DISCRETIZATIONS FOR THE INCOMPRESSIBLE NAVIER–STOKES EQUATIONS BASED ON THE LATTICE BOLTZMANN METHOD*

MICHAEL JUNK† AND AXEL KLAR‡

Abstract. A discrete velocity model with spatial and velocity discretization based on a lattice Boltzmann method is considered in the low Mach number limit. A uniform numerical scheme for this model is investigated. In the limit, the scheme reduces to a finite difference scheme for the incompressible Navier–Stokes equation, which is a projection method with a second order spatial discretization on a regular grid. The discretization is analyzed and the method is compared to Chorin's original spatial discretization. Numerical results supporting the analytical statements are presented.

Key words. discrete velocity models, lattice Boltzmann method, low Mach number limit, incompressible Navier–Stokes equations, Chorin's projection scheme, finite difference method, relaxation systems

1. Introduction.

Lattice Boltzmann methods (LBMs) use discrete velocity models of kinetic equations to obtain approximate solutions of the incompressible Navier–Stokes system. The idea of the LBM rests on the observation that the kinetic and the incompressible Navier–Stokes models are equivalent in the limit of small Knudsen and Mach numbers. See [11, 3, 7] for reviews on LBMs and [28] for a review on discrete velocity models. In recent years, numerous articles on the LBM have appeared in which the method is analyzed. We refer to the references in the above cited reviews and, for example, to [1, 13, 15, 6, 33]. For connections to kinetic schemes, see [22].

A disadvantage of standard lattice Boltzmann (LB) discretizations is that the stiffness of the kinetic equation in the limit of small Knudsen and Mach numbers is not taken into account; see also [27]. Since the discretization is fully explicit, very fine time and space steps have to be used, slowing down the method considerably. To allow for larger discretization steps, the algorithm should at least be partially implicit. Such an approach has been successfully used for a large number of kinetic equations with stiff relaxation terms in fluid dynamic or diffusive limits and has led to the development of asymptotic preserving methods, see [4, 20, 18, 19, 26, 23, 24]. For an LB-type discrete velocity model with a diffusive scaling, a scheme working uniformly in the incompressible Navier–Stokes limit, using a semi-implicit time discretization and leading to a Chorin projection scheme with MAC grid, has been suggested in [25].

In this work, our starting point is the following: numerically, it has been proven by many authors that the LBM yields stable and reliable results for the incompressible Navier–Stokes equation [30, 16]. Moreover, pressure oscillations, as in the original Chorin method, are not observed although the scheme works on a regular (collocated)

grid. The aim, to extract the reason for this nice behavior, is accomplished by developing a method based on the LB spatial discretization and comparing it to Chorin's original method.

Our approach is based on the observation that the velocity-discrete kinetic equation is in one-to-one correspondence with a system of moment equations; see, for example [12, 10]. The system includes the equations of mass and momentum which yield the Navier–Stokes equations in a suitable diffusion limit (related to small Knudsen and Mach numbers). Using essentially the space-discretization of LBM, we automatically obtain a discretization of the moment system which leads to a new spatial discretization for the incompressible Navier–Stokes equations. The discretization is used together with the Chorin projection.

As has been investigated in detail, for example, in [34, 35], that the original Chorin space discretization leads to an alternating error of first order in the pressure. This type of instability is not seen in the projection method if the MAC grid is used. In this case a second order approximation of the pressure is obtained without alternating terms in the error expansion for the pressure at first order. However, one has to use staggered grids having different locations for pressure and velocity. We mention that higher order approximation or regularizing methods have been used to avoid staggered grids and alternating terms in the error expansion (see [34]). It turns out that the spatial discretization of the scheme presented here is second order for both the pressure and the velocity, not using grid staggering. However, although the error in pressure is reduced compared to Chorin's scheme the errors in velocity are larger.

The paper is organized as follows: Section 2 introduces an LB-type discrete velocity model and its associated closed moment system. In section 3 the time and space discretization of the numerical scheme for the discrete velocity model is described. Section 4 deals with the low Mach number limit of the discretized equations leading to the projection method for the incompressible Navier–Stokes equations with the new spatial discretization. Section 5 contains remarks on the treatment of the boundary conditions and an analytical investigation of the scheme following the work in [34]. In particular, the scheme is compared to Chorin's original method. Finally, section 6 presents a numerical investigation of the second order convergence for the pressure which has been found analytically. A numerical comparison with Chorin's scheme is included as well.

2. An LB-type discrete velocity model and the associated moment system. The basic kinetic model is given by the Boltzmann equation

$$\frac{\partial f}{\partial t} + \mathbf{v}\nabla f = J(f) \tag{2.1}$$

which describes the evolution of a particle density $f(\mathbf{x}, \mathbf{v}, t)$. The left-hand side of (2.1) represents free transport of the particles while the right-hand side describes interactions through collisions. The difference between continuous and discrete velocity models is the structure of the phase space $\mathcal{X} \times \mathcal{V}$. In the classical Boltzmann equation, the space part $\mathcal{X}$ is a subset of $\mathbb{R}^3$ and the velocity domain $\mathcal{V}$ is the full space $\mathbb{R}^3$. For discrete models we have

$$\mathcal{V} = \{\mathbf{c}_0, \ldots, \mathbf{c}_{N-1}\}, \qquad \mathbf{c}_i \in \mathbb{R}^d.$$

In our particular example, we consider a two-dimensional model ($d = 2$) with nine velocities ($N = 9$)

$$\mathbf{c}_1 = \left(\begin{smallmatrix}1\\0\end{smallmatrix}\right), \quad \mathbf{c}_2 = \left(\begin{smallmatrix}0\\1\end{smallmatrix}\right), \quad \mathbf{c}_3 = \left(\begin{smallmatrix}-1\\0\end{smallmatrix}\right), \quad \mathbf{c}_4 = \left(\begin{smallmatrix}0\\-1\end{smallmatrix}\right),$$
$$\mathbf{c}_5 = \left(\begin{smallmatrix}1\\1\end{smallmatrix}\right), \quad \mathbf{c}_6 = \left(\begin{smallmatrix}-1\\1\end{smallmatrix}\right), \quad \mathbf{c}_7 = \left(\begin{smallmatrix}-1\\-1\end{smallmatrix}\right), \quad \mathbf{c}_8 = \left(\begin{smallmatrix}1\\-1\end{smallmatrix}\right),$$

and $\mathbf{c}_0 = \mathbf{0}$. In the discrete case, the $\mathbf{v}$-dependence of the particle distribution $f(\mathbf{x}, \mathbf{v}, t)$ is uniquely determined through N functions

$$f_i(\mathbf{x}, t) = f(\mathbf{x}, \mathbf{c}_i, t), \qquad i = 0, \ldots, N-1.$$

Macroscopic quantities like mass–, momentum–, or energy density are obtained by taking velocity moments of f. If ψ is any $\mathbf{v}$-dependent function, we denote the discrete velocity integral by

$$\langle \psi \rangle = \sum_{i=0}^{N-1} \psi(\mathbf{c}_i).$$

Then, mass and momentum density can be written as

$$\begin{aligned} \rho(\mathbf{x}, t) &= \langle f(\mathbf{x}, \mathbf{v}, t) \rangle = \sum_{i=0}^{N-1} f_i(\mathbf{x}, t), \\ \rho \mathbf{u}(\mathbf{x}, t) &= \langle \mathbf{v} f(\mathbf{x}, \mathbf{v}, t) \rangle = \sum_{i=0}^{N-1} \mathbf{c}_i f_i(\mathbf{x}, t); \end{aligned} \tag{2.2}$$

compare, for example, [31]. In LB applications, the collision operator $J(f)$ in (2.1) is typically of BGK-type

$$J(f) = -\frac{1}{\tau}(f - f^{eq}). \tag{2.3}$$

The parameter $\tau > 0$ is called *relaxation time* and f^{eq} is the *equilibrium distribution*. In the isothermal case, f^{eq} depends on f through the parameters ρ and $\mathbf{u}$ which are calculated according to (2.2); see, for example, [13]. For the standard D2Q9-model [29] with nine velocities, we have

$$f^{eq}(\rho, \mathbf{u}; \mathbf{v}) = \rho \left(1 + 3\mathbf{u} \cdot \mathbf{v} - \frac{3}{2}|\mathbf{u}|^2 + \frac{9}{2}(\mathbf{u} \cdot \mathbf{v})^2\right) f^*(\mathbf{v}),$$

where f^* is defined by

$$f^*(\mathbf{c}_i) = \begin{cases} \frac{4}{9} & i = 0, \\ \frac{1}{9} & i = 1, \ldots, 4, \\ \frac{1}{36} & i = 5, \ldots, 8. \end{cases}$$

The equilibrium distribution is constructed in such a way that

$$\langle J(f) \rangle = 0 \qquad \text{and} \qquad \langle \mathbf{v} J(f) \rangle = \mathbf{0},$$

which reflects conservation of mass and momentum in the collision process.

In order to obtain a relation between the kinetic equation (2.1) and the incompressible Navier–Stokes system, we introduce the diffusive scaling $\mathbf{x} \to \mathbf{x}/\epsilon$, $t \to t/\epsilon^2$ together with a rescaling of velocity $\mathbf{u} \to \epsilon\mathbf{u}$. This scaling describes the small Knudsen and low Mach number limit of kinetic equations; see [32, 9, 2, 17] for details. Under these transformations, (2.1) turns into

$$\frac{\partial f}{\partial t} + \frac{1}{\epsilon}\mathcal{D}f = -\frac{1}{\epsilon^2\tau}(f - f^{eq}(\rho, \epsilon\mathbf{u})), \tag{2.4}$$

where $\mathcal{D} = \mathbf{v}.\nabla$ has been used as abbreviation for the space derivatives. In our exemplary case, (2.4) consists of nine equations for the occupation numbers $f_0, \ldots, f_8$. In order to get closer in notation to the Navier–Stokes system, we transform (2.4) into an equivalent set of moment equations (see also [25, 10] for a similar approach). Based on the $\mathbf{v}$-polynomials (compare [12])

(2.5)

$$\begin{aligned}
&P_0(\mathbf{v}) = 1,\\
&P_1(\mathbf{v}) = \frac{v_1}{\epsilon}, && P_2(\mathbf{v}) = \frac{v_2}{\epsilon},\\
&P_3(\mathbf{v}) = \frac{v_1^2}{\epsilon^2} - \frac{1}{3\epsilon^2}, && P_4(\mathbf{v}) = \frac{v_1 v_2}{\epsilon^2}, && P_5(\mathbf{v}) = \frac{v_2^2}{\epsilon^2} - \frac{1}{3\epsilon^2},\\
&P_6(\mathbf{v}) = \frac{(3|\mathbf{v}|^2 - 4)v_1}{\epsilon^3}, && P_7(\mathbf{v}) = \frac{(3|\mathbf{v}|^2 - 4)v_2}{\epsilon^3},\\
&P_8(\mathbf{v}) = \frac{9|\mathbf{v}|^4 - 15|\mathbf{v}|^2 + 2}{\epsilon^4},
\end{aligned}$$

we obtain an invertible linear mapping $f \to \mathbf{P}f$ defined by

$$\mathbf{P}f = (\langle P_0 f\rangle, \ldots, \langle P_8 f\rangle)^T.$$

Applying $\mathbf{P}$ to (2.4) results in an equivalent set of equations with a differential operator which is still linear and hyperbolic

$$\left(\frac{\partial}{\partial t} + \frac{1}{\epsilon}\mathbf{P}\mathcal{D}\mathbf{P}^{-1}\right)\mathbf{P}f = -\frac{1}{\epsilon^2\tau}\left(\mathbf{P}f - \mathbf{P}f^{eq}(\rho, \epsilon\mathbf{u})\right). \tag{2.6}$$

In order to write (2.6) in a more explicit form, we introduce names for the moments. Note that $\langle P_0 f\rangle = \rho$ and $\langle P_i f\rangle = \rho u_i$ for $i = 1, 2$. The second order moments form a symmetric tensor

$$\Theta = \begin{pmatrix}\Theta_{11} & \Theta_{12}\\ \Theta_{12} & \Theta_{22}\end{pmatrix} = \begin{pmatrix}\langle P_3 f\rangle & \langle P_4 f\rangle\\ \langle P_4 f\rangle & \langle P_5 f\rangle\end{pmatrix}$$

and for the remaining moments we set

$$\mathbf{q} = \begin{pmatrix}\langle P_6 f\rangle\\ \langle P_7 f\rangle\end{pmatrix}, \qquad s = \langle P_8 f\rangle.$$

The first two equations in (2.6) are those of mass and momentum conservation

$$\begin{aligned}
\partial_t \rho + \operatorname{div} \rho\mathbf{u} &= 0,\\
\partial_t \rho\mathbf{u} + \operatorname{div} \Theta + \frac{1}{3\epsilon^2}\nabla\rho &= 0.
\end{aligned} \tag{2.7}$$

Here, the divergence is applied to the rows of Θ. The equation for Θ is

$$\partial_t \Theta + \frac{2}{3\epsilon^2} S[\rho \mathbf{u}] + \frac{1}{3} Q = -\frac{1}{\epsilon^2 \tau}(\Theta - \rho \mathbf{u} \otimes \mathbf{u}), \tag{2.8}$$

where

$$S_{ij}[\rho \mathbf{u}] = \frac{1}{2}\left(\frac{\partial \rho u_i}{\partial x_j} + \frac{\partial \rho u_j}{\partial x_i}\right) \qquad \text{and} \qquad Q = \begin{pmatrix} \partial_{x_2} q_2 & \partial_{x_2} q_1 + \partial_{x_1} q_2 \\ \partial_{x_2} q_1 + \partial_{x_1} q_2 & \partial_{x_1} q_1 \end{pmatrix}.$$

Finally, the third and fourth order moments satisfy

$$\begin{aligned} \partial_t \mathbf{q} + \frac{1}{\epsilon^2} \operatorname{div} \begin{pmatrix} \Theta_{22} & 2\Theta_{12} \\ 2\Theta_{12} & \Theta_{11} \end{pmatrix} + \frac{1}{6} \nabla s &= -\frac{1}{\epsilon^2 \tau} \mathbf{q}, \\ \partial_t s + \frac{4}{\epsilon^2} \operatorname{div} \mathbf{q} &= -\frac{1}{\epsilon^2 \tau} s. \end{aligned} \tag{2.9}$$

Altogether, we obtain a hyperbolic system with stiff relaxation terms. The diffusion limit of the above system is straightforwardly determined. From the momentum equation in (2.7) we conclude that $\nabla \rho$ tends to zero as $\epsilon \to 0$. Hence, ρ approaches a constant $\bar{\rho}$ (which is the Boussinesq relation in the isothermal case). Writing $\rho = \bar{\rho}(1 + 3\epsilon^2 p)$, (2.7) transforms into

$$\begin{aligned} \partial_t p + \frac{1}{3\epsilon^2} \operatorname{div} \mathbf{u} &= -\operatorname{div} p\mathbf{u}, \\ \partial_t \mathbf{u} + \operatorname{div} \frac{1}{\bar{\rho}} \Theta + \nabla p &= -3\epsilon^2 \partial_t p \mathbf{u}. \end{aligned} \tag{2.10}$$

For $\epsilon \to 0$, (2.8) yields in lowest order

$$\frac{1}{\bar{\rho}} \Theta = \mathbf{u} \otimes \mathbf{u} - \frac{2\tau}{3} S[\mathbf{u}]. \tag{2.11}$$

Since (2.9) decouples completely from the other equations (in lowest order) and since $2 \operatorname{div} S[\mathbf{u}] = (\Delta + \nabla \operatorname{div})\mathbf{u}$, we obtain from (2.10) and (2.11) the incompressible Navier–Stokes equations as limiting system

$$\begin{aligned} \operatorname{div} \mathbf{u} &= 0, \\ \partial_t \mathbf{u} + \operatorname{div} \mathbf{u} \otimes \mathbf{u} + \nabla p &= \frac{\tau}{3} \Delta \mathbf{u}. \end{aligned} \tag{2.12}$$

Compare [14] for another approach. The Reynolds number is related to the relaxation time by $Re = 3/\tau$.

We remark that (2.7), (2.8), and (2.9) can be viewed as a relaxation system for (2.12). Since the LBM is a particular discretization of (2.4) and since a discretization of (2.4) automatically turns into a discretization of the moment system under the transformation $\mathbf{P}$, we conclude that the LBM can be viewed as a relaxation method for the incompressible Navier–Stokes system [21].

3. The numerical scheme: Spatial and temporal discretization. To obtain a spatial discretization of the moment system (2.7), (2.8), and (2.9), we use a first order upwind method for the operator $\mathcal{D} = \mathbf{v} \cdot \nabla$ in (2.6). This choice is motivated by the LBM where the upwind approximation is combined with an explicit

Euler discretization for the time derivative. To get a proper treatment of the stiff pressure–velocity coupling, however, we choose a semi-implicit time discretization instead of the explicit one (see also [25]). In the limit $\epsilon \to 0$, a projection scheme for the incompressible Navier–Stokes equations is obtained.

Before we describe the discretization of the moment system, let us first show how the LBM is obtained in this context; see also [5, 13, 15]. The discretization of $\mathcal{D} = \mathbf{v} \cdot \nabla$ is taken as

$$(\mathcal{D}_h f)(\mathbf{x}, \mathbf{v}, t) = \frac{1}{h}(f(\mathbf{x}, \mathbf{v}, t) - f(\mathbf{x} - h\mathbf{v}, \mathbf{v}, t)). \tag{3.1}$$

Together with an explicit Euler discretization of the time derivative and an evaluation of the collision operator at a shifted $\mathbf{x}$-position, (2.4) turns into

$$f(\mathbf{x}, \mathbf{v}, t + \Delta t) - f(\mathbf{x}, \mathbf{v}, t) + \frac{\Delta t}{\epsilon h}(f(\mathbf{x}, \mathbf{v}, t) - f(\mathbf{x} - h\mathbf{v}, \mathbf{v}, t)) \\ = -\frac{\Delta t}{\epsilon^2 \tau}(f - f^{eq}(\rho, \epsilon\mathbf{u}))(\mathbf{x} - h\mathbf{v}, \mathbf{v}, t).$$

Setting $\Delta t = \epsilon^2$, $h = \epsilon$, $\mathbf{v} = \epsilon\mathbf{w}$, and transforming the space variable $\mathbf{x} \to \mathbf{x} + \mathbf{w}\Delta t$ yields for the occupation numbers

$$f_i(\mathbf{x} + \mathbf{w}_i\Delta t, t + \Delta t) - f_i(\mathbf{x}, t) = -\frac{1}{\tau}\Big(f_i(\mathbf{x}, t) - f_i^{eq}(\rho(\mathbf{x}, t), \epsilon\mathbf{u}(\mathbf{x}, t))\Big),$$

which is the standard discretization in the LBM (see [29, 6, 1]).

To describe the effect of the discretization (3.1) on the moment system, we introduce the vectors

$$\mathbf{M} = \mathbf{P}f = (\rho, \rho u_1, \rho u_2, \Theta_{11}, \Theta_{12}, \Theta_{22}, q_1, q_2, s)^T$$

and

$$\mathbf{M}^{eq} = \mathbf{P}f^{eq}(\rho, \epsilon\mathbf{u}) = (\rho, \rho u_1, \rho u_2, \rho u_1^2, \rho u_1 u_2, \rho u_2^2, 0, 0, 0)^T.$$

Using (3.1) to replace $\mathcal{D}$ in (2.6), the discretized moment system can be written in the compact form

$$\frac{\partial \mathbf{M}}{\partial t} + \frac{1}{\epsilon}\mathbf{P}\mathcal{D}_h\mathbf{P}^{-1}\mathbf{M} = -\frac{1}{\tau\epsilon^2}(\mathbf{M} - \mathbf{M}^{eq}).$$

If $\{\mathbf{e}_i : i = 0, \ldots, 8\}$ are the standard unit vectors in $\mathbb{R}^9$, we can write the contribution of M_j to the equation for M_i as

$$\frac{1}{\epsilon}\mathbf{e}_i \cdot \Big(\mathbf{P}\mathcal{D}_h\mathbf{P}^{-1}\Big)M_j\mathbf{e}_j = \frac{1}{\epsilon}\mathbf{e}_i \cdot \Big(\mathbf{P}\frac{1}{h}(M_j(\mathbf{x}, t) - M_j(\mathbf{x} - h\mathbf{v}))\mathbf{P}^{-1}\mathbf{e}_j\Big). \tag{3.2}$$

With the abbreviation $g_j = \mathbf{P}^{-1}\mathbf{e}_j$, (3.2) can be transformed into

$$\frac{1}{\epsilon}\mathbf{e}_i \cdot \Big(\mathbf{P}\mathcal{D}_h\mathbf{P}^{-1}\Big)M_j\mathbf{e}_j = \frac{1}{\epsilon h}\Big(M_j(\mathbf{x}, t)\delta_{ij} - \langle P_i(\mathbf{v})g_j(\mathbf{v})M_j(\mathbf{x} - \mathbf{v}h)\rangle\Big) \\ = \frac{1}{\epsilon h}\Big(M_j(\mathbf{x}, t)\delta_{ij} - \sum_{k=0}^{8} P_i(\mathbf{c}_k)g_j(\mathbf{c}_k)M_j(\mathbf{x} - \mathbf{c}_k h)\Big).$$

Hence, the contribution of M_j to equation i can be written as a finite difference stencil with the general form

$$\frac{1}{\epsilon h}\begin{bmatrix} -P_i g_j(\mathbf{c}_8) & -P_i g_j(\mathbf{c}_4) & -P_i g_j(\mathbf{c}_7) \\ -P_i g_j(\mathbf{c}_1) & \delta_{ij} - P_i g_j(\mathbf{c}_0) & -P_i g_j(\mathbf{c}_3) \\ -P_i g_j(\mathbf{c}_5) & -P_i g_j(\mathbf{c}_2) & -P_i g_j(\mathbf{c}_6) \end{bmatrix}. \tag{3.3}$$

In particular, for each space derivative in the moment system (2.7), (2.8), and (2.9), a corresponding stencil is found. The discretization of x_1- and x_2-derivatives occurs in three different ways. For $\operatorname{div} \rho\mathbf{u}$ in the mass conservation equation as well as for $\nabla\rho$ in the momentum equation, the following stencils appear:

$$\frac{\partial}{\partial x_1} \approx \frac{1}{12h}\begin{bmatrix} -1 & 0 & 1 \\ -4 & 0 & 4 \\ -1 & 0 & 1 \end{bmatrix}, \qquad \frac{\partial}{\partial x_2} \approx \frac{1}{12h}\begin{bmatrix} 1 & 4 & 1 \\ 0 & 0 & 0 \\ -1 & -4 & -1 \end{bmatrix}. \tag{3.4}$$

They also occur in the momentum equation to approximate $\partial_{x_1}\Theta_{11}, \partial_{x_2}\Theta_{22}$ and in (2.8) for $\partial_{x_1}\rho u_1, \partial_{x_2}\rho u_2$. The derivatives of Θ_{12} as well as $\rho u_1 u_2$ are always discretized by

$$\frac{\partial}{\partial x_1} \approx \frac{1}{4h}\begin{bmatrix} -1 & 0 & 1 \\ 0 & 0 & 0 \\ -1 & 0 & 1 \end{bmatrix}, \qquad \frac{\partial}{\partial x_2} \approx \frac{1}{4h}\begin{bmatrix} 1 & 0 & 1 \\ 0 & 0 & 0 \\ -1 & 0 & -1 \end{bmatrix}. \tag{3.5}$$

These stencils also appear in (2.8) for $\partial_{x_1}\rho u_2, \partial_{x_2}\rho u_2$ and $\partial_{x_1} q_2, \partial_{x_2} q_1$. The remaining derivatives in the moment system turn out to be approximated by

$$\frac{\partial}{\partial x_1} \approx \frac{1}{6h}\begin{bmatrix} -1 & 0 & 1 \\ -1 & 0 & 1 \\ -1 & 0 & 1 \end{bmatrix}, \qquad \frac{\partial}{\partial x_2} \approx \frac{1}{6h}\begin{bmatrix} 1 & 1 & 1 \\ 0 & 0 & 0 \\ -1 & -1 & -1 \end{bmatrix}. \tag{3.6}$$

We remark that each stencil is second order accurate. In fact, the stencils can be viewed as convex combinations of standard central difference approximations. For example, the ∂_{x_1}-stencil in (3.4) can be written as

$$\frac{1}{12h}\begin{bmatrix} -1 & 0 & 1 \\ -4 & 0 & 4 \\ -1 & 0 & 1 \end{bmatrix} = \frac{1}{6}\left(\frac{1}{2h}\begin{bmatrix} -1 & 0 & 1 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} + \frac{4}{2h}\begin{bmatrix} 0 & 0 & 0 \\ -1 & 0 & 1 \\ 0 & 0 & 0 \end{bmatrix} + \frac{1}{2h}\begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ -1 & 0 & 1 \end{bmatrix} \right).$$

Up to now, we have investigated the approximations of the space derivatives appearing in the moment system. However, if we consider, for example, the discretized mass conservation equation, we find that apart from $M_1 = \rho u_1$ and $M_2 = \rho u_2$, the other variables $M_0, M_3, \ldots, M_8$ contribute also. Of course, this contribution is of higher order in the discretization parameter h and the appearance of such terms is not surprising since we started with a first order upwind approximation (3.1). As an example, we mention the contribution of ρ to the mass conservation equation (i.e., $i = j = 0$ in 3.3). Evaluating (3.3), we find up to a constant factor

$$\frac{1}{6h}\begin{bmatrix} -1 & -4 & -1 \\ -4 & 20 & -4 \\ -1 & -4 & -1 \end{bmatrix} = -h\Delta + \mathcal{O}(h^3),$$

which is the standard nine-point stencil for the Laplacian. If we keep all terms which appear in that way and which are of first order in h, we obtain the *modified equation* of the finite difference approximation (i.e., the equation which is approximated to second order accuracy). The modified equation corresponding to (2.7) is

$$\begin{aligned} \partial_t \rho + \operatorname{div} \rho \mathbf{u} &= \left(\frac{1}{6\epsilon} \Delta \rho + \frac{\epsilon}{2} \operatorname{div} \operatorname{div} \Theta \right) h, \\ \partial_t \rho \mathbf{u} + \operatorname{div} \Theta + \frac{1}{3\epsilon^2} \nabla \rho &= \left(\frac{1}{6\epsilon} (\Delta + 2\nabla \operatorname{div}) \rho \mathbf{u} + \frac{\epsilon}{6} \operatorname{div} Q \right) h. \end{aligned} \tag{3.7}$$

Similarly, equations are obtained for $\Theta, \mathbf{q}$ and s. Note that the additional terms have a stabilizing effect because they act as artificial viscosity. In the original LB approach, this viscosity is partly compensated by a negative viscosity due to the explicit Euler discretization of the time derivative and partly it is combined with the physical viscosity in the Navier–Stokes equation (which is possible since $(\Delta + 2\nabla \operatorname{div})\rho \mathbf{u}$ has the correct structure). In this way, second order accuracy of the LBM is obtained. Since we want to avoid the explicit time discretization but still obtain a second order accurate scheme, we neglect all the stencils described by (3.3) which do not have counterparts in the moment system. With this step, we focus only on the interplay between the stencils (3.4), (3.5), and (3.6). Another possibility is to start with a second order upwind discretization of $\mathcal{D}$ instead of the first order approach (3.1) (compare here, for example, [20]).

To introduce the time discretization, we will not replace the space derivatives by their finite difference approximations (3.4), (3.5), and (3.6) but restrict to the spatially continuous case to avoid confusion. Of course, the complete scheme is obtained by combining both space and time discretizations.

Introducing the momentum vector $\mathbf{m}^k(\mathbf{x}) = \rho \mathbf{u}(\mathbf{x}, k\Delta t)$ and the pressure variable p^k by $\rho(\mathbf{x}, k\Delta t) = \bar{\rho}(1 + 3\epsilon^2 p^k(\mathbf{x}))$, we define p^{k+1} and $\mathbf{m}^{k+1}$ based on a semi-implicit discretization of (2.7)

$$\begin{aligned} p^{k+1} &= p^k - \frac{\Delta t}{3\bar{\rho}\epsilon^2} \operatorname{div} \mathbf{m}^{k+1}, \\ \mathbf{m}^{k+1} &= \mathbf{m}^k - \Delta t (\operatorname{div} \Theta^k + \bar{\rho} \nabla p^{k+1}). \end{aligned} \tag{3.8}$$

Inserting $\mathbf{m}^{k+1}$ into the pressure equation yields a Helmholtz problem

$$\left(\Delta - \frac{3\epsilon^2}{\Delta t^2} \right) p^{k+1} = \frac{1}{\bar{\rho} \Delta t} \operatorname{div} \mathbf{m}^k - \operatorname{div} \operatorname{div} \frac{1}{\bar{\rho}} \Theta^k - \frac{3\epsilon^2}{\Delta t^2} p^k. \tag{3.9}$$

We remark that the discretization of the second order operators Δ and div div is automatically given by a composition of the discretizations (3.4), (3.5), and (3.6). As time discretization of (2.8), we choose

$$\Theta^{k+1} = \Theta^k - \frac{2\Delta t}{3\epsilon^2} S[\mathbf{m}^{k+1}] + \frac{\Delta t}{3} Q^k - \frac{\Delta t}{\epsilon^2 \tau} \left(\Theta^{k+1} - \left(\frac{\mathbf{m} \otimes \mathbf{m}}{\rho} \right)^{k+1} \right). \tag{3.10}$$

Finally, (2.9) is treated according to

$$\begin{aligned} \mathbf{q}^{k+1} &= \mathbf{q}^k - \frac{\Delta t}{\epsilon^2} \operatorname{div} \begin{pmatrix} \Theta_{22} & 2\Theta_{12} \\ 2\Theta_{12} & \Theta_{11} \end{pmatrix}^k - \frac{\Delta t}{6} \nabla s^{k+1} - \frac{\Delta t}{\epsilon^2 \tau} \mathbf{q}^{k+1}, \\ s^{k+1} &= s^k - \frac{4\Delta t}{\epsilon^2} \operatorname{div} \mathbf{q}^{k+1} - \frac{\Delta t}{\epsilon^2 \tau} s^{k+1}, \end{aligned}$$

which again leads to an elliptic problem (with $\alpha = \tau/\Delta t$)

$$\left(1 - \frac{4\tau^2\epsilon^2}{6(1+\epsilon^2\alpha)^2}\Delta\right) s^{k+1} = \frac{\epsilon^2\alpha}{1+\epsilon^2\alpha} s^k - \frac{4\tau\epsilon^2\alpha}{(1+\epsilon^2\alpha)^2} \operatorname{div} \mathbf{q}^k + \frac{4\tau^2}{(1+\epsilon^2\alpha)^2} \operatorname{div} \operatorname{div} \begin{pmatrix} \Theta_{22} & 2\Theta_{12} \\ 2\Theta_{12} & \Theta_{11} \end{pmatrix}^k.$$

The elliptic problems for p and s, which result from the semi-implicit treatment, can be solved by an iterative procedure. The remaining equations for $\mathbf{m}, \Theta$, and $\mathbf{q}$ are explicit.

4. The discretization of the incompressible Navier–Stokes equations. The discretization of the moment system described in the last section tends, as $\epsilon \to 0$, to a Chorin-type projection method for the incompressible Navier–Stokes equations. Since $\rho \to \bar{\rho}$ in that limit, we have $\mathbf{m} = \rho\mathbf{u} \to \bar{\rho}\mathbf{u}$ and the momentum equation in (3.8) yields

$$\mathbf{u}^{k+1} = \mathbf{u}^k - \Delta t \operatorname{div} \frac{1}{\bar{\rho}}\Theta^k - \Delta t \nabla p^{k+1}. \tag{4.1}$$

The Helmholtz equation (3.9) for the pressure turns into

$$\Delta p^{k+1} = \frac{1}{\Delta t} \operatorname{div} \mathbf{u}^k - \operatorname{div} \operatorname{div} \frac{1}{\bar{\rho}}\Theta^k. \tag{4.2}$$

Both (4.1) and (4.2) are combined with the limit of (3.10)

$$\frac{1}{\bar{\rho}}\Theta^{k+1} = \mathbf{u}^{k+1} \otimes \mathbf{u}^{k+1} - \frac{2\tau}{3} S[\mathbf{u}^{k+1}]. \tag{4.3}$$

For (4.1), this implies

$$\mathbf{u}^{k+1} = \mathbf{u}^k - \Delta t \operatorname{div} \mathbf{u}^k \otimes \mathbf{u}^k - \Delta t \nabla p^{k+1} + \frac{2\tau\Delta t}{3} \operatorname{div} S[\mathbf{u}^k]. \tag{4.4}$$

By construction, each differential operator in (4.4) is composed of derivatives from the original moment system for which we have derived the discretizations (3.4), (3.5), and (3.6). If $\bar{D}_1, \bar{D}_2$ denote the approximations in (3.4) and $\tilde{D}_1, \tilde{D}_2$ denote those in (3.5), we find for the pressure gradient and the convective term in (4.4)

$$\nabla p \leftrightarrow \bar{G}p = \begin{pmatrix} \bar{D}_1 p \\ \bar{D}_2 p \end{pmatrix}, \qquad \operatorname{div} \mathbf{u} \otimes \mathbf{u} \leftrightarrow \hat{D}\mathbf{u}^k \otimes \mathbf{u}^k = \begin{pmatrix} \bar{D}_1 u_1^2 + \tilde{D}_2 u_1 u_2 \\ \tilde{D}_1 u_1 u_2 + \bar{D}_2 u_2^2 \end{pmatrix}. \tag{4.5}$$

The viscous term is of the form

$$2 \operatorname{div} S[\mathbf{u}] \leftrightarrow \hat{L}\mathbf{u} = \begin{pmatrix} 2\bar{D}_1^2 u_1 + \tilde{D}_2^2 u_1 + \tilde{D}_2 \tilde{D}_1 u_2 \\ \tilde{D}_1 \tilde{D}_2 u_1 + \tilde{D}_1^2 u_2 + 2\bar{D}_2^2 u_2 \end{pmatrix}. \tag{4.6}$$

Under discrete divergence-free condition, $\bar{D}\mathbf{u} = 0$, a reorganization yields

$$\begin{pmatrix} 2\bar{D}_1^2 u_1 + \tilde{D}_2^2 u_1 + \tilde{D}_2 \tilde{D}_1 u_2 \\ \tilde{D}_1 \tilde{D}_2 u_1 + \tilde{D}_1^2 u_2 + 2\bar{D}_2^2 u_2 \end{pmatrix} = \begin{pmatrix} \bar{D}_1^2 u_1 + \tilde{D}_2^2 u_1 \\ \tilde{D}_1^2 u_2 + \bar{D}_2^2 u_2 \end{pmatrix} + \left[\tilde{D}_1 \tilde{D}_2, \bar{D}_1 \bar{D}_2\right] \mathbf{u},$$

where $[\cdot,\cdot]$ denotes the commutator. Since both $\tilde{D}_1\tilde{D}_2$ and $\bar{D}_1\bar{D}_2$ are second order accurate approximations of the mixed derivative $\partial_{x_1}\partial_{x_2}$, the commutator vanishes in the order of accuracy of the method

$$\left[\tilde{D}_1\tilde{D}_2, \bar{D}_1\bar{D}_2\right]\mathbf{u} = \mathcal{O}(h^2).$$

Thus, $\hat{L}$ is a second order approximation of the Laplacian. Finally, $\operatorname{div}\mathbf{u}^k$ and the Laplacian in (4.2) turn out to be discretized by

$$\operatorname{div}\mathbf{u} \leftrightarrow \bar{D}\mathbf{u} = \bar{D}_1 u_1 + \bar{D}_2 u_2,$$
$$\Delta p \leftrightarrow \bar{L}p = \bar{D}\bar{G}p = \left(\bar{D}_1^2 + \bar{D}_2^2\right)p.$$

According to (4.3), the double divergence in (4.2) splits into two contributions. The convective part $\operatorname{div}\operatorname{div}\mathbf{u}\otimes\mathbf{u}$ is discretized by $\bar{D}\hat{D}\mathbf{u}\otimes\mathbf{u}$ where $\hat{D}\mathbf{u}\otimes\mathbf{u}$ is given in (4.5). The part involving third order derivatives is treated similarly, discretizing $\operatorname{div}\operatorname{div} S[\mathbf{u}]$ by $\bar{D}\hat{D}S[\mathbf{u}]$. Altogether, the discrete versions of (4.2) and (4.4) can be written as

$$\bar{L}p^{k+1} = \frac{1}{\Delta t}\bar{D}\mathbf{u}^k - \bar{D}\hat{D}\mathbf{u}^k \otimes \mathbf{u}^k + \frac{\tau}{3}\bar{D}\hat{L}\mathbf{u}^k$$

and

$$\mathbf{u}^{k+1} = \mathbf{u}^k - \Delta t\hat{D}\mathbf{u}^k \otimes \mathbf{u}^k - \Delta t\bar{G}p^{k+1} + \frac{\tau\Delta t}{3}\hat{L}\mathbf{u}^k,$$

which is a Chorin-type projection method with spatial discretization induced by the LB approach.

5. Boundary conditions and remarks on alternating errors. In this section appropriate boundary conditions for our method are introduced and oscillating pressure error terms are discussed. The following investigations are motivated by the detailed analysis of finite difference schemes for the incompressible Navier–Stokes equations in [34].

In Chorin's method [8], the pressure is only first order accurate (with respect to the spatial discretization parameter h) despite the fact that all finite difference approximations are second order consistent. As shown in [34], this behavior results from an interaction of the discretized viscous term in the Navier–Stokes equations and the pressure Poisson equation. More precisely, the wide stencil for the Laplacian in the pressure equation essentially decouples the problem into two Poisson problems on separate subgrids. Since the subproblems are subject to boundary conditions which differ at third order, alternating errors at third order are introduced (i.e., error terms are present on one subgrid and absent on the other). If the Laplacian in the viscous term is discretized with the standard five-point stencil, as in Chorin's method, the application to an alternating function yields contributions of order $1/h^2$. In this way, the third order oscillating error is brought down to first order. To avoid this phenomenon, several approaches have been proposed and some of them are analyzed in [34]. In the LB-induced discretization of the Navier–Stokes equations described in section 4, the accuracy of the pressure remains second order. In contrast to the methods investigated in [34], an amplification of the alternating error at third order is avoided due to the wide stencil $\hat{L}$ for the Laplacian in the viscous term.

To explain the basic principles which lead to the alternating error terms in Chorin's method, we consider the Stokes equation in a periodic channel as a model

problem. The extension of the boundary treatment to the new discretization will then be straight forward.

By neglecting the nonlinear terms in the Navier–Stokes equations, we obtain the Stokes equation

$$\begin{aligned} \partial_t \mathbf{u} + \nabla p &= \nu \Delta \mathbf{u}, \\ \operatorname{div} \mathbf{u} = \mathbf{0} \quad \text{in } \Omega, \qquad \mathbf{u}|_{t=0} &= \mathbf{u}_0. \end{aligned} \tag{5.1}$$

As in [34], we choose $\Omega = (0,1) \times (0,1)$ with no-slip conditions $\mathbf{u} = \mathbf{0}$ on the top and bottom boundaries and periodic conditions in horizontal direction. The pressure p is determined by the constraint $\operatorname{div} \mathbf{u} = 0$; i.e., p has to be chosen in such a way that the gradient part of the vector field

$$\mathbf{a} = \nu \Delta \mathbf{u}$$

is exactly compensated. Following the notation in [34], the divergence-free projection of $\mathbf{a}$ is given by

$$\mathcal{P}\mathbf{a} = \mathbf{a} - \nabla q,$$

where q solves the Neumann–Poisson problem

$$\Delta q = \operatorname{div} \mathbf{a} \quad \text{in } \Omega, \qquad \frac{\partial q}{\partial \mathbf{n}} = \mathbf{n} \cdot \mathbf{a} \quad \text{on } \partial\Omega$$

with a normalization condition $\int_\Omega q \, dx = 0$. To get a discrete representation of the projection operator, we introduce discretizations G and D of the gradient and the divergence. Then, the discrete divergence-free part $\mathcal{P}_h \mathbf{a}$ of $\mathbf{a}$ is obtained by solving

$$DGq = D\mathbf{a} \tag{5.2}$$

with suitably discretized Neumann and normalization conditions. Indeed, setting

$$\mathcal{P}_h \mathbf{a} = \mathbf{a} - Gq$$

we find, by construction, $D\mathcal{P}_h \mathbf{a} = 0$.

In Chorin's method, G and D are based on standard central difference approximations on the regular square grid $\Omega_h = \{x_{ij} = (ih, jh) : i, j = 0, \dots, N\}$, where $h = 1/N$. With

$$D_1 = \frac{1}{2h} \begin{bmatrix} -1 & 0 & 1 \end{bmatrix} \qquad \text{and} \qquad D_2 = \frac{1}{2h} \begin{bmatrix} 1 \\ 0 \\ -1 \end{bmatrix},$$

the discrete gradient acting on a scalar function q is given by

$$(Gq)_{ij} = \begin{pmatrix} (D_1 q)_{ij} \\ (D_2 q)_{ij} \end{pmatrix} = \frac{1}{2h} \begin{pmatrix} q_{i+1,j} - q_{i-1,j} \\ q_{i,j+1} - q_{i,j-1} \end{pmatrix}.$$

(The weight in the center of the stencil always refers to the point where the stencil is applied.) At points x_{ij} well inside the domain ($2 \le j \le N-2$), the divergence D acts on a vector field $\mathbf{u}$ according to

$$D\mathbf{u} = D_1 u_1 + D_2 u_2.$$

The iterated operator $L = DG$ appearing in (5.2) is then the wide Laplacian

$$L = \frac{1}{4h^2}\begin{bmatrix} & & 1 & & \\ & & 0 & & \\ 1 & 0 & -4 & 0 & 1 \\ & & 0 & & \\ & & 1 & & \end{bmatrix}. \tag{5.3}$$

At points x_{ij} next to the boundary ($j = 1$ or $j = N-1$), the original operator D_2 is, according to Chorin's approach, replaced by

$$D_2^{(1)} = \frac{1}{2h}\begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix} \qquad \text{and} \qquad D_2^{(N-1)} = \frac{1}{2h}\begin{bmatrix} 0 \\ 0 \\ -1 \end{bmatrix}.$$

For the velocity field $\mathbf{u}$, the discrete operator

$$(D^{(j)}\mathbf{u})_{ij} = (D_1 u_1)_{ij} + (D_2^{(j)} u_2)_{ij}, \qquad j \in \{1, N-1\},$$

still approximates the divergence since $\mathbf{u} = \mathbf{0}$ on the boundary so that $(D^{(j)}\mathbf{u})_{ij} = (D\mathbf{u})_{ij}$. However,

$$L^{(1)} = D^{(1)}G = D_1 D_1 + D_2^{(1)} D_2 = \frac{1}{4h^2}\begin{bmatrix} & & 1 & & \\ & & 0 & & \\ 1 & 0 & -3 & 0 & 1 \\ & & 0 & & \\ & & 0 & & \end{bmatrix}$$

now has the interpretation as a discrete Laplacian with an incorporated boundary condition. Indeed, $(L^{(1)}q)_{i1} = (D^{(1)}\mathbf{a})_{i1}$ can be rewritten in terms of the undisturbed operators $(Lq)_{i1} = (D\mathbf{a})_{i1}$ together with the condition

$$(D_2 q)_{i0} = (a_2)_{i0}$$

which is a second order accurate approximation of the Neumann boundary condition $\frac{\partial q}{\partial \mathbf{n}} = \mathbf{a} \cdot \mathbf{n}$ at the lower boundary. (Similar considerations apply to the upper boundary.)

Finally, in boundary points, the x_1-derivative of the divergence is deleted completely ($D_1^{(j)} = 0$ for $j \in \{0, N\}$) and the x_2-derivative is obtained from the half-sided difference

$$D_{2,hs} = \frac{1}{2h}\begin{bmatrix} -1 \\ 4 \\ -3 \\ 0 \\ 0 \end{bmatrix} \tag{5.4}$$

by deleting the central weight. The equation $(L^{(0)}q)_{i0} = (D^{(0)}\mathbf{a})_{i0}$ based on the iterated operator

$$L^{(0)} = D^{(0)}G = D_1^{(0)} D_1 + D_2^{(0)} D_2$$

can again be interpreted as $(Lq)_{i0} = (D\mathbf{a})_{i0}$ but now with the boundary condition

$$(BD_2q - Ba_2)_{i,0} = \frac{h}{3}(D_1D_1q - D_1a_1)_{i,0}.$$

Here, B is the linear interpolation operator

$$B = \frac{1}{3}\begin{bmatrix} -1 \\ 3 \\ 0 \\ 1 \\ 0 \end{bmatrix} = 1 + \mathcal{O}(h^3) \tag{5.5}$$

so that $B(D_2q - a_2)$ also approximates the Neumann condition.

Before we apply the construction of the boundary stencils to the discretization induced by the LB, let us briefly comment on the mechanism which introduces alternating errors (see also [34]). An important observation is that the wide Laplacian (5.3) involves either even layers ($j = 0, 2, \ldots, N$), or odd layers ($j = 1, 3, \ldots, N-1$) but does not mix in between them. (We assume for simplicity that N is even.) Since the boundary stencils $L^{(1)}$ and $L^{(N-1)}$ respect this separation, the Poisson problem on the odd subgrid decouples completely. (Here, we assume for simplicity that the integral normalization is discretized separately on each subgrid. Moreover, the accuracy of the integration rule is assumed to be at least fourth order, which again simplifies the argument.) To analyze the solution of

$$\begin{aligned} (Lq_{\text{odd}} - D\mathbf{a})_{ij} &= 0, \qquad j = 1, 3, \ldots, N-1, \\ (D_2q_{\text{odd}} - a_2)_{ij} &= 0, \qquad j \in \{1, N-1\}, \end{aligned} \tag{5.6}$$

with the discretized integral normalization, we assume an expansion of the form

$$q_{\text{odd}} = q^{(0)}_{\text{odd}} + hq^{(1)}_{\text{odd}} + h^2q^{(2)}_{\text{odd}} + h^3q^{(3)}_{\text{odd}} + \mathcal{O}(h^4). \tag{5.7}$$

Inserting (5.7) into (5.6), performing a Taylor expansion, and considering equal orders in h, we find equations satisfied by the coefficients. In lowest order, the original problem

$$\Delta q^{(0)} = \operatorname{div}\mathbf{a}, \qquad \frac{\partial q^{(0)}}{\partial x_2} = a_2 \quad \text{on } \partial\Omega, \qquad \int_\Omega q^{(0)}\,dx = 0 \tag{5.8}$$

is recovered. Due to the second order accuracy of the stencils in (5.6), the equations for $q^{(1)}_{\text{odd}}$ and $q^{(3)}_{\text{odd}}$ are homogeneous so that $q^{(1)}_{\text{odd}} = q^{(3)}_{\text{odd}} = 0$ because of unique solvability. In second order, we find $q^{(2)}_{\text{odd}}$ as solution of

$$\begin{aligned} \Delta q^{(2)} &= \frac{1}{6}\left(\frac{\partial^3 a_1}{\partial x_1^3} + \frac{\partial^3 a_2}{\partial x_2^3}\right) - \frac{1}{3}\left(\frac{\partial^4}{\partial x_1^4} + \frac{\partial^4}{\partial x_2^4}\right) q^{(0)}, \\ \frac{\partial q^{(2)}}{\partial x_2} &= -\frac{1}{6}\frac{\partial^3 q^{(0)}}{\partial x_2^3} \quad \text{on } \partial\Omega, \qquad \int_\Omega q^{(2)}\,dx = 0. \end{aligned} \tag{5.9}$$

Altogether, we obtain the expansion

$$q_{\text{odd}} = q^{(0)}_{\text{odd}} + h^2q^{(2)}_{\text{odd}} + \mathcal{O}(h^4). \tag{5.10}$$

In the next step we can solve the problem on the even subgrid which uses q_{odd} in the boundary conditions

$$
\begin{aligned}
(Lq_{\text{even}} - D\mathbf{a})_{ij} &= 0 \qquad j = 0, 2, \dots, N, \\
\frac{1}{3}\Big[(D_2 q_{\text{even}} - a_2)_{i,-1} + 3(D_2 q_{\text{even}} - a_2)_{i,1}\Big] & \\
&= \frac{1}{3}(D_2 q_{\text{odd}} - a_2)_{i,2} + \frac{h}{3}(D_1 D_1 q_{\text{even}} - D_1 a_1)_{i,0}.
\end{aligned} \tag{5.11}
$$

(A corresponding condition applies on the upper boundary.) The coefficients in

$$q_{\text{even}} = q^{(0)}_{\text{even}} + h q^{(1)}_{\text{even}} + h^2 q^{(2)}_{\text{even}} + h^3 q^{(3)}_{\text{even}} + \mathcal{O}(h^4)$$

are determined with the same procedure as above. It turns out that $q^{(0)}_{\text{even}} = q^{(0)}_{\text{odd}}$ is the solution of (5.8) and $q^{(1)}_{\text{even}}$ solves

$$\Delta q^{(1)} = 0, \qquad \frac{\partial q^{(1)}}{\partial x_2} = \frac{1}{4}\left(\frac{\partial^2 q^{(0)}}{\partial x_1^2} - \frac{\partial a_1}{\partial x_1}\right) \quad \text{on } \partial\Omega, \qquad \int_\Omega q^{(1)}\, dx = 0.$$

In general, the solution to this problem is nontrivial. However, if $\mathbf{a} = \nu\Delta\mathbf{u}$ and $q^{(0)} = p$ are related to a smooth solution of the Stokes equation, a compatibility condition assures that $\partial^2 q^{(0)}/\partial x_1^2 = \partial a_1/\partial x_1$ so that, in fact, $q^{(1)}_{\text{even}} = 0$. (Basically, the Stokes equation implies $\nabla p = \nu\Delta\mathbf{u}$ on the boundary so that the compatibility relation follows by applying an additional x_1-derivative.)

For the coefficient $q^{(2)}_{\text{even}}$, we recover (5.9) with boundary condition

$$\frac{\partial q^{(2)}_{\text{even}}}{\partial x_2} = \frac{\partial q^{(2)}_{\text{odd}}}{\partial x_2}$$

so that also $q^{(2)}_{\text{even}} = q^{(2)}_{\text{odd}}$. Only in third order, we observe a difference between the solutions on the odd and even subgrids. While $q^{(3)}_{\text{odd}} = 0$, the coefficient $q^{(3)}_{\text{even}}$ solves

$$
\begin{aligned}
\Delta q^{(3)} = 0, \qquad \int_\Omega q^{(3)}\, dx = 0, & \\
\frac{\partial q^{(3)}}{\partial x_2} = \frac{1}{12}\left(\frac{\partial^4 q^{(0)}}{\partial x_2^4} - \frac{\partial^3 a_2}{\partial x_2^3}\right) - \frac{1}{4}\left(\frac{\partial^2 q^{(2)}}{\partial x_2^2} + \frac{1}{6}\frac{\partial^4 q^{(0)}}{\partial x_2^4}\right) & \quad \text{on } \partial\Omega.
\end{aligned}
$$

Combining the solutions on the subgrids we find the expansion

$$q_{ij} = q^{(0)}_{ij} + h^2 q^{(2)}_{ij} + h^3 q^{(3)}_{ij} + (-1)^j h^3 \hat{q}^{(3)}_{ij} + \mathcal{O}(h^4),$$

where $q^{(0)}, q^{(2)}$ solve (5.8) and (5.9) and

$$q^{(3)} = \frac{1}{2}(q^{(3)}_{\text{even}} + q^{(3)}_{\text{odd}}), \qquad \hat{q}^{(3)} = \frac{1}{2}(q^{(3)}_{\text{even}} - q^{(3)}_{\text{odd}}).$$

In the case of the Stokes (or Navier–Stokes) equation, the Poisson problem is coupled with the evolution equation for the velocity field $\mathbf{u}$, giving rise to a similar expansion

$$\mathbf{u}_{ij} = \mathbf{u}^{(0)}_{ij} + h^2 \mathbf{u}^{(2)}_{ij} + h^3 \mathbf{u}^{(3)}_{ij} + (-1)^j h^3 \hat{\mathbf{u}}^{(3)}_{ij} + \mathcal{O}(h^4). \tag{5.12}$$

The input $\mathbf{a}$ to the Poisson problem is given by $\nu\Delta\mathbf{u}$ where, in Chorin's method, the Laplacian is discretized with the usual five-point stencil. Applying this stencil to (5.12), the term $(-1)^j h^3 \hat{\mathbf{u}}_{ij}^{(3)}$ yields the alternating contribution

$$(-1)^j \left(h \begin{bmatrix} & -1 & \\ 1 & -4 & 1 \\ & -1 & \end{bmatrix} \hat{\mathbf{u}}^{(3)} \right)_{ij}.$$

Since

$$h \begin{bmatrix} & -1 & \\ 1 & -4 & 1 \\ & -1 & \end{bmatrix} = -4h + h^3 \left(\frac{\partial^2}{\partial x_1^2} - \frac{\partial^2}{\partial x_2^2} \right) + \mathcal{O}(h^5),$$

the source term $\mathbf{a}$ in the Poisson equation contains an alternating, first order contribution so that the problem for $q^{(1)}$ now has a nontrivial alternating source. This implies that the approximate pressure p in the Stokes problem is only first order accurate with an alternating error. (For a more detailed analysis, we refer again to [34].)

Let us now define boundary stencils for the new discretization derived in section 4. The discrete gradient $\bar{G}$ is always given by $\bar{D}_1$, $\bar{D}_2$ defined in (3.4). The divergence $\bar{D}$ is also composed of these stencils for points inside the domain ($j = 2, \ldots, N-2$). The corresponding Laplacian has the form

$$\bar{L} = \bar{D}\bar{G} = \frac{1}{72} \begin{bmatrix} 1 & 4 & 8 & 4 & 1 \\ 4 & & -8 & & 4 \\ 8 & -8 & -36 & -8 & 8 \\ 4 & & -8 & & 4 \\ 1 & 4 & 8 & 4 & 1 \end{bmatrix}. \tag{5.13}$$

At points next to the boundary, we modify $\bar{D}_1$ and $\bar{D}_2$ by deleting boundary weights giving rise to $\bar{D}^{(j)}$ and $\bar{L}^{(j)} = \bar{D}^{(j)}\bar{G}$ for $j = 1, N-1$. On the boundary itself, we replace $\bar{D}_1$ by zero (as in Chorin's method) and choose half-sided differences for $\bar{D}_2$. Although these half-sided stencils do not follow directly from the LB approach, there is a natural choice based on the observation that $\bar{D}_2$ can be written as convex combination of central differences

$$\bar{D}_2 = \bar{C}D_2 \qquad \text{with} \qquad \bar{C} = \frac{1}{6}\begin{bmatrix} 1 & 4 & 1 \end{bmatrix}.$$

As in Chorin's method, where D_2 is replaced by $D_2^{(0)}$ (a second order, half-sided approximation with deleted central weight) we set

$$\bar{D}_2^{(0)} = \bar{C}D_2^{(0)} = \frac{1}{12h} \begin{bmatrix} -1 & -4 & -1 \\ 4 & 16 & 4 \\ & 0 & \\ & 0 & \\ & 0 & \end{bmatrix}.$$

A similar choice at the upper boundary yields $\bar{D}_2^{(N)}$ and finally gives rise to $\bar{L}^{(j)} = \bar{D}^{(j)}\bar{G}$ for $j = 0, N$.

In contrast to the wide Laplacian (5.3), the stencil (5.13) does not decouple odd and even subgrids. However, the coupling is not very strong which can be seen if $\bar{L}$ is

applied to a function which is constant in x_1 direction. Then, the stencil has the same effect as (5.3) leading to the decoupling known from Chorin's method. Rewriting the boundary stencils in terms of the interior discretization, we again find two different realizations of the Neumann boundary condition (which is an important structural feature for the occurrence of alternating terms). At the lower boundary, we have

$$\left[\bar{C}(\bar{D}_2 q - a_2) - \frac{h}{3}(\bar{D}_1\bar{D}_1 q - D_1 a_1)\right]_{i,0} = 0,$$
$$\left[B(\bar{D}_2 q - a_2) - \frac{2h}{3}(\bar{D}_1\bar{D}_1 q - D_1 a_1)\right]_{i,0} = 0,$$

where B is defined in (5.5). If the compatibility condition $\partial^2 q/\partial x_1^2 = \partial a_1/\partial x_1$ is satisfied, both conditions differ only in third order, exactly as in the case of Chorin's method.

The fundamental difference compared to Chorin's approach is the structure of the Laplacian $\hat{L}$ (4.6) which is used to discretize the viscosity term $\nu\Delta\mathbf{u}$. We neglect second order terms in the definition of $\hat{L}$ and consider

$$\hat{L}\mathbf{u} = \begin{pmatrix} \bar{D}_1^2 u_1 + \tilde{D}_2^2 u_1 \\ \tilde{D}_1^2 u_2 + \bar{D}_2^2 u_2 \end{pmatrix}.$$

Granting that $\mathbf{u}$ has an expansion as in (5.12), the Laplacian $\hat{L}$ does not amplify the alternating term as the standard five-point stencil. In fact, applying $\hat{L}$ to $h^3 A\hat{\mathbf{u}}^{(3)}$ (where A is an alternating function with $A_{ij} = (-1)^j$) leads to an alternating term of the same order

$$h^3\hat{L}A\hat{\mathbf{u}}^{(3)} = h^3 A \begin{pmatrix} \frac{1}{9}\frac{\partial \hat{u}_1^{(3)}}{\partial x_1^2} + \frac{\partial \hat{u}_1^{(3)}}{\partial x_2^2} \\ \Delta \hat{u}_2^{(3)} \end{pmatrix} + \mathcal{O}(h^5).$$

In contrast to the five-point Laplacian, the wide stencil $\hat{L}$ requires a special treatment at points next to the boundary. As for the boundary divergence, we consider the participating stencils as convex combinations of usual central differences which are replaced by half-sided approximations if necessary. For example, $\tilde{D}_2$ defined in (3.5) can be written as $\tilde{D}_2 = \tilde{C}D_2$ with $\tilde{C} = \frac{1}{2}\begin{bmatrix}1 & 0 & 1\end{bmatrix}$. Close to the boundary, we replace D_2 by $D_{2,hs}$ defined in (5.4). Altogether, we set

$$(\hat{L}^{(j)}\mathbf{u})_{ij} = \begin{pmatrix} \bar{D}_1 D_1 u_1 + \tilde{D}_2\tilde{C}D_{2,hs}u_1 \\ \tilde{D}_1 D_1 u_2 + \bar{D}_2\tilde{C}D_{2,hs}u_2 \end{pmatrix}_{ij}, \qquad j \in \{1, N-1\}.$$

This modified stencil now again amplifies an alternating term but only by one order

$$\hat{L}^{(j)}A\hat{\mathbf{u}}^{(3)} = \frac{4}{h}\frac{\partial}{\partial x_2}\hat{\mathbf{u}}^{(3)} + \mathcal{O}(1).$$

Consequently, a second order alternating contribution appears in the calculated pressure and adds to the second order error already present giving rise to a second order accurate scheme. (The amplification can even be avoided altogether by using $D_{2,hs}$ based on twice the grid size. Then, the approximate second x_2-derivative operates only on the even subgrid and thus is unaffected by alternating terms.)

Motivated by the analysis of the LB-induced discretization, we can set up other schemes with a similar behavior but with simpler stencils. We just use the feature of

TABLE 1

a wide Laplacian in the discretization of $\nu\Delta\mathbf{u}$ to avoid amplifications of high-order alternating terms. For example, to simplify the numerical effort, one may use, instead of $\hat{L}$, the stencil $\bar{L}$—with appropriate boundary modifications—to approximate the viscous term. Another possibility is to use the wide five point stencil (5.3). As with the LB-induced discretization, $h^3 A\hat{\mathbf{u}}^{(3)}$ is not amplified inside the domain and is amplified at most by one order next to the boundary so that second order schemes in velocity and pressure are obtained.

6. Numerical investigations. Our numerical test problem is taken from [34]. The periodic channel problem (5.1) is initialized with the velocity field

$$u_1(x_1, x_2) = 6x_2(1 - x_2) + 16(2x_2 - 6x_2^2 + 4x_2^3)\sin(2\pi x_1)/2\pi,$$
$$u_2(x_1, x_2) = -16(x_2^2 - 2x_2^3 + x_2^4)\cos(2\pi x_1),$$

which relaxes to plane Poiseuille flow for $t \to \infty$. Errors due to time integration are kept small by using very small time steps. The results obtained with Chorin's method and the LB-induced discretization are presented at $t = 1$. As mentioned at the end of the previous section, we consider a simplification of the method described above, using the stencil defined by (5.3) instead of $\hat{L}$. (With $\bar{L}$ instead of $\hat{L}$, the same behavior is observed.) The orders of convergence of the pressure for the different methods are given in Table 1.

First order convergence for the pressure is found with Chorin's method in contrast to the second order convergence with the LB-based method. This is in accordance with the analytical considerations, since wide Laplacians are used to discretize the viscous terms in the velocity equation. We mention that second order convergence for the pressure can also be obtained with Chorin's method if filtering of the pressure is used; see [34]. However, filtering introduces additional errors so that Chorin's scheme including filtering shows an error larger than the LB-type method.

The convergence of velocity is second order in both cases, as shown in Table 2.

Here, the absolute errors of the LBM exceed those of Chorin's method by a factor of four. This loss of resolution is due to the fact that a wide stencil of size $2h$ is used to approximate the viscous term instead of a usual five-point stencil as in Chorin's method.

7. Conclusions. Starting from an LB-type discrete velocity model with the diffusion scaling, a relaxation system for an equivalent set of velocity moments is

derived. A simple upwind discretization of the kinetic equation, similar to the one used in the original LB scheme, gives rise to a spatial discretization of the moment system. A semi-implicit time discretization which respects the stiffness of the problem then leads to a Chorin-type projection method for the incompressible Navier–Stokes equations as limiting system. In contrast to Chorin's original method, second order convergence of the pressure is observed. This improvement is related to the use of wide stencils in the velocity equation. On the other hand, wide stencils reduce resolution so that absolute errors in velocity are larger compared to Chorin's method although both schemes are second order accurate in velocity. The analytical results are based on an analysis of alternating error terms and are supported by numerical investigations.

RUNGE–KUTTA SOLUTIONS OF A HYPERBOLIC CONSERVATION LAW WITH SOURCE TERM*

MARK A. AVES†, DAVID F. GRIFFITHS†, AND DESMOND J. HIGHAM‡

Abstract. Spurious long-term solutions of a finite-difference method for a hyperbolic conservation law with a general nonlinear source term are studied. Results are contrasted with those that have been established for nonlinear ordinary differential equations. Various types of spurious behavior are examined, including spatially uniform equilibria that exist for arbitrarily small time-steps, nonsmooth steady states with profiles that jump between fixed levels, and solutions with oscillations that arise from nonnormality and exist only in finite precision arithmetic. It appears that spurious behavior is associated in general with insufficient spatial resolution. The potential for curbing spuriosity by using adaptivity in space or time is also considered.

Key words. adaptivity, finite difference, nonnormality, spurious solution, steady state

1. Introduction.

1.1. Background. There is a growing interest in the analysis of time-stepping methods for the long-term solution of nonlinear evolutionary equations. In particular, the propensity for widely used methods to generate spurious steady states is receiving much attention. In the context of ordinary differential equations (ODEs), many examples of spurious behavior have been identified [6, 12, 24]. Theoretical work in this area includes the study of spurious fixed points for small time-steps [10], the identification or construction of methods that guarantee to avoid spurious fixed points [7, 12], and the use of bifurcation theory to study routes to spuriosity [13, 20]. In [1] the potential for spurious behavior with an adaptive ODE algorithm was investigated, and both positive and negative results concerning the effectiveness of error control were derived.

Our aim in this work is to analyze spurious behavior arising from a discretized hyperbolic partial differential equation (PDE) of the form

$$u_t + (f(u))_x = g(u), \quad 0 < x < 1, \quad t > 0, \tag{1}$$

where the flux f and the source term g are nonlinear. Motivating this work is our desire to highlight new features that arise from the introduction of a spatial derivative, and hence to contrast the results with those that have been established for ODEs.

Difficulties arise in the numerical solution of (1) when the source term is "stiff"; that is, the time scale associated with reaction is very much shorter than that associated with advection. One of the most common problems addressed in the literature is that of incorrect speed of propagation of waves; see, for example, [3, 5, 15, 23]. This

has lead to the development of methods, often implicit or semi-implicit, for time-accurate solutions. In this work we are concerned with the amplitude of the waves, rather than with the speed.

1.2. Model problem. To simplify the presentation, we focus on the case of linear advection, so that the model problem becomes

$$u_t + au_x = g(u), \quad 0 < x < 1, \quad t > 0, \tag{2}$$

where $a > 0$ is constant and the source term g is nonlinear. In section 6 we indicate how our results carry through to the more general nonlinear flux case (1). For the purpose of illustration we will frequently refer to the logistic source term

$$g(u) = \alpha u(1 - u), \tag{3}$$

where $\alpha > 0$ is constant. This prototypical nonlinear function has been used in many studies of the dynamics of numerical methods.

Making the change of coordinates $s = x - at, \tau = t$ transforms (2) to

$$\frac{du}{d\tau} = g(u). \tag{4}$$

Hence, along the characteristics, where $x-at$ is constant, solutions solve the ODE (4). (The underlying ODE (4), will, of course, also play an important role in the analysis of numerical methods for (2).) For the logistic function (3), given $u_{\tau=0} = u_0$, (4) has the solution

$$u(\tau) = \frac{u_0}{u_0[1 - \exp(-\alpha\tau)] + \exp(-\alpha\tau)}.$$

Hence, when the initial condition is positive the solution tends to the stable fixed point $u \equiv 1$ as $\tau \to \infty$.

We consider both the periodic initial value problem (PIVP) and the initial boundary value problem (IBVP) for (2). In the PIVP case, we are given $u(x, 0)$ for $0 < x < 1$ and u is assumed to be periodic in space: $u(1+x, t) = u(x, t)$. It is clear from the discussion above that with g given by (3) and positive initial data, the solution converges to the fixed point $u \equiv 1$ as $t \to \infty$.

In the IBVP case we are given $u(x, 0)$ for $0 < x < 1$ and $u(0, t)$ for $t > 0$. For simplicity, we will assume a constant boundary condition, $u(0, t) \equiv u^0$. With the logistic source term (3), if the initial and boundary data are positive, then the solution tends to a (generally) nonuniform steady state with profile

$$u(x, t) = \frac{u^0}{u^0[1 - \exp(-\alpha x/a)] + \exp(-\alpha x/a)}. \tag{5}$$

1.3. Numerical method. If the spatial derivative in (2) is approximated using first order upwind differences [21], then we obtain an ODE system of the general form

$$\mathbf{U}_t = -\tfrac{a}{\Delta x} A\mathbf{U} + \mathbf{g}(\mathbf{U}) + \tfrac{a}{\Delta x}\mathbf{b} =: S(\mathbf{U}), \tag{6}$$

where Δx is a spatial meshsize and $U_j(t) \approx u(j\Delta x, t)$. Here, $\mathbf{g}(\mathbf{U})_j = g(U_j)$. We let $N = 1/\Delta x$, so that $\mathbf{U}(t) \in \mathbb{R}^N$. For the PIVP we have

$$A = \begin{bmatrix} 1 & & & -1 \\ -1 & 1 & & \\ & \ddots & \ddots & \\ & & -1 & 1 \end{bmatrix}, \quad \mathbf{b} \equiv \mathbf{0}, \tag{7}$$

while for the IBVP

$$A = \begin{bmatrix} 1 & & & \\ -1 & 1 & & \\ & \ddots & \ddots & \\ & & -1 & 1 \end{bmatrix}, \quad \mathbf{b} = \begin{bmatrix} u^0 \\ 0 \\ \vdots \\ 0 \end{bmatrix}. \tag{8}$$

To approximate the semidiscrete system (6) we consider a general explicit, two-stage, second order Runge–Kutta (RK) formula [14, p. 154] with tableau

$$\begin{array}{c|cc} 0 & 0 & \\ 1/(2\theta) & 1/(2\theta) & 0 \\ \hline & 1-\theta & \theta \end{array}.$$

Here $\theta \neq 0$ is a free parameter and we always assume that $0 < \theta \leq 1$. Common choices are $\theta = \frac{1}{2}$ and $\theta = 1$, giving the improved Euler and modified Euler methods, respectively. These time-stepping methods are widely used in the finite-difference discretization of advection problems; see, for example, [11].

Letting Δt denote the time-step, the RK method applied to (6) produces approximations $\mathbf{U}^n \in \mathbb{R}^N$ with $U_j^n \approx U(j\Delta x, n\Delta t)$ according to

$$\mathbf{U}^{n+1} = \mathbf{U}^n + \Delta t \left[(1-\theta)S(\mathbf{U}^n) + \theta S(\mathbf{U}^n + \tfrac{\Delta t}{2\theta} S(\mathbf{U}^n))\right]. \tag{9}$$

2. Fixed points of the semidiscrete problem. Although we are mainly concerned with the numerical solutions generated by the overall algorithm, a useful starting point is to study the fixed points of the system (6).

2.1. Initial BVP. For the IBVP (6) has a fixed point when

$$U_{j-1} = U_j - \tfrac{\Delta x}{a} g(U_j), \qquad j = 1, 2, \ldots, N, \tag{10}$$

with $U_0 = u^0$. Maps of this type have received considerable attention in the literature; see, for example, [16]. Generically, there are parameter ranges for which periodic cycles of any period may be generated.

The following results give insight into the behavior of the map (10) around a zero of g.

THEOREM 2.1. *Suppose $g \in C^1$ with $g(\beta) = 0$ and $g'(\beta) < 0$ for some $\beta \in \mathbb{R}$. Let $I \subseteq \mathbb{R}$ be an open, connected interval containing β such that $g'(u) < 0$ for all $u \in I$. Then, if $U_0 \in I$, there exists a solution sequence $\{U_j\}_{j=0}^N$ of (10) in which the components U_j approach β monotonically as j increases. Furthermore, this fixed point of the semidiscrete IBVP (6) is linearly stable.*

Proof. Consider the general case where $U_{j-1} \in I$ with $U_{j-1} \neq \beta$. Define $h_{j-1} : \mathbb{R} \mapsto \mathbb{R}$ by

$$h_{j-1}(u) = u - \frac{\Delta x}{a} g(u) - U_{j-1}. \tag{11}$$

Then, using the mean value theorem,

$$h_{j-1}(U_{j-1}) = -\frac{\Delta x}{a} g(U_{j-1}) = -\frac{\Delta x}{a}(g(U_{j-1}) - g(\beta)) = -\frac{\Delta x}{a} g'(\xi_{j-1})(U_{j-1} - \beta),$$

where $\xi_{j-1} \in I$. Hence, $h_{j-1}(\beta)h_{j-1}(U_{j-1}) = (\Delta x/a)g'(\xi_{j-1})(U_{j-1} - \beta))^2 < 0$; so there is a zero U_j of h_{j-1} between U_{j-1} and β.

The Jacobian of the ODE (6) at this fixed point is lower triangular with strictly negative diagonal entries. Hence, the fixed point is linearly stable. ∎

Theorem 2.1 gives the reassuring result that there are stable, smooth, fixed points of (6) that mimic those of the underlying PDE. The next result shows that unstable, oscillatory, fixed points may also exist if the spatial resolution is inadequate.

THEOREM 2.2. *Suppose $g \in C^1$ with $g(\beta) = 0$ and $g'(\beta) > 2a/\Delta x$ for some $\beta \in \mathbb{R}$. Let $I \subseteq \mathbb{R}$ be an open, connected interval containing β such that $g'(u) > 2a/\Delta x$ for all $u \in I$. Then if $U_0 \in I$ and $U_0 - \Delta x g(U_0)/a \in I$ there exists a solution sequence $\{U_j\}_{j=0}^N$ of (10) in which the components U_j approach β as j increases, with successive components lying on opposite sides of β. Furthermore, this fixed point of the semidiscrete IBVP (6) is linearly unstable.*

Proof. Consider the general case where $U_{j-1} \in I$ with $U_{j-1} \neq \beta$, and let $W_{j-1} := U_{j-1} - \Delta x g(U_{j-1})/a \in I$. From the mean value theorem,

$$(W_{j-1} - \beta)(U_{j-1} - \beta) = (U_{j-1} - \beta)^2(1 - \Delta x g'(\xi_{j-1})/a) < 0,$$

where $\xi_{j-1} \in I$. Hence, U_{j-1} and W_{j-1} lie on opposite sides of β. Let h_{j-1} be defined by (11). Then $h'_{j-1}(u) < -1$ for all $u \in I$.

Now, consider the case where $U_{j-1} < \beta$. Note that $h_{j-1}(\beta) > 0$. For any $u \in I$ with $u > U_{j-1}$ we have

$$h_{j-1}(u) = h_{j-1}(U_{j-1}) + \int_{U_{j-1}}^{u} h'_{j-1}(u)\, du < h_{j-1}(U_{j-1}) - u + U_{j-1}.$$

Putting $u = W_{j-1}$ gives $h_{j-1}(W_{j-1}) < 0$. Hence, h_{j-1} has a root $U_j \in (\beta, W_{j-1})$. Also, we note that $W_j := U_j - \Delta x g(U_j)/a = U_{j-1} \in I$.

In the case where $U_{j-1} > \beta$, a similar argument shows that h_{j-1} has a root $U_j \in (W_{j-1}, \beta)$.

Linear instability follows by observing that the relevant Jacobian of the ODE (6) is lower triangular with strictly positive diagonal entries. ∎

For the logistic source term (3), these results lead to the following corollary.

COROLLARY 2.3. *Consider the semidiscrete IBVP (6) with logistic source term (3).*

If $U_0 \in (1/2, \infty)$, then there exists a linearly stable fixed point $\{U_j\}_{j=0}^N$ of (6) for which the components U_j approach 1 monotonically as j increases.

If $0 < \psi < 1/2$ and $(1 - \psi - \sqrt{1 - 3\psi^2})/2 < U_0 < (1/2) - \psi$, where $\psi := a/(\alpha \Delta x)$, then there exists a linearly unstable fixed point $\{U_j\}_{j=0}^N$ of (6) for which the components U_j approach zero as j increases with successive components lying on opposite sides of β.

A spatially uniform fixed point (SUFP) has the form $\mathbf{U} = \beta\mathbf{e}$, where $\mathbf{e} = [1, 1, \ldots, 1]^T$. It is clear from the form of (6) that such a fixed point exists only if $g(\beta) = 0$ and $u^0 = \beta$. In this case, $\beta\mathbf{e}$ is a discrete analogue of a fixed point of (4), and hence of the problem (2). (Note that strict spatial uniformity requires the appropriate boundary condition to be specified. However, as illustrated by Theorems 2.1 and 2.2, fixed points that are almost spatially uniform arise generically.)

The Jacobian of the ODE (6) at a point $\mathbf{U} = \beta\mathbf{e}$ is $g'(\beta)I - (a/\Delta x)A$. This matrix is lower bidiagonal, and hence, it has the single eigenvalue $\lambda = g'(\beta) - a/\Delta x$. This implies that a fixed point $\mathbf{U} = \beta\mathbf{e}$ is stable for

$$g'(\beta) - \tfrac{a}{\Delta x} < 0, \tag{12}$$

a condition that is automatically satisfied if $g'(\beta) \leq 0$ and $a > 0$. However, the Jacobian may be highly nonnormal, leading to extreme transient growth of perturbations in (6) and a negligible basin of attraction for the fixed point. In this case it is more profitable to study the pseudospectrum of the Jacobian [17]. Omitting the details, the pseudospectrum of this matrix in an appropriate limit is given by (see [18])

$$g'(\beta) - \tfrac{a}{\Delta x}(1 - z), \qquad z \in \mathbb{C}, \quad |z| \leq 1.$$

In order to have stability in a practical sense when N is large, it is necessary that the pseudospectrum lie in the left half of the complex plane. This reduces to the condition $g'(\beta) < 0$, which is identical to the corresponding constraint for the PIVP (see section 2.2).

2.2. Periodic IVP. The PIVP version of (6) has a fixed point when (10) holds, with the interpretation that $U_0 \equiv U_N$. As in the IBVP case, we may study fixed points that are close to a zero of g. The arguments used in Theorems 2.1 and 2.2 remain valid, and, because of the "wrap-around" effect, the following stronger result holds.

THEOREM 2.4. *Suppose $g \in C^1$ with $g(\beta) = 0$ for some $\beta \in \mathbb{R}$.*

If $g'(\beta) < 0$, let $I \subseteq \mathbb{R}$ be the largest open, connected interval containing β such that $g'(u) < 0$ for all $u \in I$. Then the only fixed point of the semidiscrete PIVP (6) *for which $U_0 \in I$ is the linearly stable SUFP $\beta\mathbf{e}$.*

If $g'(\beta) > 2a/\Delta x$, let $I \subseteq \mathbb{R}$ be the largest open, connected interval containing β such that $g'(u) > 2a/\Delta x$ for all $u \in I$. Then the only fixed point of the semidiscrete PIVP (6) *for which $U_0 \in I$ and $U_0 - \Delta x g(U_0)/a \in I$ is the linearly unstable SUFP $\beta\mathbf{e}$.*

3. Fixed points of the overall algorithm.

3.1. Time-stepping on the underlying ODE. We begin this section by examining fixed points of the underlying RK(θ) method on the scalar ODE $u_t = g(u)$. Introducing z to represent an intermediate stage value, a fixed point β of the RK(θ) scheme must satisfy

$$\beta + \tfrac{\Delta t}{2\theta} g(\beta) = z, \tag{13}$$

$$(1 - \theta)g(\beta) + \theta g(z) = 0. \tag{14}$$

It is clear that if $g(\beta) = 0$, then $z = \beta$ is a solution—so that fixed points of the ODE are inherited by the RK scheme. (This is true for all RK schemes [12].) However, for general nonlinear g, spurious fixed points, where $g(\beta) \neq 0$, may be admitted.

It is possible to make some general comments about spurious fixed points in (13)–(14). (Recall our assumption that $0 < \theta \leq 1$.) First, from (14), there must be at least one zero of g between z and β. Moreover, if u is such that $g(u) = 0$, $g'(u) \neq 0$, and $\beta = u + c_1\epsilon + c_2\epsilon^2 + \cdots$ for some small parameter ϵ and constants $c_1, c_2, \ldots$, then

$$(1 - \theta)\beta + \theta z = u + O(\epsilon^2).$$

This tells us that z is better than β as an approximation to u when $\theta \in (1/2, 1]$ and ϵ is small.

Fixed points arising with the logistic nonlinearity (3) have been studied by many authors. For any $0 < \theta \leq 1$, the fixed point $u = 1$ is stable for $0 < \Delta t < 2$. Letting $r := \alpha\Delta t$, the following results about spurious fixed points are known for the popular choices of $\theta = 1/2$ and $\theta = 1$, [6].

$\theta = 1$: spurious fixed points $u = 1 + 2/r$ and $u = 2/r$ exist for all r. The former is stable for $0 < r < -1 + \sqrt{5}$, and the latter is stable for $2 < r < 1 + \sqrt{5}$.

$\theta = \frac{1}{2}$: spurious fixed points $u = [2 + r \pm \sqrt{r^2 - 4}]/(2r)$ exist for $r > 2$ and are stable for $2 < r < \sqrt{8}$.

Two points are worth emphasizing.

- In these examples, spurious fixed points either cease to exist or become arbitrarily large in modulus as $\Delta t \to 0$. Humphries [10] proved a general result in this vein—for any RK formula and any locally Lipschitz g, a spurious fixed point that persists for small Δt must blow up as $\Delta t \to 0$.
- The $\theta = 1$ case above shows that although spurious fixed points must blow up as $\Delta t \to 0$, they may remain stable for arbitrarily small Δt.

3.2. Spatially uniform fixed points of the PIVP. For the PIVP it is straightforward to confirm that $\beta\mathbf{e}$ is a fixed point of the overall algorithm if and only if β is a fixed point for the RK method on the scalar ODE $u_t = g(u)$. Hence, the question of *existence* of SUFPs has been answered in the previous subsection. *Stability*, however, is a separate issue.

Suppose first that $\beta\mathbf{e}$ is a nonspurious SUFP, so that $g(\beta) = 0$. Then we know from [12, Theorem 3] that the appropriate condition for linear stability is $|R(z)| < 1$ for every $z = \Delta t\lambda$, where λ is an eigenvalue of $-aA/\Delta x + g'(\beta)I$ and $R(z) = 1 + z + z^2/2$. The matrix A has eigenvalues $1 - \exp(i\varphi)$, where $\varphi \equiv \varphi_j = 2\pi j/N$, $j = 1, 2, \ldots, N$. Treating $\varphi \in [0, 2\pi)$ as a continuous variable (which may be justified when N is large), it follows that the spectrum of A lies on a circle centered on the negative real axis. It may then be shown that the real eigenvalues of A always dominate the stability condition and the required constraint may be written

$$0 < -\Delta t g'(\beta) < 2 - 2c. \tag{15}$$

For the logistic source term (3) with $\beta = 1$, this becomes $0 < r < 2 - 2c$, where $r = \alpha\Delta t$. This region is shown in light gray in the plots of Figure 1.

Generally, writing the map (9) as $\mathbf{U}^{n+1} = G(\mathbf{U}^n)$, after some manipulation the Jacobian of G at a point $\mathbf{U} = \beta\mathbf{e}$ may be written in the form

$$G'(\beta\mathbf{e}) = (1 + \rho - \tfrac{1}{2}\gamma^2)I + \tfrac{1}{2}(cA - \gamma I)^2, \tag{16}$$

where

$$\gamma = 1 + \tfrac{1}{2}\Delta t(g'(\beta) + g'(z)), \tag{17}$$

$$\rho = \Delta t((1 - \theta)g'(\beta) + \theta g'(z) + \tfrac{1}{2}\Delta t g'(\beta)g'(z)), \tag{18}$$

with z defined in (13). We use $c := a\Delta t/\Delta x$ to denote the Courant number [21]. For the logistic source term it is possible to determine the stable parameter ranges of the spurious fixed points corresponding to each value of θ. This leads to "almost triangular" regions with a vertical edge determined by the eigenvalue $\lambda(A) = 0$ and the "hypotenuse" by $\lambda(A) = 2$, $(\varphi = \pi)$. The remaining eigenvalues reduce the regions by rounding the apex in such a way as to create a C^1 smooth boundary. The details are omitted in view of their complexity. These regions are shown in darker gray in Figure 1 for $\theta = 1/2, 3/4, 1$.

Two key points arise from Figure 1. First, for $\theta > \frac{1}{2}$ it is possible to choose parameter values where both the correct and spurious fixed points are stable. In such cases, the choice of initial data will determine which, if either, of the two steady states

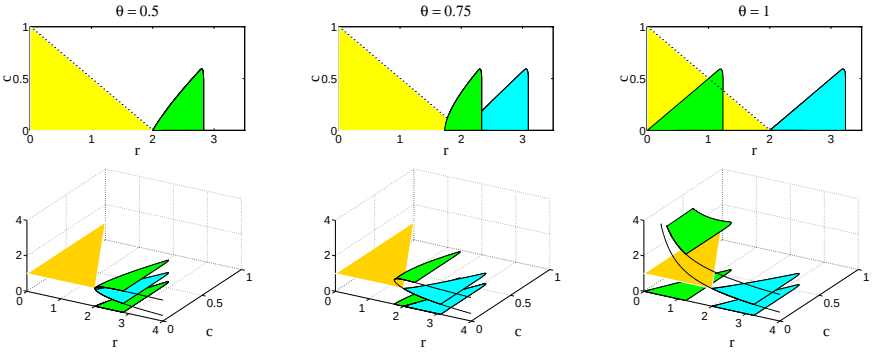

FIG. 1. *Stable parameter ranges in the (r, c)-plane for steady states of the RK(θ) methods with $\theta = 0.5, 0.75, 1.0$ on the PIVP with* (3)*. On the bottom row the vertical axis shows the magnitude of the steady state solution.*

is computed. A numerical illustration of this effect is given in section 3.4. The second point concerns the stability of spurious fixed points for small Δt. We know from section 3.1 that for $\theta = 1$ on the scalar ODE the spurious fixed point $u = 1 + 2/r$ is stable for $0 < r < -1 + \sqrt{5} \approx 1.2$. This stability interval is seen along the $c = 0$ axis at the base of the dark shaded $\theta = 1$ region in Figure 1. However, it is clear that if we increase c beyond zero, moving from the ODE to the PDE, then the spurious fixed point is always unstable for small r, that is, small Δt. We now develop some theory to show that this behavior is generic.

The lemma below concerns the scalar ODE.

LEMMA 3.1. *Consider the RK(θ) method* (9) *(with $0 < \theta \leq 1$) applied to the scalar ODE* (4)*. Suppose that $g : \mathbb{R} \mapsto \mathbb{R}$ is bounded and differentiable on every bounded interval, the zeros of g are separated, and $g(u)$ is monotonic for all $|u|$ sufficiently large. Suppose further that for sufficiently small Δt there is a spurious fixed point $\beta = \beta(\Delta t)$ with β depending C^1 continuously upon Δt and with $g(\beta)$ bounded away from zero for small Δt.*

(1) *For $\theta = 1$, we have $g'(\beta) < -2/\Delta t$ for sufficiently small Δt.*
(2) *For $0 < \theta < 1$, the fixed point β of the method* (9) *is linearly unstable for sufficiently small Δt.*

Proof. Let $z = z(\Delta t)$ be defined by (13). Note that if β is bounded as $\Delta t \to 0$, then $\Delta t g(\beta) \to 0$, so that $z \to \beta$ in (13). In this case, from (14), $g(\beta) \to 0$. This contradicts the assumption that $g(\beta)$ is bounded away from zero for small Δt, and hence, we must have $|\beta| \to \infty$ as $\Delta t \to 0$.

For the remainder of the proof we assume without comment that Δt is sufficiently small for our arguments to hold. We use a dot to represent differentiation with respect to Δt so that, for example, $\dot{\beta}$ denotes $d\beta/d\Delta t$.

For $\theta = 1$ we have $g(z) = 0$ from (14). Hence, z is fixed as $\Delta t \to 0$. It follows from (13) that $\beta g(\beta) < 0$ and hence, from the monotonicity of g, that $g'(\beta) < 0$. Differentiating (13) with respect to Δt gives

$$\beta\dot{\beta}(2 + \Delta t g'(\beta)) = -\beta g(\beta) > 0. \tag{19}$$

Now β^2 increases as $\Delta t \to 0$, so $d(\beta^2)/d\Delta t < 0$; that is, $2\beta\dot{\beta} < 0$. Using this in (19) gives $g'(\beta) < -2/\Delta t$.

For $0 < \theta < 1$ it follows from (14) that $g(\beta)$ and $g(z)$ are of opposing sign.

From the boundedness and monotonicity assumptions on g, we must have $|z| \to \infty$ as $\Delta t \to 0$, with $z\beta < 0$. In (13) we then find that

$$\beta^2 + \frac{\Delta t \beta g(\beta)}{2\theta} = z\beta < 0,$$

and hence, $\beta g(\beta) < 0$. The monotonicity of g then forces $g'(\beta) < 0$.

Now (13) and (14) give

$$2(1-\theta)z + \Delta t g(z) = 2(1-\theta)\beta. \tag{20}$$

Differentiating (13) and (20) with respect to Δt gives

$$(2\theta + \Delta t g'(\beta))\dot{\beta} + g(\beta) = 2\theta \dot{z},$$
$$(2 - 2\theta + \Delta t g'(z))\dot{z} + g(z) = 2(1-\theta)\dot{\beta}.$$

This may be written

$$\begin{bmatrix} 2\theta + \Delta t g'(\beta) & -2\theta \\ -2(1-\theta) & (2 - 2\theta + \Delta t g'(z)) \end{bmatrix} \begin{bmatrix} \dot{\beta} \\ \dot{z} \end{bmatrix} = - \begin{bmatrix} g(\beta) \\ g(z) \end{bmatrix}. \tag{21}$$

The determinant of the two-by-two matrix in (21) is 2ρ, where ρ is defined in (18). Hence,

$$2\rho \begin{bmatrix} \dot{\beta} \\ \dot{z} \end{bmatrix} = - \begin{bmatrix} (2 - 2\theta + \Delta t g'(z))g(\beta) + 2\theta g(z) \\ (2-2\theta)g(\beta) + (2\theta + \Delta t g'(\beta))g(z) \end{bmatrix}.$$

Using (14), this simplifies to

$$2\rho \begin{bmatrix} \dot{\beta} \\ \dot{z} \end{bmatrix} = - \begin{bmatrix} \Delta t g(\beta) g'(z) \\ \Delta t g(z) g'(\beta) \end{bmatrix}.$$

Thus, multiplying the first component by β gives

$$\rho \frac{d\beta^2}{d\Delta t} = -\Delta t \beta g(\beta) g'(z). \tag{22}$$

Our earlier arguments showed that $\beta g(\beta) < 0$, and since z and β tend to $\pm\infty$ in opposite directions, it follows from the monotonicity of g that $g'(z) < 0$. Hence, the right-hand side of (22) is negative. Since $d(\beta^2)/d\Delta t < 0$, we deduce that $\rho > 0$. This gives $G'(\beta) > 1$ in (16) (with the dimension set to $N = 1$ and with $A = 0$), and therefore, the spurious fixed point is unstable. ∎

We now use Lemma 3.1 to establish a result about the stability of spurious SUFPs of the semidiscrete PDE. The theorem below applies to a general class of semidiscrete problems, for which the PIVP (6) is a special case. (Adding this level of generality makes the theorem more widely applicable and does not complicate the proof.) The result shows that stable, spurious SUFPs occur only where there is a lack of spatial resolution.

THEOREM 3.2. *Consider the RK(θ) method* (9) *(with* $0 < \theta \leq 1$*) applied to an ODE system of the form*

$$\mathbf{U}_t = -\tfrac{a}{\Delta x^m} A\mathbf{U} + \mathbf{g}(\mathbf{U}), \tag{23}$$

where $a, \Delta x > 0$ *and* $\mathbf{g}(\mathbf{U})_i \equiv g(U_i)$ *with* g *satisfying the assumptions in Lemma* 3.1. *Suppose that* $A \in \mathbb{R}^{N\times N}$ *satisfies* $A\mathbf{e} = \mathbf{0}$ *and has an eigenvalue* $0 < \lambda \in \mathbb{R}$. *Consider a spurious SUFP* $\beta\mathbf{e}$, *where* $\beta = \beta(\Delta t)$ *depends* C^1 *continuously upon* Δt, *with* $g(\beta)$ *bounded away from zero for small* Δt.

(1) *For $\theta = 1$, such a SUFP cannot be stable for small Δt if*

$$\Delta x^m < \frac{a\lambda}{g'(z)}, \tag{24}$$

where the intermediate stage value z is defined in (13).

(2) *For $0 < \theta < 1$, such a SUFP cannot be stable for small Δt.*

Proof. First, note that since $A\mathbf{e} = 0$, if $\beta\mathbf{e}$ is a SUFP for the RK(θ) method on (23), then β is a fixed point for the same method on the scalar problem (4). Hence, we may appeal to Lemma 3.1.

Stability of the SUFP $\beta\mathbf{e}$ is determined by the spectrum of the matrix $G'(\beta\mathbf{e})$ in (16)–(18), with $c := a\Delta t/\Delta x^m$. Since A has an eigenvalue $\lambda \in \mathbb{R}$, $G'(\beta\mathbf{e})$ has a real eigenvalue of the form

$$\mu = 1 + \rho + \tfrac{1}{2}c^2\lambda^2 - \gamma c\lambda.$$

Instability of the SUFP $\beta\mathbf{e}$ follows if we can show that $\mu - 1 > 0$.

Consider first the case $\theta = 1$. It is straightforward to verify that

$$\mu - 1 = \tfrac{1}{2}(\lambda c - \Delta t g'(\beta) - 2)(\lambda c - \Delta t g'(z)),$$

where, from Lemma 3.1, the first factor on the right-hand side is positive for small Δt. Consequently, $\mu - 1 > 0$ if $\lambda c > \Delta t g'(z)$, from which, using $c = a\Delta t/\Delta x^m$, we obtain (24).

The result for $0 < \theta < 1$ is almost immediate from Lemma 3.1. Since $\mu > 1$ when $c = 0$, it follows by continuity that $\mu > 1$ for small c. ∎

For the picture in the top right-hand corner of Figure 1 we have $\theta = 1$, $\lambda = 2$, $m = 1$, $\beta = 1 + 2/(\alpha\Delta t)$, $z = 0$, $g'(0) = \alpha > 0$. So the condition in Theorem 3.2 for no stable spurious SUFPs when Δt is small becomes $\Delta x < 2a/\alpha$; that is, $c > r/2$. Figure 1 shows this bound to be sharp.

3.3. Spatially uniform fixed points of the IBVP. For the IBVP the PDE has a SUFP if and only if $g(u^0) = 0$. In this case, the map (9) inherits the fixed point $\beta\mathbf{e}$, with $\beta = u^0$. The Jacobian of the map at this point is lower triangular with Toeplitz form. The matrix has a single eigenvalue, which is real, and restricting this to lie in the interval $(-1, 1)$ produces the stability condition

$$0 < c - \Delta t g'(\beta) < 2. \tag{25}$$

The left-hand inequality requires $\Delta x g'(\beta) < a$, which forces Δx to be sufficiently small when $g'(\beta) > 0$, but imposes no restriction when $g'(\beta) < 0$. The right-hand inequality then requires

$$\Delta t < \frac{2\Delta x}{a - \Delta x g'(\beta)}. \tag{26}$$

However, since the Jacobian is (potentially) highly nonnormal, eigenvalues may be misleading indicators of stability. This phenomenon is well known in the analysis of linear stability of PDE methods [17] and corresponds to the classical result [19] that stability of the PIVP is a necessary condition for stability of the IBVP.

We now show the nonexistence of spurious SUFPs.

THEOREM 3.3. *For the IBVP, when $N \geq 3$, the numerical method* (9) *does not admit a spatially uniform, spurious fixed point.*

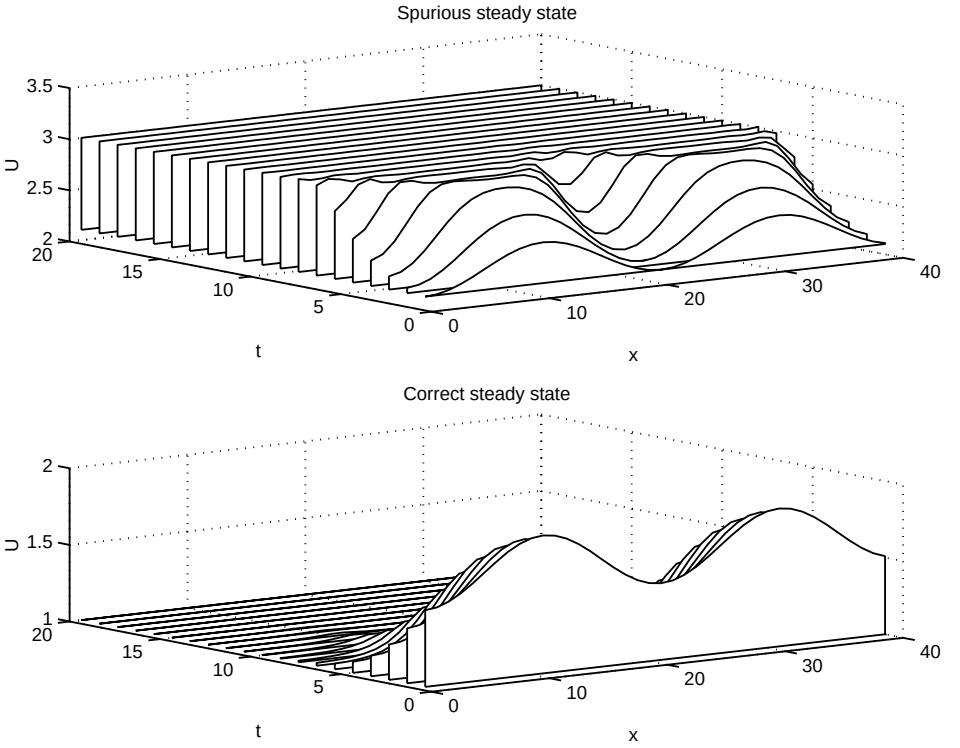

FIG. 2. *Spurious and correct steady states for the PIVP.*

Proof. If $\beta\mathbf{e}$ is a SUFP, then

$$(1-\theta)S(\beta\mathbf{e}) + \theta S\left(\beta\mathbf{e} + \frac{\Delta t}{2\theta}S(\beta\mathbf{e})\right) = 0. \tag{27}$$

From the form of S in (6), considering the jth component of (27), where $j > 2$ leads to the condition

$$(1-\theta)g(\beta) + \theta g\left(\beta + \frac{\Delta t}{2\theta}g(\beta)\right) = 0. \tag{28}$$

This shows that β must be a fixed point for the RK(θ) method applied to the underlying scalar ODE. Now, taking the second component in (27) and using (28) gives

$$u^0 - \beta = 0. \tag{29}$$

Finally, using (28) and (29) in the first component of (27) shows that

$$\frac{a\Delta t}{2\Delta x}g(\beta) = 0.$$

Hence, $g(\beta) = 0$, and the fixed point is not spurious. ∎

From the proof of Theorem 3.3 it is clear that if β is a spurious fixed point for the RK(θ) method applied to the underlying scalar ODE, then $\beta\mathbf{e}$ satisfies the conditions required for a fixed point on the IBVP problem, except near the boundary $j = 0$. We will see in the next section that it is possible for the method to settle to a fixed point that is close to β except near the left-hand boundary.

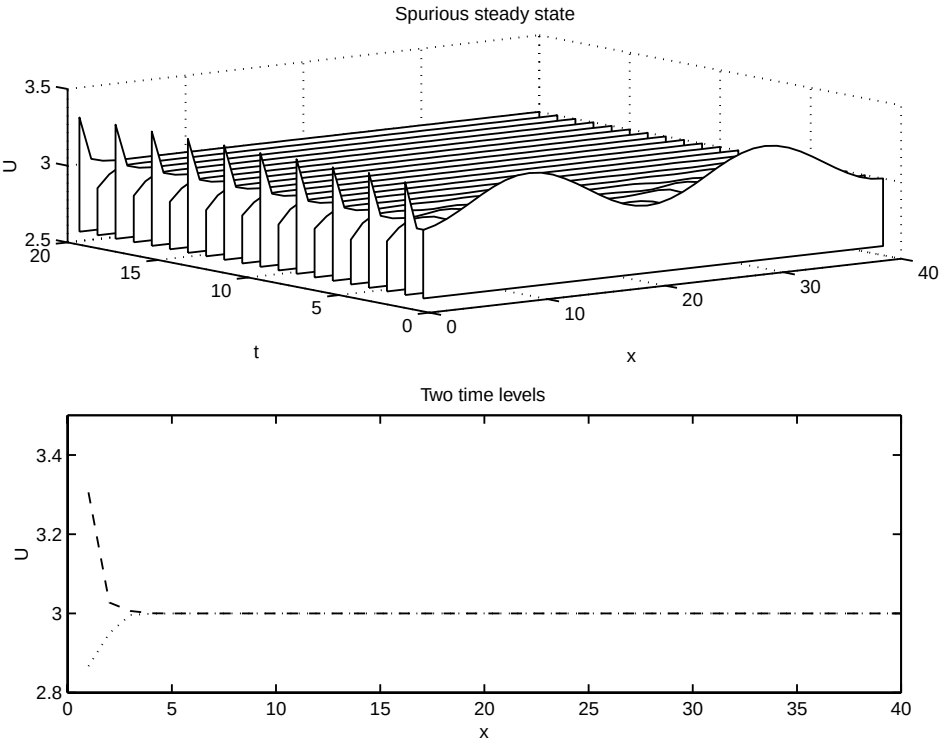

FIG. 3. *Spurious nonuniform steady state for the IBVP.*

3.4. Numerical examples and further analysis. We now present some numerical results. All computations used $a = 1$ in (2) and $\theta = 1$ in (9). We begin by illustrating that stable spurious and stable correct fixed points may coexist. Figure 2 shows the first 20 time-levels for the PIVP using $\Delta x = 1/N = 1/40$, $\Delta t = 0.1\Delta x$ and with $\alpha = 400$ in the logistic source term (3). This gives $r = 1$ and $c = 0.1$, and we see from the top right-hand picture in Figure 1 that the fixed points $\mathbf{U} = \beta\mathbf{e}$ with $\beta = \beta_{\text{corr}} := 1$ (correct) and $\beta = \beta_{\text{spur}} := 1 + 2/r = 3$ (spurious) are stable. The upper picture in Figure 2 was generated using initial data $u(x,0) = 0.7\beta_{\text{spur}} + 0.4\sin(2\pi x)^2$, and the solution is attracted to the spurious level. The lower picture used $u(x,0) = 0.5\beta_{\text{spur}} + 0.4\sin(2\pi x)^2$, which is seen to be in the basin of attraction of the true fixed point.

The upper picture in Figure 3 gives the result when the same parameter values as above are used on the IBVP with initial data $u(x,0) = \beta_{\text{spur}} + 0.3\sin(2\pi x)^2$ and a boundary condition of $u^0 = \beta_{\text{spur}}$. In this case, most components have settled close to the spurious level β_{spur}, but there are oscillations at the left-hand boundary. (For clarity, the boundary value is not plotted.) The overall solution is period two in time. The lower picture in Figure 3 gives the two profiles between which the solution oscillates. Note that Theorem 3.3 shows that a spatially uniform spurious fixed point cannot be computed for the IBVP.

In the course of our experiments, we found that, on both the IBVP and PIVP, it was common for the solution to settle down to a stable steady state that consisted of disjoint "locally uniform" patches that mix together spurious and correct levels. Figure 4 gives an example. This stable steady state arose on the PIVP with the same

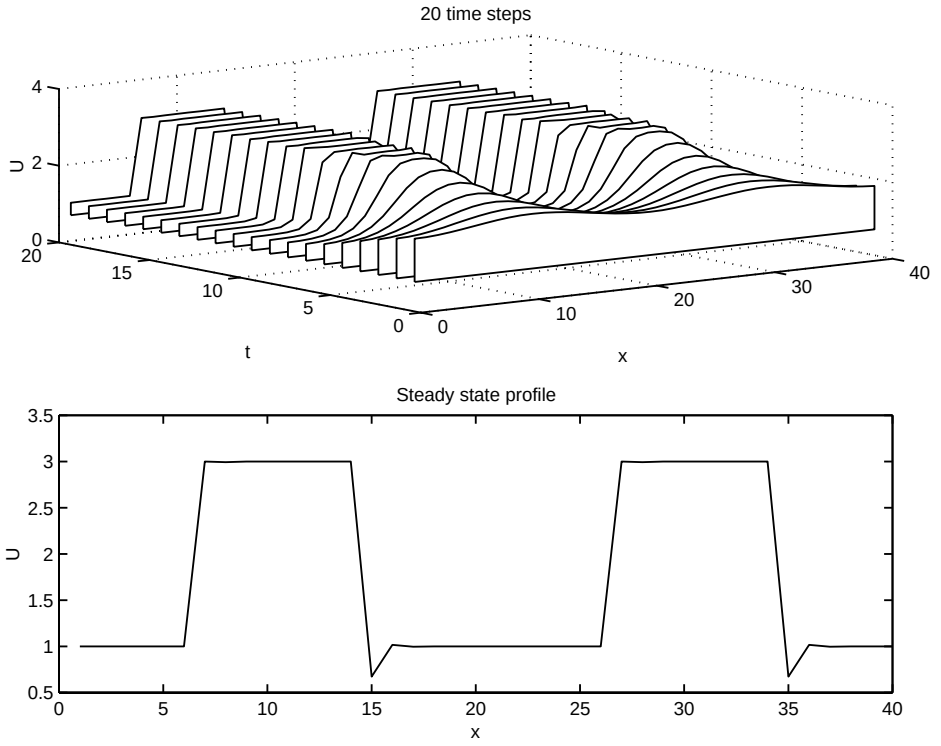

FIG. 4. *Stable steady state with jumps.*

parameters as above; we simply changed the initial condition to $u(x,0) = 0.6\beta_{\text{spur}} + 0.3\sin(2\pi x)^2$. In this example, some initial data has been attracted to the spurious level β_{spur} and some to the correct level β_{corr}. The lower picture in Figure 4 gives the profile of the steady state.

The profile shown in Figure 4 can be analyzed further, as follows. Writing the map (9) as $\mathbf{U}^{n+1} = G(\mathbf{U}^n)$, a fixed point must satisfy $\mathbf{U} = G(\mathbf{U})$, which reduces to a set of scalar equations for the components:

$$-\frac{a}{\Delta x}[U_j - U_{j-1}] + \frac{a^2\Delta t}{2\Delta x^2}[U_j - 2U_{j-1} + U_{j-2}] - \frac{a\Delta t}{2\Delta x}[g(U_j) - g(U_{j-1})] + g\left(U_j - \frac{a\Delta t}{2\Delta x}(U_j - U_{j-1}) + \frac{\Delta t}{2}g(U_j)\right) = 0,$$

for $j = 2, 3, \ldots$. Hence, the sequence $\{U_j\}_{j=0}^N$ satisfies a two-step recurrence that we may write as

$$q(U_{j-2}, U_{j-1}, U_j) = 0. \tag{30}$$

Note that as an equation for U_j (given U_{j-2} and U_{j-1}), (30) is implicit. On the other hand, if we regard (30) as an equation for U_{j-2} (given U_j and U_{j-1}), then the map is explicit.

With the logistic source term, to explain the upward jumps in Figure 4 we look for a solution sequence for (30) of the form

$$\ldots, 1, 1, 1 + \frac{2}{r} + c^2 V_0, 1 + \frac{2}{r} + c^2 V_1, 1 + \frac{2}{r} + c^2 V_2, \ldots. \tag{31}$$

Since $q(1,1,1+2/r)=0$, we take $V_0=0$. The equation $q(1,1+2/r,1+\frac{2}{r}+c^2V_1)=0$ has a solution $V_1=-2/(r^2(r+2))+O(c)$. Generally, assuming that the $\{V_j\}$ are small and linearizing produces the relation

$$V_j\,(r+2+c)\,(r-c)+2cV_{j-1}\,(1+c)-c^2V_{j-2}=0. \tag{32}$$

The characteristic polynomial of this recurrence has roots $-c/(r-c)$ and $c/(r+2+c)$. Since $r>0$ and $c>0$, it follows that $V_j\to 0$ as $j\to\infty$ in (32) if $r>c$, with very rapid convergence when $r\gg c$.

Next we look for a downward jump solution of the form

$$\ldots,1+\frac{2}{r},1+\frac{2}{r},1+V_0,1+V_1,1+V_2,\ldots. \tag{33}$$

Setting $q(1+2/r,1+2/r,1+V_0)=0$ gives the quadratic

$$V_0^2r^2+V_0^2r\,(r+c-2)-4c.$$

We will take the smaller root, for which $V_0=\frac{4c}{r(r-2)}+O(c^2)$. Linearizing $q(1+2/r,1+V_0,1+V_1)$ gives

$$V_1\approx 2c\frac{r^2V_0+rcV_0-c-V_0r}{(r+c-2)\,r\,(r+rcV_0+c)}.$$

Generally, linearizing the equation $g(1+V_{j-2},1+V_{j-1},1+Vj)=0$ gives the recurrence

$$V_j\,(r+c)\,(r+c-2)-2cV_{j-1}\,(c-1+r)+c^2V_{j-2}=0, \tag{34}$$

whose characteristic polynomial has the roots $c/(r+c),c/(r+c-2)$. It follows that a sufficient condition for $V_j\to 0$ as $j\to\infty$ in (34) is $r<2-c$.

The existence of the c^2 factor in the sequence (31) suggests that upward jumps settle to the new level more rapidly than downward jumps. This agrees with the profile in Figure 4.

Next, we show that for small c it is generic to have steady states profiles of the type pictured in Figure 4, that is, profiles that jump between levels, with each level corresponding to a stable (correct or spurious) fixed point for the RK map on the underlying scalar ODE. Note that this result formalizes an argument given in [4].

THEOREM 3.4. *Suppose $g\in C^1$. Regard Δt and Δx as fixed and allow $c=a\Delta t/\Delta x$ to vary. Suppose $\mathbf{U}^*\in\mathbb{R}^N$ is such that every component of $\mathbf{U}^*$ is a stable (correct or spurious) fixed point of the RK(θ) method on the underlying scalar ODE* (4). *Then there exists $c^*>0$ such that for all $0\le c\le c^*$ there is a stable fixed point $\mathbf{U}=\mathbf{U}(c)$ of the RK method on the PIVP* (6), *where $\mathbf{U}(c)$ depends continuously upon c and $\mathbf{U}(0)=\mathbf{U}^*$.*

Proof. Write the RK method on the PIVP (6) as

$$\mathbf{U}^{n+1}=\mathbf{U}^n+\Delta tH(c,U^n). \tag{35}$$

We know that $H(0,\mathbf{U}^*)=0$. At $c=0$ the map (35) uncouples; the Jacobian $\partial H(0,\mathbf{U})/\partial\mathbf{U}$ is diagonal. Since each component of $\mathbf{U}^*$ represents a *stable* fixed point on the underlying scalar ODE, we have

$$\left|1+\Delta t\left(\frac{\partial H(0,\mathbf{U}^*)}{\partial\mathbf{U}}\right)_{i,i}\right|<1,\quad 0\le i\le N.$$

It follows that each element on the diagonal of $\partial H(0, \mathbf{U}^*)/\partial \mathbf{U}$ is nonzero, and hence, the Jacobian is nonsingular. The implicit function theorem may therefore be invoked, to show that there exists $c^* > 0$ such that for all $0 \le c \le c^*$ there is a solution $\mathbf{U}(c)$ of the nonlinear system $H(c, \mathbf{U}(c)) = 0$, where $\mathbf{U}(c)$ depends continuously upon c and $\mathbf{U}(0) = \mathbf{U}^*$. Since the eigenvalues of a matrix depend continuously upon its entries, it follows that by further reduction of c^*, if necessary, we can ensure that the eigenvalues of $I + \Delta t \partial H(c, \mathbf{U}(c))/\partial \mathbf{U}$ remain inside the unit disc for all $0 \le c \le c^*$. □

4. Nonnormality in the IBVP. We now describe a type of spurious behavior that arises on the IBVP in the presence of finite precision and nonnormality. The effect is linear, in the sense that the same behavior can be seen when the logistic source term is replaced by $\alpha(1 - u)$.

Figure 5 shows the results of a computation on the IBVP with the logistic source term (3) using $\alpha = 400$, $\Delta x = 1/N = 1/40$, and $\Delta t = .97\Delta t_{\lim}$. Here, $\Delta t_{\lim} := 2\Delta x/(1 + \alpha \Delta x)$ is the eigenvalue stability limit, that is, the time-step beyond which the correct steady state $\mathbf{U}^n = \mathbf{e}$ becomes linearly unstable. We took $u(x, 0) = 1 + 10^{-8}$ for the initial data and $u^0 = 1$ as the boundary condition. The upper picture in Figure 5 shows the solution evolving over the first 120 time-steps (with every fourth time level plotted). In this regime, small oscillations are growing in magnitude and moving to the right. The lower picture in Figure 5 shows time-levels $n = 4010$ to $n = 4040$. This illustrates the typical long-term behavior: there are $O(1)$ oscillations around the right-hand boundary that persist for all time.

This type of behavior arises only when (a) the time step is chosen near the linear stability limit, and (b) the initial data and boundary condition are close to the true steady state. In such circumstances the numerical solution was observed either to blow up or tend to a state of the type illustrated in Figure 5.

Spurious behavior of this form was first described on a slightly different model PDE in [9], and the following simple argument explains the broad details.

After linearizing the problem, the iteration (9) has the form $\mathbf{E}^{n+1} = B\mathbf{E}^n$, where $\mathbf{E}^n = \mathbf{U}^n - \mathbf{e}$ and $B = G'(\mathbf{e})$. The matrix B has a spectral radius of .94, and hence, in exact arithmetic we have $\mathbf{E}^n \to 0$ as $n \to \infty$. However, in the presence of rounding errors the appropriate model is $\mathbf{E}^{n+1} = \widehat{B}^n \mathbf{E}^n$, where $\widehat{B}^n$ is a perturbation of B. In our case, B is highly nonnormal and so the eigenvalues of $\widehat{B}^n$ may be very different from those of B. If $\widehat{B}^n$ has an eigenvalue close to the boundary of the unit disc, then $\mathbf{E}^n$ will not decay, and hence, $\mathbf{U}^n$ will not approach the steady state $\mathbf{e}$. In our example B has a single eigenvalue .94, but there is a perturbation of Euclidean norm 10^{-15} that produces an eigenvalue with real part beyond +1. What we observe in the lower picture in Figure 5 are *pseudoeigenvectors* of B; that is, eigenvectors of perturbed matrices $\widehat{B}^n$.

5. Adaptivity. So far, we have analyzed a finite difference scheme on a uniform grid. In this section we ask whether adaption in either space or time is inimical to spuriosity.

