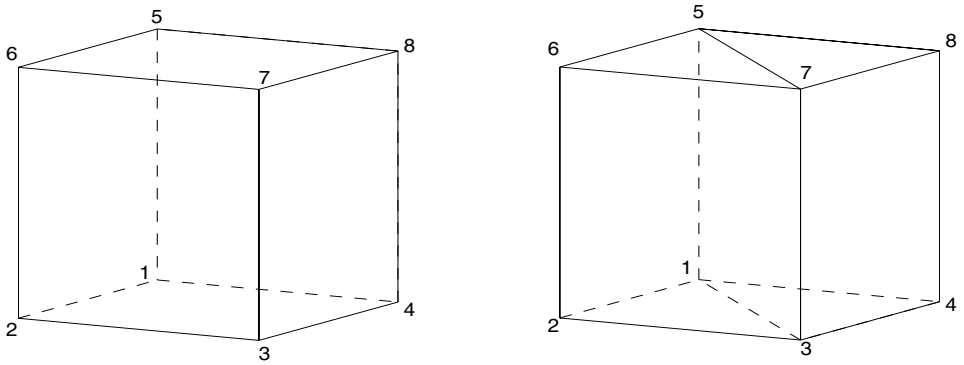
Remark 2.6. Theorem 2.5 may fail when $n = 1$. In fact, even for the one-dimensional case, there is no superconvergence point for function values when piecewise linear elements are employed [22].

Remark 2.7. Notice that ψ is a piecewise polynomial on the master cell and is $2h$-periodic in Ω_0. Theorems 2.4 and 2.5 tell us that the FE local errors in derivatives and function values can be majorized by $\partial\psi/\partial x_i$ and ψ, respectively. Therefore, the task of finding superconvergence points in Ω_1 can be narrowed down to the master cell or, equivalently, to the reference cell under polynomial inputs. The study of superconvergence in a locally translation invariant mesh is from now on carried out in K.

3. Three-dimensional FEs. In this section, hexahedral, pentahedral, and tetrahedral elements are considered. In a hexahedral mesh, a cell in the physical domain serves as an element, which can be mapped to the reference cell K illustrated in Figure 1(a) by the affine mapping

$$(\xi, \eta, \zeta) = \left(\frac{x_1 - x_1^*}{h}, \frac{x_2 - x_2^*}{h}, \frac{x_3 - x_3^*}{h} \right), \tag{3.1}$$

where $\boldsymbol{x}^* = (x_1^*, x_2^*, x_3^*)$ is the center of the physical cell.



(a) Hexahedral Element (b) Pentahedral Elements

FIG. 1. *Partition of K for hexahedral and pentahedral elements.*

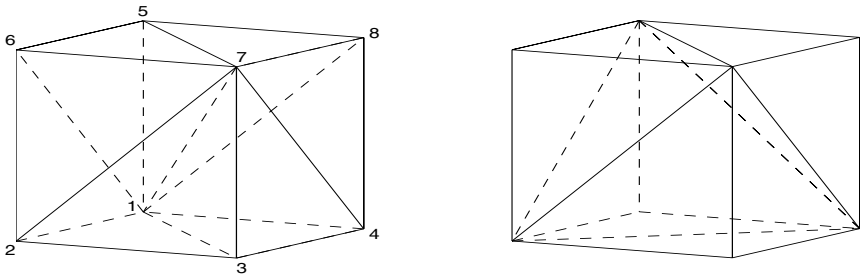
For pentahedral elements, our consideration is for a mesh in which each cell in the physical domain is mapped to the reference cell illustrated in Figure 1(b) by (3.1). The cross-section of this 3D mesh in the x_1x_2-plane is a 2D triangular mesh in a regular pattern [18].

For tetrahedral meshes, two schemes are usually used to partition a unit cell. See Figure 2. Scheme 1 is called *Kuhn partition* of the unit cell, which produces six isomorphic tetrahedra. The master cell can be mapped to the reference cell K by the mapping (3.1). Superconvergence results in [7, 9, 12, 13] are all for tetrahedral elements under Kuhn partition.

Scheme 2 divides a cell into five tetrahedra, four of which are isomorphic. Unlike the previous partitions, to get a translation invariant patch under this scheme, at least eight cubes are needed. As illustrated in Figure 3, there are two candidates for a master cell, which are essentially the same. We consider the first patch in this paper. See Figure 4 for partition of the reference cell. Few superconvergence results are available in the literature for tetrahedral elements under this partition.

We next construct FE spaces $V_n(K)$ and $V_n^\pi(K)$. Hierarchic basis functions are used for $V_n(K)$, which are organized into four categories: nodal shape functions, edge modes, face modes, and internal modes [21]. The nodal shape functions are the standard shape functions, each of which has value 1 at the corresponding node and value 0 at the other nodes. The modal shape functions are, in principle, products of the nodal shape functions of the nodes in the edges, faces, or polyhedra.

Periodic bases of $V_n^\pi(K)$ can be obtained from the basis of $V_n(K)$. In particular, the sum of the nodal shape functions is periodic. The sums of the same order edge modes associated with the three groups of parallel sides, and the sums of the same



Scheme 1 Scheme 2

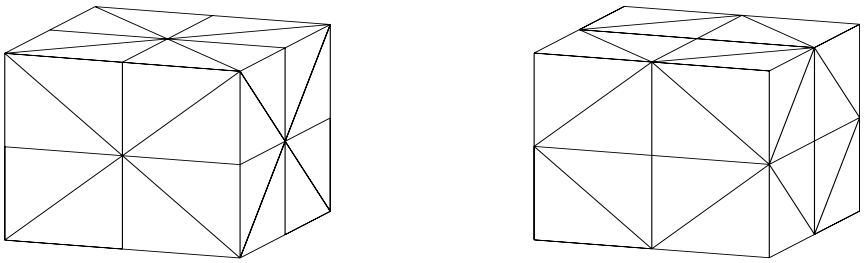

FIG. 3. *Translation invariant patches under scheme* 2.

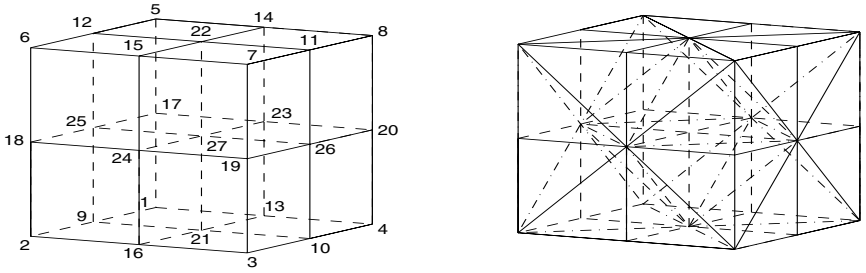

Nodes in K Partition of K

FIG. 4. *Partition of K for tetrahedral elements under scheme* 2.

order face modes for the opposite faces, are all periodic functions. The internal modes are automatically periodic. For more details, see [17].

A basis of Lagrangian pentahedral FE space and a basis of Serendipity pentahedral FE space of degree n are constructed as an example. In Figure 1(b), $\{(\xi,\eta,\zeta)|\xi \geq \eta\}$ is referred to as the first element and the other the second element. We consider Lagrangian elements first.

