Let us denote the system matrix in (1.12) by A. The symmetric matrix A is indefinite due to the zero diagonal block of dimension $NBC = NE + NIF + NNC$. The structure of nonzero elements in the matrix from a small model problem can be seen in Figure 1. Partition the submatrix C in A as $(C_1\ C_2)$, where $C_1 \in \mathcal{R}^{NA,NIF}$ corresponds to the interior interelement faces in the discretized domain and $C_2 \in \mathcal{R}^{NA,NNC}$ is the face-condition incidence matrix corresponding to the element faces with Neumann boundary conditions. Note that every column of C_1 contains only two nonzero entries equal to 1. The singular values of C_1 are all equal to $\sqrt{2}$ and the matrix block C_2 has orthogonal columns. Moreover, the whole matrix block C also has singular values equal to $\sqrt{2}$ or 1. The matrix B has a special structure. The

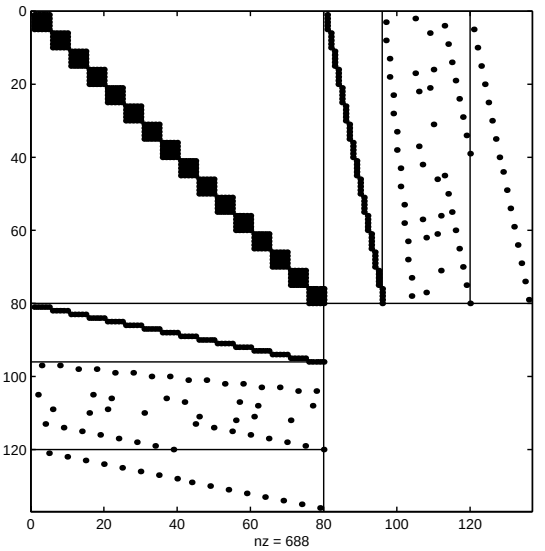

FIG. 1. *Structural pattern of the matrix obtained from mixed hybrid finite element approximation of a model problem with* $h = 1/2$ *(to be discussed in section* 5*).*

nonzero elements correspond to the face-element incidence matrix with values equal to -1. Thus all singular values of the matrix B are equal to $\sqrt{5}$. (The matrix B is, up to the normalization coefficients, orthogonal.)

It is easy to see from the definition of approximation spaces (see [14] or [15]) that the symmetric positive definite block is 5×5 block diagonal, and it was shown in [15] that the spectrum of the matrix block A satisfies

$$\sigma(A) \subset [c_1 \sqrt[3]{NE}, c_2 \sqrt[3]{NE}], \tag{1.13}$$

where c_1 and c_2 are positive constants independent of the discretization parameters and dependent on the domain and the tensor $\mathbf{A}$. It is also easy to see that the system matrix A in (1.12) is nonsingular if and only if the block $(B\ C)$ has a full column rank. Clearly, if the condition $\partial\Omega_D = \emptyset$ holds (all boundary conditions are Neumann conditions), then the matrix block $(B\ C)$ is singular due to the fact that all sums of row elements are zero. In other words, the function p is unique up to a constant function in the case $\partial\Omega_D = \emptyset$. Assuming $\partial\Omega_D \neq \emptyset$ it follows from the analysis presented in [15] that there exist positive constants c_3 and c_4 such that for the singular values of the matrix block $(B\ C)$ we have

$$sv(B\ C) \subset [c_3/\sqrt[3]{NE}, c_4]. \tag{1.14}$$

Moreover, for eigenvalues of the whole symmetric indefinite matrix A it follows asymptotically $(h \to 0)$

$$\sigma(\mathsf{A}) \subset [-c_5/\sqrt[3]{NE}, -c_6/NE] \cup [c_7 \sqrt[3]{NE}, c_8 \sqrt[3]{NE}], \tag{1.15}$$

where c_5, c_6, c_7, and c_8 are positive constants independent of system parameters.

In this paper, for solving the symmetric indefinite systems (1.12), the successive reduction to Schur complement systems is proposed. We consider three successive

Schur complement systems arising during the block elimination of unknowns which correspond to matrix blocks A, B, and C_2, respectively, or in other words, which correspond to the elimination of the velocity variables u, the pressure variables p, and of a part of the Lagrange multipliers λ. While the concept of reduction to the first and second Schur complement systems is well known as a static condensation (described, e.g., in [4], section V, or in [11]), the proposed reduction to the third Schur complement system seems to be new. The main contribution of the paper consists in a detailed investigation of the structure of nonzero entries and the spectral properties of the Schur complement matrices. This enables thorough complexity analysis of the direct or iterative solution of corresponding Schur complement systems. A brief analysis of the structure of the first Schur complement matrix can be found in [4], as well as a straightforward observation that its principal leading block is a diagonal. Here we extend this analysis and discuss the mutual relation between the number of nonzero entries in the first Schur complement matrix and the number of nonzeros in the system matrix (1.12). We show further that no fill-in occurs during the process of reduction to the second and third Schur complement system. Moreover, we prove that the number of nonzeros in both these two Schur complements is always less than the number of nonzeros in (1.12). It is shown also that the spectral properties of matrices in such Schur complement systems do not deteriorate during the successive elimination. Thus an approach based on the block reduction and subsequent iterative solution is well justified.

The outline of the paper is as follows. In section 2, we examine the structural pattern of resulting Schur complement matrices and give estimates for their number of nonzero elements in terms of the discretization parameters listed above. Section 3 is devoted to the solution of the whole indefinite system (1.12) via three Schur complement reductions and subsequent direct solution. Using the graph theoretical results we give the asymptotic bound of the computational complexity for the Cholesky decomposition method applied to the third Schur complement system. In section 4, we concentrate on the spectral properties of the Schur complement system matrices. The theoretical convergence rate of the iterative conjugate gradient-type method in terms of the discretization parameters is estimated. The asymptotic bounds for the computational work of the iterative solution are given. Section 5 contains some numerical experiments illustrating the previously developed theoretical results. Finally, we give some concluding remarks and mention some open questions for our future work.

2. Structural properties of the Schur complement matrices. In this section we take a closer look at the discretized indefinite system and corresponding Schur complements, and we extend the brief analysis from [4]. There are several possibilities for the choice of a block ordering in the consecutive elimination. We shall concentrate on the block ordering which seems to be the most natural and efficient from the point of view of solving the final Schur complement system by a direct solver or by a conjugate gradient-type method. The same ordering for the elimination of the first two blocks was used also in [4, p. 178–181] or in [11]. Note that the static condensation is not the only way to form the successive Schur complements. For example, in [17] the case of the Raviart–Thomas discretization for the closely related nodal methods was studied and reduction to a different second Schur complement system was discussed.

The following simple result gives the number of nonzero elements in the triangular part of the matrix A. By the triangular part of a matrix M we mean its upper (lower) strict triangle + diagonal. We will deal only with the structural nonzero elements here; we do not take into account accidental cancellations and possible initial zero

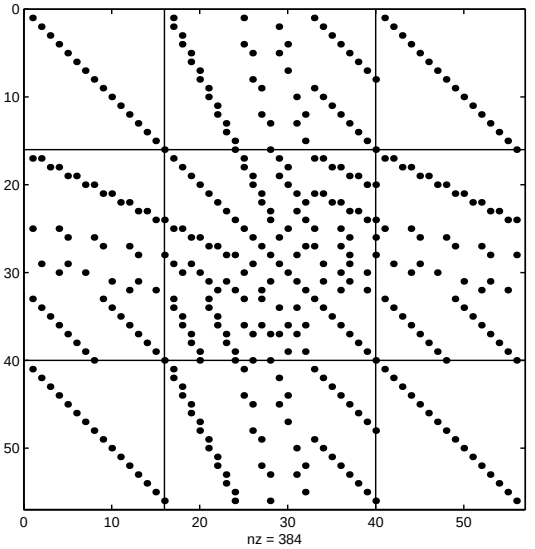

FIG. 2. *Structural pattern of the Schur complement matrix* A/A *for* A *from Figure* 1.

values of the tensor of hydraulic permeability. By the structure of a matrix M we mean $Struct(M) = \{(i,j)|M_{ij} \neq 0\}$.

LEMMA 2.1. *The number of nonzeros in the triangular part of* A *is given by*

$$|sym(A)| = 20NE + 2NIF + NNC. \tag{2.1}$$

Proof. The triangular part of A has $15NE$ nonzeros, the block B contributes by $5NE$ nonzeros, C_1 has $2NIF$ nonzeros, and C_2 contains NNC nonzeros. □

The symmetric positive definite matrix block A in (1.12) is block-diagonal, each 5×5 block corresponds to certain element in the discretization of the domain. Therefore it is straightforward to eliminate the velocity variables u and to obtain the first Schur complement system with the matrix

$$\mathsf{A}/A = -\begin{pmatrix} B^T \\ C_1^T \\ C_2^T \end{pmatrix} A^{-1} \begin{pmatrix} B & C_1 & C_2 \end{pmatrix} = -\begin{pmatrix} A_{11} & A_{12} & A_{13} \\ A_{12}^T & A_{22} & A_{23} \\ A_{13}^T & A_{23}^T & A_{33} \end{pmatrix}.$$

The structure of the matrix A/A for our example problem is shown in Figure 2. For details we also refer to [4, p. 180–181] or [11]. For the number of nonzeros in the matrix A/A we can show the following result.

LEMMA 2.2. *The number of nonzeros in the triangular part of the Schur complement matrix* A/A *is equal to*

$$|sym(\mathsf{A}/A)| = NE + \frac{3}{2}NIF + \frac{3}{2}NNC + \frac{1}{2}\sum_{i \in \mathcal{E}_h}(NIF_i + NNC_i)^2 + \frac{1}{2}\sum_{i \in \mathcal{E}_h}\sum_{j \in Adj(i)} NIF_j.$$

Proof. Clearly, $|sym(A_{11})| = NE$ and $|A_{12}| = |B^T A^{-1} C_1| = 2NIF$. Note that the fill-in for $A^{-1}C_1$ is considerably higher (it is equal to $10NIF$). Further, $|A_{13}| = NNC$ and $|sym(A_{33})| = \frac{1}{2}\sum_{i \in \mathcal{E}_h} NNC_i(NNC_i + 1) = \frac{1}{2}NNC + \frac{1}{2}\sum_{i \in \mathcal{E}_h} NNC_i^2$. The number

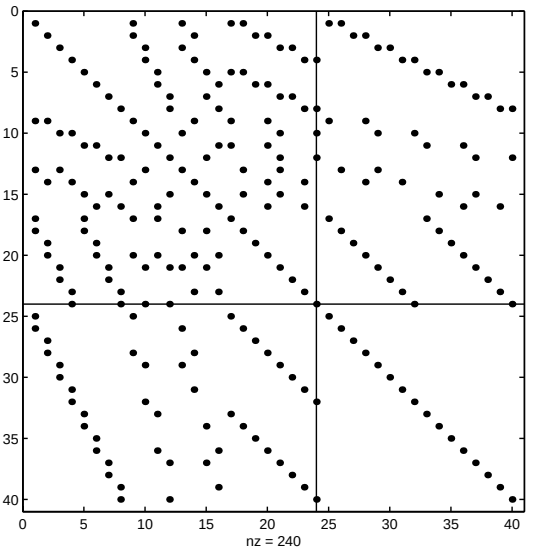

FIG. 3. *Structural pattern of the Schur complement matrix* $(-\mathsf{A}/A)/A_{11}$ *for* A *from Figure* 1.

of nonzeros in A_{23} is equal to $\sum_{i\in\mathcal{E}_h} NNC_i\, NIF_i$. Finally, note that

$$Struct(A_{22}) = Struct(C_1^T A^{-1} C_1) = Struct(C_1^T B B^T A^{-1} C_1) = Struct(C_1^T B B^T C_1).$$

Observe that the directed graph of the matrix $B^T C_1$ has the set of arcs

$$E_{B^T C_1} = \{(i,f) \in \mathcal{E}_h \times int(\Gamma_h) |\ f \text{ is an interior face of } i\}.$$

The undirected graph of $C_1^T B B^T C_1$ therefore expresses element-element adjacency relation based on the connectivity through the interior faces inside the domain. It follows that

$$|A_{22}| = \sum_{f\in int(\Gamma_h)} (NIF_{e(f)} + NIF_{\bar{e}(f)} - 1) = \sum_{i\in\mathcal{E}_h} NIF_i(NIF_i - 1) + \sum_{i\in\mathcal{E}_h} \sum_{j\in Adj(i)} NIF_j,$$

where $e(f)$ and $\bar{e}(f)$ are the two elements from $\mathcal{E}_h$ such that $e(f) \cap \bar{e}(f) = \{f\}$. Therefore, considering the relation $2NIF = \sum_{i\in\mathcal{E}_h} NIF_i$ we obtain $|sym(A_{22})| = \frac{1}{2}(|A_{22}| + NIF) = \frac{1}{2}\sum_{i\in\mathcal{E}_h}(NIF_i)^2 + \frac{1}{2}\sum_{i\in\mathcal{E}_h}\sum_{j\in Adj(i)} NIF_j - \frac{1}{2}NIF$. Putting all the partial sums together we get the desired result. □

Consider now the second Schur complement matrix

$$(-\mathsf{A}/A)/A_{11} = -\begin{pmatrix} A_{12}^T \\ A_{13}^T \end{pmatrix} A_{11}^{-1} \begin{pmatrix} A_{12} & A_{13} \end{pmatrix} + \begin{pmatrix} A_{22} & A_{23} \\ A_{23}^T & A_{33} \end{pmatrix} = \begin{pmatrix} B_{11} & B_{12} \\ B_{12}^T & B_{22} \end{pmatrix}.$$

The structure of $(-\mathsf{A}/A)/A_{11}$ for our example matrix is shown in Figure 3. The matrix block A_{11} in the first Schur complement matrix A/A is diagonal [4], [11]. The following result shows that it is worth to form the Schur complement matrix $(-\mathsf{A}/A)/A_{11}$ from the matrix A/A since no further fill-in appears during the elimination of the block A_{11} corresponding to pressure variables p and so we can further reduce the dimension of the system.

THEOREM 2.1.

$$Struct\begin{pmatrix} B_{11} & B_{12} \\ B_{12}^T & B_{22} \end{pmatrix} = Struct\begin{pmatrix} A_{22} & A_{23} \\ A_{23}^T & A_{33} \end{pmatrix}.$$

Proof. We have the following structural equivalences:

$$\begin{aligned} Struct(B_{11}) &= Struct(A_{22}) + Struct(A_{12}^T A_{11}^{-1} A_{12}) \\ &= Struct(A_{22}) + Struct(C_1^T A^{-1} B A_{11} B^T A^{-1} C_1) \\ &= Struct(A_{22}) + Struct(C_1^T A^{-1} B B^T A^{-1} C_1) \\ &= Struct(A_{22}) + Struct(C_1^T B B^T C_1) = Struct(A_{22}), \end{aligned}$$

$$\begin{aligned} Struct(B_{12}) &= Struct(A_{23}) + Struct(A_{12}^T A_{11}^{-1} A_{13}) \\ &= Struct(A_{23}) + Struct(C_1^T A^{-1} B B^T A^{-1} C_2) \\ &= Struct(A_{23}) + Struct(C_1^T B B^T C_2) \\ &= Struct(A_{23}) + Struct(C_1^T A^{-1} C_2) = Struct(A_{23}), \end{aligned}$$

$$\begin{aligned} Struct(B_{22}) &= Struct(A_{33}) + Struct(A_{13}^T A_{11}^{-1} A_{13}) \\ &= Struct(A_{33}) + Struct(C_2^T A^{-1} B A_{11}^{-1} B^T A^{-1} C_2) \\ &= Struct(A_{33}) + Struct(C_2^T A^{-1} C_2) = Struct(A_{33}). \end{aligned}$$ ∎

From previous theorem it is also easy to see that right lower block B_{22} is block-diagonal with blocks of varying size (depending on number of faces with Neumann conditions in each element) each corresponding to a certain element in the discretization. So in the following we will consider the third Schur complement matrix

$$((-\mathsf{A}/A)/A_{11})/B_{22} = B_{11} - B_{12} B_{22}^{-1} B_{12}^T$$

induced by the block B_{22} in the matrix $(-\mathsf{A}/A)/A_{11}$. We can prove a similar result to the one given in Theorem 2.1. Therefore, the Schur complement system with the matrix $-(\mathsf{A}/A)/A_{11}$ can be reduced to the Schur complement matrix $((-\mathsf{A}/A)/A_{11})/B_{22}$ of dimension equal to *NIF* without inducing any additional fill-in. Moreover, this can be done using incomplete factorization procedures.

THEOREM 2.2.

$$Struct(B_{11} - B_{12} B_{22}^{-1} B_{12}^T) = Struct(A_{22}).$$

Proof. Using Theorem 2.1 we get

$$\begin{aligned} Struct(B_{11} - B_{12} B_{22}^{-1} B_{12}^T) &= Struct(B_{11}) + Struct(B_{12} B_{22}^{-1} B_{12}^T) \\ &= Struct(A_{22}) + Struct(A_{23} A_{33}^{-1} A_{23}^T) \\ = Struct(A_{22}) + Struct(C_1^T A^{-1} C_2 C_2^T A^{-1} C_2 C_2^T A^{-1} C_1). \end{aligned}$$

Since $Struct(C_1^T A^{-1} C_2 C_2^T A^{-1} C_2 C_2^T A^{-1} C_1) \subset Struct(A_{22})$ (with equality only in the trivial singular case with $|\mathcal{E}_h| = 1$ and $NNC = 5$) we get the desired result $Struct(B_{11} - B_{12} B_{22}^{-1} B_{12}^T) = Struct(A_{22})$. ∎

The following simple corollary gives the number of nonzero elements in the second and third Schur complement matrices $(-\mathsf{A}/A)/A_{11}$ and $((-\mathsf{A}/A)/A_{11})/B_{22}$. We shall use these results later.

COROLLARY 2.1. *The number of nonzeros in the triangular part of* $(-\mathsf{A}/A)/A_{11}$ *is given by*

$$|sym((-\mathsf{A}/A)/A_{11})| = \\ = \frac{1}{2}\sum_{i\in\mathcal{E}_h}(NIF_i + NNC_i)^2 + \frac{1}{2}\sum_{i\in\mathcal{E}_h}\sum_{j\in Adj(i)} NIF_j + \frac{1}{2}(NNC - NIF) \tag{2.2}$$

and the number of nonzeros in the triangular part of $(-\mathsf{A}/A)/A_{11})/B_{22}$ *is given by*

$$|sym(((-\mathsf{A}/A)/A_{11})/B_{22})| = \frac{1}{2}\sum_{i\in\mathcal{E}_h} NIF_i^2 + \frac{1}{2}\sum_{i\in\mathcal{E}_h}\sum_{j\in Adj(i)} NIF_j - \frac{1}{2}NIF. \tag{2.3}$$

Apart from explicit assembly of the Schur complement matrices or using them implicitly there is another possibility which may be considered—keeping the Schur complements in factorized form. Consider the following decomposition:

$$\begin{aligned} \mathsf{A}/A &= -[L_A^{-1}\begin{pmatrix} B & C_1 & C_2\end{pmatrix}]^T[L_A^{-1}\begin{pmatrix} B & C_1 & C_2\end{pmatrix}] \\ &= \begin{pmatrix}\hat{B} & \hat{C}_1 & \hat{C}_2\end{pmatrix}^T\begin{pmatrix}\hat{B} & \hat{C}_1 & \hat{C}_2\end{pmatrix}, \end{aligned} \tag{2.4}$$

where $A = L_A L_A^T$. In contrast to the previous case, where the local numbering of the faces corresponding to the individual elements did not play a role, this is not the case now.

THEOREM 2.3. *Assume that all the elements within the diagonal blocks of the matrix* A *are nonzero. The fill-in in* $\begin{pmatrix}\hat{B} & \hat{C}_1 & \hat{C}_2\end{pmatrix}$ *is minimal if the faces with Dirichlet boundary conditions are numbered first in the local ordering of each finite element.*

Proof. Because of the block structure of A we can consider the individual finite elements independently. The minimum value of the nonzero count of $\hat{C}_1 \cup \hat{C}_2$ in five subsequent rows which correspond to the same finite element is $\frac{1}{2}\sum_{i\in\mathcal{E}_h}(NIF_i + NNC_i)(NIF_i + NNC_i + 1)$ and it is easily checked to be minimal in this case. ∎

Therefore, from now we assume that within each element we have first numbered the faces corresponding to Dirichlet boundary conditions, then the interior interelement faces and finally the faces with Neumann boundary conditions. The matrix (2.4) can be written in the form

$$\begin{pmatrix}\hat{B} & \hat{C}_1 & \hat{C}_2\end{pmatrix}^T\begin{pmatrix}\hat{B} & \hat{C}_1 & \hat{C}_2\end{pmatrix} = \begin{pmatrix}\hat{B}^T\hat{B} & \hat{B}^T\hat{C}_1 & \hat{B}^T\hat{C}_2 \\ \hat{C}_1^T\hat{B} & \hat{C}_1^T\hat{C}_1 & \hat{C}_1^T\hat{C}_2 \\ \hat{C}_2^T\hat{B} & \hat{C}_2^T\hat{C}_1 & \hat{C}_2^T\hat{C}_2\end{pmatrix}. \tag{2.5}$$

It is clear that it is more advantageous to keep most of the blocks of (2.5) in the explicit form multiplying the factors directly. A typical example is the block $\hat{B}^T\hat{B}$, which is a diagonal matrix. The main question here is whether we can reduce the system further as in the previous case and at the same time keep the matrix blocks in a factorized form. Unfortunately, there is one basic obstacle. Whereas we are able to embed the structure of $A_{12}^T A_{11}^{-1} A_{12}$ into the structure of A_{22} we cannot in general express $\hat{C}_1^T\hat{C}_1 - C_1^T\hat{B}(\hat{B}^T\hat{B})^{-1}\hat{B}^T C_1 = \hat{C}_1^T(I - \hat{B}(\hat{B}^T\hat{B})^{-1}\hat{B}^T)C_1$ in the factorized form as $\hat{C}_1^T L_{B_{11}} L_{B_{11}}^T \hat{C}_1$, where $L_{B_{11}}$ is factor which can be easily computed.

We have considered the partially factorized structure (2.5) since it is important from a computational point of view. Using a structural prediction based on such factors is exactly the way how to obtain the *sparsity structure* of explicit Schur complement matrices $-\mathsf{A}/A$, $(-\mathsf{A}/A)/A_{11}$, and $((-\mathsf{A}/A)/A_{11})/B_{22}$ in an efficient way. In our implementations we used a procedure similar to the one from [16] to get these structures.

3. Direct solution of the Schur complement systems. In the following we will discuss the direct solution of the Schur complement systems. Namely, we will concentrate on the system with the matrix $((-\mathsf{A}/A)/A_{11})/B_{22} \in \mathcal{R}^{NIF,NIF}$. The following theorem gives a bound on the asymptotic work necessary to solve the linear system (1.12), which is dominated by the decomposition of the matrix $((-\mathsf{A}/A)/A_{11})/B_{22}$.

THEOREM 3.1. *The number of arithmetic operations to solve the symmetric indefinite system* (1.12) *directly via three consecutive block eliminations and using the Cholesky decomposition is* $O(NIF^2)$.

Proof. We will only give a sketch of the proof here. The work is dominated by the decomposition of $B_{11} - B_{12}B_{22}^{-1}B_{12}^T$, which has the same nonzero structure as A_{22}.

Our uniform regular finite element mesh is a well-shaped mesh in a suitable sense (see [19]). The proof of Lemma 2.2 and the statements of Theorems 2.1 and 2.2 imply that the graph G of $((-\mathsf{A}/A)/A_{11})/B_{22}$ is also the graph of a well-shaped mesh. Namely, it is a bounded-degree subgraph of some overlap graph (see [18], [19]). It was shown in [25] that the upper bound on the second-smallest eigenvalue of the Laplacian matrix of G (the Fiedler value) is of the order $O(1/NIF^{2/3})$. Then using the techniques from [25] we obtain that there exists a $O(NIF^{2/3})$-size bisector of G.

Therefore, G satisfies the so-called $NIF^{2/3}$-separator theorem: there exist constants $1/2 \leq \alpha\langle 1, \beta\rangle 0$ such that the vertices of G can be partitioned into sets G_A, G_B and the vertex separator G_C such that $|G_A|, |G_B| \leq \alpha NIF$ and $|G_C| \leq \beta NIF^{2/3}$. Moreover, any subgraph of G satisfies the $NIF^{2/3}$-separator theorem. The technique of recursive partitioning of G called generalized nested dissection and used to reorder the considered Schur complement matrix provides an elimination ordering with an $O(NIF^2)$-bound on the arithmetic work of Cholesky decomposition (see Theorem 6 in [12]). □

Note that the explicit computation of the matrix $((-\mathsf{A}/A)/A_{11})/B_{22}$ is necessary in the framework of direct methods. Theorem 3.1 provides a theoretical result which is based on spectral partitioning methods. The reordering algorithms based on the separators obtained by the spectral partitioning techniques and applied recursively within the nested dissection need not necessarily be the best practical approach to get a reasonable matrix reordering. Nevertheless, experimental results with various partitioning schemes show that high quality reorderings can be efficiently computed in this way (see [7]). Also some other reorderings which combine global procedures (partitioning of large meshes) and local algorithms (like MMD) can provide reasonable strategies to find a fill-in minimizing permutation.

4. The conjugate gradient method applied to the Schur complement systems. In this section we concentrate on the iterative solution of the Schur complement systems discussed in section 3. We consider the conjugate gradient method applied to the symmetric positive definite systems with matrices $-\mathsf{A}/A$, $((-\mathsf{A}/A)/A_{11})$, and $((-\mathsf{A}/A)/A_{11})/B_{22}$. It is well known that the convergence rate of the conjugate gradient method can be bounded in terms of the condition number of the corresponding Schur complement matrix [9], [6], [26]. We show that the condition number of the matrix A/A is asymptotically the same as the conditioning of the negative part of spectrum of the whole indefinite matrix A. Moreover, we prove that condition numbers of the matrices $((-\mathsf{A}/A)/A_{11})$ and $((-\mathsf{A}/A)/A_{11})/B_{22}$ grow like $1/h^2$ with respect to the discretization parameter h and they do not deteriorate during the successive eliminations. Based on these results we estimate the number of iteration steps necessary to achieve the prescribed tolerance in error norm reduction. We show that the number of iteration steps necessary to reduce the error norm by the factor of ε

grows asymptotically like $1/h$ for all three Schur complement systems. Therefore, the total number of flops in the iterative algorithm can be significantly reduced due to decrease of the matrix order during the elimination. First, we consider the following theorem.

THEOREM 4.1. *Let $\mu_1 \geq \mu_2 \geq \cdots \geq \mu_{NA} > 0$ be the eigenvalues of the positive definite block $A \in \mathcal{R}^{NA,NA}$, $\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_{NBC} > 0$ be the singular values of the matrix block $(B\ C) \in \mathcal{R}^{NA,NBC}$. Then for the eigenvalues of the Schur complement matrix $-\mathsf{A}/A = (B\ C)^T A^{-1}(B\ C)$ we have*

$$\sigma(-\mathsf{A}/A) \subset [\sigma^2_{NBC}/\mu_1, \sigma^2_1/\mu_{NA}]. \tag{4.1}$$

Moreover, for the eigenvalues of the positive definite matrix blocks $\begin{pmatrix} A_22 & A_23 \\ A_{22}^T & A_33 \end{pmatrix} = (C_1\ C_2)^T A^{-1}(C_1\ C_2)$ and $A_{11} = B^T A^{-1} B$ it follows that

$$\sigma \begin{pmatrix} A_{22} & A_{23} \\ A_{23}^T & A_{33} \end{pmatrix} \subset [1/\mu_1, 2/\mu_{NA}], \tag{4.2}$$

$$\sigma(A_{11}) \subset [5/\mu_1, 5/\mu_{NA}]. \tag{4.3}$$

The condition number of the Schur complement system matrix $-\mathsf{A}/A$ then can be bounded by the expression

$$\kappa(-\mathsf{A}/A) \leq \frac{\sigma_1^2 \mu_1}{\sigma^2_{NBC}\mu_{NA}} = \kappa^2((B\ C))\kappa(A). \tag{4.4}$$

Proof. The positive definite matrix A^{-1} has the spectrum $0 < 1/\mu_1 \leq 1/\mu_2 \leq \cdots \leq 1/\mu_{NA}$. The first inclusion in the theorem follows from the following two inequalities

$$\frac{1}{\mu_1}((B\ C)x, (B\ C)x) \leq ((B\ C)^T A^{-1}(B\ C)x, x) \leq \frac{1}{\mu_{NA}}((B\ C)x, (B\ C)x),$$
$$\sigma^2_{NBC}(x,x) \leq ((B\ C)^T (B\ C)x, x) \leq \sigma_1^2(x,x).$$

Similarly, from the inequalities

$$\frac{1}{\mu_1}(Cx, Cx) \leq (C^T A^{-1} Cx, x) \leq \frac{1}{\mu_{NA}}(Cx, Cx),$$
$$(x,x) \leq (C^T Cx, x) \leq 2(x,x)$$

we obtain the second inclusion. The third part of the proof is completely analogous to the second part. ∎

COROLLARY 4.1. *There exist positive constants c_9 and c_{10} such that for the spectrum of the Schur complement matrix $-\mathsf{A}/A$ we have*

$$\sigma(-\mathsf{A}/A) \subset [c_9/NE, c_{10}/\sqrt[3]{NE}], \tag{4.5}$$

where $c_9 = c_3^2/c_2$ and $c_{10} = c_4^2/c_1$. The condition number of the matrix $-\mathsf{A}/A$ can be bounded as

$$\kappa(-\mathsf{A}/A) \leq c_{11}\sqrt[3]{NE^2}, \quad c_{11} = c_{10}/c_9. \tag{4.6}$$

The Schur complement system with positive definite matrix $-\mathsf{A}/A$ can be solved iteratively by the conjugate gradient method [9] or the conjugate residual method [6]. It is well known that the conjugate gradient method generates the approximate solutions which minimize the energy norm of the error at each iteration step [26], [6]. The closely related conjugate residual method that differ only in the definition of innerproduct, on the other hand, generates the approximate solutions which minimize their residual norm at every iteration [6]. It is also a well known fact that there exists so-called peak/plateau connection between these methods [5] showing that there is no significant difference in the convergence rate of these methods when measured by the residual norm of an approximate solution. In our paper we use the conjugate gradient method together with the minimal residual smoothing procedure applied on its top to get monotonic residual norms [28]. Applying such techniques allows better monitoring of the convergence by residual norm and it is mathematically equivalent to the residual minimizing conjugate residual method [6]. The computational cost of this technique is minimal and it costs only two inner products and one vector update per iteration. In the framework of iterative methods the number of operations in matrix-vector products is what is usually the most important. These products, performed repeatedly in each iteration loop, contribute in a substantial way to the final efficiency of iterative solver. When solving the system with Schur complement matrix $-\mathsf{A}/A$ the number of flops per iteration for an unpreconditioned method is dominated by the matrix vector multiplication with the matrix $-\mathsf{A}/A$. Its number of nonzeros was given by Lemma 2.2. Moreover, using the estimates (1.13) and (1.14), the condition number of the Schur complement matrix $-\mathsf{A}/A$ can be bounded by the term $O(\sqrt[3]{NE^2})$. Consequently, the number of flops for conjugate gradients necessary to achieve a reduction by ε is of order

$$O\left(\left[NE + NIF + NNC + \sum_{i\in\mathcal{E}_h}(NIF_i + NNC_i)^2 + \sum_{i\in\mathcal{E}_h}\sum_{j\in Adj(i)} NIF_j\right]\sqrt[3]{NE}\right).$$

Assuming overestimates $(NIF_i + NNC_i) \le 5$ and $NIF_i \le 5$, we obtain the asymptotic estimate of order $O(NE\sqrt[3]{NE})$.

The previous considerations did not take into account the Schur complement systems with matrices $((-\mathsf{A}/A)/A_{11})$ and $(((-\mathsf{A}/A)/A_{11})/B_{22})$. The convergence rate of the iterative conjugate gradient method applied to the second and third Schur complement systems depend analogously on the condition number of the Schur complement matrices [9], [6], [26]. The analysis of the spectrum of the matrix $((-\mathsf{A}/A)/A_{11})$ is given in the following theorem.

THEOREM 4.2. *Let $\mu_1 \ge \mu_2 \ge \cdots \ge \mu_{NA} > 0$ be the eigenvalues of the positive definite block $A \in \mathcal{R}^{NA,NA}$, $\sigma_1 \ge \sigma_2 \ge \cdots \ge \sigma_{NBC} > 0$ be the singular values of the matrix block $(B\ C) \in \mathcal{R}^{NA,NBC}$. Then for the spectrum of the Schur complement matrix $(-\mathsf{A}/A)/A_{11}$ we have*

$$\sigma((-\mathsf{A}/A)/A_{11}) \subset \left[\sigma^2_{NBC}/\mu_1, 2/\mu_{NA}\right]. \tag{4.7}$$

Consequently, the condition number of the matrix $(-\mathsf{A}/A)/A_{11}$ can be bounded as follows

$$\kappa((-\mathsf{A}/A)/A_{11}) \le \frac{2}{\sigma^2_1}\kappa(-\mathsf{A}/A). \tag{4.8}$$

Proof. From the definition of the Schur complement matrix $(-\mathsf{A}/A)/A_{11}$ and the statement of Theorem 4.1 we have

$$\begin{aligned}((-\mathsf{A}/A)/A_{11}x,x) &= \left(\begin{pmatrix} A_{22} & A_{23} \\ A_{23}^T & A_{33}\end{pmatrix} x, x\right) - (A_{11}^{-1}\,(A_{12}\ A_{13})\,x, (A_{12}\ A_{13})\,x) \\ &\le 2/\mu_{NA}(x,x).\end{aligned}$$

The bound for the minimal eigenvalue can be obtained considering the following result (see [20, p. 201]):

$$(-\mathsf{A}/A)^{-1} = \begin{pmatrix} A_{11} & A_{12} & A_{13} \\ A_{12}^T & A_{22} & A_{23} \\ A_{13}^T & A_{23}^T & A_{33}\end{pmatrix}^{-1} =$$

$$\begin{pmatrix} A_{11}^{-1} + A_{11}^{-1}(A_{12}A_{13})[(-\mathsf{A}/A)/A_{11}]^{-1}\begin{pmatrix} A_{12}^T \\ A_{13}^T\end{pmatrix}A_{11}^{-1} & -A_{11}^{-1}(A_{12}\ A_{13})[(-\mathsf{A}/A)/A_{11}]^{-1} \\ -[(-\mathsf{A}/A)/A_{11}]^{-1}\begin{pmatrix} A_{12}^T \\ A_{13}^T\end{pmatrix}A_{11}^{-1} & [(-\mathsf{A}/A)/A_{11}]^{-1}\end{pmatrix}.$$

Then from the interlacing property of the eigenvalue set of symmetric matrix $-\mathsf{A}/A$ (see, e.g., [8]) it follows that

$$\left\|[(-\mathsf{A}/A)/A_{11}]^{-1}\right\| \le \left\|(-\mathsf{A}/A)^{-1}\right\| \le \frac{\mu_1}{\sigma_{NBC}^2}.$$

Considering the previous inequalities we get the lower bound for the minimal eigenvalue of the matrix $(-\mathsf{A}/A)/A_{11}$, which completes the proof. □

We have shown that the condition number of the Schur complement system matrix $(-\mathsf{A}/A)/A_{11}$ is bounded by a multiple of the condition number of the matrix $-\mathsf{A}/A$. Therefore the number of iteration steps for the conjugate gradient method necessary to reduce the error norm (or after smoothing the residual norm) by some factor is asymptotically the same as before. The complexity of the matrix-vector multiplication is lower and according to Corollary 2.1 is of the order

$$O\left(\sum_{i\in\mathcal{E}_h}(NIF_i + NNC_i)^2 + \sum_{i\in\mathcal{E}_h}\sum_{j\in Adj(i)} NIF_j + (NNC - NIF)\right).$$

Assuming again the overestimates $(NIF_i + NNC_i) \le 5$ and $NIF_i \le 5$, we obtain the asymptotic estimate $O(NE)$. The total number of flops for the conjugate gradients or the conjugate residual method necessary to achieve a reduction by the factor ε is then again of order $O(NE\sqrt[3]{NE})$. From the statements of Theorems 4.1 and 4.2 it is clear that the reduction to the Schur complement systems does not affect the asymptotic conditioning of the positive definite matrices $-\mathsf{A}/A$ and $(-\mathsf{A}/A)/A_{11}$. The same is true for the spectral properties of the third Schur complement system with the matrix $((-\mathsf{A}/A)/A_{11})/B_{22}$. Since the proof is completely analogous to the proof of Theorem 4.2 we shall present only the following statement (cf. [10, p. 256]).

THEOREM 4.3. *The condition number of* $((-\mathsf{A}/A)/A_{11})/B_{22}$ *is bounded by the condition number of the matrix* $(-\mathsf{A}/A)/A_{11}$

$$\kappa(((-\mathsf{A}/A)/A_{11})/B_{22}) \le \kappa((-\mathsf{A}/A)/A_{11}). \tag{4.9}$$

In the following we present two additional results concerning the matrix-vector multiplications with Schur complement matrices. Theorem 4.4 compares the number

of nonzeros in the Schur complement matrices $(-\mathsf{A}/A)/A_{11}$ and $((-\mathsf{A}/A)/A_{11})/B_{22}$ to the number of nonzeros in the original matrix A.

THEOREM 4.4. *The number of nonzero entries in the matrix* $((-\mathsf{A}/A)/A_{11})$ *or the matrix* $(((-\mathsf{A}/A)/A_{11})/B_{22})$ *is smaller than the number of nonzeros in the matrix* A.

Proof. Using the fact that $2NIF = \sum_{i\in\mathcal{E}_h} NIF_i \le 5NE$ and also $\sum_{i\in\mathcal{E}_h}(NIF_i + NNC_i) \le 5NE$, it follows from Lemma 2.1 and Theorem 2.1 that

$$
\begin{aligned}
&|(-\mathsf{A}/A)/A_{11}| - |\mathsf{A}| \\
&= \sum_{i\in\mathcal{E}_h} NIF_i^2 - 2NIF + \sum_{i\in\mathcal{E}_h}\sum_{j\in Adj(i)} NIF_j + \sum_{i\in\mathcal{E}_h} NNC_i^2 \\
&+2\sum_{i\in\mathcal{E}_h} NIF_i NNC_i - 35NE - 4NIF - 2NNC \\
&= \sum_{i\in\mathcal{E}_h}(NIF_i + NNC_i)^2 - 5\sum_{i\in\mathcal{E}_h} NIF_i - 4\sum_{i\in\mathcal{E}_h} NNC_i - \sum_{i\in\mathcal{E}_h}\sum_{j\in Adj(i)} NNC_j \\
&+2\sum_{i\in\mathcal{E}_h}(NIF_i + NNC_i) + \sum_{i\in\mathcal{E}_h}\sum_{j\in Adj(i)}(NIF_j + NNC_j) - 35NE \\
&\le 2\sum_{i\in\mathcal{E}_h}(NIF_i + NNC_i) + \sum_{i\in\mathcal{E}_h}\sum_{j\in Adj(i)}(NIF_j + NNC_j) - 35NE \le 0. \qquad \square
\end{aligned}
$$

Clearly, the number of nonzeros in the matrix $(((-\mathsf{A}/A)/A_{11})/B_{22})$ is even smaller.

Note that the number of nonzeros in the original matrix A can be smaller or larger than the corresponding number of nonzeros in the matrix $-\mathsf{A}/A$. Consider now the factorized Schur complement in the form (2.5). It can be shown also that there is no clear winner between the number of floating-point operations to multiply a dense vector by the matrix $\begin{pmatrix}\hat{B} & \hat{C}_1 & \hat{C}_2\end{pmatrix}^T \begin{pmatrix}\hat{B} & \hat{C}_1 & \hat{C}_2\end{pmatrix}$ or the number of operations to get a product of a matrix $((-\mathsf{A}/A)/A_{11})/B_{22}$ with a dense vector of appropriate dimension, respectively. The result depends on the shape of the domain and its boundary conditions. Nevertheless, the following Theorem 4.5 shows that if we do not form the Schur complement explicitly it is worth it to use the factorized form (2.4) and the reordering of the Schur complement from Theorem 2.3 instead of its implicit form.

THEOREM 4.5. *Let* v *be a dense vector. The number of floating-point operations to compute* $\begin{pmatrix}\hat{B} & \hat{C}_1 & \hat{C}_2\end{pmatrix}^T \begin{pmatrix}\hat{B} & \hat{C}_1 & \hat{C}_2\end{pmatrix} v$ *is smaller than the number of floating-point operations to compute*

$$
\begin{pmatrix} B^T \\ C_1^T \\ C_2^T \end{pmatrix} A^{-1} \begin{pmatrix} B & C_1 & C_2 \end{pmatrix} v.
$$

Proof. Taking into account the local ordering from Theorem 2.3 the difference between these two quantities can be bounded by

$$
\begin{aligned}
&10NE + \sum_{i\in\mathcal{E}_h}(NIF_i + NNC_i)(NIF_i + NNC_i + 1) - 35NE - 4NIF - 2NNC \\
&\le -2NIF - NNC \le 0. \qquad \square
\end{aligned}
$$

5. Numerical experiments. In the following we present numerical experiments which illustrate the results developed in the theoretical part of the paper.

Two model potential flow problems (1.1) and (1.2) in a rectangular domain with Neumann conditions prescribed on the bottom and on the top of the domain have been considered. Dirichlet conditions that preserve the nonsingularity of the whole system matrix A were imposed on the rest of the boundary. The choice of boundary conditions in these examples is motivated by our application and it comes from a modelling of a confined aquifer (see [3]) between two impermeable layers.

In order to verify the theoretical results derived in previous sections we will restrict our attention first to the simplest geometrical shape—cubic domain and report the results obtained from a uniformly regular mesh refinement. In practical situations, however, relatively thin aquifers with possible cracks in the rock are frequently modeled, and so the number of Neumann conditions may represent a big portion of the whole boundary. As our second model example, we consider a rectangular domain discretized by six layers of elements in the mesh. As we will see later, the reduction to the third Schur complement proposed in this paper can become even more significant than for the cubic domain. Prismatic discretizations of domains with NE elements were used [14], [11]. For the cubic domain we have then $NE = 2/h^3$. Discretization parameters h, NE, NIF, NNC, dimension N of the resulting indefinite system matrix A and the dimensions of the corresponding Schur complement matrices $-\mathsf{A}/A$, $(-\mathsf{A}/A)/A_{11}$, and $((-\mathsf{A}/A)/A_{11})/B_{22}$ are given in Table 1 for a cubic domain and in Table 2 for a more realistic domain. We note again that the difference between dimensions of the second and third Schur complement matrix is significantly larger in the case of modeling of thin layers that arise regularly in our application.

For the example of a cubic domain the spectral properties of the matrix blocks A and $(B\ C)$ as well as of the whole symmetric indefinite matrix A have been investigated. The extremal positive and negative eigenvalues of the matrix A and the extremal singular values of the block $(B\ C)$ (squared roots of the extremal eigenval-

ues of the matrix $(B\ C)^T(B\ C)$) were approximated by a reduction to the symmetric tridiagonal form of the matrix using 1500 steps of the symmetric Lanczos algorithm [8] and by a subsequent eigenvalue computation of the resulting tridiagonal matrix using the LAPACK double precision subroutine DSYEV [1]. Extremal eigenvalues of the diagonal matrix block A were computed directly by the LAPACK eigenvalue solver element by element. It can be seen that the computed extremal eigenvalues of the block A are in perfect agreement with the theory (see Table 3). Similarly, we can observe approximately a linear decrease of the computed minimal singular value of the matrix block $(B\ C)$ with respect to the mesh discretization parameter h. From the computed extremal eigenvalues of the whole indefinite system A we can conclude that even if our mesh size parameters h are rather small and give rise to very large system dimensions (see Table 1), they are outside of the asymptotic inclusion set (1.15). Indeed for our example and our mesh size interval we have $c_1/h \ll c_4$, $c_2/h \ll c_4$, and with the exception of $h = 1/35$ and $h = 1/40$ also $c_2/h < c_3 h$. Then using Lemma 2.1 in [22, pp. 3–4] (see also [15]) we obtain the inclusion set in the form

$$\sigma(\mathsf{A}) \subset \left[-c_4, -\frac{1}{2}\left(c_2\sqrt[3]{NE} - \sqrt{(c_2\sqrt[3]{NE})^2 + 4(c_3/\sqrt[3]{NE})^2}\right)\right] \cup [c_1\sqrt[3]{NE}, c_4], \tag{5.1}$$

which is in good agreement with the results in Table 3.

Using the same technique we have approximated the extremal eigenvalues of the Schur complement matrices $-\mathsf{A}/A$, $(-\mathsf{A}/A)/A_{11}$, and $((-\mathsf{A}/A)/A_{11})/B_{22}$ coming from a problem on a cubic domain. From Table 4 it can be seen that the inclusion set for the extremal eigenvalues of the first Schur complement matrix $-\mathsf{A}/A$ coincides with the bounds given in Theorem 4.1. We can see that the extremal eigenvalues of the second Schur complement matrix $(-\mathsf{A}/A)/A_{11}$ are bounded by the extremal eigenvalues of the matrix $-\mathsf{A}/A$. Similarly, the extremal eigenvalues of the third Schur complement matrix $((-\mathsf{A}/A)/A_{11})/B_{22}$ are bounded by the extremal eigenvalues of the matrix $(-\mathsf{A}/A)/A_{11}$. This behavior is in accordance with the asymptotic bounds given in Theorems 4.2 and 4.3.

The smoothed conjugate gradient method has been applied to the resulting three Schur complement systems (see also the discussion in previous section). Unpreconditioned and also preconditioned versions with the IC(0) preconditioner [23], [24] for the solution of these symmetric positive definite systems have been used. For the solution of the whole indefinite system the minimal residual method has been used. For the preconditioned version the positive definite block-diagonal preconditioning with ILUT(0,20) for the decomposition of the block corresponding to constraints (see, e.g., [22], [21]) was used. The choice of ILUT(0,20) was motivated by our effort to ob-

tain rather precise factorization with restricted memory requirements which should be close to the full decomposition of the block $(B\ C)^T(B\ C)$. This preconditioner was found generally better than the indefinite block-diagonal preconditioning with the same ILUT(0,20) decomposition or than the indefinite preconditioner discussed in [13] or [21]. The initial approximation x_0 was set to zero, the relative residual norm $\frac{\|r_n\|}{\|r_0\|} = 10^{-8}$ was used as the stopping criterion. For the implementation details of iterative solvers we refer to [6]. Our experiments were performed on an SGI Origin 200 with processor R10000. In Tables 5 and 6 we consider iteration counts and CPU times in the minimal residual method (unpreconditioned/preconditioned) applied to the whole system (1.12) and in the conjugate gradient method (unpreconditioned/preconditioned) applied to the Schur complement systems with the matrices $-\mathsf{A}/A$, $(-\mathsf{A}/A)/A_{11}$, and $((-\mathsf{A}/A)/A_{11})/B_{22}$ for a model problem with a cubic and more realistic domain, respectively. The dependence of the iteration counts presented in all columns of Table 5 corresponds surprisingly well to the theoretical order $O(\sqrt[3]{NE})$. The convergence behavior of the smoothed conjugate gradient method applied to the third Schur complement system with the matrix $((-\mathsf{A}/A)/A_{11})/B_{22}$ for this case is presented in Figure 4. From the results in Tables 5 and 6 it follows that while the gain from the solution of the third Schur complement system is rather moderate in the case of a cubic domain and in the case of the realistic flat domain it becomes more significant.

6. Conclusions. Successive block Schur complement reduction for the solution of symmetric indefinite systems has been considered in the paper. It was shown that due to the particular structure of matrices which arise from mixed-hybrid finite element discretization of the potential fluid flow problem, the resulting Schur complement matrices remain sparse. Moreover, their spectral properties do not deteriorate and the iterative conjugate gradient method can be successfully applied. Theoretical bounds for the convergence rate of this method in terms of the discretization parameters have been developed and tested on a model problem example. Numerical experiments indicate that the given theoretical bounds on the eigenvalue set are realistic not only for the system matrix and its blocks, but also for the Schur complement matrices. The iteration counts for the conjugate gradient method are also in a good agreement with the theoretical predictions. Direct solution of the third Schur complement system is also a possible alternative. Nevertheless, its comparison with iterative solvers is outside the scope of this paper.

In case of structured grids, a geometric multigrid solver and/or preconditioner for solving the final Schur complement system can be used. Namely, the stencil from the first Schur complement which expresses element-element connectivity in the domain

(see proof of Lemma 2.2) remains unchanged after the subsequent two reduction and an appropriate method could be based on that.

Another approach for the solution of symmetric indefinite systems seems to be promising. As was pointed out in [2], the classical null-space algorithm can be implemented. QR factorization of the off-diagonal block $(B\ C)$ is considered and the solution of the indefinite system is transformed to the solution of a block lower triangular system, where the subproblem corresponding to the diagonal block can be solved using the Cholesky factorization or an iterative conjugate gradient-type algorithm. This approach has the advantage of performing the matrix-vector multiplication by the Q factor using elementary Householder transformations. Although the Q factor may be structurally full, the elementary Householder vectors may be quite sparse. Moreover, a roundoff error analysis of the algorithm can be carried out.

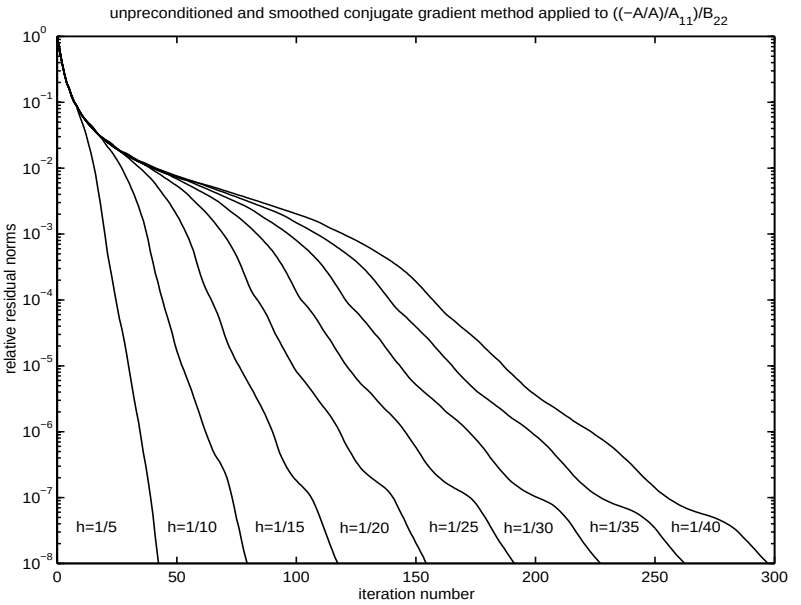

FIG. 4. *Convergence of the smoothed conjugate gradient method applied to the third Schur complement system.*

Acknowledgment. Authors would like to thank Michele Benzi for careful reading of manuscript and anonymous referees for their many useful comments which significantly improved the presentation of the paper. We are indebted to Jiří Mužák from the Department of Mathematical Modeling in DIAMO, s.e., Stráž pod Ralskem for providing us with a model numerical example for the experimental part of this paper and to Jörg Liesen for giving us the reference [20].

A MULTIRESOLUTION TENSOR SPLINE METHOD FOR FITTING FUNCTIONS ON THE SPHERE*

TOM LYCHE† AND LARRY L. SCHUMAKER‡

Abstract. We present the details of a multiresolution method we proposed at the Taormina Wavelet Conference in 1993 (see "L-spline wavelets" in *Wavelets: Theory, Algorithms, and Applications*, C. Chui, L. Montefusco, and L. Puccio, eds., Academic Press, New York, pp. 197–212) which is suitable for fitting functions or data on the sphere. The method is based on tensor products of polynomial splines and trigonometric splines and can be adapted to produce surfaces that are either tangent plane continuous or almost tangent plane continuous. The result is a convenient compression algorithm for dealing with large amounts of data on the sphere. We give full details of a computer implementation that is highly efficient with respect to both storage and computational cost. We also demonstrate the performance of the method on several test examples.

Key words. multiresolution, spherical data compression, tensor splines

1. Introduction.

In many applications (e.g., in geophysics, meteorology, medical modeling, etc.), one needs to construct smooth functions defined on the unit sphere S which approximate or interpolate data. As shown in [13], one way to do this is to work with tensor-product functions of the form

$$f(\theta,\phi) := \sum_{i=1}^{m}\sum_{j=1}^{\widetilde{m}} c_{ij}\varphi_i(\theta)\tilde{\varphi}_j(\phi) \tag{1.1}$$

defined on the rectangle

$$H := \{(\theta,\phi):\ -\pi/2 \le \theta \le \pi/2 \ \text{ and } \ 0 \le \phi \le 2\pi\},$$

where the φ_i are quadratic polynomial B-splines on $[-\pi/2,\pi/2]$, and the $\tilde{\varphi}_j$ are periodic trigonometric splines of order 3 on $[0,2\pi]$. With some care in the choice of the coefficients (see section 2), the associated *surface*

$$\mathcal{S}_f := \{f(\theta,\phi)\boldsymbol{v}(\theta,\phi):\ (\theta,\phi)\in H\}$$

with $\boldsymbol{v}(\theta,\phi) = [\cos(\theta)\cos(\phi), \cos(\theta)\sin(\phi), \sin(\theta)]^T$ will be tangent plane continuous.

In practice we often encounter very large data sets, and to get good fits using tensor product splines (1.1), a large number of knots is required, resulting in many basis functions and many coefficients. Since two spline spaces are nested if their

knot sequences are nested, one way to achieve a more efficient fit without sacrificing quality is to look for a multiresolution representation of (1.1), i.e., to recursively decompose it into splines on coarser meshes and corresponding correction (wavelet) terms. Then compression can be achieved in the standard way by thresholding out small coefficients; see [1], for example.

The paper is organized as follows. In section 2 we introduce notation and give details on the tensor product splines to be used here. In section 3 we describe the general decomposition and reconstruction algorithm in matrix form, while in section 4 we present a tensor version of the algorithms. The required matrices corresponding to the polynomial and trigonometric spline spaces, respectively, are derived in sections 5 and 6. Section 7 is devoted to details of implementing the algorithm, while in section 8 we discuss the case of almost tangent plane continuity. In section 9 we present test examples, and in section 10, several concluding remarks.

The method of this paper was presented at the Taormina Wavelet Conference in October 1993 but was not described in detail in the corresponding proceedings paper [8]. A very similar method based on exponential splines was developed independently in [2], [15], but with no implementation details. Alternative wavelet methods for the sphere can be found in [4], [5], [6], [10], [11]. The method in [4] uses discretizations of certain continuous wavelet transforms based on singular integral operators, while the method in [10] uses tensor functions based on polynomials and trigonometric polynomials. The methods in [6], [11] are based on triangulations. For a complete review of the various methods, see [5].

2. Tangent plane continuous tensor splines. Let $\varphi_1, \dots, \varphi_m$ be the standard quadratic B-splines associated with the knot sequence

$$-\pi/2 = x_1 = x_2 = x_3 < x_4 < \cdots < x_m < x_{m+1} = x_{m+2} = x_{m+3} = \pi/2.$$

Recall that φ_i is supported on the interval $[x_i, x_{i+3}]$ and that the B-splines form a partition of unity on $[-\pi/2, \pi/2]$. Let $T_1, \dots, T_{\widetilde{m}}$ be the classical trigonometric B-splines of order 3 defined on the knot sequence $\tilde{x}_1, \dots, \tilde{x}_{\widetilde{m}+3}$, where

$$0 = \tilde{x}_1 < \tilde{x}_2 < \cdots < \tilde{x}_{\widetilde{m}} < 2\pi$$

and $\tilde{x}_{\tilde{m}+i} := \tilde{x}_i + 2\pi$, $i = 1, \dots, 3$; see section 6. Recall that T_j is supported on the interval $[\tilde{x}_j, \tilde{x}_{j+3}]$. Let

$$\tilde{\varphi}_j(x) = \begin{cases} T_j(x), & j = 1, \dots, \widetilde{m} - 2, \\ T_j(x) + T_j(x - 2\pi), & j = \widetilde{m} - 1, \widetilde{m}, \end{cases}$$

be the associated 2π-periodic trigonometric B-splines; see [12]. These splines can be normalized so that for $\phi \in [0, 2\pi]$

$$1 = \sum_{j=1}^{\widetilde{m}} \cos\left(\frac{\tilde{x}_{j+2} - \tilde{x}_{j+1}}{2}\right) \tilde{\varphi}_j(\phi), \tag{2.1}$$

$$\cos(\phi) = \sum_{j=1}^{\widetilde{m}} \cos\left(\frac{\tilde{x}_{j+1} + \tilde{x}_{j+2}}{2}\right) \tilde{\varphi}_j(\phi), \tag{2.2}$$

$$\sin(\phi) = \sum_{j=1}^{\widetilde{m}} \sin\left(\frac{\tilde{x}_{j+1} + \tilde{x}_{j+2}}{2}\right) \tilde{\varphi}_j(\phi). \tag{2.3}$$

Since the boundaries of H corresponding to $\theta = \pm\pi/2$ map to the north and south poles, respectively, a function f of the form (1.1) will be well defined on S if and only if

$$c_{1,j} = f_{\mathcal{S}} \cos\left(\frac{\tilde{x}_{j+2} - \tilde{x}_{j+1}}{2}\right), \quad j = 1, \ldots, \widetilde{m}, \tag{2.4}$$

and

$$c_{m,j} = f_{\mathcal{N}} \cos\left(\frac{\tilde{x}_{j+2} - \tilde{x}_{j+1}}{2}\right), \quad j = 1, \ldots, \widetilde{m}, \tag{2.5}$$

where $f_{\mathcal{S}}$ and $f_{\mathcal{N}}$ are the values at the poles. Now since f is 2π-periodic in the ϕ variable and is C^1 continuous in both variables, we might expect that the corresponding surface $\mathcal{S}_f$ has a continuous tangent plane at nonpolar points. However, since we are working in a parametric setting, more is needed. The following theorem shows that under mild conditions on f which are normally satisfied in practice, we do get tangent plane continuity except at the poles.

THEOREM 2.1. *Suppose f is a spline as in* (1.1) *that satisfies the conditions* (2.4) *and* (2.5)*, and that in addition $f(\theta, \phi) > 0$ for all $(\theta, \phi) \in H$. Then the corresponding surface $\mathcal{S}_f$ is tangent plane continuous at all nonpolar points of S.*

Proof. Since f is a C^1 spline, the partial derivatives f_θ and f_ϕ are continuous on H. Now $t_1(\theta, \phi) := D_\theta[f(\theta, \phi)\boldsymbol{v}(\theta, \phi)]$ and $t_2(\theta, \phi) := D_\phi[f(\theta, \phi)\boldsymbol{v}(\theta, \phi)]$ are two tangents to the surface $\mathcal{S}_f$ at the point $f(\theta, \phi)\boldsymbol{v}(\theta, \phi)$. The normal vector to the surface at this point is given by the cross product $\boldsymbol{n} := t_1 \times t_2$. By the hypotheses, $\boldsymbol{n}$ is continuous, and thus to ensure a continuous tangent plane, it suffices to show that $\boldsymbol{n}$ has positive length (which insures that the surface does not have singular points or cusps). Using Mathematica, it is easy to see that

$$|\boldsymbol{n}(\theta, \phi)|^2 = f(\theta, \phi)^2\big[\cos(\theta)^2 f(\theta, \phi)^2 + f_\phi(\theta, \phi)^2 + \cos(\theta)^2 f_\theta(\theta, \phi)^2\big],$$

which is clearly positive for all values of $(\theta, \phi) \in H$ with $\theta \neq \pm\pi/2$. ∎

With some additional side conditions on the coefficients of f, we can make the surface $\mathcal{S}_f$ also be tangent plane continuous at the poles. The required conditions (cf. [3], [13]) are that

$$c_{2,j} = c_{1,j} + \frac{(x_4 - x_3)}{2}\left[A_{\mathcal{S}} \cos\left(\frac{\tilde{x}_{j+1} + \tilde{x}_{j+2}}{2}\right) + B_{\mathcal{S}} \sin\left(\frac{\tilde{x}_{j+1} + \tilde{x}_{j+2}}{2}\right)\right]$$

and

$$c_{m-1,j} = c_{m,j} - \frac{(x_{m+1} - x_m)}{2}\left[A_{\mathcal{N}} \cos\left(\frac{\tilde{x}_{j+1} + \tilde{x}_{j+2}}{2}\right) + B_{\mathcal{N}} \sin\left(\frac{\tilde{x}_{j+1} + \tilde{x}_{j+2}}{2}\right)\right]$$

for $j = 1, \ldots, \widetilde{m}$, where $A_{\mathcal{S}}$, $B_{\mathcal{S}}$, $A_{\mathcal{N}}$, and $B_{\mathcal{N}}$ are constants.

3. Basic decomposition and reconstruction formulae. Suppose $\mathcal{V}_0, \mathcal{V}_1, \ldots$ is a nested sequence of finite-dimensional linear subspaces of an inner-product space X, i.e.,

$$\mathcal{V}_0 \subset \mathcal{V}_1 \subset \cdots \subset \mathcal{V}_k \subset \cdots.$$

Let

$$\mathcal{V}_k = \mathcal{V}_{k-1} \oplus \mathcal{W}_{k-1}$$

be the corresponding orthogonal decompositions.

For our application, it is convenient to express decomposition and reconstruction in matrix form, as is done, e.g., in [14]. Let $\varphi_{k,1}, \ldots, \varphi_{k,m_k}$ be a basis for $\mathcal{V}_k$, and let $\psi_{k-1,1}, \ldots, \psi_{k-1,n_{k-1}}$ be a basis for $\mathcal{W}_{k-1}$, where $n_{k-1} = m_k - m_{k-1}$. Then by the nestedness, there exists an $m_k \times m_{k-1}$ matrix P_k such that

$$\varphi_{k-1}^T = \varphi_k^T P_k, \tag{3.1}$$

where

$$\varphi_k = (\varphi_{k,1}, \ldots, \varphi_{k,m_k})^T. \tag{3.2}$$

The equation (3.1) is the usual *refinement relation.* Similarly, there exists an $m_k \times n_{k-1}$ matrix Q_k such that

$$\psi_{k-1}^T = \varphi_k^T Q_k, \tag{3.3}$$

where

$$\psi_{k-1} = (\psi_{k-1,1}, \ldots, \psi_{k-1,n_{k-1}})^T. \tag{3.4}$$

Let

$$\begin{aligned} G_k =& (\langle \varphi_{k,i}, \varphi_{k,j} \rangle), \\ H_{k-1} =& (\langle \psi_{k-1,i}, \psi_{k-1,j} \rangle) \end{aligned}$$

be the Gram matrices of size $m_k \times m_k$ and $n_{k-1} \times n_{k-1}$, respectively. It is easy to see that

$$H_{k-1} = Q_k^T G_k Q_k. \tag{3.5}$$

Clearly, the Gram matrices G_k and H_{k-1} are symmetric. The linear independence of the basis functions $\phi_{k,i}$ and of $\psi_{k,i}$ implies that both G_k and H_{k-1} are positive definite and thus nonsingular.

The following lemma shows how to decompose and reconstruct functions in $\mathcal{V}_k$ in terms of functions in $\mathcal{V}_{k-1}$ and $\mathcal{W}_{k-1}$.

LEMMA 3.1. *Let $f_k = \varphi_k^T a_k$ be a function in $\mathcal{V}_k$ associated with a coefficient vector $a_k \in \mathbb{R}^{m_k}$, and let*

$$f_k = f_{k-1} + g_{k-1} \tag{3.6}$$

be its orthogonal decomposition, where

$$f_{k-1} = \varphi_{k-1}^T a_{k-1} \in \mathcal{V}_{k-1}, \qquad g_{k-1} = \psi_{k-1}^T b_{k-1} \in \mathcal{W}_{k-1}.$$

Then

$$\begin{aligned} a_{k-1} =& G_{k-1}^{-1} P_k^T G_k a_k, \\ b_{k-1} =& H_{k-1}^{-1} Q_k^T G_k a_k. \end{aligned}$$

Moreover,

$$a_k = P_k a_{k-1} + Q_k b_{k-1}. \tag{3.7}$$

Proof. To find a_{k-1}, we take the inner-product of both sides of (3.6) with $\varphi_{k-1,i}$ for $i = 1, \ldots, m_{k-1}$. Using the refinement relation (3.1) and the orthogonality of the $\varphi_{k-1,i}$ with $\psi_{k-1,j}$, we get

$$P_k^T G_k a_k = G_{k-1} a_{k-1},$$

which gives the formula for a_{k-1}. If we instead take the inner-products with ψ_{k-1}, we get the formula for b_{k-1}. In view of the linear independence of the functions $\varphi_{k,1}, \ldots, \varphi_{k,m_k}$, the reconstruction formula (3.7) follows immediately from (3.6) and the refinement relations. ∎

Throughout the remainder of this paper we work with inner-products of the form $\langle f, g\rangle = \int_a^b fg$. In this case the function f_{k-1} in the representation (3.6) is nothing more than the best approximation of f_k from $\mathcal{V}_{k-1}$ in the L_2 norm on $[a, b]$.

4. Tensor-product decomposition and reconstruction. In this section we discuss decomposition and reconstruction of functions in tensor product spaces $\mathcal{V}_k \times \widetilde{\mathcal{V}}_\ell$, where the $\mathcal{V}_k$ are as in the previous section and where $\widetilde{\mathcal{V}}_\ell$ are similar subspaces of an inner-product space $\widetilde{X}$. In particular, suppose

$$\widetilde{\mathcal{V}}_0 \subset \widetilde{\mathcal{V}}_1 \subset \cdots \subset \widetilde{\mathcal{V}}_\ell \subset \cdots$$

and that

$$\widetilde{\mathcal{V}}_\ell = \widetilde{\mathcal{V}}_{\ell-1} \oplus \widetilde{\mathcal{W}}_{\ell-1}.$$

Let P_k, Q_k, G_k, and H_k be as in the previous section, and let $\widetilde{P}_\ell$, $\widetilde{Q}_\ell$, $\widetilde{G}_\ell$, and $\widetilde{H}_\ell$ be the analogous matrices associated with the spaces $\widetilde{\mathcal{V}}_\ell$.

THEOREM 4.1. *Let $f_{k,\ell} = \varphi_k^T A_{k,\ell} \tilde{\varphi}_\ell$ be a function in $\mathcal{V}_k \times \widetilde{\mathcal{V}}_\ell$ associated with a coefficient matrix $A_{k,\ell}$. Then $f_{k,\ell}$ has the orthogonal decomposition*

$$f_{k,\ell} = f_{k-1,\ell-1} + g^{(1)}_{k-1,\ell-1} + g^{(2)}_{k-1,\ell-1} + g^{(3)}_{k-1,\ell-1}, \tag{4.1}$$

with

$$\begin{aligned}
f_{k-1,\ell-1} &= \varphi_{k-1}^T A_{k-1,\ell-1} \tilde{\varphi}_{\ell-1} \in \mathcal{V}_{k-1} \times \widetilde{\mathcal{V}}_{\ell-1},\\
g^{(1)}_{k-1,\ell-1} &= \varphi_{k-1}^T B^{(1)}_{k-1,\ell-1} \tilde{\psi}_{\ell-1} \in \mathcal{V}_{k-1} \times \widetilde{\mathcal{W}}_{\ell-1},\\
g^{(2)}_{k-1,\ell-1} &= \psi_{k-1}^T B^{(2)}_{k-1,\ell-1} \tilde{\varphi}_{\ell-1} \in \mathcal{W}_{k-1} \times \widetilde{\mathcal{V}}_{\ell-1},\\
g^{(3)}_{k-1,\ell-1} &= \psi_{k-1}^T B^{(3)}_{k-1,\ell-1} \tilde{\psi}_{\ell-1} \in \mathcal{W}_{k-1} \times \widetilde{\mathcal{W}}_{\ell-1},
\end{aligned}$$

where the matrices $A_{k-1,\ell-1}$, $B^{(1)}_{k-1,\ell-1}$, $B^{(2)}_{k-1,\ell-1}$, and $B^{(3)}_{k-1,\ell-1}$ are computed from the system of equations

$$\begin{aligned}
G_{k-1} A_{k-1,\ell-1} \widetilde{G}_{\ell-1} &= P_k^T D_{k,\ell} \widetilde{P}_\ell,\\
G_{k-1} B^{(1)}_{k-1,\ell-1} \widetilde{H}_{\ell-1} &= P_k^T D_{k,\ell} \widetilde{Q}_\ell,\\
H_{k-1} B^{(2)}_{k-1,\ell-1} \widetilde{G}_{\ell-1} &= Q_k^T D_{k,\ell} \widetilde{P}_\ell,\\
H_{k-1} B^{(3)}_{k-1,\ell-1} \widetilde{H}_{\ell-1} &= Q_k^T D_{k,\ell} \widetilde{Q}_\ell
\end{aligned} \tag{4.2}$$

with

$$D_{k,\ell} := G_k A_{k,\ell} \widetilde{G}_\ell.$$

Moreover,

$$A_{k,\ell} = P_k A_{k-1,\ell-1} \widetilde{P}_\ell^T + P_k B^{(1)}_{k-1,\ell-1} \widetilde{Q}_\ell^T + Q_k B^{(2)}_{k-1,\ell-1} \widetilde{P}_\ell^T + Q_k B^{(3)}_{k-1,\ell-1} \widetilde{Q}_\ell^T. \tag{4.3}$$

Proof. To find the formula for $A_{k-1,\ell-1}$, we take the inner-product of both sides of (4.1) with $\varphi_{k-1,i}$ for $i = 1, \ldots, m_{k-1}$ and with $\tilde{\varphi}_{\ell-1,j}$ for $j = 1, \ldots, \tilde{m}_{\ell-1}$. The formulae for the $B^{(i)}_{k-1,\ell-1}$ are obtained in a similar way. The reconstruction formula (4.3) follows directly from (4.1) after inserting the refinement relations and using the linear independence of the components of the vectors φ_k and in $\tilde{\varphi}_\ell$. ∎

Note that computing the matrices $A_{k-1,\ell-1}$ and $B^{(i)}_{k-1,\ell-1}$ in a decomposition step can be done quite efficiently since several matrix products occur more than once, and we need only solve linear systems of equations involving the four matrices G_{k-1}, H_{k-1}, $\widetilde{G}_{\ell-1}$, and $\widetilde{H}_{\ell-1}$. As we shall see below, in our setting the first two of these are banded matrices, and the second two are periodic versions of banded matrices. All of them can be precomputed and stored in compact form.

5. The decomposition matrices for the polynomial splines. In this section we construct the matrices P_k, Q_k, and G_k needed for the decomposition and reconstruction of quadratic polynomial splines on the closed interval $[-\pi/2, \pi/2]$. Consider the nested sequence of knots

$$-\pi/2 = x_1^k = x_2^k = x_3^k < x_4^k < \cdots < x_{m_k}^k < x_{m_k+1}^k = x_{m_k+2}^k = x_{m_k+3}^k = \pi/2,$$

where

$$x_i^k = -\pi/2 + (i-3)h_k, \qquad i = 4, \ldots, m_k, \tag{5.1}$$

with $h_k = \pi/(m_k - 2)$ and $m_k = 3 \cdot 2^k + 2$. Let $\{\varphi_{k,i}\}_{i=1}^{m_k}$ be the associated quadratic B-splines with supports on the intervals $[x_i^k, x_{i+3}^k]$, $i = 1, \ldots, m_k$. We assume they are normalized so that

$$\sum_{i=1}^{m_k} \varphi_{k,i} \equiv 1. \tag{5.2}$$

We choose this normalization since in performing compression we want to control the error in the uniform norm. For each k, the span $\mathcal{V}_k$ of $\varphi_{k,1}, \ldots, \varphi_{k,m_k}$ is the m_k dimensional linear space of C^1 quadratic splines with knots at the x_i^k. These spaces are clearly nested. In addition to the well-known *refinement relations*

$$\varphi_{k-1,i} = \frac{(\varphi_{k,2i-3} + 3\varphi_{k,2i-2} + 3\varphi_{k,2i-1} + \varphi_{k,2i})}{4}, \qquad i = 3, \ldots, m_{k-1} - 2, \tag{5.3}$$

a simple computation shows that

$$\begin{aligned}
\varphi_{k-1,1} &= (4\varphi_{k,1} + 2\varphi_{k,2})/4, \\
\varphi_{k-1,2} &= (2\varphi_{k,2} + 3\varphi_{k,3} + \varphi_{k,4})/4, \\
\varphi_{k-1,m_{k-1}-1} &= (2\varphi_{k,m_k-1} + 3\varphi_{k,m_k-2} + \varphi_{k,m_k-3})/4, \\
\varphi_{k-1,m_{k-1}} &= (4\varphi_{k,m_k} + 2\varphi_{k,m_k-1})/4.
\end{aligned} \tag{5.4}$$

Equations (5.3), (5.4) provide the entries for the matrix P_k. In particular, the first two and last two columns are determined by (5.4), while for any $3 \le i \le m_{k-1} - 2$, the ith column of P_k contains all zeros except for the four rows $2i-3, \dots, 2i$ which contain the numbers 1/4, 3/4, 3/4, and 1/4. For example,

$$P_1 = \frac{1}{4}\begin{pmatrix} 4 & 0 & 0 & 0 & 0 \\ 2 & 2 & 0 & 0 & 0 \\ 0 & 3 & 1 & 0 & 0 \\ 0 & 1 & 3 & 0 & 0 \\ 0 & 0 & 3 & 1 & 0 \\ 0 & 0 & 1 & 3 & 0 \\ 0 & 0 & 0 & 2 & 2 \\ 0 & 0 & 0 & 0 & 4 \end{pmatrix}.$$

In general, P_k has at most two nonzero entries in each row and at most four nonzero entries in each column.

In order to compute the entries of the matrices Q_k, we need explicit bases for the *wavelet spaces* $\mathcal{W}_{k-1}$ on the interval $[-\pi/2, \pi/2]$. Although their construction is well known, for completeness we give details. Let $n_{k-1} = m_k - m_{k-1} = 3 \cdot 2^{k-1}$.

THEOREM 5.1. *Given $k \ge 1$, let*

$$\psi_{k-1,1} := \sum_{j=1}^{6} q_{j,1}\varphi_{k,j},$$

$$\psi_{k-1,n_{k-1}} := \sum_{j=1}^{6} q_{j,1}\varphi_{k,m_k-j+1},$$

and for $k \ge 2$, let

$$\psi_{k-1,2} := \sum_{j=2}^{8} q_{j,2}\varphi_{k,j},$$

$$\psi_{k-1,n_{k-1}-1} := \sum_{j=2}^{8} q_{j,2}\varphi_{k,m_k-j+1},$$

where

$$\begin{pmatrix} q_{1,1} \\ q_{2,1} \\ q_{3,1} \\ q_{4,1} \\ q_{5,1} \\ q_{6,1} \end{pmatrix} = \frac{1}{14}\begin{pmatrix} -6864 \\ 8346 \\ -4967 \\ 2083 \\ -406 \\ 14 \end{pmatrix}, \qquad \begin{pmatrix} q_{2,2} \\ q_{3,2} \\ q_{4,2} \\ q_{5,2} \\ q_{6,2} \\ q_{7,2} \\ q_{8,2} \end{pmatrix} = \frac{1}{11}\begin{pmatrix} 780 \\ -1949 \\ 3481 \\ -3362 \\ 1618 \\ -319 \\ 11 \end{pmatrix}. \tag{5.5}$$

In addition, for $k \ge 2$, let

$$\begin{aligned} \psi_{k-1,i} := {} & -\varphi_{k,2i-3} + 29\varphi_{k,2i-2} - 147\varphi_{k,2i-1} + 303\varphi_{k,2i} - 303\varphi_{k,2i+1} \\ & + 147\varphi_{k,2i+2} - 29\varphi_{k,2i+3} + \varphi_{k,2i+4} \end{aligned} \tag{5.6}$$

for $i = 3, \dots, n_{k-1} - 2$, and set

$$\psi_{0,2} := -\varphi_{1,2} + \frac{5}{2}\varphi_{1,3} - \frac{9}{2}\varphi_{1,4} + \frac{9}{2}\varphi_{1,5} - \frac{5}{2}\varphi_{1,6} + \varphi_{1,7}.$$

Then $\psi_{k-1,1}, \dots, \psi_{k-1,n_{k-1}}$ form a basis for $\mathcal{W}_{k-1}$.

Proof. The wavelets in (5.6) are just the well-known quadratic spline wavelets; see, e.g., [1]. The coefficients of the boundary wavelets $\psi_{k-1,1}$, $\psi_{k-1,n_{k-1}}$, $\psi_{k-1,2}$, and $\psi_{k-1,n_{k-1}-1}$ can be computed by forcing orthogonality to $\mathcal{V}_{k-1}$. In view of (3.3), the wavelets $\psi_{k-1,1}, \dots, \psi_{k-1,n_{k-1}}$ are linearly independent if and only if the matrix Q_k is of full rank. This follows since the submatrix of Q_k obtained by taking rows $2, 4, \dots, 3 \cdot 2^{k-1}$ and $3 \cdot 2^{k-1} + 3, 3 \cdot 2^{k-1} + 5, \dots, 3 \cdot 2^k + 1$ can easily be seen to be diagonally dominant. For an alternate proof of linear independence, see Lemma 11 of [7]. □

Using elementary properties of B-splines, it is easy to see that

$$\begin{aligned} \psi_{k-1,i}(\pm\pi/2) &= 0, \qquad i = 2, \dots, n_{k-1} - 1, \\ D_\theta \psi_{k-1,i}(\pm\pi/2) &= 0, \qquad i = 3, \dots, n_{k-1} - 2. \end{aligned} \tag{5.7}$$

We now describe the matrices Q_k. By Theorem 5.1,

$$Q_1 = \begin{pmatrix} q_{1,1} & 0 & 0 \\ q_{2,1} & -1 & 0 \\ q_{3,1} & 5/2 & q_{6,1} \\ q_{4,1} & -9/2 & q_{5,1} \\ q_{5,1} & 9/2 & q_{4,1} \\ q_{6,1} & -5/2 & q_{3,1} \\ 0 & 1 & q_{2,1} \\ 0 & 0 & q_{1,1} \end{pmatrix}$$

and

$$Q_2 = \begin{pmatrix} q_{1,1} & 0 & 0 & 0 & 0 & 0 \\ q_{2,1} & q_{2,2} & 0 & 0 & 0 & 0 \\ q_{3,1} & q_{3,2} & -1 & 0 & 0 & 0 \\ q_{4,1} & q_{4,2} & 29 & 0 & 0 & 0 \\ q_{5,1} & q_{5,2} & -147 & -1 & 0 & 0 \\ q_{6,1} & q_{6,2} & 303 & 29 & 0 & 0 \\ 0 & q_{7,2} & -303 & -147 & q_{8,2} & 0 \\ 0 & q_{8,2} & 147 & 303 & q_{7,2} & 0 \\ 0 & 0 & -29 & -303 & q_{6,2} & q_{6,1} \\ 0 & 0 & 1 & 147 & q_{5,2} & q_{5,1} \\ 0 & 0 & 0 & -29 & q_{4,2} & q_{4,1} \\ 0 & 0 & 0 & 1 & q_{3,2} & q_{3,1} \\ 0 & 0 & 0 & 0 & q_{2,2} & q_{2,1} \\ 0 & 0 & 0 & 0 & 0 & q_{1,1} \end{pmatrix}.$$

For general $k \geq 2$, the nonzero elements in the third column of Q_k are repeated in columns $4, \dots, n_{k-1} - 2$, where in each successive column they are shifted down by two rows. The first two and last two columns of Q_k contain the same nonzero elements as Q_2. Clearly, Q_k has at most four nonzero entries in each row and at most eight nonzero entries in each column.

We now describe the Gram matrices G_k, which in general are symmetric and five-banded. To get G_k, we start with the matrix with $66h_k/120$ on the diagonal, $26h_k/120$ on the first subdiagonal, and $h_k/120$ on the second subdiagonal. Then replace the entries in the 3×3 submatrices in the upper left and lower right corners by

$$UL_k := \frac{h_k}{120}\begin{pmatrix} 24 & 14 & 2 \\ 14 & 40 & 25 \\ 2 & 25 & 66 \end{pmatrix}, \qquad LR_k := \frac{h_k}{120}\begin{pmatrix} 66 & 25 & 2 \\ 25 & 40 & 14 \\ 2 & 14 & 24 \end{pmatrix}.$$

For example,

$$G_0 = \frac{h_0}{120}\begin{pmatrix} 24 & 14 & 2 & 0 & 0 \\ 14 & 40 & 25 & 1 & 0 \\ 2 & 25 & 66 & 25 & 2 \\ 0 & 1 & 25 & 40 & 14 \\ 0 & 0 & 2 & 14 & 24 \end{pmatrix}$$

and

$$G_1 = \frac{h_1}{120}\begin{pmatrix} 24 & 14 & 2 & 0 & 0 & 0 & 0 & 0 \\ 14 & 40 & 25 & 1 & 0 & 0 & 0 & 0 \\ 2 & 25 & 66 & 26 & 1 & 0 & 0 & 0 \\ 0 & 1 & 26 & 66 & 26 & 1 & 0 & 0 \\ 0 & 0 & 1 & 26 & 66 & 26 & 1 & 0 \\ 0 & 0 & 0 & 1 & 26 & 66 & 25 & 2 \\ 0 & 0 & 0 & 0 & 1 & 25 & 40 & 14 \\ 0 & 0 & 0 & 0 & 0 & 2 & 14 & 24 \end{pmatrix}.$$

6. The decomposition matrices for the trigonometric splines. In this section we present the matrices $\widetilde{P}_\ell$, $\widetilde{Q}_\ell$, and $\widetilde{G}_\ell$ needed for the decomposition and reconstruction of periodic trigonometric splines of order 3 defined on the interval $[0, 2\pi]$. Suppose $\ell \geq 1$ and that

$$\tilde{x}_i^\ell = (i-1)\tilde{h}_\ell, \qquad i = 1, \ldots, \widetilde{m}_\ell + 3, \tag{6.1}$$

is a nested sequence of knots, where $\tilde{h}_\ell = 2^{(1-\ell)}\pi/3$ and $\widetilde{m}_\ell = 3 \cdot 2^\ell$. Let

$$M_{\ell,i}(\phi) := T_{\tilde{h}_\ell}(\phi - \tilde{x}_i^\ell),$$

where

$$T_h(\phi) := \begin{cases} \frac{\sin(\phi/2)^2}{\sin(h/2)\sin(h)}, & 0 \leq \phi \leq h, \\ \frac{1}{\cos(h/2)} - \frac{\sin((\phi-h)/2)^2 + \sin((2h-\phi)/2)^2}{\sin(h/2)\sin(h)}, & h \leq \phi \leq 2h, \\ \frac{\sin((3h-\phi)/2)^2}{\sin(h/2)\sin(h)}, & 2h \leq \phi \leq 3h, \\ 0, & \text{otherwise} \end{cases} \tag{6.2}$$

is the usual trigonometric B-spline of order 3 associated with uniformly spaced knots $(0, h, 2h, 3h)$. Set

$$\tilde{\varphi}_{\ell,i}(\phi) = \begin{cases} M_{\ell,i}(\phi), & i = 1, \ldots, \widetilde{m}_\ell - 2, \\ M_{\ell,i}(\phi) + M_{\ell,i}(\phi - 2\pi), & i = \widetilde{m}_\ell - 1, \widetilde{m}_\ell. \end{cases}$$

For later use we define $\tilde{\varphi}_{\ell,\widetilde{m}_\ell+i} = \tilde{\varphi}_{\ell,i}$ for $i = 1, \ldots, 6$. With this normalization, the $\tilde{\varphi}_{\ell,i}$ satisfy (2.1)–(2.3), and it follows that

$$\sum_{i=1}^{\widetilde{m}_\ell} \tilde{\varphi}_{\ell,i} \equiv \frac{1}{\cos(\tilde{h}_\ell)} \le 2 \tag{6.3}$$

for $\ell \ge 1$.

The span $\widetilde{\mathcal{V}}_\ell$ of $\tilde{\varphi}_{\ell,1}, \ldots, \tilde{\varphi}_{\ell,\widetilde{m}_\ell}$ is the space of periodic trigonometric splines of order 3. Clearly, these spaces are nested, and in fact we have the following *refinement relation*.

THEOREM 6.1. *For all $\ell \ge 1$ and $1 \le i \le \tilde{m}_{\ell-1}$,*

$$\tilde{\varphi}_{\ell-1,i} = u(\tilde{h}_\ell)\tilde{\varphi}_{\ell,2i-1} + v(\tilde{h}_\ell)\tilde{\varphi}_{\ell,2i} + v(\tilde{h}_\ell)\tilde{\varphi}_{\ell,2i+1} + u(\tilde{h}_\ell)\tilde{\varphi}_{\ell,2i+2}, \tag{6.4}$$

where

$$u(h) := \frac{1}{4\cos(h/2)\cos(h)}, \qquad v(h) := \frac{\cos(h/2)}{\cos(h)} - u(h).$$

Proof. By nestedness and the nature of the support of T_h,

$$T_{2h}(\phi) = u(h)T_h(\phi) + v(h)T_h(\phi - h) + w(h)T_h(\phi - 2h) + z(h)T_h(\phi - 3h)$$

for some numbers u, v, w, z. By symmetry, it is enough to compute u and v. To find u, we note that on $[0, h]$,

$$T_{2h}(\phi) = u(h)T_h(\phi).$$

Then using (6.2) we can solve for u. To find v we note that

$$T_{2h}(2h) = u(h)T_h(2h) + v(h)T_h(h),$$

and then solve for v using (6.2). □

Theorem 6.1 can now be used to find the entries in the matrix $\widetilde{P}_\ell$ needed in section 2. In particular, each column has exactly the four nonzero elements $u(\tilde{h}_\ell), v(\tilde{h}_\ell), v(\tilde{h}_\ell), u(\tilde{h}_\ell)$, starting in the first row in column 1, and shifted down by two rows each time we move one column to the right (where in the last column the last two elements are moved to the top of the column). For example,

$$\widetilde{P}_1 := \begin{pmatrix} u(\tilde{h}_1) & 0 & v(\tilde{h}_1) \\ v(\tilde{h}_1) & 0 & u(\tilde{h}_1) \\ v(\tilde{h}_1) & u(\tilde{h}_1) & 0 \\ u(\tilde{h}_1) & v(\tilde{h}_1) & 0 \\ 0 & v(\tilde{h}_1) & u(\tilde{h}_1) \\ 0 & u(\tilde{h}_1) & v(\tilde{h}_1) \end{pmatrix}.$$

Next we describe a basis for the *wavelet space* $\widetilde{\mathcal{W}}_{\ell-1}$ on $[0, 2\pi]$ which has dimension $\tilde{n}_{\ell-1} = 3 \cdot 2^{\ell-1}$ for $\ell \ge 1$.

THEOREM 6.2. *Given $\ell \ge 1$, let*

$$\tilde{\psi}_{\ell-1,i} = \sum_{j=0}^{7} \tilde{q}_j(\tilde{h}_\ell)\tilde{\varphi}_{\ell,2i+j-1}, \quad i = 1, \ldots, \tilde{n}_{\ell-1}, \tag{6.5}$$

where

$$\begin{aligned}
\tilde{q}_0(h) &= 1,\\
\tilde{q}_1(h) &= \frac{-h + 5h\cos(h) - h\cos(2h) - 3\sin(h)}{D(h)},\\
\tilde{q}_2(h) &= \frac{3h - 7h\cos(h) - 5h\cos(2h) + 3\sin(3h)}{D(h)},\\
\tilde{q}_3(h) &= \frac{-2h - 7h\cos(h) + 4h\cos(2h) - 4h\cos(3h) + 3\sin(3h)}{D(h)},
\end{aligned}$$

and

$$\tilde{q}_{7-j}(h) = -\tilde{q}_j(h), \qquad j = 0, \ldots, 3,$$

with

$$D(h) := 2h + h\cos(h) - 3\sin(h).$$

Then $\tilde{\psi}_{\ell-1,1}, \ldots, \tilde{\psi}_{\ell-1,\tilde{n}_{\ell-1}}$ *is a basis for the space* $\widetilde{\mathcal{W}}_{\ell-1}$.

Proof. To construct wavelets in $\widetilde{\mathcal{W}}_{\ell-1}$, we apply [8, Theorem 5.1], which gives explicit formulae for the $\tilde{q}_i$ in terms of inner-products of $\tilde{\varphi}_{\ell,i}$ with $\tilde{\varphi}_{\ell-1,j}$. To show that $\tilde{\psi}_{\ell-1,1}, \ldots, \tilde{\psi}_{\ell-1,\tilde{n}_{\ell-1}}$ are linearly independent, it suffices to show that $\widetilde{Q}_\ell$ is of full rank. To see this, we construct an $\tilde{n}_{\ell-1} \times \tilde{n}_{\ell-1}$ matrix B_ℓ by moving the last column of $\widetilde{Q}_\ell$ in front of the first column and then selecting rows $2, 4, \ldots, \widetilde{m}_\ell$. We now show that this matrix is strictly diagonally dominant, and thus of full rank.

First, we note that in each row of B_ℓ the element on the diagonal is $\tilde{q}_3(\tilde{h}_\ell)$ while the sum of the absolute values of the off-diagonal elements is $|\tilde{q}_1(\tilde{h}_\ell)| + |\tilde{q}_5(\tilde{h}_\ell)| + |\tilde{q}_7(\tilde{h}_\ell)|$. A simple computation shows that each of the functions $D(h)$ and $r_i(h) := \tilde{q}_i(h)D(h)$ has a Taylor expansion which is an alternating series. In particular, using the first two terms of each series, we get

$$\begin{aligned}
D(h) &> h^5[1/60 - h^2/1260] > 0,\\
r_1(h) &< h^5[-29/60 + 26h^2/315] < 0,\\
r_2(h) &> h^5[49/20 - 89h^2/105] > 0,\\
r_3(h) &< h^5[-101/20 + 1009h^2/420] < 0
\end{aligned}$$

for $0 \le h \le \pi/3 = \tilde{h}_1$. Now it is easy to see that

$$a(h) := \big[|\tilde{q}_3(h)| - |\tilde{q}_1(h)| - |\tilde{q}_5(h)| - |\tilde{q}_7(h)|\big]D(h) = -r_3(h) - r_2(h) + r_1(h) - D(h)$$

also has an alternating series expansion, and we get

$$a(h) > h^5[71/10 - 103h^2/70] > 0$$

for the same range of h. This shows that B_ℓ is strictly diagonally dominant, and the proof is complete. ∎

The formulae for the $\tilde{q}_i$ in Theorem 6.2 are not appropriate for small values of $\tilde{h}_{\ell-1}$. In this case we can use the following Taylor expansions:

$$\begin{aligned}
\tilde{q}_0(h) &= 1,\\
\tilde{q}_1(h) &= -29 + \frac{25}{7}h^2 - \frac{103}{588}\,h^4 + \frac{1255}{271656}\,h^6 + \cdots,\\
\tilde{q}_2(h) &= 147 - \frac{307}{7}\,h^2 + \frac{3301}{588}\,h^4 - \frac{545273}{1358280}\,h^6 + \cdots,\\
\tilde{q}_3(h) &= -303 + \frac{908}{7}\,h^2 - \frac{3131}{147}\,h^4 + \frac{642583}{339570}\,h^6 + \cdots.
\end{aligned}$$

Rather than computing them each time we need them, we can precompute and store the necessary values of $\tilde{q}_1(\tilde{h}_\ell)$, $\tilde{q}_2(\tilde{h}_\ell)$, and $\tilde{q}_3(\tilde{h}_\ell)$ for various levels ℓ; see Table 1. We can now describe the matrix $\widetilde{Q}_\ell$ needed in section 2 for decomposing and reconstructing with trigonometric splines. For $\ell = 1$ we have

$$\widetilde{Q}_1 = \begin{pmatrix}
\tilde{q}_0 + \tilde{q}_6 & \tilde{q}_4 & \tilde{q}_2\\
\tilde{q}_1 + \tilde{q}_7 & \tilde{q}_5 & \tilde{q}_3\\
\tilde{q}_2 & \tilde{q}_0 + \tilde{q}_6 & \tilde{q}_4\\
\tilde{q}_3 & \tilde{q}_1 + \tilde{q}_7 & \tilde{q}_5\\
\tilde{q}_4 & \tilde{q}_2 & \tilde{q}_0 + \tilde{q}_6\\
\tilde{q}_5 & \tilde{q}_3 & \tilde{q}_1 + \tilde{q}_7
\end{pmatrix},$$

where all $\tilde{q}_i$ are evaluated at $\tilde{h}_1$. For $\ell \geq 2$, each column of $\widetilde{Q}_\ell$ contains the eight entries $\tilde{q}_0, \tilde{q}_1, \tilde{q}_2, \tilde{q}_3, \tilde{q}_4, \tilde{q}_5, \tilde{q}_6, \tilde{q}_7$, evaluated at $\tilde{h}_\ell$. In particular, these entries start in row 1 in column 1 and are shifted down by two each time we move one column to the right (where in the last three columns, entries falling below the last row are moved to the top). Clearly, $\widetilde{Q}_\ell$ has exactly four nonzero entries in each row. For example,

$$\widetilde{Q}_2 = \begin{pmatrix}
\tilde{q}_0 & 0 & 0 & \tilde{q}_6 & \tilde{q}_4 & \tilde{q}_2\\
\tilde{q}_1 & 0 & 0 & \tilde{q}_7 & \tilde{q}_5 & \tilde{q}_3\\
\tilde{q}_2 & \tilde{q}_0 & 0 & 0 & \tilde{q}_6 & \tilde{q}_4\\
\tilde{q}_3 & \tilde{q}_1 & 0 & 0 & \tilde{q}_7 & \tilde{q}_5\\
\tilde{q}_4 & \tilde{q}_2 & \tilde{q}_0 & 0 & 0 & \tilde{q}_6\\
\tilde{q}_5 & \tilde{q}_3 & \tilde{q}_1 & 0 & 0 & \tilde{q}_7\\
\tilde{q}_6 & \tilde{q}_4 & \tilde{q}_2 & \tilde{q}_0 & 0 & 0\\
\tilde{q}_7 & \tilde{q}_5 & \tilde{q}_3 & \tilde{q}_1 & 0 & 0\\
0 & \tilde{q}_6 & \tilde{q}_4 & \tilde{q}_2 & \tilde{q}_0 & 0\\
0 & \tilde{q}_7 & \tilde{q}_5 & \tilde{q}_3 & \tilde{q}_1 & 0\\
0 & 0 & \tilde{q}_6 & \tilde{q}_4 & \tilde{q}_2 & \tilde{q}_0\\
0 & 0 & \tilde{q}_7 & \tilde{q}_5 & \tilde{q}_3 & \tilde{q}_1
\end{pmatrix},$$

where all $\tilde{q}_i$ are evaluated at $\tilde{h}_2$. Table 1 gives the values of $\tilde{q}_1(\tilde{h}_k)$, $\tilde{q}_2(\tilde{h}_\ell)$, and $\tilde{q}_3(\tilde{h}_\ell)$ for $\ell = 1, \ldots, 12$ needed for the $\widetilde{Q}_\ell$.

Finally, we describe the Gram matrices.

THEOREM 6.3. *For $\ell \geq 1$, the $3 \cdot 2^\ell \times 3 \cdot 2^\ell$ Gram matrix $\widetilde{G}_\ell$ associated with the*

TABLE 1
Trigonometric spline wavelet coefficients for various ℓ.

$\tilde{\varphi}_{\ell,i}$ is given by

$$\widetilde{G}_\ell := \begin{pmatrix} I_{00} & I_{01} & I_{02} & 0 & \cdots & 0 & I_{02} & I_{01} \\ I_{01} & I_{00} & I_{01} & I_{02} & 0 & \cdots & 0 & I_{02} \\ I_{02} & I_{01} & I_{00} & I_{01} & I_{02} & \cdots & 0 & 0 \\ & \ddots & & \ddots & & \ddots & & \\ & & \ddots & & \ddots & & \ddots & \\ 0 & 0 & \cdots & I_{02} & I_{01} & I_{00} & I_{01} & I_{02} \\ I_{02} & 0 & \cdots & 0 & I_{02} & I_{01} & I_{00} & I_{01} \\ I_{01} & I_{02} & 0 & \cdots & 0 & I_{02} & I_{01} & I_{00} \end{pmatrix},$$

where

$$I_{02} := \int_{\tilde{x}_i^\ell}^{\tilde{x}_{i+1}^\ell} \tilde{\varphi}_{\ell,i}\ \tilde{\varphi}_{\ell,i-2} = \gamma_\ell[4\tilde{h}_\ell + 2\tilde{h}_\ell\cos(2\tilde{h}_\ell) - 3\sin(2\tilde{h}_\ell)],$$

$$I_{01} := \int_{\tilde{x}_i^\ell}^{\tilde{x}_{i+2}^\ell} \tilde{\varphi}_{\ell,i}\ \tilde{\varphi}_{\ell,i-1} = \gamma_\ell[-4\tilde{h}_\ell - 20\tilde{h}_\ell\cos(2\tilde{h}_\ell) + 6\sin(2\tilde{h}_\ell) + 3\sin(4\tilde{h}_\ell)],$$

$$I_{00} := \int_{\tilde{x}_i^\ell}^{\tilde{x}_{i+3}^\ell} \tilde{\varphi}_{\ell,i}^2 = \gamma_\ell[4\tilde{h}_\ell\cos(2\tilde{h}_\ell) + 8\tilde{h}_\ell\cos(4\tilde{h}_\ell) + 24\tilde{h}_\ell - 6\sin(2\tilde{h}_\ell) - 6\sin(4\tilde{h}_\ell)],$$

with

$$\gamma_\ell := \frac{1}{64\sin(\tilde{h}_\ell)^4\cos(\tilde{h}_\ell)^2}.$$

Moreover,

$$\widetilde{G}_0 := \begin{pmatrix} I_{00} & I_{01}+I_{02} & I_{01}+I_{02} \\ I_{01}+I_{02} & I_{00} & I_{01}+I_{02} \\ I_{01}+I_{02} & I_{01}+I_{02} & I_{00} \end{pmatrix}.$$

Proof. Using (6.2), the necessary integrals can be computed directly. ∎

The formulae in Theorem 6.3 are clearly not appropriate for small values of $\tilde{h}_\ell$, in which case the following formulae can be used:

$$I_{02} = \frac{\tilde{h}_\ell}{120}\left[1 + \frac{31}{21}\tilde{h}_\ell^2 + \frac{134}{105}\tilde{h}_\ell^4 + \frac{2971}{3465}\tilde{h}_\ell^6 + \cdots\right],$$

$$I_{01} = \frac{13\tilde{h}_\ell}{60}\left[1 + \frac{295}{273}\tilde{h}_\ell^2 + \frac{146}{195}\tilde{h}_\ell^4 + \frac{299}{693}\tilde{h}_\ell^6 + \cdots\right],$$

$$I_{00} = \frac{11\tilde{h}_\ell}{20}\left[1 + \frac{71}{77}\tilde{h}_\ell^2 + \frac{674}{1155}\tilde{h}_\ell^4 + \frac{12233}{38115}\tilde{h}_\ell^6 + \cdots\right].$$

Table 2 contains the values of $I_{00}/\tilde{h}_\ell$, $I_{01}/\tilde{h}_\ell$, and $I_{02}/\tilde{h}_\ell$ for $\ell = 1, \ldots, 12$.

7. Implementation.

7.1. Decomposition. The decomposition procedure begins with a tensor spline of the form (1.1) based on polynomial splines $\varphi_{k,i}(\theta)$ at a given level $k \geq 1$ and periodic trigonometric splines $\tilde{\varphi}_{\ell,j}(\phi)$ at a given level $\ell \geq 1$ with coefficient matrix $C := A_{k,\ell}$ of size $m_k \times \widetilde{m}_\ell$. To carry out one step of the decomposition, we solve the systems (4.2) for $A_{k-1,\ell-1}$, $B^{(1)}_{k-1,\ell-1}$, $B^{(2)}_{k-1,\ell-1}$, $B^{(3)}_{k-1,\ell-1}$ and set

$$C = \begin{pmatrix} A_{k-1,\ell-1} & B^{(1)}_{k-1,\ell-1} \\ B^{(2)}_{k-1,\ell-1} & B^{(3)}_{k-1,\ell-1} \end{pmatrix}. \tag{7.1}$$

To continue the decomposition, we now carry out the same procedure on the matrix $A_{k-1,\ell-1}$. This process can be repeated at most $\min(k,\ell)-1$ times, where at each step the new spline coefficients and wavelet coefficients are stored in C. Thus, the entire decomposition process requires no additional storage beyond the original coefficient matrix.

The systems of equations (4.2) which have to be solved to carry out each step of the decomposition process can be efficiently solved due to their tensor nature. All of the matrices that have to be inverted are symmetric positive definite and are either banded or periodic banded. In particular, G_k is five-banded and H_k is seven-banded, while $\widetilde{G}_\ell$ and $\widetilde{H}_\ell$ are periodic five-banded and seven-banded, respectively. In our implementation we created special code to compute the band-Cholesky decompositions.

The matrices $H_k, G_k, \widetilde{G}_\ell$, and $\widetilde{H}_\ell$ are fixed and do not depend on the particular spline being processed. Thus, they can be precomputed and stored in the program.

7.2. Thresholding. Typically, at each step of the decomposition, many of the entries in the matrices $B^{(i)}_{k-j,\ell-j}$ of wavelet coefficients will be quite small. Thus, to achieve compression, these can be removed by a thresholding process. In view of (5.7), tangent plane continuity will be maintained at the poles if we retain all coefficients in the first two and last two rows of these matrices. As a guide to the thresholding process, we now estimate the effect of removing a set of wavelet coefficients.

THEOREM 7.1. *Suppose*

$$s = (\,\varphi^T_{k-1} \quad \psi^T_{k-1}\,)\, C \begin{pmatrix} \tilde{\varphi}_{\ell-1} \\ \tilde{\psi}_{\ell-1} \end{pmatrix},$$

where C is the matrix in (7.1) *and $\varphi^T_{k-1}, \psi^T_{k-1}, \tilde{\varphi}_{\ell-1}, \tilde{\psi}_{\ell-1}$ are vectors of basis functions as in* (3.2) *and* (3.4). *Given $\varepsilon > 0$, let $\hat{s}$ be the associated spline where the coefficients c_{ij} in C are set to zero whenever*

$$|c_{ij}| < \begin{cases} \varepsilon & \text{if } c_{ij} \in B^{(1)}_{k-1,\ell-1} \cup B^{(2)}_{k-1,\ell-1}, \\ \varepsilon/300 & \text{if } c_{ij} \in B^{(3)}_{k-1,\ell-1}. \end{cases}$$

Then

$$\|s - \hat{s}\|_\infty \le 4000\ \varepsilon. \tag{7.2}$$

Proof. Let Z_ν be the sets of indices i, j of coefficients in $B^{(\nu)}_{k-1,\ell-1}$ which are set to zero. Then

(7.3)

$$s - \hat{s} = \sum_{(i,j)\in Z_1} c_{ij}\varphi_{k-1,i}\tilde{\psi}_{\ell-1,j} + \sum_{(i,j)\in Z_2} c_{ij}\psi_{k-1,i}\tilde{\varphi}_{\ell-1,j} + \sum_{(i,j)\in Z_3} c_{ij}\psi_{k-1,i}\tilde{\psi}_{\ell-1,j}.$$

We now estimate the size of the first sum. Let $\tilde{q}^{(\ell)}_{rj}$ be the entries of the matrix $\widetilde{Q}_\ell$, so that $\tilde{\psi}_{\ell-1,j} = \sum_r \tilde{q}^{(\ell)}_{rj}\tilde{\varphi}_{\ell,r}$. Then using $|c_{ij}| < \varepsilon$ along with (6.3) and (5.2), we have

$$\left| \sum_{(i,j)\in Z_1} c_{ij}\varphi_{k-1,i} \sum_r \tilde{q}^{(\ell)}_{rj}\tilde{\varphi}_{\ell,r} \right| \le \varepsilon \sum_r \left(\sum_j |\tilde{q}^{(\ell)}_{rj}| \right) \tilde{\varphi}_{\ell,r} \le 2\varepsilon \|\widetilde{Q}_\ell\|_\infty,$$

where $\|\widetilde{Q}_\ell\|_\infty$ is the matrix norm subordinate to the vector infinity norm.

Similar estimates hold for the other two sums in (7.3), and thus

$$|(s - \hat{s})(\theta, \phi)| \le \varepsilon \left(2\|\widetilde{Q}_\ell\|_\infty + \|Q_k\|_\infty + \frac{2\|\widetilde{Q}_\ell\|_\infty \|Q_k\|_\infty}{300} \right). \tag{7.4}$$

It is clear that

$$\|Q_k\|_\infty = \frac{51363}{77} < 668,$$

and using Mathematica, it can be seen that

$$\|\widetilde{Q}_\ell\|_\infty = \frac{128\tilde{h}_\ell \cos(\frac{\tilde{h}_\ell}{2})^2 \sin(\frac{\tilde{h}_\ell}{2})^4}{2\tilde{h}_\ell + \tilde{h}_\ell \cos(\tilde{h}_\ell) - 3\sin(\tilde{h}_\ell)} \le 480.$$

The last inequality follows by expanding the fraction into an alternating series in $\tilde{h}_\ell$ around 0. Inserting these estimates in (7.4) gives (7.2). □

The large size of the constant in (7.2) is due to the way in which the wavelets have been scaled, and in fact, is quite pessimistic. In practice we have observed numerically that $\|s - \hat{s}\|_\infty$ is usually about 100 times as large as ε.

Theorem 7.1 leads immediately to several reasonable thresholding algorithms. For example, we can simply remove coefficients as described in the theorem. Alternatively (and this is what we do in the experiments below), at the jth level we can use a threshold of $\varepsilon/2^{j-1}$ for the coefficients in $B^{(1)}_{k-j,\ell-j} \cup B^{(2)}_{k-j,\ell-j}$ and a threshold of $\varepsilon/(300 \cdot 2^{j-1})$ for the coefficients in $B^{(3)}_{k-j,\ell-j}$. This level-dependent thresholding scheme retains more coefficients at the coarser levels.

7.3. Reconstruction. In view of (4.3), to carry out one reconstruction step simply involves matrix multiplication involving the matrices $P_k, Q_k, \widetilde{P}_\ell$, and $\widetilde{Q}_\ell$. These matrices are fixed and do not depend on the particular spline being operated on. Since they are also very sparse, we can simply store their entries in the program.

7.4. Storage. Due to their special structure, all of the fixed matrices needed to describe both decomposition and reconstruction can be stored in band form. This will require $\mathcal{O}(\max(N, \tilde{N}))$ storage, assuming that the largest starting coefficient matrix is of size $N \times \tilde{N}$. It is clear that in carrying out both decomposition and reconstruction, all of the coefficients arising in the intermediate steps can be stored in the original coefficient matrix C. Thus, it follows that the *total amount of storage* needed is $N \times \tilde{N} + \mathcal{O}(\max(N, \tilde{N}))$.

7.5. Complexity. To carry out one decomposition step on an initial coefficient matrix C of size $N \times \tilde{N}$, we need to solve $\tilde{N}$ systems of size $N \times N$ and then N systems of size $\tilde{N} \times \tilde{N}$. Since these systems are at most seven-banded (or periodic seven-banded) and positive definite, the total operation count is $\mathcal{O}(N \times \tilde{N})$. Since at each level of decomposition the number of coefficients to be dealt with is reduced by a factor of 4, it follows that the *total operation count for decomposition* is of order $\mathcal{O}(N \times \tilde{N})$.

To compute the total operation count for reconstruction, we first discuss the step that produces the coefficients at the finest level. This step requires multiplication by matrices with at most eight nonzero elements in each row or column. Thus the complexity for this step is $\mathcal{O}(N \times \tilde{N})$. Adding up the operations required for the coarser steps, it follows that the *total operation count for reconstruction* is also $\mathcal{O}(N \times \tilde{N})$.

7.6. Conditioning. Using Mathematica, we computed the sup-norm condition numbers of the matrices G_k, H_k, $\widetilde{G}_\ell$, and $\widetilde{H}_\ell$ for $1 \le k \le 9$. The results are shown in Table 3. Since none of the condition numbers exceeds 13, we conclude that the algorithm is highly robust.

TABLE 3

TABLE 4
Computational times.

.

k	ℓ	Coefficients	Seconds
6	6	37,248	.87
7	7	148,224	3.51
8	8	591,360	14.19
8	9	1,182,720	28.76
9	9	2,362,368	57.41

7.7. Timing. Due to the efficient coding, both decomposition and reconstruction are extremely fast. Table 4 lists the computational times for full decomposition and reconstruction for various choices of k and ℓ. The table clearly shows that the computational time depends linearly on the number of coefficients in the initial spline. The computation was done on a Sun Ultra 1 with a 167 MHz Sun UltraSPARC CPU with 512 KB cache.

8. Almost tangent plane continuity. In the method described above, we do not allow the thresholding process to remove coefficients in the first two and last two rows of the wavelet matrices $B^{(i)}_{k-j,\ell-j}$. This is required to guarantee tangent plane continuity at the poles and is a disadvantage since retaining these coefficients reduces compression rates.

It is easy to see that the number of retained coefficients at the poles at level k, ℓ is at most $6\widetilde{m}_\ell$, and thus after performing $\min(k,\ell)-1$ decomposition steps, at most $12\widetilde{m}_\ell$ coefficients are retained at the poles. Since the number of initial coefficients is $m_k \times \widetilde{m}_\ell$, it follows that the compression rate is bounded above by

$$\frac{m_k \times \widetilde{m}_\ell}{12\widetilde{m}_\ell} = \frac{m_k}{12} \approx 2^{k-2}.$$

The limit on compression rates with tangent plane continuity is thus 64 and 128 for $k = 8$ and $k = 9$, respectively.

It is easy to modify the thresholding process described in section 7.2 to get much higher compression rates at the expense of losing exact smoothness at the poles. There are two possibilities:

(T^0) We allow coefficients in the second and next-to-last rows of the matrices $B^{(i)}_{k-j,\ell-j}$ to be removed by thresholding,

(T^{-1}) We allow all coefficients in matrices $B^{(i)}_{k-j,\ell-j}$ to be removed by thresholding.

In both cases we get a reconstructed surface that is still tangent plane continuous at all nonpolar points. With strategy T^0, we lose exact tangent-plane continuity at the poles (but still have it approximately). With strategy T^{-1}, we may even lose continuity of the surface at the poles. If we are willing to accept minor artifacts at the poles, then much higher compression rates can be achieved. The corresponding algorithms based on thresholding strategies T^0 and T^{-1} both require exactly the same storage as in the restricted case, and also have the same efficiency and stability properties. We compare the performance of the various algorithms in the following section.

9. Examples. To test the general performance of the algorithms, we begin with the following simple example.

Example 1. Let $k = 8$ and $\ell = 9$, and let s be the tensor spline with coefficients

$$c_{ij} = \cos((\tilde{x}^9_{j+2} - \tilde{x}^9_{j+1})/2), \qquad i = 1, \ldots, m_8, \quad j = 1, \ldots, \widetilde{m}_9.$$

Discussion. Since the normalized quadratic B-splines form a partition of unity, it follows from (2.1) that with these coefficients, $s \equiv 1$ for all $(\theta, \phi) \in H$, i.e, the corresponding surface is exactly the unit sphere. In this case the coefficient matrix is of size 770×1536 and involves 1,182,720 coefficients. To test the algorithms, we performed decomposition with various values of ε, including zero. In all cases, after reconstruction we got coefficients that were correct to machine accuracy (working in double precision). □

To illustrate the ability of our multiresolution approach to achieve high levels of compression while retaining important features of a surface, we created a tensor spline fit to a smooth surface with a number of bumps.

Example 2. Let $\mathcal{B}$ be the surface shown in the upper left-hand corner of Figure 1.

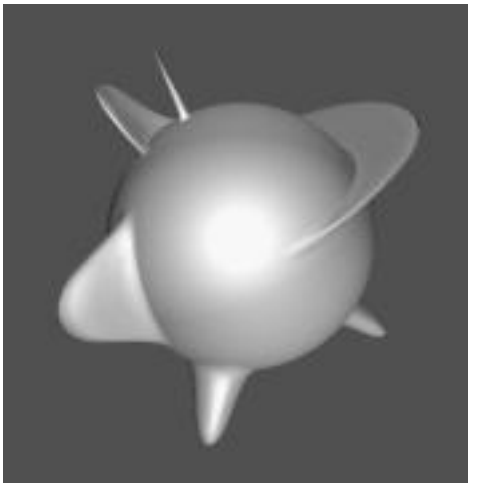
Discussion. The surface $\mathcal{B}$ was created by fitting a spline $f_{8,8}$ to data created by choosing 10 random sized subrectangles at random positions in H and adding tensor product quadratic B-splines of maximum height 3/4 with support on each such rectangle to the constant values corresponding to the unit sphere. For $k = \ell = 8$, the coefficient matrix is of size 770×768 and involves 591,360 coefficients. To test the algorithms, we performed decomposition with the thresholding values $\varepsilon_r = 10^{-r}$ for $r = 1, \ldots, 9$. Table 5 shows the number of coefficients *nco* remaining at each level for the case where $\varepsilon = .001$. Almost 3/4 of the coefficients are removed in the first step of decomposition, and after seven steps we end up with only 9734 coefficients (which amounts to a 60:1 compression ratio). Table 6 shows the differences between the original coefficients and the coefficients obtained after reconstruction. The table lists both the *maximum norm*

$$e_\infty := \max_{ij} |c_{ij} - \tilde{c}_{ij}|$$

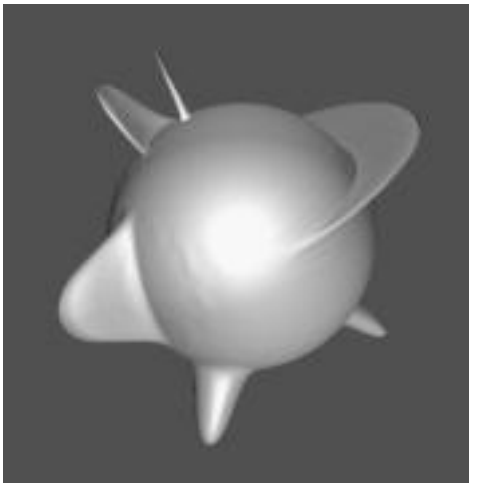
and the *average* ℓ_1 *norm*

$$e_1 := \frac{\sum_{ij} |c_{ij} - \tilde{c}_{ij}|}{m\widetilde{m}},$$

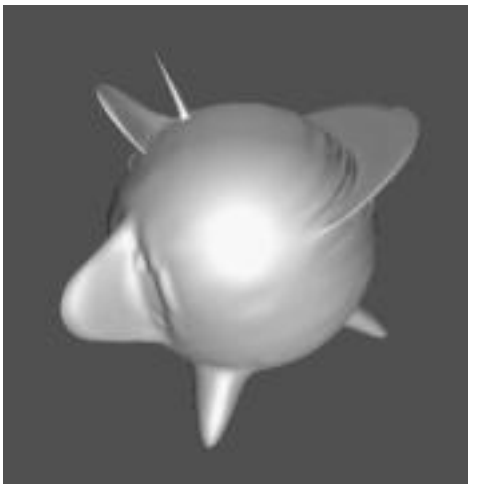
where c_{ij} are the original coefficients and $\tilde{c}_{ij}$ are the reconstructed ones.



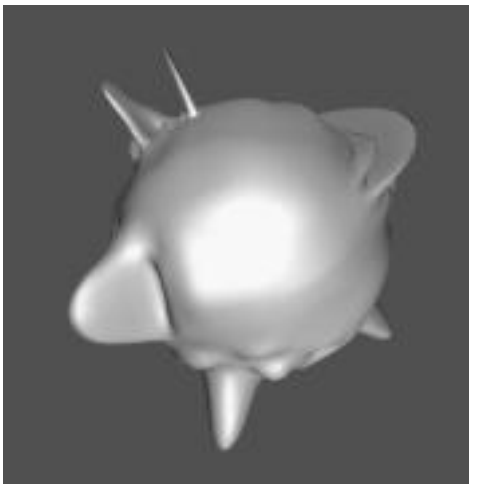
$\varepsilon = 0,\ nco = 591360$



$\varepsilon = .0001,\ nco = 11089$



$\varepsilon = .001,\ nco = 9734$



$\varepsilon = .01,\ nco = 9261$

The surfaces corresponding to the values $\varepsilon = 0, 10^{-4}, 10^{-3}, 10^{-2}$ are shown in Figure 1. At $\varepsilon = .0001$ we get near perfect looking reconstruction, while at $\varepsilon = .001$ the major features are reproduced with only small wiggles in the surface. At $\varepsilon = .01$ we have somewhat larger errors in the surface. □

We now present analogous results for Example 2 using the modified thresholding procedures of section 8. Table 7 shows the numbers of coefficients remaining after thresholding with $\varepsilon = .0001$ using the strategies T^0 and T^{-1}. In this case the original 591,360 coefficients are reduced to 6703 and 2277, respectively, after seven decomposition steps. This corresponds to compression ratios of 88.22 and 259.71, respectively.

To illustrate the accuracy of the modified thresholding procedures, in Table 8 we list the maximum and average ℓ_1 errors in the coefficient vector of Example 2 after reconstruction using the thresholding strategy T^{-1}. As can be seen by comparing with Table 6, the accuracies are essentially the same as with restricted thresholding, but with much higher compression ratios. The errors corresponding to T^0 thresholding are very similar.

The reconstructed surfaces corresponding to T^0 and T^{-1} thresholding look almost identical to those shown in Figure 1, with only small disturbances at the poles for larger values of ε. To get an idea of what such disturbances look like, in Figure 2 we show polar views of the reconstructed surface for Example 2 in the case $\varepsilon = .001$. The results for T^0 and T^{-1} are shown on the left and right, respectively. The pole is located midway between the "ears" and is virtually invisible for T^0 thresholding.

10. Remarks.

Remark 10.1. For convenience, we have elected to use orthogonal wavelets in both the polynomial and the trigonometric spline spaces. This leads to linear systems with very small band size which can be solved efficiently. The need to solve

$\varepsilon = .001,\ nco = 776$

FIG. 2. *Surfaces with T^0 and T^{-1} thresholding.*

such systems could be avoided altogether with the use of appropriate (but possibly complicated) biorthogonal bases. However, using our bases leads to a decomposition and reconstruction algorithm whose complexity is of the same order as the number of initial coefficients. Thus, no gain in complexity is possible regardless of what other bases one chooses.

Remark 10.2. An alternative way of making sure that tangent plane continuity is maintained at the poles is to decompose the original tensor product function s into two parts s_H and s_P, where

$$s_H := \sum_{i=3}^{m_k-2} \sum_{j=1}^{\widetilde{m}_\ell} c_{ij} \varphi_{k,i} \tilde{\varphi}_{\ell,j}$$

and $s_P := s - s_H$. Then decomposition, thresholding, and reconstruction can be performed on s_H. After adding s_P, the reconstructed spline possesses tangent plane continuity at the poles. Our implementation of this method exhibits essentially the same performance in terms of compression and accuracy as the method described

here, but for higher compression ratios, it produces surfaces that are not quite as visually pleasing near the poles.

Remark 10.3. The method described here can be extended to the case of nonuniform knots in both the θ and ϕ variables. This can be advantageous when the surface is given on nonuniform knots to start with. There is some computational cost in using nonuniform knots, however, since the various matrices appearing in the decomposition and reconstruction processes can no longer be precomputed and stored.

Remark 10.4. In section 4 we have presented the details of the tensor-product decomposition and reconstruction algorithms assuming that the initial function $f_{k,\ell}$ lies in the space $\mathcal{V}_k \times \widetilde{\mathcal{V}}_\ell$, with k and ℓ not necessarily the same. Since these spaces can always be reindexed, this is not strictly necessary in the abstract setting, but was convenient for our application, where there is a natural indexing for our spaces.

Remark 10.5. In computing the coefficients needed in sections 5 and 6, we found it convenient to use Mathematica.

Remark 10.6. There are several methods for computing approximations of the form (1.1). An explicit quasi-interpolation method using data on a regular grid (along with derivatives at the north and south poles) can be found in [13]. The same paper also describes a two-stage method that can be used to interpolate scattered data and a least squares method that can be used to fit noisy data. A general theory of quasi-interpolation operators based on trigonometric splines can be found in [9].

Remark 10.7. A closed, bounded, connected set U in $\mathbb{R}^3$ which is topologically equivalent to a sphere is called a *sphere-like surface*. This means that there exists a one-to-one mapping of U onto the unit sphere S. Moreover, there exists a point O inside the volume surrounded by U, such that every point on the surface U can be seen from O. Such surfaces are also called *star-like*. For applications, we can focus on the class of sphere-like surfaces of the form

$$U = \{v\rho(v) : \ v \in S\},$$

where ρ is a smooth function defined on S. Then each function f defined on U is just the composition $f(\cdot) = g(\rho(\cdot))$ with ρ of a function g defined on S.

Remark 10.8. As indicated in [11], compression methods on the sphere can be adapted to the problem of creating multiresolution representations of *bidirectional reflection distribution functions* (BRDFs), although the basic domain for such functions is actually a hemisphere. We are currently exploring the use of our method for this purpose.

Remark 10.9. It is well known that the polynomial B-splines are stable. In particular, for quadratic B-splines (φ_i) with general knots

$$\frac{1}{3}\|c\|_\infty \le \|\sum c_i\varphi_i\|_{L_\infty} \le \|c\|_\infty$$

for all coefficient vectors c. The same bounds hold for trigonometric splines since the linear functionals

$$\lambda_i f := \left[-f(\tilde{x}_{i+1}) + 2(1+\sigma_i)f\Big(\frac{\tilde{x}_{i+1}+\tilde{x}_{i+2}}{2}\Big) - f(\tilde{x}_{i+2})\right]/2$$

introduced in [13] are dual to the $\tilde{\varphi}_i$, i.e.,

$$\lambda_i\tilde{\varphi}_j = \delta_{ij}, \qquad i,j = 1,\dots,\widetilde{m},$$

where $\sigma_i := \cos((\tilde{x}_{i+2})-\tilde{x}_{i+1})/2)$. Analogous stability results hold for general p-norms with appropriately normalized B-splines.

ITERATIVE METHODS FOR NEARLY SINGULAR LINEAR SYSTEMS*

WILLIAM W. HAGER†

Abstract. Iterative methods are developed and studied for near-singular linear systems $\mathbf{Cx} = \mathbf{b}$. Our approach, called the transformed minimal residual algorithm (TMRES), is derived from any convergent iterative scheme $\mathbf{Sx}_{k+1} = \mathbf{Tx}_k + \mathbf{b}$ associated with a splitting $\mathbf{C} = \mathbf{S} - \mathbf{T}$. In each step of TMRES, the transformed residual $\mathbf{S}^{-1}(\mathbf{b} - \mathbf{Cx})$ is minimized over a Krylov space generated by $\mathbf{S}^{-1}\mathbf{T}$. The original iterative scheme typically converges slowly when $\mathbf{C}$ is nearly singular, while a Krylov space generated by $\mathbf{S}^{-1}\mathbf{T}$ often contains a much better approximation to a solution. TMRES is algebraically equivalent to the generalized minimal residual algorithm (GMRES) preconditioned by $\mathbf{S}^{-1}$, although there are numerical differences since a different matrix $\mathbf{S}^{-1}\mathbf{C}$ is used to generate the Krylov space in preconditioned GMRES. Special attention is given to sparsity and convergence issues related to linear systems of the form $(\mathbf{AA}^{\mathsf{T}} + \sigma\mathbf{I})\mathbf{x} = \mathbf{b}$, where $\sigma \geq 0$.

Key words. singular linear system, ill-conditioned system, Krylov space, matrix splitting, preconditioning, generalized minimal residual, successive overrelaxation, Gauss–Seidel, conjugate gradients, linear programming, sparse matrices

1. Introduction.

Iterative methods are developed and analyzed for singular or near-singular linear systems $\mathbf{Cx} = \mathbf{b}$, where $\mathbf{C}$ is an $m \times m$ matrix, possibly nonsymmetric. In the generalized minimal residual algorithm (GMRES) of Saad and Schultz [43], the residual $\mathbf{r}(\mathbf{x}) = \mathbf{b} - \mathbf{Cx}$ is minimized over a Krylov space generated by the matrix $\mathbf{C}$. Our transformed minimal residual approach (TMRES) is based on a splitting $\mathbf{C} = \mathbf{S} - \mathbf{T}$, where $\mathbf{S}$ is nonsingular and the spectral radius of $\mathbf{S}^{-1}\mathbf{T}$ is less than one. The transformed residual $\mathbf{S}^{-1}\mathbf{r}(\mathbf{x})$ is minimized over $\mathbf{x} = \mathbf{x}_0 + \mathbf{z}$ with $\mathbf{z}$ in the Krylov space

$$\mathcal{K}(\mathbf{S}^{-1}\mathbf{T}, \mathbf{g}, k) = \text{span}\{\mathbf{g}, (\mathbf{S}^{-1}\mathbf{T})\mathbf{g}, (\mathbf{S}^{-1}\mathbf{T})^2\mathbf{g}, \ldots, (\mathbf{S}^{-1}\mathbf{T})^{k-1}\mathbf{g}\}$$

generated by $\mathbf{S}^{-1}\mathbf{T}$ starting from the vector $\mathbf{g} = \mathbf{S}^{-1}(\mathbf{b} - \mathbf{Cx}_0)$. Even though the associated iterative scheme $\mathbf{Sx}_{k+1} = \mathbf{Tx}_k + \mathbf{b}$ converges slowly when $\mathbf{C}$ is nearly singular, we observe that $\mathcal{K}(\mathbf{S}^{-1}\mathbf{T}, \mathbf{g}, k)$ often yields a good approximation to a solution of $\mathbf{Cx} = \mathbf{b}$ for relatively small k. Theoretically, the Krylov space generated by $\mathbf{S}^{-1}\mathbf{T}$ is the same as that generated by the GMRES preconditioned matrix $\mathbf{S}^{-1}\mathbf{C}$. Numerically, these spaces differ since the matrices $\mathbf{S}^{-1}\mathbf{T}$ and $\mathbf{S}^{-1}\mathbf{C}$ are different.

The splittings that we consider include successive overrelaxation (SOR), damped Jacobi (see Hageman and Young [22]), and a new splitting applicable to situations where the columns in a matrix are selected from the columns of a larger matrix. Some early work on preconditioned conjugate gradient methods generated by splittings was developed by Concus, Golub, and O'Leary [12, 13]. Work leading up to GMRES includes that of Paige and Saunders [40], who developed a minimum residual algorithm MINRES for symmetric systems. Other related work includes [31] and [50]. In [18]

Greenbaum examines various preconditioners for the conjugate gradient method in the context of partial differential equations. In [7] Brown and Walker examine the convergence (or lack of it) for GMRES applied to singular or near-singular matrices. The use of deflation with GMRES is studied in [37].

In [4] Baglama et al. develop preconditioned restarted GMRES algorithms in which the preconditioner is generated by Sorensen's implicitly restarted Arnoldi method [46]. Their approach approximates an invariant subspace of the matrix associated with eigenvalues close to the origin. This subspace is used in a preconditioner that moves these small eigenvalues to one, leading to more rapid convergence in the GMRES algorithm. In this paper, we observe that for any convergent splitting $\mathbf{C} = \mathbf{S} - \mathbf{T}$, the eigenvalues of $\mathbf{C}$ close to the origin are often associated with eigenvalues of $\mathbf{S}^{-1}\mathbf{T}$ of nearly largest magnitude; as a result, a good approximation to the solution of a nearly singular system $\mathbf{Cx} = \mathbf{b}$ is often obtained from the Krylov space $\mathcal{K}(\mathbf{S}^{-1}\mathbf{T}, \mathbf{g}, k)$ for relatively small k.

One possible application of the methods developed in this paper is to quadratic programming with a sphere constraint. Problems of this form must be solved in each iteration of the trust region algorithm [8, 10, 16, 38, 42]. The first-order optimality system for these quadratic programs leads to a linear system whose matrix becomes more singular as we increase either the radius of the sphere or the norm of the linear term in the cost function. Hence, the quadratic programs arising in trust region methods can lead to near-singular linear systems for which TMRES is well suited. Other possible application areas include homotopy continuation methods [2], nonlinear eigenvalue problems [11], and seismic inversion problems.

Throughout this paper, we illustrate convergence properties in the near-singular setting using a prototype linear system of the form

$$(\mathbf{A}\mathbf{A}^{\mathsf{T}} + \sigma\mathbf{I})\mathbf{x} = \mathbf{b}, \tag{1.1}$$

where $\sigma \geq 0$ and $\mathbf{A}$ is an $m \times n$ real matrix. Systems of this form, with σ a small positive number, are solved in each iteration of the LP dual active set algorithm [23]. In interior point methods for linear programming [33, 51], each iteration involves solving a linear system with matrix of the form $\mathbf{Z}\mathbf{\Sigma}\mathbf{Z}^{\mathsf{T}}$. This system has the form (1.1) when we take $\mathbf{A} = \mathbf{Z}\mathbf{\Sigma}^{1/2}$ and $\sigma = 0$. The test matrices in this paper are obtained from the LP problems in David Gay's Netlib collection (www.netlib.org/lp). These matrices, which are all sparse, can be obtained in a variety of formats through the COAP Software Forum (www.math.ufl.edu/∼coap).

For symmetric linear systems of the form (1.1), the TMRES scheme with SSOR preconditioning and an SSOR preconditioned conjugate gradient scheme [6, 12, 13] exhibit similar convergence when applied to ill-conditioned matrices emanating from linear programming. In theory, these two schemes generate iterates in the same Krylov space, but they differ in the merit function used to select the approximation from the Krylov space.

To illustrate convergence problems that are encountered when solving nearly singular linear systems, we consider a netlib/lp matrix $\mathbf{A}$ for the (small) problem beaconfd ($m = 173$, $n = 295$). The right side $\mathbf{b}$ was randomly generated on the unit sphere[1] in $\mathbf{R}^m$, $\sigma = 0$, and the columns of $\mathbf{A}$ in (1.1) were scaled to be unit vectors. This column scaling is the one we use in the LP dual active set algorithm. In interior

[1] A vector can be randomly generated on the Euclidean unit sphere by first randomly generating its components using a Gaussian distribution with mean 0 then dividing the resulting vector by its length.

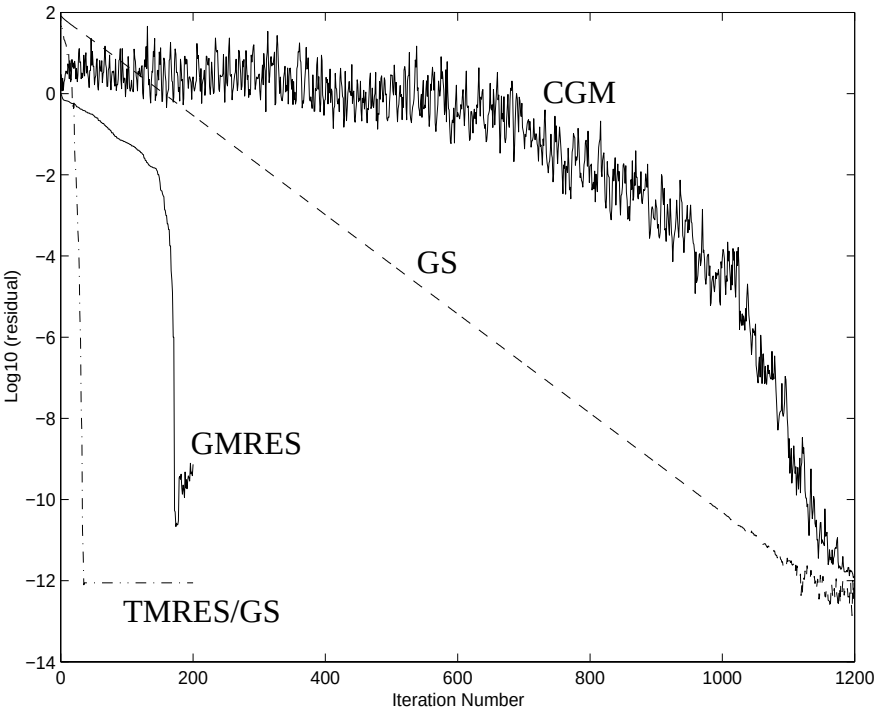

FIG. 1.1. *Convergence for the conjugate-gradient method (CGM), the Gauss–Seidel method (GS), the generalized minimal residual algorithm (GMRES) without restarts, and the transformed minimal residual algorithm (TMRES) obtained from Gauss–Seidel splitting when* $\mathbf{A}$ *in* (1.1) *is the test problem beaconfd.*

point methods, the diagonal scaling matrix $\mathbf{\Sigma}$ becomes increasingly ill-conditioned, and the condition number of the associated $\mathbf{A}\mathbf{A}^{\mathsf{T}}$ could be much larger than that for the normalized $\mathbf{A}$ used in our experiments.

We solve the linear system (1.1) using three different iterative methods: Gauss–Seidel (GS), conjugate gradients (CGM), and GMRES. Although various Lanczos and conjugate gradient type methods [41, 44, 45] have been developed for special versions of (1.1), we do not take into account special structure for (1.1) in our computations; rather, we treat this system as having the form $\mathbf{C}\mathbf{x} = \mathbf{b}$, where $\mathbf{C}$ is an $m \times m$ symmetric, positive definite matrix. All of the schemes, GS, CGM, and GMRES, are guaranteed to converge (see [49, p. 77], [36, Chap. 8], and [43]). Moreover, the conjugate gradient method yields the best approximation to the solution from an associated Krylov space, where the approximation quality is measured using the C-norm defined by $\|\mathbf{x}\|_C = \sqrt{\mathbf{x}^{\mathsf{T}}\mathbf{C}\mathbf{x}}$. GMRES minimizes the residual norm $\|\mathbf{b} - \mathbf{C}\mathbf{x}\|$, where $\|\cdot\|$ is the Euclidean norm, over the same Krylov space. According to the convergence theory, both CGM and GMRES solve $\mathbf{C}\mathbf{x} = \mathbf{b}$ in at most m iterations, assuming exact arithmetic.

With the starting guess $\mathbf{x} = \mathbf{0}$, we plot in Figure 1.1 the iteration number versus the base 10 logarithm of the residual norm for the associated iterate. The computations were done in double precision in Matlab on a Sun workstation. For this small problem, the Gauss–Seidel and conjugate gradient methods converge slowly to the solution, taking nearly 1200 iterations. The generalized minimal residual algorithm

requires about 173 iterations, the number of rows in $\mathbf{A}$. Paige and Saunders' MINRES routine would probably yield results similar to GMRES because $\mathbf{C} = \mathbf{A}\mathbf{A}^\mathsf{T} + \sigma\mathbf{I}$ is symmetric and the two routines are algebraically equivalent in this case. TMRES will be developed in sections 3 and 4. Its convergence behavior shown in Figure 1.1 for a Gauss–Seidel splitting is typical for many netlib/lp test problems.

With GMRES and TMRES, restarts may be essential to reduce the storage requirements when the matrix is nonsymmetric. In this paper, we do not analyze restarts.

2. Convergence properties. Let us study more closely the convergence behavior illustrated in Figure 1.1. The matrix associated with the test problem beaconfd, like many of the problems in netlib/lp, has some rows that are nearly linear combinations of other rows. The 10 smallest and largest eigenvalues of $\mathbf{A}\mathbf{A}^\mathsf{T}$ are the following:

0.00000177	2.8954
0.00000415	3.5490
0.00001338	4.9565
0.00002115	5.1235
0.00002367	6.5875
0.00004273	7.1127
0.00004399	7.5612
0.00004847	10.9200
0.00005424	43.9156
0.00006267	63.2578

The matrix $\mathbf{A}\mathbf{A}^\mathsf{T}$ is nearly singular in the sense that the ratio between the largest and the smallest eigenvalue of $\mathbf{A}\mathbf{A}^\mathsf{T}$ is of order 10^7, much larger than 1.

Let $\mathbf{C} = \mathbf{L} + \mathbf{U}$ be symmetric and positive definite, where

$$l_{ij} = c_{ij} \text{ and } u_{ij} = 0 \text{ for } i \geq j, \quad l_{ij} = 0 \text{ and } u_{ij} = c_{ij} \text{ for } i < j. \tag{2.1}$$

The Gauss–Seidel method for solving $\mathbf{C}\mathbf{x} = \mathbf{b}$ is given by the iteration

$$\mathbf{x}_{k+1} = -\mathbf{L}^{-1}(\mathbf{U}\mathbf{x}_k - \mathbf{b}).$$

If $\mathbf{x}_*$ is the exact solution to $\mathbf{C}\mathbf{x} = \mathbf{b}$, then the error $\mathbf{e}_k = \mathbf{x}_k - \mathbf{x}_*$ satisfies the recurrence $\mathbf{e}_{k+1} = \mathbf{M}\mathbf{e}_k$, where $\mathbf{M} = -\mathbf{L}^{-1}\mathbf{U}$. When $\mathbf{C}$ is positive definite, the spectral radius of $\mathbf{M}$, denoted $\rho(\mathbf{M})$, is strictly less than 1 [49, p. 77]. The spectral radius measures the convergence speed in the sense that the magnitude of error components associated with eigenvectors whose eigenvalue magnitudes are equal to the spectral radius is multiplied by the spectral radius in each iteration.

If $\mathbf{C}$ is singular and $\mathbf{z}$ is a nonzero vector such that $\mathbf{C}\mathbf{z} = \mathbf{0}$, then the relation $(\mathbf{L} + \mathbf{U})\mathbf{z} = \mathbf{0}$ implies that $\mathbf{z} = -\mathbf{L}^{-1}\mathbf{U}\mathbf{z}$, or $\mathbf{z} = \mathbf{M}\mathbf{z}$. Hence, $\mathbf{z}$ is an eigenvector of $\mathbf{M}$ corresponding to the eigenvalue 1, and the spectral radius of $\mathbf{M}$ is at least 1. Consequently, the error $\mathbf{e}_k$ in the Gauss–Seidel iteration may not tend to zero. If $\mathbf{C}$ is nearly singular, then the distance between the eigenvalues of $\mathbf{M}$ and 1 can be estimated using Gerschgorin's theorem.

PROPOSITION 2.1. *Let $\mathbf{C}_0$ be a square singular matrix, and consider the perturbed matrix $\mathbf{C} = \mathbf{C}_0 + \tau\mathbf{I}$. Let $\mathbf{S}$ be any nonsingular matrix for which $\mathbf{S}^{-1}\mathbf{C}_0$ is diagonalizable: $\mathbf{S}^{-1}\mathbf{C}_0 = \mathbf{F}\mathbf{\Phi}\mathbf{F}^{-1}$, where $\mathbf{\Phi}$ is a diagonal matrix containing the eigenvalues. If $\mathbf{T}$ is chosen so that $\mathbf{C} = \mathbf{S} - \mathbf{T}$ (i.e., $\mathbf{T} = \mathbf{S} - \mathbf{C}_0 - \tau\mathbf{I}$), then for τ sufficiently close*

to zero, the eigenvalues $\mu_1, \mu_2, \ldots, \mu_n$ *of* $\mathbf{S}^{-1}\mathbf{T}$ *satisfy*

$$\min_i |\mu_i - 1| \leq |\tau| \|\mathbf{F}\|_1 \|\mathbf{F}^{-1}\|_1 \|\mathbf{S}^{-1}\|_1,$$

where $\|\cdot\|_1$ *is the matrix* 1*-norm (largest absolute column sum).*

Proof. Observe that

$$\mathbf{F}^{-1}(\mathbf{S}^{-1}\mathbf{T})\mathbf{F} = \mathbf{F}^{-1}(\mathbf{I} - \mathbf{S}^{-1}\mathbf{C}_0 - \tau\mathbf{S}^{-1})\mathbf{F} = \mathbf{I} - \mathbf{\Phi} - \tau\mathbf{F}^{-1}\mathbf{S}^{-1}\mathbf{F}. \tag{2.2}$$

Since $\mathbf{C}_0$ is singular, one of the diagonal elements of $\mathbf{\Phi}$ is zero. Hence, one of the diagonal elements of $\mathbf{I} - \mathbf{\Phi}$ is 1. Let δ be the minimum absolute difference between distinct diagonal elements of $\mathbf{\Phi}$ and choose τ close enough to zero that

$$|\tau| \|\mathbf{F}\|_1 \|\mathbf{F}^{-1}\|_1 \|\mathbf{S}^{-1}\|_1 < \delta.$$

By Gerschgorin's theorem and the fact that $\mathbf{S}^{-1}\mathbf{T}$ and $\mathbf{F}^{-1}(\mathbf{S}^{-1}\mathbf{T})\mathbf{F}$ are similar, it follows from (2.2) that $\mathbf{S}^{-1}\mathbf{T}$ has an eigenvalue in the sphere in the complex plane with center 1 and radius $|\tau| \|\mathbf{F}\|_1 \|\mathbf{F}^{-1}\|_1 \|\mathbf{S}^{-1}\|_1$. This completes the proof. ∎

Loosely speaking, eigenvalues of $\mathbf{C}$ near 0 correspond to eigenvalues of $\mathbf{M} = \mathbf{S}^{-1}\mathbf{T}$ near 1 and to slow convergence of the Gauss–Seidel method.

A number of papers [32, 35, 47] have appeared in the literature relating the spectrum of the conjugate gradient method to its convergence. More recent work is surveyed in [1]. Here we focus on the effect of near singularity on convergence. The following result is the key to understanding the behavior for CGM depicted in Figure 1.1.

PROPOSITION 2.2. *If* $\mathbf{C}$ *is a symmetric matrix, then as* σ *tends to zero, we have*

$$\sigma(\sigma\mathbf{I} + \mathbf{C})^{-1} = \mathbf{P} + O(\sigma),$$

where $\mathbf{P}$ *denotes the orthogonal projection into the null space of* $\mathbf{C}$ *and* $O(\sigma)$ *denotes a term that can be bounded in magnitude by a constant times* $|\sigma|$.

Proof. Let $\mathbf{C} = \mathbf{Q}\mathbf{\Lambda}\mathbf{Q}^{\mathsf{T}}$ denote the diagonalization of $\mathbf{C}$, where $\mathbf{Q}$ is the orthogonal matrix of eigenvectors and $\mathbf{\Lambda}$ is a diagonal matrix whose diagonal elements $\lambda_1, \lambda_2, \ldots, \lambda_m$ are the eigenvalues. We assume that the eigenvalues are ordered so that

$$|\lambda_1| \geq |\lambda_2| \geq \cdots \geq |\lambda_k| > 0 \quad \text{and } \lambda_i = 0 \text{ for } i > k.$$

Hence,

$$\sigma(\sigma\mathbf{I} + \mathbf{C})^{-1} = \sigma\mathbf{Q}(\mathbf{\Lambda} + \sigma\mathbf{I})^{-1}\mathbf{Q}^{\mathsf{T}} \tag{2.3}$$

and

$$\sigma(\mathbf{\Lambda} + \sigma\mathbf{I})^{-1} = \mathbf{J} + O(\sigma), \tag{2.4}$$

where

$$\mathbf{J} = \begin{pmatrix} \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{I} \end{pmatrix}.$$

Above, the lower right $\mathbf{I}$ is $(m-k) \times (m-k)$, and $\mathbf{0}$ stands for a block of zeros. Since $\mathbf{Q}\mathbf{J}\mathbf{Q}^{\mathsf{T}} = \mathbf{P}$, (2.3) and (2.4) complete the proof. ∎

The CGM applied to the linear system $\mathbf{Cx} = \mathbf{b}$, where $\mathbf{C}$ is symmetric and positive definite, is the following [25, p. 340]: $\mathbf{d}_0 = \mathbf{r}_0 = \mathbf{b} - \mathbf{Cx}_0$ and for $k \geq 0$,

$$\begin{array}{ll} \mathbf{p}_k & \leftarrow \mathbf{Cd}_k, \\ \mathbf{x}_{k+1} & \leftarrow \mathbf{x}_k + \alpha_k \mathbf{d}_k, \quad \text{where } \alpha_k = \mathbf{r}_k^{\mathsf{T}}\mathbf{r}_k / \mathbf{d}_k^{\mathsf{T}}\mathbf{p}_k, \\ \mathbf{r}_{k+1} & \leftarrow \mathbf{r}_k - \alpha_k \mathbf{p}_k, \\ \mathbf{d}_{k+1} & \leftarrow \mathbf{r}_{k+1} + \beta_k \mathbf{d}_k, \quad \text{where } \beta_k = \mathbf{r}_{k+1}^{\mathsf{T}}\mathbf{r}_{k+1} / \mathbf{r}_k^{\mathsf{T}}\mathbf{r}_k. \end{array}$$

In each step of the conjugate gradient method, the current direction $\mathbf{d}_k$ is multiplied by $\mathbf{C}$ in the process of obtaining the new direction $\mathbf{d}_{k+1}$. By induction, $\mathbf{x}_k = \mathbf{x}_0 + \mathbf{z}_k$, where $\mathbf{z}_k$ lies in the Krylov space $\mathcal{K}(\mathbf{C}, \mathbf{r}_0, k)$.

Let $\mathbf{x}_* = \mathbf{C}^{-1}\mathbf{b}$ denote the solution to $\mathbf{Cx} = \mathbf{b}$. The conjugate gradient method is designed to minimize $\|\mathbf{x}_k - \mathbf{x}_*\|_C$ over $\mathbf{x}_k = \mathbf{x}_0 + \mathbf{z}_k$ with $\mathbf{z}_k \in \mathcal{K}(\mathbf{C}, \mathbf{r}_0, k)$. Observe that

$$\|\mathbf{x} - \mathbf{x}_*\|_C = \sqrt{(\mathbf{x} - \mathbf{x}_*)\mathbf{C}(\mathbf{x} - \mathbf{x}_*)} = \sqrt{(\mathbf{Cx} - \mathbf{b})^{\mathsf{T}}\mathbf{C}^{-1}(\mathbf{Cx} - \mathbf{b})} = \sqrt{\mathbf{r}(\mathbf{x})^{\mathsf{T}}\mathbf{C}^{-1}\mathbf{r}(\mathbf{x})},$$

where $\mathbf{r}(\mathbf{x}) = \mathbf{b} - \mathbf{Cx}$. If $(\lambda_i, \mathbf{q}_i)$, $i = 1, \ldots, m$, are orthonormal eigenpairs of $\mathbf{C}$, then

$$\|\mathbf{x} - \mathbf{x}_*\|_C^2 = \sum_{i=1}^{m} c_i(\mathbf{x})^2 / \lambda_i, \quad \text{where } c_i(\mathbf{x}) = \mathbf{r}(\mathbf{x})^{\mathsf{T}}\mathbf{q}_i. \tag{2.5}$$

Since the reciprocal of the eigenvalues appears in this expression, the components c_i of the residual $\mathbf{r}$ associated with the smallest eigenvalues are amplified the most in (2.5).

Suppose that we apply CGM to a linear system of the form (1.1), where the rows of $\mathbf{A}$ are linearly dependent and σ is small. By Proposition 2.2, the solution $\mathbf{x} \approx \mathbf{Pb}/\sigma$, the projection of $\mathbf{b}$ into the null space of $\mathbf{A}^{\mathsf{T}}$, divided by σ. On the other hand, the kth conjugate gradient iterate lies in the Krylov space $\mathcal{K}(\mathbf{C}, \mathbf{b}, k)$ if $\mathbf{x}_0 = \mathbf{0}$. The vectors forming this space are all contained in the range of $\mathbf{C}$, and if σ is small, then each of these vectors is nearly in the range of $\mathbf{A}$. We saw in (2.5) that CGM attaches the greatest weight to those components of the error associated with the smallest eigenvalues. Hence, the conjugate gradient method is using vectors that nearly lie in the range of $\mathbf{A}$ to approximate solution components that are nearly orthogonal to the range. In theory, CGM is guaranteed to reach the solution in a finite number of steps. This convergence must involve the subtraction of nearly equal numbers followed by the division of numbers that are nearly zero.

For the example depicted in Figure 1.1 with $\sigma = 0$, the effect is very similar. The rows of $\mathbf{A}$ are nearly dependent, the solution nearly lies in the space spanned by eigenvectors associated with the smallest eigenvalues of $\mathbf{AA}^{\mathsf{T}}$, while the conjugate gradient iterates nearly lie in the space spanned by eigenvectors associated with the largest eigenvalues of $\mathbf{AA}^{\mathsf{T}}$. For a nice survey of results concerning the convergence of the conjugate gradient method in finite precision arithmetic, see the paper [20] of Greenbaum and Strakoš. There they observe that the finite precision conjugate gradient method behaves similarly to the exact algorithm applied to a matrix with nearby eigenvalues.

In the generalized minimal residual algorithm applied to $\mathbf{Cx} = \mathbf{b}$, the kth approximation $\mathbf{x}_k$ to the solution is obtained by solving the problem

$$\min \ \|\mathbf{r}(\mathbf{x})\| \quad \text{subject to } \mathbf{x} = \mathbf{x}_0 + \mathbf{z}, \quad \mathbf{z} \in \mathcal{K}(\mathbf{C}, \mathbf{r}_0, k). \tag{2.6}$$

Thus when $\mathbf{C}$ is symmetric, the GMRES iterates are contained in the same Krylov space used by the conjugate gradient method. Unlike CGM, GMRES does not weight the components of the residual in (2.6). As k increases, the components of the vector $\mathbf{C}^k\mathbf{r}_0$ associated with the large eigenvalues of $\mathbf{C}$ become much larger in magnitude than the components associated with the small eigenvalues. Hence, we expect that GMRES approximates the solution components associated with the largest eigenvalues first. As the number of iterations approaches the dimension of the matrix, GMRES generates vectors orthogonal to the eigenvectors associated with the large eigenvalues. These orthogonal vectors correspond to the space associated with the eigenvectors of the smallest eigenvalues. Observe in Figure 1.1 that when the approximating space approaches the space corresponding to the smallest eigenvalues, the GMRES error quickly decreases. In order to improve on GMRES in this near-singular setting, we will strive to reach this space sooner. Note that for nonsymmetric matrices, the convergence of GMRES depends on both eigenvalues and departure from normality. For example, see [9, 19, 39] for related results and discussion.

3. Krylov, Arnoldi, and TMRES. With CGM or GMRES, the approximate solution lies in a Krylov space, and an orthonormal basis for this space is generated by the Arnoldi (Gram–Schmidt) process. The following algorithm generates such an orthonormal basis $\{\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_k\}$ for the Krylov space $\mathcal{K}(\mathbf{M}, \mathbf{g}, k)$:

ALGORITHM 1 (Arnoldi).

$\mathbf{v}_1 \leftarrow \mathbf{g}/\|\mathbf{g}\|$
for $j = 1 : k-1$
  $\mathbf{s} \leftarrow \mathbf{M}\mathbf{v}_j$
  for $i = 1 : j$
    $h_{ij} \leftarrow \mathbf{s}^{\mathsf{T}}\mathbf{v}_i \quad (= \mathbf{v}_i^{\mathsf{T}}\mathbf{M}\mathbf{v}_j)$
    $\mathbf{s} \leftarrow \mathbf{s} - h_{ij}\mathbf{v}_i$
  end
  $h_{j+1,j} \leftarrow \|\mathbf{s}\|$
  $\mathbf{v}_{j+1} \leftarrow \mathbf{s}/h_{j+1,j}$
end
end Algorithm 1

Obviously, if $h_{k+1,k} = 0$ for some k, the Arnoldi process should stop because

$$\mathcal{K}(\mathbf{M}, \mathbf{g}, j+1) = \mathcal{K}(\mathbf{M}, \mathbf{g}, j) \quad \text{for all } j \geq k. \tag{3.1}$$

CGM or GMRES corresponds to the choice $\mathbf{M} = \mathbf{C}$.

In order to more quickly generate vectors near the space spanned by the eigenvectors of $\mathbf{C}$ associated with the smallest eigenvalues, we consider the matrix $\mathbf{M} = \mathbf{S}^{-1}\mathbf{T}$ associated with a splitting $\mathbf{C} = \mathbf{S} - \mathbf{T}$, where $\mathbf{S}$ is nonsingular. This splitting leads to an iterative method

$$\mathbf{S}\mathbf{x}_{k+1} = \mathbf{T}\mathbf{x}_k + \mathbf{b}, \tag{3.2}$$

which converges to a solution of $\mathbf{C}\mathbf{x} = \mathbf{b}$ for all choices of the initial condition $\mathbf{x}_0$ if and only if $\rho(\mathbf{S}^{-1}\mathbf{T}) < 1$. The terminology "convergent splitting" will mean that $\rho(\mathbf{S}^{-1}\mathbf{T}) < 1$. From the discussion of section 2, we know that the eigenpairs of $\mathbf{C}$ whose eigenvalues are near zero correspond to eigenpairs of $\mathbf{S}^{-1}\mathbf{T}$ whose eigenvalues are near 1. Hence, the eigenvectors of $\mathbf{S}^{-1}\mathbf{T}$ associated with its eigenvalues of largest magnitude include approximations to the eigenvectors of $\mathbf{C}$ associated with its eigenvalues of smallest magnitude. Suppose that $\mathbf{S}^{-1}\mathbf{T}$ has m linearly independent eigenvectors $\mathbf{f}_1, \mathbf{f}_2, \ldots, \mathbf{f}_m$ and associated eigenvalues $\mu_1, \mu_2, \ldots, \mu_m$. If

$\mathbf{g} = c_1\mathbf{f}_1 + c_2\mathbf{f}_2 + \cdots + c_m\mathbf{f}_m$ is the expansion of $\mathbf{g}$ in terms of the eigenvectors, then

$$\mathbf{M}^k\mathbf{g} = (\mathbf{S}^{-1}\mathbf{T})^k\mathbf{g} = c_1\mu_1^k\mathbf{f}_1 + c_2\mu_2^k\mathbf{f}_2 + \cdots + c_m\mu_m^k\mathbf{f}_m.$$

It follows that the components of $\mathbf{g}$ associated with the absolute largest eigenvalues of $\mathbf{M}$ are amplified more rapidly than the components of $\mathbf{g}$ associated with the absolute smallest eigenvalues. Loosely speaking, the Krylov space $\mathcal{K}(\mathbf{M}, \mathbf{g}, k)$ converges, as k grows, to those eigenvectors associated with the absolute largest eigenvalues of $\mathbf{M}$ much more quickly than to those eigenvectors associated with the absolute smallest eigenvalues of $\mathbf{M}$. Since those eigenvectors associated with the large eigenvalues of $\mathbf{M}$ correspond to eigenvalues of $\mathbf{C}$ associated with its smallest eigenvalues, we converge to that space associated with the small eigenvalues of $\mathbf{C}$ that is critical in the near-singular setting.

After generating a Krylov space and a basis for it using Algorithm 1, we now return to the linear system $\mathbf{Cx} = \mathbf{b}$. If we were to minimize the norm of the residual $\mathbf{r} = \mathbf{b} - \mathbf{Cx}$ over the space spanned by the basis vectors $\mathbf{v}_i$, $1 \le i \le k$, we would need to multiply each $\mathbf{v}_i$ by $\mathbf{C}$. To circumvent this multiplication, we minimize the transformed residual $\mathbf{t}$ given by

$$\mathbf{t}(\mathbf{x}) = \mathbf{S}^{-1}\mathbf{r}(\mathbf{x}) = \mathbf{S}^{-1}(\mathbf{b} - \mathbf{Cx}) = \mathbf{S}^{-1}\mathbf{b} - (\mathbf{I} - \mathbf{M})\mathbf{x}.$$

Now when $\mathbf{x}$ is expanded in the basis vectors $\mathbf{v}_i$ and we minimize the norm of $\mathbf{t}$, we need to compute the product $\mathbf{Mv}_i$, which is available from Algorithm 1.

At step k, the TMRES approximation $\mathbf{x}_k$ to $\mathbf{x} = \mathbf{C}^{-1}\mathbf{b}$ is the solution to the transformed problem

$$\min \|\mathbf{t}(\mathbf{x})\| \quad \text{subject to } \mathbf{x} = \mathbf{z} + \mathbf{x}_0, \quad \mathbf{z} \in \mathcal{K}(\mathbf{M}, \mathbf{g}, k). \tag{3.3}$$

Making the special choice $\mathbf{g} = \mathbf{S}^{-1}(\mathbf{b} - \mathbf{Cx}_0)$, and substituting $\mathbf{x} = \mathbf{z} + \mathbf{x}_0$, we obtain the problem

$$\min \|\mathbf{g} - (\mathbf{I} - \mathbf{M})\mathbf{z}\| \quad \text{subject to} \quad \mathbf{z} \in \mathcal{K}(\mathbf{M}, \mathbf{g}, k). \tag{3.4}$$

If $\mathbf{V}_k$ denotes the matrix whose columns are the vectors $\mathbf{v}_1$, $\mathbf{v}_2$, ... , $\mathbf{v}_k$ generated by the Arnoldi process, then (3.4) reduces to the following equivalent problem:

$$\min_{\mathbf{y}} \|\mathbf{g} - (\mathbf{I} - \mathbf{M})\mathbf{V}_k\mathbf{y}\|. \tag{3.5}$$

The solution to the least-squares problem (3.5) can be obtained by a process similar to that described in [43]. If $\mathbf{H}$ is the $(k+1) \times k$ upper Hessenberg matrix whose elements are given by the Arnoldi process, then the following relation holds:

$$\mathbf{MV}_k = \mathbf{V}_{k+1}\mathbf{H}. \tag{3.6}$$

Let $\mathbf{e}$ denote the vector whose first component is $\|\mathbf{g}\|$ and whose remaining components are zero. After substituting $\mathbf{g} = \mathbf{V}_{k+1}\mathbf{e}$ in (3.5) and utilizing (3.6), we obtain the equivalent problem

$$\min_{\mathbf{y}} \|\mathbf{V}_{k+1}\mathbf{e} - \mathbf{V}_k\mathbf{y} + \mathbf{V}_{k+1}\mathbf{Hy}\|. \tag{3.7}$$

Since the columns of $\mathbf{V}_{k+1}$ are orthonormal, we have

$$\begin{aligned}\|\mathbf{V}_{k+1}\mathbf{e} - \mathbf{V}_k\mathbf{y} + \mathbf{V}_{k+1}\mathbf{H}\mathbf{y}\| &= \|\mathbf{V}_{k+1}\mathbf{e} - \mathbf{V}_{k+1}\begin{bmatrix}\mathbf{y}\\0\end{bmatrix} + \mathbf{V}_{k+1}\mathbf{H}\mathbf{y}\| \\ &= \|\mathbf{V}_{k+1}\mathbf{e} + \mathbf{V}_{k+1}\left(\mathbf{H} - \begin{bmatrix}\mathbf{I}\\\mathbf{0}\end{bmatrix}\right)\mathbf{y}\| \\ &= \|\mathbf{e} + \bar{\mathbf{H}}\mathbf{y}\|,\end{aligned}$$

where $\bar{\mathbf{H}}$ is the same as the Hessenberg matrix $\mathbf{H}$ generated by Algorithm 1 except that 1's have been subtracted from the diagonal elements. With this substitution, (3.7) simplifies to

$$\min_{\mathbf{y}} \|\mathbf{e} + \bar{\mathbf{H}}\mathbf{y}\|. \tag{3.8}$$

Finally, the vector $\mathbf{e} + \bar{\mathbf{H}}\mathbf{y}$ is multiplied on the left by a series of Givens rotations reducing $\bar{\mathbf{H}}$ to triangular form $\mathbf{R}$ and reducing $\mathbf{e}$ to a vector $\mathbf{f}$. Our approximation to the solution of $\mathbf{C}\mathbf{x} = \mathbf{b}$ is $\mathbf{x}_k = \mathbf{x}_0 + \mathbf{V}_k\mathbf{y}$, where $\mathbf{y}$ is the solution of the triangular system $(\mathbf{R}\mathbf{y})_{1:k} = \mathbf{f}_{1:k}$. The minimum norm in (3.8) is $|f_{k+1}|$.

In the following statement of TMRES, we overwrite $\mathbf{H}$ and $\mathbf{e}$ with $\mathbf{R}$ and $\mathbf{f}$, respectively. This algorithm is basically the same as preconditioned GMRES; in GMRES preconditioned by $\mathbf{S}^{-1}$, the multiplication by $\mathbf{S}^{-1}\mathbf{T}$ is replaced by $\mathbf{S}^{-1}\mathbf{C}$ and the diagonal of $\mathbf{H}$ is not modified. The function Givens($\mathbf{a}$) below generates a 2×2 rotation matrix $\mathbf{Q}$ with the property that $(\mathbf{Q}\mathbf{a})_2 = 0$.

ALGORITHM 2 (TMRES for $\mathbf{C}\mathbf{x} = \mathbf{b}$).

$\mathbf{C} = \mathbf{S} - \mathbf{T}$, $\mathbf{S}$ nonsingular, $\rho(\mathbf{S}^{-1}\mathbf{T}) \le 1$
$\mathbf{g} \leftarrow \mathbf{S}^{-1}(\mathbf{b} - \mathbf{C}\mathbf{x}_0)$, $\quad \mathbf{v}_1 \leftarrow \mathbf{g}/\|\mathbf{g}\|$, $\quad \mathbf{e} \leftarrow \mathbf{0}$, $\quad e_1 \leftarrow \|\mathbf{g}\|$
for $j = 1, 2 \ldots$ until convergence
  $\mathbf{s} \leftarrow \mathbf{S}^{-1}(\mathbf{T}\mathbf{v}_j)$
  for $i = 1 : j$
    $h_{ij} \leftarrow \mathbf{s}^{\mathsf{T}}\mathbf{v}_i$
    $\mathbf{s} \leftarrow \mathbf{s} - \mathbf{v}_i h_{ij}$
  end
  $h_{j+1,j} \leftarrow \|\mathbf{s}\|$
  $\mathbf{v}_{j+1} \leftarrow \mathbf{s}/h_{j+1,j}$
  $h_{ii} \leftarrow h_{ii} - 1$
  for $i = 1 : j - 1$
    $\mathbf{H}(i : i+1, j) \leftarrow \mathbf{Q}_i\mathbf{H}(i : i+1, j)$
  end
  $\mathbf{Q}_j \leftarrow \text{Givens}(\mathbf{H}(j : j+1, j))$
  $\mathbf{H}(j : j+1, j) \leftarrow \mathbf{Q}_j\mathbf{H}(j : j+1, j)$
  $\mathbf{e}(j : j+1) \leftarrow \mathbf{Q}_j\mathbf{e}(j : j+1)$
end
$\mathbf{x}_j \leftarrow \mathbf{x}_0 - \mathbf{V}_j\left(\mathbf{H}(1 : j, 1 : j)^{-1}\mathbf{e}(1 : j)\right)$
end Algorithm 2

Possible choices of $\mathbf{S}$ with the property that $\rho(\mathbf{S}^{-1}\mathbf{T}) < 1$ are the following: (i) if $\mathbf{C}$ is symmetric and positive definite, then $\mathbf{S} = \mathbf{L}$, where $\mathbf{L}$ is the lower triangular matrix whose lower triangle matches that of $\mathbf{C}$ (Gauss–Seidel choice); (ii) if $\mathbf{C}$ is row diagonally dominant, then $\mathbf{S} = \mathbf{L}$ or $\mathbf{S} = \mathbf{D}$, where $\mathbf{D}$ is the diagonal matrix whose diagonal matches that of $\mathbf{C}$ (Jacobi choice); (iii) if $\mathbf{C} = \mathbf{A}\mathbf{A}^{\mathsf{T}} + \sigma\mathbf{I}$ where the columns of $\mathbf{A}$ come from the columns of a larger matrix $\mathbf{B} = (\mathbf{A}|\mathbf{N})$, then $\mathbf{S} = \mathbf{B}\mathbf{B}^{\mathsf{T}} + \sigma\mathbf{I}$ (see Theorem 6.2 below).

4. Convergence analysis. The convergence of TMRES follows readily from previously established theory. Recall [29, p. 471] that the index of the matrix $\mathbf{M}$ with respect to the zero eigenvalue is the size of the largest singular Jordan block. If $\mathcal{R}(\mathbf{C})$ denotes the range of $\mathbf{C}$, then we have the following result.

THEOREM 4.1. *Let $\mathbf{C}$ be a square matrix with $\mathbf{C} = \mathbf{S} - \mathbf{T}$, where $\mathbf{S}$ is nonsingular, and define $\mathbf{M} = \mathbf{S}^{-1}\mathbf{T}$. Then $\mathbf{Cx} = \mathbf{b}$ has a solution in the Krylov space $\mathcal{K}(\mathbf{M}, \mathbf{S}^{-1}\mathbf{b}, k)$ for some k if and only if $\mathbf{S}^{-1}\mathbf{b} \in \mathcal{R}((\mathbf{I}-\mathbf{M})^i)$, where i is the index of the zero eigenvalue of $\mathbf{I} - \mathbf{M}$.*

Proof. By [30, Thm. 2] the linear system $(\mathbf{I} - \mathbf{M})\mathbf{x} = \mathbf{g}$ has a solution in the Krylov space $\mathcal{K}(\mathbf{I}-\mathbf{M}, \mathbf{g}, k)$ for k sufficiently large if and only if $\mathbf{g} \in \mathcal{R}((\mathbf{I}-\mathbf{M})^i)$, where i is the index of the zero eigenvalue of $\mathbf{I} - \mathbf{M}$. If P_k denotes the set of polynomials of degree at most k, it can be shown that

$$P_k = \{p(y) : y = 1 - x,\ p \in P_k\}.$$

As a result, we have $\mathcal{K}(\mathbf{M}, \mathbf{g}, k) = \mathcal{K}(\mathbf{I} - \mathbf{M}, \mathbf{g}, k)$. Hence, by [30, Thm. 2] the linear system $(\mathbf{I} - \mathbf{M})\mathbf{x} = \mathbf{g}$ has a solution in the Krylov space $\mathcal{K}(\mathbf{M}, \mathbf{g}, k)$ for k sufficiently large if and only if $\mathbf{g} \in \mathcal{R}((\mathbf{I} - \mathbf{M})^i)$. We take $\mathbf{g} = \mathbf{S}^{-1}\mathbf{b}$ to complete the proof. ∎

If one is not an eigenvalue of $\mathbf{M}$, then the index of the zero eigenvalue of $\mathbf{I} - \mathbf{M}$ is zero and the condition $\mathbf{S}^{-1}\mathbf{b} \in \mathcal{R}(\mathbf{I})$ holds trivially. If one is a nondefective eigenvalue of $\mathbf{M}$, then the index of the zero eigenvalue of $\mathbf{I} - \mathbf{M}$ is one and the condition $\mathbf{S}^{-1}\mathbf{b} \in \mathcal{R}(\mathbf{I} - \mathbf{M})$ is equivalent to $\mathbf{b} \in \mathcal{R}(\mathbf{C})$.

An analysis of the convergence of TMRES in terms of the spectrum of $\mathbf{M}$ can be given along the lines of the analysis for the conjugate gradient method in [48] or [14], and for GMRES in [43]. For example, we have the following result.

THEOREM 4.2. *Suppose that $\mathbf{C} = \mathbf{S} - \mathbf{T}$, where $\mathbf{S}$ is invertible, and that there exists a nonsingular matrix $\mathbf{F}$ such that $\mathbf{M} = \mathbf{S}^{-1}\mathbf{T} = \mathbf{F}\mathbf{\Phi}\mathbf{F}^{-1}$, where $\mathbf{\Phi}$ is diagonal. If $\mathbf{x}_k$ denotes a solution to (3.3), and μ_i is the ith diagonal element of $\mathbf{\Phi}$, then we have*

$$\|\mathbf{t}(\mathbf{x}_k)\| \le \|\mathbf{F}\|\ \|\mathbf{F}^{-1}\|\ \|\mathbf{t}(\mathbf{x}_0)\| \min_{\substack{p \in P_k \\ p(0)=1}} \max_i\ |p(1-\mu_i)|.$$

Proof. Simply apply [43, Prop. 4] to the transformed system $(\mathbf{I}-\mathbf{M})\mathbf{z} = \mathbf{g}$, where $\mathbf{g} = \mathbf{t}(\mathbf{x}_0)$. ∎

5. More examples. When $\mathbf{C}$ is symmetric and positive definite, the Gauss–Seidel splitting is convergent and, hence, yields an appropriate TMRES splitting. Figure 1.1 shows the iterates for the TMRES/GS algorithm applied to (1.1) where $\mathbf{A}$ is the matrix from beaconfd and $\sigma = 0$. After about 35 iterations, the norm of the residual has been reduced by 12 orders of magnitude, providing relatively rapid convergence.

Next, we examine the convergence for progressively larger problems from the netlib/lp directory. Figure 5.1 shows the convergence for the system (1.1) where $\mathbf{A}$ is the matrix from fffff800 ($m = 524$, $n = 1028$, $\sigma = 0$). The condition number for $\mathbf{A}\mathbf{A}^\mathsf{T}$ is of order 10^{19}. Also, in Figure 5.1 we show the convergence of preconditioned GMRES with the preconditioner $\mathbf{S} = \mathbf{L}$, the lower triangular part of $\mathbf{C}$. Theoretically, the TMRES and the preconditioned GMRES curves should coincide since the Krylov spaces generated by $\mathbf{M}$ and by $\mathbf{I} - \mathbf{M}$ are identical, algebraically. Note though that when a vector is multiplied by $\mathbf{I} - \mathbf{M}$, some subtraction of nearly equal numbers occurs: If $\mathbf{f}$ is an eigenvector of $\mathbf{M}$ whose associated eigenvalue μ is near one, then

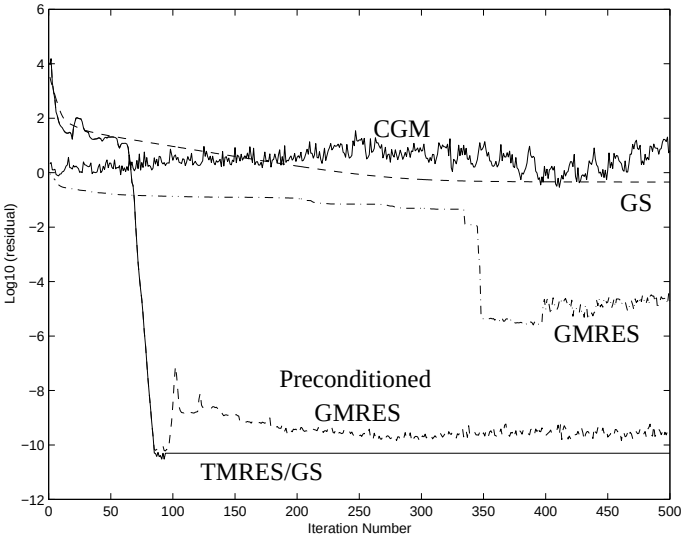

FIG. 5.1. *Convergence for the test problem* fffff800, $\sigma = 0$.

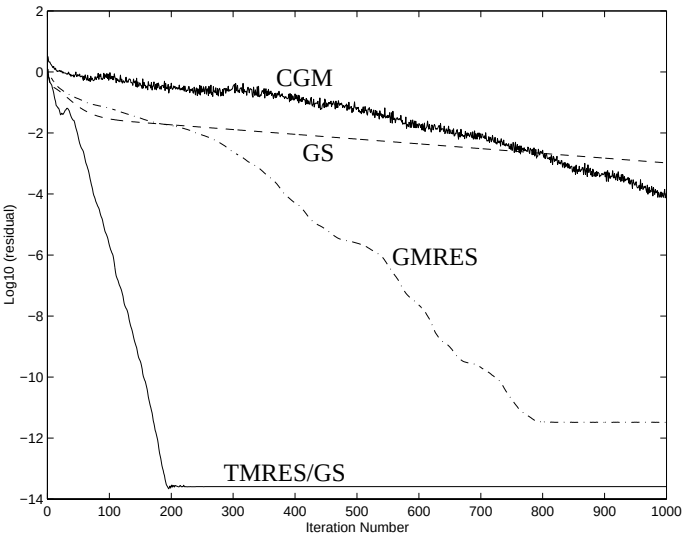

FIG. 5.2. *Convergence for the test problem greenbea, zero rows deleted,* $\sigma = 0$.

$(\mathbf{I} - \mathbf{M})\mathbf{f} = (1 - \mu)\mathbf{f} \approx \mathbf{0}$. As is well known (see [25, sects. 1–4]), the subtraction of nearly equal numbers can produce a large relative error and numerical differences between TMRES and GMRES.

Figures 5.2 and 5.3 show the convergence for greenbea ($m = 2392$, $n = 5598$). Since 3 rows in greenbea are completely zero, we ran two variations of the problem. In the variation of Figure 5.2, the zero rows are deleted, while in the variation of Figure 5.3, the zero rows are included, but $\sigma = 10^{-6}$ to keep the diagonal of $\mathbf{C}$ nonzero. In each case, the TMRES algorithm exhibits an attractive convergence rate. Since the TMRES algorithm minimizes the norm of the transformed residual in

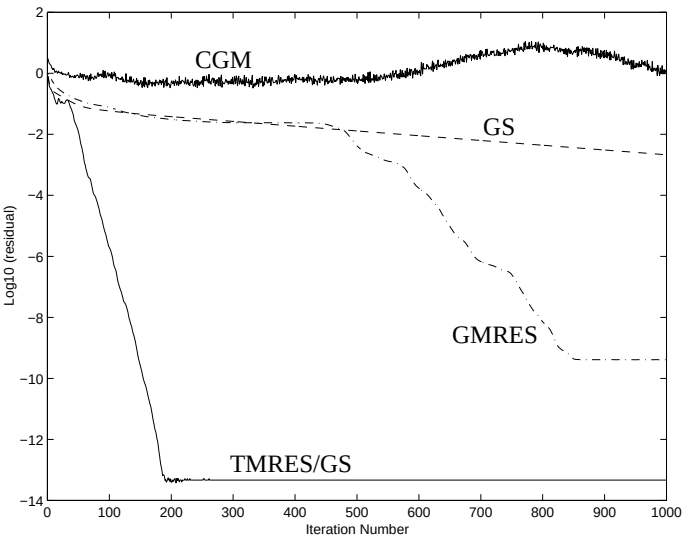

FIG. 5.3. *Convergence for the test problem greenbea, zero rows included,* $\sigma = 10^{-6}$.

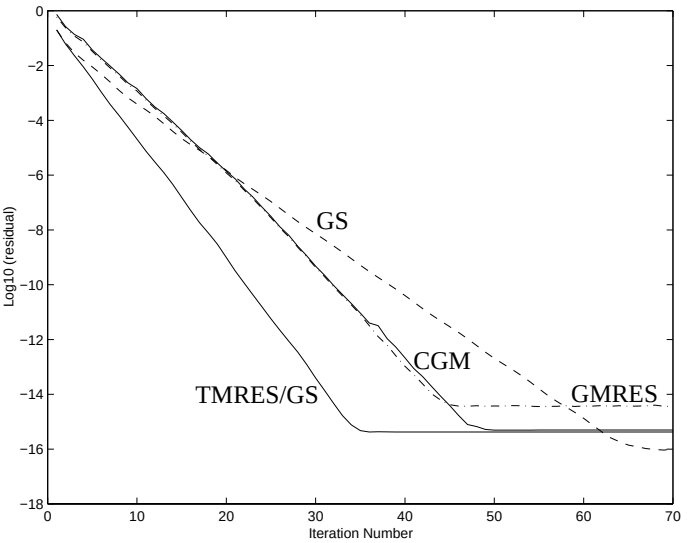

FIG. 5.4. *Convergence for the test problem greenbea,* $\sigma = 10$.

each step, the norm of the residual itself, plotted in Figures 1.1 and 5.1–5.3, is not guaranteed to decay in each iteration. In fact, GMRES is the only algorithm depicted in these figures that is guaranteed (in theory) to reduce the norm of the residual in each step.

Finally, we took $\sigma = 10$ in greenbea in order to examine the convergence speed when the eigenvalues of the matrix are strongly bounded away from zero and the matrix is well-conditioned. As seen in Figure 5.4, all the schemes converge quickly. The convergence of CGM and GMRES is almost identical since the ratio between the largest and smallest eigenvalue in (2.5) is of order 1, and hence, CGM and GMRES

minimize almost the same expression in each step. We emphasize that although TMRES with Gauss–Seidel splitting is effective for nearly singular linear systems such of those found in netlib/lp, its convergence when applied to a well-conditioned partial differential equation may be no better than either CGM or GMRES.

6. Symmetric TMRES. It is well known that for the Arnoldi process (Algorithm 1), the leading submatrices of the upper Hessenberg matrix $\mathbf{H}$ are tridiagonal if $\mathbf{M} = \mathbf{S}^{-1}\mathbf{T}$ is symmetric. Hence, in this symmetric case, we can skip the evaluation of h_{ij} when $i < j - 1$. In the spirit of Hageman and Young's terminology [22], we say that the iteration (3.2) is symmetrizable if there exists an invertible matrix $\mathbf{W}$ such that $\mathbf{WMW}^{-1}$ is symmetric. With the change of variables $\mathbf{x} = \mathbf{W}^{-1}\mathbf{w} + \mathbf{x}_0$, the iteration (3.2) can be written

$$\mathbf{w}_{k+1} = \mathbf{WMW}^{-1}\mathbf{w}_k + \mathbf{Wg}, \quad \mathbf{g} = \mathbf{S}^{-1}(\mathbf{b} - \mathbf{Cx}_0). \tag{6.1}$$

We now form a least-squares problem analogous to (3.4) to obtain an approximation $\mathbf{x}_k$ to a solution of $\mathbf{Cx} = \mathbf{b}$. In particular, $\mathbf{x}_k = \mathbf{W}^{-1}\mathbf{z}_k + \mathbf{x}_0$, where $\mathbf{z}_k$ is a solution to

$$\min \|\mathbf{Wg} - (\mathbf{I} - \mathbf{WMW}^{-1})\mathbf{z}\| \quad \text{subject to} \quad \mathbf{z} \in \mathcal{K}(\mathbf{WMW}^{-1}, \mathbf{Wg}, k). \tag{6.2}$$

This symmetric least squares problem can be solved using Algorithm 2. After taking into account the tridiagonal structure of $\mathbf{H}$, the resulting algorithm is closely connected with Paige and Saunders' MINRES algorithm [40]. Although the orthonormal vectors $\mathbf{v}_i$ for $i \le j$ are needed in Algorithm 2, the following idea of Paige and Saunders [40, 41] can be used to avoid their storage. Instead of evaluating

$$\mathbf{V}_j \left(\mathbf{H}(1:j, 1:j)^{-1}\mathbf{e}(1:j)\right)$$

as we do in Algorithm 2, Paige and Saunders evaluate

$$\left(\mathbf{V}_j\mathbf{H}(1:j, 1:j)^{-1}\right)\mathbf{e}(1:j).$$

Let $\mathbf{R}$ denote the upper triangular matrix $\mathbf{H}(1:j, 1:j)$ generated by Algorithm 2, and define $\mathbf{Z} = \mathbf{V}_j\mathbf{R}^{-1}$. Since the Hessenberg matrix used to generate $\mathbf{R}$ is tridiagonal, $\mathbf{R}$ has three bands, a diagonal band and two superdiagonal bands. Hence, the jth column $\mathbf{z}_j$ of $\mathbf{Z}$ is given by the recurrence

$$\mathbf{z}_j = (\mathbf{v}_j - \mathbf{z}_{j-1}r_{j-1,j} - \mathbf{z}_{j-2}r_{j-2,j})/r_{jj}.$$

The complete algorithm is the following.

ALGORITHM 3 (TMRES for $\mathbf{Cx} = \mathbf{b}$, $\mathbf{WS}^{-1}\mathbf{CW}^{-1}$ symmetric).

$\mathbf{g} \leftarrow \mathbf{S}^{-1}(\mathbf{b} - \mathbf{Cx}_0)$, $\mathbf{e} \leftarrow \mathbf{0}$, $e_1 \leftarrow \|\mathbf{Wg}\|$, $\mathbf{v}_1 \leftarrow \mathbf{Wg}/e_1$
$u \leftarrow 0$, $\mathbf{Q}_0 \leftarrow \mathbf{I}$, $\mathbf{Q}_{-1} \leftarrow \mathbf{0}$
for $j = 1, 2, \ldots$ until convergence
  $\mathbf{r} \leftarrow \mathbf{W}^{-1}\mathbf{v}_j$
  $\mathbf{s} \leftarrow \mathbf{W}(\mathbf{Mr})$ $(\mathbf{C} = \mathbf{S} - \mathbf{T}, \quad \mathbf{M} = \mathbf{S}^{-1}\mathbf{T})$
  $d \leftarrow \mathbf{s}^{\mathsf{T}}\mathbf{v}_j$, $\bar{u} \leftarrow u$
  $\mathbf{s} \leftarrow \mathbf{s} - d\mathbf{v}_j - u\mathbf{v}_{j-1}$
  $u \leftarrow \|\mathbf{s}\|$
  $\mathbf{v}_{j+1} \leftarrow \mathbf{s}/u$
  $d \leftarrow d - 1$

$[t\ \bar{u}] \leftarrow [0\ \bar{u}]\mathbf{Q}_{j-2}^{\mathsf{T}}$
$[\bar{u}\ d] \leftarrow [\bar{u}\ d]\mathbf{Q}_{j-1}^{\mathsf{T}}$
$\mathbf{Q}_j \leftarrow \text{Givens}(d, u)$
$\mathbf{e}(j : j+1) \leftarrow \mathbf{Q}_j \mathbf{e}(j : j+1)$
$d \leftarrow ([d\ u]\mathbf{Q}_j^{\mathsf{T}})_1$
$\mathbf{z}_j \leftarrow (\mathbf{r} - \bar{u}\mathbf{z}_{j-1} - t\mathbf{z}_{j-2})/d$
$\mathbf{x}_j \leftarrow \mathbf{x}_{j-1} - \mathbf{z}_j e_j$
end
end Algorithm 3

Since an iteration of Algorithm 3 requires only the vectors $\mathbf{v}_j$, $\mathbf{v}_{j-1}$, $\mathbf{z}_{j-1}$, $\mathbf{z}_{j-2}$, and $\mathbf{x}_{j-1}$, all the preceding vectors can be discarded. As in Algorithm 2, for a nearly singular linear system $\mathbf{Cx} = \mathbf{b}$, the iteration (6.1) should be devised in such a way that $\rho(\mathbf{M}) \leq 1$. If $\mathbf{z}$ lies in the null space of $\mathbf{C}$, then $\mathbf{Wz}$ is an eigenvector of $\mathbf{WMW}^{-1} = \mathbf{W}(\mathbf{S}^{-1}\mathbf{T})\mathbf{W}^{-1}$ whose eigenvalue is 1. Thus the eigenvalues of smallest modulus in the original problem are associated with eigenvalues of largest modulus in the transformed problem.

There are various ways to choose a symmetrizing matrix $\mathbf{W}$. If $\mathbf{C} = \mathbf{S} - \mathbf{T}$ is a splitting for which $\rho(\mathbf{M}) = \rho(\mathbf{S}^{-1}\mathbf{T}) < 1$ where $\mathbf{S}$ is symmetric and positive definite and $\mathbf{T}$ is symmetric, then we can take $\mathbf{W} = \mathbf{S}^{1/2}$. With this choice for $\mathbf{W}$, we can avoid squares roots in Algorithm 3 if vectors like $\mathbf{s}$ and $\mathbf{v}_j$ are replaced by new variables that are equal to $\mathbf{W}^{-1}$ times old variables. The resulting algorithm is the following.

ALGORITHM 3a (TMRES for $\mathbf{Cx} = \mathbf{b}$, $\mathbf{WS}^{-1}\mathbf{CW}^{-1}$ symmetric).
$\mathbf{g} \leftarrow \mathbf{S}^{-1}(\mathbf{b} - \mathbf{Cx}_0), \quad \mathbf{e} \leftarrow \mathbf{0}, \quad e_1 \leftarrow \|\mathbf{Wg}\|, \quad \mathbf{v}_1 \leftarrow \mathbf{g}/e_1$
$u \leftarrow 0, \quad \mathbf{Q}_0 \leftarrow \mathbf{I}, \quad \mathbf{Q}_{-1} \leftarrow \mathbf{0}$
for $j = 1, 2, \ldots$ until convergence
$\mathbf{r} \leftarrow \mathbf{v}_j$
$\mathbf{s} \leftarrow \mathbf{Mr} \quad (\mathbf{C} = \mathbf{S} - \mathbf{T}, \quad \mathbf{M} = \mathbf{S}^{-1}\mathbf{T})$
$d \leftarrow (\mathbf{Ws})^{\mathsf{T}}(\mathbf{Wv}_j), \quad \bar{u} \leftarrow u$
$\mathbf{s} \leftarrow \mathbf{s} - d\mathbf{v}_j - u\mathbf{v}_{j-1}$
$u \leftarrow \|\mathbf{Ws}\|$
Continue as in Algorithm 3
end
end Algorithm 3a

In this variation of Algorithm 3, $\mathbf{W}$ enters as a product $\mathbf{W}^{\mathsf{T}}\mathbf{W}$. Hence, when $\mathbf{W} = \mathbf{S}^{1/2}$, we have $\mathbf{W}^{\mathsf{T}}\mathbf{W} = \mathbf{S}$, and the square root is gone.

As an illustration of this symmetrization, suppose that $\mathbf{C}$ is symmetric and positive definite and $\mathbf{D}$ is a block diagonal matrix whose diagonal blocks match those of $\mathbf{C}$. The damped Jacobi iteration (see [22]) corresponding to the splitting $\mathbf{S} = \omega\mathbf{D}$ is convergent when the damping parameter ω is sufficiently large, and for this splitting, $\mathbf{S}$ is positive definite. To determine a suitable value for ω, observe that

$$\mathbf{S}^{-1}\mathbf{T} = \mathbf{I} - \frac{1}{\omega}\mathbf{D}^{-1}\mathbf{C},$$

where $\mathbf{D}^{-1}\mathbf{C}$ is similar to the symmetric, positive definite matrix $\mathbf{D}^{-1/2}\mathbf{C}\mathbf{D}^{-1/2}$. The eigenvalues of $\mathbf{S}^{-1}\mathbf{T}$ are real and less than 1 for any choice of $\omega > 0$, and for $\omega > \frac{1}{2}\rho(\mathbf{D}^{-1}\mathbf{C})$, the eigenvalues of $\mathbf{S}^{-1}\mathbf{T}$ are greater than -1. Since the spectral radius of a matrix is bounded by any matrix norm, we have $\rho(\mathbf{M}) \leq \|\mathbf{M}\|_1$. An estimate for the 1-norm of a matrix can be obtained using the algorithm developed

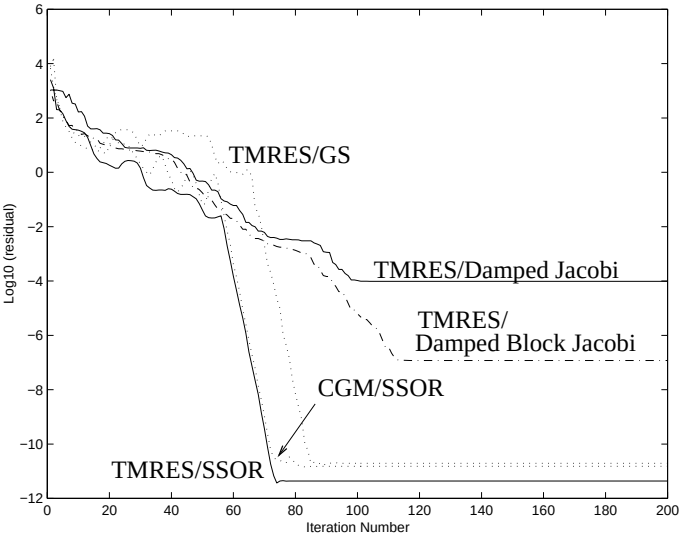

FIG. 6.1. *Convergence for* TMRES *using the test problem* fffff800 *and various symmetrization schemes.*

in [24]. Also see [25, p. 139] and [15, Alg. 7] for symbolic formulations of this algorithm. A Matlab version of this 1-norm estimation algorithm, due to Tim Davis, is available in Mathwork's contributed m-files ftp site, ftp.mathworks.com, as the file pub/contrib/v4/linalg/normest1.m, while Nick Higham gives a Fortran implementation in ACM TOMS Algorithm 674 [28].

In Figure 6.1, we show the convergence of TMRES using the damped Jacobi scheme, where $\mathbf{D}$ is the diagonal of $\mathbf{C}$ and ω is $\frac{2}{3}\|\mathbf{D}^{-1}\mathbf{C}\|_1$, for the test problem fffff800. We also show in Figure 6.1 convergence for TMRES/GS and for a damped Jacobi scheme associated with a block diagonal $\mathbf{D}$ gotten from the Chaco partitioning code [27] of Hendrickson and Rothberg by permuting the rows and columns in order to maximize the number of nonzero elements of $\mathbf{C}$ in diagonal blocks of size 8×8 and 9×9 (60 blocks altogether). Similar partitions are generated by the code Metis [34]. Observe that the TMRES/Block Jacobi scheme converges slightly faster than TMRES/Jacobi, but not as fast as TMRES/GS.

For schemes like Gauss–Seidel or successive overrelaxation (SOR), the $\mathbf{S}$ matrix is not symmetric, and the square root $\mathbf{S}^{1/2}$ may be complex or nonsymmetric. However, when $\mathbf{C} = \mathbf{S} - \mathbf{T}$ is symmetric, a two-step symmetrization is possible using the original iteration followed by its transpose:

$$\mathbf{S}\mathbf{x}_{k+1/2} = \mathbf{T}\mathbf{x}_k + \mathbf{b}, \quad \mathbf{S}^{\mathsf{T}}\mathbf{x}_{k+1} = \mathbf{T}^{\mathsf{T}}\mathbf{x}_{k+1/2} + \mathbf{b}.$$

If the two steps are combined into one step, then

$$\mathbf{x}_{k+1} = \mathbf{M}_2\mathbf{x}_k + \mathbf{g}, \quad \text{where} \quad \mathbf{M}_2 = \mathbf{S}^{-\mathsf{T}}\mathbf{T}^{\mathsf{T}}\mathbf{S}^{-1}\mathbf{T} \quad \text{and} \quad \mathbf{g} = \mathbf{S}^{-\mathsf{T}}(\mathbf{T}^{\mathsf{T}}\mathbf{S}^{-1} + \mathbf{I})\mathbf{b}.$$

In particular, for the SOR splitting of $\mathbf{C}$, this two-step scheme is the same as symmetric SOR (SSOR). As we now show, these two-step schemes are always symmetrizable when $\mathbf{C}$ is symmetric and positive definite.

PROPOSITION 6.1. *If* $\mathbf{C} = \mathbf{S} - \mathbf{T}$, *where* $\mathbf{S}$ *is nonsingular and* $\mathbf{C}$ *is symmetric and positive definite, then* $\mathbf{M}_2 = \mathbf{S}^{-\mathsf{T}}\mathbf{T}^{\mathsf{T}}\mathbf{S}^{-1}\mathbf{T}$ *is symmetrizable with* $\mathbf{W} = \mathbf{C}^{1/2}$.

Proof. Substituting $\mathbf{T} = \mathbf{S} - \mathbf{C}$, we obtain

$$\mathbf{M}_2 = \mathbf{I} - \mathbf{S}^{-\mathsf{T}}\mathbf{C} - \mathbf{S}^{-1}\mathbf{C} + \mathbf{S}^{-\mathsf{T}}\mathbf{C}\mathbf{S}^{-1}\mathbf{C}.$$

Hence, $\mathbf{C}^{1/2}\mathbf{M}_2\mathbf{C}^{-1/2}$ is symmetric. ∎

Let $\mathbf{D}$ be the diagonal of a symmetric, positive definite matrix $\mathbf{C}$. For the SOR splitting $\mathbf{S} = \mathbf{L} + \rho\mathbf{D}$, where $\rho = (1-\omega)/\omega$ and $0 < \omega < 2$, another possible symmetrization is $\mathbf{W} = \mathbf{D}^{-1/2}(\mathbf{L}+\rho\mathbf{D})^{\mathsf{T}}$ (see [22, p. 31]). In Figure 6.1, the curve labeled TMRES/SSOR, we show the convergence of symmetrized TMRES for the Gauss–Seidel/SOR splitting $\mathbf{S} = \mathbf{L}$ ($\rho = 0$). Also in Figure 6.1 we show the convergence of a preconditioned conjugate gradient method [6, 12, 13] with SSOR preconditioner ($\omega = 1$). Observe that the convergence of TMRES/SSOR and CGM/SSOR are very similar. Both schemes generate iterates in the same Krylov space, but they differ in the merit function used to select the approximate solution.

The following identities can be used to streamline the implementation of the SSOR preconditioned iteration:

$$\begin{aligned} \mathbf{M}_2 &= \mathbf{I} - (2\rho+1)(\mathbf{S}^{-\mathsf{T}}\mathbf{D}\mathbf{S}^{-1})\mathbf{C}, \\ \mathbf{W}\mathbf{M}_2\mathbf{W}^{-1} &= \mathbf{I} - (2\rho+1)\mathbf{D}^{1/2}\mathbf{S}^{-1}\mathbf{C}\mathbf{S}^{-\mathsf{T}}\mathbf{D}^{1/2}. \end{aligned} \tag{6.3}$$

From this relation, we see that if $\mathbf{z}$ lies in the null space of $\mathbf{C}$, then $\mathbf{W}\mathbf{z}$ is an eigenvector of $\mathbf{W}\mathbf{M}_2\mathbf{W}^{-1}$ with eigenvalue 1. Hence, eigenvalues of smallest modulus for $\mathbf{C}$ again correspond to eigenvalues of largest modulus for $\mathbf{W}\mathbf{M}_2\mathbf{W}^{-1}$.

In some optimization applications, such as the LP dual active set algorithm, we need to solve many different systems of the form (1.1) where the columns of $\mathbf{A}$ come from the columns of a larger matrix $\mathbf{B}$: $\mathbf{B} = (\mathbf{A}|\mathbf{N})$. As a consequence of the following result, which is basically a reformulation of the classical convergence theorem used for the SOR scheme, the splitting obtained by taking $\mathbf{S} = \mathbf{B}\mathbf{B}^{\mathsf{T}} + \sigma\mathbf{I}$ and $\mathbf{T} = \mathbf{N}\mathbf{N}^{\mathsf{T}}$ is convergent.

THEOREM 6.2. *Suppose that* $\mathbf{C}$ *is symmetric and positive definite and* $\mathbf{C} = \mathbf{S}-\mathbf{T}$, *where* $\mathbf{S}$ *is invertible. If* $\mathbf{S}+\mathbf{T}^{\mathsf{T}}$ *is positive definite, then* $\rho(\mathbf{M}) < 1 > \rho(\mathbf{M}_2)$.

Proof. Our proof that $\rho(\mathbf{M}) < 1$ is essentially that which appears in [49, p. 77] recast in terms of a matrix splitting. A proof that $\rho(\mathbf{M}_2) < 1$ for the SOR iteration appears in [21] (also see the classic reference [52]), while here we obtain a more general result.

Let $\mathbf{f}$ be any vector and define $\mathbf{g} = \mathbf{M}\mathbf{f}$ and $\boldsymbol{\delta} = \mathbf{f}-\mathbf{g}$. From the identity $\mathbf{S}\mathbf{g} = \mathbf{T}\mathbf{f}$, we obtain the following relations:

$$(\mathbf{S}-\mathbf{T})\mathbf{g} + \mathbf{T}\mathbf{g} = \mathbf{T}\mathbf{f} \quad \text{or } \mathbf{C}\mathbf{g} = \mathbf{T}\boldsymbol{\delta},$$

and

$$\mathbf{S}\mathbf{g} = (\mathbf{T}-\mathbf{S})\mathbf{f} + \mathbf{S}\mathbf{f} \quad \text{or } \mathbf{C}\mathbf{f} = \mathbf{S}\boldsymbol{\delta}.$$

Multiplying the first relation by $\mathbf{g}^*$ (the conjugate transpose of $\mathbf{g}$) and the second relation by $\mathbf{f}^*$, subtracting, and exploiting the identity $\mathbf{S}\mathbf{g} = \mathbf{T}\mathbf{f}$, we have

$$\begin{aligned} \mathbf{f}^*\mathbf{C}\mathbf{f} - \mathbf{g}^*\mathbf{C}\mathbf{g} &= (\mathbf{f}^*\mathbf{S} - \mathbf{g}^*\mathbf{T})\boldsymbol{\delta} \\ &= (\mathbf{f}^*\mathbf{S} - \mathbf{g}^*\mathbf{T})\boldsymbol{\delta} + (\mathbf{T}\mathbf{f} - \mathbf{S}\mathbf{g})^*\boldsymbol{\delta} \\ &= \mathbf{f}^*(\mathbf{S}+\mathbf{T}^{\mathsf{T}})\boldsymbol{\delta} - \mathbf{g}^*(\mathbf{T}+\mathbf{S}^{\mathsf{T}})\boldsymbol{\delta}. \end{aligned} \tag{6.4}$$

Since $\mathbf{C}$ is symmetric,

$$\mathbf{C}^{\mathsf{T}} = \mathbf{S}^{\mathsf{T}} - \mathbf{T}^{\mathsf{T}} = \mathbf{C} = \mathbf{S} - \mathbf{T}.$$

Hence, $\mathbf{S} + \mathbf{T}^{\mathsf{T}} = \mathbf{S}^{\mathsf{T}} + \mathbf{T}$, and substituting this in (6.4) gives

$$\mathbf{f}^*\mathbf{C}\mathbf{f} - \mathbf{g}^*\mathbf{C}\mathbf{g} = \boldsymbol{\delta}^*(\mathbf{S} + \mathbf{T}^{\mathsf{T}})\boldsymbol{\delta}. \tag{6.5}$$

If $\mathbf{f}$ is an eigenvector associated with an absolute largest eigenvalue λ of $\mathbf{M}$, then $\mathbf{g} = \mathbf{M}\mathbf{f} = \lambda\mathbf{f}$, and it follows from (6.5) that

$$(1 - |\lambda|^2)\mathbf{f}^*\mathbf{C}\mathbf{f} = \boldsymbol{\delta}^*(\mathbf{S} + \mathbf{T}^{\mathsf{T}})\boldsymbol{\delta} \geq 0$$

since $\mathbf{S} + \mathbf{T}^{\mathsf{T}}$ is positive definite. Since $\mathbf{C}$ is also positive definite, we conclude that $|\lambda| \leq 1$. If $|\lambda| = 1$, then $\boldsymbol{\delta} = \mathbf{0}$, or $\mathbf{g} = \mathbf{f} = \mathbf{M}\mathbf{f}$. Rearranging this last identity gives $\mathbf{C}\mathbf{f} = \mathbf{0}$, which is impossible since $\mathbf{C}$ is invertible. Hence $|\lambda| < 1$ and $\rho(\mathbf{M}) < 1$.

With $\mathbf{h}$ defined by $\mathbf{h} = \mathbf{S}^{-\mathsf{T}}\mathbf{T}^{\mathsf{T}}\mathbf{g} = \mathbf{S}^{-\mathsf{T}}\mathbf{T}^{\mathsf{T}}\mathbf{S}^{-1}\mathbf{T}\mathbf{f} = \mathbf{M}_2\mathbf{f}$, the same manipulations used to obtain (6.5), but with $\mathbf{S}$ and $\mathbf{T}$ replaced by $\mathbf{S}^{\mathsf{T}}$ and $\mathbf{T}^{\mathsf{T}}$, yield the relation

$$\mathbf{g}^*\mathbf{C}\mathbf{g} - \mathbf{h}^*\mathbf{C}\mathbf{h} = \boldsymbol{\epsilon}^*(\mathbf{S} + \mathbf{T}^{\mathsf{T}})\boldsymbol{\epsilon}, \quad \boldsymbol{\epsilon} = \mathbf{g} - \mathbf{h}.$$

Adding this relation to (6.5), we obtain

$$\mathbf{f}^*\mathbf{C}\mathbf{f} - \mathbf{h}^*\mathbf{C}\mathbf{h} = \boldsymbol{\delta}^*(\mathbf{S} + \mathbf{T}^{\mathsf{T}})\boldsymbol{\delta} + \boldsymbol{\epsilon}^*(\mathbf{S} + \mathbf{T}^{\mathsf{T}})\boldsymbol{\epsilon} \geq 0.$$

Now, if $\mathbf{f}$ is an eigenvector associated with the absolute largest eigenvalue μ of $\mathbf{M}_2$, then $|\mu| \leq 1$ and $|\mu| = 1$ if and only if $\boldsymbol{\delta} = \mathbf{0} = \mathbf{f} - \mathbf{g}$ and $\boldsymbol{\epsilon} = \mathbf{0} = \mathbf{g} - \mathbf{h}$. Again, the identity $\mathbf{g} = \mathbf{f} = \mathbf{M}\mathbf{f}$ implies that $\mathbf{C}$ is singular. Hence $|\mu| < 1$ and $\rho(\mathbf{M}_2) < 1$. ∎

7. Sparsity considerations. If TMRES is implemented using either a Gauss–Seidel or an SOR splitting, then for a linear system of the form (1.1), it would appear that the product $\mathbf{A}\mathbf{A}^{\mathsf{T}}$ must be evaluated. After forming this product, the number of multiplications and additions needed to perform the iteration is $\mathrm{nnz}(\mathbf{A}\mathbf{A}^{\mathsf{T}})$, where nnz is (Matlab) notation for the number of nonzero elements. When $\mathbf{A}$ is sparse, $\mathbf{A}\mathbf{A}^{\mathsf{T}}$ often has more nonzero entries than $\mathbf{A}$ itself. Hence, for some sparse matrices, it may be more efficient to express an iteration for (1.1) in terms of $\mathbf{A}$ itself rather than $\mathbf{A}\mathbf{A}^{\mathsf{T}}$. In [6] (also see [5, p. 284]) Björck and Elfving show that for SSOR preconditioned conjugate gradient iterations, the matrix-vector product $(\mathbf{W}\mathbf{M}_2\mathbf{W}^{-1})\mathbf{x}$ associated with the SSOR matrix (6.3) and $\mathbf{A}\mathbf{A}^{\mathsf{T}}$ can be evaluated in about $4\mathrm{nnz}(\mathbf{A})$ multiplications since products of the form $\mathbf{S}^{-\mathsf{T}}\mathbf{x}$ and $\mathbf{A}(\mathbf{S}^{-\mathsf{T}}\mathbf{x})$ can be simultaneously evaluated in $2\mathrm{nnz}(\mathbf{A})$ multiplications altogether. A similar approach applies to SOR splittings as we now observe.

If $\mathbf{y}$ and $\mathbf{z}$ denote the iterates $\mathbf{x}_k$ and $\mathbf{x}_{k+1}$, respectively, in (3.2) (so that $\mathbf{S}\mathbf{z} = \mathbf{T}\mathbf{y} + \mathbf{b}$), then for the SOR iteration with relaxation parameter $0 < \omega < 2$, we have

$$z_i - y_i = \frac{\omega\left(b_i - \sum_{j=1}^{i-1} c_{ij}z_j - \sum_{j=i}^{m} c_{ij}y_j\right)}{c_{ii}}, \quad i = 1 \text{ to } m.$$

Since $\mathbf{C} = \mathbf{A}\mathbf{A}^{\mathsf{T}} + \sigma\mathbf{I}$ for the system (1.1), it follows that

$$c_{ij} = \mathbf{a}_i^{\mathsf{T}}\mathbf{a}_j \text{ for } i \neq j, \quad c_{ii} = \sigma + \|\mathbf{a}_i\|^2,$$

TABLE 1
Method and approximate number of multiplications and additions.

Method	Operations
TMRES/SSOR	4nnz($\mathbf{A}$)
CGM/SSOR	4nnz($\mathbf{A}$)
TMRES/SOR	2nnz($\mathbf{A}$)
GS	2nnz($\mathbf{A}$)
GMRES	2nnz($\mathbf{A}$)
TMRES/Jacobi	2nnz($\mathbf{A}$)
CGM	2nnz($\mathbf{A}$)

where $\mathbf{a}_i$ denotes the ith column of $\mathbf{A}^\mathsf{T}$. Let us define $\mathbf{q}_i \in \mathbf{R}^n$ by

$$\mathbf{q}_i = \sum_{j=1}^{i-1} \mathbf{a}_j z_j + \sum_{j=i}^{m} \mathbf{a}_j y_j.$$

From this definition, it follows that

$$z_i - y_i = \omega(b_i - \sigma y_i - \mathbf{q}_i^\mathsf{T}\mathbf{a}_i)/c_{ii}, \quad \text{where } \mathbf{q}_{i+1} = \mathbf{q}_i + \mathbf{a}_i(z_i - y_i).$$

Hence, an iteration of SOR, overwriting the current iterate $\mathbf{x}_k$ by the new iterate $\mathbf{x}_{k+1}$, can be implemented in the following way.

ALGORITHM 4 (SOR for $(\mathbf{A}\mathbf{A}^\mathsf{T} + \sigma\mathbf{I})\mathbf{x} = \mathbf{b}, \mathbf{q} = \mathbf{A}^\mathsf{T}\mathbf{x}_k$).
for $i = 1 : m$
$d \leftarrow \omega(b_i - \sigma x_i - \mathbf{q}^\mathsf{T}\mathbf{a}_i)/(\sigma + \|\mathbf{a}_i\|^2)$
$\mathbf{q} \leftarrow \mathbf{q} + \mathbf{a}_i d$
$x_i \leftarrow x_i + d$
end
end Algorithm 4

After completing the loop in Algorithm 4, $\mathbf{q}$ contains $\mathbf{A}^\mathsf{T}\mathbf{x}_{k+1}$ and $\mathbf{x}$ contains $\mathbf{x}_{k+1}$, assuming $\mathbf{x}$ initially stores $\mathbf{x}_k$. Note that this SOR iteration requires 2nnz($\mathbf{A}$) multiplications and additions.

8. Conclusions. In Table 1 we give work estimates for various iterative schemes studied in this paper and for the prototype system (1.1). We assume that the product $\mathbf{A}\mathbf{A}^\mathsf{T}$ is not formed, and that the computations utilize $\mathbf{A}$ by itself. Table 1 only gives the matrix-vector product work; for Algorithm 3 and symmetric schemes such as CGM, TMRES/SSOR, CGM/SSOR, and TMRES/Jacobi, each iteration involves a small number (between 5 and 10) of additional vector-vector or scalar-vector products. For schemes based on the nonsymmetric Algorithm 2, there are about $(k-1)(k+2)$ additional vector-vector or scalar-vector products.

The numerical experiments in this paper show that iterative schemes may converge slowly when the matrix is nearly singular. In the TMRES approach, we start with a convergent splitting $\mathbf{C} = \mathbf{S} - \mathbf{T}$ and compute an orthonormal basis for a Krylov space generated by $\mathbf{M} = \mathbf{S}^{-1}\mathbf{T}$. Since TMRES is algebraically equivalent to GMRES preconditioned by $\mathbf{S}^{-1}$, TMRES converges in theory if and only if GMRES preconditioned by $\mathbf{S}^{-1}$ converges. We observed that when $\rho(\mathbf{S}^{-1}\mathbf{T}) < 1$, a small dimensional Krylov space often contains a good approximation to the solution of a nearly singular linear system. For the prototype system (1.1), TMRES/SSOR and CGM/SSOR exhibited similar (rapid) convergence and were more efficient than unpreconditioned

schemes. The efficiency of TMRES/Jacobi was comparable to that of the SSOR-based schemes when its lower operation count 2nnz(**A**) was taken into account.

Acknowledgment. The author gratefully acknowledges the many thoughtful and perceptive comments of the referees and their pointers to related work.

A CIRCULANT PRECONDITIONER FOR THE SYSTEMS OF LMF-BASED ODE CODES*

D. BERTACCINI†

Abstract. In this paper, a recently introduced block circulant preconditioner for the linear systems of the codes for ordinary differential equations (ODEs) is investigated. Most ODE codes based on implicit formulas, at each integration step, need the solution of one or more unsymmetric linear systems that are often large and sparse. Here, the boundary value methods, a class of implicit methods for the numerical integration of ODEs based on linear multistep formulas, are considered more in detail for initial value problems.

Theoretical and practical arguments are given to show that the block circulant preconditioner can give fast preconditioned iterations for various classes of differential problems. Moreover, the *P-circulants*, a recently introduced circulant approximation for unsymmetric Toeplitz matrices, are shown to be more suitable sometimes than other circulant matrices for the underlying block preconditioner.

Key words. circulant preconditioning, unsymmetric block (almost) Toeplitz linear systems, numerical solution of differential equations, boundary value methods, implicit linear multistep formulas

1. Introduction.

The aim of this paper is to study a new class of block preconditioners for the linear systems

$$Mx = b \tag{1.1}$$

arising in the codes for the numerical integration of ordinary differential equations (ODEs) based on linear multistep formulas (LMFs) (see, e.g., [18]). The solution of the large and sparse system of equations, arising at each integration step, is one of the crucial parts in a numerical integrator based on implicit formulas; see, e.g., [12, 4]. Here will be considered the linear systems arising in boundary value methods (BVMs) (see [3] and references therein) or that can be reduced to those with some transformation on (1.1). BVMs are a class of numerical methods based on LMFs solving initial and boundary value problems for ordinary differential equations.

The underlying block preconditioner is based on the circulant approximation of the (small rank perturbation of) band Toeplitz matrices arising in (1.1). To this end, a new type of circulant approximation for Toeplitz matrices introduced in [1], the *P-circulant matrices*, or *P-circulants*, can be effective. T. F. Chan's *optimal* [5] and Strang's circulant [23] will also be considered. Other techniques for band Toeplitz linear systems can be found, e.g., in [11, 6, 16], but they are effective only in the symmetric case while, in general, matrices for (1.1) are not symmetric.

An $n \times n$ matrix T is said to be *Toeplitz* if its entries are constant along its diagonals; an $n \times n$ matrix C is called *circulant* if it is a Toeplitz matrix with the

following pattern:

$$C = circ(c_0, \ldots, c_{n-1}) = \begin{pmatrix} c_0 & c_1 & \ldots & c_{n-1} \\ c_{n-1} & c_0 & & c_{n-2} \\ \vdots & \vdots & \ddots & \vdots \\ c_1 & c_2 & \ldots & c_0 \end{pmatrix}. \tag{1.2}$$

In the last decade, there has been intensive work on preconditioners for Toeplitz matrices and their spectral properties; see, for instance, the survey [8], and the references therein, and [11, 5, 6, 7, 14, 16, 21, 23, 24].

Consider for simplicity the linear initial value problem (IVP)

$$\begin{cases} y'(t) &= f(t, y(t)) := J\, y(t) + g(t), \quad t \in (t_0, T], \\ y(t_0) &= \eta, \end{cases} \tag{1.3}$$

where $y(t), g(t) : \mathbb{R} \to \mathbb{R}^m$, $J \in \mathbb{R}^{m \times m}$, $\eta \in \mathbb{R}^m$. The matrix M (1.1) related to the underlying LMF-based code, in general, can be written as

$$M = A \otimes I_m - hB \otimes J, \tag{1.4}$$

where A, B are the matrices of the integration method, h is the integration stepsize, and $\otimes$ is the Kronecker product (see, e.g., [19, Chapter 12]). A and B are usually reducible to Toeplitz plus small rank perturbation pattern. M turns out to be large and sparse when the Jacobian matrix of the underlying system of ODEs (and/or A and B) is so. In that case, the solution of the linear system (1.1) via a direct method is often computationally expensive and not easily parallelizable; therefore the use of a preconditioned iterative method is preferable.

We stress that the proposed iterative technique can be naturally generalized to the case of d-level structures arising in d-dimensional partial differential equations (PDEs). In that case, the direct solvers become very expensive since they do not exploit properly the multiple band structure (see section 5, Example 2).

It is interesting to observe that P-circulants preserve important properties occurring in the matrices A, B in (1.4), such as

- invertibility,
- eigenvalues in the right half plane,
- almost the same sparsity pattern.

Moreover, our block preconditioner has interesting implementation potentialities, in both a scalar and a parallel computing environment.

Under appropriate hypotheses, the results obtained here can be extended to the case where the given ODE is nonlinear. Indeed, we can observe that the discrete nonlinear problem corresponding to the approximation by an LMF can be solved iteratively by considering, at each step, discrete problems such as (1.1). Notice that there are several important additional topics to take into account in the nonlinear case, such as the convergence of the modified Newton approach (see, e.g., [13]) and the mesh selection strategy.

The paper is organized as follows. In section 2 we recall some classes of BVMs. In section 3 we introduce the block circulant preconditioner and the circulant approximations. Section 4 contains some notes on the computational cost and on the convergence of preconditioned iterations. Finally, section 5 contains some numerical tests.

2. BVMs and their matrix form. Recently, the class of BVMs for differential equations has been introduced (see [3] and references therein). Such methods are based on LMFs. In order to briefly describe them, suppose for simplicity that we have the linear IVP (1.3). A BVM approximates the solution of (1.3) by means of a discrete boundary value problem (BVP). The latter is obtained by using a k-step linear multistep formula of order p over a uniform mesh $t_j = t_0 + j\,h,\ j = 0, \ldots, s$, $h = (T - t_0)/s$:

$$\sum_{i=-\nu}^{k-\nu} \alpha_{i+\nu} y_{n+i} = h \sum_{i=-\nu}^{k-\nu} \beta_{i+\nu} f_{n+i}, \quad n = \nu, \ldots, s-k+\nu. \tag{2.1}$$

As usual, y_n is the discrete approximation to $y(t_n)$, $f_n = f(t_n, y_n) \equiv J\,y_n + g_n$, $g_n = g(t_n)$, and the values

$$y_0, \ldots, y_{\nu-1}, \quad y_{s-k+\nu+1}, \ldots, y_s \tag{2.2}$$

are given. We observe that the IVP (1.3) provides only the initial value y_0. It is possible to avoid supplying the other conditions in (2.2) by coupling the *main method* (2.1) with other difference schemes of order p, called *additional methods*, which provide the set of equations

$$\sum_{i=0}^{k} \alpha_i^{(j)} y_i = h \sum_{i=0}^{k} \beta_i^{(j)} f_i, \quad j = 1, \ldots, \nu-1, \tag{2.3}$$

$$\sum_{i=0}^{k} \alpha_{k-i}^{(j)} y_{s-i} = h \sum_{i=0}^{k} \beta_{k-i}^{(j)} f_{s-i}, \quad j = s-k+\nu+1, \ldots, s, \tag{2.4}$$

independent of those in (2.1). For simplicity, such formulas are assumed to have the same number of steps as the main method. The equations (2.1), (2.3), and (2.4) define the use of a BVM on problem (1.3). The advantage in using BVMs, over the known LMFs requiring only initial conditions, derives from their stability properties.

It is useful to cast BVMs in matrix form. This is done by introducing the matrices $A, B \in \mathbb{R}^{(s+1)\times(s+1)}$

$$A = \begin{pmatrix} 1 & \cdots & 0 & & & & \\ \alpha_0^{(1)} & \cdots & \alpha_k^{(1)} & & & & \\ \vdots & \vdots & \vdots & & & & \\ \alpha_0^{(\nu-1)} & \cdots & \alpha_k^{(\nu-1)} & & & & \\ \alpha_0 & \cdots & \alpha_k & & & & \\ & \alpha_0 & \cdots & \alpha_k & & & \\ & & \ddots & \ddots & \ddots & & \\ & & & \alpha_0 & \cdots & \alpha_k & \\ & & & \alpha_0^{(s-k+\nu+1)} & \cdots & \alpha_k^{(s-k+\nu+1)} & \\ & & & \vdots & \vdots & \vdots & \\ & & & \alpha_0^{(s)} & \cdots & \alpha_k^{(s)} & \end{pmatrix}, \tag{2.5}$$

and B similarly but with β_j's instead of α_j's and all zeros in its first row. The discrete problem generated by the application of the BVM (2.1)–(2.4) to problem (1.3) is then

given by

$$M\,Y = e_1 \otimes \eta + h\,(B \otimes I)g, \tag{2.6}$$
$$e_1 = (1, 0, \ldots, 0)^T \in \mathbb{R}^{s+1}, \quad Y = (y_0, \ldots, y_s)^T, \quad g = (g_0, \ldots, g_s)^T,$$

$$M = A \otimes I_m - h\,B \otimes J.$$

The matrix M in (2.6) turns out to be large and sparse when $s \gg k$ and/or J is large and sparse.

2.1. Some families of BVMs. Here we give the definitions of some families of BVMs (see [3] for details). All considered methods are consistent, i.e., they satisfy the conditions

$$\rho(1) = 0, \qquad \rho'(1) = \sigma(1),$$

where $\rho(z)$ and $\sigma(z)$ denote, as usual, the two characteristic polynomials associated with the given method, i.e.,

$$\rho(z) = z^\nu \sum_{j=-\nu}^{k-\nu} \alpha_{j+\nu}\, z^j, \quad \sigma(z) = z^\nu \sum_{j=-\nu}^{k-\nu} \beta_{j+\nu}\, z^j. \tag{2.7}$$

The generalized BDF, or GBDF, are a generalization of the backward differentiation formulas (BDF) (see [13]). They can be written in the form

$$\sum_{i=-\nu}^{k-\nu} \alpha_{i+\nu}\, y_{n+i} = h\, f_n, \quad n = \nu, \ldots, s-k+\nu, \tag{2.8}$$

where the coefficients $\{\alpha_i\}$ are uniquely determined by imposing that the method has maximum order, i.e., k, for all $k \geq 1$, with $\nu = (k+2)/2$ if k is even and $\nu = (k+1)/2$ if k is odd. Such methods are well suited for stiff problems. (See [3, Chapter 5] for details.)

The generalized Adams methods (GAM) are a generalization of the Adams–Moulton methods (see [13]). They can be written in the form

$$y_{n+\nu} - y_{n+\nu-1} = h \sum_{i=-\nu}^{k-\nu} \beta_{i+\nu}\, f_{n+i}, \tag{2.9}$$

where the coefficients $\{\beta_i\}$ are uniquely determined by imposing that the method has maximum order, i.e., $k+1$, for all $k \geq 1$, with $\nu = k/2$ if k is even and $(k+1)/2$ if k is odd. When k is odd, they are called extended trapezoidal rules (ETR), because they share the same stability properties of the trapezoidal rule. Such methods turn out to be well suited for approximating either Hamiltonian problems or continuous BVPs. When k is even, GAM are well suited for stiff problems (see [3, Chapters 6 and 7] for details).

ETR_2 are another generalization of the trapezoidal rule belonging to the class of symmetric schemes:

$$\sum_{i=-\nu}^{\nu-1} \alpha_{i+\nu}\, y_{n+i} = \frac{h}{2}(f_n + f_{n-1}), \tag{2.10}$$

where $k = 2\nu - 1$ is odd and the coefficients $\{\alpha_i\}$ are uniquely determined by imposing that the method has maximum order, i.e., $k+1$, $k = 1, 3, 5, \ldots$. When $\nu = 1$, then $k = 1$ and the formulas (2.10), (2.9) become the trapezoidal rule. Indeed, all such formulas can be regarded as generalizations of this method, sharing the same stability properties. Such methods turn out to be well suited for approximating both Hamiltonian problems and continuous BVPs (see [3, Chapter 7] for details).

3. Circulant approximations for the block preconditioner. Let M in (2.6) be the small rank perturbation of a block Toeplitz matrix generated by a BVM as in the previous section. A way to solve such large, sparse linear systems is through an iterative method; see, e.g., [12, 4]. To accelerate convergence, a preconditioner P should be chosen to approximate the matrix M while keeping the system

$$P\,x = c$$

cheap enough to solve with respect to the unpreconditioned iterations.

In order to obtain the preconditioner, let us consider the following approximation of the matrix M:

$$P = \breve{A} \otimes I_m - h\,\breve{B} \otimes \hat{J}, \tag{3.1}$$

where $\hat{J}$ can be a suitable approximation of the Jacobian matrix of the ODE, or the Jacobian itself. $\breve{A}$, $\breve{B}$ are circulant matrices the entries of which are derived from the coefficients of the main method (2.1) as follows:

$$\begin{aligned} &\breve{A} = circ(\tilde{\alpha}_j), \qquad \tilde{\alpha}_j = c_{j,1}(s)\alpha_{j+\nu} + c_{j,2}(s)\alpha_{j+\nu-(s+1)}, \\ &\breve{B} = circ(\tilde{\beta}_j), \qquad \tilde{\beta}_j = c_{j,3}(s)\beta_{j+\nu} + c_{j,4}(s)\beta_{j+\nu-(s+1)}, \qquad j = 0, \ldots, s, \end{aligned} \tag{3.2}$$

where the $c_{j,i}(s)$, $i = 1, \ldots, 4$, $j = 0, \ldots, s$ are linear in j. It is understood that α_j (β_j) is zero for $j < 0$ or $j > k$ in (3.2). The coefficients $c_{i,j}(s)$ in (3.2) are chosen in such a way that $\breve{A}$, $\breve{B}$ are suitable approximations of A, B in (2.5), respectively.

The approximation of A, B with Chan's optimal circulant (see [5]) requires that

$$c_{j,1}(s) = c_{j,3}(s) = 1 - \frac{j}{s+1}, \qquad c_{j,2}(s) = c_{j,4}(s) = \frac{j}{s+1}, \qquad j = 0, \ldots, s, \tag{3.3}$$

while for Strang's natural circulant (see [23])

$$c_{j,1}(s) = c_{j,3}(s) = 1, \qquad j = 0, \ldots, \left\lfloor \frac{s+1}{2} \right\rfloor,$$

$$c_{j,2}(s) = c_{j,4}(s) = 1, \qquad j = \left\lfloor \frac{s+1}{2} \right\rfloor + 1, \ldots, s, \qquad c_{r,j}(s) = 0 \ \text{ otherwise.} \tag{3.4}$$

Let us observe that, for an $(s+1) \times (s+1)$ Toeplitz matrix T, Chan's circulant $C = C(T)$ is defined to be the minimizer of

$$\|T - C\|_F \tag{3.5}$$

over all $(s+1) \times (s+1)$ circulant matrices C; see [5]. ($\|\cdot\|_F$ is the Frobenius norm.) Consider, instead of (3.3), the following definition of the coefficients $c_{j,i}(s)$:

$$c_{j,1}(s) = c_{j,3}(s) = 1 + \frac{j}{s+1}, \qquad c_{j,2}(s) = c_{j,4}(s) = \frac{j}{s+1}, \qquad j = 0, \ldots, s. \tag{3.6}$$

We will call P-circulants the circulant matrices defined in (3.2), (3.6). The definitions (3.2), (3.3), (3.2), (3.4) and (3.2), (3.6) differ for a quantity that vanishes as s increases for banded matrices, and (3.5) is not minimized for P-circulants. Despite this, the P-circulant matrices $\breve{A}$, $\breve{B}$, defined as (3.2), (3.6), are nonsingular and appropriate approximations of A, B given by (2.5), as observed in [2].

3.1. Spectral properties of the block preconditioner. We observe that positive stability is a sufficient condition for the invertibility of a matrix. Recall that a square matrix A is said to be positive stable if its eigenvalues have positive real part (see, e.g., [15]). The matrices A, B of the BVMs we consider here are assumed to be positive stable. This assumption is a consequence of the stability properties of the formulas; see [3]. It is interesting to observe that the P-circulant approximations $\breve{A}$, $\breve{B}$ given by (3.2), (3.6) preserve positive stability for the methods described in section 2.1 (see [2]). Let $\breve{A} = circ(\tilde{\alpha}_j)$ be a $(s+1) \times (s+1)$ circulant matrix defined in (3.2), (3.6) from the first characteristic polynomial of the main method (2.1). The eigenvalues ϕ_j, $j = 0, \ldots, s$, of $\breve{A}$ can be written as linear combinations of the entries of its first row (see [10]):

$$\phi_l = \sum_{j=0}^{s} \tilde{\alpha}_j \epsilon^{jl}, \quad l = 0, \ldots, s, \quad \epsilon = e^{2\pi \mathbf{i}/(s+1)}, \tag{3.7}$$

where $\mathbf{i}$ is the imaginary unit. From (3.2), (3.6) one obtains

$$\phi_l = \sum_{j=0}^{s} \alpha_{j+\nu} \left(1 + \frac{j}{s+1}\right) \epsilon^{jl} + \sum_{j=0}^{s} \left(\frac{j}{s+1} \alpha_{j+\nu-(s+1)}\right) \epsilon^{jl},$$

which can be restated as

$$\phi_l = \sum_{j=-\nu}^{k-\nu} \alpha_{j+\nu} \left(1 + \frac{j}{s+1}\right) \epsilon^{jl}, \qquad l = 0, \ldots, s. \tag{3.8}$$

A similar expression holds for the eigenvalues of $\breve{B}$:

$$\psi_l = \sum_{j=-\nu}^{k-\nu} \beta_{j+\nu} \left(1 + \frac{j}{s+1}\right) \epsilon^{jl}, \qquad l = 0, \ldots, s. \tag{3.9}$$

In [2] we have observed that, for some A-stable ($A_{\nu,k-\nu}$-stable, a generalization of A-stability for (2.1) if $k > \nu$; see [3]) BVMs, the $l2$-norms of the P-circulant matrices $\breve{A}$, $\breve{B}$ are uniformly bounded and the $l2$-norms of their inverses are bounded with respect to the number of steps k of the method (2.1), i.e.,

$$\|\breve{A}\|_2 \leq c_1, \qquad \|\breve{B}\|_2 \leq c_2, \qquad \|\breve{A}^{-1}\|_2 \leq c_3 \cdot (s+1), \qquad \|\breve{B}^{-1}\|_2 \leq c_4 \cdot (s+1), \tag{3.10}$$

where c_j, $j = 1, \ldots, 4$, are constants of the order of unity. Exceptions are the GBDF (they have $\breve{B} \equiv I$) and the ETR_2.

Notice that the circulant matrix $\breve{A}$ defined as the optimal circulant (3.2), (3.3), may become severely ill-conditioned as k increases (see [2]).

We can give a sample of sufficient conditions for the block preconditioner (3.1) to be positive stable. From here on, for simplicity, we will assume the Jacobian matrix to be diagonalizable.

PROPOSITION 3.1. *Suppose that the eigenvalues μ_r, $r = 1, \ldots, m$, of the approximation of the Jacobian matrix J of the given ODE are in the left half plane, i.e., they have nonpositive real part. Each of the following conditions is sufficient for the positive stability of the block preconditioner P given by* (3.1):

1. *$\breve{A}$, $\breve{B}$ are P-circulants and* (2.1) *belongs to GBDF;*
2. *$\breve{A}$, $\breve{B}$ are positive stable and $\breve{B}$ is Hermitian;*
3. *$\breve{A}$, $\breve{B}$ are positive stable and, for $j \neq 0, (s+1)/2$, we have*

$$|\mathrm{Im}(\mu_r)| < \left(\frac{\mathrm{Re}(\phi_j) - h\mathrm{Re}(\psi_j)\mathrm{Re}(\mu_r)}{h\,|\mathrm{Im}(\psi_j)|} \right), \ r = 1, \ldots, m, \tag{3.11}$$

where ϕ_j, ψ_j, $j = 0, \ldots, s$, are the eigenvalues of $\breve{A}$, $\breve{B}$, respectively.

Proof. If J is the Jacobian matrix,

$$V^{-1} J V = D = \mathrm{diag}(\mu_1, \ldots, \mu_m). \tag{3.12}$$

The circulant matrices $\breve{A}$ and $\breve{B}$ are simultaneously diagonalized by the unitary Fourier matrix F (see [10])

$$F = (F)_{j,r}\,, \qquad (F)_{j,r} = \frac{1}{\sqrt{s+1}} \epsilon^{jr}, \qquad \epsilon = e^{2\pi\,\mathbf{i}/(s+1)}, \qquad 0 \leq j, r \leq s, \tag{3.13}$$

i.e.,

$$F\,\breve{A}\,F^* = \Lambda_A = \mathrm{diag}(\phi_0, \ldots, \phi_s), \quad F\,\breve{B}\,F^* = \Lambda_B = \mathrm{diag}(\psi_0, \ldots, \psi_s).$$

We can write

$$\begin{aligned} P &= (F^* \otimes I_m)\ (\Lambda_A \otimes I_m - \Lambda_B \otimes h\,J)\,(F \otimes I_m) \\ &= (F^* \otimes V)\ (\Lambda_A \otimes I_m - \Lambda_B \otimes h\,D)\left(F \otimes V^{-1}\right), \end{aligned} \tag{3.14}$$

where Λ_A, Λ_B are nonsingular diagonal matrices of size $s+1$. Let

$$\breve{\Lambda} = \Lambda_A \otimes I_m - \Lambda_B \otimes h\,D, \tag{3.15}$$

$$\begin{aligned} \breve{\Lambda} = \mathrm{diag}\,(&\phi_0 - h\psi_0\mu_1, \ldots, \phi_0 - h\psi_0\mu_m, \ldots, \\ &\phi_s - h\psi_s\mu_1, \ldots, \phi_s - h\psi_s\mu_m)\,. \end{aligned} \tag{3.16}$$

$\breve{\Lambda}$ is diagonal and, if

$$\mathrm{Re}(\phi_j - h\psi_j\mu_r) > 0, \quad j = 0, \ldots, s, \quad r = 1, \ldots, m, \tag{3.17}$$

then $\breve{\Lambda}$ (and P) is also positive stable. If $\breve{A}$, $\breve{B}$ are P-circulants, or, more generally, for all block preconditioners whose matrices $\breve{A}$, $\breve{B}$ are positive stable and $\breve{B}$ is Hermitian, we have that (3.17) holds true. Indeed, by the hypotheses, we have

$$\mathrm{Re}(\mu_r) \leq 0, \qquad \mathrm{Re}(\phi_j), \mathrm{Re}(\psi_j) > 0$$

and $\mathrm{Im}(\psi_j) = 0$, $j = 0, \ldots, s$, $r = 1, \ldots, m$.

If $\breve{B}$ is not Hermitian, the condition (3.17) is equivalent to

$$\mathrm{Re}(\phi_j) + h(\mathrm{Im}(\psi_j)\mathrm{Im}(\mu_r) - \mathrm{Re}(\psi_j)\mathrm{Re}(\mu_r)) > 0, \tag{3.18}$$

which can be restated as in (3.11). ∎

Notice that P may not be positive stable for certain formulas, even if the Jacobian matrix J has the spectrum in the left half plane.

Let us observe that, if the eigenvalues μ_r, $r = 1, \ldots, m$, of the matrix J of the IVP are in the left half plane, then the block preconditioner's matrix P is nonsingular for all schemes whose matrices $\breve{A}$, $\breve{B}$ in (3.2) are such that

$$\mathrm{Re}\left(\frac{\phi_j}{\psi_j}\right), \quad j = 0, \ldots, s, \tag{3.19}$$

is positive. Indeed, P is singular if and only if there exists at least a couple j, r, $j \in \{0, \ldots, s\}$, $r \in \{1, \ldots, m\}$, such that (see Proposition 3.1 and (3.16))

$$\phi_j - h\psi_j \mu_r = 0.$$

This cannot happen if $\mathrm{Re}(\phi_j/\psi_j)$ is positive.

We have verified that this is the case of P-circulant matrices for the BVMs introduced in section 2.1. Notice that for GBDF, this is a consequence of positive stability of P-circulants.

PROPOSITION 3.2. *If* $\mathrm{Re}(\mu_r) < -\delta$, $r = 1, \ldots, m$, *and* $\delta > 0$, *the block preconditioner* P *given by* (3.1) *which uses Strang's approximation* (3.2), (3.4) *is invertible, regardless of the stepsize* $h > 0$, *for all* $A_{\nu,k-\nu}$*-stable methods such that their boundary locus* $\rho(z)/\sigma(z)$, $|z| = 1$, *is a regular Jordan curve.*

Proof. Indeed, under the above hypotheses, we have

$$\mathrm{Re}(\rho(z)/\sigma(z)) \geq 0, \qquad |z| = 1$$

(see [3, Theorem 4.7.2]). By observing that $\mathrm{Re}(\rho(\epsilon^j)/\sigma(\epsilon^j))$, $j = 0, \ldots, s$, $\epsilon = e^{2\pi \mathbf{i}/(s+1)}$, is the ratio (3.19) when Strang's approximation is in use, it follows that $\phi_j - h\psi_j\mu_r$ cannot be zero. ∎

For more details on the boundary locus of an LMF, see [18] or [3].

Strang's approximation (3.4) for our block preconditioner was considered also in [9].

4. Using the preconditioner.

4.1. The computational cost. We have that the typical computational cost of the block circulant preconditioner (3.1) for an iterative Krylov subspace method is of the order of

$$(c_1 ms \log s + c_2\, c_3 \chi_1(J))\, n + c_3 \chi_2(J) \tag{4.1}$$

floating point operations. The c_i, $i = 1, 2$, are constants of moderate size, $c_3 \leq (s+1)$, n is the number of iterations of the iterative method, and $\chi_i(J)$, $i = 1, 2$, are suitable functions of the size and the structure of J, as explained in the sequel.

From (3.14), we can write P as

$$P = (F^* \otimes I_m) G (F \otimes I_m). \tag{4.2}$$

G is a $(s+1)$-block diagonal matrix with $m \times m$ diagonal blocks,

$$G_j = \phi_j I_m - h\psi_j\, J, \quad j = 0, \ldots, s, \tag{4.3}$$

that, under suitable assumptions (see, e.g., the previous section) are nonsingular matrices. Thus, to solve the linear systems whose matrices are given by (3.1), we need to apply FFTs of length $s+1$ to suitable permutations of the vector $\tilde{v}$ (asymptotic cost: $O(ms\log(s))$ operations). After this, we have to solve the $s+1$ linear systems whose matrices are given by (4.3). Denote with $\chi_2(J)$ the number of flops required for the factorization of G_j and with $\chi_1(J)$ the cost of the related back-substitution. We have, as an example, $\chi_i(J) = O(m)$, $i = 1, 2$, if J has a few nonzero diagonal entries (this is the case of the examples of section 5), or $\chi_2(J) = O(m^3)$, $\chi_1(J) = O(m^2)$, if J is dense and unstructured, etc. The decompositions should be computed only once and then stored.

If J is cheap enough to be diagonalized, and the condition number of V is moderate, where $D = V^{-1}JV$, the solution of the linear systems (2.6) can be found by direct inversion. Unfortunately, such hypotheses are relatively infrequent, especially for nonlinear problems. This is why we have not used the direct inversion for Examples 1 and 2 in section 5 even if possible (Example 3 has a nondiagonalizable Jacobian).

Notice that sometimes we do not need to solve all $s+1$ linear systems (4.3). Indeed, *after* the stepsize h has been chosen, we can check if (for those $j = 0, \ldots, s$ such that $\phi_j \neq 0$), the following condition is satisfied:

$$h \left| \frac{\psi_j}{\phi_j} \right| \|J\| < 1, \tag{4.4}$$

where ψ_j, ϕ_j are the eigenvalues of $\breve{B}$, $\breve{A}$, respectively. For those j such that (4.4) holds true, it can be observed that

$$G_j^{-1} \approx \phi_j^{-1} \left(I_m + h\frac{\psi_j}{\phi_j} J + h^2 \frac{\psi_j^2}{\phi_j^2} J^2 + \cdots + h^r \frac{\psi_j^r}{\phi_j^r} J^r \right), \tag{4.5}$$

where $r \geq 1$ is an integer and $\|\cdot\|$ is any norm such that $\|I\| = 1$. We have experienced that, truncating (4.5) to the linear term, we have a cheap and effective approximation for G_j^{-1}.

The condition (4.4) has proved useful also for stiff (nonlinear) problems. Indeed, often there are several subintervals of integration where the condition (4.4) is satisfied for some values of $j \in \{0, \ldots, s\}$. As an example, this is the case of van der Pol's equation

$$\begin{cases} y_1' = y_2, \\ y_2' = -y_1 + \mu y_2(1 - y_1^2), \quad t \in [0, \mu], \\ y_1(0) = 2, \qquad y_2(0) = 0. \end{cases} \tag{4.6}$$

If μ is large, (4.6) is stiff (see, e.g., [13]). However, we have experienced (up to $\mu = 1000$) that the condition (4.4) is satisfied in several mesh intervals for most of the indexes j (except in the layer regions when μ is large). Notice that $R_j = |\psi_j/\phi_j|$ is less than 1 for the BVMs considered here for several j, $j \in \{0, \ldots, s\}$. See Figure 4.1.

The matrices G_j occur in conjugate pairs, and several other ideas are possible to exploit their special structure; see [13, chapter IV.8].

The computational cost of the underlying block circulant preconditioners can be reduced defining ad hoc methods for differential equations. Indeed, the coefficients α_j, β_j, $j = 0, \ldots, k$, for the LMF (2.1) can be chosen such that the following ratio is

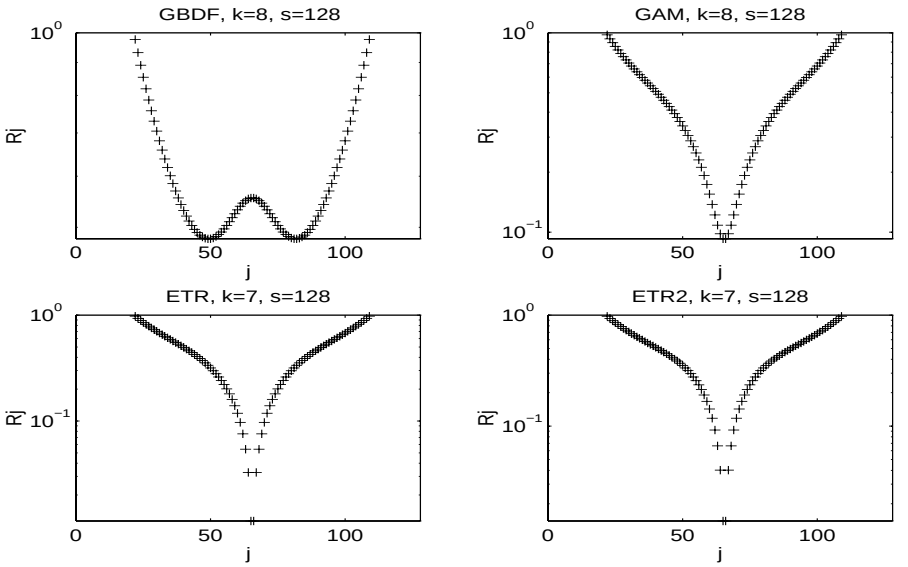

FIG. 4.1. $R_j = |\psi_j/\phi_j|$, $j = 0, \ldots, s$, *for* $k = 7, 8$ *(GBDF, GAM, ETR, ETR$_2$ formulas).*

kept constant:

$$\frac{\psi_j}{\phi_j} = \lambda, \ j = 0, \ldots, s,$$

where ϕ_j, ψ_j are, respectively, the eigenvalues of the P-circulant matrices $\breve{A}$, $\breve{B}$. Using those methods, we need only one factorization of an $m \times m$ matrix which has (almost) the same sparsity pattern of the Jacobian matrix of the underlying ODE. Notice that this process has some analogy with the diagonally implicit Runge–Kutta methods (see [13]).

An alternative approach to the direct solution of the linear systems (4.3) can be effective for particular problems. This is the case of the systems of time-dependent partial differential equations; see [14] and references therein. We will pursue a similar approach for our block preconditioner in a future work.

Finally, the block preconditioner is inherently parallel. The $s + 1$ linear systems (4.3) are independent and can be solved in parallel.

4.2. Convergence of the preconditioned iterations. We expect fast convergence of preconditioned iterations if the spectrum of the block preconditioned matrix is clustered around $(1, 0) \in \mathbb{C}$. To this end, notice that $P^{-1}M$, where P is the block P-circulant or the block Strang's preconditioner, can be written as the sum of the identity, a low rank and a small norm matrix.

THEOREM 4.1. *Let M be the matrix of the linear system* (2.6) *for the schemes described in section* 2.1, *and let P be its block P-circulant preconditioner as* (3.1). *Then, for fixed $\delta > 0$, there exist $C_\delta \geq 0$, $s_\delta \geq k$ such that, for all $s \geq s_\delta$ ($s+1$ is the size of A, B),*

$$P^{-1} M = I + M_\delta^{(1)} + M_\delta^{(2)}, \tag{4.7}$$

where $\operatorname{rank}(M_\delta^{(2)}) \le m\,[2(k+1)+C_\delta]$ *and* $\|M_\delta^{(1)}\|_2 \le \delta\, c_J$, *where* c_J *does not depend on* s.

If P *is defined as Strang's circulant,* $C_\delta = \|M_\delta^{(1)}\| = 0$.

Proof. Let $E = M - P$,

$$\begin{aligned} E &= (A - \breve{A}) \otimes I_m - h(B - \breve{B}) \otimes J \\ &= E_A \otimes I_m - h\, E_B \otimes J \\ &= (E_A^{(1)} + E_A^{(2)}) \otimes I_m - h(E_B^{(1)} + E_B^{(2)}) \otimes J. \end{aligned} \tag{4.8}$$

Here $E_A^{(1)}$ is an $(s+1) \times (s+1)$ Toeplitz matrix with bandwidth $m(k+1)$ defined from the coefficients α_j of the main method (2.1)

$$E_A^{(1)} = (e_{A,rl}^{(1)}), \quad e_{A,rl}^{(1)} = e_{A,r-l}^{(1)} = e_{A,j}^{(1)}, \quad j = -s, \dots, s,$$

and, for P-circulants and optimal circulants,

$$e_{A,j}^{(1)} = \begin{cases} \dfrac{-j}{s+1}\alpha_{j+\nu}, & j = -\nu, \dots, k-\nu \ \text{ (P-circulant)}, \\ \dfrac{|j|}{s+1}\alpha_{j+\nu}, & j = -\nu, \dots, k-\nu \ \text{ (optimal circulant)}, \\ 0 & \text{otherwise.} \end{cases} \tag{4.9}$$

The entries of $E_B^{(1)}$ are defined similarly to (4.9), but with β_j instead of α_j. For Strang's natural circulant it is easy to check that $E_A^{(1)}$, $E_B^{(1)}$ are the null matrix; see (3.2), (3.4).

From the previous equations, we have

$$\begin{aligned} P^{-1}M = I + P^{-1}E &= I + P^{-1}(E_A^{(1)} \otimes I_m - h\, E_B^{(1)} \otimes J) \\ &\quad + P^{-1}(E_A^{(2)} \otimes I_m - h\, E_B^{(2)} \otimes J) = I + \tilde{M}^{(1)} + \tilde{M}^{(2)}, \end{aligned} \tag{4.10}$$

where $E_A^{(2)}$, $E_B^{(2)}$ are $(s+1) \times (s+1)$ matrices whose entries are nonzero at most in the following four corners:

1. $\nu \times (k+1)$ in the upper left;
2. $\nu \times \nu$, upper right;
3. $(k-\nu) \times (k+1)$, lower right;
4. $(k-\nu) \times (k-\nu)$, lower left.

From the above arguments, we have that

$$\operatorname{rank}(E_A^{(2)}) \le k+1, \qquad \operatorname{rank}(E_B^{(2)}) \le k+1,$$

and, if P^{-1} is well defined,

$$\operatorname{rank}(\tilde{M}^{(2)}) \le 2m\,(k+1),$$

independently on the size of $\breve{A}$, $\breve{B}$. Thus, if $\breve{A}$, $\breve{B}$ are the Strang's circulants as (3.2), (3.4), the thesis follows by setting $M_\delta^{(2)} = \tilde{M}^{(2)}$ and by observing that $C_\delta = \|M_\delta^{(1)}\| = 0$.

Let us consider $\tilde{M}^{(1)}$ when $\breve{A}$, $\breve{B}$ are P-circulant matrices. From (4.10) we have

$$\tilde{M}^{(1)} = \frac{1}{s+1} P^{-1} \left(\hat{E}_A^{(1)} \otimes I_m - h\, \hat{E}_B^{(1)} \otimes J \right), \tag{4.11}$$

where $\hat{E}_A^{(1)} = (s+1)E_A^{(1)}$, $\hat{E}_B^{(1)} = (s+1)E_B^{(1)}$ are banded Toeplitz matrices whose infinity norm is constant with respect to their dimension $s+1$.

We are interested in the behavior of $P^{-1}M$ for $s \to \infty$ (and then for $h \to 0$, $h = (T - t_0)/s$; see section 2.1). To this end, for the spectral properties of the P-circulant matrices $\breve{A}$, $\breve{B}$ (see [2] and section 3.1), $\tilde{M}^{(1)}$ in (4.10) can be written as the sum of a small rank and a small $l2$-norm matrix. Indeed, as in the proofs of [21, Theorems 3.2, 3.4], let us fix $\delta > 0$ and consider the cardinality C_δ of the set

$$\left\{ l \in \{0, \ldots, s\} : |\lambda_l(\breve{A})| \leq \frac{1}{\delta} \frac{1}{s+1} \right\},$$

where $\lambda_l(\breve{A})$ are the $s+1$ distinct eigenvalues of $\breve{A}$. For (3.8), $\lambda_l(\breve{A}) = \phi_k(x_l)$, $x_l = 2\pi l/(s+1)$, $l = 0, \ldots, s$, where

$$\phi_k(x) = \sum_{j=-\nu}^{k-\nu} \alpha_{j+\nu} \left(1 + \frac{j}{s+1} \right) e^{\mathbf{i} j x}. \tag{4.12}$$

The expression $\phi_k(x)$ is a trigonometric polynomial and, as observed in [2], for the formulas in (2.1),

$$\lim_{s\to\infty} \phi_k(x_0) = \lim_{s\to\infty} \phi_k(0) = 0,\ \phi_k'(x_0) \neq 0, \qquad \lim_{s\to\infty} \phi_k'(x_0) \neq 0, \tag{4.13}$$

i.e., x_0 is a simple zero for $\lim_{s\to\infty} \phi_k(x)$ and

$$\frac{c_1}{s+1} \leq |\phi_k(x)| \leq c_2, \qquad \mathrm{Re}\,(\phi_k(x)) > 0, \qquad x \in \mathbb{R}, \tag{4.14}$$

where c_1, c_2 are constants of the order of unity. The matrix $\breve{A}$ is normal (because it is circulant), thus $|\lambda_l(\breve{A})| = |\phi_k(x_l)|$ is a singular value. Moreover, for (4.13), (4.14), and (4.12), if l is small with respect to s,

$$|\phi_k(x_l)| \geq \hat{c} \frac{l}{s+1},$$

and, as a consequence,

$$C_\delta \leq \# \left\{ l : \hat{c} \frac{l}{s+1} \leq \frac{1}{\delta} \frac{1}{s+1} \right\} \leq \left\lceil \frac{1}{\delta\, \hat{c}} \right\rceil, \tag{4.15}$$

which does not depend on s since $\hat{c}$ is a constant.

Recalling that the circulant matrices are simultaneously diagonalized by the matrix F in (3.13) (see [10]), consider the following splitting:

$$\frac{1}{s+1} \breve{A}^{-1} = \hat{\Theta}_1 + \hat{\Theta}_2, \tag{4.16}$$

where the $s+1$ singular values of the circulant matrices $\hat{\Theta}_2$, $\hat{\Theta}_1$ are

$$\{a_0, \ldots, a_{C_\delta - 1},\ 0, \ldots, 0\}, \qquad \{0, \ldots, 0, a_{C_\delta}, \ldots, a_s\}, \tag{4.17}$$

respectively, and $\delta < a_j$, $j = 0, \ldots, C_\delta - 1$; $a_j < \delta$, $j = C_\delta, \ldots, s$, $a_j \geq a_i \geq 0$ if $0 \leq j < i \leq s$.

Thus, from (4.11) and (4.16) we can set $\tilde{M}^{(1)}$ as

$$\tilde{M}^{(1)} = \left(I_{s+1} \otimes I_m - h\breve{A}^{-1}\breve{B} \otimes J\right)^{-1} \left((\hat{\Theta}_1 + \hat{\Theta}_2) \otimes I_m\right) \left(\hat{E}_A^{(1)} \otimes I_m - h\hat{E}_B^{(1)} \otimes J\right),$$

i.e., we can split the above matrix as

$$\tilde{M}^{(1)} = M_\delta^{(1)} + \tilde{M}_\delta^{(2)},$$

where the products containing $\hat{\Theta}_2$ are collected in $\tilde{M}_\delta^{(2)}$, while those containing $\hat{\Theta}_1$ are in $M_\delta^{(1)}$. As a consequence of the above arguments and of (4.10), (4.11), fixed $\delta > 0$, we can find s_δ such that, for all $s \geq s_\delta$,

$$\tilde{M}^{(1)} = M_\delta^{(1)} + \tilde{M}_\delta^{(2)}, \quad \operatorname{rank}(\tilde{M}_\delta^{(2)}) \leq m\, C_\delta, \quad \|\hat{\Theta}_1 \hat{E}_A^{(1)}\|_2 \leq \delta\, c, \quad \|\hat{\Theta}_1 \hat{E}_B^{(1)}\|_2 \leq \delta\, c,$$

where c does not depend on s and usually is of the order of unity. If we define $M_\delta^{(2)} = \tilde{M}^{(2)} + \tilde{M}_\delta^{(2)}$, the first half of the thesis follows. To check that $M_\delta^{(1)}$ is a small norm matrix, we can transform $M_\delta^{(1)}$ by the matrices $(F \otimes V^{-1})$, $(F^* \otimes V)$, $J = VDV^{-1}$. (We suppose for simplicity that the Jacobian matrix J is diagonalizable.) Thus, if $N = (F \otimes V^{-1}) M_\delta^{(1)} (F^* \otimes V)$, we have

$$\begin{aligned} N &= \left(I_{s+1} \otimes I_m - h\Lambda_A^{-1}\Lambda_B \otimes D\right)^{-1} (F \otimes I_m) \\ &\quad \cdot (\hat{\Theta}_1 \otimes I_m) \left(\hat{E}_A^{(1)} \otimes I_m - h\hat{E}_B^{(1)} \otimes D\right) (F^* \otimes I_m) \\ &= \left(I_{s+1} \otimes I_m - h\Lambda_A^{-1}\Lambda_B \otimes D\right)^{-1} (\Lambda_1\, F \otimes I_m) \\ &\quad \cdot \left(\hat{E}_A^{(1)} \otimes I_m - h\hat{E}_B^{(1)} \otimes D\right) (F^* \otimes I_m), \end{aligned} \tag{4.18}$$

where $\hat{\Theta}_1 = F^*\Lambda_1 F$, $\breve{A} = F^*\Lambda_A F$, $\breve{B} = F^*\Lambda_B F$, and Λ_1, Λ_A, Λ_B are diagonal matrices. From (4.18) and the above arguments we have the following bound:

$$\begin{aligned} \|N\|_2 &\leq \|\left(I_{s+1} \otimes I_m - h\Lambda_A^{-1}\Lambda_B \otimes D\right)^{-1}\|_2 \|F\hat{\Theta}_1 E_A^{(1)} F^* \otimes I_m\|_2 \\ &\quad + \max_r \|(I_{s+1} \otimes I_m - h\mu_r \Lambda_A^{-1}\Lambda_B)^{-1}(h\mu_r \Lambda_1\, F\, \hat{E}_B^{(1)} F^*)\|_2 \\ &\leq \frac{\|F\hat{\Theta}_1 \hat{E}_A^{(1)} F^*\|}{\min_{j,r}\left|1 + h(-\mu_r)\dfrac{\psi_j}{\phi_j}\right|} + \frac{\|\Lambda_1 F \hat{E}_B^{(1)} F^*\|_2}{\min_{j,r}\left|\dfrac{1}{h(-\mu_r)} + \dfrac{\psi_j}{\phi_j}\right|} \\ &\leq \frac{\|\hat{\Theta}_1 \hat{E}_A^{(1)}\|_2}{c_{J,1}} + \frac{\|\hat{\Theta}_1 \hat{E}_B^{(1)}\|_2}{c_{J,2}} \leq \delta\, \hat{c}_J. \end{aligned} \tag{4.19}$$

Excluding the trivial case $\mu_r = 0$, we have that $\operatorname{Re}(1/(h(-\mu_r))) \geq 0$ if the Jacobian matrix J has eigenvalues whose real parts are nonpositive, and $c_{J,1}$, $c_{J,2}$ in the above expression can be bounded uniformly in s if $\operatorname{Re}(\psi_j/\phi_j) \geq \epsilon > 0$.We have verified that

this holds, e.g., for the methods of section 2.1. Thus, $\hat{c}_J$, c_J and then the bound for $\|M_\delta^{(1)}\|_2$ are independent from s.

Notice that when $h\,\mu_r$ is small, such as in the nonstiff case, we have simply that

$$\|M_\delta^{(1)}\|_2 \le c_2 \|\hat{\Theta}_1 \hat{E}_A^{(1)}\|_2 \le \delta\, c\, c_2,$$

where c_2 is a constant. □

Unfortunately, we cannot state a similar result for the block preconditioner (3.1) based on the optimal circulants because of the ill-conditioning arising when k is large (see [2]). Nonetheless, if (4.14) hold true, for fixed k suitably small, similar arguments to those used for P-circulants can be used to prove convergence.

Despite the fact that $\|M_\delta^{(1)}\|$ and C_δ are zero for P given by (3.1) using Strang's approximations, we have observed that such a preconditioner is often less suitable than others. Indeed, as an example, the Strang's circulants can be severely ill-conditioned or even singular, e.g., for problems such that some of the eigenvalues of their Jacobian matrix have zero or small modulus real part (or imaginary part large in absolute value with respect to the real part). Unfortunately, this is not infrequent, e.g., for stiff problems; see Example 1 and the remarks in the next section.

5. Numerical results. To show the effectiveness of our block preconditioner, we will integrate some test problems with the formulas (2.9), a generalization of Adams–Moulton methods. Such formulas have been found to be quite effective (see [17]).

Further numerical examples using other formulas can be found in [1].

We will compare the number of matrix-vector products needed to converge for Bi-CGSTAB [25] (Bi-CGSTAB(2) [22] for Example 1 because Bi-CGSTAB has shown much more erratic unpreconditioned convergence) and GMRES [20].

The initial guess for the iterative solvers is always zero. The stopping criterion is $\|r_k\| < 10^{-6}\|b\|$, r_k true residual. The stability properties of the LMF considered here (see [3]) allow an application without stepsize restriction. Hence, we will use a constant stepsize h. All calculations are done in Matlab.

In the columns labeled I_s, P_s, C_s and S_s in the tables below, we will give the number of matrix-vector products needed to the convergence of the unpreconditioned iterations, preconditioned iterations using P-circulants, and Chan's and Strang's approximations, respectively. A "−" means that convergence was not attained.

The column labeled "rfp" gives a rough estimate of the ratio of the floating points operations required for, respectively, the P-circulant preconditioned and the unpreconditioned GMRES.

Example 1. *Wave equation.*

Let us consider the wave equation

$$\text{(5.1)} \qquad \begin{cases} u_{tt} - c u_{xx} = 0, & \\ u(x,0) = g_1(x),\ u_t(x,0) = g_2(x), & x \in [0,\pi], \\ u(0,t) = u(\pi,t) = 0, & t \in [0,T]. \end{cases}$$

Approximating the operator $\partial^2/\partial x^2$ in (5.1) with centered differences and reducing the obtained IVP to the first order gives the system of $2N$ ODEs:

$$\text{(5.2)} \qquad \begin{cases} y'(t) = H_{2N} y(t), & t \in [0,T], \\ y(0) = \eta, & \eta = (g_1(x_1)\ \cdots\ g_1(x_N) g_2(x_{N+1})\ \cdots\ g_2(x_{2N}))^T. \end{cases}$$

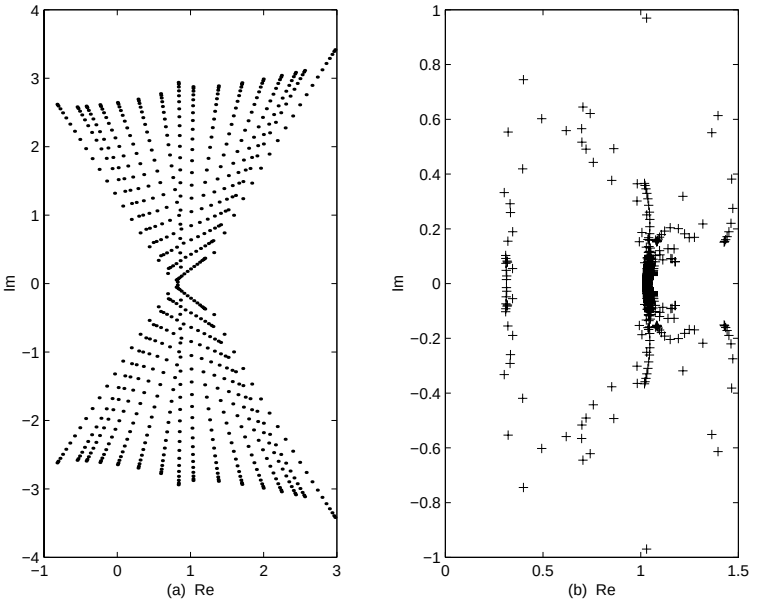

FIG. 5.1. *Wave equation* (5.1). *Spectrum of eigenvalues of the matrix* M (2.6) *before and after P-circulant preconditioning.* ($c = 1$, *GAM with* $k = 3$, $s = 16$, $N = 20$, $T = 2\pi$.)

The matrix H_{2N} is a Hamiltonian definite one:

$$H_{2N} = \begin{pmatrix} \mathbf{0} & I_N \\ T_N & \mathbf{0} \end{pmatrix}_{2N \times 2N}. \tag{5.3}$$

The matrix H_{2N} has the spectrum of eigenvalues on the imaginary axis. In Table 5.1, we can see the effect of the block preconditioner on the number of iterations needed to solve the IVP (5.2) using the fourth order GAM ($k = 3$), $T = 2\pi$, $g_1(x) = 0$, $g_2(x) = x$. In Figures 5.1 and 5.2 we can see the effect on the spectrum of eigenvalues of the matrix M.

Notice that the block preconditioner based on the Strang's circulants does not show the best preconditioned behavior, despite the fact that $M_\delta^{(1)}$, the small norm matrix in (4.7), is zero; see also Table 5.2. To this end, see also the remarks at the end of this section.

Example 2. *Heat equation in a rectangle.*

Consider the two-dimensional heat equation defined in a rectangular domain:

$$\text{(5.4)} \qquad \begin{cases} u_t - (u_{xx} + u_{yy}) = 0, & (x,y) \in \Omega = [0,\pi] \times [0,\pi], \\ u((x,y),0) = g(x,y), & (x,y) \in \Omega, \\ u((x,y),t) = 0, & (x,y) \in \partial\Omega,\ 0 \le t \le T. \end{cases}$$

Using centered differences to approximate the Laplacian operator in the rectangle Ω with a uniform grid

$$\Delta x = \Delta y = \Delta, \quad \Delta = \pi/(N+1)$$

gives the IVP

$$\text{(5.5)} \qquad \begin{cases} y'(t) = \dfrac{1}{\Delta^2} \hat{L}_N y(t), & t \in [0,T], \\ y(0) = \eta, & \eta = (g(x_1,y_1)), \ldots, g(x_N,y_N)^T, \end{cases}$$

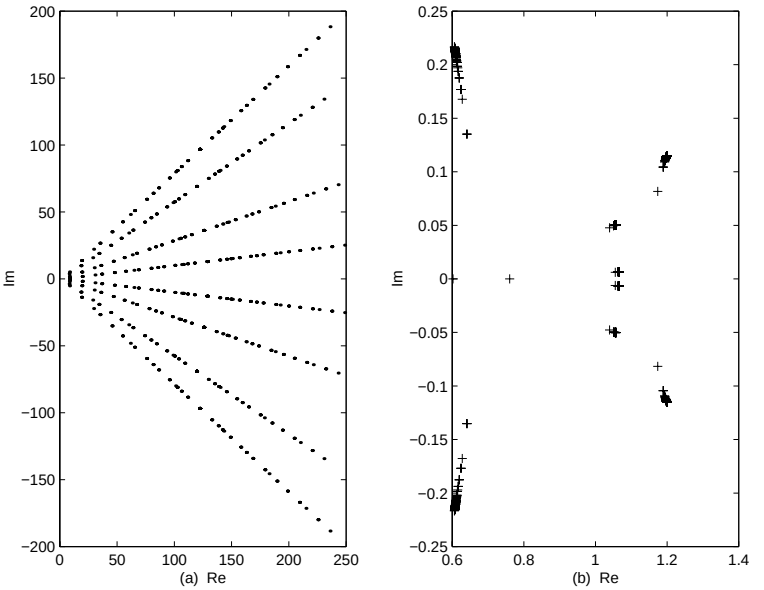

FIG. 5.3. *Heat equation* (5.4). *Spectrum of the eigenvalues of the matrix* M (2.6) *before and after P-circulant block preconditioning. (GAM,* $k = 4$, $s = 16$, $N = 20$.*)*

where $\hat{L}_N$ is a $N^2 \times N^2$ block tridiagonal matrix:

$$\hat{L}_N = \begin{pmatrix} \hat{T}_N & I_N & & \\ I_N & \ddots & \ddots & \\ & \ddots & \ddots & I_N \\ & & I_N & \hat{T}_N \end{pmatrix}, \qquad \hat{T}_N = \begin{pmatrix} -4 & 1 & & \\ 1 & \ddots & \ddots & \\ & \ddots & \ddots & 1 \\ & & 1 & -4 \end{pmatrix} \tag{5.6}$$

and x_i, y_j, $i, j = 1, \ldots, N$, in (5.5) are defined accordingly. In Table 5.3, we can see the effect of the block preconditioner on the number of iterations needed to solve the IVP (5.5) using fifth order GAM ($k = 4$), $T = 2\pi$, $g(x, y) = x\,y$. In Figure 5.3 we can see the effect on the spectrum of eigenvalues of the matrix M.