5.1. Adaptivity in space. First, we consider a "static" spatial equidistribution algorithm of the type described in [2, 22]. The algorithm proceeds as follows. Suppose that at time-level n we have an approximation $\mathbf{U}^n$ on a spatial mesh given by $\Delta x_i^n := x_{i+1}^n - x_i^n$. Then the finite difference scheme (9) (with appropriate modifications of the spatial differences to accommodate the nonuniform mesh) is used to produce an

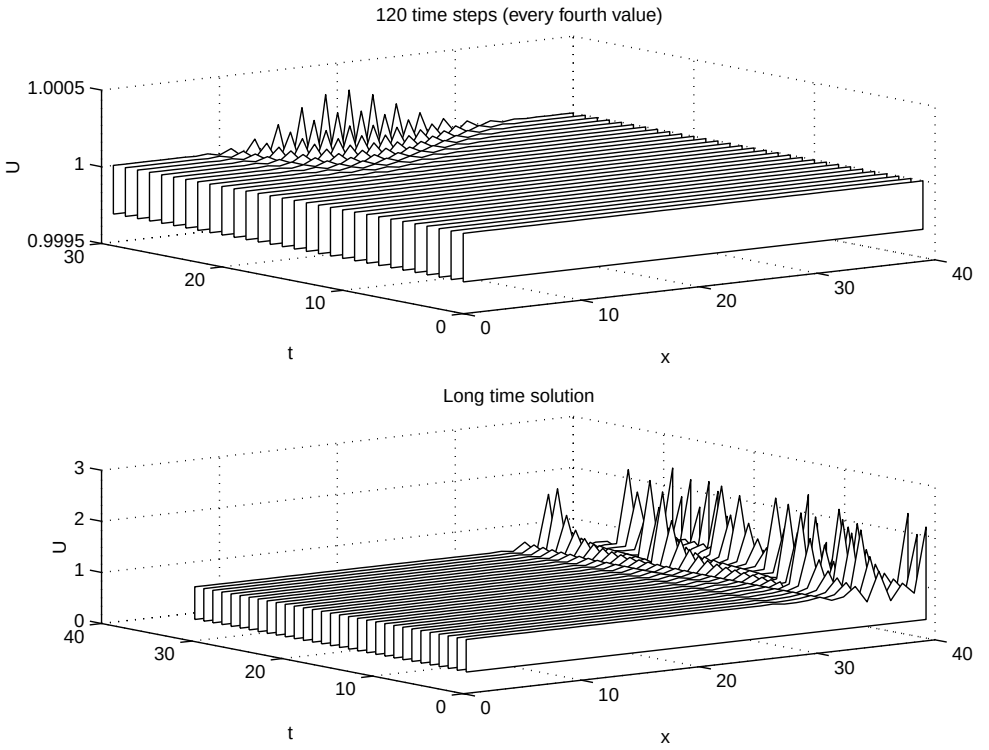

FIG. 5. *Spurious long-term behavior on the IBVP caused by nonnormality.*

approximation $\widehat{\mathbf{U}}^{n+1}$ at time-level $n+1$. We then form the weights

$$w_i^{n+1} := \sqrt{1 - \mu + \mu(d_i^{n+1})^2},$$

which involve the gradient approximations

$$d_i^{n+1} := \frac{\widehat{U}_{j+1}^{n+1} - \widehat{U}_j^{n+1}}{\Delta x_i^n}$$

and the parameter $\mu \in [0, 1]$. The new mesh $\{\Delta x_i^{n+1}\}$ is found by setting $w_i \Delta x_i^{n+1}$ equal for all i. This represents a linear system to be solved for the new mesh. The final numerical solution $\mathbf{U}^{n+1}$ is obtained by piecewise cubic interpolation from the original data $\{x_i^n, \widehat{\mathbf{U}}^{n+1}\}$ to the new mesh $\{x_i^{n+1}\}$. The motivation for this algorithm is that the weights measure the "sharpness" of the solution, and so the sharpness per unit interval is fixed. In this way, the algorithm aims to place more meshpoints in regions of x where there is rapid spatial change in the solution. The choice $\mu = \frac{1}{2}$ equidistributes a discretization of the arclength, while $\mu = 0$ gives a uniform mesh.

In experimenting with this algorithm, we fixed $a = 1$ and at each time-level chose a value $0.1 \min_i\{\Delta x_i^n\}$ for the time-step. In this way the Courant number is bounded above by 0.1.

It is immediately clear that the equidistribution algorithm described above cannot eliminate spatially uniform, spurious fixed points. (Inserting a SUFP $\mathbf{U}^n = \beta\mathbf{e}$, with $\Delta x_i^n \equiv 1/N$, we see that the solution, the spatial mesh, and the time-step are

unchanged at the next time-level.) Analyzing the *stability* of such a fixed point is a complicated process, since the solution, the spatial mesh, and the time-step may be perturbed. Also, the stability potentially depends upon the fine-details of the algorithm, such as the choice of μ and the type of interpolation process used.

In our tests, we found that some of the spatially uniform spurious fixed points that we identified for a fixed spatial mesh in section 3.2 were stable as solutions for the equidistribution algorithm. Hence, the algorithm can be made to compute spurious fixed points. However, because of the Courant number control, this behavior only arose when the initial data was close to the uniform spurious level. For other types of initial data, spatial variation of the solution caused a reduction in $\min_i\{\Delta x_i^n\}$, and hence, in the time-step, and this in turn forced the numerical solution away from the spurious level.

We also found, as we intuitively expected, that the equidistribution algorithm eliminated spurious solutions with "jumps" of the form illustrated in Figures 3 and 4.

In summary, although the spatial mesh movement offered an improvement, it did not completely eliminate the potential for spatially uniform spurious fixed points.

5.2. Adaptivity in time. We now consider adaptation of the time-step as a means to eliminate spurious behavior. In the context of ODE solvers, this issue has been looked at in [1], and positive results have been obtained about the benefit of error control.

We will analyze the standard approach of using an embedded pair of formulas for the system (6). We assume that the spatial mesh remains uniform. The second order RK formula in (9) is coupled with Euler's method, which is first order, to give

$$\mathbf{U}^{n+1} = \mathbf{U}^n + \Delta t^n \left[(1-\theta) S(\mathbf{U}^n) + \theta S\left(\mathbf{U}^n + \frac{\Delta t^n}{2\theta} S(\mathbf{U}^n) \right) \right], \tag{36}$$

$$\mathbf{U}_{\mathrm{E}}^{n+1} = \mathbf{U}^n + \Delta t^n S(\mathbf{U}^n). \tag{37}$$

The secondary formula (37) is used only in the estimation of the error and selection of a new time-step.

The step is regarded as acceptable if

$$\frac{\| \mathbf{U}^{n+1} - \mathbf{U}_{\mathrm{E}}^{n+1} \|_\infty}{\Delta t^n} \le \tau, \tag{38}$$

where $\tau > 0$ is the error tolerance. If the error criterion (38) is not satisfied, then the step is retaken with a smaller Δt^n. The details of how the time-step is altered after successful or rejected steps will not affect our conclusions. Also, we mention that changing the norm in (38) or using the error-per-step alternative $\| \mathbf{U}^{n+1} - \mathbf{U}_{\mathrm{E}}^{n+1} \|_\infty \le \tau$ would not impact the results greatly.

We first prove a result that holds when the RK pair (36)–(37) is used to solve a general ODE system. We show that any fixed point cannot be genuinely spurious, in the sense that the residual is bounded by the error tolerance.

LEMMA 5.1. *Suppose that the pair* (36)–(37) *subject to the error criterion* (38) *is used to solve a general ODE system* $\mathbf{U}_t = S(\mathbf{U})$. *If* $\mathbf{U}^n = \mathbf{U}^{n+1} = \mathbf{U}^*$, *then* $\| S(\mathbf{U}^*) \|_\infty \le \tau$.

Proof. If $\mathbf{U}^n = \mathbf{U}^{n+1} = \mathbf{U}^*$, then from (36)

$$S(\mathbf{U}^*) = \theta \left[S(\mathbf{U}^*) - S\left(\mathbf{U}^* + \frac{\Delta t^n}{2\theta} S(\mathbf{U}^*) \right) \right]. \tag{39}$$

However, the error criterion (38) ensures that

$$\left\| \theta \left[S(\mathbf{U}^*) - S\left(\mathbf{U}^* + \frac{\Delta t^n}{2\theta} S(\mathbf{U}^*) \right) \right] \right\|_\infty \leq \tau. \tag{40}$$

Combining (39) and (40) gives the result. □

This result is closely related to those proved for regular RK pairs in [8]. In fact, (36)–(37) is a very special case of a regular pair and the result is therefore stronger than those in [8]. (In particular the residual bound does not involve a Lipschitz constant of S.)

Lemma 5.1 translates immediately into a result about SUFPs of the PIVP. However, the following result is more widely applicable.

THEOREM 5.2. *Suppose that the pair* (36)–(37) *subject to the error criterion* (38) *is used for either the IBVP or PIVP. If, for some* $j \geq 2$, $U_{j-1}^n = U_j^n = U_j^{n+1} = \beta$, *then* $|g(\beta)| \leq \tau$.

Proof. Since $U_j^{n+1} = U_j^n$, we have

$$(1-\theta) S(\mathbf{U}^n)_j + \theta S\left(\mathbf{U}^n + \frac{\Delta t^n}{2\theta} S(\mathbf{U}^n) \right)_j = 0.$$

Hence,

$$S(\mathbf{U}^n)_j = \theta \left[S(\mathbf{U}^n)_j + S\left(\mathbf{U}^n + \frac{\Delta t^n}{2\theta} S(\mathbf{U}^n) \right)_j \right].$$

So the error criterion (38) ensures that

$$| S(\mathbf{U}^n)_j | \leq \tau. \tag{41}$$

Since $U_j^n = U_{j-1}^n = \beta$ and $j \geq 2$, using the form of S we find

$$S(\mathbf{U}^n)_j = g(\beta). \tag{42}$$

The result follows from (41) and (42). □

Note that this result requires only a very weak type of spatial uniformity and spuriosity: a single component must be constant locally across space and time. Hence, in addition to ruling out SUFPs on the PIVP, this type of error control is also guaranteed to eliminate "jagged" spurious fixed points of the type illustrated in Figure 4.

In our experiments with the tolerance set to $\tau = \Delta x$, no spurious fixed points were encountered.

We remark that the design of error control strategies for time-dependent PDEs involves many considerations, in particular with regard to the balance of spatial and temporal errors. Theorem 5.2 illustrates that a simple ODE-based approach offers immediate advantages from a spuriosity perspective. We are currently investigating the use of more sophisticated adaptive procedures.

6. Nonlinear flux. We briefly discuss how the results obtained in the previous sections extend to the more general conservation law (1) with nonlinear flux. The semidiscrete system (6) takes the form

$$\mathbf{U}_t = -\tfrac{1}{\Delta x} A\, \mathbf{f}(\mathbf{U}) + \mathbf{g}(\mathbf{U}) + \tfrac{1}{\Delta x} \mathbf{b},$$

where $\mathbf{f}(\mathbf{U})_j = f(U_j)$. The matrix A given by (7) or (8) is based on upwind differencing and it is therefore appropriate to assume that

$$\infty > f'(u) \geq a > 0.$$

The assumption that $f'(u)$ is bounded strictly away from zero is imposed to avoid degeneracy at fixed points β, where $f'(\beta) = 0$. The results of section 2 on existence of SUFPs may then be generalized by replacing g by the composition $ag \circ f^{-1}$ (so that g' becomes ag'/f').

The Jacobian of the fully discrete system may, in this more general setting, be defined by

$$G'(\beta\mathbf{e}) = I + \Delta t\left((1-\theta)F'(\beta) + \theta F'(z)\right) + \frac{1}{2}\Delta t^2 F'(\beta)F'(z),$$

where $F'(u) = g'(u)I - (1/\Delta x)f'(u)A$. This reduces to (16) when $f(u) = au$. Our main stability result, Theorem 3.2, then extends naturally and the condition (24) is replaced by

$$\Delta x^m < \frac{\lambda f'(z)}{g'(z)}.$$

7. Summary. This work concerns spurious behavior of finite difference schemes, with emphasis on the new features that arise on moving from an ODE to a hyperbolic PDE model.

For the case of uniform meshes, the main results may be summarized as follows:

- Theorem 3.2 for the PIVP shows that, unlike in the ODE case, as the mesh is refined in a natural manner, spatially uniform spurious fixed points are generically unstable.
- The computations and analysis in section 3.4 show that nonuniform spurious fixed points arise naturally. In particular, Theorem 3.4 and the accompanying analysis highlights the existence of stable nonsmooth steady states that jump between levels.
- The discussion in section 4 shows how a different type of spurious solution arises on the IBVP, as a consequence of nonnormality. This behavior exists only in the presence of finite precision arithmetic.

Section 5 gives results for adaptive algorithms, where the mesh is varied to take account of the solution. An equidistribution algorithm for the spatial grid offers some help in the avoidance of spurious behavior but does not completely eliminate spatially uniform spurious fixed points. In the case of a standard ODE-based time-step control, Theorem 5.2 provides a rigorous bound on the level of spuriosity.

ON EFFICIENT SOLUTIONS TO THE CONTINUOUS SENSITIVITY EQUATION USING AUTOMATIC DIFFERENTIATION*

JEFF BORGGAARD† AND ARUN VERMA‡

Abstract. Shape sensitivity analysis is a tool that provides quantitative information about the influence of shape parameter changes on the solution of a partial differential equation (PDE). These shape sensitivities are described by a continuous sensitivity equation (CSE). Automatic differentiation (AD) can be used to perform this sensitivity analysis without writing any additional code to solve the sensitivity equation. The approximate solution of the PDE uses a spatial discretization (mesh) that often depends on the shape parameters. Therefore, the straightforward application of AD introduces derivatives of the mesh. There are two drawbacks to this approach. First, extra computational effort (especially memory) is used in these calculations due to mesh sensitivities. Second, this mesh sensitivity information needs to be computed in order to obtain accurate results. In this work, we provide a methodology that avoids mesh sensitivities (and their drawbacks) by defining a modified PDE on a fixed domain (i.e., independent of the shape parameter) such that AD provides the desired approximation of the CSE. Using two examples, we demonstrate significant improvement in the computational effort, both in terms of floating point operations and memory requirements. We explain how these code modifications can be applied to a wide variety of practical problems with minimal changes to the original code. These changes are negligible when compared to the complexity of writing a separate solver for the sensitivity equation.

1. Introduction.

Shape optimization problems frequently take the form of finding parameters that describe the shape of an object or a region in order to minimize a given design objective (such as weight or drag). In many practical situations, the behavior of *states* in the system can be modeled as the solution to a partial differential equation (PDE). Calculating the dependence of the state solution on these shape design parameters (the so-called *state sensitivity*) is of interest to design engineers who want to gain more insight into their problem. Furthermore, these sensitivity variables can be used to evaluate the gradient of the objective function (and other constraint functions) at a given design, which can be readily coupled with an optimization algorithm in an attempt to find the optimal parameter values.

The state sensitivity variables satisfy the continuous sensitivity equation (CSE), which can be derived formally by implicit differentiation of the state PDE and the corresponding boundary conditions [4]. This sensitivity equation is always *linear* and *shares structure* with the state PDE. In particular, these coupled PDEs share the same linearization and boundary condition type (Dirichlet, Neumann, etc.). Nearly all problems of interest require numerical techniques in order to approximate the

solutions to these equations. Because these equations share the same structure, many computations which would be used to solve the state PDE alone can be reused in the solution of the sensitivity equation. Thus, obtaining the sensitivity variables can be performed for a fraction of the cost of computing the state variables.

In many cases, the software to solve the state PDE is already available, representing years of development and testing. This software needs to be modified in order to solve the coupled system. This is often impractical for a variety of reasons. Design engineers are often not experts on the simulation software, which may contain "legacy code" (where the software developer is no longer available to consult on code modifications) or "spaghetti code" (where the structure of the code is fragile or poor), making the necessary modification very difficult. In addition, the resources required to modify and debug an existing code may not be available. Automatic differentiation (AD) tools have been developed to simplify this process as they read in the original code and produce new software to solve for the state and sensitivity variables simultaneously [1, 17].

We point out that we have alluded to two fundamentally different approaches for computing the sensitivity variables. In the first, we derive the sensitivity equation and then apply solution techniques, i.e., we *differentiate-then-approximate*. In the second, we consider the traditional application of automatic differentiation. Essentially, we *approximate-then-differentiate* the state PDE. The operations of differentiation and approximation commute in many situations. For example, this fact is often exploited when developing algorithms for nonlinear problems [18]. However, when the shape of the boundary is parameter dependent, the discretization of the domain (finite difference mesh points, finite element nodes, etc.) depends upon these parameters. Derivatives of these discretization quantities, the so-called *mesh sensitivities*, appear when using the approximate-then-differentiate approach; however, they do not arise when differentiation occurs first. The result is that traditional application of AD in these problems introduces a number of "chain-rule"-like terms that contain the mesh sensitivities. Not only is there an increased overhead in calculating the mesh sensitivities themselves, but computing all of the additional terms that contain them adds significant computational effort. Some related issues in the ODE setting are discussed in [14].

Recent studies in the use of AD [11] have shown that the exploitation of the structure of the underlying algorithms can greatly enhance the performance of these tools and produce, in certain instances, code that approaches the performance of hand-coded algorithms. This requires that the design engineer expose the structure of the problem to the AD tools, and this may require minor code modifications. Finding ways to exploit the algorithm structure is currently an area of active research [11, 9, 10, 21].

In this work, we present a technique for exploiting structure at the problem level rather than at the algorithm level. This technique usually requires only minor code modification, specifically in how the boundary conditions and forcing functions are implemented. The modification is performed *before* handing the software over to AD tools. These changes essentially lead to approximating the CSE and avoid altogether the mesh derivatives and the chain-rule terms which contain them. The result is improved efficiency and a substantial reduction in memory requirements for the final differentiated code. Furthermore, eliminating mesh derivatives allows straightforward coupling of this technique with any adaptive mesh refinement strategy, a useful feature in automatic design optimization algorithms [5, 6, 8].

The remainder of this work is organized as follows. In the next section, we provide background on different techniques for computing the state sensitivities and the relationships between them. To facilitate this discussion, we introduce two example problems. The first is a nonlinear two-point boundary value problem solved by a finite element method and the second is the Laplace equation in two-dimensional coordinates solved by a finite difference method. These allow us to describe our present AD methodology in section 3. In section 4, this methodology is applied and the results demonstrate its effectiveness on these example problems. Finally, we present our conclusions and extensions in section 5.

2. Background.

2.1. Example: Nonlinear two-point boundary value problem. As our first example, we consider a nonlinear two-point boundary value problem in the interval $(0, a)$, $a > 1$,

$$\mathcal{A}_a(u(x;a)) \equiv \frac{\partial^2}{\partial x^2} u(x;a) + \frac{1}{8}\left[\frac{\partial}{\partial x} u(x;a)\right]^3 = 0 \tag{1}$$

with boundary conditions

$$u(x=0;a) = 0 \qquad \text{and} \qquad u(x=a;a) = 4.$$

The subscript on $\mathcal{A}_a$ indicates dependence of the operator on the parameter a, which occurs either through the boundary conditions or, by introducing a mapping function, through variable coefficients in the mapped operator (the operator obtained by mapping the problem to a fixed domain, e.g., (0,1) [7]).

This example was used in [7, 19] since it has sufficient complexity (nonlinear with a parameter-dependent domain) as well as a closed form solution:

$$u_{\text{ex}}(x;a) = 4\sqrt{x + \frac{(a-1)^2}{4}} - 2(a-1).$$

CSE. We define the state sensitivity for the problem (1) to be $s = \frac{\partial u}{\partial a}$. This quantity describes the behavior of the solution as the right end point (parameterized by a) is changed. As shown in [7], s solves the CSE

$$\mathcal{L}_a(u)s \equiv \frac{\partial^2}{\partial x^2} s(x;a) + \frac{3}{8}\left[\frac{\partial}{\partial x} u(x;a)\right]^2 s(x;a) = 0 \tag{2}$$

with boundary conditions

$$s(x=0;a) = 0 \qquad \text{and} \qquad s(x=a;a) = -\frac{\partial}{\partial x} u(x=a;a).$$

The term $\mathcal{L}_a(u)s$ is the linearization of $\mathcal{A}_a$ at u applied to s.

Boundary conditions for (2) are derived by setting the total (or material) derivative of u with respect to a to zero,

$$\frac{Du}{Da}(x;a) = \frac{\partial u}{\partial a}(x;a) + \frac{\partial u}{\partial x}(x;a)\Pi_a(x;a) = s(x;a) + \frac{\partial u}{\partial x}(x;a)\Pi_a(x;a) = 0,$$

where Π_a represents the derivative of the spatial location with respect to a. This term arises since the location where the boundary condition is evaluated is parameter dependent. For this problem $\Pi_a(x = 0; a) = 0$ and $\Pi_a(x = a; a) = 1$, leading to the boundary conditions in (2). An important observation is that Π_a only needs to be defined and evaluated on the boundary. Since we specify the parameterization of the shape, this quantity is well defined. It can be verified that differentiating u_{ex} with respect to a provides a closed form solution to (2) and satisfies the boundary conditions (using u_{ex}).

Note that the sensitivity equation is a linear PDE. For the case above where $\mathcal{A}_a$ is nonlinear, this equation requires the solution u in order to define $\mathcal{L}_a$. Additionally, for shape sensitivity problems ($\Pi_a \neq 0$), u is required to compute the boundary conditions. Therefore, the solution to (1) needs to be obtained *before* the sensitivity equation can be solved.

Finite element algorithm. To illustrate our AD methodology in section 3, we consider a finite element approximation to the above equations. The domain $(0, a)$ is subdivided into N elements which allow for either a piecewise linear or piecewise quadratic representation of the solution. The standard Galerkin procedure leads to a system of nonlinear algebraic equations which are solved using Newton's method. Convergence is declared when the ℓ_2-norm of the residual drops below 10^{-8}. Note that (1) and (2) share the same linearization and boundary condition types. Therefore, using a Newton method to solve the nonlinear finite element system for (1) produces the same system matrix as the finite element solution for (2) (using the previous iterate for u). The solution to the second linear system can be performed efficiently by solving the Newton system with an LU factorization and reusing this factorization to solve the second system. However, there are often computational advantages in using other linear system solvers, such as the conjugate gradient method. Thus, in many cases, code modifications to solve both linear systems may not be able to take advantage of this structure.

These algorithms are implemented in MATLAB. In particular, the Jacobian matrix is stored in the `sparse` data structure in order to minimize storage and CPU requirements. MATLAB vectorization is used in the Jacobian build to create a faster code. MATLAB features such as the sparse data structures and vectorization are exploited in the AD tools.

2.2. Example: Laplace equation in two dimensions. This example features the finite difference solution to Laplace's equation in a parameter-dependent region. The region resembles a unit square with the exception of the bottom edge, which is a multiple of the sine function (see Figure 1). Thus, we define the parameter-dependent portion of the boundary by the parametric curve

$$\Gamma_a = \{(x, a\sin(\pi x)) \mid x \in (0, 1)\}.$$

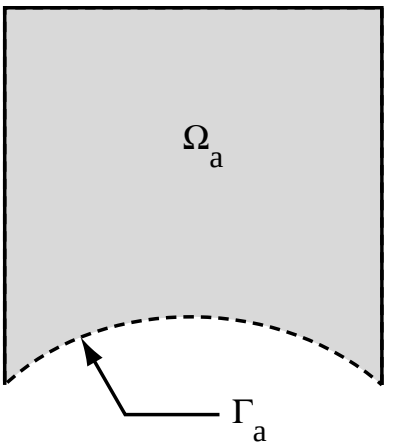

FIG. 1. *Parameter-dependent region.*

Let $\mathcal{A}_a : \mathrm{H}^1(\Omega_a) \to \mathrm{H}^{-1}(\Omega_a)$ be the Laplacian operator, $f \in \mathrm{H}^{-1}(\Omega_a)$ be a prescribed forcing function, and u be the solution to

$$\mathcal{A}_a(u(x,y;a)) \equiv \frac{\partial^2}{\partial x^2}u(x,y;a) + \frac{\partial^2}{\partial y^2}u(x,y;a) = f(x,y;a) \tag{3}$$

subject to

$$\begin{aligned} u(x=0,y;a) = u(x=1,y;a) &= 0, && y \in (0,1), \\ u(x,y=1;a) &= 0, && x \in (0,1), \quad \text{and} \\ u(x,y=a\sin(\pi x);a) &= \sin(\pi x) && x \in (0,1). \end{aligned}$$

Note that although $\mathcal{A}_a$ is linear, we use the notation $\mathcal{A}_a(u)$ to parallel the example in the previous section.

For this example, we define the function f such that u has the closed form solution

$$u_{\mathrm{ex}}(x,y;a) = \frac{1-y}{1-a\sin(\pi x)}\sin(\pi x).$$

Thus, f will be a nontrivial function of a in this example.

CSE. The CSE, which describes the state sensitivity, can be derived by performing implicit differentiation of (3) with respect to a and interchanging orders of differentiation (assuming necessary smoothness). We make an additional assumption that $\frac{\partial f}{\partial a} \in \mathrm{H}^{-1}(\Omega_a)$ so that the solution s has the same regularity as u (as we effectively solve this equation with the same approximation scheme as problem (3)).

$$\mathcal{L}_a(u)s(x,y;a) \equiv \frac{\partial^2}{\partial x^2}s(x,y;a) + \frac{\partial^2}{\partial y^2}s(x,y;a) = \frac{\partial}{\partial a}f(x,y;a) \tag{4}$$

subject to

$$\begin{aligned} s(0,y;a) = s(1,y;a) &= 0, && y \in (0,1), \\ s(x,1;a) &= 0, && x \in (0,1), \end{aligned}$$

and

$$s(x, y = a\sin(\pi x); a) = -\frac{\partial}{\partial y}u(x, y = a\sin(\pi x); a)\Pi_a(x, y = a\sin(\pi x); a), \quad x \in (0,1).$$

For this example, the function describing the influence of the parameter on the boundary, Π_a, is trivial on all sides except for Γ_a. On this side, $\Pi_a(x, y = a\sin(\pi x); a) = \sin(\pi x)$ and appears in the boundary condition above.

Note that $\mathcal{L}_a$ is a differential operator which represents the linearization of $\mathcal{A}_a$ with respect to u. As above, even though $\mathcal{A}_a$ is linear, we'll maintain this notation throughout the paper for easy generalization to nonlinear problems (as in section 2.1).

Finite difference algorithm. For purposes of applying finite differences to solve problem (3), we introduce the mapping $\mathcal{M}_a$, which is a bijection of the form

$$\mathcal{M}_a : \Omega_a \ni (x,y) \to (\xi,\eta) \in (0,1)\times(0,1) \equiv \tilde{\Omega}.$$

Transformation to the square simplifies the construction of high order difference stencils, which can now be set up on a lattice. This mapping procedure also covers the case where finite difference points are clustered in regions where more accurate differences are needed. To treat a wider class of problems with more irregularly shaped domains, domain decomposition can be used to create subdomains, each of which can be mapped in this way. In practice, algorithms for calculating this mapping may require the solution of another PDE [20].

The differential equation in Ω_a is then transformed to $\tilde{\Omega}$ by representing functions in the new coordinates, i.e.,

$$f(x,y;a) = \tilde{f}(\mathcal{M}_a(x,y;a);a) = \tilde{f}(\xi(x,y;a),\eta(x,y;a);a) = \tilde{f}(\xi,\eta;a),$$

and by replacing the differential operators in the obvious way, e.g.,

$$\frac{\partial u}{\partial x} = \frac{\partial \tilde{u}}{\partial \xi}\frac{\partial \xi}{\partial x} + \frac{\partial \tilde{u}}{\partial \eta}\frac{\partial \eta}{\partial x}.$$

Transforming problem (3) in this way leads to the equation

$$\tilde{\mathcal{A}}_a\left(\tilde{u}(\xi,\eta;a)\right) = \tilde{f}(\xi,\eta;a)$$

or

$$\begin{aligned} &\left(\left(\frac{\partial \xi}{\partial x}\right)^2 + \left(\frac{\partial \xi}{\partial y}\right)^2\right)\frac{\partial^2 \tilde{u}}{\partial \xi^2} + 2\left(\frac{\partial \xi}{\partial x}\frac{\partial \eta}{\partial x} + \frac{\partial \xi}{\partial y}\frac{\partial \eta}{\partial y}\right)\frac{\partial^2 \tilde{u}}{\partial \xi \partial \eta} + \left(\left(\frac{\partial \eta}{\partial x}\right)^2 + \left(\frac{\partial \eta}{\partial y}\right)^2\right)\frac{\partial^2 \tilde{u}}{\partial \eta^2} \\ &\qquad + \left(\frac{\partial^2 \xi}{\partial x^2} + \frac{\partial^2 \xi}{\partial y^2}\right)\frac{\partial \tilde{u}}{\partial \xi} + \left(\frac{\partial^2 \eta}{\partial x^2} + \frac{\partial^2 \eta}{\partial y^2}\right)\frac{\partial \tilde{u}}{\partial \eta} = f\left(\mathcal{M}_a^{-1}(\xi,\eta);a\right), \end{aligned} \tag{5}$$

subject to

$$\begin{aligned} \tilde{u}(\xi=0,\eta;a) = \tilde{u}(\xi=1,\eta;a) &= 0, && \eta \in (0,1), \\ \tilde{u}(\xi,\eta=1;a) &= 0, && \xi \in (0,1), \quad \text{and} \\ \tilde{u}(\xi,\eta=0;a) &= \sin\left(\pi \mathcal{M}_a^{-1}(\xi,\eta=0)\right), && \xi \in (0,1). \end{aligned}$$

Once the mapping is defined, the PDE in $\tilde{\Omega}$ can be readily approximated since finite difference approximations in $\tilde{\Omega}$ are performed on a lattice,

$$\frac{\partial \tilde{u}}{\partial \xi}(\xi,\eta;a) \approx \frac{u(\xi+\Delta\xi,\eta;a) - u(\xi-\Delta\xi,\eta;a)}{2\Delta\xi}, \text{ etc.}$$

A finite difference method is applied to (5) in the usual manner, considering second order central differences for all of the derivative terms. The resulting numerical approximation to the PDE in $\tilde{\Omega}$ is denoted by $\tilde{u}^N$, representing $\tilde{u}$ at the discrete points of the lattice. The finite difference approximation defines an algebraic equation

$$\tilde{A}_a(\tilde{u}^N) = \tilde{b}. \tag{6}$$

Note that $\tilde{b}$ contains point evaluations of the forcing function and the nonhomogeneous values of the boundary conditions. The solution to (6) can be found by solving the linear system and this solution can be mapped back to Ω_a ($u^N(x,y;a) = \tilde{u}^N(\mathcal{M}(x,y;a);a)$).

2.3. Discrete sensitivity equations and mesh sensitivities. In this section, we introduce the concept of mesh sensitivities and emphasize the differences and similarities between the differentiate-then-approximate and approximate-then-differentiate approaches to obtain state sensitivities. To simplify this discussion, we restrict our attention to the finite difference algorithm from the previous section.

Rather than deriving the sensitivity equation and finding an approximation for it, many practitioners apply implicit differentiation to the discrete form of the equations, e.g., (6), in order to determine the dependence of the solution on the parameter a. Straightforward differentiation leads to

$$\nabla_u \tilde{A}_a(\tilde{u}^N) \frac{\mathrm{D}\tilde{u}^N}{\mathrm{D}a} = \nabla_a \tilde{b} - \tilde{B}_a(\tilde{u}^N). \tag{7}$$

The Jacobian matrix on the left-hand side of the equation above is the linearization of $\tilde{A}_a$ and may be available in factored form if a direct solver is used to solve (6). The term $\nabla_a \tilde{b}$ contains terms arising from differentiating the boundary conditions and forcing functions in $\tilde{b}$. The expression $\tilde{B}_a$ contains terms which involve derivatives of the mapping $\mathcal{M}_a$ with respect to a. In other words, these are terms from the differentiation of the variable coefficients in $\tilde{A}$ that include

$$\frac{\partial \xi}{\partial a}, \ldots, \frac{\partial^2 \xi}{\partial a \partial x}, \ldots, \frac{\partial^3 \xi}{\partial a \partial x^2}, \ldots, \text{etc.}$$

All of the above terms are collectively referred to as the mesh sensitivities, since they represent how the discrete points in Ω (or the mesh) depend on a. It is these quantities and the evaluation of $\tilde{B}_a$ that we wish to avoid altogether.

Of course, it is also possible to apply the finite difference technique directly to the sensitivity equation (4). Thus, we transform the sensitivity equation to $\tilde{\Omega}$ as for (3): s to $\tilde{s}$, the differential operator $\mathcal{L}_a$ to $\tilde{\mathcal{L}}_a$, etc. Linearization of $\mathcal{A}_a$ with respect to u

commutes with the approximation scheme (as alluded to earlier, this is the premise of deriving many Newton algorithms). Thus, $\tilde{L}_a(\tilde{u}^N) = \nabla_u \tilde{A}_a(\tilde{u}^N)$ and the linear system for $\tilde{s}^N$ is

$$\nabla_u \tilde{A}_a(\tilde{u}^N)\tilde{s}^N = \tilde{c}. \tag{8}$$

The right-hand side vector contains the forcing function and boundary conditions (analogous to the construction of $\tilde{b}$).

Note that the linear systems for $\frac{\mathrm{D}\tilde{u}^N}{\mathrm{D}a}$ in (7) and for $\tilde{s}^N$ in (8) share the same system matrix. The differences in the right-hand sides reflect differences in the meaning of $\frac{\mathrm{D}\tilde{u}^N}{\mathrm{D}a}$ and $\tilde{s}^N$. As implied by our notation "D" in (7), when differentiation is performed on the discretized equations, the total (or material) derivative of $\tilde{u}^N$ is computed. Thus, these sensitivities capture the "convective" behavior of the solution as a is varied. This behavior is represented by the first two terms on the right-hand side below,

$$\frac{\mathrm{D}\tilde{u}^N}{\mathrm{D}a} = \frac{\partial \tilde{u}^N}{\partial \xi}\frac{\partial \xi}{\partial a} + \frac{\partial \tilde{u}^N}{\partial \eta}\frac{\partial \eta}{\partial a} + \frac{\partial \tilde{u}^N}{\partial a}.$$

This should be compared to $\tilde{s}^N$, which is the approximation $(\widetilde{\frac{\partial u}{\partial a}})^N$ (the operations on u here are differentiation, then transformation, then approximation). By comparing (7) and (8), we see that differentiating the approximation introduces terms to the calculations from the following identity:

$$\nabla_u \tilde{A}(\tilde{u}^N)\left[\frac{\partial \tilde{u}^N}{\partial \xi}\frac{\partial \xi}{\partial a} + \frac{\partial \tilde{u}^N}{\partial \eta}\frac{\partial \eta}{\partial a}\right] = \nabla_a \tilde{b} - \tilde{c} - \tilde{B}(\tilde{u}^N).$$

In the next section, we outline a methodology that bypasses the above calculations resulting in more efficient sensitivity calculations.

We point out that this methodology will not produce exactly the same end result that would be obtained by performing AD in the traditional fashion. In other words,

$$\left(\widetilde{\frac{\partial u}{\partial a}}\right)^N \neq \frac{\partial \tilde{u}^N}{\partial a},$$

as the first expression contains truncation errors from approximating the sensitivity equation, while the second expression contains the derivative of the truncation errors from approximating the state PDE. These errors will not be the same. However, in many cases, they both vanish as the approximations are refined. This observation motivates the notion of asymptotic consistency [2, 3], justifying the use of the CSE to obtain gradients in an optimal design algorithm.

2.4. AD strategies. AD is a chain-rule-based technique for evaluating the derivatives of functions defined by a high-level language computer program. AD relies on the fact that all computer programs, no matter how complicated, use a finite set of *elementary functions*. The `function` computed by the program is simply a composition of these elementary functions. The partial derivatives of these elementary functions are known, and thus derivatives of the `function` can be computed by propagating these derivatives via the chain rule. An introduction to AD can be found in [16].

Abstractly, the program to evaluate the solution u as a function of a (generally an m-vector) has the form

$$\begin{aligned} a &\equiv (a_1, a_2, \ldots, a_m), \\ &\downarrow \\ z &\equiv (z_1, z_2, \ldots, z_p), \quad p >> m + n, \\ &\downarrow \\ u &\equiv (u_1, u_2, \ldots, u_n), \end{aligned}$$

where the intermediate variables z are related through a series of these elementary functions which may be unary,

$$z_k = f^k_{\text{elem}}(z_i), \qquad i < k,$$

consisting of operations such as ($-$, pow$(\cdot)$, sin$(\cdot)$, $\ldots$), or binary,

$$z_k = f^k_{\text{elem}}(z_i, z_j), \qquad i < k, \quad j < k,$$

such as ($+$, $/$, $\ldots$).

AD has two basic modes of operation, the forward mode and the reverse mode. In the forward mode the derivatives are propagated along with the computation, e.g., in the elementary step $z_k = f^k_{\text{elem}}(z_i, z_j)$, the intermediate derivative, $\frac{dz_k}{da}$, can be propagated in the forward mode as

$$\frac{dz_k}{da} = \frac{\partial f^k_{\text{elem}}}{\partial z_i}\frac{dz_i}{da} + \frac{\partial f^k_{\text{elem}}}{\partial z_j}\frac{dz_j}{da}.$$

This propagation is done for all the intermediate variables z and for the output variables u. This process eventually produces the desired derivative $\frac{du}{da}$.

The reverse mode propagates the derivatives $\frac{du}{dz_k}$ for all intermediate variables backward (i.e., in the reverse order) through the computation. For example, in the elementary step $z_k = f^k_{\text{elem}}(z_i, z_j)$, the derivatives are propagated as

$$\frac{du}{dz_i} = \frac{\partial f^k_{\text{elem}}}{\partial z_i}\frac{du}{dz_k} \qquad \text{and} \qquad \frac{du}{dz_j} = \frac{\partial f^k_{\text{elem}}}{\partial z_j}\frac{du}{dz_k}. \tag{9}$$

At the end of this procedure we obtain the derivative $\frac{du}{da}$. However, the reverse mode requires saving the entire function computation, since the propagation is done backward through the computation. Hence, the partials $\frac{\partial f^k_{\text{elem}}}{\partial z_j}, \frac{\partial f^k_{\text{elem}}}{\partial z_i}$ need to be stored for the derivative computation in (9) making the reverse mode potentially prohibitive due to memory requirements.[1]

An application of AD to the discretized PDE solution results in the computation of additional terms involving the mesh. In the reverse mode these terms are stored and subsequently used for the derivative computation. This adds to the computational and memory requirements and adversely affects the performance in the reverse mode. These extra memory requirements are not necessary in the forward mode. The usage of reverse mode of AD is important for calculating gradients; the *cheap gradient*

[1]There are techniques that make the reverse mode efficient; e.g., a checkpointing technique due to Griewank [15] dramatically reduces the memory requirements with little increase in the computational requirements.

theorem [16] tells us that the gradient of any nonlinear function can be calculated for less than the cost of five function evaluations in the reverse mode of AD.

ADMAT (automatic differentiation for MATLAB) is an AD tool that can be applied to functions written for MATLAB [12]. ADMIT-1 is a MATLAB toolbox, which uses a generic AD plug-in tool (e.g., ADMAT or ADOL-C [17]) to compute the gradient and the (possibly sparse) Jacobian and Hessian matrices. The requirements from the users are minimal: the user is simply required to supply the code for the function computation and identify the variables. For complete information on using ADMIT-1, we refer the interested reader to the ADMIT-1 user manual [13]. ADMAT and ADMIT-1 are used to obtain the numerical results in section 4.

3. Methodology: Differentiation of an equivalent problem. In this section, we consider an AD methodology that avoids the need for mesh sensitivities. To facilitate this, we introduce a simple example: Let $f(a)$ be a function that is defined for $a \in \mathcal{P}$. Furthermore, assume f is differentiable over the set $\mathcal{P}$ and define a new function g with independent variables $a \in \mathcal{P}$ and $\alpha \in (-\epsilon, \epsilon)$ as

$$g(a, \alpha) = f(a) + \alpha \frac{df}{da}(a).$$

The following statements are obviously true:

$$\begin{array}{rcll} g(a, \alpha = 0) & = & f(a) & \forall a \in \mathcal{P}, \\ \frac{\partial g}{\partial a}(a, \alpha = 0) & = & \frac{df}{da}(a) & \forall a \in \mathcal{P}. \end{array}$$

Therefore, we have shifted the task of finding the derivative of f with respect to a to finding the derivative of g with respect to α at $\alpha = 0$.

In the sections below, we introduce a new parameter α and define a modified equivalent problem to aid our sensitivity analysis. While the example function g seems contrived, since we need to find $\frac{df}{da}(a)$ in order to construct g in the first place, it motivates how we can construct an equivalent problem to compute the derivatives we desire. This idea is used to construct a modified problem (PDE). Typically, we need only to define modified forcing functions and boundary conditions using the technique above. Since the modified problem is defined at the abstract level before any approximations are considered, it may be possible to perform minor modifications to an existing algorithm to produce a solution to this modified problem. Moreover, unlike the simple contrived example above, this problem definition does not require the sensitivity solution a priori but rather leads to the sensitivity solution. AD of this modified algorithm with respect to the parameter α produces an algorithm for approximating the CSE. The advantages of obviating differentiation of the algorithm with respect to a is that mesh sensitivities are not required. This has significant computational advantages as we demonstrate in section 4.

The procedure is illustrated in Figure 2. The typical application of AD follows the upper right path; first the PDE is approximated and then AD is applied. This is different from the continuous sensitivity approach along the lower left path, which first derives a linear PDE (the CSE) for the sensitivity variables and then performs approximation. The methodology below creates a modified PDE such that the approximation of this modified PDE yields the same result as approximating the original PDE. However, when AD is applied, it produces an approximation to the CSE (and inherits all of the advantages and disadvantages of doing so).

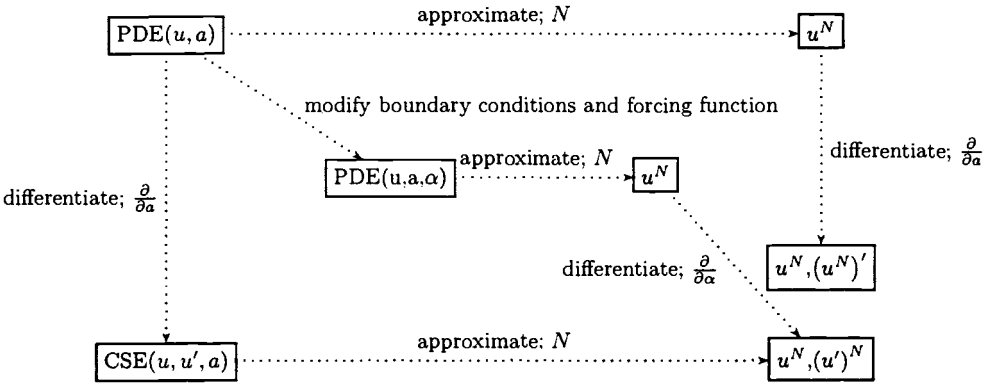

FIG. 2. *Schematic of proposed differentiation methodology.*

3.1. Differentiation methodology. The general form of the two examples from section 2 is to seek a solution u that satisfies

$$\mathcal{A}_a(u) = f \qquad \text{on } \Omega_a \tag{10}$$

subject to the boundary conditions

$$u = \hat{u} \quad \text{on } \Gamma_{\mathrm{d}} \qquad \text{and} \qquad \nabla u \cdot \hat{n} = \hat{q} \quad \text{on } \Gamma_{\mathrm{n}}$$

with $\Gamma_{\mathrm{d}} \cup \Gamma_{\mathrm{n}} = \partial\Omega_a$ and $\Gamma_{\mathrm{d}} \cap \Gamma_{\mathrm{n}} = \emptyset$. The general form of the sensitivity equation is

$$\mathcal{L}_a(u)s = g(u) \qquad \text{on } \Omega_a \tag{11}$$

subject to

$$s = \hat{s}(u) \quad \text{on } \Gamma_{\mathrm{d}} \qquad \text{and} \qquad \nabla s \cdot \hat{n} = \hat{q}_s(u) \quad \text{on } \Gamma_{\mathrm{n}}.$$

Note that the operator $\mathcal{A}_a(u)$ may depend on the parameter a. If this is the case, it results in adding a forcing function to the CSE in addition to $\frac{\partial f}{\partial a}$. This additional forcing function may also be a function of u, and the combined forcing function $g(u)$ reflects this dependence.

Next, we use the parameter α and introduce a differential equation for $v = v(x, y; a, \alpha)$ as follows. First of all, to construct a forcing function, we add α times the forcing function in (11) to the forcing function in (10). Next, we add α times the boundary conditions of the sensitivity equation (11) to the corresponding boundary conditions in the PDE (10). This leads to the following PDE with a solution v:

$$\mathcal{A}_a(v) = f + \alpha g \qquad \text{on } \Omega_a$$

with

$$v = \hat{u} + \alpha\hat{s}(v) \quad \text{on } \Gamma_{\mathrm{d}} \qquad \text{and} \qquad \nabla v \cdot \hat{n} = \hat{q} + \alpha\hat{q}_s(v) \quad \text{on } \Gamma_{\mathrm{n}}.$$

Thus, if we consider applying this to the example in section 2.2, we obtain the PDE

$$\mathcal{A}_a(v) = f + \alpha \frac{\partial f}{\partial a} \tag{12}$$

with

$$\begin{aligned} v(0,y;a,\alpha) = v(1,y;a,\alpha) &= 0, && y \in (0,1), \\ v(x,1;a,\alpha) &= 0, && x \in (0,1), \end{aligned}$$

and

$$v(x, y = a\sin(\pi x); a, \alpha) = \sin(\pi x) - \alpha \tfrac{\partial}{\partial y} v(x, y = a\sin(\pi x); a, \alpha)\sin(\pi x), \quad x \in (0,1).$$

From our assumptions on f and $\frac{\partial f}{\partial a}$, the right-hand side of (12) is in $\mathcal{H}^{-1}$. Observe the following fact.

THEOREM 3.1. *The derivative of the solution of* (3) *with respect to* a *is the same function as the derivative of the solution of* (12) *with respect to* α *at* $\alpha = 0$. *In other words,*

$$\frac{\partial u}{\partial a}(\cdot,\cdot;\cdot) = \frac{\partial v}{\partial \alpha}(\cdot,\cdot;\cdot,\alpha = 0).$$

Proof. Note that when $\alpha = 0$, (12) reduces to (3) (the same operator on the same domain with the same boundary conditions) so they have the same solution, i.e.,

$$u(\cdot,\cdot;\cdot) = v(\cdot,\cdot;\cdot,\alpha = 0).$$

Consider the sensitivity equation for problem (12) with parameter α; then $r = \frac{\partial v}{\partial \alpha}$ satisfies the following PDE:

$$\mathcal{L}_a(u) r = \frac{\partial f}{\partial a} \tag{13}$$

with

$$\begin{aligned} r(0,y;a,\alpha) = r(1,y;a,\alpha) &= 0, && y \in (0,1), \\ r(x,1;a,\alpha) &= 0, && x \in (0,1), \quad \text{and} \\ r(x, y = a\sin(\pi x); a, \alpha) &= -\tfrac{\partial}{\partial y} v(x, y = a\sin(\pi x); a, \alpha)\sin(\pi x), && x \in (0,1). \end{aligned}$$

We now show that the sensitivity of v in (12) with respect to α (our r above) evaluated at $\alpha = 0$ is the same as s in (4). It is easy to see that the derivative of the forcing function in (12) with respect to α gives the forcing function in (4). We now consider the boundary condition expressions in (12). Differentiating the Dirichlet boundary condition in (12) with respect to α leads to

$$r(x,y;a,\alpha) = -\frac{\partial}{\partial y} v(x,y;a,\alpha)\sin(\pi x) - \alpha \frac{\partial}{\partial y} r(x,y;a,\alpha)\sin(\pi x).$$

When $\alpha = 0$ this is precisely the boundary condition that appears in (4) (since $u = v$ as noted above):

$$r(x,y;a,\alpha = 0) = -\frac{\partial}{\partial y} v(x,y;a,\alpha = 0)\sin(\pi x) = -\frac{\partial}{\partial y} u(x,y;a)\sin(\pi x).$$

A similar argument holds for the Neumann boundary condition. □

It is important to point out that the parameter α has no influence on the geometry of the problem, only on the forcing function and the boundary conditions that are applied. Therefore, we propose modifying the software so that it approximates (12) instead of approximating (3). Then, application of AD tools results in software that produces an approximation to the CSE (11) and all of the unnecessary calculations associated with the mesh sensitivities are avoided.

3.2. Implementation details. We now discuss the implementation of this AD methodology for the two examples in section 2. Each example requires that we modify the approximation scheme for the PDE so that it approximates an augmented PDE. Fortunately, these modifications are only necessary in the routines that calculate forcing functions and boundary conditions. These routines typically account for a small percentage of the code.

The modification of the forcing function is straightforward. If we can explicitly differentiate the forcing function with respect to a, then this function can be modified to accept another argument, α, and return the value of $f + \alpha(\frac{\partial f}{\partial a})$. In the event that the code to evaluate f is complicated, AD can be used to compute $\frac{\partial f}{\partial a}$. A new routine, say `f_new`, can be created to call `f_original` (for f) and the differentiated version of this function (to compute $\frac{\partial f}{\partial a}$), then calculate the appropriate linear combination. For example, with the ADMIT toolbox, AD can be performed in a nested fashion to carry this out:

```
function f_new(x,y,a,alpha)
   return f_original(x,y,a) + alpha*f_original(x,y,D(a));
```

where `f_original(x,y,D(a))` is the AD of the function `f_original` with respect to `a`.

The treatment of the boundary conditions is more complex and will be specified for each example shortly. For now, we describe where this complexity arises. If we consider a boundary condition of the form

$$r = \frac{\partial \hat{u}}{\partial a} - \nabla v \cdot \Pi_a$$

(as appears in (13)), this cannot be implemented by differentiating a program with the boundary condition

$$v = \hat{u} + \alpha \left(\frac{\partial \hat{u}}{\partial a} - \nabla v \cdot \Pi_a \right).$$

Since most differentiated code solves for v and r simultaneously, we can't expect v (and ∇v in particular) to be available before we calculate r. Current AD tools generally don't have information about the structure of the problem (where the equations for v and r can be decoupled), so this type of structure needs to be exposed to the AD tools. Therefore, the boundary condition routine needs to be modified so that it imposes the condition

$$v + \alpha \nabla v \cdot \Pi_a = \hat{u} + \alpha \frac{\partial \hat{u}}{\partial a}$$

even though α will eventually be set to zero. Using this modified boundary condition allows us to impose

$$r + \alpha \nabla r \cdot \Pi_a = \frac{\partial \hat{u}}{\partial a} - \nabla v \cdot \Pi_a$$

in the differentiated code (which is our desired boundary condition when $\alpha = 0$).

Application to the nonlinear two-point boundary value problem. We consider the implementation for the problem in section 2.1. In order to approximate the sensitivity equation using our AD tools, we consider the following two-point boundary value problem instead:

$$\frac{\partial^2}{\partial x^2} v(x;a,\alpha) + \frac{1}{8}\left[\frac{\partial}{\partial x} v(x;a,\alpha)\right]^3 = 0 \tag{14}$$

with boundary conditions

$$v(x=0;a,\alpha) = 0 \qquad \text{and} \qquad v(x=a;a,\alpha) + \alpha \frac{\partial}{\partial x} v(x=a;a,\alpha) = 4.$$

Note that changes in the algorithm to compute an approximation to v rather than to u occur only in the implementation of the boundary conditions and that

$$u(x;a) = v(x;a,\alpha=0)$$

and

$$s(x;a) \equiv \frac{\partial u}{\partial a}(x;a) = \frac{\partial v}{\partial \alpha}(x;a,\alpha=0) \equiv r(x;a,\alpha=0).$$

The finite element approximation of (1) leads to a system of nonlinear algebraic equations. These equations can be solved, e.g., using Newton's method. In this case, an update of the solution δu is constructed to improve the current guess of the solution. The boundary conditions for the update are

$$\delta u(x=0;a) = 0 - u(x=0;a)$$

and

$$\delta u(x=0;a) = 4 - u(x=a;a).$$

In the algebraic system, the last boundary condition takes the form

$$\begin{aligned} L(N,N) &= 1, \\ b(N) &= 4 - u(N), \end{aligned}$$

where L is considered to be an approximation to $\mathcal{L}_a(u)$, or the Jacobian of the nonlinear algebraic equations.

For the modified problem, the boundary conditions for the update of v are

$$\delta v(x=0;a,\alpha) = 0 - v(x=0;a,\alpha)$$

and

$$\delta v(x=a;a,\alpha) + \alpha \frac{\partial}{\partial x} \delta v(x=a;a,\alpha) = 4 - \left[v(x=a;a,\alpha) + \alpha \frac{\partial}{\partial x} v(x=a;a,\alpha) \right].$$

The second boundary condition can be implemented as

$$\begin{aligned} L(N,N-1) &= -\frac{\alpha}{\Delta x}, \\ L(N,N) &= 1 + \frac{\alpha}{\Delta x}, \\ b(N) &= 4 - \left(v(N) + \frac{\alpha}{\Delta x}(v(N) - v(N-1)) \right). \end{aligned}$$

Thus, AD can be applied to (14) with respect to α, rather than to problem (1) with respect to a. The required modification only occurs in a few lines of MATLAB code.

Application to the Laplace equation in two dimensions. To use our AD methodology on the problem in section 2.2, we need to modify the finite difference algorithm so that it approximates

$$\frac{\partial^2}{\partial x^2} v(x,y;a,\alpha) + \frac{\partial^2}{\partial y^2} v(x,y;a,\alpha) = f(x,y;a) + \alpha \frac{\partial f}{\partial a}(x,y;a) \tag{15}$$

with boundary conditions

$$\begin{aligned} v(0,y;a,\alpha) = v(1,y;a,\alpha) &= 0, \qquad y \in (0,1), \\ v(x,1;a,\alpha) &= 0, \qquad x \in (0,1), \end{aligned}$$

and

$$v(x, y = a\sin(\pi x); a, \alpha) + \alpha \tfrac{\partial}{\partial y} v(x, y = a\sin(\pi x); a, \alpha) \sin(\pi x) = \sin(\pi x), \quad x \in (0,1),$$

instead of the system (3) and evaluates this at $\alpha = 0$. The code that evaluates f can be modified in a straightforward manner by passing an additional argument for α and returning the new forcing function. In this problem, $f(x,y;a)$ is given by an explicit formula; thus $\frac{\partial f}{\partial a}$ is also known explicitly. Therefore the modification is straightforward as illustrated for the one-dimensional (1-D) problem.

Once again, the modification of the boundary conditions is more challenging. Dirichlet boundary conditions in a finite difference approximation of (3) may be implemented by creating rows in the system matrix that impose

$$\tilde{u}(\xi, \eta = 0) = \sin(\pi x(\xi, \eta = 0)) \qquad \text{for } \xi = \Delta\xi, 2\Delta\xi, \ldots, 1 - \Delta\xi.$$

The boundary condition for (15) can be implemented by imposing

$$\tilde{v}(\xi,\eta=0) + \alpha \left(\frac{\partial \xi}{\partial y}(\xi,\eta=0) \frac{\partial \tilde{v}}{\partial \xi}(\xi,\eta=0) + \frac{\partial \eta}{\partial y}(\xi,\eta=0) \frac{\partial \tilde{v}}{\partial \eta}(\xi,\eta=0) \right) \sin(\pi x(\xi,\eta=0))$$
$$\text{for } \xi = \Delta\xi, 2\Delta\xi, \ldots, 1 - \Delta\xi,$$

where the terms $\frac{\partial \tilde{v}}{\partial \xi}$ and $\frac{\partial \tilde{v}}{\partial \eta}$ are implemented via finite differences, a central difference for $\frac{\partial \tilde{v}}{\partial \xi}$ (as described in section 2.2), and a one-sided difference for $\frac{\partial \tilde{v}}{\partial \eta}$.

This modification requires the addition of nonzero elements in the system matrix $\tilde{A}$ as in the previous example (in general, we would also need to make additions to $\tilde{b}$, but this could be handled in the same way as the forcing function). By modifying $\tilde{A}$ in this way, the proper boundary conditions are realized when AD is performed with respect to α.

4. Numerical results. In this section, we present numerical results for the methodology presented above. AD is performed on both the 1-D nonlinear two-point boundary value problem (1) and the two-dimensional (2-D) Laplace equation (3) as well as the corresponding modified problems, (14) and (15). Since the modified problems avoid the computation of mesh sensitivities, comparing these results (in both the forward and reverse modes of AD) illustrate the gains that can be made with our modification. We use the following three metrics to compare the performance of these differentiated codes:

- FLOPs for the forward mode. In the modified problem, the required floating point operations (FLOPs) are expected to be less than in the original problem since the computation of mesh sensitivities is avoided. Hence, this measure indicates the amount of computation that can be saved using the modified problem. FLOP1 in Tables 1 and 2 represents the FLOPs for the modified problem and FLOP2 represents the FLOPs for the original problem. These calculations are made using the forward mode of AD. The problem size, N, (the solution is of size N in the 1-D problem and of size $N \times N$ in the 2-D problem) is varied to demonstrate how these savings scale.

- Space complexity for the reverse mode. This quantity measures the memory requirements for the reverse mode of AD. Recall that the reverse mode requires storing the function trace for the derivative computation. Hence, this measure indicates how much space is saved by avoiding the mesh sensitivity terms. In Tables 1 and 2, SPACE1 represents the space complexity (the number of floating point numbers that are stored) for the modified problem and SPACE2 is the space complexity for the original problem.

- FLOPs for the reverse mode. This measure indicates how much computation can be saved by avoiding the mesh sensitivities in the reverse mode. In Tables 1 and 2, RFLOP1 represents the FLOPs for the modified problem in the reverse mode, while RFLOP2 represents the corresponding FLOPs for the original problem.

4.1. Nonlinear two-point boundary value problem. We begin by discussing results for the nonlinear two-point boundary value problem introduced in sections 2.1 and 3.2. AD is applied to the original finite element code for (1) as well as to the modified code to approximate (14). The values of our three metrics are listed in Table 1 for various problem sizes. We observe significant gains in terms of both FLOPs (for both modes) and space requirements. All three performance metrics are more or less independent of problem size. This can be explained by the fact that the complexity of the linear system in the finite element code is linear in the problem size, N (every nonlinear equation solved converged in five iterations). The amount of time required to define the mesh and the finite element matrix is also linear in the problem size, hence, the FLOPs gain remains essentially constant. In addition, the amount of space allocated to define the mesh is proportional to N, causing the memory savings to be independent of N.

The FLOPs in the forward mode and the FLOPs and space complexity in the reverse mode are displayed in Figures 3, 5, and 4, respectively. Note that in each case, these metrics behave linearly in N.

The sensitivity solution. AD of the modified problem computes the sensitivity solution correctly. Figure 6 displays the ℓ_2-norm of the error between the sensitivity solution computed using the methodology of section 3 and the correct analytic sensitivity. The analytic sensitivity is obtained by differentiating u_{ex} and evaluating it at the nodes of the finite element mesh.

In the next section we produce the results for the 2-D Laplace equation problem, where the gains are more dramatic, especially in terms of memory requirements.

4.2. Laplace equation in two dimensions. Table 2 provides computational metrics for AD of the 2-D problem introduced in sections 2.2 and 3.2. Results are provided for various problem sizes. In this case, the trend is that the improvement in the FLOPs requirement diminishes with increasing problem size. This is explained by the fact that the most expensive step in the computation is the solution of the linear system. This step dominates defining the mesh, the system matrix, etc. Therefore, the difference in the FLOPs required to compute the different right-hand sides becomes negligible.

The FLOPs requirement in the reverse mode depends on both the space complexity metric (since all stored derivatives need to be accessed again in the reverse pass) as well as the FLOPs to perform the derivative calculations themselves. Hence, in the reverse mode, the FLOPs gain is greater than that in the forward mode. However, the dependence of the space complexity metric on the FLOPs count is insignificant compared to the FLOPs required to perform the linear system solve. Figures 7 and 9 display how the FLOPs in the forward mode and reverse mode compare for the two AD methodologies. The substantial order-of-magnitude gain in space complexity can be seen in Figure 8.

The efficiency of the code generated by our AD methodology compares favorably with software written specifically to solve the CSE. We display the FLOPs requirements for solving the CSE using AD of the modified problem as well as traditional application of AD in Table 3. Note that there is very little overhead involved with this AD approach over a direct approximation. These results correspond to the same approximation of the CSE that is used for the PDE.

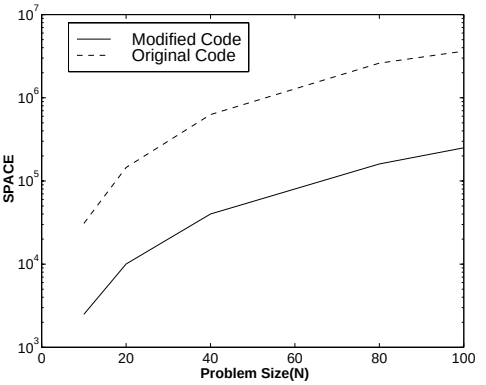

FIG. 8. *Space complexity for the* 2*-D problem.*

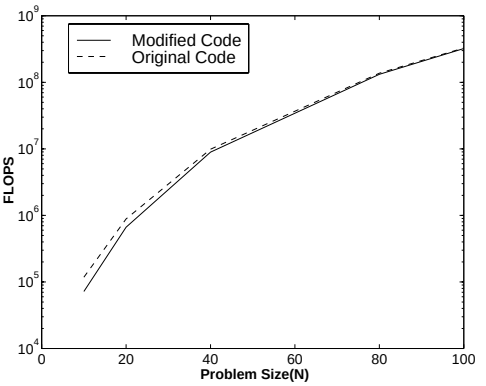

FIG. 9. *Reverse mode FLOPs for* 2*-D problem.*

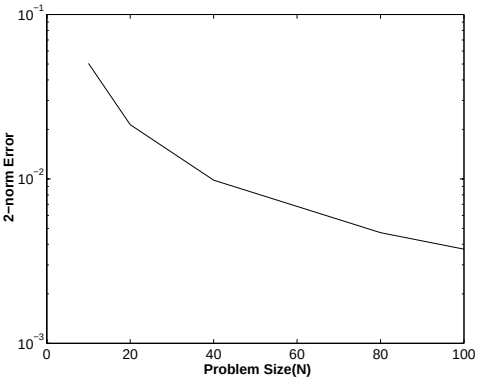

FIG. 10. *The ℓ_2-norm of the error in the sensitivity solution.*

The sensitivity solution. The ℓ_2-norm of the error in sensitivity calculations versus problem size is plotted in Figure 10. As in section 4.1, the exact solution is defined by evaluating the analytic sensitivity at the $N \times N$ finite difference nodes. Again, we see that accurate sensitivity solutions are calculated using AD of the modified problem.

4.3. Analysis of the numerical results. These results show that a sometimes dramatic, and usually substantial, gain in terms of FLOPs and memory requirements can be achieved by using the modified problem. To develop an a priori estimate of the potential gains of this AD methodology, we present the following recipe. Consider the following PDE solution code which can be broadly divided into two main parts: the code to define the mesh and the code for computing the solution. Consider a general template (here a denotes the independent variables, e.g., the shape parameters):

function $u =$ **pdesolution**(a)

Compute the Mesh, $M(a)$. (Complexity: memory $= S_m$, FLOPs $= F_m$)

Compute the Solution, $u = F(a, M(a))$. (Complexity: memory $= S_s$, FLOPs $= F_s$)

end

For generality, we assume a multiparameter case. Assume the number of parameters is given by p. In the above framework, the various complexities can now be estimated by

- FLOPs for the forward mode. For AD of the modified problem, the FLOPs will be $\mathsf{FLOP1} = F_m + (p+1)F_s$, while for the original problem it will be $\mathsf{FLOP2} = (p+1)(F_m + F_s)$. The gain is
$$\frac{\mathsf{FLOP2} - \mathsf{FLOP1}}{\mathsf{FLOP2}} \times 100\% = \frac{pF_m}{\mathsf{FLOP2}} \times 100\%.$$
If F_m is substantial, i.e., the mesh definition requires a lot of computation as in elliptic grid generation [20], then a significant gain can be expected. *In the 1-D problem, F_m is a significant portion of the computational effort as N is increased; thus the gain remains significant as the problem size increases.*
- Space complexity for the reverse mode. For the modified problem the space complexity will be $\mathsf{SPACE1} = S_m + (p+1)S_s$ while for the original problem

it will be $\mathsf{SPACE2} = (p+1)(S_m + S_s)$. The gain is

$$\frac{\mathsf{SPACE2} - \mathsf{SPACE1}}{\mathsf{SPACE2}} \times 100\% = \frac{pS_m}{\mathsf{SPACE2}} \times 100\%.$$

If the space requirement for the mesh setup, S_m, is substantial compared to the solution step, S_s, then a significant gain is expected in the space complexity. *In the 2-D problem, the memory required to store the mesh and its derivatives, S_m, remains a significant portion of the overall total memory required (since the system matrix is sparse); thus the gain remains substantial as the problem size is increased.*

- FLOPs for the reverse mode. For the modified problem, the FLOPs required for the reverse mode of AD will be $\mathsf{RFLOP1} = \mathsf{FLOP1} + \mu\mathsf{SPACE1}$ while for the original problem it will be $\mathsf{RFLOP2} = \mathsf{FLOP2} + \mu\mathsf{SPACE2}$, where μ is constant which determines the FLOPs required to save and access one unit of memory (stored for accessing in the reverse pass). The gain is

$$\frac{\mathsf{RFLOP2} - \mathsf{RFLOP1}}{\mathsf{RFLOP2}} \times 100\% = \frac{(1+\mu)\, pF_m}{\mathsf{rFLOP2}} \times 100\%.$$

5. Comments and conclusions. To summarize, recall that when a problem has a parameter-dependent domain, differentiating the discrete form of the equations (the traditional use of AD) can lead to mesh sensitivities. These terms lead to additional computations and storage in the differentiated code. This extra computation can be avoided by using AD to generate code to approximate the CSE. Minor modifications to the original software were outlined for two example problems so that AD of the modified code produced the desired result. Numerical experiments indicated that the number of FLOPs and the required memory were both reduced when this methodology was applied. In some cases, the savings were substantial (up to 25% improvement in the FLOPs requirements for a 1-D finite element problem and better than 10-fold improvement in the memory requirements for a 2-D finite difference problem). These are savings over and above the calculation of the mesh sensitivity terms themselves. In the previous section, we provided formulae that can be used to estimate the amount of savings that this AD methodology will produce.

The methodology is useful in problems where the domain is fixed, yet $\mathcal{M}_a$ is still parameter dependent (e.g., this occurs when adaptive mesh refinement strategies are used). To handle this case with AD, the mesh is simply specified as a fixed constant (it is possible to do this in most AD software). The CSE are solved on this mesh using the technique described in section 3. Since the approximation takes place after the differentiation, sensitivities are found without mesh derivatives [5]. Note that fixing the mesh is also possible in the approximate-then-differentiate approach if the domain is not parameter dependent.

This methodology has no benefit in problems where $\mathcal{M}_a = \mathcal{M}$, however, as the operations of differentiation and approximation commute in this case. For this situation, it is better to apply AD to the original code (with respect to a) than to apply the proposed AD methodology (with respect to α).

In some instances, the modification of the boundary conditions can be very difficult. Programs which are set up to handle zero Dirichlet boundary conditions may not have the capability of treating nontrivial data without some significant program modification. These cases require extending the solution vector to include the boundary points and increasing the size of the system matrix. These changes may not be

straightforward when this occurs and the benefits reported in section 4 need to be weighed against the resources required to perform the necessary changes. It's possible that the traditional application of AD is more attractive in this case.

Our methodology was presented for the situation where either the boundary conditions, forcing functions, or the shape of the domain was parameter dependent. However, it can be extended to a more general case when, for example, $\mathcal{A}_a$ has other dependencies on a, such as parameter-dependent coefficients. When this situation occurs, the CSE contains additional functions of u. These extra terms can be combined with the function $g(u)$ in problem (4). The implementation of this methodology can be more difficult in this case since we need to extract the necessary code out of the computation of $A_a(u^N)$ in order to build the modified right-hand side.

This approach is applicable to a wide variety of PDE approximation schemes. In this work, we have demonstrated the applicability of this approach for PDEs that are approximated with either finite differences or finite element methods. However, one should take the point of view that AD is being used to approximate the sensitivity equation in these problems. Therefore the success of this approach comes from the fact that the approximation scheme can be changed so that it approximates a modified PDE (and that these modifications are small, occurring in a small portion of the code). The application of AD to this modified code will yield the desired sensitivity solution.

MESH PARTITIONING: A MULTILEVEL BALANCING AND REFINEMENT ALGORITHM*

C. WALSHAW† AND M. CROSS†

Abstract. Multilevel algorithms are a successful class of optimization techniques which addresses the mesh partitioning problem. They usually combine a graph contraction algorithm together with a local optimization method which refines the partition at each graph level. In this paper we present an enhancement of the technique which uses imbalance to achieve higher quality partitions. We also present a formulation of the Kernighan–Lin partition optimization algorithm which incorporates load-balancing. The resulting algorithm is tested against a different but related state-of-the-art partitioner and shown to provide improved results.

Key words. graph-partitioning, mesh partitioning, load-balancing, multilevel algorithms

AMS subject classifications. 05C85, 65Y05

1. Introduction.

The need for mesh partitioning arises naturally in many finite element (FE) and finite volume (FV) applications. Meshes composed of elements such as triangles or tetrahedra are often better suited than regularly structured grids for representing completely general geometries and resolving wide variations in behavior via variable mesh densities. Meanwhile, the modeling of complex behavior patterns means that the problems are often too large to fit onto serial computers, either because of memory limitations or computational demands, or both. Distributing the mesh across a parallel computer so that the computational load is evenly balanced and the data locality maximized is known as mesh partitioning. It is well known that this problem is NP-complete [7], so in recent years much attention has been focused on developing suitable heuristics, and some powerful methods, many based on a graph corresponding to the communication requirements of the mesh, have been devised, e.g., [5].

A particularly popular and successful class of algorithms which addresses this mesh partitioning problem is known as multilevel algorithms. They usually combine a graph contraction algorithm which creates a series of progressively smaller and coarser graphs together with a local optimization method which, starting with the coarsest graph, refines the partition at each graph level. In this paper we present an enhancement of the technique which uses imbalance to achieve higher quality partitions. We also present a formulation of the Kernighan–Lin (KL) partition optimization algorithm which incorporates load-balancing.

We focus here on serial partitioning. Although emphasis in the field is switching to parallel partitioning methods, we aim here to address one of the fundamental mechanisms of the multilevel paradigm and thus a serial implementation provides a clear and relatively parameter-free environment for establishing how imbalance can affect the overall performance of the strategy. However, elsewhere we have provided a different but related parallel formulation [21], and indeed the algorithms described here are used directly as part of that parallel strategy.

1.1. Overview. Below, in section 1.2, we introduce the mesh partitioning problem and establish some terminology. In section 2 we then describe the multilevel paradigm and present a new enhancement in the idea of a multilevel balancing schedule. Next, in section 3, we describe a KL-type optimization algorithm which both balances a partition of the graph to within some given tolerance and also refines it. In section 4 we present results from the multilevel balancing and refinement algorithm, comparing it with a similar formulation which only incorporates multilevel refinement. We also compare different multilevel balancing schedules. Finally in section 5 we draw some conclusions and present some ideas for further investigation.

The principal innovations described in this paper are twofold:

- In section 2.2 we formalize the idea of combining multilevel refinement with a multilevel balancing schedule.
- In section 3.4 we describe a new formulation of a KL-type partitioning algorithm (incorporating hill-climbing), which both balances and refines.

Two implementation ideas are also described:

- In section 3.3 we describe a ranking for prioritizing vertices for migration which incorporates their weight as well as their gain.
- In section 3.5 we describe how we deal with vertices which are neighbors to more than one subdomain.

1.2. Notation and definitions. To define the mesh partitioning problem, let $G = G(V, E)$ be an undirected graph of vertices V, with edges E which represent the data dependencies in the mesh. We assume that the graph is connected. (Although if this is not the case we have, elsewhere, discussed an algorithm for connecting the components together [25].) We also assume that both vertices and edges are weighted (with positive integer values) and that $|v|$ denotes the weight of a vertex v and similarly for edges and sets of vertices and edges. The vertex weight is used to approximate processor loading whilst the edge weights model communication costs (although see section 3.1). Typically both vertex and edge weights are given a unit cost although there has been some recent work on accurate cost modeling [15], and for some real applications the processor load can depend on many other factors such as data access patterns. However, since this is a function of the final partition it is not possible to estimate such costs a priori, and we do not address this issue here.

Given that the mesh needs to be distributed to P processors, define a partition π to be a mapping of V into P disjoint subdomains S_p such that $\bigcup_P S_p = V$. The partition π induces a *subdomain graph* on G which we shall refer to as $G_\pi = G_\pi(S, C)$; there is an edge $(S_p, S_q) \in C$ if there are vertices $v_1, v_2 \in V$ with $(v_1, v_2) \in E$, and $v_1 \in S_p$, $v_2 \in S_q$, and the weight of a subdomain is just the sum of the weights of the vertices in the subdomain, $|S_p| = \sum_{v \in S_p} |v|$. We denote the set of intersubdomain or cut edges (i.e., edges cut by the partition) by E_c (note that $|E_c| = |C|$). Vertices which have an edge in E_c (i.e., $\{v \in V :$ there exists $v' \in V$, with $(v, v') \in E_c\}$) are referred to as *border* vertices.

The definition of the graph-partitioning problem is to find a partition which evenly balances the load (i.e., vertex weight) in each subdomain whilst minimizing the communications cost. To balance the load, the optimal subdomain weight is given by $\overline{S} := \lceil |V|/P \rceil$ (where the ceiling function $\lceil x \rceil$ returns the smallest integer $\geq x$) and the *imbalance* is then defined as the maximum subdomain weight divided by the optimal (since the computational speed of the underlying application is determined by the most heavily weighted processor). As is usual, throughout this paper the communications cost will be estimated by $|E_c|$, the weight of cut edges or cut-weight,

although see section 3.1 for further discussion on this point. A more precise definition of the graph-partitioning problem is therefore to find π such that $|S_p| \leq \overline{S}$ and such that $|E_c|$ is minimized. Note that perfect balance is not always possible for graphs with nonunitary vertex weights.

Throughout this paper we use some fairly specific terminology and in particular we shall refer to *refinement* as the improvement of partition quality (i.e., the cut-weight) without regard to load-balance; *balancing* will then refer to the improvement of imbalance and *optimization* refers to refinement and balancing. We also make the distinction between those algorithms, such as that of Kernighan and Lin [14], which refine a *bisection* and algorithms which refine a partition of P subdomains. Such algorithms have been known as k-way (e.g., [13]) or multiway (e.g., [24]) algorithms, but here we shall simply refer to them as *partition* (as opposed to bisection) refinement algorithms. Finally we shall use the words processor and subdomain interchangeably; the mesh is partitioned into P subdomains each of which will be mapped onto one processor.

2. The multilevel paradigm. In recent years it has been recognized that an effective way of both accelerating partition refinement and, perhaps more importantly, giving it a global perspective is to use multilevel techniques. The idea is to group vertices together to form *clusters*, use the clusters to define a new graph, and recursively iterate this procedure to create a series of increasingly coarse graphs until the size of the coarsest graph falls below some threshold. A fast and possibly crude initial partition of the coarsest graph is calculated and then successively interpolated onto and optimized on each of the graphs in reverse order. This sequence of contraction followed by repeated expansion/refinement loops is known as the multilevel paradigm and has been successfully developed as a strategy for overcoming the localized nature of the KL [14] (and other) algorithms. The multilevel idea was first proposed by Barnard and Simon [1] as a method of accelerating spectral bisection and improved by both Hendrickson and Leland [9] and Bui and Jones [2], who generalized it to encompass local refinement algorithms.

2.1. Implementation. To create a coarser graph $G_{l+1}(V_{l+1}, E_{l+1})$ from $G_l(V_l, E_l)$ we use a variant of the graph contraction algorithm proposed by Hendrickson and Leland [9]. The idea is to find a maximal independent subset of graph edges or *matching* of graph vertices and then collapse them. The set is independent if no two edges in the set are incident on the same vertex (so no two edges in the set are adjacent), and maximal if no more edges can be added to the set without breaking the independence criterion. Having found such a set, each selected edge is collapsed and the vertices, $u_1, u_2 \in V_l$ say, at either end of it are merged to form a new vertex $v \in V_{l+1}$ with weight $|v| = |u_1| + |u_2|$. Edges which have not been collapsed are inherited by the child graph, G_{l+1}, and, where they become duplicated, are merged with their weight summed. This occurs if, for example, the edges (u_1, u_3) and (u_2, u_3) exist when edge (u_1, u_2) is collapsed. Because of the inheritance properties of this algorithm, it is easy to see that the total graph weight remains the same, $|V_{l+1}| = |V_l|$, and the total edge weight is reduced by an amount equal to the weight of the collapsed edges.

A simple way to construct a maximal independent subset of edges is to visit the vertices of the graph in a random order and pair up or match unmatched vertices with an unmatched neighbor. It has been shown [12] that it can be beneficial to the optimization to collapse the most heavily weighted edges and our matching algorithm uses this heuristic.

The initial partition. Having constructed the series of graphs until the number of vertices in the coarsest graph is smaller than some threshold, the normal practice of the multilevel strategy is to carry out an initial partition. Here, following the idea of Gupta [8] we contract until the number of vertices in the coarsest graph is the same as the number of subdomains, P, and then simply assign vertex i to subdomain S_i. Unlike Gupta, however, we do not carry out repeated expansion/contraction cycles of the coarsest graphs to find a well balanced initial partition but instead, since our optimization algorithm incorporates balancing, we commence on the expansion/optimization sequence immediately.

Note that contraction down to P vertices should always be possible provided the graph is connected (assumed, section 1.2). To see this consider that every connected graph of V vertices must have at least $V-1$ edges and that the collapsing of an edge results in a connected graph. Thus, if $V > P$ there must be at least one edge which can be collapsed to create a graph with $V-1$ vertices and so on by induction.

Note also that for certain graphs the resulting initial partition can be extremely imbalanced as a result of the weights becoming extremely inhomogeneous in the coarsest graphs. This suggests that perhaps, for such examples, contraction down to P vertices does not enhance the final partition. However, because the final contractions are relatively very cheap and this imbalance does not seem to affect the final partition quality we retain this feature in order not to introduce another parameter (i.e., a contraction threshold) to the method.

Partition expansion. Having optimized the partition on a graph G_l, the partition must be interpolated onto its parent G_{l-1}. The interpolation itself is a trivial matter; if a vertex $v \in V_l$ is in subdomain S_p then the matched pair of vertices that it represents, $v_1, v_2 \in V_{l-1}$, will be in S_p.

2.2. Multilevel balancing schedule. It has been noted previously (originally in [18] and subsequently in [13, 23]) that allowing a small amount of imbalance often leads to a higher partition quality. We also observe that one of the most attractive features of the multilevel paradigm is the way in which the partition quality (usually the number of cut edges) is refined *gradually* as the expansion proceeds; i.e., after each refinement the partition quality of a given graph G_l is usually better than that of G_{l+1} (because there are more degrees of freedom). In this paper we combine both observations (imbalance can lead to higher partition quality and gradual refinement of quality being an attractive feature) by allowing a variable amount of *imbalance* which is reduced gradually as the expansion proceeds. The idea is that by allowing a large imbalance in the coarsest graphs a better partition may be found than if balance was rigidly enforced, but that this imbalance will not cause degradation in the final partition of the finest graph if removed gradually throughout the expansion procedure. Note particularly the second statement—if the finest graph starts the refinement with a high quality but poorly balanced partition, then much of the quality may be destroyed by balancing. (See the end of this section for an example of this behavior.)

In fact it is often not possible to achieve perfect balance in the coarsest graphs because the vertices may be heavily weighted and very inhomogeneous (e.g., if balance requires moving a weight of 10 from one subdomain to another but all vertices are of weight 20 or over, perfect balance cannot be attained). Hence it could be argued that all multilevel algorithms employ this idea of multilevel balancing. Indeed, our previous work in this area, e.g., [24], employs a diffusive load-balancer *at every* refinement level and so the idea has been implicit in our work for sometime. In this paper, however,

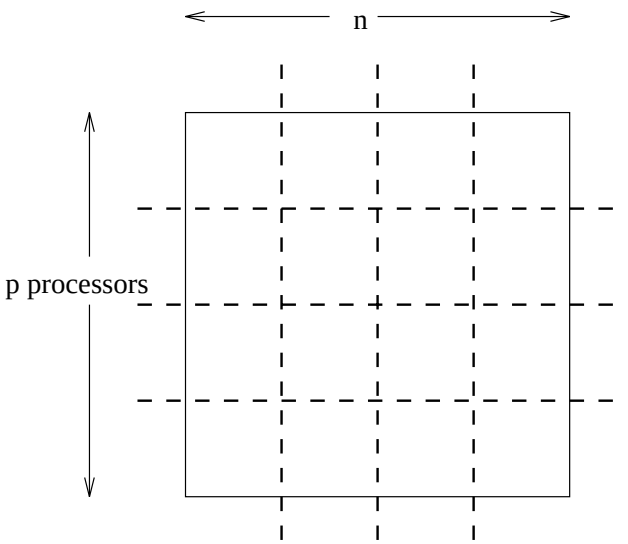

FIG. 1. *A regular domain of $N = n^2$ vertices perfectly partitioned into $P = p^2$ subdomains.*

we formalize the idea of balancing and refinement at every level and also describe an optimization algorithm which both achieves a given level of imbalance (if possible) and refines for quality. Note that we make the distinction between this work and that in the multilevel diffusion algorithm of Schloegel, Karypis, and Kumar [16], where a diffusive load-balancer is employed at each coarse level until balance is attained and thereafter partition quality refinement without active balancing is employed.

In order to talk about improving the balance gradually from one graph level to another, for each graph, G_l, let T_l be the target subdomain weight. If every subdomain, S_p, is not heavier than this target (i.e., $\max |S_p| \leq T_l$), then we say that the graph is balanced and the optimization can concentrate on refinement alone (so long as the balance is not destroyed). However, if $\max |S_p| > T_l$, then the optimization must concentrate on balancing (with some regard to refinement). Clearly this series $\{T_l\}$ is an arbitrary heuristic, but it must be determined with two caveats:

- If it ascends too rapidly, the balance inherited by G_l from G_{l+1} may cause the partition quality to be lost in trying to attain T_l. (See the end of this section for an example of this behavior.)
- If it ascends too slowly, the benefits for the partition quality of having a high imbalance tolerance may never be seen.

Some results with different functions for T_l are given in section 4.2, but with the above in mind we derive T_l as follows:

Let $G(V, E)$ be regular graph with N $(= n \times n)$ vertices perfectly partitioned into P $(= p \times p)$ subdomains as in Figure 1. The *maximum* border length of a subdomain is then given by

$$4\left(\frac{N}{P}\right)^{\frac{1}{2}}.$$

The average weight of a vertex is $|V|/N$, and so we can estimate the weight of border

vertices in the subdomain as

$$4\left(\frac{N}{P}\right)^{\frac{1}{2}} \times \frac{|V|}{N} = \frac{4|V|}{(PN)^{\frac{1}{2}}}.$$

Recall that for each graph G_l we wish to define a target subdomain weight T_l which will not cause too much degradation in partition quality when balancing its parent G_{l-1} down to its target T_{l-1}. After some experimentation, we have chosen to allow an excess weight in any given subdomain of approximately half one border layer of a subdomain in the parent graph. The target weight is given by the optimal subdomain weight plus the excess weight and so, using the regular two-dimensional (2D) model, we set T_l to be

$$T_l = \lceil |V|/P \rceil + \frac{1}{2} \times \frac{4|V|}{(PN_{l-1})^{\frac{1}{2}}}.$$

If we define the imbalance tolerance, θ_l, to be the maximum allowable subdomain weight expressed as a proportion of the optimal subdomain weight, then

$$\theta_l = \frac{\lceil |V|/P \rceil + 2|V|(PN_{l-1})^{-\frac{1}{2}}}{\lceil |V|/P \rceil} \approx 1 + 2\left(\frac{P}{N_{l-1}}\right)^{\frac{1}{2}}.$$

In other words a graph G_l is considered balanced if the imbalance is less than $\theta_l = 1 + 2(\frac{P}{N_{l-1}})^{\frac{1}{2}}$ for $l > 0$. For the final (and original) graph, G_0, which has no parent, we can either set $\theta_0 = 1$ to aim for perfect balancing or, as is often the case (e.g., [13]), allow a slight imbalance. For the results in this paper we have chosen to set $\theta_0 = 1.03$ and then we set $\theta_l = \max(\theta_0, 1 + 2(\frac{P}{N_{l-1}})^{\frac{1}{2}})$ for $l > 0$. Note that we have chosen a 2D model of the regular partition; a three-dimensional (3D) model using the same arguments gives $\theta_l = 1 + 3(\frac{P}{N_{l-1}})^{\frac{1}{3}}$, and results using this model can be found in section 4.2.

Figure 2 shows an example of some typical behavior for the balancing schedule derived above and the algorithm described in section 3. The dotted line plots the target weight or balancing schedule, and each step down represents the transition from one graph level G_l to its parent G_{l-1}. Notice that at the start of the iterations the tolerance is around 2.3—i.e., the graph is considered balanced if every subdomain is smaller than 2.3 times the optimal weight. The solid line represents the attained balance—this is below the target level most of the time and, by iteration 30, it tracks the target weight exactly, showing that the optimization algorithm in section 3 is very good at taking advantage of any leeway in the imbalance tolerance. (The final imbalance tolerance for the method is set at $\theta_0 = 1.03$ which is why the balance never reaches 1.0.) Finally the dashed line shows the evolution of the cut edges (scaled by a large factor to fit onto the graph). The peaks early on in the iterations correspond to balances which exceed the tolerance and as mentioned above this causes serious degradation in the partition quality as the algorithm balances the graph. However, after about iteration 30 the cut-weight decreases monotonically.

3. The balancing and refinement optimization algorithm. In this section we describe an optimization algorithm which combines load-balancing and partition quality refinement. It is a KL-type algorithm incorporating a hill-climbing mechanism to enable it to escape from local minima; in other words vertex migration from subdomain to subdomain can be *accepted* even if it degrades the partition quality and later,

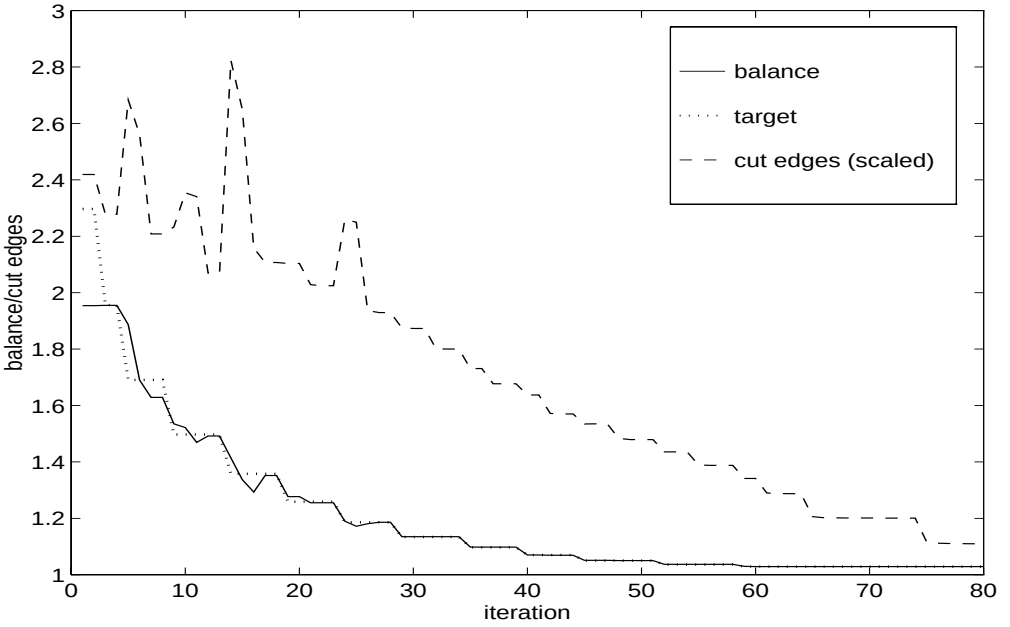

FIG. 2. *An example of the evolution of balance and cut-weight for the multilevel balancing and refinement algorithm.*

based on the subsequent evolution of the partition, either rejected or *confirmed*. The algorithm uses bucket sorting (see section 3.3), the linear time complexity improvement of Fiduccia and Mattheyses [6], and is a partition optimization formulation; in other words it optimizes a partition of P subdomains rather than a bisection. In this respect it most closely resembles the algorithm of Karypis and Kumar [13], but additionally incorporates load-balancing (using the diffusive algorithm of Hu and Blake [11]; see section 3.2. The algorithm described here is strictly serial in nature, but a parallel formulation (in which essentially each intersubdomain interface is treated as a separate problem) can be found in [21].

3.1. The gain function. A key concept in the method is the idea of *gain*. Loosely, the gain $g(v, q)$ of a vertex v in subdomain S_p can be calculated for every other subdomain, S_q, $q \neq p$, and it expresses some "estimate" of how much the partition would be "improved" were v to migrate to S_q. The gain is usually directly related to some cost function which measures the quality of the partition and which we aim to minimize. Typically the cost function used is simply the total weight of cut edges, $|E_c|$, and then the gain expresses the change in $|E_c|$. More recently, there has been some debate about the most important quantity to minimize, and in [20] Vanderstraeten and Keunings demonstrate that it can be extremely effective to vary the cost function based on a knowledge of the solver. Whichever cost function is chosen, however, the idea of gains is generic. For the purposes of this paper we shall assume that the gain $g(v, q)$ just expresses the reduction in the cut-weight, $|E_c|$.

3.2. Load-balancing: Calculating the flow. Given a graph partitioned into unequal sized subdomains, we need some mechanism for distributing the load equally. To do this we solve the load-balancing problem on the subdomain graph, G_π, in order to determine a *balancing flow*, a flow along the edges of G_π which balances the weight

of the subdomains. By keeping the flow localized in this way, vertices are not migrated between nonadjacent subdomains, and hence (hopefully) the partition quality is not degraded (since a vertex migrating to a subdomain to which it is not adjacent is almost certain to have a negative gain).

This load-balancing problem, i.e., how to distribute N tasks over a network of P processors so that none have more than $\lceil N/P \rceil$, is a very important area for research in its own right with a vast range of applications. The topic is introduced in [17] and some common strategies are described. Much work has been carried out on parallel or distributed algorithms and, in particular, on diffusive algorithms [3]; here we use an elegant diffusive variant developed by Hu and Blake [11] with fast convergence. This method was derived to minimize the Euclidean norm of the transferred weight, although it has recently been shown that all diffusion methods minimize this quantity [4, 10]. The algorithm simply involves solving the system $L\mathbf{x} = \mathbf{b}$, where L is the Laplacian of the subdomain graph:

$$L_{pq} = \begin{cases} \text{degree}(S_p) & \text{if } p = q, \\ -1 & \text{if } p \neq q \text{ and } S_p \text{ is adjacent to } S_q, \\ 0 & \text{otherwise,} \end{cases}$$

and where $b_p = |S_p| - \overline{S}$, the weight of S_p less the optimal weight. The weight to be transferred across edge (S_p, S_q) is then given by $x_p - x_q$. Note that this method is closely related to the standard diffusion algorithm [3], except that the diffusion coefficients are not fixed but are determined at each iteration by a conjugate gradient search.

This algorithm (or, in principle, any other distributed load-balancing algorithm) is used to determine *how much* weight to transfer across edges of the subdomain graph and the optimization technique below is then used to decide *which* vertices to move. The algorithm is employed as suggested in [11], solving iteratively with a conjugate gradient solver; it is solved for a real solution and the (integer) flow is determined by rounding. Note, however, that the Laplacian of any undirected graph contains a zero eigenvalue with the corresponding eigenvector $[1, 1, \ldots, 1]$ and the solution iterates are orthogonalized against this [11]. If any other singularities are detected (e.g., if the graph is disconnected) the software will switch to another method, an intuitive and entirely localized distributed load-balancing algorithm due to Song [19].

Occasionally whilst optimization is taking place vertex migration can cause the subdomain graph to change (e.g., two nonadjacent subdomains may become adjacent). If an edge disappears over which flow is scheduled to move the subdomain graph must be rebalanced, although we speed this process up by adding the extraneous flow back into its source subdomain and rebalancing the graph from that point. We also limit the number of possible rebalances on any graph since otherwise the system can exhibit cyclic behavior.

3.3. Bucket sorting. The bucket sort is an essential tool for the efficient and rapid sorting and adjustment of vertices by their gain. The concept was first suggested by Fiduccia and Mattheyses in [6], and the idea is that all vertices of a given gain g are placed together in a "bucket" which is ranked g. Finding a vertex with maximum gain then simply consists of finding the (nonempty) bucket with the highest rank and picking a vertex from it. If the vertex is subsequently migrated from one subdomain to another then its gain and the gains of all its neighbors have to be adjusted and resorted by gain. Using a bucket sort for this operation simply requires recalculating the gains of the vertex and its neighbors and transferring them to the appropriate

buckets, an essentially localized operation. If a bucket sort were not used and, say, the vertices were simply stored in a list in gain order, then the entire list would require resorting (or at least merge-sorting with the sorted list of adjusted vertices) an essentially $O(N)$ operation for every migration.

In our implementation each bucket is (as usual) represented by a double linked list of vertices (since vertices must be extracted from the list without having to search through it). However, we additionally prefer to sort the vertices by gain and then by weight. The reasoning behind this is simple: if, for example, a transfer of weight 3 between 2 subdomains is required, then it is preferable to pick 3 vertices each of gain 1 and weight 1 rather than 1 vertex of gain 1 and weight 3. Conversely, if a transfer of weight 2 is required, then it is better to move 1 vertex of weight 2 and gain -1, rather than 2 vertices of weight 1 and gain -1. Thus we order the vertices primarily by gain and then by weight, lightest first for positive gains and heaviest first for negative gains. Rather than sorting the contents of each bucket we simply provide a different bucket for each gain/weight combination, and so if W represents the weight of the largest vertex in a given graph $g(v)$ the gain of a vertex v, we rank v with the formula:

$$\text{rank}(v) = \begin{cases} g(v) \times W + W - |v| & \text{if } g(v) > 0, \\ g(v) \times W + |v| - 1 & \text{otherwise,} \end{cases}$$

which provides the desired ordering. The ranking is unique for each combination of $g(v)$ and $|v|$ because $1 \le |v| \le W$ for all vertices v (it is assumed that $|v| > 0$), and so

$$\text{rank}(v) \le g(v) \times W + W - 1 < g(v) \times W + W = [g(v) + 1] \times W.$$

Hence

$$g(v) \times W \le \text{rank}(v) < [g(v) + 1] \times W.$$

In other words, for a given vertex v with gain $g(v)$, the upper bound on $\text{rank}(v)$ is strictly less than the lower bound on $\text{rank}(w)$ for any vertex w with gain $g(w) = [g(v) + 1]$.

Note that in the very coarse graphs at the top of the multilevel process, it is possible or even common to produce graphs with a wide range of vertex weights and potential gains. For this reason, rather than maintaining a sparse but potentially huge array of pointers to buckets, we store the nonempty buckets in a binary tree adding and deleting buckets as required (see Figure 3). This tree structure may still be large but cannot exceed the number of border vertices in the graph in size. In the sections below the term bucket tree will be used to refer to the binary tree of buckets.

3.4. The iterative optimization algorithm. The serial optimization algorithm, as is typical for KL-type algorithms, has inner and outer iterative loops with the outer loop terminating when no migration takes place during an inner loop. The algorithm is shown in pseudocode form in Figure 4. The optimization uses two bucket trees (see section 3.3), and is initialized by calculating the gain for all border vertices and inserting them into one of the bucket trees. These vertices will subsequently be referred to as *candidate* vertices and the tree containing them as the *candidate tree*. The idea of only inserting the border vertices into the bucket tree (rather than all vertices) was first described in [23] and has subsequently been described as lazy initialization [9].

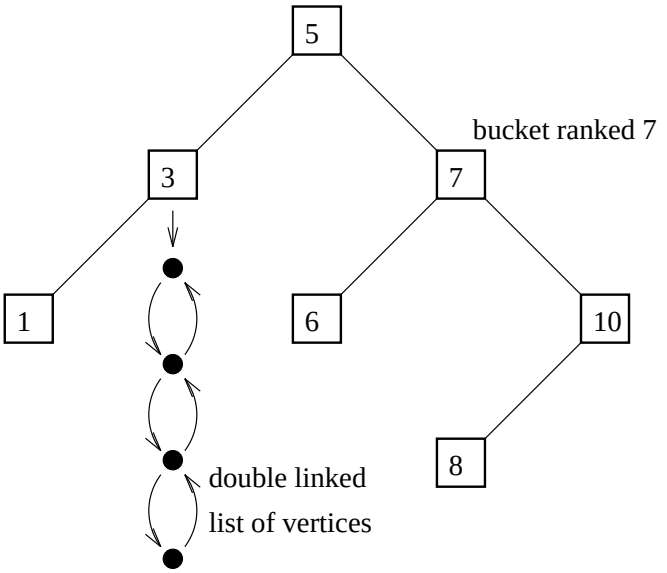

FIG. 3. *A bucket tree.*

The inner loop proceeds by examining candidate vertices highest gain first (by always picking vertices from the highest ranked bucket), testing whether the vertex is acceptable for migration, and then transferring it to the other bucket tree (the tree of *examined* vertices). This inner loop terminates when the candidate tree is empty, although it may terminate early if the partition cost (i.e., the number of cut edges) rises too far above the cost of the best partition found so far. This type of early termination is typical of KL-type algorithms; without it, the entire graph may be searched with diminishing prospect of finding a better solution along the search path. Once the inner loop has terminated any vertices remaining in the candidate tree are transferred to the examined tree and finally pointers to the two trees are swapped ready for the next pass through the inner loop.

Migration acceptance. Let T refer to the target weight for the graph (section 2.2) and W represent the weight of the largest subdomain, $W = \max_P |S_p|$. If the required flow from subdomain S_p to subdomain S_q is F_{pq}, a candidate vertex v with weight $|v|$ (≥ 0) is accepted for migration from S_p to S_q (with weights $|S_p|$ and $|S_q|$) if

$$\begin{array}{lll} & \text{(a) } W > T \quad \text{and} \quad 2F_{pq} > |v| \\ \text{or} & \text{(b) } W \leq T \quad \text{and} \quad |S_q| + |v| \leq T. \end{array} \tag{3.1}$$

These criteria reflect the aim of trying to balance the graph down to the target weight, T, and then keeping it there. If the graph is not yet within the imbalance tolerance (i.e., $W > T$), then (3.1a) only allows migration which reduces the required flow. Condition (3.1b) guarantees that once balance is achieved the graph cannot become unbalanced again.

Note that in order to satisfy the flow entirely we would only move a vertex if from S_p to S_q if the flow, F_{pq}, was greater than or equal to the vertex's weight (i.e., $F_{pq} \geq |v|$). The wider acceptance condition (3.1a), $2F_{pq} > |v|$, however, also allows moves where $|v|$ exceeds F_{pq} but which reduces the total required flow in the system.

```
while (optimizing) { /* outer loop */
    optimizing = 0
    best cost = cost
    while (vertices in candidate tree) { /* inner loop */
        vertex = best candidate
        if (migration acceptable for vertex) {
            optimizing = 1
            migrate vertex {
                adjust flow and subdomain weights
                adjust gains of neighboring vertices
                    and transfer to appropriate buckets
            }
            adjust gain of vertex and transfer to examined tree
            if (better partition) { /* confirm migration */
                best_cost = cost
                reset recent move list
            } else {
                append vertex to recent move list
                if (cost - best_cost > limit) /* early termination */
                    break
            } /* hill-climbing mechanism */
        }
        transfer vertex to examined tree
    } /* inner loop */
    for (vertices in recent move list) /* hill-climbing mechanism */
        migrate vertex back to previous partition
    for (vertices in candidate tree)
        transfer vertex to examined tree
    swap pointers to candidate and examined trees
} /* outer loop */
```

FIG. 4. *The Kernighan–Lin partition optimization algorithm.*

For example, if $|v| = 5$ and $F_{pq} = 3$, the migration would not be acceptable under the condition $F_{pq} \geq |v|$, but using (3.1a) the move is acceptable and F_{pq} changes to -2 (alternatively, $F_{qp} = 2$) after migration, which is a reduction in the total.

When a vertex is accepted for migration, its subdomain is changed and the subdomain weights and flow are adjusted. The gains are recalculated for the vertex and all of its neighbors and they are transferred to the appropriately ranked buckets. Note that examined vertices are transferred between buckets in the examined bucket tree and candidate vertices are transferred between buckets in the candidate bucket tree. Neighboring vertices which were not in the border at this point but which become border vertices as a result of the migration are put into the candidate tree. In this way it is actually possible for a vertex to be migrated more than once during the course of an inner loop (if it is moved out of and back into the border region by migration it becomes a candidate vertex at each stage), but accepted vertices which have not yet been confirmed (see below) cannot be transferred to the candidate tree as this can lead to infinitely cyclic behavior.

Migration confirmation and hill-climbing. The algorithm uses a KL-type

hill-climbing strategy. As can be seen from (3.1) migrations can be *accepted* even if they increase the partition cost (i.e., have negative gain). During each pass through the inner loop, a record of the optimal partition achieved by migration within that loop is maintained together with a list of vertices which have migrated since that value was attained. If subsequent migration finds a "better" partition, then the migration is *confirmed* and the list is reset. Once the inner loop is terminated, any vertices remaining in the list (vertices whose migration has not been confirmed) are migrated back to the subdomains they came from when the optimal cost was attained.

To define a "better" partition, let $\overline{\pi}$ represent the optimal partition reached so far and π^i the subsequent partition after some migration (i.e., after some iterations of the inner loop). Each partition has a cost associated with it, $C(\pi)$ (in this case just the total weight of cut edges), and an imbalance which depends on $W(\pi)$, the weight of the largest subdomain in that partition. Again let T represent the target weight for the graph (see section 2.2). Denoting $C(\pi^i)$ and $W(\pi^i)$ by C^i and W^i (and similarly for $\overline{\pi}$), then π^i is confirmed as a new optimal partition if:

$$\begin{array}{lll} & \text{(a) } C^i < \overline{C}, & \\ \text{or} & \text{(b) } C^i = \overline{C} & \text{and } W^i < \overline{W}, \\ \text{or} & \text{(c)} & T \leq W^i < \overline{W}. \end{array} \tag{3.2}$$

Condition (3.2c) simply states that, while the graph is unbalanced (i.e., $W^i > T$), any partition which improves the balance is confirmed. Conditions (3.2a) and (3.2b) are more typical of KL-type algorithms and confirm any partition which either improves on the optimal cost (3.2a) or improves on the optimal balance without raising the cost (3.2b). Note that whilst the partition is unbalanced, the conditions in (3.2) do not actually define an ordering of partitions (i.e., if π_1 and π_2 are partitions with $C_1 < C_2$ and $T < W_2 < W_1$, then either π_1 or π_2 would be confirmed in preference to the other). However, because of condition (3.1a), the behavior of the unbalanced system is monotonic in the sense that only changes that reduce $\Sigma_p \Sigma_q F_{pq}$ are accepted.

3.5. Vertices adjacent to several subdomains. In general, for graphs arising from FE/FV meshes with coarse granularity partitions (i.e., $V \gg P$), most border vertices will only be adjacent to vertices in one other subdomain. However, those vertices that are adjacent to several subdomains are treated slightly differently in that, if a tested migration is not acceptable, they are replaced in the *candidate* tree at the level of their next highest gain. They are not transferred to the examined tree until either being successfully migrated or all possible migrations have been tested. This is best illustrated with an example: suppose a vertex is adjacent to four subdomains, S_p, S_q, S_r, and S_s, and suppose that the respective gains are $g_p > g_q = g_r > g_s$. The vertex is initially placed in the candidate tree and ranked g_p. When subsequently tested, if migration is not acceptable using the criteria in 3.1, the vertex is replaced in the candidate tree and ranked g_q $(= g_r)$. When the vertex next comes up for testing, migration to S_p, S_q, and S_r is assessed (note that a move to S_p may now be acceptable due to the intervening migration), and if none are acceptable the vertex is replaced in the candidate tree with a rank g_s. When the vertex is again tested, migration to S_p, S_q, S_r, and S_s is tested, and if none are acceptable the vertex is transferred to the examined tree ranked g_p. Of course, it might be considered unnecessary to retest moves which have already been tested (i.e., those with gains greater than the migration under consideration), but since the edge weights to all adjacent subdomains must be calculated to determine the next highest gain, there is no great extra expense involved in doing so.

4. Results. We have implemented the algorithms described here within the framework of JOSTLE, a mesh partitioning software tool developed at the University of Greenwich and freely available for academic and research purposes under a licensing agreement[1]. The experiments were carried out on a Sun SPARC 20 with a 50 MHz CPU and 320 Mbytes of memory. The test graphs have been chosen to be a representative sample of medium to large scale real-life problems and include both 2D and 3D examples of nodal graphs (where the mesh nodes are partitioned) and dual graphs (where the mesh elements are partitioned). We have also included two non mesh-based graphs (vibrobox and memplus) and two weighted graphs (oliker and bmw1c). Such weighted graphs are not widely available since most applications do not accurately instrument costs and it is difficult to know whether such graphs are representative; however, they do seem to perform in a broadly similar fashion to those with unit weights.

Table 4.1 gives a list of the graphs, their sizes, the maximum, minimum, and average degree of the vertices, and a short description. The degree information (the degree of a vertex is the number of vertices adjacent to it) gives some idea of the character of the graphs. These range from the relatively homogeneous dual graphs, where every vertex represents a mesh element, in these cases a triangle (2D), tetrahedron (3D), or brick (3D), and so every vertex has at most 3, 4, or 6 neighbors, respectively, to the non mesh-based graphs memplus which has vertices of degree 573 and vibrobox, where the average degree is 26.8. Most of the graphs are not weighted and so the number of vertices in V is the same as the total vertex weight $|V|$, and similarly for the edges E. However we use two weighted graphs; oliker (with weighted vertices only and $|V| = 111,690$) is the root mesh for an hierarchical adaptively refined mesh and the weights represent the number of leaf elements that each root element has been refined into, whilst bmw1c (with $|V| = 1,073,726,486$ and $|E| = 3,396,572$) arises from an attempt to correctly instrument and model costs [15].

The results of using the multilevel balancing and refinement algorithm are shown in Table 4.2 for 4 values of P (the number of processors/subdomains). The table shows the total weight of cut edges, $|E_c|$, and the run time in seconds, t_s. The algorithm is allowed a final imbalance tolerance of $\theta_0 = 1.03$ (although this may be reset at runtime). In the following sections we compare the results with different balancing schedules and with a similar multilevel mesh partitioner which does not use

a multilevel balancing schedule. In these sections the $|E_c|$ results in Table 4.2 are also referred to as $|E_c(J)|$ and $|E_c(T_2)|$.

4.1. Comparison results. To demonstrate the quality of the partitions, we have compared the results in Table 4.2 with those produced by METIS, another state-of-the-art partitioning package [13]. The version we have used, kmetis 2.0.6, provides multilevel coarsening with a heavy edge heuristic and we have used the option of a KL partition refinement algorithm. (The default is a greedy partition refinement algorithm which is slightly faster but provides slightly lower quality partitions.) The primary distinctions between the two partitioners, aside from implementation details, is that METIS coarsens to 2,000 vertices and then carries out a balanced initial partition, whilst JOSTLE coarsens to P vertices (one per subdomain) and then uses the multilevel balancing schedule described in section 2.2 and the balancing refinement algorithm described in section 3.4. A more recent version of METIS is now available but only allows greedy refinement.

Table 4.3 shows a comparison of the cut-weight $|E_c|$. For each value of P, the first column shows the value of $|E_c|$ for METIS, $|E_c(M)|$, while the second column shows the ratio of $|E_c|$ for METIS over that for JOSTLE, $|E_c(M)|/|E_c(J)|$. As can be seen, with 4 exceptions (mesh1m, $P = 16$; oliker, $P = 32$, and $P = 128$; vibrobox, $P = 64$), the results for METIS are always worse and can be 17% larger (4elt, $P = 16$). The average difference in the quality ranges between 4% and 9% over the different values of P and as an overall average METIS produces partitions which are 5.9% worse than JOSTLE. Note that for the 2 weighted graphs METIS failed to partition bmw1c for any value of P (apparently becoming stuck in an infinite loop—we have removed this result from the averaging) and ran very slowly for oliker. Although this does not demonstrate a dramatic improvement for our algorithm, it does indicate a consistent improvement on results perceived as state-of-the-art.

We also tried using METIS in a similar manner to JOSTLE, coarsening down to P vertices. Although not as recommended by the code authors, this gave very similar results to Table 4.3 with an overall average partition quality 6.2% worse than JOSTLE.

It is not the primary aim of this paper to compare run times for the algorithms, but Table 4.4 shows a similar comparison of t_s. Unfortunately the results are somewhat distorted by idiosyncrasies of the partitioners. METIS performed particularly badly

for the weighted graphs, failing completely on bmw1c and running relatively very slowly for oliker (up to 22 times slower, $P = 16$), which heavily influences the averages. In contrast, JOSTLE runs relatively slowly for the non mesh-based graphs (up to 10 times slower for memplus, $P = 128$); this is because, as we discuss below (section 4.2), the vertex weight inhomogeneity in the coarse graphs means that the load-balancer is called with unnecessary frequency.

However, if we neglect the weighted and non mesh-based graphs, this table highlights a difference in implementations more than anything. For both codes the operation count is approximately linearly dependent on the number of border vertices (which increase with P), however, JOSTLE loops over border vertices while METIS loops over all vertices in the graph. This means that for coarse granularities (larger meshes or smaller values of P), where a relatively small number of vertices are in the subdomain borders, JOSTLE is faster since it visits a much smaller proportion of the data. However, for finer granularities (smaller meshes or larger values of P) METIS, by accessing the data contiguously, gains from a relatively good cache hit rate, while JOSTLE, which is essentially accessing the data at random, starts to lose out. These differences can be quite marked; for $P = 16$ on a large graph, JOSTLE is up to 1.68

times faster (mesh1m), while for $P = 128$, METIS can take about half the time (144).

4.2. Different balancing schedules. Constant schedule. The balancing schedule derived in section 2.2 is essentially an arbitrary heuristic and in this section we test some different schedules. First, Table 4.5 shows a comparison of the cut-weight for a constant schedule, $|E_c(T_c)|$, where θ_l is set to 1.03 for every graph G_l. For each value of P, the second column compares the results from this fixed schedule with the results in Table 4.2 using the 2D schedule and referred to as $|E_c(T_2)|$. As can be seen the constant schedule provides partition qualities which with 6 exceptions are always worse; the average difference in the quality ranges between 3% and 7% over the different values of P and can be as bad as 17%. This constant schedule strategy is similar to that used by METIS (which also has an imbalance tolerance of 1.03), where balance is established early on in the expansion/refinement process (in the case of METIS, during the initial partitioning) and maintained thereafter and indeed the average difference in the quality is about the same for the METIS results (Table 4.3).

Interestingly, five out of the six results for which the constant schedule is better than the 2D schedule are for the non mesh-based graphs. Our algorithms have all been tuned for performance with meshes (since that is where our own requirement for mesh partitioning lies), and so perhaps this is unsurprising. However a detailed study of the results suggests perhaps a more simple explanation. The non mesh-based graphs are very inhomogeneous, certainly in terms of vertex degree (see Table 4.1), and as a result the final coarsest graphs (indeed most of the coarse graphs) have very inhomogeneous vertex weights. This in turn means that most partitions of the coarser graphs are unbalanced (by the definition in section 2.2), and so the balancing schedule actually has very little effect since the optimization behaves in the same way while the graph is unbalanced, whether the imbalance is close to the threshold (as it might be for the 2D schedule) or far away (as in the constant schedule).

3D schedule. Table 4.6 shows a comparison of the cut-weight for the 3D schedule, $|E_c(T_3)|$, mentioned in section 2.2, and where the imbalance tolerance for graph G_l is set to $\theta_l = 1+3(\frac{P}{N_{l-1}})^{\frac{1}{3}}$. Again for each value of P, the second column compares the results from this fixed schedule with the results in Table 4.2 using the 2D schedule, $|E_c(T_2)|$. Overall both sets of results are very similar although on the average the 3D

results are marginally worse; the average difference in the quality ranges between 1% better and 1% worse with an overall average of just 0.22% deterioration. One might suspect that the 3D meshes would fare better with a 3D schedule than the 2D ones, but this does not seem to be borne out. In fact we have experimented with a number of different formulations and found the algorithm relatively insensitive to the schedule provided that the initial imbalance tolerance is sufficiently high.

4.3. Summary. Overall, we conclude from these results, together with the comparisons with METIS, and other experiments not presented here, that the use of a multilevel balancing schedule can improve the partition quality. The improvement is not enormous because the multilevel paradigm with a static schedule already provides excellent results (and hence the margin for improvement is small). However, it does exist and provides on average a 5–6% decrease in the cut-weight.