(1) *Nodal shape functions.* There are 8 nodal shape functions, which are defined

as

$$N^p(\xi,\eta,\zeta)=\begin{cases}\frac{1}{4}(1-\xi)(1+\zeta_p\zeta),\\ \frac{1}{4}(1-\eta)(1+\zeta_p\zeta),\end{cases}\quad p=1,5,$$

$$N^p(\xi,\eta,\zeta)=\begin{cases}\frac{1}{4}(\xi-\eta)(1+\zeta_p\zeta),\\ 0,\end{cases}\quad p=2,6,$$

$$N^p(\xi,\eta,\zeta)=\begin{cases}\frac{1}{4}(1+\eta)(1+\zeta_p\zeta),\\ \frac{1}{4}(1+\xi)(1+\zeta_p\zeta),\end{cases}\quad p=3,7,$$

$$N^p(\xi,\eta,\zeta)=\begin{cases}0,\\ \frac{1}{4}(\eta-\xi)(1+\zeta_p\zeta),\end{cases}\quad p=4,8,$$

where ζ_p is the ζ-coordinate of the pth node. Hereafter, the two expressions of each basis function are its definitions in elements one and two, respectively.

(2) *Edge modes.* There are $(n-1)$ edge modes on each side with index $i=2,\dots,n$. In particular, the edge modes on $l_{1,2}$ are defined as

$$E_i^{1,2}=\begin{cases}\frac{1}{8}(1-\xi)(\xi-\eta)(1-\zeta)\varphi_{i-2}(\xi-\frac{1}{2}\eta-\frac{1}{2}),\\ 0,\end{cases}$$

where φ_i's are defined from the auxiliary functions in (2.1) by

$$\phi_{i+2}(x)=\frac{1}{4}(1-x^2)\varphi_i(x).$$

Note that each $\phi_k(x)$ has a factor $1-x^2$. Analogously, we define basis functions on sides parallel to the ξ and η axes such as $E_i^{1,4},E_i^{5,6},E_i^{5,8},E_i^{2,3},E_i^{3,4},E_i^{6,7},E_i^{7,8}$. On edges $l_{1,5}$ and $l_{2,6}$, we have

$$E_i^{1,5}=\begin{cases}\frac{1}{8}(1-\xi)(1-\zeta^2)\varphi_{i-2}(\zeta),\\ \frac{1}{8}(1-\eta)(1-\zeta^2)\varphi_{i-2}(\zeta),\end{cases}$$

$$E_i^{2,6}=\begin{cases}\frac{1}{8}(\xi-\eta)(1-\zeta^2)\varphi_{i-2}(\zeta),\\ 0.\end{cases}$$

The edge modes associated with $l_{3,7}$ and $l_{4,8}$ are similarly defined. Finally, for the diagonal edge $l_{1,3}$, we define

$$E_i^{1,3}=\begin{cases}\frac{1}{8}(1-\xi)(1+\eta)(1-\zeta)\varphi_{i-2}(\frac{\xi+\eta}{2}),\\ \frac{1}{8}(1+\xi)(1-\eta)(1-\zeta)\varphi_{i-2}(\frac{\xi+\eta}{2}),\end{cases}$$

and we define $E_i^{5,7}$ similarly.

(3) *Face modes.* On each rectangular face, $(n-1)^2$ shape functions are defined when $n\ge 2$. For instance, on faces 2-3-6-7 and 1-3-5-7, the face modes are

$$F_{i,j}^{2,3,6,7}=\begin{cases}\frac{1}{16}(1+\eta)(\xi-\eta)(1-\zeta^2)\varphi_{i-2}(\eta-\frac{\xi}{2}+\frac{1}{2})\varphi_{j-2}(\zeta),\\ 0,\end{cases}$$

$$F_{i,j}^{1,3,5,7}=\begin{cases}\frac{1}{16}(1-\xi)(1+\eta)(1-\zeta^2)\varphi_{i-2}(\frac{\xi+\eta}{2})\varphi_{j-2}(\zeta),\\ \frac{1}{16}(1+\xi)(1-\eta)(1-\zeta^2)\varphi_{i-2}(\frac{\xi+\eta}{2})\varphi_{j-2}(\zeta),\end{cases}$$

with $i, j = 2, \ldots, n$. On each triangular face, $(n-1)(n-2)/2$ shape functions are defined when $n \geq 3$. For example, on face 1-2-3, the face modes are

$$F_{i,j}^{1,2,3} = \begin{cases} \frac{1}{16}(1-\xi)(\xi-\eta)(1+\eta)(1-\zeta)\xi^i\eta^j, \\ 0, \end{cases}$$

with $i, j = 0, \ldots, n-3$ and $i + j = 0, \ldots, n-3$.

(4) *Internal modes.* There are $(n-1)^2(n-2)/2$ internal modes in every element. For $i, j = 0, \ldots, n-3$, $i+j = 0, \ldots, n-3$, and $k = 2, \ldots, n$, we define internal modes of the first element as

$$I_{i,j,k}^{e_1} = \begin{cases} \frac{1}{32}(1-\xi)(\xi-\eta)(1+\eta)(1-\zeta^2)\xi^i\eta^j\varphi_{k-2}(\zeta), \\ 0. \end{cases}$$

Internal modes of the second elements are analogous.

For Serendipity elements, the nodal shape functions, edge modes, and triangular face modes are congruent as above. However, rectangular face modes are defined as above only when $n \geq 4$, with $i, j = 2, \ldots, n-2$ and $i + j = 4, \ldots, n$. Internal modes are involved when $n \geq 5$; these are defined as above with $i, j = 0, \ldots, n-5$, $k = 2, \ldots, n-3$, and $i + j + k = 2, \ldots, n-3$.

For hierarchic basis functions of hexahedral and tetrahedral elements, the reader is referred to [4, 17, 25].

4. Periodic FE approximation. Let $\Phi_{n+1}(K)$ be a subset of $\Pi_{n+1}^{\pi}(K)$, so that each function ψ in $\Phi_{n+1}(K)$ can be decomposed into the polynomial space $\Pi_{n+1}(K)$ and the piecewise continuous polynomial space $\Pi_n^w(K)$, and

$$\int_K \nabla\psi \cdot \nabla v = 0 \quad \forall v \in \Pi_n^{\pi}(K) \quad \text{and} \quad \int_K \psi = 0. \tag{4.1}$$

That is, for any $\psi \in \Phi_{n+1}(K)$, we have $\psi = \chi + r$ satisfying (4.1), where $\chi \in \Pi_{n+1}(K)$ and $r \in \Pi_n^w(K)$. It is straightforward to show the following result [17, 18].

PROPOSITION 4.1. $\dim \Phi_{n+1}(K) = \dim \Pi_{n+1}(K) - \dim \Pi_n(K)$.

The proposition says that, for each monomial of degree $n+1$, there is a unique function in $\Phi_{n+1}(K)$ corresponding to it. Similarly, for each homogeneous harmonic polynomial of degree $n+1$, there is a unique function in $\Phi_{n+1}(K)$ corresponding to it. In particular, we define the following set, which will be used to study superconvergence of FE solutions for Laplace equations:

$$\Phi_{n+1}^{\mathcal{H}}(K) = \{\, \psi \in \Phi_{n+1}(K) \mid \psi = \chi + r,\ \chi \in \mathcal{H}_{n+1}(K),\ r \in \Pi_n^w(K) \,\}. \tag{4.2}$$

We next introduce a process for determining a basis for $\Phi_{n+1}(K)$ and $\Phi_{n+1}^{\mathcal{H}}(K)$. Here we use tetrahedral elements under scheme 1 as an example; see Figure 2. Let u be a polynomial of degree $n+1$ and define an interpolation operator I_n into $V_n(K)$, such that the following hold:

(1) $I_n u(\xi_p, \eta_p, \zeta_p) = u(\xi_p, \eta_p, \zeta_p)$, $p = 1, \ldots, 8$, where (ξ_p, η_p, ζ_p) is the pth node of K.