As an example, notice that the built-in Matlab sparse direct solver for the linear system (2.6) used for Example 2 with $N = 20$, $s = 8$ ($N = 20$, $s = 16$) needs 6

(18) times more flops than the P-circulant block preconditioned GMRES. In general, we can save flops provided that M in (2.6) is large enough and the convergence of preconditioned iterations is achieved in a moderate number of iterations.

Example 3. *Wave equation of first order.*

$$\left\{\begin{array}{ll} u_t - u_x = 0, & \\ u(x,0) = g(x), & x \in [0,\pi], \\ u(\pi,t) = 0, & t \in [0,2\pi]. \end{array}\right. \tag{5.7}$$

We discretize the partial derivative $\partial/\partial x$ with the first order forward difference and stepsize $\Delta x = \pi/N$, $x_j = j\Delta x$ (upwind discretization). We obtain the system of N ODEs

$$\left\{\begin{array}{ll} y'(t) = L_N y(t), & t \in [0,2\pi], \\ y(0) = \eta, & \eta = (g(x_0) \ \cdots \ g(x_{N-1}))^T, \end{array}\right. \tag{5.8}$$

$$L_N = \frac{1}{\Delta x}\begin{pmatrix} -1 & 1 & & \\ & \ddots & \ddots & \\ & & \ddots & 1 \\ & & & -1 \end{pmatrix}_{N\times N}.$$

In Table 5.4, we can see the effect of the block preconditioner on the number of iterations needed to solve the IVP (5.7) using fifth order GAM ($k = 4$), $T = 2\pi$, $g(x) = \sqrt{x(\pi - x)}$. In Figure 5.4 we can see the effect on the spectrum of eigenvalues of the matrix M.

As expected, the block preconditioner (3.1) is effective for those classes of differential problems for which the preconditioned matrix $P^{-1}M$, M in (2.6), has a clustered spectrum. For Theorem 4.1, this is true if $M_\delta^{(1)}$ in (4.7) either is zero (as is the case of Strang's circulants) or is a suitable perturbation of the null matrix (e.g., has eigenvalues clustered around the origin of the complex plane, as is the case of P-circulants) *and* P is not ill-conditioned. Moreover, the small rank matrix $M_\delta^{(2)}$ should have few and possibly clustered outliers (i.e., the eigenvalues outside the multiple eigenvalue in the origin of $\mathbb{C}$).

Notice that the above properties may not hold if the preconditioner is ill-conditioned, e.g., because $\breve{A}$ or $\breve{B}$ are ill-conditioned or even singular. As an example, see Example 1 for the block preconditioner using Strang's or Chan's approximations. A similar behavior can be observed for Example 2 if a fast decaying diffusion coefficient is considered. The effect of the ill-conditioning on the convergence of preconditioned iterations can be reduced significantly if special initial conditions for the underlying partial differential equations are considered; see the numerical tests in [9]. More details and analysis of the rate of convergence of preconditioned iterations will be given in a forthcoming paper.

In this section, we have considered methods based on the formula (2.9). In general, the same behavior can be observed also for the other formulas of section 2.1, e.g., (2.10) for Example 1 and (2.8) for Examples 2 and 3.

6. Concluding remarks. In this work we have considered a block circulant preconditioner we introduced in [1] for the linear systems of certain codes for ordinary differential equations. Such preconditioners are used here implicitly with iterative Krylov subspace methods for nonsymmetric systems such as Bi-CGSTAB, Bi-CGSTAB(2) and GMRES.

It has been observed that, for some classes of differential problems, the preconditioned iterations are almost independent from the discretization.

Moreover, a recently introduced circulant approximation, called P-circulant, has been found to be promising in comparison to optimal approximations, in the sense of the norm (see, e.g., [8, p. 432–434]), such as Strang's and Chan's. This has been confirmed by the analysis in [2].

Despite the fast convergence, the above block preconditioner has a moderate theoretical parallel complexity and an interesting serial computational cost for the classes of differential problems such that the spectrum of the block preconditioned matrix $P^{-1}M$ is clustered.

Acknowledgments. The author would like to thank both the referees and Michele Benzi of the Los Alamos National Laboratory for very helpful comments that have improved this presentation. The author is grateful to Luigi Brugnano and Donato Trigiante of the University of Firenze for their suggestions and constructive criticism.

NUMERICAL SHADOWING USING COMPONENTWISE BOUNDS AND A SHARPER FIXED POINT RESULT*

ERIK S. VAN VLECK†

Abstract. Shadowing provides a means of obtaining global error bounds for approximate solutions of nonlinear differential equations with interesting dynamics, in particular, for initial value problems with positive Lyapunov exponents. Shadowing breaks down in the presence of zero Lyapunov exponents, although some results such as shadowing with rescaling of time have been obtained. Using a reformulation of the original differential equations and an improved fixed point result we take advantage of componentwise local error bounds to use relatively smaller error tolerances in nonhyperbolic and contractive directions (i.e., in directions corresponding to zero and negative Lyapunov exponents). The result is a decrease in the shadowing global error.

Key words. shadowing lemma, hyperbolicity, global error estimation

AMS subject classification. 65L

1. Introduction.

Global error analysis using a shadowing lemma approach involves treating the error equation as a boundary value problem (BVP) as opposed to an initial value problem (IVP). This allows for shadowing-type error analysis results for problems with expansive and contractive directions. The difficulty occurs when there are directions that are neither exponentially expansive nor contractive, and we call these nonhyperbolic directions. Most shadowing lemma techniques rely on a fixed point result that is similar to using the numerically computed solution as an initial guess for a modified Newton's method to find a true trajectory to the given differential equation. This leads to the need to find and bound an inverse (in our case a right inverse) of the Jacobian for the modified Newton's method.

In this paper, we consider an improved fixed point result and find that what is important is not so much the norm of a right inverse of the Jacobian, but the action of the right inverse on several vectors. This produces sharper results and the ability to gain a better understanding of the breakdown of shadowing in the presence of nonhyperbolic directions. We reformulate the original differential equation in terms of a new coordinate system that corresponds to the directions associated with the Lyapunov exponents of the linearized problem that we denote by the columns of an orthogonal matrix function $Q \equiv Q(t)$. This allows us to write the dependent variable x of the nonlinear differential equation in terms of these directions of different growth and decay rates and write $x = Qy$ and solve for Q and y instead of x. With this reformulation we derive componentwise bounds on the magnitude of the local error in directions corresponding to different rates of growth and decay, and with the improved fixed point result we are able to derive sharper shadowing bounds by employing smaller local error tolerances in the nonhyperbolic and contractive directions.

Our focus numerically is in employing existing IVP solvers, including the extrapolation code `ODEX` from [17] and the Runge–Kutta suite `RKSUITE` from [3]. The

numerical shadowing methods presented here provide accurate results, due to the componentwise error bounds and the improved fixed point result, and are obtained with relatively small cost due to the use of efficient numerical linear algebra techniques.

Recent work on shadowing has involved extending shadowing to allow for rescaling of time, i.e., allowing for perturbations in the time step (see the work of Coomes [6], Coomes, Kocak, and Palmer [7], Palmer [22], Van Vleck [26], and Franke and Selgrade [12], [13]). Rescaling of time can be thought of as allowing for a special perturbation of the differential equation. Work on numerical shadowing includes the ground breaking work of Hammel, Yorke, and Grebogi [18], [19], the shadowing-type results of Beyn [2], the work of Chow, Lin, and Palmer (e.g., [4]), Chow and Palmer (e.g., [5]), the numerical work of Sauer and Yorke [24], and the initial work on the breakdown of shadowing of Dawson et al. [8]. We also mention here a related concept known as backward error analysis in which one considers a modified differential equation and provides error statements with respect to this modified equation. This has proved to be a very useful concept of error, especially in the case of Hamiltonian systems (see, e.g., [1], [15], [16], and [23]).

This paper is organized as follows. In section 2 we present the shadowing setup that we will employ throughout this paper, and in section 3 we present an improved fixed point result that has two fewer norm bounds than the previous result. In section 4 we consider a reformulation of the given differential equation and its linear variational equation by writing the dependent variable $x(t)$ as $x(t) = Q(t)y(t)$ and a fundamental matrix solution $X(t) = Q(t)R(t)$, respectively, where $Q(t)$ is a square orthogonal matrix and $R(t)$ is an upper triangular matrix, and by solving for y, Q, and R instead of x and X. Based upon this reformulation, we consider in section 5 the form of a right inverse, in our case the pseudoinverse, of a linear operator that approximates the Jacobian, and we provide bounds in section 6 on the elements of the vectors multiplying the right inverse. Section 7 contains algorithmic formulations and details, section 8 contains our numerical results, and section 9 contains our conclusions.

2. Shadowing setup. Consider the autonomous IVP where f is a C^2 function,

$$\left\{ \begin{array}{rl} \dot{x} & = f(x), \\ x(0) & = x_0, \end{array} \right. \tag{2.1}$$

and $x \equiv x(t) : \mathbb{R} \to \mathbb{R}^N$ for a positive integer N.

We assume that a numerical orbit $x \equiv \{x_n\}_0^M$ using time steps $h \equiv \{h_n\}_0^{M-1}$, for a positive integer M, has been produced, and let $t_{n+1} = t_n + h_n$ with $t_0 = 0$. Consider the nonlinear operator $F(x,h)$ with nth block component given by

$$(F(x,h))_n = x_{n+1} - \phi(x_n, h_n) =: \delta_{n+1}, \tag{2.2}$$

for $n = 0, \ldots, M-1$, where ϕ is the local solution operator and δ_{n+1} is the local error at the nth step. The linearization of $F(x,h)$ is given by $(D_{x_n}\phi(x_n,h_n) \equiv \frac{\partial \phi}{\partial x_n}(x_n,h_n)$ and $D_{h_n}\phi(x_n,h_n) \equiv \frac{\partial \phi}{\partial h_n}(x_n,h_n))$,

$$(DF(x,h)(\Delta x, \Delta h))_n = \Delta x_{n+1} - D_{x_n}\phi(x_n,h_n)\Delta x_n - \theta D_{h_n}\phi(x_n,h_n)\Delta h_n, \tag{2.3}$$

for $n = 0, \ldots, M-1$, where $\theta \geq 0$ is a scaling factor (see [26]). We assume that $DF(x,h)$ is approximated by a linear operator,

$$(L(\Delta x, \Delta h))_n = \Delta x_{n+1} - Y_n \Delta x_n - \theta f_{n+1} \Delta h_n, \tag{2.4}$$

for $n = 0, \ldots, M-1$. Throughout the paper we consider $z = x \in \mathbb{R}^{(M+1)N}$ for $\theta = 0$ and $z = (x, h) \in \mathbb{R}^{(M+1)N} \times \mathbb{R}^M$ for $\theta > 0$, with norms $||z|| = \sup_n ||x_n||$ for $\theta = 0$ and $||z|| = ||(x,h)|| = \max\{\sup_n ||x_n||, \sup_n |\theta^{-1} h_n|\}$ for $\theta > 0$. For $n = 0, \ldots, M-1$ the nth $N \times N$ block column of $DF(z)$ and of L is nonzero only in the nth block component. In addition, for $\theta > 0$ the remaining M columns of $DF(z) - L$ contain a nonzero block component of the form $\theta[f_{n+1} - D_{h_n}\phi(x_n, h_n)]$. The nth block component of $F(z)$ is given by δ_{n+1}.

3. Fixed point result. The following is an improved version of a fixed point result that has been used in many instances to prove the existence of a nearby solution in a shadowing context. The proof is basically the same, but it allows for the use of more precise componentwise information. The statement of the fixed point theorem is very similar to the statement of Theorem 1, p. 536, in Kantorovich and Akilov [20], and the proof is a minor modification of Proposition 4.1 in [4].

THEOREM 3.1. *Suppose that $\mathcal{X}, \mathcal{Y}$ are Banach spaces, $F : \mathcal{X} \to \mathcal{Y}$ is C^1, and that there exist positive constants ϵ_0, $\alpha < 1$, β, a point $z \in \mathcal{X}$, and a linear operator $L : \mathcal{X} \to \mathcal{Y}$ with right inverse $L^\dagger$ such that*

$$||L^\dagger(DF(w) - L)|| \le \alpha \quad \text{for} \quad ||w - z|| \le \epsilon_0. \tag{3.1}$$

If, for $0 < \epsilon \le \epsilon_0$,

$$||L^\dagger F(z)|| \le (1 - \alpha)\epsilon =: \beta, \tag{3.2}$$

then the equation $F(w) = 0$ has a solution with

$$||w - z|| \le \epsilon. \tag{3.3}$$

Our goal now is to find a bound $\alpha < 1$ in (3.1) and a bound on β in (3.2) so that we can set $\epsilon = \beta/(1 - \alpha)$ provided $\epsilon \le \epsilon_0$.

4. Reformulation of the differential equation. In order to decrease the shadowing distance when there are nonhyperbolic directions, for instance, in the neighborhood of a nontrivial attracting set or in the presence of first integrals, we rewrite the differential equation (2.1) to take advantage of componentwise local error tolerances. We introduce an auxiliary matrix differential equation that will also be useful in solving the linear variational equation. To make the idea clear, suppose for each time t we have an orthogonal matrix $Q(t) \in \mathbb{R}^{N \times N}$ whose columns correspond to directions of different rates of growth. Then we can write $x(t)$, the solution to (2.1), as a linear combination of the columns of $Q(t)$, i.e., $x(t) = Q(t)y(t)$. The components of $y(t)$ correspond to the growth rates in the directions given by the columns of $Q(t)$. If we write the solution to the linear variational equation, $X(t)$, as $X(t) = Q(t)R(t)$ (see [9]), where $Q(t)$ is orthogonal and $R(t)$ is upper triangular, then $Q(t)$ satisfies the following matrix differential equation, where $S(Q) \equiv S(Q, A(t))$ is a skew-symmetric matrix and $A(t) \equiv Df(x(t))$,

$$\dot{Q} = QS(Q) \quad \text{with} \quad S(Q)_{ij} = \begin{cases} (Q^T A Q)_{ij}, & i > j, \\ 0, & i = j, \\ -(Q^T A Q)_{ji}, & i < j. \end{cases} \tag{4.1}$$

Since $x(t) = Q(t)y(t)$, we have $\dot{x}(t) = \dot{Q}(t)y(t) + Q(t)\dot{y}(t)$, so $y(t)$ satisfies the differential equation

$$\dot{y} = Q^T f(Qy) - S(Q)y. \tag{4.2}$$

The equation for $R(t)$ is given by

$$\dot{R} = \tilde{A}R \quad \text{with} \quad \tilde{A} = Q^T AQ - S(Q); \tag{4.3}$$

the coefficient matrix $\tilde{A}(t)$ is thus upper triangular.

By solving numerically (4.1), (4.2), and (4.3), we obtain approximations to the original nonlinear problem and the linear variational equation. If we write $x_{n+1} = Q_{n+1}y_{n+1}$ and $\phi(x_n, h_n) = \tilde{Q}_{n+1}\psi(y_n, h_n)$, where ψ is the local solution operator for (4.2), then by (2.2), we have

$$Q_{n+1}^T\delta_{n+1} = Q_{n+1}^T[x_{n+1} - \phi(x_n, h_n)] = y_{n+1} - \psi(y_n, h_n) + (\tilde{Q}_{n+1}^T - Q_{n+1}^T)\phi(x_n, h_n). \tag{4.4}$$

We solve using (4.2) as opposed to (2.1) so that componentwise local error control may be obtained with respect to the moving coordinate system given by $Q(t)$. This could be accomplished by solving with (2.1) but would require that the error control for the x variable depend on our approximation to Q. Solving by using (4.1) and (4.3) is a numerically stable way of approximating the linear variational equation.

5. Form of the pseudoinverse. We choose for the right inverse, $L^\dagger$, in Theorem 3.1, the pseudoinverse. This allows us to find $L^\dagger$ explicitly, which is useful when determining the bounds for α and β in (3.1) and (3.2). The choice of the pseudoinverse also has the advantage that it is independent of the dynamics of the problem, i.e., does not depend on the number of stable, unstable, or neutral modes, and it is the optimal choice with respect to the two norm.

We solve (4.1) and (4.2) numerically to produce sequences $\{Q_n\}_0^M$ and $\{y_n\}_0^M$. Simultaneously, for $n = 0, \dots, M-1$, we solve

$$\begin{cases} \dot{\tilde{R}}_n(t) = & \tilde{A}(t + t_n)\tilde{R}_n(t), \\ \tilde{R}_n(0) = & I \end{cases} \tag{5.1}$$

for $0 \le t \le h_n$. If we let R_n denote the approximation to $\tilde{R}(h_n)$, then in (2.4) we have $Y_n = Q_{n+1}R_nQ_n^T$. Notice that L in (2.4) can be written as $L = \overline{Q}U\hat{Q}^T$, where $\overline{Q}, \hat{Q}$ are block diagonal matrices given by $\overline{Q} = \text{diag}(Q_1, \dots, Q_M)$, $\hat{Q} = \text{diag}(Q_0, \dots, Q_M, I_M)$, where I_M is the $M \times M$ identity matrix, and in block indices,

$$(U(z, \tau))_n = z_{n+1} - R_nz_n - \theta g_{n+1}\tau_n, \tag{5.2}$$

where $f_{n+1} = Q_{n+1}g_{n+1}$ and $f_{n+1} = f(x_{n+1})$. Thus, the pseudoinverse of L, $L^\dagger$, can be written as

$$L^\dagger = \hat{Q}U^\dagger\overline{Q}^T, \tag{5.3}$$

where $U^\dagger$ is the pseudoinverse of U. We write $U^\dagger = U^T(UU^T)^{-1}$ and note that UU^T is symmetric and block tridiagonal with entries $(UU^T)_{n,n} = I + R_nR_n^T + \theta^2 g_{n+1}g_{n+1}^T$ for $n = 0, \dots, M-1$ and $(UU^T)_{n-1,n} = -R_n^T$ for $n = 1, \dots, M-1$.

We decompose $L^\dagger$ as in (5.3) and determine componentwise bounds on $\overline{Q}^T[DF(w) - L]$ and $\overline{Q}^TF(z)$. Once componentwise bounds are obtained we find the bounds α and β in (3.1) and (3.2), respectively, using the following simple idea. Let u denote

an arbitrary column of $\overline{Q}^T[DF(w) - L]$ or let u denote $\overline{Q}^T F(z)$. Assume that the ith component of u, u_i, satisfies $|u_i| \leq \gamma_i$ for some $\gamma_i > 0$. If $y = \hat{Q}U^\dagger u$, then we have

$$|y_i| \leq \sum_j |(\hat{Q}U^\dagger)_{ij}| \cdot \gamma_j. \tag{5.4}$$

Using the results in [21] and the references therein we have that the (i, j) block of $(UU^T)^{-1}$ has the form

$$\Gamma_{ij} \equiv (UU^T)^{-1}_{ij} = \begin{cases} \Psi_i \Omega_j^T & \text{for} \quad i \leq j, \\ \Omega_i \Psi_j^T & \text{for} \quad i > j, \end{cases} \tag{5.5}$$

where Ψ_i and Ω_j are $N \times N$ matrices. In addition, the block vectors $\Psi = (\Psi_0^T, \ldots, \Psi_{M-1}^T)^T$ and $\Omega = (\Omega_0^T, \ldots, \Omega_{M-1}^T)^T$ can be determined by solving

$$(UU^T)\Omega = \Xi_0 \quad \text{and} \quad (UU^T)\Psi = \Xi_{M-1}\Omega_{M-1}^{-T}, \tag{5.6}$$

where Ξ_0 denotes the block vector with the identity matrix in the 0th block and Ξ_{M-1} denotes the block vector with the identity in the $(M-1)$th block (with all other blocks zero). In general, (5.6) is not a numerically stable way to form $(UU^T)^{-1}$.

In the next section we will obtain componentwise bounds on $\overline{Q}^T F(z)$ and $\overline{Q}^T[DF(w) - L]$ to form the vectors that will multiply the matrix $\hat{Q}U^\dagger$ which has, using the form of $(UU^T)^{-1}$, the block entries,

$$(\hat{Q}U^\dagger)_{ij} = \begin{cases} -Q_0 R_0^T \Gamma_{0,j}, & i = 0, \\ Q_i[\Gamma_{i-1,j} - R_i^T \Gamma_{i,j}], & i = 1, \ldots, M-1, \\ Q_M \Gamma_{M-1,j}, & i = M \end{cases} \tag{5.7}$$

for $j = 0, \ldots, M-1$, and for $\theta > 0$, the remaining M rows of $\hat{Q}U^T(UU^T)^{-1}$ have the form

$$-\theta(g_i^T \Gamma_{i-1,0}, \ldots, g_i^T \Gamma_{i-1,M-1}) \quad \text{for} \quad i = 1, \ldots, M. \tag{5.8}$$

Note that, by using the form of L, we have (for $\theta = 0$) that (2.2) is of the form

$$Q_{n+1}^T \Delta x_{n+1} - R_n Q_n^T \Delta x_n = Q_{n+1}^T \delta_{n+1}, \tag{5.9}$$

which after a change of variables ($z_n = Q_n^T \Delta x_n$ and $\rho_n = Q_n^T \delta_n$) has the form

$$z_{n+1} - R_n z_n = \rho_{n+1}. \tag{5.10}$$

Consider the following simplified example of (5.10) with

$$R_n = \begin{pmatrix} R_{11} & R_{12} & R_{13} \\ 0 & R_{22} & R_{23} \\ 0 & 0 & R_{33} \end{pmatrix}, \tag{5.11}$$

where $R_{11} > 1$, $0 < R_{33} < 1$, $R_{22} = 1$, and $\rho_n \equiv \rho$ for all n. If we solve (5.10) forward in time for the second and third components of z with initial conditions of 0 and backward in the first component of z with terminal condition 0, then we obtain linear growth in the solution z unless we set the second and third components of ρ to $O(M^{-1})$ times the first component of ρ. This suggests having, after considering

(4.4), a relatively smaller local error tolerance for the components of y and columns of Q that correspond to nonhyperbolic and contractive directions (assuming that the directions are ordered as in our simple example). Similarly, we will use a relatively smaller local error tolerance for the rows of R corresponding to nonhyperbolic and contractive directions. It is important to point out that, although our plan is to require smaller error tolerances when computing the coupled set of equations for y, Q, and R numerically, this should really only restrict our time step in the integration of Q since the time step for y and R should be based on the unstable directions.

6. Bounds on $\overline{Q}^T F(z)$ and $\overline{Q}^T[DF(w) - L]$. In what follows, let $\mathtt{U}$ denote the set of indices corresponding to unstable directions and let $\mathtt{CS}$ denote the set indices corresponding to nonhyperbolic and stable directions based upon some criteria, for instance, the average magnitude of the diagonal elements of the upper triangular coefficient matrix $\tilde{A}(t)$ from (4.3).

We first consider the case in which $\theta = 0$ and wish to determine componentwise bounds on $Q_{n+1}^T \delta_{n+1}$ and on $Q_{n+1}^T[D_{w_n}\phi(w_n, h_n) - Y_n]$, which we rewrite as

$$\begin{aligned} (6.1)\quad & Q_{n+1}^T (DF(w) - L)_{n,n} \\ & := Q_{n+1}^T [D_{w_n}\phi(w_n, h_n) - D_{x_n}\phi(x_n, h_n)] + Q_{n+1}^T [D_{x_n}\phi(x_n, h_n) - Y_n]. \end{aligned}$$

For $0 \le t \le h_n$ define $y_n(t)$ and $Y_n(t)$ with $y_n(0) = x_n$ and $Y_n(0) = I$ as the numerical solution to the original nonlinear problem and the linear variational equation, respectively, using dense or continuous output (see [17, p. 176]). Let $E_n(t) := D_{x_n}\phi(x_n, t) - Y_n(t)$ for $0 \le t \le h_n$, where $E_n(0) = 0$. In the following lemma we consider componentwise local errors in $Q_{n+1}^T \delta_{n+1}$ and in $Q_{n+1}^T E_n(h_n)$ when componentwise local errors are satisfied in y, Q, and R.

LEMMA 6.1. *Let $\eta_{\mathtt{U}}$ and $\eta_{\mathtt{CS}}$ denote the local errors in the components of y, the columns of Q, and the rows of R_n corresponding to the indices* $\mathtt{U}$ *and* $\mathtt{CS}$*, respectively, with $\eta_{\mathtt{U}} \ge \eta_{\mathtt{CS}}$. Then we have*

$$(6.2)\qquad |(Q_{n+1}^T \delta_{n+1})_i| \le (1 + ||x_{n+1}||_1)\eta_\iota + O(\eta_{\mathtt{U}}^2) =: \mu_n \eta_\iota + O(\eta_{\mathtt{U}}^2),$$

(6.3)

$$|(Q_{n+1}^T E_n(h_n))_{ij}| \le \left(\chi_{\{i\le j\}} + \sum_{k=1}^{j} |(R_n)_{kj}|\right)\eta_\iota + O(\eta_{\mathtt{U}}^2) =: (\chi_{\{i\le j\}} + \sigma_{nj})\eta_\iota + O(\eta_{\mathtt{U}}^2),$$

where $\iota := \mathtt{U}$ for $i \in \mathtt{U}$, $\iota := \mathtt{CS}$ for $i \in \mathtt{CS}$, and $\chi_{\{i\le j\}}$ is 1 for $i \le j$ and 0 otherwise.

Proof. The inequality (6.2) follows using (4.4) and the fact that we have $x_{n+1} - \phi(x_n, h_n) = \delta_{n+1}$. The inequality (6.3) follows similarly. ∎

Remark 6.1. Note that if we bound the local error for the ith column of Q by $\eta_\iota/(1+\max\{||R_n||_1, ||x_{n+1}||_1\})$, then the bounds (6.2) and (6.3) in Lemma 6.1 become $2\eta_\iota + O(\eta_{\mathtt{U}}^2)$ and $(\chi_{\{i\le j\}}+1)\eta_\iota + O(\eta_{\mathtt{U}}^2)$, respectively, where $\iota := \mathtt{U}$ for $i \in \mathtt{U}$, and $\iota := \mathtt{CS}$ for $i \in \mathtt{CS}$.

Given the bound (6.3) for $Q_{n+1}^T E_n(t)$ we focus on determining componentwise bounds on $Q_{n+1}^T[D_{w_n}\phi(w_n, h_n) - D_{x_n}\phi(x_n, h_n)]$. Consider the linear equations

$$(6.4)\qquad Q_{n+1}^T \dot{W} = [Q_{n+1}^T Df(\phi(w_n, t))Q_{n+1}]Q_{n+1}^T W \equiv B(t)Q_{n+1}^T W,\ W(0) = I,$$

and

$$(6.5)\qquad Q_{n+1}^T \dot{X} = [Q_{n+1}^T Df(\phi(x_n, t))Q_{n+1}]Q_{n+1}^T X \equiv C(t)Q_{n+1}^T X,\ X(0) = I.$$

Let $V(t) := Q_{n+1}^T[W(t) - X(t)]$ and observe that $V(0) = 0$. Then we have

$$\dot{V} = B(t)V + [B(t) - C(t)](Q_{n+1}^T[Y_n(t) + E_n(t)]). \tag{6.6}$$

DEFINITION 6.1. *Define a and b_j as constants that satisfy $a \geq \sup_{0\leq t\leq h_n} ||B(t)||_\infty$ and $b_j \geq \sup_{0\leq t\leq h_n} ||\Pi_j||_\infty$, where Π_j denotes the jth column of*

$$[B(t) - C(t)](Q_{n+1}^T[Y_n(t) + E_n(t)]). \tag{6.7}$$

LEMMA 6.2. *With the assumptions of Lemma* 6.1 *we have*

$$|(Q_{n+1}^T[D_{w_n}\phi(w_n, h_n) - D_{x_n}\phi(x_n, h_n)])_{ij}| \leq \frac{b_j}{a}(\exp(ah_n) - 1). \tag{6.8}$$

Proof. Let $z_j(t)$ denote the supremum norm of the jth column of $V(t)$. Then we have

$$\frac{d}{dt}z_j(t) \leq az_j(t) + b_j, \tag{6.9}$$

so by Gronwall's inequality (see [25, p. 108]) and using the fact that $z_j(0) = 0$, we have

$$z_j(h_n) \leq \frac{b_j}{a}(\exp(ah_n) - 1). \qquad \square \tag{6.10}$$

Using (6.3) and (6.8), we obtain the following bounds on the magnitude of the components of $Q_{n+1}^T[D_{w_n}\phi(w_n, h_n) - Y_n]$.

COROLLARY 6.1. *With the assumptions of Lemma* 6.1 *we have*

$$\begin{aligned} |(Q_{n+1}^T[D_{w_n}\ \phi(w_n, h_n) - Y_n])_{ij}| &\leq \left(\chi_{\{i\leq j\}} + \sum_{k=1}^{j} |(R_n)_{kj}|\right)\eta_\iota + O(\eta_{\mathtt{U}}^2) \\ &+ \frac{b_j}{a}(\exp(ah_n) - 1) =: (\chi_{\{i\leq j\}} + \sigma_{nj})\eta_\iota + \rho_{nj} + O(\eta_{\mathtt{U}}^2), \end{aligned} \tag{6.11}$$

where $\iota := \mathtt{U}$ for $i \in \mathtt{U}$, and $\iota := \mathtt{CS}$ for $i \in \mathtt{CS}$.

Our task now is to determine computable bounds on a and b_j. The difficulty occurs because the matrix functions $B(t)$ and $C(t)$ are not explicitly known.

We assume that either f satisfies a one-sided Lipschitz condition (see [25, p. 173]) so there exists a constant L_{os} such that

$$\langle f(w_n(t)) - f(x_n(t)), w_n(t) - x_n(t)\rangle \leq L_{\text{os}}||w_n(t) - x_n(t)||_2^2, \tag{6.12}$$

or f is locally Lipschitz so that there exists a nonnegative constant L_{loc} such that

$$||f(w_n(t)) - f(x_n(t))||_\infty \leq L_{\text{loc}}||w_n(t) - x_n(t)||_\infty. \tag{6.13}$$

Using Gronwall's inequality for $\Lambda = L_{\text{os}}$ (and $\varepsilon_0 = \sqrt{N}\epsilon_0$) or $\Lambda = L_{\text{loc}}$ (and $\varepsilon_0 = \epsilon_0$), respectively, we have

$$||w_n(t) - x_n(t)||_\infty \leq \exp(\Lambda t) \cdot \varepsilon_0. \tag{6.14}$$

Let L_{Df} denote the Lipschitz constant for Df so that

$$\begin{aligned} ||Df(w_n(t)) - Df(x_n(t))||_\infty &\leq L_{Df}||w_n(t) - x_n(t)||_\infty, \\ ||Df(x_n(t)) - Df(y_n(t))||_\infty &\leq L_{Df}||x_n(t) - y_n(t)||_\infty. \end{aligned} \tag{6.15}$$

Thus,

$$\begin{aligned} |Df(w_n(t))_{ij} - Df(x_n(t))_{ij}| &\le \varepsilon_0 \exp(\Lambda t) L_{Df} =: G_1(t), \\ |Df(x_n(t))_{ij} - Df(y_n(t))_{ij}| &\le L_{Df} ||\delta_{n+1}(t)||_\infty =: G_2(t), \end{aligned} \tag{6.16}$$

where $\delta_{n+1}(t)$ is the local error at the nth step at time t for $0 \le t \le h_n$. Then we have

$$\begin{aligned} |Df(w_n(t))_{ij}| &\le |Df(w_n(t))_{ij} - Df(x_n(t))_{ij}| \\ &\quad + |Df(x_n(t))_{ij} - Df(y_n(t))_{ij}| + |Df(y_n(t))_{ij}| \\ &\le G_1(t) + G_2(t) + |Df(y_n(t))_{ij}| =: H_{ij}(t). \end{aligned} \tag{6.17}$$

We have the following for a:

$$a := \sup_{0\le t\le h_n} \max_{1\le i\le N} \sum_{j=1}^{N}\sum_{k=1}^{N}\sum_{l=1}^{N} |(Q_{n+1})_{ki}| \cdot H_{kl}(t) \cdot |(Q_{n+1})_{lj}|. \tag{6.18}$$

For b_j we obtain

$$\begin{aligned} b_j := \sup_{0\le t\le h_n} \sum_{i=1}^{N}\sum_{k=1}^{N}\sum_{l=1}^{N} |(Q_{n+1})_{ki}| \cdot |G_1(t)(Q_{n+1})_{kl}| \cdot (|(Q_{n+1}^T Y_n(t))_{lj}| \\ +|(Q_{n+1}^T E_n(t))_{lj}|). \end{aligned} \tag{6.19}$$

The bounds for a and b_j given in (6.18) and (6.19), respectively, combined with Lemma 6.1 and Corollary 6.1 provide bounds on the components of $\overline{Q}^T F(z)$ and $\overline{Q}^T(DF(w) - L)$ for $||w - z|| \le \epsilon_0$ when $\theta = 0$.

When $\theta > 0$, we need to determine bounds on

$$Q_{n+1}^T[D_{w_n}\phi(w_n, t) - D_{w_n}\phi(w_n, h_n)] \quad \text{and} \quad Q_{n+1}^T[f(\phi(w_n, t)) - f_{n+1}] \tag{6.20}$$

for $|t - h_n| \le \theta\epsilon$ and $||w_n - x_n||_\infty \le \epsilon_0$.

DEFINITION 6.2. *Define constants such that a_θ satisfies $a_\theta \ge \sup_{|t-h_n|\le\theta\epsilon} ||B(t)||_\infty$, $b_{\theta,j}$ satisfies $b_{\theta,j} \ge \sup_{|t-h_n|\le\theta\epsilon} ||\Lambda_j||_\infty$, where Λ_j denotes the jth column of*

$$B(t)Q_{n+1}^T D_{w_n}\phi(w_n, h_n), \tag{6.21}$$

and c_θ and d satisfy

$$c_\theta \ge \sup_{\{t:0\le t\le s, |s-h_n|\le\theta\epsilon\}} ||B(t)Q_{n+1}^T f(\phi(w_n, h_n))||_\infty$$

and

$$d \ge \sup_{0\le t\le h_n} ||[B(t) - C(t)]Q_{n+1}^T f(\phi(x_n, t))||_\infty.$$

LEMMA 6.3. *With the assumptions of Lemma 6.1 we have for $|t - h_n| \le \theta\epsilon$,*

$$|(Q_{n+1}^T[D_{w_n}\phi(w_n, t) - D_{w_n}\phi(w_n, h_n)])_{ij}| \le \frac{b_{\theta,j}}{a_\theta}(\exp(a_\theta\theta\epsilon) - 1). =: \gamma_{j,n}. \tag{6.22}$$

Proof. First derive an expression similar to (6.6), and then the proof follows using the same technique as the proof of Lemma 6.2. ∎

We have

$$
\begin{aligned}
Q_{n+1}^T[f(\phi(w_n,t)) - f_{n+1}] &= Q_{n+1}^T[\{f(\phi(w_n,t)) - f(\phi(w_n,h_n))\} \\
&\quad +\{f(\phi(w_n,h_n)) - f(\phi(x_n,h_n))\} + \{f(\phi(x_n,h_n)) - f_{n+1}\}]
\end{aligned} \tag{6.23}
$$

for $|t-h_n| \le \theta\epsilon$. Using the fact that $Q_{n+1}^T f(\phi(w_n,t))$ satisfies (6.4) and $Q_{n+1}^T f(\phi(x_n,t))$ satisfies (6.5), we may obtain bounds on the left-hand side of (6.23) in a similar fashion to those previously obtained.

LEMMA 6.4. *With the assumptions of Lemma* 6.1 *we have, for* $|t-h_n| \le \theta\epsilon$,

$$
\begin{aligned}
||Q_{n+1}^T[f(\phi(w_n,t)) - f_{n+1}]||_\infty &\le \tfrac{c_\theta}{a_\theta}(\exp(a_\theta\theta\epsilon) - 1) + \tfrac{d}{a}(\exp(ah_n) - 1) \\
&\quad +||Q_{n+1}^T[f(\phi(x_n,h_n)) - f_{n+1}]||_\infty := \zeta_n.
\end{aligned} \tag{6.24}
$$

We now determine computable bounds on a_θ, $b_{\theta,j}$, c_θ, and d_θ in a similar spirit to those for a and b_j. For a_θ we use (6.17) with the limits of the supremum changed to $|t-h_n| \le \theta\epsilon$ in (6.18). To find the bound for $b_{\theta,j}$, we bound $B(t)$ as for a_θ and then bound $Q_{n+1}^T D_{w_n}\phi(w_n,h_n)$ using (6.3) and (6.8). We bound c_θ and d in a fashion similar to that of $b_{\theta,j}$ and b_j, respectively, and employ the bound

$$
||Q_{n+1}^T[f(\phi(x_n,h_n)) - f_{n+1}]||_\infty \le ||Q_{n+1}^T||_\infty L_f||\delta_{n+1}||_\infty. \tag{6.25}
$$

Putting all of these bounds together we have the following theorem that summarizes the bounds for $\theta = 0$ and $\theta > 0$.

THEOREM 6.5. *With the assumption of Lemma* 6.1, *for* $\theta = 0$ *the bounds on the nonzero components of* $\overline{Q}^T F(z)$ *are given by inequality* (6.2) *in Lemma* 6.1, *while the bounds on the nonzero components of* $\overline{Q}^T(DF(w) - L)$ *are given by inequality* (6.11) *in Corollary* 6.1. *Bounds on the quantities* a *and* b_j *in Corollary* 6.1 *may be obtained using inequalities* (6.12)–(6.19).

For $\theta > 0$ *the bounds for the nonzero components of* $\overline{Q}^T(DF(w) - L)$ *are given by combining the bound* (6.11) *in Corollary* 6.1 *with the bound* (6.22) *in Lemma* 6.3 *and the bound* (6.24) *in Lemma* 6.4. *In addition, bounds on* a_θ, $b_{\theta,j}$, c_θ, *and* d *may be obtained using the inequalities* (6.12)–(6.25).

7. Implementation. The basic outline of our algorithm for solving and producing a shadowing distance estimate for an approximate solution of the IVP (2.1) is as follows.

ALGORITHM. Given constants $\epsilon_0 > 0$ and $\theta \ge 0$ and componentwise tolerances, $\eta_{\mathtt{U}} \ge \eta_{\mathtt{CS}} > 0$ with respect to the indices `U` and `CS`.

1. Simultaneously approximate solutions to (4.1), (4.2), and (4.3).
2. Update the elements of the matrix UU^T, and store y_n, Q_n, R_n, and f_{n+1}.
3. Bound componentwise the quantities $\overline{Q}^T F(z)$ and $\overline{Q}^T(DF(w) - L)$ using Theorem 6.5.
4. Decompose the matrix UU^T and form $\hat{Q}U^\dagger$ (see (5.3)).
5. Using the results from steps 3 and 4, estimate α in (3.1) and β in (3.2) using (5.4).
6. If $\alpha < 1$ and $\beta/(1-\alpha) \le \epsilon_0$, then set the shadowing distance $\epsilon := \beta/(1-\alpha)$.

Implementation Details.

1. We employ ODEX [17] or RKSUITE [3] to approximate the differential equations and use a projected integration scheme to maintain orthogonality of Q (see [9]) using a modified Gram–Schmidt procedure [14]. We modified the error control of ODEX to enforce componentwise error tolerances. The use of componentwise tolerances is a standard feature in RKSUITE. We bound the local error for the columns of Q as described in Remark 6.1 and set $\mu_n = 2$ and $\sigma_{nj} = 1$ for all n and j. For RKSUITE we employ the $(7, 8)$ Runge–Kutta pair.

2. We use symmetric block tridiagonal storage when forming UU^T.

3. We estimate $\overline{Q}^T F(z)$ and $\overline{Q}^T(DF(w) - L)$ by sampling at the mesh points $\{t_n\}_0^M$ so that $\sup_{0\le t\le h_n}$ is replaced by $\max_{t\in\{0,h_n\}}$ and we neglect the $O(\eta_{\mathtt{U}}^2)$ terms in (6.2) and (6.3).

4. We solve for some of the rows of $\hat{Q}U^\dagger$ and then use (5.4) to estimate α and β. This provides lower bounds on α and β that will be sharp if the "correct" rows are used. We use the first and last block rows of $\hat{Q}U^\dagger$ and several picked at random to obtain an estimate on α without the full cost of solving for all of $U^\dagger$. To determine block rows of $U^\dagger$ we use the block tridiagonal solver TRDBLK [11].

8. Numerical results. In this section we present numerical results of our shadowing algorithm applied to several nonlinear IVPs. We obtain approximate solutions and local error estimates from the IVP solvers ODEX and RKSUITE. In the description of our numerical results we denote by "M" the number of time steps taken; "U" denotes the set of indices for which the local error tolerance "$\eta_{\mathtt{U}}$" is employed, while the local error tolerance "$\eta_{\mathtt{CS}}$" is used for the remaining indices. The value "T" is the final time reached during the numerical computation; "QhUdnorm" is the maximum row sum of the rows of $\hat{Q}U^\dagger$ that were computed. For the numerical experiments recorded here we computed six block rows: the first two, last two, and middle two block rows. When $\theta > 0$ we compute the corresponding additional rows of $\hat{Q}U^\dagger$. We found some variation in QhUdnorm when using other rows of $\hat{Q}U^\dagger$, but always within the same order of magnitude and, in fact, never greater than twice the value of QhUdnorm reported here. We recommend randomly choosing the rows of $\hat{Q}U^\dagger$ to be computed, but have chosen to compute these particular six block rows for definiteness. We also report on the value "α" in (3.1) and the value of the shadowing distance "ϵ" that was obtained. We will indicate with "–" if there was no value of ϵ_0 for which we were able to satisfy $\alpha < 1$ and $\epsilon \le \epsilon_0$. All computations where performed on a Linux workstation with 512MB memory using a 400MHz processor. We found that the computation of y, Q, and R comprised approximately 85 percent of the computation time when using ODEX and approximately 70 percent of the computation time when using RKSUITE.

To compare the numerical shadowing technique presented here with other shadowing techniques we consider two categories of techniques: (i) "BVP techniques"—these are based upon forming a right inverse by specifying boundary conditions using the stability properties of the system and then bounding the norm of a solution to this BVP; (ii) "pseudoinverse techniques"—this is the approach taken here and involves finding and bounding the norm of a particular right inverse, the pseudoinverse. In general, the BVP technique (see, e.g., [5], [7]) provide somewhat conservative values for the shadowing distance, but they are obtained rather inexpensively. The pseudoinverse techniques (see, e.g., [26] and this paper) are expensive, but sharper. The expense is due to the requirement that we find $L^\dagger$ explicitly so the norm of the pseudoinverse is obtained essentially exactly. By obtaining only selected rows of $L^\dagger$

TABLE 8.1
Forced vdP ($M = 1E+5$, $\mathtt{U} = \{1\}$, $\eta_{\mathtt{U}} = 1.E-6$).

Meth	$\eta_{\mathtt{CS}}/\eta_{\mathtt{U}}$	θ	T	QhUdnorm	α	ϵ
RKSUITE	$1.E0$	$0.E0$	$1.56E+4$	$2.1E+2$	$1.3E-1$	$4.9E-4$
RKSUITE	$1.E0$	$1.E-1$	$1.56E+4$	$1.9E+1$	$1.9E-2$	$4.0E-5$
RKSUITE	$1.E-1$	$1.E-1$	$1.23E+4$	$2.4E+1$	$1.9E-2$	$2.8E-5$
RKSUITE	$1.E-2$	$1.E-1$	$9.80E+3$	$2.8E+1$	$1.9E-2$	$3.4E-5$
ODEX	$1.E0$	$0.E0$	$2.58E+4$	$1.9E+2$	–	–
ODEX	$1.E-1$	$0.E0$	$2.27E+4$	$1.8E+2$	$6.0E-1$	$9.0E-4$
ODEX	$1.E-2$	$0.E0$	$1.50E+4$	$2.0E+2$	$3.4E-1$	$5.9E-4$
ODEX	$1.E0$	$1.E-1$	$2.58E+4$	$1.5E+1$	$1.0E-1$	$3.3E-5$
ODEX	$1.E-1$	$1.E-1$	$2.27E+4$	$1.3E+1$	$8.3E-2$	$1.4E-5$
ODEX	$1.E-2$	$1.E-1$	$1.50E+4$	$3.6E+1$	$6.3E-2$	$2.2E-5$

we have decreased the expense but at the cost of perhaps not having a bound on the norm of the entire pseudoinverse. Regardless of how the right inverse has been chosen and bounded, a result similar to Proposition 4.1 in [4] has been used (see [5], [7], and [26]) to determine the shadowing distance ϵ. With the standard fixed point result, which takes $\alpha = 1/2$ and has two additional norm bounds, the shadowing distance is approximately $2||L^{\dagger}||\delta$ where δ is a uniform bound on the norm of the local error. With the formulation and fixed point result presented here, for $\eta_{\mathtt{CS}}/\eta_{\mathtt{U}} = 1$ the best possible shadowing distance is $\epsilon = \mathtt{QhUdnorm} \cdot 2\eta_{\mathtt{U}}$, where $2\eta_{\mathtt{U}}$ is our bound on the supremum norm of the local error tolerance (see Remark 6.1), and the results can only improve for $\eta_{\mathtt{CS}}/\eta_{\mathtt{U}} < 1$.

Example 8.1. As our first example we consider a forced van der Pol oscillator

$$\ddot{y} + \alpha(y^2 - 1)\dot{y} + y = \beta\cos(\omega t) \tag{8.1}$$

with $\alpha = \frac{2}{5}$, $\beta = 2\alpha^2$, and $\omega = \sqrt{1-\alpha^2}$ and the initial conditions $(0,0)$. In our numerical experiments, we set $\epsilon_0 = 5.E-4$ when using RKSUITE and set $\epsilon_0 = 1.E-3$ when using ODEX.

In Table 8.1, we see a decrease by an order of magnitude in QhUdnorm for $\theta > 0$ since one of the Lyapunov exponents is close to zero. In addition, there is some improvement in the shadowing distance ϵ when $\eta_{\mathtt{CS}}/\eta_{\mathtt{U}} < 1$. There is a trade-off here in that there is some decrease in the average stepsize when $\eta_{\mathtt{CS}}/\eta_{\mathtt{U}} < 1$, which tends to increase QhUdnorm, but in spite of this there is a decrease in ϵ especially for $\eta_{\mathtt{CS}}/\eta_{\mathtt{U}} = 1.E-1$. This is not a particularly good example for our method since both of the Lyapunov exponents are negative (we are using $\mathtt{U} = \{1\}$); nonetheless we do obtain some improvement with $\eta_{\mathtt{CS}}/\eta_{\mathtt{U}} < 1$.

Example 8.2. The Lorenz equation is given by

$$\begin{pmatrix} \dot{x} \\ \dot{y} \\ \dot{z} \end{pmatrix} = \begin{pmatrix} \sigma(y-x) \\ \rho x - xz - y \\ xy - \beta z \end{pmatrix}. \tag{8.2}$$

We consider the parameter values $\sigma = 10$, $\rho = 28$, and $\beta = 8/3$, and the initial condition is chosen to be $(x_0, y_0, z_0) = (0, 1, 0)$. In our numerical experiments, we set $\epsilon_0 = 5.E-5$ when using RKSUITE and set $\epsilon_0 = 2.E-6$ when using ODEX. In Table 8.2, observe the decrease by an order of magnitude in the shadowing distance approximation ϵ with RKSUITE when changing $\eta_{\mathtt{CS}}/\eta_{\mathtt{U}}$ from $1.E0$ to $1.E-1$. In general, we tend to observe smaller shadowing distances for ODEX than for RKSUITE, ostensibly

TABLE 8.4
Coupled oscillators ($\mathtt{U} = \{1,2\}$, $\eta_{\mathtt{U}} = 1.E-10$, $\epsilon_0 = 2.E-7$).

Meth	$\eta_{\mathtt{CS}}/\eta_{\mathtt{U}}$	θ	T	QhUdnorm	M	ϵ
RKSUITE	$1.E0$	$0.E0$	$1.07E+2$	$2.9E+5$	$1E+4$	–
RKSUITE	$1.E0$	$1.E-2$	$1.07E+2$	$9.1E+2$	$1E+4$	$1.8E-7$
RKSUITE	$1.E-1$	$1.E-2$	$8.41E+1$	$1.2E+3$	$1E+4$	$1.1E-7$
RKSUITE	$1.E-2$	$1.E-2$	$6.40E+1$	$1.7E+3$	$1E+4$	$1.3E-7$
RKSUITE	$1.E-1$	$1.E-2$	$8.49E+2$	$1.2E+3$	$1E+5$	$1.1E-7$
ODEX	$1.E0$	$0.E0$	$4.50E+2$	$4.1E+5$	$1E+4$	–
ODEX	$1.E0$	$1.E-2$	$4.50E+2$	$3.9E+2$	$1E+4$	$7.9E-8$
ODEX	$1.E-1$	$1.E-2$	$4.29E+2$	$2.7E+2$	$1E+4$	$2.4E-8$
ODEX	$1.E-2$	$1.E-2$	$4.05E+2$	$2.9E+2$	$1E+4$	$3.9E-8$
ODEX	$1.E-1$	$1.E-2$	$4.25E+3$	$2.7E+2$	$1E+5$	$2.4E-8$

due to the larger average stepsize achieved by the higher order of the two methods, ODEX. In Table 8.3, we report on longer time simulations performed with $M = 4E+5$ time steps.

Example 8.3. The next example we consider is a ring of oscillators with an external force proportional to the position component of the limit cycle of a van der Pol oscillator. In particular, we consider the following system, similar to that considered in [10],

$$\begin{aligned} &\ddot{y} + \alpha(y^2-1)\dot{y} + \omega^2 y = 0, \\ &\ddot{x}_i + d_i\dot{x}_i + \gamma[\Phi'(x_i - x_{i-1}) - \Phi'(x_{i+1} - x_i)] = \sigma y \delta_{i1}\,, \quad i = 1,\ldots,\hat{N}\,. \end{aligned} \tag{8.3}$$

The function $\Phi(x) = (x^2/2) + (x^4/4)$ is the single well Duffing potential, $\alpha, \omega, \gamma, \sigma$ are scalar parameters, x_i is the displacement of the ith particle, d_i is the damping coefficient, and we have periodic boundary conditions ($x_0 = x_{\hat{N}}$ and $x_{\hat{N}+1} = x_1$). For the experiments we set $\hat{N} = 2$, $\alpha = 1$, $\omega = 1.82$, $\gamma = 1$, $\sigma = 4$, and $d_1 = d_2 = 3.E-2$ and employ the initial conditions $(y, \dot{y}, x_1, \dot{x}_1, x_2, \dot{x}_2) = (1,0,0,0,0,0)$. In Table 8.4 we report on simulations for the forced coupled oscillators. The importance of rescaling of time is seen in the decrease in QhUdnorm as we increase θ from $0.E0$ to $1.E-2$. In addition, we see the benefits of $\eta_{\mathtt{CS}}/\eta_{\mathtt{U}} < 1$ especially when using ODEX, in particular for $\theta = 1.E-2$ we see a nontrivial decrease in the shadowing distance when $\eta_{\mathtt{CS}}/\eta_{\mathtt{U}}$ is changed from $1.E0$ to $1.E-1$. In Figure 1 we exhibit plots

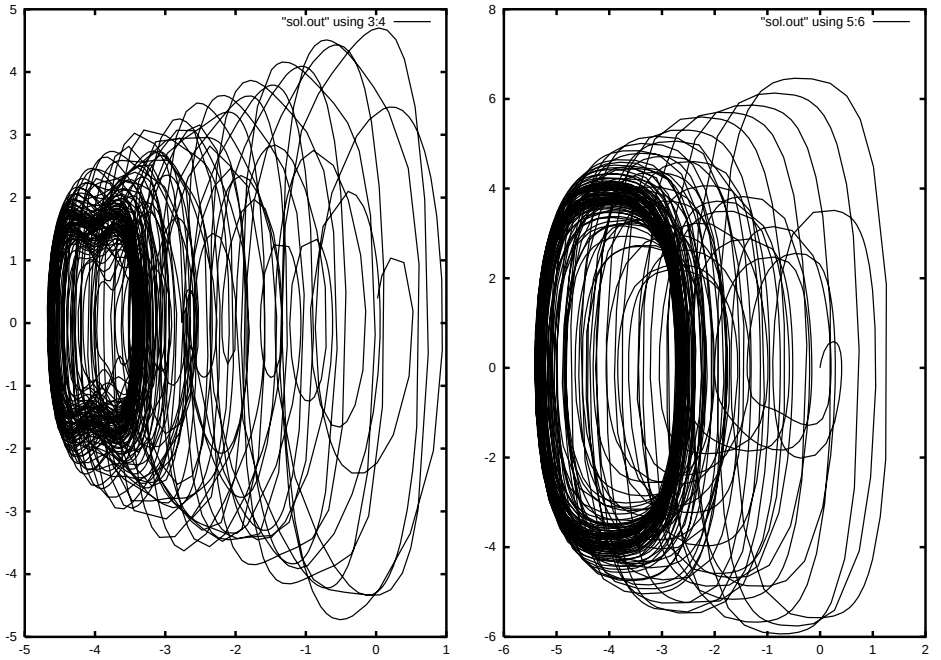

FIG. 1. *Plots of solution components* $(x_1, \dot{x}_1)$ *and* $(x_2, \dot{x}_2)$.

of the solution components $(x_1, \dot{x}_1)$ and $(x_2, \dot{x}_2)$. In Figure 2 we plot the four largest instantaneous Lyapunov exponents versus time. These instantaneous exponents are simply the diagonal elements of $\tilde{A}$ (see (4.3)), the coefficient matrix for R. Notice the variation of the exponents about zero which shows a lack of hyperbolicity and makes this a difficult problem for obtaining good shadowing distances. In fact, for $\theta = 0$ we were not able to shadow the approximate solution.

9. Conclusions. In this paper we devised a new approach to posteriori error analysis for approximate solutions to IVP ODEs using a shadowing lemma-type approach. Using an improved fixed point theorem and a reformulation of the differential equations we were able to obtain improved shadowing results. The cost of the numerical method for providing these global error estimates is small relative to the cost of approximating the differential equations. In particular, the method is $O(M)$ in both time and memory, and we found that the cost of providing the global error estimate is a fraction of the computation time. Any improvements to the estimates in section 6 would translate into improvements in the global error estimates. The use of different local error tolerances for different components of the differential equations, made possible by the reformation of the differential and taken advantage of with the improved fixed point result, allow for improved shadowing distances without severe degradation in the average time step. In all three examples there was improvement in the shadowing distance with the use of componentwise error control. The most substantial improvement was in Example 8.2, the Lorenz equation (one positive, one zero, and one negative Lyapunov exponent), which is a good fit to our prototype example (see (5.9)–(5.11) and the discussion thereafter), while in Example 8.1 (two negative exponents) and Example 8.3 (several finite time exponents oscillating about zero) we had some improvement.

AN EFFICIENT STOCHASTIC ALGORITHM FOR STUDYING COAGULATION DYNAMICS AND GELATION PHENOMENA*

ANDREAS EIBECK† AND WOLFGANG WAGNER†

Abstract. A new class of efficient stochastic algorithms for the numerical treatment of coagulation processes is proposed. The algorithms are based on the introduction of fictitious jumps combined with an acceptance-rejection technique for distributions depending on particle size. The increased efficiency is demonstrated by numerical experiments. In particular, gelation phenomena are studied.

Key words. coagulation equation, stochastic particle method, simulation algorithm, gelation phenomena

1. Introduction.

The continuous coagulation equation

$$\frac{\partial}{\partial t}\,c(t,x) = \frac{1}{2}\int_0^x K(x-y,y)\;c(t,x-y)\;c(t,y)\;dy - \int_0^\infty K(x,y)\;c(t,x)\;c(t,y)\;dy \tag{1.1}$$

with initial condition

$$c(0,x) = c_0(x) \geq 0 \tag{1.2}$$

describes the time evolution of the average concentration of particles of size $x > 0$. Here the nonnegative and symmetric function $K(x,y)$ denotes the coagulation rate of clusters of size x and y. According to (1.1), the concentration $c(x,t)$ can increase by coagulation of clusters of size $y < x$ and $x-y$ (first term) and decrease by coagulation of an x-cluster with a cluster of any size y (second term).

If the clusters can take only sizes $k = 1, 2, \ldots$, then the coagulation dynamics is governed by a discrete version of equation (1.1), where all integrals are replaced by sums. The discrete coagulation equation

$$\frac{\partial}{\partial t}\,c(t,k) = \frac{1}{2}\sum_{j=1}^{k-1} K(k-j,j)\,c(t,k-j)\,c(t,j) - \sum_{j=1}^{\infty} K(k,j)\,c(t,k)\,c(t,j) \tag{1.3}$$

was first published in [23] and is referred to as Smoluchowski's coagulation equation. Both the continuous and the discrete equations have a wide range of applications, e.g., in astrophysics, biology, chemistry, and meteorology (see the survey papers [6] and [2]).

Stochastic particle systems related to the coagulation equation were introduced by several authors (cf. [18], [11], [17]). They are of the form

$$x_i(t)\,, \quad i = 1, \ldots, n(t)\,, \qquad t \geq 0\,, \tag{1.4}$$

where $x_i(t)$ represents the size of particle i at time t and $n(t)$ is the number of particles in the system. The initial system consisting of a large number $n(0)$ of particles is supposed to approximate the initial condition (1.2). A random dynamics is defined such that the system at later times approximates the solution to (1.1). The stochastic approach to coagulation was reviewed in [2]. Recently, rigorous results concerning the weak law of large numbers for the relevant stochastic particle systems with general kernels have been obtained (see [2, Problem 10(a)], [13], [14], [15], [19], [7]). Besides the derivation of the coagulation equation, stochastic particle systems play a significant role in numerical algorithms for that equation (see [12], [5]). We refer to [21] for a survey on Monte Carlo methods and to [20] concerning recent applications.

The purpose of this paper is to introduce a new class of efficient stochastic algorithms for the numerical treatment of the coagulation equation. The idea was mentioned in [7], where we studied the convergence problem. Here we give a detailed description of the numerical procedure and apply it to the investigation of some interesting phenomena.

The paper is organized as follows. In section 2 we describe the new class of algorithms. Markov processes with fictitious jumps are introduced, which are based on appropriate majorant kernels. An efficient acceptance-rejection procedure for the generation of the relevant probability distributions is proposed. In section 3 we apply the numerical technique to the study of coagulation dynamics. For several coagulation kernels we investigate approximation properties and gelation phenomena. In section 4 we discuss the results and mention some directions for further study.

2. Description of the algorithm.

2.1. Markov processes with fictitious jumps. We introduce a sequence of jump processes

$$U^N(t)\,, \qquad t \geq 0\,, \qquad N = 1, 2 \dots\,, \tag{2.1}$$

taking values in the space of discrete measures

$$\mathcal{S}^N = \left\{ p = \frac{1}{N} \sum_{i=1}^{n} \delta_{x_i}\,, \quad x_i > 0\,, \quad n = 1, 2, \dots \right\},$$

where δ denotes the Dirac measure. The process (2.1) is represented by a system of particles (1.4),

$$U^N(t, dx) = \frac{1}{N} \sum_{i=1}^{n(t)} \delta_{x_i(t)}(dx)\,. \tag{2.2}$$

For $\Phi \in C_b(\mathcal{S}^N)$ the infinitesimal generator of the process is defined as

$$\mathcal{K}^N \Phi(p) = \frac{1}{2N} \sum_{1 \leq i \neq j \leq n} \Big[\Phi(J(p, i, j)) - \Phi(p) \Big] K(x_i, x_j)\,, \qquad p \in \mathcal{S}^N\,, \tag{2.3}$$

where

$$J(p, i, j) = p + \frac{1}{N} (\delta_{x_i + x_j} - \delta_{x_i} - \delta_{x_j})\,. \tag{2.4}$$

The initial condition is assumed to be deterministic and such that (cf. (1.2))

$$\lim_{N\to\infty} \int_0^\infty \varphi(x)\, U^N(0, dx) = \int_0^\infty \varphi(x)\, c_0(x)\, dx \tag{2.5}$$

for a sufficiently wide class of test functions φ. In particular, for $\varphi = 1$, one obtains

$$n(0) \sim N \int_0^\infty c_0(x)\, dx\,. \tag{2.6}$$

Convergence of $U^N(t)$ (as $N \to \infty$) to the solution of a measure-valued version of (1.1) was studied in [19].

We will describe a class of simulation algorithms related to the stochastic systems determined by (2.3)–(2.5). For that purpose, the generator (2.3) is rewritten in the usual form of a jump process generator [8, Chapter 4, section 2]

$$\mathcal{K}^N \Phi(p) = \int_{\mathcal{S}^N} \Big[\Phi(q) - \Phi(p)\Big]\, \mathcal{Q}(p, dq)\,, \tag{2.7}$$

where

$$\begin{aligned} &\mathcal{Q}(p, dq) \\ &\quad = \frac{1}{2N} \sum_{1\le i\ne j\le n} \Big\{ K(x_i, x_j)\, \delta_{J(p,i,j)}(dq) + \Big[\hat{K}(x_i, x_j) - K(x_i, x_j)\Big]\, \delta_p(dq) \Big\} \end{aligned} \tag{2.8}$$

and $\hat{K}$ is an appropriate majorant kernel satisfying

$$K(x, y) \le \hat{K}(x, y) \qquad \forall\, x, y > 0\,. \tag{2.9}$$

The pathwise behavior of a jump process with the infinitesimal generator (2.7)–(2.8) is as follows. Coming to a state $p \in \mathcal{S}^N$, the process stays there for a random waiting time $\tau(p)$, which has an exponential distribution with the parameter

$$\varrho(p) = \mathcal{Q}(p, \mathcal{S}^N) = \frac{1}{2N} \sum_{1\le i\ne j\le n} \hat{K}(x_i, x_j)\,, \tag{2.10}$$

i.e.,

$$\mathrm{Prob}\,\{\tau(p) \ge s\} = \exp(-\varrho(p)\, s)\,, \qquad s \ge 0\,. \tag{2.11}$$

After the time $\tau(p)$, the process jumps into a state $q \in \mathcal{S}^N$, which is distributed according to the jump distribution

$$\begin{aligned} &\varrho(p)^{-1}\, \mathcal{Q}(p, dq) \\ &\quad = \sum_{1\le i\ne j\le n} \frac{\hat{K}(x_i, x_j)}{2N\, \varrho(p)} \left\{ \frac{K(x_i, x_j)}{\hat{K}(x_i, x_j)}\, \delta_{J(p,i,j)}(dq) + \left[1 - \frac{K(x_i, x_j)}{\hat{K}(x_i, x_j)}\right] \delta_p(dq) \right\}. \end{aligned} \tag{2.12}$$

Distribution (2.12) is represented as a superposition of simpler distributions.

This description leads to the following algorithm for generating trajectories of the process.

0. Construct the initial state $U^N(0) = p \in \mathcal{S}^N$ in accordance with (2.5).

1. Wait in state p during a random time step $\tau(p)$ distributed according to (2.11).
2. Choose a pair i, j according to the index distribution (cf. (2.12))

$$\frac{\hat{K}(x_i, x_j)}{2N\,\varrho(p)}\,, \qquad 1 \le i \ne j \le n\,. \tag{2.13}$$

3. With probability

$$1 - \frac{K(x_i, x_j)}{\widehat{K}(x_i, x_j)}\,, \tag{2.14}$$

perform a fictitious jump (cf. (2.12)), i.e., stay in state p, and go to step 1.
4. Replace p by the new state $J(p, i, j)$ (cf. (2.4)), i.e., remove the clusters x_i and x_j and add the cluster $x_i + x_j$, and go to step 1.

Note the mass conservation property

$$\int_0^\infty x\,U^N(t, dx) = \int_0^\infty x\,U^N(0, dx)\,, \qquad t \ge 0\,, \tag{2.15}$$

which is a consequence of (2.4).

The distribution of the Markov process and its convergence behavior do not depend on the choice of the majorant kernel $\hat{K}$ in (2.9), since those properties are completely determined by the generator (2.3) and the initial condition (2.5). However, the choice of this function is of importance for numerical purposes, since it provides different ways of generating trajectories of the process and thus influences the efficiency of the simulation procedure. We illustrate this by two examples.

Example 2.1. The choice

$$\hat{K}(x, y) = K(x, y)\,, \qquad x, y > 0\,, \tag{2.16}$$

corresponds to the direct "physical" simulation of the process (see [12], [5]). No fictitious jumps occur (cf. (2.14)). This is the smallest possible majorant kernel satisfying (2.9). Thus, the time steps, having the average value $\varrho(p)^{-1}$ (cf. (2.11)), are as large as possible. However, the calculation of (2.10) and the generation of the distribution (2.13) are very time consuming if n is large and K has a complicated structure.

Example 2.2. The choice

$$\hat{K}(x, y) = K_{max}(p) = \max_{i,j=1,\dots,n} K(x_i, x_j)\,, \qquad x, y > 0\,, \tag{2.17}$$

represents the other extreme case compared with Example 2.1, providing the largest (reasonable) majorant kernel satisfying (2.9) (see, e.g., [12], [10], [21]). In this case the calculation of (2.10) and the generation of the distribution (2.13) are extremely simple. Indeed, the waiting time parameter takes the form

$$\varrho(p) = K_{max}(p)\,\frac{n\,(n-1)}{2N}\,, \tag{2.18}$$

and the index distribution (2.13) is uniform. However, the time steps are much smaller compared with Example 2.1, and many fictitious jumps occur (cf. (2.14)). This leads to low efficiency of the algorithm in situations where K is unbounded and clusters of significantly different sizes are contained in the system.

2.2. Choice of the majorant kernel. First we specify the algorithm from the previous subsection for the majorant kernel (cf. (2.9))

$$\hat{K}(x,y) = C\, x^{\varepsilon_1}\, y^{\varepsilon_2}\,, \qquad C>0\,, \quad \varepsilon_1\,, \varepsilon_2 \geq 0\,. \tag{2.19}$$

The waiting time parameter (2.10) takes the form

$$\varrho(p) = \frac{C}{2N} \sum_{i=1}^{n} x_i^{\varepsilon_1} \sum_{j=1,\ldots,n,\, j\neq i} x_j^{\varepsilon_2} = \frac{C}{2N} \left[\sum_{i=1}^{n} x_i^{\varepsilon_1} \sum_{j=1}^{n} x_j^{\varepsilon_2} - \sum_{i=1}^{n} x_i^{\varepsilon_1+\varepsilon_2} \right]. \tag{2.20}$$

The index distribution (2.13) is generated using the acceptance-rejection technique (cf., e.g., [9, section 3.6]). To this end the events $i=j$ are added to the state space and the zero probability for $i=j$ in (2.13) is replaced by an appropriate term proportional to $x_i^{\varepsilon_1}\, x_j^{\varepsilon_2}$. Then the index distribution takes the form

$$\frac{x_i^{\varepsilon_1}}{\sum_{l=1}^{n} x_l^{\varepsilon_1}}\, \frac{x_j^{\varepsilon_2}}{\sum_{l=1}^{n} x_l^{\varepsilon_2}}\,, \qquad i,j=1,\ldots,n\,,$$

so that the indices i and j are independent. The simulation procedure is as follows.

1. Generate i according to

$$\frac{x_i^{\varepsilon_1}}{\sum_{l=1}^{n} x_l^{\varepsilon_1}}\,, \qquad i=1,\ldots,n\,. \tag{2.21}$$

2. Generate j according to

$$\frac{x_j^{\varepsilon_2}}{\sum_{l=1}^{n} x_l^{\varepsilon_2}}\,, \qquad j=1,\ldots,n\,. \tag{2.22}$$

3. If $i=j$, then go to step 1.

A method for generating random variables with distributions of the form (2.21), (2.22) will be introduced in the next subsection.

Next we consider the majorant kernel

$$\hat{K}(x,y) = \hat{K}_1(x,y) + \cdots + \hat{K}_L(x,y)\,, \qquad L \geq 2\,, \tag{2.23}$$

where the components $\hat{K}_k\,,\ k=1,\ldots,L\,,$ are of the form (2.19). The waiting time parameter (2.10) is

$$\varrho(p) = \varrho_1(p) + \cdots + \varrho_L(p)\,,$$

where

$$\varrho_k(p) = \frac{1}{2N} \sum_{1\leq i\neq j\leq n} \hat{K}_k(x_i,x_j)\,, \qquad k=1,\ldots,L\,.$$

The index distribution (2.13) takes the form

$$\sum_{k=1}^{L} \frac{\varrho_k(p)}{\varrho(p)}\, \frac{\hat{K}_k(x_i,x_j)}{2N\,\varrho_k(p)}\,, \qquad 1\leq i\neq j\leq n\,.$$

Thus, one first chooses a number k according to the probabilities

$$\frac{\varrho_k(p)}{\varrho(p)}\,, \qquad k=1,\dots,L\,, \tag{2.24}$$

and then generates i,j according to the distribution

$$\frac{\hat K_k(x_i,x_j)}{2N\,\varrho_k(p)}\,, \qquad 1\le i\ne j\le n\,,$$

which is of the form (2.19).

Example 2.3. Consider the case

$$\hat K(x,y)=C\,(x+y)\,, \qquad x,y>0\,. \tag{2.25}$$

This kernel has the form (2.23). One obtains the waiting time parameter

$$\varrho(p)=C\,m_1\,(n-1)\,, \tag{2.26}$$

where $m_1=\frac{1}{N}\sum_{i=1}^n x_i$. Note that

$$m_1=\int_0^\infty x\,U^N(0,dx) \tag{2.27}$$

according to the mass conservation property (2.15). The index i is generated according to the distribution

$$\frac{x_i}{N\,m_1}\,, \qquad i=1,\dots,n\,. \tag{2.28}$$

The index j is generated uniformly on the set $\{k=1,\dots,n\,,\quad k\ne i\}$ avoiding the acceptance-rejection step. The random choice according to (2.24) is omitted, since the result of the interaction (2.4) does not depend on the order of the indices.

Example 2.4. Consider the case

$$\hat K(x,y)=C\,x\,y\,, \qquad x,y>0\,. \tag{2.29}$$

This kernel has the form (2.19) with $\varepsilon_1=\varepsilon_2=1$. From (2.20) one obtains the waiting time parameter

$$\varrho(p)=\frac{C\,N\,m_1^2}{2}-\frac{C}{2\,N}\sum_{i=1}^n x_i^2\,,$$

where m_1 is defined in (2.27). Note that $n=1$ implies $x_1=N\,m_1$ and $\varrho(p)=0$. The indices i,j are generated independently, according to the distribution (2.28). They are rejected if $i=j$.

2.3. Generation of a size dependent distribution. It remains to describe a procedure for generating samples of a random variable with a distribution of the form (cf. (2.21), (2.22), (2.28))

$$\frac{x_j^\varepsilon}{\sum_{l=1}^n x_l^\varepsilon}\,, \qquad j=1,\dots,n\,, \qquad \varepsilon>0\,. \tag{2.30}$$

A direct application of the inverse transform method (cf., e.g., [9, section 3.2.4]) is rather time consuming when n is large. The same applies to the straightforward version of the acceptance-rejection technique, since the particle sizes $x_1, \ldots, x_n$ vary significantly.

In order to generate the distribution (2.30) efficiently, we introduce a group structure of the particle system. The particles are organized in γ groups, i.e., their sizes are denoted by

$$y_{j,k}\,, \qquad j = 1, \ldots, \gamma\,, \quad k = 1, \ldots, \alpha_j\,,$$

so that

$$b_{j-1} < y_{j,k} \le b_j \qquad \forall j = 1, \ldots, \gamma\,, \quad k = 1, \ldots, \alpha_j\,,$$

where

$$0 =: b_0 < b_1 < \cdots < b_\gamma \tag{2.31}$$

and (cf. (2.27))

$$N\, m_1 \le b_\gamma\,. \tag{2.32}$$

Note that $N\, m_1$ is the upper bound for the particle size.

The distribution (2.30) is rewritten as

$$\frac{y^\varepsilon_{j,k}}{c}\,, \qquad j = 1, \ldots, \gamma\,, \quad k = 1, \ldots, \alpha_j\,, \tag{2.33}$$

where the normalizing constant is

$$c = \sum_{l=1}^{n} x^\varepsilon_l = \sum_{j=1}^{\gamma} \sum_{k=1}^{\alpha_j} y^\varepsilon_{j,k}\,. \tag{2.34}$$

The representation (2.33), (2.34) suggests the following simulation procedure using the inverse transform method at step 1 and the acceptance-rejection technique at steps 2 and 3.

1. Choose the group index according to the probabilities

$$P_j = \frac{1}{c} \sum_{k=1}^{\alpha_j} y^\varepsilon_{j,k}\,, \qquad j = 1, \ldots, \gamma\,. \tag{2.35}$$

2. Choose the particle index $k = 1, \ldots, \alpha_j$ uniformly within the group j.
3. The particle index is accepted with probability

$$\frac{y^\varepsilon_{j,k}}{b^\varepsilon_j}\,. \tag{2.36}$$

Otherwise, go to step 2.

With

$$b_j = \beta^{j-1}\,, \qquad j = 1, 2, \ldots\,,$$

where $\beta > 1$, the acceptance probability (2.36) for groups $j \geq 2$ is bounded from below by

$$\frac{1}{\beta^{\varepsilon}}\,. \tag{2.37}$$

The necessary number of groups $\gamma = \gamma(N, \beta)$ is obtained from the estimate (cf. (2.32))

$$\beta^{\gamma-2} < N\,m_1 \leq \beta^{\gamma-1} \qquad \text{or} \qquad \gamma - 2 < \frac{\log(N\,m_1)}{\log\beta} \leq \gamma - 1\,. \tag{2.38}$$

Remark 2.5. For $\beta \searrow 1$, the number of rejections decreases according to (2.37), leading to higher efficiency. On the other hand, the number of groups γ increases according to (2.38), and generating the distribution (2.35) becomes more and more time consuming.

3. Applications to coagulation dynamics. According to (2.2), functionals of the solution of (1.1) are approximated as

$$\int_0^\infty \varphi(x)\,c(t,x)\,dx \sim \int_0^\infty \varphi(x)\,U^N(t,dx) = \frac{1}{N}\sum_{i=1}^{n(t)} \varphi(x_i(t))\,, \qquad t \geq 0, \tag{3.1}$$

where φ is some test function. Many functionals of interest are expressed via moments of the solution

$$m_\delta(t) = \int_0^\infty x^\delta\,c(t,x)\,dx\,, \qquad \delta \geq 0\,. \tag{3.2}$$

In particular, $m_0(t)$ is the total concentration of particles, $m_1(t)$ is the total mass of the system, and

$$S(t) = \frac{m_1(t)}{m_0(t)} = \frac{\int_0^\infty x\,c(t,x)\,dx}{\int_0^\infty c(t,x)\,dx}$$

is the average particle size. Moments (3.2) are approximated according to (3.1) as

$$m_\delta(t) \sim \frac{1}{N}\sum_{i=1}^{n(t)} x_i(t)^\delta\,. \tag{3.3}$$

In the following we restrict our considerations to the discrete equation (1.3) with monodispersal initial condition

$$c(0,1) = 1\,, \qquad c(0,k) = 0\,, \quad k = 2,3,\dots\,. \tag{3.4}$$

In this case some explicit solutions are available (cf., e.g., [2, section 2.2]). This is convenient for validating the algorithm. The solution represents the concentration of particles of given size and is approximated as

$$c(t,k) \sim \frac{1}{N}\,\#\{i\,:\,x_i(t) = k\}\,, \qquad k = 1,2,\dots\,, \quad t \geq 0\,. \tag{3.5}$$

According to (3.4) we start with the particle system (cf. (2.5), (2.6))

$$x_i(0) = 1\,, \qquad i = 1,\dots,N\,. \tag{3.6}$$

Confidence bands with confidence level 99.9% are constructed using R independent runs, where $R\,N = 10^7$.

3.1. Explicit solutions. The special case of constant coagulation rate and initial condition (3.4) was solved in the original paper [23]. For

$$K(i,j) = 1$$

one obtains

$$c(t,k) = \frac{4}{(2+t)^2}\left(\frac{t}{2+t}\right)^{k-1}, \qquad t \geq 0\,, \quad k = 1,2,\dots\,,$$

and

$$m_0(t) = \frac{2}{2+t}\,, \qquad m_1(t) = 1\,, \qquad m_2(t) = 1+t\,, \qquad t \geq 0\,.$$

In the special case

$$K(i,j) = i + j \tag{3.7}$$

one obtains

$$c(t,k) = e^{-t}\,\frac{k^{k-1}}{k!}\,(1-e^{-t})^{k-1}\,e^{-k(1-e^{-t})}\,, \qquad t \geq 0\,, \quad k = 1,2,\dots\,, \tag{3.8}$$

and

$$m_0(t) = e^{-t}\,, \qquad m_1(t) = 1\,, \qquad m_2(t) = e^{2t}\,, \qquad t \geq 0\,.$$

In the special case

$$K(i,j) = i\,j \tag{3.9}$$

the global solution of (1.3) is given by (cf. [16, Theorem 2.2])

$$c(t,k) = \begin{cases} \frac{k^{k-2}}{k!}\,t^{k-1}\,\exp(-kt) & \text{if } 0 \leq t \leq 1\,, \\ \\ \frac{k^{k-2}}{k!}\,\exp(-k)\,t^{-1} & \text{if } 1 < t\,. \end{cases} \tag{3.10}$$

For the total concentration one obtains

$$m_0(t) = \begin{cases} 1 - \frac{t}{2} & \text{if } 0 \leq t \leq 1\,, \\ \frac{1}{2t} & \text{if } 1 < t\,. \end{cases}$$

The total mass behaves like

$$m_1(t) = \begin{cases} 1 & \text{if } 0 \leq t \leq 1\,, \\ \frac{1}{t} & \text{if } 1 < t\,, \end{cases} \tag{3.11}$$

and the second moment takes the form

$$m_2(t) = \frac{1}{1-t}\,, \qquad 0 \leq t < 1\,.$$

Remark 3.1. Note that the function

$$\tilde{c}(t,x) = \mu\,c(\mu\,\sigma\,t,x)\,, \qquad t \geq 0\,, \quad x > 0\,, \quad \mu,\sigma \geq 0\,,$$

solves (1.1) with the kernel $\tilde{K} = \sigma\,K$ instead of K and initial condition $\tilde{c}_0 = \mu\,c_0$ instead of c_0.

3.2. Examples of coagulation kernels. The kernel K in (1.3) represents physical properties of the medium governing the coagulation process. For example, when coagulation of spherical particles is controlled by Brownian diffusion, Smoluchowski [23] derived the kernel

$$K(i,j) = (i^{\frac{1}{3}} + j^{\frac{1}{3}})\,(i^{-\frac{1}{3}} + j^{-\frac{1}{3}})\,.$$

For spherical particles in a laminar shear field the coagulation kernel takes the form

$$K(i,j) = \kappa\,(i^{\frac{1}{3}} + j^{\frac{1}{3}})^3\,.$$

This kernel has also been used in connection with coagulation processes in turbulent flows (cf. [20]). In this case the constant κ depends on physical quantities like the mean rate of dissipation of kinetic energy and kinematic viscosity. More examples of practically relevant coagulation kernels can be found in [6, section 4.3].

In our numerical investigations we use three coagulation kernels. One arises in applications; the other two are model kernels, for which some analytical results are available. This allows us to validate the numerical method and to study some special phenomena.

The first kernel is

$$K_1(i,j) = \frac{1}{4}\,(i^{\frac{1}{3}} + j^{\frac{1}{3}})^3\,. \tag{3.12}$$

Note that

$$K_1(u\,i, u\,j) = u\,K_1(i,j) \qquad \forall u > 0\,. \tag{3.13}$$

According to

$$\frac{1}{4}\,(i+j) \le K_1(i,j) \le i + j\,,$$

the majorant kernel (2.25) is used (cf. (2.9)).

The second kernel is

$$K_2^{(a)}(i,j) = \frac{2\,i^a\,j^a}{(i+j)^a - i^a - j^a}\,, \qquad a \in (1,2]\,. \tag{3.14}$$

For this kernel an explicit formula for some moments is known (see, e.g., [1]), namely

$$m_a(t) = \frac{1}{1-t}\,, \qquad t \in [0,1)\,. \tag{3.15}$$

Note that

$$K_2^{(a)}(u\,i, u\,j) = u^a\,K_2^{(a)}(i,j) \qquad \forall u > 0\,. \tag{3.16}$$

According to

$$K_2^{(a)}(i,j) \le \frac{2}{2^a - 2}\,i\,j\,, \tag{3.17}$$

the majorant kernel (2.29) is used. In case $a = 2$ there is equality in (3.17).

The third kernel is

$$K_3^{(a)}(i,j) = i^a\,j^a\,, \qquad a \in (0.5, 1]\,. \tag{3.18}$$

This kernel has the form (2.19) and the (trivial) majorant kernel (2.16) will be used. Note that

$$K_3^{(a)}(u\,i, u\,j) = u^{2a}\,K_3^{(a)}(i,j) \qquad \forall u > 0\,. \tag{3.19}$$

3.3. Approximation properties. To get a first impression of how the algorithm works, we consider the linear kernel (3.7). Here one takes $\hat{K} = K$ (cf. Example 2.3) and no fictitious jumps occur. Using a particle number $N = 10^6$ we calculate the solution $c(t,k)$ and some integrated functionals of the form

$$C(t,k) = \sum_{l \geq k} c(t,l) \tag{3.20}$$

for different values of size k. The results are displayed in Figure 1, where the analytic curves (cf. (3.8)) are represented by solid lines and the confidence bands by dotted lines. The components of the solution $c(t,k)$ are sufficiently well approximated up to $k = 200$. The time instants where these functions take their maximum can be clearly detected. The fluctuations grow with increasing size, since the values of the functionals become very small. Functionals of the form (3.20) are well approximated even up to $k = 2000$.

Next we compare the solution for the kernel (3.12) with the solution for the linear kernel (3.7). Since at time zero both kernels are identical in case of initial configuration (3.6), it is of interest to study the deviation of both solutions during the time evolution. The confidence bands for the solution corresponding to the kernel (3.12) are shown in Figure 2 and compared with the exact solutions for the kernel (3.7) (solid lines).

Finally we illustrate the convergence with respect to the initial particle number N for the kernel (3.14) with $a = 1.5$. We calculate the behavior of the moment $m_{1.5}(t)$ on the time interval $[0,1]$ via (3.3) and compare the results with the explicit expression (3.15). The results are displayed in Figure 3. For $N = 10^4$ the exact solution (solid line) is almost indistinguishable from the confidence band up to the time $t = 0.8$. For larger N the exact solution leaves the confidence band at later times.

3.4. Gelation phenomena. In the case of the multiplicative kernel (3.9) the total mass is not conserved (cf. (3.11)). This effect is interpreted as formation of infinite clusters and is called gelation (cf. [2], [15]). Our test kernels (3.12), (3.14), and (3.18) are homogeneous (cf. (3.13), (3.16), (3.19)) with exponents 1, a, and $2a$, respectively. Homogeneous kernels with exponents greater than 1 are expected to be gelling (see [2, section 2.3]).

In the finite particle system (1.4) the total mass is always conserved (cf. (2.15)). An appropriate indicator for gelation is the behavior of the largest component $M_1(t)$ in the system. For the multiplicative kernel (3.9), the particle with the largest size is of order N after the gelation time

$$t_g = \inf \{t > 0 \,:\, m_1(t) < m_1(0)\}$$

and of lower order before t_g (see [2, section 4.4]). The quantity $\frac{M_1(t)}{N}$ is convenient for studying general gelling kernels (see [2, section 5.2]) using the stochastic algorithm. Note that $\frac{M_1(t)}{N} \in [0,1]$ and $M_1(t) \leq M_1(t')\,,\ t \leq t'$.

As an example we consider the kernel (3.18) with $a = 0.7, 0.8, 0.9, 1.0$. The curves for the quantity $\frac{M_1(t)}{N}$ with $N = 10^4, 10^5, 10^6$ are shown by dotted, dashed, and solid lines, respectively, in Figure 4. The behavior of the second-largest component divided by N for $N = 10^4$ (dotted), $N = 10^5$ (dashed), and $N = 10^6$ (solid) is shown in Figure 5. For comparison the curves for both components and $N = 10^6$ are displayed together on the same scale in Figure 6, where, in addition, the dashed lines represent

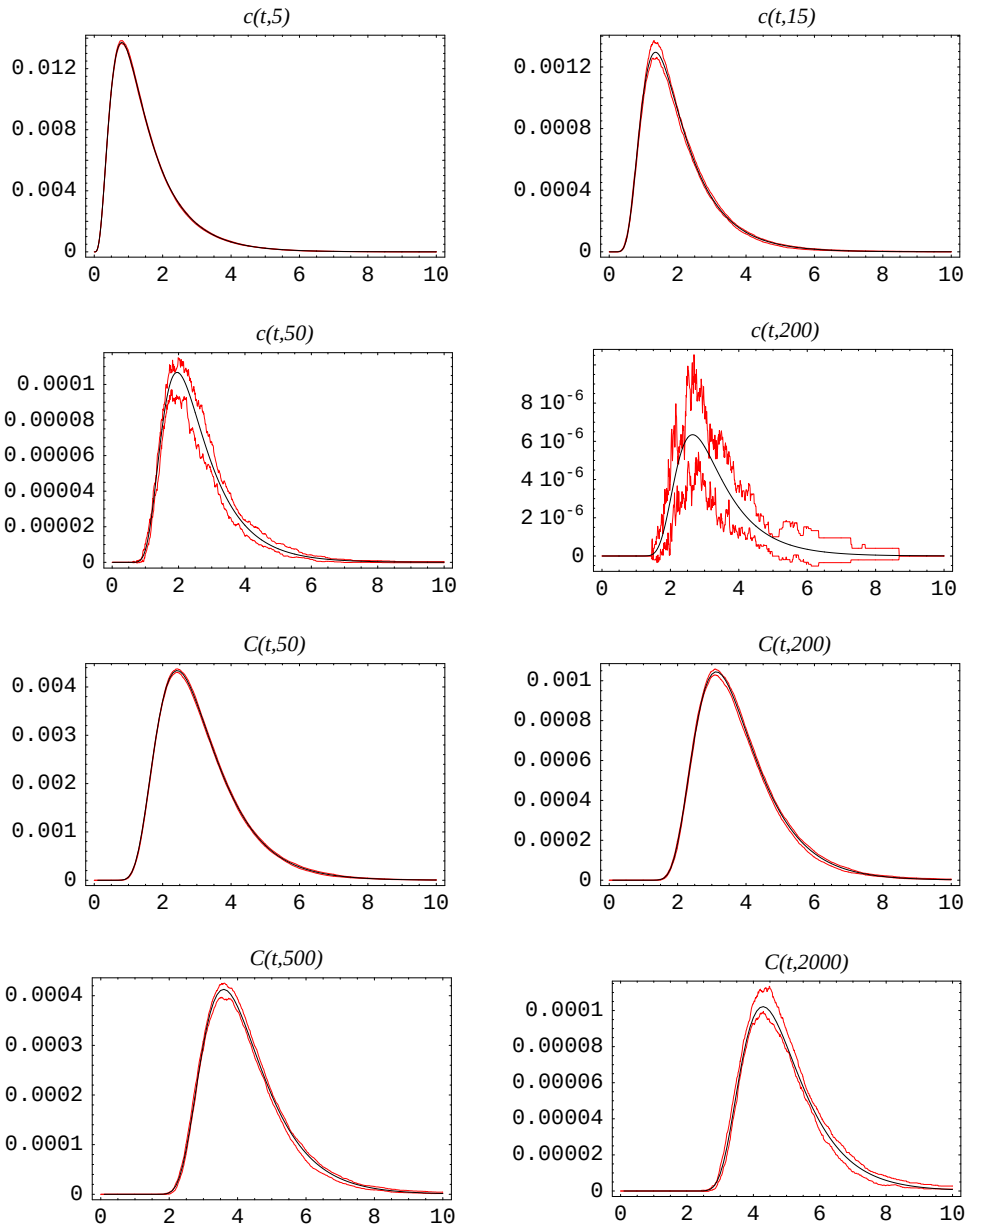

FIG. 1. *Concentration functionals* $c(t,k)$ *and* $C(t,k)$ *for the linear kernel* (3.7).

the total concentration $m_0(t)$. Analogous results for the kernel (3.14) with $a = 1.5$ are shown in Figures 7 and 8.

Next we consider the multiplicative kernel (3.9) and the equation (cf. [22])

$$\frac{\partial}{\partial t}\,\hat{c}(t,k) = \frac{1}{2}\sum_{j=1}^{k-1} j\,(k-j)\,\hat{c}(t,j)\,\hat{c}(t,k-j) \;-\; k\,\hat{c}(t,k)\,. \tag{3.21}$$

According to (3.11), equation (1.3) coincides with (3.21) up to the gelation point

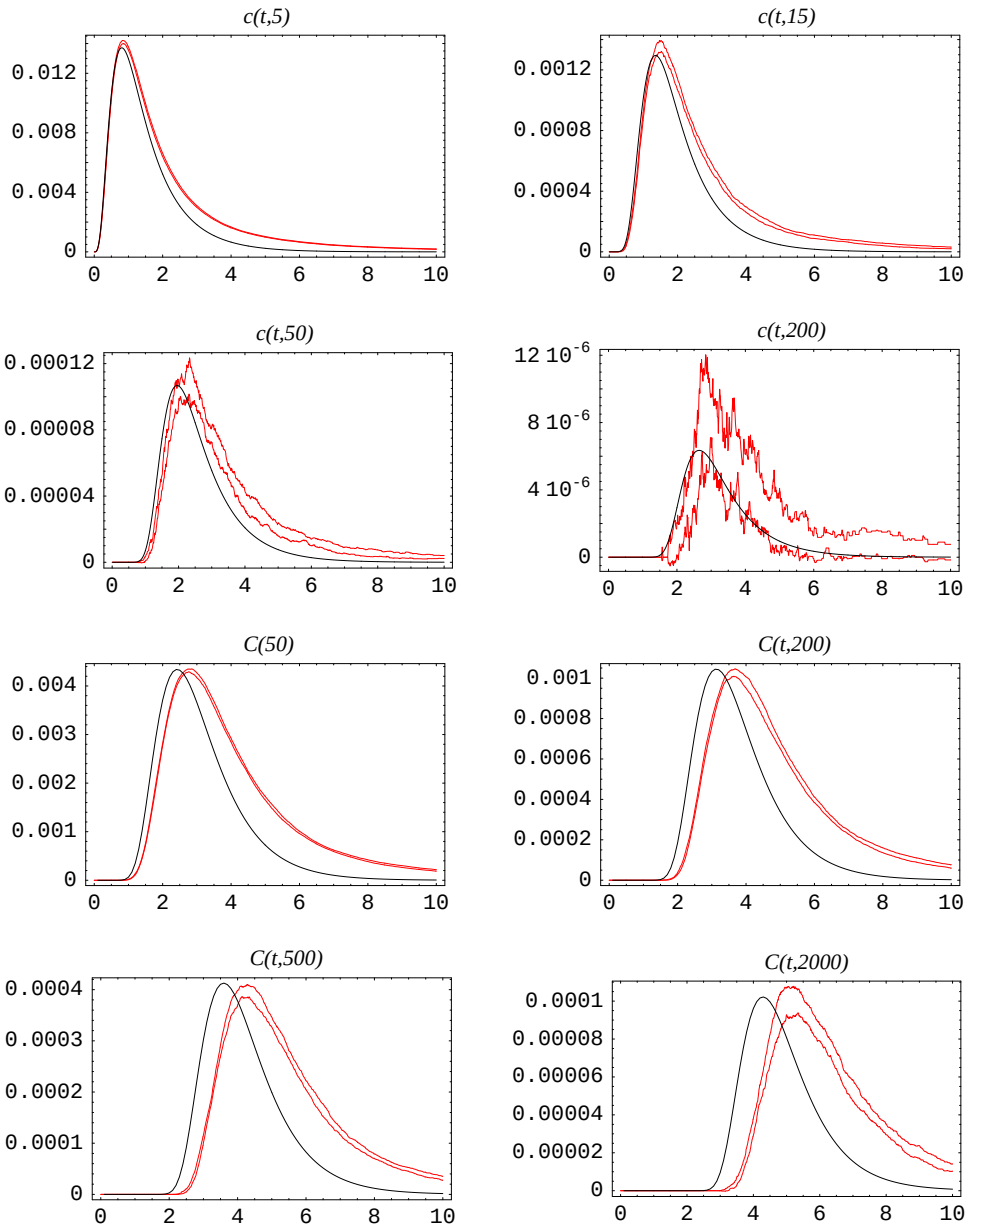

FIG. 2. *Concentration functionals* $c(t,k)$ *and* $C(t,k)$ *for the kernel* (3.12).

$t_g = 1$. The unique solution of (3.21) is (compare with (3.10))

$$\hat{c}(t,k) = \frac{k^{k-2}}{k!}\, t^{k-1}\, \exp(-kt)\,, \qquad t \geq 0\,. \tag{3.22}$$

The total mass has the form (compare with (3.11))

$$\widehat{m}_1(t) = \begin{cases} 1 & \text{if } 0 \leq t \leq 1\,, \\ \frac{t^*}{t} & \text{if } 1 < t\,, \end{cases} \tag{3.23}$$

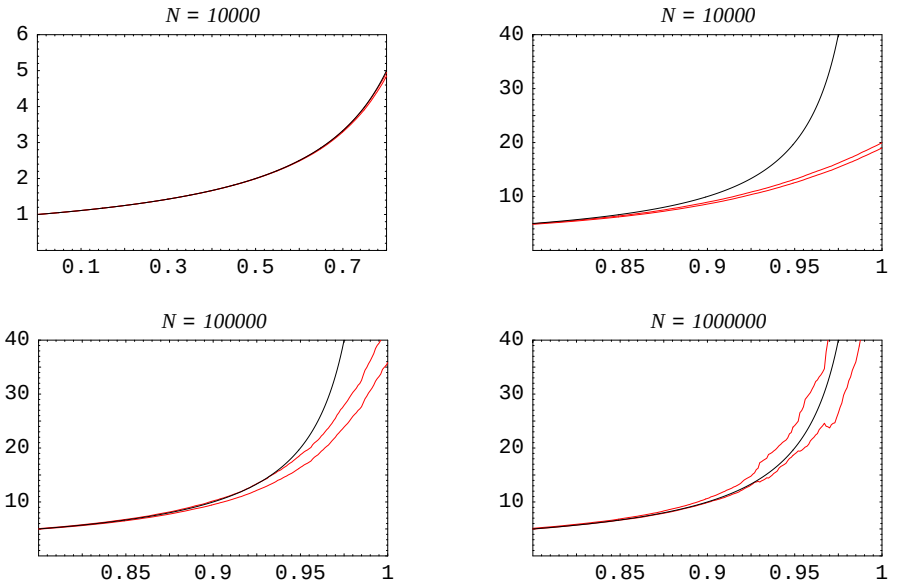

FIG. 3. *Moment* (3.15) *for the kernel* (3.14) *with* $a = 1.5$.

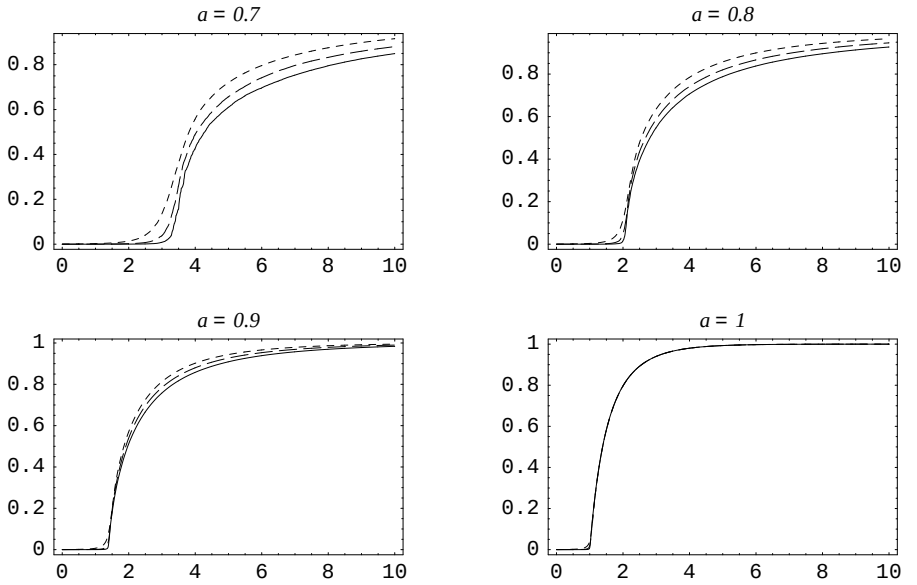

FIG. 4. *Largest component* $\frac{M_1(t)}{N}$ *for the kernel* (3.18) *and different* N.

where $t^* = t^*(t)$ is determined by the equation

$$t^* \exp(-t^*) = t \exp(-t)\,, \qquad t^* \in (0,1)\,, \quad t > 1\,.$$

The solution (3.22) describes the limiting behavior (cf. [4, Corollary 1]) of the stochastic particle system beyond the gelation point. The results of the stochastic algorithm for different concentration functionals are shown in Figure 9. In these

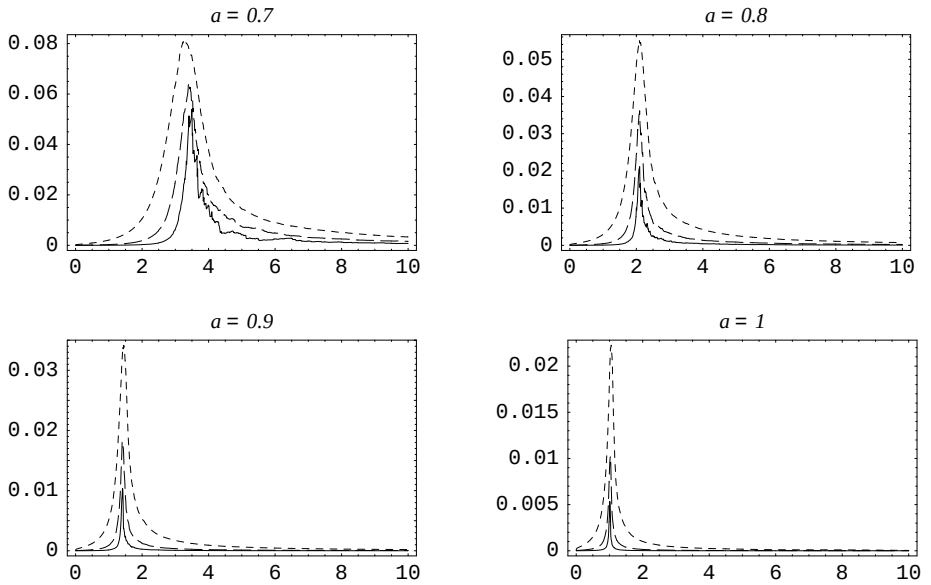

FIG. 5. *Second largest component* $\frac{M_2(t)}{N}$ *for the kernel* (3.18) *and different* N.

calculations the initial number of particles is $N = 10^6$. The exact curves for (3.21) are shown by solid lines, the confidence bands by dotted lines, and the curves for the Smoluchowski equation (1.3) by dashed lines. The loss of total mass (cf. (3.23)) is approximated by the largest component of the particle system (see Figure 10)

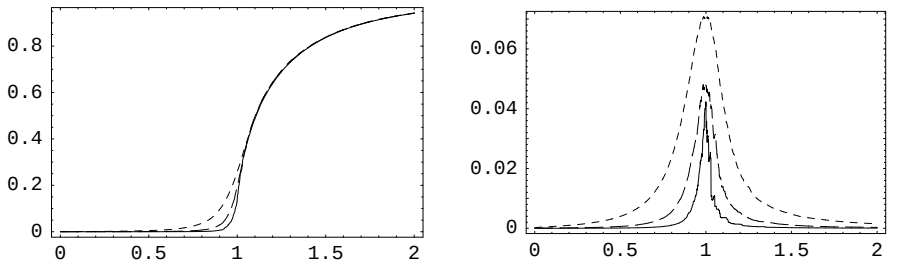

FIG. 7. *Largest and second largest components for the kernel* (3.14) *with* $a = 1.5$.

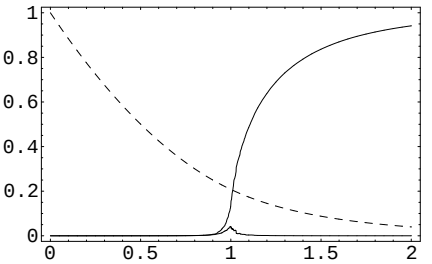

FIG. 8. *Two largest components and* $m_0(t)$ *for the kernel* (3.14) *with* $a = 1.5$.

illustrating the property

$$1 - \widehat{m}_1(t) = \lim_{N\to\infty} \frac{M_1(t)}{N}\,. \tag{3.24}$$

The confidence band is almost indistinguishable from the solid line.

3.5. Efficiency. The decisive criterion for efficiency is the necessary computation time for reaching a sufficiently low error. Two basic indicators influencing the computational effort are the number of fictitious jumps and the number of rejections. The number of fictitious jumps is determined by the majorant kernel (cf. (2.14)) indicating its "quality." The number of rejections is determined by the choice of the group bounds (2.31) (cf. (2.36)). We consider the kernel (3.12) and compare the efficiency of the algorithms with two different majorant kernels. The initial number of particles is $N = 10^6$. The dashed lines correspond to the linear majorant kernel (2.25) and the solid lines to the maximum majorant kernel (2.17).

The absolute numbers of jump attempts and the relative numbers of fictitious jumps are shown in Figure 11. The number of jump attempts equals the number of time steps (cf. (2.18), (2.26)). The relative number of fictitious jumps is about 13% in one case and 97% in the other case at time $t = 4$. Note that the number of real jumps does not depend on the choice of the majorant kernel and can be determined from the total concentration via $N\,(1 - m_0(t))$.

In the algorithm with the maximum majorant kernel no rejections occur. The relative number of rejections for the linear majorant kernel are shown in Figure 12. The proportion of rejections for this algorithm is about 35% (the basis $\beta = 2$ was used). The upper bound (2.37) for the relative number of the rejections takes the form $1 - \frac{1}{\beta}$ (cf. (2.28), (2.30)).

A comparison of the CPU time (in seconds) for both algorithms is given in Fig-

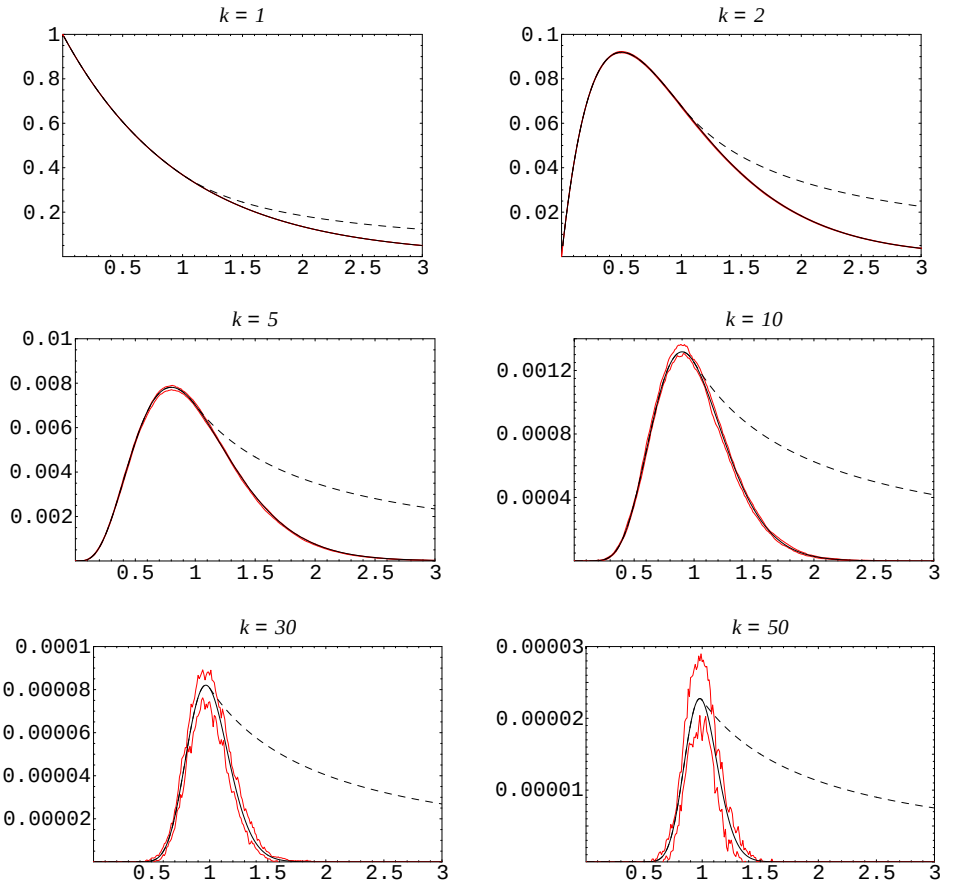

FIG. 9. *Solutions* (3.10) *(dashed) and* (3.22) *(solid) for the multiplicative kernel* (3.9).

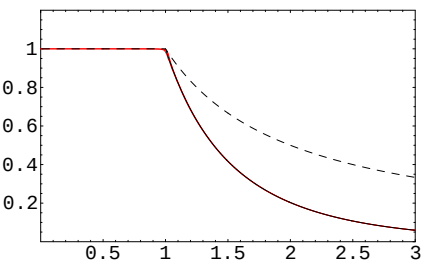

FIG. 10. *Functionals* (3.11) *(dashed) and* (3.23) *(solid) for the multiplicative kernel* (3.9).

ure 13. There is a significant gain factor depending on the length of the time interval. Note that for gelling kernels calculations with the maximum majorant kernel (2.17) become very time consuming when approaching the gelation point.

4. Concluding remarks. A class of stochastic algorithms for the numerical treatment of coagulation processes was introduced. By an appropriate choice of the majorant kernel, a remarkable gain in efficiency has been achieved. This effect is based mainly on a significant reduction of the number of fictitious jumps for systems

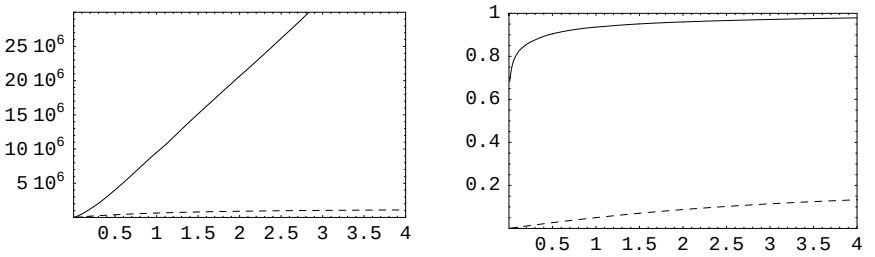

FIG. 11. *Number of time steps (left) and relative number of fictitious jumps (right).*

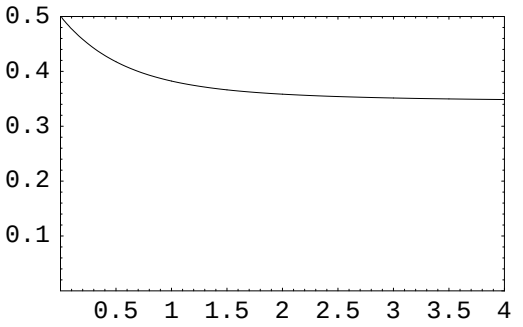

FIG. 12. *Rejections.*

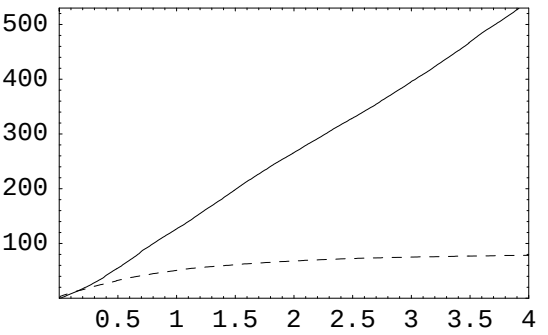

FIG. 13. *CPU time.*

with unbounded kernels and strongly varying cluster sizes.

The algorithm works both in the discrete and the continuous case. Generalizations to equations with fragmentation [7] and source terms are straightforward. Further improvements are possible. In particular, the rejections in the case $i = j$ (cf. (2.21), (2.22)) can be avoided, which is of some relevance in situations where large particles occur. In the discrete case it is more efficient to use the particle number representation (cf. (3.5)) instead of the particle representation (1.4) for particles with lower sizes.

The algorithm in its present form is not suitable for calculations on very long time intervals, since the number of simulation particles is strictly decreasing. There are some interesting ideas in the literature on how to handle this problem. The number

of particles in the system may be doubled, when necessary, by dividing each particle into two equal parts, or, more generally, particles with variable weights may be used (see [21]). An algorithm based on the mass flow instead of the particle number flow was proposed in [3]. Here the number of simulation particles is preserved. These ideas can be implemented in the framework of the new class of algorithms and will be studied in the near future.

The main practical effect of the improved efficiency of our algorithm is that it can be used as a tool for calculations up to and even beyond the gelation point. This seems to be very useful for getting some heuristical insight into the gelation phenomenon for general gelling kernels.

Rigorous convergence results for general coagulation kernels are known up to the gelation point [19]. Convergence to the solution of the Smoluchowski equation after the gelation point is expected [15] for kernels $K(i,j) = o(i)\,o(j)$. However, the case of multiplicative kernel (3.9) shows that the limiting behavior of the stochastic particle system after the gelation point is described by an equation (cf. (3.21)) different from the Smoluchowski equation (1.3). Numerical observations illustrate the known results and confirm the hypothesis of convergence after the gelation point to some deterministic limit.

The numerical studies of the behavior of the largest component in the particle system suggest that several properties, known for the multiplicative kernel (3.9), might be true for larger classes of gelling kernels. There are numerical indications that the quantity $\frac{M_1(t)}{N}$ converges to a deterministic limit. This limit can be used to determine the time of emergence of a cluster of order N as

$$t_g^s = \inf\left\{ t > 0 \,:\, \lim_{N\to\infty} \frac{M_1(t)}{N} > 0 \right\}.$$

It is of interest to find out for which kernels $t_g^s = t_g$ holds. For the multiplicative kernel, this property is illustrated in Figure 4 ($a = 1$). For the kernel (3.14), Figure 7 provides numerical evidence for $t_g = t_g^s = 1$ (cf. [1]). The question for which kernels the limit of the normalized largest component determines (as in (3.24)) the loss of total mass of the corresponding solution is a related open problem.

Acknowledgments. The authors appreciate useful discussions with H. Babovsky, F. Guiaş, and K. Sabelfeld on numerical issues related to the coagulation equation.

AN IMPROVED LAGUERRE EIGENSOLVER FOR UNSYMMETRIC MATRICES*

JORGEN L. NIKOLAJSEN†

Abstract. A Laguerre iteration procedure is described for finding the eigenvalues of unsymmetric matrices with improved efficiency. Compared to the QR method, the processing time for dense matrices is reduced by roughly a factor of 1.6 and for sparse matrices by a factor of up to 2.8 without sacrificing accuracy. This is achieved primarily by means of a new procedure for reducing the original matrix to sparse Hessenberg form. Alternatively, the Laguerre procedure will typically provide one additional significant digit, compared to the QR method, when allowed to run for as long as the QR method.

Key words. unsymmetric matrix, eigenvalues, Laguerre's method, matrix reduction

1. Introduction.

Many science and engineering problems lead to the standard eigenvalue problem, [A] $\{x\} = z\{x\}$, where [A] is an unsymmetric matrix. The eigenvalues z are typically calculated by means of the QR method of Francis [1]. This remains one of the most efficient and robust methods available despite efforts by many researchers to find more efficient alternatives.

The current effort to improve the efficiency of eigencalculations focuses mainly on reducing the original dense, unsymmetric matrix [A] beyond Hessenberg form to a sparser form, which permits more efficient eigenvalue extraction without loss of accuracy. Dax and Kaniel [2] largely initiated this direction of work with an improvement in the stability of the reduction to tridiagonal form, which is amenable to very rapid eigencalculation, for example, by LR iteration. This work was resumed by Geist [3], who further improved the stability of tridiagonalization and was able to calculate the eigenvalues by LR iteration more that three times faster than with the QR method. However, Geist observed an unacceptable deterioration in accuracy with matrix size. In a subsequent paper, Dongarra, Geist, and Romine [4] used this procedure to obtain approximate eigenpairs which were subsequently refined iteratively to surpass the QR method in accuracy. However, only 20% of the eigenpairs could be calculated during the time it took for the QR method to calculate them all. Howell [5] pointed out that the stability of Geist's tridiagonalization procedure could be further improved by omitting the least stable similarity transformations. This led to a band matrix with increasing bandwidth whose eigenvalues could still be calculated by LR iteration but with reduced efficiency. Further testing appears to be needed to determine the efficiency of this approach.

This paper seeks to alleviate the instability problems associated with full matrix tridiagonalization by terminating the elimination process when no further stable similarity transformations can be found. This can be arranged to produce a sparse Hessenberg matrix whose eigenvalues can be calculated by Laguerre iteration. The procedure was found to be typically 1.6 times faster than the QR method without

(a) Stage 1 reduction (b) Stage 2 reduction

FIG. 1. *Matrix reduction to sparse Hessenberg form.*

sacrificing accuracy. Alternatively, one additional significant digit can typically be achieved, compared to the QR method, within the QR processing time. The procedure is outlined below.

2. Matrix reduction to sparse Hessenberg form. The eigensolver described here uses the familiar steps of matrix balancing, matrix reduction, and eigeniteration. The standard balancing procedure of Parlett and Reinsch [6] is used. The subsequent matrix reduction procedure transforms a dense unsymmetric matrix to upper Hessenberg form with a sparse upper triangle. The efficiency of the subsequent Laguerre iteration increases with the sparseness of the upper triangle but is unaffected by the location of the nonzero elements. The matrix reduction procedure is therefore designed to minimize the number of nonzero elements without any concern for their location. The reduction is performed in two stages, both by elementary similarity transformations.

2.1. Stage 1 reduction. The standard procedure for reduction to Hessenberg form (see Martin and Wilkinson [7]) is extended to include alternate row eliminations to the right of the superdiagonal, as first suggested by Geist [3]. The row eliminations continue for as long as sufficient stability can be ensured, as defined by the parameter c introduced below. Figure 1(a) shows a matrix with column 1, row 1, and column 2 reduced in that order. The next step, reduction of row 2, will be described in detail.

All the *column* reductions (toward upper Hessenberg form) use standard partial pivoting with all multipliers less than unity to ensure stability. This is also the case for the row reductions except that the superdiagonal element (a_{23} in row 2) cannot participate unless it is already the pivot (largest) element. This is because the associated row and column interchanges would destroy zeros in the lower triangle. However, standard partial pivoting can be used to eliminate all the row elements to the right of a_{24}, after which a choice can be made as to whether it is acceptable to eliminate a_{24} with a_{23} as a pivot.

Thus, the reduction of row 2 in Figure 1(a) proceeds as follows:

1. Identify the largest (pivot) element a_p from among $|a_{23}|$, $|a_{24}|$, $|a_{25}|$, and $|a_{26}|$.
2. If $a_p = |a_{23}|$, then a_{24}, a_{25}, and a_{26} are eliminated by stable similarity transformations and the process moves on to column 3, then to row 3, etc.
3. If $a_p \neq |a_{23}|$, then a_p is moved to position a_{24} by appropriate row and column interchanges and a_{25} and a_{26} are eliminated with a_p as pivot. These eliminations are stable and do not destroy previous zeros.

4. If $a_p \leq |a_{23}| \cdot 2^c$ (where c is a user supplied parameter), then $a_p = (\text{new } a_{24})$ is eliminated using a_{23} as the pivot and the process moves on to column 3. Thus, the user decides, through the choice of c, whether $|a_{23}|$ is large enough to eliminate a_p with the required accuracy. $c = 0$ provides the stability of standard partial pivoting but $c \geq 1$ usually provides satisfactory accuracy for all eigenvalues within the current overall strategy, as demonstrated in section 6.
5. If $a_p > |a_{23}| \cdot 2^c$, then the elimination of $a_p = (\text{new } a_{24})$ is deemed too unstable and is omitted. This single failure prevents any further zeroing of elements in the upper triangle during Stage 1 reduction, since previous zeros would be destroyed. In this case, standard Hessenberg reduction takes over until the Hessenberg matrix of Figure 1(b) has emerged.

2.2. Stage 2 reduction. In Figure 1(b), Stage 1 reduction, including alternate row reductions, has been completed with one successful row elimination. (As seen later, a much larger number of rows can normally be eliminated during Stage 1.)

The row eliminations are now resumed, without pivoting which would destroy the zero lower triangle as follows:

1. Find the largest (pivot) element p_1 from among $|h_{23}|$, $|h_{24}|$, $|h_{25}|$, and $|h_{26}|$ and use it to eliminate all the elements to the right of p_1. These eliminations are stable.
2. Find the largest element p_2 to the left of p_1 (and to the right of h_{22}) and use it to eliminate all the elements between p_1 and p_2. These eliminations are stable.
3. If $p_1 \leq p_2 \cdot 2^c$ (where c is a user-supplied parameter), then p_1 is eliminated with p_2 as the pivot. As in Stage 1 reduction, $c = 0$ provides the stability of standard partial pivoting but satisfactory accuracy of all eigenvalues is usually obtained in practice with $c \geq 1$.
4. If $p_1 > p_2 \cdot 2^c$, then the elimination of p_1 is deemed too unstable and is omitted. When this happens, no element from p_1's column can ever again be used as a pivot since this would destroy previous zeros.
5. Go back to step 2 until elimination of all the elements to the right of h_{23} has been attempted.
6. Proceed with the following row until elimination of all elements above the superdiagonal has been attempted.

3. Laguerre iteration. Laguerre's method is well known as one of the most efficient procedures for finding the roots of polynomials. Convergence is virtually global and the rate of convergence is cubic in the vicinity of simple roots. Parlett [8] appears to have been the first to apply Laguerre iteration to unsymmetric eigenproblems. Parlett provides a comprehensive discussion of Laguerre iteration applied to eigensolution with dense Hessenberg matrices. Thus, only a summary will be given here. Parlett's procedure was applied by Ward [9] who found it comparable to the QR method in efficiency on parallel computers. However, tests by Foster [10] indicated that Laguerre's method was only half as efficient as the QR method.

Finding the eigenvalues z of a Hessenberg matrix [H] is equivalent to finding the roots of its characteristic polynomial $p(z) = \det([\mathrm{H}] - z[\mathrm{I}])$. Laguerre iteration toward a root z proceeds as follows:

$$z_{i+1} = z_i - \Delta z_i, \tag{3.1}$$

where

$$\Delta z_i = n \Big/ \left[f_i \pm \sqrt{(n-1)(nh_i - f_i^2)} \right], f_i = p_i'/p_i, \text{ and } h_i = f_i^2 - p_i''/p_i. \tag{3.2}$$

p_i' and p_i'' are the polynomial derivatives and n is the order of [H].

Roots z_j, already found, are suppressed by setting

$$p = p \Big/ \sum_j (z - z_j), \tag{3.3}$$

which turns out to be equivalent to setting

$$f = f - \sum_j 1/(z - z_j) \text{ and } h = h - \sum_j 1/(z - z_j)^2. \tag{3.4}$$

Iteration toward complex eigenvalues requires slight modifications (see Parlett [8]), but (3.1)–(3.4) are sufficient for later illustration of the implementation.

4. Hyman's method. The determinant value p and its derivatives p' and p'' in (3.2) are calculated by Hyman's method; see Wilkinson [11]. For maximum efficiency, an additional similarity transformation is performed on the Hessenberg matrix to obtain unit subdiagonal elements as shown in (4.1); see [11]. As outlined earlier, the upper triangle of [H] will usually be sparse.

$$[\mathrm{H}] = \begin{bmatrix} h_{11} & h_{12} & h_{13} & h_{14} & h_{15} & h_{16} \\ 1 & h_{22} & h_{23} & h_{24} & h_{25} & h_{26} \\ 0 & 1 & h_{33} & h_{34} & h_{35} & h_{36} \\ 0 & 0 & 1 & h_{44} & h_{45} & h_{46} \\ 0 & 0 & 0 & 1 & h_{55} & h_{56} \\ 0 & 0 & 0 & 0 & 1 & h_{66} \end{bmatrix}. \tag{4.1}$$

Hyman's method leads to the following recursive formulas for p, p', and p'' for use in (3.2):

$$\begin{cases} p_5 = (z - h_{66}), \\ p_4 = (z - h_{55})p_5 - h_{56}, \\ p_3 = (z - h_{44})p_4 - h_{45}p_5 - h_{46}, \\ p_2 = (z - h_{33})p_3 - h_{34}p_4 - h_{35}p_5 - h_{36}, \\ p_1 = (z - h_{22})p_2 - h_{23}p_3 - h_{24}p_4 - h_{25}p_5 - h_{26}, \\ -p = (z - h_{11})p_1 - h_{12}p_2 - h_{13}p_3 - h_{14}p_4 - h_{15}p_5 - h_{16}, \end{cases} \tag{4.2}$$

$$\begin{cases} p_4' = (z - h_{55}) + p_5, \\ p_3' = (z - h_{44})p_4' - h_{45} + p_4, \\ p_2' = (z - h_{33})p_3' - h_{34}p_4' - h_{35} + p_3, \\ p_1' = (z - h_{22})p_2' - h_{23}p_3' - h_{24}p_4' - h_{25} + p_2, \\ -p' = (z - h_{11})p_1' - h_{12}p_2' - h_{13}p_3' - h_{14}p_4' - h_{15} + p_1, \end{cases} \tag{4.3}$$

$$
(4.4)\qquad \begin{cases} p_3'' = 2(z - h_{44}) + 2p_4', \\ p_2'' = (z - h_{33})p_3'' - 2h_{34} + 2p_3', \\ p_1'' = (z - h_{22})p_2'' - h_{23}p_3'' - 2h_{24} + 2p_2', \\ -p'' = (z - h_{11})p_1'' - h_{12}p_2'' - h_{13}p_3'' - 2h_{14} + 2p_1'. \end{cases}
$$

Equations (4.2) through (4.4) are easily generalized. p, p', and p'' are usually complex. They must be calculated at each Laguerre iteration step for each eigenvalue. Apart from the matrix reduction, this is the most time-consuming part of the eigencalculations. Zeroing of a large number of elements h in the upper triangle of [H], as discussed earlier, becomes essential to reduce the work load below that of the QR method. The numerical implementation must check for and skip all multiplications and additions involving zero elements.

5. Numerical implementation. An excellent outline of the numerical implementation of Laguerre iteration for nonsymmetric eigenproblems can be found in Parlett [8]. The current implementation is based on Parlett's work and focuses on improvements that maximize efficiency. The main improvement is the matrix reduction to sparse Hessenberg form, as outlined earlier. This section highlights additional improvements, mainly in the choice of start values and stop criteria, to minimize the number of iterations.

The current implementation rejects eigenproblems which are so ill-conditioned that one or more eigenvalues can only be determined to one significant digit. This simplifies the procedure considerably and is justified by arguing that eigenvalues with one significant digit are probably inadequate in most applications. The specific parameter values recommended in the following are for double-precision implementation (15–16 significant digits). These parameter values are based on extensive experimentation and test experience.

5.1. First start value. The choice of the start value z_0 for the first eigenvalue is problematic because of the assumed total lack of knowledge of the locations of all eigenvalues. Parlett [8] recommended using "the Laguerre iterate of infinity" which is larger than the modulus of the largest eigenvalue. This rarely fails to work. The drawback is that a relatively large number of iterations may be required to reach the nearest eigenvalue.

In the current implementation, a first start value z_0 near zero is used instead. This is, on average, much closer to an eigenvalue and therefore provides faster convergence. In addition, the search for an acceptable z_0 near zero can be arranged to automatically identify all roots near zero, which greatly simplifies the stop criteria outlined later. Thus z_0 is found as follows:

1. Set $z_0 = 0$.
2. Do one complex Laguerre iteration, in accordance with (3.1) and (3.2), and check on the size of $|\Delta z_i|$.
3. If $|\Delta z_i| > 8^*$matrix-norm, including processor-defined "infinity" and "NAN" (not a number), and p has underflow, then z_0 is so close to a root that the Laguerre iteration has broken down. Set the flag to indicate near-zero root, set $z_0 = z_0 + 2^{-7}$ to get away from the root, and go back to 2.
4. If $|\Delta z_i| > 8^*$matrix-norm, including "infinity" and "NAN," but p does not underflow, then z_0 is a local extremum point causing the iterate to shoot toward infinity. Remove the extremum temporarily by declaring a dummy

root at z_0 (to be removed when the next true root has been found). Set $z_0 = z_0 + 2^{-7}$ to get away from the dummy root, and go back to 2.

5. If $|\Delta z_i| < 2^{-7}$, then z_0 is probably close to a root. Set the flag to indicate near-zero root, set $z_0 = z_0 + 2^{-7}$ to get away from the root, and go back to 2.
6. If $2^{-7} < |\Delta z_i| < 8^*$matrix-norm and the flag indicates near-zero root (set during the previous iteration), then shift the eigenproblem by z_0 (i.e., subtract z_0 from all the diagonal elements), enter the mainstream iteration (as defined by (3.1)–(3.4)), and find the (shifted) root using $-z_0$ as the start value. Shift the eigenproblem (including the root) back again, record and suppress the root (see (3.4)), clear the flag for near-zero root, set $z_0 = z_0 + 2^{-7}$, and go back to 2 to look for additional near-zero roots. (Shifting the root away from zero allows it to be determined using the stop criteria outlined below.)
7. If $2^{-7} < |\Delta z_i| < 8^*$matrix-norm and near-zero root is not flagged, then no undiscovered near-zero roots exist. Proceed with mainstream iteration, as defined by (3.1)–(3.4).

5.2. Subsequent start values. Parlett [8] suggested that the penultimate Laguerre iterate z_{qi} toward the root z_q could be used to provide a "free" Newton iteration step toward the next root z_τ as follows:

$$z_{\tau 1} = z_q - 1/s, \tag{5.1}$$

where

$$s = \frac{p''(z_{qi})}{2p'(z_{qi})} - \sum_j \frac{1}{z_{qi} - z_j}, \tag{5.2}$$

where z_j are all the roots found previously, excluding z_q.

Parlett's start value $z_{\tau 1}$ is adopted here, except that, when z_q is complex, its complex conjugate, z_q^*, is included among the z_j's in (5.2). This removes the attraction of z_q^*, resulting in a better approximation of $z_{\tau 1}$ to the next root z_τ.

The use of $z_{\tau 1}$ speeds up convergence considerably, but it can fail because Newton iteration lacks global convergence and because there is no guaranteeing that it will bring $z_{\tau 1}$ outside the area of indeterminacy of z_q, in which case the iteration may converge toward z_q again. A safe alternative start value $z_{\tau 0}$ is therefore needed. It is chosen as the last iterate toward z_q which has less than seven significant binary digits (∼2 decimal digits). This is the smallest number of digits accepted for any root without aborting the eigencalculations. It thus insures that z_0 is outside the area of indeterminacy of all roots. A check is made to determine whether (1) $z_{\tau 1}$ is within the area of indeterminacy of z_q, (2) $|z_{\tau 1}| > 8 \cdot$matrix-norm, or (3) $|z_{\tau 1}| > 8 \cdot z_q$. In either case, $z_{\tau 1}$ is rejected as the start value and $z_{\tau 0}$ is used instead.

5.3. Stop criteria. The following stop criteria were devised to ensure that the iteration stops immediately when all available significant digits have been determined:

1. If $|z_i/\Delta z_i| > 2^{52}$ (see (3.1)), then z_{i+1} has at least 52 significant binary digits (∼15 decimal digits) and is declared a root. This stop criterion normally handles convergence after one or two iterations.
2. If $|z_{i+1}/\Delta z_{i+1}| \le |z_i/\Delta z_i|$ (i.e., number of significant digits of $z_{i+1} \le$ number of significant digits of z_i), then z_{i+1} has reached the area of indeterminacy, thus, no further significant digits can be extracted and a root is declared. This is because once convergence has started, the convergence rate does not slow down until the area of indeterminacy has been reached. This check primarily finds ill-conditioned roots that have relatively few significant digits.

3. If $(z_{i+1}/\Delta z_{i+1})^2/|z_i/\Delta z_i| > 2^{52}$, then z_{i+2} will be a root. Example: If $|z_i/\Delta z_i| \cong 2^7$ and $|z_{i+1}/\Delta z_{i+1}| \cong 2^{20}$, then the current convergence rate is roughly $20/7 \cong 2.9$ (i.e., almost cubic). The next iterate, z_{i+2}, will therefore either achieve at least $(20/7) \cdot 20 \cong 57$ significant binary digits (more than double-precision accuracy) or it will reach the area of indeterminacy. Thus z_{i+2} will be a root. This check primarily finds well-conditioned roots, which have many significant digits, at both fast and slow convergence rates.
4. Finally, if a root has not been found within 32 iterations, then the current iterate is accepted as a root and a warning code is set.

Convergence must have started before stop criterion step 2 can be applied safely. Convergence is deemed to have started if both of the following criteria are satisfied:

1. $z_i/\Delta z_i \geq 2^3$, $z_{i+1}/\Delta z_{i+1} \geq 2^4$, and $z_{i+2}/\Delta z_{i+2} \geq 2^5$. In other words, the number of significant binary digits of three consecutive iterates must be at least 3, 4, and 5.
2. $(z_{i+1}/\Delta z_{i+1})/(z_i/\Delta z_i) \geq 2^1$ and $(z_{i+2}/\Delta z_{i+2})/(z_{i+1}/\Delta z_{i+1}) \geq 2^1$. This is equivalent to saying that at least one additional significant binary digit must have been found in each of the two last consecutive iterations.

The stop criteria have been condensed into the current form by extensive experimentation and testing. Their simplicity and robustness have been achieved partly by making them applicable to nonzero roots only. Near-zero roots are extracted and suppressed beforehand, as outlined earlier.

When a root $z = x + iy$ has been found, its complex conjugate z^* is declared and suppressed simultaneously provided z is definitely complex. Complexity of z is considered confirmed if $|y/x| > 2^{-7}$ in which case y is outside the area of indeterminacy of x for the most ill-conditioned root accepted without aborting the eigencalculations. If $|y/x| < 2^{-7}$, then only z is declared a root. z^* will then emerge separately if z is truly complex.

Double or multiple roots slow the convergence rate from cubic to near linear. When a near-linear convergence rate persists, the iteration increment Δz_i in (3.2) is replaced by

$$\Delta z_i = n \Big/ \Big[f_i \pm \sqrt{(n-k)/k \cdot (nh_i - f_i^2)} \Big], \tag{5.3}$$

which provides cubic convergence for a k-fold root. The first such iteration is "free" if p, p', and p'' from the previous iteration are used. The overhead involved in switching to (5.3) was found on balance to be justified only for $k = 2$ (i.e., double-roots). If $k = 2$ does not improve convergence, then $k = 1$ is reinstated for the rest of the iteration toward the current root.

Both a real and a complex iteration path were implemented to prevent the inefficient use of complex arithmetic for finding real roots. Switching between the two paths is automatic and biased toward a switch from complex to real arithmetic whenever warranted.

5.4. Miscellaneous improvements. The following additional measures were taken to further improve the efficiency and accuracy of the eigencalculations:

1. The matrix was scaled to prevent overflow and underflow. The similarity transformations leading to unit subdiagonal elements (see section 4) are particularly prone to overflow.
2. Matrix splitting is employed when negligible sub- or superdiagonal elements are encountered. This leads to two or more smaller eigenproblems, which are solved separately.

6. Test results. The Laguerre procedure was tested extensively for speed, accuracy, and robustness on a wide variety of matrices. The results were compared with those from a commercially available QR procedure based on EISPACK. The tests were carried out on a slow (33MHz) 80486 based PC to provide good resolution in the processing time measurements. Both the Laguerre and the QR procedure were implemented entirely in assembly language and in double precision. Both employ the familiar sequence of matrix balancing, matrix reduction, and eigenvalue iteration.

Equation (6.1) shows one of the matrix types used for testing:

$$[\mathrm{A}] = \left[\begin{array}{cc:cc:cc:c} 1 & -1 & 0 & 0 & 0 & 0 & . \\ 1 & 1 & 0 & 0 & 0 & 0 & . \\ \hdashline 2 & 2 & 2 & -2 & 0 & 0 & . \\ 2 & 2 & 2 & 2 & 0 & 0 & . \\ \hdashline 3 & 3 & 3 & 3 & 3 & -3 & . \\ 3 & 3 & 3 & 3 & 3 & 3 & . \\ \hdashline . & . & . & . & . & . & . \end{array}\right]. \tag{6.1}$$

These matrices have exact eigenvalues of $\lambda_e = 1 \pm i,\ 2 \pm 2i,\ 3 \pm 3i$, etc., allowing exact error calculations. Neither the Laguerre nor the QR method recognized the lower Hessenberg form of [A]. Both proceeded with balancing and reduction to upper Hessenberg form followed by eigeniteration.

Figure 2 shows a 30×30 matrix, of the type indicated by (6.1), after reduction to sparse Hessenberg form for various values of parameter c. The 1's in Figure 2 represent all nonzero elements. A negative c invokes standard Hessenberg reduction with row elimination disabled. A nonnegative c results in multipliers less than 2^c being accepted during elimination of row-pivots; see section 2.2. Thus, with $c = 0$, standard partial pivoting is applied to all row reductions, i.e., all multipliers are less than unity. With $c = 1$, the procedure accepts multiplier values of up to 2 for row-pivot elimination, etc. c does not affect the column eliminations which are always carried out with multipliers less than unity. Notice that a significant number of upper triangle elements can be zeroed with standard partial pivoting ($c = 0$). For random matrices with elements between -1 and 1, $c = 0$ results in zeroing of approximately half the upper triangle. Surprisingly, the nonzero upper triangle elements tend to congregate near the diagonal rather than being randomly distributed across the triangle. The explanation appears to be that matrix balancing, and to some extent Hessenberg reduction, tend to produce larger near-diagonal elements for matrices of the type shown in (6.1). This promotes elimination of row elements far from the diagonal. Preliminary investigations have confirmed that rebalancing after Stage 1 reduction (see section 2.1) increases the size of the near-diagonal elements significantly, allowing a large number of additional upper triangle elements to be zeroed with standard partial pivoting ($c = 0$). The efficiency of rebalancing is currently being investigated. It has not yet been implemented.

Notice in Figure 2(d) that $c = 4$ leads to full tridiagonalization. Generally, the larger the matrix, the larger the c-value required for tridiagonalization.

All the matrix types tried, including, for example, random matrices and the test matrices from Gregory and Karney [12], show very similar levels of sparsity for given values of c. They also show the same trend of bunching of elements near the diagonal.

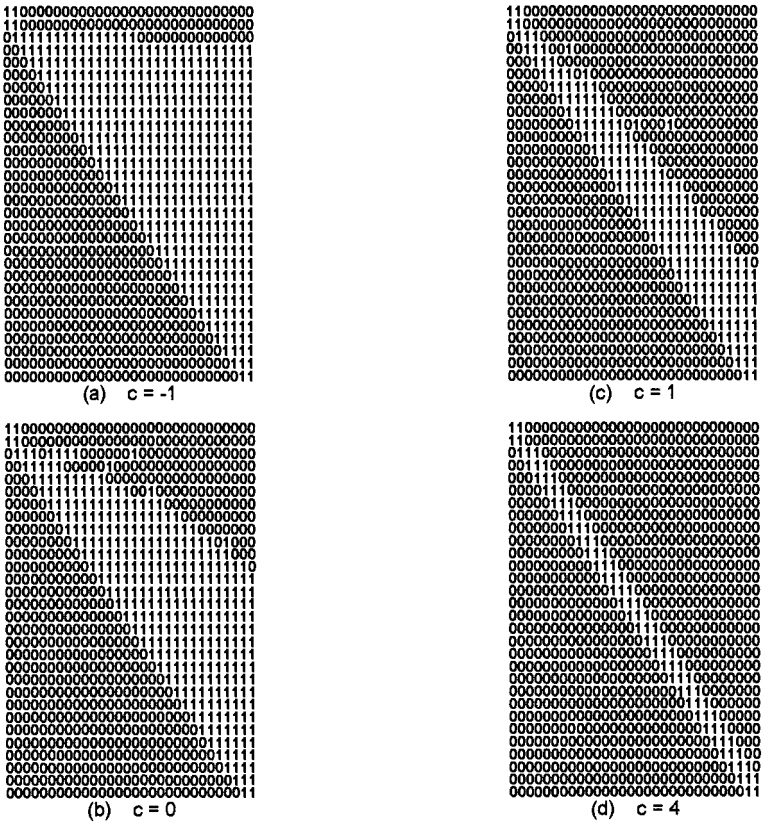

FIG. 2. *Effect of multiplier size on sparseness of Hessenberg form.*

Figure 3 shows the maximum relative error, $|(\lambda_e - \lambda_a)/\lambda_e|_{\max}$ of the calculated eigenvalues for matrices of the type shown in (6.1). λ_e and λ_a are the exact and the calculated eigenvalues, respectively. Comparison with the QR method shows that the Laguerre procedure usually provides approximately one additional significant digit when row elimination is disabled ($c = -1$). When the matrices are almost fully tridiagonalized ($c = 4$), the Laguerre method still matches the QR method in terms of accuracy in most cases. However, the error on the Laguerre procedure is becoming erratic and drops well below the QR accuracy for matrices of order 60 and 70. Care should be taken to ensure that the error is acceptable for the specific problem at hand. This can be done with a preliminary run with maximum accuracy ($c = -1$) before "production runs" with larger c's which reduce processing time as demonstrated later.

The overall reduction in accuracy with increasing c seems surprisingly small. Two explanations are offered.

(1) As outlined in section 2.2, irrespective of the value of c, standard partial pivoting is used to eliminate all but the relatively few row-pivots themselves, thus minimizing the number of unstable eliminations.

(2) The QR iteration procedure, by its nature, repeatedly modifies and stores the matrix elements in their double precision storage locations (15–16 significant digits). This is accompanied by a small but steady accumulation of round-off errors. The Laguerre iteration does not modify the elements of the reduced matrix and therefore

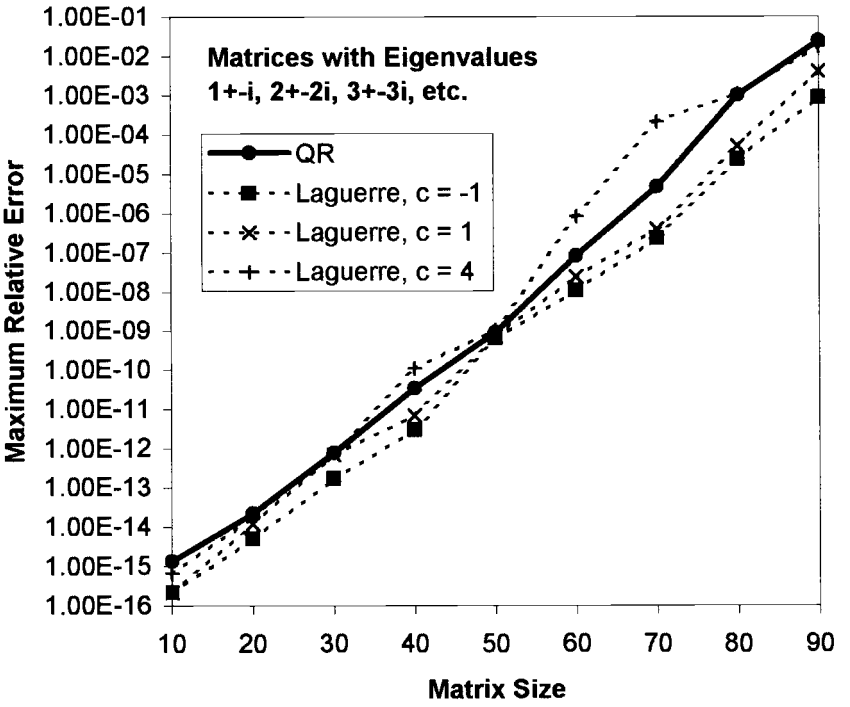

FIG. 3. *Comparison of maximum errors for dense matrices.*

does not incur these round-off errors. Instead, the Laguerre procedure is able to accumulate inner products throughout the iteration phase, in this case with the standard 19 significant digits of a PC processor.

Notice that the graphs in Figure 3 are not smooth. This is in line with expectations since the properties of matrices, of the type shown in (6.1), do not necessarily change smoothly with matrix size.

The corresponding speed comparison is shown in Figure 4. Roughly 1/3 of the upper triangle elements are zero when $c = 0$; see, for example, Figure 2. However, the Laguerre procedure does not become faster than the QR procedure until $c = 1$, when roughly 2/3 of the upper triangle is zero. This is most likely due to the additional time needed for the reduction to sparse Hessenberg form, before Laguerre iteration, compared to the shorter time needed for standard Hessenberg reduction, prior to QR iteration. The result is that a relatively large number of upper triangle zeros are required before the speed advantage of the Laguerre iteration can be realized. The maximum speed advantage is about a factor of 1.6 for $c = 4$, and this is relatively independent of matrix size ($c = 4$ tridiagonalizes the matrices up to order 30×30.)

The speed advantage for very sparse matrices is illustrated in Figure 5 for Fibonacci matrices of the type

$$A = \begin{bmatrix} 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix}. \tag{6.2}$$

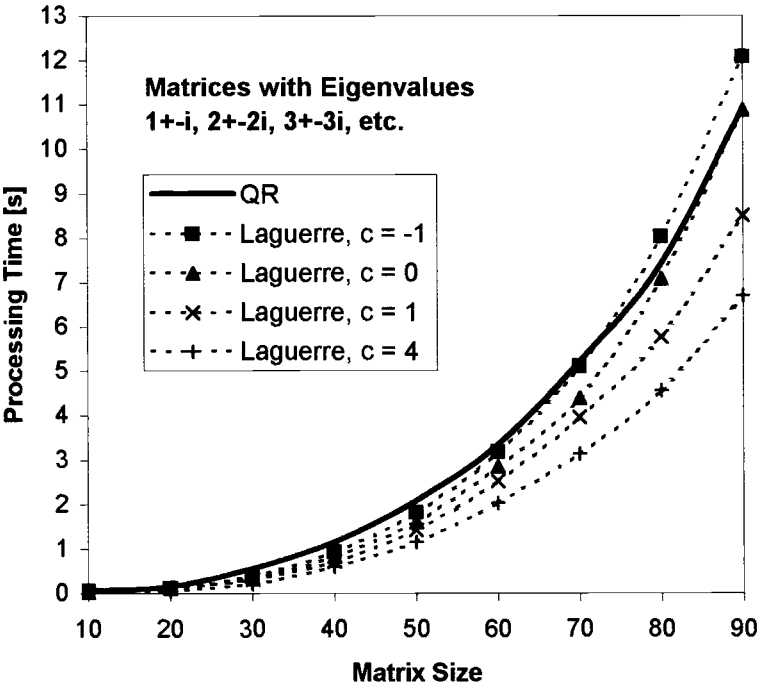

FIG. 4. *Comparison of processing time for dense matrices.*

Such matrices have all their eigenvalues located on the unit circle in the complex plane. Figure 5 shows a speed advantage of about 2.8 for the Laguerre procedure. The main reasons for the large speed advantage are probably the following:

1. Matrix reduction is unnecessary, leaving the QR method without the advantage of the quicker reduction to standard Hessenberg form.
2. The QR iterations destroy the zeros of the upper triangle, i.e., they do not benefit from the sparseness of [A].

All the eigenvalues from these test runs had full double precision accuracy (15–16 significant digits).

Some of the small ill-conditioned test matrices from Gregory and Karney [12] were also tried. These matrices were too small to provide a speed comparison. In terms of accuracy, no firm trend could be established. In some cases the QR method was slightly more accurate, and in other cases the Laguerre method with $c = -1$ was slightly more accurate. But on average, the QR method had a slight edge. One likely contributing factor is that the matrices are too small for the QR iteration to accumulate any appreciable round-off errors. The QR and Laguerre performances being so close, no attempt was made to improve the Laguerre performance for these small matrices.

7. Summary. In summary, the Laguerre procedure has been found to provide considerable versatility for large matrices, allowing the user to either increase the processing speed or improve the accuracy of the calculated eigenvalues, as compared to the QR method. This is useful in design work where repeated eigencalculations are often required to gauge the effect of small design changes or when Campbell diagrams

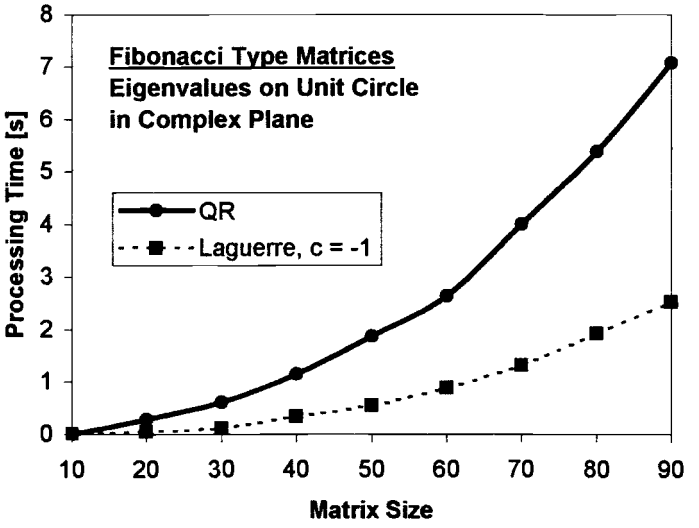

FIG. 5. *Comparison of processing time for sparse matrices.*

must be generated to trace the eigenvalues of matrices which are functions of a parameter. The Laguerre procedure can save time in such work by allowing the user to gain processing speed in exchange for significant digits, which may not be needed. Alternatively, when all possible digits must be extracted from an ill-conditioned matrix, the Laguerre procedure will often provide one additional significant digit compared to the QR method. A large number of test runs with a wide variety of matrices have confirmed these general conclusions.

There is scope for further improvement of the efficiency of the Laguerre eigensolver as follows:

- Replace the Newton start step with a Laguerre start step as suggested by Foster [10] to further reduce the number of iterations.
- Implement an option for user-supplied start values to reduce the number of iterations in design calculations and generation of Campbell diagrams for matrices, which are functions of a parameter.
- Calculate only the required eigenvalues, which often are those with a modulus below a user-supplied value. Such a procedure is currently being implemented based on the work of Delves and Lyness [13].
- Rebalance the matrix after Stage 1 Hessenberg reduction. This is currently being investigated as a means of increasing the size of the near-diagonal elements. Preliminary results show that this leads to stable elimination of many additional elements in the upper triangle.
- A reviewer of this paper has kindly suggested that advantage be taken of the envelope structure of the matrices; see Figure 2. The address of the rightmost nonzero element of each row could be saved and used to truncate the Hyman equations, (4.2)–(4.4).

8. Conclusion. A Laguerre iteration procedure has been implemented for eigensolution with unsymmetric matrices. Extensive testing indicates that the procedure

is superior to the QR method for large matrices, providing a speed advantage of between 1.6 and 2.8, often without sacrificing accuracy. When accuracy is paramount, a parameter can be set to extract typically one additional significant digit, compared to the QR method, at roughly the same processing speed as the QR method.

RESIDUAL REPLACEMENT STRATEGIES FOR KRYLOV SUBSPACE ITERATIVE METHODS FOR THE CONVERGENCE OF TRUE RESIDUALS*

HENK A. VAN DER VORST† AND QIANG YE‡

Abstract. In this paper, a strategy is proposed for alternative computations of the residual vectors in Krylov subspace methods, which improves the agreement of the computed residuals and the true residuals to the level of $O(\mathbf{u})\|A\|\|x\|$. Building on earlier ideas on residual replacement and on insights in the finite precision behavior of the Krylov subspace methods, computable error bounds are derived for iterations that involve occasionally replacing the computed residuals by the true residuals, and they are used to monitor the deviation of the two residuals and hence to select residual replacement steps, so that the recurrence relations for the computed residuals, which control the convergence of the method, are perturbed within safe bounds. Numerical examples are presented to demonstrate the effectiveness of this new residual replacement scheme.

Key words. Krylov subspace methods, finite precision, residuals, residual replacement

1. Introduction.

Krylov subspace iterative methods for solving a large linear system $Ax = b$ typically consist of iterations that recursively update approximate solutions x_n and the corresponding residual vectors r_n $(= b - Ax_n)$. They can be written in a general form as follows.

ALGORITHM 1. Template for Krylov subspace methods.
Input: an initial approximation x_0; $r_0 = b - Ax_0$;
For $n = 1, 2, \ldots$ until convergence
    generate a correction vector q_n by the method;
    $x_n = x_{n-1} + q_n$,
    (the vector x_n does not occur in other statements),
    $r_n = r_{n-1} - Aq_n$
End for

Most Krylov subspace iterative methods, including the conjugate gradient method (CG) [13], the biconjugate gradient method (BiCG) [4, 14], CGS [21], and BiCGSTAB [24], fit in this framework (see [2, 12, 17] for other methods).

In exact arithmetic, the recursively defined r_n in Algorithm 1 is exactly the residual for the approximate solution x_n, because $b - Ax_n - r_n = b - Ax_{n-1} - r_{n-1} = b - Ax_0 - r_0 = 0$. In a floating point arithmetic, however, the round-off patterns for x_n and r_n will be different. It is important to note that any error made in the computation of x_n is not reflected by a corresponding error in r_n, or in other words, computational errors to x_n do not force the method to correct, since x_n has no influ-

ence on the iteration process. This leads to the well known situation that $b-Ax_n$ and r_n may differ significantly. This phenomenon has been extensively discussed in the literature; see [20, 11, 12, 19] and the references cited therein. Indeed, if we denote the computed results of x_n, r_n by $\hat{x}_n, \hat{r}_n$, respectively (but we still use q_n to denote the computed update vector of the algorithm), then we have

(1) $\hat{x}_n = fl(\hat{x}_{n-1} + q_n) = \hat{x}_{n-1} + q_n + \psi_n, \qquad |\psi_n| \le \mathbf{u}|\hat{x}_n| + O(\mathbf{u}^2),$
(2) $\hat{r}_n = fl(\hat{r}_{n-1} - Aq_n) = \hat{r}_{n-1} - Aq_n + \eta_n, \quad |\eta_n| \le \mathbf{u}(|\hat{r}_n| + N|A||q_n|) + O(\mathbf{u}^2),$

where $fl(z)$ denotes the computed result of z in finite arithmetic, the absolute value and inequalities on vectors are componentwise, $\mathbf{u}$ is the machine roundoff unit, and N denotes the maximum number of nonzero entries per row of A. The vectors ψ_n and η_n represent rounding error terms, and they can be bounded by a straightforward error analysis (see section 3 for details). In particular, the relations (1) and (2) show that ψ_n and η_n depend only on the iteration vectors $\hat{x}_n$, $\hat{r}_n$, and q_n.

We will call $b - A\hat{x}_n$ the *true residual* for the approximation $\hat{x}_n$ and call $\hat{r}_n$, as obtained by recurrence formula (2), the *computed residual* (or the *updated residual*). Then the difference between the two satisfies (using the finite precision recurrences (1) and (2))

$$\begin{aligned} b - A\hat{x}_n - \hat{r}_n &= b - A\hat{x}_{n-1} - \hat{r}_{n-1} - A\psi_n - \eta_n, \\ &= -\Sigma_{i=1}^{n}(A\psi_i + \eta_i), \end{aligned}$$

where we assume for now that $b-Ax_0-r_0 = 0$. Hence, the difference between the true and the updated residuals is a result of accumulated rounding errors. In particular, a significant deviation of $b - A\hat{x}_n$ from $\hat{r}_n$ may be expected, if there is a $\hat{x}_i$ or $\hat{r}_i$ with large norm during the iteration (a not uncommon situation for BiCG and CGS). On the other hand, even when all ψ_i and η_i are small (as is common for CG), but if it takes a relatively large number of iterations for convergence, the sheer accumulation of ψ_i and η_i could also lead to a nontrivial deviation.

What makes all this so important is that, in a finite precision implementation, the sequence $\hat{r}_n$ satisfies, almost to machine precision $\mathbf{u}$, its defining recurrence relation, and as was observed for many Krylov subspace methods, this is the driving force behind convergence of $\hat{r}_n$ [10, 11, 15, 16, 19, 22]. Indeed, residual bounds have been obtained in [22] for CG and BiCG, which show that even a significantly perturbed recurrence relation (with perturbations much larger than the machine precision) usually still leads to eventual convergence of the computed residuals. This theoretical insight has been our motivation and justification for the residual replacement scheme to be presented in section 2.1. On the other hand, the true residual $b - A\hat{x}_n$ itself has no self-correcting mechanism for convergence, mainly because any perturbation made to $\hat{x}_n$ does not have an effect on the iteration parameters, whereas errors in $\hat{r}_n$ immediately lead to other iteration parameters.

Thus, in a typical convergent iteration process, $\hat{r}_n$ converges to a level much smaller than $\mathbf{u}$ eventually, but the true residual $b-A\hat{x}_n$ can only converge to the level dictated by $\Sigma_{i=1}^{n}(A\psi_i + \eta_i)$, since

$$b - A\hat{x}_n = \hat{r}_n - \Sigma_{i=1}^{n}(A\psi_i + \eta_i).$$

Namely, when $\hat{r}_n$ is still bigger than the accumulated error $\Sigma_{i=1}^{n}(A\psi_i + \eta_i)$, $b - A\hat{x}_n$ agrees well with $\hat{r}_n$ in magnitude, but when $\hat{r}_n$ has converged to a level that is smaller than the accumulated error, then $b - A\hat{x}_n \sim \Sigma_{i=1}^{n}(A\psi_i + \eta_i)$ is just the accumulated

error and has no agreement at all with $\hat{r}_n$. In summary, a straightforward implementation would reduce the true residuals at best to $\Sigma_{i=1}^{n}(A\psi_i + \eta_i)$. A bound for this has been obtained in [11] and it is called the *attainable accuracy*. We note that this term could be significant even if only one of ψ_i or η_i is large, or if n is large.

The above problems become most serious in methods such as CGS and BiCG where intermediate $\hat{x}_n$ and $\hat{r}_n$ can have very large norm, and this may result in a large ψ_n or η_n. Several popular methods, such as BiCGSTAB [24], BiCGSTAB(ℓ) [18], QMR [7], TFQMR [5], and composite step BiCG [1], have been developed to reduce the norm of $\hat{r}_n$ (see [6] for details). We note that controlling the size of $\|\hat{r}_n\|$ alone does not solve the deviation problem in all situations, as intermediate vectors in these methods may still have a large norm which, while invisible in $\|\hat{r}_n\|$, could still have significant effects to the difference between the *true* and *computed* residuals. In any case, the accumulation of tiny errors over a long iteration may also result in a nontrivial deviation.

A simple approach for solving the deviation problem is to replace the computed residuals by the true residuals at some iteration step to restore the agreement. Then the deviation at subsequent steps will be the error accumulation after that iteration only. This includes a complete replacement strategy that simply computes r_n by $b - Ax_n$ at every iteration, and a periodic replacement strategy that updates r_n by $b - Ax_n$ only at intervals of the iteration count. While such a strategy maintains agreement of the two kinds of residuals, it turns out that the convergence of the r_n may deteriorate (as we will see, it may result in unacceptably large perturbations to the Lanczos recurrence relation for the residual vectors that steers the convergence; see section 2.3). Recently, Sleijpen and van der Vorst [19], motivated by suggestions made by Neumaier (see [12, 19]), introduced an efficient replacement scheme that includes a so-called *flying-restart* procedure. It was demonstrated that this new residual replacement strategy can be very effective in the sense that it can improve the convergence of the true residuals by several orders of magnitude. For practical implementations, such a strategy is very useful because it leads to meaningful residuals and this is important for stopping the iteration process at the right point. Of course, one could, after termination of the classical process, simply test the true residual, but the risk is that the true residual stagnated already long before termination, so that much work has been done in vain.

The present paper will follow the very same idea of replacing the computed residual by the true residual at selected steps, in order to maintain close agreement between the two residuals, but we propose a simpler strategy so that the replacement is done only when it is necessary and at phases in the iteration where it is harmless, that is, when convergence mechanism for $\hat{r}_n$ is not destroyed. Specifically, we shall present a rigorous error analysis for iterations with residual replacement and we will propose computable bounds for the deviation between the computed and true residuals. This will be used to select the replacement phases in the iteration in such a way that the Lanczos three term recurrence among $\hat{r}_n$ is sufficiently well maintained. For the resulting strategy, it will be shown that, provided that the computed residuals converge, the true residual will converge to the level $O(\mathbf{u})\|A\|\|x\|$, the smallest level that one can expect for an approximation.

We note that, in many practical applications, one is only interested in a modest reduction of the residual norm, rather than to the level of $O(\mathbf{u})\|A\|\|x\|$ considered here, but even in such cases, the true residual could potentially stagnate at a level above the desirable threshold if there is sufficiently large growth of intermediate vec-

tors. This is not necessarily a result of ill-conditioning of A but could simply arise when a Ritz value in the underlying Lanczos process for BiCG, as determined by the initial approximation, is very close to 0. Although such a situation must be rare, it poses a risk to direct implementations. Therefore, it would still be beneficial to use the residual replacement scheme as a guard in such applications, given that it invokes very little extra cost.

The paper has been organized as follows. In section 2, we develop a refined residual replacement strategy and we discuss some strategies that have been reported by others. We give an error analysis in section 3, and we derive some bounds for the deviation to be used in the replacement condition. We present a complete implementation in section 4. It turns out that the residual replacement strategy can easily be incorporated in existing codes. Some numerical examples are reported in section 5, and we finish with remarks in section 6.

The vector norm used in this paper is one of the 1, 2, or ∞-norm.

2. Residual replacement strategy. In this section, we develop a replacement strategy that maintains the convergence of the true residuals. A formal analysis is postponed to the next section. The specific iterative method can be any of those that fit in the general framework of Algorithm 1. Throughout this paper, we shall consider only iteration processes for which the computed residual $\hat{r}_n$ converges to a sufficiently small level.

As mentioned in section 1, we follow the basic idea to replace the computed residual $\hat{r}_m$ by the true residual $fl(b - A\hat{x}_m)$ at some selected steps $m = m_1, m_2, \ldots, m_k$. We will refer to such an iteration step as one where *residual replacement* occurs. Hence, the residual generated at an arbitrary step n could be either the usual updated residual $\hat{r}_n = fl(\hat{r}_{n-1} - Aq_{n-1})$ or the true residual $fl(b - A\hat{x}_n)$, depending on whether replacement has taken place or not at step n. In order to distinguish the two possible formulations, we denote by r_n the residual obtained at step n of the process with the replacement strategy, that is,

$$r_n = \begin{cases} fl(b - A\hat{x}_n), & \text{if } n = m_1, m_2, \ldots, m_k, \\ \hat{r}_n = fl(r_{n-1} - Aq_{n-1}), & \text{otherwise.} \end{cases}$$

With the residual replacement at step m ($m = m_1, m_2, \ldots, m_k$), the residual deviation is immediately reduced to

$$\delta_m \equiv b - A\hat{x}_m - r_m = b - A\hat{x}_m - fl(b - A\hat{x}_m) = -\xi_m,$$

and it can be shown (see Lemma 1 of section 2.2) that $|\xi_m| \leq \mathbf{u}(|r_m| + N|A||\hat{x}_m|) + O(\mathbf{u}^2)$. For the subsequent iterations $n > m$, but before the next replacement step, we clearly have that

$$\begin{aligned} \delta_n &= b - A\hat{x}_n - r_n = b - A\hat{x}_m - r_m - \Sigma_{i=m+1}^{n}(A\psi_i + \eta_i) \\ &= -\xi_m - \Sigma_{i=m+1}^{n}(A\psi_i + \eta_i). \end{aligned} \tag{3}$$

Therefore, the accumulated deviation before step m has no effect to the deviation after updating ($n > m$). However, in order for such a strategy to succeed, two conditions must be met, namely,

- the computed residual r_n should preserve the convergence mechanism of the original process that has been steered by the $\hat{r}_n$ vectors;
- from the last updating step m to the termination step K, the accumulated error $\Sigma_{i=m+1}^{K}(A\psi_i + \eta_i)$ should be small relative to $\mathbf{u}(|r_m| + N|A||\hat{x}_m|)$, which is the upperbound for $|\xi_m|$.

We discuss in the next two subsections how to satisfy these two objectives.

2.1. Maintaining convergence of computed residuals. In order that r_n maintains the convergence mechanism of the original updated residuals, it should preserve the property that gives rise to the convergence of the original $\hat{r}_n$. We therefore need to identify the properties that lead to convergence of the iterative method *in finite precision arithmetic*. While this may be different for each individual method, it has been observed for several Krylov subspace methods (including CG [11, 22], BiCG [22], CGS, BiCGSTAB, and BiCGSTAB(ℓ) [19]) that the recurrence $r_n = r_{n-1} - Aq_n$ and a similar one for q_n is satisfied almost to machine precision and this small local error is one of the properties behind the convergence of the computed residuals. Furthermore, the analysis of [22] suggests that convergence is well maintained even when the recurrence equations are perturbed with perturbations that are significantly greater than the machine precision. This latter property is the basis for our residual replacement strategy. Therefore, we briefly discuss this perturbation phenomenon for BiCG (or CG), as presented in [22].

Consider the BiCG iteration which contains $r_n = r_{n-1} - \alpha_{n-1}Ap_{n-1}$ and $p_n = r_n + \beta_n p_{n-1}$. In finite arithmetic, $\hat{r}_n$ and $\hat{p}_n$, which denote the computed results of r_n and p_n, respectively, satisfy the perturbed recurrence

$$\hat{r}_n = \hat{r}_{n-1} - \alpha_{n-1}A\hat{p}_{n-1} + \eta_n \quad \text{and} \quad \hat{p}_n = \hat{r}_n + \beta_n\hat{p}_{n-1} + \tau_n,$$

where η_n and τ_n are rounding error terms that can be bounded in terms of $\mathbf{u}$. Combining these two equations, we obtain the following perturbed matrix equation in a normalized form

$$AZ_n = Z_nT_n - \frac{1}{\alpha'_n}\frac{\hat{r}_{n+1}}{\|\hat{r}_1\|}e_n^T + F_n \quad \text{with} \quad Z_n = \left[\frac{\hat{r}_1}{\|\hat{r}_1\|}, \ldots, \frac{\hat{r}_n}{\|\hat{r}_n\|}\right], \tag{4}$$

where T_n is an invertible tridiagonal matrix,[1] $\alpha'_n = \|\hat{r}_n\|\alpha_n/\|r_1\| = e_n^T T_n^{-1} e_1$ and $F_n = [f_1, \ldots, f_n]$ with

$$f_n = \frac{A\tau_n}{\|\hat{r}_n\|} + \frac{1}{\alpha_n}\frac{\eta_{n+1}}{\|\hat{r}_n\|} - \frac{\beta_n}{\alpha_{n-1}}\frac{\eta_n}{\|\hat{r}_n\|}. \tag{5}$$

We note that (4) is just an equation satisfied by an exact BiCG iteration under a perturbation F_n. In particular, detailed bounds on τ_n and η_n will, under some mild assumptions, lead to $F_n \sim O(\mathbf{u})$.

The main result of [22] states that if a sequence $\hat{r}_n$ satisfies (4) and Z_{n+1} has full rank, then we have

$$\|\hat{r}_{n+1}\| \le (1 + K_n) \min_{p\in\mathcal{P}_n, p(0)=1} \|p(A + \Delta A_n)\hat{r}_1\|, \tag{6}$$

where $K_n = \|(AZ_n - F_n)T_n^{-1}\|\,\|Z_{n+1}^+\|$ and $\Delta A_n = -F_n Z_n^+$. The case $F_n = 0$ reduces to the known theoretical bound for the exact BiCG residuals [1]. Therefore, even when $\hat{r}_n$ and its exact counterpart are completely different, their norms are bounded by similar quantities and are usually comparable. Of course, in both cases, the bounds depend on the quality of the constructed basis. More importantly, a closer examination of the bound reveals that even if the perturbation F_n is in magnitude much larger than $\mathbf{u}$, the quantities in the bound, and thus $\|\hat{r}_{n+1}\|$, may not be significantly affected. Indeed, in [22] numerical experiments were presented, where relatively large

[1] We assume that no breakdowns of the iteration process have occurred.

artificial random perturbations had been injected to the recurrence for r_n; yet it did not significantly affect the convergence mechanism.

An implication of this analysis is that, regardless of how $\hat{r}_n$ is generated but as long as it satisfies (4), its norm can be bounded by (6). Hence, we can replace $\hat{r}_n$ by $r_n = fl(b - Ax_n)$ when $\eta_n = r_n - (r_{n-1} - Aq_n)$ are not too large relative to $\|r_n\|$ and $\|r_{n-1}\|$ (see (5)), and we may still expect it to converge in a similar fashion. Indeed, this criterion explains why the residual replacement strategies like $r_n = fl(b - Ax_n)$ work sometimes but do not work always (see section 2.3). Here, it will be used to determine when it is safe to replace $\hat{r}_n$ by $r_n = fl(b - Ax_n)$. We note that the above discussion is for BiCG, but the phenomenon it reveals seems to be valid for many other methods, especially for those methods that are based on BiCG (CGS, BiCGSTAB, and others).

Now we consider the case that residual replacement is carried out at step m, that is, $r_m = fl(b - A\hat{x}_m) = b - A\hat{x}_m + \xi_m$. It follows from the definition of δ_m and $\hat{r}_m$ that $b - A\hat{x}_m = \hat{r}_m + \delta_m = r_{m-1} - Aq_{m-1} + \eta_m + \delta_m$. So, the updated residual r_m satisfies

$$r_m = r_{m-1} - Aq_{m-1} + \eta'_m \quad \text{with} \quad \eta'_m = \eta_m + \delta_m + \xi_m. \tag{7}$$

Thus depending on the magnitude of $\|\eta'_m\|$ relative to $\|r_m\|$ and $\|r_{m-1}\|$, the use of $r_m = fl(b - A\hat{x}_m)$ may result in large perturbations to the recurrence relation. Therefore, a residual replacement strategy should ensure that the replacement is only done when $\|\eta'_m\|/\min\{\|r_m\|, \|r_{m-1}\|\}$ is not too large.

In a typical iteration, as the iteration proceeds, $\|\delta_n\|$, and hence $\|\eta'_n\|$, increases while $\|\hat{r}_n\|$ decreases. Replacement will reduce δ_n but, in order to maintain the recurrence relation, it should be carried out before $\|\eta'_n\|$ becomes too large relative to $\|\hat{r}_n\|$. For this reason, we propose to set a threshold ϵ and carry out a replacement when $\|\eta'_n\|/\|\hat{r}_n\|$ reaches the threshold. To be precise, we replace the residual at step n by $r_n = b - Ax_n$, if

$$\|\eta'_{n-1}\| \le \epsilon\|\hat{r}_{n-1}\| \quad \text{and} \quad \|\eta'_n\| > \epsilon\|\hat{r}_n\|. \tag{8}$$

We note that, in principle, residual replacement can be carried out for all steps up to where $\|\eta'_n\|$ reaches a certain point. However, from the stability point of view, it is preferred to generate the residual by the recurrence as much as possible, since $\|\eta'_n\|$ is generally bigger than the recurrence rounding error $\|\eta_n\|$ (of order $\mathbf{u}$).

2.2. Groupwise solution updating to reduce error accumulations. From the discussions of section 2.1, we learn that residual replacement should only be carried out up to a certain point. In this subsection, we will discuss how to maintain, after the last replacement, the deviation at the order of $\mathbf{u}|A||x_n|$, in which case x_n is a backward stable solution. Note that, for any x_n, $\mathbf{u}\|A\|\|x_n\|$ is the lowest value one can expect for its residual. This is simply because even with the exact solution x, both $b - A(fl(x))$ and $fl(b - Ax) \sim \mathbf{u}|A||x|$.

If $m = m_k$ is the last updating step, which means that we are in the final phase of the iteration process, then, because of (3), the deviation at step $n > m$ is

$$\delta_n = -\xi_m - \Sigma_{i=m+1}^{n}\eta_i - \Sigma_{i=m+1}^{n}A\psi_i.$$

From our updating condition, we have that $\|r_n\| \le \|\eta'_n\|/\epsilon \sim O(\frac{\mathbf{u}}{\epsilon})$. So, if ϵ is chosen not too close to $\mathbf{u}$, $\|r_n\|$ is small and $\hat{x}_n \sim x$ for $n \ge m$. We now discuss the three different parts of δ_n. The discussion here is only to motivate the groupwise updating strategy; a more rigorous analysis will be given in the next section.

- $|\xi_m| \le \mathbf{u}(|r_m| + N|A||\hat{x}_m|) \sim O(\mathbf{u})|A||x|$.
- Since $|\hat{r}_i| \ll |b| \le |A||x|$ and $|\eta_i| \sim \mathbf{u}|\hat{r}_i|$, we have that $\Sigma_{i=m+1}^{n}|\eta_i| \ll O(\mathbf{u})|A||x|$.
- For the ψ_i part, $|\psi_i| \sim \mathbf{u}|\hat{x}_i| \sim \mathbf{u}|x|$. Hence, $\Sigma_{i=m+1}^{n}|A\psi_i| \sim \Sigma_{i=m+1}^{n}\mathbf{u}\|A\|\|x\| = (n-m)\mathbf{u}\|A\|\|x\|$. If $n-m$ is large, the accumulation of errors over $n-m$ steps can be significant. We note that this is the same type of error accumulation in evaluating a sum $S = \Sigma_{i=1}^{\infty}c_i$ of small numbers by direct recursive additions, which can fortunately be corrected through appropriately grouping the arithmetic operations as $S_1+S_2+\cdots = (c_1+\cdots+c_{m_1})+(c_{m_1+1}+\cdots+c_{m_2})+\cdots$ with terms of similar order of magnitude in the same group S_i and $S_1 \gg S_2 \gg \cdots$. In this way, the rounding errors associated with a large number of additions inside a group S_i is of the magnitude of $\mathbf{u}S_i$, which can be much smaller than $\mathbf{u}S$. The same technique can be adopted for computing x_n as

$$x_n = x_0 + \Sigma_{i=1}^{n}q_i = x_0 + (q_1 + \cdots + q_{m_1}) + (q_{m_1+1} + \cdots + q_{m_2}) + \cdots .$$

Specifically, the recurrence for x_n can be carried out in the following equivalent form:

Groupwise solution update: $z = x_0$; $\hat{x}_0 = 0$;
For $n = 1, 2, \ldots$ until convergence
  $\hat{x}_n = fl(\hat{x}_{n-1} + q_n) = \hat{x}_{n-1} + q_n + \psi_n$
  if $n = m_i$ (i.e., group update)
    $z = fl(z + \hat{x}_n) = z + \hat{x}_n + \zeta_n$,
    $\hat{x}_n = 0$
  end if
End for

Such a groupwise update scheme has been suggested by Neumaier, and it has been worked out by Sleijpen and van der Vorst (see [19] for both references). By doing so, the error in the local recurrence is reduced. Indeed, for $i \ge m$, $|\hat{x}_i| = |z+\hat{x}_i-z| \sim |x-z| \ll |x|$. Then $|\psi_i| \sim \mathbf{u}|\hat{x}_i|$ (instead of $\mathbf{u}|x_i|$). Hence, $\Sigma_{i=m+1}^{n}|A\psi_i| \ll (n-m)\mathbf{u}|A||x|$.

In summary, with groupwise updating of the approximated solution, all three parts of δ_n can be maintained at the level of $\mathbf{u}|A||x|$. We mention that groupwise updating can also be used to obtain better performance of a code for modern architectures, because it allows for level-3 BLAS operations. This has been suggested in [23, p. 52, note 5].

2.3. Some other residual replacement strategies. We briefly comment on some other residual replacement strategies.

For the naive strategy of "replacing always" (the residuals are computed always as $b - Ax_n$) or for "periodic replacement" (update periodically at every ℓ steps), replacement is carried out throughout the iteration, even when $\|r_n\|$ is very small. This, as we know, may result in large perturbations to the recurrence equations relative to $\|r_n\|$, since $|\eta'_n|$ is at least $|\xi_n| \sim \mathbf{u}|A||x_n|$; see (7). In that case, as $\|r_n\|$ decreases, the recurrence relation may be perturbed too much and hence the convergence property deteriorates. This is the typical behavior observed in such implementations.

We note that if ξ_n can be made to decrease as $\|r_n\|$ does, then replacement can be carried out at later stages of the iterations. This leads to the strategy of "flying-restart" of Sleijpen and van der Vorst [19], which significantly reduces ξ_n, and hence

η'_n, at a replacement step. In the flying-restart strategy b is replaced by $fl(b - Ax_m)$ at some but not all of the residual replacement steps (say $m = n_1, n_2, \ldots, n_l$), in addition to the residual replacement $r_m = fl(b - Ax_m)$. The advantage of this is that, at the flying-restart step n_{i+1}, the residual is updated by $r_{n_{i+1}} = fl(r_{n_i} - A\hat{x}_{n_{i+1}}) = r_{n_i} - A\hat{x}_{n_{i+1}} + \xi_{n_{i+1}}$ (noting that $b \leftarrow r_{n_i}$) and $|\xi_{n_{i+1}}| \sim \mathbf{u}(|r_{n_i}| + |A||\hat{x}_{n_{i+1}}|)$. Then

$$|r_{n_i} - A\hat{x}_{n_{i+1}} - r_{n_{i+1}}| = |\zeta_{n_{i+1}}| \sim \mathbf{u}(|r_{n_i}| + |A||\hat{x}_{n_{i+1}}|),$$

which decreases as r_{n_i} and $\hat{x}_{n_{i+1}}$ decrease. This is the term that determines the perturbation to the recurrence and can be kept small relative to r_n. However, the deviation satisfies

$$b - Ax_{n_{i+1}} - r_{n_{i+1}} = b - Ax_{n_i} - r_{n_i} - \xi_{n_{i+1}}$$

(assuming $x_{n_{i+1}} = x_{n_i} + \hat{x}_{n_{i+1}}$). Namely, the deviation at each flying-restart step carries forward to the later steps. Therefore flying-restart should only be used at carefully selected steps where $\xi_{n_i} \sim \mathbf{u}(\|b\| + N\|A\|\|x\|)$. However, it is not easy to identify a condition to monitor this. It is also necessary to have two different conditions for the residual replacement and flying-restart. Fortunately, our discussion in the last two subsections shows that carrying out replacement carefully at some selected steps, in combination with groupwise update, is usually sufficient. We shall not pursue the flying-restart idea further in this paper.

3. Error analysis of the residual replacement scheme. In this section, we formally analyze the residual replacement strategy as developed in section 2.1 (and presented in Algorithm 2 below). In particular, we develop a computable bound for $\|\delta_n\|$ and $\|\eta'_n\|$, that can be used for the implementation of the residual replacement condition.

We first summarize residual replacement strategy in the following algorithm, written in a form that identifies relevant rounding errors for later theoretical analysis.

ALGORITHM 2. Iterative method with residual replacement.
Given an initial approximation $z = x_0$ (a floating point vector);
set $\hat{x}_0 = 0$; $r_0 = fl(b - Ax_0) = b - Ax_0 + \xi_0$;
For $n = 1, 2, \ldots$ until convergence
    generate a correction vector q_n by the method;
    $\hat{x}_n = fl(\hat{x}_{n-1} + q_n) = \hat{x}_{n-1} + q_n + \psi_n$,
    $\hat{r}_n = fl(r_{n-1} - Aq_n) = r_{n-1} - Aq_n + \eta_n$,
    if residual replacement condition (8) holds
        $z = fl(z + \hat{x}_n) = z + \hat{x}_n + \zeta_n$,
        $\hat{x}_n = 0$,
        $r_n = fl(b - Az) = b - Az + \xi_n$
    else
        $r_n = \hat{r}_n$
    end if
    (denote but not compute $x_n = z + \hat{x}_n$ and $\delta_n = b - Ax_n - r_n$)
End for
$z = fl(z + \hat{x}_n) = z + \hat{x}_n + \zeta_n$

Note that x_n and δ_n are theoretical quantities as defined by the formulas and are not to be computed. The vectors $\psi_n, \eta_n, \zeta_n, \xi_n$ represent rounding error terms, due to finite precision arithmetic.

At step n of the iterative method, q_n is computed in finite precision arithmetic by the algorithm. However, the rounding errors involved in the computation of q_n are irrelevant for the deviation of the two residuals, which solely depends on the different treatment of q_n in the recurrences for r_n and x_n.

Throughout this paper, we assume that A is a floating point matrix. Our error analysis is based on the following standard model for roundoff errors in basic matrix computations [8, p. 66] (all inequalities are componentwise):

$$fl(x+y) = x + y + e \quad \text{with} \quad |e| \leq \mathbf{u}(|x+y|), \tag{9}$$

$$fl(Ax) = Ax + e \quad \text{with} \quad |e| \leq \mathbf{u}N|A||x| + O(\mathbf{u}^2), \tag{10}$$

where x, y are floating point vectors, N is a constant associated with the matrix-vector multiplication (for instance, the maximal number of nonzero entries per row of A).

It is easy to show that

$$fl(y + Ax) = y + Ax + e \quad \text{with} \quad |e| \leq \mathbf{u}(|y + Ax| + N|A||x|) + O(\mathbf{u}^2).$$

Using this, the following lemma, which includes (1) and (2), is obtained.

LEMMA 3.1. *The error terms in the computed recurrence of Algorithm* 2 *are bounded as follows:*

$$|\psi_n| \leq \mathbf{u}|\hat{x}_n| + O(\mathbf{u}^2), \tag{11}$$

$$|\eta_n| \leq \mathbf{u}(|\hat{r}_n| + N|A||q_n|) + O(\mathbf{u}^2). \tag{12}$$

For a step at which a residual replacement is carried out

$$|\zeta_n| \leq \mathbf{u}|x_n| + O(\mathbf{u}^2), \tag{13}$$

$$|\xi_n| \leq \mathbf{u}(|r_n| + N|A||x_n|) + O(\mathbf{u}^2). \tag{14}$$

Proof. From (9), we have that $|\psi_n| \leq \mathbf{u}|\hat{x}_{n-1} + q_n| \leq \mathbf{u}(|\hat{x}_n| + |\psi_n|)$. This leads to the bound for $|\psi_n|$. For a residual replacement step, the updated z is x_n by definition, that is, $x_n = z + \hat{x}_n + \zeta_n$. Therefore, $|\zeta_n| \leq \mathbf{u}|x_n| + O(\mathbf{u}^2)$. The bounds for η_n and ξ_n follow similarly. ∎

LEMMA 3.2. *Let m be the number of step at which a residual replacement is carried out and let $n > m$ denote a later step, but still before the next replacement step. Then, we have that*

$$\Sigma_{i=m+1}^{n}|\psi_i| \leq \mathbf{u}\Sigma_{i=m+1}^{n}|\hat{x}_i| + O(\mathbf{u}^2),$$

$$\Sigma_{i=m+1}^{n}|q_i| \leq (2+\mathbf{u})\Sigma_{i=m+1}^{n}|\hat{x}_i|,$$

and

$$\Sigma_{i=m+1}^{n}|\eta_i| \leq \mathbf{u}\Sigma_{i=m+1}^{n}|\hat{r}_i| + 2\mathbf{u}N|A|\Sigma_{i=m+1}^{n}|\hat{x}_i| + O(\mathbf{u}^2).$$

Proof. The first bound follows directly from Lemma 1. For $i \geq m+1$ we have that $q_i = \hat{x}_i - \hat{x}_{i-1} - \psi_i$. Noting that $\hat{x}_m = 0$, it follows that

$$\Sigma_{i=m+1}^{n}|q_i| \leq \Sigma_{i=m+1}^{n}(|\hat{x}_i| + |\hat{x}_{i-1}| + |\psi_i|) \leq (2+\mathbf{u})\Sigma_{i=m+1}^{n}|\hat{x}_i|.$$

Similarly,

$$\begin{aligned}\Sigma_{i=m+1}^{n}|\eta_i| &\le \mathbf{u}\Sigma_{i=m+1}^{n}(|\hat{r}_i| + N|A||q_i|) + O(\mathbf{u}^2)\\ &\le \mathbf{u}\Sigma_{i=m+1}^{n}|\hat{r}_i| + 2\mathbf{u}N|A|\Sigma_{i=m+1}^{n}|\hat{x}_i| + O(\mathbf{u}^2). \qquad \square\end{aligned}$$

We now consider the deviation of the two residuals.

LEMMA 3.3. *Let m be the number of an iteration step at which residual replacement is carried out and let $n > m$ denote a later iteration step, still before the next replacement step. Then, we have that $\delta_m = -\xi_m$ and*

$$\delta_n = \delta_{n-1} - (A\psi_n + \eta_n) = -\xi_m - \Sigma_{i=m+1}^{n}(A\psi_i + \eta_i).$$

Proof. At step m, by the definition of x_m in Algorithm 2, $x_m = z + \hat{x}_m = z$ with z being the updated z-vector and $\hat{x}_m = 0$. Furthermore, $r_m = fl(b - Az) = fl(b - Ax_m) = b - Ax_m + \xi_m$. Therefore $\delta_m = -\xi_m$. Hence, for the range of $n > m$, and before the next residual replacement step,

$$\begin{aligned}\delta_n &= b - Ax_n - r_n = b - A(z + \hat{x}_n) - \hat{r}_n\\ &= b - A(z + \hat{x}_{n-1} + q_n + \psi_n) - (\hat{r}_{n-1} - Aq_n + \eta_n)\\ &= \delta_{n-1} - A\psi_n - \eta_n\\ &= \delta_m - \Sigma_{i=m+1}^{n}(A\psi_i + \eta_i). \qquad \square\end{aligned}$$

With Lemma 2, we obtain the following computable bound on δ_n.

LEMMA 3.4. *Let m be the number of an iteration step at which residual replacement is carried out and let $n > m$ denote a later iteration step, still before the next replacement step. Then, we have $\|\delta_m\| \le \mathbf{u}(\|r_m\| + N\|A\|\|x_m\|) + O(\mathbf{u}^2)$ and*

$$\|\delta_n\| \le \mathbf{u}N\|A\|\|x_m\| + \mathbf{u}(1+2N)\|A\|\Sigma_{i=m+1}^{n}\|\hat{x}_i\| + \mathbf{u}\Sigma_{i=m}^{n}\|r_i\| + O(\mathbf{u}^2).$$

Proof. The bound for $\|\delta_m\|$ follows from that for ξ_m; see (14). From Lemma 2 and Lemma 3, it follows that

$$\begin{aligned}|\delta_n| &\le |\xi_m| + \Sigma_{i=m+1}^{n}(|A||\psi_i| + |\eta_i|)\\ &\le \mathbf{u}(|r_m| + N|A||x_m|) + |A|\mathbf{u}\Sigma_{i=m+1}^{n}|\hat{x}_i|\\ &\quad + \mathbf{u}\Sigma_{i=m+1}^{n}|\hat{r}_i| + 2\mathbf{u}N|A|\Sigma_{i=m+1}^{n}|\hat{x}_i| + O(\mathbf{u}^2)\\ &= \mathbf{u}N|A||x_m| + \mathbf{u}(1+2N)|A|\Sigma_{i=m+1}^{n}|\hat{x}_i| + \mathbf{u}\Sigma_{i=m}^{n}|r_i| + O(\mathbf{u}^2),\end{aligned}$$

which leads to the bound for δ_n in terms of norms. $\square$

We note that it is possible to obtain a sharper bound by accumulating the vectors in the bound for $|\delta_n|$. Our experiments do not show any significant advantage of such an approach. We next consider the perturbation to the recurrence.

THEOREM 3.5. *Consider step n of the iteration and let $m < n$ be the last step before n, at which a residual replacement is carried out. If replacement is also done at step n, then let $x'_n = fl(x_m + \hat{x}_n) = x_m + \hat{x}_n + \zeta_n$ be the computed approximate solution and $r'_n = fl(b - Ax'_n) = b - Ax'_n + \xi_n$ be the residual. Then the residual r'_n satisfies the following approximate recurrence:*

$$r'_n = r_{n-1} - Aq_n + \eta'_n, \tag{15}$$

where $\eta'_n = \eta_n + \delta_n - A\zeta_n + \xi_n$ and

$$\|\eta'_n\| \le \mathbf{u}\|A\|(1+2N)(\|x_m\| + \Sigma_{i=m+1}^{n}\|\hat{x}_i\|) + \mathbf{u}\Sigma_{i=m}^{n}\|r_i\| + O(\mathbf{u}^2). \tag{16}$$

Proof. First, in the notation of Algorithm 2, $x'_n = x_m + \hat{x}_n + \zeta_n = x_n + \zeta_n$. Then,

$$\begin{aligned} r'_n &= b - Ax_n - A\zeta_n + \xi_n \\ &= r_n + \delta_n - A\zeta_n + \xi_n \\ &= r_{n-1} - Aq_n + \eta_n + \delta_n - A\zeta_n + \xi_n \\ &= r_{n-1} - Aq_n + \eta'_n, \end{aligned}$$

where we have used that $b - Ax_n = r_n + \delta_n$ and $r_n = \hat{r}_n = r_{n-1} - Aq_n + \eta_n$. Furthermore, by Lemma 3,

$$\eta_n + \delta_n = \xi_m - \Sigma_{i=m+1}^{n} A\psi_i - \Sigma_{i=m+1}^{n-1}\eta_i.$$

Also, $\|A\zeta_n\| \leq \mathbf{u}\|A\|(\|x_m\| + \|\hat{x}_n\|)$ and $\|\xi_n\| \leq \mathbf{u}(\|r'_n\| + N\|A\|\|x'_n\|) + O(\mathbf{u}^2) \leq \mathbf{u}(\|r'_n\| + N\|A\|\|x_m\| + N\|A\|\|\hat{x}_n\|) + O(\mathbf{u}^2)$. Combining these three inequalities, and using that $r'_n = r_n + O(\mathbf{u})$, the bound on $\|\eta'_n\|$ is obtained as in Lemma 4. ∎

Note that bound (16) is computable at each iteration step. Therefore, we can implement the residual replacement criterion (8) with this bound instead of $\|\eta'_n\|$. We note that the factor 2 in the bound comes from the bound for q_i in Lemma 2, which is pessimistic since $q_i \sim \hat{x}_i$. Therefore, we can use the following d_n as an estimate for $\|\eta'_n\|$:

$$d_n \equiv \mathbf{u}N\|A\|(\|x_m\| + \Sigma_{i=m+1}^{n}\|\hat{x}_i\|) + \mathbf{u}\Sigma_{i=m}^{n}\|r_i\|. \tag{17}$$

Hence, we shall use the following residual replacement criterion, that is, residual replacement is done if

$$d_{n-1} \leq \epsilon\|\hat{r}_{n-1}\| \text{ and } \; d_n > \epsilon\|\hat{r}_n\|. \tag{18}$$

With this strategy, the replaced residual vector r_n satisfies the recurrence equation (15) with $\|\eta'_n\| \sim O(\epsilon)\|\hat{r}_n\|$. With this property, we consider situations where r_n converges. We now discuss convergence of the true residual.

THEOREM 3.6. *Consider Algorithm* 2 *with the residual replacement criterion* (18)*, and assume that the algorithm terminates at step* $n = K$ *with* $\|r_K\| < \mathbf{u}\|A\|\,\|x_K\|$*. Let* m *be the number of the last residual replacement iteration step before termination. If*

$$L = (K - m + 1)(1 + 2N)\|A\|\|A^{-1}\|(1 + 3/\epsilon) < 1/\mathbf{u}, \tag{19}$$

then

$$\begin{aligned} \|b - Ax_K\| &\leq \|r_K\| + \mathbf{u}N\|A\|\|x_K\|/(1 - \mathbf{u}L) + O(\mathbf{u}^2) \\ &\sim \mathbf{u}N\|A\|\|x_K\|. \end{aligned}$$

Proof. From (17), we have $d_K > \mathbf{u}N\|A\|(\|x_m\| + \|\hat{x}_K\|) \geq \mathbf{u}\|A\|\,\|x_K\|$. Furthermore, at the termination step, we have $\|r_K\| < \mathbf{u}\|A\|\,\|x_K\|$ and hence $d_K > \|r_K\| > \epsilon\|r_K\|$. Since m is the last updating step, we have for $n \geq m$, $d_n > \epsilon\|r_n\|$ as otherwise there would be another residual replacement after m. That implies $\|r_n\| < d_n/\epsilon \leq d_K/\epsilon$. Define

$$\tilde{d}_n \equiv \mathbf{u}N\|A\|\|x_m\| + \mathbf{u}\|A\|(1 + 2N)\Sigma_{i=m+1}^{n}\|\hat{x}_i\| + \mathbf{u}\Sigma_{i=m}^{n}\|\hat{r}_i\|,$$

which is an upper bound for $\|\delta_n\|$ (Lemma 4) and $\tilde{d}_n \geq d_n$. Then

$$\begin{aligned}\|\hat{x}_n\| &= \|x_n - x_m\| = \|A^{-1}((b - Ax_m) - (b - Ax_n))\| \\ &= \|A^{-1}(r_m + \delta_m - r_n - \delta_n)\| \\ &\leq \|A^{-1}\|(\|r_m\| + \|r_n\| + \|\delta_n - \delta_m\|) \\ &\leq \|A^{-1}\|(1 + 2/\epsilon)\tilde{d}_K + O(\mathbf{u}^2),\end{aligned}$$

where $\|\delta_n - \delta_m\| \leq \tilde{d}_n + O(\mathbf{u}^2) \leq \tilde{d}_K + O(\mathbf{u}^2)$. Thus,

$$\begin{aligned}\tilde{d}_K &= \mathbf{u}N\|A\|\|x_K - \hat{x}_K\| + \mathbf{u}(1 + 2N)\|A\|\Sigma_{i=m+1}^{K}\|\hat{x}_i\| + \mathbf{u}\Sigma_{i=m}^{K}\|\hat{r}_i\| \\ &\leq \mathbf{u}N\|A\|\|x_K\| + \mathbf{u}N\|A\|\|\hat{x}_K\| + \mathbf{u}(1 + 2N)\|A\|\Sigma_{i=m+1}^{K}\|\hat{x}_i\| + \mathbf{u}\Sigma_{i=m}^{K}\|\hat{r}_i\| \\ &\leq \mathbf{u}N\|A\|\|x_K\| + \mathbf{u}(K - m + 1)(1 + 2N)\|A\|\|A^{-1}\|(1 + 2/\epsilon)\tilde{d}_K \\ &\quad + \mathbf{u}(K - m + 1)\tilde{d}_K/\epsilon + O(\mathbf{u}^2) \\ &\leq \mathbf{u}N\|A\|\|x_K\| + \mathbf{u}(K - m + 1)(1 + 2N)\|A\|\|A^{-1}\|(1 + 3/\epsilon)\tilde{d}_K + O(\mathbf{u}^2) \\ &\leq \mathbf{u}N\|A\|\|x_K\| + \mathbf{u}L\tilde{d}_K + O(\mathbf{u}^2),\end{aligned}$$

which implies

$$\tilde{d}_K \leq \mathbf{u}N\|A\|\|x_K\|/(1 - \mathbf{u}L) + O(\mathbf{u}^2).$$

Thus the bound follows from

$$\|b - Ax_K\| \leq \|r_K\| + \|\delta_K\| \leq \|r_K\| + \tilde{d}_K + O(\mathbf{u}^2). \qquad \square$$

We add two remarks with respect to this theorem.

Remark 1. If the main condition (19) is satisfied, then the deviation, and hence the true residual, will remain at the level of $\mathbf{u}N\|A\|\|x_K\|$ at termination. Such an approximate solution is backward stable and it is the best one can expect. The condition suggests that ϵ should not be chosen too small. Otherwise, the replacement strategy will be terminated too early so that the accumulation after the last replacement might become significant. As can be expected, however, the theoretical condition is more restrictive than practically necessary and our numerical experience suggests that ϵ can be much smaller than what (19) dictates, without destroying the conclusion of the theorem.

Remark 2. On the other hand, in section 2.1 we have seen that ϵ controls perturbations to the recurrence of r_n, and for this reason it is desirable to choose it as small as possible. In our experience, there is a large range of ϵ around $\sqrt{\mathbf{u}}$ that balances the two needs.

4. Reliable implementation of iterative methods. In this section, we summarize the main results of the previous sections into a complete implementation. We also address some implementation issues.

It is easy to see from the definition of d_n (see (17)) that it increases except at the residual replacement steps when it is reset to $\mathbf{u}(N\|A\|\|x_m\| + \|r_m\|)$. Our residual replacement strategy is to reduce d_n whenever necessary (as determined by the replacement criterion) so as to keep it at the level of $\mathbf{u}N\|A\|\|x_K\|$ at termination. With the use of criterion (18), however, there are situations where the residual replacement is carried out in consecutive steps while d_n remains virtually unchanged, namely, when $\|r_n\|$ stays around $d_n/\epsilon \sim \mathbf{u}N\|A\|\|x_n\|/\epsilon$. From the stability point of view, it is preferred not to replace the residuals in such situations. To avoid unnecessary replacement in such cases, we impose as an additional condition that residual

replacement is carried out only when d_n has a nontrivial increase from the d_m of the previous replacement step m.

Therefore, we propose $d_n > 1.1d_m$ as a condition in addition to (18) for the residual replacement. The following scheme sketches a complete implementation.

ALGORITHM 3. Reliable implementation of Algorithm 1.

Input: an initial approximation $z = x_0$;
  a residual replacement threshold ϵ; an estimate of $N\|A\|$;
Set $r_0 = b - Ax_0$; $\hat{x}_0 = 0$; $d_{init} = d_0 = \mathbf{u}(\|r_0\| + N\|A\|\|x_0\|)$,
For $n = 1, 2, \ldots$ until convergence
  generate a correction vector q_n by the iterative method;
  $\hat{x}_n = \hat{x}_{n-1} + q_n$,
  $r_n = r_{n-1} - Aq_n$,
  $d_n = d_{n-1} + \mathbf{u}N\|A\|\,\|\hat{x}_n\| + \mathbf{u}\|r_n\|$,
  if $d_{n-1} \le \epsilon\|r_{n-1}\|$, $d_n > \epsilon\|r_n\|$ and $d_n > 1.1d_{init}$
    $z = z + \hat{x}_n$,
    $\hat{x}_n = 0$,
    $r_n = b - Az$,
    $d_{init} = d_n = \mathbf{u}(\|r_n\| + N\|A\|\|z\|)$
  end if
End for
$z = z + \hat{x}_n$

Remark. For this reliable implementation, we need to put a value for N (the maximal number of nonzero entries per row of A) and $\|A\|$. The number of nonzero entries may, in applications, vary from row to row, and selecting the maximum number may not be very realistic. In our experience with sparse matrices, the simple choice $N = 1$ still leads to a practical estimate d_n for $\|\delta_n\|$. In any case, we note that precise values are not essential, because the replacement threshold ϵ can be adjusted. We also need to choose this ϵ. Our extensive numerical testing (see section 5) suggests that $\epsilon \sim \sqrt{\mathbf{u}}$ is a practical criterion. However, there are examples where this choice leads to stagnating residuals at some unacceptable level. In such cases, choosing a smaller ϵ will regain the convergence to $O(\mathbf{u})$.

The presented implementation requires one extra matrix-vector multiplication when an replacement is carried out. Since only a few steps with replacement are required, this extra cost is marginal relative to the other costs. However, some savings can be made by selecting a slightly smaller ϵ and carrying out residual replacement at the step next to the one for which the residual replacement criterion is satisfied (cf. [19]). It also requires one extra vector storage for the groupwise solution update (for z) and computation of a vector norm $\|\hat{x}_n\|$ for the update of d_n ($\|r_n\|$ is usually computed in the algorithm for stopping criteria).

5. Numerical examples. In this section, we present some numerical examples to show how Algorithm 3 works and to demonstrate its effectiveness. We present our testing results for CG, BiCG, and CGS. All tests are carried out in MATLAB on a SUN Sparc-20 workstation, with $\mathbf{u} \approx 10^{-16}$.

In all examples, unless otherwise specified, the replacement threshold ϵ is chosen to be 10^{-8}. $\|A\|_\infty$ is explicitly computed and N is set to 1. In Examples 1 and 2, we also compare d_n and the deviation $\|\delta_n\|$.

Example 1. The matrix is a finite-difference discretization on a 64×64 grid for

$$-\nabla(a(x,y)\nabla u) = f(x,y) \text{ on } R = (0,1) \times (0,1),$$

with a homogeneous Dirichlet boundary condition. $a(x,y) = exp(y^2)$ and $f(x,y) = x^2y$. We apply CG and reliable CG (i.e., Algorithm 3) to solve this linear system and the convergence results are given in Figure 1.

In Figure 1 (and similarly in Figures 2 and 3 for the next example), we give in (a) the convergence history of the (normalized) computed residual for CG (solid line), the (normalized) true residuals for CG (dash line), and for reliable CG (dotted line). In (b), we also give the (normalized) deviations of the two residuals $\|\delta_n\| = \|b - Ax_n - r_n\|$ for CG (dash-dotted line) and for reliable CG (dotted line) and the bound d_n for reliable CG (in x-mark).

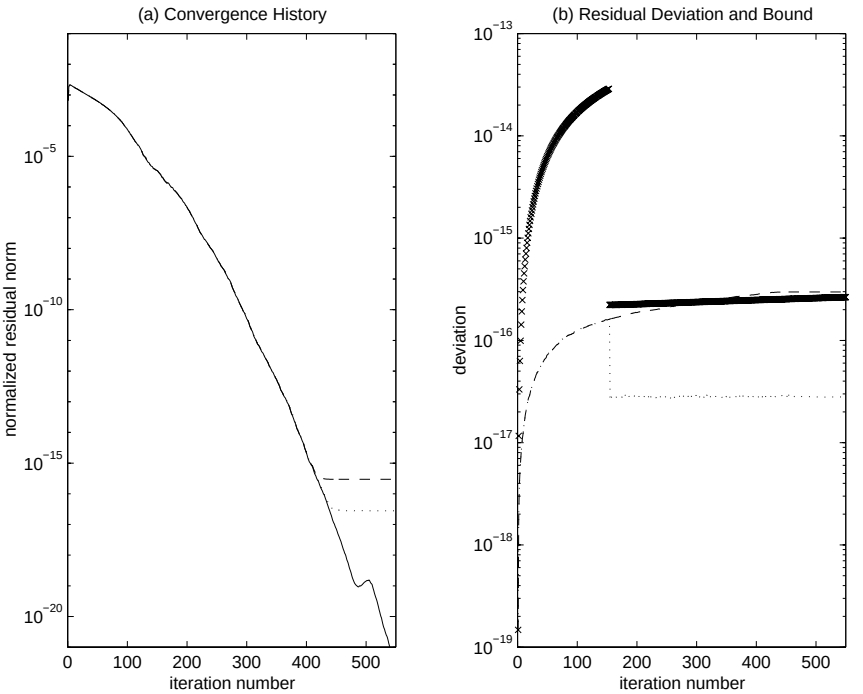

FIG. 1. *Example* 1. *CG:* (a) *solid—computed residual of CG; dash—true residual of CG; dotted—true residual of reliable CG;* (b) *dash-dotted—*$\|b - Ax_n - r_n\|$ *of CG; dotted—*$\|b - Ax_n - r_n\|$ *of reliable CG;* x*—bound* d_n *for reliable CG.*

This example is to illustrate that even for CG, our refined implementation can slightly improve the true residual. We note, however, that such an improvement is very minor and would only be useful when a solution of highest accuracy possible is wanted. Also note that in CG it is possible to estimate the A-norm of the true residual without explicitly computing it (see [9]).

We next consider applications to BiCG and CGS.

Example 2. The matrix is a finite-difference discretization on a 64×64 grid for the following convection diffusion equation:

$$-\triangle u + \gamma(xu_x + yu_y) + \beta u = f(x,y) \quad \text{on} \quad (0,1)^2,$$

with a homogeneous Dirichlet boundary condition. The function f is a constant. We consider BiCG and CGS for solving the linear systems with $\gamma = -250, \beta = 0$, and $\gamma = -10, \beta = 1$, respectively. The results are shown in Figure 2 for BiCG and in Figure 3 for CGS.

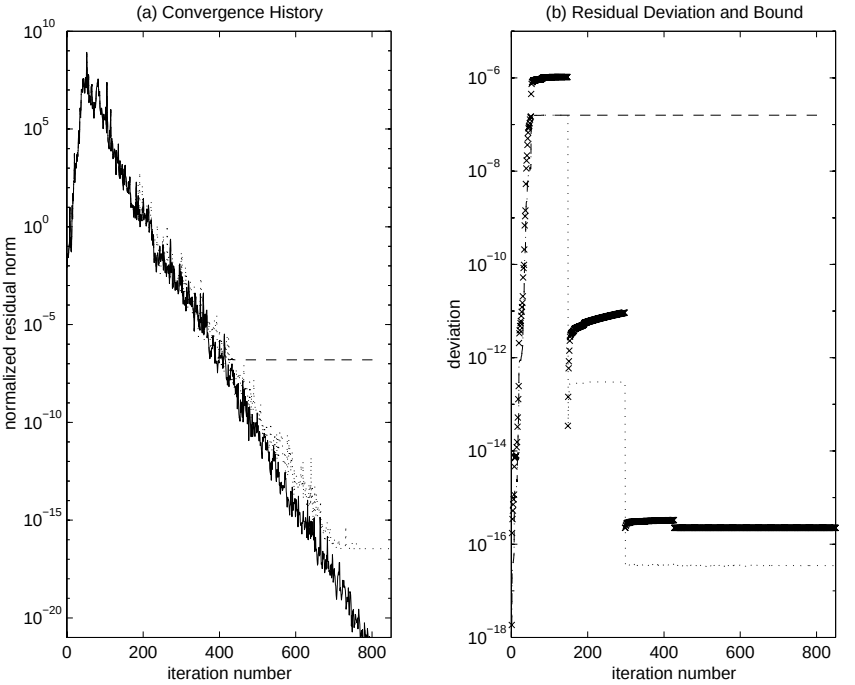

FIG. 2. *Example* 2. *BiCG:* (a) *solid—computed residual of BiCG; dash—true residual of BiCG; dotted—true residual of reliable BiCG;* (b) *dash—*$\|b - Ax_n - r_n\|$ *of BiCG; dotted—*$\|b - Ax_n - r_n\|$ *of reliable BiCG;* x*—bound* d_n *for reliable BiCG.*

In the above examples, we have observed the following typical convergence behavior. For the original implementations, the deviation increases and finally stagnates at some level, which is exactly where the true residual stagnates, while the computed residual continues to converge. With the reliable implementations, when the deviation increases to a certain level relative to r_n, a residual replacement is carried out and this reduces the error level. Eventually, the deviation and hence the true residual arrives at the level of $\mathbf{u}\|A\|\|x\|$. We also note that the bound d_n captures the behavior of $\|\delta_n\|$ very closely, although it may be an overestimate for δ_n by a few orders of magnitude. In all three cases, the final residual norms for the reliable implementation are smaller than the ones as obtained by the MATLAB function $A\backslash b$.

Example 3. In this case, we have tested the algorithm for BiCG (or CG if symmetric definite) and CGS on the Harwell–Boeing collection of sparse matrices [3]. We compare the original implementations, the reliable implementations, and the implementations of Sleijpen and van der Vorst [19] (based on their replacement criteria (16) and (18)). In Table 1, we give the results for those matrices for which the computed residuals converge to a level smaller than $\mathbf{u}\|A\|\|x\|$ so that there is a deviation of the two residuals. For those cases where b is not given, we choose it such that a given random vector is the solution. We note that for some matrices, it may take $10n$ iterations to achieve that, which is not practical. However, we have included these results in order to show that even with excessive numbers of iterations, we still arrive at small true residuals eventually. We list the normalized residuals $res = \|b - Ax_n\|/(\|A\|\|x_n\|)$ attained by the three implementations and by Gaussian elimination with partial pivoting (MATLAB $A\backslash b$). We also list the number of residual

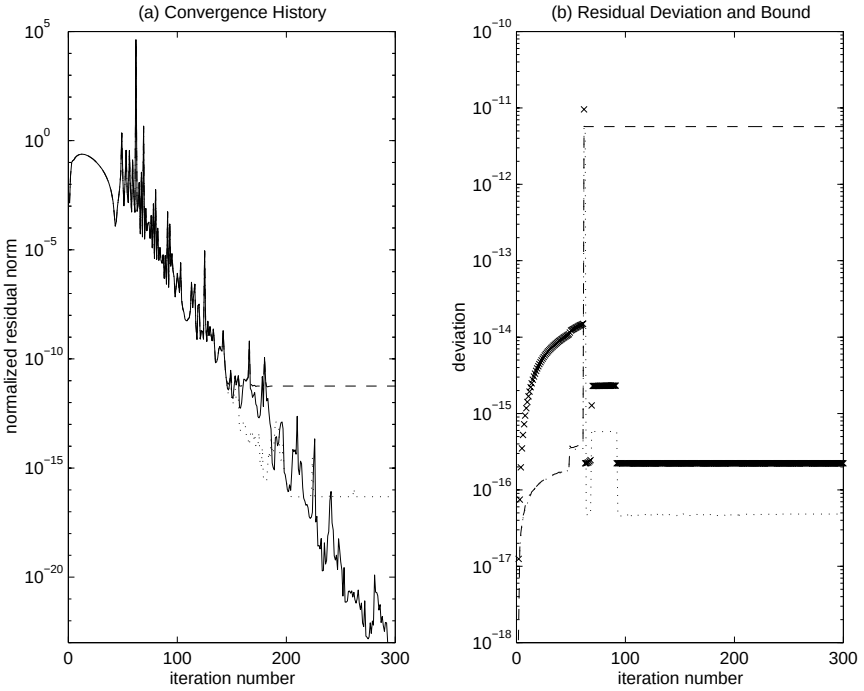

FIG. 3. *Example* 2. *CGS:* (a) *solid—computed residual of CGS; dash—true residual of CGS; dotted—true residual of reliable CGS;* (b) *dash—*$\|b - Ax_n - r_n\|$ *of CGS; dotted—*$\|b - Ax_n - r_n\|$ *of reliable CGS;* x*—bound* d_n *for reliable CGS.*

replacements (n_r) for our reliable implementations and the number of flying-restart (n_f) and the number of residual replacements (n_r) for the implementations of Sleijpen and van der Vorst (SvdV). There are two cases for which the computed residuals do not converge to $O(\mathbf{u})$ with the choice of $\epsilon = 1e-8$. For those cases, a slightly smaller ϵ will recover the stability and the results are listed in the last row of the table.

We see that in all cases, the reliable implementation reduces the normalized residual to $O(\mathbf{u})$ and $res2$ is the smallest among the three implementations, even smaller than MATLAB $A\backslash b$. The improvement on the true residual is more apparent in CGS than in BiCG (or CG). Except in a few cases, both the reliable implementation presented here and the implementation of Sleijpen and van der Vorst work well and are comparable. So the main advantage of the new approach is its simplicity and an occasional improvement in accuracy.

6. Concluding remarks. We have presented a new residual replacement scheme for improving the convergence of the true residuals in finite precision implementations of Krylov subspace iterative methods. By carefully monitoring the deviation of the computed residual and the true residual and incorporating the earlier ideas on residual replacement, we obtain a reliable implementation that preserves the convergence mechanism of the computed residuals, as well as sufficiently small deviations. An error analysis shows that this approach works under certain conditions, and numerical tests demonstrate its effectiveness. Comparison with an earlier approach shows that the new scheme is simpler and easier to implement as an add-on to existing implementations for iterative methods.

1: zero pivot encountered in $A\backslash b$
2: $res2 = 1e-17$, if $\epsilon = 1e-12$; 3: $res2 = 1e-17$, if $\epsilon = 1e-12$;

We point out that the basis for the present work is the understanding that the convergence behavior (of computed residuals) in finite precision arithmetic is preserved under small perturbations to the recurrence relations. Such a supporting analysis is available for BiCG (and CG) [22], but it is still an empirical observation for most other Krylov subspace methods. It would be interesting to derive a theoretical analysis confirming this phenomenon for those methods as well.

Acknowledgments. We would like to thank Ms. Lorrita McKnight for assistance in carrying out the tests on Harwell–Boeing matrices. We thank both referees for their helpful comments.

A PARTICLE-PARTITION OF UNITY METHOD FOR THE SOLUTION OF ELLIPTIC, PARABOLIC, AND HYPERBOLIC PDES*

MICHAEL GRIEBEL† AND MARC ALEXANDER SCHWEITZER†

Abstract. In this paper, we present a meshless discretization technique for instationary convection-diffusion problems. It is based on operator splitting, the method of characteristics, and a generalized partition of unity method. We focus on the discretization process and its quality. The method may be used as an h-version or a p-version. Even for general particle distributions, the convergence behavior of the different versions corresponds to that of the respective version of the finite element method on a uniform grid. We discuss the implementational aspects of the proposed method. Furthermore, we present the results of numerical examples, where we considered instationary convection-diffusion, instationary diffusion, linear advection, and elliptic problems.

Key words. meshless methods, gridless discretizations, particle methods, Galerkin methods, partition of unity methods, Lagrange multipliers, h-version, p-version, advection, convection-diffusion

1. Introduction.

The discretization of partial differential equations (PDEs) is usually obtained by covering the domain of interest by a suitable grid. Then, after time discretization, linearization, and space discretization (by finite elements, finite differences, or finite volumes), a linear system of discrete equations is set up and solved. Here, beside uniform structured grids which are most simple to handle, block structured grids and unstructured grids also are employed successfully. Furthermore, for dealing with nonsmooth data or solutions, adaptive refinement is a must for efficiency reasons; see [7, 8, 9, 10, 13, 22, 23, 39, 64].

However, all grid- or mesh-based methods are quite involved when it comes to time-dependent problems with complicated geometries, free moving boundaries, and interfaces. Then the geometry of the domain may change over time, the nonsmooth part of the data or the nonsmooth part of the solution changes with time, or the location of singularities of the solution may vary time dependently. Examples for such problems are crack propagation in elasticity theory [12], free surface flow or multiphase flow in fluid dynamics [65], or accretion disks, jets, and cloud simulations in magnetohydrodynamics [20].

In the Eulerian approach, an adaptive mesh technique (h-version, hp-version) must follow the time-dependent features of the data or solution by local refinement and coarsening of the mesh [7, 22, 39, 46, 64]. But time-dependent adaptive mesh refinement and coarsening is not simple, especially for three-dimensional (3D) problems. It is quite involved, programming is complicated, data structures are not easy to handle, and the storage overhead is significant. Besides, good local and global error estimators are necessary. Therefore, there exist only a few unstructured adaptive programs which are able to handle 3D application-oriented problems with time-dependent change of the geometry, the data, or the solution.

†Sonderforschungsbereich 256 Nonlinear Partial Differential Equations, Project D Meshless numerical methods for the simulation of 3D flows with free boundaries, Institut für Angewandte Mathematik, Universität Bonn, Wegelerstr. 6, D-53115 Bonn, Germany (griebel@iam.uni-bonn.de, schweitz@iam.uni-bonn.de).

The Lagrangian viewpoint allows the mesh itself to be moved (r-method) [6, 53, 54]. But an implementation is still cumbersome, since the mesh may become tangled and twisted, elements may collapse, or angles of some elements may degenerate over time due to the movement of the nodes. The proper treatment of these problems is not an easy task, especially in 3D applications. At least for the two-dimensional (2D) case, the so-called monotone mesh method [65] can cope with these problems to some extent.

Besides, in real life engineering applications, a very time-consuming portion of the overall computation is the mesh generation from CAD input data. Typically, more than 70 percent of the overall computing time is spent by mesh generators.

Hence, especially within the engineering community, there is growing interest in other discretization methods which involve no mesh at all. These approaches are summarized under the term meshless or gridless methods. The main idea is to consider points only, i.e., we omit any fixed relation between the nodes such as element boundaries, and to move just these points in a time-dependent setting. Here, the location of the points and the distribution of the points account for the description of the changing geometry, the change in data, and the time-dependent changing variation of the solution or its gradient.

Generally speaking, there are two different types of meshless approaches—the classical particle methods [57, 58, 60, 61], and gridless discretizations based on data fitting techniques [11, 26]. Traditional particle methods stem from physics applications like Boltzmann equations [1, 33]. They are truly Lagrangian methods, i.e., they are based upon a time-dependent formulation or conservation law. In a particle method we use a discrete set of points to discretize the domain of interest and the solution at a certain time. The PDE is transformed into equations of motion for the discrete set of particles such that the particles can be moved via these equations. After time discretization of the equations of motion we obtain a certain particle distribution for every time step. Therefore, we get an approximate solution to the PDE via the definition of a density function for these particle distributions. These methods are easy to implement. However, they exhibit in general relatively poor convergence properties in weak norms.

The so-called gridless methods follow a different approach. Here, patches or volumina are attached to each point whose union forms an open covering of the domain. Then, local shape functions are constructed with the help of methods from data fitting. These shape functions are used in a Galerkin or collocation discretization process to set up a linear system of equations. Finally this system must be solved efficiently. In contrast to particle methods, such gridless discretizations may also be applied to stationary and elliptic problems. According to the data fitting method involved we can distinguish basically the following three approaches: Shepard's method [69], which has a consistency of first order only, the moving least squares method (MLSM) [44, 45], which generalizes Shepard's approach implicitly to the case of higher order shape functions, and the partition of unity p-version method, which generalizes Shepard's approach explicitly to higher consistency orders. Meanwhile, different realizations of these approaches exist. First, there is the smoothed particle hydrodynamics (SPH) technique of Lucy and Monaghan [31, 32, 51, 55, 56, 71], which resembles (up to area weighted scaling) Shepard's method. Then, Duarte and Oden [26, 27] used in their hp-cloud approach the moving least squares (MLS) idea. Belytschko and coworkers [11, 12] apply similar techniques based on the MLS approach to engineering problems. Furthermore, Dilts [24] used the MLS technique to extend the SPH method to the

so-called MLS particle hydrodynamics (MLSPH) method. Babuška and Melenk [3, 4] proposed the so-called partition of unity method (PUM), which mainly has been applied to uniform point distributions up to now. Liu, Jun, and Zhang [50] proposed variants of the SPH method based on the idea of reproducing kernels of higher order and wavelets. There also exist generalizations of the finite difference approach to the gridless setting [49]. Furthermore, Kansa [40, 41], Franke and Schaback [28, 29], and Wendland [73] used the radial basis approach from approximation theory to construct meshless methods for the discretization of PDEs. The mass-packet method of Yserantant [74, 75] is somewhat different from the classical particle methods. Here, the particles are not considered in the sense of statistical mechanics but they are understood as comparatively big mass-packets, and the conservation of mass is automatically guaranteed by this ansatz. For an overview on meshless methods see [76] and the references therein.

All these data fitting approaches do not depend (at least to a great extent) upon a mesh or any fixed relation between gridpoints (particles). However, the realization and implementation of such a method is not so simple in general: there are often problems with stability and consistency. Furthermore, in a Galerkin method, the discretization of the differential operator, i.e., the integration of the stiffness matrix entries, is in general quite involved in comparison with the conventional grid-based approach. Another challenging task is the discrete formulation of Dirichlet boundary conditions, since the constructed shape functions are in general noninterpolatory. Nevertheless, the different variants of gridless methods are interesting from both the practical and the theoretical point of view. These methods, which are up to now merely in an experimental premature state, possess some potential and might have an interesting future.

The meshless method we propose in this paper is based on the Lagrangian approach for time-dependent problems used within classical particle methods and the ideas of Babuška and Melenk [3, 4], but it allows for a random point distribution. We consider time-dependent convection-diffusion problems, which we decompose into a parabolic and a hyperbolic subproblem using a simple operator splitting. The hyperbolic problem is discretized via a Lagrange-type particle method, i.e., we define equations of motion for the particles corresponding to the problem and move the particles accordingly. We discretize the remaining parabolic subproblem with a two-step Particle–Galerkin method. In the first step we move the particles $\{x_i\}$ via a Monte Carlo step to adapt the particle distribution to the diffusion process. Then, an implicit Eulerian time discretization reduces the parabolic problem to an elliptic problem in every time step. For its discretization in space we employ the PUM approach to randomly distributed points $\{x_i\}$. Here, following ideas from scattered data approximation [21, 69], we set up a partition of unity $\{\varphi_i\}$ over the domain Ω using a localized version of Shepard's method. Since a partition of unity achieves first order consistency only, we need to improve on the approximation quality of the constructed space $V = \operatorname{span}(\{\varphi_i\})$ to allow its use in a collocation or Galerkin method. Thus, we expand the functions φ_i by multiplication with a local polynomial ψ^i of degree p_i, defined on $\operatorname{supp}(\varphi_i)$, and we define the space $V = \operatorname{span}(\{\varphi_i\psi^i\})$. We use these functions as trial and test functions in a Galerkin method. Altogether we obtain an analogue of the h-, p-, and hp-version of the finite element method for general particle distributions. Furthermore, the results of our numerical experiments show that the convergence properties of the proposed method are similar to those of the finite element method.

The remainder of this paper is organized as follows. In section 2, we develop a Lagrangian discretization of the instationary convection-diffusion problem using a simple operator splitting. The resulting hyperbolic subproblem is discretized via a particle method, which is presented in section 3. For the remaining parabolic problem we use a simple time stepping technique. It reduces the parabolic problem to a sequence of elliptic problems. In section 4, we discuss their discretization using a generalized Particle–Galerkin method based on the PUM. Then, in section 5, we present the results of our numerical experiments. Finally, we give some concluding remarks.

2. An operator splitting method for instationary convection-diffusion problems. A widely used approach for the discretization of instationary convection-diffusion problems

$$\begin{array}{rcll} \nabla A \nabla u + v \nabla u & = & u_t & \text{for all } (x,t) \in \Omega \subset \mathbb{R}^d \times (0,T), \\ u(x,0) & = & u_0(x) & \text{for all } x \in \Omega \subset \mathbb{R}^d, \\ Bu(x,t) & = & g(x,t) & \text{for all } (x,t) \in \partial\Omega \times (0,T) \end{array} \tag{2.1}$$

is the operator splitting method [70]. This method can be summarized as follows: Let $S(t)$ be the solution operator for the hyperbolic problem

$$v \nabla u^A = u_t^A, \quad u^A(x,0) = u_0^A(x) \tag{2.2}$$

such that $u^A(x,t) = S(t)u_0^A(x)$ is the entropy solution to (2.2), and let $H(t)$ be the solution operator for the parabolic problem

$$\nabla A \nabla u^D = u_t^D, \quad u^D(x,0) = u_0^D(x), \quad Bu^D(x,t) = g(x,t) \mid_{\partial\Omega} \tag{2.3}$$

such that $u^D(x,t) = H(t)u_0^D(x)$ is the solution to (2.3). A combination of these two continuous solution operators is used as an approximative solution operator for (2.1). This continuous solution operator is evaluated at certain times but is still kept continuous in space, i.e.,

$$u_n(x) = u(x, n\Delta t) \approx [H(\Delta t)S(\Delta t)]^n u_0(x) \tag{2.4}$$

is the semidiscrete approximative solution to (2.1) at time $n\Delta t$. Based on this principle, different variants of the method have been developed; see [37, 38, 48]. The splitting (2.4) inherits its approximation properties from $H(t)$ and $S(t)$, depending on the respective time discretization. In this paper we stick to the most straightforward approach (2.4) for reasons of simplicity.

Now the next step in the discretization process of (2.1) is the choice of approximations to the solution operators $S(t)$ and $H(t)$. The hyperbolic problem (2.2) can be solved analytically with the help of the method of characteristics. Therefore, a natural choice for the discretization of (2.2) is a method which can exploit this knowledge about a continuous solution to (2.2). Such a method would be a Lagrangian particle method, since here a characteristic through a given point x_i^A in space may be interpreted as the path the point will follow over time. This particle method works as follows: First, we sample the initial value u_0 in appropriate points $\{x_i^A\}$; this gives a set of pairs $\{(x_i^A, u_0^i)\}$. Then, we construct the characteristic through every particle x_i^A at time t and move each particle along its corresponding characteristic to its new position at time $t + \Delta t$. Finally, we define an approximate solution $\tilde{u}$ at time $t + \Delta t$

using shape functions that are constructed with respect to the particle distribution. This process is covered in more detail in section 3.

Now, the discretization of the parabolic problem (2.3) should be compatible to the discretization of (2.2). Since we use a Lagrangian particle method for (2.2), we need a discretization method for (2.3) which can handle (almost) random distributions of nodes (particles). Moreover, we want to treat (2.3) also from the Lagrangian point of view. In a pure particle method a parabolic problem like (2.3) is discretized using a Monte Carlo method. Here the shape functions themselves—not only the particles—are moved across the domain without being changed, which causes the poor accuracy of these methods. In our approach we also move the particles. The shape functions, however, are not only moved across the domain. We construct new shape functions in every time step based on the new particle distribution.

We move the particles across the computational domain to simulate the effect of the diffusive transport of (2.3) on the shape functions and approximation space which adapts the distribution of the spatial degrees of freedom only. An approximate solution of (2.3) is then computed via a variational approach with the newly generated approximation space. Therefore the proposed method inherits the advantages of particle methods in adapting the particle distribution via a Monte Carlo step but does not inherit the poor approximation quality of a Monte Carlo method.

Overall we propose the following three-step approximation of (2.3):

1. Time discretization of (2.3) and $u(x,t)$:

$$\begin{aligned} (0,T) &\rightarrow (t_0,\dots,t_n), \quad t_k = k\Delta t, \\ u(x,t) &\rightarrow u(x,t_k) = u^k(x), \\ \nabla A \nabla u^D = u_t^D &\rightarrow -\Delta t \nabla A \nabla u_{m+1}^D + u_{m+1}^D = u_m^D. \end{aligned}$$

2. Use a Monte Carlo step to translate the diffusion equation (2.3) into equations of motion for the particles $\{x_i^A\}$, i.e., use a random walk process

$$x_i^A \rightarrow x_i^A + \sqrt{2\Delta t} A^{\frac{1}{2}} \xi = x_i^D,$$

where ξ are independent random numbers with Gaussian distribution, vanishing mean, and variance one.

3. Now that the particle distribution $\{x_i^D\}$ is suitable for the approximation of the solution of (2.3) in the next time step, we approximate the remaining elliptic problem

$$-\Delta t \nabla A \nabla u_{m+1}^D + u_{m+1}^D = u_m^D \tag{2.5}$$

using a spatial discretization method which allows the use of a random node arrangement. Here, a gridless method seems to be the most natural choice.

In section 4 we present a generalized partition of unity method for elliptic problems, give a short discussion on the implementational difficulties—which are often neglected in other papers, and give some ideas on how to overcome these difficulties.

3. A Lagrangian discretization of hyperbolic problems using a particle method. The main problem of an Eulerian discretization is the following: The initial mesh may be adapted to the initial data but may not be appropriate for the resolution of the solution in future time steps. Therefore we have to use expensive coarsening and refinement strategies—or even complete remeshing—to adapt the mesh to the solution

over time. In contrast to that, a Lagrangian discretization uses the given PDE itself to define a transformation that maps the distribution of the spatial degrees of freedom to appropriate positions over time. Hence, the degrees of freedom follow the solution over time.

We consider the 2D transport problem

$$\frac{\partial u}{\partial t}(p,q,t) + a(p,q,t,u)\nabla_{(p,q)}u(p,q,t) = 0 \tag{3.1}$$

in $\Omega \times (0,T)$ with $\Omega \subset \mathbb{R}^2$ and the general transformation

$$T : (\xi,\eta,\tau) \mapsto (p,q,t) = (p(\xi,\eta,\tau), q(\xi,\eta,\tau), t(\xi,\eta,\tau)).$$

Now we suppose that the function $u(p,q,t)$ is carried into the function $\hat{u}(\xi,\eta,\tau)$ under the transformation T, i.e.,

$$u(p,q,t) = u \circ T(\xi,\eta,\tau) = \hat{u}(\xi,\eta,\tau). \tag{3.2}$$

Using the chain rule, we obtain the τ-derivative of $\hat{u}$

$$\begin{aligned}\frac{\partial \hat{u}(\xi,\eta,\tau)}{\partial \tau} = {} & \frac{\partial u(p,q,t)}{\partial p}\frac{\partial p(\xi,\eta,\tau)}{\partial \tau} + \frac{\partial u(p,q,t)}{\partial q}\frac{\partial q(\xi,\eta,\tau)}{\partial \tau} \\ & + \frac{\partial u(p,q,t)}{\partial t}\frac{\partial t(\xi,\eta,\tau)}{\partial \tau}\,.\end{aligned} \tag{3.3}$$

If we restrict ourselves to transformations T with $t(\xi,\eta,\tau) = \tau$, we have $\partial t/\partial \tau = 1$. Simple reordering of (3.3) gives

$$\frac{\partial u(p,q,t)}{\partial t} = \frac{\partial \hat{u}(\xi,\eta,\tau)}{\partial \tau} - \frac{\partial u(p,q,t)}{\partial p}\frac{\partial p(\xi,\eta,\tau)}{\partial \tau} - \frac{\partial u(p,q,t)}{\partial q}\frac{\partial q(\xi,\eta,\tau)}{\partial \tau}\,.$$

Now we plug this relation into (3.1) and obtain the so-called Lagrangian form [6] of our PDE (3.1)

$$\frac{\partial \hat{u}}{\partial \tau} + \frac{\partial u}{\partial p}\left(a_1 - \frac{\partial p}{\partial \tau}\right) + \frac{\partial u}{\partial q}\left(a_2 - \frac{\partial q}{\partial \tau}\right) = 0\,. \tag{3.4}$$

A solution of (3.4) independent of $\nabla_{(p,q)}u$ may now be obtained from the system of ODEs

$$\frac{\partial p(\xi,\eta,\tau)}{\partial \tau} = a_1(p,q,t,u)\,, \quad \frac{\partial q(\xi,\eta,\tau)}{\partial \tau} = a_2(p,q,t,u)\,, \quad \text{and} \quad \frac{\partial \hat{u}(\xi,\eta,\tau)}{\partial \tau} = 0\,.$$

Note that this is essentially the method of characteristics. The solution $(p,q,\hat{u})$ can now be approximated by a numerical ODE solver like an Euler or Runge–Kutta method, i.e., the transformation T of (3.2) is approximated by a transformation $\tilde{T}$ which is found by numerical integration. The solution to (3.1) can then be approximated by plugging this transformation $\tilde{T}$ into (3.2), which expresses the well-known fact that a solution of (3.1) is constant along characteristics, i.e., on the images of T, giving

$$\tilde{u}(p,q,t) = u \circ \tilde{T}(\xi,\eta,\tau) \simeq \hat{u}(\xi,\eta,\tau). \tag{3.5}$$

We can evaluate the solution at the current time by evaluating the solution at a former time at the corresponding position on the characteristic. Therefore, we use a backward

integration $I^B_{\Delta t}$ to compute $\tilde{T}$. But the particles $\{x_i^t\}$ are propagated forward in time along the approximated characteristic since they have to provide the spatial resolution of the current solution, i.e., a new particle distribution $\{x_i^{(t+\Delta t)}\}$ is defined in every time step. A spatial approximation $\tilde{u}_S(x, t+\Delta t) = \sum_i u_i^{(t+\Delta t)} \phi_i^{(t+\Delta t)}(x)$ to (3.5) is set up with the use of some shape functions $\{\phi_i^{(t+\Delta t)}\}$ which are centered in these new particle positions $\{x_i^{(t+\Delta t)}\}$. Here, the specific choice of the shape functions $\{\phi_i^{(t+\Delta t)}\}$ determines the respective particle method. Since we want to combine the particle method for the hyperbolic subproblem (2.2) with our gridless discretization method for the elliptic subproblem (2.5), we use the shape functions employed there; see section 4. Again, in a pure particle method the shape functions are fixed over time, i.e., they are attached to a certain particle and never changed during the computation. Hence, the current particle position and overall particle distribution are not taken into account. This is one of the reasons for the poor approximation quality of these methods. In our approach we move the particles and construct new shape functions based on the newly generated particle distribution. Therefore, the shape functions are not fixed over time but rather always adapted to the current particle distribution.

We obtain a discrete two-step particle scheme:

1. Time discretization:
   - Treat nonlinearities of a, choose ODE solver(s) $I^{F/B}_{\Delta t}$ and time intervals
   $$(0, T) \to (t_0, \dots, t_n), \quad t_k = k\Delta t.$$
2. Spatial discretization:
   - Propagate particles $\{x_i^{k-1}\}$ forward along their characteristic
   $$x_i^k = I^F_{\Delta t}(a, x_i^{k-1}).$$
   - Project the approximate solution $\tilde{u}_S^{k-1} \circ I^B_{\Delta t}(a, \cdot)$ onto new approximation space
   $$\tilde{u}_S^k(x) = \sum u_i^k \phi_i^k(x) = \tilde{u}_S^{k-1} \circ I^B_{\Delta t}(a, x) = \sum u_i^{k-1} \phi_i^{k-1} \circ I^B_{\Delta t}(a, x).$$

The shape functions $\{\phi_i^k\}$ are constructed in every time step k according to the new particle positions $\{x_i^k\}$ (see section 4), hence the shape functions themselves are propagated along the characteristic. We compute an approximate solution $\tilde{u}_S^k$ by testing a transformed of the solution $\tilde{u}_S^{k-1}$ from the former time step with the new basis functions $\{\phi_i^k\}$, i.e., we have to solve the mass matrix problem for the new shape functions $\{\phi_i^k\}$.

4. Gridless discretization of elliptic problems. In the following, we describe our approach for a gridless discretization of an elliptic problem. The approach is roughly as follows: The discretization is stated in terms of the points only. To obtain test and trial spaces, patches or volumina $\omega_i \subset \mathbb{R}^d$ are attached to each point x_i whose union forms an open cover $\{\omega_i\}$ of the domain Ω, i.e., $\Omega \subset \bigcup \omega_i$. Now, from given weight functions W_i, local shape functions are constructed by Shepard's method. They form a partition of unity $\{\varphi_i\}$. Then, each shape function φ_i is multiplied with a sequence of local polynomials $\{\psi_i^k\}$ to gain higher degree shape functions. These are finally plugged into the weak form to set up a linear system of equations.

4.1. Construction of trial and test space using PUM. Necessary conditions for a trial and test space to perform well in a Galerkin method are local approximability and interelement continuity. Here, local approximability means that

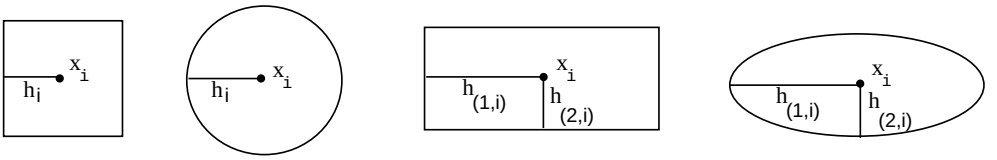

FIGURE 4.1. *Typical examples of the shapes of a patch* ω_i.

the shape functions can approximate the exact solution well locally, and interelement continuity means that any linear combination of shape functions satisfies some global continuity condition. In the finite element method (FEM) we achieve the local approximability via the choice of local polynomials and fulfill the condition of interelement continuity by imposing restrictions onto these polynomials on the element edges. The PUM approach [3, 4] instead focuses on the fulfillment of the condition of interelement continuity via the choice of an appropriate partition of unity (PU) $\{\varphi_i\}$ subordinate to a cover $\{\omega_i\}$. Local expansion of the functions φ_i by the multiplication with local approximation spaces $V_i(\omega_i)$ causes the generated space

$$V := \left\{ \sum_{i=1}^{N} \varphi_i v_i \,|\, v_i \in V_i \right\}$$

to fulfill the condition of local approximability. Theorem 4.3 (see below) states that the global approximation space V inherits the approximation quality of the local spaces V_i. Furthermore, the space V inherits the smoothness of the PU (and the local spaces V_i). Here, the approximation property of the space V may be achieved either by the smallness of the patches (h-version) or by the approximation quality of V_i (p-version).

4.1.1. Open covering of the domain. The starting point for any gridless discretization approach is a collection of N points

$$\{x_i \in \mathbb{R}^d : x_i \in \overline{\Omega}, i = 1, \ldots, N\}. \tag{4.1a}$$

Then, to each point x_i, a patch

$$\omega_i = \{x \in \mathbb{R}^d : ||x_i - x|| \leq h_i\} \subset \mathbb{R}^d \tag{4.1b}$$

is attached. Here, $h_i \in \mathbb{R}$ is the half of the diameter of the patch ω_i. The norm $||\cdot||$ is the Euclidean distance for circles or balls and it is the $||\cdot||_\infty$-norm for quadratic or cube type patches. It is easy to see that this concept can be generalized to patches of more general form: If we allow individual nonuniform sizes $h_i = (h_i^{(1)}, h_i^{(2)}, \ldots, h_i^{(d)})$ in the different coordinate directions and accordingly generalized additive norms $||\cdot||$, we obtain also patches with ellipsoid shape and rectangular or brick type objects.[1] Figure 4.1 shows typical examples of the shapes of a patch ω_i.

The construction of the patches $\{\omega_i\}$ from a given set of grid points $\{x_i\}$ is a first crucial step in the discretization process. Keeping in mind that these patches

[1]We performed experiments using different norms and thus different shapes of the local patches ω_i. It turned out that circles or balls are computationally much more difficult to handle than supports of quadratic or rectangular shape without giving substantial advantage. Therefore, we decided to stick to rectangular shapes in our gridless method.

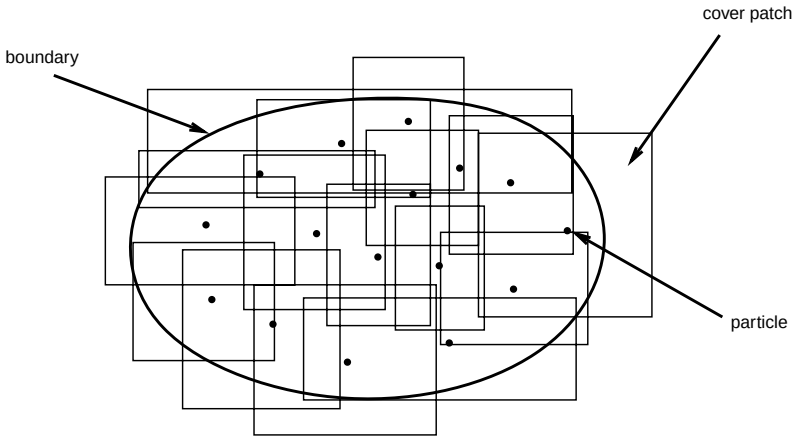

FIGURE 4.2. *Example of an open covering of* Ω.

will be the supports of the trial and test functions in a Galerkin method, the most basic property these patches have to fulfill is that they cover[2] the complete domain $\bigcup_{i=1}^{N} \omega_i \supset \overline{\Omega}$. In other words, for each point $x \in \overline{\Omega}$ there exists at least one patch ω_i which contains x. Figure 4.2 gives an example of an open covering of the domain Ω. A naive approach to the construction of such a cover $\{\omega_i\}$ would be the design of patches $\tilde{\omega_i}$ in such a way that every particle $x_i \in \tilde{\omega_j}$ for some $j \neq i$. But this procedure (in general) does not lead to a cover $\{\tilde{\omega_j}\}$ of the complete domain Ω, i.e., $\bigcup_j \tilde{\omega_j} \not\supset \overline{\Omega}$, since the particles $\{x_i\}$ may not be uniformly distributed in the domain Ω. Therefore, we have to use a more sophisticated algorithm. We use the following variant of an algorithm developed in [27] which resolves the problem mentioned above by using a set P of particles x_i and pseudoparticles ξ_k which we choose to be the nodes of a coarse mesh. The pseudoparticles ξ_k are introduced to guarantee that the patches ω_i completely cover the entire domain Ω.

1. For all $i = 1, \ldots, N$: Set ω_i such that $\operatorname{diam}(\omega_i) = 0$.
2. For all $y \in P$:
   - Evaluate the set $S_{y,R}$ of all particles x_i that fall within a searching square B_R which is centered in y and whose side length is equal to $2R$. If $S_{y,R} = \emptyset$ or $S_{y,R} = y$ in the case of $y = x_i$, increase the size of the searching square, i.e., R, and try again.
   - Compute the distances $h_i^y = \|y - x_i\|$ for all $x_i \in S_{y,R}$ with $x_i \neq y$.
   - Determine the particle $x_j \neq y$ with $h_j^y = \min_i h_i^y$.
   - If $y \notin \omega_j$ increase ω_j appropriately such that $y \in \omega_j$ holds.
3. For all $i = 1, \ldots, N$: Set $\operatorname{diam}(\omega_i) = \alpha \operatorname{diam}(\omega_i)$.

Crucial for the efficient implementation of the above algorithm is the evaluation of the sets $S_{y,R}$. Note that a similar search problem appears in the SPH. There an efficient algorithm for such problems was developed in [71]. Other algorithms for such a cover construction can be derived from tree-algorithms, such as quadtrees or AVL-trees [42]. The overall complexity of the above algorithm is $O(\operatorname{card}(P) \log(N))$.

Since the entries $a_{ij} = a(v_j, v_i)$ of the stiffness matrix A will be nonzero only for functions v_i, v_j with $\operatorname{supp}(v_i) \cap \operatorname{supp}(v_j) \neq \emptyset$, we want to control the number of

[2]Other gridless methods like SPH allow for holes in the domain Ω. Methods based on the MLSM [24, 27] have to impose more severe geometric conditions onto the cover $\{\omega_i\}$.

patches overlapping the same point $x \in \Omega$, i.e., the number of overlapping patches $\{\omega_i\}$ should be minimal. The amount of overlap of the patches $\{\omega_i\}$, however, has a significant effect on the smoothness of our shape functions. Therefore, the overlap $\omega_i \cap \omega_j$ of two patches ω_i and ω_j should be sufficiently large (if it is not empty). This motivates the stretch parameter α in step 3 of the algorithm above which is used to control the interplay between the smoothness of the shape functions and the density of the stiffness matrix.

4.1.2. Weight functions and partition of unity. Now we associate a certain weight function $W_i(x)$ to each subdomain ω_i. Since we decided to use rectangular patches only, i.e., $\omega_i = \bigotimes_{k=1}^{d} \omega_i^{(k)}, \omega_i^{(k)} = \{x^{(k)} \in \mathbb{R}, |x_i^{(k)} - x^{(k)}| \leq h_i^{(k)}\}$, the most natural choice is to use a product approach of one-dimensional local functions, i.e., $W_i(x) = \bigotimes_{k=1}^{d} W_i^{(k)}(x^{(k)})$, where $\operatorname{supp}(W_i) = \overline{\omega_i}$. If we use $[-1,1]$ as reference interval and define the affine linear mapping $T_i^{(k)} : [-1,1] \to \omega_i^{(k)}$, $x^{(k)} \to T_i^{(k)}(x^{(k)})$, we can define the respective weight functions as $W_i^{(k)}(x^{(k)}) = W(T_i^{(k)}(x^{(k)}))$, where the one-dimensional weight function W can be any nonnegative function. Furthermore, we obtain the mapping T_i from the reference element $[-1,1]^d$ to ω_i as the product $T_i : [-1,1]^d \to \omega_i, x \to T_i(x) = \bigotimes_{k=1}^{d} T_i^{(k)}(x^{(k)})$. The weight functions[3] W we use in this paper are the well-known linear, quadratic, and cubic B-splines.

Now, in the next step, we construct shape functions φ_i from these given weight functions W_i with the help of data fitting techniques. In general, a data fitting method [36] produces an approximation $\tilde{u}$ of a function u by

$$\tilde{u}(x) = \sum_{i=1}^{N} u_i \cdot \varphi_i(x),$$

where u_i are given data or are derived from that. Shepard's method uses the idea of inverse distance weighting, which leads to shape functions

$$\varphi_i(x) = \frac{W_i(x)}{\sum_{j=1}^{N} W_j(x)}, \tag{4.2}$$

where $W_i(x) = \|x - x_i\|^{-\beta}$. But since such shape functions have global support, they would lead to a dense stiffness matrix and a quadratic complexity of the method. We therefore use a localized version of Shepard's approach. There are basically two variants. In [45] a locally supported singular weight function such as

$$W_i(x) = L_i(x)\|x - x_i\|^{-\beta}, \quad \text{where } L_i \in \mathcal{C}^\infty \quad \text{and } \operatorname{supp}(L_i) = \omega_i,$$

is used. This approach generates an interpolatory partition of unity, i.e., $\varphi_i(x_j) = \delta_{ij}$. Another approach is to employ a locally supported smooth weight function, e.g., W_i is chosen to be a B-spline[4] [36]. We use the latter approach to circumvent the evaluation of a quotient of singular functions close to their singularity during the numerical integration of the stiffness matrix entries.

[3]Besides these weight functions, the thin-plate splines, Gaussians, and especially the so-called SPH-spline [11, 26, 31, 51] are used in other meshless methods. Note that circular patch shapes would allow for radial functions as weight functions W_i [28, 29, 40, 41, 73].

[4]Note that, together with collocation and area weighting of the resulting shape functions, this gives basically the smoothed particle hydrodynamics method SPH, which was first proposed in [51] and further elaborated in [32, 55, 56, 71].

Since we postulate that the union of the ω_i covers the domain Ω, by (4.2), we are at least able to reproduce constant functions exactly, i.e., the functions (4.2) form a *partition of unity*. Interestingly, this is valid for any choice of weight function, particle distribution, and topology of the cover. Thus, we obtain a consistency order[5] of one in the L^2-norm. The particle distribution $\{x_i\}$ and the cover $\{\omega_i\}$ affect only the computational effort necessary to evaluate the functions φ_i, since the sum in (4.2) has to be taken over all patches ω_j with $\omega_i \cap \omega_j \neq \emptyset$. Furthermore, the amount of overlap of the cover patches and the choice of weight functions W_i affect the smoothness of the Shepard functions φ_i. On the one hand, the partition of unity inherits the smoothness of the weight functions W_i since $\big(W_i \in \mathcal{C}^k(\mathbb{R}^d) \wedge \text{ for all } x \ \sum_i W_i(x) \neq 0\big) \Rightarrow \varphi_i \in \mathcal{C}^k(\mathbb{R}^d)$ holds. On the other hand, the amount of overlap affects the smoothness of φ_i. If the cover is minimal, i.e., there is exactly one patch ω_j for every $x \in \overline{\Omega}$ with $x \in \overline{\omega_j}$, the partition of unity degenerates to the characteristic functions $\varphi_i = \chi_{\omega_i}$ independent of the chosen weight functions W_i. Thus we see that small overlaps will cause very large gradients of φ_i close to the boundary of the respective support ω_i.

First order consistency is in general not sufficient. Hence, some effort is necessary to improve the consistency order. Here, the MLSM [11, 24, 26, 27] allows the construction of shape functions with higher reproduction and consistency order but increases the computational effort dramatically. Furthermore, one has to impose severe geometric restrictions onto the cover [27] to make the method work at all. Therefore we use a different approach. We use the partition of unity to collect local approximation spaces V_i defined on the cover patches ω_i, thus generating a global approximation space V on Ω (see the following section). This space may also reproduce the constant only, but it was shown in [3, 4] that the consistency order of the global space V is nevertheless the same as the consistency order of the local spaces V_i (see section 4.1.4).

4.1.3. Local polynomial expansion. The partition of unity functions φ_i are able to reproduce the constant function. However, for the discretization of a PDE by a Galerkin method, they are not yet sufficient. First, depending on the computed cover $\{\omega_i\}$ and the choice of weight functions W_i, their derivatives can be unbounded and the entries of the stiffness matrix cannot be evaluated in a stable way. We can circumvent these difficulties by the construction of cover patches ω_i with sufficient overlap, but still the consistency error of the discretization would be only of first order in the L^2-norm.

Therefore, we additionally use a hierarchy of local polynomial basis functions of higher degree. To this end, we multiply the partition of unity functions φ_i locally with polynomials. Since we use rectangular patches ω_i only, a local tensor-product space is the most natural choice.

Consider on the reference interval $[-1, 1]$ the Legendre polynomials

$$L_p(x) = \frac{2p+1}{p} x L_{p-1}(x) - \frac{p-1}{p} L_{p-2}(x), \qquad p = 2, 3, \dots, \tag{4.3}$$

with $L_0(x) = 1$ and $L_1(x) = x$. Now, we can define a multidimensional hierarchical

[5]Consistency orders are usually given as exponents of h, i.e., $\|u - \tilde{u}\| = O(h^\alpha)$ with α being the consistency order. However, this formulation is applicable to uniform node arrangements only. Hence, we have to use a different notation in a meshless method. Taking into account that we have $\|x_i - x_j\| = O(N^{-1/d})$ for equidistributed particles $\{x_i\}$ and that $h = N^{-1/d}$ for uniform node arrangements, it seems natural to define the consistency order α of a meshless method as $\alpha := (d \log(\|u - \tilde{u}\|))/\log(N)$.

basis $\{\mathcal{L}_k\}$ with $\mathcal{L}_k(x) = \bigotimes_{j=1}^d L_{k_j}(x^{(j)})$, where $k = (k_1, \ldots, k_d) \in \mathbb{N}^d$ is a multi-index. Then via the affine map T_i from $\omega_i = \bigotimes_{j=1}^d [x_i^{(j)} - h_i^{(j)}, x_i^{(j)} + h_i^{(j)}]$ to $[-1,1]^d$, with $T_i = \bigotimes_{j=1}^d T_i^{(j)}$, where $T_i^{(j)} : [x_i^{(j)} - h_i^{(j)}, x_i^{(j)} + h_i^{(j)}] \to [-1,1]$, we can define a local approximation space V_i on ω_i $V_i = \text{span}\ \{\mathcal{L}_k \circ T_i, \quad k \in I_i\}$. Here $I_i \subset \mathbb{N}_0^d$ is some set of multi-indices $k = (k_1, \ldots, k_d)$, e.g., the full tensor product set $I_i^T = \{k \in \mathbb{N}_0^d : |k|_\infty \le p_i\}$ or the set $I_i^C = \{k \in \mathbb{N}_0^d : |k|_1 \le p_i\}$. The use of the set I_i^C leads to the space V_i^C of complete polynomials of degree p_i, which was also used for the p-version of the finite element method [5].

The global approximation space V is then defined as

$$V = \sum_i \varphi_i V_i \,. \tag{4.4}$$

Note that the local spaces V_i are independent, i.e., there are no compatibility requirements among them. Therefore, not only can the degrees p_i for the sets I_i vary locally, but even different basis functions, e.g., monomials, Taylor polynomials, or harmonic functions [3, 4], might be used on some patches ω_i. In the following, we stick to the Legendre polynomials (4.3). Note that in a general situation with varying sets I_i and bases $\{\psi_k^i\}$, there are some further conditions on the amount of overlap of the cover $\{\omega_i\}$ to ensure that the products $\{\varphi_i \psi_k^i\}$ of the partition of unity functions $\{\varphi_i\}$ and the local basis functions $\{\psi_k^i\}$ are a basis of the global space (4.4); see [4, 68].

4.1.4. Basic convergence theory for PUM. In this section we state the notation and basic theory of the PUM as developed by Babuška and Melenk in [3, 4]. Crucial to the theory of the partition of unity method is the notion of an (M, C_∞, C_∇) partition of unity. The conditions formulated in the following definitions allow us to show the basic approximation properties of the PUM space V of (4.4) as given in Theorem 4.3.

DEFINITION 4.1 (partition of unity). *Let $\Omega \subset \mathbb{R}^d$ be an open set, and let $\{\omega_i\}$ be an open cover of Ω satisfying a point-wise overlap condition*

$$\exists M \in \mathbb{N} \quad \text{for all } x \in \Omega \quad \text{card}\,\{i \,|\, x \in \omega_i\} \le M \,.$$

Let $\{\varphi_i\}$ be a Lipschitz partition of unity subordinate to the cover $\{\omega_i\}$ satisfying

$$\begin{array}{rcl@{\qquad}rcl} \text{supp}(\varphi_i) & \subset & \overline{\omega_i} \quad \text{for all } i\,, & \sum_i \varphi_i & \equiv & 1 \text{ on } \Omega\,, \\ \|\varphi_i\|_{L^\infty(\mathbb{R}^d)} & \le & C_\infty\,, & \|\nabla \varphi_i\|_{L^\infty(\mathbb{R}^d)} & \le & \frac{C_\nabla}{\text{diam}\,(\omega_i)}\,, \end{array}$$

where C_∞ and C_∇ are two constants. Then $\{\varphi_i\}$ is called an (M, C_∞, C_∇) partition of unity subordinate to the cover $\{\omega_i\}$. The partition of unity is said to be of degree $k \in \mathbb{N}_0$ if $\varphi_i \in \mathcal{C}^k(\mathbb{R}^d)$ for all i. The covering sets ω_i are called patches.

DEFINITION 4.2 (PUM space). *Let $\{\omega_i\}$ be an open cover of $\Omega \subset \mathbb{R}^d$ and let $\{\varphi_i\}$ be a (M, C_∞, C_∇) partition of unity subordinate to $\{\omega_i\}$. Let $V_i \subset H^1(\Omega \cap \omega_i)$ be given. Then the space*

$$V := \left\{ \sum_{i=1}^n \varphi_i v_i \,|\, v_i \in V_i \right\}$$

is called a PUM space. The PUM space V is said to be of degree $k \in \mathbb{N}$ if $V \subset \mathcal{C}^k(\Omega)$. The spaces V_i are referred to as the local approximation spaces.

THEOREM 4.3 (approximation property). *Let $\Omega \subset \mathbb{R}^d$ be given. Let $\{\omega_i\}$, $\{\varphi_i\}$, and V_i be as in Definitions* 4.1 *and* 4.2. *Let $u \in H^1(\Omega)$ be the function to be approximated. Assume that the local approximation spaces V_i have the following approximation properties: On each patch $\Omega \cap \omega_i$, the function u can be approximated by a function $v_i \in V_i$ such that $\|u - v_i\|_{L^2(\Omega\cap\omega_i)} \leq \epsilon_1(i)$, and $\|\nabla(u - v_i)\|_{L^2(\Omega\cap\omega_i)} \leq \epsilon_2(i)$ hold. Then the function $u_{\mathrm{ap}} := \sum_i \varphi_i v_i \in V \subset H^1(\Omega)$ satisfies*

$$\begin{aligned} \|u - u_{\mathrm{ap}}\|_{L^2(\Omega)} &\leq \sqrt{M} C_\infty \left(\textstyle\sum_i \epsilon_1^2(i)\right)^{1/2}, \\ \|\nabla(u - u_{\mathrm{ap}})\|_{L^2(\Omega)} &\leq \sqrt{2M} \left(\textstyle\sum_i \left(\frac{C_\nabla}{\operatorname{diam}(\omega_i)}\right)^2 \epsilon_1^2(i) + C_\infty^2 \epsilon_2^2(i)\right)^{1/2}. \end{aligned} \tag{4.5}$$

Proof. See [3, 4].

Due to this theorem we can use the PUM as an h-version, a p-version, or even an hp-version. From (4.5) we can see that the approximation property of the approximation space V may be improved via the reduction of the diameters of the cover patches $\{\omega_i\}$ (the insertion of particles $\{x_i\}$) or via the enhancement of the approximation qualities of the local spaces V_i (the increment of the polynomial order p_i). These refinement strategies are independent, thus we may use both at the same time. Assume that we have a local error estimate $\epsilon_1(i) \leq c_i(\operatorname{diam}(\omega_i))^{\nu_i} p_i^{-\mu_i} \|u\|_{L^2(\Omega\cap\omega_i)}$ for some μ_i, ν_i. Then the error estimates (4.5) of Theorem 4.3 take the form

$$\|u - u_{\mathrm{ap}}\|_{L^2(\Omega)} \leq M C_\infty \max_i \left\{ c_i(\operatorname{diam}(\omega_i))^{\nu_i} p_i^{-\mu_i} \right\} \|u\|_{L^2(\Omega)},$$

demonstrating the hp-like behavior of the method.

Since the PUM only employs a scattered data set, an adaptive h-refinement (by the insertion of new particles $\{x_i\}$) does not have to cope with problems caused by the grid-structure like hanging nodes, etc. Furthermore, there are no compatibility restrictions on the local spaces V_i. Thus we may also employ an adaptive p-refinement on the local spaces V_i. Hence the development of an appropriate error estimator (or at least indicator) is of great interest and is a main topic for future research.

Theorem 4.3 gives an error estimate for u_{ap} which is the linear combination of the locally optimal solutions v_i. The Galerkin method, however, constructs a different approximate solution u_{G}. Here, we do not use the local information from V_i only but rather all information from the spaces V_j with $\omega_j \cap \omega_i \neq \emptyset$. Therefore we sometimes may expect an even better convergence than Theorem 4.3 implies.

Note that the partition of unity $\{\varphi_i\}$ with φ_i from (4.2) and the space V in (4.4) fulfill Definitions 4.1 and 4.2. Consequently, we obtain the approximation properties and error estimates as stated in Theorem 4.3 for our approximation space V. In the following we use the space V in a Galerkin discretization of our elliptic subproblem (2.3).

4.2. Galerkin method with the PUM space. We want to solve elliptic boundary value problems of the type

$$\begin{aligned} Lu &= f \quad \text{in } \Omega \subset \mathbb{R}^d, \\ Bu &= g \quad \text{on } \partial\Omega, \end{aligned} \tag{4.6}$$

where L is a symmetric partial differential operator of second order and B expresses suitable boundary conditions.

Here, the following two major questions come up: How can we efficiently evaluate the integrals which arise in the Galerkin discretization for the stiffness matrix and the right-hand side? And how can we deal with boundary conditions properly?

4.2.1. Construction of appropriate Gauss quadrature formulas. In the following let $a(\cdot,\cdot)$ be the continuous and elliptic bilinear form induced by L on $H^1(\Omega)$. We discretize the partial differential equation using Galerkin's method. Then, we have to compute the stiffness matrix

$$A = (a_{ij}) \quad \text{with } a_{ij} = a(v_j, v_i)$$

and the right-hand side vector

$$\hat{f} = (f_i) \quad \text{with } f_i = \int_\Omega f v_i \,,$$

where $\{v_i\}$ is a basis of the PUM space V.

The partition of unity functions $\{\varphi_i\}$ are (in general) not of the same shape due to the use of a scattered particle set $\{x_i\}$ and the varying overlap of the cover patches $\{\omega_i\}$. Therefore the trial and test functions $\varphi_i\psi_k^i$ also are not of the same shape and we cannot simply use a transformation onto a reference element to compute the integrals (as is done in the FEM). Furthermore, we cannot employ a straightforward integration scheme to compute the integrals because of the low order global continuity of the trial and test functions $\varphi_i\psi_k^i$ and their derivatives.

Assume that the functions $\{\varphi_i\psi_k^i\}$ form a basis of V. If we restrict ourselves for reasons of simplicity to the case $L = -\Delta$ we have to compute the integrals $\int_\Omega \varphi_i\psi_k^i f$ for the right-hand side and the integrals $\int_\Omega \nabla(\varphi_i\psi_k^i)\nabla(\varphi_j\psi_l^j)$ for the stiffness matrix. Recall that φ_i is defined by (4.2). Now we carry out the differentiation. With the notation

$$\mathcal{G}_i := \left(\nabla W_i \sum_m W_m - W_i \sum_m \nabla W_m \right) ,$$

we end up with the integrals

$$\begin{aligned} &\int_\Omega \left(\frac{1}{\sum_m W_m}\right)^4 \mathcal{G}_i\psi_k^i \mathcal{G}_j\psi_l^j \,, \quad \int_\Omega \left(\frac{1}{\sum_m W_m}\right)^2 W_i\nabla\psi_k^i W_j\nabla\psi_l^j \,, \\ &\int_\Omega \left(\frac{1}{\sum_m W_m}\right)^3 \mathcal{G}_i\psi_k^i W_j\nabla\psi_l^j \,, \quad \int_\Omega \left(\frac{1}{\sum_m W_m}\right)^3 W_i\nabla\psi_k^i \mathcal{G}_j\psi_l^j \end{aligned} \tag{4.7}$$

for the stiffness matrix and the integrals

$$\int_\Omega \frac{1}{\sum_m W_m} W_i\psi_k^i f \tag{4.8}$$

for the right-hand side. Since we use piecewise polynomial weights W_i, the functions $\mathcal{G}_i$ may have quite a number of jumps of significant size within their support ω_i. Therefore, the integrals (4.7) should not be computed by a simple quadrature formula which does not respect these discontinuities.

All of the integrals (4.7) and (4.8) are of the form $\int_\Omega (\sum_m W_m)^{-p} \chi$, which leads to the idea of constructing Gauss quadrature formulas with respect to the weight functions $(\sum_m W_m)^{-p}$. Since the functions χ have support $\Omega \cap \omega_i$ or even $\Omega \cap \omega_i \cap \omega_j$, the construction of global quadrature formulas on Ω with respect to each of these weights is not advisable. However, the construction of Gauss quadratureformulas for

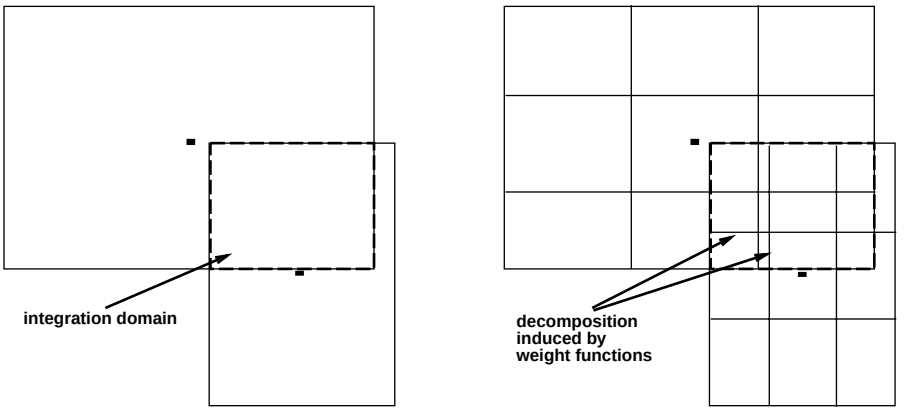

FIGURE 4.3. *Integration domain $\Omega_{ij} = \omega_i \cap \omega_j$ (left). Decomposition $\{C_n\}$ of the integration domain Ω_{ij} via the subdivision induced by the weight functions W_i and W_j (right). Here, the weights are tensor products of quadratic B-splines.*

each integration domain $\Omega \cap \omega_i \cap \omega_j$ and each integration weight is rather expensive. Therefore, we developed a different approach which is an improvement of the integration scheme introduced in [68]. Here, a decomposition of the integration domain induced by the employed shape functions was proposed. More recently a similar yet simpler approach was proposed by Dolbow and Belytschko in [25]. They also make use of the tensorproduct structure of the supports of their shape functions but they construct a *global* decomposition of the domain Ω. In our approach, we decompose each *local* integration domain $\Omega \cap \omega_i \cap \omega_j$ independent of all ω_k with $\omega_k \cap (\Omega \cap \omega_i \cap \omega_j) = \emptyset$. Furthermore, the number of cells of such a local decomposition[6] is almost minimal.

We exploit the tensor product structure of the weight functions W_i and the cover patches ω_i to decompose the integration domain into subpatches with simple geometry on which the functions φ_i are *rational*. Here, we also use the fact that the employed weights W_i are tensor products of B-splines, i.e., they are piecewise polynomial. Consider the integration domain $\Omega_{ij} = \omega_i \cap \omega_j \subset \Omega$. The intersection Ω_{ij} of two cover patches ω_i, ω_j which are tensor products of intervals is also a tensor product of intervals; see Figure 4.3 (left). Furthermore, the employed weight functions W_k are tensor products of B-splines of order l, i.e., they are piecewise polynomials of degree l. Therefore, these weight functions W_k induce a subdivision of each cover patch ω_k into $(l+1) \times (l+1)$ subpatches $\{\omega_{kp}\}$ on which $W_k\big|_{\omega_{kp}}$ is polynomial. Furthermore, these subpatches $\{\omega_{kp}\}$ are also tensor products of intervals. With the help of these subpatches $\{\omega_{ip}\}$, $\{\omega_{jp}\}$ we can define a decomposition $\{C_n\}$ of Ω_{ij}; see Figure 4.3 (right). On the cells C_n of this decomposition we have that $W_i\big|_{C_n}$ and $W_j\big|_{C_n}$ are polynomials of degree l, but all other $W_m\big|_{C_n}$ may still be piecewise polynomial only. Therefore, we refine the decomposition $\{C_n\}$ by further subdividing the cells C_n with the help of the $\{\omega_{kp}\}$ subpatches for all k with $\Omega_{ij} \cap \omega_k \neq \emptyset$; see Figure 4.4 (left). The cells $\hat{C}_n$ of this decomposition may be L-shaped; see Figure 4.4 (left). Such an L-shaped cell $\hat{C}_n$ is further subdivided into two rectangular cells $\tilde{C}_n^1$, $\tilde{C}_n^2$ (see Figure 4.4 (right)) to allow the use of a tensor product quadrature scheme on each cell of

[6]The decomposition is closely connected to the cover construction. The decomposition may be computed during the construction of the cover with only a slight increase of computational work.