Note also that differences in quality tend to diminish as P increases. It is tempting to speculate that this is because the margins for difference decrease as the number of vertices per subdomain ($\approx V/P$) decreases. Indeed in the limit where $V = P$ the only balanced partition (for an unweighted graph at least) is to put one vertex in each subdomain and so the differences vanish altogether.

5. Conclusions and future directions. We have presented an enhancement to the multilevel paradigm where the freedom allowed by a balancing schedule is used to find higher quality partitions. We have also presented a formulation of a KL-type partition optimization algorithm which incorporates a diffusive balancing flow. The resultant algorithm has been shown to provide higher quality partitions than a state-of-the-art partitioner and, depending on granularity, is often faster.

The algorithms are fairly simple to describe and relatively parameter-free and as a result provide an ideal setting for testing new ideas before implementing them within the framework of a fully parallel mesh partitioner. Recently we have provided further results using the algorithms to address more complex partitioning problems such as balancing multiple computational phases [25], and to minimize alternative objective functions such as subdomain aspect ratio [22]. We also hope to use them in the near future to optimize mapping onto parallel machine topologies (rather than just cut-weight).

COMPUTING CONNECTING ORBITS VIA AN IMPROVED ALGORITHM FOR CONTINUING INVARIANT SUBSPACES*

J. W. DEMMEL†, L. DIECI‡, AND M. J. FRIEDMAN§

Abstract. A successive continuation method for locating connecting orbits in parametrized systems of autonomous ODEs was considered in [*Numer. Algorithms*, 14 (1997), pp. 103–124]. In this paper we present an improved algorithm for locating and continuing connecting orbits, which includes a new algorithm for the continuation of invariant subspaces. The latter algorithm is of independent interest and can be used in contexts different than the present one.

Key words. connecting orbits, invariant subspaces, bifurcations, numerical continuation

1. Introduction.

Homoclinic and *heteroclinic orbits*, also called *connecting orbits*, are trajectories connecting equilibrium points of a system of autonomous ODEs. Computation of connecting orbits is becoming increasingly important, both in dynamical systems research, such as understanding chaotic dynamics and in a variety of applied problems, including wave propagation in combustion models, chemical reactions, neuronal interactions, solitary waves in fluid, solitons in nonlinear optical fiber, and communication processes in living cells, to name a few. The corresponding numerical problem is that of finding solutions $(u(t), \lambda)$ of the system of autonomous ODEs

$$u'(t) - f(u(t), \lambda) = 0, \quad u(\cdot), f(\cdot, \cdot) \in \mathbb{R}^n, \lambda \in \mathbb{R}^{n_\lambda}, \tag{1.1}$$

$$\lim_{t \to -\infty} u(t) = u_0, \quad \lim_{t \to +\infty} u(t) = u_1. \tag{1.2}$$

Most algorithms for the numerical analysis of connecting orbits reduce (1.1), (1.2) to a *boundary value problem* on a finite interval using linear or higher-order approximations of stable and unstable manifolds near u_0 and u_1, respectively. See recent papers by Champneys, Kuznetsov, and Sandstede [4], Doedel, Friedman, and Kunin [10], and Moore [14] for the history of the question and the bibliography. Note that in the last work an alternative approach was used based on the arclength parametrization instead of using time t as a parameter.

The algorithms in [4] use a version of Beyn's continuation algorithm based on projection boundary conditions (see [1], [2]). They were implemented in a set of routines, `HomCont`, which are currently part of `AUTO97` [8]. `HomCont` has capabilities for detailed bifurcation analysis of homoclinic orbits and some bifurcations of heteroclinic orbits. It has limited capabilities for locating connecting orbits, namely, a simplified version of the algorithm in [10].

The algorithms in [10] have their primary focus on locating connecting orbits and use a modification of a continuation algorithm based on projection boundary conditions (see Friedman and Doedel [12]). They were implemented in an experimental code based on AUTO94 [9].

In order to have a well-posed problem, it is necessary for the boundary conditions to be sufficiently smooth with respect to parameters. In both [4] and [10], the boundary conditions are defined with respect to bases of stable or unstable eigenspaces of $f_u(u_0, \lambda)$ and $f_u(u_1, \lambda)$. The approach in [4] is to compute an orthonormal basis in the appropriate eigenspace, *at each pseudoarclength continuation step*, using a "black box" routine based on the real Schur factorization and then to adapt this basis to be smooth with respect to parameters, using a technique due to Beyn [2, Appendix C] which amounts to the solution of a linear system of the dimension of the eigenspace in question. The approach in [10] is to compute initially an orthonormal basis in the appropriate eigenspace via the real Schur factorization and then to continue the real Schur factorization equations (as a part of boundary conditions). At the same time precise convergence of the algorithm in [10] is not clear, and it is somewhat cumbersome to use. In some recent work Dieci and Eirola [6] provide a general differential equation framework for continuation of the block Schur factorization as well as other matrix factorizations. Reference [6] includes a comprehensive set of references for smooth matrix factorization for parameter dependent matrices.

In this paper we present an improved algorithm for locating and continuing connecting orbits, which includes a new algorithm for the continuation of invariant subspaces (CIS). This CIS algorithm is based on iterative refinement techniques originally due to Stewart [15] and later revisited by Demmel [5]. We provide some new twists to these techniques: (i) we justify these iterative refinement techniques using the differential equations which model continuation of block Schur forms, and (ii) we make use of these differential equations to obtain an accurate approximation of the relevant invariant subspace.

In the end, the new algorithm is more efficient than the algorithms in [4] and [10] and is very robust. In particular, it provides several possible safeguards against fast variation of eigenvalues. It has been implemented in an experimental code based on AUTO97, which is essentially a modification of the HomCont part of AUTO97, to include the algorithm in [10] for locating and continuing connecting orbits and the CIS algorithm, while preserving the bifurcation analysis part of HomCont.

2. An improved algorithm for locating and continuing connecting orbits. Assume, for simplicity of notation, that the fixed points u_0 and u_1 are hyperbolic, and the eigenvalues of $f_u(u_0, \lambda)$ and $f_u(u_1, \lambda)$, respectively, satisfy

$$\begin{aligned} &\mathrm{Re}\mu_{0,n} \le \cdots \le \mathrm{Re}\mu_{0,n_0+1} < 0 < \mu_{0,1} < \mathrm{Re}\mu_{0,2} \le \cdots \le \mathrm{Re}\mu_{0,n_0}, \\ &\mathrm{Re}\mu_{1,1} \le \cdots \le \mathrm{Re}\mu_{1,n_1} < 0 < \mathrm{Re}\mu_{1,n_1+1} \le \cdots \le \mathrm{Re}\mu_{1,n}. \end{aligned}$$

In this paper, we will assume that the matrices $f_u(u_{0,1}, \lambda)$ are smooth functions of λ (for λ in an appropriate subset of $\mathbb{R}^{n_\lambda}$).

The method extends to the case $\mu_{0,1} = 0$, as in [4]. It also extends to the cases of complex and multiple $\mu_{0,1}$ by a simple modification of Step 0, (2.9) below, of the algorithm (see [10, Section 4.3] for a computational example). The algorithm requires evaluation of various projections associated with the eigenspaces of $f_u(u_0, \lambda)$ and $f_u(u_1, \lambda)$. Initially these projections are constructed using the real Schur factorizations [13]

$$f_u(u_0,\lambda) = Q_0 R_0 Q_0^T, \quad f_u(u_1,\lambda) = Q_1 R_1 Q_1^T.$$

The first factorization has been chosen so that the first n_0 columns $q_{0,1},\dots,q_{0,n_0}$ of Q_0 form an orthonormal basis of the right invariant subspace S_0 of $f_u(u_0,\lambda)$, corresponding to $\mu_{0,1},\dots,\mu_{0,n_0}$, and the remaining $n-n_0$ columns $q_{0,n_0+1},\dots,q_{0,n}$ of Q_0 form an orthonormal basis of the orthogonal complement $S_0^\perp$. Similarly, the first n_1 columns $q_{1,1},\dots,q_{1,n}$ of Q_1 form an orthonormal basis of the right invariant subspace S_1 of $f_u(u_1,\lambda)$, corresponding to $\mu_{1,1},\dots,\mu_{1,n_1}$, and the remaining $n-n_1$ columns $q_{1,n_1+1},\dots,q_{1,n}$ of Q_1 form an orthonormal basis of the orthogonal complement $S_1^\perp$. In the algorithm below the matrices $Q_0(\lambda)$ and $Q_1(\lambda)$ are assumed to be computed at each continuation step by a "black box" routine, described in section 3, which ensures their continuity.

The approximate finite interval problem is to find a branch of solutions $(u(t),\lambda,u_0,u_1,T)$, $u\in C^1([0,1],\mathbb{R}^n)$, $\lambda\in\mathbb{R}^{n_\lambda}$, provided $n_\lambda = n-(n_0+n_1)+2$; $n_\lambda\ge 0$, $u_0,u_1\in\mathbb{R}^n$, $T>0$, is the length of the time interval, for some small $\epsilon_0,\epsilon_1>0$, of the time-scaled differential equation

$$u'(t) - Tf(u(t),\lambda) = 0, \quad 0<t<1, \tag{2.1}$$

subject to left boundary conditions

$$(u(0)-u_0)\cdot q_{0,n_0+i}(u_0,\lambda) = 0, \quad i=1,\dots,n-n_0, \tag{2.2}$$

$$|u(0)-u_0| = \epsilon_0, \tag{2.3}$$

right boundary conditions

$$(u(1)-u_1)\cdot q_{1,n_1+i}(u_1,\lambda) = 0, \quad i=1,\dots,n-n_1, \tag{2.4}$$

$$|u(1)-u_1| = \epsilon_1, \tag{2.5}$$

and stationary state conditions

$$f(u_0,\lambda) = 0, \tag{2.6}$$

$$f(u_1,\lambda) = 0. \tag{2.7}$$

Remark 1. Initially, we integrate in time to obtain a typically crude orbit with initial point $u(0)\in S_0$, but the terminal point $u(1)\notin S_1$, in general. Hence, τ_i defined by

$$\tau_i = (u(1)-u_1)\cdot q_{1,n_1+i}(u_1,\lambda)/\epsilon_1, \quad i=1,\dots,n_\tau = n-n_1 \tag{2.8}$$

are, in general, nonzero, and the initial connecting orbit on the branch of connecting orbits is found via a sequence of homotopies that locate successive zero intercepts of the τ_j in (2.8). In each homotopy step we compute a branch, that is, a one-dimensional manifold, of solutions. For this we must have $n_c - n_v = n-1$, where n_c is the number of constraints, and n_v is the number of scalar variables. We keep $u(1)$ free, while $u\,(0)$ is allowed to vary on the surface of the sphere in S_0 of radius ϵ_0: (i) according to (2.10) below at steps 0 through n_0, when λ is fixed and c_i in (2.10) play the role of the control parameters; and (ii) according to (2.3) at steps n_0+1 through n_0+n_λ, when λ varies.

Let $S_{0,k}$, $k=1,\dots,n_0$, be the right invariant subspace of $f_u(u_0,\lambda_0)$ corresponding to the eigenvalues $\mu_{0,1},\dots,\mu_{0,k}$. Then the first k columns $q_{0,1},\dots,q_{0,k}$ of Q_0 form an orthonormal basis of $S_{0,k}$ and the remaining $n-k$ columns $q_{0,k+1},\dots,q_{0,n}$ of Q_0 form an orthonormal basis of the orthogonal complement $S_{0,k}^\perp$.

1. Initialization.

Step 0. Initialize the problem parameter vector λ, and set the algorithm parameters ϵ_0 and T to small, positive values, so that $u(t)$ is approximately constant on $[0, T]$. Set

$$u(t) = u_0 + \epsilon_0 c_1 q_{01}, \quad 0 \le t \le 1, \tag{2.9}$$

or

$$u(t) = u_0 + \epsilon_0 c_1 q_{01} e^{\mathrm{Re}\mu_{0,1} t}, \quad 0 \le t \le 1, \quad \mathrm{Re}\mu_{0,1} > 0,$$

$\epsilon_1 = |u(1) - u_1|$, $c_1 = 1$, or -1 and $c_2 = \cdots = c_{n_0} = 0$.

2. Locating a connecting orbit, λ is fixed.

Step 1. Time integrate to get an initial orbit. Compute a solution branch to the system (2.1), (2.2), (2.8), (2.5), and

$$(u(0) - u_0) \cdot q_{0,i}(u_0, \lambda)/\epsilon_0 - c_i = 0, \;\; i = 1, \ldots, n_c = n_0, \tag{2.10}$$

in the direction of increasing T, until $u(1)$ reaches an ϵ_1-neighborhood of u_1 for some $\epsilon_1 > 0$. Scalar variables are T, $\epsilon_1 \in \mathbb{R}$, $\tau \in \mathbb{R}^{n-n_1}$. There are n differential equations with $n_c = 2n - n_1 + 1$ constraints and $n_v = n - n_1 + 2$ scalar variables, and hence $n_c - n_v = n - 1$. In practice one typically continues until ϵ_1 stops decreasing, its value being not necessarily small.

Step k, $k = 2, \ldots, n_0$ (for $n_0 > 1$). Compute a branch of solutions to the system (2.1)–(2.3), (2.8), (2.5)–(2.10) to locate a zero of, say, τ_{k-1} (while $\tau_1, \ldots, \tau_{k-2} = 0$, fixed). Free scalar variables are $\epsilon_1, c_1, \ldots, c_k, \tau_{k-1}, \ldots, \tau_{n-n_1}$. There are n differential equations with $n_c = 2n - n_1 + 2$ constraints and $n_v = n - n_1 + 3$ scalar variables, and hence $n_c - n_v = n - 1$.

3. Locating a connecting orbit, λ varies.

Step k, $k = n_0 + 1, \ldots, n_0 + n_\lambda \equiv n - n_1 + 1$. Compute a branch of solutions to the system (2.1)–(2.3), (2.8), (2.5)–(2.7) to locate a zero of, say, τ_{k-1} (while $\tau_1, \ldots, \tau_{k-2} = 0$, fixed). Free scalar variables are $\epsilon_1, \tau_{k-1}, \ldots, \tau_{n-n_1}, \lambda_1, \ldots, \lambda_{k-n_0} \in \mathbb{R}$, $u_0, u_1 \in \mathbb{R}^n$. There are n differential equations with $n_c = 4n - n_0 - n_1 + 2$ constraints and $n_v = 3n - n_0 - n_1 + 3$ scalar variables, and hence $n_c - n_v = n - 1$.

4. Increasing the accuracy of the connecting orbit.

Compute a branch of solutions to the system (2.1)–(2.7) in the direction of decreasing ϵ_1 until it is "small." Free scalar variables are $\epsilon_1, T, \lambda_1, \ldots, \lambda_{n_\lambda - 1} \in \mathbb{R}$, $u_0, u_1 \in \mathbb{R}^n$. As before, $n_c = 4n - n_0 - n_1 + 2$, $n_v = 3n - n_0 - n_1 + 3$.

5. Continue the connecting orbit.

Compute a branch of solutions to the system (2.1)–(2.7). Free variables are the (real) scalar T, and $\lambda_1, \ldots, \lambda_{n_\lambda}$, and the vectors $u_0, u_1 \in \mathbb{R}^n$. As before, $n_c = 4n - n_0 - n_1 + 2$, $n_v = 3n - n_0 - n_1 + 3$. Alternatively, a phase condition

$$\int_0^1 (u'(t) - q'(t)) \cdot u''(t)\, dt = 0 \tag{2.11}$$

may be added if T is kept fixed and ϵ_0 and ϵ_1 are allowed to vary. Here $q(t)$ is a previously computed orbit on the branch.

Remark 2. In principle, our algorithm of continuation of invariant subspaces of $f_u(u_0, \lambda)$ and $f_u(u_1, \lambda)$ in section 3 breaks down only if two eigenvalues, one associated with the subspace being continued and one not, approach the same point on the imaginary axis (one from the left and one from the right). In this case the algorithm should stop anyway since a bifurcation is being approached.

3. Continuation of invariant subspaces. Let $A(\lambda) \in \mathbb{R}^{n\times n}$ denote one of the following: $f_u(u_0, \lambda)$, $f_u(u_1, \lambda)$. The basic continuation algorithm requires at each pseudoarclength continuation step computation of a right invariant (typically, stable or unstable) m-dimensional subspace $S(\lambda)$ of $A(\lambda)$. In general, the function A is smooth in λ (say, differentiable), and it is important that $S(\lambda)$ be smooth also, as otherwise convergence difficulties can be expected.

In this section we show how to constructively obtain smooth and orthogonal $Q(\lambda) = [Q_1(\lambda)\ Q_2(\lambda)] \in \mathbb{R}^{n\times n}$, $Q_1(\lambda) \in \mathbb{R}^{n\times m}$, $Q_2(\lambda) \in \mathbb{R}^{n\times(n-m)}$ so that $Q_1(\lambda)$ span $S(\lambda)$ and $Q_2(\lambda)$ span the orthogonal complement $S(\lambda)^\perp$. Moreover, if we let $S_k(\lambda)$, $k = 1, \ldots, m$, be the right invariant subspaces of $A(\lambda)$ corresponding to the first k eigenvalues $\mu_1, \ldots, \mu_k$ of A, then the first k columns $q_1, \ldots, q_k$ of $Q(\lambda)$ form an orthonormal basis of $S_k(\lambda)$, and the remaining $n - k$ columns form an orthonormal basis of the orthogonal complement $S_k(\lambda)^\perp$.

To justify our construction, we should recall that in our continuation procedure we parametrize a solution branch in terms of so called pseudoarclength; let s denote the pseudoarclength variable.[1] Thus, both fixed points u_0 and u_1 (see (2.6)–(2.7)) as well as the parameter(s) λ are smooth functions of s. The matrix-valued function $A : \lambda \in \mathbb{R}^{n_\lambda} \to \mathbb{R}^{n\times n}$ can thus be viewed as a smooth function from $s \in \mathbb{R} \to \mathbb{R}^{n\times n}$. As a consequence, we can and will think of the continuation of invariant subspaces with respect to the scalar pseudoarclength variable s. For this reason, we will abuse notation and freely write $A(s)$ for $A(\lambda)$. In what follows, a "$\dot{}$" will indicate differentiation with respect to s.

Remark 3. If $n_\lambda = 1$ in (1.1), then one may be able to continue in λ itself, rather than reparametrizing the problem by arclength.

The basic issue is the following: suppose that initially we have the (real) block Schur factorization

$$A(0) = Q(0)R(0)Q^T(0), \quad Q(0) = [Q_1(0)\ Q_2(0)], \tag{3.1}$$

where $R(0)$ is block upper triangular ($R_{ii}(0)$, $i = 1, 2$, are not required to be triangular)

$$R(0) = \begin{bmatrix} R_{11}(0) & R_{12}(0) \\ 0 & R_{22}(0) \end{bmatrix},$$

the columns of $Q_1(0)$ span an invariant subspace $S(0)$ of $A(0)$, and the columns of $Q_2(0)$ span the orthogonal complement $S(0)^\perp$. We want to obtain a block Schur factorization for the matrix $A(s)$, close to $A(0)$, exploiting (if possible) the work already done to obtain the block Schur form for $A(0)$.

This problem fits within the general framework developed in [6]. Suppose that the matrix $A(s)$ has two groups of eigenvalues, $\Lambda_1(s)$ and $\Lambda_2(s)$, which stay disjoint for all s around 0. Then, in an interval about $s = 0$ there is the smooth factorization

$$A(s) = Q(s)R(s)Q^T(s), \quad Q(s) = [Q_1(s)\ Q_2(s)], \tag{3.2}$$

where $R(s)$ is in block Schur form $R(s) = \left[\begin{smallmatrix} R_{11}(s) & R_{12}(s) \\ 0 & R_{22}(s) \end{smallmatrix}\right]$. Here, R_{11} has eigenvalues Λ_1 and R_{22} has eigenvalues Λ_2. A constructive procedure to obtain the factorization

[1] Typically, this is the general procedure of most practical continuation algorithms; e.g., this is the strategy implemented in `AUTO`.

QRQ^T of A can be based upon differential equations models. As in [6], we differentiate the relations $A = QRQ^T$ and $Q^TQ = I$, let $H := Q^T\dot{Q}$, and obtain

$$\dot{R} = Q^T\dot{A}Q + RH - HR, \tag{3.3}$$

$$\dot{Q} = QH. \tag{3.4}$$

Now we use triangularity of R and the fact that H must be skew symmetric, $H^T = -H$; we partition H in the same way as R, and then can determine H_{12} by solving the Sylvester equation

$$R_{22}H_{12}^T - H_{12}^T R_{11} = (Q^T\dot{A}Q)_{21}. \tag{3.5}$$

The blocks H_{11} and H_{22} are not uniquely determined, and we may set them to 0 (in any case, they must be chosen skew symmetric). Thus, in principle, we can solve (3.3)–(3.4) subject to initial conditions (ICs) obtained from the factorization of $A(0)$, in order to obtain a smooth path of block Schur factorizations.

We can accumulate the transformations in such a way that we are always looking for corrections close to the identity. To be more precise, we can rewrite (for all s)

$$Q(s) = Q(0)U(s), \quad \text{with} \quad U(0) = I, \tag{3.6}$$

and use this in (3.4), thereby obtaining a differential equation for U, $\dot{U} = UH$ (notice that H is the same as before). We now look for exact solutions to the U differential equation. For all s, partition $U(s) = [U_1(s)\ U_2(s)] = \left[\begin{smallmatrix} U_{11}(s) & U_{12}(s) \\ U_{21}(s) & U_{22}(s) \end{smallmatrix}\right]$, with the same block dimensions as R. Since $U(0) = I$, there is an open interval about 0, call it I_0, where we can require that U_1 has the structure $U_1 = \left[\begin{smallmatrix} I \\ U_{21}U_{11}^{-1} \end{smallmatrix}\right] U_{11}$. Next, for all $s \in I_0$, we define

$$Y(s) := U_{21}(s)U_{11}^{-1}(s), \tag{3.7}$$

use the orthogonality relation $U_1^TU_1 = I$, and choose U_{11} symmetric,[2] to obtain $U_1 = \left[\begin{smallmatrix} I \\ Y \end{smallmatrix}\right](I + Y^TY)^{-1/2}$. In a similar way, for U_2 we use $U_2^TU_2 = I$ and $U_1^TU_2 = 0$, to eventually obtain, for every $s \in I_0$,

$$U(s) = \left[\begin{pmatrix} I \\ Y \end{pmatrix}(I + Y^TY)^{-1/2} \quad \begin{pmatrix} -Y^T \\ I \end{pmatrix}(I + YY^T)^{-1/2}\right]. \tag{3.8}$$

Thus, we need to find the function $Y \in \mathbb{R}^{(n-m)\times m}$ in (3.8). For any given $s \in I_0$, define $E(s)$ by

$$Q^T(0)A(s)Q(0) = Q^T(0)[A(0) + (A(s) - A(0))]Q(0) =: R(0) + E(s) = \begin{bmatrix} \widehat{R}_{11} & \widehat{R}_{12} \\ E_{21} & \widehat{R}_{22} \end{bmatrix}. \tag{3.9}$$

Now we substitute $Q(s)$ given by (3.6), (3.8), and $A(s)$ obtained from (3.9) into the invariant subspace relation,

$$Q_2^T(s)A(s)Q_1(s) = 0, \tag{3.10}$$

[2]This way, U_{11}^{-1} is the unique positive definite square root of $I + Y^TY$.

to obtain the following algebraic Riccati equation for Y:

$$\widehat{R}_{22}Y - Y\widehat{R}_{11} = -E_{21} + Y\widehat{R}_{12}Y \tag{3.11}$$

or

$$F(Y) = 0, \quad F(Y) := \widehat{R}_{22}Y - Y\widehat{R}_{11} + E_{21} - Y\widehat{R}_{12}Y. \tag{3.12}$$

Remark 4. If we think of $S(0)$ and $Q(0)$ as approximations to $S(s)$ and $Q(s)$, for s given, then we may interpret the form (3.8) as well as the resulting Riccati (3.11) as an iterative refinement technique to improve the accuracy of computed invariant subspaces. This is the viewpoint in the works of Stewart [15], Dongarra, Moler, and Wilkinson [11], Chatelin [3], and Demmel [5]. However, we prefer to think of (3.8) as the exact solution at a given s of the differential equation $\dot{U} = UH$ (see (3.4) and (3.6)). We will exploit this fact later.

How to solve (3.11). The following two iterative methods have been often advocated to solve the Riccati equation (3.11) (or (3.12)).

1. The iteration [15]:

$$\widehat{R}_{22}\Delta_k - \Delta_k\widehat{R}_{11} = -F(Y_{k-1}) \ , \ \ Y_k = \Delta_k + Y_{k-1}, \tag{3.13}$$

with $Y_0 = 0$, $k = 1, 2, \ldots$.

2. The Newton iteration [5]:

$$(\widehat{R}_{22} - Y_{k-1}\widehat{R}_{12})\Delta_k - \Delta_k(\widehat{R}_{11} + \widehat{R}_{12}Y_{k-1}) = -F(Y_{k-1}) \ , \ \ Y_k = \Delta_k + Y_{k-1}, \tag{3.14}$$

with $Y_0 = 0$, $k = 1, 2, \ldots$.

Therefore, we need to solve a Sylvester equation in the inner loop of the iterative refinement. This can be effectively done by using `LAPACK` routines. As shown in the convergence analysis for the iterations (3.13) and (3.14) by Stewart [15] and Demmel [5], respectively, if we let

$$\kappa = \frac{\|\widehat{R}_{12}\|_F \|E_{21}\|_F}{\mathrm{sep}^2(\widehat{R}_{11}, \widehat{R}_{22})}, \tag{3.15}$$

then under the assumptions $\kappa < 1/4$ and $\kappa < 1/12$, the iterations (3.13) and (3.14) converge linearly and quadratically, respectively. In (3.15), $\| \cdot \|_F$ is the Frobenius norm of a matrix.

The parameter κ can be interpreted as follows. Its numerator, $\|\widehat{R}_{12}\|_F \|E_{21}\|_F$, measures the quality of the initial approximate invariant subspace: it will be small when the approximation is good, and the factor $\|E_{21}\|_F$ will be zero if and only if the initial approximation is in fact correct. The function $\mathrm{sep}(\widehat{R}_{11}, \widehat{R}_{22})$ in the denominator is the smallest singular value of the operator which maps Y to $\widehat{R}_{22}Y - Y\widehat{R}_{11}$, and it measures the separation of the spectra of $\widehat{R}_{11}$ and $\widehat{R}_{22}$. If $\mathrm{sep}(\widehat{R}_{11}, \widehat{R}_{22})$ is small, it means that some eigenvalues of $\widehat{R}_{11}$ and $\widehat{R}_{22}$ can be made to merge with small changes in $\widehat{R}_{ii}$; this means that the invariant subspaces belonging to the two parts of the spectrum are unstable and hard to compute. Thus κ will be small if we start with a good initial approximate invariant subspace and if the eigenvalues associated with that subspace are well separated from the remainder of the spectrum. Oversimplifying, both algorithms converge if (i) the spectra of $R_{11}(0)$ and $R_{22}(0)$ are far enough apart and (ii) the perturbation $E(s)$ of $R(0)$ is small enough.

Remark 5. We point to some additional safeguards, which ensure proper performance of the algorithms (3.13) and (3.14).

1. Note that from (3.9) we have $\|E_{21}\|_F \le \|E\|_F \le \|A(s) - A(0)\|_F$. Hence, from (3.15), if

$$\alpha\|A(s) - A(0)\|_F \le \frac{1}{4}, \quad \alpha = \frac{\|\widehat{R}_{12}\|_F}{\mathrm{sep}^2(\widehat{R}_{11}, \widehat{R}_{22})}, \tag{3.16}$$

then $\kappa < 1/4$. Therefore we are guaranteed that for any matrix $X \in \mathbb{R}^{n\times n}$ with $\alpha\|X - A(0)\|_F \le \frac{1}{4}$ we can find the invariant subspaces S and $S^\perp$ by Algorithm (3.13), say. And no eigenvalue of $A\,|_S$ can "merge" with an eigenvalue from $A\,|_{S^\perp}$, where $A\,|_S$ denotes the restriction of A to S, etc. In other words, the eigenvalues of $A\,|_S$ and $A\,|_{S^\perp}$ remain separated for all matrices in a ball around $A(0)$ of radius $1/(4\alpha)$. Thus, employing the safeguard (3.16) ensures that the iterations (3.13) and (3.14) will diverge only when a small perturbation $A(s)$ of $A(0)$ will make an eigenvalue from $S(s)$ and an eigenvalue from $S(s)^\perp$ coalesce.

2. The quantity $\|E_{21}\|_F/\mathrm{sep}(\widehat{T}_{11}, \widehat{T}_{22})$ can be interpreted [13, pp. 347–348] as an estimate from above of the tangent of the angle between the subspaces $S(0)$ and $S(s)$ spanned by $Q_1(0)$ and $Q_1(s)$, respectively. Hence the convergence of our algorithms implies that this angle always stays between 0 and $\pi/2$. It is useful to monitor this angle and, in some situations, control it. A convenient measure in this case is the sine of this angle [13, p. 77] given by

$$\mathrm{dist}(S(0), S(s)) = \sqrt{1 - \sigma^2_{\min}\left(Q_1^T(0)Q_1(s)\right)}.$$

Taking into account that by (3.2), (3.6), and (3.8),

$$Q_1(s) = (Q_1(0) + Q_2(0)Y)(I + Y^TY)^{-1/2},$$

this reduces to

$$\mathrm{dist}(S(0), S(s)) = \sqrt{1 - \sigma^2_{\min}\left(I + Y^TY\right)^{-1/2}} = \frac{\|Y\|_2}{\sqrt{1 + \|Y\|_2^2}}. \tag{3.17}$$

The previous discussion has been motivated by the standard linear algebra viewpoint, that is, of "how to refine the initial trivial estimate $U = I$." In particular, this gave us the initial conditions $Y_0 = 0$ for the iterations (3.13) and (3.14). However, from the point of view of continuation, this is usually not the best strategy, since it amounts to starting with the old solution as initial guess. We can do better by using the differential equation formulation and taking an Euler approximation to the solution.

Recall that the matrix Y, solution of (3.11), is related to U by (3.7): $Y(s) = U_{21}(s)U_{11}^{-1}(s)$ for all s in a neighborhood of 0. Here, $U_1 = \left[\begin{smallmatrix} U_{11} \\ U_{21} \end{smallmatrix}\right]$, and $U = [U_1\ U_2]$ solves the differential equation $\dot{U} = UH$ (see (3.4)–(3.6)). That is,

$$\dot{U}_1 = U_1H_{11} + U_2H_{21}, \quad \dot{U}_2 = -U_1H_{21}^T + U_2H_{22}. \tag{3.18}$$

Recall that the factor H_{21} is determined by (3.5), but there is freedom insofar as the choice of H_{11} and H_{22}. We now show that the range of s-values guaranteeing invertibility of $U_{11}(s)$ is unaffected by the choice of H_{11} and H_{22} in (3.18), and hence there is little reason not to set H_{11} and H_{22} both equal to 0 when we represent U as in (3.8).

LEMMA 3.1. *Let $U = [U_1\ U_2]$ be the solution of* (3.18) *with $U(0) = I$, obtained by setting $H_{11} = 0$ and $H_{22} = 0$ in* (3.18)*, while determining H_{21} by* (3.5)*. Let $\tilde{U}(s) = [\tilde{U}_1\ \tilde{U}_2]$ be the solution of* (3.18) *with $\tilde{U}(0) = I$ and H_{11} and H_{22} nonzero skew symmetric matrices. Then, we have (for all s)*

$$\tilde{U}_1(s) = U_1(s)C(s),$$

where $C(s) \in \mathbb{R}^{m\times m}$ is orthogonal. Therefore, partitioning $U_1 = \left[\begin{smallmatrix} U_{11} \\ U_{21} \end{smallmatrix}\right]$, and similarly for $\tilde{U}_1$, we have $Y(s) = U_{21}(s)U_{11}^{-1}(s) = \tilde{U}_{21}(s)\tilde{U}_{11}^{-1}(s)$ for the same range of s values.

Proof. For all s, let $p(\lambda, s)$ be the characteristic polynomial of the matrix $A(s)$. Then, we have the factorization $p(\lambda, s) = p_1(\lambda, s)p_2(\lambda, s)$, where the factors p_1 and p_2 have no common root, and the roots of p_1 give Λ_1, while the roots of p_2 give Λ_2. Thus, we have

$$p_1(Q^T(0)A(s)Q(0), s)U_1(s) = 0$$

and

$$p_1(Q^T(0)A(s)Q(0), s)\tilde{U}_1(s) = 0.$$

Therefore, since $\operatorname{rank}(p_1(A(s), s)) = n - m$, then $\tilde{U}_1(s) = U_1(s)C(s)$, where $C(s)$ is orthogonal (since $\tilde{U}_1^T(s)\tilde{U}_1(s) = I$). ∎

Now, because of Lemma 3.1, we can just integrate the differential equations (3.18) with H_{11} and H_{22} equal to 0:

$$[\dot{U}_1\ \dot{U}_2] = [U_2H_{21}\ \ -U_1H_{21}^T], \quad U(0) = I.$$

So, the idea is to approximate the solution of these differential equations from 0 to s in order to get an approximation V_1 to $U_1(s)$ and thus obtain an approximation to $Y(s)$ from $V_{21}V_{11}^{-1}$, where we have partitioned $V_1 = \left[\begin{smallmatrix} V_{11} \\ V_{21} \end{smallmatrix}\right]$. We use a forward Euler step to obtain V_1.[3]

1. Initialization.

Set $U(0) = I$ and obtain $H_{21}(0)$ from solving the Sylvester equation

$$R_{22}(0)H_{21}(0) - H_{21}(0)R_{11}(0) = -\,(0\ I)\,Q(0)^T\dot{A}(0)Q(0)\,(I\ 0)^T\,. \tag{3.19}$$

2. Euler step.

Let $V_1 = U_1(0) + sU_2(0)H_{21}(0)$. Obtain initial guess for the Riccati equation (3.11) (or (3.12)):

$$Y_0 = V_{21}V_{11}^{-1}. \tag{3.20}$$

Remark 6. We now look at how this new initial guess Y_0 in (3.20) impacts convergence of the iterations (3.13) and (3.14). We also make some comments on expense.

1. Observe that the value of Y_0 in (3.20) is nothing but $Y_0 = sH_{21}(0)$. It is easy to verify that this is precisely the same approximation we would have obtained by using a forward Euler step to approximate the solution at s of the differential equation satisfied by Y.

[3]Use of the Euler step is an accepted standard in continuation algorithms, and it is the strategy implemented in `AUTO`.

2. By our construction, we see that Y_0 in (3.20) is a second order approximation (in s) to the exact solution $Y(s)$. More precisely, from Taylor expansion at $s = 0$ of the exact solution $Y(s)$, we immediately get that $Y(s) = s\dot{Y}(0)+O(s^2) = sH_{21}(0)+O(s^2)$. On the other hand, the initial guess $Y_0 = 0$ is only an $O(s)$ approximation to $Y(s)$.

3. In practice, in (3.19), we do not have a close expression for $\dot{A}(0)$, but we can replace it by the difference quotient $(1/s)(A(s) - A(0))$. With this choice, the value of Y_0 (defined as in (3.20)) turns out to be the solution of the Sylvester equation

$$R_{22}(0)Y_0 - Y_0R_{11}(0) = -E_{21}. \tag{3.21}$$

Since $\dot{A}(0) = (1/s)(A(s) - A(0)) + O(s^2)$, the value of Y_0 in (3.21) is still a $O(s^2)$ approximation to the exact $Y(s)$.

4. The estimates (and proof) of convergence for (3.13) and (3.14) relied on the value of κ in (3.15) to be sufficiently small. Much the same arguments can be used for the refined guess in (3.20) by the following simple modification. In $U(s)$ in (3.8), we let $Y(s) = Y_0 + \Delta Y$ and use this form of U in the invariant subspace relation (3.10). So doing, we obtain the new Riccati equation

$$(\widehat{R}_{22} - Y_0\widehat{R}_{12})\Delta Y - \Delta Y(\widehat{R}_{11} + \widehat{R}_{12}Y_0) = -F(Y_0) + \Delta Y R_{12}\Delta Y. \tag{3.22}$$

Now, it is a simple verification that iterative solution of (3.22) by either of the two iterations, (3.13) or (3.14), appropriately reformulated for the unknown ΔY, produces precisely the same sequence as the original iterations on the unknown Y had they been started with initial guess Y_0 in (3.20). As a consequence, the convergence results we quoted after (3.15) hold unchanged, except that we have a new κ value, call it $\tilde{\kappa}$:

$$\tilde{\kappa} = \frac{\|\widehat{R}_{12}\|_F\|F(Y_0)\|_F}{\mathrm{sep}^2(\tilde{R}_{11}, \tilde{R}_{22})}, \quad \tilde{R}_{11} = \widehat{R}_{11} + \widehat{R}_{12}Y_0, \quad \tilde{R}_{22} = \widehat{R}_{22} - Y_0\widehat{R}_{12}. \tag{3.23}$$

We now look at the ratio

$$\frac{\tilde{\kappa}}{\kappa} = \frac{\|F(Y_0)\|_F}{\|E_{21}\|_F}\left(\frac{\mathrm{sep}(\widehat{R}_{11}, \widehat{R}_{22})}{\mathrm{sep}(\tilde{R}_{11}, \tilde{R}_{22})}\right)^2.$$

By our previous remark, $F(Y_0)$ is close to 0 at second order in s, whereas E_{21} is only first order close to 0. To compare $\mathrm{sep}(\tilde{R}_{11}, \tilde{R}_{22})$ with $\mathrm{sep}(\widehat{R}_{11}, \widehat{R}_{22})$, we realize that $\mathrm{sep}(\tilde{R}_{11}, \tilde{R}_{22})$ is a second order approximation to $\mathrm{sep}(R_{11}(s),\ R_{22}(s))$, whereas $\mathrm{sep}(\widehat{R}_{11}, \widehat{R}_{22})$ is only a first order approximation to the same quantity. Therefore, in first approximation, $\left(\frac{\mathrm{sep}(\widehat{R}_{11}, \widehat{R}_{22})}{\mathrm{sep}(\tilde{R}_{11}, \tilde{R}_{22})}\right)^2$ is $1 + O(s/\mathrm{sep}(R_{11}(s),\ R_{22}(s)))$. To summarize, we have that

$$\tilde{\kappa}/\kappa = O(s), \tag{3.24}$$

with an obvious improvement in the radius of convergence for both iterations (3.13) and (3.14).

5. By creating the initial guess Y_0 from (3.20) we need to solve the Sylvester equation (3.19) or (3.21). Typically, this involves Schur reduction of the matrices $R_{11}(0)$ and $R_{22}(0)$, which is somewhat expensive. However, suppose we use the Newton iteration (3.14); then, at each iteration step we need to Schur factor the matrices $\widehat{R}_{11}+\widehat{R}_{12}Y_{k-1}$ and $\widehat{R}_{22}-Y_{k-1}\widehat{R}_{12}$. At the convergence of Newton's method, these are

precisely the matrices we will need for the next continuation step in (3.19). Therefore, no extra factorizations are needed in this case. For a practical comparison of the iterations for the two initial guesses (3.20) and $Y_0 = 0$, we refer to the next section. A more extensive comparison and further details can be found in [7].

Remark 7. An alternative to our approach for continuing orthogonal invariant subspaces could be easily obtained as follows. Let $Q(0) : Q^T(0)A(0)Q(0)$ be a Schur factorization of $A(0)$, $Q(0) = [Q_1(0)\ Q_2(0)]$ as usual, so that (say) $Q_1(0)$ spans the invariant subspace relative to the eigenvalues with positive real parts. Next, consider $A(s)$ which has the same number of eigenvalues with a positive real part as $A(0)$. Then, one may think to take the ordered Schur factorization of the matrix $A(s) :\ P^T A(s)P$, and partition $P = [P_1\ P_2]$ so that P_1 spans the invariant subspace relative to the eigenvalues with a positive real part of $A(s)$. In general, P_1 is not smooth (that is, it is not true that $P_1 = Q_1(0) + s\dot{Q}_1(0) + \cdots$). To enforce smoothness, we may solve an orthogonal Procrustes problem and replace P_1 with P_1V, where V is the orthogonal polar factor of $P_1^T Q_1(0)$ (see [13]). Essentially, this is the approach used by Beyn [2], and then implemented in `HomCont` [4]. However, we believe that the approach we have adopted is preferable to the one we just outlined. For one thing, the latter is usually more expensive than our approach. Moreover, unlike the one we just outlined, our approach to continuation of invariant subspaces is more in tune with the original continuation problem: continuation of the subspaces influences the continuation step, and using first derivative information (as we did to obtain (3.20)) is bound to reflect genuine difficulties of the original differential equation (such as nearing a bifurcation) into the continuation algorithm.

4. Example: Heteroclinic orbits in a four-dimensional singular perturbation problem. Consider the problem of finding traveling wave front solutions to the FitzHugh–Nagumo equations with two diffusive variables,

$$v_t = v_{xx} + v(v-a)(1-v) - w, \quad w_t = \delta w_{xx} + \epsilon(v - \gamma w), \tag{4.1}$$

for small positive ϵ, where δ ranges between a small and large value. For δ small this is a singularly perturbed reaction-diffusion system. In moving coordinates, $v_1 = v(z)$, $v_2 = v'(z)$, $w_1 = w(z)$, $w_2 = w'(z)$ with $z = t + cx$, the reduced ODE is

$$\begin{aligned} v_1' &= v_2, \\ v_2' &= cv_2 - v_1(1-v_1)(v_1 - a) + w, \\ w_1' &= w_2, \\ w_2' &= [cw_2 - \epsilon(v_1 - \gamma w_1)]/\delta. \end{aligned} \tag{4.2}$$

In [10] we located a heteroclinic orbit of (4.2). Here we first reproduced this result with our new code and then located a heteroclinic orbit with $\delta = \epsilon = 0.001$, $\gamma = 13.23529$, $a = 0.3$, and $c = 0.2571271$. In this case $n_0 = n_1 = 2$, where the relevant eigenvalues are $\mu_{0,1} = 0.6958$, $\mu_{0,2} = 257.2$, $\mu_{1,1} = -0.4247$, and $\mu_{1,2} = -0.06553$. We then performed a two parameter continuation in (δ, c) in the direction of increasing δ; see Figure 4.1 for the bifurcation diagram and Figure 4.2 for some typical solutions in (v_1, t) coordinates.

We have implemented four methods to solve the Riccati equation: (i) the "simple iteration" (3.13) with zero initial guess, (ii) Newton's method (3.14) with zero initial guess, (iii) simple iteration (3.13) with Euler initial guess, and (iv) Newton's method with Euler initial guess. The numerical results agree with our theoretical results; in

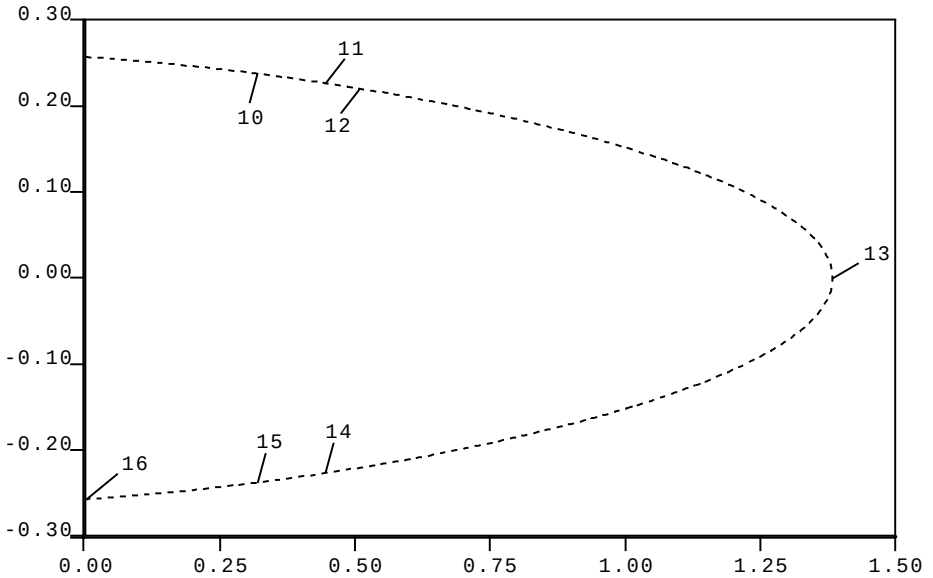

FIG. 4.1. *Bifurcation diagram in* (δ, c) *coordinates. At label* 10 $(\delta, c) = (0.3198,\ 0.2376)$ *and the eigenvalues are* $\mu_{0,1} = \mu_{0,2} = 0.7406$, $\mu_{1,1} = -0.4357$, *and* $\mu_{1,2} = -0.06502$. *At label* 11 $(\delta, c) = (0.4462, 0.2265)$ *and the eigenvalues are* $\mu_{0,1} = \mu_{0,2} = 0.6204$, $\mu_{1,1} = -0.4409$, *and* $\mu_{1,2} = -0.06565$. *The eigenvalues are complex between the labels* 10 *and* 11. *At label* 12 $(\delta, c) = (0.5085, 0.2202)$ *and the eigenvalues are* $\mu_{0,1} = 0.5098$, $\mu_{0,2} = 0.6538$, $\mu_{1,1} = -0.4436$, *and* $\mu_{1,2} = -0.06612$, *where* $|\mu_{1,1}| + |\mu_{1,2}| = \mu_{0,1}$. *At label* 13 $(\delta, c) = (1.383, 0)$ *and the eigenvalues are* $\mu_{0,1} = -\mu_{1,2} = 0.1099$, $\mu_{0,2} = -\mu_{1,1} = 0.5454$. *The part of the branch below the* δ*-axis is symmetric to the one above the* δ*-axis.*

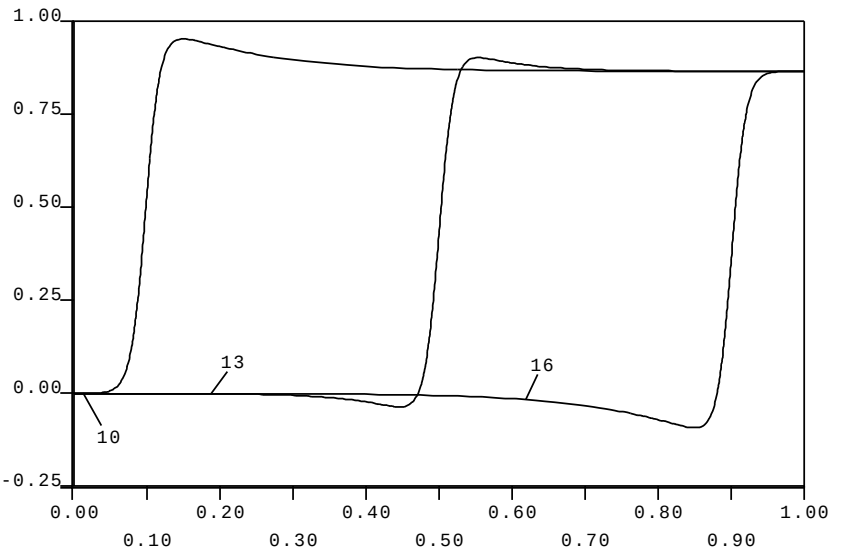

FIG. 4.2. *Some typical solutions in* (v_1, t) *coordinates.*

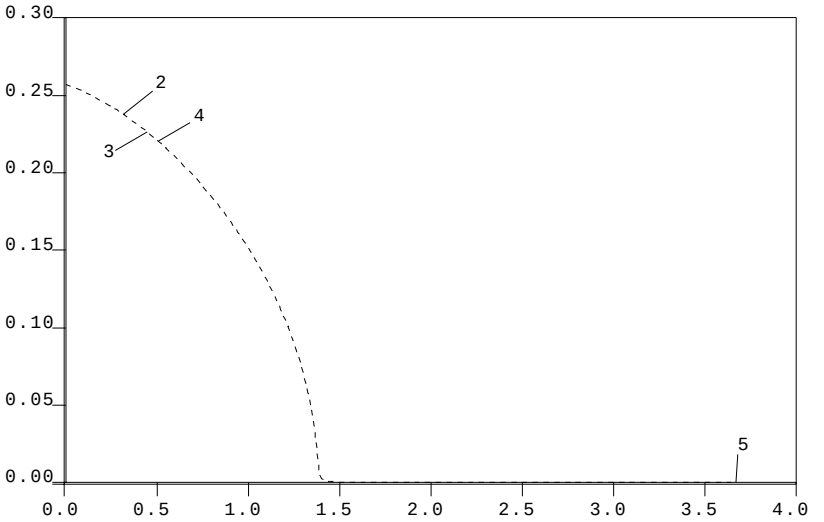

FIG. 4.3. *Bifurcation diagram in* (δ, c) *coordinates computed by* `HomCont` *(*`AUTO97`*).*

particular, the choice of the Euler initial guess is a big improvement with respect to the simpler zero guess. Specifically, for the same pseudoarclength continuation step (it took 433 such steps to compute the branch), (iii) and (iv) required much fewer iterations to converge than (i) and (ii). Some insight in the advantages gained by use of the Euler guess is obtained by considering the typical convergence behavior of the 4 methods (i)–(iv): on average, method (i) required 7 iterations for convergence, method (ii) needed 5, method (iii) needed slightly more than 4, and method (iv) required less than 3 iterations for convergence. In one exceptional case, methods (i) and (ii) required as many as 25 iterations. Finally, (i) and (ii) failed to converge in some cases (at the end of the continuation), because the continuation step was not small enough, whereas (iii) and (iv) never failed to converge.

Labels 10, 11, 12, 14, and 15 mark local bifurcations (of the eigenvalues), while label 13 marks a global bifurcation, the intersection of the current branch with the branch $c = 0$ (the detailed analysis of these bifurcations will be given elsewhere). For comparison, we repeated the computation of the above branch using `HomCont` (in `AUTO97`); see Figure 4.3. Note that in this case we have not suceeded in continuing the original branch beyond the global bifurcation point and instead switched branches. Indeed, by varying the continuation step size, with our code we could select the desired branch at label 13, but we could not achieve the same result with `HomCont`. Though we do not have a precise explanation for this difference in performance, we feel that this example confirms our theoretical insight that our numerical method is more in tune with the original continuation problem.

Acknowledgments. The authors wish to thank Z. Bai, University of Kentucky, for helpful discussions and for providing a subroutine for solving the Sylvester equation and W.-J. Beyn, University of Bielefeld, for helpful comments on an earlier version of the manuscript. The third author is also grateful to the IMA of University of

Minnesota, the Department of Mathematics of the University of Utah, the Computer Science Division of the University of California at Berkeley, and the Center for Dynamical Systems and Nonlinear Studies at the School of Mathematics of Georgia Tech for their hospitality during parts of his sabbatical stay, when this work was completed.

A PARALLEL JACOBI–DAVIDSON-TYPE METHOD FOR SOLVING LARGE GENERALIZED EIGENVALUE PROBLEMS IN MAGNETOHYDRODYNAMICS*

MARGREET NOOL† AND AUKE VAN DER PLOEG‡

Abstract. We study the solution of generalized eigenproblems generated by a model which is used for stability investigation of tokamak plasmas. The eigenvalue problems are of the form $Ax = \lambda Bx$, in which the complex matrices A and B are block-tridiagonal, and B is Hermitian positive definite. The Jacobi–Davidson method appears to be an excellent method for parallel computation of a few selected eigenvalues because the basic ingredients are matrix vector products, vector updates, and inner products. The method is based on solving projected eigenproblems of order typically less than 30.

We apply a complete block LU decomposition in which reordering strategies based on a combination of block cyclic reduction and domain decomposition result in a well-parallelizable algorithm. One decomposition can be used for the calculation of several eigenvalues. Spectral transformations are presented to compute certain interior eigenvalues and their associated eigenvectors. The convergence behavior of several variants of the Jacobi–Davidson algorithm is examined. Special attention is paid to the parallel performance, memory requirements, and prediction of the speed-up. Numerical results obtained on a distributed memory Cray T3E are shown.

1. Introduction.

Consider the generalized eigenvalue problem

$$Ax = \lambda Bx, \qquad A, B \in \mathbb{C}^{N_t \times N_t}, \tag{1}$$

where A and B are complex block-tridiagonal $N_t \times N_t$ matrices and B is Hermitian positive definite. The number of diagonal blocks is denoted by N and the blocks are $n \times n$; therefore $N_t = N \times n$.

Eigenvalue problems arise in many applications. We are particularly interested in generalized eigenvalue problems as they occur in linear magnetohydrodynamics (MHD). Such problems are generated by a finite-element spectral code CASTOR (complex Alfvén spectrum of toroidal plasmas) [8]. This code is applied intensively at the FOM Institute voor Plasmafysica, Nieuwegein (the Netherlands) for the stability investigation of tokamak plasmas [9, 13]. The physicists are particularly interested in accurate approximations of certain interior eigenvalues, called the *Alfvén spectrum* and their associated eigenvectors. Figure 1 shows the complete and the Alfvén spectrum of (1) for a small test problem with $N = 50$ and $n = 32$. A target σ is given in the neighborhood in which we want to find several eigenvalues with corresponding eigenvectors. In general, the subblocks of A are dense and N_t can be very large,

so computer storage demands are very high. Until now powerful shared memory machines with a huge amount of memory, such as the Cray C90, were used for this purpose. In this paper, we study as an alternative the feasibility of parallel computers with a large distributed memory for solving large generalized eigenvalue problems.

A promising method for computing selected eigenvalues of (1) is the Jacobi–Davidson (JD) algorithm [16, 3, 4, 5, 15]. The method has become very popular, and since we have started this project many aspects have been investigated, for instance, a variant with harmonic Ritz values has already been implemented [12]. In the future, we consider implementation of the Jacobi–Davidson QZ algorithm (JDQZ) [6] and inclusion of explicit deflation. In section 2 we briefly describe the JD algorithm for solving a block-tridiagonal eigenvalue problem. Within JD a parallel method to compute the action of the inverse of the block-tridiagonal matrix $A - \sigma B$ is used. In this approach, called DDCR, a block-reordering based on a combination of domain decomposition and cyclic reduction is combined with a complete block-tridiagonal LU decomposition of $A - \sigma B$, so $LU = A - \sigma B$. Both the construction of L and U and the triangular solves parallelize well. In this report we concentrate on the application of DDCR within JD. Originally, it was developed as a parallel preconditioner to apply within JD and appropriate for solving MHD eigenvalue problems. Some aspects of this technique are discussed in section 3.

However, the availability of a complete LU decomposition gives us the opportunity to apply the Jacobi–Davidson method to a *standard* eigenvalue problem instead of a *generalized* eigenvalue problem. Writing (1) as $(A - \sigma B)x = (\lambda - \sigma)Bx$, we have

$$x = (\lambda - \sigma)(A - \sigma B)^{-1}Bx.$$

If we define Q as $(A - \sigma B)^{-1}B$, for some value σ, we obtain the standard eigenvalue problem

$$Qx = \mu x \quad \text{with } \mu = \frac{1}{\lambda - \sigma} \Leftrightarrow \lambda = \sigma + \frac{1}{\mu}. \tag{2}$$

The eigenvalues μ of (2) form the dominant part of the spectrum, which makes them relatively easy to compute. In practice, one has to be careful because small pivot elements can be generated during the decomposition of $A - \sigma B$, especially when σ is

very close to an eigenvalue. In that case, taking $Q = (LU)^{-1}B$ in (2) may influence the computed spectrum. It is advisable to visualize the obtained eigenvalue spectrum and to compare it with results of a run with another target in the neighborhood of the spectrum. A smaller tolerance can also give information about the accuracy.

As a basis for the development of the parallel code, we have taken a sequential `FORTRAN` code for the JD algorithm, which was developed by the late Albert Booten at CWI [3, 4, 5]. The data structure for storing the matrices was modified in such a way that we could use optimized `BLAS` routines as much as possible. Furthermore, that part of the CASTOR code [8] which generates the matrices A and B has been parallelized and coupled with the JD code. Of course, other (generalized) eigenvalue problems satisfying (1) can be solved by our code. Several subroutines are available to read data efficiently from files and to distribute them to the processors. Section 4 describes the data organization of the JD code on the Cray T3E. Moreover, the memory requirements are given for both our sequential and parallel implementation.

In section 5 the convergence behavior of several variants of the Jacobi–Davidson algorithm is examined. Numerical results for three MHD eigenproblems obtained by a Cray T3E are presented and analyzed, and an analysis for the parallel speed-up is given. Conclusions are drawn in section 6.

2. The JD algorithm. Recently the JD method has been introduced as a new powerful technique for solving a variety of eigenproblems [16]. In this section we describe the method briefly and comment on our implementation. Suppose an eigenvector x is approximated by a linear combination of k search vectors v_j, $j = 1, 2, \ldots, k$, where k is very small compared with N_t. Let V_k be the $N_t \times k$ matrix whose columns are given by v_j. Then the approximation to the eigenvector can be written as $V_k s$, for some k-vector s. The search directions v_j are made orthonormal to each other, hence $V_k^* V_k = I$.

Suppose that an approximation to an eigenvalue is denoted by θ. The vector s and the scalar θ are constructed in such a way that the vector $r = QV_k s - \theta V_k s$ is orthogonal to the k search directions. From this Rayleigh–Ritz requirement it follows that

$$V_k^* Q V_k s = \theta V_k^* V_k s \Longleftrightarrow V_k^* Q V_k s = \theta s. \tag{3}$$

In this way one obtains a "projected" eigenvalue problem in which the order of the matrix $V_k^* Q V_k$ is k. By using a proper restart technique, k can remain so small that this problem can be solved by the QR method. The approximate eigenvalue θ is the eigenvalue of the projected system with the largest modulus.

At each step of the algorithm, a new search direction is constructed. Suppose that we have obtained an approximation $u = V_k s$ of the *true* eigenvector x associated with some eigenvalue μ. We assume that $\|u\|_2 = 1$, hence $\theta = u^* Q u$ is an approximation of μ. Let us define $P = uu^*$ as the orthogonal projector onto the subspace spanned by $\{u\}$. Then $I - P$ is the projector onto the orthogonal complement of span$\{u\}$, which is denoted by $u^\perp$. Any vector $x \in \mathbb{C}^n$ can be written as $x = x_1 + x_2$ with $x_1 \in$ span$\{u\}$ and $x_2 \in u^\perp$. We can scale x such that $x = u + z$ with $z \perp u$. In the JD algorithm a correction vector $z \in u^\perp$ is constructed. The restriction of Q to $u^\perp$ is given by

$$Q_{\mathrm{P}} = (I - P)Q(I - P). \tag{4}$$

If we rewrite (4) and substitute the resulting expression for Q into $Qx = \mu x$, we

Jacobi–Davidson for $Qx = \mu x, Q = (A - \sigma B)^{-1}B$.
Parameters: $iter, N_{ev}, tol_{JD}, k_{min}, m$ $(m \geq k_{min} + N_{ev})$, it_{SOL}.
step 0: initialize
Choose an initial vector v_1 with $\|v_1\|_2 = 1$; set $V_1 = [v_1]$;
$W_1 = [Qv_1]$; $k = 1$; $it = 1$; $n_{ev} = 0$
step 1: update the projected system
Compute the last column and row of $H_k := V_k^* W_k$
step 2: solve and choose approximate eigensolution of projected system
Compute the eigenvalues $\theta_1, \ldots, \theta_k$ of H_k and choose $\theta := \theta_j$ with $|\theta_j|$ maximal and $\theta_j \neq \mu_i$, for $i = 1, \ldots, n_{ev}$; compute associated eigenvector s with $\|s\|_2 = 1$
step 3: compute Ritz vector and check accuracy
Let u be the Ritz vector $V_k s$; compute the vector $r := W_k s - \theta u$;
`if` the residual $\hat{r} := (A - (\sigma + \frac{1}{\theta})B)u$ satisfies $\|\hat{r}\|_2/|\sigma + \frac{1}{\theta}| < tol_{JD}$ `then`
$n_{ev} := n_{ev} + 1$; $\mu_{n_{ev}} := \theta$; `if` $n_{ev} = N_{ev}$ `stop`; `goto` **2**
`else if` $it = iter$ `stop`
`end if`
step 4: solve correction equation approximately with it_{SOL} steps of GMRES
Determine an approximate solution $\tilde{z}$ of z in
$(I - uu^*)(Q - \theta I)(I - uu^*)z = -r \quad \wedge \quad u^* z = 0$
step 5: restart if projected system has reached its maximum order
`if` $k = m$ `then`
5a: set $k = k_{min} + n_{ev}$; compute the k eigenvalues of H_m with largest modulus; construct $C \in \mathbb{C}^{m \times k}$ with columns the associated eigenvectors; orthonormalize columns of C; compute $H_k := C^* H_m C$
5b: compute $V_k := V_m C$; $W_k := W_m C$
`end if`
step 6: add new search direction
$k := k + 1$; $it := it + 1$; call *MGS* $[V_{k-1}, \tilde{z}]$; set $V_k = [V_{k-1}, \tilde{z}]$; $W_k = [W_{k-1}, Q\tilde{z}]$;
`goto` **1**

FIG. 2. *JD algorithm after spectral transformation.*

obtain, using $Qu - \theta u = r$, $z \perp u$, $Pu = u$, and $Pz = 0$,

$$(Q_{\mathrm{P}} - \mu I)z = -r + (\mu - \theta - u^* Q z)u. \tag{5}$$

Since r is orthogonal to u, premultiplication of (5) by u^* yields $\mu = \theta + u^* Q z$. Note that μ is unknown and its best approximation will be θ. In this way, we obtain as a correction equation for z

$$(I - P)(Q - \theta I)(I - P)z = -r, \qquad u^* z = 0. \tag{6}$$

It is sufficient to solve (6) only approximately. This can be done by some steps of an iterative method, for example, GMRES [14]. When an approximate solution $\tilde{z}$ of (6) has been constructed, it is made orthogonal to the previous search directions, and the new search vector v_{k+1} is taken equal to $\tilde{z}/\|\tilde{z}\|_2$. Then k is increased by 1, and the new matrix $V_k^* Q V_k$ is constructed by expanding the "old" matrix by one new row and one new column.

Our implementation of the JD method for the computation of *several* eigenvalues is shown in Figure 2. The following remarks apply to the algorithm:

(i) The number of iteration steps that have been performed is denoted by it. The maximum allowed number of iterations is equal to $iter$.

(ii) The method is accelerated by searching for the best eigenvector approximation by selecting θ such that $|\theta|$ is maximal. To include the possibility of multiple eigenvalues, the condition $\theta_j \neq \mu_i, j = 1, \ldots, k$ must be interpreted as follows: an accepted eigenvalue μ_i can be equal to only one θ_j. So, if the projected system contains more than one θ_j close to μ_i, then it may be a multiple eigenvalue and, since its modulus is maximal, it becomes the next selected eigenvalue.

(iii) The value n_{ev} indicates the number of eigenvalues found so far that satisfy the acceptance criterion, and the parameter N_{ev} is the number of eigenvalues that we are looking for. The approximate eigenvalues θ that satisfy the acceptance criterion

$$\frac{\|\hat{r}\|_2}{|\sigma + \frac{1}{\theta}|} < tol_{JD} \quad \text{with } \hat{r} := (A - (\sigma + \tfrac{1}{\theta})B)u, \tag{7}$$

are referred to as μ_i for $i = 1, \ldots, n_{ev}$. The algorithm stops when n_{ev} is equal to N_{ev} or when *it* equals *iter*. In order to reduce computation time, we compute the actual residual $\hat{r}$ only if r satisfies

$$\frac{\|r\|_2}{|\theta|} < 100 \times tol_{JD} \quad \text{with } r := W_k s - \theta u = (Q - \theta I)u. \tag{8}$$

From experiments we observe that (7) is hardly satisfied when (8) is violated.

(iv) In the actual implementation of the algorithm, precautions have to be taken in step 2: theoretically, it is possible that all eigensolutions of the projected system satisfy the acceptance criterion. If that would happen, no new θ and corresponding approximate eigenvector u can be found in step 2. In that case, a vector $\tilde{z}$ is chosen that is not in the subspace spanned by V_k, and the algorithm proceeds at step 5.

(v) The subspace spanned by V_k contains the eigenvectors corresponding to the eigenvalues found before, together with some search directions. In this way, implicit deflation is incorporated automatically, which means that the detected eigenvectors are not filtered out. Of course, they may not influence the progress in finding the next eigenpair or lead to an eigenpair already found. The process of acceleration to find the next eigenpair, as described above, ensures that each accepted eigenpair will be unique. This technique differs from the deflation technique described in [6] which uses explicit deflation. The latter technique can be more stable but requires more operations per iteration step.

(vi) We require that the number of search directions k may not become too large. Therefore, if k has reached the value m, the upper bound for the order of the projected eigenvalue problem, k is reduced to $k_{min}+n_{ev}$. This is accomplished by extracting the most interesting information from H_k: the vectors which lead to previously accepted eigenvectors of the original problem are kept in the system together with those vectors that correspond to the k_{min} most promising eigenvalues, with $|\theta|$ maximal. In other words, $m-(k_{min}+n_{ev})$ vectors are thrown away. The columns of the remaining matrix $C \in \mathbb{C}^{m \times k}$ are again orthonormalized and a new H_k is obtained by $H_k := C^* H_m C$. Postmultiplication of V_m and W_m with C provides the new bases V_k and W_k. This restart technique is also applied in [6].

(vii) We use modified Gram–Schmidt (MGS) [7] to orthonormalize vectors;"call *MGS* $[V_{k-1}, \tilde{z}]$" in step 6 means that $\tilde{z}$ is made orthonormal to the columns of V_{k-1}. As suggested in [16] we apply MGS twice. Although classical Gram–Schmidt (CGS) has better parallel properties, we use MGS because it is more stable. Evidently, all inner products and all vector updates in our parallel implementation have been parallelized.

(viii) The original code that was taken as a basis for this project did not use harmonic Ritz values [6, 16]. Numerical experiments with a comparable algorithm using harmonic Ritz values have been described in [12]. The main advantage is that the LU decomposition of $A - \sigma B$ is used as a preconditioner and not as a shift and invert technique; then rounding-off errors in the decomposition for very large eigenvalue problems have less influence on the eigenvalue spectrum. We mention that the harmonic approach requires more memory and costs about 20% more execution time per Jacobi–Davidson iteration step.

2.1. Solving the correction equation. In step 4 of the JD algorithm (Figure 2), we must solve the correction equation

$$(I - uu^*)(Q - \theta I)(I - uu^*)z = -r \quad \text{and} \quad u^*z = 0 \tag{9}$$

approximately. From $u^*z = 0$, (9) can be rewritten as $(I-uu^*)(Q-\theta I)z = -r$, which is equivalent to $(Q - \theta I)z + \varepsilon u = -r$ with $\varepsilon = -u^*(Q - \theta I)z$ (cf. [16]). In order to construct a suitable preconditioner for (9), it may be useful to write the equation in the augmented form of order $N_t + 1$,

$$\begin{bmatrix} Q - \theta I & u \\ u^* & 0 \end{bmatrix} \begin{bmatrix} z \\ \varepsilon \end{bmatrix} = \begin{bmatrix} -r \\ 0 \end{bmatrix} \tag{10}$$

(cf. also [15, Theorem 3.5]). If $Q - \theta I$ is nearly singular, then the matrix will be ill-conditioned; the augmented form leads to a better conditioned matrix. The augmented correction equation can be solved, for instance, by applying some fixed number of steps of GMRES(m) (at most m steps with full GMRES, no restarts). A special choice for m is 0 (or $it_{SOL} = 0$), in which case the JD algorithm is closely related to the Arnoldi method [7]. Important differences between the JD algorithm of Figure 2 with $it_{SOL} = 0$ and the Arnoldi method are the structure of the matrix H_k and the way the restarts are performed. The projected matrices H_k obtained by applying the Arnoldi factorization are always upper Hessenberg with nonnegative subdiagonal elements. The matrices H_k obtained by k steps of JD do not have this structure (except for $it_{SOL} = 0$ and $k \leq m$, although rounding errors may appear for growing k). So, the computation of the eigenvalues of H_k requires an extra step to transform H_k to upper Hessenberg. Since JD does not have to repair the Hessenberg form, the restart technique in step 5 can be kept simple (see section 2). For details on the restart technique in the implicitly restarted Arnoldi method (IRAM), in which the Hessenberg structure of H_k has to be retained, we refer to [10]. A third difference with Arnoldi is the choice of θ; by selecting $|\theta|$ maximal the JD method is accelerated. We also refer to Discussion 4.1 in [15] for a clear discussion on the relation between the JD method, including the exact solution of the correction equation and shift-and-inverse Arnoldi. In that discussion no restarts are considered.

The convergence of GMRES(m) may be accelerated by incorporating a suitable (cheap) preconditioner. As in Booten et al. [5] and Sleijpen et al. [15], we rewrite the inverse of the augmented matrix, with $K = Q - \theta I$, as

$$\begin{bmatrix} K & u \\ u^* & 0 \end{bmatrix}^{-1} = \begin{bmatrix} I & -K^{-1}u \\ 0^* & 1 \end{bmatrix} \begin{bmatrix} I & 0 \\ u^*/\nu & -1/\nu \end{bmatrix} \begin{bmatrix} K^{-1} & 0 \\ 0^* & 1 \end{bmatrix} \tag{11}$$

with $\nu = u^*K^{-1}u$. It is easy to verify that

$$K = Q - \theta I = -\theta(A - \sigma B)^{-1}[(A - (\sigma + \tfrac{1}{\theta}B)] \tag{12}$$

and K^{-1} may be approximated by $-\frac{1}{\theta}I$. Hence, by replacing K^{-1} with $-\frac{1}{\theta}I$ in (11) and ν by $-\frac{1}{\theta}u^*u = -\frac{1}{\theta}$, we obtain the preconditioner $\mathcal{M}^{-1}$:

$$\begin{bmatrix} K & u \\ u^* & 0 \end{bmatrix}^{-1} \approx \begin{bmatrix} -\frac{1}{\theta}(I - uu^*) & u \\ u^* & \theta \end{bmatrix} = \mathcal{M}^{-1}. \tag{13}$$

The augmented equation (10) can be preconditioned by $\mathcal{M}^{-1}$ and then in almost all cases the number of JD iterations needed to find the first eigenvalue will be smaller than in cases where no preconditioning is used, as numerical experiments demonstrate in section 5.

3. The LU decomposition. To calculate an Alfvén spectrum we choose some target values σ in the neighborhood of this spectrum. For each σ we compute a complete LU decomposition of $A-\sigma B$. One (L, U) pair can be used for the calculation of several eigenvalues. However, if the method becomes too slow, it might be useful to choose a new target σ.

3.1. Block-tridiagonal LU approach. The matrices A and B in (1) have the same block-tridiagonal structure and therefore $A-\sigma B$ is also block-tridiagonal. Since the subblocks are more than 50% full, a complete LU decomposition of $A - \sigma B$ is relatively cheap: the total number of nonzeros in $L+U$ is at most twice as much as in $A-\sigma B$. In the rest of this paper, this technique is referred to as the block-tridiagonal LU approach. The decomposition is performed on a block level. This enables us to use partial pivoting, which makes the decomposition more robust. In order not to disturb the block-tridiagonal structure, the search for pivot elements is restricted to the blocks on the main diagonal. In our experiments, this pivot strategy seems to work well.

For a large number of diagonal blocks, the total number of complex multiplications required for the construction of L and U is approximately $\frac{7}{3}\ Nn^3$, and the number of multiplications required for performing the triangular solves with both L and U once is approximately $3Nn^2$.

3.2. The DDCR method. To improve parallelization possibilities of block-tridiagonal LU decomposition, we use a reordering based on a combination of domain decomposition (DD) and cyclic reduction (CR), discussed in [18].

Let p be the number of processors that is actually used, and let the integer $N_p = \lceil \frac{N}{p} \rceil$ [1] represent the number of diagonal blocks to be treated on each processor (except possibly the last processor, on which the number of diagonal blocks can be less). The first step of the DDCR method is to perform a block-reordering of both block rows and block columns based on a domain decomposition strategy with p nonoverlapping subdomains. The second step of the DDCR method is to construct a block lower-triangular matrix L and a block upper-triangular matrix U in such a way that $A - \sigma B = LU$ and all blocks on the main diagonal of U are identity matrices.

For N_p large, the construction of a block-tridiagonal LU decomposition of the first block-tridiagonal matrix on the first processor costs about $\frac{7}{3}\ n^3N_p$ multiplications. In [18] it is shown that the rest of the block-tridiagonal LU decomposition costs about $\frac{19}{3}\ n^3(N - N_p)$ multiplications. Hence the total number of multiplications required for the construction of L and U is approximately

$$(\tfrac{7}{3}\ N_p + \tfrac{19}{3}\ (N - N_p))n^3 = \tfrac{1}{3}\ (19N - 12N_p)n^3. \tag{14}$$

[1] By $\lceil x \rceil$ we denote the smallest integer $\geq x$ and by $\lfloor x \rfloor$ the largest integer $\leq x$.

In the same way it can be shown that for large N_p the number of multiplications required for performing the triangular solves with both L and U once is approximately

$$(3N_p + 5(N - N_p))n^2 = (5N - 2N_p)n^2. \tag{15}$$

4. The parallel implementation and data organization. We started this project with the parallelization of the original code [3, 4, 5] on a Cray T3D in Eagan, MN. The last part of the development has been done on a Cray T3E in Delft, the Netherlands. Some important characteristics of the Cray T3E in Delft are listed in Table 1.

TABLE 1
Main characteristics of the Cray T3E at HPαC centre, Delft.

# processors	80 (72 in parallel)
Clock period	3.33 ns clock
Peak performance / processor	600 Mflop/s
Total peak performance	33.6 Gflop/s
Local memory	128 Mbytes
Total memory	10 Gbytes
Data cache size	8 Kbytes
Compiling system	Cray CF90
GiGaRing channels	available

The communication steps in the recent code have been implemented with fast `SHMEM` routines (shared memory access library). These `SHMEM` routines are data passing library routines similar to message passing library routines and minimize the overhead associated with data passing requests, maximize bandwidth, and minimize data latency. Optimized `BLAS` routines are used as much as possible to achieve high performance per processor, and for the linear algebra part LAPACK routines [1] are called. For considerations on the programming technique, data distribution and communication on the MHD application, we refer to [11].

4.1. Distribution of the MHD matrices. For large problems with a lot of data, the I/O is often very expensive. Therefore, we do not read the MHD matrices from the files but generate them during execution, which takes only a few seconds. A part of the CASTOR code, which computes the matrix elements, has been coupled with our JD code. Moreover, it has been parallelized such that the available processors generate their own pieces of the matrices A and B in (1). The matrices are distributed block-row-wise along the processors; each processor gets one or more main diagonal blocks with their nearest sub- and superdiagonal blocks belonging to the same block row. All vectors are distributed accordingly. As a consequence, for a matrix-vector multiplication the memory traffic (of only two vectors of length n) is reduced to the first sub- and last superdiagonal block per processor.

4.2. Data format: CRS format versus dense block-tridiagonal format. The compressed row storage (CRS) format puts the subsequent nonzeros of the matrix rows in contiguous memory locations. To describe a sparse matrix A, we need three vectors, one for complex nonzero floating point numbers (mat_A) and two for integers ($colind\_A$, $rowptr\_A$). For more details and examples, we refer to [2].

CRS format has the advantage that it can be used to store general sparse matrices. However, the DDCR decomposition is completely based on the block-tridiagonal form of $A - \sigma B$. This implies that, for our applications, CRS format can be advantageous only if the blocks of A and B are sparse enough. From Table 2, which gives the

TABLE 2
Times for the matrix–vector multiplication on a single processor of a Cray T3E. Results for the block-tridiagonal form (dense blocks including zero values) are denoted by `DENSE`*. Results for CRS format are denoted by* `CRS`*(A) and* `CRS`*(B) for A and B, respectively.*

Execution times in μ-seconds on a Cray T3E, $N = 40$.					
MATVEC	$n = 16$	$n = 32$	$n = 48$	$n = 64$	$n = 80$
`DENSE BLOCKS`	4490	14577	32055	54666	93924
`CRS`(A)	2469	9874	22518	33733	52861
`CRS`(B)	1421	4979	10806	15814	24374
Number of nonzeros in A and B.					
$nnz(A)$	11392	47906	109542	196300	308180
$nnz(B)$	5934	22778	50532	89196	138770

execution times for matrix-vector multiplications on a single processor of a Cray T3E for matrices A and B generated by the CASTOR code, we may conclude that CRS format is to be preferred for both A and B on this platform.

4.3. Memory requirements. In this section, we will indicate which amount of memory is required for both the sequential and parallel implementation, expressed in $nnz(A)$ and $nnz(B)$, the numbers of nonzero values in the A and B, respectively, and N, n, and N_{ev}, where N denotes the number of diagonal blocks, n the blocksize of the block-tridiagonal matrices, and N_{ev} the number of eigenvalues we are looking for. The last parameter is m, the maximum allowed value of the projected system. As stated in section 2, m is much smaller than the order $N \times n$ of the matrices A and B.

A `CRS`-formatted matrix of $nnz(A)$ nonzero values requires 16 $nnz(A)$ bytes for storing *mat_A* and 8 $nnz(A)$ bytes for *colind_A*, respectively (cf. section 4.2). The integer array *rowptr_A* uses an additional 8 Nn bytes. The memory space for the `CRS`-formatted matrix B can be expressed in $nnz(B)$, analogously. The block-tridiagonal LU decomposition needs 3 Nn^2 `COMPLEX` words. The subspace matrix V_k and associated space W_k use 2 Nnm `COMPLEX` words, and the restart in step 5 of Figure 2 requires (in the worst case) another Nnm `COMPLEX` words. The total requirements for those matrices are 3 Nnm `COMPLEX` words. The accepted eigenvectors are stored in a matrix of order $Nn \times N_{ev}$. An additional working space for some vectors takes 5 Nn `COMPLEX` words.

Besides the matrix H_k, its Hessenberg form and its eigenvectors plus some working space require $4m(m+1)$ `COMPLEX` words. Summarizing, the amount of memory required for the current *sequential* implementation in complex arithmetic, where one `COMPLEX` word corresponds with 16 bytes, is approximately

$$24\,(nnz(A) + nnz(B)) + 16Nn(3(n+m) + N_{ev} + 7) + 64m(m+1) \text{ bytes.} \tag{16}$$

For the MHD matrices, the average sparsity of the sub-, super-, and diagonal blocks of A is approximately 41% and of B 20%, i.e., $nnz(A) \approx 0.41 \times 3Nn^2$ and $nnz(B) \approx 0.20 \times 3Nn^2$. Thus, the amount of memory for the sequential implementation (16) approximates

$$16Nn(5.75n + 3m + N_{ev} + 7) + 64m(m+1) \text{ bytes.} \tag{17}$$

The parallel implementation requires per processor approximately an additional $32n(N_p n + 3n)$ bytes for the DDCR solver and some extra memory (10 %) to distribute the CRS matrices, in case their sparsity is not equally partitioned over the block

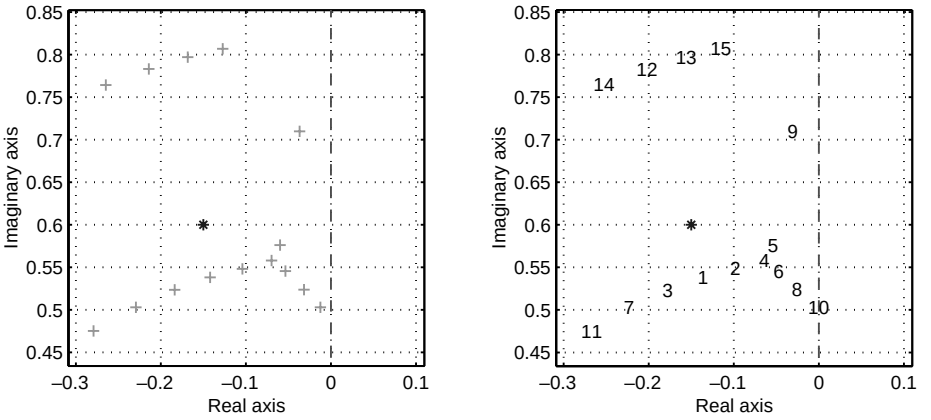

FIG. 3. *Part of the eigenvalue spectrum of an MHD problem with* $N = 40, n = 64$. *The target* σ *is indicated by an "*$*$*". In the right picture the order in which they appear are shown.*

rows. The small matrix of the projected system is present on all processors, and sequential steps, like the solution of the projected eigenvalue problem, are performed by all processors to avoid communication. Summarizing, the amount of memory (per processor) for our *parallel* implementation approximates

$$\begin{aligned} &48N_p n^2 + 16N_p n(3(n+m) + N_{ev} + 7) + 32n(N_p n + 3n) + 64m(m+1) \text{ bytes} \\ &= 128N_p n^2 + 16N_p(3m + N_{ev} + 7) + 96n^2 + 64m(m+1) \text{ bytes.} \end{aligned} \tag{18}$$

5. Numerical results.

5.1. The influence of the correction equation. In the left picture of Figure 3, the eigenvalues of an MHD problem with $N = 40$ and $n = 64$ near the target $\sigma = (-0.15, 0.60)$ are plotted. In the right picture, the eigenvalues are numbered consecutively as they are found. The solid line in Figure 4 displays the convergence behavior of this MHD problem solved by JD with $it_{SOL} = 0$. Each "$\circ$" indicates a converged eigenvalue. Obviously, to find the first eigenvalue is rather expensive, but after that only a few iteration steps are required to find the next ones. Note that after 30 and 39 JD iteration steps two eigenvalues were even found in one step. It appears that with this target even more eigenvalues (probably of the upper Alfvén branch) can be found than the 15 we asked for. However, since an implicit restarting technique is used, the order of the projected system will then grow . A better solution will be to choose a new target based on the results of the last (few) runs.

The question arises if it is possible to reduce the number of JD iteration steps when `GMRES(m)` is applied to the augmented correction equation (10). In Table 3, we distinguish four variants to solve the correction equation:

- `JD-sol`: in each JD step `GMRES(m)` is applied *without* preconditioning.
- `JD-sol`*: `GMRES(m)` is applied only if $\|\hat{r}\|_2 < \varepsilon_{tr}$ *without* preconditioning.
- `JD-solP`: in each JD step `GMRES(m)` is applied *with* preconditioning from the left by $\mathcal{M}^{-1}$.
- `JD-solP`*: `GMRES(m)` is applied only if $\|\hat{r}\|_2 < \varepsilon_{tr}$ *with* preconditioning from the left by $\mathcal{M}^{-1}$.

The preconditioning matrix $\mathcal{M}^{-1}$ has been introduced in section 2.1. The JD-sol variant does not improve the convergence process: from Figure 4 we know that if $it_{SOL} = 0$, 23 iterations are needed to get the first eigenvalue. It is known that in the

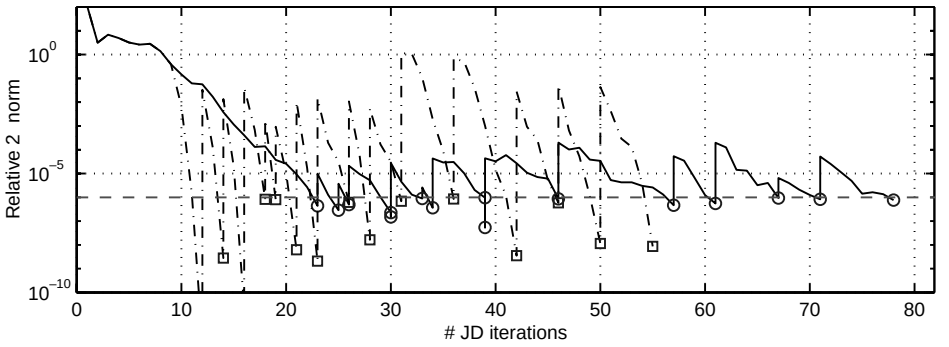

FIG. 4. *Convergence behavior of JD with* $it_{SOL} = 0$ *(solid line with "○"s) and* `JD-solP*`, `GMRES(20)` *(dashed line with "□"s);* $N = 40, n = 64$.

TABLE 3

Both the number of JD iterations as well as the execution time (in seconds on four processors) are given for several JD implementations with $it_{SOL} = 1$ *and* $\varepsilon_{tr} = 1.0$.

	Number of JD steps to find first eigenvalue					
	`GMRES(1)`	`GMRES(2)`	`GMRES(5)`	`GMRES(10)`	`GMRES(15)`	`GMRES(20)`
`JD-sol`	23	25	26	30	32	26
`JD-sol*`	23	24	21	21	13	12
`JD-solP`	23	33	13	19	22	28
`JD-solP*`	23	28	15	12	12	12
	Execution time to find first eigenvalue					
`JD-sol`	1.68	2.55	4.89	10.09	15.58	16.38
`JD-sol*`	1.44	1.97	2.69	4.51	2.33	2.28
`JD-solP`	1.69	3.46	2.31	6.20	10.49	17.82
`JD-solP*`	1.45	2.46	1.49	1.36	1.76	2.29
	Number of JD steps to find 15 eigenvalues					
`JD-sol`	72	139	140	109	107	82
`JD-sol*`	72	105	122	100	92	70
`JD-solP`	74	188	117	97	79	71
`JD-solP*`	75	147	119	90	71	55
	Execution time to find 15 eigenvalues					
`JD-sol`	7.19	17.61	29.82	39.25	54.80	54.53
`JD-sol*`	6.87	12.94	24.98	33.77	43.61	40.43
`JD-solP`	7.43	23.74	25.08	35.20	40.63	47.26
`JD-solP*`	7.26	18.15	24.33	30.25	31.83	30.45

first steps of the process the vectors v_k are usually poor approximations of the wanted eigenvectors, and solving the correction equation more accurately will not speed up the convergence. Therefore, we take in the first steps $it_{SOL} = 0$ until the 2-norm of the actual residual $\hat{r}$ in (7) drops below a threshold value ε_{tr}, i.e., for $\varepsilon_{tr} = 1.0$ after 9 "Arnoldi" steps then only an additional 3 steps are required to find the first eigenvalue (`JD-sol*`, `GMRES(20)`). We refer to [6] for more details, discussions and variants of the JD method and the influence of the way the correction equation is solved on the convergence behavior of the JD method.

If the correction equation is solved by `GMRES(m)` preconditioned from the left by $\mathcal{M}^{-1}$, then in almost all cases the number of JD iterations to the first eigenvalue is smaller than when no preconditioning is applied. This is also true for the complete process of finding 15 eigenvalues, when sufficient `GMRES` inner iterations are applied. Compared to a multiplication with $Q - \theta I$, the application of $\mathcal{M}^{-1}$ is relatively cheap

and as a consequence, the P-variants are usually much faster than those without preconditioning. The convergence history of JD-solP* with GMRES(20) is also displayed in Figure 4. Notice that the residual after an eigenpair is accepted in case $it_{SOL} = 0$ remains much smaller ($\approx 10^{-4}$) compared to the JD-solP*-variant.

However, each GMRES(m) step requires a multiplication with $Q - \theta I$, a very expensive operation even when performed in parallel. As a consequence, a reduction in the number of JD steps due to applying GMRES(m) does not guarantee a reduction in execution time. In fact, the timings listed in Table 3 indicate that GMRES(1) provides the fastest way to find 15 eigenvalues. When we replace step 4 in the algorithm of Figure 2 by $\tilde{z} = r$ (corresponding to $it_{SOL} = 0$) the number of JD steps hardly increases, resulting in the lowest execution time (see Table 4). Based on these and other results (not included in this paper), we continue with JD with $it_{SOL} = 0$.

TABLE 4
Both the number of Jacobi–Davidson iterations as well as the execution time (in seconds on four processors) is given for JD with $it_{SOL} = 0$.

	1 eigenvalue		15 eigenvalues	
	# JD steps	Time	# JD steps	Time
JD, $it_{SOL} = 0$	23	0.99	78	5.23

5.2. Parallel performance on the Cray T3E. In the rest of this paper, we set $it_{SOL} = 0$ which implies that $\tilde{z} = r$ (cf. Table 2, step 4). From numerical experiments this appears to be the best choice for minimizing the total wall clock time, as is illustrated in section 5.1. Three generalized eigenvalue problems, exploited by the linearized MHD equations (7)–(10) in [17] with resistivity $\eta = 5 \cdot 10^{-6}$ and ratio of specific heats $\gamma = \frac{5}{3}$, generated by CASTOR have been timed. Their specifications are given in Table 5. N is the number of diagonal block and the number of Fourier

TABLE 5
The MHD problems used in the numerical experiments.

Problem	N	n	σ	$nnz(A)$	$nnz(B)$
I	40	64	(-0.15, 0.70)	196300	89196
II	160	64	(-0.20, 0.70)	798632	362991
III	320	128	(-0.20, 0.70)	6491568	2886495

modes is equal to $n/16$, where n denotes the blocksize. All problems describe the same physical problem. In [17] more information on the background concerning resistive magnetohydrodynamic spectra in tokomaks can be found. The other parameters in the algorithm were chosen as follows:

$$iter = 300;\ N_{ev} = 15;\ tol_{JD} = 10^{-6};\ k_{min} = 10;\ m = 30.$$

Table 6 shows the results for the test problems I, II, and III. The third column shows the wall clock time (measured in seconds) required for the construction of the parallel block-tridiagonal LU decomposition. The numbers in parentheses show the Mflop rates, calculated by using the estimate (14) for the number of multiplications. For the block-tridiagonal LU decomposition we obtain a reasonable fraction of the theoretical peak performance, which is due to the level-3 BLAS routines that perform most of the work in this preprocessing phase. Problem I shows that when the number of processors increases from one to two, the wall clock time increases, also. This is due to the computation of the extra fill-in blocks in L and U which are generated

when the reordering technique for parallel processing is performed. Increasing the number of processors again by a factor two approximately halves the wall clock time. The reduction in wall clock time for $p = 40$ compared with $p = 20$ is very poor due to the fact that pure cyclic reduction has been applied, since $N = p$. When we calculate those speed-ups for Problems II and III, we see that a gain of 1.44 and 1.65 is reached, respectively. From the performance of more than 10 Gflop/s on 64 processors achieved for the largest problem, we may conclude that the block-tridiagonal LU decomposition is extremely suitable for this platform. However, we must realize that for growing block size the decomposition becomes very expensive.

TABLE 6

Wall clock times (in seconds) of several parts of the JD process on the Cray T3E for Problems I, II, *and* III.

Problem	p	Time for the LU decomposition		Time for JD process	Number of JD steps	Sequential time	Total time triangular solves	
I	1	1.06	(184)	16.99	81	0.77	4.74	(67)
I	2	1.15	(315)	10.07	85	0.81	3.92	(114)

II	20	0.62	(3305)	21.08	300	4.61	8.18	(942)
II	32	0.45	(4654)	16.13	300	4.08	6.06	(1282)
II	40	0.43	(4857)	10.26	198	2.41	4.01	(1281)
III	10	13.52	(2355)	184.07	300	3.49	95.88	(630)
III	16	8.81	(3708)	109.82	300	3.58	61.91	(991)
III	20	7.28	(4525)	92.13	300	3.38	53.64	(1149)
III	32	4.97	(6700)	39.38	196	2.19	23.87	(1700)
III	40	4.42	(7565)	54.45	300	3.53	33.80	(1842)
III	64	3.22	(10461)	39.50	300	3.59	25.41	(2461)

The fourth column shows the wall clock time required for the JD process without the time required for preprocessing. Since a part of the algorithm is not performed in parallel (solution of the projected eigenvalue problem), we cannot expect linear speed-up. The fifth column gives the number of Jacobi–Davidson iteration steps. If this number is equal to 300, less than 15 eigenpairs have been found. In those cases it should have been better to choose a smaller value for N_{ev}. For Problem II approximately 54 iterations were needed to obtain 14 eigenpairs. We emphasize that it is hard to predict how many eigenvalues can be found in the neighborhood of some target σ. It appears that the first 12 eigenvalues of Problem III are easy to find within 100 iterations, whereas 300 iterations are not sufficient to get 15 of them.

The sixth column displays the time spent by solving the eigenvalue problem on the projected system. For an equal number of iterations, this time should be independent of the number of processors involved. However, we found deviating values for $p = 20$ and $p = 32$ in the case of Problem II. We observe that the contribution of the

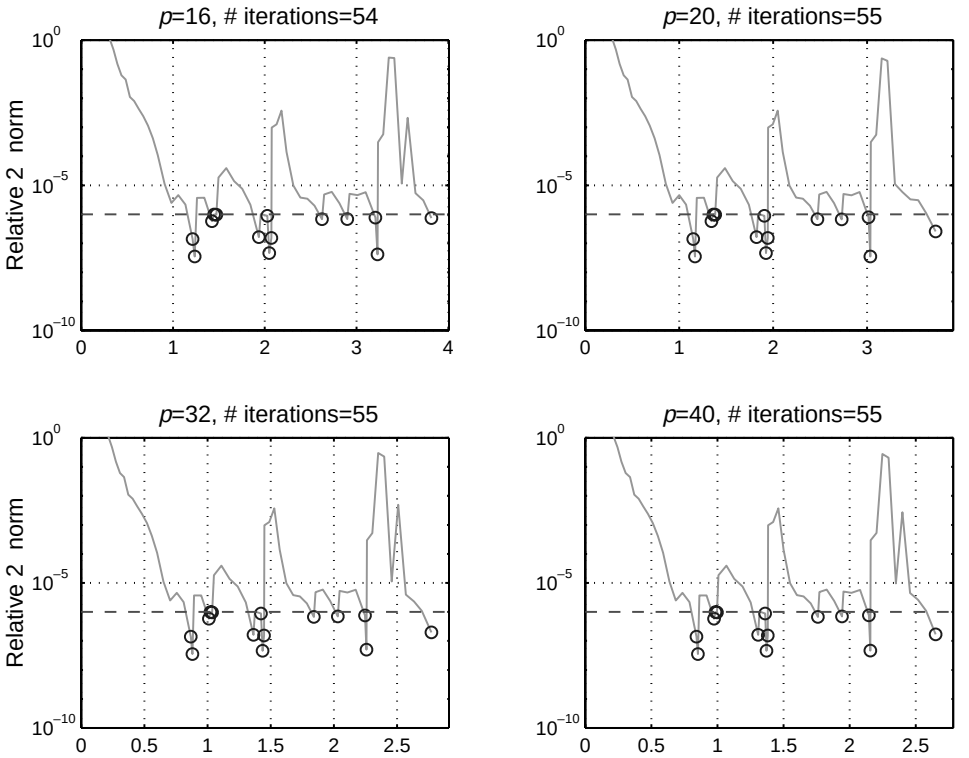

FIG. 5. *The relative* 2*-norm of the residual* (7) *or* (8) *against the wall clock times (in seconds) of Problem* II *(first* 14 *eigenpairs) obtained on* $p = 16, 20, 32, 40$ *processors of the Cray T3E.*

sequential part to the total wall clock time is small, especially for large $\lceil \frac{N}{p} \rceil$.

The seventh column shows the total time spent in performing the triangular solves. Again the numbers in parentheses show the Mflop rates, which have been calculated by using the estimate (15) of the number of multiplications. The level-2 `BLAS` routines used for the triangular solves are significantly slower than the level-3 `BLAS` routines used for the construction of L and U, because the ratio of computations and memory-to-processor data transfer is much more favorable for level-3 `BLAS` than for level-2 `BLAS`. Therefore, the Mflop rates are significantly lower than those obtained for the construction of L and U. The triangular solves in combination with one matrix-vector multiplication with the matrix B form the expensive application of the operator $Q = (LU)^{-1}B$.

In general, the convergence history hardly depends on the number of processors. This is illustrated by Figure 5, which shows the history of Problem II for the first 14 eigenpairs on 16, 20, 32, and 40 processors. In all cases, the"same" eigenvalues were found in the same order. The distance between the "same" eigenvalues is about 10^{-6} as we might expect, since $tol_{JD} = 10^{-6}$.

5.3. Analysis of the speed-ups. The computations in the JD algorithm can be divided into three parts: the solution of the (small) projected eigenvalue problems, the triangular solves with L and U, and a part consisting of matrix-vector multiplications with B and $A-\sigma B$, inner products and vector updates. The CPU times per processor for these parts are denoted by $t_{seq}^{(p)}$, $t_{LU}^{(p)}$, and $t_{lp}^{(p)}$, respectively; in case p processors are

used for execution. If we assume that the time for communication can be neglected and the inner products scale linearly, the expected speed-up $S_{JD}^{(p)}$ on p processors is

$$S_{JD}^{(p)} = \frac{t_{seq}^{(1)} + t_{LU}^{(1)} + t_{lp}^{(1)}}{t_{seq}^{(p)} + \frac{t_{LU}^{(p)}}{S_{LU}^{(p)}} + \frac{t_{lp}^{(p)}}{p}}, \tag{19}$$

in which $S_{LU}^{(p)}$ is the expected speed-up for the triangular solves. In the following, we will show that an approximation of $S_{LU}^{(p)}$, $p > 1$, is given by ($N_p = \lceil \frac{N}{p} \rceil$)

$$\begin{aligned} S_{LU}^{(p)} &\approx \frac{3pN}{(5-\frac{2}{p})(N+1-p)+5p\lceil \log_2 p - 1 \rceil} && \text{for } N_p > 1, \\ S_{LU}^{(p)} &\approx \frac{3p}{5\lfloor \log_2 p \rfloor} && \text{for } N_p = 1. \end{aligned} \tag{20}$$

If the JD code executes on one processor, the sequential block-tridiagonal LU approach is applied and in that case the number of multiplications in the triangular solves is approximately $3Nn^2$. Almost every multiplication can be combined with one addition, hence the wall clock time required on one processor is approximately $3Nn^2 t_{mul}$, in which t_{mul} is the time required for performing a complex multiplication combined with an addition. On p processors, the parallel direct solver `(SOL)DDCR` is applied. The first part of the triangular solves corresponds to the solution of $N - p + 1$ block-tridiagonal systems, which scales linearly. The number of multiplications in this part is approximately $3(N - p + 1)n^2\omega$, in which ω is the number of multiplications in the `DDCR` approach divided by the number of multiplications in the block-tridiagonal LU approach. From (15) it follows that $\omega \approx (5 - \frac{2}{p})/3$. Hence the wall clock time required for the domain decomposition part is approximately $(3\omega(N-p+1)n^2 t_{mul})/p$.

The second part deals with cyclic reduction. The wall clock time required for this part is approximately $5n^2 t_{mul}$ multiplied by the number of steps in cyclic reduction. In case $N_p > 1$, $p - 1$ processors perform the cyclic reduction in $\lceil \log_2 p - 1 \rceil$ steps. Otherwise, in the case of pure cyclic reduction ($N_p = 1$), the process is performed on p processors in $\lfloor \log_2 p \rfloor$ steps. The expressions in (20) are obtained by dividing the approximate wall clock time on one processor by the sum of the wall clock times required for the first and second part of the triangular solves on p processors.

Figure 6 shows both the predicted speed-ups by (19) and (20) and the measured speed-ups obtained from Table 6. Since this table does not contain the information for $p = 1$ for Problems II and III, the execution time must be approximated by, for instance,

$$T^{(1)} = t_{seq}^{(p)} + S_{LU}^{(p)} \times t_{LU}^{(p)} + p \times t_{lp}^{(p)} \quad \text{for both } p = 2 \text{ (Problem II) and } p = 10 \text{ (Problem III).} \tag{21}$$

The large variation in the number of JD steps has been balanced out by dividing $t_{seq}^{(p)}$, $t_{LU}^{(p)}$, and $t_{lp}^{(p)}$ by those numbers. For Problem I the predicted speed-up $S_{JD}^{(p)}$ is a little too high for p large compared with the measured speed-up. This is caused by the fact that the simple prediction model assumes that the inner products scale linearly, which is not quite true for small vectors.

Notice that the speed-ups become higher when the problem size grows, which could be expected. If we increase the order of A and B, $t_{seq}^{(p)}$ hardly changes, when we keep the order of the projected systems fixed. Accordingly, the communication time due to inner products remains equal. However, the computational work expressed by $t_{LU}^{(p)}$ and $t_{lp}^{(p)}$ will increase with the order of the eigenvalue problem.

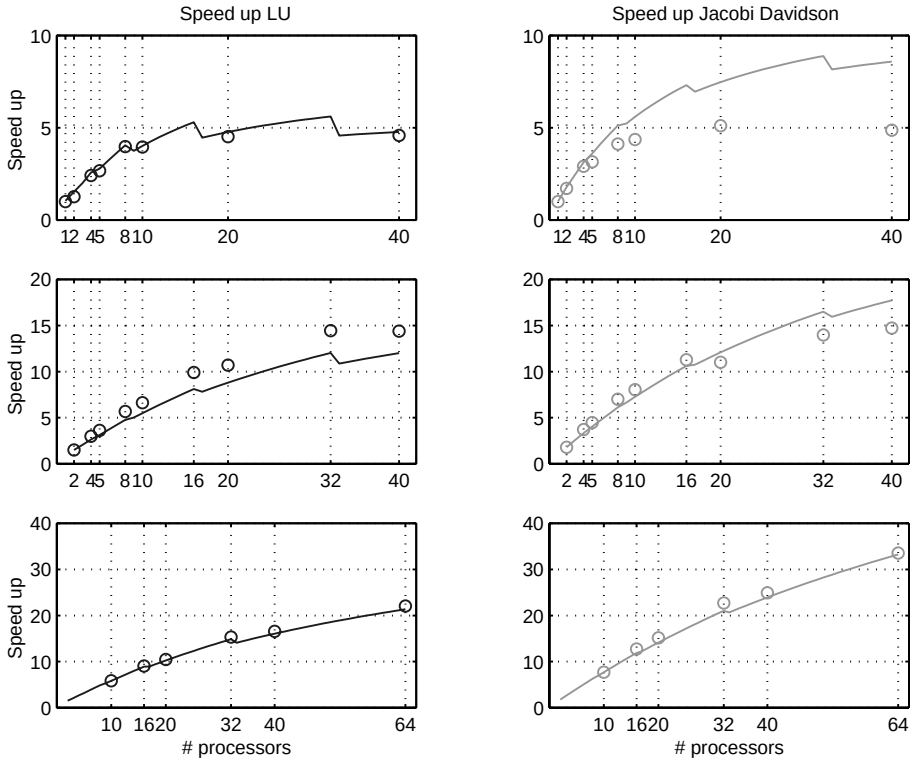

FIG. 6. *The predicted (solid line) and measured speed–up ("○") of the block-tridiagonal LU factorization and the JD algorithm for Problems* I, II, *and* III, *respectively.*

6. Conclusions. We have studied the JD method for the parallel computation of a few selected eigenvalues of large generalized eigenvalue problems arising in the stability investigation of tokamak plasmas. The method has been combined successfully with a parallel complete block-tridiagonal LU decomposition, which appears to be robust because pivoting is used. However, in order not to disturb the block structure of the matrix, the search for pivot elements is restricted to the blocks on the main diagonal. Numerical experiments performed on a Cray T3E demonstrate that this method parallelizes well.

Most other ingredients in the JD method like the matrix-vector multiplications, vector updates and inner products parallelize very well. Only the construction and solution of the small projected eigenvalue problems in the JD method do not parallelize. However, the order of these systems is kept small and is independent of the problem size. Hence for large applications, the total time spent in solving the projected systems is small compared with the time spent in the parallel parts of the method.

We observe that for large problems the measured speed-up corresponds quite well with the prediction. More important is that the speed-up for large problems is much higher than for smaller ones; therefore we may conclude that the JD method is very well suited for parallel execution.

The main reason to study implementations on distributed memory machines, like the Cray T3E for large eigenvalue problems, is the memory bound of shared memory

machines. If n and N are large ($n \gg m$ and $N \gg p$), then our parallel implementation of JD requires approximately $128Nn^2$ bytes of memory. Our sequential implementation requires approximately $92Nn^2$ bytes. The total amount of memory of the Cray T3E at HPαC, Delft, is only slightly larger than the 8 Gbytes of main memory of the Dutch National supercomputer with shared memory, a Cray C90 with 12 CPUs at SARA, Amsterdam. Hence on the current Delft configuration, we can solve problems of approximately the same size on the Cray C90. Recently, we got the opportunity to execute our code on a 512 processor Cray T3E, which enables us to examine larger eigenvalue problems (see also [12]).

We remark that the JD method is applicable for generalized eigenvalue problems $Ax = \lambda Bx$ in which the action of the inverse of A, B, or $A - \sigma B$ for a target σ is not available. The projections included in the correction equation guarantee a proper update of an approximate eigenvector in the "right" direction. When we started our research, we hoped to be able to exploit the sparsity pattern within the block-tridiagonal structure of $A - \sigma B$, by using an *incomplete* LU decomposition as a preconditioner for `GMRES(m)` to solve the correction equation approximately. If an *incomplete* decomposition would have been used, the transformation described by (2) would not have been possible and in that case the application of JD applied to the *generalized* eigenvalue problem would probably have been more efficient than Arnoldi's method. However, it turned out to be more efficient to construct a *complete* block-tridiagonal LU decomposition of $A - \sigma B$, because the block tridiagonal structure of this matrix can be exploited. Moreover, since the decomposition is performed on a block level, `BLAS` routines can be used, which guarantees an efficient implementation per processor. We therefore end up with the *standard* eigenvalue problem (2) in which the spectrum of interest is also the dominant part of the spectrum.

For this special eigenvalue problem it is not efficient to use several `GMRES` steps for the correction equation that appears in the JD method. Four variants have been examined and the best results were obtained when the iteration process starts with some Arnoldi-like steps, until the residual is sufficiently small. The process can be accelerated by applying a (cheap) preconditioner within `GMRES(m)`. However, a reduction in the number of Jacobi–Davidson steps does not guarantee a reduction in execution time. From numerical experiments, it appears that the best choice for minimizing the wall clock time is to take $\tilde{z} = r$ in step 4 of the algorithm in Figure 2. If we should use a (very) good preconditioner and solve the correction equation exactly, then the convergence to the next eigenvector will be quadratic (see [15, Theorem 3.2]). For this special case, it is probably more efficient to use Arnoldi's method than JD. However, the difference in efficiency will not be large, because the most expensive operation in both JD and Arnoldi's method is the matrix-vector multiplication with Q in (2) and both methods need approximately the same number of matrix-vector multiplications.

Acknowledgments. The authors wish to thank Herman te Riele for many stimulating discussions and numerous suggestions for improving the presentation of the paper. They also thank Gerard Sleijpen and Jos van Dorsselaer for carefully reading the paper and suggesting several improvements. We also appreciate the helpful comments by the referees very much.

Further they would like to thank Ronald van Pelt of Cray Research, the Netherlands, for his programming advice for both the Cray T3D and Cray T3E, and HPαC (Delft) and SARA (Amsterdam) for their technical support. They gratefully acknowledge Cray Research for a sponsored account on the Cray T3D, and the Dutch National Computing Facilities Foundation NCF for the provision of computer time on the Cray

C90 and the Cray T3E.

TOWARD FRONT TRACKING BASED ON CONSERVATION IN TWO SPACE DIMENSIONS *

MAO DE-KANG†

Abstract. A two-dimensional front tracking method based on conservation for scalar conservation law and for the Euler system of gas dynamics is being developed. In the method, discontinuities are tracked by enforcing the conservation properties of the PDEs. Unlike the traditional front tracking methods, for which the conservation is only a property that may or may not be preserved, in this front tracking method the conservation is the mechanism by which the tracking is performed. The method is also extended to treat the reflection wall boundary in the Euler system. As an attempt to treat the interactions of discontinuities by enforcing the conservation properties without solving two-dimensional Riemann problems, three special cases of treatment of discontinuity interactions in scalar conservation law and in the Euler system of gas dynamics are studied. Finally, numerical experiments are implemented in both scalar and system cases to show the efficiency of the method.

Key words. front tracking, cell-average, recovery of discontinuity curve

1. Introduction.

In this paper we are concerned with the nonlinear hyperbolic system of conservation laws

$$u_t + \sum_{i=1}^{m} f_i(u)_x = 0, \tag{1.1}$$

where u and $f(u)$ can be either scalars or vectors and $m = 1, 2$. It is well known that solutions to (1.1) can develop discontinuities, no matter how smoothly the initial and boundary conditions are proposed. It is also well known that in most cases the interior structure of discontinuities is of little interest, but the effect of the discontinuity relations (the Rankine–Hugoniot conditions) on the hydrodynamic scale flow is important for applications. On these two observations the so-called front tracking methods have been developed, which treat discontinuities as interior moving boundaries coupled to finite difference calculation for the smooth part of solution.

One of the important features of front tracking methods is the usage of lower dimensional grids, called fronts, which fit the discontinuities in the numerical solutions. In regions that are surrounded by fronts, the numerical solutions to (1.1) are solved separately using methods designed for smooth solutions. The propagation of the fronts and the updating of the states on their two sides are performed by the requirement that the jump conditions be satisfied across the fronts in some way.

An approach that is widely accepted for advancing fronts is to compute the propagation speed of the fronts in every time step. This can essentially be done by solving the Riemann problems between the states on the two sides of the fronts. Once the propagation speed is obtained, the discontinuity locations at the new time can be

computed, and then the front tracking can be carried on to the next time step. In doing so, the conservation properties of the system (1.1) is generally not preserved.

In the last three decades, a great number of front tracking methods of this type have been developed; see [1], [9], [10], [11], [12], [13], [14], [18], [32], [35], [39], and the references cited therein. Here we call the front tracking methods of this type the traditional front tracking methods. The traditional front tracking methods have been proved successful in application in the sense that high accuracy and resolution can be achieved for both solutions in smooth regions and discontinuity locations on significantly coarse grids. However, the price for high accuracy and resolution is the complexity of the algorithm.

We would particularly mention the contributions of Glimm and his coworkers to the traditional front tracking. In their systematic development of front tracking methods they have been building a very extensive set of tools to deal with the complexity of the algorithm so that the high accuracy and resolution on coarse grids can be obtained even for some problems with geometrically and toplogically complex fronts. However, their algorithm is really expensive.

The reason for the complexity of the algorithm is not difficult to see. The basis of the traditional front tracking methods is the assumption that the solution to be solved is piecewise smooth. The high accuracy and resolution of the methods rely heavily on the fact that the locations of fronts are accurately computed in every time step. If an error of large magnitude occurs at a time, there is no mechanism in the tracking methods to delete it in the later computation. However, the accurate computation of front locations will become difficult when solutions have geometrically and topologically complex fronts, and the assumption of piecewise smoothness becomes questionable. At this moment, much work of the algorithm must be spent on resolving the geometrical and topological configuration of the fronts for obtaining high accuracy, and often knowledge of the exact solutions is invested for this purpose.

For many years the author has been working on a different approach of front tracking in which discontinuities are advanced by enforcing the conservation properties of (1.1) rather than by computing their propagation speed. The philosophy of the work comes from, in addition to the above observation on the traditional front tracking methods, the following two observations on front capturing methods.

(1) In front capturing methods the conservation properties insure the correct propagation speed of discontinuities in numerical solutions. Capturing difference schemes are always designed in the conservative form so that when solutions are smooth the scheme is consistent with (1.1), and when discontinuities are involved and there are errors of large magnitude, the errors will be controlled by the conservation properties so that the discontinuity locations are still correct even though the consistency does not hold any more [23].

(2) Harten's subcell resolution [15] shows that the conservation properties can actually be used to locate discontinuities within grid cells.

These observations motivate us to develop a front tracking method which uses the conservation properties of (1.1) as its tracking mechanism. It is expected that the correct front locations can be guaranteed by enforcing the conservation properties. When fronts are simple, the method is consistent with (1.1) in smooth regions and its jump conditions on the fronts, and when the fronts are complex and errors of large magnitude occur, the errors can be controlled by conservation and can be deleted when the complex fronts are gone. Thus, the requirement that the locations of fronts

be accurately computed in every time step can be relaxed, the complexity of the algorithm can be greatly reduced, and the algorithm itself will be much more robust.

This approach has been proved successful in one space dimension. The one-dimensional front tracking method of this type developed in [25], [27], [28], [29], and [30] shows the following advantages over the traditional front tracking methods:

(1) The method can be applied to any front capturing schemes and it works as an adjustment of the schemes near discontinuities. Therefore, the algorithm can be easily coded in a nearly front capturing fashion.

(2) The algorithm is implemented on uniform Cartesian grids; thus, we avoid the use of adaptive grids and get rid of the related small-cell problem that troubles all the traditional front tracking methods.

(3) The method preserves the conservation of the solution; therefore, the handling of discontinuity collisions and formations is quite simple and robust. Due to a so-called "stacking technique" described in section 4 in [30], the handling is also very detail-resolving.

Some studies have been done on the accuracy, stability, and entropy satisfaction of the method in the one-dimensional scalar case. In [25] a study was made on the accuracy of the discontinuity position when the numerical solution was piecewise smooth, and it was shown that when the underlying scheme was of rth order and the reconstruction of the numerical solution in the critical cell was of $(r-1)$ order, the discontinuity position was rth order accurate. In [19], a total variation diminishing (TVD) study was made for the method and it was shown that when the underlying scheme was TVD and the time step was restricted by the Courant–Friedrichs–Lewy (CFL) condition then the whole algorithm was TVD. In [31], a study was made on the entropy satisfaction of the method and it was shown that when the underlying scheme satisfied the entropy condition and some criterions were also satisfied for the tracked fronts, the numerical solution satisfied the entropy condition.