(2) Along each edge l in the partition of K,

$$\int_l (u - I_n u) r^j \, \mathrm{d}r = 0, \quad j = 0, 1, \ldots, n-2. \tag{4.3}$$

(3) On each face S in the partition of K,

$$\int_S (u - I_n u) r^j s^k \, \mathrm{d}r \, \mathrm{d}s = 0, \quad j,k \geq 0, \quad j+k = 0,1,\ldots,n-3. \tag{4.4}$$

(4) In each tetrahedron T in the partition of K,

$$\int_T (u - I_n u)\xi^j \eta^k \zeta^l \, \mathrm{d}\xi \, \mathrm{d}\eta \, \mathrm{d}\zeta = 0, \quad j,k,l \geq 0, \quad j+k+l = 0,1,\ldots,n-4. \tag{4.5}$$

Note that $u - I_n u$ is a periodic function in K [4, 22]. Thus, we may find a periodic FE approximation z^π of $u - I_n u$ by solving

$$\int_K \nabla(u - I_n u - z^\pi) \cdot \nabla v = 0 \quad \forall v \in V_n^\pi(K). \tag{4.6}$$

To determine z^π uniquely, we also need

$$\int_K (u - I_n u - z^\pi) = 0. \tag{4.7}$$

Then $\psi|_u = u - I_n u - z^\pi \in \Phi_{n+1}(K)$. See [17, 25] for examples and more details. Letting u run through all monomials of degree $n+1$, we obtain a basis of space $\Phi_{n+1}(K)$ by this approach. Using the process described above, we can also have a unique correspondence of $u \in \mathcal{H}_{n+1}$ in $\Phi_{n+1}^{\mathcal{H}}(K)$.

With a symbolic computation software like Maple, the basis functions of $\Phi_{n+1}(K)$ and $\Phi_{n+1}^{\mathcal{H}}(K)$ can be explicitly determined. Therefore, the process is analytic. Here we list only results for tetrahedral elements of scheme 1. As for results in other geometric shapes, such as tetrahedral elements of scheme 2 and pentahedral elements, the reader is referred to [17].

Notice that the process developed above provides functions ψ which satisfy conditions in Theorems 2.4 and 2.5. The following theorems are thus consequences of Theorems 2.4 and 2.5.

THEOREM 4.2. *Let the assumptions of Theorems* 2.4 *and* 2.5 *hold. Then the following hold:*

(i) *For $n > 1$, the function value superconvergence points of $V_n(K)$ for the Poisson equation are the intersections of the following collection of curves:*

$$\{\, \psi = 0 \mid \psi \in \Phi_{n+1}(K) \backslash V_n(K) \,\}.$$

(ii) *For $n \geq 1$, the derivative superconvergence points of $V_n(K)$ in the ξ-direction for the Poisson equation are the intersections of the following collection of curves:*

$$\left\{ \frac{\partial \psi}{\partial \xi} = 0 \mid \psi \in \Phi_{n+1}(K) \backslash V_n(K) \right\}.$$

A similar result holds for derivatives in other directions.

THEOREM 4.3. *Let the assumptions of Theorems* 2.4 *and* 2.5 *hold. Then the following hold:*

(i) *For $n > 1$, the function value superconvergence points of $V_n(K)$ for the Laplace equation are the intersections of the following collection of curves:*

$$\{\, \psi = 0 \mid \psi \in \Phi_{n+1}^{\mathcal{H}}(K) \backslash V_n(K) \,\}.$$

(ii) *For $n \geq 1$, the derivative superconvergence points of $V_n(K)$ in the ξ-direction for the Laplace equation are the intersections of the following collection of curves:*

$$\left\{ \frac{\partial \psi}{\partial \xi} = 0 \mid \psi \in \Phi_{n+1}^{\mathcal{H}}(K) \backslash V_n(K) \right\}.$$

A similar result holds for derivatives in other directions.

Remark 4.4. From Theorems 4.2 and 4.3, one concludes that, if bases of $\Phi_{n+1}(K)\backslash V_n(K)$ and $\Phi_{n+1}^{\mathcal{H}}(K)\backslash V_n(K)$ are determined, then the superconvergence points can be located by solving a system of polynomial equations, which is a routine exercise of numerical computation.

5. Structures of $\boldsymbol{\Phi_{n+1}(K)\backslash V_n(K)}$ and $\boldsymbol{\Phi_{n+1}^{\mathcal{H}}(K)\backslash V_n(K)}$. To determine the spaces $\Phi_{n+1}(K)\backslash V_n(K)$ and $\Phi_{n+1}^{\mathcal{H}}(K)\backslash V_n(K)$, one may first determine a basis of $\Pi_{n+1}(K) \setminus V_n(K)$ and $\mathcal{H}_{n+1}(K) \setminus V_n(K)$, respectively, and then use the approach developed in section 4 to find the corresponding basis functions in the desired spaces.

5.1. Hexahedral elements. Consider Lagrangian hexahedral elements. We note that the nth degree local FE space $V_n(K)$ contains not only functions in $\Pi_n(K)$, but also polynomials of degree higher than n. In particular,

$$\Pi_{n+1}(K) \setminus V_n(K) = \operatorname{Span}\left\{\xi^{n+1}, \eta^{n+1}, \zeta^{n+1}\right\}.$$

It is straightforward to verify that

$$\Phi_{n+1}(K)\backslash V_n(K) = \operatorname{Span}\left\{\tilde{\phi}_{n+1}(\xi), \tilde{\phi}_{n+1}(\eta), \tilde{\phi}_{n+1}(\zeta)\right\},$$

where $\tilde{\phi}_n$ is defined in (2.2). $\Phi_{n+1}^{\mathcal{H}}(K)\backslash V_n(K)$ can be specified analogously.

For Serendipity hexahedral elements, there are fewer basis functions in $V_n(K)$. In particular, we have

$$\Pi_{n+1}(K) \setminus V_n(K) = \operatorname{Span}\left\{\xi^i \eta^j \zeta^k \mid i+j+k = n+1,\ i,j,k \neq 1\right\}.$$

Then $\Phi_{n+1}(K)\backslash V_n(K)$ is determined accordingly, and so is $\Phi_{n+1}^{\mathcal{H}}(K)\backslash V_n(K)$. See [23] for similar formulations obtained from a different approach.

5.2. Pentahedral elements. Consider Lagrangian pentahedral elements. We have

$$\Pi_{n+1}(K) \setminus V_n(K) = \operatorname{Span}\left\{\zeta^{n+1}, \xi^{n+1-i}\eta^i \mid i = 0, \ldots, n+1\right\}.$$

Then $\Phi_{n+1}(K)\backslash V_n(K)$ can be determined. It turns out to be spanned by $\tilde{\phi}_{n+1}(\zeta)$ and the basis of the triangular elements for a regular pattern in [18]. In addition, $\Phi_{n+1}^{\mathcal{H}}(K)\backslash V_n(K)$ has a basis consisting of $\tilde{\phi}_{n+1}(\zeta)$ and two harmonic basis functions of triangular regular pattern in [18].

For Serendipity pentahedral elements, we have

$$\Pi_{n+1}(K) \setminus V_n(K) = \operatorname{Span}\left\{\xi^{n+1-i-j}\eta^i\zeta^j \mid i,j,i+j = 0, \ldots, n+1,\ j \neq 1, n\right\}.$$

Using the process introduced in section 4, we can determine $\Phi_{n+1}(K)\backslash V_n(K)$ and $\Phi_{n+1}^{\mathcal{H}}(K)\backslash V_n(K)$ accordingly. Note that when $n = 1$ and 2, the spaces for Serendipity elements are the same as those for Lagrangian elements. When $n \geq 3$, the spaces are different.