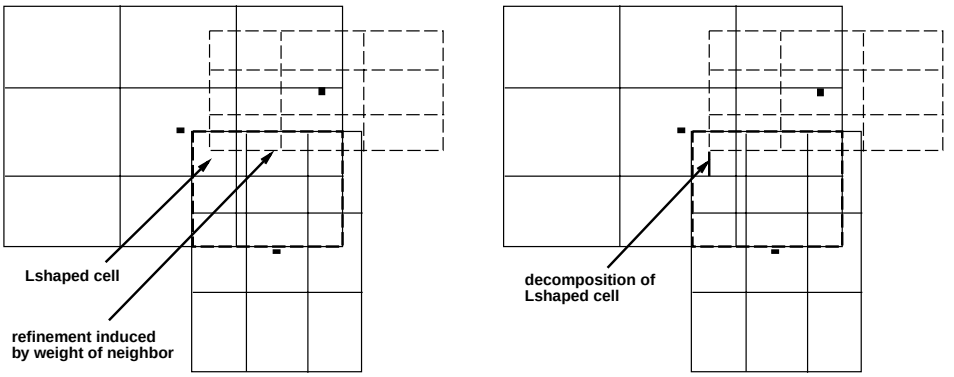

FIGURE 4.4. *Refinement of the decomposition* $\{C_n\}$ *of the integration domain* Ω_{ij} *via the subdivision induced by the weight function* W_k *(tensor product of quadratic B-splines) of one neighboring particle* x_k *(left). Further decomposition of L-shaped cells of this refinement step (right).*

the decomposition. The resulting decomposition[7] $\{\tilde{C}_n\}$ consists of rectangular cells $\tilde{C}_n$ on which all weight functions $W_m|_{\tilde{C}_n}$ are polynomials of degree l. Therefore, the functions $\mathcal{G}_i$ and the integration weights $(\sum_m W_m)^{-p}$ are rational on these cells. Due to the restrictions imposed in section 4.1.4 on the partition of unity $\{\varphi_i\}$ and on the cover $\{\omega_i\}$, the functions $(\sum_m W_m)^{-p}$ are nonsingular on the cells $\tilde{C}_n$. Hence, we can use any standard numerical integration[8] scheme to compute the integrals on the cells $\tilde{C}_n$.

According to Strang's second lemma we have to integrate all entries of the stiffness matrix sufficiently accurately to maintain the convergence order of the discretization error. The shape functions $\varphi_i\psi_k^i$ with $\psi_k^i \neq 1$ are smoother than the partition of unity function φ_i, i.e., a function $\varphi_i\psi_k^i$ is the sum of a polynomial and a rational function whereas φ_i is a rational function only. In a naive approach we could try to exploit this smoothness to reduce the computational costs of the numerical integration of the integrals involving $\varphi_i\psi_k^i$ with $\psi_k^i \neq 1$ by using a quadrature scheme which has a lower order than the quadrature scheme we used for the integrals involving the function φ_i only. But this might lead to the loss of the wanted convergence rate of the discretization error since we now compute the entries of the stiffness matrix with varying accuracy only.

Therefore, we have to find a different way to reduce the computational costs of the numerical integration which allows for a uniform error bound in k and l, i.e.,

$$\left\| \int_\Omega \nabla(\varphi_i\psi_k^i)\nabla(\varphi_j\psi_l^j) - I_\Omega^h \left(\nabla(\varphi_i\psi_k^i)\nabla(\varphi_j\psi_l^j) \right) \right\| \leq Ch^q \quad \text{for all } k, l\,.$$

In any case, we have to evaluate the functions φ_i and their derivatives $\nabla\varphi_i$ in the quadrature points of a sufficiently high order scheme to compute the integrals of the

[7]Note, that this approach is not restricted to domains Ω which are unions of rectangles but rather applicable to general domains. For integration domains $\omega_i \cap \omega_j \cap \Omega$ with $\omega_i \cap \omega_j \not\subset \Omega$ we apply this construction to the fictitious integration domain $\omega_i \cap \omega_j$. The cells $\tilde{C}_n$ with $\tilde{C}_n \cap \partial\Omega \neq \emptyset$ of this decomposition $\{\tilde{C}_n\}$ are then further subdivided using a polygonal approximation to the boundary $\partial\Omega$ of the computational domain Ω. Hence the final cell decomposition for integrals close to the boundary of general domains consists of rectangles and triangles.

[8]Since we use polynomials as local spaces V_i, we may even compute the integrals analytically, i.e., by symbolic computation, if we consider, for example, the Laplacian or more general operators involving polynomial coefficient functions [68].

nonsmooth functions φ_i. Furthermore, it is quite clear that an evaluation of φ_i and $\nabla\varphi_i$ is far more expensive than an evaluation of a local basis function ψ_k^i and its derivatives $\nabla\psi_k^i$. Taking this and the product structure of the approximation space into account we can reduce the computational costs by using the already computed values of the functions φ_i, φ_j and their derivatives for the evaluation of the integrals

$$\int_\Omega \nabla(\varphi_i\psi_k^i)\nabla(\varphi_j\psi_l^j) \quad \text{for all } k,l\,. \tag{4.9}$$

We carry out the differentiation in (4.9) and use the product structure of the shape functions $\{\varphi_i\psi_k^i\}$ to obtain the following integrals

$$\int_\Omega \nabla\varphi_i\nabla\varphi_j\psi_k^i\psi_l^j + \nabla\varphi_i\varphi_j\psi_k^i\nabla\psi_l^j + \varphi_i\nabla\varphi_j\nabla\psi_k^i\psi_l^j + \varphi_i\varphi_j\nabla\psi_k^i\nabla\psi_l^j \tag{4.10}$$

for all k, l. Now we have to integrate products of partition of unity functions φ_i, φ_j, their gradients $\nabla\varphi_i$, $\nabla\varphi_j$, local basis functions ψ_k^i, ψ_l^j and gradients $\nabla\psi_k^i$, $\nabla\psi_l^j$ of local basis functions. Therefore, we can reuse the computed values of φ_i, φ_j and their gradients $\nabla\varphi_i$, $\nabla\varphi_j$ to compute the integrals (4.10) for all k, l. Here, we evaluate the partition of unity functions φ_i and its gradient $\nabla\varphi_i$ only once per quadrature point for the complete local approximation space V_i, consequently reducing the costs but still computing all integrals with the same order of error. Hence, we have to consider the maximal polynomial degrees p_i, p_j of the local functions $\{\psi_k^i\}$, $\{\psi_l^j\}$ and the regularity of the functions φ_i, φ_j for the selection of the order q of the numerical integration scheme on the cells $\tilde{C}_n$.

Note that a further reduction of the costs of the integration can be achieved by using so-called sparse grid integration schemes [30, 63] instead of tensor product formulas on the subpatches.

4.2.2. Boundary conditions and Lagrangian multipliers. Our PUM shape functions $\{\varphi_i\psi_k^i\}$ are noninterpolatory since the partition of unity functions $\{\varphi_i\}$ are (in general) noninterpolatory, i.e., $\varphi_i(x_j) \neq \delta_{ij}$. Furthermore, the usage of local approximation spaces V_i with $\dim(V_i) > 1$ generates an approximation space $V = \sum_i \varphi_i V_i$ with more degrees of freedom than interpolation nodes $\{x_i\}$. Thus, we have to cope with the problem of how to fulfill boundary conditions.

First consider (4.6) with Neumann boundary conditions $Bu = \partial u/\partial n_L = g$ on $\Gamma := \partial\Omega$. We learn from the variational formulation

$$F(v) = \frac{1}{2}a(v,v) - (f,v) - \int_\Gamma gv d\Gamma \to \min\{v \in H^1(\Omega)\} \tag{4.11}$$

that the trial functions v only have to be from the definition space $H^1(\Omega)$ of the differential operator L in its weak form. The functions v do not have to fulfill any additional condition such as boundary values. Thus, the basis of a finite-dimensional subspace V of $H^1(\Omega)$ used to approximate the solution of (4.11) may be compiled of any function $v \in H^1(\Omega)$ and does not need to be interpolatory. Hence, we may directly use our functions $\varphi_i\psi_k^i$ as trial and test functions in the Galerkin procedure without problems.

However, Dirichlet boundary conditions $u = g$ on Γ explicitly impose the values of the solution u on the boundary Γ. Thus, the trial space of the usual weak formulation

$$\text{Find } u \in H^1(\Omega) \cap \{u = g \text{ on } \Gamma\} : a(u,v) = (f,v) \text{ for all } v \in H_0^1(\Omega) \tag{4.12}$$

is not the complete space $H^1(\Omega)$. Therefore, any finite-dimensional space V used to approximate the solution of (4.12) has to consist of functions $\tilde{u}$ fulfilling the boundary condition $\tilde{u} = g$ on Γ. This is usually achieved in the FEM by interpolation of the boundary value $\tilde{u} = \tilde{g}$. Since our shape functions are noninterpolatory, this approach cannot be pursued.

For Dirichlet problems, we use a result from the theory of Lagrange multipliers which states that a solution of (4.12) creates a stationary point of

$$F(v,q) = \frac{1}{2}a(v,v) - (f,v) - \int_\Gamma q(v-g)d\Gamma\,. \tag{4.13}$$

In this formulation the functions v do not have to satisfy the boundary conditions $v = g$ on Γ explicitly, since the additional term enforces the boundary conditions. The respective weak form of (4.13) is as follows: Find $(u,q) \in H^1(\Omega) \times H^{-1/2}(\Gamma)$ with

$$\begin{array}{rcrcl} a(u,v) & + & (\gamma(v),p) & = & (f,v) \text{ for all } v \in H^1(\Omega), \\ (\gamma(u),q) & & & = & (g,q) \text{ for all } q \in H^{-1/2}(\Gamma), \end{array} \tag{4.14}$$

where $\gamma : H^1(\Omega) \to H^{1/2}(\Gamma)$ is the trace operator. We can use the shape functions $\{\varphi_i\psi_k^i\}$ from the construction presented in section 4.1 for the discretization of the *saddle point problem* (4.14) since it only employs the space $H^1(\Omega)$ as trial and test space instead of the restricted spaces $H^1(\Omega) \cap \{u = g \text{ on } \Gamma\}$ as trial and $H_0^1(\Omega)$ as test space for problem (4.12). Thus, there is no need for interpolatory basis functions. The Lagrange multiplier approach in the finite element context can be found in [2, 15], for applications with wavelets, see [43], and within the fictitious domain and mortar element approach compare [52, 59].

Now we have to construct an appropriate finite dimensional subspace $Q \subset H^{-1/2}$ for the discretization of (4.14). Here, we use the particles $\{x_i \in \overline{\Omega}\}$ from (4.1) to construct a new particle distribution $\{x_j^\Gamma\}$ on the boundary Γ. The particles $\{x_i \in \overline{\Omega}\}$ with $\omega_i \cap \Gamma \neq \emptyset$ are projected in the direction of the outer normal onto the boundary Γ and give a new set of particles $\{x_j^\Gamma\}$, which live on the boundary Γ. Then, following the construction described in the previous sections, we set up the finite dimensional PUM space Q on the boundary using the PUM approach: From the newly generated particles $\{x_j^\Gamma\}$ we construct a cover $\{\omega_j^\Gamma\}$ of the $(d-1)$-dimensional manifold Γ, define a partition of unity using Shepard's approach, and choose polynomials on the patches $\{\omega_j^\Gamma\}$ to define a PUM space Q on the boundary. Note that this procedure has to be done with respect to the interior PUM space V. Necessary for the existence and uniqueness of a solution of the saddle point problem

$$\begin{array}{rcrcll} a(u,v) & + & (\gamma(v),p) & = & (f,v) & \text{for all } v \in V \subset H^1(\Omega)\,, \\ (\gamma(u),q) & & & = & (g,q) & \text{for all } q \in Q \subset H^{-1/2}(\Gamma) \end{array} \tag{4.15}$$

is the fulfillment of the discrete Ladyzhenskaya–Babuška–Brezzi (LBB) condition [19]

$$\inf_{q\in Q, q\neq 0} \sup_{v\in V, v\neq 0} \frac{|(\gamma(v),q)|}{\|v\|_V \|q\|_Q} \geq c_0\,. \tag{4.16}$$

According to the results in [15] the boundary space Q has to have a resolution coarse enough compared with the resolution of V in the interior to fulfill the discrete LBB condition (4.16). This coarser resolution of the space Q may be achieved by properly[9]

[9]We propose the use of a particle distribution with fewer particles but approximately the same density distribution as the complete particle distribution $\{x_j^\Gamma\}$.

thinning out the particle distribution, i.e., using only an appropriate subset of $\{x_j^\Gamma\}$, or by the choice of lower order polynomials on the boundary than in the interior. Both of these approaches have shown good results in our numerical experiments; see [68].

4.3. Solution of the discrete saddle point problem. Now we have to solve a linear system with saddle point structure, i.e.,

$$\begin{pmatrix} A & B^t \\ B & 0 \end{pmatrix} \begin{pmatrix} u \\ q \end{pmatrix} = \begin{pmatrix} f \\ g \end{pmatrix}, \tag{4.17}$$

where $B \in \mathbb{R}^{\dim(Q)} \times \mathbb{R}^{\dim(V)}$, $q \in \mathbb{R}^{\dim(Q)}$, $u \in \mathbb{R}^{\dim(V)}$ and $A \in \mathbb{R}^{\dim(V)} \times \mathbb{R}^{\dim(V)}$ is symmetric and positive definite and thus invertible. Block Gaussian elimination directly leads to the Schur complement system

$$BA^{-1}B^T q = BA^{-1}f - g. \tag{4.18}$$

The unique solvability of (4.17) is given when (4.16) holds.

A possible approach for the solution of (4.17) is now to iteratively solve (4.18) by a (preconditioned) conjugate gradient method and then to obtain u by backward substitution, i.e., $u = A^{-1}(f - B^T q)$. A realization of this method with a linear iteration is the (preconditioned) Uzawa algorithm; see [14, 47]. It reads

$$\begin{aligned} u_{i+1} &= u_i + A^{-1}(f - (Au_i + B^T q_i)), \\ q_{i+1} &= q_i + \omega_B C_B (Bu_{i+1} - g), \end{aligned} \tag{4.19}$$

where ω_B is an iteration parameter and C_B is a preconditioner for the Schur complement $BA^{-1}B^T$. The drawback of this method is that the action of A^{-1} must be computed in each iteration step, which makes the method expensive.

If we now replace A^{-1} by some steps of an iterative method, most preferable a multigrid method or a multilevel preconditioner, we employ only an approximation C_A to A^{-1} and obtain the so-called inexact Uzawa algorithm [16, 17]

$$\begin{aligned} u_{i+1} &= u_i + \omega_A C_A (f - (Au_i + B^T q_i)), \\ q_{i+1} &= q_i + \omega_B C_B (Bu_{i+1} - g) \end{aligned} \tag{4.20}$$

with iteration parameters ω_A, ω_B. Altogether, in this algorithm only the action of the matrices A, B, B^T and preconditioners C_A, C_B onto vectors must be programmed.

Here, we can exploit the block-structure of the matrices A and B, which is induced by the product structure of the shape functions $\varphi_i \psi_k^i$. The block corresponding to all the φ_i's can be solved efficiently with an algebraic multigrid solver (AMG) [34, 66, 67] and this solver may further be used as a preconditioner on the diagonal blocks corresponding to $\psi_k^i \neq 1$. Altogether, this procedure gives an efficient preconditioner C_A for the inexact Uzawa algorithm.

Now we have to find an efficient iterative solution method or preconditioner C_B for the Schur complement $BA^{-1}B^T$. Currently we use only $C_B = I$; therefore the iterative solution of (4.17) is not yet optimal, i.e., the condition number of the system matrix still depends on $h \simeq N^{-1/d}$. In the future, effective Schur complement preconditioners C_B have to be constructed to make our gridless method competitive. An approach could be the generalization of the methods developed in [18, 43] to matrices from gridless discretizations.

5. Numerical experiments. In this section we present the results of our numerical experiments. We apply the particle-partition of unity method to a linear advection problem, several elliptic problems, the heat-equation, and an instationary convection-diffusion problem.

5.1. Hyperbolic problem. In the following we consider a standard test case for linear advection problems, the so-called Molenkamp problem [72]:

$$\frac{\partial u}{\partial t} + \begin{pmatrix} -y \\ x \end{pmatrix} \nabla u = 0 \text{ in } \Omega := (-1,1)^2 \times (0,T) \tag{5.1}$$

with an initial value $u(x,y,0) = \exp(-100((x-\frac{1}{4})^2+(y-\frac{1}{4})^2))$. For the exact solution $u(x,y,2l\pi) = u(x,y,0)$ for $l \in \mathbb{N}$ holds and mass $\int_\Omega u$ and energy $\|u\|_{L^2}^2$ are conserved.

We discretize (5.1) using the particle method described in section 3 with the shape functions from the particle-PUM. For the resolution of the initial value we choose a simple block-structure approach. Since $u(x,y,0)$ almost vanishes outside of some $\hat{\Omega} \subset \Omega$, we need only a few particles $\{\xi_i^B\}$ in $\Omega \setminus \hat{\Omega}$ for the construction of the shape functions. We distribute these particles $\{\xi_i^B\}$ in $\Omega \setminus \hat{\Omega}$ using a $(2,3)$ Halton sequence[10] (see Figure 5.1) with about 200 points, and another $(2,3)$ Halton sequence with 256 particles $\{\xi_i^I\}$ is used to resolve the initial value $u(x,y,0)$ in $\hat{\Omega}$ (see Figure 5.2). Note that a further adaptation of the initial particle distribution can be achieved following the ideas of [35].

Some of the particles $\{\xi_i\}$ leave the domain during the computation since we propagate the particles along their corresponding characteristic. To cope with the particle loss, we embed the domain Ω in a larger domain $\tilde{\Omega}$ and distribute a set of background particles $\{\xi_i^B\}$ rather in $\tilde{\Omega}\setminus\hat{\Omega}$ than $\Omega\setminus\hat{\Omega}$. We move all particles $\{\xi_i^B\}\cup\{\xi_i^I\}$ along their characteristic, but a PUM shape function is constructed in those particles $\xi_i \in \{\xi_i^B\} \cup \{\xi_i^I\}$ with $\xi_i \in \Omega$ only. Hence, some particles $\{\xi_i\}$ still leave the domain,

[10]Halton sequences are pseudo Monte Carlo sequences, which are used in sampling and numerical integration [62]. Consider $n \in \mathbb{N}_0$ given as $\sum_j n_j p^j = n$ for some prime p. We can define the transformation H_p from $\mathbb{N}_0$ to $[0,1]$ with $n \mapsto H_p(n) = \sum_j n_j p^{-j-1}$. Then, the (p,q) Halton sequence with N points is defined as $\{(H_p(n), H_q(n))\}$, where $n = 0, \ldots, N-1$.

but there also are some particles $\{\xi_i^B\}$ (re)entering Ω. Therefore, we have an almost constant number of particles in Ω and $\hat{\Omega}$ over time.

We use a stretch parameter $\alpha = 1.25$, the well-known hat function, and complete quadratic Legendre polynomials V_i^C for the construction of the shape functions in this experiment. Hence, the approximation space has about 2700 degrees of freedom, of which we have 1500 within the approximate support $\hat{\Omega}$. As ODE solver in this experiment we use a simple Euler and a fourth order Runge–Kutta method. The increase of computational work by applying a Runge–Kutta method instead of the Euler method is negligible since we only have more evaluations of the velocity field which is independent of the solution of (5.1).

We solve the mass matrix problem using a preconditioned CG method with a tolerance of 10^{-8}. The error $u - u_{\mathrm{ap}}$ in the L^∞-norm and the oscillations

$$u_{\mathrm{ap}}^{\mathrm{osc}} = \begin{cases} \min u - \min u_{\mathrm{ap}} & : \ |\min u_{\mathrm{ap}} - \min u| > |\max u - \max u_{\mathrm{ap}}|, \\ \max u_{\mathrm{ap}} - \max u & : \ |\min u_{\mathrm{ap}} - \min u| \le |\max u - \max u_{\mathrm{ap}}| \end{cases}$$

(both computed on a 500×500 grid), the mass defect $d_{\mathrm{M}} = 1 - \int_\Omega u_{\mathrm{ap}} / \int_\Omega u$, and the energy defect $d_{\mathrm{E}} = 1 - \|u_{\mathrm{ap}}\|_{L^2}^2 / \|u\|_{L^2}^2$ for the computed solution u_{ap} at various times t for several values of Δt are given in Table 5.1 for the Euler method. The corresponding values for the Runge–Kutta method are displayed in Table 5.2. From these numbers we see the anticipated convergence behavior in the L^∞-norm, i.e., $O(\Delta t)$ for the Euler and $O(\Delta t^4)$ for the Runge–Kutta method.

We compute an approximate solution u_{ap} in every time step k by projecting a transformed former solution onto the current approximation space,

$$u_{\mathrm{ap}}^k = \Pi^k \left(u_{\mathrm{ap}}^{k-1} \circ \tilde{T}^{\Delta t} \right). \tag{5.2}$$

Hence, for the defects in mass d_{M} and energy d_{E} we get the equivalences

$$d_{\mathrm{M}}^k = 1 - \frac{\int_\Omega \Pi^k \left(u_{\mathrm{ap}}^{k-1} \circ \tilde{T}^{\Delta t} \right)}{\int_\Omega u^0}, \qquad d_{\mathrm{E}}^k = 1 - \frac{\int_\Omega \| \Pi^k \left(u_{\mathrm{ap}}^{k-1} \circ \tilde{T}^{\Delta t} \right) \|^2}{\int_\Omega \|u^0\|^2}, \tag{5.3}$$

where $u(\cdot, k\Delta t) = u^k = u^0 \circ T^{k\Delta t}$ and $T^{k\Delta t}$ is the transformation induced by the exact characteristic at $k\Delta t$ with $|\det J_{T^{k\Delta t}}| = 1$. Not only the transformation $\tilde{T}^{\Delta t}$

but also the projection Π^k, i.e., the approximation space, depend on the applied ODE solver since the particles which define the approximation space are propagated forward along the characteristic. Therefore, we have two sources for a time-dependent error component in (5.3), $|\det J_{\tilde{T}^{\Delta t}}|$ and Π^k. A convergence behavior similar to that of the applied ODE solver can be perceived from the measured defects $d_{\mathrm{M/E}}$. As one can expect, for both ODE solvers we have $d_{\mathrm{M}} = d_{\mathrm{E}}$ if the defects are large compared with the spatial resolution, i.e., the displayed defects $d_{\mathrm{M/E}}$ are significant only if the local errors can be resolved (beyond oscillations) by the approximation space. For the Euler method we have a loss of energy and mass over time which is due to the fact that the backward Euler integration contracts the support of the approximate solution, i.e., the characteristics are approximated by a contracting spiral. For the particle distribution, though, we approximate the characteristic by forward integration. Hence, the path of a single particle is a widening spiral and the particles are propagated away from the support of the solution. The particles may even leave the domain of interest whereas the approximate solution will move to the center with a contracted support. Therefore, the approximate solution may vanish once its support is contracted beyond the spatial resolution of the approximation space (see Table 5.1). Hence, we have an additional loss of spatial resolution due to the difference in forward-backward time integration. This error affects the quality of the projection Π^k which is the main source for the oscillations $u_{\mathrm{ap}}^{\mathrm{osc}}$. The displayed oscillations $u_{\mathrm{ap}}^{\mathrm{osc}}$ are also a measure for peak attenuation since $u_{\mathrm{ap}}^{\mathrm{osc}} = \min u - \min u_{\mathrm{ap}}$ in all our experiments.

In Figure 5.2 the isolines of the approximate solution, the isolines of the error, and the corresponding particle distribution at times $(6\Delta t, 12\Delta t, 18\Delta t, 24\Delta t)$ with $\Delta t = 2\pi/25$ are displayed. We clearly see that the spatial degrees of freedom follow the evolution of the solution. From these figures we cannot see a difference in the forward-backward time integration for the Runge–Kutta method, i.e., the particles and the solution are propagated along the "same" path. This can also be observed from the oscillations displayed in Table 5.2 since $u_{\mathrm{ap}}^{\mathrm{osc}}$ is (almost) independent of Δt and t.

From the displayed isolines we notice the "conservation" of the peak of the solution. Moreover, we see that the overall error is dominated by the error in space rather than in time for small values of Δt. Further experiments showed the antici-

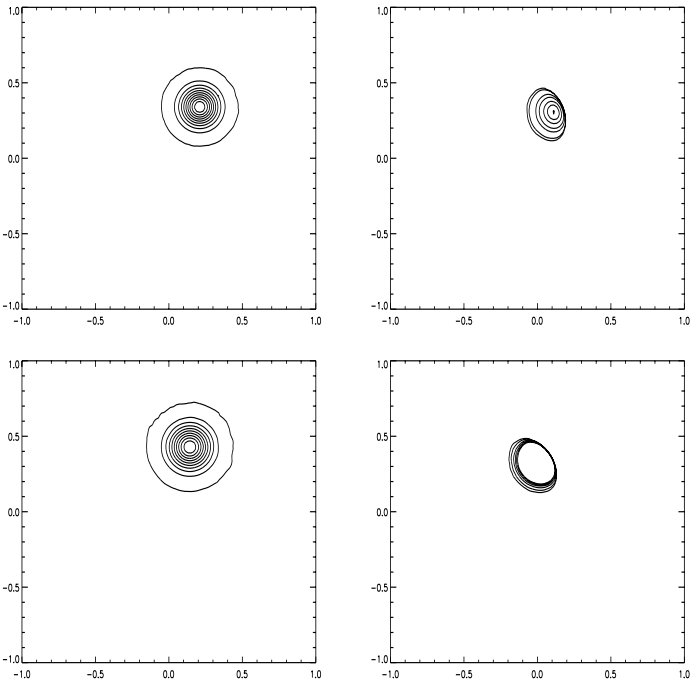

FIGURE 5.3. *Isolines* $(0.005, 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9)$ *of the computed solution (left) and isolines* $(0.005, 0.01, 0.05, 0.1, 0.2, 0.3, 0.4)$ *of the error (right) for* (5.1) *using a fourth order Runge–Kutta method after* 3 *(*$t = 19\Delta t$*, top) and* 6 *(*$t = 38\Delta t$*, bottom) revolutions with* $\Delta t = 4\pi/25$.

pated "third order" convergence in space (see section 5.2). Here, the error is located in a small region around the approximate support $\hat{\Omega}$ where the resolution of the approximation space is significantly less than in $\hat{\Omega}$. Hence, the error could probably be reduced by using an initial particle distribution which is more adapted to the initial value. The isolines of the computed solution after (slightly more than) three and six full revolutions using the Runge–Kutta method with $\Delta t = 4\pi/25$ are displayed in Figure 5.3. Again, we see the conservation of the peak. But here we can also observe the mass and energy defect. The diameter of every isoline grows, i.e., we have an increase in mass and energy over time. Furthermore, the isolines of the corresponding errors are displayed which show the dominance of the error in time rather than in space for large values of Δt.

5.2. Elliptic problems. In the following we consider the model problem

$$-\nabla A \nabla u + bu = f \text{ in } \Omega := (0,1)^2 \tag{5.4}$$

with suitable boundary conditions $Bu = g$ on $\Gamma := \partial\Omega$. We discretize this elliptic problem using our particle-PUM as described in section 4. The particle distribution we use is generated via either a Halton sequence or a graded uniform distribution.

According to the results of [3, 4] (see section 4.1.4), we can estimate the global error with respect to $\max_i \operatorname{diam}(\omega_i)$ only. We can expect erratic fluctuations in the convergence rates if we measure the convergence based on such error estimates since we use a pseudo Monte Carlo sequence to generate the particle distribution. Furthermore, we may get a convergence behavior of the global space V which is superior to the one of the local spaces V_i due to the overlapping of the cover patches; see section 4.1.4.

Therefore, we measure convergence rates ρ with respect to the number of degrees of freedom $\mathsf{dof} = \sum_{i=1}^{N} \dim(V_i)$, i.e., we propose an algebraic error estimate

$$\|u - \tilde{u}\| = O(\mathsf{dof}^{\rho}).$$

We compute ρ from the measured errors $\|u - \tilde{u}_l\|$ and $\|u - \tilde{u}_{l-1}\|$ on two successive levels l and $l-1$ via the relation

$$\rho = \frac{\log\left(\frac{\|e_l\|}{\|e_{l-1}\|}\right)}{\log\left(\frac{\mathsf{dof}_l}{\mathsf{dof}_{l-1}}\right)}, \quad \text{where } e_l = u - \tilde{u_l}. \tag{5.5}$$

These convergence rates ρ can be translated into the well-accepted h^{α} notation in the case of a uniform particle distribution and $\dim(V_i) = \mathsf{const}$. Here, we have $h \sim N^{-1/d} \sim \mathsf{dof}^{-1/d}$. Therefore we get the relation $-\alpha/d \sim \rho$. For example, the analogue of a convergence of the order $O(h^2)$ in the L^2-norm is achieved if we measure $\rho_{L^2} = -1$ for a 2D problem.

Example 1 (h-version of particle-PUM, smooth solution). Our first elliptic example is the simple Helmholtz equation

$$-\Delta u + u = f \text{ in } \Omega = (0,1)^2 \tag{5.6}$$

with Neumann boundary conditions $\partial u/\partial n = g$ on $\Gamma = \partial\Omega$. We choose f and g such that the continuous solution to the problem is given as

$$u(x,y) = \arctan\left(100\left(\frac{x+y}{\sqrt{2}} - 0.8\right)(x - x^2)(y - y^2)\right). \tag{5.7}$$

The weight function W_i in this experiment is the quadratic B-spline, the stretch parameter $\alpha = 1.5$, the local approximation spaces V_i are the linear Legendre polynomials, and the underlying particle distribution is the pseudo Monte Carlo distribution generated via a $(2,3)$ Halton sequence. Therefore, we expect to measure convergence rates $\rho_{L^2} \sim -1$ in the L^2-norm and $\rho_{H^1} \sim -0.5$ in the H^1-norm. The solution (5.7) and the error for the experiment with 256 particles are displayed in Figure 5.4.

Table 5.3 and Figure 5.5 give the error in different norms and the associated convergence rates for varying particle numbers. We clearly see a rate of -1 in the L^2-norm and L^∞-norm and a rate of -0.5 for the H^1-norm (i.e., a convergence of the order $O(h^2)$ in the L^2-norm and L^∞-norm and a convergence of the order $O(h)$ in the H^1-norm). These results demonstrate that the particle-PUM based on a pseudo Monte Carlo particle distribution matches the convergence behavior of the h-version of the finite element method on a uniform grid. Thus, our method incorporates the advantages of a particle method but preserves at the same time the usual convergence properties of the finite element method.

Example 2 (h-version of particle-PUM, singular solution). In our second experiment with an elliptic problem we consider the Laplace equation

$$-\Delta u = f \text{ in } \Omega = (0,1) \times (-0.5, 0.5) \tag{5.8}$$

with Dirichlet boundary conditions $u = g$ on $\Gamma = \partial\Omega$. We choose f and g such that

$$u(x,y) = u(z) = \mathrm{Re}(z^{1/2}) = (x^2 + y^2)^{1/4} \cos\left(\frac{\arctan(\frac{x}{y})}{2}\right) \tag{5.9}$$

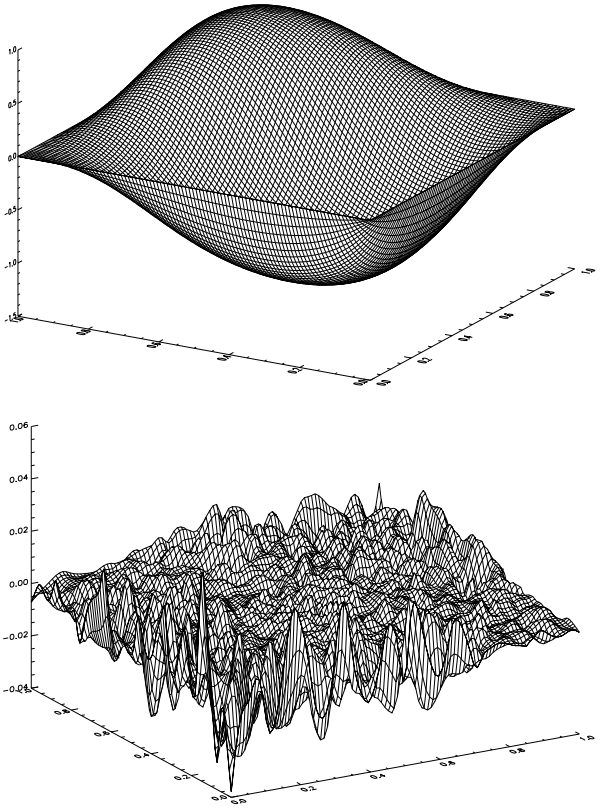

FIGURE 5.4. *Graph of solution* (5.7) *and graph of error for Example* 1 *using* 256 *particles.*

is the continuous solution to the problem. Besides a uniform particle distribution we also use a graded particle sequence (see Figure 5.8) to cope with the singularity of the solution (5.9). Note that all particles ξ_i of the uniform distribution are interior points of the domain Ω, i.e., $\xi_i \in \Omega \setminus \partial\Omega$. We use the same weight functions and local approximation spaces as in Example 1 and a stretch parameter $\alpha = 1.25$ for the uniform and the graded particle distribution. The Dirichlet boundary conditions are enforced by Lagrangian multipliers which are constructed according to section 4.2.2. Here, we are using the constant function only as local approximation spaces for the multiplier space Q_h to have a coarser resolution on the boundary than in the interior so that the discrete LBB condition (4.16) holds. We measure a convergence rate ρ_{L^∞} of about -0.35 for the uniform particle distribution (see Table 5.4). This is slightly better than the well-known convergence of the order $O(h^{1/2})$ of the finite element method in the L^∞-norm for this problem. Since the pointwise convergence of

the finite element method in points sufficiently far away from the singularity is of the order $O(h^{3/2})$, we can expect a convergence rate ρ_{L^2} in the L^2-norm less than -0.75. We measure a convergence rate ρ_{L^2} which is close to -0.75 for the uniform particle distribution. Figure 5.6 shows the solution (5.9) and the error for 256 particles of the graded particle distribution. From Figure 5.7 and Table 5.4 we see that the use of a graded particle distribution improves the convergence behavior of the method.

Now, we measure convergence rates ρ_{L^2} and ρ_{L^∞} of about -0.8 in the L^2-norm and -0.5 in the L^∞-norm. Since the grading we employ to the particle distribution (see Figure 5.8) is not optimal, we are not able to completely recover $\rho_{L^2,L^\infty} \sim -1$. Here, error estimators for adaptive particle refinement must be developed in the future to fully exploit the capabilities of the method.

The results from Examples 1 and 2 demonstrate that the particle-PUM does work on irregular or scattered data with roughly the same convergence behavior as the finite element method on a uniform grid. Furthermore, Example 2 indicates that we might also resolve singularities of the solution by local refinement, i.e., by increasing the particle density close to the singularity. Thus, we can achieve a similar convergence as we would obtain with an adaptive finite element method but can circumvent the geometric constraints we have to face there (angle conditions, hanging nodes, proper local grid refinement, quasi-uniformity of the grid, etc.). With the particle-PUM we may insert particles (almost) anywhere near the singularity without worrying much about the neighboring particles and their respective patch size.

Example 3 (p-version of particle-PUM, smooth solution). We again consider

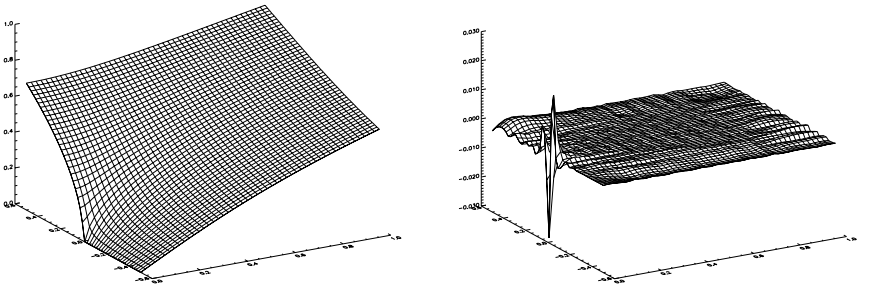

FIGURE 5.6. *Graph of solution* (5.9) *and graph of error for Example* 2 *using* 256 *particles.*

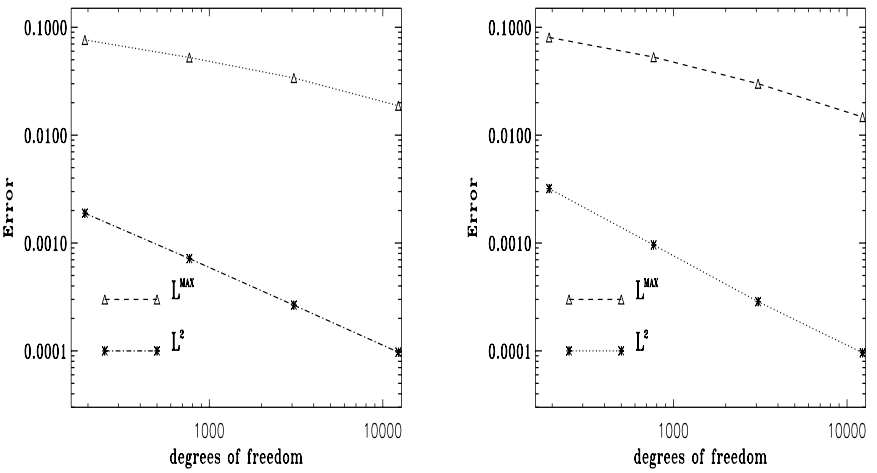

FIGURE 5.7. *Convergence history for Example* 2 *for the uniform particle distribution (left) and the graded particle distribution (right).*

the continuous problem from Example 1, but we will now apply the p-version of our particle-PUM. Here, the particle distribution is fixed, and we use 256 particles generated via a $(2, 3)$ Halton sequence and a stretch parameter $\alpha = 1.5$. The weight function used in this experiment is the well-known hat function. Furthermore, we use the complete polynomials V_i^C as local approximation spaces with degrees $p_i = p$ and p ranging from one to five. We choose tensor products of Legendre polynomials as local basis functions.

For analytic solutions u we may estimate the error $u - \tilde{u}$ on every cover patch ω_i using the Taylor-series expansion (see section 4.1.4). We obtain the local estimate

$$\|u - \tilde{u}\| = O\left(\|D^{(p+1)}u\| \frac{h^{p+1}}{(p+1)!}\right) \tag{5.10}$$

for an approximation $\tilde{u}$ of degree p, which leads to an exponential error estimate

$$\|u - \tilde{u}\| = O\left(\exp(-b\sqrt{\mathsf{dof}_p})\right) \tag{5.11}$$

on every cover patch ω_i. In our first experiment with the p-version we choose f and

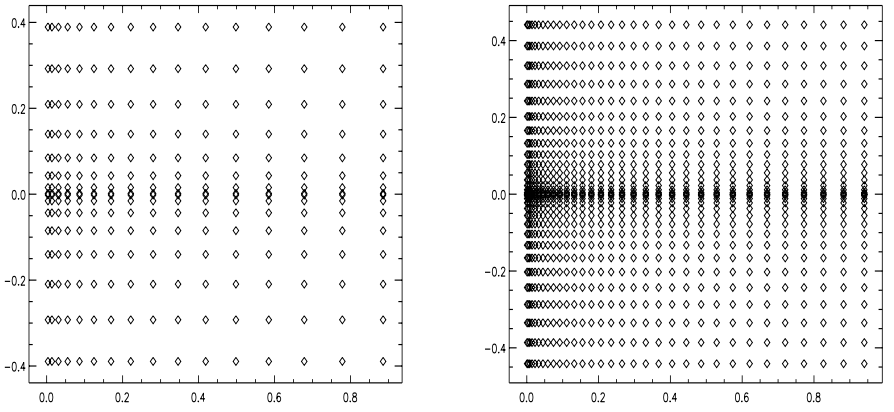

FIGURE 5.8. *Graded particle distribution via transformation:* $(x, y) \mapsto (x^2, \pm 2y^2)$.

g such that the continuous solution to the problem is given as

$$u(x, y) = \exp(4(x + y)). \tag{5.12}$$

This solution is sufficiently smooth for (5.11) to hold. Therefore, we expect to see an exponential convergence in this experiment. The plots of the measured errors against the number of degrees of freedom are displayed in Figure 5.9 (left). Their gradients ρ as defined in (5.5) are given in Table 5.5. These results clearly show the expected exponential convergence behavior.

Example 4 (p-version of particle-PUM, limited smoothness of solution). In a second experiment with the p-version of our particle-PUM we choose f and g such that the continuous solution to the problem is given by

$$u(x, y) = (x^2 + y^2)^{5/4}. \tag{5.13}$$

Here, the estimate (5.11) does not hold since (5.13) is not analytic. Therefore, we may not expect an exponential convergence behavior of the p-version of our particle-PUM in this experiment.

We use the same particle distribution, the same cover, and the same local approximation spaces V_i as in Example 3 with p now ranging from one to eight. Figure 5.10 shows the solution (5.13) and the error for $p = 5$. The measured errors are displayed in Figure 5.9 (right). The corresponding rates ρ and the measured errors are given in Table 5.6. From these results we clearly see an algebraic convergence behavior of the p-version of our particle-PUM for problems with solutions with limited smoothness properties. A similar behavior can be observed when we employ a finite element discretization with the p-version on a fixed uniform grid. In fact, a convergence rate of $2 \cdot 5/4$ ($\rho_{H^1} = -2.5$) in the H^1-norm is well known for the classical p-version of the FEM [5] for this problem and we (almost) recover this convergence behavior with our particle-PUM.

This experiment again demonstrates that the p-version of the particle-PUM based on a pseudo Monte Carlo particle distribution converges as well as the corresponding p-version of the finite element method.

In summary, the results of our numerical experiments with the h-version and p-version of our particle-PUM applied to elliptic problems clearly show that the method possesses the advantages of a particle method. At the same time, it exhibits a convergence behavior similar to that of the respective version of the finite element method.

5.3. Parabolic problem. In the following we consider the heat-equation

$$\frac{\partial u}{\partial t} - \Delta u = 0 \text{ in } \Omega := (-0.5, 0.5)^2 \times (0, T) \tag{5.14}$$

with vanishing Neumann boundary conditions $\partial u/\partial n = 0$ on $\Gamma := \partial\Omega$ and initial value $u(x, y, 0) = \exp(-100(x^2+y^2))$ in $\Omega := (-0.5, 0.5)^2$. For this parabolic model problem we use a random walk process as described in section 2 to simulate the diffusive transport on the particle positions. Furthermore, we reduce the parabolic problem to a sequence of elliptic problems via a standard implicit Eulerian time discretization which gives the usual $O(\Delta t)$ convergence behavior in time. We employ the shape functions from the PUM based on the particle positions after the random walk process to discretize the elliptic problem in every time step. Here, the weight functions W_i are the hat functions. The stretch parameter in this experiment is $\alpha = 1.25$. As local approximation spaces V_i we use the complete quadratic polynomials V_i^C. We use a block-structure approach using an approximate support $\hat{\Omega}$ of the initial value as described in section 5.1 to resolve the initial value. The particle distributions and isolines of the solution at times $(5\Delta t, 15\Delta t, 25\Delta t, 35\Delta t)$ with $\Delta t = 0.001$ are displayed in Figure 5.11. Here, we clearly see the diffusive particle transport and the reduction of the total number of particles over time. The diffusive particle transport adapts the distribution of the spatial degrees of freedom appropriately to the evolution of the solution. The solution gets smoother over time due to the diffusion. Here, the solution can be resolved to the same accuracy as the initial value with fewer unknowns, i.e., a successively reduced number of particles is sufficient to give a good approximation on Ω. We start with 469 particles (see Figure 5.12) and after 35 time steps there are

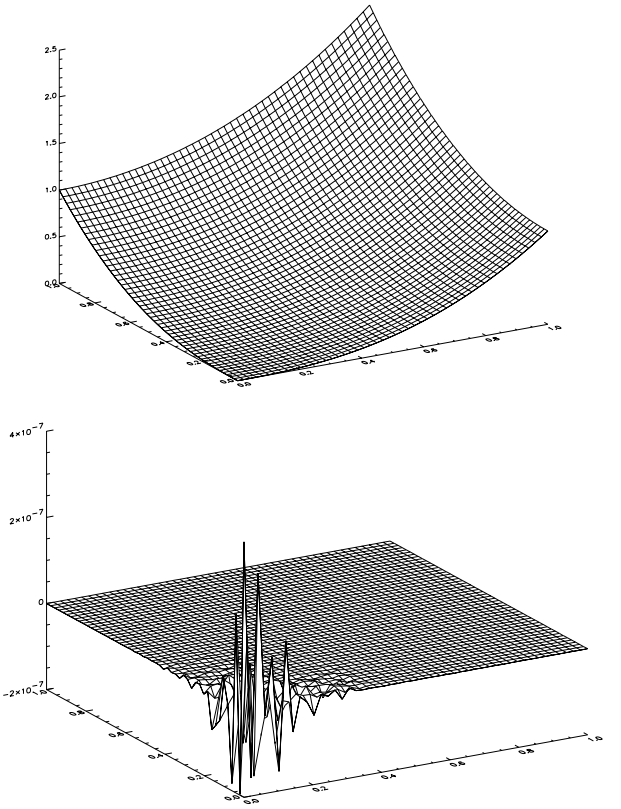

FIGURE 5.10. *Graph of solution* (5.13) *and graph of error for Example* 4 *with* $p = 5$.

TABLE 5.6
Errors and convergence rates for Example 4.

N	p	dof	$\|e\|_{L^\infty}$	ρ_{L^∞}	$\|e\|_{L^2}$	ρ_{L^2}	$\|e\|_{H^1}$	ρ_{H^1}

only 374 left (see Figure 5.11). But the number of particles within the approximate support $\hat{\Omega}$ (while $\hat{\Omega} \subset \Omega$) is almost constant over time, i.e., the solution in every time step is represented by an almost constant number of degrees of freedom in space. This is due to the Monte Carlo simulation of the diffusion onto the particle distribution and the Neumann boundary conditions. Overall, we only reduce the computational work by applying the Monte Carlo step, but the spatial resolution in every time step is sufficiently high to give a good approximation of the solution to (5.14). Due to use of quadratic polynomials V_i^C we have a "third order" convergence in space.

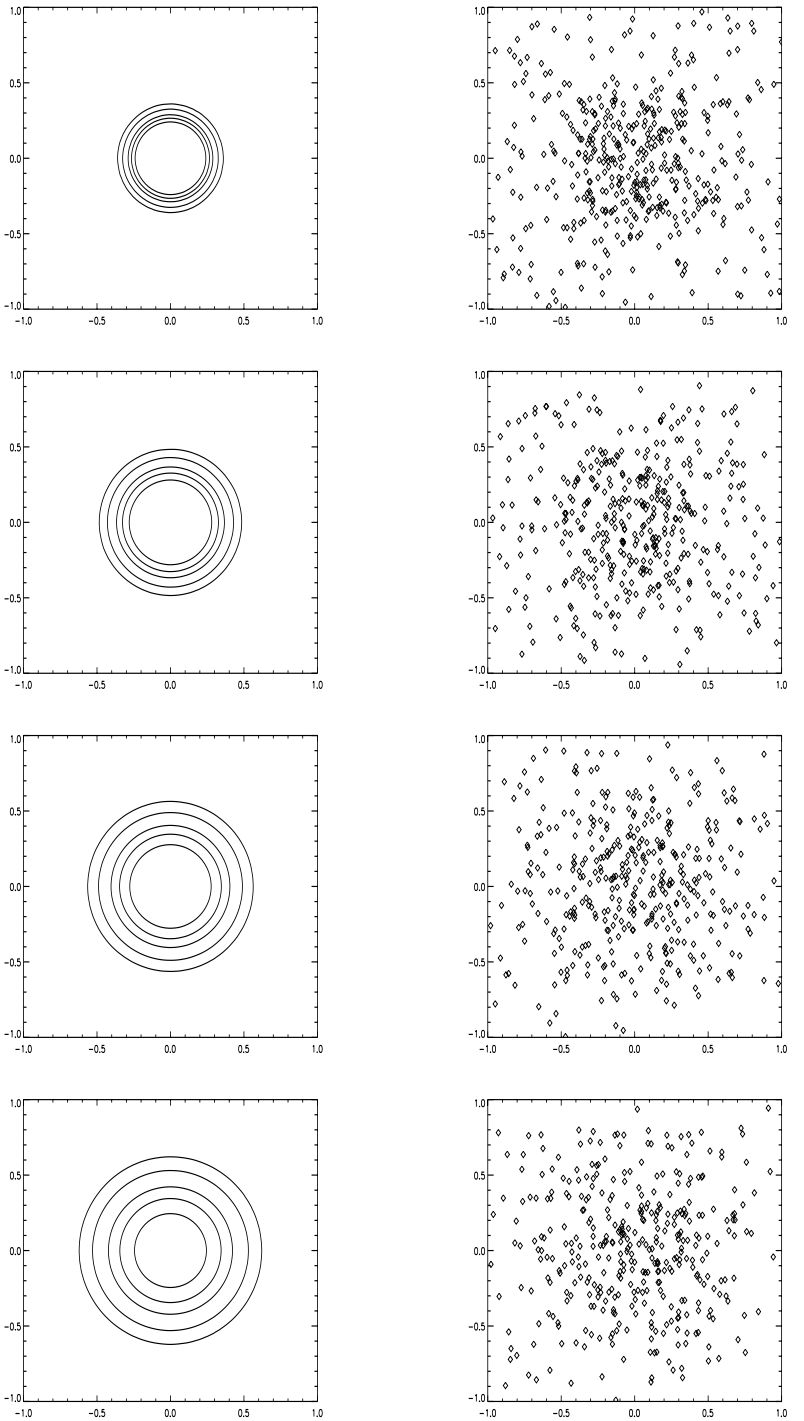

FIGURE 5.11. *Particle distributions and isolines* $(0.005, 0.01, 0.02, 0.03, 0.045)$ *of the approximate solution for* (5.14) *at times* $(5\Delta t, 15\Delta t, 25\Delta t, 35\Delta t)$ *with* $\Delta t = 10^{-3}$.

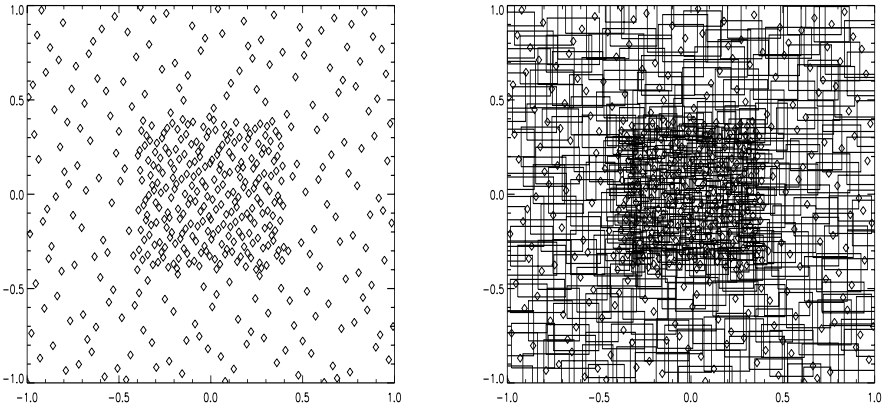

FIGURE 5.12. *Initial particle distribution (left) and the constructed cover (right) for* (5.14).

5.4. Convection-diffusion problem. In the following we consider the model problem

$$\frac{\partial u}{\partial t} - \frac{1}{125}\Delta u + \frac{1}{\sqrt{x^2+y^2}} \begin{pmatrix} -y \\ x \end{pmatrix} \nabla u = 0 \text{ in } \Omega := (-1,1)^2 \times (0,T) \tag{5.15}$$

with vanishing Neumann boundary conditions $\partial u/\partial n = 0$ on $\Gamma := \partial\Omega$ and initial value $u(x,y,0) = \exp(-100((x-\frac{1}{4})^2 + (y-\frac{1}{4})^2))$.

We discretize (5.15) via the particle method presented in section 2. First, we split the operator $\frac{\partial}{\partial t} - \nu\Delta + v\nabla$ into a hyperbolic operator $\frac{\partial}{\partial t} + v\nabla$ and a parabolic operator $\frac{\partial}{\partial t} - \nu\Delta$. Then, we apply the corresponding particle method to the resulting hyperbolic problem (see section 3, section 5.1) with a fourth order Runge–Kutta method, and to the remaining parabolic problem (see section 2, section 5.3). Again, we use $\alpha = 1.25$, hat functions as weight functions W_i for the construction of the partition of unity $\{\varphi_i\}$ and a block-structure approach to resolve the initial value. As local approximation spaces V_i we use the complete quadratic polynomials V_i^C.

The particle distributions and isolines of the solution at $(5\Delta t, 10\Delta t, 15\Delta t, 20\Delta t)$ with $\Delta t = 2\pi/50$ are displayed in Figure 5.13. Here, we see that the diffusive particle movement together with the particle movement induced by the Lagrangian discretization of the convective terms of (5.15) causes the particles to follow the solution over time. Thus, we have roughly the same number of degrees of freedom for the resolution of the solution in every time step. Note that the Lagrangian treatment of the convection part circumvents the stability problems we might experience with a finite element discretization for the convective terms of (5.15). Further experiments showed the expected discretization error of "third order" in space and the expected $O(\Delta t)$ discretization error in time which is due to the first order implicit Eulerian time discretization for the parabolic subproblem.

6. Concluding remarks. We presented a meshless Lagrangian discretization method for instationary convection-diffusion problems. The method combines a particle approach and a meshless method for the generation of shape functions and the adaptation of the distribution of nodes (particles). We gave the details of the implementation and results of our numerical experiments. They showed that the convergence properties of the h-version and p-version of our particle-PUM for elliptic problems are comparable to those of the h-version and p-version of the FEM, respectively.

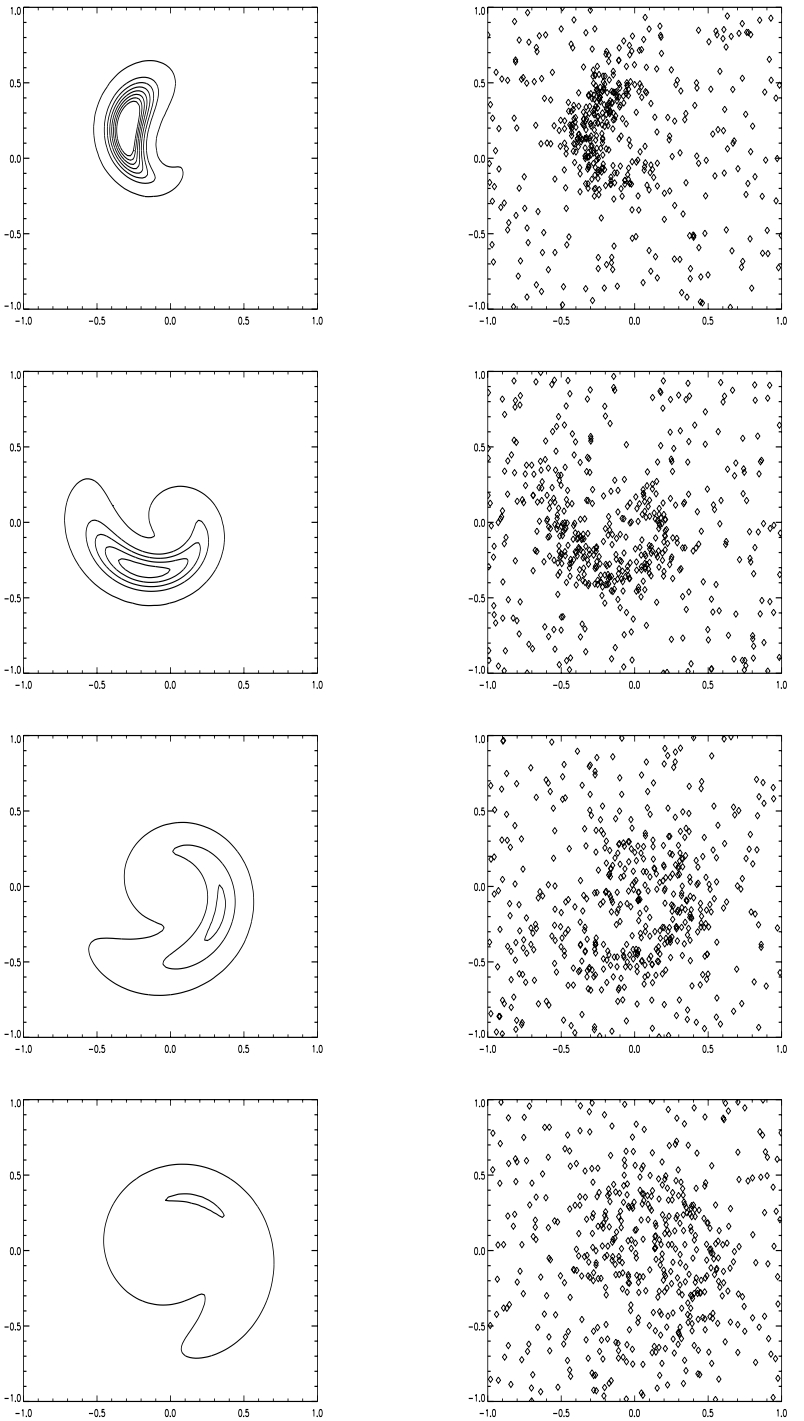

FIGURE 5.13. *Particle distributions and isolines* $(0.01, 0.05, 0.075, 0.1, 0.125, 0.15, 0.175, 0.2)$ *of the approximate solution for* (5.15) *at times* $(5\Delta t, 10\Delta t, 15\Delta t, 20\Delta t)$ *with* $\Delta t = 2\pi/50$.

The convergence behavior in time of the proposed method for hyperbolic problems corresponds to the convergence behavior of the employed ODE solver. Furthermore, a fewer number of degrees of freedom in space than with a uniform semi-Lagrangian method or even Euler method may be used since the degrees of freedom follow the solution over time. Hence, we do not have to resolve the complete computational domain with the same accuracy. Adaptive semi-Lagrangian or Euler methods would have to apply refinement and coarsening in every time step whereas our method will transform an adaptively refined particle distribution for the initial value into an adaptively refined particle distribution in every time step without applying explicit refinement and coarsening.

Up to now, the method is in an experimental state and is surely not yet competitive to existing grid-based methods. The efficiency of the method has to be improved. The most room for improvement is during the construction of a cover, the integration of the shape functions and the iterative solution of the resulting linear system, especially in the case of an elliptic problem with Dirichlet boundary conditions where we have to solve a saddle point problem. Furthermore, an adaptive refinement, i.e., the proper insertion of particles (h-version) as well as the local increment of the degree of the polynomials used (p-version) or both together (hp-version), needs the development of reliable local error indicators and estimators. Moreover, an adaptive control of the time step size, the use of local time stepping methods and the choice of more sophisticated operator splittings could further improve the performance of the method for time-dependent problems.

In summary, much additional work remains to be done, but the results presented in this paper demonstrate the promising properties of the particle-PUM and encourage its further development.

A PARALLEL SCHWARZ METHOD FOR A CONVECTION-DIFFUSION PROBLEM*

M. GARBEY†, YU. A. KUZNETSOV‡, AND YU. V. VASSILEVSKI§

Abstract. This paper describes a parallel convection-diffusion solver which may be used as part of a Navier–Stokes solver for three-dimensional channel flow at moderately large Reynolds numbers [S. Turek, *Efficient Solvers for Incompressible Flow Problems: An Algorithmic Approach in View of Computational Aspects*, Springer-Verlag, 1999]. The solver uses a multiplicative Schwarz domain decomposition with overlapping subdomains to solve singularly perturbed convection-diffusion equations where convection is dominant. Upwind finite differences are used for the spatial discretization. The algorithm uses special features of the singularly perturbed convection-diffusion operator. The error due to a local perturbation of the boundary conditions decays extremely fast, in the upwind as well as the crosswind direction, so the overlap in the domain decomposition can be kept to a minimum. The algorithm parallelizes well and is particularly suited for applications in three dimensions. Results of two- and three-dimensional numerical experiments are presented.

Key words. convection-diffusion, overlapping domain decomposition, maximum principle, upwind finite differences, damping factor

1. Introduction.

The importance of efficient convection-diffusion solvers is difficult to overestimate. Apart from their direct use in modeling schemes, for example, in pollution propagation, they constitute an essential part of several numerical techniques for the Navier–Stokes equations [8, 22]. In this paper, we present a new parallel convection-diffusion solver, which may be incorporated in a Navier–Stokes solver for three-dimensional channel flow at moderately large Reynolds number [21]. We focus on algorithmic (rather than approximation) issues for the convection-diffusion equations (adaptive grids, boundary layers, etc.). It is well known that the performance of an algorithm for linear singular perturbation problems depends not so much on the actual value of the small perturbation parameter as on its value relative to the mesh size [5]. In this paper we focus therefore on the analysis of the discrete operator, taking this relative value into account.

To solve a singularly perturbed convection-diffusion equation with strongly dominant convection, we apply the multiplicative Schwarz method for domain decomposition with overlapping subdomains. The algorithm is based on special features of the singularly perturbed convection-diffusion operator [20]. In particular, we take advantage of an anisotropic propagation of the perturbation associated with any local perturbation of the boundary conditions. In the case of a constant transport vector, a pointwise perturbation causes the perturbation to propagate only in the downwind direction and vanish rapidly both in the *upwind* and *crosswind* directions. Figure 1 (upper row) illustrates this phenomenon for a pointwise perturbation of homogeneous

Dirichlet boundary conditions at the midpoints of the left, upper, and right boundaries of the unit square. For an arbitrary transport vector, this is no longer the case. Directional variations of the transport vector in the vicinity of a pointwise perturbation of the boundary conditions tend to smear-out the solution perturbation. Figure 1 (bottom row) illustrates this phenomenon for a strong vortex near a pointwise perturbation of the boundary conditions.

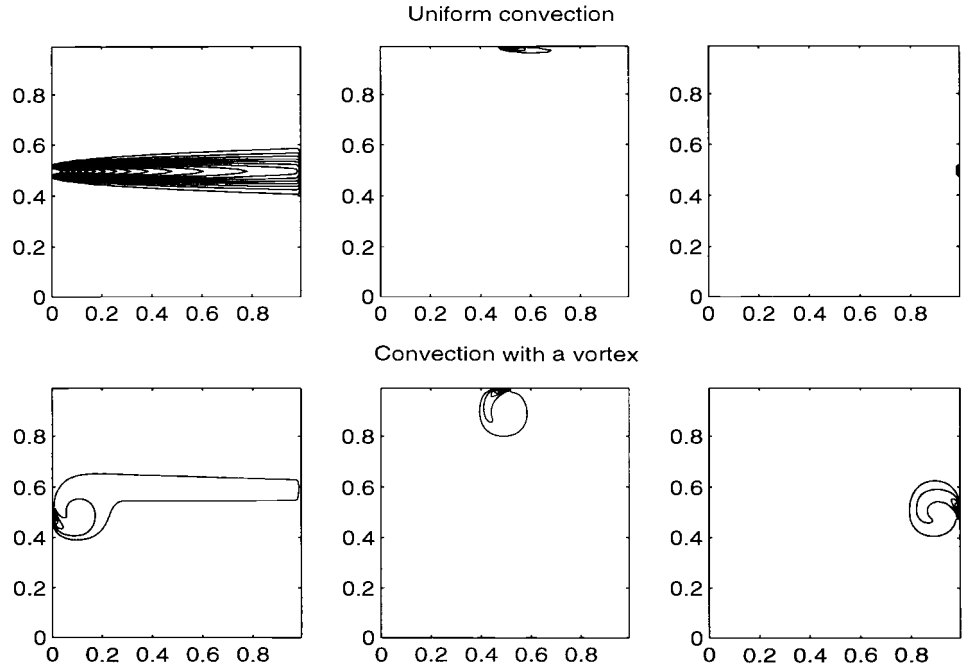

FIG. 1. *Solutions to problems with a pointwise perturbation of homogeneous Dirichlet boundary conditions.*

We propose a parallel algorithm for the solution of singularly perturbed convection-diffusion problems described by the operator

$$\mathcal{L} = -\varepsilon\Delta + B^1(x_1, x_2) \cdot \frac{\partial}{\partial x_1} + B^2(x_1, x_2) \cdot \frac{\partial}{\partial x_2},$$

where $\vec{B} = (B^1, B^2)^T$, with B^1 positive in the main part of the domain and B^2 of the same order as B^1 or smaller.

Problems with transport vectors $\vec{B}$ with *small deviations* from the prescribed downwind direction (B^2 small compared to B^1) are solved by the following two-level Schwarz method. At the outer level, we split the original domain into overlapping crosswind strips (slices). The classical Schwarz method in the downwind direction is the outer part of the algorithm. If the trace of B^1 on the artificial interfaces is positive and bounded below by a positive constant B_0 of order one, very few outer iterations are needed to reach a prescribed accuracy. The fast convergence is a consequence of the upwind decay. It is natural to use a Schwarz method for the inner iterations. We split each strip-subdomain into overlapping boxes and define the inner iterations using a version of either the multiplicative or the additive Schwarz method. The novel feature of the version of the Schwarz method selected for the inner iterations is

that the choice of overlapping domain decomposition is based on the fast crosswind decay phenomenon which is present when the trace of B^2 is smaller than the trace of B^1 on the artificial interfaces. At the level of the inner iterations, we have natural parallelism, since each of the box-subdomains can be treated by its own processor. Actually, one can consider a family of parallel methods by varying the type of solver within the strip-subdomain. It is very important that the number of iterations between the box-subdomains with odd and even indices may be very small (1 or 2) and small overlappings practically do not affect the fast convergence of the algorithm.

For problems with a transport vector with *large deviations* from the prescribed downwind direction we introduce an adaptive two-level Schwarz method based on the automatically adapted first-stage domain decomposition. The first-stage splitting is chosen in such a way that the B^1-component of the transport vector is strictly positive on the artificial interfaces. For instance, if the transport vector contains a strong stagnant vortex in some region, the strip-subdomain has to be chosen sufficiently "thick" to contain the vortex. Moreover, the number of iterations between the box-subdomains with odd and even indices has to be increased in those thick strip-subdomains that slow down the iterations. Nevertheless, we show that the method maintains a fast convergence rate. As long as the vertex zone is small compared to the size of the domain, the algorithm is efficient and readily parallelizable. The techniques are readily generalized to the three-dimensional case.

The theoretical analysis of the above algorithm is given in [6, 7]. It is performed on the discrete level. The properties of grid functions satisfying certain systems of algebraic equations constitute the core of the analysis. The approximation scheme, which uses finite differences, must satisfy the discrete maximum principle.

Numerical results for the additive version of the two-stage Schwarz method applied to singularly perturbed convection-diffusion problem are presented in [10]. For domain-decomposition algorithms based on discrete upwind decaying phenomenon, we refer to [9, 19]. Other results concerning domain-decomposition methods for singularly perturbed elliptic equations can be found in [1, 4, 5, 2, 12, 13, 14]. The decay of the discrete Green's function has been analyzed in [11, 15] for the case of streamline upwinding Petrov–Galerkin discretization. For a comprehensive study of differential solution properties, we refer to [20, 3]. Parallel multigrid techniques relevant to the problem of interest are considered in [17, 18].

The remainder of the paper is organized as follows. In section 2 we consider the simplest singularly perturbed convection-diffusion operator with a constant transport vector. First, we investigate the upwind and crosswind error propagation. Second, we assemble the results for the propagation errors to analyze the convergence property of the two-level Schwarz method. Section 3 is devoted to the convection-diffusion operator with a variable transport vector. We present an adaptive version of the two-level Schwarz method for solving the discrete problem and discuss the convergence of the method. Section 4 gives implementation details for the adaptive technique for splitting the computational domain and providing fast convergence and efficient parallelization of the algorithm. In section 5, we present the results of the numerical experiments. In sections 5.1 and 5.2, we consider two- and three-dimensional problems and report on the numerical results in terms of the convergence and parallel performance.

2. Convection-diffusion problem with a constant transport vector. We consider a two-dimensional convection-diffusion equation with constant coefficients in

the unit square:

$$\begin{aligned} \mathcal{L}u &= f \qquad \text{in } \Omega = (0;1)\times(0;1), \\ u &= g \qquad \text{on } \Gamma_D, \\ \frac{\partial u}{\partial \nu} &= 0 \qquad \text{on } \Gamma_N, \end{aligned} \tag{2.1}$$

where

$$\mathcal{L} = -\varepsilon\Delta + \frac{\partial}{\partial x_1}, \tag{2.2}$$

$\varepsilon \equiv \text{const} \in (0;1)$, $\Gamma_N = \{x \equiv (x_1, x_2) : x \in \partial\Omega, x_1 = 1, 0 < x_2 < 1\}$, $\Gamma_D = \partial\Omega \setminus \Gamma_N$, and ν is the outer conormal vector to Γ_N. We assume that the functions g and f are sufficiently smooth, nonnegative, and bounded from above by 0.5. The above restrictions on g and f are dictated only by simplicity of presentation. We introduce the Neumann boundary condition for the sake of generality; the case $\Gamma_N = \emptyset$ is covered by the analysis as well.

Let Ω_h be a square grid with the step size $h = 1/n$, where n is a positive integer. Then the system of the finite difference equations can be presented in the following form:

$$\begin{aligned} \mathcal{L}_h\, u_{ij} &= f_{ij}, \qquad x_{ij} \in \Omega \cup \Gamma_N, \\ u_{ij} &= g_{ij}, \qquad x_{ij} \in \partial\Omega \setminus \Gamma_N, \end{aligned} \tag{2.3}$$

where $x_{ij} = (ih, jh)$, $i, j = 0, \ldots, n$. Here

$$\mathcal{L}_h\, u_{ij} = \begin{cases} \dfrac{\varepsilon}{h^2}\left[4u_{ij} - u_{i+1j} - u_{i-1j} - u_{ij-1} - u_{ij+1}\right] + \dfrac{u_{ij} - u_{i-1j}}{h}, & x_{ij} \in \Omega, \\ \dfrac{\varepsilon}{h^2}\left[3u_{ij} - u_{i-1j} - u_{ij-1} - u_{ij+1}\right] + \dfrac{u_{ij} - u_{i-1j}}{h}, & x_{ij} \in \Gamma_N; \end{cases} \tag{2.4}$$

that is, the convection term is approximated by the upwind finite differences. In what follows, the term "upwind" stands for the opposite direction to the first coordinate axis and "crosswind" stands for the orthogonal direction.

We note that grid operator (2.4) satisfies the well-known maximum principle [16]. Taking into account restrictions on f and g and applying the grid maximum principle we get

$$\max_{x_{ij} \in \bar{\Omega}} u_{ij} \le 1.$$

2.1. Upwind and crosswind error propagation. Let n_a and n_b be positive integers such that $n_a < n_b \le n$. We set $a = n_a \cdot h$ and $b = n_b \cdot h$ and consider a grid problem (Figure 2)

$$\begin{aligned} \mathcal{L}_h\, v_{ij} &= f_{ij} \qquad \text{in } \Omega_b = (0;b)\times(0;1), \\ v_{ij} &= g_{b,j} \qquad \text{on } \Gamma_b = \{x : x_1 = b, 0 < x_2 < 1\}, \\ v_{ij} &= g_{ij} \qquad \text{on } \partial\Omega_b \setminus \Gamma_b, \end{aligned} \tag{2.5}$$

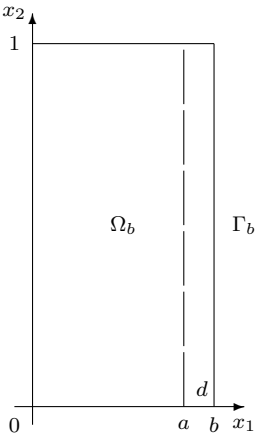

FIG. 2. *Strip subproblem in* Ω_b.

where

$$g_{b,j} = (1 - j \cdot h) \cdot g(b, 0) + j \cdot h \cdot g(b, 1). \tag{2.6}$$

Our goal is to find for given n_a and $\delta \in (0; 1)$ a value of n_b, possibly smaller to satisfy the inequality

$$\max_{\substack{0 \le i \le n_a \\ 0 \le j \le n}} |v_{ij} - u_{ij}| \le \delta. \tag{2.7}$$

LEMMA 2.1. *Let* $d = h \cdot (n_b - n_a)$. *Then* (2.7) *holds true for any* d *which satisfies the inequality*

$$d \ge h \, \frac{\ln(1/\delta)}{\ln q_1}, \qquad q_1 = 1 + \frac{h}{\varepsilon}. \tag{2.8}$$

Proof. The grid function $w_{ij} = v_{ij} - u_{ij}$ is the solution of the grid problem

$$\begin{aligned} \mathcal{L}_h \, w_{ij} &= 0 && \text{in } \Omega_b, \\ w_{ij} &= 0 && \text{on } \partial\Omega \setminus \Gamma_b, \\ w_{ij} &= g_{b,j} - u_{ij} && \text{on } \Gamma_b. \end{aligned}$$

Using the grid maximum principal we can show that

$$|w_{ij}| \le w_i, \qquad x_{ij} \in \bar{\Omega},$$

where the grid function

$$w_i = \frac{q_1^i - 1}{q_1^{n_b} - 1}, \qquad i = 0, \ldots, n_b, \qquad q_1 = 1 + \frac{h}{\varepsilon},$$

is the solution to the finite difference system

$$\frac{\varepsilon}{h^2}[2w_i - w_{i-1} - w_{i+1}] + \frac{1}{h}(w_i - w_{i-1}) = 0, \qquad i = 1, \ldots, n_b - 1,$$
$$w_0 = 0, \qquad w_{n_b} = 1.$$

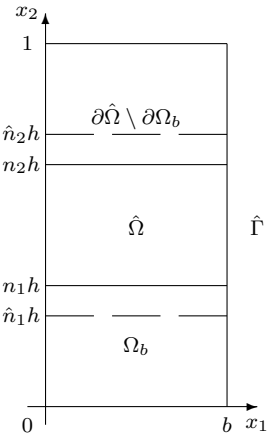

FIG. 3. *Box subproblem.*

Thus,

$$w_i \le q_1^{i-n_b}. \qquad \square$$

Remark 1. We see that in the case $\varepsilon \sim h^\alpha, \alpha > 1$ (that is, $\varepsilon \ll h$), $\ln\left(1+\frac{h}{\varepsilon}\right) \simeq (\alpha-1)\ln h^{-1}$. Therefore, the overlap required by (2.8) is as much as a few mesh steps:

$$d \ge h\frac{\ln(1/\delta)}{(\alpha-1)\ln h^{-1}}.$$

In the opposite case $h \ll \varepsilon$ we rewrite (2.8) as

$$d \ge \varepsilon\,\frac{\ln(1/\delta)}{\ln \kappa_1}, \quad \kappa_1 = (1+h/\varepsilon)^{\varepsilon/h},$$

and note that $\kappa_1 \to e$ as $h/\varepsilon \to 0$. The last estimate coincides with the differential estimate [20]. $\square$

Now, we consider an approximation to the solution of the problem (2.5) by the solution of an auxiliary problem.

We assume that n_1 and n_2, $n_1 \le n_2$, are given nonnegative integers, and $\hat{n}_1$ and $\hat{n}_2$ are also nonnegative integers such that $\hat{n}_1 \le n_1$ and $n_2 \le \hat{n}_2 \le n$. We consider a finite difference problem (Figure 3)

$$\begin{aligned}
\mathcal{L}_h \hat{v}_{ij} &= f_{ij} \qquad \text{in } \hat{\Omega} = (0;b)\times(\hat{n}_1 h; \hat{n}_2 h),\\
\hat{v}_{ij} &= g_{b,j} \qquad \text{on } \hat{\Gamma} = \partial\hat{\Omega} \cap \Gamma_b,\\
\hat{v}_{ij} &= \begin{cases} g_{ij} & \text{on } \partial\hat{\Omega} \cap \partial\Omega_b \setminus \Gamma_b,\\ 1 & \text{on } \partial\hat{\Omega} \setminus \partial\Omega_b. \end{cases}
\end{aligned} \tag{2.9}$$

The grid function $g_{b,j}$ is defined in (2.6).

Our goal is to find for given n_1, n_2, and $\delta \in (0;1)$ values of $\hat{n}_1$ and $\hat{n}_2$ as close as possible to the values of n_1 and n_2, respectively, such that the estimate

$$\max_{\substack{0\le i\le n_b\\ n_1\le j\le n_2}} |v_{ij} - \hat{v}_{ij}| \le \delta \tag{2.10}$$

holds true.

LEMMA 2.2. *To provide estimate* (2.10)*, choose*

$$\begin{aligned} \hat{n}_1 &= \max\{0; n_1 - n_b - [n^*]\}, \\ \hat{n}_2 &= \min\{n; n_2 + n_b + [n^*]\}, \end{aligned} \tag{2.11}$$

where $[n^*]$ *is the integer part of* n^* *and*

$$n^* = \frac{\ln 2/\delta}{\ln q_2}, \qquad q_2 = 1 + \frac{h}{2\varepsilon}. \tag{2.12}$$

Proof. The error grid function $w_{ij} = v_{ij} - \hat{v}_{ij}$ satisfies the equations

$$\begin{aligned} \mathcal{L}_h w_{ij} &= 0 \qquad \text{in } \hat{\Omega}, \\ w_{ij} &= \begin{cases} 0 & \text{on } \partial\hat{\Omega} \cap \partial\Omega_b, \\ v_{ij} - 1 & \text{on } \partial\hat{\Omega} \setminus \partial\Omega_b. \end{cases} \end{aligned}$$

It follows from the grid maximum principle that the solution grid function to (2.5) satisfies the inequality (due to the assumptions $0 \le f \le 0.5$ in Ω and $0 \le g \le 0.5$ on $\partial\Omega$)

$$\max_{\substack{0 \le i \le n_b \\ 0 \le j \le n}} v_{ij} \le 1.$$

Hence,

$$\max_{\partial\hat{\Omega}} |w_{ij}| \le 1.$$

We consider an additional grid problem

$$\begin{aligned} \mathcal{L}_h \hat{w}_{ij} &= 0 \qquad \text{in } \hat{\Omega}, \\ \hat{w}_{ij} &= \begin{cases} 0 & \text{on } \partial\hat{\Omega} \cap \partial\Omega_b, \\ 1 & \text{on } \partial\hat{\Omega} \setminus \partial\Omega_b. \end{cases} \end{aligned} \tag{2.13}$$

It is obvious that $|w_{ij}| \le \hat{w}_{ij}$ in $\hat{\Omega} \cup \partial\hat{\Omega}$.

For the sake of simplicity we consider the situation when $\hat{n}_2 < n$ and $\hat{n}_1 = 0$. Then (2.13) can be presented by

$$\begin{aligned} \mathcal{L}_h \hat{w}_{ij} &= 0 \qquad \text{in } \hat{\Omega}, \\ \hat{w}_{ij} &= 1 \qquad \text{on } \hat{\Gamma}_2 = \{x : 0 < x_1 < b, \qquad x_2 = \hat{n}_2 h\}, \\ \hat{w}_{ij} &= 0 \qquad \text{on } \partial\hat{\Omega} \setminus \hat{\Gamma}_2. \end{aligned} \tag{2.14}$$

We replace (2.14) by the same sort of the finite difference problem in the smaller domain $G = \{x : x \in \hat{\Omega}, x_1 + x_2 < (\hat{n}_2 + 1)h\}$:

$$\begin{aligned} \mathcal{L}_h z_{ij} &= 0 \qquad \text{in } G, \\ z_{ij} &= 0 \qquad \text{on } \partial G \cap \partial\hat{\Omega}, \\ z_{ij} &= 1 \qquad \text{on } \partial G \setminus \partial\hat{\Omega}. \end{aligned} \tag{2.15}$$

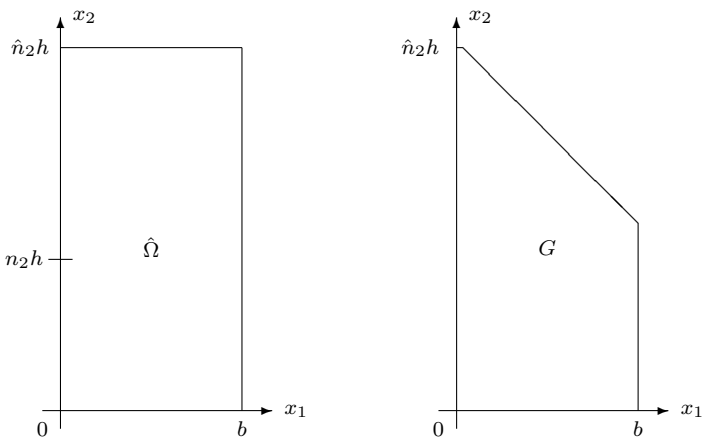

FIG. 4. *An example of domains* $\hat{\Omega}$ *and* G.

According to the grid maximum principle the following estimate holds true:

$$\hat{w}_{ij} \le z_{ij}, \qquad x \in G.$$

An example of the domains $\hat{\Omega}$ and G is presented in Figure 4.

Let us define the values

$$z_l = \max_{i+j=l} z_{ij}, \qquad l = 1, \dots, \hat{n}_2 + 1.$$

We fix some l and write (2.15) for the grid node where $z_l = z_{ij}$. Negative terms we substitute by their low estimates and get from (2.15) the system of inequalities [4]

$$-\frac{2\varepsilon}{h^2}\left[z_{l-1} + z_{l+1} - 2z_l\right] + \frac{z_l - z_{l-1}}{h} \le 0, \qquad l = 2, \dots, \hat{n}_2,$$

with the boundary conditions

$$z_1 = 0, \qquad z_{\hat{n}_2+1} = 1.$$

Consider the system

$$-\frac{2\varepsilon}{h^2}\left[\hat{z}_{l-1} + \hat{z}_{l+1} - 2\hat{z}_l\right] + \frac{\hat{z}_l - \hat{z}_{l-1}}{h} = 0, \qquad l = 2, \dots, \hat{n}_2, \tag{2.16}$$

$$\hat{z}_1 = 0, \qquad \hat{z}_{\hat{n}_2+1} = 1.$$

The grid maximum principle results are

$$z_l \le \hat{z}_l, \qquad l = 1, \dots, \hat{n}_2.$$

Applying the analysis from the proof of Lemma 2.1 to system (2.16) we get estimates

$$\hat{z}_l \le q_2^{-(\hat{n}_2+1-l)}, \qquad l = 1, \dots, \hat{n}_2,$$

where

$$q_2 = 1 + h/2\varepsilon.$$

Thus, to provide estimate (2.10) we can choose the value of $\hat{n}_2$ equal to the integer part of $\hat{n}_2^* + 1$, where $\hat{n}_2^*$ is the solution of the equation

$$\delta/2 = q_2^{-(\hat{n}_2^*+1-n_b-n_2)},$$

while $\hat{n}_1$ is equal to the integer part of $\hat{n}_1^*$, where $\hat{n}_1^*$ is the solution of the equation

$$\delta/2 = q_2^{-(-\hat{n}_1^*-1-n_b+n_1)}. \qquad \square$$

Remark 2. We see that in the case $2\varepsilon \sim h^\alpha, \alpha > 1$ (i.e., $\varepsilon \ll h$), $\ln\left(1+\frac{h}{\varepsilon}\right) \simeq (\alpha-1)\ln h^{-1}$. Therefore, the overlap required by (2.11) is as much as n_b plus a few mesh steps:

$$n^\star \geq \frac{\ln(1/\delta)}{(\alpha-1)\ln h^{-1}}.$$

In the opposite case $h \ll \varepsilon$ we rewrite (2.12),

$$n^* h = 2\varepsilon\,\frac{\ln 2/\delta}{\ln \kappa_2}, \quad \kappa_2 = (1+h/2\varepsilon)^{2\varepsilon/h},$$

and note that $\kappa_2 \to e$ as $h/\varepsilon \to 0$. The width of additional overlap n^*h is proportional to ε (cf. Remark 1) though the overall crosswind overlap is still of order of $n_b h$. Numerical experiments clearly point out that the term $n_b h$ is superfluous. Below we consider two cases when the term $n_b h$ may be omitted. $\square$

In the asymptotic case $\varepsilon \ll h$ estimates (2.11)–(2.12) may be considerably enhanced [7] as shown in the next lemma.

LEMMA 2.3. *Let $\varepsilon \ll h$. To provide estimate* (2.10)*, choose*

$$\begin{aligned} \hat{n}_1 &= \max\{0; n_1 - [n^*]\}, \\ \hat{n}_2 &= \min\{n; n_2 + [n^*]\}, \end{aligned} \tag{2.17}$$

where $[n^*]$ is the integer part of n^* and

$$n^* = \frac{\ln 2/\delta}{\ln \mu}, \quad \mu = \frac{h}{\varepsilon} \gg 1. \tag{2.18}$$

Proof. We take advantage of the initial steps of the proof of Lemma 2.2 and start the analysis of the solution of the problem (2.14).

We fix n_b and denote $p = n_b - 1$ and define a set of the lines $P_l = \{x = (x_1, x_2) : x_1 + p x_2 = l,\ l = 1, 2, \ldots, p(\hat{n}_2 + 1)\}$. Let

$$z_l = \max_{x_{ij} \in P_l} \hat{w}_{ij}, \qquad l = 1, \ldots, p(\hat{n}_2 + 1),$$

where x_{ij} stands for any grid node in $\hat{\Omega}$. Due to the discrete maximum principle

$$z_l = 0,\ l = 1, \ldots, p, \qquad z_l = 1,\ l = p\hat{n}_2 + 1, \ldots, p(\hat{n}_2 + 1). \tag{2.19}$$

From (2.14) we pass to a system of inequalities

$$-\frac{\varepsilon}{h^2}\left[z_{l-p} + z_{l-1} + z_{l+1} + z_{l+p} - 4z_l\right] + \frac{z_l - z_{l-1}}{h} \leq 0, \quad l = p+1, \ldots, p\hat{n}_2,$$

equipped with the boundary conditions (2.19). We consider a solution $\hat{z}_l$ to the system

$$-\frac{\varepsilon}{h^2}\left[\hat{z}_{l-p}+\hat{z}_{l-1}+\hat{z}_{l+1}+\hat{z}_{l+p}-4\hat{z}_l\right]+\frac{\hat{z}_l-\hat{z}_{l-1}}{h}=0, \quad l=p+1,\dots,p\hat{n}_2, \tag{2.20}$$

subjected to

$$\hat{z}_l=0,\ l=1,\dots,p, \qquad \hat{z}_l=1,\ l=p\hat{n}_2+1,\dots,p(\hat{n}_2+1). \tag{2.21}$$

Due to the discrete maximum principle

$$z_l\le\hat{z}_l, \qquad l=p+1,\dots,p\hat{n}_2.$$

Let R_i, $i=1,\dots,2p$, be the roots of the polynomial

$$Q(\hat{z})=-1-(\mu+1)\hat{z}^{p-1}+(\mu+4)\hat{z}^p-\hat{z}^{p+1}-\hat{z}^{2p}$$

with $\mu\equiv\frac{h}{\varepsilon}$. We will show that for the case $\mu\gg1$

$$|R_{2p}|=\max_{1\le i\le 2p}|R_i|\approx\mu^{\frac{1}{p}}.$$

Indeed, the formal asymptotic expansion yields

$$\mu|R_{2p}|^p\approx|R_{2p}|^{2p}$$

or

$$\mu^{p\beta+1}\approx\mu^{2p\beta}, \tag{2.22}$$

provided that

$$|R_{2p}|\approx\mu^{\beta}. \tag{2.23}$$

(2.22) and (2.23) result in

$$|R_{2p}|\approx\mu^{\frac{1}{p}}, \quad \mu\gg1. \tag{2.24}$$

To justify the formal asymptotic expansion, we analyze $|\,|R_{2p}|-\mu^{\frac{1}{p}}\,|$ for $p>2$, $\mu\gg1$:

$$|\,|R_{2p}|-\mu^{\frac{1}{p}}\,|\le C\frac{|Q(R_{2p})-Q(\mu^{\frac{1}{p}})|}{|Q'(\mu^{\frac{1}{p}})|}\le C\frac{|0+\mu^{2-\frac{1}{p}}|}{|-p\mu^{2-\frac{1}{p}}|}\le C\frac{1}{p}.$$

Thus, (2.24) is valid.

To evaluate $\hat{z}_l$, we consider the sequence

$$\tilde{z}_l=\frac{R_{2p}^l+\bar{R}_{2p}^l-(R_{2p}+\bar{R}_{2p})}{R_{2p}^{p\hat{n}_2+1}+\bar{R}_{2p}^{p\hat{n}_2+1}-(R_{2p}+\bar{R}_{2p})}, \quad l=1,\dots,p(\hat{n}_2+1).$$

$\tilde{z}_l$ are real numbers and satisfy to (2.20), while

$$\tilde{z}_1=0,\ \tilde{z}_l>0,\ l=2,\dots,p, \quad \tilde{z}_{p\hat{n}_2+1}=1,\ \tilde{z}_l>1,\ l=p\hat{n}_2+2,\dots,p(\hat{n}_2+1).$$

For $e_l\equiv\tilde{z}_l-\hat{z}_l$ we have

$$-\frac{\varepsilon}{h^2}\left[e_{l-p}+e_{l-1}+e_{l+1}+e_{l+p}-4e_l\right]+\frac{e_l-e_{l-1}}{h}=0,\quad l=p+1,\dots,p\hat{n}_2,$$

$$e_1=0,\ e_l>0,\ l=2,\dots,p,\qquad e_{p\hat{n}_2+1}=0,\ e_l>0,\ l=p\hat{n}_2+2,\dots,p(\hat{n}_2+1).$$

Due to the discrete maximum principle

$$e_l\geq 0,\quad l=p+1,\dots,p\hat{n}_2,$$

that is to say

$$\hat{z}_l\leq\tilde{z}_l,\quad l=p+1,\dots,p\hat{n}_2.$$

Hence,

$$\hat{z}_l\leq\delta$$

when

$$\frac{R_{2p}^l+\bar{R}_{2p}^l-(R_{2p}+\bar{R}_{2p})}{R_{2p}^{p\hat{n}_2+1}+\bar{R}_{2p}^{p\hat{n}_2+1}-(R_{2p}+\bar{R}_{2p})}\leq\delta. \tag{2.25}$$

Since $|R_{2p}|\approx\mu^{\frac{1}{p}}\gg 1$, (2.25) is equivalent to

$$\mu^{\frac{l-(p\hat{n}_2+1)}{p}}\leq\delta$$

or

$$\frac{l-1}{p}\leq\hat{n}_2-\frac{\ln\delta^{-1}}{\ln\mu}.$$

Taking into account the slope of the lines P_l we get the estimate

$$\hat{w}_{ij}\leq\delta,\qquad j<\hat{n}_2-\frac{\ln\delta^{-1}}{\ln\mu}.\qquad\square$$

For certain grids the values $h(\hat{n}_1-n_1)$, $h(n_2-\hat{n}_2)$ may be reduced without assumption $\varepsilon\ll h$, estimate (2.10) being still valid. Consider $\hat{\Omega}=(0,b)\times(0,c)$ and a rectangular grid with mesh steps $h_1=b/n_{x_1}$, $h_2=c/n_{x_2}$ and the grid problem

$$\begin{aligned}\bar{\mathcal{L}}_h\,\hat{w}_{ij}&=0 &&\text{in }\hat{\Omega},\\ \hat{w}_{ij}&=1 &&\text{on }\hat{\Gamma}_2=\{x:0<x_1<b,\ x_2=c\},\\ \hat{w}_{ij}&=0 &&\text{on }\partial\hat{\Omega}\setminus\hat{\Gamma}_2,\end{aligned}$$

where

$$\bar{\mathcal{L}}_h\,\hat{w}_{ij}=\frac{\varepsilon}{h_1^2}\left[2\hat{w}_{ij}-\hat{w}_{i+1j}-\hat{w}_{i-1j}\right]+\frac{\varepsilon}{h_2^2}\left[2\hat{w}_{ij}-\hat{w}_{ij+1}-\hat{w}_{ij-1}\right]+\frac{\hat{w}_{ij}-\hat{w}_{i-1j}}{h_1}.$$

LEMMA 2.4. *There exists ratio h_2/h_1 such that for h_1 sufficiently small*

$$\begin{aligned}&\hat{w}_{ij}\leq\delta\ \textit{on}\ \Omega_\delta=(0,b)\times(0,c_\delta),\\ &c_\delta=c-2\sqrt{\varepsilon b\ln 1/\delta}.\end{aligned} \tag{2.26}$$

Proof (see [7]). By analogy with the proof of Lemma 2.2 we get

$$\hat{w}_{ij} \le \delta \text{ on } \Omega_\delta = (0,b) \times (0, c_\delta),$$
$$c_\delta = c - h_2 \frac{\ln 1/\delta}{\ln q} - b\frac{h_2}{h_1},\ q = 1 + \frac{h_1}{\varepsilon(h_1^2/h_2^2 + 1)}.$$

We can maximize Ω_δ by optimizing c_δ provided that h_1 is small. It is maximal when $h_2 = h_1\sqrt{\frac{\varepsilon \ln 1/\delta}{b}}$:

$$c_\delta = c - 2b\frac{h_2}{h_1} = c - 2\sqrt{\varepsilon b \ln 1/\delta}. \qquad \square$$

We see that for specific grids one can satisfy (2.10) with an extension $2\sqrt{\varepsilon b \ln 2/\delta}$. Since we can choose h_1 vanishing we come to the conclusion that the differential problem has the same property. Consequently, up to a pointwise approximation error, the discrete problem posed on square grids yields (2.26) as well. In particular, (2.26) is valid in the case $h << \varepsilon$. For the case of $b \approx 1$ results similar to (2.26) are reported in [11, 15], where authors dealt with the streamline upwind Petrov–Galerkin (SUPG) discretization.

2.2. Two-level Schwarz method. Let $\{n_{a,k}\}$ and $\{n_{b,k}\}$ be strongly monotone sequences of integers such that $0 = n_{a,1} < n_{a,2} < \cdots < n_{a,m} < n$ and $n_{a,k+1} < n_{b,k} \le n$, $k = 1, \ldots, m-1$, $n_{b,m} = n$, $a_k = n_{a,k} \cdot h$, $a_{m+1} = 1$, and $b_k = n_{b,k} \cdot h$, $k \le n$. We partition the domain $\Omega = (0;1) \times (0;1)$ into m overlapping strip subdomains $\Omega_k = (a_k; b_k) \times (0;1)$ and each strip Ω_k we partition into p overlapping subdomains $\Omega_{k,s} = (a_k; b_k) \times (\hat{n}_1^{(s)}h; \hat{n}_2^{(s)}h)$ (Figure 5). Here $\hat{n}_1^{(s)}$ and $\hat{n}_2^{(s)}$ are chosen for given $n_1^{(s)}$ and $n_2^{(s)}$, respectively, using the formulae (2.11)–(2.12).

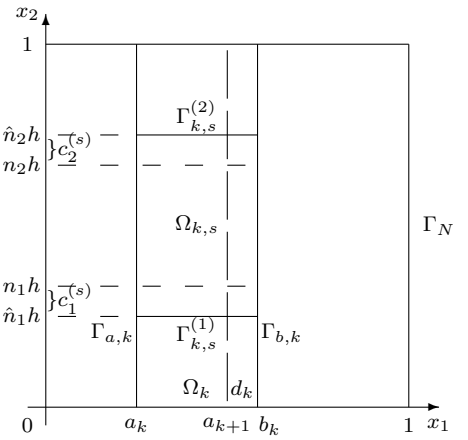

FIG. 5. *Two-level domain decomposition.*

Let u_{ij}^{t-1} be a current guess to u_{ij}. A new approximation u_{ij}^t to the solution grid function u_{ij} of the problem (2.3) will be found with the multiplicative Schwarz method based on the two-level overlapping domain decomposition

$$\Omega = \bigcup_{k=1}^{m} \bigcup_{s=1}^{p} \Omega_{k,s}. \tag{2.27}$$

One complete iteration step includes solving a sequence of subproblems in the strip subdomains Ω_k, $k = 1, \ldots, m$, (outer Schwarz loop) and each kth strip subproblem consists of p subproblems in the subdomains $\Omega_{k,s}$, $s = 1, \ldots, p$. In order to specify the inner iterates within each strip subdomain we introduce the following notations.

Let

$$\Gamma_{a,k} = \{x,\ x_1 = a_k,\ 0 < x_2 < 1\},\ \Gamma_{b,k} = \{x,\ x_1 = b_k,\ 0 < x_2 < 1\}, \quad k = 1, \ldots, m,$$

$$\Gamma_{k,s}^{(1)} = \{x : a_k < x_1 < b_k, x_2 = \hat{n}_1^{(s)} h\},\ \Gamma_{k,s}^{(2)} = \{x : a_k < x_1 < b_k, x_2 = \hat{n}_2^{(s)} h\}, \tag{2.28}$$

and let the value of k be fixed ($k \geq 1$) and u_{ij}^t be given on $\Gamma_{a,k}$ ($u_{ij}^t = g_{ij}$ on $\Gamma_{a,1}$). For $k < m$ we denote the subproblem

$$\begin{aligned} \mathcal{L}_h \hat{u}_{ij}^{(s)} &= f_{ij} && \text{in } \Omega_{k,s}, \\ \hat{u}_{ij}^{(s)} &= u_{ij}^t && \text{on } \partial\Omega_{k,s} \cap \Gamma_{a,k}, \\ \hat{u}_{ij}^{(s)} &= u_{ij}^{t-1} && \text{on } \partial\Omega_{k,s} \setminus \Gamma_{a,k}, \end{aligned}$$

by

$$\mathcal{A}_{k,s}^t \hat{u}_{ij}^{(s)} = f_{ij},$$

and assuming $\hat{u}_{ij}^{(s-1)}, \hat{u}_{ij}^{(s+1)}$ are given on $\Gamma_{k,s}^{(1)}, \Gamma_{k,s}^{(2)}$, we denote the subproblem

$$\begin{aligned} \mathcal{L}_h \hat{u}_{ij}^{(s)} &= f_{ij} && \text{in } \Omega_{k,s}, \\ \hat{u}_{ij}^{(s)} &= u_{ij}^t && \text{on } \partial\Omega_{k,s} \cap \Gamma_{a,k}, \\ \hat{u}_{ij}^{(s)} &= u_{ij}^{t-1} && \text{on } \partial\Omega_{k,s} \cap \Gamma_{b,k}, \\ \hat{u}_{ij}^{(s)} &= \hat{u}_{ij}^{(s-1)} && \text{on } \Gamma_{k,s}^{(1)},\ s > 1, \\ \hat{u}_{ij}^{(s)} &= \hat{u}_{ij}^{(s+1)} && \text{on } \Gamma_{k,s}^{(2)},\ s < p, \end{aligned}$$

by

$$\mathcal{M}_{k,s}^t \hat{u}_{ij}^{(s)} = f_{ij}.$$

For $k = m$ we substitute the nonhomogeneous Dirichlet boundary condition on $\Gamma_{b,m}$ by the homogeneous Neumann boundary condition on $\Gamma_{b,m} = \Gamma_N$.

Now we are able to state the two-stage Schwarz method (Figure 6).

ALGORITHM. Given the current guess u_{ij}^{t-1} and positive integers T_k, $k = 1, \ldots, m$:

For $k = 1, \ldots, m$ find the restriction of u_{ij}^t onto $(a_k; a_{k+1}] \times (0; 1)$ by the following inner iterations:

1. Set $l = 0$. For all even s solve $\mathcal{A}_{k,s}^t \hat{u}_{ij}^{(s)} = f_{ij}$.
2. Do while ($l \leq T_k$)
   Set $l = l + 1$.
   If l is odd then
   for all odd s solve $\mathcal{M}_{k,s}^t \hat{u}_{ij}^{(s)} = f_{ij}$
   else
   for all even s solve $\mathcal{M}_{k,s}^t \hat{u}_{ij}^{(s)} = f_{ij}$
   End do

3. Define the grid function u_{ij}^t on $[a_k, a_{k+1}] \times (0;1)$ by

$$u_{ij}^t = \hat{u}_{ij}^{(s)}, \quad x \in [a_k, a_{k+1}] \times [n_1^{(s)}h; n_2^{(s)}h], \quad s = 1, \ldots, p.$$

The above algorithm is rather flexible. By varying the value of T_k one can formulate different types of the approximate solvers in the crosswind strips Ω_k:

- Different T_k generate different numbers of the multiplicative Schwarz iterations between the subdomains $\Omega_{k,s}$ with odd and even indexes s.
- Instead of the condition $l > T_k$ the stopping criterion might be a decrease of the residual for the strip problem.
- Additive solvers may be formulated:
  1. For all s solve $\mathcal{A}_{k,s}^t \hat{u}_{ij}^{(s)} = f_{ij}$.
  2. Define the grid function u_{ij}^t on $[a_k, a_{k+1}] \times (0;1)$ by

$$u_{ij}^t = \hat{u}_{ij}^{(s)}, \quad x \in [a_k, a_{k+1}] \times [n_1^{(s)}h; n_2^{(s)}h], \quad s = 1, \ldots, p.$$

To evaluate the convergence rate of the above multiplicative Schwarz method, we have to estimate the maximum norm of the grid function $u_{ij} - u_{ij}^t$. For simplicity we present the result related to the multiplicative version with $T_k = 1$, $k = 1, \ldots, m$. Hereinafter, we denote by d_k the downwind overlap $b_k - a_{k+1}$ and by $c_1^{(s)}$, $c_2^{(s)}$ the crosswind overlaps $(\hat{n}_1^{(s)} - n_1^{(s)})h$, $(n_2^{(s)} - \hat{n}_2^{(s)})h$, respectively, and define b as $\max\limits_{1 \le k \le m} (b_k - a_k)$.

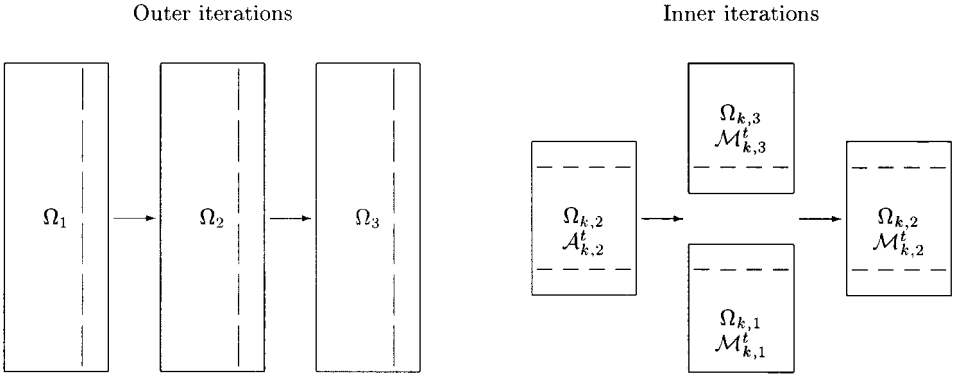

FIG. 6. *Two-stage Schwarz method.*

THEOREM 2.5. *Let* $d \equiv \min\limits_{1 \le k \le m-1} d_k$,

$$c_1^{(s)} \equiv c_2^{(s)} = b + \left[\frac{d}{h} \frac{\ln q_1}{\ln q_2} \right] h, \quad q_1 = 1 + \frac{h}{\varepsilon}, \quad q_2 = 1 + \frac{h}{2\varepsilon}, \tag{2.29}$$

and let a nonnegative grid function u_{ij}^{t-1} *be given in* $\bar{\Omega}$ *such that*

$$\max_{\Omega_h} |u_{ij} - u_{ij}^{t-1}| \le 1. \tag{2.30}$$

Then

$$\max_{\Omega_h} |u_{ij} - u_{ij}^t| \le 3m q_1^{-d/h} \max_{\Omega_h} |u_{ij} - u_{ij}^{t-1}|. \tag{2.31}$$

Proof. Let $r_{t-1} = \max_{\Omega_h} |u_{ij} - u_{ij}^{t-1}|$. To estimate $|u_{ij} - u_{ij}^{t}|$, we consider the following strip equations $(1 \le k < m)$(Figure 5):

$$\begin{cases} \mathcal{L}_h w_{ij}^{(k,s)} &= 0 & \text{in } \Omega_{k,s},\ s \textbf{ even}, \\ w_{ij}^{(k,s)} &= \delta_{k-1} & \text{on } \partial\Omega_{k,s} \cap \Gamma_{a,k}, \\ w_{ij}^{(k,s)} &= 0 & \text{on } \partial\Omega_{k,s} \cup \partial\Omega, \\ w_{ij}^{(k,s)} &= r_{t-1} & \text{on } \partial\Omega_{k,s} \setminus (\Gamma_{a,k} \cup \partial\Omega), \end{cases}$$

$$\begin{cases} \mathcal{L}_h w_{ij}^{(k,s)} &= 0 & \text{in } \Omega_{k,s},\ s \textbf{ odd}, \\ w_{ij}^{(k,s)} &= \delta_{k-1} & \text{on } \partial\Omega_{k,s} \cap \Gamma_{a,k}, \\ w_{ij}^{(k,s)} &= r_{t-1} & \text{on } \partial\Omega_{k,s} \cap \Gamma_{b,k}, \\ w_{ij}^{(k,s)} &= w_{ij}^{(k,s-1)} & \text{on } \Gamma_{k,s}^{(1)}, \\ w_{ij}^{(k,s)} &= w_{ij}^{(k,s+1)} & \text{on } \Gamma_{k,s}^{(2)}, \end{cases}$$

where $\Gamma_{k,s}^{(1)}$ and $\Gamma_{k,s}^{(2)}$ are defined in (2.28), $\delta_0 = 0$, $\delta_{k-1} \equiv \text{const} \in (0;1)$. Let us fix the value of $k, 1 \le k < m$, and introduce the grid function $w_{ij}^{(k)}$ as the solution of the system

$$\begin{cases} \mathcal{L}_h w_{ij}^{(k)} &= 0 & \text{in } \Omega_k, \\ w_{ij}^{(k)} &= \delta_{k-1} & \text{on } \Gamma_{a,k}, \\ w_{ij}^{(k)} &= r_{t-1} & \text{on } \Gamma_{b,k}, \\ w_{ij}^{(k)} &= 0 & \text{on } \partial\Omega \setminus (\Gamma_{a,k} \cup \Gamma_{b,k}), \end{cases}$$

where $\Omega_k, \Gamma_{a,k}$, and $\Gamma_{b,k}$ are defined as in (2.28).

Then the grid functions

$$\tilde{w}_{ij}^{(k,s)} = w_{ij}^{(k,s)} - w_{ij}^{(k)}, \quad s = 1, \dots, p,$$

satisfy the equations

$$\begin{cases} \mathcal{L}_h \tilde{w}_{ij}^{(k,s)} &= 0 & \text{in } \Omega_{k,s},\ s \textbf{ even}, \\ \tilde{w}_{ij}^{(k,s)} &= 0 & \text{on } \partial\Omega_{k,s} \cap \partial\Omega_k, \\ \tilde{w}_{ij}^{(k,s)} &= r_{t-1} - w_{ij}^{(k)} & \text{on } \partial\Omega_{k,s} \setminus \partial\Omega_k, \end{cases}$$

$$\begin{cases} \mathcal{L}_h \tilde{w}_{ij}^{(k,s)} &= 0 & \text{in } \Omega_{k,s},\ s \textbf{ odd}, \\ \tilde{w}_{ij}^{(k,s)} &= 0 & \text{on } \partial\Omega_{k,s} \cap \partial\Omega_k, \\ \tilde{w}_{ij}^{(k,s)} &= \tilde{w}_{ij}^{(k,s-1)} & \text{on } \Gamma_{k,s}^{(1)},\ s > 1, \\ \tilde{w}_{ij}^{(k,s)} &= \tilde{w}_{ij}^{(k,s+1)} & \text{on } \Gamma_{k,s}^{(2)} r,\ s < p. \end{cases}$$

By virtue of the fact that

$$b + \left[\frac{d}{h}\frac{\ln q_1}{\ln q_2}\right] h = b + \left[\frac{\ln \frac{1}{q_1^{-d/h}}}{\ln q_2}\right] h$$

and Lemma 2.2, the values of $\hat{n}_1^{(s)}$ and $\hat{n}_2^{(s)}$ are chosen to satisfy the estimates

$$\max_{\text{even } s} \max_{\substack{a_k \le x_{1,i} \le b_k \\ n_1^{(s)} \cdot h \le x_{2,j} \le n_2^{(s)} \cdot h}} |\tilde{w}_{ij}^{(k,s)}| \le 2q_1^{-d/h} r_{t-1}.$$

Then, using the maximum principle we get the estimation

$$\max_{\text{odd } s} \max_{\substack{a_k \le x_{1,i} \le b_k \\ n_1^{(s)} \cdot h \le x_{2,j} \le n_2^{(s)} \cdot h}} |\tilde{w}_{ij}^{(k,s)}| \le 2q_1^{-d/h} r_{t-1}.$$

Based on the discrete maximum principle and Lemma 2.1 one derives the estimation for $w_{ij}^{(k)}$:

$$\max_{\substack{a_k \le x_{1,i} \le a_{k+1} \\ 0 \le x_{2,j} \le 1}} |w_{ij}^{(k)}| \le \delta_{k-1} + q_1^{-d/h} r_{t-1}.$$

Hence,

$$\max_{\substack{a_k \le x_{1,i} \le a_{k+1} \\ n_1^{(s)} \cdot h \le x_{2,j} \le n_2^{(s)} \cdot h}} |w_{ij}^{(k,s)}| \le \delta_{k-1} + 3q_1^{-d/h} r_{t-1}, \quad s = 1, \ldots, p,$$

and

$$\max_{\substack{a_k \le x_{1,i} \le a_{k+1} \\ 0 \le x_{2,j} \le 1}} |u_{ij} - u_{ij}^t| \le \delta_{k-1} + 3q_1^{-d/h} r_{t-1}$$

hold true.

By recursion we have

$$\delta_k \le \delta_{k-1} + 3q_1^{-d/h} r_{t-1}$$

and

$$\delta_{k-1} \le 3(k-1) {q_1}^{-d/h} r_{t-1}, \quad k = 1, \ldots, m. \tag{2.32}$$

Applying the above technique and (2.32) for each strip, we have

$$\max_{\Omega_h} |u_{ij} - u_{ij}^t| \le 3mq_1^{-d/h} r_{t-1}. \qquad \square$$

COROLLARY 2.6. *Let* $\varepsilon \ll h$, $d \equiv \min\limits_{1 \le k \le m-1} d_k$,

$$c_1^{(s)} \equiv c_2^{(s)} = d, \tag{2.33}$$

and let a nonnegative grid function u_{ij}^{t-1} *be given in* $\bar{\Omega}$ *such that*

$$\max_{\Omega_h} |u_{ij} - u_{ij}^{t-1}| \le 1. \tag{2.34}$$

Then

$$\max_{\Omega_h} |u_{ij} - u_{ij}^t| \le 3mq_1^{-d/h} \max_{\Omega_h} |u_{ij} - u_{ij}^{t-1}|, \quad q_1 = \frac{h}{\varepsilon}. \tag{2.35}$$

Remark 3. A consequence of (2.35) is that in the case $\varepsilon \ll h$ the overlap between subdomains $\Omega_{k,s}$ of order of h provides a very good value of the damping factor $\frac{\max_{\Omega_h} |u_{ij}-u_{ij}^t|}{\max_{\Omega_h} |u_{ij}-u_{ij}^{t-1}|}$. □

3. Convection-diffusion problem with a variable transport vector. We proceed to the problem (2.1) with a variable convection:

$$\mathcal{L} = -\varepsilon\Delta + B^1(x_1, x_2) \cdot \frac{\partial}{\partial x_1} + B^2(x_1, x_2) \cdot \frac{\partial}{\partial x_2}. \tag{3.1}$$

We assume that the functions B^1 and B^2 are sufficiently smooth, their moduli being bounded from above by 1, and $B^1(1, x_2) > 0$. The discrete problem can be written in the form (2.3), where $\mathcal{L}_h$ stands for the upwind finite differences counterpart of $\mathcal{L}$. We note that having in mind the Navier–Stokes applications we confine our consideration by the transport vectors $\vec{B} = (B^1, B^2)^T$ typical for the channel problems. In these problems the flow is almost unidirectional and the leading component of $\vec{B}$ dominates the others everywhere except in recirculation zones. We will exploit this assumption in what follows.

We partition the domain $\Omega = (0; 1) \times (0; 1)$ into m overlapping strip subdomains $\Omega_k = (a_k; b_k) \times (0; 1)$ such that the transport vector $\vec{B}$ in the subdomains Ω_k, $k = 1, \ldots, m$, satisfies one of two conditions: either

$$B_{ij}^1 \ge B_0 > 0, \quad -B_{ij}^2 \le R \cdot B_0 \text{ in } \Omega_k, \tag{3.2}$$

with certain constants $0 < R < 1$, $0 < B_0$, or

$$B_{ij}^1 \ge B_0 > 0, \text{ in } \Omega_k \setminus (a_k; a_{k+1}) \times (0; 1). \tag{3.3}$$

The first condition (3.2) corresponds to the case when the transport vector has small deviations from the prescribed downwind direction. The second condition (3.3) corresponds to the more general case when the B^1-component of $\vec{B}$ is positive and bounded from below by a positive constant B_0 on the interface $\Gamma_{b,k}$ and as a consequence, in the rightmost narrow part of Ω_k, but $\vec{B}$ has large deviations from the prescribed downwind direction in Ω_k. In line with the above assumption, we split the set of all the indexes $k = 1, \ldots, m$, into two parts, $\mathcal{P}_s$ and $\mathcal{P}_v$, such that if (3.2) holds true in Ω_k, then $k \in \mathcal{P}_s$, otherwise $k \in \mathcal{P}_v$. Each strip Ω_k, $k = 1, \ldots, m$, we partition into p overlapping subdomains $\Omega_{k,s} = (a_k; b_k) \times (\hat{n}_1^{(s)} h; \hat{n}_2^{(s)} h)$, where $\hat{n}_1^{(s)}$ and $\hat{n}_2^{(s)}$ have to be chosen for given $n_1^{(s)}$ and $n_2^{(s)}$, respectively.

The two-level Schwarz algorithm is no different from the method presented in the previous section. We adapt only the sequence T_k governing the iterations. Let T be a large positive integer. We define the sequence T_k by

$$T_k = \begin{cases} T, & k \in \mathcal{P}_v, \\ 1, & k \in \mathcal{P}_s. \end{cases}$$

To evaluate the convergence rate of the above multiplicative Schwarz method, we assume that $T \gg 1$, which is to say that the errors due to the iterative solvers in

the strips Ω_k, $k \in \mathcal{P}_v$, are negligible. Hereafter, we denote by $\#\mathcal{P}_v$ the number of elements in $\mathcal{P}_v$ and redefine b as $\max_{k\in\mathcal{P}_s}(b_k - a_k)$.

THEOREM 3.1. *Let $\varepsilon \ll h$, $T \gg 1$, and let a nonnegative grid function u_{ij}^{t-1} be given in $\bar{\Omega}$ such that*

$$\max_{\Omega_h} |u_{ij} - u_{ij}^{t-1}| \le 1. \tag{3.4}$$

Let there exist such positive constants B_0 and $R < 1$ that in Ω_k, $k \in \mathcal{P}_v$, $\vec{B}$ satisfies (3.3) *and*

$$\min_{k\in\mathcal{P}_v} d_k \ge h + h\frac{\ln 2\#\mathcal{P}_v}{\ln q_3},\ q_3 = 1 + \frac{B_0 h}{\varepsilon},$$

and in Ω_k, $k \in \mathcal{P}_s$, $\vec{B}$ satisfies (3.2). *If*

$$d = \min_{k\in\mathcal{P}_s} d_k \ge h \cdot \frac{\ln 6m}{\ln q_3}, \tag{3.5}$$

and

$$c_2^{(s)} = c_1^{(s)} \ge b + \left[\frac{d}{h}\frac{\ln q_3}{\ln q_4}\right] h, \qquad q_4 = \frac{1 + \frac{B_0 h}{2\varepsilon}}{1 + R \cdot \frac{B_0 h}{2\varepsilon}}, \tag{3.6}$$

then

$$\max_{\Omega_h} |u_{ij} - u_{ij}^{t}| \le Q \max_{\Omega_h} |u_{ij} - u_{ij}^{t-1}|, \tag{3.7}$$

with certain constant $Q < 1$.

The proof is similar to the proof of the Theorem 2.5 and is based on the following lemmas [7].

LEMMA 3.2. *Consider the problem* (2.5)–(2.6). *Let $B_{ij}^1 \ge B_0 > 0$ in Ω_b. Then* (2.7) *holds true for any $d = h \cdot (n_b - n_a)$ which satisfies the inequality*

$$d \ge h\ \frac{\ln(1/\delta)}{\ln q_3}, \quad q_3 = 1 + \frac{B_0 h}{\varepsilon}. \tag{3.8}$$

LEMMA 3.3. *Consider the problem* (2.9). *Let*

$$B_{ij}^1 \ge B_0 > 0, \quad -B_{ij}^2 \le R \cdot B_0 \text{ in } \hat{\Omega}, \tag{3.9}$$

with a certain constant $0 < R < 1$. To provide estimate (2.10), *choose*

$$\begin{aligned} \hat{n}_1 &= \max\{0; n_1 - n_b - [n^*]\}, \\ \hat{n}_2 &= \min\{n; n_2 + n_b + [n^*]\}, \end{aligned} \tag{3.10}$$

where $[n^*]$ is the integer part of n^* and

$$n^* = \frac{\ln 2/\delta}{\ln q_4}, \quad q_4 = \frac{1 + \frac{B_0 h}{2\varepsilon}}{1 + R \cdot \frac{B_0 h}{2\varepsilon}}. \tag{3.11}$$

LEMMA 3.4. *Consider a grid problem*

$$\begin{aligned} \mathcal{L}_h\, v_{ij} &= 0 \qquad \text{in } \Omega_b = (0;b)\times(0;1), \\ v_{ij} &= 1 \qquad \text{on } \Gamma_b = \{x : x_1 = b, 0 < x_2 < 1\}, \\ v_{ij} &= 0 \qquad \text{on } \partial\Omega_b \setminus \Gamma_b. \end{aligned} \tag{3.12}$$

Let $\varepsilon \ll h$, $b = n_b h$, $\Omega_a = (0; n_a h)\times(0;1)$, *where* $0 < n_a < n_b$. *Furthermore, let*

$$|B^1_{ij}| \le 1,\ |B^2_{ij}| \le 1, \quad 0 < i < n_b,\ 0 < j < n, \tag{3.13}$$

while in the complement of Ω_a *to* Ω_b,

$$B^1_{ij} \ge B_0 > 0, \qquad n_a < i < n_b,\ 0 < j < n. \tag{3.14}$$

Then

$$\max_{\substack{0\le i\le n_a \\ 0\le j\le n}} |v_{ij}| \le \delta \tag{3.15}$$

holds true for any n_b *which satisfies the inequality*

$$n_b \ge n_a + 1 + \frac{\ln \delta^{-1}}{\ln q_5}, \quad q_5 = 1 + \frac{B_0 h}{\varepsilon}. \tag{3.16}$$

Remark 4. The convergence result of Theorem 3.1 is worse than that of Theorem 2.5: the damping factor in (3.7) is not estimated as in (2.31). The reasons are possible crosswind error propagations and nonemptiness of $\mathcal{P}_v$. □

Remark 5. The condition $\varepsilon \ll h$ may be substituted by $\max_{k\in\mathcal{P}_v}(a_{k+1} - a_k)/h \gg 1$, $h/\varepsilon > p_0 > 0$, Lemma 3.4 and Theorem 3.1 being still valid [7]. This means that fast convergence is assured either in the asymptotic case or in the case of wide enough strips Ω_k, $k \in \mathcal{P}_v$. □

4. Computer realization. As follows from Theorem 2.5 and Theorem 3.1, three decomposition parameters are the crucial factors affecting the convergence of the method. These are the crosswind overlaps $c_1^{(s)}$, $c_2^{(s)}$, the downwind overlap d_k of the decomposition into overlapping subdomains, and the position of interfaces. In the case of the variable transport vector the influence of the crosswind overlaps may be reduced by applying $T_k > 1$ Schwarz iterations within each crosswind strip instead of one iteration. In our experiments, even two multiplicative Schwarz iterations compensate well the deviations of B^2 from 0 and provide a strong crosswind damping factor. Hereinafter, we shall apply $T_k = 2$ Schwarz iterations within each crosswind strip Ω_k, $k \in \mathcal{P}_s$. However, the decomposition into overlapping crosswind strips Ω_k has to be adapted to the transport vector $\vec{B}$ in order to provide fast upwind error damping at each fractional step of the global outer Schwarz iteration. To be more precise, the trace of B^1 is bound to be strictly positive on the artificial interfaces: $B^1_{ij} \ge B_0 > 0$. This ensures the fast convergence of the method.

It remains now to present an adaptive technique providing the above decomposition. Given a transport vector $\vec{B} = (B^1, B^2)$, one estimates the fractional damping factors F_k associated with the strips Ω_k, $k = 1, \dots, m-1$. For each $F_k > \frac{1}{m-1}\sum_{i=1}^{m-1} F_i$, one merges the strips Ω_k and Ω_{k+1} and gets new decomposition into crosswind overlapping strips for which one applies the two-level Schwarz method with $T_k = 2, k \in \mathcal{P}_s$, $T_k = T \gg 1, k \in \mathcal{P}_v$.

The structure of the algorithm and features of its adaptive counterpart pose natural restrictions to the transport vector $\vec{B}$. First, the major part of the computational domain has to be occupied by the transport field $\vec{B}$ with the dominant direction coincident with the x_1-axis (for high convergence of the outer Schwarz iterations). Second, the remaining part of Ω, being projected to the x_1-axis, forms a set with a small one-dimensional measure (for minimizing the cost of many iterates in the strips $\Omega_k, k \in \mathcal{P}_v$). For instance, this is the case of a presence of several isolated strong vortices in a global downwind flow.

Now we discuss briefly the parallel implementation of the algorithm. Although it is possible to pipeline the Schwarz fractional steps associated with the global downwind propagation, we do not consider this opportunity since we deal with the fast convergent algorithm which makes the pipelining inefficient. In spite of the sequential realization of the downwind computations, we can parallelize the algorithm when solving the crosswind subproblems. More precisely, the i-processor treats subdomains $\Omega_{k,2i-1}$, $\Omega_{k,2i}$, and exchanges with the processors $i-1$, $i+1$, by the solution traces on $\partial\Omega_{k,s}$, $s = 2i-2, 2i+1$. In practical situations, instead of choosing certain large integers T one could perform iterations until the residual associated with the discrete problem in Ω_k reduces by a factor of 10. In our numerical experiments we fixed the number of iterations $T_k = T = 14$, $k \in \mathcal{P}_v$.

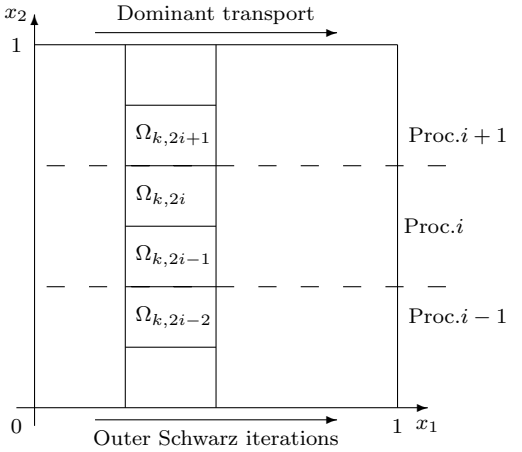

FIG. 7. *Data allocation in parallel implementation.*

Thus, given $P = p/2$ processors, the i-processor deals with data associated with the downwind strip $\cup_{k=1}^{m}$ $(\Omega_{k,2i-1} \cup \Omega_{k,2i})$, $i = 1, \ldots, P$ (Figure 7). We solve the subdomains problems exactly, taking advantage of a factorization technique. We motivate factorizing the respective matrices by the nature of the domain decomposition algorithm: first, we factorize matrices only at the stage of initialization; second, the algorithm is well suited to computation on a massively parallel computer which enables us to reduce considerably both the dimensions of the subproblems and the natural bandwidth of the matrices; third, with factorization we avoid the problem of an optimal stop criterion for any iterative solver. Since we solve the grid subproblems in $\Omega_{k,s}$ by a factorization technique, for the same grid and the same overlap the increase of P would decrease the arithmetical complexity of the global Schwarz iter-

ation. At the same time, with P growing the communications time does not vanish due to the latency time. These conflicting tendencies are presented in the iterations time measurements. Numerical experiments were carried out on a parallel computer DEC TruCluster.

In order to compare the proposed method to other techniques for parallel solution of the convection-diffusion problem, we count the arithmetical complexity of the algorithm implemented at P processors. Let $\mathcal{P}_v = \emptyset$ and let the numbers of grid nodes in the downwind and crosswind directions be $n_1 = 2Pl_1 + 1$ and $n_2 = \sum_{k=1}^{m} l_{2,k} + 1$, respectively. Let l_1, $l_{2,k}$, $k = 1, \ldots, m$, be small fixed integers. The values of n_1 and n_2 are varied according to the values of P, the number of processors, and m, the number of the crosswind strips. First, we estimate the arithmetical complexity of one iteration at one processor. The estimates of the bandwidth and the size of the matrix associated with subdomain $\Omega_{k,s}$ are $O(l_1)$ and $O(l_1 l_{2,k})$, in the case of rectangular grids. Thus, the factorization and the solution procedure will take $O(l_1^3 l_{2,k})$ (ops) and $O(l_1^2 l_{2,k})$ (ops), respectively. The arithmetical work per one iteration done by one processor is $O(\sum_{k=1}^{m} l_1^2 l_{2,k}) = O(l_1 \cdot l_1 n_2)$ (ops). Hence, the arithmetical complexity is of optimal order with respect to the number of nodes associated with the processor (for l_1 fixed). In the three-dimensional case we apply the above two-dimensional decomposition, and subdomains $\Omega_{k,s}$ become long narrow "bricks" with the long side associated with n_3 nodes. The subdomain matrix bandwidth becomes $O(l_1 l_{2,k})$ and the arithmetical work per one iteration done by one processor is $O(\sum_{k=1}^{m} l_1 l_{2,k} \cdot l_1 l_{2,k} n_3)$. Thus, in the case of a singularly perturbed convection-diffusion operator with small deviations of the transport vector from the prescribed downwind direction ($\mathcal{P} = \emptyset$), the arithmetical work done by each processor at each iteration is proportional to the number of unknowns associated with the processor. The estimate of the arithmetical complexity is therefore asymptotically unimprovable. As far as the rate of convergence of the method is concerned, it follows from (2.31) that theoretically the convergence rate is independent of the number of processors P and is proportional to the number of crosswind strips m. In our numerical experiments, however, the number of iterations is insensitive both to P and m, in the case of singular perturbation for the grid operator with $\varepsilon \ll h$.

5. Numerical experiments.

5.1. Two-dimensional problems. The set of numerical experiments presented here may be split into two parts related to different grid problems. First, we consider the simplest grid problem (2.3) and investigate the convergence and parallel properties of the two-level Schwarz method with $T_k = 2$, $k = 1, \ldots, m$, (Figures 8 and 9). The numerical results confirm the theoretical prediction given in Theorem 2.5. Then, we consider the case of $\vec{B}$ affecting the convergence of the above Schwarz method. It is the case of strong stagnant vortices; see Figure 10. In Figure 11 we show the comparative characteristics between the two-level Schwarz methods based on the uniform and adaptive domain decompositions. Although the standard Schwarz method demonstrates deterioration of the convergence rate, the adaptive version results in a fast convergent method, in accordance with Theorem 3.1. It is worth mentioning that the adaptive procedure is fully automatic and does not require from the user any knowledge of the algorithm features.

Given a domain $\Omega = (0, 1) \times (0, 1)$ and a square grid with a mesh step $h = 1/n$, we consider the problem (2.3) with

$$f_{ij} = \quad 0, \qquad\qquad x_{ij} \in \Omega \cup \Gamma_N,$$

$$g_{ij} = \begin{cases} \sin(\pi jh), & x_{ij} = (0, jh),\ 0 < j < n, \\ 0, & x_{ij} = (ih, 0),\ 0 \le i \le n, \\ 0, & x_{ij} = (ih, 1),\ 0 \le i \le n. \end{cases}$$

Given a number of processors $P = p/2$, we decompose Ω into $p \times p$ subdomains $\Omega_{k,s} = (a_k, b_k) \times (\hat{n}_1^{(s)} h, \hat{n}_2^{(s)} h)$,

$$\begin{array}{llll} a_k = n_{a,k} h, & n_{a,k} = \max((k-1)n/p - 1, 0), & k = 1, \ldots, p, \\ b_k = n_{b,k} h, & n_{b,k} = \min(kn/p + 1, n), & k = 1, \ldots, p, \\ \hat{n}_1^{(s)} = \max(n_1^{(s)} - 1, 0), & n_1^{(s)} = (s-1)n/p, & s = 1, \ldots, p, \\ \hat{n}_2^{(s)} = \min(n_2^{(s)} + 1, n), & n_2^{(s)} = sn/p, & s = 1, \ldots, p. \end{array} \tag{5.1}$$

Note that we use here equal subdomains, the overlap between them being equal to $2h$.

In Figure 8 we present the number of iterations and the iterations time needed to reduce the Euclidean norm of the residual by a factor of 10^6 starting from the trivial initial guess.

As follows from the results, $\varepsilon = 10^{-2}$ does not correspond to a discrete singular perturbation operator for considered values of h, since the number of iterations grows significantly with increasing P. The reason is that the above method does not incorporate a global coarse problem and does not take into account possible error propagation in upwind and crosswind directions due to high diffusion. By contrast, $\varepsilon \le 10^{-3}$ provides a fast convergence even with the minimal overlap $2h$. However, the iterations time has a tendency to stagnation with increasing P, particularly for small n. Such behavior is conditioned by the latency time of the message passing and the deterioration of the communication time with the number of processors P getting larger. This is clearly illustrated in Figure 9, where we show the elapsed time per iteration and the weight of the communications time in the iterations time.

Figure 11 presents the comparison of the iterations count and the time measurement related to application of the two-level method based on uniform and adaptive domain decompositions, to problem (2.3) with the same boundary conditions and the transport vector containing two strong vortices; see Figure 10. The convergence of the Schwarz iterations practically is not affected by the numbers of subdomains and processors, due to adaptive domain splitting.

5.2. Three-dimensional problems. We present three-dimensional numerical experiments in a way similar to the previous section. Given a domain $\Omega = (0,1)^3$ and a cubic grid with a mesh step $h = 1/n$, we consider the grid problem

$$\begin{aligned} \mathcal{L}_h\, u_{ijl} &= f_{ijl}, \qquad x_{ijl} \in \Omega \cup \Gamma_N, \\ u_{ijl} &= g_{ijl}, \qquad x_{ijl} \in \partial\Omega \setminus \Gamma_N, \end{aligned} \tag{5.2}$$

where $\mathcal{L}_h$ is the upwind finite difference's three-dimensional counterpart of (3.1),

$$x_{ijl} = (ih, jh, lh),\ i, j, l = 0, \ldots, n,\ \Gamma_N = \{x \equiv (x_1, x_2, x_3) : x_1 = 1, 0 < x_i < 1,\ i = 2, 3\},$$

$$f_{ijl} = \quad 0, \qquad\qquad x_{ijl} \in \Omega \cup \Gamma_N,$$

$$g_{ijl} = \begin{cases} \sin(\pi jh)\sin(\pi lh), & x_{ijl} = (0, jh, lh),\ 0 < j, l < n, \\ 0 & \text{otherwise.} \end{cases}$$

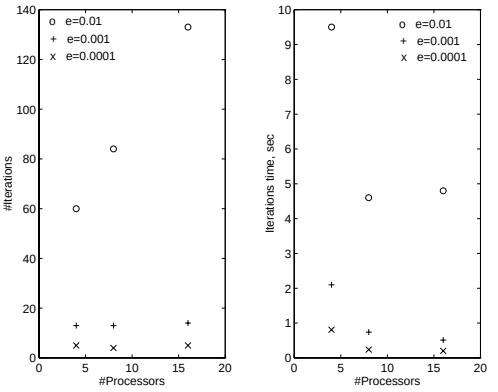

FIG. 8. *Number of iterations and iterations time,* $n = 256$.

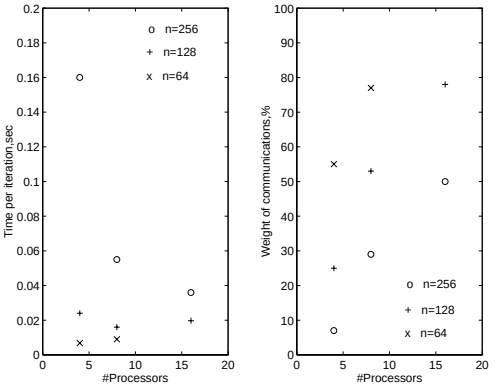

FIG. 9. *Elapsed time per iteration and communications weight.*

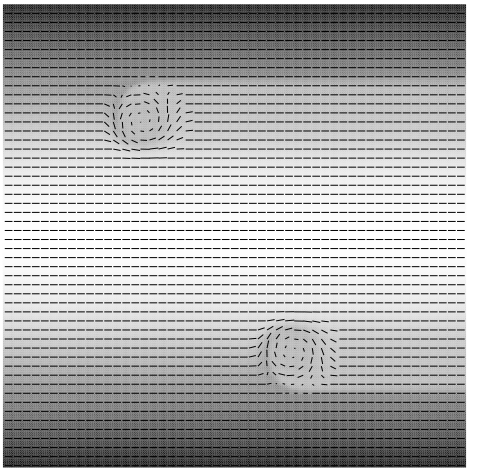

FIG. 10. *Solution of* (2.3) *in the case of strong stagnant vortices.*

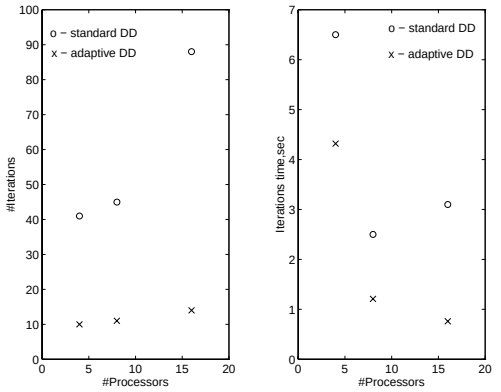

FIG. 11. *Uniform versus adaptive DD,* $\varepsilon = 10^{-3}$, $n = 256$.

TABLE 1
Number of iterations (iterations time, sec).

	Uniform DD, $\vec{B} = (1,0,0)^T$					Adaptive DD, $\vec{B}$ contains two vortices				
p	8	16		32		8	16		32	
P	4	8		16		4	8		16	
$\varepsilon \setminus n$	32	32	64	64	96	32	32	64	64	96
10^{-3}	4(0.31)	5(0.28)	5(1.7)	6(1.4)	7(4.3)	9(1.3)	6(0.55)	7(5.7)	8(3.2)	9(14.3)
10^{-4}	3(0.25)	3(0.17)	3(1.0)	3(0.7)	4(2.5)	9(1.3)	6(0.55)	7(5.7)	8(3.2)	9(14.3)

Given a number of processors $P = p/2$, we split Ω into $p \times p$ overlapping stretched subdomains $\Omega_{k,s} = (a_k, b_k) \times (\hat{n}_1^{(s)} h, \hat{n}_2^{(s)} h) \times (0,1)$, a_k, b_k, $\hat{n}_1^{(s)}$, $\hat{n}_2^{(s)}$ being defined in (5.1). The overlap between subdomains equals $2h$. Since the domain decomposition is two-dimensional, the three-dimensional Schwarz method is no different from the two-dimensional version. The stretched shape of the subdomains Ω_{ks} is well suited to the subdomain solver based on the factorization technique since it reduces significantly the natural bandwidth of the matrices to be factorized.

In Table 1 we display the number of the iterations and iterations time needed to reduce the Euclidean norm of the residual by a factor of 10^6 starting from the trivial initial guess. The uniform domain decomposition is applied to the problem with the constant transport vector, whereas the adaptive domain decomposition is extended for the solution of the problem with the transport vector containing two strong stagnant vortices; see Figure 12. Fast convergence is observed in both cases and the influence of the problem parameters such as ε, $h = n^{-1}$, P, is very small if not negligible. However, the data presented in this table do not allow us to judge the speed-up for a fixed grid problem. This being so, in Table 2 we display a scalability of the method in terms of the ratio of the time per iteration and the number of processors. We fix the grid subdomain and build up the number of unknowns by increasing the number of subdomains and the number of processors. Taking into account that the arithmetical work per processor is proportional to P, we exhibit the scalability in terms of the ratio of the time per iteration and the number of processors. If the parallel implementation is scalable, then the last value remains constant independent of the number of processors. Table 2 shows this is the case.

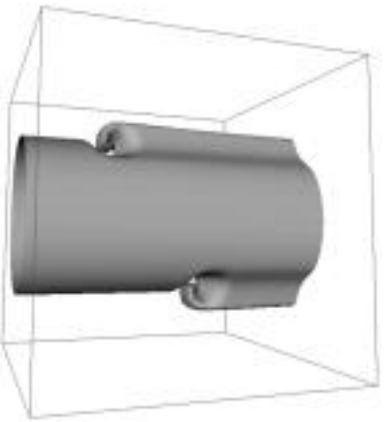

FIG. 12. *ISO-surface* $u = 0.685$ *for a three-dimensional solution of* (5.2), $\varepsilon = 10^{-4}$, *in the case of strong stagnant vortices.*

TABLE 2
Scalability, time per iteration/number of processors, $\cdot 10^{-2}$.

problem	Uniform DD				Adaptive DD			
P	4	8	12	16	4	8	12	16
grid	64×24^2	64×48^2	64×72^2	64×96^2	64×24^2	64×48^2	64×72^2	64×96^2
Scalability	2.3	2.5	2.5	2.1	4.6	4.8	5.4	5.9

6. Conclusion. We have presented the two-level Schwarz method for parallel solution of the discrete singularly perturbed convection-diffusion problems. To provide the fast convergence of the method in the case of convection fields with severe deviations from the prescribed constant direction, the adaptive domain decomposition is applied. The analysis of the method is presented. The method is readily parallelized. The results of parallel numerical experiments have shown the efficiency of the approach. Based on the above technique we develop a three-dimensional Navier–Stokes solver for channel problems.

NUMERICAL METHODS FOR THE EINSTEIN EQUATIONS IN NULL QUASI-SPHERICAL COORDINATES*

ROBERT BARTNIK† AND ANDREW H. NORTON†

Abstract. We describe algorithms used in our construction of a fourth-order in time evolution for the full Einstein equations and assess the accuracy of some representative solutions. The scheme employs several novel geometric and numerical techniques, including a geometrically invariant coordinate gauge, which leads to a characteristic-transport formulation of the underlying hyperbolic system, combined with a "method of lines" evolution; convolution splines for radial interpolation, regridding, differentiation, and noise suppression; representations using spin-weighted spherical harmonics; and a spectral preconditioner for solving a class of first-order elliptic systems on S^2. Initial data for the evolution is unconstrained, subject only to a mild size condition. For sample initial data of "intermediate" strength (19% of the total mass in gravitational energy), the code is accurate to 1 part in 10^5, until null time $z = 55$M when the coordinate condition breaks down.

1. Introduction.

The Einstein equations present difficulties of size and complexity somewhat greater than those normally encountered in scientific computation, starting with the theoretical problem of finding a well-posed and geometrically natural formulation of the full system of Einstein equations. Numerical algorithms are then needed which can control the various facets of this system, efficiently, since very large data structures are inevitable when modeling fully 3+1-dimensional spacetimes. Finally there are the twin theoretical and practical problems of understanding the nature of the solution represented by the data, and of certifying its reliability.

In [4] we presented a new coordinate formulation for the vacuum Einstein equations, based on a characteristic (null) coordinate and a quasi-spherical foliation [3]. This null quasi-spherical (NQS) formulation is well adapted to modeling spacetimes containing a single black hole, extending from the black hole to null infinity.

The purpose of this paper is to describe the numerical algorithms we have used to solve the NQS Einstein equations, and to present results of some accuracy tests of the code. Interactive access to the data sets described here, and many other simulations, is available online at [8].

From the numerical point of view, the most significant features of the code are:

1. a characteristic coordinate $z \sim t - r$ (cf. [56]) plays the role of "time," with the numerical evolution in the direction of increasing z;
2. spherical polar coordinate grids are used on the z-level sets $\mathcal{N}_z$;
3. S^2 dependencies are handled by a combination of: spectral coefficients with respect to a basis of spin-weighted spherical harmonics (for spins $0, 1, 2$, corresponding to scalar, vector, and tensor harmonics); field values on a uniform grid in the spherical polar coordinates (ϑ, φ); and Fourier coefficients of field values on the polar grid;

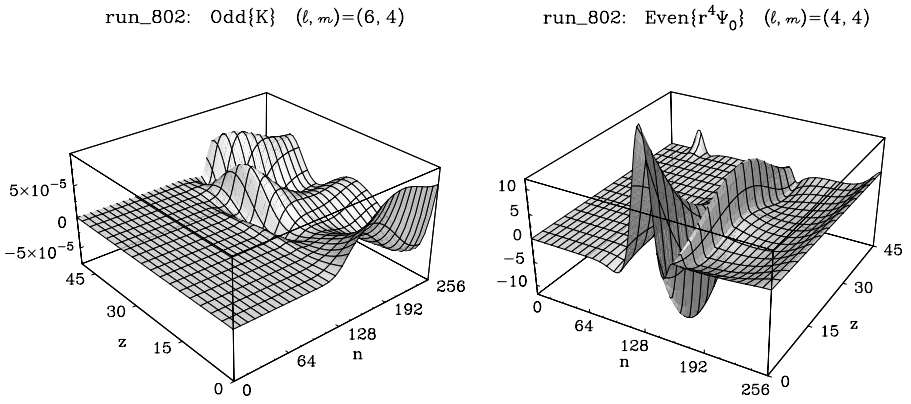

FIG. 1.1. *Sample field plots: heuristically, K and Ψ_0 represent outgoing and incoming radiation, respectively* [4]. *Observe that the nonzero limit of $r^4\Psi_0$ at $r = \infty$ ($n = 256$) is inconsistent with the Bondi–Penrose peeling hypothesis.*

4. a nonuniform radial grid in the outgoing null hypersurfaces $\mathcal{N}_z$, which compactifies future null infinity $\mathcal{I}^+$ and is adjusted dynamically so radial grid points approximately follow the inward null geodesics;

5. reformulations of the hypersurface (radial) Einstein equations which enable the numerical modeling of the asymptotic expansions of fields near null infinity;

6. fourth-order Runge–Kutta (RK4) time evolution;

7. the characteristic transport (hypersurface, radial) equations are treated using spectral collocation and integrated using an eighth-order Runge–Kutta (RK8) method [46];

8. an eighth-order convolution spline is used for interpolation, for computing radial derivatives, to realign the fields with the dynamically varying radial grid, and for suppressing high-frequency modes;

9. a first-order elliptic system on S^2 is solved at each radius and time step by an iterative method with spectral preconditioning.

Numerical consistency checks suggest that most quantities of interest which are calculated by the code (e.g., the NQS metric functions, the connection coefficients, and the Weyl curvature spinors) have relative errors of about 0.001% for simulations where the gravitational waves carry no more than 20% of the total spacetime mass. Of course, greater accuracy is found for more nearly linear, weak field, simulations. The major factor limiting the accuracy appears to be the spherical harmonic resolution, currently at $L \leq 15$. Although the code can run with $L \leq 31$, present hardware restrictions limit use at this higher resolution.

The code was developed on a 300MHz DEC Alpha with 512Mb memory and presently runs on a 300MHz Sun Ultra 2 with 784Mb, with a typical ($L = 15$) run taking between two and four days. Preliminary descriptions of the code were given in [5, 9, 7, 39, 40]. Figure 1.1 shows sample displays from the interactive website [8]. The Cauchy and characteristic initial value problems differ significantly in the nature of their appropriate initial conditions. Cauchy initial data consists of the initial 3-metric and extrinsic curvature [54], whereas initial data for a characteristic initial surface is just the null metric. In the NQS case the null metric is

$$ds^2_{\mathcal{N}_z} = (r\,d\vartheta + \beta^1\,dr)^2 + (r\sin\vartheta\,d\varphi + \beta^2\,dr)^2, \tag{1.1}$$

parameterized by the angular shear vector $\beta = \frac{1}{\sqrt{2}}(\beta^1 - \mathrm{i}\,\beta^2) = \beta(z, r, \vartheta, \varphi)$. Unlike the Cauchy problem, the NQS Einstein equations [4] do not impose any additional algebraic or differential constraints on β, so the initial data $\beta(z = 0)$ is an arbitrary vector function of the spherical polar coordinates (r, ϑ, φ), except for a mild size constraint (2.17). Heuristically β represents the in-going gravitational radiation of the spacetime; an interpretation which is consistent with the initial $(z = 0)$ values of β being freely specifiable. Note that the geometric invariant σ_{NP}/ρ_{NP} [43] becomes $-2\eth\beta/(2 - \mathrm{div}\beta)$ in NQS coordinates [4].

The NQS gauge provides a formulation of the Einstein equations as an explicit *characteristic transport* system (2.20)–(2.23), coupled to a time evolution equation. This structure is also found in characteristic formulations of other hyperbolic equations such as the wave equation, and is well known for the Einstein equations in other characteristic coordinate gauges [29, 50, 56, 37]. Although there are existence results for characteristic initial value formulations of hyperbolic equations, these rely on reduction to the Cauchy problem [48, 66]. The only exception of which we are aware is the analysis of the linear wave equation in [1, 2]. It would be valuable to have theoretical existence results for systems of characteristic transport equations, which could justify the numerical formulation described here.

The characteristic-based approach has been advocated by Winicour and coworkers [13, 27, 26], who have developed codes for solving the scalar wave equation [27], axially symmetric spacetimes [25], and for the full Einstein equations [12], based on the Bondi coordinate system [29]. These works have been fundamental in establishing the feasibility of numerical formulations based on a characteristic coordinate and in motivating the present implementation. However, the stability analyses and experience of [27, 25] are not directly applicable to our evolution procedure, since the formulations and numerical methods used have significant differences. Like the Bondi parameterization, the NQS gauge conditions are directly implemented in the metric form; however, the NQS Einstein equations are considerably simpler than the Bondi coordinate form of the Einstein equations [4, 12].

The treatment of angular derivatives is greatly simplified by the quasi-spherical condition, which encourages the use of spherical harmonic expansions. This assists comparison with black hole perturbation theory results [47, 65, 35, 20] and underpins the use of spectral methods for angular derivatives.

The combination of the characteristic-transport and method of lines techniques considerably simplifies the use of high-order algorithms, such as RK4 for time evolution. The method of lines approach to evolution equations is common in fluid dynamics [19] but has not been attempted previously in numerical relativity. Note that other high-order algorithms have been developed by Berger and Moncrief [11] to study cosmological singularities.

Higher-order techniques can produce considerably more accurate results than would be possible with second-order finite difference methods. However, there are restrictions, both geometric and algorithmic, on the class of spacetimes which can be modeled by our code.

The algorithms assume the spacetime metric is quite smooth, and hence they should not be expected to reliably treat spacetimes with strongly localized features, such as planets and gravitational shocks [4]. However, gravitational radiation arising from disruptions of a black hole is expected to be very smooth and slowly varying in angular directions, and this is strongly supported by our numerical results.

The use of an outgoing characteristic coordinate restricts the code to model-

ing spacetime regions admitting a foliation by expanding null cones. This includes the exterior regions of spacetimes which are asymptotically Minkowski/Schwarzschild (considered here) or anti-DeSitter. It turns out (see section 4.1) that it is geometrically natural and algorithmically convenient to impose inner boundary conditions corresponding to a central interior black hole. Thus the code is very well suited to modeling gravitational waves in the exterior region of a single roughly spherical black hole.

The existence of quasi-spherical coordinates [4] is not an issue here, since the code directly constructs spacetimes with NQS coordinates. Indeed, the success of the numerical code itself provides indirect support for the conjecture that NQS coordinates exist in the exterior regions of generic spacetimes with outgoing null foliations.

The paper is organized as follows.

Section 2 gives the NQS form of the equations and describes the structure of the equations and the formal steps in the solution algorithm. The geometric significance of the resulting equations is described in [4].

Section 3 describes the numerical techniques, including the representations used for fields on S^2, and the high-order convolution splines used for interpolation and differentiation in the radial direction.

Two aspects of the treatment of S^2 fields appear to be nonstandard [42, 18]: the use of fast Fourier transforms (FFTs) in both the φ and ϑ directions, based on the "torus" model of S^2 [39]; and the use of *spin-weighted* spherical harmonics to handle vector and higher rank tensor fields as well as covariant angular derivative operators.

Section 4 describes the various stages in the evolution algorithm: solving the hypersurface equations out to null infinity $\mathcal{I}^+$; reconstructing the metric from the connection variables (which includes the solution of a first-order elliptic system on the 2-sphere at each radial grid position); and the evolution of the primary field β.

Section 5 describes techniques for estimating the accuracy of the code, testing both numerical and geometric properties of the numerical solution. Numerical convergence tests estimate the effects of separately refining the resolution in the radial, time, and angular directions. The consistency of the numerical spacetime metric is tested by verifying the constraint equations for the Einstein tensor components G_{nn}, G_{nm} ((2.24), (2.25)), and by checking the accuracy of the solution at infinity using the Trautman–Bondi mass decay formula [63, 64, 15, 29]. These provide highly nontrivial tests of the consistency of the numerical solution.

2. Einstein equations and NQS metric functions.

2.1. Spacetime metric. We consider spacetimes admitting global null-polar coordinates $(z, r, \vartheta, \varphi)$ in which the metric takes the NQS form [4]

$$ds^2_{NQS} = -2u\,dz(dr + v\,dz) + (r\,d\vartheta + \beta^1\,dr + \gamma^1\,dz)^2 + (r\sin\vartheta\,d\varphi + \beta^2\,dr + \gamma^2\,dz)^2,$$

where $u > 0, v$, and $\beta = \beta^1\partial_\vartheta + \beta^2\csc\vartheta\partial_\varphi$, $\gamma = \gamma^1\partial_\vartheta + \gamma^2\csc\vartheta\partial_\varphi$ are the six unknown NQS metric functions. Note that $\partial_\vartheta, \partial_\varphi$ denote equivalently the coordinate tangent vectors and the coordinate partial differential operators $\frac{\partial}{\partial\vartheta}$, $\frac{\partial}{\partial\varphi}$. We may consider β, γ either as vector fields on S^2 or as spin 1 quantities, defined by the complex combinations [24]

$$\beta = \tfrac{1}{\sqrt{2}}(\beta^1 - \mathrm{i}\,\beta^2), \qquad \gamma = \tfrac{1}{\sqrt{2}}(\gamma^1 - \mathrm{i}\,\gamma^2). \tag{2.1}$$

The canonical example of a spacetime with metric in NQS form is Schwarzschild

spacetime in Eddington–Finkelstein retarded coordinates [21, 31]

$$ds^2_{Schw} = -2dz\,(dr + \tfrac{1}{2}(1 - 2\mathrm{M}/r)\,dz) + r^2(d\vartheta^2 + \sin^2\vartheta\,d\varphi^2) \tag{2.2}$$

with $u = 1$, $v = \frac{1}{2}(1 - 2\mathrm{M}/r)$, $\beta^A = \gamma^A = 0$, and $\mathrm{M} = const.$ This includes Minkowski space $\mathbb{R}^{3,1}$ as the case $\mathrm{M} = 0$ and $z = t - r$.

2.2. Edth. Using the complex notation (2.1), we have the canonical angular covariant derivative operator "edth" [24, 44, 22],

$$\eth\eta = \frac{1}{\sqrt{2}}\left(\frac{\partial}{\partial\vartheta} - s\cot\vartheta - \frac{\mathrm{i}}{\sin\vartheta}\frac{\partial}{\partial\varphi}\right)\eta, \tag{2.3}$$

acting on a spin s field η, and its "conjugate" operator $\bar{\eth}$,

$$\bar{\eth}\eta = \frac{1}{\sqrt{2}}\left(\frac{\partial}{\partial\vartheta} + s\cot\vartheta + \frac{\mathrm{i}}{\sin\vartheta}\frac{\partial}{\partial\varphi}\right)\eta. \tag{2.4}$$

All geometric angular derivative operators may be defined in terms of $\eth$, $\bar{\eth}$. For example, the covariant directional derivative of a spin s field η in the direction β is $\nabla_\beta\eta = \beta\bar{\eth}\eta + \bar{\beta}\eth\eta$; the divergence and curl (of a vector) are

$$\mathrm{div}\beta = \bar{\eth}\beta + \eth\bar{\beta} = \nabla_1\beta^1 + \nabla_2\beta^2, \tag{2.5}$$

$$\mathrm{curl}\beta = \mathrm{i}\,(\bar{\eth}\beta - \eth\bar{\beta}) = \nabla_1\beta^2 - \nabla_2\beta^1\ ; \tag{2.6}$$

and the spherical Laplacian is

$$\Delta\eta = (\eth\bar{\eth} + \bar{\eth}\eth)\eta\ . \tag{2.7}$$

Further properties of edth are described in section 3 and in [22, 44, 4, 10].

2.3. Connection variables. In addition to the metric functions (u, v, β, γ) we introduce the connection fields $H, J, K, Q, Q^\pm$

$$H = u^{-1}(2 - \mathrm{div}\beta), \tag{2.8}$$

$$J = v(2 - \mathrm{div}\beta) + \mathrm{div}\gamma, \tag{2.9}$$

$$K = v\eth\beta - \eth\gamma, \tag{2.10}$$

$$Q^\pm = u^{-1}(Q \pm \eth u), \tag{2.11}$$

$$Q = r\frac{\partial\beta}{\partial z} - r\frac{\partial\gamma}{\partial r} + \gamma + \nabla_\beta\gamma - \nabla_\gamma\beta. \tag{2.12}$$

Observe that u, v, H, J are real and have spin 0, whereas $\beta, \gamma, Q, Q^+, Q^-$ have spin 1 and K has spin 2.

Given the metric functions u, v, β, γ on a z-level set $\mathcal{N}_z$, we may construct H, J, K on $\mathcal{N}_z$ directly, and Q (and $Q^\pm$) may be reconstructed if in addition, $\partial\beta/\partial z$ is also known on $\mathcal{N}_z$. It is clear from (2.8)–(2.12) that this construction does not require any compatibility conditions on the data $u, v, \beta, \gamma, \frac{\partial}{\partial z}\beta$.

There is a converse construction for the metric functions u, v, γ, and $\partial\beta/\partial z$, which also involves totally free and unconstrained data, namely the connection variables H, J, K, Q. This contrasts sharply with the description of the connection via the Newman–Penrose spin coefficients [36, 44], which requires numerous differential constraint equations, expressing the property that the connection is torsion-free.

The converse construction works as follows. Given β and the connection variables (H, J, K) on $\mathcal{N}_z$, we reconstruct u via the relation

$$u = H^{-1}(2 - \mathrm{div}\beta), \tag{2.13}$$

and we find v, γ by solving an elliptic system for γ,

$$\mathcal{L}_\beta \gamma := \eth\gamma + \frac{\eth\beta}{2 - \mathrm{div}\beta}\,\mathrm{div}\gamma = J\frac{\eth\beta}{2 - \mathrm{div}\beta} - K, \tag{2.14}$$

and setting

$$v = \frac{J - \mathrm{div}\gamma}{2 - \mathrm{div}\beta}. \tag{2.15}$$

The system (2.14) is $\mathbb{R}$-linear and elliptic with 6-dimensional kernel, provided $\eth\beta$ is not too large ($|\eth\beta| < (2 - \mathrm{div}\beta)/\sqrt{3}$ is sufficient). Prescribing the $l = 1$ spherical harmonic coefficients of γ (for example, by requiring $\gamma_{l=1} = 0$) suffices to determine the solution γ uniquely. The remaining connection parameter Q, together with the now known values of β, γ on $\mathcal{N}_z$, determines the *evolution equation*

$$\frac{\partial\beta}{\partial z} = \frac{\partial\gamma}{\partial r} + \frac{1}{r}(Q + \nabla_\gamma\beta - \nabla_\beta\gamma - \gamma). \tag{2.16}$$

To summarize, given β on a single level set $\mathcal{N}_z$, satisfying the size constraint

$$|\eth\beta| < (2 - \mathrm{div}\beta)/\sqrt{3}, \tag{2.17}$$

the map $(u, v, \gamma, \beta_z) \mapsto (H, J, K, Q, \gamma_{l=1})$ is invertible, assuming all fields are sufficiently smooth. In section 4.4 we describe the numerical implementation of the inverse map.

2.4. NQS Einstein equations. To compute the NQS form of the Einstein tensor, we introduce the complex null vector frame $(\ell, n, m, \bar{m})$,

$$\begin{aligned} \ell &= \partial_r - r^{-1}\beta, \\ n &= u^{-1}(\partial_z - r^{-1}\gamma - v(\partial_r - r^{-1}\beta)), \\ m &= \frac{1}{r\sqrt{2}}(\partial_\vartheta - \mathrm{i}\,\csc\vartheta\,\partial_\varphi), \end{aligned} \tag{2.18}$$

and the directional derivative operators

$$\mathcal{D}_r = \partial_r - r^{-1}\nabla_\beta\,, \qquad \mathcal{D}_z = \partial_z - r^{-1}\nabla_\gamma. \tag{2.19}$$

Expressions for the Newman–Penrose spin coefficients [36] with respect to the frame $(\ell, n, m, \bar{m})$ are given in terms of H, J, K, Q in [4].

The frame components of the Einstein tensor G_{ab}, $a, b = \ell, n, m, \bar{m}$, may be written in terms of the NQS metric functions and NQS connection variables. These expressions may be grouped into *hypersurface equations* (or *main equations* [29, 51]):

$$r\mathcal{D}_r H = \left(\tfrac{1}{2}\mathrm{div}\beta - \frac{2|\eth\beta|^2 + r^2 G_{\ell\ell}}{2 - \mathrm{div}\beta}\right) H, \tag{2.20}$$

$$r\mathcal{D}_r Q^- = (\eth\bar{\beta} - uH)Q^- + \bar{Q}^-\eth\beta + 2\bar{\eth}\eth\beta + u\eth H - H\eth u + 2r^2 G_{\ell m}, \tag{2.21}$$

$$r\mathcal{D}_r J = -(1 - \mathrm{div}\beta)J + u - \tfrac{1}{2}u|Q^+|^2 - \tfrac{1}{2}u\,\mathrm{div}(Q^+) - ur^2 G_{\ell n}, \tag{2.22}$$

$$r\mathcal{D}_r K = \left(\tfrac{1}{2}\mathrm{div}\beta + \mathrm{i}\,\mathrm{curl}\beta\right) K - \tfrac{1}{2}J\eth\beta + \tfrac{1}{2}u\eth Q^+ + \tfrac{1}{4}u(Q^+)^2 + \tfrac{1}{2}ur^2 G_{mm}, \tag{2.23}$$

the *boundary equations* (or *subsidiary equations*)

$$(2.24)\quad r\,\mathcal{D}_z\,(J/u) = v^2\,r\mathcal{D}_r\,(J/(uv)) + \tfrac{1}{2}(\mathrm{div}\gamma - v\,\mathrm{div}\beta)J/u + 2u^{-1}|K|^2 - \nabla_{Q^+}v - \Delta v + ur^2G_{nn},$$

$$(2.25)\quad r\,\mathcal{D}_zQ^+ = (v\,r\mathcal{D}_r + J - v\eth\bar\beta + \eth\bar\gamma)Q^+ - K\bar Q^+ + 2\bar\eth K + 2u^{-1}r\mathcal{D}_r(u\eth v) - (2 + \mathrm{i}\,\mathrm{curl}\beta)\eth v + \eth J - 2u^{-1}J\eth u - 2ur^2G_{nm},$$

and the *trivial equation*

$$(2.26)\quad ur^2G_{m\bar m} = r\mathcal{D}_rJ - \tfrac{1}{2}\mathrm{div}\beta\,J - u|Q^+|^2 + \tfrac{1}{2}u\,\mathrm{div}Q^+ + \bar Q^+\eth u + Q^+\bar\eth u + \bar K\eth\beta + K\bar\eth\bar\beta + r^2(v\mathcal{D}_r - \mathcal{D}_z)(u^{-1}\mathcal{D}_ru) + u^{-1}r^2\mathcal{D}_r(u\mathcal{D}_rv).$$

Of course, the Einstein tensor components in these formulae are set to zero for the vacuum equations.

Observe that the hypersurface equations (2.20)–(2.23) have no explicit z-derivatives, and they each contain only one radial (r) derivative. The form of the connection variables (H, J, K, Q) was determined by exactly these properties. Consequently, the hypersurface equations may be written schematically in terms of $U = (H, Q^-, J, K)$ in the "characteristic-transport" form

$$(2.27)\qquad r\frac{\partial U}{\partial r} = F(\beta(z,r), U(z,r))$$

by treating angular derivatives such as $\eth U$ as determined by the set of values $U(z,r)$ on the full S^2. This system has the effect of transporting the fields U along the characteristic curves with tangent vector ℓ which foliate the null hypersurfaces $\mathcal{N}_z$.

Note that alternative reformulations of the hypersurface equations are possible, preserving the general characteristic transport structure. For reasons associated with reliably capturing the asymptotic behavior of the fields, the present version of the code integrates the following radial equations, for the variables $\log(H/2)$ (instead of H), $j = \frac{1}{4}r(2 - HJ) - \mathrm{M}$ (instead of J), and rQ^+ (instead of Q^-):

$$(2.28)\quad r\partial_r\log(\tfrac{1}{2}H) = \nabla_\beta\log(H/2) + \tfrac{1}{2}\mathrm{div}\beta - \frac{2|\eth\beta|^2 + r^2G_{\ell\ell}}{2 - \mathrm{div}\beta},$$

$$(2.29)\quad r\partial_r(rQ^+) = \nabla_\beta(rQ^+) - (1 - 2\eth\bar\beta)(rQ^+) + \nabla_{rQ^+}\beta + 2r\eth(r\mathcal{D}_r\log u) + 2r\beta - \mathrm{i}\,r\eth\mathrm{curl}\beta + 2r^3G_{\ell m},$$

$$(2.30)\quad r\partial_rj = \nabla_\beta j + \left(\tfrac{3}{2}\mathrm{div}\beta - \frac{2|\eth\beta|^2}{2 - \mathrm{div}\beta}\right)(j + \mathrm{M} - \tfrac{1}{2}r) + \tfrac{1}{4}r\mathrm{div}\beta + \tfrac{1}{8}r(2 - \mathrm{div}\beta)(|Q^+|^2 + \mathrm{div}Q^+) + \tfrac{1}{4}r^3(u^{-1}JG_{\ell\ell} + uHG_{\ell n}),$$

$$(2.31)\quad 2r\partial_rK = 2\nabla_\beta K + (\mathrm{div}\beta + 2\mathrm{i}\,\mathrm{curl}\beta)\,K - J\eth\beta + u\eth Q^+ + \tfrac{1}{2}u(Q^+)^2 + ur^2G_{mm}.$$

Here $\mathrm{M} = 1$ fixes the bare mass of the background Schwarzschild black hole.

It is remarkable that the boundary equations (2.24), (2.25) and the trivial equation (2.26) may be regarded as *compatibility* relations, by virtue of the conservation (contracted Bianchi) identity $G_{ab}{}^{;b} = 0$ [51, 4]. This identity is valid for any Einstein tensor G_{ab}, regardless of the metric. Substituting the hypersurface equations $G_{\ell\ell} = G_{\ell m} = G_{\ell n} = G_{mm} = 0$ into the conservation identity, yields equations $HG_{m\bar m} = 0$ and a propagation system for G_{nn}, G_{nm} which has the unique solution

$G_{nn} = G_{nm} = 0$ if the boundary equations are satisfied on one hypersurface transverse to the outgoing null surfaces $\mathcal{N}_z$. Thus, in order to construct a solution of the full vacuum Einstein equations, it suffices to satisfy the hypersurface equations everywhere, and the boundary equations just on the boundary surface $r = r_0$.

3. Numerical techniques. In this section we describe the data representation and manipulation techniques. These consist mainly of techniques for handling angular fields and derivatives, and an unusual convolution spline used for interpolation, differentiation, and high frequency filtering in the radial and time directions.

3.1. Fields on S^2. The evolution algorithm treats the angular derivatives $\frac{\partial}{\partial\vartheta}, \frac{\partial}{\partial\varphi}$ as "lower order," compared to the radial and time derivatives $\frac{\partial}{\partial r}, \frac{\partial}{\partial z}$. This attitude in a numerical computation can be justified only if it is possible easily and accurately to compute and manipulate angular derivatives. This is achieved by using spectral representations (both Fourier and spherical harmonic) for fields on S^2. This approach is widely used in geophysical and meteorology applications [34, 42, 16, 58, 61] and is known to have significant advantages compared to finite difference approaches [18], based on either angular coordinate grids or overlapping stereographic projection charts [55, 53, 28]. Nevertheless, spectral methods have been used only rarely in numerical general relativity (cf. [45, 14]) and they have not been used previously for solving the full Einstein equations.

The basic manipulations required of S^2 fields are:

(i) computing nonlinear algebraic terms, such as $1/(2 - \mathrm{div}\beta)$, $u|Q^+|^2$, etc.;

(ii) computing angular derivative terms, such as $\mathrm{div}\beta$, $\eth Q^+$, etc.;

(iii) inverting the linear elliptic operator $\mathcal{L}_\beta$ (see (2.14)); and

(iv) projecting S^2 grid values of aliased or noisy fields onto certain subspaces of spin-weighted spherical harmonics.

Three separate representations for fields on S^2 have been implemented to carry out these manipulations:

(i) *field values* $\eta_{jk} = \eta(\vartheta_j, \varphi_k)$ at the polar coordinate grid points

$$(\vartheta_j, \varphi_k) = ((j - \tfrac{1}{2})\Delta\vartheta, (k-1)\Delta\varphi), \tag{3.1}$$

where $\Delta\vartheta = 2\pi/N$, $\Delta\varphi = 2\pi/N$ with $1 \le j \le N/2, 1 \le k \le N$, and (in our implementations) $N = 16$, 32, or 64;

(ii) *Fourier coefficients* arising from FFT transforms in either the ϑ or φ directions, of the field values η_{jk};

(iii) spin-weighted *spherical harmonic coefficients* η^{lm}, $|m| \le l$, $l = s, \ldots, L$, $L = N/2 - 1$ (for spin $s = 0, 1$ or 2).

The field values are used when computing nonlinear algebraic terms such as $u|Q^+|^2$. The Fourier representation is used for computing ϑ and φ angular derivatives, which are needed in the formulas for $\eth$, div, for example. The spherical harmonic representation is used in solving the elliptic system (2.14), to spectrally limit field values by projection to spherical harmonic data, and to save the results.

For fields which do not alias on the (ϑ, φ)-grid, the three representations are equivalent in the sense that conversion between them is essentially exact, depending only on machine precision and algebraic details of the FFT. The requirement that a field does not alias is satisfied when it can be represented by a finite expansion in spin-weighted spherical harmonics with angular momentum $l \le L = N/2 - 1$. We use spectral cutoffs $L = 15$ (for $N = 32$) and $L = 31$ (for $N = 64$).

Transformation to the spherical harmonic representation involves a projection, because both the field value and Fourier representations have approximately twice as many degrees of freedom. For example, a (real) spin 0 field with $l \le L = N/2 - 1$ has $(L+1)^2 = N^2/4$ spherical harmonic coefficients, whereas it has $N^2/2$ values on the (ϑ, φ)-grid. The space of nonaliasing spherical harmonics is a *linear* subspace of the space of functions represented by either Fourier coefficients or field values.

For example, when the (ϑ, φ)-grid field values of the product of two fields is calculated, the result, which will contain components up to $l \le 2L$, is aliased onto the grid in such a way that its field values no longer lie in the appropriate spin-weighted spherical harmonic subspace. To clean up after such nonlinear effects, we project the result back onto the correct subspace, as described in section 3.5.

To minimize the possibility of unstable feedback of quadratic aliasing errors, we may invoke the Orszag 2/3 rule [19, 41] at various points within the code. The effective spectral resolution of the code is then $l_{\max} \approx 2L/3$ ($l_{\max} = 10$ for $N = 32$ and $l_{\max} = 20$ for $N = 64$).

3.2. Spherical harmonics. We first summarize the more important properties of $\eth$ ("edth") and spin-weighted spherical harmonics. The edth formalism provides a unified geometric approach to the treatment of angular derivatives on S^2 and of vector and higher-rank tensor harmonics. Detailed descriptions of the properties of spin-weighted fields and spherical harmonics may be found in Penrose and Rindler [44] or [24, 22]. Here we describe only the basic formulae.

We use a real-valued basis Y_{lm}, $l = 0, 1, 2, \ldots$, $m = -l, \ldots, l$ for the space of spin 0 spherical harmonic functions, defined by

$$Y_{lm} = \overline{P}_{lm}(\vartheta) F_m(\varphi)\,, \tag{3.2}$$

where

$$F_m(\varphi) = \begin{cases} 1 & m = 0, \\ \sqrt{2}\cos m\varphi & m > 0, \\ \sqrt{2}\sin |m|\varphi & m < 0, \end{cases} \tag{3.3}$$

and the $\overline{P}_{lm}(\vartheta) = \overline{P}_{l|m|}(\vartheta)$ are related to the associated Legendre functions P_{lm} by

$$\overline{P}_{lm}(\vartheta) = (-1)^m \sqrt{2l+1} \sqrt{\frac{(l-m)!}{(l+m)!}} P_{lm}(\cos\vartheta)\,, \tag{3.4}$$

$$P_{lm}(\cos\vartheta) = \frac{(-1)^m}{2^l l!} \sin^m\vartheta \left[\frac{d^{l+m}}{dx^{l+m}} (x^2-1)^l \right]_{x=\cos\vartheta}. \tag{3.5}$$

The spin s spherical harmonics Y^s_{lm} are then defined explicitly by [44]

$$Y^s_{lm} = (-1)^s \left[\frac{2^s (l-s)!}{(l+s)!} \right]^{1/2} \eth^s Y_{lm}\,, \qquad s > 0, \tag{3.6}$$

$$Y^{-s}_{lm} = \left[\frac{2^s (l-s)!}{(l+s)!} \right]^{1/2} \bar{\eth}^s Y_{lm}\,, \qquad -s < 0, \tag{3.7}$$

where necessarily $l \ge |s|$. Note that the differential operator $\eth$ is spin-raising, sending spin s into spin $(s+1)$ fields, and $\bar{\eth}$ is spin-lowering,

$$\eth Y^s_{lm} = -\left[\tfrac{1}{2}(l+s+1)(l-s)\right]^{1/2} Y^{s+1}_{lm}, \tag{3.8}$$

$$\bar{\eth} Y^s_{lm} = \left[\tfrac{1}{2}(l-s+1)(l+s)\right]^{1/2} Y^{s-1}_{lm}, \tag{3.9}$$

TABLE 3.1
Nomenclatures and representations for the Hodge–Helmholtz decomposition of a vector field on S^2.

Even:	polar	irrotational	$\eth f$	$\operatorname{grad} f$	$(\nabla_1 f)\, v_1 + (\nabla_2 f) v_2$
Odd:	axial	divergence-free	$\mathrm{i}\,\eth g$	$\operatorname{curl} g$	$(\nabla_2 g)\, v_1 - (\nabla_1 g) v_2$

for all $s \in \mathbb{Z}$, and that Y^s_{lm} and Y^{-s}_{lm} are related by complex conjugation,

$$Y^{-s}_{lm} = (-1)^s \bar{Y}^s_{lm}. \tag{3.10}$$

Since $\Delta Y_{lm} = -l(l+1)Y_{lm}$, the fundamental commutation relation

$$[\bar{\eth}, \eth]\eta = (\bar{\eth}\eth - \eth\bar{\eth})\eta = s\eta, \tag{3.11}$$

for any spin s field η, may be used to show that

$$\Delta Y^s_{lm} = (s^2 - l(l+1))Y^s_{lm}, \tag{3.12}$$

where $\Delta = \eth\bar{\eth} + \bar{\eth}\eth$. With these conventions we have the orthogonality relations

$$\frac{1}{4\pi}\int_{S^2} Y^s_{lm}\, \bar{Y}^s_{l'm'} \sin\vartheta \, d\vartheta d\varphi = \delta_{ll'}\delta_{mm'},$$

which show that the Y^s_{lm} form a basis (over $\mathbb{C}$) of the Hilbert space of square-integrable spin s fields on S^2, which is orthonormal in the natural Hermitian inner product

$$\langle \phi, \psi \rangle = \frac{1}{4\pi}\oint_{S^2} \mathrm{Re}(\bar{\phi}\psi). \tag{3.13}$$

From (3.2)–(3.5) it is evident that the spin 0 harmonics Y_{lm} are trigonometric polynomials in ϑ and φ. Using expression (2.3) for $\eth$, we also see that the Y^s_{lm} are trigonometric polynomials. The highest wave number Fourier modes which occur in the set of basis functions $\{Y^s_{lm} : s \le l \le L,\ |m| \le l\}$ are $\cos(L\vartheta)$, $\sin(L\vartheta)$, $\cos(L\varphi)$, and $\sin(L\varphi)$. Therefore, a uniform (ϑ, φ)-grid of size $N/2 \times N$ can represent spin-weighted spherical harmonic functions up to $L = N/2 - 1$.

3.3. Even/odd decomposition. Because $\eth$ is surjective onto the space of smooth spin s fields for $s \ge 1$ [44], the decomposition of spin 0 fields into real and imaginary parts may be propagated to higher spin. The resulting decomposition into *even* and *odd* components plays an important role in the analysis of the linearized Einstein equations about the Schwarzschild spacetime [47]. Because the NQS geometry distinguishes the Schwarzschild metric and is also based on spherical harmonics, it is ideally suited to comparing nonlinear evolution to the comparatively well-understood black hole linearized Einstein equations [20, 23].

We say that the spin $s \ge 0$ field η is *even* if $\eta = \eth^s f$ for some real-valued function f, and η is *odd* if $\eta = \mathrm{i}\,\eth^s g$ for some real-valued function g. This matches the usage in [47]—note that for axially symmetric fields the terms *polar* (for even) and *axial* (for odd) are sometimes used [20]. The surjectivity of $\eth$ onto spin $s \ge 1$ ensures that every spin s field may be uniquely decomposed into a sum of even and odd parts. For $s = 1$ this decomposition corresponds to the Hodge–Helmholtz decomposition of a vector field into the sum of a gradient and a dual gradient (curl); see Table 3.1. This has a

natural interpretation in terms of the spectral decomposition

$$\eta = \sum_{l=s}^{\infty} \sum_{m=-l}^{l} \eta^{lm} Y^s_{lm} \tag{3.14}$$

of a spin s field η, because we are using a basis of real-valued Y_{lm}. Namely, η is *even* if the spectral coefficients η^{lm} are real, and *odd* if the coefficients are pure imaginary. We may thus decompose $\eta = \mathrm{Even}(\eta) + \mathrm{Odd}(\eta)$ with

$$\mathrm{Even}(\eta) = \sum \mathrm{Re}(\eta^{lm}) Y^s_{lm}, \qquad \mathrm{Odd}(\eta) = \mathrm{i} \sum \mathrm{Im}(\eta^{lm}) Y^s_{lm}. \tag{3.15}$$

Observe that $\eth Y^s_{sm} = 0$ for $s \geq 0$, and thus $\eth$ acting on spin s fields with $s \geq 0$ has kernel having (complex) dimension $2s+1$. Likewise the formal adjoint $-\bar{\eth}$ acting on spin $s \leq 0$ fields has $(2|s|+1)$-dimensional kernel. In particular, $\eth$ acting on spin 1 fields has kernel consisting of the $\mathbb{C}$-linear space spanned by the three $l = 1$ spin 1 spherical harmonics Y^1_{1m}—the corresponding real vector fields are the dual gradients of functions linear in $\mathbb{R}^3$, which are the infinitesimal rotations, and the gradients, which are the infinitesimal conformal dilations.

The correspondence between vector fields on S^2 and spin 1 fields generalizes to spin 2 fields, which correspond to symmetric traceless 2-tensors on S^2. If λ is a symmetric traceless 2-tensor, then with respect to the standard orthonormal frame

$$e_1 = \partial_\vartheta, \quad e_2 = \csc\vartheta\, \partial_\varphi, \tag{3.16}$$

we have the correspondence $\lambda = \lambda^{ij} e_i \otimes e_j \sim \frac{1}{2}(\lambda^{11} - \lambda^{22} - 2\mathrm{i}\,\lambda^{12})$. This correspondence extends to higher integer spins with higher rank symmetric traceless tensors on S^2.

3.4. Fourier representation. The FFT is used to transform between Fourier coefficients and field values on the uniform (ϑ, φ)-grid. Fourier convergence problems arising from discontinuities in coordinate derivatives and vector and tensor components at the poles are sidestepped by an observation relating fields on S^2 to fields on the torus $\mathbb{T}^2 = S^1 \times S^1$ [39]. The torus method enables derivatives for all types of field on S^2 to be computed using Fourier methods, so is particularly well suited to handling the derivative operator $\eth$ (2.3). This approach to handling component discontinuities at the poles is simpler than the techniques reviewed in [59] for manipulating vector fields and readily extends to any rank $s \geq 0$.

For integer s the real and imaginary parts of a spin s field on S^2 may be identified with the two independent frame components of a completely symmetric trace-free tensor of rank $|s|$ on S^2 [44]. Since the frame e_1, e_2 (3.16) is not continuous at the poles, the tensor components will not be continuous at the poles, so are not obviously suited to Fourier expansion in the ϑ direction.

However, along any smooth curve crossing through a pole, both basis vectors e_1 and e_2 reverse direction at the pole. Thus, for any smooth tensor field $T = T^{j_1 \cdots j_s} e_{j_1} \otimes \cdots \otimes e_{j_s}$, by continuity of T the component functions $T^{j_1 \cdots j_s}$ will change by a factor $(-1)^s$ across the poles. Consequently, if we extend the domain of definition of $T^{j_1 \cdots j_s}$ to $\vartheta \in [-\pi, \pi]$ by

$$T^{j_1 \cdots j_s}(-\vartheta, \varphi) \;=\; (-1)^s T^{j_1 \cdots j_s}(\vartheta, \varphi + \pi)\,, \quad \text{for } \vartheta \in [0, \pi] \tag{3.17}$$

(using the 2π periodicity in φ), then the resulting extension is 2π-periodic and continuous in ϑ. This argument extends to higher (covariant) derivatives of T, showing that

the extension is in fact *smooth* and periodic in ϑ. Derivatives of $T^{j_1\cdots j_s}$ with respect to ϑ can then be calculated just as for φ derivatives, provided that the direction of increasing ϑ is properly taken into account.

In effect, the extension just described defines a (smooth) field $T^{j_1\cdots j_s}$ on the torus $\mathbb{T}^2 = S^1 \times S^1$. This may be understood geometrically by noting that the map

$$\Upsilon : \mathbb{T}^2 \to S^2, \quad (\vartheta, \varphi) \mapsto \begin{cases} (\vartheta, \varphi), & \vartheta \in (0, \pi],\ \varphi \in [0, 2\pi) \\ (-\vartheta, \varphi + \pi), & \vartheta \in (-\pi, 0],\ \varphi \in [0, 2\pi) \end{cases} \tag{3.18}$$

is in fact *smooth*. This follows by noting that because ϑ is a radial coordinate near the north pole $\vartheta = 0$, the differential structure near the pole is represented by the rectangular coordinates $(\xi, \eta) = (\vartheta \cos\varphi, \vartheta \sin\varphi)$ and the map $(\vartheta, \varphi) \mapsto (\xi, \eta)$ is manifestly C^∞ for ϑ near 0. Consequently any smooth tensor T on S^2, when expressed in a cotangent basis, pulls back to a smooth tensor on $\mathbb{T}^2$ (i.e., $\Upsilon^*(T) \in C^\infty(\mathbb{T}^2)$), and thus admits a well-behaved Fourier representation on $\mathbb{T}^2$. The converse is of course false: a smooth tensor on $\mathbb{T}^2$ does not necessarily arise from a smooth tensor on S^2, even if it satisfies the parity condition (3.17) satisfied by pull-back tensors.

The ϑ and φ derivatives in the coordinate form (2.3) of $\eth$ (and similarly any other covariant angular derivative operator) can be evaluated easily by transforming to the appropriate Fourier representation of the field, multiplying the Fourier coefficients by the appropriate wavenumber factors, then transforming back to the field value representation. Thus, computing a derivative operator such as $\eth$ is an $O(N^2 \log N)$ operation. Since $\csc(\frac{1}{2}\Delta\vartheta) \simeq 10$ for $N = 32$, there is no significant loss of precision in calculating (2.3) near the poles.

It should be emphasized that because the Y^s_{lm} are trigonometric polynomials in (ϑ, φ), the FFT computation of their numerical derivatives is *algebraically exact*. For example, the Laplacian relation (3.12) is numerically verified to 1 part in 10^{12} [39].

3.5. The spherical harmonic representation. In this section we describe the methods used to transform fields from the field value and Fourier representations to the spherical harmonic representation. Transformations for fields of spin 0, 1, and 2 are required in the code; the spin 0 case which we describe here to illustrate the technique is slightly less complicated, since we may assume the field f is real-valued.

There are $(L+1)^2$ basis functions in the set $\{Y_{lm} : 0 \le |m| \le l \le L\}$. However, to represent these functions as trigonometric polynomials on a regular S^2 grid we require a grid of size $(L+1) \times 2(L+1)$, and thus $2(L+1)^2$ real coefficients. The spin 0 functions of angular momentum at most L therefore form a subspace of real dimension $(L+1)^2$ in the space of Fourier series representable on the grid, which has real dimension $2(L+1)^2$. We use a projection onto the spherical harmonic subspace which is orthogonal with respect to the natural inner product in the Fourier space,

$$\begin{aligned} \langle f_1,\, f_2 \rangle_{_F} &= \frac{1}{4\pi^2} \int_0^{2\pi} \int_{-\pi}^{\pi} f_1(\vartheta, \varphi) f_2(\vartheta, \varphi)\, d\vartheta d\varphi \\ &= \frac{1}{N^2} \sum_{i=1}^{N} \sum_{j=1}^{N} f_1(\vartheta_i, \varphi_j) f_2(\vartheta_i, \varphi_j)\,, \end{aligned} \tag{3.19}$$

where $\{(\vartheta_i, \varphi_j) : i, j = 1, \ldots, N\}$ are grid points (cf. (3.1)) and $N = 2(L+1)$.

To make use of (3.19) we use (3.17) to extend functions defined on S^2 to functions defined on the torus $\mathbb{T}^2 = S^1 \times S^1$. In particular, given any set of values $\{f_{ij} \in \mathbb{R} : i = 1, \ldots, N/2,\ j = 1, \ldots, N\}$ on the S^2 grid, we use (3.17) to construct grid values

on $\mathbb{T}^2$. There is then a unique interpolating trigonometric polynomial f such that $f(\vartheta_i, \varphi_j) = f_{ij}$. We project f to the $l \le L$ spherical harmonic subspace as follows.

The Y_{lm} are not orthonormal with respect to (3.19), but instead have Fourier inner product

$$G_{lm\, l'm'} = \langle Y_{lm},\, Y_{l'm'} \rangle_F = \langle \overline{P}_{lm}(\vartheta),\, \overline{P}_{l'm}(\vartheta) \rangle_F \, \delta_{mm'} \,. \tag{3.20}$$

Here, the index pair lm (and $l'm'$) is a combined index which takes $(L+1)^2$ values, and (3.20) is the matrix for the induced Fourier metric on the spin 0 subspace. The summation convention will be employed for raised and lowered repeated indices.

For fixed m, the inner product (3.20) of the $\overline{P}$ functions forms a matrix,

$$A_{(m)ll'} = \langle \overline{P}_{lm}(\vartheta),\, \overline{P}_{l'm}(\vartheta) \rangle_F \,.$$

These matrices are defined only for $|m| \le l, l' \le L$, so are square and of size $(L+1-|m|) \times (L+1-|m|)$. Denoting the inverse matrix by $A^{ll'}_{(m)}$, we have

$$G_{lm\, l'm'} = A_{(m)ll'} \delta_{mm'} \,, \tag{3.21}$$

and the components of the inverse metric are given by

$$G^{lm\, l'm'} = A^{ll'}_{(m)} \delta^{mm'} \quad \text{(no sum on } m\text{)}. \tag{3.22}$$

The dual basis vectors for the spin 0 subspace are

$$Y^{lm} = G^{lm\, l'm'} Y_{l'm'} \,, \tag{3.23}$$

and satisfy $\langle Y_{lm},\, Y^{l'm'} \rangle_F = \delta^{l'}_{l}\, \delta^{m'}_{m}$. The orthogonal projection of f onto the subspace is given by $\mathrm{proj}(f) = \langle f,\, Y^{lm} \rangle_F Y_{lm} = f^{lm} Y_{lm}$, where

$$f^{lm} = \langle f,\, Y^{lm} \rangle_F \tag{3.24}$$

are the spherical harmonic coefficients of the function f. To calculate the inner product (3.24), first note that using (3.2), (3.22), and (3.23), the dual basis vectors can be written as

$$Y^{lm} = \overline{P}^{lm}(\vartheta) F^m(\varphi) \tag{3.25}$$

(in analogy with (3.2)), where we have set

$$\overline{P}^{lm}(\vartheta) = A^{ll'}_{(m)} \overline{P}_{l'm}(\vartheta) \,, \quad F^m(\varphi) = F_m(\varphi). \tag{3.26}$$

By Fourier analysis of f in the φ direction we can write $f = \hat{f}^k(\vartheta) F_k(\varphi)$. In particular, by φ-FFT of $\{f_{ij}\}$ we get the numbers $\hat{f}^k(\vartheta_i)$. The spectral coefficients f^{lm} can then be evaluated using (3.19) and (3.25) as

$$\begin{aligned} f^{lm} &= \langle \hat{f}^k(\vartheta) F_k(\varphi),\, \overline{P}^{lm}(\vartheta) F^m(\varphi) \rangle_F \\ &= \langle \hat{f}^m(\vartheta),\, \overline{P}^{lm}(\vartheta) \rangle_F \\ &= \frac{1}{N} \sum_{i=1}^{N} \hat{f}^m(\vartheta_i) \overline{P}^{lm}(\vartheta_i) \,. \end{aligned} \tag{3.27}$$

The converse process of reconstructing the function values $f_{ij} = f(\vartheta_i, \varphi_j)$ from the spherical harmonic coefficients f^{lm} follows from

$$f = f^{lm}\, Y_{lm}(\vartheta, \varphi) = f^{lm} \overline{P}_{lm}(\vartheta) F_m(\varphi)\,.$$

First we construct the quantities

$$\hat{f}^m(\vartheta_i) = \sum_{l=|m|}^{L} f^{lm} \overline{P}_{lm}(\vartheta_i) \qquad \text{(no sum on } m\text{)}, \tag{3.28}$$

and then we use inverse FFTs in the φ direction to reconstruct f_{ij} via

$$f_{ij} = \sum_{m=-L}^{L} \hat{f}^m(\vartheta_i) F_m(\varphi_j)\,.$$

Both constructions, of f^{lm} from f_{ij} and conversely, are $O(L^3)$ operations, due to the matrix multiplications in (3.27), (3.28). Routines for transforming between grid values and spherical harmonic coefficients have been implemented for maximum angular momentum $L = 7, 15,$ and 31. The grid values $\overline{P}^{lm}(\vartheta_i)$ which appear in the sum (3.27) were precomputed in multiple precision using REDUCE [32]. The functions $\overline{P}^{lm}(\vartheta)$ defined by (3.26) were constructed symbolically using exact inversion of the matrices $A_{(m)\,ll'}$. This symbolic approach is feasible because the metric $G_{lm\,l'm'}$ factorizes as the tensor product (3.20), thus allowing exact inversion of G using matrices of size at most $(L+1) \times (L+1)$ rather than $(L+1)^2 \times (L+1)^2$.

The analysis of spin 1 and spin 2 grid functions into spherical harmonic coefficients is similar, but is complicated by the fact that the induced metric on the subspace factorizes as a tensor product only in a complex (mixed parity) basis. Separating the even and odd parity coefficients therefore requires some extra book-keeping.

Techniques for handling spherical harmonic representations have been described by many authors [34, 42, 58, 18, 33]. Our method differs from the Muchenhauer and Daly projection (see [58]) in the choice of inner product (3.19) used to define the orthogonal subspace. These methods are also $O(L^3)$. Jakob [33] gives an $O(L^2 \log L)$ spectral projection, which however bypasses the construction of spherical harmonic coefficients. Because we work with a relatively small value of L, and need the spectral coefficients, the Jakob projection would not provide any improvement.

The torus method described here and in [39] has the advantage that it applies also to higher-rank tensors, in particular vectors and 2-tensors. Representations in terms of spin-weighted fields are more efficient for vectors (spin $s = 1$) than 3-vector representations [59, 60], and the operator $\eth$ gives a transparent derivation of all invariant derivative combinations [59].

3.6. Convolution splines. At various stages it is necessary to interpolate and differentiate grid-based fields. For example, each step of the radial integration of the hypersurface equations by the RK8 method requires interpolation of the source field β at 10 intermediate points; the dynamic regridding of the radial grid uses interpolation to determine the field values of β at the new grid points; and derivatives such as $\partial\gamma/\partial r$ and $\partial Q^+/\partial z$ must be computed from field values on grids. A convolution spline algorithm described in [38] provides a convenient technique.

TABLE 3.2
Convolution coefficients $a_i^{(9)}$.

i:	$1,8$	$2,7$	$3,6$	$4,5$

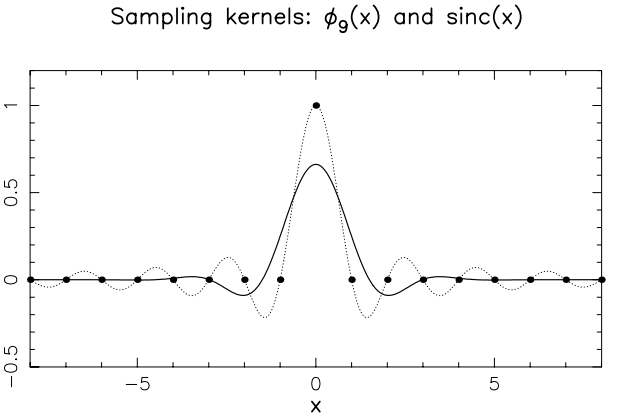

FIG. 3.1. *Comparison of the* C^7 *spline kernel* ϕ_9 *(solid curve) and the sinc method* [17, 57] *kernel* $\mathrm{sinc}(x) = \sin(\pi x)/\pi x$ *(dotted curve). The kernel for a sampling method is the response to the delta-like discrete data (solid dots). The advantages of the convolution spline method are that the kernels have finite support (*$[-8, 8]$ *in this case) and the data is automatically filtered. The convolution* (3.29) *using kernel* ϕ_9 *exactly reproduces polynomials of degree* 7 *or less.*

The method has the effect of fitting a spline curve to sample data, and is implemented by a convolution of the form [38]

$$\bar{f}(x) = \sum_{k\in\mathbb{Z}} f(k)\phi_n(x-k), \tag{3.29}$$

where the $f(k)$ are the raw data (samples) and $\phi_n(x)$ is a C^{n-2} sampling kernel. ϕ_n is constructed as a certain sum of central B-splines M_n of order n,

$$\phi_n(x) = \sum_{i=1}^{n-1} a_i^{(n)} M_n(x - \tfrac{n}{2} + i), \tag{3.30}$$

where the coefficients $a_i^{(n)}$, $i = 1, \ldots, n-1$ are chosen so that the convolution (3.29) acts as the identity on polynomials $f(x)$ of degree $n-1$ (n even) or $n-2$ (n odd). Recall that the central B-spline $M_n(x)$ is a C^{n-2} piecewise polynomial of degree $n-1$ normalized by $\sum_{k\in\mathbb{Z}} M_n(x-k) = 1$, with support on $|x| \le n/2$ [52]. The support of the kernel $\phi_n(x)$ is therefore $|x| \le n-1$.

Algorithms for computing the $a_i^{(n)}$ and tabulations for $n \le 11$ are given in [38]. Coefficients for the kernel ϕ_9 used in the code are given in Table 3.2, and ϕ_9 is plotted in Figure 3.1. The expressions (3.29), (3.30) may be rearranged into a form which is more efficient for numerical calculations,

$$\bar{f}(x) = \sum_{k\in\mathbb{Z}} \tilde{f}_k M_n(x - \tfrac{n}{2} - k), \tag{3.31}$$

where the modified sample values $\tilde{f}_k$ are given by

$$\tilde{f}_k = \sum_{i=1}^{n-1} f(k+i) a_i^{(n)}.$$

The advantage of (3.31) is that the $\tilde{f}_k$ can be computed once and then reused to evaluate $\bar{f}(x)$ at many different points x, using the explicitly known values of the B-spline $M_n(x)$. The same $\tilde{f}_k$ values may also be used to compute derivatives of the spline function $\bar{f}$,

$$\bar{f}^{(j)}(x) = \sum_{k\in\mathbb{Z}} \tilde{f}_k M_n^{(j)}(x - k - \tfrac{n}{2}), \tag{3.32}$$

where again the derivatives $M_n^{(j)}(x)$ are known functions. These techniques are routinely used to supply intermediate values and derivatives of fields in the radial and time directions.

Nonuniform distributions of sample points are handled by a mapping between the independent variable and the sample number variable (x in the above). Numerical derivatives are then calculated using the chain rule. For example, the radial grid described in section 4.2 is nonuniform, specified by some known relation of the general form $r = r(n)$ (where n is now being used to denote the sample number variable, with radial grid points being at $n = 0, \ldots, n_\infty$). The operator $\frac{\partial}{\partial r}$ is then implemented as $\left(\frac{dr}{dn}\right)^{-1} \frac{\partial}{\partial n}$, with a formula for the first factor being known explicitly.

Similarly, one can transform to an independent variable $s = s_0 + hx$ which has grid spacing h, to examine the behavior of the approximation (3.29) as $h \to 0$. Let $g(s) := f((s - s_0)/h) = f(x)$, so $g^{(j)}(s) = h^{-j} f^{(j)}(x)$. It can be shown [38] that using the ϕ_9 kernel, the Taylor series truncation errors for (3.29) at a grid point s are

$$|\bar{g}^{(j)}(s) - g^{(j)}(s)| = c_j h^8 |g^{(8+j)}(s)| + O(h^9), \quad j = 0, 1, 2, \tag{3.33}$$

where $c_0 = \frac{2021}{134400}$, $c_1 = \frac{4547}{302400}$, $c_2 = \frac{4549}{302400}$. This reflects the fact that convolution with ϕ_9 is exact on polynomials of degree 7.

The predicted h^8 convergence of the ϕ_9 spline convolution is clearly evident in Figure 3.2. Here the function $v(x) = e^x \sin 10x$ has been approximated at varying grid resolutions corresponding to $N = 2^p$ grid points over the interval $[-1, 1]$. Convolution splines do not generally preserve sample values, except for samples from polynomials of degree less than or equal to the degree of reproduction. This results in some damping of high-frequency components of the data, which we expect helps to suppress numerical noise and algorithmic instabilities.

Within the context of spectral methods for PDEs, the direct filtering of Fourier coefficients of a numerical solution is common practice and has been extensively studied (cf. [19, section 8.3] and the references therein). On the other hand, explicit use of a digital filter [30] in conjunction with finite difference methods is comparatively rare. Nevertheless, from an algorithmic point of view, this is the effect of using a convolution spline.

The filtering inherent in the method can be examined via the response function

$$\Phi_n(\theta) = \sum_{k\in\mathbb{Z}} \phi_n(k) \cos k\theta, \quad 0 \le \theta \le \pi, \tag{3.34}$$

which is equal to the factor by which the Fourier mode $e^{\mathrm{i}\,\theta x}$ is amplified by the approximation (3.29) at a grid point $x \in \mathbb{Z}$. The value $\theta = \pi$ corresponds to the Nyquist

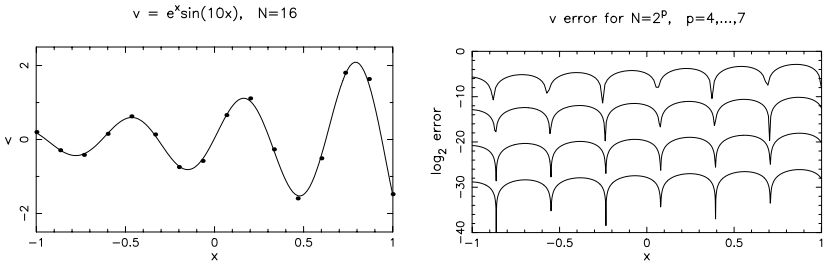

FIG. 3.2. *Convergence of the ϕ_9 spline convolution:* (a) *samples of $v(x) = e^x \sin 10x$ at $N = 16$ points over $[-1, 1]$, and the corresponding convolution spline;* (b) *logarithmic plots of the absolute error $|v(x) - \bar{v}(x)|$ for grid resolutions of $N = 2^p$ with $p = 4, \ldots, 7$, showing a reduction in the error by a factor of 2^8 on each doubling of the resolution.*

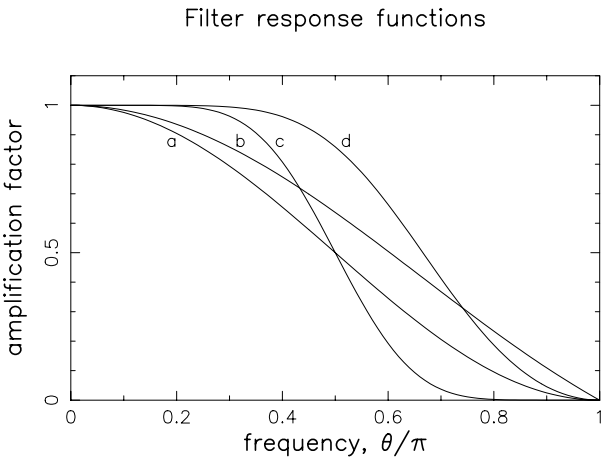

FIG. 3.3. *Filter response functions:* (a) *raised cosine filter $\sigma(\theta) = \frac{1}{2}(1 + \cos\theta)$;* (b) *Lanczos filter $\sigma(\theta) = \theta^{-1} \sin\theta$;* (c) *sharpened raised cosine* [19]*;* (d) $\Phi_9(\theta)$.

frequency for the grid. Figure 3.3 shows the response function $\Phi_9(\theta)$, compared to the well-known Lanczos and raised cosine (artificial viscosity) filters [30]. The filtering characteristics of convolution splines and their derivatives are described in [38]. The limitations of convolution splines are illustrated in Figure 3.4, which shows Gibbs-like effects associated with approximation of step-like data. The figures also give an indication of the number of grid points needed to resolve a sharp transition. In order that the convolution spline smoothing should introduce only negligible errors, the grid resolution should be chosen sufficiently fine that typical field variations take place over enough grid points that the expected frequency θ of the field data lies well within the part of the Nyquist frequency interval where $\Phi_n(\theta) \approx 1$. Of course this requires some prior knowledge of the length scale of the field, and cannot be applied where shocks (or arbitrarily rapid variations) occur in the data. In such cases the spherical harmonic representation would become equally unsuitable.

The choice of high-order convolution splines (h^8 rather than say h^4) was motivated by the need to reduce storage requirements. The smoothing associated with low-order spline convolutions results in a markedly reduced usable proportion of the Nyquist interval [38], so to achieve comparable accuracy with a low-order method would require

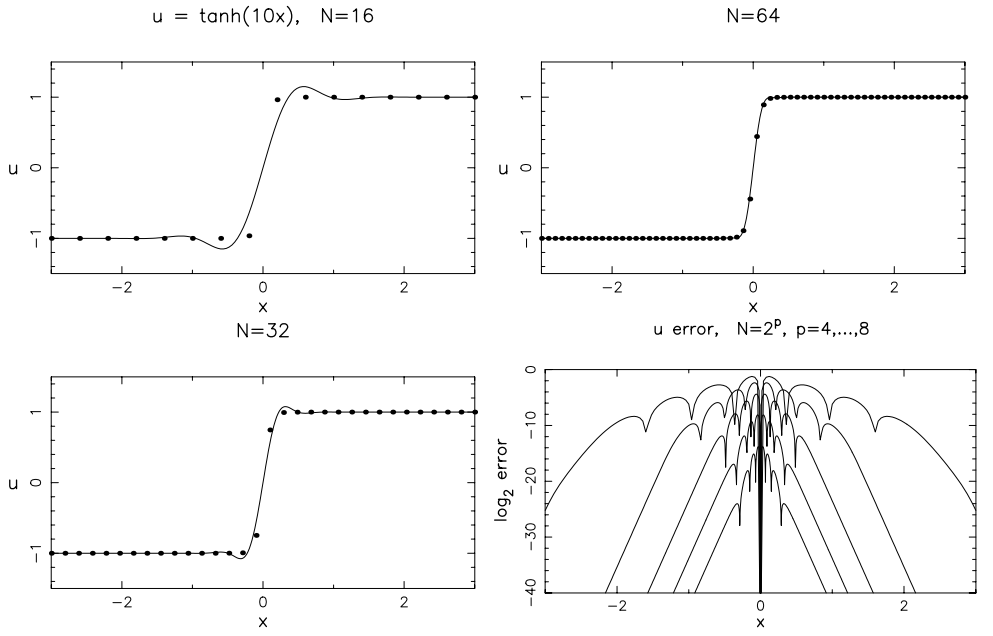

FIG. 3.4. *Convolution spline approximation of step-like data. Here the function* $u = \tanh(10x)$ *is represented by* N *samples over the interval* $[-3, 3]$. *For* $N = 16$, *the transition from* $u \approx -1$ *to* 1 *takes just one grid interval and a Gibbs-like phenomenon is evident. The convolution splines are constructed using the* $\phi_9(x)$ *kernel. The logarithmic plot shows the absolute error,* $|u(x) - \bar{u}(x)|$.

significantly higher grid point densities. The ϕ_9 kernel was chosen also because its accuracy matches that of the RK8 method used for the radial integration.

To use convolution splines near endpoints of a data set we extend the data set, using a suitable mapping between the independent variable and the sample number variable [40]. The mapping is chosen so that when expressed in terms of the sample number variable n, $0 \le n \le n_\infty$, the fields admit expansions in powers of n^2 near $n = 0$ and $(n_\infty - n)^2$ near $n = n_\infty$. The sampling kernel convolution is then applied to the even extension of the fields through $n = 0$ or $n = n_\infty$. This technique is particularly important in extracting radiation data near null infinity (scri, $\mathcal{I}^+$), where the radial grid is chosen so that $n_\infty - n = O(r^{-1/2})$, as described in section 4.2.

4. Solution algorithm. The hypersurface equations (2.20)–(2.23) suggest the following process for evolving the metric in the exterior region with interior boundary the cylinder $r = r_0$:

1. Choose boundary data (H, Q^-, J, K) on the cylinder $r = r_0$, consistent with the boundary equations (2.24), (2.25);

2. Assume β is given on a null hypersurface $\mathcal{N}_z$;

3. Solve the $\mathcal{N}_z$ hypersurface equations $r\partial_r U = F(\beta, U)$ by integrating along $(z, \vartheta, \varphi) = const.$ with initial conditions at $r = r_0$ determined in step 1;

4. Reconstruct the metric functions u, v, γ from H, J, K, and β using the converse construction (2.13)–(2.15);

5. Reconstruct $\partial\beta/\partial z$ from Q, using (2.16) and the known values of β, γ on $\mathcal{N}_z$;

6. Use $\partial\beta/\partial z$ from step 5 to evolve β to the "next" null hypersurface $\mathcal{N}_{z+\Delta z}$ and repeat from step 3.

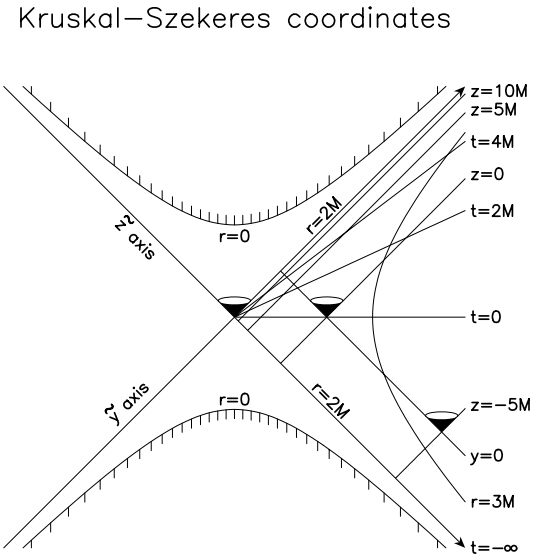

FIG. 4.1. *Schwarzschild spacetime in Kruskal–Szekeres coordinates. Radial light rays are at* 45°.

In the following we will show how this heuristic algorithm is implemented numerically, using the techniques and data representations of the previous section.

4.1. Geometry and inner boundary conditions. The code models gravitational waves propagating on a black hole spacetime, with metric approximating that of the Schwarzschild solution in the Kruskal–Szekeres coordinates [31]. Introducing the double-null coordinates

$$z = t - r^*, \qquad y = t + r^*, \qquad r^* = r + 2\mathrm{M}\log\left(\frac{r}{2\mathrm{M}} - 1\right),$$

the Schwarzschild metric (2.2) becomes $ds^2_{Schw} = -(1 - 2\mathrm{M}/r)\,dy\,dz + r^2 d\Omega^2$, where $d\Omega^2 = d\vartheta^2 + \sin^2\vartheta\, d\varphi^2$. The coordinate singularities at the past and future horizons $t = \pm\infty$ are removed by defining $\tilde{y} = e^{y/4\mathrm{M}}$, $\tilde{z} = e^{-z/4\mathrm{M}}$, giving the metric

$$ds^2_{Schw} = \frac{32\mathrm{M}^3}{r} e^{-r/2\mathrm{M}}\, d\tilde{y} d\tilde{z} + r^2\, d\Omega^2\,,$$

where $r = r(\tilde{y}, \tilde{z})$ is defined implicitly by (see Figure 4.1)

$$e^{r/2\mathrm{M}}\left(\frac{r}{2\mathrm{M}} - 1\right) = \tilde{y}\tilde{z}. \tag{4.1}$$

The surfaces $\tilde{z} = 0$ and $\tilde{y} = 0$ (i.e., $r = 2\mathrm{M}$) form the past and future event horizons, and these are smooth hypersurfaces with bounded curvature. The approximate Minkowski structure of Schwarzschild spacetime is better illustrated by the radial null geodesics in (r, t) coordinates; see Figure 4.2. Note however that the (r, t) coordinates are singular along the event horizons $r = 2\mathrm{M}$. Initial conditions for β are imposed on $\{z = 0, r \geq 2\mathrm{M}\}$ (with $\mathrm{M} = 1$ usually), by specifying the spherical harmonic coefficient functions $\beta_{lm}(r)$. The initial coefficient functions $\beta_{lm}(r)$ may be freely chosen, subject only to the size condition (2.17).

For simplicity the inner boundary conditions are set at $r_0 = 2\mathrm{M} = 2$ to agree with the Schwarzschild past horizon: $H_0 = 2$, $Q_0 = J_0 = K_0 = 0$. Since we choose

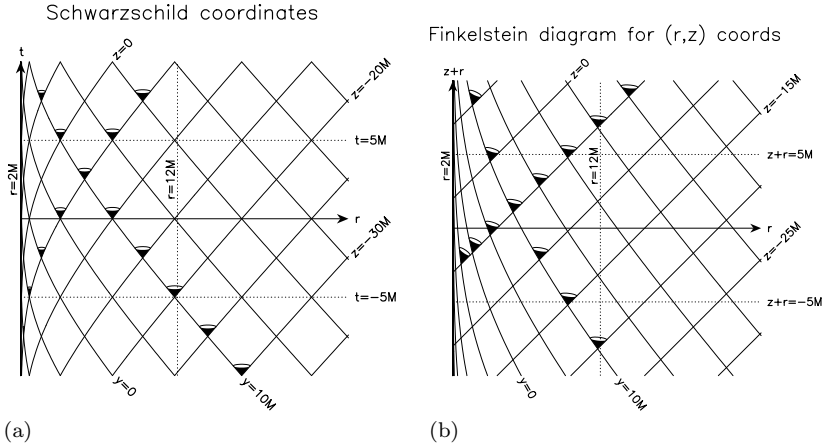

FIG. 4.2. *Exterior region $r > 2\text{M}$ of Schwarzschild spacetime, with radial null geodesics.* (a) *In Schwarzschild coordinates (r, t);* (b) *in retarded Eddington–Finkelstein coordinates (r, z).*

$\beta(0, r) = 0$ for $2 \leq r \leq 5$, by causality the solution should agree with the Schwarzschild metric in a neighborhood of $r = 2$ for all time $z \geq 0$, producing a "white hole" past horizon in the spacetime. This choice of inner boundary condition has the considerable advantage that the boundary equations (2.24), (2.25) are automatically satisfied, and it is not necessary for this class of simulations to separately ensure that the boundary data are numerically compatible with the boundary equations.

The resulting spacetimes have the geometry of an isolated black hole with future event horizon at $z = \infty$, $r > 2\text{M}$, and Schwarzschild-like white hole boundary along $r = 2\text{M}, 0 \leq z < \infty$. Adding shear β at the initial hypersurface $z = 0$ results in spacetimes with gravitational radiation interacting with a single black hole.

Although the fixed past horizon boundary conditions used in the present code allow many interesting issues to be addressed, it would be desirable to implement more general inner boundary conditions. Such conditions specify H, J, K, Q^+ at an inner surface ($r = 1$, for example), subject to the dynamical ($\partial/\partial z$) constraints on the evolution of J/u and Q^+ determined by the boundary equations (2.24),(2.25) [4]. The free data on the inner boundary consist of u_0, K_0, where u_0 represents a certain coordinate gauge freedom, while K_0 describes the gravitational radiation injected into the system through the inner boundary. Various exact solutions with such boundary conditions are described in [6] (Robinson–Trautman [49], boosted Schwarzschild, twisted Minkowski space), and would provide useful accuracy checks on the numerical methods. However, implementing general inner boundary conditions raises numerical difficulties, and constraining the radiation data K_0 such that the spacetime is still Schwarzschild near the past horizon is a difficult geometric problem. An arbitrary choice of K_0 will inject additional energy into the spacetime.

4.2. Dynamic radial grid. There are two geometric features which the code should model accurately: future null infinity ("scri" or $\mathcal{I}^+$, where $r \to \infty$, z finite), and the future horizon $r \sim 2\text{M}$, $z \to \infty$.

The field near null infinity $\mathcal{I}^+ \cap \mathcal{N}_z = (r = \infty, z)$ determines the outgoing gravitational waves as seen by a distant observer and is consequently very important for applications to gravitational wave astronomy. Experience with 3+1 codes shows that it is not possible (as yet) to provide boundary conditions on an outer time-like

boundary at a finite radius which do not either inject radiation or reflect radiation back into the grid. This deficiency has the effect of severely limiting the overall time duration of most $3+1$ simulations. We avoid all such reflection problems by using a radial grid coordinate n, which compactifies $r=\infty$ and leads to accurate modeling of gravitational radiation.

The (z,r) coordinates become singular near the future horizon $z\to\infty$ in the Schwarzschild spacetimes (see Figures 4.1, 4.2). In our case this picture is not exact, since the spacetime geometry is only approximately Schwarzschild, and thus the future horizon will not be located exactly at $z=\infty$. However, the NQS parameterization must still become singular eventually, as the outgoing null hypersurfaces $\mathcal{N}_z$ approach the future event horizon.

One effect of nearly singular coordinates (r,z) at late times is that the in-falling gravitational features near the event horizon will be compressed into a region of small r-variation, and this compression will accelerate in time z, while retaining field structures from early times. Consequently no r-grid which is constant in time is able to accurately represent the in-falling radiation at late times. We have observed that numerical problems with a fixed radial grid arise as early as $z=10$.

To overcome these problems, a dynamic and variable radial grid is used, based on double null coordinates $(z,\tilde{y})$. The time steps in the evolution direction are regular, with $\Delta z = 0.1, 0.05, 0.025$ being typical. The grid in the radial direction is chosen to satisfy the criteria that it compactify null infinity and concentrate grid points in the region of greatest variation in the seed field β. Because the field features propagate along the inward and outward null characteristics, which correspond, respectively, to the curves $\tilde{y}=const.$ (approximately!) and $z=const.$ (exactly), the numerical grid is taken to be rectangular in the $(z,\tilde{y})$ coordinates, with radial grid point positions being determined by an initial distribution of grid points on the surface $z=0$.

Introducing the radial grid coordinate n with range $0\le n\le n_\infty$ (with typical values of n_∞ being 128, 256, 512, and grid points at integer n), we specify an initial grid point distribution $r(z=0,n)=f(n)$, where f is some monotone increasing function such that $f(n_\infty)=\infty$. The radial grid points on the initial ($z=0$, $\tilde{z}=1$) surface have $\tilde{y}$ ordinates given by (4.1),

$$\tilde{y} = (f(n)/2\mathrm{M}-1)\exp(f(n)/2\mathrm{M}) = \phi(f(n)/2\mathrm{M}), \tag{4.2}$$

where $\phi(x):=(x-1)e^x$ is monotone and invertible for $x\ge 0$. Since $\tilde{y},z,r$ are related by $\tilde{y}=e^{z/4\mathrm{M}}\phi(r/2\mathrm{M})$ and the grid points are required to inflow along the curves of constant $\tilde{y}$, we can determine the dynamic radial grid point distribution $r=r(z,n)$ in terms of the initial grid distribution function $f(n)$ by

$$r(z,n) = 2\mathrm{M}\,\phi^{-1}(\exp(-z/4\mathrm{M})\phi(f(n)/2\mathrm{M}))\,, \tag{4.3}$$

where the inverse function $\phi^{-1}:[-1,\infty)\to[0,\infty)$ is evaluated numerically. With this definition, the surfaces $n=const.$ correspond to in-falling null hypersurfaces in the reference Schwarzschild metric. To express the hypersurface equations in terms of n rather than r, we compute $\partial r/\partial n$ from (4.3),

$$\frac{\partial r}{\partial n} = e^{-z/4\mathrm{M}}\frac{f(n)}{r(z,n)}\exp\left(\frac{f(n)-r(z,n)}{2\mathrm{M}}\right)\frac{df}{dn}. \tag{4.4}$$

It remains to choose the initial grid distribution $f(n)$. The condition $n_\infty - n = O(r^{-1/2})$ is achieved by setting $f(n)=f_1(\nu)/(1-\nu)^2$, where $\nu=n/n_\infty$ and f_1 :

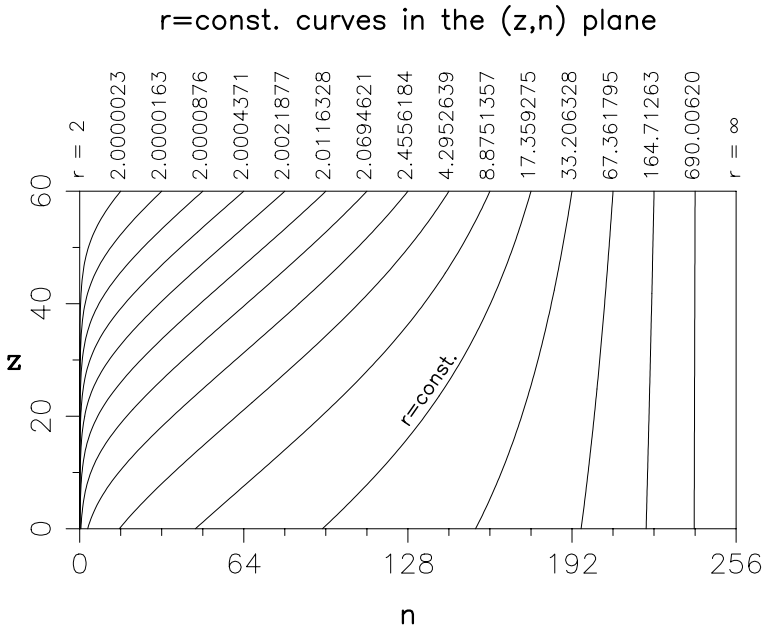

FIG. 4.3. *The map between radial grid point number n and radius r is dynamic, chosen so that grid points approximately follow inward null geodesics. At late null-time z, grid points cluster near the black hole horizon at $r = 2$.*

$[0,1] \to \mathbb{R}$ is any suitable smooth monotone bounded function. In the code, f_1 is a quadratic polynomial, with coefficients chosen to concentrate grid points across the support of the chosen initial data $\beta(z = 0)$. Figure 4.3 shows sample curves $r(z, n) = const.$, illustrating the in-falling nature of the (z, n) grid coordinates. This heuristic prescription for distributing the grid points works well in practice—Figure 4.4 shows the shear over the (z, n) plane for `run_160` and clearly demonstrates the in-falling structure of this solution. The simulation eventually terminates at $z = 55$ because of some geometric effect associated with breakdown of the NQS gauge condition near the future event horizon.

4.3. Hypersurface equations. The hypersurface equations are solved by treating them as a large system of ODEs, with the radial grid coordinate n playing the role of independent variable, and the dependent variables being the values taken by the fields (H, J, Q, K) at the $N^2/2$ points of the (ϑ, φ)-grid.

The form ((2.28)–(2.31)) of the hypersurface equations, for the variables $\log H$, rQ^+, j and K, proves to be better behaved near $r = \infty$, since each of these variables has a finite (usually nonzero) limit. Integration of these radial ODEs is possible up to and including the final point $n = n_\infty$, with results whose numerical effectiveness may be seen by inspecting the field values in a neighborhood of null infinity [8]. Tests described in the following section, in particular the consistency of the constraint equations and the accuracy of the Trautman–Bondi mass decay formula (Figure 5.9) also confirm that asymptotic behavior has been reliably calculated.

Note that unlike methods based on Bondi–Sachs or Newman–Unti coordinates [29, 37], integration along the r-coordinate lines does not correspond to integrating along the radial null geodesics (the characteristics of the Einstein equations), since in general the NQS shear β is nonzero and the null direction is $\ell = \partial/\partial r - r^{-1}\beta$.

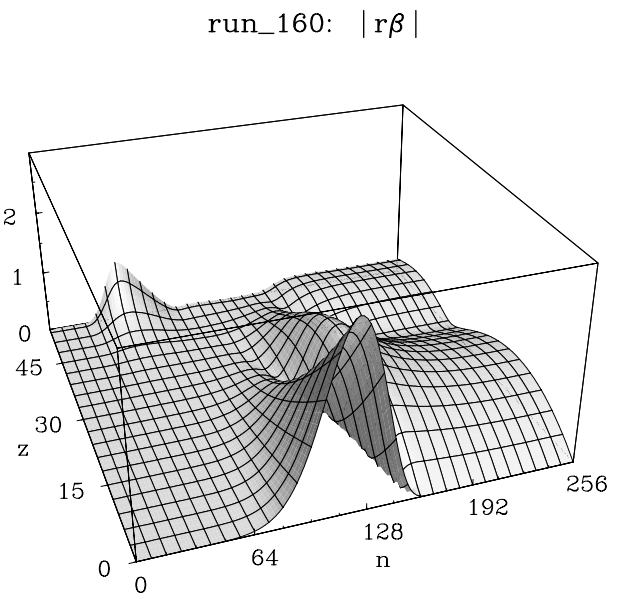

FIG. 4.4. *Evolution of $r\beta$ for $0 \le z \le 55$, in radial in-falling coordinates. Observe that the in-falling grid tracks the dynamical evolution. This simulation has timestep $\Delta z = 0.05$, $n = 0$ is the past horizon $r = 2\text{M}$, and $n = 256$ represents future null infinity $\mathcal{I}^+$.*

The radial integration with respect to n is performed using an RK8 scheme [46], with RK step size $\Delta n = 1$. This method requires 13 derivative evaluations per RK step, of which 10 are at intermediate points not on the radial grid. Values of β and its angular derivatives at these intermediate points are provided by convolution splines generated using the kernel ϕ_9 with samples at integer n.

4.4. Reconstructing the metric. Step 4 of the solution algorithm requires us to reconstruct the metric functions (u, v, γ) from the solution (H, J, K, Q) of the hypersurface system ((2.20)–(2.23)) with seed β and boundary data $(H, J, K, Q)|_{r=r_0}$. The reconstruction is carried out as described in section 2.3. This process requires solving the system (2.14) on each S^2 of the radial grid. If β is not too large, then (2.14) is an elliptic system of PDEs on the sphere S^2, mapping surjectively to the space of spin 2 fields. We solve (2.14) by introducing the preconditioning variable $\Gamma = \eth\gamma$, so (2.14) becomes

$$\Gamma + \frac{\eth\beta}{2 - \text{div}\beta}\text{div}(\eth^{-1}\Gamma) = -K + J\frac{\eth\beta}{2 - \text{div}\beta}\,, \tag{4.5}$$

where $\eth^{-1}$ is defined spectrally by

$$\eth^{-1}Y^2_{lm} = -\left[\tfrac{1}{2}(l+2)(l-1)\right]^{-1/2} Y^1_{lm}, \quad l \ge 2.$$

Note that this definition of $\eth^{-1}$ gauges the $l = 1$ spherical harmonic components of γ to zero—a similar but more expensive construction may be used if nonzero $\gamma_{l=1}$ components are desired. The advantage of (4.5) over (2.14) is that the operator in (4.5) is close to the identity for small $B := \eth\beta/(2 - \text{div}\beta)$.

Writing (4.5) as $(1+\mathcal{A})\Gamma = F$, where $\Gamma \mapsto \mathcal{A}\Gamma = B\text{div}\eth^{-1}\Gamma$ is an $\mathbb{R}$-linear operator

and $F = -K + JB$, suggests the iterative algorithm

$$\Gamma_{n+1} = F - \mathcal{A}\Gamma_n, \quad n = 0, 1, \ldots. \tag{4.6}$$

For $\Gamma = \sum_{l\geq 2,m} \Gamma^{lm} Y^2_{lm}$ we have the explicit spectral representation

$$\mathrm{div}\eth^{-1}\Gamma = -\sum_{l=2}^{\infty}\sum_{m=-l}^{l}\left[\frac{l(l+1)}{(l-1)(l+2)}\right]^{1/2}(\Gamma^{lm} + \bar{\Gamma}^{lm})Y_{lm}, \tag{4.7}$$

which shows that $\mathrm{div}\eth^{-1}$ is a zero-order operator with kernel consisting of purely odd spin 2 fields. It follows that (4.6) converges for B small.

The action of $\mathcal{A}$ is evaluated using (4.7) to compute $\mathrm{div}\eth^{-1}\Gamma$, then using the field value representation to compute the product with $B = \eth\beta/(2 - \mathrm{div}\beta)$, and finally converting back to the spectral representation. The iterations (4.6) continue until the error, measured by the sum of squares of spherical harmonic coefficients of the difference of the two sides of (4.5), is 10^{-2} times the size of the aliasing error in the source term. This aliasing error is the difference between the raw field values of the source term (which is necessarily calculated in the field value representation because it involves products and quotients) and its field values after projection into the subspace spanned by spin 2 spherical harmonics. It provides an estimate of the error in the source term, and hence (because the operator $1 + \mathcal{A}$ is close to the identity) it is reasonable to accept a solution of comparable accuracy.

The iteration scheme (4.6) turns out to be quite efficient, typically requiring fewer than 10 iterations for an S^2 grid of size $N/2 \times N = 16 \times 32$. On this size grid we resolve all components of Γ up to angular momentum $L = N/2 - 1 = 15$, so in this case we solve for $2((L+1)^2 - 4) = 504$ spectral coefficients.

Solving for Γ in the spectral representation uses fewer unknowns $(2(L+1)^2 - 8$ compared to $4(L+1)^2$ grid values), and gauge conditions which specify the $l = 1$ components of γ (e.g., $\gamma_{l=1} = 0$) can be directly implemented. It is possible to adapt the algorithm to allow for other NQS gauges (e.g., $\beta_{l=1} = 0$), which could have some geometric advantages [6], but this is numerically more expensive since (2.14) must be solved four times at each sphere rather than once.

4.5. Evolution. Given β on a null hypersurface $\mathcal{N}_z$, we construct the time derivative $\partial\beta/\partial z$ by solving the hypersurface equations with seed β, determining γ, v as outlined in the previous section, and then using formula (2.16) to evaluate $\partial\beta/\partial z$. Let us write the result of this process as

$$\frac{\partial\beta}{\partial z} = \mathcal{B}(\beta, U_0), \tag{4.8}$$

where the operator $\mathcal{B}$ is determined by the value of β on the hypersurface $\mathcal{N}$ and the initial conditions $U_0 = (H_0, Q_0, J_0, K_0)$ at $r = r_0$ for the hypersurface equations.

The evolution formula (4.8) provides the basis of the spacetime evolution algorithm, which incorporates (4.8) into a standard RK4 algorithm. This is just the method of lines, treating the evolution equations as a large system of ODEs for the (r, ϑ, φ)-grid values of $\beta(z) = \beta_{|\mathcal{N}_z}$.

The method of lines, applied blindly in this manner, is generally prone to instabilities. Tests suggest the relative stability of the NQS code derives from the smoothing effects (a) of the convolution spline and (b) of the spectral projection. The filtering implicit in the convolution spline is applied to β during the radial integration of the

hypersurface equations, at each of the four stages of the RK4 algorithm. It is not possible to turn off this radial filtering because the convolution splines for β are an essential part of the algorithm for evaluating the right-hand side (RHS) of (4.8).

Smoothing of β in the angular directions is done explicitly, by projecting β onto the spin 1 subspace with maximum angular momentum L or $2L/3$ (the Orszag 2/3 rule, to eliminate quadratic aliasing). This angular filtering is done after each of the four stages of the RK4 algorithm. Removal of the angular filtering results in very rapid disintegration of the evolution, which then typically lasts only a few integration steps.

For simplicity, the four RK4 stages evolve β in the z direction in the (z, r) coordinates, along $r = const$. At the end of each full RK4 time step the key field β is interpolated onto the new radial grid (4.3) using a convolution spline for β.

The RK4 time integration of β evolves field values on the (r, ϑ, φ)-grid. Equivalently, we could have evolved its spherical harmonic coefficients, of which there are half as many. However, the computation saved by doing so is insignificant in comparison to that required to evaluate $\partial\beta/\partial z$, so this choice is made for convenience.

Likewise, the RK8 radial integration of the system of hypersurface equations uses the field value representation. In this case, however, it is found that projecting the fields onto their appropriate spherical harmonic subspaces during the integration is not required for either stability or accuracy. There is a definite computational advantage in staying within the field value representation, since many relatively expensive $O(L^3)$ projections are avoided.

Evaluating $\partial\beta/\partial z$ requires $\partial\gamma/\partial r$ (2.16). Numerical r-derivatives of γ are calculated as the derivatives of convolution splines for γ in the radial direction, making use of formula (4.4) and the chain rule for derivatives. The radial derivative term $\mathcal{D}_r \log u$ which appears in the hypersurface equation (2.29) can be expressed using (2.28) and (2.13) in terms of the 1st radial and angular derivatives of β.

The program is normally run until the solution ceases to be well behaved. Blowup is detected by monitoring $2 - \mathrm{div}\beta$, which must remain everywhere positive. For the initial data that we have used, the blowup always occurs in $l = 2$ modes of β, at low n values corresponding to $r \approx 2\mathrm{M}$ (see Figures 4.3, 4.4). Although the precise cause of blowup is not yet understood, it is not a numerical instability, since it is unaffected by changes in radial or timestep resolutions, nor does it appear to be primarily geometric, since most curvature scalars remain bounded. This suggests the blowup is a coordinate effect arising from proximity to the future event horizon.

For smooth initial data of intermediate strength, the evolution extends to $z \sim 55$. The final time varies with the strength of the initial data—see Table 5.1. The evolution of an intermediate strength solution is shown in Figure 4.4, which plots the mean square or $L^2(S^2)$ size of β at each radial sphere, for time $0 \le z \le 55$. The blowup feature is at low radius, and is apparent from time $z = 45$ onwards.

5. Accuracy tests. The complexity of the NQS Einstein equations and the variety of algorithms employed in the code make it problematic to prove rigorously that the simulations accurately model the physics and geometry of the spacetime. Instead we rely on a range of tests to justify the reliability of the code, probing the numerical accuracy of the solutions through their convergence and geometric consistency.

We consider here tests based on the *numerical convergence* of the solutions as algorithmic parameters are varied; and on the *algebraic consistency* of the numerical solutions. The consistency tests measure the constraint identities and the Trautman–Bondi mass decay formula [63, 29].

TABLE 5.1
Sizes of the example initial data sets

Field strength:	weak	intermediate	strong
$\beta(0)$ scale factor:	1	4.48	10
$m_B(0)/\mathrm{M} - 1$:	0.9472×10^{-2}	0.1915	0.9940
Last z:	61	55	51

The resolution of the simulations is determined by three parameters: the spherical harmonic spectral limit L (or effective limit $l_{\max}$); the number of radial zones n_∞; and the time step Δz. We shall examine in turn how the accuracy of a solution depends on each of these parameters.

It is clear that numerical convergence can be estimated from the convergence properties of the key field β. However, convergence of β guarantees only that the (limit) solution satisfies *some* system of equations, which may not coincide with the desired vacuum Einstein equations. (For example, the Einstein equations may have been incorrectly implemented.) Thus, to assert that the correct equations have been solved, it is essential to provide independent tests of the correctness of the code.

The most natural independent test is to compare the numerical solution with an explicitly known solution. Unfortunately the Schwarzschild metric (2.2) is trivial in the NQS gauge and does not provide a useful comparison test, while the twisted shear-free metrics [6] require interior boundary conditions which are more general than those available in the present version of the code.

Instead we consider here another class of independent tests based on constraint relations. Such relations are typical of geometric equations arising in geometry and physics, which admit gauge and coordinate freedoms. Thus, we check the geometric consistency of the solution by evaluating $r^2 G_{nn}$ and $r^2 G_{nm}$ using (2.24) and (2.25). Neither of these relations is used in generating the numerical solutions, and in theory these components should evaluate to zero. In practice, since each is a sum of terms having magnitude approximately $|\beta| \sim 1$, the extent to which $r^2 G_{nn}$, $r^2 G_{nm}$ evaluate to zero serves both to confirm the consistency of the numerical solution with the vacuum Einstein equations, and also to assess the relative accuracy of the solution.

The Trautman–Bondi mass decay formula provides another such test of geometric consistency, and of the accuracy of the solution near $r = \infty$. This theoretical result is a relation between the asymptotic ($r = \infty$) values and z-derivatives of the fields H, J, and K, and may be readily tested for our numerical solutions.

In the following we discuss numerical solutions generated by three reference initial $\beta(z = 0)$ fields, which differ only by the scale factors in Table 5.1. In each case the initial β consists of pure $l = 2, m = 2$ spherical harmonics with equal strength odd and even parts, and radial profile being a bump supported on $5 \le r \le 40$. We use the terms *weak*, *intermediate*, and *strong* to describe these solutions.

A convenient measure of the strength of the gravitational field is the initial relative mass difference $m_B(0)/\mathrm{M} - 1$, between the initial Bondi mass of the numerical spacetime (cf. (5.3)) and the background Schwarzschild mass ($\mathrm{M} = 1$). Table 5.1 gives the initial relative mass differences for the three reference initial β fields.

The qualitative conclusions of the error analysis of this section are:

1. The major factor determining the overall accuracy is the spectral limit L. Truncating spherical harmonic coefficients at L has the effect of modifying the equations being solved to a system for which the constraint identities are no longer valid.

With $L = 15$ the weak and intermediate field solutions can be well resolved, but this is not sufficient to obtain adequate (beyond 10^{-3}) accuracy for strong field simulations.

2. Unstable quadratic aliasing can be suppressed using Orszag's 2/3 rule.

3. Within the bounds governed by the spectral limit L, accuracy can be improved by increasing the radial resolution n_∞. For the weak field solution, $n_\infty = 1024$ reduces the radial error to the level of the spectral truncation error (see Figure 5.6(b)).

4. For given resolutions L and n_∞, there is a range of values Δz for which the simulation remains stable. Outside this range, the simulation follows the standard solution for some time, then rapidly blows up. The simulation errors are largely insensitive to the value of Δz within the stable range, so Δz may be chosen as large as possible, consistent with stable evolution.

5.1. Dependence on the spectral limit *L*. Using our current hardware it is not generally feasible to run the code at $L = 31$, and $L = 7$ is too low to be of interest. The code is normally run at the $L = 15$ resolution (16×32 (ϑ, φ)-grid) with an antialiasing cutoff at $l_{\max} = 10$.

Orszag [19, 41] observed that quadratic aliasing can be eliminated by periodically removing the upper 1/3 of the spectral bandwidth of a numerical solution. If fields contain only modes for which $l \leq \frac{2}{3}L$, then a quadratic product is band limited to $l \leq \frac{4}{3}L$. With a working bandwidth L, the modes for which $L \leq l \leq \frac{4}{3}L$ become aliased onto the modes $\frac{2}{3}L \leq l \leq L$. Therefore, truncation at $l_{\max} = \frac{2}{3}L$ will remove quadratic aliasing contamination.

If no $l_{\max}$ cutoff is used (i.e., the full $L = 15$ resolution is retained), then the high l-modes of the intermediate strength simulations blow up at $z \approx 8$. The time until blow up is largely independent of the time step and radial resolution. This suggests that the nonlinear aliasing contamination is best regarded as changing the system into one which has unstable solutions.

Because the nonlinear interactions are predominantly quadratic, it is not surprising that the $l_{\max} = 10$ cutoff is sufficient for long term stability. The intermediate strength solution lasts until $z = 55$, when the code terminates for other reasons.

Figure 5.1(a) shows blow up of `run_453`, an $L = 15$ simulation of the intermediate field strength solution with no antialiasing cutoff. The $l = 15$ modes show rapid growth beyond $z = 6$, indicating the instability of the aliasing feedback. Figure 5.1(b) shows the difference between `run_453` and the stable simulation `run_456`, which has an $l_{\max} = 10$ cutoff. Until the onset of the high l-mode instability (i.e., for $z \leq 6$) there is good agreement between the two simulations, with approximately 10^{-10} relative difference for $l = 2$ modes and 10^{-2} relative difference for $l = 10$ modes. The spectral limit L is critical in determining the relation between gravitational field strength and simulation accuracy. This can be appreciated by observing the decay rate of the l-spectrum of β, as in Figure 5.2. By extrapolation, the absolute error introduced by the antialiasing cutoff at $l_{\max} = 10$ should be no larger than the $l = 10$ coefficient, and a relative error estimate follows by comparing the $l = 10$ and the $l = 2$ coefficients.

Figures 5.2(a) and 5.2(b) show the dramatic difference in decay rates of the l-modes of β for weak and strong fields. Assuming an $l_{\max} = 10$ cutoff, it is evident that the relative errors should be at most 10^{-8} for weak field simulations and 10^{-3} for strong field simulations, assuming the error is dominated by the spectral limit. From the observed decay rate of the l-modes of β for a given field strength, it is possible to estimate the resolution L required to achieve a prescribed accuracy. Thus although we cannot directly investigate the behavior of errors with varying spectral limit L

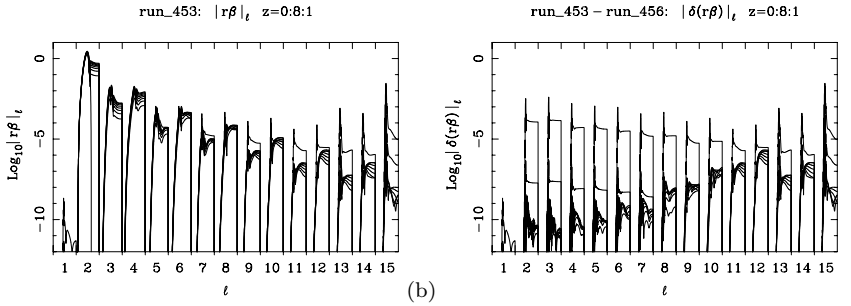

FIG. 5.1. *Orszag's* 2/3 *rule is used to remove aliasing instability:* (a) *unstable evolution of the high* l*-modes of an* $L = 15$ *simulation (no antialiasing cutoff);* (b) *difference between an unstable* $L = 15$ *simulation (no cutoff) and a stable simulation with an* $l_{\max} = 10$ *cutoff. Each* l*-bin contains a radial plot (linear in* n*, with* $n = 0, \ldots, n_\infty$*) of the square root of the sum of the squares of the* (l, m)*-components for fixed* l *with* $m = -l, \ldots, l$*. These simulations have* $n_\infty = 512$ *and* $\Delta z = 0.05$*.*

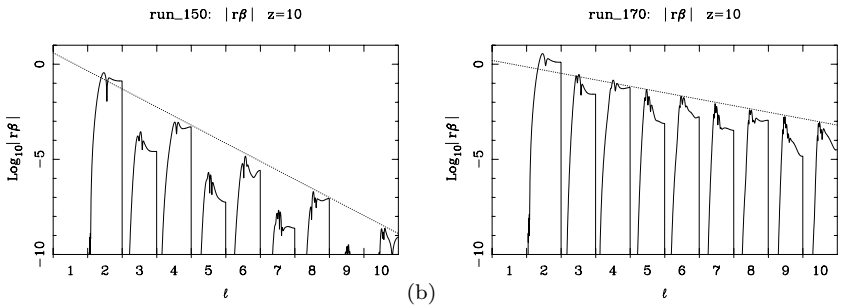

FIG. 5.2. *Spectral resolution and field strength:* (a) *well-resolved weak field with fast* l*-mode decay;* (b) *poorly resolved strong field with slow decay of* l*-modes (see Table* 5.1 *for field strength details).*

(due to hardware constraints), we can still investigate spectral resolution effects by altering the β field strength.

Figures 5.3(a) and 5.3(b) show the effect of field strength (weak, intermediate, strong) on the constraint quantities $r^2 G_{nn}$ and $r^2 G_{nm}$. The parameters for these simulations are $l_{\max} = 10$, $n_\infty = 256$, and $\Delta z = 0.05$. The four curves in each band are for times $z = 10, 20, 30, 40$. There is no significant z dependence of either G_{nn} or G_{nm} until within about 5M of the final blow up time. The second Bianchi identity implies the conservation law $G^{;b}_{ab} = 0$, which leads to a radial system of equations for G_{nn}, G_{nm} with sources linear in the hypersurface Einstein tensor components $G_{\ell\ell}$, $G_{\ell m}$, $G_{\ell n}$, G_{mm}. Thus G_{nn}, G_{nm} give a measure of the accumulated error in the hypersurface equations in the radial direction. This provides some explanation of the structure of the G_{nn}, G_{nm} graphs, particularly for the strong field solution: the numerical solution of the hypersurface equations will have greatest error in the region where the fields are strongest, in this case the range $64 < n < 128$, and this is precisely the region of greatest increase in G_{nn}, G_{nm}.

5.2. Dependence on radial grid resolution n_∞. The radial regridding and interpolation of β, the radial differentiation of γ, and the radial integration of the hypersurface equations are all formally eighth-order accurate. Figure 5.4 shows this is consistent with the observed convergence of β on increasing the radial resolution. The constraint quantities G_{nn} and G_{nm} also exhibit convergence. Figures 5.5(a) and

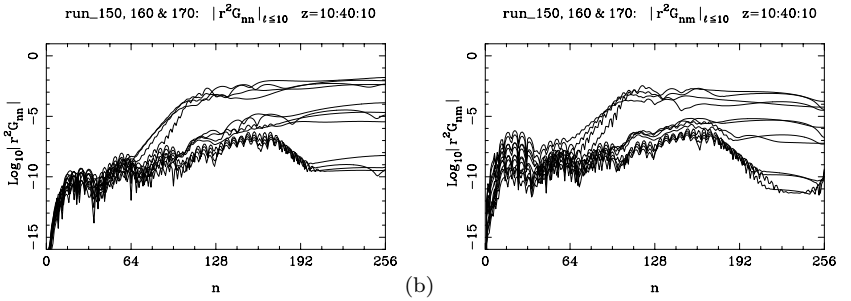

FIG. 5.3. *Effect of spectral resolution on constraint quantities* (a) $|r^2G_{nn}|_{S^2}$*;* (b) $|r^2G_{nm}|_{S^2}$*, at times* $z = 10, 20, 30, 40$ *for strong (top* 4 *curves), intermediate (middle* 4 *curves), and weak fields (bottom* 4 *curves).*

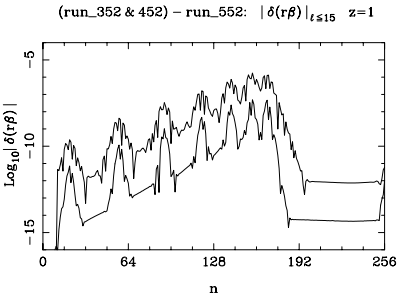

FIG. 5.4. *Convergence of* β *with increasing radial resolution: weak field solutions with* $n_\infty = 256, 512$ *compared to* $n_\infty = 1024$*. The error decreases by approximately a factor of* 2^8 *on doubling the radial resolution.*

5.5(b) show significant improvement between $n_\infty = 256$ and 512, but little between 512 and 1024. The form of the $n_\infty = 1024$ curve indicates that constraint errors at the highest radial resolution are dominated by spectral truncation.

5.3. Dependence on time step Δz. At the typical resolutions at which the code is run, the RK4 errors are completely dominated by errors arising from the spectral truncation L and/or the radial resolution n_∞. This is illustrated by Figure 5.6(a), which shows no significant difference in the constraint quantity G_{nn} between $\Delta z = 0.1$ and $\Delta z = 0.05$ when $n_\infty = 256$. However, when the solution is highly resolved in the radial direction, an effect can be observed, cf. Figure 5.6(b), for $n_\infty = 1024$. Figure 5.7 shows $r\beta$ errors for runs with $\Delta z = 0.1, 0.05$ and $n_\infty = 512$. Again convergence with decreasing Δz is evident only where the RK4 error is not dominated. Consequently, Δz is optimally chosen as large as possible, subject to resulting in stable evolution. For $n_\infty = 256$ and $L = 15$ with an antialiasing $l_{\max} = 10$ cutoff, the evolution is stable for $\Delta z = 0.1$ and unstable for $\Delta z = 0.2$, which blows up at time $z = 25$, after 125 RK4 steps.

5.4. Energy and asymptotic decay tests. The Hawking mass

$$m_H(\Sigma) = \sqrt{\frac{\mathrm{area}(\Sigma)}{16\pi}}\left(1 - \frac{1}{2\pi}\oint_\Sigma \rho_{NP}\mu_{NP}\, dv_\Sigma\right) \tag{5.1}$$

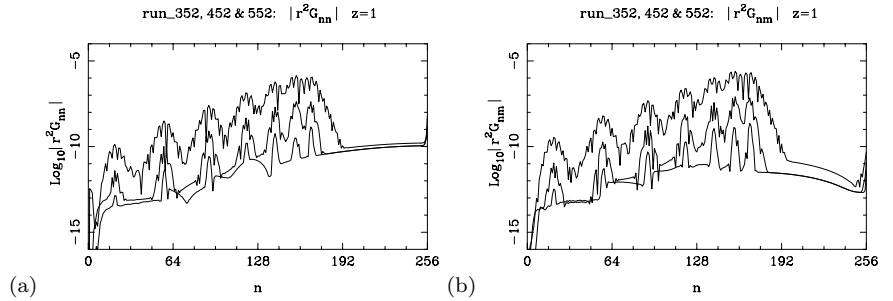

FIG. 5.5. *Effect of radial resolution on weak field constraint quantities* (a) $|r^2 G_{nn}|_{S^2}$, (b) $|r^2 G_{nm}|_{S^2}$. *In each case the three curves are for* $n_\infty = 256, 512, 1024$ *(top, middle, and bottom curves, respectively).*

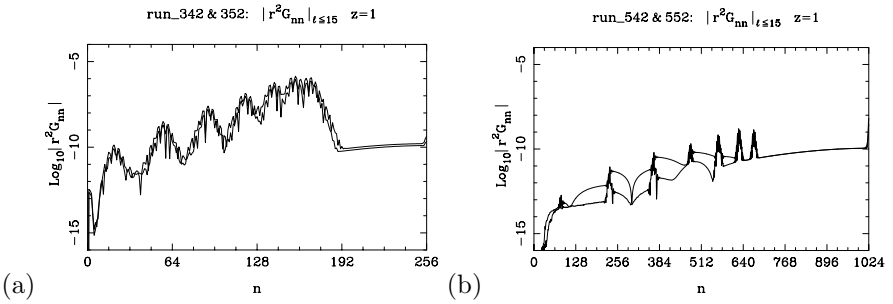

FIG. 5.6. *Effect of time step resolution on the constraint quantity* $|r^2 G_{nn}|_{S^2}$ *for the weak field solution:* (a) $n_\infty = 256, \Delta z = 0.1, 0.05$*: the error is dominated by the radial discretization error for* $n < 192$ *and by the spectral truncation error for* $n > 192$*. Refining* Δz *produces no appreciable improvement in the solution.* (b) $n_\infty = 1024, \Delta z = 0.1, 0.05$*: the radial discretization error is small enough that the RK4 integration error can be observed. For* $n > 700$ *the error is dominated by the spectral truncation, resulting in the same tail as in* (a)*, while for* $n < 700$ *the constraint improves in places, consistent with a factor of* 16 *decrease in the error.*

of a 2-surface Σ reduces in the NQS gauge to

$$m_H(z,r) = \tfrac{1}{2} r \left(1 - \frac{1}{8\pi} \oint_{S^2} HJ\right). \tag{5.2}$$

$m_H(z,r)$ provides a quantity representing the "quasi-local" mass contained within the sphere (z,r), and has asymptotic limit equal to the Bondi mass

$$m_B(z) = \lim_{r\to\infty} m_H(r,z). \tag{5.3}$$

The Bondi mass is easily computed numerically, by $m_B(z) = m_H(n = n_\infty, z)$. Figure 5.8(a) shows the Hawking mass plotted against the radial coordinate, for times $z = 0, 1, \ldots, 55$. There are several features of interest in this plot: the limit Bondi mass (Figure 5.8(b)) decays in time, reflecting the Trautman–Bondi mass loss formula (5.4); the energy is radiated in bursts, reflecting near-linear behavior dominated by pure $l = 2$ modes; the Hawking and Bondi masses decay to the background black hole mass $\mathrm{M} = 1$ at late times, suggesting that in this example, almost all the gravitational radiation has been scattered to $\mathcal{I}^+$ and essentially none is absorbed by the black hole; and finally, the rapidly growing feature at about $n = 20$ at late times in Figure 4.4 does not affect the Hawking mass.

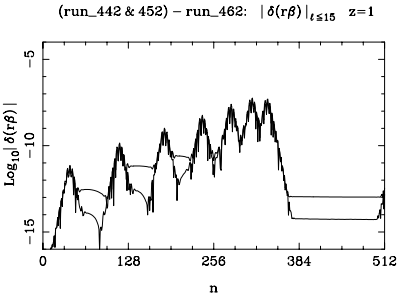

FIG. 5.7. *Convergence of β with decreasing time step: weak field solutions for $\Delta z = 0.1, 0.05$, compared against $\Delta z = 0.025$. Where the error is not dominated by the radial discretization error, the curves show a decrease in error which is consistent with fourth-order convergence.*

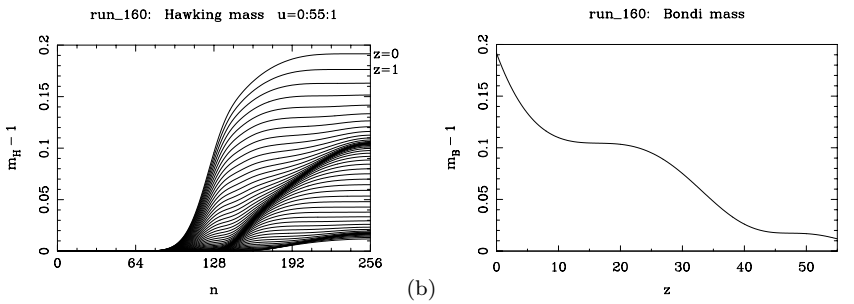

FIG. 5.8. *Mass functions:* (a) *Hawking mass for times $z = 0, 1, \ldots, 55$;* (b) *Bondi mass.*

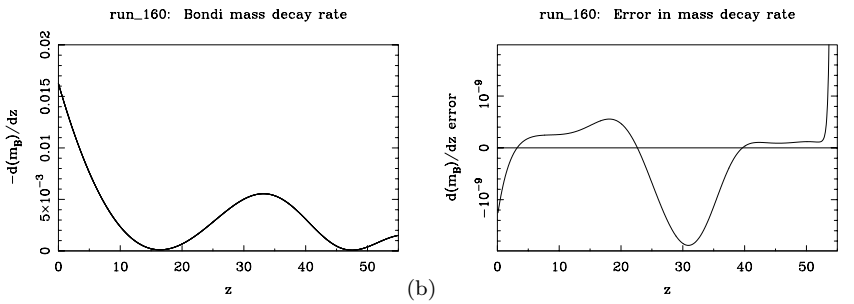

FIG. 5.9. *Trautman–Bondi mass loss formula as a test of numerical accuracy at $r = \infty$:* (a) *Bondi mass decay rate;* (b) *error in the mass decay formula, given by* LHS(5.4) − RHS(5.4).

The Trautman–Bondi mass loss formula [62, 63, 15, 29]

$$\frac{d}{dz} m_B(z) = -\frac{1}{16\pi} \lim_{r\to\infty} \oint_{S^2(z,r)} H|K|^2 \tag{5.4}$$

provides a test of the geometric consistency of the solution, particularly near null infinity. By comparing the numerical derivative dm_B/dz with the computed value of the RHS (evaluated at $n = n_\infty$), we may construct the error $\frac{d}{dz} m_B - \mathrm{RHS}(5.4)$. Figure 5.9(b) plots this error against time z, suggesting that the asymptotic ($r = \infty$) fields of `run_160` are accurate to about 0.00001%.

COMPUTING PERIODIC ORBITS AND THEIR BIFURCATIONS WITH AUTOMATIC DIFFERENTIATION*

JOHN GUCKENHEIMER† AND BRIAN MELOON†

Abstract. This paper formulates several algorithms for the direct computation of periodic orbits as solutions of boundary value problems. The algorithms emphasize the use of coarse meshes and high orders of accuracy. Convergence theorems are given in the limit of increasing order with a fixed mesh. The algorithms are implemented with the use of MATLAB and ADOL-C, a software package for automatic differentiation. Automatic differentiation enables accurate computation of high-order derivatives of functions without the truncation errors inherent in finite difference calculations. We embed the algorithms in a continuation framework and extend them to compute saddle-node bifurcations of periodic orbits directly. We present data from numerical studies of four test problems, making some comparisons with other methods for computing periodic orbits. These results demonstrate that high-order methods based upon automatic differentiation are capable of high precision with small meshes.

Key words. periodic orbit, automatic differentiation, saddle-node bifurcation

1. Introduction.

Periodic orbits are fundamental objects in dynamical systems. They are frequently important in applications of the dynamical systems theory. Computational tools that locate periodic orbits and their bifurcations are an essential ingredient for the numerical investigation of vector fields. Stable periodic orbits are often found in these investigations as the limit sets of trajectories computed with numerical integration. However, there are many circumstances in which we want to compute periodic orbits that are not accessible in this manner. Direct methods based upon the solution of boundary value problems are called for in these circumstances. Formulation and implementation of effective boundary value solvers for periodic orbits is a difficult task. There are a few tools that have been developed for this purpose, notably the package AUTO [10] based upon a collocation method. This paper examines alternate approaches for computing periodic orbits of dynamical systems.

Our goal is to explore the limits of accuracy that are attainable for these calculations within the pragmatic context of IEEE floating point arithmetic. A previous paper [17] described a global boundary value solver of very high-order accuracy that relies upon automatic differentiation. We extend that work here, introducing multiple shooting algorithms that use automatic differentiation and augmenting these to perform direct computation of saddle-node bifurcations. We compare our algorithms with other numerical methods for finding periodic orbits, examining robustness and accuracy.

Robust algorithms facilitate the automated analysis of dynamical systems. Accuracy is necessary to achieve robustness for two reasons. First, many dynamical systems have fine scale structure that makes them difficult to compute. This is especially true of dynamical systems with multiple time scales and systems that are

chaotic. Second, defining equations for bifurcations of periodic orbits involve derivatives of the vector field along the orbit. Newton's method applied to the bifurcation equations requires first derivatives of the defining equations and second derivatives of the periodic orbit equations. Calculation of second derivatives with finite differences layered on imprecise calculation of periodic orbits is hardly a recipe for robustness. Improved algorithms of greater accuracy for computing periodic orbits and the use of automatic differentiation to compute defining equations enhance existing technology for analysis of dynamical systems.

Our algorithms approach the limits of precision attainable with double precision IEEE-754 arithmetic for computing periodic orbits. The algorithms utilize three strategies that contribute to their accuracy:

- Automatic differentiation is employed to calculate high-order derivatives of a vector field and its trajectories.
- The methods emphasize compact parametrizations of function spaces that include high-order approximations to the periodic orbits.
- A posteriori error estimates of the accuracy of numerically computed periodic orbits are used for mesh adaptation.

The methods have additional attractive geometric features from both theoretical and geometric perspectives. They utilize directly the geometric objects that are prominent in the theory. These objects can be readily examined and manipulated, and they can be used adaptively to enable the algorithms to respond to changes in the geometry of a periodic orbit during continuation. The algorithms give dense output of uniform order. More specifically, no further interpolation is required to approximate periodic orbits at all points to the same order of accuracy as at mesh points. Constraints are readily imposed upon mesh points, enabling the accurate computation of periodic orbits of piecewise analytic vector fields.

The plan of the paper is as follows. Section 2 describes four algorithms for computing periodic orbits, each of which uses Taylor series expansions at the mesh points to achieve high-order. Section 3 describes a continuation framework for the algorithms and formulates defining equations for local bifurcations of periodic orbits. Section 4 describes how we implemented the algorithms and discusses our strategies for mesh adaptation. Section 5 presents data from numerical studies of four systems. These examples were chosen to test the accuracy and robustness of the methods on challenging problems. The paper ends with a brief set of conclusions.

2. Periodic orbit algorithms. The equations describing periodic orbits are boundary value problems for a system of ordinary differential equations [2]. Only a small number of algorithms have been widely used for the computation of periodic orbits. These fall into three *classes* [2]:

1. Numerical integration of initial values in the domain of attraction of a stable periodic orbit γ converge to γ [20, 21]. (Despite the robustness of numerical integration algorithms, we display examples where they are unable to compute stable periodic orbits.)
2. Shooting methods apply root finding algorithms to approximate flow maps computed with numerical integration [8, 25, 7].
3. Global methods project the differential equations onto spaces of discretized closed curves and solve these projected equations with root finding algorithms [2, 10].

We discuss both shooting methods and global methods of high order. Our methods fall within general classes that have been studied previously, but we explore the limit

of increasing order in the methods as contrasted with the usual limit of increasingly fine meshes. This has some resemblance to p refinement in "h-p" methods studied extensively by Babuška and Suri [3], though we appear to go much farther in our investigation of convergence on fixed meshes. Although Taylor series integration has been previously studied [4] and Taylor series methods have been described for two-point boundary value problems [27], its use in periodic orbit algorithms appears to be new.

This section presents four different algorithms that we have implemented using automatic differentiation to compute Taylor series of trajectories. We give convergence proofs, showing that the methods converge to hyperbolic periodic orbits on fixed meshes with increasing order. We use a common terminology for all the algorithms that is now described.

A *periodic orbit* of a vector field

$$\dot{x} = f(x),\ f : R^n \to R^n \tag{2.1}$$

with period T is a trajectory with $x(T) = x(0)$. T is called the *period* of the orbit. As a point set in the phase space, a periodic orbit may be isolated, but time translation gives a one parameter family of different parametrized curves corresponding to each periodic orbit. Local analysis of a periodic orbit is based upon the formulation of linear variational equations along the periodic orbit:

$$\dot{\xi} = Df_{x(t)}\xi.$$

Taking ξ as a matrix variable, the time T solution of the variational equation with identity initial condition at $t = 0$ is called the *monodromy matrix* of the periodic orbit. The eigenvalues of the monodromy matrix are independent of the coordinate system and the parametrization of the periodic orbit. There is always an eigenvalue 1 with eigenvector tangent to the periodic orbit. A periodic orbit is *elementary* if 1 is a simple eigenvalue of the monodromy matrix. Elementary periodic orbits are isolated in the sense described above, and they vary smoothly with parameters. We shall denote the flow of the system of equations by $\phi_t(x)$: ϕ_t is the map that advances points t time units along their trajectories.

Periodic orbits are also studied by introduction of *return maps*. A cross-section Σ to f is a codimension 1 submanifold of R^n with the property that f is never tangent to Σ. The return map $\theta : \Sigma \to \Sigma$ is defined by $\theta(y) = y(s)$ with $y(s)$ the first point of the trajectory with initial condition y that lies in Σ. Periodic orbits have cross-sections whose return maps have fixed points at the intersection of the cross-section with the periodic orbit. The Jacobian derivative of the return map at such a fixed point is closely related to the monodromy matrix of the periodic orbit. In particular, the Jacobian of the return map can be obtained as a quotient of the monodromy matrix by projecting out the flow direction. The fixed point of a return map for an elementary periodic orbit is an isolated, regular fixed point of the return map. This observation can be used as the basis for simple shooting algorithms for computing the periodic orbits.

We assume throughout this paper that $f(x)$ is analytic. Periodic orbits of analytic vector fields are analytic, but spaces of functions that are discontinuous and/or piecewise smooth underlie algorithms that compute approximate periodic orbits. Since computational representations of periodic orbits only use finite sets of data, we work with finite-dimensional function spaces and sequences of such spaces, indexed by a degree. The spaces are parametrized by discrete closed curves, defined below. Each

discrete closed curve is used to parametrize a sequence of function spaces of fixed dimension that provide increasingly good approximations to periodic orbits. Different algorithms use different function spaces.

The data structure that we use to represent an approximate periodic orbit is a discrete closed curve. A *discrete curve* $\delta = [(t_0, x_0), (t_1, x_1), \ldots, (t_N, x_N)]$ is defined as a set of times $t_0 < t_1 < \cdots < t_N$ and points $x_0, x_1, \ldots, x_N \in R^n$ associated to these times. If $x_0 = x_N$, then we say that the discrete curve is *closed* and has period $t_N - t_0$. The $(n+1)(N+1)$-dimensional space of discrete curves with $N+1$ points will be denoted $D_{(n,N)}$. The discrete closed curves comprise a linear subspace $D^c_{(n,N)}$ of $D_{(n,N)}$ of dimension $N(n+1)+1$ and codimension n. Each periodic orbit is represented by an $N+1$ dimensional family of discrete closed curves, coming from the selection of different points on the periodic orbit (N degrees of freedom) and time translation. In formulating boundary value methods, we seek systems of defining equations that are square and regular. This can be done by either restricting the domain of the defining equations to a subspace of discrete closed curves which contains a (locally) unique representative of each periodic orbit, or by adjoining additional equations that select a unique discrete closed curve representing the periodic orbit we seek. We have experimented with both strategies. We always remove the degree of freedom due to time translation by restriction to the subspace $t_0 = 0$. Restriction to a subspace that eliminates the degrees of freedom due to moving points on the periodic orbit results in smaller systems of defining equations but can make the computation of the defining equations more difficult. For example, the strategy used in [17] for selecting a subspace of discrete closed curves is to select N cross-sections Σ_i to the periodic orbit and restrict x_i to lie in Σ_i. This requires that we define coordinate systems for the Σ_i and incorporate transformations between these coordinates and Euclidean coordinates in our algorithms. On the other hand, adjoining additional equations only increases the number of equations from nN to $(n+1)N$, and as the system size increases, the extra work in solving the augmented system becomes relatively small. Abstractly, the difference between the two strategies can be expressed as the difference between solving a triangular system of equations

$$\begin{aligned} g(x, y) &= 0, \\ h(y) &= 0, \end{aligned}$$

by elimination, first solving $h(y) = 0$ for y and then substituting this value into $g(x, y) = 0$, as contrasted with solving the two-dimensional system simultaneously for x and y. We have found in the canard example described below that augmenting the system of defining equations produced much better results than the elimination method.

There are two different choices of subspaces of $D^c_{(n,N)}$ that we use to fix the location of points along a periodic orbit. The first is to use cross-sections to the vector field as described above. Cross-sections are hyperplanes of R^n with the property that f is never tangent to Σ_i in the region of interest, defined in the algorithms as hyperplanes perpendicular to the vector field at a point. The subspace $D^s_{(n,N)}$ of $D^c_{(n,N)}$ with $t_0 = 0$ and $x_i \in \Sigma_i$ has an isolated point of intersection with an elementary periodic orbit. The methods most often employed in previous work on computing periodic orbits attempt as much as possible to fix the times $t_0 < t_1 < \cdots < t_N$ of the points $x_0, x_1, \ldots, x_{N-1}, x_N = x_0$ in the discrete closed curve. Fixing all of the times does not work because the period $t_N - t_0$ of the orbit is not known and must be obtained as part of the solution of the defining equations. There is one degree of

freedom that must be retained in allowing the times to vary. This is done typically by either fixing $t_0 < t_1 < \cdots < t_{N-1}$ and allowing t_N to vary, or by fixing the ratios $(t_{i+1} - t_i)/(t_i - t_{i-1})$ for $0 < i < N$. One additional constraint, called a phase condition, must be imposed on the points x_i that eliminates the degree of freedom coming from moving all of the points along the flow simultaneously by time τ and replacing t_i by $t_i - \tau$. Two choices of phase condition that have been employed are to restrict x_0 to lie on a cross-section, and to fix the value of a scalar integral on the periodic orbit.

The next step in defining equations for approximate periodic orbits is to map the spaces of discrete curves to function spaces. Let $\mathcal{C}$ be the space of piecewise smooth curves $g : R \to R^n$ defined by the following properties: $g \in \mathcal{C}$ if there are $u_0 < u_1 < \cdots < u_l$ such that g is analytic on the intervals (u_i, u_{i+1}) and has a C^∞ extension to the closed interval $[u_i, u_{i+1}]$. We consider nonlinear maps $E : D^c_{n,N} \to \mathcal{C}$ with the property that the image functions are analytic on the intervals (t_i, t_{i+1}), $0 \le i < N$. Note that E is allowed to depend upon the vector field f.