We are going to extend this conservative front tracking method in two space dimensions, and for this purpose we plan to write a series of papers. This paper, the first one of the series, is mainly devoted to presenting the basic ideas by describing the tracking of single discontinuity curves (with some restriction in topology). Some special cases of the treatment of discontinuity interactions are studied in this paper. The systematic treatment of discontinuity interactions and some other issues of the two-dimensional front tracking method are still in development and will appear in our future papers.

The main difficulty in extending the front tracking method in two space dimensions lies in the recovery of discontinuity curves out of the cell-averages of the numerical solution in critical cells, the cells that are cut through by the discontinuity curves (see section 3). In the one-dimensional case the discontinuity positions are recovered by the requirement that the solution be conserved in the critical cells. However, in the two-dimensional case the discontinuity in a critical cell is represented by a segment of curve, the recovery of which, conceptually speaking, needs an infinite amount of information. The requirement of conservation in the critical cell provides only one equation, which is not enough for the recovery.

A recovery procedure is developed in section 3, which is close in spirit to the "reconstruction via primitive function" described in [15]. The procedure uses the cell-averages in the critical cell as well as the cell-averages in the nearby critical cells cut through by the same discontinuity to recover the segment of curve. Upon this recovery procedure a front advancing algorithm is built. In section 3 we will show

that this front advancing algorithm is more substantial, natural, and much simpler than that of the traditional front tracking methods.

There are a few other front tracking methods that also relate to the conservation properties of (1.1). Chern and Colella [2] use a "flux redistribution" algorithm to maintain the conservation in their front tracking method. The "flux differences" produced in advancing the fronts are distributed into nearby cells based on the characteristic aspects in the vicinity of the tracked discontinuity.

LeVeque and Shyue [20], [21] use a wave propagation method to track discontinuities. The cell-averages in both regular and irregular grid cells are updated by computing the waves propagating in and out of the cells during the time step so that the conservation of the solution is maintained.

However, in those front tracking methods, the conservation is only considered as an important property that should be preserved, rather than used as the mechanism of tracking as in the method presented in this paper. The front locations are still computed by computing the propagation speed from the solutions to the Riemann problems.

Therefore, the front locations do not get as much feedback from the conservation as in this method, and the methods are more complex.

In his early paper [26] the author also presented an extension of the tracking method in two space dimensions. However, the method described in that paper is still very much of the traditional type in which even the conservation is not preserved. The front locations are still computed by computing the propagation speed. The difference is that the propagation speed along the horizontal or vertical grid lines is computed, instead of the normal propagation speed as in the other traditional front tracking methods mentioned above. The method is much more complex than the present one.

The paper is organized in the following way: section 2 is a brief recall of the tracking method in one space dimension. Section 3 presents the two-dimensional tracking method for the scalar conservation law. The method is presented in the semidiscrete form because the direct full-discretization of the method will be complicated. Section 4 extends the tracking method to the Euler system of gas dynamics in two space dimensions. Section 5 uses the idea of the tracking method to develop a treatment of reflection wall boundary in the Euler system of gas dynamics. Section 6 presents the treatments of three special cases of discontinuity interactions on the observation of conservation without solving two-dimensional Riemann problems. Section 7 displays two numerical examples in the scalar conservation law and one numerical example of regular shock reflection in the Euler system of gas dynamics for the tracking method.

2. A brief recall of the tracking method in one space dimension. In this section we briefly recall the tracking method in the one-dimensional case. In our early paper we presented the method in the context of conservation error (see [25]); however, in this paper we present the method in the context of cell-average, considering that the later presentation is more natural and convenient.

We are concerned with the tracking method for the hyperbolic system of conservation laws

$$u_t + f(u)_x = 0, \tag{2.1}$$

where $u : R \times R \to R^m$ is an m-dimensional vector of conserved quantities, and $f(u)$ is a vector-valued function of u, called flux function for the system.

We begin with the scalar case in which both u and f are scalar. Assume that the

underlying difference scheme

$$u_j^{n+1} = u_j^n - \lambda(\hat{f}_{j+1/2}^n - \hat{f}_{j-1/2}^n) \tag{2.2}$$

is of Godunov type, where u_j^n is a cell-average approximation to the solution, $\hat{f}_{j+1/2}^n$ is a flux average approximation to $f(u)$ on the cell boundary, and $\lambda = \tau/h$ is the mesh ratio with τ and h being the time and space increments of the grid, respectively. As is well known, the numerical flux in the Godunov-type scheme is computed as follows: On each time level a piecewise polynomial function $\tilde{u}^n(x, t_n)$ is reconstructed out of the cell-averages, which is a polynomial of the same order in each grid cell $[x_{j-1/2}, x_{j+1/2}]$. The reconstruction maintains the conservation in the sense that in each cell

$$\frac{1}{h}\int_{x_{j-1/2}}^{x_{j+1/2}} \tilde{u}^n(x, t_n)dx = u_j^n. \tag{2.3}$$

We solve (2.1) (approximately at most time) with $\tilde{u}^n(x, t_n)$ as the initial data to obtain the solution $\tilde{u}^n(x, t)$, and then the numerical flux is computed as

$$\hat{f}_{j+1/2}^n = \frac{1}{\tau}\int_{t_n}^{t_{n+1}} f(\tilde{u}^n(x_{j+1/2}, t))dt. \tag{2.4}$$

Constructed in this way, the scheme is of $(2k + 1)$-points; i.e, the numerical flux is a function of $2k$ variables

$$\hat{f}_{j+1/2}^n = \hat{f}(u_{j-k+1}^n, \ldots, u_{j+k}^n), \tag{2.5}$$

where k is a number related to the order of the polynomial in each cell, and is consistent with the flux in (2.1) in the sense that $\hat{f}(u, \ldots, u) = f(u)$; see [23].

Assume that the cell $[x_{j_1-1/2}, x_{j_1+1/2}]$ harbors a discontinuity at t_n, which is called a critical cell. In the critical cell, in addition to the ordinary cell-average $u_{j_1}^n$, we define two more cell-averages $u_{j_1}^{n,-}$ and $u_{j_1}^{n,+}$, which are computed using information only from the left and right sides of the discontinuity, respectively. The discontinuity position can then be recovered from these cell-averages by enforcing the conservation property and the recovery will be described later.

Now we describe the step of computation from t_n to t_{n+1}. First, we extend the cell-averages on the two sides of the discontinuity by extrapolation to the other sides and obtain $u_{j_1+1}^{n,-}, \ldots, u_{j+k}^{n,-}$ and $u_{j-k}^{n,+}, \ldots, u_{j_1-1}^{n,+}$, where the data with "$-$" are from the left to the right and the data with "$+$" are from the right to the left. Then the numerical solution on the next time level are computed on the left and right sides as

$$u_j^{n+1} = u_j^n - \lambda(\hat{f}_{j+1/2}^{n,-} - \hat{f}_{j-1/2}^{n,-}) \tag{2.6}$$

for $j < j_1$, and

$$u_j^{n+1} = u_j^n - \lambda(\hat{f}_{j+1/2}^{n,+} - \hat{f}_{j-1/2}^{n,+}) \tag{2.7}$$

for $j > j_1$, respectively, where $\hat{f}_{j+1/2}^{n,-}$ and $\hat{f}_{j+1/2}^{n,+}$ are defined as

$$\hat{f}_{j+1/2}^{n,-} = \hat{f}(u_{j-k+1}^n, \ldots, u_{j_1-1}^n, u_{j_1}^{n,-}, \ldots, u_{j+k}^{n,-}) \tag{2.8}$$

and

$$\hat{f}^{n,+}_{j+1/2} = \hat{f}(u^{n,+}_{j-k+1}, \ldots, u^{n,+}_{j_1}, u^{n}_{j_1+1}, \ldots, u^{n}_{j+k}). \tag{2.9}$$

In the critical cell, the cell-averages $u^{n+1,-}_{j_1}$ and $u^{n+1,+}_{j_1}$ are computed from $u^{n,-}_{j}$ and $u^{n,+}_{j}$ as in (2.6) and (2.7). In doing so, we let the computation on each side of the discontinuity use information only from the same side. However, the cell-average $u^{n+1}_{j_1}$ is computed as

$$u^{n+1}_{j_1} = u^{n}_{j_1} - \lambda(\hat{f}^{n,+}_{j_1+1/2} - \hat{f}^{n,-}_{j_1-1/2}) \tag{2.10}$$

under the consideration that the two cell boundaries are on the two sides of the discontinuity.

We see that in the algorithm extrapolated data from one side are widely used, which is an another important feature of the method. A problem that is faced by the front tracking is that when near the fronts there will never be enough regular cells on one side to carry out the computation by the underlying scheme. Most tracking methods solve this problem by introducing adaptive grids and define cell-averages of the numerical solution on the irregular cells; however, complexities follow. In our method, the extrapolation provides all the data necessary for carrying out the computation by the underlying scheme on one side; in doing so, we avoid the complexity of adaptive grid.

We now reconstruct a piecewise polynomial function, still denote by $\tilde{u}^{n+1}(x, t_{n+1})$, out of the cell-averages at t_{n+1}. In ordinary cells, it is reconstructed by the reconstruction procedure of the underlying Godunov type scheme, only the extrapolated data from the same sides should be used when the cells are near the discontinuity. In the critical cell, we reconstruct $\tilde{u}^{n+1,-}(x, t_{n+1})$ and $\tilde{u}^{n+1,+}(x, t_{n+1})$ out of the cell-averages on the left and right sides of the discontinuity and their extrapolated data on the other sides, respectively. We then consider $\tilde{u}^{n+1}(x, t_{n+1})$ in the critical cell to be a piecewise polynomial function of the form

$$\tilde{u}^{n+1}(x, t_{n+1}) = \begin{cases} \tilde{u}^{n+1,-}(x, t_{n+1}), & x < \xi^{n+1}; \\ \tilde{u}^{n+1,+}(x, t_{n+1}), & x \geq \xi^{n+1}, \end{cases} \tag{2.11}$$

where ξ^{n+1} is the discontinuity position at t_{n+1}. Then ξ^{n+1} can be determined from

$$\begin{aligned} \frac{1}{h}\int_{x_{j_1-1/2}}^{x_{j_1+1/2}} \tilde{u}^{n+1}(x, t_{n+1})dx = \frac{1}{h}\Bigg(&\int_{x_{j_1-1/2}}^{\xi^{n+1}} \tilde{u}^{n+1,-}(x, t_{n+1})dx \\ &+ \int_{\xi^{n+1}}^{x_{j_1+1/2}} \tilde{u}^{n+1,+}(x, t_{n+1})dx\Bigg) = u^{n+1}_{j_1}, \end{aligned} \tag{2.12}$$

which comes from the requirement of conservation in the critical cell. In particular, when the underlying scheme is Godunov and the reconstruction is piecewise constant, the solution to (2.12) is simply

$$\xi^{n+1} = x_{j_1-1/2} + h\frac{u^{n+1}_{j_1} - u^{n+1,+}_{j_1}}{u^{n+1,-}_{j_1} - u^{n+1,+}_{j_1}}. \tag{2.13}$$

Once the discontinuity position is obtained, the critical cell at t_{n+1} can then be determined. If $[x_{j_1-1/2}, x_{j_1+1/2}]$ is still the critical cell, the numerical solution on the

new level will not be changed. Otherwise, one of the two adjacent cells will become the critical cell and the numerical solution in the related cells should be adjusted accordingly. For example, if the discontinuity position moves to the left adjacent grid cell at t_{n+1}, then the left adjacent cell is the critical cell at the new time. Meanwhile the numerical solution should be changed as follows:

$$\begin{aligned} u_{j_1-1}^{n+1,-} &:= u_{j_1-1}^{n+1}, \\ u_{j_1-1}^{n+1,+} &:= u_{j_1-1}^{n+1,+}, \\ u_{j_1-1}^{n+1} &:= u_{j_1-1}^{n+1} + u_{j_1}^{n+1} - u_{j_1}^{n+1,+}, \\ u_{j_1}^{n+1} &:= u_{j_1}^{n+1,+}, \end{aligned} \tag{2.14}$$

where $u_{j_1-1}^{n+1,+}$ on the right side is the extrapolated data of the cell-averages from the right in this cell. In this change, the numerical solution on the right is extended in the new critical cell in a piecewise polynomial fashion and the sum $u_{j_1-1}^{n+1} + u_{j_1}^{n+1}$ is conserved. The case that the discontinuity position moves to the right can be treated analogously.

Thus, a step of the tracking method is completed.

When (2.1) is a system, in analogy with the scalar case, we define the cells that harbor a discontinuity to be the critical cells. However, in this case, (2.1) has m different kinds of characteristics and, therefore, has m different kinds of discontinuities. Hence, the critical cells are classified in m kinds according to the types of the discontinuities they harbor. For example, if (2.1) is the Euler system of gas dynamics, (see, e.g., [3] and [23]), we say a critical cell $[x_{j_1-1/2}, x_{j_1+1/2}]$ is a left shock critical cell, denoted by LSCC, if the solution to the Riemann problem $R(u_{j_1}^{n,-}, u_{j_1}^{n,+})$ has a strong left shock, where $R(u_l, u_r)$ denotes the Riemann problem with u_l and u_r as its left and right states. The right shock critical cell, denoted by RSCC, and the contact discontinuity critical cell, denoted by CDCC, can be defined analogously.

The computation in critical cells is still implemented as in the scalar case, only we are now dealing with vectors rather than scalars. However, the recovery of discontinuity positions and the reconstruction of the solution in critical cells are more complex than those in the scalar case, in which the boundary conditions on the tracked discontinuities are to be implemented. As one can see, the conserved quantities are exchanged through any interfaces by means of propagation of waves corresponding to different characteristics. The boundary conditions on a discontinuity interface represent, physically speaking, the waves that correspond to the characteristics entering the region through the interface. Therefore, in the system case we should separate the waves associated with different characteristic fields in the critical cell so that the waves associated with the characteristic fields other than those of the tracked discontinuity can enter in the corresponding regions.

We use the Euler system as an example to describe the recovery and reconstruction. The recovery and reconstruction to be presented here are only piecewise constant; therefore, they are only first-order. A high-order piecewise polynomial version of recovery and reconstruction is still in development.

As in the scalar case, we compute the left and right cell-averages $u_{j_1}^{n+1,-}$ and $u_{j_1}^{n+1,+}$ at t_{n+1}. We solve the Riemann problem $R(u_{j_1}^{n+1,-}, u_{j_1}^{n+1,+})$. As is well known, the solution to the Riemann problem is $u_{j_1}^{n+1,-}$ far enough to the left and is $u_{j_1}^{n+1,+}$ far enough to the right, and between them there are left and right centered waves, either shocks or rarefaction waves, a contact discontinuity, and two constant states,

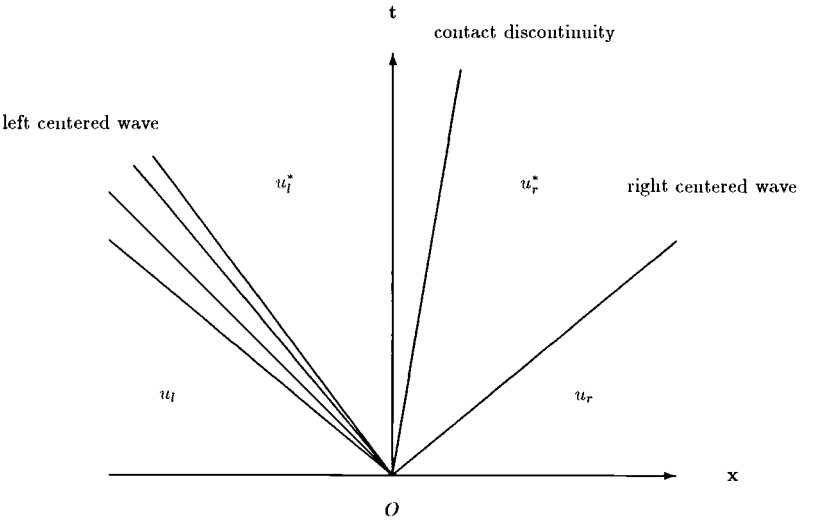

FIG. 1. *Solution to a Riemann problem. On the far left is u_l and on the far right is u_r, between them are two centered waves, either shock or rarefaction waves, a contact discontinuity, and two intermediate states u_l^* and u_r^* to connect u_l and u_r.*

denoted by u_l^* and u_r^*, respectively, to connect $u_{j_1}^{n+1,-}$ to $u_{j_1}^{n+1,+}$, as shown in Figure 1; see section 3.3 in [3]. We consider the solution in the critical cell to be a piecewise constant function of the form

$$\tilde{u}^{n+1}(x,t_{n+1}) = \begin{cases} u_{j_1}^{n+1,-}, & x < \xi_l^{n+1}; \\ u_l^*, & \xi_l^{n+1} \le x < \xi_m^{n+1}; \\ u_r^*, & \xi_m^{n+1} \le x < \xi_r^{n+1}; \\ u_{j_1}^{n+1,+}, & \xi_r^{n+1} \le x, \end{cases} \tag{2.15}$$

where ξ_l^{n+1}, ξ_m^{n+1}, and ξ_r^{n+1} are scalars that are to be solved (see Figure 2). When all the waves in the Riemann problem are discontinuities, we see that (2.15) is exactly the solution with ξ_l^{n+1}, ξ_m^{n+1}, and ξ_r^{n+1} as the three discontinuity positions. When there are rarefaction waves of first and third characteristic fields in the solution and when they are very weak, (2.15) is approximate to the exact solution up to the second order of the strength of the rarefaction waves.

ξ_l^{n+1}, ξ_m^{n+1} and ξ_r^{n+1} can be determined again by the requirement of conservation in the critical cell, which now turns to be

$$\frac{\xi_l^{n+1} - x_{j_1-1/2}}{h} u_{j_1}^{n+1,-} + \frac{\xi_m^{n+1} - \xi_l^{n+1}}{h} u_l^* + \frac{\xi_r^{n+1} - \xi_m^{n+1}}{h} u_r^* + \frac{x_{j_1+1/2} - \xi_r^{n+1}}{h} u_{j_1}^{n+1,+} = u_{j_1}^{n+1} \tag{2.16}$$

and is a linear system of equations.

If the critical cell is an LSCC, then ξ_l^{n+1} is the discontinuity position at the new time. In this case, $u_{j_1}^{n+1,+}$ should be adjusted according to the picture of the reconstructed solution in the critical cell. As one can see, the reconstructed $\tilde{u}^{n+1,+}(x,t_{n+1})$

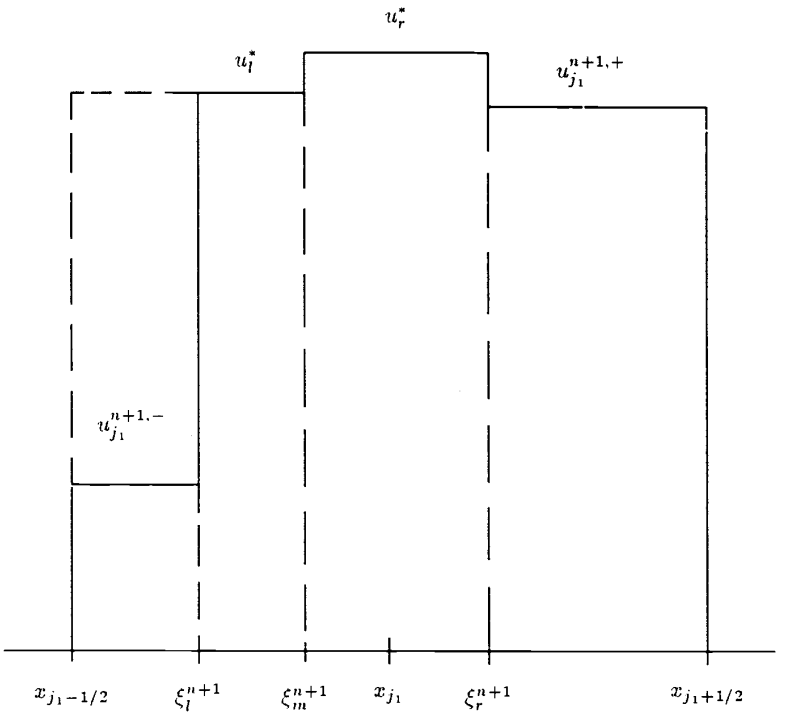

FIG. 2. *The reconstructed solution (solid line) in a critical cell is a piecewise constant vector function as shown in the figure. The two intermediate states u_l^* and u_r^* are obtained from the Riemann problem $R(u_{j_1}^{n+1,-}, u_{j_1}^{n+1,+})$. ξ_l^{n+1}, ξ_m^{n+1}, and ξ_r^{n+1} are the three discontinuity positions to be solved. The reconstructed u^+ in the critical cell is obtained by extending the right structure of u across ξ_l^{n+1} to the left as u_l^* (dash line).*

is a piecewise constant function

$$\tilde{u}^{n+1,+}(x, t_{n+1}) = \begin{cases} u_l^*, & x < \xi_m^{n+1}; \\ u_r^*, & \xi_m^{n+1} \le x < \xi_r^{n+1}; \\ u_{j_1}^{n+1,+}, & \xi_r^{n+1} \le x, \end{cases} \tag{2.17}$$

which is obtained by extending the right part of $\tilde{u}^{n+1}(x, u^{n+1})$ across ξ_l^{n+1} to the left as u_l^* (see Figure 2). According to (2.17) and the definition of cell-average, $u_{j_1}^{n+1,+}$ should be updated as

$$\begin{aligned} u_{j_1}^{n+1,+} &:= \frac{\xi_m^{n+1} - x_{j_1-1/2}}{h} u_l^* + \frac{\xi_r^{n+1} - \xi_m^{n+1}}{h} u_r^* + \frac{x_{j_1+1/2} - \xi_r^{n+1}}{h} u_{j_1}^{n+1,+} \\ &= u_{j_1}^{n+1} - \frac{\xi_l^{n+1} - x_{j_1-1/2}}{h} (u_{j_1}^{n+1,-} - u_l^*). \end{aligned} \tag{2.18}$$

In doing so, the waves associated with the second and third characteristic fields are included in the right cell-average, and thus the boundary conditions on the discontinuity are implemented. The cases of RSCC and CDCC can be treated analogously. In the case of RSCC $u_{j_1}^{n+1,-}$ is changed and $u_{j_1}^{n+1,+}$ is not, and in the case of CDCC both $u_{j_1}^{n+1,-}$ and $u_{j_1}^{n+1,+}$ are changed.

Once the discontinuity positions are obtained, the critical cells on the new time level can be determined as in the scalar case. However, in the system case in the adjustment of cell-averages, the intermediate states should be used instead of the extrapolated data. For example, if the critical cell is an LSCC and the discontinuity position moves to the left at t_{n+1}, then the $u_{j_1-1}^{n+1,+}$ on the right side of (2.14) should be replaced by u_l^*. The other cases can be treated analogously. Thus, a step of computation is completed.

As one can see, in critical cells the waves associated with the characteristic fields other than those of the tracked discontinuity are often very weak. For example, in an LSCC u_l^*, u_r^*, and $u_{j_1}^{n+1,+}$ are often quite close to each other. In this case, the coefficient matrix of (2.16) will become ill-conditioned and particular care should be taken in solving it. We set $(\xi_l^{n+1} - x_{j_1-1/2})/h$, $(\xi_m^{n+1} - x_{j_1-1/2})/h$, and $(\xi_r^{n+1} - x_{j_1-1/2})/h$ as the unknowns in the system; thus, the coefficients of $(\xi_l^{n+1} - x_{j_1-1/2})/h$ will be dominant in the coefficient matrix when the other waves are weak.

We use the Gauss elimination to solve (2.16) and choose a critical number ϵ. When the pivot in the kth step is found to be smaller than $\epsilon A_{1,1}$, where $A_{1,1}$ is the pivot in the first step, we stop the elimination and set the unknowns corresponding to the remaining part to be zero. In doing so, (2.16) is sometimes not exactly satisfied and the solved ξ_m^{n+1} and ξ_r^{n+1} are not reliable. However, the solved ξ_l^{n+1} is still reliable because the coefficients of $(\xi_l^{n+1} - x_{j_1-1/2})/h$ are still of $O(1)$. Therefore, in any case we adjust $u_{j_1}^{n+1,+}$ according to the second part of (2.18), which uses only ξ_l^{n+1}. In the numerical examples in [25], ϵ is chosen to be 10^{-4}.

Techniques that deal with interactions of discontinuities are also developed on the observation of conservation, and they resolve the numerical solution in the vicinity of the interaction points on subcell scale; see [25].

3. The tracking method for scalar conservation law in two space dimensions. From now on we develop our tracking method for conservation laws in two space dimensions

$$u_t + f(u)_x + g(u)_y = 0, \tag{3.1}$$

where $u(x, y, t)$ is either a scalar or a vector function of x, y, and t, and $f(u)$ and $g(u)$ are either scalar or vector functions of u. We first begin in this section with the scalar case, in which all u, f, and g are scalars.

We are going to develop the tracking method in semidiscretization, considering that this will be easier than the development direct in full-discretization. To this end, we partition the (x, y)-plane by setting

$$x_{i+1/2} = (i + 1/2)h, \qquad y_{j+1/2} = (j + 1/2)h \qquad (i, j \in \mathbf{Z}) \tag{3.2}$$

and denote the grid cell centered at (ih, jh) by $\Delta_{i,j}$, where h is the space increment. It will also be useful to define x_i and y_j by

$$x_i = ih, \qquad y_j = jh \qquad (i, j \in \mathbf{Z}). \tag{3.3}$$

Integrating (3.1) over $\Delta_{i,j}$ for fixed t and dividing it by h^2 gives the semidiscrete form of (3.1),

$$\frac{du_{i,j}}{dt} = -\frac{1}{h}(\hat{f}_{i+1/2,j} - \hat{f}_{i-1/2,j}) - \frac{1}{h}(\hat{g}_{i,j+1/2} - \hat{g}_{i,j-1/2}), \tag{3.4}$$

where $u_{i,j}(t)$ is a cell-average approximation to the solution at t and $\hat{f}_{i+1/2,j}(t)$ and $\hat{g}_{i,j+1/2}(t)$ are flux average approximations to $f(u)$ and $g(u)$ on the vertical and horizontal cell boundaries at the time, respectively; see section 17 in [23]. We still assume that the scheme is of Godunov-type, which means that piecewise polynomial functions are reconstructed out of cell-averages in x and y directions and the numerical fluxes are evaluated by solving Riemann problems at cell boundaries. In order to avoid using data on diagonal directions, we assume the numerical fluxes to be of the forms

$$\hat{f}_{i+1/2,j}(t) = \hat{f}(u_{i-k+1,j}(t), \ldots, u_{i+k,j}(t)) \tag{3.5}$$

and

$$\hat{g}_{i,j+1/2}(t) = \hat{g}(u_{i,j-k+1}(t), \ldots, u_{i,j+k}(t)). \tag{3.6}$$

We assume that the solution involves a discontinuity across a smooth surface in the (x, y, t)-space, on the two sides of which the solution is smooth. It is seen that at any fixed time t the discontinuity is represented by a smooth curve in the (x, y)-plane, which we denote by $C(t)$. We define the two sides of $C(t)$ to be the negative and positive sides and mark the quantities associated with the two sides by "$-$" and "$+$," respectively (the negative side may not lie on the left of the positive one).

In the two-dimensional case the critical cells are defined to be the grid cells that are cut through by $C(t)$, and the discontinuity positions are defined to be the intersection points of $C(t)$ with grid lines (see Figure 3). The discontinuity positions are classified into two kinds: the ones on horizontal grid lines, denoted by $\xi^n_{i_1,j_1-1/2}$, are called x-positions and the ones on vertical grid lines, denoted by $\eta^n_{i_1+1/2,j_1}$, are called y-positions, where Δ_{i_1,j_1} is a critical cell. Every critical cell has two discontinuity positions on its boundaries, which it shares with its adjacent critical cells (see Figure 3). The critical cells are classified into three types according to the ways $C(t)$ cuts through them. The critical cells with two x-positions or two y-positions are of xx-type or yy-type, respectively, while the ones with an x-position and a y-position are of xy-type.

The numerical solution in a critical cell Δ_{i_1,j_1}, as in the one-dimensional case, consists of three data, $u_{i_1,j_1}(t)$, the ordinary cell-average, and $u^-_{i_1,j_1}(t)$ and $u^+_{i_1,j_1}(t)$, the cell-averages computed using information only from the negative and positive sides. The discontinuity curve $C(t)$ will be recovered out of these cell-averages.

As in the one-dimensional case, the evolution of cell-averages in cells distant from the discontinuity is governed by (3.4), which is a system of ordinary differential equations (ODEs). The evolution of cell-averages in cells near the discontinuity and the evolution of positive and negative cell-averages in critical cells involve information only from the same sides. This can be done by employing extrapolated data of the cell-averages on the two sides of the discontinuity. For example, in the yy-type critical cell Δ_{i_2,j_2} with two y-positions, $\eta_{i_2-1/2,j_2}$ and $\eta_{i_2+1/2,j_2}$ (see Figure 3), the negative cell-average $u^-_{i_2,j_2}(t)$ satisfies

$$\frac{du^-_{i_2,j_2}}{dt} = -\frac{1}{h}(\hat{f}^-_{i_2+1/2,j_2} - \hat{f}^-_{i_2-1/2,j_2}) - \frac{1}{h}(\hat{g}^-_{i_2,j_2+1/2} - \hat{g}^-_{i_2,j_2-1/2}), \tag{3.7}$$

where f^- and g^- are numerical fluxes evaluated using extrapolated data from the negative side. In the evaluation, the x-fluxes use only extrapolated data in x direction while the y-fluxes use only extrapolated data in y direction. This is possible because the numerical fluxes are defined to be of the form (3.5) and (3.6). Analogously, the

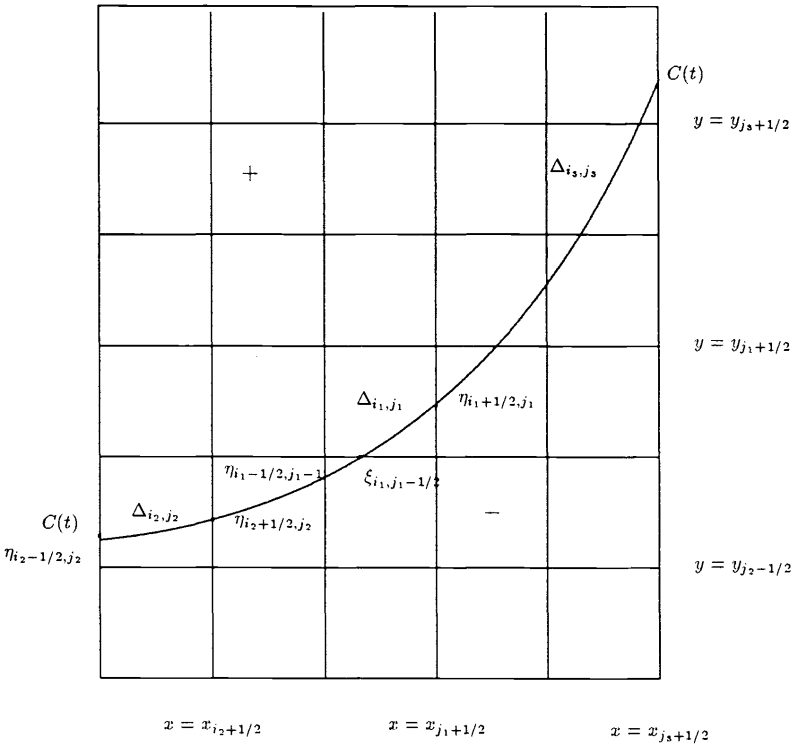

FIG. 3. *The discontinuity curve $C(t)$ cuts through the grid and divides the solution region into two parts. The negative and positive sides are indicated as in the figure. $\xi_{i_1,j_1-1/2}$ is an x-position and eta$_{i_1+1/2,j_1}$ is a y-position. δ_{i_1,j_1} is an xy-type critical cell, δ_{i_2,j_2} is a yy-type critical cell, and δ_{i_3,j_3} is an xx-type critical cell.*

positive cell-average $u^+_{i_2,j_2}(t)$ satisfies a system of equations involving information only from the positive side.

The ordinary cell-average in critical cells are computed as follows: In the yy-type critical cell Δ_{i_2,j_2}, $u_{i_2,j_2}(t)$ satisfies

$$\frac{du_{i_2,j_2}}{dt} = -\frac{1}{h}(\tilde{f}_{i_2+1/2,j_2} - \tilde{f}_{i_2-1/2,j_2}) - \frac{1}{h}(\hat{g}^+_{i_2,j_2+1/2} - \hat{g}^-_{i_2,j_2-1/2}), \tag{3.8}$$

where, according to the picture of the solution,

(3.9)

$$\tilde{f}_{i+1/2,j_2}(t) \simeq \frac{1}{h}\left(\int_{y_{j_2-1/2}}^{\eta_{i+1/2,j_2}} f(u^-(x_{i+1/2},y,t))dy + \int_{\eta_{i+1/2,j_2}}^{y_{j_2+1/2}} f(u^+(x_{i+1/2},y,t))dy\right)$$
$$i = i_2 - 1, i_2.$$

Noticing that $\hat{f}$'s are flux averages approximations, one can evaluate the two integrals in (3.9) by "reconstruction via primitive function" described in [15] on given flux averages $\hat{f}$'s, $\hat{f}^-$'s, and $\hat{f}^+$'s and the two discontinuity positions up to any specified order of accuracy. The computation in an xx-type critical cell can be carried out analogously in a symmetric way.

However, the computation is not carried out directly in an xy-type critical cell. Adjacent xy-type critical cells should first be organized to form either an xx-type or a yy-type rectangle of two cells, called *rectangle for computation* (RC). Then the computation in it is carried out as described above. For example, the critical cell Δ_{i_1,j_1} and Δ_{i_1,j_1-1} can be organized to form an RC of yy-type with two discontinuity positions $\eta_{i_1-1/2,j_1-1}$ and $\eta_{i_1+1/2,j_1}$. We define the cell-average of the RC to be

$$v_{i_1,j_1-1/2}(t) = u_{i_1,j_1}(t) + u_{i_1,j_1-1}(t). \tag{3.10}$$

Then $v_{i_1,j_1-1/2}(t)$ satisfies

$$\begin{aligned}\frac{dv_{i_1,j_1-1/2}}{dt} &= -\lambda(\tilde{f}_{i_1+1/2,j_1} + \hat{f}^-_{i_1+1/2,j_1-1} - \hat{f}^+_{i_1-1/2,j_1} - \tilde{f}_{i_1-1/2,j_1-1}) \\ &\quad -\lambda(\hat{g}^+_{i_1,j_1+1/2} - \hat{g}^-_{i_1,j_1-3/2}).\end{aligned} \tag{3.11}$$

Thus, before carrying out the computation in critical cells, we should first organize them in RCs of either xx-type or yy-type. They consist of only one grid cell when the organized critical cells are of xx-type or yy-type and consist of two grid cells when the organized critical cells are of xy-type. By organizing the critical cells in this way the small-cell problem will be avoided and the algorithm will be in a dimension-by-dimension fashion, which will be seen in the following discussion.

Now we obtain a system of ODEs that governs the evolution of the numerical solution. However, it is not closed because it involves discontinuity positions in critical cells. To close it, one needs to represent the discontinuity positions by cell-averages; in other words, one needs to recover the discontinuity positions out of the cell-averages.

To describe the recovery procedure, we begin with a special case illustrated in Figure 4(a), in which the discontinuity curve $C(t)$ crosses over a sequence of yy-type RCs of one cell centered at (x_i, y_{j_1}) for $i_1 - r \le i \le i_1 + r$; the negative and positive sides are as indicated in the figure. We are going to recover the curve segment in the cell Δ_{i_1,j_1}. It is seen that $C(t)$ can be described by a function $y = y(x)$ (we ignore the dependence of y on t since the time is fixed). We say that this discontinuity curve is of y-type, and our task is to determine the function $y(x)$.

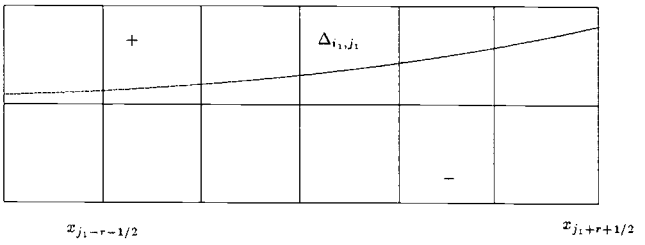
First, we reconstruct $u^-(x, y, t)$ and $u^+(x, y, t)$, the solution on the two sides of the discontinuity, by using reconstruction procedure of the underlying scheme in the y direction. The reconstruction of $u^-(x, y, t)$ uses extrapolated data in the y direction from the negative side while the reconstruction of $u^+(x, y, t)$ uses extrapolated data in the y direction from the positive side.

Now we define a function $F(x)$ as

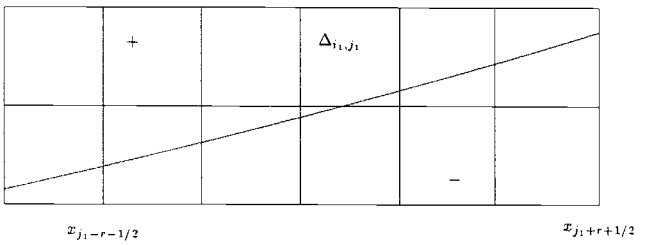
$$F(x) = \int_{x_{i_1-r-1/2}}^{x} ds \left(\int_{y_{j_1-1/2}}^{y(s)} u^-(s, y, t)dy + \int_{y(s)}^{y_{j_1+1/2}} u^+(s, y, t)dy \right). \tag{3.12}$$

On the observation of conservation and from the definition of cell-average we have

$$\begin{aligned} h^2 u_{i,j_1}(t) &= \int_{x_{i-1/2}}^{x_{i+1/2}} ds \left(\int_{y_{j_1-1/2}}^{y(s)} u^-(s, y, t)dy + \int_{y(s)}^{y_{j_1+1/2}} u^+(s, y, t)dy \right) \\ &= F(x_{i+1/2}) - F(x_{i-1/2}). \end{aligned} \tag{3.13}$$



(a)



(b)

FIG. 4. (a) *The discontinuity curve $C(t)$ crosses over a sequence of yy-type RCDs of one cell.* (b) *The discontinuity curve $C(t)$ crosses over a sequence of yy-type RCDs of either one or two cells. In the two pictures, δ_{i_1,j_1} is the yy-type critical cell in which the discontinuity is to be recovered.*

From (3.13) we can easily compute the point values $\{F(x_{i+1/2})\}$ by summation:

$$F(x_{i+1/2}) = h^2 \sum_{l=i_1-r}^{i} u_{i,j_1}(t). \tag{3.14}$$

Let $H_{r+1}(x;F)$ be an $(r+1)$th-order interpolation of F at the points $\{x_{i+1/2}\}$, where r is the order of the underlying scheme. That is,

$$H_r(x_{i+1/2};F) = F(x_{i+1/2}), \tag{3.15a}$$

$$\frac{d^m}{dx^m}H_{r+1}(x;F) = \frac{d^m}{dx^m}F(x) + O(h^{r+1-m}), \qquad 0 \le m \le r. \tag{3.15b}$$

In particular, for $m = 1$ we have

$$\begin{aligned} H'_{r+1}(x;F) &= F'(x) + O(h^r) \\ &= \int_{y_{j_1-1/2}}^{y(x)} u^-(x,y,t)dy + \int_{y(x)}^{y_{i_1+1/2}} u^+(x,y,t)dy + O(h^r). \end{aligned} \tag{3.16}$$

Then the segment of the discontinuity curve in the critical cell can be recovered by solving for $y(s)$ form (3.16). In particular, when u^- and u^+ are piecewise constant and the interpolation $H_{r+1}(x;F)$ is piecewise linear, the recovered curve in the critical cell Δ_{i_1,j_1} is a segment of line

$$y(x) = \xi = y_{j_1-1/2} + h\frac{u_{i_1,j_1}(t) - u^+_{i_1,j_1}(t)}{u^-_{i_1,j_1}(t) - u^+_{i_1,j_1}(t)} \qquad \text{for } x_{i_1-1/2} \le x \le x_{i_1+1/2}. \tag{3.17}$$

The discontinuity curve can also be recovered if it crosses over RCs of two cells, only in this case more rows of cell-averages should be involved in defining $F(x)$ (see Figure 4(b))

Recovered in such a way, the curve is actually not continuous but piecewise smooth. We should reorganize the curve segments to produce a continuous curve. For example, we can define $C(t)$ as follows: Assume that the curve segments recovered in the critical cells Δ_{i_1,j_1} and Δ_{i_1+1,j_1} are $y_{i_1}(x)$ and $y_{i_1+1}(x)$. Then the segment of the discontinuity curve in $[x_{i_1}, x_{i_1+1}]$ is defined as

$$y(x) = \frac{x - x_{i_1}}{h} y_{i_1+1}(x) + \frac{x_{i_1+1} - x}{h} y_{i_1}(x). \tag{3.18}$$

In doing so, the discontinuity position $\eta_{i_1+1/2,j_1}$ is defined just as the mean value of the two recovered positions at $x_{i_1+1/2}$.

A discontinuity curve of x-type can be defined and recovered analogously. Conceptually speaking, a general smooth discontinuity curve can always be covered by several subcurves that are either of x-type or of y-type, and each of them can be recovered as above. At the overlapped part of two adjacent subcurves the recovered curve segment can be taken as a mean weighted in some way of the two segments recovered in the two subcurves. However, in this paper we consider only discontinuity curves of either x-type or y-type and leave the issue of general curve to a future study.

It is seen that the recovery procedure is close in spirit to the "reconstruction via primitive function" for essentially nonoscillatory (ENO) schemes described in [15]. It uses several cell-averages in the vicinity to recover the segment of discontinuity. As is well known, the "reconstruction via primitive function" has degrees of freedom of selecting the stencil for the interpolation. For Godunov-type schemes, various stencil selections are designed to eliminate spurious oscillations and to retain the smoothness of the numerical solutions, among which the ENO stencil selections distinguish themselves by their moving feature that always obtains information from regions of smoothness when discontinuities are present; see [16], [17]. We see that the stencil selections of Godunov-type schemes, in particular the ENO stencil selections, can also be applied to the interpolation in this recovery procedure to stabilize the computation.

Now we close the system of ODEs that governs the evolution of the numerical solution by substituting the recovered discontinuity positions into it. Thus, the tracking method in semidiscrete form is completed and its spatial accuracy is of high order. To obtain a full-discretization of the method that is of high order in time as well as in space, we can discretize the system by the Runge–Kutta method. As one can see, the right side of the system of ODEs, which involves the recovery procedure, is not so explicit; therefore, the direct full-discretization of the tracking method will be complicated.

Finally, we need to determine the critical cells at the new time according to the picture of the discontinuity curve at the time. In doing this, the conservation should be preserved. Two typical cases illustrated in Figure 5 are discussed in the following, and the other cases can be treated analogously.

If $C(t_{n+1})$ is as shown in Figure 5(a), then Δ_{i_1,j_1} is a critical cell at t_{n+1}. If Δ_{i_1,j_1} is also the critical cell at t_n, then the numerical solution has nothing to change. Otherwise, if Δ_{i_1,j_1-1} is the critical cell at t_n, then in Δ_{i_1,j_1-1}, $u^{n+1}_{i_1,j_1-1}$ is defined to be the computed $u^{n+1,-}_{i_1,j_1-1}$, and in Δ_{i_1,j_1}, $u^{n+1,+}_{i_1,j_1}$ is defined to be the computed $u^{n+1}_{i_1,j_1}$, $u^{n+1,-}_{i_1,j_1}$ is defined to be the extrapolated data of the cell-averages from the negative side in the y direction, and the ordinary cell-average $u^{n+1}_{i_1,j_1}$ is computed by

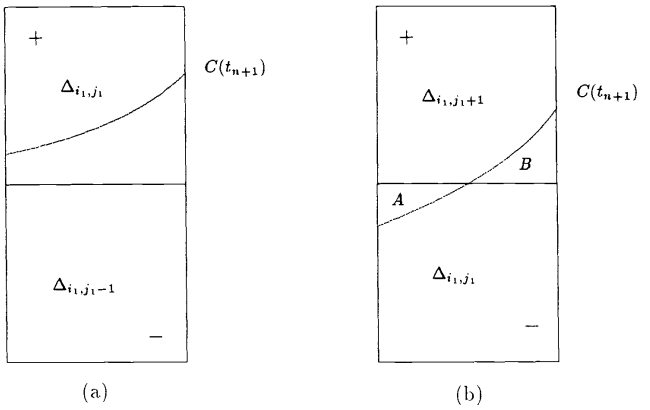


FIG. 5. (a) *Discontinuity curve $C(t_{n+1})$ crosses one grid cell in y direction.* (b) $C(t_{n+1})$ *crosses two cells in y direction.*

the requirement that the sum of the cell-averages in the two grid cells be conserved.

If $C(t_{n+1})$ is as shown in Figure 5(b), then both Δ_{i_1,j_1} and Δ_{i_1,j_1+1} are critical cells at t_{n+1}. The negative and positive cell-averages can still be computed according to the locations of the critical cells at t_n. According to the picture, it seems that the ordinary cell-averages in the two cells can be computed as

$$Q_1 = \frac{1}{h^2}\left(\iint_{\Delta_{i_1,j_1}\setminus A} u^{n,-}(x,y,t_{n+1})dxdy + \iint_A u^{n,+}(x,y,t_{n+1})dxdy\right) \tag{3.19}$$

and

$$Q_2 = \frac{1}{h^2}\left(\iint_B u^{n,-}(x,y,t_{n+1})dxdy + \iint_{\Delta_{i_1,j_1+1}\setminus B} u^{n,+}(x,y,t_{n+1})dxdy\right), \tag{3.20}$$

where A and B are the curved triangles formed by $C(t_{n+1})$ and the cell-boundaries. However, taking Q_1 and Q_2 as the new cell-averages may not maintain the conservation. To maintain the conservation we take

$$u^{n+1}_{i_1,j_1} = \frac{1}{2}(v^{n+1}_{i_1,j_1+1/2} + Q_1 - Q_2) \tag{3.21}$$

and

$$u^{n+1}_{i_1,j_1+1} = \frac{1}{2}(v^{n+1}_{i_1,j_1+1/2} + Q_2 - Q_1), \tag{3.22}$$

where $v^{n+1}_{i_1,j_1+1/2}$ is the sum of the two cell-averages. In doing so, the adjustment will not favor any one of the new critical cells. Thus, we complete a step of computation.

Now we are going to give some interesting observations on the tracking method to end this section. To this end, we assume the discontinuity curve still to be of y-type as shown in Figure 4(a). We see that the recovered discontinuity positions in the critical cell Δ_{i_1,j_1} depend on the cell-averages from $\bar{u}_{i_1-r-1,j_1}(t)$ through $\bar{u}_{i_1+r+1,j_1}(t)$; therefore, we have from (3.8) that $\bar{u}_{i_1,j_1}$ satisfies

$$\frac{d\bar{u}_{i_1,j_1}}{dt} = -\frac{1}{h}(\mathcal{F}_{i_1+1/2,j_1} - \mathcal{F}_{i_1-1/2,j_1}) + \mathcal{G}_{i_1,j_1}, \tag{3.23}$$

where

$$\mathcal{F}_{i_1+1/2,j_1} = \mathcal{F}(\bar{u}_{i_1-r,j_1}, \ldots, \bar{u}_{i_1+r+1,j_1}) \tag{3.24}$$

is a function depending on cell-averages from $\bar{u}_{i_1-r,j_1}(t)$ through $\bar{u}_{i_1+r+1,j_1}(t)$ and

$$\mathcal{G}_{i_1,j_1} = -\frac{1}{h}(g^+_{i_1,j_1+1/2} - g^-_{i_1,j_1-1/2}) \tag{3.25}$$

is a known term. Equation (3.23) is a conservative scheme that describes the evolution of the cell-average in the critical cell. The first question is, To what differential equation does (3.23) approximate? For this regard, we fix the x-space increment and shrink the y-space increment to zero (in doing so we have assumed the grid to be rectangular) and obtain

$$\frac{\partial \int_{y_{j_1-1/2}}^{y_{j_1+1/2}} u(x,y,t)dy}{\partial t} + \frac{\partial \int_{y_{j_1-1/2}}^{y_{j_1+1/2}} f(u(x,y,t))dy}{\partial x} + G(x, y_{j_1}, t) = 0, \tag{3.26}$$

where

$$\int_{yj_1-1/2}^{y_{j_1+1/2}} f(u(x,y,t))dy = \int_{y_{j_1-1/2}}^{y(x,t)} f(u^-(x,y,t))dy + \int_{y(x,t)}^{y_{j_1+1/2}} f(u^+(x,y,t))dy), \tag{3.27}$$

in which $y(x,t)$ is the discontinuity position that is determined from $\int_{y_{j_1-1/2}}^{y_{j_1+1/2}} u(x,y,t)dy$ by

$$\int_{y_{j_1-1/2}}^{y_{j_1+1/2}} u(x,y,t)dy = \int_{y_{j_1-1/2}}^{y(x,t)} u^-(x,y,t)dy + \int_{y(x,t)}^{y_{j_1+1/2}} u^+(x,y,t)dy \tag{3.28}$$

and

$$G(x, y_{j_1}, t) = g(u(x, y_{j_1+1/2}, t)) - g(u(x, y_{j_1-1/2}, t)). \tag{3.29}$$

In derivation of (3.26) we have used

$$\mathcal{F}(u, \ldots, u) = \int_{y_{j_1-1/2}}^{y_{j_1+1/2}} f(u(x,y,t))dy, \tag{3.30}$$

which is obvious in the discussion. Equation (3.26) is a partial differential equation (PDE) of conservation law with source term, which describes the evolution of the quantity $\int_{y_{j_1-1/2}}^{y_{j_1+1/2}} u(x,y,t,)dy$.

The second question is, What is the relation between (3.26) and the Hugoniot condition? For this regard, we substitute (3.27) and (3.28) into (3.26) and view $y(x,t)$ as the dependent variable in (3.26). Then by differentiation and noticing (3.1) we obtain

$$(u^+ - u^-)\frac{\partial y}{\partial t} + (f(u^+) - f(u^-))\frac{\partial y}{\partial x} - (g(u^+) - g(u^-)) = 0, \tag{3.31}$$

which is only the Hugoniot condition of the two-dimensional conservation law in the form with x and t being the independent variables; see [24].

In all the other types of front tracking methods mentioned in this paper, the tracked fronts are moved by the normal propagation speed computed from the solutions to the Riemann problems. In doing so, the Hugoniot condition is treated as a group of ODEs rather than as a PDE, from which many geometrical and topological complexities follow. In those methods much of the algorithm has to be spent on dealing with the reorganizing of the new fronts, untangling the tangled fronts, etc. However, as can be seen in the above discussion, in our method the Hugoniot condition is treated as a PDE rather than as a group of ODEs, and (3.23) shows that the complexity of the algorithm is only of that of a one-dimensional front capturing method, no reorganizing and untangling are needed.

4. The tracking method for the Euler system of gas dynamics in two space dimensions. The Euler system of gas dynamics in two space dimensions is

$$u_t + f(u)_x + g(u)_y = 0, \tag{4.1a}$$

$$u = (\rho, m^x, m^y, E)^T, \tag{4.1b}$$

$$f(u) = q^x u + (0, p, 0, q^x p)^T, \tag{4.1c}$$

$$g(u) = q^y u + (0, 0, p, q^y p)^T, \tag{4.1d}$$

$$p = (\gamma - 1)\left(E - \frac{1}{2}\rho q^2\right), \qquad q^2 = (q^x)^2 + (q^y)^2, \tag{4.1e}$$

where ρ, q^x, q^y, p, and E are the density, x-component, and y-component of velocity, pressure, and total energy, respectively, $m^x = \rho q^x$ is the x-component of momentum, $m^y = \rho q^y$ is the y-component of momentum, and γ is the ratio of specific heats.

The one-dimensional Riemann problem for the two-dimensional Euler system is an initial value problem with the initial data consisting of two constant states u^- and u^+ separated by a jump of a straight line. This problem can be solved in the normal direction of the straight line by neglecting the velocity parallel to the jump. Any difference in the parallel component is assumed to take place across the contact surface. Thus, the solution has a similar structure as that in one space dimension. It consists of four constant states, two centered waves, either shocks or rarefactions, and a contact discontinuity consisting of a discontinuity of density and a discontinuity of tangential velocity, a slip-line. The two intermediate states $u^{*,-}$ and $u^{*,+}$ have the same pressure and normal velocity but different densities and tangential velocities. Here we shall introduce in addition to the four constant states one more intermediate state $u^{*,t}$ which has the velocity and pressure of $u^{*,-}$ and the density of $u^{*,+}$. Defined in this way, $u^{*,t}$ is connected with $u^{*,-}$ by a density discontinuity and is connected with $u^{*,+}$ by a slip-line. The necessity of doing this will be seen in the following discussion.

The tracking method to be presented in this section is first-order only. This will be seen in the following discussion. The high-order tracking method is still under investigation. As one has seen in section 2, the things that need to be revised in the extension of the method in the system case because of the presence of different characteristics are (1) the classification of critical cells and of discontinuity curves and (2) the reconstruction of the numerical solution in critical cells.

We define the orientation of a discontinuity curve to be that of the normal to the curve points from the negative side to the positive side. In an LSCC the one-dimensional Riemann problem in the normal direction $\vec{n}$, $R(u^-_{i_1,j_1}(t), u^+_{i_1,j_1}(t), \vec{n})$, has

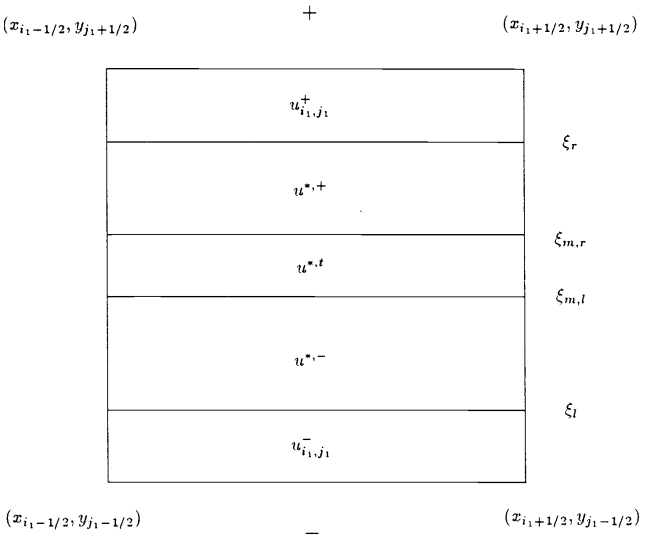

FIG. 6. *The reconstruced solution in the critical cell δ_{i_1,j_1} is constant in each rectangle, where ξ_l, $\xi_{m,l}$, and ξ_r are the locations of the jumps.*

a strong left shock, while in an RSCC and a CDCC it has a strong right shock and a strong contact discontinuity, respectively. A discontinuity curve is said to be LS, RS, or CD if all its critical cells are LSCC, RSCC, or CDCC, respectively.

We still consider the method in semidiscrete form and consider the special case illustrated in Figure 4(a) for the reconstruction of solution. The cases containing the RC of two cells can be treated also by involving more rows of cell-averages. We consider that the solution to be reconstructed in the critical cell Δ_{i_1,j_1} is piecewise constant. However, unlike the scalar case, in the system case it should involve all the five states that come from the Riemann problem $R(u^-_{i_1,j_1}(t), u^+_{i_1,j_1}(t), \vec{n})$. We also consider that the jumps of the solution in the critical cell are segments of straight lines parallel to the x axis; i.e., the solution has the form

$$u(x,y,t) = \begin{cases} u^-_{i_1,j_1}, & y_{j_1-1/2} < y \le \xi_l, \\ u^{*,-}, & \xi_l < y \le \xi_{m,l}, \\ u^{*,t}, & \xi_{m,l} < y \le \xi_{m,r}, \\ u^{*,+}, & \xi_{m,r} < y \le \xi_r, \\ u^+_{i_1,j_1}, & \xi_r < y \le y_{j_1+1/2}, \end{cases} \tag{4.2}$$

where ξ's are the positions of the jumps as shown in Figure 6. We then follow the idea described in section 3 to recover the discontinuity curve in Δ_{i_1,j_1}. Under the above considerations, the discontinuity is recovered only by the cell-averages in this cell, and we are led to the 4×4 linear system

$$\begin{aligned} &\frac{\xi_l - y_{j_1-1/2}}{h} u_{i_1,j_1} + \frac{\xi_{m,l} - \xi_l}{h} u^{*,-} + \frac{\xi_{m,r} - \xi_{m,l}}{h} u^{*,t} \\ &+ \frac{\xi_r - \xi_{m,r}}{h} u^{*,+} + \frac{y_{j_1+1/2} - \xi_r}{h} u_{i_1,j_1} = u_{i_1,j_1}, \end{aligned} \tag{4.3}$$

which comes from the requirement of conservation in the critical cell.

We see that the contact discontinuity has two degrees of freedom. One can has a contact discontinuity with only a density jump and one can have a contact discontinuity with only a tangential velocity jump. These two degrees of freedom must be separated in the reconstruction. Otherwise, if we still define only one discontinuity position for the contact discontinuity, (4.3) will become a system of four equations but with only three unknowns and, thus, will be overdetermined.

Once (4.3) is solved, the discontinuity curve in the critical cell can be recovered. If the tracked discontinuity is an LS, the recovered discontinuity curve in the critical cell is a segment of line

$$y = \xi_l, \quad x_{i_1-1/2} < x \le x_{i_1+1/2} \ . \tag{4.4}$$

The positive cell-average in the critical cell $u^+_{i_1,j_1}$ should be adjusted as

(4.5)

$$\begin{aligned} u^+_{i_1,j_1} &:= \frac{\xi_{m,l} - y_{j_1-1/2}}{h} u^{*,-} + \frac{\xi_{m,r} - \xi_{m,l}}{h} u^{*,t} + \frac{\xi_r, -\xi_{m,l}}{h} u^{*,+} + \frac{y_{j_1+1/2} - \xi_r}{h} u^+_{i_1,j_1} \\ &= u_{i_1,j_1} - \frac{\xi_l - y_{j_1-1/2}}{h} (u^-_{i_1,j_1} - u^{*,-}). \end{aligned}$$

Once the discontinuity curve is recovered in each critical cell, a continuous discontinuity curve can be produced as in (3.18). An RS can be treated analogously.

When the discontinuity is a CD, there will be two computed positions $\xi_{m,l}$ and $\xi_{m,r}$ for it. According to the structure of the solution to the Riemann problem, $\xi_{m,l}$ and $\xi_{m,r}$ are supposed to be the same since the density discontinuity and the slip-line coincide. However, in the numerical computation they are different due to the truncation errors and round-off errors. The final discontinuity position of the contact discontinuity can be taken as a weighted mean of $\xi_{m,l}$ and $\xi_{m,r}$, and the error of doing this is of the same order as the truncation error. The weight can be taken, say, according to the strengths of the density jump and the slip-line. However, in this paper we consider only shocks and leave the issue to our future study.

As in the one-dimensional case, the coefficient matrix of (4.3) will often become ill-conditioned because the waves associated with the other characteristics are often quite weak. The particular care described in section 3 should also be taken in solving (4.3) by the Gauss elimination. However, the situation in two space dimensions is a bit more severe than that in one space dimension. We design the critical number ϵ as follows: We select three numbers $\epsilon_1 < \epsilon_2 < \epsilon_3$ for the critical number. First we set ϵ to be ϵ_1 and then check the computed discontinuity positions. If any one of them is found more than two cells away from the center of the critical cell, we set ϵ to be ϵ_2 and then check the computed discontinuity positions again. If again any one of them is found more than two cells away from the center of the critical cell, we set ϵ to be ϵ_3. In the numerical example of the regular reflection problem presented in section 7, the ϵ_1, ϵ_2, and ϵ_3 are taken to be 10^{-3}, 2.5×10^{-3}, and 5×10^{-3}. We found that almost all the cases can be taken care of with ϵ_1, only very few cases should be taken care of with ϵ_2 and ϵ_3, and the bad cases occur only in the regions near to the foot of the reflected shock and very occasionally.

Up to now the normal direction $\vec{n}$ needed in defining the Riemann problem is still unknown. The normal direction can only be computed from the discontinuity positions. For example, the normal can be taken as the normal to the line connecting

the two discontinuity positions in the critical cell. Therefore, the above discussion does not actually recover the discontinuity positions because the discontinuity positions themselves are used in it. However, it produces an operator equation about the discontinuity positions,

$$(\xi, \eta) = \mathcal{P}(\xi, \eta), \tag{4.6}$$

where $\mathcal{P}$ stands for the recovery procedure described above. In the full-discretization of the tracking method we can use the discontinuity positions obtained at the previous time step in the right side of (4.6). For example, when we use the predictor-corrector method to discretize the time derivative, in the predictor step the discontinuity positions at t_n are used to compute the normal, and in the corrector step the discontinuity positions obtained in the predictor step are used to compute the normal. In doing so, the first order of accuracy is maintained.

Finally, critical cells on the new time level are determined according to the picture of the discontinuity curve on this level. Only in the system case should the left or right intermediate states be used to define the positive and negative cell-averages in the new critical cells when the discontinuity moves to new grid cells, as it was done in the one-dimensional case. Thus, we complete a step of computation.

The tracking method presented here is only first-order. To obtain the high-order tracking method, we should replace the piecewise constant reconstruction by a piecewise polynomial reconstruction to reconstruct the solution, replace the piecewise constant recovery by a piecewise polynomial recovery to recover the discontinuity curve, and find a feasible solver of the operator equation (4.6) which is high-order accurate.

5. Treatment of reflection wall boundary. The basic ideas of the tracking method can be summarized as follows:

(1) On each side of a discontinuity the computation uses information only from the same side.

(2) We reconstruct the solution and locate the discontinuity positions based on conservation.

(3) We extend the solution on each side of the discontinuity properly to the other side so that the solution is well defined on either side in critical cells (refer, for example, to (2.18) and (4.5)).

These ideas can also be applied to treat a reflection wall (RW) boundary for the Euler system of gas dynamics so that the computation in this part will be carried out on a uniform Cartesian grid. The things that are different for an RW boundary are as follows:

(1) The RW boundary is fixed in the flow; therefore, it needs not to be tracked,

(2) The Hugoniot conditions do not hold on the RW boundary; instead, the flow flux is reflected on it.

We develop a treatment of RW boundaries in this section. As we will see in the following discussion, the treatment is only first-order because it is developed under the consideration that the numerical solution is piecewise constant.

Assume that there is a reflection wall and that it is represented by a fixed curve C at all the times. The grid cells that are cut through by C are called the reflection wall critical cells (RWCC). The discontinuity positions, geometrical types of the critical cells, are defined as those for physical discontinuities. As one can see, discontinuity positions of an RW boundary are fixed in the flow; therefore, the treatment of an RW boundary can be developed in full-discrete form.

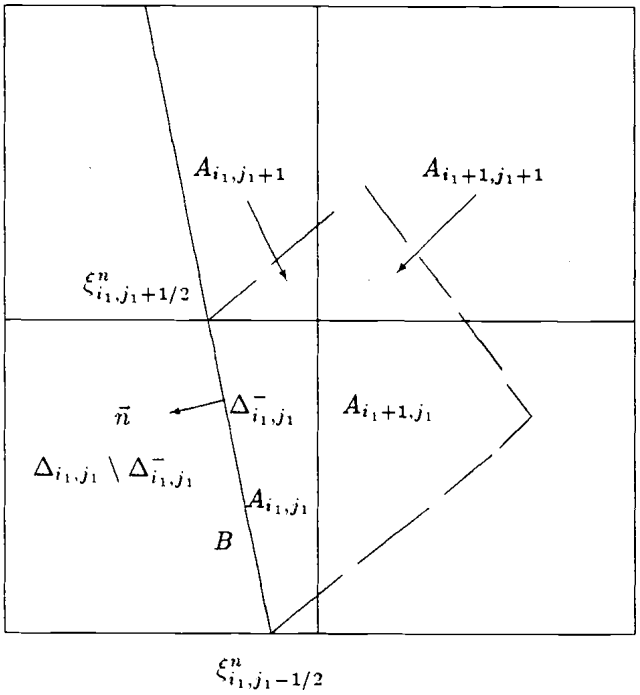

FIG. 7. *δ_{i_1,j_1} is an xx-type RWCC with two discontinuity positions $\xi^n_{i_1,j_1+1/2}$ and $\xi^n_{i_1,j_1-1/2}$. A_{i_1,j_1}, A_{i_1+1,j_1}, A_{i_1+1,j_1+1} are the intersections of the mirror image of $\delta_{i_1,j_1} \setminus \delta^-_{i_1,j_1}$ with the grid cell δ_{i_1,j_1}, δ_{i_1+1,j_1}, δ_{i_1+1,j_1+1}, and δ_{i_1,j_1+1}, respectively.*

We describe only the treatment of xx-type RWCC; the other types of RWCC can be treated analogously without any substantial difference. Assume that Δ_{i_1,j_1} is an xx-type RWCC with two x-positions $\xi_{i_1,j_1-1/2}$ and $\xi_{i_1,j_1+1/2}$ as shown in Figure 7. The wall boundary in Δ_{i_1,j_1} is denoted by B and is assumed to be a segment of a line. For the RW boundary, there is only one side of the flow; the flow in the other side does not exist. We define the side in the flow to be the negative side and define $u^{n,-}_{i_1,j_1}$ to be the cell-average at t_n computed using information only from the negative side. We also define $\Delta^-_{i_1,j_1}$ to be the part of the critical cell that lies on the negative side and define $u^{n,p}_{i_1,j_1}$ to be the partial cell-average that approximates the quantity

$$\frac{1}{h^2}\iint_{\Delta^-_{i_1,j_1}} u(x,y,t_n)dxdy. \tag{5.1}$$

In $\Delta^-_{i_1,j_1}$ the exact solution of the Euler system satisfies

$$\begin{aligned}&\frac{1}{h^2}\iint_{\Delta^-_{i_1,j_1}} u(x,y,t_{n+1})dxdy\\ &= \frac{1}{h^2}\iint_{\Delta^-_{i_1,j_1}} u(x,y,t_n)dxdy - \lambda f^n_{i_1+1/2,j_1} - \lambda(g^{n,p}_{i_1,j_1+1/2} - g^{n,p}_{i_1,j_1-1/2}) - \lambda\mathcal{F}^{n,b},\end{aligned} \tag{5.2}$$

where

$$f^n_{i_1+1/2,j_1} = \frac{1}{h\tau}\int_{t_n}^{t_{n+1}}\int_{y_{j_1-1/2}}^{y_{j_1+1/2}} f(u(x_{i_1+1/2},y,t))dydt, \tag{5.3}$$

$$g^{n,p}_{i_1,j_1\mp 1/2} = \frac{1}{h\tau}\int_{t_n}^{t_{n+1}}\int_{\xi_{i_1,j_1\mp 1/2}}^{x_{i_1+1/2}} g(u(x,y_{j_1\mp 1/2},t))dxdt, \tag{5.4}$$

and

$$\mathcal{F}^{n,b} = \frac{1}{h\tau}\int_{t_n}^{t_{n+1}}\int_B (f(u),g(u))\cdot\vec{n}dsdt, \tag{5.5}$$

where $\vec{n}$ is the outward normal vector of the wall boundary. $\mathcal{F}^{n,b}$ is, in fact, the average of the flux reflected by the wall. A main ingredient in the treatment is the evaluation of $\mathcal{F}^{n,b}$.

Assume that the full-discrete scheme for (3.1) is

$$u^{n+1}_{i,j} = u^n_{i,j} - \lambda(\hat{f}^n_{i+1/2,j} - \hat{f}^n_{i-1/2,j} + \hat{g}^n_{i,j+1/2} - \hat{g}^n_{i,j-1/2}), \tag{5.6}$$

where $u^n_{i,j}$ and $u^{n+1}_{i,j}$ are the cell-average approximations at the two times, $\hat{f}^n_{i+1/2,j}$ and $\hat{g}^n_{i,j+1/2}$ are the flux average approximations, and $\lambda = \tau/h$ is the mesh ratio. First we compute a provisional value of $u^{n+1,-}_{i_1,j_1}$ by (5.6) using information only from the negative side. Now we discretize (5.2) as follows:

$$u^{n+1,p}_{i_1,j_1} = u^{n,p}_{i_1,j} - \lambda\hat{f}^n_{i_1+1/2,j_1} - \lambda(\hat{g}^{n,p}_{i_1,j_1+1/2} - \hat{g}^{n,p}_{i_1,j_1-1/2}) - \lambda\hat{\mathcal{F}}^{n,b}, \tag{5.7}$$

where $u^{n,p}_{i_1,j_1}$ and $u^{n+1,p}_{i_1,j_1}$ are the approximations to the partial cell-averages at the two times, $\hat{g}^{n,p}_{i_1,j_1+1/2}$ and $\hat{g}^{n,p}_{i_1,j_1-1/2}$ are the approximations to $g^{n,p}_{i_1,j_1+1/2}$ and $g^{n,p}_{i_1,j_1-1/2}$, and $\hat{\mathcal{F}}^{n,b}$ is the approximation to $\mathcal{F}^{n,b}$.

The flux averages $g^{n,p}_{i_1,j_1\mp 1/2}$ can be computed from the $\hat{g}^n_{i,j+1/2}$'s and the discontinuity positions in the way as the two integrals in (3.9) are computed from $\hat{f}_{i+1/2,j}$'s and the discontinuity positions. $\hat{\mathcal{F}}^{n,b}$ is computed as follows: For a given normal direction $\vec{n}$, we define an operator $\mathcal{R}_{\vec{n}}$ such that $\mathcal{R}_{\vec{n}}(u)$ is a state which has the same density, pressure, and tangential velocity of u but opposite normal velocity of u. In the RWCC Δ_{i_1,j_1}, we solve the Riemann problem $R(u^{n,-}_{i_1,j_1}, \mathcal{R}_{\vec{n}}(u^{n,-}_{i_1,j_1}), \vec{n})$ and obtain the intermediate state $u^{n,*}$ (this Riemann problem has only one intermediate state). We do the same job for $u^{n+1,-}_{i_1,j_1}$ and obtain $u^{n+1,*}$. Then $\hat{\mathcal{F}}^{n,b}$ is computed as

$$\hat{\mathcal{F}}^{n,b} = 0.5(f(u^{n,*}) + f(u^{n+1,*}), g(u^{n,*}) + g(u^{n+1,*}))\cdot\vec{n}\frac{|B|}{h}, \tag{5.8}$$

where $|B|$ is the length of the segment B.

Once $u^{n+1,p}_{i_1,j_1}$ is computed, $u^{n+1,-}_{i_1,j_1}$ should be recomputed. According to the definition,

$$u^{n+1,-}_{i_1,j_1} \simeq \frac{1}{h^2}\iint_{\Delta_{i_1,j_1}} u^{n,-}dxdy = \frac{1}{h^2}\iint_{\Delta^-_{i_1,j_1}} u^n dxdy + \iint_{\Delta_{i_1,j_1}\setminus\Delta^-_{i_1,j_1}} u^{n,-}dxdy. \tag{5.9}$$

The first term on the left side of (5.9) is approximated by $u^{n+1,p}_{i_1,j_1}$. The difficulty is the evaluation of the second term since the solution on the positive side does not exist.

The question is how to properly extend u in $\Delta_{i_1,j_1} \setminus \Delta^-_{i_1,j_1}$ so that the waves reflected by the wall will go into the flow.

It is well known that the reflection wall boundary conditions can be accomplished by setting on the other side of the wall a state that has the same density, pressure, and tangential velocity but opposite normal velocity. This means that on the wall boundary we should solve the Riemann problem between the two states and the solution u should be extended to the positive side as the intermediate state in the Riemann problem. Under this consideration we compute $u^{n+1,-}_{i_1,j_1}$ as follows: We mirror $\Delta_{i_1,j_1} \setminus \Delta^-_{i_1,j_1}$ at the wall and obtain its mirror image lying in the flow (see Figure 7, the area indicated by dash lines). The mirror image intersects with the grid cells on the negative side and we denote by $A_{i,j}$ the intersection of the image with the cell $\Delta_{i,j}$ and by $|A_{i,j}|$ the area of the intersection. In each cell that intersects with the mirror image we solve the Riemann problem $R(\tilde{u}^{n+1}_{i,j}, \mathcal{R}_{\vec{n}}(\tilde{u}^{n+1}_{i,j}), \vec{n})$ to obtain an intermediate state $u^*_{i,j}$, where $\tilde{u}^{n+1}_{i,j}$ is $u^{n+1}_{i,j}$ if the cell is ordinary and is the provisional value of $u^{n+1,-}_{i,j}$ if the cell is an RWCC. Then $u^{n+1,-}_{i_1,j_1}$ is evaluated as

$$u^{n+1,-}_{i_1,j_1} = u^{n+1,p}_{i_1,j_1} + \frac{1}{h^2} \sum_{i,j} |A_{i,j}| u^*_{i,j}. \tag{5.10}$$

Thus, the treatment of the RWCC is completed.

Here we would like to mention the work of [22], [6], and [7], in which treatments of RW boundaries are also studied. The idea of the mirror image and its intersections with the grid cells actually comes from those papers. However, the boundary treatment presented here is different from theirs in essence.

6. Treatments of three special cases of discontinuity interactions. As was discussed in the introduction, there are difficulties for the traditional front tracking methods in dealing with complex fronts. One typical case of complex fronts is the discontinuity interactions. The treatment of discontinuity interactions of the traditional front tracking methods relies heavily on the knowledge of the exact solutions to two dimensional Riemann problems; see [11] and the references cited therein. However, the solutions to two-dimensional Riemann problems are much more complicated than those for one-dimensional problems; see [8]. This situation makes the two-dimensional traditional front tracking methods very expansive and it is impossible to build general algorithms for them. The solutions to two-dimensional Riemann problems have too many possible cases and it is not realistic to build an algorithm that covers all of them.

The problem seems to have a solution in our conservative front tracking method. As was discussed in the introduction, the method works by enforcing the conservation properties of the PDE; thus, it relaxes the requirement that the discontinuity positions be accurately computed in every time step. This relaxation allows us to not solve the two dimensional Riemann problems in treating the two dimensional discontinuity interactions.

In this section, as a beginning of the study, we present the treatments of three special cases of discontinuity interactions on the observation of conservation without solving two-dimensional Riemann problems. These cases will occur in the numerical examples in the following section. The idea of the treatments applies to more complex cases. The development of a systematic treatment of discontinuity interactions will be discussed in our future papers. The treatments are presented in full-discrete form.

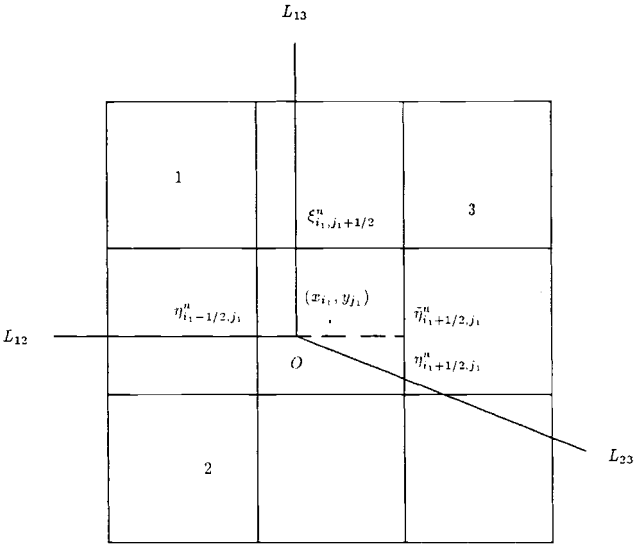

FIG. 8. *Incoming discontinuites L_12 and L_13 meet at O and produce an outgoing discontinuity L_23. The three discontinuities divide the whole region into three parts marked by 1, 2, and 3, respectively. The cell δ_{i_1,j_1}, which contains O, is the node cell. $\xi^n_{i_1,j_1+1/2}$, $\eta^n_{i_1+1/2,j_1}$, and $\eta^n_{i_1-1/2,j_1}$ are the three discontinuity positions of the node cell. The imaginary y-postion $\tilde{\eta}^n_{i_1+1/2,j_1}$ that belongs to L_12 is the intersection point of the extension of L_12 and the grid $x = x_{i_1+1/2}$.*

(1) *Triple point in scalar conservation law.*

We are concerned with the scalar conservation law and are using (5.6) as the underlying scheme. Assume that there is a horizontal discontinuity L_{12} moving to the above and a vertical discontinuity L_{13} moving to the left. They meet at point O and produce the third discontinuity L_{23}, which is of either x-type or y-type. The xy plane is then divided into three regions in which the numerical solution is denoted by $u^{n,1}$, $u^{n,2}$, and $u^{n,3}$, respectively (see Figure 8). It is seen that L_{12} and L_{13} are the incoming discontinuities, L_{23} is the outgoing discontinuity, and O is the triple point.

We call the grid cell containing O the node cell. In the node cell the numerical solution has four cell-averages, $u^n_{i_1,j_1}$, the ordinary cell-average, and $u^{n,1}_{i_1,j_1}$, $u^{n,2}_{i_1,j_1}$, and $u^{n,3}_{i_1,j_1}$, the cell-averages computed using information only from regions 1, 2, and 3, respectively, where (x_{i_1}, y_{j_1}) is the center of the node cell. The node cell has three discontinuity positions, $\eta^n_{i_1-1/2,j_1}$, belonging to L_{12}, $\xi^n_{i_1,j_1+1/2}$, belonging to L_{13}, and either $\xi^n_{i_1,j_1-1/2}$ or $\eta^n_{i_1+1/2,j_1}$, belonging to L_{23} (see also Figure 8).

We define three critical cells overlapping in the node cell, each of which belongs to one of the discontinuities. For each critical cell, one of the discontinuity positions is one of the discontinuity positions of the node cell, and the other one is obtained by the smooth extension of the corresponding discontinuity to the cell boundary. For example, for the critical cell belonging to L_{12}, one of its discontinuity positions is $\eta^n_{i_1-1/2,j_1}$, and for the other one, $\tilde{\eta}^n_{i_1+1/2,j_1}$ is the intersection point of the extension of L_{12} and the vertical grid line $x = x_{i_1+1/2}$ (see also Figure 8). Once the imaginary discontinuity position is obtained, the "ordinary" cell-averages on each critical cell can be computed according to the picture of the discontinuity. Of course, this "ordinary" cell-average has only imaginary meaning.

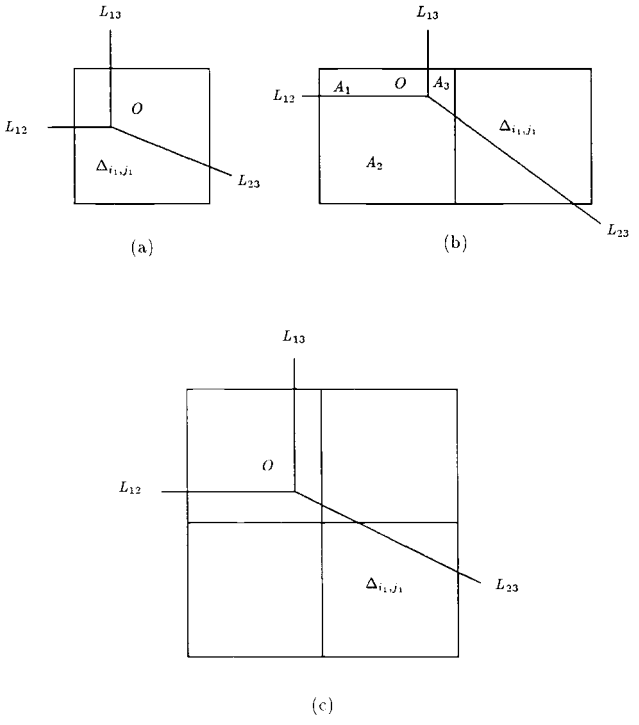

FIG. 9. (a) *O is still in the cell* δ_{i_1,j_1}. (b) *O moves into the cell* δ_{i_1-1,j_1+1}.

The computation in all ordinary and critical cells, including the imaginary critical cells in the node cell, is implemented as described in the previous sections. In doing so, we also compute the numerical fluxes $\tilde{f}^n_{i+1/2,j}$'s and $\tilde{g}^n_{i,j+1/2}$'s defined as in (3.9). On the cell boundaries of the node cell we have three sets of numerical fluxes corresponding to the three overlapping critical cells, which are denoted by $\tilde{f}^{n,12}$ and $\tilde{g}^{n,12}$, $\tilde{f}^{n,13}$ and $\tilde{g}^{n,13}$, and $\tilde{f}^{n,23}$ and $\tilde{g}^{n,23}$, respectively.

To determine the node cell, we first locate the triple point O at t_{n+1}, which is the intersection point of the two incoming discontinuities L_{12} and L_{13}. Under the conventional restriction of the CFL number there can be only three possible cases: (1) O is still in Δ_{i_1,j_1}, (2) O is in either Δ_{i_1-1,j_1} or $\Delta_{i_1.j_1+1}$, and (3) O is in Δ_{i_1-1,j_1+1} (see Figure 9). In the following we are going to discuss the three cases one-by-one.

1. O is still in Δ_{i_1,j_1}. In this case $u^{n+1}_{i_1,j_1}$ is computed from $u^n_{i_1,j_1}$ using numerical fluxes chosen according to the picture of the discontinuities in the node cell. For example, in the case illustrated in Figure 9(a), L_{23} is a y-type discontinuity curve,

$$u^{n+1}_{i_1,j_1} = u^n_{i_1,j_1} - \lambda(\tilde{f}^{n,23}_{i_1+1/2,j_1} - \tilde{f}^{n,12}_{i_1-1/2,j_1}) - \lambda(\tilde{g}^{n,13}_{i_1,j_1+1/2} - \tilde{g}^{n,2}_{i_1,j_1-1/2}). \tag{6.1}$$

In (6.1) $\tilde{g}^{n,2}_{i_1,j_1-1/2}$ is a numerical flux using information only from region 2, which is also $\tilde{g}^{n,23}_{i_1,j_1-1/2}$ or $\tilde{g}^{n,12}_{i_1,j_1-1/2}$ according to the definition of the three sets of numerical fluxes. Δ_{i_1,j_1} is still the node cell on the new time level.

2. O is in Δ_{i_1-1,j_1}. In this case we combine the cells Δ_{i_1,j_1} and Δ_{i_1-1,j_1} and compute $u^{n+1}_{i_1,j_1} + u^{n+1}_{i_1-1,j_1}$ from $u^n_{i_1,j_1} + u^n_{i_1-1,j_1}$ by choosing numerical fluxes on the boundary of the union of the two grid cells according to the picture of the discontinuities, as we compute $u^{n+1}_{i_1,j_1}$ in the previous case. Then we evaluate $u^{n+1}_{i_1-1,j_1}$ according

to the picture of the solution in the grid cell. For example, in the case illustrated in Figure 9(b),

$$u^{n+1}_{i_1-1,j_1} = \frac{1}{h^2}\left(\iint_{A_1} u^1(x,y,t_{n+1})dxdy + \iint_{A_2} u^2(x,y,t_{n+1})dxdy + \iint_{A_3} u^3(x,y,t_{n+1})dxdy\right), \tag{6.2}$$

where u^1, u^2, and u^3 are the solutions reconstructed in the three regions using information only from the same regions and A_1, A_2, and A_3 are the three areas indicated in Figure 9(b). Once $u^{n+1}_{i_1-1,j_1}$ is computed $u^{n+1}_{i_1,j_1}$ can be computed by subtracting $u^{n+1}_{i_1-1,j_1}$ from $u^{n+1}_{i_1-1,j_1} + u^{n+1}_{i_1,j_1}$. Δ_{i_1-1,j_1} is the node cell on the new time level. Discontinuity L_{12} loses a critical cell and L_{23} obtains a critical. The case that O is in Δ_{i_1,j_1+1} can be treated likewise.

3. O is in Δ_{i_1-1,j_1+1}. In this case we combine the four grid cells, Δ_{i_1,j_1}, Δ_{i_1-1,j_1}, Δ_{i_1,j_1+1}, and Δ_{i_1-1,j_1+1}, and compute the sum of the cell-averages on them using the properly chosen numerical fluxes on the boundary of the union of the four grid cells. Then we evaluate $u^{n+1}_{i_1-1,j_1+1}$, $u^{n+1}_{i_1-1,j_1}$, and $u^{n+1}_{i_1,j_1+1}$ according to the picture of the solution in the corresponding grid cells in the same way as $u^{n+1}_{i_1-1,j_1}$ is evaluated in (6.2) in case 2. Once they are computed, $u^{n+1}_{i_1,j_1}$ can be computed by subtracting them from the sum of the four cell-averages. Δ_{i_1-1,j_1+1} is the node cell on the new time level. Both L_{12} and L_{13} lose a critical cell and L_{23} obtain two critical cells.

In cases 2 and 3 we evaluate $u^{n+1}_{i_1,j_1}$ after the evaluation of cell-averages on the other cells, under the consideration that the discontinuity L_{23} is produced by the interaction of L_{12} and L_{13}.

(2) *Reflection point of regular shock reflection.*

We are concerned with the Euler system of gas dynamics in two space dimensions (4.1). A shock travels down a reflection wall to the right with a sufficiently large angle and forms a regularly reflected shock behind it as shown in Figure 10. The dashed lines represent the incident and reflection shocks at t_n and the solid lines represent them at t_{n+1}. The incident and reflection shocks divide the region of solution into three regions denoted by 1, 2, and 3 as shown in the figure.

The wall is taken to be the bottom of the region of solution and a Cartesian grid is set as shown in the figure, on which the wall is set on the line $y = -0.5h$ with h the space increment. We denote by O' and O the reflection points at t_n and t_{n+1} and again call the grid cells containing the reflection points the node cells. In the node cell at t_n the numerical solution has four cell-averages, $u^n_{i_1,0}$, the ordinary cell-average, and $u^{n,1}_{i_1,0}$, $u^{n,2}_{i_1,0}$, and $u^{n,3}_{i_1,0}$, the cell-averages computed using information only from region 1, 2 and 3, respectively, where $(x_{i_1}, 0)$ is the center of the node cell. The node cell has three discontinuity positions: $\eta^n_{i_1+1/2,0}$, belonging to the incident shock; $\eta^n_{i_1-1/2,0}$, belonging to the reflected shock; and $\xi^n_{i_1,-1/2}$, the x-coordinate of the reflection point.

As in the previous case, we define two critical cells overlapping in the node cell, each of which belongs to either the incident or reflected shock. For each critical cell, one of the discontinuity positions is one of the discontinuity positions of the node cell, and the other one is obtained by the smooth extension of the corresponding shock to the cell boundary. For example, for the critical cell belonging to the reflected shock, one of its discontinuity positions is $\eta^n_{i_1-1/2,0}$, and the other one, $\tilde{\eta}^n_{i_1+1/2,0}$, is the intersection point of the extension of the reflected shock and the vertical grid line

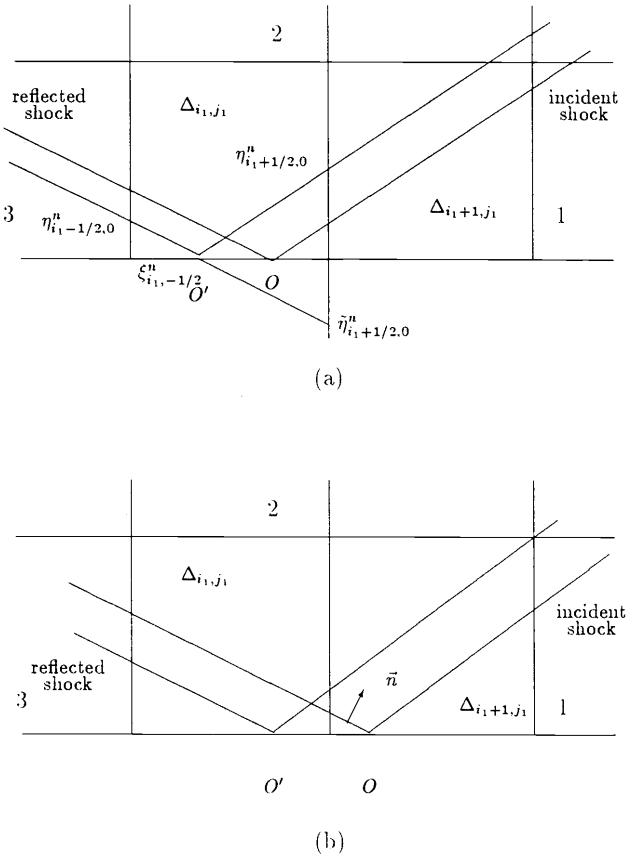

FIG. 10. (a) *The reflection point at t_n is still in δ_{i_1,j_1}.* (b) *The reflection point at t_n+1 moves to the right adjacent cell.*

$x = x_{i_1+1/2}$. As one sees, the imaginary discontinuity position is out of the region of solution. One way to solve this problem is to extend the solution across the wall to define one more critical cell and then define an RC of two cells (see section 3). However, in this paper we consider the RC is still of one cell by viewing part of its interior pulled out by the moving out of one of its discontinuity positions. Once the imaginary discontinuity position is obtained, the imaginary ordinary cell-average on each critical cell can then be computed on the above observation. For example, the imaginary ordinary cell-average in the RC of the reflected shock at t_n can be computed as

$$\frac{1}{h^2}\left\{\left(0.5h - \frac{1}{2}(\eta^n_{i_1-1/2,0} + \tilde{\eta}^n_{i_1+1/2})\right) u^{n,2}_{i_1,0} + \left(\frac{1}{2}(\eta^n_{i_1-1/2,0} + \tilde{\eta}^n_{i_1+1/2}) - 0.5h\right) u^{n,3}_{i_1,0}\right\}.$$

Again as in the previous case, the computation in all ordinary and critical cells, including the imaginary critical cells in the node cell, is implemented as described in the previous sections. The reflection point is determined as the intersection point of the incident shock and the wall. There will be two possible cases for the node cell at t_{n+1}.

1. The reflection point O at t_{n+1} is still in $\Delta_{i_1,0}$ as shown in Figure 10(a). In this case, the cell is still the node cell, and the ordinary cell-average is computed by the

properly chosen numerical fluxes on the boundary of the cell according to the picture of the discontinuities. In particular, the flux on the bottom boundary is evaluated as

$$\begin{aligned}\tilde{g}^n_{i_1,-1/2} &= \frac{\frac{1}{2}(\xi^n_{i_1,-1/2}+\xi^{n+1}_{i_1,-1/2})-x_{i_1-1/2}}{h}\hat{g}^{n,3}_{i_1,-1/2}\\ &\quad+\frac{x_{i_1+1/2}-\frac{1}{2}(\xi^n_{i_1,-1/2}+\xi^{n+1}_{i_1,-1/2})}{h}\hat{g}^{n,1}_{i_1,-1/2}.\end{aligned}\tag{6.3}$$

2. The reflection point O moves to $\Delta_{i_1+1,0}$ as shown in Figure 10(b). In this case $\Delta_{i_1+1,0}$ is the critical cell at t_{n+1}, and the sum of the ordinary cell-averages on the two cells is computed by the properly chosen numerical fluxes on the boundary of the union of the two cells. In this case the fluxes on the bottom boundary are evaluated as

$$\begin{aligned}&\tilde{g}^n_{i_1,-1/2}+\tilde{g}^n_{i_1+1,-1/2}\\ &=\frac{\frac{1}{2}(\xi^n_{i_1,-1/2}+\xi^{n+1}_{i_1,-1/2})-x_{i_1-1/2}}{h}\hat{g}^{n,3}_{i_1,-1/2}+\frac{x_{i_1+3/2}-\frac{1}{2}(\xi^n_{i_1,-1/2}+\xi^{n+1}_{i_1,-1/2})}{h}\hat{g}^{n,1}_{i_1+1,-1/2}.\end{aligned}\tag{6.4}$$

The cell-averages in each region in the two cells should be updated according to the picture of the discontinuities. In particular, $u^{n+1,3}_{i_1+1,0}$ in the new node cell is computed as follows: Extrapolate the numerical solution in region 3 on the y direction and denote the extrapolated data in this cell by v. Solve the Riemann problem $R(v, u^{n+1,2}_{i_1+1,0}, \vec{n})$ and obtain the intermediate state $u^{*,+}$, where $\vec{n}$ is the normal of the reflected shock as shown in the figure, which can be evaluated from the corresponding discontinuity positions. We then define the first, second, and fourth components of $u^{n+1,3}_{i_1+1,0}$ to be that of $u^{*,+}$ and the third component to be 0, considering that the flow on the reflection wall has zero vertical velocity. The ordinary cell-average in the new node cell is computed according to the picture of the discontinuities, and the cell-average in $\Delta_{i_1,0}$ is computed by the requirement that the sum of the cell-averages in the two cells be conserved.

(3) *Foot point of vertical shock on reflection wall.*

A vertical shock travels up on a reflection wall as shown in Figure 11. The shock divides the region of solution into two regions denoted by 1 and 2. We also denote the imaginary region on the other side of the wall by 3. We denote the foot point of the shock on the wall by O.

A Cartesian grid is set such that the reflection wall crosses the grid obliquely. Again, we call the grid cell that contains the foot point O the node cell. We assume that the node cell is at (x_{i_1}, y_{j_1}) as shown in the figure. The ideas used in the previous two cases can still be used in the present case, only we shall deal with partial cell-averages because of the presence of the wall.

First we extend the tracked shock vertically across the wall to the imaginary region and denote the intersection point of the extension and the vertical grid line $x = x_{i_1-1/2}$ by $\tilde{\eta}^n_{i_1-1/2,j_1}$. We then define a yy-type critical cell in the cell with $\eta^n_{i_1+1/2,j_1}$ and $\tilde{\eta}^n_{i_1-1/2,j_1}$ as the two discontinuity positions and with regions 1 and 2 as the two sides. The ordinary cell-average in this critical cell then can be computed according to the picture of the shock. Of course, this ordinary cell-average has only imaginary meaning.

The computation in all ordinary and critical cells, including the imaginary critical cell, is implemented as described in the previous sections. The foot point at the new

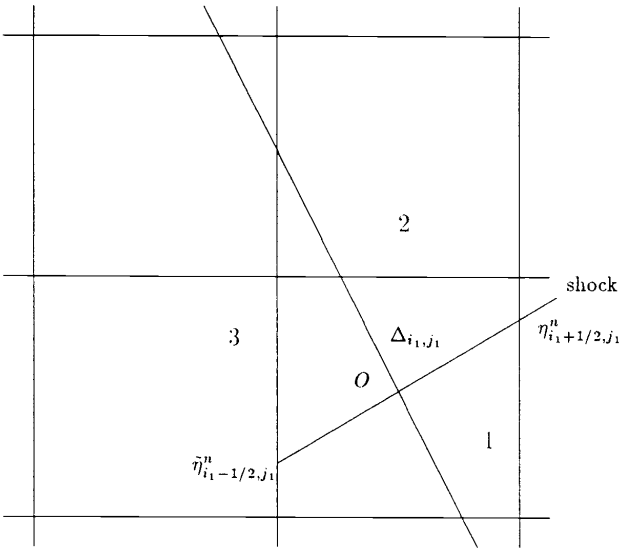

FIG. 11. *The foot point of the vertical shock on the reflection wall is O.* $\eta^n_{i_1+1/2,j_1}$ *is the discontinuity position of the tracked shock and* $\tilde{\eta}^n_{i_1-1/2,j_1}$ *is the imaginary discontinuity position of the tracked on the other side of the wall.*

time is determined as the intersection point of the vertical shock and the wall, which can be computed from the corresponding discontinuity positions. The node cell at the new time is then determined after the foot point is determined.

In the present case partial cell-averages on the node cell should be dealt with instead of the ordinary cell-averages because the node cell is an reflection wall cell. For example, if the foot point is still in Δ_{i_1,j_1} at t_{n+1}, we compute the partial cell-average $u^{n+1,p}_{i_1,j_1}$ which is the approximation to partial cell-average of the exact solution

$$\frac{1}{h^2}\iint_{\Delta^{1,2}_{i_1,j_1}} u(x,y,t_{n+1})dxdy, \tag{6.5}$$

where $\Delta^{1,2}_{i_1,j_1}$ is the part of the grid cell that lies in regions 1 and 2. This cell-average can also be computed by the properly chosen numerical fluxes on the boundary of the cell according to the picture of the shock and the wall boundary. We then reconstruct a piecewise constant function on the part of the cell lying in regions 1 and 2 as in (4.2) and (4.3) with $u^-_{i_1,j_1}$, $u^+_{i_1,j_1}$, and u_{i_1,j_1} replaced by $u^{n+1,1}_{i_1,j_1}$, $u^{n+1,2}_{i_1,j_1}$, and $u^{n+1,p}_{i_1,j_1}$, respectively. We see that the ξ's now still have the geometric meaning that, e.g., $\xi_{m,l} - \xi_l$ represents the area in which the function is valued as $u^{*,-}$. We then update the partial cell-averages in region 1 or region 2 in the way as $u^+_{i_1,j_1}$ is updated in (4.5). Thus the computation is completed.

If the foot point moves out of the original node cell, then we should combine the corresponding cells, as we have done in the previous cases, and implement the computation on the union of the combined cells.

It is seen that the treatments of the node cells in all the three cases maintain the conservation of the numerical solution and does not solve two-dimensional Riemann problems.

7. Numerical examples. In this section we display three numerical examples of the method. Two of them are in scalar conservation law and the third one is a regular shock reflection problem in the Euler system of gas dynamics.

The following scalar conservation law in two space dimensions

$$u_t + \left(\frac{1}{2}u^2\right)_x + \left(\frac{1}{2}u\right)_y = 0 \tag{7.1}$$

is considered. The underlying semidiscrete scheme (3.4) is a second-order TVD scheme of the type described in [33]. The time derivative is discretized by the predictor-corrector method. The recovery of discontinuity curve is of piecewise constant; i.e., it is first-order. Two Riemann problems studied in [37] are tested. Their initial data are defined as

$$u_0(x,y) = \begin{cases} u_1, & x > 0, y > 0, \\ u_2, & x \le 0, y > 0, \\ u_3, & x \le 0, y \le 0, \\ u_4, & x > 0, y \le 0. \end{cases} \tag{7.2}$$

The first problem is with the initial data

$$(u_1, u_2, u_3, u_4) = (-0.2, -1.0, 0.5, 0.8). \tag{7.3}$$

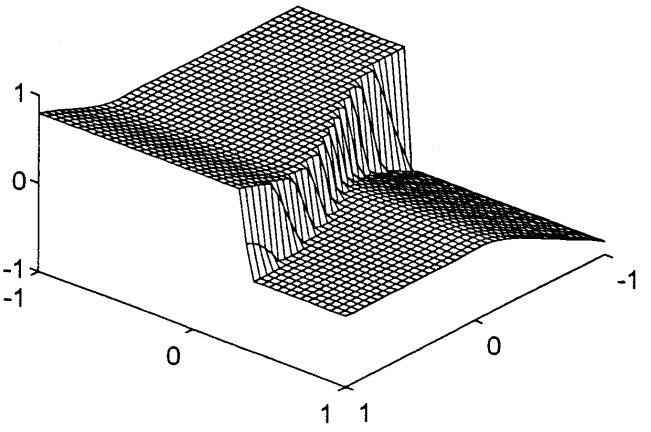
The solution has a y-type shock curve, which has several corner points, the points of discontinuity in first derivative. The test is taken on a grid of 40×40 and the numerical solution is shown in Figure 12. Figure 12(a) represents the surface of the numerical solution and Figure 12(b) represents the contour plot of the solution plus the discontinuity curve. The analysis of the data shows that both the numerical solution and the shock curve have second-order accuracy except at the corner points, where they still have first-order accuracy. We compare the numerical shock to the exact shock and find that they almost coincide. Only near the corner points can small differences be observed in an amplified picture.

The second problem is with the initial data

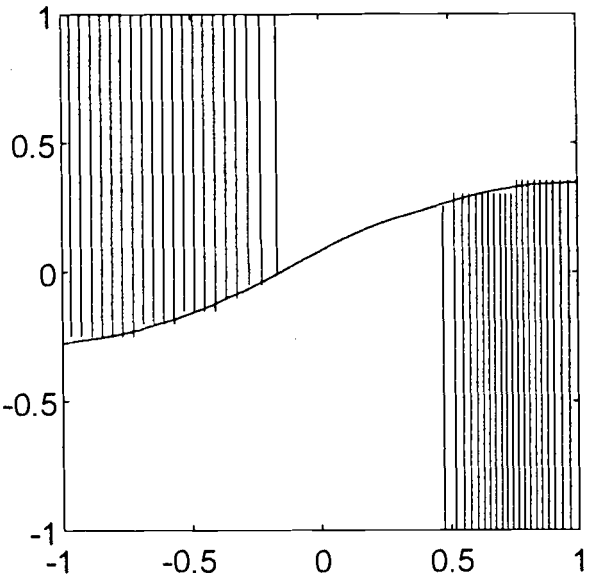
$$(u_1, u_2, u_3, u_4) = (-1.0, -0.3, 0.5, 0.8). \tag{7.3}$$

The solution has two y-type shock curves, an x-type shock curve, and a triple point of the kind discussed in the previous section. The test is again taken on a grid of 40×40 and the numerical solution is shown in Figure 13. Figure 13(a) represents the surface of the numerical solution and Figure 13(b) represents the contour plot of the numerical solution plus the discontinuity curves. We see that one of the y-type shock curves has a sharp corner; however, the numerical results around it still have first-order accuracy and the computation is stable.

Now we consider the Euler equations (4.1). We test our tracking method on a nonsteady regular shock reflection problem and compare the numerical solution with the experimental results in [5]. The Euler system for γ-law gas with $\gamma = 5/3$ is considered. A planar shock with Mach number 2.05 is moving down a shock tube and impinges on a wedge with an angle of 60°. A reflected shock is formed, which extends from the reflection point to the shock tube wall, where it forms a bow shock in front of the wedge, as shown in Figure 14. The solution to this initial value problem is self-similar, i.e., $u(x,t) = u(\sigma t, \sigma x)$ for every σ. The solution consists of three regions denoted by 1, 2, and 3, two shocks of y-type, two RW boundaries, and two node



(a)

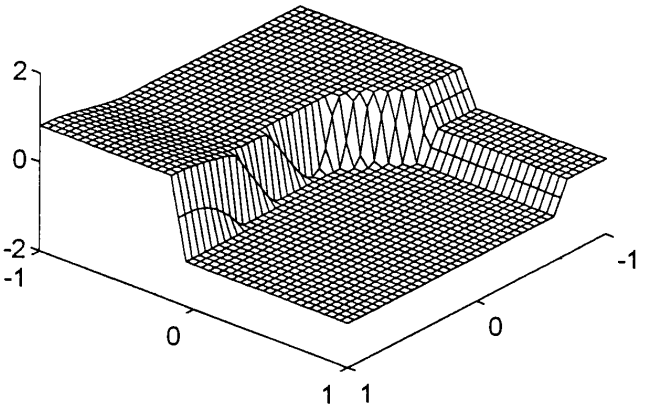


(b)

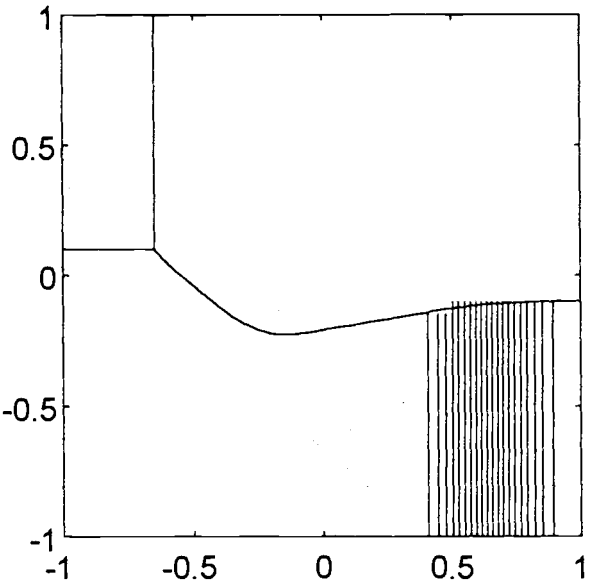
FIG. 12. *The first Riemann problem.* (a) *The surface of the solution.* (b) *The contour plot of the solution plus shock curve.*

points, the reflection point, and the foot point of the reflected shock at the shock tube.

The underlying scheme is still a second-order TVD scheme of the type described in [33], and the recovery of the discontinuity curve is of piecewise constant, so it is first-order. The wedge is set be the bottom of the region of solution as in the second case in the previous section, and the corner point that connects the wedge and the



(a)



(b)

FIG. 13. *The second Riemann problem.* (a) *The surface of the solution.* (b) *The contour plot of the solution plus the shock curves.*

shock tube is located at the grid point $(x_{i_0-1/2}, -1/2h)$, as shown in Figure 15. At the initial time the reflected shock possesses only two xy-type critical cells centered at $(x_{i_0-1}, 0)$ and $(x_{i_0}, 0)$, which are also the two node cells, the cells contain the node points. In these two critical cells, the initial data of the numerical solution in region 3 is set as follows.

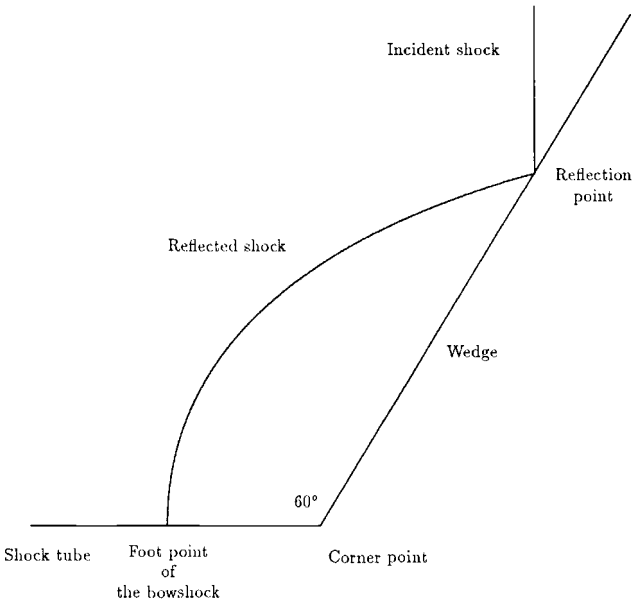


FIG. 14. *A planar shock with Mach number* 2.05 *is moving down a shock tube and impinges on a wedge with an angle of* 60°. *A reflected shock is formed, which extends from the reflection point to the shock tube wall, where it forms a bow shock in front of the wedge.*

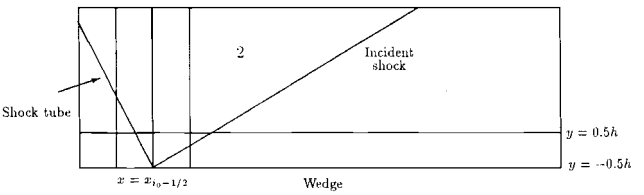

FIG. 15. *The initialization of the numerical experiment is shown as in the figure. The wedge is set to be the bottom of the solution region. The corner point connecting the shock tube and wedge is located at* $(x_{i_0-1/2}, -0.5h)$. *The region* 3, *i.e., the region between the bow shock and the wedge, starts with zero area. This region contains initially two critical cells centered at* $(x_{i_0-1}, 0)$ *and* $(x_{i_0}, 0)$, *respectively. The initial data in these cells are evaluated as described in this section.*

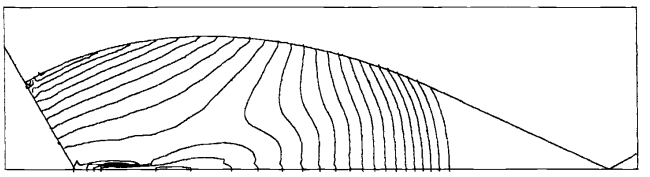
We denote the state in region 2. by u_2 and solve the one-dimensional Riemann problem $R(u_2, \mathcal{R}_{\vec{n}}(u_2), \vec{n})$ in the vertical direction $\vec{n} = (0, -1)$ and obtain a middle state u^*. In the grid cell centered at $(x_{i_0}, 0)$ the initial cell-average is set to be u^* under the consideration that the flow is reflected on the wedge. To define the initial data in the cell centered at $(x_{i_0-1}, 0)$ we solve the Riemann problem $R(u^*, \mathcal{R}_{\vec{n}_1}(u^*), \vec{n}_1)$ in the normal direction of the shock tube $\vec{n}_1$. Then the initial cell-average in the cell is set to be the middle state in the solution to the second Riemann problem under the consideration that the flow in this cell is reflected also by the shock tube.

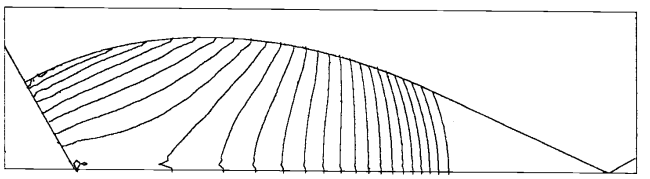
All the initial discontinuity positions of the reflected shock are set to locate at the grid point $(x_{i_0-1/2}, -1/2h)$. This means that the reflected shock is started with a "bubble" of zero area. In such a setting, both the regular cell-averages in the two critical cells are u_2.

As one can see, the above initialization is quite reasonable and arbitrary, in which we do not solve two-dimensional Riemann problems.



DENSITY

(a)



PRESSURE

(b)

FIG. 16. *Numerical results of a regular shock reflection on a grid of* 40×160. *Contour plots of physical quantities in region* 3 *plus shock curves.* (a) *Density.* (b) *Pressure.*

The numerical experiment is carried out on grids of 40×160 (which should be considered quite coarse from the viewpoint of computation). The shocks, node cells, and RW boundaries are treated by the methods described in the previous sections. Figure 16 shows the numerical solution. In the figures, picture (a) presents the contour plot of the density in region 3 plus the discontinuity curve and picture (b) presents that for the pressure. It is seen that the numerical solution agrees quite well with the physical results presented in [5].

The whole computation is quite stable, even at the very beginning. The fronts at the beginning should be considered complex because they have structures of the magnitude of mesh size. However, the small structures are not resolved accurately at this stage of the run, but are resolved roughly by the conservation properties. To show the efficiency of the algorithm in handling complex structures, we display the numerical results at two very early stages. Figure 17 displays the numerical solution at the 25th time step, the bubble of the reflected shock is about two cells in height, and Figure 18 displays the solution at the 60th time step, the bubble is about four cells in height (results are displayed on a grid of 5×20). The computation on the grid of 40×160 took in total 500 time steps. Both the results show that the numerical solution began to show its self-similar form at these early stages.

Figure 19 displays the density distribution along the wall of the numerical solution. There are small oscillations in the distribution on the shock tube part. This is because the cell-averages displayed in this part are not centered at the wall but are on the two sides of the wall with varying distances of $O(h)$.

There are some wiggles behind the reflected shocks in the density and pressure contours. There are two possible reasons for this phenomena. (1) The front tracking

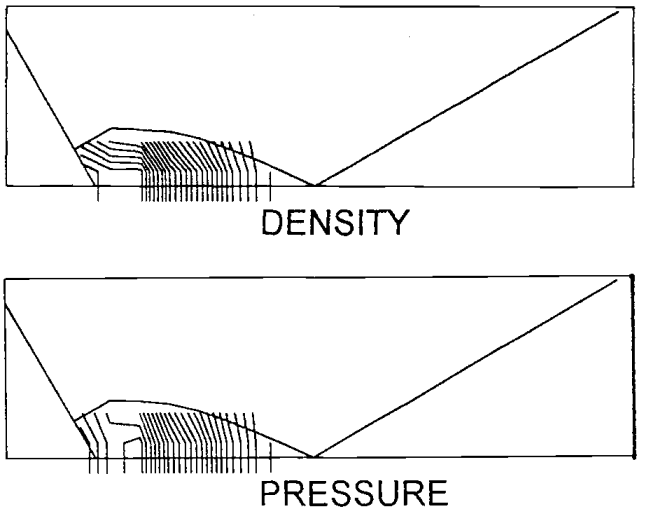


FIG. 17. *The numerical solution at the* 25*th time step; the bubble of the reflected shock is about two cells in height.*

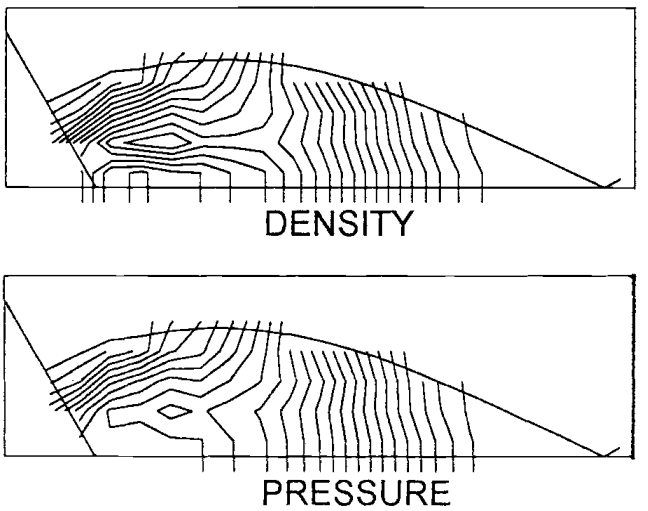

FIG. 18. *The numerical solution at the* 60*th time step; the bubble of the reflected shock is about four cells in height.*

method is only first-order since the reconstruction in the critical cell is first-order; see section 5. Therefore, there might be first-order errors related to the characteristic fields other than that of the tracked reflected shock in the area. (2) The density and pressure contours in region 3 are plotted by MATLAB in the following way. In the cells that are out of a region we set the corresponding cell-averages to be "NaN" and then plot them. In doing so, the plotted region is not regular, neither a rectangle nor a square, but a region with part of its boundary being zigzag lines, which affects the plot quality in this area. Right now we can not tell which reason is more important.