TABLE 1

4	HD_4	None	None
5	HD_5	HSet3	HSet3
6	HD_6	None	None

5.3. Tetrahedral elements. For tetrahedral elements, we have

$$\Pi_n(K) \subset \Pi_n^w(K) = V_n(K).$$

Note that $V_n(K)$ does not contain any polynomial of degree greater than n; thus,

$$\Pi_{n+1}(K) \setminus V_n(K) = \Pi_{n+1}(K) \setminus \Pi_n(K).$$

Therefore, $\Phi_{n+1}(K)\backslash V_n(K) = \Phi_{n+1}(K)$. A basis of $\Phi_{n+1}^{\mathcal{H}}(K)$ can be obtained from a basis of $\mathcal{H}_{n+1}$.

6. Superconvergence results. Once the bases of spaces $\Phi_{n+1}(K)\backslash V_n(K)$ and $\Phi_{n+1}^{\mathcal{H}}(K)\backslash V_n(K)$ are determined, one may apply Theorems 4.2 and 4.3 to the basis functions and obtain superconvergence points for the Poisson and Laplace equations, respectively.

6.1. Hexahedral elements. In Tables 1 and 2, we collect superconvergence results for Lagrangian and Serendipity hexahedral elements of degree up to 6, though our method can produce superconvergence results for elements of higher degrees. Here, "None" means no superconvergence results. The other sets are defined below.

$\text{SPH} = \{\ (\xi,\eta,\zeta) \in K \mid \xi,\eta,\zeta = -1, 0, 1\ \};$

$\text{HF}_n = \{\ (\xi,\eta,\zeta) \in K \mid \phi_{n+1}(\xi) = 0,\ \phi_{n+1}(\eta) = 0,\ \phi_{n+1}(\zeta) = 0\ \};$

$\text{HD}_n = \{\ (\xi,\eta,\zeta) \in K \mid P_n(\xi) = 0\ \};$

$\text{HSet1} = \{\ (\pm\frac{\sqrt{-9+6\sqrt{3}}}{3}, \pm\frac{\sqrt{-9+6\sqrt{3}}}{3}, \pm\frac{\sqrt{-9+6\sqrt{3}}}{3}),$
$(\pm\frac{\sqrt{-9+6\sqrt{3}}}{3}, \pm\frac{\sqrt{-9+6\sqrt{3}}}{3}, \pm\frac{\sqrt{-225+210\sqrt{3}}}{15}),$
$(\pm\frac{\sqrt{-9+6\sqrt{3}}}{3}, \pm\frac{\sqrt{-225+210\sqrt{3}}}{15}, \pm\frac{\sqrt{-9+6\sqrt{3}}}{3}),$
$(\pm\frac{\sqrt{-225+210\sqrt{3}}}{15}, \pm\frac{\sqrt{-9+6\sqrt{3}}}{3}, \pm\frac{\sqrt{-9+6\sqrt{3}}}{3})\ \};$

$\text{HSet2} = \{\ (\xi,\eta,\zeta) \in K \mid \xi = 0\ \} \cup \{\ (\pm\sqrt{3/5}, \pm\sqrt{1/3}, \pm\sqrt{1/3})\ \};$

$\text{HSet3} = \{\ (0,0,0), (0,\pm1,0), (0,0,\pm1), (0,\pm1,\pm1)\ \};$

$\text{HSet4} = \{\ (\xi,\eta,\zeta) \in K \mid \xi = 0, \quad \text{or } \xi = \pm\sqrt{\tfrac{1+6\eta^2}{5}} \text{ and } \zeta = \pm\eta\ \};$

where P_n is the Legendre polynomial of degree n, and ϕ_n is defined in (2.1). Superconvergence results of the η- and ζ-derivatives can be obtained analogously.

6.2. Pentahedral elements. Tables 3 and 4 are devoted to superconvergence results for Lagrangian and Serendipity pentahedral elements. Elements of degree up to 5 are studied.

TABLE 3

The sets in the tables are defined as

$\mathrm{PF}_n = \{(\xi,\eta,\zeta) \mid (\xi,\eta) \in \mathrm{FSR}_n, \quad \phi_{n+1}(\zeta) = 0\};$

$\mathrm{PD1}_n = \{(\xi,\eta,\zeta) \mid P_n(\zeta) = 0\};$

$\mathrm{PD2}_n = \{(\xi,\eta,\zeta) \mid (\xi,\eta) \in \mathrm{DSR}_{\xi,n}\};$

$\mathrm{PSet1} = \{(\xi,\eta,\zeta) \mid \xi,\eta = \pm 1, 0, \quad \phi_5(\zeta) = 0\};$

$\mathrm{PSet2} = \{(\xi,\eta,\zeta) \mid \xi = 0, \ \eta = \pm 1\};$

$\mathrm{PSet3} = \{(\xi,\eta,\zeta) \mid \xi = \pm\sqrt{3}/3, \ \eta = \pm 1\};$

$\mathrm{PSet4} = \{(0,\pm 1,\pm 1), \ (0,\pm 1,0)\};$

$\mathrm{PSet5} = \{(0,0,0), \ (\pm 1,0,0), \ (0,\pm 1,0), \ (\pm 1,\pm 1,0)\};$

$\mathrm{PSet6} = \{(\xi,\eta,\zeta) \mid \zeta = 0\} \cup \{\pm(1 - \frac{\sqrt{3}}{3}, -1 + \frac{\sqrt{3}}{3}, \pm\frac{\sqrt{90-50\sqrt{3}}}{5})\};$

where FSR_n is the collection of the nth order 2D regular pattern function value superconvergence points of the Laplace equation, and $\mathrm{DSR}_{\xi,n}$ is the set of nth order 2D regular pattern ξ-derivative superconvergence points of the Laplace equation [18]. Superconvergence results of the η-derivatives are analogous to those of the ξ-derivatives.

6.3. Tetrahedral elements. Superconvergence results for tetrahedral elements of degree up to 4 are collected in Tables 5 and 6.

Here, TSet1 is the set of vertices and midpoints of edges of K; TSet2 is the set of vertices of K and midpoints of diagonal edges of K (e.g., edges $l_{1,21}$, $l_{1,23}$, $l_{1,25}$ in Figure 4); TSet3 is the set of midpoints of the edges of K which are parallel to the ξ-axis; and TSet4 is the set of second order Gaussian points along the edges of

TABLE 5

4	None	None	None

K which are parallel to the ξ-axis. Note that TSet$m$ and TSet$m$* are different due to the different partition schemes. For η- and ζ-derivatives, superconvergence results can be obtained analogously.

In addition, under partition scheme 2, if we consider derivatives along diagonal directions (e.g., directions of edges $l_{1,21}$, $l_{1,23}$, $l_{1,25}$ in Figure 4), there are superconvergence results. In particular, when $n = 1$ and 3, the midpoints of the edges parallel to the tangential direction are superconvergence points; when $n = 2$, the second order Gaussian points of the tangential direction edges are superconvergence points; when $n = 4$, there are no superconvergence points. The results hold for both the Poisson and the Laplace equations.

7. Concluding remarks. In this article, a systematic and analytic approach in determining 3D FE superconvergence points is presented. We investigate hexahedral, pentahedral, and tetrahedral elements, which are widely used in engineering applications. The results for the Poisson equation can be applied to many problems which have second order elliptic operators, including some nonlinear problems. The approach can be used to locate superconvergence points of any degree and provides conclusive results. We conclude this article by the following remarks.

Remark 7.1. In most 3D elements, superconvergence points of both the Poisson and Laplace equations are the same, as demonstrated in section 6. This is in contrast with the 2D cases, where there are many more superconvergence points of the Laplace equation than that of the Poisson equation for higher order elements. The reason is that, when $n \geq 2$, there are only two basis functions in the space of harmonic polynomials for each degree n in two dimensions, while there are $2n+3$ basis functions in the space of harmonic polynomials for each degree n in three dimensions. The likelihood of $2n + 3$ polynomials passing a common point is much smaller than the probability of two polynomials intersecting.