A map $E : D^c_{n,N} \to \mathcal{C}$ pulls back the periodic orbit equations from $\mathcal{C}$ to $D^c_{(n,N)}$. These equations give a horrendously overdetermined system on $D^c_{n,N}$, an infinite set of nonlinear equations on a finite-dimensional space. Therefore, a finite set of nN equations is selected from the periodic orbit equations. The choice of the map E together with the definition of a regular set of defining equations, perhaps on a subspace $D^s_{(n,N)}$ of $D^c_{(n,N)}$, determines the boundary value solver. We give here a list of four different solvers, specifying the approximate periodic orbit equations for each.

- *Forward multiple shooting:* Let $\delta = [(t_0, x_0), \ldots, (t_N, x_N)]$ be a discrete closed curve. The map E assigns to each time interval (t_i, t_{i+1}) of δ the degree d Taylor polynomial p_i of the trajectory with $x(t_i) = x_i$. Since polynomials are analytic on the entire line, this associates a piecewise analytic function in $\mathcal{C}$ to δ. The approximate periodic orbit equations are now defined by

  $$P(\delta) = (p_0(t_1) - x_1, \ldots, p_{N-1}(t_N) - x_N).$$

  P vanishes on discrete closed curves δ for which $E(\delta)$ is continuous. It is evident that P is smooth as a map from $R^{(n+1)N+1}$ to R^{nN} since the degree d Taylor series of a trajectory of an analytic vector field depends smoothly on the initial point. The approximate periodic orbit equations P restricted to $D^s_{(n,N)}$ are a set of nN equations in nN variables. Here $D^s_{(n,N)}$ can be the subspace of $D^c_{(n,N)}$ defined via cross-sections and $t_0 = 0$, or by fixing N times and a phase condition. One can also fix $t_0 = 0$ and augment the periodic orbit equations with a set of N additional equations. In the theorem proved below we describe several ways of choosing N augmenting linear equations so that the resulting set of $(n + 1)N$ equations in the variables $(x_0, \ldots, x_{N-1}; t_1, \ldots, t_N)$ are regular.
- *Symmetric multiple shooting:* Symmetric multiple shooting is a small modification of the multiple shooting method described above that makes the method time reversible. Let $\delta = [(t_0, x_0), \ldots, (t_N, x_N)]$ be a discrete closed curve. We set $u_0 = t_0 - (t_N - t_{N-1})/2$ and $u_i = (t_i + t_{i-1})/2$, $0 < i \le N$. The map E then assigns to each time interval (u_i, u_{i+1}) the degree d Taylor polynomial p_i of the trajectory with $x(t_i) = x_i$. We define the map P by

  $$P(\delta) = (p_0(u_0) - p_{N-1}(u_N), p_1(u_1) - p_0(u_1), \ldots, p_{N-1}(u_{N-1}) - p_{N-2}(u_{N-1})).$$

  Finally, P is restricted to $D^s_{n,N}$ to obtain a set of nN equations in nN variables, or the set of defining equations is augmented with N additional

equations. In implementations of these algorithms, we replace the variables t_i by the equivalent set of variables $t_i - t_{i-1}$ representing the time increment of each mesh interval.

- *Hermite interpolation:* Let $\delta = [(t_0, x_0), \ldots, (t_N, x_N)]$ be a discrete closed curve. The map E assigns to each time interval (t_i, t_{i+1}) of δ the polynomial p_i of degree $2d+1$ that has the same Taylor series of degree d as the trajectories with $x(t_i) = x_i$ and $x(t_{i+1}) = x_{i+1}$. The image of E lies in the set of piecewise analytic functions that are continuous and d times differentiable. We define the function P by

$$P(\delta) = (e_0, \ldots, e_{N-1})$$

with $e_i = f(p_i((t_i + t_{i+1})/2)) - \dot{p}_i((t_i + t_{i+1})/2)$. P is restricted to $D^s_{n,N}$ to obtain nN equations in nN variables.

- *Smooth weighting:* Let $\delta = [(t_0, x_0), \ldots, (t_N, x_N)]$ be a discrete closed curve, and let $\beta : [0,1] \to [0,1]$ be a monotonic C^∞ function that is flat at its endpoints ($\beta^{(k)}(u) = 0$ for all $k > 0$) and has $\beta(0) = 0$, $\beta(1) = 1$. We assume that β is analytic in $(0,1)$ with positive derivative. Let p_i be the degree d Taylor polynomial of the trajectory with $x(t_i) = x_i$. To each interval (t_i, t_{i+1}), we assign the C^∞ function

$$g_i(t) = (1 - \beta((t - t_i)/(t_{i+1} - t_i)))p_i(t) + \beta((t - t_i)/(t_{i+1} - t_i))p_{i+1}(t).$$

This defines a C^∞ closed curve that interpolates the degree d Taylor series expansions at the mesh points. We define the function P by

$$P(\delta) = (e_0, \ldots, e_{N-1})$$

with $e_i = f(g_i((t_i + t_{i+1})/2)) - \dot{g}_i((t_i + t_{i+1})/2)$. P is restricted to $D^s_{n,N}$ to obtain nN equations in nN variables.

Each of these four methods yields a system of equations defined by a map P that depends on the same number of equations as variables. Note that there is an inherent difference between the first two algorithms and the last two. The first two are multiple shooting algorithms that use spaces of discontinuous functions and their maps P do not depend directly upon evaluating the vector field. The approximation to the periodic orbit is implicit in the choice of the function space and depends upon the accuracy of the trajectory segments. The last two solvers are global methods defined on smooth curves (the degree of smoothness of the Hermite interpolations depends on d) and their equations P evaluate both the vector field at selected points and the tangent vectors to curves in the function space.

We want convergence proofs and error estimates for these algorithms in terms of the vector field, characteristics of the periodic orbit, and algorithmic parameters. There are two types of limits that are of interest: increasing degree d of Taylor expansions and increasing mesh fineness. For fixed degree of the Taylor polynomials and increasingly fine meshes, the algorithms are variants of standard shooting and collocation algorithms. Therefore, we focus our mathematical discussion on the limit of increasing degree with a fixed mesh. This provides mathematical foundations for algorithms that seek to compute periodic orbits using polynomials of high degree with coarse meshes.

The theorems stated below depend upon the geometry of the periodic orbits that are being approximated. If periodic orbits are not elementary, there is little hope

that the projected equations P will be regular. Thus, our convergence results focus on the case of elementary periodic orbits. We assume that all discrete closed curves $\delta = [(t_0, x_0), (t_1, x_1), \ldots, (t_N, x_N)]$ have the property that the radius of convergence of the trajectories through the points x_i are larger than $t_i - t_{i-1}$ and $t_{i+1} - t_i$. Within a compact subset of R^n, there is a number $D > 0$ such that this property will be satisfied if $|t_i - t_{i-1}| < D$ for each i. In particular, this assumption implies that the Taylor polynomials of the trajectories converge uniformly to the trajectories with increasing degree throughout each mesh interval. The assumption that meshes are sufficiently fine that each mesh interval is contained in the radius of convergence of the trajectories at its endpoints will be maintained throughout this paper.

THEOREM 2.1. *Let γ be a periodic orbit of the vector field $\dot{x} = f(x)$ such that 1 is a simple eigenvalue of its monodromy matrix. Let $D \subset R^{(n+1)(N+1)}$ be the $(n+1)(N)$-dimensional subspace with coordinates $(x_0, \ldots, x_N; t_0, \ldots, t_N)$ defined by $x_0 = x_N$ and $t_0 = 0$. For any $\epsilon > 0$, there are*

- *a neighborhood U of γ,*
- *$\tau > 0$,*
- *integers d, N,*

so that the system of equations

$$|x_{i+1} - p_i(t_{i+1})| = 0,\ i = 0, \ldots, N-1$$

has a smooth N parameter family of solutions in D with

- *p_i the Taylor polynomial of degree d for the trajectory taking the value x_i at t_i,*
- *$0 < s_i = t_{i+1} - t_i < \tau$,*
- *$|x_{i+1} - \phi_{s_i}(x_i)| < \epsilon$.*

The Jacobian of the system of equations has maximal rank nN.

Proof. Select a neighborhood U of γ and τ so that the Taylor series of trajectories with initial point in U have radius of convergence larger than τ. Next, select a set of N points $y_0, \ldots, y_{N-1}, y_N = y_0$ on γ so that $y_{i+1} = \phi_{u_i}(y_i)$ with $u_i < \tau$. Set

$$r_i = \sum_{j=0}^{i} u_j.$$

Consider the map $F_f^d : D \to R^{nN}$ defined by

$$\begin{gathered} p_0(r_0) - x_1 \\ p_1(r_1) - x_2 \\ \vdots \\ p_{N-2}(r_{N-2}) - x_{N-1} \\ p_{N-1}(r_{N-1}) - x_0 \end{gathered}$$

as an approximation of the map $F_f^\infty : D \to R^{nN}$

$$\begin{gathered} \phi_{s_0}(x_0) - x_1 \\ \phi_{s_1}(x_1) - x_2 \\ \vdots \\ \phi_{s_{N-2}}(x_{N-2}) - x_{N-1} \\ \phi_{s_{N-1}}(x_{N-1}) - x_0. \end{gathered}$$

The map F_f^d depends upon the degree d of the Taylor polynomials and converges to the map F_f^∞ as $d \to \infty$. (Since the maps F_f^∞ and F_f^d are defined on finite-dimensional spaces of discrete closed curves, convergence is independent of norms for these spaces.) The map F_f^∞ has an N-dimensional manifold S of zeros passing through the discrete closed curve $[(r_0, y_0), \ldots, (r_N, y_N)] \in D$. S is obtained by varying the points y_i along γ and making suitable changes in the u_i. If this zero of F_f^∞ is regular, then, for sufficiently large d, F_f^d will have a regular zero that converges to the zero of F_f^∞. Thus, the crux of the proof lies in demonstrating that the rank of DF_f^∞ is nN.

We relate the Jacobian of F_f^∞ to the monodromy matrix of γ. In D, we use coordinates $(x_0, \ldots, x_{N-1}; t_1, \ldots, t_N)$. The Jacobian DF_f^∞ has a block structure

$$DF_f^\infty = \begin{pmatrix} D_1 & -I & & & & v_1 & & & & & \\ & D_2 & -I & & & -v_2 & v_2 & & & & \\ & \cdots & \cdots & & & & \cdots & \cdots & & & \\ & & \cdots & \cdots & & & & \cdots & \cdots & & \\ & & & D_{N-1} & -I & & & & -v_{N-1} & v_{N-1} & \\ -I & & & & D_N & & & & & -v_N & v_N \end{pmatrix}$$

with $D_i = D_x(\phi)(x_{i-1}, t_i - t_{i-1})$ and $v_i = f(x_i)$. Note that $D_i(v_{i-1}) = v_i$. The blocks D_i are nonsingular since the flow maps ϕ_t are diffeomorphisms. To determine the rank of the matrix DF_f^∞, we compute its LU factorization in the form

$$L = \begin{pmatrix} I & & & & \\ & \ddots & & & \\ & & & I & \\ L_1 & L_2 & \ldots & L_{n-1} & I \end{pmatrix},$$

$$U = \begin{pmatrix} D_1 & -I & & & & v_1 & & & & & \\ & D_2 & -I & & & -v_2 & v_2 & & & & \\ & \cdots & \cdots & & & & \cdots & \cdots & & & \\ & & \cdots & \cdots & & & & \cdots & \cdots & & \\ & & & D_{N-1} & -I & & & & -v_{N-1} & v_{N-1} & \\ & & & & \tilde{D}_N & w_1 & w_2 & \ldots & \ldots & w_{N-1} & w_N \end{pmatrix}.$$

This yields a system of equations for the L_i, $\tilde{D}_N$, and w_i:

$$\begin{aligned} L_1 D_1 &= -I, \\ L_i D_i - L_{i-1} I &= 0, \\ \tilde{D}_N - L_{N-1} I &= D_N, \\ L_{i-1} v_{i-1} - L_i v_i + w_{i-1} &= 0, \\ L_{N-1} v_{N-1} + w_{N-1} &= -v_N, \\ w_N &= v_N, \end{aligned}$$

where $1 < i < N$. The solutions of this system are

$$\begin{aligned} L_i &= -D_1^{-1} \cdots D_i^{-1}, \\ \tilde{D}_N &= D_N - D_1^{-1} \cdots D_{N-1}^{-1}, \\ w_i &= 0, \\ w_N &= v_N, \end{aligned}$$

with $0 < i < N$. The factor L has rank nN since it is lower triangular with ones along the diagonal. The factor U has rank nN if and only if the rank of $\tilde{D}_N$ is $n-1$ and v_N does not lie in the image of $\tilde{D}_N$. By definition, γ is an elementary periodic orbit if and only if 1 is a simple eigenvalue of the monodromy matrix $D_N \cdots D_1$. Thus, $\tilde{D}_N$ has rank $n-1$ with kernel v_{N-1} if γ is elementary. If $v_N = v_0$ is in the image of $\tilde{D}_N$, then $v_{N-1} = D_{N-1} \cdots D_1(v_0)$ is in the image of $D_{N-1} \cdots D_1 \tilde{D}_N = D_{N-1} \cdots D_1 D_N - I$. But $D_{N-1} \cdots D_1 D_N$ is the monodromy matrix with initial point y_{N-1} and v_{N-1} is the eigenvector for the simple eigenvector 1, so v_{N-1} is not in the image of $D_{N-1} \cdots D_1 D_N - I$. We conclude that if γ is elementary, then v_N does not lie in the image of $\tilde{D}_N$ and U has rank nN. Thus the system of equations F_f^∞ has maximal rank at a zero formed from N points on an elementary periodic orbit γ. Perturbations of this system also have maximal rank and the manifold of solutions varies smoothly with perturbation. Since the Taylor polynomials of the flow map converge to the flow map on time intervals of length smaller than τ, the conclusions of the theorem will be satisfied for the map F_f^d when the degree d of the Taylor polynomials is sufficiently large. This proves the theorem.

Similar arguments to the one used above prove the convergence of other multiple shooting algorithms, notably the symmetric multiple shooting algorithm with increasing degree. The zeros of the map F_s^∞

$$\begin{array}{c} \phi_{s_1}(x_0) - \phi_{-s_1}(x_1) \\ \phi_{s_2}(x_1) - \phi_{-s_2}(x_2) \\ \vdots \\ \phi_{s_{N-1}}(x_{N-2}) - \phi_{-s_{N-1}}(x_{N-1}) \\ \phi_{s_N}(x_{N-1}) - \phi_{-s_N}(x_0) \end{array}$$

with $s_i = (t_i - t_{i-1})/2$ give discrete closed curves on the periodic orbit γ. The Jacobian DF_s^∞ of F_s^∞ has a similar block structure to F_f^∞:

$$\begin{pmatrix} D_1 & -E_1 & & & & v_1 & & & & & \\ & D_2 & -E_2 & & & -v_2 & v_2 & & & & \\ & \cdots & \cdots & & & & \cdots & \cdots & & & \\ & & \cdots & \cdots & & & & \cdots & \cdots & & \\ & & & D_{N-1} & -E_{N-1} & & & & -v_{N-1} & v_{N-1} & \\ -E_N & & & & D_N & & & & & -v_N & v_N \end{pmatrix}$$

with D_i the Jacobian of ϕ_{s_i} at x_{i-1}, E_i the Jacobian of ϕ_{-s_i} at x_i and $v_i = f(\phi_{-s_i}(x_i))$. Multiplying DF_s^∞ on the left by the block diagonal matrix with entries

$$E_1^{-1}, E_2^{-1}, E_3^{-1}, \ldots, E_N^{-1}$$

gives the same matrix as DF_f^∞ above.

Restriction of F_f^∞ or F_f^d to a subspace $L \subset R^{(n+1)N}$ is equivalent to augmenting these maps with an additional linear map whose kernel gives the subspace L. There are three choices of subspace we have used in our numerical work. The method used in AUTO [10] is to fix a single linear constraint of the phase space variables x_i (called a *phase condition*) and to fix the times t_i up to a scale factor that yields the period of the periodic orbit. The second method is to fix cross-sections Σ_i orthogonal to the vector field at x_i and constrain x_i to vary in Σ_i. The Jacobian DF_f^∞ for the

augmented map is

$$J_c = \begin{pmatrix} D_1 & -I & & & & v_1 & & & & & \\ & D_2 & -I & & & -v_2 & v_2 & & & & \\ & \cdots & \cdots & & & & \cdots & \cdots & & & \\ & & \cdots & \cdots & & & & \cdots & \cdots & & \\ & & & D_{N-1} & -I & & & & -v_{N-1} & v_{N-1} & \\ -I & & & & D_N & & & & & -v_N & v_N \\ v_0^t & & & & & & & & & & \\ & v_1^t & & & & & & & & & \\ & \cdots & \cdots & & & & & & & & \\ & & \cdots & \cdots & & & & & & & \\ & & & v_{N-2}^t & & & & & & & \\ & & & & v_{N-1}^t & & & & & & \end{pmatrix}.$$

If γ is an elementary periodic orbit, then J_c is non-singular. This is proved as follows. If $J_c(y_0^t, \ldots, y_{N-1}^t, u_1, \ldots, u_N) = 0$, then

$$v_i \cdot y_i = 0,$$
$$D_{i+1} y_i - y_{i+1} = (u_i - u_{i+1}) v_{i+1},$$

for $i = 0, \ldots, N-1$ with $u_0 = 0$. Let π_i be the projection of R^n onto Σ_i. Then $\pi_i D_i y_{i-1} - \pi_i y_i = 0$. $y_0 \neq 0$ is an eigenvector of $\pi_N D_N \cdots \pi_1 D_1$ with eigenvalue 1 if it does not vanish. But $\pi_N D_N \cdots \pi_1 D_1$ is the Jacobian of the return map of Σ_0, and 1 is not an eigenvalue. We conclude that $y_0 = 0$ and consequently $\pi_1 y_1 = 0$. Together with the equation $v_1 \cdot y_1 = 0$, this implies $y_1 = 0$. Proceeding inductively in this fashion, we conclude that $y_i = 0$ for $0 \leq i < N$. Finally, we conclude that $(u_{i+1} - u_i) v_{i+1} = 0$, implying $u_i = 0$ for $1 \leq i \leq N$. Thus J_c is regular.

The third way we restrict F_f^∞ to a subspace appears to be novel, but natural. We observe that if $[(t_0, x_0), \ldots, (t_N, x_N)]$ is a discrete closed curve lying in γ, then so is the curve that replaces (t_i, x_i) by $(t_i + h, \phi_h(x_i))$. We restrict to the subspace orthogonal to these curves for $i = 1, \ldots, N-1$. For $i = 0$, we preserve the constraint $t_0 = 0$ by restricting to the orthogonal complement to the vector $(v_0, \ldots, 0; -1, \ldots -1, 0)$ corresponding to $x_0 \to \phi_h(x_0)$ and $t_i \to t_i - h$ for $i = 1, \ldots, N-1$. This gives a restricted subspace that is orthogonal to the manifold of solutions of $F_f^\infty = 0$. The block structure of the Jacobian for this method is shown in section 4.1. The proof that it is regular is very similar to the argument for J_c and is not given here.

The theory underlying the Hermite interpolation algorithm is somewhat more complex than the other algorithms described here because the Hermite polynomials on a fixed mesh interval approach a discontinuous function with increasing degree. A particular example illustrates this. Consider polynomials p_d of degree $2d+1$ with the properties that $p_d(-1) = 0$, $p_d(1) = 1$ and $p_d^{(j)}(\pm 1) = 0$ for $1 < j \leq d$. There is an explicit formula for p_d, namely $p_d = (\frac{1+x}{2})^{(d+1)} q_d$, where q_d is the degree d Taylor polynomial of $(\frac{1+x}{2})^{-(d+1)}$ at $x = 1$. Figure 2.1 shows a plot of p_{11}. The polynomials p_d are Hermite interpolants between the points $(x_0, t_0) = (0, -1)$ and $(x_1, t_1) = (1, 1)$ for the trivial vector field $\dot{x} = 0$ on R. As d increases, the p_d converge to constant functions 0 and 1 on $[-1, 0)$ and $(0, 1]$ with a "transition" layer of length comparable to $1/\sqrt{d}$. This behavior is typical.

THEOREM 2.2 (see Shen and Strang [28, 29]). *Let g and h be two functions analytic on the interval $[-1, 1]$, let g_d and h_d be the degree d Taylor polynomials of g and h at -1 and 1, and let p_d be the polynomial of degree $2d+1$ whose Taylor*

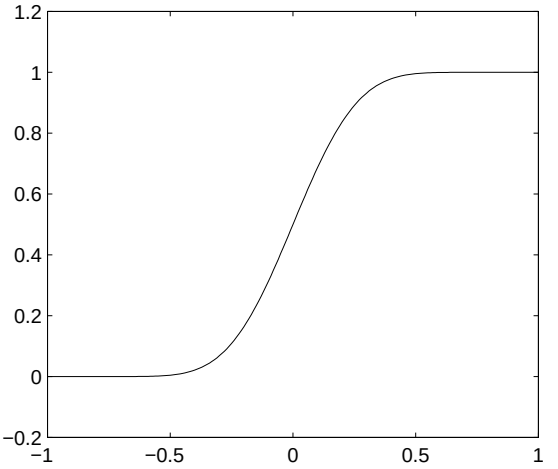

FIG. 2.1. *The Hermite interpolating polynomial of degree* 23 *connecting constant functions* 0 *and* 1 *on the interval* $[-1,1]$. *The interpolating polynomial is almost flat at the ends of the interval with a monotonic transition layer near its center.*

polynomials of degree d *at* -1 *and* 1 *agree with those of* g *and* h, *respectively. Assume that the Taylor series of* g *at* -1 *and* h *at* 1 *have radius of convergence larger than* 1. *As* d *increases*

$$p_d(x) = \begin{cases} g(x) + O(\frac{|1-x^2|^d}{\sqrt{d}|x|}), & x < 0, \\ h(x) + O(\frac{|1-x^2|^d}{\sqrt{d}|x|}), & x > 0. \end{cases}$$

Remark. The values $p_d(0)$ and $p_d'(0)$ are both linear combinations of the Taylor series coefficients of g and h. The magnitude of $p_d'(0)$ is comparable to $|g(0)-h(0)|\sqrt{d}$.

The Hermite interpolation algorithm constructs interpolating polynomials on each interval of a discrete closed curve from the Taylor series coefficients of trajectories at mesh points. The system of defining equations for the algorithm comes from collocation in each mesh interval: $p'(\tau)-f(p(\tau))=0$ with p the Hermite interpolating polynomial and τ the midpoint of the interval. To obtain a limiting set of equations for a discrete closed curve lying in a periodic orbit, these equations need to be scaled by $\sqrt{d}$ with increasing d.

THEOREM 2.2. *Let* γ *be a periodic orbit of the vector field* $\dot{x} = f(x)$ *such that* 1 *is a simple eigenvalue of its monodromy matrix. If* $\delta = [(t_0,x_0),(t_1,x_1),\ldots,(t_N,x_N)]$ *is a discrete closed curve, denote by* p_i *the degree* $2d+1$ *Hermite interpolation of the Taylor series of the trajectory segment on mesh interval* i *of* δ, *by* τ_i *the midpoint (in time) of mesh interval* i *and set* $H_i = (p_i'(\tau_i) - f(p_i(\tau_i)))/\sqrt{d}$. *If* d *is sufficiently large,* δ *is close to* γ, *and the mesh of* δ *is sufficiently fine, then the system of equations* $H_i = 0$ *with the* x_i *constrained to lie on a set of cross-sections to* γ *form a regular system of equations whose solutions converge uniformly to* γ *as* $d \to \infty$.

We give only a brief outline for the proof of this theorem. There are two aspects of the proof; namely, the analysis outlined above of how the Hermite polynomials approximate trajectory segments and demonstration that the Jacobian of the system of equations is a regular, square matrix. Denoting the degree d Taylor series approximations to γ at the points of δ by q_i, the magnitude of $(p_i'(\tau_i) - f(p_i(\tau_i)))/\sqrt{d}$ is

comparable to $|q_{i+1}(\tau_i) - q_i(\tau_i)|$. This is the leading order term of the asymptotic expansion of $(p_i'(\tau_i) - f(p_i(\tau_i)))/\sqrt{d}$ in d. Since we assume that each mesh interval is contained within the domain of convergence of the Taylor series for the trajectories at its endpoints, there is a $0 < \rho < 1$ so that $|q_i(\tau_i) - \phi(x_i, \tau_i - t_i)|$ decreases at a rate faster than ρ^d. Therefore, $|\phi(x_{i+1}, \tau_i - t_{i+1}) - \phi(x_i, \tau_i - t_i)|$ decreases at a rate faster than ρ^d as d increases, implying that the solutions of $H_i = 0$ converge uniformly to points of γ as $d \to \infty$. The Jacobian has a block matrix structure of the same kind as a symmetric multiple shooting algorithm since the leading order term of $(p_i'(\tau_i) - f(p_i(\tau_i)))/\sqrt{d}$ approaches $|\phi(x_{i+1}, \tau_i - t_{i+1}) - \phi(x_i, \tau_i - t_i)|$. The regularity of the system of equations $H_i = 0$ follows from the regularity of the Jacobian of symmetric multiple shooting with phase points restricted to a set of cross-sections to the periodic orbit.

3. Continuation and bifurcation. Introduction of parameters prompts two extensions to the algorithms of the previous section, namely,

1. computing families of solutions with changing parameters, and
2. computing bifurcations: parameter values at which the stability properties of the periodic orbits change.

This section discusses these two topics. *Continuation methods*, algorithms for computing curves of solutions to a system of k equations in $k+1$ variables have been extensively studied [1, 26]. They can be used in a straightforward way with the periodic orbit algorithms described above. The principle underlying continuation methods stems from the implicit function theorem. If a system of equations $F(x_1, \ldots, x_{k+1}) = 0$ has maximal rank, the set of solutions is a smooth curve whose tangent direction is the kernel of DF. The solution curve can be parametrized either by arc length or, locally, by a suitable coordinate x_i. Points on the solution curve can be calculated by simple predictor-corrector methods using an Euler step along the curve as a predictor and a Newton iteration in a hyperplane of R^{k+1} as a corrector. Methods for adapting the step length along the solution curves have been incorporated into computer packages for continuation [26, 10, 22]. For computing equilibria or periodic orbits of a system of ordinary differential equations, one of the coordinates in the system of equations $F(x_1, \ldots, x_{k+1}) = 0$ is a system parameter, called the *active parameter*.

Local bifurcations of periodic orbits involve a change of stability along a smooth family of periodic orbits or the collapse of a family of periodic orbits at a point of equilibrium Hopf bifurcation [18]. Global bifurcations of periodic orbits are associated with the period of an orbit becoming unbounded, either by approaching an orbit homoclinic to a saddle or by approaching a saddle-node in cycle bifurcation [18] at which there is a saddle-node equilibrium point having a trajectory that approaches the equilibrium point in both forward and backward time. Here we consider only local bifurcations of periodic orbits, i.e, those involving a change of stability in the periodic orbit. The defining equations for such bifurcations can be formulated most easily in terms of the Jacobian J of the return map for an orbit. A codimension 1 bifurcation occurs if J has an eigenvalue of modulus 1 and suitable nondegeneracy conditions are satisfied. There are three cases: saddle-node bifurcation with eigenvalue 1, period doubling (also called flip) bifurcation with eigenvalue -1, and Hopf (also called torus) bifurcation in the case of a complex pair of eigenvalues of modulus 1.

The principal algorithmic question in computing bifurcations is the formulation of defining equations. Since the defining equations are expressed in terms of the Jacobian J of the return map or the monodromy matrix of the periodic orbit, it is important to compute these matrices accurately. Our work seeks to connect the

accurate calculation of periodic orbits and their return maps with the best algorithms from linear algebra for computing defining equations for bifurcation. Where possible, we seek to reduce the defining equations to a single equation expressing the singularity of a matrix. Theoretically, this is easily done for eigenvalues ± 1: the determinants of the matrices $J \mp I$ are defining equations for the saddle-node and period doubling bifurcations. For Hopf bifurcation, the tensor product matrix $J \otimes J$ acting on skew-symmetric tensors has eigenvalues that are pairwise products of distinct eigenvalues of J. Therefore, the determinant of the matrix $J \otimes J - I \otimes I$ gives a defining equation for Hopf bifurcation. Methods for constructing defining equations for Hopf bifurcation of equilibria were described by Guckenheimer, Myers, and Sturmfels [19].

While determinants of matrices give defining equations for determining whether a matrix A is singular, there are better methods. The smallest singular value of A is a better conditioned and more reliable measure than $\det A$ of the distance of A from the set of singular matrices. Bordered matrix methods [15] provide an efficient way to compute a quantity proportional to the smallest singular value using Gaussian elimination with partial pivoting. If A has corank 1, then for generic vectors B and C, the bordered matrix

$$\begin{pmatrix} A & B \\ C^t & 0 \end{pmatrix}$$

is nonsingular. In this case, the equations

$$\begin{pmatrix} A & B \\ C^t & 0 \end{pmatrix} \begin{pmatrix} V \\ G \end{pmatrix} = \begin{pmatrix} 0 \\ 1 \end{pmatrix},$$

$$\begin{pmatrix} W^t & G \end{pmatrix} \begin{pmatrix} A & B \\ C^t & 0 \end{pmatrix} = \begin{pmatrix} 0 & 1 \end{pmatrix}$$

have unique solutions V, W, G with G a scalar that is proportional to the smallest singular value of A [15]. For computing saddle-node bifurcations, we shall choose matrices A related to the Jacobian DF_*^d of our system of periodic orbit equations F_*^d. It has a block structure, and is nonsingular if and only if 1 is not an eigenvalue for the return map of γ. Therefore, we border DF_*^d and add the equation $G = 0$ as the augmenting defining saddle-node bifurcation.

In applying Newton's method to the system

$$\begin{pmatrix} F_*^d \\ G \end{pmatrix} = 0$$

we need partial derivatives of F_*^d and G with respect to x_i, t_i, and λ. Derivatives of G can be reduced to computation of second derivatives of DF_*^d in this situation [15, 14]. For $z \in \{t_i, x_i, \lambda\}$,

$$G_z = -W^t \left(\frac{\partial DF_*^d}{\partial z} \right) V.$$

4. Implementations and adaptation. This section describes implementations of the algorithms described in previous sections. MATLAB 5 [24] was used to program the higher level parts of the algorithms, and ADOL-C 1.7 [16] was used to compute the Taylor series expansions of trajectories with automatic differentiation. We modified

a function in ADOL-C that computes the derivatives of the Taylor series coefficients with respect to the phase space variables so that it also computes derivatives of the Taylor series coefficients with respect to parameters. Summing the derivatives of these Taylor series coefficients gives the Jacobian of the flow map and the derivative of the flow map with respect to parameters. We have investigated several variations of the algorithms. As with numerical integration of initial value problems, a single algorithm is unlikely to be optimal for all problems and individual preferences are likely to persist in the use of different algorithms. Here we describe three algorithms, each of which appears to work well on at least some of the test problems described in the next section.

4.1. Forward multiple shooting with adaptive step lengths. The first algorithm whose implementation we describe is forward multiple shooting. The input for the algorithm is $\delta = [(t_0, x_0), (t_1, x_1), \ldots, (t_N, x_N)]$, a discrete closed curve that approximates a periodic orbit. The desired output is a new discrete closed curve $\pi = [(s_0, y_0), (s_1, y_1), \ldots, (s_N, y_N)]$ that approximates the periodic orbit with high precision. This is achieved by computing the approximate flow map $p_{t_{i+1}-t_i}(x_i)$ using the Taylor polynomial of ϕ at x_i and forming the map

$$F_f^d(\delta) = (e_0, \ldots, e_{N-1}), \qquad e_i = p_{t_{i+1}-t_i}(x_i) - x_{i+1}$$

that evaluates the difference between a point of δ and the flow from the previous point on the discrete closed curve. Restricting to the subspace defined by $x_0 = x_N$ and $t_0 = 0$, there are still N more independent variables than equations in F_f^d. We want to apply Newton's method to F_f^d. This is done by requiring that the Newton updates are orthogonal to the N vectors $f(x_i)\partial x_i + \partial t_i$ for $0 < i < N$ and $f(x_0)\partial x_0 - \sum_{i=1}^{N-1} \partial t_i$. Concretely, we use coordinates $(x_0, \ldots, x_{N-1}, t_1, \ldots, t_N)$ and add N rows to DF_f^d to obtain the matrix

$$J_o = \begin{pmatrix}
D_1 & -I & & & & v_1 & & & & & \\
 & D_2 & -I & & & -v_2 & v_2 & & & & \\
 & \cdots & \cdots & & & & \cdots & \cdots & & & \\
 & & \cdots & \cdots & & & & \cdots & \cdots & & \\
 & & & D_{N-1} & -I & & & & -v_{N-1} & v_{N-1} & \\
-I & & & & D_N & & & & & -v_N & v_N \\
v_0^t & & & & & -1 & -1 & \cdots & -1 & -1 & \\
 & v_1^t & & & & 1 & & & & & \\
 & & \cdots & & & & \cdots & & & & \\
 & & & v_{N-2}^t & & & & & 1 & & \\
 & & & & v_{N-1}^t & & & & & 1 &
\end{pmatrix}.$$

We iterate the Newton map that subtracts the vector

$$J_o^{-1}(e_0, \ldots, e_{N-1}, 0, \ldots, 0)$$

from $(x_0, \ldots, x_{N-1}, t_1, \ldots, t_N)$ to converge to a discrete closed curve that approximates the periodic orbit.

The accuracy of the solution to equations $F_f^d = 0$ as an approximation to the periodic orbit depends upon the accuracy of the time steps of numerical integration. These are computed by evaluation of Taylor polynomials with a fully adaptive step length procedure. The Taylor polynomials themselves and their Jacobians are computed with the programs `forode` and `accode` in the computer package ADOL-C [16].

These automatic differentiation algorithms use no finite difference calculations and typically produce Taylor series of high degree that are close to the numerical precision of IEEE-754 floating point arithmetic. Step lengths are chosen based upon two criteria:

1. the estimated radius of convergence of the Taylor series, and
2. agreement between the tangent vector to the Taylor polynomial and the vector field at the end of the step.

Our implementation of the first criterion assumes that the rate of growth of the computed coefficients a_i of the Taylor series is a good estimate of the radius of convergence of the Taylor series. The quantity $\rho = \sup |a_i|^{-1/i}$ over some range of degrees i is used to estimate the radius of convergence. Assuming that the degree j term in the Taylor series of the trajectory is bounded by ρ^j, we estimate a step length h with the property that the remainder of the Taylor series is smaller than the numerical precision of the computations along the step. If the size of the estimated step is larger than the time to the next mesh point, we reduce it to end at the time of the next mesh point. With this choice of step we hope that the accuracy of the computed step is within unit precision of the floating point arithmetic from the exact value. As an a posteriori check on the accuracy of the numerical trajectory, its tangent vector at the end of the step is compared with the value of the vector field at this point. If the difference between these exceeds a specified (relative or absolute) tolerance, the step size is reduced (we used a factor of 0.7) and the test repeated at the end point of the step of reduced length. If no step larger than a minimum specified step length satisfied the desired bound for the difference between tangent vector and vector field, then the algorithm halted with an error message. The map F_f^d is computed by numerically integrating each mesh point to the time of the next mesh point in this manner. As the numerical integration is done, the Jacobian of the flow is also computed, using the derivatives of the Taylor series coefficients with respect to the phase space variables, as computed with ADOL-C.

The motivation for using multiple shooting rather than single shooting stems largely from situations in which the norm of the flow map along parts of a trajectory become so large that the computation of the flow maps are horribly ill-conditioned. In extreme situations like those illustrated in the canard example of the next section, some trajectory segments within a periodic orbit are so unstable that a numerical integration cannot follow them without extreme floating point precision. We need flow maps from one mesh point to the next to be sufficiently well conditioned that small changes in the initial point of the trajectory produce small changes in its final point. We use a mesh refinement algorithm to produce such flow maps. The algorithm monitors the magnitude of the Jacobian of the flow map from the previous mesh point. When this magnitude exceeds a specified bound, then a new mesh point is inserted. The result is a discrete closed curve with imposed bounds on the magnitude of the Jacobian of the flow map from the beginning to the end of each trajectory segment.

In addition to mesh refinement, we also implement an algorithm for mesh coarsening. The strategy which is used is the following. The first point of the mesh is kept. If the last mesh point which is kept has index i, its trajectory is integrated to the time of the next mesh point. If $|p(x_i, t_{i+1} - t_i) - x_{i+1}|$ is larger than a chosen tolerance or the norm of the Jacobian of p is larger than a chosen bound, then the mesh point (t_{i+1}, x_{i+1}) is kept. If neither of these conditions fails, the numerical integration is continued to the first time t_{i+k+1} at which either $|p(x_i, t_{i+k+1} - t_i) - x_{i+k+1}|$ is larger than its tolerance or the Jacobian of p is larger than its bound. The mesh point

(t_{i+k}, x_{i+k}) with index $i+k$ is then retained and the numerical integration restarted from x_{i+k}. Finally, (t_N, x_N) is retained so that we have a discrete closed curve.

Our implementation of this forward shooting algorithm is embedded in a simple continuation framework. A parameter λ is designated as the active parameter, and an additional column giving the derivatives of F_f^d with respect to λ is added to the matrix JA, producing a matrix J_a. Computation of these derivatives required modifications to the program `accode` in ADOL-C. As the active parameter is varied, the equations $F_f^d = 0$ have an $N+1$ dimensional manifold of solutions. The curve on the solution manifold that satisfies the constraints imposed above has tangent vector lying in the null space J_a, spanned by the unit vector C. This null space is computed with MATLAB, and the discrete closed curve $[(t_0, x_0), \ldots, (t_N, x_N); \lambda]$ is augmented by adding a small multiple of C to the last computed discrete closed curve to obtain the initial seed for the next Newton iteration. When computing periodic orbits in the canard family, it is necessary to allow the parameter to vary during the Newton iteration since the amplitude of periodic orbits is extremely sensitive to parameter values. Thus we add one more row to J_a, the transpose of C, and solve for Newton updates of the variables $(x_0, \ldots, x_{N-1}, t_1, \ldots, t_N, \lambda)$. The code to implement this algorithm on top of ADOL-C is very small. Including continuation of the periodic orbits with a varying parameter, it comprises less than 600 lines of MATLAB m-files, and two C++ files to evaluate the vector field and provide the interface between MATLAB and ADOL-C used in computing Taylor series of trajectories.

4.2. Hermite polynomial interpolation. The Hermite polynomial global algorithm is somewhat more complicated than the multiple shooting algorithm described above for three reasons:

1. The algorithm constrains the phase space variables to lie on cross-sections and uses the time increments $s_i = t_i - t_{i-1}$, $0 < i \leq N$, as independent variables.
2. The calculation of the Hermite polynomials from the Taylor series at the ends of a mesh interval is more sensitive to round-off errors for high degree interpolation.
3. The defining equations for the approximate periodic orbit and their Jacobians are more complicated than for the multiple shooting algorithms.

The algorithm takes as input a discrete closed curve $\delta = [(t_0, x_0), \ldots, (t_N, x_N)]$ and seeks to compute a new discrete closed curve whose Hermite interpolation is an accurate approximation to a periodic orbit. The core of the algorithm is a Newton iteration to solve the equations $H_i = 0$ defined in our discussion of the theoretical foundations of this algorithm. We compute the Hermite polynomials by translating each mesh interval $[t_i, t_{i+1}]$ to $[-\beta, \beta]$ with $\beta = (t_{i+1} - t_i)/2$ and use a basis for the polynomials of degree $2d+1$ consisting of the polynomials

$$(1 - (t/\beta)^2)^j \qquad \text{and} \qquad (t/\beta)(1 - (t/\beta)^2)^j,\ 0 \leq j \leq d.$$

Using this normalization, the value of the interpolating polynomial and its derivative at the midpoint of the mesh interval is expressed directly as a weighted sum of the coefficients of the Taylor series at the mesh points. The Taylor series and the derivatives of the Taylor series coefficients with respect to phase space variables are computed using the routines `forode` and `accode` in the ADOL-C package. Cross-section coordinates are used in the Newton iteration. At the beginning of the Newton iteration, the vector field f is evaluated at each mesh point x_i and an orthonormal basis for the subspace Σ_i orthogonal to x_i is computed as the last $n-1$ columns of the Q factor

of the QR decomposition of the matrix $[f(x_i)\, I]$. Coordinates with respect to this basis are used to parametrize Σ_i. The Jacobian of the H_i is computed with respect to these coordinates at x_i and x_{i+1}, as well as with respect to changes in s_i, the length of mesh interval i.

The goal of the Hermite interpolation algorithm is to produce a curve p with $E(x) = |p'(x) - f(p(x))|$ smaller than a specified bound. Following convergence of the Newton iteration, we expect to meet this criterion at the endpoints and midpoints of the mesh intervals. To estimate whether the bound is satisfied uniformly along p, we evaluate E at additional points equally spaced in each mesh interval. If the desired bound on E is not met, we refine the mesh by adding to the mesh the midpoints of the mesh intervals with the largest values of E. We experimented with different criteria for determining when a mesh interval would be subdivided. The performance of the varied mesh refinement strategies appeared to be comparable to one another. We employed a different mesh coarsening strategy in this algorithm than in the forward shooting algorithm described above. Here, mesh points are deleted if the apparent errors of Hermite interpolating polynomials on the neighboring mesh intervals lie below a specified bound. We do not think that this is an optimal coarsening strategy, but it was simple to implement and its performance was satisfactory with the test problems we investigated.

4.3. Saddle-node bifurcations with multiple shooting. The next algorithm we describe is a symmetric multiple shooting algorithm for finding saddle-node bifurcations of periodic orbits. The algorithm takes a discrete closed curve that approximates a periodic orbit and a starting parameter λ_0 as input. The desired output is a new discrete closed curve $[(t_0, x_0), (t_1, x_1), \ldots, (t_N, x_N)]$ and a new parameter λ which approximates with high accuracy a periodic orbit undergoing a saddle-node bifurcation.

The method is implemented with points constrained to lie in fixed cross-sections, so we define a set of cross-sections Σ_i orthogonal to the vector field at the current mesh and introduce coordinates $w_i \in R^{n-1}$ for Σ_i. Each (half) mesh interval is traversed in a single step of length $s_i = (t_{i+1} - t_i)/2$.

We compute the approximate flow maps $p_{s_i}(w_i)$ and $p_{-s_i}(w_{i+1})$ using the degree d Taylor polynomials of ϕ at w_i and w_{i+1}. These are used to form the map $F = D_s^d$

$$F(s_0, w_0, \ldots, s_{N-1}, w_{N-1}, \lambda) = (e_0, \ldots e_{N-1}), \qquad e_i = p_{s_i}(w_i) - p_{-s_i}(w_{i+1}),$$

where e_i evaluates the difference between the trajectory segments shooting forward from mesh point ith and shooting backward from mesh point $i+1$. The Jacobian DF is nonsingular if and only if the periodic orbit is regular. Thus the singularity of DF determines points of saddle-node bifurcation. We compute the singularity of DF with a bordered matrix computation. Assume that DF has only one singular value that is close to 0. We can then border DF by a single row and column to form a matrix M whose smallest singular value is far from zero. The last component of the solution v to the matrix equation $Mv = (0, \ldots, 0, 1)^t$ is comparable to the smallest singular value of the matrix DF [15]. Denote this last component of v by $G(s, w, \lambda) = 0$. In our algorithms, G is computed from M by functions that are part of MATLAB.

We next apply Newton's method to the system

$$\begin{pmatrix} F \\ G \end{pmatrix} = 0.$$

In doing this, we need to compute the Jacobian of the system, which has the following

form:

$$K = \begin{pmatrix} DF & \frac{\partial F}{\partial \lambda} \\ \frac{\partial H}{\partial (x,\delta)} & \frac{\partial G}{\partial \lambda} \end{pmatrix}.$$

Given our modifications to ADOL-C, the computation of $\frac{\partial F}{\partial \lambda}$ is straightforward. Derivatives of G at solutions to $G = 0$ satisfy $G_z = -W^t(DF_z)V$ with W^t and V left and right eigenvectors of DF and z a component of (s, w, λ). Thus we need only compute a few of the second derivatives of F to obtain G_z. Some of these have been computed with finite differences in our codes thus far. (ADOL-C cannot be called recursively, so functions whose definition invokes ADOL-C cannot be differentiated using ADOL-C.)

Once we've computed the necessary second derivatives, we assemble the Jacobian of the system, and Newton's method is straightforward. The convergence of Newton's method appears to be limited by the condition number of K. Although DF becomes singular as we approach the bifurcation point, the condition number of K is generally well behaved. The mesh is adapted periodically during these computations as follows. To add mesh points, we begin by computing the L_∞ error $\max |p'(s_j) - f(p(s_j))|$ for a set of evenly spaced points $\{r_j\} \in [-s_i, s_i]$ in each mesh interval. If, for a particular interval joining the ith and $(i+1)$st mesh points, the error is greater than a specified multiple of the average error for all intervals, we add a new mesh point at the average of the points obtained by shooting forward from the ith mesh point and shooting backward from the $(i+1)$st mesh point. To remove mesh points, we check for each mesh point the resulting error if that point is removed, and remove it if the new error is no more than a prescribed tolerance relative to the sum of the previous errors.

The length of this code is about 600 lines of MATLAB (which includes the version of the algorithm to converge to a simple periodic orbit), and three C++ files, for evaluation of the vector field and the interface between MATLAB and ADOL-C. The appendix gives a more complete description of this algorithm in terms of pseudocode that corresponds closely to our MATLAB implementation.

5. Case studies. In this section, we present comparisons of computations on several test problems chosen to evaluate different aspects of the algorithms.

5.1. A periodic orbit in an algebraic curve. The first test problem was chosen so that the location of its periodic orbit is explicitly given by an algebraic formula. The vector field is defined as

$$\begin{aligned} \dot{x} &= y - y^2 - x(x^2 - y^2 + 2y^3/3 + c), \\ \dot{y} &= x + (y - y^2)(x^2 - y^2 + 2y^3/3 + c). \end{aligned}$$

This vector field has a stable periodic orbit that lies in the zero set of the polynomial $g(x, y) = x^2 - y^2 + 2y^3/3 + c$ when $c \in (0, 1/3)$. Thus, evaluation of g along computed trajectories is an explicit measure of their accuracy. We shall call $\max |g(u(t))|$ the *residual* of a numerically computed orbit $u(t)$, where the residual map is evaluated as a discrete function at mesh points or regarded as a continuous function using a mapping of discrete closed curves into a function space.

For $c = 0.07$, we compared three ways of computing the periodic orbit: the collocation method implemented in the AUTO package, numerical integration with a fourth-order Runge–Kutta algorithm, and a multiple shooting code that uses automatic differentiation.

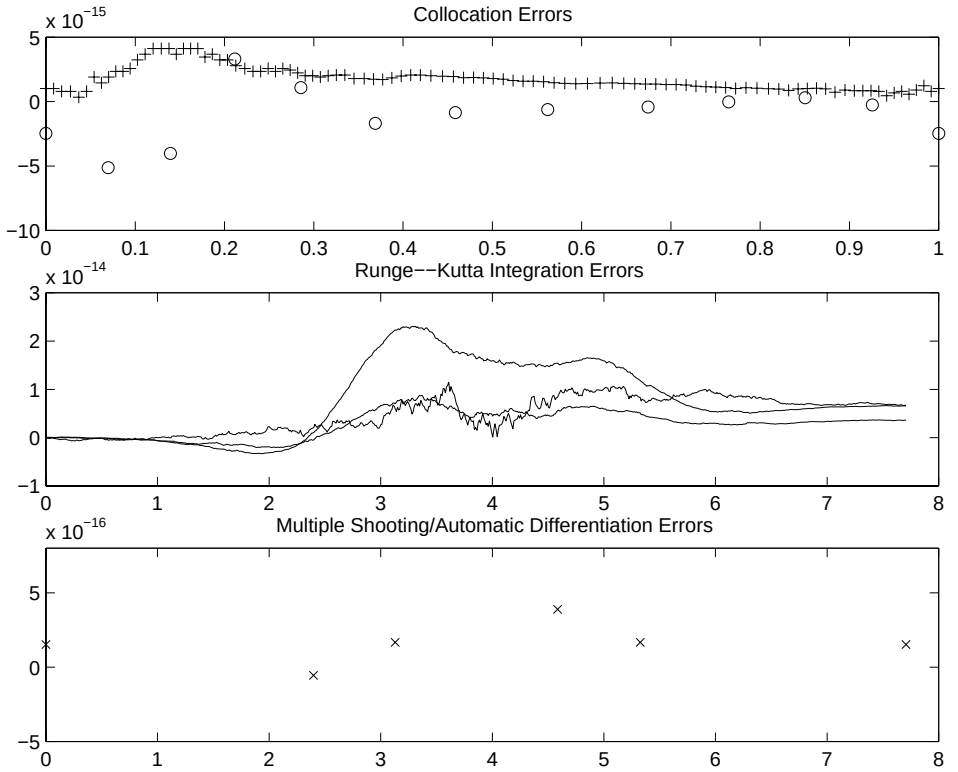

FIG. 5.1. *Three different methods have been used to compute a periodic orbit that lies in a polynomial curve in the plane. The value of the polynomial g along the periodic orbit is plotted as a function of time during one traversal of the periodic orbit. The data in the top panel were produced by AUTO and give the value of g at mesh points for (+) a mesh of* 100 *points with* 4 *collocation points per interval and for (o) a mesh of* 12 *points with* 7 *collocation points per interval. The three curves in the middle panel are the values of g at each time step of trajectories computed with a fourth-order Runge–Kutta method, using fixed time steps of* 0.00125, 0.001, *and* 0.0001 *in the three cases. The bottom panel shows the values of g produced with a multiple shooting algorithm employing automatic differentiation on a mesh with* 5 *intervals.*

The computer program AUTO [10] is widely regarded as the best available tool for the computation of periodic orbits. AUTO uses a collocation method with between 2 and 7 collocation points per mesh interval to compute orbits. The algorithm used by AUTO is superconvergent at the mesh points. The top panel of Figure 5.1 displays the value of the polynomial g at mesh points along a periodic orbit computed by AUTO. The "+" symbols were computed using 100 mesh intervals and 4 collocation points per interval. The "o" symbols were computed using 12 mesh intervals and 7 collocation points per interval. For each case of 4 and 7 collocation points per mesh interval, we tested several mesh sizes. The data in the figure have the smallest residuals we obtained.

The "standard" fourth-order Runge–Kutta algorithm [20] for the system $\dot{x} = f(x)$ with step size h is described by the following formulas that yield the approximation x_1 to $\phi_h(x_0)$:

$$k_1 = hf(x_0),$$

$$k_2 = hf(x_0 + k_1/2),$$
$$k_3 = hf(x_0 + k_2/2),$$
$$k_4 = hf(x_0 + k_3),$$
$$x_1 = x_0 + \frac{1}{6}(k_1 + 2k_2 + 2k_3 + k_4).$$

Setting $x_1 = \rho_h(x_0)$, $\rho_h : R^n \to R^n$ is a map that approximates the flow map ϕ_h to fourth-order in the step size h. This implies that the errors made in computing one step of the algorithm are comparable to h^5 and that the errors associated with computing a trajectory for bounded time are comparable to h^4. When h is very small, round off errors dominate the truncation errors in the finite difference calculations of derivatives of f that are implicit in the algorithm. As h is reduced, we observed that there is an optimal step size h_o for accuracy at which the round off and truncation errors appear to be balanced. This is illustrated by data from numerical experiments in which the Runge–Kutta algorithm is used to evolve the trajectory with initial point $(0, 0.2952161257895192)$ with different step sizes. The initial point lies on the periodic orbit to within round-off error, and the trajectory was computed until it returned to the y-axis near the initial point.

The apparent value of h_o is approximately 0.001. For step sizes larger than 0.001, the residual of the computed orbits decrease with h at a rate that appears consistent with the fourth-order convergence of the Runge–Kutta algorithm. For step sizes smaller than 0.001, the residual increases in an erratic manner. The second panel of Figure 5.1 shows the value of g as a function of time along Runge–Kutta trajectories with step sizes 0.00125, 0.001, and 0.0001. The smallest observed value of the residual was approximately 8×10^{-15} with step size 0.001. Since the orbit has period approximately 7.7, the numerical integration with step length 0.001 required over 7,700 steps and approximately 30,000 function evaluations. The observed optimal step size for the Runge–Kutta and mesh sizes for the AUTO calculations are consistent with predictions based upon their asymptotic orders of accuracy. The collocation method employed by AUTO is superconvergent at mesh points, with the result that the mesh points lie much closer to the desired periodic orbit than the intermediate collocation points used in the calculation. For example, the residuals of the collocation points and mesh points for our computation with seven collocation points per mesh interval and twelve mesh intervals are approximately 10^{-9} and 5×10^{-15}, respectively. The corresponding data for the orbit computed with four collocation points per mesh interval and 100 mesh intervals are 10^{-10} and 4×10^{-15}.

The bottom panel of the figure shows the results of a calculation using a symmetric multiple shooting algorithm employing automatic differentiation. There are 5 mesh intervals and the maximum value of $|g|$ is approximately 6×10^{-16}. The degree of the Taylor series polynomials used in the calculation is 16. Convergence is obtained in approximately 6 Newton steps starting with mesh points that are far from the computed solution. Thus our method produces solutions to this problem that are close to an order of magnitude more accurate than those produced by the most accurate numerical integration possible with the standard fourth-order Runge–Kutta algorithm or with the collocation method in AUTO. Given the differences in the way in which each of these algorithms was implemented, direct comparisons of their efficiency were not made. Nonetheless, it is apparent that the small mesh sizes and rapid convergence of the Taylor series method make it very efficient compared to other methods of computing periodic orbits to high accuracy.

5.2. Bifurcations in a planar vector field with multiple limit cycles. Dangelmayr and Guckenheimer [6] investigated the dynamics of the four parameter family of vector fields:

$$\begin{aligned}\dot{x} &= y,\\ \dot{y} &= -(x^3 + rx^2 + nx + m) + (b - x^2)y.\end{aligned}$$

The system describes the effect of symmetry imperfections in the unfolding of a codimension 2 bifurcation of an equilibrium with symmetry rotation by π. The dynamics of this family is surprisingly complex, with over 20 different inequivalent phase portraits. In a small region of the parameter space, there are phase portraits with a single equilibrium point and four nested limit cycles. The existence of this parameter region was deduced from an analysis of unfoldings of subsidiary codimension 3 bifurcations in Dangelmayr and Guckenheimer [6]. Parameter values at which this phase portrait occurs were first determined by Malo [23]. Malo developed simple shooting algorithms to trace curves of saddle-node bifurcations of periodic orbits. Applying these to the above system, he demonstrated that, when $r = 0.87$ and $m = -1$ the parameter region in the (n, b) plane for which the system has four nested limit cycles is a strip of width approximately 3×10^{-9}. We used this example to test our algorithms for computation and continuation of saddle-node bifurcations of periodic orbits.

Periodic orbits of the vector field with parameters $n = -1.127921667$ and $b = 0.897258546$ are displayed in Figure 5.2. The inset shows details of the three inner periodic orbits near their left intersection with the x axis. The saddle-node bifurcation points in this system were computed with the symmetric shooting method described earlier. However, the sensitivity of the problem made it a rather difficult undertaking. The shape of the three inner curves makes the computation difficult, as there is a very slow, tight turn, and a very fast, wide turn in the orbits. In order to converge from a mesh of regularly spaced points, we needed to coarsen the mesh several times before applying Newton steps. In this way, we were able to obtain representations for each of the nested periodic orbits. Each of these representations uses about 20 to 30 mesh points.

Only the middle of the three inner orbits yielded starting data sufficient to converge directly to a saddle-node bifurcation. Since we could only find one of the saddle-node bifurcations, we used a continuation strategy to find the other. We continued the first saddle-node curve with increasing n until we reached the neighborhood of an apparent cusp point. We then hoped to jump onto the second saddle-node curve and continue back to the original value of n. The computation to the cusp was quite easy: we were able to take large (size 2×10^{-6}) steps in n at first, and were able to quickly come close to the cusp point, gradually decreasing our step sizes to 10^{-8}. Once we were close to this point, we took a step of size -2.7×10^{-8}, from where the routines converged to a saddle-node bifurcation on the new curve. Following this curve back to the original value of n was significantly more difficult than computing the previous curve. We were unable to take large step sizes when we were close to the cusp because large steps converged back to the previously computed saddle-node curve. The computation was also quite sensitive to initial conditions, so we often couldn't take uniform steps. The Jacobians of the augmented systems along this curve are generally on the order of 10^{10}. Consequently, our approximations to these orbits generally have an L_∞ error on the order of 10^{-5}. Values we have computed for a portion of the saddle-node curves near Malo's parameters are given in Table 5.1.

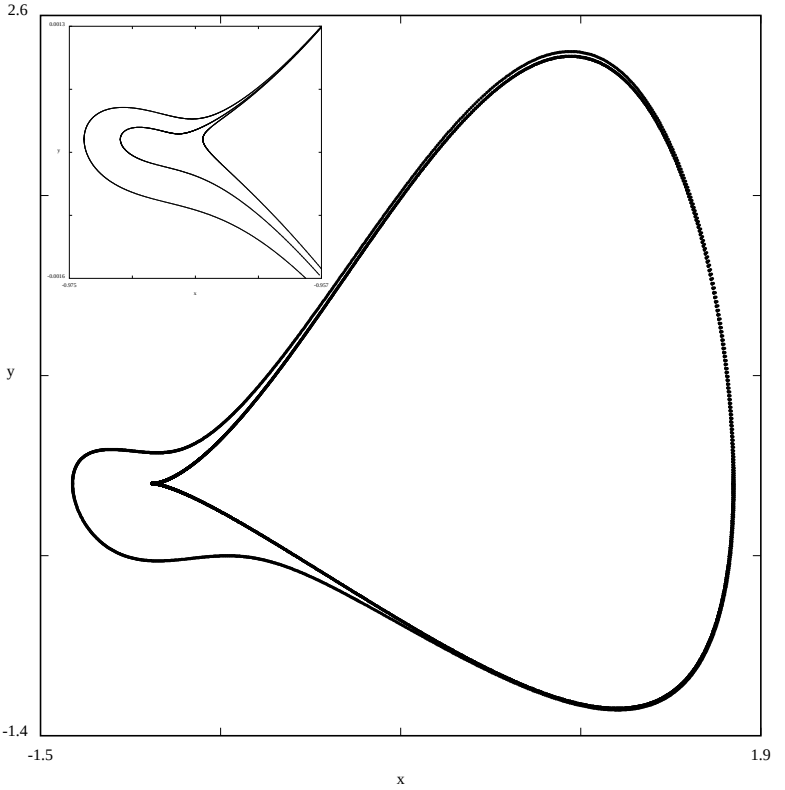

FIG. 5.2. *Four nested periodic orbits in the vector field* $y\partial_x + ((0.897258546 - x^2)y - (x^3 + 0.87x^2 + -1.127921667x - 1))\partial_y$ *The three inner orbits are not resolved in the large figure. The inset shows a small region near the left intersection of the inner orbits with the* x*-axis, bounded by the rectangle at* $[-0.975, -0.957] \times [-0.0016, 0.0013]$.

5.3. Multiple time scales and canards. The term canard describes trajectories of singularly perturbed systems that have segments which are close to unstable slow manifolds. Inspiration for the term comes from limit cycles of the dynamical system

$$\dot{x} = (y - x^2 - x^3)/\epsilon,$$
$$\dot{y} = a - x.$$

As $\epsilon \to 0$, this system has a slow manifold that approaches the cubic curve $y = x^2 + x^3$. The fast vector field is horizontal in the limit $\epsilon = 0$. The portion of the slow manifold between $x = -2/3$ and $x = 0$ is unstable, while the remainder is stable. When $a = 0$, there is an equilibrium point at the origin where the fast vector field is tangent to the slow manifold. Hopf bifurcation occurs at this point. As a decreases from 0, a family of stable periodic orbits grows rapidly with the magnitude of a. The orbits quickly stabilize as relaxation oscillations approximated by stable segments of the slow manifold and horizontal segments connecting the origin with $(-1, 0)$ and $(-2/3, 4/27)$ with $(1/3, 4/27)$. The periodic orbits of intermediate amplitude take the shape of canards in which there is a segment that follows the unstable portion of the slow manifold. An extensive analysis of the canard solutions has been undertaken from the three different perspectives of nonstandard analysis, [9], classical asymptotic

TABLE 5.1

Computed values of saddle-node bifurcation of the cubic vector field. The first column gives values of the parameter n, the second and third columns are computed values of b at the two curves of saddle-node bifurcation for the specified value of n, and the fourth column is the difference between the two values of saddle-node bifurcation.

analysis [12], and geometric singular perturbation theory [11]. Here we investigate the numerical computation of canards with our adaptive step length multiple shooting algorithm and compare these results with AUTO calculations.

The canard phenomenon is subtle. We recall a few of the results from the theory. Fenichel [13] established the existence of a slow manifold for positive values of ϵ as well as $\epsilon = 0$. Eckhaus [12] computed asymptotic expansions for the slow manifold. Its distance from the cubic curve $y = x^2 + x^3$ has order ϵ. Away from the turning points, trajectories flow towards or away from the cubic characteristic at exponential rates of order $1/\epsilon$. A very large region of initial points has trajectories that follow the unstable branch of the slow manifold for approximately the same distance and then jump back to a stable branch at approximately the same height. Asymptotic formulas for this critical height have been obtained. The critical height is extremely sensitive to the value of the parameter a, varying at a rate comparable to $\exp(-Q/\epsilon)$, where Q is given by the asymptotic theory. The critical height determines the size of a canard. All trajectories starting near the stable left branch of the slow manifold flow to the local maximum of the cubic characteristic and then jump to the right branch of the slow manifold. They then follow the right branch to the local minimum of the cubic curve. If the parameter a is in the range in which the canards "with heads" occur, the trajectory then climbs the unstable portion of the slow manifold to the critical height before jumping back to the left branch of the slow manifold. Thus, all trajectories that begin on the left branch of the slow manifold are swept into a small neighborhood of the canard cycle before they have completed a single circuit around the cycle. Nonetheless, tiny variations in an initial condition near the minimum of the cubic characteristic produce trajectories that separate from each other after traveling only a short distance along the unstable branch of the slow manifold.

Instability of the middle branch of the slow manifold prevents computation of canards with numerical integration. To make our discussion concrete, consider what happens with $\epsilon = 0.001$. The Jacobian of the vector field is

$$\begin{pmatrix} 1000(-2x - 3x^2) & 1000 \\ -1 & 0 \end{pmatrix}.$$

When $x \in [-1/2, -1/6]$ and $a < 0$, the x components of nearby trajectories separate at a rate at least $\exp(250t)$ while the y component of the vector field increases at a rate at most $1/2$. Thus a trajectory requires at least time $2/3$ to traverse the portion

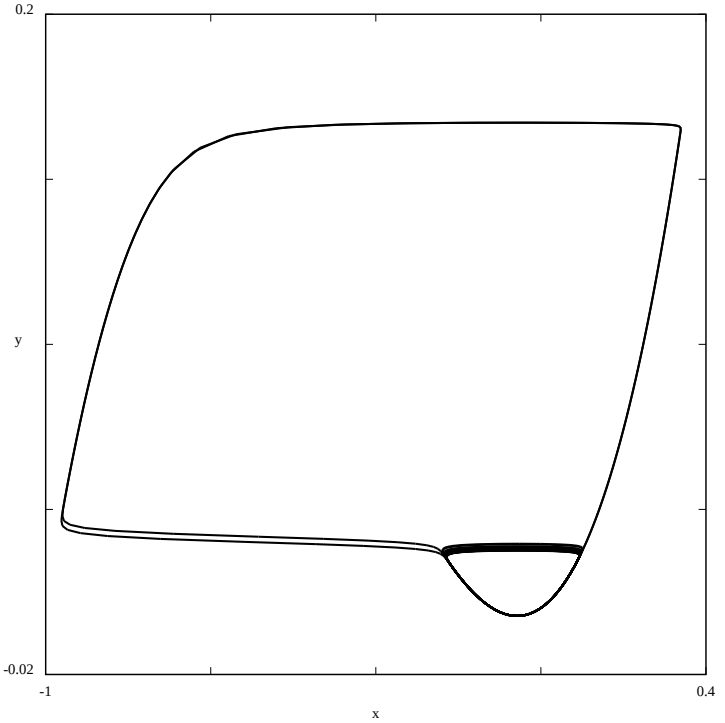

FIG. 5.3. *Fourth-order Runge–Kutta integration of the canard vector field. Due to the massive instability of the unstable branch of the slow manifold, the integration is unable to compute trajectories that follow this branch. Compare with the family of canards shown in Figure* 5.4.

of the slow manifold with $x \in [-1/2, -1/6]$. During this time, the relative separation of trajectories in the x direction increases by a factor of well over $\exp(150)$. Thus, if an initial condition has distance greater than $\exp(-150)$ from the slow manifold, it will not track it until x reaches $-1/2$. It is evident that extended precision beyond the 53 bit precision of IEEE-754 floating point arithmetic is required for this task. If we try to follow the unstable portion of the slow manifold by choosing initial conditions that lie as close together as possible on opposite sides of the manifold, then Runge–Kutta integration was observed to return to opposite sides of the unstable manifold erratically. Figure 5.3 shows such a "chaotic" trajectory. The numerical integration algorithm has qualitative behavior inconsistent with the trajectories of any planar vector field. There is no numerical trajectory that approximates the canards even crudely.

We used a forward multiple shooting method and the program AUTO to compute this family of canards. The AUTO parameters were set to use 200 mesh intervals and error tolerances of 10^{-12}. Starting at the Hopf bifurcation point, AUTO was able to compute the entire family of canard orbits. Figure 5.4 shows selected orbits from this family. We sought to evaluate the precision of the AUTO computations. To achieve this goal we took the trajectory of one canard computed in AUTO as an initial discrete closed curve for computation with an adaptive step length forward multiple

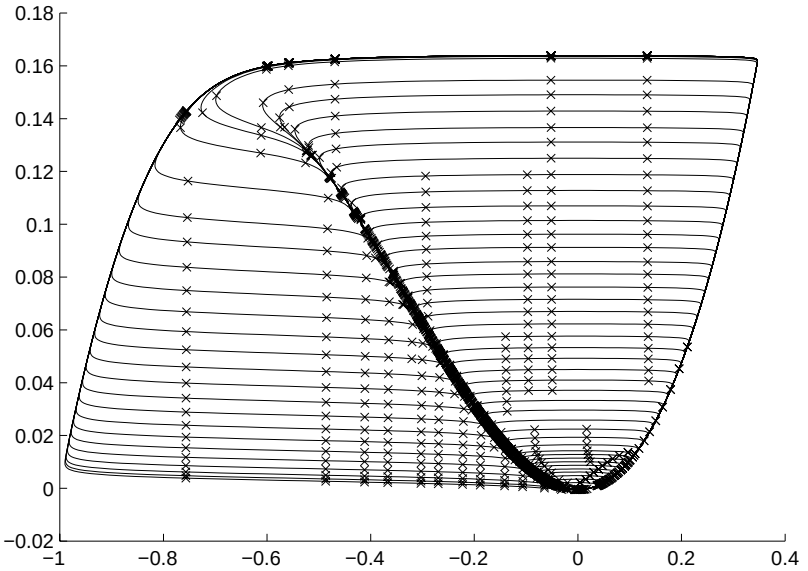

FIG. 5.4. *A family of canards computed with the forward multiple shooting algorithm described in section* 3. *The parameter* $\epsilon = 0.001$.

shooting algorithm. This algorithm first computes Taylor polynomial approximations to the trajectory segments of the discrete closed curve obtained from AUTO. These computations yield an estimate of approximately 5×10^{-9} for the maximum mismatch from the end of one trajectory segment to the initial point of the next, despite the stringent error tolerances used in the calculation and the superconvergence at mesh points of the AUTO collocation algorithm. The condition number of the Newton method Jacobian at this orbit was approximately 1×10^{50} with the parameter a fixed. The algorithm did not converge. However, fixing the period and varying a, the condition number was approximately 3.5×10^{7} and one Newton step produced an approximate discrete closed curve with the distance from the endpoint of one trajectory segment to the initial point of the next having magnitude smaller than 6×10^{-15}. The maximum length of the difference between the tangent vector to the Taylor polynomials and the vector field at the ends of the time steps is approximately 1×10^{-13}. Dividing the length of the difference by the length of the vector field produces an estimate of approximately 2×10^{-13} for the maximum deviation of the approximate periodic orbit from the flow direction.

The distance between the discrete closed curve computed by AUTO and the discrete closed curve produced by the multiple shooting algorithm is approximately 1.4×10^{-7}. Figure 5.5 displays a three-dimensional plot of the difference of the y coordinates of the two discrete trajectories. The differences between the x coordinates of the two trajectories are much smaller. The largest differences occur when the trajectory leaves the slow manifold and appear smooth enough that it is unlikely that the differences are due to round-off error. AUTO calculations with coarser meshes yield a similar pattern, with larger differences that have a similar shape along the jumps of the canard. Thus, we believe that our calculation is sufficiently precise that the difference between the two trajectories is an estimate for the distance of the mesh points computed by AUTO from the actual periodic orbit. The parameter values

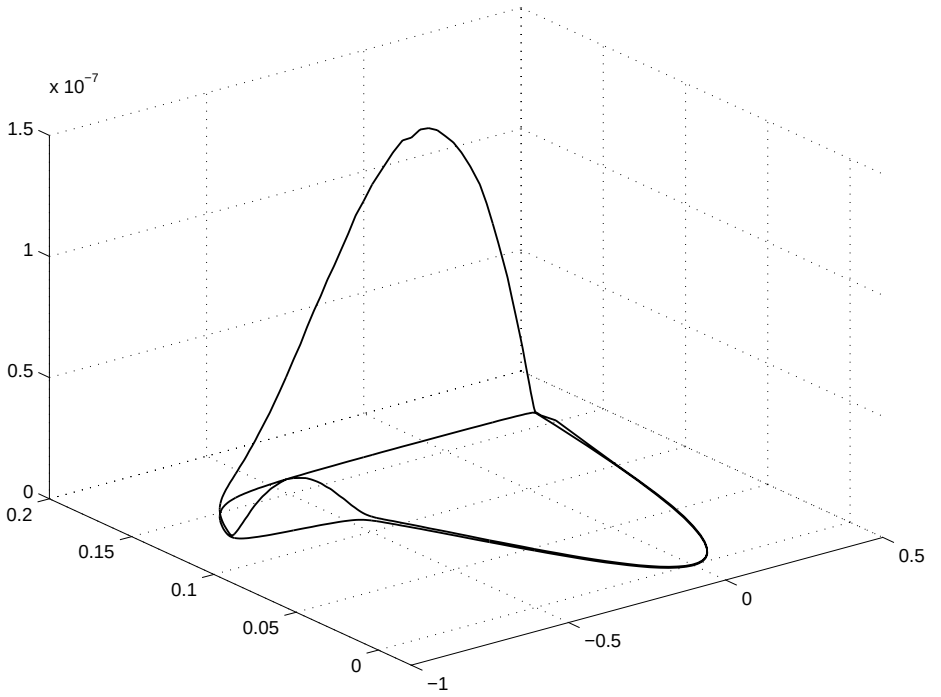

FIG. 5.5. *This three-dimensional plot gives the difference between a canard computed with AUTO and a canard computed with a Taylor series, forward shooting method. The canard is plotted in the horizontal plane and the magnitude of the difference between the two computations is plotted on the vertical axis.*

imported from AUTO for the canards had 11 significant digits. The parameter value obtained with Newton's method differs from the AUTO parameter by approximately 1.5×10^{-15}, agreeing to the last digit of the value from AUTO. We next used the period as a continuation parameter in order to track the family of canards. These calculations gave parameter values that differ in the 13th significant digit, and they do so erratically. Thus, the sensitivity of the canards to parameter variations is so great that our algorithms are unable to compute the qualitative behavior of this parameter variation. This is hardly surprising since the asymptotic theory described above estimates the parameter variation across the canard family to be smaller than 10^{-20}. Calculation of the parameter variation appears to be beyond the bounds that are readily feasible without using greater precision than IEEE-754 double precision floating point arithmetic. Our attempts to construct continuation codes for tracking the canard solutions have not achieved the robustness we seek. However, the orbits themselves appear to be computed with precision that is dominated by round-off errors as in the case of nonstiff systems.

5.4. Monodromy in a model of coupled Josephson junctions. Swift and Watanabe [30] studied the dynamics of arrays of N Josephson junction oscillators shunted by a series LRC load, a system symmetric with respect to all interchanges of the oscillators. These systems have "splay-phase" solutions in which the N oscillators all undergo the same motion but out of phase with one another. Denoting the motion

of oscillator i in the splay phase state by $\phi_i(t)$, the oscillators can be numbered so that $\phi_{i+1}(t) = \phi_i(t + 2\pi/N)$. In the limit that the Stewart–McCumber parameter of these systems is zero, the splay-phase state is neutrally stable. Numerical integration of the system with other values of this parameter suggested that the splay-phase states might be neutrally stable for positive values of the Stewart–McCumber parameter as well, with a return map possibly having eigenvalue 1 with multiplicity $N - 3$. Swift and Watanabe studied the case of four coupled junctions carefully and demonstrated that the splay-phase states are represented by hyperbolic periodic orbits for generic values of the Stewart–McCumber parameter. They did so by computing the splay phase states using AUTO86 and then computing the monodromy matrix of the periodic orbit outside of AUTO. (The computation of Floquet multipliers has been greatly improved in AUTO97 compared to AUTO86, but AUTO97 was not available when Swift and Watanabe did their work.)

The vector field f that represents an array of four junctions is defined by the ten-dimensional system:

$$\begin{aligned}
\dot{x}_1 &= x_5,\\
\dot{x}_2 &= x_6,\\
\dot{x}_3 &= x_7,\\
\dot{x}_4 &= x_8,\\
\dot{x}_5 &= (I - x_5 - sin(x_1 - x_{10}))/b,\\
\dot{x}_6 &= (I - x_6 - sin(x_2 - x_{10}))/b,\\
\dot{x}_7 &= (I - x_7 - sin(x_3 - x_{10}))/b,\\
\dot{x}_8 &= (I - x_8 - sin(x_4 - x_{10}))/b,\\
\dot{x}_9 &= x_{10},\\
\dot{x}_{10} &= ((x_1 + x_2 + x_3 + x_4)/4 - rx_{10} - x_9/c)/l.
\end{aligned}$$

Since Swift and Watanabe had difficulty computing the splay phase states and their stability, we sought to confirm their results with an automatic differentiation based solver. We used the Hermite interpolation global method to compute the splay phase state, starting with linear varying phase for each oscillator. The parameter values were $I = 2.5, l = 0.75, r = 0, c = 20$, and Stewart–McCumber parameter $b = 0.2$. With 20 mesh intervals and degree 16 Taylor series approximations at the mesh points, the algorithm converged in six Newton steps to an approximate periodic orbit $p(t)$. Using the uniform norm in R^{10}, the norm of $p'(t) - f(p(t))$ appears to be smaller than 2×10^{-13}. The computed eigenvalues of the monodromy matrix are displayed in Table 5.2. The monodromy matrix of a periodic orbit has an eigenvalue 1. The precision with which this eigenvalue is computed is a measure for the accuracy of the computation of the periodic orbit and its monodromy matrix. In our calculation, the error for

this eigenvalue is 6×10^{-15}. We also note that the eigenvalue 1.003009060195232 is in excellent agreement with the perturbation analysis of Swift and Watanabe [30, Figure 8]. As a final check on the precision of these calculations, we repeated them with a coarser mesh having 10 mesh intervals. The algorithm converged in 7 Newton steps. The monodromy matrix agreed with the values in Table 5.2 above to 10 decimal places. The error in the eigenvalue 1 was approximately 5.5×10^{11}. Thus, these periodic orbit calculations seem to be converging quickly and accurately.

6. Conclusions. Numerical computation of periodic orbits of vector fields is a difficult component in understanding the qualitative structure of dynamical systems. With prevailing methods, achieving high accuracy in the direct computation of periodic orbits leads to large systems of equations through the use of large meshes. We have developed algorithms for computing periodic orbits that achieve high accuracy with small meshes through the use of high-order algorithms. A key feature of these algorithms is that increasing order does not require the introduction of larger root finding to obtain the periodic orbit. Instead, our algorithms utilize Taylor series of trajectories computed with automatic differentiation. Taylor polynomials of trajectories can be computed to arbitrary degree, and the defining equations for hyperbolic periodic orbits converge with increasing degree.

We have implemented our algorithms within MATLAB 5 together with the automatic differentiation package ADOL-C. The implementations have been tested on several problems. One of the test problems was designed to have a periodic orbit along an explicitly known polynomial curve so that the absolute accuracy of different methods for computing the periodic orbit could be tested. Our results demonstrate that the automatic differentiation based algorithms can indeed produce more accurate approximations to a periodic orbit than either numerical integration with a standard Runge–Kutta algorithm or a boundary value solver based upon collocation. We attribute the increased accuracy to the fact that there are no finite difference calculations of derivatives implicit in our methods. Moreover, the meshes used by our algorithm are coarse, reflecting the high order of the algorithms.

The three additional test problems presented in this paper were chosen for their difficulty. One of these, the planar cubic system, has limit cycles and bifurcations that are very close to one another. The second test problem shows that our methods are capable of computing canards, solutions to differential equations with multiple time scales that are not readily computed with numerical integration. The final problem tests the accuracy of computing the monodromy matrix on a higher-dimensional problem, where the desired unstable periodic orbit has a multiplier slightly larger than 1.

We are encouraged by our results. While it has been shown in the past that Taylor series methods can be competitive with other methods of numerical integration in both efficiency and accuracy [4, 5, 27], we believe that there is even more to be gained from their use in direct computation of periodic orbits as boundary value problems. The methods are very flexible with regard to mesh adaptation and conceptually simple. They are readily extended to methods that yield defining equations for bifurcations of periodic orbits. With further refinement, we look forward to our implementations becoming mature software packages that can be added to tool kits for numerical exploration of dynamical systems.

Appendix.

Main procedure: Continue saddle-node bifurcations.

Load data and parameters, and set global variables:
dim is the dimension of the phase space
data is a matrix whose rows are the mesh points (t_i, x_i)
delta is a vector containing the interval sizes (divided by 2)
nint is the number of intervals
Call procedure Find Orbit
for number of continuation points requested **do**
Call procedure Find Saddle-Node Bifurcation
Call procedure Symmetric Compute Return Map Jacobian
Save representation for the located periodic orbit: Taylor coefficients and total derivatives at the mesh points, *data*, *delta*, $ReturnMapJacobian$ and parameter values
Add continuation stepsize to the continuation parameter
if we have another point to find **then**

NUMERICAL DISCRETIZATION OF ENERGY-TRANSPORT MODELS FOR SEMICONDUCTORS WITH NONPARABOLIC BAND STRUCTURE*

PIERRE DEGOND†, ANSGAR JÜNGEL‡, AND PAOLA PIETRA§

Abstract. The energy-transport models describe the flow of electrons through a semiconductor crystal, influenced by diffusive, electrical, and thermal effects. They consist of the continuity equations for the mass and the energy, coupled with Poisson's equation for the electric potential. These models can be derived from the semiconductor Boltzmann equation.

This paper consists of two parts. The first part concerns the modeling of the energy-transport system. The diffusion coefficients and the energy relaxation term are computed in terms of the electron density and temperature, under the assumptions of nondegenerate statistics and nonparabolic band diagrams. The equations can be rewritten in a drift-diffusion formulation which is used for the numerical discretization.

In the second part, the stationary energy-transport equations are discretized using the exponential fitting mixed finite element method in one space dimension. Numerical simulations of a ballistic diode are performed.

Key words. mixed finite element method, exponential fitting, nonparabolic band structure, semiconductors

1. Introduction.

Semiconductor devices can be simulated by means of the semiconductor Boltzmann equation, which is usually numerically solved by employing the Monte Carlo method. However, this method is too costly and time consuming to model real problems in semiconductor production mode where simulation results are needed in hours or minutes. Acceptable accuracy can be reached by solving macroscopic semiconductor models derived from the Boltzmann equation. The simplest models are drift-diffusion models which consist of the mass continuity equation for the charge carriers and a definition for the particle current density (see, e.g., [25]). These models, however, are not accurate enough for submicron device modeling, owing to temperature effects, for instance.

The energy-transport equations consist of the conservation laws of mass and energy, together with constitutive relations for the particle and energy currents, and are able to model temperature effects in submicron devices. Since the energy-transport equations are of parabolic type, the numerical solution needs less effort than the hy-

drodynamic models. Moreover, the energy-transport equations can be written in a drift-diffusion formulation, therefore the numerical effort is comparable to the drift-diffusion models.

In this paper a numerical scheme for energy-transport models is presented and numerical results for a one-dimensional ballistic diode are given. The originality of this paper consists of three facts: First, we compute explicitly, for rather general band diagrams, diffusion coefficients and the energy relaxation term in terms of the electron density and temperature. For nonparabolic bands in the sense of Kane, the coefficients can be computed analytically. The resulting model is *completely* derived from the Boltzmann equation. Second, we show that *any* energy-transport model, derived from the Boltzmann equation via the *spherical harmonic expansion* (SHE) model under rather weak assumptions on the semiconductor band structure, allows a drift-diffusion formulation. Finally, based on the drift-diffusion formulation, we discretize and solve the equations by means of mixed finite elements and point out the differences of various models used in the physical literature.

The first part of this paper is concerned with the computation of the diffusion coefficients and the energy relaxation term, assuming general nonparabolic band diagrams and Boltzmann statistics (section 2). In [5] the energy-transport equations are derived from the semiconductor Boltzmann equation by means of the Hilbert expansion method. First, the SHE model is obtained in the diffusion limit, under the assumption of dominant elastic scattering. Then, through a diffusion approximation, respectively making electron-electron or phonon scattering large, the energy-transport equations are derived from the SHE model. The stationary energy-transport model reads as follows:

$$-\operatorname{div} J_1 = 0, \tag{1.1}$$

$$-\operatorname{div} J_2 = -J_1 \cdot \nabla V + W(n,T), \tag{1.2}$$

$$J_1 = L_{11}\Big(\nabla\frac{q\mu}{k_BT} - \frac{q\nabla V}{k_BT}\Big) + L_{12}\nabla\Big(-\frac{1}{k_BT}\Big), \tag{1.3}$$

$$qJ_2 = L_{21}\Big(\nabla\frac{q\mu}{k_BT} - \frac{q\nabla V}{k_BT}\Big) + L_{22}\nabla\Big(-\frac{1}{k_BT}\Big), \tag{1.4}$$

$$\varepsilon_s\Delta V = q(n-C). \tag{1.5}$$

The variables are the chemical potential μ, the electron temperature T, and the electric potential V. Furthermore, J_1, J_2 are the particle and energy current densities, respectively. The physical constants are the elementary charge q, the Boltzmann constant k_B, and the semiconductor permittivity ε_s. The electron density n depends on μ and T. For instance, for Boltzmann statistics and parabolic bands, the relation $n = N_iT^{3/2}\exp(q\mu/k_BT)$ with $N_i > 0$ holds. The space dependent function $C = C(x)$ is the doping profile, $L_{ij} = L_{ij}(n,T)$ are the diffusion coefficients, and $W = W(n,T)$ is the energy relaxation term. These equations hold in the (bounded) semiconductor domain Ω, and they have to be complemented with mixed Dirichlet–Neumann boundary conditions

$$\begin{aligned} n = n_D, \quad T = T_D, \quad V = V_D \text{ on } \Gamma_D, \\ J_1\cdot\nu = J_2\cdot\nu = \nabla V\cdot\nu = 0 \text{ on } \Gamma_N, \end{aligned}$$

modeling the Ohmic contacts Γ_D and the insulating boundary parts Γ_N. Then, $\partial\Omega = \Gamma_D \cup \Gamma_N$ and $\Gamma_D \cap \Gamma_N = \emptyset$ must be satisfied. The exterior normal unit vector on $\partial\Omega$ is denoted by ν.

The mathematical analysis of (1.1)–(1.5) has been studied recently in [11, 12, 13, 18] (see also [1, 16]). The existence and uniqueness of solutions to both the stationary and the time-dependent equations have been proved. In the physical literature, the energy-transport equations have been investigated numerically for several years [2, 9, 10, 22, 33, 34, 35], using parabolic band structure and Boltzmann statistics. Nonparabolic and non-Maxwellian distribution effects are discussed in [9, 34], but no comparisons of energy-transport models with parabolic and nonparabolic band diagrams have been performed.

In section 2 we compute the diffusion coefficients L_{ij}, the electron density n, the internal energy E, and the energy relaxation term W in terms of μ and T. We assume that the energy-band diagram of the semiconductor crystal is spherically symmetric and monotone in the modulus of the wave vector $\vec{k}$, that nondegenerate Boltzmann statistics can be used, and that a momentum relaxation time τ can be defined by $\tau(\varepsilon) \sim \varepsilon^{-\beta} N(\varepsilon)^{-1}$, where ε is the energy, $N(\varepsilon)$ denotes the density of states, and $\beta > -2$ is a parameter. Then, using the general formulas for the coefficients and densities from [5], we get more explicit expressions than those of [5], involving the energy-band function $\varepsilon(\vec{k})$ and depending on the temperature T (see section 2.2).

Furthermore, we get *analytical* expressions under the additional assumption of nonparabolic bands in the sense of Kane [20]:

$$\varepsilon(1+\alpha\varepsilon) = \frac{\hbar^2}{2m_0}|\vec{k}|^2,$$

where $\hbar$ is the reduced Planck constant, m_0 the effective electron mass, and $\alpha > 0$ the nonparabolicity parameter.

The second part of this paper is concerned with the numerical discretization of the energy-transport equations (section 3). An important observation is that the current densities can be written in a drift-diffusion formulation of the form

$$J_i = \nabla g_i(n,T) - g_i(n,T)\frac{\nabla V}{T}, \quad i = 1,2, \tag{1.6}$$

where g_1 and g_2 are nonlinear functions of n and T. This formulation is valid for any current densities coming from a SHE model involving Boltzmann statistics (see section 2.3); it is the basis for our numerical discretization. For constant temperature, the expression (1.6) reduces to the standard drift-diffusion current definition.

The continuity equations (1.6) are discretized in one space dimension with a variant of the mixed exponential fitting scheme, which has been developed and studied in [6, 7, 8, 24] for the linear drift-diffusion equations and extended to a nonlinear drift-diffusion model in [19]. The most important features of these schemes are the current conservation (the current is introduced as an independent variable and continuity is directly imposed) and the ability of well-approximating solutions with steep gradient. (The scheme introduces exponentials of electric potential differences, which automatically account for the diffusion-dominant part and the drift-dominant part of the operator.) Moreover, the ideas of the discretization are not intrinsically monodimensional, and a two-dimensional extension is currently under investigation. The current discretization (in one-dimensional) can be seen as a nonlinear Scharfetter–Gummel discretization [31]. Other generalizations of the Scharfetter–Gummel discretization can be found, for instance, in [15, 28, 29].

The numerical scheme is applied to the simulation of a one-dimensional n^+nn^+ ballistic diode, which is a simple model of the channel of a MOS transistor. In the

numerical simulations, we also use nonparabolic energy bands. The numerical experiments are performed by employing two energy-transport models, the Lyumkis and the Chen models, which are defined by different momentum relaxation time functions. These two models are already used in the physical literature but only for parabolic band diagrams.

The numerical results show that the spurious velocity overshoot spike at the anode junction becomes smaller in the nonparabolic band case, compared to the parabolic case, and almost vanishes for the Chen model. The question of velocity overshoot peaks is addressed in [14].

2. Formulation of the model.

2.1. Scaling of the equations. We bring (1.1)–(1.5) into a scaled and dimensionless form. Let C_m be the maximal value of the doping profile, ℓ^* the diameter of the device, μ_0 the low-field mobility constant, T_0 the lattice temperature, and $U_T = k_B T_0/q$ the thermal voltage. Using the scaling

$$n \to C_m n, \quad C \to C_m C, \quad T \to T_0 T, \quad V \to U_T V, \quad \mu \to U_T \mu, \quad x \to \ell^* x,$$
$$J_1 \to (q\mu_0 U_T C_m/\ell^*) J_1, \quad J_2 \to (q\mu_0 U_T^2 C_m/\ell^*) J_2,$$
$$L_{ij} \to ((qU_T)^{i+j-1}\mu_0 C_m) L_{ij}, \quad W \to (q\mu_0 U_T^2 C_m/\ell^{*2}) W,$$

we get the system

$$-\operatorname{div} J_1 = 0, \tag{2.1}$$
$$-\operatorname{div} J_2 = -J_1 \cdot \nabla V + W, \tag{2.2}$$
$$J_1 = L_{11}\Big(\nabla\frac{\mu}{T} - \frac{\nabla V}{T}\Big) + L_{12}\nabla\Big(-\frac{1}{T}\Big), \tag{2.3}$$
$$J_2 = L_{21}\Big(\nabla\frac{\mu}{T} - \frac{\nabla V}{T}\Big) + L_{22}\nabla\Big(-\frac{1}{T}\Big), \tag{2.4}$$
$$\lambda^2 \Delta V = n - C, \tag{2.5}$$

where $\lambda^2 = \varepsilon_s U_T/(qC_m\ell^{*2})$ denotes the square of the scaled Debye length.

2.2. General nonparabolic band diagrams. In this subsection we reformulate the diffusion coefficients for the energy-transport model (2.1)–(2.5), as derived in [5], and we make precise our assumptions on the energy relaxation term. We assume in this and the following subsections that all physical variables and parameters are in scaled form. In order to get more explicit expressions for the coefficients L_{ij} in terms of n, T (or μ, T), we have to impose some physical assumptions:

(H1) The energy-band diagram ε of the semiconductor crystal is spherically symmetric and a strictly monotone function of the modulus $k = |\vec{k}|$ of the wave vector $\vec{k}$. Therefore, the Brillouin zone equals $\mathbb{R}^3$ and $\varepsilon : \mathbb{R} \to \mathbb{R}$, $k \mapsto \varepsilon(k)$.

(H2) A momentum relaxation time can be defined by

$$\tau(\varepsilon) = \big(\phi_0(2N_0+1)\varepsilon^\beta N(\varepsilon)\big)^{-1}, \qquad \beta > -2, \quad \phi_0 > 0, \tag{2.6}$$

where $N(\varepsilon) = 4\pi k^2/|\varepsilon'(k)|$ is the density of states of energy $\varepsilon = \varepsilon(k)$ [5, formula (III.31)] and N_0 is the phonon occupation number [4, section 4].

(H3) The electron density n and the internal energy E are given by nondegenerate Boltzmann statistics.

The assumptions (H1)–(H2) are imposed in order to get simpler expressions for the variables. In the physical literature, the values $\beta = 0$ [9] and $\beta = 1/2$ [22] have been used in the case of parabolic band structure (see section 2.4). The nondegeneracy assumption (H3) is valid for semiconductor devices with a doping concentration which is below 10^{19}cm^{-3}. Almost all devices in practical applications satisfy this condition.

Under these assumptions, the diffusion coefficients are given by

$$L_{ij} = L_{ij}(\mu, T) = e^{\mu/T} \int_0^\infty d(\varepsilon)\varepsilon^{i+j-2} e^{-\varepsilon/T} d\varepsilon, \tag{2.7}$$

where

$$d(\varepsilon) = \frac{4\pi}{3}\tau(\varepsilon)|\varepsilon'(k)|k^2 \quad \text{and} \quad \varepsilon = \varepsilon(k)$$

(see [5, formulas (IV.17), (III.33)]). We refer to [5] for more general expressions for the diffusion coefficients under weaker assumptions.

Further, due to assumption (H3), we have [5, formula (IV.16)]

$$n = n(\mu, T) = e^{\mu/T} \int_0^\infty e^{-\varepsilon/T} N(\varepsilon) d\varepsilon, \tag{2.8}$$

$$E = E(\mu, T) = e^{\mu/T} \int_0^\infty \varepsilon e^{-\varepsilon/T} N(\varepsilon) d\varepsilon. \tag{2.9}$$

Let $\gamma(\varepsilon) = k^2$ be the inverted $\varepsilon(k)$ relation. Then $N(\varepsilon) = 2\pi\gamma(\varepsilon)^{1/2}\gamma'(\varepsilon)$ and, using (2.6),

$$d(\varepsilon) = \frac{8\pi}{3}\tau(\varepsilon)\frac{\gamma(\varepsilon)^{3/2}}{\gamma'(\varepsilon)} = \frac{4}{3\phi_0(2N_0+1)}\frac{\gamma(\varepsilon)}{\varepsilon^\beta \gamma'(\varepsilon)^2},$$

which yields

$$L_{ij} = \frac{4}{3\phi_0(2N_0+1)} e^{\mu/T} \int_0^\infty \varepsilon^{i+j-\beta-2} \frac{\gamma(\varepsilon)}{\gamma'(\varepsilon)^2} e^{-\varepsilon/T} d\varepsilon$$

or

$$L_{ij} = T^{i+j-\beta-1} e^{\mu/T} P_\beta(T, i+j) \tag{2.10}$$

with

$$P_\beta(T, \ell) = \frac{4}{3\phi_0(2N_0+1)} \int_0^\infty u^{\ell-\beta-2} \frac{\gamma(Tu)}{\gamma'(Tu)^2} e^{-u} du.$$

The electron density and the internal energy read (see (2.8), (2.9))

$$n = 2\pi e^{\mu/T} \int_0^\infty \gamma(\varepsilon)^{1/2}\gamma'(\varepsilon) e^{-\varepsilon/T} d\varepsilon,$$

$$E = 2\pi e^{\mu/T} \int_0^\infty \varepsilon\gamma(\varepsilon)^{1/2}\gamma'(\varepsilon) e^{-\varepsilon/T} d\varepsilon,$$

or

$$n = Te^{\mu/T} Q(T, 0), \qquad E = T^2 e^{\mu/T} Q(T, 1) \tag{2.11}$$

with

$$Q(T,\ell) = 2\pi \int_0^\infty u^\ell \gamma(Tu)^{1/2} \gamma'(Tu) e^{-u} du.$$

The energy relaxation term is given by

$$W = \int_0^\infty S_1(e^{(\mu-\varepsilon)/T}) \varepsilon d\varepsilon,$$

where S_1 is the phonon collision operator [5, formula (IV.18)]. In the Fokker–Planck approximation, we can write this operator as (see [32])

$$S_1(e^{(\mu-\varepsilon)/T}) = \frac{\partial}{\partial \varepsilon} \left\{ \delta(\varepsilon) \left[\left(1 + T_0 \frac{\partial}{\partial \varepsilon} \right) e^{(\mu-\varepsilon)/T} \right] \right\},$$

where $\delta(\varepsilon) = \phi_0 \varepsilon^\beta N(\varepsilon)^2$, $\beta > -1$, and $T_0 = 1$ is the (scaled) ambient temperature. With the definition of $\delta(\varepsilon)$, the above expression can be simplified:

$$\begin{aligned} W &= -e^{\mu/T} \int_0^\infty \delta(\varepsilon) e^{-\varepsilon/T} \left(1 - \frac{T_0}{T} \right) d\varepsilon \\ &= \phi_0 e^{\mu/T} T^\beta (T_0 - T) \int_0^\infty u^\beta N(Tu)^2 e^{-u} du \\ &= 4\pi^2 \phi_0 e^{\mu/T} T^\beta (T_0 - T) \int_0^\infty \gamma(Tu) \gamma'(Tu)^2 u^\beta e^{-u} du. \end{aligned}$$

Introducing

$$R_\beta(T) = \int_0^\infty \gamma(Tu) \gamma'(Tu)^2 u^\beta e^{-u} du, \tag{2.12}$$

the energy relaxation term can be written as

$$W = \frac{3}{2} \frac{n(T_0 - T)}{\tau_\beta(T)},$$

with the temperature-dependent relaxation time

$$\tau_\beta(T) = \frac{3}{8\pi^2 \phi_0} \frac{T^{1-\beta} Q(T,0)}{R_\beta(T)}. \tag{2.13}$$

2.3. A drift-diffusion formulation for the current densities. A remarkable observation is that the current densities J_1 and J_2 can be written in a drift-diffusion formulation of the type

$$J_1 = \nabla g_1(n,T) - g_1(n,T) \frac{\nabla V}{T}, \tag{2.14}$$

$$J_2 = \nabla g_2(n,T) - g_2(n,T) \frac{\nabla V}{T}. \tag{2.15}$$

(Here and in the following, the gradient ∇ always means differentiation with respect to the space variable.) Indeed, in the general case the current densities are given by

$$J_i = \int_0^\infty d(\varepsilon) \left(\nabla e^{(\mu-\varepsilon)/T} + \nabla V \frac{\partial}{\partial \varepsilon} e^{(\mu-\varepsilon)/T} \right) \varepsilon^{i-1} d\varepsilon, \quad i = 1, 2. \tag{2.16}$$

This relation holds true under weak assumptions (see [5] for details) and in particular under the assumptions (H1)–(H3) of section 2.2.

From (2.16) we get

$$J_i = \nabla \int_0^\infty d(\varepsilon) e^{(\mu-\varepsilon)/T} \varepsilon^{i-1} d\varepsilon - \frac{\nabla V}{T} \int_0^\infty d(\varepsilon) e^{(\mu-\varepsilon)/T} \varepsilon^{i-1} d\varepsilon,$$

which equals (2.14), (2.15), respectively, setting

$$g_1 = \int_0^\infty d(\varepsilon) e^{(\mu-\varepsilon)/T} d\varepsilon, \qquad g_2 = \int_0^\infty d(\varepsilon) e^{(\mu-\varepsilon)/T} \varepsilon d\varepsilon.$$

The functions g_1 and g_2 can be computed in terms of n and T, under the assumptions (H1)–(H3) of section 2.2. Indeed, by (2.7), we get $g_1 = L_{11}$ and $g_2 = L_{21}$, and using (2.10) and (2.11), we can write

$$g_1(n,T) = \frac{P_\beta(T,2)}{Q(T,0)} T^{-\beta} n, \qquad g_2(n,T) = \frac{P_\beta(T,3)}{Q(T,0)} T^{1-\beta} n \tag{2.17}$$

or

$$g_1(n,T) = \mu_\beta^{(1)}(T) T n, \qquad g_2(n,T) = \mu_\beta^{(2)}(T) T^2 n$$

with the temperature-dependent mobilities

$$\mu_\beta^{(i)}(T) = \frac{P_\beta(T,i+1)}{Q(T,0)} T^{-1-\beta}, \quad i = 1,2. \tag{2.18}$$

We can write the stationary energy-transport model in the drift-diffusion formulation either in the variables n, T, and V or in the variables g_1, g_2, and V. In both cases only the current density relations change. In the former case we have

$$J_1 = \nabla(\mu_\beta^{(1)}(T) T n) - \mu_\beta^{(1)}(T) n \nabla V,$$
$$J_2 = \nabla(\mu_\beta^{(2)}(T) T^2 n) - \mu_\beta^{(2)}(T) T n \nabla V,$$

and in the latter case

$$J_i = \nabla g_i - \frac{g_i}{T(g_1,g_2)} \nabla V, \quad i = 1,2.$$

The electron density is given in terms of g_1 and g_2 by (see (2.17))

$$n(g_1,g_2) = \frac{Q(T(g_1,g_2),0)}{P_\beta(T(g_1,g_2),2)} T(g_1,g_2)^\beta g_1. \tag{2.19}$$

The energy relaxation term in the variables g_1 and g_2 now writes (recall that $T_0 = 1$)

$$W = \frac{3}{2\tau_\beta(T)T} \left(\frac{g_1}{\mu_\beta^{(1)}(T)} - \frac{g_2}{\mu_\beta^{(2)}(T)} \right). \tag{2.20}$$

In order to compute the electron temperature in terms of g_1 and g_2, we have to invert the following function (see (2.17)):

$$f(T) \stackrel{\text{def}}{=} \frac{P_\beta(T,3)}{P_\beta(T,2)} T = \frac{g_2}{g_1}. \tag{2.21}$$

This is possible if and only if the derivative of f is positive for all $T > 0$. The following lemma shows that this is true if and only if the diffusion matrix (L_{ij}) is positive definite. Now, this property has to be satisfied in order to get a well-posed mathematical problem.

LEMMA 2.1. *Let the hypotheses* (H1)–(H3) *hold. Then*

$$f'(T) = \frac{\det(L_{ij})}{(Tg_1)^2}. \tag{2.22}$$

Proof. Using the relation

$$TP'_\beta(T,\ell-1) = P_\beta(T,\ell) - (\ell-\beta-2)P_\beta(T,\ell-1),$$

which can be proved by integration by parts, we obtain

$$f'(T) = P_\beta(T,2)^{-2}[P_\beta(T,4)P_\beta(T,2) - P_\beta(T,3)^2].$$

Then, from the formulas

$$\det(L_{ij}) = e^{2\mu/T}T^{4-2\beta}[P_\beta(T,4)P_\beta(T,2) - P_\beta(T,3)^2]$$

and $n = Q(T,0)Te^{\mu/T}$ (see (2.10) and (2.11)), it follows that

$$f'(T) = \left(\frac{Q(T,0)T^{\beta-1}}{P_\beta(T,2)n}\right)^2 \det(L_{ij}) = \frac{\det(L_{ij})}{(Tg_1)^2}. \qquad \square$$

For later reference, we rewrite the complete energy-transport model in the (g_1, g_2, V) formulation:

$$-\text{div } J_1 = 0, \tag{2.23}$$

$$-\text{div } J_2 = -J_1\cdot\nabla V + W, \tag{2.24}$$

$$J_1 = \nabla g_1 - \frac{g_1}{T}\nabla V, \tag{2.25}$$

$$J_2 = \nabla g_2 - \frac{g_2}{T}\nabla V, \tag{2.26}$$

$$\lambda^2\Delta V = n - C(x) \quad \text{in } \Omega, \tag{2.27}$$

subject to the mixed Dirichlet–Neumann boundary conditions

$$g_1 = g_{D,1}, \quad g_2 = g_{D,2}, \quad V = V_D \text{ on } \Gamma_D, \tag{2.28}$$

$$J_1\cdot\nu = J_2\cdot\nu = \nabla V\cdot\nu = 0 \text{ on } \Gamma_N, \tag{2.29}$$

where we have set $g_{D,i} = g_i(n_D, T_D)$, $i = 1, 2$. The functions n and W depend on g_1 and g_2 according to (2.19) and (2.20), respectively. The dependence of T on g_1 and g_2 is given by the nonlinear equation (2.21).

2.4. A nonparabolic band approximation. In this section we compute the diffusion coefficients and the energy relaxation term for nonparabolic band diagrams in the sense of Kane. Related models incorporating nonparabolic bands can be found in [9, 36]. Moreover, we show that for the parabolic band approximation, we get the same relations as in the physical literature [9, 22].

The nonparabolic band structure in the sense of Kane [20] is defined as follows:

(H4) Let the energy $\varepsilon(k)$ satisfy

$$\varepsilon(1+\alpha\varepsilon) = \frac{k^2}{2m^*}.$$

The constant m^* is the (scaled) effective electron mass given by $m^* = m_0 k_B T_0/\hbar^2 k_0^2$, where m_0 is the unscaled effective mass, k_0 is a typical wave vector, and $\alpha > 0$ is the (scaled) nonparabolicity parameter. Notice that we get a parabolic band diagram if $\alpha = 0$.

The assumption (H4) implies $\gamma(Tu) = 2m^*Tu(1+\alpha Tu)$, and by introducing the functions

$$p_\beta(\alpha T,\ell) = \int_0^\infty \frac{1+\alpha Tu}{(1+2\alpha Tu)^2} u^{\ell-\beta-1}e^{-u}du,$$
$$q(\alpha T,\ell) = \int_0^\infty (1+\alpha Tu)^{1/2}(1+2\alpha Tu)u^{1/2+\ell}e^{-u}du,$$

we can rewrite P_β and Q as (see section 2.2)

$$P_\beta(T,\ell) = \frac{2}{3\phi_0(2N_0+1)m^*}Tp_\beta(\alpha T,\ell),$$
$$Q(T,\ell) = 2\pi(2m^*)^{3/2}T^{1/2}q(\alpha T,\ell).$$

Therefore, the electron density and internal energy from (2.11) become

$$n = N(T)T^{3/2}e^{\mu/T}, \quad E = \frac{q(\alpha T,1)}{q(\alpha T,0)}Tn,$$

where $N(T) = 2\pi(2m^*)^{3/2}q(\alpha T,0)$. For the mobilities (2.18) we get the expressions

$$\mu_\beta^{(i)}(T) = \mu_0\frac{p_\beta(\alpha T,i+1)}{q(\alpha T,0)}T^{-1/2-\beta}, \quad i=1,2.$$

Here, the mobility constant μ_0 is given by

$$\mu_0 = \left(3\pi\phi_0(2N_0+1)m^*(2m^*)^{3/2}\right)^{-1}.$$

Furthermore, introducing

$$r_\beta(\alpha T) = \int_0^\infty (1+\alpha Tu)(1+2\alpha Tu)^2u^{1+\beta}e^{-u}du,$$

we obtain (see (2.12))

$$R_\beta(T) = (2m^*)^3 r_\beta(T)T,$$

and the energy relaxation time (2.13) becomes

$$\tau_\beta(T) = \tau_0\frac{3q(\alpha T,0)}{2r_\beta(\alpha T)}T^{1/2-\beta},$$

where

$$\tau_0 = \left(2\pi\phi_0(2m^*)^{3/2}\right)^{-1}.$$

Notice that the function r_β is in fact a polynomial:

$$r_\beta(\alpha T) = \Gamma(\beta+2) + 5\Gamma(\beta+3)\alpha T + 8\Gamma(\beta+4)(\alpha T)^2 + 4\Gamma(\beta+5)(\alpha T)^3.$$

The symbol Γ denotes the Gamma function defined by

$$\Gamma(s) = \int_0^\infty u^{s-1}e^{-u}du, \quad s > 0.$$

(Here we use the hypothesis $\beta > -2$.)

Finally, the energy relaxation term (2.20) can be rewritten as

$$W = \frac{T^{2\beta-1}}{\mu_0\tau_0} r_\beta(\alpha T)\left(\frac{g_1}{p_\beta(\alpha T, 2)} - \frac{g_2}{p_\beta(\alpha T, 3)}\right).$$

In the parabolic band approximation case ($\alpha = 0$) the above expressions simplify. Since $q(0,0) = \Gamma(3/2) = \sqrt{\pi}/2$ and $q(0,1) = \Gamma(5/2) = 3\sqrt{\pi}/4$, we get for the electron density and the internal energy the well-known relations

$$n = (2\pi m^*)^{3/2}T^{3/2}e^{\mu/T}, \quad E = \frac{3}{2}Tn.$$

In order to compute the mobilities and the energy relaxation time, we have to specify the parameter β. As mentioned in section 2.2, in the literature the values $\beta = 1/2$ (used by Chen et al. [9]) and $\beta = 0$ (used by Lyumkis et al. [22]) have been employed.

First let $\beta = 1/2$. Then $p_{1/2}(0,2) = \sqrt{\pi}/2$ and $p_{1/2}(0,3) = r_{1/2}(0) = 3\sqrt{\pi}/4$ and therefore,

$$\mu_{1/2}^{(1)}(T) = \mu_0 T^{-1}, \quad \mu_{1/2}^{(2)}(T) = \frac{3}{2}\mu_0 T^{-1}, \quad \tau_{1/2}(T) = \tau_0.$$

Hence, we get the same current density relations and the same energy relaxation term as Chen et al. in [9]:

$$\begin{aligned} J_1 &= \mu_0\Big(\nabla n - \frac{n}{T}\nabla V\Big), \\ J_2 &= \frac{3}{2}\mu_0\Big(\nabla(nT) - n\nabla V\Big), \\ W &= \frac{3}{2}\,\frac{n(T_0 - T)}{\tau_0}. \end{aligned}$$

The energy-transport model with the above relations will be called the *Chen model*.

When $\beta = 0$, we have $p_0(0,2) = r_0(0) = 1$, $p_0(0,3) = 2$, and

$$\mu_0^{(1)}(T) = \frac{2\mu_0}{\sqrt{\pi}}T^{-1/2}, \quad \mu_0^{(2)}(T) = \frac{4\mu_0}{\sqrt{\pi}}T^{-1/2}, \quad \tau_0(T) = \frac{3\sqrt{\pi}}{4}\tau_0 T^{1/2},$$

so that the current densities and the energy relaxation term become

$$\begin{aligned} J_1 &= \frac{2\mu_0}{\sqrt{\pi}}\Big(\nabla(nT^{1/2}) - \frac{n}{T^{1/2}}\nabla V\Big), \\ J_2 &= \frac{4\mu_0}{\sqrt{\pi}}\Big(\nabla(nT^{3/2}) - nT^{1/2}\nabla V\Big), \\ W &= \frac{2}{\sqrt{\pi}}\,\frac{n(T_0 - T)}{\tau_0 T^{1/2}}. \end{aligned}$$

The energy transport equations with these expressions will be called the *Lyumkis model*.

We conclude this section with a remark on the choice of the parameters. In order to determine the energy-transport model completely, the parameters α, β, ϕ_0, N_0, and k_0 have to be chosen. The mobility constant μ_0 depends on ϕ_0, N_0, and k_0 (the dependence on k_0 comes in via m^*), and the constant τ_0 depends on ϕ_0 and k_0. Instead of choosing the parameters ϕ_0, N_0, and k_0, we prescribe μ_0 and τ_0 whose values (depending on the semiconductor material) can be derived from physical experiments.

3. Numerical approximation. In the following we describe in detail the discretization of the one-dimensional energy flux continuity equations (2.24), (2.26) by means of an exponential fitting mixed finite element method. The discretization of (2.23), (2.25) is similar but simpler (since the zeroth order term and the right-hand side of (2.23) are zero). The Poisson equation (2.27) is discretized with a P_1 finite element scheme. Consequently, in the following, V denotes a piecewise linear function and V_x its (piecewise constant) derivative. The exponential fitting mixed finite element method introduced for the drift-diffusion continuity equation (cf. [6, 7, 8, 24]) can be sketched as follows: (i) transformation of the problem by means of the Slotboom variable to a symmetric form; (ii) discretization of the symmetric form with mixed finite elements (consequently, the flux is introduced as an independent variable); (iii) suitable discrete change of variable to rewrite the equations in terms of the original variables g_2. Due to the nonconstant electron temperature, a Slotboom variable does not exist in the present case. As a starting point of the discretization scheme we define a "local" Slotboom variable, assuming that the temperature is a prescribed piecewise constant function defined in the global iteration process. We refer to the end of the section for an explicit choice of the procedure. A related idea has been used in [19] for the discretization of the nonlinear drift-diffusion continuity equation.

More precisely, introduce a partition $0 = x_0 < x_1 < \cdots < x_N = 1$ of $(0,1)$ and set $I_i = (x_{i-1}, x_i)$, $h_i = x_i - x_{i-1}$ for $i = 1, \ldots, N$, and $h = \max_i h_i$. We denote by $\overline{T}$ the piecewise constant approximation of the temperature (see (3.22) for the precise definition). The equations to be solved are then

$$J_2 = (g_2)_x - g_2 V_x/\overline{T}, \tag{3.1}$$

$$-(J_2)_x + \overline{c}_2 g_2 = -J_1 V_x + \overline{c}_1 g_1, \tag{3.2}$$

where we set

$$\overline{c}_\ell = \frac{3}{2\overline{T}\tau_\beta(\overline{T})\mu_\beta^{(\ell)}(\overline{T})},$$

for $\ell = 1, 2$, and, for simplicity of notation, we denote again by J_ℓ, g_ℓ, for $\ell = 1, 2$, the variables.

In each interval I_i, "local" Slotboom variables are introduced by

$$y_2 = e^{-V/\overline{T}} g_2 \quad \text{in } I_i, \tag{3.3}$$

and (3.1) and (3.2) are written in the interval I_i as

$$e^{-V/\overline{T}} J_2 - (y_2)_x = 0, \tag{3.4}$$

$$-(J_2)_x + \overline{c}_2 e^{V/\overline{T}} y_2 = -J_1 V_x + \overline{c}_1 g_1. \tag{3.5}$$

A similar idea for the transformation of the energy-transport equations has been used in [17]. Jerome [15] and Jerome and Shu [16] have employed a slightly different Slotboom transformation by introducing $\phi(x) = \int_0^x V_x(s)/T(s)ds$.

To define the mixed finite element scheme we follow [24], where a monotonic scheme for the two-dimensional current continuity equation in the presence of zeroth order term has been developed. The finite dimensional space for the flux variable contains functions of $L^2(\Omega)$, which are in each interval polynomials of the form $\sigma(x) = a_i + b_i P_i(x)$, with a_i, b_i constant and $P_i(x)$ a second order polynomial uniquely defined in the interval I_i as follows. Let $P(x)$ be the second order polynomial with the following properties:

$$\int_0^1 P(x)dx = 0, \quad P(0) = 0, \quad P(1) = 1, \tag{3.6}$$

that is, $P(x) = 3x^2 - 2x$. Moreover, it holds that $\int_0^1 P'(x)dx = 1, \int_0^1 P(x)^2 dx = \frac{2}{15}$. We define $P_i(x)$ (depending on V) by

$$P_i(x) = -P\left(\frac{x_i - x}{h_i}\right) \qquad \text{if } i_{min} = i - 1, \tag{3.7}$$

$$P_i(x) = P\left(\frac{x - x_{i-1}}{h_i}\right) \qquad \text{if } i_{min} = i, \tag{3.8}$$

where i_{min} is the point of minimum of the potential $V(x)$ in the interval I_i. We shall denote by V_{min} its minimum value. Notice that the minimum is always attained at one end point of the interval, since V is linear in I_i. If $V(x)$ is constant in I_i, we define $P_i(x) = P(\frac{x - x_{i-1}}{h_i})$.

Let us introduce the following finite dimensional spaces:

$$\begin{aligned} X_h &= \{\sigma \in L^2(\Omega) \,:\, \sigma(x) = a_i + b_i P_i(x) \text{ in } I_i,\ i = 1, \ldots, N\}, \\ W_h &= \{\xi \in L^2(\Omega) \,:\, \xi \text{ is constant in } I_i,\ i = 1, \ldots, N\}, \\ \Lambda_{h,\chi} &= \{q \text{ is defined at the nodes } x_0, \ldots, x_N\, q(x_0) = \chi(0),\ q(x_N) = \chi(1)\}. \end{aligned}$$

The mixed-hybrid approximation of (3.1)–(3.2) is then as follows:

Find $J_2^h \in X_h$, $\overline{g}_2^h \in W_h$, $g_2^h \in \Lambda_{h,g_{D,2}}$, such that

$$\sum_{i=1}^N \left(\int_{I_i} A_i J_2^h \sigma + \int_{I_i} B_i \overline{g}_2^h \sigma_x - \left[e^{-V/\overline{T}} g_2^h \sigma \right]_{x_{i-1}}^{x_i} \right) = 0, \tag{3.9}$$

$$\sum_{i=1}^N \left(-\int_{I_i} (J_2^h)_x \xi + \int_{I_i} \overline{c}_2 \overline{g}_2^h \xi \right) = \sum_{i=1}^N \int_{I_i} (-J_1^h V_x + \overline{c}_1 \overline{g}_1^h)\xi, \tag{3.10}$$

$$\sum_{i=1}^N [q J_2^h]_{x_{i-1}}^{x_i} = 0 \tag{3.11}$$

for all $\sigma \in X_h$, $\xi \in W_h$, $q \in \Lambda_{h,0}$. $J_1^h \in X_h$ is the approximation of the current density J_1, $\overline{g}_1^h \in W_h$ is the piecewise constant approximation of g_1, stemming from the discretization of the current continuity equation (see (3.19)–(3.21) below). In the first equation A and B denote the piecewise constant functions (approximation of

$e^{-V/\overline{T}}$) defined in each interval I_i by

$$A|_{I_i} = A_i \overset{\text{def}}{=} \frac{1}{h_i}\int_{x_{i-1}}^{x_i} e^{-V(s)/\overline{T}}ds, \quad i=1,\ldots,N,$$
$$B|_{I_i} = B_i \overset{\text{def}}{=} e^{-V_{min}/\overline{T}}, \qquad\qquad i=1,\ldots,N.$$

J_2^h is an approximation of the energy flux J_2, $\overline{g}_2^h$ is a piecewise constant approximation of g_2, and g_2^h is an approximation of g_2 at the nodes (see [3, 23]). The first equation is obtained from a weak version of (3.4), using integration by parts and summation over all I_i together with the inverse of the Slotboom transformation (3.3). Notice that the discrete inverse transformation is not the same for the variables $\overline{g}_2^h$ and g_2^h. We refer to [24] for a detailed discussion on the need of different approximations of the exponential function due to (possibly) large values of V_x. The second equation is a discrete weak version of (3.2), obtained from (3.5), where $e^{V/\overline{T}}$ is approximated by B^{-1} and the discrete inverse Slotboom transformation for $\overline{g}_2^h$ is used. The third equation implies the continuity of J_2^h at the nodes.

The variables J_2^h and $\overline{g}_2^h$ can be eliminated a priori by static condensation, leading to a final algebraic system in the variables g_2^h only. We write $J_2^h \in X_h$ as

$$J_2^h(x) = J_{2,i}^0 + J_{2,i}^1 P_i(x) \quad \text{for } x \in I_i, \tag{3.12}$$

for some constants $J_{2,i}^0$, $J_{2,i}^1$, $i=1,\ldots,N$. Set $\overline{g}_{2,i} = \overline{g}_2^h|_{I_i}$, $g_{2,i} = g_2^h(x_i)$, $V_i = V(x_i)$, and $q_i = q(x_i)$. Taking $\sigma \in X_h$ such that $\sigma = 1$ in I_i and $\sigma = 0$ elsewhere in (3.9) gives

$$h_i A_i J_{2,i}^0 = e^{-V_i/\overline{T}} g_{2,i} - e^{-V_{i-1}/\overline{T}} g_{2,i-1}.$$

The integral in the definition of A_i can be computed explicitly and we arrive after elementary computations at

$$J_{2,i}^0 = \frac{V_i - V_{i-1}}{2\overline{T}} \coth\left(\frac{V_i - V_{i-1}}{2\overline{T}}\right)\frac{g_{2,i} - g_{2,i-1}}{h_i} - \frac{g_{2,i} + g_{2,i-1}}{2\overline{T}}\frac{V_i - V_{i-1}}{h_i}. \tag{3.13}$$

This discretization can be seen as a nonlinear Scharfetter–Gummel scheme (cf. [6]). The constants $J_{2,i}^1$ are computed by using (3.10) once $\overline{g}_{2,i}$ is given. Indeed, taking $\xi = 1$ in I_i and $\xi = 0$ elsewhere in (3.10), it follows that

$$J_{2,i}^1 = \overline{c}_2 h_i \overline{g}_{2,i} - h_i r_i, \tag{3.14}$$

where we set $r_i = \frac{1}{h_i}\int_{I_i}(-J_1^h V_x + \overline{c}_1 \overline{g}_1^h)dx$. Taking now $\sigma \in X_h$ such that $\sigma = P_i(x)$ in I_i and $\sigma = 0$ elsewhere in (3.9), we obtain

$$\frac{2}{15} h_i A_i J_{2,i}^1 = -e^{-V_{min}/\overline{T}}\overline{g}_{2,i} + e^{-V_{min}/\overline{T}} g_{2,i_{min}}. \tag{3.15}$$

Using (3.14) and (3.15), we can eliminate $J_{2,i}^1$ and get

$$\overline{g}_{2,i}^h = (\overline{\gamma}\ \overline{c}_2 + 1)^{-1}(\overline{\gamma} r_i + g_{2,i_{min}}), \tag{3.16}$$

where $\overline{\gamma} = \frac{2}{15} h_i^2 A_i e^{V_{min}}$. Replacing (3.16) into (3.14) we get $J_{2,i}^1$ in terms of $g_{2,i}$:

$$J_{2,i}^1 = \frac{\overline{c}_2 h_i}{\overline{\gamma}\ \overline{c}_2 + 1} g_{2,i_{min}} - \frac{h_i}{\overline{\gamma}\ \overline{c}_2 + 1} r_i. \tag{3.17}$$

Finally, (3.11), with $q_i = 1$ and $q_k = 0$ for all $k \neq i$, gives

$$J^0_{2,i} + J^1_{2,i} P_i(x_i) = J^0_{2,i+1} + J^1_{2,i+1} P_{i+1}(x_i), \qquad i = 1, \ldots, N. \tag{3.18}$$

We recall that, due to definition (3.6)–(3.8), $P_i(x_i) = 0$ ($P_{i+1}(x_i) = 0$, respectively) if the minimum of V on I_i is in x_{i-1} (x_{i+1}, respectively); otherwise it is $P_i(x_i) = 1$ ($P_{i+1}(x_i) = -1$, respectively). Using the expression (3.13) for $J^0_{2,i}$ and (3.17) for $J^1_{2,i}$, the last equation (3.18) can be written in terms of the variables $g_{2,i}$ only, giving rise to a tridiagonal algebraic system, with the (positive) contribution of the zeroth order term appearing only in the diagonal entry. Then the energy flux J^h_2 is computed locally in each interval by (3.12) and $\overline{g}^h_2$ is computed locally by (3.16).

Discretizing the current continuity equation (2.23), (2.25) with the same scheme and applying the (simpler) static condensation procedure (J^h_1 is piecewise constant in this case), we obtain

$$J^0_{1,i} = J^0_{1,i+1}, \qquad i = 1, \ldots, N, \tag{3.19}$$

with

$$J^0_{1,i} = \frac{V_i - V_{i-1}}{2\overline{T}} \coth\left(\frac{V_i - V_{i-1}}{2\overline{T}}\right) \frac{g_{1,i} - g_{1,i-1}}{h_i} - \frac{g_{1,i} + g_{1,i-1}}{2\overline{T}} \frac{V_i - V_{i-1}}{h_i}. \tag{3.20}$$

Moreover, the analogue of (3.16) gives the upwind expression

$$\overline{g}_{1,i} = g_{1,i_{min}}, \qquad i = 1, \ldots, N. \tag{3.21}$$

In order to complete the scheme, we still have to specify how the piecewise constant temperature $\overline{T}$ is defined. The temperature is defined implicitly in terms of g_1 and g_2 according to the nonlinear equation (2.21). Lemma 2.1 shows that this equation can be solved uniquely. Numerically, we define $\overline{T}$ in each interval I_i as the approximate solution of

$$\frac{\overline{g}_{2,i}}{\overline{g}_{1,i}} = f(\overline{T}_i), \qquad i = 1, \ldots, N, \tag{3.22}$$

with $\overline{T}_i \overset{\text{def}}{=} \overline{T}|_{I_i}$ and $\overline{g}_{1,i}$, $\overline{g}_{2,i}$ given by the mixed scheme (see (3.21), (3.16)). The nonlinear equation reduces to a linear one when $\alpha = 0$ (parabolic band). For $\alpha > 0$ a single iteration of the (scalar) Newton scheme is sufficient to obtain $\overline{T}$ with an accuracy of 10^{-8}, when the initial guess is the temperature at the previous global iteration procedure step. Moreover, f' can be explicitly computed by (2.22).

For the discretization of the two-dimensional problem, one can freeze the temperature, defined in the global iteration procedure, and use the ideas of [24].

In contrast to the strongly coupled equations (2.1)–(2.4) in the variables μ/T and $-1/T$, the two continuity equations (2.23) and (2.24) are *weakly* coupled through the temperature (which varies only slowly during the iterations). Consequently, we defined the global iteration procedure as follows. The temperature is frozen at the previous iteration step, and a full Newton method is used to solve the nonlinear system in g_1, g_2, and V. At each iteration, the temperature is updated according to equation (3.22). The associated linear system is solved by using a GMRES solver. Finally, we remark that a Gummel-type iteration procedure can be employed (instead of the Newton method) in the parabolic band case.

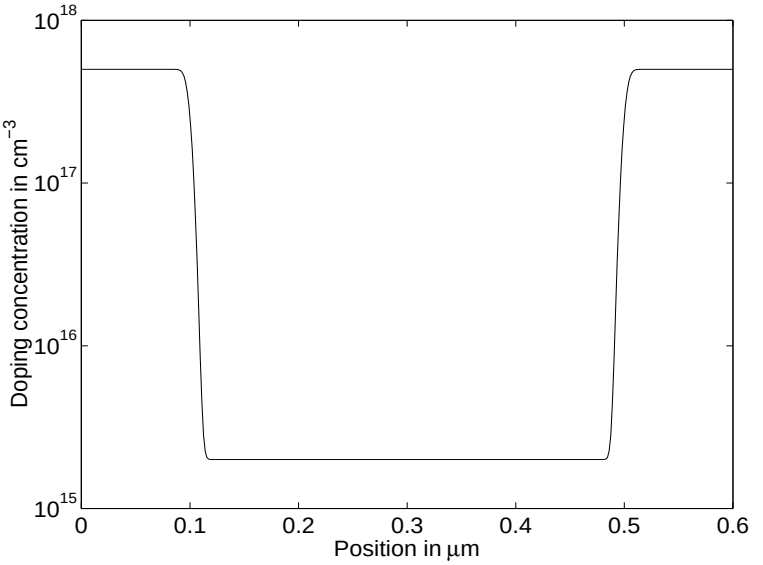

FIG. 4.1. *Doping concentration in the n^+nn^+ diode.*

4. Numerical results. As a numerical example we present the simulation of a one-dimensional n^+nn^+ ballistic silicon diode which is a simple model for the channel of a MOS transistor. The semiconductor domain is given by the interval $\Omega = (0, \ell^*)$ with $\ell^* > 0$. In the n^+-regions the maximal doping concentration is $5 \cdot 10^{17}\,\mathrm{cm}^{-3}$; in the n-channel the minimal doping profile is $2 \cdot 10^{15}\,\mathrm{cm}^{-3}$. The doping profile is shown in Figure 4.1. The length of the n^+-regions is $0.1\,\mu$m, whereas the length of the channel region equals $0.4\,\mu$m.

The numerical values of the physical parameters (for a silicon diode) are given in Table 4.1.

On the boundary points $x = 0$ and $x = \ell^*$ we assume that the (unscaled) total space charge $C - n$ vanishes and that the (unscaled) temperature has the ambient temperature

$$n(0) = n(\ell^*) = c_1, \qquad T(0) = T(\ell^*) = T_0, \qquad V(0) = 0, \quad V(\ell^*) = -U,$$

where $U > 0$ is the applied voltage. We take the value $U = 1.5\,\mathrm{V}$. The unscaled relaxation time τ_0 and the low-field mobility μ_0 depend on ϕ_0 and k_0 (see section 2.4). These parameters are chosen such that τ_0 and μ_0 take the values shown in Table 4.1. We have chosen the data such that our results can be compared to the numerical results of the literature (see, e.g., [9, 27, 34]).

We perform numerical results for a uniform mesh of 100 nodes. In Figure 4.2 we present the electron temperature for vanishing and nonvanishing nonparabolicity parameter α using Lyumkis's model. As expected the temperature in the n-channel is high; i.e., the electrons are "hot." The maximal temperature for $\alpha = 0$ is $T = 3970\,\mathrm{K}$ and $T = 3240\,\mathrm{K}$ for $\alpha = 0.5\,(\mathrm{eV})^{-1}$. The corresponding thermal energies are $E_{th} = \frac{3}{2}k_BT = 0.51\,\mathrm{eV}$ and $E_{th} = 0.42\,\mathrm{eV}$, respectively. Therefore, the temperature is reduced due to the nonparabolicity effects. Similar results can be observed by employing Chen's model (Figure 4.3). Here, the maximal temperature (thermal energy) values are $T = 2330\,\mathrm{K}$ ($E_{th} = 0.30\,\mathrm{eV}$) for $\alpha = 0$ and $T = 1610\,\mathrm{K}$

TABLE 4.1
Physical parameters.

Parameter	Physical meaning	Numerical value
q	elementary charge	$1.6 \cdot 10^{-19}\,\mathrm{As}$
ε_s	permittivity constant	$10^{-12}\,\mathrm{AsV^{-1}cm^{-1}}$
μ_0	(low field) mobility constant	$1.5 \cdot 10^3\,\mathrm{cm^2V^{-1}s^{-1}}$
U_T	thermal voltage at $T_0 = 300\,\mathrm{K}$	$0.026\,\mathrm{V}$
ℓ^*	length of the device	$0.6\,\mu\mathrm{m}$
ℓ_0	length of the n^+ region	$0.1\,\mu\mathrm{m}$
c_0	doping concentration in the n region	$2 \cdot 10^{15}\,\mathrm{cm^{-3}}$
c_1	doping concentration in the n^+ region	$5 \cdot 10^{17}\,\mathrm{cm^{-3}}$
τ_0	energy relaxation time	$0.4 \cdot 10^{-12}\,\mathrm{s}$
α	nonparabolicity parameter	$0.5\,(\mathrm{eV})^{-1}$

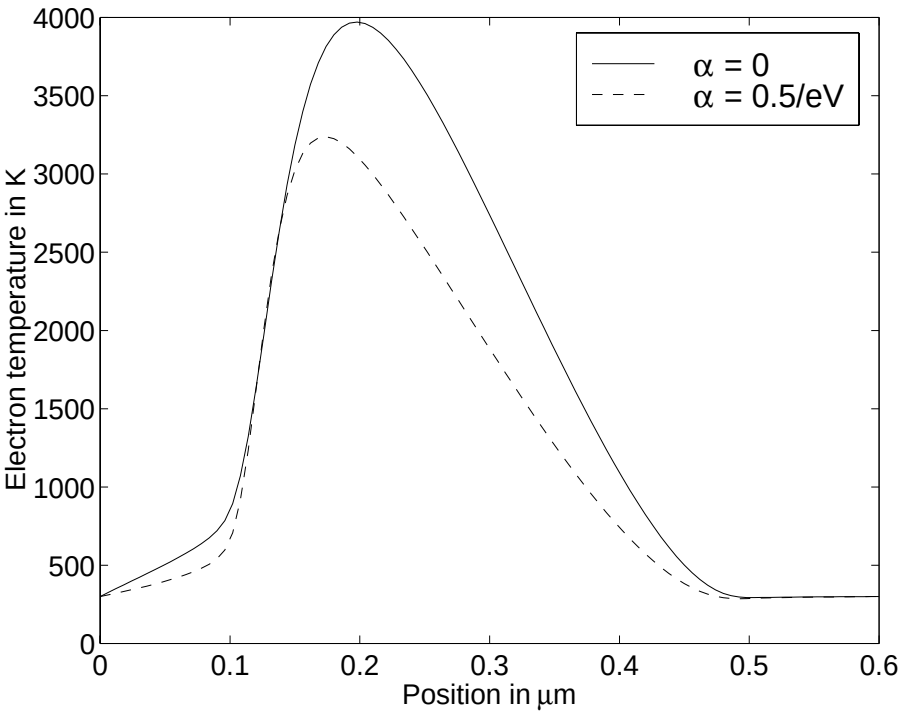

FIG. 4.2. *Electron temperature versus position in a ballistic diode using Lyumkis's model.*

($E_{th} = 0.21\,\mathrm{eV}$) for $\alpha = 0.5\,(\mathrm{eV})^{-1}$. The *effective* scaled relaxation time in the Lyumkis model is $(3\sqrt{\pi}/4)\tau_0\sqrt{T}$ and τ_0 in the Chen model. Therefore, the effective relaxation time in the Chen model is smaller than that in the Lyumkis model, and we expect that the maximal temperature in the Chen model is smaller than in the Lyumkis model. This observation follows from the fact that in the vanishing relaxation-time limit, the temperature relaxes to the lattice temperature, and it is confirmed by our numerical experiments.

In Figure 4.4 the electron mean velocity for the two different values of the nonparabolicity parameter α using Lyumkis's model is shown. The mean velocity u is

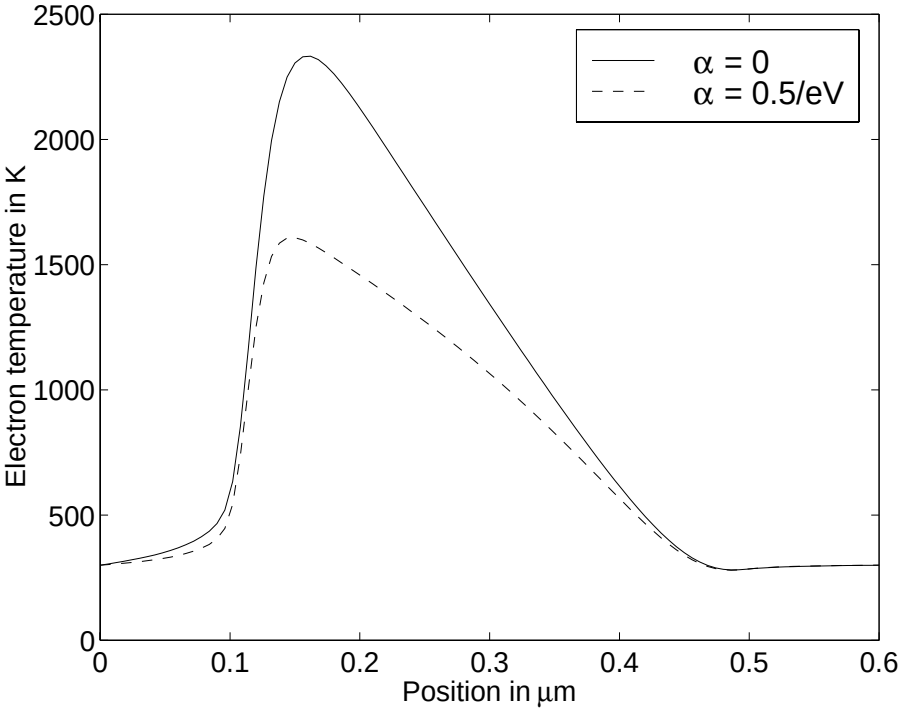

FIG. 4.3. *Electron temperature versus position in a ballistic diode using Chen's model.*

defined by $u = J_1/(qn)$. The spurious velocity overshoot peak at the left junction becomes smaller for nonvanishing nonparabolicity parameter. The maximal mean velocity for $\alpha = 0$ is $u = 2.92 \cdot 10^7$ cm/s and $u = 1.51 \cdot 10^7$ cm/s for $\alpha = 0.5\,(\mathrm{eV})^{-1}$. The same effect can be observed using Chen's model (see Figure 4.5), where the spurious velocity overshoot spike almost vanishes for $\alpha = 0.5\,(\mathrm{eV})^{-1}$. The maximal velocities are $u = 1.44 \cdot 10^7$ cm/s for $\alpha = 0$ and $u = 1.25 \cdot 10^7$ cm/s for $\alpha = 0.5\,(\mathrm{eV})^{-1}$.

The mean velocities for the nonparabolic case, using Chen's or Lyumkis's models, are compared to the mean velocity from the standard drift-diffusion model in Figure 4.6. In the latter model, no velocity saturation effects are taken into account, i.e., the drift-diffusion model equals the energy-transport equations in the case of *constant* temperature. The velocity overshoot from the drift-diffusion model is much larger than for the energy-transport equations (Figure 4.6). This can be explained by the fact that the total energy of the energy-transport model is composed of the thermal *and* the kinetic energy, whereas the total energy of the drift-diffusion model is determined only by the kinetic energy.

In Figure 4.7 we present the current-voltage characteristics for the different energy-transport models. The particle current density J_1 is always smaller in nonparabolic band situations. Its dependence on the applied voltage U seems to be sublinear. Indeed, in the voltage range $U \in [0.5\mathrm{V}, 1.5\mathrm{V}]$, the dependence of J_1 on U is approximately $J_1 \sim U^\gamma$, where γ is between 0.88 and 1, depending on the model (see Table 4.2). We remark that increasing the number of nodes does not change the values of the current.

TABLE 4.2
Slopes of the logarithmic current-voltage curves for $U \in [0.5\,V, 1.5\,V]$.

Model	slope
Lyumkis: $\alpha = 0.0$	1.00
Lyumkis: $\alpha = 0.5/\text{eV}$	0.88
Chen: $\alpha = 0.0$	0.90
Chen: $\alpha = 0.5/\text{eV}$	0.90

TABLE 4.3
RE for the variables.

N	RE for ψ_h	RE for T_h	RE for n_h	RE for $g_{2,h}$
50	$7.23 \cdot 10^{-2}$	$8.63 \cdot 10^{-2}$	$2.37 \cdot 10^{-2}$	$3.13 \cdot 10^{-2}$
100	$3.47 \cdot 10^{-2}$	$4.16 \cdot 10^{-2}$	$6.52 \cdot 10^{-3}$	$9.72 \cdot 10^{-3}$
200	$1.69 \cdot 10^{-2}$	$1.89 \cdot 10^{-2}$	$2.26 \cdot 10^{-3}$	$3.76 \cdot 10^{-3}$
400	$8.0 \cdot 10^{-3}$	$7.56 \cdot 10^{-3}$	$8.08 \cdot 10^{-4}$	$1.45 \cdot 10^{-3}$

In Table 4.3 we report on the relative errors for the computed variables using the Chen model in the parabolic band situation. As a reference solution we choose the computed solution with a mesh of $N+1 = 1201$ nodes. The relative error (RE) for ψ_h is defined by $\|\psi_h - \psi\|_{H^1}/\|\psi\|_{H^1}$, where ψ_h is the discrete solution with discretization parameter $h = 1/N$. From Table 4.3 it can be seen immediately that the order of convergence for the relative error for ψ_h is one, which is expected. The relative errors for T_h, n_h, $g_{2,h}$ are defined as above but in the L^2-norm. Since $n = g_1$ in the Chen model, we do not need to report on the error for g_1. The orders of convergence for T_h, n_h, and $g_{2,h}$ are 1.23, 1.62, and 1.48, respectively. Similar results are obtained by employing the Lyumkis model and nonparabolic band situations, except that the order of convergence for n_h is smaller due to the nonlinear dependence of n_h on T_h.

5. Conclusions. In this paper we have derived energy-transport models for semiconductors for general nonparabolic band diagrams. The diffusion coefficients and the energy relaxation term can be written analytically in terms of the electron density and the temperature if nonparabolic bands in the sense of Kane are considered. The energy-transport models are completely derived from the semiconductor Boltzmann equation. There appear two parameters: the nonparabolicity parameter α and the parameter in the definition of the momentum relaxation time β. For parabolic bands ($\alpha = 0$), we recover two models already studied in the literature: the so-called Lyumkis model ($\beta = 0$) [22] and the so-called Chen model ($\beta = 1/2$) [9].

Thanks to a drift-diffusion formulation valid for a large class of energy-transport models, we presented a mixed exponential fitting finite element discretization of the stationary equations and numerical experiments of a ballistic diode in one space dimension. It turns out that the spurious velocity overshoot peak is smaller in Chen's model than in Lyumkis' model and for nonparabolic bands compared to parabolic ones. Furthermore, the spurious peak almost vanishes in the nonparabolic Chen model. This shows that the energy-transport models describe the charge flow of electrons in a ballistic diode with reasonable accuracy.

REMARKS ON HIGH-RESOLUTION SPLIT SCHEMES COMPUTATION*

M. BEN-ARTZI†, J. FALCOVITZ†, AND U. FELDMAN†

Abstract. The high-resolution generalized Riemann problem (GRP) conservation laws scheme for compressible flows combined with Strang-type operator splitting is applied to computing an initial value problem having a discontinuous initial data. Imperfect representation of the initial data on the Cartesian grid, where the smooth curve of discontinuity is approximated by a jagged line, gives rise to spurious waves when using high-resolution integration with operator splitting. The nature of these waves is clarified by comparison to a one-dimensional model. We demonstrate that it is not the operator splitting that gives rise to these waves, but rather the better quality of the hyperbolic (one-dimensional) solver, which is not degraded by the operator splitting. It is expected that this property of retaining sharp features of initial data will also be produced by other second-order conservation laws schemes.

1. Introduction.

Consider the numerical solution of compressible time-dependent flow in two space dimensions, where the discontinuous initial data consists of two uniform states, U_L, U_R, separated by a curve $\mathcal{L}$. The fluid is initially at rest; i.e., all velocities vanish. The solutions are computed via the generalized Riemann problem (GRP) conservation laws scheme [1, 2, 3], using a Cartesian grid of square cells. When $\mathcal{L}$ intersects grid cells, the initial data specified in those cells cannot conform exactly to the given initial data. Thus we used three methods of initialization to clarify the effect of these alternates on the numerical solution. It was found that computation results were quite sensitive to the particular procedure by which the initial cell data was adjusted to approximately represent the exact initial data. By comparing the 2-D solutions with equivalent quasi-1-D solutions, using high-resolution and low-resolution methods, we conclude that the spurious waves result from the high-resolution property of the method that is not degraded by two-dimensional (2-D) operator splitting. Indeed, in the low-resolution one-dimensional (1-D) computation those waves were smeared out.

The purpose of this note is to present our findings in this regard and to suggest that caution be exercised when computing multidimensional flows with discontinuous initial data. It is noted in passing that the problem of averaging discontinuous data in cells is encountered also in multimaterial Eulerian schemes, where uniform velocity and pressure are maintained in mixed cells, following finite-difference integration of the conservation laws.

In section 2 we discuss the three alternate initialization methods. In section 3 we give a brief account of the governing equations, the GRP conservation laws

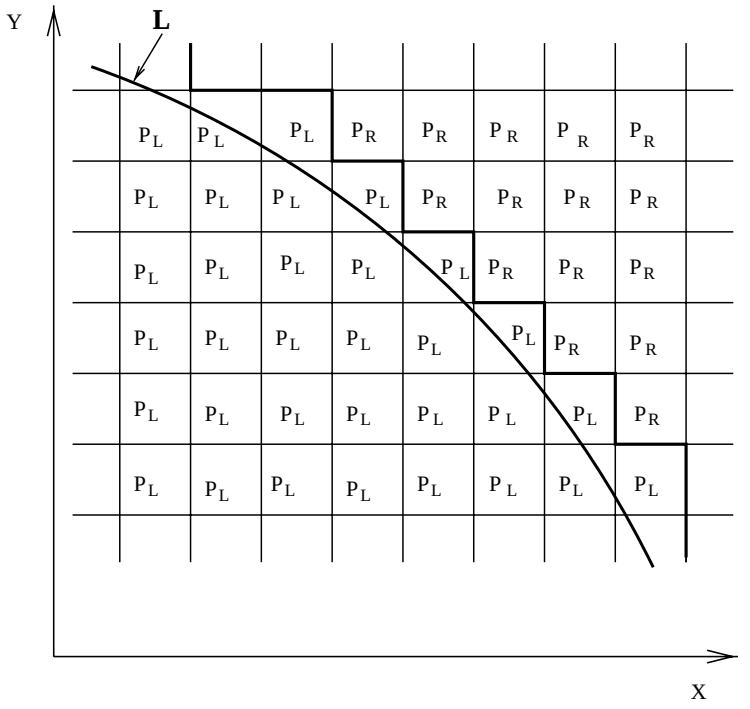

FIG. 1. *Discontinuous initial data. Line L approximated in a stepwise manner.*

scheme, and the "splitting strategy." Section 4 describes the computation results for an exploding high-pressure cylinder, demonstrating the previously outlined findings.

2. Initialization of discontinuous data. In this study, the data in cells intersected by $\mathcal{L}$ were initialized as follows. The density was always obtained by a "conservative averaging" of the exact discontinuous data (i.e., area-weighted average of the two densities ρ_L, ρ_R per cell).

The pressure, however, was obtained by one of the following approximation procedures:

(A) Initial cell pressure is set to either one of the two pressures p_L, p_R. This amounts to a "pressure-jump-preserving" stepwise approximation of $\mathcal{L}$ (as illustrated in Figure 1), where $\mathcal{L}$ is approximated by a "jagged" curve, thereby introducing "hot spots" in cells having high pressure and low density.

(B) Cell pressure is obtained by a "conservative averaging" procedure identical to the density initialization outlined above (see the schematic illustration in Figure 2). This procedure is consistent with the conservation laws (the pressure for a perfect gas being proportional to the energy per unit volume), at the sacrifice of spreading the pressure jump over one or two cells.

(C) Initial cell pressure in intersected cell "A," where the density is ρ_A, is set to be equal to p_A, so that (ρ_L, p_L) and (ρ_A, p_A) lie on the same isentropic curve in the (ρ, p) plane. We take (ρ_L, p_L) to be the "high-pressure state"; i.e., $p_L > p_R$.

3. Outline of the numerical method. Assuming an inviscid compressible fluid and an ideal gas equation of state, the 2-D flow is governed by the laws for

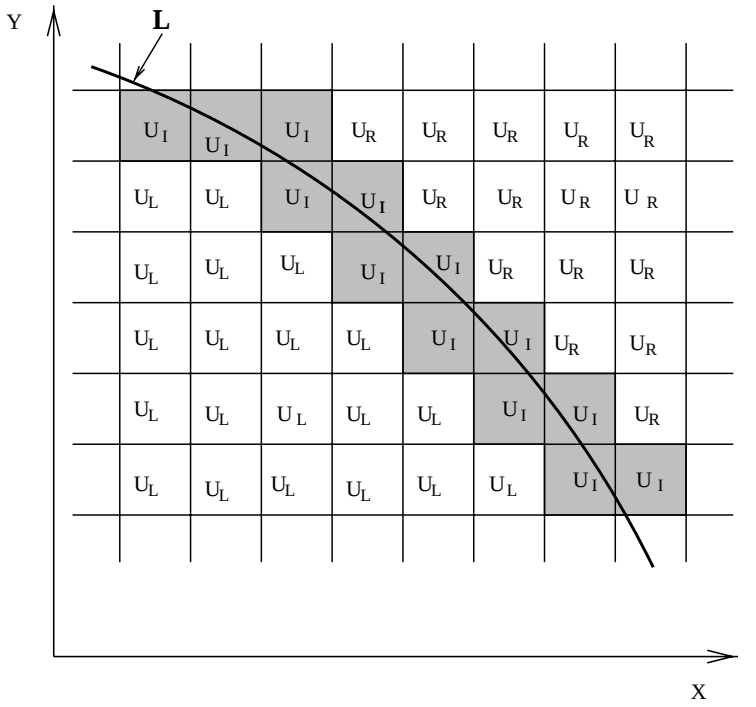

FIG. 2. *Initial data approximated by intermediate state* U_I.

conservation of mass, momentum, and energy, expressed in Cartesian coordinates (x, y) as

$$\partial_t U + \partial_x F(U) + \partial_y G(U) = 0,$$

$$U(x,y,t) = \begin{bmatrix} \rho \\ \rho u \\ \rho v \\ \rho E \end{bmatrix}, \quad F(U) = \begin{bmatrix} \rho u \\ \rho u^2 + p \\ \rho uv \\ u(\rho E + p) \end{bmatrix}, \quad G(U) = \begin{bmatrix} \rho v \\ \rho uv \\ \rho v^2 + p \\ v(\rho E + p) \end{bmatrix}, \tag{1}$$

$$p = (\gamma - 1)\rho e, \quad \gamma = \text{constant } > 1, \tag{2}$$

$$e = E - \frac{1}{2}(u^2 + v^2). \tag{3}$$

In (1) we denote by ρ, p, e, E, u, v the density, pressure, specific-energy, specific total energy, and (x, y)-velocity components, respectively.

The 2-D finite-difference approximation to (1) is formulated as a "Strang-type" operator splitting [6], using the GRP scheme [1, 2, 3] as the 1-D finite-difference operator. Our point is that this basic algorithm gives a very accurate result, even under the difficult conditions where the initial data is discontinuous at a curved surface cutting obliquely across the Cartesian grid, as will be demonstrated by comparison to an equivalent 1-D solution. The splitting procedure can be outlined as follows.

The system (1) is split into the two simpler systems,

$$\partial_t U + \partial_x F(U) = 0, \tag{4i}$$

$$\partial_t U + \partial_y G(U) = 0. \tag{4ii}$$

Loosely speaking, the system (4) is taken to mean that the evolution of an initial state U_o by (1) over a short time interval Δt can be approximated by evolving U_o first subject to (4i) (over time Δt) obtaining a state U_1, then evolving U_1 in accordance with (4ii) again over time Δt.

Let $L_x(\Delta t)$, $L_y(\Delta t)$, $L(\Delta t)$ denote finite-difference approximation operators for the integration by a time-step Δt of (4i), (4ii), (1), respectively. Then the "Strang-type" operator sequence

$$L(\Delta t) = L_x\left(\frac{1}{2}\Delta t\right) L_y(\Delta t) L_x\left(\frac{1}{2}\Delta t\right) \tag{5}$$

is a second-order finite-difference approximation to (1).

The 1-D operators $L_x(\Delta t), L_y(\Delta t)$ are given by the "GRP solvers" [1, 2, 3]. The basic idea (in terms of L_x) is the following. The grid consists of the sequence of points $x_{i+1/2} = (i+1/2)\Delta x$, $i = 0, 1, 2, \ldots, i_{\max}$, where Δx is the grid spacing and the cell i is the interval $x_{i-1/2} < x < x_{i+1/2}$. $U(x, y, t)$ (for a fixed y) is approximated at time $t = t_n = n\Delta t$ by $U^n(x, y)$, a piecewise linear distribution in cells, having the average value U_i^n in cell i. The finite-difference GRP solver L_x, yielding $\{U_i^{n+1}\}_{i=1}^{i_{\max}}$ in terms of $\{U_i^n\}_{i=1}^{i_{\max}}$ is explicitly given by

$$U_i^{n+1} = U_i^n - \frac{\Delta t}{\Delta x}\left[F(U)_{i+1/2}^{n+1/2} - F(U)_{i-1/2}^{n+1/2}\right], \tag{6}$$

where the time-centered fluxes $F(U)_{i+1/2}^{n+1/2}$ are determined analytically from solutions to GRPs that arise at the cell interfaces $x_{i+1/2}$. More specifically, these solutions are obtained as exact (up to second-order) solutions to (4i) when the initial data is given by the piecewise linear distribution $U^n(x, y)$. We refer the reader to [1, 2, 3] for a comprehensive account of the GRP analysis and the resulting scheme, and to [4] for an overview of GRP methods and their diverse applications.

4. Numerical examples. We consider a case where the initial value problem could be reduced to a flow problem with cylindrical symmetry (at least up to a certain time). Thus the solution could be obtained by an accurate (quasi-) 1-D GRP code.

Turning to the sample problem, we set the data as follows. The fluid is an ideal gas having $\gamma = 1.4$ and it is initially at rest everywhere. The curve $\mathcal{L}$ is the circle centered at $(x, y) = (0, 0)$, having radius $R = 50$. It encircles the high-pressure state $(\rho_L, p_L) = (10, 20)$, while the low-pressure state outside $\mathcal{L}$ is $(\rho_R, p_R) = (1, 1)$. The computational domain is the square $(0 < x < 100, 0 < y < 100)$, which is divided into a grid of 100×100 square cells. The integration was carried out with a constant time step $\Delta t = 0.16$, up to the final time of $T = 12.5$. Compliance with the Courant–Friedrichs–Lewy stability condition [5] throughout the computation was verified.

As a reference calculation, we used the quasi-1-D GRP scheme (with the same grid spacing of $\Delta r = 1$) to compute the flow profiles, as functions of the radial coordinate r. The pressure and density profiles are shown in Figure 3. They represent a sharp outgoing shock wave.

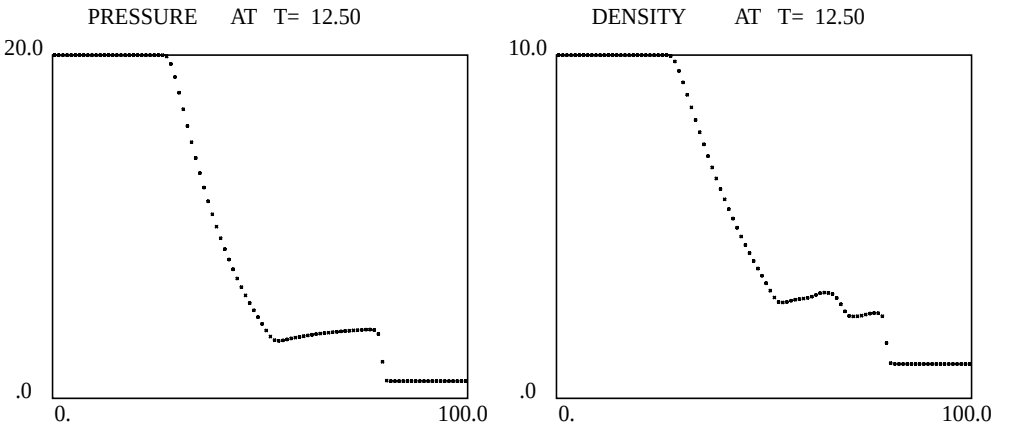

FIG. 3. *One-dimensional computation results.*

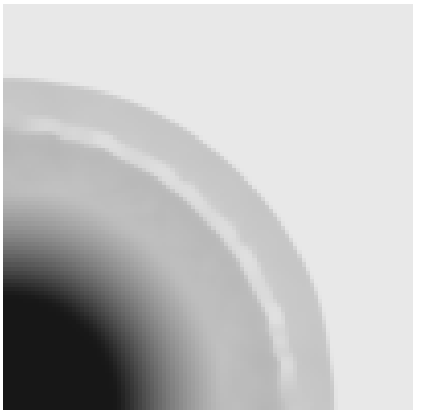

FIG. 4. *Density—Gray scale plot on* (x, y) *plane. Initial conditions type* (A).

Taking the initial data as in case (A) of section 2 (corresponding to Figure 1), and using the 2-D code as outlined above, we obtain the density distribution shown in Figure 4. We show only the density distribution, since the pressure is continuous at the contact discontinuity (see Figure 3) and does not show the spurious wave. The amount of gray shading is proportional to the density. In Figure 5 we display the cross section of the same profile along the diagonal. It is noted that all 1-D and 2-D plots are drawn to the same scale. The diagonal profile, having a mesh size larger by a factor of $\sqrt{2}$, resolves the same flow region by proportionately fewer cells.

On the other hand, by taking the initial data as in cases (B) or (C) of section 2, the results were in excellent agreement with the quasi-1-D computation (Figure 3). In Figure 6 we show the density distribution, using the initial data as in case (C) (i.e., in boundary cells the values (ρ, p) lie on the isentropic curve through (ρ_L, p_L)). Figure 7 shows the cross section of that profile along the diagonal.

The discrepancy between the results shown in Figures 4–7 can be explained as follows. In any boundary cell (namely, a cell intersected by the initial contact discontinuity), the value of the density is determined uniquely by mass conservation. Thus the only "degree of freedom" is expressed in the initial pressure value. Let $\bar{\rho}$ be the

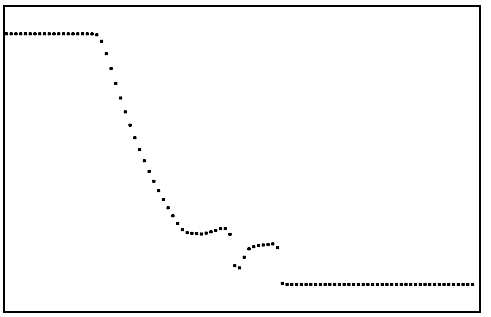

FIG. 5. *Density—Diagonal cross section. Initial conditions type* (A).

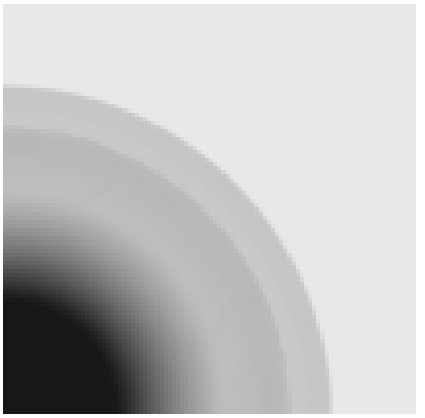

FIG. 6. *Density—Gray scale plot on* (x, y) *plane. Initial conditions type* (C).

density in that cell, and let $p_L, \bar{p}$ be the values determined by the strategies (A), (C), respectively. Clearly $p_L > \bar{p}$. Thus in case (A) the boundary cell constitutes a "hot spot," having entropy (hence temperature) higher than its neighboring cells. This "high-temperature" shell (along the contact discontinuity) is then propagated by the flow, as shown in Figures 4 and 5.

To support this explanation, we show in Figure 8 the results of a quasi-1-D calculation, using the same initial data as that used in Figure 3, except for one change, as follows. In the cell immediately to the right of the initial jump, where formerly (Figure 3) p_L, ρ_L were set, we "planted" density $\bar{\rho} = \frac{1}{2}(\rho_L + \rho_R)$ and $\bar{p} = p_L$, thus generating again a "hot spot." The results in Figure 8 are now in agreement with those of Figure 5. In particular, we stress that the split algorithm did not smooth out this spurious wave in the second-order computation.

We further underline this point by repeating the 2-D computation using the (first-order accurate) Godunov method, with type (A) initial conditions. These are the initial conditions that produced the "dip" in the density in the second-order accurate computation (see Figure 5). The results are shown as a density distribution along the diagonal in Figure 9. By comparing Figure 9 to Figure 5, it is evident that the first-order scheme does not retain the sharp features in the initial data as well as the second-order scheme, since the "dip" in the density distribution has disappeared. This should not be taken to mean that the first-order (Godunov) scheme is superior to the second-order (GRP) scheme. Rather, it demonstrates that due to its low

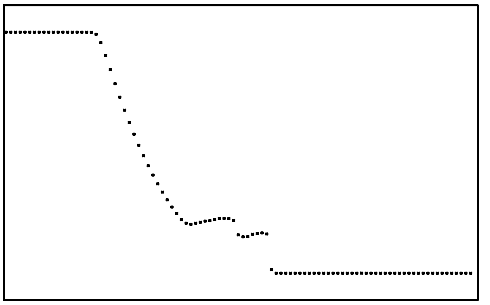

FIG. 7. *Density—Diagonal cross section. Initial conditions type* (C).

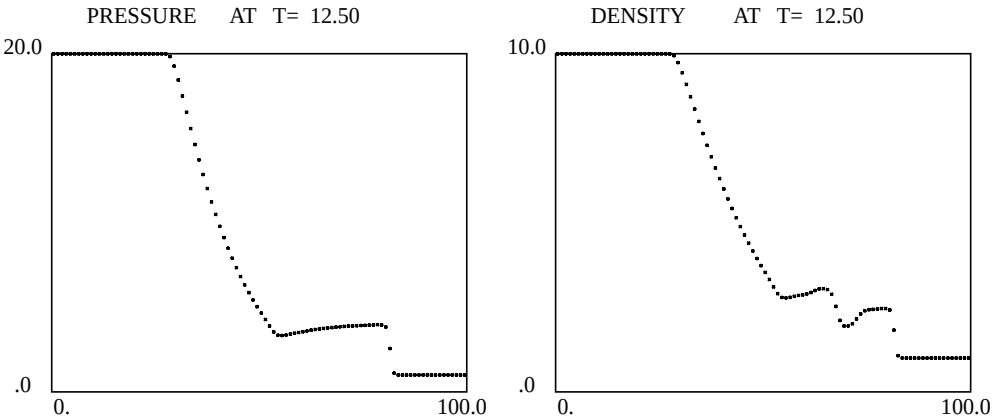

FIG. 8. *One-dimensional computation with data similar to type* (A).

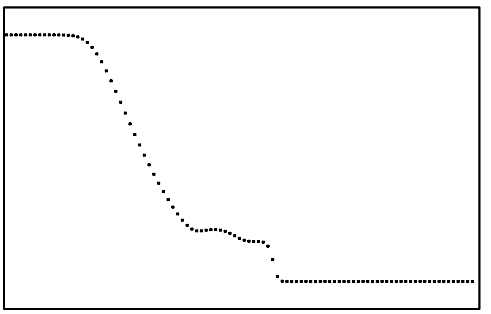

FIG. 9. *First-order density diagonal cross section. Initial conditions type* (A).

resolution quality, the Godunov scheme smears out the narrow "hot spot" that had been deliberately introduced in the initial data.

We may therefore summarize this study by pointing out the significance of approximating discontinuous initial data. In cases where geometric restrictions make it impossible to retain the exact initial data, some singular features may accompany the contact discontinuity curve in the ensuing flow. In particular, we note that these features are not smoothed out by the operator-splitting strategy associated with the high-resolution GRP scheme. It is expected that this property of retaining sharp fea-

tures of initial data will not be restricted to our GRP scheme. Other high-resolution schemes of the extended Godunov type may well exhibit similar characteristics.

A TIME-REVERSIBLE, REGULARIZED, SWITCHING INTEGRATOR FOR THE N-BODY PROBLEM*

ANNE KVÆRNØ† AND BEN LEIMKUHLER‡

Abstract. This article describes a gravitational N-body integration algorithm conserving linear and angular momentum and time-reversal symmetry. Forces are dynamically partitioned based on interbody separation, so that the long-range forces are evaluated relatively rarely, and close approaches are treated by an efficient regularization technique. The method incorporates an automatic stepsize adjustment based on a Sundman time-transformation. Although the scheme is formally second order, the most intensive computations (the close-approach dynamics) are executed at higher order, thus improving the overall accuracy. Numerical experiments indicate that the method can effectively treat few-body gravitational problems with two-body close approaches, and it compares favorably with other schemes presented in the literature.

Key words. N-body problems, Hamiltonian systems, time-reversible discretization, smooth switching functions

1. Introduction.

The N-body problem of celestial mechanics is described by a Hamiltonian,

$$\mathscr{H}(\boldsymbol{p},\boldsymbol{q}) = T(\boldsymbol{p}) + f(\boldsymbol{q}),$$

where $T : \mathbb{R}^{3N} \to \mathbb{R}$ and $f : \mathbb{R}^{3N} \to \mathbb{R}$ are smooth kinetic and potential energy functions defined in terms of the individual momenta $\boldsymbol{p}_1, \boldsymbol{p}_2, \ldots, \boldsymbol{p}_N \in \mathbb{R}^3$ and positions $\boldsymbol{q}_1, \boldsymbol{q}_2, \ldots, \boldsymbol{q}_N \in \mathbb{R}^3$ of the bodies by

$$T(\boldsymbol{p}) = T(\boldsymbol{p}_1, \boldsymbol{p}_2, \ldots, \boldsymbol{p}_N) := \sum_{i=1}^{N} \frac{|\boldsymbol{p}_i|^2}{2m_i},$$

and

$$f(\boldsymbol{q}) = f(\boldsymbol{q}_1, \boldsymbol{q}_2, \ldots, \boldsymbol{q}_N) := -\sum_{i=1}^{N-1} \sum_{j=i+1}^{N} \frac{Gm_i m_j}{r_{ij}}, \qquad r_{ij} = |\boldsymbol{q}_i - \boldsymbol{q}_j|,$$

where G is the gravitational constant and m_i represents the mass of the ith body.

The N-body problem is the seminal problem of dynamical systems, and study of its solutions, ergodic properties, and topological structure continues to generate a

great deal of mathematical and physical interest (see [18] and other recent references therein). Its numerical simulation also remains of terrific importance. This problem is solved routinely in studies of stellar and planetary dynamics [37, 27, 1], and related problems arise in quasi-classical studies of atomic systems [29, 10, 32].

While many numerical schemes for the N-body problem have been developed over the years [13, 1], these codes may exhibit deficiencies in very long time integration or in scattering studies. One approach to improving the qualitative behavior of numerical simulation methods is to incorporate some of the many geometric properties of the phase flow, such as time-reversal symmetry, symplectic structure, and integrals such as angular momentum. Methods which preserve symmetries and invariants are sometimes referred to as *geometric* or *mechanical* integrators [30, 21, 3]. Symplectic and symmetric algorithms for smooth N-body trajectories (without close approaches) have been successfully used for long-term simulations of the solar system [37].

Close approaches introduce both theoretical and computational challenges for the Coulombic N-body problem. In the approach described here, we assume that there is potentially a large number of bodies, but at any given time only a few bodies are engaged in very close approaches. None of the geometric algorithms can be expected to preserve structure or provide substantial efficiency improvements under frequent discontinuous switchings (such as may be used for close encounters). This problem was discovered and explained by Calvo and Sanz-Serna [4] in the context of variable stepsize symplectic integration: *frequent changes in the timestepping map lead to a deterioration of the numerical stability of geometric methods.* For variable stepsizes, it turns out to be more practical to use a Sundman or Poincaré-type time-transformation to rescale the vector field or Hamiltonian in such a way that (i) geometric structure is preserved, and (ii) the new system can be solved with a fixed timestep. Articles by Stoffer [33], Hut et al. [17], and Leimkuhler with collaborators [15, 14] developed the use of time-reversible variable stepsizes for N-body problems. More recently several articles have indicated how regularization methods can be incorporated in a reversible or symplectic framework [23, 20, 16].

Another approach to variable stepsize integration, based on a hierarchical splitting, was developed by Skeel and Biesiadecki [31], and we exploit this idea in a somewhat different way to define a *smooth switching* of the close-approaching bodies. We then separate the weaker interactions by splitting, and we identify potential close approaches using *Verlet neighbor lists* [35], partitioning the bodies into small groups. The multiple timestepping framework of molecular dynamics (r-RESPA [34]) allows some control of the amount of computation performed between evaluations of the long-range forces. A Sundman time transformation is also incorporated in the manner of [14, 20].

For problems with only two-body close approaches, much of the computational work following splitting will be in the resolution of isolated pairs. The switches somewhat complicate the dynamics of the two-body pairs (they are no longer pure Kepler problems). We describe an efficient technique for recovering their dynamics, based on a reduced coordinate set, a regularization, and an efficient implementation of a higher order implicit Gauss–Legendre integrator.

When three or more body interactions in close approach must be taken into consideration (in the localized subsystem), a system of relative variables can be introduced and a regularization developed in terms of two-body pairs. In the standard approach based on Kustaanheimo–Stiefel transformation, the coupling of variables in the regularized Hamiltonian makes high-accuracy geometric integrators very costly.

We suggest instead an approach based on relative coordinates, splitting, and two-body pair integration.

Some other methods similar to our own have recently appeared in the astronomical literature. To date, no other writers appear to have successfully combined smooth switching of close encounters, coordinate regularization, and variable stepsize time-reversible integration. Chambers [5] uses a C^1 switch and a splitting into weak and strong terms. The strong terms are integrated using a fixed stepsize method, which, though not itself reversible, is used with a small enough timestep so that these terms can be viewed as exactly resolved. We believe that this approach is inefficient compared to our own, since no time or coordinate regularization is used. Moreover, we find that the radius of the switch, which is critical to the efficiency of the algorithm, can be substantially reduced in our scheme, compared to the observations of Chambers, due to our use of variable stepsize. To implement variable stepsize, Duncan, Levison, and Lee [7] follow the idea of Skeel and Biesiadecki [31], using a hierarchy of shells (inducing a C^1 or C^3 splitting) to reduce stepsize according to body separation. This method is time-reversible—also symplectic—but cannot treat extreme close approaches, for which it is well known that some sort of coordinate regularization is needed. An article by Rauch and Holman [28] considers several techniques (some of which are not geometric integrators) which incorporate switches, together with a time-only regularization ("Poincaré transformation") as in Waldvogel [36], Zare and Szebehely [39], and Mikkola [25]. In numerical experiments, our method generally appears to perform well in comparison with these different alternatives when close approaches are present. Athough very different timestep costs make precise efficiency comparisons difficult, some preliminary comparative discussion may be found in the section on numerical experiments.

The remainder of the article is arranged as follows. In section 2, we introduce the smoothly switched vector field splitting and show how it can be combined with multiple timestepping and the reversible adaptive Verlet method. Section 3 describes how the bodies are partitioned for the purposes of efficient propagation, and section 4 considers in detail the computation of the switched two-body dynamics for close approaching pairs. Section 5 then discusses efficient regularization groups of more than two bodies. Finally, section 6 includes numerical experiments with a Kepler problem and several variants of the "two fixed-points problem" as well as some discussion of comparisons with existing methods presented recently in the astronomical literature.

In summary, we propose a new N-body integrator that combines a time-reversible adaptive stepsize integrator with smooth switches to isolate close approaching bodies. Two-body close encounters are solved by a new efficient, regularized, high order Gauss–Legendre integrator. If more than two bodies are involved in a close interaction, we suggest a new approach to split these into two-body problems. Our integrator could easily be adapted to the Coulombic problems arising in quasi-classical simulations of atomic systems [29, 10, 32, 20], to systems with multiple fixed bodies, or to systems subject to applied fields or arbitrary perturbing potentials, using additional splittings.

2. Smooth switches, splitting, multiple timestepping, and reversible adaptive timestepping. We use the term *smooth switch* to describe a real (backward sigmoidal) function χ which smoothly passes from one to zero in some finite subinterval of $\mathbb{R}_+$:

$$\chi \in C^k(\mathbb{R}_+, [0,1]), \qquad \chi(r) = 1, \quad r < r_-, \qquad \chi(r) = 0, \quad r \geq r_+, \qquad \chi'(r) \leq 0.$$

Piecewise polynomial switches of any desired smoothness can be constructed as follows. First define a polynomial

$$p(x) = \left(1 - \left(\frac{x}{h}\right)^2\right)^{k+1}.$$

This function is positive in $(-h, h)$ and is easily seen to satisfy the conditions $p(0) = 1$, $p^{(l)}(h) = p^{(l)}(-h) = 0$, $l = 0, 1, \ldots, k$. Normalizing the integral of this polynomial on the interval $[-h, h]$ and subtracting from unity results in a new polynomial,

$$q(x) = 1 - \frac{\int_{-h}^{x} p(\xi)d\xi}{\int_{-h}^{h} p(\xi)d\xi}.$$

Now for given r_- and r_+ we set $h = (r_+ - r_-)/2$, $\bar{r} = (r_+ + r_-)/2$; then the function

$$\chi(r) = \begin{cases} 1, & r \le r_-, \\ q(r - \bar{r}), & r_- \le r < r_+, \\ 0, & r \ge r_+ \end{cases} \tag{2.1}$$

is a C^{k+1} switch (See Figure 2.1). The fact that we can choose χ to be piecewise polynomial will be found to have some positive ramifications for the efficiency of our code.

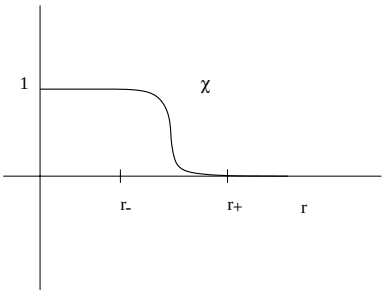

FIG. 2.1. *A smooth switch.*

The purpose of the smooth switch is to limit the high-accuracy resolution of trajectories to close approaching bodies, while reducing the number of force evaluations for weak interactions. We decompose each pair interaction in the gravitational potential using smooth switches:[1]

$$f = \underbrace{-\sum_{i=1}^{N-1}\sum_{j=i+1}^{N} \chi(r_{ij})\frac{Gm_im_j}{r_{ij}}}_{f_{\text{loc}}} + \underbrace{-\sum_{i=1}^{N-1}\sum_{j=i+1}^{N} (1 - \chi(r_{ij}))\frac{Gm_im_j}{r_{ij}}}_{f_{\text{weak}}}.$$

In a two-body problem, there are three distinct regimes in the dynamics of f_{loc}. For separations $r \le r_-$, the dynamics are pure Keplerian. For $r \ge r_+$, the bodies

[1]For simplicity, we here suppose that the parameters r_-, r_+ of each switch are all identical. In many cases, it may be more practical to choose the parameters of the switch dependent on the masses of the particles of the pair. In the related classical atomic model, the switch might also depend on the product of the charges of the particle pair.

are in free motion. For $r \in (r_-, r_+)$, the motion is determined by the (somewhat artificial) dynamics of the switch, integrable dynamics in a decaying force field.

To design a one-step method, we utilize a Hamiltonian splitting of the form $\mathscr{H} = \mathscr{H}_{\rm loc} + f_{\rm weak}$, where

$$\mathscr{H}_{\rm loc} := T + f_{\rm loc}.$$

Let $\mathbf{\Phi}_{t,\mathscr{H}}$ represent the t- flow map on Hamiltonian $\mathscr{H}$. We construct a splitting method using multiple timestepping [34, 9] with m inner substeps:

$$\mathbf{\Phi}_{\Delta t,\mathscr{H}} \approx \hat{\mathbf{\Phi}}_{\Delta t,\mathscr{H}} := \mathbf{\Phi}_{\Delta t, f_{\rm weak}} \left[\hat{\mathbf{\Phi}}_{\frac{1}{m}\Delta t,\mathscr{H}_{\rm loc}} \right]^m.$$

(In most cases, we would take $m = 1$, but the incorporation of multiple timestepping adds some flexibility.) Here $\hat{\mathbf{\Phi}}_{\Delta t,\mathscr{H}_{\rm loc}}$ is a time-reversible approximation method for solving the localized gravitational problem, as described in the next section.

The method $\hat{\mathbf{\Phi}}_{\Delta t,\mathscr{H}}$ is a first order fixed stepsize integrator, and it is not time-reversible. We use this method as the basis for constructing a second order variable stepsize reversible integrator according to the prescription of [14]:

$$\begin{aligned} \begin{pmatrix} \boldsymbol{q}^{n+1/2} \\ \boldsymbol{p}^{n+1/2} \end{pmatrix} &= \hat{\mathbf{\Phi}}_{\frac{1}{2}\Delta t_n,\mathscr{H}} \begin{pmatrix} \boldsymbol{q}^{n} \\ \boldsymbol{p}^{n} \end{pmatrix}, \\ \frac{1}{\Delta t_n} + \frac{1}{\Delta t_{n+1}} &= \frac{2}{g_{n+1/2}\Delta t}, \\ \begin{pmatrix} \boldsymbol{q}^{n+1} \\ \boldsymbol{p}^{n+1} \end{pmatrix} &= \hat{\mathbf{\Phi}}^*_{\frac{1}{2}\Delta t_{n+1},\mathscr{H}} \begin{pmatrix} \boldsymbol{q}^{n+1/2} \\ \boldsymbol{p}^{n+1/2} \end{pmatrix}, \end{aligned} \tag{2.2}$$

where

$$g_{n+1/2} = g(\boldsymbol{q}^{n+1/2}, \boldsymbol{p}^{n+1/2})$$

and $g(\boldsymbol{q}, \boldsymbol{p})$ is the time-reparameterization function, a smooth, positive, scalar-valued function which is invariant under $\boldsymbol{p} \to -\boldsymbol{p}$ (see below). The adjoint method needed above is easily computed since $\hat{\mathbf{\Phi}}_{\Delta t,\mathscr{H}}$ is the composition of symmetric maps:

$$\hat{\mathbf{\Phi}}^*_{\Delta t,\mathscr{H}} = \left[\hat{\mathbf{\Phi}}_{\frac{1}{m}\Delta t,\mathscr{H}_{\rm loc}} \right]^m \mathbf{\Phi}_{\Delta t, f_{\rm weak}}.$$

Although the method is formally second order (symmetric methods have even order [11]), we expect to utilize a higher order integrator for the local interaction dynamics, as described in the next and following sections. Viewed as a second order method, the scheme is therefore expected to have a relatively small leading error constant compared to a method such as Störmer–Verlet, which does nothing special to integrate close approaching bodies. If desired, a third order splitting method could be used in place of $\hat{\mathbf{\Phi}}_{\Delta t,\mathscr{H}}$, resulting in a fourth order method overall. (See [22] for a discussion of how to construct such splittings.)

We anticipate that the considerations for the choice of time-transformation will be similar to those discussed in [2, 20]. To ensure stable integration near close encounters, we need a transformation of the form $g \sim \min_{ij} r_{ij}^2$, where $\min_{ij} r_{ij}$ represents the smallest pair separation. The use of such an approach is not efficient for even moderately difficult trajectories; in the presence of very close encounters the progress

of the integration will practically be halted. Thus, we adopt the control suggested in [20],

$$g_{\min} = \frac{1}{1 + (\min_{ij} r_{ij})^{-3/2}}. \tag{2.3}$$

In some cases, it may be desirable to have a smooth control, in which case we could use

$$g_{\mathrm{sm}} = \frac{1}{1 + \left(\sum_{i<j} r_{ij}^{-3m/2}\right)^{1/m}},$$

where m is a positive integer [2].

3. Integration of $\mathscr{H}_{\mathbf{loc}}$. In this and the following section, we describe the integrator for $\mathscr{H}_{\mathrm{loc}}$. We will assume that the solution is desired on the time interval $[0, \Delta t]$, that initial positions $\boldsymbol{q}^0$ and momenta $\boldsymbol{p}^0$ are provided, and that new values $\boldsymbol{q}^1$ and $\boldsymbol{p}^1$ are to be computed.

Because of the use of switching functions, a relatively small number of the interaction terms are active in $\mathscr{H}_{\mathrm{loc}}$ at any given timestep; most of the particles simply drift linearly with fixed momenta. We introduce the concept of a *local interaction graph* G based on the nonzero potential interactions between the bodies. This graph will be used to limit the local computation (in the relatively expensive regularization variables) to minimal subgroups of bodies. However, there is some question about how to define G. Clearly the vertices of G are the body indices, but what should we take for the edges?

Given vertices i and j, it is evidently not sufficient to add the edge $\bar{ij}$ only when $\|\boldsymbol{q}_i^0 - \boldsymbol{q}_j^0\| \le r_+$, since, during the timestep, the two bodies may move closer to each other and thus have a close interaction by the end of the timestep. Moreover, the one-step methods we propose for integrating the few-body problems will evaluate the forces at an intermediate point in the subinterval. Still it is not sufficient to simply link i and j based on the initial, final, and intermediate steps, since it is necessary to know these interactions *at the start* of the timestep (after all, the whole purpose of constructing the graph is to restrict the computation to local groups!). To define the interaction graph, we therefore need a very cheap method to predict, based only on the initial positions and velocities, which particles have the potential to have a local interaction during the current timestep. The same technique used to construct *Verlet neighbor lists* [35] in molecular dynamics can be used for this purpose.

To identify potential close approaches, we proceed as follows for the ith body (being careful to work with squared distances to avoid computation of extra square roots). We iterate over the bodies with index $j > i$. Define

$$\boldsymbol{\Delta q} = \boldsymbol{q}_i^0 - \boldsymbol{q}_j^0, \qquad \boldsymbol{\Delta p} = \boldsymbol{p}_i^0 - \boldsymbol{p}_j^0.$$

We first compute $\sigma^0 = |\boldsymbol{\Delta q}|^2$. Clearly if $\sigma^0 < r_+^2$, we should add edge $\bar{ij}$ to G, but because our method is heuristic (based only on linear trajectories), we include a safety factor $\beta > 1$ and check instead $\sigma^0 < \beta r_+^2$. Next, we compute the time of closest approach of the linear trajectories through $(\boldsymbol{q}_i^0, \boldsymbol{p}_i^0)$ and $(\boldsymbol{q}_j^0, \boldsymbol{p}_j^0)$:

$$t^* = -\frac{\boldsymbol{\Delta q} \cdot \boldsymbol{\Delta p}}{|\boldsymbol{\Delta p}|^2}.$$

If $t^* \in [0, \Delta t]$, then we compute the squared separation between these two trajectories at t^*, $\sigma^* = |\boldsymbol{\Delta q} + t^* \boldsymbol{\Delta p}|^2$, and check if $\sigma^* < \beta r_+^2$. Finally, we compute the separation at the right endpoint of the time interval, $\sigma^1 = |\boldsymbol{\Delta q} + \Delta t \boldsymbol{\Delta p}|^2$, adding the edge if this is less than βr_+^2.

After updating the interaction graph, we subdivide it into L disjoint connected components $\Omega_1, \Omega_2, \ldots, \Omega_L$. These components will generally consist of one or several indices. The cost of resolving the close approaches rises very rapidly with the number of bodies, while the attainable accuracy diminishes, but close approaches of three or more bodies are rare. In the next section we focus on the case of two-body approaches. Later, we will describe a method for handling higher-body collisions.

4. Fast integrator for the switched problem: Two-body case. The computation of the close encounters is typically the most costly part of the calculation, so substantial algorithmic effort is warranted in the interest of overall efficiency. In this section we describe a technique for two-body approaches based on polar coordinates in the plane of motion, regularization, and the Gauss–Legendre family of higher order implicit Runge–Kutta methods.

Any Hamiltonian system of the form

$$H_{\text{2bdy}} = \frac{1}{2m_1}|\boldsymbol{p}_1|^2 + \frac{1}{2m_2}|\boldsymbol{p}_2|^2 + \phi(|\boldsymbol{q}_1 - \boldsymbol{q}_2|)$$

is integrable. For Kepler's problem, an elegant solution was known at least to Gauss and is detailed in [19]. A number of papers have considered efficient numerical methods for solving the associated nonlinear equation (see, e.g., [24, 26]). A method avoiding all transcendental functions was used in [20], based on implicit midpoint applied in the Kustaanheimo–Stiefel variables, but this scheme may not provide sufficient accuracy in some cases.

Solutions for special cases of the two-body problem with various power potentials are discussed in [8]; however, for *arbitrary* ϕ, the computation of the associated quadrature and nonlinear equations becomes complicated by potential singularities and a sign change of the integrand, and an involved procedure is then needed to perform the computations, including a special quadrature algorithm and case-dependent changes of variables.

Converting to relative coordinates, rotating the plane of motion (with normal $\boldsymbol{n} = (\boldsymbol{q}_1 - \boldsymbol{q}_2) \times (\boldsymbol{p}_1 - \boldsymbol{p}_2) = \text{constant}$) onto the xy coordinate plane, and then introducing polar coordinates gives the Hamiltonian

$$H_{\text{plane}} = \frac{1}{2\bar{m}} p_r^2 + \frac{1}{2\bar{m}} \frac{l^2}{r^2} + \phi(r),$$

where $l = p_\theta$ is the local angular momentum of the particular approaching pair. This is an integrable system. We could proceed to recover the solution by piecing together solutions of the separable scalar ODE

$$\frac{d}{dt} r = \pm \sqrt{2\bar{m} \left(E_0 - \phi(r) - \frac{l^2}{r^2} \right)},$$

where $E_0 = H_{\text{plane}}$ is the energy of the reduced problem. For general ϕ, the numerical solution of this differential equation in terms of quadratures is inefficient. Not only do we have to design an accurate numerical quadrature subject to a switching of sign, but the solution is then obtained only in implicit form, defined by a certain nonlinear

equation. Observe also that there is nothing to prevent $l = 0$; thus arbitrarily close approaches of the bodies (or even collisions) are indeed possible, causing a singularity in the integrand. Despite these problems, a viable method for the general case could undoubtedly be derived based on quadrature, but we are skeptical that it would be as efficient and robust as the alternative we describe in what follows.

The canonical equations of H_{plane} are

$$\begin{aligned}\frac{d}{dt}r &= \frac{1}{\bar{m}}p_r,\\ \frac{d}{dt}p_r &= \frac{1}{\bar{m}}\frac{l^2}{r^3} - \phi'(r),\\ \frac{d}{dt}\theta &= \frac{1}{\bar{m}}\frac{l}{r^2}.\end{aligned}$$

By introducing a new variable $\eta = r \cdot p_r$, performing a Sundman transformation $dt/d\tau = r$, and taking advantage of the constant energy, this system can be written as

$$\frac{d}{d\tau}r = \frac{1}{\bar{m}}\eta, \tag{4.1}$$

$$\frac{d}{d\tau}\eta = 2rE_0 - 2r\phi(r) - r^2\phi'(r), \tag{4.2}$$

$$\frac{d}{d\tau}t = r, \tag{4.3}$$

$$\frac{d}{d\tau}\theta = \frac{1}{\bar{m}}\frac{l}{r}. \tag{4.4}$$

These equations are no longer Hamiltonian; however, the symmetry of the original system is retained. The first three of these equations can be solved independent of the last one. And, since $\phi(r) = -\gamma/r \cdot \chi(r)$, $\chi(r)$ piecewise polynomial, all singularities have been removed from (4.1)–(4.2); thus, at least theoretically, they can be solved even through head-on collisions.

The solution of the regularized equations (4.1)–(4.4) requires an accurate and stable geometric integration method such as the efficiently implemented Gauss–Legendre method described below.

High order is needed in this step because the regularization process (absolutely essential to stable integration) introduces the energy of the two-body problem as a parameter of the differential equations, hence upsetting the iterated-map property which guarantees structural stability properties such as orbital symmetry [20]. Only in the case of a pure Kepler problem is the invariant H_{plane} quadratic, hence conserved by the Gauss methods [6]. Especially in the switching regime of our two-body potential, the energy may fluctuate significantly; thus a high-order method is likely to be needed.

A Gauss–Legendre method for the regularized reduced problem. We will here briefly describe the implementation of a fully implicit Runge–Kutta method applied to the regularized problem (4.1)–(4.4). A discussion of implementation issues for general ordinary differential equations can be found in [12, IV.8]. In this section, we concentrate on issues specific to the given problem, which in what follows will be written as

$$\frac{d^2}{d\tau^2}r = \frac{1}{\bar{m}}f(r), \quad \frac{d}{d\tau}t = r, \quad \frac{d}{d\tau}\theta = \frac{1}{\bar{m}}\alpha(r), \quad \text{and} \quad \eta = \bar{m}\frac{d}{d\tau}r. \tag{4.5}$$

These equations are solved by some (possibly) high order Gauss–Legendre methods [12, IV.5]. Using the standard Butcher notation, the coefficients in an s-stage method are given by a matrix $\boldsymbol{A} = (a_{ij})_{i,j=1}^{s}$ and vectors $\boldsymbol{b} = (b_1, b_2, \dots, b_s)^T$ and $\boldsymbol{c} = (c_1, c_2, \dots, c_s)^T$. Applied to (4.5), it results in the following system of nonlinear equations ($\hat{a}_{ij}$ being the elements of the matrix $\boldsymbol{A}^2$):

$$R_i = r_n + \frac{1}{\bar{m}} c_i \Delta\tau \eta_n + \frac{1}{\bar{m}} \Delta\tau^2 \sum_{j=1}^{s} \hat{a}_{ij} f(R_j), \quad i = 1, 2, \dots, s, \tag{4.6}$$

and the solution is updated by

$$t_{n+1} = t_n + \Delta\tau \sum_{i=1}^{s} b_i R_i, \tag{4.7}$$

$$r_{n+1} = r_n + \Delta\tau \frac{1}{\bar{m}} \eta_n + \frac{1}{\bar{m}} \Delta\tau^2 \sum_{i=1}^{s} \sum_{j=1}^{s} b_i a_{ij} f(R_j), \tag{4.8}$$

$$\eta_{n+1} = \eta_n + \Delta\tau \sum_{i=1}^{s} b_i f(R_i), \tag{4.9}$$

$$\theta_{n+1} = \theta_n + \frac{1}{\bar{m}} \Delta\tau \sum_{i=1}^{s} b_i \alpha(R_i). \tag{4.10}$$

A curious twist is that the timestep $\Delta t_n = t_{n+1} - t_n$ is known, but the corresponding fictive timestep $\Delta\tau$ must be computed. Thus (4.6) and (4.7) must be solved for $R_1, \dots, R_s$ and $\Delta\tau$ simultaneously. Newton iteration techniques normally will be adequate. The Jacobian matrix of this system of $s + 1$ nonlinear equations can be written in block form,

$$\boldsymbol{J} = \begin{pmatrix} \hat{\boldsymbol{J}} & \boldsymbol{v} \\ \boldsymbol{u}^T & w \end{pmatrix}.$$

The elements of the $(s \times s)$-matrix $\hat{\boldsymbol{J}}$ are

$$J_{ij} = \delta_{ij} - \frac{\Delta\tau^2}{\bar{m}} \hat{a}_{ij} f'(R_j),$$

where δ_{ij} is 1 if $i = j$ and otherwise zero, $\boldsymbol{v}$ has elements

$$v_i = -\frac{1}{\bar{m}} c_i \eta_n - \frac{2}{\bar{m}} \Delta\tau \sum_{i=1}^{s} \sum_{j=1}^{s} \hat{a}_{ij} f(R_j),$$

$\boldsymbol{u} = -\Delta\tau \boldsymbol{b}^T$, and $w = -\sum_{i=1}^{s} b_i R_i$. The Jacobian can be computed in the beginning of each step and then held fixed during the iterations. Having a good predictor is critical for the overall success of the method. One option is to use a high order Taylor series approximation, obtained through differentiation of the differential equation. This is especially viable because the function $f(r)$ is piecewise polynomial. Extrapolating values from a previous step (using the collocation polynomial) is inadvisable since the integration of (4.5) over one (outer) step is only a part of the overall algorithm; thus the right-hand side of the equation changes from step to step. For the same reason, the Jacobian cannot be kept fixed over several steps.

For very close encounters, the Jacobian $\boldsymbol{J}$ tends to become singular, and special care has to be taken for the solution of the nonlinear equations.

Since the energy E_0 is used as a parameter in the regularized equations, time symmetry is not really retained. However, since high order methods are used, we are willing to accept this small destruction of time symmetry. In fact, as we will show later, experiments show that this discrepancy in energy has less effect on the time symmetry than the roundoff errors introduced when solving the unregularized equations.

5. Higher-body close encounters. We next briefly consider numerical integrators for the case that a component of the local interaction graph can include three or more bodies. The equations in this case are no longer integrable, so the only possibility is to derive an appropriate numerical discretization scheme. In general, our problem is to integrate numerically a d-body problem with Hamiltonian of the form

$$\frac{1}{2}\sum_{i=1}^{d}\frac{|\boldsymbol{p}_i|^2}{m_i}+\sum_{i=1}^{d-1}\sum_{j=i+1}^{d}\phi(|\boldsymbol{q}_i-\boldsymbol{q}_j|).$$

Due to our use of splitting and time-reparametrization, we can restrict attention to the case where the number of bodies d is small.

As is the usual practice (see, e.g., [23]), we first introduce relative coordinates for the pair separations,

$$\begin{aligned}\boldsymbol{\delta}_1=\boldsymbol{q}_1-\boldsymbol{q}_2,\quad \boldsymbol{\delta}_2=\boldsymbol{q}_1-\boldsymbol{q}_3,\quad \ldots,\quad \boldsymbol{\delta}_{d-1}=\boldsymbol{q}_1-\boldsymbol{q}_d,\\ \boldsymbol{\delta}_d=\boldsymbol{q}_2-\boldsymbol{q}_3,\quad \ldots,\quad \boldsymbol{\delta}_{2d-3}=\boldsymbol{q}_2-\boldsymbol{q}_d,\\ \ldots,\quad \boldsymbol{\delta}_{\frac{1}{2}(d^2-d)}=\boldsymbol{q}_{d-1}-\boldsymbol{q}_d.\end{aligned}$$

Together with the center of mass, the $D=(d^2-d)/2$ variables (although redundant for $d>3$ since in that case $D>d$) are adequate to describe any configuration. Canonical equations can be developed in terms of the relative variables by introducing momenta $\boldsymbol{\pi}_i$ canonically conjugate to the $\boldsymbol{\delta}_i$. Neglecting the center of mass motion, the Hamiltonian becomes

$$H_{\rm rel}=\sum_{i=1}^{D}\frac{|\boldsymbol{\pi}_i|^2}{2\bar{m}_i}+\sum_{i=1}^{D}\sum_{\substack{j=1\\ j\neq i}}^{D}\sigma_{ij}\boldsymbol{\pi}_i\cdot\boldsymbol{\pi}_j+\sum_{i=1}^{D}\phi(|\boldsymbol{\delta}_i|),$$

where $\bar{m}_i=1/(1/m_\alpha+1/m_\beta)$, with m_α and m_β the masses of the bodies of the ith pair, and σ_{ij} is either zero (if the pairs on which $\boldsymbol{\delta}_i$ and $\boldsymbol{\delta}_j$ are based involve no common body) or else $\pm$ the reciprocal of the common mass of the ith and jth pairs of bodies, depending on the order of the differences.

Now there are several ways to proceed. A traditional course, described concisely in [23], is to apply the Kustaanheimo–Stiefel regularizing transformation to all the variables. The kinetic energy metric is then position dependent and rather complicated. The nonseparable nature of the Hamiltonian precludes the use of (known classes of) explicit geometric integrators, leaving us essentially with implicit methods such as the Gauss–Legendre Runge–Kutta methods or Lobatto IIIA-B partitioned Runge–Kutta pairs [11], but in this case, there are no simple reductions of the numbers of variables such as we found in the previous section. For example, a fourth order method for the three-body problem would require the solution of a nonlinear system of dimension $2\times 24=48$ at each step. This is clearly unacceptable in long-term simulations, for which many such nonlinear systems may need to be solved.

Instead, we will look for a splitting of $H_{\rm rel}$ that requires only the solution of two-body problems at each step. The numerical method of the previous section can then be used to solve the two-body problems.

One such splitting would break $H_{\rm rel}$ into two parts,

$$H_{\rm rel} = H_1 + H_2,$$

where

$$H_1 = \sum_{i=1}^{D} \frac{|\boldsymbol{\pi}_i|^2}{2\bar{m}_i} + \sum_{i=1}^{D} \phi(|\boldsymbol{\delta}_i|),$$

and

$$H_2 = \sum_{i=1}^{D} \sum_{\substack{j=1 \\ j\neq i}}^{D} \sigma_{ij} \boldsymbol{\pi}_i \cdot \boldsymbol{\pi}_j.$$

H_1 consists of D decoupled two-body problems, whereas H_2 is only $\boldsymbol{\pi}$ dependent; hence both terms are integrable.

An alternative splitting method would divide H into D parts,

$$H_{\rm rel} = G_1 + G_2 + \cdots + G_D,$$

where

$$G_i = \frac{|\boldsymbol{\pi}_i|^2}{2\bar{m}_i} + \phi(|\boldsymbol{\delta}_i|) + \sum_{\substack{j=1 \\ j\neq i}}^{D} \sigma_{ij} \boldsymbol{\pi}_i \cdot \boldsymbol{\pi}_j.$$

Each of the D terms can be seen to be integrable, since only the ith momentum vector changes during the integration of G_i. In the case of a three-body problem, this splitting has three terms. For higher order, the number would rapidly increase.

The differential equations on $H_{\rm rel}$ are given by, for $i = 1, \ldots, D$,

$$\begin{aligned} \frac{d}{dt}\boldsymbol{\delta}_i &= \frac{1}{\bar{m}_i}\boldsymbol{\pi}_i + \sum_{\substack{j=1 \\ j\neq i}}^{D} \sigma_{ij}\boldsymbol{\pi}_j, \\ \frac{d}{dt}\boldsymbol{\pi}_i &= -\frac{\phi'(|\boldsymbol{\delta}_i|)}{|\boldsymbol{\delta}_i|}\boldsymbol{\delta}_i. \end{aligned}$$

Define $\boldsymbol{L} = \sum_{i=1}^{D} \boldsymbol{\delta}_i \times \boldsymbol{\pi}_i$. Then it is easy to see that

$$\begin{aligned} \frac{d}{dt}\boldsymbol{L} &= \sum_{i=1}^{D} \left(\frac{d}{dt}\boldsymbol{\delta}_i \times \boldsymbol{\pi}_i + \boldsymbol{\delta}_i \times \frac{d}{dt}\boldsymbol{\pi}_i \right) \\ &= \sum_{i=1}^{D} \left(\left(\frac{1}{\bar{m}_i}\boldsymbol{\pi}_i + \sum_{\substack{j=1 \\ j\neq i}}^{D} \sigma_{ij}\boldsymbol{\pi}_j \right) \times \boldsymbol{\pi}_i - \boldsymbol{\delta}_i \times \left(\frac{\phi'(|\boldsymbol{\delta}_i|)}{|\boldsymbol{\delta}_i|}\boldsymbol{\delta}_i \right) \right) \\ &= -\sum_{i=1}^{D} \sum_{\substack{j=1 \\ j\neq i}}^{D} \sigma_{ij}\boldsymbol{\pi}_i \times \boldsymbol{\pi}_j \\ &= 0 \end{aligned}$$

using the antisymmetry of the cross product and the fact that $\sigma_{ij} = \sigma_{ji}$; $\boldsymbol{L}$ can be viewed as a representation of the angular momentum of the system. Moreover, both splittings are also easily seen to conserve angular momentum, since each of the terms has this feature and the discretization is constructed by concatenation of the exact flows (or conserving approximations of the exact flows) on each term.

To obtain higher order methods, we suggest use of the concatenation technique [38, 22, 30]. For the alternative decomposition, second and fourth order splitting methods are also easily derived.

6. Numerical experiments. In the experiments described below, we have used an adaptive Verlet-leapfrog method, for which one step of the method is given by

$$\boldsymbol{\Phi}_{\frac{1}{2}\Delta t_n, f_{\text{weak}}} \circ \hat{\boldsymbol{\Phi}}_{\Delta t_n, \mathscr{H}_{\text{loc}}} \circ \boldsymbol{\Phi}_{\frac{1}{2}\Delta t_n, f_{\text{weak}}}.$$

The stepsize is updated between the steps, using (2.2) with $g = g(\boldsymbol{q}^n, \boldsymbol{p}^n)$, g given by (2.3) or its smooth equivalent.[2] For close encounters, $\hat{\boldsymbol{\Phi}}_{\Delta t_n, \mathscr{H}_{\text{loc}}}$ is solved by an eighth order Gauss method, as described.

Example 1: *The Kepler problem.* Our first example, the two-dimensional Kepler problem, has been chosen to demonstrate the reliability of the smooth switch for solving two-body close encounters. The Hamiltonian is

$$H = \frac{1}{2}(p_1^2 + p_2^2) - \frac{1}{\sqrt{q_1^2 + q_2^2}}.$$

As initial values we choose

$$q_1(0) = 1 + e, \quad q_2(0) = 0, \quad p_1(0) = 0, \quad p_2(0) = \sqrt{(1-e)/(1+e)};$$

thus the solution (q_1, q_2) forms an ellipse with eccentricity e, $0 \le e < 1$, and with period 2π. The smallest distance from the origin is $r_{\min} = 1 - e$. The system with $e = 0.9999$ was integrated over 32 periods.

In the experiment, we compare

(a) the variable stepsize leapfrog method without a switch

with the same method using

(b) a hard switch, meaning that the switch is turned on, that is $\chi = 1$, whenever $r < \bar{r}$ in the beginning of the step; otherwise the switch is turned off;

(c) an improved hard switch, in which linear extrapolation is used to decide whether r is less than $\bar{r}$ over the whole step, in which case the switch is turned on;

(d) the smooth switch (2.1) with $k = 8$.

For the variable stepsize method, the fictive stepsize was $\Delta t = 0.04$ and the average stepsize about 0.01. For the smooth switch we have used $r_+ = 0.02$, $r_m = r_+/8$ and for the hard switches $\bar{r} = (r_+ + r_-)/2$.

The superiority of the smooth switch is clearly demonstrated by Figures 6.1 and 6.2. The adaptive leapfrog without switch suffers from a precession caused by the high energy error in the close domain. The hard switches partly eliminate that precession, but a severe drift in the energy error is introduced. The combination of leapfrog and the smooth switch eliminates both.

Figure 6.3 illustrates how the energy varies over one period. To better visualize the behavior of the methods within the close domain, the energy error is shown as

[2] After the first half step, this is equivalent to the symmetric adaptive Verlet method [14].

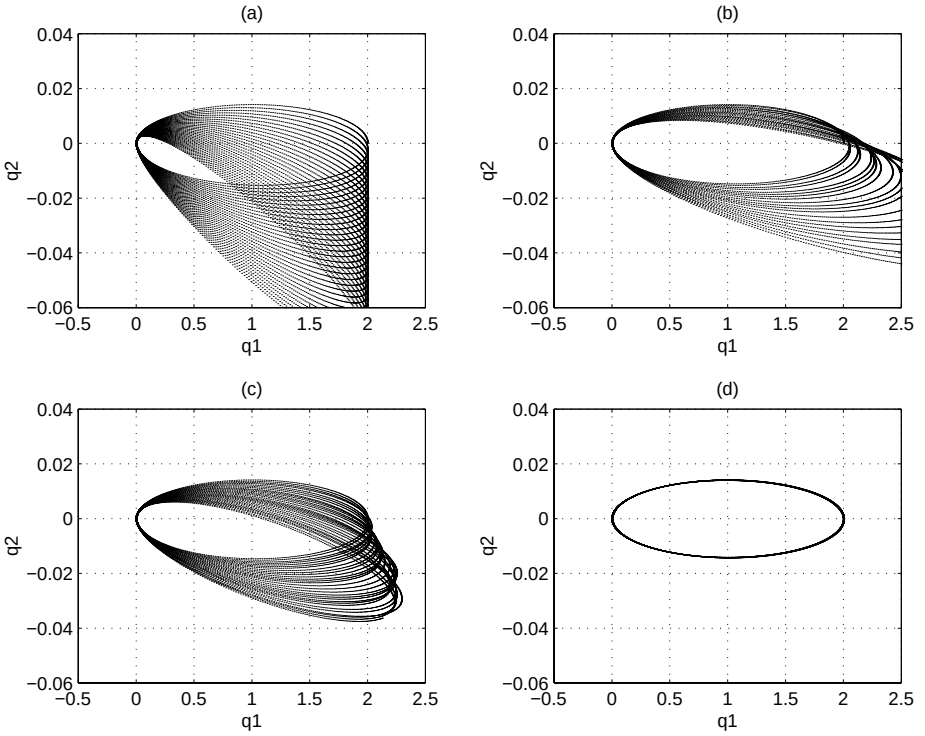

FIG. 6.1. *The orbit of the Kepler problem* ($e = 0.9999$) *solved by the variable stepsize leapfrog method* (a) *without switch, with* (b) *hard switch,* (c) *improved hard switch, and* (d) *smooth switch.*

functions of the number of steps. For comparision, the energy fluctuations for two eccentricities, $e = 0.9999$ and $e = 0.999999$, are shown. We can clearly see how the switches "cut the peak" off the energy error of the leapfrog method. The hard switches are, however, unable to regain the energy level when out of the close domain, a problem that gets worse for higher eccentricities. It is also interesting to notice that the energy error for the smooth switch is almost independent of the eccentricity. However, the smooth switch creates fluctuations in the switching regime. Experiments show that these fluctuations become worse when r_+ and r_- are close to each other.

It is also of interest to see how the switches affect the time symmetry. To this end, the Kepler problem is integrated forward one period and then backward using the same stepsize sequence. Figure 6.4 shows the norm of the displacement of $\boldsymbol{q}$ caused by this process for several choices of $r_{\min} = 1 - e$. Thus, for $r_{\min}$ less than r_+ (or $\bar{r}$ for the hard switches), the orbit is always outside the switching regime. However, when in effect, the simple hard switch ($\star$) destroys the time symmetry completely. It is also interesting to note that the method without switches ($\times$), which is known to retain time symmetry, at least in the theory, loses this property in practice.

This is caused by large rounding errors introduced in solving the unregularized equations close to the singularity. The smooth switch ($\circ$) as well as the improved hard switch ($+$) retain the time symmetry fairly well. Thus, it seems that the benefits of solving the regularized equations outweigh the disadvantage of the energy error introduced in the switching regime.

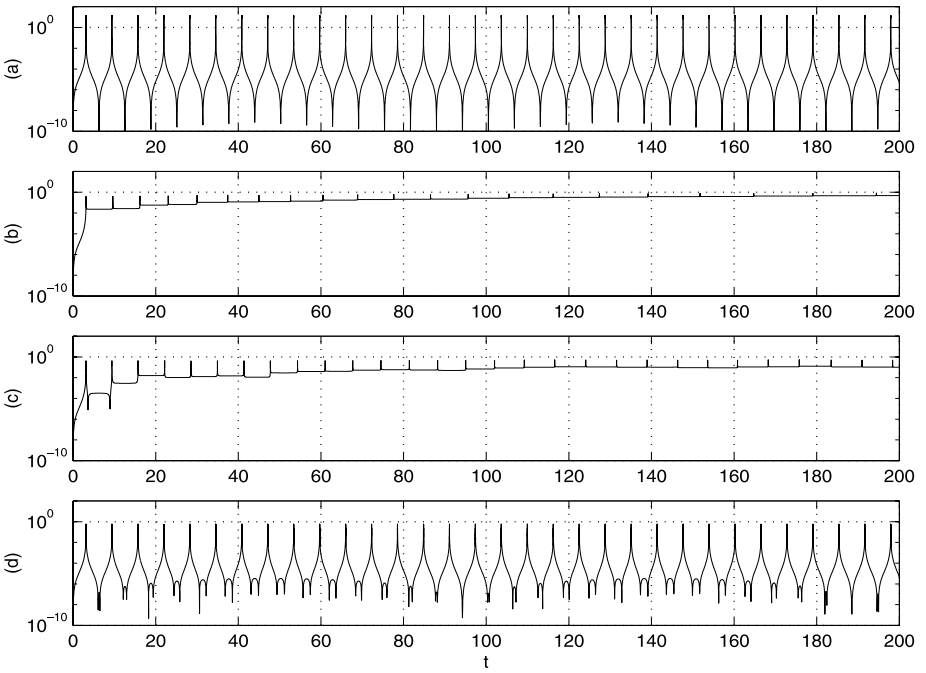

FIG. 6.2. *The relative energy error in simulation of the Kepler problem* ($e = 0.9999$). (a) *Without switch, with* (b) *hard switch,* (c) *improved hard switch, and* (d) *smooth switch.*

Even if time symmetry is maintained fairly well for the hard switch, we have already seen that the numerical solution produced by this method shows a quite irregular behavior. (This may be partly explained by the existence of an approximating continuous time-reversible flow—a truncated form of the "modified equations"—for the smoothly switched method.)

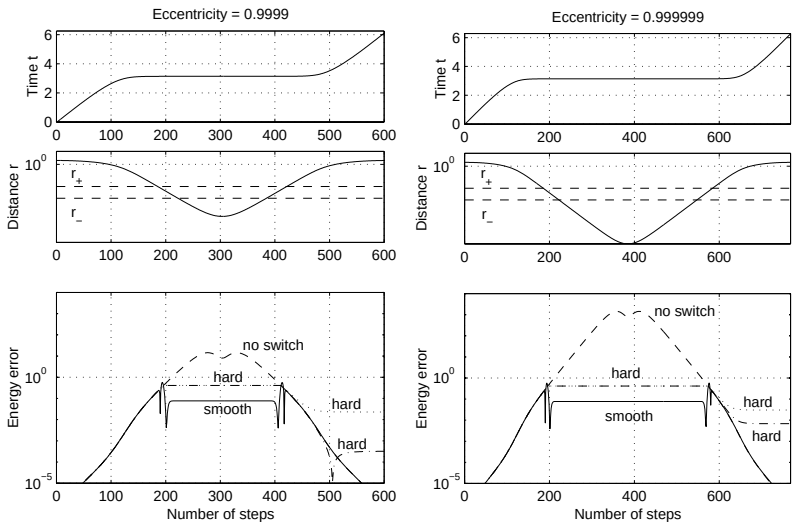

FIG. 6.3. *The distance r and the energy error over one period for the variable stepsize method without switch* (- -)*, with hard switch* ($\cdots$)*, improved hard switch* ($\cdot$—)*, and smooth switch* (–).

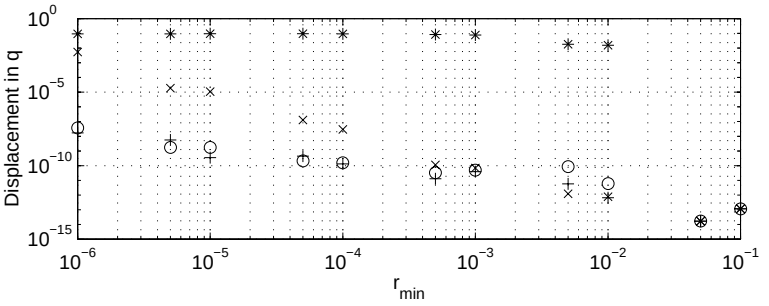

FIG. 6.4. *The displacement of* $\boldsymbol{q}$ *after integrating forward one period, and then backward again, without switch* ($\times$), *with hard switch* ($\star$), *improved hard switch* ($+$), *and smooth switch* ($\circ$).

Finally, Figure 6.5 shows the development of the global error in $\boldsymbol{q}$. As expected, both the method without the switch and the method with a smooth switch show linear error growth, although the error of the latter is only about 20% of the first one. The hard switches give no such regular behavior of the growth of the global error, and further, the magnitude of the global error is quite alarming.

Example 2: *Two fixed point problem.* We next seek to test the long-term stability behavior of the integrator. For this purpose, we employ the two fixed point (TFP) problem, which describes a particle of unit mass moving in the gravitational field of two fixed centers. The Hamiltonian is given by

$$H = \frac{1}{2}(p_1^2 + p_2^2) - \frac{m_1}{\sqrt{q_1^2 + q_2^2}} - \frac{m_2}{\sqrt{(q_1 + q_p)^2 + q_2^2}}.$$

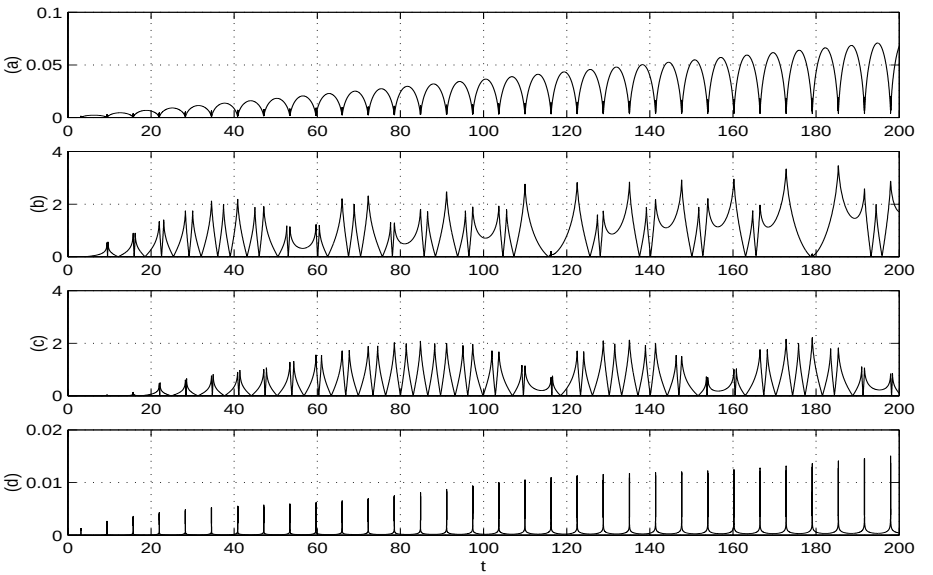

FIG. 6.5. *The global error in simulation of the Kepler problem* ($e = 0.9999$). (a) *Without switch, with* (b) *hard switch,* (c) *improved hard switch, and* (d) *smooth switch.*

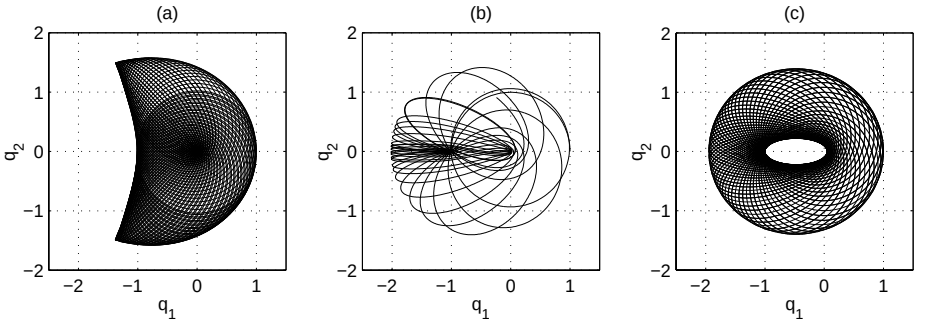

FIG. 6.6. *The orbits of the TFP problem with* (a) $q_p = 1.5$, (b) $q_p = 1.02$, *and* (c) $q_p = 0.95$.

The masses are $m_1 = 1$ and $m_2 = 0.01$, and the initial values are $q_1(0) = 1$, $q_2(0) = 0$, $p_1(0) = 0$, and $p_2(0) = 1$. The distance q_p between the two fixed centers controls the behavior of the systems. We have used three different values of q_p; exactly the same problem has been used by Rauch and Holman [28] to compare long-term stability behavior of several integrators for planetary orbits. In each case the relative energy error is monitored. The results are given in Figures 6.6 and 6.7.

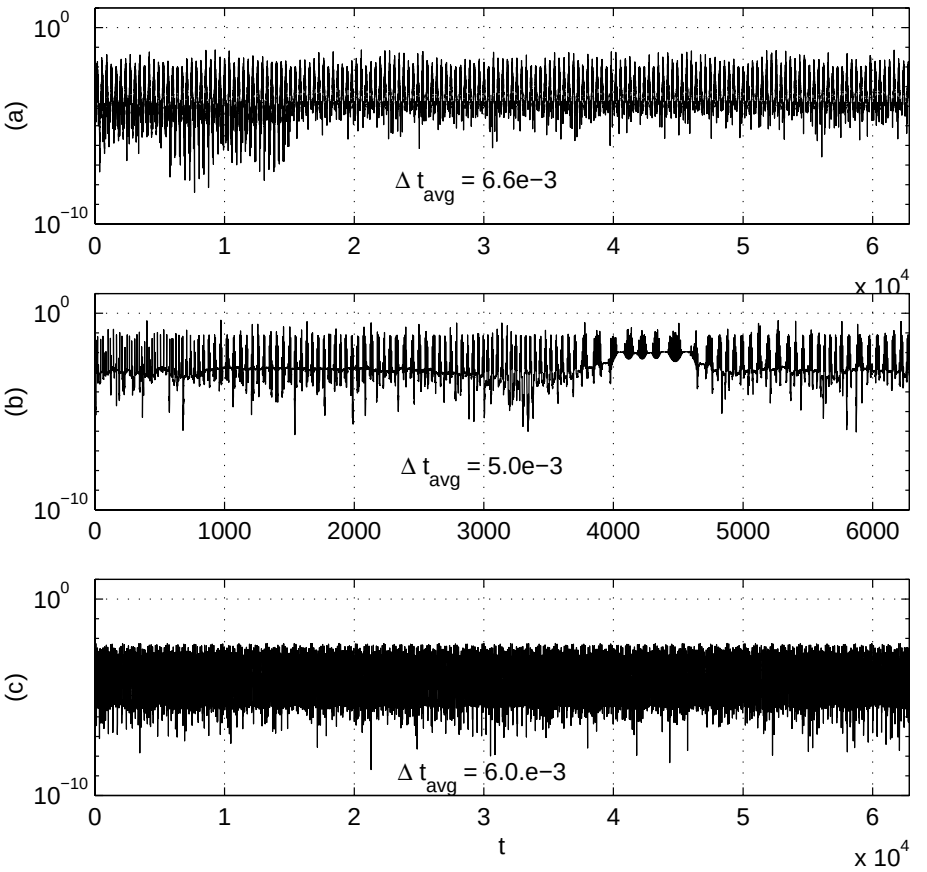

FIG. 6.7. *The relative energy error of the TFP problem with* (a) $q_p = 1.5$, (b) $q_p = 1.02$, *and* (c) $q_p = 0.95$.

(a) $q_p = 1.5$. There are no close encounters with the small mass m_2, but periodically the orbit becomes highly eccentric. No drift in the energy error can be observed.
(b) $q_p = 1.02$. In this case there are frequent close encounters with both masses, and there is no limit to how close they can be. Again, we observe that the integrator is reasonably stable. However, jumps in the energy error have been detected in some experiments. This happens when the moving body comes too close to m_2, typically if the distance becomes less than $\sim 10^{-8}$. The integrator handles very close encounters with m_1 very well.
(c) $q_p = 0.95$. The moving particle is never sufficiently close to any of the two fixed centers to activate the switch. Still, the variable stepsize algorithm is sufficient to solve the problem without any drift in the energy error.

It is natural to compare our results with the ones reported by Rauch and Holman [28]. They consider three different integrators: The Wisdom–Holman mapping [37], a potential splitting method by Duncan, Levison, and Lee [7], and a method based on Stark splitting. All of the methods are tested with and without use of the time-regularization of Mikkola [25]. Precise comparisons with our method are difficult since there are so many factors that determine the timestep cost for each method (e.g., size of the switching regime, order and type of method used for close approaches). For example, the Stark splitting method is an implicit scheme and formally, at least, requires the iteration of what is essentially a Kepler solver, although it is not clear that the authors do perform this iteration (or how they determine that it is not needed). We will summarize a few of our observations based on many experiments using our method and our reading of the article of Rauch and Holman.

In general, it appears that our method behaves at least as stably as the others in the long term, in the sense that the average energy error does not increase over time. In the first example, the energy error is about the same magnitude as for the

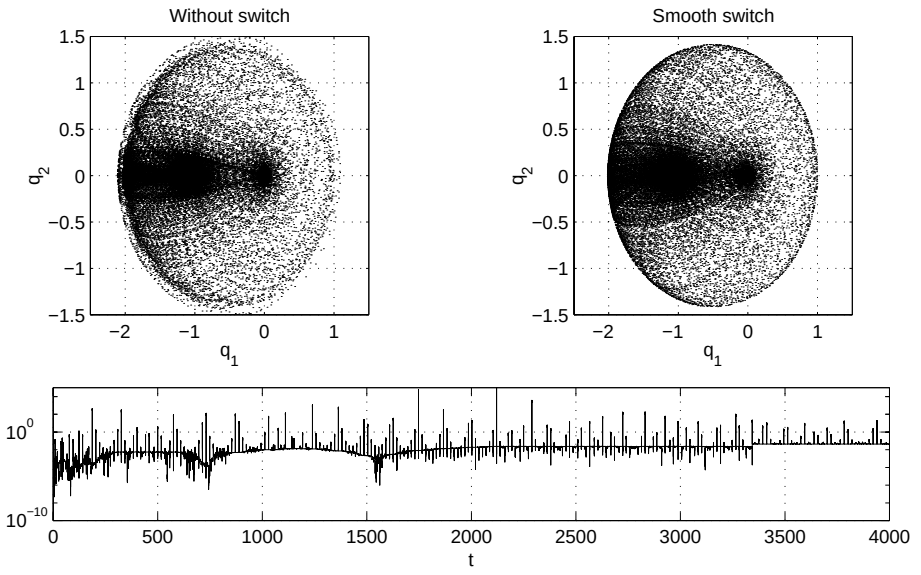

FIG. 6.8. *The upper panel gives the numerical solution points when integrating with and without the smooth switch. The lower panel shows the relative energy error for the method without switch.*

unregularized methods of Rauch and Holman; however, the error of their regularized methods are substantially smaller.

In the second example, where the body can approach both masses, our method outperforms all the methods by Rauch and Holman, with the exception of the regularized potential splitting method, which uses a relatively costly transcendental function for switching.

In the last example, our method exhibits a larger energy error than the methods of Rauch and Holman for similar average timestep. On the other hand, in these cases the moving body never enters the switching regime, so per timestep cost of our scheme is very low compared with the other methods.

Finally, in Figure 6.8 we show the numerical solution of the TFP problem with $q_p = 1.02$ when integrated with and without the smooth switch. We can clearly see how the drift in the energy error gradually destroys the regular appearance of the orbit. The unswitched method was able to solve the problem only for $t < 4400$.

7. Discussion. In this paper, we have presented a gravitational N-body integration algorithm. Smooth switching functions have been used to split the potential terms into local and weak parts. Close approaches between bodies are solved through a regularized system of equations, using a high order Gauss method. The cost of this can still be justified since close encounters are generally isolated events occurring relatively rarely along trajectories. Numerical experiments clearly demonstrate the excellent qualitative behavior of the proposed algorithm and show that the method is at least competitive with alternatives presented in the astronomical literature; particularly in cases with arbitrary close approaches, it appears to be superior to existing schemes. The number of steps within the switching regime can be reduced by reducing the switching regime; thus a correct choice of r_+ and r_- is critical for the overall performance of the method. Several other implementation issues, such as how to solve the nonlinear equations arising from applying the Gauss method to the regularized equations, still need to be addressed. Also, the proposed algorithms for solving higher-body close encounters must be studied more thoroughly and tested numerically. These and other issues are under consideration by the authors and will be addressed in a forthcoming article. However, the preliminary results given in this article are very promising and more than justify further work on the topic.

Acknowledgments. The authors would like to thank Marvin McNett (KU) for many fruitful discussions during the work, and Martin Lo (NASA JPL) for his encouragement at the start of the project.

The authors also wish to thank the referees for their helpful suggestions regarding the recent astronomical literature.

NEW FAST ALGORITHMS FOR ERROR RATE-BASED STEPWISE VARIABLE SELECTION IN DISCRIMINANT ANALYSIS*

S. AEBERHARD†, O. Y. DE VEL‡, AND D. H. COOMANS§

Abstract. Variable selection is an important technique for reducing the dimensionality in multivariate predictive discriminant analysis and classification. In the past, direct evaluation of the subsets by means of a classifier has been computationally too expensive, rendering necessary the use of heuristic measures of class separation, such as Wilk's Λ or the Mahalanobis distance between class means. We present new fast algorithms for stepwise variable selection based on quadratic and linear classifiers with time complexities which, to within a constant, are the same as those applying measures of class separation. Comparing the new algorithms to previous implementations of classifier-based variable selection, we show that dramatic speed-ups are achieved.

Key words. dimensionality reduction, classification, classifier-based variable selection

1. Introduction.

1.1. Discriminant analysis and variable selection. Consider a classification problem with a total of N_p observation vectors $\mathbf{x} = (x_1, x_2, \ldots, x_d)$, sampled from K groups or classes. The aim of *predictive* discriminant analysis is to construct a rule for the allocation of future observations to one or several of the K classes. Linear and quadratic discriminant analysis is the name given to two rules constructed under the assumption that the data are multivariate normally distributed. The former assumes equal, the latter unequal, covariance matrices. *Descriptive* discriminant analysis investigates how the groups differ, which can also be indirectly assessed with the predictive approach. This paper focuses on stepwise variable selection applied in conjunction with predictive discriminant analysis, also called *classification*.

The benefits of variable subset selection differ depending on the ultimate aim of the underlying investigation. If the data at hand are from a preliminary study, a major consideration may be the reduction of the cost in sampling future data by a decreased number of variables. If the aim of the investigation is to analyze class differences, variables selection may lead to a more parsimonious description. If the goal is that of allocating future unknown observations to one or several of the K classes, variable subset selection may increase the discriminant power of the classification method [16]. As the potential benefits increase with increased numbers of variables, variable selection is particularly useful in high-dimensional settings. For a more general overview of discriminant analysis refer to [3] or [10].

1.2. Variable selection. Variable selection is essentially a search problem over all combinations of variables, consisting of two main components:

- a search procedure used to determine the variable subsets that are evaluated;
- a criterion $J(\mathcal{V}^{(l)})$ used to evaluate which of the subsets is "best," where $\mathcal{V}^{(l)}$ denotes a variable subset of size l, $1 \leq l \leq d$. Examples used in this paper are the error rate of linear and quadratic discriminant rules and class separability measures.

1.2.1. Search heuristics. There are $2^d - 1$ distinct subsets of d variables, rendering an exhaustive search computationally infeasible for all problems except those with low dimensionality. However, it is still possible to efficiently find the optimal subset using the branch-and-bound algorithm if the criterion $J(\mathcal{V}^{(l)})$ is monotonic [11]. If $J(\mathcal{V}^{(l)})$ is not monotonic, such as the error rate of classifiers, heuristic search strategies have to be used. Among these, the stepwise procedures are popular; variables are either selected in a forward manner, sequentially deleted in the backward elimination approach, or selected by a combination of the two [11].

1.2.2. Selection criteria $J(\mathcal{V}^{(l)})$. In predictive discriminant analysis, assuming equal cost of misclassification, one possible optimal criterion $J(\mathcal{V}^{(l)})$ to assess the subsets is the error rate. However, even the relatively simple stepwise procedures consider too many subsets to be computationally feasible for medium- to high-dimensional problems, as obtaining the error rates is an expensive procedure in itself. Consequently, there have been relatively few reports in this area; [5] and [7] support the use of error rates; however, their experiments had to be limited to data with relatively few dimensions. For these cost reasons, error rates are usually replaced with measures of class separation, which can be computed much more efficiently. Two commonly used measures are Wilk's Λ and the Mahalanobis distance between the two nearest class means (see [8], [3] for more details). Another useful measure is the Lawley–Hotelling trace sometimes used in the multivariate analysis of variance [9]. However, the computational advantage of these criteria are traded off by several disadvantages [13]:

- Variable selection is terminated based on the application of a test statistic to the values of $J(\mathcal{V}^{(l)})$ at adjacent levels. The number of variables that are included depends on the critical value of the statistic, and no general rule for their determination is known.
- Because the variable that maximizes the increase in $J(\mathcal{V}^{(l)})$ (forward selection) is selected at each step, the actual significance levels are unknown.
- Maximizing class separability does not necessarily minimize error rates. This is especially true for problems with more than two classes.

Simpler approaches to variable selection choose the variables based on canonical variate analysis or based on ranking of the variables under the assumption of their mutual independence. However, these methods are less powerful and have been criticized in the comprehensive review by McKay and Campbell [13].

1.2.3. Classifier performance evaluation. Variable selection based on classifier performance requires the evaluation of the classifier. Several sample-based evaluation techniques are in common use, but only the resubstitution and cross validation methods are computationally suitable in this context [1]. Further, because variable selection is often performed with ill- or poorly posed problems, the optimistic bias of the resubstitution method precludes its use. An improvement to the bias can be made using Snapinn and Knoke's smoothed resubstitution method for two classes [17]

and the multiclass extension proposed by Hirst [9]. Among the cross-validation techniques, the leave-one-out method [12] has the advantage of being nearly unbiased and computationally efficient through the use of fast downdating formulas (see [2], [4]). One drawback of the leave-one-out method is its large variance, which, in combination with the many subsets investigated by the search procedure, unfortunately leads to optimistically biased performance estimates. However, similar bias also occurs when the selection is based on measures of class separation rather than error rates [15].

A straightforward implementation of stepwise variable selection based on the performance of linear discriminant analysis (LDA) or quadratic discriminant analysis (QDA) has $O(N_p d^4)$ time complexity,[1] where N_p is the total number of observations and d is the dimensionality, i.e., the total number of variables. If downdating formulas are used, a single leave-one-out evaluation of QDA or LDA has $O(N_p d^2)$ time complexity. At each iteration of stepwise variable selection, the number of variables considered is of order $O(d)$. As the number of iterations is also of order $O(d)$, the overall time complexity is $O(N_p d^4)$, if implemented in a straightforward manner. However, it is possible to reduce that complexity by a combined application of two sets of downdating formulas. The resulting new algorithms have a time complexity of $O(N_p d^2)$, which is optimal and the same as that for a single discriminant analysis.

In this paper we bring some known results together with some new results for stepwise variable selection into a set of streamlined and efficient algorithms. We derive the algorithm for forward selection in section 2, followed by a summary of the corresponding formulas for backward elimination. The fourth and last section reports on run-time comparisons of the new algorithms with previous implementations and with two approaches that use measures of class separation.

2. New $O(N_p d^2)$ algorithms for forward selection based on the performance of QDA and LDA. With the forward selection approach, variables are sequentially included into $\mathcal{V}^{(l)}$ until further inclusion reduces the estimate of the classification accuracy, or until $\mathcal{V}^{(l)}$ reaches a specified size. This stopping criterion was chosen for its simplicity and for its easy implementation. However, the user may choose a more complex stopping criterion as this will not affect the variable selection algorithm. In order to achieve the optimal time complexity $O(N_p d^2)$, the combination of two sets of downdating formulas is required. The first set allows the efficient computation of the inverse and determinant of the covariance matrix in the case where one variable is added to, or deleted from, the current set of variables $\mathcal{V}^{(l)}$. The second set of formulas are applied in the context of the leave-one-out estimation. Before deriving the algorithms, we present these two sets of formulas.

2.1. Adding or deleting one variable from $\mathcal{V}^{(l)}$. The formulas below are used to efficiently calculate the inverse and determinant of the sample covariance matrix when one variable is added to, or deleted from, $\mathcal{V}^{(l)}$.

Consider the case where variable j is added to $\mathcal{V}^{(l)}$, and assume without loss of generality that the sample covariance matrix $\mathbf{S}_k^{(l+1)}$ of class ω_k at level $l+1$ is constructed from the sample covariance matrix $\mathbf{S}_k^{(l)}$ at level l as follows:

$$\mathbf{S}_k^{(l+1)} = \begin{bmatrix} \mathbf{S}_k^{(l)} & \mathbf{d}_{k,j} \\ \mathbf{d}_{k,j}^T & s_{k,j,j} \end{bmatrix}, \tag{2.1}$$

[1] A function $f(n)$ is said to be $O(g(n))$ if there are positive constants K and n_0 such that $\forall n \geq n_0$, $f(n) \leq Kg(n)$.

where $[\mathbf{d}_{k,j}^T\ ,\ s_{k,j,j}]$ is the row corresponding to the newly included variable j. Then $\overset{(l+1)}{\mathbf{S}_k^{-1}}$ is given in terms of $\overset{(l)}{\mathbf{S}_k^{-1}}$ by (see [6])

$$\overset{(l+1)}{\mathbf{S}_k^{-1}} = \begin{bmatrix} \overset{(l)}{\mathbf{S}_k^{-1}} + \frac{1}{a_{k,j}}\overset{(l)}{\mathbf{S}_k^{-1}}\mathbf{d}_{k,j}\mathbf{d}_{k,j}^T\overset{(l)}{\mathbf{S}_k^{-1}} & -\frac{1}{a_{k,j}}\overset{(l)}{\mathbf{S}_k^{-1}}\mathbf{d}_{k,j} \\ -\frac{1}{a_{k,j}}\mathbf{d}_{k,j}^T\overset{(l)}{\mathbf{S}_k^{-1}} & \frac{1}{a_{k,j}} \end{bmatrix}, \tag{2.2}$$

where

$$a_{k,j} = s_{k,j,j} - \mathbf{d}_{k,j}^T\overset{(l)}{\mathbf{S}_k^{-1}}\mathbf{d}_{k,j}. \tag{2.3}$$

For the case where variable j is deleted from $\mathcal{V}^{(l)}$, assume without loss of generality that variable j corresponds to the last row and column in $\overset{(l)}{\mathbf{S}_k^{-1}}$, which we then write as

$$\overset{(l)}{\mathbf{S}_k^{-1}} = \begin{bmatrix} \mathbf{A} & \mathbf{c}_j \\ \mathbf{c}_j^T & b_j \end{bmatrix}. \tag{2.4}$$

$\overset{(l-1)}{\mathbf{S}_k^{-1}}$ can then efficiently be computed from $\overset{(l)}{\mathbf{S}_k^{-1}}$ by (see [6])

$$\overset{(l-1)}{\mathbf{S}_k^{-1}} = \mathbf{A} - \frac{1}{b_j}\mathbf{c}_j\mathbf{c}_j^T. \tag{2.5}$$

The ratio of the determinants at adjacent levels is the diagonal element of $\overset{(l)}{\mathbf{S}_k^{-1}}$ corresponding to variable j,

$$\left|\overset{(l)}{\mathbf{S}_k^{-1}}\right| = b_j \left|\overset{(l-1)}{\mathbf{S}_k^{-1}}\right|. \tag{2.6}$$

Then, using (2.4) and (2.5), the following equation for a quadratic form is easily derived (see [1]):

$$\mathbf{x}_1^{(l-1)T}\overset{(l-1)}{\mathbf{S}_k^{-1}}\mathbf{x}_2^{(l-1)} = \mathbf{x}_1^{(l)T}\overset{(l)}{\mathbf{S}_k^{-1}}\mathbf{x}_2^{(l)} - \frac{1}{b_j}\left(\mathbf{x}_1^{(l-1)T}\mathbf{c}_j + b_j\mathbf{x}_{1,j}\right)\left(\mathbf{c}_j^T\mathbf{x}_2^{(l-1)} + b_j\mathbf{x}_{2,j}\right). \tag{2.7}$$

Here, $\mathbf{x}_1^{(l)}$ and $\mathbf{x}_2^{(l)}$ are two column vectors of length l, $\mathbf{x}_{1,j}$ and $\mathbf{x}_{2,j}$ are their jth element, and $\overset{(l)}{\mathbf{S}_k^{-1}}$, $\mathbf{c}_j$, and b_j are defined by (2.4). Equation (2.7) is used at a later stage for the derivation of the algorithms; it allows the efficient computation of a quadratic form given its value with one extra variable included or excluded.

2.2. Leaving one observation out. The following, second set of formulas is used to downdate the class sample mean vector $\mathbf{x}_{\bullet k}^{(l)}$, $\overset{(l)}{\mathbf{S}_k^{-1}}$, and $|\overset{(l)}{\mathbf{S}_k^{-1}}|$ in the case where observation $\mathbf{x}_i$ is omitted from the training set. Let ω_λ be the class to which $\mathbf{x}_i$ belongs, and let N_λ be the number of training observations in ω_λ. The subscript "$\backslash i$" indicates that the corresponding quantity is computed with observation $\mathbf{x}_i$ left out.

The formulas for QDA are given by (see [2])

$$\mathbf{x}_{\bullet\,\lambda\setminus i}^{(l)} = \mathbf{x}_{\bullet\,\lambda}^{(l)} - \frac{1}{N_\lambda - 1}(\mathbf{x}_i^{(l)} - \mathbf{x}_{\bullet\,\lambda}^{(l)}), \tag{2.8}$$

$$\mathbf{S}_{\lambda\setminus i}^{-1\,(l)} = \frac{N_\lambda - 2}{N_\lambda - 1}\left[\mathbf{S}_\lambda^{-1\,(l)} + \frac{N_\lambda \mathbf{S}_\lambda^{-1\,(l)}(\mathbf{x}_i^{(l)} - \mathbf{x}_{\bullet\,\lambda}^{(l)})(\mathbf{x}_i^{(l)} - \mathbf{x}_{\bullet\,\lambda}^{(l)})^T \mathbf{S}_\lambda^{-1\,(l)}}{(N_\lambda - 1)^2 - N_\lambda(\mathbf{x}_i^{(l)} - \mathbf{x}_{\bullet\,\lambda}^{(l)})^T \mathbf{S}_\lambda^{-1\,(l)}(\mathbf{x}_i^{(l)} - \mathbf{x}_{\bullet\,\lambda}^{(l)})}\right], \tag{2.9}$$

$$\left|\mathbf{S}_{\lambda\setminus i}^{(l)}\right| = \left(\frac{N_\lambda - 1}{N_\lambda - 2}\right)^l \left|\mathbf{S}_\lambda^{(l)}\right| \left[1 - \frac{N_\lambda}{(N_\lambda - 1)^2}(\mathbf{x}_i^{(l)} - \mathbf{x}_{\bullet\,\lambda}^{(l)})^T \mathbf{S}_\lambda^{-1\,(l)}(\mathbf{x}_i^{(l)} - \mathbf{x}_{\bullet\,\lambda}^{(l)})\right]. \tag{2.10}$$

In the case of LDA, the downdating formula for the mean vector is the same. Furthermore, as LDA uses the *pooled* covariance matrix $\mathbf{S}_p^{(l)}$, the determinant $\left|\mathbf{S}_p^{(l)}\right|$ is the same for all classes and is hence omitted. The formula for downdating the inverse $\mathbf{S}_p^{-1\,(l)}$ of the pooled covariance matrix is (see [1])

$$\begin{aligned}\mathbf{S}_{p\setminus i}^{-1\,(l)} &= \frac{N_p - K - 1}{N_p - K} \\ &\times \left[\mathbf{S}_p^{-1\,(l)} + \frac{N_\lambda \mathbf{S}_p^{-1\,(l)}(\mathbf{x}_i^{(l)} - \mathbf{x}_{\bullet\,\lambda}^{(l)})(\mathbf{x}_i^{(l)} - \mathbf{x}_{\bullet\,\lambda}^{(l)})^T \mathbf{S}_p^{-1\,(l)}}{(N_p - K)(N_\lambda - 1) - N_\lambda(\mathbf{x}_i^{(l)} - \mathbf{x}_{\bullet\,\lambda}^{(l)})^T \mathbf{S}_p^{-1\,(l)}(\mathbf{x}_i^{(l)} - \mathbf{x}_{\bullet\,\lambda}^{(l)})}\right],\end{aligned} \tag{2.11}$$

where N_p is the total number of observations.

2.3. Forward selection based on QDA. In the forward selection step, given l variables already included, one seeks to find the variable that, when added to $\mathcal{V}^{(l)}$, maximizes the classification performance of QDA. This is done by tentatively including each prospective variable and estimating the resulting error rate. For each of these estimates, we need to compute the K class discriminant scores for all N_p observations. The algorithm halts when further addition of variables increases the error rate estimate. The discriminant or classification score is the outcome of the discriminant function for a particular data vector.

2.3.1. Discriminant score for class of object $\mathbf{x}_i$ left out. Let the object left out be $\mathbf{x}_i$, and let j be the variable considered for inclusion. We want to compute the score

$$f_{\lambda,\setminus i,j}^{(l+1)} = (\mathbf{x}_i^{(l+1)} - \mathbf{x}_{\bullet\,\lambda\setminus i}^{(l+1)})^T \mathbf{S}_{\lambda\setminus i}^{-1\,(l+1)}(\mathbf{x}_i^{(l+1)} - \mathbf{x}_{\bullet\,\lambda\setminus i}^{(l+1)}) + \ln\left|\mathbf{S}_{\lambda\setminus i}^{(l+1)}\right| - 2\ln\left(P(\omega_\lambda)\right), \quad j \notin \mathcal{V}^{(l)}, \tag{2.12}$$

for observation $\mathbf{x}_i$, for its class ω_λ, with variable j added to $\mathcal{V}^{(l)}$ (i.e., $\mathcal{V}^{(l+1)} = \mathcal{V}^{(l)} \cup j$). Writing $\mathbf{S}_{\lambda\setminus i}^{-1\,(l+1)}$ as

$$\mathbf{S}_{\lambda\setminus i}^{-1\,(l+1)} = \begin{bmatrix} \mathbf{A} & \mathbf{c}_j \\ \mathbf{c}_j^T & b_j \end{bmatrix} \tag{2.13}$$

and applying (2.7), we find that the first term in (2.12) becomes

$$\begin{aligned}(\mathbf{x}_i^{(l+1)} - \mathbf{x}_{\bullet\,\lambda\setminus i}^{(l+1)})^T \mathbf{S}_{\lambda\setminus i}^{-1\,(l+1)}(\mathbf{x}_i^{(l+1)} - \mathbf{x}_{\bullet\,\lambda\setminus i}^{(l+1)}) &= (\mathbf{x}_i^{(l)} - \mathbf{x}_{\bullet\,\lambda\setminus i}^{(l)})^T \mathbf{S}_{\lambda\setminus i}^{-1\,(l)}(\mathbf{x}_i^{(l)} - \mathbf{x}_{\bullet\,\lambda\setminus i}^{(l)}) \\ &+ \frac{1}{b_j}\left\{[\mathbf{c}_j^T\ ,\ b_j](\mathbf{x}_i^{(l+1)} - \mathbf{x}_{\bullet\,\lambda\setminus i}^{(l+1)})\right\}^2.\end{aligned} \tag{2.14}$$

Note that the variable j left out corresponds to the last row of $\mathbf{S}_{\lambda\setminus i}^{-1\,(l+1)}$ for notational convenience only. From (2.8) and (2.9), the first term on the right-hand side of (2.14) becomes

$$(\mathbf{x}_i^{(l)} - \mathbf{x}_{\bullet\lambda\setminus i}^{(l)})^T \mathbf{S}_{\lambda\setminus i}^{-1\,(l)} (\mathbf{x}_i^{(l)} - \mathbf{x}_{\bullet\lambda\setminus i}^{(l)}) = \frac{N_\lambda^2 (N_\lambda - 2)}{(N_\lambda - 1)^3} \left[(\mathbf{x}_i^{(l)} - \mathbf{x}_{\bullet\lambda}^{(l)})^T \mathbf{S}_\lambda^{-1\,(l)} (\mathbf{x}_i^{(l)} - \mathbf{x}_{\bullet\lambda}^{(l)}) \right.$$

$$\left. + \frac{N_\lambda (\mathbf{x}_i^{(l)} - \mathbf{x}_{\bullet\lambda}^{(l)})^T \mathbf{S}_\lambda^{-1\,(l)} (\mathbf{x}_i^{(l)} - \mathbf{x}_{\bullet\lambda}^{(l)}) (\mathbf{x}_i^{(l)} - \mathbf{x}_{\bullet\lambda}^{(l)})^T \mathbf{S}_\lambda^{-1\,(l)} (\mathbf{x}_i^{(l)} - \mathbf{x}_{\bullet\lambda}^{(l)})}{(N_\lambda - 1)^2 - N_\lambda (\mathbf{x}_i^{(l)} - \mathbf{x}_{\bullet\lambda}^{(l)})^T \mathbf{S}_\lambda^{-1\,(l)} (\mathbf{x}_i^{(l)} - \mathbf{x}_{\bullet\lambda}^{(l)})} \right]. \tag{2.15}$$

For computational simplicity, the same ordering of the rows of $\mathbf{S}_\lambda^{-1\,(l)}$ as for the variables themselves is kept. Because the jth row of $\mathbf{S}_\lambda^{-1\,(l)}$ will not generally correspond to variable j, we index the row of $\mathbf{S}_\lambda^{-1\,(l)}$ corresponding to the variable j as j^*. Focusing on the second term in (2.14), we see that $[\mathbf{c}_j^T \ , \ b_j]$ is the row of $\mathbf{S}_{\lambda\setminus i}^{-1\,(l+1)}$ corresponding to the newly included variable. Using (2.8) and (2.9),

$$[\mathbf{c}_j^T, b_j](\mathbf{x}_i^{(l+1)} - \mathbf{x}_{\bullet\lambda\setminus i}^{(l+1)}) = \frac{N_\lambda}{N_\lambda - 1} \left[\mathbf{S}_{\lambda\setminus i}^{-1\,(l+1)} \right]_{j^*} (\mathbf{x}_i^{(l+1)} - \mathbf{x}_{\bullet\lambda}^{(l+1)})$$

$$= \frac{N_\lambda (N_\lambda - 2)}{(N_\lambda - 1)^2} \left[\left[\mathbf{S}_\lambda^{-1\,(l+1)} \right]_{j^*} (\mathbf{x}_i^{(l+1)} - \mathbf{x}_{\bullet\lambda}^{(l+1)}) \right.$$

$$\left. + \frac{N_\lambda \left[\mathbf{S}_\lambda^{-1\,(l+1)} \right]_{j^*} (\mathbf{x}_i^{(l+1)} - \mathbf{x}_{\bullet\lambda}^{(l+1)}) (\mathbf{x}_i^{(l+1)} - \mathbf{x}_{\bullet\lambda}^{(l+1)})^T \mathbf{S}_\lambda^{-1\,(l+1)} (\mathbf{x}_i^{(l+1)} - \mathbf{x}_{\bullet\lambda}^{(l+1)})}{(N_\lambda - 1)^2 - N_\lambda (\mathbf{x}_i^{(l+1)} - \mathbf{x}_{\bullet\lambda}^{(l+1)})^T \mathbf{S}_\lambda^{-1\,(l+1)} (\mathbf{x}_i^{(l+1)} - \mathbf{x}_{\bullet\lambda}^{(l+1)})} \right]. \tag{2.16}$$

Similarly, b_j in (2.14) becomes

$$b_j = \left[\mathbf{S}_{\lambda\setminus i}^{-1\,(l+1)} \right]_{j^*,j^*}$$

$$= \frac{N_\lambda - 2}{N_\lambda - 1} \left[\left[\mathbf{S}_\lambda^{-1\,(l+1)} \right]_{j^*,j^*} + \frac{N_\lambda \left[\mathbf{S}_\lambda^{-1\,(l+1)} \right]_{j^*} (\mathbf{x}_i^{(l+1)} - \mathbf{x}_{\bullet\lambda}^{(l+1)}) (\mathbf{x}_i^{(l+1)} - \mathbf{x}_{\bullet\lambda}^{(l+1)})^T \left[\mathbf{S}_\lambda^{-1\,(l+1)} \right]_{j^*}^T}{(N_\lambda - 1)^2 - N_\lambda (\mathbf{x}_i^{(l+1)} - \mathbf{x}_{\bullet\lambda}^{(l+1)})^T \mathbf{S}_\lambda^{-1\,(l+1)} (\mathbf{x}_i^{(l+1)} - \mathbf{x}_{\bullet\lambda}^{(l+1)})} \right]. \tag{2.17}$$

We also need to downdate the determinant term in (2.12). Using (2.6) and (2.10), we find that

$$\left| \mathbf{S}_{\lambda\setminus i}^{(l+1)} \right| = \left(\frac{N_\lambda - 1}{N_\lambda - 2} \right)^{l+1} a_{\lambda,j} \left| \mathbf{S}_\lambda^{(l)} \right|$$

$$\times \left(1 - \frac{N_\lambda}{(N_\lambda - 1)^2} (\mathbf{x}_i^{(l+1)} - \mathbf{x}_{\bullet\lambda}^{(l+1)})^T \mathbf{S}_\lambda^{-1\,(l+1)} (\mathbf{x}_i^{(l+1)} - \mathbf{x}_{\bullet\lambda}^{(l+1)}) \right), \tag{2.18}$$

where $a_{\lambda,j}$ is defined by (2.2) and (2.3).

In order to simplify the above expressions, we define

$$m^{(l)}_{k,t,i:j} = (\mathbf{x}_i^{(l+1)} - \mathbf{x}_{\bullet k}^{(l+1)})^T \overset{(l+1)}{\mathbf{S}_k^{-1}} (\mathbf{x}_i^{(l+1)} - \mathbf{x}_{\bullet t}^{(l+1)}), \qquad j \notin \mathcal{V}^{(l)}, \;\; k,t = 1,\ldots,K. \tag{2.19}$$

If $k = t$, as is always the case for formulas associated with QDA, $m^{(l)}_{k,k,i:j}$ is the Mahalanobis distance between $\mathbf{x}_i$ and $\mathbf{x}_{\bullet k}^{(l+1)}$ at level $l+1$ if the variable j is added to $\mathcal{V}^{(l)}$. Also, let

$$p^{(l)}_{k,i,j} = \left[\overset{(l+1)}{\mathbf{S}_k^{-1}}\right]_{j^*} (\mathbf{x}_i^{(l+1)} - \mathbf{x}_{\bullet k}^{(l+1)}), \qquad j \notin \mathcal{V}^{(l)}, \;\; k = 1,\ldots,K; \tag{2.20}$$

i.e., $p^{(l)}_{k,i,j}$ is the inner product of the row $\left[\overset{(l+1)}{\mathbf{S}_k^{-1}}\right]_{j^*}$ corresponding to the variable j added to $\mathcal{V}^{(l)}$, and $(\mathbf{x}_i^{(l+1)} - \mathbf{x}_{\bullet k}^{(l+1)})$. Note that the index l in $m^{(l)}_{k,k,i:j}$ and $p^{(l)}_{k,i,j}$ denotes the level at which these quantities are computed, and not the length of the vectors involved, which is $l+1$.

We further define

$$\eta^{(l)}_{k,t,i} \equiv m^{(l-1)}_{k,t,i:q} = (\mathbf{x}_i^{(l)} - \mathbf{x}_{\bullet k}^{(l)})^T \overset{(l)}{\mathbf{S}_k^{-1}} (\mathbf{x}_i^{(l)} - \mathbf{x}_{\bullet t}^{(l)}), \tag{2.21}$$

where variable q was included at level $l-1$. Again, $k = t$ for QDA, and the $\eta^{(l)}_{k,k,i}$ are the $K \times N_p$ Mahalanobis distances between the N_p objects and the K mean vectors at the present level l.

Combining (2.14)–(2.21), and substituting them into (2.12), we see that the leave-one-out classification score for the class of $\mathbf{x}_i$ becomes

$$\begin{aligned} f^{(l+1)}_{\lambda,\setminus i,j} &= \frac{N_\lambda^2(N_\lambda-2)}{(N_\lambda-1)^3}\left[\eta^{(l)}_{\lambda,\lambda,i} + \frac{N_\lambda\left(\eta^{(l)}_{\lambda,\lambda,i}\right)^2}{(N_\lambda-1)^2 - N_\lambda \eta^{(l)}_{\lambda,\lambda,i}}\right] \\ &+ \frac{N_\lambda^2(N_\lambda-2)}{(N_\lambda-1)^3}\left(\frac{1}{a_{\lambda,j}} + \frac{N_\lambda\left(p^{(l)}_{\lambda,i,j}\right)^2}{(N_\lambda-1)^2 - N_\lambda m^{(l)}_{\lambda,\lambda,i:j}}\right)^{-1}\left(p^{(l)}_{\lambda,i,j} + \frac{N_\lambda p^{(l)}_{\lambda,i,j} m^{(l)}_{\lambda,\lambda,i:j}}{(N_\lambda-1)^2 - N_\lambda m^{(l)}_{\lambda,\lambda,i:j}}\right)^2 \\ &+ \ln\left[a_{\lambda,j}\left(\frac{N_\lambda-1}{N_\lambda-2}\right)^{l+1}\left|\mathbf{S}^{(l)}_\lambda\right|\left(1 - \frac{N_\lambda m^{(l)}_{\lambda,\lambda,i:j}}{(N_\lambda-1)^2}\right)\right] - 2\ln\left(P(\omega_\lambda)\right). \end{aligned} \tag{2.22}$$

2.3.2. Score for classes other than those of object $\mathbf{x}_i$. Equation (2.22) gives the score for object $\mathbf{x}_i$ left out for the class ω_λ of $\mathbf{x}_i$. Similar to (2.12), the leave-one-out score of $\mathbf{x}_i$ for classes other than its own is written as

$$f^{(l+1)}_{k,\setminus i,j} = (\mathbf{x}_i^{(l+1)} - \mathbf{x}_{\bullet k}^{(l+1)})^T \overset{(l+1)}{\mathbf{S}_k^{-1}} (\mathbf{x}_i^{(l+1)} - \mathbf{x}_{\bullet k}^{(l+1)}) + \ln\left|\mathbf{S}^{(l+1)}_k\right| - 2\ln\left(P(\omega_k)\right) \;. \tag{2.23}$$

Note that $\overset{(l+1)}{\mathbf{S}_k^{-1}} = \overset{(l+1)}{\mathbf{S}_{k\setminus i}^{-1}}$ since $\mathbf{x}_i$ belongs to class ω_k, $k \neq \lambda$.

We assume again that j is the newly included variable and thus write $\mathbf{S}^{(l+1)}_k$ as follows:

$$\overset{(l+1)}{\mathbf{S}_k^{-1}} = \begin{bmatrix} \mathbf{A} & \mathbf{c}_j \\ \mathbf{c}_j^T & b_j \end{bmatrix}. \tag{2.24}$$

Then, using (2.6) and (2.7), (2.23) becomes

$$f_{k,\setminus i,j}^{(l+1)} = (\mathbf{x}_i^{(l)} - \mathbf{x}_{\bullet k}^{(l)})^T \mathbf{S}_k^{-1(l)} (\mathbf{x}_i^{(l)} - \mathbf{x}_{\bullet k}^{(l)}) + b_j^{-1} \left\{ [\mathbf{c}_j^T, b_j] (\mathbf{x}_i^{(l+1)} - \mathbf{x}_{\bullet k}^{(l+1)}) \right\}^2$$

$$+ \ln \left[b_j^{-1} \left| \mathbf{S}_k^{(l)} \right| \right] - 2 \ln \left(P(\omega_k) \right). \tag{2.25}$$

Applying (2.20) and (2.21) to (2.25), and using $b_j^{-1} = a_{k,j}$, we have that

$$f_{k,\setminus i,j}^{(l+1)} = \eta_{k,k,i}^{(l)} + a_{k,j} (p_{k,i,j}^{(l)})^2 + \ln \left(a_{k,j} \left| \mathbf{S}_k^{(l)} \right| \right) - 2 \ln \left(P(\omega_k) \right). \tag{2.26}$$

The above result is the score for classes other than the one to which $\mathbf{x}_i$ belongs.

In order for the algorithm to be efficient, we need to be able to efficiently precompute $p_{k,i,j}^{(l)}$ and $m_{k,k,i:j}^{(l)}$ at each level. In the next section, we derive formulas that allow these quantities to be computed in constant time from their previous values at the level below.

2.3.3. The computational scheme. Let

$$\theta_{k,i,j}^{(l)} = \mathbf{d}_{k,j}^T \mathbf{S}_k^{-1(l)} (\mathbf{x}_i^{(l)} - \mathbf{x}_{\bullet k}^{(l)}), \qquad j \notin \mathcal{V}^{(l)}, \tag{2.27}$$

$$\Delta_{k,i,j} = (\mathbf{x}_{i,j} - \mathbf{x}_{\bullet k,j}), \qquad j \notin \mathcal{V}^{(l)}, \tag{2.28}$$

where $\mathbf{d}_{k,j}$ is given by (2.1). Considering $p_{k,i,j}^{(l)}$, from (2.2) and (2.20),

$$\begin{aligned} p_{k,i,j}^{(l)} &= \left[-\frac{1}{a_{k,j}} \mathbf{d}_{k,j}^T \mathbf{S}_k^{-1(l)}, \frac{1}{a_{k,j}} \right] \left(\left[\mathbf{x}_i^{(l)T}, \mathbf{x}_{i,j} \right]^T - \left[\mathbf{x}_{\bullet k}^{(l)T}, \mathbf{x}_{\bullet k,j} \right]^T \right) \\ &= -\frac{1}{a_{k,j}} \mathbf{d}_{k,j}^T \mathbf{S}_k^{-1(l)} (\mathbf{x}_i^{(l)} - \mathbf{x}_{\bullet k}^{(l)}) + \frac{1}{a_{k,j}} \left(\mathbf{x}_{i,j} - \mathbf{x}_{\bullet k,j} \right) \\ &= -\frac{1}{a_{k,j}} \left(\theta_{k,i,j}^{(l)} - \Delta_{k,i,j} \right). \end{aligned} \tag{2.29}$$

Working with $m_{\lambda,\lambda,i:j}^{(l)}$, from (2.2) and (2.19), we have that

$$\begin{aligned} m_{k,k,i:j}^{(l)} &= \left(\left[\mathbf{x}_i^{(l)T}, \mathbf{x}_{i,j} \right]^T - \left[\mathbf{x}_{\bullet k}^{(l)T}, \mathbf{x}_{\bullet k,j} \right]^T \right)^T \\ &\quad \times \begin{bmatrix} \mathbf{S}_k^{-1(l)} + \frac{1}{a_{k,j}} \mathbf{S}_k^{-1(l)} \mathbf{d}_{k,j} \mathbf{d}_{k,j}^T \mathbf{S}_k^{-1(l)} & -\frac{1}{a_{k,j}} \mathbf{S}_k^{-1(l)} \mathbf{d}_{k,j} \\ -\frac{1}{a_{k,j}} \mathbf{d}_{k,j}^T \mathbf{S}_k^{-1(l)} & \frac{1}{a_{k,j}} \end{bmatrix} \\ &\quad \times \left(\left[\mathbf{x}_i^{(l)T}, \mathbf{x}_{i,j} \right]^T - \left[\mathbf{x}_{\bullet k}^{(l)T}, \mathbf{x}_{\bullet k,j} \right]^T \right) \\ &= (\mathbf{x}_i^{(l)} - \mathbf{x}_{\bullet k}^{(l)})^T \mathbf{S}_k^{-1(l)} (\mathbf{x}_i^{(l)} - \mathbf{x}_{\bullet k}^{(l)}) \\ &\qquad + \frac{1}{a_{k,j}} (\mathbf{x}_i^{(l)} - \mathbf{x}_{\bullet k}^{(l)})^T \mathbf{S}_k^{-1(l)} \mathbf{d}_{k,j} \mathbf{d}_{k,j}^T \mathbf{S}_k^{-1(l)} (\mathbf{x}_i^{(l)} - \mathbf{x}_{\bullet k}^{(l)}) \\ &\qquad - \frac{2}{a_{k,j}} (\mathbf{x}_{i,j} - \mathbf{x}_{\bullet k,j}) (\mathbf{x}_i^{(l)} - \mathbf{x}_{\bullet k}^{(l)})^T \mathbf{S}_k^{-1(l)} \mathbf{d}_{k,j} + \frac{1}{a_{k,j}} (\mathbf{x}_{i,j} - \mathbf{x}_{\bullet k,j})^2 \\ &= \eta_{k,k,i}^{(l)} + \frac{1}{a_{k,j}} \left({\theta_{k,i,j}^{(l)}}^2 - 2 \Delta_{k,i,j} \theta_{k,i,j}^{(l)} + \Delta_{k,i,j}^2 \right). \end{aligned} \tag{2.30}$$

Hence we can efficiently compute the $m^{(l+1)}_{k,k,i:j}$ and $p^{(l+1)}_{k,i,j}$ if the $\theta^{(l+1)}_{k,i,j}$ are precomputed. This is done using fast updating formulas derived below.

Let

$$r^{(l)}_{k,j,h} = \mathbf{d}^T_{k,j} \overset{(l)}{\mathbf{S}}{}^{-1}_k \mathbf{d}_h, \qquad j \notin \mathcal{V}^{(l)}. \tag{2.31}$$

In order to consider $\theta^{(l+1)}_{k,i,j}$, we assume that the variable q was included at level l, and that $\mathbf{d}^{(l)}_{k,j}$ from the previous level corresponds to the l first elements in $\mathbf{d}^{(l+1)}_{k,j}$. Hence

$$\theta^{(l+1)}_{k,i,j} = \left[\mathbf{d}^{(l)}_{k,j}, s_{k,j,q}\right]^T \overset{(l+1)}{\mathbf{S}}{}^{-1}_k (\mathbf{x}^{(l+1)}_i - \mathbf{x}^{(l+1)}_{\bullet k}), \tag{2.32}$$

where $s_{k,j,q}$ is the covariance of the jth and qth variables. Then

$$\begin{aligned}
\theta^{(l+1)}_{k,i,j} &= \left[\mathbf{d}^{(l)\,T}_{k,j}, s_{k,j,q}\right] \begin{bmatrix} \overset{(l)}{\mathbf{S}}{}^{-1}_k + \frac{1}{a_{k,q}} \overset{(l)}{\mathbf{S}}{}^{-1}_k \mathbf{d}_{k,q} \mathbf{d}^T_{k,q} \overset{(l)}{\mathbf{S}}{}^{-1}_k & -\frac{1}{a_{k,q}} \overset{(l)}{\mathbf{S}}{}^{-1}_k \mathbf{d}_{k,q} \\ -\frac{1}{a_{k,q}} \mathbf{d}^T_{k,q} \overset{(l)}{\mathbf{S}}{}^{-1}_k & \frac{1}{a_{k,q}} \end{bmatrix} \\
&\qquad \times \left(\left[\mathbf{x}^{(l)\,T}_i, \mathbf{x}_{i,q}\right]^T - \left[\mathbf{x}^{(l)\,T}_{\bullet k}, \mathbf{x}_{\bullet k,q}\right]^T \right) \\
&= \mathbf{d}^{(l)\,T}_{k,j} \overset{(l)}{\mathbf{S}}{}^{-1}_k (\mathbf{x}^{(l)}_i - \mathbf{x}^{(l)}_{\bullet k}) + \frac{1}{a_{k,q}} \mathbf{d}^{(l)\,T}_{k,j} \overset{(l)}{\mathbf{S}}{}^{-1}_k \mathbf{d}_{k,q} \mathbf{d}^T_{k,q} \overset{(l)}{\mathbf{S}}{}^{-1}_k (\mathbf{x}^{(l)}_i - \mathbf{x}^{(l)}_{\bullet k}) \\
&\qquad - \frac{1}{a_{k,q}} (\mathbf{x}_{i,q} - \mathbf{x}_{\bullet k,q}) \mathbf{d}^{(l)\,T}_{k,j} \overset{(l)}{\mathbf{S}}{}^{-1}_k \mathbf{d}_{k,q} - \frac{1}{a_{k,q}} s_{k,j,q} \mathbf{d}^T_{k,q} \overset{(l)}{\mathbf{S}}{}^{-1}_k (\mathbf{x}^{(l)}_i - \mathbf{x}^{(l)}_{\bullet k}) \\
&\qquad + \frac{1}{a_{k,q}} s_{k,j,q} (\mathbf{x}_{i,q} - \mathbf{x}_{\bullet k,q}) \\
&= \theta^{(l)}_{k,i,j} + \frac{1}{a_{k,q}} \left(r^{(l)}_{k,j,q} - s_{k,j,q} \right) \left(\theta^{(l)}_{k,i,q} - \Delta_{k,i,q} \right).
\end{aligned} \tag{2.33}$$

The updating formulas for $r^{(l)}_{k,j,h}$ are found in a similar way:

$$\begin{aligned}
r^{(l+1)}_{k,j,h} &= \mathbf{d}^{(l+1)\,T}_{k,j} \overset{(l+1)}{\mathbf{S}}{}^{-1}_k \mathbf{d}^{(l+1)}_{k,h} \\
&= \left[\mathbf{d}^{(l)\,T}_{k,j}, s_{k,j,q}\right] \\
&\qquad \times \begin{bmatrix} \overset{(l)}{\mathbf{S}}{}^{-1}_k + \frac{1}{a_{k,q}} \overset{(l)}{\mathbf{S}}{}^{-1}_k \mathbf{d}_{k,q} \mathbf{d}^T_{k,q} \overset{(l)}{\mathbf{S}}{}^{-1}_k & -\frac{1}{a_{k,q}} \overset{(l)}{\mathbf{S}}{}^{-1}_k \mathbf{d}_{k,q} \\ -\frac{1}{a_{k,q}} \mathbf{d}^T_{k,q} \overset{(l)}{\mathbf{S}}{}^{-1}_k & \frac{1}{a_{k,q}} \end{bmatrix} \left[\mathbf{d}^{(l)\,T}_{k,h}, s_{k,h,q}\right]^T \\
&= \mathbf{d}^{(l)\,T}_{k,j} \overset{(l)}{\mathbf{S}}{}^{-1}_k \mathbf{d}^{(l)}_{k,h} + \frac{1}{a_{k,q}} \mathbf{d}^{(l)\,T}_{k,j} \overset{(l)}{\mathbf{S}}{}^{-1}_k \mathbf{d}_{k,q} \mathbf{d}^T_{k,q} \overset{(l)}{\mathbf{S}}{}^{-1}_k \mathbf{d}^{(l)}_{k,h} \\
&\qquad + \frac{1}{a_{k,q}} s_{k,h,q} \mathbf{d}^{(l)\,T}_{k,j} \overset{(l)}{\mathbf{S}}{}^{-1}_k \mathbf{d}_{k,q} - \frac{1}{a_{k,q}} s_{k,j,q} \mathbf{d}^T_{k,q} \overset{(l)}{\mathbf{S}}{}^{-1}_k \mathbf{d}^{(l)}_{k,h} + \frac{1}{a_{k,q}} s_{k,j,q} s_{k,h,q} \\
&= r^{(l)}_{k,j,h} + \frac{1}{a_{k,q}} \left(r^{(l)}_{k,j,q} - s_{k,j,q} \right) \left(r^{(l)}_{k,h,q} - s_{k,h,q} \right).
\end{aligned} \tag{2.34}$$

Equations (2.33) and (2.34) allow the computation of $\theta^{(l+1)}_{k,i,j}$ and $r^{(l+1)}_{k,j,h}$ from their values at the previous level in constant O(1) time.