To see the gain of accuracy in using the tracking method, we refer to the last numerical example in [2]. This is of the same problem; however, its reflected shock is

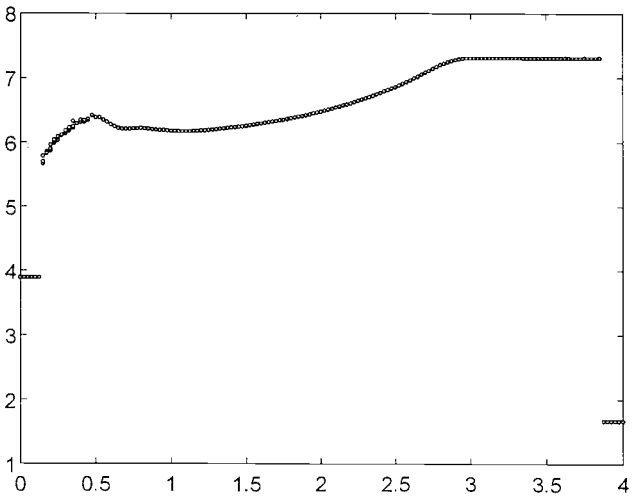

FIG. 19. *The density distribution along the wall of the numerical solution on the grid.*

computed by front capturing method. The example was run on a grid of 100×400. We see that the quality of the smooth part is almost the same as that of our example on the grid of 40×160, but our tracked reflected shock is much sharper than theirs. We also refer to the numerical examples in [11] and [1], which are of a similar problem and are computed by a traditional tracking method, to see the comparison between this tracking method and the traditional tracking methods.

The algorithm is coded in Fortran language. The Fortran used for the numerical experiment is an old version, which only partially supports the Fortran 90 features, with no pointer and module. Therefore, the realization of some data structures are very poor in the code. The numerical experiment on the grid of 40×160 ran for 330 minutes on a PC-586 Pentium 100, not a fast one. The computer does not have the function to check the CPU time consumed in each part; therefore, we cannot tell precisely the CPU time ratio. However, we manually check the CPU times for each part and found that more than 90% of the time was consumed on the computation in the smooth regions in one time step. This confirms the analysis in the end of section 3 that the complexity of the front tracking part is only that of a one-dimensional front capturing method.

Acknowledgments. The author wishes to thank the Graduate Student Office at Shanghai University of Science and Technology for allowing him to use its computer facilities. Part of the numerical experiments reported in section 7 were completed on the PC-386 computer in this office.

EFFICIENT NONPARAMETRIC DENSITY ESTIMATION ON THE SPHERE WITH APPLICATIONS IN FLUID MECHANICS*

ÖMER EĞECIOĞLU† AND ASHOK SRINIVASAN‡

Abstract. The application of nonparametric probability density function estimation for the purpose of data analysis is well established. More recently, such methods have been applied to fluid flow calculations since the density of the fluid plays a crucial role in determining the flow. Furthermore, when the calculations involve directional or axial data, the domain of interest falls on the surface of the sphere. Accurate and fast estimation of probability density functions is crucial for these calculations since the density estimation is performed at each iteration during the computation. In particular the values $f_n(X_1), f_n(X_2), \ldots, f_n(X_n)$ of the density estimate at the sampled points X_i are needed to evolve the system. Usual nonparametric estimators make use of kernel functions to construct f_n. We propose a special sequence of weight functions for nonparametric density estimation that is especially suitable for such applications. The resulting method has a computational advantage over kernel methods in certain situations and also parallelizes easily. Conditions for convergence turn out to be similar to those required for kernel-based methods. We also discuss experiments on different distributions and compare the computational efficiency of our method with kernel based estimators.

1. Introduction.

Nonparametric density estimation is the problem of the estimation of the values of a probability density function, given samples from the associated distribution. No assumption is made about the type of the distribution from which the samples are drawn. This is in contrast to parametric estimation in which the density is assumed to come from a given family, and the parameters are then estimated by various statistical methods. Early contributors to the theory of nonparametric estimation include Smirnov [21], Rosenblatt [16], Parzen [15], and Chentsov [3]. Extensive descriptions of various approaches to nonparametric estimation along with a comprehensive bibliography can be found in books by Silverman [23] and Nadaraya [14]. More recent developments are presented in books by Scott [18] and Wand and Jones [27]. Results of the experimental comparison of some widely used methods appear in [10, 25].

In addition to data analysis, an important application of nonparametric density estimation is in computational fluid mechanics. When the flow calculations are performed in a Lagrangian framework, a set of points in space are evolved through time using the governing equations. In time, points that were initially close can move apart, leading to mesh distortion and numerical difficulties. Problems with mesh distortion can be eliminated to a certain extent by the use of smoothed particle hydrodynamics (SPH) techniques [2, 13, 9, 12]. SPH treats the points being tracked as samples coming from an unknown probability distribution. These calculations often require the computation of the values of not only the unknown density, but its gradient as well.

In contrast to applications concerned with the display of the density, where it is sufficient to estimate the density on some grid, in these fluid flow calculations the density estimate is required at each sample point. Another difference in these two types of applications is that when dealing with data analysis, one is usually concerned with the optimal accuracy one can get for a given sample size. In fluid flow calculations, where additional "data" can be obtained with increased discretization, one is usually more concerned with the optimal variation of the computational effort as a function of error.

In some applications, for example, in problems involving directional data [24], the samples lie on the unit circle S^1 or along the surface of the unit sphere S^2. A special case of directional data is axial data, in which the density is symmetric about the center of the circle or the sphere, that is, $f(\vec{x}) = f(-\vec{x})$.

Various methods have been proposed for nonparametric density estimation in mathematical statistics, such as the kernel [15, 1, 28] and the orthogonal series methods [17, 11]. The kernel method has been extensively studied, and it is probably the most popular scheme in applications such as SPH. In this method, the value of the density at the point x is estimated as

$$f_n(x) = \frac{1}{nA_h} \sum_{i=1}^{n} K\left(\frac{x - X_i}{h}\right), \tag{1}$$

where f_n is the estimate of the density given a sample of size n, X_i are the positions of the samples drawn from a probability distribution with an unknown density function f, K is a kernel function, h is the window width, and A_h is a normalization factor to make f_n into a probability density. One of the drawbacks of the kernel method is the computational cost involved. Even though it is possible to reduce the cost in the one-dimensional case using the expansion of a polynomial kernel and an updating strategy [19], this strategy cannot be easily extended to higher dimensions [5]. Binning methods [5] can be used in any dimension. However, since the density in this case is evaluated on a uniform grid, this method is not suitable for the fluid flow calculations in which we are interested, where an estimate is required at each sample point.

We propose a cosine-based weight function estimator $c_m(x)$ for nonparametric density estimation, which is a special case of the class of estimators that form a δ sequence [26, 28]. This estimator is similar to the kernel estimator but has the ease of evaluation of a series expansion. The role of the window width parameter h of the kernel method is replaced by a smoothing parameter m in our method, and f_n is now of the form

$$f_n(x) = \frac{1}{n} \sum_{i=1}^{n} c_m\left(x - X_i\right). \tag{2}$$

Our choice of c_m is particularly suitable for applications in fluid flow calculations where the values $f_n(X_1)$, $f_n(X_2)$, ..., $f_n(X_n)$ at the sampled directions themselves are required at each point in each time step in the flow simulation. We show that with this estimator the required n values can be computed efficiently using only $O(m^{1+d}n)$ arithmetic operations for directional data and $O(m^d n)$ arithmetic operations for axial data in d dimensions, where m need not be large as long as it increases without bound with n. This is in contrast to the $O(n^2)$ operations required by the kernel method for this computation in the worst case and an expected complexity of $O(h^d n^2)$ with kernels having bounded support. However, in the special case of $d = 1$, the complexity of the kernel method can be reduced to linear after an initial sorting step.

We derive conditions under which the sequence of estimated density functions f_n constructed in this fashion converge to the unknown density f, and experimentally verify the accuracy and the efficiency of our method in practical test cases. Experiments and theoretical analyses also indicate how m should vary with n for optimal accuracy.

The paper is organized as follows. In section 2 we define the weight function estimator c_m and give the conditions for the convergence of the mean integrated square error (MISE) when the sample space is S^1 (Theorem 3). The conditions guarantee that

$$\int E(f_n(x) - f(x))^2 dx \to 0$$

as $n \to \infty$. We also present corresponding results for S^2. In section 3 schemes for efficient computation of these estimates on S^1 and S^2 are presented. In sections 4 and 5, we describe experimental results with our estimator and compare it with the kernel method for some distributions encountered in practice. Our experiments imply a net savings on the number of operations performed over kernel methods in certain situations and also verify the formula found for the optimal choice of m. The results show that the kernel method and our estimator perform well in different settings, and thus complement each other. The main conclusions are presented in section 6. The appendix contains additional test results.

2. The cosine estimator and the convergence of MISE. In this section, we first mention some related work done on spherical data; then we define our estimator and derive conditions for its convergence for directional data on the circle, and give corresponding results for directional and axial data on the sphere and axial data on the circle.

The kernel method for nonparametric density estimation for directional and axial data is discussed in [6, 8]. While dealing with directional data, Fisher, Lewis, and Embleton [6] recommend using the following kernel:

$$W_n(P, P_i) = \left[\frac{C_n}{4\pi \sinh(C_n)}\right] \exp\left[C_n(x^T X_i)\right]. \tag{3}$$

For axial data they recommend the kernel

$$W_n(P, P_i) = A(C_n) \exp\left[C_n(x^T X_i)\right], \tag{4}$$

where $A(C_n)$ normalizes W to a probability density function, and C_n is the reciprocal of h used in the definition of kernel estimators. x and X_i are the Cartesian representation of points P and P_i, respectively, and $x^T X_i$ is the inner product of these two vectors. $W_n(P, P_i)$ plays the role of $K(x - X_i)$ of (1). Hall, Watson, and Cabrera [8] analyze estimators for directional data with the $x - X_i$ term in (1) replaced by $1 - x^T X_i$. Observe that the term $x^T X_i$ is the cosine of the angle between the points P and P_i, and therefore $1 - x^T X_i$ is a measure of the distance along the surface of the sphere between points P and P_i. Inner product plays a crucial role in these estimators. We consider an estimator that can be written in terms of powers of the inner product, the power playing the role of the smoothing parameter. This enables us to expand the estimator in a series and facilitates fast computation.

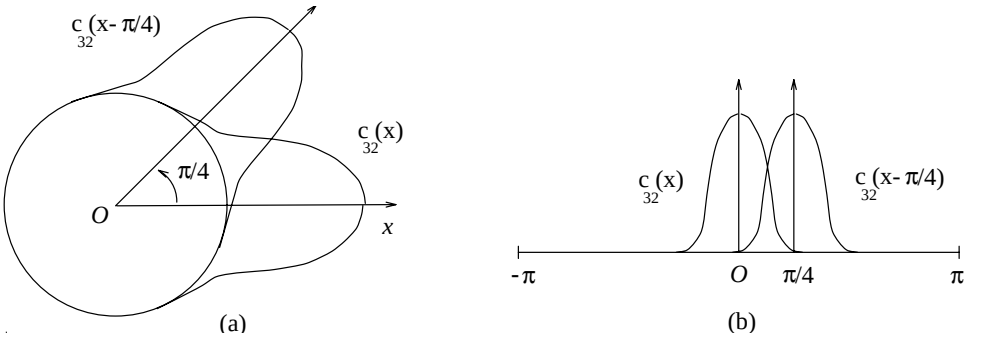

FIG. 1. *The functions* $c_{32}(x)$ *and* $c_{32}(x - \frac{\pi}{4})$ *on* S^1 *and on* $[-\pi, \pi]$.

2.1. The case of S^1. We first define our estimator on S^1. Assume X_j, $j = 1, 2, \ldots, n$, is a sequence of independently and identically distributed (i.i.d.) random variables (observations) for directional data on $[-\pi, \pi]$ with probability density function $f \in C^2[-\pi, \pi]$. We impose the additional condition that $f(-\pi) = f(\pi)$ since the random variables X_j are defined on the unit circle S^1.

As an estimator of the density of directional data $f(x)$, $x \in [-\pi, \pi]$, we consider a nonparametric estimator of the form given by (2) with

$$c_m(x) \;=\; \frac{1}{A_m} \cos^{2m}\left(\frac{x}{2}\right) \tag{5}$$

on $[-\pi, \pi]$. The normalization factor A_m given below makes $c_m(x)$ integrate to 1 on $[-\pi, \pi]$:

$$A_m = \int_{-\pi}^{\pi} \cos^{2m}\left(\frac{x}{2}\right) dx.$$

Making use of a table of integrals such as Gradshteyn and Ryzhik [7] and by using Stirling's formula, it can be shown that

$$A_m \;=\; \frac{\pi}{2^{2m-1}} \binom{2m}{m} \;\sim\; \frac{2\sqrt{\pi}}{\sqrt{m}}\ . \tag{6}$$

As examples, the functions $c_m(x)$ and $c_m(x - \frac{\pi}{4})$ for $m = 32$ are shown on S^1 in Figure 1(a) and on the interval $[-\pi, \pi]$ in Figure 1(b).

We wish to find sufficient conditions under which the sequence of estimators f_n converges to f in the MISE sense. In order to do this, we first show the convergence of the bias and then derive the conditions under which the variance converges to 0. We shall then use these results to prove convergence of MISE on S^1.

First we show that as $m \to \infty$, the expected value of the estimate $f_n(x)$ approaches the actual density $f(x)$ uniformly for any given n.

LEMMA 1. *Suppose* $f \in C^2[-\pi, \pi]$ *and let* $f_n(x)$ *be as given in* (2). *Then* $Ef_n(x) \to f(x)$ *as* $m \to \infty$ *uniformly, independently of* n.

Proof.

$$Ef_n(x) = \int_{-\pi}^{\pi} c_m(x - s) f(s) ds, \tag{7}$$

as shown in Silverman [20] and Whittle [29]. By a change of variable

$$\int_{-\pi}^{\pi} c_m(x-s)f(s)ds = \int_{x-\pi}^{x+\pi} c_m(-y)f(x+y)dy = \int_{x-\pi}^{x+\pi} c_m(y)f(x+y)dy \tag{8}$$

since $c_m(y) = c_m(-y)$. By using the periodicity of c_m and f, along with (7), (8), and the mean value theorem,

$$Ef_n(x) = \int_{-\pi}^{\pi} c_m(y)f(x+y)dy \ = \int_{-\pi}^{\pi} c_m(y)(f(x) + f'(x)y + f''(\xi_x(y))y^2/2)dy,$$

where $\xi_x(y)$ is some point between x and y. Therefore

$$Ef_n(x) = f(x)\int_{-\pi}^{\pi} c_m(y)dy + \int_{-\pi}^{\pi} c_m(y)f'(x)ydy + \int_{-\pi}^{\pi} c_m(y)f''(\xi_x(y))y^2/2dy.$$

From (6), the first integral evaluates to 1, and since $yc_m(y)$ is an odd function, the second integral evaluates to 0. Let $2M' = \max_{x\in[-\pi,\pi]} |f''(x)|$. We then have the following estimate for the bias:

$$\begin{aligned} |Ef_n(x) - f(x)| &\le \left| \int_{-\pi}^{\pi} c_m(y)f''(\xi_x(y))y^2dy \right| \\ &\le M' \int_{-\pi}^{\pi} c_m(y)y^2dy = M' \int_{-\pi}^{\pi} \frac{1}{A_m}\cos^{2m}(y/2)y^2dy. \end{aligned}$$

For any δ such that $0 < \delta \le \pi$,

$$\begin{aligned} |Ef_n(x) - f(x)| &\le M' \int_{|y|<\delta} \frac{1}{A_m}\cos^{2m}(y/2)y^2dy \ + \ M' \int_{|y|\ge\delta} \frac{1}{A_m}\cos^{2m}(y/2)y^2dy \\ &\le M'\delta^2 \int_{|y|<\delta} \frac{1}{A_m}\cos^{2m}(y/2)dy \ + \ \frac{2\pi^3 M'}{3}\frac{1}{A_m}\cos^{2m}(\delta/2) \end{aligned} \tag{9}$$

since $\cos y$ decreases as $|y|$ increases on the interval under consideration. Furthermore, the integral in (9) is bounded above by 1. Therefore,

$$\begin{aligned} |Ef_n(x) - f(x)| &\le M'\delta^2 \ + \ \frac{2\pi^3 M'}{3} \ \frac{\cos^{2m}(\delta/2)}{A_m} \\ &\le M'\delta^2 \ + \ \frac{2\pi^3 M'}{3} \ \frac{\left(1 - \delta^2/8 + \delta^4/384\right)^{2m}}{A_m} \\ &= M'\delta^2 \ + \ \frac{2\pi^3 M'}{3} \ \frac{\left(1 - \delta^2(1 - \delta^2/48)/8\right)^{2m}}{A_m}. \end{aligned} \tag{10}$$

In order to get a bound, we will choose δ as a function of m. If we take $\delta \to 0$ as $m \to \infty$, then $\left(1 - \delta^2(1 - \delta^2/48)/8\right)^{2m} \to \exp(-m\delta^2(1 - \delta^2/48)/4)$. Observe that if $m\delta^2 \to \infty$ as $m \to \infty$, then this term decays exponentially. The second expression in (10) is the product of this term and $1/A_m = O(\sqrt{m})$, and thus the product approaches 0 since the exponential decay dominates. In order to get a good bound on the first term of (10), we wish to choose δ satisfying the condition that $m\delta^2 \to \infty$ such that the δ^2 is as small as possible. We can choose $\delta = 1/m^{\frac{1}{2}-\epsilon}$, where $\epsilon > 0$ is arbitrarily small. Thus M'/m is an asymptotic bound on the bias. Furthermore, the bound is independent of x; hence, the convergence is uniform. ∎

LEMMA 2. *Suppose* $f \in C^2[-\pi,\pi]$ *and let* $f_n(x)$ *be as given in* (2). *Then* $var\ f_n(x) \to 0$ *uniformly as* $n \to \infty$, *provided* $m \to \infty$ *as* $n \to \infty$, *and* $m = o(n^2)$.

Proof.

$$var\ f_n(x) = \frac{1}{n}\int_{-\pi}^{\pi} c_m(x-s)^2 f(s)ds - \frac{1}{n}\left\{\int_{-\pi}^{\pi} c_m(x-s)f(s)ds\right\}^2$$

as shown in Whittle [29]. As a consequence of Lemma 1, the second integral approaches $f(x)$ asymptotically, and hence, the second term approach 0 since f is bounded. It thus suffices to show the convergence of the first integral to 0.

Let $M = \max_{x\in[-\pi,\pi]} |f(x)|$. As in Lemma 1, making a change of variable $y = x - s$ and using periodicity as in (8), we get

$$\frac{1}{n}\int_{-\pi}^{\pi} c_m(y)^2 f(x+y)dy \ \le\ \frac{MA_{2m}}{nA_m^2} \to \frac{M}{\sqrt{8\pi}}\frac{\sqrt{m}}{n},$$

where the expression on the right-hand side is a consequence of the asymptotic expression for A_m in (6). Since $m/n^2 \to 0$ as $n \to \infty$, the above integral converges to 0. Since m is independent of x, the convergence is uniform. Therefore the variance of $f_n(x)$ converges uniformly to 0 under the conditions of the lemma. □

Note that the bound on the bias for the cosine method given by Lemma 1 is of the form

$$|Ef_n(x) - f(x)| \le \frac{1}{2}\max|f''(x)|/m, \tag{11}$$

and the bound for the variance given by Lemma 2 is

$$var\ f_n(x) \le \frac{1}{\sqrt{8\pi}}\max|f(x)|\sqrt{m}/n\ . \tag{12}$$

Therefore, the role played by m for the cosine method is the same as h^{-2} of the kernel based methods, where h is the window width of the kernel estimator. In other words when $m \sim h^{-2}$, the bounds on the bias and the variance of the cosine estimator are in accordance with the asymptotic behavior of the kernel method found in Silverman [23]. Such similarity of rates of convergence is to be expected since the cosine estimator is essentially like the kernel estimator, though the forms of the functions differ. It will be shown later that the main advantage of the cosine estimator lies in its computational efficiency.

THEOREM 3. *Suppose* $f \in C^2[-\pi,\pi]$ *and* $f_n(x)$ *is as given in* (2). *If* $m \to \infty$ *as* $n \to \infty$, *and* $m = o(n^2)$, *then*

$$\text{MISE} \ =\ \int_{-\pi}^{\pi} E(f_n(x) - f(x))^2 dx \to 0$$

as $n \to \infty$.

Proof.

$$\int E(f_n(x) - f(x))^2 dx = \int (Ef_n(x) - f(x))^2 dx + \int var\ f_n(x)dx$$

as shown in Whittle [29]. From Lemmas 1 and 2, each of the integrals approaches 0. Hence, the MISE converges to 0. □

In fact, the MISE is of the form

$$\text{MISE} = O(1/m^2) + O(\sqrt{m}/n), \tag{13}$$

where the asymptotic bounds on the constants are as given in (11) and (12). However, as we shall explain later, the exact asymptotic constants are not all that important for practical computations.

Conditions for the convergence of the estimates and its derivatives on the real line instead of S^1 can be found in [4]. Next we consider the case when the directional data lie along the surface of the unit sphere.

2.2. The case of S^2. Let $X_j,\ j = 1, 2, \ldots, n$, be a sequence of i.i.d. random variables (observations) with values on the surface of the unit sphere S^2 centered at the origin in $\mathbb{R}^3$. Suppose that the probability density function $f(x)$ of the X_j has bounded second derivatives. We consider a nonparametric estimator of the form

$$f_n(x) = \frac{1}{n}\sum_{i=1}^{n} c_m(x, X_i) \tag{14}$$

for some m to be determined as a function of n. The c_m are defined in this case as follows. If α_{xX} denotes the angle between points x and X, then

$$c_m(x, X) \ = \ \frac{1}{A_m}\cos^{2m}\left(\frac{\alpha_{xX}}{2}\right). \tag{15}$$

The normalizing factor A_m is given below:

$$A_m \ = \ \frac{4\pi}{m+1}\ .$$

Through a derivation along the lines of the case of the circle, the following theorem can be proved for the convergence of the estimators.

THEOREM 4. *Suppose $f \in C^2(S^2)$ and let $f_n(x)$ be as given in* (14). *If $m \to \infty$ as $n \to \infty$ and $m = o(n)$, then*

$$\text{MISE} \ = \ \int E(f_n(x) - f(x))^2 dx \to 0.$$

Analogous to (13), the form of the MISE is found to be

$$\text{MISE} = O\left(\frac{1}{m^2}\right) + O\left(\frac{m}{n}\right). \tag{16}$$

From this expression for MISE we see that as in the case of S^1, $m \sim h^{-2}$, where h is the window width of the kernel estimator.

When dealing with axial data, we can consider the following axial estimator for spherical data:

$$c_m(x, X) \ = \ \frac{1}{A_{2m}}\cos^{2m}(\alpha_{xX}).$$

We can also define a corresponding estimator on the circle, where we take the cosine of the arc length between two points, instead of the cosine of half the arc length as in the case of directional data. The relationship between the asymptotic MISE, m and n, is the same as in (13) and (16) for the cases of the circle and the sphere, respectively.

3. Efficient evaluation of the density estimator. In this section, we shall describe an efficient algorithm for the computation of the density estimates $f_n(x)$ evaluated at a set of n observed points $X_1, X_2, \ldots, X_n$ on the unit circle S^1 ($d = 1$ case) and on the unit sphere S^2 ($d = 2$ case). We also show that if the value of f_n at some arbitrary x is desired, then this is also easily accomplished once $f_n(X_1), f_n(X_2), \ldots, f_n(X_n)$ have been computed. The efficiency of our method is based on the fact that $f_n(x)$ is defined in terms of the functions $c_m(x)$ as given in (5) or (15).

Suppose we represent the positions of the observed points $X_1, X_2, \ldots, X_n$ by their Cartesian coordinates. We show that for any x, $f_n(x)$ can be expressed as a polynomial of total degree m in the coordinates of x. The coefficients of this polynomial can be determined in turn from the coordinates of the X_i. Moreover, the coefficients are the sums of the contributions due to each X_i independently.

First we consider the case of directional data on S^1. From (2), (5), and the half-angle formula for cosine we get

$$f_n(x) = \frac{1}{nA_m} \sum_{i=1}^{n} \left(\frac{1 + \cos(x - X_i)}{2} \right)^m . \tag{17}$$

Denote the points on S^1 corresponding to the angles x and X_i for $i = 1, 2, \ldots, n$, by $\vec{x} = (x_1, x_2)$ and $\vec{X}_i = (X_{i1}, X_{i2})$ in Cartesian coordinates and let $\langle , \rangle$ represent the standard inner product on $\mathbb{R}^2$. Then $\cos(x - X_i) = \langle \vec{x}, \vec{X}_i \rangle$. Substituting this into (17) we get

$$f_n(x) = \frac{1}{n2^m A_m} \sum_{i=1}^{n} \left(1 + \langle \vec{x}, \vec{X}_i \rangle \right)^m = \frac{1}{n2^m A_m} \sum_{i=1}^{n} \left(1 + x_1 X_{i1} + x_2 X_{i2} \right)^m . \tag{18}$$

The expression (18) is a polynomial of degree m in x_1 and x_2. For a fixed m, we can compute the coefficients by adding the contribution of each X_i as follows. Using the multinomial theorem and (18)

$$f_n(x) = \frac{1}{n2^m A_m} \sum_{i=1}^{n} \sum_{r+s \le m} \binom{m}{r, s} x_1^r x_2^s \, X_{i1}^r X_{i2}^s, \tag{19}$$

where the inner summation is over all $r + s \le m$ with $r, s \ge 0$. Changing the order of summation

$$f_n(x) = \frac{1}{2^m A_m} \sum_{r+s \le m} \binom{m}{r, s} M(r, s) \, x_1^r x_2^s, \tag{20}$$

where

$$M(r, s) = \frac{1}{n} \sum_{i=1}^{n} X_{i1}^r X_{i2}^s,$$

and A_m is as given by (6). If we use the asymptotic expression for A_m in (6) for computational ease, then (20) simplifies to

$$f_n(x) = \frac{\sqrt{m}}{2^{m+1}\sqrt{\pi}} \sum_{r+s \le m} \binom{m}{r, s} M(r, s) \, x_1^r x_2^s \tag{21}$$

TABLE 1
Computational complexity of the cosine estimator.

	Circle ($d = 1$)	Sphere ($d = 2$)
Axial data	mn	m^2n
Directional data	m^2n	m^3n

for large m. Now we consider the number of operations required for the evaluation of $f_n(x)$ given the observations $X_1, X_2, \ldots, X_n$. The powers X_{i1}^r and X_{i2}^r for a fixed i and $r = 1, 2, \ldots, m$ can be computed with $O(m)$ multiplications. Doing this for $i = 1, 2, \ldots, n$ requires $O(mn)$ multiplications. After the conclusion of this step, each of the $O(m^2)$ averages $M(r, s)$ for a given r and s can be computed with an additional $O(n)$ operations. Since there are a total of $O(m^2)$ terms in $f_n(x)$ corresponding to the pairs r, s with $0 \leq r, s, \leq m$, this means that the coefficients of the polynomial in (20) or (21) can be computed with a total of $O(m^2n)$ arithmetic operations.

Once the coefficients of $f_n(x)$ have been computed, to evaluate $f_n(x)$ with $\vec{x} = (x_1, x_2)$ we calculate the powers x_1^r and x_2^r for $r = 1, 2, \ldots, m$ in $O(m)$ operations. Since the coefficients are already available, the remaining computation in (20) requires only an additional $O(m^2)$ multiplications and additions. The results for different cases are summarized in Table 1.

Remark. For our MISE convergence condition for S^1 (Theorem 3) to be satisfied, m must increase without bound with n. Theoretically, we can take m to be as slowly increasing as we like. Then the above result implies that the computation of the density at all of the sample points can be accomplished using only about $O(n)$ arithmetic operations if the magnitude of m gives acceptable accuracy for $f_n(x)$. The problem with taking m to be too slowly growing is that the magnitude of m controls the error terms in our convergence proofs.

An efficient algorithm for the evaluation of $f_n(\vec{x})$ for directional data on S^2 is constructed similarly. When $\vec{X}_1, \vec{X}_2, \ldots, \vec{X}_n$ are observations on S^2 drawn from an unknown density, it can be shown [4] that

$$f_n(x) = \frac{m+1}{\pi 2^{m+2}} \sum_{r+s+t \leq m} \binom{m}{r, s, t} M(r, s, t)\, x_1^r x_2^s x_3^t, \tag{22}$$

where the summation is over all $r + s + t \leq m$ with $r, s, t \geq 0$, and

$$M(r, s, t) = \frac{1}{n} \sum_{i=1}^{n} X_{i1}^r X_{i2}^s X_{i3}^t \ .$$

This time the coefficients of the polynomial in (22) can be computed with a total of $O(m^3n)$ arithmetic operations. After this preprocessing, each evaluation of $f_n(x)$ for $x \in S^2$ requires only an additional $O(m^3)$ operations.

Corresponding results can be derived for axial data as summarized in Table 1.

It should also be noted that we needed the Cartesian representation of the data. If the data are given in spherical coordinates, then there will be an additional overhead for obtaining the Cartesian representation. However, this overhead takes only linear time and so will be negligible for sufficiently large data. Furthermore, it has been shown [24] that for an important class of applications, Cartesian coordinates are preferable to spherical coordinates, as the latter system is not numerically stable for solving the differential equations that arise.

In the subsequent parts of this section we shall compare the computational efficiency of our scheme with that of the kernel method.

3.1. Parallelization. One of the advantages of the computational strategy described above is the ease of parallelization. Parallelization is required in many fluid flow calculations due to the large sizes of the systems. The kernel method is somewhat difficult to parallelize. If we use an efficient kernel implementation that performs kernel evaluations only for those points which are within a cut-off distance h of the given sample, then an efficient implementation of the parallelization requires periodic load balancing and domain decomposition so that points that are close by remain on the same processor, and so that each processor has roughly the same load in terms of the computational effort. Also, the communication pattern for the kernel method is not very regular. In contrast, parallelization for the cosine estimator can easily be accomplished by a global reduction operation, for which efficient implementations are usually available. This method requires the same computational effort for each point, and so the load is easily balanced by having the same number of points in each processor. Domain decomposition does not play an important role in this scheme, since the points can be on any processor.

3.2. Theoretical comparison of the kernel and the cosine estimators. Now we analyze the computational efficiency of the kernel and the cosine density estimation methods. An important measure of the efficiency of the algorithms is not just the convergence rate of the error with sample size n, but the relationship of the computational effort C required as a function of the error E. For the kernel estimator, we can write the asymptotic MISE E as

$$E = O\left(h^4 + \frac{1}{h^d n}\right), \tag{23}$$

where h is the smoothing parameter, $d = 1, 2$ is the dimension, and n is the sample size. The computational effort required for this nonparametric density estimation can be expressed as

$$C = O(h^\beta n^\gamma), \tag{24}$$

where $0 \le \beta \le d$ and $\gamma = 1$ or 2 depending on the details of the algorithm used. For a given sample size, (23) gives the optimal h as $h \sim n^{-1/(d+4)}$. However, since the equation for the computational complexity also depends on h, we need to consider the possibility that a value of h smaller than this optimal value may actually result in a lower computational effort.

Let us consider a variation of h with n of the form

$$h = O(n^{-\alpha}), \quad 1/(d+4) \le \alpha < 1/d\ . \tag{25}$$

From (25), (24), and (23) we obtain

$$C = n^{-\alpha\beta+\gamma} \Rightarrow n = C^{\frac{1}{\gamma-\beta\alpha}} \Rightarrow E = C^{\frac{-4\alpha}{\gamma-\beta\alpha}} + C^{\frac{d\alpha-1}{\gamma-\beta\alpha}}.$$

For minimum error, the exponent of both the terms on the right should be the same, otherwise the error due to the higher term will dominate. This leads to $\alpha = 1/(d+4)$ which is the same as the value of optimal α for a given n. If we let h_{optn} represent the optimal h minimizing the MISE for a given n, and h_{optC} represent the optimal

h minimizing the computational effort as a function of the error, then the expression derived above for α does not necessarily imply that $h_{optn} = h_{optC}$ since the relation $h_{optn} = kh_{optC}$ would still satisfy the expression for α for some constant k. If $k < 1$, then we can choose a suboptimal value of h in order to improve the speed of the algorithm.

The optimal variation of error with computational complexity using this value of α is given by

$$C = E^{\frac{\beta}{4} - \frac{(d+4)\gamma}{4}}.$$

Let us now consider the cosine estimator. We can write the asymptotic MISE as follows:

$$E = O\left(m^{-2} + \frac{m^{d/2}}{n}\right)$$

where E is the MISE, m is the smoothing parameter, d is the dimension ($d = 1$ for the circle and $d = 2$ for the sphere), and n is the sample size. The computational effort required for this estimator can be expressed as $C = O(m^{\xi} n)$, where ξ can be determined from Table 1. The expression for C above is the same as (24) with $\gamma = 1$, and $\beta = -2\xi$, recalling that m behaves as h^{-2}. By an analysis similar to the previous case we can show that the optimal variation of error with computational complexity is given by

$$C = E^{\frac{-(d/2+\xi)}{2} - 1}.$$

As examples, for the cosine estimator on the circle ($d = 1$) with axial data ($\xi = 1$) and directional data ($\xi = 2$), the computational complexity and the error are related by $C = E^{-1.75}$ and $C = E^{-2.25}$, respectively.

The complexity of the kernel estimator is the same for axial and directional data. However, several different possibilities exist depending on how efficient the implementation of the estimator is. If we consider estimators of the form given by (3) and (4), then we have $d = 1$, $\beta = 0$, $\gamma = 2$, and therefore

$$C = E^{-2.5}. \tag{26}$$

However, if we consider a kernel with bounded support, and use an efficient implementation of the algorithm that computes the kernel only for those points that have a nonzero contribution, then the *expected* value of β is 1 and we get $C = E^{-2.25}$ for data on the circle. Note that the worst case complexity remains as in (26). For the $d = 1$ case, we can consider an efficient algorithm using polynomial kernels and updating [19], which uses a linear time after an initial $O(n \log n)$ sorting step. In this case $\beta = 0$, $\gamma = 1$, and $C = E^{-1.25}$, which means that the kernel method has a better asymptotic complexity than the cosine kernel. However there appears to be no natural generalization of this update strategy to higher dimensions [5].

Results for the different cases can be determined in the manner demonstrated above and are presented in Table 2. We wish to mention that the exact asymptotic constants in Theorem 3 are not quite that important (compared with the exponent on E), since asymptotically the slowdown incurred by the cache misses dominates the overall running time. We can expect that the simpler memory access pattern of our estimator will make it advantageous over the kernel method in the asymptotic case.

TABLE 2

*Variation of the optimal computational effort versus MISE. The numbers in the table represent η, where the relationship between the computational effort C and $E = MISE$ is given by $C = E^{-\eta}$. *Does not take into account an initial sorting step.*

Estimator	Circle ($d = 1$)	Sphere ($d = 2$)
Cosine, axial data	1.75 ($\xi = 1$)	2.5 ($\xi = 2$)
Cosine, directional data	2.25 ($\xi = 2$)	3.0 ($\xi = 3$)
Kernel, worst case	1.25 * ($\beta = 0$, $\gamma = 1$)	3.0 ($\beta = 0$, $\gamma = 2$)
Kernel, expected case	1.25 * ($\beta = 0$, $\gamma = 1$)	2.5 ($\beta = 2$, $\gamma = 2$)

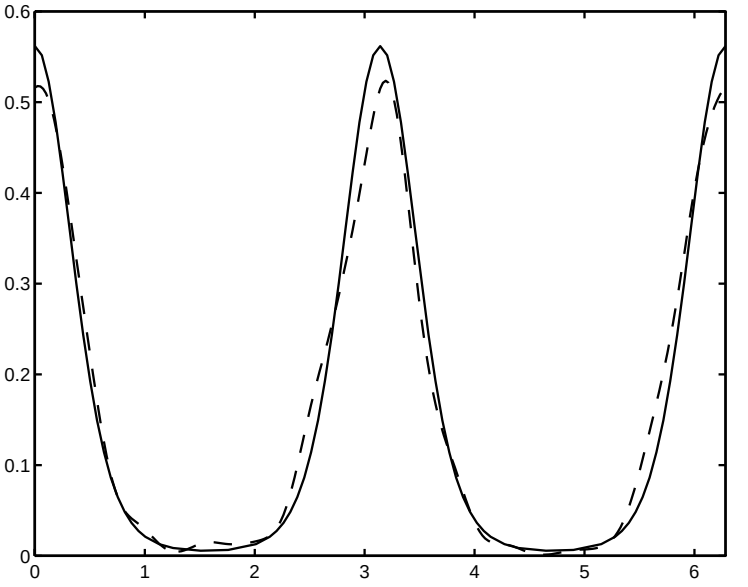
Since the worst case complexities of the kernel method and the cosine estimator for directional data on the sphere have the same order, the relative efficiencies of the methods can be tested only through experiments. Similarly, since the worst case complexity of the cosine estimator for axial data on the sphere is the same as the expected case for an efficient implementation of the kernel estimator, we need to perform experiments to test the relative merits of the two estimators.

4. Experimental results. We performed numerical experiments for axial and directional data on the circle and sphere in order to test the effectiveness of our estimator. We first plot estimates for known distributions and then demonstrate that the MISE follows expected trends for certain distributions. We finally compare the computational efficiency of our estimator with that of kernel methods. More empirical results are presented in the appendix.

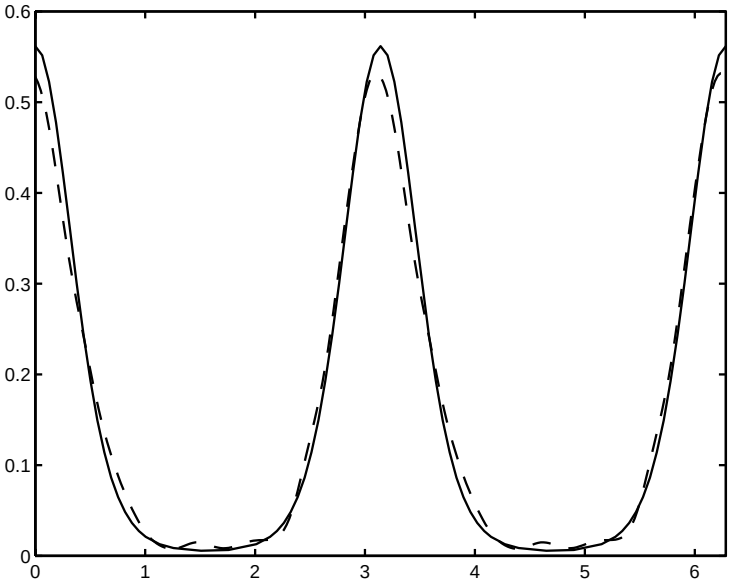
We consider the function $\psi(\phi, \theta) = \exp(US\cos^2(\theta))/A$ where A normalizes the function to be a density on the surface of a sphere and S is a known function of U. The angles ϕ and θ are the azimuth and the elevation in spherical coordinates. This is the solution to a particular problem in fluid mechanics. In Figure 2(a) we present a typical estimate for the $d = 1$ version of the above density function where ψ was taken to be $\psi(x) = \exp(US\cos^2(x))/A$. In this figure, we take the data to be directional. However, since this function is symmetric with respect to the center of the circle, we can consider the data as axial and use the axial estimator. We can see from Figure 2(b) that this requires a much smaller value of m.

In Figure 3(a) the MISE is compared versus m and n for the one-dimensional ψ distribution using the axial cosine estimator. We also compare with one case of the directional estimator in order to show the benefit of using the axial estimator. In Figure 3(b) the MISE is compared versus m and n for the two-dimensional version of the ψ distribution on the surface of a sphere using the directional estimator.

We next present results for experiments comparing the speed of the cosine and the kernel estimators. We consider the optimal variation of the computational effort with MISE. In order to get the optimal computational effort for a given MISE, we allow for the possibility that we may require different sample sizes for the kernel and the cosine estimators. This is justified because in iterative calculations one can easily change the "sample" size by changing the discretization of the system. We have performed these comparisons only for spherical data. The case of data on the circle was not considered because of the asymptotic analyses of the previous section which clearly indicate that the linear kernel algorithm in the one-dimensional case will outperform the cosine estimator. However, in a parallel implementation, the sorting step for the linear kernel algorithm may be slow, and then one may wish to consider the cosine estimator.



(a)



(b)

FIG. 2. *Cosine estimates for* $\psi(x) = \exp(US\cos^2(x))/A$*, the one-dimensional case of the* ψ *function defined above. The solid line represents the true density.* (a) *The dashed line represents the directional estimate with* $m = 100$*,* $n = 500$*.* (b) *The dashed line represent the axial estimate with* $m = 40$*,* $n = 500$*.*

The following kernel was chosen for the comparisons:

$$K(x) = \begin{cases} \frac{1}{A}(1 - 1.5x^2 + 0.75x^3), & x \in [0,1], \\ \frac{1}{A}0.25(2-x)^3, & x \in [1,2], \\ 0 & \text{otherwise}, \end{cases}$$

in fluid mechanics calculations [12]. Furthermore, we cannot expect any other kernel to give a significantly better performance, for the following reasons: (i) It is well known that most kernels are equally good [23, Table 3.1] with respect to "efficiency," as defined in [23]. (ii) Given that the efficiency is about the same, the only other consideration is the computational effort involved. Our kernel takes between 6 and 10 floating point operations for a nonzero evaluation (including the cost of computing the square of the distance). Any other reasonable kernel would require at least 6 floating point operations. Apart from this, the memory access times and zero-evaluations would add the same constant to all kernels.

Figures 4 and 5 compare the computational effort required for the cosine weight function estimator and the kernel estimator for certain densities. We obtained the data using the following procedure. We performed estimates for various values of n, m, and h and obtained the MISE and the time for the calculations. For the cosine and the kernel estimates, we separately plotted the data for the time required for the calculations versus the error. We chose the lower envelope of the data as the curve for that particular estimator since the values of m, n for the data on the lower envelope give the best obtainable speed for a given MISE.

In the implementation of the kernel estimator, we divided the sphere into cells such that the sides of the cells had length at least $2h$ (since the kernel defined above has window width $2h$, rather than h). We placed each sample in the appropriate cell. When computing the density for a point in a particular cell, we need to search over points in only a few cells. The expected complexity of this scheme is $O(n^2h^2)$.

We first consider data estimated using the axial cosine estimator and an axial variant of the kernel estimator. Figure 4 shows the results for the two-dimensional ψ distribution. This is an example of a highly nonuniform distribution. We can see that the kernel and the cosine estimators are about equally fast.

We next consider a more uniform distribution given by $f(\phi, \theta) \propto \cos(\theta) + 1/(8\pi)$, where ϕ is the azimuth and θ is the elevation. The results presented in Figure 5(a) show that the cosine estimator outperforms the kernel estimator by more than an order of magnitude when the axial forms of both the estimators are used.

After this we considered the two densities mentioned above but treated the data as directional and estimated them using the directional variants of the kernel and the cosine estimators. For the ψ distribution, the cosine estimator performed very poorly in computational efficiency, and we do not present results for this case. Figure 5(b) presents the results for the distribution given by $f(\phi, \theta) \propto \cos(\theta) + 1/(8\pi)$. We can see that the cosine estimator still outperforms the kernel estimator, though only slightly.

5. Discussion. The comparison of the estimates with the true density indicate that the cosine estimator produces accurate results for the distributions tested. Plots of MISE versus m and n follow the expected trends. As the sample size increases, the error for the optimal m decreases. Besides, the optimal value of m increases as the sample size increases. It can also be seen that as the number of points increases, the range of m over which the estimate performs well also increases. We can use this to our advantage by choosing a suboptimal value of m which decreases the computational effort significantly but increases the error only slightly.

The experiments comparing the computational efficiencies show that the cosine estimator outperforms the kernel estimator for axial data when the distribution is moderately uniform. If the distribution is highly nonuniform, then the two estimators give comparable performance for axial data. The cosine estimator outperforms the kernel estimator slightly for directional data when the distribution is moderately uniform. However, the timing results for the cosine estimator are poor for highly nonuniform directional data. In general, when the data is not very nonuniform, smoother weight functions are used. This gives a low value of m which implies a fast evaluation using the cosine estimator. However, this leads to a higher h for the kernel estimator, which implies that more samples contribute to the kernel evaluation of each sample point and, hence, this leads to more computational effort. Conversely, when the distribution is highly nonuniform, especially for directional data, the kernel method is to be preferred. The empirical test results presented in the appendix further demonstrate this point.

We also analyzed our experimental data to estimate an optimum variation of m with n. Using the results of our experiments, we can perform a least squares analysis and approximate m as $kn^{1/2.5}$ for one-dimensional density estimation which is the same as that expected based on the asymptotic expression for the MISE. Choosing $m = kn^{1/3}$ appears to give reasonable estimates for density on the surface of a sphere. This result is also consistent with the theoretical predictions. Here, the magnitude of k depends on the complexity of the density function. It varies between 1 and 10 for the distributions considered here.

We also noted the values of m, n, and h, which gave the optimal computational effort for a given MISE, and compared the results for the kernel and the cosine estimators. We observed that the values of h were close to the values which gave the minimum MISE for the given sample size. However, the values of m were significantly lower than the values which gave the minimum MISE for the given sample size, though the error involved itself was not much higher than the minimum MISE. Thus, it appears that we can choose a suboptimal smoothing parameter in order to increase the speed in the case of the cosine estimator.

6. Conclusions. In this paper, we have described a weight function estimator for nonparametric estimation of probability density functions based on cosines, and we provided conditions under which the estimate and its derivatives converge to the actual functions. We have developed a scheme for the efficient computation of the density and presented experimental results to check the performance of the estimator for practical problems. These results are particularly relevant to certain fluid mechanics calculations and, in general, to situations where the sample size can be controlled, for example, though refinement of the discretization. We have also given an empirical formula for choosing the weight function exponent parameter of the estimator. Our experimental results suggest that the cosine estimator outperforms the kernel estimator for both directional and axial data that are moderately uniform. It gives performance comparable to the kernel estimator for highly nonuniform axial data, while the kernel method is preferable for highly nonuniform directional data. There is potential for further theoretical study of our estimator.

Appendix. Further test results. We present more test results in this section in order to study the relative efficiencies of the cosine and the kernel techniques, as the density function is varied systematically from being relatively uniform to being sharply peaked on the unit sphere.

For these tests, we chose density functions $g(\phi; s) = k \cosh(s \sin\phi)$, where s is a constant that governs the sharpness of the density function, ϕ is the elevation, and $k = s/(4\pi \sinh s)$ normalizes this to a probability density function. Figure 6 shows the density as a function of the elevation alone for different values of the parameter s. This function is symmetric about the center of the sphere, and thus we can use the axial estimators, as in section 4. We can also ignore our knowledge of this symmetry and use the general directional estimators.

We present the results of the experiments as plots of time versus MISE for the kernel estimator versus the cosine estimator, for both axial and directional data. The kernel estimator is the one used in the empirical tests in section 4. The tests were performed on an Intel Celeron 300MHz processor with 64 MB memory. The C code was compiled with the gcc compiler at optimization level $-O3$.

We can see from Figures 7, 8, 9, 10, and 11 that when the density function is not very sharp, the cosine estimator outperforms the kernel estimator for both axial and directional data. As the density becomes sharper, the kernel method starts outperforming the cosine estimator for directional data, though the latter is still better for axial data. When the density becomes extremely sharp, the kernel method becomes better for both types of data, though for axial data the two methods are still comparable to a certain extent in terms of speed. These results follow the theoretically predicted trends and demonstrate that these two methods complement each other for different types of data.

Appendix. We thank the referees for their detailed comments and advice, especially for directing our attention to the current literature.

A DATA-BOUNDED QUADRATIC INTERPOLANT ON TRIANGLES AND TETRAHEDRA*

MARTIN BERZINS†

Abstract. Many real-world problems are successfully modeled by partial differential equations. Many numerical solvers for these problems use triangular and tetrahedral meshes to accurately model complex geometries. Such problems often involve shocks and discontinuities, and it is important to devise interpolation methods that can accurately approximate solutions containing such features. These interpolants are required for the postprocessing of the solution, e.g., for visualization and to recover solution values at arbitrary points over the numerical domain. This paper describes a triangle-based quadratic interpolant that is "data-bounded" and so will not create any values outside of the range of the existing data points. The method is compared with the standard quadratic interpolant and extended to the case of quadratic tetrahedral elements.

1. Introduction.

In scientific computing, the visualization of the solution to real-world problems is an essential aid to the understanding of the physical problem being modeled. Interpolation schemes that will respect the physical properties of the underlying data are thus needed, one example being to preserve positivity. Many data sets that require such interpolants result from the numerical solution of partial differential equations (PDEs). Many of the methods used to solve such PDE problems compute solutions on rectangular or hexahedral meshes. A good survey of a number of interpolants for such meshes which are appropriate for scientific visualization in that they provide values that are bounded by the data values (data bounded) and possibly preserve the shape of data values is given by Brodlie and Mashwama [6]. These interpolants are piecewise linear bilinear and trilinear and are piecewise cubic and bicubic. One such interpolant is a bounded bicubic interpolant on a rectangular mesh [6].

In two and three spatial dimensions a number of general purpose PDE solvers employ triangular and tetrahedral elements in conjunction with triangular and tetrahedral mesh generators to solve problems defined on complex domains. The best example of this being the finite element method [12]. Alternatively, a number of authors use a cell-centered or cell-vertex finite volume spatial discretization schemes to solve convection-dominated PDEs; see [5], [7], [11] for details. An important feature of these problems is that initial smooth conditions may develop into steep gradients or even shocks and discontinuities.

Standard quadratic interpolation techniques [8], [12] can be used to fit six shape functions over each triangle to give an approximation to the surface. Section 2 below and [10] both show that this method can easily produce interpolated values outside the physical range of the data values. Similar problems arise with the standard quadratic interpolant for tetrahedra [12].

†School of Computer Studies, The University of Leeds, Leeds LS2 9JT, U.K. (martin@csc.leeds.ac.uk).

There have been many methods which have attempted to overcome some of the problems associated with such interpolants. Some of the earliest work is that of Barnhill and co-authors [2], [3]. This work will be described in outline form and used as a starting point for the new triangular interpolant developed here. Two other important interpolation methods in this area are those of Abgrall [1] and Barth [4]. Both these schemes have the common approach of using adaptive multitriangle stencils to achieve high-order accuracy for problems which may have shocks and discontinuities. The problem is that the number of possible combinations grows rapidly, the stencil used is potentially large, and the points considered may be some distance from the original node. Abgrall's good results provide a more than adequate justification of the scheme however.

A recent paper by Pratt and Berzins [10] showed that by adopting a relatively simple approach which involved sacrificing accuracy at the midpoints of edges it was possible to achieve positivity for problems with steep gradients. The aim here is to overcome this deficiency and to consider a simpler alternative to Abgrall's scheme. This will be done by decomposing a standard quadratic interpolant into a combination of four one-dimensional quadratics. Replacing each of these one-dimensional interpolants by ones which preserve data-boundedness, possibly by replacing one quadratic by two piecewise quadratics, enables a new data-bounded interpolant to be devised. This interpolant is bounded by the minimum and maximum data values defining it and may therefore be utilized to preserve positivity. It can also be used for the visualization of the solution and by the numerical solver to recover values over the numerical domain. A novel feature of the new scheme is that the method is local to each triangle or tetrahedral element. The price that is paid for this is that when the interpolant is modified to preserve data-boundedness the resulting piecewise polynomial is only C^0 continuous rather than C^1 continuous.

The extension of the approach to tetrahedra proves to be straightforward by using a combination of positivity preserving one-dimensional and triangular interpolants.

2. The standard quadratic triangular interpolation scheme. A two-dimensional quadratic triangular interpolant of an unknown function $u(x, y)$ needs six data points: these points are usually at the vertices of the triangle and the midpoints of the sides [12]. These can be mapped to area coordinates (L_1, L_2, L_3). Six shape functions can be fitted to these points such that each is unified at one point and zero at the others. These shape functions are shown in (1):

$$\begin{aligned} \phi_1 &= (2L_1 - 1)L_1, & \phi_2 &= (2L_2 - 1)L_2, \\ \phi_3 &= (2L_3 - 1)L_3, & \phi_4 &= 4L_2L_1, \\ \phi_5 &= 4L_3L_2, & \phi_6 &= 4L_1L_3. \end{aligned} \tag{1}$$

The area coordinates of points, (L_1, L_2, L_3), 1 to 6 being $(1, 0, 0)$, $(0, 1, 0)$, $(0, 0, 1)$, $(\frac{1}{2}, \frac{1}{2}, 0)$, $(0, \frac{1}{2}, \frac{1}{2})$, and $(\frac{1}{2}, 0, \frac{1}{2})$, respectively. The interpolated value U_I is then defined by

$$U_I(L_1, L_2, L_3) = \sum_{i=1}^{6} \phi_i(L_1, L_2, L_3)U_i. \tag{2}$$

The position of the points U_i is shown in Figure 1. $U_i, i = 1, 2, 3$ being the points at which the corresponding $L_i = 1$.

The problem with the standard interpolation formula is that the shape functions associated with the three vertex values are negative over large parts of the triangle.

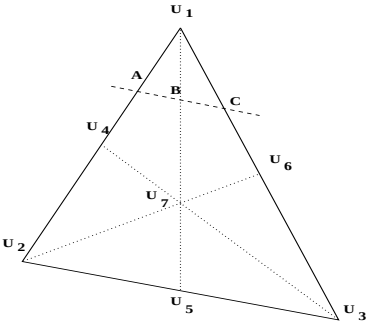

FIG. 1. *Example triangle.*

Thus it is possible that new and unphysical extrema may be introduced [10]. Consider, e.g., the centroid of the triangle marked as U_7 in Figure 1. In the case when standard quadratic interpolation based on the values $U_i, i = 1, 6$ is used, then

$$U_7 = U\left(\frac{1}{3}, \frac{1}{3}, \frac{1}{3}\right) = \frac{4}{9}(U_4 + U_5 + U_6) - \frac{1}{9}(U_1 + U_2 + U_3). \tag{3}$$

Hence if all the values $U_i, i = 1, 6$ are positive but the values U_1, U_2, and U_3 are in some sense large compared to U_4, U_5, and U_6, then U_7 may be negative. More generally, possible extrema of the standard quadratic interpolant polynomial U_I defined by (2) lie at the points at which (after replacing L_3 with $1 - L_1 - L_2$) $\frac{\partial U}{\partial L_1} = 0$ and $\frac{\partial U}{\partial L_2} = 0$. Differentiating U_I and collecting terms together gives a pair of equations for L_1, L_2, the critical points:

$$4L_1(U_1 + U_3 - 2U_6) + 4L_2(U_3 + U_4 - U_5 - U_6) = (U_1 + 3U_3 - 4U_6),$$
$$4L_1(U_3 + U_4 - U_5 - U_6) + 4L_2(U_3 + U_2 - 2U_5) = (U_2 + 3U_3 - 4U_5).$$

The standard multivariable calculus test for determining extrema is that $D < 0$, where $D = (\frac{\partial^2 U_I}{\partial x \partial y} - \frac{\partial^2 U_I}{\partial x^2}\frac{\partial^2 U_I}{\partial y^2})$. The case when $D > 0$ defines saddle points, or if $D = 0$ the test fails, and there may be no maximum or minimum or a line of critical points. A lengthy but straightforward derivation shows that D has the same sign as $-Det$, where Det is the determinant of the preceding pair of equations.

Although this test provides useful help in understanding why the standard interpolant may not be data-bounded, it does not directly help to construct a data-bounded interpolant. It is this problem, that of constructing a data-bounded quadratic interpolant, that will be addressed in sections 4 and 5 below. This will be achieved by showing that the original polynomial may be interpreted as a combination of one-dimensional quadratics. A geometrical outline of the approach is indicated by Figure 1 which indicates how a point on the line ABC is defined in terms of quadratics using U_2, U_4, and U_1 to define a value at A, U_5, U_7, and U_1 to define a value at B, and using U_3, U_6, and U_1 to define a value at C. A further quadratic interpolation using ABC then defines points on that line. The problems are thus reduced to that of finding data-bounded quadratic polynomials in one space dimension and of finding a suitable centroid value.

3. Two data-bounded piecewise quadratic polynomials. In this section two data-bounded one-dimensional piecewise quadratic polynomials are devised. These polynomials will play an important role in the triangular interpolant in section 4 and

in the tetrahedral interpolant in section 8. The approach taken to ensure data boundedness will be, when necessary, to decompose the original quadratic polynomial into two piecewise polynomial quadratics.

3.1. Polynomial P_1. Consider the case of the standard one-dimensional quadratic interpolant for the function $u(x)$ defined on the interval $[0,h]$ mapped onto $[0,1]$ with data points at $0, \frac{1}{2}$, and 1 given by $U_0, U_{\frac{1}{2}}$, and U_1. Let this polynomial be defined by

$$q_1(U_0, U_{\frac{1}{2}}, U_1, L_1) = U_0\hat{\phi}_1 + U_{\frac{1}{2}}\hat{\phi}_2 + U_1\hat{\phi}_3, \tag{4}$$

where

$$\hat{\phi}_1 = (1-L_1)(1-2L_1), \quad \hat{\phi}_2 = 4L_1(1-L_1), \quad \hat{\phi}_3 = L_1(2L_1-1),$$

and $L_1 + L_2 = 1$. Differentiating with respect to L_1 gives

$$\frac{dq_1}{dL_1} = 0 \text{ at } L_1 = \frac{1}{2} + r, \quad \text{where } \; r \; = \frac{U_1 - U_0}{4(2U_{\frac{1}{2}} - U_1 - U_0)} \tag{5}$$

and differentiating again with respect to L_1 gives

$$\frac{d^2q_1}{dL_1^2} = 4(-2U_{\frac{1}{2}} + U_1 + U_0), \tag{6}$$

which is also a second-order difference approximation to $h^2\frac{d^2u}{dx^2}(\frac{1}{2})$. This result shows that the polynomial may have extrema at nonnodal points. If the second derivative is zero then as q is linear and hence takes its extrema at the ends of the interval.

In order to get a data-bounded interpolant for which any extrema lie at data points, the key observation in modifying the polynomial is that on the interval $[0, \frac{1}{2}]$ a completely different value of U_1 may be used from the original. Similarly, on the interval $[\frac{1}{2}, 1]$ a completely different value of U_0 from the original may be used without destroying C^0 but not C^1 continuity of the solution. Thus the original polynomial is replaced by two piecewise quadratic polynomials.

Let these new values of U_0 and U_1 be denoted by U_0^* and U_1^*, respectively. The new piecewise polynomial is then defined by

$$p_1(U_0, U_{\frac{1}{2}}, U_1, L_1) = U_0\hat{\phi}_1 + U_{\frac{1}{2}}\hat{\phi}_2 + U_1^*\hat{\phi}_3, \quad 0 \le L_1 \le \frac{1}{2}, \tag{7}$$

$$= U_0^*\hat{\phi}_1 + U_{\frac{1}{2}}\hat{\phi}_2 + U_1\hat{\phi}_3, \quad \frac{1}{2} < L_1 \le 1. \tag{8}$$

These new values of U_0^* and U_1^* will be defined by moving extrema to the closest nodal point, denoted by L_{ext}^{new}, by using (5). In the case when $r \le -\frac{1}{2}$ or $r \ge \frac{1}{2}$, then $U_0^* = U_0$ and $U_1^* = U_1$ and the original polynomial is unchanged

$$L_{ext}^{new} = 0, -\frac{1}{2} < r \le -\frac{1}{4}, U_1^* = 4U_{\frac{1}{2}} - 3U_0, \tag{9}$$

$$L_{ext}^{new} = \frac{1}{2}, \quad -\frac{1}{4} < r \le 0, \;\; U_1^* = U_0, \tag{10}$$

$$L_{ext}^{new} = \frac{1}{2}, \quad 0 < r \le \frac{1}{4}, \quad U_0^* = U_1, \tag{11}$$

$$L_{ext}^{new} = 1, \quad \frac{1}{4} < r \le \frac{1}{2}, \quad U_0^* = 4U_{\frac{1}{2}} - 3U_1. \tag{12}$$

In all the above four cases $U_1 - U_1^*$ and $U_0 - U_0^*$ may be rewritten in a more convenient form as

$$L_{ext}^{new} = 0, \quad U_1^* - U_1 = 4U_{\frac{1}{2}} - 3U_0 - U_1 = \frac{(1+2r)}{2} 4\ (2U_{\frac{1}{2}} - U_0 - U_1), \tag{13}$$

$$L_{ext}^{new} = \frac{1}{2}, \quad U_1^* - U_1 = \quad U_0 - U_1 \quad = \ - \ r \quad 4\ (2U_{\frac{1}{2}} - U_0 - U_1), \tag{14}$$

$$L_{ext}^{half} = \frac{1}{2}, \quad U_0^* - U_0 = \quad U_1 - U_0 \quad = \quad r \quad 4\ (2U_{\frac{1}{2}} - U_0 - U_1), \tag{15}$$

$$L_{ext}^{new} = 1, \quad U_0^* - U_0 = 4U_{\frac{1}{2}} - 3U_1 - U_0 = \frac{(1-2r)}{2}\ 4\ (2U_{\frac{1}{2}} - U_0 - U_1). \tag{16}$$

From the last four equations and (6)

$$U_1 - U_1^* = \alpha(r)\ \frac{d^2 q_1}{dL_1^2}, \quad \text{where} \quad -1/2 \le r \le 0, \tag{17}$$

$$U_0 - U_0^* = \alpha(r)\ \frac{d^2 q_1}{dL_1^2}, \quad \text{where} \quad 0 \le r \le 1/2, \tag{18}$$

and where $0 \le \alpha(r) \le 1/4$ is the piecewise linear function defined as in (13)–(16). Thus the algorithm adds a nonlinear multiple of the second derivative in order to get a data-bounded interpolant. The extra term introduced by this approach is given by

$$q_1(\ldots, L_1) - p_1(\ldots, L_1) = (U_1^* - U_1)\hat{\phi}_3, \quad 0 \le L_1 \le \frac{1}{2}, \tag{19}$$

$$= (U_0^* - U_0)\hat{\phi}_1, \quad \frac{1}{2} < L_1 \le 1. \tag{20}$$

As a consequence of this, the error as defined on $[\frac{1}{2}, 1]$ is no longer defined by the standard form on $[h/2, h]$ given by

$$u(x) - q_1(U_0, U_{\frac{1}{2}}, U_1, L_1) = x(x - h/2)(x - h)\ \frac{1}{6}\frac{d^3 u}{dx^3}(\xi_1), \quad \xi_1 \epsilon [0, h], \tag{21}$$

where $u(x)$ is defined at the start of this section, but by

$$u(x) - p_1(U_0, U_{\frac{1}{2}}, U_1, L_1) = x(x - h/2)(x - h)\ \frac{1}{6}\frac{d^3 u}{dx^3}(\xi_1)$$

$$- \frac{2}{h^2}(U_0^* - U_0)(x - h/2)(x - h). \tag{22}$$

Substituting from (15) and (16) for $U_0^* - U_0$ gives

$$u(x) - p_1(U_0, U_{\frac{1}{2}}, U_1, L_1) =$$

$$(x - h/2)(x - h)\ \left[4\ \alpha(r)\ \frac{4(-2U_{\frac{1}{2}} + U_0 + U_1)}{2\ h^2}\ +\ \frac{x}{6}\frac{d^3 u}{dx^3}(\xi_1)\right]. \tag{23}$$

Thus in the same way as limiter schemes in the solution of hyperbolic PDEs vary the order of the method to preserve positivity (see [5]) the function $\alpha(r)$ varies the order between second order $|\alpha(r)| = 1/4$ and third order $\alpha = 0$ to preserve data-boundedness. The case $\alpha(r) = 1/4$ occurs only if $U_0 = U_{\frac{1}{2}}$ or $U_1 = U_{\frac{1}{2}}$ and then the use of a linear polynomial is unavoidable.

In contrast, when linear interpolation is used, e.g., on the subinterval $[h/2, h]$, to substitute for the polynomial q_1 the approximation polynomial is

$$l_1(U_{\frac{1}{2}}, U_1, L_1) = U_{\frac{1}{2}} 2(1 - L_1) + U_1(2L_1 - 1) \tag{24}$$

and the modified form of the error may, for comparison purposes, be written as $u(x) - l_1(.) = u(x) - q_1(.) - (l_1(.) - q_1(.))$. After some manipulation this may be written as

$$u(x) - l_1(U_{\frac{1}{2}}, U_1, L_1) = \\ (x - h/2)(x - h) \left[\frac{4(-2U_{\frac{1}{2}} + U_0 + U_1)}{2\ h^2} + \frac{x}{6} \frac{d^3u}{dx^3}(\xi_1) \right]. \tag{25}$$

A comparison between (23) and (25) shows that when the term $\frac{d^3u}{dx^3}(\xi_1)$ vanishes then the ratio of the two errors is $4\alpha(r) : 1$. This is not generally the case. In the examples below, for example, the ratios of the errors in the two cases are obtained by comparing the bracketed terms ([ ]) in (23) and (25). Furthermore, if the original polynomial $q_1(.)$ violates the positivity of the data values, then in order for the modified polynomial to be data bounded there must be a significant cancellation in the two terms in [ ] in (23) and (25). This is also shown in the examples below.

3.1.1. Numerical examples. In this section the cases $U_0 = 100, U_{\frac{1}{2}} = 0.3$, and $U_1 = 0.1$, and $U_0 = 1.0, U_{\frac{1}{2}} = 0.3$, and $U_1 = 0.1$ are considered as data points for the function $u(x)$ defined by

$$u(x) = U_1\ e^{a(1-x)^b}, \tag{26}$$

where

$$a = \log(U_0/U_1), \quad c = \log(U_{\frac{1}{2}}/U_1), \quad \text{and} \quad b = (\log(a) - \log(c))/\log(2).$$

In the first case $U_0 = 100$ and the new and original polynomials are identical in $[0, 0.5]$. Table 1 shows the values of the interpolants at points in $(0.5, 1.0)$ and Table 2 shows the errors in the interpolants. In particular, the original quadratic polynomial has a minimum of about -12, whereas the new polynomial remains positive. In this case the new value of U_0^* is 0.9, $U_0^* - U_0 = -99.1$ $\alpha(r) = 0.246$, and the change to the original polynomial has to be substantial to achieve data-boundedness. Also shown are the results from the linear polynomial l_1 defined by (24).

Now consider the case when the value of U_0 is changed to $U_0 = 1, U_{\frac{1}{2}} = 0.3$, and $U_1 = 0.1$. The new and original polynomials are identical in $[0, 0.5]$. Table 1 shows the differences at points in $(0.5, 1.0)$. In particular, the original quadratic polynomial q_1 has a minimum of about 0.0975, whereas the new polynomial p_1 remains within the range of the data. In this case the new value of U_0^* is 0.9, $U_0^* - U_0 = -0.1$, and $\alpha(r) = 0.05$. Thus the change to the original polynomial is quite small to ensure that the data values stay within the range of the data. It should be noted that the new polynomial is the same for both values of U_0 as the value of r in both cases defines the same value of U_0^*. Also shown are the results from the linear polynomial l_1 defined by (24).

3.2. Polynomial P_2. Consider now the case of the one-dimensional quadratic interpolant to the function $u(x)$ on $[0,1]$ with data points at $0, \frac{1}{3}$, and 1 given by $U_0, U_{\frac{1}{3}}$, and U_1 defined by

$$q_2(U_0, U_{\frac{1}{3}}, U_1, L_1) = U_0\bar{\phi}_1 + U_{\frac{1}{3}}\bar{\phi}_2 + U_1\bar{\phi}_3, \tag{27}$$

where

$$\bar{\phi}_1 = (1-L_1)(1-3L_1), \quad \bar{\phi}_2 = 4.5L_1(1-L_1), \quad \bar{\phi}_3 = \frac{1}{2}L_1(3L_1-1),$$

and $L_1 + L_2 = 1$. Differentiating with respect to L_1 gives

$$\frac{dq_2}{dL_1} = 0 \text{ at } L_1 = \frac{1}{2} + s, \quad \text{where } s = \frac{U_1 - U_0}{3(3U_{\frac{1}{3}} - U_1 - 2U_0)}. \tag{28}$$

Differentiating again with respect to L_1 gives

$$\frac{d^2q_2}{dL_1^2} = 3(-3U_{\frac{1}{3}} + U_1 + 2U_0). \tag{29}$$

As above, this polynomial may have extrema at nonnodal points which may be removed by modifying the polynomial on the interval $[0, \frac{1}{3}]$ by using a completely different value of U_1 from the original or on the interval $[\frac{1}{3}, 1]$ by using a completely different value of U_0 from the original. This approach preserves C^0 but not C^1 continuity of the solution. The new polynomial is defined by

$$p_2(U_0, U_{\frac{1}{3}}, U_1, L_1) = U_0\bar{\phi}_1 + U_{\frac{1}{3}}\bar{\phi}_2 + U_1^*\bar{\phi}_3, \quad 0 \le L_1 \le \frac{1}{3} \tag{30}$$

$$= U_0^*\bar{\phi}_1 + U_{\frac{1}{3}}\bar{\phi}_2 + U_1\bar{\phi}_3, \quad \frac{1}{3} < L_1 \le 1. \tag{31}$$

Define the values of U_0^* and U_1^* by moving extrema to the closest nodal point, denoted by L_{ext}^{new}. In the case when $s \leq -\frac{1}{2}$ or $s \geq \frac{1}{2}$, then $U_0^* = U_0$ and $U_1^* = U_1$ and the original polynomial is unchanged. Define the values of U_0^* and U_1^1 by again moving extrema to the closest nodal point:

$$L_{ext}^{new} = 0, -\frac{1}{2} < s \leq -\frac{1}{3},\ U_1^* = 9U_{\frac{1}{3}} - 8U_0, \tag{32}$$

$$L_{ext}^{new} = \frac{1}{3}, -\frac{1}{3} < s \leq -\frac{1}{6},\ U_1^* = 4U_0 - 3U_{\frac{1}{3}}, \tag{33}$$

$$L_{ext}^{new} = \frac{1}{3},\ -\frac{1}{6} < s \leq \frac{1}{6},\ \ U_0^* = (U_1 + 3U_{\frac{1}{3}})/4, \tag{34}$$

$$L_{ext}^{new} = 1,\ \ \frac{1}{6} < s \leq \frac{1}{2},\quad U_0^* = (9U_{\frac{1}{3}} - 5U_1)/4. \tag{35}$$

The extra error introduced by this approach is given by

$$q_2(\ldots, L_1) - p_2(\ldots, L_1) = (U_1 - U_1^*)\hat{\phi}_3,\ \ 0 \leq L_1 \leq \frac{1}{3}, \tag{36}$$

$$= (U_0 - U_0^*)\hat{\phi}_1,\ \ \frac{1}{3} < L_1 \leq 1, \tag{37}$$

where

$$\begin{aligned}
L_{ext}^{new} = 0,\ U_1^* - U_1 &= \ \ 9U_{\frac{1}{3}} - 8U_0 - U_1 \ \ = (1+2s) \quad 3(3U_{\frac{1}{3}} - U_1 - 2U_0),\\
L_{ext}^{new} = \frac{1}{3},\ U_1^* - U_1 &= \ \ 4U_0 - 3U_{\frac{1}{3}} - U_1 \ \ = -\left(\frac{1}{3} + 2s\right)\ 3(3U_{\frac{1}{3}} - U_1 - 2U_0),\\
L_{ext}^{new} = \frac{1}{3},\ U_0^* - U_0 &= (U_1 + 3U_{\frac{1}{3}})/4 - U_0 = \left(\frac{1}{12} + \frac{s}{2}\right)\ \ 3(3U_{\frac{1}{3}} - U_1 - 2U_0),\\
L_{ext}^{new} = 1,\ U_0^* - U_0 &= (9U_{\frac{1}{3}} - 5U_1)/4 - U_0 = \left(\frac{1}{4} - \frac{s}{2}\right) \quad 3(3U_{\frac{1}{3}} - U_1 - 2U_0).
\end{aligned}$$

From the last four equations and (5) $U_1 - U_1^* = \beta(s)\ \frac{d^2 q_2}{dL_1^2}$, where $0 \leq \beta(s) \leq 1/3$ and similarly for $U_0 - U_0^*$. Hence similar arguments as put forward by (21)–(25) in section 3.1 apply.

4. A data-bounded two-dimensional quadratic interpolant. In extending the ideas behind the one-dimensional schemes above to two dimensions there are a number of possible ways to proceed. A direct two-dimensional analogy for the previous section would be to notice that the value of U_1 could be changed to U_1^* for values of $L_1 < \frac{1}{2}$ and similarly for U_2 and U_3. Although this approach can be made to work for a single triangle, there is a problem in enforcing continuity of the solution along exterior edges in a mesh of triangles. For a positive interpolant in a mesh of triangles it is thus important for the scheme to treat edges independently.

The starting point for the two-dimensional quadratic scheme is the observation that the ordinary quadratic interpolant may be written as a combination of four one-dimensional quadratic interpolants; two along exterior edges, one through the centroid, and the final one across the other three. There are three such interpolants which will be denoted by $U_{I,j}, j = 1, 2, 3$; the subscript I being used to avoid confusion

with data points. For example, referring to Figure 1, let

$$\begin{aligned} U_A &= q_1(U_2, U_4, U_1, L_1), \\ U_B &= q_2(U_5, U_7, U_1, L_1), \\ U_C &= q_1(U_3, U_6, U_1, L_1), \\ U_{I,1} &= q_1\left(U_A, U_B, U_C, \frac{L_3}{L_2 + L_3}\right), \end{aligned} \tag{38}$$

where $L_3/(L_2+L_3)$ represents the position along the line ABC in that $L_3 = 0$ at A and $L_2 = 0$ at C. As each polynomial is exact for a quadratic this interpolant will reproduce a quadratic function. This approach has some similarities with that of Barnhill and co-authors [2], [3] except that they use three combinations of two quadratics along edges only with linear interpolation between them and subtracted a multiple of linear interpolation using the values U_1, U_2, and U_3. The main differences here are the use of the centroid value U_7 and the use throughout of quadratic polynomials. The two other ways of writing the interpolant are

$$\begin{aligned} U_D &= q_1(U_2, U_5, U_3, L_3), \\ U_E &= q_2(U_4, U_7, U_3, L_3), \\ U_F &= q_1(U_1, U_6, U_3, L_3), \\ U_{I,2} &= q_1\left(U_D, U_E, U_F, \frac{L_1}{L_2 + L_1}\right); \end{aligned} \tag{39}$$

$$\begin{aligned} U_G &= q_1(U_1, U_4, U_2, L_2), \\ U_H &= q_2(U_6, U_7, U_2, L_2), \\ U_K &= q_1(U_3, U_5, U_2, L_2), \\ U_{I,3} &= q_1\left(U_G, U_H, U_K, \frac{L_3}{L_1 + L_3}\right). \end{aligned} \tag{40}$$

In the case of the standard quadratic interpolant the centroid value, U_7 is computed using (3). This value, as has already been shown in section 2, will not preserve data-boundedness.

Using the notation of section 2 it is now straightforward to describe the bounded positive quadratic interpolant. Let $\hat{U}_A$ be the value corresponding to U_A above but replacing the polynomial q_1 with p_1 and letting the values $\hat{U}_B, \hat{U}_C, \hat{U}_D, \hat{U}_E, \hat{U}_F, \hat{U}_G, \hat{U}_H$, $\hat{U}_K$ be similarly defined using the data-bounded polynomials p_1 and p_2, and using a centroid value U_7 that is itself bounded by the data values $U_j, j = 1, \ldots, 6$. The method used to compute this centroid value will be given in the next section.

Define the polynomials $\hat{U}_{I,j}, j = 1, 3$ by

$$\hat{U}_{I,1} = p_1\left(\hat{U}_A, \hat{U}_B, \hat{U}_C, \frac{L_3}{L_2 + L_3}\right), \tag{41}$$

$$\hat{U}_{I,2} = p_1\left(\hat{U}_D, \hat{U}_E, \hat{U}_F, \frac{L_1}{L_2 + L_1}\right), \tag{42}$$

$$\hat{U}_{I,3} = p_1\left(\hat{U}_G, \hat{U}_H, \hat{U}_K, \frac{L_3}{L_1 + L_3}\right), \tag{43}$$

each of these polynomials being data-bounded and piecewise quadratic. The effect of using the different combinations of bounded quadratics means that the polynomials

are no longer identical and may be directionally biased. For these reasons the bounded positive interpolant used is $\hat{U}_I$, where

$$\hat{U}_I(L_1, L_2, L_3) = \frac{1}{3}(\hat{U}_{I,1} + \hat{U}_{I,2} + \hat{U}_{I,3}). \tag{44}$$

5. Choosing the centroid value, U_7. In the case of the cell-centered finite volume schemes [5], [7] values at the centroids of triangles are the primary ones generated by the method. In this case interpolation techniques are used to compute the values at the midpoints of edges [5] and at the nodes [10]. In the case of triangular quadratic finite element based schemes [12], however, the centroid values are not available and must be computed.

The primary requirement is that the centroid value is itself data-bounded and that any error introduced is comparable to other errors already present. In the case when the standard quadratic value U_7, defined by (3), is data-bounded, then this value is used unchanged.

Let $U_{\max}$ and $U_{\min}$ be the maximum and minimum of the values $U_1, \ldots, U_6$. In the case when U_7 lies outside of the range of these values, then U_7 is set to either $U_{\max}$ or $U_{\min}$ using the following procedure. For convenience, consider the case when $U_7 > U_{\max}$, the other case follows without difficulty. Let the (data-bounded) linear interpolant value at the centroid be denoted by U_7^L and defined by

$$U_7^L = \frac{1}{3}(U_1 + U_2 + U_3); \tag{45}$$

then from (3)

$$U_7 = U_7^L - \frac{2}{9}\left[(U_1 - 2U_4 + U_2) + (U_2 - 2U_5 + U_3) + (U_3 - 2U_6 + U_1)\right]. \tag{46}$$

Let h_1, h_2, and h_3 be the lengths of the three edges connecting U_1 and U_2, U_2, and U_2, and U_3 and U_1, respectively; then

$$U_1 - 2U_4 + U_2 \quad = \quad h_1^2 \frac{\partial^2 U_I}{\partial z_1^2}, \tag{47}$$

where z_i is the local coordinate along the ith edge with length h_i. A similar interpretation of the other terms in (46) gives

$$U_7 - U_7^L = \frac{2}{9}\left[h_1^2 \frac{\partial^2 U_I}{\partial z_1^2} + h_2^2 \frac{\partial^2 U_I}{\partial z_2^2} + h_3^2 \frac{\partial^2 U_I}{\partial z_3^2}\right]. \tag{48}$$

As the linear value U_7^L is data-bounded and the quadratic one is not, it follows that we can find a constant $0 \leq \gamma \leq 1$ such that

$$\gamma = \frac{U_{\max} - U_7^L}{U_7 - U_7^L} \tag{49}$$

and hence in replacing U_7 by $U_{\max}$ an extra source of error is introduced, which will be denoted by e_7, where $e_7 = U_7 - U_{\max}$, and note that

$$e_7 = (1 - \gamma)\ \frac{2}{9}\ \left[h_1^2 \frac{\partial^2 U_I}{\partial z_1^2} + h_2^2 \frac{\partial^2 U_I}{\partial z_2^2} + h_3^2 \frac{\partial^2 U_I}{\partial z_3^2}\right]. \tag{50}$$

6. Error and continuity analysis. The interpolation error of the standard quadratic triangular interpolant is given by Johnson [9], for example. In order to estimate the value of the extra error incurred by using the one-dimensional data-bounded polynomials consider the case of the interpolant defined by (38). The values $\hat{U}_A, \hat{U}_B, \hat{U}_C$ each have an error of the type considered in sections 3.1 and 3.2. Let these errors be denoted by $e\hat{U}_A, e\hat{U}_B$, and $e\hat{U}_C$, respectively. In addition there is a possible extra error due to the use of the approximate centroid value. From (27) this can be written as $e_7\bar{\phi}_2(L_1)$. Hence the additional error due to preserving data-boundedness in $\hat{U}_{I,1}$, which is denoted by $e\hat{U}_{I,1}$, is given by

$$\begin{aligned} e\hat{U}_{I,1} &= q_1\left(U_A, U_B, U_C, \frac{L_3}{L_2+L_3}\right) \\ &\quad - p_1\left(U_A + e\hat{U}_A, U_B + e\hat{U}_B + e_7\bar{\phi}_2(L_1), U_C + e\hat{U}_C, \frac{L_3}{L_2+L_3}\right). \end{aligned} \tag{51}$$

Adding and subtracting the term $q_1(U_A+e\hat{U}_A, U_B+e\hat{U}_B+e_7\bar{\phi}_2(L_1), U_C+e\hat{U}_C, \frac{L_3}{L_2+L_3})$ and simplifying using the results in section 3.1 gives

$$\begin{aligned} e\hat{U}_{I,1} &= -q_1\left(e\hat{U}_A, e\hat{U}_B + e_7\bar{\phi}_2(L_1), e\hat{U}_C, \frac{L_3}{L_2+L_3}\right) + \\ &\bar{\phi}_1\left(\frac{L_3}{L_2+L_3}\right)\alpha(\hat{r})\left[(U_A - 2U_B + U_C) + (e\hat{U}_A - 2(e\hat{U}_B + e_7\bar{\phi}_2(L_1)) + e\hat{U}_C)\right], \end{aligned} \tag{52}$$

where $\alpha(\hat{r})$ is calculated by using the modified solution values, i.e., $\hat{U}_A$ instead of U_A, etc. The errors $e\hat{U}_{I,2}$ and $e\hat{U}_{I,3}$ may be similarly estimated. This expression shows how the additional errors introduced by the one-dimensional interpolations, $e\hat{U}_A, e\hat{U}_B$, and $e\hat{U}_C$ combine with the centroid error to introduce an additional error, of the same order as the one-dimensional errors, into the interpolant. The first term in (52) is the quadratic interpolant of the errors at points A, B, and C while the second term consists of a term similar to that arising from ensuring that the polynomial q_1 is data-bounded, e.g., see (23), but with errors in the data values.

Regarding the continuity of the interpolant defined in this way, the polynomials defined along the edges of each triangle and through its centroid are clearly continuous. The question remains as to whether or not the dependency of the modified polynomials on r and s might cause discontinuities. Both r and s depend in a fixed well-defined way on the nodal data values and so the new interpolant is a composition of continuous functions of (x, y) and so is continuous.

7. Numerical examples. In order to illustrate the properties of the interpolant three simple examples defined on a triangle with vertices at $(0,0), (0,1)$, and $(1,0)$ are used. The first problem has a maximum at (x_0, y_0) the second problem has a minimum at (x_0, y_0) while the third problem has a ridge of maximum values across the triangle.

Problem 1.

$$u(x,y) = \frac{1}{0.1 + (x-x_0)^2 + (y-y_0)^2}, \quad x_0 = 0.25, \quad y_0 = 0.1. \tag{53}$$

Problem 2.

$$u(x,y) = 10[(x-x_0)^2 + (y-y_0)^2], \quad x_0 = \frac{1}{3}, \quad y_0 = \frac{1}{3}. \tag{54}$$

Problem 3.

$$u(x,y) = 2 - \frac{1}{2}(x + y_0 y)^2 + x_0\ (x + y_0 y), \quad x_0 = -\frac{1}{3}, \quad y_0 = -2.0. \tag{55}$$

Figures 2–10 display the results for these three problems, and the associated numerical tables in Appendices A, B, and C show the solution values to two significant figures at the mesh points $(0.1i, 0.1j)$, where $i = 0, \ldots, 10$, $j = 0, \ldots, 10$, and $i+j \leq 10$. For each of the three problems the original quadratic and new quadratic interpolants are shown. For Problems 2 and 3 the exact solution is identical to the standard quadratic interpolant and so is not shown. In the case of Problem 1 the exact solution is shown.

In the case of Problem 1 the original interpolant has a maximum value of about 9.8 along the line $x = 0$, whereas the new polynomial does not allow the solution to rise above the largest nodal value of 5.7971, thus giving rise to the large maximum error shown in Figure 4.

For Problem 2 the data and original interpolant are both zero at the centroid $x = \frac{1}{3}, y = \frac{1}{3}$ but the new interpolant (correctly given its intent) does not allow the solution values to dip below the smallest data value of 0.56.

In the case of Problem 3, the original quadratic interpolant peaks at 2.1, but the new polynomial remains bounded by the maximum nodal value of 2.041 at point 6. Overall, these results show that the new interpolant remains bounded between the maximum and minimum data values.

8. Extension to tetrahedral elements. The method described above is readily extended to the case of the standard quadratic interpolant on tetrahedra [12] in which each exterior triangular face has the same data points as the triangular quadratic interpolant in Figure 1. The data points are shown in Figure 11 and are numbered 1 to 10. Suppose that we wish to find the value of the interpolant at a point lying on the QRS triangle defined by the points Q, R, and S on which the volume coordinate L_3 is constant. Let QR, RS, and QS be the midpoints of the lines between Q and R, R and S, and between Q and S, respectively. Furthermore let c_1 be the centroid of the triangular face defined by points 1, 2, 3; c_2 be the centroid of the triangle defined by the points 1, 3, 8; and c_3 be the centroid of the triangle defined by the points 2, 3, 8.

The central idea is to use the monotone positive polynomials p_1 and p_2 defined in section 2 to compute sufficient values on the triangle defined by Q, R, and S so that the triangular interpolant described in section 3 may be used to find the value of the interpolant. The values at Q, R, and S are computed using the p_1 polynomials along the tetrahedral edges, while the values at the midpoints QR, RS, and QS are computed using the p_2 polynomial and the centroid values U_{c_1}, U_{c_2}, and U_{c_3}, respectively, on the exterior faces of the tetrahedron. The three centroid values are calculated in the same way as in section 5. In other words,

$$\begin{aligned}
U_Q &= p_1(U_2, U_5, U_3, QL_3),\\
U_S &= p_1(U_8, U_7, U_3, SL_3),\\
U_R &= p_1(U_1, U_6, U_3, RL_3),\\
U_{QR} &= p_2(U_4, U_{c_1}, U_3, QRL_3),\\
U_{RS} &= p_2(U_9, U_{c_2}, U_3, RSL_3),\\
U_{QS} &= p_2(U_{10}, U_{c_3}, U_3, QSL_3),
\end{aligned}$$

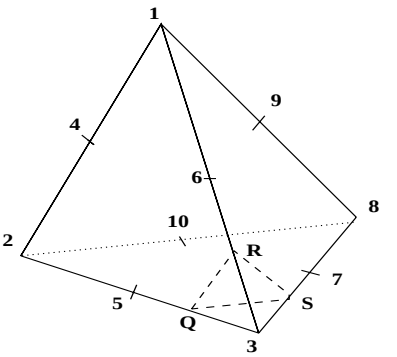

FIG. 11. *Example tetrahedron.*

where QL_3 is the L_3 coordinate of point Q, and similarly for the other five values of L_3 .

The final step is to use the values $U_Q, U_R, U_S, U_{QR}, U_{RS}, U_{QS}$ in the positive triangular interpolant described in section 6 to compute the required value. The accuracy and positivity properties follow from the properties of the individual linear and triangular interpolants.

As in the case of triangles where for any point there are three such interpolants of this type there are four such tetrahedral interpolants, the one described being associated with the volume coordinate L_3. Again as in the triangular case, providing that the standard quadratics q_1, q_2, and the standard quadratic triangular interpolant defined by (1) are used, then all four interpolants will give the same answer. When the positivity preserving polynomials p_1 and p_2 and the positivity preserving triangular

interpolant defined by (36) are used the four values will no longer be identical, though all will be in the range of the data. One solution is to average the four values. Alternatively the closest value to the original quadratic could be used.

9. Conclusions and extensions. This new method for quadratic interpolation on triangles and tetrahedra, based on combinations of linear monotone quadratic polynomials, will preserve positivity in the data in that the interpolant created will be bounded by the maximum and minimum function values used to define it.

An obvious extension of the approach is to consider the interpolant values on a triangle by global rather than local data values, e.g., [6]. This may be done by locating extrema on each edge, if necessary replacing them by global extremal data values, and using a data-bounded quadratic to interpolate in between these new values on that part of the subedge where the extremal value lies. In this way, if a nonnodal extremal value outside the data bounds was detected, each quadratic edge polynomial would be decomposed into three piecewise quadratic polynomials.

In this case the original quadratic interpolant peaks at 2.1, but the new polynomial remains bounded by the maximum nodal value of 2.041 at point 6.

Acknowledgements. The author would like to thank Ken Brodlie for pointing out the work of Barnhill et al. at a critical moment. The referees are also thanked for their thoughtful comments including suggesting the use of the term "data-bounded."

ARE BILINEAR QUADRILATERALS BETTER THAN LINEAR TRIANGLES?*

E. F. D'AZEVEDO†

Abstract. This paper compares the theoretical effectiveness of bilinear approximation over quadrilaterals with linear approximation over triangles. Anisotropic mesh transformation is used to generate asymptotically optimally efficient meshes for piecewise linear interpolation over triangles and bilinear interpolation over quadrilaterals. For approximating a convex function, although bilinear quadrilaterals are more efficient, linear triangles are more accurate and may be preferred in finite element computations; whereas for saddle-shaped functions, quadrilaterals may offer a higher-order approximation on a well-designed mesh. A surprising finding is different grid orientations may yield an order of magnitude improvement in approximation accuracy

Key words. mesh generation, interpolation, quadrilateral patch, triangulation, bilinear approximation

1. Introduction.

This paper compares the theoretical effectiveness of bilinear approximation over quadrilaterals with linear approximation over triangles. The novelty is in the use of anisotropic mesh transformation to generate asymptotically optimally efficient meshes in the comparison. Elementary analysis based on a simple quadratic data model is used. Although both linear and bilinear interpolants are $O(h^2)$ accurate, the results suggest linear triangles are *always* more accurate than general convex bilinear quadrilaterals in approximating a convex function but bilinear approximation may offer a higher-order approximation for saddle-shaped functions on a well-designed mesh. A surprising finding is different grid orientations may yield an order of magnitude "superconvergence" improvement in approximation accuracy. This work is a basic study on optimal meshes with the intention of gaining insight into the more complex meshing problems in finite element analysis.

We consider the problem of interpolating a given smooth data function with continuous piecewise linear triangles or bilinear quadrilaterals over a domain to satisfy a given error tolerance. A mesh that achieves this error tolerance with the *fewest* elements is defined to be optimally efficient. Intuitively, one would expect smaller and denser elements in regions where the function has sharp peaks or large variations. Since each convex quadrilateral can be split across either one of the diagonals into two triangles, one can imagine embedding a refined triangular mesh within the quadrilateral mesh. A practical question arises as to whether the bilin-

ear approximation over quadrilaterals or linear approximation over triangles is more effective.

To make a fair comparison, we need to compare bilinear approximation over an "optimal" quadrilateral mesh versus linear approximation over an "optimal" triangular mesh. Provably optimal triangular meshes [7, 9] have been produced by anisotropic mesh transformation.

Anisotropic mesh generation using a Riemannian metric is emerging as an effective technique for unstructured grid generation where the vertex distribution is highly nonuniform. The central idea is to control the element shapes and sizes by specifying a symmetric metric tensor that measures the approximation error. The metric tensor determines the corresponding anisotropic transformation. The anisotropic mesh is then the image of a uniform mesh of optimal shape elements under the anisotropic transformation. Simpson [18] gives a survey on anisotropic meshes.

Nadler [14], D'Azevedo and Simpson [8, 9], and D'Azevedo [7] have studied *local* anisotropic transformation for the generation of optimally efficient triangular meshes. Peraire et al. [15], Fortin and coworkers [10, 1], Borouchaki and coworkers [2, 3, 4] have used a local metric in anisotropic mesh generation for dynamic remeshing in solving compressible flow problems. In these works, a local metric is used to control the size and shape of elements on the computational mesh.

Several techniques are used to generate anisotropic meshes. Bossen [5] uses a physically-based model of interacting "particles" to define vertices of a triangulation. The attractive (repulsive) forces are derived using a local Riemannian metric. The particles are triangulated to produce a modified Delaunay mesh in the Riemannian space defined by the metric. Shimada [16, 17] uses a similar physically-based close packing of elliptic "bubbles" for generating isotropic meshes. The ellipses are nearly circular bubbles over the transformed space. Ait-Ali-Yahia et al. [1] use a physical spring analogy to perturb points in a structured mesh to generate an anisotropic quadrilateral mesh. George, and George and Hecht [11, 12] use a point insertion process and mesh smoothing to generate an anisotropic triangular mesh. Triangles can be further merged to form a quadrilateral mesh. Common to the above described approaches, the metric tensor is interpolated from piecewise constant values defined over an underlying "background" mesh.

The approach used in this investigation has two major differences. First, we assume a *continuous* Hessian metric is available and we derive a *continuous* global coordinate transformation to the *isotropic* space. The underlying theory relies on a classical result in differential geometry described in section 2.3. A well-shaped (regular) mesh over the isotropic space is transformed back to the original physical space to produce an anisotropic mesh. Second, the Hessian "metric" need not be positive definite. In fact, it is precisely the nonpositive definite case that yields the interesting superconvergent result.

An outline of the paper follows. In section 2, we review the key ideas in [7] for generating optimally efficient triangular meshes. In section 3, we consider error properties of bilinear interpolation. We consider the optimal geometry for quadrilateral patches in section 3.2. We compare the effectiveness of quadrilaterals versus triangular meshes using the local quadratic model in section 4. Numerical experiments and the results are described in section 5. Finally section 6 gives a brief summary.

2. Triangular patch. This section is a brief review of the basic ideas in [7] for determining optimal triangle geometry. We show a linear transformation of a regular mesh of optimal-shape triangles yields an optimally efficient mesh for interpolating a

quadratic function.

2.1. Quadratic model. We shall consider a local analysis where we assume the data function $f(x,y)$ in the neighborhood of (x_c, y_c) is well approximated by its quadratic Taylor expansion,

$$\begin{aligned} f(x,y) &= f(x_c + dx, y_c + dy) \\ &\approx f(x_c, y_c) + \nabla f(x_c, y_c)[dx, dy] + \frac{1}{2}[dx, dy]H[dx, dy]^t. \end{aligned} \tag{2.1}$$

Let the error formula be $E_T(x,y) = p_\ell(x,y) - f(x,y)$, where $p_\ell(x,y)$ is the linear interpolant. By our assumption, $E_T(x,y)$ is a quadratic function and level curves for $E_T(x,y) = c$ form a family of conics with a common center at (x_c, y_c). They form a family of ellipses if $\det(H) > 0$ and hyperbolas if $\det(H) < 0$. Note by the interpolation condition, the curve $E_T(x,y) = 0$ passes through all vertices of the triangle. If $\det(H) > 0$ (conic is an ellipse), then $E_T(x,y)$ attains the local maximum at the center (x_c, y_c); otherwise, $\det(H) < 0$ (conic is a hyperbola) the maximum error is attained at the midpoint of an edge. The error at a displacement from the center is given by

$$E_T(x_c + dx, y_c + dy) = \mathcal{E}_T - \frac{1}{2}[dx, dy]H[dx, dy]^t, \quad \mathcal{E}_T = E_T(x_c, y_c). \tag{2.2}$$

The key insight in [7] is in interpreting the Hessian matrix H in (2.2) as a symmetric metric tensor. Let the symmetric Hessian matrix be diagonalizable as

$$\begin{aligned} H &= Q^t \begin{bmatrix} \lambda_1 & 0 \\ 0 & \lambda_2 \end{bmatrix} Q = S^t \begin{bmatrix} 1 & 0 \\ 0 & \epsilon \end{bmatrix} S, \quad \text{where } \epsilon = \operatorname{sign}(\det(H)), \\ S &= \begin{bmatrix} \sqrt{|\lambda_1|} & 0 \\ 0 & \sqrt{|\lambda_2|} \end{bmatrix} Q, \quad \text{and } Q \text{ is orthogonal, } Q^t Q = I. \end{aligned} \tag{2.3}$$

Note that transformation S is essentially a rotation to align eigenvectors along the coordinate axes then followed by a simple scaling. Under this transformation S, the expression $[dx, dy]H[dx, dy]^t$ reduces to $(d\tilde{x})^2 + \epsilon(d\tilde{y})^2$, where $[\tilde{x}, \tilde{y}]^t = S[x, y]^t$. The error function can be rewritten as

$$\begin{aligned} E_T(x_c + dx, y_c + dy) &= \mathcal{E}_T - \frac{1}{2}[dx, dy]H[dx, dy]^t \\ &= \mathcal{E}_T - \frac{1}{2}\left((d\tilde{x})^2 + \epsilon(d\tilde{y})^2\right) \\ &= \tilde{E}_T(\tilde{x}_c + d\tilde{x}, \tilde{y}_c + d\tilde{y}), \end{aligned} \tag{2.4}$$

where $\tilde{E}_T(\tilde{x}, \tilde{y})$ denotes the corresponding error function under transformation S in $(\tilde{x}, \tilde{y})$-space. The error expression $\tilde{E}_T(\tilde{x}, \tilde{y})$ has no preferred direction (except for the sign), hence we shall call the $(\tilde{x}, \tilde{y})$-space the "isotropic" space.

2.2. Optimal shape. In the following, we shall determine the best triangle shape that minimizes the interpolation error. We can determine the "efficiency" of the elements by computing their ratio of error to area. A small ratio indicates a more efficient element, i.e., one can achieve a lower error tolerance and tile the domain with about the same number of elements.

We consider first the case $f(x,y)$ is convex ($\det(H) > 0, \epsilon = 1$) and level curves or contours of $\tilde{E}_T(\tilde{x},\tilde{y})$ are concentric circles given by

$$\tilde{E}_T(\tilde{x}_c + d\tilde{x}, \tilde{y}_c + d\tilde{y}) = \mathcal{E}_T - \frac{1}{2}\left((d\tilde{x})^2 + (d\tilde{y})^2\right). \tag{2.5}$$

Let $\tilde{T}$ be the transformed image of triangle T over the isotropic space, with vertices at $(\tilde{x}_1,\tilde{y}_1)$, $(\tilde{x}_2,\tilde{y}_2)$, and $(\tilde{x}_3,\tilde{y}_3)$. The circumcircle of $\tilde{T}$ corresponds to the level curve of value zero. Hence the radius of this circumcircle is $\mathrm{sqrt}(2|\mathcal{E}_T|)$ and relates directly to the maximum error attainable (at the center). If this center is exterior to triangle T, the maximum error is attained at the midpoint of the longest edge (of length L) with value $L^2/8$. We can easily see that an equilateral triangle covers the most area for a fixed circumcircle, therefore an equilateral triangle for $\tilde{T}$ is of optimal shape.

If $f(x,y)$ is not convex but has a saddle-shaped graph ($\det(H) < 0$, $\epsilon = -1$), then

$$\begin{aligned}\tilde{E}_T(\tilde{x},\tilde{y}) &= \tilde{E}_T(\tilde{x}_c + d\tilde{x}, \tilde{y}_c + d\tilde{y}) \\ &= \mathcal{E}_T - \frac{1}{2}\left((d\tilde{x})^2 - (d\tilde{y})^2\right) \\ &= \mathcal{E}_T - \frac{1}{2}\left((\tilde{x}-\tilde{x}_c)^2 - (\tilde{y}-\tilde{y}_c)^2\right).\end{aligned} \tag{2.6}$$

We note that the error function $\tilde{E}_T(\tilde{x},\tilde{y})$ is a harmonic function and thus attains its extrema on the boundary of $\tilde{T}$. By calculus, we can show that the local extrema along edge $(\tilde{x}_i,\tilde{y}_i)$, $(\tilde{x}_j,\tilde{y}_j)$ is attained at the midpoint with value

$$\tilde{E}\left(\frac{\tilde{x}_i+\tilde{x}_j}{2}, \frac{\tilde{y}_i+\tilde{y}_j}{2}\right) = \frac{1}{8}\left|(\tilde{x}_i-\tilde{x}_j)^2 - (\tilde{y}_i-\tilde{y}_j)^2\right|.$$

The details for finding the optimal-shape triangle in this case are found in [7]. The optimal-shape triangle geometry that minimizes the efficiency ratio (error/area) is not unique, but the same maximum error is attained at the midpoint of each edge.

From the above two results on optimal-shape triangles, we see that a *regular* mesh of optimal-shape triangles over the isotropic $(\tilde{x},\tilde{y})$-space corresponds to an optimally efficient mesh over the original (x,y)-space. Every triangle attains the same maximum error; moreover, these triangles cover the most area for the error attained and so are optimally efficient. Since the linear transformation S is basically a rotation followed by a rescaling of coordinate axes, we find the areas of triangles are scaled accordingly. Hence the inverse transformation S^{-1} maps this regular mesh to produce an optimally efficient mesh in the original (x,y)-space.

2.3. Differential geometry. The *constant* Hessian matrix H in (2.1) determines the coordinate transformation S that maps $[\tilde{x},\tilde{y}]^t = S[x,y]^t$ so that

$$[dx,dy]H[dx,dy]^t = (d\tilde{x}^2 + \epsilon d\tilde{y}^2).$$

We may view the Hessian matrix $H(x,y)$ as a local metric for measuring the interpolation error $[dx,dy]H[dx,dy]^t$. If a function is approximated by piecewise quadratic patches, then each patch would define a constant Hessian matrix and a corresponding coordinate transformation. In the limit where each quadratic patch is infinitestimally small, we need to determine a *continuous* transformation $(\tilde{x}(x,y),\tilde{y}(x,y))$, that satisfies $[dx,dy]H(x,y)[dx,dy]^t = d\tilde{x}^2 + \epsilon d\tilde{y}^2$, where $H(x,y)$ is the Hessian matrix of a general function.

The necessary and sufficient conditions for finding the anisotropic coordinate transformation $(\tilde{x}(x,y), \tilde{y}(x,y))$ are given by a classical result in differential geometry for characterizing a "flat" space [19]: that the Riemann–Christoffel tensor formed from the metric tensor $H = \{h_{ij}\}$ is identically zero. This condition reduces to

$$0 = \Gamma = \det \begin{pmatrix} h_{11} & \frac{\partial h_{11}}{\partial x} & \frac{\partial h_{11}}{\partial y} \\ h_{12} & \frac{\partial h_{12}}{\partial x} & \frac{\partial h_{12}}{\partial y} \\ h_{22} & \frac{\partial h_{22}}{\partial x} & \frac{\partial h_{22}}{\partial y} \end{pmatrix} . \tag{2.7}$$

In this case, a sufficient condition is for $H = \{h_{ij}\}$ to satisfy

$$K_1 h_{11} + K_2 h_{12} + K_3 h_{22} = 0$$

for some constants K_1, K_2, K_3. The coordinate transformation $(\tilde{x}(x,y), \tilde{y}(x,y))$ may be found by solving an initial value ordinary differential equation. Again, the inverse transformation $(x(\tilde{x},\tilde{y}), y(\tilde{x},\tilde{y}))$ maps a regular mesh of optimal shaped triangles to yield an optimally efficient mesh.

3. Quadrilateral patch. In this section, we follow the approach of using a simple quadratic data function in deriving the error term for a triangular patch to derive the error term for bilinear approximation over a quadrilateral patch.

3.1. Bilinear interpolant. We shall use the isoparametric formulation (commonly used in finite element analysis) by considering basis functions over the normalized (p,q)-space over the unit square, $0 \le p, q \le 1$. Basis functions are

$$\begin{aligned} &\phi_1(p,q) = (1-p)(1-q), && \phi_2(p,q) = p(1-q), \\ &\phi_3(p,q) = pq, && \phi_4(p,q) = (1-p)q \end{aligned} \tag{3.1}$$

that satisfy $\phi_i(x_j, y_j) = \delta_{ij}$ and sum to one, $1 = \sum_{i=1}^{i=4} \phi_i(p,q)$.

Mapping from (p,q) to the original (x,y)-space is by

$$\begin{aligned} x(p,q) &= x_1\phi_1(p,q) + x_2\phi_2(p,q) + x_3\phi_3(p,q) + x_4\phi_4(p,q), \\ y(p,q) &= y_1\phi_1(p,q) + y_2\phi_2(p,q) + y_3\phi_3(p,q) + y_4\phi_4(p,q) \end{aligned} \tag{3.2}$$

that maps vertex $(0,0)$ to (x_1,y_1), $(1,0)$ to (x_2,y_2), $(1,1)$ to (x_3,y_3), and $(0,1)$ to (x_4,y_4). The bilinear interpolant (over (p,q)-space) is given by

$$p_b(x(p,q), y(p,q)) = \sum_{i=1}^{i=4} f(x_i,y_i)\phi_i(p,q) \ . \tag{3.3}$$

3.2. Optimal shape. In the following, we shall determine the best quadrilateral shape that minimizes the interpolation error. The error function for quadratic interpolation over a *parallelogram* can be shown by direct algebraic expansion (see Appendix A) to be

$$\begin{aligned} E_Q(p,q) &= p_b(x(p,q), y(p,q)) - f(x(p,q), y(p,q)) \\ &= \mathcal{E}_Q - \frac{1}{2}\left(\mu_1(p-p_c)^2 + \mu_2(q-q_c)^2\right), \end{aligned} \tag{3.4}$$

with centroid at $[p_c, q_c] = [1/2, 1/2]$,

$$[u_x, u_y] = [x_2 - x_1, y_2 - y_1], \quad [v_x, v_y] = [x_4 - x_1, y_4 - y_1],$$

$$\begin{aligned}
\mathcal{E}_Q &= E_Q(p_c, q_c) = \frac{1}{8}\left(\mu_1 + \mu_2\right), \\
0 &= \frac{\partial}{\partial p} E_Q(p_c, q_c) = \frac{\partial}{\partial q} E_Q(p_c, q_c), \\
\mu_1 &= [u_x, u_y] H [u_x, u_y]^t, \quad \mu_2 = [v_x, v_y] H [v_x, v_y]^t.
\end{aligned} \tag{3.5}$$

For a convex function ($\det(H) > 0$), μ_1 and μ_2 are positive, hence the maximum error is attained at the centroid $[p_c, q_c]$.

For this convex case, we can show a square over the isotropic space is of optimal shape by minimizing the efficiency ratio (error/area). Since the isoparametric bilinear interpolant (3.3) exactly fits linear functions [13], the error attained at the centroid (x_c, y_c) (which is a lower bound on the maximum error) can be written as

$$\begin{aligned}
\mathcal{E}_M &= \frac{1}{4}\left(\sum_{i=1}^{i=4} \frac{1}{2}[x_i, y_i] H [x_i, y_i]^t\right) - \frac{1}{2}[x_c, y_c] H [x_c, y_c]^t \\
&= \frac{1}{2}\left(\sum_{i=1}^{i=4} \left(\frac{1}{4}[x_i, y_i] H [x_i, y_i]^t\right) - [x_c, y_c] H [x_c, y_c]^t\right),
\end{aligned} \tag{3.6}$$

$$[x_c, y_c] = [(x_1 + x_2 + x_3 + x_4)/4, (y_1 + y_2 + y_3 + y_4)/4] \ . \tag{3.7}$$

This expression can be further simplified over the isotropic space where H is the identity

$$\begin{aligned}
\mathcal{E}_M &= \frac{1}{8}\left(\sum_{i=1}^{i=4} \left((\tilde{x}_i^2 + \tilde{y}_i^2) - (\tilde{x}_c^2 + \tilde{y}_c^2)\right)\right) \\
&= \frac{1}{8}\left((\tilde{x}_1^2 + \tilde{x}_2^2 + \tilde{x}_3^2 + \tilde{x}_4^2) - 4\tilde{x}_c^2 + (\tilde{y}_1^2 + \tilde{y}_2^2 + \tilde{y}_3^2 + \tilde{y}_4^2) - 4\tilde{y}_c^2\right) \\
&= \frac{1}{8}(L_1^2 + L_2^2 + L_3^2 + L_4^2), \quad \text{with } L_i^2 = (\tilde{x}_i - \tilde{x}_c)^2 + (\tilde{y}_i - \tilde{y}_c)^2,
\end{aligned}$$

where $[\tilde{x}_i, \tilde{y}_i]^t = S[x_i, y_i]^t$ and $[\tilde{x}_c, \tilde{y}_c]^t = S[x_c, y_c]^t$ are the corresponding coordinates over the isotropic space. The area of this transformed convex quadrilateral is (see Figure 1)

$$\text{Area} = \frac{1}{2}\left(L_1 L_2 \sin(\theta_1) + L_2 L_3 \sin(\theta_2) + L_3 L_4 \sin(\theta_3) - L_4 L_1 \sin(\theta_1 + \theta_2 + \theta_3)\right).$$

Since the isotropic transformation S in (2.3) is a rotation followed by a rescaling of the coordinate axis, the area of quadrilateral over the isotropic space is scaled by $\text{sqrt}(|\lambda_1 \lambda_2|) = \text{sqrt}(\det(H))$ (intrinsic to H). By calculus, we can show this ratio of $\mathcal{E}_M$/area is minimized and *attained* by a square with $L_1 = L_2 = L_3 = L_4$ and $\theta_1 = \theta_2 = \theta_3 = \pi/4$. Hence the most efficient shape among *all* general convex bilinear quadrilaterals is a square over the isotropic space with an efficiency ratio of 1/4.

If $f(x, y)$ is saddle-shaped ($\det(H) < 0$), the error expression for a parallelogram is still

$$E_Q(p, q) = \frac{1}{8}(\mu_1 + \mu_2) - \frac{1}{2}(\mu_1 (p - p_c)^2 + \mu_2 (q - q_c)^2) \ .$$

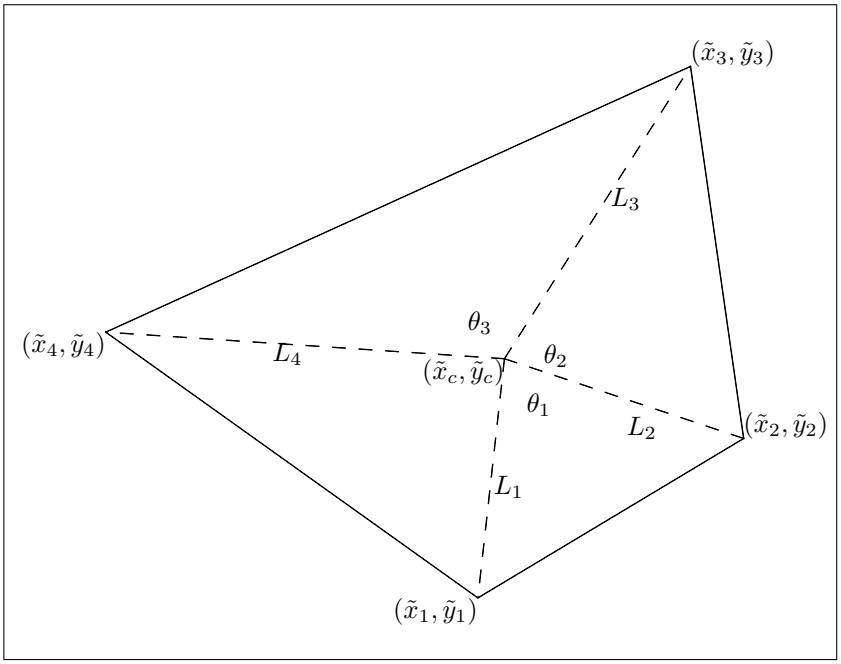

FIG. 1. *Convex quadrilateral over isotropic space.*

Under the anisotropic transformation S,

$$\mu_1 = \tilde{u}_x^2 - \tilde{u}_y^2, \quad \mu_2 = \tilde{v}_x^2 - \tilde{v}_y^2 \ , \quad \begin{bmatrix} \tilde{u}_x & \tilde{v}_x \\ \tilde{u}_y & \tilde{v}_y \end{bmatrix} = S \begin{bmatrix} u_x & v_x \\ u_y & v_y \end{bmatrix}.$$

Now both μ_1 and μ_2 vanish for

$$[\tilde{u}_x, \tilde{u}_y] = [L, L], \quad [\tilde{v}_x, \tilde{v}_y] = [-L, L], \tag{3.8}$$

which corresponds to a square rotated by $\pi/4$. The above indicates an "exact fit" ($E_Q(p,q) = 0$) if $\mu_1 = \mu_2 = 0$. This suggests bilinear approximation is a better interpolant than linear interpolation and the simple quadratic model is inadequate to fully capture the error properties in this case.