Remark 7.2. Although some superconvergence points can also be predicted by the symmetry theory and the tensor-product technique, we nevertheless provide conclusive results and demonstrate that in some cases symmetry points and/or points obtained by tensor-product are the only superconvergence points, while in other cases there are more superconvergence points which are not these types of points.

Remark 7.3. As indicated in [27, Chap. 14], many recovery techniques utilize a priori knowledge of natural superconvergence points. Therefore, the results in this paper are not only interesting by themselves but also good "hints" for more flexible and robust recovery methods.

Acknowledgment. The authors are grateful to the anonymous referees for their helpful comments and suggestions, which improved and polished the presentation of this article.

ANALYSIS OF AN ASYMPTOTIC PRESERVING SCHEME FOR THE EULER–POISSON SYSTEM IN THE QUASINEUTRAL LIMIT*

PIERRE DEGOND†, JIAN-GUO LIU‡, AND MARIE-HÉLÈNE VIGNAL†

Abstract. In a previous work [P. Crispel, P. Degond, and M.-H. Vignal, *J. Comput. Phys.*, 223 (2007), pp. 208–234], a new numerical discretization of the Euler–Poisson system was proposed. This scheme is "asymptotic preserving" in the quasineutral limit (i.e., when the Debye length ε tends to zero), which means that it becomes consistent with the limit model when $\varepsilon \to 0$. In the present work, we show that the stability domain of the present scheme is independent of ε. This stability analysis is performed on the Fourier transformed (with respect to the space variable) linearized system. We show that the stability property is more robust when a space-decentered scheme is used (which brings in some numerical dissipation) rather than a space-centered scheme. The linearization is first performed about a zero mean velocity and then about a nonzero mean velocity. At the various stages of the analysis, our scheme is compared with more classical schemes and its improved stability property is outlined. The analysis of a fully discrete (in space and time) version of the scheme is also given. Finally, some considerations about a model nonlinear problem, the Burgers–Poisson problem, are also discussed.

Key words. stiffness, Debye length, electron plasma period, Burgers–Poisson, sheath problem, Klein–Gordon

1. Introduction.

In a previous work [9] (see also [7]), a new numerical discretization of the Euler–Poisson system was proposed. The Euler–Poisson system under consideration consists of the isentropic Euler equations for the particle and momentum densities coupled with the Poisson equation through a source term modeling the electrostatic force. In dimensionless units, the coupling constant can be expressed in terms of a parameter ε which represents the scaled Debye length. When ε is small, the coupling is strong. In this situation, the particle density is constrained to be close to the background density of the oppositely charged particle, which we suppose to be uniform and equal to 1 in scaled units. The velocity then evolves according to the incompressible Euler equation. The limit $\varepsilon \to 0$ is called the quasineutral limit, since the charge density almost vanishes identically. When two or more particle species are considered, the limit $\varepsilon \to 0$ leads to a more complex model usually referred to in the physics literature as a quasineutral model. In the present work, we restrict ourselves to the case of a single particle species as described above.

The scheme which has been proposed in [9] and [7] is "asymptotic preserving" (AP) in the quasineutral limit, which means that it becomes consistent with the limit model when $\varepsilon \to 0$. The goal of the present work is to analyze the stability properties of this scheme in a one-dimensional framework and to show that its stability domain is independent of ε. This stability analysis is performed on the Fourier transformed (with

respect to the space variable) linearized system. We show that the stability property is more robust when a space-decentered scheme is used (which brings in some numerical dissipation) rather than a space-centered scheme. The linearization is first performed about a zero mean velocity and then about a nonzero mean velocity. At the various stages of the analysis, our scheme is compared with more classical schemes and its improved stability property is outlined. The analysis of a fully discrete (in space and time) version of the scheme is also given. Finally, some considerations about a model nonlinear problem, the Burgers–Poisson problem, are also discussed.

The Euler–Poisson model is one of the most widely used fluid models in plasma and semiconductor physics (see, e.g., [21], [1] for plasmas and [25] for semiconductors). It can be derived from a moment expansion of kinetic models such as the Vlasov or Boltzmann–Poisson equations supplemented with a convenient closure assumption (see the references cited above).

There are two important physical length and time scales associated with this model (see, e.g., [1], [21]): the Debye length and the electron plasma period. These two scales are related one to each other by the thermal speed, which is an order one quantity. We are interested in the quasineutral regime where both parameters can be very small compared with typical macroscopic length and time scales. A standard explicit scheme must resolve these microscale phenomena in order to remain stable. The satisfaction of these constraints requires huge computational resources which make the use of explicit methods almost impracticable.

The search for schemes free of such constraints has been the subject of a vast literature. A number of works deal with particle-in-cell (PIC) methods, which are specific discretizations of the kinetic model, the Vlasov–Poisson system (see, e.g., the direct implicit method [3], [23] and the implicit moment method [26], [27]). These methods have proved extremely efficient in a number of situations, but there are still regions where short time steps must be used (see, e.g., the recent discussion in [19]). So the improvement of classical time-stepping strategies, if possible, would offer attractive perspectives. More references can be found in [9]. We also mention that the strategy developed in the present paper has been applied to PIC codes in [10].

The present work deals with fluid models. For fluid models the literature is comparatively less abundant. We can refer the reader to the pioneering work [16] and the more recent works [2], [4], [28], [29]. When the fluid models are drift-diffusion models, implicit strategies have been proposed in [31], [32], [24].

To cancel the fast scales associated with electron plasma frequency, quasineutral models have been very frequently considered [15] (see also references in [9]). Recently, two-fluid quasineutral models have been studied [6], [8], [11], [12], [13], [14].

However, in situations where quasineutral and nonquasineutral regions coexist, a specific treatment is needed to connect the quasineutral model with a nonquasineutral model across the interface. Such situations arise in sheath problems (see, e.g., [18], [20], [12]; other references can be found in [9]). In such problems, one has often to deal with a dynamic interface—the tracking of which gives rise to a complex numerical problem. Additionally, the interface dynamics is not a priori known and either must be derived from an asymptotic analysis like in [12], [13], or [20] or must be inferred from physical considerations. In both cases, great care is required to ensure that the proper dynamics is implemented. Another problem is related to the fact that the quasineutral to nonquasineutral transition may not be a sharp transition, but rather a fairly diffuse one, and its approximation into a sharp interface may actually lead to some unphysical behavior.

For these reasons, it is highly desirable to develop numerical methods which automatically shift from a quasineutral to a nonquasineutral model across the transition region when such a transition is encountered. The scheme proposed in [9] serves this purpose. Additionally, it has been shown that the numerical cost of this scheme is the same as the standard strategy (we refer the reader to [9] for more details). The goal of the present work is to provide elements toward a rigorous analysis of its stability properties. We shall mostly restrict ourselves to a linearized stability analysis (except in section 5), although linearized stability analysis is insufficient when the solution is not close to the reference state.

The paper is organized as follows. In section 2, we present the model and our AP strategy. Our AP scheme consists in an implicit time-differencing of both the flux term in the mass balance equation and the source term in the momentum equation. For this reason, we shall refer to it as an implicit-implicit II scheme. It will be compared to schemes in which either one or the other or both terms are treated explicitly (referred to as the IE, EI, or EE schemes). For instance, the IE scheme is implicit in the mass flux term and explicit in the momentum source term. The classical strategy is the EI scheme, where the mass flux term is explicit and the momentum source term is implicit [16]. The EE strategy is unconditionally unstable as was shown by Fabre in [16] and as reviewed below. We will always consider an explicit time-differencing for the momentum flux term, so there will be no mention of it in our terminology.

In section 3, the Euler–Poisson system is linearized about zero mean velocity. The linearized Euler–Poisson LEP system has a wave-equation–like formulation, which is indeed a Klein–Gordon equation with an $O(\varepsilon)$ mass term, as shown in section 3.1.