2.3.4. Summary of the relevant formulas for QDA. The following is a summary of the formulas constituting the algorithm for QDA-based forward variable selection.

The classification score for the class of $\mathbf{x}_i$:

$$
\begin{aligned}
f_{\lambda,\setminus i,j}^{(l+1)} &= \frac{N_\lambda^2(N_\lambda-2)}{(N_\lambda-1)^3}\left[\eta_{\lambda,\lambda,i}^{(l)} + \frac{N_\lambda\left(\eta_{\lambda,\lambda,i}^{(l)}\right)^2}{(N_\lambda-1)^2 - N_\lambda\eta_{\lambda,\lambda,i}^{(l)}}\right] \\
&\quad + \frac{N_\lambda^2(N_\lambda-2)}{(N_\lambda-1)^3}\left(\frac{1}{a_{\lambda,j}} + \frac{N_\lambda\left(p_{\lambda,i,j}^{(l)}\right)^2}{(N_\lambda-1)^2 - N_\lambda m_{\lambda,\lambda,i:j}^{(l)}}\right)^{-1} \\
&\quad \times \left(p_{\lambda,i,j}^{(l)} + \frac{N_\lambda p_{\lambda,i,j}^{(l)} m_{\lambda,\lambda,i:j}^{(l)}}{(N_\lambda-1)^2 - N_\lambda m_{\lambda,\lambda,i:j}^{(l)}}\right)^2 \\
&\quad + \ln\left[a_{\lambda,j}\left(\frac{N_\lambda-1}{N_\lambda-2}\right)^{l+1}\left|\mathbf{S}_\lambda^{(l)}\right|\left(1-\frac{N_\lambda m_{\lambda,\lambda,i:j}^{(l)}}{(N_\lambda-1)^2}\right)\right] - 2\ln(P(\omega_k)).
\end{aligned} \tag{2.35}
$$

The score for all other classes is

$$
f_{k,\setminus i,j}^{(l+1)} = \eta_{k,k,i}^{(l)} + a_{k,j}\left(p_{k,i,j}^{(l)}\right)^2 + \ln\left(a_{k,j}\left|\mathbf{S}_k^{(l)}\right|\right) - 2\ln\left(P(\omega_k)\right). \tag{2.36}
$$

Where

$$
a_{k,j} = s_{k,j,j} - r_{k,j,j}^{(l)}, \tag{2.37}
$$

$$
\Delta_{k,i,j} = (\mathbf{x}_{i,j} - \mathbf{x}_{\bullet k,j}), \tag{2.38}
$$

$$
p_{k,i,j}^{(l)} = -\frac{1}{a_{k,j}}\left(\theta_{k,i,j}^{(l)} - \Delta_{k,i,j}\right), \tag{2.39}
$$

$$
m_{k,k,i:j}^{(l)} = \eta_{k,k,i}^{(l)} + \frac{1}{a_{k,j}}\left(\theta_{k,i,j}^{(l)} - \Delta_{k,i,j}\right)^2. \tag{2.40}
$$

$s_{k,j,j}$ is the (j,j) element in the covariance matrix $\mathbf{S}_k^{(d)}$, which is computed using all variables.

Initialization is undertaken at level $l=0$:

$$
\theta_{k,i,j}^{(0)} = r_{k,j,h}^{(0)} = 0, \qquad \left|\mathbf{S}_k^{(0)}\right| = 1. \tag{2.41}
$$

Let q be the variable added at level l. The following formulas allow the quantities necessary at level $l+1$ to be recursively calculated from their values at level l:

$$
r_{k,j,h}^{(l+1)} = r_{k,j,h}^{(l)} + \frac{1}{a_{k,q}}\left(r_{k,j,q}^{(l)} - s_{k,j,q}\right)\left(r_{k,h,q}^{(l)} - s_{k,h,q}\right), \qquad j,h \notin \mathcal{V}^{(l+1)}, \tag{2.42}
$$

$$
\theta_{k,i,j}^{(l+1)} = \theta_{k,i,j}^{(l)} + \frac{1}{a_{k,q}}\left(r_{k,j,q}^{(l)} - s_{k,j,q}\right)\left(\theta_{k,i,q}^{(l)} - \Delta_{k,i,q}\right), \qquad j \notin \mathcal{V}^{(l+1)}, \tag{2.43}
$$

$$
\eta_{k,k,i}^{(l+1)} = \eta_{k,k,i}^{(l)} + \frac{1}{a_{k,q}}\left(\theta_{k,i,q}^{(l)} - \Delta_{k,i,q}\right)^2, \tag{2.44}
$$

$$
\left|\mathbf{S}_k^{(l+1)}\right| = a_{k,q}\left|\mathbf{S}_k^{(l)}\right|. \tag{2.45}
$$

Equations (2.35)–(2.41) can be evaluated in constant time. Hence, since there are N_p scores for $d-l$ variables, the next variable to add in forward selection is found in optimal $\mathrm{O}(N_p d)$ time. Since up to d variables can be selected, the overall complexity of the algorithm is $\mathrm{O}(N_p d^2)$.

2.4. Forward selection based on LDA. The derivation of the algorithm is very similar to that of QDA and is therefore omitted. However, there is one main difference. Because LDA uses the pooled covariance matrix, the leave-one-out scores of $\mathbf{x}_i$ for classes $\omega_k, k \neq \lambda$ are essentially derived in the same way as that for class ω_λ. The only difference is that only the mean $\mathbf{x}_{\bullet\lambda}$ of class ω_λ is affected by omitting $\mathbf{x}_i$, resulting in an extra factor of $N_\lambda^2/(N_\lambda-1)^2$ for the score of ω_λ. Other than that, the derivation for the scores of all classes (2.48) and (2.49) is the same as that for the score of ω_λ for the algorithm of QDA (2.12)–(2.22), with (2.11) replacing (2.9).

Similarly, the derivation of the computational scheme is the same as that for QDA, except that the $\theta^{(l)}_{k,i,j}$ of (2.27) are replaced with the two equations

$$v^{(l)}_{i,j} = \mathbf{d}^T_{k,j} \overset{(l)}{\mathbf{S}_p^{-1}} \mathbf{x}^{(l)}_i, \tag{2.46}$$

$$w^{(l)}_{k,j} = \mathbf{d}^T_{k,j} \overset{(l)}{\mathbf{S}_p^{-1}} \mathbf{x}^{(l)}_{\bullet k}. \tag{2.47}$$

The recursive formulas for both $v^{(l)}_{i,j}$ and $w^{(l)}_{k,j}$ ((2.56) and (2.57)) are derived in the same way as those for $\theta^{(l)}_{k,i,j}$ (2.32)–(2.33). Full details are given in [1].

2.4.1. Summary of the relevant formulas for LDA. The following is a summary of the formulas constituting the algorithm for LDA-based forward variable selection.

The classification score for the class of $\mathbf{x}_i$ with variable j added to the present subset $\mathcal{V}^{(l)}$ is

$$\begin{aligned} f^{(l+1)}_{\lambda,\setminus i,j} = {} & \frac{N_\lambda^2(N_p-K-1)}{(N_\lambda-1)^2(N_p-K)} \left[\eta^{(l)}_{\lambda,\lambda,i} + \frac{N_\lambda \left(\eta^{(l)}_{\lambda,\lambda,i}\right)^2}{(N_\lambda-1)(N_p-K) - N_\lambda \eta^{(l)}_{\lambda,\lambda,i}} \right] \\ & + \frac{N_\lambda^2(N_p-K-1)}{(N_\lambda-1)^2(N_p-K)} \left(\frac{1}{a_{p,j}} + \frac{N_\lambda \left(p^{(l)}_{\lambda,i,j}\right)^2}{(N_\lambda-1)(N_p-K) - N_\lambda m^{(l)}_{\lambda,\lambda,i:j}} \right)^{-1} \\ & \times \left(p^{(l)}_{\lambda,i,j} + \frac{N_\lambda p^{(l)}_{\lambda,i,j} m^{(l)}_{\lambda,\lambda,i:j}}{(N_\lambda-1)(N_p-K) - N_\lambda m^{(l)}_{\lambda,\lambda,i:j}} \right)^2 - 2\ln\left(P(\omega_k)\right). \end{aligned} \tag{2.48}$$

The score for all other classes is

$$\begin{aligned} f^{(l+1)}_{k\setminus i,j} = {} & \frac{N_p-K-1}{N_p-K} \left[\eta^{(l)}_{k,k,i} + \frac{N_\lambda \left(\eta^{(l)}_{\lambda,k,i}\right)^2}{(N_\lambda-1)(N_p-K) - N_\lambda \eta^{(l)}_{\lambda,\lambda,i}} \right] \\ & + \frac{N_p-K-1}{N_p-K} \left(\frac{1}{a_{p,j}} + \frac{N_\lambda \left(p^{(l)}_{\lambda,i,j}\right)^2}{(N_\lambda-1)(N_p-K) - N_\lambda m^{(l)}_{\lambda,\lambda,i:j}} \right)^{-1} \end{aligned}$$

$$\times \left(p_{k,i,j}^{(l)} + \frac{N_\lambda p_{\lambda,i,j}^{(l)} m_{\lambda,k,i:j}^{(l)}}{(N_\lambda - 1)(N_p - K) - N_\lambda m_{\lambda,\lambda,i:j}^{(l)}} \right)^2 - 2\ln\left(P(\omega_k)\right), \tag{2.49}$$

where

$$a_{p,j} = s_{p,j,j} - r_{p,j,j}^{(l)}, \tag{2.50}$$

$$\Delta_{k,i,j} = (\mathbf{x}_{i,j} - \mathbf{x}_{\bullet k,j}), \tag{2.51}$$

$$p_{k,i,j}^{(l)} = -\frac{1}{a_{p,j}} \left(v_{i,j}^{(l)} - w_{k,j}^{(l)} - \Delta_{k,i,j} \right), \tag{2.52}$$

$$m_{k,t,i:j}^{(l)} = \eta_{k,t,i}^{(l)} + \frac{1}{a_{p,j}} \left(v_{i,j}^{(l)} - w_{k,j}^{(l)} - \Delta_{k,i,j} \right) \left(v_{i,j}^{(l)} - w_{t,j}^{(l)} - \Delta_{t,i,j} \right). \tag{2.53}$$

$s_{p,j,j}$ is the (j,j) element in the pooled covariance matrix $\mathbf{S}_p^{(d)}$, formed using all variables.

Initialization is performed at level $l = 0$:

$$v_{i,j}^{(0)} = w_{k,j}^{(0)} = r_{k,j,h}^{(0)} = 0. \tag{2.54}$$

Let q be the variable added at level l. The following formulas allow the quantities necessary at level $l+1$ to be recursively calculated from those at level l:

$$r_{p,j,h}^{(l+1)} = r_{p,j,h}^{(l)} + \frac{1}{a_{p,q}} \left(r_{p,j,q}^{(l)} - s_{p,j,q} \right) \left(r_{p,h,q}^{(l)} - s_{p,h,q} \right), \qquad j \notin \mathcal{V}^{(l+1)}, \tag{2.55}$$

$$v_{i,j}^{(l+1)} = v_{i,j}^{(l)} + \frac{1}{a_{p,q}} (r_{k,j,q}^{(l)} - s_{p,j,q})(v_{i,q}^{(l)} - \mathbf{x}_{i,q}), \qquad j \notin \mathcal{V}^{(l+1)}, \tag{2.56}$$

$$w_{k,j}^{(l+1)} = w_{k,j}^{(l)} + \frac{1}{a_{p,q}} (r_{p,j,q}^{(l)} - s_{p,j,q})(w_{k,q}^{(l)} - \mathbf{x}_{\bullet k,q}), \qquad j \notin \mathcal{V}^{(l+1)}, \tag{2.57}$$

$$\eta_{k,t,i}^{(l+1)} = \eta_{k,t,i}^{(l)} + \frac{1}{a_{p,q}} \left(v_{i,q}^{(l)} - w_{k,q}^{(l)} - \Delta_{k,i,q} \right) \left(v_{i,q}^{(l)} - w_{t,q}^{(l)} - \Delta_{t,i,q} \right). \tag{2.58}$$

Again, (2.48)–(2.54) can be evaluated in constant time; hence the next variable to be selected is found in $O(N_p d)$ time, which is optimal.

3. New $O(N_p d^2)$ algorithms for backward elimination based on the performance of QDA and LDA. With backward elimination, the aim is to delete the variable from the present subset $\mathcal{V}^{(l)}$ such that the performance of a classifier is maximized with the remaining variables. This procedure is repeated until a further reduction in variables increases the error rate estimate or until a specified number of variables remains.

For brevity we omit the derivation of the formulas but present a summary of the equations constituting the algorithm. Full details, as well as formulas for combined forward and backward elimination steps, are given in [1]. With one exception, all quantities in the equations below have been defined in the previous sections. The exception is $\rho_{k,i,j}^{(l)}$, which is defined as follows:

$$\rho_{k,i,j}^{(l)} = \left[\mathbf{S}_k^{(l)-1} \right]_{j^*} (\mathbf{x}_i^{(l)} - \mathbf{x}_{\bullet k}^{(l)}), \qquad j \in \mathcal{V}^{(l)}. \tag{3.1}$$

3.1. Summary of the formulas for backward elimination based on QDA. The following is a summary of the formulas constituting the algorithm for QDA-based backward elimination of variables.

The classification score for the class of $\mathbf{x}_i$ with variable j deleted from $\mathcal{V}^{(l)}$ follows:

$$\begin{aligned} f^{(l-1)}_{\lambda\setminus i,j} = {} & \frac{N_\lambda^2(N_\lambda-2)}{(N_\lambda-1)^3}\left(\eta^{(l)}_{\lambda,\lambda,i}+\frac{N_\lambda\left(\eta^{(l)}_{\lambda,\lambda,i}\right)^2}{(N_\lambda-1)^2-N_\lambda\eta^{(l)}_{\lambda,\lambda,i}}\right) \\ & -\frac{N_\lambda^2(N_\lambda-2)}{(N_\lambda-1)^3}\left(\left[\mathbf{S}_\lambda^{(l)-1}\right]_{j^*,j^*}+\frac{N_\lambda\left(\rho^{(l)}_{\lambda,i,j}\right)^2}{(N_\lambda-1)^2-N_\lambda\eta^{(l)}_{\lambda,\lambda,i}}\right)^{-1} \\ & \times\left(\rho^{(l)}_{\lambda,i,j}+\frac{N_\lambda\rho^{(l)}_{\lambda,i,j}\eta^{(l)}_{\lambda,\lambda,i}}{(N_\lambda-1)^2-N_\lambda\eta^{(l)}_{\lambda,\lambda,i}}\right)^2+(l-1)\ln\left(\frac{N_\lambda-1}{N_\lambda-2}\right) \\ & \times\ln\left[\left|\mathbf{S}^{(l)}_\lambda\right|\left(1-\frac{N_\lambda\eta^{(l)}_{\lambda,\lambda,i}}{(N_\lambda-1)^2}\right)\left(\left[\mathbf{S}_\lambda^{(l)-1}\right]_{j^*,j^*}+\frac{N_\lambda\left(\rho^{(l)}_{\lambda,i,j}\right)^2}{(N_\lambda-1)^2-N_\lambda\eta^{(l)}_{\lambda,\lambda,i}}\right)\right] \\ & -2\ln(P(\omega_k)). \end{aligned} \tag{3.2}$$

The score for all other classes is

$$\begin{aligned} f^{(l-1)}_{k\setminus i,j} = {} & \eta^{(l)}_{k,k,i}-\frac{{\rho^{(l)}_{k,i,j}}^2}{\left[\mathbf{S}_k^{(l)-1}\right]_{j^*,j^*}} \\ & +\ln\left(\left[\mathbf{S}_k^{(l)-1}\right]_{j^*,j^*}\left|\mathbf{S}^{(l)}_k\right|\right)-2\ln(P(\omega_k)), \qquad k\neq\lambda. \end{aligned} \tag{3.3}$$

Initialization at level d follows:

$$\mathbf{S}^{(d)}_k=\frac{1}{N_k-1}\sum_{i=1}^{N_k}(\mathbf{x}^{(d)}_i-\mathbf{x}^{(d)}_{\bullet k})(\mathbf{x}^{(d)}_i-\mathbf{x}^{(d)}_{\bullet k})^T, \tag{3.4}$$

$$\eta^{(d)}_{k,k,i}=(\mathbf{x}^{(d)}_i-\mathbf{x}^{(d)}_{\bullet k})^T\mathbf{S}_k^{(d)-1}(\mathbf{x}^{(d)}_i-\mathbf{x}^{(d)}_{\bullet k}), \tag{3.5}$$

$$\rho^{(d)}_{k,i,j}=\left[\mathbf{S}_k^{(d)-1}\right]_{j^*}(\mathbf{x}^{(d)}_i-\mathbf{x}^{(d)}_{\bullet k}). \tag{3.6}$$

Having found variable q to be deleted at level l, we see that the quantities needed at level $l-1$ are computed as follows.

Let

$$\mathbf{S}_k^{(l)-1}=\begin{bmatrix}\mathbf{A} & \mathbf{c}_q\\ \mathbf{c}_q^T & b_q\end{bmatrix}. \tag{3.7}$$

From (2.5),

$$\mathbf{S}_k^{(l-1)^{-1}} = \mathbf{A} - \frac{1}{b_q}\mathbf{c}_q\mathbf{c}_q^T, \tag{3.8}$$

$$\eta_{k,k,i}^{(l-1)} = \eta_{k,k,i}^{(l)} - \frac{1}{b_q}\left\{[\mathbf{c}_q, b_q](\mathbf{x}_i^{(l)} - \mathbf{x}_{\bullet k}^{(l)})\right\}^2, \tag{3.9}$$

$$\left|\mathbf{S}_k^{(l-1)}\right| = b_q \left|\mathbf{S}_k^{(l)}\right|, \tag{3.10}$$

$$\rho_{k,i,j}^{(l-1)} = \rho_{\lambda,i,j}^{(l)} - \mathbf{c}_{q,j^*}(\mathbf{x}_{i,q} - \mathbf{x}_{\bullet k,q}) - \frac{\mathbf{c}_{q,j^*}}{b_q}\mathbf{c}_q^T(\mathbf{x}_i^{(l-1)} - \mathbf{x}_{\bullet k}^{(l-1)}). \tag{3.11}$$

3.2. Summary of the formulas for backward elimination based on LDA. The following is a summary of the formulas constituting the algorithm for LDA-based backward elimination of variables.

The classification score for class ω_λ of $\mathbf{x}_i$ with variable j deleted from $\mathcal{V}^{(l)}$ follows:

$$\begin{aligned} f_{\lambda\setminus i,j}^{(l-1)} = {} & \frac{N_\lambda^2(N_p - K - 1)}{(N_\lambda - 1)^2(N_p - K)}\left(\eta_{\lambda,\lambda,i}^{(l)} + \frac{N_\lambda\left(\eta_{\lambda,\lambda,i}^{(l)}\right)^2}{(N_\lambda - 1)(N_p - K) - N_\lambda\eta_{\lambda,\lambda,i}^{(l)}}\right) \\ & - \frac{N_\lambda^2(N_p - K - 1)}{(N_\lambda - 1)^2(N_p - K)}\left(\left[\mathbf{S}_p^{(l)^{-1}}\right]_{j^*,j^*} + \frac{N_\lambda\left(\rho_{\lambda,i,j}^{(l)}\right)^2}{(N_\lambda - 1)(N_p - K) - N_\lambda\eta_{\lambda,\lambda,i}^{(l)}}\right)^{-1} \\ & \times \left(\rho_{\lambda,i,j}^{(l)} + \frac{N_\lambda\rho_{\lambda,i,j}^{(l)}\eta_{\lambda,\lambda,i}^{(l)}}{(N_\lambda - 1)(N_p - K) - N_\lambda\eta_{\lambda,\lambda,i}^{(l)}}\right)^2 - 2\ln(P(\omega_k)). \end{aligned} \tag{3.12}$$

The score of all other classes is

$$\begin{aligned} f_{k,\setminus i,j}^{(l-1)} = {} & \frac{N_p - K - 1}{N_p - K}\left[\eta_{k,k,i}^{(l)} + \frac{N_\lambda\left(\eta_{\lambda,k,i}^{(l)}\right)^2}{(N_\lambda - 1)(N_p - K) - N_\lambda\eta_{\lambda,\lambda,i}^{(l)}}\right] \\ & - \frac{N_p - K - 1}{N_p - K}\left(\left[\mathbf{S}_p^{(l)^{-1}}\right]_{j^*,j^*} + \frac{N_\lambda\left(\rho_{\lambda,i,j}^{(l)}\right)^2}{(N_\lambda - 1)(N_p - K) - N_\lambda\eta_{\lambda,\lambda,i}^{(l)}}\right)^{-1} \\ & \times \left(\rho_{k,i,j}^{(l)} + \frac{N_\lambda\rho_{\lambda,i,j}^{(l)}\eta_{\lambda,k,i}^{(l)}}{(N_\lambda - 1)(N_p - K) - N_\lambda\eta_{\lambda,\lambda,i}^{(l)}}\right)^2 - 2\ln\left(P(\omega_k)\right). \end{aligned} \tag{3.13}$$

Initialization at level d (total number of variables):

$$\mathbf{S}_p^{(d)} = \frac{1}{N_p - K}\sum_{k=1}^{K}(N_k - 1)\mathbf{S}_k^{(d)}, \tag{3.14}$$

$$\eta^{(d)}_{k,t,i} = (\mathbf{x}^{(d)}_i - \mathbf{x}^{(d)}_{\bullet k})^T \mathbf{S}^{(d)\,-1}_p (\mathbf{x}^{(d)}_i - \mathbf{x}^{(d)}_{\bullet t}), \tag{3.15}$$

$$\rho^{(d)}_{k,i,j} = \left[\mathbf{S}^{(d)\,-1}_p\right]_{j^*} (\mathbf{x}^{(d)}_i - \mathbf{x}^{(d)}_{\bullet k}). \tag{3.16}$$

Having found variable q to be deleted at level l, the quantities needed at level $l-1$ are computed as follows.

Let

$$\mathbf{S}^{(l)\,-1}_p = \begin{bmatrix} \mathbf{A} & \mathbf{c}_q \\ \mathbf{c}_q^T & b_q \end{bmatrix}. \tag{3.17}$$

From (2.5),

$$\mathbf{S}^{(l-1)\,-1}_p = \mathbf{A} - \frac{1}{b_q}\mathbf{c}_q\mathbf{c}_q^T, \tag{3.18}$$

$$\begin{aligned} \eta^{(l-1)}_{k,t,i} = \eta^{(l)}_{k,t,i} - \frac{1}{b_q} &\left((\mathbf{x}^{(l-1)}_i - \mathbf{x}^{(l-1)}_{\bullet k})^T \mathbf{c}_q + b_q(\mathbf{x}_{i,q} - \mathbf{x}_{\bullet k,q})\right), \\ &\times \left(\mathbf{c}_q^T(\mathbf{x}^{(l-1)}_i - \mathbf{x}^{(l-1)}_{\bullet t}) + b_q(\mathbf{x}_{i,q} - \mathbf{x}_{\bullet t,q})\right), \end{aligned} \tag{3.19}$$

$$\rho^{(l-1)}_{k,i,j} = \rho^{(l)}_{\lambda,i,j} - \mathbf{c}_{q,j^*}(\mathbf{x}_{i,q} - \mathbf{x}_{\bullet k,q}) - \frac{\mathbf{c}_{q,j^*}}{b_q}\mathbf{c}_q^T(\mathbf{x}^{(l-1)}_i - \mathbf{x}^{(l-1)}_{\bullet k}), \qquad j \in \mathcal{V}^{(l-1)}. \tag{3.20}$$

4. Run-time comparisons on two data sets. To illustrate the relative computational speed of the various alternatives, the new optimal algorithms were compared with their previous implementations and with two measures of class separation. Note that for the implementations of the previous QDA- and LDA-based variable selection, fast downdating formulas (2.8)–(2.11) were made use of for the evaluation of the resulting classifier when adding or deleting one variable. The two measures used as the class separation criteria $\mathcal{V}^{(l)}$ are Wilk's Λ and the Mahalanobis distance between the two nearest class means (see [8]). The implementations of these also employ fast down- and updating formulas (2.2) and (2.5), reducing their time complexities from $O(d^4)$ to $O(d^3)$.

Two real data sets were used. The first, the wine data set [14], is 13-dimensional with three classes and 59, 71, and 48 objects per class. The classes correspond to three different cultivars, and the 13 variables measure the different constituents of the three resulting wines. The second data set, the sonar data [14], is 60-dimensional with two classes of size 111 and 97, respectively. The two classes correspond to sonar signals bounced off a metal cylinder and reflected off a roughly cylindrical rock.

In order to compare the measures of class separation and the classifier performance-based algorithms, and also between forward selection and backward elimination, the time measured was the CPU time taken for half the total number of variables available for selection to be added (forward selection) or deleted (backward elimination). All algorithms were implemented in the language C++ on a DEC-Alpha (133 MHz) computer.

TABLE 4.1

CPU times for forward selection and backward elimination for the new "fast" algorithms for QDA and LDA, their previous "slow" implementations, and two F-test-based heuristics. The time recorded is the CPU time taken to add or eliminate half of the total number of variables available for selection.

	Wine		*Sonar*	
	Forward	*Backward*	*Forward*	*Backward*
Fast QDA	5.3 sec	5.3 sec	87.3 sec	70.9 sec
Slow QDA	25.5 sec	62.4 sec	3066 sec	15840 sec
Fast LDA	5.2 sec	8.4 sec	77.0 sec	100.3 sec
Slow LDA	27.5 sec	66.1 sec	3138 sec	15696 sec
Wilk's Λ	1.2 sec	1.1 sec	17.4 sec	16.7 sec
Mahal. dist.	1.2 sec	1.0 sec	17.8 sec	11.7 sec

Table 4.1 summarizes the results and several interesting points are noted. The fastest algorithms are the F-test-based measures, by about a factor of five. An important point to note is that this factor did not change from the medium-dimensional wine data to the high-dimensional sonar data, reflecting the similarity of the time complexities of the two types of algorithms. In contrast, the traditional implementations of QDA and LDA require very large CPU times in the case of the sonar data. For LDA in backward elimination, for example, the speed-up provided by the new algorithm increased from a factor of about 8 to about 160. Hence the speed-up factor itself increased by a factor of about 20, while the dimensionality increased by a factor of less than 5. This reflects that the difference in the time complexity of the algorithms is $O(d^2)$; i.e., the speed-up increases quadratically with the dimensionality. Also note that the F-test and classifier performance-based algorithms are about as fast for the forward and backward approaches, while the previous algorithms for QDA- and LDA-based variable selection are significantly slower for backward elimination.

5. Discussion and conclusions. In stepwise variable selection, the aim is to find the variable to add or delete from the present set of variables such that, in the context of classification, the performance of a classifier is maximized. Due to the excessive computational cost of selecting the variables based on the evaluation of a classifier, measures of the class separation had to be used in the past. We have presented algorithms for variable selection based on the evaluation of a linear or quadratic classifier that, to within a constant factor, are as fast as those used with the measures of class separation. Therefore, because of this dramatic speed-up over the old algorithms, it is now possible to perform classifier performance-based variable selection for data that before would have required the use of a class separability measure.

Acknowledgment. The authors wish to thank the Australian Research Council for supporting this work.

PARALLEL ADAPTIVE SOLUTION OF A POISSON EQUATION WITH MULTIWAVELETS*

A. AVERBUCH†, E. BRAVERMAN‡, AND M. ISRAELI‡

Abstract. We present an adaptive algorithm for the solution of the Poisson equation. The domain is divided into subdomains. The resolution of each subdomain depends on the smoothness of the right-hand side of the Poisson equation. This determines the adaptivity of the algorithm. In each subdomain a particular solution is found. These solutions are patched by introducing double/single layers at the interfaces of the subdomains. The influence of these layers is effectively computed using multiwavelets. In the wavelet bases kernels of integrals which represent double layers are sparse. When the number of grid points increases as N, the number of essential wavelet coefficients, which represent a vector, increases as $\log N$. Hence, using this sparsity reduces the number of operations from $O(N^2)$ to $O(N \log N)$. The algorithm was implemented on parallel computers of SP2 and SGI types while each processor was assigned to each box. The efficiency of the algorithm was demonstrated.

1. Introduction.

Problems in elasticity, fluid dynamics, material science, semiconductor device simulations lead to large-scale initial-boundary value problems for nonlinear parabolic partial differential equations (PDEs). This paper proposes a numerical solution for evolution equations with parabolic terms like the incompressible Navier–Stokes equations.

Semi-implicit discretization in time removes the stringent diffusive stability limit but requires the solution of many elliptic problems. The solution of such equations, at the high resolution necessary in typical applications, requires considerable computation resources. This can be achieved on parallel computers if efficient parallelization is possible. The numerical solution of PDEs has the potential for efficient parallelization on massively parallel multiprocessors because partial derivatives represent in principle local behavior. Of course, it is well known that local changes reach all parts of the computational domain and this dictates global communication. Global communication can degrade the performance of the achieved parallel speedup. There are cases (see [10, 12]) where the effect of local changes usually decays quickly with distance in the time stepping scheme.

In this paper the parallelization of the serial algorithm is achieved by decomposition of the computational domain into smaller domains, mainly of rectangular (cubic) shape. The solution in each rectangular domain is fast and accurate, and it is based on the algorithm that was developed in [3, 4] for the 2-D case and in [8] for the 3-D case. The particular solutions, which were obtained by this approach, have discontinuities on the domain interfaces. The discontinuities can be removed by adding

singularity layers. The effects of the layers on all the other interfaces are computed. The number of computations can essentially be reduced if the corresponding operators are efficiently represented.

An algorithm for a fast solution of the Poisson equation by decomposition of the domain into square domains and the subsequent matching of these solutions by the fast multipole method was developed in [9]. We note the following advantages of the proposed algorithm.

1. The fast implementation of the algorithm in [9] was stipulated by the division of the global domain into squares with a small number of points in each subdomain. This is done since $O(N^3)$ algorithm is applied for the solution of the Poisson equation in the subdomains (here N is a number of points in each direction). Our algorithm has complexity of $O(N^2 \log N)$ in each subdomain. The complexity is independent of the size of the subdomain. The number of subdomains is determined only by the number of processors in the multiprocessor environment.
2. The algorithm has an inherent parallel structure. Therefore, we do not have to modify the serial algorithm when it is ported onto a parallel computer. When the algorithm runs on a parallel computer each subdomain is assigned to a distinct processor. Therefore, each neighboring subdomain (processor) has to transfer to each other the information (jumps of the function or its first derivative represented in wavelet bases) on the common interfaces. Since we transfer between the processors only the information on the interfaces, it costs $O(N)$. The representation by multiwavelets reduces the data to be transmitted to $O(\log N)$, even to the nearest neighbors of the processor.
3. We use a very efficient method to compute the solution of Poisson/Laplace equations inside each domain. The construction of the general solution via matching of the independent solutions in each subdomain can degrade the gain of the solutions inside the domains. Since the computations of the matching among the subdomains are based on double/single layer influences which are not more expensive than the algorithms inside the domain, we are successful in having an efficient solution for the matching step as well. The efficiency of the matching step is due to the usage of multiwavelets discretization.

A basic problem in the numerical solution of differential and integral equations is to find an efficient discrete representation of the underlying continuous operators. The problem with classical methods is that they lead to a dense representation for most operators. That means that matrices are full whereas sparse representation has the advantage of minimizing the operation count during the application of the operator. Dealing with sparse matrices also leads to a decrease of the computational time. Therefore, an important step in the numerical solution consists of building algorithms which lead to a better representation of the usual operators. A good representation means "few coefficients for the same accuracy."

The method that was described in [5, 6] is based on the wavelet transform which provides sparse representations of operator kernels. This transform consists of expanding a given function or an operator over a set of wavelet basis functions obtained by dilations and translations of an elementary function localized in both physical and Fourier spaces. The wavelet transform leads to less computations than those obtained with the regular Fourier transform. The reason to have an efficient solution in [5, 6] is that there is a description for an efficient discretization and adaptive solution of PDEs which are forced by the right-hand side (RHS) with regions of smooth (nonoscilla-

tory) behavior and possibly localized regions with nonsmooth structures. In addition, the wavelet basis allows automatic adaptation (using thresholding) in the sense that only a few coefficients are needed to describe smooth sections of the RHS while more coefficients are needed for sharp transitions and singular points. This saving is due to the vanishing moments property of high-order wavelets. The algorithms are adaptive, i.e., the number of operations performed is proportional to the number of significant coefficients in the wavelet expansion of the "inputs" of a given differential equation problem. The basic tool in this approach is the preconditioned conjugate gradient iteration in a "constrained" form. In the wavelet basis diagonal preconditioners are available which render the condition number of elliptic operators to O(1). This means that a constant number of iterations is required for solution to a prescribed accuracy. In [5, 6] there is a description of a fast 1-D–3-D adaptive method for solving certain elliptic equations with periodic boundary conditions using tensor wavelets with sparse structures.

In this paper we employ a multiwavelet representation of the integral operators which represent single and double layers. The layers are introduced in order to match the particular solutions which were obtained separately in the subdomains. A double layer is introduced on each interface in order to correct the discontinuities of the solution. We assume that we have Dirichlet conditions on the original boundary and matching Neumann conditions on the interfaces. Therefore, we assume that the mixed problems are solved for the nonhomogeneous equation in each subdomain. For faster communication it is preferable to use double layers on the inner boundaries of the subdomains interfaces since they decay faster with distance. A basis that was built in [2] was chosen due to its local character which does not lead to the Gibbs phenomenon. The obtained sparse representation reduces both the computation and the communication time required for parallel processing.

The paper is organized as follows. Section 2 describes the problem, the plan for its solution, and presents a simple 1-D example which illustrates the idea of the solution. Section 3 is focused on the matching step of the algorithm. It contains relevant formulas, numerical examples with the associated operation count. In section 4 we treat the singularities arising from the computation of the influence of the layer at a line which intersects the layer. Section 5 describes the matching step associated with the adaptive algorithm. The adaptation is needed because the resolution in each subdomain is different. Section 6 outlines the parallelization details and illustrates how the amount of communication is reduced if the multiwavelets coefficients are transferred among domains instead of the pointwise values. It also contains timing results for the performance of the parallel algorithm. The appendix contains a brief description of multiwavelets basis developed in [2].

2. The problem. We solve the Poisson equation

$$\Delta u = f(x, y) \quad \text{in} \quad \Omega \tag{2.1}$$

in the rectangular domain $\Omega = [0, L] \times [0, 1]$ with either Dirichlet,

$$u = \Phi(x, y) \quad \text{on} \quad \partial\Omega, \tag{2.2}$$

or Neumann,

$$\frac{\partial u}{\partial n} = \Phi(x, y) \quad \text{on} \quad \partial\Omega, \tag{2.3}$$

boundary conditions where n is the internal normal to $\partial\Omega$. A mixed Dirichlet/Neumann-type boundary condition can also be considered.

To have a parallel solution the domain Ω is divided into l rectangular subdomains. The solution process includes the following steps:

1. In each subdomain a particular solution $u_1^{(s)}$ of the nonhomogeneous equation with arbitrary Neumann (Dirichlet) boundary conditions is found.
2. The collection of particular solutions $u_1^{(s)}$, $s = 1, \ldots, l$, usually have discontinuities (or discontinuities in the derivatives) on the boundaries of the subdomains. We introduce double (single) layers on the boundaries to match the solutions from different domains to have continuous global solution. The effect of these layers on other boundaries is calculated.
3. With the boundary conditions that were computed in the previous step, the solutions $u_1^{(s)}$ are patched by adding the solutions $u_2^{(s)}$, $s = 1, \ldots, l$, of the Laplace equation.
4. An additional solution of the Laplace equation is added to satisfy the boundary conditions on $\partial\Omega$. Namely, for the Dirichlet case the solution u_3 of the homogeneous equation on the boundary $\partial\Omega$ is derived by

$$u_3(x, y) = \Phi(x, y) - u_1(x, y) - u_2(x, y). \tag{2.4}$$

(The case with Neumann boundary conditions is treated similarly.) Thus $u = u_1 + u_2 + u_3$ is the solution of the nonhomogeneous equation with the initial nonhomogeneous boundary conditions.

The following 1-D example illustrates the constructive idea of the algorithm.

Example. We consider the problem

$$u''(x) = 2, \quad x \in [-1, 2], \quad u(-1) = 1, \quad u(2) = 4. \tag{2.5}$$

Step 1. The domain $[-1, 2]$ is divided into three equal subsegments,

$$[-1, 2] = [-1, 0] \cup [0, 1] \cup [1, 2],$$

with arbitrary boundary conditions such that the following three nonhomogeneous boundary value problems are being solved:

$$u_1''(x) = 2, \quad x \in [-1, 0], \quad u_1(-1) = 0, \quad u_1'(0) = 0,$$

$$u_1''(x) = 2, \quad x \in [0, 1], \quad u_1'(0) = 0, \quad u_1(1) = 1,$$

$$u_1''(x) = 2, \quad x \in [1, 2], \quad u_1(1) = 1, \quad u_1(2) = 0.$$

The obtained solution is

$$u_1(x) = \begin{cases} x^2 - 1, & x \in [-1, 0), \\ x^2, & x \in (0, 1), \\ x^2 - 4x + 4, & x \in (1, 2]. \end{cases} \tag{2.6}$$

The global solution is unmatched on 0 as we see in Figure 1.

Step 2. However, the obtained solution has discontinuity in the function on $x = 0$ and discontinuity in the derivative on $x = 1$. We can fix both discontinuities by imposing double and single layers potentials, respectively. In one dimension

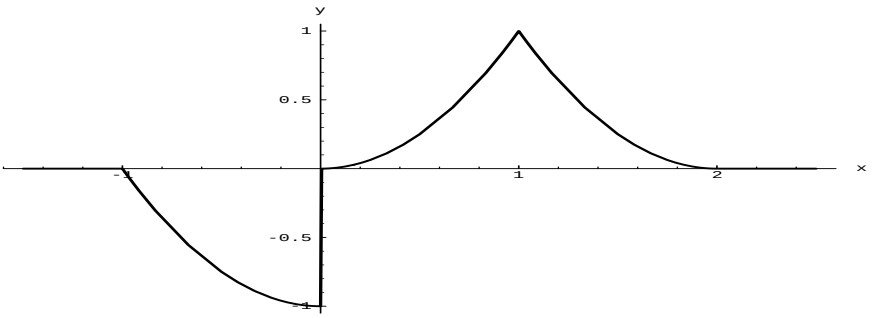

FIG. 1. *Different parts of the solution in each subdomain are unmatched.*

TABLE 1
The influence of double and single layers potential on the boundaries -1,0,1,2.

x	-1	0	1	2
Double layer influence	0.5	0.5/-0.5	-0.5	-0.5
Single layer influence	4	2	0	2
Total influence	4.5	2.5/1.5	-0.5	1.5
Initial value	0	-1/0	1	0
Sum	4.5	1.5	0.5	1.5

the double layer influence is equivalent to adding plus/minus half of the jump to the left/right of the "layer point," respectively. Here, the jump is 1, so 0.5 has to be added to the values of the function for $x < 0$ and -0.5 for $x > 0$. In addition, the single layer in $x = 1$ adds the linear function $a(x-1)/2$ $(-a(x-1)/2$) to each $x < 1$ $(x > 1)$, where $a = u_1'(1+) - u_1'(1-) = -4$. We compute the influence only on the boundaries at $x = -1, 0, 1, 2$.

Step 3. In each domain the homogeneous equation

$$u_2'' = 0$$

is solved with the following boundary conditions (using Figure 1):

$$u_2(-1) = 4.5, \quad u_2(0) = 2.5, \quad x \in (-1, 0),$$

$$u_2(0) = 1.5, \quad u_2(1) = -0.5, \quad x \in (0, 1),$$

$$u_2(1) = -0.5, \quad u_2(2) = 1.5, \quad x \in (1, 2),$$

which corresponds to the row *total influence* in Table 1.
Evidently,

$$u_2(x) = \begin{cases} -2x + 2.5, & x \in [-1, 0), \\ -2x + 1.5, & x \in (0, 1), \\ 2x - 2.5, & x \in (1, 2]. \end{cases} \tag{2.7}$$

The resulting $u_1 + u_2 = x^2 - 2x + 1.5$ is a continuous function which does not satisfy the boundary conditions of (2.5) (see Figure 2), but

$$u_1(-1) + u_2(-1) = 4.5, \quad u_1(2) + u_2(2) = 1.5.$$

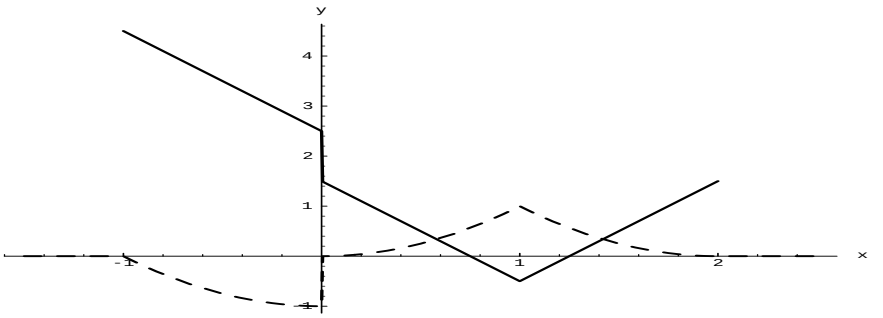

FIG. 2. *Matching of the global solution. Still it does not satisfy the boundary conditions.*

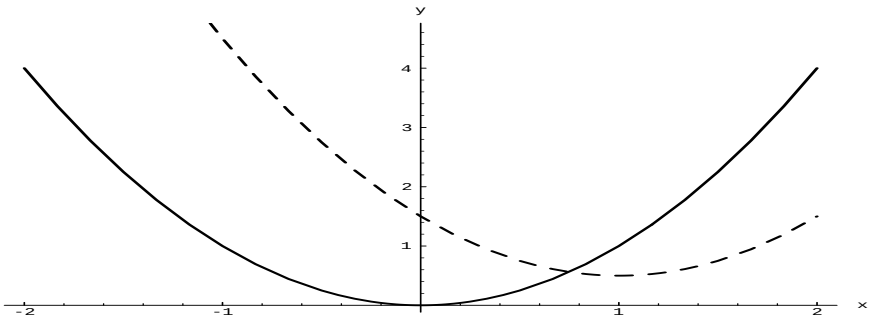

FIG. 3. *Global solution which satisfies the boundary conditions.*

Step 4. We find and add the solution of the homogeneous equation

$$u_3''(x) = 0, \quad u_3(-1) = -3.5, \quad u_3(2) = 2.5.$$

Thus, we obtain the solution for the initial problem. Namely, $u_3 = 2x - 1.5$. Finally, $u(x) = u_1(x) + u_2(x) + u_3(x) = x^2$ (see Figure 3).

The main focus of this paper is how to implement and compute efficiently the influence of the double (single) layer on the other interfaces and boundaries. This corresponds to Step 2 of the above algorithm. All the other steps of the algorithm are discussed in [3, 10, 12].

A double layer is introduced on each interface in order to correct the discontinuities of the solution. From now on we assume that the mixed problems were solved for nonhomogeneous equation in each subdomain. Mixed problem means that we assume that we have Dirichlet conditions on the original boundary and matching Neumann conditions on the interfaces. We use double layers on the inner boundaries of the subdomains interfaces since they decay faster with distance.

3. Computation of the influence of double layer potential. Let us assume the geometry of Figure 4.

3.1. The form of the double layer in the current geometry. The potential of a unit strength dipole which is located at x_0 and has orientation in the $e \in \mathcal{R}^2$ direction is defined by

$$\phi_{x_0,e}(x) = \frac{\partial}{\partial t}(\phi_{x_0}(x + te))\Big|_{t=0} = \frac{e(x - x_0)}{\pi \|x - x_0\|^2}.$$

The potential of the double layer which is introduced on the line $x = \gamma(t),\ t \in [0, L]$ with a dipole density $\tau(t)$ is

$$P_\tau(x) = \int_0^L \phi_{\gamma(t),N(t)}(x)\tau(t)\ dt.$$

We consider the case where the domain $[0, L]\times[0, 1]$ is decomposed into L squares. Half of the jump of the solution on the kth boundary, which is denoted by τ_k, is

$$\tau_k(y) = \frac{u_k(k+0, y) - u_{k-1}(k-0, y)}{2}, \quad k = 1, \ldots, L-1. \tag{3.1}$$

The influence of the dipole layer introduced on the segment $[0, 1]$ of the Y axis with dipole density $\tau(y)$ is evaluated by the following equation on the parallel line $x = d$ and the perpendicular line $y = 0$, respectively:

$$P_d^{paral}(y) = \frac{1}{\pi}\int_0^1 \frac{d}{d^2 + (x-y)^2}\tau(x)dx, \quad 0 \le y \le 1, \tag{3.2}$$

$$P_0^{cross}(x) = \frac{1}{\pi}\int_0^1 \frac{x}{x^2 + y^2}\tau(y)dy, \qquad 0 < x \le L. \tag{3.3}$$

Similarly, the influence of double layers on the other interfaces is computed.

The evaluation of (3.3) and (3.2) is a time consuming step. The representation of the integral operators is done through matrix-vector multiplication [7, 2]. The matrix-vector multiplication in this case can be implemented efficiently using *wavelet* or *multiwavelet* methods.

The representation of the kernels of the integral operators in the multiwavelet bases is precomputed. These kernels depend only on the known geometry of the domain and the subdomains. The coefficients of the multiwavelet representations of τ_k are to be transmitted from processor to processor where the integral of double layer potential is calculated. However, this vector is expected to be sparse for τ_k which is smooth. The sparsity of the coefficient vector also reduces the number of computations needed for the integration.

We describe now the algorithm that computes the integral

$$\mathcal{T}(x) = \int_0^1 T(x, y)\tau_k(y)dx, \quad y \in [0, 1], \tag{3.4}$$

where T is the potential for (x, y) in the mth subdomain, $m \ge k$,

$$T(x, y) = \frac{m - k + x}{(m - k + x)^2 + y^2}, \quad x \in [0, 1],\ y \in [0, 1] \tag{3.5}$$

(other integrals are similarly treated). T is smooth everywhere except at the intersection point of the layer line and the line where the potential is calculated $x = 0,\ y = 0$ if $m = k$.

The integral operator (3.4) is discretized using a simple equispaced quadrature. Thus we define n equispaced points

$$x_i = \frac{i-1}{n-1}, \tag{3.6}$$

and the elements T_{ij} of the $n \times n$ matrix become

$$T_{ij} = \begin{cases} \frac{1}{n-1} T(y_i, x_j), & m-k \neq 0 \text{ or } i \neq 1 \text{ or } j \neq 1, \\ 0, & \text{otherwise.} \end{cases} \tag{3.7}$$

This corresponds to a trapezoid-like quadrature discretization of the operator $\mathcal{T}$.

We decompose the matrix $\{T_{ij}\}$ in a multiwavelet basis of $L^2(\mathcal{R})$ that was developed in [1, 2] which is useful here due the following reasons: 1. Its locality. 2. The multiwavelets computation in each domain does not need any information from neighboring domains. 3. Automatic adaptation to smooth and nonsmooth areas via thresholding. It means that if a function has a mix of singularities and smooth areas, then the number of significant multiwavelet coefficients in its multiscale decomposition is determined by the number of singularities and the number of multiwavelet coefficients that are needed to describe these singularities [5, 6].

We employ here a generalization of this basis which was designed in [2]. The description of the basis is given in the appendix.

3.2. Numerical examples.

3.2.1. Evaluation of the sparsity of the matrices that represent the influence of the layer.

Example 1. We solve the nonhomogeneous Laplace equation

$$\Delta u = 4$$

in the rectangle $0 \leq x \leq 3,\ 0 \leq y \leq 1$ in each of three squares

$$0 \leq x \leq 1,\ 0 \leq y \leq 1,$$

$$1 \leq x \leq 2,\ 0 \leq y \leq 1,$$

$$2 \leq x \leq 3,\ 0 \leq y \leq 1,$$

with Neumann conditions on the boundaries between them:

$$\frac{\partial u}{\partial x}(1-, y) = \frac{\partial u}{\partial x}(1+, y) = 0, \qquad \frac{\partial u}{\partial x}(2-, y) = \frac{\partial u}{\partial x}(2+, y) = 4.$$

Suppose that we solved the three problems and the obtained solution (see Figure 5)

$$u(x, y) = \begin{cases} 2y^2 - 2y + 2, & 0 \leq x < 1, \\ 2x^2 - 4x + 4, & 1 < x < 2, \\ x^2 + y^2 - y, & 2 < x < 3, \end{cases}$$

is discontinuous on the boundaries $y = 1, 2$:

$$\begin{aligned} u(1+, y) - u(1-, y) &= 2 - 2y^2 + 2y - 2 = 2y(1-y), u(2+, y) - u(2-, y) \\ &= 4 + y^2 - y - 8 + 8 - 4 = y^2 - y = y(y-1). \end{aligned}$$

(One can easily check that the derivative in x is continuous for $x = 1, 2$.)

To remove these discontinuities we introduce the double layers with $\tau_1(y) = y(1-y)$ for $x = 1$ and $\tau_2(y) = y(y-1)/2$ for $x = 2$. Evidently, $\tau_1(y) = -2\tau_2(y)$, thus for

TABLE 2

The number of points on the interface is given by the row called "number of points." This number is equal to the number of points on the parallel line at distance 1 *where the influence of the double layer is computed. "Nonzero coefficients" refers to the number of elements above the threshold in the multiwavelet representation of the matrix* $1/(1+(x-y)^2)$. *This matrix is the kernel of the dipole layer potential on the parallel line. The average number of nonzero coefficients per row is also computed. The multiwavelet basis is chosen with* 4 *vanishing moments. The accuracy is given by the maximal absolute error.*

precision analysis it is sufficient to estimate the influence f_1 (or f_2) of the layer with the dipole density $\tau_1(y)$. It is antisymmetric for the segments $y = 1, 0 < x < 1$ and $1 < x < 2$. Besides, $\tau_1(y)$ is symmetric, thus for $y = 0,\ 0 < y < 1$ this influence is antisymmetric to the influence on $1 < x < 2$ for $y = 1$. Furthermore, the influence on the parallel lines $x = 2$ and $x = 0$ is the same with the opposite sign. Thus, for the precision analysis we consider the effect of the dipole layer on the crossing segment $y = 1, 1 < x < 3$ and on two parallel segments $x = 2$ (see Table 2) and $x = 3$ (see Table 3) for $0 < y < 1$.

It is natural to assume that the number of essential coefficients decays with the increase of the distance between two parallel segments: one segment is where the double layer is introduced, and the second segment is where the influence of this layer is computed. Table 3 gives the number of essential coefficients in the matrix, and the achieved accuracy when other coefficients for the parallel line at the distance equal to 2 are ignored.

It is to be emphasized that when the matrix in the multiwavelet basis is decomposed all the intermediate results below the threshold are ignored.

We conclude this example with an estimate of how the number of significant wavelet coefficients decays as the distance from the single layer increases in Table 4. We assume the geometry of Figure 4 and compute the representation of the kernel of the *single layer* potential at a parallel line in a multiwavelet basis with four vanishing moments. The distance from the single layer is from 1–16. Obviously for a double layer the decay of the number of significant coefficients is quicker (compare Tables 2, 3).

Example 2. In the previous example we were concerned with a very smooth function for the density of the double layer. Now we consider the case when the density of the double layer is $\exp\{-5(y-0.2)^2\} + \exp\{-50(y-0.7)^2\}$.

TABLE 3

The same computation as in Table 2, but here the influence of the double layer is computed on the parallel line at distance 2. This corresponds to the kernel $2/(4+(x-y)^2)$.

TABLE 4

The number of multiwavelet coefficients above 10^{-7} *for the matrix that describes a single layer potential at a parallel line at distance* d.

Number of coef. above 10^{-7}	Distance d				
	1	2	4	8	16
128×128	234	112	25	15	10
256×256	410	393	62	26	12

It is obvious that the number of essential elements in the matrix, which represents the kernel in the multiwavelet basis, is the same as in the previous example. Therefore, we present here only the accuracy results.

It is important to emphasize that the kernel for a double/single layer depends only on the geometry of the problem. The sparse representation and the structure of this kernel is computed at the preprocessing step. It is common for all the problems with the same geometry and domain decomposition.

3.2.2. Evaluation of the sparsity of the wavelet representation of the density of layers. The complexity of the matching step is determined by the sparsity of the matrix and the vector that are involved in the matrix-vector multiplication. The matrix represents the influence of the layer in the wavelet basis, while the vector represents the density of the layer in the same basis. The number of operations depends not only on the sparsity of the matrix but also on the sparsity of the vector. For instance, in Example 2 the vector was a quadratic polynomial, so its multiwavelet representation had only three nonzero coefficients at the coarsest level if the number of vanishing moments is not less than three. In the case when the vector is a steep Gaussian function the accuracy results are given in Table 5 and the sparsity results are presented in Table 6.

At the matching step first each dipole layer density is represented in the multiwavelet basis. In the parallel implementation, then, the multiwavelet coefficients are transmitted to each processor in order to compute the influence of all double layers on

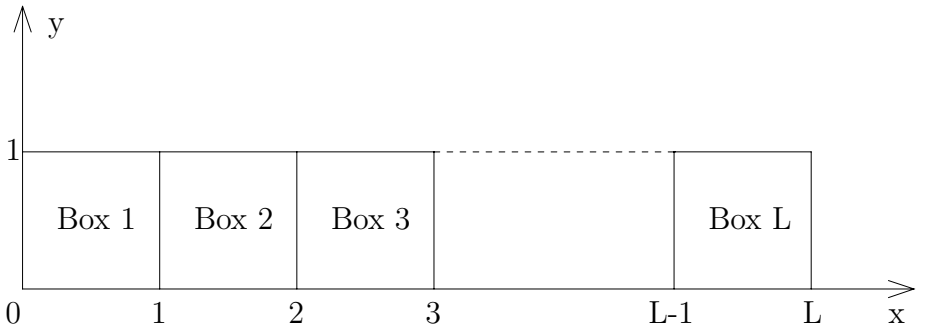

FIG. 4. *The domain is decomposed into L subdomains. Double layers are introduced on the* $L-1$ *interfaces.*

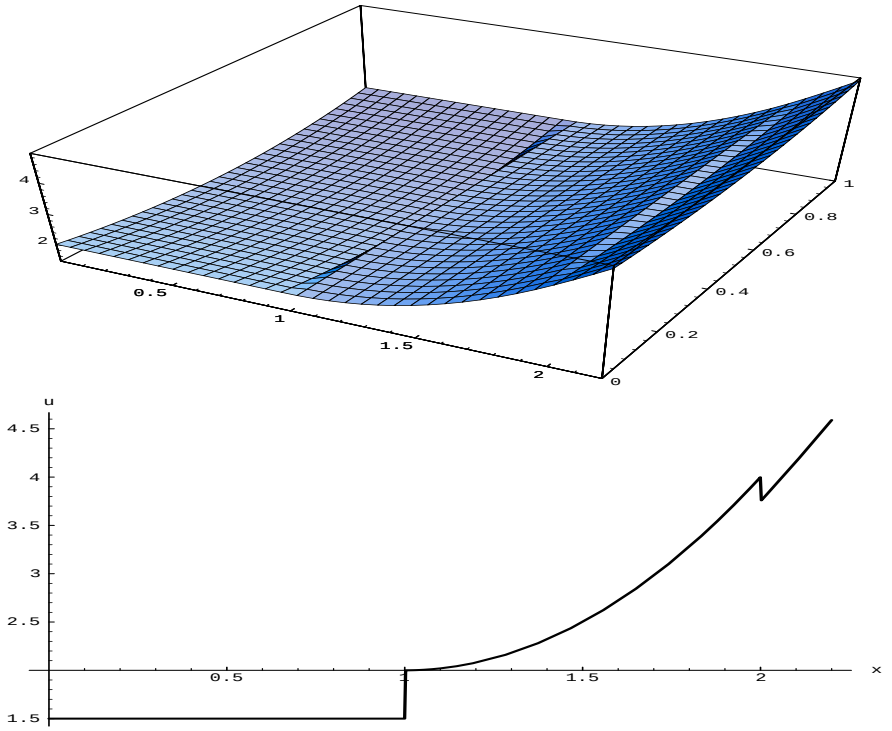

FIG. 5. *A surface plot and graph of* $u(0.5, y)$.

its boundaries. Only the coefficients above the threshold are transmitted. Therefore, the sparsity of the multiwavelet coefficients vector reduces the volume of the communication. If the density is constant then only one coefficient has to be transmitted. Consider the case where the density is in the form of a Gaussian bell

$$\tau(y) = e^{-\alpha(y-y_0)^2}.$$

Table 6 describes the comparison between the number of essential coefficients in the original function and in the multiwavelet representation. The number of vanishing moments is $k = 4$ and $y_0 = 0.5$.

TABLE 5

Accuracy of the computation in the multiwavelet basis with 4 *vanishing moments in the case when the density of the double layer is* $\exp\{-5(y-0.2)^2\} + \exp\{-50(y-0.7)^2\}$. *The line where the effect of the double layer is computed is parallel at distance* 1.

The influence of the dipole layer decays as $1/r$, where r is the distance from the point to the dipole line (in our case, the distance between the parallel lines is an integer; see Figure 4). This is important to the parallel communication when the essential elements are transmitted from a subdomain to a subdomain. Small elements are not transmitted to large distances. It reduces the information stream to remote processors.

3.2.3. Implementation of the algorithm. The full algorithm was implemented on the configuration depicted in Figure 4. First, the Dirichlet problem for the Poisson equation was solved in each of the three boxes. The boundary conditions were chosen to provide the continuity of the solutions. The single layers were introduced to match the first derivative in the adjacent boxes. The sum of influences of these layers was computed at all the interfaces. Then, the Laplace equation was solved with the boundary conditions equal to the sum of influences. Finally, the global Dirichlet problem was solved in the domain $0 \le x \le L$, $0 \le y \le 1$ to satisfy the original boundary conditions. All the algorithms were chosen to provide $O(h^4)$ convergence. The algorithm employed for the solution of the Poisson and the Laplace equations was developed in [3].

Assume that u is the exact solution and u' is the computed solution. In the

TABLE 7

32	2.0e-9	5.4e-10	9.2e-10
64	2.0e-9	5.4e-10	9.2e-10
128	2.0e-9	5.4e-10	9.2e-10

examples we will use the following measures to estimate the errors:

$$\begin{aligned} \varepsilon_{MAX} &= \max \|u_i' - u_i\|, \\ \varepsilon_{MSQ} &= \sqrt{\frac{\sum_{i=1}^{N} (u_i' - u_i)^2}{n}}, \\ \varepsilon_{\mathcal{L}^2} &= \sqrt{\frac{\sum_{i=1}^{N} (u_i' - u_i)^2}{\sum_{i=1}^{N} u_i^2}}. \end{aligned}$$

Example 3. We solve the Poisson equation $\Delta u = -2 \cos x \cos y$ with the boundary conditions corresponding to the exact solution $u(x,y,z) = \cos x \cos y$ in the domain $[0,3] \times [0,1]$ divided into three equal boxes (see Table 7).

We recall that for the solution of the Poisson equation the RHS is extended into a wider domain such that it is periodic in the area including $N + 2N_\epsilon$ grid points in each direction. First, the Poisson equation is solved in the extended domain; then the solution in the original domain is considered as a partial solution. Table 8 describes the dependency between the accuracy and the length of the extension N_ϵ when the number of points in each subdomain is equal to 128×128 and the number of subdomains is three. We can see that when the extension exceeds 11 grid points the accuracy does not change.

Example 4. Consider the Poisson equation with the same solution as in Example 3 in the domain $[0,8] \times [0,1]$ divided into eight equal boxes (see Table 9).

Table 10 presents the accuracy of the numerical solution when the exact solution is $u(x,y,z) = \cos x \cos y$ and the number of boxes is varied.

We can see that the error is nearly independent of the number of processors.

Example 5. We solve the Poisson equation with the boundary conditions corresponding to the exact solution

$$u(x,y) = \exp\left\{\alpha\left((x-x_0)^2 + (y-y_0)^2\right)\right\},$$

TABLE 9

16	5.3e-8	1.5e-9	2.5e-8

with $x_0 = 1.5,\ y_0 = 0.5,\ \alpha = 2$ in the domain $[0,3] \times [0,1]$ divided into three equal boxes (see Table 11).

In Figure 6 the solution before the matching step is presented. It has discontinuities in the x derivative at the lines $x = 1$ and $x = 2$.

After the matching step the solution becomes smooth (see Figure 7).

Table 12 presents the accuracy of the algorithm for a Gaussian function as the exact solution when the steepness $\alpha = 0.5,\ 2,\ 8$ varies.

Example 6. We solve the Poisson equation with an exact solution in $[0,4] \times [0,1]$ being a sum of random Gaussian functions $u(x,y) = \exp\left\{\alpha_i\left((x-x_i)^2 + (y-y_i)^2\right)\right\}$, centered at the points (0.002,0.4), (1.7,0.8), (1.95,2.5), (2.3,1.1), (1.4,2.3), (3.8,2.9), (1.5,3.6), (2.05,1.8), (0.4,3.3), (2.8,1.6), (3.5,3.1), (0.6,3.8), with $\alpha_i = 3,\ 7,\ 1,\ 0.5,\ 4,\ 0.7,\ 2.5,\ 0.2,\ 5.5{,}1.5,\ 3.2,\ 0.8$, respectively. Some of the centers are close to the boundaries and interfaces. The domain was divided into four equal squares. Table 13 presents the accuracies obtained.

3.3. Operation count. Consider the case when the domain is divided into L square subdomains as in Figure 4. We estimate the number of operations while taking into consideration the influences of the double layers which were introduced on the interfaces.

Preprocessing. The preprocessing contains a representation of the kernels of the integrals (3.2) and (3.3) in the multiwavelet basis. We have to treat L kernels which correspond to the influence of double layers on the boundaries (interfaces) parallel to the y axis with distance of $1, 2, \ldots, L$ from the double layer. The same number of kernels describes the influences of double layers on perpendicular boundaries. (It is obvious that the influences on $y = 0$ and $y = 1$ lines lead to the same matrices.) Representation of each kernel requires $O(Nk^2)$ operations [2], where k is the number of vanishing moments and N is the number of discretization points. Therefore, this requires $2LO(Nk^2)$ operations. This is the most time consuming step in the whole algorithm. However, this procedure is implemented as a preprocessing step since it depends only on the geometry of the subdomains. Once this is completed, various

problems with different RHSs and boundary conditions can be treated. For example, if we solve the Navier–Stokes equation in a certain domain the integral operators of the type (3.2) and (3.3) are represented in the multiwavelet basis only once.

The resulting matrices have $O(N)$ essential elements above the threshold. The matrices which describe the influence of the layer on distant boundaries and interfaces have only $O(1)$ elements with absolute value above a certain threshold.

The actual computation. The algorithm incorporates the following steps:

1. We compute the difference between the adjacent solutions which costs $O(N)$ operations. Double layers for matching solutions are introduced. The densities of double layers τ_k, $k = 1, \ldots, L-1$ are decomposed in multiwavelet bases. This requires $O(Nk)$ operations for each density [2]. It is worth mentioning that we used the standard form for the matrix representation in a multiwavelet base [7]. This leads to a sparse representation of τ_k for a smooth dipole density τ_k.

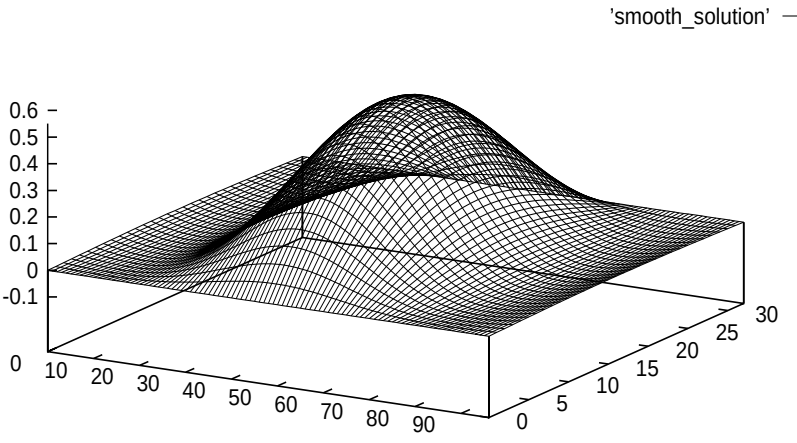

FIG. 7. *The global solution after the matching step.*

2. Matrix-vector multiplication for a matrix with not more than $O(N)$ essential elements and a sparse vector with $O(1)$ essential elements can be implemented in $O(N)$ operations using sparse data structures. Tables 2–6 demonstrate the obtained sparsity of matrices and vectors, even in the cases when the density is a steep function. In matrices which represent kernels of integral operators the number of essential elements per row decreases with the increase of N.
3. The reconstruction of the resulting vector from the multiwavelet coefficients back to the physical space requires $O(Nk)$ operations.

Therefore, the total number of operations is $O(Nk^2)$ for the preprocessing step and $O(Nk)$ for the actual implementation, where N is the number of discretization points on the long side of the rectangle and k is the number of vanishing moments.

4. Treatment of singularities on a line intersecting the double layer. Consider (3.3) for the computation of the influence of the double layer on the inter-

TABLE 13

secting line. It contains an improper integral with the kernel

$$K(y,x) = \frac{x}{x^2+y^2},$$

which is unbounded at the origin $(0,0)$. Such an integral cannot be efficiently evaluated by the equispaced trapeze method. High accuracy can be achieved if we make the substitution $y = \varphi(t)$ in the integral

$$\int_0^1 K(x,y)\tau(y)\ dy = \int_0^1 K(x,\varphi(t))\tau(\varphi(t))\varphi'(t)\ dt.$$

Here $\varphi(t)$ is an increasing function of t which defines a one-to-one mapping of [0,1] and has m vanishing derivatives at $t = 0$ and $t = 1$. After the substitution the error of the trapezoidal rule in the variable t becomes $O(n^{-2m-1})$, where n is a number of the discretization points [11]. This method corresponds to a nonequispaced discretization where the grid points are concentrated near the edges. We employed the trigonometric $\sin^m$ transformation of [11] with $m = 4$ vanishing derivatives at the end points

$$\varphi(t) = \frac{1}{12\pi}(12\pi t - 8\sin 2\pi t + \sin 4\pi t).$$

The theoretical error in this special case is $O(n^{-2m-2}) = O(n^{-10})$, i.e., for each doubling of the number of points the error is reduced 1000 times. Table 14 shows the influence of the double layer with density $\tau(y) = y(1-y)$ at the parallel line at distance 1 using the $\varphi(t)$ substitution.

Table 15 shows the influence of the double layer with density $\tau(y) = y^3(1-y)$ on the perpendicular line using the $\sin^4$ transformation.

This method gives accurate results for a smooth and nonoscillating density function. However, it fails for both oscillating (for example, $\tau(y) = \cos 6y$ was checked) and δ-type functions (such as steep Gaussians). Moreover, it requires nonequispaced discretization. The densities of the double layers are established as the jumps between adjacent particular solutions which are found in the equispaced points. These are the reasons why the above method was not used by us.

TABLE 15

The accuracy for computing the influence of the double layer with density $\tau(y) = y^3(1-y)$ on the perpendicular line. The $\sin^4$ *transformation was used.*

Number of points	8	16	32
Accuracy (maximal error)	1.4e-5	9.5e-9	7e-12

TABLE 16

Accuracy for the computation of the influence of the double layer on the intersecting line. The kernel of the integral representing the influence is equal to $xy^3/(x^2+y^2)$; the density of the double layer is $\tau(y) = 1-y$. Middle point integration method was applied.

Number of points	8	16	32	64	128	256
Maximal error	9.3e-5	2.5e-5	6.4e-6	1.62e-6	4.04e-7	1.01e-7
Left point error	6.0e-5	7.8e-6	1e-6	1.3e-7	1.6e-8	2e-9

We use the subtraction technique which allows to keep both accuracy and equispaced discretization. Due to the Taylor series in $y = 0$ each density function $\tau(y)$ can be written as

$$\tau(y) = A + By + Cy^2 + y^3\delta(y),$$

where $\delta(y)$ is a continuous function in $y = 0$. Therefore, one easily finds that

$$\int_0^1 K(x,y)\tau(y)dy = \left(-A\arctan\frac{x}{y} + B\frac{x}{2}\ln(x^2+y^2) + Cxy + Cx^2\arctan\frac{x}{y}\right)\Bigg|_0^1 + \int_0^1 K_1(y,x)\delta(y)dy,$$

where the kernel $K_1(x,y) = xy^3/(x^2+y^2)$ is nonsingular. The accuracy results from the computation of the last integral is presented in Table 16. The following errors were computed: the error at the closest point to the point of intersection (left point error), and the maximal absolute value of all the errors at the boundary (maximal, or l_∞, error).

In fact, subtraction of two terms is sufficient in order to reach the same accuracy as in the case of the parallel lines.

5. Adaptive algorithm. In this section we describe an adaptive implementation of the algorithm for the solution of the Poisson equation. The main strategy is similar to that developed in [9]. The domain is divided into subdomains where the grid is chosen according to the smoothness of the RHS. This allows avoidance of massive computation in the domains where the solution is smooth, and thus, even a small number of points is enough to reach a high accuracy. In section 5.1 we illustrate this idea with some examples which demonstrate high accuracy and quick convergence for an adaptive grid. In these examples the RHS is such that the exact solution is a steep Gaussian centered in the middle of the domain. The domain is divided into three sections, where a denser grid is applied in the central section. Similarly, a hierarchy of grids can be chosen according to the behavior of the RHS. In section 5.2 the matching procedure for subdomains with different grids is discussed. The number of operations in matching procedure is evaluated when the corresponding matrix-vector multiplications are accomplished in multiwavelet basis. The efficiency of the algorithm depends on the sparsity of the matrix obtained.

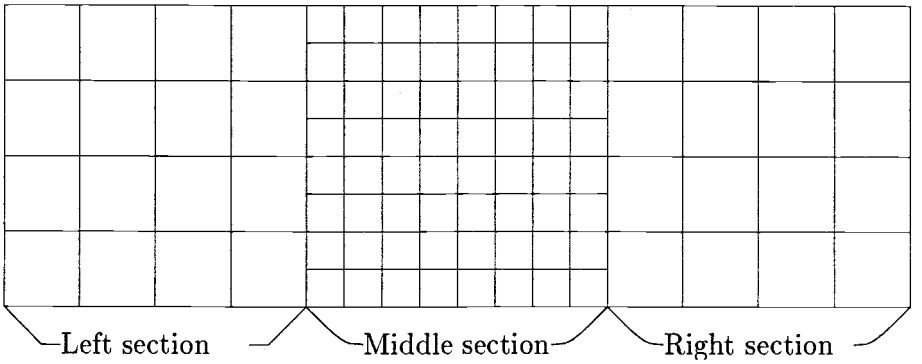

FIG. 8. *The domain is divided into three sections, where the grid in each section depends on the smoothness of the RHS in the Poisson equation.*

TABLE 17

512×512	256×256	4.0e-9	8.4e-10	3.7e-9	21.0

5.1. Implementation of an adaptive algorithm. Let the domain be a rectangular $[0,3] \times [0,1]$ (see Figure 8). Consider the case when the steepest parts of the RHS are concentrated near the center of the domain. For example, the exact solution is a Gaussian (a sum of Gaussians) centered near (1.5,0.5). We divide the domain into three equal squares. The finest grid is chosen in the middle section to ensure the necessary resolution of the steep RHS. The grid in the side sections is coarser: it contains four times fewer points than in the middle section. Examples 7–8 illustrate the convergence and accuracy of the adaptive algorithm.

Example 7. We solve the Poisson equation with an exact solution in $[0,3] \times [0,1]$ being a Gaussian function $u(x,y) = \exp\left\{-10\left((x-1.5)^2 + (y-0.5)^2\right)\right\}$ (see Figure 8).

The first and the second columns of Tables 17 and 18 present the number of points in the middle and the side squares, respectively; columns 3–5 give the errors of the algorithm implementation. The last column computes the decrease of the maximal error in the global domain when the number of grid points in each direction is doubled. We recall that the expected accuracy of the algorithm is $O(h^4)$, i.e., the error should be 16 times less when the grid step is twice less than the previous grid step.

Example 8. We solve the Poisson equation with an exact solution in $[0,3] \times [0,1]$ being a sum of steep and smooth Gaussian functions

$$\exp\left\{-12\left((x-1.3)^2 + (y-0.6)^2\right)\right\}$$

$$+ \exp\left\{-25\left((x-1.5)^2 + (y-0.5)^2\right)\right\} + \exp\left\{-3\left((x-1.8)^2 + (y-0.3)^2\right)\right\}$$

TABLE 18

128×128	64×64	1.6e-5	2.7e-6	4.5e-6	23.8
256×256	128×128	7.4e-7	9.9e-8	1.6e-7	21.6
512×512	256×256	3.7e-8	4.1e-9	6.7e-9	20.0

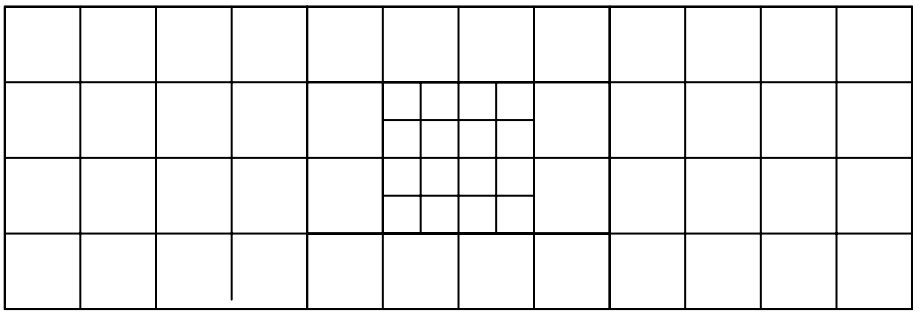

FIG. 9. *The grid in the small box in the middle is two times denser in each direction than in the remaining domain (each box contains several grid points according to the table.*

and with the same Figure 8. Table 18 presents the accuracies obtained.

In this and the previous examples one can observe that the error decays faster than $O(h^4)$ due to the adaptivity of the grid to the behavior of the RHS. The RHS is very steep; however, high accuracy is obtained for comparatively small number of grid points.

Example 9. We solve the Poisson equation with an exact solution in $[0,3] \times [0,1]$ being a Gaussian function $u(x,y) = \exp\left\{-15\left((x-1.5)^2 + (y-0.5)^2\right)\right\}$ (see Figure 9 and Table 19).

The domain is again divided into three sections, where the grid in each section may depend on the smoothness of the RHS in the Poisson equation.

The grid in the small box in the middle is two times denser in each direction.

Example 10. We solve the Poisson equation with an exact solution in $[0,3] \times [0,1]$ being a Gaussian function $u(x,y) = \exp\left\{-25\left((x-1.5)^2 + (y-0.5)^2\right)\right\}$ (see Figure 10 and Table 20).

The grid in the small box in the middle is four times denser in each direction.

5.2. The matching step for adaptive algorithms. In this section we consider the domains' matching procedure using multiwavelets and evaluate the number of operations that are necessary for its implementation in the adaptive case. The domain is divided into subdomains, possibly of different sizes and different resolution in each subdomain (see Figure 11). In the beginning we will consider the case where the subdomain is divided into unequal squares of different resolutions. Then we will consider the case where the domain consists of rectangular subdomains of different aspect ratios and resolutions.

5.2.1. Matching of square boxes. We compute the effect of the double layer on the interface between boxes 1 and 2,3 on the left side of box 4 (see Figure 12). We

use the middle point integration. Multiwavelet coefficients of the decomposed matrix which are below the threshold are ignored.

Tables 21–26 describe cases where the number of points on the interface with the double layer is not equal to the number of points on the boundary where the effect is computed. We calculate the effect of the double layer at the closest parallel boundary of the chosen box.

We compute the effect of the double layer on the interface between boxes 1 and 2,3 on the left side of box 4. We use the middle point integration. The matrix representing the kernel of the integral

$$\int_0^4 \frac{y-4}{(y-4)^2+(x-5)^2}\tau(x)\,dx$$

is decomposed into the multiwavelet bases with four vanishing moments. Elements with absolute values which are below the threshold are ignored. We first take the same number of points on both interfaces.

5.2.2. Matching of arbitrary rectangular boxes. In this section we consider the case when the domain is divided into arbitrary rectangular subdomains (see Figure 13).

Consider a domain which is divided into arbitrary rectangular subdomains and compute the influence of the double layer introduced at one of the interfaces on a certain boundary (for example, the boundary of box 4). Consider the influence of the double layer at the interface between box 1 and 2,3 on the left and the upper

TABLE 21

The number of points on the interface is given in the row labeled "number of points." The number of points on the interface is equal to the number of points on the boundary where the effect of the double layer is computed. The boundary is parallel to the interface where the double layer is introduced (the influence of the double layer between boxes 1 *and* 2,3 *is computed on the left boundary of box* 4*). "Nonzero coefficients" refers to the number of elements above the threshold in the matrix which represents the influence of the double layer. This number is considered the degree of sparsity of the matrix. The average number of nonzero coefficients per row is also computed. The multiwavelet basis is chosen with* 4 *vanishing moments. The accuracy is computed for a density of the double layer* $\exp\{-5(x-0.2)^2\} + \exp\{-50(x-0.7)^2\}$.

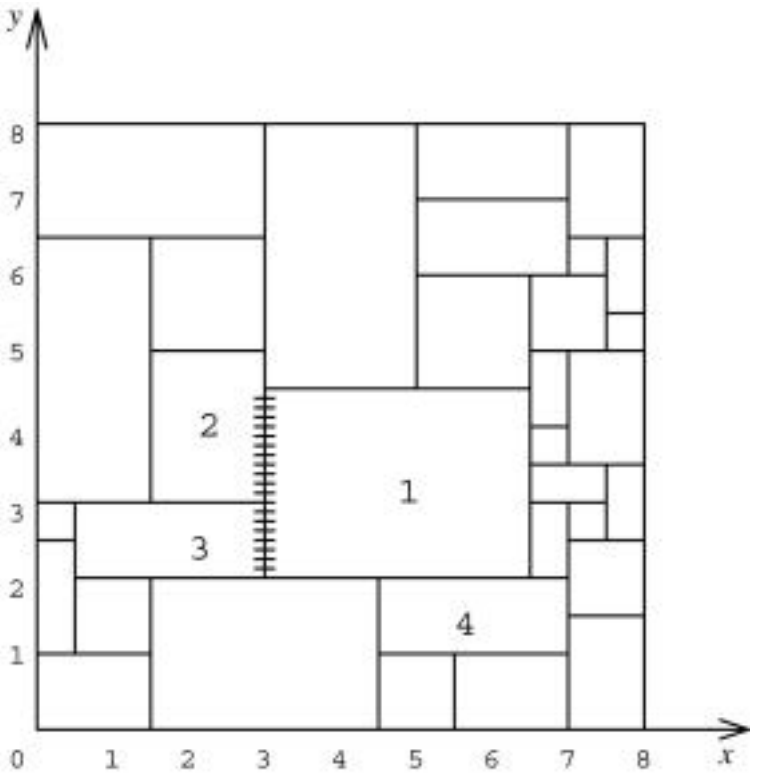

FIG. 13. *The domain is divided into some subdomains of an arbitrary rectangular form with different resolution. We compute the influence of the double layer introduced on the boundary between boxes* 1 *and* 2,3. *The influence is evaluated at the left and top boundaries of box* 4.

boundaries of box 4. It is expressed by the integral

$$\int_2^5 \frac{1.5}{2.25 + (x-y)^2} \tau(x)\, dx, \tag{5.1}$$

at the left boundary of box 4, and

$$\int_2^5 \frac{y-3}{(x-2)^2 + (y-3)^2} \tau(x)\, dx, \tag{5.2}$$

at the top boundary of box 4, where the density of the double layer was chosen as

$$\tau(x) = \exp\left\{5(x-3.2)^2\right\} + \exp\left\{50(x-2.7)^2\right\} + x(x-1). \tag{5.3}$$

Table 27 presents the sparsity of matrices representing the kernels in the multiwavelet bases with four vanishing moments and the computation error for the left boundary of box 4. Table 28 presents the same data for the top boundary. We note that in the computations the intermediate results below a certain threshold were omitted. The error is stipulated by the error of the middle point integration ($\sim (1/n)^2$), which is dominant for a small number of points n and the error of "threshold truncation," which is dominant for large n and thresholds. (In the latter case the round-off error also grows.) Therefore, for each n such a threshold exists for which the error is minimal.

TABLE 27

6. Parallel implementation. The multiple domain algorithm was implemented on MIMD parallel computers with minor modifications. We assume that the topology of the domain and subdomains is described by Figure 4. Each domain is assigned to a processor. In the parallel implementations the Dirichlet problem was solved in each subdomain and single layers were introduced afterwards to match the first derivatives. The parallel algorithm includes the following steps.

1. *Preprocessing step.*
   Initially, the kernel matrices are downloaded into the memory of each processor. This step also contains obtaining sparse representation for these matrices in multiwavelet bases.
2. *Solution of the nonhomogeneous equation in each subdomain.*
   In each subdomain the RHS of the Poisson equation is defined and the smooth

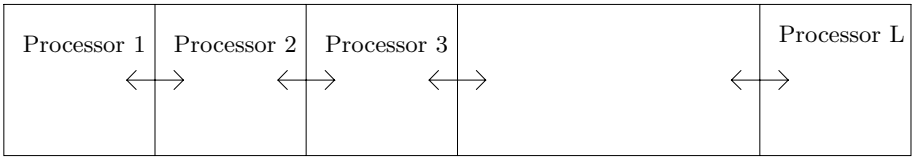

FIG. 14. *The domain is decomposed into L subdomains. Each domain is assigned to a certain processor. Double/single layers are introduced on the $L-1$ interfaces. Adjacent processors communicate to compute the values of the layers.*

boundary conditions are determined. Then the particular solution of the nonhomogeneous equation with the above boundary conditions is found in each subdomain.

3. *Computation and transmission of discontinuities.*
   In order to remove the discontinuities in the derivatives between the subdomains, the differences between the first derivatives on the boundaries are found. This requires communication between adjacent processors only. Then, each single layer density is represented in the multiwavelet basis. The multiwavelet coefficients are transmitted from each processor to each adjacent processor in order to compute the influence of all the double layers on its boundaries. In practice this is implemented as follows. Each processor communicates only with its neighbors: it obtains the information on the layer from its left neighbor and passes the information to its right neighbor. After $L-1$ communication steps, all the processors have the complete information on the layers. Only the sparse data structures that contain the coefficients above the threshold are transmitted. Thus, the sparsity of the multiwavelet coefficients vector reduces the amount of the communication.
4. *Computation of final boundary conditions in subdomains.*
   To avoid the communication bottleneck at the last (global) step and reduce the number of computations, the above algorithm can be improved in the following way. Two last steps of the original (nonimproved) algorithm are changed by this and the following ones. Each processor computes the influence of each double layer on the boundaries of the domain. The correction at the global boundaries, which is necessary to satisfy the original boundary conditions, is computed. Each processor then computes the corrections at its own boundaries, as a consequence of the solution of the global Laplace equation with the corrected boundary conditions. We combine these boundary condition corrections with the previously computed corrections due to the matching step. The accumulation of all the above corrections determines the final local boundary conditions.
5. *Solution of the Laplace equations in subdomains.*
   The Laplace equation is solved in each subdomain with the boundary conditions which were computed at the previous step. Combining the result with the solution of the Poisson equation leads to a smooth global solution satisfying the initial (global) boundary conditions.

The current parallel implementation assumes the geometry of Figure 14.

The rectangular domain is divided into L boxes in a line that correspond to L processors. The algorithm was performed on the parallel SGI computer of type Origin 2000 and IBM SP2. The parallel program differs from the serial one only by

the communication constructions from MPI.

Each processor communicates only with its neighbors: it obtains the information on the layer from its left neighbor and passes the information to its right neighbor. After $L-1$ communication steps all the processors possess the complete information on the layers. Note that this is not an efficient communication scheme for SP2 and even one of the worst for the SGI computer which is a shared memory system. In the future we plan to use the native collective communication like gather, scatter, etc.

Let T_{par} be the total computation time for the parallel program. The most important measures of performance for a parallel program are the speed-up and efficiency. The speed-up S is defined as the ratio of the time, T_{ser}, required to run the serial program for a problem of a given size, to the time, T_{par}, required for an equivalent calculation on a parallel computer. The efficiency is equal to $T_{ser}/(T_{par}L)$, where L is the number of processors.

First, we investigate the parallel implementation of the multiple domain algorithm on two computers: IBM SP2 and SGI Origin 2000. The speed-up is computed with respect to the serial implementation of the same algorithm (see Tables 29, 30).

A question may be raised concerning the serial time used in the definition of speed-up. Often the speed-up is computed using the best serial algorithm; therefore, we should investigate the performance of the multiple domain algorithm when compared to the single domain algorithm. The latter algorithm was described in [4] and uses the

TABLE 31

The theoretical ratio of times required for the implementation of the serial programs for the primary solution of the Poisson equation with and without domain decomposition T_{sd}/T_{md}. Here N is the number of grid points in subdomains in each direction; N_ϵ is the number of extension points.

128	10	1.01	1.04	1.05	1.08	1.10	1.14	1.19	1.25	1.45	1.85
256	10	1.06	1.08	1.10	1.13	1.16	1.19	1.24	1.30	1.49	1.87
1024	10	1.08	1.11	1.13	1.16	1.18	1.20	1.26	1.30	1.47	1.79

first two steps of the multiple domain algorithm implemented in one global domain.

Consider the theoretical performance of the first step of the multiple domain algorithm (solving the Poisson equation in all the subdomains as compared to its solution in one global domain). For example, let the domain $[0, L] \times [0, 1]$ be divided into L subdomains, $N \times N$ points in each, and let the extension be N_ϵ in each direction. Then the solution of the Poisson equation in subdomains requires

$$O(L(N + 2N_\epsilon)^2 \log(N + 2N_\epsilon)$$

operations, the solution of the Laplace equation in subdomains requires $O(LN^2 \log N)$, the computation of the influence of layers—$O(L^2 N \log N)$, and the global solution of the Laplace equation—$O(LN^2(\log N + \log(LN)))$. On the other hand, the primary solution of the Poisson equation in the global domain requires

$$O((N + 2N_\epsilon)(NL + 2N_\epsilon)(\log(NL + 2N_\epsilon) + \log(N + 2N_\epsilon)))$$

operations. Let us compare the time T_{md} above for the multiple domain algorithm with the time T_{sd} for the same step in the single domain. This ratio is equal to

$$\frac{T_{sd}}{T_{md}} = \frac{(NL + 2N_\epsilon)(\log(NL + 2N_\epsilon) + \log(N + 2N_\epsilon))}{2L(N + 2N_\epsilon) \log(N + 2N_\epsilon)}. \tag{6.1}$$

In the case $N_\epsilon = N/2$ one gets

$$\frac{T_{sd}}{T_{md}} = \frac{(L + 1)(\log(L + 1) + 2 \log N + 1)}{4L(\log N + 1)}.$$

Note that the number of points $N_\epsilon = N/2$ chosen for extension is excessive (see Example 3). Table 31 presents the theoretical efficiency of the local Poisson step for $N_\epsilon = N/2, 10$ and various values of L and N.

It is to be emphasized that the efficiency of the algorithm (see Table 31) can exceed one. This means that the multiple domain algorithm becomes more efficient than the global algorithm. This effect was employed in [9]. In our case the local algorithm for the solution of the Poisson equation requires $O(N^2 \log N)$ operations. The $\log N$ factor does not scale in proportion to the area and is the cause of the deterioration of the one domain case.

Now we investigate the efficiency of the multiple domain algorithm when the number of extension points is 11 when compared to the single domain algorithm. The measurements of the running times for two serial programs were implemented on an SGI computer. The results are summarized in Table 32 and Figure 15.

TABLE 32

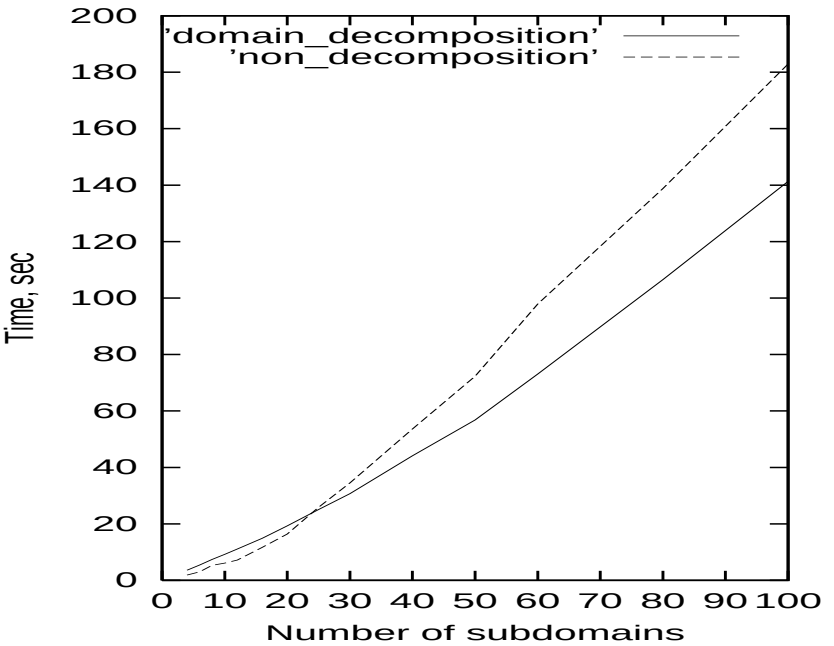

FIG. 15. *The comparison of the times necessary for the implementation of two serial programs on SGI computer: with and without domain decomposition. The number of points in each subdomain is* 128×128*; the number of extension points is* 11.

We can see from Table 32 that the domain decomposition algorithm is competitive as the number of subdomains exceeds 25. This can be achieved either by the choice of the parallel computer with more than 25 processors or by the additional decomposition of the domains assigned to a certain processor.

It is to be emphasized that the information transmitted between the processors is not more than $O(N)$, while the number of grid points is $O(N^2)$. Thus the communication did not degrade the efficiency (see Tables 29 and 30) of the parallel algorithm

in our implementation. However for large systems the communication and the computation of the influences of the matching layers increases as L^2 does (in a naive implementation) and may affect the efficiency. On the other hand, we have investigated in previous sections the compression effect of the multiwavelet representation. It results in a reduction of the number of coefficients required for the computation of the influence of the matching layers. Thus the growth of the effort required for matching will be considerably reduced. In the present computer implementations this effect was not utilized in view of the rather modest requirements of the task.

However the present implementation of the parallel does not employ a sparse data structure. If we use the sparse data structure for computing effect of the layers, the running time for this part of the algorithm will be considerably reduced. The evaluation of this effect for double layers was given in the previous sections. For a single layer, the results were presented in Table 4.

7. Summary and conclusions. We developed an algorithm for fast computation of the influence of the double/single layer on domain interfaces. This is a part of a more general algorithm for the solution of elliptic equations in a domain which is decomposed into subdomains. The computation of the influence of singularity layers is necessary in the matching step. The present algorithm enjoys the following properties:

1. The algorithm is adaptive since the resolution in a subdomain depends on the smoothness of the RHS. Moreover, the domain decomposition can be adaptive as in [9].
2. The kernels of the integrals which represent singularity layers are sparse in multiwavelet bases. The sparse matrix-vector multiplication reduces the number of operations to $O(N)$, where N is the number of grid points on the interface. In fact, the number of operations is even less if the density of the double layer is smooth and both the double layer and the interface have a simple geometry. The representation of functions in wavelet/multiwavelet bases provides an automatic adaptation to its "problematic," such as nonsmooth, oscillating points. The representation of the kernels of the integrals in multiwavelet bases is done once during the preprocessing step. This is possible since they depend only on the geometry of subdomains. These are the reasons why the algorithm is fast.
3. The accuracy of the algorithm is preserved near the points where the double layer intersects the interface due to the subtraction technique which was applied. Here we used the fact that we know the analytic expression for the kernel of the integral.
4. The algorithm can be evaluated in parallel. The parallelization is effective since in the computational process only few coefficients, which are representatives of layers densities, have to be transmitted between neighboring processors.

The method can be extended to 3-D cases when a double layer is introduced on the plane. This will become a step in the algorithm for fast solution of 3-D elliptic equations using domain decomposition. The first step for a fast 3-D solution of the equation in each subdomain is described in [8].

Appendix: Construction and properties of discrete multiwavelet bases. Let $S = \{x_1, x_2, \ldots, x_n\} \subset \Re$ be an increasing set of n distinct points (discretization). For simplicity we assume $n = k \cdot 2^l$, where k and l are positive integers. The basis constructed enjoys the following properties:

1. All but k basis vectors have k vanishing moments.

A vector $b = (b_1, b_2, \ldots, b_n)$ is said to have k vanishing moments if

$$\sum_{i=1}^{n} b_i x_i^j = 0, \ j = 0, 1, \ldots, k-1.$$

2. The basis vectors are nonzero on different scales.

These properties of local support and vanishing moments lead to efficient representation of functions which are smooth except at a finite set of singularities. Besides, the conditions of "local" support and zero moments determine the basis vectors uniquely (up to the sign) if, out of the k vectors nonzero on $x_1, \ldots, x_{2k}$, we require that one has k vanishing moments, a second $k+1$, a third has $k+1$, and so on, and the kth has $2k-1$ vanishing moments. When constructing such bases we define the $2k \times 2k$ moment matrices, for $i = 1, \ldots, n/(2k)$ by the formula

$$M_{1,i} = \begin{pmatrix} 1 & x_{s_i+1} & \ldots & x_{s_i+1}^{2k-1} \\ 1 & x_{s_i+2} & \ldots & x_{s_i+2}^{2k-1} \\ \vdots & & & \vdots \\ 1 & x_{s_i+2} & \ldots & x_{s_i+2k}^{2k-1} \end{pmatrix},$$

where $s_i = (i-1)2k$. For a $(2k \times 2k)$-matrix V, we let V^U and V^L denote two $k \times 2k$-matrices, V^U consisting of the upper k rows and V^L the lower k rows of V, i.e.,

$$V = \begin{pmatrix} V^U \\ V^L \end{pmatrix}.$$

The first basis matrix U_1 is given by the formula

$$U_1 = \begin{pmatrix} U_{1,1}^L & & & \\ & U_{1,2}^L & & \\ & & \ddots & \\ & & & U_{1,n/(2k)}^L \\ U_{1,1}^U & & & \\ & U_{1,2}^U & & \\ & & \ddots & \\ & & & U_{1,n/(2k)}^U \end{pmatrix},$$

where the transposed $U_{1,i}^T$ is obtained by the column-by-column Gram–Schmidt orthogonalization of M_1, i.

Further, the following basis matrices are constructed successively. The jth basis matrix, $j = 2, \ldots, \log_2(n/k)$, is a product $U_j \ldots U_1$, with U_j defined by the formula

$$U_j = \begin{pmatrix} I_{n-n/2^{j-1}} & \\ & U_j' \end{pmatrix},$$

where I_m is the $m \times m$ identity matrix and U'_j is given by the formula

$$U_j = \begin{pmatrix} U^L_{j,1} & & & & \\ & U^L_{j,2} & & & \\ & & \ddots & & \\ & & & U^L_{j,n/(2^j k)} & \\ U^U_{j,1} & & & & \\ & U^U_{j,2} & & & \\ & & \ddots & & \\ & & & U^U_{j,n/(2^j k)} & \end{pmatrix},$$

where $U^T_{j,i}$ is obtained by the orthogonalization of $M_{j,i}$, and

$$M_{j,i} = \begin{pmatrix} U^U_{j-1,2i-1} & M_{j-1,2i-1} \\ U^U_{j-1,2i} & M_{j-1,2i} \end{pmatrix}.$$

The final basis matrix $U = U_l \dots U_1$, where $l = \log_2(n/k)$, represents the multiwavelet basis of parameter k on $x_1, \dots, x_n$.

It is apparent that the application of the matrix U to an arbitrary vector of length n may be accomplished in order $O(n)$ operations by the application of $U_1, \dots, U_l$ in turn. Similarly, $U^{-1} = U^T$ may be applied to a vector in order $O(n)$ operations. The construction and application of discrete multiwavelets is described in detail in [2].

Acknowledgments. The authors are very grateful to Dr. L. Ioffe for her contribution to the parallel implementation of the algorithm and to the referees for their valuable remarks.

ON SOME APPLICATIONS OF THE SUPERPOSITION PRINCIPLE WITH FOURIER BASIS*

MARC GARBEY†

Abstract. This paper presents several applications of (local) Fourier basis combined with corrector techniques via the superposition principle to compute solutions of boundary value problems. Our methodology is inspired by the well-known corrector technique used in asymptotic singular perturbation theory—see, for example, [W. Eckhaus, *Asymptotic Analysis of Singular Perturbations*, North-Holland, Amsterdam, 1979]. We build solvers for time dependent boundary value problems and/or singular perturbation problems using Fourier expansions combined to additional convenient set of time independent basis functions to enforce the boundary conditions. The algorithms are very well suited for parallel computing because they rely mainly on FFTs and basis functions given analytically or computed (in parallel) once and for all. Our method can be spectral accurate for simple geometry. We obtain in addition interesting new results for boundary value problems with complex geometry. We describe in this paper the implementation of the method and the numerical results for many linear and nonlinear problems: our goal is to test the advantages and the limits of our approach in order to motivate further theoretical investigations. Our method applied to steady one-dimensional problems is similar to the work of Israeli, Vozovoi, and Averbuch [*J. Sci. Comput.*, 8 (1993), pp. 135–149] on domain decomposition with local Fourier basis for the Helmotz problem. However our methodology for time-dependent problem and/or two space dimensions geometry is rather different in its spirit and complements previous investigations of Israeli, Vozovoi, and Averbuch.

Key words. Fourier expansion, superposition principle, singular perturbation, corrector technique, spectral method

1. Introduction.

Let us consider the linear elliptic problem:

$$L[u] = f \text{ in } \Omega \subset \mathbb{R}^n,\ B[u] = g \text{ on } \partial\Omega, \tag{1}$$

with Ω such that $\Omega \subset [0\ ,\ 2\pi]^n$,

$$L[u] \equiv \sum_{i,j=1,\ldots,n} a_{i,j}(x)\frac{\partial^2 u}{\partial x_i \partial x_j}\ +\ \sum_i b_i(x)\frac{\partial u}{\partial x_i}\ +\ c(x)u,$$

and all datas $a,\ b,\ c,\ f,\ g$ in $C^\infty(\Omega)$. We suppose that (1) has a unique smooth solution. Let us consider the following two problems:

$$\bar{L}[v] = \bar{f}\ in\ [0\ ,\ 2\pi]^n,\ v\ 2\pi \text{ periodic}, \tag{2}$$

and

$$L[w] = 0 \text{ in } \Omega \subset \mathbb{R}^n,\ B[w] = g - B[v] \text{ on } \partial\Omega. \tag{3}$$

In (2), $\bar{L}$ denotes the operator

$$\bar{L}[v] \equiv \sum_{i,j=1,\ldots,n} \bar{a}_{i,j}(x)\frac{\partial^2 v}{\partial x_i \partial x_j}\ +\ \sum_i \bar{b}_i(x)\frac{\partial v}{\partial x_i}\ +\ \bar{c}(x)v$$

and $\bar{f}$ (resp., $\bar{a}$, $\bar{b}$, $\bar{c}$) is a smooth periodic extension of f (resp., a, b, c), i.e., $\bar{f}$ 2π periodic with respect to each variable and $\bar{f} \equiv f$ in Ω. Then clearly the superposition principle gives

$$u \equiv v + w \text{ in } \Omega.$$

From the numerical point of view, the decomposition (2)–(3) of (1) seems to be rather useless at first sight since it increases the complexity of the computation. However, it might be the best way to approximate numerically the solution of (1) for the following reasons:

1. One has to compute (1) for many right-hand sides (rhs) f, *and* w solution of (3) can be approximated using a set of basis functions w_k computed *once and for all*.
2. (1) and (3) have solutions with essentially different behaviors, and therefore one wants to use different discretizations and/or possibly different schemes to compute v and w. A special case corresponds to problems in which w is obtained analytically.
3. $\partial\Omega$ has some complex geometrical structure, w is stiff and vanishes exponentially inside Ω: in such case one wants to approximate w on a local stretched coordinate system.
4. In order to obtain a *parallel* algorithm, we replace (1) with an equivalent *domain decomposition* formulation as follows. Let $\bigcup_{i=1,\dots,N} \Omega_i$ be a nonoverlapping domain decomposition of Ω:

$$L[u_i] = f \text{ in } \Omega_i,\ B[u_i] = g \text{ on } \partial\Omega \bigcap \Omega_i,\ i = 1, \dots, N, \tag{4}$$

$$u_i = u_j \text{ on } \partial\Omega_i \bigcap \partial\Omega_j,\ i, j = 1, \dots, N, i \neq j, \tag{5}$$

$$\frac{\partial}{\partial n} u_i = \frac{\partial}{\partial n} u_j \text{ on } \partial\Omega_i \bigcap \partial\Omega_j,\ i, j = 1, \dots, N, i \neq j. \tag{6}$$

The analogue of the decomposition (2) + (3) for each subproblem (4), (5), and (6) is written:

$$\bar{L}[v_i] = \bar{f}_i \text{ in } [0\ ,\ 2\pi]^n,\ v\ 2\pi \text{ periodic}, \tag{7}$$

and

$$\begin{aligned} L[w_i] = 0 \text{ in } \Omega_i,\ B[w_i] = g - B[v_i] \text{ on } \partial\Omega \bigcap \Omega_i,\ i = 1, \dots, N, \\ v_i + w_i = v_j + w_j \qquad \text{on } \partial\Omega_i \bigcap \Omega_j,\ i, j = 1, \dots, N, i \neq j, \\ \frac{\partial}{\partial n}(v_i + w_i) = \frac{\partial}{\partial n}(v_j + w_j) \qquad \text{on } \partial\Omega_i \bigcap \Omega_j,\ i, j = 1, \dots, N, i \neq j. \end{aligned} \tag{8}$$

Each problem of type (7) can be solved in parallel. To be more precise, each subdomain Ω_i is mapped into a subset of $[0\ ,\ 2\pi]^n$ in order to increase the efficiency of the parallel computation. So (7) is in fact obtained after an appropriate rescaling and shifting of the subdomain Ω_i. Further, we observe that the problems of type (8) are weakly coupled when the terms w_i have a fast decay property in space. We refer to the pioneer work of Israeli, Vozovoi,

and Averbuch in [15], [16], [5] and Vozovoi, Israeli, and Averbuch in [25] that makes intensive use of this approach. Our recent work in [10], [12] gives an example of the good parallel efficiency of this method for combustion problems.

Classical examples that fall in one of the above categories are:

- *Computation of evolution problems.*
  Let us consider formally the time-dependent PDE

$$\frac{\partial u}{\partial t} = \Delta u + F(u) \text{ in } \Omega$$

  with some appropriate initial and boundary conditions. A semi-implicit Euler scheme is written

$$\frac{u^{n+1} - u^n}{dt} = \Delta u^{n+1} + F(u^n).$$

  So one has to solve for each time step:

$$-dt\ \Delta u^{n+1} + u^{n+1} = u^n + dtF(u^n).$$

  Then the arguments (1) and (4) of the previous list may apply to this time-dependent problem.
- *Computation of singular perturbation problems.*
  Let us consider formally the following abstract linear singular perturbation problem:

$$\epsilon \mathcal{A}[u] + \mathcal{B}[u] = f \text{ in } \Omega,\ u = g \text{ on } \partial\Omega.$$

  It is well known that such problems may have boundary layers when a solution of the formal limit problem

$$\mathcal{B}[u] = f \text{ in } \Omega$$

  cannot satisfy the Dirichlet boundary condition $u = g$ on $\partial\Omega$. In the meantime solutions of (2) may have no boundary layer. So the decomposition (2) and (3) of problem (1) can be viewed as a numerical application of the so-called *corrector* technique well known in singular perturbation theory [3], [18]. Then the arguments (2) and (3) of the previous list may apply to this singular perturbation problem.

The goal of this paper is to give some examples of the use of the superposition principle combined to (local) Fourier expansions in numerical schemes for time dependent problems as well as singular perturbation problems. The implementation of the method used well-separated modules: one for FFT to approximate solution of (2), one to build appropriate periodic extensions of rhs of the equations and coefficients of the operators, one to approximate the corrector, solution of (3). To be valuable, the cost of the computation in CPU time should be dominated by the cost of FFT. We will refer then to this method as the *modulefou* method. We are mainly interested to find out how good this method is from the numerical point of view. The benefit of the method for parallel computing is discussed in [10], [11], [12]. So we have looked for test cases for which the method works as well as test cases for which the method does not work. Our conclusion is that the numerical efficiency of the method might be worthwhile in many situations. In recent works, we have been able to obtain a

high-order accurate code to simulate a nontrivial two-dimensional (2D) combustion problem that works for periodic as well nonperiodic boundary conditions with the *same data structure* thanks to the *modulefou* method [8]. The applications that we consider in this paper are less specific and we hope that this preliminary study will serve as a motivation for further theoretical investigations. The plan of the paper is as follows; In section 2, we illustrate the method with the Poisson problem on a disk. In section 3, we give a rigorous presentation of the method in one space dimension. In section 4, we give some examples of applications to time-dependent problem as well as time-dependent singular perturbation problems in one space dimension. We give in particular some details on the implementation of *modulefou* on time-dependent schemes that are critical in order to avoid some Gibbs phenomenon. In section 5 we apply the *modulefou* method to a two space dimension classical singular perturbation problems on a domain with a smooth boundary. We then consider different extensions of the method to time-dependent problems.

2. Poisson problem on a disk. We consider the Poisson problem on a disk $B(0,R)$ of radius $R < \frac{L}{2}$ and center $O = (\frac{L}{2}, \frac{L}{2})$ included in$(O,L)^2$

$$\Delta u \ = \ f \text{ in } B(O,R) \subset (-\pi,\pi)^2, \ u \ = \ g \text{ on } \partial\Omega. \tag{9}$$

A classical numerical approach is to write this problem in polar coordinates (ρ,θ). Then one look for the approximate solution of (9) as

$$u_{N,M} = \sum_{l=-N,N} \sum_{k=0,M} a_{k,l} T_k(\rho) \exp(i\ l\ \theta),$$

with T_k Chebyshev polynomial of degree k. However, this method has two disadvantages: first the grid points are needlessly concentrated at the origin, second the pseudospectral approximation of the corresponding operator in radial direction,

$$\frac{\partial^2}{\partial\rho^2} + \frac{1}{\rho}\frac{\partial}{\partial\rho} + \frac{l^2}{\rho^2} Id,$$

with Dirichlet boundary condition in $\rho = R$ and homogeneous Neuman boundary condition in $\rho = 0$, has a condition number that grows very fast with the degree M of the Chebyshev polynomial. Matlab, for example, gives an estimation of the condition number of order 10^6 for $M = 20$ and $l = 1$; of order 10^9 for $M = 100$ and $l = 1$.

On the contrary, it is extremely easy to compute with Fourier an accurate approximation v_N of a solution of the problem

$$\Delta v \ = \ \bar{f} \text{ in } (O,L)^2, \tag{10}$$

as long as $\bar{f}$ is a smooth periodic given function of $(O,L)^2$. We choose, for example,

$$v_N(x,y) = \sum_{l_1,l_2=-N,N,\ l_1\neq 0,\ l_2\neq 0} - \frac{L^2}{4\,\pi^2}\ \frac{\hat{f}_{l_1,l_2}}{l_1^2+l_2^2} \exp\left(i\ \frac{2\,\pi}{L}\ (l_1\ x\ +\ l_2\ y)\ +\ \frac{1}{4}\hat{f}_{0,0}\ (x^2+y^2)\right),$$

when

$$\bar{f}_N(x,y) = \sum_{l_1,l_2=-N,N} \hat{f}_{l_1,l_2} \exp\left(i\ \frac{2\,\pi}{L}\ (l_1\ x\ +\ l_2\ y)\right).$$

Let

$$h_N(\theta) = \sum_{q=-N,N} \hat{h}_q \exp(i\ q\ \theta)$$

be a discrete Fourier approximation of $g - v_N$ on $\partial B(O,R)$. The solution of the homogeneous problem

$$\Delta w \ = \ 0 \text{ in } B(O,R),\ w = h_N \text{ on } \partial B(O,R) \tag{11}$$

is then given *explicitly* by the formula

$$w_N(\rho,\theta) = \sum_{q=-N,N} \hat{h}_q\ \rho^{|q|} \exp(i\ q\ \theta).$$

The *modulefou* method to compute approximation of (9) then follows these three steps:

1. Construct a smooth periodic extension of f on $(O,L)^2$.
2. Compute v_N via FFTs.
3. Add corrector w_N.

The sensitive part of this algorithm is the numerical construction of $\bar{f}$. We proceed as follows: we assume for simplicity that f is in $C^\infty(B(O,R))$. Let $(x_{l_1}, y_{l_2})_{l_1,l_2=0,2N-1}$ be the uniform grid of $(O,L)^2$ used in Fourier approximation. Let d be positive so that $R + d < \frac{L}{2}$. For every grid point of polar coordinates (ρ,θ) located in the ring $B(0,(R,R+d))$ bounded by the circles of radius R and $R+d$ centered at the origin O, we compute the value of the polynomial of Hermite interpolation $P_\theta(\rho) \in \mathbb{P}^{2n+1}$ that satisfies

$$\frac{\partial^j P_\theta}{\partial \rho^j}(R) = \frac{\partial^j f}{\partial \rho^j}(R,\theta),\ j = 0,\ldots,n, \tag{12}$$

$$\frac{\partial^j P_\theta}{\partial \rho^j}(R+d) = 0,\ j = 0,\ldots,n.$$

We then let $\bar{f} \equiv f$ in $B(0,R)$, $\bar{f} \equiv P_\theta$ in $B(0,(R,R+d))$, and $\bar{f} \equiv 0$ elsewhere.

We have implemented this method and forced the rhs of the Poisson equation to be such that the formula of some exact infinitely smooth solution is given in $B(O,R)$. In addition, since f is known *only* inside $B(O,R)$, we approximate the normal derivatives of f in (12) with one-side finite differences. Thanks to the coding of Boulin, we have tested the accuracy of our method on many different solutions. Table 1 that follows gives a representative example of the accuracy of our method. In this example, the exact solution is

$$u(x,y) = 20\ (x^6 + y^5) \exp(-(\log(6)\ (x^2 + y^2)),\ R = 1,$$

and the error is given in maximum norm. Nevertheless the space step in radial direction used to obtain numerical approximation of normal derivatives of $f = \Delta u$ at $\partial B(0,R)$ is 10^{-3}.

TABLE 1
Error with modulefou *for the Poisson problem on the disk.*

N	$n=0$	$n=2$	$n=4$	$n=6$
8	$2.5\ 10^{-2}$	$1.5\ 10^{-3}$	$8.3\ 10^{-4}$	$2.6\ 10^{-3}$
16	$2.7\ 10^{-3}$	$2.3\ 10^{-5}$	$8.6\ 10^{-6}$	$3.8\ 10^{-5}$
24	$3.6\ 10^{-4}$	$2.2\ 10^{-6}$	$8.5\ 10^{-7}$	$1.2\ 10^{-5}$
32	$2.7\ 10^{-4}$	$5.6\ 10^{-7}$	$4.\ 10^{-7}$	$4.4\ 10^{-6}$
64	$2.4\ 10^{-5}$	$2.7\ 10^{-8}$	$4.4\ 10^{-8}$	$1.\ 10^{-6}$

This first set of experiments demonstrates that the *modulefou* method is worthwhile at least with circular domains.

3. Theoretical basis of the method in one space dimension. In this section we are going to estimate the accuracy of the *modulefou* method on the two-point boundary value problem

$$-u'' + \lambda u = f \text{ in } \mathcal{I} = [0, L],\ u(0) = 0,\ u(L) = 0 \tag{13}$$

with λ a positive real number and f an arbitrary smooth function, i.e., f is not necessarily periodic on $\mathcal{I}$ and $f \in C^\infty(\mathcal{I})$. We introduce then the following decomposition

$$-v'' + \lambda v = \bar{f} \text{ in } \mathcal{J} = [0, L + d],\ v\ (L + d) \text{ periodic}, \tag{14}$$

and

$$-w'' + \lambda w = 0 \text{ in } \mathcal{I} = [0, L],\ w(0) = -v(0),\ w(L) = -v(L). \tag{15}$$

The extension $\bar{f}$ of f is built in such a way that

$$\bar{f}(x) = f(x),\ x \in \mathcal{I},$$

$$\bar{f}(x) = P(x),\ P \in \mathbb{P}^{2n+1},\ x \in \mathcal{J} \setminus \mathcal{I},$$

$$\bar{f}\ (L + d) \text{ periodic},\ \bar{f} \in C^n(\mathbb{R}),$$

where $\mathbb{P}^{2n+1}$ is the set of polynomial of degree $2n + 1$. Let v_N be the discrete Fourier approximation of solution v of (14). Let u_N be $v_N + w_N$, where w_N is the *exact* solution of

$$-w'' + \lambda w = 0 \text{ in } \mathcal{I} = [0, L],\ w(0) = -v_N(0),\ w(L) = -v_N(L). \tag{16}$$

We are going to estimate $||u - u_N||_{\infty,\mathcal{I}}$, the error in maximum norm on the interval $\mathcal{I}$. A classical Fourier estimate is [14]

$$||v - v_N||_{\infty,\mathcal{J}} \leq C^t \frac{|v|_q}{N^q} \left\{ \frac{\text{meas}(\mathcal{J})}{2\pi} \right\}^q,$$

with C^t a positive real number independent of N, $|v|_q = ||v^{(q)}||_{\infty,\mathcal{J}}$, $\text{meas}(\mathcal{J}) = L + d$, and $v^{(q)}$ the q^{ieme} derivatives of v.

It is easy to obtain from (14) the estimate

$$|v|_q \leq C^t ||\bar{f}||_{q-2},$$

where C^t is a positive number independent of q and $||\bar{f}||_i = \sum_{j=0,i} |\bar{f}|_j$. However, the key point is to obtain an estimate of the error $||v - v_N||_{\infty,\mathcal{J}}$ as a function of some norm of f on $\mathcal{I}$ only. We have

$$|\bar{f}|_{j,\mathcal{J}} \leq \ (|f|_{j,\mathcal{I}} + \ 2\ ||\bar{f}||_{H^{j+1}(\mathcal{J}\setminus\mathcal{I})}),$$

and consequently

$$||v - v_N||_{\infty,\mathcal{J}} \leq \frac{C^t}{N^q} \ \left\{\frac{\text{meas}(\mathcal{J})}{2\pi}\right\}^q \ (|f|_{q-2,\mathcal{I}} + ||\bar{f}||_{H^{q-1}(\mathcal{J}\setminus\mathcal{I})}).$$

Let $\{h_i^0,\ h_i^1,\ i = 0..n\}$ be the set of basis functions of $\mathbb{P}^{2n+1}$ used in Hermite interpolation such that

$$\bar{f}_{|\mathcal{J}\setminus\mathcal{I}} = \sum_{i=0,\ldots,n} f^{(i)}(L)h_i^0(x) + f^{(i)}(0)h_i^1(x).$$

We have for $q \leq n+2$,

$$||\bar{f}||_{H^{q-1}(\mathcal{J}\setminus\mathcal{I})} \leq \sum_{i=0,\ldots,n} (|f^{(i)}(L)| + |f^{(i)}(0)|)||h_i^0||_{H^{q-1}(\mathcal{J}\setminus\mathcal{I})})$$

and

$$||h_i^0||^2_{H^{q-1}(\mathcal{J}\setminus\mathcal{I})} = ||h_i^1||^2_{H^{q-1}(\mathcal{J}\setminus\mathcal{I})}) = \sum_{l=0,\ldots,q-1} d^{2i+1-2l}\ C^i_{l,n},$$

where

$$C^i_{l,n} = \int_0^1 \left(\frac{\partial^l g_i}{\partial \xi^l}(\xi)\right)^2 d\xi$$

and $g_i \in \mathbb{P}^{2n+1}(0,1)$ such that

$$\frac{\partial^l g_i}{\partial \xi^l}(0) = \delta^i_l,\ \frac{\partial^l g_i}{\partial \xi^l}(1) = 0,\ i,l = 0,\ldots,n.$$

Since the corrector w_N solution of (16) is given analytically as a function of the trace $v_{N,|\partial\mathcal{I}}$,

$$||u - u_N||_{\infty,\mathcal{I}} \leq \ 2\ ||v - v_N||_{\infty,\mathcal{J}}.$$

We have then finally for $q \leq n+2$,

(17)

$$||u - u_N||_{\infty,\mathcal{I}} \leq \frac{C^t}{N^q} \ \left\{\frac{L+d}{2\pi}\right\}^q \left(|f|_{q-2,\mathcal{I}} + \left(\sum_{i=0,\ldots,n} (|f^{(i)}(L)| + |f^{(i)}(0)|)^2 G_i^n(d)\right)^{\frac{1}{2}}\right),$$

with

$$G_i^n(d) = \left(\sum_{l=0,\ldots,q-1} d^{2i+1-2l}\ C^i_{l,n}\right).$$

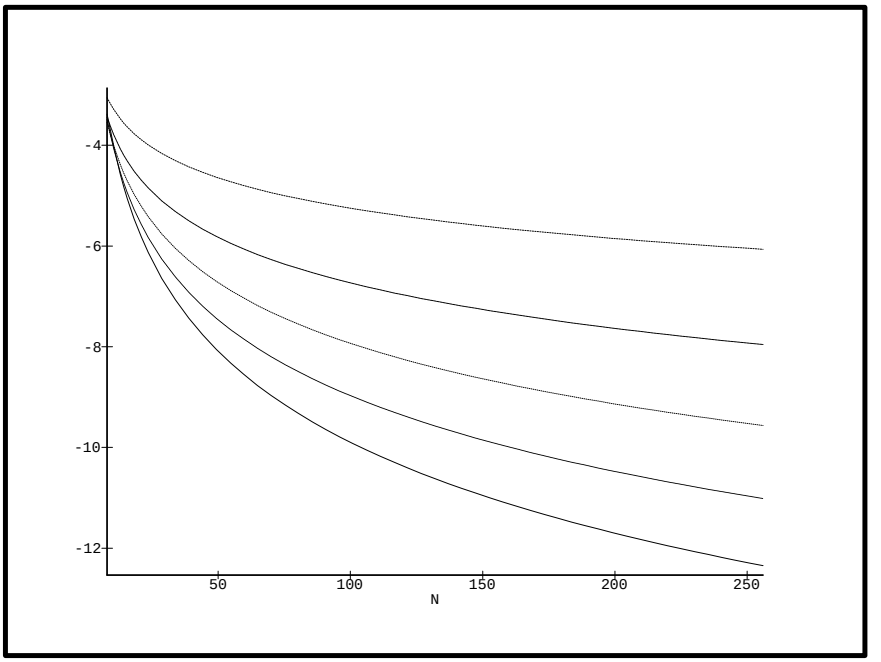

FIG. 1. *Estimate of the error in maximum norm with* $L = 1.6\,\pi,\ d = 0.25$.

The method *modulefou* is consequently of order $n+2$ if $\bar{f}$ is in $C^n(\mathbb{R})$. In addition a direct computation of

$$H(l,d) = \left\{\frac{L+d}{2\pi}\right\}^q \left(\sum_{i=0,\ldots,n} (G_i^n(d))\right)^{\frac{1}{2}}$$

with Maple shows that this quantity is relatively unsensitive to the measure of the extension d for large N; see Figures 1 and 2. We have implemented the method *modulefou* on problem (13) with $f(x) = \sin(x)$. In each run, $L+d$ and L are chosen so that f is not a smooth L-periodic function and $\bar{f}$ is not the sine function on the extension of the domain. The numerical error in maximum norm that we have obtained then is compatible with our estimate; see Figures 3 and 4.

4. Applications in one space dimension.

4.1. Singular perturbation problems. Let us consider the following elementary singular perturbation problems:

$$L_{2,0}[u] = -\epsilon u'' + \gamma(x)u = f(x),\ x \in (0,L), u(0) = \alpha,\ u(L) = \beta \tag{18}$$

and

$$L_{2,1}[u] = -\epsilon u'' + \gamma(x)u' = f(x),\ x \in (0,L), u(0) = \alpha,\ u(L) = \beta. \tag{19}$$

Both problems exhibit boundary layers and possibly turning points.

We recall that by using domain decomposition, we could divide the domain into subdomains so that there is no layer inside the subdomains. Consequently we restrict

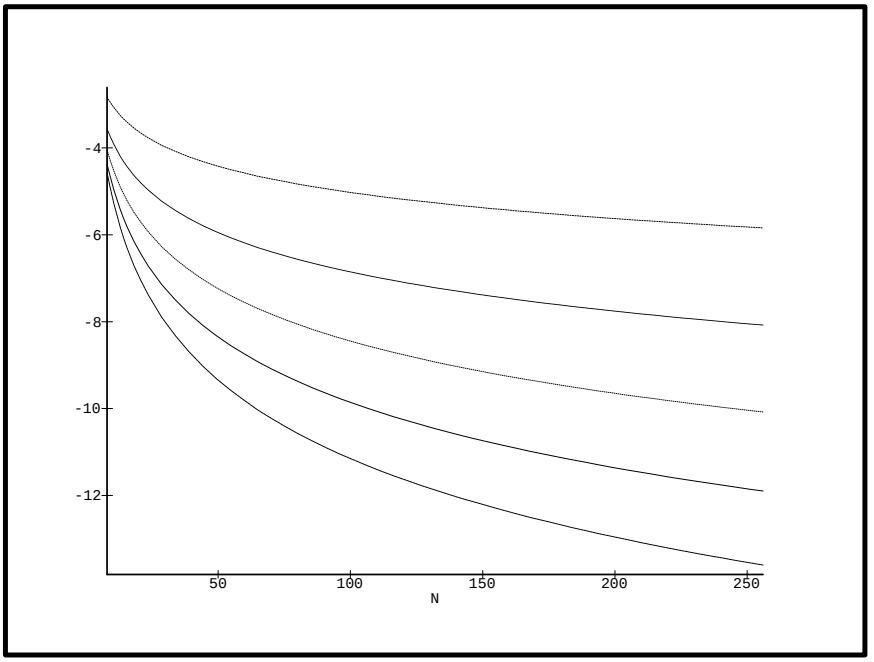

FIG. 2. *Estimate of the error in maximum norm with* $L = 1.6\ \pi,\ d = 1$.

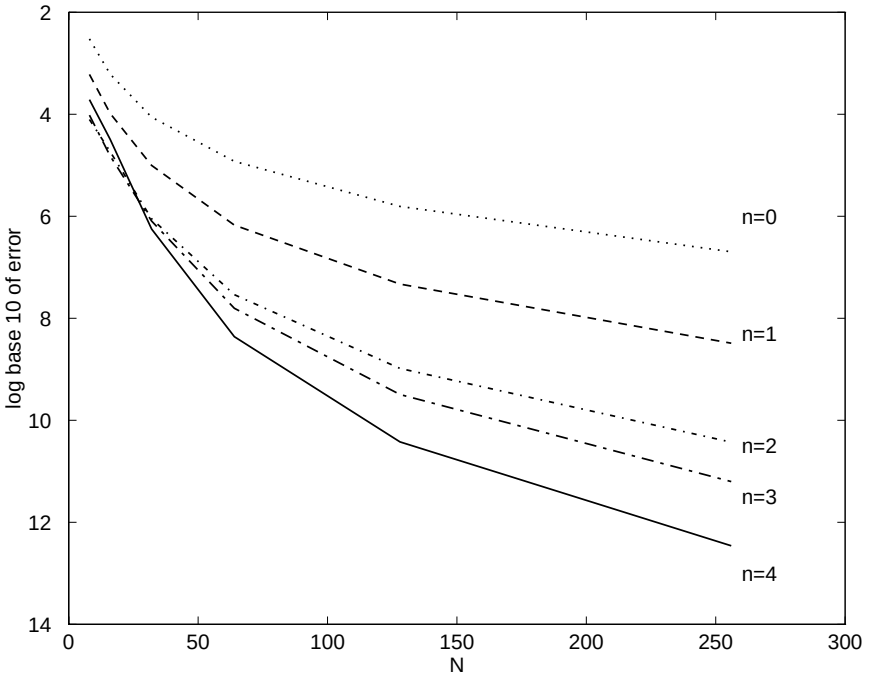

FIG. 3. *Numerical error in maximum norm with* $L = 1.6\ \pi,\ d = 0.25$.

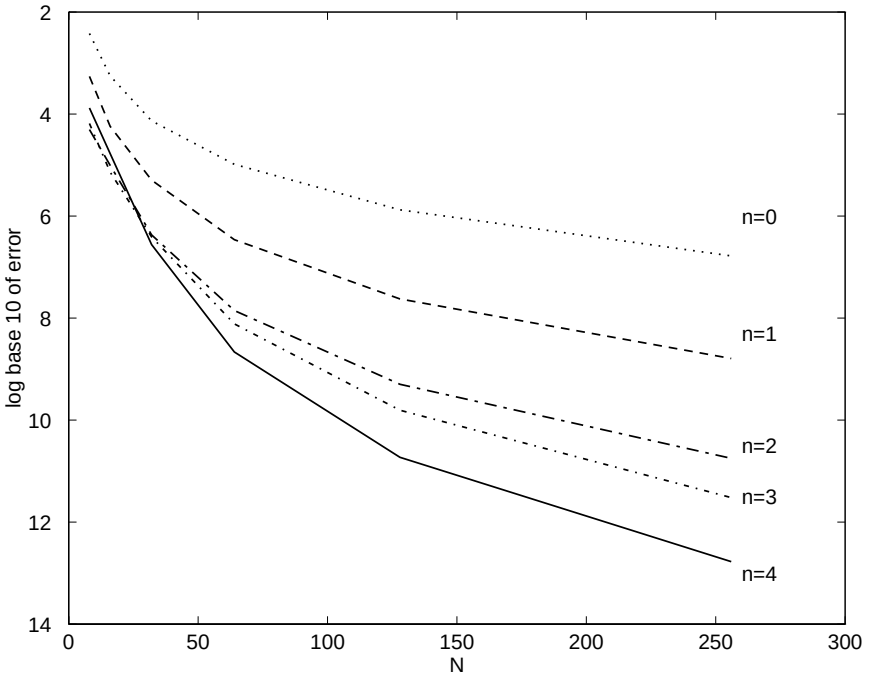

FIG. 4. *Numerical error in maximum norm with* $L = 1.6\,\pi,\ d = 1$.

ourselves to the case of boundary layers possibly at both ends of the interval. Let us consider the problems (18) or (19) with periodic boundary conditions

$$\bar{L}_{2,k}[v] \ = \ \bar{f}(x),\ x \in (0, L+d),\ v\ (L+d) \text{ periodic}, \tag{20}$$

with $\bar{f}$ (resp., $\bar{\gamma}$) a smooth $(L+d)$ periodic extension of f (resp., γ) in $C^n(\mathbb{R})$. We observe that the solutions of (20) have no boundary layer. Although the solution of (20) with $k = 1$ is defined up to a constant, the computation of the solution is easy by Fourier approximation. The solution of the corrector problem

$$L_{2,k}[w] \ = \ 0,\ x \in (0, L), w(0) = \alpha - v(0), w(L) = \beta - v(L) \tag{21}$$

belongs to a 2D vector space spanned by (w_1,w_2) the solutions of

$$L_{2,k}[w_1] \ = \ 0,\ x \in (0, L), w_1(0) = 1, w_1(L) = 0 \tag{22}$$

and

$$L_{2,k}[w_2] \ = \ 0,\ x \in (0, L), w_2(0) = 0, w_2(L) = 1. \tag{23}$$

The set of basis functions w_1,w_2 can be computed numerically with a specially-designed scheme to approximate boundary layers functions on refined grids or symbolically with, for example, Maple. We have implemented the *modulefou* method for the basic problems (18) and (19) with constant coefficients. We can estimate the error as in section 2: we obtain easily an estimate similar to (17) except that the rhs has a factor ϵ^{-1} because of the definition of the operator $L_{2,k}$. The direct numerical simulation confirms this result; see Figures 5 and 6 corresponding to the constant

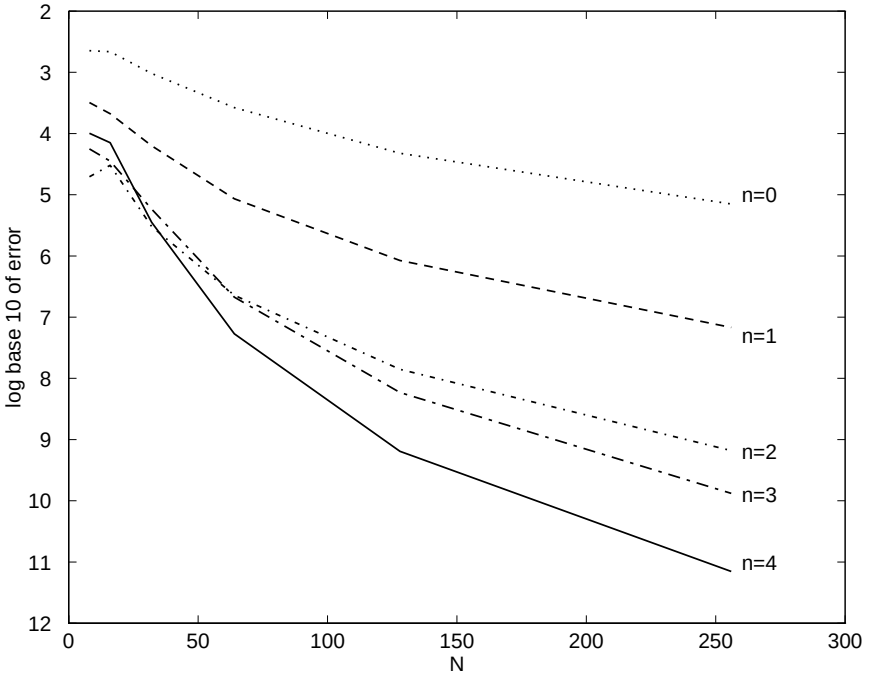

FIG. 5. *Error in maximum norm with* $k = 0,\ f \equiv \sin(x),\ L = 1.6\,\pi,\ d = 1,$ *and* $\epsilon = 0.1$.

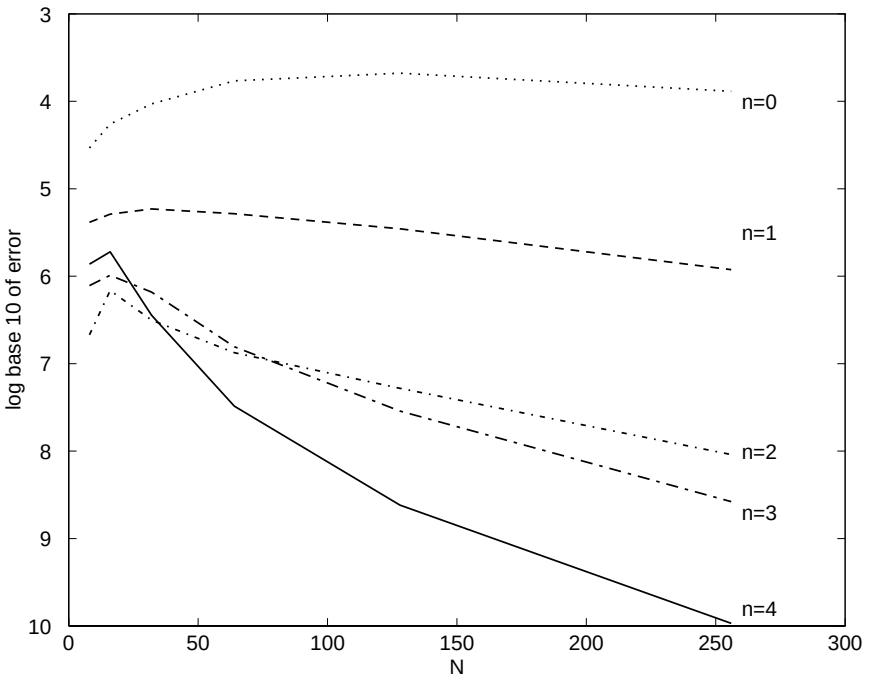

FIG. 6. *Error in maximum norm with* $k = 0,\ f \equiv \sin(x),\ L = 1.6\,\pi,\ d = 1,$ *and* $\epsilon = 0.01$.

coefficient $\gamma = 1$ case. In particular, we do not have any Gibbs phenomenon. One interesting feature of the numerical results of Figure 6 is that the accuracy is better than expected for small N. The reason for that is that the error is computed at the grid point and that there is no grid point in the layer for small N.

4.2. Heat equation. Let us consider the heat problem:

$$\frac{\partial u}{\partial t} - \frac{\partial^2 u}{\partial x^2} = f,\ x \in (0,1), t \in (0,T),$$

$$u(x,0) = u_0(x),\ x \in (0,1),$$

$$u(0,t) = g(t),\ u(1,t) = h(t),\ t \in (0,T).$$

We consider the following semidiscrete second-order (resp., second- and third-order) scheme in time:

$$\frac{u^n - u^{n-1}}{dt} = \frac{1}{2}(u^n_{xx} + f^n) + \frac{1}{2}(u^{n-1}_{xx} + f^{n-1}), \tag{24}$$

respectively,

$$\frac{\frac{3}{2}u^n - 2u^{n-1} + \frac{1}{2}u^{n-2}}{dt} - u^n_{xx} = f^n, \tag{25}$$

respectively,

$$\frac{\frac{11}{6}u^n - 3u^{n-1} + \frac{3}{2}u^{n-2} - \frac{1}{3}u^{n-3}}{dt} - u^n_{xx} = f^n. \tag{26}$$

u_{xx} denotes the second-order derivative with respect to the space variable x. Equation (24) is the Crank–Nicolson scheme, and (25), (26) are multilevel time-step schemes. These three schemes are unconditionally stable when u_{xx} is approximated by second-order centered finite difference formulas. For each time step t^n, we have to solve the two point boundary value problems:

$$-\frac{dt}{2}\, u^n_{xx} + u^n = rhs_1^{n-1}, u^n(0,t^n) = g(t^n), u^n(1,t^n) = h(t^n),$$

respectively,

$$-dt\, u^n_{xx} + \frac{3}{2}u^n = rhs_2^{n-1}, u^n(0,t^n) = g(t^n), u^n(1,t^n) = h(t^n),$$

respectively,

$$-dt\, u^n_{xx} + \frac{11}{6}u^n = rhs_3^{n-1}, u^n(0,t^n) = g(t^n), u^n(1,t^n) = h(t^n),$$

with

$$rhs_1^{n-1} = u^{n-1} + \frac{dt}{2}(u^{n-1}_{xx} + f^{n-1} + f^n),$$

respectively,

$$rhs_2^{n-1} = 2u^{n-1} - \frac{1}{2}u^{n-2} + dt\, f^{n-1},$$

respectively,

$$rhs_3^{n-1} = 3u^{n-1} - \frac{3}{2}u^{n-2} + \frac{1}{3}u^{n-3} + dt\ f^{n-1}.$$

The application of *modulefou* raises three questions: First, the accuracy of *modulefou* to solve the singular perturbation problem has been demonstrated in section 3.1, but the stability of the corresponding time-dependent scheme is not obvious. Second, rhs_1^n in the Crank–Nicolson scheme contains a second-order derivative in space that needs to be computed numerically. Third, how do we extend the rhs rhs^n defined on (0,1) into a smooth periodic function $r\bar{h}s^n$ of period $(1+d)$ on the interval $(0,\ 1+d)$, where d is the size of the extension, since rhs^n is known only *numerically* at the grid points $(x_i)_{i=1,\ldots,N}$ of (0,1)?

The second question is the easiest to answer. We have investigated two possibilities: let v^n (resp., w^n) be the periodic solution on the extended domain, (resp., the corrector) at time step t_n. We can use the splitting $u_{xx}^n = v_{xx}^n + w_{xx}^n$, where u_{xx}^n is computed with Fourier expansion and w_{xx}^n is given analytically as a function of w^n. Another solution is to derive u_{xx}^n from the equation of the scheme itself at previous time steps, i.e.,

$$u_{xx}^{n-1} = \frac{2}{dt}(u^{n-1} - rhs_1^{n-2})$$

in order to avoid the use of differentiation in the construction of the rhs.

The third question is solved in the following way.

Let $r\bar{h}s^n \equiv rhs^n$ *on* $(0,1)$; we interpolate numerically $r\bar{h}s^n$ on $(1, 1+d)$, so that

$$r\bar{h}s^n(1) = rhs^n(1),\ r\bar{h}s^n(1+d) = rhs^n(0), \tag{27}$$

and

$$\frac{\partial^j r\bar{h}s^n}{\partial x^j}(1) = \frac{\partial^j rhs^n}{\partial x^j}(1)\ +\ O(h^k),\ j = 1, \ldots, q, \tag{28}$$

$$\frac{\partial^j r\bar{h}s^n}{\partial x^j}(1+d) = \frac{\partial^j rhs^n}{\partial x^j}(0)\ +\ O(h^k),\ j = 1, \ldots, q. \tag{29}$$

We proceed by Hermite interpolation based on one side *k-order* finite difference approximations of the derivatives of rhs^n at the end of the interval of computation $(0,1)$ using only discrete values of rhs^n at the grid points inside $(0,1)$.

Finally we have investigated the question of stability of the resulting time-dependent scheme with several numerical experiments. More precisely, we have implemented these three schemes with the *modulefou* technique and compared the accuracy of the solution to finite difference implementations with centered second-order finite differences in space. In our comparisons, we use the same space step for all methods.

We define $f,\ u_o,\ g,\ h$ in the heat equation problem such that $u(x,t) = \sin(t)\ \cos(x)$ is the exact solution. The Hermite interpolation of $r\bar{h}s^n$ defined in (27)–(29) satisfies $k = q = 2$; we observe that $\bar{f}$ in the numerical scheme is not close to the periodic function f in $(1, 1+d)$.

Figure 7 gives the error in maximum norm for $t \leq \frac{\pi}{2}$. In each plot, the curves with a "+" (resp., "o") correspond to second-order finite differences in space (resp., *modulefou*). The flat part of curves corresponds to the interval of time step where the

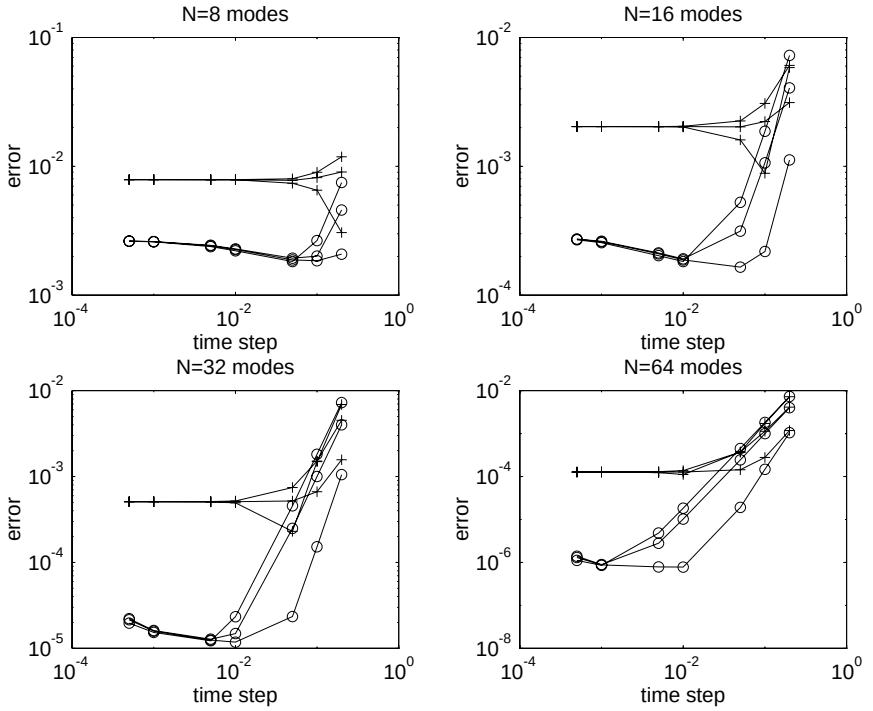

FIG. 7. *Numerical error in maximum norm for the heat equation problem.*

accuracy is limited by the spatial discretization. This numerical experiment shows a real advantage of *modulefou* compared to the classical second-order finite difference in space. In our experiments, the Crank–Nicolson scheme is slightly less accurate than the second-order scheme (25) for both types of space discretizations. The third-order scheme (26) gives effectively the best accuracy with respect to the time step. Although we had not observed any stability problem with *modulefou* even for very large time step, it is interesting to notice that the accuracy of the *modulefou* method for a fixed number of modes may deteriorate when the time step becomes too small. As a matter of fact, the operator $-dtu_{xx} + u$ does correspond to a singular perturbation problem similar to (18), and we have seen in section 3.1 that the accuracy in space with Fourier approximation deteriorates when the small perturbation parameter goes to zero.

4.3. Wave equation. We have seen that the *modulefou* method works quite well with the heat operator. However, the stability of the numerical method might be a consequence of the very nice smoothing properties of the heat operator. This should not be the case with the wave operator that we do consider now. Let us consider the wave problem

$$\frac{\partial^2 u}{\partial t^2} - c^2 \frac{\partial^2 u}{\partial x^2} = f,\ x \in (0,1), t \in (0,T),$$
$$u(x,0) = u_0(x),\ x \in (0,1),$$
$$\frac{\partial u}{\partial t}(x,0) = u_1(x),\ x \in (0,1),$$

$$u(0,t) = g(t),\ u(1,t) = h(t),\ t \in (0,T).$$

We consider the following semidiscrete second-order scheme in time:

$$\frac{u^{n+1} - 2u^n + u^{n-1}}{dt^2} = \frac{c^2}{2} u_{xx}^{n+1} + \frac{c^2}{2} u_{xx}^{n-1} + f^n. \tag{30}$$

u_{xx} is the notation for the second-order derivative with respect to the space variable x. The procedure to implement *modulefou* for this scheme is entirely analogous to the procedure used for the heat equation problem. We solve for each time step t^{n+1} the two point boundary value problems:

$$-\frac{dt^2 c^2}{2} u_{xx}^n + u^n = rhs_2^{n-1}, u^n(0,t^n) = g(t^n), u^n(1,t^n) = h(t^n),$$

with

$$rhs_2^n = c^2 \frac{dt^2}{2} u_{xx}^{n-1} + dt^2 f^n + 2u^n - u^{n-1}.$$

u_{xx}^n in the rhs can be either derived from the scheme at previous time step as follows

$$u_{xx}^{n-1} = \frac{2}{c^2 dt^2}(u^{n-1} - rhs_2^{n-2}),$$

or computed using the splitting $u^n = v^n + w^n$. We notice that (30) is unconditionally stable when we use a second-order finite difference in space. We have compared in our numerical experiments the *modulefou* technique with this finite difference version for several test cases. With a second-order Hermite interpolation, we found a better accuracy with *modulefou*. The following tables give the error in maximum norm when the exact solution of the wave problem is $u(x,t) = \sin(2\ \pi\ p\ (x - x_0))\ \cos(2\ \pi\ p\ t)$ with the wave number $p = 3$, the size of the extension $d = 0.2$, and the interval of time $(0, \pi)$. We restrict ourselves to use the same number $2\ M$ of discretization points for each method.

Error with second-order finite differences.

Time step	$M = 8$	$M = 16$	$M = 32$	$M = 64$
0.05	1.12	0.27	0.12	0.076
0.01	1.05	0.21	0.054	0.015
0.005	1.05	0.21	0.052	0.013
0.001	1.05	0.21	0.052	0.012
0.0005	1.05	0.21	0.052	0.012

Error with modulefou.

Time step	$M = 8$	$M = 16$	$M = 32$	$M = 64$
0.05	0.387	0.078	0.067	0.064
0.01	0.322	0.024	0.005	0.0028
0.005	0.320	0.023	0.003	0.0009
0.001	0.320	0.023	0.003	0.0003
0.0005	0.320	0.023	0.003	0.0003

In addition, we found no stability constraint on the time step even for large time steps. Figure 8 gives the typical evolution in time of the error for both methods. The thicker line corresponds to *modulefou*.

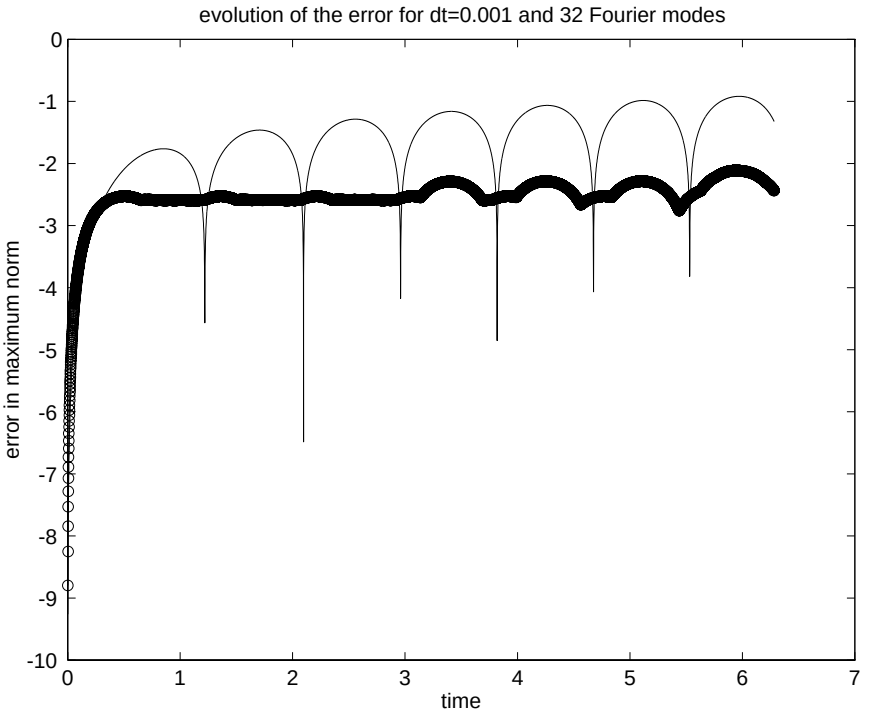

FIG. 8. *Numerical error in maximum norm for the wave equation problem.*

4.4. Hyperbolic-hyperbolic singular perturbation. Let us consider the following hyperbolic-hyperbolic singular perturbation problem:

$$\epsilon\left(\frac{\partial^2 u}{\partial t^2} - c^2\frac{\partial^2 u}{\partial x^2}\right) + \left(\frac{\partial u}{\partial t} + b\frac{\partial u}{\partial x}\right) = f,\ x \in (0,1), t \in (0,T),$$

$$u(x,0) = u_0(x),\ x \in (0,1),$$

$$\frac{\partial u}{\partial t}(x,0) = u_1(x),\ x \in (0,1),$$

$$u(0,t) = g(t),\ u(1,t) = h(t),\ t \in (0,T).$$

This model problem describes the propagation of waves with wave hierarchies [26] and occurs in many physical problems [24], [2]. We assume for simplicity that b and c are positive constants. We assume that the operator is time-like, i.e.,

$$-|c| < b < |c|.$$

The formal limit of this singular perturbation problem when $\epsilon \to 0$ is written

$$\frac{\partial u^0}{\partial t} + b\frac{\partial u^0}{\partial x} = f,\ x \in (0,1), t \in (0,T),$$

$$u^0(x,0) = u_0(x),\ x \in (0,1),$$

$$\frac{\partial u^0(x,0)}{\partial t} = u_1(x),\ x \in (0,1),$$

$$u^0(0,t) = g(t),\ u^0(1,t) = h(t),\ t \in (0,T).$$

Both initial conditions cannot be satisfied at the same time, and u exhibits an initial layer of ϵ thickness in time. Both boundary conditions cannot be satisfied as well, and u exhibits a boundary layer of ϵ thickness in space, at one end of the interval depending on the sign of the convection factor b. At first order, for b positive and for time of order one, u is approximated outside the initial layer in time and boundary layer in the neighborhood of 1 by

$$\frac{\partial u^0}{\partial t} + b\frac{\partial u^0}{\partial x} = f,\ x \in (0,1), t \in (0,T),$$

$$u^0(x,0) = u_0(x),\ x \in (0,1),$$

$$u^0(0,t) = g(t).$$

In addition, there are some other singular perturbation effects for large time, if the domain is large in space variable or unbounded: the second-order hyperbolic perturbation has then a diffusive effect. We refer to [4], [13] for the detailed analysis of the singular perturbation problem. We have tested the *modulefou* approach on this nontrivial singular perturbation problem with the following second-order scheme in time:

$$\epsilon\left[\frac{u^{n+1} - 2u^n + u^{n-1}}{dt^2} - \frac{c^2}{2}(u_{xx}^{n+1} + u_{xx}^{n-1})\right] + \frac{u^{n+1} - u^{n-1}}{2dt} + \frac{b}{2}(u_x^{n+1} + u_x^{n-1}) = 0. \tag{31}$$

A Fourier analysis shows that this time-dependent scheme combined with second-order finite differences in space for second-order spatial derivative and one side appropriate first-order derivative for the convective term is stable for our test case. The implementation of the *modulefou* technique is straightforward. In particular all derivatives that have to be computed in the rhs of (31) use the splitting $u^{n+1} = v^{n+1} + w^{n+1}$ at previous time steps. v^{n+1} is the solution of the periodic solution of the nonhomogeneous problem on an extension of the domain, w^{n+1} is the corrector.

We can make few observations:

- If one is not interested in having an accurate representation of the solution in the initial layer, it is convenient to start the computation with a scheme that is unconditionally stable. As a matter of fact, the effect of the initial layer decreases asymptotically as $\exp(-\frac{t}{\epsilon})$.
- The corrector w^{n+1} in the *modulefou* schemes does not capture the phenomenon of boundary layer because the rhs in the time-dependent scheme for the periodic problem is stiff. With no filtering, we need experimentally at least two grid points in the layer to avoid spurious oscillations. Otherwise, the scheme becomes numerically unstable.

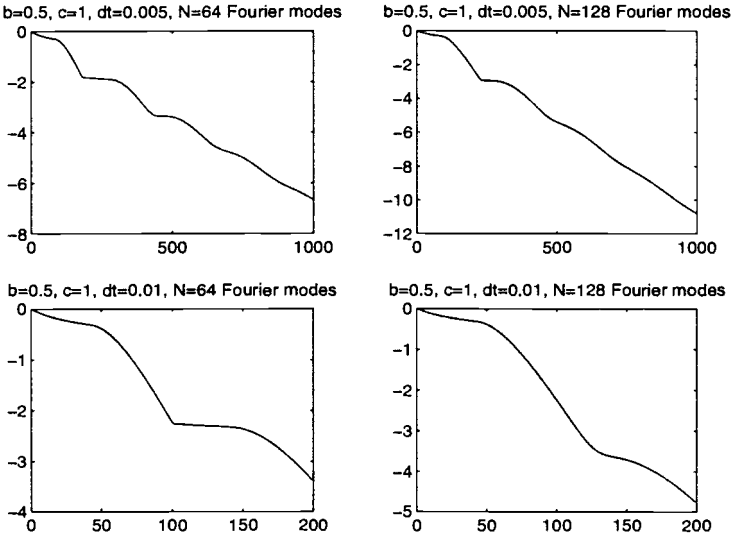

FIG. 9. *Variation in time of the amplitude of the wave for* $\epsilon = 0.05$.

Let us consider the following test case:

$$f \equiv 0,\ u_0(x) = \exp\left(-5\left(x - \frac{1}{2}\right)^2\right),\ u_1 \equiv 0,\ g \equiv 0,\ h \equiv 0,\ b = 0.5,\ c = 1,\ \epsilon = 0.05.$$

Our numerical experiment shows that the *modulefou* method can give inaccurate solutions when the space step in the layer is not small enough compared to the thickness of the layer. Figure 9 shows the evolution of the numerical value of $\log_{10}(\max_{x\in(0,1)} u(x,t))$ as a function of the space step for various discretization parameters in space and time. We observe an artificial wave that goes back and forth in time into the interval $(0,1)$: this signal is damped every time it hits the right boundary $x = 1$. The height of the second step strongly depends on the number of modes as well as the time step; it is also a lower bound on the numerical accuracy of the method. Our validation of this result has included comparison with second-order finite differences solutions as well as piecewise Chebyshev polynomials for which this phenomenon does not occur.

4.5. Burgers's equation and other nonlinear examples. Let us consider the initial boundary value problem with the Burgers equation

$$\frac{\partial u}{\partial t} = \epsilon \frac{\partial^2 u}{\partial x^2} + u\frac{\partial u}{\partial x}, \qquad x \in (-1,1), t \in (0,T), \tag{32}$$

$$u(x,0) = u_0(x),\ x \in (0,1); u(-1,t) = g(t),\ u(1,t) = h(t),\ t \in (0,T). \tag{33}$$

This simple model problem has a number of interesting properties that can make the numerical computation rather challenging [19], [20]. Let us illustrate these difficulties with some examples.

We suppose that we have balanced boundary conditions with $g(t) \equiv 1$ and $h(t) \equiv -1$; we assume also that u_0 is linear and continuous on $(-1,1)$ and satisfies the symetry $u_0(-x) = u_0(x)$. Then the solution $u(x,t)$ has the symmetry property $u(x,t) = -u(-x,t)$ for all time. After some evolution of the solution during a period of time

of order one, $u(x,t)$ will be exponentially close to the steady state solution [19]:

$$u(x,\infty) = \delta(\epsilon)\tanh\left(\frac{\delta(\epsilon)}{2\epsilon}x\right),$$

with δ solution of the transcendental equation

$$\delta = 1 + (\delta+1)\exp\left(\frac{-\delta}{\epsilon}\right).$$

Asymptotically we have

$$\delta(\epsilon) = 1 + 2\exp\left(-\frac{1}{\epsilon}\right) - \frac{2}{\epsilon}(2-\epsilon)\exp\left(-\frac{2}{\epsilon}\right) + O\left(\exp\left(-\frac{3}{\epsilon}\right)\right).$$

$u(x,t)$ is then stiff with a so-called shock layer of order ϵ thickness. This shock layer is formed at some time t_0 depending on the initial condition [21]. The fast variation of the solution in the shock layer is the first type of difficulty that the numerical method should overcome.

A second difficulty that should not be ignored in numerical tests with problem (32) is that the solution is supersensitive to boundary conditions.

As a matter of fact, let us change slightly the boundary conditions with, for example,

$$g(t) \equiv 1 + 2\,\exp\left(\frac{-b}{\epsilon}\right).$$

Then the steady state changes dramatically, more precisely [19],

$$u(x,\infty) \sim \tanh\left(\frac{x-1+b}{2\epsilon}\right).$$

This phenomenon is not limited to the steady solution; let us consider, for example, the balanced boundary conditions case defined above but with a new initial condition that is

$$u_0(x) = \tanh\left(\frac{x-x_0}{2\epsilon}\right).$$

Then $u(x,t)$ will stay asymptotically close to the travelling wave $u_0(x^*(t))$ with $\frac{d}{dt}(x^*)$ exponentially small. In particular, the zero of $u(x,t)$ will move exponentially slowly in time.

We have implemented the *modulefou* method to compute the solution of the initial boundary value problem (32) written in conservative form in a straightforward way with the Euler semi-implicit scheme

$$\frac{u^n - u^{n-1}}{dt} = \epsilon\frac{\partial^2 u^n}{\partial x^2} + \frac{1}{2}\frac{\partial (u^{n-1})^2}{\partial x}.$$

The problem is splitted at each iteration into a nonhomogeneous problem with periodic boundary conditions

$$-\epsilon\, dt\frac{\partial^2 v^n}{\partial x^2} + v^n = r\bar{h}s^{n-1},\ x \in (0,2\pi),$$

with

$$rhs^{n-1} = u^{n-1} + \frac{dt}{2}\,\frac{\partial (u^{n-1})^2}{\partial x}$$

and a homogeneous problem for the corrector with Dirichlet boundary conditions

$$-\epsilon\, dt \frac{\partial^2 w^n}{\partial x^2} + w^n = 0,\ w(-1) = g(t^n) - v^n(-1), w(1) = h(t^n) - v^n(1).$$

We first observe that rhs^n is stiff as soon as a shock is formed. So the solution v^n of the periodic problem is somewhat stiff as well. The results of section 3.1 in terms of accuracy therefore do not apply. We observe in addition that the layer for the corrector problem has a thickness of order $\sqrt{\epsilon dt}$, but the thickness of the shock layer is of order ϵ. In conclusion we cannot expect any smoothing process from *modulefou* since we do not approach the real corrector of Burgers's equation with this straightforward implementation.

In addition, in order to approximate $\frac{\partial (u^{n-1})^2}{\partial x}$, we first extend the flux into a periodic function and then apply Fourier differentiation. This process somehow deteriorates the accuracy of the scheme. An alternative approach is to implement a nonconservative scheme with *modulefou* and decompose $\frac{\partial u^{n-1}}{\partial x}$ into $\frac{\partial v^{n-1}}{\partial x} + \frac{\partial w^{n-1}}{\partial x}$, where the first term is computed via Fourier expansion and the second term is derived analytically from the representation of w^{n-1}. However, our experiment with a nonconservative scheme did not give good numerical accuracy.

We have summarized in the following tables our comparison of our implementation of *modulefou* with a classic second-order finite difference scheme. Since we want to investigate the spatial accuracy of our discretization and its stability, we have computed the steady solution of the symetric solution of Burgers's equation in the case of balanced boundary conditions. We found that the computation with the *modulefou* method is then accurate and does not show serious spurious oscillations when the space step is less than ϵ. On the contrary, if ϵ is too small compared to the space step, the *modulefou* scheme becomes unstable because of the Gibbs phenomenon. Because the theory of filtering with Fourier expansion is well known, we can work eventually with larger space step using some filters to remove the spurious oscillations.

Error with modulefou.

ϵ	$M = 8$	$M = 16$	$M = 32$	$M = 64$
0.1	10^{-3}	$5.\ 10^{-4}$	$6.\ 10^{-6}$	$6.\ 10^{-7}$
0.05	*diverge*	$8.\ 10^{-4}$	10^{-5}	$9.\ 10^{-7}$
0.01	*diverge*	*diverge*	*diverge*	$3.\ 10^{-3}$

Error with second-order finite differences.

ϵ	$M = 8$	$M = 16$	$M = 32$	$M = 64$
0.1	$1.8\ 10^{-2}$	$5.\ 10^{-3}$	$1.2\ 10^{-3}$	$3.\ 10^{-4}$
0.05	$8.\ 10^{-2}$	$1.7\ 10^{-2}$	$5.\ 10^{-3}$	10^{-3}
0.01	$1.5\ 10^{-1}$	$1.8\ 10^{-1}$	10^{-1}	$2.8\ 10^{-2}$

We have also investigated the accuracy of our scheme with respect to the boundary conditions. This computation is far more difficult and requires exponentially large T time to reach the steady solution as demonstrated in the following table. Therefore, a straightforward integration in time of the Burgers equation is by no means an

efficient way of solving the problem [23]. However, it is a good test on the stability of a numerical computation. We have compared *modulefou* to second-order finite differences computation with 32 discretization points, as well as adaptive pseudospectral Chebyshev with two subdomains and 39 Chebyshef points per subdomain. Our criterion is to compare the zero of our solution u with its asymptotic prediction. Since the computation was done with only 16 Fourier modes, *modulefou* seems to perform very well.

Test with supersensitivity.

δ	Modulefou	Finite differences	Chebysheff	Asymptotic	T
500 $\exp(\frac{-1}{\epsilon})$	0.5608	0.5668	0.5610	0.5521	300
100 $\exp(\frac{-1}{\epsilon})$	0.3933	0.4046	0.3937	0.3912	600
20 $\exp(\frac{-1}{\epsilon})$	0.2315	0.2483	0.23184	0.23025	1800

In order to improve the accuracy of the computation with respect to the stiffness of the solution, we have introduced an adaptive domain decomposition of (32) [6]. Let us consider the case of balanced boundary conditions with a continuous linear initial condition. We use three subdomains as in [7, p. 1191] except that there is no overlapping between the subdomains. In particular, there is a large ratio between the space step in the subdomain centered on the shock layer and the two other subdomains (see Figure 10) in such a way that the space step in the inner domain is of the order of ϵ. The interesting and somewhat surprising conclusion of our numerical experiment is that the adaptive domain decomposition allows us to effectively avoid oscillations in the zone where the solution is stiff, although very small spurious oscillations in the two subdomains where the solution is regular induce a shifting of the solution in the inner domains. This is a direct consequence of the supersensitivity of the inner solution on the interface conditions with the left and right regular domains. This unfortunate circumstance makes the solution inaccurate after all! Figure 10 gives some picture of the three subdomain computation. The shift of the solution in the shock layer compared to the exact steady state ("o" plots) is increasing very slowly in time as expected from the asymptotic theory.

Now we consider the simplified model of reacting flow of Majda [22], that is,

$$\frac{\partial u}{\partial t} + \frac{\partial}{\partial x}\left[\frac{1}{2}u^2 - Q_0 Z\right] = \epsilon \frac{\partial^2 u}{\partial x^2},$$

$$Z_x = \epsilon^{-1}\phi(u)Z,$$

where $\phi(u) = 1$ if $u > 0$ and 0 elsewhere. We refer to [22] and its references for the derivation of this model and its precise statement. This problem admits various travelling wave solutions with sharp transition layers of ϵ thickness. These travelling waves are written $u(\frac{x-s\,t}{\epsilon})$ with the asymptotic behavior $u_x \to u_{l/r}$ when $x \to \mp\infty$. We report here on the computation of this model problem with *modulefou* and a first-order semi-implicit Euler time stepping. We consider two cases: first a strong detonation wave that corresponds to $u_l = 1, u_r = -1.5, s = 0.7, Q_0 = 2.375$, second a weak detonation wave that corresponds to $u_l = 1, u_r = -0.407, s = 0.7, Q_0 = 0.568$. Strong detonations are very difficult to compute because the viscous terms and the reaction terms are of the same asymptotic order in the sharp reacting layer. Figure 11 shows the profile of the solutions for $\epsilon = 0.03$ after 2 units of time. The initial condition is $\frac{u_l - u_r}{2}(1 - \tanh(\frac{x-1}{0.1})) + u_r$. With a space step $h = 0.0236$ a time step as

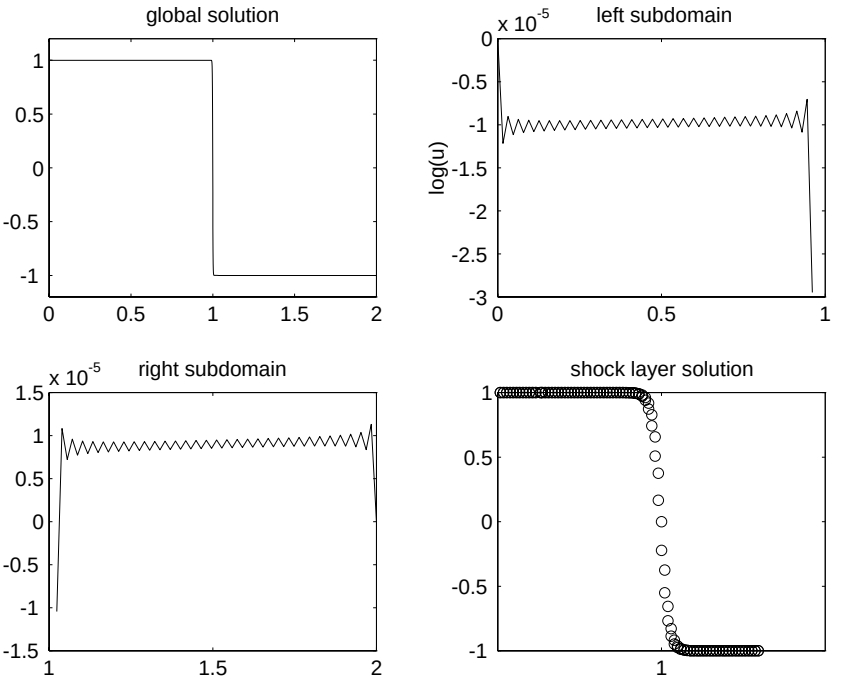

FIG. 10. *Adaptive domain decomposition for Burgers's problem.*

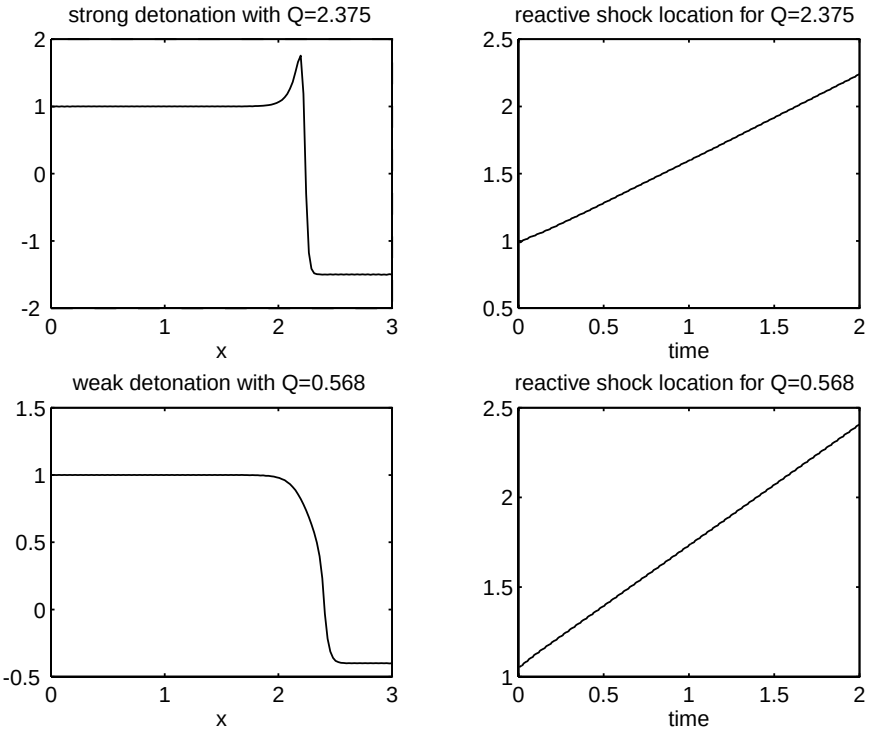

FIG. 11. *Majda's simplified model of reacting flow.*

small as 2.5 10^{-3} and 82 Fourier modes, the error on the speed velocity is about 10 percent in the first case and 5 percent in the second case. This accuracy is satisfactory considering the fact that we do not use any adaptivity in space. As a matter of fact, when one doubles the viscosity coefficient in the previous numerical experiment, i.e., $\epsilon = 0.06$, the observed numerical error on the front velocity is divided by two in each previous test case.

5. Extension to two-space dimension problems. We consider the singular perturbation problem

$$-\epsilon\Delta u + u = f \text{ in } \Omega \subset (0,\ 2\pi)^2,\ u = g \text{ on } \partial\Omega, \tag{34}$$

where Δ is the Laplace operator, Ω is a regular domain of $\mathbb{R}^2$, $f \in C^\infty(\Omega)$, and $g \in C^\infty(\partial\Omega)$. The solution of this singular perturbation problem has a boundary layer of $\sqrt{\epsilon}$ thickness. Let $\bar{f}$ be a smooth 2π periodic extension of f, with $\bar{f} \in C^n(\mathbb{R}^2)$. Then the 2π periodic solution of the following problem:

$$-\epsilon\Delta v + v = \bar{f} \text{ in } (0,\ 2\pi)^2 \tag{35}$$

has no boundary layer. On the other hand, the solution of the corrector problem

$$-\epsilon\Delta w + w = 0 \text{ in } \Omega \subset (0,\ 2\pi)^2,\ w = g - v \text{ on } \partial\Omega$$

can either be approximated by an asymptotic expansion [3] or computed numerically on an adapted stretched local coordinate system. We retrieve the solution of the original singular perturbation problem (34) using the superposition principle. We are first going to show using the arguments (2) and (3) of the introduction that *modulefou* is an attractive way to solve the singular perturbation problem (34). However, our real goal is to design solvers of (34) that are useful to compute the time-dependent problem. So second we are going to see how in practice one can implement the *modulefou* method on domain with smooth but relatively complex shape to serve this purpose.

5.1. Combined numerical-symbolical solution. We first construct numerically $\bar{f}$ an appropriate periodic extension of f, in a similar manner to section 2. Let (ρ, θ) be a local coordinate system valid in a ring Ω_e defined below, with θ a parametrization of $\partial\Omega$ and ρ the distance to $\partial\Omega$. We assume that $f_{|\partial\Omega}$ and its normal derivatives $\frac{\partial^i f}{\partial\rho^i}_{|\partial\Omega}$ up to order i are given on $\partial\Omega$. We assume that it exists $\rho_0 > 0$ such that

$$\Omega_e = \{M(x,y) \in \mathbb{R}^2 \setminus \Omega,\ \text{dist}(M, \partial\Omega) \le \rho_0\} \subset (0,\ 2\pi)^2$$

and the local coordinates system (ρ, θ) are well defined in Ω_e. Then we construct $\bar{f}$ as follows:

$$\bar{f}(x,y) = P_\theta(\rho),\ P_\theta \in \mathbb{P}^{2n+1},\ M(x,y) \in \Omega_e,$$

$$\frac{\partial^i P}{\partial\rho^i}(0) = \frac{\partial^i f}{\partial\rho^i} \text{ on } \partial\Omega,\ i = 0, \ldots, n,$$

$$\frac{\partial^i P}{\partial\rho^i}(\rho_0) = 0,\ i = 0, \ldots, n,$$

$$\bar{f} \equiv 0 \text{ in } (0,\ 2\pi)^2 \setminus \left(\Omega \bigcup \Omega_e\right),$$

$$\bar{f} \equiv f \text{ in } \Omega.$$

Second we approximate v solution of (35) by a discrete Fourier expansion v_N as in section 2 except that the solution is unique. The last step is the computation of w the solution of the corrector problem

$$-\epsilon \Delta w + u = f \text{ in } \Omega \subset (0,\ 2\pi)^2,\ w = g - v \text{ on } \partial\Omega, \tag{36}$$

based on an asymptotic expansion of w and the Fourier approximation $g - v_N$ of the boundary condition. Let us review briefly the construction of the asymptotic expansion of the corrector. The ρ coordinate is stretched according to the thickness of the boundary layer, i.e., $\xi = \frac{\rho}{\sqrt{\epsilon}}$. In these coordinates, the Laplace operator is written

$$\epsilon\Delta = \frac{\partial^2}{\partial\xi^2} \ +\ \epsilon\ q_0^1\ \frac{\partial^2}{\partial\theta^2} \ +\ \sqrt{\epsilon}\ q_0^{-1}\ q_1\ \frac{\partial}{\partial\xi} \ -\ \epsilon\ \ q_0^{-2}\ q_2\ \frac{\partial}{\partial\theta},$$

with $q_0 = 1 + 2\sqrt{\epsilon}\xi\phi + \epsilon\xi^2\psi$, $q_1 = \sqrt{\epsilon}\xi\psi + \phi$, $q_2 = \sqrt{\epsilon}\xi\phi' + \frac{1}{2}\epsilon\xi^2\psi'$, $\phi = \langle n', \hat{x}'\rangle$, $\psi = \langle n', n'\rangle$. " $'$ " denotes the differentiation with respect to θ, n the outward normal direction to $\partial\Omega$, and $\langle .,. \rangle$ the scalar product.

It is known [3] that w solution of (36) admits an asymptotic expansion of the following type:

$$w(\xi,\theta) = w_0(\xi,\theta) + \sqrt{\epsilon}w_1(\xi,\theta) + \epsilon w_2(\xi,\theta) + \cdots + \epsilon^{\frac{m}{2}} w_m(\xi,\theta) + O(\epsilon^{\frac{m+1}{2}}),$$

with arbitrary large order m. The validity of this expansion in maximum norm is proved using the maximum principle. The effective construction of this expansion can be done with a symbolic manipulation language as Maple. $w_i,\ i = 0, \ldots, 2$, for example, are solutions of the following ODE problems parametrized by θ:

$$-\frac{\partial^2 w_0}{\partial\xi^2}(\xi,\theta) + w_0(\xi,\theta) = 0,$$
$$w_0(0,\theta) = h(\theta),\ w_0(+\infty,\theta) = 0,$$

with $h(\theta) = g - v,\ on\ \partial\Omega$,

$$-\frac{\partial^2 w_1}{\partial\xi^2}(\xi,\theta) + w_1(\xi,\theta) = \phi(\theta)\frac{\partial w_0}{\partial\xi}(\xi,\theta),$$
$$w_1(0,\theta) = 0, w_1(+\infty,\theta) = 0,$$

$$-\frac{\partial^2 w_2}{\partial\xi^2}(\xi,\theta) + w_2(\xi,\theta)$$
$$= \phi(\theta)\ \frac{\partial w_1}{\partial\xi}(\xi,\theta) \ +\ \frac{\partial^2 w_0}{\partial\theta^2}(\xi,\theta) \ +\ (2\xi\phi^2(\theta)\xi\psi(\theta))\ \frac{\partial w_0}{\partial\xi}(\xi,\theta),$$
$$w_2(0,\theta) = 0,\ w_2(+\infty,\theta) = 0.$$

We obtain the explicit formula of the corrector at order $\epsilon^{\frac{3}{2}}$,

$$w_0(\xi,\theta) = h(\theta)e^{-\xi},$$

$$w_1(\xi,\theta) = h_1^1(\theta)\xi)e^{-\xi},$$

$$w_2(\xi,\theta) = (h_2^1(\theta)\xi + h_2^2(\theta)\xi^2)e^{-\xi},$$

with

$$h_1^1(\theta) = -\frac{1}{2}\phi(\theta)h(\theta),\ h_2^1(\theta) = \frac{1}{8}\psi(\theta)h(\theta) + \frac{1}{2}h''(\theta),\ h_2^2(\theta) = \frac{3}{8}\psi(\theta)h(\theta).$$

It can be proved by induction that

$$w_i = \sum_{j=1,\ldots,m} h_i^j(\theta)\xi^j e^{-\xi},$$

and that h_i^j depends on derivatives of $h(\theta)$ up to order i at most.

We can generate with Maple, the fortran code to compute the explicit formula of the asymptotic expansion of the corrector at any fixed order m. However, these formula require the computation of derivatives of $h(\theta)$ up to order m. In order to approximate these derivatives, we introduce the discretization in θ variable: $\theta_k = \frac{2\,k\,\pi}{2M+1}, k = 1,\ldots,2\,M$. Let v_N be the Fourier expansion of v solution of (35). We interpolate v_N on $\partial\Omega$ for $\theta = \theta_k,\ k = 1,\ldots,2\,M$, and derive a discrete Fourier expansion h_M of $h(\theta)$. The derivatives of $h(\theta)$ are then approximated with the corresponding derivatives of h_M. Since the i^{eme} term of the asymptotic expansion of the corrector depends on the i^{eme} derivative at most of h_M, the relative accuracy on w_i compared to the accuracy on w_0 is of order M^{-i}. The contribution of this term to the error in the asymptotic corrector formula is then of order $\epsilon^{\frac{i}{2}}M^{-i}$ times the error on w_0.

Therefore, the numerical approximation of the asymptotic expansion of the corrector $\sum_{i=0,\ldots,m}\epsilon^{\frac{i}{2}}w_i$ will not deteriorate (in theory) when m increases as long as $\sqrt{\epsilon}$ is of order M^{-1} at most.

This symbolic computation of the corrector w combined to the Fourier approximation of v seems to be quite natural to specifically solve the singular perturbation problem (34). However, we have to recall that the asymptotic expansion of w *does not converge* as the number of terms in the asymptotic expansion grows. For every ϵ and boundary condition h, there is an optimum value of the number of term of the asymptotic expansion that gives the best accurate solution. This does not sound like a practical solution to implement the *modulefou* method for the time-dependent problem.

We have checked for example that the solver obtained with the first-order asymptotic correction w_0 applied to the heat equation is numerically stable in our experiments. However, for the time being, we have not been able to obtain any convincing numerical convergence of this scheme to some exact specific steady solution of the heat equation problem when the number of Fourier modes grows and the time step goes to zero. Higher-order asymptotic corrections did not improve the situation significantly either.

5.2. A numerical solver for the time-dependent problem. The goal of this section is to generalize our approach for the time-dependent problem in one space dimension to two space dimensions. We are now going to compute the corrector of problem (34) *numerically* instead of asymptotically for the reasons mentioned above. So we focus our attention to the numerical solution of the following Dirichlet homogeneous problem:

$$-\epsilon\,\Delta w\ +\ w\ =\ 0 \text{ in } \Omega,\ w = h \text{ on } \partial\Omega. \tag{37}$$

For simplicity, we assume that the boundary $\partial\Omega$ of Ω can be defined in polar coordinates as follows:

$$\rho = S(\theta),\ \theta \in (0, 2\,\pi),$$

with S 2π periodic and $S(\theta) \in C^\infty[0, 2\,\pi]$. It is clear that when Ω is a disc and h is a finite discrete Fourier expansion, we just get analytically w using some Bessel functions. We could then reproduce the algorithm of section 2. In this paper, we would like to tackle the case of complex geometry. We introduce the change of variable $\hat{\rho} = S(\theta) - \rho,\ \hat{\theta} = \theta$ and rewrite (37) in this new coordinate system:

$$-\epsilon\left(\alpha(\hat{\rho},\hat{\theta})\,\frac{\partial^2\hat{w}}{\partial\hat{\rho}^2} + \beta(\hat{\rho},\hat{\theta})\,\frac{\partial\hat{w}}{\partial\hat{\rho}} + \gamma(\hat{\rho},\hat{\theta})\,\frac{\partial^2\hat{w}}{\partial\hat{\rho}}\partial\hat{\theta} + \delta(\hat{\rho},\hat{\theta})\,\frac{\partial^2\hat{w}}{\partial\hat{\theta}^2}\right) + w = 0 \tag{38}$$

$$\text{for } \hat{\rho} \in (0, S(\hat{\theta})),\ \hat{\theta} \in [0, 2\,\pi],$$

$$\hat{w}(0,\hat{\theta}) = h(\hat{\theta}),\ \hat{\theta} \in [0, 2\pi], \tag{39}$$

with

$$\alpha(\hat{\rho},\hat{\theta}) = 1 + \frac{S'^2(\hat{\theta})}{(S(\hat{\theta}) - \hat{\rho})^2},$$

$$\beta(\hat{\rho},\hat{\theta}) = \frac{S''(\hat{\theta})}{(S(\hat{\theta}) - \hat{\rho})^2} - \frac{1}{S(\hat{\theta}) - \hat{\rho}},$$

$$\gamma(\hat{\rho},\hat{\theta}) = 2\frac{S'(\hat{\theta})}{(S(\hat{\theta}) - \hat{\rho})^2},$$

$$\delta(\hat{\rho},\hat{\theta}) = \frac{1}{(S(\hat{\theta}) - \hat{\rho})^2}.$$

Because of the required asymptotic behavior of the corrector, we can close the problem with the following approximate boundary condition:

$$\hat{w}(L_\infty,\hat{\theta}) = 0,\ \hat{\theta} \in [0, 2\pi], \tag{40}$$

where L_∞ is a positive constant such that the local coordinate system $(\hat{\rho},\hat{\theta})$ is well defined in Ω. In theory, for ϵ small enough, we make an exponentially small error because we know that the true corrector w is exponentially small outside a boundary layer of $\sqrt{\epsilon}$ thickness. But since ϵ is a given number in our numerical computations, we have to choose carefully L_∞ large enough in such a way that the computation of the corrector becomes independent of L for $L > L_\infty$ within truncation error.

A more consistent approach is to use the stretched local coordinate system described in section 5.1. But the strip for which this local coordinate system is properly defined can be so narrow that a boundary condition similar to (40) does not work.

We have chosen therefore to approximate numerically the corrector on a structured regular grid in $\hat{\rho} = S(\theta) - \rho,\ \hat{\theta} = \theta$ variables.

We restrict ourselves to moderately small values of ϵ, let's say, in $(0.001,\ 0.1)$; we compute the solution of (38), (39), (40) by means of second-order central finite differences with a space step that is smaller than $\sqrt{\epsilon}$ in radial direction. If the space step in θ variable is significantly larger than the space step in radial direction, we can apply a fast (parallel) iterative solver of the discretized linear system [9] with appropriate relaxations.

In addition, we can compute once and for all a set of basis functions for the corrector $\hat{w}$ as follows: Let h_M be a discrete cosine expansion of h,

$$h_M = \sum_{j=0,\dots,M} a_j \cos(j\ \hat{\theta}).$$

Let $\hat{w}_j$ be a solution of (38) with boundary conditions

$$\hat{w}_j(0,\hat{\theta})\ =\ \cos(j\ \hat{\theta}),\ \hat{\theta} \in [0, 2\pi]$$

and (40) computed once for all. Then $\hat{w}$ is approximated by

$$\hat{w}_M = \sum_{j=0,\dots,M} a_j \hat{w}_j.$$

We illustrate now the *modulefou* technique to approximate the solution of the 2D heat equation in Ω with Dirichlet boundary equations

$$\frac{\partial u}{\partial t}\ =\ \Delta u\ +\ F \text{ in } \Omega,\ u\ =\ g \text{ on } \partial\Omega.$$

Let us consider an implicit first-order Euler scheme in time. For each time step, we have to solve

$$-dt\ \Delta u^{n+1} + u^{n+1} = u^n + dt\ F^{n+1} \text{ in } \Omega,\ u^{n+1}\ =\ g^{n+1} \text{ on } \partial\Omega.$$

We use the *modulefou* technique exactly as in the one space dimension case, except that v is computed by 2D Fourier transform, and w the corrector is computed numerically. In addition, one needs at each time step to extend u^n into a 2π periodic function $\bar{u}^n$ on $(0,\ 2\pi)^2$. To get the continuity of this extension is easy by linear interpolation. We obtain a better accuracy by using C^2 Hermite interpolation, based on decentered finite difference approximation of the normal derivatives of $\frac{\partial v^n}{\partial \rho^2}$ and $\frac{\partial w^n}{\partial \rho^2}$. It is not wise to compute second-order normal derivatives of v^n at $\partial\Omega$ by means of Fourier expansion because of the Gibbs phenomenon. Small oscillations are then amplified by the Hermite interpolation and the scheme becomes unstable.

Let us denote by N the number of Fourier modes used in each direction to approximate v^{n+1} and by M the number of Fourier mode used to approximate the boundary condition $h = g^{n+1} - \bar{v}^{n+1}$ on $\partial\Omega$ for the corrector problem.

We have tested the spatial accuracy of our method against an exact *steady* solution of the heat problem defined as

$$U(x,y)\ =\ \alpha \exp(-\beta(x^2+y^2))\ +\ \zeta,$$

with $\alpha,\ \beta,\ \zeta$ some real numbers. In addition the boundary of the domain is defined in this test case as $S(\theta) = 1\ +\ \gamma \cos(p\Theta)\ +\ \delta\ \exp(-\sin^2(\theta))$.

We have tried many different parameters: the following table gives a representative example of the error in maximum norm on the Cartesian grid inside the domain Ω with $\alpha = -0.5,\ \beta = 2,\ \zeta = 0.2,\ \gamma = 0.15,\ p = 3,\ \delta = 0.1$. We fix $M = 4\ N$ and 88 discretization points in radial direction for the computation of the corrector. The time step is 0.01. A smaller time step deteriorates the numerical accuracy for the *steady solution*. In order to have a rough idea of the efficiency of the method, we have included in the following table a comparison with second-order finite difference methods that use fitted grids at the boundary and the same regular grid as the *modulefou* method inside the domain.

Error with modulefou *for* $S(\theta) = 1 + 0.15\cos(3\theta) + 0.15\exp(-\sin^2(\theta))$.

N	$n = 0$	$n = 2$	$n = 4$	2^{nd} order finite differences
8	$1.3\ 10^{-3}$	$1.4\ 10^{-3}$	$1.6\ 10^{-3}$	$1.4\ 10^{-2}$
16	$5.2\ 10^{-4}$	$8.3\ 10^{-4}$	$6.1\ 10^{-4}$	$3.5\ 10^{-3}$
24	$2.7\ 10^{-4}$	$6.4\ 10^{-4}$	$3.9\ 10^{-4}$	$1.5\ 10^{-3}$
32	$3.0\ 10^{-4}$	$2.0\ 10^{-4}$	$1.7\ 10^{-4}$	$8.6\ 10^{-4}$
64	$2.5\ 10^{-4}$	$1.7\ 10^{-4}$	$1.9\ 10^{-4}$	$2.2\ 10^{-4}$

We observe that the numerical error stays almost the same when the number of modes is larger than 24. We speculate that our lower-order numerical approximation of the stiff corrector problem limits the accuracy of our method. This should be investigated further and improved with, for example, a pseudospectral discretization of (38). In particular, the same test case but for the disk geometry gives better results, but not as good as for the Poisson problem in section 2, for which the corrector is given by an analytical formula.

Error with modulefou *for the disk.*

N	$n = 0$	$n = 2$	$n = 4$
8	$2.6\ 10^{-3}$	$7.2\ 10^{-4}$	$1.6\ 10^{-3}$
16	$4.9\ 10^{-4}$	$3.5\ 10^{-5}$	$2.9\ 10^{-5}$
24	$1.\ 10^{-4}$	$2.0\ 10^{-5}$	$1.7\ 10^{-5}$
32	$1.1\ 10^{-4}$	$1.8\ 10^{-5}$	$1.6\ 10^{-5}$
64	$3.5\ 10^{-5}$	$1.3\ 10^{-5}$	$1.1\ 10^{-5}$

Similar results can be obtained with the Crank–Nicolson scheme instead of the implicit first-order Euler scheme.

Our second test is the computation of the wave equation in Ω with homogeneous Dirichlet boundary conditions and the second-order implicit scheme in time:

$$\frac{u^{n+1} - 2u^n + u^{n-1}}{dt^2} - \frac{\Delta u^{n+1} + \Delta u^{n-1}}{2} = F^n \text{ in } \Omega.$$

As mentioned before, this test case is of particular interest to investigate the eventual numerical unstability problems. The principle is the same except that we have to compute the Laplacian of u at each time step to get the rhs. Once again, we use the splitting $\Delta u^n = \Delta v^n + \Delta w^n$. The equation satisfied by the corrector give us $\Delta w^n = \frac{2\,w^n}{dt^2}$, and therefore the scheme is written

$$-\frac{dt^2}{2}\Delta u^{n+1} + u^{n+1} = 2u^n - u^{n-1} + \frac{dt^2}{2}\Delta v^{n-1} + w^{n-1}.$$

This can be written as

$$-\frac{dt^2}{2}\Delta u^{n+1} + u^{n+1} = 2u^n - v^{n-1} + \frac{dt^2}{2}\Delta v^{n-1}.$$

We finally obtain Δv^{n-1} either from its Fourier expansion or from the equation satisfied by v^{n-1}. Our numerous numerical experiments suggest the following heuristic: the *modulefou* scheme is numerically stable as long as the number of Fourier modes is large enough to represent the underline boundary layer of dt thickness in the periodic problem satisfied by v_N. For example, when $dt = 0.1$ and the diameter of Ω is two, we need 64 Fourier modes at least. The accuracy of our solution of the wave equation is therefore rather limited by the time discretization and the *modulefou* method is not a good method.

Finally, we observe that the arithmetic complexity of our algorithm for our two previous examples is dominated by the complexity of the 2D FFTs, once the set of basis function w_j defined above is computed. In particular, the linear combination of the w_j and the interpolation technique to extend the rhs into a periodic smooth rhs should concern only a small fraction of the grid points close to the boundary of the domain. In addition, our algorithm seems to be suitable for parallel computing for mainly two reasons: first FFT [17] has been very well optimized and standardized on parallel computers. Alternatively, one can avoid use of global FFT by using wavelet transforms [1]. Second, all extra operations as interpolation to smooth out the rhs and linear combination of the basis function w_j to correct v^n are local operators in the neighborhood of $\partial\Omega$.

6. Conclusion. The goal of this paper was to explore the implementation of various iterative schemes with the *modulefou* technique. This technique combines FFT and a solution of local problems via analytical or asymptotical or numerical technique. Numerical accuracy and stability of the methods has been tested against a large number of linear and nonlinear test cases. The results of our numerical experiments are quite encouraging and should motivate further analysis. More recent works show that these methods can be extended successfully to parallel computing by combined use of filtering and domain decomposition [10], [11], [12].

EXTENSIBLE LATTICE SEQUENCES FOR QUASI-MONTE CARLO QUADRATURE*

FRED J. HICKERNELL†, HEE SUN HONG†, PIERRE L'ÉCUYER‡, AND CHRISTIANE LEMIEUX‡

Abstract. Integration lattices are one of the main types of low discrepancy sets used in quasi-Monte Carlo methods. However, they have the disadvantage of being of fixed size. This article describes the construction of an infinite sequence of points, the first b^m of which forms a lattice for any nonnegative integer m. Thus, if the quadrature error using an initial lattice is too large, the lattice can be extended without discarding the original points. Generating vectors for extensible lattices are found by minimizing a loss function based on some measure of discrepancy or nonuniformity of the lattice. The spectral test used for finding pseudorandom number generators is one important example of such a discrepancy. The performance of the extensible lattices proposed here is compared to that of other methods for some practical quadrature problems.

Key words. discrepancy, good lattice point sets, multidimensional, spectral test

1. Introduction.

Multidimensional integrals appear in a wide variety of applications in finance [4, 50, 52], physics and engineering [30, 43, 51, 60], and statistics [8, 12, 13]. The integration domain may often be assumed, after some appropriate transformation, to be the unit cube, in which case the integral takes the form

$$I(f) \equiv \int_{[0,1)^s} f(x)\,dx$$

for some known integrand, f.

Adaptive methods, such as [2], have been developed for approximating multidimensional integrals, but their performance deteriorates as the dimension increases. For finance problems the dimension can be in the hundreds or even thousands. An alternative to adaptive quadrature is Monte Carlo methods, where the integral is approximated by the sample mean of the integrand evaluated on a set, P, of N independent random points drawn from a uniform distribution on $[0,1)^s$:

$$Q(f) \equiv \frac{1}{N}\sum_{z\in P} f(z). \tag{1.1}$$

The quadrature error for Monte Carlo methods is typically $\mathrm{O}(N^{-1/2})$. One reason for this relatively low accuracy is that the points in P are chosen independently of each other. Thus, some parts of the integration domain contain clumps of points, while other parts are empty of points.

To obtain greater accuracy one may replace the random set P by a carefully chosen deterministic set that is more uniformly distributed on $[0,1)^s$. As is explained in section 3, one may define a *discrepancy* that measures how much the empirical distribution function of P differs from the continuous uniform distribution. Then one chooses P in quadrature rule (1.1) to have as small a discrepancy as possible. The quadrature methods based on low discrepancy sets are called quasi-Monte Carlo methods. They are discussed in several review articles [3, 16, 41, 61] and monographs [28, 45, 55].

Two important families of low discrepancy sets are

i. integration lattices [45, Chap. 5] and [55], and
ii. digital nets and sequences [45, Chap. 4].

These two families are introduced in section 2. One advantage of the second family is that any number of consecutive points from a good digital sequence has low discrepancy. If one needs more points, one may use additional terms from the digital sequence without discarding the original ones. On the other hand, until now the number of points in an integration lattice has had to be specified in advance. So far, there has been no systematic way of adding points to an integration lattice while still retaining its lattice structure.

The purpose of this article is to provide a method for constructing *infinite lattice sequences*, thereby eliminating the need to know N, the number of points, in advance. Although the emphasis is on rank-1 lattices, the method may be applied to integration lattices of arbitrary rank. Given an infinite lattice sequence one may approximate a multidimensional integrand with a quadrature rule of the form (1.1) for a moderate number of points N_0. If the error estimate is unacceptably high, then one may choose an additional $N_1 - N_0$ points from the lattice sequence to obtain a quadrature rule with N_1 points and so on.

The following section describes the new method for obtaining infinite lattice sequences. Section 3 briefly reviews some results on discrepancy and quadrature error analysis for quasi-Monte Carlo methods. These are used to find the generating vectors for the new lattice sequences in section 4. The issue of error estimation is addressed in section 5. Two practical examples are explored in section 6, where the new lattice sequences are compared with existing quadrature methods. The last section contains some concluding remarks.

2. Integration lattices and digital sequences. This section begins by introducing integration lattices. Next, digital sequences and (t,s)-sequences are described. Finally, the idea underlying digital sequences is used to produce infinite lattice sequences.

2.1. Integration lattices. Rank-1 lattices, also known as good lattice point (GLP) sets, were introduced by Korobov [32] and have been widely studied since then (see [28, 45, 55] and the references therein). The formula for a shifted rank-1 lattice set is simply

$$P = \{\{ih/N + \Delta\} : i = 0, \dots, N-1\}, \tag{2.1}$$

where N is the number of points, h is an s-dimensional generating vector of integers (a GLP) that depends on N, Δ is an s-dimensional shift vector in $[0,1)^s$, and $\{x\}$ denotes the fractional part of a vector x, i.e., $\{x\} = x \mod 1$. Sloan [54] and Sloan and Kachoyan [56] later generalized GLP sets by introducing more than one generating vector. A shifted integration lattice with $N = N_1 \dots N_p$ points based on generating

vectors $h^{(1)}, \ldots, h^{(p)}$ is

$$P = \left\{ \{ i_1 h^{(1)}/N_1 + \cdots + i_p h^{(p)}/N_p + \Delta \} : i_k = 0, \ldots, N_k - 1,\ k = 1, \ldots, p \right\}.$$

Integration lattices and their use for quadrature are discussed in the monograph [55].

For a given N there is the problem of choosing good generating vectors. Although theoretical constructions exist for $s = 1$ and 2, in higher dimensions one typically finds generating vectors by minimizing a discrepancy or measure of nonuniformity of the lattice. Several examples of discrepancies are given in section 3.

2.2. Digital nets and sequences. Digital nets and sequences are another method of constructing low discrepancy sets (see [33] and [45, Chapter 4]). Let b denote a positive integer greater than one. For any nonnegative integer one may extract the digits of its base b representation, $i_1, i_2, \ldots \in \{0, \ldots, b-1\}$, only finitely many of which are nonzero:

$$i = \ldots i_3 i_2 i_1 \text{ (base } b) = i_1 + i_2 b + i_3 b^2 + \cdots . \tag{2.2a}$$

The ith term of a digital net or sequence is given by

$$z^{(i)} = (z_1^{(i)}, \ldots, z_s^{(i)}), \tag{2.2b}$$

$$z_j^{(i)} = 0.\zeta_{j1}^{(i)} \zeta_{j2}^{(i)} \ldots \text{(base } b) = \zeta_{j1}^{(i)} b^{-1} + \zeta_{j2}^{(i)} b^{-2} + \cdots , \tag{2.2c}$$

where

$$\begin{pmatrix} \zeta_{j1}^{(i)} \\ \zeta_{j2}^{(i)} \\ \vdots \end{pmatrix} = \mathbf{C}_j \begin{pmatrix} i_1 \\ i_2 \\ \vdots \end{pmatrix} \mod b, \quad j = 1, \ldots, s. \tag{2.2d}$$

If the generating matrices $\mathbf{C}_1, \ldots, \mathbf{C}_s$ are $m \times m$, then this construction yields a digital net $\{z^{(i)} : i = 0, \ldots, b^m - 1\}$ with b^m points. If the generating matrices are $\infty \times \infty$, i.e., each $\mathbf{C}_j$ has entries c_{jkl} defined for $k, l = 1, 2, \ldots$, then one has a digital sequence $\{z^{(i)} : i = 0, 1, \ldots\}$.

The prototype digital sequence is the one-dimensional Van der Corput sequence, $\{\phi_b(i) : i = 0, 1, \ldots\}$. This is defined by taking $s = 1$ and $\mathbf{C}_1$ equal to the identity matrix:

$$\phi_b(i) = 0.i_1 i_2 \ldots \text{ (base } b) = i_1 b^{-1} + i_2 b^{-2} + \cdots . \tag{2.3}$$

In essence, the Van der Corput sequence takes the b-ary representation of an integer and reflects it about the decimal point.

2.3. (t, m, s)-nets and (t, s)-sequences. Similar to integration lattices one has the problem of how to choose the generating matrices $\mathbf{C}_j$ in (2.2). Usually this is done to optimize the quality factor of the net or sequence. For any nonnegative s-vector k of integers, and for a base b, consider the following set of disjoint boxes whose union is the unit cube:

$$\mathcal{B}_k = \{[n_1 b^{-k_1}, (n_1 + 1) b^{-k_1}) \times \cdots \times [n_s b^{-k_s}, (n_s + 1) b^{-k_s}) : n_j = 0, \ldots, b^{k_j} - 1\}. \tag{2.4}$$

Each such box in $\mathcal{B}_k$ has volume $b^{-k_1-\cdots-k_s}$. A (t,m,s)-net in base b is a set of $N=b^m$ points in $[0,1)^s$ such that every box in $\mathcal{B}_k$ contains $b^{m-k_1-\cdots-k_s}$ of these points for any k satisfying $m-k_1-\cdots-k_s \ge t$. Thus, any function that is piecewise constant on the boxes in $\mathcal{B}_k$ will be integrated exactly according to quadrature rule (1.1) if

$$k_1+\cdots+k_s \le m-t. \tag{2.5}$$

The integer parameter t is called the quality parameter of the net and it takes values between 0 and m. A smaller value of t means a better net.

A (t,s)-sequence is an infinite sequence of points in $[0,1)^s$ such that the b^m points numbered lb^m to $(l+1)b^m-1$ always form a (t,m,s)-net for any nonnegative integer l for all integers $m \ge t$. By using a (t,s)-sequence to do quasi-Monte Carlo calculations, one need not know the number of points required in advance. If the first b^{m_1} points do not give sufficient accuracy, then one may add the next $b^{m_2}-b^{m_1}$ points in the sequence to get a net with b^{m_2} points, without throwing away the first b^{m_1} points.

There is a connection between digital nets and sequences as defined above and (t,m,s)-nets and (t,s)-sequences [33]. Let $c_{ji\bullet}^{(m)}$ denote the vector containing the first m elements of the ith row of the generating matrix $\mathbf{C}_j$. Given a nonnegative integer s-vector k, let $\mathcal{C}(m,k)$ be the following set of the first k_j rows of the jth generating matrix for $j=1,\ldots,s$:

$$\mathcal{C}(m,k)=\left\{\mathbf{c}_{ji\bullet}^{(m)} : i=1,\ldots,k_j,\ j=1,\ldots,s\right\}.$$

Furthermore, let

$$\begin{aligned} T(m,s) &= \min_t\{t : \mathcal{C}(m,k) \text{ is a linearly independent set of vectors} \\ &\qquad\qquad \text{for all } k \text{ with } k_1+\cdots+k_s=m-t\}, \\ T(s) &= \max_m T(m,s). \end{aligned}$$

The following theorem (see [33]) gives the condition for which a digital net is a (t,m,s)-net and a digital sequence is a (t,s)-sequence.

THEOREM 2.1. *For prime bases b the digital net defined above in* (2.2) *is a $(T(m,s),m,s)$-net. If, in addition, $T(s)$ is finite, then the digital sequence defined in* (2.2) *is a $(T(s),s)$-sequence.*

Finding good generating matrices for digital nets and sequences is an active area of research. Virtually all generators found so far have been based on number theoretic arguments. Early sequences include those of Sobol' [58], Faure [9], and Niederreiter [44]. Algorithms for these sequences can be found in the ACM Transactions on Mathematical Software collection. The FINDER software developed at Columbia University by Traub and Papageorgiou implements generalized Sobol' and generalized Faure sequences. New constructions with smaller t values are given by Niederreiter and Xing [48].

2.4. Infinite lattice sequences. The idea underlying digital sequences may be extended to integration lattices to obtain infinite lattice sequences. The ith term of a rank-1 lattice, which is $\{ih/N\}$, depends inherently on the number of points, N. Thus, the formula for a lattice must be rewritten in a way that does not involve N explicitly. A way to do this was first suggested in [24].

Suppose that the number of points, N, is some integer power of a base $b \geq 2$, i.e., $N = b^m$. This is the same assumption as for a digital or (t, m, s)-net. The first N values of the Van der Corput sequence, defined in (2.3), are

$$\frac{0}{b^m}, \ldots, \frac{b^m - 1}{b^m},$$

although in a different order. Therefore, the term $i/N = i/b^m, i = 0, \ldots, N-1$, that appears in the definition of the rank-1 lattice may be replaced by $\phi_b(i)$, a term that does not depend on N.

The s-dimensional generating vector h in (2.1) typically depends on N also. It may be expressed in b-ary form as

$$h = (h_{1m} \ldots h_{11},\ h_{2m} \ldots h_{21},\ \ldots,\ h_{sm} \ldots h_{s1}) \quad (\text{base } b),$$

where $h_{jk} \in \{0, \ldots, b-1\}$ are digits. For $k > m$ the digits h_{jk} do not affect the definition of the rank-1 lattice set with $N = b^m$ points since they contribute only integers to the product $\phi_b(i)h$. Therefore, each component of h may be written (in principle) as an infinite string of digits:

$$h = (\ldots h_{12}h_{11},\ \ldots h_{22}h_{21},\ \ldots,\ \ldots h_{s2}h_{s1}) \quad (\text{base } b). \tag{2.6}$$

This single "infinite" generating vector may serve for all possible values of m.

The preceding paragraphs provide the basis for defining an infinite rank-1 lattice sequence. Altering the original definition in (2.1) leads to the following definition.

DEFINITION 2.2. *An infinite rank-1 lattice sequence in base b with generating vector h of the form* (2.6) *and shift Δ is defined as*

$$\{\{\phi_b(i)h + \Delta\} : i = 0, 1, 2, \ldots\}. \tag{2.7}$$

The first b^m terms of the infinite rank-1 lattice sequence (2.7) are rank-1 lattices. Moreover, just as certain subsets of a (t, s)-sequence are (t, m, s)-nets, so subsets of an infinite rank-1 lattice sequence are shifted rank-1 lattices.

THEOREM 2.3. *Suppose that P is the set consisting of the $(l+1)$st run of b^m terms of the infinite lattice rank-1 sequence defined in* (2.7).

$$P = \{\{\phi_b(lb^m + i)h + \Delta\} : i = 0, \ldots, b^m - 1\}, \quad l = 0, 1, \ldots.$$

Then, P is a rank-1 lattice with shift $\phi_b(l)b^{-m-1}h + \Delta$, i.e.,

$$P = \left\{\{\phi_b(i)h + \phi_b(l)b^{-m-1}h + \Delta\} : i = 0, \ldots, b^m - 1\right\}.$$

Proof. The proof follows directly from the definition of the Van der Corput sequence. For all $i = 0, \ldots, b^m - 1$, note that

$$\phi_b(lb^m + i) = \phi_b(i) + \phi_b(lb^m) = \phi_b(i) + \phi_b(l)b^{-m-1}.$$

Substituting the right-hand side into the definition of P completes the proof. ∎

The definition of an infinite rank-1 lattice sequence may be extended to integration lattices of arbitrary rank.

DEFINITION 2.4. *An infinite lattice sequence (of arbitrary rank) with bases $b_1, \ldots, b_p$ and generating vectors $h^{(1)}, \ldots, h^{(p)}$ of the form* (2.6) *and shift Δ is defined as*

$$\left\{\{\phi_{b_1}(i_1)h^{(1)} + \cdots + \phi_{b_p}(i_p)h^{(p)} + \Delta\} : i_1, \ldots, i_p = 0, 1, 2, \ldots\right\} \tag{2.8}$$

A practical complication for an integration lattice of rank greater than 1 is that there are multiple indices, i_k, each of which may or may not tend to infinity, and each at its own rate. Because of this complication we will focus on rank-1 lattices in the sections that follow. Theorem 2.3 also has a natural extension to infinite lattice sequences of arbitrary rank, and its proof is similar.

3. Discrepancy. Unlike (t, m, s)-nets for which there exist explicit constructions of the generating matrices $\mathbf{C}_j$, there are no such explicit constructions of generating vectors h for rank-1 lattices for arbitrary s. Tables of generating vectors for lattices that do exist (see [8, 14, 28]) are usually obtained by minimizing some measure of nonuniformity, or discrepancy, of the lattice. This section describes several useful discrepancy measures.

Let $\mathrm{Err}(f; P)$ denote the quadrature error for a rule of the form (1.1) for an arbitrary set P. Worst-case error analysis of the quadrature error leads to a Koksma–Hlawka-type inequality of the form [23]

$$|\mathrm{Err}(f; P)| \equiv |I(f) - Q(f)| \le D(P)V(f), \tag{3.1}$$

where $D(P)$ is the discrepancy or measure of nonuniformity of the point set defining the quadrature rule, and $V(f)$ is the variation or fluctuation of the integrand, f. The precise definitions of the discrepancy and the variation depend on the particular space of integrands.

In the traditional Koksma–Hlawka inequality (see [27] and [45, Thm. 2.11]), the variation is the variation in the sense of Hardy and Krause, and the discrepancy is the $\mathcal{L}_\infty$-star discrepancy:

$$D^*(P) = \|F_{\mathrm{unif}}(x) - F_P(x)\|_\infty = \left\| x_1 \dots x_s - \frac{|P \cap [0, x]|}{N} \right\|_\infty . \tag{3.2}$$

Here F_{unif} is the uniform distribution on the unit cube, F_P is the empirical distribution function for the sample P, and $|\cdot|$ denotes the number of points in a set. The notation $\|\cdot\|_p$ denotes the $\mathcal{L}_p$-norm or the ℓ_p-norm, depending on the context. Error bounds of the form (3.1) involving the $\mathcal{L}_p$-star discrepancy have been derived by [59, 64]. Error bounds involving generalizations of the star discrepancy appear in [21, 22, 23, 57].

When the integrands belong to a reproducing kernel Hilbert space, error bound (3.1) may be easily obtained [21, 23]. The discrepancy may be written in terms of the reproducing kernel

(3.3)

$$\begin{aligned} D(P) &= \left\{ \int_{[0,1)^{2s}} K(x, y)\ d(F_{\mathrm{unif}} - F_P)(x)\ d(F_{\mathrm{unif}} - F_P)(y) \right\}^{1/2} \\ &= \left\{ \int_{[0,1)^{2s}} K(x, y)\ dx\ dy - \frac{2}{N} \sum_{z \in P} \int_{[0,1)^s} K(z, y)\ dy + \frac{1}{N^2} \sum_{z,t \in P} K(z, t) \right\}^{1/2} . \end{aligned}$$

For example, the $\mathcal{L}_2$-star discrepancy, whose formula was originally derived in [62], is a special case of the above formula with $K(x, y) = \prod_{j=1}^{s} [1 - \max(x_j, y_j)]$. An advantage of considering reproducing kernel Hilbert spaces of integrands is that the computational complexity of the discrepancy is relatively small (at worst $\mathrm{O}(N^2)$ operations). By contrast the $\mathcal{L}_\infty$-star discrepancy requires $\mathrm{O}(N^s)$ operations to evaluate.

The discrepancy of type (3.3) can also be interpreted as an average-case quadrature error [25, 42, 63]. Suppose that the integrand is a random function lying in the sample space $\mathcal{A}$, and suppose that the integrand has zero mean and covariance kernel, $K(x, y)$, i.e.,

$$E_{f\in\mathcal{A}}[f(x)] = 0 \text{ and } E_{f\in\mathcal{A}}[f(x)f(y)] = K(x, y) \quad \forall x, y \in [0, 1)^s.$$

Then the root mean square quadrature error over $\mathcal{A}$ is the discrepancy as defined in (3.3):

$$\sqrt{E_{f\in\mathcal{A}}[\mathrm{Err}(f; P)]^2} = \sqrt{E_{f\in\mathcal{A}}\left|I(f) - Q(f)\right|^2} = D(P). \tag{3.4}$$

If P is a simple random sample, then the mean square discrepancy is [25]

$$E_P\{[D(P)]^2\} = \frac{1}{N}\left\{\int_{[0,1)^s} K(x, x)\ dx - \int_{[0,1)^s\times[0,1)^s} K(x, y)\ dy\ dx\right\}. \tag{3.5}$$

This formula serves as a benchmark for other (presumably superior) low discrepancy sets. Since the mean square discrepancy is $\mathrm{O}(N^{-1})$, the discrepancy itself is typically $\mathrm{O}(N^{-1/2})$ for a simple random sample. The variance of a function, f, may be defined as

$$\mathrm{Var}(f) \equiv \int_{[0,1)^s} f^2\ dx - \left(\int_{[0,1)^s} f\ dx\right)^2.$$

The mean value of the variance over the space of average-case integrands can be shown to be [25]

$$E_{f\in\mathcal{A}}[\mathrm{Var}(f)] = \int_{[0,1)^s} K(x, x)\ dx - \int_{[0,1)^{2s}} K(x, y)\ dy\ dx, \tag{3.6}$$

which is just the term in braces in (3.5).

It may seem odd at first that the discrepancy can serve both as an average-case and worst-case quadrature error. The explanation is that the space of integrands, $\mathcal{A}$, in the average-case analysis is much larger than the space of integrands, $\mathcal{W}$, in the worst-case analysis. See [21, 25] and the references therein for the proofs of the above results as well as further details.

There are some known asymptotic results for the discrepancies of (t, m, s)-nets. The $\mathcal{L}_\infty$-star discrepancy of any (t, m, s)-net is $\mathrm{O}(N^{-1}[\log N]^{s-1})$ [45, Thm. 4.10]. Moreover, the typical (in the sense of an average taken over all possible nets) $\mathcal{L}_2$-star discrepancy of (t, m, s)-nets is $\mathrm{O}(N^{-1}[\log N]^{(s-1)/2})$ [19, 26]—the best possible for any set. For discrepancies of the form (3.3) with sufficiently smooth kernels, typical (t, m, s)-nets have $\mathrm{O}(N^{-3/2}[\log N]^{(s-1)/2})$ discrepancy [25, 26].

Lattice rules, the topic of this article, are known to be particularly effective for integrating periodic functions. Suppose that the integrand has an absolutely convergent Fourier series with Fourier coefficients $\hat{f}(k)$:

$$f(x) = \sum_{k\in\mathbf{Z}^s} \hat{f}(k)e^{2\pi ik'x}, \qquad \hat{f}(k) = \int_{[0,1)^s} f(x)e^{-2\pi ik'x}\ dx. \tag{3.7}$$

Here $k'x$ denotes the dot product of the s-dimensional wavenumber vector k with x.

The quadrature error for a particular integrand with an absolutely convergent Fourier series is simply the sum of the quadrature errors of each term:

$$\mathrm{Err}(f;P) = -\sum_{\substack{k\in\mathbf{Z}^s\\ k\neq 0}} \hat{f}(k)\left[\frac{1}{N}\sum_{z\in P} \mathrm{e}^{2\pi i k'z}\right],$$

where the term corresponding to $k=0$ does not enter because constants are integrated exactly. One can multiply and divide by arbitrary weights $w(k)$ inside this sum. Then by applying Hölder's inequality one has the following error bound of the form (3.1) [23]:

$$|\mathrm{Err}(f;P)| \le D_{\mathcal{F},p}(P) V_{\mathcal{F},q}(f), \quad \frac{1}{p}+\frac{1}{q}=1, \tag{3.8a}$$

$$D_{\mathcal{F},p}(P) = \left\| \left(\frac{1_{\{k\neq 0\}}}{w(k)} \left[\frac{1}{N}\sum_{z\in P} e^{2\pi i k'z} \right] \right)_{k\in\mathbf{Z}^s} \right\|_p, \tag{3.8b}$$

$$V_{\mathcal{F},q}(f) = \left\| \left(1_{\{k\neq 0\}} w(k)\hat{f}(k)\right)_{k\in\mathbf{Z}^s} \right\|_q. \tag{3.8c}$$

Here $1_{\{\cdot\}}$ denotes the indicator function. In order to insure that the discrepancy is finite we assume that the weights increase sufficiently fast as k tends to infinity:

$$\left\| \left(\frac{1}{w(k)} \right)_{k\in\mathbf{Z}^s} \right\|_p < \infty.$$

If P is the node set of an integration lattice, then it is known that trigonometric polynomials are integrated exactly for all nonzero wavenumbers *not* in the dual lattice, $L^\perp$ (see [55, Lem. 2.7]):

$$\frac{1}{N}\sum_{z\in P} e^{2\pi i k'z} = 1_{\{k\in L^\perp\}}.$$

The dual lattice is the set of all k satisfying $k'z = 0 \pmod 1$ $\forall z \in P$. Thus, for node sets of lattices the definition of discrepancy above may be simplified to

$$D_{\mathcal{F},p}(P) = \left\| \left(\frac{1_{\{0\neq k\in L^\perp\}}}{w(k)} \right)_{k\in\mathbf{Z}^s} \right\|_p.$$

Certain explicit choices of $w(k)$ have appeared in the literature. For example, one may choose

$$w(k) = \left[\overline{(\beta_1^{-1}k_1)}\cdots\overline{(\beta_s^{-1}k_s)}\right]^\alpha, \quad \alpha>0, \tag{3.9}$$

where the over-bar notation is defined as

$$\bar{k}_j = \begin{cases} |k_j| & \text{for } k_j \neq 0, \\ 1 & \text{for } k_j = 0, \end{cases} \tag{3.10}$$

$\beta_1,\ldots,\beta_s$ are arbitrary positive weights, and α is a measure of the assumed smoothness of the integrand. If $\beta_1 = \cdots = \beta_s = 1$ and P is the node set of a lattice, then

$D_{\mathcal{F},p}(P) = [P_{\alpha p}(L)]^{1/p}$ for $1 \le p < \infty$, where $P_\gamma(L)$ is a traditional figure of merit for lattices [55]. Furthermore, for $p = \infty$ the discrepancy is $D_{\mathcal{F},\infty}(P) = [\rho(L)]^{-\alpha}$, where $\rho(L)$ is the *Zaremba figure of merit* for lattice rules [45, Def. 5.31]. The more general case of P that is not a lattice is considered in [20], and the case of unequal weights β_j is discussed in [22].

If the weight function $w(k)$ takes the form (3.9) for *positive integer* α, then for $p = q = 2$ the infinite sum defining the discrepancy in (3.8b) may be written as a finite sum:

$$D_{\mathcal{F},2}(P) = \left\{ -1 + \frac{1}{N^2} \sum_{z,t \in P} \prod_{j=1}^{s} \left[1 - \frac{(-4\pi^2 \beta_j^2)^\alpha}{(2\alpha)!} B_{2\alpha}(\{z_j - t_j\}) \right] \right\}^{1/2}, \tag{3.11a}$$

for general sets P, where $B_{2\alpha}$ denotes the Bernoulli polynomial of degree 2α [1, Chap. 23]. When P is the node set of an integration lattice, the double sum can be simplified to a single sum:

$$D_{\mathcal{F},2}(P) = \left\{ -1 + \frac{1}{N} \sum_{z \in P} \prod_{j=1}^{s} \left[1 - \frac{(-4\pi^2 \beta_j^2)^\alpha}{(2\alpha)!} B_{2\alpha}(z_j) \right] \right\}^{1/2}. \tag{3.11b}$$

Another choice for $w(k)$ is a weighted ℓ_r-norm of the vector k to some power:

$$w(k) = \left[\left(\frac{k_1}{\beta_1} \right)^r + \cdots + \left(\frac{k_s}{\beta_s} \right)^r \right]^{\alpha/r}, \quad \alpha > 0,$$

again for arbitrary positive weights $\beta_1, \ldots, \beta_s$. When these weights are unity, P is the node set of a lattice, and $p = \infty$, then

$$D_{\mathcal{F},\infty}(P) = \max_{0 \ne k \in L^\perp} \|k\|_r^{-\alpha} = \left\{ \min_{0 \ne k \in L^\perp} \|k\|_r \right\}^{-\alpha}. \tag{3.12}$$

For $r = 2$ this discrepancy is equivalent to the *spectral test*, commonly employed to measure the quality of linear congruential pseudorandom number generators [31, 34]. The spectral test has been used to select lattices for quasi-Monte Carlo quadrature in [7, 35, 36, 37]. The case $r = 1$, which one might call an ℓ_1-spectral test, is also interesting. We will return to these two cases in the next section.

4. Good generating vectors for lattice sequences. As mentioned at the beginning of the previous section, finding good generating vectors for lattices typically requires optimizing some discrepancy measure. In this subsection we propose some loss functions and optimization algorithms for choosing good generating vectors for extensible rank-1 lattice sequences.

In principle one would like to have an $\infty \times \infty$ array of digits h_{jk}. However, in practice it is only necessary to have an $s_{\max} \times m_{\max}$ array of digits h_{jk}, where $N_{\max} = b^{m_{\max}}$ is the maximum number of points and $s_{\max}$ is the maximum dimension to be considered. In finance calculations, for example, the necessity of timely forecasts may constrain one to a budget of $10^3 - 10^4$ points [49].

For simplicity we consider generating vectors h that are of the form originally proposed by Korobov, i.e.,

$$h = (1, \eta, \eta^2, \ldots, \eta^{s-1}). \tag{4.1}$$

This means that only the digits $\eta_1, \eta_2, \ldots, \eta_{m_{\max}}$ need to be chosen, for which there are $b^{m_{\max}} = N_{\max}$ choices. The generating vector is tested for dimensions up to $s_{\max}$, but in fact it can be extended to any dimension.

The number η defining the generating vector is chosen by minimizing a loss function, G, of the form

$$G(\eta) = \max_{m,s} \tilde{G}(\eta, m, s). \tag{4.2}$$

Here the function $\tilde{G}(\eta, m, s)$ is related to one of the measures of discrepancy introduced in section 3, and the maximum over some range of values of m and s insures that the resulting generating vector is good for a range of numbers of points and dimensions. However, since the discrepancy itself depends significantly on the number of points and the dimension, it must be appropriately scaled to arrive at the function $\tilde{G}$. The details of this scaling are given below.

4.1. Generating vectors based on minimizing P_α. The discrepancy defined in (3.11), which is a generalization of the P_α figure of merit for lattice rules, has the advantage of requiring only $\mathrm{O}(sN)$ operations to evaluate for lattices. To remove some of the dimension dependence of this discrepancy it is divided by the square root of right-hand side of (3.6). The root mean square of this scaled discrepancy for a random sample is then $N^{-1/2}$, independent of s. The formula for the scaled discrepancy of the node set of a lattice with $\alpha = 1$ and $4\pi^2\beta_j^2 = 6$ is

$$D(P) = \left[\left(\frac{3}{2}\right)^s - 1\right]^{-1/2} \left\{-1 + \frac{1}{N}\sum_{z\in P}\prod_{j=1}^{s}\left[1 + 3B_2(z_j)\right]\right\}^{1/2}.$$

The specific choice of the value of β_j here is not crucial but seems to give good results.

For one-dimensional lattices, i.e., evenly spaced points on the interval $[0, 1)$, this discrepancy is N^{-1}, and one would expect that as the dimension increases this scaled discrepancy would tend to (or at least do no worse than) $N^{-1/2}$. Therefore, to remove this remaining dimension dependence the above scaled discrepancy is divided by the function

$$D_{\mathrm{asy}}(m, s) = b^{-m}\left(1 + \frac{m\log b}{s-1}\right)^{(s-1)/2} = N^{-1}\left(1 + \frac{\log N}{s-1}\right)^{(s-1)/2}.$$

For a fixed s, D_{asy}(m,s) is asymptotically $\mathrm{O}(b^{-m}m^{(s-1)/2}) = \mathrm{O}(N^{-1}[\log N]^{(s-1)/2})$ as N tends to infinity. This is the asymptotic order for $(0, m, s)$-nets [25], and what we hope to achieve for lattice sequences. Furthermore, $N^{-1} = b^{-m} \le D_{\mathrm{asy}}(m, s) \le b^{-m/2} = N^{-1/2}$ for any m and s. In summary, the resulting loss function is

$$\begin{aligned}\tilde{G}_1(\eta, m, s) = \frac{D(P)}{D_{\mathrm{asy}}(m, s)} &= b^m\left(1 + \frac{m\log b}{s-1}\right)^{-(s-1)/2}\left[\left(\frac{3}{2}\right)^s - 1\right]^{-1/2} \\ &\quad\times\left\{-1 + \frac{1}{b^m}\sum_{i=0}^{b^m-1}\prod_{j=1}^{s}\left[1 + 3B_2(\{\phi_b(i)\eta^{j-1}\})\right]\right\}^{1/2}.\end{aligned} \tag{4.3}$$

The optimal values of η found by minimizing $G_1(\eta)$ for $b = 2$ and for different ranges of m and s are given in Table 4.1. The algorithm for optimizing $G_1(\eta)$ may

be described as an intelligent exhaustive search. One need not compute $G_1(\eta)$ for all possible values of η. Suppose at any stage of the optimization η_* is the best known value of η, and one finds that $\tilde{G}_1(\tilde{\eta}, m, s) > G_1(\eta_*)$ for some $\tilde{\eta}$. Since $\tilde{G}_1(\eta, m, s)$ depends only on the first $m-1$ digits of η, one can immediately eliminate from consideration all η that have the same first $m-1$ digits as $\tilde{\eta}$. This same search strategy is also used for the other loss functions described below.

TABLE 4.1
Values of η defining generating vectors of the form (4.1) *for rank-*1 *lattice sequences with base $b = 2$, and minimizing* (4.9).

i	m_0	m_1	s_1	η	$G_i(\eta, m_0, m_1, s_1)$	$G_{i,\min}(\eta, m_0, m_1, s_1)$
1	0	17	32	17797	4.11	0.78
1	0	12	32	203	2.33	0.78

4.2. Generating vectors based on the spectral test. The use of the spectral test to analyze the lattice structure of linear congruential generators is described in [31], and tables of good integration lattices are given in [35]. The difference here is that nearly all smaller lattices imbedded in the largest lattice considered must have low discrepancy. In [35], only the full lattice was examined.

The length of the shortest nonzero vector in the dual lattice $L^\perp$ is

$$d_2(\eta, m, s) = \min\{\|k\|_2 : k \neq 0,\ k'(1, \eta, \ldots, \eta^{s-1}) = 0 \mod b^m\}, \tag{4.4}$$

which is related to the discrepancy (3.12) with $r = 2$. This length has the absolute upper bound

$$d_2^*(m, s) = \begin{cases} \gamma_s b^{m/s}, & 1 \leq s \leq 8, \\ \rho_s b^{m/s}, & 8 < s, \end{cases} \tag{4.5}$$

where the constants γ_s and ρ_s depend only on s (see [35] and the references therein). The bound for $s \leq 8$ is the least upper bound for a general s-dimensional lattice with real-valued coordinates and with b^{-m} points per unit of volume. The bound for $s > 8$ is not the least upper bound, but it is still reasonably tight, as our numerical results will show. We define the normalized ℓ_2-spectral test discrepancy as

$$\tilde{G}_2(\eta, m, s) = \frac{d_2^*(m, s)}{d_2(\eta, m, s)}, \tag{4.6}$$

which is larger than 1 and is the inverse of the quantity S_t defined in [35]. (The different notation here is to be consistent with the rest of this article.) The loss function to be minimized is of the form (4.2) with $\tilde{G} = \tilde{G}_2$.

We note that $1/d_2(\eta, m, s)$ can be interpreted as the (Euclidean) distance between the successive hyperplanes that contain all the points of the *primal* lattice L for the family of hyperplanes for which this distance is the largest. The problem of computing a shortest vector in (4.4) can be formulated as a quadratic optimization problem with s integer decision variables, because k can be written as a linear combination of the s vectors of a basis of the dual lattice, with integer coefficients. The decision variables are these coefficients. (See [31] for details.) We solved this problem by using the branch-and-bound algorithm of Fincke and Pohst [10], with a few heuristic modifications to improve the speed. The *worst-case* time complexity of this algorithm is exponential in $d_2(\eta, m, s)$, and polynomial in s for $d_2(\eta, m, s)$ fixed [10]. In practice, it (typically) works nicely even when $d_2(\eta, m, s)$ is large. For example, one can compute $d_2(\eta, 30, s)$ for $b = 2$, an arbitrary η and $s = 2, \ldots, 30$ in less than 1 second on a Pentium-II computer.

4.3. Generating vectors based on the ℓ_1-spectral test. With the ℓ_1 norm, the length of the shortest nonzero vector in $L^\perp$ is

$$d_1(\eta, m, s) = \min\{\|k\|_1 : k \neq 0,\ k'(1, \eta, \ldots, \eta^{s-1}) = 0 \mod b^m\}, \tag{4.7}$$

which is related to the discrepancy (3.12) with $r = 1$. One has the upper bound

$$d_1(\eta, m, s) \leq d_1^*(m, s) \stackrel{\text{def}}{=} (s! b^m)^{1/s},$$

which was established by Marsaglia [38] by applying the general convex body theorem of Minkowski. This suggests the normalized ℓ_1-spectral test quantity:

$$\tilde{G}_3(\eta, m, s) = \frac{d_1^*(m, s)}{d_1(\eta, m, s)}. \tag{4.8}$$

Here, we want to minimize the loss function (4.2) with $\tilde{G} = \tilde{G}_3$.

One can interpret $d_1(\eta, m, s)$ (or $d_1(\eta, m, s) - 1$ in certain cases; see [31]) as the minimal number of hyperplanes that cover all the points of P. We computed $d_1(\eta, m, s)$ via the algorithm of Dieter [6], which works fine for s up to about 10 (independently of m), but becomes very slow for larger s (the time is exponential in s).

The ℓ_1-spectral test quantity in (4.8) has an interpretation similar to that of the quality parameter t for (t, m, s)-nets. Define

$$T(\eta, m, s) = \log_b(\tilde{G}_3(\eta, m, s)) = \frac{m + \log_b(s!)}{s} - \log_b(d_1(\eta, m, s)).$$

Since $\tilde{G}_3 \geq 1$ and $d_1(\eta, m, s) \geq 1$, it follows that $0 \leq T(\eta, m, s) \leq [m + \log_b(s!)]/s$. Thus, the rank-1 lattice defined by η integrates exactly all trigonometric polynomials of wavenumber k when

$$\log(|k_1| + \cdots + |k_s|) \leq \frac{m + \log_b(s!)}{s} - T(\eta, m, s).$$

If one considers $T(\eta, m, s)$ as the quality parameter of the lattice, then this condition is similar to that in (2.5). There, t determines the resolution at which piecewise

constant functions are exactly integrated by a net. Here, $T(\eta, m, s)$ determines the resolution at which trigonometric polynomials are integrated exactly by a lattice.

The discrepancy for the node set of this lattice as defined in (3.12) with $r = 1$ is

$$D_{\mathcal{F},\infty}(P) = d_1(\eta, m, s)^{-\alpha} = (s!)^{-\alpha/s} b^{\alpha T(\eta,m,s)} N^{-\alpha/s}.$$

If one can construct an infinite sequence of digits, η, for which

$$T(\eta, s) = \max_m T(\eta, m, s) < \infty,$$

then the above discrepancy decays like $N^{-\alpha/s}$. Again, the parameter α indicates the assumed smoothness of the integrands.

4.4. Tables of coefficients. We made computer searches to find the best η's, based on minimizing the worst-case loss function

$$G_i(\eta, m_0, m_1, s_1) = \max_{\substack{m_0 \le m \le m_1 \\ 1 \le s \le s_1}} \tilde{G}_i(\eta, m, s) \tag{4.9}$$

for $i = 1, 2, 3$ and selected values of m_0, m_1, and s_1. The bounds m_0, m_1, and s_1 define a range of number of points in the lattice, and maximal number of dimensions, in which we are interested. Selecting different parameters η for different ranges of values of m and s is a convenient compromise between the extreme cases of choosing a different η for each pair (m, s) and choosing the same η for all pairs (m, s). In practice one typically has a general idea of how many points one is going to take. By selecting an η specialized for that range, one can obtain a lattice with a better figure of merit for this particular range.

Table 4.1 gives the optimal η's and the corresponding figures of merit (4.9) for $i = 1, 2, 3$ and certain triples (m_0, m_1, s_1). Because of computational efficiency constraints, for the searches, we limited ourselves to $m_1 \le 20$ for $i = 1$ and to $s_1 \le 10$ for $i = 3$. Then, for the best η that we found, we verified the performance when m_0 was reduced or when m_1 or s_1 was increased and retained the smallest m_0 and largest m_1 and s_1 for which G_i was unchanged. The table also gives the value of $G_{i,\min}(\eta, m_0, m_1, s_1)$, defined by replacing max by min in (4.9). This best-case figure tells us the range of values taken by $\tilde{G}_i(\eta, m, s)$ over the given region. We made exhaustive searches also with $s_1 = 15$ for all the entries where $i = 1$ or 2 in the table, and we obtained the same values of η and $G_i(\eta, m_0, m_1, s_1)$ in all cases.

5. Estimating quadrature error. The advantage of an extensible lattice sequence is that N need not be specified in advance. Therefore, in practice one would estimate the quadrature error for an initial lattice and continue to increase the lattice size until the quadrature error meets the desired tolerance. Although the discrepancy, $D(P)$, is a good measure for the quality of a set P, it cannot be used directly for error estimation. The worst-case error bounds (3.1) are often quite conservative, and there is no easy way to estimate the variation of the integrand. The average case error given, (3.4), is sensitive to how one defines the kernel—multiplying the kernel by a factor of c^2 changes the average case error by a factor of c.

Quadrature error estimates for lattice rules have been investigated by [5, 29, 55]. Two different kinds of quadrature rules and error estimates have been proposed. Both involve estimating the error for $Q(f; P)$ in terms of $Q(f; P)$ and $Q(f; P_l)$, $l = 1, \ldots, M$, where the P_l are node sets of lattices and $P = P_1 \cup \cdots \cup P_M$.

The method proposed in [55] takes P to be composed of 2^s shifted copies of a rank-1 lattice. Rather than considering copy rules, we take P_l to be the node sets of shifted lattices of size b^{m_1} imbedded in the extensible lattice described in section 2.4:

$$P_l = \{\{\phi_b((l-1)b^{m_1}+i)h + \Delta\} : i = 0, \dots, b^{m_1}-1\}, \quad l = 1, \dots, M, \tag{5.1a}$$

$$P = \{\{\phi_b(i)h + \Delta\} : i = 0, \dots, Mb^{m_1}-1\}. \tag{5.1b}$$

Another quadrature rule and error estimate takes the P_l to be independent random shifts of a lattice. This can be done by taking

$$P_l = \{\{\phi_b(i)h + \Delta_l\} : i = 0, \dots, b^{m_1}-1\}, \quad l = 1, \dots, M, \tag{5.2a}$$

$$P = \{\{\phi_b(i)h + \Delta_l\} : i = 0, \dots, b^{m_1}-1,\ l = 1, \dots, M\}, \tag{5.2b}$$

where the Δ_l are independent, uniformly distributed random vectors in $[0,1]^s$.

Note that for both (5.1) and (5.2) the set P can be extended in size as necessary by increasing m_1. The theory behind the error estimates for cases (5.1) and (5.2) are given in the following theorem.

THEOREM 5.1. *Suppose that a quadrature rule $Q(\cdot;P)$ based on some arbitrary P, as given in* (1.1)*, is the average value of the quadrature rules based on the sets $P_1, \dots, P_M$, i.e.,*

$$Q(\cdot;P) = \frac{1}{M}\sum_{l=1}^{M} Q(\cdot;P_l). \tag{5.3}$$

First, consider the case where the integrands are random functions from a sample space $\mathcal{A}$ as described in the paragraph preceding (3.4)*. Then it follows that*

$$E_{f\in\mathcal{A}}[I(f)-Q(f;P)]^2 = \left\{-1 + \frac{1}{M}\sum_{l=1}^{M}\left[\frac{D(P_l)}{D(P)}\right]^2\right\}^{-1} \frac{1}{M}\sum_{l=1}^{M} E_{f\in\mathcal{A}}[Q(f;P_l)-Q(f;P)]^2, \tag{5.4}$$

where D is the discrepancy based on the covariance kernel for $\mathcal{A}$.

Second, consider the case of a fixed integrand, f, but where the P_l are random shifts of a set P_0, i.e.,

$$P = P_1 \cup \cdots \cup P_M, \qquad P_l = \{\{z + \Delta_l\} : z \in P_0\}, \tag{5.5}$$

for independent, uniformly distributed $\Delta_1, \dots, \Delta_M$. Then

$$E_{\Delta_l}\{[I(f)-Q(f;P)]^2\} = \frac{1}{M(M-1)}\sum_{l=1}^{M} E_{\Delta_l}[Q(f;P_l)-Q(f;P)]^2. \tag{5.6}$$

Proof. Assuming that the quadrature rules satisfy (5.3), it follows that the mean square deviation of the $Q(f;P_l)$ from $Q(f;P)$ may be written as

$$\begin{aligned}\frac{1}{M}\sum_{l=1}^{M}[Q(f;P_l)-Q(f;P)]^2 &= \frac{1}{M}\sum_{l=1}^{M}\{[I(f)-Q(f;P)]-[I(f)-Q(f;P_l)]\}^2 \\ &= -[I(f)-Q(f;P)]^2 + \frac{1}{M}\sum_{l=1}^{M}[I(f)-Q(f;P_l)]^2.\end{aligned} \tag{5.7}$$

If the integrand is a random function from a sample space $\mathcal{A}$ with covariance kernel K, then average case error analysis in (3.4) plus (5.7) leads to the following equations:

$$E_{f\in\mathcal{A}}[I(f)-Q(f;P)]^2=[D(P)]^2,$$
$$E_{f\in\mathcal{A}}[I(f)-Q(f;P_l)]^2=[D(P_l)]^2,$$
$$E_{f\in\mathcal{A}}\left\{\frac{1}{M}\sum_{l=1}^{M}[Q(f;P_l)-Q(f;P)]^2\right\}=-[D(P)]^2+\frac{1}{M}\sum_{l=1}^{M}[D(P_l)]^2.$$

The equations above may be rearranged to give (5.4).

The quadrature error for rule $Q(f;P)$ may also be written as

$$\begin{aligned}[I(f)-Q(f;P)]^2&=\left\{\frac{1}{M}\sum_{l=1}^{M}[I(f)-Q(f;P_l)]\right\}^2\\&=\frac{1}{M^2}\sum_{l=1}^{M}[I(f)-Q(f;P_l)]^2\\&\quad+\frac{2}{M^2}\sum_{1\le k<l\le M}[I(f)-Q(f;P_i)][I(f)-Q(f;P_l)].\end{aligned}$$

Substituting the sum of the $[I(f)-Q(f;P_l)]^2$ by (5.7) gives

$$\begin{aligned}(5.8)\quad[I(f)-Q(f;P)]^2&=\frac{1}{M(M-1)}\sum_{l=1}^{M}[Q(f;P_l)-Q(f;P)]^2\\&\quad+\frac{2}{M(M-1)}\sum_{1\le k<l\le M}[I(f)-Q(f;P_k)][I(f)-Q(f;P_l)].\end{aligned}$$

If the P_l are random shifts as in (5.5), then the expected value of the term $[I(f)-Q(f;P_k)][I(f)-Q(f;P_l)]$ vanishes for all $k\neq l$ and taking the expected value of (5.8) yields (5.6). □

Some remarks are in order to explain the assumptions and conclusions of the above theorem. These are given below.

Assumption (5.3), and thus conclusion (5.4), holds for both the cases (5.1) and (5.2) above. In fact, this part of the theorem holds for any imbedded rule or any rule where the P_l all contain the same number of points, and their union is P or multiple copies of P. For example, (5.4) would apply to the case where P is a (t,m,s)-net made up of a union of subnets P_l.

Assumption (5.5), and therefore conclusion (5.6), holds for (5.2). There is a difficulty if one tries to derive a result like (5.6) for an imbedded rule of the form (5.1), where Δ is a random shift. The argument leading to (5.6) assumes that the points in different P_l are uncorrelated, which is not true for (5.1). However, if the extensible lattice is a good one, it is expected that the terms $[I(f)-Q(f;P_k)][I(f)-Q(f;P_l)]$ in (5.8) are on average negative. Under this assumption one may then conclude that the right-hand side of (5.6) is a conservative (too large) upper bound on the expected square quadrature error.

The factor in (5.4) above involving the discrepancies of P and the P_l does not depend strongly on the particular choice of discrepancy but on the asymptotic rate

of decay only. If, for example, $D(P) \approx CN^{-\alpha}$ for some unknown C, but known α, where N is the number of points in P, then

$$E_{f\in\mathcal{A}}[I(f) - Q(f;P)]^2 \approx \frac{1}{M(M^{2\alpha}-1)} \sum_{l=1}^{M} E_{f\in\mathcal{A}}[Q(f;P_l) - Q(f;P)]^2. \tag{5.9}$$

Although conclusions (5.6) and (5.9) are derived under different assumptions, they both suggest error estimates of the form

$$[I(f) - Q(f;P)]^2 \lessapprox \frac{c^2}{M(M^{2\alpha}-1)} \sum_{l=1}^{M} [Q(f;P_l) - Q(f;P)]^2, \tag{5.10}$$

where $\alpha = 1/2$ for (5.6) and α indicates the rate of decay of the discrepancy for (5.9). The factor $c > 1$ depends on how conservative one wishes to be. The Chebyshev inequality implies that the above inequality will hold "at least" $100(1 - c^{-2})\%$ of the time. Error estimate (5.10) leads to the stopping criteria:

$$\frac{c^2}{M(M-1)} \sum_{l=1}^{M} [Q(f;P_l) - Q(f;P)]^2 < \epsilon^2, \tag{5.11}$$

where ϵ is the absolute error tolerance. Note that if the stopping criteria is not met, one would normally increase the *size* of the P_l by increasing m_1, rather than increasing the *number* of the P_l by increasing M.

For some high-dimensional problems the discrepancy of a lattice (or other low discrepancy set) may decay as slowly as the Monte Carlo rate of $\mathrm{O}(N^{-1/2})$ for small N (see [18, 42]). Therefore, even when using (5.9), it may be advisable to make a conservative choice of $\alpha = 1/2$. This choice makes the approach of error estimate (5.9), based on random integrands, equivalent to that of (5.6), based on randomly shifted P_l.

Sloan and Joe [55, Sect. 10.3] suggest an error estimate of the form

$$[I(f) - Q(f;P)]^2 \lessapprox \frac{c^2}{s} \sum_{l=1}^{s} [Q(f;P_l) - Q(f;P)]^2,$$

where P is formed from 2^s copies of a rank-1 lattice, and each $Q(f;P_l)$ is an imbedded rule based on half of the points in P. Although this case does not exactly fit Theorem 5.1, the arguments in the proof can be modified to obtain a result similar to (5.4):

$$E_{f\in\mathcal{A}}[I(f) - Q(f;P)]^2 = \left\{ -1 + \frac{1}{s} \sum_{l=1}^{s} \left[\frac{D(P_l)}{D(P)} \right]^2 \right\}^{-1} \frac{1}{s} \sum_{l=1}^{s} E_{f\in\mathcal{A}}[Q(f;P_l) - Q(f;P)]^2.$$

This would suggest that the error estimation formula of Sloan and Joe is reasonable when $D(P_l) \geq \sqrt{2}D(P)$ on average. The disadvantage of 2^s-copy rules is that they require at least 2^s points, which may be unmanageable for large s.

To summarize, both imbedded lattice rules, (5.1), and independent random shifts of lattices, (5.2), have similar error estimates, (5.10), and stopping criteria, (5.11). The advantage of the independent random shifts approach is that the theory holds

for any integrand, not the average over a space of integrands. One advantage of the imbedded rules approach is that one need generate only a single extensible lattice. Furthermore, the set P for the imbedded rule is the node set of a lattice (if M is a power of b), which is never the case for the independent random shifts approach. Thus, the accuracy of the imbedded rule approach is likely to be better. In the examples in the next section, the imbedded lattice rules based on (5.1) are used.

6. Examples of multidimensional quadrature. Two example problems are chosen to demonstrate the performance of the new rank-1 lattice sequences proposed in section 2.4. The first example is the computation of multivariate normal probabilities, and the second is the evaluation of a multidimensional integral arising in physics problems.

6.1. Multivariate normal probabilities. Consider the following multivariate normal probability:

$$\frac{1}{\sqrt{|\mathbf{\Sigma}|(2\pi)^s}} \int_{a_1}^{b_1} \cdots \int_{a_s}^{b_s} e^{-\frac{1}{2}\theta' \mathbf{\Sigma}^{-1}\theta} \, d\theta, \tag{6.1a}$$

where a and b are known s-dimensional vectors, and $\mathbf{\Sigma}$ is a given $s \times s$ positive definite covariance matrix. Some a_j and/or b_j may be infinite.

Unfortunately, the original form is not well suited for numerical quadrature. Therefore, Alan Genz [12] proposed a transformation of variables that results in an integral over an $(s-1)$-dimensional unit cube. See [12, 13] for the details of the transformation, and see [13, 15] for comparisons of different methods for calculating multivariate normal probabilities.

The particular test problem is one considered by [13, 24] and may be described as follows:

$$a_1 = \cdots = a_s = -\infty, \tag{6.1b}$$

$$b_j \text{ i.i.d. uniformly on } [0, \sqrt{s}], \tag{6.1c}$$

$$\mathbf{\Sigma} \text{ generated randomly according to [13, 39].} \tag{6.1d}$$

Numerical comparisons were made using three types of algorithms:

i. the adaptive algorithm DCHURE [2],
ii. an older Korobov rank-1 lattice rule with a different generating vector for each N and s—this algorithm is a part of NAG and is used in [5, 12]—and
iii. the new rank-1 lattice sequences proposed in section 2.4 with generating vectors given in Table 4.1.

For the second and third algorithms we applied the periodizing transformation $x'_j = |2x_j - 1|$ to the integrand over the unit cube. This appears to increase the accuracy of the lattice rule methods. The computations were carried out in FORTRAN on a Unix work station in double precision. The absolute error tolerance was chosen to be $\epsilon = 10^{-4}$, and this was compared with the actual error E. Since the true value of the integral is unknown for this test problem, the value given by the Korobov algorithm with a tolerance of $\epsilon = 10^{-8}$ was used as the "exact" value for computing the error. For the new rank-1 lattice sequences the stopping criterion (5.11) was used with M between 4 and 7 and $c = 3$.

For each dimension, 50 random test problems were generated and solved by the various quadrature methods. The scaled absolute errors E/ϵ and the computation times in seconds are given in the box and whisker plots of Figure 6.1. The boxes con-

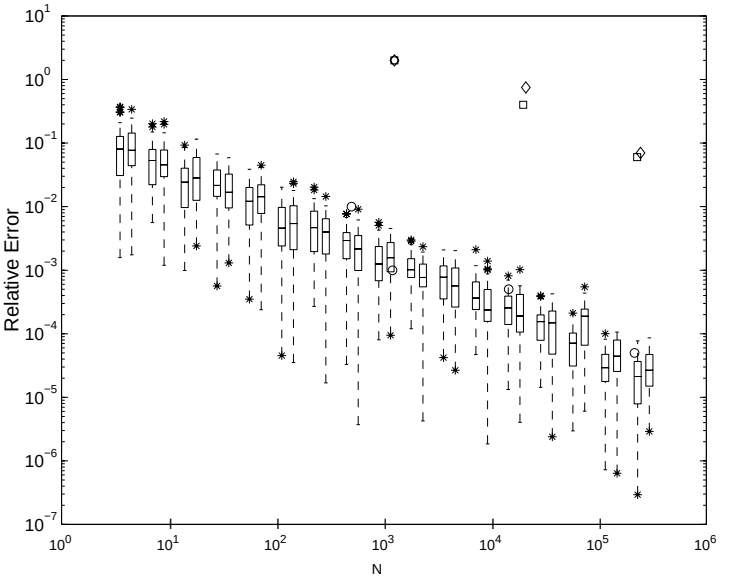

FIG. 6.2. *Plots of the relative error obtained in approximating* (6.2) *for* $s = 25$ *for the McNamee and Stenger* (□)*, Genz and Patterson* (◇)*, generalized Faure* (○) *quadrature rules. The box and whisker plots show the performance of the extensible lattice sequence rules for* $\eta = 17797$ *and* 1267 *from Table* 4.1 *for* $N = 4, 8, \ldots, 2^{17}$.

tain the middle half of the values, and the whiskers give the range of most values except the outliers (denoted by $*$).

Ideally, the scaled error should nearly always be less than one, otherwise the error estimate is not conservative enough. On the other hand, if the scaled error is too small, then the error estimate is too conservative. Figure 6.1 shows that the adaptive rule performs well for smaller dimensions but underestimates the error and is quite slow in higher dimensions. The lattice rules do well even in higher dimensions, and the new rank-1 lattice sequences appear to be faster than the older Korobov-type rule. This is likely due to the fact that the lattice sequences proposed here can reuse the old points when N must be increased.

6.2. A multidimensional integral from physics. Keister [30] considered the following multidimensional integral that has applications in physics:

$$\int_{\mathbf{R}^s} \cos(\|x\|_2) e^{-\|x\|_2^2}\, dx = \pi^{s/2} \int_{[0,1)^s} \cos\left(\sqrt{\sum_{j=1}^{s} \frac{[\Phi^{-1}(y_j)]^2}{2}}\right) dy, \tag{6.2}$$

where Φ denotes the standard Gaussian distribution function. Keister gave an exact formula for the answer and compared the quadrature methods of McNamee and Stenger [40], Genz [11], and Patterson [53] for evaluating this integral. Later, Papageorgiou and Traub [51] applied the generalized Faure sequence from FINDER to this problem.

The results of numerical experiments for the above integral for dimension 25 are shown in Figure 6.2. The exact value of the integral is reported in [51]. To be

consistent with the numerical results reported in [30, 51], we did not perform error estimation but just computed the actual error for each kind of numerical method as a function of N, the number of points. Because $\Phi^{-1}(0) = -\infty$, there is a technical difficulty with using an unshifted lattice rule, so when performing the numerical experiments, the lattice sequences were given random shifts (modulo 1). Box and whisker plots show how well the new rank-1 lattice sequences perform for 50 random shifts.

According to Figure 6.2, the generalized Faure sequence (in base 29) and the lattice sequence perform much better than the other two rules. In some cases the lattice sequences perform better than the generalized Faure sequence.

7. Conclusion. Lattice rules are simpler to code than digital nets. Given the construction in section 2.4, it is now possible to have extensible lattice sequences in the same way that one has (t, s)-sequences. Good generating vectors for these lattice sequences may be found by using the spectral test or minimizing other discrepancy measures, as shown in section 4. The performance of these lattice rules is in many cases comparable to other multidimensional quadrature rules and in some cases superior.

Acknowledgments. Thanks to Alan Genz for making his software for computing multivariate normal distributions available. Thanks also to Joe Traub and Anargyros Papageorgiou for making the FINDER software available.

APPROXIMATE PROJECTION METHODS: PART I. INVISCID ANALYSIS*

ANN S. ALMGREN†, JOHN B. BELL†, AND WILLIAM Y. CRUTCHFIELD†

Abstract. The use of approximate projection methods for modeling low Mach number flows avoids many of the numerical complications associated with exact projection methods, but introduces additional design choices in developing a robust algorithm. In this paper we first explore these design choices in the setting of inviscid incompressible flow using several computational examples. We then develop a framework for analyzing the behavior of the different design variations and use that analysis to explain the features observed in the computations. As part of this work we introduce a new variation of the approximate projection algorithm that combines the advantages of several of the previous versions.

Key words. projection method, approximate projection, incompressible flow

1. Introduction.

The term "projection methods" refers to a class of fractional step algorithms for modeling unsteady low Mach number flows characterized by a divergence constraint on the velocity field. In these methods an intermediate velocity field is constructed by advancing the momentum equations in time without enforcing the constraint. In the next step of the algorithm this field is projected back onto the constraint.

Projection methods have been used for incompressible flow modeling for several decades, but approximate projection methods have appeared only in the past few years. They have been numerically tested on a number of flows in two and three spatial dimensions, but adequate analysis of their properties has been lacking to date. In this paper we provide an analytical basis for understanding the behavior of approximate projection methods and some of the design decisions that accompany their use.

For the purposes of this paper we will focus on inviscid, constant density flows, with numerical examples in two dimensions. In the second paper in this series we will extend the analysis to the modeling of viscous flows. The extension to variable density flows, and adaptive projection methods with subcycling in time, will follow.

In the original projection method developed by Chorin [5] the projection step of the algorithm is specified by defining discrete operators $\mathbf{D}$ and $\mathbf{G}$, approximating divergence and gradient, respectively, which are skew-adjoint; i.e., $\mathbf{D} = -\mathbf{G}^T$. With this definition the discrete projection, $\mathbf{P} = \mathbf{I} - \mathbf{G}(\mathbf{D}\mathbf{G})^{-1}\mathbf{D}$ (with boundary conditions implicitly defined by the flow problem), is a discrete orthogonal projection on the finite-dimensional space of vector fields defined on the mesh. In Chorin's formulation both pressure and velocity are specified at nodes and central differences are used for the definition of $\mathbf{D}$ and $\mathbf{G}$. This results in an expanded five-point stencil for the

†MS 50A-1148, Lawrence Berkeley National Laboratory, Berkeley, CA 94720 (ASAlmgren@lbl.gov, JBBell@lbl.gov, WYCrutchfield@lbl.gov).

discrete Laplacian, $L = \mathbf{DG}$, which must be inverted to apply the projection. This expanded stencil produces a local decoupling of the mesh points and leads to a 2^d-dimensional kernel for $\mathbf{G}$ where d is the dimension of the problem. Bell, Colella, and Glaz [3] use a discretization of the projection based on a finite element method due to Fortin [7] which uses pressure defined on cell centers with velocities given at nodes. This approach produces a more compact stencil but also generates a local decoupling of the grid and dim ker $\mathbf{G} > 1$. (For two-dimensional problems dim ker $\mathbf{G} = 2$.) Bell, Colella, and Howell [4] use a fully cell-centered analogue of Chorin's algorithm. This scheme exhibits a local decoupling; however, in the presence of Dirichlet boundary conditions, the cell-centered approximation eliminates the nonconstant elements in ker $\mathbf{G}$. (For periodic problems dim ker $\mathbf{G} = 2^d$ as in the original Chorin algorithm.)

In the absence of boundaries the additional elements in ker $\mathbf{G}$ are not a problem for incompressible flow modeling because the operator $(\mathbf{DG})^{-1}$ is applied to a vector field that lies in the range of $\mathbf{D}$. In the presence of boundaries, however, the nonconstant elements in the kernel introduce additional, artificial compatibility constraints on the boundary of the physical domain. In addition, for more complex low Mach number models, such as low Mach number combustion, a term that is not in the range of the divergence operator is often added to the divergence constraint to represent the expansion or contraction of the fluid due to additional physics. The presence of this additional source term can result in marked oscillations in the solution, as noted by Lai [10] and Lai, Bell, and Colella [11]. An additional difficulty associated with the local decoupling is that the nonstandard discretizations of $\mathbf{DG}$ require specialized solution methods that properly respect the stencil that is used. (See [4, 8] for a discussion of such a procedure.)

Almgren, Bell, and Szymczak [2] first introduced the notion of an approximate projection to circumvent the numerical difficulties with exact discrete projections. Approximate projections are defined by replacing the projection operator $\mathbf{P}$ by an approximation $\widetilde{\mathbf{P}} = \mathbf{I} - \mathbf{G}(L)^{-1}\mathbf{D}$, where L is an approximation to, but not identically, $\mathbf{DG}$. The approximate projection methods discussed here were designed to operate on cell-centered colocated velocities, to avoid any local decoupling of the stencils, to provide a symmetric discretization of the potential flow inherent in inhomogeneous boundary conditions, and to generate a linear system that fits the framework of conventional fast iterative techniques (e.g., multigrid) for second-order elliptic equations. (See [2] for further discussion of the motivation for approximate projections.)

The approximate projection introduced by Almgren, Bell, and Szymczak [2] defines pressure on nodes and uses a finite element formulation with bilinear basis functions to derive a nine-point (in two dimensions) stencil for the Laplacian operator. The finite element derivation gives a characterization of this projection as an exact discrete projection onto an enriched space followed by an L^2 projection onto a subspace corresponding to piecewise constant velocity fields. This derivation provides an analytic characterization of the effect of the "approximateness" and proves stability of the approximation. A standard five-point nodal approximation to the Laplacian can also be used. This approximation can be constructed in a similar manner by specifying pressure to be piecewise linear on the standard triangularization of a square mesh. The analogous three-dimensional seven-point nodal discretization has been successfully used by Almgren et al. in [1], but lacks the finite element derivation.

Lai [10] introduced a cell-centered approximate projection where pressure is defined at cell centers and which uses a standard five-point centered-difference stencil for the Laplacian. The stability of such a scheme was shown in [10]; this approximate

projection has been used by Martin [12] in an adaptive projection algorithm, and a variation of this (with the same L but a higher-order $\mathbf{D}$) by Minion [14] in an adaptive scheme.

Approximate projections have been successfully used in the modeling of more general low Mach number flows such as those arising in combustion (e.g., [17, 18]). However, in spite of these successful applications, approximate projection algorithms are not without their own problems. Adopting an approximate projection approach introduces a number of design choices that are not relevant for an exact discrete projection. When applied to "difficult" problems or to long-time integrations, approximate projection algorithms can produce poor results. Rider discusses some of these design choices for the five-point cell-centered scheme [19] and describes a collection of filtering techniques to deal with artifacts he observes in numerical tests [20].

The goal of this paper is to develop an analytical framework to explain the performance of different variations of approximate projection methods and to explore methods for improving their behavior. In the next section we will give a brief overview of projection methods using an exact projection; in section 3 we introduce several different formulations of approximate projection schemes. In the following two sections we present a temporal analysis of approximate projections, then a spatial analysis of the three specific approximate projections discussed here. In section 6 we discuss issues related to the coupling between the advection scheme and the choice of approximate projection, and in section 7 we present our conclusions and discussion.

2. Overview of exact projection methods. In this paper we will consider constant density, inviscid, incompressible flow, governed by

$$\mathbf{U}_t + (\mathbf{U}\cdot\nabla)\mathbf{U} + \nabla p = 0, \tag{2.1}$$

$$\nabla\cdot\mathbf{U} = 0, \tag{2.2}$$

where (in two dimensions) $\mathbf{U} = (u, v)$ and p represent the velocity and pressure, respectively.

The projection method is a fractional step scheme for solving (2.1)–(2.2). In the advection step we solve (2.1) without enforcing the constraint. In the projection step, we then apply a projection to the intermediate velocity field to enforce the constraint. For the advection step we solve

$$\frac{\mathbf{U}^{*,n+1} - \mathbf{U}^n}{\Delta t} + [(\mathbf{U}\cdot\nabla)\mathbf{U}]^{n+1/2} = -\mathbf{G}p^{n-1/2} \tag{2.3}$$

for the intermediate velocity $\mathbf{U}^{*,n+1}$. The pressure gradient is evaluated at $t^{n-1/2}$ and is treated as a source term. For the computations presented here, the advection term, $\mathbf{N}^{n+1/2} = [(\mathbf{U}\cdot\nabla)\mathbf{U}]^{n+1/2}$, is approximated at time $t^{n+1/2}$ to second-order in space and time using an explicit predictor-corrector scheme described in Appendix A. (We note that the analysis presented later in the paper is applicable when other approaches are used to compute $\mathbf{N}^{n+1/2}$. Experiments with different options in the predictor-corrector scheme presented in section 6 are suggestive of the degree to which the conclusions reached here are applicable to other methods.)

The velocity field $\mathbf{U}^{*,n+1}$ is not, in general, divergence-free. In the projection step of the algorithm the intermediate velocity field can be decomposed into a discrete gradient of a scalar potential and a discretely divergence-free vector field which

correspond, respectively, to the new pressure gradient and the new velocity, i.e.,

$$\mathbf{U}^{n+1} = \mathbf{P}\mathbf{U}^{*,n+1},$$
$$\Delta t\, \mathbf{G}p^{n+1/2} = \Delta t\, \mathbf{G}p^{n-1/2} + (\mathbf{I} - \mathbf{P})\mathbf{U}^{*,n+1}.$$

To apply the projection operator we solve $\mathbf{DG}\phi = \mathbf{DV}$ for a scalar field ϕ, where, in this case, $\mathbf{V} = \mathbf{U}^{*,n+1}$. We then define the divergence-free part of $\mathbf{V}$, in this case $\mathbf{U}^{n+1}$, by $\mathbf{V}_d = \mathbf{V} - \mathbf{G}\phi$. By construction $\mathbf{DV}_d = 0$; thus, $\mathbf{U}^{n+1}$ exactly satisfies the discrete form of divergence constraint.

3. Approximate projections. For an exact projection, $\mathbf{V}$ can take many forms, all of which lead to exactly the same solution (assuming an exact solution of the resulting Poisson equation). Two natural candidates for $\mathbf{V}$ are the velocity itself or the update to velocity. One could also modify each of these by removing the pressure gradient component of the update. Specifically, one might choose any of the following (with the Δt scaling for convenience):

$$(1) \quad \mathbf{V} = \frac{\mathbf{U}^{*,n+1}}{\Delta t},$$
$$(2) \quad \mathbf{V} = \frac{\mathbf{U}^{*,n+1}}{\Delta t} + \mathbf{G}p^{n-1/2},$$
$$(3) \quad \mathbf{V} = \frac{\mathbf{U}^{*,n+1} - \mathbf{U}^{n}}{\Delta t},$$
$$(4) \quad \mathbf{V} = \frac{\mathbf{U}^{*,n+1} - \mathbf{U}^{n}}{\Delta t} + \mathbf{G}p^{n-1/2}.$$

Then, after solving $\mathbf{DG}\phi = \mathbf{DV}$ (or $L\phi = \mathbf{DV}$ for an approximate projection) and setting $\mathbf{V}_d = \mathbf{V} - \mathbf{G}\phi$, the new velocity and pressure would be defined, respectively, by

$$(1) \quad \mathbf{U}^{n+1} = \Delta t\, \mathbf{V}_d, \qquad p^{n+1/2} = p^{n-1/2} + \phi,$$
$$(2) \quad \mathbf{U}^{n+1} = \Delta t\, \mathbf{V}_d, \qquad p^{n+1/2} = \phi,$$
$$(3) \quad \mathbf{U}^{n+1} = \mathbf{U}^{n} + \Delta t\, \mathbf{V}_d, \qquad p^{n+1/2} = p^{n-1/2} + \phi,$$
$$(4) \quad \mathbf{U}^{n+1} = \mathbf{U}^{n} + \Delta t\, \mathbf{V}_d, \qquad p^{n+1/2} = \phi.$$

For approximate projections the choice of $\mathbf{V}$ has a nontrivial effect on the solution. Because the approximate projection operators are second-order accurate approximations to an exact projection, the methods which result from each choice of $\mathbf{V}$ are all second-order accurate for smooth problems, but not identical.

For the sake of clarity, we here introduce some notation for the different spatial and temporal discretizations. We will refer to the approximate projection with the nine-point nodal discretization of L as **N9**, that with the five-point nodal discretization of L as **N5**, and that with the five-point cell-centered discretization of L as **C5**. In addition, for all results we will specify which version of $\mathbf{V}$ is being projected; e.g., **N9_3** will indicate the nine-point nodal scheme, version (3) of $\mathbf{V}$. In the published literature, Almgren et al. [1, 2] have presented results using **N5_3** and **N9_3**; Martin [12] used **C5_2**, and Minion [14] has used **C5_4**. Rider [19] presents extensive testing of **C5_1-4** in conjunction with the development of filters to reduce numerical artifacts.