To summarize, a square over the isotropic space in any orientation is optimal for the elliptic case and a square rotated by $\pi/4$ is optimal for the hyperbolic case.

4. Comparison of quadrilaterals versus triangles. In this section, we shall show a refined triangulation produced by the Delaunay triangulation (DT) will always produce better accuracy for approximating a *convex* quadratic function. We shall apply the geometric interpretation of the maximum interpolation error over the transformed isotropic space.

THEOREM 4.1. *Any convex quadrilateral over the isotropic space can be decomposed into two triangles with no increase in maximum interpolation error for approximating a convex quadratic.*

Proof. We shall use the DT [8] in selecting the diagonal for decomposing the general convex quadrilateral into two triangles. The DT has an interesting property

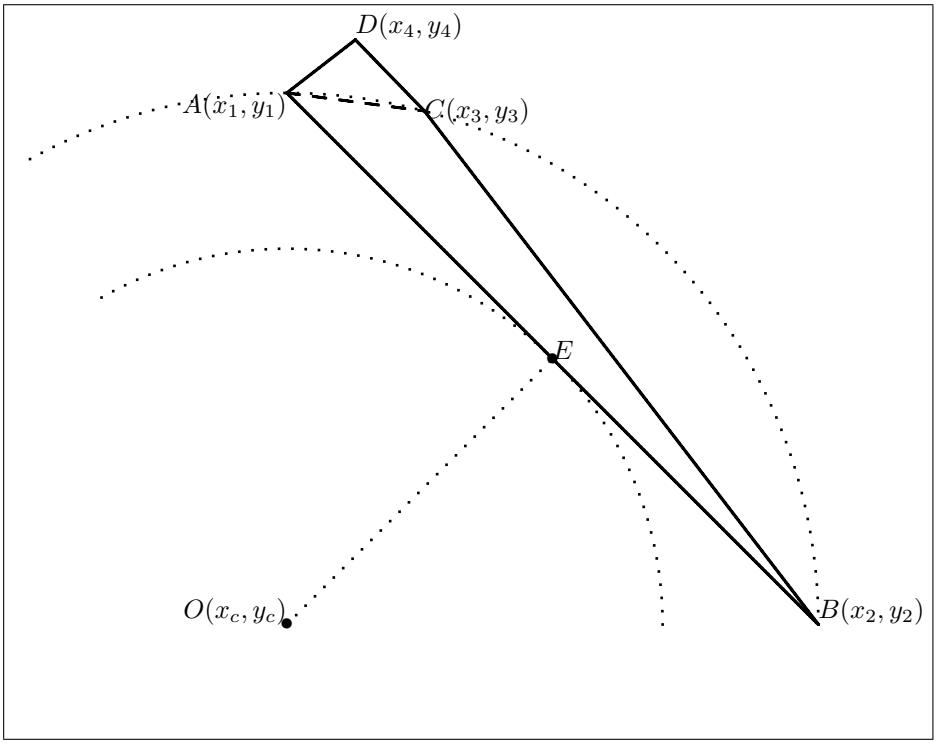

FIG. 2. *Maximum triangulation error attained on boundary edge.*

that three vertices form a triangle in DT iff no other vertex is interior to the circumcircle formed by these vertices. This is also commonly known as the "empty circle" property.

Case 1. The maximum error of the DT is attained at the midpoint (E) of a boundary edge (see Figure 2). In this case the error attained is due to linear interpolation along the edge AB, with value $|AB|^2/8$. Since the isoparametric bilinear interpolant over the quadrilateral also reduces to linear interpolation along the boundary edge, the maximum error for bilinear quadrilateral cannot be less than this value. Therefore the theorem holds.

Case 2. The maximum error of the DT is attained at the center of circumcircle, (x_c, y_c) (see Figure 3). For simplicity and without loss of generality, we perform a translation such that the isotropic quadratic data function is $\frac{1}{2}((x-x_c)^2 + (y-y_c)^2)$. The maximum error is $R^2/2$, where R is the radius of the circumcircle. The interpolation error given by the quadrilateral is (3.3),

$$E_Q(x_c, y_c) = \left(\sum_{i=1}^{i=4} f_i \phi_i(p, q)\right) - f(x_c, y_c), \quad f_i = f(x_i, y_i)$$

$$= \big((1 - \phi_3(p, q))R^2/2 + \phi_3(p, q) f_3\big) - 0 \tag{4.1}$$

since $f_1 = f_2 = f_3 = R^2/2$ and $f(x_c, y_c) = 0$. We have

$$f(x_3, y_3) = ((x_3 - x_c)^2 + (y_3 - y_c)^2)/2 > R^2/2\ , \tag{4.2}$$

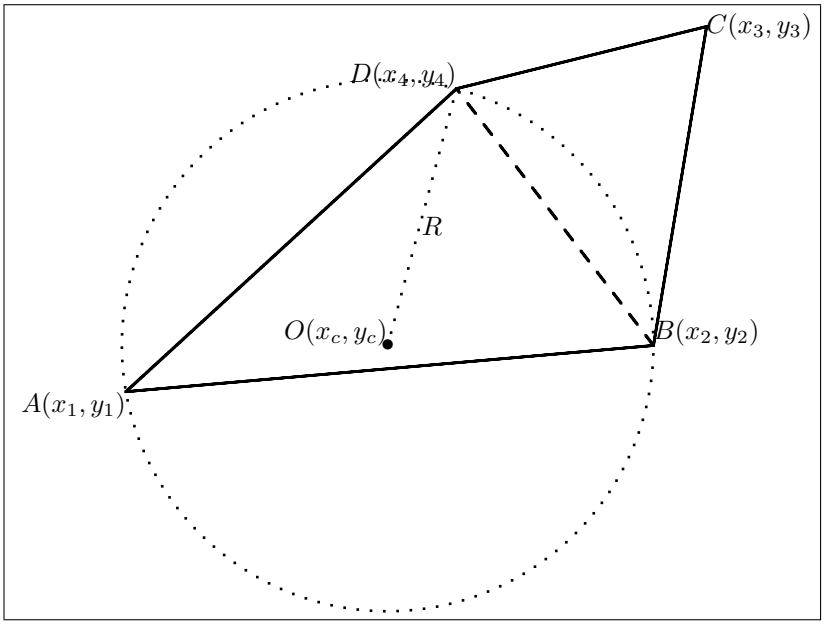

FIG. 3. *Maximum triangulation error attained at center of circum-circle.*

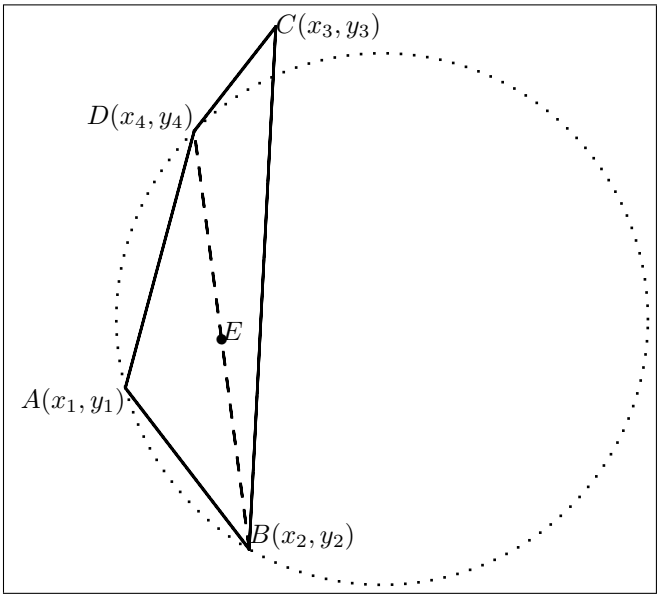

FIG. 4. *Maximum triangulation error cannot be on diagonal.*

and therefore the error attained by quadrilateral at (x_c, y_c) is higher than $R^2/2$, thus the theorem holds.

Cases 1 and 2 are exhaustive since the maximum error of the DT cannot be attained at the the midpoint of a diagonal, unless it also satisfies Case 1 or Case 2 as in a square (see Figure 4). We have $\angle BCD \leq \pi/2$ to satisfy the "empty circle"

property. If $\angle CDB > \pi/2$ (similar argument for $\angle CBD > \pi/2$), then by cosine rule for triangles,

$$|BC|^2 = |CD|^2 + |BD|^2 - 2|CD||BD|\cos(\angle CDB) > |BD|^2 \ , \tag{4.3}$$

thus the maximum error is attained in $\triangle BCD$ on edge BC (Case 1). The remaining alternative is where $\triangle BCD$ forms an acute triangle. Then $\triangle BCD$ will have a larger maximum error given in terms of radius of the circumcircle, which is covered in Case 2.

Therefore over the isotropic space, the DT refined linear triangulation is more accurate than the isoparametric bilinear quadrilateral. □

This theorem suggests if the data function is not saddle shaped, the refine DT triangulation (over the isotropic space) produced above will yield better approximation accuracy, even on arbitrary meshes of general convex quadrilaterals.

4.1. Comparison of efficiency ratio. For the optimal shape equilateral triangle, the area, $\mathcal{A}_T$, is $\sqrt{3}L^2/4$, from (2.4) we obtain an efficiency ratio of

$$\frac{\mathcal{E}_T}{\mathcal{A}_T} = \frac{L^2/6}{\sqrt{3}L^2/4} = 2\sqrt{3}/9 \approx 0.385.$$

Area of the optimal square configuration is L^2, thus the ratio is $1/4 = 0.25$. Hence for an *element-by-element* comparison, the quadrilateral is more efficient. In other words, if we were to approximate a function with either N quadrilaterals or N triangles, quadrilaterals are preferred.

On the other hand, triangles may have advantages over quadrilaterals for finite element computations. Matrix assembly and the solution of the sparse linear equations are commonly the most intensive calculations. If we decompose a quadrilateral mesh into triangles as done above, no extra nodes are introduced. There will be twice as many triangular elements but the resulting assembled matrix has a similar sparsity pattern and the same number of unknowns. Matrix assembly with a *general* convex quadrilateral usually requires costly evaluations of the Jacobian distortion in numerical quadrature over the isoparametric space, whereas assembly of linear triangle elements is simpler. Therefore if computation with N quadrilaterals is as costly as using $2N$ triangles, then triangles are preferred due to their better accuracy and simplicity. The actual computation costs may depend on the implementation of the finite element code.

Consider the approximation of a saddle-shaped function by a square (unrotated) over the isotropic space. The error formula gives

$$\begin{aligned} E_Q(p,q) &= \frac{1}{8}(\mu_1+\mu_2) - \frac{1}{2}(\mu_1(p-p_c)^2 + \mu_2(q-q_c)^2), \quad (p_c,q_c) = \left(\frac{1}{2},\frac{1}{2}\right) \\ &= -\frac{1}{2}((p-p_c)^2L^2 - (q-q_c)^2L^2), \quad \text{where } \mu_1 = L^2 = -\mu_2 \ . \end{aligned} \tag{4.4}$$

The maximum error is attained at the midpoint of each edge. Let $(p,q) = (1,1/2)$, then $\mathcal{E}_Q = L^2/8$. This gives an efficiency ratio of $1/8 = 0.125$. One optimal triangle shape for the saddle-shaped function is the triangle with vertices at $(0,0)$, $(L,0)$, $(1/2L, \sqrt{5}/2L)$ over the isotropic space [7], which has area $\sqrt{5}L^2/4$. The maximum error is $L^2/8$ and attained at the midpoint of each edge. This gives an efficiency ratio of $1/(2\sqrt{5}) \approx 0.224$. Thus over the isotropic space, a mesh with N (unrotated) squares should yield roughly the same accuracy as $2N$ triangles. This is verified in the numerical experiments.

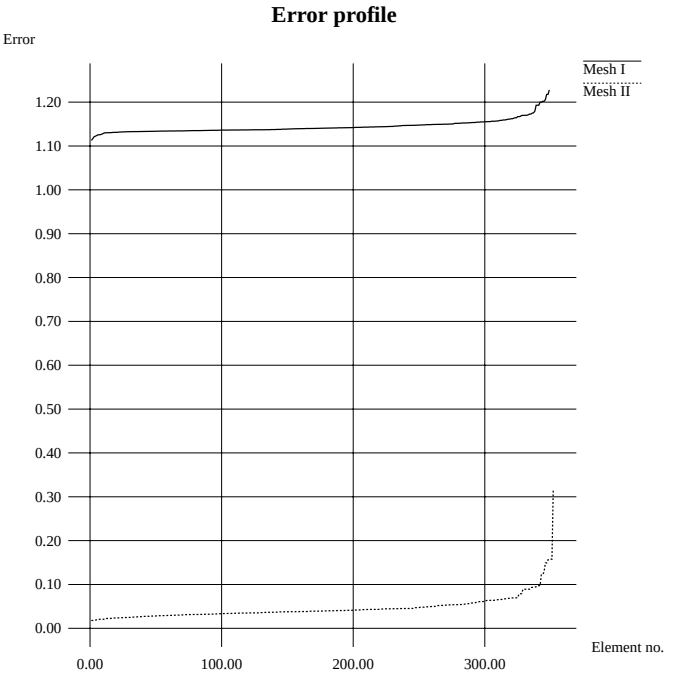

FIG. 7. *Error profiles for Example* 2.

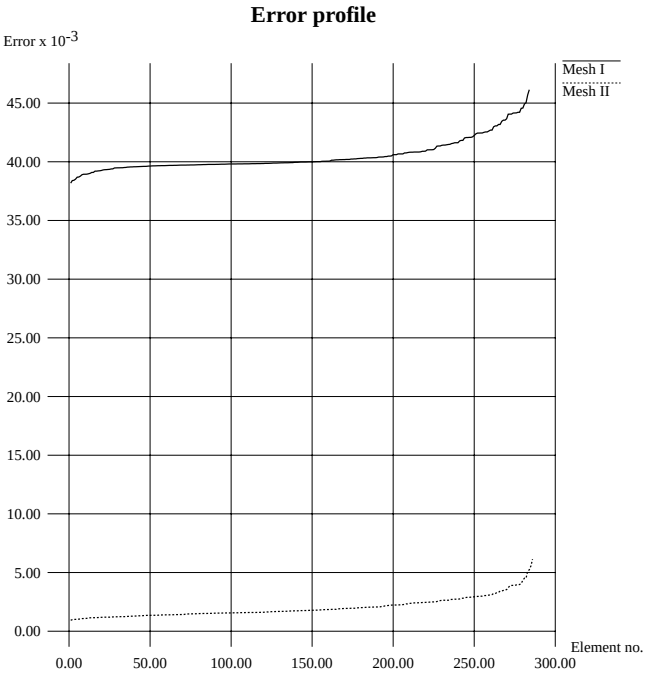

FIG. 8. *Error profiles for Example* 3.

TABLE 1
Summary of results for Example 1.

	Minimum error	Median error	90 percentile	Maximum error	Number of elements
Triangle	5.27E-2	5.39E-2	5.50E-2	5.74E-2	2923
Mesh I	5.75E-2	5.76E-2	5.78E-2	5.79E-2	1488
Mesh II	2.29E-4	4.62E-4	8.30E-4	3.04E-3	1480

5. Numerical experiments. In this section, we demonstrate that a well-designed mesh for bilinear interpolation of a saddle-shaped function may give substantial improvements over a triangular mesh. The examples are taken from [7]. The procedure in [7] for generating optimal triangular meshes is modified to generate optimal quadrilateral meshes. Only elements entirely interior to the unit square are generated to simplify the presentation.

Example 1. Exponential increase along x-axis,

$$f(x,y) = \exp(5x)\sin(5y).$$

Example 2. A near singularity at $(x_0, y_0) = (0.5, 0.2)$,

$$f(x,y) = \frac{(x-x_0)^2 - (y-y_0)^2}{((x-x_0)^2 + (y-y_0)^2)^2}.$$

Example 3. A more severe near singularity,

$$f(x,y) = \frac{((x-x_0)^2 + (y-y_0)^2)^2 - 8(x-x_0)^2(y-y_0)^2}{((x-x_0)^2 + (y-y_0)^2)^4}.$$

Example 4. Example 4 is Example 2 modified by a rescaling of y-axis,

$$f(x,y) = \frac{(x-x_0)^2 - (\sqrt{10}y - y_0)^2}{((x-x_0)^2 + (\sqrt{10}y - y_0)^2)^2}.$$

The results of the experiments are summarized in Figures 5–8 and Tables 1–4. Mesh I is generated by optimal squares over the isotropic space. Mesh II is generated by optimal squares with a $\pi/4$ rotation over the isotropic space to capture the "superconvergence" behavior. Both meshes have similar element size, element shape, and density and differ mainly in their orientation. The meshes are displayed in Figures 9–16. Results for optimal triangular meshes produced in [7] are included for comparison. Mesh I produces an almost level error profile. This indicates an equilibration of interpolation error evenly over all elements. Error profile for Mesh I is roughly comparable to an optimal triangular mesh with about twice as many triangles and in agreement with discussions in section 4. Mesh II displays the "superconvergence" behavior by consistently achieving an error 5–10 times smaller than Mesh I.

It can be shown [6] that the coordinate lines in the isotropic space are mapped to eigentrajectories of the Hessian matrix. Thus as the curved element boundaries are poorly approximated by straight edges, the resulting quadrilateral will no longer have parallel sides (Figures 13, 14). The simple analysis for superconvergence in section 3 for parallelograms may not be adequate and this leads to an anomalous increase in the error displayed in Example 3 of a severe singularity.

TABLE 2
Summary of results for Example 2.

	Minimum error	Median error	90 percentile	Maximum error	Number of elements
Triangle	1.87E-2	2.01E-2	2.16E-2	2.57E-2	1072
Mesh I	2.13E-2	2.15E-2	2.17E-2	2.21E-2	550
Mesh II	2.82E-4	4.69E-4	7.33E-4	1.38E-3	546

TABLE 3
Summary of results for Example 3.

	Minimum error	Median error	90 percentile	Maximum error	Number of elements
Triangle	1.02	1.16	1.32	1.70	650
Mesh I	1.11	1.14	1.16	1.23	349
Mesh II	1.80E-2	3.94E-2	6.75E-2	3.16E-1	352

TABLE 4
Summary of results for Example 4.

	Minimum error	Median error	90 percentile	Maximum error	Number of elements
Triangle	2.91E-2	3.68E-2	4.61E-2	6.46E-2	608
Mesh I	3.81E-2	4.00E-2	4.24E-2	4.61E-2	284
Mesh II	9.36E-4	1.76E-3	3.04E-3	6.13E-3	286

Table 5 shows the effect of generating finer meshes over the isotropic space. If we consider the median error, Mesh I shows the expected $O(h^2)$ convergence. From the efficiency ratio (error/area), we can also predict the decrease of error is proportional to the number of elements. Results for Mesh II clearly display the higher than $O(h^2)$ "superconvergence" behavior. From another perspective, about 5–10 times *more* elements are needed for Mesh I to match the accuracy of Mesh II.

6. Summary. We have used a simple locally quadratic model to develop a geometric interpretation of the interpolation error. We determine the optimal element shapes and their efficiency ratio (error/area) over the isotropic space. The analysis shows for approximating convex data functions, although bilinear quadrilaterals are more efficient, linear triangles are more accurate and may be preferred in finite element computations. For approximating saddle-shaped data functions, a well-designed quadrilateral mesh may show "superconvergence" improvements in approximation accuracy. Numerical experiments show good agreement with the analysis, and a surprising finding is different grid orientations may have an order of magnitude improvement in accuracy.

Appendix A. In this section, we show the error function for quadratic interpolation over a parallelogram is given by (3.4) by simple algebraic expansion. Let the data function be

$$f(x,y) = \frac{1}{2}[x,y]H[x,y]^t + [g_1,g_2][x,y]^t + c \tag{A.1}$$

and the affine isoparametric transformation be

$$\begin{bmatrix} x(p,q) \\ y(p,q) \end{bmatrix} = T \begin{bmatrix} p \\ q \end{bmatrix} + \begin{bmatrix} x_1 \\ y_1 \end{bmatrix},\ T = \begin{bmatrix} u_x & v_x \\ u_y & v_y \end{bmatrix} = \begin{bmatrix} x_2 - x_1 & x_4 - x_1 \\ y_2 - y_1 & y_4 - y_1 \end{bmatrix}. \tag{A.2}$$

TABLE 5
Convergence test on Example 3.

	Minimum error	Median error	90 percentile	Maximum error	Number of elements
Mesh I	11.1E-1	11.4E-1	11.6E-1	12.3E-1	349
Mesh I	3.22E-1	3.23E-1	3.24E-1	3.26E-1	1223
Mesh I	8.03E-2	8.07E-2	8.12E-2	8.23E-2	5063
Mesh I	1.99E-2	2.02E-2	2.04E-2	2.08E-2	20603
Mesh II	1.80E-2	3.94E-2	6.75E-2	3.16E-1	352
Mesh II	2.35E-3	4.22E-3	9.16E-3	6.35E-2	1260
Mesh II	3.10E-4	7.20E-4	1.29E-3	9.41E-3	5244
Mesh II	5.19E-5	1.79E-4	3.78E-4	1.24E-3	21389

Then the interpolation error can be shown to be

$$\begin{aligned} E_Q(p,q) &= p_b(x(p,q),y(p,q)) - f(x(p,q),y(p,q)) \\ &= \mathcal{E}_Q - \frac{1}{2}\left(\mu_1(p-p_c)^2 + \mu_2(q-q_c)^2\right), \end{aligned} \tag{A.3}$$

with centroid at $[p_c, q_c] = [\frac{1}{2}, \frac{1}{2}]$,

$$\begin{aligned} \mathcal{E}_Q &= E_Q(p_c,q_c) = \frac{1}{8}\left(\mu_1+\mu_2\right), \\ \mu_1 &= [u_x,u_y]H[u_x,u_y]^t, \quad \mu_2 = [v_x,v_y]H[v_x,v_y]^t. \end{aligned}$$

Let the data function over (p,q)-space be written as

$$\begin{aligned} \tilde{f}(p,q) &= f(x(p,q),y(p,q)) \\ &= \frac{1}{2}[p,q]\tilde{H}[p,q]^t + [\tilde{g}_1,\tilde{g}_2][p,q]^t + \tilde{c}, \end{aligned}$$

$$\text{where} \quad \tilde{H} = T^t H T = \begin{bmatrix} \tilde{h}_{11} & \tilde{h}_{12} \\ \tilde{h}_{12} & \tilde{h}_{22} \end{bmatrix} \quad \text{and} \tag{A.4}$$

$$\begin{aligned} [\tilde{g}_1,\tilde{g}_2] &= \left([g_1,g_2] + [x_1,y_1]H\right)T\,, \\ \tilde{c} &= c + [g_1,g_2][x_1,y_1]^t + \frac{1}{2}[x_1,y_1]H[x_1,y_1]^t\,. \end{aligned} \tag{A.5}$$

The function values at the four interpolating corners are

$$\begin{aligned} f_1 = \tilde{f}(0,0) = \tilde{c}\,, \quad f_3 = \tilde{f}(1,1) = \frac{1}{2}(\tilde{h}_{11}+\tilde{h}_{22}+2\tilde{h}_{12}) + \tilde{g}_1 + \tilde{g}_2 + \tilde{c}\,, \\ F_2 = \tilde{f}(1,0) = \frac{1}{2}\tilde{h}_{11} + \tilde{g}_1 + \tilde{c}\,, \quad f_4 = \tilde{f}(0,1) = \frac{1}{2}\tilde{h}_{22} + \tilde{g}_2 + \tilde{c}\,. \end{aligned} \tag{A.6}$$

By (3.3) and (A.3) (note the vanishing of linear and constant terms),

$$\begin{aligned} E_Q(p,q) &= \left(\sum_{i=1}^{i=4} f_i\phi_i(p,q)\right) - \tilde{f}(p,q) \\ &= \frac{1}{2}\Big(p(1-q)\tilde{h}_{11} + pq(\tilde{h}_{11}+\tilde{h}_{22}+2\tilde{h}_{12}) \end{aligned}$$

$$
\begin{aligned}
&\quad +(1-p)q\tilde{h}_{22} - (p^2\tilde{h}_{11} + q^2\tilde{h}_{22} + 2pq\tilde{h}_{12})\Big) \\
&= \frac{1}{2}\left(p\tilde{h}_{11} + q\tilde{h}_{22} + 2pq\tilde{h}_{12} - p^2\tilde{h}_{11} - q^2\tilde{h}_{22} - 2pq\tilde{h}_{12}\right) \\
&= \frac{1}{2}\left(p(1-p)\tilde{h}_{11} + q(1-q)\tilde{h}_{22}\right) \\
&= \frac{1}{8}(\tilde{h}_{11} + \tilde{h}_{22}) - \frac{1}{2}\left(\tilde{h}_{11}\left(p - \frac{1}{2}\right)^2 + \tilde{h}_{22}\left(q - \frac{1}{2}\right)^2\right). \qquad \text{(A.7)}
\end{aligned}
$$

From (A.2) and (A.4), we have $\tilde{h}_{11} = \mu_1$ and $\tilde{h}_{22} = \mu_2$; hence the error function has the form given in (A.3).

ALTERNATING PLANE SMOOTHERS FOR MULTIBLOCK GRIDS*

IGNACIO M. LLORENTE†, BORIS DISKIN‡, AND N. DUANE MELSON§

Abstract. Standard multigrid methods are not well suited for problems with anisotropic discrete operators, which can occur, for example, on grids that are stretched in order to resolve a boundary layer. One of the most efficient approaches to yield robust methods is the combination of standard coarsening with alternating-direction plane relaxation in the three dimensions. However, this approach may be difficult to implement in codes with multiblock structured grids because there may be no natural definition of global lines or planes. This inherent obstacle limits the range of an implicit smoother to only the portion of the computational domain in the current block. This report studies in detail, both numerically and analytically, the behavior of blockwise plane smoothers in order to provide guidance to engineers who use block-structured grids. The results obtained so far show alternating-direction plane smoothers to be very robust, even on multiblock grids. In common computational fluid dynamics multiblock simulations, where the number of subdomains crossed by the line of a strong anisotropy is low (up to four), textbook multigrid convergence rates can be obtained with a small overlap of cells between neighboring blocks.

Key words. robust multigrid methods, multiblock grids, anisotropic discrete operators

AMS subject classification. 65M55

1. Introduction and previous work.

Standard multigrid techniques are efficient methods for solving many types of partial differential equations (PDEs), due to their optimal complexity (the required work is linearly proportional to the number of unknowns) [2], optimal memory requirements, and good efficiency and scalability in parallel implementations [12, 14]. Although highly efficient multigrid methods have been developed for a wide class of problems governed by PDEs, these methods are still underutilized in production and commercial codes [21]. One reason for this underutilization is that the textbook efficiency achieved in solving uniformly elliptic problems is not maintained in anisotropic problems; i.e., convergence rates of standard multigrid methods degrade on problems that have anisotropic discrete operators.

Several methods to deal with anisotropic operators have been studied in the multigrid literature. One popular approach is semicoarsening where the multigrid coarsening process is not applied uniformly to all of the coordinate directions [15, 16, 18, 23]. By selectively *not* coarsening the grid in certain directions, the anisotropy can be reduced on the coarser grids. This process makes the smoothing problem easier because only part of the high-frequency error (namely, the error components oscillating in the directions of coarsening) should be eliminated in relaxation.

Another approach for dealing with anisotropic problems is to develop robust smoothers that can eliminate all the high-frequency errors in the presence of strong

anisotropies [13, 17, 22]. These robust smoothers can be efficiently implemented in the framework of a multigrid method with full coarsening. Plane-implicit relaxation schemes belong to this family of robust smoothers. These schemes are natural for structured grids. (It is more difficult to apply them to unstructured grids because there is no natural definition of a plane or even a line.) Other intermediate alternatives that combine implicit relaxation with partial and full coarsening have been presented in the multigrid literature [6, 7, 9, 10, 19, 25].

Previously [13], we studied the behavior of plane-relaxation methods as multigrid smoothers on single-block grids in three dimensions. With numerical experiments and the local mode analysis, we compared different methods by considering the dependence of their smoothing factors on the anisotropy strength. It was observed that for strong anisotropies and practical grid sizes, there are significant differences in the smoothing factors, depending on whether periodic or Dirichlet boundary conditions are employed. For Dirichlet boundary conditions, increasing anisotropy turns the smoother into an exact solver. (The convergence factor is inversely proportional to the anisotropy strength.)

It has long been known (see, e.g., [2]) that the alternating-direction plane relaxation scheme is a simple, extremely efficient, and robust method. Its efficiency, in fact, is improved in the presence of strong anisotropies. This scheme was considered to be essentially more expensive (in work-count per relaxation sweep) than point relaxation schemes. However, it was found (see [13]) that the overall convergence rate of the three-dimensional (3-D) multigrid solver does not deteriorate if, instead of exactly solving two-dimensional (2-D) problems arising in plane-relaxation sweeps, just one 2-D V-cycle with alternating-line smoother is used in each point. A similar idea of performing plane relaxation with a 2-D multigrid method has been successfully implemented in [9]. With this improvement, the convergence factor per work unit of the 3-D V-cycle employing the alternating-direction plane relaxation scheme for an *isotropic* problem is just twice that of the most efficient cycle using a pointwise smoother. This cost does not look excessive, taking into account the excellent robustness of the alternating-direction plane relaxation smoother in treating anisotropic problems.

Such single-block algorithms are very efficient (especially for structured grids with stretching) due to their relatively easy implementation (on both sequential and parallel computers) and good architectural properties (parallelism and cache memory exploitation). However, multiblock grids are needed to deal with complex geometries or to facilitate parallel processing. This multiblock approach is already useful in serial computers: it improves the data locality properties and efficiently exploits the memory hierarchy of the underlying computer [8].

Plane smoothers have been successfully applied to solve the incompressible Navier–Stokes equations on *rectangular* multiblock grids (multiblock grids where lines and planes are globally defined) [17]. The methods combining semicoarsening with block smoothers (see, e.g., [7]) are also very efficient on such grids. On *general* multiblock grids (multiblock grids without global definitions of planes or lines), however, algorithms based on global semicoarsening are not viable. Moreover, the plane-implicit smoother can be applied only within the current block, and so this plane smoother becomes a blockwise plane smoother. The purpose of this paper is to study whether the optimal properties of plane-implicit smoothers deteriorate for general multiblock grids where these smoothers are not applied globally, but inside each block.

The idea of relaxing not whole lines but portions of lines first appeared in [1]. This issue was also discussed by Jones and Melson in [11], who suggested that multiblock

grids have a detrimental effect on the performance of implicit schemes. By using numerical experiments and rigorous analysis, they derived relations between the block size, the amount of overlap between blocks, and the strength of the anisotropy that must hold for the resulting multigrid algorithm to be efficient. By looking at the model problem, they showed that textbook multigrid efficiency is achieved only when the block sizes (and, therefore, the range of the implicit operators) are proportional to the strength of the anisotropy.

We have developed a flexible 3-D code to study the behavior of blockwise plane smoothers and determine whether the result relating the convergence rate with the block size, the overlap size, and the anisotropy strength obtained for the 2-D case holds for 3-D. The current version of the code solves the nonlinear diffusion-convection equation by using a full multigrid approach with the *full approximation scheme* [2, 24] for V-cycles. This report presents results for the linear anisotropic diffusion equation. This equation can be solved in a multiblock, cell-centered, stretched grid for complex geometries. Each block can overlap with neighboring blocks. The code is implemented in Fortran 77 and has been parallelized with the standard OpenMP directives for shared-memory parallel computing.

The research code is described in section 2. We have analyzed two cases of anisotropy. The first case is an anisotropic equation discretized on uniform grids (section 3) and the second case is an isotropic equation discretized on stretched grids (section 4). Different strategies for parallelizing multigrid solvers with blockwise relaxation schemes are outlined in section 5. Finally, section 6 presents some conclusions and future research directions.

2. The numerical problem. We will study the behavior of plane smoothers on multiblock grids when solving the anisotropic diffusion equation

$$a\frac{\partial^2 u(x,y,z)}{\partial x^2} + b\frac{\partial^2 u(x,y,z)}{\partial y^2} + c\frac{\partial^2 u(x,y,z)}{\partial z^2} = f(x,y,z) \tag{2.1}$$

on a 3-D rectangular open domain Ω, with suitable boundary conditions on $\delta\Omega$, where u is an unknown function and f is a specified source function. Coefficients a, b, and c in (2.1) can, in general, be functions of the spatial variables. A finite volume discretization of (2.1) is applied on a cell-centered computational grid Ω^1, where the explicit form of the function u at the boundary $\delta\Omega$ is used to implement the Dirichlet boundary conditions. The discretization is given by the system of equations $L^1 u^1 = f^1$.

This paper studies two sources of anisotropy: anisotropic equation coefficients and nonunitary cell aspect ratios due to grid stretching. These sources reflect different situations: the former represents problems with a uniform anisotropy throughout the domain, while the latter exhibits problems with an anisotropy that varies from cell to cell. Grid stretching is commonly used in computational fluid dynamics (CFD) grid generation to pack points in regions with large solution gradients while avoiding an excess of points in more benign regions. In the present work, the stretching of the grid in a given direction is characterized by the stretching ratio (quotient between two consecutive mesh sizes in the same direction). See Figure 2.1 for examples of stretched grids. Varying local grid aspect ratios cause the mesh sizes (and, therefore, the anisotropy strength) to be different in each cell. Note that for an exponential stretching in all the directions, every cell can have a different anisotropy.

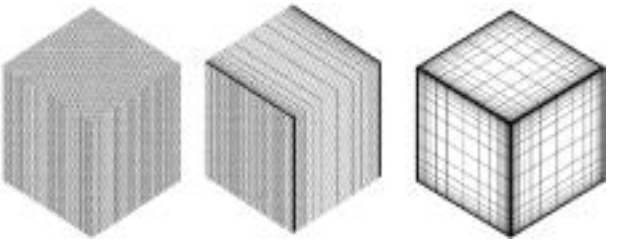

FIG. 2.1. $32 \times 32 \times 32$ *uniform grid,* $32 \times 32 \times 32$ *grid stretched along x-direction* (*stretching ratio* 1.5)*, and* $32 \times 32 \times 32$ *grid stretched along all directions* (*stretching ratio* 1.5).

2.1. The single-block algorithm. Our research code implements the *full approximation scheme* (FAS) to deal with nonlinearity. However, in the simplified (linear problem) case studied in this report the FAS performance is exactly the same as for the *correction scheme.*

A sequence of nonnested grids $\Omega^l (l = 1, \ldots, M)$ is used in the multigrid scheme where Ω^1 is the finest target grid and the rest of the grids are obtained by applying cell-centered coarsening. The coarse grids are uniform grids covering the target domain with one-cell-width margins. The finite volume discretization is defined on all the grids. Dirichlet boundary conditions are implemented by linear interpolation between two neighboring (marginal and inner) cell centers to the real boundary location. In nonstretched-grid solvers, $h_l = 2h_{l-1}$ and $h_1 = h$. $L^l u^l = f^l$ is the discretization of (2.1) on Ω^l. The following iterative algorithm represents a V(γ_1, γ_2)-cycle to solve the system $L^1 u^1 = f^1$.

ALGORITHM 1.

step 1: Apply γ_1 sweeps of the smoothing method to $L^1 u^1 = f^1$

RESTRICTION PART

for $l = 2$ to M

step 2: Compute the residual $r^{l-1} = f^{l-1} - L^{l-1} u^{l-1}$

step 3: Restrict the residual $r^l = I_l^{l-1} r^{l-1}$

step 4: Restrict the current approximation $v^l = I_l^{l-1} u^{l-1}$

step 5: Compute the right-hand side function $f^l = r^l + L^l v^l$

If $(l < M)$, then

step 6: Apply γ_1 sweeps of the smoothing method to $L^l u^l = f^l$

else

step 7: Solve the problem $L^M u^M = f^M$ on the coarsest grid

PROLONGATION PART

for $l = M - 1$ to 1

step 8: Correct the current approximation $u^l = u^l + I_{l+1}^l (u^{l+1} - v^{l+1})$

step 9: Apply γ_2 sweeps of the smoothing method to $L^l u^l = f^l$.

The intergrid operators that perform the restriction (I_l^{l-1} at Steps 3 and 4) and the prolongation (I_{l+1}^l at Step 8) connect the grid levels. The prolongation operator maps data from the coarser level to the current one while the restriction operators transfer values from the finer level to the current one. We used volume weighted summation for the restriction operator and trilinear interpolation in the computational

FIG. 2.2. *Alternating-direction plane-implicit smoother.*

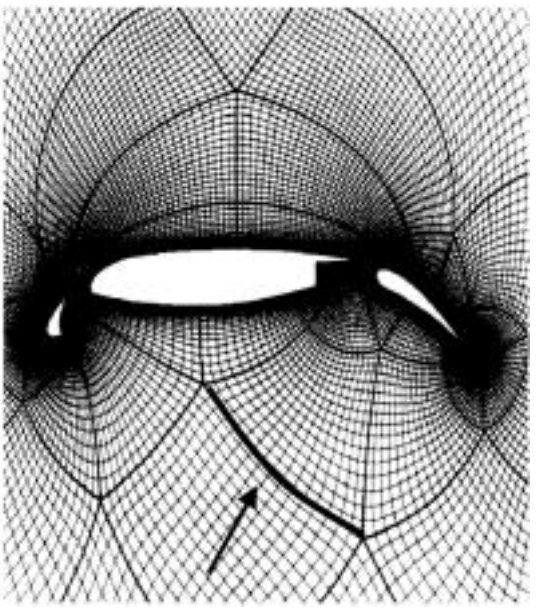

FIG. 2.3. *Multiblock grid for a multielement airfoil. Neighboring subgrids share a grid plane.*

space was used for the prolongation operator. (See [24] for detailed definitions of these intergrid operators.)

Alternating-direction plane smoothers (see Figure 2.2 for Steps 1, 6, and 9), in combination with full coarsening, have been found to be highly efficient and robust for anisotropic discrete operators on single-block grids [13].

- *Optimal work per cycle.* An exact solution of each plane is not necessary; an approximate solution obtained by a single, 2-D multigrid cycle gives the same convergence rate of the 3-D multigrid cycle as an exact solution of each plane, but in much less execution time.
- *Very low convergence factor.* The convergence rate improves as the anisotropy becomes stronger.

2.2. Multiblock grids. Multiblock grids divide domain Ω into P subdomains Ω_p $(p = 1, \ldots, P)$

$$\Omega = \cup_{p=1}^{P} \Omega_p, \tag{2.2}$$

where each subdomain Ω_p is covered with a structured grid Ω_p^1. The grid blocking is generated by the grid generation software to deal with geometric complexities (Fig-

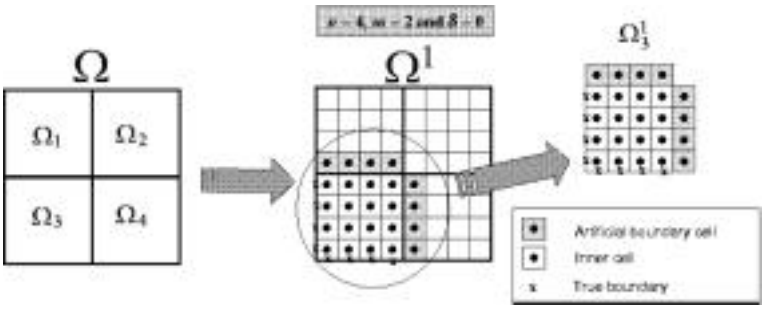

FIG. 2.4. *Data structure of a subgrid without overlap: n is the number of cells per side in every block, m is the number of blocks per side in the split, and δ is the number of overlapping cell planes.*

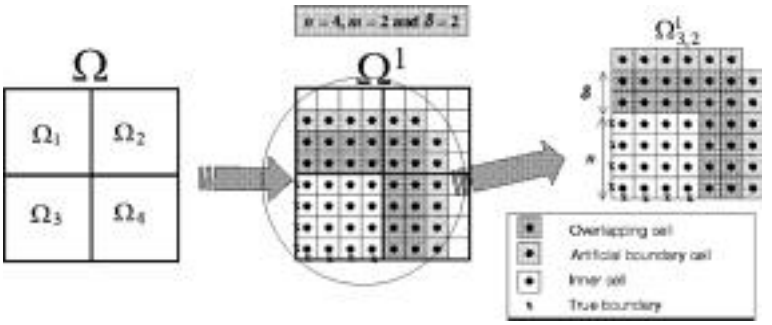

FIG. 2.5. *Data structure of a subgrid with overlap: n is the number of cells per side in every block, m is the number of blocks per side in the split, and δ is the number of overlapping cell planes.*

ure 2.3). A similar blocking is induced on the coarser grid levels. For multigrid, we construct a sequence of grids Ω^l $(l = 1, \ldots, M)$; each grid is defined as the union of P blocks:

$$\Omega^l = \cup_{p=1}^{P} \Omega_p^l; \ (l = 1, \ldots, M). \tag{2.3}$$

We assume that the grid lines are contiguous (possessing C^0 continuity) across the block interfaces (Figure 2.3).

This decomposition generates artificial boundaries within the original domain. It is necessary to apply some boundary conditions to the governing equations at these interfaces. In practice, a Dirichlet boundary condition is applied at artificial boundary cells (Figure 2.4). (Artificial boundary cells are cells adjacent to the boundary of the given block.) The values of the unknowns assigned to these boundary cells are derived from the values at the corresponding cells in the neighboring blocks. Therefore, subgrids are extended to include these artificial boundary cells.

2.3. Overlapping subdomains. Let us define the extended subgrid $\Omega_{p,\delta}^l$ which is the subgrid Ω_p^l including all the inner and artificial boundary cells, plus an external margin of δ-cells deep overlapping into the neighboring block (Figure 2.5). In the general case of a cubic (3-D) partitioning when the overlap can be different in each of the six directions, δ is a six-component vector $(\delta_x^p, \delta_x^m, \delta_y^p, \delta_y^m, \delta_z^p, \delta_z^m)$. The expressions $L_p^l u_p^l = f_p^l$ and $L_{p,\delta}^l u_{p,\delta}^l = f_{p,\delta}^l$ denote discretizations on Ω_p^l and $\Omega_{p,\delta}^l$, respectively.

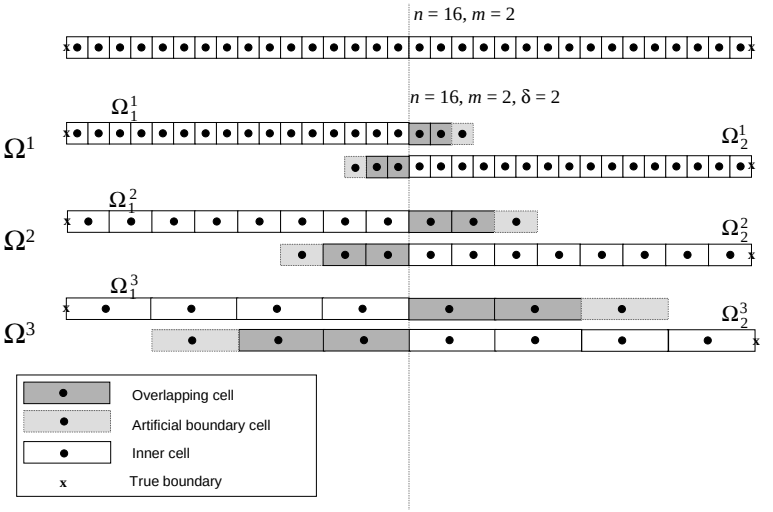

FIG. 2.6. *Grid hierarchy of overlapping subdomains with a fixed number of overlapping cells: n is the number of cells per side in every block, m is the number of blocks per side in the split, and δ is the number of overlapping cell planes.*

For simplicity, we consider a uniform overlapping (the same δ) throughout all the block interfaces. We must distinguish between the number of overlapping cells (2δ) and the physical size of the overlap ($(2\delta + 1)h$). The latter is defined as the distance between centers of the artificial boundary cells of the two extended subgrids sharing a block interface. There are two strategies for the coarse-level block overlapping:

- *Fixed overlap.* The overlap parameter δ is the same in all the levels of the multigrid hierarchy (Figure 2.6). Consequently, the overlapping space increases on the coarse levels. (It is doubled in each coarsening step.) This expansion happens because the number of the overlapping cells in the cross-interface direction remains fixed, while the size of each cell is doubled.
- *Decreasing overlap.* The number of overlapping cells in the cross-interface direction is reduced (δ is divided by 2 for each coarser level; see Figure 2.7). The overlapping space may also increase but much more slowly than in the previous case.

Again, in order to compare these strategies, we have to consider the performance (i.e., convergence rate per work unit) of the obtained algorithms. The work-count per cycle is a bit higher in the algorithm with a fixed overlap, due to the memory and computation overhead on the coarse levels. However, these two alternatives do not exhibit the same convergence rate (see discussion in section 3). Much of the efficiency of the multigrid algorithm is lost when using a decreasing overlap. Consequently, the fixed-overlap strategy was found to be globally more efficient.

The grid generation code generates a multiblock grid decomposed into subgrids in which grid lines are continuous through the block boundaries. The coarsening procedure is performed simultaneously on all the blocks. We assume that the block boundaries are visible on all the coarse grids (except possibly the coarsest grid covering the whole domain). This implies that the grid lines remain continuous on all the coarse levels. Extended subgrids are defined on all the levels at the beginning of the simulation code. The margin cells are constructed to coincide with the corresponding

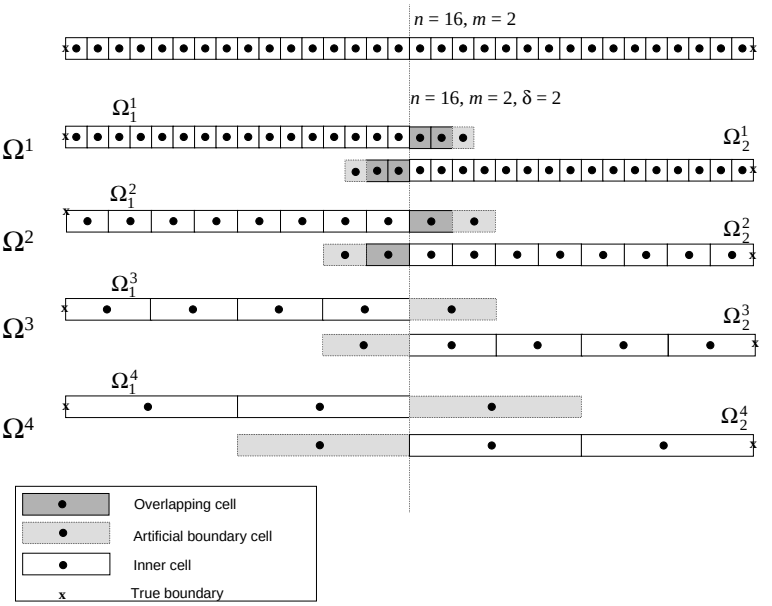

FIG. 2.7. *Grid hierarchy of overlapping subdomains with a decreasing number of overlapping cells: n is the number of cells per side in every block, m is the number of blocks per side in the split, and δ is the number of overlapping cell planes.*

inner cells in overlap regions. Note that overlapping cells may belong to several (more than 2) subgrids. This inherently implies a deterioration of the efficiency in a parallel setting.

In a general multiblock grid, there is no global definition of a line or a plane and so we have two alternatives to implement a V-cycle with an implicit smoother:

- *Domain decomposition with multigrid* applies the V-cycle inside each block.
- *Multigrid with blockwise plane smoother (multigrid with domain decomposition smoother)* applies the V-cycle on the entire multiblock domain, while the smoothers (Steps 1, 6, and 9) are performed inside each block.

2.4. Domain decomposition technique with multigrid. The following iterative algorithm represents a domain decomposition $\mathrm{V}_{\mathrm{DD}}(\gamma_1, \gamma_2)$-cycle to solve the system $L^1 u^1 = f^1$, where Ω^1 is a multiblock grid decomposed into P subgrids.

ALGORITHM 2.

for $p = 1$ to P

step 1: Apply $\mathrm{V}(\gamma_1, \gamma_2)$-cycle to solve the system $L^1_{p,\delta} u^1_{p,\delta} = f^1_{p,\delta}$ on $\Omega^1_{p,\delta}$

update 1: Update the overlap cells of neighboring blocks with values obtained in step 1.

This technique is widely known by the computational community; it is the one-level multiplicative approach to solve the problem in a domain decomposition manner [20]. This alternative does not present a high level of parallelism because blocks are updated in sequential order. Other alternatives (Jacobi or colored ordering) with a higher parallelism can be found in the domain decomposition literature. The main drawback of the one-level multiplicative approach is its slow convergence rate. The convergence of this technique cannot be better than the convergence of the Schwartz

method, which is known to be very poor. In fact, the convergence of a multigrid cycle with blockwise plane smoother will be bounded above by the convergence rate of the domain decomposition solver.

2.5. Multiblock with blockwise smoother. This approach is a priori more efficient because the multigrid algorithm is applied on the whole domain. Its efficiency and excellent parallelization potential already have been demonstrated for *isotropic* elliptic problems [4] where pointwise red-black smoothers were used. In the proposed multigrid method for multiblock grids, the plane smoothers are applied within each block because no global definition of plane or line is assumed. However, the rest of the operators (restriction and prolongation) are completely local and do not need any global information. This method is a simple modification of the one-block approach, with the smoother applied blockwise. The following iterative algorithm represents a V_{BW}-cycle with the blockwise smoother to solve the system $L^1 u^1 = f^1$, where Ω^1 is a multiblock grid.

ALGORITHM 3.

Apply γ_1 sweeps of the blockwise smoother:
  for $p = 1$ to P
    step 1: Apply the smoothing method to the system $L^1_{p,\delta} u^1_{p,\delta} = f^1_{p,\delta}$
    update 1: Update the overlap cells of neighboring blocks with $u^1_{p,\delta}$

RESTRICTION PART

for $l = 2$ to M
  for $p = 1$ to P
    step 2: Compute the residual $r^{l-1}_p = f^{l-1}_p - L^{l-1}_p u^{l-1}_p$
    step 3: Restrict the residual $r^l_p = (I^l_{l-1}) r^{l-1}_p$
    step 4: Restrict the current approximation $v^l_p = (I^l_{l-1}) u^{l-1}_p$
  for $p = 1$ to P
    update 2: Update $v^l_{p,\delta}$ and $r^l_{p,\delta}$ in the external margin cells by using v^l_p and r^l_p of neighboring blocks
  for $p = 1$ to P
    step 5: Compute the right-hand side $f^l_{p,\delta} = r^l_{p,\delta} + L^l_{p,\delta} v^l_{p,\delta}$
  If $(l < M)$, then
    Apply γ_1 sweeps of
      for $p = 1$ to P
        step 6: Apply the smoothing method to the system $L^l_{p,\delta} u^l_{p,\delta} = f^l_{p,\delta}$
        update 3: Update the overlap cells of neighboring blocks with $u^l_{p,\delta}$
  else
    step 7: Solve the coarsest-grid problem $L^l u^l = f^l$ on the whole domain
    for $p = 1$ to P
      update 4: Update $u^l_{p,\delta}$ in the external margin cells by using u^l_p of neighboring blocks

PROLONGATION PART

for $l = M - 1$ to 1
  for $p = 1$ to P
    step 8: Correct the current approximation $u^l_p = u^l_p - (I^l_{l+1})(u^{l+1}_p - v^{l+1}_p)$
  for $p = 1$ to P
    update 5: Update $u^l_{p,\delta}$ in the external margin cells by using u^l_p of neighboring blocks.
  Apply γ_2 sweeps of
    for $p = 1$ to P

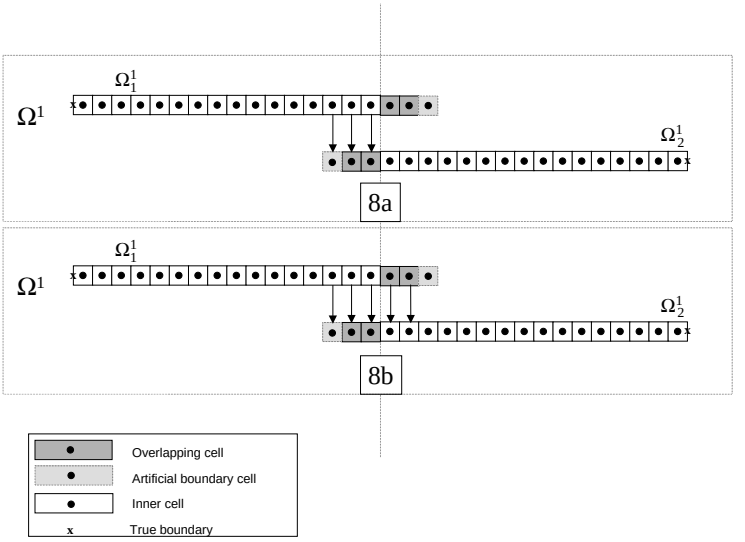

FIG. 2.8. *The algorithm presents two different update processes.*

step 9: Apply the smoothing method to the system $L^l_{p,\delta} u^l_{p,\delta} = f^l_{p,\delta}$
update 6: Update the overlap cells of neighboring blocks using $u^l_{p,\delta}$.

At Step 7, the problem is solved exactly on the coarsest grid common to all the blocks. The cost of solving the system on this grid is negligible compared with the total work.

At updates 2, 4, and 5 the external margin of overlapping cells of neighboring blocks are updated by using inner cells of the current block (Figure 2.8a). At updates 1, 3, and 6 the overlapping cells of neighboring blocks are updated by using inner and external overlapping cells of the current block (Figure 2.8b).

The algorithm includes two computation-update processes:

- Global computation of the residual, restriction, and prolongation (Steps 2, 3, 4, and 8) are performed on inner cells of Ω^l_p for all the blocks. Then the external margin of overlap cells of all the blocks are simultaneously updated (updates 2, 4, and 5).
- Within a smoothing step (Steps 1, 6, and 9), the update of the solution values at the internal and external overlap cells of neighboring blocks (updates 1, 3, and 6) is performed immediately after completing the smoothing process at the current block $\Omega^l_{p,\delta}$. The new, smoothed $u^l_{p,\delta}$ approximation is used. Thus, the order of these updates repeats the order in which the blocks are treated in the smoothing steps.

Next, we study the properties of the plane-smoother technique for multiblock grids in two situations:

- anisotropic equation discretized on uniform grids;
- isotropic equation discretized on stretched grids.

3. Anisotropic equation discretized on uniform grids. A cell-centered discretization of (2.1) on a uniform grid is given by

$$
\begin{aligned}
Lu_{i_x,i_y,i_z} \quad &\equiv \frac{\epsilon_1}{h_x^2}(u_{i_x-1,i_y,i_z} - 2u_{i_x,i_y,i_z} + u_{i_x+1,i_y,i_z}) \\
&+ \frac{\epsilon_2}{h_y^2}(u_{i_x,i_y-1,i_z} - 2u_{i_x,i_y,i_z} + u_{i_x,i_y+1,i_z}) \\
&+ \frac{1}{h_z^2}(u_{i_x,i_y,i_z-1} - 2u_{i_x,i_y,i_z} + u_{i_x,i_y,i_z+1}) = f'_{i_x,i_y,i_z},
\end{aligned} \tag{3.1}
$$

where (i_x, i_y, i_z) are coordinates of cell centers, $i_x = 1, \ldots, n_x, i_y = 1, \ldots, n_y, i_z = 1, \ldots, n_z$, $\epsilon_1 = a/c$, and $\epsilon_2 = b/c$ are the anisotropy coefficients; f' is a discretization of the continuous function $f(x, y, z)/c$; and h_x, h_y, and h_z are the mesh sizes in the x, y, and z directions, respectively. The equation is cell centered and the grid nodes are at the cell vertices. The grid may have different mesh sizes in each dimension.

A multigrid method separates the treatment of different error components: the high-frequency components of the error are reduced in relaxation (smoothing) steps and the low-frequency error components are eliminated in the coarse-grid correction. Thus, the efficiency of a multigrid solver depends strongly on the smoothing factor of the relaxation. Indeed, the derivation of a good smoother is probably the most important step when developing multigrid algorithms.

Consequently, the efficiency of our multigrid technique is determined by the smoothing properties of the blockwise plane smoother. Of course, the smoothing factor of the blockwise plane smoother approaches the factor of a pointwise smoother when the number of blocks increases. In the limit, each block consists of one cell only and the blockwise smoother reverts to a pointwise smoother. This is not a realistic case. We always assume that the number of cells per block is large. Our goal is to study the behavior of the blockwise smoothers when the number of subdomains crossed by the line of a strong anisotropy is low (up to four). This is common in CFD simulations. It is unlikely that regions of very strong anisotropies will traverse many blocks, especially for stretched grids. In such cases, textbook convergence rates could be obtained by allowing larger overlaps in the blocks with the strong anisotropy, while in other blocks the overlaps can be small. Even when an extremely strong anisotropy traverses four blocks in a line, we obtain good convergence rates when using a moderate overlap.

The smoothing properties of a blockwise plane smoother are analyzed for the model (3.1) for an anisotropy (in the equation coefficients) ranging from 1 to 10^6. The number of subdomains crossed by the strong anisotropy is either two or four. As a point of reference, we take the convergence rate obtained by a V(1,0)-cycle for the isotropic problem on a single-block grid with a Gauss–Seidel plane smoother. This cycle demonstrates a textbook multigrid convergence rate of about 0.36 (the plane-smoother convergence of reference) [13]. The convergence rate of the same V(1,0)-cycle with the pointwise Gauss–Seidel smoother is about 0.55 (the point-smoother convergence of reference).

3.1. Numerical results. Let us assume an N^3 global grid partitioned in m^3 blocks (cubic partitioning). Each block is covered with $\Omega^l_{p,\delta}$ extended subgrid. Our aim is to obtain the dependence of the convergence rate $\rho(m, n, \delta, \epsilon)$ on the following parameters:

- number of blocks per side, m;
- number of cells per block side, n $(n = \frac{N}{m})$;
- overlap parameter describing intersection between neighboring blocks, δ;
- strength of the anisotropy, ϵ.

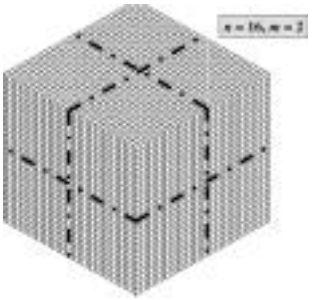

FIG. 3.1. *Rectangular uniform multiblock grid used in the numerical experiments: n is the number of cells per side in every block and m is the number of blocks per side in the split.*

3.1.1. Description of test problem. All the numerical experiments reported here deal with the numerical solution of (2.1) on the unit cube $\Omega = (0,1)\times(0,1)\times(0,1)$ with the right-hand side of

$$f(x,y,z) = -(a+b+c)\sin(x+y+z) \tag{3.2}$$

discretized on 64^3 and 128^3 multiblock grids (Figure 3.1) with different overlaps ($\delta = 0, 2, 4,$ and 8). Dirichlet boundary conditions are enforced on the boundary by evaluating

$$u(x,y,z) = \sin(x+y+z). \tag{3.3}$$

The asymptotic convergence rate monitored in the numerical tests is the asymptotic rate of reduction of the L_2 norm of the residual function in one V(1,1)-cycle.

The (x,y)-plane Gauss–Seidel smoother is applied inside each block and the blocks are updated in lexicographic order. For intergrid transfers, the same operators as defined in section 2.1 are used. The 2-D problems defined in each plane are solved by one 2-D V(1,1)-cycle with x-line Gauss–Seidel smoothing.

3.1.2. Discussion of results. Two sets of calculations were performed to determine the experimental asymptotic convergence rate as a function of the anisotropies. In the first set, two parameters (ϵ_1 and ϵ_2) are varied, and in the second, just one parameter (ϵ_1) is varied while the second parameter (ϵ_2) remains equal to 1.

- Both ϵ_1 and ϵ_2 are varied for the single block case ($m = 1$) and two multiblock cases ($m = 2$ and $m = 4$). Different overlaps between blocks ($\delta = 0$, 1, and 2) are examined. The upper graphs in Figures 3.2 and 3.3 show the results for 64^3 ($N = 64$) and 128^3 ($N = 128$) grids, respectively.
- Only the parameter ϵ_1 is varied for the single block case ($m = 1$), and two multiblock cases ($m = 2$ and $m = 4$). Different overlaps between blocks ($\delta = 0$, 1, and 2) are examined. The lower graphs in Figures 3.2 and 3.3 show these results for 64^3 ($N = 64$) and 128^3 ($N = 128$) grids, respectively.

All the graphs exhibit a similar behavior with respect to δ and ϵ. We can distinguish three different cases:

- In the single-block case ($m = 1$), the convergence rate decreases quickly for an anisotropy larger than 100, tending to (nearly) zero for very strong anisotropies. In fact, the convergence rate per V(1,1)-cycle decreases quadratically with increasing anisotropy strength, as was predicted in earlier work [13].

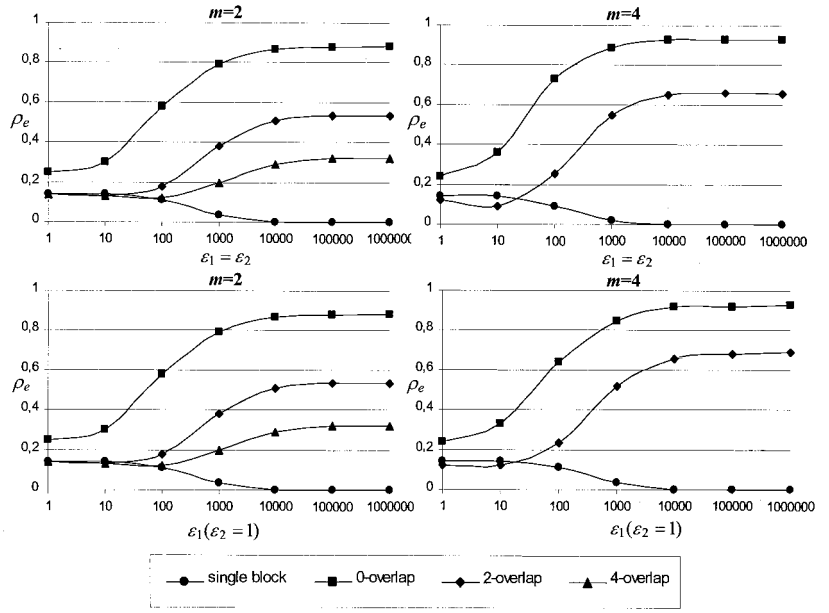

FIG. 3.2. *Experimental convergence factors, ρ_e, of one 3-D V (1, 1)-cycle with blockwise (x, y)-plane smoother in a 64^3 grid with respect to the anisotropy strength (ϵ_1 and ϵ_2) for different values of the overlap (δ) and the number of blocks per side (m).*

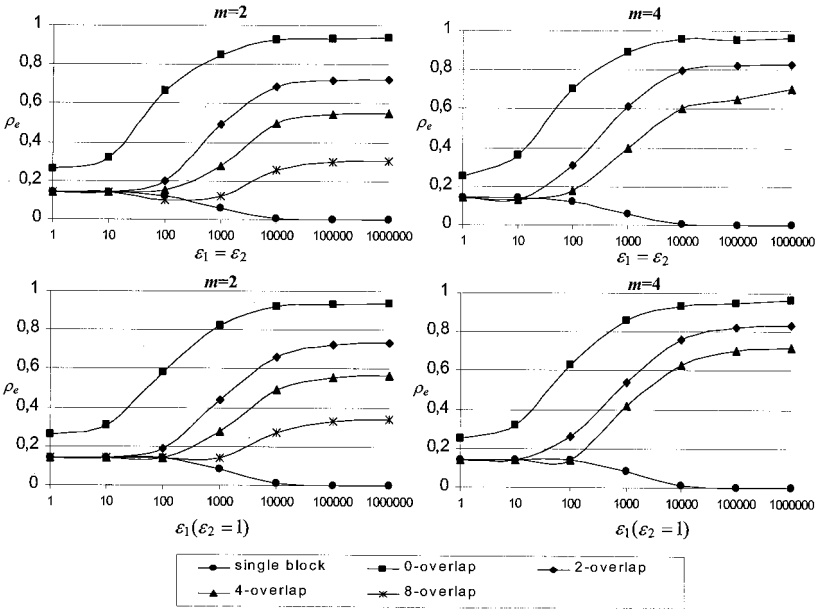

FIG. 3.3. *Experimental convergence factors, ρ_e, of one 3-D V(1, 1)-cycle with blockwise (x, y)-plane smoother in a 128^3 grid with respect to the anisotropy strength (ϵ_1 and ϵ_2) for different values of the overlap (δ) and the number of blocks per side (m).*

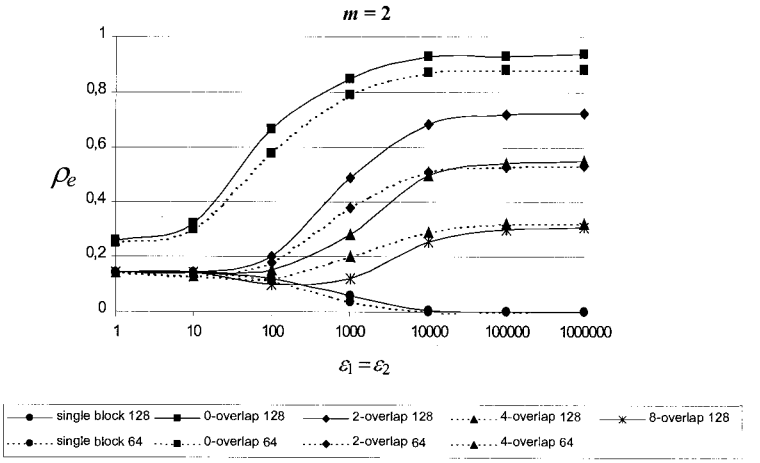

FIG. 3.4. *Experimental convergence factors, ρ_e, of one 3-D $V(1,1)$-cycle with blockwise (x,y)-plane smoother in 128^3 and 64^3 grids with respect to the anisotropy strength (ϵ_1 and ϵ_2) for different values of the overlap (δ) and 2 blocks per side ($m = 2$).*

- If the domain is blocked with the minimal overlapping ($m > 1$ and $\delta = 0$), the convergence rate for small anisotropies ($1 \leq \epsilon \leq 100$) is similar to that obtained with a single block with a pointwise smoother on the whole domain (i.e., point-smoother convergence of reference, which is about 0.55^2). It increases to a fixed value for larger anisotropies. This limit is defined by the convergence in the corresponding domain decomposition algorithm. The convergence rate for strong anisotropies gets closer to one for finer grids (compare Figures 3.2 and 3.3 for the same m and δ but different N).
- If the domain is blocked with larger overlapping ($m > 1$ and $\delta \geq 2$), the convergence rate for small anisotropies is similar to that obtained without blocking on the whole domain (i.e., plane-smoother convergence of reference which is about 0.36^2) and increases to the fixed domain decomposition limit for very strong anisotropies. The asymptotic value for strong anisotropies gets closer to one for smaller overlaps and finer grids (compare Figures 3.2 and 3.3 for the same m but different δ and N).

Numerical results show the following properties of the convergence behavior:

- Convergence is very poor with the minimal overlap ($\delta = 0$), but it improves rapidly with larger overlaps ($\delta \geq 2$).
- If we compare the results for 64^3 and 128^3 and $m = 2$ (Figures 3.2 and 3.3), we realize that the convergence rate for large anisotropies is bounded if the overlap is increased in proportion to the size of the block, i.e., $\rho(2, n, \delta, \epsilon) \approx \rho(2, 2n, 2\delta, \epsilon)$ (see Figure 3.4). Therefore, mesh-independent convergence rates can be obtained for large anisotropies by increasing the number of overlap cells in proportion to the number of cells per side in the subgrid. The amount of extra work (in relative terms) to maintain the convergence rate at a fixed level does not increase for finer grids.
- For 17-cell overlap ($\delta = 8$), 2 blocks per side ($m = 2$), and 32^3 cells per block ($n = 32$), we obtain for all anisotropies (nearly) the same convergence rate as for the isotropic case without blocking (plane-smoother convergence of reference). This overlap results in only a 25 percent computation and memory

penalty (these results are not shown in the figures).
- The smoothing factor for very strong anisotropies degenerates with an increasing number of blocks m because the blockwise smoother tends to be a pointwise smoother.

3.2. Analysis. The full-space Fourier analysis is known as a simple and very efficient tool to predict convergence rates of multigrid cycles in elliptic problems. However, this analysis is inherently incapable of accounting for boundary conditions. In isotropic elliptic problems where boundary conditions affect just a small neighborhood near the boundary, this shortcoming does not seem to be very serious. The convergence rate of a multigrid cycle is mostly defined by the relaxation smoothing factor in the *interior* of the domain, and therefore predictions of the Fourier analysis prove to be in amazing agreement with the results of numerical calculations. In the presence of a strong anisotropy, boundary conditions have a stronger effect on the overall convergence factor that a multigrid cycle can achieve. If the strong anisotropy direction aligns with the grid (as in (3.1)) and the domain is not blocked, then the smoothing factor calculated by the full-space Fourier analysis still predicts well the multigrid cycle convergence rate. In the case of nonalignment, however, the full-space analysis cannot reflect the poorness of the coarse-grid correction, which slows down the convergence (see [5, 3]) and so the half-space analysis must be used instead. The multiblock structure brings additional difficulties: in strongly anisotropic problems on decomposed domains, artificial boundaries have a large effect on the solution in the interior (e.g., on the relaxation stage), making even the half-space analysis inadequate. In the extreme case of a very large anisotropy, the behavior of a plane smoother is similar to that exhibited by a one-level overlapping Schwartz method [20]. The following analysis is an extension of the half-space Fourier analysis, taking into account the influence of a second boundary.

We will consider the discrete equation (3.1) on a layer $(i_x, i_y, i_z) : 0 \le i_x \le N$, $-\infty < i_y, i_z < \infty$. This domain is decomposed by overlapped subdomains in an x-line partitioning. The boundaries of all the subdomains are given by the set of cell planes orthogonal to the x-coordinate axis. Boundary conditions are represented by one 2-D Fourier component at a time. In this way, the original 3-D problem is translated into a one-dimensional (1-D) problem where frequencies of the Fourier component are considered parameters. When estimating the smoothing factor for the 3-D alternating-direction plane smoother, we analyze only the high-frequency Fourier components. A 2-D Fourier component $e^{i(\theta_y i_y + \theta_z i_z)}$, $(|\theta_y| \le \pi;\ |\theta_z| \le \pi)$ is a high-frequency component if the absolute value of either θ_y or θ_z is greater than or equal to $\pi/2$.

We are given values of $N, m, n, \delta, \epsilon_1$ and ϵ_2 (see definitions in section 3.1), and we let the integers $i_x = 0, \ldots, N$ numerate the cells. We also label the blocks with numbers from 1 to m. To predict the smoothing factors observed in our numerical experiments, we assume that the strongest anisotropy direction is aligned with the x axis, i.e., $\epsilon_1 > \epsilon_2 \ge 1$. The actual boundary separating two neighboring blocks is placed *between* the cell centers. Recall that the overlap parameter δ corresponds to the case where the width of the domain shared by two overlapped blocks is $(2\delta + 1)h$. The left boundary condition of the first block is defined at the center of the actual (not artificial) left boundary cell $l_1 = 0$; the right boundary condition is defined at $r_1 = n + \delta + 1$. Each block k $(k = 2, \ldots, m-1)$ has two (artificial) boundary planes settled in the interior of the domain: the center of the left boundary cell is located at $l_k = (k-1)n - \delta$ and the center of the right boundary cell is at $r_k = kn + \delta + 1$. The left boundary cell of the last mth block is centered at $l_m = (m-1)n - \delta$ and

the center of the right boundary cell is at $r_m = N$. One application of the 3-D alternating-direction plane smoother on the kth block includes three plane-relaxation sweeps. In the analysis, we assume that in the first sweep, the smoother proceeds in the x direction from $i_x = l_k$ to $i_x = r_k$, solving the corresponding y-z-plane problems exactly. In numerical tests, just one V(1,1)-cycle is applied to approximate the 2-D solutions. The second and third sweeps are performed in the y and z directions, respectively.

Let us consider (3.1) with the initial approximation $\tilde{u}_{i_x,i_y,i_z}$ and the source function f'_{i_x,i_y,i_z} given in the form

$$\begin{aligned}
&\tilde{u}_{i_x,i_y,i_z} = A(i_x)e^{i(\theta_y i_y + \theta_z i_z)},\\
&f'_{i_x,i_y,i_z} = F(i_x)e^{i(\theta_y i_y + \theta_z i_z)},\\
&i_x = 0,\dots,N,
\end{aligned}$$

where A and F are $(N+1)$-dimensional complex-valued vectors. $A(i_x)$ and $F(i_x)$ represent the corresponding amplitudes of the Fourier component at i_x.

Let $E(i_x)$ be the amplitude of the algebraic error in the kth block after updating the solution values at the overlap $[l_k,(k-1)n]$. We have $E(i_x) = U(i_x) - A(i_x)$, where $U(i_x)$ is the amplitude of the exact discrete solution

$$\begin{aligned}
&U(0) = U_0, \qquad U(N) = U_1,\\
&\epsilon_1 U(i_x - 1) + \mu_1 U(i_x) + \epsilon_1 U(i_x + 1) = F(i_x),\\
&i_x = 1,\dots,N-1,\\
&\mu_1 = -2\epsilon_1 + 2\epsilon_2\Big(\cos\theta_y - 1\Big) + 2\Big(\cos\theta_z - 1\Big),
\end{aligned}$$

with given boundary conditions U_0 and U_1.

In the first sweep, the new amplitude $E_1(i_x)$ is defined from

$$\begin{aligned}
&E_1(l_k) = E(l_k), \qquad E_1(r_k) = E(r_k),\\
&\epsilon_1 E_1(i_x - 1) + \mu_1 E_1(i_x) = -\epsilon_1 E(i_x + 1),\\
&i_x = l_k + 1,\dots,r_k - 1.
\end{aligned} \tag{3.4}$$

After the second sweep the new amplitude $E_2(i_x)$ is the solution of the following system of equations:

$$\begin{aligned}
&E_2(l_k) = E(l_k), \qquad E_2(r_k) = E(r_k),\\
&\epsilon_1 E_2(i_x - 1) + \mu_2 E_2(i_x) + \epsilon_1 E_2(i_x + 1) = -\epsilon_2 e^{i\theta_y} E_1(i_x),\\
&i_x = l_k + 1,\dots,r_k - 1,\\
&\mu_2 = -2\epsilon_1 + \epsilon_2\Big(e^{-i\theta_y} - 2\Big) + 2\Big(\cos\theta_z - 1\Big).
\end{aligned} \tag{3.5}$$

Finally, the amplitude $E_3(i_x)$ of the approximate solution obtained after the third sweep is found from the following system of equations:

$$\begin{aligned}
&E_3(l_k) = E(l_k), \qquad E_3(r_k) = E(r_k),\\
&\epsilon_1 E_3(i_x - 1) + \mu_3 E_3(i_x) + \epsilon_1 E_3(i_x + 1) = -e^{i\theta_z} E_2(i_x),\\
&i_x = l_k + 1,\dots,r_k - 1,\\
&\mu_3 = -2\epsilon_1 + 2\epsilon_2\Big(\cos\theta_y - 1\Big) + \Big(e^{-i\theta_z} - 2\Big).
\end{aligned} \tag{3.6}$$

The smoothing factor of the alternating-direction plane smoother step is the ratio between the L_2 norms of high-frequency errors before and after the step is performed. This analysis is very rigorous and especially useful for predicting the convergence in full multigrid (FMG) algorithms (see, e.g., [2]). In these algorithms, where only a few smoothing steps are performed on each grid and the initial error is basically the difference between solutions on successive grids, this analysis allows a direct estimation of the algebraic error at any stage of the algorithm.

To estimate asymptotic convergence rates, the following simplifications can be adopted.

3.2.1. Simplifications in different regimes. There are two processes affecting the amplitude of high-frequency error components. The first is the smoothing in the interior of the blocks. The effect of this smoothing is very similar to that on the single-block domain. It is well described by the smoothing factor, SM, derived from the usual full-space Fourier mode analysis (see [2, 13, 24]). If the problem is essentially isotropic ($\epsilon_1 = O(1)$), then each of the three sweeps (3.4)–(3.6) contributes to the alternating-direction plane-relaxation smoothing factor. This smoothing factor proves to be very small ($SM = 1/\sqrt{125} \approx 0.089$ in the pure isotropic problem), but the overall convergence rate in a V-cycle is worse because it is dictated by the coarse-grid correction. To predict the asymptotic convergence rate in a V-cycle, the two-level analysis should be performed. In problems with a moderate anisotropy in the x direction ($\epsilon_1 = O(h^{-1})$), the high-frequency error is reduced mainly in the third sweep (3.6) and the smoothing factor approaches the 1-D factor $SM = 1/\sqrt{5}$ (see [13]). In strongly anisotropic problems ($\epsilon_1 = O(h^{-2})$), the third sweep reduces the smooth error components as well, actually solving the problem rather than just smoothing the error.

The second process influencing the high-frequency error is the error propagation from incorrectly specified values at the block boundaries. The distance on which this high-frequency boundary error penetrates inside blocks strongly depends on the anisotropy. It can be estimated by considering a semi-infinite problem associated with the sweep (3.6). The left-infinite problem stated for the kth block assumes a zero right-hand side and omits the left boundary condition

$$E(r_k) = B, \qquad E_2(i_x) = 0, \qquad -\infty < i_x < r_k.$$

The solution of this problem is

$$E_3(i_x) = B\lambda_l\Big(\theta_y, \theta_z\Big)^{i_x - r_k},$$

where $\lambda_l(\theta_y, \theta_z)$ satisfies

$$\epsilon_1\lambda^{-1} + \mu_3 + \epsilon_1\lambda = 0, \qquad |\lambda| \geq 1. \tag{3.7}$$

For high-frequencies under the assumption $\epsilon_1 > \epsilon_2 \geq 1$,

$$\Big|\lambda_l\Big(\theta_y, \theta_z\Big)\Big| \geq \Lambda_l = \Big|\lambda_l\Big(0, \pi/2\Big)\Big|.$$

The right-infinite problem is similarly solved, providing

$$\Big|\lambda_r\Big(\theta_y, \theta_z\Big)\Big| \leq \Lambda_r = \Big|\lambda_r\Big(0, \pi/2\Big)\Big|,$$

where $\lambda_r(\theta_y, \theta_z)$ is a root of (3.7) satisfying $|\lambda| \leq 1$.

The roots of quadratic equation (3.7) for $\theta_y = 0$ and $\theta_z = \frac{\pi}{2}$ are given by

$$\Lambda_l = \left| -\frac{\hat{\mu}_3}{2} + \sqrt{\frac{\hat{\mu}_3^2}{4} - 1} \right| \quad \text{and}$$

$$\Lambda_r = \Lambda_l^{-1} = \left| -\frac{\hat{\mu}_3}{2} - \sqrt{\frac{\hat{\mu}_3^2}{4} - 1} \right|,$$

where

$$\hat{\mu}_3 = -2 - \frac{(i+2)}{\epsilon_1}.$$

Thus, if

$$\Lambda_r^{r_k - l_k - 2\delta - 1} \ll \Lambda_r^{2\delta+1},$$

i.e., the influence of the far boundary (e.g., r_{k+1} boundary on r_k), is negligible in comparison with the influence of the nearby boundary (l_{k+1} on r_k), then the high-frequency error amplitude reduction factor, RF, is estimated as the ratio between the amplitudes on the right boundary r_k before and after the plane-smoother step is performed. After relaxing the kth block, the amplitude at l_{k+1} is about $B\Lambda_l^{-2\delta-1}$ and after relaxing the $(k+1)$-th block, the estimated amplitude at r_k is $B(\Lambda_r/\Lambda_l)^{2\delta+1} = B(\Lambda_r)^{4\delta+2}$. Thus, the reduction factor could be approximated by

$$RF \approx \left(\Lambda_r\right)^{4\delta+2}. \tag{3.8}$$

If the anisotropy is strong ($\epsilon_1 = O(h^{-2})$), both boundaries (far and nearby) affect the error amplitude reduction factor. If the number of blocks m is not too large, then the corresponding problem includes m coupled problems (like 3.6) with zero right-hand sides. This multiblock problem can directly be solved. For the two-block partition it results in

$$RF = \left(\frac{\Lambda_l^{n-\delta-1} - \Lambda_r^{n-\delta-1}}{\Lambda_l^{n+\delta} - \Lambda_r^{n+\delta}} \right)^2. \tag{3.9}$$

In all the numerical tests described in sections 3.1–3.2, the V(1,1)-cycle convergence rate can be predicted by the (squared) smoothing factor, which is calculated as the maximum value of SM or RF.

3.2.2. Relation to domain decomposition convergence theory. When the anisotropy is very strong and the number of blocks is much greater than two, convergence rates observed in numerical tests are well described by the domain decomposition convergence theory [20]. In this case, we are not interested in the smoothing properties of the 3-D smoother but in its resolution properties because it becomes an exact method to solve N noncoupled 2-D problems (when ϵ_1 and ϵ_2 are very large) or N^2 1-D problems (when only ϵ_1 is large). In fact, asymptotic convergence rates for large anisotropies are in good agreement with convergence rates predicted for 1-D or 2-D domain-decomposition Schwartz methods.

TABLE 3.1

Experimental, ρ_e, and analytical, ρ_a, convergence factors of a single 3-D $V(1,1)$-cycle with blockwise (x,y)-plane Gauss–Seidel smoother ($2 \times 2 \times 2$ partition) versus anisotropy strength, width of the overlap, and the block size.

ϵ_1	δ	$n = 64$		$n = 128$

	2	0.18	0.14	0.19	0.14
	4	0.12	0.14	0.14	0.14
	8			0.14	0.14

3.2.3. Comparison with numerical tests. For simplicity, we consider the V(1,1)-cycle with only z-planes used in the smoothing step. The assumption that $\epsilon_1 > \epsilon_2 \geq 1$ validates this simplification. The predicted smoothing factor for this relaxation is $SM = 1/\sqrt{5}$ [13]. In numerical calculations for isotropic problems on single-block domains, the asymptotic convergence rate was 0.14 per V(1,1)-cycle, which is very close to the value predicted by the two-level Fourier analysis (0.134).

The next case we present is the comparison of the analytical predictions and the numerical results for the V(1,1)-cycle convergence rates for different anisotropies for the domain decomposed into two blocks in each direction. In this case, for predicting the reduction factor, RF, analytical expression (3.9) can be used. The formula for the asymptotic convergence rate ρ_a is

$$\rho_a = \max\Big(RF^2, 0.14\Big). \tag{3.10}$$

Table 3.1 presents a representative sample of experiments for the case $\epsilon_1 \gg \epsilon_2 = 1$. In this table, ρ_e corresponds to asymptotic convergence rates observed in the numerical experiments, while ρ_a is calculated by means of (3.10). The results demonstrate nearly perfect agreement.

The asymptotic convergence rate deteriorates as the number of blocks grows. For a multiblock partition, an accurate value of RF can still be calculated. (In the case when the domain is partitioned into m blocks, it will be the spectral radius of a $(m-1)$-by-$(m-1)$ matrix.) We decided, however, to present another, simplified, methodology. Here the convergence upper bound, ρ_{DD}, which is the asymptotic convergence rate in the multiblock domain decomposition solver is estimated numerically as $\rho_{DD} = \rho_e$ for $\epsilon_1 = \infty$. The reduction factor RF is calculated from expression (3.8), and the predicted convergence rate is

$$\rho_a = \max\Big(\min(RF^2, \rho_{DD}), 0.14\Big). \tag{3.11}$$

Practically, this formula implies that for small anisotropies ($\epsilon_1 \leq 10$) and for very large anisotropies ($\epsilon_1 \geq 10^4$) the asymptotic convergence rate is estimated by

TABLE 3.2
Moderate anisotropy: experimental, ρ_e, and analytical, ρ_a, convergence factors versus overlap parameter, block size, and number of blocks.

ϵ_1	δ	ρ_a	ρ_e			
			$n=16$	$n=32$		$n=64$
			$m=4$	$m=2$	$m=4$	$m=2$
10^2	0	0.56	0.64	0.58	0.63	0.58
	2	0.14	0.23	0.18	0.26	0.19
10^3	0	0.83	0.85	0.79	0.86	0.82
	2	0.40	0.52	0.38	0.54	0.44
	4	0.19		0.20	0.42	0.28

some constants calculated numerically. The analytical expression is correct in the range of moderate anisotropies. Notice that RF depends only on two parameters (ϵ_1 and δ) which means that estimate (3.11) provides a good prediction only if $n \gg \delta$. Table 3.2 compares this analytical prediction with the results of numerical tests for some moderate anisotropies and different values of the overlap parameter δ.

We can now discuss the different convergence behavior exhibited by fixed and decreasing overlaps. A decreasing overlap introduces errors on the coarse grids which become smooth errors on the fine grids and, therefore, cannot be eliminated by the smoother on the fine grids. This is especially true in cases of weak to moderate anisotropy when the reduction factor is defined by smoothing properties rather than by the properties of a domain decomposition solver. The convergence in this case is still bounded above by the convergence rate of the domain decomposition solver, but we lose a lot of efficiency, especially because the domain decomposition solver is sensitive to such issues as number of blocks and overlap size.

For a given m and δ/n ratio, if the domain decomposition solver is efficient enough, then it is possible to use the same δ/n ratio on coarser grids rather than using a fixed number of cells in the overlap regions. However, adopting a fixed δ/n ratio as a general rule for overlapping reduces the solver down to the level of a domain decomposition solver. In the case of fixed overlap, the domain decomposition solver efficiency is just an upper bound on the convergence rate. The bound is sharp only for huge anisotropies (huge in strength and relevant region size).

4. Isotropic equation discretized on stretched grids. In this section, we study numerically the behavior of plane-implicit smoothers for multiblock grids when the anisotropy is not uniform but exponential. For stretched grids, each cell can have a unique level of anisotropy (see Figure 4.1). The stretching is applied near the boundary to mimic grids used in CFD simulations.

Consider an N^3 global grid partitioned into m^3 blocks (cubic partitioning)(Figure 4.1). Again, each block is supplied with an extended $\Omega^l_{p,\delta}$ subgrid. Our goal is to analyze the dependence of the convergence rate $\rho(m, n, \delta, \alpha)$ on the following parameters:

- number of blocks per side, m;
- number of grid cells per block side, n;
- overlap parameter, δ;
- stretching ratio, $\alpha = \frac{h_{i+1}}{h_i}$.

4.1. Description of test problem. All the numerical experiments reported here deal with the numerical solution of (2.1) on the unit cube $\Omega = (0,1)\times(0,1)\times(0,1)$ with the right-hand side and boundary conditions given by expressions (3.2) and (3.3). The discretization is done on 64^3 and 128^3 rectangular stretched multiblock grids with

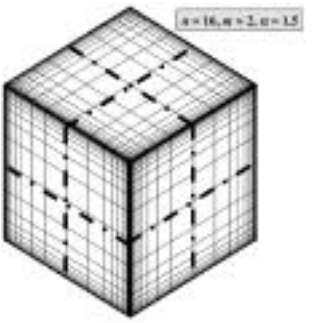

FIG. 4.1. *Rectangular stretched multiblock grid used in the numerical experiments: n is the number of cells per side in every block, m is the number of blocks per side in the split, and α is the stretching ratio.*

various overlaps ($\delta = 0, 2, 4, 8$).

As before, we tested a FAS version of V(1,1)-cycle with the blockwise alternating-direction plane smoother, unweighted solution averaging, volume-weighted residual averaging, and trilinear correction interpolation. The solutions of the 2-D problems in each plane are approximated by one 2-D V(1,1)-cycle employing alternating-direction line Gauss–Seidel smoothing. The asymptotic convergence rates observed in the numerical tests are presented in Figures 4.2 and 4.3.

4.2. Discussion of results. Numerical simulations were performed to obtain the experimental convergence rate with respect to the stretching ratio, α. The single-block and multiblock grids ($m = 1, 2$, and 4) with different overlaps ($\delta = 0, 2$, and 4) were tested. Figure 4.2 shows the results for a 64^3 grid, and Figure 4.3 for a 128^3 grid. The results can be summarized in the following two observations:

- With a 2^3 partitioning, even the minimum overlap ($\delta = 0$) is enough to exhibit good convergence rates. The results for a multiblock grid with overlap of $\delta = 2$ match with the results obtained for the single-block anisotropic case. That is, the convergence rate tends toward zero as the anisotropy increases.
- With a 4^3 partitioning, results are not as good. With the minimal overlap ($\delta = 0$), the convergence rate degrades for finer grids. However, with a larger overlap ($\delta = 2$), the convergence rate again tends towards the convergence rate demonstrated in single-block grid anisotropic cases.

5. Parallel implementation of multigrid technique. Blockwise smoothers may also be used to facilitate the parallel implementation of a multigrid method on a single-block (rectangular) grid. Notice that in this case there are global lines and planes and we are interested in blockwise smoothers only for purposes of parallel computing. To get a parallel implementation of a multigrid method, one can adopt one of the following strategies (see, e.g., [14]).

- *Domain decomposition*: A domain decomposition is applied first. Then, a multigrid method is used to solve problems inside each block.
- *Grid partitioning*: A multigrid method is used to solve the problem in the whole grid.

Domain decomposition is easier to implement and implies fewer communications (better parallel properties), but it has a negative impact on the convergence rate. On the other hand, grid partitioning implies more communication but it retains the convergence rate of the sequential algorithm (better numerical properties).

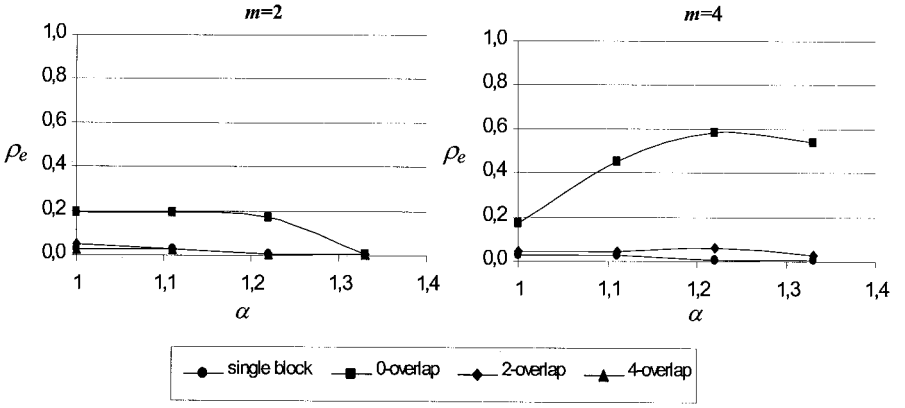

FIG. 4.2. *Experimental convergence factors, ρ_e, of one 3-D $V(1,1)$-cycle with blockwise alternating-direction plane smoother in a 64^3 grid with respect to the stretching ratio (α) for different values of the overlap (δ) and number of blocks per side (m).*

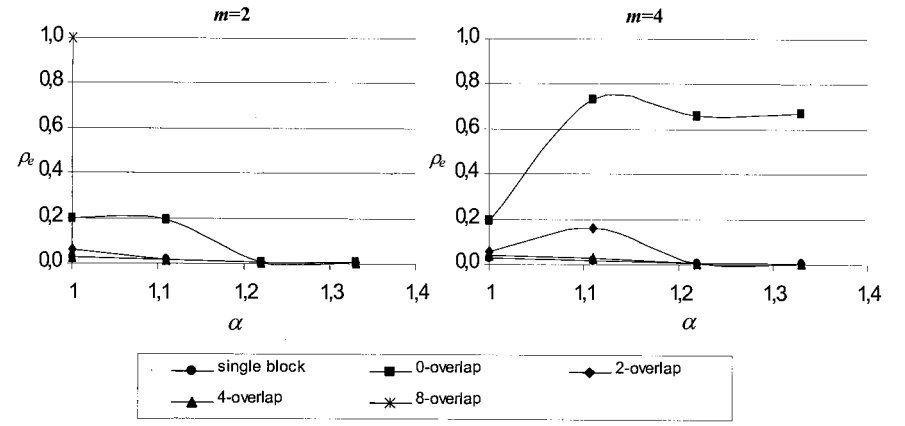

FIG. 4.3. *Experimental convergence factors, ρ_e, of one 3-D $V(1,1)$-cycle with blockwise alternating-direction plane smoother in a 128^3 grid with respect to the stretching ratio (α) for different values of the overlap (δ) and number of blocks per side (m).*

From a parallel code designer point of view, our approach is somewhere between domain decomposition and grid partitioning. Blockwise plane smoothers appear to be a tradeoff between architectural and numerical properties (domain decomposition and grid partitioning).

- *Convergence rate.* For the isotropic case the convergence rate is equal to that obtained with grid partitioning, and it approaches the convergence rate of a domain decomposition method as the anisotropy becomes stronger.
- *Communications.* Although higher than in domain decomposition, the number of communications is lower than in grid-partitioning algorithms.

However, it should be noted that due to the lack of definition of global planes and lines, grid partitioning is not viable in general multiblock grids.

Therefore, the use of blockwise smoothers is justified to facilitate parallel processing when the problem does not possess a strong anisotropy crossing the whole domain. In such a case, the expected convergence rate (when using moderate overlaps

at the block interfaces crossed by a strong anisotropy) is similar to the rate achieved with grid partitioning, but the number of communications is considerably lower.

6. Conclusions and future directions. We have analyzed the smoothing properties of blockwise plane smoothers for multiblock grids. For simplicity, our analysis and test problems have focused on rectangular grids, although the results can be extrapolated to more general multiblock grids. As a point of reference, we take the convergence rate obtained by the plane smoother in the isotropic problem on a single-block grid.

Typically, in true CFD simulations, there are no very large anisotropies crossing the whole domain. The regions of very strong anisotropies are narrow (usually where there are thin boundary layers). Therefore, it is unlikely that such a region will be divided into many blocks in the direction normal to the thin layer. Anisotropies crossing one, two, or up to four blocks are very practical, especially for stretched grids. For these cases, the overall convergence rate is still very good with a moderate overlap, as has been demonstrated in the present report.

The blockwise plane method works as a smoother for low anisotropies and becomes a domain decomposition solver for very large anisotropies. We have obtained an analytical expression that predicts the smoothing properties of the blockwise plane-implicit smoother with respect to the block size, the amount of overlap, and the strength of the anisotropy. The expression has been validated with numerical experiments.

As an example, for a line of strong anisotropy partitioned into two blocks, the multigrid convergence of reference can be obtained with an overlap of just 25 percent of the number of cells in the block, and this convergence rate can be maintained by increasing linearly the number of overlapping cells with the problem size. In actual problems, a much smaller overlap is likely to be sufficient.

We have also analyzed the case of an isotropic equation on grids which are stretched near to the boundaries, a common case in practical CFD problems. This case is even more favorable, as the convergence rate obtained for the single-block grid is maintained in multiblock grids with very small overlaps, tending to zero with increasing anisotropy strength.

Blockwise alternating-direction plane relaxation methods are found to be robust smoothers and their use should be considered for inclusion in the next generation of production CFD codes. A robust multiblock code should check whether there is an anisotropy crossing a block interface. If so, an extended subgrid overlapping with the neighboring block should be constructed. A multiblock strategy opens the possibility of using an adaptive smoother—that is, different smoothers for different portions of the domain, where choice of the smoother is based on a minimization of operation count while retaining optimum smoothing performance. An example of this would be using a plane-implicit smoother in the portions of the domain that have strong anisotropies while using a point smoother in the regions that are isotropic.

The present code updates the blocks following the lexicographic ordering. However, in order to run the code on a parallel computer, so that each processor solves a set of blocks, the update ordering must present a higher parallelism grade. The next step will be to analyze the convergence rate and architectural properties of red-black (or general-colored) ordering of the blocks. We intend to continue the work on the block-structured algorithms. In particular, we will study the applicability of blocked

alternating-direction plane methods as multigrid smoothers for convection-dominated problems and more complicated PDEs.

Acknowledgments. The results of the simulations were obtained on the Silicon Graphics Incorporated Origin 2000 operated by the Aerodynamic and Acoustic Methods Branch at the NASA Langley Research Center.

AN EFFICIENT PRIMAL-DUAL INTERIOR-POINT METHOD FOR MINIMIZING A SUM OF EUCLIDEAN NORMS*

KNUD D. ANDERSEN†, EDMUND CHRISTIANSEN‡, ANDREW R. CONN§, AND MICHAEL L. OVERTON¶

Abstract. The problem of minimizing a sum of Euclidean norms dates from the 17th century and may be the earliest example of duality in the mathematical programming literature. This nonsmooth optimization problem arises in many different kinds of modern scientific applications. We derive a primal-dual interior-point algorithm for the problem, by applying Newton's method directly to a system of nonlinear equations characterizing primal and dual feasibility and a perturbed complementarity condition. The main work at each step consists of solving a system of linear equations (the Schur complement equations). This Schur complement matrix is not symmetric, unlike in linear programming. We incorporate a Mehrotra-type predictor-corrector scheme and present some experimental results comparing several variations of the algorithm, including, as one option, explicit symmetrization of the Schur complement with a skew corrector term. We also present results obtained from a code implemented to solve large sparse problems, using a symmetrized Schur complement. This has been applied to problems arising in plastic collapse analysis, with hundreds of thousands of variables and millions of nonzeros in the constraint matrix. The algorithm typically finds accurate solutions in less than 50 iterations and determines physically meaningful solutions previously unobtainable.

1. Introduction.

A problem which arises in many applications is to minimize a sum of Euclidean vector norms, i.e.,

$$D: \quad \min \left\{ \sum_{i=1}^{n} \|\boldsymbol{z}_i\| \ : \ \boldsymbol{y} \in \Re^m; \ \boldsymbol{z}_i \in \Re^d; \ \boldsymbol{A}_i^T \boldsymbol{y} + \boldsymbol{z}_i = \boldsymbol{c}_i, \ i = 1, \ldots, n \right\},$$

where $\boldsymbol{A}_i \in \Re^{m \times d}$, $\boldsymbol{c}_i \in \Re^d$, $i = 1, \ldots, n$, are given. In most applications $d = 2$ or $d = 3$ so that the terms in the sum are norms of vectors in a two or three-dimensional Euclidean space. If $d = 1$, the problem D is equivalent to a linear program (LP). The minimization objective is convex but not differentiable at any point where some $\boldsymbol{z}_i = 0$.

The sum of norms problem, D, has a long and interesting history. The special case $d = m = 2$, $n = 3$, $\boldsymbol{A}_i = \boldsymbol{I}$, was studied by Fermat in the 17th century. This amounts to finding the point in $\Re^2$ which minimizes the sum of distances from it

to three given points. In the early 19th century it was realized that this particular convex optimization problem has a natural dual maximization formulation. Kuhn [Kuh91] regards this as the first instance of duality in the mathematical programming literature. Further history is given in [Kuh67].

Duality theory for D is easily described using min-max theory. Let $\boldsymbol{x}_i \in \Re^d$, $i = 1, \ldots, n$. For consistency with standard notation for LP, we refer to $\boldsymbol{x}_i$ as the primal variables and $\boldsymbol{y}$, $\boldsymbol{z}_i$ as the dual variables, even though in our experience it is usually the dual problem D which explicitly arises in applications. We have

$$\begin{aligned}
\min_{A_i^T y + z_i = c_i} \sum_{i=1}^n \|\boldsymbol{z}_i\| &= \min_{A_i^T y + z_i = c_i} \max_{\|x_i\| \le 1} \sum_{i=1}^n \boldsymbol{x}_i^T \boldsymbol{z}_i \\
&= \max_{\|x_i\| \le 1} \min_{A_i^T y + z_i = c_i} \sum_{i=1}^n \boldsymbol{x}_i^T \boldsymbol{z}_i \\
&= \max_{\|x_i\| \le 1} \min_{y} \left(\sum_{i=1}^n \boldsymbol{c}_i^T \boldsymbol{x}_i - \boldsymbol{y}^T \sum_{i=1}^n \boldsymbol{A}_i \boldsymbol{x}_i \right) \\
&= \max \left\{ \sum_{i=1}^n \boldsymbol{c}_i^T \boldsymbol{x}_i \ : \ \|\boldsymbol{x}_i\| \le 1; \ \sum_{i=1}^n \boldsymbol{A}_i \boldsymbol{x}_i = \boldsymbol{0} \right\}.
\end{aligned}$$

The first equality follows from Cauchy–Schwartz, the second from min-max theory [Roc70, Cor. 37.3.2], the third trivially, and the fourth because if $\sum_{i=1}^n \boldsymbol{A}_i \boldsymbol{x}_i$ is not zero, the minimized value would be $-\infty$. Therefore, the dual of D is the primal problem

$$P: \quad \max \left\{ \sum_{i=1}^n \boldsymbol{c}_i^T \boldsymbol{x}_i \ : \ \boldsymbol{x}_i \in \Re^d, \ \|\boldsymbol{x}_i\| \le 1, \ i = 1, \ldots, n; \ \sum_{i=1}^n \boldsymbol{A}_i \boldsymbol{x}_i = \boldsymbol{0} \right\}.$$

This result is an easy generalization of the duality theory in [Kuh67] and is a special case of a much more general theory of convex optimization given in [NN94]. Nonetheless, we are not aware of its explicit appearance in the literature earlier than [And96b].

Although the duality theory has been known in its simplest form for nearly two centuries, it was not understood until relatively recently how to exploit duality in algorithms for minimizing D. Iteratively reweighted least squares (Weiszfeld's method [Wei37]) has long been used as a robust though slowly converging method to solve D. Another well-known approach is to replace the terms $\|\boldsymbol{z}_i\|$ in the objective by the differentiable quantity $\sqrt{\|\boldsymbol{z}_i\|^2 + \mu^2}$, where μ is a fixed positive number. This method is also robust but converges arbitrarily slowly as $\mu \to 0$. Neither of these algorithms use any aspect of duality. In both cases, the reason for the slow convergence is that, in most interesting applications, some of the norms in the objective D have zero as their optimal value.

Calamai and Conn [CC80,CC87] and Overton [Ove83] solved D using Newton methods combined with an active set approach to determine which norms $\|\boldsymbol{z}_i\|$ are zero at an optimal solution. These methods were the first to exploit the duality structure of the problem, as they explicitly compute both primal and dual solutions. However, Newton's method was derived in the $\boldsymbol{y}, \boldsymbol{z}$ space only, with the $\boldsymbol{x}$ variables computed by least-squares estimates. The methods of Calamai and Conn and Overton are quite efficient if not many norms $\|\boldsymbol{z}_i\|$ are zero. However, if this number is large, the number of iterations is typically also large because the active set of zero norms must be updated at every step.

During the past decade, it was realized that the class of interior-point methods, so successful for solving LP's, could be extended to solve many convex optimization problems; the primary reference for this important development is Nesterov and Nemirovskii [NN94]. Andersen [And96b] gave a specific method for solving D which is based on a primal interior-point method for LP. In this method the terms $\|\boldsymbol{z}_i\|$ are replaced by $\sqrt{\|\boldsymbol{z}_i\|^2 + \mu^2}$, but the quantity μ is treated as an extra variable, whose value is determined by duality estimates. Using this method, Andersen was the first to be able to solve D rapidly and accurately even when the number of variables is large and many norms $\|\boldsymbol{z}_i\|$ are zero at a solution point. In [AC98] it was demonstrated how the linearly constrained problem can be reduced to the unconstrained case using an exact l_1 penalty function, while still preserving the sparsity structure.

In this paper we present a primal-dual interior-point method for solving P and D. The basic algorithm is easy to motivate and implement. The number of iterations needed is substantially less than that required for the primal interior-point method used by Andersen [And96b]. This is consistent with general experience with primal-dual versus primal interior-point methods for LP [Wri97].

The sum of norms problem is a special case of quadratically constrained quadratic programming (QCQP), also known as optimization over the quadratic cone. Nesterov and Todd [NT98a,NT98b] gave a theoretical discussion of algorithms for optimization over homogeneous self-dual cones, including the quadratic cone. See also Adler and Alizadeh [AA95] for another primal-dual algorithmic approach to QCQP. Our view is that the sum of norms problem is sufficiently important that a specialized approach is justified. Also taking this view, Xue and Ye [XY97] gave a complexity analysis of the sum of norms problem, using an interior-point method and exploiting the general theory given in [NT98a,NT98b].

Our primal-dual algorithm is derived in the next section, applying Newton's method to three conditions: primal and dual feasibility, and complementarity. A key point is the derivation of the appropriate complementarity condition. The main work at each step consists of solving a system of linear equations (the Schur complement equations). This Schur complement matrix is not symmetric, unlike its counterpart in linear programming.

Section 3 discusses a Mehrotra predictor-corrector enhancement to the algorithm and considers symmetrizing the Schur complement equations, including a compensating skew corrector term. Section 4 presents experimental results for some small Steiner tree test problems.

Section 5 discusses a large-scale implementation using a symmetrized Schur complement. This has been used to solve applied problems arising in plastic collapse analysis with hundreds of thousands of variables and millions of nonzeros in the constraint matrix. The algorithm typically finds accurate solutions in less than 50 iterations and determines physically meaningful solutions that were considered unobtainable until now.

In fact, problem D arises in many applications. These include least-distance problems in two or three-dimensional Euclidean space, such as the classical Steiner tree problem. Xue and his coauthors [XLD99a,XLD99b] have investigated a wide variety of problems of this kind; see their papers for other references. However, problem D also arises in very different contexts. Alpert et al. [ACK$^+$98] have recently applied a variant of our algorithm presented in this paper to the placement of circuits in VLSI design. Chan, Golub, and Mulet [CGM96] applied a nonlinear version of the algorithm to some applications in image reconstruction. Ito and Kunisch [IK99] used

an active set method to solve related image reconstruction problems. Byrnes and Bright [BB] used iteratively reweighted least-squares to solve trajectory optimization problems in space exploration. In fact, this method (Weiszfeld's method) has long been used at the Jet Propulsion Laboratory as a basic workhorse to solve problems of the form D that arise in spacecraft missions such as the Galileo and Pioneer "fly-by's" of the outer planets [Mai87,Mic]. Strang [Str79] considered an isoparametric design problem to which Overton [Ove84] applied a version of his algorithm mentioned above. Parks [Par91] has applied related methods to solve minimal surface (soap bubble) problems. Alexander and Maddocks [AM93] used the method of [Ove83] to solve friction problems arising in robotics. Finally, plastic collapse analysis problems have been mentioned already and are discussed at greater length in the final section of the paper. A key similarity in all these applications is that some, and perhaps many, of the norms in the sum to be minimized can be expected to have the value zero at an optimal solution.

We believe there is great opportunity to apply the primal-dual method given in this paper to these and many other interesting applications.

Notation. Let $\boldsymbol{I}_d$ denote the $d \times d$ identity matrix. Let

$$\boldsymbol{x} = \begin{bmatrix} \boldsymbol{x}_1 \\ \vdots \\ \boldsymbol{x}_n \end{bmatrix} \in \Re^{dn}, \quad \boldsymbol{z} = \begin{bmatrix} \boldsymbol{z}_1 \\ \vdots \\ \boldsymbol{z}_n \end{bmatrix} \in \Re^{dn}, \quad \boldsymbol{c} = \begin{bmatrix} \boldsymbol{c}_1 \\ \vdots \\ \boldsymbol{c}_n \end{bmatrix} \in \Re^{dn},$$

$$\boldsymbol{A} = \begin{bmatrix} \boldsymbol{A}_1 & \cdots & \boldsymbol{A}_n \end{bmatrix} \in \Re^{m \times dn}.$$

The primal feasible region is given by

$$\mathcal{X} = \left\{ \boldsymbol{x} \in \Re^{dn} : \boldsymbol{A}\boldsymbol{x} = \boldsymbol{0}; \quad \|\boldsymbol{x}_i\| \leq 1, \ i = 1, \ldots, n \right\} \tag{1}$$

and the dual feasible region is

$$\mathcal{Y} = \left\{ (\boldsymbol{y}, \boldsymbol{z}) \in \Re^m \times \Re^{dn} : \boldsymbol{A}^T\boldsymbol{y} + \boldsymbol{z} = \boldsymbol{c} \right\}. \tag{2}$$

Consequently, we may rewrite D as

$$D: \quad \min \left\{ \sum_{i=1}^{n} \|\boldsymbol{z}_i\| \ : \ (\boldsymbol{y}, \boldsymbol{z}) \in \mathcal{Y} \right\}$$

and P as

$$P: \quad \max \ \left\{ \boldsymbol{c}^T\boldsymbol{x} \ : \ \boldsymbol{x} \in \mathcal{X} \right\}.$$

2. Complementarity and Newton's method. Suppose $\boldsymbol{x} \in \mathcal{X}$ and $(\boldsymbol{y}, \boldsymbol{z}) \in \mathcal{Y}$ are, respectively, primal and dual feasible. Then the duality gap, i.e., difference between the primal and dual objective functions, is

$$\sum_{i=1}^{n} \|\boldsymbol{z}_i\| - \sum_{i=1}^{n} \boldsymbol{c}_i^T\boldsymbol{x}_i = \sum_{i=1}^{n} \left(\|\boldsymbol{z}_i\| - \boldsymbol{x}_i^T\boldsymbol{z}_i \right) \geq 0. \tag{3}$$

The duality gap must be zero at an optimal solution. It is zero if and only if, for each $i = 1, \ldots, n$, either $\|\boldsymbol{z}_i\|$ is zero or $\boldsymbol{x}_i = \boldsymbol{z}_i / \|\boldsymbol{z}_i\|$. This complementarity condition can be conveniently expressed as

$$\boldsymbol{z}_i - \|\boldsymbol{z}_i\|\boldsymbol{x}_i = \boldsymbol{0}, \quad i = 1, \ldots, n. \tag{4}$$

It follows from the complementarity condition that for each i, either $\boldsymbol{z}_i = 0$ or $\|\boldsymbol{x}_i\| = 1$; we say that strict complementarity holds if, for each i, only one of these two conditions holds. It may happen that no strictly complementary solution exists, unlike in LP.

Primal-dual interior-point methods are based on Newton's method applied to three sets of equations: primal feasibility, dual feasibility, and an appropriate complementarity/centering condition. The feasibility equations are, respectively,

$$\boldsymbol{A}\boldsymbol{x} = \boldsymbol{0} \tag{5}$$

and

$$\boldsymbol{A}^T\boldsymbol{y} + \boldsymbol{z} = \boldsymbol{c}. \tag{6}$$

We assume from now on that the $m \times dn$ matrix $\boldsymbol{A}$ has full rank. We also assume that $m < dn$, since otherwise P and D are solved by $\boldsymbol{x} = \boldsymbol{0}$, $\boldsymbol{z} = \boldsymbol{0}$.

The primal and dual feasibility equations consist of $m + dn$ equations in the $m + 2dn$ scalar variables represented by $\boldsymbol{y}$ and $\boldsymbol{x}$, $\boldsymbol{z}$. To make this a square system we need another dn equations, which are available in the form of the complementarity condition (4). This condition is not differentiable if $\|\boldsymbol{z}_i\|$ is zero, but it may be replaced by the centering condition

$$\boldsymbol{z}_i - \left(\|\boldsymbol{z}_i\|^2 + \mu^2\right)^{\frac{1}{2}} \boldsymbol{x}_i = \boldsymbol{0}, \quad i = 1, \ldots, n, \tag{7}$$

where $\mu > 0$.

The following theorem is from [And96b], showing that the centering condition (7) is in fact the complementarity condition for the following pair of smooth optimization problems:

$$D_\mu : \quad \min \left\{ \sum_{i=1}^{n} \left(\|\boldsymbol{z}_i\|^2 + \mu^2\right)^{\frac{1}{2}} : \ (\boldsymbol{y}, \boldsymbol{z}) \in \mathcal{Y} \right\},$$

$$P_\mu : \quad \max \left\{ \boldsymbol{c}^T\boldsymbol{x} + \mu \sum_{i=1}^{n} \left(1 - \|\boldsymbol{x}_i\|^2\right)^{\frac{1}{2}} : \ \boldsymbol{x} \in \mathcal{X} \right\}.$$

THEOREM 1. *The problems D_μ and P_μ are a primal-dual pair. Specifically, D_μ has the solution $(\boldsymbol{y}(\mu), \boldsymbol{z}(\mu))$ and P_μ has the solution $\boldsymbol{x}(\mu)$, all satisfying* (5), (6), *and* (7).

Proof. The proof is a simple modification of the proof (given in section 1) that P and D are a primal-dual pair. See [And96b] for details. □

This theorem shows that introducing the centering parameter μ in the complementarity conditions for the original pair of problems is equivalent to smoothing the norms in D and introducing a cost into P which moves the primal solution away from its boundary. The solutions $(\boldsymbol{x}(\mu), \boldsymbol{y}(\mu), \boldsymbol{z}(\mu))$ of P_μ, D_μ, for $\mu > 0$, define a sort of central path for P, D, though not one derived from a logarithmic barrier function and therefore not centered in the usual sense.