The Fourier transformed (with respect to the space variable) system is considered in section 3.2, and the stability of the time-stepping strategy is analyzed on this model system. This analysis is a model for the analysis of a fully discrete scheme (in space and time) using a centered space-differencing. Indeed, the symbol of the continuous space derivative and that of a centered space-differencing are both purely imaginary and therefore behave in a similar way for stability considerations. Using the symbol of the continuous operator instead of the discrete one makes the computations a little bit simpler (we shall see that they are already quite complex) while still providing a significant insight into the properties of the fully discrete scheme. Of course, to mimic the fact that a fully discrete scheme cannot resolve large wave-numbers, the range of admissible wave-numbers is limited to a value $\pi/\Delta x$, where Δx is the value of the underlying space discretization. To support this approach, the fully discrete scheme will be analyzed in a particular situation.

In this section, we show that the AP strategy (i.e., the II scheme) is stable uniformly with respect to ε while the IE scheme is limited by a stability constraint of the form $\delta \leq O(\varepsilon)$, where δ is the time step. The IE scheme corresponds to an explicit time discretization of the wave-equation formulation of the LEP system, while the II is an implicit one. In the case of the II scheme, a stability analysis of a fully discrete scheme is given. This analysis shows that the scheme is stable provided that ε is small enough (compared to Δx). This can be easily understood since, when ε is large, the system is close to the standard Euler system for which a centered space-differencing is known to be unstable (even though the mass flux term is treated implicitly, the momentum flux is treated explicitly, and the standard instability of the centered scheme manifests itself).

For this reason, in section 3.3, the influence of a decentered space-differencing is investigated. The numerical diffusion is modeled by a diffusion term added to the mass

and momentum balance equations in the continuous model, leading to a linearized viscous Euler–Poisson (LVEP) model. Energy estimates for this system and for a space discretization of this system are given. The similarity of these estimates encourages us to discard the space discretization, and instead, we consider the Fourier transform (with respect to the space variable) of the continuous system, and we perform a stability analysis of the various time discrete schemes under consideration. The AP strategy (i.e., the II scheme) is compared with the EI scheme (which corresponds to the standard approach; see, e.g., [16]) and the EE scheme. Only the II scheme has a uniform stability with respect to ε. The EI scheme has a stability constraint of the form $\delta \leq O(\varepsilon)$, while the EE scheme is unconditionally unstable, as already noted by Fabre [16].

Only the II scheme has the desired asymptotic stability property. It remains to check if this property remains true when the system is linearized about a nonzero velocity u_0. This is performed in section 4. In this section, we restrict ourselves to the II scheme, but we investigate the influence of the space discretization by looking first at the Fourier transformed nonviscous LEP system (mimicking a space-centered differencing) and then at the LVEP system. As already pointed out, the II scheme for the nonviscous LEP system is only "marginally" uniformly stable in the sense that it is stable if ε is small enough (depending on u_0 and other parameters such as Δx), while the II scheme for the LVEP system is uniformly stable with respect to ε: there exists a stability region for δ which is independent of ε for ε ranging in the whole interval $[0, \infty)$. This result shows that the II scheme associated with a decentered space-differencing has the requested uniform stability property with respect to ε. This has been observed numerically in the simulations shown in [9].

There remains the question of knowing whether these results which are proved for the linearized system translate to the fully nonlinear system. In section 5, we consider a toy model for the Euler–Poisson system: the Burgers–Poisson system. We show that this system has an entropy-entropy flux pair and that a space semidiscrete system shares this property with the continuous model. This leads to a stability result for this semidiscrete scheme which allows us to prove a convergence estimate (at least as long as the solution of the Burgers–Poisson problem remains regular). The question whether an II time discretization of this model would show the same stability property is still an open question which will be investigated in future work. Another open problem is to show the stability of this scheme for weak solutions in the presence of shocks. This is a difficult question which has also been put aside in the present work (see, e.g., [5], [22] for the convergence analysis of numerical schemes for entropy solutions in the case of a standard hyperbolic problem).

The extension of the present analysis to two or more space dimensions is still an open problem. For example, in section 4, we restrict ourselves to waves propagating in the same direction as the constant velocity u_0 about which the linearization is performed. A more general setting would be a propagation at an oblique angle with respect to u_0. However, the analysis of section 4 is already quite complicated, and we shall leave this extension to future work. Let us just mention that the numerical simulations reported in [9] suggest that the scheme is actually uniformly stable also in the two-dimensional case.

A short conclusion is drawn in section 6.

A last short comment is in order to address the issue of convergence. Here, we are seeking stability for large time steps compared with ε. Therefore, the scheme cannot be a good approximation of the original (ε perturbed) problem but should

be an approximation of the limit quasineutral model. In the present one-dimensional linearized setting, the quasineutral limit is trivial (the linearized solution is identically zero). It is readily seen that taking the limit ε and Δt to 0 keeping $\varepsilon \ll \Delta t$ in all the AP schemes developed below leads to this limit, showing that they are all consistent with the quasineutral model. Using this remark, and the Wendroff technique combining stability and consistency, it is certainly possible to show the convergence of the AP scheme toward the solution of the quasineutral model. However, we shall not pursue this route in this paper.

2. Quasineutral limit of the Euler–Poisson system and asymptotically stable schemes.

2.1. Quasineutral limit. In this work, we are mainly concerned with the Euler–Poisson model. For the sake of simplicity, we shall restrict ourselves to a one-species model, but our scheme construction can be easily extended to any number of charged-particle species (see [7], [9]). The scaled one-species Euler–Poisson model (EP) is written

$$\partial_t n + \nabla \cdot q = 0, \tag{2.1}$$

$$\partial_t q + \nabla \cdot \left(\frac{q \otimes q}{n} \right) + \nabla p(n) = n \nabla \phi, \tag{2.2}$$

$$\varepsilon^2 \Delta \phi = n - 1, \tag{2.3}$$

where $n = n(x,t)$ is the particle number density, $p(n)$ is the hydrodynamic pressure, $q = q(x,t)$ is the momentum (i.e., $q = nu$, where $u(x,t)$ is the average velocity), $p(n) = n^\gamma$ is the pressure law with $\gamma \geq 1$, and $\phi = \phi(x,t)$ is the potential, where $x \in \mathbb{R}^d$ is the position and $t > 0$ is the time. The scheme construction can be easily extended to a model including the full energy equation in place of the isentropic assumption on the pressure.

Here, we consider negatively charged electrons (with scaled charge equal to -1), and the right-hand side of the Poisson equation involves a uniform ion background density equal to 1 in the present scaled variables. Again, this simplification is for the sake of clarity only and a space-dependent ion background density or a model with simultaneously evolving electrons and ions could be considered as well (see [7], [9]).

The dimensionless parameter $\varepsilon = \lambda_D / L$ is the scaled Debye length, i.e., the ratio of the actual Debye length λ_D to the macroscopic length scale L. We recall that the Debye length has the following expression in physical variables:

$$\lambda_D = \left(\frac{\epsilon_0 k_B T}{e^2 n_0} \right)^{1/2},$$

where ϵ_0 is the vacuum electric permittivity, k_B the Boltzmann constant, T the average plasma temperature, e the absolute electron charge, and n_0 the average plasma density.

In many instances, the Debye length is very small compared to the macroscopic length and thus $\varepsilon \ll 1$. In this case, the quasineutral limit $\varepsilon \to 0$ of system (2.1)–(2.3) can be considered. It leads to $n = 1$; i.e., the electron density must be everywhere equal to the background ion density and to the following quasineutral model (QN)

for the flux q:

$$\nabla \cdot q = 0, \tag{2.4}$$

$$\partial_t q + \nabla \cdot (q \otimes q) = \nabla \phi. \tag{2.5}$$

We note that ϕ is now the Lagrange multiplier of the incompressibility constraint (2.4) and, upon changing ϕ into $-\pi$, that the quasineutral model is nothing but the incompressible Euler equations with hydrostatic pressure π.