We also note here that for each of the approximate projection operators $\widetilde{\mathbf{P}}$, there is a corresponding exact discrete projection $\mathbf{P} = \mathbf{I} - \mathbf{G}(\mathbf{DG})^{-1}\mathbf{D}$ defined using the

same **D** and **G** used to define $\widetilde{\mathbf{P}}$. We will refer to the exact nodal projection as **N_EX** and the exact cell-centered projection as **C_EX.**

To demonstrate the second-order accuracy of the different versions of the approximate projections, we present results from a time-periodic test case with diagonally translating vortices. The initial data are

$$u(x,y) = 1 - 2\cos(x)\sin(y),$$
$$v(x,y) = 1 + 2\sin(x)\cos(y)$$

on a square domain, 2π x 2π. The exact solution to the Euler equations with this initial data is

$$u_{ex}(x,y,t) = 1 - 2\cos(x-t)\sin(y-t),$$
$$v_{ex}(x,y,t) = 1 + 2\sin(x-t)\cos(y-t),$$
$$p_{ex}(x,y,t) = -\cos(2(x-t)) - \sin(2(y-t)).$$

For each version of **V** and each approximate projection we present results at three different resolutions: 32^2, 64^2, and 128^2. The L^2 norms of the error in u and p_x are shown in Figure 1. It is clear that each method is second-order accurate; in addition, it is evident that there are differences between the solutions resulting from the different forms of the projections, most noticeably **C5_4**. We will explain these differences in the next two sections.

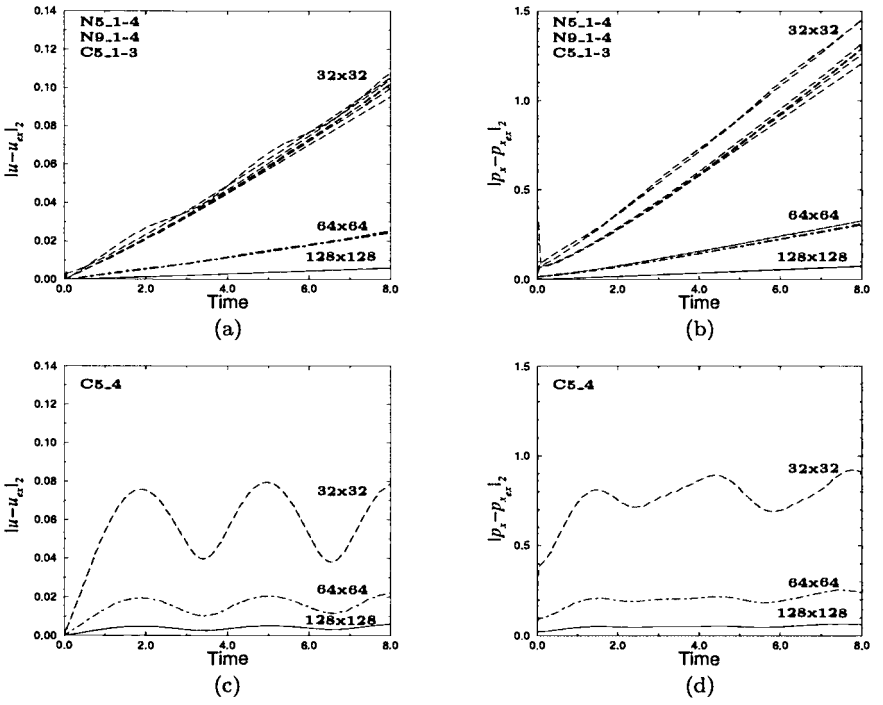

FIG. 1. L^2 *norms of error in* u (a,c) *and* p_x (b,d) *for the translating vortices problem.*

As demonstrated above, the difficulty with using approximate projections is not a question of formal accuracy on smooth problems. Instead, problems tend to appear

as a buildup of "noise" during longer time integrations of more complex problems. To illustrate this behavior we present results from each of the approximate projections run on on a more complex problem, namely the inviscid dynamics of a random initial distribution of vorticity. A key feature of this problem is that it contains substantially more high frequency content than the previous test case. The initial data for this problem are given by specifying a random stream function with spectral characteristics defined by

$$\hat{\psi}(k) = \frac{\omega}{|k|(1 + (|k|/6)^4)},$$

where ω is a normally distributed random variable mapped into the complex domain with the appropriate symmetries so that the inverse Fourier transform of $\hat{\psi}$ is a real function, ψ. We then define $\mathbf{U}^0$ as the discrete curl of ψ. The initial data for this problem are similar to the initial data used to test the decay at high Reynolds number of the two-dimensional Navier–Stokes equations to the sinh-Poisson mean field equations derived by Joyce and Montgomery [9]. This type of problem has been studied extensively by a number of authors. (See the early work by McWilliams [13] and other studies such as Montgomery, Shan, and Matthaeus [15] and the references cited therein.) We note that the key difference between the initial data we have constructed and the data used in the above studies is that in those studies the kinetic energy scales like k^{-3} for large k, but here we are imposing a more rapid decay for large k. This more rapid decay reduces the very high frequency components of the solution so that the computations are less sensitive to the behavior of the advection scheme. (Results similar to those presented here are also obtained with the richer spectrum but the anomalies occur at higher resolution and longer time integrations, which are prohibitive for extensive testing.)

We examine the evolution of the solution from time $t = 0$ to 10, over which time the initial random vorticity essentially coalesces into two smooth patches of counter-rotating vorticity. In Figure 2(a) and 2(e) we show raster plots of the vorticity and p_x at $t = 10$ on a 64^2 grid calculated with **N9_2.** The domain is the unit square with doubly periodic boundary conditions, and all calculations are run with CFL = 0.9 (i.e., $\Delta t = 0.9\ h\ /\ \max(\max_{(i,j)}|u|, \max_{(i,j)}|v|)$, where $\max_{(i,j)}|\cdot|$ is the maximum over all grid cells, and h is the mesh spacing).

Several variations of the approximate projection produce poor results for this problem. In particular, in Figure 2(b)–(d), (f)–(h) we show the vorticity and p_x at $t = 10$ as calculated using **N9_1**, **C5_3**, and **N5_4**. For the **N9_1** case, checkerboarding (high frequency error in the solution) is evident in p_x (Figure 2(f)) and to a lesser extent in the vorticity (Figure 2(b)). Similarly, for **C5_3**, high frequency error is visible, though due to the cell-centered discretization the error appears more as "striping" than checkerboarding in the vorticity (Figure 2(c)). More coherently structured but equally unphysical features are evident in both the vorticity (Figure 2(d)) and pressure gradient (Figure 2(h)) for **N5_4**.

In Figure 3 we plot the numerical divergence of velocity (calculated in each case with the same **D** as the approximate projection used) as a function of time for all 12 cases (**C5_1-4, N9_1-4, N5_1-4**), at resolutions 64^2 and 128^2. While the divergence does decrease with increased resolution, the differences between the variations of the projection persist. (In fact **N5_1** becomes more unstable at higher resolution.) An examination of all 12 cases indicates that for solutions with relatively small divergence, the plots of vorticity and pressure gradient are similar to Figure 2(a) and Figure 2(e), respectively. Similarly, for solutions with relatively larger divergence, the plots of

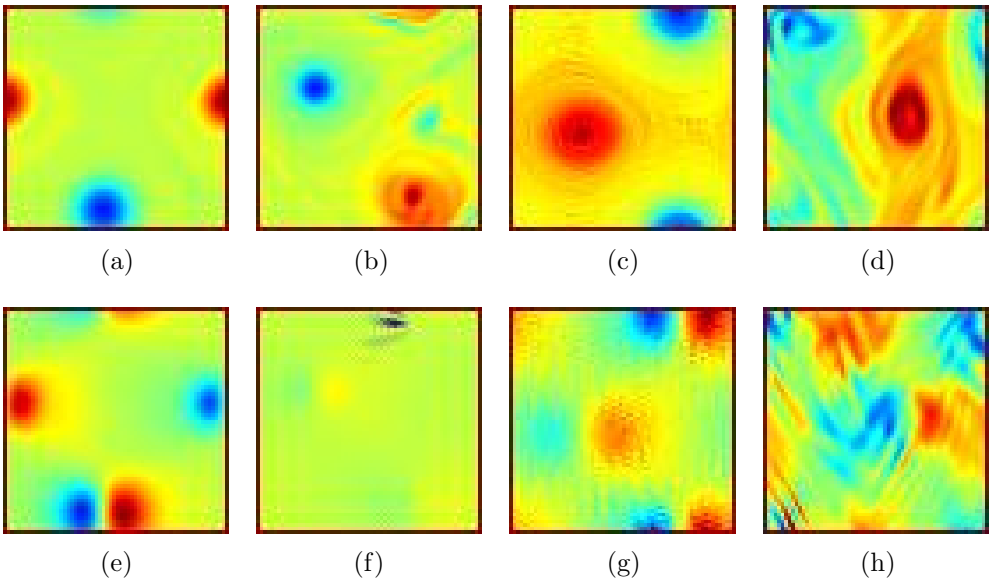

FIG. 2. *Vorticity* (a)–(d) *and* p_x (e)–(h) *at* $t = 10$ *for the random initial vorticity calculation at resolution* 64^2. (a), (e) **N9_2**; (b), (f) **N9_1**; (c), (g) **C5_3**; (d), (h) **N5_4**.

vorticity and pressure gradient more closely resemble Figure 2(b)–(d) and Figure 2(f)–(h), respectively. It is evident that the divergence is a useful indicator of solution quality for problems such as this one for which an exact solution is not known.

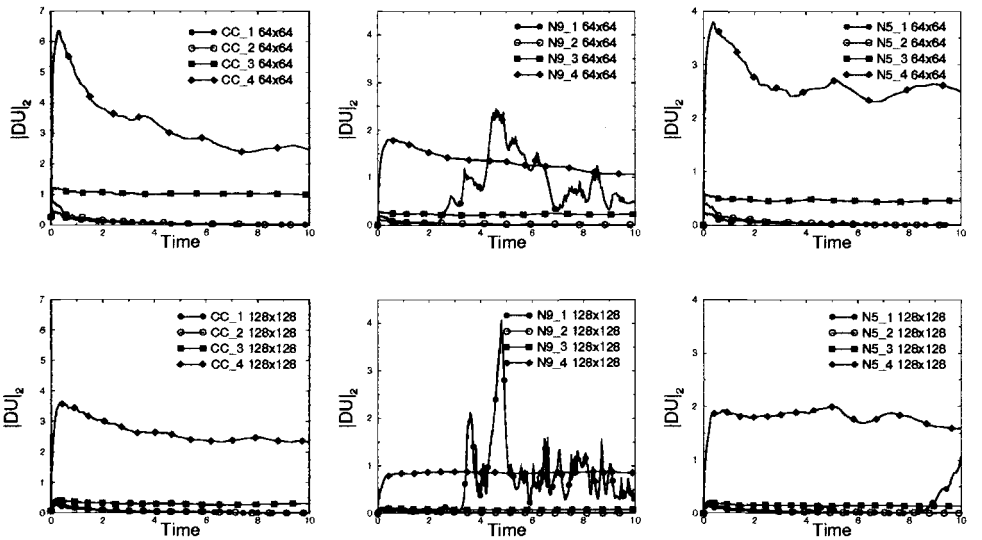

FIG. 3. L^2 *norms of* **DU** *from* $t = 0$ *to* 10 *for the random initial vorticity problem at two different resolutions.*

For the random initial vorticity problem, it appears that the only acceptable formulation of the approximate projection across all three discretizations is version (2). Version (2), however, is not without its drawbacks. As we will see analytically in

the next section, the divergence of the solution found with version (2) is typically larger than when version (1) is used, provided version (1) remains stable. To demonstrate this, we consider a very simple steady problem for which we know the exact solution. The initial data (and steady solution) are $u_{ex} = \sin(y)$, $v_{ex} = \cos(x)$.

To eliminate issues of predictor-projection coupling which will be discussed in section 7, here we use the exact analytic solution to define the advective terms at each time step, i.e., we set $\mathbf{N}_{i,j}^{n+1/2} = (\cos(x_i)\cos(y_j), -\sin(x_i)sin(y_j))$, where $x_i = ih, y_j = jh$ with h the mesh spacing. All calculations are run with CFL = 0.9 and resolution 32^2.

Figure 4 shows the L^2 error in u from time $t = 0$ to 150 for versions (1) and (2) with each approximate projection. The solid curves using version (1) are indistinguishable in this figure from the x-axis; the three remaining curves were computed with version (2). Clearly the error grows steadily for version (2), while remaining essentially zero for version (1).

While the difference between versions (1) and (2) is especially noticeable for a steady problem, analogous behavior is seen in the initial iteration of the algorithm which is used to define the initial pressure field. At the beginning of a calculation, the initial velocity field is projected once to enforce the divergence constraint. Then an iteration is performed to compute $\mathbf{G}p^{-1/2}$. In each step of this iteration a full time step is taken; after the projection step the pressure field is updated, but the velocity is reset to its previous value.

If version (1) or (3) of the approximate projection is used, then in the limit as the number of iterations becomes infinite, the initial pressure converges to the correct value (that which would be found with infinitely many iterations of an exact projection). With versions (2) or (4), however, because these versions are nonincremental in pressure, the pressure does not converge, regardless of the number of iterations.

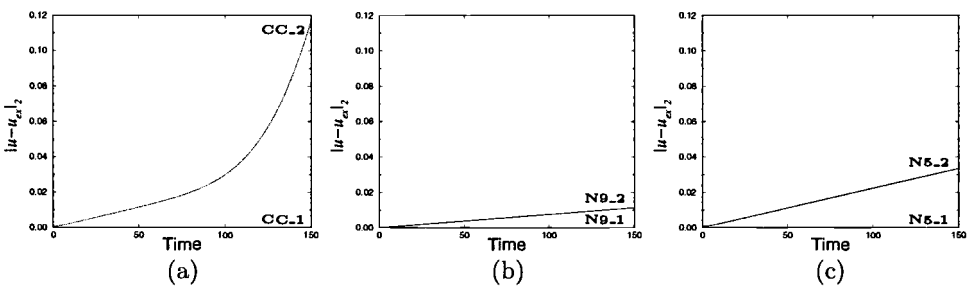

FIG. 4. *L^2 norms of the error in u from $t = 0$ to $t = 150$ from calculations of the steady problem for versions* (a) **CC_1-2**, (b) **N9_1-2**, (c) **N5_1-2**. *Curves using projection version* (1) *overlay the x-axis.*

4. Temporal analysis of approximate projections. The goal of this and the next section is to develop an analytical framework to explain the results of the computations presented in the previous section. The expressions presented by Rider [19] for the divergence of velocity suggest that version (1) should produce the lowest divergence, that versions (2) and (3) should produce similar results, and that version (4) should generate the highest divergence. These predictions hold true in some cases but do not fully explain the computations presented in the previous section or the computations in [19], specifically the lack of robustness of version (1) and the differences in behavior between versions (2) and (3).

In order to understand the behavior of the different variations of approximate projections, in Tables 1 and 2 we express the velocity and pressure gradient after n time steps, $\mathbf{U}^n$ and $\mathbf{G}p^{n-1/2}$, in terms of the initial data, $\mathbf{U}^0$ and $\mathbf{G}p^{-1/2}$, the advective updates at each time step, $\mathbf{N}^{i+1/2}$, and the approximate projection operator, $\widetilde{\mathbf{P}}$. These expressions are derived by substituting the expression for $\mathbf{U}^{*,n+1}$ from (2.3) into the definitions of $\mathbf{U}^{n+1}$ for each version of the approximate projection defined in section 3. Successive substitution provides the desired characterization of each version of the algorithm.

TABLE 1
$\mathbf{U}^n$ *in terms of* $\mathbf{U}^0$, $\mathbf{G}p^{-1/2}$, *and* $\mathbf{N}$. *All sums are from* $i = 1$ *to* n *unless otherwise noted.*

Version	$\mathbf{U}^n =$
Exact	$\mathbf{U}^0 - \sum \mathbf{P}(\Delta t\, \mathbf{N}^{n+1/2-i})$
(1)	$\mathbf{U}^n = \mathbf{Q}_\rho^n \mathbf{U}^0 - \mathbf{Q}_\beta^n(\Delta t\, \mathbf{G}p^{-1/2}) - \sum \mathbf{Q}_\alpha^i(\Delta t\, \mathbf{N}^{n+1/2-i})$
(2)	$\widetilde{\mathbf{P}}^n \mathbf{U}^0 - \sum \widetilde{\mathbf{P}}^i(\Delta t\, \mathbf{N}^{n+1/2-i})$
(3)	$\mathbf{U}^0 - \sum \widetilde{\mathbf{P}}^i(\Delta t\, \mathbf{N}^{n+1/2-i}) - \sum \widetilde{\mathbf{P}}^i(\Delta t\, \mathbf{G}p^{-1/2})$
(4)	$\mathbf{U}^0 - \sum \widetilde{\mathbf{P}}(\Delta t\, \mathbf{N}^{n+1/2-i})$

TABLE 2
$\Delta t\, \mathbf{G}p^{n-1/2}$ *in terms of* $\mathbf{U}^0$, $\mathbf{G}p^{-1/2}$, *and* $\mathbf{N}$. *All sums are from* $i = 1$ *to* n *unless otherwise noted.*

Version	$\Delta t\, \mathbf{G}p^{n-1/2} =$
Exact	$-(\mathbf{I} - \mathbf{P})(\Delta t\, \mathbf{N}^{n-1/2})$
(1)	$-\Delta t \sum \mathbf{Q}_\gamma^i \mathbf{N}^{n+1/2-i} - \Delta t\, \mathbf{Q}_\delta^n \mathbf{G}p^{-1/2}$
(2)	$-(\mathbf{I} - \widetilde{\mathbf{P}})(\Delta t\, \mathbf{N}^{n-1/2})$ $+ (\mathbf{I} - \widetilde{\mathbf{P}})\widetilde{\mathbf{P}}^{n-1}\mathbf{U}^0 - \sum_{i=2}^n (\widetilde{\mathbf{P}}^{i-1} - \widetilde{\mathbf{P}}^i)(\Delta t\, \mathbf{N}^{n+1/2-i}))$
(3)	$\widetilde{\mathbf{P}}^n \mathbf{G}p^{-1/2} - (\mathbf{I} - \widetilde{\mathbf{P}}) \sum \widetilde{\mathbf{P}}^{i-1} \Delta t\, \mathbf{N}^{n+1/2-i}$
(4)	$-(\mathbf{I} - \widetilde{\mathbf{P}})(\Delta t\, \mathbf{N}^{n-1/2})$

The coefficients in the formula for $\mathbf{U}^n$ using version (1) are defined by the recursion relations

$$\mathbf{Q}_\alpha^n = \widetilde{\mathbf{P}}(\mathbf{Q}_\alpha^{n-1}) - (\mathbf{I} - \widetilde{\mathbf{P}})(\mathbf{Q}_\beta^{n-1}), \quad \mathbf{Q}_\beta^n = \widetilde{\mathbf{P}}(\mathbf{Q}_\alpha^{n-1} + \mathbf{Q}_\beta^{n-1}),$$

with starting values $\mathbf{Q}_\alpha^1 = \mathbf{Q}_\beta^1 = \widetilde{\mathbf{P}}$, $\mathbf{Q}_\alpha^2 = 2\widetilde{\mathbf{P}}^2 - \widetilde{\mathbf{P}}$, $\mathbf{Q}_\beta^2 = 2\widetilde{\mathbf{P}}^2$, $\mathbf{Q}_\alpha^3 = 4\widetilde{\mathbf{P}}^3 - 3\widetilde{\mathbf{P}}^2$, and $\mathbf{Q}_\beta^3 = 4\widetilde{\mathbf{P}}^3 - \widetilde{\mathbf{P}}^2$. Note that $\mathbf{Q}_\alpha^n$ and $\mathbf{Q}_\beta^n$ are polynomials in $\widetilde{\mathbf{P}}$ and that the coefficient of $\widetilde{\mathbf{P}}^n$ in each is 2^{n-1}. Note also that the sum of the coefficients in $\mathbf{Q}_\alpha^n$ is one, and the sum of the coefficients in $\mathbf{Q}_\beta^n$ is n.

The coefficients in the formula for $\mathbf{G}p^{n-1/2}$ using version (1) are defined by the recursion relations

$$\mathbf{Q}_\gamma^n = \widetilde{\mathbf{P}}(\mathbf{Q}_\gamma^{n-1}) - (\mathbf{I} - \widetilde{\mathbf{P}})(\mathbf{Q}_\delta^{n-1}), \quad \mathbf{Q}_\delta^n = \widetilde{\mathbf{P}}(\mathbf{Q}_\gamma^{n-1} + \mathbf{Q}_\delta^{n-1}),$$

with starting values $\mathbf{Q}_\delta^1 = -\widetilde{\mathbf{P}}$ and $\mathbf{Q}_\gamma^1 = (\mathbf{I} - \widetilde{\mathbf{P}})$.

It is clear there is a trade-off in choosing any one form of $\mathbf{V}$. In the numerical results of the previous section, version (1) gives the smallest divergence of velocity when it remains stable; however, it suffers from a lack of robustness. Version (4), by contrast, defines the pressure gradient using only the most recent advection terms, as does an exact discrete projection, but produces very poor computational results. Version (2) appears to be robust and reliable but the velocity field, as seen in the steady example, can accumulate the imprint of the pressure gradient from previous times.

To date, approximate projection methods have followed the lead of exact projection methods in using a single projection to define both the new velocity and pressure. Here, however, motivated by the problems with each form, we introduce the concept of separate projections for the velocity and pressure. We propose an approximate projection method in which a version (1) projection is used to define the new velocity field, and a version (4) projection is then used to define the new pressure gradient. We will call this version (5). If the second projection is solved to full precision, this doubles the computational work of the projection step. However, in our numerical tests we have found that because the pressure from the first projection using version (1) is a good first guess for the pressure which would result from version (4), an algebraic reformulation of the second projection allows one to solve for the difference between these two pressures rather than for the new pressure itself. It is then only necessary to approximately solve the second equation (e.g., to require that the iterative solver reduce the residual by only one order of magnitude), resulting in little additional computational work. Note that the scalar being solved for is the difference in pressure due to the difference in formulation, not the pressure update in time. We will use this strategy for the results presented in this paper. This new version (5) has been successfully used to model incompressible axisymmetric flow with swirl in [16].

We comment here that computational cost is not a relevant factor in deciding between versions. The cost of solving $\mathbf{DG}\phi = \mathbf{DV}$ for ϕ, given $\mathbf{D}$ and $\mathbf{G}$, using an iterative solver, is a function of the smoothness of $\mathbf{V}$, the boundary conditions, and the desired reduction in residual. These factors vary between problems, and do not uniquely determine a "cheapest" version. Version (5) requires slightly more computational work than the others because of the need for a second solve, but using the approximation described above, the additional work is typically less than 10% of the total work of the projection step.

The expressions for projection (5) corresponding to those in Tables 1 and 2 are

$$\mathbf{U}^n = \widetilde{\mathbf{P}}^n \mathbf{U}^0 - \widetilde{\mathbf{P}}^n(\Delta t\ \mathbf{G}p^{-1/2}) - \widetilde{\mathbf{P}}(\Delta t\ \mathbf{N}^{n-1/2}) - \sum_{i=1}^{n-1} \widetilde{\mathbf{P}}^i(2\widetilde{\mathbf{P}} - \mathbf{I})(\Delta t\ \mathbf{N}^{n-1/2-i}),$$

$$\mathbf{G}p^{n-1/2} = (\mathbf{I} - \widetilde{\mathbf{P}})(\Delta t\ \mathbf{N}^{n-1/2}).$$

We note here that version (5) is fully second-order accurate for smooth problems; on the translating vortices problem the results are almost indistinguishable from those with version (2). For the random initial vorticity problem, the magnitude of the divergence with version (5) remains low in all cases; it is in fact always lower than that with version (2), typically by 20–40%, and it lacks the instability of version (1). For the simple steady problem, the curves for version (5) are indistinguishable from those for version (1).

Before performing a more detailed analysis of the projection version, we note that the results for each version can be expressed in a general form as

$$\mathbf{U}^n = \rho_n(\widetilde{\mathbf{P}})\mathbf{U}^0 - \Delta t \sum_{i=1}^{n} \alpha_i(\widetilde{\mathbf{P}})\mathbf{N}^{n+1/2-i} - \beta_n(\widetilde{\mathbf{P}})\mathbf{G}p^{-1/2}, \tag{4.1}$$

$$\Delta t\ \mathbf{G}p^{n-1/2} = -\Delta t\ (\mathbf{I}-\widetilde{\mathbf{P}})\mathbf{N}^{n-1/2} - \Delta t \sum_{i=2}^{n} \gamma_i(\widetilde{\mathbf{P}})\mathbf{N}^{n+1/2-i} + \gamma_n(\widetilde{\mathbf{P}})\mathbf{U}^0 - \Delta t\ \delta_n(\widetilde{\mathbf{P}})\mathbf{G}p^{-1/2}, \tag{4.2}$$

with the polynomial coefficients for each version and for an exact projection given in Table 3.

TABLE 3
Coefficients for each version of the approximate projection and for an exact projection.

Version	ρ_n	α_i	β_n	γ_i	δ_n
Exact	1	$\mathbf{P}$	0	0	0
(1)	$\mathbf{Q}_\alpha^n$	$\mathbf{Q}_\alpha^i$	$\mathbf{Q}_\beta^n$	$\mathbf{Q}_\gamma^i$	$\mathbf{Q}_\delta^n$
(2)	$\widetilde{\mathbf{P}}^n$	$\widetilde{\mathbf{P}}^i$	0	$\widetilde{\mathbf{P}}^{i-1} - \widetilde{\mathbf{P}}^i$	0
(3)	1	$\widetilde{\mathbf{P}}^i$	$\sum_{i=1}^n \widetilde{\mathbf{P}}^i$	$\widetilde{\mathbf{P}}^{i-1} - \widetilde{\mathbf{P}}^i$	$\widetilde{\mathbf{P}}^n$
(4)	1	$\widetilde{\mathbf{P}}$	0	0	0
(5)	$\widetilde{\mathbf{P}}^n$	$2\widetilde{\mathbf{P}}^{i+1} - \widetilde{\mathbf{P}}^i$	$\widetilde{\mathbf{P}}^n$	0	0

Performing a complete error analysis for each of these approximate schemes is not tractable. Instead, to characterize the effect of the "approximateness" of the

approximate projection in greater detail, we will use the formulae in (4.1)–(4.2) to compare the solution found using the approximate projection to the solution of the same problem found using the corresponding exact discrete projection $\mathbf{P}$. If we denote by $(\mathbf{U}^n, \mathbf{G}p^{n-1/2})$ the solution with $\widetilde{\mathbf{P}}$ and $(\mathbf{V}^n, \mathbf{G}q^{n-1/2})$ the solution with $\mathbf{P}$, then

$$\mathbf{U}^n - \mathbf{V}^n = (\rho^n(\widetilde{\mathbf{P}}) - \mathbf{P})\mathbf{U}^0 + \Delta t \left(-\sum_{i=1}^{n} \alpha_i(\widetilde{\mathbf{P}})\mathbf{N}_U^{n+1/2-i} + \sum_{i=1}^{n} \mathbf{P}\mathbf{N}_V^{n+1/2-i} - \beta_n(\widetilde{\mathbf{P}})\mathbf{G}p^{-1/2} \right)$$

and

$$\begin{aligned}\Delta t\ (\mathbf{G}p^{n-1/2} - \mathbf{G}q^{n-1/2}) = &-\Delta t\ (\mathbf{I} - \widetilde{\mathbf{P}})\mathbf{N}_U^{n-1/2} + \Delta t\ (\mathbf{I} - \mathbf{P})\mathbf{N}_V^{n-1/2} \\ &-\Delta t\ \sum_{i=2}^{n} \gamma_i(\widetilde{\mathbf{P}})\mathbf{N}_U^{n+1/2-i} + \gamma_n(\widetilde{\mathbf{P}})\mathbf{U}^0 - \Delta t\ \delta_n(\widetilde{\mathbf{P}})\mathbf{G}p^{-1/2},\end{aligned}$$

where $\mathbf{N}_U$ and $\mathbf{N}_V$ denote evaluation of the advective terms with $(\mathbf{U}^n, \mathbf{G}p^{n-1/2})$ and $(\mathbf{V}^n, \mathbf{G}q^{n-1/2})$, respectively.

If we rewrite these expressions, adding and subtracting terms involving $\mathbf{P}\mathbf{N}_U^{n+1/2-i}$ to the equations, we obtain

$$\begin{aligned}\mathbf{U}^n - \mathbf{V}^n = &(\rho^n(\widetilde{\mathbf{P}}) - \mathbf{P})\mathbf{U}^0 - \Delta t\ \sum_{i=1}^{n} (\alpha_i(\widetilde{\mathbf{P}}) - \mathbf{P})\mathbf{N}_U^{n+1/2-i} \\ &-\Delta t\ \sum_{i=1}^{n} \mathbf{P}(\mathbf{N}_U^{n+1/2-i} - \mathbf{N}_V^{n+1/2-i}) - \Delta t\ \beta_n(\widetilde{\mathbf{P}})\mathbf{G}p^{-1/2}\end{aligned}$$

and

$$\begin{aligned}\Delta t\ (\mathbf{G}p^{n-1/2} - \mathbf{G}q^{n-1/2}) = &-\Delta t\ (\mathbf{P} - \widetilde{\mathbf{P}})\mathbf{N}_U^{n-1/2} - \Delta t\ (\mathbf{I} - \mathbf{P})(\mathbf{N}_U^{n-1/2} - \mathbf{N}_V^{n-1/2}) \\ &-\Delta t\ \sum_{i=2}^{n} \gamma_i(\widetilde{\mathbf{P}})\mathbf{N}_U^{n+1/2-i} + \gamma_n(\widetilde{\mathbf{P}})\mathbf{U}^0 - \Delta t\ \delta_n(\widetilde{\mathbf{P}})\mathbf{G}p^{-1/2}.\end{aligned}$$

If we now take norms and use the fact that $||\mathbf{P}|| = 1$ and $||\mathbf{I} - \mathbf{P}|| = 1$, we obtain

$$\begin{aligned}||\mathbf{U}^n - \mathbf{V}^n|| \le &||(\rho^n(\widetilde{\mathbf{P}}) - \mathbf{P})\mathbf{U}^0|| + \Delta t\ \sum_{i=1}^{n} ||(\alpha_i(\widetilde{\mathbf{P}}) - \mathbf{P})\mathbf{N}_U^{n+1/2-i}|| \\ &+\Delta t\ \sum_{i=1}^{n} ||\mathbf{N}_U^{n+1/2-i} - \mathbf{N}_V^{n+1/2-i}|| + \Delta t\ ||\beta_n(\widetilde{\mathbf{P}})\mathbf{G}p^{-1/2}||\end{aligned} \tag{4.3}$$

and

$$\begin{aligned}\Delta t\ ||\mathbf{G}p^{n-1/2} - \mathbf{G}q^{n-1/2}|| \le &\Delta t\ ||(\mathbf{P} - \widetilde{\mathbf{P}})\mathbf{N}_U^{n-1/2}|| + \Delta t\ ||\mathbf{N}_U^{n-1/2} - \mathbf{N}_V^{n-1/2}|| \\ &+\Delta t\ \sum_{i=2}^{n} ||\gamma_i(\widetilde{\mathbf{P}})|N_U^{n+1/2-i}|| + ||\gamma_n(\widetilde{\mathbf{P}})|U^0|| + \Delta t\ ||\delta_n(\widetilde{\mathbf{P}})\mathbf{G}p^{-1/2}||.\end{aligned} \tag{4.4}$$

For the methods considered here $\mathbf{N}_U$ depends on $\mathbf{U}$ and $\mathbf{G}p$ smoothly, likewise $\mathbf{N}_V$ depends on $\mathbf{V}$ and $\mathbf{G}q$ smoothly, so we can assume $||\mathbf{N}_U - \mathbf{N}_V||$ terms are small and can be absorbed into the left-hand side of the equation with the introduction of a

constant multiplier C on the right-hand side. With that assumption, summing (4.3) and (4.4) over n yields

$$\sum_{n=1}^{N}\{||\mathbf{U}^n - \mathbf{V}^n|| + \Delta t\,||\mathbf{G}p^{n-1/2} - \mathbf{G}q^{n-1/2}||\} \le C\sum_{n=1}^{N}\Bigg\{||\rho^n(\widetilde{\mathbf{P}}) - \mathbf{P})\mathbf{U}^0||$$

$$+\Delta t\,\sum_{i=1}^{n}||(\alpha_i(\widetilde{\mathbf{P}}) - \mathbf{P})\mathbf{N}_U^{n+1/2-i}|| + \Delta t\,||\beta_n(\widetilde{\mathbf{P}})\mathbf{G}p^{-1/2}|| + ||\gamma_n(\widetilde{\mathbf{P}})\mathbf{U}^0|| \tag{4.5}$$

$$+\Delta t\,||\delta_n(\widetilde{\mathbf{P}})\mathbf{G}p^{-1/2}|| + \Delta t\,||(\mathbf{P} - \widetilde{\mathbf{P}})\mathbf{N}_U^{n-1/2}|| + \Delta t\,\sum_{i=2}^{n}||\gamma_i(\widetilde{\mathbf{P}})\mathbf{N}_U^{n+1/2-i}||\Bigg\}.$$

From (4.5) we can exactly identify the polynomial expressions which contribute to the error due to the approximateness of the projection; these terms will be examined further in the next section.

Before examining the spatial structure of the different approximate projection schemes, we note that the derivation presented here also provides a characterization of the divergence of the solution of the approximate projection solution. If we apply $\mathbf{D}$ to (4.1) we obtain

$$\mathbf{D}\mathbf{U}^n = \mathbf{D}\rho^n(\widetilde{\mathbf{P}})\mathbf{U}^0 - \Delta t\,\sum_{i=1}^{n}\mathbf{D}\alpha_i(\widetilde{\mathbf{P}})\mathbf{N}_U^{n+1/2-i} - \Delta t\,\mathbf{D}\beta_n(\widetilde{\mathbf{P}})\mathbf{G}p^{-1/2}.$$

Thus, the structure of the spatial operators described below also provides a characterization of the divergence. Furthermore, since $\widetilde{\mathbf{P}}$ and $\mathbf{P}$ do not change discretely divergence-free fields, the error terms in the estimate (4.5) are discrete gradients. This explains the correspondence between the quality of the computational results and the behavior of the discrete divergence of the solution.

5. Spatial analysis of the projection. The temporal analysis of the previous section provides a basic framework for understanding the behavior of approximate projection schemes. The details of this behavior depend on the details of the spatial structure of the approximate projections. In this section we will analyze that behavior for the **N5, N9**, and **C5** approximate projections. In particular, we will look at how well the polynomials of $\widetilde{\mathbf{P}}$ that characterize the approximate projections approximate the corresponding exact discrete projection.

Before looking at the behavior of the approximate projections, however, we first need to characterize the structure of the corresponding exact discrete projection, $\mathbf{I} - \mathbf{G}(\mathbf{D}\mathbf{G})^{-1}\mathbf{D}$. As noted earlier, the difficulties associated with using these exact discrete projections arise from the (locally) decoupled stencils associated with $\mathbf{D}\mathbf{G}$. This local decoupling is related to the presence of elements in the kernel of $\mathbf{G}$ other than constants. In two dimensions, for the nodal scheme dim ker $\mathbf{G} = 2$ and for the cell-centered scheme dim ker $\mathbf{G} = 4$. For each of these methods one of these elements corresponds to constants and the other modes are spurious. For the nodal scheme this additional mode corresponds to the Nyquist frequency in both directions. This mode is also in ker $\mathbf{G}$ for the cell-centered scheme, as well as vertical and horizontal "stripe" modes corresponding to the Nyquist frequency in one component and constant in the other. These modes can be seen in Figure 2(c), (g).

To characterize the projections we will look at their Fourier behavior. After the Fourier transform, the projection has the form of a 2×2 matrix for each wave number. As noted above, discretely divergence-free vector fields are unchanged by

both the exact discrete and the approximate projections, thus both the exact discrete and approximate versions share an eigenvalue of 1 with a common eigenvector. To characterize the behavior we can then focus on the other eigenvalue, λ_{min}. For $\mathbf{P}$, $\lambda_{min} = 0$ except for wave numbers corresponding to elements in ker $\mathbf{G}$. In Figure 5 we show λ_{min} for the **N9, N5**, and **C5** approximate projection operators, $\widetilde{\mathbf{P}}$. The plots of λ_{min} for **N_EX** would have a single spike to value 1 at the center, corresponding to the checkerboard mode; the plots for **C_EX** would have spikes at the center and the midpoints of each side, corresponding to the checkerboard and "stripe" modes. In Figures 5–9 the center of each plot corresponds to the Nyquist frequency in both directions with constants at the corner. (The peak at constants has been suppressed.)

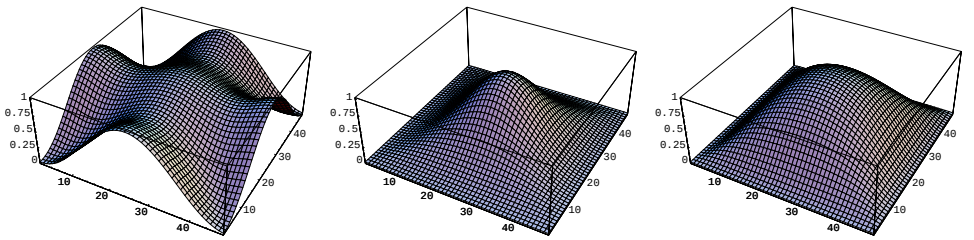

FIG. 5. *Smallest eigenvalue λ_{min} of the approximate projections* (a) **C5**, (b) **N9**, *and* (c) **N5**.

In each case we see that λ_{min} for the approximate projection operator has a smooth peak near the elements of ker $\mathbf{G}$ for the corresponding exact discrete projection. Thus, because of additional elements in ker $\mathbf{G}$ the cell-centered discretization broadens the range over which the approximation is a poor one. We also note that the eigenvalue structure of the five-point nodal projection is similar to that of the nine-point nodal only with a slightly wider distribution. A key property of each discretization is that $\widetilde{\mathbf{P}}^n \to \mathbf{P}$ as $n \to \infty$.

From the characterization of the approximate projection in Figure 5 we can already explain the poor performance of versions (3) and (4) of the approximate projection method. In version (4), $\alpha_i(\widetilde{\mathbf{P}}) = \widetilde{\mathbf{P}}$ and so, recalling (4.1), we see that at each time step $\mathbf{U}$ accumulates a portion of the discrete gradient component of $\mathbf{N}$, resulting in an error that builds over time. By contrast, for version (2), $\alpha_i(\widetilde{\mathbf{P}}) = \widetilde{\mathbf{P}}^i$, so that the contributions from any fixed time converge to the correct contribution as n increases, because $\widetilde{\mathbf{P}}^n \to \mathbf{P}$.

The difficulty with version (3), on the other hand, is caused by a residual imprint of pressure as characterized by the β_n. Recall that for version (3), $\beta_n = \sum_i \widetilde{\mathbf{P}}^i$. For each eigenvalue we can write

$$\widetilde{\mathbf{P}}(\mathbf{G}\phi(\xi)) = \lambda(\xi)\mathbf{G}\phi(\xi), \quad 0 < \lambda < 1;$$

then for version (3)

$$\beta_n(\widetilde{\mathbf{P}})\mathbf{G}(\xi) \equiv (\widetilde{\mathbf{P}} + \widetilde{\mathbf{P}}^2 + \cdots + \widetilde{\mathbf{P}}^n)\mathbf{G}\phi(\xi) \to \frac{\lambda}{\lambda - 1}\mathbf{G}\phi(\xi),$$

so that the pressure gradient terms in $\mathbf{U}$ that are annihilated by the exact discrete projection asymptote to a nonnegligible error in $\mathbf{U}$ with an approximate projection. By contrast, we note that this type of term is absent for version (2) (i.e., $\beta_n = 0$) which is otherwise similar in structure to version (3).

To characterize the other versions of the approximate projection we look at the α_i in more detail. For each of the other three versions ((1), (2), and (5)) of the approximate projection, the lowest power of $\widetilde{\mathbf{P}}$ in α_i increases with i. Furthermore, the coefficients in α_i sum to 1. Therefore, for each version $\alpha_i(\widetilde{\mathbf{P}}) \to \mathbf{P}$ as $i \to \infty$. To obtain a more detailed comparison we need to look at the behavior of the α_i for small i.

For each version $\alpha_1(\widetilde{\mathbf{P}}) = \widetilde{\mathbf{P}}$ which is described above and illustrated in Figure 5. For the next two terms in the expressions, for version (1), $\alpha_2 = 2\widetilde{\mathbf{P}}^2 - \widetilde{\mathbf{P}}$, $\alpha_3 = 4\widetilde{\mathbf{P}}^3 - 3\widetilde{\mathbf{P}}^2$; for version (2), $\alpha_2 = \widetilde{\mathbf{P}}^2, \alpha_3 = \widetilde{\mathbf{P}}^3$; and for version (5), $\alpha_2 = 2\widetilde{\mathbf{P}}^2 - \widetilde{\mathbf{P}}, \alpha_3 = 2\widetilde{\mathbf{P}}^3 - \widetilde{\mathbf{P}}^2$. In Figures 6 and 7 we plot α_2 and α_3, respectively, for **C5_1**, **C5_2**, and **C5_5**, and **N9_1**, **N9_2**, and **N9_5**. (The **N5** results are similar to the **N9** results, only somewhat wider.)

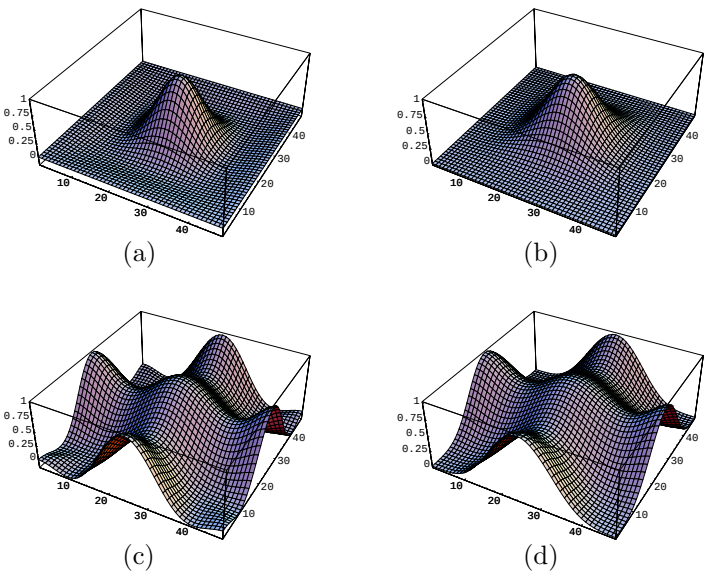

FIG. 6. α_2 *for* (a) **C5_1, C5_5**, (b) **C5_2**, (c) **N9_1, N9_5**, (d) **N9_2**.

For α_2, we note that for versions (1) and (5) there is a narrower peak than for version (2) near the frequencies that are in ker $\mathbf{G}$, with some small negative values at intermediate frequencies. Overall it is smaller in an L^2 integral sense. A similar pattern is observed for the α_3's. For version (2), the peak is fairly broad but the values are between 0 and 1. For version (5), the peak is narrow and there is a small region where the values are slightly negative ($\lambda_{min} > -.04$). For version (1), the peak near the ker $\mathbf{G}$ elements is sharpest but there are fairly large negative values ($\lambda_{min} = -.25$). Although version (1) is the smallest in an integral sense, the negative values can introduce perturbations into the solution which may be a contributing factor to the nonrobustness of version (1).

There are two other potential sources for the behavior of version (1). As with version (3), version (1) contains a residual contribution from the pressure gradient (i.e., $\beta_n \neq 0$). For version (2) there is no such term; for version (5) this term is $\widetilde{\mathbf{P}}^n$ which goes to zero on the range of $\mathbf{G}$ as $n \to \infty$. For version (1), this behavior is characterized by the behavior of the $\mathbf{Q}_\beta$'s defined in section 5. In Figure 8 we

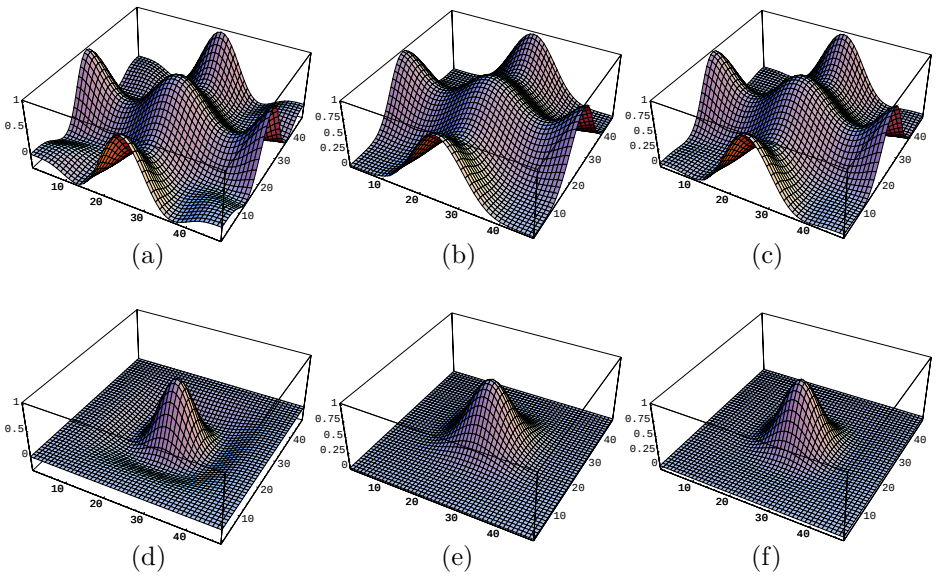

FIG. 7. α_3 *for* (a) **C5_1**, (b) **C5_2**, (c) **C5_5**, (d) **N9_1**, (e) **N9_2**, (f) **N9_5**.

plot the functions β_2, β_3, and β_4 for **N9_1**. Unlike the operators for version (3) which asymptotically converge to nonzero values, the operators described here do not converge to zero for any fixed frequency except those near elements in ker G. However, the peak value near elements in ker $\mathbf{G}$ is n for the β_n for version (1), just as in version (3) but with a narrower peak. This growth in residual influence of $\mathbf{G}p^{-1/2}$ also has the potential for contribution to the nonrobust behavior of version (1).

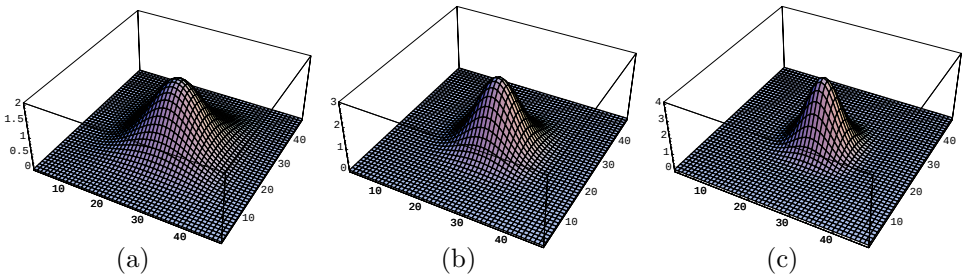

FIG. 8. (a) β_2, (b) β_3, *and* (c) β_4 *for the* **N9_1** *approximate projection.*

The final issue regarding the spatial structure associated with the approximate projection versions concerns the error in $\mathbf{G}p^{n-1/2}$ associated with the $\mathbf{N}$'s (recall equation (4.2)). For all versions the leading error term looks like $\mathbf{P} - \widetilde{\mathbf{P}}$, which we have already examined. For versions (4) and (5) there are no other terms. In Figure 9 we show γ_2, γ_3, and γ_4 for **N9_1**. The functions γ_i for **N9_2** and **N9_3** are similar to those shown but have smaller overall magnitudes (0.2 v. 0.4 for γ_2, 0.15 v. 0.3 for γ_3, and 0.1 v. 0.3 for γ_4) and, unlike for version (1), remain positive at all frequencies.

To summarize the findings, we first note that the unacceptable performance of versions (3) and (4) can be related to an imprint of the old pressure gradients and a failure to damp the gradient components of the advection terms, respectively. We have

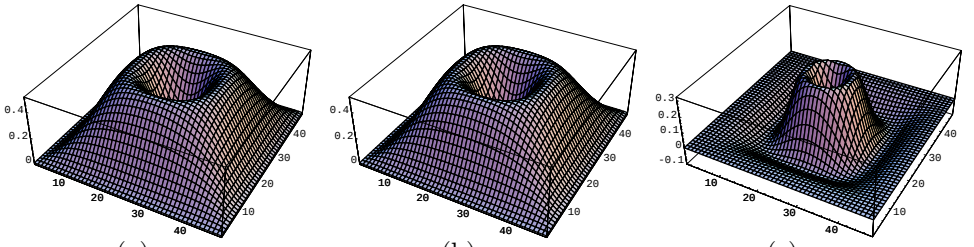

FIG. 9. (a) γ_2, (b) γ_3, *and* (c) γ_4 *for the* **N9_1** *approximate projection.*

identified three features of version (1) which may contribute to its lack of robustness. The first is the oscillatory nature of the α_i; however, this is a relatively small effect and probably plays a negligible role in determining the overall behavior. The other two features, a growing imprint of the old pressure gradient on $\mathbf{U}$ given by the β_i's combined with the errors introduced into $\mathbf{G}p$ from the advection terms specified by the γ_i's, provide a mechanism for feeding back oscillatory behavior into the solution.

6. Advection-projection coupling. As we can see from the numerical results and the analysis, the nature of the difficulties for versions (3) and (4) differs from that of version (1). This is evident as well in further numerical testing. Here we perform two additional numerical experiments with the random initial vorticity problem. In the first we halve the time step in each calculation by reducing the CFL number from 0.9 to 0.45 to examine the effect on the solution. In the top row of Figure 10, for resolution 64^2, we see that the results from versions (3) and (4) are essentially unchanged but the results from version (1) are markedly improved (i.e., lower divergence) relative to the results shown in Figure 3. Version (1) has also been rerun for resolution 128^2, with the same improvement.

Our second experiment is to modify the predictor so that the coupling between the pressure gradient $\mathbf{G}p^{n-1/2}$ and the advective update term $\mathbf{N}^{n+1/2}$ is reduced, by MAC-projecting the advected velocities as well as the advection velocities in the predictor step. This modification is described in more detail in Appendix A. The results for the same cases as above are shown in the bottom row of Figure 10; here the results of versions (3) and (4) are worsened (in the sense that the divergence is larger) but the divergence from version (1) is again noticeably lower, again compared to Figure 3. This experiment was run with CFL = 0.9.

The results in this section suggest that the poor results obtained with versions (3) and (4), and the acceptable results of versions (2) and (5), are independent of the choice of advection scheme. By contrast, the behavior of version (1) for inviscid flow is intimately coupled to the details of the particular advection method.

7. Conclusions and future work. When adopting an approximate projection formulation in which the projection operator does not exactly enforce a discrete divergence condition on the velocity field, there are several options for choosing which vector field to project. In this paper we have explored these options computationally and developed an analytical framework that explains the computational results. The results show that projecting the velocity field rather than the velocity increment is necessary to produce acceptable results. We also find that projecting $\frac{\mathbf{U}^{*,n+1}}{\Delta t}$ (version (1)) can produce a lower divergence in the computed solution than projecting $\frac{\mathbf{U}^{*,n+1}}{\Delta t} + \mathbf{G}p^{n-1/2}$ (version (2)); however, it is not as robust as version (2) which always

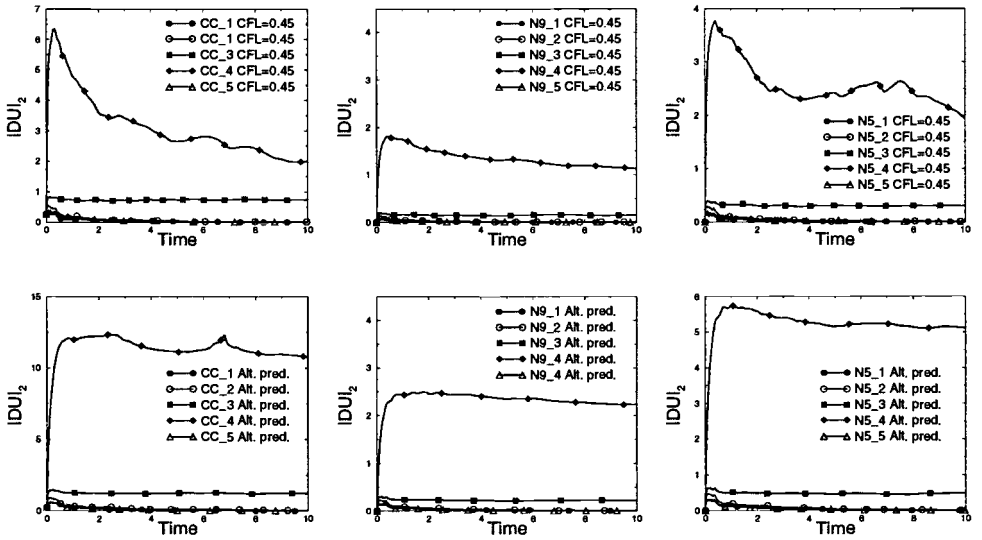

FIG. 10. *L^2 norms of* $\mathbf{DU}$ *from* $t = 0$ *to* 10 *for the random initial vorticity problem with CFL* $= 0.45$ *(top row), or the alternate predictor (bottom row).*

produces acceptable results.

We have also introduced a new approximate projection formulation based on projecting $\frac{\mathbf{U}^{*,n+1}}{\Delta t}$ to update $\mathbf{U}^{n+1}$ while projecting $\frac{\mathbf{U}^{*,n+1}-\mathbf{U}^n}{\Delta t}+\mathbf{G}p^{n-1/2}$ as an iterative correction to update p. The new formulation produces results similar to version (1) when version (1) is successful and exhibits the same robustness as version (2).

In Part II we will present the extension of the analysis to viscous flows, in the context of a Crank–Nicolson discretization of the viscous terms. This discretization requires the application of the inverse diffusion operator before the projection step. As a consequence, the expressions for $\mathbf{U}^n$ and $\mathbf{G}p^{n-1/2}$, presented in Tables 1 and 2 of this paper, and the analysis of these expressions, become much more complicated. One interesting consequence is that while minor variations in the advection step can be exploited to obtain better results with version (1) in the case of inviscid flow, when viscosity is introduced the poor behavior of version (1) cannot be salvaged.

Further issues and future work will include the extension of the analysis for variable density flows, adaptive mesh calculations with subcycling in time, and low Mach number flows with nonzero divergence constraints.

Appendix A. The predictor/corrector step. In this section we first describe the construction of the advective update $\mathbf{N}^{n+1/2}$ used in our original tests; then we discuss the modifications as discussed in section 6.

In the predictor we first extrapolate the normal velocities to cell faces at $t^{n+1/2}$. For face $(i+1/2, j)$ this gives

$$\widetilde{u}^{L,n+1/2}_{i+1/2,j} = u^n_{i,j} + \left(\frac{\Delta x}{2} - u^n_{i,j}\frac{\Delta t}{2}\right)(u_x^{n,lim})_{i,j} + \frac{\Delta t}{2}(-(\widehat{vu_y})_{i,j} - (G_x p)^{n-1/2}_{i,j})$$

extrapolated from (i, j), and

$$\widetilde{u}^{R,n+1/2}_{i+1/2,j} = u^n_{i+1,j} - \left(\frac{\Delta x}{2} + u^n_{i+1,j}\frac{\Delta t}{2}\right)(u_x^{n,lim})_{i+1,j} + \frac{\Delta t}{2}(-(\widehat{vu_y})_{i+1,j} - (G_x p)^{n-1/2}_{i+1,j})$$

extrapolated from $(i+1,j)$. Here the first derivatives normal to the face (in this case $u_x^{n,lim}$) are evaluated using a monotonicity-limited fourth-order slope approximation [6] (except in the translating vortices problem, where unlimited fourth-order slopes are used), and the transverse derivative terms ($\widehat{vu_y}$ in this case) are evaluated exactly as in [1]. $\mathbf{G} = (G_x, G_y)$ is a discretization of the gradient operator. For a nodal pressure field,

$$(G_x p)_{i,j} = \frac{1}{4\Delta x}(p_{i+1/2,j+1/2} + p_{i+1/2,j-1/2} - p_{i-1/2,j+1/2} - p_{i-1/2,j-1/2}),$$
$$(G_y p)_{i,j} = \frac{1}{4\Delta y}(p_{i+1/2,j+1/2} + p_{i-1/2,j+1/2} - p_{i+1/2,j-1/2} - p_{i-1/2,j-1/2}).$$

For a cell-centered pressure field,

$$(G_x p)_{i,j} = \frac{1}{2\Delta x}(p_{i+1,j} - p_{i-1,j}),$$
$$(G_y p)_{i,j} = \frac{1}{2\Delta x}(p_{i,j+1} - p_{i,j-1}).$$

Analogous formulae are used to predict values for $\widetilde{u}^{L/R,n+1/2}_{i-1/2,j}$, $\widetilde{v}^{F/B,n+1/2}_{i,j+1/2}$, and $\widetilde{v}^{F/B,n+1/2}_{i,j-1/2}$.

The normal velocity at each face is then determined by an upwinding procedure based on the states predicted from the cell centers on either side.

$$\widetilde{u}^{n+1/2}_{i+1/2,j} = \begin{cases} \widetilde{u}^{L,n+1/2} & \text{if } \widetilde{u}^{L,n+1/2} > 0 \text{ and } \widetilde{u}^{L,n+1/2} + \widetilde{u}^{R,n+1/2} > 0, \\ 0 & \text{if } \widetilde{u}^{L,n+1/2} \le 0, \widetilde{u}^{R,n+1/2} \ge 0 \text{ or } \widetilde{u}^{L,n+1/2} + \widetilde{u}^{R,n+1/2} = 0, \\ \widetilde{u}^{R,n+1/2} & \text{if } \widetilde{u}^{R,n+1/2} < 0 \text{ and } \widetilde{u}^{L,n+1/2} + \widetilde{u}^{R,n+1/2} < 0. \end{cases}$$

We follow a similar procedure to construct $\widetilde{v}^{n+1/2}_{i,j+1/2}$.

In order to enforce the divergence-free condition on these edge-based velocities we now impose the MAC projection (see [4]). The equation

$$\mathbf{D}^{MAC}(\mathbf{G}^{MAC}\phi^{MAC}) = \mathbf{D}^{MAC}(\widetilde{U}^{n+1/2})$$

is solved for ϕ^{MAC}, with homogeneous Neumann boundary conditions on all physical boundaries except for outflow, where ϕ^{MAC} is set to zero to enforce the "no tangential acceleration" criterion. Here

$$\mathbf{D}^{MAC}(\widetilde{U}^{n+1/2}) = \frac{\widetilde{u}^{n+1/2}_{i+1/2,j} - \widetilde{u}^{n+1/2}_{i-1/2,j}}{\Delta x} + \frac{\widetilde{v}^{n+1/2}_{i,j+1/2} - \widetilde{v}^{n+1/2}_{i,j-1/2}}{\Delta y}$$

and $\mathbf{G}^{MAC} = -(\mathbf{D}^{MAC})^T$ so that

$$(G_x^{MAC}\phi^{MAC})_{i+1/2,j} = \frac{(\phi^{MAC}_{i+1,j} - \phi^{MAC}_{i,j})}{\Delta x}, \quad (G_y^{MAC}\phi^{MAC})_{i,j+1/2} = \frac{(\phi^{MAC}_{i,j+1} - \phi^{MAC}_{i,j})}{\Delta x}.$$

The advection velocity U^{ADV} is then defined by

$$u^{ADV}_{i+1/2,j} = \widetilde{u}^{n+1/2}_{i+1/2,j} - (G_x^{MAC}\phi^{MAC}),$$
$$v^{ADV}_{i,j+1/2} = \widetilde{v}^{n+1/2}_{i,j+1/2} - (G_y^{MAC}\phi^{MAC}).$$

At this point the tracing step from cell centers to edges is performed for both the normal and tangential velocity components exactly as above, except that the upwinding now depends on the MAC-projected advection velocity, i.e.,

$$\widetilde{U}_{i+1/2,j} = \begin{cases} \widetilde{U}^L & \text{if } u^{ADV}_{i+1/2,j} > 0, \\ 1/2(\widetilde{U}^L + \widetilde{U}^R) & \text{if } u^{ADV}_{i+1/2,j} = 0, \\ \widetilde{U}^R & \text{if } u^{ADV}_{i+1/2,j} < 0. \end{cases}$$

For the original advective term, we now define

$$\mathbf{N}_{i,j} = \frac{(u^{ADV}_{i+1/2,j}\widetilde{U}_{i+1/2,j} - u^{ADV}_{i-1/2,j}\widetilde{U}_{i-1/2,j})}{\Delta x} + \frac{(v^{ADV}_{i,j+1/2}\widetilde{U}_{i,j+1/2} - v^{ADV}_{i,j-1/2}\widetilde{U}_{i,j-1/2})}{\Delta y}.$$

The modification of the predictor as described in section 6 is the replacement of $\widetilde{U}$ by $\widetilde{\widetilde{U}} = (\widetilde{\widetilde{u}}, \widetilde{\widetilde{v}})$ in the above expression, where

$$\begin{aligned} \widetilde{\widetilde{u}}_{i+1/2,j} &= u^{ADV}_{i,j+1/2}, \\ \widetilde{\widetilde{u}}_{i,j+1/2} &= \widetilde{u}_{i,j+1/2} - \frac{1}{4\Delta x}(\phi^{MAC}_{i+1,j} + \phi^{MAC}_{i+1,j-1} - \phi^{MAC}_{i-1,j} - \phi^{MAC}_{i-1,j-1}), \\ \widetilde{\widetilde{v}}_{i+1/2,j} &= \widetilde{v}_{i+1/2,j} - \frac{1}{4\Delta x}(\phi^{MAC}_{i,j+1} + \phi^{MAC}_{i-1,j+1} - \phi^{MAC}_{i,j-1} - \phi^{MAC}_{i-1,j-1}), \\ \widetilde{\widetilde{v}}_{i,j+1/2} &= v^{ADV}_{i+1/2,j}. \end{aligned}$$

Then

$$\mathbf{N}_{i,j} = \frac{(u^{ADV}_{i+1/2,j}\widetilde{\widetilde{U}}_{i+1/2,j} - u^{ADV}_{i-1/2,j}\widetilde{\widetilde{U}}_{i-1/2,j})}{\Delta x} + \frac{(v^{ADV}_{i,j+1/2}\widetilde{\widetilde{U}}_{i,j+1/2} - v^{ADV}_{i,j-1/2}\widetilde{\widetilde{U}}_{i,j-1/2})}{\Delta y}.$$

Appendix B. Approximate projection operators in three dimensions. In this appendix we provide a characterization of the extension of the three different spatial approximate projections considered above to three space dimensions. We will refer to the seven-point cell-centered discretization as **C7**, the 21-point nodal discretization as **N21**, and the seven-point nodal discretization as **N7.** As before, the approximate projections do not alter discretely divergence-free vector fields. In three dimensions this means that the discrete projection operator is a 3×3 matrix for each frequency with two eigenvalues of 1. The other eigenvalue, λ_{min}, represents the degree to which gradients are damped by the projection. For **C7** there are 8 elements in ker **G** while for **N7** and **N21** there is a one-dimensional family of elements. As a further characterization of these schemes, we can expand the smallest eigenvalue about the constant mode to obtain the behavior of the different approximations for low frequencies. In particular, for **C7** we obtain

$$\lambda_{min}(k_1, k_2, k_3) = \frac{(k_1^4 + k_1^4 + k4^2)}{2(k_1^2 + k_2^2 + k_3^2)},$$

for **N21** we obtain

$$\lambda_{min}(k_1, k_2, k_3) = \frac{(k_1^2k_2^2 + k_1^2k_3^2 + k_2^2k_3^2)}{6(k_1^2 + k_2^2 + k_3^2)},$$

and for **N7** we obtain

$$\lambda_{min}(k_1, k_2, k_3) = \frac{(k_1^2 k_2^2 + k_1^2 k_3^2 + k_2^2 k_3^2)}{2(k_1^2 + k_2^2 + k_3^2)}.$$

A LEVINSON–GALERKIN ALGORITHM FOR REGULARIZED TRIGONOMETRIC APPROXIMATION*

THOMAS STROHMER†

Abstract. Trigonometric polynomials are widely used for the approximation of a smooth function from a set of nonuniformly spaced samples. If the samples are perturbed by noise, a good choice for the polynomial degree of the trigonometric approximation becomes an essential issue to avoid overfitting and underfitting of the data. Standard methods for trigonometric least squares approximation assume that the degree for the approximating polynomial is known a priori, which is usually not the case in practice. We derive a multilevel algorithm that recursively adapts to the least squares solution of suitable degree. We analyze under which conditions this multilevel approach yields the optimal solution. The proposed algorithm computes the solution in at most $\mathcal{O}(rM + M^2)$ operations (M being the polynomial degree of the approximation and r being the number of samples) by solving a family of nested Toeplitz systems. It is shown how the presented method can be extended to multivariate trigonometric approximation. We demonstrate the performance of the algorithm by applying it in echocardiography to the recovery of the boundary of the left ventricle of the heart.

1. Introduction.

The necessity of recovering a function from a finite set of nonuniformly spaced measurements arises in areas as diverse as digital signal processing, geophysics, spectroscopy, and medical imaging. The measurements $\{s_j\}_{j=1}^r$ are often distorted by several kinds of errors. Hence a complete reconstruction of the function from the perturbed data $s_j^\varepsilon = s_j + \nu_j$ is not possible. Often the function to be reconstructed is smooth, in which case a trigonometric polynomial of relatively low degree (compared with the possibly huge number of samples) can provide a good approximation to the function. This trigonometric approximation may be found by solving the least squares problem

$$\min_{p \in \boldsymbol{P}_M} \sum_{j=1}^{r} |p(x_j) - s_j^\varepsilon|^2 w_j, \tag{1.1}$$

where $w_j > 0$ are weights and $\boldsymbol{P}_M$ is the space of trigonometric polynomials of degree less than or equal to M.

Many efficient algorithms have been developed to solve (1.1); e.g., see the articles [22, 7, 25, 11, 10]. But surprisingly little attention has been paid to the problem of how to control the smoothness of the approximation in order to avoid overfitting and underfitting of the data. An adaptation of the smoothness of the approximation can be achieved, for instance, by providing a suitable upper bound for the degree M of the space $\boldsymbol{P}_M$ in (1.1). In most of the aforementioned algorithms a necessary requirement to get useful results in applications is that a good a priori guess of the degree of the

trigonometric approximation is available. However, a priori it is not clear what is a suitable degree for the solution, in terms of how to choose a reasonable degree M when solving (1.1). Determining M by "trial and error" is certainly not a satisfactory alternative.

It is the goal of this paper to derive an efficient algorithm that computes the trigonometric approximation that provides the "optimal" balance between fitting the given data and preserving smoothness of the solution. Here optimality is meant in the sense that the solution has minimal degree among all trigonometric polynomials that satisfy a certain least squares criterion. The algorithm recursively adapts to the least squares approximation of optimal degree by solving a family of nested Toeplitz systems in at most $\mathcal{O}(Mr + M^2)$ operations.

If the data $\{s_j^\varepsilon\}_{j=1}^r$ (i) were unperturbed and (ii) stem from sampling a trigonometric polynomial (with degree less than $r/2$), then the solution of (1.1) would automatically have the appropriate degree, since the original function could be completely recovered in this case. However, the assumptions (i) and (ii) are rarely met in applications, and controlling the smoothness of the solution becomes essential to avoid overfitting and underfitting of the data. If we choose the upper bound for the degree in (1.1) too large, the solution will almost always take on the maximal possible degree; hence it will be too wiggly and pick up too much noise (overfit); see also Figure 1.1(a)–(b). In the extreme case $2M + 1 = r$ we will get an interpolating polynomial, mostly with strong oscillations and far away from approximating the function between the given samples. On the other hand, if we choose M too small, then the approximation will be very smooth but will poorly fit the given data (underfit). Figure 1.1(c) illustrates this behavior. The "regularized" trigonometric approximation obtained by the algorithm proposed in this paper—which we will refer to as the *Levinson–Galerkin algorithm*—is shown in Figure 1.1(d).

The paper is organized as follows. In sections 2 and 4 we present the main results, including the Levinson–Galerkin algorithm and a theoretical analysis that clarifies under which conditions this algorithm provides optimal results. In section 3 we show how properly chosen weights can be used as a simple but efficient tool to precondition the least squares problem. Some aspects of extending the algorithm to multivariate trigonometric polynomials are discussed in section 5. In section 6 we apply the proposed algorithm to a problem in echocardiography.

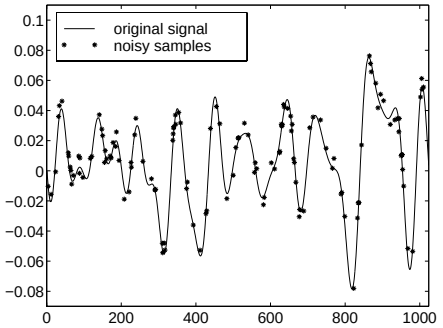
Before we proceed we introduce some notation and conventions. The inner product is denoted by $\langle \cdot, \cdot \rangle$, and the conjugate transpose of a matrix A by A^*. The space of trigonometric polynomial of degree equal to or less than M is defined as

$$\boldsymbol{P}_M = \left\{ p : p(x) = \sum_{k=-M}^{M} c_k e^{2\pi i k x} \right\}. \tag{1.2}$$

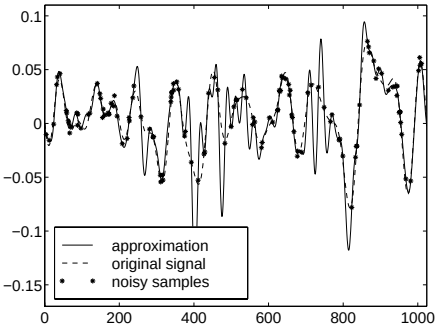
The norm of $p(x) = \sum_{k=-M}^{M} c_k e^{2\pi i k x} \in \boldsymbol{P}_M$ is given by

$$\|p\| = \left(\int_0^1 |p(x)|^2 \, dx \right)^{\frac{1}{2}} = \left(\sum_{k=-M}^{M} |c_k|^2 \right)^{\frac{1}{2}} = \|c\|, \tag{1.3}$$

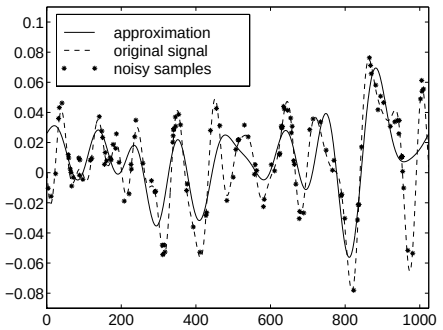
where $c = \{c_k\}_{k=-M}^{M}$. In some applications it is advantageous to deal with complex-valued polynomials (see also section 6); hence we do not restrict ourselves to the case of real-valued trigonometric approximation.



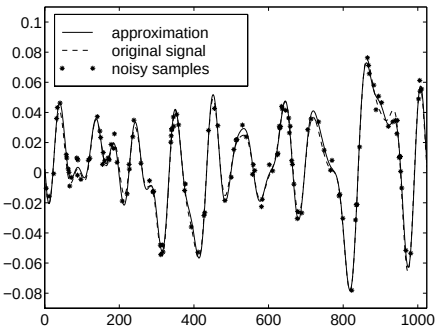
(a) Original signal and perturbed samples



(b) Least squares approximation using a too large upper bound for the degree of the polynomial (overfit)



(c) Least squares approximation using a too small upper bound for the degree of the polynomial (underfit)



(d) Regularized approximation by proposed Levinson–Galerkin algorithm

FIG. 1.1. *Controlling the smoothness of the solution is essential for trigonometric approximation from perturbed data in order to avoid overfitting and underfitting of the data. The proposed Levinson–Galerkin algorithm automatically adapts to the least squares solution of optimal degree.*

For $a = [a_{-M}, a_{-M+1}, \ldots, a_{M-1}, a_M] \in \mathbb{C}^{2M+1}$ we define the orthogonal projections P_N by

$$P_N a = [0, \ldots, 0, a_{-N}, a_{-N+1}, \ldots, a_{N-1}, a_N, 0, \ldots, 0] \tag{1.4}$$

for $N = 1, 2, \ldots, M$ and identify the image of P_N with the $2N+1$-dimensional space $\mathbb{C}^{2N+1}$.

Let p^M and p^N be trigonometric polynomials of degree M and N, respectively, with coefficient vectors $c^M \in \mathbb{C}^{2M+1}$, $c^N \in \mathbb{C}^{2N+1}$. If $N < M$, then we can always interpret p^N as a polynomial of degree M by adding an appropriate number of zero coefficients, and by doing so we are embedding the vector c^N into a zero-padded vector of length $2M+1$. We will henceforth tacitly assume that such an embedding has been made, when we compute expressions such as $\|c^M - c^N\|$.

2. Multilevel least squares approximation. A standard method in numerical analysis to find the optimal balance between fitting the given data and preserving smoothness of the solution is to introduce a regularization parameter. The best value of this regularization parameter is then determined, for instance, by generalized cross validation [15] or via the L-curve [20]. Here we understand regularization not as a way to stabilize ill-conditioned problems, but in a broader context as a means of finding the best compromise between fitting a given set of data and preserving smoothness of the solution. As we will see, in our case it is not necessary to introduce an additional parameter, since we can regularize the smoothness of the solution by varying the parameter M of the space $\boldsymbol{P}_M$ in which we are searching for the solution of (1.1).

For the derivation of the algorithm we consider first the following situation. Assume $p_*(x) = \sum_{k=-N_*}^{N_*} (c_*)_k e^{2\pi i k x} \in \boldsymbol{P}_{N_*}$, and let $s^\varepsilon = \{s_j^\varepsilon\}_{j=1}^r, 2M+1 \le r$ with $s_j^\varepsilon = s_j + \nu_j = p_*(x_j) + \nu_j$ be given noisy samples satisfying

$$\|s^\varepsilon - s\|^2 \le \varepsilon \|s^\varepsilon\|^2. \tag{2.1}$$

For convenience we assume that r, the number of samples, is odd.

The aim is to approximate p_* from the data $\{s_j^\varepsilon\}_{j=1}^r$. Let us first assume that we already know that we are searching for our least squares solution in the space $\boldsymbol{P}_{N_*}$. In this case the coefficient vector of the polynomial that solves (1.1) is the least squares solution of

$$W V_{N_*} c = W s^\varepsilon\,, \tag{2.2}$$

where V_{N_*} is an $r \times (2N_*+1)$ Vandermonde matrix with entries

$$(V_M)_{j,k} = e^{2\pi i k x_j}, \quad j = 1, \dots, r, \quad k = -N_*, \dots, N_*, \tag{2.3}$$

and $W = \operatorname{diag}(\{\sqrt{w_j}\})$.

We will discuss the role and specific choice of the weights in more detail in section 3. To reduce the notational burden we absorb the weight matrix W in the Vandermonde matrix and in the sampling values. Thus for given degree, M, say, we consider the linear system of equations

$$V_M c = s^\varepsilon, \tag{2.4}$$

where V_M is now the $r \times (2M+1)$ "weighted Vandermonde" matrix. We will denote the least squares solution of (2.4) by $c^{(M)} = \{c_k^{(M)}\}_{k=-M}^M$, and the corresponding polynomial is $p^{(M)}(x) = \sum_{k=-M}^M c_k^{(M)} e^{2\pi i k x}$.

Since in general we do not know the optimal degree or *level* M of the space $\boldsymbol{P}_M$ in which we should solve the least squares problem, the situation becomes considerably more complicated. If we want to solve (1.1) under the information (2.1) without knowing the degree of the polynomial, one may argue that we have to accept any trigonometric polynomial $p(x) = \sum_{k=-N}^N c_k e^{2\pi i k x}$ with $\|V_N c - s^\varepsilon\| \le \varepsilon \|s^\varepsilon\|$ as an approximate solution to p_*, since it is compatible with the only knowledge we have on the data.

In general there may be infinitely many such polynomials, which raises the questions of how to find a polynomial p that yields a small approximation error $\|p_* - p\|$ and at the same time can be computed efficiently.

2.1. A multilevel algorithm and an efficient stopping criterion. The heuristic considerations above suggest the following approach.

ALGORITHM 1. *Set $N = 0$ and solve $V_0 c^{(0)} = s^\varepsilon$. If $c^{(0)}$ satisfies the condition $\|V_0 c^{(0)} - s^\varepsilon\| \le \varepsilon \|s^\varepsilon\|$, take $c^{(0)}$ as the solution. Otherwise set $N = N + 1$ and solve*

$$V_N c^{(N)} = s^\varepsilon \,, \tag{2.5}$$

until $c^{(N)}$ satisfies for the first time the stopping criterion

$$\|V_N c^{(N)} - s^\varepsilon\| \le \varepsilon \|s^\varepsilon\| \tag{2.6}$$

at some level $N = N_0$. Set $c^{(N_0)} = c^{(N)}$. The approximation to p_* is then $p^{(N_0)}(x) = \sum_{k=-M}^{M} c_k^{(N_0)} e^{2\pi i k x}$.

The stopping criterion (2.6) is well defined, since it is definitely satisfied for $N = (r-1)/2$, in which case the left side of (2.6) equals 0. Thus Algorithm 1 selects among all least squares solutions $p^{(N)}$ with degree $N = 0, \dots, (r-1)/2$, that polynomial with minimal degree N_0.

Algorithm 1 and stopping criterion (2.6) can be justified by the following theoretical considerations.

One readily verifies that the matrices $V_N, N = 0, \dots, (r-1)/2$, satisfy the following relations:

(i) There exists a left inverse V_N^+ such that

$$V_N^+ V_N = I_N \quad \text{with } V_N^+ = (V_N^* V_N)^{-1} V_N^*, \tag{2.7}$$

where I_N is the identity matrix on $\mathbb{C}^{2N+1}$.

(ii) Let $a \in \mathbb{C}^{2M+1}$ be the coefficient vector of some $p \in \boldsymbol{P}_M$. Then

$$V_N a = V_M a \qquad \text{for all } N > M,\ a \in \mathbb{C}^{2M+1}. \tag{2.8}$$

In (ii) we have made use of the fact that the coefficient vector a can be interpreted as a coefficient vector of a polynomial of degree N by extending it to a vector of length $2N+1$ via zero padding. The matrix–vector multiplication $V_M a$ and (2.8) should be understood in this sense.

LEMMA 2.1. *If $N \ge N_*$, then $c^{(N)}$ satisfies $\|V_N c^{(N)} - s^\varepsilon\| \le \varepsilon \|s^\varepsilon\|$; hence the stopping criterion* (2.6) *always becomes active at some level $N_0 \le N_*$.*

Proof. Note that $V_N V_N^+$ is the orthogonal projection into range(V_N) and $s \in$ range$(V_{N_*}) \subseteq$ range(V_N) for $N_* \le N$; hence $V_N V_N^+ s = s$. Therefore

$$\|V_N c^{(N)} - s^\varepsilon\|^2 = \|V_N V_N^+ (s+\nu) - (s+\nu)\|^2 = \|\nu - V_N V_N^+ \nu\|^2 \tag{2.9}$$

$$= \|\nu\|^2 - \|V_N V_N^+ \nu\|^2 \le \varepsilon^2 \|s^\varepsilon\|^2, \tag{2.10}$$

where we have used condition (2.1) in the last step. It follows from (2.10) that Algorithm 1 terminates at some level $N_0 \le N_*$. ∎

The following lemma shows that from the viewpoint of numerical stability it is advisable to keep the level N of the space $\boldsymbol{P}_N$ in which we search for our solution as small as possible.

LEMMA 2.2. cond$(V_N^* V_N) \ge$ cond$(V_M^* V_M)$ *for $N \ge M$.*

Proof. Since

$$P_M (V_N^* V_N) P_M = V_M^* V_M \qquad \text{for } M \le N,$$

Cauchy's interlace theorem [16] implies that $\operatorname{cond}(V_N^* V_N) \geq \operatorname{cond}(V_M^* V_M)$ for $N \geq M$. □

In what follows we demonstrate that the fact that Algorithm 1 terminates at some level $\leq N_*$ is a desired property in many cases. We show that stopping criterion (2.6) is even optimum in a number of cases.

Let us first consider two special cases: (i) noisefree samples and (ii) uniformly spaced samples.

2.1.1. Noisefree samples. Any reasonable stopping criterion has to satisfy the following lemma.

LEMMA 2.3. *For noisefree data the stopping criterion* (2.6) *yields the exact solution.*

Proof. One readily verifies that Algorithm 1 terminates at level N_*. Hence for $N = N_*$,

$$\|p^{(N)} - p_*\| = \|c^{(N)} - c_*\| = \|V_N^+ s^\varepsilon - c_*\| = \|V_N^+ V_N c_* - c_*\| = 0, \tag{2.11}$$

since $V_N^+ V_N c_* = c_*$ for $N \geq N_*$. □

Lemmas 2.2 and 2.3 together show that stopping criterion (2.6) yields the optimum solution for noisefree data while providing maximum numerical stability.

2.1.2. Uniformly spaced samples. If the sampling points $x_j, j = 1, \ldots, r$, are uniformly spaced and we choose $w_j = 1/r$ as weights, then a simple calculation shows that V_N is unitary on $\mathbb{C}^{2N+1}$, i.e., $V_N^* V_N = I_N$ for $N = 0, 1, \ldots, (r-1)/2$.

In this case

$$\|c_* - c^{(N)}\| = \|c_* - V_N^* s^\varepsilon\| = \|c_* - V_N^* V_{N_*} c_* - V_N^* \nu\|. \tag{2.12}$$

$N \geq N_*$ implies $V_N^* V_{N_*} = I_N$ and hence

$$\|c_* - c^{(N)}\| = \|V_N^* \nu\|. \tag{2.13}$$

Note that

$$\|V_N^* \nu\| = \langle V_N^* \nu, V_N^* \nu \rangle = \langle V_N V_N^* \nu, \nu \rangle = \|V_N V_N^* \nu\|, \tag{2.14}$$

since $V_N V_N^*$ is an orthogonal projection. Equation (2.14) yields

$$\|V_M^* \nu\| \leq \|V_N^* \nu\| \qquad \text{for } M \leq N. \tag{2.15}$$

Consequently

$$\|c_* - c^{(M)}\| \leq \|c_* - c^{(N)}\| \qquad \text{if } N_* \leq M \leq N. \tag{2.16}$$

Thus for uniformly spaced samples any stopping criterion should terminate Algorithm 1 at the latest at $N = N_*$. Under a mild condition on the coefficients c_* we can show that the proposed stopping criterion provides the optimal solution among all least squares solutions.

PROPOSITION 2.4. *Assume that the samples are regularly spaced. Then the solution* $p^{(N_0)}$ *computed via Algorithm* 1 *satisfies*

$$\|p_* - p^{(N_0)}\| \leq \|p_* - p^{(N)}\| \qquad \textit{for all } N \geq N_*. \tag{2.17}$$

If, furthermore, p_* satisfies

$$\|(I_{N_*} - P_N)c_*\| \geq \|(I_{N_*} - P_N)V_{N_*}^*\nu\|, \tag{2.18}$$

then

$$\|p_* - p^{(N_0)}\| \leq \|p_* - p^{(N)}\| \qquad \textit{for all } N. \tag{2.19}$$

Condition (2.18) is satisfied, e.g., if all coefficients of p_* are larger than the relative noise level, i.e., $|c_k| \geq \varepsilon\|s^\varepsilon\|$.

Proof. Lemma 2.1 yields that $N_0 \leq N_*$; thus (2.16) implies (2.17).

To prove assertion (2.19) we have only to show that

$$\|c_* - c^{(N_0)}\| \leq \|c_* - c^{(N)}\| \qquad \text{for all } N < N_*.$$

For $N < N_*$ note that $(c_* - V_N^* V_{N_*} c_*)$ is orthogonal to $V_N^*\nu$, since

$$\langle c_*, V_N^*\nu\rangle = \langle V_{N_*}^* V_{N_*} c_*, V_N^*\nu\rangle \tag{2.20}$$

$$= \langle V_{N_*} c_*, V_{N_*}^* V_N^*\nu\rangle = \langle V_{N_*} c_*, V_N V_N^*\nu\rangle; \tag{2.21}$$

hence

$$\langle c_* - V_N^* V_{N_*} c_*, V_N^*\nu\rangle = 0.$$

Therefore

$$\|c_* - c^{(N)}\|^2 = \|c_* - V_N^+ V_{N_*} c_* + V_N^*\nu\|^2 = \|c_* - V_N^+ V_{N_*} c_*\|^2 + \|V_N^*\nu\|^2 .$$

In order to prove $\|c_* - c^{(N_0)}\| \leq \|c_* - c^{(N)}\|$ for all $N < N_*$ we need to verify $\|c_* - V_N^+ V_{N_*} c_*\|^2 + \|V_N^*\nu\|^2 \geq \|V_{N_*}^*\nu\|^2$. Since

$$\|c_* - V_N^+ V_{N_*} c_*\|^2 = \sum_{|k|=N+1}^{N_*} |(c_*)_k|^2 = \|(I_N - P_N)c_*\|^2$$

and

$$\|(V_{N_*})^*\nu\|^2 - \|V_N^*\nu\|^2 = \sum_{|k|=N+1}^{N_*} |(V_{N_*}^*\nu)_k|^2 = \|(I_N - P_N)V_{N_*}^*\nu\|^2,$$

the result follows now from the assumption (2.18). ∎

Remark. Proposition 2.4 shows that the least squares polynomial that gives the best approximation to p_* is not necessarily of degree N_*.

2.1.3. Noisy nonuniform samples. For noisy nonuniformly spaced data we observe that

$$\|p_* - p^{(N)}\| = \|c_* - c^{(N)}\| \leq \|c_* - V_N^+ V_{N_*} c_*\| + \|V_N^+\nu\|,$$

and for $N \geq N_*$,

$$\|p_* - p^{(N)}\| \leq \|V_N^+\nu\|, \tag{2.22}$$

since $\|c_* - V_N^+ V_{N_*} c_*\| = 0$ in this case.

If V_N is not unitary then $\|V_N^+ \nu\|$ is not necessarily monotonically increasing with increasing level N. One can argue heuristically that since $\|V_N^+\|$ is increasing with increasing level N due to Lemma 2.2, we may fairly assume that $\|V_N^+ \nu\|$ will also increase (although not strictly monotonically). Also from the viewpoint of numerical stability it is reasonable to keep the level N small, since by Lemma 2.2 we know that $\mathrm{cond}(V_N^* V_N) \geq \mathrm{cond}(V_M^* V_M)$ for $N \geq M$. This together with (2.22) suggests that we choose a stopping criterion that terminates at or before level N_*, which is guaranteed for stopping criterion (2.6) by Lemma 2.1.

We can conclude that the stopping criterion will provide excellent results if the noise level ε is small or if the condition number of $V_N^* V_N$ is small (which implies that V_N is approximately unitary). In order to verify the latter it is useful to have estimates for the condition number of $V_N^* V_N$. We will address this issue in Proposition 3.1.

2.2. A Toeplitz system and trigonometric approximation. Instead of directly solving $V_M c^{(M)} = s^\varepsilon$ it is more efficient in our case to consider the normal equations

$$V_M^* V_M^* c^{(M)} = V_M^* s^\varepsilon. \tag{2.23}$$

The reason is that from a numerical point of view the structural properties of the matrix $V_M^* V_M$ are much more attractive than those of V_M, which in turn leads to faster numerical algorithms; see also section 4.

Set $T_M = V_M^* V_M$; then a simple calculation shows that the entries of the hermitian matrix T_M are

$$(T_M)_{k,l} = \sum_{j=1}^{r} w_j e^{2\pi i (k-l) x_j}, \qquad k, l = -M, \ldots, M. \tag{2.24}$$

T_M is a Toeplitz matrix, since the entries $(T_M)_{k,l}$ depend only on the difference $k-l$. Obviously T_M is invertible if $2M+1 \leq r$.

The following result is just a reformulation of (2.23) together with relation (2.8), but since it plays a key role in section 4 it is helpful to state it in detail (cf. also [18]).

THEOREM 2.5. *Given the sampling points $0 \leq x_1 < \cdots < x_r < 1$, the samples $\{s_j^\varepsilon\}_{j=1}^N$, positive weights $\{w_j\}_{j=1}^r$, and the degree M with $2M+1 \leq r$. The polynomial $p^{(M)} \in \boldsymbol{P}_M$ that solves* (1.1) *is given by*

$$p^{(M)}(x) = \sum_{k=-M}^{M} c_m^{(M)} e^{2\pi i k x} \in \boldsymbol{P}_M, \tag{2.25}$$

where its coefficients $c_k^{(M)}$ satisfy

$$T_M c^{(M)} = b^{(M)} \ \in \mathbb{C}^{(2M+1)^2}, \tag{2.26}$$

with

$$b_k^{(M)} = \sum_{j=1}^{r} s_j^\varepsilon w_j e^{2\pi i k x_j} \qquad \text{for } |k| \leq M, \tag{2.27}$$

and T_M as defined in (2.24).

3. Weights as simple preconditioner. Vandermonde matrices are known to be ill conditioned if the nodes x_j are clustered [13]. To improve the stability of systems (2.4) and (2.26) we can use the weights as a simple diagonal preconditioner. This leads to the problem of how to choose the weights w_j.

We propose to use the size of the area of the Voronoi region [23] associated with the sampling point x_j as weight w_j. In one dimension this reduces to

$$w_j = \frac{x_{j+1} - x_{j-1}}{2}\,. \tag{3.1}$$

This choice is motivated by the following observations.

In this section we let V_N denote the Vandermonde matrix defined in (2.3) without weights. Let $p \in \boldsymbol{P}_M$ with coefficient vector c. Since

$$\langle T_M c, c\rangle = \langle WV_M c, WV_M c\rangle = \|WV_M c\|^2 = \sum_{j=1}^{r} |p(x_j)|^2 w_j, \tag{3.2}$$

the inequality

$$C_1\|c\|^2 \le \sum_{j=1}^{r} |p(x_j)|^2 w_j \le C_2\|c\|^2 \tag{3.3}$$

holds for all $c \in \mathbb{C}^{2M+1}$ with constants $C_1 = \lambda_{\min}$ and $C_2 = \lambda_{\max}$, where $\lambda_{\min}$ and $\lambda_{\max}$ denote the minimal and maximal eigenvalues, respectively, of T_M.

(i) The lower bound of T_M is mainly determined by the large gaps in the sampling set. Suppose there is a large gap in the sampling set and denote the interval corresponding to this gap by Γ (hence $x_j \notin \Gamma$). Choose a trigonometric polynomial $p \in \boldsymbol{P}_M$, which, like the prolate spheroidal functions, concentrates most of its energy in the interval Γ. Then the sampling values of p will not pick up any information about the main concentration of the polynomial energy. Consequently, if we use no weights (or set $w_j = 1$), we get

$$\sum_{j\notin\Gamma} |p(x_j)|^2 \ll \|p\|^2 = \|c\|^2.$$

For such a sampling set the lower frame bound C_1 in the inequality (3.3) must be small. Generically, large gaps and the ensuing lack of information always result in bad condition numbers. This problem cannot be fixed by preconditioning.

(ii) On the other hand, we can choose a trigonometric polynomial that is mainly concentrated in the region where the sampling points are located. In this case the same local information is counted and added several times. Thus

$$\sum_{j\notin\Gamma} |p(x_j)|^2 \gg \|p\|^2 = \|c\|^2$$

and the upper constant C_2 in (3.3) will be large. Yet, as mentioned in (i), a cluster will not contribute much to the lower bound and to the uniqueness of the problem. In this case the condition number is large, because too much local information is given in certain areas of the polynomial.

Problem (ii) can be addressed by introducing properly chosen weights. The idea is to compensate for the local variation of the sampling density by using weights in

inequality (3.3). Suppose that $0 \le x_1 \le x_2 \le \cdots \le x_r < 1$ is a sampling set in $[0,1]$. Then a natural choice for the weights is $w_j = (x_{j+1} - x_{j-1})/2$. Thus if many samples are clustered near a point x_j, then the weight w_j is small. If x_j is the only sampling point in a large neighborhood, then the corresponding weight is large. This choice has not only been confirmed by extensive numerical experiments [11] but also by the following optimization approach.

A standard approach for the construction of preconditioners for a matrix A is the following. One attempts to find the matrix P in a given class $\mathcal{M}$ of matrices (e.g., the class of all circulant matrices or the class of all diagonal matrices) that solves

$$\min_{P \in \mathcal{M}} \|I - PA\|_F \,, \tag{3.4}$$

where $\|.\|_F$ denotes the Frobenius norm.

In our setting this translates into the optimization problem

$$\min_{W \in \mathcal{D}} \|I - (WV)^* WV\|_F \,, \tag{3.5}$$

where $\mathcal{D}$ is the class of all $r \times r$ diagonal matrices and I is the $(2M+1) \times (2M+1)$ identity matrix.

Note that we require that $w_j > 0$, whereas (3.5) could in principle yield weights that violate this condition. However, since we will make use of (3.5) in our actual algorithm, we are somewhat sloppy here.

An alternative approach is to consider the solution of

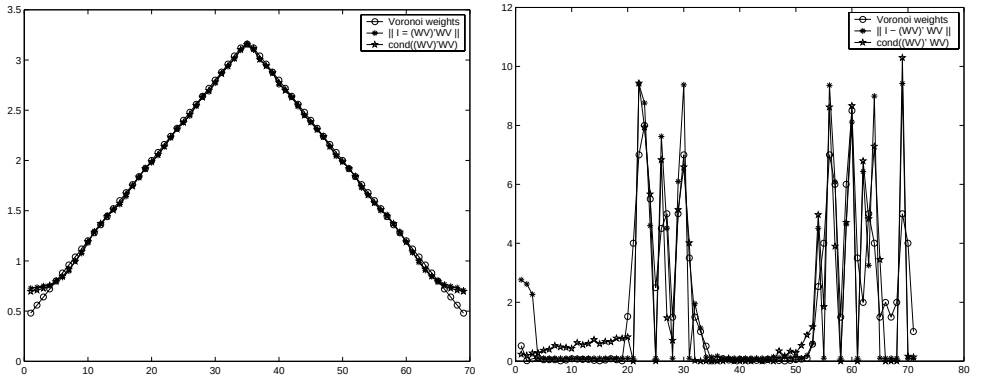
$$\begin{gathered} \min\{\mathrm{cond}[(WV)^* WV]\} \\ \text{subject to } W \in \mathcal{D}. \end{gathered} \tag{3.6}$$

This optimization problem can be transformed to a general eigenvalue problem (see [4]), which can be solved by convex optimization algorithms.

In the simple case of regular sampling it is easy to check that the solution of both optimization problems is given by $W = \mathrm{diag}(\{\sqrt{w_j}\})$ with $w_j = (x_{j+1} - x_{j-1})/2 = 1/r$. However, in the more interesting case of nonuniform sampling neither problem (3.5) nor (3.6) in general has an analytic solution. Thus, using these approaches for the actual construction of a preconditioner would be ridiculous, since the computational costs to solve these optimization problems are considerably larger than solving the trigonometric approximation problem. Nevertheless, solving (3.5) and (3.6) numerically for a variety of different examples is useful to gain insight into the type of weights obtained by these approaches.

The numerical results confirm the choice of the Voronoi-type weights defined in (3.1). Sampling points in densely sampled areas are assigned a small weight, whereas sampling points in sparse sampled regions are assigned a large weight. Two typical comparisons of the weights obtained via optimization and the Voronoi weights are illustrated in Figure 3.1. In the first case we consider a sampling set with high density at the endpoints and strongly decreasing density toward the center. The weights obtained by solving (3.5) and (3.6) are almost identical and are very close to the Voronoi weights, as can be seen in Figure 3.1(a). The difference at the endpoints is probably due to boundary effects.

In the second example we consider a random sampling set with several areas with high sampling density and relatively few samples between these clusters. Again all three approaches give weights that show a similar behavior; see Figure 3.1(b). The



(a) (b)

FIG. 3.1. *Comparison of weights obtained by different approaches.*

condition number of the nonweighted Toeplitz matrix in this example is 33, compared with the significantly smaller condition number 3.3 when using Voronoi-type weights. Using the weights obtained via (3.5) gives $\mathrm{cond}(T_M) = 3.1$, and for the weights resulting from (3.6) we get $\mathrm{cond}(T_M) = 2.9$, which is only a slight improvement compared with the Voronoi-type weights.

Obtaining good estimates for the condition number of a Toeplitz matrix is a difficult problem. It is gratifying that by using the weights defined in (3.1) it is possible to get an upper bound for the condition number.

PROPOSITION 3.1 (Gröchenig [18]). *Assume that the sampling set* $\{x_j\}_{j=1}^r$ *satisfies*

$$\max(x_{j+1} - x_j) := \gamma < \frac{1}{2M}$$

and set $w_j = (x_{j+1} - x_{j-1})/2$. *Then the condition number of the Toeplitz matrix* T_M *defined in* (2.24) *is bounded by*

$$\kappa(T_M) \leq \left(\frac{1+\gamma}{1-\gamma}\right)^2. \tag{3.7}$$

4. A Levinson–Galerkin algorithm for trigonometric approximation. The method described in Algorithm 1 can be seen as a Galerkin-type approach, since we try to determine an approximation by searching for a solution in a finite-dimensional space spanned by orthogonal polynomials, and by increasing the dimension of the space we increase the resolution of our approximation by adding more and more details.

When we use Levinson's algorithm [16] to solve (2.26) for $M = 0, 1, \ldots, N_0$ the total computational effort would be of $\mathcal{O}(N_0^3)$, since the solution of each system $T_M c^{(M)} = b^{(M)}$ requires $\mathcal{O}(M^2)$ operations. Using one of the fast Toeplitz algorithms [2, 5] reduces this effort to $\mathcal{O}(kM \log M)$ for each level M, where k is the number of iterations, thus leading to a total of $\mathcal{O}(kN_0^2 \log N_0)$ operations. In this section we show that the systems $T_M c^{(M)} = b^{(M)}, M = 0, 1, \ldots, N_0$ can be solved in

$\mathcal{O}(N_0^2)$ operations and the total effort (including the calculation of the entries of T_M and the evaluation of the stopping criterion (2.6)) for computing $p^{(N_0)}$ is $\mathcal{O}(rN_0+N_0^2)$ operations.

The following observation is crucial for the derivation of the proposed Levinson–Galerkin algorithm.

LEMMA 4.1. *For fixed degree M and $M+1$ let $T_M, b^{(M)}$ and $T_{M+1}, b^{(M+1)}$ be the Toeplitz matrices and right-hand sides as defined in* (2.24) *and* (2.27)*, respectively. Then T_M and $b^{(M)}$ are embedded in T_{M+1} and $b^{(M+1)}$ in the following way:*

$$T_{M+1} = \begin{bmatrix} t_0 & \dots & \bar{t}_{2(M+1)} \\ \vdots & \boxed{T_M} & \vdots \\ t_{2(M+1)} & \dots & t_0 \end{bmatrix}, \quad b^{(M+1)} = \begin{bmatrix} b_{-(M+1)} \\ b^{(M)} \\ b_{M+1} \end{bmatrix}. \tag{4.1}$$

Proof. Equation (4.1) follows immediately from the definition of T_M and $b^{(M)}$ and (2.8). ∎

Unfortunately the solutions $c^{(M)}$ and $c^{(M+1)}$ of the systems $T_M c^{(M)} = b^{(M)}$ and $T_{M+1}c^{(M+1)} = b^{(M+1)}$ are not related in such a simple manner. But we can exploit the nested structure of the family $\{T_M\}_{M=1}^{N_0}$ by solving the systems $T_M c^{(M)} = b^{(M)}$ recursively via a modified Levinson algorithm. The standard Levinson algorithm cannot be applied directly, since it only addresses Toeplitz systems, where the principal leading submatrix and the principal leading subvector of the right-hand side stay unchanged during the recursion, which is not the case here. For T_{M+1} it does not matter if we enlarge T_M by appending new entries below or above, whereas the right-hand side $b^{(M)}$ cannot be rearranged in such a way that the principal leading subvector of the right-hand side will be changed if we switch from $b^{(M)}$ at level M to $b^{(M+1)}$ at level $M+1$.

To adapt Levinson's algorithm to our situation, we have to split up the change from the system $T_M c^{(M)} = b^{(M)}$ at level M to the system $T_{M+1}c^{(M+1)} = b^{(M+1)}$ at level $M+1$ into two separate steps. Instead of indexing the matrix T_M and the vectors $b^{(M)}, c^{(M)}$ by the degree M, it is therefore advantageous to index them according to their dimension. For clarity of presentation we reserve the subscript (M) for the degree of the polynomial and its coefficient vector, respectively, and use the subscript (ℓ) when we refer to the dimension of the corresponding coefficient vector in $\mathbb{C}^\ell$. Thus for even ℓ, $b^{(\ell)} = [b_{-\frac{\ell}{2}+1}, \dots, b_{\frac{\ell}{2}}]^T \in \mathbb{C}^\ell$, and for odd ℓ we set $b^{(\ell)} = [b_{-\frac{\ell-1}{2}}, \dots, b_{\frac{\ell-1}{2}}]^T$ (whence $b^{(1)} = b_0$), analogously for $c^{(\ell)}$. Further, it is useful in what follows to denote $t^{(\ell)} = [t_1, \dots, t_\ell]^T$. Then the Toeplitz matrix T_ℓ of size $\ell \times \ell$ is generated by the vector $[t_0, (t^{(\ell-1)})^T]^T$ with $t_k = \sum_{j=1}^r w_j e^{2\pi i k x_j}$ according to (2.24).

Assume we have already solved the system $T_M c^{(M)} = b^{(M)}$ at level M (with $\ell = 2M+1$) and now we want to switch to the next level $M+1$. As we have agreed, we do this in two steps. In the first step ($\ell \to \ell+1$) the Toeplitz system can be written as

$$\begin{bmatrix} T_\ell & E_\ell \overline{t^{(\ell)}} \\ (t^{(\ell)})^T E_\ell & t_0 \end{bmatrix} \begin{bmatrix} v^{(\ell)} \\ v_{\frac{\ell+1}{2}} \end{bmatrix} = \begin{bmatrix} b^{(\ell)} \\ b_{\frac{\ell+1}{2}} \end{bmatrix}, \tag{4.2}$$

where E_ℓ is the rotated identity matrix on $\mathbb{C}^\ell$, i.e.,

$$E_\ell = \begin{bmatrix} 0 & & 1 \\ & \iddots & \\ 1 & & 0 \end{bmatrix}.$$

System (4.2) can be solved recursively by the standard Levinson algorithm [21, 16]. To be more precise, we assume that we have already solved the system $T_\ell c^{(\ell)} = b^{(\ell)}$ for $\ell = 2M+1$ and assume further that the solution of the ℓth-order *Yule–Walker system* $T_\ell y^{(\ell)} = -t^{(\ell)}$ is available. Then the solution of (4.2) can be computed recursively by

$$\begin{aligned} v_{\frac{\ell+1}{2}} &= (b_{\frac{\ell+1}{2}} - [t^{(\ell)}]^T E_\ell c^{(\ell)})/\beta_\ell, \\ v^{(\ell)} &= c^{(\ell)} + v_{\frac{\ell+1}{2}} E_\ell \overline{y^{(\ell)}}, \end{aligned}$$

where

$$\begin{aligned} \beta_\ell &= t_0 + [t^{(\ell)}]^T \overline{y^{(\ell)}} = (1 - \alpha_{\ell-1}\overline{\alpha_{\ell-1}})\beta_{\ell-1}, \\ \alpha_\ell &= -(t_{\ell+1} + [t^{(\ell)}]^T E_\ell y^{(\ell)})/\beta_\ell, \\ z^{(\ell)} &= y^{(\ell)} + \alpha_\ell E_\ell \overline{y^{(\ell)}}, \\ y^{(\ell+1)} &= \begin{bmatrix} z^{(\ell)} \\ \alpha_\ell \end{bmatrix}. \end{aligned}$$

Now we can proceed to the second step ($\ell + 1 \to \ell + 2 = 2(M+1)+1$), where the Toeplitz system can be expressed as

$$\begin{bmatrix} t_0 & (t^{(\ell+1)})^* \\ t^{(\ell+1)} & T_{\ell+1} \end{bmatrix} \begin{bmatrix} v_{-\frac{\ell+1}{2}} \\ v^{(\ell+1)} \end{bmatrix} = \begin{bmatrix} b_{-\frac{\ell+1}{2}} \\ b^{(\ell+1)} \end{bmatrix} \tag{4.3}$$

with $c^{(\ell+2)} = [v_{-\frac{\ell+1}{2}}, (v^{(\ell+1)})^T]^T = c^{(M+1)}$. Observe that (4.3) cannot be transformed to a system of the form (4.2) by simple permutations, i.e., just by interchanging rows and columns. Since we have already solved the systems $T_{\ell+1}c^{(\ell+1)} = b^{(\ell+1)}$ and $T_{\ell+1}y^{(\ell+1)} = -t^{(\ell+1)}$ we can write

$$v^{(\ell+1)} = (T_{\ell+1})^{-1}(b^{(\ell+1)} - t^{(\ell+1)}v_{-\frac{\ell+1}{2}}) = c^{(\ell+1)} + v_{-\frac{\ell+1}{2}} y^{(\ell+1)}$$

and

$$\begin{aligned} v_{-\frac{\ell+1}{2}} =& (b_{-\frac{\ell+1}{2}} - [t^{(\ell+1)}]^* v^{(\ell+1)})/t_0 \\ =& (b_{-\frac{\ell+1}{2}} - [t^{(\ell+1)}]^* c^{(\ell+1)} - [t^{(\ell+1)}]^* v_{-\frac{\ell+1}{2}} y^{(\ell+1)})/t_0 \\ =& (b_{-\frac{\ell+1}{2}} - [t^{(\ell+1)}]^* c^{(\ell+1)})/\beta_{\ell+1}, \end{aligned}$$

where we have used in the last step that $T_\ell = [T_\ell]^*$, which implies that $(t^{(\ell+1)})^* y^{(\ell+1)}$ is real and therefore $t_0 + (t^{(\ell+1)})^* y^{(\ell+1)} = t_0 + (t^{(\ell+1)})^T \overline{y^{(\ell+1)}} = \beta_{\ell+1}$.

Note that at each level M we have to check if the stopping criterion (2.6) is satisfied. The evaluation of the expression

$$\sum_{j=1}^{r} |p^{(M)}(x_j) - s_j^\varepsilon|^2 w_j \tag{4.4}$$

can be considerably simplified and by avoiding the evaluation of $p^{(M)}$ at the nonuniformly spaced points x_j we can reduce the computational effort from $\mathcal{O}(Mr)$ to $\mathcal{O}(M)$ operations.

To do this we define the subspace $\mathcal{R} = \left\{\{p(x_j)\}_{j=1}^r : p \in \boldsymbol{P}_M\right\} \subseteq \mathbb{C}^r$ with the weighted inner product $\langle y, z\rangle_{\mathcal{R}} = \sum_{j=1}^r y_j \bar{z}_j w_j$ for $y, z \in \mathbb{C}^r$. The solution of the least

squares problem (1.1) is the orthogonal projection of the vector $\{s_j^\varepsilon\}_{j=1}^r \in \mathbb{C}^r$ onto $\mathcal{R}$ and therefore must satisfy

$$\langle \{p^{(M)}(x_j)\} - \{s_j^\varepsilon\}, \{p^{(M)}(x_j)\}\rangle_{\mathcal{R}} = \sum_{j=1}^r (p^{(M)}(x_j) - s_j^\varepsilon)\overline{p^{(M)}(x_j)} w_j = 0,$$

which implies

$$\langle \{p^{(M)}(x_j)\}, \{s_j^\varepsilon\}\rangle_{\mathcal{R}} = \langle \{p^{(M)}(x_j)\}, \{p^{(M)}(x_j)\}\rangle_{\mathcal{R}}\,. \tag{4.5}$$

Since

$$\begin{aligned}\sum_{j=1}^r |s_j^\varepsilon - p^{(M)}(x_j)|^2 w_j &= \sum_{j=1}^r |s_j^\varepsilon|^2 w_j - 2\,\mathrm{Re}\,\langle s^\varepsilon, \{p^{(M)}(x_j)\}\rangle_{\mathcal{R}} + \sum_{j=1}^r |p^{(M)}(x_j)|^2 w_j \\ &= \sum_{j=1}^r |s_j^\varepsilon|^2 w_j - \sum_{j=1}^r |p^{(M)}(x_j)|^2 w_j\end{aligned}$$

by (4.5), and because

$$\begin{aligned}\sum_{j=1}^r |p^{(M)}(x_j)|^2 w_j &= \sum_{j=1}^r w_j \left(\sum_{m=-M}^M c_m^{(M)} e^{2\pi i m x_j}\right)\left(\sum_{n=-M}^M \overline{c_n^{(M)}} e^{2\pi i n x_j}\right) \\ &= \sum_{m=-M}^M \sum_{n=-M}^M c_m^{(M)}\overline{c_n^{(M)}} \left(\sum_{j=1}^r w_j e^{2\pi i (m-n) x_j}\right) \\ &= \langle T_M c^{(M)}, c^{(M)}\rangle = \langle b^{(M)}, c^{(M)}\rangle\,,\end{aligned} \tag{4.6}$$

it follows that

$$\sum_{j=1}^r |s_j^\varepsilon - p^{(M)}(x_j)|^2 w_j = \sum_{j=1}^r |s_j^\varepsilon|^2 w_j - \langle b^{(M)}, c^{(M)}\rangle\,. \tag{4.7}$$

Since $\sum_{j=1}^r |s_j^\varepsilon|^2 w_j$ has to be computed only once at the beginning of the algorithm, the evaluation of (4.4) can be carried out in $\mathcal{O}(M)$ operations.

Summing up we have arrived at the following algorithm to compute $p^{(N_0)}$.

ALGORITHM 2 (Levinson–Galerkin algorithm for trigonometric polynomials). *Let the sampling points $\{x_j\}_{j=1}^r$, sampling values $\{s_j^\varepsilon\}_{j=1}^r$, weights $w_j > 0$, and the data error estimate ε be given. Then the trigonometric polynomial $p^{(N_0)}$ determined in Algorithm 1 can be computed in $\mathcal{O}(rN_0 + N_0^2)$ operations by the following algorithm:*

Initialize: $t_0 = \sum_{j=1}^r w_j, t_1 = \sum_{j=1}^r w_j e^{2\pi i x_j}, b_0 = \sum_{j=1}^r s_j^\varepsilon w_j, \sigma = \sum_{j=1}^r |s_j^\varepsilon|^2 w_j$, $y^{(1)} = -t_1/t_0, c^{(1)} = b_0/t_0, \beta_0 = t_0, \alpha_0 = -t_1/t_0, \varepsilon_1 = (\sigma - b_0^2/t_0)/\sigma, \ell = 1.$

while $\varepsilon_\ell > \varepsilon$

$\beta_\ell = (1 - \alpha_{\ell-1}\overline{\alpha_{\ell-1}})\beta_{\ell-1}$

if $\ell \equiv 1 \mod 2$

$$b_{\frac{\ell+1}{2}} = \sum_{j=1}^r s_j^\varepsilon w_j e^{\pi i(\ell+1)x_j}$$

$$v_{\frac{\ell+1}{2}} = \frac{b_{\frac{\ell+1}{2}} - \langle E_\ell \overline{c^{(\ell)}}, t^{(\ell)}\rangle}{\beta_\ell}$$

$$v^{(\ell)} = c^{(\ell)} + v_{\frac{\ell+1}{2}} E_\ell \overline{y^{(\ell)}}$$

$$c^{(\ell+1)} = \begin{bmatrix} v^{(\ell)} \\ v_{\frac{\ell+1}{2}} \end{bmatrix}$$

$$b^{(\ell+1)} = \begin{bmatrix} b^{(\ell)} \\ b_{\frac{\ell+1}{2}} \end{bmatrix}$$

elseif $\ell \equiv 0 \mod 2$

$$b_{-\frac{\ell}{2}} = \sum_{j=1}^r s_j^\varepsilon w_j e^{-\pi i \ell x_j}$$

$$v_{-\frac{\ell}{2}} = \frac{b_{-\frac{\ell}{2}} - \langle \overline{c^{(\ell)}}, t^{(\ell)}\rangle}{\beta_\ell}$$

$$v^{(\ell)} = c^{(\ell)} + v_{-\frac{\ell}{2}} y^{(\ell)}$$

$$c^{(\ell+1)} = \begin{bmatrix} v_{-\frac{\ell}{2}} \\ v^{(\ell)} \end{bmatrix}$$

$$b^{(\ell+1)} = \begin{bmatrix} b_{-\frac{\ell}{2}} \\ b^{(\ell)} \end{bmatrix}$$

$$\varepsilon_{\ell+1} = |\sigma - \langle b^{(\ell+1)}, c^{(\ell+1)}\rangle|/\sigma$$

end

$$t^{(\ell+1)} = \sum_{j=1}^r w_j e^{2\pi i(\ell+1)x_j}$$

$$\alpha_\ell = -\frac{t^{(\ell+1)} + \langle E_\ell \overline{y^{(\ell)}}, t^{(\ell)}\rangle}{\beta_\ell}$$

$$z^{(\ell)} = y^{(\ell)} + \alpha_\ell E_\ell \overline{y^{(\ell)}}$$

$$y^{(\ell+1)} = \begin{bmatrix} z^{(\ell)} \\ \alpha_\ell \end{bmatrix}$$

$$t^{(\ell+1)} = \begin{bmatrix} t^{(\ell)} \\ t_{\ell+1} \end{bmatrix}$$

$\ell = \ell + 1$

end

$N_0 = \ell/2$

$$p^{(N_0)}(x) = \sum_{k=-N_0}^{N_0} c_k^{(N_0)} e^{2\pi i k x}$$

Remark. Usually one evaluates the final approximation on regularly spaced gridpoints; hence the last step of the algorithm can be realized by a fast Fourier transform (FFT). The most costly steps are the computation of the entries of $t^{(\ell)}$ and $b^{(\ell)}$. According to Corollary 1 in [11] the entries of T_M and $b^{(M)}$ can also be computed via FFT by embedding the x_j into a regular grid (since the x_j can be stored only in finite precision). In this case one automatically gets all entries $t_0, \ldots, t_r$ at once. However, this trick is useful only if the number of points of the regular grid is of the same magnitude as the number of sampling points. Alternatively one may use the numerical attractive formulas of Dutt and Rokhlin [9] or Beylkin [3] for a fast evaluation of trigonometric sums at unequally spaced nodes.

Algorithm 2 can be simplified for real-valued data; this modification is left to the reader.

Fast Vandermonde solvers require $\mathcal{O}(Mr)$ operations for the solution of $V_M c^{(M)} = s^{\varepsilon}$; cf. [25]. It is not clear, however, if these algorithms can utilize the nested structure of the sequence of matrices $\{V_M\}_M$ in order to give rise to an efficient implementation of Algorithm 1. Moreover, it is an open problem if the Vandermonde solvers can be extended to multivariate trigonometric approximation. We will see in the next section that the extension of Algorithm 2 to higher dimensions is straightforward.

5. Multivariate trigonometric approximation. An advantage of the proposed approach, besides its numerical efficiency, is the fact that it can be easily extended to multivariate trigonometric approximation. In this section we briefly discuss some results for the 2-D case.

We define the space of 2-D trigonometric polynomials $\boldsymbol{P}_M^2$ by

$$\boldsymbol{P}_M^2 = \left\{ p : p(x,y) = \sum_{j,k=-M}^{M} c_{j,k} e^{2\pi i (jx+ky)} \right\}. \tag{5.1}$$

To reduce the notational burden, we have assumed in (5.1) that p has degree equal to M in each coordinate; the extension to polynomials with different degree in each coordinate is straightforward.

For an arbitrary sampling set $\{(x_j, y_j)\}_{j=1}^r \in [0,1)^2$ and given degree M the system matrix according to the 2-D version of Theorem 2.5 is [28]

$$(T_M)_{k,l} = \sum_{j=1}^{r} w_j e^{2\pi i (k-l)(x_j+y_j)}, \qquad k,l = 0, \ldots, 2M. \tag{5.2}$$

One can easily verify that T_M is a hermitian block Toeplitz matrix with $2M+1$ different Toeplitz blocks of size $(2M+1) \times 2M+1$; cf. [28]. For a given sampling set let T_M be the block Toeplitz matrix for degree M and T_{M+1} the block Toeplitz matrix for degree $M+1$. There is a similar relationship between T_M and T_{M+1} as in the 1-D case. More precisely, denote the Toeplitz blocks of T_M and T_{M+1} by $(B_M)_k, k = 0, \ldots, 2M$, and $(B_{M+1})_k, k = 0, \ldots, 2M+2$, respectively. Then one readily verifies the following embedding:

$$T_{M+1} = \begin{bmatrix} (B_{M+1})_0 & \cdots & (B_{M+1})_{2(M+1)}^* \\ \vdots & \boxed{T_M} & \vdots \\ (B_{M+1})_{2(M+1)} & \cdots & (B_{M+1})_0 \end{bmatrix}, \tag{5.3}$$

$$B_{M+1} = \begin{bmatrix} t_0 & \dots & \bar{t}_{2(M+1)} \\ \vdots & \boxed{B_M} & \vdots \\ t_{2(M+1)} & \dots & t_0 \end{bmatrix}. \tag{5.4}$$

In [1] Levinson's algorithm has been extended to general block Toeplitz systems. With this extension and relation (5.3) at hand, we can easily generalize Algorithm 2 to 2-D (and along the same lines to multivariate) trigonometric approximation.

The analysis of the stopping criterion (2.6) in section 2 can be applied line by line to the 2-D (actually to the n-D) setting. The only difficulty arises in the search for simple criteria for the invertibility of the block Toeplitz matrix T_M. The condition

$$(2M+1)^d \leq r$$

is necessary in dimension $d > 1$, but is no longer sufficient, since the fundamental theorem of algebra does not hold in dimensions larger than one. In [19] Gröchenig has derived estimates for the condition number of T_M in higher dimensions. In two dimensions these estimates can be stated as follows.

Let $D_\delta(a,b) = \{(x,y) \in \mathbb{R}^2 : (x-a)^2 + (y-b)^2 < \delta^2\}$ be the disc of radius δ centered at (a,b). We say that a set $\{(x_j, y_j), j = 1, \dots, r\}$ is δ-dense in $[0,1] \times [0,1]$, if $\bigcup_{j=1}^r D_\delta(x_j, y_j) \supseteq [0,1] \times [0,1]$. In other words, the distance of a given sample (x_j, y_j) to its nearest neighbor $(x_k, y_k), k \neq j$ is at most 2δ.

Analogously to section 3 we choose the size of the Voronoi region V_j associated with x_j as weight w_j in the computation of the block Toeplitz matrix T_M in (5.2). Suppose that the sampling set $\{(x_j, y_j), j = 1, \dots, r\} \subseteq [0,1] \times [0,1]$ is δ-dense and

$$\delta < \frac{\log 2}{4\pi M}. \tag{5.5}$$

Gröchenig [19] has shown that under these conditions

$$\operatorname{cond}(T_M) \leq \frac{4}{(2 - e^{4\pi M \delta})^2}. \tag{5.6}$$

In particular, for arbitrary δ-dense sampling sets, the block Toeplitz matrix T_M is invertible and the 2-D version of Algorithm 2 is applicable.

5.1. Line-type nonuniform sampling in two dimensions. In the following we consider a special case of trigonometric approximation in two dimensions. This case arises when a function is irregularly sampled along lines. A typical example is illustrated in Figure 5.1. Such sampling patterns are encountered, for instance, in geophysics and medical imaging; see also section 6.2.

COROLLARY 5.1. *Let $p \in \boldsymbol{P}_M^2$ and let $\{x_j, y_{j,k}\}, j = 1, \dots, r, k = 1, \dots, r_j$, be a sampling set in $[0,1)^2$ such that*

$$A_1 \|p\|^2 \leq \sum_{k=1}^{r_j} |p(y_{j,k})|^2 \leq B_1 \|p\|^2, \qquad A_1, B_1 > 0, \tag{5.7}$$

for every $p \in \boldsymbol{P}_M$ and for all j. Further assume that $\{x_j\}_{j \in \mathbb{Z}}$ is a sampling set such that

$$A_2 \|p\|^2 \leq \sum_{j=1}^{r} |p(x_j)|^2 \leq B_2 \|p\|^2, \qquad A_2, B_2 > 0, \tag{5.8}$$

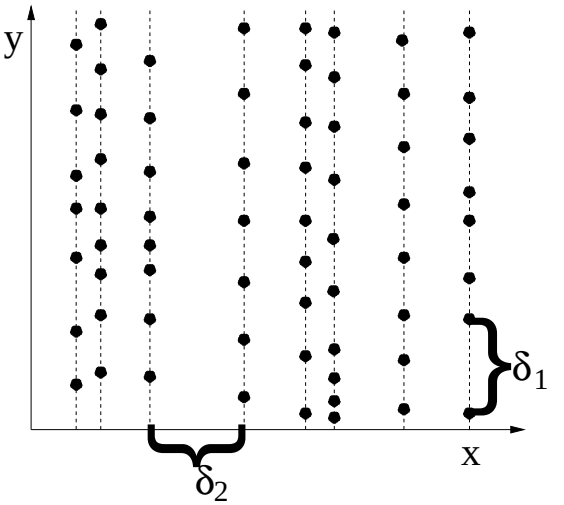


FIG. 5.1. *Line-type nonuniform sampling set.*

for every $p \in \boldsymbol{P}_M$. *Then*

$$A_1 A_2 \|p\|^2 \le \sum_{j=1}^{r} \sum_{k=1}^{r_j} |p(x_j, y_{j,k})|^2 \le B_1 B_2 \|p\|^2 \tag{5.9}$$

for every $p \in \boldsymbol{P}_M^2$.

If $\{x_j\}$ *and* $\{y_{j,,k}\}$ *are sampling sets with* $\sup_k (x_{k+1} - x_k) = \delta_2 < \frac{1}{2M}$ *and* $\sup_{j,k}(y_{j,k+1} - y_{j,k}) = \delta_1 < \frac{1}{2M}$, *then* $A_l = (1-\delta_l)^2, B_l = (1+\delta_l)^2, l = 1, 2$, *and the condition number of the block Toeplitz matrix* T_M *is bounded by*

$$\kappa(T_M) \le \frac{(1+\delta_1)^2(1+\delta_2)^2}{(1-\delta_1)^2(1-\delta_2)^2}\,. \tag{5.10}$$

Proof. Let x be fixed. Then $y \to p(x, y) \in \boldsymbol{P}_M$ and hence for all j,

$$A_1 \int_0^1 |p(x_j, y)|^2\, dy \le \sum_{k=1}^{r_j} |p(x_j, y_{j,k})|^2 \le B_1 \int_0^1 |p(x_j, y)|^2\, dy \tag{5.11}$$

by assumption (5.7). It follows that

$$A_1 \sum_{j=1}^{r} \int_0^1 |p(x_j, y)|^2\, dy \le \sum_{j,k} |p(x_j, y_{j,k})|^2 \le B_1 \sum_{j=1}^{r} \int_0^1 |p(x_j, y)|^2\, dy. \tag{5.12}$$

Now let y be fixed. Then $x \to p(x, y) \in \boldsymbol{P}_M$ and

$$A_2 \int_0^1 |p(x, y)|^2\, dx \le \sum_{j=1}^{r} |p(x_j, y)|^2 \le B_2 \int_0^1 |p(x, y)|^2\, dx\,. \tag{5.13}$$

Since

$$\sum_{j=1}^{r} \int_0^1 |p(x_j, y)|^2\, dy = \int_0^1 \sum_{j=1}^{r} |p(x_j, y)|^2\, dy\,, \tag{5.14}$$

assertion (5.9) follows by combining (5.12) and (5.13) with (5.14). The estimate of the constants A_l, B_l and of the condition number of the block Toeplitz matrix T_M follows from Theorem 2.5. □

The proof of Corollary 5.1 is due to Gröchenig [17]. Corollary 5.1 not only guarantees that $p \in \boldsymbol{P}_M^2$ can be recovered from its samples $p(x_j, y_{j,k})$, it provides more. An immediate consequence is that it can be reconstructed by an efficient algorithm relying on a successive application of Algorithm 2 and the Gohberg–Semencul representation of the inverse of a Toeplitz matrix. See section 6.2 for more details and an application in medical imaging.

6. Curve and surface approximation by trigonometric polynomials. Trigonometric polynomials can be used to model the boundary or the surface of smooth objects. Let us consider a 2-D object, obtained, e.g., by a planar cross section from a 3-D object and assume that the boundary of this 2-D object is a closed curve in $\mathbb{R}^2$. We denote this curve by f and parameterize it by $f(u) = (x_u, y_u)$, where x_u and y_u are the coordinates of f at "time" u in the x- and y-direction, respectively. Obviously we can interpret f as a 1-D continuous, complex, and periodic function, where x_u represents the real part and y_u represents the imaginary part of $f(u)$. It follows from the theorem of Weierstrass (and from the theorem of Stone–Weierstrass [26] for higher dimensions) that a continuous periodic function can be approximated uniformly by trigonometric polynomials. If f is smooth, we can fairly assume that trigonometric polynomials of low degree provide an approximation of sufficient precision.

Assume that we know only some arbitrary, perturbed points $s_j = (x_{u_j}, y_{u_j}) = f(u_j) + \delta_j, j = 1, \dots, r$ of f, and we want to recover f from these points. By a slight abuse of notation we interpret s_j as a complex number and write

$$s_j = x_j + iy_j\,. \tag{6.1}$$

We relate the curve parameter u to the boundary points s_j by computing the distance between two successive points s_{j-1}, s_j via

$$u_1 = 0, \tag{6.2}$$

$$u_j = u_{j-1} + d_j, \tag{6.3}$$

$$d_j = \sqrt{(x_j - x_{j-1})^2 + (y_j - y_{j-1})^2} \tag{6.4}$$

for $j = 2, \dots, r$. Via the normalization $t_j = t_j/L$ with $L = u_r + d_N$ we force all sampling points to be in $[0, 1)$. Other choices for d_j in (6.1) can be found in [8] in conjunction with curve approximation using splines.

Having carried out the transformations (6.1)–(6.4), we can solve the problem of recovering the curve f from its perturbed points s_j by Algorithm 2.

6.1. Object boundary recovery in echocardiography. Trigonometric polynomials are certainly not suitable to model the shape of arbitrary objects. However, they are often useful in cases where an underlying (stationary) physical process implies smoothness conditions of the object. Typical examples arise in medical imaging, for instance in clinical cardiac studies, where the evaluation of cardiac function using parameters of left ventricular contractibility is an important constituent of an echocardiographic examination [30]. These parameters are derived using boundary tracing of endocardial borders of the left ventricle (LV). The extraction of the boundary of the LV comprises two steps, once the ultrasound image of a cross section of the LV is given; see Figure 6.1(a)–(d). First, an edge detection is applied to the ultrasound

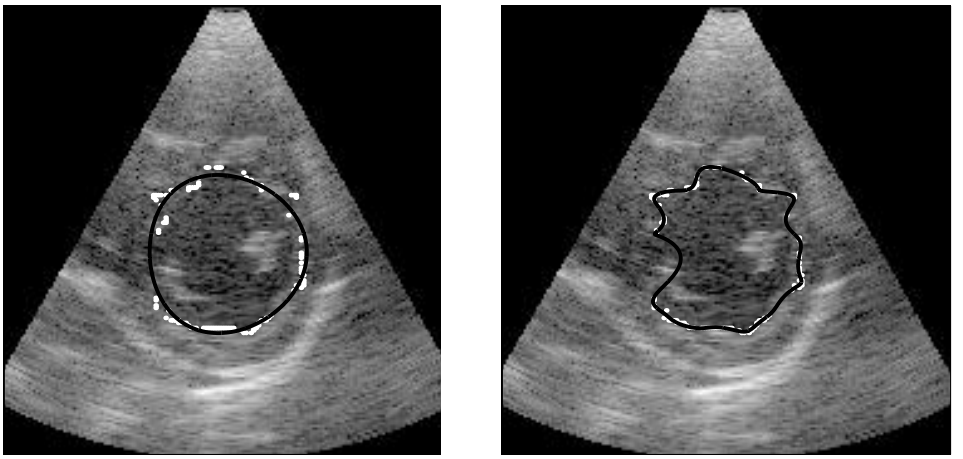
image to detect the boundary of the LV; cf. Figure 6.1(c). However, this procedure may be hampered by the presence of interfering biological structures (such as papillar muscles), the unevenness of boundary contrast, and various kinds of noise [29]. Thus edge detection often provides only a set of nonuniformly spaced, perturbed boundary points rather than a connected boundary. Therefore a second step is required to recover the original boundary from the detected edgepoints; cf. Figure 6.1(d). Since the shape of the LV is definitely smooth, trigonometric polynomials are particularly well suited to model its boundary.

After having transformed the detected boundary points as described in (6.1)–(6.4)



(a) Underfitted solution (b) Overfitted solution

FIG. 6.2. *The approximation in the left image results from using a too small polynomial degree, the approximation in the right image from a too large degree for the trigonometric approximation.*

we can use Algorithm 2 to recover the boundary. The noise level δ depends on the technical equipment being used; it can be determined from experimental experience. Figure 6.2(a)–(b) demonstrates the importance of determining a proper degree for the approximating polynomial. The approximation displayed in Figure 6.2(a) has been computed by solving (1.1), where M has been chosen too small; obviously we have underfitted the data. The overfitted approximation obtained by solving (1.1) using a too large M is shown in Figure 6.2(b). The approximation shown in Figure 6.1(d) has been computed by Algorithm 2; it provides the optimal balance between fitting the data and smoothness of the solution.

6.2. Boundary recovery from a sequence of images. In cardiac clinical studies one is more interested in the behavior of the LV over a period of time rather than in a single "snapshot." Thus for a fixed cross section we are given a sequence of ultrasound images (usually regularly spaced in time) describing the variation of the shape of the LV with time. One cycle from diastole (the state of maximal contraction of the LV), passing systole (the state of maximal expansion) to the next diastole consists typically of about 30 image frames. Since the behavior of the LV is (at least for a short period of time) almost periodic, one can model the varying shape of a fixed cross section of the LV as a distorted 2-D torus, which in turn can be interpreted as a 2-D trigonometric polynomial. Clearly, we have to use a different degree for the time coordinate τ and for the spatial coordinate u.

Due to interfering biological structures and other distortions it sometimes happens that some of the image frames cannot be used to extract any reliable boundary information. Thus we have to approximate these missing boundaries from the information of the other image frames. To be more precise, assume that an echocardiographic examination provides a sequence of ultrasound images I_τ taken at timepoints $\tau = 0, 1, \ldots, T-1$, where T is approximately the length of one diastolic cycle (the timepoints could also be nonuniformly spaced). Assume that some of the images I_τ

provide no useful information, so that we can only detect boundary points $\{s_{j,k}\}_{k=1}^{r_j}$ from the images I_{τ_j}, where $\{\tau_j\}_{j=1}^{r}$ is a subset of $0, 1, \ldots, T-1$. In order to get a complete description of the LV for the time interval $[0, T]$, we have not only to approximate the boundaries f_j from each I_j, but we also have to recover the boundaries corresponding to the missing images. In other words we look for a 2-D trigonometric polynomial $p_* \in \boldsymbol{P}_M^2$ of appropriate degree M that satisfies $p(\tau_j, u_{j,k}) \equiv (x_{j,k}, y_{j,k})$, where the parameter u is related to $s_{j,k} = x_{j,k} + iy_{j,k}$ by formulas (6.2)–(6.4). This approximation can be computed by the 2-D version of Algorithm 2, as indicated in the beginning of section 5.

Under certain conditions we can use the 1-D version of Algorithm 2 instead of its 2-D version. As long as the assumptions of Corollary 5.1 are satisfied, we can compute $p_* \in \boldsymbol{P}_M^2$ by a successive application of Algorithm 2. We first approximate the boundaries f_j for each j separately from its samples $\{s_{j,k}\}_{k=1}^{r_j}$, which yields j different polynomials $p^{(M_j)} \in \boldsymbol{P}_{M_j}$. Having done this, the next step is to recover the missing boundaries at those timepoints where no information is available. We proceed by approximating successively the missing information "line by line." We choose $u = 0$, say, and approximate the missing information from the samples $p^{(M_j)}(u)$ taken at the time points $\tau_j, j = 1, \ldots, r$.

Note that the Toeplitz matrices of the systems $(T_M)_u c_u^{(M)} = b_u^{(M)}$ coincide for all u, since the sampling geometry is constant along the u-coordinate (because we have recovered all samples at each τ_j). Thus, we have to solve multiple Toeplitz systems with the same system matrix but a different right-hand side. It is well known that this can be done efficiently by exploiting the Gohberg–Semencul representation of the inverse of the Toeplitz matrix [14]. In our context this reads as follows. We solve

$$(T_M)_u c_u^{(M)} = b_u^{(M)} \tag{6.5}$$

for one u by Algorithm 2. We can solve now all other systems efficiently by establishing $(T_M)^{-1}$ in the Gohberg–Semencul form

$$(T_M)^{-1} = \left([L^{(M)}]^* L^{(M)} - U^{(M)} [U^{(M)}]^* \right) / z_0, \tag{6.6}$$

where $L^{(M)}$ is a lower triangular Toeplitz matrix with $z = [z_0, z_1, \ldots, z_{2M}]^T$ as its first column and $U^{(M)}$ is an upper triangular Toeplitz matrix with $[0, z_1, \ldots, z_{2M}]^T$ as its last column (z being the first column of $(T_M)^{-1}$). The matrix–vector multiplications to compute $c_u^{(M)} = (T_M)_u^{-1} b_u^{(M)}$ can now be carried out quickly using the FFT by embedding $L^{(M)}$ and $U^{(M)}$ into circulant matrices.

7. Miscellaneous remarks. For sampling sets with large gaps it can happen that the system $T_M c^{(M)} = b^{(M)}$ becomes ill conditioned with increasing degree M and therefore Algorithm 2 may become unstable [6]. In this case one can use a different, more robust, approach, which comes at higher computational cost [27]. We solve the system $T_M c^{(M)} = b^{(M)}$ iteratively, e.g., by the conjugate gradient method until a certain stopping criterion is satisfied at iteration k, say, yielding the solution $c_k^{(M)}$. We use this solution as an initial guess at the next level $M+1$ by setting $c_0^{(M+1)} = [0\ (c_k^{(M)})^T\ 0]^T$. The crucial point in this procedure is to find a stopping criterion that guarantees convergence of the iterates; see [27, 24] for more details.

The computation of the entries of the Toeplitz matrix in section 6 involves the nodes u_j, which in this particular case depend on the (perturbed) samples s_j. Therefore not only the right-hand side $b^{(M)}$, but also T_M is subject to perturbations. Hence,

in principle one might use the concept of total least squares (see [12]) instead of a least squares approach. A detailed discussion of this modification is beyond the scope of this paper.

Acknowledgments. The major part of this work was completed during my stay at Stanford University. I want to thank Prof. David Donoho and the Department of Statistics for their hospitality.

POSITIVITY-PRESERVING SCHEMES IN MULTIDIMENSIONS*

AMBADY SURESH†

Abstract. The performance of the MUSCL–Hancock upwind scheme is examined on problems of two-dimensional advection. It is found that when the advection direction is skewed relative to the mesh, most discrete total variation (TVD) limiters give rise to large spurious oscillations near discontinuities. The cause of these oscillations is traced to reconstructions that are not bounded by neighboring cell averages. It is proved that if the reconstruction in each cell is bounded by the cell averages of first order neighbors, then the MUSCL–Hancock scheme is positivity preserving. A simple limiter that achieves such bounded reconstructions is presented next along with a variant that is uniformly second order accurate. Numerical experiments show that the new schemes are accurate and efficient and compare favorably with other schemes.

Key words. advection, positivity preserving, upwind

1. Introduction.

Upwind methods [1], [2], [3], [4] for solving partial differential equations in general and the Euler equations of fluid flow in particular have gained popularity in the last decade due to their ability to capture discontinuities without the spurious oscillations incurred by other methods. Since their inception, upwind methods have been incorporated into a number of academic as well as commercial flow solvers.

Most upwind methods are first developed for the one-dimensional advection equation, where theoretical properties of the numerical scheme, such as the decrease of the discrete total variation (TVD), or monotonicity preservation, can be proved. The extension of these methods to multidimensions is typically carried out on a dimension-by-dimension basis where the one-dimensional algorithm is applied separately in each dimension. Although not much can be said about their nonoscillatory properties, these schemes have been quite successful in resolving complex patterns of interacting shocks and smooth waves [5].

For two-dimensional advection, where exact solutions are known, these schemes do not perform so well. In fact, this paper is motivated by the poor performance of one such scheme on these problems. The base scheme we choose is the MUSCL–Hancock scheme [6] which uses a midpoint rule in time and a linear reconstruction in each cell. The linear reconstruction is obtained by TVD limiters, like Superbee, Minmod, etc. acting on one-dimensional slivers of data. We find that when the advection direction is skewed relative to the mesh, all limiters except for the most dissipative Minmod limiter give rise to large spurious overshoots and undershoots near discontinuities. Indeed, some of these solutions are no better than the base scheme without any limiting at all (see Figures 1 and 2).

The reasons for these oscillations are traced to reconstructions that are not bounded by the initial data and lead us to another class of schemes proposed in recent years, namely, positivity-preserving (PP) schemes [7], [8], [9], [10], [11], [12].

†Dynacs Engineering, Inc., NASA Glenn Research Center, Cleveland, OH 44135 (ambady.suresh@grc.nasa.gov).

For positive initial data, these schemes have the property that the solution at any future time is also positive. These schemes are also called positive definite, shape preserving, and bounded schemes in the literature. We show that if the reconstruction is bounded by the data, then the MUSCL–Hancock scheme can be proved to be PP. An efficient limiter that achieves such bounded reconstructions is presented next along with a fix for uniform second order accuracy. Finally, we present some numerical experiments to assess the performance of PP schemes and compare them to a few existing schemes.

2. TVD schemes on two-dimensional advection problems. Let us consider the two-dimensional advection equation given by

$$u_t + au_x + bu_y = 0 \tag{2.1}$$

The numerical scheme we use is the MUSCL–Hancock scheme, which employs a midpoint rule in time and linear reconstructions in each cell, a combination widely used in many commercial codes for the Euler equations. We assume a uniform grid of spacing Δx and Δy and $a \geq 0$ and $b \geq 0$. If we denote by $u_{i,j}$ the approximations to the cell averages at time level n, the scheme can be written as

$$u_{i,j}^{n+1} = u_{i,j}^n - \lambda_x(u_{i+1/2,j}^{n+1/2} - u_{i-1/2,j}^{n+1/2}) - \lambda_y(u_{i,j+1/2}^{n+1/2} - u_{i,j-1/2}^{n+1/2}), \tag{2.2}$$

where $\lambda_x = a\Delta t/\Delta x$, $\lambda_y = b\Delta t/\Delta y$. The interface values are obtained by a Taylor series expansion inside the upwind cell, i.e.,

$$u_{i+1/2,j}^{n+1/2} = u_{i,j}^n + \frac{1}{2}\Delta x\,(u_x)_{i,j} + \frac{1}{2}\Delta t\,(u_t)_{i,j}. \tag{2.3}$$

Substituting for u_t from (2.1) and denoting the normalized values of $(u_x)_{i,j}$ and $(u_y)_{i,j}$ by $S_{i,j}^x$ and $S_{i,j}^y$, the interface values can be derived as

$$\begin{aligned} u_{i+1/2,j}^{n+1/2} &= u_{i,j}^n + \tfrac{1}{2}(1-\lambda_x)S_{i,j}^x - \tfrac{1}{2}\lambda_y S_{i,j}^y, \\ u_{i,j+1/2}^{n+1/2} &= u_{i,j}^n + \tfrac{1}{2}(1-\lambda_y)S_{i,j}^y - \tfrac{1}{2}\lambda_x S_{i,j}^x. \end{aligned} \tag{2.4}$$

If $S_{i,j}^x$ and $S_{i,j}^y$ are given by their central difference estimates, i.e.,

$$\begin{aligned} S_{i,j}^x &= \tfrac{1}{2}(u_{i+1,j} - u_{i-1,j}), \\ S_{i,j}^y &= \tfrac{1}{2}(u_{i,j+1} - u_{i,j-1}), \end{aligned} \tag{2.5}$$

then (2.2) is second order accurate in time and space and stable in the region $\lambda_x \geq 0$, $\lambda_y \geq 0$, $\lambda_x + \lambda_y \leq 1$. Thus, the time step can be defined in terms of a CFL number $\sigma = \lambda_x + \lambda_y$ by

$$\Delta t = \sigma/(a/\Delta x + b/\Delta y). \tag{2.6}$$

The slopes $S_{i,j}^x$ and $S_{i,j}^y$ are obtained by one-dimensional TVD limiters acting on slivers of one-dimensional data. For the x direction, if we define

$$\begin{aligned} s_+ &= (u_{i+1,j} - u_{i,j}), \\ s_- &= (u_{i,j} - u_{i-1,j}), \end{aligned} \tag{2.7}$$

then the Minmod, Average, and Superbee limiters can be written as

$$
\begin{aligned}
S^x_{i,j} &= \tfrac{1}{2}\,[\mathrm{sgn}(s_+) + \mathrm{sgn}(s_-)]\,\mathrm{Min}(|s_-|, |s_+|),\\
S^x_{i,j} &= \tfrac{1}{2}\,[\mathrm{sgn}(s_+) + \mathrm{sgn}(s_-)]\,\mathrm{Min}(|s_+ + s_-|/2,\, 2|s_-|,\, 2|s_+|),\\
S^x_{i,j} &= \tfrac{1}{2}\,[\mathrm{sgn}(s_+) + \mathrm{sgn}(s_-)]\,\mathrm{Min}(\mathrm{Max}(|s_+|, |s_-|),\, 2|s_-|,\, 2|s_+|).
\end{aligned}
\tag{2.8}
$$

Note that in one dimension, all these schemes give updates bounded by the initial data; i.e., it can be shown that (see the appendix) if $b = 0$ and $a > 0$, then

$$
u^{n+1}_{i,j} \in [\mathrm{Min}(u^n_{i,j}, u^n_{i-1,j}), \mathrm{Max}(u^n_{i,j}, u^n_{i-1,j})]
\tag{2.9}
$$

so that if $u^n_{i,j} > 0$, for all i, j, then so is $u^{n+1}_{i,j}$. Such schemes are called PP schemes. However, this property does not carry over to two dimensions as we shall see below.

The results of a typical calculation with these schemes on a grid of 120×120 cells over the domain of $[-1, 1] \times [-1, 1]$, with $a = 1.0$, $b = 0.1$, $\sigma = 0.8$ at the final time $t = 20$ (1650 time steps), are shown in Figures 1 and 2. The initial condition is

$$
\begin{aligned}
u(x, y, 0) &= 1 \quad \text{for } (x^2 + y^2)^{1/2} < 0.4\\
&= 0 \quad \text{otherwise.}
\end{aligned}
\tag{2.10}
$$

Figure 1 actually shows the numerical solutions obtained on the line $y = -0.258$, while Figure 2 shows solutions on the line $y = 0.392$. As can be seen, both the Superbee and the Average limiters show large overshoots and undershoots. The Minmod limiter gives acceptable but diffused results.

Our numerical experiments over a wide range of initial conditions, propagation directions, and Courant numbers indicate that most TVD limiters give oscillatory solutions when the convection angle is not aligned with either axis or the diagonal. The worst oscillations are observed with the Superbee limiter while none are observed with the Minmod limiter.

3. PP schemes in two dimensions. To understand why these oscillations occur it is instructive to rewrite (2.2) and (2.4) as

$$
\begin{aligned}
u^{n+1}_{i,j} &= (1 - \lambda_x - \lambda_y)(u_{i,j} - \tfrac{1}{2}\lambda_x\, S^x_{i,j} - \tfrac{1}{2}\lambda_y\, S^y_{i,j})\\
&+\lambda_x(u_{i-1,j} + \tfrac{1}{2}(1 - \lambda_x)\, S^x_{i-1,j} - \tfrac{1}{2}\lambda_y\, S^y_{i-1,j})\\
&+\lambda_y(u_{i,j-1} - \tfrac{1}{2}\lambda_x\, S^x_{i,j-1} + \tfrac{1}{2}(1 - \lambda_y)\, S^y_{i,j-1})
\end{aligned}
\tag{3.1}
$$

If the reconstruction assumed in each cell is written in normalized coordinates as

$$
R_{i,j}(\xi, \eta) = u_{i,j} + S^x_{i,j}\xi + S^y_{i,j}\eta,
\tag{3.2}
$$

with $|\xi|, |\eta| \le 1/2$, then the above equation can be written as

$$
\begin{aligned}
u^{n+1}_{i,j} = \;& (1 - \lambda_x - \lambda_y)\, R_{i,j}(-\lambda_x/2, -\lambda_y/2)\\
&+\lambda_x\, R_{i-1,j}((1 - \lambda_x)/2, -\lambda_y/2)\\
&+\lambda_y\, R_{i,j-1}(-\lambda_x/2, (1 - \lambda_y)/2).
\end{aligned}
\tag{3.3}
$$

This shows that the value of $u_{i,j}$ at the next time step is a convex combination of sampled reconstructed values from the three cells (i, j), $(i - 1, j)$, and $(i, j - 1)$. Moreover, under the stability limit, $\lambda_x \ge 0$, $\lambda_y \ge 0$, $\lambda_x + \lambda_y \le 1$, the points where

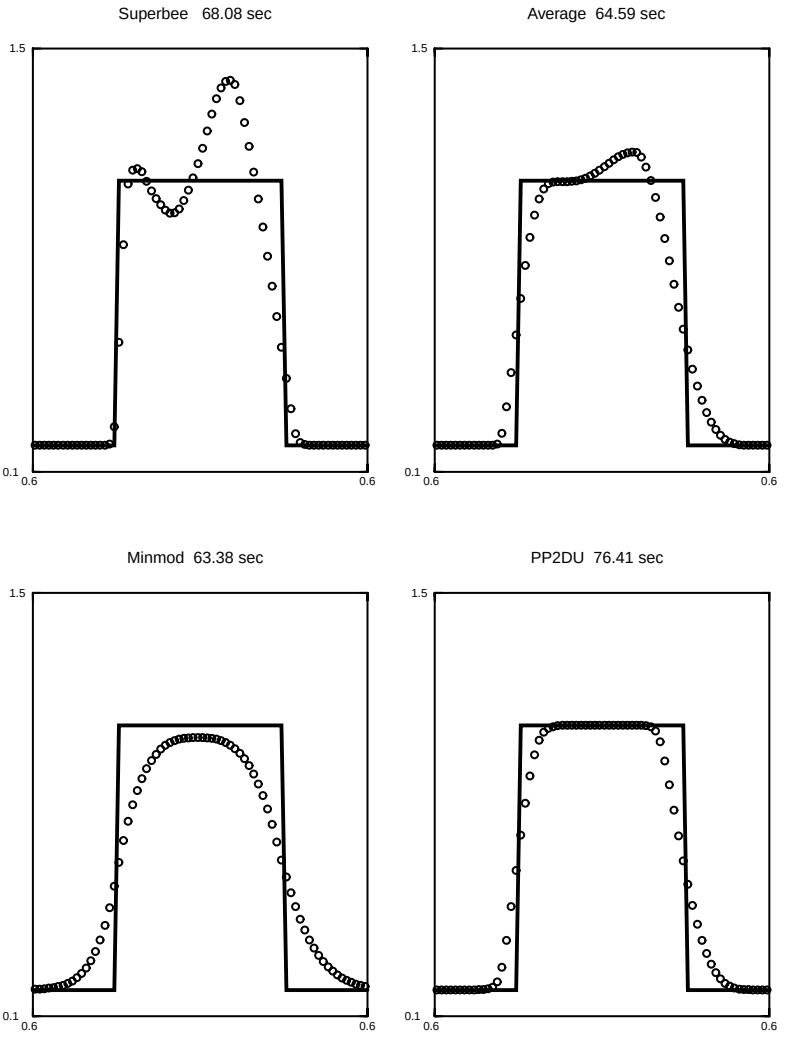

FIG. 1. *Advection of* (2.10) *with* $a = 1.0$, $b = 0.1$, *CFL* $= 0.8$, *and* $t = 20.120 \times 120$ *uniform grid. Results are shown on the line* $y = -0.258$.

the reconstructions are sampled lie inside their respective cells. Thus, a simple way of keeping $u_{i,j}^{n+1}$ bounded is to bound the reconstructions $R_{i,j}$.

To this end, let us define $N_{i,j}$ to be the set of cell averages of the immediate first order neighbors of the cell (i, j) and $u_{i,j}$,

$$N_{i,j} = \begin{bmatrix} u_{i-1,j+1}, & u_{i,j+1}, & u_{i+1,j+1}, \\ u_{i-1,j}, & u_{i,j}, & u_{i+1,j}, \\ u_{i-1,j-1}, & u_{i,j-1}, & u_{i+1,j-1} \end{bmatrix}. \tag{3.4}$$

Let $U_{i,j}$ be the range of variation of u on $N_{i,j}$,

$$U_{i,j} = [\mathrm{Min}[N_{i,j}], \mathrm{Max}[N_{i,j}]]. \tag{3.5}$$

The following result is then obvious from (3.3).

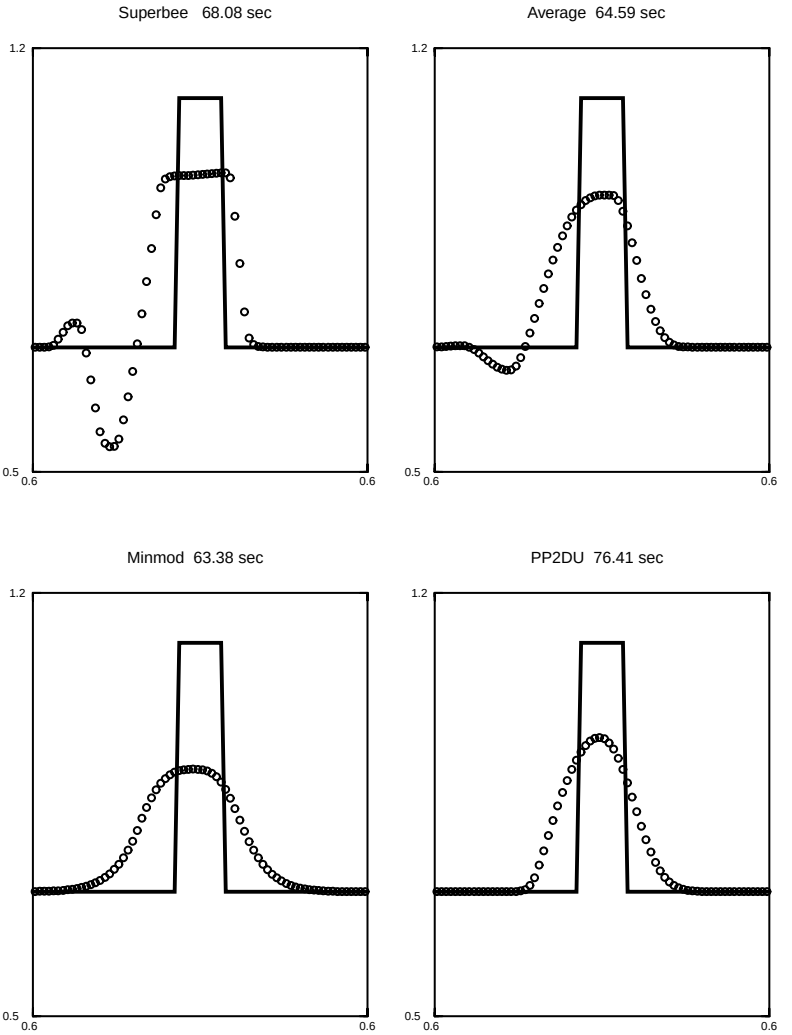

FIG. 2. *Advection of* (2.10) *with* a=1.0, $b = 0.1$, *CFL* $= 0.8$, *and* $t = 20.120 \times 120$ *uniform grid. Results are shown on the line* $y = 0.392$.

THEOREM 3.1. *Assume that for the scheme* (2.2)–(2.4) *the reconstruction in each cell is bounded by its immediate neighbors; i.e., for all* (i, j),

$$R_{i,j} \in U_{i,j}. \tag{3.6}$$

Then, for $\lambda_x + \lambda_y \leq 1$,

$$u_{i,j}^{n+1} \in U_{i,j} \cup U_{i-1,j} \cup U_{i,j-1}, \tag{3.7}$$

i.e., the cell average at the next time step lies inside the union of the averages in the neighborhoods of (i, j), $(i-1, j)$, *and* $(i, j-1)$.

Thus, if (3.6) is satisfied in each cell, the scheme becomes PP. As a counter

example to this theorem, consider positive data given by

$$u_{-2,0} = 100, \quad \begin{array}{lll} u_{-1,1} = 1, & u_{0,1} = 0, & \\ u_{-1,0} = 1, & u_{0,0} = 0, & u_{1,0} = 0, \\ u_{-1,-1} = 1, & u_{0,-1} = 10, & u_{1,-1} = 100, \\ & u_{0,-2} = 100. & \end{array} \tag{3.8}$$

With the Superbee and Average limiters the reconstruction $R_{0,-1}$ has large negative values and does not satisfy (3.6). Not surprisingly, for $\lambda_x = 0.6, \lambda_y = 0.2$, both theses schemes give $u_{0,0}^{n+1} = -8/25$, which shows that these schemes do not preserve positivity. On the other hand, the Minmod limiter gives reconstructions that are bounded by first order neighbors and gives $\bar{u}_{0,0}^{n+1} = 57/50$, which is acceptable. This explains the large undershoots/overshoots observed in Figures 1 and 2.

It is easily verified that Theorem 3.1 holds true for all propagation directions provided the interface values (2.4) are defined from upwind cells. The general CFL limit is then $|\lambda_x| + |\lambda_y| \le 1$.

Results similar to Theorem 3.1 have been proved in the literature in related contexts. Batten, Lambert, and Causon [11] prove a PP condition for multidimensional advection on unstructured meshes. Perthame and Shu [9] and Linde and Roe [12] prove PP conditions on unstructured meshes for the two-dimensional Euler equations. However, both of these are for convex time Runge–Kutta time stepping, for which the TVD limiters applied dimension-by-dimension can be shown to be PP under a reduced CFL limit.

We note that the only thing positivity preservation guarantees is that the cell averages at all future times will lie in a certain range governed by the initial conditions. It does not rule out spurious oscillations in this range. However, in practice, in numerical experiments, we see that the PP constraint goes a long way toward getting rid of all spurious oscillations.

The condition that the reconstruction be bounded over the whole cell by all its immediate neighbors (including corner neighbors) was introduced by Barth and Jesperson [13] in the context of unstructured grids. The above result shows that this condition is useful for constructing PP schemes on structured meshes as well. It is also similar in spirit to the earlier work of Spekreijse [14], although the details are different.

In the next section, we derive an efficient limiter that enforces (3.6) but is not as dissipative as the Minmod limiter. We remark that the choice of stencil, i.e., (3.4) used above, is somewhat arbitrary. In fact, for the Minmod scheme, the reconstruction is so tightly constrained that $R_{i,j}$ actually lies inside the range of $u_{i,j}$ and two linearly independent cells from $u_{i\pm1,j}$ and $u_{i,j\pm1}$. From this it follows that $u_{i,j}^{n+1}$ is bounded by the four values $u_{i,j}$, $u_{i-1,j}$, $u_{i,j-1}$, and $u_{i-1,j-1}$, a much smaller stencil than (3.7).

4. A PP limiter. The procedure for modifying the slopes to satisfy (3.6) is far from unique. The approach described here is similar to the approach of Barth and Jesperson [13], adapted to structured grids and modified so as to depend continuously on the data.

To satisfy (3.6) within a cell, the idea is to restrict the slopes so that the reconstructed values at the four corners of the cell lie inside the required interval, i.e., (3.5). Without loss of generality, we can adjust the value of $u_{i,j}$ to zero and define

$$V_{min} = \text{Min} \begin{bmatrix} u_{i-1,j+1} - u_{i,j}, & u_{i,j+1} - u_{i,j}, & u_{i+1,j+1} - u_{i,j}, \\ u_{i-1,j} - u_{i,j}, & 0, & u_{i+1,j} - u_{i,j}, \\ u_{i-1,j-1} - u_{i,j}, & u_{i,j-1} - u_{i,j}, & u_{i+1,j-1} - u_{i,j} \end{bmatrix}, \tag{4.1}$$

$$V_{max} = \text{Max}\begin{bmatrix} u_{i-1,j+1}-u_{i,j}, & u_{i,j+1}-u_{i,j}, & u_{i+1,j+1}-u_{i,j}, \\ u_{i-1,j}-u_{i,j}, & 0, & u_{i+1,j}-u_{i,j}, \\ u_{i-1,j-1}-u_{i,j}, & u_{i,j-1}-u_{i,j}, & u_{i+1,j-1}-u_{i,j} \end{bmatrix}. \tag{4.2}$$

Then, for the north-east corner, we compute (with the slopes given by (2.5))

$$u_{NE} = \frac{1}{2}S^x_{i,j} + \frac{1}{2}S^y_{i,j} \tag{4.3}$$

and a ϕ_{NE} as follows:

$$\begin{array}{llll} \textit{if} & u_{NE} > & V_{max}, & \phi_{NE} = V_{max}/u_{NE}, \\ \textit{if} & u_{NE} < & V_{min}, & \phi_{NE} = V_{min}/u_{NE}, \\ \textit{else} & & & \phi_{NE} = 1. \end{array} \tag{4.4}$$

We repeat these calculations for all corners, and the final slopes are given by

$$\begin{aligned} S^x_{i,j} &\leftarrow \text{Min}(\phi_{NE}, \phi_{NW}, \phi_{SE}, \phi_{SW})\, S^x_{i,j}, \\ S^y_{i,j} &\leftarrow \text{Min}(\phi_{NE}, \phi_{NW}, \phi_{SE}, \phi_{SW})\, S^y_{i,j}, \end{aligned} \tag{4.5}$$

where the arrow notation stands for replacement or overwriting.

One problem with the above algorithm is the value of ϕ_{NE} does not depend continuously on the data. For example, if $V_{max} = 0$ such as near an extrema, and u_{NE} approaches zero through positive values, the value of ϕ_{NE} jumps from zero to one. This can be fixed by redefining V_{max} and V_{min} as

$$V_{min} = \text{Min}\begin{bmatrix} u_{i-1,j+1}-u_{i,j}, & u_{i,j+1}-u_{i,j}, & u_{i+1,j+1}-u_{i,j}, \\ u_{i-1,j}-u_{i,j}, & -\epsilon, & u_{i+1,j}-u_{i,j}, \\ u_{i-1,j-1}-u_{i,j}, & u_{i,j-1}-u_{i,j}, & u_{i+1,j-1}-u_{i,j} \end{bmatrix}, \tag{4.6}$$

$$V_{max} = \text{Max}\begin{bmatrix} u_{i-1,j+1}-u_{i,j}, & u_{i,j+1}-u_{i,j}, & u_{i+1,j+1}-u_{i,j}, \\ u_{i-1,j}-u_{i,j}, & +\epsilon, & u_{i+1,j}-u_{i,j}, \\ u_{i-1,j-1}-u_{i,j}, & u_{i,j-1}-u_{i,j}, & u_{i+1,j-1}-u_{i,j} \end{bmatrix}, \tag{4.7}$$

where ϵ is a small positive number (10^{-20} in all our computations).

Further simplifications to the algorithm defined by (2.5), (4.3)–(4.7), are possible due to the symmetry of the grid. It turns out that restricting all the corner values to lie inside $[V_{min}, V_{max}]$ is equivalent to restricting $|S^x_{i,j}| + |S^y_{i,j}|$ to lie inside another interval. We skip the details and give the result in algorithm form.

Let the slopes be defined initially by their centered difference values, namely, (2.5), and let V_{min} and V_{max} be defined by (4.6) and (4.7). Then we define

$$V = 2\,\frac{\text{Min}(|V_{min}|, |V_{max}|)}{(|S^x_{i,j}| + |S^y_{i,j}|)}. \tag{4.8}$$

The final slopes are then

$$\begin{aligned} S^x_{i,j} &\leftarrow \text{Min}(1\,, V)\, S^x_{i,j}, \\ S^y_{i,j} &\leftarrow \text{Min}(1\,, V)\, S^y_{i,j}. \end{aligned} \tag{4.9}$$

It can be verified that after limiting, the reconstructed values in the cell (i, j) lie inside the interval $U_{i,j}$ and that the reconstruction depends continuously on the data.

The main problem with this limiter is the loss of accuracy near critical points (a critical point is where the gradient of a function vanishes) which makes these schemes only first order accurate in the Max. norm. If a scheme is required to be second order accurate everywhere (i.e., in the Max. norm), such a scheme will advect second order polynomials exactly. It follows that while advecting smooth extrema such a scheme will give updates not bounded by the data. It thus appears that second order accuracy in the Max. norm and positivity preservation are mutually exclusive, even in one dimension.

In the next section we present a compromise that relaxes the PP constraint near critical points so that uniform second order accuracy can be achieved.

5. Uniform second order accuracy. The essential idea behind this fix is to redefine the interval $[V_{min}, V_{max}]$ so that near discontinuities it is the same as above but near a smooth critical point, such as an extremum, it is strictly larger so that the limiting process leaves the original values of the slopes unaltered. We are able to do this with some success only on a corner by corner basis and not for the whole cell. Thus, we focus on the limiting process defined by (4.3), (4.4), and (4.5), with V_{min} and V_{max} defined by (4.6), (4.7).

When u_{NE} falls outside $[V_{min}, V_{max}]$, there are two possibilities: (1) we are near a discontinuity so that the above limiting process is appropriate; (2) we are near a smooth critical point where no limiting is appropriate. We distinguish between these two situations by looking at the data along the diagonal $u_{i+p,j+p}$, $p = -1, 2$. If the interval $[u_{i,j}, u_{i+1,j+1}]$ falls outside the interval $[u_{i-1,j-1}, u_{i+2,j+2}]$, we conclude that we are near a smooth critical point; otherwise we conclude we are near a discontinuity. Thus, we define

$$
\begin{aligned}
t_{max} &= \mathrm{Max}(u_{i,j}, u_{i+1,j+1}),\\
t_{min} &= \mathrm{Min}(u_{i,j}, u_{i+1,j+1}),\\
w_{max} &= \mathrm{Max}(u_{i-1,j-1}, u_{i+2,j+2}),\\
w_{min} &= \mathrm{Min}(u_{i-1,j-1}, u_{i+2,j+2}),\\
d_1 &= \mathrm{Max}(t_{max} - w_{max}, w_{min} - t_{min}, 0.0),
\end{aligned}
\tag{5.1}
$$

so that d_1 is positive near a critical point and zero otherwise. Then we define new values of V_{min} and V_{max} as

$$
\begin{aligned}
\hat{V}_{min} &= V_{min} - \epsilon_2\, d_1,\\
\hat{V}_{max} &= V_{max} + \epsilon_2\, d_1,
\end{aligned}
\tag{5.2}
$$

where ϵ_2 is a positive constant. Since d_1 is positive, the new interval $[\hat{V}_{min}, \hat{V}_{max}]$ is strictly larger than the old interval and depends continuously on the data. The value of ϕ_{NE} is then calculated as

$$
\begin{aligned}
&\text{if } u_{NE} > V_{max}, && \phi_{NE} = \mathrm{Min}(1, \hat{V}_{max}/u_{NE}),\\
&\text{if } u_{NE} < V_{min}, && \phi_{NE} = \mathrm{Min}(1, \hat{V}_{min}/u_{NE}),\\
&\text{else} && \phi_{NE} = 1.
\end{aligned}
\tag{5.3}
$$

These calculations are repeated for all corners and the final slopes calculated from (4.5).

Let us describe how this algorithm works in words so that its inherent limitations are clear. On fine enough meshes, when one of the corner values falls outside $[V_{min}, V_{max}]$, it means we are either near a discontinuity or a smooth critical point

(maxima, minima, saddle point, etc.). If we are near a discontinuity, we hope the data will be monotone on the diagonal line going through the corner and so d_1 will be zero and the slopes are limited just as in the original PP scheme. If we are near a critical point, however, data along the diagonal will not be monotone. Then $d_1 > 0$ and gives enough room so that the u_{NE} will be swallowed inside the new interval $[\hat{V}_{min}, \hat{V}_{max}]$, yielding $\phi_{NE} = 1$.

Since the two types of data, i.e., data near discontinuities and data near a critical point, are not easily characterized in two dimensions, not much can be theoretically proved about this algorithm. If $u_{i,j}$ is independent of j and $b = 0$, the corresponding one-dimensional scheme can be proved to be monotonicity-preserving and uniformly second order accurate for $\epsilon_2 > 0.25$. Thus we use $\epsilon_2 = 0.275$ in all our computations. In one dimension, this fix for uniform accuracy is a simplified version of the fix for uniform accuracy presented in Suresh and Huynh [15], in the context of higher order Runge–Kutta schemes.

For coding purposes, we summarize the final algorithm. In each cell, we first calculate the slopes by (2.5). Then for the north-east corner, we calculate u_{NE} by (4.3) and V_{min} and V_{max} by (4.6) and (4.7). Then we calculate ϕ_{NE} from (5.3). Note that the modified interval (i.e., (5.1), (5.2)) needs to be computed only when u_{NE} falls outside the original interval, which happens for relatively few cells. This is repeated for all the corner cells and the final slopes obtained from (4.5).

6. Two-dimensional Euler equations. The two schemes presented above are easily extended to the Euler equations. Following the usual approach, the primitive variables $V = (\rho, u, v, p)$ (where ρ is the density, (u, v) are the x and y components of the velocity, and p is the pressure), are reconstructed in each cell using the reconstruction procedure presented above. This yields the gradient of the primitive variables in each cell, which is used to march to the half time step. The values of V at the half time step on each side of a face are used to compute the flux via the Roe approximate Riemann solver modified with an entropy fix. Since the extension is fairly standard, we omit the details, which can be found in [16].

This scheme requires only one Riemann solver call per face per time step, while those using Runge–Kutta time stepping require at least two for second order accuracy. The time step is defined in terms of the CFL number σ by

$$\Delta t = \text{Min}\left(\frac{\sigma}{(|u| + c)/\Delta x + (|v| + c)/\Delta y}\right), \tag{6.1}$$

where the minimum is over all cells and c is the speed of sound given by $(\gamma p/\rho)^{1/2}$, with $\gamma = 1.4$.

7. Numerical experiments. We present some numerical experiments to assess the accuracy, efficiency, and nonoscillatory properties of the two schemes presented above. We refer to the strictly PP scheme (i.e., (4.8), (4.9)) as PP2D and the scheme with the fix for uniform accuracy as PP2DU. We are particularly interested in the following: (1) Does the fix for uniform accuracy in PP2DU give rise to spurious oscillations near discontinuities? (2) How bad is the loss of accuracy at critical points for PP2D? (3) How do these schemes compare in accuracy and efficiency with other schemes like MPDATA [18] or UTOPIA [10]?

All computations were performed on an isolated IRIS 100-MHZ R4000 SGI Indigo workstation. The execution times were obtained by using the timex utility.

We solved (2.1) on rectangular domains with periodic boundary conditions at the boundaries. A number of initial conditions, advection directions, and time steps

TABLE 1

	120	2.03(-2)	2.17	6.81(-3)	2.18	
	240	4.79(-3)	2.08	1.60(-3)	2.09	228.99

were explored, but only a few cases are reported here. For initial conditions with discontinuities, we scanned the computed solution for overshoots, undershoots, and spurious oscillations, and we present line plots through these regions. These represent the worst-case results. In all these cases, PP2DU performed well without spurious oscillations.

Example 1. We return to the example already cited above. Here the domain of $[-1,1] \times [-1,1]$ is covered by a uniform grid of 120×120 cells, with $a = 1.0$, $b = 0.1$, $\sigma = 0.8$, and final time $t = 20$ (1650 time steps). This corresponds to 10 periods in x and one period in y. The initial condition is (2.10). The minimum and maximum values over the whole domain for Minmod, Average, Superbee, PP2D, and PP2DU are, respectively, $[0, 0.997]$, $[-0.093, 1.108]$, $[-0.400, 1.380]$, $[0, 1]$, and $[0, 1]$. The results of PP2DU, on the line $y = -0.258$, are also shown in Figure 1, which is less diffuse than the Minmod scheme and is nonoscillatory with no overshoots or undershoots. However, shock resolution is still quite poor for all schemes except perhaps Superbee. The result from PP2D is identical and is not shown. In terms of efficiency, PP2DU is about 20% more expensive than the Minmod scheme.

Figure 2 shows results from the same computation but this time on the line $y = 0.392$. Although the discontinuity is rather narrow, the Minmod and PP2DU schemes give acceptable results, while both the Superbee and Average limiters show large undershoots.

Example 2. The next problem involves smooth periodic initial conditions on the domain $[-1,1] \times [-1,1]$, which are given by

$$u(x, y, 0) = \sin^4(\pi(x + 1)) + \sin^4(\pi(y + 1)) \tag{7.1}$$

along with $a = 0.2$, $b = 1.0$, $\sigma = 0.8$, and final time $t = 10$. In this case we solve on three meshes and estimate the order of accuracy of the scheme. We compare the results with the unlimited scheme.

The results are presented in Table 1. As can be seen, there is little difference between PP2DU and the unlimited scheme, especially on the finer meshes. This indicates that the fix for uniform accuracy is working well and is not too expensive (about 12% more than PP2D). As expected, the results from PP2D show much higher Max. errors due to the loss of accuracy at extrema and less than second order accuracy in this norm.

Example 3. In this example, we compare with the scheme of Thuburn [10] for multidimensional advection. This scheme (TH1) (see Table 2) is a limited form of the UTOPIA scheme of Leonard, MacVean, and Lock [8]. Unlike the approach presented here, the limiting is performed directly on the interface fluxes at the half time step,

TABLE 2
Advection of (7.2) *with* $\sigma = 0.5$, $\Delta x = \Delta y = 1/31$. *Problem* 1: $a = 1$, $b = 0$, 62 *time steps; Problem* 2: $a = 1$, $b = 1$, 124 *time steps.*

	Problem 1		Problem 2	
Scheme	Min. value	Max. value	Min. value	Max. value
TH1	0.000	0.927	0.000	0.847

PP2D	0.000	0.891	0.000	0.760

i,e. on $u^{n+1/2}_{i+1/2,j}$.

The domain here is $[0,1] \times [0,1]$ which is covered by a uniform grid of 31×31 cells and the initial condition is

$$u(x,y,0) = \exp(-\beta((x-x_0)^2 + (y-y_0)^2)) \tag{7.2}$$

with $\beta = 31^2/18$, $x_0 = y_0 = 1/2$. For the first problem the velocities are $a = 1$ and $b = 0$, $\sigma = 0.5$ and the results studied after 62 timesteps. In the second problem, $a = 1$ and $b = 1$, $\sigma = 0.5$ and the number of time steps is 124.

The results are shown in Table 2 and Figure 3. The peak values obtained with PP2DU are slightly better than that of Thuburn's scheme. However, for Problem-2, both PP2D and PP2DU indicate slightly more distortion in the contours than TH1. This distortion can perhaps be reduced further by a more accurate choice of the initial slopes in (2.5).

TABLE 3
Advection of (7.4) *with velocity field* (7.3). $\sigma_{max} = 0.99$, 628 *time steps,* $\Delta x = \Delta y = 1$.

Scheme	Min. value	Max. value
MPDATA #4	0.000	3.263
MPDATA #3	0.000	3.261
PP2DU	0.000	3.463
PP2D	0.000	3.257
Superbee	-0.027	3.439
Average	-0.003	3.271
Minmod	0.000	2.770
Unlim.	-0.065	3.464

Example 4. In this example, we compare our results with the scheme of MPDATA [18] and its many recent enhancements. The initial condition here is a conical initial function that is in solid-body rotation. The domain is $[0,100] \times [0,100]$, which is covered by a uniform grid of 100×100 cells. The velocities are given by

$$\begin{aligned} a(x,y) &= -w\,(y - y_0), \\ b(x,y) &= +w\,(x - x_0), \end{aligned} \tag{7.3}$$

with $(x_0, y_0) = (50, 50)$ and $w = 0.1$. The initial condition can be written as

$$\begin{aligned} r &= ((x-x_c)^2 + (y-y_c)^2)^{1/2}, \\ u(x,y,0) &= 4\,(1 - r/15) \quad \text{for} \quad r < 15, \\ u(x,y,0) &= 0 \quad \text{for} \quad r \geq 15, \end{aligned} \tag{7.4}$$

with $x_c = 75$ and $y_c = 50$. The time step is chosen so that the maximum Courant number is 0.99. The results are studied after 628 time steps and are shown in Table 3. Contour plots of the solution after 3768 time steps are shown in Figure 4.

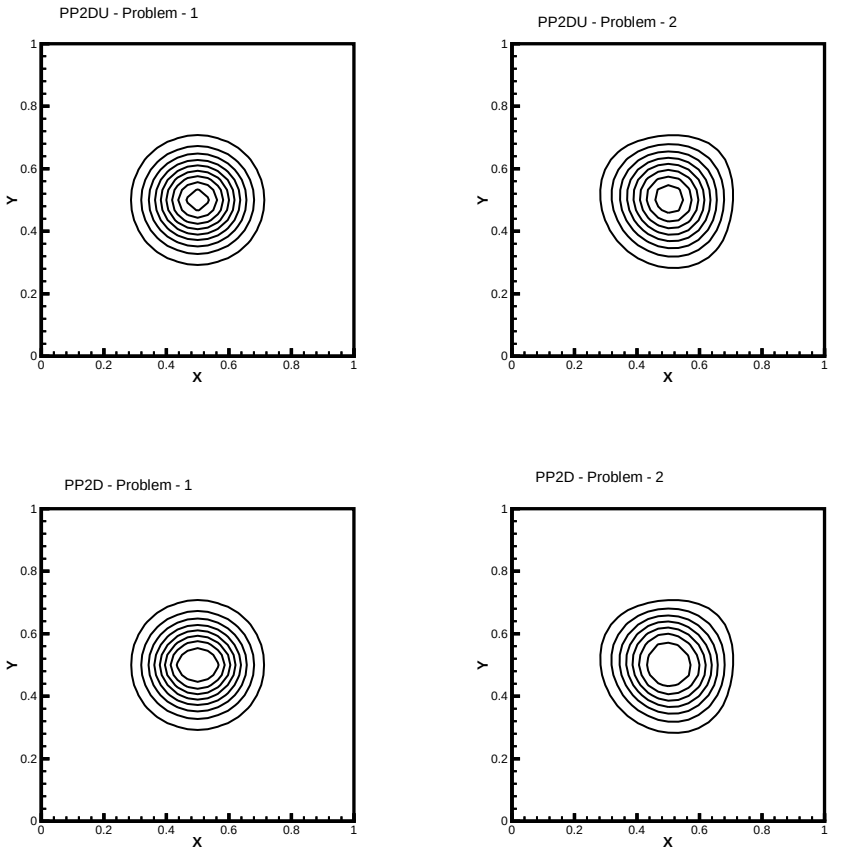

FIG. 3. *Advection of* (7.2) *on a* 31×31 *grid. Problem* 1: $a = 1$, $b = 0$, $\sigma = 0.5$, 62 *time steps; Problem* 2: $a = 1$, $b = 1$, $\sigma = 0.5$, 124 *time steps. The contours are from* $(0.1, 1.0)$ *with an increment of* 0.1. *Max. and Min. values are given in Table* 2.

From Table 3, the peak values of both PP2D and PP2DU are comparable to MPDATA. However, from Figure 4, both seem to have slightly larger distortion than the results of MPDATA.

Example 5. Our last problem is the well known double Mach reflection problem in two-dimensional gas dynamics. The computational domain is $[0, 4] \times [0, 1]$. The reflecting wall is from $(1/6, 0)$ to $(4, 0)$. Initially, a Mach 10 shock is incident on this wall at $(1/6, 0)$ making an angle of 60 degrees with the x-axis. To the right of the shock is undisturbed fluid of uniform pressure 1 and density 1.4. To the left of the shock, the conditions are

$$(\rho, u, v, p) = (8.0, 7.1447, -4.125, 116.5).$$

As the shock reflects off the wall, a diffraction pattern is formed. The final time is $t = 0.2$. A detailed description of the problem and various solutions can be found in [5]. The problem is solved on a uniform grid of 120×30 cells with $\sigma = 0.8$.

The boundary conditions are as follows: at the bottom, from $(0, 0)$ to $(1/6, 0)$, linear extrapolation; from $(1/6, 0)$ to $(4, 0)$, solid boundary; at the right, linear extrapolation; at the left, supersonic inflow; at the top, time-dependent conditions determined by the exact motion of the Mach 10 shock.

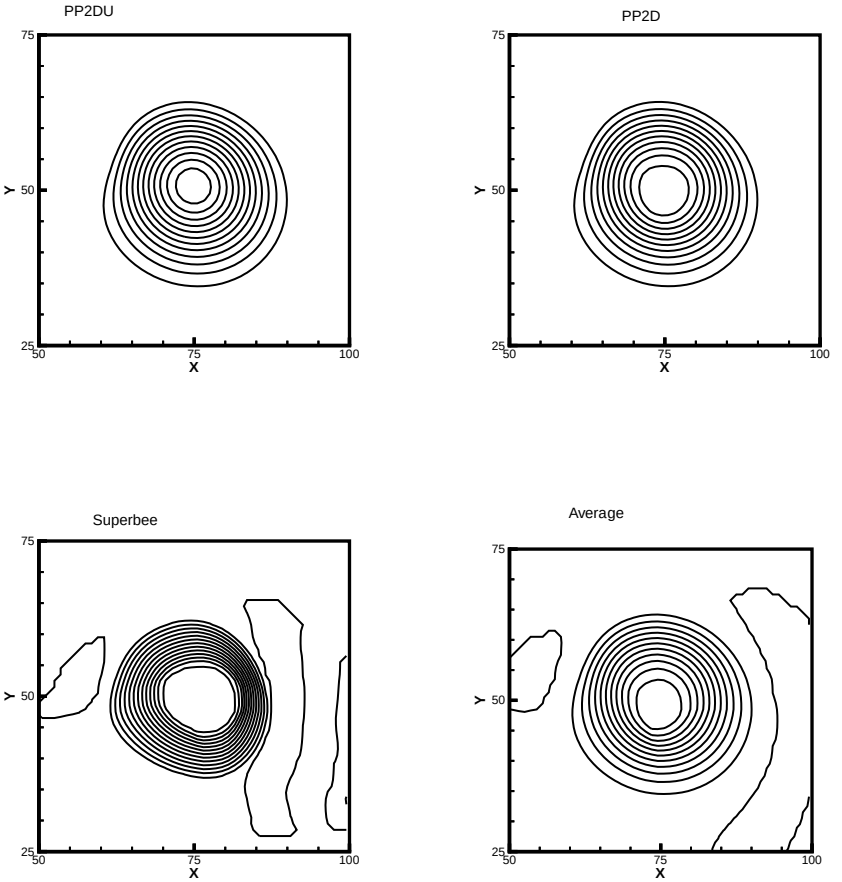

FIG. 4. *Advection of* (7.4) *on a* 100×100 *grid with velocity field* (7.3). $\sigma_{max} = 0.99$, 3768 *time steps. The contours are from* $(-0.25, 3.5)$ *with an increment of* 0.25.

The PP2DU, PP2D solutions are compared with the solution from the TVD scheme using the Average limiter in Figure 5, which shows contour plots of density. In this problem, there does not seem to be much difference between the three solutions.

8. Conclusions. In this paper, we have considered the problem of why the MUSCL–Hancock scheme with one-dimensional TVD limiters applied on a dimension-by-dimension basis gives rise to spurious oscillations near discontinuities on problems of two-dimensional advection. We have shown that if the reconstruction over the whole cell is bounded by its first order neighbors, then the MUSCL–Hancock scheme can be proved to be positivity preserving. An efficient limiter that achieves this and depends continuously on the data is also presented along with a fix for the loss of accuracy near extrema. Numerical experiments reveal that the new schemes perform well and are competitive with other methods for multidimensional advection.

Appendix. In this appendix, we recall a quick proof which states that in one dimension, the MUSCL–Hancock scheme with the slopes given by any of the one-dimensional TVD limiters of (2.8) does indeed satisfy (2.9) for $0 \leq \lambda_x \leq 1$. Using

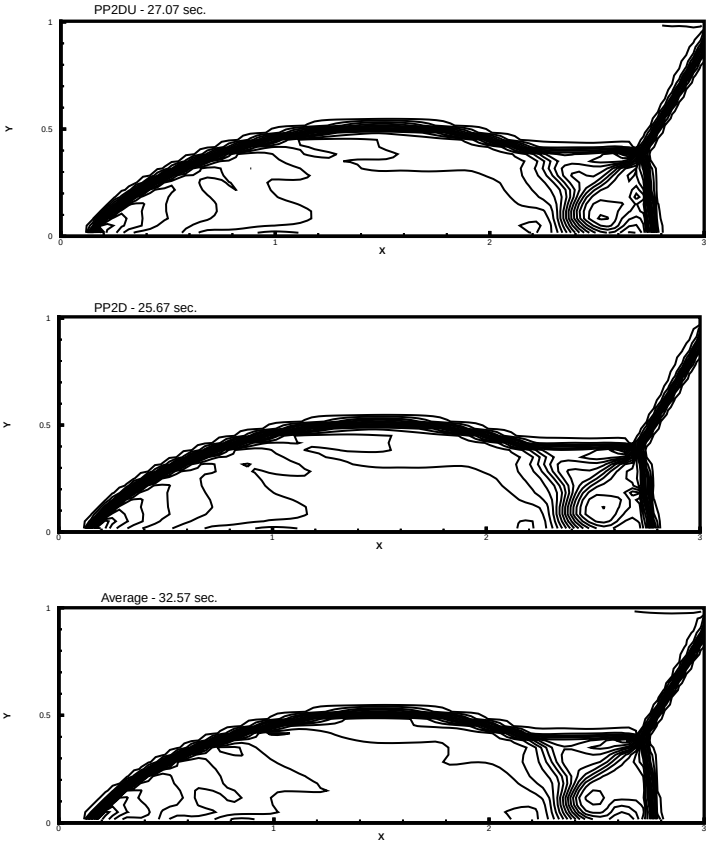

FIG. 5. *The double Mach reflection problem on a* 120×30 *grid with* $\sigma = 0.8$, $t = 0.2$. *The density contours are from* $(0.17, 21)$ *with an increment of* 0.6423.

(2.2) and (2.4) with $b = 0$ and $a > 0$, the update can be written as

$$u_i^{n+1} = (1 - \lambda_x)\left(u_i - \frac{1}{2}\lambda_x\, S_i^x\right) + \lambda_x\left(u_{i-1} + \frac{1}{2}(1 - \lambda_x)\, S_{i-1}^x\right). \tag{A.1}$$

If $u_i = u_{i-1}$, then both the slopes S_i^x and S_{i-1}^x are zero and the result follows. If not, by subtraction and division of the data, we need only consider the case where $u_{i-1} = 0$ and $u_i = 1$. In this case, for all limiters, both slopes are positive and bounded above by 2. This implies that $u_i - \frac{1}{2}\lambda_x\, S_i^x$ lies in $[0, 1]$ and $u_{i-1} + \frac{1}{2}(1 - \lambda_x)\, S_{i-1}^x$ also lies in $[0, 1]$. From the above update equation, the result follows.

It is worth noting that (2.9) can be proved in a more general setting, including reconstructions that are arbitrary functions. For a discussion, see Suresh [17].

A DOMAIN DECOMPOSITION METHOD WITH LAGRANGE MULTIPLIERS AND INEXACT SOLVERS FOR LINEAR ELASTICITY*

AXEL KLAWONN† AND OLOF B. WIDLUND‡

Abstract. A new domain decomposition method with Lagrange multipliers for elliptic problems is introduced. It is based on a reformulation of the well-known finite element tearing and interconnecting (FETI) method as a saddle point problem with both primal and dual variables as unknowns. The resulting linear system is solved with block-structured preconditioners combined with a suitable Krylov subspace method. This approach allows the use of inexact subdomain solvers for the positive definite subproblems. It is shown that the condition number of the preconditioned saddle point problem is bounded independently of the number of subregions and depends only polylogarithmically on the number of degrees of freedom of individual local subproblems. Numerical results are presented for a plane stress cantilever membrane problem.

Key words. domain decomposition, Lagrange multipliers, finite element tearing and interconnecting, preconditioners, elliptic systems, finite elements

1. Introduction.

In the past decade a great deal of research has been carried out on nonoverlapping domain decomposition methods using Lagrange multipliers. In these methods the original domain is decomposed into nonoverlapping subdomains. The continuity is then enforced by using Lagrange multipliers across the interface defined by the subdomain boundaries. A computationally quite efficient member of this class of domain decomposition algorithms is the finite element tearing and interconnecting (FETI) method introduced by Farhat and Roux [7]. In its original version, a Neumann problem is solved on each subdomain and the method is known to be scalable in the sense that its rate of convergence is independent of the number of subproblems. In a variant of the FETI method introduced in Farhat, Mandel, and Roux [6] an additional Dirichlet problem is solved exactly on each subdomain, in each iteration. This makes the rate of convergence of the iteration even less sensitive to the number of unknowns of the local problems. The use of inexact Dirichlet solvers is possible without a radical change of the FETI method. However, the use of inexact Neumann solvers does require a redesign of these algorithms; this is the topic of the present work.

In this paper, a new domain decomposition method with Lagrange multipliers is introduced by first reformulating the system of the FETI algorithm as a saddle point problem with both primal and dual variables. The resulting system is then solved

using block-structured preconditioners and a suitable Krylov subspace method. We can then avoid potentially quite costly direct solvers relying instead on any of a number of well-tested preconditioners for positive definite subproblems, such as incomplete LU methods, (algebraic) multigrid, etc. The good features of the FETI method such as scalability and efficiency are preserved. Essentially, the storage and factorization costs related to use of exact solvers in the FETI algorithm are eliminated while the new method will incur new costs for the preconditioners on the subdomains and additional storage of primal variable components in the iteration; we also have to expect that the iteration count will increase in comparison to when exact subdomain solvers are employed. A complete theory, based quite directly on the pioneering work of Mandel and Tezaur [16], and on earlier work by Klawonn [11], is also developed in this paper; see Theorems 9 and 15. In addition, we show how these results can be improved for a different family of preconditioners developed in [14]; see Theorems 10 and 16.

The remainder of this article is organized as follows. In section 2, we present the equations of linear elasticity and a finite element discretization thereof. In section 3, we review the FETI method and we develop our new method in section 4. In subsection 5.1, the convergence analysis of Mandel and Tezaur [16] is extended from scalar, second order elliptic equations to the system of equations of linear elasticity. A convergence analysis and condition number estimates for the block-diagonal preconditioner are given in subsection 5.2. The paper concludes with section 6, in which we report on some of our numerical experiments.

We note that a short conference paper [13] prepared previously describes and discusses a slightly different version of our main algorithm.

2. The elliptic problem. In this section, we introduce our model problem, the elliptic system arising from the displacement formulation of compressible, linear elasticity and its discretization by conforming finite elements.

2.1. The equations of linear elasticity. The equations of linear elasticity model the displacement of a linear elastic material under the action of external and internal forces. We denote the elastic body by $\Omega \subset \mathbf{R}^d, d = 2, 3$, and its boundary by $\partial\Omega$ and assume that one part of the boundary, Γ_0, is clamped, i.e., with homogeneous Dirichlet boundary conditions, and that the rest, $\Gamma_1 := \partial\Omega \setminus \Gamma_0$, is subject to a surface force $\mathbf{g}$, i.e., a natural boundary condition. We can also introduce a body force $\mathbf{f}$, e.g., gravity. The appropriate space for a variational formulation is the Sobolev space $H^1_{\Gamma_0}(\Omega) := \{\mathbf{v} \in H^1(\Omega)^d \ : \ \mathbf{v}_{|\Gamma_0} = 0\}$. The linear elasticity problem consists of finding the displacement $\mathbf{u} \in H^1_{\Gamma_0}(\Omega)$ of the elastic body Ω, such that

$$G \int_\Omega \varepsilon(\mathbf{u}) : \varepsilon(\mathbf{v}) dx \ + \ G\beta \int_\Omega \operatorname{div} \mathbf{u} \operatorname{div} \mathbf{v} \, dx = \langle \mathbf{F}, \mathbf{v} \rangle \quad \forall \ \mathbf{v} \in H^1_{\Gamma_0}(\Omega). \tag{1}$$

Here G and β are material parameters depending on the Poisson ratio ν and Young's modulus E with $\nu \in (0, 1/2]$ and $E > 0$. In the case of plane stress, we have $G = E/(1+\nu), \beta = \nu/(1-\nu)$, and for plane strain and three-dimensional elasticity we have $G = E/(1+\nu), \beta = \nu/(1-2\nu)$. Furthermore, $\varepsilon_{ij}(\mathbf{u}) := \frac{1}{2}(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i})$ is the linearized strain tensor, and

$$\varepsilon(\mathbf{u}) : \varepsilon(\mathbf{v}) = \sum_{i,j=1}^{d} \varepsilon_{ij}(\mathbf{u}) \varepsilon_{ij}(\mathbf{v}), \quad \langle \mathbf{F}, \mathbf{v} \rangle := \sum_{i=1}^{d} \int_\Omega f_i v_i \, dx \ + \ \sum_{i=1}^{d} \int_{\Gamma_1} g_i v_i d\sigma.$$

The associated bilinear form of linear elasticity is

$$a(\mathbf{u},\mathbf{v}) = G\int_\Omega \varepsilon(\mathbf{u}) : \varepsilon(\mathbf{v})dx \quad + \quad G\,\beta\int_\Omega \operatorname{div}\mathbf{u}\,\operatorname{div}\mathbf{v}\,dx.$$

In this article, we consider only the case of compressible elasticity. This means that the Poisson ratio ν is bounded away from $1/2$. We will also focus on the case of $d = 2$ in order to simplify our notation. We note that all our work extends easily to the case of $d = 3$ and to many other elliptic problems.

We will also use the standard Sobolev space norm

$$\|\mathbf{u}\|_{H^1(\Omega)} := \left(|\mathbf{u}|^2_{H^1(\Omega)} + \|\mathbf{u}\|^2_{L_2(\Omega)}\right)^{1/2}$$

with $\|\mathbf{u}\|^2_{L_2(\Omega)} := \int_\Omega |\mathbf{u}|^2 dx$, and $|\mathbf{u}|^2_{H^1(\Omega)} := \|\nabla\mathbf{u}\|^2_{L_2(\Omega)}$. It is obvious that the bilinear form $a(\cdot,\cdot)$ is continuous with respect to $\|\cdot\|_{H^1(\Omega)}$. However, proving ellipticity is far less trivial but it can be established from Korn's first inequality; see, e.g., Ciarlet [3].

LEMMA 1 (Korn's first inequality). *Let $\Omega \subset \mathbf{R}^d, d \geq 2$, be a Lipschitz domain. Then, there exists a positive constant $c = c(\Omega,\Gamma_0)$, such that*

$$\int_\Omega \varepsilon(\mathbf{u}) : \varepsilon(\mathbf{u})dx \geq c\,|\mathbf{u}|^2_{H^1(\Omega)} \quad \forall\ \mathbf{u} \in H^1_{\Gamma_0}(\Omega).$$

The well-posedness of the linear system (1) follows immediately from the continuity and ellipticity of the bilinear form $a(\cdot,\cdot)$.

It follows from Korn's first inequality that $\|\varepsilon(\mathbf{u})\|_{L_2(\Omega)}$ is equivalent to $\|\mathbf{u}\|_{H^1(\Omega)}$ on $H^1_{\Gamma_0}(\Omega)$. This result is not directly valid for the case of pure natural boundary conditions when we are working with the space $(H^1(\Omega))^d$. This case is of interest when considering interior subregions, i.e., those that do not touch Γ_0. However, a Gårding inequality is provided by Korn's second inequality

LEMMA 2 (Korn's second inequality). *Let $\Omega \subset \mathbf{R}^d, d \geq 2$, be a Lipschitz domain with diameter one. Then, there exists a positive constant $c = c(\Omega)$, such that*

$$\int_\Omega \varepsilon(\mathbf{u}) : \varepsilon(\mathbf{u})dx + \|\mathbf{u}\|^2_{L_2(\Omega)} \geq c\,\|\mathbf{u}\|^2_{H^1(\Omega)} \quad \forall\ \mathbf{u} \in (H^1(\Omega))^d.$$

There are several proofs; see, e.g., Nitsche [19].

We can now derive a Korn inequality on the space $\{\mathbf{u} \in (H^1(\Omega))^d : \mathbf{u} \perp \ker(\varepsilon)\}$. The null space $\ker(\varepsilon)$ is the space of rigid body motions. Thus, for $d = 2$, the linearized strain tensor of $\mathbf{u}$ and its divergence vanish only for the elements of the space spanned by the two translations

$$\mathbf{r}_1 := \begin{bmatrix} 1 \\ 0 \end{bmatrix}, \qquad \mathbf{r}_2 := \begin{bmatrix} 0 \\ 1 \end{bmatrix}$$

and the single rotation

$$\mathbf{r}_3 := \begin{bmatrix} x_2 \\ -x_1 \end{bmatrix}.$$

In three dimensions the corresponding space is spanned by three translations and three rotations.

For convenience, we also introduce the notation

$$(\varepsilon(\mathbf{u}),\varepsilon(\mathbf{v}))_{L_2(\Omega)} := \int_\Omega \varepsilon(\mathbf{u}) : \varepsilon(\mathbf{v}) dx$$

and introduce two inner products on $(H^1(\Omega))^2$, for a region Ω with diameter one,

$$(\mathbf{u},\mathbf{v})_{E_1} := (\varepsilon(\mathbf{u}),\varepsilon(\mathbf{v}))_{L_2(\Omega)} + (\mathbf{u},\mathbf{v})_{L_2(\Omega)}$$

and

$$(\mathbf{u},\mathbf{v})_{E_2} := (\varepsilon(\mathbf{u}),\varepsilon(\mathbf{v}))_{L_2(\Omega)} + \sum_{i=1}^{3} l_i(\mathbf{u}) l_i(\mathbf{v}),$$

where the $l_i(\cdot)$ are defined by

$$l_i(\mathbf{u}) := \int_\Omega (\mathbf{r}_i)^t \mathbf{u} dx.$$

By using Lemma 2, $\|\cdot\|_{E_1}$, given by the inner product $(\cdot,\cdot)_{E_1}$, is a norm and not just a seminorm, and so, by construction, is $\|\cdot\|_{E_2}$.

The norms, just introduced, are equivalent.

LEMMA 3. *There exist constants $0 < c \le C < \infty$, such that*

$$c\,\|\mathbf{u}\|_{E_1} \le \|\mathbf{u}\|_{E_2} \le C\,\|\mathbf{u}\|_{E_1} \quad \forall\ \mathbf{u} \in (H^1(\Omega))^2.$$

Proof. The proof of the right inequality follows immediately from the Cauchy–Schwarz inequality. The left inequality is proven by contradiction and by using Rellich's theorem as in a proof of generalized Poincaré–Friedrichs inequalities, cf., e.g., Nečas [18, Chap. 2.7]. ∎

We obviously have

$$\|\varepsilon(\mathbf{u})\|_{L_2(\Omega)} \le \|\nabla \mathbf{u}\|_{L_2(\Omega)} \quad \forall\ \mathbf{u} \in (H^1(\Omega))^2. \tag{2}$$

Using (2) and Lemmas 2 and 3, we obtain the following.

LEMMA 4. *There exists a constant $0 < c$, such that*

$$c\,\|\nabla \mathbf{u}\|_{L_2(\Omega)} \le \|\varepsilon(\mathbf{u})\|_{L_2(\Omega)} \le \|\nabla \mathbf{u}\|_{L_2(\Omega)} \quad \forall\ \mathbf{u} \in (H^1(\Omega))^2, \mathbf{u} \perp \ker(\varepsilon).$$

2.2. Finite elements and the discrete problem. Since we consider only compressible elastic materials, it follows from Lemma 1 that the bilinear form $a(\cdot,\cdot)$ is uniformly elliptic. We can therefore successfully discretize the system (1) with low-order, conforming finite elements, such as linear or bilinear elements.

We assume that a triangulation τ^h of Ω is given which is shape regular and has a typical element diameter of h. We denote by $\mathbf{W}^h(\Omega) \subset H^1_{\Gamma_0}(\Omega)$ the corresponding conforming space of finite element functions, e.g., piecewise linear or bilinear continuous functions. Thus, it is our goal to solve the discrete problem

$$a(\mathbf{u}_h,\mathbf{v}_h) = \langle \mathbf{F},\mathbf{v}_h\rangle \quad \forall\ \mathbf{v}_h \in \mathbf{W}^h(\Omega). \tag{3}$$

In what follows, we work exclusively with the discrete problem and we drop the subscript h from now on.

3. A review of the FETI method. In this section, we give a brief review of the original FETI method introduced in Farhat and Roux [7] and the variant with a Dirichlet preconditioner introduced in Farhat, Mandel, and Roux [6]. For more detailed descriptions and proofs, we refer to [4, 5, 17, 22] and the references therein.

Let the domain $\Omega \subset \mathbf{R}^2$ be decomposed into N nonoverlapping subdomains $\Omega_i, i = 1, \ldots, N$, each of which is the union of elements and such that the finite element nodes on the boundaries of neighboring subdomains match across the interface $\Gamma := (\bigcup_{i=1}^N \partial\Omega_i) \setminus \partial\Omega$. Let the corresponding conforming finite element spaces be $\mathbf{W}_i = \mathbf{W}^h(\Omega_i), i = 1, \ldots, N$, and let $\mathbf{W} := \prod_{i=1}^N \mathbf{W}_i$ be the associated product space. When it is necessary to use vectors of nodal values, which define the elements of a finite element space, we underline; e.g., $\underline{\mathbf{W}}$ is the product space that corresponds to $\mathbf{W}$. Analogously, we denote the vector of nodal values associated with the finite element function $\mathbf{u}$ by $\underline{\mathbf{u}}$.

For each subdomain $\Omega_i, i = 1, \ldots, N$, we assemble the local stiffness matrices K_i and local load vectors $\underline{\mathbf{f}}_i$ by integrating the appropriate expressions over individual subdomains. We denote the local vectors of nodal values by $\underline{\mathbf{u}}_i$.

We can now formulate a minimization problem with constraints given by the intersubdomain continuity conditions.

Find $\underline{\mathbf{u}} \in \underline{\mathbf{W}}$, such that

$$\left.\begin{array}{c} J(\underline{\mathbf{u}}) := \frac{1}{2}\underline{\mathbf{u}}^t K \underline{\mathbf{u}} - \underline{\mathbf{f}}^t \underline{\mathbf{u}} \rightarrow \ \min \\ B\underline{\mathbf{u}} = 0 \end{array}\right\}, \tag{4}$$

where

$$\underline{\mathbf{u}} = \begin{bmatrix} \underline{\mathbf{u}}_1 \\ \vdots \\ \underline{\mathbf{u}}_N \end{bmatrix}, \quad \underline{\mathbf{f}} = \begin{bmatrix} \underline{\mathbf{f}}_1 \\ \vdots \\ \underline{\mathbf{f}}_N \end{bmatrix}, \quad \text{and } K = \begin{bmatrix} K_1 & O & \cdots & O \\ O & K_2 & \ddots & \vdots \\ \vdots & \ddots & \ddots & O \\ O & \cdots & O & K_N \end{bmatrix}.$$

The matrix $B = [B_1, \ldots, B_N]$ is constructed from $\{0, 1, -1\}$ such that the values of the solution $\underline{\mathbf{u}}$, associated with more than one subdomain, coincide when $B\underline{\mathbf{u}} = 0$. The local stiffness matrices K_i are positive semidefinite. The problem (4) is uniquely solvable if and only if $\ker(K) \cap \ker(B) = \{0\}$, i.e., K is invertible on the null space of B. This condition holds since the original finite element model is elliptic.

By introducing a vector of Lagrange multipliers $\underline{\lambda}$ to enforce the constraint $B\underline{\mathbf{u}} = 0$, we obtain a saddle point formulation of (4):

Find $(\underline{\mathbf{u}}, \underline{\lambda}) \in \underline{\mathbf{W}} \times \underline{\mathbf{U}}$, such that

$$\left.\begin{array}{rcrcl} K\underline{\mathbf{u}} & + & B^t\underline{\lambda} & = & \underline{\mathbf{f}} \\ B\underline{\mathbf{u}} & & & = & 0 \end{array}\right\}. \tag{5}$$

We note that the solution $\underline{\lambda}$ of (5) is in general only unique up to an additive vector from $\ker(B^t)$. The space of Lagrange multipliers $\underline{\mathbf{U}}$ is therefore chosen as the range (B); see also discussion below.

We will also use a full rank matrix, built from the rigid body motions of the subdomains

$$R = \begin{bmatrix} R_1 & O & \cdots & O \\ O & R_2 & \ddots & \vdots \\ \vdots & \ddots & \ddots & O \\ O & \cdots & O & R_N \end{bmatrix},$$

such that range $(R) = \ker(K)$; the subdomains with nonsingular stiffness matrices do not contribute any columns to R.

The solution of the first equation in (5) exists if and only if $\underline{\mathbf{f}} - B^t\underline{\lambda} \in \text{range}\,(K)$; this constraint will lead to the introduction of a projection P. We obtain

$$\underline{\mathbf{u}} = K^\dagger(\underline{\mathbf{f}} - B^t\underline{\lambda}) + R\underline{\alpha} \text{ if } \underline{\mathbf{f}} - B^t\underline{\lambda} \perp \ker(K), \tag{6}$$

where $K^\dagger$ is a pseudoinverse of K and $\underline{\alpha}$ has to be determined; see the discussion below.

We assume, for the time being, that B has full rank; i.e., the constraints are linearly independent. Substituting $\underline{\mathbf{u}}$ into the second equation of (5) gives

$$BK^\dagger B^t\underline{\lambda} = BK^\dagger\underline{\mathbf{f}} + BR\underline{\alpha}.$$

By considering the component orthogonal to BR, we find that

$$\left.\begin{array}{rcl} PF\underline{\lambda} & = & P\underline{\mathbf{d}} \\ G^t\underline{\lambda} & = & \underline{\mathbf{e}} \end{array}\right\} \tag{7}$$

with $G := BR, F := BK^\dagger B^t, \underline{\mathbf{d}} := BK^\dagger\underline{\mathbf{f}}, P := I - G(G^tG)^{-1}G^t$, and $\underline{\mathbf{e}} := R^t\underline{\mathbf{f}}$. The second equation in (7) is a consequence of the orthogonality condition of (6). We note that P is an orthogonal projection from $\underline{\mathbf{U}}$ onto $\ker(G^t)$.

Any solution $\underline{\lambda}$ of (5) and (7) yields the same solution $\underline{\mathbf{u}}$ of (4) and (5) if $\underline{\alpha} := -(G^tG)^{-1}G^t(\underline{\mathbf{d}} - F\lambda)$ is chosen; see Mandel, Tezaur, and Farhat [17, Thm. 2.4].

We define the space of admissible increments by

$$\underline{\mathbf{V}} := \{\underline{\mu} \in \underline{\mathbf{U}} : \underline{\mu} \perp B\underline{\mathbf{w}} \quad \forall\, \underline{\mathbf{w}} \in \ker(K)\} = \ker(G^t).$$

The original FETI method is a conjugate gradient method in the space $\underline{\mathbf{V}}$ applied to

$$PF\underline{\lambda} = P\underline{\mathbf{d}}, \qquad \underline{\lambda} \in \underline{\lambda}_0 + \underline{\mathbf{V}} \tag{8}$$

with an initial approximation $\underline{\lambda}_0$ chosen such that $G^t\underline{\lambda}_0 = \underline{\mathbf{e}}$. To introduce preconditioned variants, let D be a diagonal matrix. Then, the preconditioner M^{-1}, introduced in Farhat, Mandel, and Roux [6], is of the form

$$M^{-1} = B \begin{bmatrix} O & O \\ O & D^{-1}SD^{-1} \end{bmatrix} B^t$$

with

$$S = \begin{bmatrix} S_1 & O & \cdots & O \\ O & S_2 & \ddots & \vdots \\ \vdots & \ddots & \ddots & O \\ O & \cdots & O & S_N \end{bmatrix}.$$

The matrix S is the Schur complement of K obtained by eliminating the interior degrees of freedom of each of the subdomains. This computation clearly can be carried out in parallel and results in the block-diagonal matrix S which operates only on the degrees of freedom on the subdomain boundaries. In the application of M^{-1} to a vector, N independent Dirichlet problems have to be solved in each iteration step; M^{-1} is therefore often called the Dirichlet preconditioner. The simplest choice for D

is the identity matrix; this choice is made for the original Dirichlet preconditioner as introduced in Farhat, Mandel, and Roux [6]. Another possibility, which leads to faster convergence, is to choose D as a diagonal matrix, where the diagonal elements equal the number of subdomains to which the interface node belongs. This multiplicity scaling (MS) is discussed in Rixen and Farhat [22, 23]; see also further discussion in [14].

To keep the search directions of this preconditioned conjugate gradient method in the space $\underline{\mathbf{V}}$, the application of the preconditioner M^{-1} has to be followed by another application of the projection P. Hence, the Dirichlet variant of the FETI method is the conjugate gradient algorithm applied to the preconditioned system

$$PM^{-1}PF\,\underline{\lambda} = PM^{-1}P\,\underline{\mathbf{d}}, \qquad \underline{\lambda} \in \underline{\lambda}_0 + \underline{\mathbf{V}}, \tag{9}$$

with an initial approximation $\underline{\lambda}_0$ chosen such that $G\underline{\lambda}_0 = \underline{\mathbf{e}}$. We note that, for $\underline{\lambda} \in \underline{\mathbf{V}}$, $PM^{-1}PF\,\underline{\lambda} = PM^{-1}P^tP^tFP\,\underline{\lambda}$ and that we can therefore view the operator on the left-hand side of the preconditioned FETI system as the product of two symmetric matrices as required for the conjugate gradient algorithm.

4. The block-diagonal preconditioner. Using the decomposition $\lambda = \lambda_0 + \mu$, with $\mu \in V$, we can rewrite (8) as

$$PBK^{\dagger}B^t\underline{\mu} = PBK^{\dagger}(\underline{\mathbf{f}} - B^t\underline{\lambda}_0). \tag{10}$$

Since $\underline{\mathbf{u}} = K^{\dagger}(\underline{\mathbf{f}} - B^t\underline{\lambda}) + R\underline{\alpha}$ and $B\underline{\mathbf{u}} = 0$, we see that the solution of (10) satisfies

$$\begin{bmatrix} K & B^t \\ PB & O \end{bmatrix} \begin{bmatrix} \underline{\mathbf{u}} \\ \underline{\mu} \end{bmatrix} = \begin{bmatrix} \underline{\mathbf{f}} - B^t\underline{\lambda}_0 \\ 0 \end{bmatrix}.$$

We note that the elimination of the displacement variables of this system, by applying $K^{\dagger}$ to the first equation, gives us (10). Using that $\underline{\mu} \in \underline{\mathbf{V}}$, i.e., $P\underline{\mu} = \underline{\mu}$, and that $P^t = P$, we can make the system matrix symmetric such that

$$\begin{bmatrix} K & (PB)^t \\ PB & O \end{bmatrix} \begin{bmatrix} \underline{\mathbf{u}} \\ \underline{\mu} \end{bmatrix} = \begin{bmatrix} \underline{\mathbf{f}} - B^t\underline{\lambda}_0 \\ 0 \end{bmatrix}. \tag{11}$$

The displacement variable is not uniquely defined by this system; we are enforcing $PB\underline{\mathbf{u}} = 0$ but not $B\underline{\mathbf{u}} = 0$. Given any solution $\underline{\mathbf{u}}$ of (11), we obtain a solution that satisfies all the requirements by computing $\underline{\mathbf{u}} - R(G^tG)^{-1}G^tB\underline{\mathbf{u}}$; this is quite similar to the choice of the null space component of (6).

For the solution of the saddle point problem (11), we propose a preconditioned conjugate residual method with a block-diagonal preconditioner. For a detailed description of this algorithm, see Hackbusch [9] or Klawonn [11, 12]. We note that this algorithm will be designed such that the first component of each iterate belongs to range (K).

Our preconditioner has the form

$$\mathcal{B} = \begin{bmatrix} \widehat{K} & O \\ O & \widehat{M} \end{bmatrix}.$$

Here $\widehat{K}$ is assumed to be symmetric and a good preconditioner for $K + D_H\,Q$,

where

$$Q = \begin{bmatrix} Q_1 & O & \cdots & O \\ O & Q_2 & \ddots & \vdots \\ \vdots & \ddots & \ddots & O \\ O & \cdots & O & Q_N \end{bmatrix},$$

with Q_i the mass matrices associated with the mesh on Ω_i and $D_H = \operatorname{diag}_{i=1}^{N}(H_i^{-2} I_i)$ is a diagonal matrix. Here H_i denotes the diameter of the subdomain Ω_i. We further assume that $\widehat{M}$ is symmetric and a good preconditioner for M; i.e., we assume there exist constants k_0, k_1, m_0, m_1 with $0 < c \leq m_0 \leq m_1 \leq C < \infty$ and $0 < c \leq k_0 \leq k_1 \leq C < \infty$, such that

$$\begin{array}{ccccc} k_0\, \underline{\mathbf{u}}^t (K + D_H Q) \underline{\mathbf{u}} & \leq & \underline{\mathbf{u}}^t \widehat{K} \underline{\mathbf{u}} & \leq & k_1\, \underline{\mathbf{u}}^t (K + D_H Q) \underline{\mathbf{u}} \quad \forall \underline{\mathbf{u}} \in \underline{\mathbf{W}}, \\ m_0\, \underline{\lambda}^t M \underline{\lambda} & \leq & \underline{\lambda}^t \widehat{M} \underline{\lambda} & \leq & m_1\, \underline{\lambda}^t M \underline{\lambda} \quad \forall \underline{\lambda} \in \underline{\mathbf{V}}. \end{array} \tag{12}$$

Here c and C are generic constants independent of, or only weakly dependent on, the mesh size. Because of the block-diagonal structure of K and M and the preconditioners, c and C do not depend on the number of subdomains.

A preconditioner is often said to be optimal when the constants c and C can be chosen to be independent of the mesh size and the number of subdomains. We also note that all that is required here are preconditioners for quite benign positive definite problems on individual subregions and that the bounds are independent of the number of subdomains.

From these assumptions it is clear that our preconditioner $\mathcal{B}$ is symmetric positive definite and thus it can be used with the preconditioned conjugate residual method. In order to have a computationally efficient preconditioner, we must also assume that $\widehat{K}^{-1}$ and $\widehat{M}^{-1}$ can be applied to a vector at a low cost.

To guarantee that the iterates belong to range (K), we make use of the orthogonal projection P_R onto range (K) which is given by

$$P_R := I - R(R^t R)^{-1} R^t.$$

Consequently, we have that range $(R) = \ker(K)$ and we note that P_R is a block matrix with a 3×3 block for each interior subdomain; the expense of applying P_R to a vector is therefore very modest.

Our domain decomposition method is now the conjugate residual algorithm applied to the preconditioned system

$$\mathcal{B}^{-1} \mathcal{A} \underline{\mathbf{x}} = \mathcal{B}^{-1} \underline{\mathbf{F}}$$

with

$$\mathcal{A} = \begin{bmatrix} K & (PB)^t \\ PB & O \end{bmatrix}, \qquad \mathcal{B}^{-1} = \begin{bmatrix} P_R \widehat{K}^{-1} P_R^t & O \\ O & P \widehat{M}^{-1} P^t \end{bmatrix}, \tag{13}$$

$$\underline{\mathbf{x}} = \begin{bmatrix} \underline{\mathbf{u}} \\ \underline{\mu} \end{bmatrix}, \qquad \underline{\mathbf{F}} = \begin{bmatrix} \underline{\mathbf{f}} - B^t \underline{\lambda}_0 \\ 0 \end{bmatrix}.$$

We note that it is easy to see that only two matrix-vector products with the projection P and one with the projection P_R are required in each step. We note that the iterates of the conjugate residual method belong to $\underline{\mathbf{W}}_R \times \underline{\mathbf{V}}$ with $\underline{\mathbf{W}}_R := \text{range}\,(K)$.

5. Analysis. In this section, we will work with both finite element functions and vectors of nodal values representing them. We will make no distinction between operators and their matrix representation.

We will use the spaces $\mathbf{W}$, $\mathbf{U}$, and $\mathbf{V}$, and we begin by defining a norm $\|\cdot\|_W$ and a seminorm $|\cdot|_W$ on $\mathbf{W}$ by

$$\|\mathbf{v}\|_W^2 := \sum_{i=1}^N \|\mathbf{v}_i\|_{H^1(\Omega_i)}^2, \qquad |\mathbf{v}|_W^2 := \sum_{i=1}^N |\mathbf{v}_i|_{H^1(\Omega_i)}^2,$$

where $\|\mathbf{v}_i\|_{H^1(\Omega_i)}^2 := |\mathbf{v}_i|_{H^1(\Omega_i)}^2 + \frac{1}{H_i^2}\|\mathbf{v}_i\|_{L_2(\Omega_i)}^2$ for $\mathbf{v} = [\mathbf{v}_1, \ldots, \mathbf{v}_N] \in \mathbf{W}$. We also need the orthogonal decomposition of $\mathbf{W}$ into $\mathbf{W}_R := \text{range}\,(K)$ and its orthogonal complement $\mathbf{W}_R^\perp := \ker(K)$, i.e.,

$$\mathbf{W} = \mathbf{W}_R \oplus \mathbf{W}_R^\perp.$$

For the analysis we need to consider the trace space $\mathbf{W}_\Gamma$ of $\mathbf{W}$. We equip the space $\mathbf{W}_\Gamma$ with the seminorm and norm

$$|\mathbf{w}_\Gamma|_{W_\Gamma}^2 := \sum_{i=1}^N |\mathbf{w}_{\Gamma,i}|_{H^{1/2}(\partial\Omega_i)}^2, \qquad \|\mathbf{w}_\Gamma\|_{W_\Gamma}^2 := |\mathbf{w}_\Gamma|_{W_\Gamma}^2 + \sum_{i=1}^N \frac{1}{H_i}\|\mathbf{w}_{\Gamma,i}\|_{L_2(\partial\Omega_i)}^2.$$

We also define

$$B_\Gamma : \mathbf{W}_\Gamma \to \mathbf{U} \quad B_\Gamma := B_{|\mathbf{w}_\Gamma}.$$

From the construction of the jump operator B it is clear that

$$B\mathbf{w} = B_\Gamma \mathbf{w}_\Gamma \text{ for } \mathbf{w} \in \mathbf{W} \text{ where } \mathbf{w}_\Gamma = \mathbf{w}_{|\Gamma},$$

since continuity is enforced only across the interface. As a consequence, we obtain $\ker(B^t) = \ker(B_\Gamma^t)$. A direct computation yields

$$F = BK^\dagger B^t = B_\Gamma S^\dagger B_\Gamma^t.$$

Let us now introduce a norm on $\mathbf{V}$ by $\|\lambda\|_V := |B_\Gamma^t \lambda|_{W_\Gamma}$. This defines a norm, and not only a seminorm, since $\text{range}\,(B_\Gamma^t) \perp \ker(S)$. We will also use the dual space $\mathbf{V}'$ with a norm defined by $\|\lambda\|_{V'} := \sup_{\mu \in V} \frac{(\lambda,\mu)}{\|\mu\|_V}$. For the sake of simplicity, we will identify the space $\mathbf{V}'$ with $\mathbf{V}$, but we will use both norms. The above definitions are essentially the same as in [16].

Let us also define the product space $\mathbf{X} := \mathbf{W} \times \mathbf{V}$ which we equip with the graph norm $\|\mathbf{x}\|_X := \sqrt{\|\mathbf{v}\|_W^2 + \|\lambda\|_{V'}^2}$ for $\mathbf{x} = (\mathbf{v}, \lambda) \in \mathbf{X}$. We also need the subspace $\mathbf{X}_R := \mathbf{W}_R \times \mathbf{V}$ with the same norm as $\mathbf{X}$.

5.1. FETI for linear elasticity. For scalar, second order elliptic equations, it has been shown by Mandel and Tezaur [16] that the condition number of the FETI method with the original Dirichlet preconditioner (D = I) satisfies

$$\kappa(PM^{-1}PF) \leq C\,(1 + \log(H/h))^3.$$

We note that $(H/h)^2$ is proportional to the number of degrees of freedom of a subdomain. An improved result for a family of Dirichlet preconditioners using multiplicity

scaling, which leads to a $C\,(1+\log(H/h))^2$ estimate, is given in Klawonn and Widlund [14]; this work is also extended to problems with discontinuous coefficients.

In this section, we extend the results of Mandel and Tezaur [16] from scalar elliptic equations to the system of linear elasticity. To be able to use the results of [16], we now introduce the vector-valued Laplacian to be used only in our analysis. We denote by

$$K_\Delta := \begin{bmatrix} K_{\Delta,1} & O & \cdots & O \\ O & K_{\Delta,2} & \ddots & \vdots \\ \vdots & \ddots & \ddots & O \\ O & \cdots & O & K_{\Delta,N} \end{bmatrix}$$

a block-diagonal matrix, where the local stiffness matrices $K_{\Delta,i}, i = 1,\dots,N$, are obtained from the discretization of the inner product $(\nabla\mathbf{u},\nabla\mathbf{u})_{H^1(\Omega_i)}$ using the same finite element space as for $a(\cdot,\cdot)$. We denote by S_Δ the Schur complement of K_Δ obtained by eliminating the interior variables of each Ω_i, just as in the case of K and S.

It is well known that

$$(S_\Delta \mathbf{u}_\Gamma, \mathbf{u}_\Gamma) = \min_{\substack{\mathbf{v}\in\mathbf{W}\\ \mathbf{v}_{|\Gamma}=\mathbf{u}_\Gamma}} (K_\Delta \mathbf{v},\mathbf{v}) = (K_\Delta \mathbf{v}_{\rm harm},\mathbf{v}_{\rm harm})$$

for $\mathbf{u}_\Gamma \in \mathbf{W}_\Gamma$. Here $\mathbf{v}_{\rm harm} \in \mathbf{W}$ is the discrete harmonic extension of $\mathbf{u}_\Gamma \in \mathbf{W}_\Gamma$ defined as the unique solution of

$$(K_\Delta \mathbf{v}_{\rm harm},\mathbf{v}) = 0 \ \ \forall\ \mathbf{v}\in\mathbf{W}_0 \text{ with } \mathbf{v}_{{\rm harm}|\Gamma} = \mathbf{u}_\Gamma,$$

where $\mathbf{W}_0$ is the subspace of $\mathbf{W}$ with elements that vanish on the interface Γ.

Returning to the elasticity case, it can also easily be seen that

$$(S\mathbf{u}_\Gamma, \mathbf{u}_\Gamma) = \min_{\substack{\mathbf{v}\in\mathbf{W}\\ \mathbf{v}_{|\Gamma}=\mathbf{u}_\Gamma}} (K\mathbf{v},\mathbf{v}) = (K\mathbf{v}_{\rm elast},\mathbf{v}_{\rm elast})$$

for $\mathbf{u}_\Gamma \in \mathbf{W}_\Gamma$. Here $\mathbf{v}_{\rm elast} \in \mathbf{W}$ is the extension of $\mathbf{u}_\Gamma \in \mathbf{W}_\Gamma$ with the smallest elastic energy defined as the unique solution of

$$(K\mathbf{v}_{\rm elast},\mathbf{v}) = 0 \ \ \forall\ \mathbf{v}\in\mathbf{W}_0 \text{ with } \mathbf{v}_{{\rm elast}|\Gamma} = \mathbf{u}_\Gamma.$$

Using these formulas and the continuity of $a(\cdot,\cdot)$, we find that for $\mathbf{u}_\Gamma \in \mathbf{W}_\Gamma$,

$$\begin{aligned}(S\mathbf{u}_\Gamma, \mathbf{u}_\Gamma) &= \min_{\substack{\mathbf{v}\in\mathbf{W}\\ \mathbf{v}_{|\Gamma}=\mathbf{u}_\Gamma}} (K\mathbf{v},\mathbf{v}) \\ &\le (K\mathbf{v}_{\rm harm},\mathbf{v}_{\rm harm}) \\ &\le C\,(K_\Delta \mathbf{v}_{\rm harm},\mathbf{v}_{\rm harm}) \\ &= C \min_{\substack{\mathbf{v}\in\mathbf{W}\\ \mathbf{v}_{|\Gamma}=\mathbf{u}_\Gamma}} (K_\Delta\mathbf{v},\mathbf{v}) \\ &= C(S_\Delta \mathbf{u}_\Gamma, \mathbf{u}_\Gamma).\end{aligned}$$

To bound $(S\mathbf{u}_\Gamma, \mathbf{u}_\Gamma)$ from below, we restrict ourselves to a subspace. Using the left inequality in Lemma 4, we obtain for $\mathbf{u}_\Gamma \in \text{range}\,(S)$,

$$\begin{aligned}(S_\Delta \mathbf{u}_\Gamma, \mathbf{u}_\Gamma) &= \min_{\substack{\mathbf{v}\in\mathbf{W}\\ \mathbf{v}_{|\Gamma}=\mathbf{u}_\Gamma}} (K_\Delta \mathbf{v}, \mathbf{v})\\ &\le (K_\Delta \mathbf{v}_{\text{elast}}, \mathbf{v}_{\text{elast}})\\ &\le C\,(K\mathbf{v}_{\text{elast}}, \mathbf{v}_{\text{elast}})\\ &= C \min_{\substack{\mathbf{v}\in\text{range}\,(K)\\ \mathbf{v}_{|\Gamma}=\mathbf{u}_\Gamma}} (K\mathbf{v}, \mathbf{v})\\ &= C(S\mathbf{u}_\Gamma, \mathbf{u}_\Gamma).\end{aligned}$$

Since $(S_\Delta \mathbf{u}_\Gamma, \mathbf{u}_\Gamma)$ and $|\mathbf{u}_\Gamma|^2_{W_\Gamma}$ are equivalent for $\mathbf{u}_\Gamma \in \text{range}\,(S)$, we have proven the following.

LEMMA 5. *There exist constants $0 < c \le C < \infty$, independent of the mesh size and the subdomain diameters, such that*

$$c\,|\mathbf{u}_\Gamma|^2_{W_\Gamma} \le (S\mathbf{u}_\Gamma, \mathbf{u}_\Gamma) \le C\,|\mathbf{u}_\Gamma|^2_{W_\Gamma} \quad \forall\ \mathbf{u}_\Gamma\ \in\ \text{range}\,(S).$$

The next lemma follows from Mandel and Tezaur [16, proof of Lem. 3.11].

LEMMA 6.

$$\begin{aligned}\inf_{\lambda\in\mathbf{V}} \sup_{\mathbf{w}_\Gamma\in\mathbf{W}_\Gamma} \frac{(\lambda, B_\Gamma \mathbf{w}_\Gamma)}{\|\lambda\|_{V'}\|\mathbf{w}_\Gamma\|_{W_\Gamma}} &\ge C\,(1+\log(H/h))^{-1/2},\\ \sup_{\lambda\in\mathbf{V}} \sup_{\mathbf{w}_\Gamma\in\mathbf{W}_\Gamma} \frac{(\lambda, B_\Gamma \mathbf{w}_\Gamma)}{\|\lambda\|_{V'}\|\mathbf{w}_\Gamma\|_{W_\Gamma}} &\le C\,(1+\log(H/h)).\end{aligned}$$

The next result is essentially an extension of that lemma to the system of equations of linear elasticity.

LEMMA 7. *There exist constants $0 < c \le C < \infty$, independent of the mesh size and the number of subdomains, such that*

$$c(1+\log(H/h))^{-1}\|\lambda\|^2_{V'} \le (F\lambda, \lambda) \le C(1+\log(H/h))^2\|\lambda\|^2_{V'} \quad \forall\ \lambda \in V.$$

Proof. As shown in [16, proof of Lem. 3.11], we have for $\lambda \in V$

$$(F\lambda, \lambda) = \sup_{\mathbf{w}_\Gamma\in\text{range}\,(S)} \frac{(\lambda, B_\Gamma \mathbf{w}_\Gamma)^2}{(S\mathbf{w}_\Gamma, \mathbf{w}_\Gamma)}.$$

Using Lemma 5 and that $B^t_\Gamma \lambda \perp \ker(S)$ for $\lambda \in \mathbf{V}$, we obtain

$$\begin{aligned}(F\lambda, \lambda) &\le C \sup_{\mathbf{w}_\Gamma\in\text{range}\,(S)} \frac{(\lambda, B_\Gamma \mathbf{w}_\Gamma)^2}{|\mathbf{w}_\Gamma|^2_{W_\Gamma}} \le C \sup_{\mathbf{w}_\Gamma\in\text{range}\,(S)} \frac{(\lambda, B_\Gamma \mathbf{w}_\Gamma)}{\inf_{\mathbf{z}_\Gamma\in\ker(S)} \|\mathbf{w}_\Gamma + \mathbf{z}_\Gamma\|^2_{W_\Gamma}}\\ &= C \sup_{\substack{\tilde{\mathbf{w}}_\Gamma = \mathbf{w}_\Gamma + \mathbf{z}_\Gamma \in \mathbf{W}_\Gamma\\ \mathbf{w}_\Gamma\in\text{range}\,(S), \mathbf{z}_\Gamma\in\ker(S)}} \frac{(\lambda, B_\Gamma \mathbf{w}_\Gamma)}{\|\mathbf{w}_\Gamma + \mathbf{z}_\Gamma\|^2_{W_\Gamma}} = C \sup_{\tilde{\mathbf{w}}_\Gamma\in\mathbf{W}_\Gamma} \frac{(\lambda, B_\Gamma \tilde{\mathbf{w}}_\Gamma)^2}{\|\tilde{\mathbf{w}}_\Gamma\|^2_{W_\Gamma}}.\end{aligned}$$

Analogously, we obtain

$$(F\lambda, \lambda) \ge c \sup_{\mathbf{w}_\Gamma\in\mathbf{W}_\Gamma} \frac{(\lambda, B_\Gamma \mathbf{w}_\Gamma)^2}{\|\mathbf{w}_\Gamma\|^2_{W_\Gamma}}.$$

The bounds of $(F\lambda, \lambda)$ now follow from Lemma 6. ∎

Combining the definitions of the (exact) Dirichlet preconditioner M^{-1} and of the norm $\|\cdot\|_V$ with Lemma 5, we obtain the next lemma.

LEMMA 8. *There exist constants $0 < c \leq C < \infty$, independent of the mesh size and the number of subdomains, such that*

$$c \, \|\lambda\|_V^2 \leq (M^{-1}\lambda, \lambda) \leq C \, \|\lambda\|_V^2 \quad \forall \, \lambda \in V.$$

A condition number estimate of $PM^{-1}PF$ follows easily from these estimates; cf. also [16]. The proof for the algorithm using an inexact Dirichlet solver proceeds along very similar lines.

THEOREM 9. *There exists a positive constant C, independent of the mesh size and the number of subdomains, such that*

$$\kappa(PM^{-1}PF) \leq C \, (1 + \log(H/h))^3,$$

where $\kappa(PM^{-1}PF) := \sigma_{max}/\sigma_{min}$ is the spectral condition number defined by the ratio of the largest and the smallest eigenvalue σ_{max} and σ_{min} of $PM^{-1}PF$.

Similarly, there exists a positive constant C, independent of the mesh size and the number of subdomains, such that

$$\kappa(P\widehat{M}^{-1}PF) \leq C \, (1 + \log(H/h))^3,$$

for any preconditioner $\widehat{M}^{-1}$ that is spectrally equivalent to the exact Dirichlet preconditioner.

We note that Tezaur [27] established a condition number estimate of the form $C(1 + \log(H/h))^2$ for an algebraic FETI method developed by Park and Felippa [20] and Park, Justino, and Felippa [21]; see also the discussion in Rixen et al. [24].

Recently, a modified family of Dirichlet preconditioners, which includes the one with multiplicity scaling for both redundant and nonredundant Lagrange multipliers was introduced and analyzed by the authors in [14]. Using redundant Lagrange multipliers amounts to choosing the maximal number of constraints, pairwise connecting all degrees of freedom which belong to the same point x, and using a Lagrange multiplier for each possible pair. In contrast, nonredundant Lagrange multipliers are obtained by choosing the minimal number which ensures continuity of the displacements at each point on the interface.

For the case of nonredundant Lagrange multipliers, our preconditioner is of the form

$$\widehat{M}_{nr}^{-1} := (BB^t)^{-1} B \begin{bmatrix} O & O \\ O & S \end{bmatrix} B^t (BB^t)^{-1} = (B_\Gamma B_\Gamma^t)^{-1} B_\Gamma S B_\Gamma^t (B_\Gamma B_\Gamma^t)^{-1}$$

and for the redundant case, we have

$$\widehat{M}_r^{-1} := M^{-1} = B \begin{bmatrix} O & O \\ O & D^{-1}SD^{-1} \end{bmatrix} B^t = B_\Gamma D^{-1} S D^{-1} B_\Gamma^t,$$

where D is defined by multiplicity scaling; cf. section 3. We note that in the case of discontinuous coefficients, the preconditioners $\widehat{M}_{nr}$ and $\widehat{M}_r$ have to be enhanced using a more elaborate scaling; we refer to [14] for a more detailed discussion.

In [14], condition number estimates of $C \, (1 + \log(H/h))^2$ are given for second order scalar elliptic equations for both the preconditioners $\widehat{M}_{nr}$ and $\widehat{M}_r$. We note that the construction and analysis in [14] also hold for problems with discontinuous coefficients. In [14, proof of Thm. 1], we show in the nonredundant case

$$\begin{aligned} \sup_{w_\Gamma \in \text{range}\,(S)} \frac{\langle \lambda, B_\Gamma w_\Gamma \rangle}{|w_\Gamma|_S^2} &\geq \langle \widehat{M}_{nr}\lambda, \lambda \rangle, \\ \sup_{w_\Gamma \in \text{range}\,(S)} \frac{\langle \lambda, B_\Gamma w_\Gamma \rangle}{|w_\Gamma|_S^2} &\leq C \, (1 + \log(H/h))^2 \, \langle \widehat{M}_{nr}\lambda, \lambda \rangle. \end{aligned} \tag{14}$$

Similar inequalities can be obtained using $\widehat{M}_r$. In that paper, [14, Lem. 3], we define a norm on V in terms of the preconditioner $\widehat{M}_{nr}$, i.e., $\|\lambda\|_V := \langle \widehat{M}_{nr}^{-1}\lambda, \lambda\rangle$; the roles of $\|\lambda\|_V$ and $\|\lambda\|_{V'}$ are reversed in [14] compared to this paper. The dual norm $\|\lambda\|_{V'}$ can now be defined, as before, using the new V-norm. A simple computation gives $\lambda\|_{V'}^2 = \langle \widehat{M}_{nr}\lambda, \lambda\rangle$. The same arguments are equally valid for $\widehat{M}_r$ in the redundant case.

Using the inf-sup and sup-sup estimates (14), Lemma 5, and the definition of $\|\lambda\|_{V'}$, we obtain a condition number estimate for the FETI preconditioners for linear elasticity, using the same arguments as in the proof of Theorem 9. We note that the improved condition number estimate is a result of the optimality of the inf-sup constant in the first inequality in (14).

THEOREM 10. *There exists a positive constant C, independent of the mesh size and the number of subdomains, such that*

$$\kappa(P\widehat{M}^{-1}PF) \le C\,(1+\log(H/h))^2,$$

where $\widehat{M}$ is either $\widehat{M}_r$ or $\widehat{M}_{nr}$.

5.2. Analysis of the block-diagonal preconditioner. In this section, we give a condition number estimate for the block-diagonal preconditioner for the systems of equations arising from linear elasticity. This results in a convergence estimate for the preconditioned conjugate residual method.

As shown in section 4, the system of equations (11) involves an operator from $\mathbf{W}\times\mathbf{V}$ onto itself. The component of $\mathbf{u}$ in $\ker(K)$ is determined after the completion of the iteration. It is therefore appropriate to consider the restriction of the operator $\mathcal{A}$ to the subspace $\mathbf{X}_R = \mathbf{W}_R \times \mathbf{V}$. Similarly, we can view the preconditioner $\mathcal{B}^{-1}$ as a mapping from $\mathbf{X}_R$ onto itself; see (13).

An upper bound for the convergence rate of the conjugate residual method can be given in terms of the condition number $\kappa(\mathcal{B}^{-1}\mathcal{A})$ of the preconditioned system. A theory of block-diagonal preconditioners for saddle point problems of different origins has been developed by several authors; see Rusten and Winther [25], Silvester and Wathen [26], Kuznetsov [15], and Klawonn [12]. To the best of our knowledge, the first proof for block-preconditioners applied to saddle point problems with a singular block K is given in Klawonn [10, 11] and independently in Arnold, Falk, and Winther [1]. In order to obtain a condition number estimate for $\mathcal{B}^{-1}\mathcal{A}$, we follow the short argument given in [1] which is in the same spirit as that given by Mandel and Tezaur [16, Lem. 3.1] for the positive definite case. For completeness, we include the short proof here using our notation and the norms of X_R and its dual. Denoting by $\rho(\cdot)$ the spectral radius of a matrix, we find

$$\begin{aligned}\kappa(\mathcal{B}^{-1}\mathcal{A}) &= \rho(\mathcal{B}^{-1}\mathcal{A})\rho((\mathcal{B}^{-1}\mathcal{A})^{-1})\\ &\le \|\mathcal{B}^{-1}\mathcal{A}\|_{X_R\to X_R}\|(\mathcal{B}^{-1}\mathcal{A})^{-1}\|_{X_R\to X_R}\\ &\le \|\mathcal{B}^{-1}\|_{X_R'\to X_R}\|\mathcal{A}\|_{X_R\to X_R'}\|\mathcal{B}\|_{X_R\to X_R'}\|\mathcal{A}^{-1}\|_{X_R'\to X_R}.\end{aligned}$$

Hence, we need estimates of the norms of the operators $\mathcal{B}, \mathcal{A}$, and their inverses. The next lemma is due to Brezzi [2] and is given here in our notation.

LEMMA 11. *Let $B : \mathbf{W}_R \to \mathbf{V}$ satisfy an inf-sup and a sup-sup condition, i.e.,*

$$\begin{aligned}\inf_{\lambda\in\mathbf{V}}\sup_{\mathbf{w}\in\mathbf{W}_R}\frac{(\lambda, B\mathbf{w})}{\|\lambda\|_{V'}\|\mathbf{w}\|_W} &\ge \beta_0,\\ \sup_{\lambda\in\mathbf{V}}\sup_{\mathbf{w}\in\mathbf{W}_R}\frac{(\lambda, B\mathbf{w})}{\|\lambda\|_{V'}\|\mathbf{w}\|_W} &\le \beta_1,\end{aligned} \tag{15}$$

where $\beta_0, \beta_1 > 0$.

Furthermore, let $K : \mathbf{W}_R \to \mathbf{W}_R$ *be a symmetric operator satisfying*

$$\begin{array}{rcll} |(K\mathbf{w}, \mathbf{v})| & \leq & \alpha_1 \|\mathbf{w}\|_W \|\mathbf{v}\|_W & \forall\ \mathbf{w}, \mathbf{v} \in \mathbf{W}_R, \\ (K\mathbf{w}, \mathbf{w}) & \geq & \alpha_0 \|\mathbf{w}\|_W^2 & \forall\ \mathbf{w} \in \mathbf{W}_R, \end{array} \tag{16}$$

where $\alpha_0, \alpha_1 > 0$.

Then, $\mathcal{A} : \mathbf{X}_R \to \mathbf{X}_R$ *is an isomorphism with* $\|\mathcal{A}\|_{X_R \to X_R'} \leq \bar{C}(\alpha_1, \beta_1)$ *and* $\|\mathcal{A}^{-1}\|_{X_R' \to X_R} \leq \underline{C}(\alpha_0, \alpha_1, \beta_0)$, *where* $\bar{C}(\alpha_1, \beta_1) := \alpha_1 + \beta_1$ *and* $\underline{C}(\alpha_0, \alpha_1, \beta_0) := \max\{(\alpha_0^{-1} + \beta_0^{-1}(1 + \alpha_1/\alpha_0)), (\beta_0^{-1} + \alpha_1 \beta_0^{-2})(1 + \alpha_1/\alpha_0)\}$.

The uniform boundedness and ellipticity of K on $\mathbf{W}_R$ follow directly from the definition of the norm $\|\cdot\|_W$. Thus, we obtain constants $\alpha_0, \alpha_1 > 0$ which are independent of h, H.

We are left with showing the inf-sup and sup-sup conditions for B.

LEMMA 12.

$$\begin{array}{rcl} \inf\limits_{\lambda \in \mathbf{V}} \sup\limits_{\mathbf{w} \in \mathbf{W_R}} \dfrac{(\lambda, B\mathbf{w})}{\|\lambda\|_{V'} \|\mathbf{w}\|_W} & \geq & C\,(1 + \log(H/h))^{-1/2} =: \beta_0, \\ \sup\limits_{\lambda \in \mathbf{V}} \sup\limits_{\mathbf{w} \in \mathbf{W_R}} \dfrac{(\lambda, B\mathbf{w})}{\|\lambda\|_{V'} \|\mathbf{w}\|_W} & \leq & C\,(1 + \log(H/h)) =: \beta_1. \end{array}$$

Proof. For $\lambda \in \mathbf{V}$, let us now consider

$$\begin{aligned} \sup_{\mathbf{w} \in \mathbf{W_R}} \frac{(\lambda, B\mathbf{w})}{\|\mathbf{w}\|_W} &\leq \sup_{\mathbf{w} \in \mathbf{W_R}} \frac{(\lambda, B\mathbf{w})}{|\mathbf{w}|_W} \\ &\leq C \sup_{\mathbf{w} \in \mathbf{W_R}} \frac{(\lambda, B\mathbf{w})}{(K\mathbf{w}, \mathbf{w})^{1/2}} \\ &= C \sup_{\mathbf{w} \in \mathbf{W_R}} \frac{(\lambda, B_\Gamma \mathbf{w}_\Gamma)}{\inf\limits_{\substack{\mathbf{v} \in \mathbf{W} \\ \mathbf{v}|_\Gamma = \mathbf{w}_\Gamma}} (K\mathbf{v}, \mathbf{v})^{1/2}} \\ &= C \sup_{\mathbf{w}_\Gamma \in \mathrm{range}\,(S)} \frac{(\lambda, B_\Gamma \mathbf{w}_\Gamma)}{(S\mathbf{w}_\Gamma, \mathbf{w}_\Gamma)^{1/2}} \\ &\leq C \sup_{\mathbf{w}_\Gamma \in \mathbf{W}_\Gamma} \frac{(\lambda, B_\Gamma \mathbf{w}_\Gamma)}{\|\mathbf{w}_\Gamma\|_{W_\Gamma}} \\ &\leq \beta_1 \|\lambda\|_{V'} \end{aligned}$$

with $\beta_1 := C\,(1 + \log(H/h))$. The last inequality follows from Lemma 6. Analogously, we obtain

$$\sup_{\mathbf{w} \in \mathbf{W_R}} \frac{(\lambda, B\mathbf{w})}{\|\mathbf{w}\|_W} \geq \beta_0 \|\lambda\|_{V'}$$

with $\beta_1 := C\,(1 + \log(H/h))^{-1/2}$. ∎

Combining these results with Lemma 11, we obtain estimates of the norm of $\mathcal{A}$ and $\mathcal{A}^{-1}$ as follows.

LEMMA 13. *The operator* $\mathcal{A} : \mathbf{X}_R \to \mathbf{X}_R$ *is an isomorphism and satisfies*

$$\begin{aligned} \|\mathcal{A}\|_{X_R \to X_R'} &\leq C\,(1 + \log(H/h)), \\ \|\mathcal{A}^{-1}\|_{X_R' \to X_R} &\leq C\,(1 + \log(H/h)), \end{aligned}$$

where $C > 0$ is a generic constant independent of the mesh size and the subdomain diameters.

The next lemma provides bounds for $\|\mathcal{B}\|_{X_R \to X_R'}$ and $\|\mathcal{B}^{-1}\|_{X_R' \to X_R}$.

LEMMA 14. *There exist constants $0 < c \leq C < \infty$, which depend only on k_0, k_1, m_0, and m_1, such that*

$$\|\mathcal{B}\|_{X_R \to X_R'} \leq C, \quad \|\mathcal{B}^{-1}\|_{X_R' \to X_R} \leq \frac{1}{c}.$$

These bounds are uniform with respect to the mesh size and the number of subdomains if $\mathcal{B}$ is an optimal preconditioner, i.e., if the constants k_0, k_1, m_0, m_1 are uniformly bounded.

Proof. From the first inequalities of (12) and Korn's second inequality (Lemma 2), we obtain by a standard scaling argument that $(\widehat{K}\mathbf{u}, \mathbf{u})$ and $\|\mathbf{u}\|_W^2$ are spectrally equivalent $\mathbf{u} \in \mathbf{W}_R$. From the second inequalities in (12) and Lemma 5, it follows that for $\mu \in \mathbf{V}$

$$(\widehat{M}^{-1}\mu, \mu) \leq C\,(M^{-1}\mu, \mu) = C\,(B_\Gamma S B_\Gamma^t \mu, \mu) \leq C\,|B_\Gamma^t \mu|_{W_\Gamma}^2 = C\,\|\mu\|_V^2.$$

In the last inequality, we have used that $\mu \in \mathbf{V}$ implies $B_\Gamma^t \mu \in \text{range}\,(S)$. Analogously, we obtain

$$(\widehat{M}^{-1}\mu, \mu) \geq c\,\|\mu\|_V^2.$$

By using these inequalities, we get for $\lambda \in \mathbf{V}$

$$\|\lambda\|_{V'}^2 = \sup_{\mu \in V} \frac{(\lambda, \mu)^2}{\|\mu\|_V^2} \leq C \sup_{\mu \in V} \frac{(\lambda, \mu)^2}{(\widehat{M}^{-1}\mu, \mu)} = C \sup_{\nu \in V} \frac{(\lambda, \widehat{M}^{1/2}\nu)^2}{(\nu, \nu)} = C\,(\widehat{M}\lambda, \lambda)$$

and analogously

$$\|\lambda\|_{V'}^2 \geq c\,(\widehat{M}\lambda, \lambda).$$

From the definition of $\mathcal{B}$ follows

$$(\mathcal{B}\mathbf{x}, \mathbf{x}) = (\widehat{K}\mathbf{u}, \mathbf{u}) + (\widehat{M}\lambda, \lambda) \leq C(\|\mathbf{u}\|_W^2 + \|\lambda\|_{V'}^2) = C\,\|\mathbf{x}\|_X^2$$

with $\mathbf{x} = (\mathbf{u}, \lambda) \in \mathbf{X_R}$ and

$$(\mathcal{B}\mathbf{x}, \mathbf{x}) \geq c\,\|\mathbf{x}\|_X^2.$$

The boundedness of $\mathcal{B}$ and $\mathcal{B}^{-1}$ follows by using the following formulas:

$$\|\mathcal{B}\|_{X_R \to X_R'} = \sup_{\mathbf{x} \in \mathbf{X}_R} \frac{(\mathcal{B}\mathbf{x}, \mathbf{x})}{\|\mathbf{x}\|_X^2},$$

$$\|\mathcal{B}^{-1}\|_{X_R' \to X_R}^{-1} = \inf_{\mathbf{x} \in \mathbf{X}_R} \frac{(\mathcal{B}\mathbf{x}, \mathbf{x})}{\|\mathbf{x}\|_X^2}. \qquad \square$$

From Lemmas 13 and 14 the next theorem follows.

THEOREM 15.

$$\kappa(\mathcal{B}^{-1}\mathcal{A}) \leq C\,(1 + \log(H/h))^2$$

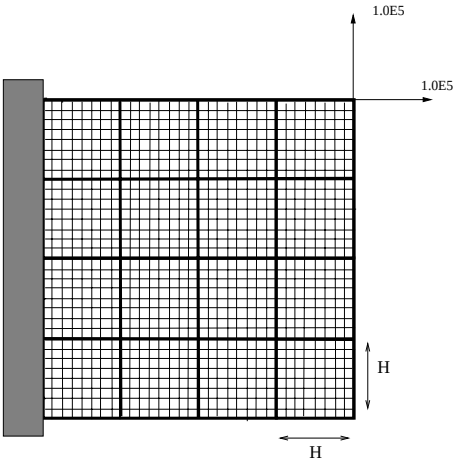

FIG. 1. *Sample domain decomposition of the cantilever with* 16 *subdomains.*

with a constant C *independent of* H, h.

We can also improve the results of Theorem 15 by using the results of [14], just as Theorem 10 represents an improvement of Theorem 9. We see that the inf-sup estimate used in the proof of Lemma 12 can be replaced with the improved constant bound given by the first inequality of (14). Revising the arguments in the proof of Theorem 15 in this respect, we obtain the following.

THEOREM 16. *There exists a constant* $C > 0$ *independent of* H, h *such that*

$$\kappa(\mathcal{B}^{-1}\mathcal{A}) \leq C\,(1 + \log(H/h)).$$

It is known that the convergence rate of the conjugate residual method depends linearly on the condition number, whereas that of the conjugate gradient algorithm does depend on its square root. Thus, from the improved estimates in Theorems 10 and 16, we see that both methods have an asymptotic convergence rate on the order of $(1 + \log(H/h))$. This is also reflected in the numerical experiments in section 6.

6. Numerical results. We have applied our domain decomposition method to a plane stress problem described in section 2. The Poisson ratio is $\nu = 0.3$ and the elasticity modulus $E = 2.1 \cdot 10^{11} N/m^2$, which models steel. The domain Ω is the unit square fixed on the left-hand side and free on the remainder of the boundary except for the upper-right corner element. The only nonzero components of the load vector are associated with the node at that corner; cf. Figure 1.

All our computations have been performed in MATLAB 5.3. Our Krylov subspace method is the preconditioned conjugate residual method with a zero initial guess. The stopping criterion is $\|\underline{\mathbf{r}}_n\|_2/\|\underline{\mathbf{r}}_0\|_2 < 10^{-6}$, where $\underline{\mathbf{r}}_n$ and $\underline{\mathbf{r}}_0$ are the nth and initial residuals.

Our domain Ω is decomposed into $N \times N$ square subdomains with $H := 1/N$; see Figure 1. In our implementation, we use redundant Lagrange multipliers; see the end of subsection 5.1 for a definition. This is known to yield a smaller number of iterations. An explanation from a mechanical viewpoint is given in Rixen and Farhat [23]; see also Klawonn and Widlund [14] for an analysis and connections between the cases of redundant and nonredundant Lagrange multipliers.

We report on two different series of experiments for different combinations of preconditioners $\widehat{K}$ and $\widehat{M}$ in order to analyze the numerical scalability of the method. In our first set of runs, we keep the dimension of the subproblems, and H/h, fixed and increase the number of subdomains and thus the overall problem size. In a second series, we keep a fixed number of subdomains and increase the value of H/h resulting in a smaller h.

In order to see how our method behaves in the best possible case, we first report on results for $\widehat{K} = K + \frac{1}{H^2}Q$ and $\widehat{M} = M$; cf. Tables 1 and 2 and Figures 2 and 3. For both cases, we present results for $\widehat{M}$ constructed using $D = I$ as well as with the multiplicity scaling $D = MS$; cf. section 3. We also compare the iteration counts of our new method with those of the original FETI method using the Dirichlet preconditioner M; see Tables 1 and 2 and Figures 2 and 3. In the experiments with the FETI algorithm, we stop the iteration when the preconditioned projected residual is smaller than $10^{-6}\|f\|_2$; see Farhat and Roux [8]. In all cases, the convergence is considerably faster with MS; using this scaling the asymptotic convergence rate is also reached much earlier than for $D = I$. For both choices of D, we obtain scalable domain decomposition methods in both series of experiments.

To gain insight into the convergence behavior with inexact blocks $\widehat{K}$ and $\widehat{M}$, we use preconditioners based on an incomplete Cholesky factorization (ILU). In the following, ILU(0) stands for an incomplete Cholesky factorization with no fill in while ILU(tol) is a threshold ILU factorization, with a threshold of tol, as provided in MATLAB 5.3; any entry in a column of the Cholesky factor L is dropped if its magnitude is smaller than the drop tolerance tol times the norm of its column. We denote by $\hat{S}$ the matrix that replaces S when ILU(0) is used to solve the Dirichlet problems in each subdomain. Three different combinations are considered: 1. $\widehat{K} =$

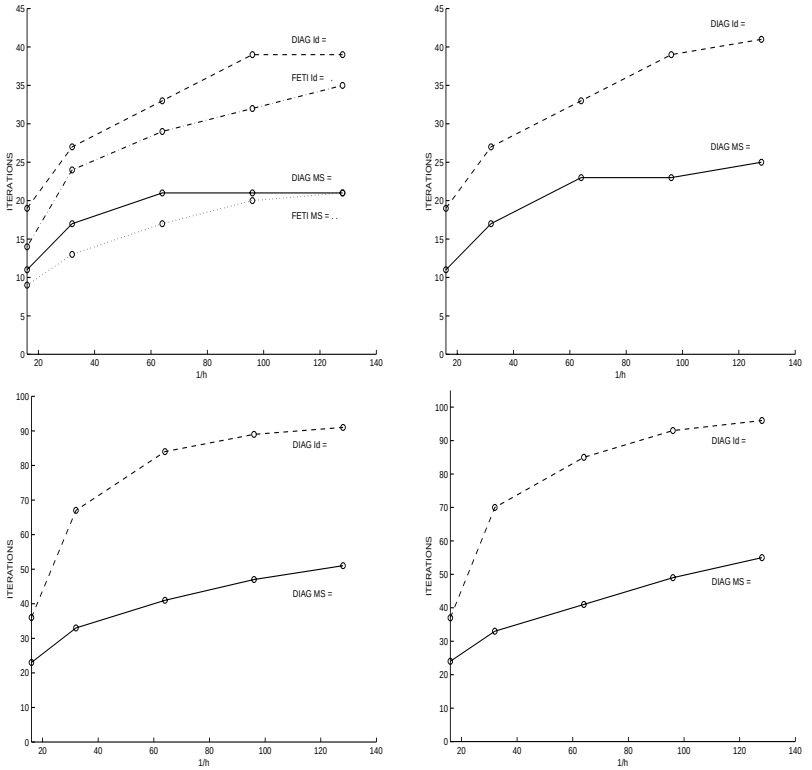

FIG. 2. *Iteration counts for an increasing number of subdomains of constant size.* $H/h = 8$. *Upper left:* $\widehat{K} = K + \frac{1}{H^2}Q, \widehat{M} = M$. *Upper right:* $\widehat{K} = K + 1/H^2 M_Q$ *and* $\widehat{M}$ *using* ILU(0). *Lower left:* $\widehat{K}$ ILU(10^{-3}) *of* $K + 1/H^2 M_Q$ *and* $\widehat{M} = M$. *Lower right:* $\widehat{K}$ *using* ILU(10^{-3}) *of* $K + 1/H^2 M_Q$ *and* $\widehat{M}$ *using* ILU(0).

$K + \frac{1}{H^2}Q$ and

$$\widehat{M}^{-1} = B \begin{bmatrix} O & O \\ O & D^{-1}\hat{S}D^{-1} \end{bmatrix} B^t;$$

2. $\widehat{K}$ is built with ILU(10^{-3}) applied to $K + \frac{1}{H^2}Q$ and $\widehat{M}^{-1} = M^{-1}$; 3. $\widehat{K}$ is built with ILU(10^{-3}) applied to $K + \frac{1}{H^2}Q$ and $\widehat{M}^{-1}$, as in combination 1., by using the inexact Schur complement $\hat{S}$. The computational results are given in Tables 1 and 2; cf. also Figures 2 and 3.

We also present results with a more accurate ILU decomposition based on a threshold tolerance $tol = 10^{-6}$ in Table 3. We see that a more accurate preconditioner $\widehat{K}$ improves the overall rate of convergence significantly. Comparing these results and the number of iterations obtained for the new method and the original FETI algorithm, both with the exact Dirichlet preconditioner, there is a strong indication that the increase in the iteration counts, which results when using the ILU(10^{-3}) preconditioner, would be largely eliminated if a better block-preconditioner, e.g., (algebraic) multigrid, were used as $\widehat{K}$.

QUASI-ORTHOGONAL GRIDS WITH IMPEDANCE MATCHING*

AHMED KHAMAYSEH† AND GLEN HANSEN†

Abstract. An elliptic, quasi-orthogonal grid generation system is formulated based on quasi-conformal mapping for arbitrary anisotropic (long and skinny) regions. The resulting system is a generalization of the well-known elliptic grid generation system derived from conformal mapping. Coupled with the grid generation system, the impedance-matching principle describes a methodology for preserving the discrete accuracy of the simulation, both internal to the domain and near internal geometric interfaces. Empirically, satisfying the impedance principle tends to minimize mesh effects on the solution results; meshes that are impedance-matched tend to reduce or eliminate spurious wave reflection and/or attenuation at internal interfaces. The resulting grid generation system is used to construct impedance-matched quasi-orthogonal grids on domains containing internal geometric constraints given an algebraic grid and a grid impedance function as initial conditions.

Key words. quasi-conformal mapping, elliptic grid generation, grid orthogonality, impedance matching

1. Introduction.

In computational modeling using discrete methods, such as the solution of the Navier–Stokes equations on a domain discretized with a grid, the term "grid quality" is often used to describe how a particular grid lends itself to accurate solutions of the governing equations of interest. Indeed, the accuracy of the simulation is a strong function of how the grid matches the problem domain, domain boundaries, and the discretization technique employed. Ideally, one would choose a grid that preserves the accuracy of the discrete equations being solved on the domain, that provides the ability to capture the geometrical complexity and detail present, and that possesses sufficient resolution to capture the smallest length scale of interest to the simulation. Several grid quality metrics are in common use. A "good" grid may possess the following: orthogonality at the boundaries and quasi- orthogonality within critical regions, smoothness, bounded aspect ratios, solution adaptive behavior, etc. While traditional grid generation (and/or relaxation) techniques designed to optimize one or more of the above are used often very effectively, the desire to provide a stronger relationship between observed simulation anomalies and the grid generation/relaxation process remains.

Impedance is classically defined as the ratio of "pressure" to "displacement" (or voltage to current), in describing the response of a physical system. Examples include electrical impedance, acoustic impedance, and mechanical impedance. For the case of grid generation, one could consider the impedance of the grid to wave propagation in terms of establishing a mesh that provides a constant impedance for a chosen wave propagation force per unit area and wave displacement; a desirable grid is one that does not induce aphysical resistance to the wave. In general, the approach of selecting a grid whose characteristics provide the desired response to the physical system could

also be described as selecting a grid whose "impedance" matches the "impedance" of the equations to be solved on the mesh. Thus, in this context, the concept of "impedance matching" will be defined as the use of terms or constraints that arise from the discretization of the governing equations to generate the grid.

Experience shows that impedance mismatches local to internal mesh boundaries (e.g., in the neighborhood of internal geometric boundaries between objects of different material properties) may result in spurious solution behavior, particularly when solution discontinuities are present. Study of this phenomena is warranted, as applications in computational field simulation frequently involve wave propagation as in, for example, the modeling of shock waves moving through solid materials. In this example, physical artifacts may take the form of spurious shock reflections or artificially occluded shocks at an interface. Experimentally, it is possible to reduce these effects with the placement of particular constraints on the mesh near internal interfaces. Global impedance mismatches, where the grid induces errors in a continuous manner within bulk regions, may result in wave diffusion that is not as easily identified in the simulation result.

This paper builds on published work by first presenting a general elliptic grid generation system based on quasi-conformal mapping for arbitrary anisotropic regions. This system may be used to construct quasi-orthogonal smooth grids with an externally specified spacing normal to the boundaries of the domain. Second, this system is improved with the use of the impedance-matching principle, applied to satisfy the above external constraint in the neighborhood of internal geometric interfaces.

2. Quasi-conformal grid generation. The preservation of the discrete accuracy of a simulation does not mandate absolute grid cell orthogonality. If this were a requirement, the types of geometry that could be accurately modeled would be very limited. This paper approaches orthogonality from a global perspective, where orthogonality is "encouraged" within the mesh, but not mandated. A robust grid generator is desired that provides boundary grid orthogonality, and some control over grid aspect ratio and skew angles within the mesh, while preserving simulation accuracy across internal interfaces. This section develops a quasi-elliptic grid generation system that addresses these criteria; this system is derived using quasi-conformal mapping.

Quasi-conformal mapping is viewed often as a generalization of conformal mapping (Ahlfors [1] and Krushkal [2]). Renelt [3] based his treatment of general elliptic systems of first-order partial differential equations entirely on quasi-conformal mapping. Likewise, Bers [4] used quasi-conformal mapping in the study of gas dynamics on the plane. Additionally, there are other classical applications of the conformal transformation of a surface onto a planar region and the reduction of elliptic partial differential equations to canonical form, proposed by Khamayseh and Mastin [5] and Mastin and Thompson [6], respectively.

The primary motivation for the use of quasi-conformal mapping in grid generation is the ease of expressing orthogonal curvilinear coordinate systems on simply connected two-dimensional regions (Godunov and Prokopov [7] and Arina [8]). The function $\mathbf{x}(\zeta) = x(\xi,\eta) + iy(\xi,\eta)$ describes a quasi-conformal mapping of a simply connected region $\mathcal{R}$ contained in the extended complex plane $\mathbb{C}_\infty$, provided that $\mathbf{x}$ maps $\mathcal{R}$ homeomorphically onto a region Ω, and $\mathbf{x}$ is a solution to Beltrami's equation

$$\mathbf{x}_{\bar{\zeta}} = \nu \mathbf{x}_{\zeta},$$

where $\bar{\zeta} = \xi - i\eta$ and $\zeta = \xi + i\eta$. The complex dilation $\nu(\xi,\eta)$ is a measurable function in $\mathcal{R}$ that satisfies the condition $||\nu||_\infty < 1$. By definition, the real and imaginary

parts of $\mathbf{x}$ are solutions to Beltrami's equations

$$\begin{aligned} x_\xi &= \gamma y_\eta + \beta y_\xi, \\ -x_\eta &= \alpha y_\xi + \beta y_\eta, \end{aligned}$$

where α, β, γ are functions of (ξ, η), $\alpha > 0$, $\gamma > 0$, and satisfy $\alpha\gamma - \beta^2 = 1$ in $\mathcal{R}$. This result is regarded as being a generalization to the Cauchy–Riemann equations. In this application, the Beltrami system may be further simplified. If $\beta = 0$, then $\nu = \frac{\mu-1}{\mu+1}$, where $\mu = \alpha = \frac{1}{\gamma}$. This system then reduces to

$$\begin{aligned} \mu x_\xi &= y_\eta, \\ x_\eta &= -\mu y_\xi. \end{aligned} \tag{2.1}$$

In this result, let $\mu = \sqrt{\frac{g_{22}}{g_{11}}}$, given the metrics $g_{11} = \mathbf{x}_\xi \cdot \mathbf{x}_\xi = x_\xi^2 + y_\xi^2$ and $g_{22} = \mathbf{x}_\eta \cdot \mathbf{x}_\eta = x_\eta^2 + y_\eta^2$. From (2.1), it follows that the coordinate functions $x(\xi, \eta)$ and $y(\xi, \eta)$ are solutions of the second-order quasi-linear elliptic system

$$\begin{aligned} \mu^2 \left(x_{\xi\xi} + \frac{\mu_\xi}{\mu} x_\xi \right) + \left(x_{\eta\eta} - \frac{\mu_\eta}{\mu} x_\eta \right) = 0, \\ \mu^2 \left(y_{\xi\xi} + \frac{\mu_\xi}{\mu} y_\xi \right) + \left(y_{\eta\eta} - \frac{\mu_\eta}{\mu} y_\eta \right) = 0. \end{aligned} \tag{2.2}$$

The quantities μ_ξ and μ_η may be derived from (2.1), yielding

$$\begin{aligned} \mu_\xi &= \frac{-\mu^2 \mathbf{x}_\xi \cdot \mathbf{x}_{\xi\xi} - \mathbf{x}_\xi \cdot \mathbf{x}_{\eta\eta}}{\mu g_{11}}, \\ \mu_\eta &= \frac{\mathbf{x}_\eta \cdot \mathbf{x}_{\eta\eta} + \mu^2 \mathbf{x}_\eta \cdot \mathbf{x}_{\xi\xi}}{\mu g_{11}}. \end{aligned} \tag{2.3}$$

Combining equations (2.1), (2.2), and (2.3) forms the basis for the quasi-orthogonal grid generation method. In this case, the coordinates x and y are solutions of the quasi-linear elliptic system

$$g_{22}(\mathbf{x}_{\xi\xi} + \mathcal{P}\mathbf{x}_\xi) + g_{11}(\mathbf{x}_{\eta\eta} + \mathcal{Q}\mathbf{x}_\eta) = 0, \tag{2.4}$$

where

$$\begin{aligned} \mathcal{P} &= \frac{\mu_\xi}{\mu} = -\frac{\mathbf{x}_\xi \cdot \mathbf{x}_{\xi\xi}}{g_{11}} - \frac{\mathbf{x}_\xi \cdot \mathbf{x}_{\eta\eta}}{g_{22}}, \\ \mathcal{Q} &= -\frac{\mu_\eta}{\mu} = -\frac{\mathbf{x}_\eta \cdot \mathbf{x}_{\eta\eta}}{g_{22}} - \frac{\mathbf{x}_\eta \cdot \mathbf{x}_{\xi\xi}}{g_{11}}. \end{aligned} \tag{2.5}$$

The source terms $\mathcal{P}$ and $\mathcal{Q}$ are called *control functions* in the grid generation literature. These control functions are often used to concentrate grid points in certain areas of the grid, such as along particular boundary segments. In this case, the control functions (2.5) will be used to provide additional control over the orthogonality of the mesh. This system is similar to the Thompson et al. quasi-elliptic method [9], given the condition $\mathbf{x}_\xi \cdot \mathbf{x}_\eta = 0$.