Let us write the centering condition (7) as

$$\Theta(\mu, \boldsymbol{z})\boldsymbol{x} - \boldsymbol{z} = \boldsymbol{0}, \quad \text{where} \quad \Theta(\mu, \boldsymbol{z}) = \operatorname{Diag}\left(\left(\|\boldsymbol{z}_i\|^2 + \mu^2\right)^{\frac{1}{2}} \boldsymbol{I}_d\right). \tag{8}$$

Collecting (6), (5), and (8) together, we have the nonlinear system of equations

$$\boldsymbol{G}_\mu(\boldsymbol{x},\boldsymbol{y},\boldsymbol{z}) = \begin{pmatrix} \boldsymbol{A}^T\boldsymbol{y} + \boldsymbol{z} - \boldsymbol{c} \\ \boldsymbol{A}\boldsymbol{x} \\ \Theta(\mu,\boldsymbol{z})\boldsymbol{x} - \boldsymbol{z} \end{pmatrix} = \boldsymbol{0}, \tag{9}$$

whose solution is $(\boldsymbol{x}(\mu),\boldsymbol{y}(\mu),\boldsymbol{z}(\mu))$. Newton's method applied to $\boldsymbol{G}_\mu$ at a given point $(\boldsymbol{x},\boldsymbol{y},\boldsymbol{z})$ gives the following linear system defining updates to the variables:

$$\begin{bmatrix} \boldsymbol{0} & \boldsymbol{A}^T & \boldsymbol{I}_{dn} \\ \boldsymbol{A} & \boldsymbol{0} & \boldsymbol{0} \\ \boldsymbol{E}_\mu & \boldsymbol{0} & -\boldsymbol{F}_\mu \end{bmatrix} \begin{bmatrix} \Delta\boldsymbol{x} \\ \Delta\boldsymbol{y} \\ \Delta\boldsymbol{z} \end{bmatrix} = \begin{bmatrix} \boldsymbol{r}_d \\ \boldsymbol{r}_p \\ \boldsymbol{r}_c \end{bmatrix}, \tag{10}$$

where

$$\boldsymbol{r}_d = \boldsymbol{c} - \boldsymbol{A}^T\boldsymbol{y} - \boldsymbol{z}, \quad \boldsymbol{r}_p = -\boldsymbol{A}\boldsymbol{x}, \quad \boldsymbol{r}_c = \boldsymbol{z} - \boldsymbol{E}_\mu\boldsymbol{x}, \tag{11}$$

$$\boldsymbol{E}_\mu = \operatorname{Diag}\left(\omega_i^\mu \boldsymbol{I}_d\right), \quad \boldsymbol{F}_\mu = \operatorname{Diag}\left(\boldsymbol{I}_d - \frac{1}{\omega_i^\mu}\boldsymbol{x}_i\boldsymbol{z}_i^T\right), \tag{12}$$

and

$$\omega_i^\mu = \left(\|\boldsymbol{z}_i\|^2 + \mu^2\right)^{\frac{1}{2}}. \tag{13}$$

The equation $\boldsymbol{r}_d = \boldsymbol{0}$ is maintained exactly at each step, by always defining $\boldsymbol{z} = \boldsymbol{c} - \boldsymbol{A}^T\boldsymbol{y}$. Although $\boldsymbol{r}_p$ can be set to zero initially by setting the first iterate $\boldsymbol{x} = \boldsymbol{0}$ or setting $\boldsymbol{x}$ to a null vector of $\boldsymbol{A}$, we do not assume this, since primal feasibility cannot be maintained exactly in the presence of rounding errors.

Eliminating $\Delta\boldsymbol{z}$ and using $\boldsymbol{r}_d = \boldsymbol{0}$, we have

$$\begin{bmatrix} \boldsymbol{F}_\mu^{-1}\boldsymbol{E}_\mu & \boldsymbol{A}^T \\ \boldsymbol{A} & \boldsymbol{0} \end{bmatrix} \begin{bmatrix} \Delta\boldsymbol{x} \\ \Delta\boldsymbol{y} \end{bmatrix} = \begin{bmatrix} \boldsymbol{F}_\mu^{-1}\boldsymbol{r}_c \\ -\boldsymbol{A}\boldsymbol{x} \end{bmatrix}. \tag{14}$$

Defining $\boldsymbol{H}_\mu = \boldsymbol{E}_\mu^{-1}\boldsymbol{F}_\mu$, and using the definition of $\boldsymbol{r}_c$ in (11), we find after one more elimination step that

$$\boldsymbol{A}\boldsymbol{H}_\mu\boldsymbol{A}^T\Delta\boldsymbol{y} = \boldsymbol{A}\boldsymbol{E}_\mu^{-1}\boldsymbol{z} \tag{15}$$

and

$$\Delta\boldsymbol{x} = \boldsymbol{E}_\mu^{-1}\left(\boldsymbol{F}_\mu\Delta\boldsymbol{z} + \boldsymbol{r}_c\right), \tag{16}$$

where (immediately from dual feasibility)

$$\Delta\boldsymbol{z} = -\boldsymbol{A}^T\Delta\boldsymbol{y}. \tag{17}$$

The operations of multiplying vectors by $\boldsymbol{F}_\mu$ and $\boldsymbol{E}_\mu^{-1}$ are trivial since $\boldsymbol{F}_\mu$ is block diagonal and $\boldsymbol{E}_\mu$ is positive diagonal. Notice the explicit dependence of $\boldsymbol{E}_\mu$ and $\boldsymbol{F}_\mu$ on the centering parameter μ, in contrast to the situation in LP, where the corresponding diagonal matrices depend only on the current variables. This is a consequence of the more complicated nature of the complementarity condition (4).

The main cost of this process is forming and factoring the Schur complement $\boldsymbol{A}\boldsymbol{H}_\mu\boldsymbol{A}^T$. Except in the trivial case $d = 1$, the block-diagonal matrix $\boldsymbol{H}_\mu$ is not generally symmetric, since $\boldsymbol{F}_\mu$ is not. This presents difficulties for large sparse problems, where it is highly desirable to use sparse Cholesky techniques which apply only to symmetric, positive definite systems. Sparse LU factorization techniques for nonsymmetric linear systems are more costly since they require pivoting for stability and therefore are not able to exploit sparsity as effectively as Cholesky methods.

However, note that $\boldsymbol{F}_\mu$ is positive definite (in the sense that $v^T\boldsymbol{F}_\mu v > 0$ for all $v \neq 0$) as long as $\boldsymbol{x} \in \mathcal{X}$, and therefore so are $\boldsymbol{H}_\mu$ and $\boldsymbol{A}\boldsymbol{H}_\mu\boldsymbol{A}^T$ (since $\boldsymbol{E}_\mu$ and $\boldsymbol{F}_\mu$ commute). Furthermore, it follows from (7) that for $(\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{z}) = (\boldsymbol{x}(\mu), \boldsymbol{y}(\mu), \boldsymbol{z}(\mu))$ (see Theorem 1), the matrix $\boldsymbol{F}_\mu$ and therefore also $\boldsymbol{H}_\mu$ and $\boldsymbol{A}\boldsymbol{H}_\mu\boldsymbol{A}^T$ are symmetric for all $\mu > 0$. Consequently, when defined sufficiently close to the "central path," $\boldsymbol{A}\boldsymbol{H}_\mu\boldsymbol{A}^T$ is nearly symmetric. One of the issues we shall discuss in the next section is the effect of symmetrizing $\boldsymbol{H}_\mu$ by defining it to be $\frac{1}{2}\boldsymbol{E}_\mu^{-1}(\boldsymbol{F}_\mu + \boldsymbol{F}_\mu^T)$ instead of $\boldsymbol{E}_\mu^{-1}\boldsymbol{F}_\mu$.

As $\mu \to 0$, for each i, either $\boldsymbol{z}_i(\mu)$ or $\boldsymbol{x}_i(\mu) - \boldsymbol{z}_i(\mu)/\|\boldsymbol{z}_i(\mu)\|$ converges to zero. In the latter case, the limit of the ith block of the corresponding $\boldsymbol{F}_\mu$ is singular, while in the former case the limit of the ith block of the corresponding $\boldsymbol{E}_\mu$ is zero.

We now discuss how to update the iterates $\boldsymbol{x}$, $\boldsymbol{y}$, and $\boldsymbol{z}$ after $\Delta\boldsymbol{x}$, $\Delta\boldsymbol{y}$, and $\Delta\boldsymbol{z}$ are computed. We start by observing that $\Delta\boldsymbol{z}$ is a descent direction for the smoothed dual objective function in D_μ: the gradient of this function with respect to $\boldsymbol{z}$ is easily seen to be $\boldsymbol{E}_\mu^{-1}\boldsymbol{z}$. Using (17) and (15), we have

$$\begin{aligned}(\Delta\boldsymbol{z})^T\boldsymbol{E}_\mu^{-1}\boldsymbol{z} &= -(\Delta\boldsymbol{y})^T\boldsymbol{A}\boldsymbol{E}_\mu^{-1}\boldsymbol{z} \\ &= -(\Delta\boldsymbol{y})^T\boldsymbol{A}\boldsymbol{H}_\mu\boldsymbol{A}^T\Delta\boldsymbol{y} \\ &< 0\end{aligned}$$

(unless $\boldsymbol{z} = \boldsymbol{0}$), since the symmetric part of $\boldsymbol{A}\boldsymbol{H}_\mu\boldsymbol{A}^T$ is positive definite. Consequently, it is natural to update $\boldsymbol{y}$ and $\boldsymbol{z}$ by using a line search on the smoothed dual function in D_μ, as follows.

Dual line search rule.

$$\tilde{\boldsymbol{y}} = \boldsymbol{y} + \hat{\beta}\Delta\boldsymbol{y}, \quad \tilde{\boldsymbol{z}} = \boldsymbol{z} + \hat{\beta}\Delta\boldsymbol{z}, \tag{18}$$

where

$$\hat{\beta} \approx \arg\min_{0\leq\beta\leq 1} \sum_{i=1}^{n} \left(\|\boldsymbol{z}_i + \beta\Delta\boldsymbol{z}_i\|^2 + \mu^2\right)^{\frac{1}{2}}. \tag{19}$$

The same steplength must be used for $\boldsymbol{y}$ and $\boldsymbol{z}$ to maintain dual feasibility. Of course, the univariate minimization problem need not be solved exactly.

The direction $\Delta\boldsymbol{x}$ is not necessarily an ascent direction for the penalized primal objective function in P_μ, so a line search is not appropriate to update the primal iterate $\boldsymbol{x}$. We consider two possibilities: the primal scaling rule and the primal steplength rule.

Primal scaling rule.

$$\tilde{\boldsymbol{x}} = \bar{\gamma}\,(\boldsymbol{x} + \Delta\boldsymbol{x}), \tag{20}$$

where

$$\bar{\gamma} = \max\{\gamma : \quad \gamma\|\boldsymbol{x}_i + \Delta\boldsymbol{x}_i\| \leq 1 \quad i = 1, \ldots, n\}. \tag{21}$$

The scaling rule is a trivial computation.

Primal steplength rule. The step to the boundary is given by

$$\alpha_{\max} = \max\{\alpha : \ \|\boldsymbol{x}_i + \alpha \Delta \boldsymbol{x}_i\| \leq 1, \ i = 1, \ldots, n\} \ = \ \min_i \alpha_i,$$

where α_i is the positive root of a quadratic equation:

$$\alpha_i = \frac{-\Delta \boldsymbol{x}_i^T \boldsymbol{x}_i + \sqrt{\|\Delta \boldsymbol{x}_i\|^2 \left(1 - \|\boldsymbol{x}_i\|^2\right) + \left(\Delta \boldsymbol{x}_i^T \boldsymbol{x}_i\right)^2}}{\|\Delta \boldsymbol{x}_i\|^2}, \quad i = 1, \ldots, n.$$

We choose $0 \ll \tau < 1$ and define

$$\bar{\alpha} = \tau \alpha_{\max}. \tag{22}$$

Then the steplength rule is defined by

$$\tilde{\boldsymbol{x}} = \boldsymbol{x} + \min(1, \bar{\alpha}) \Delta \boldsymbol{x}. \tag{23}$$

Both rules preserve primal feasibility in exact arithmetic. For the steplength rule, conventional experience with primal-dual interior-point methods dictates a choice of τ less than 1, but not much less, for example, $\tau = .99$ or $\tau = .999$. For sums of norms, however, we found that $\tau = 1$ also works quite well. This allows iterates $\boldsymbol{x}$ to actually reach the boundary of the feasible region, but the matrix $\boldsymbol{F}_\mu$ still cannot be singular as long as $\mu > 0$. Increased ill-conditioning of the linear systems which are solved as convergence takes place is a standard feature of interior-point methods and generally does not cause great difficulties except when the iterates are nearly optimal. The reason we do not allow $\tau = 1$ is that rounding errors may then cause the updated $\boldsymbol{x}$ to lie just outside the feasible region.

The scaling rule always places $\boldsymbol{x}$ exactly on the boundary of the feasible region. This is not appropriate if the solution $\boldsymbol{x}$ has all component norms $\|\boldsymbol{x}_i\| < 1$, but this is a trivial case since then the dual solution must be zero by complementarity. As far as we know, the scaling rule does not have an analogy in standard interior-point implementations: such a rule is possible only when the primal equality constraints are homogeneous as they are here.

Equations (15), (16), (17), and the updating rules just described define the basic ingredients of a primal-dual interior-point method for solving P and D. To complete the description of the algorithm we must define a rule for updating the parameter μ: for this we introduce a predictor-corrector method.

3. Mehrotra's predictor-corrector method and a symmetrized algorithm with a skew correction term. Mehrotra's predictor-corrector method is a standard tool in primal-dual interior-point software for LP. The basic idea is to first compute a predictor step defined by first-order approximations to the optimality conditions (i.e. Newton's method), and to follow this with a corrector step which also takes second-order terms into account. A key point is that both predictor and corrector use the same matrix factorization; only the right-hand sides of the linear equations defining the steps differ. Another key component is a technique for estimating the centering parameter μ. Mehrotra's method was originally given in [Meh92]; an excellent discussion may be found in [Wri97, Chapter 10].

We now discuss how to adapt Mehrotra's method to our problem. Let us replace $\boldsymbol{x}$, $\boldsymbol{y}$, and $\boldsymbol{z}$ in the centering condition (8) by $\boldsymbol{x}+\Delta\boldsymbol{x}$, $\boldsymbol{y}+\Delta\boldsymbol{y}$, and $\boldsymbol{z}+\Delta\boldsymbol{z}$, respectively, obtaining, for $i = 1, \ldots, n$,

$$\boldsymbol{z}_i + \Delta\boldsymbol{z}_i - \left(\|\boldsymbol{z}_i + \Delta\boldsymbol{z}_i\|^2 + \mu^2\right)^{\frac{1}{2}} (\boldsymbol{x}_i + \Delta\boldsymbol{x}_i) = \boldsymbol{0},$$

i.e.,

$$\boldsymbol{z}_i + \Delta\boldsymbol{z}_i - \omega_i^{\mu} \left(1 + 2\frac{\boldsymbol{z}_i^T \Delta\boldsymbol{z}_i}{(\omega_i^{\mu})^2} + \frac{\|\Delta\boldsymbol{z}_i\|^2}{(\omega_i^{\mu})^2}\right)^{\frac{1}{2}} (\boldsymbol{x}_i + \Delta\boldsymbol{x}_i) = \boldsymbol{0},$$

which gives

$$\boldsymbol{z}_i + \Delta\boldsymbol{z}_i - \omega_i^{\mu} \left(1 + \frac{\boldsymbol{z}_i^T \Delta\boldsymbol{z}_i}{(\omega_i^{\mu})^2} + \frac{\|\Delta\boldsymbol{z}_i\|^2}{2(\omega_i^{\mu})^2} - \frac{(\boldsymbol{z}_i^T \Delta\boldsymbol{z}_i)^2}{2(\omega_i^{\mu})^4} + \cdots\right) (\boldsymbol{x}_i + \Delta\boldsymbol{x}_i) = \boldsymbol{0}.$$

Moving first-order terms to the left-hand side, constant and second-order terms to the right-hand side, neglecting higher than second-order terms, and changing the sign of the equation we obtain

$$(\boldsymbol{E}_{\mu}\,\Delta\boldsymbol{x} - \boldsymbol{F}_{\mu}\,\Delta\boldsymbol{z})_i = (\boldsymbol{r}_c)_i - \frac{\boldsymbol{z}_i^T \Delta\boldsymbol{z}_i}{\omega_i^{\mu}} \Delta\boldsymbol{x}_i - \frac{\|\Delta\boldsymbol{z}_i\|^2}{2\omega_i^{\mu}} \boldsymbol{x}_i + \frac{(\boldsymbol{z}_i^T \Delta\boldsymbol{z}_i)^2}{2(\omega_i^{\mu})^3} \boldsymbol{x}_i \tag{24}$$

for $i = 1, \ldots, n$. The idea, then, is to compute the predictor steps $\Delta\boldsymbol{x}$, $\Delta\boldsymbol{y}$, and $\Delta\boldsymbol{z}$ from (15)–(17), and then use these to define the second-order terms which are included in the right-hand side of the linear system solved to obtain the corrector step, using the factorization of $\boldsymbol{A}\boldsymbol{H}_{\mu}\boldsymbol{A}^T$ a second time.

As noted above, a key component of Mehrotra's method is to exploit the result of the predictor step to define a heuristic value for the centering parameter μ to be used in the computation of the corrector step. This is provided by

$$\tilde{\mu} = \frac{(\mathrm{gap}(\boldsymbol{x} + \Delta\boldsymbol{x}, \boldsymbol{z} + \Delta\boldsymbol{z}))^3}{n\,(\mathrm{gap}(\boldsymbol{x}, \boldsymbol{z}))^2}, \tag{25}$$

where

$$\mathrm{gap}(\boldsymbol{x}, \boldsymbol{z}) = \sum_{i=1}^{n} \left(\|\boldsymbol{z}_i\| - \boldsymbol{x}_i^T \boldsymbol{z}_i\right). \tag{26}$$

This is a natural generalization of Mehrotra's formula for LP. The value $\tilde{\mu}$ may be substituted for μ in *all* the terms on the right-hand side of (24), including the second-order terms as well as the constant term, giving

$$\boldsymbol{h}_i^{(1)} = \boldsymbol{z}_i - \omega_i^{\tilde{\mu}} \boldsymbol{x}_i - \frac{\boldsymbol{z}_i^T \Delta\boldsymbol{z}_i}{\omega_i^{\tilde{\mu}}} \Delta\boldsymbol{x}_i - \frac{\|\Delta\boldsymbol{z}_i\|^2}{2\omega_i^{\tilde{\mu}}} \boldsymbol{x}_i + \frac{(\boldsymbol{z}_i^T \Delta\boldsymbol{z}_i)^2}{2(\omega_i^{\tilde{\mu}})^3} \boldsymbol{x}_i, \tag{27}$$

where

$$\omega_i^{\tilde{\mu}} = \left(\|\boldsymbol{z}_i\|^2 + \tilde{\mu}^2\right)^{\frac{1}{2}}. \tag{28}$$

It is not practical to substitute $\tilde{\mu}$ for μ on the left-hand side of (24), since the factorization of $\boldsymbol{H}_\mu$ has already been computed using the previous value for μ. Consequently, we also add to the right-hand side of (24) further corrector terms of the form

$$\boldsymbol{h}_i^{(2)} = \left(\omega_i^\mu - \omega_i^{\tilde{\mu}}\right) \Delta \boldsymbol{x}_i + \left(\frac{1}{\omega_i^\mu} - \frac{1}{\omega_i^{\tilde{\mu}}}\right) \left(\boldsymbol{z}_i^T \Delta \boldsymbol{z}_i\right) \boldsymbol{x}_i. \tag{29}$$

As noted in the previous section, the nonsymmetry of $\boldsymbol{H}_\mu$ is a major disadvantage for large sparse problems. We therefore consider here the idea of explicitly symmetrizing $\boldsymbol{H}_\mu$, defining it to be $\frac{1}{2}\boldsymbol{E}_\mu^{-1}(\boldsymbol{F}_\mu + \boldsymbol{F}_\mu^T)$ instead of $\boldsymbol{E}_\mu^{-1}\boldsymbol{F}_\mu$. This suggests subtracting a skew correction term $\frac{1}{2}\boldsymbol{E}_\mu^{-1}(\boldsymbol{F}_\mu - \boldsymbol{F}_\mu^T)\Delta\boldsymbol{z}$ from the right-hand side, i.e., adding terms

$$\boldsymbol{h}_i^{(3)} = \frac{1}{2\omega_i^\mu} \left((\Delta \boldsymbol{z}_i^T \boldsymbol{x}_i)\boldsymbol{z}_i - (\Delta \boldsymbol{z}_i^T \boldsymbol{z}_i)\boldsymbol{x}_i\right) \tag{30}$$

to (24). Note the use of ω_i^μ, not $\omega_i^{\tilde{\mu}}$, in the denominator. Putting all this together, the corrector step is defined by

$$\boldsymbol{E}_\mu \, \Delta \boldsymbol{x} - \boldsymbol{F}_\mu \, \Delta \boldsymbol{z} = \boldsymbol{r}_c^c, \tag{31}$$

where the ith block of the "corrected centering" residual is

$$(\boldsymbol{r}_c^c)_i = \begin{cases} \boldsymbol{h}_i^{(1)} + \boldsymbol{h}_i^{(2)} & \text{if} \quad \boldsymbol{H}_\mu = \boldsymbol{E}_\mu^{-1}\boldsymbol{F}_\mu, \\ \boldsymbol{h}_i^{(1)} + \boldsymbol{h}_i^{(2)} + \boldsymbol{h}_i^{(3)} & \text{if} \quad \boldsymbol{H}_\mu = \frac{1}{2}\boldsymbol{E}_\mu^{-1}\left(\boldsymbol{F}_\mu + \boldsymbol{F}_\mu^T\right), \end{cases} \tag{32}$$

using (27), (29), and (30).

Substituting $\boldsymbol{r}_c^c$ for $\boldsymbol{r}_c$ in (14), we therefore compute the corrector steps from

$$\boldsymbol{A}\boldsymbol{H}_\mu\boldsymbol{A}^T\Delta\boldsymbol{y} = \boldsymbol{A}\left(\boldsymbol{E}_\mu^{-1}\boldsymbol{r}_c^c + \boldsymbol{x}\right) \tag{33}$$

and

$$\Delta\boldsymbol{x} = \boldsymbol{E}_\mu^{-1}\left(\boldsymbol{F}_\mu\Delta\boldsymbol{z} + \boldsymbol{r}_c^c\right) \tag{34}$$

with $\Delta\boldsymbol{z}$ given by (17).

Note that by analogy with standard practice in LP, it might seem appropriate to modify the right-hand side $\boldsymbol{r}_c$ used by the predictor step by substituting 0 for μ in its definition.[1] In practice, whether or not this is done seems to have little effect, but one reason not to make this choice is that then the dual predictor step is no longer guaranteed to be a descent direction for the smoothed objective function in D_μ. There is no guarantee that the dual corrector step is a descent direction for either this function or the corresponding function defined using $\tilde{\mu}$ instead of μ, although it usually is. If it is a descent direction for the latter function, we update the iterates as before, using $\tilde{\mu}$ instead of μ in the objective function in the dual line search. Otherwise, we abandon both primal and dual corrector steps and use the predictor steps instead.

We now summarize the algorithm. We initialize it with $\boldsymbol{x} = \boldsymbol{0}$, $\boldsymbol{y}$ set to the minimizer of $\|\boldsymbol{c} - \boldsymbol{A}^T\boldsymbol{y}\|$, and $\boldsymbol{z} = \boldsymbol{c} - \boldsymbol{A}^T\boldsymbol{y}$. Assume that an initial value of $\mu > 0$ is given, as well as a termination tolerance ϵ.

[1] In fact, this was done in the experiments reported in section 5.

PREDICTOR-CORRECTOR ALGORITHM FOR MINIMIZING A SUM OF NORMS.

(1) Define ω_i^μ, $\boldsymbol{E}_\mu$, and $\boldsymbol{F}_\mu$ by (12)–(13).
(2) Define $\boldsymbol{H}_\mu$ by either $\boldsymbol{E}_\mu^{-1}\boldsymbol{F}_\mu$ or $\frac{1}{2}\boldsymbol{E}_\mu^{-1}(\boldsymbol{F}_\mu + \boldsymbol{F}_\mu^T)$ and find either the LU or Cholesky factorization, respectively, of $\boldsymbol{A}\boldsymbol{H}_\mu\boldsymbol{A}^T$. In the former case, quit if the LU factorization generates a zero pivot. In the latter case, either quit if the Cholesky factorization fails, or modify the factorization, effectively redefining $\boldsymbol{H}_\mu$ by a nearby positive definite approximation.
(3) Determine the predictor steps $\Delta\boldsymbol{y}$, $\Delta\boldsymbol{z}$, and $\Delta\boldsymbol{x}$ from (15), (17), and (16).
(4) Define $\tilde{\boldsymbol{x}}$ from the primal scaling rule (see (20) and (21)) or the primal steplength rule (see (22) and (23)), and $\tilde{\boldsymbol{y}}, \tilde{\boldsymbol{z}}$ by the dual line search rule (see (18) and (19)). Quit if the dual line search fails to achieve a reduction in the smoothed dual.
(5) Define $\tilde{\mu}$ by (25) and $\omega_i^{\tilde{\mu}}$ by (28).
(6) Determine the corrector steps $\Delta\boldsymbol{y}$, $\Delta\boldsymbol{z}$, and $\Delta\boldsymbol{x}$ from (33), (17), and (34).
(7) If $(\boldsymbol{E}_{\tilde{\mu}}^{-1}\boldsymbol{z})^T\Delta\boldsymbol{z} < 0$, redetermine $\tilde{\boldsymbol{x}}$, $\tilde{\boldsymbol{y}}$, and $\tilde{\boldsymbol{z}}$ using the primal scaling or steplength rule with $\tilde{\mu}$ instead of μ, and the dual line search rule with $\tilde{\mu}$ instead of μ. Quit if the dual line search rule fails to achieve a reduction in the smoothed dual objective.
(8) Replace $\boldsymbol{x}$, $\boldsymbol{y}$, $\boldsymbol{z}$, and μ by $\tilde{\boldsymbol{x}}$, $\tilde{\boldsymbol{y}}$, $\tilde{\boldsymbol{z}}$, and $\tilde{\mu}$, respectively.
(9) If $\|\boldsymbol{A}\boldsymbol{x}\| > \text{gap}(\boldsymbol{x}, \boldsymbol{z})$, quit. (This cannot happen in exact arithmetic and indicates that rounding errors will dominate any further computation.)
(10) If $\text{gap}(\boldsymbol{x}, \boldsymbol{z}) < \epsilon$ and $\|c - \boldsymbol{A}^T\boldsymbol{y} - \boldsymbol{z}\| + \|A\boldsymbol{x}\| < \epsilon$, quit; otherwise repeat.

There are several ways the algorithm might terminate when rounding errors prevent further progress: breakdown of the factorization, failure in the line search, or growth in the primal infeasibility $\|\boldsymbol{A}\boldsymbol{x}\|$ with respect to the duality gap measure $\text{gap}(\boldsymbol{x}, \boldsymbol{z})$. The occurrence of any of these conditions essentially indicates that the convergence tolerance ϵ is set too small; in any case, when they occur, the current or previous approximation is generally quite accurate.

4. Experiments on small problems. We now report some numerical results for this algorithm, comparing the symmetrized and nonsymmetrized versions and other algorithmic options described above. These results were obtained using a Matlab implementation run on a set of small topologically-constrained Steiner tree test problems (for more details, see [DO98]). The sparsity in the data is determined by the tree structure and its topological constraint, but subject to these qualifications, the data are generated randomly. Each table shows a summary of results from many runs with different random data on the same problem class. Sparsity was not exploited. In all cases $d = 2$. The dual line search was performed using the Matlab **fmin** function with its default tolerance. The machine used was a Sparc Ultra with IEEE double precision arithmetic.

The tables show, for various cases, the number of iterations, the final values of $\text{gap}(\boldsymbol{x}, \boldsymbol{z})$ (defined in (26)), and the infeasibility norm sum $\|\boldsymbol{A}\boldsymbol{x}\| + \|\boldsymbol{c} - \boldsymbol{A}^T\boldsymbol{y} - \boldsymbol{z}\|$, each as medians over a set of randomly generated problems in a given class. The termination tolerance ϵ was set to 10^{-10}.

In Tables 1 and 2, we consider a class of Steiner tree problems with $n = 50$, $m = 62$, for which strict complementarity holds at the solution, and for which the median number of indices for which $\|\boldsymbol{z}_i\| = 0$ at the optimal solution is 15. We compare the nonsymmetric and symmetrized variants of the algorithm ($\boldsymbol{H}_\mu = \boldsymbol{E}_\mu^{-1}\boldsymbol{F}_\mu$ and $\boldsymbol{H}_\mu = \frac{1}{2}\boldsymbol{E}_\mu^{-1}(\boldsymbol{F}_\mu + \boldsymbol{F}_\mu^T)$, respectively) with two choices for updating the primal variable: the scaling rule and the steplength rule with $\tau = 0.999$. All variants used the

dual line search rule. For the symmetrized algorithm, we tested both a version which quits if the Cholesky factorization of $\boldsymbol{H}_\mu$ fails and one that modifies the factorization and continues iterating: the latter is standard practice in LP [Wri97, p. 219]. We also tested a variant of the symmetrized version which omits the skew correction $\boldsymbol{h}_i^{(3)}$. Finally, we also tested the effect of omitting the correction $\boldsymbol{h}_i^{(2)}$, but this had essentially no effect in any case.

Table 1 shows the results for the primal scaling rule and Table 2 shows the results using the primal steplength rule. The notations "skew corr" and "mod Chol" refer to the use of the skew correction term and the modified Cholesky factorization, respectively.

The results clearly confirm three remarkable properties of primal-dual predictor-corrector algorithms now well known for linear programming:

- Robust convergence to an optimal solution in all cases tested.
- Rapid local convergence so a consistently small number of iterations is required despite the demand for high accuracy.
- Highly accurate solutions achieved despite the extremely ill-conditioned linear systems being solved toward the end of the solution process.

We now comment in more detail on the results in Tables 1 and 2. First, notice the high accuracy achieved by the nonsymmetric version of the algorithm; the symmetrized version without the modified Cholesky factorization cannot reach the same level of accuracy. With modified Cholesky, high accuracy is achievable, but more iterations are required. The inclusion of the skew correction term $\boldsymbol{h}_i^{(3)}$ substantially improves the performance of the symmetrized version of the algorithm whether or not the Cholesky factorization is modified.

For both the nonsymmetric and symmetrized versions the primal scaling rule has a slightly lower iteration count than the primal steplength rule, apparently because this version of the algorithm has a somewhat faster local convergence rate. However, we note that the scaling rule has the significant disadvantage that it is not applicable if nonhomogeneous linear constraints are added to the problem.

In Tables 3 through 6 we display results for a different class of topologically constrained Steiner tree examples based on the Chung–Graham ladder problem (see

[DO98]). For these examples, $n = 85$, $m = 84$, and the median number of indices for which $\|\boldsymbol{z}_i\|$ equals 0 at the optimal solution is 10. For most of these problems, no strictly complementary (SC) solution exists. (Recall from section 2 that a solution is said to be strictly complementary if, for each i, exactly one of the two conditions $\|\boldsymbol{z}_i\| = 0$ and $\|\boldsymbol{x}_i\| = 1$ holds.)

Tables 3 and 4 show results for the 20 cases out of 200 generated where an SC solution is found (using the primal scaling and primal steplength rules, respectively), while Tables 5 and 6 show results for the other 180 cases where no SC solution is found, presumably because such a solution does not exist. The algorithm achieves the same accuracy (by the duality gap and feasibility measures) on the SC and non-SC problems, but the iteration count is markedly higher in the non-SC case, and the rate of convergence of the algorithm was observed to be slower in the non-SC case. For the non-SC problems, the residuals $\|\boldsymbol{z}_i\|$ are not reduced nearly as close to zero for indices i for which SC does not hold. The reason for this is that the duality gap tolerance requires the products $\boldsymbol{z}_i^T(\boldsymbol{z}_i/\|\boldsymbol{z}_i\| - \boldsymbol{x}_i)$ to be small and *both* factors in the product for such an index i converge to zero as the solution is approached.

For these problems, the modified Cholesky factorization is not needed: the results are identical whether or not it is used.

On the basis of the experiments reported in this section, we recommend the symmetrized version of the algorithm with the skew correction term and the modified Cholesky factorization, using the dual line search and either the primal scaling or the primal steplength rule. The choice of the symmetrized version is based on the substantial advantage of being able to use the Cholesky factorization instead of the LU factorization.

5. Large sparse problems arising in plastic collapse analysis. A variant of the algorithm described above has been used to solve some challenging large sparse problems arising in plastic collapse analysis. We used a symmetrized version of the algorithm, with $\boldsymbol{H}_\mu = \frac{1}{2}\boldsymbol{E}_\mu^{-1}(\boldsymbol{F}_\mu + \boldsymbol{F}_\mu^T)$, so that the Schur complement $\boldsymbol{A}\boldsymbol{H}_\mu\boldsymbol{A}^T$ can be factored by Cholesky decomposition, modified to ensure positive definiteness as

discussed earlier. This is the primary cost of the algorithm. Details of this and other numerical linear algebra issues are available in [AA97,AY97,And96a]. The primal steplength rule was used, with $\tau = 0.99$ in (22).

This sparse implementation was developed over several years with large-scale applications in mind. There are two primary differences from the algorithm discussed in section 3. The first is that a different generalization of Mehrotra's method was used, based on differentiating a form of the centering condition which incorporates the symmetrization of $\boldsymbol{F}_\mu$ directly, and therefore does not require a skew correction term. The second is that individual centering parameters were used instead of one parameter, namely,

$$\tilde{\mu}_i = \begin{cases} \tilde{\mu} & \text{if} \quad 0.25 < \left(1 - \|\tilde{\boldsymbol{x}}_i\|^2\right), \\ \tilde{\mu}\left(1 - \|\tilde{\boldsymbol{x}}_i\|^2\right)^{-\frac{1}{2}} & \text{if} \quad \mu \le \left(1 - \|\tilde{\boldsymbol{x}}_i\|^2\right) \le 0.25, \\ \sqrt{\tilde{\mu}} & \text{if} \quad \left(1 - \|\tilde{\boldsymbol{x}}_i\|^2\right) < \mu \end{cases}$$

for $i = 1, \ldots, n$. This modification was found to give significant improvements in performance for the large-scale problems.

The first three classes of test problems are taken from [And96b], where a primal barrier method was used. We are unaware of any other published results for large sparse problems of the form (D). These test problems are finite-dimensional discretizations of collapse problems in rigid plasticity. The discretization step and the physical interpretation of the results can be found in [Chr96,ACO98]. The discrete optimization problems are the same as in [And96b]. The $m \times dn$ matrix $\boldsymbol{A}$ is a typical finite element matrix which in plastic analysis is not square since the equilibrium equation for the continuum is underdetermined. As earlier, $\boldsymbol{H}_\mu$ is block diagonal with block size $d \times d$. In the cases reported here d is either 2 or 3. The runs were made on the same Convex 3240 vector machine (using IEEE-compatible double precision) as in [And96b] so comparisons of accuracy and CPU time are meaningful.

In Tables 7–11, n and m specify the problem dimensions, while $|\boldsymbol{A}|$, $|\boldsymbol{A}\boldsymbol{H}_\mu\boldsymbol{A}^T|$, and $|\boldsymbol{L}|$, respectively, denote the number of nonzeros in $\boldsymbol{A}$, the upper triangle of $\boldsymbol{A}\boldsymbol{H}_\mu\boldsymbol{A}^T$, and the Cholesky factor $\boldsymbol{L}$ of $\boldsymbol{A}\boldsymbol{H}_\mu\boldsymbol{A}^T$. These numbers are the same as in [And96b], except for small variations in sparsity due to improvements in the implementation. The iteration count is denoted by "iter" and "cpu" is the CPU time in seconds. The heading "$\|\boldsymbol{z}_i\| = 0$" indicates the number of norms in the dual objective that are zero at the optimal solution. More precisely, $\|\boldsymbol{z}_i\|$ is interpreted as being zero if it is less than the tolerance 10^{-10}. The heading "relgap" denotes the relative duality gap

$$\frac{\left|\sum_{i=1}^n \|\boldsymbol{z}_i\| - \boldsymbol{c}^T\boldsymbol{x}\right|}{\sum_{i=1}^n \|\boldsymbol{z}_i\| + 1}.$$

In addition to being scaled this expression is the left-hand side of (3) rather than the right-hand side used in (26): if $\boldsymbol{A}\boldsymbol{x} = \boldsymbol{0}$ exactly we have

$$\boldsymbol{c}^T\boldsymbol{x} = (\boldsymbol{A}^T\boldsymbol{y} + \boldsymbol{z})^T\boldsymbol{x} = \boldsymbol{x}^T\boldsymbol{z}.$$

Hence the difference is dominated by the primal infeasibility $\|\boldsymbol{A}\boldsymbol{x}\|$ indicated in the last column.

Table 7 summarizes the results for the first set of problems, denoted ssp$N$ (simply supported plate with a point load solved on an $N \times N$ grid). They all have the same structure but vary in size, depending on the grid in the finite element analysis. In this problem $d = 3$. This set of problems is characterized by having no zero norms in the solution, i.e., they are, in fact, smooth optimization problems. In [And96b] the constraints $\|\boldsymbol{x}_i\| \leq 1$ are satisfied within a tolerance of order 10^{-9}. These constraints are satisfied exactly in the primal-dual method. Except for this small improvement in accuracy, the primal-dual method shows no significant difference, for these problems, compared to the primal barrier method in [And96b]. There is a small reduction in the iteration count but not in the CPU time. This is a consequence of the fact that these problems are smooth. We shall see below that the primal-dual method handles the presence of zero norms more efficiently than the primal method.

For this problem, as well as for the other results reported below, there is no significant difference in the final duality gap and primal infeasibility achieved by the two algorithms. They are, in all cases, about 10^{-8} or less.

The second set of problems, denoted by $lNa13$, arises in the plane strain model in plasticity. Again N indicates the grid size. In these problems $d = 2$. Characteristics and results are given in Table 8.

In this problem set, the number of zero norms varies from 25 percent for $N = 3$ to 87 percent for $N = 120$. Compared with the primal barrier method in [And96b] there is a significant reduction in the number of iterations and in CPU time. This is shown in Table 9. The primal-dual algorithm also obtains significantly more zero norms in the optimal solution. From our physical understanding of the solution we believe this is correct. It is one of several indications that the primal-dual method is more accurate than the primal barrier method.

There is an important physical interpretation of the complementarity condition (4) in the plasticity problems considered in this section: the vectors $\boldsymbol{z}_i$ represent the deformation (strain) tensor at discrete points in the continuum while the $\boldsymbol{x}_i$ represent the stresses. Thus, if there is any deformation at a point, then the stresses at that point are on their bounds (have norm one) and their directions are determined by the complementarity condition. With this interpretation the complementarity condition

is the so-called "flow rule" for the material.

In the third set of test problems, only a small part of the material undergoes deformation; therefore a very large number of the norms are expected to be zero in the optimal solution. As shown in Table 10, the number of zero norms varies from 62 to 96 percent of the total number of terms. Comparison with [And96b] confirms the observations from Table 9: for the primal-dual method the iteration count is significantly reduced and increases very slowly with the problem size. The CPU time is reduced by a factor 4 or more, and we are able to solve larger instances of the problem.

The last class of test problems is taken from [AC98]. These are problems of the form (D) with additional linear equality constraints:

$$\min\left\{\sum_{i=1}^{n}\lVert\boldsymbol{z}_i\rVert\,,\ \text{such that } \boldsymbol{A}_i^T\boldsymbol{y}+\boldsymbol{z}_i=\boldsymbol{c}_i, i=1,\ldots,n,\ \text{ and } \boldsymbol{E}^T\boldsymbol{y}=\boldsymbol{d}\right\}, \tag{35}$$

where $\boldsymbol{E}\in\Re^{m\times l}$ and $\boldsymbol{d}\in\Re^l$, i.e., l is the number of linear constraints. In [AC98], it is shown how the ℓ_1 penalty function approach makes it possible to transform the linearly constrained problem to the unconstrained form (D) in section 1, and the physical interpretation and setup of the test problems are described. This class of problems is denoted cl$N$13.

Characteristics and results for these constrained problems are seen in Table 11. In addition to the number l of linear constraints, there is a new column, "constr", indicating the relative infeasibility of these constraints measured by the expression

$$\frac{\left\lVert\boldsymbol{E}^T\boldsymbol{y}-\boldsymbol{d}\right\rVert}{\lVert\boldsymbol{d}\rVert+1}.$$

For the primal barrier method in [AC98], the number of iterations varies from 30 (for $N=3$ and $N=12$) to 201 (for $N=300$). For the primal-dual method the variation is from 11 (for $N=3$) to 24 (for $N=201$) and 35 (for $N=399$). For the case $N=201$ the CPU time is reduced from 36,371 seconds in [AC98] to 6,179 using the primal-dual method. However, we can do even better: in the cl$N$13 problems there is one column that is relatively dense, resulting in considerable fill-in during the

399*	35	34776	146326	$7.8e-14$	$2.0e-13$	$6.3e-13$

factorization. Using the technique described in [And96a] for handling dense columns these problems can be solved more efficiently, making it possible to solve for larger values of N. The asterisk in the table indicates that the result for $N = 399$ was obtained by this method. Using the same technique, the case $N = 201$ required 4,293 CPU seconds, and there were 6,367,553 nonzero elements in the $\boldsymbol{L}$ factor.

We conclude that for nonsmooth problems the primal-dual method is significantly more efficient than the primal barrier method applied in [And96b,ACO98,AC98]. The number of iterations increases slowly with the size of the problem. Finally, the primal-dual method appears to be less vulnerable to ill-conditioning near the optimal solution.

THE NUMERICAL SOLUTION OF THE STEADY STATE SOLID FUEL IGNITION MODEL AND ITS OPTIMAL CONTROL*

ALFIO BORZÌ† AND KARL KUNISCH†

Abstract. We present a finite difference multigrid technique that efficiently solves optimal control problems associated with the steady state solid fuel ignition model. This is a nonlinear indefinite problem which gives rise to singular optimal control systems. Regarding the direct problem, necessary and sufficient conditions for existence of solutions are given and second-order convergence of numerical solution errors with respect to the mesh size is proven. A robust nonlinear multigrid method is implemented to validate this convergence estimate.

Two optimal control strategies for solid fuel ignition phenomena are considered and compared. The corresponding optimality systems are solved to second-order accuracy by a multigrid method whose convergence properties are independent of the values of the weights in the cost functionals and of the number of grid points.

Key words. steady state solid fuel ignition model, finite difference method, convergence estimates, optimal control problem, nonlinear multigrid method

1. Introduction.

Modeling of combustion phenomena is an important task in various fields of application. Combustible systems give rise to reaction-diffusion problems where heat production occurs and must be controlled. Control can be required, for example, to avoid blow-up phenomena or to obtain an optimal combustion process.

Our goal is to develop a finite difference multigrid method that accurately and efficiently solves singular optimal control problems for such systems. We further compare two different control formulations with respect to their ability and cost to influence the temperature distribution. The steady state solid fuel ignition model, which can give rise to blow-up phenomena [4, 9, 10, 11, 14, 15, 16, 18, 21, 22, 23], is given by

$$\begin{aligned} \Delta u + \delta \exp(u) &= f \text{ in } \Omega, \\ u &= 0 \text{ on } \partial\Omega. \end{aligned} \tag{1.1}$$

Due to the nonmonotonic sign in front of the exponential term, this nonlinear indefinite problem may admit multiple solutions or no solution at all depending on Ω and on the value of the positive coefficient δ. Actually, the absence of coerciveness represents a major difficulty in the analysis and the solution of this problem.

We present new results concerning existence of solutions of (1.1) and of its discretized counterpart in the presence of control, $f \neq 0$. Our analysis is based on the upper and lower solutions method [10, 16, 22, 23]. We extend a result of Bramble [5] to prove second-order accuracy of the numerical solution with respect to the mesh size.

†Institut für Mathematik, Karl-Franzens-Universität Graz, Heinrichstraße 36, A-8010 Graz, Austria (alfio.borzi@kfunigraz.ac.at, karl.kunisch@kfunigraz.ac.at).

The nonlinear algebraic problem arising from the discretization of (1.1) is solved by a nonlinear multigrid method [1, 6, 7, 8, 12, 24]. For the smoother, the Gauss–Seidel variant of the Picard iteration considered in the theory of upper and lower solutions method is used. We prove that the sequence of approximations obtained by this iterative scheme is monotone and converges under certain conditions to the solution of the discrete problem.

The optimal control problems we consider are defined by

$$\begin{aligned} &\min_{f\in L^2(\Omega)} J(u(f), f), \\ &\Delta u + \delta \exp(u) = f \text{ in } \Omega, \\ &u = 0 \text{ on } \partial\Omega, \end{aligned} \tag{1.2}$$

where two tracking-type cost functionals are considered. Notice that the optimal control problems associated to the steady state solid fuel ignition model are "singular"; see [17]. Proper functional settings within which the existence of solutions to (1.2) is guaranteed are proposed and analyzed in [14, 15]. However, it is not obvious whether with either of the two formulations a significant degree of control of the state variable can be achieved and which of the two cost functions performs preferably. For this reason, we implement reliable multigrid algorithms for both formulations and give a comparison from the point of view of open loop control.

More precisely, we apply multigrid techniques to the optimality system associated with (1.2). This will allow to solve the optimal control problem in a few multigrid cycles. These multigrid algorithms have contraction factors independent of the number of grid points and of the value of the weights in the cost functionals. For the smoothing process, we show that the Gauss–Seidel–Newton (GSN) method is superior to the Gauss–Seidel–Picard (GSP) approach.

In the next section we derive and analyze the steady state solid fuel ignition model. In section 3 the discretization of this model and its accuracy are considered. In the following, section 4, the nonlinear multigrid method is discussed and numerical experiments with the steady state solid fuel ignition model are presented. In section 5 optimal control problems for this model are formulated. The numerical solution process for the optimal control problem is presented and the results of numerical experiments are discussed.

2. Derivation and analysis of the model. In the following two subsections we derive the steady state solid fuel ignition model and prove necessary and sufficient conditions for the existence of solutions to this model.

2.1. Derivation of the model. Consider a solid explosive material and assume that this material is contained in a bounded two-dimensional domain Ω. Unless otherwise specified it is assumed that $\partial\Omega$ is smooth or that Ω is a quadrilateral. The ignition process is characterized by the appearance of a localized warm region in which heat is produced due to a chemical reaction process. By considering a solid fuel we actually study the pointwise balance between chemically generated heat and heat transfer due to conduction; see, e.g., [4].

We consider a combustion system whose equilibrium state is characterized by a temperature T_0, pressure p_0, density ρ_0, and the oxidant mass fraction y_0. In terms of these reference values the combustion model can be written in a nondimensional form by the transformation $T \to T/T_0$, $p \to p/p_0$, $\rho \to \rho/\rho_0$, and $y \to y/y_0$. The following system of equations describing the combustion of the solid fuel is obtained [4]:

$$\begin{aligned} \partial_t T - \Delta T &= \epsilon\delta y^m \exp\left(\frac{T-1}{\epsilon T}\right), \\ \partial_t y - \beta\Delta y &= -\epsilon\delta\Gamma y^m \exp\left(\frac{T-1}{\epsilon T}\right), \end{aligned} \tag{2.1}$$

with initial and boundary conditions given by

$$\begin{aligned} &T(x,0) = 1, \quad y(x,0) = 1, \quad x \in \Omega, \\ &T(x,t) = 1, \quad \frac{\partial y(x,t)}{\partial \eta} = 0, \quad x \in \partial\Omega, \quad t \in (0,\infty), \end{aligned} \tag{2.2}$$

where β, Γ, and δ are nonnegative constants and $\frac{\partial}{\partial \eta}$ denotes the normal derivative. Further $m = \nu_F + \nu_O$, with ν_F and ν_O stoichiometric constants. The parameter ϵ is given by $\epsilon = \frac{RT_0}{E}$, where R is the gas constant and E is the total energy of the system.

If the following conditions are met,

(I) the heat loss is sufficiently large compared to the energy release (energy equilibrium is established);

(II) the maximum system temperature is never significantly different from the initial value due to the relatively cold boundary,

then a first-order approximation with respect to the changes in T and y of (2.1)–(2.2) is justified. We set

$$T = 1 + \epsilon u, \quad y = 1 - \epsilon c,$$

where u and c are two auxiliary quantities to express temperature- and oxidant mass-fraction changes. If further $\epsilon \ll 1$, the equations in u and c decouple and the following model for u is obtained:

$$\begin{aligned} \partial_t u - \Delta u &= \delta \exp(u) - f \text{ in } \Omega, \quad t \in (0,\infty), \\ u &= 0 \text{ in } \Omega, \qquad t = 0, \\ u &= 0 \text{ on } \partial\Omega, \quad t \in (0,\infty), \end{aligned} \tag{2.3}$$

which is called the *solid fuel ignition model* [4]. Here we introduced a continuous source term function f that will be used to describe the control mechanism.

The equation for c reads $\partial_t c - \beta\Delta c = \delta\Gamma \exp(u)$. It is linear in c and its solution depends on u. We shall not consider this problem any further.

The stationary version of (2.3) is called the *steady state solid fuel ignition model* [4] and it is given by

$$\begin{aligned} \Delta u + \delta \exp(u) &= f \text{ in } \Omega, \\ u &= 0 \text{ on } \partial\Omega. \end{aligned} \tag{2.4}$$

Although this model is obtained from assumptions simplifying the full solid fuel problem it provides many features of this model; see [4] and references therein. The investigation of the steady state model is important for the analysis from the point of view of dynamical systems as well as numerical analysis of the time-dependent problem, which will be considered in a forthcoming paper.

2.2. Analytical results. In this section we determine necessary and sufficient conditions for existence of solutions to the steady state solid fuel ignition problem with control. For the convenience of the reader we recall some analytical results for the case without control,

$$\Delta u + \delta e^u = 0 \text{ in } \Omega, \tag{2.5}$$

with homogeneous Dirichlet boundary conditions in two spatial dimensions. In [10] it is shown that (2.5) can have at most two solutions. If solutions of (2.5) exist, then there exists a unique minimal (global) solution defined by $u \leq v$, where v is any other solution of (2.5) [10]. A necessary condition for the existence of at least one solution is expressed by the following theorem [10].

THEOREM 2.1. *Let λ_0 be the smallest eigenvalue of $-\Delta$ under homogeneous Dirichlet boundary conditions. If $\lambda_0 < \delta e$, then the set of solutions is empty.*

Thus, in order to have at least one solution we must have $\lambda_0 \geq \delta e$. For the proof of Theorem 2.1 one should notice that a solution u of (2.5) must satisfy Jensen's inequality [10]:

$$-\lambda_0 J + \delta e^J \leq 0, \quad J = (\Phi_0, u)_{L^2},$$

where Φ_0 is the eigenfunction of $-\Delta$ corresponding to λ_0, with the normalization $(\Phi_0, 1) = 1$. Further we notice that if $\lambda_0 < \delta e$ Jensen's inequality is not satisfied, henceforth there exists no solution. Moreover, recalling that the eigenvalues of $-\Delta$ on $\Omega = [0, L] \times [0, L]$ are given by $\lambda_{mn} = \pi^2(m^2 + n^2)/L^2$, $m, n = 1, 2, \ldots$, we conclude that the set of solutions becomes empty for Ω sufficiently large.

If Ω is a unit square, then there exists a critical value $\delta^* > 0$ such that [4, 11, 10]:

- If $\delta > \delta^*$, there is no solution.
- If $\delta \in]0, \delta^*]$ ($\delta \in]0, \delta^*[$), then there exists at least one and at most two solution which belong to $W^{2,p}(\Omega)$, $p \geq 1$.
- If $\delta = \delta^*$, there exists one solution $u^* \in H_0^1(\Omega) \cap W^{2,p}(\Omega)$, $p \geq 1$, and δ^* is referred to as the turning point.

For the case of $\Omega = [0, 1] \times [0, 1]$, the turning point has been estimated, based on continuation techniques [9, 11, 18]; see Table 1.

We next consider the inhomogeneous case (2.4) where the existence of solutions depends also on the inhomogeneity f. We can generalize the Jensen inequality to this case:

$$-\lambda_0 J + \delta e^J \leq (f, \Phi_0)_{L^2}, \quad J = (\Phi_0, u)_{L^2}, \tag{2.6}$$

which gives a necessary condition such that the steady state solid fuel ignition model with forcing term can have a solution.

Sufficient conditions for existence of solutions to (2.4) can be obtained by means of the upper and lower solutions method [10, 16, 22, 23]. In order to present our results obtained by this method, let us consider a general nonlinear elliptic problem:

$$\begin{aligned} -\Delta u &= F(u) \text{ in } \Omega, \\ u &= 0 \quad \text{ on } \partial\Omega, \end{aligned} \tag{2.7}$$

where Ω is of class $C^{2+\alpha}$, $\alpha > 0$, and F is Hölder continuous in (x, u). For the case of the solid fuel ignition problem we have $F(x, u) = \delta e^u - f(x)$, where f is a continuous function on $\overline{\Omega}$. We need the following definition.

DEFINITION 2.2. *A function $\tilde{u} \in C^\alpha(\overline{\Omega}) \cap C^2(\Omega)$, $\alpha > 0$, is called upper solution of* (2.7) *if*

$$-\Delta\tilde{u} \geq F(\tilde{u}) \text{ in } \Omega; \quad \tilde{u} = 0 \text{ on } \partial\Omega. \tag{2.8}$$

Similarly, $\hat{u} \in C^\alpha(\overline{\Omega}) \cap C^2(\Omega)$, $\alpha > 0$, is called lower solution if it satisfies the reversed inequality.

A pair of upper and lower solutions is called *ordered* if $\tilde{u} \geq \hat{u}$ in $\overline{\Omega}$. For any pair of ordered upper and lower solutions, we denote by $\langle \tilde{u}, \hat{u} \rangle$ the sector of all functions $u \in C(\overline{\Omega})$ such that $\hat{u} \leq u \leq \tilde{u}$ in $\overline{\Omega}$.

Assume that $F(x, u)$ satisfies a one-sided local Lipschitz condition, i.e., for every $\tilde{u} \geq \hat{u}$ there exists a continuous nonnegative function c in $\overline{\Omega}$ such that

$$F(x, u_1) - F(x, u_2) \geq -c(x)(u_1 - u_2) \text{ for } \hat{u} \leq u_2 \leq u_1 \leq \tilde{u}. \tag{2.9}$$

If $F(u) = \delta \exp(u) - f$ this condition is satisfied with $c(x)$ identically zero. We define a sequence $\{u^{(k)}\}$ by the following iteration process:

$$-\Delta u^{(k)} = F(u^{(k-1)}) \text{ in } \Omega; \quad u^{(k)} = 0 \text{ on } \partial\Omega. \tag{2.10}$$

Upper and lower sequences $\{\overline{u}^{(k)}\}$ and $\{\underline{u}^{(k)}\}$, corresponding to initial conditions $u^{(0)} = \tilde{u}$ and $u^{(0)} = \hat{u}$, with $\tilde{u}$ and $\hat{u}$ upper and lower solutions, respectively, are of special interest. The following properties hold. (See, e.g., [22].)

LEMMA 2.3. *Upper and lower sequences are well defined and possess the monotone property,*

$$\hat{u} \leq \underline{u}^{(k)} \leq \underline{u}^{(k+1)} \leq \overline{u}^{(k+1)} \leq \overline{u}^{(k)} \leq \tilde{u} \text{ in } \overline{\Omega}$$

for every k.

The next theorem follows from results in [22].

THEOREM 2.4. *Let $\tilde{u}$ and $\hat{u}$ be ordered upper and lower solutions of* (2.7)*, and let F be Hölder continuous in (x, u) and satisfy the Lipschitz condition* (2.9)*. Then $\{\overline{u}^{(k)}\}$ converges monotonically from above to a solution $\bar{u}$, and $\{\underline{u}^{(k)}\}$ converges monotonically from below to a solution $\underline{u}$, and both solutions of* (2.7) *belong to $C^{2+\alpha}(\overline{\Omega})$, $\alpha > 0$. Moreover, $\underline{u} \leq \bar{u}$.*

To assert the existence of one solution to (2.4) it remains to construct an ordered pair of upper and lower solutions. To construct a lower solution choose $\hat{u} = \psi$, with ψ the solution of the Poisson problem, $\Delta\psi = f$, with homogeneous Dirichlet boundary conditions and $f \in C(\overline{\Omega})$. In fact,

$$-\Delta\psi = -f < \delta e^{\hat{u}} - f = F(\hat{u}),$$

as desired.

We next construct an upper solution to (2.4) for δ sufficiently small. For this purpose we express $f = f^+ - f^-$ with f^+ and f^- nonnegative functions defined by $f^+ = \max_\Omega(f, 0)$ and $f^- = \max_\Omega(-f, 0)$. Consider the linear problem

$$-\Delta\omega = c\omega + 1 + f^- \text{ in } \Omega; \quad \omega = 0 \text{ on } \partial\Omega, \tag{2.11}$$

where $0 < c < \lambda_0$ with λ_0 the smallest positive eigenvalue of $-\Delta$ with homogeneous Dirichlet boundary conditions. From the Fredholm alternative and the maximum principle it follows that (2.11) has a unique solution $\omega^* > 0$ in Ω. Then $\tilde{u} = \omega^*$ is an upper solution to (2.4), provided that δ is sufficiently small. In fact we have

$$-\Delta\omega^* = c\omega^* + 1 + f^- \geq \delta e^{\omega^*} + f^- \geq \delta e^{\tilde{u}} - (f^+ - f^-) \geq \delta e^{\tilde{u}} - f = F(\tilde{u})$$

for all sufficiently small $\delta > 0$.

Finally notice that $\tilde{u} \geq \hat{u}$. In fact, since $\tilde{u}$ and f^+ are positive functions in Ω it follows from $-\Delta(\tilde{u} - \hat{u}) = c\tilde{u} + 1 + f^+$ that $\tilde{u} - \hat{u} \geq 0$. That is, $\tilde{u}$ and $\hat{u}$ are ordered upper and lower solutions of (2.4) and the existence of solutions to (2.4) follows from Theorem 2.4.

3. The numerical solution of the steady state solid fuel ignition model. In the next two sections we define a finite difference multigrid algorithm for the steady state solid fuel ignition model. We prove that the solution of the nonlinear indefinite discrete problem provides second-order accurate solutions. In order to validate this estimate numerically we solve the problem by using the multigrid scheme. This solver is optimal in terms of number of computer operations, and it is robust in the sense that it reliably computes solutions very close to the turning point.

3.1. The discretization of the steady state solid fuel ignition problem. We commence by describing the finite difference approximation [19] of the steady state solid fuel ignition problem on $\Omega = [0, 1] \times [0, 1]$. Let Ω_{h_k}, $k = 1, 2, \ldots, M$, denote a sequence of uniform grids. The integer k is called the level number. The coarsest grid corresponds to $k = 1$ with mesh size $h_1 = 1/4$, and the finest corresponds to $k = M$ with mesh size $h_M = h_1/2^{(M-1)}$. The set of mesh points is defined by (x_i, y_j), $x_i = (i-1)h_k$ and $y_j = (j-1)h_k$, $i, j = 1, \ldots, N_k$, where $N_k = 2^{(k+1)}+1$. A numerical function on Ω_{h_k} will be denoted by u^{h_k}. To every continuous function u on Ω there exists an associated numerical function defined by its pointwise restriction to the grid points of Ω_{h_k} denoted by $u(x_i, y_j)$, or u_{ij} for short.

The five-point stencil finite difference discretization of (2.4) on Ω_h is denoted by

$$\begin{aligned} \Delta^h u^h + \delta \exp(u^h) &= f^h \text{ in } \Omega_h, \\ u^h &= 0 \text{ on } \partial\Omega_h. \end{aligned} \tag{3.1}$$

The methods used in the previous section to prove necessary and sufficient conditions for existence of solutions to the steady state solid fuel ignition model can be extended to the present discrete case. In particular, a necessary condition for existence of solutions is given by the inequality (2.6) with λ_0 the smallest eigenvalue of $-\Delta^h$ with homogeneous Dirichlet boundary conditions.

A sufficient condition for existence of solutions to (3.1) can be obtained by adaptation of the upper and lower solutions method to the discrete system of finite difference equations which correspond to (3.1) [21]. A discrete function $\tilde{u}^h$ ($\hat{u}^h$) is called an upper (lower) solution of (3.1) if $-\Delta^h\tilde{u}^h \geq F^h(\tilde{u}^h)$ ($-\Delta^h\hat{u}^h \leq F^h(\hat{u}^h)$), with

$F^h(u^h) = \delta \exp(u^h) - f^h$. Utilizing the upper and lower solutions method of the previous section we can construct an ordered pair of upper and lower solutions for the discretized problem (3.1). The existence of a solution to (3.1) follows from a modification of Theorem 2.4 to the discrete case. (Compare Theorem 3.3 of [21].)

3.2. Accuracy of the numerical approximation. The new result of this section is the second-order accuracy of the solution to (3.1). The linear indefinite case was considered in [5]. We extend those results to the present nonlinear indefinite case.

Let u be the minimal solution to the steady state solid fuel ignition model. We have the following lemma.

LEMMA 3.1. *Let $u \in C^4(\overline{\Omega})$ be one bounded solution to the steady state solid fuel ignition model* (2.4) *and let u^h satisfy* (3.1), *with $\lim_{h\to 0} ||u - u^h||_0 = 0$, where $||\cdot||_0$ denotes the maximum norm on Ω_h. Then for sufficiently small mesh sizes h,*

$$||u - u^h||_0 = O(h^2).$$

To prove this lemma notice that $u \in C^4(\overline{\Omega})$ satisfies

$$\begin{aligned} \Delta^h u + \delta \exp(u) &= f^h + T^h(u) \text{ in } \Omega_h, \\ u &= 0 \text{ on } \partial\Omega_h, \end{aligned} \tag{3.2}$$

where $T^h(u)$ is the local truncation error given by

$$T^h(u_{ij}) = \frac{1}{12}h^2 \left(\frac{\partial^4 u}{\partial x^4} + \frac{\partial^4 u}{\partial y^4} \right) + O(h^4).$$

For every mesh size h define a function $v \in C^4(\overline{\Omega})$, with $v = 0$ on $\partial\Omega$, such that its restriction v^h to Ω_h satisfies $v^h = u - u^h$. For these functions one can use the following estimate due to Bramble [5]:

$$||v^h||_0 \le C||\Delta^h v^h + \kappa v^h||_0, \tag{3.3}$$

where C is independent of h and κ is a positive function satisfying

$$|\kappa|_{\overline{\Omega}} \equiv \max_{\overline{\Omega}} |\kappa(x)| \le \bar{\kappa},$$

where $\bar{\kappa}$ must not coincide with an eigenvalue λ of the problem: $\Delta W + (\kappa - \bar{\kappa})W + \lambda W = 0$ in Ω, $W = 0$ on $\partial\Omega$. We apply Bramble's estimate with $\kappa = \delta e^u$. Using Taylor's expansion for e^{u^h} around u, and the fact that $\Delta^h u^h + \delta e^{u^h} = f^h$, we obtain

$$||v^h||_0 \le C||\Delta^h v^h + \delta e^u v^h||_0 = C||\Delta^h u - \Delta^h u^h + \delta e^u (u - u^h)||_0$$

$$= C||\Delta^h u - \Delta^h u^h + \delta e^u - \delta e^{u^h} + \delta \sum_{n=0}^{\infty} (-1)^n \frac{(u - u^h)^{n+2}}{(n+2)!} e^u||_0$$

$$\le C||\Delta^h u + \delta e^u - f^h||_0 + \delta||u - u^h||_0^2 \sum_{n=0} \frac{||u - u^h||_0^n}{(n+2)!}||e^u||_0.$$

Utilizing (3.2) we find

$$||u - u^h||_0 \le C||T^h(u)||_0 + B_h\delta||e^u||_0||u - u^h||_0^2 \le C\frac{1}{6}h^2 M_4 + B_h\bar{\kappa}||u - u^h||_0^2,$$

where

$$B_h = \sum_{n=0} \frac{||u-u^h||_0^n}{(n+2)!} \text{ and } M_4 = \max\left(\max_{\Omega}\left|\frac{\partial^4 u}{\partial x^4}\right|, \max_{\Omega}\left|\frac{\partial^4 u}{\partial x^4}\right|\right).$$

Since by assumption $\lim_{h\to 0}||u-u^h||_0 = 0$ there exists an h_0 sufficiently small such that $1 - B_h\bar{\kappa}||u-u^h||_0 > 0$ for any $h \le h_0$. This implies the estimate

$$0 \le (1 - B_h\bar{\kappa}||u-u^h||_0)||u-u^h||_0 \le C\frac{1}{6}h^2 M_4, \quad h \le h_0.$$

Consequently, $||u-u^h||_0 = O(h^2)$ for h sufficiently small as desired.

The estimate of Lemma 3.1 will be demonstrated by numerical experiments. We shall show that as the mesh is refined according to $h \to h' = h/2$, the norm of the solution error reduces with a factor of 4.

4. A multigrid method for the steady state solid fuel ignition problem. After proving existence of the numerical approximation and its degree of accuracy we now construct a multigrid algorithm that computes these discrete solutions in an efficient way, i.e., with a contraction number which is much smaller than one and independent of the mesh size. By this method we are able to validate the second-order accuracy estimate given above.

The approach we use is the full approximation scheme of Brandt [6] which we describe in the following sections. As a smoother for problems of the type considered here the GSP iteration is choosen; see, e.g., [18]. Convergence for the GSP scheme will be proved. This relaxation process is then accelerated by multigrid techniques.

4.1. The GSP iterative method. A monotone sequence $\{u^{(h,m)}\}$ of approximations to (3.1) can be obtained by repeated application of the Picard iteration:

$$-\Delta^h u^{(h,m)} = F^h(u^{(h,m-1)}) \text{ in } \Omega_h, \quad u^{(h,m)} = 0 \text{ on } \partial\Omega_h. \tag{4.1}$$

This iteration has the drawback of requiring the solution to a Poisson problem at each step. We shall therefore consider a Gauss–Seidel version that does not require the exact solution of the discrete Poisson problem, but nevertheless provides a monotone sequence.

Consider the standard regular splitting $A^h = D^h - (L+U)^h$, where A^h represents the matrix of coefficients for $-\Delta^h$ with Dirichlet boundary conditions.

A Gauss–Seidel iterative method for $A^h u^h = F^h$ can be expressed as $u^{(h,m)} = [I - (D^h - L^h)^{-1}A^h]u^{(h,m-1)} + (D^h - L^h)^{-1}F^h$. That is,

$$u^{(h,m)} = u^{(h,m-1)} - (D^h - L^h)^{-1}[-\Delta^h u^{(h,m-1)} - F(u^{(h,m-1)})]. \tag{4.2}$$

This iteration has the following property.

LEMMA 4.1. *The repeated application of the GSP iteration* (4.2) *with lower (upper) solution as initial value defines a monotonically increasing (decreasing) sequence* $\{u^{(h,m)}\}$ *of lower (upper) solutions.*

To prove this lemma let us consider the case of a lower solution as initial approximation. (The case of an upper solution can be proven the same way.) Observe that $(D^h - L^h)^{-1}$ is positive definite. (See, e.g., [25].) This implies that if $u^{(h,m-1)}$ is a lower solution, that is, $-\Delta^h u^{(h,m-1)} - F(u^{(h,m-1)}) \le 0$, then $u^{(h,m)} \ge u^{(h,m-1)}$ and the sequence is monotonic increasing.

To prove that $u^{(h,m)}$ is also a lower solution let us apply $(D^h - L^h)$ from the left to (4.2) to obtain

$$(D^h - L^h)u^{(h,m)} = (D^h - L^h)u^{(h,m-1)} - [A^h u^{(h,m-1)} - F(u^{(h,m-1)})].$$

Notice that all elements of U^h are positive. Then add and subtract $-U^h u^{(h,m)}$ on the left-hand side and $-U^h u^{(h,m-1)}$ on the right-hand side to obtain

$$\begin{aligned}(D^h - L^h - U^h)u^{(h,m)} + U^h u^{(h,m)} &= (D^h - L^h - U^h)u^{(h,m-1)} + U^h u^{(h,m-1)} \\ &\quad - [A^h u^{(h,m-1)} - F(u^{(h,m-1)})],\end{aligned}$$

$$A^h u^{(h,m)} = -U^h(u^{(h,m)} - u^{(h,m-1)}) + F(u^{(h,m-1)}),$$

$$A^h u^{(h,m)} \le F(u^{(h,m-1)}) \le F(u^{(h,m)}),$$

and therefore $-\Delta^h u^{(h,m)} - F(u^{(h,m)}) \le 0$, which proves Lemma 4.1.

Since the GSP iteration is slow it cannot be recommended for the solution of (3.1). An efficient solver is obtained by implementing a multigrid method where the GSP iteration acts as a smoother. By using the GSP scheme we avoid the difficulties reported in [9, 18] to define a robust multigrid smoother to solve the present problem.

4.2. The multigrid method for nonlinear problems. We construct a multigrid algorithm by combining the GSP iteration used as the smoother and the coarse grid correction. The resulting algorithm solves (3.1) to the level of the truncation error in a number of operations proportional to the number of variables. To sketch this method, called *full approximation scheme* (FAS), consider the discrete problem (3.1) expressed as

$$\mathcal{A}^h(u^h) = f^h \text{ on } \Omega_h. \tag{4.3}$$

On the grid of level k, with mesh size h, the smoothing procedure is denoted by $u^h = S^\nu(u^h, f^h)$, where S^ν is the smoothing operator applied ν times. This corresponds, for example, to ν steps of the GSP scheme. To correct for the smooth component of the error, a coarse grid correction (CGC) is defined. First, a coarse grid problem is constructed on the grid with mesh size $H = h_{k-1}$,

$$\mathcal{A}^H(u^H) = I_h^H f^h + \tau_h^H, \tag{4.4}$$

where $I_h^H : \Omega_h \to \Omega_H$ denotes a restriction operator, and τ_h^H is the fine-to-coarse defect correction defined by

$$\tau_h^H = \mathcal{A}^H(\hat{I}_h^H u^h) - I_h^H \mathcal{A}^h(u^h), \tag{4.5}$$

with $\hat{I}_h^H : \Omega_h \to \Omega_H$ being a restriction operator not necessarily equal to I_h^H. For example, $\hat{I}_h^H$ can be the straight injection. Once the coarse grid problem is solved, the coarse grid correction follows,

$$u_{new}^h = u^h + I_H^h(u^H - I_h^H u^h), \tag{4.6}$$

where $I_H^h : \Omega_H \to \Omega_h$ represents an interpolation operator. If the high frequency components of the error on the finer grid are indeed well damped, then the grid

Ω_H should provide enough resolution for u^h, and hence $I_H^h u^H$ should be a good approximation for u^h. This idea of transferring to a coarser grid can be applied along the set of nested meshes. One starts at level M with a zero approximation and applies the smoothing iteration ν_1 times. Then the problem is transferred to a coarser grid and so on. Once the coarsest grid is reached, one solves the coarsest problem to convergence by applying, as we do, a few steps of the smoothing iteration. The solution obtained on each grid is then used to correct the approximation on the next finer grid. The coarse grid correction followed by ν_2 postsmoothing steps is applied from one grid to the next, down to the finest grid with level M. This entire process represents one multigrid cycle.

The application of N FAS cycles is denoted by N-FAS. One can choose a starting grid with a level number $K < M$ which is coarser than the finest grid where the solution is desired. In this case one applies N-FAS on level K and then the solution is interpolated on the next finer grid. The interpolation provides a first approximation for the N-FAS on this finer level and so on until the finest grid is reached. The combination of the nested iteration technique and the N-FAS scheme is called the N-FMG scheme.

4.2.1. Prolongation and restriction operators. It is useful to recall the algebraic interpretation of the multigrid method in order to choose optimal prolongation and restriction operators for the present nonlinear problem. See [1, 8, 24] for a general discussion on this aspect of multigrid methods.

In one spatial dimension, it is known that a standard choice of multigrid components can lead to an effective direct solver (cyclic reduction). For example, combining the algebraic equations of the discrete system, which corresponds to (3.1) on Ω_h, one obtains

$$u_{i-2} - 2u_i + u_{i+2} + H^2\delta\left[\frac{e^{u_{i-1}} + 2e^{u_i} + e^{u_{i+1}}}{4}\right] = H^2\left[\frac{f_{i-1} + 2f_i + f_{i+1}}{4}\right],$$

where $H = 2h$. Whereas, if we represent our problem on the grid Ω_H we have,

$$u_{i-2} - 2u_i + u_{i+2} + H^2\delta e^{u_i} = H^2\hat{f}_i.$$

Hence, one can derive an expression for $\hat{f}_i$ so that the solution of the two algebraic problems coincide, that is,

$$\hat{f}_i = \frac{f_{i-1} + 2f_i + f_{i+1}}{4} - \delta\left[\frac{e^{u_{i-1}} + 2e^{u_i} + e^{u_{i+1}}}{4}\right] + \delta e^{u_i}.$$

Comparing this formula with the definition of the coarse problem (4.4) in the FAS scheme, where

$$f^H = I_h^H f^h + \mathcal{A}^H(\hat{I}_h^H u^h) - I_h^H \mathcal{A}^h(u^h),$$

an explicit expression for I_h^H is obtained. Namely, in stencil notation,

$$I_h^H = [1 \quad 2 \quad 1]/4,$$

and $\hat{I}_h^H$ is the straight injection operator.

In two dimensions these operators correspond to the half-weighted restriction and the simple injection, respectively, [12, 24]. By using I_h^H and $\hat{I}_h^H$ optimal convergence properties are observed as can be seen in Table 2 in the next section. For prolongation I_H^h we use the bilinear interpolation operator.

TABLE 2

4.3. Experiments with the steady state solid fuel ignition model. We conducted numerical experiments to measure efficiency, accuracy, and robustness of the solution process defined by finite difference discretization and multigrid methods.

Before we consider specific examples let us define some quantities which will be used to describe the numerical features of our algorithm. We shall report the values of the maximum norm of the solution error, $e^h = u^h - u$, on the grid Ω_h, that is, $||e^h||_0 = \max_{\Omega_h} |u^h - u|$. If an exact solution of the continuous problem is not known we take the solution on Ω_h as the reference solution, compute the intergrid error $E^H = u^H - \hat{I}_h^H u^h$ on Ω_H, and the norm $||E^H||_0 = \max_{\Omega_H} |u^H - I_h^H u^h|$ [7].

We define the contraction factor as the "asymptotic" value of the ratio between the discrete L^2-norm of the residuals $r(u)^h = f^h - \mathcal{A}^h(u^h)$ resulting from two successive multigrid cycles on a given mesh [12],

$$\rho^* = \lim_N \frac{||r(u)^h_{(N)}||_{L^2}}{||r(u)^h_{(N-1)}||_{L^2}}. \tag{4.7}$$

In order to measure the computational cost of a multigrid cycle let us use the "work unit" (WU) [7]. A work unit is the computational work done by one smoothing step on the finest grid.

For the experiments reported in the following sections some parameters of the multigrid algorithm are held fixed: Two pre- and one postsmoothing step are used on each level. Further, $K = 3$ if an N-FMG algorithm is applied. We use the half-weighted restriction operator discussed in the previous section. This choice provides the best contraction number for the multigrid cycle as can be seen in Table 2. (In the tables, the notation (-k) means 10^{-k}.)

We consider two examples. For the first one we choose $u(x, y) = \frac{1}{\pi^2} \sin(\pi x) \sin(\pi y)$ and $\delta = 6.0$. By substituting this function into the steady state solid fuel ignition model (3.1) we obtain an expression for f so that (3.1) admits u as a solution. In the second example, $f = 0$ is taken, and because $\delta < \delta^* \sim 6.80$ we know that the model admits at least one solution. In both cases, the Jensen inequality is satisfied.

4.3.1. Example 1. In this case the function f is given such that the solution u of (3.1) is known. Results of numerical experiments are reported in Table 3. The quantity $||e^h||_0$ computed by the N-FMG scheme is reported for each level. ($M = \{3, 4, 5, 6\}$.) Observe that already for 4-FMG, the norm of the error reduces almost exactly by a factor $H^2/h^2 = 4$ as stated in Lemma 3.1. Similar results can be shown relative to the norm of the residual of (3.1), in agreement with the fact that the truncation error behaves like $O(h^2)$. This means that the problem has been solved to the level of this error. Therefore no improvement in the solution can be expected by further cycling of the multigrid method. This is clearly shown by comparison of the results obtained by 4-FMG and 6-FMG.

In Table 4 we report the values of the quotient $\frac{||r(u)^h_{(N)}||_{L^2}}{||r(u)^h_{(N-1)}||_{L^2}}$ appearing in (4.7) to show that the present algorithm has a contraction factor independent of the number of grid points.

4.3.2. Example 2. We repeat the experiment presented above for the case $f = 0$ and $\delta = 6.0$, for which (3.1) admits at least one solution. In Table 5 the quantity $||E^H||_0$ is reported for each level ($M = \{3, 4, 5, 6\}$) after the application of the N-FMG scheme as in the Example 1. As in the previous example a second-order accurate solution is obtained by N-FMG for $N \geq 4$. Contraction factors similar to those found with the example above can be reported for the present case as well. Let us now choose $\delta = 6.8$ for which the solution is known to be very close to the turning point. In Table 6 we can see that the multigrid algorithm preserves its property of a mesh-size independent contraction factor.

5. Optimal control of the steady state solid fuel ignition model. In this section we show that multigrid methods can be used to efficiently solve the optimality systems arising in open loop optimal control for steady state problems. Control will be exerted by adding or subtracting thermal energy to the fuel through a source term. Due to the lack of coercivity of the state equation it is at first not obvious how to properly formulate optimal control problems related to the solid fuel ignition model. In previous work two formalisms were considered:

$$\begin{aligned} &\min_{f\in L^2(\Omega)} J(u(f),f),\\ &\Delta u+\delta\exp(u)=f \text{ in } \Omega,\\ &u=0 \text{ on } \partial\Omega, \end{aligned} \tag{5.1}$$

where the cost functional $J(u,f)$ is chosen either as

$$J_1(u,f)=\frac{1}{2}||u-z||^2_{L^2(\Omega)}+\frac{\beta}{2}||e^u-e^z||^2_{L^2(\Omega)}+\frac{\nu}{2}||f||^2_{L^2(\Omega)} \tag{5.2}$$

(see [15]), or as

$$J_2(u,f)=\frac{1}{2}||u-z||^2_{L^2(\Omega)}+\frac{1}{2}||\nabla u-\nabla z||^2_{L^2(\Omega)}+\frac{\nu}{2}||f||^2_{L^2(\Omega)} \tag{5.3}$$

(see [14]). In (5.2) and (5.3) the next to last terms guarantee the existence of solutions to (5.1). In these cost functionals ν is the weight of the cost of the control, β is a positive scaling factor, and $z\in H^2(\Omega)$ is the desired state. In both cases radial unboundedness of J in (5.1) is guaranteed by the choice of the cost functional. Thus, minimizing sequences are a priori bounded and existence of a solution $(f^*,u^*)=(f^*,u(f^*))$ to the optimal control problem (5.1) with $J=J_1$ or $J=J_2$ can be established. (For $J=J_2$, only the time-dependent case is considered in [14], but the same techniques can be used to treat the stationary case.)

To derive necessary optimality conditions of first order, we introduce the Lagrangian,

$$L(u,f,\lambda)=J(u,f)+<\Delta u+\delta\exp(u)-f,\lambda>_{H^{-1},H^1_0}. \tag{5.4}$$

Let $G:H^1_0(\Omega)\to H^{-1}$ denote the linearization of the nonlinear operator in (2.4) at an optimal solution u^*,

$$Gv=\Delta v+\delta e^{u^*}v.$$

Note that G, considered as operator in $L^2(\Omega)$, has compact resolvent so its spectrum consists only of eigenvalues. We assume that zero is not an eigenvalue of G. Under this condition it can be shown that there exists $\lambda^*\in H^1_0(\Omega)$ such that the first-order optimality conditions hold:

$$L_{(u,f)}(u^*,f^*,\lambda^*)=0 \quad \text{and} \quad \Delta u^*+\delta e^{u^*}=f^*,$$

where $L_{(u,f)}$ denotes the derivative of L with respect to (u,f). For $J=J_1$ this results in the optimality system

$$\begin{aligned} \Delta u+\delta\exp(u)-f&=0,\\ \Delta\lambda+\delta\exp(u)\lambda+(u-z)+\beta e^u(e^u-e^z)&=0,\\ \nu f-\lambda&=0, \end{aligned} \tag{OPC1}$$

where for convenience we omitted the superscript *. Similarly, the optimality condition for $J = J_2$ is found to be

$$\begin{aligned} \Delta u + \delta \exp(u) - f &= 0, \\ \Delta\lambda + \delta \exp(u)\lambda + (u - z) - \Delta(u - z) &= 0, \\ \nu f - \lambda &= 0. \end{aligned} \tag{OPC2}$$

In the following sections we shall concentrate on the numerical solution of (OPC1) and (OPC2) and their comparison from the point of view of open loop control. Before doing so, we first look at the regularity properties of (u, f, λ). Due to the last equation in (OPC1) and (OPC2) we have $f \in H^1(\Omega) \subset L^p(\Omega)$ for every $p \in [1, \infty)$. It follows that $u \in W^{2,p}(\Omega)$ and $\lambda \in W^{2,p}(\Omega)$ for both (OPC1) and (OPC2). In particular, u and λ as well as f are elements of $C(\Omega)$, so the numerical framework developed above is applicable.

6. Numerical solution of the optimal control problem. To solve the systems (OPC1) and (OPC2) we first discretize them using finite differences and then solve the resulting nonlinear algebraic systems using a multigrid method similar to that used for the steady state solid fuel ignition model.

The discrete system corresponding to (OPC1) is denoted by

$$\begin{aligned} \Delta^h u^h + \delta \exp(u^h) - f^h &= 0, \\ \Delta^h \lambda^h + \delta \exp(u^h)\lambda^h + (u^h - z^h) + \beta e^{u^h}(e^{u^h} - e^{z^h}) &= 0, \\ \nu f^h - \lambda^h &= 0, \end{aligned} \tag{6.1}$$

and for (OPC2) we have

$$\begin{aligned} \Delta^h u^h + \delta \exp(u^h) - f^h &= 0, \\ \Delta^h \lambda^h + \delta \exp(u^h)\lambda^h + (u^h - z^h) - \Delta(u^h - z^h) &= 0, \\ \nu f^h - \lambda^h &= 0. \end{aligned} \tag{6.2}$$

While we shall not analyze the convergence of the coupled systems (6.1) and (6.2) we observe that for given f the state equations in (6.1) and (6.2) have second-order convergence property by the results of section 3. Further the costate equations are linear in λ^h so that the results of Bramble [5] apply and we expect to obtain second-order accurate solutions of the optimality systems.

To solve (6.1) and (6.2) two smoothing schemes are considered in the construction of the multigrid algorithm. In the first case, as in [2, 3], we make the following definition: *An iteration step, $u^h = S^\nu(u^h, f^h)$, consists of one step of an iterative solver applied to the state equation, then one step of an iterative solver applied to the costate equation and finally update of the control function by means of $f = \lambda/\nu$.* As iterative solver for each equation we take one iteration of the GSP iteration.

In the second case, one iteration of the GSN iteration is used. It is a Newton step applied at each grid point to the set of variables $\phi = (u, \lambda, f)$. It is defined by

$$\phi_{ij}^{(\text{new})} = \phi_{ij}^{(\text{old})} - [\mathbf{G}'(\phi_{ij})]^{-1}\mathbf{G}(\phi_{ij}). \tag{6.3}$$

The vector equation $\mathbf{G}(u^h, \lambda^h, f^h) = \mathbf{0}$ represents (6.1) or (6.2) and $\mathbf{G}'(u^h, \lambda^h, f^h)$ denotes the Jacobian of $\mathbf{G}$.

We shall use either the GSP-multigrid method with the GSP scheme used as the smoother or the GSN-multigrid method with the GSN iteration scheme used as the smoother. Both methods are summarized as follows:

GSP- or GSN-multigrid method for solving $A^h(\phi^h) = f^h$.
(1) Apply ν_1 smoothing steps: $\phi^h = S^{\nu_1}(\phi^h, f^h)$.
(2) Transfer the approximate solution: $\phi^H = \hat{I}_h^H \phi^h$.
(3) Compute the right-hand side of the FAS equation: $f^H = I_h^H f^h + \tau_h^H$.
(4) Apply γ-FAS scheme to $A^H(\hat{\phi}^H) = f^H$ (iterative solution if $k = 1$).
(5) Use coarse level correction: $\phi^h = \phi^h - I_H^h(\phi^H - \hat{\phi}^H)$.
(6) Apply ν_2 smoothing steps: $\phi^h = S^{\nu_2}(\phi^h, f^h)$.

Notice that this algorithm does not involve any global linearization of the optimal control problem. It is applied directly to the optimal control system whereas other multigrid approaches [13] set up an integral equation characterizing the optimal control. Both the GSP-multigrid and GSN-multigrid solve (OPC1) and (OPC2) in a few multigrid cycles to second-order accuracy.

6.1. Experiments with the optimal control of the steady state solid fuel ignition model. In this section we give examples demonstrating the efficiency of the proposed methods to solve optimal control problems. We report the values of the tracking functionals $||u^h - z^h||_0$ as well as of the control costs $||f||_{L^2} = ||\lambda||_{L^2}/\nu$. The numerical accuracy of the solution can be expressed by $||E^H||_0$ and the norm of the error of the adjoint variable λ is defined by $||V^H||_0 = \max_{\Omega_H} |\lambda^H - \hat{I}_h^H \lambda^h|$. The residual of the adjoint equation is denoted by $r(\lambda)^h$. We recall that the critical value for δ is $\delta^* = 6.808$.

We first consider the GSP-multigrid method. For the desired state we take $z(x, y) = \frac{1}{\pi^2} \sin(\pi x) \sin(\pi y)$ and we set the parameters $\delta = \beta = 6.0$ and $\nu = 5 \cdot 10^{-3}$. For this value of ν good results are obtained. It turns out, however, that for smaller values of ν the performance of the GSP-multigrid method quickly degenerates. Thus the method is not robust with respect to this parameter. Some results with (OPC1) are reported in Table 7 where we can note that the values of $||u^h - z^h||_0$ quickly reach an optimal value and that second-order convergence of E^H holds. In Table 8 analogous results are presented for (OPC2). In both cases the N-FMG scheme with $N > 2$ guarantees an efficient optimal control and second-order convergence. The advantage of using multigrid acceleration of the GSP scheme can be seen in Figure 1 where the convergence history of the GSP-multigrid and the GSP iteration are compared for solving (OPC1). A similar behavior is obtained for (OPC2). In this figure one can notice that for the GSP iteration the error of the costate equation may initially increase, but nevertheless the GSP-multigrid method shows the desired convergence properties.

We have obtained a significant improvement in robustness upon the GSP-multigrid method by implementing the GSN-multigrid scheme. This method computes the solution of (OPC1) and (OPC2) in a few work units with values of ν as small as 10^{-9}. See the convergence history of the GSN-multigrid method illustrated in Figures 2 and 3. We were not able to obtain similar results with the GSP scheme.

The results reported in Tables 9, 10, and 11 confirm the expected optimal control behavior: As ν decreases, $||f^h||_{L^2}$ increases and $||u^h - z^h||_0$ decreases, both for (OPC1) and (OPC2). In both cases the values of $||u^h - z^h||_0$ are almost independent of the discretization level, showing that the numerical solution quickly attains its optimal value. As $||u^h - z^h||_0$ measures tracking ability, we observe the difference of values between (OPC1) and (OPC2) and note that, relative to control force, the J_2-based formulation allows better tracking than the J_1-based formulation.

A direct comparison among these tables shows that the GSN-multigrid method is very robust with respect to changes of ν. By inspecting the values of $||E^H||_0$ and

$||V^H||_0$ reported in the Tables 9, 10, and 11, we can state that the GSN-multigrid algorithm provides second-order convergent solutions to the optimal control systems. In fact, provided $M > 3$, we already observe for the 3-FMG method a ν-independent reduction of $||E^H||_0$ and $||V^H||_0$ by a factor of four from one mesh to the next. Moreover, from Table 12 we conclude that only a few work units are employed by the 3-FMG method and by the 5-FMG method to reduce the values of the residuals below a small tolerance. (Here, we used $\beta = \delta = 6.8$.)

In Table 13 we depict the convergence factors for the state and the costate equations of (OPC1) and (OPC2), with various values for δ, $\beta = \delta$, and $\nu = 10^{-5}$. We observe that for a wide range of δ-values the convergence factors are quite independent of the number of variables. Note here that the controlled system is considered for values of δ significantly larger than the critical value δ^* beyond which the uncontrolled system does not admit solutions. A slight deterioration is revealed as the coefficient of the nonlinearity becomes very large.

When solving (OPC1) a value of the scaling factor β must be chosen. In Table 14 the influence of this factor on the numerical solution of (OPC1) is documented. Note that $||u^h - z^h||^2_{L^2(\Omega)}$ decreases as β is increased.

The convergence properties of the GSN-multigrid method discussed above have been tested against a wide range of choices for z. For example, take $z_a(x, y) =$

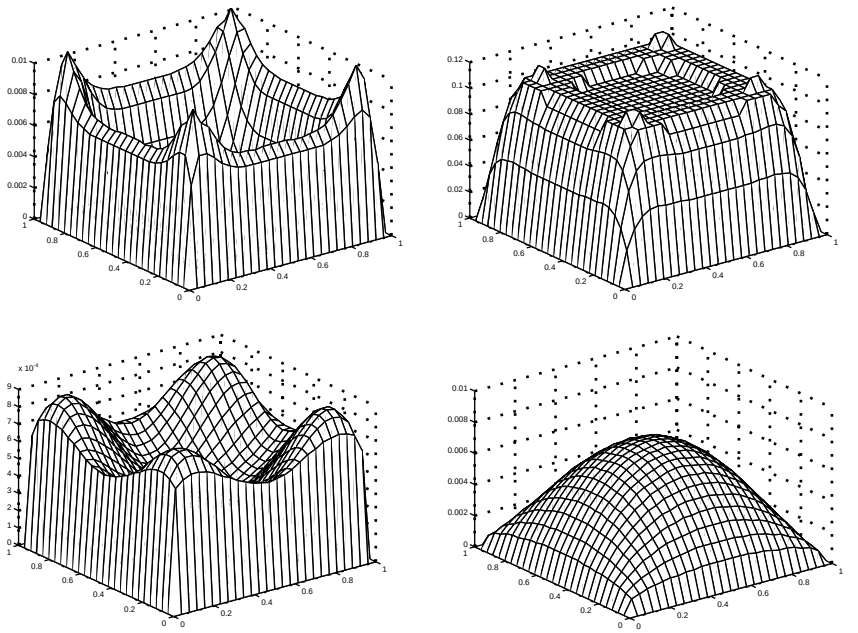

FIG. 4. *Numerical solutions of* (OPC1) *(top) and* (OPC2) *(bottom) with objective functions* z_1 *(left) and* z_2 *(right).*

Other examples were tested using the following objective functions:

$$z_1(x,y) = \frac{1}{\pi^2}\sin(\pi x)\sin(\pi y)(x-1/2)^2(y-1/2)^2$$

and

$$z_2(x,y) = \frac{1}{\pi^2}.$$

Here z_2 does not satisfy homogeneous Dirichlet boundary conditions and therefore is not attainable by any control. In both cases the GSN-multigrid scheme performs well, as can be seen in Table 16. To better interpret these last results see Figure 4.

7. Conclusions. Optimal solution and control algorithms for the steady state solid fuel ignition model were presented. They are based on finite difference discretization and multigrid techniques. Two alternative formulations of the optimal control

problem were considered and in both cases the desired optimal control behavior has been obtained. The numerical solution process was based on the results of our analysis: We gave necessary and sufficient conditions for existence of solutions to the direct problem and proved second-order accuracy of the numerical solution. The main tool was the method of upper and lower solutions that was also used to analyze a suitable numerical iterative method. We considered two types of smoothers in the nonlinear multigrid scheme. This method solves the optimal control problem to the level of truncation errors in only a few cycles. Moreover, in the refining process, second-order accuracy of the solution to the direct problem as well as to optimality systems was observed. The method appears to be very efficient and robust with respect to changes in the value of the weights in the cost functionals.

Acknowledgments. The authors would like to thank Dr. A. Kauffmann, Dr. M. Vanmaele, and Dr. S. Volkwein for helpful discussions.

CONSTRUCTION OF SOLUTION CURVES FOR LARGE TWO-DIMENSIONAL PROBLEMS OF STEADY-STATE FLOWS OF INCOMPRESSIBLE FLUIDS*

VALMOR F. DE ALMEIDA† AND JEFFREY J. DERBY†

Abstract. This work represents a step toward advancing classical methods of bifurcation analysis in conjunction with very large-scale scientific computing needed to model realistically processes which involve laminar and steady flows of incompressible fluids. A robust method of analysis based on pseudoarclength continuation, Newton's method, and direct solution of linear systems is proposed and applied to the analysis of a representative system of fluid mechanics, namely the tilted lid driven cavity. Accurate solution curves, possessing simple singular points, were computed for Reynolds numbers varying from 0 to 10,000 and for different angles of tilt. The results demonstrate that two-dimensional models with up to 1,000,000 algebraic equations can be studied feasibly using the methods described here with state-of-the-art vector supercomputers.

Key words. incompressible and viscous fluids, Navier–Stokes equations, parameter continuation, path following, factorization of large unsymmetric sparse matrices, lid driven cavity

1. Introduction.

Steady-state flows of incompressible fluids are at the heart of many materials and chemical processing systems [Derby et al., 1994; Salinger et al., 1994]. Typically, the fluid flows in such processes can be very complicated, three-dimensional (3D), time-dependent, and most often capricious. Their study, along with coupled physical phenomena such as heat transfer, mass transfer, and chemical reaction, often requires extremely large-scale computations, with fine discretizations, to resolve phenomena occurring at disparate length scales. Analysis, design, and optimization demand an understanding of the system's behavior under systematic change of its physical parameters—a prime example of the utility of bifurcation analysis but, at the same time, an enormous challenge due to the computational effort involved in obtaining accurate steady-state solutions.

Classical bifurcation analysis has been extremely useful for the understanding of mathematical models that depend on parameters. The most successful method is a combination of pseudoarclength parameter continuation [Keller, 1992], Newton's method, and factorization of the matrices of coefficients of the underlying systems of linear algebraic equations. Unfortunately, the high cost of this approach has delayed computer-aided bifurcation analysis of fluid systems in 3-D space. The bottleneck and most expensive part of the solution process is the factorization of large and sparse matrices. However, this situation is changing rapidly in view of the increasing computational power of parallel computers and important developments in computational

linear algebra. Of importance to this investigation are high performance BLAS2/3 [Basic Linear Algebra Subprograms, Dongarra et al., 1990] kernels supported by many vendors of high performance computers, fast and high quality graph partitioning and ordering [Karypis and Kumar, 1995], sparse factorization methods that exploit parallelism, and combined direct/iterative methods for solution of really challenging linear algebra problems [Duff, 1996].

Our overall goal is to develop classical methods of bifurcation analysis so that they become viable for realistic problems arising from modeling of materials processing systems in 3-D space. This article takes a first step in that direction by analyzing very large-scale two-dimensional flow problems. Its primary concern is to seek for modifications of the classical methods of bifurcation analysis that substantially increase their performance at a lower cost. These modifications must be simple enough to allow straightforward implementation on modern message passing parallel computers. In addition, the resulting method ought to be tested extensively with representative test cases.

Section 2 describes a representative two-dimensional system of fluid mechanics, namely, the lid driven cavity (LDC), which is subjected to analysis in the remaining sections. The corresponding 3-D system is the topic of [de Almeida and Derby, 1999]. The mathematical model is characterized by a single parameter, namely, the Reynolds number.

A classical method of approximate solution of the Navier–Stokes equations, namely, the Galerkin finite element method, is presented in section 3—the method is iterative owing to nonlinearity. The iterates satisfy a full linearization of the original equations. This iterative method, known as Newton's method, converges quadratically for a suitable initial guess, and it is the most well-known robust method for solving nonlinear systems of equations. Its cost, however, is high and is dominated by the factorization of a large and sparse Jacobian matrix at each iteration. Although a multitude of alternative methods [Gomes-Ruggiero, Martinez, and Moretti, 1992] appeared in the literature promising lower costs, we concluded that the complexity of the resultant algorithms hinders their message passing parallel implementation.

The purpose of section 3 is twofold. First, it presents Newton's method in the context of solving Galerkin's weak form of the Navier–Stokes equations for a fixed Reynolds number. The iterates are then approximated with the finite element method. Second, it advocates the use of an inner iteration within each (outer) Newton's iteration. Each inner iteration attempts to accelerate convergence by solving the linear system of equations with the existent factorization of the Jacobian matrix. The maximum number of inner iterations must cost only a prescribed fraction of a factorization and each inner iteration must reduce the magnitude of the iterates' correction. Otherwise, the inner iteration is interrupted and the outer iteration is resumed with a new factorization of the Jacobian matrix. It is shown that for the particular case of the Navier–Stokes equations, Newton's method combined with inner iterations (NMI) delivers higher convergence rates at a cost lower than that of Newton's method alone. This is no accident. According to [Brent, 1973], the method just described was first proposed by [Shamanskii, 1967] as a modification of Newton's method.

The method was severely tested on a state-of-the-art vector supercomputer, the Cray C-90, in order to determine its limitations in realistic large-scale numerical simulations. The geometry of the domain where the Navier–Stokes equations apply was chosen so that the underlying system of algebraic equations was the most challenging for current reordering methods. Nevertheless, identical convergence rates were ob-

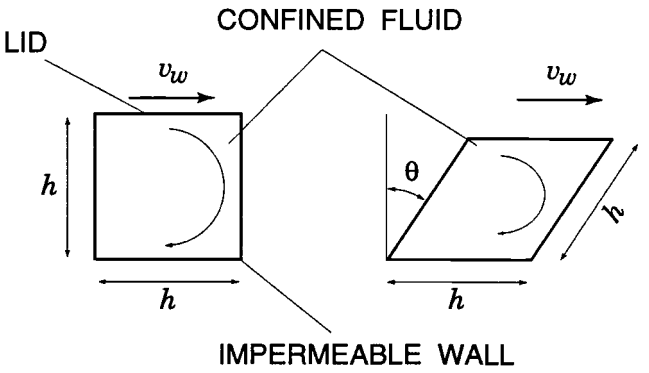

FIG. 2.1. *Lid driven cavity with rhombus geometry.*

tained for very refined distinct finite element partitions. It was also concluded that with the current powerful vector supercomputers and fast algorithms for factorization of sparse matrices, nonlinear systems of up to 1,000,000 algebraic equations resulting from the discretization of Navier–Stokes equations can be solved.

In section 4 a predictor-corrector method for construction of solution curves of the Navier–Stokes equations is put forward. The method consists of several simple modifications of the classical pseudoarclength continuation of [Keller, 1992] aimed at lowering cost while preserving robustness. The predictor step is an explicit Euler method. Because this first-order accurate method requires the solution of a linear system, it is only employed in curved portions of the solution curve. Otherwise, in flat portions of the solution curve, the predictor step is approximated by simple finite differences. Similarly, the corrector step with pseudoarclength parametrization of the solution curve is used only in curved portions of the solution curve, while the method described in section 3, NMI, is the corrector method of choice for flat portions of the solution curve.

A dramatic cost reduction was obtained by recycling an existent factorization of the Jacobian matrix along the solution curve. This was possible because of the generous radius of convergence of Newton's method when applied to the Navier–Stokes equations. The predictor-corrector method (section 4) was also subjected to extensive tests, with the LDC problem, (section 5) that constructed solution curves for Reynolds numbers up to 10,000 in the presence of simple singular points. The method performed outstandingly.

Last but not least, section 6 briefly discusses necessary modifications for the implementation of the algorithm on message passing parallel computers and extensions that allows the analysis of 3-D problems.

2. Governing equations of fluid motion in a cavity. The confined flow of an incompressible fluid in a lid driven cavity (LDC) was chosen as a representative system of fluid mechanics (Figure 2.1). Despite the system's simple boundary conditions and geometry, the fluid flow can be surprisingly nontrivial for certain speeds of the lid and/or some variations in the geometry of the cavity. In fact, the flow is characterized by multiple vortices, boundary layers with separation and reattachment, internal layers, and point singularities (see Figures 5.3 and 5.4).

Denoting Ω the region of two-dimensional Euclidean space occupied by the con-

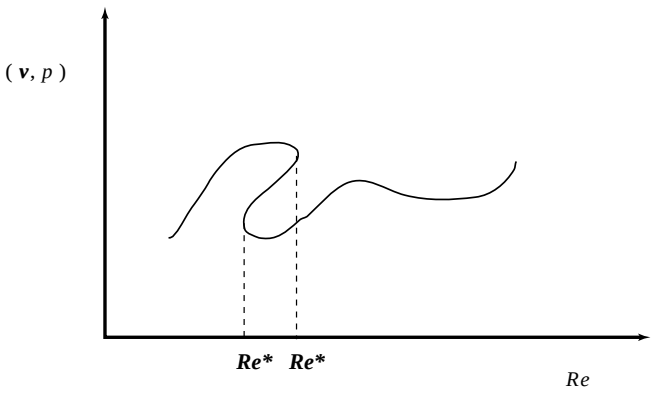

FIG. 2.2. *Sketch of solution curve.*

fined fluid in the cavity, the governing equations of steady-state motion of a Newtonian and incompressible fluid are the Navier–Stokes system,

$$
\begin{aligned}
&\text{(2.1a)} \qquad Re\ \nabla_{\boldsymbol{x}}\, \boldsymbol{v}\, \boldsymbol{v}(\boldsymbol{x}) = \operatorname{div}_{\boldsymbol{x}} \boldsymbol{T} \qquad \forall \quad \boldsymbol{x} \in \Omega\ ,\\
&\text{(2.1b)} \qquad \operatorname{div}_{\boldsymbol{x}} \boldsymbol{v} = 0 \qquad \forall \quad \boldsymbol{x} \in \Omega\ ,\\
&\text{(2.1c)} \qquad \boldsymbol{v}(\boldsymbol{x}) = \boldsymbol{v}_b(\boldsymbol{x}) \qquad \forall \quad \boldsymbol{x} \in \partial\Omega\,.
\end{aligned}
$$

Here $Re := \frac{\rho v_w h}{\mu}$ denotes the Reynolds number, where ρ is the density of the fluid and μ, its dynamic viscosity; $\boldsymbol{v}$ is the spatial velocity field in units of v_w;

$$\boldsymbol{T}(\boldsymbol{x}) := -p(\boldsymbol{x})\boldsymbol{I} + \left(\nabla_{\boldsymbol{x}}\, \boldsymbol{v} + \nabla_{\boldsymbol{x}}\, \boldsymbol{v}^{\mathsf{T}}\right)$$

is the stress in units of $\frac{\mu v_w}{h}$ at the point $\boldsymbol{x}$ in a Newtonian fluid; p is the pressure field modified by a conservative body force; and $\boldsymbol{v}_b$ is the boundary data for velocity—it is zero everywhere on $\partial\Omega$ except on the lid where its constant magnitude is one. Therefore, $\boldsymbol{v}_b$ satisfies the global mass balance compatibility condition.

A collection of solutions to (2.1) for different values of Re is best represented as a "curve" in an abstract solution space $(\boldsymbol{v}, p) \times Re$ (Figure 2.2). A parametrization of this curve with respect to the naturally appearing parameter Re,

$$\left(\boldsymbol{v}\,(\cdot, Re)\,, p\,(\cdot, Re)\right), \tag{2.2}$$

is inconvenient in virtue of the existence of simple singular points Re^*, where

$$\boldsymbol{v}'(\cdot, Re^*) := \frac{\partial \boldsymbol{v}}{\partial Re}(\cdot, Re^*) = \infty \quad \text{and} \quad p'(\cdot, Re^*) := \frac{\partial p}{\partial Re}(\cdot, Re^*) = \infty\ , \tag{2.3}$$

also known as turning points. Other possible singular points are those where $\boldsymbol{v}'(\cdot, Re^*)$ and $p'(\cdot, Re^*)$ are multivalued. In any case the singularity is often associated to the onset of multiple pairs, as indicated in Figure 2.2, for the same value of Re in (2.2). Nevertheless, this parametrization can be safely used away from such points inasmuch as a particular branch of the curve is unambiguously selected.

The solution curve of (2.1) for the LDC does exhibit singular points, particularly when the angle of tilt is not zero. The values of angle of tilt studied here are illustrated

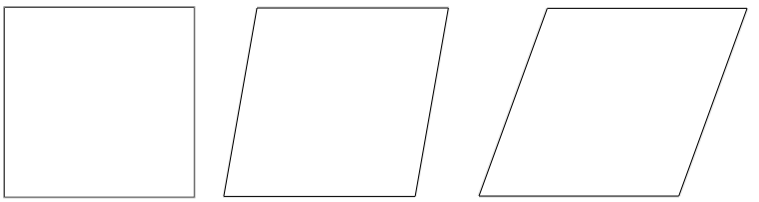

FIG. 2.3. *Angles of tilt examined.*

in Figure 2.3 (they all preserve the same aspect ratio of one). The reason for choosing this particular aspect ratio is explained in section 3.2.

An adequate parametric representation of a solution curve of (2.1) is obtained by introducing a reparametrization with a new parameter λ, that is,

$$\big(\boldsymbol{v}\,(\cdot, Re(\lambda))\,, p\,(\cdot, Re(\lambda))\big) \tag{2.4a}$$

or

$$\big(\widehat{\boldsymbol{v}}(\cdot,\lambda), \widehat{p}(\cdot,\lambda)\big), \tag{2.4b}$$

where $\widehat{\boldsymbol{v}}(\cdot,\lambda) := \boldsymbol{v}\,(\cdot, Re(\lambda))$ and $\widehat{p}(\cdot,\lambda) := p\,(\cdot, Re(\lambda))$. The reparametrization is defined (sections 4.1.2 and 4.2.2) so that simple singular points are eliminated.

This article is primarily concerned with showing cost-effective means of constructing (2.4) when solving (2.1) is extremely computationally intensive. Therefore the solution curves computed here are not used for an in-depth discussion of the physics of the LDC as modeled by (2.1).

3. Approximate solution to Galerkin's weak form. The most common weak form of (2.1) follows: find $(\boldsymbol{v}, p) \in \mathbf{V} \times \mathrm{L}^2_0(\Omega)$ such that

$$Re\ \mathrm{c}(\boldsymbol{v}\,,\boldsymbol{v}\,,\boldsymbol{u}) + \mathrm{a}(\boldsymbol{v}\,,\boldsymbol{u}) + \mathrm{b}(p\,,\boldsymbol{u}) = 0 \qquad \forall \quad \boldsymbol{u} \in \mathbf{H}^1_0(\Omega)\,, \tag{3.1a}$$

$$\mathrm{b}(q\,,\boldsymbol{v}) = 0 \qquad \forall \quad q \in \mathrm{L}^2_0(\Omega)\,, \tag{3.1b}$$

where

$$\mathrm{c}(\boldsymbol{w}\,,\boldsymbol{v}\,,\boldsymbol{u}) := \int_\Omega \nabla_{\boldsymbol{x}}\,\boldsymbol{w}\,\boldsymbol{v}(\boldsymbol{x}) \cdot \boldsymbol{u}(\boldsymbol{x})\,d\boldsymbol{x}\,, \quad \mathrm{a}(\boldsymbol{v}\,,\boldsymbol{u}) := \int_\Omega \left(\nabla_{\boldsymbol{x}}\,\boldsymbol{v} + \nabla_{\boldsymbol{x}}\,\boldsymbol{v}^{\mathsf{T}}\right) \bullet \nabla_{\boldsymbol{x}}\,\boldsymbol{u}\,d\boldsymbol{x}\,,$$

$$\mathrm{b}(p\,,\boldsymbol{u}) := \int_\Omega -p(\boldsymbol{x})\,\mathrm{div}_{\boldsymbol{x}}\,\boldsymbol{u}\,d\boldsymbol{x}\,,$$

$\mathbf{V} := \big\{\boldsymbol{v} \in \mathbf{H}^1(\Omega) \mid \boldsymbol{v} \equiv \boldsymbol{v}_b \text{ on } \partial\Omega\big\}$, and the spaces $\mathbf{H}^1(\Omega)$ and $\mathrm{L}^2_0(\Omega)$ are defined in the appendix. The inner product between two tensors is denoted $\boldsymbol{A} \bullet \boldsymbol{B}$.

3.1. Newton's method. A solution to (3.1) for a fixed Re can be found iteratively by computing a sequence $\big\{(\boldsymbol{v}^{(n)}, p^{(n)}) \in \mathbf{V} \times \mathrm{L}^2_0(\Omega) \mid n = 1, 2, \dots\big\}$, with a suitable initial guess for the velocity field $\boldsymbol{v}^{(0)} \in \mathbf{V}$—an initial guess for a pressure field can be arbitrary by virtue of the linearity of (3.1) with respect to p. Each iterate $(\boldsymbol{v}^{(n)}, p^{(n)})$ is computed by correcting its predecessor, $(\boldsymbol{v}^{(n-1)}, p^{(n-1)})$, with a

correction $(\boldsymbol{v}_c^{(n)}, p_c^{(n)}) \in \mathbf{H}_0^1(\Omega) \times \mathrm{L}_0^2(\Omega)$ so that

$$\boldsymbol{v}^{(n)} \equiv \boldsymbol{v}^{(n-1)} + \boldsymbol{v}_c^{(n)}\,, \tag{3.2a}$$

$$p^{(n)} \equiv p^{(n-1)} + p_c^{(n)}\,. \tag{3.2b}$$

The correction satisfies a linearization of (3.1),

(3.3a)

$$Re\Big\{\overbrace{\mathrm{c}\Big(\boldsymbol{v}_c^{(n)}\,,\,\boldsymbol{v}^{(n-1)}\,,\,\boldsymbol{u}\Big) + \mathrm{c}\Big(\boldsymbol{v}^{(n-1)}\,,\,\boldsymbol{v}_c^{(n)}\,,\,\boldsymbol{u}\Big)}^{\text{linearized convection}}\Big\} + \mathrm{a}\Big(\boldsymbol{v}_c^{(n)}\,,\,\boldsymbol{u}\Big) + \mathrm{b}\Big(p_c^{(n)}\,,\,\boldsymbol{u}\Big)$$

$$= -\Big\{\overbrace{Re\;\mathrm{c}\Big(\boldsymbol{v}^{(n-1)}\,,\,\boldsymbol{v}^{(n-1)}\,,\,\boldsymbol{u}\Big) + \mathrm{a}\Big(\boldsymbol{v}^{(n-1)}\,,\,\boldsymbol{u}\Big) + \mathrm{b}\Big(p^{(n-1)}\,,\,\boldsymbol{u}\Big)}^{\text{residual of (3.1a) at } (\boldsymbol{v}^{(n-1)},p^{(n-1)})}\Big\} \quad \forall\ \boldsymbol{u} \in \mathbf{H}_0^1(\Omega)\,,$$

(3.3b)

$$\mathrm{b}\Big(q\,,\,\boldsymbol{v}_c^{(n)}\Big) = -\overbrace{\mathrm{b}\Big(q\,,\,\boldsymbol{v}^{(n-1)}\Big)}^{\text{residual of (3.1b) at } \boldsymbol{v}^{(n-1)}} \qquad \forall \quad q \in \mathrm{L}_0^2(\Omega)\ .$$

The magnitude of the corrections, $\big\|\boldsymbol{v}_c^{(n)}\big\|_{\mathbf{H}^1(\Omega)}$ and $\big\|p_c^{(n)}\big\|_{\mathrm{L}^2(\Omega)}$, converges quadratically to zero in a few number of iterations, provided that the right and left sides of (3.3) are small enough for $n = 1$. The iterative method (3.2)–(3.3), known as Newton's method, is the most successful method for solving (3.1); however, it is also the most expensive. This investigation searches for simple modifications that substantially reduce the cost of the method without sacrificing its robustness. In fact the results obtained showed that it is possible to lower the cost while improving the convergence rate.