In the present paper, our goal is to analyze a class of numerical schemes for EP which remains uniformly stable in the limit $\varepsilon \to 0$. Such schemes have first been proposed and tested in [7], [9], where their uniform stability with respect to ε has been demonstrated.

The design of this class of scheme is based on the following remark. In the passage from EP to QN, the equation for the electric potential ϕ changes dramatically, from the Poisson equation (2.3) into

$$\Delta \phi = \nabla^2 : (q \otimes q), \tag{2.6}$$

where ∇^2 denotes the Hessian matrix and ":" the contracted product of rank two tensors. Any attempt to design a uniformly stable scheme in the limit $\varepsilon \to 0$ requires finding a different (and equivalent) formulation of the Poisson equation (2.3) in which the transition toward (2.6) when $\varepsilon \to 0$ appears explicitly.

Such a formulation is provided by the following equation:

$$-\nabla \cdot ((n + \varepsilon^2 \partial_{tt}^2) \nabla \phi) + \nabla^2 : f(n, q) = 0, \tag{2.7}$$

where the momentum flux tensor $f(n, q)$ is given by

$$f(n, q) = \frac{q \otimes q}{n} + p(n)\mathrm{Id}. \tag{2.8}$$

Equation (2.7) is formally equivalent to the Poisson equation provided (n, q) satisfies the mass and momentum equations (2.1), (2.2) and that the Poisson equation and its time derivative are satisfied at $t = 0$:

$$(\varepsilon^2 \Delta \phi - n + 1)|_{t=0} = 0, \quad (\partial_t (\varepsilon^2 \Delta \phi - n + 1))|_{t=0} = 0.$$

We refer the reader to [7], [9] for a proof of this equivalence. Essentially, it relies on a second order (wave-like) formulation of the Euler equations and replacing the second time derivative of the density in this formulation by the second time derivative of the Laplacian of the potential (thanks to the Poisson equation). We shall see below the importance of using a wave-like formulation of the Euler equations in this matter.

We remark that solving the elliptic equation (2.7) (after time discretization) is no more costly than solving the Poisson equation (2.3) since both of them are elliptic equations. However, one important advantage of (2.7) over (2.3) is that it does not degenerate when $\varepsilon \to 0$ and moreover reduces to the QN elliptic equation (2.6) for ϕ when $\varepsilon = 0$. Therefore, we can expect that the asymptotic stability with respect to ε is obtained if a suitable time discretization is used.

2.2. Asymptotically stable scheme in the quasineutral limit. The question of finding an asymptotically stable scheme in the QN limit is in the first place a question of time discretization. We propose a time discretization which formally satisfies this asymptotic stability property. Below, we shall suppose that the symbol D stands for space discretizations of the ∇ operator, and we shall postpone the question of finding suitable expressions of such operators to forthcoming sections.

First, we describe the most standard time marching procedure for solving the EP system. Suppose n^m, q^m, ϕ^m are approximations at time t^m of n, q, and ϕ, and let $\delta = t^{m+1} - t^m$. Then, the standard procedure consists in discretizing (2.1)–(2.3) by

$$\delta^{-1}\,(n^{m+1} - n^m) + D \cdot q^m = 0, \tag{2.9}$$

$$\delta^{-1}\,(q^{m+1} - q^m) + Df(n^m, q^m) = n^{m+1} D\phi^{m+1}, \tag{2.10}$$

$$\varepsilon^2 D^2 \phi^{m+1} = n^{m+1} - 1. \tag{2.11}$$

We note that the scheme involves an implicit computation of the electric force in the momentum equation but the cost stays the same as that of a fully explicit scheme. Indeed, n^{m+1} can be computed first by the mass equation (2.9). Then, ϕ^{m+1} is obtained by the Poisson equation (2.11). Finally, the momentum q^{m+1} can be advanced using (2.10). It is common wisdom in plasma physics that the stability of this scheme is constrained by the condition

$$\delta \lesssim \varepsilon, \tag{2.12}$$

which is very penalizing in the QN regime $\varepsilon \ll 1$.

Let us note that if an explicit electric force discretization is used at the right-hand side of (2.10), the scheme is simply unconditionally unstable [16].

Our new AP strategy consists in computing the mass flux in (2.9) implicitly. More precisely, we consider the following scheme:

$$\delta^{-1}\,(n^{m+1} - n^m) + D \cdot q^{m+1} = 0, \tag{2.13}$$

$$\delta^{-1}\,(q^{m+1} - q^m) + Df(n^m, q^m) = n^m D\phi^{m+1}, \tag{2.14}$$

$$\varepsilon^2 D^2 \phi^{m+1} = n^{m+1} - 1. \tag{2.15}$$

By reproducing the procedure which, in the continuous case, allowed us to pass from the standard formulation of the Poisson equation (2.3) to the reformulated one (2.7), we can transform the discrete Poisson equation (2.15) into a reformulated one:

$$\begin{aligned} &-D \cdot ((\delta^{-2}\varepsilon^2 + n^m) D\phi^{m+1}) \\ &\quad = -D^2 : f(n^m, q^m) - \delta^{-2}(2n^m - n^{m-1} - 1) := G(n^m, q^m, n^{m-1}). \end{aligned} \tag{2.16}$$

This is a new elliptic equation for ϕ^{m+1} which is formally equivalent to the original one (2.15), is as easy to solve, and does not degenerate when $\varepsilon \to 0$.

The first important remark about this scheme is that it provides a discretization of the QN Euler system (2.4), (2.5) when $\varepsilon = 0$; i.e., it is an AP scheme when $\varepsilon \to 0$. To see this, we can use either of the formulations (2.15) or (2.16) of the Poisson equation, coupled with (2.13)–(2.14). Of course, we suppose that at step m, the data n^m and q^m satisfy $n^m = 1$ and $D \cdot q^m = 0$. If we let $\varepsilon \to 0$ in (2.15), we first find

that $n^{m+1} = 1$. Then, given that $n^m = 1$, (2.13) yields $D \cdot q^{m+1} = 0$. Finally, (2.14) leads to

$$\delta^{-1}\,(q^{m+1} - q^m) + Df(1, q^m) = D\phi^{m+1},$$

which clearly gives a discretization of the QN Euler system (2.4), (2.5). Note that the standard scheme (2.9)–(2.11), which has an explicit mass flux, would lead to $D \cdot q^m = 0$, the other limiting equations remaining unchanged, and that this would not allow us to compute ϕ^{m+1}.

If one uses (2.16) instead of (2.15), then one first lets $\varepsilon \to 0$ in (2.16) leading to

$$-D \cdot (D\phi^{m+1}) = -D^2 : f(1, q^m)$$

(since $n^m = 1$), which is a discretization of the quasineutral potential equation (2.6). Then, by acting operator $D\cdot$ on (2.14) and using that $D \cdot q^m = 0$, we deduce that $D \cdot q^{m+1} = 0$. Finally, inserting this into (2.13), we get that $n^{m+1} = n^m = 1$, and again, we get a discretization of the QN Euler system (2.4), (2.5). Here, using the standard scheme (2.9), (2.10) (which has an explicit mass flux) in conjunction with the modified Poisson equation (2.16) would also lead to an AP scheme. However, it has been numerically experienced that this scheme is unstable, and so this possibility will be disregarded.