To complete the mathematical specification of the system (2.4), it is necessary to address the boundary conditions. Orthogonality of the grid lines at the boundary is desired, leading to the condition

$$g_{12} = \mathbf{x}_\xi \cdot \mathbf{x}_\eta = 0 \quad \text{on} \quad \partial\mathcal{R}. \tag{2.6}$$

3. Implementation of the grid generation system. In this section, the numerical procedures for implementing the quasi-elliptic grid generator (2.4) and the corresponding boundary conditions are detailed. The solution of this system constitutes an elliptic smoothing scheme for planar grids. This result is followed by a presentation of the effects and the methodologies of computing control functions in elliptic grid generation.

Standard central differencing in the ξ and η directions was used as the discretization technique of the system. An iterative method was used as a relaxation procedure to obtain $\mathbf{x}_{i,j} = (x_{i,j}, y_{i,j})$ for the interior nodes. An initial mapping $\mathbf{x}(\xi,\eta) = \big(x(\xi,\eta), y(\xi,\eta)\big)$ from computational space $\mathcal{R} = [0,m]\times[0,n]$ to the bounded physical domain $\Omega \subset \mathbb{R}^2$ was assumed. In this case, m and n are positive integers and *grid lines* are defined as the lines $\xi = i$ or $\eta = j$, with $0 \le i \le m$ or $0 \le j \le n$. The initial mapping $\mathbf{x}$ was obtained using transfinite interpolation, an algebraic grid generation method.

Thompson et al. [9] describes a general method for the construction of curvilinear structured grids that involve the solution of partial differential equations. In this work, given an initial mapping, the coordinate functions x and y are iteratively relaxed until they become solutions of the governing quasi-linear elliptic system. In this paper, successive overrelaxation (SOR) is used to solve the elliptic generation system (2.4).

To implement the SOR method first requires a formulation of the relaxation statement, which isolates the update quantity. In this case, given the discretized version of (2.4) and solving for $\mathbf{x}_{i,j}$ results in

$$\begin{aligned}\mathbf{x}_{i,j} = \frac{1}{4(\mathrm{g}_{11}+\mathrm{g}_{22})_{i,j}}\{&2\,(\mathrm{g}_{22})_{i,j}(\mathbf{x}_{i+1,j}+\mathbf{x}_{i-1,j})\\ &+(\mathrm{g}_{22})_{i,j}\mathcal{P}_{i,j}(\mathbf{x}_{i+1,j}-\mathbf{x}_{i-1,j})\\ &+2(\mathrm{g}_{11})_{i,j}(\mathbf{x}_{i,j+1}+\mathbf{x}_{i,j-1})\\ &+(\mathrm{g}_{11})_{i,j}\mathcal{Q}_{i,j}(\mathbf{x}_{i,j+1}-\mathbf{x}_{i,j-1})\}.\end{aligned} \tag{3.1}$$

To update the solution through the iterative method, the values of the physical coordinates given by (3.1) are applied through an acceleration process

$$\mathbf{x}_{i,j}^{k+1} = \omega_{i,j}\mathbf{x}_{i,j}^{k+1} + (1-\omega_{i,j})\mathbf{x}_{i,j}^{k},$$

where $\omega_{i,j}$ is the acceleration parameter. In practice, for most geometries, the choice of $\omega_{i,j} = 1$ leads to effective convergence. For certain highly curved geometries, the system (2.4) becomes progressively stiffer, requiring underrelaxation (choosing $0 < \omega_{i,j} < 1$) to attain convergence.

Prior to the relaxation process, boundary conditions must be specified. It is necessary to develop a discrete version of the orthogonality condition (2.6) on $\xi = 0, m$, and $\eta = 0, n$.

It is possible to impose orthogonality by adjusting the control functions near the boundary of the domain while holding the coordinates of the boundary points constant. In this case, the control functions (2.5) are evaluated at the boundaries then subsequently interpolated to the interior using linear transfinite interpolation. As described, these functions must be refreshed every iteration for the method to be effective. This approach was originally developed by Sorenson [10] for the imposition of boundary orthogonality on two-dimensional domains. The need for user specification

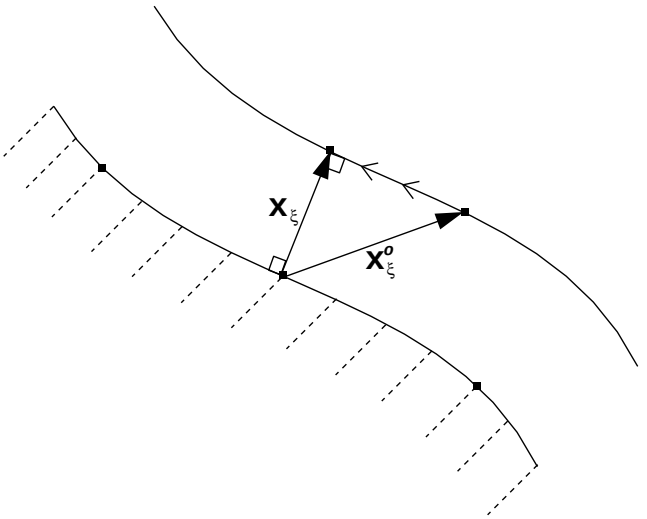

FIG. 3.1. *Projection of interior algebraic grid point to the orthogonal position.*

of grid spacing normal to the boundary in this method is a limitation. It is possible, however, to automatically derive normal grid spacing information from a sufficiently high quality initial algebraic grid.

A convenient way to infer the normal boundary spacing from the initial algebraic grid is to assume that the position of the first interior grid line adjacent to the boundary is acceptable. In practice, one usually desires that the relaxation procedure simply "swing" the boundary intersecting grid lines normal (orthogonal) to the boundary, without adjusting the positions of the grid lines parallel to the boundary (Figure 3.1). Clearly, this approach will provide boundary orthogonality without moving the actual boundary points or the boundary-adjacent grid lines established by the algebraic method.

Unfortunately, this approach also directly prescribes the positions of the first interior layer of grid points on the algebraic grid line adjacent to the boundary. This inflexibility directly leads to two areas of difficulty. First, the points $\mathbf{x}_{1,1}, \mathbf{x}_{m-1,1}, \mathbf{x}_{1,n-1}$, and $\mathbf{x}_{m-1,n-1}$ are directly adjacent to *two* boundaries, leading to contradictory definitions for their placement. Second, the direct specification of the first layer of interior boundary points while elliptically relaxing the remaining interior mesh points usually results in a distinct discontinuity in mesh properties near the grid boundaries (i.e., a very "nonsmooth" transition between the algebraic boundaries and the elliptically smooth interior). Typically, one transitions from an orthogonal mesh at the boundary to a slightly skewed mesh, within the space of a grid line. Nevertheless, these difficulties are generally easily mitigated with simple modifications.

An alternative approach for obtaining grid spacing information from the algebraic initial condition is depicted in Figure 3.2. Here, the orthogonally placed interior point is reflected an equal distance opposite the boundary curve to form a "ghost point." When repeated along the boundary, this procedure forms an "exterior curve" of ghost points adjacent to the boundary creating an image of the first algebraic grid line within the domain. The ghost points are computed prior to mesh relaxation and are not refreshed during the relaxation process. This boundary triad of points (the "ghost," boundary, and interior point) are employed in the calculation of the usual

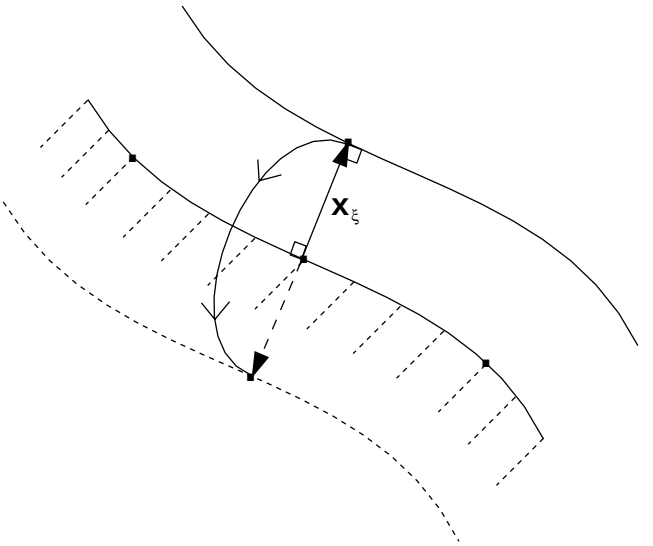

FIG. 3.2. *Reflection of orthogonalized interior grid point to form an external ghost point.*

second derivative ($\mathbf{x}_{\xi\xi}$) at the boundary and the normal spacing ($\sqrt{g_{11}}$) off the boundary. Constraining the ghost point assures that the normal spacing is not lost during the course of iteration, as occasionally occurs in the sliding orthogonality approach. Conversely, all of the interior grid points are mobile throughout the relaxation process, so smoothness of the grid is not compromised.

To quantify this approach, at the $\xi = 0$ boundary, let $(\mathbf{x}_\eta)_{0,j}$ denote the centrally differenced derivative $\frac{1}{2}(\mathbf{x}_{0,j+1} - \mathbf{x}_{0,j-1})$. Let $(\mathbf{x}^o_\xi)_{0,j}$ denote the one-sided derivative $\mathbf{x}_{1,j} - \mathbf{x}_{0,j}$ that is evaluated on the initial algebraic grid. Furthermore, let $\mathbf{a}$ be the unit vector normal to the boundary, which is defined with the use of the orthogonality condition (2.6):

$$\mathbf{a} \equiv \frac{\mathbf{x}_\xi}{||\mathbf{x}_\xi||} = \frac{(y_\eta, -x_\eta)}{\sqrt{x_\eta^2 + y_\eta^2}} = \frac{(y_\eta, -x_\eta)}{\sqrt{g_{22}}}.$$

Quantitatively, $\mathbf{x}_\xi$ in Figure 3.2 is given by

$$\mathbf{x}_\xi = \mathbf{P}_\mathbf{a}(\mathbf{x}^o_\xi), \tag{3.2}$$

where $\mathbf{P}_\mathbf{a} = \mathbf{a}\mathbf{a}^\mathbf{T}$ is the orthogonal projection onto the one-dimensional subspace spanned by the unit vector $\mathbf{a}$. Thus we obtain

$$\mathbf{x}_\xi = \mathbf{a}(\mathbf{a} \cdot \mathbf{x}^o_\xi) = \frac{(y_\eta, -x_\eta)}{g_{22}}(y_\eta x^o_\xi - x_\eta y^o_\xi). \tag{3.3}$$

The reflection operation depicted in the diagram implies that the constrained ghost point location is

$$\mathbf{x}_{-1,j} = \mathbf{x}_{0,j} - (\mathbf{x}_\xi)_{0,j}.$$

Alternatively, this can be viewed as a first-order Taylor expansion involving the orthogonal derivative $(\mathbf{x}_\xi)_{0,j}$:

$$\mathbf{x}_{-1,j} = \mathbf{x}_{0,j} + \Delta\xi(\mathbf{x}_\xi)_{0,j},$$

with $\Delta\xi = -1$. The orthogonal derivative $(\mathbf{x}_\xi)_{0,j}$ is computed in (3.3) using data from the boundary and the algebraic grid. To evaluate the control functions (2.5) at the boundary, the second derivative $\mathbf{x}_{\xi\xi}$ is computed using a central difference approximation involving the ghost point, boundary point, and the iteratively updated interior point. The metric coefficient g_{11} describing the spacing normal to the boundary is computed using (3.3),

$$(g_{11})_{0,j} = (\mathbf{x}_\xi)_{0,j} \cdot (\mathbf{x}_\xi)_{0,j}.$$

Finally, note that the value for $(\mathbf{x}_\xi)_{0,j}$ used in (2.5) is not the fixed value given by (3.3), but the iteratively updated one-sided difference formula given by

$$(\mathbf{x}_\xi)_{0,j} = \mathbf{x}_{1,j} - \mathbf{x}_{0,j}.$$

Evaluation of the boundary conditions for the $\xi = m$ boundary is a similar process, with the ghost point locations given by

$$\mathbf{x}_{m+1,j} = \mathbf{x}_{m,j} + (\mathbf{x}_\xi)_{m,j}.$$

$(\mathbf{x}_\xi)_{m,j}$ is evaluated using (3.3), which is also valid for this boundary.

At the $\eta = 0$ and $\eta = n$ boundaries, the derivatives $\mathbf{x}_\eta$ and $\mathbf{x}_{\eta\eta}$, along with the spacing g_{11}, are evaluated using the fixed boundary data using central differences. For the $\eta = 0$ boundary, the ghost point location is

$$\mathbf{x}_{i,-1} = \mathbf{x}_{i,0} - (\mathbf{x}_\eta)_{i,0},$$

where

$$\mathbf{x}_\eta = \frac{(-y_\xi, x_\xi)}{g_{11}}(-y_\xi x^o_\eta + x_\xi y^o_\eta). \tag{3.4}$$

In this case, $(-y_\eta, x_\eta)$ and g_{11} are evaluated using central differencing of the boundary data, and (x^o_η, y^o_η) represents a one-sided derivative $\mathbf{x}_{i,1} - \mathbf{x}_{i,0}$, again evaluated on the initial algebraic grid. The metric coefficient $(g_{22})_{i,0} = (\mathbf{x}_\eta)_{i,0} \cdot (\mathbf{x}_\eta)_{i,0}$ is computed using (3.4), and $\mathbf{x}_{\eta\eta}$ is computed using the ghost point, boundary point, and iteratively updated interior point. Similarly, the value of $(\mathbf{x}_\eta)_{i,0}$ used in (2.5) is not the fixed value given in (3.4) but is iteratively obtained from

$$(\mathbf{x}_\eta)_{i,0} = \mathbf{x}_{i,1} - \mathbf{x}_{i,0}.$$

Finally, the $\eta = n$ boundary is similar, with the ghost point locations given by

$$\mathbf{x}_{i,n+1} = \mathbf{x}_{i,n} + (\mathbf{x}_\eta)_{i,n},$$

and $(\mathbf{x}_\eta)_{i,n}$ is evaluated using (3.4).

Quantities for the four corner points, $\mathbf{x}_{0,0}$, $\mathbf{x}_{m,0}$, $\mathbf{x}_{0,n}$, and $\mathbf{x}_{m,n}$ are computed in a different manner. The values for $\mathbf{x}_\xi$, $\mathbf{x}_{\xi\xi}$, $\mathbf{x}_\eta$, $\mathbf{x}_{\eta\eta}$, g_{11}, and g_{22} are evaluated using one-sided difference formulas employing the requisite boundary values and are not refreshed during the course of iteration. Near the corners of the domain, *conformality* is usually more important than *orthogonality*. Precisely, orthogonality at the corners should be sacrificed in order to insure that the resulting grid does not "spill" over the physical boundaries. For the case of highly obtuse or highly acute corners, it is often necessary to relax orthogonality at boundary points extending some distance from the

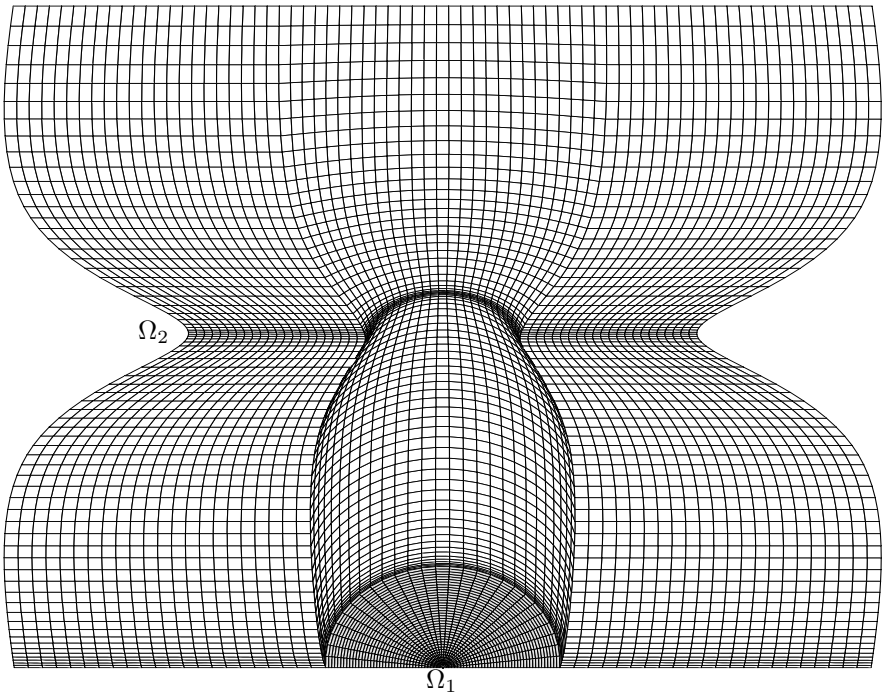

FIG. 3.3. *An algebraic planar grid on a multimaterial domain consisting of regions* Ω_1 *and* Ω_2.

true corner. To implement this case, the relevant ghost points are defined by a smooth blend beginning with the omission of the orthogonal projection operation (3.2) (i.e., definition by simple extrapolation) at the corners. This placement is modified through a transition to a weighted combination of extrapolation and orthogonal placement, then finally to the described orthogonality method some distance from the corner.

To demonstrate the effectiveness of the global technique, consider the initial algebraic planar grid spanning the bicubic geometry detailed in Figure 3.3. This mesh is created on a two material domain, with the material discontinuity located at the transition between the "pie" grid emanating from the singularity at the center of the bottom boundary (Ω_1) and the background mesh (Ω_2). The global mesh is highly skewed at certain points along the boundaries and possesses an undesirable concentration of points in the interior of the grid. Additionally, close inspection reveals folding of the algebraic grid in the central region.

Figure 3.4 shows the effectiveness of the grid generation system. The grid is smooth and boundary orthogonal, and folding at the interior has been removed. Close inspection reveals the use of the described orthogonality technique at the boundaries, as the grid point distribution (both along the boundary and normal to the boundary) remains unchanged. The concept of *preservation* of the initial grid information at the boundaries is essential to the derivation of the boundary impedance mechanism, which follows immediately.

4. Grid impedance matching. As outlined in the introduction, the impedance matching principle is a quantitative method aimed at reducing the errors of a simulation on a particular grid spanning the domain Ω. If possible, one desires a grid that preserves the physical discontinuities present in the domain without the introduction

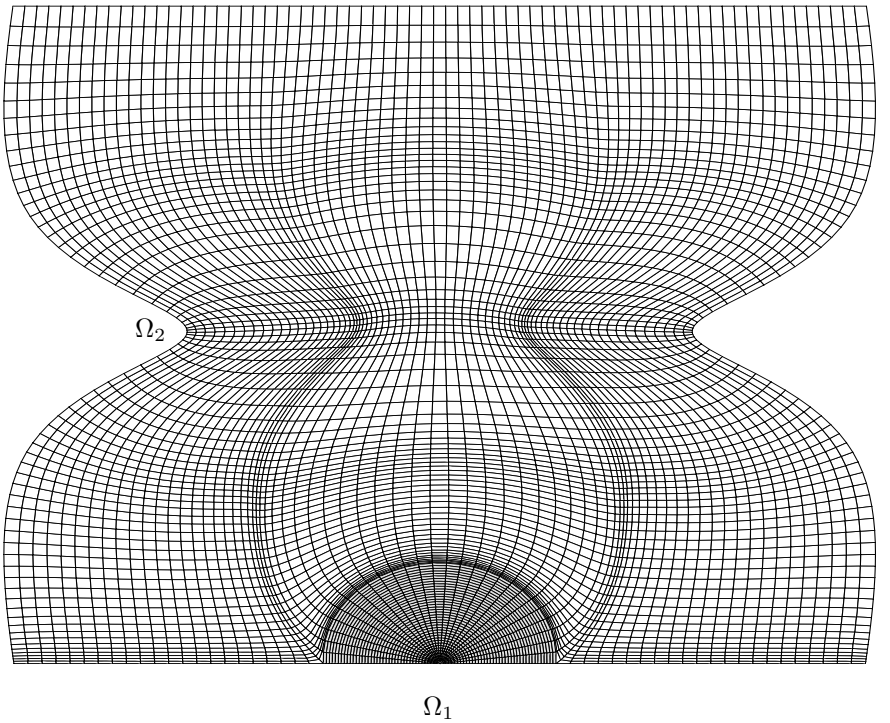

FIG. 3.4. *An elliptic planar grid on a multimaterial domain consisting of regions* Ω_1 *and* Ω_2.

of solution artifacts and one that also accommodates the assumptions of accuracy of the discrete system to be solved on the grid. These requirements are further complicated in cases of multimaterial simulations, where the domain contains dissimilar materials separated by geometric interfaces, $\Omega = \cup_{i=1}^{N} \Omega_i$. This work seeks to present impedance matching in the general, multimaterial case.

Given a mesh spanning a domain consisting of more than one material, three considerations describe the impedance matching principle. First, the mesh must be constructed such that, for an nth-order discretization, $n > 1$, the actual solution "displays" nth-order accuracy on the mesh. Second, one must insure solution accuracy in the neighborhood of internal material interfaces. Given the desire that the solution display an expected level of accuracy at the boundaries of regions leads to a necessary requirement on the mesh in the neighborhood of material interfaces. Last, this mesh must also be constructed such that the magnitude of the "ignored" higher-order terms (truncation error terms) in the discretization of the governing equations solved on the mesh are "small." The following sections discuss each of these topics and lead to the development of constraint expressions that govern the resulting impedance-matched grid generation process.

4.1. Effects of mesh spacing on truncation error. Nonuniform meshes are commonplace in numerical simulation, both due to the desire to generate boundary-fitted grids on domains defined by complex geometric boundaries and due to the desire to economize solution time by adaptively concentrating grid refinement in areas where small length scales are present in the solution. However, Hirt and Ramshaw [11] show that, for the general case, finite-difference approximations on a nonuniform mesh

may result in lower-order formal accuracy than finite-difference approximations on a uniform mesh.

To explore this concept, a truncation error analysis suggested by Hoffman [12] is employed. Let $\phi \equiv \phi(x)$ define the conservation quantity of interest on the domain Ω. Furthermore, consider the case that the discrete governing equations contain terms that require the evaluation of the first spatial derivative of ϕ that may be expressed as the central difference

$$\phi_x = \frac{\phi_{i+1} - \phi_{i-1}}{x_{i+1} - x_{i-1}}. \tag{4.1}$$

To study the truncation error of this approximation, a Taylor series expansion of ϕ about the arbitrary point x_i is developed,

$$\phi_{i\pm1} = \phi\big|_i \pm \phi_x\big|_i \Delta x_\pm + \frac{1}{2}\phi_{xx}\big|_i \Delta x_\pm^2 + O(\Delta x_\pm^3),$$

where $\Delta x_\pm$ is a forward/backward spatial difference about i. The numerator of (4.1) can be written in terms of the expansion as

$$\phi_{i+1} - \phi_{i-1} = \phi_x\big|_i (\Delta x_+ + \Delta x_-) + \frac{1}{2}\phi_{xx}\big|_i (\Delta x_+^2 - \Delta x_-^2) + O(\Delta x_\pm^3).$$

The denominator of (4.1) may be written in terms of Δx on the mesh:

$$x_{i+1} - x_{i-1} = (x_{i+1} - x_i) + (x_i - x_{i-1}) = (\Delta x_+ + \Delta x_-).$$

Finally, substitution into (4.1) reveals the expression for the first derivative of ϕ:

$$\phi_x = \phi_x\big|_i + \frac{1}{2}\phi_{xx}\big|_i (\Delta x_+ - \Delta x_-) + O(\Delta x_\pm^2). \tag{4.2}$$

Clearly, this statement suggests that the discretization is second-order accurate only when $\Delta x_+ = \Delta x_-$. This result appears to paint a bleak picture of the prospect of accurate solutions on nonuniform meshes spanning complex geometries. Fortunately, it is possible to address this apparent limitation effectively with the use of logical mapping and the interface impedance condition.

4.2. Impedance matching at grid interfaces. Material interfaces within the computational domain may be treated as region boundaries between meshes within the multimaterial domain. Given a point distribution on the boundaries and internal interfaces, it is possible to use an algebraic technique to construct a mesh within each subregion of the domain such that the algebraic mesh conforms to the interface geometry. The first step toward the generation of an impedance-matched mesh amenable to simulation is the examination of the algebraic mesh near these internal interfaces. It is first necessary to insure that the algebraic mesh near these interfaces provides second-order accuracy in the discretization of ϕ.

Consider a second-order discretization across the interface discontinuity, where

$$\lim_{\Delta x_+ \to 0} \phi^+ \neq \lim_{\Delta x_- \to 0} \phi^-.$$

In this expression, assume that the mesh point i lies on the interface boundary, $i+1$ is the point immediately to the"right" or + side of the interface, and $i-1$ is the point

immediately to the "left" or $-$ side of the interface. Furthermore, a first derivative expression of the form

$$\phi_r = \frac{(\phi_{i+1} - \phi_i) + (\phi_i - \phi_{i-1})}{r_{i+1} - r_{i-1}}$$

is desired across the interface discontinuity, where r is the coordinate normal to the interface curve. Again, it is possible to expand the components of the numerator on each side of the interface using a Taylor series, resulting in the expressions

$$\phi_{i+1} - \phi_i = \phi_r^+\big|_i \Delta r_+ + \frac{1}{2}\phi_{rr}^+\big|_i \Delta r_+^2 + O(\Delta r_+^3)$$

and

$$\phi_i - \phi_{i-1} = -\phi_r^-\big|_i \Delta r_- - \frac{1}{2}\phi_{rr}^-\big|_i \Delta r_-^2 + O(\Delta r_-^3).$$

This result may be combined to provide

$$(\phi_{i+1}-\phi_i)+(\phi_i-\phi_{i-1}) = \left(\phi_r^+\big|_i \Delta r_+ - \phi_r^-\big|_i \Delta r_-\right)+\frac{1}{2}\left[\phi_{rr}^+\big|_i \Delta r_+^2 - \phi_{rr}^-\big|_i \Delta r_-^2\right]+O(\Delta r_\pm^3).$$

The desired derivative of ϕ then takes the form

$$\phi_r = \frac{\phi_r^+\big|_i \Delta r_+ - \phi_r^-\big|_i \Delta r_-}{\Delta r_+ + \Delta r_-} + \frac{1}{2}\frac{\phi_{rr}^+\big|_i \Delta r_+^2 - \phi_{rr}^-\big|_i \Delta r_-^2}{\Delta r_+ + \Delta r_-} + O(\Delta r_\pm^2). \tag{4.3}$$

At this point, one desires the grid at the interface have the property that the first-order term in (4.3) is "small." If the numerator of this term is unconditionally zero,

$$\phi_{rr}^+\big|_i \Delta r_+^2 - \phi_{rr}^-\big|_i \Delta r_-^2 = 0,$$

the magnitude of the first-order term is zero. Rearranging this result provides the impedance condition on the grid at the interface:

$$\sqrt{\phi_{rr}^+\big|_i}\,\Delta r_+ = \sqrt{\phi_{rr}^-\big|_i}\,\Delta r_-.$$

Let $\rho(r) \equiv \phi_{rr}$ define the impedance quantity of interest, in the direction r normal to the interface. The condition that provides impedance matching across the interface reduces to

$$\sqrt{\rho^+\big|_i}\,\Delta r_+ = \sqrt{\rho^-\big|_i}\,\Delta r_-. \tag{4.4}$$

The initial algebraic mesh on the domain is effectively arbitrary; it serves only as an initial "guess" for the quasi-orthogonal grid generation system and allows the evaluation of the boundary conditions for the elliptic method. Recall, however, that the evaluation of these boundary conditions employs the first algebraically determined grid line internal to the boundary. Clearly, the position of this grid line can be evaluated using the impedance match condition (4.4), in lieu of using data from the algebraic grid, with no loss of generality. Via this mechanism, the interface impedance condition is coupled to the quasi-orthogonal grid generation system.

4.3. Impedance matching in the grid interior. A similar approach may be used within the grid interior, away from discontinuities. As seen in (4.2), this yields the requirement of a uniform mesh. This is certainly one possible impedance-matched mesh. However, using a functional mapping from a computational space in which the discrete nodal points are uniformly distributed to a physical space with nonuniformly distributed nodes also results in a mesh that displays second-order accuracy.

Let $x = x(\xi)$ and $\phi = \phi(x(\xi)) = \phi(\xi)$. The desired first derivative statement becomes

$$\phi_x = \phi_\xi \, \xi_x = \xi_x\big|_i \frac{\phi_{i+1} - \phi_{i-1}}{\xi_{i+1} - \xi_{i-1}}.$$

The numerator is again evaluated using a Taylor expansion:

$$\phi_{i\pm1} = \phi\big|_i \pm \phi_\xi\big|_i \Delta\xi + \frac{1}{2}\phi_{\xi\xi}\big|_i \Delta\xi^2 + O(\Delta\xi^3)$$

or

$$\phi_{i+1} - \phi_{i-1} = 2\phi_\xi\big|_i \Delta\xi + O(\Delta\xi^3).$$

For the uniform computational ξ mesh,

$$\xi_{i+1} - \xi_{i-1} = (\xi_i + \Delta\xi) - (\xi_i - \Delta\xi) = 2\Delta\xi.$$

Combining the above leads to

$$\phi_x = \xi_x\big|_i \, \phi_\xi\big|_i + O(\Delta\xi^2)$$

or

$$\phi_x = \frac{\phi_\xi\big|_i}{x_\xi} + O(\Delta\xi^2). \tag{4.5}$$

This result verifies that, given the mapping $x(\xi)$ and $\phi = \phi(\xi)$, a second-order solution in ξ results. Clearly, the quasi-orthogonal grid generation system (equations (2.4) and (2.5)) provides this mapping; the system was derived based on this transformation.

The effectiveness of this result is only damped by the apparent requirement that the simulation code must now operate in the computational space used to generate the grid, significantly increasing its complexity and run-time due to the required transformations. Hoffman [12] concludes, however, that solving in computational space is not a requirement, as merely the *existence* of the transformation is sufficient to provide second-order behavior on a nonuniform physical mesh. If the values of $\Delta x_\pm$,

$$\Delta x_+ - \Delta x_- = x_{\xi\xi} \, \Delta\xi^2 + O(\Delta\xi^4),$$

are chosen such that $\Delta x_+ - \Delta x_-$ quarters when $\Delta\xi$ is halved, the truncation error ϕ_x quarters (see (4.2)). This behavior of the transformation is independent of the fact that, considering the discretized physical space equations alone, the solution is formally only first-order accurate. This result allows decoupling of the transformation process employed in the grid generator from the solution process.

5. Implementation of impedance matching. Several important details remain in order to fully implement the second-order quasi-orthogonal impedance system. Section 3 developed an implementation of the quasi-conformal grid generation system and posed a set of boundary conditions necessary to enforce grid orthogonality at region interfaces (and the domain boundary). To summarize this result, to solve the quasi-elliptic grid generation system requires

1. a discretization of the boundary or interface curves,
2. use of the impedance condition to locate the first off-boundary row of grid points with the calculated normal spacing to the boundary, and
3. an initial algebraic grid to serve as an initial "guess" for the smoother on the interior of the region.

It was earlier proposed that the initial algebraic grid could be used to supply the boundary discretization. However, it is more useful to explore the use of the impedance condition, in an iterative setting, to place the points on the boundary to satisfy local impedance constraints. Using this concept, the impedance condition specifies grid point location both "along" (tangentially to) the boundary and "across" (normal to) the boundary, at least for the nearest row of grid points to the boundary. The quasi-elliptic system will then decay this off-boundary spacing to the geometric constraints and level of grid refinement in the interior of the region.

To implement the impedance-based grid generation system requires a definition of the geometrical basis of the domain. A general approach uses the assumption that domain boundaries and interfaces are defined by *parametric curves* (e.g., B-spline curves). As such, the curve geometry definition is in the form of a mapping $(x(u), y(u), z(u))$ from a *parametric u-domain* to a *physical* (x, y, z)*-domain*. This mapping is assumed differentiable and is denoted by $\mathbf{x}(u)$, where $\mathbf{x} = (x, y, z)$.

Discretization of these curves entails the placement of node points upon the curve; the actual distribution process is described by the generation of a mapping from the discrete *computational* ξ*-domain* to the *parametric u-domain*, resulting in the composite map $\mathbf{x}(\xi) = (x(\xi), y(\xi), z(\xi))$.

Physical space is a subset of $\mathbb{R}^3$, and the parametric space is a subset of $\mathbb{R}$, specifically the $[0, 1]$ unit interval. Technically, the computational space is a discrete linear set of points $\xi \in \{0, 1, \ldots, m\}$. However, to apply the concept of differentiable mappings between spaces, computational space is extended to become a continuum and is represented as the line $[0, m]$.

Let $\rho \equiv \rho(s)$ represent the impedance function of arclength s on the boundary curve in $\mathbb{R}^3$. This function is defined as the analogue of the one-dimensional case (4.4), or $\rho^{\pm}(s)\big|_i = \phi^{\pm}_{ss}\big|_i$. Similarly, the impedance condition at the boundary curves reduces to

$$\sqrt{\rho^+} s^+_\xi = \sqrt{\rho^-} s^-_\xi .$$

As an overview of the method employed, the impedance condition above is used to position the first free point at each end of the boundary curve. The remaining points on the boundary are subsequently interpolated given these end points to provide an initial guess for an elliptic relaxation procedure defined in terms of arclength s of the curve. This relaxation procedure preserves the required accuracy on the curve as it represents a variant of (4.5). Given the discrete boundaries, the initial mesh for the region is calculated using transfinite interpolation. The first row of off-boundary grid points is then adjusted using the orthogonality condition to define the local boundary normal r, with the impedance condition (4.4) used to calculate the local spacing of the

off-boundary point from the boundary. Finally, application of the quasi-orthogonal grid generation system results in an impedance-matched mesh in the interior of the region of interest.

To develop the impedance-matched point spacing on the boundary curve, consider the elliptic differential equation

$$\xi_{ss} = \Phi(s), \tag{5.1}$$

with boundary conditions

$$\frac{1}{\sqrt{\rho^+}}\xi_s^+ = \frac{1}{\sqrt{\rho^-}}\xi_s^- \quad \text{for} \quad s = s_0, s_m.$$

The impedance spacing function Φ is a function of arclength s of the boundary curve via the governing logical transformation. The change in arclength of the parametric curve is given by $ds = du||\mathbf{x}_u||$. Therefore, $\xi_s = \frac{1}{s_\xi}$, where

$$s_\xi = s_u u_\xi = ||\mathbf{x}_u|| u_\xi.$$

Additionally,

$$\xi_{ss} = -\frac{s_{\xi\xi}}{s_\xi^3},$$

where

$$s_{\xi\xi} = \frac{\mathbf{x}_u \cdot \mathbf{x}_{uu} u_\xi^2 + \mathbf{x}_u \cdot \mathbf{x}_u u_{\xi\xi}}{||\mathbf{x}_u||}.$$

The inverse transformation of (5.1) results in

$$u_{\xi\xi} + \Phi \mathrm{g} u_\xi = -u_\xi^2 \frac{\mathbf{x}_u \cdot \mathbf{x}_{uu}}{\mathbf{x}_u \cdot \mathbf{x}_u}, \tag{5.2}$$

where

$$\mathrm{g} = \mathbf{x}_\xi \cdot \mathbf{x}_\xi = \mathbf{x}_u \cdot \mathbf{x}_u u_\xi^2.$$

The boundary conditions are represented by

$$\begin{aligned} u_\xi &= \sqrt{\frac{\rho^-}{\rho^+}}\, \frac{||\Delta \mathbf{x}^-||}{||\mathbf{x}_u^+||} \quad \text{for} \quad \xi = 0, \\ u_\xi &= \sqrt{\frac{\rho^+}{\rho^-}}\, \frac{||\Delta \mathbf{x}^+||}{||\mathbf{x}_u^-||} \quad \text{for} \quad \xi = m. \end{aligned} \tag{5.3}$$

Equations (5.2) and (5.3) are applied to the boundary (or interface) nodes to iteratively obtain $\mathbf{x}_i = (x_i, y_i, z_i)$.

To implement the above on a given parametric boundary curve, u_0 and u_m are obtained from the algebraic curve grid. The ghost points u_{-1} and u_{m+1} are provided from opposite curves. Placement of the first two points interior of the curve end points is governed by the boundary conditions

$$\begin{aligned} u_1 &= u_0 + \sqrt{\frac{\rho_{-1}}{\rho_1}}\, \frac{||\mathbf{x}_0 - \mathbf{x}_{-1}||}{||\mathbf{x}_{u_0}||}, \\ u_{m-1} &= u_m - \sqrt{\frac{\rho_{m+1}}{\rho_m}}\, \frac{||\mathbf{x}_{m+1} - \mathbf{x}_m||}{||\mathbf{x}_{u_m}||}. \end{aligned}$$

The user-specified point density on the remainder of the curve is provided by the parametric values u_i for $i = 2, \ldots, m-2$. Linear interpolation,

$$u_i = t_i u_{m-1} + (1 - t_i)u_1, \quad t_i = \frac{i-1}{m-1} \quad \text{for} \quad i = 2, \ldots, m-2,$$

is an effective mechanism that may be used to provide the initial locations of these points. Impedance on these interpolated points is imposed by adjusting the impedance spacing function Φ near the boundary while holding the coordinates of the boundary points constant. To accomplish this, the impedance spacing function is evaluated at $i = 1$ and $i = m-1$ using

$$\Phi_i = -\frac{u_{\xi\xi}}{\mathrm{g} u_\xi}\bigg|_i - \frac{u_\xi}{\mathrm{g}} \frac{\mathbf{x}_u \cdot \mathbf{x}_{uu}}{\mathbf{x}_u \cdot \mathbf{x}_u}\bigg|_i \quad \text{for} \quad i = 1 \text{ and } m-1.$$

Φ is distributed to the remaining points on the curve, again using linear interpolation,

$$\Phi_i = t_i \Phi_{m-1} + (1 - t_i)\Phi_1, \quad t_i = \frac{i-1}{m-1} \quad \text{for} \quad i = 2, \ldots, m-2.$$

Let $(u_\xi)_{i,j}$ denote the central difference $\frac{1}{2}(u_{i+1} - u_{i-1})$, and $(u_{\xi\xi})_{i,j} \approx u_{i+1} - 2u_i + u_{i-1}$. In the relaxation process, the old parameter value u_0 is used in the discrete version of (5.2) to obtain u_i. This result allows the refresh of $\mathbf{x}_i = \mathbf{x}(u_i)$ along the curve. Let u_i denote $u(\xi)$ evaluated at the $\xi = i$ grid point. A central difference approach is used to approximate the solution of (5.2), to provide the boundary impedance condition

$$\begin{aligned} u_i =& \frac{1}{2}(u_{i+1} + u_{i-1}) \\ &+ \frac{1}{4}(u_{i+1} - u_{i-1})\big(\Phi_i \mathrm{g}_i\big) \\ &+ \frac{1}{8}(u_{i+1} - u_{i-1})^2 \left(\frac{\mathbf{x}_u \cdot \mathbf{x}_{uu}}{\mathbf{x}_u \cdot \mathbf{x}_u}\right)_i \quad \text{for} \quad i = 2, \ldots, m-2. \end{aligned}$$

This impedance equation is evaluated for u_i each iterative cycle.

Clearly, for the method just described to be effective, the impedance spacing function Φ_i must be refreshed every iteration prior to the computation of u_i. However, the curve boundary points u_0, u_1, u_{m-1}, and u_m only need to be initialized at the beginning of the relaxation cycle for each curve. This relaxation procedure is applied to all interface curves, in turn, until convergence is achieved.

To complete the grid generation process, the interior regions are discretized based on the bounding curves. Transfinite interpolation is used to provide an initial mesh for the quasi-orthogonal grid generation system detailed in section 3.

The boundary conditions for the system are specified by the direct application of the orthogonality condition (3.3) or (3.4), which places the off-boundary and ghost point on the vector r_i normal to the boundary at the interface point in question. The ratio of the distances of these two points from boundary point i along r is established by the direct application of the impedance condition (4.4). The magnitude of the separation distance between the off-boundary point is relaxed by the interior smoother while the ghost point separation distance is relaxed by the smoothing operation in the adjacent region. As such, the boundary condition treatment enforces orthogonality of these points with the boundary and a ratio spacing to satisfy the impedance condition at each iteration of the global smoother.

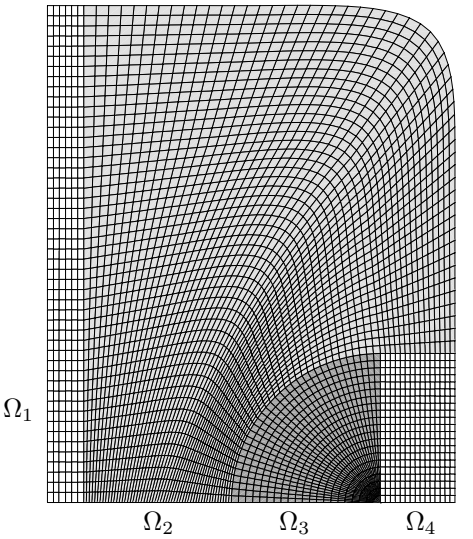

FIG. 5.1. *A multimaterial algebraic grid.*

Figure 5.1 depicts a four-material region with an algebraic grid spanning $\Omega = \cup_{i=1}^{4}\Omega_i$. Ω_1 is the region along the left side of the domain, Ω_3 is the "pie-slice" region emanating from the singularity toward the lower-right side of the figure, Ω_4 is the rectangle at the lower-right side of the figure, and Ω_2 is the remainder of the mesh. This particular figure was chosen to provide a simple example that would show the outcome of the impedance matching principle while illustrating how the coupling between impedance and the smoothing algorithm results in a "globally smooth" mesh. This example contains several interfaces separating materials of different density, with one interface simply spanning the domain and with the remaining interfaces being self intersecting in the area of the "pie slice." This topology, along with the selection of the domain geometry, results in a nontrivial test case sufficiently complex to motivate the effectiveness of the method. With a density difference in the regions of the mesh, one would expect to see a nonuniform spacing at the interface that satisfies the second-order impedance condition $\sqrt{\rho^+}s_\xi^+ = \sqrt{\rho^-}s_\xi^-$, with a smooth decay from this condition as one moves away from the interface.

Figure 5.2 details the result of the impedance-coupled quasi-orthogonal grid generation applied to the algebraic mesh, where the impedance quantities were specified as constants in each of the regions, $\rho_1 = 3.0$, $\rho_2 = 30.0$, $\rho_3 = 2.0$, and $\rho_4 = 1.0$. In this result, the effect of the interface impedance condition is clearly evident. For example, consider the interface between regions Ω_1 and Ω_2, where the internal boundary is vertical. The impedance condition may be expressed as $\sqrt{\rho_{\Omega_1}}s_\xi^{\Omega_1} = \sqrt{\rho_{\Omega_2}}s_\xi^{\Omega_2}$, which specifies an off-interface discontinuous spacing as a function of the ρ-discontinuity at the interface.

Let the ξ coordinate describe a horizontal grid line at this interface, and $\rho_1 = 3.0$ with $\rho_2 = 30.0$. Given a distance δs^+ (the distance from the interface to the first vertical grid line left of it) equal to some constant C, the impedance condition mandates that

$$\delta s^- = \sqrt{\frac{\rho_+}{\rho_-}}s_\xi^+ = \sqrt{\frac{\rho_+}{\rho_-}}C,$$

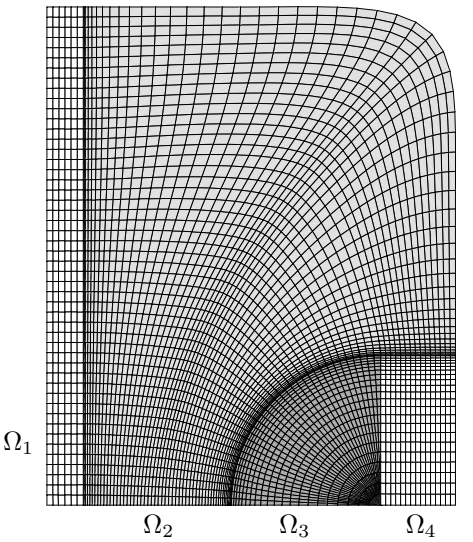

FIG. 5.2. *A quasi-orthogonal, impedance-matched multimaterial grid.*

or $\delta s^- = C/\sqrt{10}$. For this example, satisfying the impedance condition is equivalent to a local grid spacing roughly three times finer to the right of the interface than to the left. Clearly, the impedance condition has the effect of "packing" grid lines toward the lower-ρ region at material discontinuities. Additionally, the overall smoothness and orthogonality provided by the base system is apparent in the example.

The impedance principle can clearly be extended to higher-order terms in the approximation. Several authors have explored the reduction in magnitude of higher-order terms in a second-order approximation. Mastin [13] suggests sufficient conditions that arise from an examination of truncation error. This work provides intuitive bounds on the grid's departure from orthogonality, along with the rate of change of grid spacing, that are derived from a truncation analysis. Further work remains to couple the reduction of higher-order terms to a grid generation system. The results obtained here are qualitatively "smooth" and "orthogonal." However, the desire remains to guarantee that the constraints developed by Mastin et al. will be unconditionally satisfied within the grid generation system.

6. Summary. In this development of a system for the generation of quasi-orthogonal, impedance-matched meshes, an elliptic system was derived and shown to be effective in the generation of quasi-conformal mappings. Boundary conditions were imposed on general parametrically defined boundary curves. These conditions were a function of both geometric and impedance constraints.

The grid generation process begins with the user specifying the number of points desired on each boundary. The first and last points are placed using the impedance condition at the end points of each curve, with the remainder placed based on a transformation using the impedance condition as a boundary condition. The "line" of ghost points and the first line of interior grid points surrounding each region of the grid are placed using the impedance condition to specify the ratio spacing normal to the boundary, with the orthogonality condition used to specify point placement tangentially to the boundary. Transfinite interpolation is used to provide an algebraic spacing interior to each region for the purpose of providing an initial condition for the quasi-orthogonal method.

Given the algebraic mesh with impedance-matched boundaries, the quasi-orthogonal

grid generation system is used to relax the mesh to satisfy the quasi-orthogonal transformation in the interior region. As this relaxation proceeds toward convergence, an impedance-matched mesh with second-order error behavior results across the computational domain.

This approach to grid generation adds generality to grid generation methods based on elliptic systems and explores the mechanics of coupling quantitative quality measures to the grid generation process. Future challenges would include the extension of these techniques to more complex mesh topologies and a detailed examination of the effect and incorporation of higher-order terms into the grid generation system to further refine the simulation qualities of the resulting mesh.

MULTIRESOLUTION ANALYSIS AND SUPERCOMPACT MULTIWAVELETS*

RICHARD M. BEAM† AND ROBERT F. WARMING†

Abstract. The Haar wavelets can represent exactly any piecewise constant function. The motivation for the present development is Alpert's family of compact orthogonal multiwavelets that can represent exactly any piecewise polynomial function. We choose to derive the algorithm in the style and notation of Harten's multiresolution analysis as extended to multiwavelets by the authors. We begin with a description of the nested grid hierarchy. Next comes the decomposition, which is the heart of the algorithm, and finally the reconstruction. The basis functions (which are nonfractal) retain the spatial compactness of the Haar basis functions, which enhances the algorithm application to nonperiodic and piecewise continuous data.

Key words. wavelets, multiwavelets, multiresolution

1. Introduction.

Strang [6] has observed that the Haar wavelets have *almost* all the right stuff. They are compact, piecewise analytic (nonfractal), and orthogonal; however, they are lacking in approximation (only first-order or one vanishing moment). Daubechies [2] extended the order of approximation and retained the orthogonality, but the Daubechies wavelets are fractal and less compact than the Haar wavelets. Geronimo, Hardin, and Massopust [4] used multiwavelets to obtain wavelets which are second-order in approximation, symmetric, and orthogonal but have the same compactness as Daubechies and are not analytic. Strang and Strela [7] extended the multiwavelet work of Geronimo, Hardin, and Massopust [4] to retain the general order of approximation of Daubechies with more compactness. The Strang–Strela multiwavelets are more compact than the Daubechies wavelets but less compact than Haar wavelets, and they are fractal. Recently, Donovan, Geronimo, and Hardin [3] used multiresolution analyses for the construction of multiwavelets that have arbitrary regularity and orthogonality and are also symmetric and piecewise polynomial. Their wavelets have compact support but not the compactness of Haar. In this paper we present multiwavelets that retain the compactness of Haar wavelets, are piecewise polynomial and orthogonal, and can have arbitrary order of approximation.

In Harten's multiresolution analysis [5] one needs a scalar interpolation formula to transfer information between scales. The present authors extended Harten's multiresolution in [8] to include Hermite interpolation that leads to vector interpolation and multiwavelets. These wavelets are nonfractal and accurate; however, they are not orthogonal (but biorthogonal) and are less compact than Haar wavelets. Our search for the orthogonal basis with the compactness of Haar (which we call *supercompact*) led to the present paper. The supercompact multiwavelets of this paper are closely related to the multiwavelet basis of Alpert [1]. Alpert constructs the multiwavelet

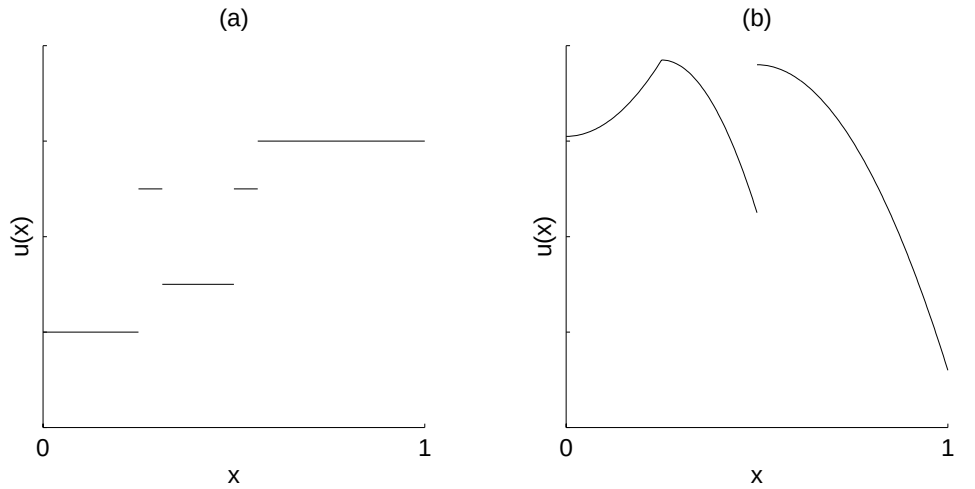

FIG. 1. *Piecewise continuous functions:* (a) *piecewise constant function,* (b) *piecewise polynomial function.*

basis (with vanishing moments) directly, whereas the multiwavelet basis in our development is a byproduct of the polynomial interpolation and the vanishing moments are assured by the order of the interpolation. In fact, neither the development nor the application of our multiresolution algorithm requires an explicit knowledge of the multiwavelet basis.

The advantages of the multiresolution algorithm with supercompact support of the basis are twofold. First, the application to functions defined on a finite interval does not require any special treatment at the boundaries of the interval. Second, the application to functions that are only piecewise continuous (internal boundaries) can be efficiently implemented.

The paper is divided as follows: In section 2 we present the multiresolution algorithm development that uses orthogonal polynomial interpolation. In section 3 we evaluate the coefficients of the multiresolution algorithm that are dependent on the choice of interpolation polynomials and give examples for Legendre polynomials. In section 4 we consider the implementation of the multiresolution algorithm for various types of initial data: analytical, discrete function values, discrete derivative values, and/or discrete integral (cell average) values. Section 5 is devoted to an exposition of the multiwavelet basis. In section 6 we give some application examples that highlight the virtues of the algorithm. We conclude the main paper with some brief concluding remarks in section 7. Details that detract from the continuity of the presentation are relegated to appendices.

2. Algorithm development. The Haar wavelets can represent exactly any piecewise constant function (Figure 1(a)). The motivation for the present development is a family of wavelets (multiwavelets) that can represent exactly any piecewise polynomial function (Figure 1(b)). We choose to derive the algorithm in the style and notation of Harten's multiresolution analysis as extended to multiwavelets by the authors in [8]. We begin with a description of the nested grid hierarchy. Next comes the interpolation, then the decomposition (which is the heart of the algorithm), and finally the reconstruction.

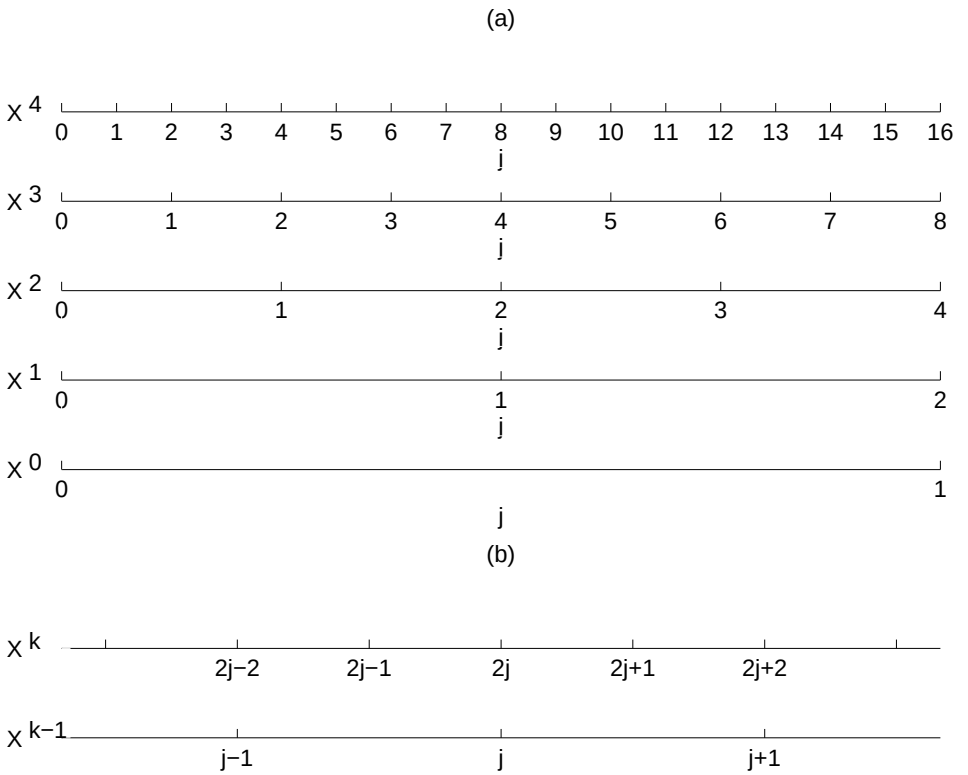

FIG. 2. *Nested grids:* (a) *nested sequence of grids,* (b) *two generic grid levels.*

2.1. Nested grid hierarchy. Let $m > n$ be positive integers and let $\{X^k\}_{k=m,m-1,\dots,n}$ denote a nested sequence of uniform grids on the unit interval $[0,1]$ defined by

$$X^k = \{x_j^k\}_{j=0}^{J_k}, \quad x_j^k = jh_k, \quad h_k = 2^{-k}, \quad J_k = 2^k, \tag{2.1}$$

where k denotes the grid level index (see, e.g., Figure 2(a)). The level index $k = m$ corresponds to the *finest* grid in the hierarchy where the number of subintervals is $J_m = 2^m$ and the subinterval (grid spacing) is $h_m = 2^{-m}$. The level index $k = n$ corresponds to the *coarsest* grid where the number of subintervals is $J_n = 2^n$ and the subinterval is $h_n = 2^{-n}$. Note that X^{k-1} is formed from X^k by removing grid points of X^k with odd indices:

$$x_j^{k-1} = x_{2j}^k, \quad j = 0, 1, 2, \dots, J_{k-1} \tag{2.2}$$

(see Figure 2(b)).

In the multiresolution algorithm development we assume that the discrete data on the finest grid comes from a piecewise continuous function $u(x)$ on the unit interval $[0,1]$. A preprocessing procedure uses a polynomial interpolation to transform $u(x)$ into a matrix $\mathbf{A}^m$ of discrete values on the finest level $k = m$ with grid X^m:

$$\mathbf{A}^m = [\boldsymbol{\alpha}_1^m, \boldsymbol{\alpha}_2^m, \dots, \boldsymbol{\alpha}_{J_m}^m], \quad J_m = 2^m. \tag{2.3}$$

For multiwavelets the vectors $\boldsymbol{\alpha}_j^m$ are column vectors whose length is determined by the order of polynomial approximation. The matrix $\mathbf{A}^m$ is the input to the multiresolution algorithm. For each grid X^k at each level k there is an associated matrix $\mathbf{A}^k$:

$$\mathbf{A}^k = [\boldsymbol{\alpha}_1^k, \boldsymbol{\alpha}_2^k, \ldots, \boldsymbol{\alpha}_{J_k}^k], \quad J_k = 2^k. \tag{2.4}$$

The matrix $\mathbf{A}^{k-1}$ has half the number of columns of $\mathbf{A}^k$ and is formed by a prescription given in the multiresolution algorithm developed below. Specific examples of the matrix $\mathbf{A}^m$ are given in section 4.

2.2. Interpolation. The next step of the multiresolution development is an algorithm to project the discrete data $\mathbf{A}^k$, matrix (2.4), from grid X^k to grid X^{k-1} (fine to coarse) and conversely from grid X^{k-1} to grid X^k (coarse to fine). The fine to coarse projection is a decomposition or decimation (less data) and the coarse to fine projection is a reconstruction or fill-in (more data). In this section we begin the development of the projection algorithms by considering the special case where $u(x)$ is a polynomial function of degree ℓ. On each interval of the coarse grid X^{k-1} we expand $u(x)$ in a family of orthogonal polynomials (degree ℓ) with coefficients $\mathbf{A}^{k-1}$, the discrete data (2.4). This choice of a compact (one grid interval) expansion with orthogonal polynomials of degree ℓ will produce supercompact orthogonal projections with order of accuracy $\ell + 1$, i.e., exact reconstruction (fill-in) for polynomials of degree ℓ. In the next section we consider the practical case where $u(x)$ is a general piecewise continuous function and the polynomial expansion is only an approximation. In section 4 we consider a specific example of a family of orthogonal polynomials, e.g., Legendre polynomials.

First we introduce some notation. Let $\phi_i(\xi)$ be a polynomial of degree ℓ or less with support on the interval $-1 < \xi \le 1$:

$$\phi_i(\xi) = \begin{cases} \sum_{p=0}^{\ell} a_{p,i}\xi^p, & -1 < \xi \le 1, \\ 0, & \text{otherwise.} \end{cases} \tag{2.5}$$

We will assume that the family of polynomials (2.5) $i = 0, 1, \ldots, \ell$ is orthonormal, i.e.,

$$\int_{-1}^{1} \phi_i(\xi)\phi_j(\xi)d\xi = \delta_{ij}. \tag{2.6}$$

We assume that ℓ is sufficiently small so the Runge phenomenon for polynomial interpolation is not an issue. The contracted form of $\phi_i(\xi)$ with support on the jth subinterval of the level k grid is

$$(\phi_i(x))_j^k = \begin{cases} \phi_i\left(1 + \frac{2}{h_k}\left(x - x_j^k\right)\right), & x_{j-1}^k < x \le x_j^k, \\ 0, & \text{otherwise,} \end{cases} \tag{2.7}$$

where we use the subscript j on the function $\phi_i(x)$ to denote the subinterval of support on the grid level indicated by the superscript k.

We denote the family of $\ell + 1$ polynomials of degree ℓ by the vector

$$\boldsymbol{\phi}_j^k = (\boldsymbol{\phi}(x))_j^k = \left[(\phi_0(x))_j^k, \quad (\phi_1(x))_j^k, \quad \ldots, \quad (\phi_\ell(x))_j^k\right]'. \tag{2.8}$$

In (2.8) and throughout the remainder of this paper we use the prime ($'$) to denote a vector or matrix transpose. (The general family of polynomials (2.8) is considered in section 3 and Appendix D.) The polynomials in the family are orthogonal on the interval $x_{j-1}^k < x \le x_j^k$. For notational simplicity we will not explicitly indicate the dependency of $\boldsymbol{\phi}$ on x, except where necessary for clarity. If we properly select a set of $\ell+1$ coefficients

$$\boldsymbol{\alpha}_j^k = \left[(\alpha_0)_j^k, \quad (\alpha_1)_j^k, \quad \dots, \quad (\alpha_\ell)_j^k\right]', \tag{2.9}$$

then any polynomial function, denoted by $u(x)$, of degree ℓ can be represented exactly on the jth subinterval of the level $k-1$ grid by

$$(u(x))_j^{k-1} = \sum_{i=0}^{\ell} (\alpha_i)_j^{k-1} (\phi_i(x))_j^{k-1} = \boldsymbol{\alpha}_j^{k-1\prime} \boldsymbol{\phi}_j^{k-1}. \tag{2.10}$$

We can represent the same function on two subintervals of grid level k:

$$(u(x))_j^{k-1} = \boldsymbol{\alpha}_{2j-1}^{k\prime} \boldsymbol{\phi}_{2j-1}^k + \boldsymbol{\alpha}_{2j}^{k\prime} \boldsymbol{\phi}_{2j}^k \tag{2.11}$$

(see the relation between grid indexing at level $k-1$ and at level k given by (2.2)).

Since each component of $\boldsymbol{\phi}_j^{k-1}$ is a polynomial, it can also be represented exactly on two subintervals of grid level k, i.e.,

$$\boldsymbol{\phi}_j^{k-1} = \mathbf{C}_0 \boldsymbol{\phi}_{2j-1}^k + \mathbf{C}_1 \boldsymbol{\phi}_{2j}^k, \tag{2.12}$$

where $\mathbf{C}_0$ and $\mathbf{C}_1$ are $(\ell+1)\times(\ell+1)$ matrices whose elements depend on the coefficients ($a_{p,i}$'s) of the family of polynomials $\boldsymbol{\phi}$ given by (2.5).

If we use the identity (2.12) in (2.10), we obtain

$$(u(x))_j^{k-1} = \boldsymbol{\alpha}_j^{k-1\prime} (\mathbf{C}_0 \boldsymbol{\phi}_{2j-1}^k + \mathbf{C}_1 \boldsymbol{\phi}_{2j}^k). \tag{2.13}$$

The two families of polynomials $\boldsymbol{\phi}_{2j-1}^k$ and $\boldsymbol{\phi}_{2j}^k$ have nonoverlapping support, and the ϕ_i's are orthogonal; therefore, we can equate their coefficients from (2.11) and (2.13):

$$\boldsymbol{\alpha}_j^{k-1\prime} \mathbf{C}_0 = \boldsymbol{\alpha}_{2j-1}^{k\prime}, \tag{2.14a}$$

$$\boldsymbol{\alpha}_j^{k-1\prime} \mathbf{C}_1 = \boldsymbol{\alpha}_{2j}^{k\prime}. \tag{2.14b}$$

Taking the transpose of (2.14a), (2.14b), one obtains

$$\boldsymbol{\alpha}_{2j-1}^k = \mathbf{C}_0{}' \boldsymbol{\alpha}_j^{k-1}, \tag{2.15a}$$

$$\boldsymbol{\alpha}_{2j}^k = \mathbf{C}_1{}' \boldsymbol{\alpha}_j^{k-1}. \tag{2.15b}$$

If we multiply (2.15a) by $\mathbf{C}_0$ and multiply (2.15b) by $\mathbf{C}_1$ and add the results, we have

$$\mathbf{C}_0 \boldsymbol{\alpha}_{2j-1}^k + \mathbf{C}_1 \boldsymbol{\alpha}_{2j}^k = (\mathbf{C}_0 \mathbf{C}_0{}' + \mathbf{C}_1 \mathbf{C}_1{}') \boldsymbol{\alpha}_j^{k-1}. \tag{2.16}$$

Since $\phi(\xi)$'s (2.5) are assumed to form an orthonormal basis, it can be shown (Appendix A) that

$$\frac{1}{2}(\mathbf{C}_0\mathbf{C}_0{}' + \mathbf{C}_1\mathbf{C}_1{}') = \mathbf{I}. \tag{2.17}$$

If we use identity (2.17) in (2.16) we obtain

$$\boldsymbol{\alpha}_j^{k-1} = \frac{1}{2}(\mathbf{C}_0\boldsymbol{\alpha}_{2j-1}^k + \mathbf{C}_1\boldsymbol{\alpha}_{2j}^k). \tag{2.18}$$

Let's summarize. If $u(x)$ is a polynomial of degree ℓ on the interval $x_{j-1}^{k-1} < x < x_j^{k-1}$, then (2.15a), (2.15b), and (2.18) provide the necessary equations for manipulating the $\boldsymbol{\alpha}$'s between level k and $k-1$. We will use the terminology that (2.18) provides the "decomposition" from the finer level k to the coarser level $k-1$ and (2.15a), (2.15b) provide the "reconstruction" from the coarser level $k-1$ to the finer level k.

2.3. Decomposition. In general the special case where $u(x)$ is a single low degree polynomial on the unit interval is not of interest. The interesting case is for any piecewise continuous function $u(x)$. In this case (2.15a), (2.15b), and (2.18) will not be identities but only approximations. Therefore, in the general case we must save additional information from the decomposition if we want exact reconstruction of $\boldsymbol{\alpha}^k$. The Harten multiresolution approach is to compute and save the interpolation error or, equivalently, a residual. For the decomposition, in the general case, we will use a weighted form of (2.18), i.e.,

$$\boldsymbol{\alpha}_j^{k-1} = \frac{1}{\sqrt{2}}(\mathbf{C}_0\boldsymbol{\alpha}_{2j-1}^k + \mathbf{C}_1\boldsymbol{\alpha}_{2j}^k), \tag{2.19a}$$

where the weighting is chosen to achieve an orthogonal transformation and an orthonormal wavelet basis.

For the residual we choose

$$\mathbf{r}_j^{k-1} = \frac{1}{\sqrt{2}}(\mathbf{D}_0\boldsymbol{\alpha}_{2j-1}^k + \mathbf{D}_1\boldsymbol{\alpha}_{2j}^k), \tag{2.19b}$$

where the matrices $\mathbf{D}_0$ and $\mathbf{D}_1$ are not yet defined. For future reference we write (2.19a), (2.19b), in matrix form:

$$\begin{bmatrix}\boldsymbol{\alpha}_j^{k-1}\\ \mathbf{r}_j^{k-1}\end{bmatrix} = \frac{1}{\sqrt{2}}\begin{bmatrix}\mathbf{C}_0 & \mathbf{C}_1\\ \mathbf{D}_0 & \mathbf{D}_1\end{bmatrix}\begin{bmatrix}\boldsymbol{\alpha}_{2j-1}^k\\ \boldsymbol{\alpha}_{2j}^k\end{bmatrix}. \tag{2.19c}$$

2.4. Reconstruction. For the reconstruction we use weighted forms of (2.15a), (2.15b), as approximations to which must be added the error $\boldsymbol{\epsilon}$:

$$\boldsymbol{\alpha}_{2j-1}^k = \frac{1}{\sqrt{2}}\mathbf{C}_0{}'\boldsymbol{\alpha}_j^{k-1} + \boldsymbol{\epsilon}_{2j-1}^k, \tag{2.20a}$$

$$\boldsymbol{\alpha}_{2j}^k = \frac{1}{\sqrt{2}}\mathbf{C}_1{}'\boldsymbol{\alpha}_j^{k-1} + \boldsymbol{\epsilon}_{2j}^k. \tag{2.20b}$$

We want the decomposition and reconstruction to be an orthogonal transformation (and the wavelet basis to be orthonormal). Therefore, the reconstruction must

be the transpose of the decomposition, i.e., the matrix in the decomposition (2.19c) must be an orthogonal matrix:

$$\left(\frac{1}{\sqrt{2}}\begin{bmatrix}\mathbf{C}_0 & \mathbf{C}_1\\ \mathbf{D}_0 & \mathbf{D}_1\end{bmatrix}\right)^{-1} = \left(\frac{1}{\sqrt{2}}\begin{bmatrix}\mathbf{C}_0 & \mathbf{C}_1\\ \mathbf{D}_0 & \mathbf{D}_1\end{bmatrix}\right)' = \frac{1}{\sqrt{2}}\begin{bmatrix}\mathbf{C}_0{}' & \mathbf{D}_0{}'\\ \mathbf{C}_1{}' & \mathbf{D}_1{}'\end{bmatrix}.$$

Consequently, the reconstruction step is

$$\boldsymbol{\alpha}_{2j-1}^{k} = \frac{1}{\sqrt{2}}(\mathbf{C}_0{}'\boldsymbol{\alpha}_j^{k-1} + \mathbf{D}_0{}'\mathbf{r}_j^{k-1}), \tag{2.21a}$$

$$\boldsymbol{\alpha}_{2j}^{k} = \frac{1}{\sqrt{2}}(\mathbf{C}_1{}'\boldsymbol{\alpha}_j^{k-1} + \mathbf{D}_1{}'\mathbf{r}_j^{k-1}). \tag{2.21b}$$

For (2.20a), (2.20b) and (2.21a), (2.21b), to be equivalent we must find matrices $\mathbf{D}_0$ and $\mathbf{D}_1$ such that

$$\boldsymbol{\epsilon}_{2j-1}^{k} = \frac{1}{\sqrt{2}}\mathbf{D}_0{}'\mathbf{r}_j^{k-1} \tag{2.22a}$$

and

$$\boldsymbol{\epsilon}_{2j}^{k} = \frac{1}{\sqrt{2}}\mathbf{D}_1{}'\mathbf{r}_j^{k-1}. \tag{2.22b}$$

In Appendix B we show that the requirements are met by the following choices:

$$\mathbf{D}_0 = \sqrt{2}\mathbf{B}\left(-\mathbf{I} + \frac{1}{2}\mathbf{C}_0{}'\mathbf{C}_0 - \frac{1}{2}\mathbf{C}_1{}'\mathbf{C}_0\right), \tag{2.23a}$$

$$\mathbf{D}_1 = \sqrt{2}\mathbf{B}\left(\mathbf{I} - \frac{1}{2}\mathbf{C}_1{}'\mathbf{C}_1 + \frac{1}{2}\mathbf{C}_0{}'\mathbf{C}_1\right), \tag{2.23b}$$

where

$$\mathbf{B} = \frac{1}{\sqrt{2}}\left\{\left[\mathbf{I} - \frac{1}{4}(\mathbf{C}_0 - \mathbf{C}_1)'(\mathbf{C}_0 - \mathbf{C}_1)\right]^{-1}\right\}^{\frac{1}{2}}. \tag{2.23c}$$

It should be noted that this choice is not unique.

2.5. Multiresolution algorithm (pseudocode). In summary, the decomposition from grid level m to grid level n is

For $k = m, m-1, \ldots, n+1$

For $j = 1, 2, \ldots, J_{k-1}$

$$\boldsymbol{\alpha}_j^{k-1} = \frac{1}{\sqrt{2}}(\mathbf{C}_0\boldsymbol{\alpha}_{2j-1}^{k} + \mathbf{C}_1\boldsymbol{\alpha}_{2j}^{k}) \tag{2.24a}$$

$$\mathbf{r}_j^{k-1} = \frac{1}{\sqrt{2}}(\mathbf{D}_0\boldsymbol{\alpha}_{2j-1}^{k} + \mathbf{D}_1\boldsymbol{\alpha}_{2j}^{k}) \tag{2.24b}$$

End

End

and the reconstruction from grid level n to grid level m is

For $k = n+1, n+2, \cdots, m$

For $j = 1, 2, \cdots, J_{k-1}$

$$\boldsymbol{\alpha}_{2j-1}^{k} = \frac{1}{\sqrt{2}}(\mathbf{C}_0{}'\boldsymbol{\alpha}_j^{k-1} + \mathbf{D}_0{}'\mathbf{r}_j^{k-1}) \tag{2.25a}$$

$$\boldsymbol{\alpha}_{2j}^{k} = \frac{1}{\sqrt{2}}(\mathbf{C}_1{}'\boldsymbol{\alpha}_j^{k-1} + \mathbf{D}_1{}'\mathbf{r}_j^{k-1}) \tag{2.25b}$$

End

End

2.6. Multiresolution code. The multiresolution algorithm (2.24) and (2.25) is easily implemented as we demonstrate with a Matlab code. A compact and efficient way to code the algorithm is to start with the input matrix $\mathbf{A}^m$ (2.3) and to overwrite at every step of the decomposition algorithm (2.24) to obtain the decomposed matrix stored in $\mathbf{A}^m$. Likewise, this decomposed matrix is the input matrix of the reconstruction algorithm that is again overwritten at every step of the reconstruction algorithm to obtain the reconstructed matrix stored in $\mathbf{A}^m$.

Decomposition algorithm.

```
function [A]=decom(A,C0,C1,D0,D1)
%multiresolution decomposition using supercompact wavelet basis
% A is the l+1 by J_m matrix of alpha column vectors (2.3)
%C0,C1,D0,D1 are multiresolution matrices (e.g., section 3)
n=0;                              %complete decomposition
[l1,J_m]=size(A);                 %l+1,J_m
m=log2(J_m);
s=1/sqrt(2);
for k=m:-1:n+1
 jk=2^k;                          %J_k
 Ao=s*A(:,1:2:jk-1);              %odd alpha columns
 Ae=s*A(:,2:2:jk);                %even alpha columns
 A(:,1:jk/2)=C0*Ao+C1*Ae;         %decimated alpha columns (2.24a)
 A(:,jk/2+1:jk)=D0*Ao+D1*Ae;      %residual columns r (2.24b)
end
```

Reconstruction algorithm.

```
function [A]=recon(A,C0,C1,D0,D1)
%multiresolution reconstruction using supercompact wavelet basis
% A is the l+1 by J_m decomposition matrix from decom
%C0,C1,D0,D1 are multiresolution matrices (e.g., section 3)
n=0;                              %complete reconstruction
[l1,J_m]=size(A);                 %l+1,J_m
```

```
m=log2(J_m);
s=1/sqrt(2);
for k=n+1:m
 jk=2^k;                          %J_k
 Ao=s*A(:,1:jk/2);                %decimated alpha columns
 Ae=s*A(:,jk/2+1:jk);             %residual columns
 A(:,1:2:jk-1)=C0'*Ao+D0'*Ae      %reconstructed odd columns (2.25a)
 A(:,2:2:jk)=C1'*Ao+D1'*Ae;       % reconstructed even columns (2.25b)
end
```

2.7. Matrix notation. For comparison with the Strang and Strela [7] notation for multiwavelets, it is useful to have the decomposition and reconstruction algorithms in matrix notation. Let $\mathcal{L}$ and $\mathcal{H}$ be the rectangular matrices

$$\mathcal{L} = \frac{1}{\sqrt{2}} \begin{bmatrix} \mathbf{C}_0 & \mathbf{C}_1 & 0 & 0 & \dots & 0 & 0 \\ 0 & 0 & \mathbf{C}_0 & \mathbf{C}_1 & \dots & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & 0 & 0 & \dots & \mathbf{C}_0 & \mathbf{C}_1 \end{bmatrix} \tag{2.26a}$$

and

$$\mathcal{H} = \frac{1}{\sqrt{2}} \begin{bmatrix} \mathbf{D}_0 & \mathbf{D}_1 & 0 & 0 & \dots & 0 & 0 \\ 0 & 0 & \mathbf{D}_0 & \mathbf{D}_1 & \dots & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & 0 & 0 & \dots & \mathbf{D}_0 & \mathbf{D}_1 \end{bmatrix}. \tag{2.26b}$$

NOTE: The matrices are block diagonal (with rectangular blocks on the diagonal), which contrasts with the nonsupercompact case where the matrices are not block diagonal.

If we rewrite the $\boldsymbol{\alpha}_j^k$'s (2.4) as a single column vector

$$\mathcal{A}^k = [\boldsymbol{\alpha}_1^{k\prime}, \boldsymbol{\alpha}_2^{k\prime}, \dots, \boldsymbol{\alpha}_{J_k}^{k\prime}]', \quad J_k = 2^k \tag{2.27}$$

(and similarly for the residual), then the decomposition steps (2.24) can be written (in pseudocode)

For $k = m, m-1, \dots, n+1$

$$\mathcal{A}^{k-1} = \mathcal{L}\mathcal{A}^k \tag{2.28a}$$

$$\mathcal{R}^{k-1} = \mathcal{H}\mathcal{A}^k \tag{2.28b}$$

End

Likewise the reconstruction steps (2.25) become

For $k = n+1, n+2, \dots, m$

$$\mathcal{A}^k = \mathcal{L}'\mathcal{A}^{k-1} + \mathcal{H}'\mathcal{R}^{k-1} \tag{2.29}$$

End

where the size of the matrices $\mathcal{L}$, $\mathcal{H}$, $\mathcal{A}$, and $\mathcal{R}$ is implied from the index k. Because of the block diagonal property, the matrices (2.26a), (2.26b), satisfy the same identities as the matrices $\mathbf{L}$ and $\mathbf{H}$ of Appendix B, i.e., (B.6), (B.8), (B.9), (B.10), and (B.11).

3. Evaluation of multiresolution matrices. The application of the multiresolution algorithm (2.24) and (2.25) requires the matrices $\mathbf{C}_0$, $\mathbf{C}_1$, $\mathbf{D}_0$, and $\mathbf{D}_1$. The $\mathbf{C}$ matrices are defined by (2.12). If we denote the elements of $\mathbf{C}_0$ and $\mathbf{C}_1$ by $c^0_{r,s}$ and $c^1_{r,s}$, respectively, they can be evaluated from the expansions (see Appendix C)

$$\phi_i(\xi) = \sum_{p=0}^{\ell} c^0_{i+1,p+1}\phi_p(2\xi+1), \quad -1 < \xi \le 0, \quad i = 0, 1, \dots, \ell \tag{3.1a}$$

and

$$\phi_i(\xi) = \sum_{p=0}^{\ell} c^1_{i+1,p+1}\phi_p(2\xi-1), \quad 0 < \xi \le 1, \quad i = 0, 1, \dots, \ell. \tag{3.1b}$$

If we use the assumed orthogonality of the ϕ's, we can write

$$c^0_{i+1,j+1} = 2\int_{-1}^{0} \phi_j(2\xi+1)\phi_i(\xi)d\xi, \quad i = 0, 1, \dots, \ell, \quad j = 0, 1, \dots, \ell \tag{3.2a}$$

and

$$c^1_{i+1,j+1} = 2\int_{0}^{1} \phi_j(2\xi-1)\phi_i(\xi)d\xi, \quad i = 0, 1, \dots, \ell, \quad j = 0, 1, \dots, \ell. \tag{3.2b}$$

The corresponding $\mathbf{D}$'s are given by (2.23a), (2.23b), and (2.23c).

The general family of orthonormal polynomials (2.8) is considered in Appendix D. In the examples we use a particular family, i.e., the Legendre polynomials.

EXAMPLE 3.1. As an example, consider Legendre polynomials which are a special case of (2.5). The first five Legendre polynomials are

$$\begin{aligned} &P_0(\xi) = 1, \qquad P_1(\xi) = \xi, \qquad P_2(\xi) = \frac{3}{2}\xi^2 - \frac{1}{2}, \\ &P_3(\xi) = \frac{5}{2}\xi^3 - \frac{3}{2}\xi, \qquad P_4(\xi) = \frac{35}{8}\xi^4 - \frac{15}{4}\xi^2 + \frac{3}{8}. \end{aligned} \tag{3.3}$$

The orthonormal basis polynomials (2.5) are

$$\phi_i(\xi) = \begin{cases} \sqrt{i+\frac{1}{2}}P_i(\xi), & -1 < \xi \le 1, \\ 0, & \text{otherwise.} \end{cases} \tag{3.4}$$

The matrices $\mathbf{C}_0$ and $\mathbf{C}_1$ for $\ell = 2$ are, from (3.2a), (3.2b), and (3.4),

$$\mathbf{C}_0 = \begin{bmatrix} 1 & 0 & 0 \\ -\frac{\sqrt{3}}{2} & \frac{1}{2} & 0 \\ 0 & -\frac{\sqrt{15}}{4} & \frac{1}{4} \end{bmatrix}, \tag{3.5a}$$

$$\mathbf{C}_1 = \begin{bmatrix} 1 & 0 & 0 \\ \frac{\sqrt{3}}{2} & \frac{1}{2} & 0 \\ 0 & \frac{\sqrt{15}}{4} & \frac{1}{4} \end{bmatrix}. \tag{3.5b}$$

The corresponding matrices $\mathbf{D}_0$ and $\mathbf{D}_1$ are obtained from (2.23a), (2.23b), and (2.23c)

$$\mathbf{D}_0 = \begin{bmatrix} -\frac{1}{2} & -\frac{\sqrt{3}}{2} & 0 \\ 0 & -\frac{1}{4} & -\frac{\sqrt{15}}{4} \\ 0 & 0 & -1 \end{bmatrix}, \tag{3.6a}$$

$$\mathbf{D}_1 = \begin{bmatrix} \frac{1}{2} & -\frac{\sqrt{3}}{2} & 0 \\ 0 & \frac{1}{4} & -\frac{\sqrt{15}}{4} \\ 0 & 0 & 1 \end{bmatrix}, \tag{3.6b}$$

and for reference the matrix $\mathbf{B}$ defined by (2.23c) is given by

$$\mathbf{B} = \frac{1}{\sqrt{2}} \begin{bmatrix} 2 & 0 & 0 \\ 0 & 4 & 0 \\ 0 & 0 & 1 \end{bmatrix}. \tag{3.6c}$$

In Appendix E we give the Mathematica code for generating the matrices for any ℓ (within the limits of Mathematica) and Legendre polynomials. We also give the $\mathbf{C}$ and $\mathbf{D}$ matrices for $\ell = 4$.

For completeness we give the $\mathbf{C}$ and $\mathbf{D}$ matrices for $\ell = 0$ and $\ell = 1$. The $\mathbf{C}$'s are submatrices of (3.5); however, the $\mathbf{D}$'s are not submatrices of (3.6).

For $\ell = 0$, i.e., Haar,

$$\mathbf{C}_0 = [1], \quad \mathbf{C}_1 = [1], \quad \mathbf{D}_0 = [-1], \quad \mathbf{D}_1 = [1], \tag{3.7}$$

and for $\ell = 1$

$$\mathbf{C}_0 = \begin{bmatrix} 1 & 0 \\ -\frac{\sqrt{3}}{2} & \frac{1}{2} \end{bmatrix}, \mathbf{C}_1 = \begin{bmatrix} 1 & 0 \\ \frac{\sqrt{3}}{2} & \frac{1}{2} \end{bmatrix}, \mathbf{D}_0 = \begin{bmatrix} -\frac{1}{2} & -\frac{\sqrt{3}}{2} \\ 0 & -1 \end{bmatrix}, \mathbf{D}_1 = \begin{bmatrix} \frac{1}{2} & -\frac{\sqrt{3}}{2} \\ 0 & 1 \end{bmatrix}. \tag{3.8}$$

4. Multiresolution implementation. It is highly unlikely that the information available for multiresolution analysis corresponds to the input array $\mathbf{A}^m$ (2.3). In this section we consider several transformations (or preprocessing procedures) that provide the required algorithm input.

4.1. Analytical function. If $u(x)$ is a piecewise continuous function on $0 < x \leq 1$, then we have a simple transformation. On the finest grid X^m we choose a polynomial degree ℓ that adequately represents the function $u(x)$:

$$(u(x))_j^m \approx \sum_{i=0}^{\ell} (\alpha_i)_j^m (\phi_i(x))_j^m, \quad j = 1, 2, \ldots, J_m. \tag{4.1}$$

Since the basis functions are orthogonal, the coefficients are simply

$$(\alpha_i)_j^m = \frac{2}{h_m} \int_{x_{j-1}^m}^{x_j^m} (u(x))_j^m (\phi_i(x))_j^m dx, \quad j = 1, 2, \ldots, J_m, \quad i = 0, 1, \ldots, \ell. \tag{4.2}$$

4.2. Discrete function values. One of the most useful applications of a multiresolution algorithm is the analysis of a vector of discrete function values. In this section we consider the preprocessing transformation from the function values to the input array (2.3).

Let's begin with the case where $u(x)$ on $0 < x \le 1$ is piecewise polynomial of degree ℓ and where (function and/or derivative) discontinuities, if any, lie only on the grid points of the finest grid X^m (see, e.g., Figure 1(b)). Clearly on each interval $x^m_{j-1} < x \le x^m_j$ of the grid X^m we can represent $u(x)$ exactly by

$$(u(x))^m_j = \sum_{i=0}^{\ell} (\alpha_i)^m_j (\phi_i(x))^m_j, \qquad x^m_{j-1} < x \le x^m_j, \tag{4.3}$$

where $(\phi_i(x))^m_j$ is defined by (2.7). Since, in this ideal case, we have the luxury of an analytic representation on each interval, the α's can be determined by choosing $\ell+1$ values of $u(x)$ on the interval. Let's select values at uniformly spaced subintervals:

$$\mathbf{x}^m_j = \begin{cases} [x^m_j], & \ell = 0, \\ [x^m_{j-1},\ x^m_{j-1+\frac{1}{\ell}},\ x^m_{j-1+\frac{2}{\ell}},\ \dots,\ x^m_j]', & \ell > 0. \end{cases} \tag{4.4}$$

The α's are the solution of the system of algebraic equations

$$(u(\mathbf{x}^m_j))^m_j = \sum_{i=0}^{\ell} (\alpha_i)^m_j (\phi_i(\mathbf{x}^m_j))^m_j, \quad j = 1, 2, \dots, J_m. \tag{4.5}$$

The notation implied by (4.5) is clarified if we write out the expansion for a specific case, say $\ell = 2$:

$$\begin{bmatrix} (u(x^m_{j-1}))^m_j \\ (u(x^m_{j-\frac{1}{2}}))^m_j \\ (u(x^m_j))^m_j \end{bmatrix} = \begin{bmatrix} (\phi_0(x^m_{j-1}))^m_j & (\phi_1(x^m_{j-1}))^m_j & (\phi_2(x^m_{j-1}))^m_j \\ (\phi_0(x^m_{j-\frac{1}{2}}))^m_j & (\phi_1(x^m_{j-\frac{1}{2}}))^m_j & (\phi_2(x^m_{j-\frac{1}{2}}))^m_j \\ (\phi_0(x^m_j))^m_j & (\phi_1(x^m_j))^m_j & (\phi_2(x^m_j))^m_j \end{bmatrix} \begin{bmatrix} (\alpha_0)^m_j \\ (\alpha_1)^m_j \\ (\alpha_2)^m_j \end{bmatrix}, \tag{4.6a}$$

$$j = 1, 2, \dots, J_m.$$

Equation (4.6a) requires data at the midpoints of the finest level subinterval $(u(x^m_{j-\frac{1}{2}}))^m_j$ which appears to be information on a grid finer than the given data. However, in practice we obtain the additional values by using a smaller number of subintervals with more points per subinterval (for higher order methods or larger ℓ). For example, see case (c) in section 6 for $\ell = 2$.

The piecewise polynomial $u(x)$ is assumed to be everywhere continuous from the left. If $u(x)$ has a discontinuity at the left end point, x_{j-1}, of the interval, $(x_{j-1}, x_j]$, then the value of $(u(x))^m_j$ at the left end point is defined by

$$(u(x_{j-1}))^m_j = u^+(x_{j-1}) = \lim_{x \to x^+_{j-1}} u(x).$$

In the implementation of a supercompact multiresolution scheme it will be convenient to write the postprocessing transformation (4.6) from $\boldsymbol{\alpha}^m_j$ to $\mathbf{u}^m_j$ in matrix notation:

$$\mathbf{u}^m_j = \mathbf{T}\boldsymbol{\alpha}^m_j, \qquad j = 1, 2, \dots, J_m, \tag{4.6b}$$

where

$$\mathbf{u}_j^m = (u(\mathbf{x}_j^m))_j^m \tag{4.7}$$

and the matrix $\mathbf{T}$ is the matrix on the right-hand side of (4.6). For the demonstration code we rewrite (4.6a) as

$$\mathbf{U}^m = \mathbf{T}\mathbf{A}^m, \tag{4.8}$$

where

$$\mathbf{U}^m = [\mathbf{u}_1^m, \mathbf{u}_2^m, \dots, \mathbf{u}_{J_m}^m]. \tag{4.9}$$

$\mathbf{U}^m$ and $\mathbf{A}^m$ are $\ell+1$ by J_m matrices, and $\mathbf{T}$ is the $\ell+1$ by $\ell+1$ postprocessing transformation matrix. Note that $\mathbf{T}$ is independent of j. Similarly, the preprocessing transformation from u to α is

$$\mathbf{A}^m = \mathbf{T}^{-1}\mathbf{U}^m. \tag{4.10}$$

EXAMPLE 4.1. If we continue the example of the previous section and choose the Legendre polynomials (3.4) and use (2.7), (4.6) becomes

$$\begin{bmatrix} (u(x_{j-1}^m))_j^m \\ (u(x_{j-\frac{1}{2}}^m))_j^m \\ (u(x_j^m))_j^m \end{bmatrix} = \begin{bmatrix} \sqrt{\frac{1}{2}} & -\sqrt{\frac{3}{2}} & \sqrt{\frac{5}{2}} \\ \sqrt{\frac{1}{2}} & 0 & -\frac{\sqrt{10}}{4} \\ \sqrt{\frac{1}{2}} & \sqrt{\frac{3}{2}} & \sqrt{\frac{5}{2}} \end{bmatrix} \begin{bmatrix} (\alpha_0)_j^m \\ (\alpha_1)_j^m \\ (\alpha_2)_j^m \end{bmatrix}, \quad j = 1, 2, \dots, J_m \tag{4.11a}$$

or

$$\mathbf{U}^m = \mathbf{T}\mathbf{A}^m, \tag{4.11b}$$

and, after solving (4.11) for $\boldsymbol{\alpha}_j^m$,

$$\begin{aligned} (\alpha_0)_j^m &= \frac{\sqrt{2}}{6}[(u(x_{j-1}^m))_j^m + 4(u(x_{j-\frac{1}{2}}^m))_j^m + (u(x_j^m))_j^m], \\ (\alpha_1)_j^m &= \frac{1}{\sqrt{6}}[-(u(x_{j-1}^m))_j^m + (u(x_j^m))_j^m], \\ (\alpha_2)_j^m &= \frac{\sqrt{10}}{15}[(u(x_{j-1}^m))_j^m - 2(u(x_{j-\frac{1}{2}}^m))_j^m + (u(x_j^m))_j^m], \\ j &= 1, 2, \dots, J_m, \end{aligned} \tag{4.12a}$$

or

$$\mathbf{A}^m = \mathbf{T}^{-1}\mathbf{U}^m. \tag{4.12b}$$

Equation (4.12a) has been taken out of matrix form to indicate that α_0, α_1, and α_2 are (weighted) undivided discrete approximations to the cell average, first derivative, and second derivative, respectively.

Equation (4.10), e.g., (4.12a), provides the preprocessing transformation from the piecewise continuous function to the discrete input matrix $\mathbf{A}$ required in the multiresolution algorithm. If the piecewise continuous function $u(x)$ is not polynomial of degree ℓ we can still use (4.5) for an approximate representation.

For completeness we give the postprocessing transformations for $\ell = 0$ and $\ell = 1$ corresponding to the **C** and **D** matrices (3.7) and (3.8):

$$\left[(u(x_j^m))_j^m\right] = \left[\sqrt{\tfrac{1}{2}}\right]\left[(\alpha_0)_j^m\right], \quad \left[(\alpha_0)_j^m\right] = \left[\sqrt{2}\right]\left[(u(x_j^m))_j^m\right], \tag{4.13}$$

$$\begin{bmatrix}(u(x_{j-1}^m))_j^m\\ (u(x_j^m))_j^m\end{bmatrix} = \begin{bmatrix}\sqrt{\frac{1}{2}} & -\sqrt{\frac{3}{2}}\\ \sqrt{\frac{1}{2}} & \sqrt{\frac{3}{2}}\end{bmatrix}\begin{bmatrix}(\alpha_0)_j^m\\ (\alpha_1)_j^m\end{bmatrix}, \quad \begin{bmatrix}(\alpha_0)_j^m\\ (\alpha_1)_j^m\end{bmatrix} = \begin{bmatrix}\sqrt{\frac{1}{2}} & \sqrt{\frac{1}{2}}\\ -\sqrt{\frac{1}{6}} & \sqrt{\frac{1}{6}}\end{bmatrix}\begin{bmatrix}(u(x_{j-1}^m))_j^m\\ (u(x_j^m))_j^m\end{bmatrix}. \tag{4.14}$$

Return now to the case where only the vector of discrete function values (with multiple values for discontinuities) is given. An obvious preprocessing transformation to the α's is to require point values at grid spacing h_m/ℓ (for $\ell > 1$) rather than h_m on the interval $0 < x \le 1$. Now we can use the postprocessing transformation (4.5) for a vector of discrete function values.

4.3. Discrete cell average values and derivative values. In some applications it is convenient to represent a function by discrete function values, discrete function derivative values, and/or discrete integral values. We could also include multiple values of each, i.e., choose multiple locations for interpolation as we did in the previous section. For demonstration we choose discrete cell average values and the first p derivatives evaluated at a single interpolation point, e.g., the midpoint of the interval:

$$\mathbf{x}_j^m = \left[x_{j-\frac{1}{2}}^m\right]. \tag{4.15}$$

The cell average is defined by

$$(\bar{u})_j^m = \frac{1}{h_m}\int_{x_{j-1}^m}^{x_j^m} (u(\eta))_j^m d\eta. \tag{4.16}$$

We choose $\ell = p$. The α's are the solution to the system of $\ell + 1$ algebraic equations:

$$\begin{aligned}
(\bar{u})_j^m &= \frac{1}{h_m}\sum_{i=0}^{\ell}(\alpha_i)_j^m \int_{x_{j-1}^m}^{x_j^m} (\phi_i(\eta))_j^m d\eta,\\
\tfrac{d}{dx}\left(u\left(x_{j-\frac{1}{2}}^m\right)\right)_j^m &= \sum_{i=0}^{\ell}(\alpha_i)_j^m \frac{d}{dx}\left(\phi_i\left(x_{j-\frac{1}{2}}^m\right)\right)_j^m,\\
&\vdots\\
\frac{d^p}{dx^p}\left(u\left(x_{j-\frac{1}{2}}^m\right)\right)_j^m &= \sum_{i=0}^{\ell}(\alpha_i)_j^m \frac{d^p}{dx^p}\left(\phi_i\left(x_{j-\frac{1}{2}}^m\right)\right)_j^m, \quad j = 1, 2, \ldots, J_m.
\end{aligned} \tag{4.17}$$

Example 4.2. If we choose the Legendre polynomials with $\ell = 2$, the solution

of (4.17) produces

$$
\begin{aligned}
(\alpha_0)_j^m &= \sqrt{2}(\bar{u})_j^m, \\
(\alpha_1)_j^m &= \frac{1}{\sqrt{6}} h_m \frac{d}{dx}\left(u\left(x_{j-\frac{1}{2}}^m\right)\right)_j^m, \\
(\alpha_2)_j^m &= \frac{\sqrt{10}}{15}\left(\frac{h_m}{2}\right)^2 \frac{d^2}{dx^2}\left(u\left(x_{j-\frac{1}{2}}^m\right)\right)_j^m, \quad j = 1, 2, \ldots, J_m.
\end{aligned} \tag{4.18}
$$

For this choice of variables (cell averages and derivatives) and polynomials (Legendre) there is a one-to-one correspondence ($\mathbf{T}$ is a diagonal matrix) between the α's and the variables. Note that (4.12) is a difference approximation to (4.18). This example can be included in the notation (4.8) if the vector $\mathbf{u}_j^m$ (4.7) is redefined:

$$
\mathbf{u}_j^m = \left[(\bar{u})_j^m, \frac{d}{dx}\left(u\left(x_{j-\frac{1}{2}}^m\right)\right)_j^m, \frac{d^2}{dx^2}\left(u\left(x_{j-\frac{1}{2}}^m\right)\right)_j^m\right]'. \tag{4.19}
$$

4.4. Accuracy of a multiwavelet analysis. From section 2.2 it is clear that if we expand a polynomial function of degree ℓ in a family of orthogonal polynomials of degree ℓ, the expansion will be exact and the interpolation error or residual defined by (2.19b) will be zero. In terms of a multiresolution algorithm, the order of accuracy, or number of vanishing moments, can be defined as follows.

Let the function $u(x)$ be the polynomial

$$
u(x) = x^q, \qquad 0 \le x \le 1, \tag{4.20}
$$

where q is a nonnegative integer. From the decomposition step (2.24b), the residual vector for $k = m$ is

$$
\mathbf{r}_j^{m-1} = \frac{1}{\sqrt{2}}(\mathbf{D}_0 \boldsymbol{\alpha}_{2j-1}^m + \mathbf{D}_1 \boldsymbol{\alpha}_{2j}^m), \quad j = 1, \ldots, J_{m-1}. \tag{4.21}
$$

The number p of vanishing residuals (moments) of a multiwavelet algorithm is defined by

$$
\left[\mathbf{r}_j^{m-1} = 0, \quad j = 1, 2, \ldots, J_{m-1}\right], \qquad q = 0, 1, \ldots, p-1 \tag{4.22a}
$$

and

$$
\left[\mathbf{r}_j^{m-1} \neq 0, \quad j = 1, 2, \ldots, J_{m-1}\right], \qquad q = p. \tag{4.22b}
$$

The order of accuracy is defined to be p which is equal to $\ell + 1$.

As a consistency check on the programming of the preprocessing step yielding the input matrix $\mathbf{A}^m$ and the decomposition algorithm (2.24), one should verify the accuracy numerically by checking for the proper number of vanishing moments. After one step of the decomposition algorithm of section 2.6, the *right half* of the matrix $\mathbf{A}$ should be zero for $q \le p - 1 = \ell$ since it contains the residual vectors $\mathbf{r}_j^{m-1}$.

As an example, for the discrete function values of section 4.2 with $\ell = 2$, one obtains for the polynomial (4.20) the vector (4.8):

$$
\mathbf{u}_j^m = \begin{bmatrix} ((x^q)_{j-1}^m)_j^m \\ \left((x^q)_{j-\frac{1}{2}}^m\right)_j^m \\ ((x^q)_j^m)_j^m \end{bmatrix}.
$$

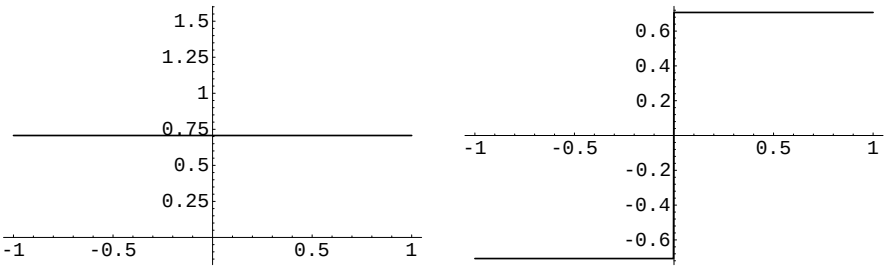

FIG. 3(a). *Scaling functions (left-hand column) and wavelets (right-hand column),* $\ell = 0$.

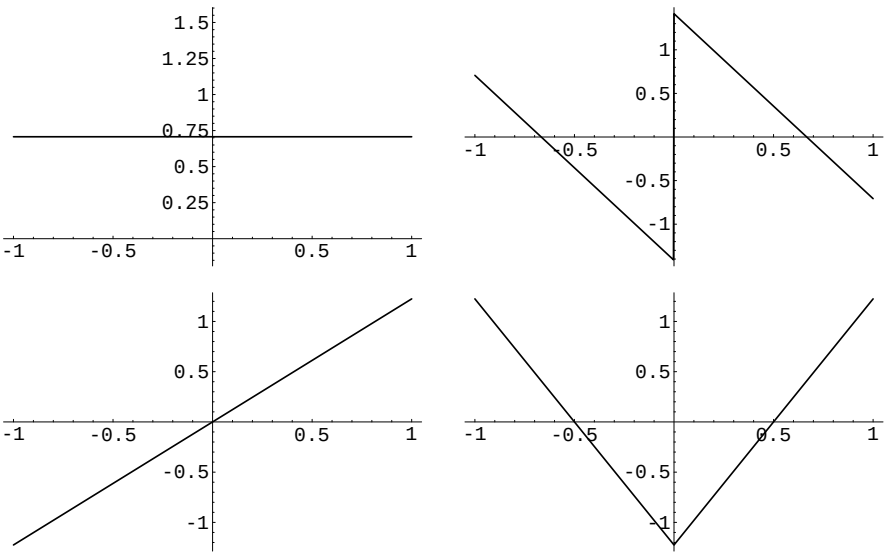

FIG. 3(b). *Scaling functions (left-hand column) and wavelets (right-hand column),* $\ell = 1$.

One finds that the number of vanishing residuals is $p = \ell + 1 = 3$ and the order of accuracy is 3.

5. Scaling functions and wavelets. Neither the development nor the application of the multiresolution algorithm (2.24) and (2.25) requires an explicit knowledge of the multiwavelets. (The multiscaling functions are the orthonormal polynomials (2.5), which must be known in order to compute the $\mathbf{C}$ and $\mathbf{D}$ matrices.) However, curiosity alone is sufficient to warrant an exposition of the wavelet basis functions.

The decomposition (2.11), i.e.,

$$(u(x))_j^{k-1} = \boldsymbol{\alpha}_{2j-1}^{k\,\prime} \boldsymbol{\phi}_{2j-1}^k + \boldsymbol{\alpha}_{2j}^{k\,\prime} \boldsymbol{\phi}_{2j}^k \tag{5.1}$$

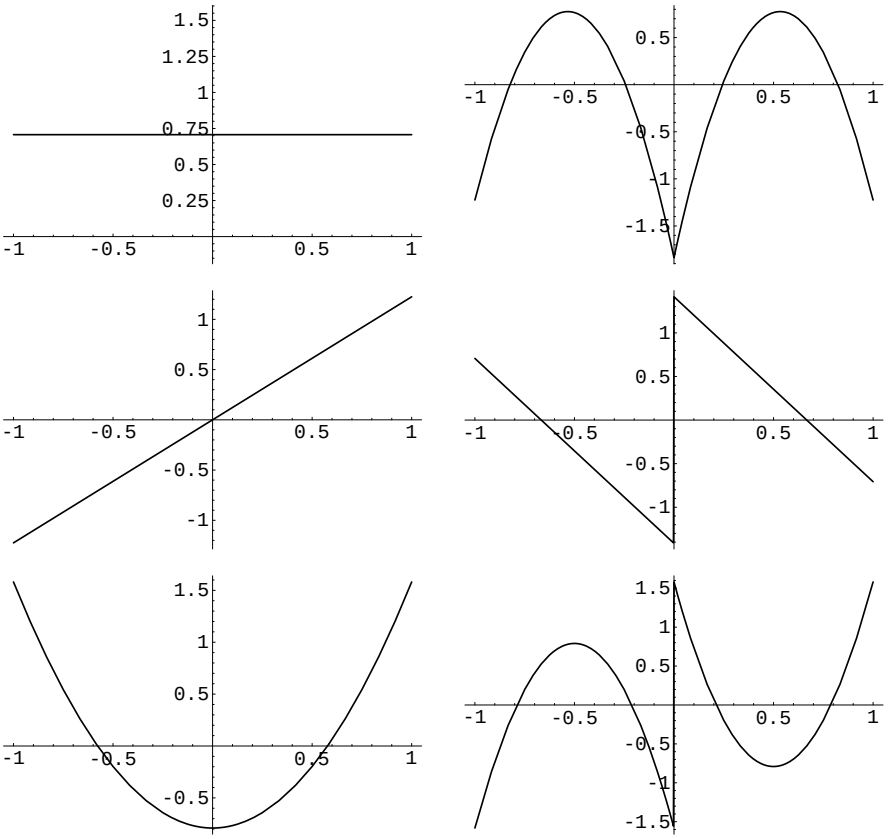

FIG. 3(c). *Scaling functions (left-hand column) and wavelets (right-hand column),* $\ell = 2$.

is exact if $u(x)$ is a polynomial of degree ℓ. In the general (nonexact) case we must replace the $\boldsymbol{\alpha}$'s with unweighted (2.20a), (2.20b):

$$(u(x))_j^{k-1} = [\mathbf{C}_0{}'\boldsymbol{\alpha}_j^{k-1} + \boldsymbol{\epsilon}_{2j-1}^k]'\boldsymbol{\phi}_{2j-1}^k + [\mathbf{C}_1{}'\boldsymbol{\alpha}_j^{k-1} + \boldsymbol{\epsilon}_{2j}^k]'\boldsymbol{\phi}_{2j}^k. \tag{5.2}$$

The error in the decomposition of $(u(x))_j^{k-1}$ is denoted by ϵ_u:

$$(\epsilon_u)_j^{k-1} = (\boldsymbol{\epsilon}_{2j-1}^k)'\boldsymbol{\phi}_{2j-1}^k + (\boldsymbol{\epsilon}_{2j}^k)'\boldsymbol{\phi}_{2j}^k. \tag{5.3}$$

If we now use unweighted (2.22a), (2.22b) in (5.3) and rearrange terms we obtain

$$(\epsilon_u)_j^{k-1} = \mathbf{r}_j^{k-1\prime}\boldsymbol{\psi}_j^{k-1}, \tag{5.4}$$

where $\boldsymbol{\psi}_j^{k-1}$ is defined by

$$\boldsymbol{\psi}_j^{k-1} = \mathbf{D}_0\boldsymbol{\phi}_{2j-1}^k + \mathbf{D}_1\boldsymbol{\phi}_{2j}^k \tag{5.5}$$

and

$$\boldsymbol{\psi}_j^k = (\boldsymbol{\psi}(x))_j^k = \left[(\psi_0(x))_j^k, \quad (\psi_1(x))_j^k, \quad \ldots, \quad (\psi_\ell(x))_j^k\right]'.$$

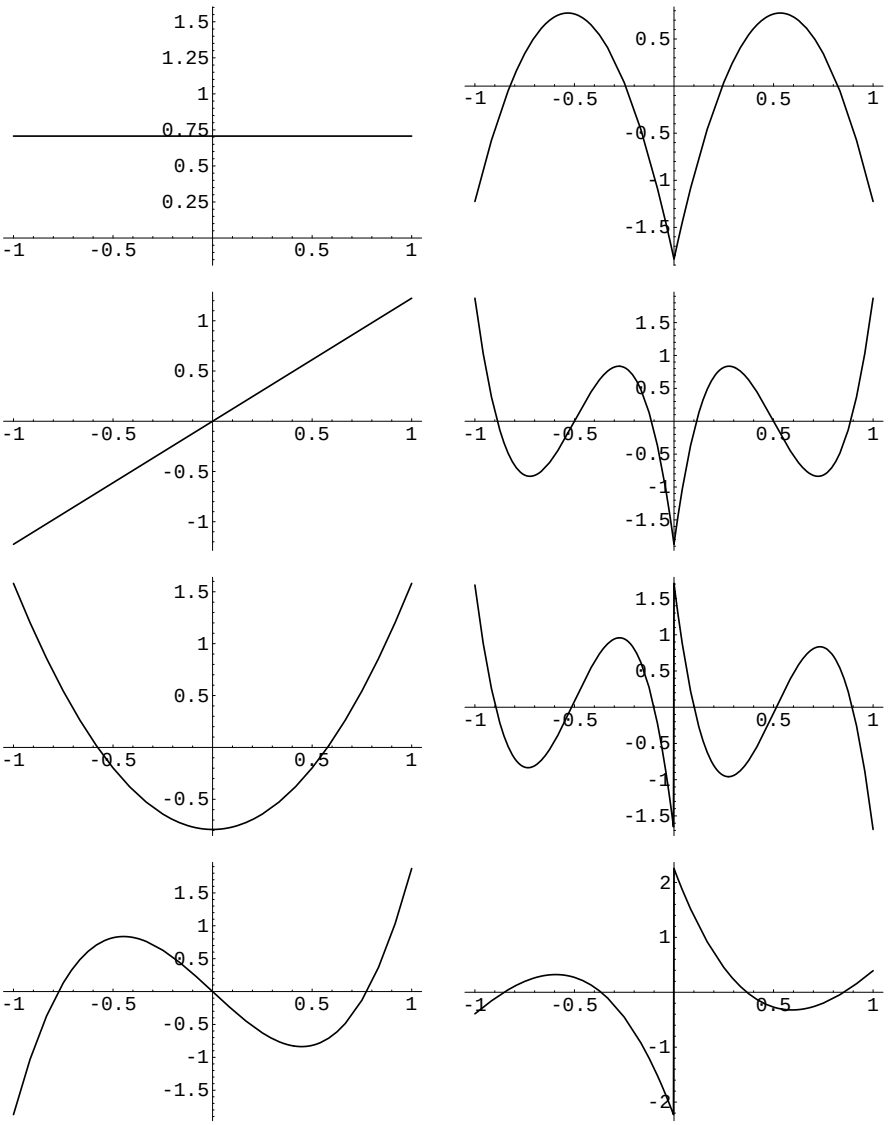

FIG. 3(d). *Scaling functions (left-hand column) and wavelets (right-hand column),* $\ell = 3$.

The orthonormal polynomials $\boldsymbol{\psi}$ are the multiwavelets that form the basis for the expansion of the error (with coefficients $\mathbf{r}$). In the following example, we display wavelets transformed to the ξ-space.

EXAMPLE 5.1. We continue our example with Legendre polynomials (3.4). It is easier to evaluate the multiwavelets defined by (5.5) by transforming the components of the vectors ϕ^k_{2j-1} and ϕ^k_{2j} to a form where the $\phi_i(\xi)$'s appear explicitly (see the transformations (C.3) of Appendix C). The resulting analytical multiwavelets given below are defined on the interval $(-1, 1]$.

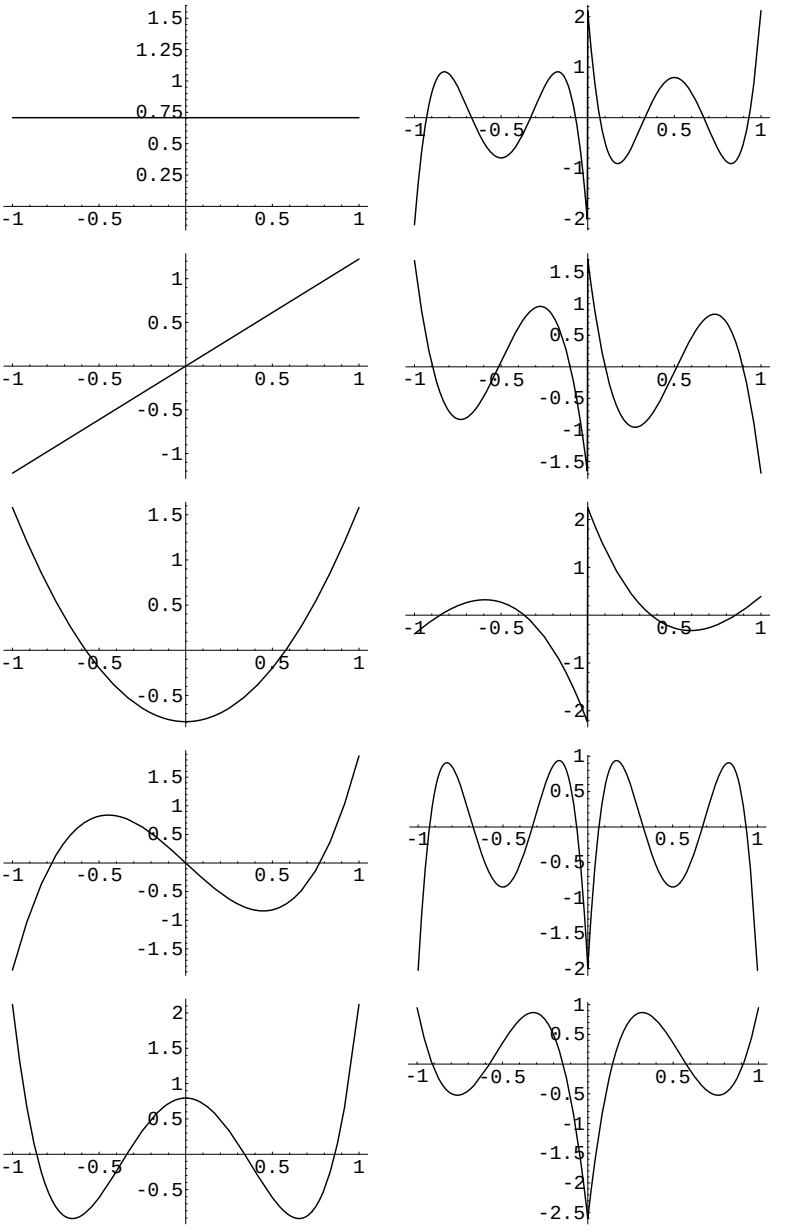

FIG. 3(e). *Scaling functions (left-hand column) and wavelets (right-hand column),* $\ell = 4$.

$\ell = 0$:

$$\psi_0(\xi) = \begin{cases} -\sqrt{\frac{1}{2}}, & -1 < \xi \le 0, \\ \sqrt{\frac{1}{2}}, & 0 < \xi \le 1; \end{cases} \tag{5.6}$$

$\ell = 1$:

$$\psi_0(\xi) = \begin{cases} -\sqrt{\frac{1}{2}}(2+3\xi), & -1 < \xi \le 0, \\ \sqrt{\frac{1}{2}}(2-3\xi), & 0 < \xi \le 1, \end{cases} \tag{5.7a}$$

$$\psi_1(\xi) = \begin{cases} -\sqrt{\frac{3}{2}}(1+2\xi), & -1 < \xi \le 0, \\ \sqrt{\frac{3}{2}}(-1+2\xi), & 0 < \xi \le 1; \end{cases} \tag{5.7b}$$

$\ell = 2$:

$$\psi_0(\xi) = \begin{cases} -\frac{1}{2}\sqrt{\frac{3}{2}}(3+16\xi+15\xi^2), & -1 < \xi \le 0, \\ \frac{1}{2}\sqrt{\frac{3}{2}}(-3+16\xi-15\xi^2), & 0 < \xi \le 1, \end{cases} \tag{5.8a}$$

$$\psi_1(\xi) = \begin{cases} -\sqrt{\frac{1}{2}}(2+3\xi), & -1 < \xi \le 0, \\ \sqrt{\frac{1}{2}}(2-3\xi), & 0 < \xi \le 1, \end{cases} \tag{5.8b}$$

$$\psi_2(\xi) = \begin{cases} -\sqrt{\frac{5}{2}}(1+6\xi+6\xi^2), & -1 < \xi \le 0, \\ \sqrt{\frac{5}{2}}(1-6\xi+6\xi^2), & 0 < \xi \le 1. \end{cases} \tag{5.8c}$$

Plots of the multiscaling functions and multiwavelets for the Legendre polynomials and $\ell = 0, 1, 2, 3, 4$ are shown in Figures 3(a)–3(e). Discrete multiscaling functions and multiwavelets are obtained by evaluating $\phi_i(x)$ and $\psi_i(x)$ on the grid X^k.

6. Applications. Two typical applications for multiresolution algorithms are the analysis of data by decomposition into scales and the compression of data after decomposition. In this section we give some simple examples that demonstrate the attributes of multiresolution using supercompact multiwavelets. We choose the discrete value examples of sections 4.2 and 4.3. The preprocessing transformations for these examples fall within the general notation (4.8), i.e.,

$$\mathbf{U}^m = \mathbf{T}\mathbf{A}^m.$$

The examples are best presented in the context of a multiresolution analysis demonstration code. As an example we use the following Matlab code.

```
function [dA,rU]=mranal(U,C0,C1,D0,D1,T)
%MATLAB Multiresolution Analysis Demonstration Code
%  INPUT
%U is an l+1 by J_m matrix defined in section 4
%C0,C1,D0,D1 are l+1 by l+1 matrices, section 3
%T is the postprocessing transformation matrix U=TA (alpha to u) (4.8)
%  OUTPUT
%dA is the decomposition of alpha (A) (2.24)
%rU is the reconstructed U matrix section 4
 %preprocessing transform U to A (u to alpha)
 A=T^(-1)*U;
 %decomposition of alpha (dA) (2.24) section 2.6 for decom code
 dA=decom(A,C0,C1,D0,D1);
 %truncate data (dA)
  %normally at this step the decomposition would
  %be truncated ("small" elements set to zero) if data compression
  % is desired,  for this example code no compression is done
  %so the reconstruction will be exact (rU=U)
 %reconstruction (rA) (2.25) section 2.6 for recon code
 rA=recon(dA,C0,C1,D0,D1);
 %postprocessing transform reconstructed alpha (rA) to reconstructed u (rU)
 rU=T*rA;
```

EXAMPLE 6.1. We have selected a simple example which is presented in sufficient detail to illustrate (1) the most intimate features of the algorithm implementation, (2) the improved "compressibility" of the decomposition with increasing order of approximation, (3) the supercompact multiwavelet resolution of discontinuities, and (4) the "filled-in" function or subinterval function representation (discussed in detail at the end of this section). For $u(x)$ on $0 < x \le 1$ we choose

$$u(x) = \begin{cases} 1 + 256x^2, & 0 < x \le \dfrac{1}{4}, \\ 17 - 512(x - \frac{1}{4})^2, & \dfrac{1}{4} < x \le \dfrac{1}{2}, \\ 16 - 256(x - \frac{1}{2})^2, & \dfrac{1}{2} < x \le 1, \end{cases} \tag{6.1}$$

which is plotted in Figure 4(d).

For the fine grid we choose $m = 4$ ($J_m = 16$ and $h_m = 1/16$) and evaluate $u(x)$ and $u^+(x)$ on the fine grid:

(6.2)

j	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16
x_j	0	$\frac{1}{16}$	$\frac{2}{16}$	$\frac{3}{16}$	$\frac{4}{16}$	$\frac{5}{16}$	$\frac{6}{16}$	$\frac{7}{16}$	$\frac{8}{16}$	$\frac{9}{16}$	$\frac{10}{16}$	$\frac{11}{16}$	$\frac{12}{16}$	$\frac{13}{16}$	$\frac{14}{16}$	$\frac{15}{16}$	$\frac{16}{16}$
u_j	$*$	2	5	10	17	15	9	-1	-15	15	12	7	0	-9	-20	-33	-48
u_j^+	1	2	5	10	17	15	9	-1	16	15	12	7	0	-9	-20	-33	$*$

,

where the * indicates that the value is not defined.

For the numerical example we assume that the given data are the discrete values u_j and u_j^+, and we will use the discrete function value implementation of section 4.2. For

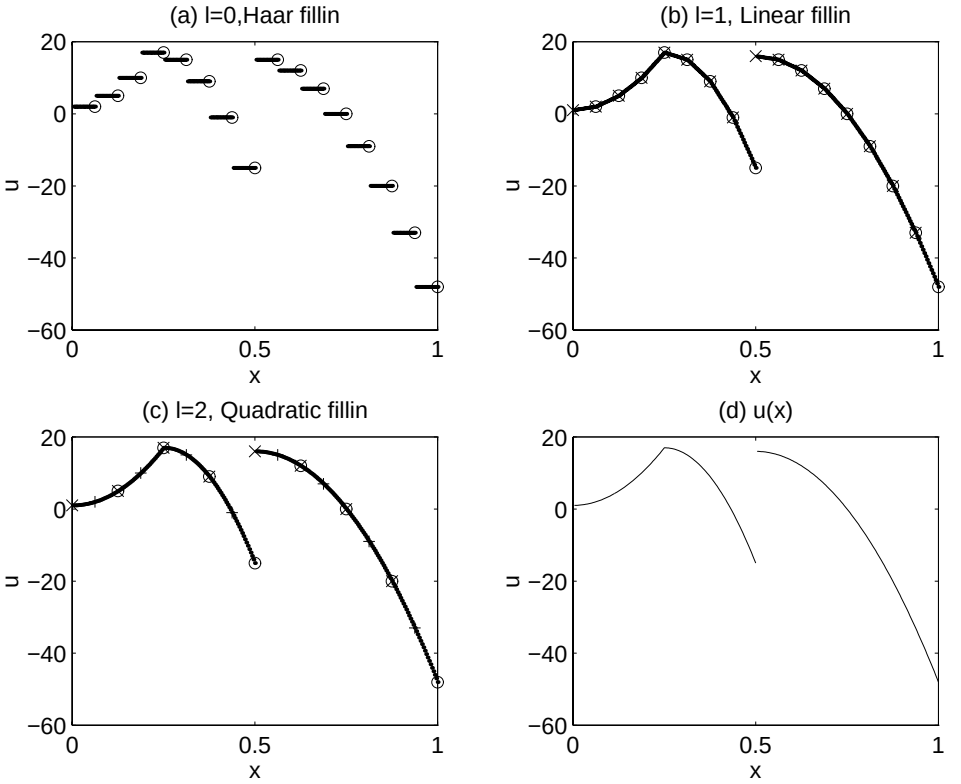

FIG. 4. *Filled-in functions for the discrete data* (6.2).

each of three multiresolution algorithms ($\ell = 0, 1, 2$) we compute $\mathbf{U}^m$, the decomposed values of $\mathbf{A}$ (i.e., $d\mathbf{A}$), and the filled-in function. First we present the numerical input and results for each of the cases, and then we follow with the discussion.

(a) $\ell = 0$, constant interpolation (Haar). For $\ell = 0$ we need the discrete function value at the right-hand end of each interval, and we use the given values of u_j; i.e., $\mathbf{U}^m$, (4.8), is

(6.3)
$$\mathbf{U}^m = \begin{bmatrix} 2 & 5 & 10 & 17 & 15 & 9 & -1 & -15 & 15 & 12 & 7 & 0 & -9 & -20 & -33 & -48 \end{bmatrix}.$$

The decomposed (residual) values $d\mathbf{A}$ (from the demonstration code) are plotted in Figure 5(a) with the symbol $\circ$. The filled-in function is plotted in Figure 4(a) where the dots are the filled-in function and the $\circ$'s are the discrete u_j input values (6.3).

(b) $\ell = 1$, linear interpolation. For $\ell = 1$ we need the discrete function values at each end of each interval. For the left-hand end we use the u_j^+ values, and for the right-hand end we use the u_j values, i.e.,

(6.4)
$$\mathbf{U}^m = \begin{bmatrix} 1 & 2 & 5 & 10 & 17 & 15 & 9 & -1 & 16 & 15 & 12 & 7 & 0 & -9 & -20 & -33 \\ 2 & 5 & 10 & 17 & 15 & 9 & -1 & -15 & 15 & 12 & 7 & 0 & -9 & -20 & -33 & -48 \end{bmatrix}.$$

Note the repetition of values between rows except at the boundaries and the function discontinuity. The decomposed values of $\mathbf{A}$ (from the demonstration code) are plotted

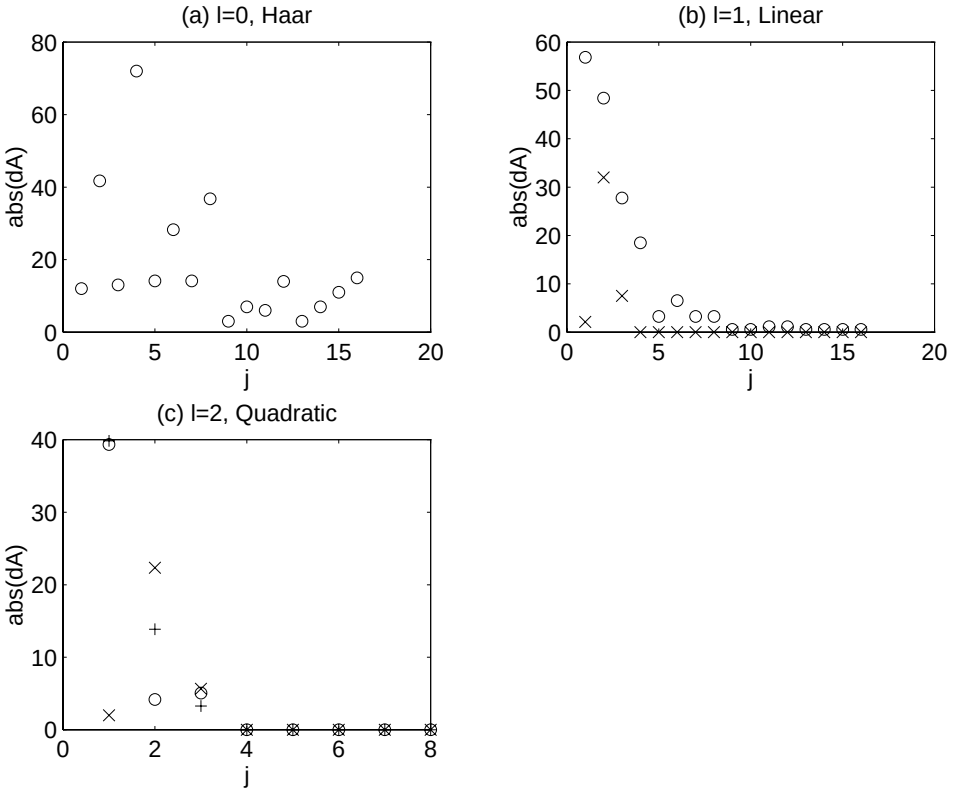

FIG. 5. *Decomposed* $\mathbf{A}$ *values,* $d\mathbf{A}$*, from the demonstration code applied to the discrete data* (6.2).

in Figure 5(b). The first row matrix values are plotted with the symbol $\times$, and the second row matrix values are plotted with the symbol $\circ$. The filled-in function is plotted in Figure 4(b), where the dots are the filled-in function, the $\times$'s are the discrete u_j^+ input values, and the $\circ$'s are the discrete u_j values (6.4).

(c) $\ell = 2$, quadratic interpolation. For $\ell = 2$ we need interval midpoint values in addition to the end point values. For this case we use only 8 intervals instead of 16 and use the "extra" function values as the midpoint values, i.e.,

$$\mathbf{U}^m = \begin{bmatrix} 1 & 5 & 17 & 9 & 16 & 12 & 0 & -20 \\ 2 & 10 & 15 & -1 & 15 & 7 & -9 & -33 \\ 5 & 17 & 9 & -15 & 12 & 0 & -20 & -48 \end{bmatrix}. \tag{6.5}$$

The decomposed (residual) values $d\mathbf{A}$ (from the demonstration code) are plotted in Figure 5(c). The first row matrix values are plotted with the symbol $\times$, the second row matrix values are plotted with the + symbol, and the third row matrix values are plotted with the symbol $\circ$. The filled-in function is plotted in Figure 4(c), where the dots are the filled-in function, the $\times$'s are the discrete u_j^+ input values, the +'s are the discrete u_j "midpoint" values, and the $\circ$'s are the discrete u_j "end-point" values (6.5).

The decomposed (residual) values $d\mathbf{A}$, Figure 5, provide a measure of the compressibility of the data; the more "small" values, the more the data can be truncated or compressed without significant loss of information. Note that as the order of

approximation increases, ℓ increases, and the number of relatively small $d\mathbf{A}$ values increases. Since the original function is piecewise quadratic, the case $\ell = 2$ has only nine nonzero $d\mathbf{A}$ values—the minimum number of values necessary to represent the three quadratic segments of $u(x)$. Note also that most of the $\times$ symbols of Figure 5(b) ($\ell = 1$) are zero. This is a result of having only one function discontinuity while the algorithm has the capability to support a discontinuity at each fine grid point.

The filled-in function (Figure 4) is the subinterval function representation (or subgrid resolution) of the particular interpolation approximation, i.e., $\ell = 0, 1, 2$. The case $\ell = 0$, or Haar, is "constant" interpolation, $\ell = 1$ is linear interpolation, and $\ell = 2$ is quadratic interpolation, which for the present example is an exact representation of the original function $u(x)$. There are several methods to numerically compute the filled-in functions (in addition to the analytical option). The filled-in functions plotted in Figure 4 were obtained by "padding" the decomposed $\mathbf{A}$ matrices ($d\mathbf{A}$) with zeros, multiplying by the appropriate power (which depends on the number of filled-in points) of the weighting factor ($\sqrt{2}$), applying the reconstruction code (recon), and multiplying the result by the postprocessing transformation matrix ($\mathbf{T}$). In Matlab speak this process is

```
Uf=T*recon([dA zeros(l+1,2^nf-2^ni)]*sqrt(2)^(nf-ni),C0,C1,D0,D1),
```

where Uf is the filled-in $\mathbf{U}$, nf is the $\log_2$ of the number of columns in the filled-in matrix Uf, and ni is the $\log_2$ of the number of columns in the matrix dA.

In many (perhaps most) applications of multiresolution algorithms, the given data are a discrete sampling of a function, e.g., in time or space. Therefore, rarely would multiple values, i.e., the u^+ values (or jump values) be available. For optimum performance of the supercompact algorithms, these additional values are required. We are currently testing algorithms that insert the multiple values (u^+) in the original sampled data. One strategy inserts discontinuities when the difference of one-sided (left *and* right) finite differences exceeds a local average value of the finite differences. These results, as well as those for data compression, will be presented elsewhere.

7. Concluding remarks. The multiresolution analysis with supercompact multiscaling functions (and wavelets) is simple to implement and has special appeal in applications on a finite interval and/or for analysis of functions that are piecewise continuous (internal boundaries). Thus the simplicity of the Haar wavelets is preserved while increased accuracy (more vanishing moments) is achieved.

Appendix A. The $\phi(\xi)$'s (2.5) are assumed to form an orthonormal basis. The $\phi(x)$'s (2.7) are orthogonal:

$$\int_{x_{j-1}^{k-1}}^{x_j^{k-1}} \boldsymbol{\phi}_j^{k-1} \boldsymbol{\phi}_j^{k-1\prime} dx = \frac{h_{k-1}}{2}\mathbf{I} \tag{A.1}$$

where $\mathbf{I}$ is the identity matrix of order $\ell + 1$. Using (2.12), one obtains

$$\int_{x_{j-1}^{k-1}}^{x_j^{k-1}} (\mathbf{C}_0\boldsymbol{\phi}_{2j-1}^k + \mathbf{C}_1\boldsymbol{\phi}_{2j}^k)(\mathbf{C}_0\boldsymbol{\phi}_{2j-1}^k + \mathbf{C}_1\boldsymbol{\phi}_{2j}^k)' dx = \frac{h_{k-1}}{2}\mathbf{I}. \tag{A.2}$$

If we expand the integrand of (A.2)

$$\int_{x_{j-1}^{k-1}}^{x_j^{k-1}} (\mathbf{C}_0\boldsymbol{\phi}_{2j-1}^k\boldsymbol{\phi}_{2j-1}^{k\prime}\mathbf{C}_0' + \mathbf{C}_0\boldsymbol{\phi}_{2j-1}^k\boldsymbol{\phi}_{2j}^{k\prime}\mathbf{C}_1' + \mathbf{C}_1\boldsymbol{\phi}_{2j}^k\boldsymbol{\phi}_{2j-1}^{k\prime}\mathbf{C}_0' + \mathbf{C}_1\boldsymbol{\phi}_{2j}^k\boldsymbol{\phi}_{2j}^{k\prime}\mathbf{C}_1')dx \tag{A.3}$$

and use the identities

$$\int_{x_{j-1}^{k-1}}^{x_j^{k-1}} \phi_{2j-1}^k \phi_{2j-1}^{k\,\prime}\, dx = \frac{h_{k-1}}{4}\mathbf{I}, \qquad \int_{x_{j-1}^{k-1}}^{x_j^{k-1}} \phi_{2j-1}^k \phi_{2j}^{k\,\prime}\, dx = 0,$$

$$\int_{x_{j-1}^{k-1}}^{x_j^{k-1}} \phi_{2j}^k \phi_{2j-1}^{k\,\prime}\, dx = 0, \qquad \int_{x_{j-1}^{k-1}}^{x_j^{k-1}} \phi_{2j}^k \phi_{2j}^{k\,\prime}\, dx = \frac{h_{k-1}}{4}\mathbf{I}, \tag{A.4}$$

then we have

$$\frac{1}{2}(\mathbf{C}_0\mathbf{C}_0{}' + \mathbf{C}_1\mathbf{C}_1{}') = \mathbf{I}. \tag{A.5}$$

Appendix B. In this appendix we derive (2.23). First we offer some notation to simplify the algebra. Let

$$\mathbf{L} = \frac{1}{\sqrt{2}}\begin{bmatrix}\mathbf{C}_0 & \mathbf{C}_1\end{bmatrix}, \tag{B.1}$$

$$\mathbf{H} = \frac{1}{\sqrt{2}}\begin{bmatrix}\mathbf{D}_0 & \mathbf{D}_1\end{bmatrix}. \tag{B.2}$$

The objective is to find $\mathbf{D}_0$ and $\mathbf{D}_1$ if we are given $\mathbf{C}_0$, $\mathbf{C}_1$ and relations (2.19a), (2.19b), (2.20a), (2.20b), (2.22a), (2.22b), and identity (2.17). In the notation of (B.1) and (B.2) we are given $\mathbf{L}$ and

$$\boldsymbol{\alpha}^{k-1} = \mathbf{L}\boldsymbol{\alpha}^k, \tag{B.3}$$

$$\mathbf{r}^{k-1} = \mathbf{H}\boldsymbol{\alpha}^k, \tag{B.4}$$

$$\boldsymbol{\alpha}^k = \mathbf{L}'\boldsymbol{\alpha}^{k-1} + \mathbf{H}'\mathbf{r}^{k-1}, \tag{B.5}$$

$$\mathbf{L}\mathbf{L}' = \mathbf{I}. \tag{B.6}$$

For simplicity of notation we have used

$$\mathbf{r}_j^{k-1} \to \mathbf{r}^{k-1}, \boldsymbol{\alpha}_j^{k-1} \to \boldsymbol{\alpha}^{k-1}, \begin{bmatrix}\boldsymbol{\alpha}_{2j-1}^k \\ \boldsymbol{\alpha}_{2j}^k\end{bmatrix} \to \boldsymbol{\alpha}^k. \tag{B.7}$$

B.1. Useful identities. In the following derivation it will be useful to have some identities that can be derived from (B.3), (B.4), (B.5), and (B.6). If we use (B.5) in (B.3), then

$$\boldsymbol{\alpha}^{k-1} = \mathbf{L}\mathbf{L}'\boldsymbol{\alpha}^{k-1} + \mathbf{L}\mathbf{H}'\mathbf{r}^{k-1}.$$

But if we use (B.6) and simplify,

$$\mathbf{L}\mathbf{H}'\mathbf{r}^{k-1} = 0$$

or

$$\mathbf{LH}' = 0 \tag{B.8}$$

since $\mathbf{r}^{k-1}$ is arbitrary. The transpose of (B.8) is

$$\mathbf{HL}' = 0. \tag{B.9}$$

If we use (B.3) and (B.4) in (B.5), then

$$\boldsymbol{\alpha}^k = \mathbf{L}'\mathbf{L}\boldsymbol{\alpha}^k + \mathbf{H}'\mathbf{H}\boldsymbol{\alpha}^k$$

or

$$\mathbf{I} = \mathbf{L}'\mathbf{L} + \mathbf{H}'\mathbf{H}. \tag{B.10}$$

Finally, if we use (B.5) in (B.4)

$$\mathbf{r}^{k-1} = \mathbf{HL}'\boldsymbol{\alpha}^{k-1} + \mathbf{HH}'\mathbf{r}^{k-1},$$

and if we now use (B.9), the result is

$$\mathbf{I} = \mathbf{HH}'. \tag{B.11}$$

B.2. Finding H. Now let's return to the objective of finding $\mathbf{H}$, given $\mathbf{L}$. Start with (B.4)

$$\mathbf{r}^{k-1} = \mathbf{H}\boldsymbol{\alpha}^k,$$

then premultiply by $\mathbf{H}'$ to obtain

$$\mathbf{H}'\mathbf{r}^{k-1} = \mathbf{H}'\mathbf{H}\boldsymbol{\alpha}^k,$$

and use (B.10) to obtain

$$\mathbf{H}'\mathbf{r}^{k-1} = (\mathbf{I} - \mathbf{L}'\mathbf{L})\boldsymbol{\alpha}^k. \tag{B.12}$$

Let the left-hand side of (B.12) be the error vector, i.e. (see (2.22a), (2.22b)),

$$\boldsymbol{\epsilon}^k = \begin{bmatrix} \boldsymbol{\epsilon}^k_{2j-1} \\ \boldsymbol{\epsilon}^k_{2j} \end{bmatrix} = \mathbf{H}'\mathbf{r}^{k-1} \tag{B.13}$$

and

$$\begin{bmatrix} \boldsymbol{\epsilon}^k_{2j-1} \\ \boldsymbol{\epsilon}^k_{2j} \end{bmatrix} = (\mathbf{I} - \mathbf{L}'\mathbf{L})\boldsymbol{\alpha}^k. \tag{B.14}$$

If we substitute $\mathbf{L}$ from (B.1) into (B.14) we obtain

$$\begin{bmatrix} \boldsymbol{\epsilon}^k_{2j-1} \\ \boldsymbol{\epsilon}^k_{2j} \end{bmatrix} = \begin{bmatrix} (\mathbf{I} - \frac{1}{2}\mathbf{C}'_0\mathbf{C}_0) & (-\frac{1}{2}\mathbf{C}'_0\mathbf{C}_1) \\ (-\frac{1}{2}\mathbf{C}'_1\mathbf{C}_0) & (\mathbf{I} - \frac{1}{2}\mathbf{C}'_1\mathbf{C}_1) \end{bmatrix} \boldsymbol{\alpha}^k. \tag{B.15}$$

Next we define the vector d^{k-1}, which is the difference of the error vector components, i.e.,

$$\mathbf{d}^{k-1} = \boldsymbol{\epsilon}^k_{2j} - \boldsymbol{\epsilon}^k_{2j-1}, \tag{B.16}$$

or if we use (B.15)

$$\mathbf{d}^{k-1} = \mathcal{D}\boldsymbol{\alpha}^k, \tag{B.17}$$

where

$$\mathcal{D} = \left[(-\mathbf{I} + \tfrac{1}{2}\mathbf{C}_0'\mathbf{C}_0 - \tfrac{1}{2}\mathbf{C}_1'\mathbf{C}_0) \quad (\mathbf{I} - \tfrac{1}{2}\mathbf{C}_1'\mathbf{C}_1 + \tfrac{1}{2}\mathbf{C}_0'\mathbf{C}_1)\right]. \tag{B.18}$$

If we now substitute $\boldsymbol{\alpha}^k$ from (B.5) into (B.17)

$$\mathbf{d}^{k-1} = \mathcal{D}(\mathbf{L}'\boldsymbol{\alpha}^{k-1} + \mathbf{H}'\mathbf{r}^{k-1}),$$

but it can easily be shown, using (B.18), (B.1), and (B.6), that

$$\mathcal{D}\mathbf{L}' = 0; \tag{B.19}$$

therefore,

$$\mathbf{d}^{k-1} = \mathcal{D}\mathbf{H}'\mathbf{r}^{k-1}. \tag{B.20}$$

It is clear from (B.20) that the vectors $\mathbf{d}^{k-1}$ and $\mathbf{r}^{k-1}$ are related by a square matrix which we denote by $\mathbf{B}$, i.e.,

$$\mathbf{r}^{k-1} = \mathbf{B}\mathbf{d}^{k-1} \tag{B.21}$$

or, from (B.20),

$$\mathbf{d}^{k-1} = \mathcal{D}\mathbf{H}'\mathbf{B}\mathbf{d}^{k-1}$$

or

$$\mathbf{I} = \mathcal{D}\mathbf{H}'\mathbf{B}. \tag{B.22}$$

NOTE: From (B.20) the residual vector $\mathbf{r}^{k-1}$ is seen to be the weighted difference of the interpolation errors.

If we postmultiply (B.22) by $\mathbf{B}^{-1}\mathbf{H}$, then use (B.10) and (B.19), and premultiply the result by $\mathbf{B}$, we have

$$\mathbf{H} = \mathbf{B}\mathcal{D}, \tag{B.23}$$

and we have found $\mathbf{H}$, except for the scaling matrix $\mathbf{B}$. The matrix $\mathbf{B}$ is determined as follows: eliminate $\mathbf{H}$ from (B.11) using (B.23), i.e.,

$$\mathbf{B}\mathcal{D}(\mathbf{B}\mathcal{D})' = \mathbf{I},$$

or

$$\mathbf{B}\mathcal{D}\mathcal{D}'\mathbf{B}' = \mathbf{I}$$

and

$$\mathcal{D}\mathcal{D}' = \mathbf{B}^{-1}(\mathbf{B}')^{-1},$$

and finally,

$$\mathbf{B}'\mathbf{B} = (\mathcal{D}\mathcal{D}')^{-1}. \tag{B.24}$$

The choice of $\mathbf{B}$ is not unique. We choose a symmetric $\mathbf{B}$ and (B.24) becomes

$$\mathbf{B}^2 = (\mathcal{D}\mathcal{D}')^{-1}$$

or

$$\mathbf{B} = ((\mathcal{D}\mathcal{D}')^{-1})^{\frac{1}{2}}. \tag{B.25}$$

After some algebra one can show, using (B.18) and (B.6), that

$$\mathcal{D}\mathcal{D}' = 2\mathbf{I} - \frac{1}{2}(\mathbf{C}_0 - \mathbf{C}_1)'(\mathbf{C}_0 - \mathbf{C}_1). \tag{B.26}$$

If we use (B.18) in (B.23) we obtain (2.23a), (2.23b). If we substitute (B.26) in (B.25) we obtain (2.23c).

Appendix C. The vector-matrix equation (2.12) can be written in component form as

(C.1)
$$(\phi_i(x))_j^{k-1} = \sum_{p=0}^{\ell} c^0_{i+1,p+1}(\phi_p(x))^k_{2j-1} + \sum_{p=0}^{\ell} c^1_{i+1,p+1}(\phi_p(x))^k_{2j}, \quad i = 0, 1, \ldots, \ell.$$

Since the orthonormal polynomials $\phi_i(\xi)$ are supported on the interval $(-1 < \xi \le 1]$, it is easier to evaluate the matrix coefficients $c^0_{r,s}$ and $c^1_{r,s}$ by transforming (C.1) to a form where the $\phi_i(\xi)$'s appear explicitly.

To scale x back to ξ, one uses

$$(x^{k-1}_{j-1} < x \le x^{k-1}_j] \longrightarrow (-1 < \xi \le 1],$$

(C.2)
$$(x^k_{2j-2} < x \le x^k_{2j-1}] \longrightarrow (-1 < \xi \le 0], \qquad (x^k_{2j-1} < x \le x^k_{2j}] \longrightarrow (0 < \xi \le 1].$$

The functions map as

$$(\phi_i(x))_j^{k-1} \longrightarrow \phi_i(\xi), \quad -1 < \xi \le 1,$$

$$(\phi_i(x))^k_{2j-1} \longrightarrow \phi_i(2\xi + 1), \qquad (\phi_i(x))^k_{2j} \longrightarrow \phi_i(2\xi - 1), \quad -1 < \xi \le 1. \tag{C.3}$$

Here we have used the compact support of the polynomials, i.e., $\phi_i(\xi) = 0$ for $\xi \notin [-1, 1]$.

Using (C.3), one can rewrite (C.1) as

$$\phi_i(\xi) = \sum_{p=0}^{\ell} c^0_{i+1,p+1}\phi_p(2\xi + 1) + \sum_{p=0}^{\ell} c^1_{i+1,p+1}\phi_p(2\xi - 1). \tag{C.4}$$

Since $\phi_p(2\xi - 1)$ and $\phi_p(2\xi + 1)$ have nonoverlapping support, we can split (C.4) into two equations, i.e., (3.1).

Appendix D. In this appendix we consider the family of orthonormal polynomials (2.8). The family consists of $\ell + 1$ polynomials of degree ℓ. For convenience, we

will choose the ξ-space representation (2.5) so that the polynomials are orthonormal on the interval $-1 < \xi \leq 1$ (see Appendix C).

For $\ell = 0$ there is only one member of the family, i.e., $\phi_0(\xi) = a_{0,0}$, and the coefficient $a_{0,0}$ from the orthonormal condition (A.1) is $a_{0,0} = 1/\sqrt{2}$, i.e.,

$$\phi_0(\xi) = \frac{1}{\sqrt{2}}. \tag{D.1}$$

The elements of the $\mathbf{C}_0$ and $\mathbf{C}_1$ matrices are defined by (3.2a), (3.2b), i.e.,

$$\mathbf{C}_0 = [1], \quad \mathbf{C}_1 = [1], \tag{D.2}$$

which corresponds to the Haar case.

For $\ell > 0$ the families of polynomials have one or more free parameters. For example, if we choose $\ell = 1$ the family has one free parameter, which we denote by b. The two orthonormal polynomials are

$$\phi_0(\xi) = \sqrt{\frac{1}{3}\left(\frac{3}{2} - b^2\right)} + b\,\xi, \tag{D.3a}$$

$$\phi_1(\xi) = -\frac{b}{\sqrt{3}} + \sqrt{\frac{3}{2} - b^2}\,\xi; \quad -\sqrt{\frac{3}{2}} \leq b \leq \sqrt{\frac{3}{2}}, \tag{D.3b}$$

and the corresponding $\mathbf{C}$ matrices are (from (3.2))

$$\mathbf{C}_0 = \begin{bmatrix} 1 - \frac{1}{3}b^2 - b\sqrt{\frac{1}{3}(\frac{3}{2} - b^2)} & \frac{1}{\sqrt{3}}b^2 - \frac{1}{\sqrt{3}}b\sqrt{\frac{1}{3}(\frac{3}{2} - b^2)} \\ -\frac{1}{\sqrt{3}}(\frac{3}{2} - b^2) - \frac{1}{\sqrt{3}}b\sqrt{\frac{1}{3}(\frac{3}{2} - b^2)} & \frac{1}{2} + \frac{1}{3}b^2 + b\sqrt{\frac{1}{3}(\frac{3}{2} - b^2)} \end{bmatrix},$$

$$\mathbf{C}_1 = \begin{bmatrix} 1 - \frac{1}{3}b^2 + b\sqrt{\frac{1}{3}(\frac{3}{2} - b^2)} & -\frac{1}{\sqrt{3}}b^2 - \frac{1}{\sqrt{3}}b\sqrt{\frac{1}{3}(\frac{3}{2} - b^2)} \\ \frac{1}{\sqrt{3}}(\frac{3}{2} - b^2) - \frac{1}{\sqrt{3}}b\sqrt{\frac{1}{3}(\frac{3}{2} - b^2)} & \frac{1}{2} + \frac{1}{3}b^2 - b\sqrt{\frac{1}{3}(\frac{3}{2} - b^2)} \end{bmatrix}. \tag{D.4}$$

If we choose $b = 0$, the polynomials (D.3) reduce to the first two orthonormal Legendre polynomials (3.4) and the corresponding $\mathbf{C}$ matrices are given by (3.8).

The Legendre polynomials produce relatively sparse $\mathbf{C}$ and $\mathbf{D}$ matrices and are used in the examples of sections 3 and 4. The advantages, if any, of other families of polynomials (e.g., $b \neq 0$ for $\ell = 1$) have not been determined.

Appendix E. In this appendix we give the Mathematica code for generating the matrices $\mathbf{C}_0$, $\mathbf{C}_1$ for any ℓ and Legendre polynomials. We also give the code for generating $\mathbf{D}_0$, $\mathbf{D}_1$ for the general case if $\mathbf{C}_0$ and $\mathbf{C}_1$ are given.

```
(*Mathematica Code*)
(*Compute C0 and C1 matrices for Legendre polynomials*)
phi[i_,x_] :=Sqrt[i+1/2] LegendreP[i,x]
c0[i_,j_] :=2 Integrate[phi[j-1,2x+1] phi[i-1,x], {x, -1, 0}]
C0m[l_] :=Array[c0,{l+1,l+1}]
c1[i_,j_] :=2 Integrate[phi[j-1,2x-1] phi[i-1,x], {x, 0, 1}]
C1m[l_] :=Array[c1,{l+1,l+1}]
(*Compute D0 and D1 matrices -Assumes C0 and C1 are input*)
Mat[m0_,m1_] :=(l=Length[m0]-1;
                im=IdentityMatrix[l+1];
                m0t=Transpose[m0];
                m1t=Transpose[m1];
                bs=Inverse[im-1/4 (m0t-m1t) .(m0-m1)];
                {e,m}=Eigensystem[bs];
                mt=Transpose[m];
                de=DiagonalMatrix[e];
                b=(1/Sqrt[2]) mt.Sqrt[de].Inverse[mt] ;
                d0m=Sqrt[2] b.    (-im+(1/2)(m0t.m0-m1t.m0)) ;
                d1m=Sqrt[2] b.    (im-(1/2)(m1t.m1-m0t.m1)) ;
                (*output C0,C1,D0,D1 matrices*)
{m0,m1,d0m,d1m} )
(*EXAMPLE {C0,C1,D0,D1}=Mat[C0m[2],C1m[2]] produces (3.5) and (3.6)*)
```

The Mathematica statement $\{C0, C1, D0, D1\} = Mat[C0m[4], C1m[4]]$ generates the array form of the matrices for the first five ($\ell = 4$) Legendre polynomials (3.3), i.e.,

$$\mathbf{C}_0 = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 \\ \frac{-\sqrt{3}}{2} & \frac{1}{2} & 0 & 0 & 0 \\ 0 & \frac{-\sqrt{15}}{4} & \frac{1}{4} & 0 & 0 \\ \frac{\sqrt{7}}{8} & \frac{\sqrt{21}}{8} & \frac{-\sqrt{35}}{8} & \frac{1}{8} & 0 \\ 0 & \frac{\sqrt{3}}{8} & \frac{3\sqrt{5}}{8} & \frac{-3\sqrt{7}}{16} & \frac{1}{16} \end{bmatrix}, \tag{E.1}$$

$$\mathbf{C}_1 = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 \\ \frac{\sqrt{3}}{2} & \frac{1}{2} & 0 & 0 & 0 \\ 0 & \frac{\sqrt{15}}{4} & \frac{1}{4} & 0 & 0 \\ \frac{-\sqrt{7}}{8} & \frac{\sqrt{21}}{8} & \frac{\sqrt{35}}{8} & \frac{1}{8} & 0 \\ 0 & \frac{-\sqrt{3}}{8} & \frac{3\sqrt{5}}{8} & \frac{3\sqrt{7}}{16} & \frac{1}{16} \end{bmatrix}. \tag{E.2}$$

The exact expressions for the $\mathbf{D}$ matrices are quite complex and we give only the approximate numerical values:

$$\mathbf{D}_0 = \begin{bmatrix} -0.239593 & -0.414988 & -0.288479 & 0.828951 & 0 \\ 0 & -0.0349215 & -0.13525 & -0.120023 & 0.982895 \\ -0.288479 & -0.49966 & -0.608198 & -0.545174 & 0 \\ 0 & -0.120023 & -0.464847 & -0.859942 & -0.173238 \\ 0 & 0 & 0 & 0 & -1 \end{bmatrix}, \tag{E.3}$$

$$\text{(E.4)} \qquad \mathbf{D}_1 = \begin{bmatrix} 0.239593 & -0.414988 & 0.288479 & 0.828951 & 0 \\ 0 & 0.0349215 & -0.13525 & 0.120023 & 0.982895 \\ 0.288479 & -0.49966 & 0.608198 & -0.545174 & 0 \\ 0 & 0.120023 & -0.464847 & 0.859942 & -0.173238 \\ 0 & 0 & 0 & 0 & 1 \end{bmatrix}.$$

For completeness we give the corresponding approximate $\mathbf{B}$ matrix:

$$\text{(E.5)} \qquad \mathbf{B} = \begin{bmatrix} 6.88098 & 0 & -3.26377 & 0 & 0 \\ 0 & 38.9165 & 0 & -5.43161 & 0 \\ -3.26377 & 0 & 2.71069 & 0 & 0 \\ 0 & -5.43161 & 0 & 1.58037 & 0 \\ 0 & 0 & 0 & 0 & 0.707107 \end{bmatrix}.$$

Acknowledgment. We are grateful to Dennis Jespersen for comments and suggestions that improved our manuscript.

DISCRETE MULTIRESOLUTION ANALYSIS USING HERMITE INTERPOLATION: BIORTHOGONAL MULTIWAVELETS*

ROBERT F. WARMING† AND RICHARD M. BEAM†

Abstract. We generalize Harten's interpolatory multiresolution representation to include Hermite interpolation. Compact Hermite interpolation with optimal order accuracy is used in both the decomposition and reconstruction algorithm. The resulting multiple basis functions (biorthogonal multiwavelets) are symmetric or skew-symmetric, compact, and analytic. Harten's approach has several advantages: the multiresolution scheme is inherently discrete, nonperiodic boundary conditions are easy to implement, and the representation can be extended to nonuniform grids in bounded domains. We demonstrate the compression features of the new multiple basis functions by application to several examples.

1. Introduction.

A multiresolution analysis is the decomposition of a function, e.g., $u(x)$, into scales. A *discrete* multiresolution analysis is a decomposition of a vector array $\mathbf{u}$ representing a point value discretization of $u(x)$ on a uniform partition of $[0,1]$. (In practice, the input array may come from a finite difference or finite element approximation to the underlying function $u(x)$.) A discrete multiresolution algorithm consists of a decomposition (analysis) which generates the scale coefficients from the input array and a reconstruction (synthesis) which recovers the input array from the scale coefficients. The reconstruction is conservative in the sense that it reproduces exactly the input array.

An interpolatory multiresolution algorithm due to Harten [Ha93, Ha94, Ha95] can be briefly described as follows. At each step of the decomposition there is a dyadic coarsening of the grid. The grid level index, denoted by the integer k, decreases with grid coarsening. In going from level k to $k-1$, the even-point values are projected and the odd-point values are decimated, i.e., discarded. At level $k-1$ of the reconstruction step, interpolation is used to predict the missing odd-point values at the finer level k. Of course the interpolated values are not, in general, exact since there is an interpolation error. However, in each decomposition step the interpolation errors are computed and saved before the odd-point values are decimated. Consequently, in each step of the reconstruction algorithm the interpolation errors are added to the interpolated values to obtain exact reconstruction. In an interpolatory multiresolution analysis, the interpolation errors at each level k are the scale coefficients. It should be noted that the input array for an interpolatory multiresolution algorithm may consist of cell-averaged values rather than point values. In this case the even-point values are not simply projected from level k to $k-1$ [Ha95].

Harten's interpolatory multiresolution analysis has a beautiful simplicity. The multiresolution algorithm for a uniform grid and periodic boundary conditions can

*Received by the editors January 20, 1997; accepted for publication (in revised form) May 18, 1998; published electronically October 25, 2000. The main results of this paper were presented at the SIAM Annual Meeting, Charlotte, North Carolina, 1995 and in NASA TM 110434, 1997.

†Advanced Computational Methods Branch, NASA Ames Research Center, Moffett Field, CA 94035-1000.

easily be extended to nonuniform grids and nonperiodic boundary conditions since the requisite interpolation formula does not depend on uniform spacing and can be modified at or near a boundary. This is in contrast to the classical theory of discrete wavelets where it is not possible to expand a function by translates and dilates of a single function on a nonuniform grid and nonperiodic boundary conditions are difficult to implement.

The scalar version of Harten's algorithm is closely related to the work of Donoho [Do92], Sweldens [Sw95], and Sweldens and Schroder [Sw96]. Donoho developed interpolating wavelet transforms where the coefficients are obtained by linear combinations of samples rather than integration. The resulting coefficients have decay properties comparable to the decay properties of smooth orthogonal wavelet decompositions. Sweldens introduced the terminology *second generation wavelets* to describe wavelets that are not necessarily translates and dilates of a single scalar function. Harten's interpolatory wavelets and their generalization to multiwavelets have this property when applied on nonuniform grids and/or finite domains. Sweldens [Sw95] describes a lifting scheme for constructing biorthogonal wavelets by generalization of a basic interpolatory multiresolution algorithm. The lifting scheme imposes an additional global property such as the conservation of some scalar quantity; however, the support of the wavelet is increased while the order of accuracy remains the same as the basic algorithm. Cai and Wang [Ca96] have developed a spline wavelet-like decomposition for a Sobolev space. The resulting wavelet expansion interpolates function values by using cubic splines.

In an interpolatory multiresolution algorithm the interpolation process plays a crucial role. For the scalar algorithm on a uniform grid, the interpolation process is equivalent to a scheme proposed by Dubuc [Du86] with extensions by Deslauriers and Dubuc [De89]. One assumes that discrete function values are given on a uniform partition of an interval. The question is how to extend these discrete values smoothly by interpolation to a nested sequence of uniformly refined dyadic grids. Dubuc defines a method of interpolation generated through a symmetric iterative process on the refined dyadic grids. The Dubuc iterative process is an interpolation scheme, i.e., a *fill-in* scheme, but not a multiresolution scheme.

In this paper we consider *compact Hermite* interpolation not considered by Harten or Dubuc. An interpolation is said to be compact Hermite if it interpolates function values on a subinterval using function values and derivative values at the subinterval end points, i.e., the interpolation points. The advantage of using compact interpolation is that for a multiresolution analysis the support of the basis functions is only two subintervals and the basis functions are piecewise polynomials (nonfractal). In contrast, the cubic interpolation used by Dubuc [Du86] and Harten [Ha93] leads to a basis function which is not analytic and has three times the support of a basis function resulting from compact Hermite interpolation. In Harten's *scalar* interpolatory multiresolution analysis a single variable (scalar) is required at each grid point. In our extension to compact Hermite interpolation, multiple variables are required at each grid point and we use the notation *vector* multiresolution analysis. Compact Hermite interpolation leads to multiple basis functions or, for brevity, *multiwavelets*. In this paper we restrict our attention to one spatial dimension. A two-dimensional multiwavelet version in nonstandard form will be described elsewhere. This work was motivated by a paper on multiwavelets by Strang and Strela [St94]. Their wavelets are orthogonal but piecewise linear and fractal. The basis vectors in this paper are biorthogonal but of arbitrary order and smooth. The biorthogonal Hermite multi-

wavelets developed in this paper can be viewed (for uniform spacing) as a particular class coming from the general theory of oblique multiwavelet transforms developed by Aldroubi [Al97]. For oblique multiwavelets there are no constraints about orthogonality or even biorthogonality.

In general, a wavelet comes from the scaling function by taking "differences" [St89], i.e., the wavelet is a linear combination of translates of the scaling function at the next finer level. In the case of a uniform grid, periodic boundary conditions, compact interpolation, and projection of the even-point values, Harten's interpolatory multiresolution approach leads to a wavelet which is a translate of the scaling function at the next finer level. Consequently, the scaling function and the wavelet have the same functional form, i.e., they are similar functions. This same property extends to multiwavelets where there are several scaling functions and the corresponding wavelets have the same functional form as the scaling functions. The resulting multiwavelets are biorthogonal. In the finite element approach of Strela and Strang [Stre95] each vector multiwavelet is a linear combination of the vector scaling functions translated at the next finer level. This leads to multiwavelets with a larger support (three intervals) as compared with our multiwavelets (two intervals). Strela and Strang achieve semiorthogonality, which is more than biorthogonality and less than orthogonality. The procedure for determining the coefficient matrices of their wavelet equation is rather complicated, and the matrices are not given in analytical form.

This paper is organized as follows. In the next section we define a nested sequence of uniform dyadic grids for a multiresolution analysis. Since our vector multiresolution analysis is a generalization of Harten's scalar analysis, we outline the development of scalar multiresolution analysis in section 3. The definition of accuracy is reviewed in section 4. Compact Hermite interpolation is presented in section 5. In section 6 we generalize Harten's scalar multiresolution analysis to a vector multiresolution analysis with point values and first derivative values specified on a given mesh. A general vector multiresolution algorithm is then developed (section 7) for any combination of function values and one or more derivative values. If only grid-point function values are given in the input array, then the requisite derivative values are computed in a preprocessing step using finite differences (section 8). Accuracy for a vector multiresolution algorithm is defined in section 9. The data compression features of the multiwavelet algorithm are illustrated in section 10. Some concluding remarks are in the final section.

Neither the development nor the application of an interpolatory multiresolution algorithm requires a knowledge of the basis vectors, the scaling functions, or the wavelets. Additionally, implementation of the algorithm does not require explicit knowledge of the dilation (scaling) equation or wavelet equation. However, one needs to select an algorithm with basis functions (which are derived from the scaling functions) appropriate for the particular application, and naturally, one would like to know what scaling functions the multiresolution algorithm generates. Analysis related to the scaling equation, the scaling function, the wavelets, and the discrete basis vectors are relegated to several appendices. In a compact interpolatory multiresolution algorithm the *unit interpolation function* plays the role of the scaling function. In Appendix A we define the unit interpolation function and derive the dilation equation which it satisfies. In Appendix B we examine the discrete basis vectors which can easily be computed numerically from the reconstruction algorithm or analytically from the scaling function. The *fill-in* algorithm, which is an iterative method of interpolating between the specified function values on a discrete grid, is described

in Appendix C. The filled-in function is the subinterval function representation (or subgrid resolution). The fill-in algorithm for vector multiresolution is described in Appendix D. Analytical formulas for the unit interpolation functions for particular cases are derived in Appendix E.

2. Nested grid hierarchy. Let $m > n$ be positive integers, and let $\{X^k\}_{k=m,m-1,\dots,n}$ denote a nested sequence of uniform dyadic grids on the unit interval $[0,1]$ defined by

$$X^k = \{x_j^k\}_{j=0}^{J_k}, \quad x_j^k = jh_k, \quad h_k = 1/2^k, \quad J_k = 2^k, \tag{2.1}$$

where the positive integer k denotes the grid level index. The level index $k = m$ corresponds to the *finest* grid in the hierarchy where the number of subintervals is $J_m = 2^m$ and the subinterval (grid spacing) is $h_m = 2^{-m}$. The level index $k = n$ corresponds to the *coarsest* grid where the number of subintervals is $J_n = 2^n$ and the increment is $h_n = 2^{-n}$. Note that X^{k-1} is formed from X^k by removing grid points of X^k with odd indices:

$$x_j^{k-1} = x_{2j}^k, \quad j = 0, 1, 2, \dots, J_{k-1}. \tag{2.2}$$

A nested sequence of uniform grids is illustrated in Figure 2.1 for $m = 4$ and $n = 0$.

At each level k a grid vector is defined by

$$\mathbf{x}^k = [x_1^k, x_2^k, \dots, 1]^T \qquad x_j^k = j/2^k. \tag{2.3}$$

The grid points x_j^k are sometimes called dyadic points. At each level k a vector $\mathbf{u}^k$ of point values is associated with the grid vector $\mathbf{x}^k$:

$$\mathbf{u}^k = [u_1^k, u_2^k, \dots, u_{J_k}^k]^T, \quad J_k = 2^k. \tag{2.4}$$

The vector $\mathbf{u}^{k-1}$ is half the length of $\mathbf{u}^k$ and is formed by a prescription given in the multiresolution algorithm developed in section 3.

Implicit in this paper is the assumption of a periodic input array with a unit period. For discrete data, periodicity with a unit period is expressed as

$$u_{j+\ell J_k}^k = u_j^k \tag{2.5}$$

for every integer ℓ. Note that the assumption of periodicity implies $u_0^k = u_{J_k}^k$. Other boundary conditions are easy to implement and will be described in a subsequent paper.

At the finest level $k = m$, the vector of point values associated with the grid $\mathbf{x}^m$ is

$$\mathbf{u}^m = [u_1^m, u_2^m, \dots, u_{J_m}^m]^T, \qquad J_m = 2^m. \tag{2.6}$$

Discrete data on the finest grid may come from a continuous periodic function $u(x)$ sampled on the unit interval $[0,1]$, i.e.,

$$u(x) \in C[0,1], \tag{2.7}$$

where $C[0,1]$ is the space of continuous periodic functions on $[0,1]$. The discrete values $u(x_j^m)$ are obtained from a point discretization on the finest grid:

$$u_j^m = u(x_j^m), \quad j = 1, 2, \dots, J_m. \tag{2.8}$$

In the following development of a multiresolution scheme, the vector $\mathbf{u}^m$ can be an arbitrary vector, and there is no assumption that it represents a point discretization of the form (2.8). However, if one considers the issue of accuracy (section 4), then an appropriate assumption on the number of continuous derivatives must be made.

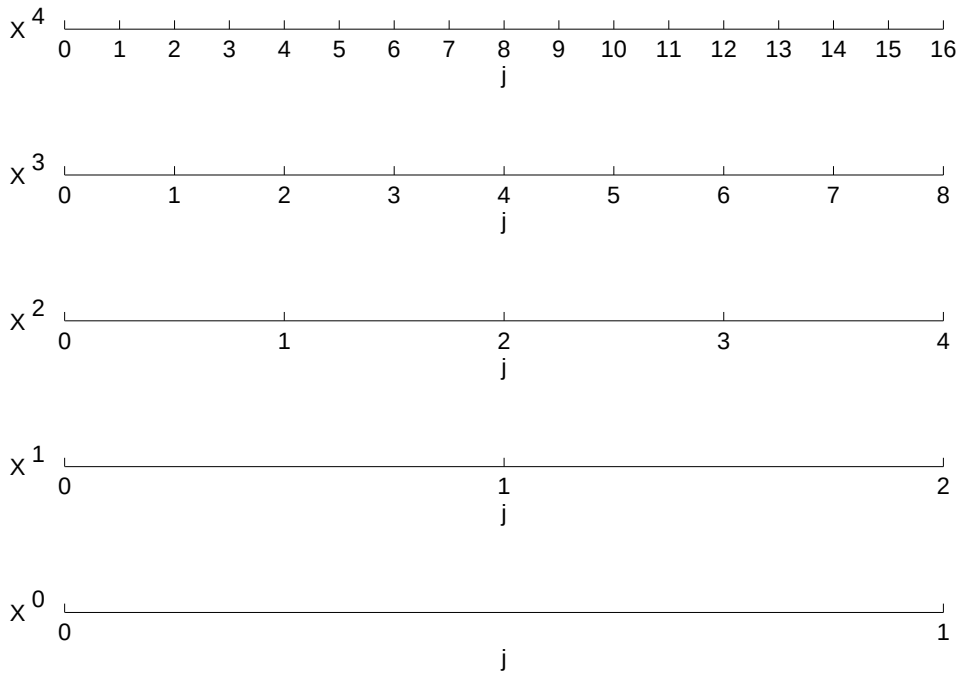

FIG. 2.1. *Nested sequence of grids.*

3. Scalar multiresolution algorithm. In this section we describe a scalar interpolatory multiresolution algorithm due to Harten [Ha93, Ha94, Ha95]. We start at an arbitrary grid level k and go down one level to $k-1$ and then go back to level k. Two generic grids at levels k and $k-1$ are shown pictorially in Figure 3.1. The goal is to achieve scale decomposition and perfect reconstruction of the original data at level k.

3.1. Algorithm development. To go down one level we project the even-point values from level k to $k-1$:

$$u_j^{k-1} = u_{2j}^k, \quad j = 1, 2, \ldots, J_{k-1}. \tag{3.1}$$

(See Figure 3.1 and (2.2).) Note that $\mathbf{u}^{k-1}$ is formed from $\mathbf{u}^k$ by decimation, i.e., discarding values of $\mathbf{u}^k$ with odd indices. Some authors refer to this step as subsampling.

Next, we want to go back up to level k. The even-point values at level k are determined by simply reversing the projection (3.1):

$$u_{2j}^k = u_j^{k-1}, \quad j = 1, 2, \ldots, J_{k-1}. \tag{3.2}$$

But how can one get the odd-point values u_{2j-1}^k at level k from data at level $k-1$? Harten [Ha93, Ha95] used interpolation, and we use linear interpolation as an example. (Interpolation formulas are discussed in detail in section 5.) Let $x_{j-1/2}^{k-1}$ be a fictitious

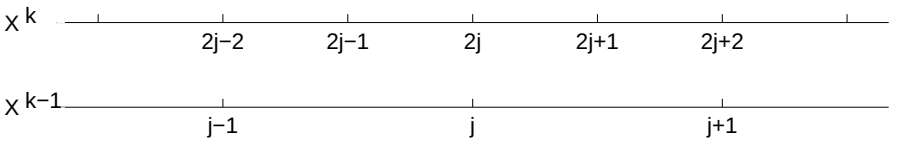

FIG. 3.1. *Two generic grid levels.*

grid point in the middle of the subinterval $[x_{j-1}^{k-1}, x_j^{k-1}]$. The point is called fictitious because it is not a point of the grid X^{k-1}; however, it is clear that

$$x_{j-1/2}^{k-1} = x_{2j-1}^{k}. \tag{3.3}$$

(See Figure 3.1.) By linear interpolation at level $k-1$, one obtains

$$\tilde{u}_{j-1/2}^{k-1} = \frac{1}{2}(u_j^{k-1} + u_{j-1}^{k-1}), \quad j = 1, 2, \ldots, J_{k-1}, \tag{3.4}$$

where $\tilde{u}_{j-1/2}^{k-1}$ is the (linearly) interpolated value at the fictitious point $x_{j-1/2}^{k-1}$. The projection (3.1) and (3.3) are used to rewrite (3.4) as

$$\tilde{u}_{2j-1}^{k} = \frac{1}{2}(u_{2j}^{k} + u_{2j-2}^{k}), \quad j = 1, 2, \ldots, J_{k-1}, \tag{3.5}$$

where $\tilde{u}_{2j-1}^{k}$ denotes a linearly interpolated value of u_{2j-1}^{k}. However, in general, (3.5) is not exact and will not have perfect reconstruction.

An obvious way to fix this deficiency is the following. While we are still at level k (in the decomposition), we have the exact odd-point values u_{2j-1}^{k}. Before we decimate the odd-point values at level k we compute interpolation *errors* or *residuals* at the odd grid points of X^k and denote the result by r_j^{k-1}:

$$r_j^{k-1} = u_{2j-1}^{k} - \tilde{u}_{2j-1}^{k}, \quad j = 1, 2, \ldots, J_{k-1}. \tag{3.6}$$

For linear interpolation $\tilde{u}_{2j-1}^{k}$ is given by (3.5). If we save the r_j^{k-1}'s, then when we go up from level $k-1$ to k (in the reconstruction), we can compute the exact value at the odd points by

$$u_{2j-1}^{k} = \tilde{u}_{2j-1}^{k} + r_j^{k-1} \quad j = 1, 2, \ldots, J_{k-1}. \tag{3.7}$$

The superscript $k-1$ of r_j^{k-1} indicates that the interpolation error or residual is stored at level $k-1$. It is used to reconstruct the exact values at the odd-point values when going from level $k-1$ to level k (see the next algorithm given below). The r_j^k's are sometimes referred to as the scale coefficients at the kth level of resolution.

Before writing down the multiresolution algorithm we introduce notation for the interpolation function. For polynomial interpolation of arbitrary order, the function $I^k(x_{2j-1}^k; u_{2j}^k)$ interpolates odd-point values u_{2j-1}^k (at odd grid points x_{2j-1}^k) using even-point values u_{2j}^k. For linear interpolation (3.5) we write

$$\tilde{u}_{2j-1}^{k} = I^k(x_{2j-1}^k; u_{2j}^k) = \frac{1}{2}(u_{2j}^{k} + u_{2j-2}^{k}), \quad j = 1, 2, \ldots, J_{k-1}. \tag{3.8}$$

As a higher order accurate example, cubic interpolation is given by

$$\tilde{u}^k_{2j-1} = I^k(x^k_{2j-1}; u^k_{2j}) = \frac{9}{16}(u^k_{2j} + u^k_{2j-2}) - \frac{1}{16}(u^k_{2j+2} + u^k_{2j-4}). \tag{3.9}$$

Finally, using (3.1), (3.6) and (3.2), (3.7) together with the interpolation function, e.g., (3.8), one can write an interpolatory multiresolution algorithm in pseudocode:

decomposition

For $k = m, m-1, \ldots, n+1$

For $j = 1, 2, \ldots, J_{k-1}$

$$\begin{aligned} u^{k-1}_j &= u^k_{2j}, \\ r^{k-1}_j &= u^k_{2j-1} - I^k(x^k_{2j-1}; u^k_{2j}), \end{aligned} \tag{3.10a}$$

End

End

reconstruction

For $k = n+1, n+2, \ldots, m$

For $j = 1, 2, \ldots, J_{k-1}$

$$\begin{aligned} u^k_{2j} &= u^{k-1}_j, \\ u^k_{2j-1} &= I^k(x^k_{2j-1}; u^k_{2j}) + r^{k-1}_j, \end{aligned} \tag{3.10b}$$

End

End

Note that the reconstruction step (3.10b) is an obvious reversal or inverse of the decomposition step (3.10a). The number of levels we go down in the decomposition step is $m-n$. The minimum value of the index n is determined by the support of the interpolation formula. For linear interpolation it is $n \geq 1$, and for cubic interpolation it is $n \geq 3$. If for cubic interpolation one picks $n < 3$, then there is a periodic wraparound of the basis function.

In the reconstruction algorithm (3.10b) the interpolation is done at level k. One could also do the interpolation at level $k-1$ as given, for example, by (3.4). The choice is determined by ease of coding or notational convenience as in the vector-matrix form given below. The function $I^{k-1}(x^{k-1}_{j-1/2}; u^{k-1}_j)$ interpolates half-integer-point values $u^{k-1}_{j-1/2}$ (at half-integer grid points $x^{k-1}_{j-1/2}$) using integer point values u^{k-1}_j. For example, linear interpolation (3.4) is denoted by

$$\tilde{u}^{k-1}_{j-1/2} = I^{k-1}(x^{k-1}_{j-1/2}; u^{k-1}_j) = \frac{1}{2}(u^{k-1}_j + u^{k-1}_{j-1}), \quad j = 1, 2, \ldots, J_{k-1}. \tag{3.11}$$

The fact that

$$I^k(x^k_{2j-1}; u^k_{2j}) = I^{k-1}(x^{k-1}_{j-1/2}; u^{k-1}_j)$$

follows directly from the projection (3.1) and the identity (3.3). Consequently, one can write the reconstruction algorithm (3.10b) as

reconstruction

For $k = n+1, n+2, \ldots, m$

For $j = 1, 2, \ldots, J_{k-1}$

$$\begin{aligned} u^k_{2j} &= u^{k-1}_j, \\ u^k_{2j-1} &= I^{k-1}(x^{k-1}_{j-1/2}; u^{k-1}_j) + r^{k-1}_j, \end{aligned} \tag{3.12}$$

End

End

3.2. Biorthogonality and perfect reconstruction. For analysis and exposition purposes we follow the notation of Strang [St89] and rewrite the multiresolution algorithm (3.10a), (3.12) in vector-matrix form as

decomposition

For $k = m, m-1, \ldots, n+1$

$$\begin{aligned} \mathbf{u}^{k-1} &= \mathbf{L}\mathbf{u}^k \\ \mathbf{r}^{k-1} &= \mathbf{H}\mathbf{u}^k \end{aligned} \tag{3.13a}$$

End

reconstruction

For $k = n+1, n+2, \ldots, m$

$$\mathbf{u}^k = \mathbf{L}^s\mathbf{u}^{k-1} + \mathbf{H}^s\mathbf{r}^{k-1} \tag{3.13b}$$

End

The length (dimension) of the column vectors $\mathbf{u}^k$ and $\mathbf{r}^k$ is 2^k (see (2.4)). The dimensions of the rectangular matrices $\mathbf{L}$ and $\mathbf{H}$ are $2^{k-1} \times 2^k$, and the dimensions of the matrices $\mathbf{L}^s$ and $\mathbf{H}^s$ are $2^k \times 2^{k-1}$. For the case of linear interpolation, the form of the matrices $\mathbf{L}$, $\mathbf{H}$, $\mathbf{L}^s$, and $\mathbf{H}^s$ is given at the end of section 7 as a special case of a vector multiresolution algorithm. The vector-matrix form (3.13) is not generally the recommended computational form, but it is useful for analytical exposition. A multiresolution algorithm must possess the perfect reconstruction property, i.e., if one starts at an arbitrary level k and goes down one level to $k-1$ and goes back to level k, then the original k-level data must be reproduced exactly. Using (3.13), one can write the perfect reconstruction property in matrix form as

$$\begin{bmatrix} \mathbf{L} \\ \mathbf{H} \end{bmatrix} \begin{bmatrix} \mathbf{L}^s & \mathbf{H}^s \end{bmatrix} = \begin{bmatrix} \mathbf{I} & \mathbf{0} \\ \mathbf{0} & \mathbf{I} \end{bmatrix}, \tag{3.14}$$

and one obtains the following identities:

$$\mathbf{L}\mathbf{L}^s = \mathbf{I}, \tag{3.15a}$$

$$\mathbf{L}\mathbf{H}^s = \mathbf{0}, \tag{3.15b}$$

$$\mathbf{H}\mathbf{L}^s = \mathbf{0}, \tag{3.15c}$$

$$\mathbf{H}\mathbf{H}^s = \mathbf{I}. \tag{3.15d}$$

Note that (3.14) has the form $\mathbf{A}\mathbf{A}^{-1} = \mathbf{I}$, where $\mathbf{A}$ is a square matrix, and consequently, we can rewrite (3.14) as

$$\begin{bmatrix}\mathbf{L}^s & \mathbf{H}^s\end{bmatrix}\begin{bmatrix}\mathbf{L}\\ \mathbf{H}\end{bmatrix} = \mathbf{I}. \tag{3.16}$$

From this equation we obtain an additional identity

$$\mathbf{L}^s\mathbf{L} + \mathbf{H}^s\mathbf{H} = \mathbf{I}, \tag{3.17}$$

which is not an identity independent from (3.15).

Perfect reconstruction requires that identities (3.15) be satisfied. A discrete multiresolution analysis is said to be *biorthogonal* if identities (3.15) are satisfied. For example, (3.15a) and (3.15b) impose the condition that the ith row of $\mathbf{L}$ is orthogonal to the jth column of $\mathbf{L}^s$ $(i \neq j)$ and all columns of $\mathbf{H}^s$. If $\mathbf{L}^s$ and $\mathbf{H}^s$ are transposes of $\mathbf{L}$ and $\mathbf{H}$, then the multiresolution analysis is said to be *orthogonal* (see Strang [St89]). The interpolatory multiresolution analysis of this paper leads to a biorthogonal multiresolution analysis.

3.3. Pyramid scheme and scale decomposition. In the following discussion it is convenient to write vectors as row vectors. To avoid awkward superscripts such as $(\mathbf{u}^k)^T$, we use an accent prime to indicate a vector transpose:

$$\acute{\mathbf{u}}^k = (\mathbf{u}^k)^T.$$

From (3.13) it is clear that a knowledge of $[\acute{\mathbf{u}}^{k-1}, \acute{\mathbf{r}}^{k-1}]$ is equivalent to a knowledge of $[\acute{\mathbf{u}}^k]$:

$$[\acute{\mathbf{u}}^k] \rightleftharpoons [\acute{\mathbf{u}}^{k-1}, \acute{\mathbf{r}}^{k-1}]. \tag{3.18}$$

Hence one can represent the multiresolution algorithm as a pyramid scheme

$$[\acute{\mathbf{u}}^m] \rightleftharpoons [\acute{\mathbf{u}}^{m-1}, \acute{\mathbf{r}}^{m-1}] \rightleftharpoons [\acute{\mathbf{u}}^{m-2}, \acute{\mathbf{r}}^{m-2}, \acute{\mathbf{r}}^{m-1}] \rightleftharpoons \cdots \rightleftharpoons [\acute{\mathbf{u}}^n, \acute{\mathbf{r}}^n, \ldots, \acute{\mathbf{r}}^k, \ldots, \acute{\mathbf{r}}^{m-2}, \acute{\mathbf{r}}^{m-1}]$$

$$= [\acute{\mathbf{d}}^m]. \tag{3.19}$$

The rightmost vector of (3.19) is defined to be the decomposition vector

$$[\acute{\mathbf{d}}^m] = [\acute{\mathbf{u}}^n, \acute{\mathbf{r}}^n, \ldots, \acute{\mathbf{r}}^k, \ldots, \acute{\mathbf{r}}^{m-2}, \acute{\mathbf{r}}^{m-1}], \tag{3.20}$$

where $\mathbf{d}^m$ is the multiresolution representation of $\mathbf{u}^m$. In (3.19) sequencing left to right $\rightharpoonup$ is the decomposition and sequencing to right to left $\leftharpoondown$ is the reconstruction. It is important to note that every vector $[\,\cdot\,]$ of (3.19) has the same length, namely 2^m. Consequently, the most convenient and compact way to code an interpolatory multiresolution algorithm is to start with an input vector $\mathbf{u}^m$ and overwrite $\mathbf{u}^m$ at every step of the decomposition (or reconstruction) as indicated in (3.19). Note that only the *left* two subvectors of the vector are changed from step to step in this pyramid scheme.

Relation (3.19) shows there is a one-to-one transformation between $\mathbf{u}^m$ and $\mathbf{d}^m$ which we denote by

$$\mathbf{d}^m = \mathbf{W}^{-1}\mathbf{u}^m, \tag{3.21a}$$

$$\mathbf{u}^m = \mathbf{W}\mathbf{d}^m, \tag{3.21b}$$

where $\mathbf{W}$ is a $2^m \times 2^m$ matrix. In component form (3.21b) is

$$\mathbf{u}^m = \sum_{\ell=1}^{2^m} d_\ell^m \mathbf{w}_\ell, \tag{3.22}$$

where the d_ℓ^m's are the elements of $\mathbf{d}^m$. The basis vector $\mathbf{w}_\ell$ denotes the ℓth column of $\mathbf{W}$.

By using the decomposition vector $\mathbf{d}^m$ defined by (3.20), one can rewrite (3.21b) as

$$\mathbf{u}^m = \hat{\mathbf{u}}^{(n)} + \mathbf{u}^{(n)} + \mathbf{u}^{(n+1)} + \cdots + \mathbf{u}^{(k)} + \cdots + \mathbf{u}^{(m-1)}, \tag{3.23a}$$

where

$$\hat{\mathbf{u}}^{(n)} = \sum_{\ell=1}^{2^n} u_\ell^n \mathbf{w}_\ell, \tag{3.23b}$$

$$\mathbf{u}^{(k)} = \sum_{\ell=1}^{2^k} r_\ell^k \mathbf{w}_{2^k+\ell}. \tag{3.23c}$$

(The notation $\mathbf{u}^{(k)}$ should not be confused with $\mathbf{u}^k$.) In (3.23c) the r_ℓ^k's are the elements of the subvector $\mathbf{r}^k$ of the decomposition vector $\mathbf{d}^m$ given by (3.20). For $n \le k \le m-1$ the *detail* $\mathbf{u}^{(k)}$ is a linear combination of 2^k multiresolution basis vectors of scale 2^{-k}. For compact interpolation (section 5), the basis vectors of scale 2^{-k} are *nonoverlapping* (see Appendix B.2.a.). It is apparent that a multiresolution decomposition splits $\mathbf{u}^m$ into components at different *scales* indexed by k. The vector $\hat{\mathbf{u}}^{(n)}$ is a linear combination of *overlapping* multiresolution basis vectors (see (B.2b)). The u_ℓ^n's are the elements of the subvector $\mathbf{u}^n$ of the decomposition vector $\mathbf{d}^m$.

For any multiresolution scheme it is instructive to plot the discrete basis vectors $\mathbf{w}_\ell$ of the expansion (3.22) for particular values of n and m. This can easily be done as described in Appendix B. The basis vectors corresponding to linear interpolation are plotted in Figure B.1 for $m = 3$. In Appendix B.2 we also examine the discrete basis vectors as determined by the dilation and translation of a piecewise polynomial basis function evaluated on a discrete grid.

In a compact interpolatory multiresolution algorithm the *unit interpolation function* plays the role of the scaling function. In Appendix A we define the unit interpolation function and derive the dilation equation which it satisfies for linear interpolation.

An auxiliary question relates to subinterval function representation. Given the vector of discrete function values (2.6) and an interpolating polynomial (not necessarily compact), how does one *fill in* between the discrete function values by an iterative interpolation method? A "filled-in" function is the subinterval function representation (or subgrid resolution) resulting from a particular interpolation formula. The fill-in algorithm for scalar multiresolution analysis is given in Appendix C, and the generalization for a vector multiresolution analysis is given in Appendix D.

4. Accuracy of a scalar multiresolution algorithm. Let the function (2.7) be a polynomial, i.e.,

$$u(x) = x^q, \qquad 0 \le x \le 1, \tag{4.1}$$

where q is a nonnegative integer. On the grid points corresponding to the grid vector

$$\mathbf{x}^m = [x_1, x_2, \ldots, 1]^T, \quad x_j = j/2^m, \tag{4.2}$$

discrete values of the polynomial (4.1) are given by

$$\mathbf{u}^m = [x_1^q, x_2^q, \ldots, 1]^T. \tag{4.3}$$

From decomposition step (3.10a) the interpolation error or residual for $k = m$ is

$$r_j^{m-1} = u_{2j-1}^m - I^m(x_{2j-1}^m; u_{2j}^m), \quad j = 1, 2, \ldots, J_{m-1}, \tag{4.4}$$

where u_{2j}^m is the $2j$th component of (4.3). The number p of vanishing residuals of a multiresolution algorithm is defined by

$$\left[r_j^{m-1} = 0, \quad j = 1, 2, \ldots, J_{m-1}\right], \qquad q = 0, 1, \ldots, p-1 \tag{4.5a}$$

and

$$\left[r_j^{m-1} \neq 0, \quad j = 1, 2, \ldots, J_{m-1}\right], \qquad q = p. \tag{4.5b}$$

The order of accuracy is defined to be p. As an example, for linear interpolation (3.8) the number of vanishing residuals is $p = 2$ and the order of accuracy is 2. For cubic interpolation (3.9) the number of vanishing residuals is $p = 4$ and the order of accuracy is 4.

It is often convenient to define accuracy using vector-matrix notation. Denote the vector (4.3) by

$$[\mathbf{x}]^q = [x_1^q, x_2^q, \ldots, 1]^T. \tag{4.6}$$

The order of accuracy of a multiresolution algorithm is the number of vanishing moments of the error or residual operator $\mathbf{H}$ of (3.13a), i.e., if

$$\mathbf{H}[\mathbf{x}]^q = \mathbf{0}, \quad q = 0, 1, \ldots, p-1, \tag{4.7a}$$

and

$$\mathbf{H}[\mathbf{x}]^p \neq \mathbf{0}, \tag{4.7b}$$

then the order of accuracy is p. For periodic boundary conditions (2.5), the vectors $\mathbf{H}[\mathbf{x}]^q$, $q < p$, will have nonzero elements near the *ends* of the vector arrays since periodicity forces a jump in the function (4.1), except for $q = 0$. After proper adjustment of the scalar interpolation formula near the ends of the unit interval to account for nonperiodic boundary conditions, (4.7) will be satisfied exactly.

For an interpolatory multiresolution algorithm it is easy to analytically check the accuracy since the truncation error of the interpolation formula is the residual in the decomposition step. The truncation error for linear interpolation is given by (5.3) in the next section, and it is obvious that the error is zero if $u(x)$ is a linear function, and consequently, $p = 2$.

5. Compact interpolation formulas. Let $u(x)$ be a continuous periodic function on the interval $[0,1]$, i.e., $u(x) \in C[0,1]$. The discrete mesh or grid X^m defined by (2.1) is a uniform partition of $[0,1]$ by the points $0 = x_0 < x_1 < \cdots < x_j < \cdots < x_{J_m} = 1$. Let $\tilde{u}(x)$ be a piecewise polynomial which coincides with $u(x)$ at the grid points X^m called the interpolation points. The function $\tilde{u}(x)$ is a piecewise polynomial of degree $2\ell-1$ if in each subinterval $[x_{j-1}, x_j]$ it is a polynomial of degree $2\ell-1$.

In this paper a piecewise interpolating polynomial is said to be compact if it interpolates function values on the subinterval $[x_{j-1}, x_j]$ using only point values and (possibly) one or more derivatives of $u(x)$ at the end points x_{j-1} and x_j. If only point values are used, we use the terminology *scalar* compact interpolation. If point values and one or more derivative values are used, we use the terminology *vector* compact interpolation since more than one variable must be assigned to each grid point. Although in the multiresolution algorithms of this paper we assume uniform grid spacing, compact interpolation formulas are applicable for arbitrary spacing $h_j = x_j - x_{j-1}$.

To summarize, in the construction of a vector compact interpolation formula the function value and $(\ell-1)$ derivatives are given at each end point of the subinterval $[x_{j-1}, x_j]$. Consequently, we match 2ℓ conditions, and the interpolating piecewise polynomial has odd degree $2\ell-1$ with $\ell-1$ continuous derivatives.

The simplest example of a compact formula is (scalar) linear interpolation:

$$\tilde{u}_j(x) = a_j(x - x_{j-1}) + b_j, \quad x_{j-1} \le x \le x_j, \quad j = 0, 1, \ldots, J_m - 1, \tag{5.1a}$$

where

$$b_j = u(x_{j-1}), \tag{5.1b}$$

$$a_j = \frac{1}{h}[u(x_j) - u(x_{j-1})], \tag{5.1c}$$

$$h = x_j - x_{j-1}. \tag{5.1d}$$

In this case, $\tilde{u}(x)$ is a polynomial of degree 1 and is a straight line defined by (5.1). Evaluation of (5.1) at the midpoint of the subinterval $x_j - h/2$ yields

$$\tilde{u}_j(x_j - h/2) = \frac{1}{2}[u(x_j) + u(x_{j-1})]. \tag{5.2}$$

If $u(x) \in C^{(2)}[0,1]$, the truncation error of the midpoint interpolation (5.2) is found by a Taylor series expansion:

$$u(x_j - h/2) - \tilde{u}_j(x_j - h/2) = -\frac{1}{8}\left.\frac{d^2u}{dx^2}\right|_{x_j - h/2} h^2 + O(h^3). \tag{5.3}$$

The interpolation formula (5.1) is exact if $u(x)$ is a first degree (linear) polynomial.

An example of a noncompact interpolation formula is Newton's cubic interpolation formula

$$\begin{aligned}\tilde{u}_j(x) &= d_j + c_j(x - x_{j-2}) + b_j(x - x_{j-2})(x - x_{j-1}) \\ &\quad + a_j(x - x_{j-2})(x - x_{j-1})(x - x_j), \qquad x_{j-1} \le x \le x_j.\end{aligned} \tag{5.4}$$

Here function values $u(x_{j-2})$ and $u(x_{j+1})$ are required in addition to the local values $u(x_{j-1})$ and $u(x_j)$ to evaluate the coefficients a_j, b_j, c_j, and d_j. We also note that cubic spline interpolation is not compact since it requires nonlocal data.

Linear interpolation (5.1) is the only compact formula using only function values, i.e., the only *scalar* compact formula. In addition to low order approximation, it has the drawback of discontinuous derivatives at the interpolation points. We can obtain higher order accurate compact formulas and at the same time obtain smoother approximations by using Hermite (vector) interpolation where one matches derivatives as well as function values at the interpolation points. If $u(x) \in C^{(2\ell)}[0,1]$, the truncation error is of the order 2ℓ, i.e., $O(h^{2\ell})$, and the interpolating polynomial converges to $u(x)$ with order 2ℓ as $h \to 0$. Note that Hermite interpolation is exact if $u(x)$ is a polynomial of degree $2\ell - 1$ or less.

As an example, we consider compact Hermite interpolation which matches function values and first derivative values at the ends of the subinterval $[x_{j-1}, x_j]$. In the following, the first derivative of $u(x)$ is denoted by $u'(x)$. Here we assume that $u(x) \in C^{(1)}[0,1]$. Since there are four conditions $u(x_{j-1})$, $u'(x_{j-1})$, $u(x_j)$, and $u'(x_j)$ to match, it is clear that the interpolating polynomial is a cubic on each subinterval $[x_{j-1}, x_j]$:

$$\tilde{u}_j(x) = a_j(x - x_{j-1})^3 + b_j(x - x_{j-1})^2 + c_j(x - x_{j-1}) + d_j, \quad x_{j-1} \le x \le x_j. \tag{5.5}$$

The first derivative is

$$\tilde{u}_j'(x) = 3a_j(x - x_{j-1})^2 + 2b_j(x - x_{j-1}) + c_j, \quad x_{j-1} \le x \le x_j. \tag{5.6}$$

We enforce the conditions that the function $\tilde{u}_j(x)$ and its derivative $\tilde{u}_j'(x)$ agree with the exact values of $u(x)$ and its derivative at the ends of the subinterval $[x_{j-1}, x_j]$:

$$u(x_{j-1}) = d_j, \tag{5.7a}$$
$$u(x_j) = a_j h^3 + b_j h^2 + c_j h + d_j, \tag{5.7b}$$
$$u'(x_{j-1}) = c_j, \tag{5.7c}$$
$$u'(x_j) = 3a_j h^2 + 2b_j h + c_j. \tag{5.7d}$$

By solving the above equations for the coefficients, one obtains

$$d_j = u(x_{j-1}), \tag{5.8a}$$
$$c_j = u'(x_{j-1}), \tag{5.8b}$$
$$b_j = \frac{3}{h^2}[u(x_j) - u(x_{j-1})] - \frac{1}{h}[u'(x_j) + 2u'(x_{j-1})], \tag{5.8c}$$
$$a_j = -\frac{2}{h^3}[u(x_j) - u(x_{j-1})] + \frac{1}{h^2}[u'(x_j) + u'(x_{j-1})]. \tag{5.8d}$$

Evaluation of (5.5) at the midpoint of the subinterval $x_j - h/2$ yields

$$\tilde{u}_j(x_j - h/2) = \frac{1}{2}[u(x_j) + u(x_{j-1})] - \frac{h}{8}[u'(x_j) - u'(x_{j-1})], \tag{5.9a}$$

and evaluation of (5.6) at the midpoint of the subinterval $x_j - h/2$ yields

$$\tilde{u}_j'(x_j - h/2) = \frac{3}{2h}[u(x_j) - u(x_{j-1})] - \frac{1}{4}[u'(x_j) + u'(x_{j-1})]. \tag{5.9b}$$

If $u(x) \in C^{(4)}[0,1]$, the truncation error of the midpoint interpolation (5.9a) is found by Taylor series expansion:

$$u(x_j - h/2) - \tilde{u}_j(x_j - h/2) = \frac{1}{384} \left.\frac{d^4u}{dx^4}\right|_{x_j - h/2} h^4 + O(h^5). \tag{5.10a}$$

Furthermore, if $u(x) \in C^{(5)}[0,1]$, the truncation error of the midpoint interpolation (5.9b) is found by Taylor series expansion:

$$u'(x_j - h/2) - \tilde{u}'_j(x_j - h/2) = \frac{1}{1920} \left.\frac{d^5u}{dx^5}\right|_{x_j - h/2} h^4 + O(h^5). \tag{5.10b}$$

The error terms shown above are consistent with the fact that Hermite interpolation formulas (5.5) and (5.6) are exact if $u(x)$ is a polynomial of degree 3 or less.

In Appendix E of [Wa97] we give two additional compact Hermite interpolation formulas. In particular, we derive compact interpolation formulas which match function values and first and second derivatives at the ends of the subinterval $[x_{j-1}, x_j]$. In addition, we derive compact interpolation formulas which match function values and second derivatives at the ends of the subinterval $[x_{j-1}, x_j]$.

In the multiresolution algorithm one only needs the interpolation formulas (5.9) at the subinterval midpoints (see section 6). However, if one wants to derive analytic formulas for the multiresolution analysis basis functions, then the Hermite interpolating polynomials (5.5) and (5.6) are required. If a compact interpolation formula is used in an interpolatory multiresolution scheme, the resulting multiple basis functions are piecewise polynomials (two pieces) of odd degree $2\ell - 1$ with $\ell - 1$ derivatives. Analytical formulas for the basis functions for several cases are given in Appendix E. (In Appendix E the basis functions are referred to as unit interpolation functions. See also the first paragraph of Appendix A.)

6. Vector multiresolution algorithm. In this section we generalize the scalar multiresolution algorithm of section 3 to vector multiresolution for the special case where a function u and its derivative u' are given on the mesh X^m. In many applications, only point values are given and the requisite derivatives may need to be computed by finite difference formulas. We consider this topic in section 8.

Point values and derivative values at even-numbered grid points are projected from level k to $k-1$:

$$u_j^{k-1} = u_{2j}^k, \quad j = 1, 2, \ldots, J_{k-1} \tag{6.1a}$$

$$u_j^{'k-1} = u'k_{2j}, \quad j = 1, 2, \ldots, J_{k-1}. \tag{6.1b}$$

Recalling the interpolation formulas (5.9) it is convenient to remove the explicit dependence on the spacing h_m by defining $v(x_j^m)$:

$$v(x_j^m) = h_m u'(x_j^m). \tag{6.2}$$

From (2.1) the spacings on two successive levels are related by $h_{k-1} = 2h_k$, and hence one can rewrite (6.1b) as

$$v_j^{k-1} = 2v_{2j}^k, \quad j = 1, 2, \ldots, J_{k-1}. \tag{6.3}$$

On the uniform grid X^{k-1} defined by (2.1), the midpoint interpolation formulas (5.9) are

$$\tilde{u}^{k-1}_{j-1/2} = I^{k-1}_u(x^{k-1}_{j-1/2}; [u^{k-1}_j, v^{k-1}_j]) = \frac{1}{2}(u^{k-1}_j + u^{k-1}_{j-1}) - \frac{1}{8}(v^{k-1}_j - v^{k-1}_{j-1}), \tag{6.4a}$$

$$\tilde{v}^{k-1}_{j-1/2} = I^{k-1}_v(x^{k-1}_{j-1/2}; [u^{k-1}_j, v^{k-1}_j]) = \frac{3}{2}(u^{k-1}_j - u^{k-1}_{j-1}) - \frac{1}{4}(v^{k-1}_j + v^{k-1}_{j-1}). \tag{6.4b}$$

The projections (6.1a) and (6.3) are used to rewrite (6.4) on grid X^k:

$$\tilde{u}^k_{2j-1} = I^k_u(x^k_{2j-1}; [u^k_{2j}, v^k_{2j}]) = \frac{1}{2}(u^k_{2j} + u^k_{2j-2}) - \frac{1}{4}(v^k_{2j} - v^k_{2j-2}), \tag{6.5a}$$

$$\tilde{v}^k_{2j-1} = I^k_v(x^k_{2j-1}; [u^k_{2j}, v^k_{2j}]) = \frac{3}{4}(u^k_{2j} - u^k_{2j-2}) - \frac{1}{4}(v^k_{2j} + v^k_{2j-2}). \tag{6.5b}$$

Here the function $I^k_u(x^k_{2j-1}; [u^k_{2j}, v^k_{2j}])$ interpolates odd-point values u^k_{2j-1} (at odd grid points x^k_{2j-1}) using even-point values $[u^k_{2j}, v^k_{2j}]$. Likewise $I^k_v(x^k_{2j-1}; [u^k_{2j}, v^k_{2j}])$ interpolates odd derivative values v^k_{2j-1} (at odd grid points x^k_{2j-1}) using even-point values $[u^k_{2j}, v^k_{2j}]$. An obvious generalization of the scalar multiresolution algorithm (3.10) is

decomposition

For $k = m, m-1, \ldots, n+1$
  For $j = 1, 2, \ldots, J_{k-1}$

$$u^{k-1}_j = u^k_{2j},$$
$$v^{k-1}_j = 2v^k_{2j},$$

$$(r_u)^{k-1}_j = u^k_{2j-1} - I^k_u(x^k_{2j-1}; [u^k_{2j}, v^k_{2j}]), \tag{6.6a}$$
$$(r_v)^{k-1}_j = v^k_{2j-1} - I^k_v(x^k_{2j-1}; [u^k_{2j}, v^k_{2j}]),$$

  End
End

reconstruction

For $k = n+1, n+2, \ldots, m$
  For $j = 1, 2, \ldots, J_{k-1}$

$$u^k_{2j} = u^{k-1}_j,$$
$$v^k_{2j} = \frac{1}{2}v^{k-1}_j,$$

$$u^k_{2j-1} = I^k_u(x^k_{2j-1}; [u^k_{2j}, v^k_{2j}]) + (r_u)^{k-1}_j, \tag{6.6b}$$
$$v^k_{2j-1} = I^k_v(x^k_{2j-1}; [u^k_{2j}, v^k_{2j}]) + (r_v)^{k-1}_j,$$

  End
End

Alternatively, the reconstruction algorithm (6.6b) can be written as

reconstruction

For $k = n+1, n+2, \ldots, m$
For $j = 1, 2, \ldots, J_{k-1}$

$$u_{2j}^k = u_j^{k-1},$$
$$v_{2j}^k = \frac{1}{2} v_j^{k-1},$$

(6.6c)
$$u_{2j-1}^k = I_u^{k-1}(x_{j-1/2}^{k-1}; [u_j^{k-1}, v_j^{k-1}]) + (r_u)_j^{k-1},$$
$$v_{2j-1}^k = \frac{1}{2} I_v^{k-1}(x_{j-1/2}^{k-1}; [u_j^{k-1}, v_j^{k-1}]) + (r_v)_j^{k-1},$$

End
End

In the generalization of the next section it will be convenient to introduce vector-matrix notation. The vector of point values at the finest level $k = m$ is defined by (2.6):

$$\mathbf{u}^m = [u_1^m, u_2^m, \ldots, u_{J_m}^m]^T, \qquad J_m = 2^m, \tag{6.7a}$$

where

$$u_j^m = u(x_j^m), \quad j = 1, 2, \ldots J_m. \tag{6.7b}$$

The vector of scaled derivatives at the finest level is denoted by

$$\mathbf{v}^m = h_m[u_1'^m, u_2'^m, \ldots, u_{J_m}'^m]^T = [v_1^m, v_2^m, \ldots, v_{J_m}^m]^T, \qquad J_m = 2^m, \tag{6.8a}$$

where

$$v_j^m = h_m \frac{d}{dx} u(x_j^m) = h_m u_j'^m. \tag{6.8b}$$

The input array is represented in matrix form as

$$\boldsymbol{\mathcal{U}}^m = [\mathbf{u}^m, \mathbf{v}^m], \tag{6.9}$$

where $\boldsymbol{\mathcal{U}}^m$ is a $J_m \times 2$ matrix. The vector multiresolution algorithm can be represented as a pyramid scheme analogous to (3.19). The output array at the end of the decomposition is

$$\boldsymbol{\mathcal{D}}^m = [\mathbf{d}_u^m, \mathbf{d}_v^m]. \tag{6.10}$$

Here $\boldsymbol{\mathcal{D}}^m$ is the multiresolution decomposition of $\boldsymbol{\mathcal{U}}^m$. As in the scalar case, a compact way to code the multiresolution pyramid algorithm is to start with the input matrix $\boldsymbol{\mathcal{U}}^m$ (or $\boldsymbol{\mathcal{D}}^m$) and overwrite $\boldsymbol{\mathcal{U}}^m$ (or $\boldsymbol{\mathcal{D}}^m$) at every step of the decomposition (or reconstruction) to obtain $\boldsymbol{\mathcal{D}}^m$ (or $\boldsymbol{\mathcal{U}}^m$).

In a vector compact interpolatory multiresolution algorithm, the unit interpolation functions play the role of the scaling functions. In Appendix A we define the unit interpolation functions and derive the vector dilation equation which they satisfy.

7. General vector multiresolution algorithm. We now want to generalize the algorithm of the previous section to a vector multiresolution algorithm for any combination of u and one or more derivatives of u. For example, one could have u, u', and u'', or u and u''.

7.1. Notation and pyramid scheme. At the finest level $k = m$ let

$$\boldsymbol{\mathcal{U}}^m = [\mathbf{u}_1^m, \mathbf{u}_2^m, \dots, \mathbf{u}_\iota^m] \tag{7.1}$$

denote a $J_m \times \iota$ matrix. The dimension of each column vector $\mathbf{u}_i^m$ is J_m. For the multiresolution of the previous section $\iota = 2$ and

$$\mathbf{u}_1^m = \mathbf{u}^m \quad \text{and} \quad \mathbf{u}_2^m = \mathbf{v}^m, \tag{7.2}$$

where $\mathbf{u}^m$ and $\mathbf{v}^m$ are defined by (6.7) and (6.8).

The multiresolution decomposition of $\boldsymbol{\mathcal{U}}^m$ is denoted by

$$\boldsymbol{\mathcal{D}}^m = [\mathbf{d}_1^m, \mathbf{d}_2^m, \dots, \mathbf{d}_\iota^m]. \tag{7.3}$$

At level k the matrices

$$\boldsymbol{\mathcal{U}}^k = [\mathbf{u}_1^k, \mathbf{u}_2^k, \dots, \mathbf{u}_\iota^k], \tag{7.4a}$$

$$\boldsymbol{\mathcal{R}}^k = [\mathbf{r}_1^k, \mathbf{r}_2^k, \dots, \mathbf{r}_\iota^k] \tag{7.4b}$$

have dimension $J_k \times \iota$. The matrix $\boldsymbol{\mathcal{R}}^k$ is the array of residual values at the kth level of resolution. For a vector multiresolution algorithm, the analogue of (3.18) is

$$[\,\acute{\boldsymbol{\mathcal{U}}}^k] \rightleftharpoons [\,\acute{\boldsymbol{\mathcal{U}}}^{k-1}, \acute{\boldsymbol{\mathcal{R}}}^{k-1}] \tag{7.5}$$

with an obvious generalization of the pyramid scheme (3.19).

$$[\,\acute{\boldsymbol{\mathcal{U}}}^m] \rightleftharpoons [\,\acute{\boldsymbol{\mathcal{U}}}^{m-1}, \acute{\boldsymbol{\mathcal{R}}}^{m-1}] \rightleftharpoons [\,\acute{\boldsymbol{\mathcal{U}}}^{m-2}, \acute{\boldsymbol{\mathcal{R}}}^{m-2}, \acute{\boldsymbol{\mathcal{R}}}^{m-1}] \rightleftharpoons \cdots$$

$$\rightleftharpoons [\,\acute{\boldsymbol{\mathcal{U}}}^n, \acute{\boldsymbol{\mathcal{R}}}^n, \dots, \acute{\boldsymbol{\mathcal{R}}}^k, \dots, \acute{\boldsymbol{\mathcal{R}}}^{m-2}, \acute{\boldsymbol{\mathcal{R}}}^{m-1}] = [\,\acute{\boldsymbol{\mathcal{D}}}^m]. \tag{7.6}$$

In (7.5) and (7.6) the accent prime denotes a matrix transpose.

The jth rows of $\boldsymbol{\mathcal{U}}^k$ and $\boldsymbol{\mathcal{R}}^k$ are denoted by

$$\boldsymbol{\mathcal{U}}_j^k = [u_{1,j}^k, u_{2,j}^k, \dots, u_{\iota,j}^k], \tag{7.7a}$$

$$\boldsymbol{\mathcal{R}}_j^k = [r_{1,j}^k, r_{2,j}^k, \dots, r_{\iota,j}^k], \tag{7.7b}$$

and hence

$$\boldsymbol{\mathcal{U}}^k = \begin{bmatrix} \boldsymbol{\mathcal{U}}_1^k \\ \boldsymbol{\mathcal{U}}_2^k \\ \cdot \\ \cdot \\ \cdot \\ \boldsymbol{\mathcal{U}}_{J_k-1}^k \\ \boldsymbol{\mathcal{U}}_{J_k}^k \end{bmatrix}, \tag{7.8a}$$

$$\boldsymbol{\mathcal{R}}^k = \begin{bmatrix} \boldsymbol{\mathcal{R}}^k_1 \\ \boldsymbol{\mathcal{R}}^k_2 \\ \cdot \\ \cdot \\ \cdot \\ \boldsymbol{\mathcal{R}}^k_{J_k-1} \\ \boldsymbol{\mathcal{R}}^k_{J_k} \end{bmatrix}. \tag{7.8b}$$

We also need a symbolic notation for the requisite interpolation formulas. A row vector of interpolated values is

$$\boldsymbol{\mathcal{I}}^k[x^k_{2j-1};\boldsymbol{\mathcal{U}}^k_{2j}] = [I^k_1(x^k_{2j-1};\boldsymbol{\mathcal{U}}^k_{2j}), I^k_2(x^k_{2j-1};\boldsymbol{\mathcal{U}}^k_{2j}), \dots, I^k_\iota(x^k_{2j-1};\boldsymbol{\mathcal{U}}^k_{2j})]. \tag{7.9}$$

Here $\boldsymbol{\mathcal{I}}^k[x^k_{2j-1};\boldsymbol{\mathcal{U}}^k_{2j}]$ interpolates odd-point values $\boldsymbol{\mathcal{U}}^k_{2j-1}$ (at odd grid points x^k_{2j-1}) using even-point values $\boldsymbol{\mathcal{U}}^k_{2j}$. For example, from the previous section, (6.5) is written as

$$\boldsymbol{\mathcal{I}}^k[x^k_{2j-1};\boldsymbol{\mathcal{U}}^k_{2j}] = [I^k_1(x^k_{2j-1};\boldsymbol{\mathcal{U}}^k_{2j}), I^k_2(x^k_{2j-1};\boldsymbol{\mathcal{U}}^k_{2j})]$$

$$= \Big[\frac{1}{2}(u^k_{2j} + u^k_{2j-2}) - \frac{1}{4}(v^k_{2j} - v^k_{2j-2}), \frac{3}{4}(u^k_{2j} - u^k_{2j-2}) - \frac{1}{4}(v^k_{2j} + v^k_{2j-2})\Big]. \tag{7.10}$$

Finally, in the projection step we need to allow for the possibility of multiplying (or dividing) each column of $\boldsymbol{\mathcal{U}}^k$ by a different constant value. Let

$$\boldsymbol{\alpha} = [\alpha_1, \alpha_2, \dots, \alpha_\iota] \tag{7.11}$$

and define

$$\boldsymbol{\mathcal{P}}_{*\boldsymbol{\alpha}}(\boldsymbol{\mathcal{U}}^k_{2j}) = [\alpha_1 u^k_{1,2j}, \alpha_2 u^k_{2,2j}, \dots, \alpha_\iota u^k_{\iota,2j}] \tag{7.12a}$$

$$\boldsymbol{\mathcal{P}}_{/\boldsymbol{\alpha}}(\boldsymbol{\mathcal{U}}^{k-1}_j) = [u^{k-1}_{1,j}/\alpha_1, u^{k-1}_{2,j}/\alpha_2, \dots, u^{k-1}_{\iota,j}/\alpha_\iota]. \tag{7.12b}$$

In MATLAB notation

$$\boldsymbol{\mathcal{P}}_{*\boldsymbol{\alpha}}(\boldsymbol{\mathcal{U}}^k_{2j}) = \boldsymbol{\mathcal{U}}^k_{2j} .* \boldsymbol{\alpha}, \qquad \boldsymbol{\mathcal{P}}_{/\boldsymbol{\alpha}}(\boldsymbol{\mathcal{U}}^k_j) = \boldsymbol{\mathcal{U}}^k_j ./ \boldsymbol{\alpha}. \tag{7.13}$$

7.2. Computational algorithm. Using the above vector-matrix notation, the decomposition and reconstruction algorithms are written as

decomposition

For $k = m, m-1, \dots, n+1$
  For $j = 1, 2, \dots, J_{k-1}$

$$\begin{aligned} \boldsymbol{\mathcal{U}}^{k-1}_j &= \boldsymbol{\mathcal{P}}_{*\boldsymbol{\alpha}}(\,\boldsymbol{\mathcal{U}}^k_{2j}), \\ \boldsymbol{\mathcal{R}}^{k-1}_j &= \boldsymbol{\mathcal{U}}^k_{2j-1} - \boldsymbol{\mathcal{I}}^k[x^k_{2j-1};\boldsymbol{\mathcal{U}}^k_{2j}], \end{aligned} \tag{7.14a}$$

  End
End

reconstruction

For $k = n+1, n+2, \ldots, m$
  For $j = 1, 2, \ldots, J_{k-1}$

$$\begin{aligned} \boldsymbol{\mathcal{U}}_{2j}^{k} &= \boldsymbol{\mathcal{P}}_{/\boldsymbol{\alpha}}(\boldsymbol{\mathcal{U}}_{j}^{k-1}), \\ \boldsymbol{\mathcal{U}}_{2j-1}^{k} &= \boldsymbol{\mathcal{I}}^{k}[x_{2j-1}^{k}; \boldsymbol{\mathcal{U}}_{2j}^{k}] + \boldsymbol{\mathcal{R}}_{j}^{k-1}, \end{aligned} \tag{7.14b}$$

  End
End

Alternatively, the reconstruction algorithm can be rewritten as

reconstruction

For $k = n+1, n+2, \ldots, m$
  For $j = 1, 2, \ldots, J_{k-1}$

$$\begin{aligned} \boldsymbol{\mathcal{U}}_{2j}^{k} &= \boldsymbol{\mathcal{P}}_{/\boldsymbol{\alpha}}(\boldsymbol{\mathcal{U}}_{j}^{k-1}), \\ \boldsymbol{\mathcal{U}}_{2j-1}^{k} &= \boldsymbol{\mathcal{P}}_{/\boldsymbol{\alpha}}(\boldsymbol{\mathcal{I}}^{k-1}[x_{j-1/2}^{k-1}; \boldsymbol{\mathcal{U}}_{j}^{k-1}]) + \boldsymbol{\mathcal{R}}_{j}^{k-1}, \end{aligned} \tag{7.14c}$$

  End
End

7.3. Vector-matrix form of algorithm. For analysis and exposition purposes the decomposition and reconstruction algorithms (7.14a) and (7.14c) can also be written in vector-matrix form as

decomposition

For $k = m, m-1, \ldots, n+1$
  For $j = 1, 2, \ldots, J_{k-1}$

$$\begin{aligned} \acute{\boldsymbol{\mathcal{U}}}_{j}^{k-1} &= \mathbf{C}_0\, \acute{\boldsymbol{\mathcal{U}}}_{2j}^{k}, \\ \acute{\boldsymbol{\mathcal{R}}}_{j}^{k-1} &= \mathbf{D}_0\, \acute{\boldsymbol{\mathcal{U}}}_{2j-2}^{k} + \mathbf{D}_1\, \acute{\boldsymbol{\mathcal{U}}}_{2j-1}^{k} + \mathbf{D}_2\, \acute{\boldsymbol{\mathcal{U}}}_{2j}^{k}, \end{aligned} \tag{7.15a}$$

  End
End

reconstruction

For $k = n+1, n+2, \ldots, m$
  For $j = 1, 2, \ldots, J_{k-1}$

$$\begin{aligned} \acute{\boldsymbol{\mathcal{U}}}_{2j}^{k} &= \mathbf{F}_1\, \acute{\boldsymbol{\mathcal{U}}}_{j}^{k-1}, \\ \acute{\boldsymbol{\mathcal{U}}}_{2j-1}^{k} &= \mathbf{F}_2\, \acute{\boldsymbol{\mathcal{U}}}_{j-1}^{k-1} + \mathbf{F}_0\, \acute{\boldsymbol{\mathcal{U}}}_{j}^{k-1} + \mathbf{E}_0\, \acute{\boldsymbol{\mathcal{R}}}_{j}^{k-1}, \end{aligned} \tag{7.15b}$$

  End
End,

where

$$\acute{\boldsymbol{\mathcal{U}}}_j^k = \begin{bmatrix} u_{1,j}^k \\ u_{2,j}^k \\ \vdots \\ u_{\iota,j}^k \end{bmatrix}, \tag{7.16a}$$

$$\acute{\boldsymbol{\mathcal{R}}}_j^k = \begin{bmatrix} r_{1,j}^k \\ r_{2,j}^k \\ \vdots \\ r_{\iota,j}^k \end{bmatrix} \tag{7.16b}$$

are column vectors (see (7.7)). The square matrices $\mathbf{C}_0$, $\mathbf{D}_j$, $\mathbf{F}_j$, and $\mathbf{E}_0$ have dimension $\iota \times \iota$. For an interpolatory multiresolution algorithm, the reconstruction step (7.15b) is an obvious reversal or inverse of the decomposition step, and hence

$$\mathbf{F}_0 = -\mathbf{D}_2\mathbf{C}_0^{-1}, \quad \mathbf{F}_1 = \mathbf{C}_0^{-1}, \quad \mathbf{F}_2 = -\mathbf{D}_0\mathbf{C}_0^{-1}. \tag{7.17}$$

For the special case of section 6 where a function and its derivative are given on the mesh X^m, the matrices are given by

$$\mathbf{C}_0 = \begin{bmatrix} 1 & 0 \\ 0 & 2 \end{bmatrix}, \tag{7.18a}$$

$$\mathbf{D}_0 = \begin{bmatrix} -1/2 & -1/4 \\ 3/4 & 1/4 \end{bmatrix}, \tag{7.18b}$$

$$\mathbf{D}_1 = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, \tag{7.18c}$$

$$\mathbf{D}_2 = \begin{bmatrix} -1/2 & 1/4 \\ -3/4 & 1/4 \end{bmatrix}, \tag{7.18d}$$

$$\mathbf{F}_1 = \mathbf{C}_0^{-1} = \begin{bmatrix} 1 & 0 \\ 0 & 1/2 \end{bmatrix}, \tag{7.18e}$$

$$\mathbf{E}_0 = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, \tag{7.18f}$$

$$\mathbf{F}_0 = -\mathbf{D}_2\mathbf{C}_0^{-1} = \begin{bmatrix} 1/2 & -1/8 \\ 3/4 & -1/8 \end{bmatrix}, \tag{7.18g}$$

$$\mathbf{F}_2 = -\mathbf{D}_0\mathbf{C}_0^{-1} = \begin{bmatrix} 1/2 & 1/8 \\ -3/4 & -1/8 \end{bmatrix}. \tag{7.18h}$$

For comparison with the notation for multiwavelets used by Strang and Strela [St94] it is convenient to have the decomposition and reconstruction algorithms in matrix notation:

decomposition

For $k = m, m-1, \ldots, n+1$

$$\begin{aligned} \mathbf{U}^{k-1} &= \mathbf{L}\mathbf{U}^{k}, \\ \mathbf{R}^{k-1} &= \mathbf{H}\mathbf{U}^{k}, \end{aligned} \tag{7.19a}$$

End

reconstruction

For $k = n+1, n+2, \ldots, m$

$$\mathbf{U}^{k} = \mathbf{L}^{s}\mathbf{U}^{k-1} + \mathbf{H}^{s}\mathbf{R}^{k-1} \tag{7.19b}$$

End,

where

$$\mathbf{U}^{k} = \begin{bmatrix} \acute{\boldsymbol{u}}_{1}^{k} \\ \acute{\boldsymbol{u}}_{2}^{k} \\ \vdots \\ \acute{\boldsymbol{u}}_{2^k}^{k} \end{bmatrix}; \qquad \mathbf{R}^{k} = \begin{bmatrix} \acute{\boldsymbol{\mathcal{R}}}_{1}^{k} \\ \acute{\boldsymbol{\mathcal{R}}}_{2}^{k} \\ \vdots \\ \acute{\boldsymbol{\mathcal{R}}}_{2^k}^{k} \end{bmatrix}. \tag{7.20}$$

The length (dimension) of the column vectors $\mathbf{U}^k$ and $\mathbf{R}^k$ is $\iota \times 2^k$. The block rectangular matrices $\mathbf{L}$ and $\mathbf{H}$ have block dimension $2^{k-1} \times 2^k$ with subblock size $\iota \times \iota$, and block matrices $\mathbf{L}^s$ and $\mathbf{H}^s$ have block dimension $2^k \times 2^{k-1}$. To indicate the form of the block matrices we write out the matrices for the special case $k = 3$ with periodic boundary conditions:

$$\mathbf{L} = \begin{bmatrix} 0 & \mathbf{C}_0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & \mathbf{C}_0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & \mathbf{C}_0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & \mathbf{C}_0 \end{bmatrix}, \tag{7.21a}$$

$$\mathbf{H} = \begin{bmatrix} \mathbf{D}_1 & \mathbf{D}_2 & 0 & 0 & 0 & 0 & 0 & \mathbf{D}_0 \\ 0 & \mathbf{D}_0 & \mathbf{D}_1 & \mathbf{D}_2 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & \mathbf{D}_0 & \mathbf{D}_1 & \mathbf{D}_2 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & \mathbf{D}_0 & \mathbf{D}_1 & \mathbf{D}_2 \end{bmatrix}, \tag{7.21b}$$

$$\mathbf{L}^{s} = \begin{bmatrix} \mathbf{F}_0 & 0 & 0 & \mathbf{F}_2 \\ \mathbf{F}_1 & 0 & 0 & 0 \\ \mathbf{F}_2 & \mathbf{F}_0 & 0 & 0 \\ 0 & \mathbf{F}_1 & 0 & 0 \\ 0 & \mathbf{F}_2 & \mathbf{F}_0 & 0 \\ 0 & 0 & \mathbf{F}_1 & 0 \\ 0 & 0 & \mathbf{F}_2 & \mathbf{F}_0 \\ 0 & 0 & 0 & \mathbf{F}_1 \end{bmatrix}, \tag{7.21c}$$

$$\mathbf{H}^s = \begin{bmatrix} \mathbf{E}_0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & \mathbf{E}_0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & \mathbf{E}_0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & \mathbf{E}_0 \\ 0 & 0 & 0 & 0 \end{bmatrix}. \tag{7.21d}$$

The rectangular matrices satisfy the identities (3.15). For orthogonal multiwavelets, one has $\mathbf{L}^s = \mathbf{L}'$ and $\mathbf{H}^s = \mathbf{H}'$, which is clearly not the case for the biorthogonal multiwavelets of this paper.

For the compact scalar algorithm (linear interpolation) of section 3, the submatrices appearing in the above matrices are scalar entries. The appropriate entry is the first element of each of the matrices (7.18):

$$C_0 = 1, \quad D_0 = -1/2, \quad D_1 = 1, \quad D_2 = -1/2, \tag{7.22a}$$

$$F_0 = 1/2, \quad F_1 = 1, \quad F_2 = 1/2, \quad E_0 = 1. \tag{7.22b}$$

7.4. Vector interpolation formulas and basis functions. To implement a vector multiresolution algorithm for any particular case, one needs the appropriate compact Hermite interpolation formulas. In Appendix F of [Wa97] we consider the case of function values and first and second derivative values and the case of function values and second derivative values.

Analytical formulas for the basis functions corresponding to several vector multiresolution algorithms based on compact Hermite interpolation are given in Appendix E of [Wa97].

The fill-in algorithm for vector multiresolution is described in Appendix D of the present paper. A "filled-in" function and one or more derivatives is the subinterval function representation (or subgrid resolution) resulting from a particular compact Hermite interpolation formula.

8. Point value implementation of a vector multiresolution algorithm. In this section we consider an implementation of a vector multiresolution algorithm if only point values are given. If the point values and first derivative values are both given on the finest grid X^m, then one can apply the algorithm of section 7 directly and form $J_m \times 2$ array

$$\boldsymbol{\mathcal{U}}^m = [\mathbf{u}^m, \mathbf{v}^m] \tag{8.1}$$

defined by (6.9). In the notation of section 7, we rewrite (8.1) as

$$\boldsymbol{\mathcal{U}}^m = [\mathbf{u}_1^m, \mathbf{u}_2^m]. \tag{8.2}$$

8.1. Preprocessing. If only point values are given on the finest grid, i.e.,

$$\mathbf{u}^m = \mathbf{u}_1^m = [u_1^m, u_2^m, \ldots, u_{J_m}^m]^T, \qquad J_m = 2^m, \tag{8.3}$$

we require a preprocessing step. The requisite derivatives at each point on the finest grid are computed using the point values (8.3) and a numerical differentiation formula.

A difference quotient consistent with the accuracy and compactness of the compact Hermite interpolation formulas (5.9) is the Hermite or Padé formula

$$u'(x_{j-1}) + 4u'(x_j) + u'(x_{j+1}) = -\frac{3}{h}[u(x_{j-1}) - u(x_{j+1})]$$

$$+\frac{1}{30}u^{(5)}(\eta)\ h^4, \quad x_{j-1} < \eta < x_{j+1}, \tag{8.4}$$

where $h = x_{j+1} - x_j$ for uniform spacing. In writing (8.4) we assume $u(x) \in C^{(5)}[0,1]$. A Hermite or Padé difference approximation is obtained from (8.4) by dropping the error term and replacing $u(x_j)$ and $u'(x_j)$ by the discrete values u_j and u'_j, i.e.,

$$u'_{j-1} + 4u'_j + u'_{j+1} = -\frac{3}{h}[u_{j-1} - u_{j+1}]. \tag{8.5}$$

Note that (8.5) is consistent with (5.9b) rewritten to coincide with the grid points.

Following this procedure would introduce a derivative value for each point value and double the size of the input array, but it would add no additional information. To retain the size of the input vector array (8.3) we keep point values at even grid points and compute the derivatives numerically at the even grid points by using odd-point values. The Hermite formula (8.4) is modified to obtain

$$u'(x_{j-2}) + 22u'(x_j) + u'(x_{j+2}) = -\frac{12}{h}[u(x_{j-1}) - u(x_{j+1})]$$

$$-\frac{17}{15}u^{(5)}(\eta)\ h^4, \quad x_{j-2} < \eta < x_{j+2}, \tag{8.6}$$

where $h = x_{j+1} - x_j$. It is obvious that derivatives computed from the above formula are exact if $u(x)$ is a quartic polynomial. On the even grid points of the discrete grid X^m, the formula (8.6) becomes the approximation

$$v_{j-2} + 22v_j + v_{j+2} = -24[u_{j-1} - u_{j+1}], \quad j = 2, 4, 6, \ldots, J_m, \tag{8.7}$$

where $v_j = 2hu'_j$. In the definition of v_j the factor $2h$ appears rather than h since the derivatives are only computed on the even grid points and the equivalent spacing is $2h$. The right-hand side of (8.7) is evaluated using odd-point values because if only even points appear on the right-hand side, one cannot recover the odd-point values at the completion of the reconstruction step of the multiresolution algorithm (see below). For periodic boundary conditions, (8.7) leads to a circulant tridiagonal Toeplitz matrix that must be "inverted" to solve for the even-point values v_j. The transformed input array is given by (8.2), where

$$\mathbf{u}_1^m = [u_2^m, u_4^m, \ldots, u_{J_m}^m]^T, \qquad J_m = 2^m \tag{8.8a}$$

$$\mathbf{u}_2^m = [v_2^m, v_4^m, \ldots, v_{J_m}^m]^T, \qquad J_m = 2^m \tag{8.8b}$$

and $v_j = 2h_m u'_j$. The modified input array size is $J_{m-1} \times 2$ and has the same number of elements as the input array (8.3).

8.2. Postprocessing. At the completion of the reconstruction step of the multiresolution algorithm, a postprocessing step is required to recover point values at the odd grid points by rewriting (8.7):

$$[u_{j-1} - u_{j+1}] = -\frac{1}{24}[v_{j-2} + 22v_j + v_{j+2}], \qquad j = 2, 4, 6, \ldots, J_m. \tag{8.9}$$

For periodic boundary conditions, one cannot solve the inverse transformation (8.9) to find the odd-point values because the resulting circulant bidiagonal Toeplitz matrix is singular. This problem always occurs with centered difference approximations and periodic boundary conditions. The singularity can be avoided by the artifice of *saving* the odd-point value u_1 and using it in the postprocessing step. The matrix is then a pure bidiagonal Toeplitz matrix, and the linear system is easily solved by a sweep across the grid.

By choosing an uncentered difference approximation, one avoids the singular matrix problem resulting from periodic boundary conditions. As an example, derivatives at the even grid points (as in the preprocessing step) can be computed from an explicit unsymmetric fourth-order difference approximation:

$$v_j = 2hu'_j = \frac{1}{6}[-u_{j-3} + 6u_{j-2} - 18u_{j-1} + 10u_j + 3u_{j+1}], \qquad j = 2, 4, 6, \ldots, J_m. \tag{8.10}$$

Derivatives computed from this difference approximation are exact if $u(x)$ is a quartic polynomial. The transformed input array is (8.2) with (8.8b) computed using (8.10). To recover the odd-point values from (8.8b), one rewrites (8.10) as

$$u_{j-2} + 18u_j - 3u_{j+2} = -6v_{j+1} + 6u_{j-1} + 10u_{j+1}, \quad j = 1, 3, \ldots, J_m - 1. \tag{8.11}$$

For periodic boundary conditions, (8.11) leads to a nonsingular circulant tridiagonal Toeplitz matrix that must be "inverted" to solve for the odd-point values.

9. Accuracy of a vector multiresolution algorithm. The definition of accuracy for a vector multiresolution algorithm is an obvious generalization of the scalar case of section 4. For example, the input array for point values and derivatives of the polynomial (4.1) of section 4 is

$$\boldsymbol{\mathcal{U}}^m = [\mathbf{u}_1^m, \mathbf{u}_2^m], \tag{9.1a}$$

where

$$\mathbf{u}_1^m = [x_1^q, x_2^q, \ldots, 1]^T, \ h_m = 1/2^m, \tag{9.1b}$$

$$\mathbf{u}_2^m = h_m[qx_1^{q-1}, qx_2^{q-1}, \ldots, q]^T, \ h_m = 1/2^m. \tag{9.1c}$$

If the point value input vector is the polynomial array (9.1b), then clearly the scaled (by h) derivative input vector is (9.1c).

From the decomposition step (7.14a) the residual vector for $k = m$ is

$$\boldsymbol{\mathcal{R}}_j^{m-1} = \boldsymbol{\mathcal{U}}_{2j-1}^m - \boldsymbol{\mathcal{I}}^m(x_{2j-1}^m; \boldsymbol{\mathcal{U}}_{2j}^m), \quad j = 1, \ldots, J_{m-1}, \tag{9.2}$$

where $\boldsymbol{\mathcal{U}}_{2j}^m$ is the $2j$th row of (9.1a). The number p of vanishing residuals of a multiwavelet algorithm is defined by

$$\left[\boldsymbol{\mathcal{R}}_j^{m-1} = \mathbf{0}, \quad j = 1, 2, \ldots, J_{m-1}\right], \qquad q = 0, 1, \ldots, p-1 \tag{9.3a}$$

and

$$\big[\boldsymbol{\mathcal{R}}_j^{m-1} \neq \mathbf{0}, \quad j = 1, 2, \ldots, J_{m-1}\big], \qquad q = p. \tag{9.3b}$$

The order of accuracy is defined to be p. Recall from section 5 that for compact interpolation, the interpolating polynomial has odd degree $2\ell - 1$. Hence the number of vanishing residuals is $p = 2\ell$. As an example, for point values and derivatives using Hermite interpolation (5.9), the number of vanishing residuals is $p = 2\ell = 4$ and the order of accuracy is 4.

For a vector interpolatory multiresolution algorithm one can easily check the accuracy since the truncation errors of the interpolation formulas are the residuals in the decomposition step. The truncation error for Hermite interpolation (5.9) is given by (5.10). It is obvious that the error is zero if $u(x)$ is a cubic polynomial and is not zero if $u(x)$ is a quartic polynomial, and consequently, $p = 4$.

As a consistency check on the programming of the decomposition step (7.14a), one can verify the accuracy numerically by checking for the proper number of vanishing moments. After one decomposition step (7.6) one has

$$[\,\acute{\boldsymbol{\mathcal{U}}}^{m}] \rightharpoonup [\,\acute{\boldsymbol{\mathcal{U}}}^{m-1}, \acute{\boldsymbol{\mathcal{R}}}^{m-1}]. \tag{9.4}$$

The array $\boldsymbol{\mathcal{R}}^{m-1}$ is the *bottom* half of the transpose of array (9.4). The second column of $\boldsymbol{\mathcal{R}}^{m-1}$ has an extra vanishing moment since the Hermite derivative interpolation formula (5.9b) is exact for a quartic polynomial (see (5.10b)). One can also verify the accuracy of the preprocessing step of section 8 by computing (8.8b) numerically using the Padé approximation (8.7) with $u_j^m = x_j^q$ and checking again for the proper number of vanishing moments.

10. Data compression. One of the primary applications of a multiresolution analysis is lossy data compression. In many data analysis problems, most of the residual coefficients of the decomposition are negligible and can be set to zero, and upon reconstruction an accurate approximation of the original data will be retained. First, we consider a scalar multiresolution algorithm.

10.1. Scalar compression. For the residuals r_j^k, we define the following truncation operator for $1 \leq j \leq J_k$ and $n \leq k \leq m-1$:

$$\hat{r}_j^k = \begin{cases} r_j^k & \text{if} \quad |r_j^k| > \epsilon_k, \\ 0 & \text{if} \quad |r_j^k| \leq \epsilon_k, \end{cases} \tag{10.1}$$

where ϵ_k is the cutoff tolerance. The decomposition vector is defined by (3.20):

$$[\acute{\mathbf{d}}^m] = [\acute{\mathbf{u}}^n, \acute{\mathbf{r}}^n, \ldots, \acute{\mathbf{r}}^k, \ldots, \acute{\mathbf{r}}^{m-2}, \acute{\mathbf{r}}^{m-1}]. \tag{10.2}$$

On applying the truncation operator (10.1) to each subvector $\mathbf{r}^k$ of (10.2), one obtains the truncated decomposition vector

$$\hat{\mathbf{d}}^m = \begin{bmatrix} \mathbf{u}^n \\ \hat{\mathbf{r}}^n \\ \vdots \\ \hat{\mathbf{r}}^k \\ \vdots \\ \hat{\mathbf{r}}^{m-2} \\ \hat{\mathbf{r}}^{m-1} \end{bmatrix}, \tag{10.3}$$

where the truncated subvectors $\hat{\mathbf{r}}^k$ are given by (10.1). Note that the subvector $\mathbf{u}^n$ is not truncated. Let the number of nonzero elements of $\hat{\mathbf{d}}^m$ be denoted by T_m. The compression ratio is defined by

$$C_r = \text{compression ratio} = \frac{J_m}{T_m}. \tag{10.4}$$

The cutoff tolerance ϵ_k is scaled according to the level k by the formula [Ha95]

$$\epsilon_k = 2^{(k-m)}\epsilon, \tag{10.5}$$

where ϵ is a constant. This scaling formula results in a smaller cutoff tolerance at the coarser scales as compared to the finer scales. If the compression ratio is specified, then ϵ can be determined so that (10.3) has the desired number of nonzero elements.

In this section we assume the compression ratio is specified. A procedure for truncating the decomposition vector when the cutoff tolerance depends on k is as follows. We first replace each subvector $\mathbf{r}^k$ of the decomposition vector $\mathbf{d}^m$ by $2^{(m-k)}\mathbf{r}^k$ and let the *scaled* decomposition vector be denoted by $\mathbf{d}_s^m$. Now the cutoff tolerance for each subvector $\mathbf{r}_s^k$ will be the same, namely ϵ (see (10.5)). Next we take the absolute value of each entry $d_s^m(j)$ of $\mathbf{d}_s^m$ and sort the array in ascending order (the *top* vector $\mathbf{u}^n$ is excluded during this process). Let

$$j_{max} = [J_m(1 - 1/C_r)] + length(\mathbf{u}^n), \tag{10.6}$$

where $[\,\cdot\,]$ denotes the largest integer function. Then ϵ is given by the element

$$d_s^m(j_{max}) = \epsilon. \tag{10.7}$$

Now we go back to the array $\mathbf{d}_s^m$ and set every element of each subvector $\mathbf{r}_s^k$ to zero if it is below the above tolerance ϵ. Finally, we form the truncated vector $\hat{\mathbf{d}}^m$ by multiplying each subvector $\hat{\mathbf{r}}_s^k$ by $2^{(k-m)}$ to obtain $\hat{\mathbf{r}}_k$. In practical applications the scaling and rescaling by 2^{k-m} is avoided by including a scaling factor in the multiresolution algorithm.

Let $\hat{\mathbf{u}}^m$ denote the reconstructed vector corresponding to truncated decomposition vector $\hat{\mathbf{d}}^m$. Harten [Ha95] has shown that one achieves a given error tolerance in the L_1 norm

$$||\mathbf{u}^m - \hat{\mathbf{u}}^m||_1 = O(\epsilon) \tag{10.8}$$

by truncating the residual vectors $\mathbf{r}^k$ with truncation levels ϵ_k determined by (10.1) and (10.5).

10.2. Vector compression. Next we consider the general multiwavelet case. The multiresolution decomposition of the matrix $\boldsymbol{\mathcal{U}}^m$ is given by (7.6).

$$[\,\acute{\boldsymbol{\mathcal{D}}}^m] = [\,\acute{\boldsymbol{\mathcal{U}}}^n, \acute{\boldsymbol{\mathcal{R}}}^n, \ldots, \acute{\boldsymbol{\mathcal{R}}}^k, \ldots, \acute{\boldsymbol{\mathcal{R}}}^{m-2}, \acute{\boldsymbol{\mathcal{R}}}^{m-1}]. \tag{10.9}$$

The jth row of the residual matrix $\boldsymbol{\mathcal{R}}^k$ is

$$\boldsymbol{\mathcal{R}}_j^k = [r_{1,j}^k, r_{2,j}^k, \ldots, r_{\iota,j}^k]. \tag{10.10}$$

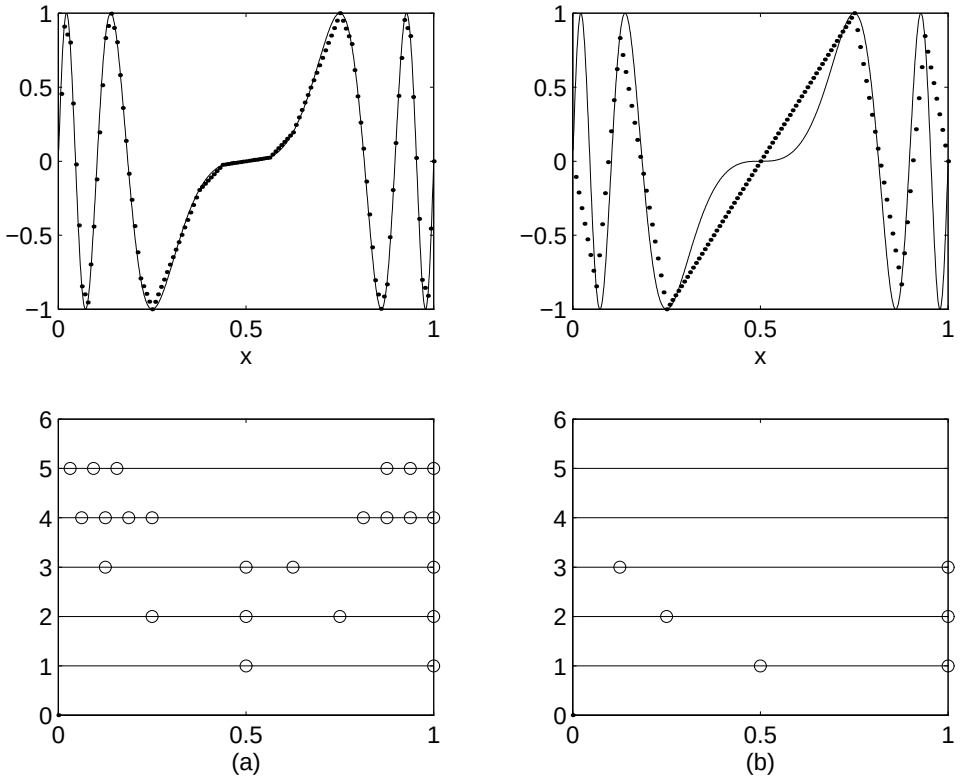

FIG. 10.1. *Compression of a periodic chirp for* $m = 7, n = 1$ *(scalar algorithm). The top figures show reconstructed compressed data, and the bottom figures show nonzero values of compressed decomposition vectors: (a) compression ratio of* $5:1$*, (b) compression ratio of* $16:1$.

For the residual $\boldsymbol{\mathcal{R}}_j^k$ row (10.10) we define the following truncation operator for $1 \le j \le J_k$ and $n \le k \le m-1$:

$$\hat{r}_{i,j}^k = \begin{cases} r_{i,j}^k & \text{if} \quad |r_{i,j}^k| > \epsilon_k \quad \text{for any } i, \qquad 1 \le i \le \iota, \\ 0 & \text{if} \quad |r_{i,j}^k| \le \epsilon_k, \quad \text{for every } i, \quad 1 \le i \le \iota. \end{cases} \tag{10.11}$$

On applying the truncation operator (10.11) to each submatrix $\boldsymbol{\mathcal{R}}^k$, one obtains the truncated decomposition matrix

$$\widehat{\boldsymbol{\mathcal{D}}}^m = \begin{bmatrix} \boldsymbol{\mathcal{U}}^n \\ \widehat{\boldsymbol{\mathcal{R}}}^n \\ \vdots \\ \widehat{\boldsymbol{\mathcal{R}}}^k \\ \vdots \\ \widehat{\boldsymbol{\mathcal{R}}}^{m-2} \\ \widehat{\boldsymbol{\mathcal{R}}}^{m-1} \end{bmatrix}, \tag{10.12}$$

where the truncated subvectors $\widehat{\boldsymbol{\mathcal{R}}}^k$ are given by (10.11).

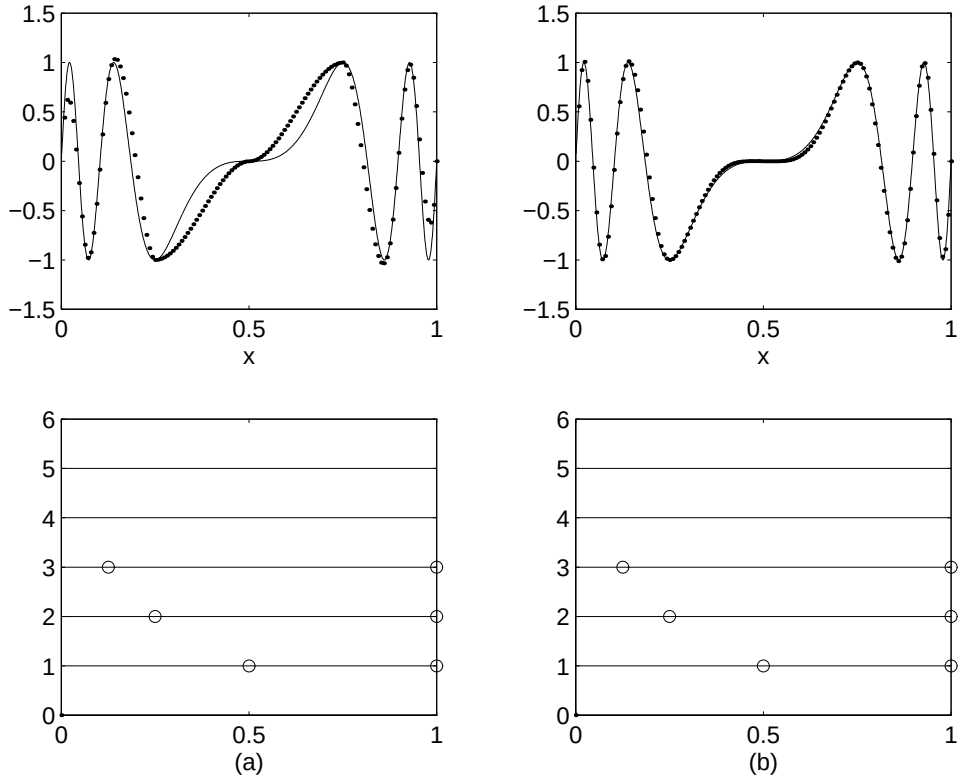

FIG. 10.2. *Compression of a periodic chirp for* $m = 7, n = 1$*, and a compression ratio of* $16 : 1$ *(vector algorithm): (a) function and its derivative are given on the mesh, (b) function and its first and second derivatives are given on the mesh.*

According to the truncation operator (10.11), at a given scale k for fixed j, if any one of the residual components $r_{i,j}^k$ satisfies the inequality $|r_{i,j}^k| > \epsilon$, then $\hat{r}_{i,j}^k = r_{i,j}^k$ for $1 \le i \le \iota$, i.e., the entire row is retained. Let the number of nontruncated rows of decomposition matrix (10.12) be denoted by T_m. The compression ratio is defined by (10.4).

10.3. Computational examples. For our first computational example, we choose a periodic *chirp* with quadratically increasing frequency

$$u(x) = \sin(\alpha\pi(x - 1/2)^3), \quad 0 \le x \le 1, \tag{10.13}$$

where α is a specified parameter. The function (10.13) for $\alpha = 32$ is plotted as a solid curve in the upper part of Figure 10.1(a).

We apply the discrete scalar multiresolution algorithm (3.10) using linear interpolation (3.8) to the input data vector defined by (2.6):

$$\mathbf{u}^m = [u_1^m, u_2^m, \ldots, u_{J_m}^m]^T, \qquad J_m = 2^m. \tag{10.14}$$

We pick $m = 7$, $n = 1$, and a compression ratio of 5:1. Hence the number of subintervals on the finest grid is $J_m = 2^m = 128$. The reconstructed (compressed) discrete data are shown in the upper plot of Figure 10.1(a) by dots. The bottom part of Figure 10.1(a) is a plot in the (space-scale) $x - k$ plane. The open circles plotted in the figure

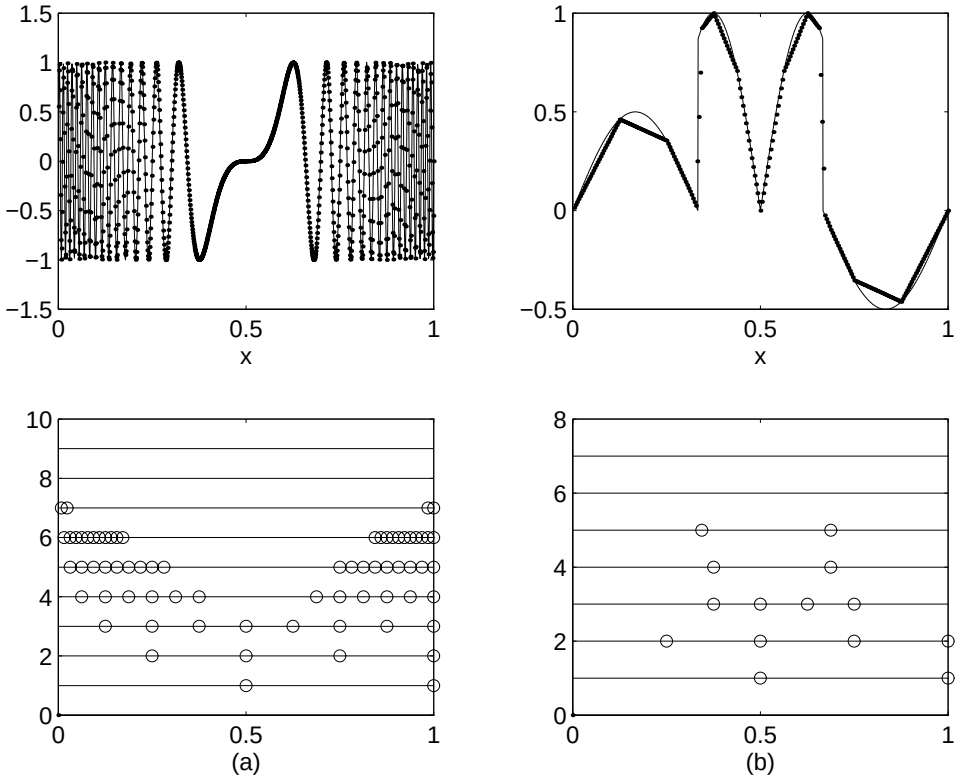

FIG. 10.3. *(a) Compression of a periodic chirp for* $m = 10, n = 1$*, and a compression ratio of* $16:1$ *(vector algorithm). (b) Compression of a function with a jump discontinuity for* $m = 8, n = 1$*, and a compression ratio of* $16:1$ *(scalar algorithm).*

indicate the nonzero values of each truncated subvector $\hat{\mathbf{r}}^k$ plotted as a function of grid X^k defined by (2.1). The scale or level index k is indicated by the integers on the left vertical axis. For example, at level $k = 5$ there are six nonzero residual values in the truncated subvector $\hat{\mathbf{r}}^5$. The open circles form a *spike* at the right end $x = 1$ where the function (10.13) has its steepest gradient. Circles do not appear at the left end $x = 0$ because of the assumption of periodicity.

All of the subsequent figures in this section have the same form as Figure 10.1(a). The upper part of each figure compares the reconstructed compressed data with the exact function, and the lower part of each figure is an $x - k$ plane plot indicating the location of the nonzero values of each truncated subvector $\hat{\mathbf{r}}^k$. For a vector multiresolution algorithm the lower part of each figure indicates the location of the nontruncated rows of each truncated subvector $\widehat{\boldsymbol{\mathcal{R}}}^k$.

We next compare the compression properties of the scalar multiresolution algorithm with two vector multiresolution algorithms using Hermite interpolation. Again we pick $m = 7$, $n = 1$, but with a compression ratio of 16:1. The reconstructed compressed data shown in Figure 10.1(b) for the scalar algorithm (3.10) using linear interpolation are clearly inaccurate for this higher compression ratio. Figure 10.2(a) shows the reconstructed compressed data obtained by applying the vector multiresolution algorithm (7.14) or (6.6) for the case where the function (10.13) and its derivative

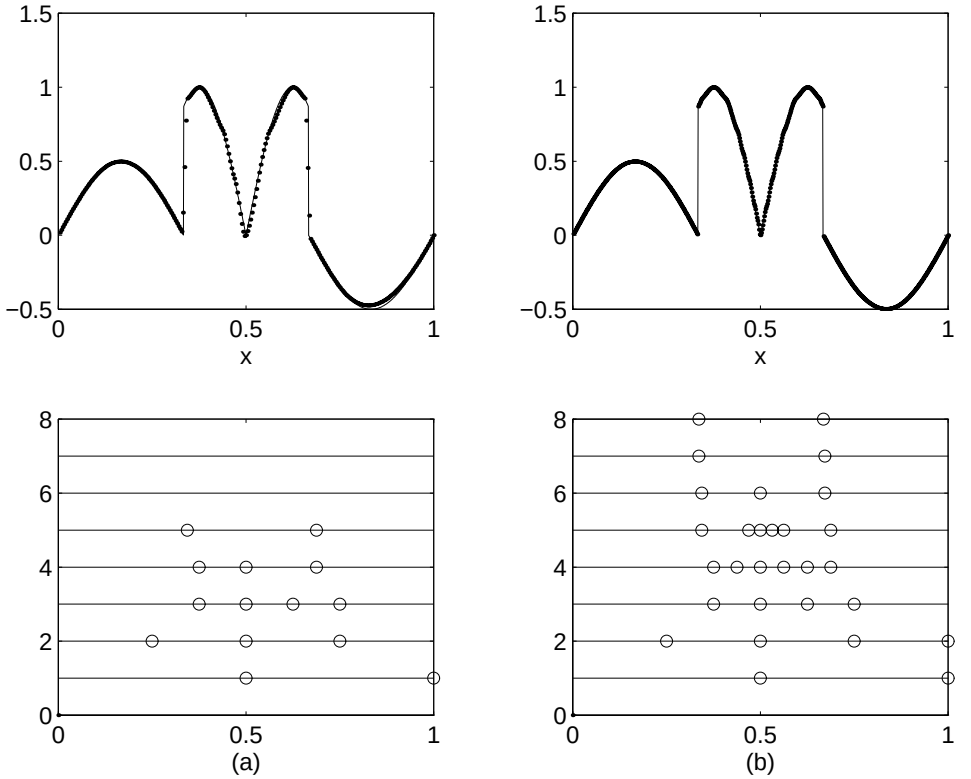

FIG. 10.4. *Compression of a function with a jump discontinuity with a compression ratio of* 16 : 1 *(vector algorithm): (a)* $m = 8$ *and* $n = 1$*, (b)* $m = 9$ *and* $n = 1$*.*

are given on the mesh X^m. In Figure 10.2(b) we plot the reconstructed compressed data obtained by applying the vector multiresolution algorithm (7.14) for the case where the function and its first *and second* derivatives are given on the mesh X^m.

It should be noted that accuracy of the compressed data for any particular case, i.e., the linear case shown in Figure 10.1(b), can be improved by either increasing m or decreasing the compression ratio. Furthermore, for smooth data the number of nonnegligible residual coefficients decreases as the order of the Hermite interpolation formula increases. On comparing Figure 10.1(b) with Figure 10.2(b) the superiority of the vector multiresolution algorithm is apparent. Although not shown in Figure 10.2(b), first and second derivative data are also compressed. On the other hand, three times as much data is retained in the vector algorithm as compared to the scalar algorithm used in Figure 10.1(b). The amount of compressed data retained is comparable in Figure 10.1(a) and Figure 10.2(b).

By increasing the α parameter of the function (10.13) to 256, one obtains the curve shown by the solid curve in Figure 10.3(a). Again we apply the vector multiresolution algorithm for the case where the function and its first and second derivatives are specified. The compression results for $m = 10$ are illustrated in Figure 10.3(a). If one increases the frequency parameter α for a fixed compression ratio, the size of the grid J_m must be increased proportionately to maintain a specified accuracy level.

In our second example, we consider a periodic function with a discontinuous

derivative and two jump discontinuities:

$$u(x) = \begin{cases} \sin(3\pi x)/2 & \text{for} \quad 0 \le x \le 1/3, \\ |\sin(2\pi(2x-1))| & \text{for} \quad 1/3 < x < 2/3, \\ -\sin(3\pi x)/2 & \text{for} \quad 2/3 \le x \le 1. \end{cases} \tag{10.15}$$

This function is plotted as a solid curve in the upper part of Figure 10.3(b). We choose $m = 8$, $n = 1$, and a compression ratio of 16:1. The compression results for the scalar multiresolution algorithm are shown in Figure 10.3(b). In Figure 10.4(a) the compression results for a vector multiresolution algorithm (function and derivative) are shown. On the basis of numerical tests (not shown), we conclude that the accuracy of the Hermite interpolation formulas is severely degraded by the presence of the discontinuities. Higher order interpolation formulas using function values and its first and second derivatives yield reconstructed compressed data that are virtually identical to compression results of Figure 10.4(a).

In Figure 10.4(b) we repeat the computation of Figure 10.4(a) but with $m = 9$, i.e., twice as many points. The reconstructed compressed data now resolve the discontinuous derivative and the two jump discontinuities. At the finest scales there is a *spike* at $x = 1/3$ and $x = 2/3$ in the $x - k$ plane indicating the presence of the discontinuities. At the coarser scales, there is a *spike* at $x = 1/2$ indicating the presence of a discontinuous derivative. This example illustrates the feature recognition properties of a multiresolution analysis.

11. Concluding remarks. A vector interpolatory multiresolution algorithm using Hermite interpolation has been developed. These biorthogonal bases (multiwavelets) have several advantages. The basis functions have the same compactness (two subintervals) regardless of the order of accuracy. For a uniform grid the basis functions are symmetric or skew-symmetric piecewise polynomials (which can easily be derived analytically). Although this paper has been restricted to uniform grids and periodic data, compact interpolation formulas do not depend on uniform spacing, so the multiwavelets can be extended to nonperiodic nonuniform grids on a finite domain. The multiwavelets considered in this paper are well suited for lossy data compression of relatively smooth data and for feature recognition. For data with jump discontinuities, supercompact multiwavelets [Be96] are more suitable.

Appendix A. Dilation equation for a multiresolution analysis. Neither the development nor the application of an interpolatory multiresolution algorithm requires a knowledge of the basis vectors or functions—they are implicitly generated in the multiresolution algorithm. Likewise, implementation of an interpolatory multiresolution algorithm does not require explicit knowledge of the dilation (scaling) equation or wavelet equation. However, in practice one needs to select basis functions (which are derived from the scaling functions) appropriate for the particular application, and naturally, one would like to know what the scaling functions look like. In a compact interpolatory multiresolution algorithm the *unit interpolation function* plays the role of the scaling function. In this appendix we define the unit interpolation function and derive the dilation equation which it satisfies. Analytic formulas for the unit interpolation functions for particular cases are derived in Appendix E. The unit interpolation functions can also be computed numerically as described in Appendix C.

A.1. Unit interpolation function. The multiresolution algorithms of this paper are discrete, i.e., they operate on vectors and return vectors. Given an input

vector, the decomposition algorithm finds the coefficients of the basis vectors described in Appendix B. There is, however, a natural extension of the basis vectors to functions, i.e., a "continuous approximation" to the basis vectors. The extension to basis functions is intimately related to the *unit interpolation function* which we denote by $\phi_i^k(x)$. For a scalar multiresolution analysis the unit interpolation function is defined by the following construction: (1) place a grid X^k on the unit interval, (2) choose the value of $\phi_i^k(x)$ to be unity at x_j^k and zero at all other grid points, and (3) determine the values of $\phi_i^k(x)$ between the grid points from the compact interpolation polynomial. For periodic boundary conditions, $\phi_i^k(x)$ is determined by a single (scaling) function $w(x)$ by dilation and translation.

In the case of Hermite interpolation (where the interpolation polynomial requires more than one value at each grid point), there will be multiple unit interpolation functions, one for each required value. For example, if function values and first derivatives are used, there will be two unit interpolation functions which we denote by ${\phi_1}_i^k(x)$ and ${\phi_2}_i^k(x)$. Examples of unit interpolation functions are given in Appendix E. The unit interpolation functions for compact interpolation are equivalent to the scaling functions for finite element multiwavelets [Stre95].

For compact interpolation the unit interpolation functions have special importance since, as we shall see, they are the scaling functions (continuous approximation to the basis vectors) for the multiresolution analysis. This equivalence between the unit interpolation functions and the scaling functions is not valid for noncompact interpolation (e.g., the cubic interpolation (5.4)). Scaling functions satisfy a dilation equation and generate the wavelets. In the following section we show that for scalar compact interpolation, the unit interpolation function is the scaling function. In section A.4 we show that for compact Hermite interpolation the multiple unit interpolation functions are the multiple scaling functions.

A.2. Scalar dilation equation. In this section we derive the dilation equation from the discrete compact (linear interpolation) multiresolution algorithm (3.10a) and (3.12):

decomposition

$$u_j^{k-1} = u_{2j}^k, \tag{A.1a}$$

$$r_j^{k-1} = u_{2j-1}^k - \frac{1}{2}(u_{2j}^k + u_{2j-2}^k), \tag{A.1b}$$

reconstruction

$$u_{2j}^k = u_j^{k-1}, \tag{A.2a}$$

$$u_{2j-1}^k = \frac{1}{2}(u_j^{k-1} + u_{j-1}^{k-1}) + r_j^{k-1}. \tag{A.2b}$$

We begin by expressing a piecewise linear function $u(x)$ on the unit interval (with periodic boundary conditions) as a series of unit interpolation functions on grid X^{k-1}

$$u(x) = \sum_{i=1,2,\ldots}^{J_{k-1}} u_i^{k-1}\phi_i^{k-1}(x). \tag{A.3}$$

Since $u(x)$ is piecewise linear on grid X^{k-1}, it can be represented exactly as a series of unit interpolation functions on grid X^k, i.e., the residual is zero ($r_j^{k-1} = 0$). Therefore, $u(x)$ on grid X^k is

$$\begin{aligned} u(x) &= \sum_{i=1,2,\ldots}^{J_k} u_i^k \phi_i^k(x) \\ &= \sum_{i=1,3,\ldots}^{J_k-1} u_i^k \phi_i^k(x) + \sum_{i=2,4,\ldots}^{J_k} u_i^k \phi_i^k(x) \\ &= \sum_{i=1,2,\ldots}^{J_{k-1}} u_{2i-1}^k \phi_{2i-1}^k(x) + \sum_{i=1,2,\ldots}^{J_{k-1}} u_{2i}^k \phi_{2i}^k(x). \end{aligned} \tag{A.4}$$

From (A.2b) (with the residual set to zero) we obtain

$$u_{2j-1}^k = \frac{1}{2}(u_j^{k-1} + u_{j-1}^{k-1}). \tag{A.5}$$

Next we use (A.2a) and (A.5) to rewrite (A.4), i.e.,

(A.6)

$$\begin{aligned} u(x) &= \sum_{i=1,2,\ldots}^{J_{k-1}} \frac{1}{2}(u_i^{k-1} + u_{i-1}^{k-1})\phi_{2i-1}^k(x) + \sum_{i=1,2,\ldots}^{J_{k-1}} u_i^{k-1}\phi_{2i}^k(x) \\ &= \sum_{1=1,2,\ldots}^{J_{k-1}} \frac{1}{2}u_i^{k-1}\phi_{2i-1}^k(x) + \sum_{i=0,1,\ldots}^{J_{k-1}-1} \frac{1}{2}u_i^{k-1}\phi_{2i+1}^k(x) + \sum_{i=1,2,\ldots}^{J_{k-1}} u_i^{k-1}\phi_{2i}^k(x) \\ &= \sum_{i=1,2,\ldots}^{J_{k-1}} u_i^{k-1}\left[\frac{1}{2}\phi_{2i-1}^k(x) + \frac{1}{2}\phi_{2i}^k(x) + \phi_{2i+1}^k(x)\right], \end{aligned}$$

where in the last line of (A.6) we have used the assumed periodicity of the u_j^k's. Finally, from a comparison of (A.3) and (A.6) we conclude

$$\phi_i^{k-1}(x) = \frac{1}{2}\phi_{2i-1}^k(x) + \phi_{2i}^k(x) + \frac{1}{2}\phi_{2i+1}^k(x), \tag{A.7}$$

which is the dilation equation for the multiresolution analysis scaling function.

For linear interpolation the unit interpolation function is derived by following the three steps of section A.1 above. For simplicity we pick $k = 1$, the grid on the unit interval is X^1 with $h_1 = 1/2$, and the unit perturbation is at the midpoint $x_1^1 = 1/2$. From Appendix E.1 one finds

$$\phi_1^1(x) = w(x) = 1 - |2x - 1|, \qquad 0 \le x \le 1, \tag{A.8}$$

where $w(x)$ is the hat function plotted in Figure A.1.

For periodic boundary conditions, $\phi_i^k(x)$ is determined from a single scaling function $w(x)$ by dilation and translation:

$$\phi_i^k(x) = w(2^{k-1}x - (i-1)/2). \tag{A.9}$$

To obtain the dilation equation in a more conventional form, we set $k = 2,\ i = 1$ in (A.7) and use (A.9) to obtain

$$w(x) = \frac{1}{2}w(2x) + w(2x - 1/2) + \frac{1}{2}w(2x - 1), \qquad 0 \le x \le 1. \tag{A.10}$$

By construction the solution is the hat function (A.8).

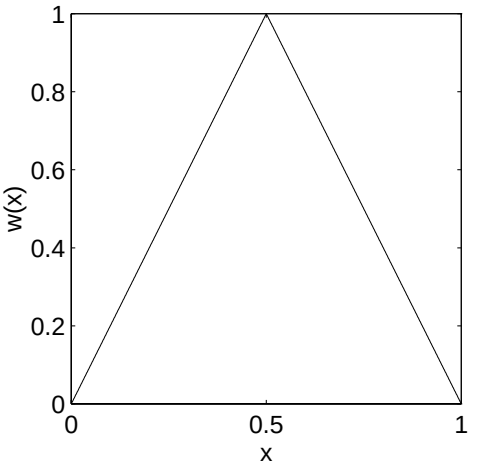

FIG. A.1. *Hat function.*

A.3. Scalar wavelets. In the previous section we assumed that there was no error in the decomposition, i.e., $u(x)$ is represented exactly on both grids X^k and X^{k-1}. If this is not the case and $u(x)$ is represented exactly only on the finer grid, then the reconstruction from the coarser grid to the finer grid results in an error, i.e., instead of (A.4) we write

$$\begin{aligned} u(x) &= \sum_{i=1,2,\ldots}^{J_k} (u_i^k + \epsilon_i^k)\phi_i^k(x) \\ &= \sum_{i=1,2,\ldots}^{J_{k-1}} (u_{2i}^k + \epsilon_{2i}^k)\phi_{2i}^k(x) + \sum_{i=1,2,\ldots}^{J_{k-1}} (u_{2i-1}^k + \epsilon_{2i-1}^k)\phi_{2i-1}^k(x). \end{aligned} \tag{A.11}$$

The error in $u(x)$, denoted by $\epsilon_u^k(x)$, is

$$\epsilon_u^k(x) = \sum_{i=1,2,\ldots}^{J_{k-1}} \epsilon_{2i}^k \phi_{2i}^k(x) + \sum_{i=1,2,\ldots}^{J_{k-1}} \epsilon_{2i-1}^k \phi_{2i-1}^k(x). \tag{A.12}$$

From (A.1a) we see that the even-numbered u's are projected and the error is zero. The error in the odd-numbered u's is r_j^{k-1}, i.e.,

$$\epsilon_u^k(x) = \sum_{i=1,2,\ldots}^{J_{k-1}} r_i^{k-1} \phi_{2i-1}^k(x). \tag{A.13}$$

The functions for the expansion of the error (or detail) are the wavelets, ψ_i^k,

$$\epsilon_u^k(x) = \sum_{i=1,2,\ldots}^{J_{k-1}} r_i^{k-1} \psi_i^{k-1}(x). \tag{A.14}$$

Therefore, for the compact linear algorithm the wavelet is simply the dilated and translated scaling function

$$\psi_i^{k-1}(x) = \phi_{2i-1}^k(x). \tag{A.15}$$

The wavelet is given by inserting (A.9) into (A.15):

$$\psi_i^{k-1}(x) = w(2^{k-1}x - (i-1)). \tag{A.16}$$

A.4. Vector dilation equation. In the derivation of the scalar dilation and wavelet equations we took advantage of the fact that (with the compact unit interpolation functions) a piecewise linear function on grid X^{k-1} can be represented exactly on grid X^k. That is, (A.3) and (A.4) are both valid when $w(x)$ is the unit interpolation function. For higher order (than linear) polynomials $u(x)$, we could try the noncompact cubic interpolation (5.4). We would find, however, that expansions (A.3) and (A.4) with $\phi(x)$ the unit interpolation function are not valid, i.e., they do not produce the same function $u(x)$ and the unit interpolation functions are not the scaling functions.

If we use the higher order compact (vector) interpolation, we can, with slight modification, repeat the analysis of sections A.2 and A.3 and show that the unit interpolation functions (there are more than one in the vector case) are the scaling functions. We demonstrate matching function values and first derivatives for the special case of Hermite interpolation, but the analysis is easily generalized to higher order compact interpolation.

We follow the notation of section 6, i.e., the weighted first derivative is denoted by v (see (6.2)). On the grid X^{k-1} we expand the piecewise cubic polynomial $u(x)$ in a double series of unit interpolation functions

$$u(x) = \sum_{i=1,2,\ldots}^{J_{k-1}} u_i^{k-1}\phi_{1_i}^{k-1}(x) + \sum_{i=1,2,\ldots}^{J_{k-1}} v_i^{k-1}\phi_{2_i}^{k-1}(x), \tag{A.17}$$

where $\phi_{1_i}^{k}(x)$ and $\phi_{2_i}^{k}(x)$ correspond to the unit interpolation functions for point value and for derivative, respectively. On the grid X^k we can write the same piecewise cubic polynomial $u(x)$

$$u(x) = \sum_{i=1,2,\ldots}^{J_k} u_i^{k}\phi_{1_i}^{k}(x) + \sum_{i=1,2,\ldots}^{J_k} v_i^{k}\phi_{2_i}^{k}(x). \tag{A.18}$$

For notational simplicity we will use the vector notation (7.7a)

$$\boldsymbol{\mathcal{U}}_j^k = [u_j^k \; v_j^k] \tag{A.19}$$

and introduce the vector form of the unit interpolation functions, i.e.,

$$\boldsymbol{\phi}_i^k = \begin{bmatrix} \phi_{1_i}^{k}(x) \\ \phi_{2_i}^{k}(x) \end{bmatrix}. \tag{A.20}$$

Note that $\boldsymbol{\mathcal{U}}$ is a row vector and $\boldsymbol{\phi}$ is a column vector. Equations (A.17) and (A.18) become

$$u(x) = \sum_{i=1,2,\ldots}^{J_{k-1}} \boldsymbol{\mathcal{U}}_i^{k-1}\boldsymbol{\phi}_i^{k-1}(x) \tag{A.21}$$

and

$$
\begin{aligned}
u(x) &= \sum_{i=1,2,\ldots}^{J_k} \boldsymbol{\mathcal{U}}_i^k \boldsymbol{\phi}_i^k(x) \\
&= \sum_{i=1,3,\ldots}^{J_k-1} \boldsymbol{\mathcal{U}}_i^k \boldsymbol{\phi}_i^k(x) + \sum_{i=2,4,\ldots}^{J_k} \boldsymbol{\mathcal{U}}_i^k(x) \boldsymbol{\phi}_i^k(x) \qquad \text{(A.22)} \\
&= \sum_{i=1,2,\ldots}^{J_{k-1}} \boldsymbol{\mathcal{U}}_{2i-1}^k \boldsymbol{\phi}_{2i-1}^k(x) + \sum_{i=1,2,\ldots}^{J_{k-1}} \boldsymbol{\mathcal{U}}_{2i}^k \boldsymbol{\phi}_{2i}^k(x).
\end{aligned}
$$

From the reconstruction algorithm (7.15b) (with the residual set to zero)

$$\boldsymbol{\mathcal{U}}_{2i}^k = \boldsymbol{\mathcal{U}}_i^{k-1} \mathbf{F}_1{}', \tag{A.23}$$

$$\boldsymbol{\mathcal{U}}_{2i-1}^k = \boldsymbol{\mathcal{U}}_{i-1}^{k-1} \mathbf{F}_2{}' + \boldsymbol{\mathcal{U}}_i^{k-1} \mathbf{F}_0{}'. \tag{A.24}$$

If we substitute from (A.23) and (A.24) into (A.22), rearrange terms as we did in (A.6), and use the assumed periodicity of the $\boldsymbol{\mathcal{U}}_i^k$'s, then (A.22) can be rewritten as

$$u(x) = \sum_{i=1,2,\ldots}^{J_{k-1}} \boldsymbol{\mathcal{U}}_i^{k-1} [\mathbf{F}_0{}' \boldsymbol{\phi}_{2i-1}^k(x) + \mathbf{F}_1{}' \boldsymbol{\phi}_{2i}^k(x) + \mathbf{F}_2{}' \boldsymbol{\phi}_{2i+1}^k(x)]. \tag{A.25}$$

A comparison of (A.21) and (A.25) leads to the vector dilation equation

$$\boldsymbol{\phi}_i^{k-1} = \mathbf{F}_0{}' \boldsymbol{\phi}_{2i-1}^k(x) + \mathbf{F}_1{}' \boldsymbol{\phi}_{2i}^k(x) + \mathbf{F}_2{}' \boldsymbol{\phi}_{2i+1}^k(x). \tag{A.26}$$

The vector analog of (A.8) is obtained from (A.20):

$$\boldsymbol{\phi}_1^1(x) = \begin{bmatrix} \phi_1{}_1^1(x) \\ \phi_2{}_1^1(x) \end{bmatrix} = \begin{bmatrix} w_1(x) \\ w_2(x) \end{bmatrix}, \tag{A.27}$$

where $w_1(x)$ is the unit interpolation function (E.8) and $w_2(x)$ is the unit interpolation function (E.11) (see Appendix E). The vector unit interpolation function (A.20) is given explicitly by

$$\boldsymbol{\phi}_i^k(x) = \begin{bmatrix} \phi_1{}_i^k(x) \\ \phi_2{}_i^k(x) \end{bmatrix} = \begin{bmatrix} w_1(2^{k-1}x - (i-1)/2) \\ w_2(2^{k-1}x - (i-1)/2) \end{bmatrix}. \tag{A.28}$$

A.5. Vector wavelets. The vector wavelet equation for the compact vector interpolation is completely analogous to the compact scalar wavelet equation. The error equation is the vector form of (A.14), i.e.,

$$\epsilon_u^k(x) = \sum_{i=1,2,\ldots}^{J_{k-1}} \boldsymbol{\mathcal{R}}_i^{k-1} \boldsymbol{\psi}_i^{k-1}(x), \tag{A.29}$$

where the wavelet is the dilated and translated scaling function

$$\boldsymbol{\psi}_i^{k-1}(x) = \boldsymbol{\phi}_{2i-1}^k(x) = \begin{bmatrix} w_1(2^{k-1}x - (i-1)) \\ w_2(2^{k-1}x - (i-1)) \end{bmatrix}. \tag{A.30}$$

Appendix B. Basis vectors for a scalar multiresolution algorithm. For any interpolatory multiresolution scheme it is instructive to plot the discrete basis vectors $\mathbf{w}_\ell$ of the expansion (3.22) for particular values of n and m. The basis vectors can easily be computed numerically from the reconstruction algorithm or analytically from the scaling function for compact interpolation.

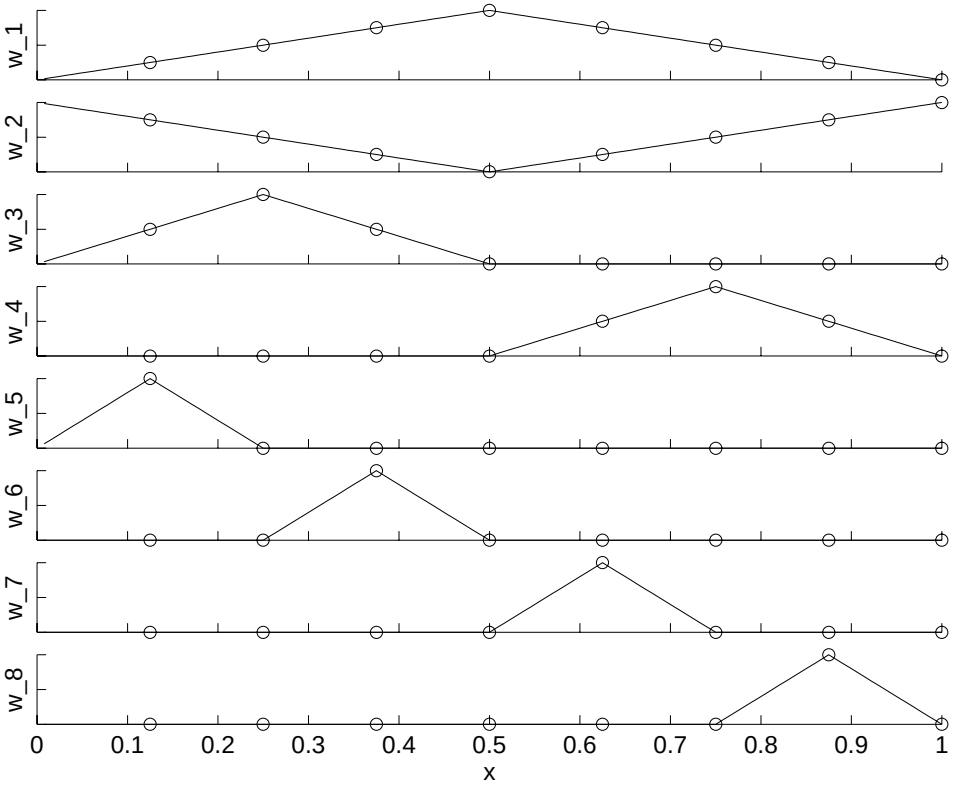

FIG. B.1. *Discrete and continuous basis functions.*

B.1. Numerical method. We first consider a direct numerical calculation. Let ϵ_ℓ^m denote a unit vector, i.e., the ℓth column of the $2^m \times 2^m$ identity matrix. (The ℓth component of ϵ_ℓ^m is unity and all other components are zero.) To numerically compute the discrete basis vector $\mathbf{w}_\ell$, set the decomposition vector $\mathbf{d}^m$ defined by (3.20) to ϵ_ℓ^m in the reconstruction pyramid algorithm (3.19) with the $\leftarrow$ symbol. Recall that the pseudocode for reconstruction is given by (3.10b). The output vector $\mathbf{u}^m$ is $\mathbf{w}_\ell$.

As an example, consider linear interpolation (3.11) on a uniform grid with periodic boundary conditions. The discrete basis vectors $\mathbf{w}_\ell$ are computed by setting $\mathbf{d}^m = \epsilon_\ell^m$ and applying the reconstruction algorithm (3.10b). For $n = 1$ and $m = 3$ the elements of the vectors $\mathbf{w}_\ell$ versus the points of the grid vector (2.3) are plotted as open circles in Figure B.1 for $1 \le \ell \le 8$. The elements of the vector $\mathbf{w}_1$ fall on the hat function plotted in Figure A.1.

An alternative numerical method of computing the basis vectors using the fill-in algorithm is discussed in Appendix C.

B.2. Analytical method. In the following discussion the unit interpolation function (scaling function) is the hat function defined by (A.8). Although $w(x)$ is a continuous function, the discrete basis vector $\mathbf{w}_1$ is obtained by evaluating $w(x)$ on the discrete grid

$$\mathbf{x}^m = [x_1^m, x_2^m, \ldots, 1]^T, \quad \text{where} \quad x_j^m = j/2^m. \tag{B.1}$$

Under dilation and translation, the scaling function $w(x)$ evaluated on the discrete grid (B.1) forms the basis vectors at all scales indicated by (3.23). In the following we assume $w(x) = 0$ for $x \not\subset [0, 1]$, i.e., the basis function $w(x)$ has compact support.

B.2.a. Basis vectors of $\mathbf{u}^{(k)}$. In this section we consider the special case of the vectors $\mathbf{w}_\ell$ in expansion (3.23c) of $\mathbf{u}^{(k)}$. In general, a wavelet comes from the scaling function by taking "differences" [St89], i.e., the wavelet is a linear combination of translates of the scaling function at the next finer level. In the case of a uniform grid, periodic boundary conditions, compact interpolation, and projection of the even-point values, an interpolatory multiresolution approach leads to a wavelet which is a single translate of the scaling function at the next finer level. Consequently, the scaling function and the wavelet have the same functional form (see (A.16)). Hence the family of wavelets is determined from the *single* unit interpolation function (scaling function) by the operations of dilation and translation:

$$w_\ell(x) = w(2^k x - i), \qquad 0 \le x \le 1, \tag{B.2a}$$

where the dilation index k and the translation index i are nonnegative integers satisfying:

$$n \le k \le m - 1, \tag{B.2b}$$

$$0 \le i < 2^k, \tag{B.2c}$$

$$\ell = 2^k + i + 1. \tag{B.2d}$$

If ℓ is specified, the indices k and i are unique. The smallest value of ℓ in (B.2d) is $\ell = 2^n + 1$. For $w(x)$ given by the hat function (A.8), continuous wavelets $w_\ell(x)$ are plotted in Figure B.1 for $3 \le \ell \le 8$. Smaller values of ℓ, which are treated as a special case in section B.2.b, define $w_\ell(x)$ in terms of a family of scaling functions.

The wavelet scale (or width) is given by

$$1/2^k, \quad \text{where} \quad k \quad \text{is the dilation index,} \tag{B.3}$$

and the wavelet location (left end) is

$$i/2^k, \quad \text{where} \quad i \quad \text{is the translation index.} \tag{B.4}$$

For compact interpolation, the support of the family of wavelets (B.2) is the interval

$$I_\ell = [i/2^k, (i + 1)/2^k]. \tag{B.5}$$

For a fixed value of k, the intervals are disjoint if the left end point is omitted.

For $2^n + 1 \le \ell \le 2^m$, the components $w_{\ell j}$, $1 \le j \le 2^m$ of the discrete wavelet vector $\mathbf{w}_\ell$ are found by evaluating (B.2) on the grid $\mathbf{x}^m$:

$$w_{\ell j} = \begin{cases} w(2^k x_j^m - i) & \text{for} \quad \dfrac{i}{2^k} \le x_j^m \le \dfrac{i+1}{2^k}, \\ 0 & \text{otherwise,} \end{cases} \tag{B.6}$$

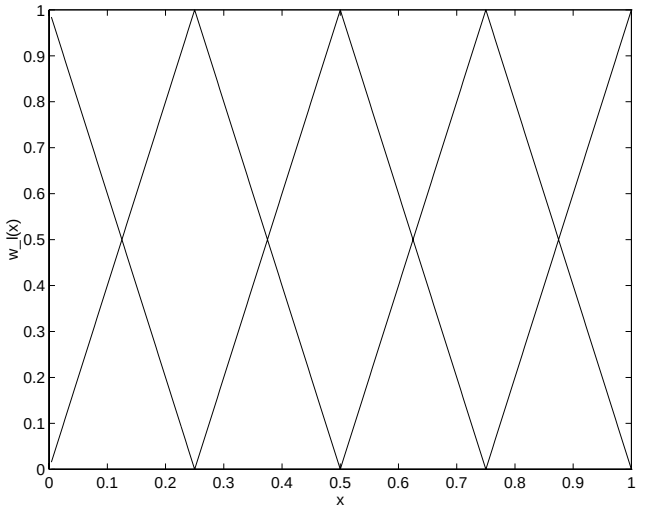

FIG. B.2. *Overlapping scaling functions for* $n = 2$.

where the relations between the indices k, i, ℓ are given by (B.2b), (B.2c), and (B.2d).

B.2.b. Basis vectors of $\hat{\mathbf{u}}^{(n)}$. The smallest value of ℓ in (B.2d) is $\ell = 2^n + 1$. For $1 \le \ell \le 2^n$, the family of scaling functions $w_\ell(x)$ is given by

$$w_\ell(x) = w(2^{n-1}x - i/2), \quad 0 \le x \le 1, \quad i = \ell - 1. \tag{B.7}$$

(See (A.9).) For $w(x)$ given by the hat function (A.8), continuous scaling functions $w_\ell(x)$ are plotted in Figure B.1 for $1 \le \ell \le 2$. The support of the family of scaling functions (B.7) is the interval

$$I_\ell = [i/2^n, (i+2)/2^n]. \tag{B.8}$$

It is clear that the intervals are not disjoint, i.e., the intervals overlap.

For $1 \le \ell \le 2^n$, the components $w_{\ell j}$, $1 \le j \le 2^m$ of the discrete scaling vector $\mathbf{w}_\ell$ are found by evaluating (B.7) on the grid $\mathbf{x}^m$:

$$w_{\ell j} = \begin{cases} w(2^{n-1}x_j^m - i/2) & \text{for} \quad \dfrac{i}{2^n} \le x_j^m \le \dfrac{i+2}{2^n}, \\ 0 & \text{otherwise}, \end{cases} \tag{B.9}$$

where $i = \ell - 1$.

Recall that we are considering the special case of the vectors $\mathbf{w}_\ell$ in the expansion (3.23b) of $\hat{\mathbf{u}}^{(n)}$. This corresponds to the lowest level of a discrete multiresolution algorithm and, as noted above, the scaling functions for an interpolatory multiresolution algorithm overlap at the lowest level $k = n$. For example, if we choose $n = 2$, then the four functions given by (B.7)

$$w_\ell(x) = w(2x - i/2), \quad i = 0, 1, 2, 3, \quad 0 \le x \le 1 \tag{B.10}$$

overlap as illustrated in Figure B.2. In writing (B.10) we have assumed that $w(x)$ is the hat function (A.8) with $w(x) = 0$ for $|x| > 1$ and that $w(2x)$, $0 \le x \le 1$ has been periodically extended to all x.

For the family of basis functions plotted in Figure B.1 the integer n is unity and the first two basis functions are scaling functions:

$$w_1(x) = w(x), \qquad w_2(x) = w(x - 1/2), \qquad 0 \le x \le 1. \tag{B.11}$$

It should be mentioned that the vector multiresolution algorithms of sections 6 and 7 have several piecewise polynomial scaling functions with compact support. Analytical formulas for particular multiple scaling functions are given in Appendix E.

Appendix C. Fill-in algorithm for scalar multiresolution. In the nested sequence of uniform grids (2.1) we assumed that $k = m$ corresponds to the *finest* grid for which a discrete vector $\mathbf{u}^m$ is defined. In this section we assume that $k = n$ corresponds to the *finest* grid for which a discrete vector $\mathbf{u}^n$ is defined, i.e.,

$$\mathbf{x}^n = [x_1^n, x_2^n, \dots, 1]^T, \quad \text{where} \quad x_j^n = j/2^n \tag{C.1}$$

on which an input vector

$$\mathbf{u}^n = [u_1^n, u_2^n, \dots, u_{J_n}^n]^T, \quad J_n = 2^n \tag{C.2}$$

is defined. Hence the nested sequence of uniform grids is $\{X^k\}_{k=n,n+1,\dots}$, where X^k is defined by (2.1). If one starts on the grid X^n and applies the reconstruction algorithm (3.12) with the error or residual term set to zero and with increasing values of k, then one obtains an iterative method of interpolation or *fill-in* between function values (C.2) on the grid X^n. The filled-in function is the subinterval function representation (or subgrid resolution).

For the scalar multiresolution algorithm of section 3 the fill-in algorithm is

fillin

For $k = n + 1, n + 2, \dots, max$
  For $j = 1, 2, \dots, J_{k-1}$

$$\begin{aligned} u_{2j}^k &= u_j^{k-1}, \\ u_{2j-1}^k &= I^{k-1}(x_{j-1/2}^{k-1}; u_j^{k-1}), \end{aligned} \tag{C.3}$$

  End
End

At each level k, additional function values, denoted by $\tilde{u}(x_{2j-1}^k)$, are generated at the dyadic grid points

$$X^k - X^{k-1} = \{x_{2j-1}^k\}_{j=1}^{J_{k-1}}. \tag{C.4}$$

In numerical computations, there is a truncated upper limit to the index k of (C.3), which is denoted by max. The number of grid points in the filled-in function is $2^{\max}$. The fill-in between the point values (C.2) is accomplished by the iterative interpolation process (C.3). This method of interpolation is due to Dubuc [Du86] and has been extended by Deslauriers and Dubuc [De89]. In the $\lim_{max\to\infty}$ the iterative process converges to a uniformly continuous function $\tilde{u}(x)$ [Du86].

The fill-in algorithm (C.3) can be recast in vector-matrix form as

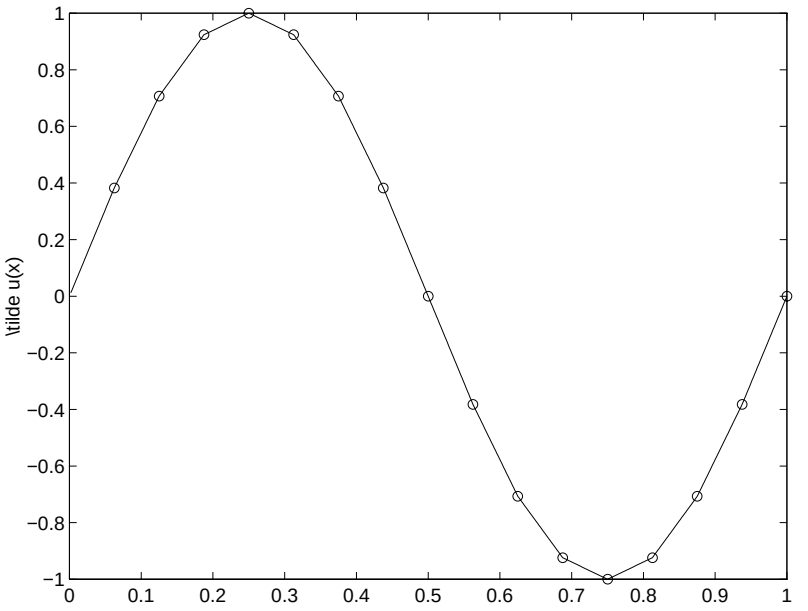

FIG. C.1. *Fill-in function for* $\sin(2\pi x)$.

fillin

For $k = n+1, n+2, \ldots, max$

$$\mathbf{u}^k = \mathbf{L}^s \mathbf{u}^{k-1} \tag{C.5}$$

End

The accuracy of the filled-in function $\tilde{u}(x)$ when compared to the function $u(x)$, whose point values were prescribed on the grid X^n, is determined by the interpolation formula used in the multiresolution algorithm. For example, the scalar algorithm (C.3) using linear interpolation (3.11) yields a piecewise linear function $\tilde{u}(x)$ between the original grid points X^n. The filled-in function for $\sin(2\pi x)$, $0 \le x \le 1$ with $n = 4$ is shown in Figure C.1. The open circles are the exact values of $\sin(2\pi x)$ on the grid (C.1).

The scaling function for a scalar interpolatory multiresolution algorithm, which we denote by $w(x)$, is easily computed numerically from the iterative *fill-in* algorithm. The scaling function is equivalent to the fundamental function defined by Dubuc [Du86]. For *compact* interpolation the support of scaling function is two intervals of the grid X^n. On the unit interval with $n = 1$ we write $[0,1] = [0,1/2] \cup [1/2,1]$. We assume that the scaling function $w(x)$ is zero at both ends of the unit interval $[0,1]$ and there is a unit perturbation at the center point $x = 1/2$:

$$w(0) = w(1) = 0, \qquad w(1/2) = 1. \tag{C.6}$$

Since the scaling function is zero on both ends of the unit interval, it is convenient to assume periodic boundary conditions when applying the fill-in algorithm. For (C.3) with $n = 1$, the *input* array corresponding to (C.2) is

$$\mathbf{w}^1 = [1,0]^T \quad \text{with} \quad \mathbf{x}^1 = [1/2,1]^T, \tag{C.7}$$

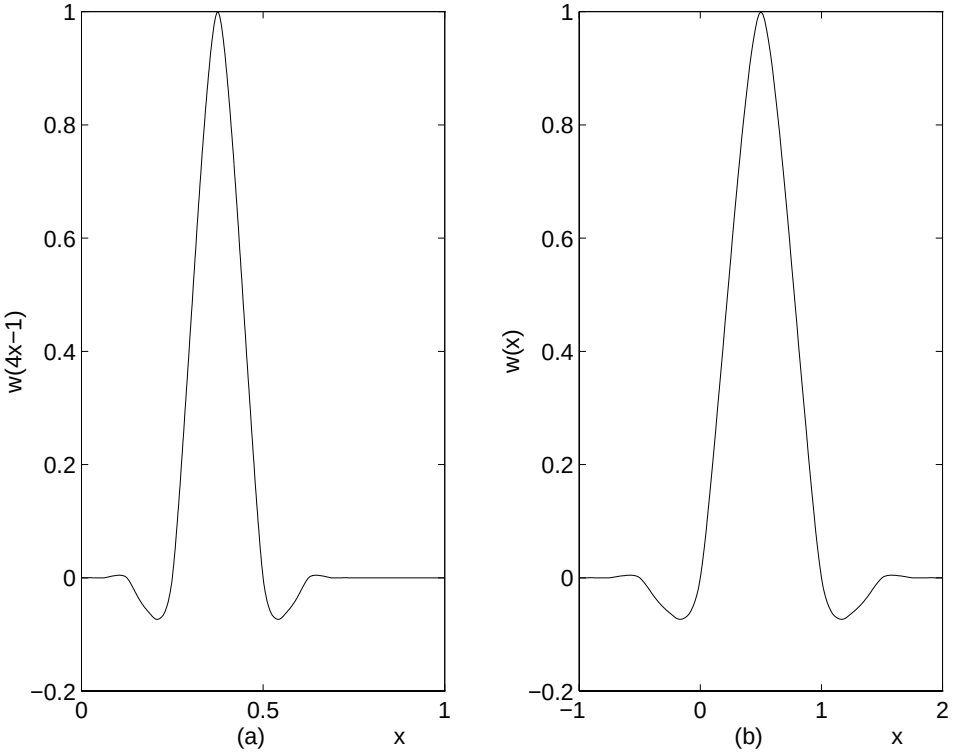

FIG. C.2. *Scaling function for noncompact cubic interpolation: (a) $w(4x-1)$, (b) $w(x)$.*

and the *output* array of the fill-in algorithm is a *table* of numerical values of $w(x)$ expressed in vector form

$$\mathbf{w}^{max} = \mathbf{tab}(w) = [w(x_1^{max}), w(x_2^{max}), \ldots, w(1)]^T \tag{C.8}$$

on the grid

$$\mathbf{x}^{max} = \mathbf{tab}(x) = [x_1^{max}, x_2^{max}, \ldots, 1]^T, \qquad x_j^{max} = j/2^{max}. \tag{C.9}$$

(The column vector notation $\mathbf{tab}(w)$ can be found, for example, in Dahlquist and Björck [Da74].) The dimensions of $\mathbf{tab}(w)$ and $\mathbf{tab}(x)$ are both 2^{max}. If one chooses the integer max large enough, then a point plot of the elements of $\mathbf{tab}(w)$ versus the points of the mesh $\mathbf{tab}(x)$ is so dense as to appear continuous. For any integer $max \geq n+1$, one has $\mathbf{tab}(w) \in \mathbf{R}^m$, $m = 2^{max}$, and in the $\lim_{max\to\infty}$ the iterative fill-in process converges to a continuous function $w(x) \in C[0,1]$.

For a scalar interpolatory multiresolution algorithm, linear interpolation is the only compact interpolation. If $max = 3$, then $2^{max} = 8$ and $\mathbf{tab}(w)$ has 8 values shown as open circles in the top plot of Figure B.1. For 2^{max} very large, a plot of $\mathbf{tab}(w)$ gives the hat function (Figure A.1). Since the interpolation is compact, the scaling function is the unit interpolation function.

For noncompact interpolation, the numerical computation of the scaling function is slightly more complicated since the support of the scaling function is larger than

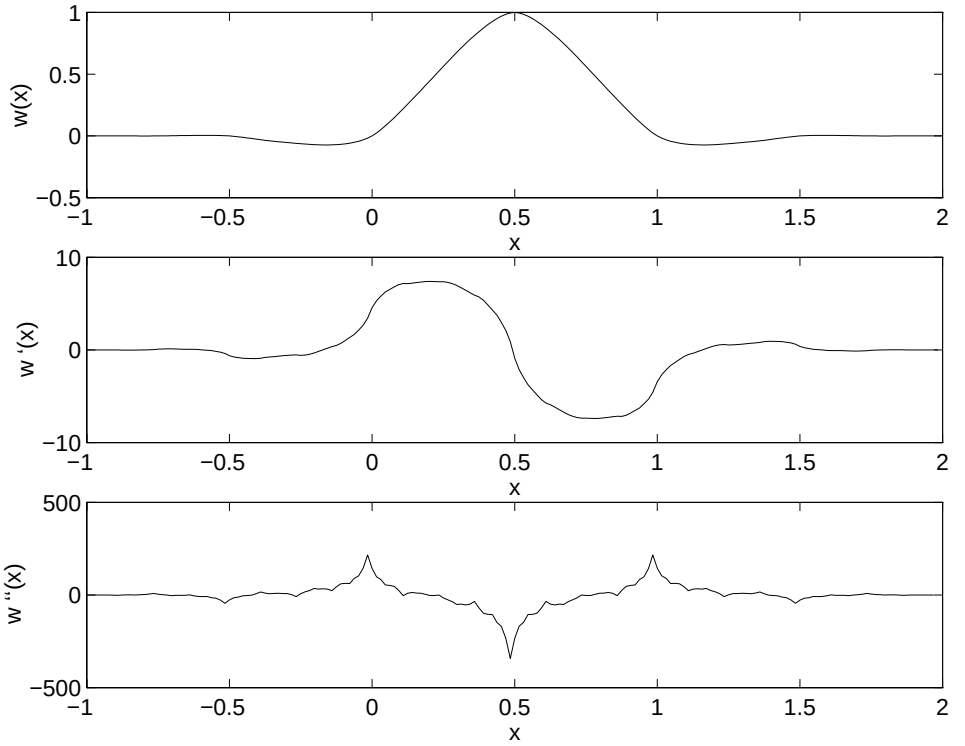

FIG. C.3.

two intervals. Furthermore, the scaling function is not a piecewise polynomial; in fact, it is not piecewise analytic (and it is not the unit interpolation function).

For noncompact cubic interpolation

$$\tilde{u}^{k-1}_{j-1/2} = I^{k-1}(x^{k-1}_{j-1/2}; u^{k-1}_j) = \frac{9}{16}(u^{k-1}_j + u^{k-1}_{j-1}) - \frac{1}{16}(u^{k-1}_{j+1} + u^{k-1}_{j-2}) \tag{C.10}$$

the support of the interpolation formula is three increments:

$$[x_{j-2}, x_{j-1}] \cup [x_{j-1}, x_j] \cup [x_j, x_{j+1}]. \tag{C.11}$$

Consequently, the support of the scaling function for cubic interpolation is six intervals. On the interval $[0, 1]$ with periodic boundary conditions, the index n must be at least 3 in the input vector (C.2) for the scaling function to *fit* in the unit interval with no periodic *wraparound*. For $n = 3$, we pick the input vector

$$\mathbf{w}^3 = [0, 0, 1, 0, 0, 0, 0, 0]^T, \quad \text{on the grid} \quad \mathbf{x}^3 = [1/8, 2/8, 3/8, \ldots, 1]^T. \tag{C.12}$$

There is a unit perturbation at $x = 3/8$, and there are three intervals of length $1/8$ to the left of $x = 3/8$ and five intervals to the right. Application of the fill-in algorithm (C.3) with the input vector (C.12) yields the scaling function (B.2a):

$$w_6(x) = w(4x - 1), \qquad 0 \le x \le 1. \tag{C.13}$$

This function is plotted in Figure C.2(a). On the unit interval the function (C.13) vanishes outside the interval $(0, 3/4)$ since the support is six intervals of length $1/8$. In

Figure C.2(b) we plot the scaling function $w(x)$ on the interval $(-1, 2)$. In the absence of any finite boundary effects, the function $w(x)$ vanishes outside the interval $(-1, 2)$. Note that the support of the scaling function for cubic interpolation is three times the support of the (hat) scaling function for linear interpolation plotted in Figure A.1.

For a *noncompact* scheme such as cubic interpolation (3.9), the scaling function (see, e.g., Figure C.2(b)) looks smooth but in fact is not even locally analytic. The *noncompact* scaling function $w(x)$ is continuously differentiable, and the function $w'(x)$ is *close* to being differentiable (see [Du86] for details). For cubic interpolation the scaling function computed by the fill-in algorithm and the first two derivatives computed by finite differences are shown in Figure C.3. At the end of his paper Dubuc [Du86] lists some open problems related to the scaling (or fundamental) function plotted in Figure C.2(b), e.g., "Is it possible that $w''(x)$ does not exist at any point x of $(-1, 2)$?".

Finally, one should note that, in the special case where the input function (C.2) is the point discretization of a polynomial of degree 3 or less, then the filled-in function $\tilde{u}(x)$ for cubic interpolation will be exact for appropriately modified nonperiodic boundary conditions.

Appendix D. Fill-in algorithm for vector multiresolution. The fill-in algorithm for vector multiresolution is an obvious generalization of the scalar algorithm given in Appendix C. If one starts at the finest grid X^n and applies the reconstruction algorithm (7.14b) with the error or residual term set to zero and with increasing values of k, then one obtains an iterative method of interpolation or the *fill-in* between function values and derivatives defined on the grid X^n. For the vector multiresolution algorithm (7.14) the fill-in algorithm is

fillin

For $k = n+1, n+2, \ldots, max$
  For $j = 1, 2, \ldots, J_{k-1}$

$$\begin{aligned} \boldsymbol{\mathcal{U}}^k_{2j} &= \boldsymbol{\mathcal{P}}_{/\boldsymbol{\alpha}}(\boldsymbol{\mathcal{U}}^{k-1}_j), \\ \boldsymbol{\mathcal{U}}^k_{2j-1} &= \boldsymbol{\mathcal{I}}^k[x^k_{2j-1}; \boldsymbol{\mathcal{U}}^k_{2j}], \end{aligned} \tag{D.1}$$

  End
End

At each level k, additional values $\tilde{\boldsymbol{\mathcal{U}}}(x^k_{2j-1})$ are generated at the dyadic grid points

$$X^k - X^{k-1} = \{x^k_{2j-1}\}_{j=1}^{J_{k-1}}. \tag{D.2}$$

The number of grid points in the filled-in function is 2^{max}.

The accuracy of the filled-in function is determined by the interpolation formula used in a vector multiresolution algorithm. Consider the vector multiresolution of section 6 where function values and derivatives are used. The cubic Hermite interpolation formula (6.4) yields a (cubic) filled-in function $\tilde{u}(x)$ between the original grid points X^n. As an example, we compute the filled-in function for $\sin(2\pi x)$, $0 \le x \le 1$ with $n = 2$. There are only four grid points and four function values (and four derivative values) on the given grid as indicated by the open circles of Figure D.1. In regards to plotting accuracy, there is no discernible difference between the exact and filled-in sine wave as illustrated in Figure D.1. One also obtains the filled-in derivative

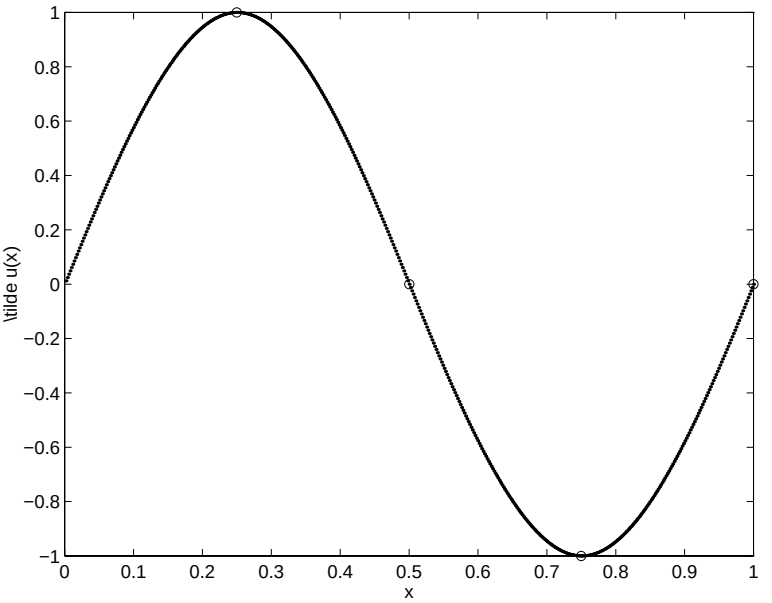

FIG. D.1. *Fill-in function for* $\sin(2\pi x)$.

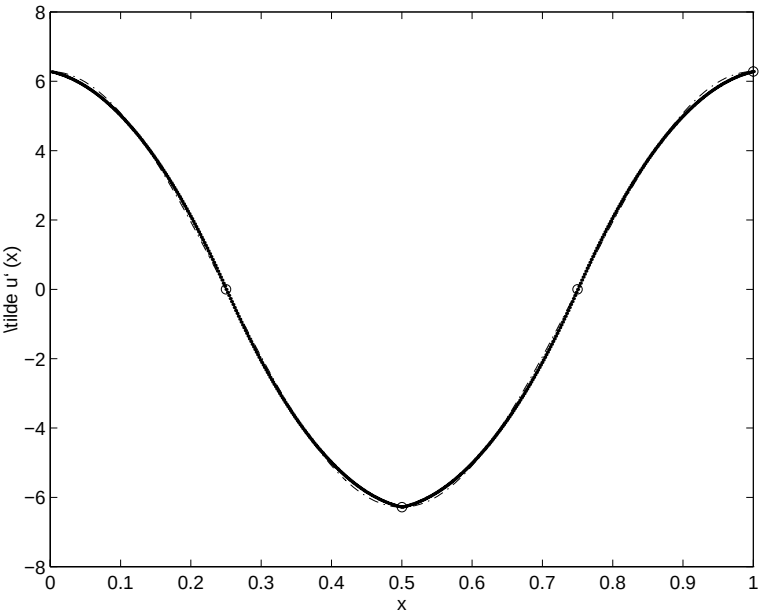

FIG. D.2. *Fill-in function for* $\sin'(2\pi x)$.

shown in Figure D.2. The filled-in derivative $\tilde{u}'(x)$ is plotted as a solid line, and the exact derivative is plotted as a dash-dot line. The filled-in derivative is a quadratic polynomial on each subinterval of the original grid.

Appendix E. Analytic formulas for the unit interpolation functions. The support of an interpolation formula is defined to be the number of subintervals spanned by the interpolation formula. Recall that in deriving a vector compact interpolation formula, the function value and $(\ell-1)$ derivatives are given at each end point of the subinterval $[x_{j-1}, x_j]$. Consequently, the support of a compact interpolation formula is one interval. The support of a unit interpolation function for an interpolatory multiresolution algorithm is equal to twice the support of the interpolation formula. Consequently, since we are utilizing compact interpolation, the support of the vector multiresolution unit interpolation functions is two intervals. The resulting unit interpolation functions are piecewise polynomials (two pieces) of odd degree $2\ell - 1$ with $\ell - 1$ continuous derivatives.

As previously noted, neither the development nor the implementation of an interpolatory multiresolution algorithm requires an explicit knowledge of the unit interpolation functions. However, in practice one needs to select unit interpolation functions appropriate for the particular application, and naturally, one would like to know what unit interpolation functions the multiresolution algorithm is producing. In this appendix we derive analytical formulas for the unit interpolation functions for several cases. The derivation follows the construction outlined in the first paragraph of section A.1. The unit interpolation functions of this appendix are called finite elements by Strela and Strang [Stre95]. They note that local interpolation distinguishes finite elements.

E.1. Linear interpolation. We divide the unit interval into two equal subintervals, write $[0, 1] = [0, 1/2] \cup [1/2, 1]$, and construct the unit interpolation function for linear interpolation (5.1). We assume that the unit interpolation function $w(x)$ is zero at both ends of the interval $[0, 1]$ and that there is a unit perturbation at the center point $w(1/2)$:

$$w(0) = 0, \tag{E.1a}$$

$$w(1) = 0, \tag{E.1b}$$

$$w(1/2) = 1. \tag{E.1c}$$

Using (E.1b) and (E.1c) evaluating the coefficients (5.1b) and (5.1c), and applying (5.1a) on the interval $[1/2, 1]$, one obtains the linear function

$$w(x) = -2(x - 1) \quad \text{for} \quad 1/2 \le x \le 1.$$

An analogous computation for the interval $[0, 1/2]$ yields the other half of a symmetric (about $x = 1/2$) piecewise linear unit interpolation function

$$w(x) = \begin{cases} 2x & \text{for} \quad 0 \le x \le 1/2 \\ -2(x-1) & \text{for} \quad 1/2 \le x \le 1. \end{cases} \tag{E.2}$$

The hat function (E.2) can also be written as (A.8) and is plotted in Figure A.1.

E.2. Hermite interpolation matching function values and first derivatives. Again the unit interval is divided into two equal subintervals. From the Hermite interpolation formula (5.5) we construct two independent unit interpolation functions. We assume that a unit interpolation function $w(x)$ and its derivative $w'(x)$ are zero at the ends of the interval $[0, 1]$:

$$w(0) = w'(0) = 0, \tag{E.3a}$$

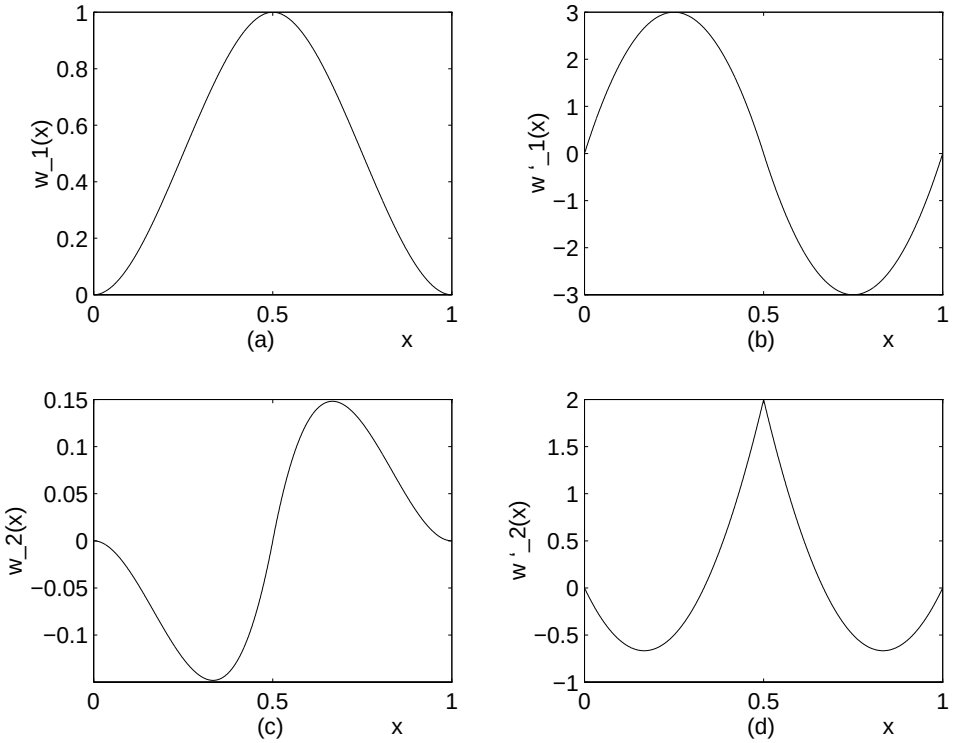

FIG. E.1. *Unit interpolation functions (and derivatives) for Hermite interpolation matching function values and first derivatives.*

$$w(1) = w'(1) = 0. \tag{E.3b}$$

For the center point $x = 1/2$ there are two cases:

$$\text{case a:} \quad w(1/2) \neq 0, \quad \text{and} \quad w'(1/2) = 0 \tag{E.4}$$

and

$$\text{case b:} \quad w(1/2) = 0, \quad \text{and} \quad w'(1/2) \neq 0. \tag{E.5}$$

For case (a) we assume there is a unit perturbation at the center point $x = 1/2$,

$$w(1/2) = 1, \tag{E.6}$$

and interpolate on the interval $[1/2, 1]$. Using the conditions (E.3b), (E.4), and (E.6), evaluating the coefficients (5.8), and applying (5.5), one obtains the cubic polynomial

$$w_1(x) = 4(x-1)^2(4x-1) \quad \text{for} \quad 1/2 \leq x \leq 1. \tag{E.7}$$

An analogous computation for the interval $[0, 1/2]$ yields the other half of a symmetric Hermite unit interpolation function

$$w_1(x) = \begin{cases} -4x^2(4x-3) & \text{for} \quad 0 \leq x \leq 1/2 \\ 4(x-1)^2(4x-1) & \text{for} \quad 1/2 \leq x \leq 1. \end{cases} \tag{E.8}$$

The unit interpolation function (E.8) is plotted in Figure E.1(a). The derivative interpolation function corresponding to case (a) is the derivative of $w_1(x)$:

$$w_1'(x) = \begin{cases} -24x(2x-1) & \text{for} \quad 0 \le x \le 1/2 \\ 24(x-1)(2x-1) & \text{for} \quad 1/2 \le x \le 1. \end{cases} \tag{E.9}$$

This function is plotted in Figure E.1(b).

For case (b) we recall from section 6 that in defining an interpolatory multiresolution algorithm it was convenient to remove the explicit dependence on the spacing h and we let $v(x) = hu'(x)$ on the mesh points. Hence we assume a unit perturbation for $hw'(x)$ at the center point $x = 1/2$:

$$hw'(1/2) = 1 \quad \text{or} \quad w'(1/2) = 2 \tag{E.10}$$

since $h = 1/2$. There follows a skew-symmetric Hermite unit interpolation function

$$w_2(x) = \begin{cases} 4x^2(2x-1) & \text{for} \quad 0 \le x \le 1/2 \\ 4(x-1)^2(2x-1) & \text{for} \quad 1/2 \le x \le 1. \end{cases} \tag{E.11}$$

The function (E.11) is plotted in Figure E.1(c). The derivative interpolation function corresponding to case (b) is the derivative of $w_2(x)$:

$$w_2'(x) = \begin{cases} 8x(3x-1) & \text{for} \quad 0 \le x \le 1/2 \\ 8(x-1)(3x-2) & \text{for} \quad 1/2 \le x \le 1. \end{cases} \tag{E.12}$$

The function (E.12) is plotted in Figure E.1(d). In the discrete multiresolution algorithm, the actual derivative interpolation functions are $hw_1'(x)$ and $hw_2'(x)$. Analytical formulas and plots of the unit interpolation functions for the case of Hermite interpolation matching function values, first derivatives, and second derivatives are given in Appendix G.3 of [Wa97]. In addition, analytical formulas and plots of the unit interpolation functions for the case of Hermite interpolation matching function values and second derivatives are given in Appendix G.4 of [Wa97].

ROBUST APPROXIMATE INVERSE PRECONDITIONING FOR THE CONJUGATE GRADIENT METHOD*

MICHELE BENZI†, JANE K. CULLUM‡, AND MIROSLAV TŮMA§

Abstract. We present a variant of the AINV factorized sparse approximate inverse algorithm which is applicable to any symmetric positive definite matrix. The new preconditioner is breakdown-free and, when used in conjunction with the conjugate gradient method, results in a reliable solver for highly ill-conditioned linear systems. We also investigate an alternative approach to a stable approximate inverse algorithm, based on the idea of diagonally compensated reduction of matrix entries. The results of numerical tests on challenging linear systems arising from finite element modeling of elasticity and diffusion problems are presented.

Key words. sparse linear systems, finite element matrices, preconditioned conjugate gradients, factorized sparse approximate inverses, incomplete conjugation, stabilized AINV, diagonally compensated reduction

1. Introduction.

We consider the solution of sparse linear systems $Ax = b$, where A is a symmetric and positive definite (SPD) matrix, by the preconditioned conjugate gradient method. In the last few years there has been considerable interest in explicit preconditioning techniques based on directly approximating A^{-1} with a sparse matrix M; see, e.g., [7], [8], [16], [18], [23], [24], [27], [31], and the recent survey [10]. Sparse approximate inverses have been shown to result in good rates of convergence of the preconditioned iteration (comparable to those obtained with incomplete factorization methods) while being well suited for implementation on vector and parallel architectures; see, e.g., [6], [9], [12], [21].

Although the main motivation for the development of sparse approximate inverse preconditioners comes from parallel processing, it is becoming clear that these techniques are also of interest because of their robustness. Sparse approximate inverses are often applicable to difficult problems where other preconditioners may break down [4]. For instance, incomplete factorization preconditioners, while widely popular and fairly robust, are not always reliable, in that the incomplete factorization process may

suffer from various types of instability [17], [20]. Even in the SPD case, existence of the standard incomplete Cholesky (IC) factorization [34] is guaranteed only for special classes of matrices, such as H-matrices [33]. For general SPD matrices, breakdown in the IC process may occur due to exceedingly small or negative pivots. For this reason, variants of IC have been developed which are applicable to any SPD matrix without breakdowns; see [1], [25], [28], [37], [38]. However, some of these modifications are expensive, while others require diagonal perturbations which introduce additional parameters in the algorithm.

We are interested in parallel preconditioners that are widely applicable, reliable, and effective at reducing the number of iterations. The factorized sparse approximate inverse (FSAI) method developed by Kolotilina and Yeremin in [31] is one of the very few naturally parallel techniques that are also quite effective and highly stable for arbitrary SPD matrices. In this method, a lower triangular matrix G is computed as a sparse approximation to L^{-1}, where $A = LL^T$ is the Cholesky factorization of A. The algorithm does not require any information about L and works exclusively with A. Entries of G are computed as solutions of small "local" linear systems having principal submatrices of A as coefficient matrices. These are SPD and can be solved in a stable way by standard direct methods. Hence, no breakdowns are possible in computing G. Also, G is necessarily nonsingular, and the preconditioner $M := G^T G \approx A^{-1}$ is SPD and can be used with the conjugate gradient method. The standard form of this algorithm requires a prescribed sparsity pattern for G. Some ideas for determining sparsity patterns can be found in [16] and [26], but the effectiveness of these heuristics for factorized approximate inverses remains to be investigated.

A different factorized sparse approximate inverse preconditioner, based on incomplete conjugation (A-orthogonalization) of the unit basis vectors, is the AINV preconditioner [7], [8]. This method does not require the sparsity pattern of the approximate inverse factors to be specified in advance; rather, a good sparsity pattern is determined *dynamically* as the preconditioner is being computed. This is done by applying a drop tolerance to the computed entries of the inverse factors. As shown in [6], the calculation of the preconditioner can be parallelized using graph partitioning. However, the preconditioner may not be well defined for a general SPD matrix, due to breakdowns—see the next section for the definition of breakdown in the context of AINV. A sufficient condition for AINV to be breakdown-free is that A be an H-matrix [7]. We recall that M-matrices and diagonally dominant matrices are examples of H-matrices. If A is far from being an M-matrix or diagonally dominant, for example, if A has large positive off-diagonal entries, the preconditioner may not be defined or may fail to be positive definite. This is indeed the case for many problems arising from finite element modeling of structures and thin shells [5] and for certain diffusion problems involving highly distorted meshes [35].

In this paper we present a variant of the AINV preconditioner which is well defined (in exact arithmetic) for an arbitrary SPD matrix. We refer to the resulting preconditioner as the stabilized AINV, or SAINV, preconditioner. It is mathematically equivalent to the standard AINV algorithm when no dropping is applied.

The price to pay for the added robustness is the slightly higher cost of computing the preconditioner with respect to the standard AINV algorithm. However, for most problems the cost of forming the preconditioner is still reasonable. As we will see, matrix reorderings and scalings can be used to reduce costs.

We mention that breakdown-free variants of AINV have also been developed, independently, by Bridson [14] and by Kharchenko et al. [29]. Bridson's scheme is

different from ours. The variant of Kharchenko et al., on the other hand, is identical to ours. Their paper offers independent further evidence of the reliability of this approach.

Together with SAINV, we explore another approach to preventing breakdowns in the AINV process, based on the notion of *diagonally compensated reduction of positive off-diagonal entries*. This technique, introduced and analyzed by Axelsson and Kolotilina in [3], associates with any SPD matrix a Stieltjes matrix (that is, a symmetric and necessarily positive definite M-matrix) in a natural way. The standard AINV process can be applied to this new matrix, without breakdowns, resulting in an approximate inverse that can be used as a preconditioner for the original system.

The remainder of the paper is organized as follows. In section 2 we recall the standard AINV algorithm and review the techniques that have been used so far to handle breakdowns. In section 3 we introduce the stabilized AINV algorithm for SPD matrices, and in section 4 we describe the alternative approach based on diagonally compensated reduction. Section 5 is devoted to numerical experiments using challenging matrices from finite element modeling, including some experiments with other methods. Finally, in section 6 we make some concluding remarks and suggestions for further work.

2. The AINV algorithm. From now on, $A \in \mathbb{R}^{n\times n}$ is assumed to be SPD. The AINV algorithm [7] builds a factorized sparse approximate inverse of the form

$$M = ZD^{-1}Z^T \approx A^{-1}, \tag{2.1}$$

where Z is a unit upper triangular matrix and D is diagonal. The approximate inverse factor Z is a sparse approximation of the inverse of the L^T factor in the LDL^T decomposition of A. When the inverse factorization is performed exactly, the diagonal matrix D is the same in the two decompositions and contains the *pivots* down the main diagonal.

The AINV algorithm computes Z and D directly from A by means of an incomplete A-orthogonalization process applied to the unit basis vectors. In this process, small elements are dropped to preserve sparsity. The underlying assumption is that most entries in L^{-1} are small in magnitude. This is true for many problems of practical interest, particularly for discretizations of partial differential equations of elliptic type. Sparsity can also be achieved by combining the dropping of small entries with suitable sparse matrix orderings, such as nested dissection and minimum degree. These orderings are beneficial in that they result in smaller time and space requirements for forming and storing the preconditioner, while at the same time improving the quality of the preconditioner in a significant number of cases; see [11], [15], [22].

In order to describe the procedure, let a_i^T denote the ith row of A. Also, let e_i denote the ith unit basis vector. The basic A-orthogonalization procedure can be written as follows.

ALGORITHM 2.1.

(1) *Let* $z_i^{(0)} = e_i \quad (1 \le i \le n)$
(2) *For* $i = 1, 2, \ldots, n$ *do*
(3) *For* $j = i, i+1, \ldots, n$ *do*
(4) $p_j^{(i-1)} := a_i^T z_j^{(i-1)}$
(5) *End do*
(6) *if* $i = n$ *go to* (11)
(7) *For* $j = i+1, \ldots, n$ *do*

(8) $$z_j^{(i)} := z_j^{(i-1)} - \left(\frac{p_j^{(i-1)}}{p_i^{(i-1)}}\right) z_i^{(i-1)}$$

(9) *End do*

(10) *End do*

(11) *Let* $z_i := z_i^{(i-1)}$ *and* $p_i := p_i^{(i-1)}$, *for* $1 \le i \le n$. *Return* $Z = [z_1, z_2, \ldots, z_n]$ *and* $D = \mathrm{diag}(p_1, p_2, \ldots, p_n)$.

Sparsity is preserved by dropping off-diagonal entries in the z-vectors after the updates at step (8). The resulting (incomplete) algorithm is sometimes referred to as the *right-looking* AINV process. A left-looking variant also exists [9], which is sometimes advantageous. These algorithms can be extended in a straightforward manner to the nonsymmetric case [8].

A *breakdown* is defined as a negative or zero value of a pivot p_i. When no dropping is applied, $p_i = z_i^T A z_i > 0$. The incomplete procedure is well defined, i.e., no breakdown can occur, if A is an H-matrix (in the absence of round-off). When no breakdown occurs, the resulting sparse approximate inverse preconditioner is usually quite effective; see [9], [10] for comparisons between AINV and other preconditioners. In the general case, breakdowns can occur. Breakdowns have a crippling effect on the quality of the preconditioner. A negative p_i would result in an approximate inverse which is not positive definite; a zero pivot would force termination of the procedure, since step (8) cannot be carried out. In practice, exactly zero pivots are very unlikely to occur, but exceedingly small pivots can happen, resulting in uncontrolled growth of the entries of Z and extremely high fill-in.

In [7], a dynamic strategy to shift negative or numerically small pivots away from zero was proposed. Unfortunately, in the vast majority of cases the resulting sparse approximate inverse is not a good preconditioner. A somewhat better strategy is to adapt to AINV the a priori diagonal shift technique introduced by Manteuffel [33] for the IC factorization. Whenever a negative or exceedingly small pivot is encountered, the AINV process is terminated and reattempted on a new matrix $A' := A + \alpha \mathrm{diag}(A)$. Here $\mathrm{diag}(A)$ denotes the main diagonal of A, and $\alpha > 0$ denotes a parameter such that A' has a stable approximate inverse factorization, to be determined by trial and error. That such an α must exist is clear, since the AINV process cannot break down on a diagonally dominant matrix, and α can be chosen so large as to make A' diagonally dominant. However, the *optimal* value of α is usually much smaller than the one that makes A' diagonally dominant. Although this shifting strategy has proved successful in handling some difficult problems, it is expensive and frequently produces preconditioners of poor quality.

In the next section we propose a reformulation of the AINV algorithm that is applicable, without breakdowns, to any SPD matrix.

3. Stabilized AINV. First we need to take a close look at the mechanism of breakdown. We begin by writing down the explicit formula for the p_j's:

$$p_j^{(i-1)} = a_i^T z_j^{(i-1)} = \sum_{l=1}^{i-1} a_{il} z_{lj}^{(i-1)} + a_{ij} \qquad (i \le j \le n). \tag{3.1}$$

Here a_{ij} is the (i,j) entry of A, and $z_{lj}^{(i-1)}$ denotes the lth entry of vector $z_j^{(i-1)}$. Suppose now that a dropping rule is applied in the calculation of the z-vectors. The modified z-vectors will be denoted by $\bar{z}_j^{(i-1)}$, and the corresponding pivots are given

by

$$\bar{p}_i^{(i-1)} = \sum_{l=1}^{i-1} a_{il}\bar{z}_{li}^{(i-1)} + a_{ii} \qquad (1 \le i \le n). \tag{3.2}$$

(We explicitly stipulate that no dropping is applied to the diagonal entries of Z or to the diagonal pivots.) When A is an M-matrix, it is easily seen by induction that all the $\bar{z}_{lj}^{(i-1)}$ are nonnegative [7]. Because the off-diagonal entries of A are nonpositive, the action of dropping one entry in the z-vector cannot cause the (inexact) pivot $\bar{p}_i^{(i-1)}$ to decrease; it either remains unchanged, or it increases, depending on whether the corresponding coefficient a_{il} is zero or not. Because the exact pivots are positive, the AINV process cannot break down. Indeed, dropping has the effect of stabilizing the AINV process even further. This is in perfect analogy with the IC factorization for M-matrices [34].

Dropping an entry at step $(i-1)$ of the AINV process amounts to setting $\bar{z}_{lj}^{(i-1)} = 0$ for some l. Therefore, if either

$$a_{il} > 0 \qquad \text{and} \qquad z_{li}^{(i-1)} > 0$$

or

$$a_{il} < 0 \qquad \text{and} \qquad z_{li}^{(i-1)} < 0,$$

then the inexact pivot will be smaller than the exact pivot. In particular, if either one of a_{il} or $z_{li}^{(i-1)}$ is positive and large and the other is positive and not small, the inexact pivot can be significantly smaller than the exact one and can even become negative. In reality, the dropping rule will cause many of the $\bar{z}_{lj}^{(i-1)}$ to be zero, and the net change in the ith pivot will be the result of cumulative effects, some of which tend to increase and others to decrease the value of $\bar{p}_i^{(i-1)}$. Such effects may cancel each other out. Nevertheless, we have observed in numerical experiments performed on matrices with relatively large positive off-diagonal entries that the inexact pivots can become negative and, in fact, rather large in absolute value. The matrices for which this behavior has been observed were not artificial examples but came from real applications in structural analysis. It is no surprise that just setting these negative pivots equal to some arbitrary positive quantity resulted in preconditioners of very poor quality.

The way to avoid nonpositive pivots is simply to recall that in the exact A-orthogonalization process, the p_i's are the diagonal entries of matrix D which satisfies the matrix equation

$$Z^T A Z = D;$$

hence for $1 \le i \le n$

$$p_i = z_i^T A z_i > 0$$

since A is SPD and $z_i \neq 0$. (Recall that the ith entry of z_i is equal to 1.) In the exact process, the following equality holds:

$$p_i = z_i^T A z_i = a_i^T z_i. \tag{3.3}$$

This identity follows immediately from the fact that Z is unit upper triangular and AZ is lower triangular. Clearly, it is more economical to compute the pivots using the expression on the right-hand side of (3.3) rather than that in the middle. The same goes for the p_j's:

$$p_j = z_i^T A z_j = a_i^T z_j. \tag{3.4}$$

(For brevity, we have omitted the $(i-1)$ superscripts in the above formulas.) However, because of dropping and the resulting loss of A-orthogonality in the $\bar{z}$-vectors, such identities no longer hold in the inexact process, and for some matrices one can have

$$a_i^T \bar{z}_i \ll \bar{z}_i^T A \bar{z}_i$$

with the concomitant possibility of breakdowns.

These simple observations point to several reformulations of the AINV algorithm that are breakdown-free in exact arithmetic. The simplest thing to do is to use the standard AINV process (Algorithm 2.1 with dropping) as far as possible, and to switch to formula $\bar{p}_i = \bar{z}_i^T A \bar{z}_i$ whenever a negative or exceedingly small pivot shows up. Unfortunately, this simple fix is not good enough. It typically results in slow convergence of the PCG iteration, and for really hard problems there may be no convergence within a reasonable number of steps. The reason is that by the time a negative pivot occurs, the loss of information about the true inverse due to dropping has already been so great that no "local" trick can succeed in recovering a good preconditioner. A more global strategy is needed.

We found that a robust algorithm requires that the $\bar{p}_i$'s be computed using the quadratic form $\bar{z}_i^T A \bar{z}_i$ throughout the entire AINV process, for $i = 1, \ldots, n$. This still leaves the question of how to compute the $\bar{p}_j$'s with $i+1 \le j \le n$. One could either use the inexpensive formula (3.1) or the more expensive bilinear form (3.4). In the latter case, we have

$$\bar{p}_j = \bar{v}_i^T \bar{z}_j, \qquad \text{where} \qquad \bar{v}_i^T := \bar{z}_i^T A.$$

Because the vector $\bar{v}_i$ has already been computed as part of the calculation of $\bar{p}_i$, this approach is only slightly more expensive than using formula (3.1). The difference depends on how much more dense $\bar{v}_i^T$ is compared to a_i^T. It turns out that using the bilinear form (3.4) results in a preconditioner of much higher quality for nearly the same cost, so it definitely pays off to use the more expensive approach.

Hence, we obtain a reliable version of the AINV algorithm based on the following reformulation of Algorithm 2.1.

ALGORITHM 3.1.

(1) *Let* $z_i^{(0)} = e_i \quad (1 \le i \le n)$
(2) *For* $i = 1, 2, \ldots, n$ *do*
(3) $\quad v_i := A z_i^{(i-1)}$
(4) $\quad$ *For* $j = i, i+1, \ldots, n$ *do*
(5) $\quad\quad p_j^{(i-1)} := v_i^T z_j^{(i-1)}$
(6) $\quad$ *End do*
(7) $\quad$ *if* $i = n$ *go to* (12)
(8) $\quad$ *For* $j = i+1, \ldots, n$ *do*
(9) $\quad\quad z_j^{(i)} := z_j^{(i-1)} - \left(\frac{p_j^{(i-1)}}{p_i^{(i-1)}} \right) z_i^{(i-1)}$

(10) *End do*
(11) *End do*
(12) *Let* $z_i := z_i^{(i-1)}$ *and* $p_i := p_i^{(i-1)}$, *for* $1 \le i \le n$. *Return*
$Z = [z_1, z_2, \ldots, z_n]$ *and* $D = \mathrm{diag}(p_1, p_2, \ldots, p_n)$.

Obviously, Algorithms 2.1 and 3.1 are mathematically equivalent. However, the incomplete process obtained by dropping in the z-vectors after step (9) of Algorithm 3.1 leads to a reliable approximate inverse procedure. This algorithm, in exact arithmetic, is applicable to any SPD matrix without breakdowns. Of course, instabilities due to positive but extremely small pivots may occur in finite precision, and a thresholding technique may still be necessary to guard against such possibility. However, we have not met this situation in our tests, and the resulting preconditioner appears to be reliable in practice. This new preconditioner will be hereafter referred to as the SAINV (for stabilized AINV) preconditioner.

What about the cost of SAINV? At first sight it might look very expensive to compute the preconditioner on the basis of Algorithm 3.1, which requires the computation of n matrix-vector products $v_i = Az_i$. To see that this is not nearly as expensive as it looks, it should be noticed that in the incomplete process the $\bar{z}_i$ vectors are kept sparse through the use of dropping (and possibly through reorderings). Hence, the n matrix-vector products can be performed in *sparse-sparse mode*, to borrow the term used in [18]. Hence, computing $\bar{v}_i$ amounts to forming a linear combination of a few columns of A, namely, those that correspond to nonzero entries in $\bar{z}_i$. Also, because $\bar{z}_i$ is the ith column of an upper triangular matrix, it is clear that at step i only the first i columns of A enter the matrix-vector product. Assuming that the drop tolerance is chosen so that the final Z contains $\mathcal{O}(n)$ nonzeros, and assuming an even distribution of nonzeros across the columns of Z, the cost of computing all the $\bar{p}_j$'s in the form of sparse bilinear expressions involving A is linear in the dimension n of the problem. As we shall see in the section on numerical experiments, the run time for computing the SAINV preconditioner is only slightly higher than that for the standard AINV algorithm when the latter does not break down, and the run time tends to be dominated by the time required to perform the iteration phase.

In the next section we briefly describe an alternative, inexpensive approach to systematically avoid breakdowns in the AINV process, based on the diagonally compensated reduction of positive off-diagonal matrix entries.

4. Diagonally compensated reduction approximate inverse. The method of diagonally compensated reduction of positive off-diagonal entries, due to Axelsson [2] and Axelsson and Kolotilina [3], associates with any SPD matrix A an SPD M-matrix $\hat{A}$. In the simplest variant of this technique, $\hat{A}$ is obtained by setting to zero the positive off-diagonal entries a_{ij} of A (reduction), which are subsequently added to the corresponding diagonal entry a_{ii} (diagonal compensation). Formally, the idea is to split A as

$$A = B + R,$$

where R contains the off-diagonal positive entries of A, and to let

$$\hat{A} = B + \Delta,$$

where Δ is the diagonal matrix satisfying

$$\Delta e = Re,$$

where e denotes the vector of all ones. Thus,

$$\hat{A} = A + (\Delta - R).$$

Notice that the symmetric matrix $\Delta - R$ is a singular M-matrix, since it has nonpositive off-diagonal entries and zero row sums; see [13], page 147. In particular, $\Delta - R$ is symmetric positive semidefinite. In turn, this shows that $\hat{A}$ is SPD, because it is the sum of an SPD matrix and a positive semidefinite one. Because $\hat{A}$ has nonpositive off-diagonal entries, it must be an M-matrix [13].

The standard AINV process can be applied to $\hat{A}$ without breakdowns, and the corresponding approximate inverse $M \approx \hat{A}^{-1}$ can be used as a preconditioner for the original linear system $Ax = b$. It is hoped that M will be a good preconditioner for A, provided that A is not too far from being an M-matrix. A rough way to estimate how much a given A deviates from being an M-matrix is to compute the Frobenius norm $\|R\|_F$ of the matrix R which contains the positive off-diagonal entries of A. To make this quantity invariant under global scalings, we divide it by $\|A\|_F$. That is, we let

$$\eta = \frac{\|R\|_F}{\|A\|_F}.$$

Notice that $0 \leq \eta < 1$, with $\eta = 0$ if and only if A is an M-matrix. In the next section we will try to ascertain whether there is a correlation between the size of η and the quality of the preconditioner M obtained by applying the standard AINV approximate inverse algorithm to $\hat{A}$. See [25] for results on the use of diagonally compensated reduction in the context of IC factorizations.

5. Numerical experiments. The standard AINV preconditioner is often applicable, with good results, to matrices that do not satisfy the H-matrix condition [7]. There are, however, applications that lead to matrices for which the standard AINV approach is unstable and produces unreliable preconditioners. This is typically the case for matrices from structural engineering, including finite element modeling of elasticity and thin shell problems [5].

Another class of problems for which the standard AINV method fails due to breakdowns consists of diffusion equations discretized on highly distorted finite element meshes (e.g., Kershaw meshes). Such meshes arise frequently in codes developed at Los Alamos and elsewhere for the modeling of phenomena with complex physics, e.g., radiation diffusion [35].

In this section we present the results of a number of numerical tests performed on a selection of 16 matrices from the 2 areas mentioned above. Of these, 14 are from structural analysis and the remaining 2 are diffusion problems. Most of the matrices from structural analysis can be downloaded from the Matrix Market website [36]. The exceptions are the NASA examples, extracted from the University of Florida Sparse Matrix Collection [19], and the SMT matrix, which was provided by R. Kouhia of the Helsinki University of Technology. The two diffusion problems were extracted from a Los Alamos diffusion package, AUGUSTUS, developed by Mike Hall. These are three-dimensional, steady-state problems defined on the unit cube discretized on a highly skewed Kershaw mesh using the scheme described in [35].

Some basic information about the tests problems is provided in Table 1. For each matrix we provide the problem size n, the number of nonzeros in the lower triangular part nnz, the value of η as defined in the previous section, and the application area. In the last column we give the number of iterations and time (in seconds) required to solve

the linear system using the conjugate gradient method with Jacobi preconditioning (JCG). The iteration was terminated when the 2-norm of the initial residual was reduced by at least 8 orders of magnitude, or when a maximum of 10,000 iterations was reached. The initial guess was the zero vector, and the right-hand side was constructed as $b = Ax$, where x is a vector with random entries, uniformly distributed in $(0, 1)$. Similar results were obtained for other choices of the right-hand side. All the runs were performed on a SUN Ultra 5 workstation, except for those with SMT and the AUGUSTUS diffusion problems, for which one processor of an SGI Origin 2000 was used. The codes were written in standard Fortran77 and compiled with the -O3 optimization option. As can be seen, several of these problems are rather difficult to solve and have substantial positive off-diagonal part R. The standard AINV algorithm is unstable on all these problems, except BCSSTK16, which is the easiest in our data set. The most challenging problems are BCSSTK25 and the thin shell S3RMQ4M1.

In the following tables we present a number of results obtained with various preconditioners. We provide the time for computing the preconditioner (P-time), the number of PCG iterations (Its), the time to perform the PCG iterations (It-time), the total time (Tot-time), and the density ρ of the preconditioner. This is defined as the ratio between the number of nonzeros in the approximate inverse factor and the number of nonzeros in the lower triangular part of A. The preconditioners considered are FSAI [31] and variants of the standard AINV algorithm and of SAINV. The variants correspond to various preliminary transformations operated on the coefficient matrix. These are symmetric diagonal scaling (J), reordering with the multiple minimum degree (MMD) algorithm [32], diagonally compensated reduction of positive off-diagonal entries (DCR), and combinations of these. Thus, for instance, J-DCR-MMD-AINV stands for the standard AINV algorithm applied to the matrix obtained from the diagonally compensated reduction of the original matrix after diagonal scaling and MMD reordering. For AINV and SAINV, the value $\tau = 10^{-1}$ of the drop tolerance is used throughout.

In Table 2 we present results obtained with the FSAI preconditioner [31]. This algorithm already incorporates a sophisticated scaling strategy; therefore, no diagonal scaling was applied. We found that MMD reordering had a beneficial effect on the

quality of FSAI preconditioning for most problems, especially the larger ones, and this ordering was used in the experiments. The sparsity pattern for the approximate inverse factor G was the same as that of the lower triangular part of $P^T AP$, where P is the permutation matrix corresponding to the MMD ordering.

These results clearly demonstrate the robustness of FSAI. This algorithm is generally more reliable and efficient than JCG. Note, however, the relatively poor performance on BCSSTK21. We mention that the performance of FSAI can be significantly improved using a better choice for the sparsity pattern and by postprocessing the preconditioner; see, e.g., the suggestions in [30].

In Table 3 we present results for BCSSTK16 using a variety of preconditioners. We show these results because the standard AINV is stable for this matrix and we wish to compare it with the new variants. The fastest total timing is in boldface.

There are several observations worth making. We note that AINV and SAINV both produce very sparse and yet quite effective preconditioners. Because of such sparsity, the cost of SAINV is not much higher than that of AINV, particularly with

symmetric scaling. On the other hand, diagonally compensated reduction (which is not needed here since AINV is stable), which also produces very sparse preconditioners, results in slower convergence and higher overall timings. These experiments suggest that SAINV can be superior to AINV even when AINV is stable, provided that the preconditioner is sufficiently sparse.

In Table 4 we show the results for a more difficult problem, BCSSTK18. These results are fairly typical, and this is why we discuss them in some detail. For this example, AINV is unstable. Applying symmetric scaling and reordering for sparsity improves the situation only slightly: convergence is extremely slow. Using diagonally compensated reduction with AINV is somewhat more effective, but worse than MMD-FSAI. We performed some experiments with a smaller value of the drop tolerance to see if a denser preconditioner would help, but this was not the case. The number of iterations was somewhat reduced but not the timings. Better results are obtained with SAINV, particularly in combination with scaling and MMD reordering. Notice that SAINV results in preconditioners which are fairly sparse, although not as much as for the previous example. The time for computing the approximate inverse with SAINV and its variants is still quite small.

In Table 5 we show the results of using AINV with diagonally compensated reduction. We see that this method is reliable but generally not very effective. On difficult matrices, such as BCSSTK18 and S3RMQ4M1, the performance is poor. In some cases, improved results can be obtained in combination with symmetric scalings and MMD reordering, but no clear trend emerges and it is difficult to make specific recommendations.

Table 6 contains results for the SAINV preconditioner. For most problems, the performance is better than that of DCR-AINV and comparable with that of MMD-FSAI. Note that MMD-FSAI performs better on the shell problems.

Finally, in Table 7 we show the results for SAINV used in conjunction with symmetric scaling and MMD reordering. While this combination is not always optimal, it was the best or nearly so in a majority of cases. Therefore we feel comfortable recommending to use this combination in practice. Note in particular that J-MMD-SAINV is on average a factor of three faster than Jacobi preconditioning. Also notice that this approach is better than using AINV with diagonally compensated reduc-

mention that for the matrices from structural analysis, which are fairly dense, the right-looking version of the SAINV code was found to be faster and it was the one used in the experiments. For the diffusion problems, which are comparatively sparse, the left-looking version is faster and was used for the runs presented here.

The experiments in this section suggest that SAINV is a robust and effective general purpose preconditioner for the conjugate gradient method, especially when used in combination with symmetric scalings and MMD ordering. The standard AINV preconditioner can be used in connection with diagonally compensated reduction, resulting in a preconditioner which is also reliable but not nearly as effective, with the possible exception of diffusion problems. Concerning this approach, we note that it is difficult to predict the performance on the basis of η. Some correlation is present, e.g., in the three shell problems, for which η increases with the difficulty of the problem. However, η is too coarse an indicator of performance to be useful in deciding when to use diagonally compensated reduction.

The SAINV preconditioner is also easy to use. As already mentioned, we have used the standard value $\tau = 10^{-1}$ for the drop tolerance in all the tests with AINV and SAINV. Much better results can be obtained in some cases with a different value of τ, but we deliberately avoided fine-tuning because we wanted to show that this is a good choice in general. Also, the performance of the algorithm is only moderately affected by the choice of τ, provided that it is not chosen too small or too large; see [12].

6. Conclusions. We have developed SAINV, a reliable version of the AINV factorized approximate inverse preconditioner for the conjugate gradient method. The algorithm is applicable to general SPD matrices, is easily parallelized, and performs well on challenging linear systems arising in finite element modeling of elasticity and diffusion problems. The new preconditioner is easy to use, as it does not require the user to specify a sparsity pattern for the approximate inverse but only the value of the drop tolerance τ. Typically, setting $\tau = 10^{-1}$ gives good results. While the setup phase is slightly more expensive than for the standard AINV preconditioner, the cost of computing the preconditioner is still reasonable and the overall algorithm is cost effective.

Our experiments indicate that the performance of SAINV can be significantly improved by applying some preliminary transformations to the matrix A, namely, symmetric diagonal scaling and MMD reordering. With these transformations the storage required for the SAINV preconditioner is often significantly less than that for the coefficient matrix A itself. We stress that the cost of these preprocessings is negligible compared to that of solving the linear system, and we recommend using them as the default options in practice.

We have also investigated the use of diagonally compensated reduction of positive off-diagonal matrix entries as an alternative, inexpensive means to stabilize the AINV preconditioner. While this approach gave good results on some of our test problems, it proved to be generally less effective than SAINV applied to the original matrix.

Acknowledgments. The first author would like to thank Sofia Benzi for postponing her birth until after the bulk of this work was completed. Parts of this paper were written while the third author was a visitor at Los Alamos National Laboratory; the hospitality and support of LANL are greatly appreciated. Thanks also to four anonymous referees for helpful comments.

PRECONDITIONING HIGHLY INDEFINITE AND NONSYMMETRIC MATRICES*

MICHELE BENZI†, JOHN C. HAWS‡, AND MIROSLAV TŮMA§

Abstract. Standard preconditioners, like incomplete factorizations, perform well when the coefficient matrix is diagonally dominant, but often fail on general sparse matrices. We experiment with nonsymmetric permutations and scalings aimed at placing large entries on the diagonal in the context of preconditioning for general sparse matrices. The permutations and scalings are those developed by Olschowka and Neumaier [*Linear Algebra Appl.*, 240 (1996), pp. 131–151] and by Duff and Koster [*SIAM J. Matrix Anal. Appl.*, 20 (1999), pp. 889–901; Tech. report Ral-Tr-99-030, Rutherford Appleton Laboratory, Chilton, UK, 1999]. We target highly indefinite, nonsymmetric problems that cause difficulties for preconditioned iterative solvers. Our numerical experiments indicate that the reliability and performance of preconditioned iterative solvers are greatly enhanced by such preprocessing.

Key words. linear systems of equations, sparse matrices, maximum transversal, nonsymmetric permutations, row and column scalings, preconditioned iterative methods, incomplete LU factorization, sparse approximate inverses

1. Introduction.

1.1. Motivation and focus. We consider the solution of sparse linear systems $Ax = b$, where A is a general sparse $n \times n$ nonsingular matrix, by preconditioned Krylov subspace methods [25], [39]. For a *general* sparse matrix we mean a matrix that has no special properties, such as symmetry, positive definiteness, diagonal dominance, etc. In particular, we focus on matrices that are highly unstructured, nonsymmetric (structurally as well as numerically), and indefinite; i.e., the eigenvalues of A can lie anywhere in the complex plane. Such matrices arise frequently in the simulation of chemical engineering processes, in economic modeling, in management science, in the analysis of circuits and power system networks, and elsewhere. These problems are very different from the ones arising from the numerical solution of elliptic partial differential equations (PDEs) and can cause serious difficulties for standard iterative methods and preconditioners.

There have been a few attempts to use preconditioned Krylov subspace methods in these contexts, but in general the results have been far from satisfactory. For

example, in [11], various incomplete factorization (ILU) preconditioners and iterative solvers were tested on a set of standard problems from chemical engineering. The main conclusions of that study were that such linear systems are difficult to solve with iterative methods (as indicated by the large number of reported failures) and that realizing the potential of iterative solvers will require improvements in the reordering and/or preconditioning schemes. Similar conclusions were reached in [33] for the use of iterative methods in circuit simulations. The use of preconditioned Krylov subspace methods for the solution of sparse linear systems arising in economic modeling has been investigated in [37] and [24]. There the conclusion was that iterative solvers are often superior to direct ones. However, some of the problems could not be solved by iterative methods; see [37].

Preconditioned iterative methods work especially well when the coefficient matrix is, at least to some degree, diagonally dominant. Reliable methods also exist to handle matrices that are symmetric positive definite, or M-matrices. Matrices with these properties arise frequently from the discretization of second-order, elliptic PDEs. Standard preconditioners, such as those based on incomplete factorizations of the coefficient matrix, are usually reliable under these circumstances and typically deliver good rates of convergence. In contrast, such preconditioners are often unstable or may not even be defined when the coefficient matrix has zeros on the main diagonal and/or is highly nonsymmetric (see the discussion in section 2). Furthermore, the presence of many eigenvalues with arbitrary real part (positive, negative, and zero) causes serious difficulties for many Krylov subspace solvers. Matrices of this kind are loosely referred to as *highly indefinite*, regardless of whether or not they are symmetric. Coefficient matrices from chemical engineering, circuits, economics, etc., often exhibit a large number of zero diagonal entries and poor spectral distributions, and they represent a challenge for preconditioned Krylov subspace solvers.

1.2. Contributions of the paper. In [36], Olschowka and Neumaier introduce new permutations and scaling strategies for Gaussian elimination. The goal is to preprocess the coefficient matrix so as to obtain an equivalent system with a matrix that is more diagonally dominant. This preprocessing reduces the need for partial pivoting, thereby speeding up the solution process, and has a beneficial effect on the accuracy of the computed solution. Although the focus in [36] is on dense systems, the sparse case and the case of incomplete factorizations are also briefly discussed. These and other heuristics have been further developed and efficiently implemented by Duff and Koster; see [18] and [19]. Some evidence of the usefulness of these preprocessings in connection with sparse direct solvers and for ILU preconditioning has been provided in [18] and [19]; see also [30]. Our contribution is to carry out a systematic experimental study of the use of these permutation and scaling algorithms in the context of preconditioned iterative methods applied to challenging linear systems. We consider a number of different preconditioners (diagonal, ILU, sparse approximate inverses) and the combined use of nonsymmetric permutations aimed at improving numerical stability with symmetric ones aimed at reducing fill-in in the preconditioner. Our experiments indicate that this preprocessing, and particularly the use of maximum product transversals, enables the stable computation of the preconditioners, resulting in an overall solution strategy that is both reliable and cost effective.

While we do not claim that this approach to preconditioning general sparse matrices will always work, we do hope that the results in this paper will contribute to a reassessment of the role of iterative solvers in areas where these methods had been almost written off as unreliable, such as chemical engineering. We also hope that

one-sided permutations (and related scalings) will find widespread use in the arena of preconditioned iterative solvers for highly indefinite and nonsymmetric linear systems.

The paper is organized as follows. In section 2 we briefly discuss the preconditioners used in the paper. In section 3, which is based on [19], we recall the one-sided permutations and scalings used to preprocess the matrices. The test problems used for the numerical experiments are described in section 4, and the numerical experiments themselves in section 5. Finally, in section 6 we present our conclusions.

2. ILU and approximate inverse preconditioners. In this section we briefly discuss the preconditioners used in the numerical experiments. We focus our attention on ILU-type techniques and on a sparse approximate inverse preconditioner in factorized form, AINV. These are general-purpose, algebraic preconditioners that have been used successfully to solve a wide range of problems, particularly from PDEs. For a detailed treatment of ILU preconditioning we refer the reader to [39]. For a recent survey of sparse approximate inverse preconditioners, see [6].

ILU methods compute sparse approximations to the triangular factors L and U of A. The incomplete factors are obtained by dropping nonzero entries generated in the course of the factorization process (*fill-ins*) according to some rule. Different dropping rules give rise to different ILU preconditioners. When all fill-ins are discarded and only nonzeros in positions corresponding to the nonzero entries of A are retained, the ILU(0) preconditioner [34] is obtained. This preconditioner is easy to implement and inexpensive to compute, but it is often not good enough, particularly for the kind of challenging problems considered in this paper. More powerful preconditioners can be obtained by allowing more fill-in in the incomplete factors, or by dropping fill-ins based on their value rather than position. These techniques include level-of-fills ILU, denoted ILU(k), and dual threshold ILU, denoted ILUT(tol, p). Here $k \geq 1$ is the fill level, $tol \geq 0$ is a drop tolerance, and $p \geq 0$ denotes the number of off-diagonal nonzeros that are retained in each row of the incomplete factor (usually the p largest ones among those nonzeros that are greater than tol in absolute value).

Although fairly robust in practice, ILU preconditioners often fail on general sparse matrices because of instabilities (see below). In fact, the incomplete factors may not even exist. One way to improve their robustness is by incorporating partial (column) pivoting in the incomplete factorization. In the case of ILUT, this leads to a variant, called ILUTP [39], which is sometimes successful when ILUT fails. However, even this approach often fails when applied to general sparse matrices; see [10] and subsection 5.4 below.

There are two types of instability that ILU preconditioners may suffer from. These instabilities have been discussed in detail in [10]; here we give a brief discussion only. Let $\bar{L}$ and $\bar{U}$ denote the incomplete factors, and let

$$R := \bar{L}\bar{U} - A$$

denote the residual matrix. Also, let

$$E := I - A(\bar{L}\bar{U})^{-1}$$

denote the error matrix, assuming that preconditioning is being applied on the right. Notice that $E = R(\bar{L}\bar{U})^{-1}$. Let $\|\cdot\|_F$ denote the Frobenius matrix norm. In the symmetric positive definite case, there is a good correlation between the size of $\|R\|_F$ and the rate of convergence of the preconditioned conjugate gradient method [20]. On the other hand, in the case of general sparse matrices, $\|R\|_F$ alone is not a reliable

indicator of the quality of the preconditioner; instead, both $\|R\|_F$ and $\|E\|_F$ should be taken into account. Note that $\|R\|_F$ can be interpreted as a measure of the *accuracy* of the preconditioner, regarded as an approximation of A, while $\|E\|_F$ gauges the *stability* of the approximation. In general, a large value of $\|R\|_F$ means a poor approximation and hence a poor preconditioner. This can be caused, for instance, by very small pivots encountered in the course of the incomplete factorization, and accounts for a first kind of instability. However, even if $\|R\|_F$ is small, it can happen that $\bar{L}^{-1}$ and/or $\bar{U}^{-1}$ have very large entries. Therefore $\|E\|_F = \|R(\bar{L}\bar{U})^{-1}\|_F$ could be large, in which case the preconditioned matrix will be far from the identity, and the preconditioned iteration will either stagnate or diverge, leading to a second kind of instability. We stress that the instability here is not in the incomplete factorization process, but in the incomplete factors. Unstable (more accurately, ill-conditioned) ILU factors occur frequently for matrices that are far from symmetric and lack diagonal dominance; see [22], [10], [4].

For general sparse matrices, it is frequently the case that both kinds of instability occur simultaneously, with a crippling effect on the quality of the preconditioner. In general, the *complete* LU factorization of A may not even be defined without pivoting, or it may be unstable. This can happen, for example, when there are zero or small entries on the main diagonal. As long as A is nonsingular it has (in exact arithmetic) an LU factorization with pivoting, but this is not true for *incomplete* factorizations [38]. On the other hand, ILU factorizations that are both accurate and stable are possible for diagonally dominant matrices.

Because of these and other limitations of ILU-type preconditioners, alternative preconditioning techniques based on sparse approximate inverses have been intensively developed in the past few years. The AINV algorithm [3], [5], based on an incomplete biconjugation process, has been shown to be one of the most effective techniques in this class. Here the preconditioner is the product of two triangular matrices, which are sparse approximations to the inverses of the L and U factors of A. Sparsity is preserved by using a drop tolerance. The approximate inverse factors are computed directly from A; no knowledge of the factors L or U is needed. Factorized approximate inverse preconditioners share one drawback with ILU-type techniques: The construction phase is guaranteed to be breakdown-free only for special classes of matrices. Sufficient conditions are that A be symmetric positive definite or an H-matrix; see [29], [3], [28], [2]. For general sparse matrices, instabilities due to very small or zero pivots can occur during the construction of the preconditioner, with disastrous effects. This is perfectly analogous to the instability of the first kind for ILU. Notice that, in contrast to ILU, the instability of the second kind—unstable ILU solves—is not an issue here.

Like for ILU, the performance of approximate inverse preconditioners in factorized form is sensitive to the ordering of the matrix. For structurally symmetric (or nearly so) matrices having a stable AINV preconditioner, it was shown in [9] and [7] that symmetric reorderings that reduce fill-in in the inverse factors, like minimum degree or (generalized) nested dissection, can be used to improve the performance of the preconditioner. However, these symmetric reorderings alone are of little use for general sparse matrices, as in this case the AINV preconditioner may not even be defined. As we shall see, the stability and effectiveness of AINV can be dramatically improved by nonsymmetric permutations and scalings aimed at placing large entries on the main diagonal.

3. Overview of algorithms for finding maximum transversals. In this section we give a summary of algorithms for determining permutations of a matrix that place entries of large absolute value on the main diagonal. The codes used to

perform the permutations were taken from MC64, a set of Fortran routines that will be included in a forthcoming release of the Harwell Subroutine Library. Further details on the algorithms and implementations are provided in [19].

We examine three approaches for permuting large entries to the diagonal of matrices. First, we discuss methods for permuting a matrix so that the diagonal contains a maximum number of nonzeros; this method is referred to as finding a *maximum transversal* or *maximum matching*. Second, we discuss a method that permutes a matrix so that the product of the absolute value of the entries on the diagonal is maximized. Third, we discuss a variant of the second method, where the matrix is permuted so that the absolute value of the smallest entry on the diagonal is maximized.

Finally, we include a discussion on how to scale the entries of a matrix so that its diagonal entries are 1 in absolute value, and its off-diagonal entries are all less than or equal to 1 in absolute value.

In our experiments we found that, in general, the best results in terms of both preconditioner fill and convergence rates were obtained when matrices were permuted so as to maximize the product of the absolute value of the entries on the diagonal, and scaled so that the diagonal entries are 1 in absolute value, and off-diagonal entries are all less than or equal to 1 in absolute value. Also note that the timing behaviors mentioned in the discussions of the algorithms below are worst-case scenarios. The implementations in MC64 are efficient and the preprocessing phase is very fast, even for relatively dense matrices.

3.1. Finding a maximum transversal. Let $A = (a_{ij})$ be a general $n \times n$ matrix. Let $\mathcal{M}$ denote a set of at most n ordered index pairs $(i, j), 1 \le i, j \le n$, in which each row index i and each column index j appears at most once. $\mathcal{M}$ is called a *transversal* or *matching*. When $\mathcal{M}$ has maximum cardinality (n for structurally nonsingular matrices), $\mathcal{M}$ is called a *maximum transversal* or *maximum matching*.

In the case where $|\mathcal{M}| = n$, then $\mathcal{M}$ defines an $n \times n$ permutation matrix $Q = (q_{ij})$, where

$$\begin{cases} q_{ji} = 1 & \text{for } (i, j) \in \mathcal{M}, \\ q_{ji} = 0 & \text{otherwise}, \end{cases}$$

and thus AQ and QA are matrices with the transversal entries on the diagonal. Because our code is row oriented, we limit our discussion to row permutations, i.e., permutations of the form QA.

One of the options in MC64 uses the algorithm MC21 implemented by Duff [14], [15]. MC21 is a depth-first search algorithm with look-ahead; for a sparse matrix with τ nonzero entries, the algorithm has worst-case complexity of $\mathcal{O}(n\tau)$ but in practice exhibits $\mathcal{O}(n + \tau)$ behavior.

The use of such a reordering strategy is fundamental as the first step of permuting sparse reducible matrices to block triangular form. We mention that permuting to a zero-free diagonal has been examined before as a reordering strategy for preconditioning; see, for instance, [11] and [5]. Clearly, such a permutation will prove beneficial when, under the original ordering, there are zeros lying on the diagonal. However, in our experiments, we encountered few cases where finding a maximum transversal provided more benefit than finding a maximum product transversal.

3.2. Finding a maximum product transversal. In this subsection, we discuss permuting a matrix so that the product of the absolute value of the entries along

the diagonal is maximized. That is, we look for a permutation σ that maximizes

$$\prod_{i=1}^{n} |a_{\sigma(i)i}|. \tag{3.1}$$

This strategy, combined with the scalings mentioned below, was introduced in [36] for pivoting in dense Gaussian elimination.

First, this maximization problem is translated into a minimization problem. Let $a_i = \max_j |a_{ij}|$ denote the maximum value in row i of the matrix A. Define the matrix $C = (c_{ij})$ by

$$c_{ij} = \begin{cases} \log a_i - \log |a_{ij}| & \text{for } a_{ij} \neq 0, \\ \infty & \text{otherwise.} \end{cases}$$

Then maximizing (3.1) is equivalent to minimizing

$$\sum_{i=1}^{n} c_{\sigma(i)i}. \tag{3.2}$$

Minimizing the sum (3.2) is equivalent to finding a minimum weight perfect matching. In combinatorial optimization, this is known as the bipartite weighted matching problem, or linear assignment problem. MC64 uses a sparse variant of the bipartite weighted matching algorithm introduced in [36]. Fundamental to finding a minimum weight perfect matching is finding a shortest augmenting path, which in turn relies on a sparse variant of Dijkstra's algorithm [13]. For a full $n \times n$ matrix, the assignment problem can be solved in $\mathcal{O}(n^3)$ time; for a sparse matrix, the problem can be solved in $\mathcal{O}(n\tau \log n)$ time.

An important aspect of applying the bipartite weighted matching algorithm to the matrix C is the following result [21]: A perfect matching $\mathcal{M}$ has minimum weight if and only if there exist vectors $u = (u_i)$ and $v = (v_i)$, each of length n, such that

$$\begin{cases} u_i + v_j = c_{ij} & \text{for } (i,j) \in \mathcal{M}, \\ u_i + v_j \leq c_{ij} & \text{for } (i,j) \notin \mathcal{M}. \end{cases} \tag{3.3}$$

These vectors u and v are used in scaling the permuted matrix (see below).

3.3. Algorithm for finding a bottleneck transversal. In this subsection we consider a simple variation of the method discussed in the previous subsection. Here we are interested in finding a permutation of A such that the smallest absolute value on the diagonal is maximized. That is, we look for a permutation σ that maximizes

$$\min_{1 \leq i \leq n} |a_{\sigma(i)i}|, \tag{3.4}$$

and define the matrix $C = (c_{ij})$ by

$$c_{ij} = \begin{cases} a_i - |a_{ij}| & \text{for } a_{ij} \neq 0, \\ \infty & \text{otherwise.} \end{cases}$$

Then maximizing (3.4) is equivalent to minimizing

$$\max_{1 \leq i \leq n} c_{\sigma(i)i}. \tag{3.5}$$

Thus the maximum product transversal algorithm can be applied here, with only minor modifications, such as to replace the sum operation (3.2) by the max operation (3.5).

Note that this method regards only the smallest entry on the diagonal of the permuted matrix. For example, as mentioned in [19], consider a matrix having a row containing only one nonzero entry whose absolute value is the smallest in the matrix. Then the bottleneck transversal algorithm may return a transversal with small values on the diagonal. MC64 takes a somewhat different approach to avoid this problem; see [18], [19] for details.

Scaling the matrix prior to finding a bottleneck transversal also alleviates this problem. Ultimately, though, we note that we found few examples where bottleneck transversal permutations proved superior to maximum product transversal permutations.

3.4. Scaling. It is often beneficial to scale the matrices using the parameters u_i and v_j from (3.3) obtained in the weighted matching algorithm. To this end, define diagonal matrices D_1 and D_2 by

$$\begin{aligned} D_1 &= \operatorname{diag}(d_1^1, d_2^1, \ldots, d_n^1), \quad d_j^1 = \exp(v_j)/a_j, \\ D_2 &= \operatorname{diag}(d_1^2, d_2^2, \ldots, d_n^2), \quad d_i^2 = \exp(u_i). \end{aligned} \tag{3.6}$$

Then QD_1AD_2 is a matrix whose diagonal entries are 1 in absolute value, and whose off-diagonal entries are all less than or equal to 1, in absolute value. Such a matrix is referred to as an I-matrix in [36]. By simply changing the sign of rows (or columns) having a diagonal entry equal to -1 we obtain a matrix with unit diagonal. The eigenvalues of such a matrix lie in discs centered at 1, with radii equal to the sum of the absolute values of the off-diagonal entries in the corresponding row. Therefore, the less the matrix deviates from a diagonally dominant matrix, the more clustered the eigenvalues will be, around 1. In the ideal case, all the discs of such a matrix will have radii less than 1, and the matrix will be strictly rowwise diagonally dominant. In turn, this guarantees that ILU and AINV preconditioners will be well defined. It is also a favorable situation for Krylov subspace methods since, in particular, all the eigenvalues will have positive real part.

4. Description of test problems. In this section we describe the matrices that were used in the numerical experiments. Most of these matrices are available in the public domain [17], [12], [35]. They are representative of problems from a variety of applications, but they have in common the fact that they are difficult to solve with iterative methods. The matrices are listed in Table 1 below, together with some basic information. In Table 9 we report the estimate for the condition number returned by MATLAB (except for the last three problems, which are too large).

The first eight matrices are from chemical engineering and represent simulations of different chemical processes. While they are not large, these matrices are interesting because of the challenge they pose to iterative solvers. They are highly unstructured, very far from being structurally symmetric, with most of the diagonal entries equal to zero. In addition, they are highly indefinite and tend to be very ill conditioned. Matrices similar to these have been used to test ILU-type preconditioners in [11]. In that paper, MC21 was used to obtain a zero-free diagonal: The results were poor.

VENKAT25	2D unstructured Euler solver, time step=25	62424	1717792

The next five matrices come from the general area of mathematical economics and management. These matrices are also highly unstructured, nonsymmetric, indefinite with most diagonal entries equal to zero, and cause difficulties for preconditioned iterative methods.

The next three matrices arise in circuit design. The first two problems are described in [33] and are available from the Matrix Market [35]. The original matrices WATSON4 and WATSON5 are rectangular; as in [33], we appended one row at the bottom of these matrices to make them square (and we changed the names to WATSON4a and WATSON5a). The row vector used was $e_n^T = (0, \ldots, 0, 1)$. All diagonal entries are nonzero. The third circuit matrix was kindly provided by Wim Bomhof of Utrecht University; see [8]. This matrix has some zero diagonal entries. All three matrices are very sparse, and they exhibit a good deal of structural symmetry.

Finally, we included six matrices from the discretization of PDEs. Of these, SHERMAN2 does not present any difficulty for ILU preconditioning, but it has been reported by several researchers as being quite challenging for sparse approximate in-

verse preconditioners; see, e.g., [1], [6], [26], and [27]. Matrix LNS3937 has a zero diagonal block corresponding to the divergence constraint in the Navier–Stokes equations and is challenging for both ILU and approximate inverse techniques; see, respectively, [10] and [1]. Zero diagonal blocks induced by constraints also occur in the unstructured finite element matrices SLIDE and TWO-DOM, which were kindly provided by Ivan Otero (Lawrence Livermore National Laboratory). Matrix UTM5940 is fairly difficult to solve with ILU-type methods [10] and is even more so by sparse approximate inverse techniques. Matrix VENKAT25 was included because it is difficult for AINV. These last two matrices have no zero diagonal entries.

These matrices are just a selection from a larger set that was used for the tests; the chosen problems are representative of the results observed. As we will see, preprocessing makes all these problems solvable by iterative methods preconditioned with ILUT and AINV, and many of them even with ILU(0) or ILU(1) preconditioning. We found, however, several problems that could not be solved by the techniques employed in this paper. In these cases, the preconditioned iteration usually converged, but to a seriously inaccurate solution. Among these matrices we mention SHYY41 (also discussed in [10]), NNC666 and NNC1374, GRAHAM1, several of the FIDAP matrices, and some of the LHR0∗c matrices from chemical engineering, all available in [12] or [35]. We tried to solve these problems by a *direct* method, namely, Gaussian elimination with partial pivoting, but again the computed solution was affected by large errors. The same happened when we used the *complete* factors computed with the direct method as preconditioners for Krylov subspace methods—a form of iterative refinement. Not surprisingly, these matrices are severely ill conditioned. One cannot blame an algorithm for being unable to produce accurate solutions to extremely ill conditioned problems. In this paper, we only present results for problems that could be solved with some accuracy.

5. Numerical experiments. In this section we report on numerical experiments aimed at assessing the impact of the MC64 permutation and scaling routines on the robustness and performance of preconditioned Krylov subspace methods. All algorithms were implemented in Fortran77 using double precision arithmetic. The codes were compiled by `f77` with the `-O3` optimization option. Test runs were performed on a Sun Ultra 5 workstation for all test problems except the last three, for which one 250 MHz processor of an SGI Origin 2000 computer was used.

Three different Krylov subspace solvers were tried: BiCGSTAB [41], GMRES [40], and TFQMR [23]. While the three algorithms performed similarly on most problems, BiCGSTAB was found to be somewhat better than the others overall. Therefore, we will present results for BiCGSTAB only. The preconditioners used are diagonal (Jacobi) scaling, ILU(0), ILU(1), ILUT, and AINV. Besides these, we performed experiments also with ILUTP [39] and SPAI [26]. In all cases, right preconditioning was used. An artificial right-hand side b was used in the runs, so that the system $Ax = b$ had the known solution $x = (x_i)$ with $x_i = i$, $1 \le i \le n$. Runs were performed also with other choices of b, with similar results. The initial guess was always the zero vector, $x_0 = 0$. The iteration was stopped when the ℓ_2-norm of the initial residual was reduced by at least eight orders of magnitude, or when a maximum number of iterations maxit $= \min\{n, 2000\}$ was reached.

Some comments on the accuracy of the approximate solutions corresponding to this stopping criterion are in order. As reported in Table 9, many of the test matrices are very ill conditioned, and a small residual does not necessarily guarantee a small error. Nevertheless, the stopping criterion adopted was sufficient to produce

solutions with good relative accuracy except in a few cases (BAYER09, GEMAT12, CIRCUIT3), where some of the components of the solution were affected by large errors. For these cases, reducing the stopping tolerance from 10^{-8} to 10^{-12} resulted in accurate solutions, at the expense of an increase in the number of iterations of roughly 30%. However, all the results presented in the subsequent sections correspond to the stopping tolerance 10^{-8}.

5.1. Testing reliability. Here we present results aimed at assessing the impact of the preprocessing on the reliability of preconditioned BiCGSTAB. Only iteration counts are reported. In Table 2 we report the results of runs using diagonal (Jacobi) preconditioning for the original matrix (under "orig") and for different preprocessings: the basic maximum transversal (under "mc21"), the bottleneck transversal (under "bt"), the maximum product transversal without scalings (under "mpd"), and with scalings (under "mps").

A "‡" means that the preconditioner was not defined, due to zeros on the main diagonal. A "†" means failure to converge within the maximum number of allowed iterations. A "*bd*" denotes a breakdown in the BiCGSTAB acceleration. Notice that mc21 leaves matrices WATSON4a, WATSON5a, SHERMAN2, UTM5940, and VENKAT25 unchanged, since these matrices have no zero diagonal entries.

The only problem that can be solved without any preprocessing is the small circuit matrix WATSON4a, which requires a number of iterations almost equal to the order of the matrix. While the maximum and bottleneck transversals lead to virtually no improvements, the maximum product transversals result in convergence in nine cases. In particular, six out of the eight chemical engineering problems and both economics problems can be solved using Jacobi preconditioning in connection with

the maximum product transversal and associated scalings. Notice that with mps, Jacobi preconditioning simply has the effect of changing the sign of those matrix columns for which the corresponding diagonal entry is -1.

The next three tables report the results obtained for various ILU-type preconditioners. As is well known, these preconditioners are sensitive to the ordering of the equations and unknowns. Therefore, after applying the various preprocessings, we also reorder the matrix with a symmetric permutation. Consider for instance mps preprocessing. Indicated with D_1 and D_2, respectively, the row and column scalings associated with the maximum product transversal and with Q the corresponding row permutation that permutes the scaled matrix to a zero-free diagonal form, the symmetric permutations are based on the adjacency graph of the symmetric matrix $\hat{A} + \hat{A}^T$, where $\hat{A} = QD_1AD_2$. Once the permutation matrix P has been determined, one solves the following linear system:

$$(P^T Q D_1 A D_2 P)y = P^T Q D_1 b.$$

The solution of the original linear system is then $x = D_2 P y$. The preconditioner calculation is carried out on the scaled and reordered matrix

$$\tilde{A} = P^T Q D_1 A D_2 P.$$

While the purpose of the scalings D_1, D_2 and of the one-sided permutation Q is to improve stability, the main effect of the symmetric permutation P is to increase the effectiveness of the preconditioner by making it more accurate. For structurally symmetric matrices that are numerically unsymmetric and far from diagonally dominant, it was found in [4] that the performance and robustness of ILU-type preconditioners was generally improved by the reverse Cuthill–McKee ordering [16], denoted "rcm" in the tables (see column "SO"). Thus, we used rcm as the default ordering for ILU preconditioners. Although it is not always the best ordering, rcm gave good results in a majority of cases, in good agreement with the conclusions in [4]. Whenever rcm performed poorly we switched to another symmetric ordering, like multiple minimum degree [32] (denoted "mmd") or generalized nested dissection [31] (denoted "gnd"). Occasionally, we found that no symmetric reordering was the best option (denoted "no" in the tables). In these tables, a "‡" indicates a failure due to pivot breakdown; i.e., a zero or exceedingly small pivot was encountered in the course of the incomplete factorization.

The results for ILU(0) preconditioning are reported in Table 3. Again, using just mc21 is ineffective, with the only exception of matrix ORANI678. Results for the bottleneck transversal are not much better. However, the robustness of ILU(0) is greatly improved when the maximum product transversal is used. No pivot breakdown occurs, and all but five problems can be solved. The five failures are due to very slow convergence except for CIRCUIT3, for which the ILU(0) factors are unstable. Using different symmetric reorderings for these problems did not help.

We notice that there are two matrices, SHERMAN2 and VENKAT25, which can be easily solved with ILU(0) preconditioning without any preprocessing. Indeed, using mps results in a slight deterioration in the rate of convergence. Clearly, if a given combination of preconditioner and Krylov subspace solver gives good results, the use of preprocessing is not necessary and should not be used. We further observe that in several cases, mpd (without scalings) gives better results than mps. The same phenomenon occurs also for Jacobi and ILU(1) preconditioning (see Tables 2 and 4).

In Table 4 we report the results obtained with ILU(1) preconditioning. Again, mc21 and bt offer little benefit, whereas the use of mpd or mps allows all but three problems to be solved. With mpd we had one failure due to pivot breakdown (WEST0655), one due to slow convergence (WATSON5a), and one due to unstable ILU factors (CIRCUIT3). For mps, unstable ILU solves were the cause of all three failures. Notice that in a few cases, ILU(1) performs worse than ILU(0). However, all PDE problems can be solved with ILU(1) when either mpd or mps is used, with mpd giving somewhat better results on average.

It is already clear from these results that the reliability of preconditioned iterative solvers is greatly enhanced by the use of one-sided permutations aimed at placing large entries on the main diagonal, even when simple preconditioners like ILU(0) and ILU(1) are used. There are, however, a few hard problems for which this approach does not work. Additional robustness can be achieved by using a drop tolerance.

In Table 5 we present results for the popular dual-threshold ILUT(tol, p) preconditioner. Our strategy for the experiments was the following. We used the default parameters $tol = 10^{-1}$, $p = 5$ with rcm as the basic symmetric reordering. Whenever we found that this combination produced poor results, we switched to a different symmetric reordering until a good one was found (in the following order: mmd, gnd, no reordering). When this didn't work we changed the ILUT parameters by decreasing tol and, if necessary, increasing p. We do not claim that this leads to an optimal, or even good preconditioning strategy: Rather, the purpose of these experiments is to demonstrate that iterative solvers can be made reliable without much need for fine-tuning. We emphasize that the values $tol = 10^{-1}$ and $p = 5$ are not typical for ILUT. Usually, a much smaller drop tolerance and a much larger value of p are used,

particularly for hard problems: see, e.g., [10]. In other words, we chose to use a very sparse preconditioner, in many cases even sparser than the original matrix. We made this choice deliberately, with the intent to show that most problems become very easy to solve once the preprocessing phase is applied. In general, better results can be obtained with a different choice of the parameters.

The results in Table 5 show that with mps, all problems can be solved with ILUT preconditioning. In a majority of cases the basic combination of rcm reordering with $tol = 10^{-1}$ and $p = 5$ was sufficient to solve the problem. In some cases, an alternative symmetric reordering and/or additional fill-in had to be used in order to achieve convergence. The hardest problems for ILUT appear to be BAYER10, CIRCUIT3, and UTM5940. Notice that complementing the maximum product transversal with scalings has the effect of improving the reliability and performance of ILUT-preconditioned BiCGSTAB in nearly all cases. The only serious exception to this rule occurs for CIRCUIT3, for which the number of iterations increases from 36 to 90.

In Table 6 we present results for the drop-tolerance-based sparse approximate inverse AINV preconditioner. Like ILU-type preconditioners, AINV is sensitive to the ordering. In [9] and [7] it was shown that mmd is generally a good ordering for AINV, with gnd a close second. On the other hand, rcm cannot be recommended in general. Thus, the default parameters used were mmd reordering and $tol = 10^{-1}$. For a few hard problems, it was necessary to switch to gnd reordering (or no reordering) and to reduce the drop tolerance. However, no effort was made to tune the parameters for optimal performance. As for the ILU preconditioner, failures due to pivot breakdowns are denoted by "‡" and failures due to slow convergence by "†."

As for ILUT, we see that mps preprocessing enables BiCGSTAB preconditioned with AINV to solve all our test problems. For instance, problem SHERMAN2, which is notoriously difficult for approximate inverse methods, becomes very easy to solve. We also see that in most cases scalings improve the performance of the maximum product transversal. More importantly, scalings improve reliability, as shown by the fact that there are four problems that cannot be solved with mpd alone.

5.2. Timing results. From the experiments performed so far it appears that mps preprocessing dramatically increases the reliability and performance of Krylov subspace methods preconditioned with drop-tolerance-based preconditioners, like ILUT and AINV. The question remains to be addressed of how expensive the preprocessing phase is in practice. This is an important question because this preprocessing phase, dependent as it is on the numerical values of the matrix coefficients, is not easy to amortize, except for the situation where a sequence of linear systems with the same coefficient matrix and different right-hand sides must be solved. If the coefficient matrix changes, the preprocessing has to be applied anew.

Timing results relative to ILUT and AINV are presented in Tables 7 and 8, respectively. We report the time to perform the mps preprocessing (under NSO-time), the time for the symmetric reordering (under SO-time), the time for computing the preconditioner (under P-time), the time to perform the iterative solve phase (It-time), and, in the last column, the total solution time (under Tot-time). Timings are in seconds, and were measured with the `dtime` function. We also report the density ρ of the preconditioner, defined as the ratio between the number of nonzeros in the preconditioner over the number of nonzeros in the original coefficient matrix A. The number of iterations to converge (Its) is also included. The parameters and symmetric

reorderings are the same as those used for the runs in Tables 5 and 6.

Concerning the cost of the preprocessing, we see that it is usually small compared with the overall solution costs. For the larger problems the cost of preprocessing, including the time to apply the symmetric reordering, is negligible compared with the total solve time. We also see that in most cases the time for the nonsymmetric permutation and scaling is comparable to the time required for the symmetric permutations, which are based on the (unweighted) graph of the matrix only.

The performance of ILUT preconditioning is impressive: In most cases, rapid convergence is obtained with a very sparse preconditioner. For the few cases where a high number of iterations is required to achieve convergence (GEMAT11, GEMAT12, SLIDE, and TWO-DOM) we found that much faster convergence and smaller timings result if more fill-in is allowed. For instance, using ILUT$(10^{-3}, 10)$ on GEMAT11 results in convergence in 40 iterations with preconditioner density $\rho = 1.46$, and the total solution time becomes 1.81 seconds.

It is our opinion that when used with mps preprocessing, ILUT preconditioning has the potential to become a useful tool for solving linear equations from chemical engineering applications. Because rapid convergence can be achieved with very sparse incomplete factorization preconditioners, this approach may be competitive with sparse direct methods. This approach also has considerable potential for matrices arising from economic modeling and management science, although we have less experience with such problems.

On the other hand, it is unclear whether this approach is really useful for matrices arising in circuit simulations. Sparse direct solvers suffer very little fill-in on such problems when a good ordering is adopted. Hence, for iterative solvers to be

competitive with direct methods they must converge extremely fast with very sparse preconditioners. From our test runs, this seems to be difficult to achieve unless the incomplete factorization closely approaches a complete one. We note that in [8] a combined direct/iterative method is described in which the preconditioned iteration is applied to a relatively small Schur complement matrix. This algorithm appears to be competitive with sparse direct solvers, so there is a role for iterative methods in this area.

In terms of timings and storage requirements, AINV (Table 8) is generally more expensive than ILUT, but it should be kept in mind that an important advantage of AINV, its parallelizability, is not captured by these one-processor experiments. There are a few cases where the density of the preconditioner is rather high. Sparser preconditioners can be obtained by using a larger value of *tol*, but this may slow down convergence considerably. This is especially true for the chemical engineering problems. On the other hand, we found that for the PDE problems faster convergence and smaller overall timings can be obtained by allowing more fill in the preconditioner. The same applies to the GEMAT$*$ problems. Notice the good performance of AINV on the matrices from economics, MAHINDAS and ORANI678. As for the circuit matrices, similar remarks as for ILUT apply. The main point here is that mps preprocessing dramatically increases the reliability of both ILUT and AINV preconditioning, therefore considerably widening the range of applicability of such techniques.

5.3. Further analysis of the results. In order to have a better understanding of the effect of the MC64 permutations and scalings used for preprocessing, we collected the statistics presented in Table 9. Under "condest" we report the condition number (estimated with the MATLAB function `condest`) for the original matrix and for the matrix scaled by the row and column scalings associated with mps preprocessing. The condition number could not be estimated for the three largest matrices.

Under "d.d. rows" we report the number of (weakly) diagonally dominant rows in the original matrix, in the matrix permuted with the maximum product transversal (mpd), and in the matrix scaled and permuted with mps. Under "d.d. cols" similar statistics are reported relative to the number of (weakly) diagonally dominant columns.

The statistics show that the chemical engineering matrices greatly benefit from the permutations and scalings: The number of diagonally dominant rows and columns is greatly increased, and ill conditioning is drastically reduced. Analogous remarks apply to problems MAHINDAS, ORANI678, BP200, and GEMAT11. Hence, it is not surprising that preconditioned iterative methods perform well on these problems when mps preprocessing is used.

For problems GEMAT12 and CIRCUIT3, the scalings have the effect of increasing the condition number. However, for GEMAT12 the number of weakly diagonally dominant rows and columns is greatly increased by the mpd preprocessing. The increase is somewhat smaller when scalings are used, but it is still a significant improvement. This makes the preconditioner computation stable, and therefore the net effect is positive. Matrices WATSON4a and WATSON5a are better conditioned after scaling and have a greater fraction of diagonally dominant rows after mpd. However, the scalings have the effect of reducing the number of diagonally dominant rows as compared with using mpd alone. Perhaps this explains why using mps often gives worse results than using mpd alone for these matrices (see Tables 3, 5, and 6).

For the matrices arising from PDE problems, the permutations and scalings are generally beneficial. For VENKAT25, it is not clear from the results reported in Table 9 whether the preprocessing does any good. However, we know that ILUT and AINV benefit from the preprocessing. Although no row or column became diagonally dominant after the permutations and scalings, we found that the Gerschgorin bounds on the real and imaginary parts of the eigenvalues were one order of magnitude smaller after mps preprocessing, suggesting that the scaled and permuted matrix is not as far from diagonally dominant and has a more clustered spectrum than the original matrix.

5.4. Experiments with ILUTP and SPAI. We also experimented with the ILUTP preconditioner [39], which is generally more reliable than ILUT. However, we found that ILUTP preconditioning applied to the original matrices, or even to those permuted with mc21, is hardly better than ILUT, unless very large amounts of fill are allowed. Moreover, we found several problems that could not be solved by ILUTP even with very large amounts of fill ($tol = 0$, $p = 30$). These are WEST0655, LHR01, LHR02, BAYER09, BAYER10, BP200, and LNS3937. The failure of ILUTP was due to pivot breakdowns in all cases, except for LNS3937, where it appeared to be due to unstable ILU factors. It is mentioned in [10] that ILUTP with row pivoting (rather than column pivoting) is able to solve LHR01, but it took 134 iterations of GMRES(50) and a rather dense preconditioner. Using ILUT with mps, we can solve LHR01 in 41 iterations with a very sparse preconditioner (see Table 7). On the other hand, none of the techniques used in [10] succeeded in solving problem LNS3937, which is easily solved by ILUT with mps preprocessing. Hence, based on our experiments,

using standard ILUT with mps preprocessing is a more robust approach than using ILUTP alone on the original problem.

When ILUTP is used in combination with mps it gives good results, sometimes better than those obtained with ILUT for the same choice of the parameters. However, the use of column pivoting makes ILUTP slightly more expensive than ILUT, and it is unclear whether ILUTP is worth using with mps preprocessing.

Additional experiments were performed with the sparse approximate inverse preconditioner SPAI [26]. This technique is based on adaptive Frobenius norm minimization. Because the SPAI preconditioner is not factorized, it is insensitive to the ordering of the equations and unknowns. However, it is sensitive to scalings. We tested SPAI on the original matrices and with mps preprocessing. We found that overall, the use of scalings improves the reliability and performance of SPAI. This was especially true for the chemical engineering matrices; none of these matrices could be solved with SPAI, even with generous amounts of fill, but all of them could be solved after applying mps preprocessing. The same happened with MAHINDAS, BP200, SHERMAN2, LNS3937, and UTM5940.

In [1, p. 112], the authors give results for LNS3937 using a parallel implementation of BiCGSTAB preconditioned with SPAI. This took 1942 iterations with an approximate inverse containing 1588045 nonzeros, corresponding to $\rho = 61.3$! The total solution time was 567.3 seconds using 16 processors of a Cray T3E. Using SPAI with mps preprocessing, we can solve LNS3937 in 660 iterations with a preconditioner containing 150270 nonzeros, corresponding to $\rho = 5.9$, for a total solution time of 88.5 seconds on a Sun Ultra 5 workstation. Nevertheless, SPAI is outperformed by ILU(1), ILUT, and AINV used in combination with mps. Furthermore, SPAI failed on GEMAT12 and CIRCUIT3 (with or without mps). Finally, we found that mps had a detrimental effect on the convergence rate obtained with SPAI applied to matrices SLIDE, TWO-DOM, and VENKAT25.

6. Conclusions. The experiments presented in this paper indicate that the reliability and performance of Krylov subspace methods preconditioned with standard incomplete factorizations can be dramatically enhanced by means of nonsymmetric permutations and scalings aimed at placing large entries on the main diagonal. A similar effect is observed for other preconditioning techniques, such as factorized sparse approximate inverses. This preprocessing phase is inexpensive, both in absolute terms and relative to the total solution costs.

Of the heuristics considered in this paper, the maximum product transversal algorithm gave the best results. With this preprocessing, many of the diagonal entries are large relative to the off-diagonal ones, and the matrix is closer to being diagonally dominant. This not only has a stabilizing effect on the computation of the preconditioner, but also results in preconditioners of high quality in terms of convergence rates in many cases. When used in combination with scalings, which in most cases improve the conditioning of the problem, preconditioners based on drop tolerances (like ILUT and AINV) become quite reliable.

Much work remains to be done before preconditioned iterative methods can become a viable alternative to direct methods in areas such as chemical engineering, economics and management, circuit design, etc. Nevertheless, it is now at least conceivable to use iterative methods in such areas, and fair comparisons with direct solvers can be established. In addition to this, our experiments suggest that nonsymmetric permutations and scalings can be useful to improve the performance of iterative solvers even in areas where these are already widely used, such as PDE problems.

Acknowledgments. We would like to thank Iain Duff and Jacko Koster for providing us with the MC64 subroutines. We are indebted to Jane Cullum, Iain Duff, Daniel Szyld, and two anonymous referees for their constructive criticism of an early draft of the paper. This work was performed while the second author was a Graduate Research Assistant at Los Alamos National Laboratory (LANL): The hospitality and support of LANL are greatly appreciated.

MODE JUMPING IN THE VON KÁRMÁN EQUATIONS*

C.-S. CHIEN†, S.-Y. GONG†, AND Z. MEI‡

Dedicated to Professor Klaus Böhmer on the occasion of his sixtieth birthday.

Abstract. We study numerical approximations of bifurcating solution curves of the von Kármán equations with simply supported and clamped boundary conditions, respectively. Of special interest here is the splitting of a double bifurcation point into two simple bifurcation points, and the tracing of the associated secondary solution branches, which corresponds to the phenomenon of mode jumping in the buckling of a rectangular plate. A continuation-unsymmetric Lanczos algorithm is utilized for curve-tracking. Our numerical results verify the theoretical prediction of Schaeffer and Golubitsky, namely, mode jumping occurs when the boundary is partially clamped, but not if it is merely simply supported.

Key words. von Kármán equations, mode jumping, bifurcation, continuation methods, unsymmetric Lanczos method

1. Introduction.

We consider a long rectangular plate P in compression. The Airy stress function $f(x, y)$ produced in P and the deformation $w(x, y)$ of P from its flat state are described by the von Kármán equations [4, 5, 6, 7, 14, 15, 24]

$$\begin{array}{rcl} \Delta^2 f \ + \ \frac{1}{2}[w,w] & = & 0 \\ \Delta^2 w \ - \ [w,f] \ + \ \lambda w_{xx} & = & 0 \end{array} \qquad \text{in} \quad \Omega = [0,l] \times [0,1]. \tag{1.1}$$

Here λ is the external load, Δ^2 is the biharmonic operator in the plane, Ω is the shape of the plate, and the bracket operator $[\cdot, \cdot]$ is defined by

$$[u, v] = u_{xx}v_{yy} - 2u_{xy}v_{xy} + u_{yy}v_{xx}.$$

As is well known, a rectangular plate can support a number of different buckled configurations, which may be distinguished by the number of buckles or wave numbers, respectively. A plate has zero deflection along its nodal lines. Bauer, Keller, and Reiss [3] observed that a double bifurcation can be split into two simple bifurcations by perturbation. Let λ_1 and λ_2 with $\lambda_1 < \lambda_2$ be the load corresponding to these two simple bifurcations. Suppose that the load λ is gradually increased from zero. For $\lambda < \lambda_1$ there is no deflection of the plate and we proceed along the trivial solution. If $\lambda_1 < \lambda < \lambda_2$, the plate is deformed and we follow the first bifurcating solution branch. When the load λ is increased far beyond λ_2, the plate jumps suddenly and violently to a new configuration, the number of buckles (or wave numbers) increasing by one. This phenomenon is called "mode jumping." For example, if there are k buckles in the solution branch bifurcating from $(0, \lambda_1)$ and $(k + 1)$ buckles in the next solution

branch, and these two branches are connected by another solution curve, then we say that "mode jumping" occurs in this system.

Mode jumping is perhaps one of the most noteworthy features of experimental studies of the postbuckling behavior of plates. Bauer, Keller, and Reiss indicated in [3] that perturbation of a multiple eigenvalue often causes secondary bifurcation, which in turn leads to mode jumping if it connects two adjacent bifurcating solution branches. It was Schaeffer and Golubitsky [24], and then Holder and Schaeffer [15], who showed that mode jumping depends on the boundary conditions of the plate. More precisely, Holder and Schaeffer considered two sets of boundary conditions for w,

(1) simply supported on all four edges;

(2) simply supported on unloaded sides, clamped on loaded ends,

and two sets of boundary conditions for f,

(a) homogeneous Dirichlet conditions $f = \Delta f = 0$;

(b) homogeneous Neumann conditions $f_n = (\Delta f)_n = 0$.

Here and in what follows $f_n = \frac{\partial f}{\partial n}$ represents the partial derivatives of f in the outer normal directions on the boundary $\partial\Omega$. We refer to the four cases as (1a), (1b), etc. Golubitsky, Holder, and Schaeffer found that mode jumping can occur in the cases (2a) and (2b) as a result of unfolding or imperfection of double bifurcations, but not in (1a) or (1b). To pursue a more detailed study of the influence of boundary conditions in the bifurcation scenario of the von Kármán equations, one may consider the following Robin boundary conditions:

$$\begin{array}{rcl} f &=& (1-\alpha)\Delta f + \alpha f_n = 0 \\ w &=& (1-\beta)\Delta w + \beta w_n = 0 \end{array} \qquad \text{on } x = 0 \text{ and } x = l,\ \alpha,\ \beta \in [0,1], \tag{1.2}$$

and

$$f = \Delta f = 0, \quad w = \Delta w = 0 \qquad \text{on } y = 0 \text{ and } y = 1.$$

For $\alpha = \beta = 0$ we obtain simply supported boundary conditions for f and w, while for $\alpha = \beta = 1$ we have the partially clamped boundary conditions for both f and w. We remark here that the Robin-type boundary conditions with the homotopy parameters $\alpha,\ \beta$ is a natural extension of classical boundary conditions, aiming for more accurate approximations of the real physical systems; see, e.g., [26, 21], and the further references cited therein. While in the context of mixed finite element schemes, the totally clamped boundary conditions

$$f = f_n = 0, \qquad w = w_n = 0 \quad \text{on } \partial\Omega$$

are imposed normally; see, e.g., [5, 6, 7].

Our aim here is to study mode jumping of a plate through numerical approximations, in particular, continuation methods [1, 2, 18]. According to the experiments of Stein [25] and the results of Schaeffer and Golubitsky [24], and Holder and Schaeffer [15], varying the length l of the plate P and the load λ can make the first bifurcation double. On the other hand, numerical discretizations and perturbations of the domain split the double bifurcation into two simple bifurcations. Moreover, perturbation of the domain is unavoidable if the length l of the domain is an irrational number. Hence, we will follow the solution curves branching from the two simple bifurcations, investigate secondary bifurcation points along the two solution curves, and calculate the secondary solution branch. If the secondary bifurcation points on

each of the two primary solution curves is connected by a secondary solution branch, we say that mode jumping occurs in this system. Otherwise there is no mode jumping at this double bifurcation. Our numerical results are consistent with the prediction of Holder and Schaeffer [15] and Schaeffer and Golubitsky [24].

This paper is organized as follows. In section 2 we follow the discussion in [24] and show how to derive the eigenfunctions of the linearized von Kármán equation. Section 3 describes some properties of the central difference discretization of the von Kármán equations. A continuation-unsymmetric Lanczos algorithm for bifurcation problems is proposed in section 4. Here the unsymmetric Lanczos method is used to solve the linear systems associated to the discrete von Kármán equations, to detect bifurcation points along the solution curves, and to compute the Ritz vector at the bifurcation point for branch-switching. Numerical results are presented in section 5.

2. Some basic results for the linearized problems. In this section we will show how double bifurcations of the von Kármán equations are generated for a rectangular domain $\Omega = [0, l] \times [0, 1]$, where the length l is considered as the second bifurcation parameter in the problem. We will restrict the discussion to the simply supported and partially clamped boundary conditions, respectively, as in [15, 24]. The more general Robin boundary conditions will be discussed elsewhere.

2.1. Simply supported boundary conditions. Let us consider the linearized von Kármán equation with simply supported boundary conditions

$$\begin{aligned} \Delta^2 w \ + \ \lambda w_{xx} = 0 \qquad & \text{in} \quad \Omega = [0, l] \times [0.1], \\ w \ = \ \Delta w = 0 \qquad & \text{on} \quad \partial\Omega. \end{aligned} \tag{2.1}$$

It has nontrivial solutions

$$w = w_{m,n}(x, y) = \sin \frac{m\pi x}{l} \cdot \sin n\pi y, \quad m, n = 1, 2, \ldots, \tag{2.2}$$

if and only if

$$\lambda = \lambda_{m,n} = \left(\frac{\pi}{l}\right)^2 \left(m + \frac{n^2 l^2}{m}\right)^2, \quad m, \ n = 1, 2, \ldots. \tag{2.3}$$

Here m, n are called the wave numbers of $w_{m,n}(x, y)$. For fixed length l elementary calculations show that the smallest eigenvalue

$$\min_{m,n} \lambda_{m,n} = \min_{m} \lambda_{m,1} = \pi^2 \min_{m} \left(\frac{m}{l} + \frac{l}{m}\right)^2$$

is achieved at one of the integers $m = [l], \ [l] + 1$. If we consider λ as a function of the length l in (2.3), then any two simple eigenvalues of (2.1) can be coupled to generate a double eigenvalue by varying m or n. For example, the equality $\lambda_{m,n} = \lambda_{m+1,n}$ holds if and only if

$$l = \frac{\sqrt{m(m+1)}}{n}. \tag{2.4}$$

Generally, if we require $\lambda_{m,n} = \lambda_{m+k,n}$ for some $k \in \mathbf{N}$, then the length l should be modified as

$$l = \frac{\sqrt{m(m+k)}}{n}. \tag{2.5}$$

For $m = n = 1$ and $k = 1,\ 3$, we obtain $l = \sqrt{2}$ and $l = 2$, respectively. Figure 1 shows how the eigenvalues of (2.1) vary with respect to the length l, where the $\lambda_{1,1}$-eigenpath intersects the $\lambda_{2,1}$-, $\lambda_{3,1}$-, and $\lambda_{4,1}$-eigenpath at $l = \sqrt{2}$, $\sqrt{3}$, and 2, respectively. For large m we have

$$l = m + \frac{k}{2} + \mathbf{O}(m^{-1}), \quad m \gg k.$$

Taking this into account and substituting (2.5) into (2.3), we obtain

$$\lambda_{m,n} = n^2\pi^2 \left(\sqrt{\frac{m}{m+k}} + \sqrt{\frac{m+k}{m}} \right)^2.$$

Therefore, the smallest eigenvalue is double and

$$\begin{aligned} \min_{m,n,k} \lambda_{m,n} &= \min_{m,k} \lambda_{m,1} \\ &= \pi^2 \min_{m} \left(\sqrt{\frac{m}{m+1}} + \sqrt{\frac{m+1}{m}} \right)^2 \\ &= 4\pi^2 + \mathbf{O}\left(\frac{1}{m}\right). \end{aligned}$$

The corresponding eigenfunctions are

$$\begin{aligned} w_{m,1}(x,y) &= \sin \frac{m\pi x}{l} \cdot \sin \pi y, \\ w_{m+1,1}(x,y) &= \sin \frac{(m+1)\pi x}{l} \cdot \sin \pi y. \end{aligned}$$

In particular, for $l = \sqrt{2}$ the smallest eigenvalue of (2.1) is double and occurs at

$$\lambda_{1,1} = \lambda_{2,1} = \frac{9}{2}\pi^2.$$

2.2. Partially clamped boundary conditions. The linearized von Kármán equation with partially clamped boundary conditions is

$$\begin{aligned} \Delta^2 w \ + \ \lambda w_{xx} = 0 \qquad & \text{in} \quad \Omega = [0,l] \times [0,1], \\ w \ = \ w_n = 0 \qquad & \text{on} \quad x = 0 \text{ and } x = l, \\ w \ = \ \Delta w = 0 \qquad & \text{on} \quad y = 0 \text{ and } y = 1. \end{aligned} \tag{2.6}$$

Following the discussion in [24] we consider separation of variables, i.e., let

$$w(x,y) = u(x)\ v(y) \neq 0.$$

From (2.6) we derive

$$\frac{u^{(4)} + \lambda u''}{u} + 2\frac{u''v''}{uv} + \frac{v^{(4)}}{v} = 0 \tag{2.7}$$

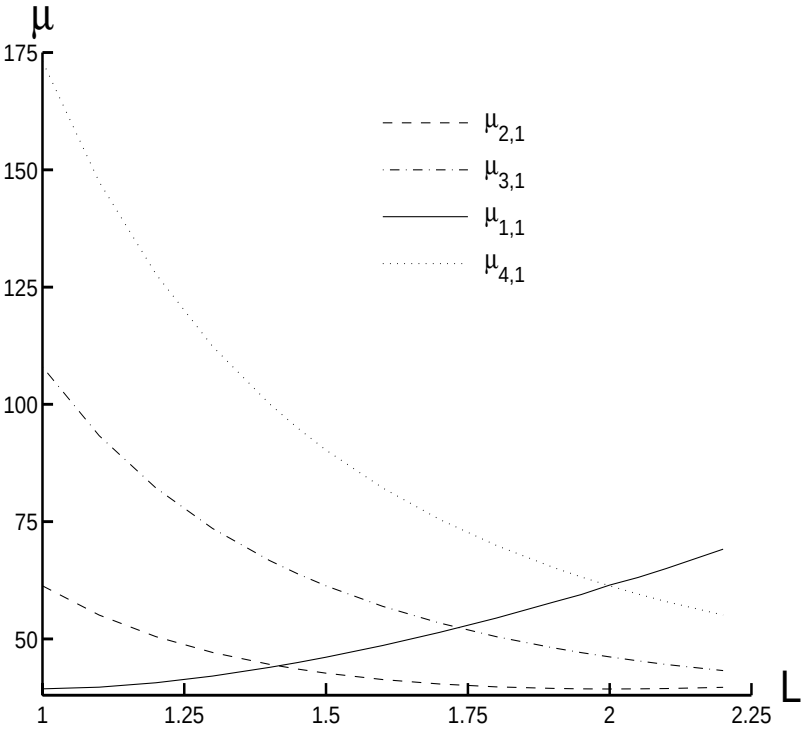

FIG. 1. *Eigenvalues of the von Kármán equations as functions of the parameter l in the domain* $\Omega := [0, l] \times [0, 1]$.

with the boundary conditions

$$u(0) = u(l) = u'(0) = u'(l) = 0, \tag{2.8a}$$

$$v(0) = v(1) = v''(0) = v''(1) = 0. \tag{2.8b}$$

The conditions in (2.8b) are satisfied by functions of the form

$$v(y) = \sin n\pi y, \quad n = 1, 2, \ldots.$$

Note that for any $n \in \mathbf{N}$ the subspace $\{u(x) \sin n\pi y;\ u(x) \in C^{4,s}[0, 1]\}$ is invariant under the operator $\Delta^2 + \lambda \frac{\partial^2}{\partial x^2}$. Thus in this subspace (2.7) reduces to

$$u^{(4)} + (\lambda - 2\ n^2\pi^2)u'' + n^4\pi^4 u = 0. \tag{2.9}$$

Its characteristic equation is

$$a^4 + [\lambda - 2\ (n\pi)^2]a^2 + (n\pi)^4 = 0$$

and has four solutions

$$a_1 := \left\{ (n\pi)^2 - \frac{\lambda}{2} + \left[\lambda \left(\frac{\lambda}{4} - n^2\pi^2 \right) \right]^{\frac{1}{2}} \right\}^{\frac{1}{2}}, \quad a_2 := -a_1,$$

$$a_3 := \left\{ (n\pi)^2 - \frac{\lambda}{2} - \left[\lambda \left(\frac{\lambda}{4} - n^2\pi^2 \right) \right]^{\frac{1}{2}} \right\}^{\frac{1}{2}}, \quad a_4 := -a_3. \tag{2.10}$$

The general solution of (2.9) is of the form

$$u(x) = \sum_{i=1}^{4} c_i e^{a_i x}, \tag{2.11}$$

where the constants $c_i \in \mathbf{C}$ will be determined by the boundary conditions (2.8a). We are interested in real solutions of (2.9). To this end, we consider the following three cases in (2.10): (a) $\frac{\lambda}{4} - (n\pi)^2 < 0$; (b) $\frac{\lambda}{4} - (n\pi)^2 = 0$; (c) $\frac{\lambda}{4} - (n\pi)^2 > 0$. In the case (a) there is no real solution for λ, while (b) implies that $u \equiv 0$, the trivial solution. For $\frac{\lambda}{4} > (n\pi)^2$ the solutions of (2.9) have the form

$$u(x) = c_1 \cos \omega_1 x + c_2 \sin \omega_1 x + c_3 \cos \omega_2 x + c_4 \sin \omega_2 x,$$

where

$$\begin{aligned} \omega_1 &= \sqrt{\alpha_1 - \alpha_2} > 0, \qquad \omega_2 = \sqrt{\alpha_1 + \alpha_2} > 0, \\ \alpha_1 &:= \frac{\lambda}{2} - (n\pi)^2, \qquad \alpha_2 := \left[\lambda \left(\frac{\lambda}{4} - n^2\pi^2 \right) \right]^{\frac{1}{2}}. \end{aligned}$$

By elementary calculations we obtain

$$\omega_1^2 + \omega_2^2 = \lambda - 2(n\pi)^2, \qquad \omega_2^2 - \omega_1^2 = \sqrt{\lambda^2 - 4\lambda\,(n\pi)^2}. \tag{2.12}$$

Elimination of λ in these equations yields

$$\omega_1 \omega_2 = (n\pi)^2.$$

The boundary conditions $u(0) = 0$ and $u'(0) = 0$ imply that $c_3 = -c_1$ and $c_4 = -c_2\omega_1/\omega_2$ in (2.11). Thus,

$$\begin{aligned} u(x) &= c_1(\cos \omega_1 x - \cos \omega_2 x) + c_2(\omega_2 \sin \omega_1 x - \omega_1 \sin \omega_2 x) \\ &:= c_1 \phi(x) + c_2 \psi(x), \end{aligned}$$

where

$$\phi(x) = \cos \omega_1 x - \cos \omega_2 x, \quad \psi(x) = \omega_2 \sin \omega_1 x - \omega_1 \sin \omega_2 x. \tag{2.13}$$

Since we are interested in double eigenvalues, both $\phi(x)$ and $\psi(x)$ can be chosen as eigenfunctions of (2.9). Note that $\psi'(x) = \omega_1\omega_2\phi(x)$. Therefore, the boundary conditions (2.8a) are equivalent to

$$\phi(l) = \phi'(l) = \psi(l) = 0, \tag{2.14}$$

which implies that

$$\omega_1 = \frac{k}{l}\pi, \quad \omega_2 = \frac{k+2m}{l}\pi$$

for some positive integers k and m. Together with (2.12) we derive

$$l = \frac{[k(k+2m)\,]^{\frac{1}{2}}}{n}, \qquad \lambda = 4n^2\pi^2 \frac{(k+m)^2}{k(k+2m)}. \tag{2.15}$$

The first double bifurcation corresponds to $m = 1$ in (2.15) and

$$l = \sqrt{k(k+2)}. \tag{2.16}$$

The eigenfunctions for (2.6) are

$$w_1(x,y) = \left[\cos\left(\frac{k}{l}\pi x\right) - \cos\left(\frac{k+2}{l}\pi x\right) \right] \sin n\pi y,$$

$$w_2(x,y) = \pi\left[\frac{k+2}{l}\sin\left(\frac{k}{l}\pi x\right) - \frac{k}{l}\sin\left(\frac{k+2}{l}\pi x\right) \right] \sin n\pi y. \tag{2.17}$$

The structure of w_1, w_2 indicates that the concept of wave numbers for (2.2) is actually no more suitable for (2.17), though it is used frequently in the literature.

In our numerical experiments we assume that $k = 1$ and $n = 1$ in (2.16) and (2.17), respectively. Then $l = \sqrt{3}$ and a mode jumping is observed; see section 5.

3. Discretization for the von Kármán equations.

3.1. Linearized problem with simply supported boundary conditions. We discretize (2.1) by the standard thirteen-point centered difference approximations with uniform meshsize $h = 1/(N+1)$ on the x- and y-axis, respectively. We have to assume that l is divisible by h, say, $l/h = L+1$ for some positive integer. The domain Ω is covered by a net of discrete points S, where

$$S = \{(x_i, y_j) : x_i = ih,\ y_j = jh,\ i = 0, 1, \ldots, L, L+1,\ j = 0, 1, \ldots, N, N+1\}.$$

At the discrete points the function $w(x,y)$ is to be approximated by a net function $W(x_i, y_j) := W_{i,j}$. If l is an irrational number, the domain must be perturbed in the numerical computations.

Let D, A, $B \in \mathbf{R}^{LN\times LN}$ be the discretization matrices corresponding to the differential operators $\frac{\partial^2}{\partial x^2}$, Δ, and Δ^2 defined in $[0,l]\times[0,1]$, respectively. Then

$$D = \text{diag}\,(A_L, \ldots, A_L) \tag{3.1}$$

with

$$A_L = \frac{1}{h^2}\begin{pmatrix} -2 & 1 & & & 0 \\ 1 & -2 & 1 & & \\ & \ddots & \ddots & \ddots & \\ & & \ddots & \ddots & 1 \\ 0 & & & 1 & -2 \end{pmatrix} \in \mathbf{R}^{L\times L} \quad \text{and}$$

$$A = \frac{1}{h^2}\begin{pmatrix} \bar{A}_L & I_L & & & 0 \\ I_L & \bar{A}_L & \ddots & & \\ & \ddots & \ddots & \ddots & \\ & & \ddots & \ddots & I_L \\ 0 & & & I_L & \bar{A}_L \end{pmatrix} \tag{3.2}$$

with

$$\bar{A}_L = A_L - 2I_L$$

and

$$B = \frac{1}{h^4}\begin{pmatrix} B_{L_1} & C_L & I_L & & & & 0 \\ C_L & B_{L_2} & C_L & I_L & & & \\ I_L & C_L & B_{L_3} & T_L & I_L & & \\ & \ddots & \ddots & \ddots & \ddots & \ddots & \\ & & \ddots & \ddots & \ddots & \ddots & I_L \\ & & & \ddots & \ddots & B_{L_{N-1}} & C_L \\ 0 & & & & I_L & C_L & B_{L_N} \end{pmatrix} \in \mathbf{R}^{LN\times LN} \tag{3.3}$$

with

$$B_{L_1} = B_{L_N} = \begin{pmatrix} 18 & -8 & 1 & & & & 0 \\ -8 & 19 & -8 & 1 & & & \\ 1 & -8 & 19 & -8 & 1 & & \\ & \ddots & \ddots & \ddots & \ddots & \ddots & \\ & & \ddots & \ddots & \ddots & \ddots & 1 \\ & & & \ddots & \ddots & 19 & -8 \\ 0 & & & & 1 & -8 & 18 \end{pmatrix} \in \mathbf{R}^{L\times L},$$

$$B_{L_j} = \begin{pmatrix} 19 & -8 & 1 & & & & 0 \\ -8 & 20 & -8 & 1 & & & \\ 1 & -8 & 20 & -8 & 1 & & \\ & \ddots & \ddots & \ddots & \ddots & \ddots & \\ & & \ddots & \ddots & \ddots & \ddots & 1 \\ & & & \ddots & \ddots & 20 & -8 \\ 0 & & & & 1 & -8 & 19 \end{pmatrix} \in \mathbf{R}^{L\times L},\ j = 2, 3, \ldots, N-1,$$

and

$$C_L = \begin{pmatrix} -8 & 2 & & & 0 \\ 2 & -8 & 2 & & \\ & \ddots & \ddots & \ddots & \\ & & \ddots & \ddots & 2 \\ 0 & & & 2 & -8 \end{pmatrix} \in \mathbf{R}^{L\times L}.$$

It follows from [10] that $A^2 = B$. The centered difference analogue of (2.1) is

$$H(W, \lambda) = BW + \lambda DW = 0, \tag{3.4}$$

where B and D are defined as above. Let $(\mu^h_{p,q}, U_{p,q})$ be an eigenpair of A. We have (see [17])

$$\begin{aligned} \mu^h_{p,q} &= -4\left[\frac{(L+1)^2}{l^2}\sin^2\left(\frac{\pi}{2}\frac{p}{L+1}\right) + (N+1)^2\sin^2\left(\frac{\pi}{2}\frac{q}{N+1}\right)\right] \\ &:= \mu^h_p + \nu^h_q, \quad 1 \le p \le L, \quad 1 \le q \le N; \end{aligned} \tag{3.5}$$

(3.6)

$$U_{p,q}(x_i, y_j) = U_p(x_i) \cdot U_q(y_j) = \left(\sin\left(\frac{ip\pi}{L+1} \right) \cdot \sin\left(\frac{jq\pi}{N+1} \right) \right), \quad 1 \le i,\ p \le L, \quad 1 \le j,\ q \le N.$$

Here (μ_p^h, U_p) and (ν_q^h, U_q) are the eigenpairs of the discretization matrices A_L and A_N corresponding to $-\frac{d^2}{dx^2}$ defined on $[0, l]$ and $[0, 1]$, respectively, with homogeneous Dirichlet boundary conditions. Actually, we have $U_{p,q} = U_q \otimes U_p$, where $\otimes$ denotes the matrix tensor product; see subsection 3.3.

The result in [10] can be generalized as follows.

THEOREM 3.1. *The eigenpairs of* (3.4) *are* $(\lambda_{p,q}^h, U_{p,q})$ *with*

$$\lambda_{p,q}^h = -\frac{(\mu_{p,q}^h)^2}{\mu_p^h}, \quad p = 1, 2, \ldots, L,\ q = 1, 2, \ldots, N; \tag{3.7}$$

$$U_{p,q}(x_i, y_j) = U_p(x_i) \cdot U_q(y_j), \quad 1 \le i \le L,\ 1 \le j \le N. \tag{3.8}$$

Proof. Let $(\lambda_{p,q}^h, U_{p,q})$ be any eigenpairs of (3.4). Since $B = A^2$, we have

$$\begin{aligned} A^2 U_{p,q} &= -\lambda_{p,q}^h D U_{p,q} \\ &= -\lambda_{p,q}^h D(U_q \otimes U_p) \ \ \text{(see [10])} \\ &= -\lambda_{p,q}^h \mu_p^h (U_q \otimes U_p). \end{aligned}$$

On the other hand,

$$A^2 U_{p,q} = (\mu_{p,q}^h)^2 U_{p,q} = (\mu_{p,q}^h)^2 (U_q \otimes U_p).$$

Hence,

$$\lambda_{p,q}^h = -\frac{(\mu_{p,q}^h)^2}{\mu_p^h}. \qquad \square$$

In general, a double bifurcation of (2.1) will be split into two simple bifurcations by using central difference discretizations. Detailed discussions for second order differential equations can be found in [20]. We are interested in how to maintain the bifurcation scenario of the von Kármán equations at a double bifurcation point in the discrete problems. To this end, the first step is to preserve the double bifurcation of the continuous problem. Let

$$\bar{\mu}_p^h = -4(L+1)^2 \sin^2\left(\frac{\pi}{2} \frac{p}{L+1} \right), \tag{3.9}$$

then $\mu_p^h = l^{-2} \bar{\mu}_p^h$ and (3.7) can be expressed as

$$\begin{aligned} \lambda_{p,q}^h &= -\frac{(l^{-2}\bar{\mu}_p^h + \nu_q^h)^2}{l^{-2} \cdot \bar{\mu}_p^h} \\ &= -\left[\ l^{-2} \cdot \bar{\mu}_p^h + 2\nu_q^h + l^2 \frac{(\nu_q^h)^2}{\bar{\mu}_p^h} \ \right]. \end{aligned}$$

In particular, the equality

$$\lambda_{p,1}^h = \lambda_{p+1,1}^h$$

holds if and only if

$$l = l^h = \left[\frac{(\bar{\mu}_p^h \cdot \bar{\mu}_{p+1}^h)}{(\nu_1^h)^2} \right]^{\frac{1}{4}}. \tag{3.10}$$

For example, if we choose $l = \sqrt{2} \approx 1.4142136$, then the double bifurcation is preserved in the discrete problem by setting $l^h = 1.4126064$ for $h = 0.1$.

In order to study mode jumping of the von Kármán equations, we take the length l as the second bifurcation parameter and make the coordinate transformation $(x, y) \leftrightarrow (l\tilde{x}, y)$. The equation (2.1) can be rewritten as

$$\begin{aligned} \left(\frac{1}{l^2}\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2}\right)^2 w \ + \ \lambda \frac{1}{l^2}\frac{\partial^2 w}{\partial x^2} = 0 \qquad & \text{in} \quad \tilde{\Omega} := [0,1]^2, \\ w \ = \ \left(\frac{1}{l^2}\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2}\right) w = 0 \qquad & \text{on} \quad \partial\tilde{\Omega}. \end{aligned} \tag{3.11}$$

Note that (3.11) has the same eigenpairs as (2.1). We discretize (3.11) with the thirteen-point centered difference approximations as before. Let

$$\tilde{S} := \{(\tilde{x}_i, y_j) \ : \ \tilde{x}_i = ih, \ y_j = jh, \ i, j = 1, 2, \ldots, N\}$$

be a net of discrete points which covers the domain $\tilde{\Omega} = [0,1]^2$, $\tilde{D} = \mathrm{diag}(A_N, \ldots, A_N)$ and $\tilde{E} \in \mathbf{R}^{N^2 \times N^2}$ be the discretization matrices corresponding $\frac{\partial^2}{\partial x^2}$ and $\frac{\partial^2}{\partial y^2}$ defined in $\tilde{\Omega} = [0,1]^2$ with homogeneous Dirichlet boundary conditions. Here $A_N \in \mathbf{R}^{N \times N}$ has the same form as A_L defined in (3.1), and $\tilde{E}$ is given by (see [10])

$$\tilde{E} = \begin{pmatrix} -2I_N & I_N & & & 0 \\ I_N & -2I_N & \ddots & & \\ & \ddots & \ddots & \ddots & \\ & & \ddots & \ddots & I_N \\ 0 & & & I_N & -2I_N \end{pmatrix}. \tag{3.12}$$

We have $\tilde{D} = I_N \otimes A_N$ and $\tilde{E} = A_N \otimes I_N$. The centered difference analogue of (3.11) corresponds to the fact that we choose the same number of discrete points in $\Omega = [0, \ell] \times [0, 1]$. If $\ell \neq 1$, the meshsizes in the x- and y-axis are different.

LEMMA 3.2. *The matrices $\tilde{D}$, $\tilde{E} \in \mathbf{R}^{N^2 \times N^2}$, defined as above, are similar to each other.*

Proof. It is easy to verify that the eigenpairs of $\tilde{D}$ are $(\mu_p^h, U_p \otimes e_i)$, while the eigenpairs of $\tilde{E}$ are $(\mu_p^h, e_i \otimes U_p)$, $p = 1, 2, \ldots, N$. Here e_i is the ith standard unit vector in $\mathbf{R}^N$, the multiplicity of μ_p^h is N, and μ_p^h and U_p are defined as in (3.5) and (3.6), respectively. This completes the proof. □

The centered difference analogue of (3.11) is

$$\left(\frac{1}{l^2}\tilde{D} + \tilde{E}\right)^2 W + \lambda \frac{1}{l^2}\tilde{D}W = 0. \tag{3.13}$$

Let $(\tilde{\mu}^h_{p,q}, U_{p,q})$ be any eigenpair of (3.13), $1 \le p,\ q \le N$. We have

$$\left(\frac{1}{l^2}\tilde{D} + \tilde{E}\right)^2 U_{p,q} = -\tilde{\mu}^h_{p,q}\frac{1}{l^2}\tilde{D}U_{p,q},$$

or

$$\left(\frac{1}{l^2}\mu^h_p + \nu^h_q\right)^2 U_{p,q} = -\tilde{\mu}^h_{p,q}\frac{1}{l^2}\mu^h_p U_{p,q},$$

where μ^h_p, ν^h_q, and $U_{p,q}$ are defined as in (3.5) and (3.6), respectively, $1 \le p,\ q \le N$. This implies

$$\tilde{\mu}^h_{p,q} = -\frac{(l^{-2}\mu^h_p + \nu^h_q)^2}{l^{-2}\mu^h_p}. \tag{3.14}$$

Concluding the discussions above, we have the following.

THEOREM 3.3. *The eigenpairs of* (3.13) *are* $(\tilde{\mu}^h_{p,q}, U_{p,q})$, $p,\ q = 1, \ldots, N$.

In comparison to (3.10), the first eigenvalue of (3.13) is double if and only if

$$l = l^h = \left[\ \frac{(\mu^h_p \cdot \mu^h_{p+1})}{(\nu^h_1)^2}\ \right]^{\frac{1}{4}}. \tag{3.15}$$

3.2. Linearized problem with partially clamped boundary conditions. For convenience we rewrite (2.6) as

$$\begin{aligned}
\left(\frac{1}{l^2}\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2}\right)^2 w \ + \ \lambda\frac{1}{l^2}\frac{\partial^2 w}{\partial x^2} = 0 \qquad & \text{in} \quad \tilde{\Omega} = [0,1]^2,\\
w \ = \ -\frac{1}{l}\frac{\partial}{\partial x}w = 0 \qquad & \text{on} \quad x = 0,\\
w \ = \ \frac{1}{l}\frac{\partial}{\partial x}w = 0 \qquad & \text{on} \quad x = 1,\\
w \ = \ \Delta w = 0 \qquad & \text{on} \quad y = 0 \text{ and } y = 1.
\end{aligned} \tag{3.16}$$

Let $\bar{D} = \text{diag}\,(\bar{A}_N, \ldots, \bar{A}_N) \in \mathbf{R}^{N^2 \times N^2}$ be the discretization matrix corresponding to $\frac{\partial^2}{\partial x^2}$ defined in (3.16), where

$$\bar{A}_N = \frac{1}{h^2}\begin{pmatrix} -2 & 2 & & & 0 \\ 1 & -2 & 1 & & \\ & \ddots & \ddots & \ddots & \\ & & 1 & -2 & 1 \\ 0 & & & 2 & -2 \end{pmatrix} \in \mathbf{R}^{N\times N}, \quad h = \frac{1}{(N+1)}. \tag{3.17}$$

It is well known that the eigenpairs of $\bar{A}_N$ are

$$\begin{aligned}
&\nu_p = -2(N+1)^2\left(1 - \cos\frac{p\pi}{N-1}\right), \qquad p = 0, 1, \ldots, N-1,\\
&\bar{U}_p(x_i) = \cos\frac{ip\pi}{N-1}, \qquad 1 \le i \le N, \quad p = 0, 1, \ldots, N-1.
\end{aligned} \tag{3.18}$$

Thus, the centered difference analogue of (3.16) is

$$\left(\frac{1}{l^2}\bar{D}+\tilde{E}\right)^2 W+\lambda\frac{1}{l^2}\bar{D}W=0, \tag{3.19}$$

where $\tilde{E}$ is defined as in (3.12).

It seems that an explicit formula for the eigenpairs of (3.16) is no more available.

3.3. Discretization for the von Kármán equations. We recall the following definition given in [10].

DEFINITION 3.4. *For any $x=(x_1,x_2,\ldots,x_N)^T$, $y=(y_1,y_2,\ldots,y_N)^T\in\mathbf{R}^N$, the vector product $z=x*y\in\mathbf{R}^N$ of x and y is defined by $z_i=x_iy_i$, $i=1,\ldots,N$. Similarly, for any $A\in\mathbf{R}^{N\times N}$ with a_i^T as the ith row, we define the convolution of A and x as*

$$A*x=\begin{pmatrix} x_1a_1^T \\ \vdots \\ x_Na_N^T \end{pmatrix}\in\mathbf{R}^{N\times N}.$$

For $\Omega=[0,l]\times[0,1]$ we will discretize the von Kármán equations (1.1) with simply supported boundary conditions. Let $D\in\mathbf{R}^{LN\times LN}$ be defined as in (3.1), which can be expressed as $D=I_N\otimes A_L$. Similarly, let $E\in\mathbf{R}^{LN\times LN}$ be the discretization matrix corresponding to $\frac{\partial^2}{\partial y^2}$. It has the same form as $\tilde{E}$ defined in (3.12), which can be written as $E=A_L\otimes I_N$. The discretization matrix associated to $\frac{\partial^2}{\partial x\partial y}$ is

$$V=\begin{pmatrix} 0 & V_L & & & 0 \\ -V_L & 0 & V_L & & \\ & \ddots & \ddots & \ddots & \\ & & \ddots & \ddots & V_L \\ 0 & & & -V_L & 0 \end{pmatrix}\in\mathbf{R}^{LN\times LN}, \tag{3.20}$$

where

$$V_L=\frac{1}{h^2}\begin{pmatrix} 0 & 1 & & & 0 \\ -1 & 0 & 1 & & \\ & \ddots & \ddots & \ddots & \\ & & \ddots & \ddots & 1 \\ 0 & & & -1 & 0 \end{pmatrix}\in\mathbf{R}^{L\times L}.$$

We have $V=V_N\otimes V_L$.

With $Z=(F,W)^T\in\mathbf{R}^{LN}$, the discrete nonlinear system of equations associated to (1.1) with simply supported boundary conditions is

$$H(Z,\lambda)=(H_1(Z,\lambda),H_2(Z,\lambda))^T=0 \tag{3.21}$$

with

$$H_1(Z,\lambda):=BF+(DW)*(EW)-\frac{1}{16}(VW)*(VW),$$

$$H_2(Z,\lambda):=BW-(DW)*(EF)-(EW)*(DF)+\frac{1}{8}(VW)*(VF)+\lambda DW,$$

where B is defined as in (3.3), and D, E, V are defined as above. The Jacobian matrix corresponding to (3.21) is

$$DH = (D_Z H,\ D_\lambda H) = \begin{pmatrix} B & M & 0 \\ & & \\ -M & \tilde{B} & DW \end{pmatrix} \in \mathbf{R}^{2LN\times(2LN+1)}, \tag{3.22}$$

where

$$M := D*(EW) + E*(DW) - \frac{1}{8}V*(VW),$$
$$\tilde{B} := B - D*(EF) - E*(DF) + \frac{1}{8}V*(VF) + \lambda D.$$

LEMMA 3.5. *The discrete nonlinear system* (3.21) *has the same bifurcation points as the discrete linearized von Kármán equation* (3.4) *along the trivial solution* $F = W = 0,\ \lambda \in \mathbf{R}$.

Proof. On the trivial solution of (3.21) we have $F = W = 0$. Thus, the Jacobian matrix DH in (3.22) reduces to

$$DH = \begin{bmatrix} B & 0 & 0 \\ & & \\ 0 & B+\lambda D & 0 \end{bmatrix}. \tag{3.23}$$

Since B is symmetric and positive definite, the singularity of $B + \lambda D$, which is just the coefficient matrix in (3.4), reveals rank-deficiency of DH, and in turn, bifurcation point of (3.21). □

In [5, 6] Brezzi, Rappaz, and Raviart have discussed error estimates for the mixed finite element approximations of the von Kármán equations. In the context of centered difference approximations one may adapt the techniques in [17] to give error analysis for the discrete solution branches of (3.21); see [10] for details.

4. Linear solvers and branch-switching techniques. Recently various conjugate gradient methods have been exploited as linear and nonlinear solvers for continuation problems; see, e.g., [9, 11, 12, 16]. Specifically, in [11] the symmetric Lanczos method was used to solve linear systems and to detect simple bifurcation points by solving the associated linear eigenvalue problems, while the band Lanczos method with reorthoganalization [22] was utilized to handle multiple bifurcations. If the discretization matrices associated to the continuation problem are nonsymmetric, the continuation-Arnoldi algorithm proposed in [12] can handle bifurcation problems as well.

It is well known that the unsymmetric Lanczos method [19] is unstable for solving unsymmetric eigenvalue problems [13]. Furthermore, a serious breakdown of this method could happen. In spite of this, the unsymmetric Lanczos algorithm can effectively handle many unsymmetric bifurcation problems for the following reasons. First, it is an efficient solver for the unsymmetric linear systems in the context of continuation methods. Next, it can reveal bifurcation points along the solution curve. Finally, it can be exploited to compute the tangent vector at a bifurcation point for branch-switching.

Let us consider the unsymmetric linear system $Ax = b$, where $A \in \mathbf{R}^{N\times N}$ is nonsingular and $b \in \mathbf{R}^N$. For $j = 1, 2, \ldots, N$ the unsymmetric Lanczos method

generates two biorthogonal systems $V_j = [v_1, v_2, \ldots, v_j]$ and $W_j = [w_1, w_2, \ldots, w_j]$ such that $W_j A V_j = T_j$ is tridiagonal. Let x_0 be the initial guess and $r_0 = b - Ax_0$ the initial residual. We seek an approximate solution x_j by requiring

$$(b - Ax_j, w_i) = 0, \quad i = 1, 2, \ldots, j, \tag{4.1}$$

and

$$x_j = x_0 + z_j, \tag{4.2}$$

where $z_j = V_j y_j \in \text{span}\,\{v_1, v_2, \ldots, v_j\} =: K_j$ for some $y_j \in \mathbf{R}^j$ and $(\cdot, \cdot)$ denotes the inner product in $\mathbf{R}^N$. It follows from (4.1) that

$$(r_0 - Az_j, w_i) = 0, \quad i = 1, 2, \ldots, j. \tag{4.3}$$

Assume that $\det(T_j) \neq 0$. Then (4.3) implies that

$$W_j^T (r_0 - Az_j) = 0. \tag{4.4}$$

Replacing z_j by $V_j y_j$ in (4.4) yields an equation for y_j,

$$T_j y_j = W_j^T r_0, \tag{4.5}$$

where

$$T_j = W_j^T A V_j = \begin{pmatrix} \alpha_1 & \beta_2 & & & 0 \\ \delta_2 & \alpha_2 & \ddots & & \\ & \ddots & \ddots & \ddots & \\ & & \ddots & \ddots & \beta_j \\ 0 & & & \delta_j & \alpha_j \end{pmatrix}.$$

The entries α_j, β_j, and δ_j will be determined later. If we set $w_1 = v_1 = r_0/\|r_0\|_2$ and $\beta = \|r_0\|_2$, then it follows from the biorthogonality that the equalities

$$W_j^T r_0 = \beta W_j^T w_1 = \beta e_1$$

hold, where $e_1 = [1, 0, \ldots, 0]^T \in \mathbf{R}^j$ is the first standard unit vector. Thereafter, via (4.5) the approximate solution x_j in (4.2) is calculated as

$$x_j = x_0 + V_j y_j = x_0 + \beta V_j T_j^{-1} e_1. \tag{4.6}$$

The unsymmetric Lanczos algorithm for solving the linear system $Ax = b$ is summarized as follows.

ALGORITHM 4.1. *Lanczos algorithm for solving unsymmetric linear system* $Ax = b$.

1. *Input*

$$x_0 = v_0 = w_0 = 0; \quad r_0 = b; \quad v_1 = w_1 = r_0/\beta \ \text{ with } \ \beta = \|r_0\|_2; \ \ \beta_1 = \delta_1 = 0.$$

2. *For* $i = 1, 2, \ldots, j$ *do*

$$\begin{aligned} \alpha_i &= (Av_i, w_i); \\ \hat{v}_{i+1} &= Av_i - \alpha_i v_i - \beta_i v_{i-1}; \\ \hat{w}_{i+1} &= A^T w_i - \alpha_i w_i - \delta_i w_{i-1}; \end{aligned}$$

furthermore, choose $\delta_{i+1} = |(\hat{v}_{i+1}, \hat{w}_{i+1})|^{\frac{1}{2}}$; $\beta_{i+1} = \delta_{i+1}$ sign $(\hat{v}_{i+1}, \hat{w}_{i+1})$; *and define*

$$v_{i+1} = \frac{\hat{v}_{i+1}}{\delta_{i+1}}; \quad w_{i+1} = \frac{\hat{w}_{i+1}}{\beta_{i+1}}.$$

3. *Form the approximate solution via*

$$x_j = x_0 + \beta V_j T_j^{-1} e_1 \tag{4.7}$$

and check the accuracy by

$$\rho_j := \|b - Ax_j\| = \|\hat{v}_{j+1}\| \cdot |e_j^T y_j|. \tag{4.8}$$

If $\rho_j < \varepsilon$, *the given error tolerance, then stop; otherwise set* $j = j + 1$ *and go back to* 2.

The approximate solution in (4.7) is easily obtained by solving the tridiagonal linear system

$$T_j y = \beta e_1 \tag{4.9}$$

via Crout's algorithm [13].

In continuation problems such as the von Kármán equations we are concerned with the bifurcation scenario at the first few bifurcation points. The discretization matrix A associated to the continuation problem with arclength as the curve parameter becomes singular at the bifurcation points. In particular, 0 is an extremal eigenvalue of A when it is evaluated at the first bifurcation point.

Suppose that at the kth continuation step we have obtained the approximating solution y_k. Let T_j be the tridiagonal matrix generated by Algorithm 4.1 and $\theta_1, \ldots, \theta_j$ be the eigenvalues of T_j such that $|\theta_1| < |\theta_2| < \cdots < |\theta_j|$. If $|\theta_1| < \varepsilon^*$ for some $\varepsilon^* > 0$ which is small enough, then a bifurcation point y^* is signaled on the solution curve, and we may use y_k as a rough approximation of y^*. Next, we compute the eigenvector v corresponding to the minimum eigenvalue θ_1, and choose $u = V_j v$ as an approximation to the tangent vector at the bifurcation point. As a summary we obtain the following continuation-unsymmetric Lanczos algorithm.

ALGORITHM 4.2. *A continuation-unsymmetric Lanczos algorithm.*

Input :

$y \in \mathbf{R}^{N+1}$ *such that* $H(y) = 0$; {*an approximate point on* $H^{-1}(0)$}
$\delta > 0$; {*initial stepsize*}
$u > 0$; {*initial tangent vector*}
$\varepsilon^* > 0$; {*tolerance of the zero eigenvalue*}

Step 1. $v := y + \delta u$ {*predictor step*}

Step 2. (i) *Use Algorithm* 4.1 *to solve the linear systems and then calculate y;* {*Newton corrector*}
(ii) *Adapt stepsize;* {*stepsize control*}

Step 3. *Test for bifurcation point and compute tangent vector:*
(i) *Compute the minimum eigenvalue* θ_1 *of* T_j.
(ii) *If* $|\theta_1| < \varepsilon^*$, *then*
compute the Ritz vector u_1 *for branch-switching;*
else
compute tangent vector by the predictor-corrector continuation methods;
goto Step 1.

until traversing is stopped.

Remarks. 1. It is possible to accelerate the rate of convergence of the unsymmetric Lanczos method by using the preconditioning techniques. Here we describe only a robust unsymmetric Lanczos algorithm.

2. From the computational point of view it seems to us that Algorithm 4.2 is superior to the continuation-Arnoldi algorithm if the unsymmetric Lanczos method does not break down. Since in Algorithm 4.2 one deals with tridiagonal matrices, while the matrices generated by the Arnoldi method are of the upper Hessenberg form.

3. In Step 3 the minimum eigenvalue of T_j can be replaced by the minimum singular value or the condition number of T_j for detecting bifurcation points along the solution branch. Our numerical experience shows that the minimum singular value of T_j and the associated singular vector gives in many cases even more accurate approximations of the bifurcation point and null vectors of the linearized operator; see section 5 and [11] for details.

At last we discuss how local perturbation may be incorporated in the context of continuation methods for branch-switching. Suppose that $y^* = (z^*, \lambda^*)$ is a detected bifurcation point on the curve $c \subset H^{-1}(0)$. Let $V \subset \mathbf{R}^{N+1}$ be a small neighborhood of y^* and $f : \mathbf{R}^{N+1} \to \mathbf{R}$ be a smooth mapping such that $f(y) = 0$ for $y = (z, \lambda) \notin V$ and $f(y) > 0$ for $y \in V$. Instead of solving $H(y) = 0$, we solve

$$H_d(y) = H(y) + f(y)d$$

in the neighborhood V of y^*; see [1, 10] for details and for other branch-switching techniques.

5. Numerical results. We use the numerical methods described in the previous sections to investigate mode jumping of the von Kármán equations. All computations were performed on a VAX 9210 machine with double precision arithmetic at National Chung-Hsing University.

Example 1. We consider the von Kármán equations defined in $\Omega = [0, \sqrt{2}] \times [0, 1]$ with simply supported boundary conditions. The first bifurcation point is double and located at $(0, \lambda_{1,1}) = (0, \lambda_{2,1}) = (0, \frac{9}{2}\pi^2)$.

To study whether mode jumping occurs in this example, we perform local perturbation and domain perturbation simultaneously with $l = 1.3,\ 1.4$, and 1.5, respectively. Figure 2 depicts the solution curves at the first two simple bifurcation points for $l = 1.3$, while Figures 3–4 show the first three solution curves for $l = 1.4,\ 1.5$, respectively. Specifically, one sees in Figures 3–4 that the double bifurcation of the continuous problem is split into two simple bifurcations, and the solution curves bifurcating from $(0, \mu_{1,1})$ and $(0, \mu_{3,1})$ connects each other. That is, the former may be viewed as the secondary solution branch of the latter, and vice versa. Note that there is no other secondary bifurcation point on the solution curve branching from $(0, \mu_{1,1})$. Figures 5–8 show how the contours of the solution curve branching from $(0, \mu_{1,1})$ vary with respect to different μ, and the wave number changes gradually from one to three. Figure 9 depicts the contour of the solution curve branching from $(0, \mu_{2,1})$ at $\mu = 55.4358$.

Example 2. We repeat the numerical experiments in [10], i.e., the von Kármán equations defined in $\Omega = [0, 2] \times [0, 1]$ and examine the double bifurcation at $(0, \lambda_{1,1}) = (0, \lambda_{4,1}) = (0, \frac{25}{4}\pi^2)$.

First, we follow the solution curve branching from $(0, \mu_{4,1})$ by choosing d with $\|d\|_\infty = 5 \cdot 10^{-5}$. Figure 10 shows that this solution curve has a secondary bifurcation at $(0, 88.3397)$. Figures 11–14 show the contours of this solution curve at different

values of μ. We observe variation of nodal lines of this solution curve with respect to μ. In particular, Figure 14 shows that the contour at $\lambda \approx 72.769$ already has the same nodal line as the solution curve bifurcating at $(0, \mu_{2,1})$. On the other hand, if we follow the solution curve bifurcating at $(0, \mu_{2,1})$, where $\| d \|_\infty = 5 \cdot 10^{-5}$, we find that this solution curve coincides with the secondary solution branch of the solution curve branching from $(0, \mu_{4,1})$. Thus the solution can be regarded as the secondary solution branch of the solution curve branching from $(0, \mu_{2,1})$, and vice versa.

Next, we follow the solution curve bifurcating at $(0, \mu_{1,1})$ by choosing d with $\|d\|_\infty = 5 \cdot 10^{-6}$. We observe that the the solution curves branching from $(0, \mu_{1,1})$ and $(0, \mu_{5,1})$ approach each other and meet at the secondary bifurcation point $(0, 96.5475)$; see Figure 10. The contours of this solution curve at different values of μ are shown in Figures 15–18. Figure 19 shows the solution curves bifurcating at $(0, \mu_{1,1})$ and $(0, \mu_{4,1})$, respectively, where the domain Ω is perturbed to $\Omega_1 = [0, 1.9] \times [0, 1]$. We remark here that part of the solution curves given in Figures 10 and 19 have the same shapes as the one given in [10].

Example 3. We consider the von Kármán equations with partially clamped boundary conditions,

$$
\begin{aligned}
\Delta^2 f \ + \ \frac{1}{2}[w, w] &= 0, \\
\Delta^2 w \ - \ [w, f] \ + \ \lambda w_{xx} &= 0 \qquad \text{in} \quad \Omega = [0, \sqrt{3}] \times [0, 1], \\
w \ = \ w_n &= 0 \qquad \text{on} \quad x = 0 \text{ and } x = \sqrt{3}, \\
w \ = \ \Delta w &= 0 \qquad \text{on} \quad y = 0 \text{ and } y = 1, \\
f \ = \ \Delta f &= 0 \qquad \text{on} \quad \partial\Omega;
\end{aligned} \tag{5.1}
$$

see section 2. To investigate mode jumping of (5.1), we perform local perturbation and domain perturbation with $l = 1.6,\ 1.7$, and 1.8, respectively. The first bifurcation is double and is split into two simple bifurcations via perturbations.

Figures 20–22 show the first two solution curves of (5.1) with $l = 1.6,\ 1.7$, and 1.8, respectively. Here W_1 and W_2 are the discrete solutions of (5.1). In Figure 20 we observe that a secondary bifurcation point is detected at $\mu \approx 59.3393$ and $\mu \approx 57.4876$ on the W_2- and W_1-solution branches, respectively. These two secondary bifurcation points are connected by a secondary solution branch, which corresponds to the phenomenon of mode jumping in this system. Figure 23 shows the contour of the W_1-solution branch at $\mu \approx 57.4876$, while Figure 24 depicts the contour of the secondary solution branch at $\lambda \approx 58.0849$. Similarly, Figures 25–27 show the contours of the W_2-solution branches at $\mu \approx 59.3373,\ 53.2187$, and 82.3688, respectively. We remark here that the contour of the W_2-solution branch varies with respect to μ, while the contour of the W_1-solution branch is invariant with respect to μ.

For $l = 1.7$ and $l = 1.8$ the contours of the W_1- and W_2-solution branches are similar to those for $l = 1.6$.

Example 4. Choosing $\Omega := [0, 1] \times [0, 1]$, we discretize the von Kármán equations with simply supported boundary conditions by the central difference approximation. We use the uniform meshsize $h = 0.0625$ on the x- and y-axis, respectively. First, we take Bi-CGSTAB and the preconditioned Bi-CGSTAB in [27] to trace the solution curve bifurcating from $(0, \mu_{1,1})$, where the diagonal of the discretization matrix is used as the preconditioner. Next, Algorithm 4.2 is implemented to trace the same

solution curve. A comparison of these methods and some information of the solution curve are described in Tables 1–2 with the following notation:

MAXNORM	:	maximal norm of W along the solution curve.
x_0	:	initial guess for the Bi-CGSTAB.
$\tilde{r}_0$	:	an arbitrary vector such that $(\tilde{r}_0, r_0) \neq 0$, e.g., $\tilde{r}_0 = r_0 = b - Ax_0$.
NCS	:	order of the continuation steps.
ε	:	tolerance in Newton corrector.
θ_1	:	minimum eigenvalue of T_j.
σ_1	:	minimum singular value of T_j.
κ_2	:	the two-norm condition number of T_j.
tol	:	stopping criterion for the unsymmetric Lanczos method.
η	:	number of negative eigenvalues of T_j.

HIGH-ORDER DIRECT STOKES SOLVERS WITH OR WITHOUT TEMPORAL SPLITTING: NUMERICAL INVESTIGATIONS OF THEIR COMPARATIVE PROPERTIES*

E. LERICHE† AND G. LABROSSE ‡

Abstract. A recently proposed direct Stokes solver which decouples the velocity and pressure operators without calling for a temporal scheme is numerically analyzed, in comparison, first with the splitting scheme proposed by G. Karniadakis, M. Israeli, and S. Orszag in [*J. Comput. Phys.*, 97 (1991), pp. 414–443], and with the unique grid $(\mathbb{P}_N, \mathbb{P}_{N-2})$ Uzawa approach for the space accuracy and computational costs. The Chebyshev collocation approximation is used to analyze the spectra of the continuous temporal evolution operators, and their discrete time versions, from the first to the fourth order. An explicit boundary condition is also involved in the proposed Stokes solver, and it is numerically shown that the trace of $\mathbf{\Delta u}$ on the boundary must be evaluated through its $-\nabla \times \nabla \times$ contribution only; otherwise the ellipticity is lost before proceeding to the time discretization. The explicit evaluation of the rotational boundary term does not prevent the first and second order in time schemes from being unconditionally stable, while the schemes built at the next two higher orders are limited by the usual explicit $(\mathcal{O}(N^{-4}))$ stability criterion on the time step. The proposed $(\mathbf{u}, p)$ decoupling gives this limitation a less restrictive coefficient and supplies the expected temporal orders on the whole explored range of time step sizes. The effective accuracy obtained for the Navier–Stokes 2D solutions has been measured, for the $Re = 1000$ lid-driven cavity problem, and has been found equivalent to what is supplied by the much more expensive Uzawa decoupling method.

Key words. Stokes equations, decoupling methods, temporal splitting methods, Stokes eigenvalues and eigenmodes, spectral Chebyshev approximation

1. Introduction.

Since the first numerical experiments were performed with the incompressible Navier–Stokes equations, solving the linear Stokes system has been of major concern with respect to its stability, accuracy, and computational efficiency once the nonlinear terms are explicitly treated as extra source. The question remains how to decouple the pressure and velocity fields in order to get an easily tractable numerical system with given stability and space-time accuracy properties. Many strategies have been proposed. They belong essentially to three main categories. The first historically proposed decoupling, the so-called Uzawa method, has been designed in a finite element framework [1] and applied within the spectral and spectral element context in many different implementations [31]. This method has the main advantage that the discrete problem is equivalent to the continuous case, and the numerical solutions converge to the exact one [25, 6]. When the diffusion terms are implicitly evaluated in time, this is obtained at the cost of an expensive, iterative inversion of the resulting full matrix, the Uzawa operator, including a vectorial Helmholtz solver [26]. An alternative comes from the fractional step methods, initially proposed by

[8] and [34, 35], and significantly improved by an extension to high temporal order discretizations [17]. In these methods, the decoupling of the velocity and pressure operators is obtained by a particular splitting of the discretized Stokes system, based on the time integration scheme. The corresponding linear system, as well as the induced properties (stability and temporal accuracy) of such a splitting are analyzed in [28]. The third category refers to the influence matrix or Green's function method [18]. Its implementation for three-dimensional (3D) flows, with N^3 nodes and no periodic direction, leads to the storage of the inverse of a large and full matrix of order $6N^2$, the capacitance matrix, and its application at each time step. As a consequence, this method is limited to two-dimensional (2D) flows simulation.

A projection-diffusion method (hereafter referred to as the PRDI method) has been introduced in [4] for the Chebyshev collocation method. No time scheme is required at the decoupling stage of the velocity and pressure operators. Thus, although not very far from the splitting formulation of [17] (hereafter referred to as the KIO method), the PRDI method is not of the fractional step type and does not suffer from the inconsistency that the authors in [17] point out for the splitting.

In contrast with the Uzawa approach which has received much theoretical attention (see [25] and the many references quoted therein), the splitting (or fractional step) methods have not yet been fully analyzed to the authors' knowledge. Theoretical works have been published for their low (1,2) time-order versions which require homogeneous boundary conditions on the pressure [33, 14]. However, according to Shen, "we can only expect a projection (or splitting) scheme to deliver higher than second-order accuracy if a more accurate boundary condition for the pressure is employed. A rigorous analysis for more general cases is not yet available" (page 1042 in [33]). Both schemes under consideration in this paper belong to this category where accurate pressure conditions are imposed on the boundaries. They involve a $-\nabla\times\nabla\times$ boundary contribution (see [27, 17] and below) which makes the theoretical work very difficult and unavailable so far. In absence of theoretical support, numerical results can be considered as a welcome help to better understand the Stokes schemes.

Thus, in this paper, a first extensive comparison of both spectral Stokes solvers, PRDI and KIO, is performed for (a) their consistency with the initial continuous problem, (b) their ability to respect the expected ellipticity, (c) their genuine stability properties, and (d) their respective temporal accuracy. The time splitting is clearly identified as responsible for inconsistencies of the KIO scheme, with an analysis which can be extrapolated to any fractional step scheme. Finally, it is shown that using the trace of $\mathbf{\Delta u}$ (instead of $-\nabla\times\nabla\times$) in a normal boundary condition breaks the ellipticity of both Stokes solvers, explaining the origin of the previously observed numerical instabilities [27, 17].

The analysis reported hereafter has been carried out in a simple test case, the bounded square Cartesian geometry, as a first step to reach before considering complex domains to be treated with more sophisticated numerical methods. Both solvers are thus based on a monodomain Chebyshev collocation method [13, 7]. As an aside, a first insight is offered into the eigenmodes of this 2D Stokes problem, since, to the authors' knowledge, they are not yet analytically known in a bounded domain.

The paper is organized as follows. After section 2, where the Stokes problem is recalled, in section 3 both methods and their main features are presented. In section 4, the continuous temporal evolution operator spectra are given for both solvers. Then, section 6 deals with the fully discretized solvers of temporal order one to four. A stability analysis is performed by eigenvalue computation. The first- and second- order

in time schemes are found to be unconditionally stable, whereas the third- and fourth-order present an $\mathcal{O}(N^{-4})$ stability restriction on the time step. This restriction is less severe for the PRDI than for the KIO solver. Then, the effective temporal accuracy of both solvers is measured by 3D numerical experiments performed with the first and second order in time collocation schemes. The PRDI method supplies exactly the expected temporal order on the whole explored time step range. Nevertheless, the best effective accuracy comes always from the KIO solver in the tests we have implemented.

The last section is dedicated to some practical comparisons between the PRDI and the unique grid $(\mathbb{P}_N, \mathbb{P}_{N-2})$ Uzawa approach applied to a classical Navier–Stokes test-case, namely the 2D regularized lid-driven cavity problem. The solutions supplied by the PRDI solver are as accurate as the Uzawa ones but obtained at a lower cost.

2. The governing equations. Let us consider the dimensionless unsteady (time t) 2D or 3D Stokes equations, written in the Cartesian open domain $\Omega = (]-1,+1[)^d$ with coordinates $\mathbf{x} = (x_i, i = 1, d)$, $\equiv (x, y)$ or $\equiv (x, y, z)$ according $d = 2, 3$, respectively, and T a real positive number,

$$\frac{\partial \mathbf{u}}{\partial t} = \boldsymbol{\Delta}\mathbf{u} - \nabla p + \mathbf{f} \qquad \text{for } (\mathbf{x}, t) \in \Omega\times]0, T[\ , \tag{2.1}$$

$$\nabla \cdot \mathbf{u} = 0 \qquad \text{for } (\mathbf{x}, t) \in \Omega\times]0, T[\ , \tag{2.2}$$

where $\mathbf{u} = (u, v, w)$ is the velocity field, p the pressure (normalized by the fluid's density), and $\mathbf{f}$ the source term. We denote the closure of Ω by $\overline{\Omega}$ and the boundary by $\partial\Omega$. For the sake of simplicity, we consider Dirichlet boundary conditions

$$\mathbf{u} = \mathbf{U} \qquad \text{for } (\mathbf{x}, t) \in \partial\Omega\times]0, T[, \tag{2.3}$$

and compatible initial conditions are given,

$$\mathbf{u}(t = 0) = \mathbf{U}^0 \quad \text{for } \mathbf{x} \in \Omega, \tag{2.4}$$

$\mathbf{U}^0$ being divergence-free. The viscosity has been inserted in the time, pressure, and source scales.

The present study is focused on the Stokes problem (2.1)–(2.2), but the Navier–Stokes equations are behind it if the source term $\mathbf{f}$ includes the nonlinear advective terms beside prescribed body forces. It is assumed from now on that the continuous spaces for the velocity and pressure are, respectively, $(H_0^1(\Omega))^d$ and $L_0^2(\Omega)$ for almost every time $t \in]0, T[$. $L_0^2(\Omega)$ is the space of functions which are square integrable in Ω with a zero mean value on Ω, $H^1(\Omega)$ is the space of functions of which the first derivative is square integrable in Ω, and $H_0^1(\Omega)$ is the closure in $H^1(\Omega)$ of the space of all functions continuously differentiable any number of times with compact support in Ω. The existence and uniqueness of a solution, lying in those spaces, of the unsteady Navier–Stokes equations are established and discussed in [29], under some assumptions considered as verified in this work. Under additional assumptions it is also possible to prove the existence of more regular solutions [16, 29].

For the forthcoming eigenmode analysis and investigation into the stability properties of the Stokes solvers, $\mathbf{f}$ is inessential and dropped from now on. The well-known equivalent continuous formulation of this problem, where the velocity and pressure are decoupled, reads as follows:

$$\boldsymbol{\Delta} p = 0 \qquad \text{for } (\mathbf{x}, t) \in \Omega\times]0, T[, \tag{2.5}$$

$$\left(\frac{\partial}{\partial t} - \boldsymbol{\Delta}\right) \boldsymbol{\Delta}\ \mathbf{u} = 0 \qquad \text{for } (\mathbf{x}, t) \in \Omega\times]0, T[. \tag{2.6}$$

Thus, the unsteady Stokes equations lead to harmonic pressure and biharmonic velocity fields.

3. The Stokes solvers. The unsteady Stokes problem is now solved with two different approaches. The first one is the well-established fractional step algorithm, denoted KIO, and it is briefly summarized in the beginning of this section. Basically linked to a time scheme, its presentation is made in a semidiscrete framework, discretized in time and continuous in space. The second one, the PRDI, comes then, with more details.

3.1. The KIO method. Proposed in 1991 as a high-order splitting method for the Navier–Stokes equations, the KIO *time* discretized system, applied to the unsteady Stokes problem, is based on the backward Euler scheme of order J_i. Its continuous-in-space version reads

$$\frac{\hat{\mathbf{u}} - \sum_{q=0}^{J_i-1} \alpha_q \mathbf{u}^{n-q}}{\Delta t} = -\nabla p \qquad \text{for } \mathbf{x} \in \Omega, \tag{3.1}$$

$$\nabla \cdot \hat{\mathbf{u}} = 0 \qquad \text{for } \mathbf{x} \in \Omega, \tag{3.2}$$

$$\frac{\gamma_0 \mathbf{u}^{n+1} - \hat{\mathbf{u}}}{\Delta t} = \boldsymbol{\Delta} \mathbf{u}^{n+1} \qquad \text{for } \mathbf{x} \in \Omega, \tag{3.3}$$

where $\hat{\mathbf{u}}$ is an intermediate velocity field, constrained to fulfill the incompressibility condition (3.2), and $\mathbf{u}^n \equiv \mathbf{u}(n\ \Delta t)$. The weights γ_0 and α_q, up to order $J_i = 3$, may be found in [17] and are gathered with the fourth-order coefficients in Table 1. The velocity field $\mathbf{u}$ satisfies the Dirichlet boundary conditions (2.3). The equations (3.1)–(3.2) are combined to lead to the Poisson equation for the pressure, which can be solved provided boundary conditions are chosen to be compatible with the temporal order (see below). They are obtained first by taking the trace on the boundary of the normal component of the sum of (3.1) and (3.3) and second by splitting $\boldsymbol{\Delta}\mathbf{u}$ into two parts,

$$\boldsymbol{\Delta}\mathbf{u} = -\nabla \times (\nabla \times \mathbf{u}) \ + \ \nabla(\nabla \cdot \mathbf{u}), \tag{3.4}$$

the solenoidal (resp., irrotational) part being treated explicitly (resp., implicitly) in time. This decomposition was first introduced in [27] to avoid exponential growth of a nonzero divergence of the velocity field $\mathbf{u}$ on the boundaries. The irrotational part is dropped in accordance with (2.2). Section 4.1 will elucidate the basic reason why such a procedure must be applied. Finally, using the extrapolation scheme of order J_e proposed in [17], the resulting continuous-in-space pressure system is

$$\boldsymbol{\Delta} p = \nabla \cdot \left(\frac{\sum_{q=0}^{J_i-1} \alpha_q \mathbf{u}^{n-q}}{\Delta t} \right) \qquad \text{for } \mathbf{x} \in \Omega, \tag{3.5}$$

$$\left[\frac{\partial p}{\partial \mathbf{n}} \right]_{\mathbf{x} \in \partial\Omega} = \left[\left(-\left(\frac{\partial \mathbf{U}}{\partial t} \right)^{n+1} - \sum_{q=0}^{J_e-1} \beta_q \nabla \times (\nabla \times \mathbf{u}^{n-q}) \right) \cdot \mathbf{n} \right]_{\mathbf{x} \in \partial\Omega} . \tag{3.6}$$

The weights β_q are listed in Table 1 and $\mathbf{n}$ is the outward normal unit vector.

This work considers only the case $J_e = J_i$.

It is worth writing the continuous-in-time problem, with decoupled pressure and velocity fields, which is equivalent to the above split system (3.1)–(3.3), and comparing

TABLE 1
The weights γ_0, α_q, and β_q.

Weights	Order 1	Order 2	Order 3	Order 4
γ_0	1	3/2	11/6	25/12
α_0	1	2	3	4
α_1	0	–1/2	–3/2	–3
α_2	0	0	1/3	4/3
α_3	0	0	0	–1/4
β_0	1	2	3	4
β_1	0	–1	–3	–6
β_2	0	0	1	4
β_3	0	0	0	–1

it with the Stokes continuous decoupled problem (2.5)–(2.6). This interesting point has already been raised in [17], whose authors pointed out that the pressure and velocity fields are now biharmonic and triharmonic, respectively. We shall reach the same conclusion by considering a continuous-in-time formulation of the system (3.1)–(3.3). At any time order, the derivative $\frac{\partial \mathbf{u}}{\partial t}$ is approximated by a linear combination of instantaneous velocities, of which one part, $-\sum_{q=0}^{J_i-1} \alpha_q \mathbf{u}^{n-q}/\Delta t$, is taken in the first step (3.1), while the second one, $\frac{\gamma_0 \mathbf{u}^{n+1}}{\Delta t}$, belongs to the diffusion step (3.3). A simple way to write an equivalent continuous-in-time formulation of this form of splitting is to consider that each part of the time derivative $\frac{\partial \mathbf{u}}{\partial t}$ is proportional to $\frac{\partial \mathbf{u}}{\partial t}$ itself. This holds for a normal mode analysis of the unsteady Stokes problem, and leads to the equivalent set of coupled continuous equations

$$\hat{\mathbf{u}} + \eta \, \frac{\partial \mathbf{u}_\eta}{\partial t} = -\nabla p_\eta \qquad \text{for } (\mathbf{x}, t) \in \Omega \times]0, T[\,, \tag{3.7}$$

$$\nabla \cdot \hat{\mathbf{u}} = 0 \qquad \text{for } (\mathbf{x}, t) \in \Omega \times]0, T[\,, \tag{3.8}$$

$$(1 - \eta) \, \frac{\partial \mathbf{u}_\eta}{\partial t} - \hat{\mathbf{u}} = \boldsymbol{\Delta} \mathbf{u}_\eta \qquad \text{for } (\mathbf{x}, t) \in \Omega \times]0, T[\,, \tag{3.9}$$

where the intermediate $\hat{\mathbf{u}}$ is now an acceleration field, and $(\mathbf{u}_\eta, p_\eta)$ the solutions of this new problem. With modes such that $\mathbf{u}_\eta^n = \kappa^n \mathbf{u}^0$ and $\kappa = \exp \lambda \Delta t$, it is easily seen that the coefficient η is related to the temporal order of the scheme by the simple relation

$$\frac{1 - \eta}{\eta} = -\frac{\gamma_0 \, \kappa}{\sum_{q=0}^{J_i-1} \alpha_q \kappa^{-q}}. \tag{3.10}$$

Obviously, there would be no such simple relation between $\frac{\partial \mathbf{u}}{\partial t}$ and its two split parts for a field $\mathbf{u}(t)$ having any time dependence. But the one adopted here can be applied to the Stokes eigenmodes. By successive differential eliminations performed on the continuous system (3.7)–(3.9), the decoupled continuous problem then reads as follows:

$$\left((1 - \eta) \frac{\partial}{\partial t} - \boldsymbol{\Delta} \right) \boldsymbol{\Delta} p_\eta = 0 \qquad \text{for } (\mathbf{x}, t) \in \Omega \times]0, T[, \tag{3.11}$$

$$\left((1 - \eta) \frac{\partial}{\partial t} - \boldsymbol{\Delta} \right) \left(\frac{\partial}{\partial t} - \boldsymbol{\Delta} \right) \boldsymbol{\Delta} \mathbf{u}_\eta = 0 \qquad \text{for } (\mathbf{x}, t) \in \Omega \times]0, T[. \tag{3.12}$$

Compared with the initial decoupled Stokes problem (2.5)–(2.6), it can be seen that a supplementary space-time operator has appeared, the first one on the left side of

these equations, directly induced by the time splitting, as mentioned in [17]. The origin of each term of this new operator is now identified. The extra time derivative is due to the splitting of $\frac{\partial \mathbf{u}}{\partial t}$ ($\eta \neq 1$), and the supplementary degree of harmonicity ($\eta = 1$) is introduced by the splitting between $\frac{\partial \mathbf{u}}{\partial t}$ and $\boldsymbol{\Delta}\mathbf{u}$. As a consequence, the approximate pressure field is biharmonic and governed by a time evolution equation, which is not physically consistent from the $\nabla \cdot \mathbf{u} = 0$ constraint. The velocity field satisfies a triharmonic time evolution equation. Both these fields are polluted by a numerical boundary layer of dimensionless thickness $\sqrt{t/|1-\eta|}$. Finally, the case $\eta = 0$ corresponds to a nonsplitting scheme, in which the incompressibility constraint (3.8) is applied on $\hat{\mathbf{u}} = \frac{\partial \mathbf{u}}{\partial t} - \boldsymbol{\Delta}\mathbf{u}$ by (3.9). As a result of this, the supplementary space-time operator no longer appears in (3.11)–(3.12). This is precisely the main feature of the PRDI method introduced now.

3.2. The PRDI method. The PRDI method looks like this fractional step method since it proceeds with two similar steps, namely, the determination of the pressure by imposing the incompressibility constraint to some appropriate field, and then the computation of the velocity $\mathbf{u}$ by a pure diffusion stage. However, the decoupling is now defined independently of any temporal scheme. Indeed, if we introduce the acceleration $\mathbf{a}^*$, where

$$\mathbf{a}^* = \frac{\partial \mathbf{u}}{\partial t} - \boldsymbol{\Delta}\mathbf{u},$$

the original problem (2.1)–(2.2) splits, for each $t \in]0, T[$, into two steps:

(1) *first step:*

$$\mathbf{a}^* + \nabla p = 0 \qquad \text{for } \mathbf{x} \in \Omega, \tag{3.13}$$

$$\nabla \cdot \mathbf{a}^* = 0 \qquad \text{for } \mathbf{x} \in \Omega, \tag{3.14}$$

$$\mathbf{a}^* \cdot \mathbf{n} = \left(\frac{\partial \mathbf{U}}{\partial t} - \boldsymbol{\Delta}\mathbf{u} \right) \cdot \mathbf{n} \qquad \text{for } \mathbf{x} \in \partial\Omega; \tag{3.15}$$

(2) *second step:*

$$\frac{\partial \mathbf{u}}{\partial t} - \boldsymbol{\Delta}\mathbf{u} = \mathbf{a}^* \qquad \text{for } \mathbf{x} \in \Omega, \tag{3.16}$$

$$\mathbf{u} = \mathbf{U} \qquad \text{for } \mathbf{x} \in \partial\Omega. \tag{3.17}$$

As stated at the end of the previous paragraph, this scheme is consistent with (2.5)–(2.6).

The projection step (3.13)–(3.15) can also be written as a Poisson–Neumann problem similar to (3.5)–(3.6),

$$\boldsymbol{\Delta} p = 0 \qquad \text{for } \mathbf{x} \in \Omega\ , \tag{3.18}$$

$$\left[\frac{\partial p}{\partial \mathbf{n}} \right]_{\mathbf{x} \in \partial\Omega} = \left[\left(-\frac{\partial \mathbf{U}}{\partial t} - \nabla \times (\nabla \times \mathbf{u}) \right) \cdot \mathbf{n} \right]_{\mathbf{x} \in \partial\Omega}. \tag{3.19}$$

Section 4.2 will highlight the numerical equivalence between these two projection approaches. The version (3.13)–(3.15) is always the one adopted with the PRDI method.

The two stages are coupled only through the normal boundary condition (3.15). The first step (3.13)–(3.15) allows the computation of the pressure through the solution of a Darcy-type problem, assuming that the right-hand side of the normal

boundary condition $\mathbf{a}^* \cdot \mathbf{n}$ is known (see below). The background and the numerical analysis of the Darcy problem with several variational formulations, in the framework of the spectral discretizations, may be found in [2].

The space discretization proceeds by expanding the $\mathbf{u}$, $\mathbf{a}^*$, and p fields in tensor product of Chebyshev polynomials of order (N, M, L) for the (x, y, z) dependencies, respectively. The collocation method consists of exactly enforcing the differential equations, and the boundary conditions, at the Gauss–Lobatto points [13, 7]. Let us introduce the discrete spaces, $\{\Omega\}$ and $\{\partial\Omega\}$, made of the set of the Gauss–Lobatto points located inside Ω and on the boundary $\partial\Omega$, respectively. The discrete space $\{\overline{\Omega}\}$ is the union of $\{\Omega\}$ and $\{\partial\Omega\}$. From now on, $\mathbf{u}$, $\mathbf{a}^*$, and p denote the set of the nodal values in $\{\overline{\Omega}\}$ of the corresponding fields. The discretization of (3.13) proceeds in a particular way. Indeed the ith component of this equation is collocated in the discrete space which excludes the two plane boundaries normal to the ith direction, where the conditions (3.15) are imposed.

The collocated Darcy problem (3.13)–(3.15) then reads

$$\mathbf{a}^* + \tilde{\mathcal{D}} p = \mathbf{f} \qquad \text{in} \quad \{\overline{\Omega}\}, \tag{3.20}$$

$$\mathcal{D}\cdot\mathbf{a}^* = 0 \qquad \text{in} \quad \{\overline{\Omega}\}. \tag{3.21}$$

$\mathcal{D}$ is the usual gradient operator, and its restriction by the collocation of (3.13) is noted $\tilde{\mathcal{D}}$. The discrete system (3.20) gathers what comes from (3.13) and (3.15), the right-hand side $\mathbf{f}$ coming exclusively from the discretized condition (3.15) noted $\mathbf{a}^* \cdot \mathbf{n} = \mathbf{a} \cdot \mathbf{n}$ on $\{\partial\Omega\}$. It is zero everywhere except where the normal boundary conditions are imposed:

$$\mathbf{f} = \mathbf{0} \qquad \text{except} \qquad (f_i)\,|_{x_i=\pm 1} = (a_i)\,|_{x_i=\pm 1}. \tag{3.22}$$

This vectorial field $\mathbf{f}$ will be denoted in a compact way:

$$\mathbf{f} = \text{“}\mathbf{a} \cdot \mathbf{n}.\text{”} \tag{3.23}$$

By substitution of (3.20) into (3.21), we obtain finally

$$\mathcal{E}_{\mathcal{P}\mathcal{D}}\, p = \mathcal{D}\cdot\mathbf{f} \qquad \text{in } \{\overline{\Omega}\}, \tag{3.24}$$

with

$$\mathcal{E}_{\mathcal{P}\mathcal{D}} = \mathcal{D}\cdot\tilde{\mathcal{D}}.$$

Taking advantage of the tensor product form of the Uzawa operator $\mathcal{E}_{\mathcal{P}\mathcal{D}}$, which is a quasi-Poisson operator, the fast diagonalization method [15] is used to “invert” it directly and to filter out its spurious pressure modes. For the Darcy problem, their number is 2^d $(d = 2, 3)$ [2] (see section 3.3).

Because the velocity $\mathbf{u}$ is unknown at the pressure step computation, the normal boundary condition (3.15) requires the same treatment as the one leading to (3.6). The condition (3.15) is then rewritten as

$$[\mathbf{a}^* \cdot \mathbf{n}]_{\{\partial\Omega\}} = \left[\left(\frac{\partial \mathbf{U}}{\partial t} + \sum_{q=0}^{J_e} \beta_q (\mathcal{D} \times (\mathcal{D} \times \mathbf{u}^{n-q})) \right) \cdot \mathbf{n} \right]_{\{\partial\Omega\}}. \tag{3.25}$$

Once the pressure is known, $\mathbf{a}^*$ is evaluated and the second step (3.16)–(3.17), which is a pure diffusion problem, can be solved. An implicit backward Euler scheme of order J_i is employed to perform the time integration:

$$\frac{\gamma_0 \mathbf{u}^{n+1} - \sum_{q=0}^{J_i} \alpha_q \mathbf{u}^{n-q}}{\Delta t} = \mathcal{A}_D \mathbf{u}^{n+1} + \mathbf{a}^*, \tag{3.26}$$

$\mathcal{A}_D$ denoting the Dirichlet–Laplacian matrix, the system being completed by $\mathbf{u} = \mathbf{U}$ on the boundaries. The time discretized equations (3.26) contain a vectorial Helmholtz system to be solved by the fast diagonalization method [15].

3.3. About the spurious pressure modes. Let $\mathbb{P}_N$ denote the space of all polynomials of degree less than or equal to N. Both the KIO and the PRDI Stokes solvers are of $(\mathbb{P}_N, \mathbb{P}_N)$ type, in each space direction, since the velocity $\mathbf{u}$ and pressure p fields are approximated in the same polynomial space. A priori, a Stokes $(\mathbb{P}_N, \mathbb{P}_N)$ solver is expected to exhibit 8 (for a 2D case) or $4(N + M + L + 1)$ (for a 3D case) spurious pressure modes [5]. Their presence can be understood equivalently from

(a) an inf-sup, or Babuška–Brezzi, compatibility condition between the polynomial spaces approximating the velocity and the pressure fields [5],

(b) the algebraic compatibility conditions that must be fulfilled between the velocity boundary conditions and the incompressibility constraint enforced at all the nodes, boundaries included [19].

This latter statement allows us to predict easily the number of spurious pressure modes in each of these solvers. The KIO method does not impose a vanishing divergence at the boundaries. Then, the compatibility condition which remains does not involve the continuity constraint but concerns only the Neumann boundary conditions on the pressure, and corresponds to the constant pressure mode. For the PRDI method with (3.13)–(3.15), the incompressibility constraint is enforced, boundaries included, on a field required to satisfy only prescribed *normal* boundary conditions. The number of compatibility conditions, i.e., of spurious pressure modes, is then [19] reduced to 2^d $(d = 2, 3)$ [2]. Their space is spanned by the following set ($T_i(x)$ is the Chebyshev polynomial of first kind of degree i):

$$\begin{aligned} \{T_0, T_N(x)\} \otimes \{T_0, T_M(y)\} \qquad & \text{when } d = 2, \\ \{T_0, T_N(x)\} \otimes \{T_0, T_M(y)\} \otimes \{T_0, T_L(z)\} \qquad & \text{when } d = 3. \end{aligned}$$

These spurious pressure modes are the constant and checker-board modes.

4. Continuous-in-time evolution operator for the 2D Stokes solvers. The PRDI method is consistent with the continuous decoupled formulation (2.5)–(2.6) and leads to a genuinely continuous-in-time evolution operator (i.e., independent of any time integration scheme). Its spectrum will indicate to what extent the ellipticity of the Stokes problem [36] is preserved in the Chebyshev collocation approximation. Moreover, as in the case of the second order differentiation operator [7], the low spatial frequency part of the numerical spectrum can be taken as a good approximation of some eigenmodes of the continuous Stokes problem not yet analytically known for a bounded 2D or 3D simple Cartesian geometry, e.g., *(cavity flow)*. The 2D numerical spectrum, and some eigenmodes, will be given as complementary data to those reported in [3] and limited to the 2D case with one periodic direction, e.g., *(channel flow)*. Homogeneous Dirichlet boundary conditions are imposed on the velocity. From now on, $\mathbf{u}$ denotes the restriction of the discrete velocity field to its internal nodal values.

TABLE 2
Asymptotic laws for the extreme eigenvalues of the collocation operators.

2D $\mathcal{A}_D$		$\mathcal{L}$	
λ_{min}	λ_{max}	λ_{min}	λ_{max}
$-0.094 * N^4$	$\frac{-\pi^2}{2}$	$-0.075 * N^4$	$\frac{-\pi^2}{4}$

The determination of the full set of eigenvalues based on the explicit construction of the matrix is limited by the matrix size. Whenever possible, the whole spectrum is computed. Otherwise, the largest eigenvalues are computed by the power method adapted when the leading eigenvalue is a complex conjugate pair [30]. The convergence of the power method has been controlled by choosing several initial conditions.

Finally, the same polynomial approximation has been taken in both spatial directions. The corresponding number of collocation points is denoted by N^2.

4.1. The PRDI method. The time evolution equation of the velocity field comes directly from (3.16), (3.20), and (3.24). It reads

$$\frac{d\mathbf{u}}{dt} = \mathcal{A}_D\mathbf{u} - \mathcal{D}(\mathcal{E}_{\mathcal{PD}})^{-1}\mathcal{D}\cdot\mathbf{f}, \tag{4.1}$$

where $\mathbf{f}$ is defined as in (3.22) with $\mathbf{a} = (\mathcal{D}\times\mathcal{D}\times)\ \mathbf{u}$ (not in its time-extrapolated form (3.25)).

Then (4.1) takes the form

$$\frac{d\mathbf{u}}{dt} = \mathcal{L}\mathbf{u} \equiv \mathcal{A}_D\mathbf{u} - \mathcal{D}(\mathcal{E}_{\mathcal{PD}})^{-1}\mathcal{D}\cdot[\text{“}(\mathcal{D}\times\mathcal{D}\times\mathbf{u})\cdot\mathbf{n}\text{”}], \tag{4.2}$$

which defines the time evolution operator $\mathcal{L}$.

The temporal evolution is governed by the expected diffusion operator, completed with the contribution of the pressure gradient, itself fed by the normal boundary conditions (3.25).

The complete $\mathcal{L}$ spectrum has been computed with $N = 49$ polynomials. The results and their analysis are now reported.

Figure 1 displays the real and imaginary parts of the eigenvalues. The whole spectrum is made of eigenvalues with negative real parts, of which about 32% (scaled approximately by an $\mathcal{O}(\sqrt{N})$ law) represent complex modes. Most of these have an extremely small imaginary part, while the remainder have an imaginary part not exceeding 8.5% of the associated real part. The collocation PRDI Stokes operator has therefore the desirable property that it leads to A-stable time integration schemes (at best up to order 2 [10]).

Applying the power method with N up to 257, the algebraically smallest eigenvalue is found to be real, negative, and to scale with an N^4 law, while the largest one approaches asymptotically $\frac{-\pi^2}{4}$. The measured asymptotic laws of these extreme eigenvalues are reported in the second column of Table 2.

Although the 2D bounded Stokes problem can be solved analytically, by biorthogonal series based on “Papkovich–Fadle”-type functions [12], to the authors' knowledge no work has been published supplying the corresponding analytical eigenmodes to which the computed ones could be compared. An analysis of the Stokes eigenspace is well beyond the scope of this paper and we will limit ourselves to presenting some results, complementary to those reported in [3] for the periodic channel flow solved by a Legendre–Uzawa–Stokes scheme. First, the 11 largest eigenvalues (divided by $\frac{-\pi^2}{4}$)

are listed in Table 3 for several polynomial expansions. Since they all converge to some value (actually, an integer multiple of $\frac{-\pi^2}{4}$, except for three of them), they give a good approximation to the continuous Stokes operator eigenvalues. In fact, many numerical eigenvalues do converge with N.

Then, Figure 2 displays the leading 450 real eigenvalues λ_k (divided by $-\frac{\pi^2}{4}$) as a function of k for $N = 49$. The observed linear law agrees with the scaling estimate proposed in [9].

Finally, six of the real eigenmodes that converge with N are presented in Figure 3, thus illustrating their different structures. They correspond, respectively, to the following multiple of $\frac{-\pi^2}{4}$ eigenvalues: 1, 9, 15.616174348, 36.754375567, 64, and 276.34507007. They are candidates, among others, as eigenmodes of the continuous Stokes problem.

Once the spectra of the Stokes time-continuous evolution operator and some of its eigenmodes are presented, two related particular aspects deserve to be briefly

commented on.

(1) As experimentally recognized previously in [27], the implicit treatment of the $(\nabla \cdot \mathbf{u})$ term in (3.4) for the normal boundary conditions ((3.6) and (3.25)) prevents the time schemes from being numerically unstable. In an attempt to trace back the origin of this instability, the authors of [17] proposed the possible effects of "propagation and accumulation of time-differencing errors." However, it will now be shown that the source of this numerical problem is deeper than is simply due to the time discretization. Indeed, let us replace the normal boundary term ("$(\mathcal{D} \times \mathcal{D} \times \mathbf{u}) \cdot \mathbf{n}$") in the definition (4.2) of the continuous-in-time evolution operator $\mathcal{L}$ by ("$(-\mathcal{A}_D \mathbf{u}) \cdot \mathbf{n}$"). The resulting operator spectrum is given in Figure 4. Positive real parts have appeared and most of the eigenvalues are complex. This Stokes solver breaks the ellipticity of the continuous problem. Stability is therefore unreachable by any time integration scheme.

(2) Let us rewrite the $\mathcal{L}$ operator of (4.2) as $\mathcal{L} = \mathcal{A}_D + \mathcal{B}$. It must be noted that $\mathcal{B}$ handles a reduced number of independent quantities, those which are defined on the boundary nodes, $4(N-2)$ actually, as can be seen by summing the size of the $(\mathcal{E}_{\mathcal{PD}})^{-1}\mathcal{D}\cdot$ and $(\mathcal{D} \times \mathcal{D}\times) \cdot \mathbf{n}$ kernels. Therefore, the coupling of $\mathcal{B}$ with the diffusion acts in a quite reduced space. This sheds some light on the way the incompressibility constraint is actually applied (rather than strictly enforced) on the numerical velocity field. Only $4(N-2)$ independent quantities are needed to drive the solenoidality of the velocity $2(N+1)^2$ nodal values. In other words, the ability of the pressure field to ensure the incompressibility constraint depends essentially on a given reduced number of independent data, normal boundary conditions, for instance, on the pressure. This meets the influence matrix basic idea. A detailed analysis of the ($\mathcal{A}_D$, $\mathcal{B}$) coupling is reported in [21]. It brings, in particular, a way of looking at the difficulty arising with the Lanczos-τ spectral formulation (see section 5 below).

4.2. The KIO method. For the PRDI solver, the time evolution equation for the discrete in space velocity field has been easily obtained. In the KIO case, because of the time splitting, this is not as straightforward. Let us start from the discretized-in-space formulation of (3.7)–(3.9):

$$\frac{d\mathbf{u}}{dt} = \mathcal{A}_D \mathbf{u} - [\mathcal{D}p]_{\{\Omega\}}\,, \tag{4.3}$$

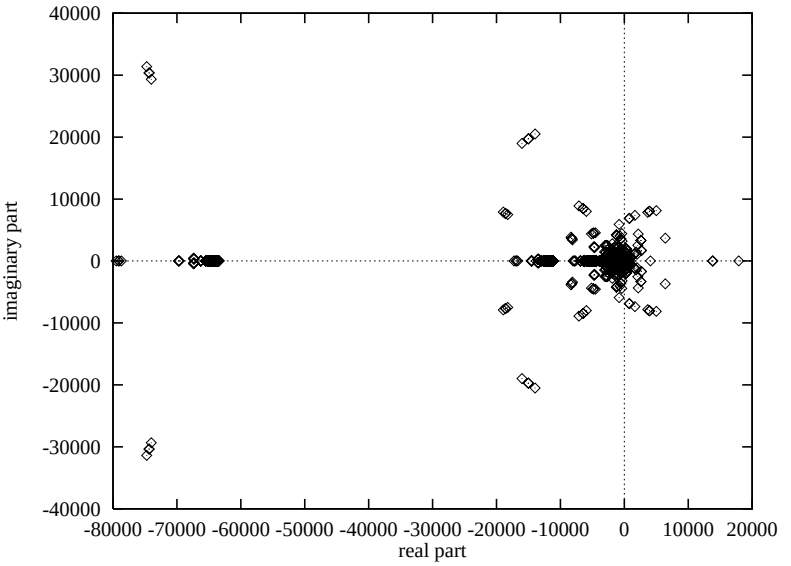

FIG. 4. *The $N = 35$ spectrum of the modified PRDI $\mathcal{L}$ operator for the collocation approximation. The $(-\mathcal{A}_D)$ term replaces the $(\mathcal{D} \times \mathcal{D}\times)$.*

with

$$[\mathcal{A}_N p]_{\{\Omega\}} = -\eta \left[\frac{d}{dt}(\mathcal{D}\cdot\mathbf{u})\right]_{\{\Omega\}}, \tag{4.4}$$

$$\left[\frac{\partial p}{\partial \mathbf{n}}\right]_{\{\partial\Omega\}} = -\left[(\mathcal{D}\times(\mathcal{D}\times\mathbf{u}))\cdot\mathbf{n}\right]_{\{\partial\Omega\}}, \tag{4.5}$$

where

(1) $\mathcal{A}_N$ is the Poisson–Neumann discrete operator,
(2) p satisfies the normal boundary conditions (4.5).

Equations (4.4)–(4.5) define the pressure as made up of two contributions, $p = p_1 + p_2$, such that

$$[\mathcal{A}_N p_1]_{\{\Omega\}} = 0, \tag{4.6}$$

$$\left[\frac{\partial p_1}{\partial \mathbf{n}}\right]_{\{\partial\Omega\}} = -\left[(\mathcal{D}\times(\mathcal{D}\times\mathbf{u}))\cdot\mathbf{n}\right]_{\{\partial\Omega\}}, \tag{4.7}$$

and

$$[\mathcal{A}_N p_2]_{\{\Omega\}} = -\eta \left[\frac{d}{dt}(\mathcal{D}\cdot\mathbf{u})\right]_{\{\Omega\}}, \tag{4.8}$$

$$\left[\frac{\partial p_2}{\partial \mathbf{n}}\right]_{\{\partial\Omega\}} = 0. \tag{4.9}$$

The p_2 contribution, induced by the splitting, forces us to take into account the temporal evolution of the velocity divergence. Each of these two pressure fields can be expressed in a concise way as

$$p_1 = -\mathcal{A}_{N1}^{-1}\left[\text{“}(\mathcal{D}\times(\mathcal{D}\times\mathbf{u})\cdot\mathbf{n})\text{”}\right], \tag{4.10}$$

$$p_2 = -\eta \mathcal{A}_{N2}^{-1} \left[\frac{d}{dt} (\mathcal{D} \cdot \mathbf{u}) \right], \tag{4.11}$$

the operator $\mathcal{A}_{N1}$ corresponding to the Poisson–Neumann problem driven only by inhomogeneous normal boundary conditions (4.7), the right-hand side being homogeneous, and $\mathcal{A}_{N2}$, to the same problem, but driven only by the right-hand side, the normal boundary conditions (4.9) being homogeneous. From this, the time evolution equation reads

$$\frac{d}{dt} \left[1 + \eta \mathcal{D} \mathcal{A}_{N2}^{-1} \mathcal{D} \cdot \right] \mathbf{u} = \left[\mathcal{A}_D \mathbf{u} + \mathcal{D} \mathcal{A}_{N1}^{-1} \text{“} (\mathcal{D} \times (\mathcal{D} \times \mathbf{u}) \cdot \mathbf{n}) \text{”} \right]. \tag{4.12}$$

In a short form, it is written as

$$\mathcal{S}(\eta) \, \frac{d\mathbf{u}}{dt} = \mathcal{L}_{PN} \mathbf{u}. \tag{4.13}$$

The right-hand side $\mathcal{L}_{PN}$ is just the analogy of the PRDI operator $\mathcal{L}$ (4.2), but from a Poisson–Neumann term instead of the quasi-Poisson one. It gives the temporal evolution of the numerical Stokes solution without splitting ($\eta = 0$). The left-hand side $\mathcal{S}(\eta)$ bears the signature of the splitting. From the knowledge of this time evolution equation, two questions are now addressed:

(1) To what extent are the Poisson-Neumann and quasi-Poisson solvers numerically equivalent?
(2) What is the long term evolution in time, given by the KIO splitting scheme, of the Stokes eigenmodes?

(1) The numerical equivalence of the Poisson–Neumann and quasi-Poisson solvers that can be established is based on the comparison of the $\mathcal{L}$ and $\mathcal{L}_{PN}$ spectra. The $\mathcal{L}_{PN}$ spectrum enjoys the properties described above (section 4.1) for the $\mathcal{L}$ operator. In particular, as shown by Table 4, the 11 largest real eigenvalues of $\mathcal{L}_{PN}$ (divided by $\frac{-\pi^2}{4}$) converge, except for 3 of them, towards an integer multiple of $\frac{-\pi^2}{4}$, but much more slowly for some of them than those of $\mathcal{L}$ (see Table 3). Furthermore, the asymptotic scaling law of the algebraically smallest eigenvalue of $\mathcal{L}_{PN}$ is in perfect agreement with the law given in Table 2.

(2) The asymptotic time evolution of the Stokes normal modes in the KIO solver. Instead of analyzing the spectrum of the evolution operator given by (4.13) for each value of the parameter η, it is more useful to characterize the long term evolution in

TABLE 5
The ranges of η for several temporal orders.

21	-1.2413E+00	-2.2569E-01	-2.4580E-02	-2.4801E-03	-2.4824E-04
35	-1.2370E+00	-2.2492E-01	-2.4496E-02	-2.4716E-03	-2.4739E-04

time that this operator imposes to any of the Stokes normal modes. It will be shown, first, that the η parameter is not so linked to the temporal order of the scheme; and second, the splitting does not affect the stability of the scheme, i.e. any Stokes normal mode is damped through the equation (4.13).

A given Stokes normal mode is characterized by $\mathbf{u} = \mathbf{U}(x, y, z)\ \exp(\lambda t)$, with λ a real negative eigenvalue of the analytical Stokes operator, and the coefficient κ quoted in (3.10) reads as $\exp(\lambda \Delta t)$ with $0 < \kappa \leq 1$. Therefore, by relation (3.10), η is a real quantity which can be defined as well by

$$\eta = 1 - \frac{\gamma_0}{\lambda \Delta t} = -\frac{1}{\lambda \Delta t} \sum_{q=0}^{J_i - 1} \alpha_q \kappa^{-q-1}. \tag{4.14}$$

These relations are such that adding $\eta\ \frac{\partial \mathbf{u}}{\partial t}$ to $(1 - \eta)\ \frac{\partial \mathbf{u}}{\partial t}$ gives back the discrete (approximation of) $\frac{\partial \mathbf{u}}{\partial t}$. The first equation shows that η is always positive, larger than 1 actually. The allowed ranges of η are listed in Table 5.

Thus giving η any value between 1 and ∞ allows one to consider any time order of the splitting scheme; this parameter refers therefore rather to the splitting nature of the numerical system than to the chosen time order. The spectrum of the part $\left[\mathcal{D}\mathcal{A}_{N2}^{-1}\mathcal{D}\cdot\right]$ of the $\mathcal{S}(\eta)$ operator has been computed. It exhibits a large kernel (half of the complete set of the eigenvalues), the remaining ones being all positive and close to unity. The spectrum of $\mathcal{S}(\eta)$ is then always real and positive with eigenvalues $\lambda_k \approx (1 + \eta)$ for all k. This offers the possibility to the complete evolution operator (4.13) of having real negative eigenvalues for all $\eta \geq 1$. The algebraically largest real eigenvalue of the generalized eigenvalue problem (4.13) for several values of η (1 to 10000) is reported for different polynomial expansions in Table 6. Figure 5 shows the monotonic behavior of this largest eigenvalue (in absolute value) with respect to η, for a fixed $N = 21$ polynomial expansion. This eigenvalue, almost unaffected by the spatial discretization for a fixed η, remains always real, negative and goes monotonically to zero with increasing values of η. The main conclusion is that the splitting preserves the exponential decrease with time of the normal Stokes eigenmodes. The time discretization is then the only source of the possible numerical instabilities.

5. About the spectral Lanczos-τ formulation of the Stokes solvers. In this section, the first historically used spectral discretization is considered instead of the collocation approach. In this Galerkin-type method, the unknowns are the expansion coefficients in Chebyshev polynomials of the velocity and pressure fields.

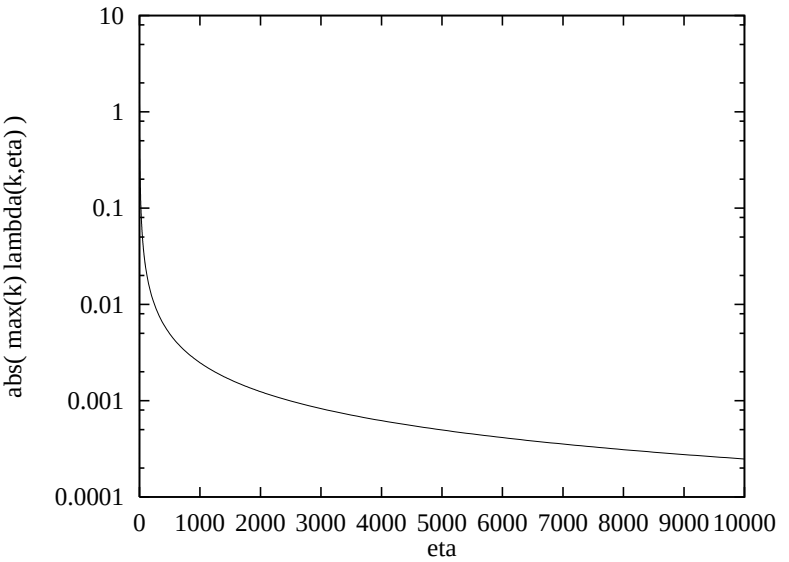

FIG. 5. *The algebraically largest real eigenvalue (in absolute value, with log-scale) of the generalized eigenvalue problem, as a function of η, with a fixed $N = 21$ polynomial expansion.*

However, the test functions (the Chebyshev polynomials themselves) do not satisfy the boundary conditions and the differential equations are enforced with a supplementary set of test functions [13].

Although commonly considered as equivalent to the collocation method, the Lanczos-τ approximation of the Stokes problem turns out to not preserve the ellipticity of the initial system. Indeed, all the previous analysis has been carried out with this spatial formulation and detailed results are reported in [21]. Only the dominant feature is quoted now, and concerns the spectrum of the time-continuous evolution operator (see (4.2)). Significantly different from the spectrum of the collocation version, it contains four eigenvalues with positive real part. The leading eigenvalue scales as $0.65 * N^4$, a result that might be related to the prediction of a very recently published analysis [11].

6. The fully discrete temporal evolution operators. Only the collocation approximation of the Stokes solvers is now considered, with a temporal discretization of order $J = J_e = J_i$ going from 1 to 4. The stability and effective order in time of their numerical solutions are addressed in this section. A 2D eigenvalue analysis and 3D numerical experiments are performed to assess these two points, respectively.

The unsteady diffusion contribution is implicitly treated with a backward Euler scheme, and the boundary condition involved in the projection stage is evaluated by an extrapolation scheme of the same order. Equations (3.1)–(3.3), (3.5)–(3.6) of section 3.1 and (3.20)–(3.26) of section 3.2 summarize the KIO and PRDI formulations, respectively.

6.1. Stability properties of the Stokes solvers. Starting from the expressions given by (4.2) and (4.13) for the PRDI and KIO continuous-in-time evolution

operators, respectively, the fully discretized evolution operators read

$$\mathbf{u}^{n+1} = (\mathcal{H})^{-1}\left[-\frac{\sum_{q=0}^{J_i}\alpha_q\mathbf{u}^{n-q}}{\Delta t} + \mathcal{D}(\mathcal{E}_{\mathcal{PD}})^{-1}\mathcal{D}\cdot\left(\sum_{q=0}^{J_e}\beta_q(\text{“}\mathcal{D}\times(\mathcal{D}\times\mathbf{u}^{n-q})\cdot\mathbf{n}\text{”})\right)\right]$$

for the PRDI method and

$$\mathbf{u}^{n+1} = (\mathcal{H})^{-1}\left[-\mathcal{I} + \mathcal{D}(\mathcal{A}_N)^{-1}\mathcal{D}\cdot\right]\left(\frac{\sum_{q=0}^{J_i-1}\alpha_q\mathbf{u}^{n-q}}{\Delta t}\right)$$

for the KIO solver. $\mathcal{H}$ is the discrete Helmholtz operator, which includes the homogeneous Dirichlet boundary conditions imposed on the velocity,

$$\mathcal{H} = \mathcal{A}_D - \frac{\gamma_0}{\Delta t}\mathcal{I},$$

$\mathcal{I}$ is the unit matrix, and $\mathcal{E}_{\mathcal{PD}}$ is the quasi-Poisson operator arising from the decoupling of the fields $\mathbf{a}^*$ and the pressure (see (3.24)). $\mathcal{A}_N$ is the Neumann–Poisson discrete operator, completed with the normal boundary condition

$$\left[\frac{\partial p}{\partial \mathbf{n}}\right]_{\{\partial\Omega\}}^{n+1} = \left[\text{“}\left(-\sum_{q=0}^{J_e-1}\beta_q\mathcal{D}\times(\mathcal{D}\times\mathbf{u}^{n-q})\right)\cdot\mathbf{n}\text{”}\right]_{\{\partial\Omega\}}.$$

These matrices are full. Their size is $[dJ(N-1)^d]^2$, where d is the space dimensionality. Thus, their complete spectrum evaluation has been limited to the 2D case with a reduced number of nodes, namely, $N = 33$ in each space direction for the first order in time discretization, and $N = 21$ otherwise. For larger N values the power method is applied to get the leading eigenvalues.

The spectra of the PRDI and KIO matrices are displayed in Figures 7 and 8 for the first to fourth order in time schemes, with time steps going from 10^{-3} to 0.1. In [21], these spectra are given for a broader range of time steps. An increase in the time order has the noticeable effect of taking the eigenvalues away from the real axis, often pushing some of them outside the unit circle when the time order reaches the third level. This effect is more pronounced with the KIO solver, as can be seen by comparing, for instance, the first order in time spectra on Figures 7 and 8, almost real with the PRDI solver and significantly complex with the KIO version. Hence, the PRDI solver is more stable for the third and fourth order in time schemes. Furthermore, both solvers are unconditionally stable with the first and second order in time schemes. This is summarized in Figure 6 which depicts, as a function of the time step, the leading eigenvalue moduli for both Stokes solvers when discretized with the four temporal schemes. The horizontal line where all the data converge, for very small time steps, is slightly below the unit value. The estimated stability criterion $\Delta t(N)$, of which some numerical values are given in Table 7, is $\Delta t(N) \simeq \mathcal{O}(N^{-4})$. This is the signature of the explicit treatment of the boundary condition used in the pressure stage.

Fixing the time step at the value 10^{+7}, the largest modulus of the eigenvalues for the first- to fourth-order time evolution operators is determined for several space discretizations N, going from $N = 7$ to $N = 129$ and given in Table 8.

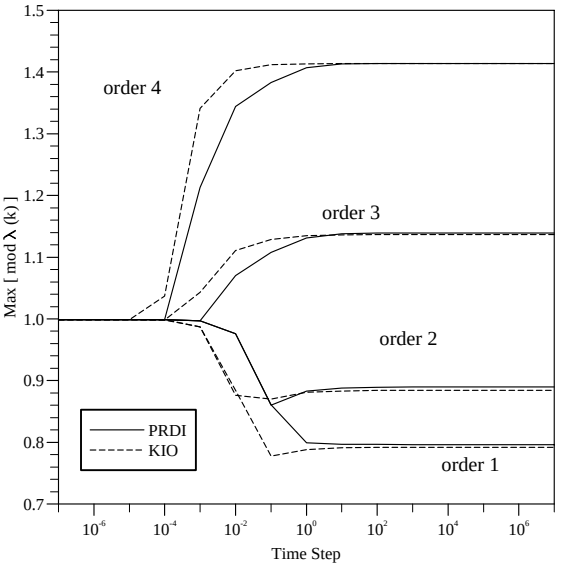

FIG. 6. *Evolution of the largest eigenvalues λ_{max} of the first- to fourth-order time evolution operators for the PRDI and KIO Stokes solvers, with the time steps going from 10^{-7} to 10^{+7} ((*mod*) means the largest eigenvalue in modulus; the number of Chebyshev collocation points in each direction is 33 for the first-order scheme, and 21 for the higher-order schemes).*

N	Order 3		Order 4	
	PRDI	KIO	PRDI	KIO
7	$1.31\ 10^{-1}$	$5.97\ 10^{-2}$	$2.10\ 10^{-2}$	$8.77\ 10^{-3}$
17	$4.05\ 10^{-3}$	$1.34\ 10^{-3}$	$5.31\ 10^{-4}$	$2.03\ 10^{-4}$
33	$2.51\ 10^{-4}$	$8.57\ 10^{-5}$	$3.32\ 10^{-5}$	$1.29\ 10^{-5}$
65	$1.56\ 10^{-5}$	$5.35\ 10^{-6}$	$2.09\ 10^{-6}$	$8.12\ 10^{-7}$
129	$9.72\ 10^{-7}$	$3.31\ 10^{-7}$	$1.30\ 10^{-7}$	$5.10\ 10^{-8}$

6.2. The effective temporal order of the Stokes solvers. A 3D test problem (inspired by the test adopted in [4]) is considered, in the cube $[-1,1]^3$, with the source term $\mathbf{f}$ of (2.1) analytically chosen so that the following velocity $\mathbf{u} = (u, v, w)$ and pressure p fields are solutions of the Stokes problem (2.1)–(2.2)

$$\begin{aligned}
u(x,y,z,t) &= -\ 0.5\sqrt{3}\sqrt{7}\sin(\sqrt{2}x+t)\cos(\sqrt{3}y+t)\cos(\sqrt{7}z+t),\\
v(x,y,z,t) &= -\ 0.5\sqrt{2}\sqrt{7}\cos(\sqrt{2}x+t)\sin(\sqrt{3}y+t)\cos(\sqrt{7}z+t),\\
w(x,y,z,t) &= \sqrt{2}\sqrt{3}\cos(\sqrt{2}x+t)\cos(\sqrt{3}y+t)\sin(\sqrt{7}z+t),\\
p(x,y,z,t) &= \sqrt{6}\sin(2x-\sqrt{5}y+\sqrt{10}z+0.7t)\sin(\sqrt{5}y++\sqrt{11}z+0.3t).
\end{aligned}$$

Note that the boundary values of the velocity are time dependent. The chosen time dependence of this test case is periodic, instead of exponentially decreasing, to allow for a nonbiased experimental confirmation of the stability criteria and of the effective temporal orders. Moreover, $N = 35$ nodes are taken for evaluating the space derivatives with enough accuracy (almost at the machine limit) to get only temporal errors in the numerical data. The Stokes problem has been integrated with the already

quoted first and second order in time schemes, during one unit of dimensionless time, with time steps ranging from 10^{-4} to 10^{-1} and the pointwise errors measured. The maximum pointwise difference obtained between the numerical and analytical velocity, the pressure, and $\nabla \cdot \mathbf{u}$ fields are plotted on Figures 9 and 10 for the first and second temporal orders, respectively. The PRDI solver supplies exactly the expected order, while the effective order coming from the KIO splitting is nonuniform on the chosen range of Δt. The expected order is effectively reached for very small time steps, $\Delta t < 10^{-3}$ actually, and beyond this approximate threshold the effective order gets higher by $\frac{1}{2}$ with respect to its expected level. For this particular test, the time accuracy is systematically in favor of the KIO method.

7. Some comparative data with the Uzawa approach. To decouple the velocity and pressure fields by the Uzawa method is, to a certain extent, a reference approach for solving accurately the Stokes problem. This has previously been attested to, for instance, by Batcho and Karniadakis [3] who choose this solver to compute the Stokes eigenmodes for the channel flow. Nonetheless, this method is very expensive when the diffusion terms are implicitly evaluated with time. The authors' point of

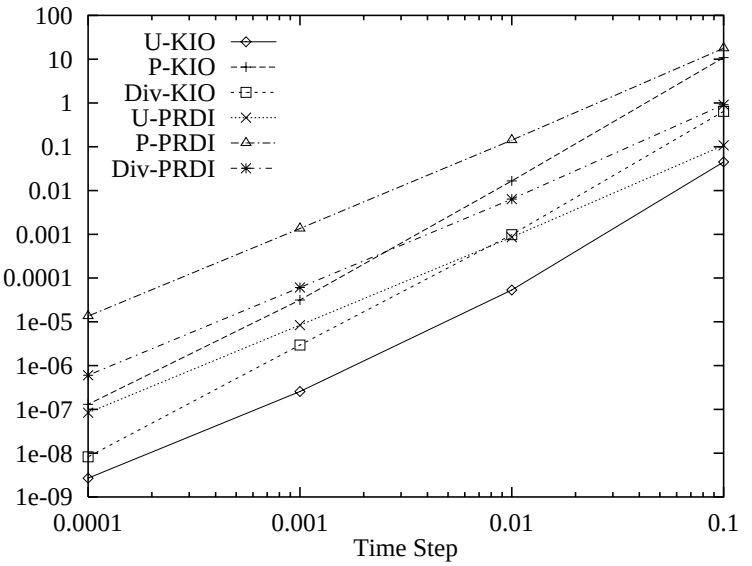

FIG. 10. *Maximum pointwise error of the computed velocity (U), the pressure (P), and* $\nabla \cdot \mathbf{u}$ (Div) *with respect to the corresponding analytical quantities for the PRDI and KIO Stokes solvers, second-order time scheme.*

TABLE 9
The operation count for the PRDI and the preconditioned Uzawa Stokes solvers.

Uzawa	$20\ d\ \mathcal{C}\mathcal{N}_{it}$
PRDI	$3\ d\ \mathcal{C}$

view is that the PRDI decoupling is an interesting alternative to get equivalent results [20] at a significantly reduced cost. This has made it possible to perform direct numerical simulation of the 3D lid-driven cavity at high Reynolds number [24, 23]. A few comparative numerical results are therefore given in this section, for the PRDI and the unique grid $(\mathbb{P}_N, \mathbb{P}_{N-2})$ Uzawa solvers.

First, for the operation count, let us introduce $\mathcal{C}$, the number of operations required to perform a matrix multiplication on a vector-data containing N^d elements, N in each direction of the dD space. Taking advantage of the tensorial structure of the matrices, one has $\mathcal{C} = N^{d+1}$.

Table 9 gives a coarse estimation of the operation count for both solvers, where $\mathcal{N}_{it}$ stands for the iteration number required to converge the Uzawa solution to machine accuracy. Indeed, an iterative method is employed in order to avoid an explicit construction of the Uzawa matrix. An efficient Navier–Stokes solver (with a biconjugate gradient [37] and a good preconditioner) has thus been implemented for moderate or high Reynolds number flow simulation, requiring small time steps because of the explicit treatment of the nonlinear terms [22].

$\mathcal{N}_{it}$ is very sensitive to the physical configuration (the Reynolds number values for instance), to the number of collocation points and the time step size [22]. As an illustration, for the two-dimensional case (to be presented hereafter), Table 10 gives $\mathcal{N}_{it}$ for several polynomial orders.

Finally, the PRDI and the preconditioned Uzawa–Stokes solvers are compared in a benchmark Navier–Stokes application, the 2D regularized lid-driven square cavity

TABLE 10
$\mathcal{N}_{it}(N, \Delta t)$ *for the* $Re = 1000$ *two-dimensional regularized lid-driven square cavity.*

N	17	35	65	129

$\mathcal{N}_{it}$	8	26	51	187

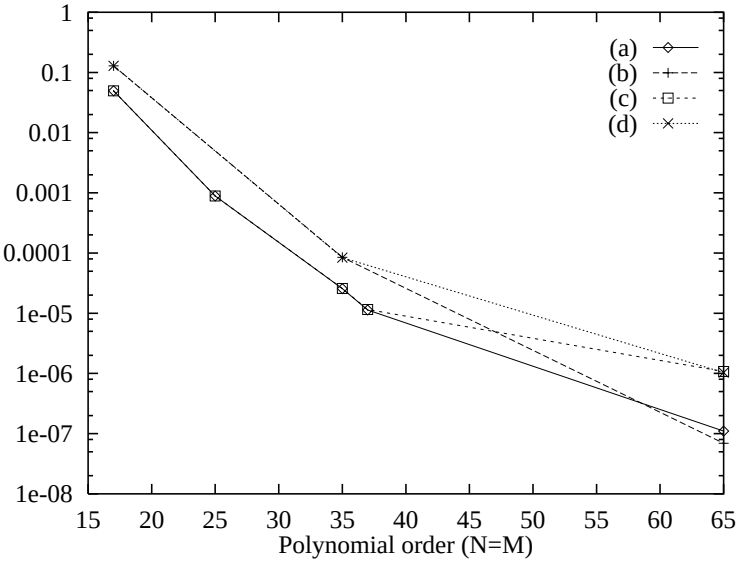

FIG. 11. *Maximum pointwise difference between the computed velocity and the reference solution:* (a) *Uzawa solutions, reference Uzawa* 129^2, (b) *PRDI solutions, reference Uzawa* 129^2, (c) *Uzawa solutions, reference PRDI* 129^2, *and* (d) *PRDI solutions, reference PRDI* 129^2.

$[0, 1]^2$ at a Reynolds value of 1000. In order to avoid the top-corners singularities, the flow is driven by a horizontal regularized velocity profile, $u(x, y = +1) = 16x^2(1-x)^2$ [32, 4, 22]. On all other sides of the cavity a zero velocity no-slip boundary condition applies. At that Reynolds number the flow is steady [32]. Both Navier–Stokes solvers have a second order accuracy in time. The steady solution is reached when the following convergence criterion is fulfilled:

$$\max_{\substack{0 \le n \le N \\ 1 \le i \le 2}} \left| \frac{u_i^{(t+\Delta t)}(x_n, y_n) - u_i^{(t)}(x_n, y_n)}{u_i^{(t)}(x_n, y_n)\ \Delta t} \right| \le 10^{-3},$$

where u_i is the ith velocity component and (x_n, y_n) are the coordinates of the collocation points. Owing to the absence of an analytical solution for this problem, the solutions based on 129^2 collocation points with the Uzawa and the PRDI solvers have been used as the references for calculating the errors. Both algorithms exhibit comparable error drops as the order of the polynomial expansion is increased. Figure 11 shows the maximum pointwise difference between the computed velocity and the reference solutions. The maximum pointwise values of the divergence of the computed velocity (in $\mathbb{P}_N$ space) are reported in Figure 12.

8. Conclusions. Projecting the complete acceleration field $\mathbf{a} = \frac{\partial \mathbf{u}}{\partial t} - \Delta \mathbf{u}$, rather than some part of it, onto the space of divergence-free polynomials, leads to a direct solver of the unsteady Stokes problem. This is consistent with the expected decoupled

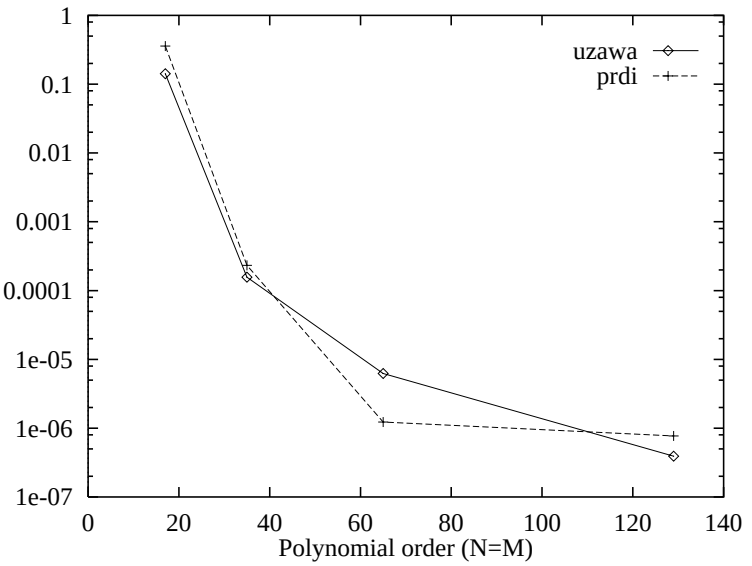

FIG. 12. *Maximum pointwise value of the divergence of the computed velocity for the PRDI and the Uzawa solvers.*

laws which govern the harmonic pressure and biharmonic velocity fields. It is as easily invertible as any other solver based on a time splitting of the velocity and pressure operators.

The main properties of its Chebyshev collocated approximations have been analyzed, comparatively to those of the fractional step approach with the ultimate improvements proposed by [17].

The basic ellipticity of the continuous Stokes system is preserved to a large extent (i.e., most of the eigenvalues are real and negative) with the new solver.

As already encountered more than ten years ago in [27], the trace of $\mathbf{a}$ on the boundary must be evaluated at the projection stage, while the velocity field has not yet been updated in time. This is the only place where the time scheme must intervene in our decoupling approach. It is shown, in this paper, that the condition to preserve the ellipticity is to reduce the $\Delta\mathbf{u}$ term to its rotational part. Otherwise, the *continuous* temporal evolution of the discrete velocity explodes exponentially.

The time explicit treatment of the rotational boundary term does not prevent the first and second order in time schemes from being unconditionally stable. However the third and fourth order schemes obey the usual explicit criterion ($\mathcal{O}(N^{-4})$) on the time step. The proposed decoupling gives this limitation a less restrictive coefficient and supplies the expected temporal orders across all the explored range of time step sizes.

Last, the effective accuracy obtained for Navier–Stokes 2D solutions has been measured with the $Re = 1000$ lid-driven cavity problem and found equivalent to what is supplied by the much more expensive Uzawa decoupling method.

Acknowledgments. The authors would like to thank Prof. M. O. Deville for helpful discussions and Dr. N. Borhani and Dr. R. Owens for proofreading the manuscript.

A NEW PARADIGM FOR PARALLEL ADAPTIVE MESHING ALGORITHMS *

RANDOLPH E. BANK† AND MICHAEL HOLST†

Abstract. We present a new approach to the use of parallel computers with adaptive finite element methods. This approach addresses the load balancing problem in a new way, requiring far less communication than current approaches. It also allows existing sequential adaptive PDE codes such as PLTMG and MC to run in a parallel environment without a large investment in recoding. In this new approach, the load balancing problem is reduced to the numerical solution of a small elliptic problem on a single processor, using a sequential adaptive solver, without requiring any modifications to the sequential solver. The small elliptic problem is used to produce a posteriori error estimates to predict future element densities in the mesh, which are then used in a weighted recursive spectral bisection of the initial mesh. The bulk of the calculation then takes place independently on each processor, with no communication, using possibly the same sequential adaptive solver. Each processor adapts its region of the mesh independently, and a nearly load-balanced mesh distribution is usually obtained as a result of the initial weighted spectral bisection. Only the initial fan-out of the mesh decomposition to the processors requires communication. Two additional steps requiring boundary exchange communication may be employed after the individual processors reach an adapted solution, namely, the construction of a global conforming mesh from the independent subproblems, followed by a final smoothing phase using the subdomain solutions as an initial guess. We present a series of convincing numerical experiments which illustrate the effectiveness of this approach. The justification of the initial refinement prediction step, as well as the justification of skipping the two communication-intensive steps, is supported by some recent [J. Xu and A. Zhou, *Math. Comp.*, to appear] and not so recent [J. A. Nitsche and A. H. Schatz, *Math. Comp.*, 28 (1974), pp. 937–958; A. H. Schatz and L. B. Wahlbin, *Math. Comp.*, 31 (1977), pp. 414–442; A. H. Schatz and L. B. Wahlbin, *Math. Comp.*, 64 (1995), pp. 907–928] results on local a priori and a posteriori error estimation.

1. Introduction.

One of the most difficult obstacles to overcome in making effective use of parallel computers for adaptive finite element codes such as PLTMG [2] and MC [15] is the load balancing problem. As an adaptive method adjusts the mesh according to the features of the solution, elements in some areas are refined, whereas others are not. If an initial mesh is distributed quite fairly among a number of processors, a very good error estimator (coupled with adaptive refinement) quickly produces a very bad work load imbalance among the processors.

A number of static and dynamic load balancing approaches for unstructured meshes have been proposed in the literature [12, 13, 14, 17, 30, 33]; most of the dynamic strategies involve repeated application of a particular static strategy. One of the difficulties in all of these approaches is the amount of communication that must be performed both to assess the current load imbalance severity, and to redistribute the work among the processors once the imbalance is detected and an improved distribution is calculated. The calculation of the improved work distribution can be quite

inexpensive (such as geometric or inertia tensor-based methods), or it may be a costly procedure, with some approaches requiring the solution of an associated eigenvalue problem or evolution of a heat equation to near equilibrium [34]. These calculations may themselves require communication if they must be solved in parallel using the existing (poor) distribution.

In recent years, clusters of fast workstations have replaced the more traditional parallel computer of the past. While this type of parallel computer is now within reach of an organization with even a modest hardware budget, it is usually difficult to produce an efficient parallel implementation of an elliptic PDE solver; this is simply due to the fact that elliptic continuum mechanics problems necessarily lead to tightly coupled discrete problems, requiring substantial amounts of communication for their solution. The load balancing problem is also more pronounced on workstation clusters: even at 100 Mbit/sec speed, the cluster communication speeds are quite slow compared to modern workstation CPU performance, and the communication required to detect and correct load imbalances results in severe time penalties.

1.1. A new approach to parallel adaptive finite element methods. In this work, we present an alternative approach which addresses the load balancing problem in a new way, requiring far less communication than current approaches. This approach also allows existing sequential adaptive PDE codes such as PLTMG and MC to run in a parallel environment without a large investment in recoding.

Our approach has three main components:

1. We solve a small problem on a coarse mesh, and use a posteriori error estimates to partition the mesh. Each subregion has approximately the same error, although subregions may vary considerably in terms of numbers of elements or grid points.
2. Each processor is provided the complete coarse mesh and instructed to sequentially solve the *entire* problem, with the stipulation that its adaptive refinement should be limited largely to its own partition. The target number of elements and gridpoints for each problem is the same.
3. A final mesh is computed using the union of the refined partitions provided by each processor. This mesh is regularized and a final solution computed using a standard domain decomposition or parallel multigrid technique.

The above approach has several interesting features. First, the load balancing problem (step 1) is reduced to the numerical solution of a small elliptic problem on a single processor, using a sequential adaptive solver such as PLTMG or MC, without requiring any modifications to the sequential solver. Second, the bulk of the calculation (step 2) takes place independently on each processor and can also be performed with a sequential solver such as PLTMG or MC with no modifications necessary for communication. (In PLTMG, one line of code was added, which artificially multiplied a posteriori error estimates for elements outside a processor's partition by 10^{-6}. In MC, two lines were added to prevent elements outside the processor's partition from entering the initial refinement queue.) Step 2 was motivated by recent work of Mitchell [20, 21, 22] on parallel multigrid methods. A similar approach appeared recently in [10]. The use of a posteriori error estimates in mesh partitioning strategies has also been considered in [26].

The only parts of the calculation requiring communication are (1) the initial fanout of the mesh distribution to the processors, once the decomposition is determined by the error estimator; (2) the mesh regularization, requiring local communication to produce a global conforming mesh; and (3) the final solution phase, which might

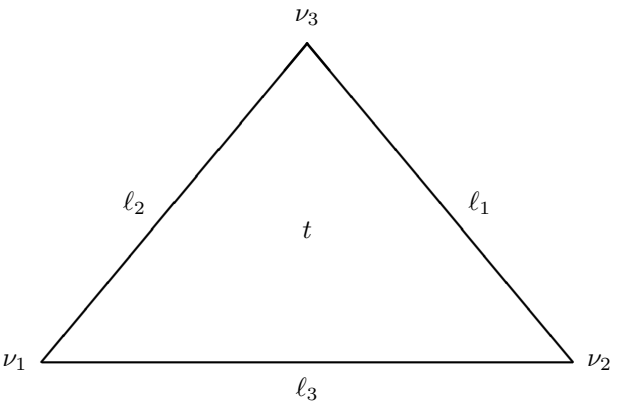

FIG. 1. *A typical element.*

require local communication (boundary exchanges). Note that a good initial guess for step 3 is provided in step 2 by taking the solution from each subregion restricted to its partition. Note also that the initial communication step to fan-out the mesh decomposition information is not actually required, since each processor can compute the decomposition independently (with no communication) as a preprocessing step.

1.2. Justification. Perhaps the largest issue arising in connection with this procedure is whether it is well founded, particularly in light of the continuous dependence of the solution of an elliptic equation on data throughout the domain. To address this issue, we first note that the primary goal of step 2 above is adaptive mesh generation. In other words, the most important issue is not how accurately the problem is solved in step 2 of this procedure, but rather the quality of the (composite) adaptively generated mesh. These two issues are obviously related, but one should note that it is not necessary to have an accurate solution in order to generate a well adapted mesh. Indeed, the ability to generate good meshes from relatively inaccurate solutions explains the success of many adaptive methods.

A secondary goal of step 2 is the generation of an initial guess for the solution on the final composite mesh. This aspect of the algorithm will be addressed in section 4. Here we focus on the primary issue of grid generation, and in particular on a posteriori error estimates, as such estimates provide the link between the computed solution and the adaptive meshing procedure. Here we consider in detail the schemes used in PLTMG and MC, but similar points can be made in connection with other adaptive algorithms.

PLTMG uses a discretization based on continuous piecewise linear triangular finite elements. The error is approximated in the subspace of discontinuous piecewise quadratic polynomials that are zero at the vertices of the mesh. In particular, let $u - u_h$ denote the error and let t denote a generic triangle in the mesh. In its adaptive algorithms, PLTMG approximates the error in triangle t using the formula

$$\|\nabla(u - u_h)\|_t^2 \equiv \int_t |\nabla(u - u_h)|^2 \, dx \approx v^t B v, \tag{1.1}$$

where (see Figure 1)

$$\nu_i = \begin{pmatrix} x_i \\ y_i \end{pmatrix} \quad \text{for } 1 \le i \le 3, \tag{1.2}$$

$$\ell_i = \nu_j - \nu_k \quad \text{for } (i,j,k) \text{ a cyclic permutation of } (1,2,3), \tag{1.3}$$

$$v = \begin{pmatrix} \ell_1^t M_t \ell_1 \\ \ell_2^t M_t \ell_2 \\ \ell_3^t M_t \ell_3 \end{pmatrix}, \qquad M_t = -\frac{1}{2}\begin{pmatrix} u_{xx} & u_{xy} \\ u_{xy} & u_{yy} \end{pmatrix}, \tag{1.4}$$

$$B = \frac{1}{48|t|}\begin{pmatrix} \ell_1^t\ell_1 + \ell_2^t\ell_2 + \ell_3^t\ell_3 & 2\ell_1^t\ell_2 & 2\ell_1^t\ell_3 \\ 2\ell_2^t\ell_1 & \ell_1^t\ell_1 + \ell_2^t\ell_2 + \ell_3^t\ell_3 & 2\ell_2^t\ell_3 \\ 2\ell_3^t\ell_1 & 2\ell_3^t\ell_2 & \ell_1^t\ell_1 + \ell_2^t\ell_2 + \ell_3^t\ell_3 \end{pmatrix}. \tag{1.5}$$

Equations (1.1)–(1.5) are derived by comparing the approximation error for linear and quadratic interpolation on t. See [2, 4] for details. The second derivatives in the 2×2 matrix M_t are taken as constants on t. The values of the second derivatives are extracted as a postprocessing step from the a posteriori error estimates. The remaining information needed to compute the right-hand side of (1.1) is generated directly from the geometry of element t.

To be effective, the approximation of the derivatives need not be extremely accurate. Many adaptive algorithms, and in particular those in PLTMG, are directed toward creating meshes in which the errors in all elements are equilibrated. Typically, adaptive algorithms develop refined meshes starting from rather coarse meshes. For reasons of efficiency, often many elements are refined between recomputing the approximate solution u_h.

MC also discretizes the solution over piecewise linear triangular or tetrahedral elements, and as in PLTMG, error estimates for each element are produced by solving a local problem using the edge-based quadratic bump functions. However, while these local problems involve inverting 3×3 matrices for scalar problems in 2D, the local problems are substantially more costly in 3D. In particular, for 3D elasticity, the local problems require the inversion of 18×18 matrices (6 bump functions and 3 unknowns per spatial point). Therefore, MC also provides an alternative less-expensive error estimator, namely, the residual of the strong form of the equation, following, e.g., [32]. In this paper, the numerical results involving MC are produced using the residual-based estimator.

While there is considerable theoretical support for the a posteriori error bounds which form the foundation for adaptive algorithms (see, e.g., the book of Verfürth [32] and its references), the adaptive algorithms themselves are largely heuristic, in particular, those aspects described above. However, there is a large and growing body of empirical evidence that such algorithms are indeed robust and effective for a wide class of problems. In particular, they are effective on coarse meshes, and on highly nonuniform meshes. The types of meshes likely to be generated in our parallel algorithm are qualitatively not very different from typical meshes where a posteriori error estimates are known to perform quite well.

In our procedure, we artificially set the errors to be very small in regions outside the subregion assigned to a given processor, so the standard refinement procedure is "tricked" into equilibrating the error on just one subregion. Since the target size of all problems solved in step 2 is the same, and each subregion initially has approximately equal error, we expect the final composite mesh to have approximately equal errors, and approximately equal numbers of elements, in each of the refined subregions created in step 2. That is, the composite mesh created in step 3 should have roughly equilibrated errors in all of its elements. This last statement is really just

an expectation, since we control only the target number of elements added in each subregion and do not control the level of error directly. This and other assumptions forming the foundation of our load balancing algorithms are discussed in more detail in section 3.2.

We note the standard adaptive procedures in PLTMG and MC have additional refinement criteria to insure conforming and shape regular meshes. Thus, some elements outside the given subregion but near its interface are typically refined in order to enforce shape regularity; the result is a smooth transition from the small elements of the refined region to larger elements in the remainder of the domain. If the target number of elements is large in comparison with the number of elements on the coarse mesh, this should be a relatively small effect.

To summarize, we expect that for any given problem, our algorithm should perform comparably to the standard algorithm applied to the same initial mesh in terms of the quality of the adaptive local mesh refinement.

2. Examples. In this section, we present some simple examples of the algorithm presented in section 1.

2.1. A convection-diffusion equation. In this example, we use PLTMG to solve the convection-diffusion equation

$$\begin{aligned} -\nabla \cdot (\nabla u + \beta u) &= 1 \qquad \text{in } \Omega, \\ u &= 0 \qquad \text{on } \partial\Omega, \end{aligned} \tag{2.1}$$

where $\beta = (0, 10^5)^t$, and Ω is the region depicted in Figure 2. This coarse triangulation has 2148 elements and 1368 vertices.

We partitioned the domain into four subregions with approximately equal error using the recursive spectral bisection algorithm, described in more detail in section 3. Then four independent problems were solved, each starting from the coarse grid and coarse grid solution. In each case the mesh is adaptively refined until a mesh with approximately 6000 unknowns (located at triangle vertices) is obtained. The mesh for one subdomain and the corresponding solution is shown in Figure 3. Notice that the refinement is largely confined to the given region, but some refinement in adjacent regions is needed in order to maintain shape regularity. We emphasize that these four problems are solved independently, by the standard sequential adaptive solver PLTMG. The only change to the code used for problem k $(1 \le k \le 4)$ was to multiply a posteriori error estimates for elements in regions $j \ne k$ by 10^{-6}, causing the adaptive refinement procedure to rarely choose these elements for refinement, except to maintain shape regularity.

The meshes from these four subproblems are combined to form a globally refined mesh with 37575 triangles and 19828 vertices. This mesh is shown in Figure 4.

The solutions from the four problems are combined to form a global solution that serves as initial guess for a global smoothing process. The final solution, as well as the a posteriori error estimates for this solution, are shown in Figure 5.

2.2. A full potential flow problem. For our second example, we use PLTMG to solve the full potential flow equation

$$\begin{aligned} -\nabla \cdot \rho(\nabla u)\nabla u &= 0 \qquad \text{in } \Omega, \\ \rho \partial u/\partial n &= g \qquad \text{on } \partial\Omega_1, \\ \rho \partial u/\partial n &= 0 \qquad \text{on } \partial\Omega_2, \end{aligned} \tag{2.2}$$

where

$$\rho(\nabla u) = (1 - u_x^2 - u_y^2)^{\frac{1}{\gamma - 1}}$$

and $\gamma = 1.4$. $\partial\Omega_1$ is the outer boundary, where the solution assumes its asymptotic behavior, while $\partial\Omega_2$ is the inner boundary, in this example the profile of an Naca0012 airfoil. The initial mesh, generated from the geometry description, had 384 triangles and 221 vertices. In Figure 6 we illustrate the initial mesh and a detail of the local Mach number $M(\nabla u)$ given by

$$M(\nabla u) = \sqrt{\frac{2c}{\gamma - 1}},$$
$$c = \frac{1}{1 - u_x^2 - u_y^2} - 1.$$

$M(\nabla u)$ is one of the main quantities of interest in this calculation, and since it depends on ∇u, it represents a more severe test of our algorithm.

As in the first example, we partitioned the domain into four subregions with approximately equal error using the recursive spectral bisection algorithm. Then four independent problems were solved with the mesh adaptively refined to one with approximately 5000 unknowns. The mesh for one subdomain and the corresponding $M(\nabla u)$ are shown in Figure 7.

The meshes from the four subproblems are combined to form a globally refined mesh with 37913 triangles and 18723 vertices. This mesh is shown in Figure 8, along with $M(\nabla u)$ computed from the initial guess for the global solution. $M(\nabla u)$ computed from the global solution, as well as the a posteriori error estimates for the final global solution, are shown in Figures 9 and 10, respectively.

2.3. A 3D elasticity problem. The two previous examples demonstrated the effectiveness of the parallel algorithm for linear and nonlinear scalar problems in 2D. To illustrate that the parallel algorithm works equally well for coupled elliptic systems and for 3D problems, we will use MC to solve the elasticity equations for our third example:

$$-\nabla \cdot T(\nabla u) = f \quad \text{in} \Omega \subset \mathrm{R}^3, \tag{2.3}$$
$$n \cdot T(\nabla u) = g \quad \text{on } \Gamma_1, \tag{2.4}$$
$$u = 0 \quad \text{on } \Gamma_0, \qquad \partial\Omega = \Gamma_0 \cup \Gamma_1, \qquad \emptyset = \Gamma_0 \cap \Gamma_1. \tag{2.5}$$

The stress tensor T is a function of the gradient ∇u of the unknown displacement u, and the corresponding deformation mapping φ and deformation gradient $\nabla\varphi$ are given by

$$\varphi = id + u : \overline{\Omega} \mapsto \mathrm{R}^3, \qquad \nabla u : \overline{\Omega} \mapsto \mathrm{M}^3, \qquad \nabla\varphi = I + \nabla u : \overline{\Omega} \mapsto \mathrm{M}^3.$$

We will use a linearized strain tensor and a linear stress-strain relation:

$$E(\nabla u) = \frac{1}{2}(\nabla u + \nabla u^T) : \overline{\Omega} \mapsto \mathrm{S}^3, \qquad T(\nabla u) = \lambda(\mathrm{tr}E)I + 2\mu E,$$

where the Lamé constants λ and μ are taken to be those of steel ($\lambda \approx 10.4403$, $\mu \approx 8.20312$). The solid object forming the domain is depicted in Figure 11. We apply traction forces to the back and top of each letter in a horizontal and slightly

upward direction, through the function g above. The base of each letter is fixed to a solid foundation, through the essential boundary condition above. No volume forces are present so that the function f above is zero. We then solve the resulting equations (2.3)–(2.5) adaptively using MC.

The initial coarse mesh in the left picture of Figure 11 has 296 tetrahedral elements and 159 vertices. As in the previous examples, we partition the domain into four subdomains with approximately equal error using the recursive spectral bisection algorithm described in section 3 below. The four subdomain problems are then solved independently by MC, starting from the complete coarse mesh and coarse mesh solution. In this example, the mesh is adaptively refined in each subdomain until a mesh with about 5000 vertices is obtained.