The second important remark is that the reformulated Poisson equation (2.16) allows us to compute ϕ^{m+1} in terms of known quantities $G(n^m, q^m, n^{m-1})$ from the previous time step. Indeed, once ϕ^{m+1} is known after solving (2.16), q^{m+1} can be computed by advancing the momentum equation (2.14), and then, n^{m+1} in turn is obtained by using the density equation (2.13). Therefore, the time marching procedure of the AP scheme (2.13)–(2.15) involves the same computational cost as that of the standard scheme (2.9)–(2.11).

Finally, even more importantly, we claim that, by contrast with the standard scheme, the AP scheme (2.13)–(2.15) is not constrained by the stability condition (2.12) but rather has a stability condition of the form

$$\delta = O(1) \quad \text{as } \varepsilon \to 0. \tag{2.17}$$

We stress, however, that the scheme is still constrained by the CFL condition of the hydrodynamic system (which is an $O(1)$ quantity in our scaled units), and this can be penalizing for electrons due to their very small mass. It is possible, however, to extend this strategy into a scheme which is asymptotically stable also in the small mass limit (see remark in [9]). This strategy will be developed in future works. We also note that similar ideas can be applied to the low Mach number limit of compressible Euler equations and to the drift approximation of highly magnetized plasmas (works also in progress).

The stability estimate (2.17) is so far formal. It has been verified in numerical computations using different types of space discretizations in [7], [9]. However, no rigorous arguments have been available so far. The goal of the present paper is to provide some rigorous support to the estimate (2.17) by analyzing the linearized system.

Two types of analyses will be performed. The first one uses Fourier analysis and keeps the time semidiscrete framework, mimicking space discretization by suitable Fourier symbols. The second one considers both a space semidiscrete setting (the so-called method of lines) and a full time and space discretization and develops energy estimates. Both methods show that the AP strategy gives rise to a stability constraint of the type (2.17) while the standard strategy has the more severe stability constraint (2.12).

3. The linearized system about zero velocity.

3.1. The linearization of the Euler–Poisson system. We linearize system (2.1)–(2.3) about the stationary homogeneous solution $n_0 = 1$, $q_0 = 0$, $\partial_x \phi_0 = 0$. We denote by $\zeta \ll 1$ the size of the initial perturbation to this stationary state. Then, we can formally expand the solution as follows: $n = 1 + \zeta n' + O(\zeta^2)$, $q = \zeta u' + O(\zeta^2)$, $\phi = \zeta \phi' + O(\zeta^2)$. Retaining only terms of order ζ, we are led to the following linearized Euler–Poisson LEP system (where the primes have been dropped for the sake of clarity):

$$\partial_t n + \partial_x u = 0, \tag{3.1}$$

$$\partial_t u + c_s^2 \partial_x n = \partial_x \phi, \tag{3.2}$$

$$\varepsilon^2 \partial_{xx} \phi = n, \tag{3.3}$$

where $c_s = \sqrt{p'(1)}$ is the speed of sound.

We note that both ϕ and u can be eliminated and the LEP system can be rephrased into a wave-like formulation (specifically a Klein–Gordon equation with mass equal to $1/\varepsilon^2$):

$$\partial_{tt}^2 n - c_s^2 \partial_{xx}^2 n + \frac{1}{\varepsilon^2} n = 0. \tag{3.4}$$

By a partial Fourier transform with respect to the x-variable, and denoting $\hat{n}(\xi, t)$, $\hat{u}(\xi, t)$, $\hat{\phi}(\xi, t)$ the transforms of n, u, and ϕ, we obtain

$$\partial_t \hat{n} + i\xi \hat{u} = 0, \tag{3.5}$$

$$\partial_t \hat{u} + i\xi c_s^2 \hat{n} = i\xi \hat{\phi}, \tag{3.6}$$

$$-\varepsilon^2 \xi^2 \hat{\phi} = \hat{n}. \tag{3.7}$$

After elimination of $\hat{\phi}$, the system reduces to a 2×2 system of the form

$$\begin{pmatrix} \partial_t \hat{n} \\ \partial_t \hat{u} \end{pmatrix} + \begin{pmatrix} 0 & i\xi \\ i\xi c_s^2 + \frac{i}{\varepsilon^2 \xi} & 0 \end{pmatrix} \begin{pmatrix} \hat{n} \\ \hat{u} \end{pmatrix} = 0. \tag{3.8}$$

Its solutions are of the form

$$\begin{pmatrix} \hat{n}(\xi, t) \\ \hat{u}(\xi, t) \end{pmatrix} = \begin{pmatrix} \hat{n}_+(\xi) \\ \hat{u}_+(\xi) \end{pmatrix} e^{i\theta^\varepsilon(\xi)t} + \begin{pmatrix} \hat{n}_-(\xi) \\ \hat{u}_-(\xi) \end{pmatrix} e^{-i\theta^\varepsilon(\xi)t}, \tag{3.9}$$

where

$$\theta^\varepsilon(\xi) = \left(c_s^2 \xi^2 + \frac{1}{\varepsilon^2} \right)^{1/2}. \tag{3.10}$$

The quantities $s_\pm = \pm i\theta^\varepsilon(\xi)$ are the two eigenvalues of the matrix A at the left-hand side of (3.8). The vectors $(\hat{n}_\pm(\xi), \hat{u}_\pm(\xi))^T$ are obtained as the projections of the initial data $(\hat{n}_0, \hat{u}_0)^T$ onto the associated eigenspaces of A (here the exponent T denotes the transpose).

From (3.9) and the fact that $|e^{\pm i\theta(\xi)t}| = 1$, we see that the L^2 norm of the solution in Fourier space stays bounded in time, which by Plancherel's identity shows that the corresponding L^2 norm in physical space also stays bounded in time. Additionally, when $\varepsilon \to 0$, we have

$$\theta^\varepsilon \sim \frac{1}{\varepsilon} \to \infty,$$

which shows that the solution has high frequency time oscillations of frequency $\sim \frac{1}{\varepsilon}$, irrespective of the value of the wave-number ξ.

Therefore, the quasineutral limit $\varepsilon \to 0$ gives rise to high frequency oscillations which are nothing but the ubiquitous plasma oscillations of the physics literature. Explicit schemes are constrained to resolve these oscillations as a condition for their stability, as we shall see below.

Another viewpoint which emphasizes the wave-like behavior of this system is that of energy estimates. Multiplying (3.4) by $2n_t$, one has

$$\partial_t\Big((\partial_t n)^2 + c_s^2(\partial_x n)^2 + \frac{1}{\varepsilon^2}n^2\Big) = 2c_s^2\partial_x\Big(\partial_x n\partial_t n\Big). \tag{3.11}$$

Integrating over the computational domain, say, (a, b), to fix the idea, we get

$$\partial_t \int_a^b \Big((\partial_t n)^2 + c_s^2(\partial_x n)^2 + \frac{1}{\varepsilon^2}n^2\Big)\,dx = 2c_s^2\Big(\partial_x n\partial_t n\Big)\Big|_a^b. \tag{3.12}$$

If periodic or homogeneous Dirichlet or homogeneous Neumann conditions are imposed at the boundary points, the right-hand side of the above equation vanishes and conservation of energy follows:

$$\partial_t \int_a^b \Big((\partial_t n)^2 + c_s^2(\partial_x^2 n)^2 + \frac{1}{\varepsilon^2}n^2\Big)\,dx = 0. \tag{3.13}$$

This energy estimate indicates a wave-like behavior. When $\varepsilon \to 0$, more and more energy is stored in the last term, which can be interpreted as a potential.

Below, we state stability criteria for various kinds of time discretizations of the LEP system.

3.2. AP strategy with centered-like space-differencing. For the LEP system in Fourier variables (3.5)–(3.7), our scheme (2.13)–(2.15) reads

$$\frac{\hat{n}^{m+1} - \hat{n}^m}{\delta} + i\xi\hat{u}^{m+1} = 0, \tag{3.14}$$