3.2. Finite dimensional approximation. It is natural to search for an approximate solution of (3.3), at the nth iteration, in a finite dimensional subspace $\mathbf{V}_c^h \times \mathrm{P}_c^h$ of $\mathbf{H}_0^1(\Omega) \times \mathrm{L}_0^2(\Omega)$, where h is a parameter associated to the dimension of the subspaces $\mathbf{V}_c^h$ and P_c^h. Let $\{\boldsymbol{u}_j \mid j = 1, 2, \ldots, N\}$ be a basis of $\mathbf{V}_c^h$ and $\{q_l \mid l = 1, 2, \ldots, M\}$, a basis of P_c^h; then the approximate solution $(\boldsymbol{v}_c^h, p_c^h)^{(n)}$ can be formally expressed as a linear combination of these bases,

$$\boldsymbol{v}_c^h \equiv \sum_{j=1}^{N} \alpha_j^{(n)}\, \boldsymbol{u}_j\,, \tag{3.4a}$$

$$p_c^h \equiv \sum_{l=1}^{M} \beta_l^{(n)}\, q_l\,, \tag{3.4b}$$

where $\alpha_j^{(n)}$ and $\beta_l^{(n)}$ are real coefficients. Similarly the test functions $\boldsymbol{u}$ and q in (3.3) can be represented in terms of the same bases—this is the Galerkin's method. After substitution of (3.4), and similar representations for $\boldsymbol{u}$ and q, into (3.3) and invoking the arbitrariness of $\boldsymbol{u}$ and q, one obtains a system of linear equations for the

coefficients α_j and β_l:

$$\sum_{j=1}^{N} A_{i,j}^{(n-1)}\,\alpha_j^{(n)} + \sum_{l=1}^{M} B_{l,i}\,\beta_l^{(n)} = -m_i^{(n-1)} \qquad i = 1, 2, \ldots, N, \tag{3.5a}$$

$$\sum_{j=1}^{N} B_{k,j}\,\alpha_j^{(n)} = -c_k^{(n-1)} \qquad k = 1, 2, \ldots, M, \tag{3.5b}$$

where

$$A_{i,j}^{(n-1)} := Re\Big\{\mathrm{c}\Big(\boldsymbol{u}_j\,,\,\boldsymbol{v}^{(n-1)}\,,\,\boldsymbol{u}_i\Big) + \mathrm{c}\Big(\boldsymbol{v}^{(n-1)}\,,\,\boldsymbol{u}_j\,,\,\boldsymbol{u}_i\Big)\Big\} + \mathrm{a}(\boldsymbol{u}_j\,,\,\boldsymbol{u}_i)\,, \tag{3.6a}$$

$$B_{k,j} := \mathrm{b}(q_k\,,\,\boldsymbol{u}_j)\,, \tag{3.6b}$$

$$m_i^{(n-1)} := Re\,\mathrm{c}\Big(\boldsymbol{v}^{(n-1)}\,,\,\boldsymbol{v}^{(n-1)}\,,\,\boldsymbol{u}_i\Big) + \mathrm{a}\Big(\boldsymbol{v}^{(n-1)}\,,\,\boldsymbol{u}_i\Big) + \mathrm{b}\Big(p^{(n-1)}\,,\,\boldsymbol{u}_i\Big)\,, \tag{3.6c}$$

$$c_k^{(n-1)} := \mathrm{b}\Big(q_k\,,\,\boldsymbol{v}^{(n-1)}\Big)\,. \tag{3.6d}$$

Remarks. In view of (3.2a) and (3.3b), $\boldsymbol{v}^{(n)}$ satisfies the weak mass balance (3.1b) for every iteration n—and so does $\boldsymbol{v}^{(n-1)}$. Therefore the residual of the mass balance $\mathrm{b}\big(q\,,\,\boldsymbol{v}^{(n-1)}\big)$ is zero for all n and $c_k^{(n-1)} = 0$ (up to round-off error).

The accuracy and stability of the approximation (3.4) depends upon the choice for the velocity and pressure correction spaces, $\mathbf{V}_c^h$ and P_c^h [Brezzi and Fortin, 1991]. A systematic method for choosing and constructing these spaces is provided by the finite element method. The choice made here employs piecewise biquadratic basis functions for velocity and linear piecewise discontinuous functions for pressure, both of them with compact support over the finite element; this is the so-called $Q_2{-}P_1$ mixed finite element.

The system of linear equations (3.5) can be put into a matrix form

$$\begin{pmatrix} \mathbf{A}^{(n-1)} & \mathbf{B}^{\mathsf{T}} \\ \mathbf{B} & \mathbf{0} \end{pmatrix} \begin{pmatrix} \boldsymbol{\alpha}^{(n)} \\ \boldsymbol{\beta}^{(n)} \end{pmatrix} = - \begin{pmatrix} \mathbf{m}^{(n-1)} \\ \mathbf{c}^{(n-1)} \end{pmatrix} \tag{3.7}$$

for each iteration in (3.3). The elements of the submatrices $\mathbf{A}$ and $\mathbf{B}$, and the residual vectors $\mathbf{m}$ and $\mathbf{c}$ are exhibited in (3.6). $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$ are the vectors of coefficients α_j and β_l, respectively. Owing to the choice of the basis functions with compact support, $\mathbf{A}$ and $\mathbf{B}$ are extremely sparse. The density of nonzero elements in these matrices is typically on the order of 0.01% for large N and M. The method of choice to solve (3.7) is a triangular factorization of the coefficient matrix

$$\mathbf{J}^{(n-1)} := \begin{pmatrix} \mathbf{A}^{(n-1)} & \mathbf{B}^{\mathsf{T}} \\ \mathbf{B} & \mathbf{0} \end{pmatrix} \tag{3.8}$$

such that

$$\mathbf{P}^{(n-1)}\,\mathbf{J}^{(n-1)}\,\mathbf{Q}^{(n-1)} = \mathbf{L}^{(n-1)}\,\mathbf{U}^{(n-1)}\,, \tag{3.9}$$

where $\mathbf{P}$ and $\mathbf{Q}$ are, respectively, row and column permutation matrices; $\mathbf{L}$ is an upper triangular unit matrix and $\mathbf{U}$ is a lower triangular matrix. The factorization method employed here is similar to that of [Duff and Scott, 1993]. Typical performance of the method is shown in Table 3.1 as applied to the test cases of sections 3.4 and 5. Of

course $\mathbf{J}$ needs to be conveniently reordered [Sloan, 1989; Duff, Reid, and Scott, 1989; Karypis, 1996, see METIS] so that its triangular factors are also sparse. In view of the aspect ratio chosen for the LDC, the methods of [Sloan, 1989] and [Duff, Reid, and Scott, 1989] do not perform any better than simply reordering the finite elements along either the horizontal or vertical directions. The multilevel nested dissection method of METIS reduces the sparsity of the $\mathbf{L}$ and $\mathbf{U}$ factors by a factor of two, however, it's not unusual for the operation count of profile-based factorization methods to exhibit a tenfold increase. In summary, the coefficient matrix $\mathbf{J}$ associated to the aspect ratio chosen for the LDC is the worst possible case for profile-reduction reordering methods.

The solution of

$$\mathbf{J}^{(n-1)}\,\mathbf{x}^{(n)} = \mathbf{b}^{(n-1)}, \tag{3.10}$$

where

$$\mathbf{b}^{(n-1)} := -\begin{pmatrix}\mathbf{m}^{(n-1)}\\ \mathbf{c}^{(n-1)}\end{pmatrix} \quad \text{and} \quad \mathbf{x}^{(n)} := \begin{pmatrix}\boldsymbol{\alpha}^{(n)}\\ \boldsymbol{\beta}^{(n)}\end{pmatrix}, \tag{3.11}$$

is obtained by forward and backward substitutions, respectively,

$$\mathbf{L}^{(n-1)}\,\mathbf{y}^{(n)} = \mathbf{P}^{(n-1)}\,\mathbf{b}^{(n-1)} \quad \text{solve for } \mathbf{y}^{(n)}, \tag{3.12a}$$

$$\mathbf{U}^{(n-1)}\,\mathbf{z}^{(n)} = \mathbf{y}^{(n)} \quad \text{solve for } \mathbf{z}^{(n)}, \tag{3.12b}$$

$$\mathbf{x}^{(n)} = \mathbf{Q}^{(n-1)}\,\mathbf{z}^{(n)}\,. \tag{3.12c}$$

3.3. Inner iteration in Newton's method. The cost of factoring $\mathbf{J}$ is the most expensive part in computing a converged solution of (3.1). This cost can be drastically reduced by exploiting multiple forward/backward substitutions with the existing factors of $\mathbf{J}$ in order to reduce the residuals and the magnitude of the corrections in (3.3). Let

$$\mathbf{J}^{(n-1)}\,\mathbf{x}^{(n)} = \mathbf{b}^{(n-1)} \tag{3.13}$$

represent a finite approximation of (3.3) at the nth iteration. After a factorization of $\mathbf{J}^{(n-1)}$ is obtained, k inner iterations of forward/backward substitutions are performed:

$$\mathbf{L}^{(n-1)}\,\mathbf{y}^{(i)} = \mathbf{P}^{(n-1)}\,\mathbf{b}^{(i)}\,, \tag{3.14a}$$

$$\mathbf{U}^{(n-1)}\,\mathbf{z}^{(i)} = \mathbf{y}^{(i)}\,, \tag{3.14b}$$

$$\mathbf{x}^{(i)} = \mathbf{Q}^{(n-1)}\,\mathbf{z}^{(i)}, \quad i = 1, 2, \ldots, k\,. \tag{3.14c}$$

The number of inner iterations is determined by the total cost of (3.14) relative to the cost of the factorization of $\mathbf{J}^{(n-1)}$, provided that the magnitude of the corrections and residuals in (3.3) are monotonically decreasing during the inner iterations (3.14).

If the cost of factoring $\mathbf{J}^{(n-1)}$ is $\mathcal{C}$ and the cost of one iteration in (3.14) is $\mathcal{C}_i$, then the maximum number of inner iterations, $k_{\max}$, is computed by

$$k_{\max} = f\,\frac{\mathcal{C}}{\mathcal{C}_i},$$

where f is the fraction of $\mathcal{C}$ that (3.14) is allowed to cost. In the experiments reported in later sections, $f = 0.5$ is used and the resultant k is typically smaller than $k_{\max}$.

It is observed that the reasons why k is often smaller than $k_{\max}$ are either because the magnitude of the residuals and corrections passed the convergence criteria before k reached $k_{\max}$ or because the magnitude of the corrections or residuals increased in the kth inner iteration (sections 3.4 and 5). When the latter occurs, the solution $\mathbf{x}^{(k)}$ is discarded and $\mathbf{x}^{(k-1)}$ is used to factor $\mathbf{J}^{(n)}$ and to resume the $(n+1)$th outer iteration.

The convergence criteria of (3.3) are

$$\frac{\left\|\boldsymbol{v}_c^{(n)}\right\|_{\mathbf{H}^1(\Omega)}}{\left\|\boldsymbol{v}^{(n)}\right\|_{\mathbf{H}^1(\Omega)}} \leq 10^{-5}, \tag{3.15a}$$

$$\frac{\left\|p_c^{(n)}\right\|_{\mathrm{L}^2(\Omega)}}{\left\|p^{(n)}\right\|_{\mathrm{L}^2(\Omega)}} \leq 10^{-5}, \tag{3.15b}$$

$$\sqrt{\frac{\sum_{i=1}^{N}\left(m_i^{(n)}\right)^2}{N}} \leq 10^{-5}. \tag{3.15c}$$

Convergence is declared if all of the above are satisfied simultaneously.

Inner iterations within Newton's method is not a new idea. The method just described belongs to a class of high-order methods, that is, methods that converge q-superlinear with q-order larger than two. According to [Brent, 1973], Shamanskii [Shamanskii, 1967] first introduced the modification (3.14) in Newton's method. In fact, the q-order of convergence is exactly $k+1$. We were unaware of Shamanskii's work and it is our belief that the method has been rediscovered by others also [Fortin, Fortin, and Gervais, 1987; Fortin and Fortin, 1985].

3.4. Results and comments. The performance of Newton's method combined with inner iterations (NMI) is reported below. The method is employed to solve (3.1) with $\theta = 0$ for three values of Re, namely, 0, 250, and 500 and three finite element approximations: (a) 10,000 finite elements and 110,802 equations, (b) 40,000 finite elements and 441,602 equations, and (c) 90,000 finite elements and 992,402 equations. The finite elements are distributed uniformly on the cavity. The initial guess $\boldsymbol{v}^{(0)}$ for the case with $Re = 250$ was the velocity field obtained from $Re = 0$. Similarly, $\boldsymbol{v}^{(0)}$ for the case with $Re = 500$ was the solution obtained from $Re = 250$.

The convergence of NMI as a function of outer iterations is illustrated in Figures 3.1 and 3.2 and compared against Newton's method. It was observed that when the tolerances (3.15) for the magnitude of the correction fields were satisfied, the root-mean-square (3.15c) of the residual vector associated to the weak momentum

balance (3.3a) was on the order of 10^{-8} or less. Furthermore, regardless of what the tolerances in (3.15) were, the root-mean-square of the residual vector associated to the weak mass balance (3.3b) was on the order of 10^{-13} or less (this is in agreement with the Remarks in section 3.2). Therefore, it was concluded that the criteria in (3.15) were conservative and gave rise to well-converged solutions with respect to the fixed-point iteration (3.3).

The NMI (3.14) had an impressive higher rate of convergence than Newton's method alone with the bonus of *a lower cost* (Figure 3.3). The lower cost arose from the fact that the inner iterations were inexpensive—compared to the cost of a full factorization (Figure 3.4), yet they were sufficient to guarantee convergence of the

method.

Another observed property of the NMI was the invariance with respect to the finite element approximation. Convergence results for 441,602 and 992,402 equations were exactly the same as those obtained with 110,802 equations (see Appendix B in [de Almeida and Derby, 1997]). The most attractive result is shown in Figure 3.2, where one single factorization aided by many forward/backward substitutions which cost less than 50% of a factorization, sufficed to obtain accurate convergence. The result was independent of the finite element approximation (see Figures B.2 and B.5 in [de Almeida and Derby, 1997]).

From the foregoing, a natural question arises: Can one do better by recycling an existing factorization from a previous value of Re to a future value of Re? This question motivated the remaining part of this article which shows that in the context of

a predictor-corrector continuation method the inner iteration performs outstandingly. It was found that several solutions of (3.1) for different values of Re can be computed with a single factorization of $\mathbf{J}$ when Re is far from singular points Re^*, while, when Re is close to Re^*, one or two factorizations suffice to obtain convergence.

4. A predictor-corrector method. A class of methods for construction of solution curves (2.2) or (2.4) is known under the generic name of predictor-corrector methods or simply continuation methods.

Let $(\boldsymbol{v}_{(m-1)}, p_{(m-1)})$ be a solution of (3.1) for a particular value of $Re = Re_{(m-1)}$, where m is an index varying from one to a prescribed number of solution points. A solution curve of (3.1) through $(\boldsymbol{v}_{(m-1)}, p_{(m-1)})$ can be constructed via a two-step approach. The first step predicts a solution at a new value of the Reynolds number, $Re^{(0)}_{(m)}$, typically by marching tangentially to the solution curve. The second step corrects the predicted solution, $Re^{(0)}_{(m)}$, iteratively until a converged solution, $Re_{(m)}$, is found.

The predictor-corrector method proposed below employs two different parametrizations of the solution curve, namely, *natural* and *pseudoarclength* parametrizations. The former is used away from singular points of the solution curve and the latter is used in the vicinity of simple singular points. The resultant method combines the robustness of the pseudoarclength parametrization with the inexpensiveness of the natural parametrization.

4.1. First-order predictor step. The most common predictor method requires the computation of the tangent vector to the solution curve at $(\boldsymbol{v}_{(m-1)}, p_{(m-1)})$. This constitutes a first-order predictor method. Other higher order methods exist but they are not cost-effective for the Navier–Stokes problem treated here.

4.1.1. Natural parametrization. Denoting the tangent vector to the solution curve illustrated in Figure 2.2

$$\big(1, (\boldsymbol{v}'_{(m-1)}, p'_{(m-1)})\big), \tag{4.1}$$

where $\boldsymbol{v}'_{(m-1)} := \boldsymbol{v}'(\cdot, Re_{(m-1)}) := \frac{\partial \boldsymbol{v}}{\partial Re}(\cdot, Re_{(m-1)})$ and $p'_{(m-1)} := p'(\cdot, Re_{(m-1)}) := \frac{\partial p}{\partial Re}(\cdot, Re_{(m-1)})$, and assuming that the tangent exists, then the tangent vector must satisfy

$$Re_{(m-1)}\Big\{\overbrace{\mathrm{c}\big(\boldsymbol{v}'_{(m-1)}\,,\,\boldsymbol{v}_{(m-1)}\,,\,\boldsymbol{u}\big) + \mathrm{c}\big(\boldsymbol{v}_{(m-1)}\,,\,\boldsymbol{v}'_{(m-1)}\,,\,\boldsymbol{u}\big)}^{\text{linearized convection}}\Big\} + \mathrm{a}\big(\boldsymbol{v}'_{(m-1)}\,,\,\boldsymbol{u}\big)$$
$$+\,\mathrm{b}\Big(p'_{(m-1)}\,,\,\boldsymbol{u}\Big) = -\overbrace{\mathrm{c}\big(\boldsymbol{v}_{(m-1)}\,,\,\boldsymbol{v}_{(m-1)}\,,\,\boldsymbol{u}\big)}^{\text{partial derivative of (3.1a) w.r.t } Re} \qquad \forall\ \boldsymbol{u} \in \mathbf{H}^1_0(\Omega)\,, \tag{4.2a}$$

$$\mathrm{b}\big(q\,,\,\boldsymbol{v}'_{(m-1)}\big) = 0 \quad \forall \quad q \in \mathrm{L}^2_0(\Omega)\,, \tag{4.2b}$$

which is the total derivative of (3.1) with respect to Re, evaluated at $(\boldsymbol{v}_{(m-1)}, p_{(m-1)}, Re_{(m-1)})$. Note that the solution pair of (4.2), $(\boldsymbol{v}'_{(m-1)}, p'_{(m-1)})$, belongs to $\mathbf{H}^1_0(\Omega) \times \mathrm{L}^2_0(\Omega)$ (see also 4.6).

A finite-dimensional approximation of (4.2) can be readily obtained by following the contents of section 3.2, which leads to a system of linear equations,

$$\begin{pmatrix} \mathbf{A} & \mathbf{B}^{\mathsf{T}} \\ \mathbf{B} & \mathbf{0} \end{pmatrix} \begin{pmatrix} \overline{\boldsymbol{\alpha}} \\ \overline{\boldsymbol{\beta}} \end{pmatrix} = - \begin{pmatrix} \overline{\mathbf{m}} \\ \mathbf{0} \end{pmatrix}, \tag{4.3}$$

where $\overline{\boldsymbol{\alpha}}$ and $\overline{\boldsymbol{\beta}}$ are the vectors of coefficients of the finite dimensional approximations of $\boldsymbol{v}'$ and p', respectively. The elements of the vector $\overline{\mathbf{m}}$ are

$$\overline{m}_i := \mathrm{c}\big(\boldsymbol{v}_{(m-1)}\,,\, \boldsymbol{v}_{(m-1)}\,,\, \boldsymbol{u}_i\big)\ . \tag{4.4}$$

It is clear that the matrix of coefficients in (4.3) is equal to the matrix $\mathbf{J}$ of (3.7) evaluated at $(\boldsymbol{v}_{(m-1)}, p_{(m-1)}, Re_{(m-1)})$. If a factorization of $\mathbf{J}$ at this solution point is available, the tangent vector to the solution curve at this point can be computed at the cost of one forward/backward substitution. If a factorization of $\mathbf{J}$ is not available, then solving (4.2) should be avoided by computing an approximate tangent vector,

$$\big(1, (\boldsymbol{v}'_{(m-1)}, p'_{(m-1)})\big) \approx \left(1, \Big(\frac{\boldsymbol{v}_{(m-1)} - \boldsymbol{v}_{(m-2)}}{Re_{(m-1)} - Re_{(m-2)}}, \frac{p_{(m-1)} - p_{(m-2)}}{Re_{(m-1)} - Re_{(m-2)}}\Big)\right), \tag{4.5}$$

given by the secant that joins the previous solution point $(\boldsymbol{v}_{(m-2)}, p_{(m-2)}, Re_{(m-2)})$ to the current point. This approximation often works well in practice inasmuch as the curvature of the solution curve is small. In fact, (4.5) is the method of choice, introduced here to compute the tangent direction. An accurate tangent is computed by solving (4.3) only if a factorization of $\mathbf{J}$ is already available or when the corrector step demands for it (section 4.3).

An approximation to the next solution point on the curve is then obtained by

$$\boldsymbol{v}_{(m)} \equiv \boldsymbol{v}_{(m-1)} + \Delta Re_{(m-1)}\, \boldsymbol{v}'_{(m-1)} \quad \text{and} \tag{4.6a}$$

$$p_{(m)} \equiv p_{(m-1)} + \Delta Re_{(m-1)}\, p'_{(m-1)}\,, \tag{4.6b}$$

where $\Delta Re_{(m-1)}$ is a prescribed steplength of Re (section 4.3) at the $(m-1)$th continuation step (see Figure 4.1).

4.1.2. Arclength parametrization. As mentioned in section 2, a parametrization of the solution curve by Re is inconvenient in the neighborhood of singular points Re^*. It was suggested that a reparametrization should take place such that the solution curve can be constructed beyond those points. It is proposed here that the reparametrization should occur when the curvature of the solution curve reaches a threshold. Owing to the high cost of computing the curvature of the solution curve, it is recommended that the angle α between successive tangents along the solution curve be computed alternatively. Thus, in the experiments reported below, when

$$\alpha := \arccos\left(\frac{1 + \boldsymbol{v}'_{(m-1)} \cdot \boldsymbol{v}'_{(m-2)} + p'_{(m-1)}\, p'_{(m-2)}}{\sqrt{1 + \big\|\boldsymbol{v}'_{(m-1)}\big\|^2_{\mathbf{H}^1(\Omega)} + \big\|p'_{(m-1)}\big\|^2_{\mathrm{L}^2(\Omega)}}\sqrt{1 + \big\|\boldsymbol{v}'_{(m-2)}\big\|^2_{\mathbf{H}^1(\Omega)} + \big\|p'_{(m-2)}\big\|^2_{\mathrm{L}^2(\Omega)}}}\right) \tag{4.7}$$

is greater than 10°, the solution curve is automatically reparametrized by λ (section 2) and the construction of the curve is resumed immediately. If α becomes smaller than 10°, then the parametrization of the solution curve is reverted to the natural

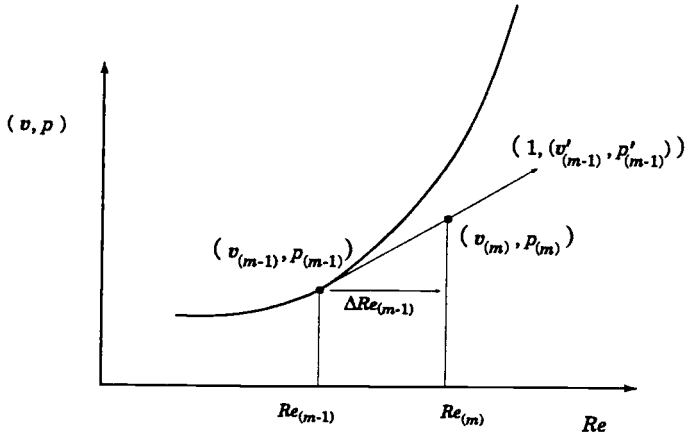

FIG. 4.1. *Predictor step with solution curve parametrized by the natural parameter Re.*

parametrization. Note that in (4.7)

$$\boldsymbol{v}'_{(m-1)} \cdot \boldsymbol{v}'_{(m-2)} := \int_\Omega \boldsymbol{v}'_{(m-1)}(\boldsymbol{x}) \cdot \boldsymbol{v}'_{(m-2)}(\boldsymbol{x})\, d\boldsymbol{x} \quad \text{and} \tag{4.8a}$$

$$p'_{(m-1)}\, p'_{(m-2)} := \int_\Omega p'_{(m-1)}(\boldsymbol{x})\, p'_{(m-2)}(\boldsymbol{x})\, d\boldsymbol{x}\,. \tag{4.8b}$$

The tangent vector to the solution curve in terms of λ is obtained by the chain rule of differentiation,

$$\dot{\boldsymbol{v}}_{(m-1)} := \dot{\boldsymbol{v}}(\cdot, \lambda_{(m-1)}) := \frac{\partial \widehat{\boldsymbol{v}}}{\partial \lambda}(\cdot, \lambda_{(m-1)}) = \boldsymbol{v}'_{(m-1)}\, \dot{Re}_{(m-1)}, \tag{4.9a}$$

$$\dot{p}_{(m-1)} := \dot{p}(\cdot, \lambda_{(m-1)}) := \frac{\partial \widehat{p}}{\partial \lambda}(\cdot, \lambda_{(m-1)}) = p'_{(m-1)}\, \dot{Re}_{(m-1)}, \tag{4.9b}$$

where $\dot{Re}_{(m-1)} := \frac{dRe}{d\lambda_{(m-1)}}$, with the independent assumption of

$$\left\|\dot{\boldsymbol{v}}_{(m-1)}\right\|^2_{\mathbf{H}^1(\Omega)} + \left\|\dot{p}_{(m-1)}\right\|^2_{\mathrm{L}^2(\Omega)} + \dot{Re}^2_{(m-1)} = 1\,, \tag{4.10}$$

necessary to determine $\dot{Re}$ uniquely (modulo a sign). Because the magnitude of the tangent as a function of λ is one, λ is the so-called arclength parameter.

Solving for $\dot{Re}_{(m-1)}$ in (4.9)–(4.10) yields

$$\dot{Re}_{(m-1)} = \frac{\pm 1}{\sqrt{1 + \left\|\boldsymbol{v}'_{(m-1)}\right\|^2_{\mathbf{H}^1(\Omega)} + \left\|p'_{(m-1)}\right\|^2_{\mathrm{L}^2(\Omega)}}}\,. \tag{4.11}$$

According to Keller's recommendation [Keller, 1992], the correct choice of the sign in (4.11) is the one that delivers $0 \le \alpha \le \frac{\pi}{2}$ (see Figure 4.2) so that the construction of the solution curve moves "forward." Therefore,

$$\left(\dot{Re}_{(m-1)}, \left(\dot{\boldsymbol{v}}_{(m-1)}, \dot{p}_{(m-1)}\right)\right) \cdot \left(\dot{Re}_{(m-2)}, \left(\dot{\boldsymbol{v}}_{(m-2)}, \dot{p}_{(m-2)}\right)\right) > 0\,,$$

$$\dot{Re}_{(m-1)} \left(1, \left(\boldsymbol{v}'_{(m-1)}, p'_{(m-1)}\right)\right) \cdot \left(\dot{Re}_{(m-2)}, \left(\dot{\boldsymbol{v}}_{(m-2)}, \dot{p}_{(m-2)}\right)\right) > 0\,.$$

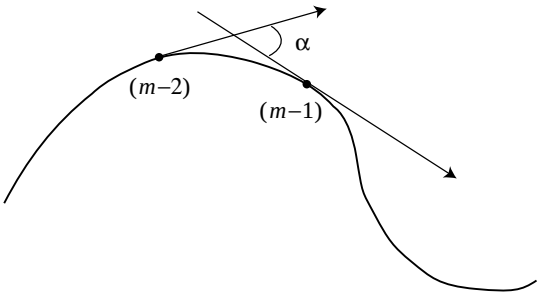

FIG. 4.2. *Correct choice of the angle α between successive tangent vectors on the solution curve.*

Thus,

$$\operatorname{sign}\big(\dot{Re}_{(m-1)}\big) = \operatorname{sign}\big(\dot{Re}_{(m-2)} + \boldsymbol{v}'_{(m-1)} \cdot \dot{\boldsymbol{v}}_{(m-2)} + p'_{(m-1)}\, \dot{p}_{(m-2)}\big)\,.$$

Substituting the above into (4.11), the working formula to find $\dot{Re}_{(m-1)}$ is

$$\boxed{\dot{Re}_{(m-1)} = \frac{\operatorname{sign}\big(\dot{Re}_{(m-2)} + \boldsymbol{v}'_{(m-1)} \cdot \dot{\boldsymbol{v}}_{(m-2)} + p'_{(m-1)}\, \dot{p}_{(m-2)}\big)}{\sqrt{1 + \big\|\boldsymbol{v}'_{(m-1)}\big\|^2_{\mathbf{H}^1(\Omega)} + \big\|p'_{(m-1)}\big\|^2_{\mathrm{L}^2(\Omega)}}}\,.} \tag{4.12}$$

In view of (4.9) and (4.12), a first-order approximation in λ to the mth solution point is simply

$$\boldsymbol{v}_{(m)} \equiv \boldsymbol{v}_{(m-1)} + \Delta\lambda_{(m-1)}\, \dot{\boldsymbol{v}}_{(m-1)}\,, \tag{4.13a}$$

$$p_{(m)} \equiv p_{(m-1)} + \Delta\lambda_{(m-1)}\, \dot{p}_{(m-1)}, \quad \text{and} \tag{4.13b}$$

$$Re_{(m)} = Re_{(m-1)} + \Delta\lambda_{(m-1)}\, \dot{Re}_{(m-1)}\,, \tag{4.13c}$$

where $\Delta\lambda_{(m-1)}$ is the steplength of the pseudoarclength parameter at the mth continuation step (section 4.3).

4.2. Corrector step. The role of the corrector is to solve (3.1) for a given initial guess obtained in the predictor step. The corrector methods described below differ on the kind of parametrization employed.

4.2.1. Natural parametrization. Given the initial guess $(\boldsymbol{v}^{(0)}_{(m)}, p^{(0)}_{(m)})$ at $Re_{(m)}$, obtained with the predictor method of section 4.1.1 (4.6), a solution of (3.1) can be computed (sections 3.1 and 3.2). An illustration of the predictor-corrector process for the mth continuation step is presented in Figure 4.3, where $(\boldsymbol{v}_{(m)}, p_{(m)})$ denotes a converged solution. This corrector method will fail in the vicinity of simple singular points such as turning points because the direction of search for a solution is perpendicular to the abscissa of the graph.

4.2.2. Pseudoarclength parametrization. A widely used corrector method [Keller, 1992] to construct solution curves in the neighborhood of turning points and other simple singular points consists of searching for a solution of (3.1) by constraining (3.3) such that the iterates $(\boldsymbol{v}^{(n)}_{(m)}, p^{(n)}_{(m)}, Re^{(n)}_{(m)})$ lie in the direction perpendicular to

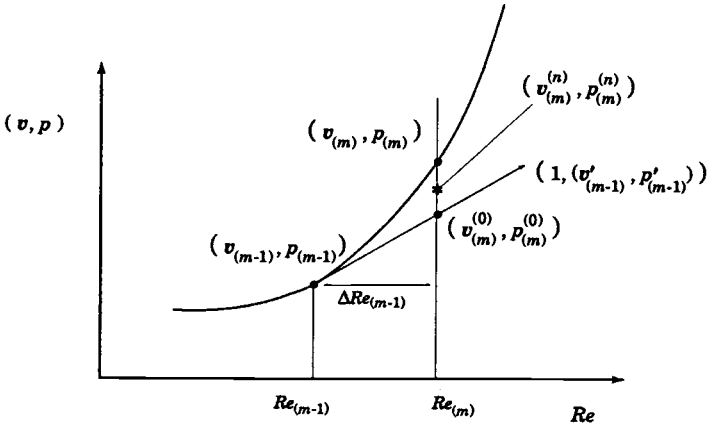

FIG. 4.3. *Predictor-corrector step with natural parametrization.*

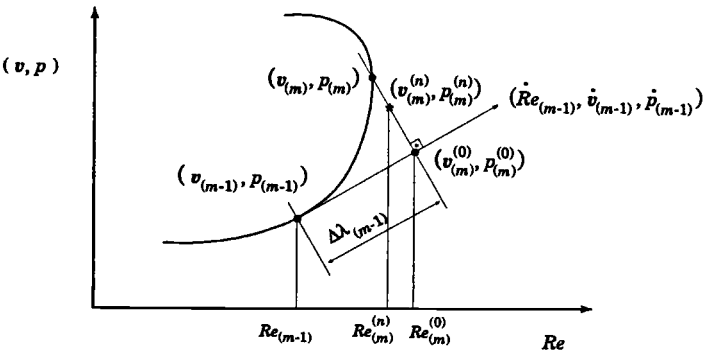

FIG. 4.4. *Predictor-corrector step with pseudoarclength parametrization.*

the tangent vector (see Figure 4.4). Therefore,

$$\left(Re^{(n)}_{(m)} - Re_{(m-1)}\right)\dot{Re}_{(m-1)} + \left(\boldsymbol{v}^{(n)}_{(m)} - \boldsymbol{v}_{(m-1)}\right)\cdot\dot{\boldsymbol{v}}_{(m-1)} + \left(p^{(n)}_{(m)} - p_{(m-1)}\right)\dot{p}_{(m-1)} = \Delta\lambda_{(m-1)}\,. \tag{4.14}$$

It is clear that neither the converged solution nor any of the iterates $(\boldsymbol{v}^{(n)}_{(m)}, p^{(n)}_{(m)}, Re^{(n)}_{(m)})$ satisfies the arclength condition, that is,

$$\sqrt{\left\|\dot{\boldsymbol{v}}^{(n)}_{(m)}\right\|^2_{\mathbf{H}^1(\Omega)} + \left\|\dot{p}^{(n)}_{(m)}\right\|^2_{\mathrm{L}^2(\Omega)} + \left(\dot{Re}^{(n)}_{(m)}\right)^2} \neq 1 \quad \forall\, n\,.$$

For this reason, λ is not the arclength parameter. However, because $\Delta\lambda$ is measured along the tangent direction on the solution curve, λ is known in the literature as the "pseudoarclength parameter." The distinction must be made clear whenever the context generates confusion. Although rarely used, a genuine arclength parameter continuation merits attention.

The mth corrector step is as follows: compute the sequence $\big\{(\boldsymbol{v}_{(m)}^{(n)}, p_{(m)}^{(n)}, Re_{(m)}^{(n)}) \in \mathbf{V} \times \mathrm{L}_0^2(\Omega) \times \mathbb{R} \mid n = 1, 2, \dots\big\}$ for a given predictor guess $(\boldsymbol{v}_{(m)}^{(0)}, p_{(m)}^{(0)}, Re_{(m)}^{(0)})$ such that

$$\boldsymbol{v}_{(m)}^{(n)} \equiv \boldsymbol{v}_{(m)}^{(n-1)} + \boldsymbol{v}_c^{(n)}\,, \tag{4.15a}$$

$$p_{(m)}^{(n)} \equiv p_{(m)}^{(n-1)} + p_c^{(n)}\,, \tag{4.15b}$$

$$Re_{(m)}^{(n)} \equiv Re_{(m)}^{(n-1)} + Re_c^{(n)}\,, \tag{4.15c}$$

where the correction $(\boldsymbol{v}_c^{(n)}, p_c^{(n)}, Re_c^{(n)}) \in \mathrm{H}_0^1(\Omega) \times \mathrm{L}_0^2(\Omega) \times \mathbb{R}$ satisfies

(4.16a)
$$\begin{aligned} Re_{(m)}^{(n-1)} \Big\{ \mathrm{c}\big(\boldsymbol{v}_c^{(n)}\,,\, \boldsymbol{v}_{(m)}^{(n-1)}\,,\, \boldsymbol{u}\big) + \mathrm{c}\big(\boldsymbol{v}_{(m)}^{(n-1)}\,,\, \boldsymbol{v}_c^{(n)}\,,\, \boldsymbol{u}\big) \Big\} + \mathrm{a}\big(\boldsymbol{v}_c^{(n)}\,,\, \boldsymbol{u}\big) + \mathrm{b}\big(p_c^{(n)}\,,\, \boldsymbol{u}\big) \\ + Re_c^{(n)}\, \mathrm{c}\big(\boldsymbol{v}_{(m)}^{(n-1)}\,,\, \boldsymbol{v}_{(m)}^{(n-1)}\,,\, \boldsymbol{u}\big) = -\Big\{ Re_{(m)}^{(n-1)}\, \mathrm{c}\big(\boldsymbol{v}_{(m)}^{(n-1)}\,,\, \boldsymbol{v}_{(m)}^{(n-1)}\,,\, \boldsymbol{u}\big) \\ + \mathrm{a}\big(\boldsymbol{v}_{(m)}^{(n-1)}\,,\, \boldsymbol{u}\big) + \mathrm{b}\big(p_{(m)}^{(n-1)}\,,\, \boldsymbol{u}\big) \Big\} \quad \forall\ \boldsymbol{u} \in \mathbf{H}_0^1(\Omega)\,, \end{aligned}$$

(4.16b)
$$\mathrm{b}\big(q\,,\, \boldsymbol{v}_c^{(n)}\big) = -\mathrm{b}\big(q\,,\, \boldsymbol{v}_{(m)}^{(n-1)}\big) \quad \forall \quad q \in \mathrm{L}_0^2(\Omega)\,,$$

(4.16c)
$$\begin{aligned} \boldsymbol{v}_c^{(n)} \cdot \dot{\boldsymbol{v}}_{(m-1)} + p_c^{(n)}\, \dot{p}_{(m-1)} + Re_c^{(n)}\, \dot{Re}_{(m-1)} \\ = \Delta\lambda_{(m-1)} - \Big\{ \big(\boldsymbol{v}_{(m)}^{(n-1)} - \boldsymbol{v}_{(m-1)}\big) \cdot \dot{\boldsymbol{v}}_{(m-1)} \\ + \big(p_{(m)}^{(n-1)} - p_{(m-1)}\big)\, \dot{p}_{(m-1)} + \big(Re_{(m)}^{(n-1)} - Re_{(m-1)}\big)\, \dot{Re}_{(m-1)} \Big\}\,. \end{aligned}$$

The magnitude of the corrections $\big\|\boldsymbol{v}_c^{(n)}\big\|_{\mathbf{H}^1(\Omega)}$, $\big\|p_c^{(n)}\big\|_{\mathrm{L}^2(\Omega)}$, and $\big|Re_c^{(n)}\big|$ converge quadratically to zero in a few number of iterations, provided that the right and left sides of (4.16) are small enough for $n = 1$.

A finite dimensional approximation of (4.16) (section 3.2) leads to a linear system of equations with a sparse matrix of coefficients,

$$\begin{pmatrix} \mathbf{J} & \mathbf{d} \\ \mathbf{a} & \dot{Re} \end{pmatrix} \begin{pmatrix} \mathbf{x} \\ Re_c \end{pmatrix} = \begin{pmatrix} \mathbf{b} \\ N \end{pmatrix}\,, \tag{4.17}$$

for each iteration n in (4.16), holding $m-1$ fixed, where

$$\begin{aligned} d_i &:= \mathrm{c}\big(\boldsymbol{v}_{(m)}^{(n-1)}\,,\, \boldsymbol{v}_{(m)}^{(n-1)}\,,\, \boldsymbol{u}_i\big)\,, \\ \mathbf{a} &:= \dot{Re}_{(m-1)}\, (\overline{\boldsymbol{\alpha}}_{(m-1)}, \overline{\boldsymbol{\beta}}_{(m-1)})^{\mathsf{T}} \text{ recall (4.3), (4.9) and (4.16c)}, \\ \mathbf{x} &:= (\boldsymbol{\alpha}^{(n)}, \boldsymbol{\beta}^{(n)})^{\mathsf{T}} \text{ recall (3.7) and (4.16a)}, \\ N &:= \Delta\lambda_{(m-1)} - \Big\{ \big(\boldsymbol{v}_{(m)}^{(n-1)} - \boldsymbol{v}_{(m-1)}\big) \cdot \dot{\boldsymbol{v}}_{(m-1)} \\ &\quad + \big(p_{(m)}^{(n-1)} - p_{(m-1)}\big)\, \dot{p}_{(m-1)} + \big(Re_{(m)}^{(n-1)} - Re_{(m-1)}\big)\, \dot{Re}_{(m-1)} \Big\}\,. \end{aligned}$$

The method of choice for solving (4.17) consists of a triangular factorization of $\mathbf{J}$ followed by block elimination. Thus,

$$\mathbf{J}\,\mathbf{v} = \mathbf{b} \qquad \text{solve for } \mathbf{v}, \tag{4.18a}$$

$$\mathbf{J}\,\mathbf{w} = \mathbf{d} \qquad \text{solve for } \mathbf{w}, \tag{4.18b}$$

$$Re_c = \frac{N - \mathbf{a}\cdot\mathbf{v}}{\dot{R}e - \mathbf{a}\cdot\mathbf{w}}\,, \tag{4.18c}$$

$$\mathbf{x} = \mathbf{v} - Re_c\,\mathbf{w}\,. \tag{4.18d}$$

Compared to (3.12), the above is twice as expensive in virtue of an extra forward-backward substitution. The strategy and convergence criteria to solve (4.17) is identical to that described in sections 3.2–3.3. Here, however, the cost of a factorization of $\mathbf{J}$ is greatly amortized (section 5) along the solution curve. That is, the $\mathbf{L}$ and $\mathbf{U}$ factors of $\mathbf{J}$ are recycled in several/many continuation steps inasmuch as the convergence criteria and the cost criterion are satisfied.

The predictor-corrector method based on the pseudoarclength parameter requires the evaluation of a number of scalar and vector products of field quantities (4.16c). In addition the angle α (4.7) needs to be computed at every predictor step. Frequent evaluation of the inner products (4.8) incurs extra costs that can be as high as, or higher than, as the cost of a forward-backward substitution. Therefore, an effort must be made to compute these products efficiently.

4.3. Steplength control and corrector failure measures. An efficient steplength strategy is vital to parameter analysis. If the steplength is too small, only a small portion of the solution curve is constructed. On the other hand, too large a steplength hinders the convergence of the corrector step. Steplength control in predictor-corrector methods of parameter analysis is typically done by observing the convergence rate of the corrector step during the computation of past solution points [Gunzburger and Peterson, 1991; Allgower and Georg, 1990; Bank and Mittelmann, 1989; Schwetlick and Cleve, 1987; Deuflhard, Fiedler, and Kunkel, 1987; Heijer and Rheinboldt, 1981; Rheinboldt, 1980].

Presumably, the collected information helps to estimate a priori the radius of convergence of the corrector step in the next solution point. One drawback of this approach is that it often fails in the vicinity of turning points because the estimates of the radius of convergence are based on portions of the solution curve that are relatively flat. In practice, one resorts to heuristic methods for adjusting the steplength. For instance, a heuristic steplength control can be designed and improved in the process of mesh refinement.

The Navier–Stokes equations have a generous radius of convergence in large portions of the solution curve up to the proximity of turning points (section 5). Only very close to a turning point, the radius of convergence diminishes dramatically. This behavior makes it difficult to make reliable estimates of the radius of convergence near turning points.

The heuristic steplength control advocated here enforces a monotonic rate of convergence on the corrector step. That is, the magnitude of the norms in (3.15), in addition to $\left|Re_c^{(n)}\right|$ in the case of the pseudo arclength parametrization, must decrease for each outer iteration n in the corrector step. Otherwise, a corrector failure is declared. The steplength is reduced by a factor of four and an accurate computation of the tangent direction is made by factoring $\mathbf{J}$ and solving (4.3). A maximum number of three failures is allowed in the corrector step before the iterations are interrupted.

If the corrector step converges without requiring a factorization of **J**, the steplength is increased by a factor of two. The natural parameter steplength is computed and compared to an upperbound. A valid steplength is the smallest value between the upperbound and the increased stepsize. In the results shown in section 5, corrector failures occur most often for solution points close to turning points. The amount of reduction or increase of the parameter steplength is problem dependent and also important to keep the method's cost low. Note that several corrector failures will incur a prohibitive cost to the predictor-corrector method. Each failure adds to the existing expenses the cost of a factorization of **J** used to compute an accurate tangent. The situation is not so critical because, as shown in section 5, the cost of factoring **J** is amortized in the corrector iterations.

4.4. Transition between parametrizations. When the angle α (4.7) between two successive tangent vectors in the solution curve is greater than 10°, the pseudoarclength parametrization of the curve is employed (sections 4.1.2 and 4.2.2). Otherwise, the natural parametrization is the method of choice. When a transition from the natural parametrization to the pseudoarclength parametrization occurs, the initial pseudoarclength parameter steplength is selected by

$$\Delta\lambda_{(m-1)} = \frac{\Delta Re_{(m-2)}}{\dot{Re}_{(m-1)}}, \tag{4.19}$$

where $(m-2)$ is the continuation step where $\alpha > 10°$ occurred. When the converse takes place, the initial natural parameter steplength is selected by

$$\Delta Re_{(m-1)} = \Delta\lambda_{(m-2)}\, \dot{Re}_{(m-2)}\,. \tag{4.20}$$

In this last case the initial natural parameter steplength is considered valid only if it is less than or equal to an upperbound. In the experiments reported below the upperbound is 100.

5. Results and discussion. Solution curves to the LDC problem (section 2) possessing 100 solution points were constructed by the methods presented in sections 3 and 4. Employing the heuristic steplength control described in section 4.3, it was found that the Reynolds number ranged between 0 and 10,000. The results were accurate with respect to the finite element approximations shown in Figure 5.1, and also with respect to the fixed-point iterations (Figures 5.6 and 5.8). Results obtained with $\theta = 20°$ and 40,000 finite elements (441,602 equations) are identical to the results presented below (see Appendix C in [de Almeida and Derby, 1997]).

The kinetic energy of the system $\mathcal{K}$, measured in units of $\frac{1}{2}\,\rho\, v_w^2\, h^2$, is defined as

$$\mathcal{K} := \int_\Omega \boldsymbol{v}(\boldsymbol{x}) \cdot \boldsymbol{v}(\boldsymbol{x})\, d\boldsymbol{x} = \big\|\boldsymbol{v}\big\|^2_{\mathbf{L}^2(\Omega)},$$

where $\boldsymbol{v}$ is measured in units of v_w and length is measured in units of h. Therefore $0 < \mathcal{K} < 1$ for any value of Re. Alternatively, the kinetic energy can be measured in units of $\frac{1}{2}\mu v_w h$, in this case

$$\widehat{\mathcal{K}} = Re\big\|\boldsymbol{v}\big\|^2_{\mathbf{L}^2(\Omega)}\,.$$

Figure 5.2 shows the kinetic energy as a function of the Reynolds number. For angles of tilt $\theta = 0$ and $\theta = 10$ the kinetic energy increases monotonically with Re

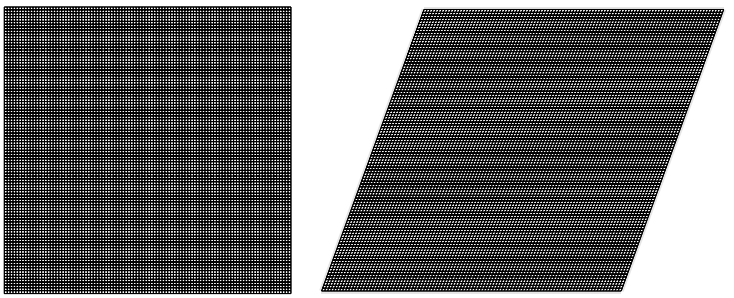

FIG. 5.1. *Finite element partition with* 10000 *finite elements and* 110,802 *equations.*

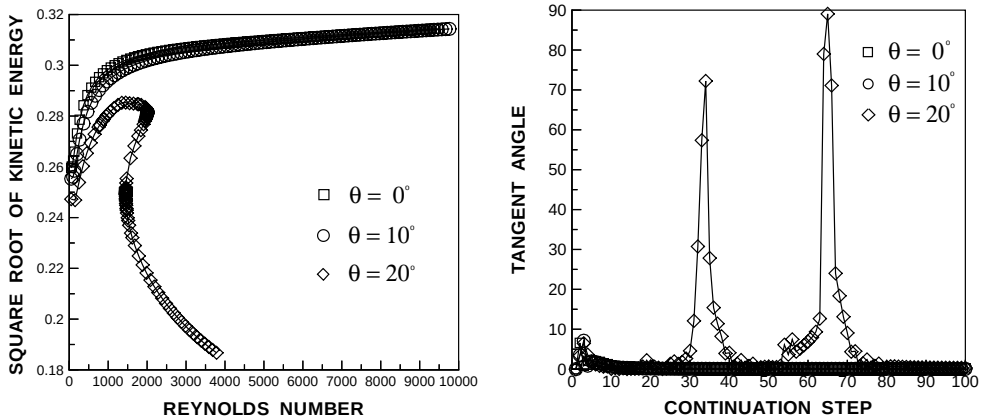

FIG. 5.2. *Solution curve with* 100 *points and* 110,802 *equations.* (a) *Square root of kinetic energy* $\mathcal{K}$ *of the LDC system for different geometries of the cavity.* (b) *Angle* α *between successive tangent vectors on the solution curves corresponding to the geometries in* (a).

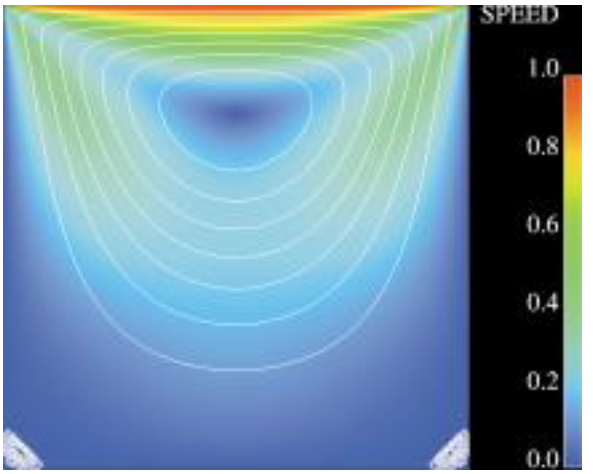
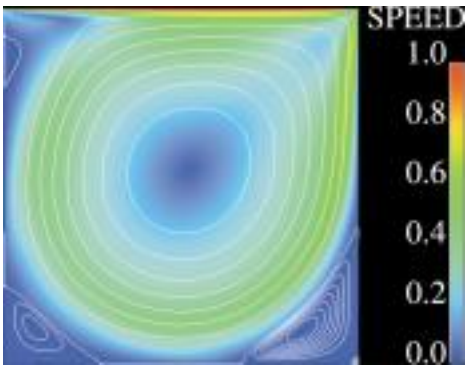
and appears to approach an asymptotic limit. This behavior is a consequence of the evolution of the primary vortex in the cavity with an increasing Reynolds number. As Figure 5.3 shows, the primary vortex grows and fills a substantial portion of the cavity, therefore the system attains a greater kinetic energy level. The growth in size and strength is initially fast, with respect to the Reynolds number, for $0 < Re < 2000$ and moderate to slow for $Re > 2000$. The secondary vortices, present at the lower corners and upper left corner do not show a significant tendency to grow; therefore they do not contend for space in the cavity. In the absence of competition, the primary vortex expands and occupies the area of the circle circumscribed in the cavity.

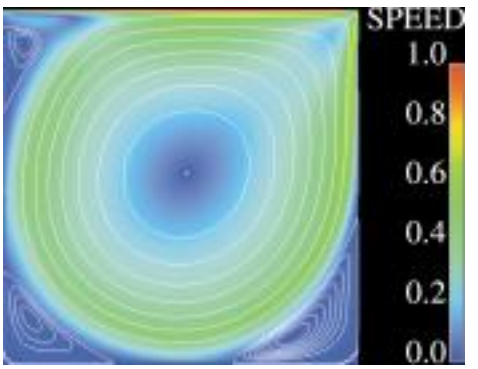
The variation of the kinetic energy with the Reynolds number for the angle of tilt $\theta = 20$ is qualitatively and quantitatively different owing to the presence of turning points. Multiple values of $\mathcal{K}$ in the range $1449.7 < Re < 2002.8$ result from the the existence of distinct configurations of vortices in the cavity with same level of kinetic energy. Figure 5.4 shows three different flow configurations at the same value of Re. The kinetic energy of the system lowers significantly for $Re > 2000$ in virtue of the expansion of secondary vortices carrying stagnant flow. In addition, $\mathcal{K}$ decreases with increasing Reynolds number in the range $1550 \leq Re \leq 2000$ on the upper branch,



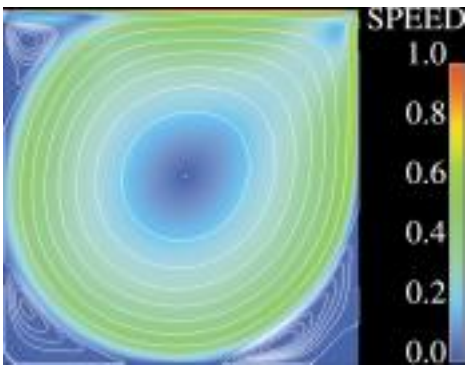
$Re = 0$



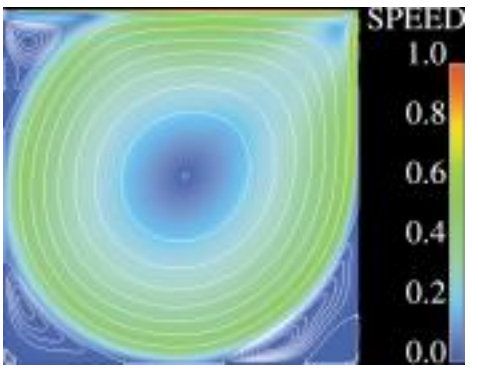
$Re = 2066.6$



$Re = 4066.6$



$Re = 8066.6$

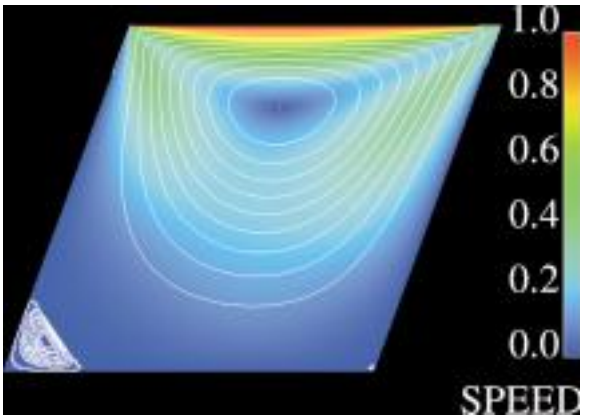


$Re = 9466.6$

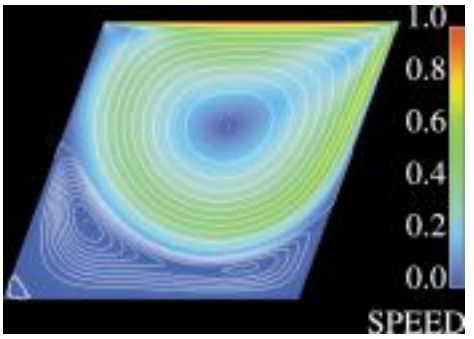
FIG. 5.3. *Flow speed and stream function contours for tilt angle* $\theta = 0$ *with finite element partition corresponding to* $110,802$ *equations.*

indicating that a change of sign on $\frac{d\mathcal{K}}{dRe}$ occurs prior to the first turning point.

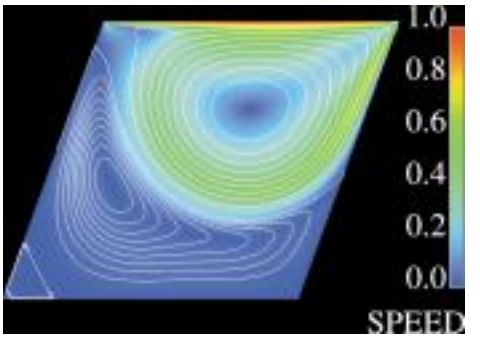
Qualitative changes in the flow with increasing Reynolds number are reflected in the performance of the predictor-corrector method (Figures 5.5 and 5.6). When the flow is rapidly changing with the Reynolds number, factorizations of $\mathbf{J}$ are needed more often but still more than one solution point can be obtained with a single



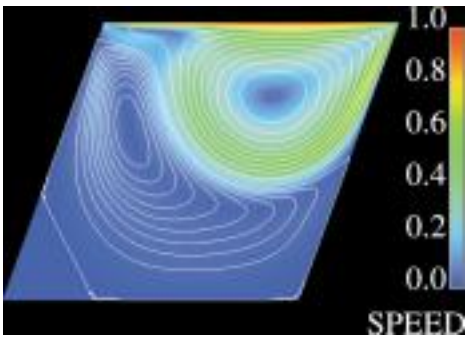
$Re = 0$



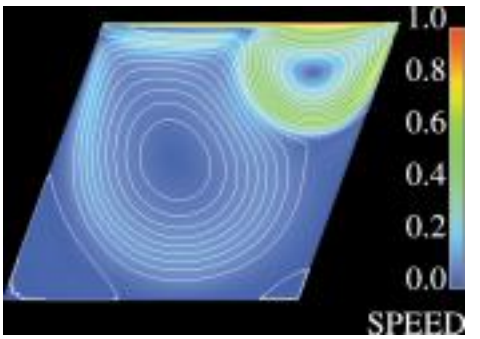
$Re = 1550$



$Re = 1550$



$Re = 1550$



$Re = 3784$

FIG. 5.4. *Flow speed and stream function contours for tilt angle* $\theta = 20$ *with finite element partition corresponding to* $110,802$ *equations. Turning points occur at* $Re = 1449.7$ *and* $Re = 2002.8$.

factorization assisted by a few inner iterations that rarely approach 50% of the cost of a factorization. For $\theta = 0$ the average number of converged solutions per factorization is 5.8, and for $\theta = 10$ it is 7.1. This shows that exploitation of a factorization of $\mathbf{J}$ along the solution curve is cost effective. Evidently, whenever a factorization takes place a high-order convergence results.

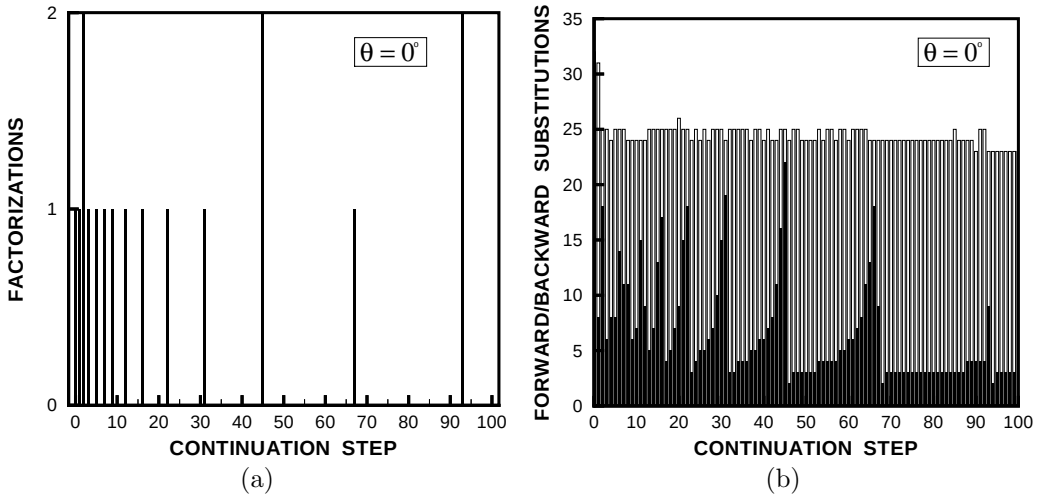


FIG. 5.5. *Performance of predictor-corrector method with* 110,802 *equations.* (a) *Factorizations of* **J** *per continuation step for tilt angle* $\theta = 0$. The most demanding case is when the flow change with Re is more dramatic, particularly in the vicinity of turning points (Figures 5.7 and 5.8). Here the corrector step automatically employs the more expensive pseudoarclength parameter continuation as long as $\alpha < 10^\circ$ (Figure 5.2b). Fortunately $\alpha > 10$ for only a few solution points. In addition, corrector failures are likely to occur. The additional expenses, mentioned in section 4.3, are reflected on extra factorizations and forward/backward substitutions that may exceed 50% of the cost of a factorization (Figure 5.7). Nevertheless the method is still attractive because the average number of converged solutions per factorization is 1.3. This is especially surprising considering the fact that the stepsize

on Re reduces four orders of magnitude before the continuation passes through the turning points.

6. Conclusions and final remarks. A cost-effective procedure for applying parametric continuation to the steady-state analysis of very large-scale process models which contain the Navier–Stokes equations to describe laminar, incompressible fluid flow was presented. The efficiency of this scheme relies on the judicious use of matrix factorizations and appropriate simplifications to the calculation of solution tangent vectors. The cost of the method, in terms of both arithmetic operations count and

data storage, is dominated by the solution of large linear systems of equations with sparse matrices of coefficients. When constructing a solution curve of the Navier–Stokes system, a factorization can be made cost effective, that is, several or many solutions can be accurately computed by recycling an existing factorization along the solution path.

The cost of constructing a solution curve can be further reduced by alternating automatically between the less expensive natural parametrization of the solution curve and the pseudoarclength parametrization. The angle between successive tangents to the solution curve can be used effectively, as an alternative to the curvature, to control the transition between parametrizations. To lessen the cost of computing the tangent angle, the tangent to the solution curve can be approximated by the secant joining two previously computed solution points; as long as the points are not in the neighborhood of a singular point—only *simple* singular points are considered here.

The proposed method was tested on a series of two-dimensional prototype problems of various sizes. In light of the results obtained, we estimate that with state-of-the-art vector supercomputers, analysis of two-dimensional models of materials and chemical processing will be feasible for nonlinear systems of up to 1,000,000 equations. This statement must be qualified by two potential limitations. For the test cases undertaken here, the limiting factor is data *storage* rather than arithmetic operation count. However, for the largest system tested, the CPU time (operation count) borders on the limit of what may be considered acceptable—the factorization of the system with 992,402 equations required approximately one hour of CPU time and the construction of the steady-state solution curve from $Re = 0$ to 10,000 and tilt angle $\theta = 0^\circ$ required a total of 34 CPU hours. The results are encouraging, since our experience indicates that discretizations of this magnitude (less than 1,000,000 equations) are more than adequate for producing numerically convergent solutions to realistic two-dimensional models. However, this satisfaction with two-dimensional model performance will certainly not hold for the analysis of 3-D counterparts. We outline our approach to such problems below.

Today's parallel supercomputers promise a substantial increase in CPU memory and computational speed. Our work [de Almeida and Derby, 1999] toward utilizing parallel computers' resources to solve 3-D models is twofold. First, the method of bifurcation analysis proposed here can be readily implemented in parallel by employing a substructuring subdomain decomposition algorithm [Chan and Mathew, 1994] and factoring the resultant subdomain matrices in parallel. The equivalent linear algebra description of this approach is the method of multiple fronts [Duff and Scott, 1994]. The difficulty with this approach is how to exploit parallelism to factor the associated Schur complement matrix. A feasible alternative is to factor the Schur matrix in parallel via nearest neighbor comunication. Again, data storage requirement is the bottleneck of a direct method of solution of the linear system.

Second, there exists a class of models of materials processing systems involving several field quantities (multiphysics applications) for which even the proposed method of analysis will likely be inadequate. For such models, a promising alternative is to resort to an iterative method of solution of linear systems of equations as a preconditioner for an existing direct method—so-called nonconventional preconditioning [Duff, 1996]. Our work towards both of these ends is reported in [de Almeida and Derby, 1999].

Appendix. Functional spaces and norms. Definitions of the standard functional spaces and norms used heretofore.

$$\mathrm{L}^2(\Omega) := \left\{ \pi \colon \Omega \to \mathbb{R} \;\mid\; \|\pi\|^2_{\mathrm{L}^2(\Omega)} < +\infty \right\},$$
$$\|\pi\|_{\mathrm{L}^2(\Omega)} := \left(\int_\Omega \pi(\boldsymbol{x})^2 \, d\boldsymbol{x} \right)^{\frac{1}{2}},$$

$$\mathrm{H}^1(\Omega) := \left\{ \psi \colon \Omega \to \mathbb{R} \;\mid\; \|\psi\|^2_{\mathrm{H}^1(\Omega)} < +\infty \right\},$$
$$\|\psi\|_{\mathrm{H}^1(\Omega)} := \left(\int_\Omega \psi(\boldsymbol{x})^2 + \nabla_{\boldsymbol{x}} \psi \cdot \nabla_{\boldsymbol{x}} \psi \, d\boldsymbol{x} \right)^{\frac{1}{2}},$$

$$\mathbf{H}^1(\Omega) := \left\{ \boldsymbol{\psi} \colon \Omega \to \mathbb{R}^2 \;\mid\; \boldsymbol{\psi}(\boldsymbol{x}) = \sum_i \psi_i(\boldsymbol{x}) \, \boldsymbol{i}_i \,, \quad \psi_i \in \mathrm{H}^1(\Omega) \text{ for } i = 1, 2 \right\},$$
$$\mathbf{H}^1_0(\Omega) := \left\{ \boldsymbol{\psi} \colon \Omega \to \mathbb{R}^2 \;\mid\; \boldsymbol{\psi} \in \mathbf{H}^1(\Omega) \text{ and } \boldsymbol{\psi} \equiv \mathbf{0} \text{ on } \partial\Omega \right\},$$
$$\|\boldsymbol{\psi}\|_{\mathbf{H}^1(\Omega)} := \left(\int_\Omega \boldsymbol{\psi}(\boldsymbol{x}) \cdot \boldsymbol{\psi}(\boldsymbol{x}) + \nabla_{\boldsymbol{x}} \boldsymbol{\psi} \bullet \nabla_{\boldsymbol{x}} \boldsymbol{\psi} \, d\boldsymbol{x} \right)^{\frac{1}{2}},$$
$$\|\boldsymbol{\psi}\|_{\mathbf{L}^2(\Omega)} := \left(\int_\Omega \boldsymbol{\psi}(\boldsymbol{x}) \cdot \boldsymbol{\psi}(\boldsymbol{x}) \, d\boldsymbol{x} \right)^{\frac{1}{2}}.$$

AN ITERATIVE ALGORITHM FOR SOLVING HAMILTON–JACOBI TYPE EQUATIONS*

JERRY MARKMAN† AND I. NORMAN KATZ†

Abstract. Solutions of the optimal control and H_∞-control problems for nonlinear affine systems can be found by solving Hamilton–Jacobi equations. However, these first-order nonlinear partial differential equations can, in general, not be solved analytically. This paper introduces an iterative algorithm which solves these equations numerically for points near the origin. The procedure converges to the stabilizing solution exponentially with respect to the iteration variable. The algorithm is implemented on both illustrative and comparative examples.

Key words. Hamilton–Jacobi equations, iterative algorithms

1. Introduction.

We consider partial differential equations of the type

$$p^T f(x) \pm p^T R(x) p + l(x) = 0, \tag{1.1}$$

where $x \in \mathbb{R}^n, p = V_x(x)$, and $R(x), l(x) \geq 0$. Equation (1.1) is a Hamilton–Jacobi type equation which arises in nonlinear theory. For example, consider the optimal control problem

$$J(x_0, u) = \int_0^\infty l(x(t, x_0)) + \|u(x(t, x_0))\|^2 dt, \tag{1.2}$$

where $l : \mathbb{R}^n \to \mathbb{R}$ is a positive definite, monotonically increasing function, $u \in \mathbb{R}^m$, and x satisfies the differential equation

$$\begin{aligned} \dot{x} &= f(x) + g(x)u, \\ x(0) &= x_0. \end{aligned} \tag{1.3}$$

It is well known [1] that the optimal control can be directly found to be $u^* = -\frac{1}{2} g^T \frac{\partial V}{\partial x}$, where V satisfies the Hamilton–Jacobi–Bellman equation

$$\frac{\partial V^T}{\partial x} f(x) - \frac{1}{4} \frac{\partial V^T}{\partial x} g(x) \left(\frac{\partial V^T}{\partial x} g(x) \right)^T + l(x) = 0. \tag{1.4}$$

Equations similar to (1.4) are derived when solving various H_∞ problems. In this case, in addition to (1.3), an output equation for $y \in \mathbb{R}^p$ is given by

$$y = h(x). \tag{1.5}$$

The system (1.3) is said to have L_2 gain $\leq \gamma$ if

$$\|y(x)\| \leq \gamma_0 \|u(x)\| \tag{1.6}$$

for all $u \in L_2[0, \infty]$, for all $t > 0$, for some $\gamma_0, 0 \leq \gamma_0 \leq \gamma$. If $V_x(x) = p$ satisfies the Hamilton–Jacobi–Isaacs equation

$$p^T f(x) + \frac{1}{4\gamma^2} p^T g(x) g^T(x) p + h^T(x) h(x) = 0, \tag{1.7}$$

then the system (1.3) has L_2-gain γ for all $u(x)$ satisfying $\|u(x)\| \leq \delta$, for sufficiently small $\delta > 0$. See [2], [3] for details. In this case, equality occurs if $u^*(x) = \frac{1}{2\gamma^2} g^T(x) p$.

Because (1.1) is a first-order nonlinear equation, closed form solutions cannot be found in general. Furthermore, the only information known about $V(x)$ is that it is a C^2 positive definite solution locally in a neighborhood around the equilibrium point $x = 0$ and $V(0) = 0$. The size of this neighborhood is not known in advance, and no boundary conditions are known, so traditional numerical methods are inapplicable. Approximate solutions of (1.1) have been found either through a power series method [4], [5] or a successive approximation approach [6], [7], [8]. In this paper, an iterative procedure is introduced which computes the stabilizing solution of (1.1) for any x_0 near the origin. Convergence is shown to be exponential, allowing the user to find a solution of any desired accuracy. By applying the algorithm to sufficiently many points near the origin, an approximate solution over the entire neighborhood can be pieced together through, for example, polynomial interpolation.

The paper is organized as follows. In section 2, the motivation and the algorithm are given. Section 3 discusses the numerical issues involved in the implementation of the procedure. Section 4 states the results pertaining to existence and rate of convergence, and gives an example highlighting these results. In section 5, two numerical examples are given. Section 6 illustrates the convergence rate graphically. Another simulation is presented comparing the algorithm to different methods in the literature. Finally it is shown how the computation along an initial manifold can be used to calculate an approximate solution in an entire neighborhood of the origin, by applying the method of characteristics.

2. Algorithm.

2.1. Motivation. First, the problem is formally defined. For the dynamic system

$$\begin{aligned} \dot{x} &= f(x) + g(x)u, \\ y &= h(x), \end{aligned} \tag{2.1}$$

with $x \in \mathbb{R}^n, u \in \mathbb{R}^m, h(x) \in \mathbb{R}^p$, where $f(x)$, $g(x)$, $h(x)$ are smooth and $f(0) = h(0) = 0$, a positive semidefinite function $V^-(x) : U_\rho \to \mathbb{R}$ is sought in an open neighborhood U_ρ around the origin which satisfies the Hamilton–Jacobi equation

$$H^*(x, V_x) \equiv V_x^T f(x) + \frac{1}{k} V_x^T g(x) g^T(x) V_x + h^T(x) h(x) = 0 \tag{2.2}$$

and renders (2.1) asymptotically stable with $u = \frac{2}{k} g^T(x) V_x^-(x)$. Here, k is a parameter which depends on the type of problem being considered. For instance, in the H_∞ problem, $k = 4\gamma^2$, while for the optimal control problem $k = -4$.

The algorithm operates in the Hamiltonian space of (2.2), i.e., it considers the $2n$-dimensional ODE

$$\begin{aligned} \frac{dx}{dt} &= H_p^*, \\ \frac{dp}{dt} &= -H_x^*. \end{aligned} \tag{2.3}$$

It can be shown that any solution of the Isaacs equation $H^*(x, V_x) = 0$ corresponds to an invariant manifold of the Hamiltonian system [2]. Furthermore, under suitable conditions for the optimal control and H_∞ problems, the Hamiltonian system is restricted to the hyperbolic case, i.e., the linearization of (2.3) has no eigenvalues on the imaginary axis. This insures the existence of an n-dimensional stable manifold. Finally, for x near the origin, the stable manifold can be expressed as a graph of x. Therefore, seeking the stabilizing solution of (2.2) at a fixed point near the origin is equivalent to identifying the stable invariant manifold of (2.3) at that point.

Define

$$\begin{aligned} z(t, z_0) &\triangleq \begin{pmatrix} x(t, x_0, p_0) \\ p(t, x_0, p_0) \end{pmatrix}, \\ z_0 &\triangleq \begin{pmatrix} x_0 \\ p_0 \end{pmatrix}, \end{aligned} \tag{2.4}$$

where $x(t, x_0, p_0)$ and $p(t, x_0, p_0)$ are the solutions of (2.3) at time t with initial conditions x_0 and p_0. Also define $\bar{H}$ as the linearization of (2.3) around the equilibrium point $(x, p)^T = (0, 0)^T$. Then (2.3) can be rewritten as

$$\begin{aligned} \dot{z} &= \bar{H} z + h(z), \quad h \in O(\|z\|^2), \\ \bar{H} &= \frac{\partial}{\partial z} \begin{pmatrix} H_p^* \\ -H_x^* \end{pmatrix}_{z=0}. \end{aligned} \tag{2.5}$$

Fix a point $x = x_0$, $x_0 \in U_\rho$. Finding the stabilizing solution of (2.2) at x_0, defined as $p_0^* \triangleq V_x^-(x_0)$, is equivalent to finding the vector p_0 which causes $z(t, z_0) \to 0$ as $t \to \infty$.

The algorithm uses this asymptotic behavior of the stabilizing solution of (2.2) to find p_0^*. For a fixed time t, it evaluates each possible solution vector p by measuring how close the trajectory of the Hamiltonian system (2.3) passing through (x_0, p) comes to the origin. This is repeated for larger and larger times to produce a sequence of vectors which converge to a point on the stable manifold.

Define the distance function

$$F(t, p_0) \triangleq \|z(t, z_0)\|^2 = \|x(t, x_0, p_0)\|^2 + \|p(t, x_0, p_0)\|^2. \tag{2.6}$$

F measures the distance from the solution of (2.5), $z(t, z_0)$ to the origin at time t with initial condition z_0. Because x_0 is fixed, F depends solely on the terminal time t and the initial condition p_0.

Since the solution of (2.2), $p_0^* = V_x^-(x_0)$, lies on the stable manifold of (2.5), $\lim_{t\to\infty} F(t, x_0, p_0^*) \to 0$. Because F is a positive semidefinite function, finding p_0^*, or

where the stable manifold intersects $x = x_0$, is equivalent to solving

$$\inf_{p_0} \lim_{t\to\infty} F(t, x_0, p_0). \tag{2.7}$$

However, because the Hamiltonian system (2.5) is nonlinear, a closed form solution for $z(t, z_0)$ is generally not available, and the minimization cannot be done analytically. To approximate a solution numerically, a sequence of times which monotonically increases towards infinity is chosen, and for each element in this sequence F is minimized with respect to p_0. For each $i = 1, 2, 3, \ldots$ define

$$t^i \uparrow \infty, \tag{2.8a}$$

$$F^i \triangleq \min_{p_0} F(t^i, p_0), \tag{2.8b}$$

$$p_0^i \triangleq \operatorname*{argmin}_{p_0} F(t^i, p_0). \tag{2.8c}$$

As i becomes larger, $t^i \to \infty$, and F can be considered, in a sense, as measuring the asymptotic behavior of candidate solutions. It will be shown in section 4 that $F^i \to 0$ and $p_0^i \to p_0^*$.

2.2. Initial guess. In order to solve (2.8b) and (2.8c) for fixed i, an iterative procedure is, in general, required. For each i, a starting estimate is taken to be the converged value p_0^{i-1}. Since the algorithm is an iterative procedure, a starting guess for p_0^* is needed. A good estimate for p_0^* which is taken to be p_0^0, can be found by considering the linearization of (2.1). For any linear system, the solution of the corresponding Hamilton–Jacobi equation is $V^L(x) = x^T P x$, where P is the stabilizing solution of the algebraic Ricatti equation

$$PA + A^T P + \frac{1}{k} PBB^T P + C^T C = 0, \tag{2.9}$$

where $A = \frac{\partial f}{\partial x}(0)$, $B = g(0)$, $C = \frac{\partial h}{\partial x}(0)$. It is assumed that $\sigma(A) \subset C^-$.

Thus, the initial guess for the algorithm is $V_x^L(x_0) = p_0^L = 2x_0^T P$.

This has a nice geometric interpretation because p_0^L is the intersection of the stable eigenspace of $\bar{H}$ with the linear variety $x = x_0$. Because x_0 is always chosen near the origin, p_0^L will lie close to p_0^*.

3. Implementation.

3.1. Minimizing the distance function over the costate variable. For each element in a sequence t^i, the algorithm solves the problem

$$p_0^i = \operatorname*{argmin}_{p_0} \quad F(t^i, p_0). \tag{3.1}$$

The minimization is done iteratively via a Gauss–Newton method. For a fixed $t = t^i$, define j as the iteration variable for the Gauss–Newton method. Then, Newton's equation is

$$(p^{j+1})^T \triangleq (p^j)^T - \nabla F (\nabla^2 F)^{-1}, \tag{3.2}$$

where ∇F and $\nabla^2 F$ are the gradient and Hessian with respect to the covector p,

$$\nabla F = z^T(t, p^j) \frac{\partial z}{\partial p},$$

$$\nabla^2 F = \frac{\partial z}{\partial p}^T \frac{\partial z}{\partial p} + z^T(t, p^j) \frac{\partial^2 z}{\partial p^2}, \tag{3.3}$$

and the derivative terms $\frac{\partial z}{\partial p}$ and $\frac{\partial^2 z}{\partial p^2}$ are also evaluated at the point (t^i, p^j). Here, the second derivative $\frac{\partial^2 z}{\partial p^2}$ represents a bilinear operator on z. More specifically, $z^T(t,p^j)\frac{\partial^2 z}{\partial p^2} = \sum_{i=1}^{2n} z_i(t,p^j)\frac{\partial^2 z_i}{\partial p^2}$, where z_i is the ith component of z.

The idea behind the Gauss–Newton method is that for points close to the minimizing point, the second derivative term of the Hessian, $\frac{\partial^2 z}{\partial p^2}$, is dominated by the first-order term. Therefore, if a starting guess near the optimum can be found, the Hessian can be replaced by the approximation

$$\tilde{\nabla}^2 F \triangleq \frac{\partial z}{\partial p}^T \frac{\partial z}{\partial p}, \tag{3.4}$$

and the iteration equation (3.2) becomes

$$\begin{aligned}(p^{j+1})^T &= (p^j)^T - z^T \frac{\partial z}{\partial p}\left(\frac{\partial z}{\partial p}^T \frac{\partial z}{\partial p}\right)^{-1} \\ &= (p^j)^T - z^T(t,p^j)\frac{\partial z}{\partial p}^+(t,p^j),\end{aligned} \tag{3.5}$$

where $\frac{\partial z}{\partial p}^+$ is the generalized inverse.

Here, the optimum costate vector for the previous time in the sequence t^i is used for the initial guess, i.e., p^0 at time t^i is the optimal initial condition p^* for time t^{i-1}. If $\delta t \triangleq (t^i - t^{i-1})$ is small, the corresponding minimizing initial conditions will lie near each other as well, i.e., $\|p^i - p^{i-1}\|$ will also be small. Since the sequence of times is chosen by the user, a "good" starting guess can always be constructed.

Because the Hamiltonian system is nonlinear, the two terms in (3.5) need to be calculated numerically as well. The vector $z(t,p^j)$ is a solution of the Hamiltonian system (2.3) with initial condition (x_0, p^j), which can be integrated using standard Runge–Kutta methods. A greater difficulty lies in calculating $\frac{\partial z}{\partial p}$. Two approximation methods are presented.

In the first method, the variational equation is adjoined to the Hamiltonian system. Write the Hamiltonian system (2.2) in terms of its linearization,

$$\dot{z} = \bar{H}z + h(z), \tag{3.6}$$

with $h(z) \in O(\|z\|^2)$. Then the variational matrix $\frac{\partial z}{\partial p}$ satisfies the equation

$$\frac{d}{dt}\frac{\partial z}{\partial p} = \left(\bar{H} + \frac{\partial h}{\partial z}(z(t,p^j))\right)\frac{\partial z}{\partial p}, \tag{3.7}$$

$$\frac{\partial z}{\partial p}\Big|_{t=0} = \begin{pmatrix}0\\ I\end{pmatrix}. \tag{3.8}$$

The initial condition is derived by noting that $\frac{\partial z}{\partial p}$ is "half" of the full variational matrix $\frac{\partial z}{\partial z_0} = (\frac{\partial z}{\partial x_0} \vdots \frac{\partial z}{\partial p_0})$.

Equation (3.7) is linear but time-varying, so in general it cannot be solved directly. But it can be rearranged and adjoined to (3.6) to form a $2n(n+1)$-dimensional system, which is then integrated numerically.

The second method to calculate $\frac{\partial z}{\partial p}$ is through a simple finite difference approximation. Define $e_i \in \mathbb{R}^n$ as the unit vector at coordinate i and let $\delta > 0$ be a

perturbation factor. Then, a forward difference approximation to the derivative is

$$\frac{\partial z}{\partial p_i}(t, p^j) \approx \frac{z(t, p^j + \delta e_i) - z(t, p^j)}{\delta e_i}. \tag{3.9}$$

Note that the forward difference approximation requires integrating a $2n$-dimensional system $n+1$ times, therefore it has the same computational cost as the first method. If higher accuracy is desired, a central difference approximation can be employed. However, in that case, the $2n$-dimensional system will need to be integrated $2n$ times, resulting in a higher computational cost. δ must be chosen small enough to approximate the derivative but not too small to lose precision.

3.2. Time of closest approach. Choosing the sequence of times used in the algorithm will have a major influence on its performance. For example, suppose the sequence of times tend to infinity too quickly, say $t^{i+1} - t^i \geq K >> 0$. Then there may be numerical problems in finding the corresponding initial conditions, or the elements in the sequence of initial conditions will have such wide spacing between them that confidence in the solution may be reduced. On the other hand, choosing $t^{i+1} - t^i$ very small may put unnecessary computational burden on the algorithm to get a satisfactory answer.

A method for choosing the sequence of times is introduced in this section. It balances the issues raised above by taking an element in p_0^i and finding the time which brings the trajectory passing through it closest to the origin. This new time, called the time of closest approach (TOCA), is chosen as the next time, t^{i+1}, in the sequence. Because the solutions of a differential equation are continuous with respect to the time and the initial condition, it follows that p_0^{i+1} lies close to p_0^i. Furthermore, the TOCA "optimizes" each initial condition p_0^i, in the sense that it pulls the trajectory passing through it as close to the origin as possible.

DEFINITION 3.1. *Consider a system of differential equations $\dot{z} = f(z)$, $z(0) = z_0$, and assume a unique solution, $z(t, z_0)$, passing through z_0 exists for $t \in [0, \infty)$. Then TOCA, t^*, is defined as the time at which the trajectory comes closest to the origin for all time greater than or equal to zero, i.e.,*

$$\|z(t^*, z_0)\|^2 \leq \|z(t, z_0)\|^2 \quad \forall t \in [0, \infty). \tag{3.10}$$

The point of closest approach (POCA) is defined as the solution of the differential equation at t^* with initial condition z_0, i.e., $z^* \triangleq z(t^*, z_0)$.

Remark 3.1. For a fixed initial condition z_0, the TOCA can be calculated by minimizing the distance function F over all positive times, i.e.,

$$t^* \triangleq \underset{t \geq 0}{\operatorname{argmin}}\ F(t, z_0). \tag{3.11}$$

The TOCA is well defined as long as a solution to the differential equation exists. Note that if z_0 lies on an asymptotically stable manifold of the system, then the POCA is zero and the TOCA is defined as ∞. Intuitively, this indicates that the sequence of times using TOCA will diverge, satisfying the conditions of the algorithm.

The TOCA can also be thought of as the time where a trajectory "turns away" from the origin. Since the algorithm seeks the trajectory which approaches the origin, the TOCA allows the algorithm to "eliminate" certain initial conditions by measuring when their trajectories stop approaching the equilibrium point.

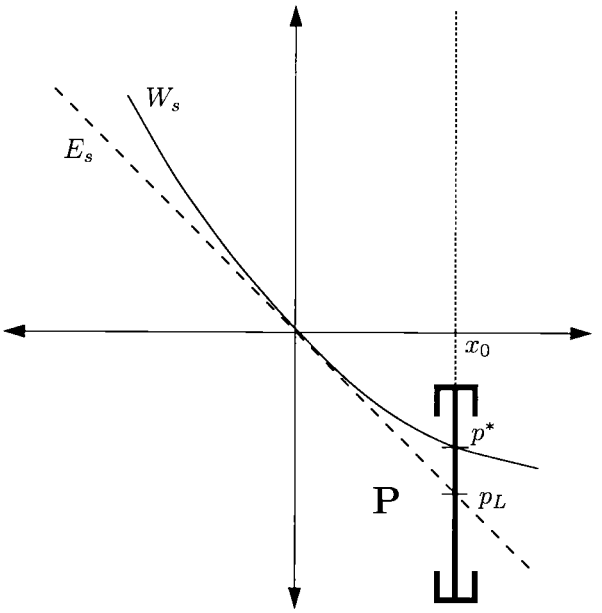

FIG. 1. *Restricting the search space of* p_0^*.

This minimization is also performed using a Gauss–Newton method, and analogously the iteration equation is

$$t^{j+1} = t^j - z^T(t^j, p_0)\frac{\partial z}{\partial t}^+(t^j, p_0). \tag{3.12}$$

As above, the initial guess for the iteration is the optimal time for the previous initial condition, i.e., $t^{j_0} = t^{i-1}$. The "interlocking" nature of the TOCA with the sequence p_0^i makes this initial guess close to the optimal in practice.

The terms in (3.12) can be found directly. $z^T(t^j, p_0)$ can be determined by integrating system (2.2). And note that $\frac{\partial z}{\partial t}(t^j, p_0) = \frac{dz}{dt}(z(t^j, x_0, p_0))$, which can be found exactly from the right-hand side of the Hamiltonian system (2.2). Therefore, for each iteration only $2n$ integrations are required.

4. Convergence results. p_0^L is the intersection of the stable eigenspace of H with the linear variety $x = x_0$. p_0^L can be found directly from the solution of the algebraic Ricatti equation (2.9) and is used as the initial guess in the iteration formulas defined by the algorithm. Because x_0 is chosen to be near the origin, at x_0 the stable manifold of (2.2) should be "close" to the stable eigenspace, i.e., p_0^* should lie near p_0^L. Therefore, instead of considering all vectors p as candidates to lie on the stable manifold, the algorithm considers the set $P \triangleq \{p : \|p - p_0^L\| \leq \delta\}$ for δ suitable large. See Figure 1.

Remark 4.1. Restricting the state space to the set P is not needed in the implementation of the algorithm, but is made here to insure the existence of accumulation points of the sequence p_0^i.

LEMMA 4.1. *$F^i \to 0$, as $t^i \to \infty$.*

Proof. p_0^* lies on the stable manifold of (2.2), so $\lim_{t^i\to\infty}\|z(t^i,x_0,p_0^*)\|\to 0$. For each t^i,

$$F^i=\|z(t^i,x_0,p_0^i)\|^2=\min_{p_0\in P}\|z(t^i,x_0,p_0)\|^2\le\|z(t^i,x_0,p_0^*)\|^2. \tag{4.1}$$

Therefore, as $t^i\to\infty$,

$$0\le\lim F^i\le\lim\|z(t^i,x_0,p_0^*)\|^2=0. \tag{4.2}$$

That is, $F^i\to 0$.

Because p_0^i lies in the closed bounded set P, it has an accumulation point $\bar p$ in P.

Assumption. For any sequence (t^j,x_0,p_0^j) and $\bar p=\lim_{j\to\infty}p_0^j$ the following holds:

$$z\lim_{j\to\infty}(t^j,x_0,p_0^j)=\lim_{j\to\infty}(t^j,x_0,\bar p).$$

This assumption will prevent situations such as that depicted in [9].

The next lemma states that any accumulation point must lie on the stable manifold of (2.3).

LEMMA 4.2. *If $F^i\to 0$, then any accumulation point of p_0^i lies on the stable manifold. Furthermore, there exists exactly one accumulation point, i.e., p_0^i is a convergent sequence.*

Proof. Define p_0^j as a subsequence of p_0^i which converges to an accumulation point $\bar p$. Then

$$\begin{aligned}\lim_{j\to\infty}\|z(t^j,x_0,p_0^j)\|&=\|\lim_{j\to\infty}z(t^j,x_0,p_0^j)\|\\&=\|z(\lim_{j\to\infty}t^j,x_0,\lim_{j\to\infty}p_0^j)\|\\&=\lim_{t\to\infty}\|z(t,x_0,\bar p)\|,\end{aligned} \tag{4.3}$$

which goes to zero from Lemma 4.1. Therefore, $\bar p$ must lie on the stable manifold.

Now suppose two accumulation points $\bar p_1$, $\bar p_2$ exist. Both points must lie on the stable manifold, but x_0 was chosen to lie inside the neighborhood where the stable manifold can be written as a graph, i.e., $M^-\triangleq p=V_x^-(x_0)$. Therefore, $\bar p_1=\bar p_2=p^*$, and the entire sequence converges to the stable manifold.

Together, the above insure convergence of the algorithm to the stabilizing solution of (2.2). The following lemma, which is proved in [9], [10], gives an upper bound on the rate of convergence.

LEMMA 4.3. *Define λ_1 as the eigenvalue with the largest negative real part of $\bar H$. Then*

$$\|p_0^i-p_0^*\|=O(e^{\mathrm{Re}\lambda_1 t}). \tag{4.4}$$

The proof of Lemma 4.3 is based on the variations of constants formula applied to the Hamiltonian system and the bound is not sharp. However, if the nonlinearities of the Hamiltonian system are removed, i.e., $\dot z=\bar Hz$, the sequence of costates generated by the algorithm can be calculated analytically and the convergence rate can be found directly. While this does not provide a "true" rate of convergence for the nonlinear case, by moving x_0 close to the origin, the nonlinear terms can be considered as a perturbation of the linearized Hamiltonian, and the following result [10] can be viewed as a better estimate for the convergence of the algorithm.

LEMMA 4.4. *For a fixed time, the minimization problem*

$$\min_{p_0} F(t, x_0, p_0) = z_0 e^{\bar{H}^T t} e^{\bar{H} t} z_0$$
$$\text{such that} \quad (I \quad 0) z_0 = x_0$$

can be directly solved. Furthermore, as $t \to \infty$,

$$\|p_0(t) - p_0^*\| = O(e^{2\mathrm{Re}\lambda_1 t}).$$

Hence, if x_0 is chosen such that the nonlinear terms have a "small" effect on the dynamics, the convergence rate can effectively double. This can be seen in the following example.

4.1. Example. Consider the H_∞ problem for the nonlinear system

$$\dot{x} = Ax + \epsilon f(x) + Bu,$$
$$y = Cx.$$

Increasing ϵ is equivalent to strengthening the effect of the nonlinear terms on the system dynamics.

Define

$$A = \begin{pmatrix} 0 & 1 \\ -1 & -2 \end{pmatrix}, \quad B = \begin{pmatrix} 0 \\ 1 \end{pmatrix}, \quad C = \begin{pmatrix} 1 & 0 \end{pmatrix},$$

$$f(x) = \begin{pmatrix} x_1^2 \\ x_1 x_2 - x_2^2 \end{pmatrix}, \quad \gamma = 1.3.$$

The algorithm was used to solve the corresponding Hamilton–Jacobi equation at the point $(0.1 \quad 0)^T$ for different values of ϵ. For all cases, the first terminal time in the sequence t^i in (2.8a) used in the program was 2.0. Since the solution to the Hamilton–Jacobi equation is not known when $\epsilon \neq 0$, for all cases the simulation was run until five significant digits were obtained in the solution. The resulting state trajectories are given in Figure 2.

This indicates that the algorithm is indeed finding a stabilizing trajectory. Figure 3 shows the error graph of the algorithm for each iteration for each value of ϵ.

The eigenvalues of the corresponding Hamiltonian matrix are $\pm 1.31, \pm 0.48$. For the linear case $\epsilon = 0$, the straight line of the error curve on the semilogarithmic axis implies exponential convergence with respect to the iteration variable. The slope of the line indicates the rate of convergence, which can be calculated using a least square fit. In this case, the rate of convergence is -0.96, which is indeed $O(e^{2\lambda_1 t})$ as expected. As ϵ increases, the nonlinear terms have a stronger effect on the algorithm, and the rate of convergence decreases accordingly.

5. Illustrative examples.

5.1. Optimal control problem with nonquadratic cost. The first example is a linear system with a nonquadratic cost function. The example is from [5],

$$\dot{x} = -ax + u, \tag{5.1}$$
$$J = \int_0^\infty x^2 + x^4 + u^2 dt.$$

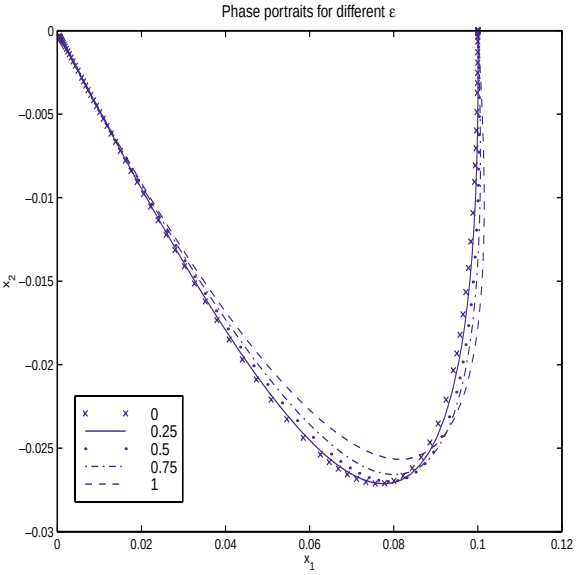

FIG. 2. *State trajectories of system with algorithmic control.*

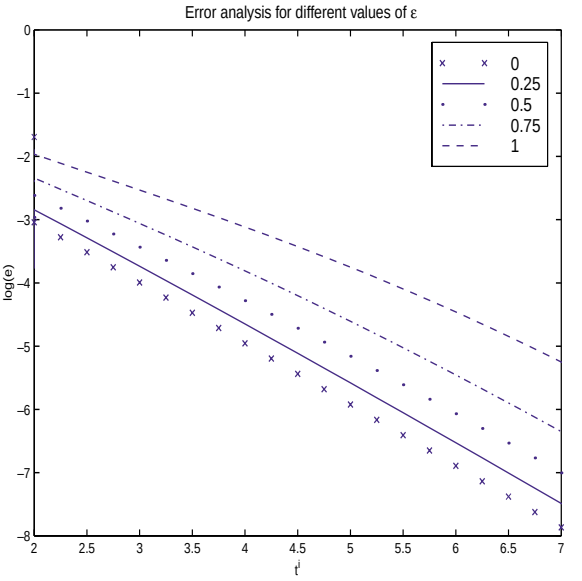

FIG. 3. *Effect of nonlinear terms on convergence.*

The corresponding Bellman equation is

$$H^*(x, V_x) = -axV_x - \frac{1}{4}V_x^2 + x^2 + x^4 = 0, \tag{5.2}$$

and the optimal control of (5.1) is $u^* = -\frac{1}{2}V_x^-$, where

$$V_x^-(x) = -2x(a - \sqrt{a^2 + 1 + x^2}). \tag{5.3}$$

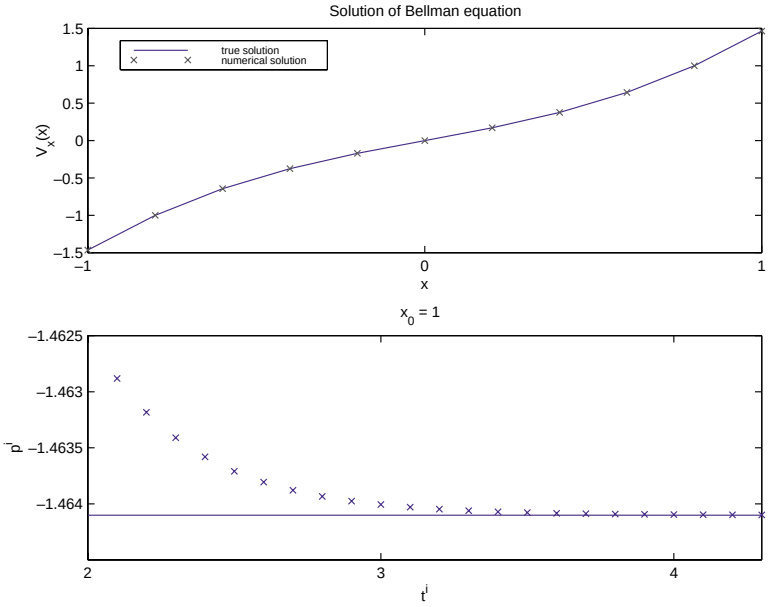

FIG. 4. *Numerical solution for system* (5.1).

In the case $a = 1$, (5.2) was solved by the algorithm for $x \in [-1, 1]$. The initial guess for $V_x^-(x)$ was chosen to be $-2x$. The starting time in the sequence t^i in (2.8a) was chosen as $t^0 = 2$ and the times were increased at each iteration by 0.1.

The top graph of Figure 4 shows that the algorithm finds the stabilizing solution of (5.2) for different fixed values of x. The graph on the bottom shows the progress of the algorithm to the correct solution for $x = -1$, which is $V_x^-(-1) = -1.46410$.

Figure 5 displays two error estimates used when the true solution is not known in advance. The graph on the top displays the first error estimate which is the residual of the Bellman equation for each minimizing initial condition p_0^i. Since the algorithm seeks a solution to the Bellman equation, each iteration should cause the residual to decrease to zero. The bottom graph shows the second error estimate which shows the progress of the distance function $F(t^i, p_0^i) = \|x(t^i, x_0, p_0^i)\|^2 + \|p(t^i, x_0, p^i)\|^2$ as t^i increases. Clearly, this function should monotonically decrease to zero as well as t^i grows bigger.

5.2. A two-dimensional linear H_∞ problem. For a linear system

$$\begin{aligned} \dot{x} &= Ax + Bu, \\ y &= Cx, \end{aligned} \tag{5.4}$$

the Hamilton–Jacobi–Isaacs equation whose solution insures the $\mathcal{L}_2$ gain from u to y is less than or equal to γ reduces to the algebraic Ricatti equation (2.9). Specifically, with $k = 4\gamma^2$, the stabilizing solution is $V_x^- = x^T X$ and the corresponding control is $u^* = \frac{1}{2\gamma^2} B^T (V_x^-)^T = \frac{1}{2\gamma^2} B^T X x$.

Although (2.9) can be solved directly, the optimal control can also be found at a

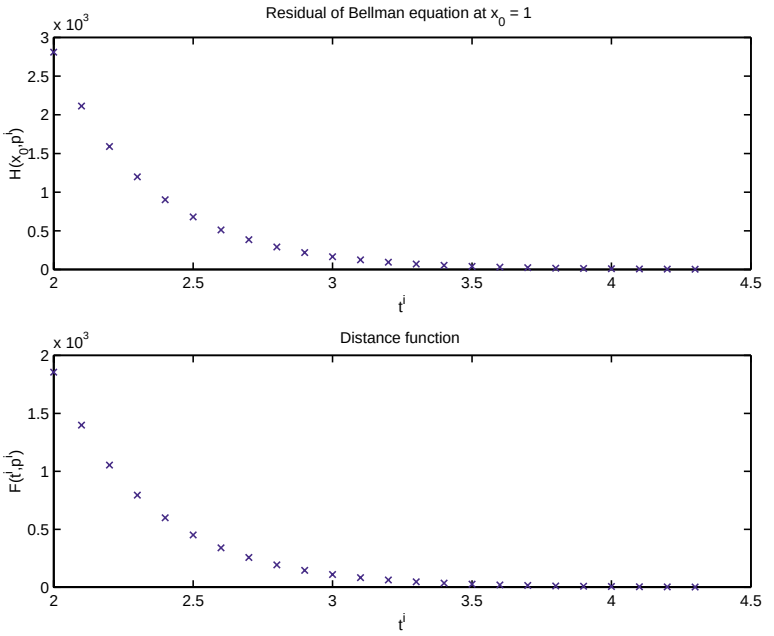

FIG. 5. *Error functions for system* (5.1).

specific initial condition by the algorithm. Let

$$A = \begin{pmatrix} 0 & 1 \\ -1 & -2 \end{pmatrix},$$
$$B = \begin{pmatrix} 0 \\ 1 \end{pmatrix}, \tag{5.5}$$
$$C = \begin{pmatrix} 1 & 0 \end{pmatrix},$$

and set $\gamma = 1.3$. The algorithm was run at the initial point $x = (1 \quad 0)^T$, with initial guess for p^* arbitrarily chosen to be $(1 \quad 1)^T$. The first time in the sequence t^i in (2.8a) used in the program was $t^0 = 5$, and the times were increased at each iteration by 0.25. The TOCA was not used.

The true solution $V_x(x) = (2.839 \quad 1.220)^T$ is found by directly solving the algebraic Ricatti equation. Figure 6 shows the convergence of each component of p^i to the true solution. The bottom two graphs show the distance function F and the residual function H^*, which indicate that the algorithm is indeed converging to a stabilizing solution of (2.9).

6. Convergence rate versus eigenvalues of a Hamiltonian. Lemma 4.4 shows that for linear systems,

$$e^i = \|p_0^i - p_0^*\| \approx Ce^{2\,\mathrm{Re}\,\lambda_1 t}, \tag{6.1}$$

where λ_1 is the eigenvalue with largest negative real part of $\bar{H}$. Therefore,

$$ln(e^i) \approx lnC + 2\,\mathrm{Re}\,\lambda_1 t^i. \tag{6.2}$$

So if the graph of the error function versus the sequence t^i is a straight line on semilog axes, then the error is truly decreasing exponentially as the times in the algorithm

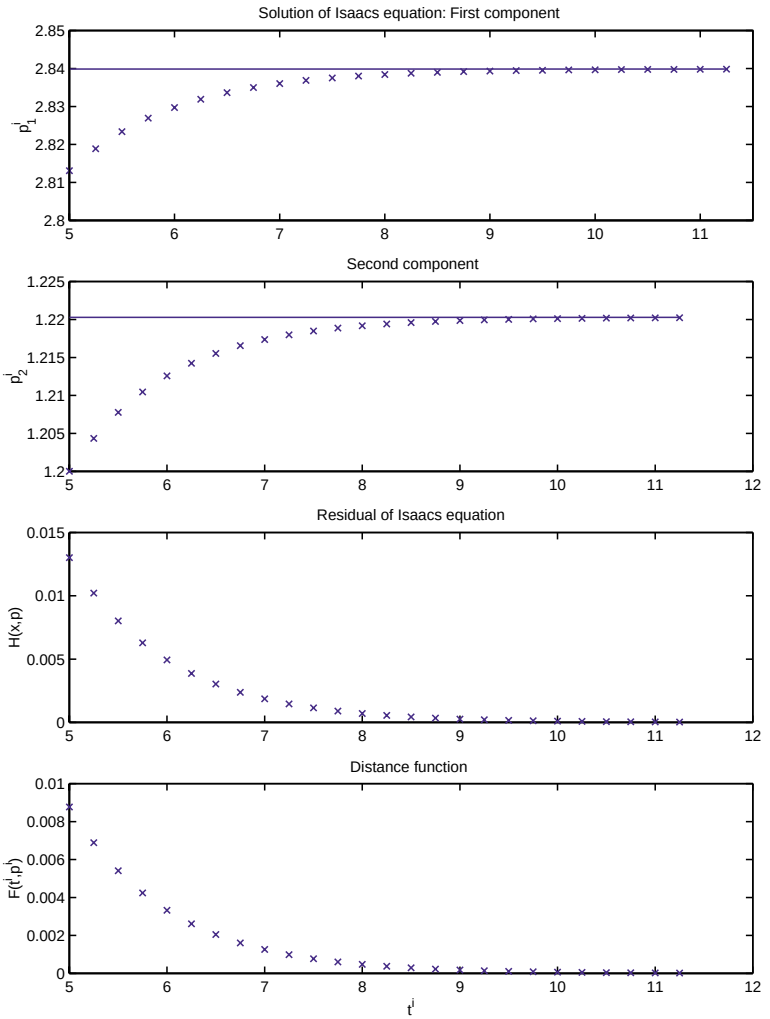

FIG. 6. *Solution and error analysis for* (2.9).

increase. Furthermore, the slope of the line will determine the time constant or the rate of decay.

The Hamiltonian matrix associated with (5.2) is

$$H = \begin{pmatrix} -a & -\frac{1}{2} \\ -2 & a \end{pmatrix}. \tag{6.3}$$

H has eigenvalues $\pm\sqrt{a^2+1}$. Running the algorithm at $x = 1$ for different values of a, Figure 7 displays the logarithmic error graph. Clearly, the curves are all linear, which imply exponential convergence. Furthermore, as a increases the slope of each line increases, indicating a faster rate of convergence. By finding the least square fit to each curve, the rate of convergence can be tested. Table 6.1 shows how the eigenvalues of the Hamiltonian and the convergence rate of the algorithm vary as a increases.

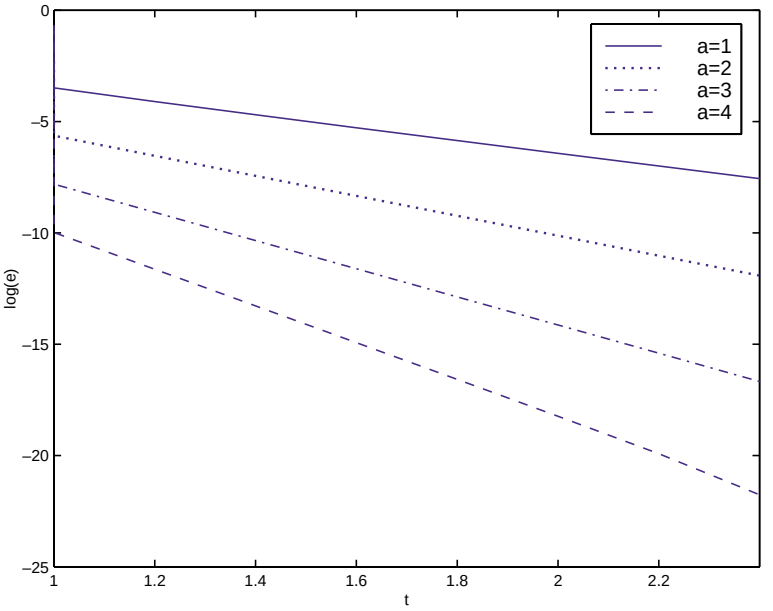

FIG. 7. *Error at each iteration for different a.*

TABLE 6.1
Eigenvalues of H versus rate of convergence.

a	λ	2λ	m_{calc}
1	$\sqrt{2}$	-2.83	-2.83
2	$\sqrt{5}$	-4.47	-4.46
3	$\sqrt{10}$	-6.32	-6.37
4	$\sqrt{17}$	-8.24	-8.25

Clearly, the rate of convergence is consistently twice the eigenvalue of the Hamiltonian matrix.

For higher dimensional systems, this convergence ration depends on the eigenvalue with largest negative real part eigenvalue of the Hamiltonian. Consider the linear H_∞ problem (5.4), (5.5). The associated Hamiltonian system of the Isaacs equation is

$$\begin{pmatrix} \dot{x} \\ \dot{p} \end{pmatrix} = \begin{pmatrix} A & \frac{1}{2\gamma^2} BB^T \\ -2C^TC & -A^T \end{pmatrix} \begin{pmatrix} x \\ p \end{pmatrix}, \tag{6.4}$$

and the eigenvalues of (6.4) are $\pm 1.31, \pm 0.48$. Figure 8 shows the graph of the error versus the time on semilog axes. The straight line indicates that the convergence is indeed exponential, and the slope confirms that the rate is approximately double the minimum eigenvalue of H.

6.1. A nonlinear second-order system. Solve the optimal control problem

$$\begin{aligned} \dot{x_1} &= x_2, \\ \dot{x_2} &= \epsilon x_1^3 + u, \end{aligned} \tag{6.5}$$

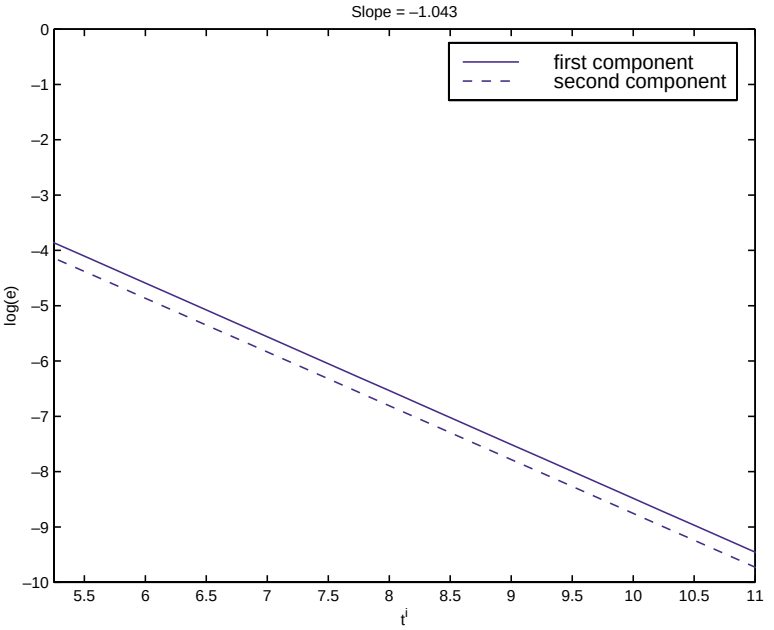

FIG. 8. *Convergence rate of algorithm for system* (5.5).

subject to to the performance index

$$J = \frac{1}{2}\int_0^\infty x_1^2 + x_2^2 + u^2 dt. \tag{6.6}$$

This problem was solved in Nishikawa [5] using a perturbation method, and by Beard [7] using a successive approximation scheme. Results using all three methods will be compared when $\epsilon = 1$.

The corresponding Bellman equation for this problem is

$$H \triangleq x_2 p_1 + x_1^3 p_2 - \frac{1}{2}p_2^2 + \frac{1}{2}x_1^2 + \frac{1}{2}x_2^2 = 0, \tag{6.7}$$

and the optimal control is simply $u^* = p_2$.

Nishikawa and Beard develop fourth-order approximations of the optimal control. They are

$$\begin{aligned} u_n(x) = &- x_1 - 1.7321x_2 - x_1^3 - 1.3235x_1^2x_2 - 0.6923x_1x_2^2 - 0.1323x_2^3, \\ u_b(x) = &- 1.0376x_1 - 1.7975x_2 - 1.3079x_1^3 - 1.3429x_1^2x_2 \\ &- 0.4664x_1x_2^2 - 0.74x_2^3. \end{aligned} \tag{6.8}$$

These controls are compared to the numerical control obtained by our algorithm for the initial conditions $x_1(0) \in (-1, 1)$ and $x_2(0) = 0$. The algorithm was run until five digits in the solution were obtained, and the results are shown in Figure 9. In the figure, J_A refers to the controls obtained by the algorithm, J_B to Beard's control, and J_N to Nishikawa's control.

The first plot shows the associated costs for all three methods. These graphs are indistinguishable, so the differences are plotted as well. It is seen that the cost

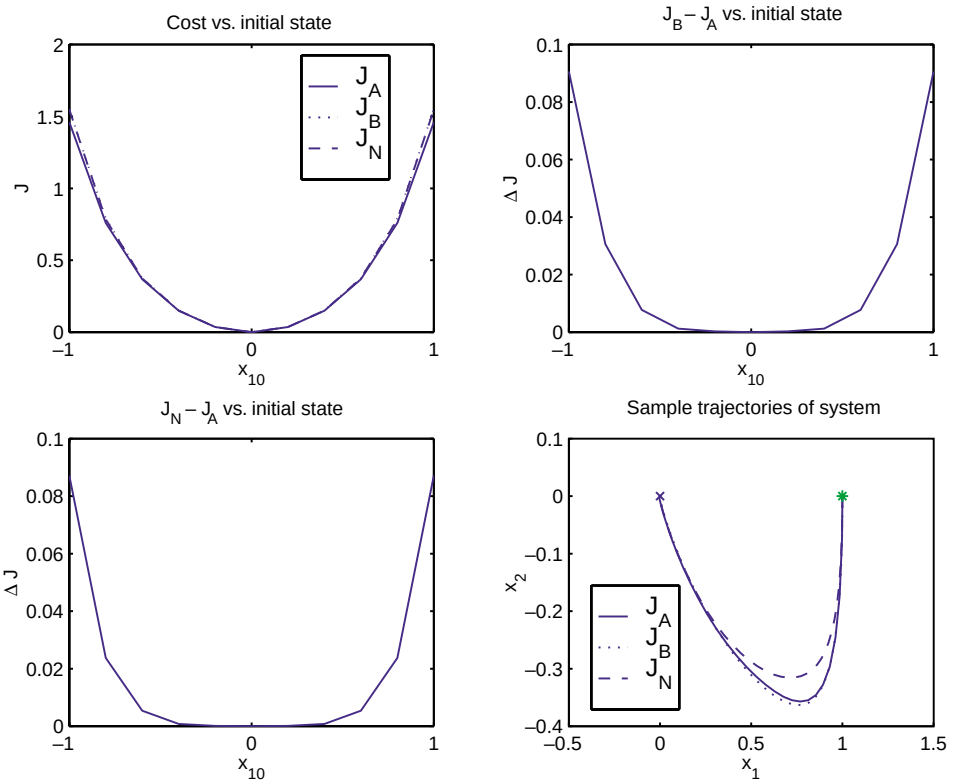

FIG. 9. *Comparison with perturbation method.*

obtained by this algorithm is comparable to the other methods. However, by strengthening the stopping criteria, the costs under our method can be decreased even further at an extra computational cost. Finally, the graph on the bottom right shows a sample trajectory of the system using all three controls.

6.2. Forming the surface numerically. Our algorithm does not find an analytic expression for the control in terms of the state x_0 like the other two methods. However, the control function can be computed numerically by choosing enough points around the origin and integrating the Hamiltonian system forward and backward in time. The forward time trajectory brings the characteristic towards the origin and the backward time trajectory propagates the solution outward. Figure 10 shows the projection of the Hamiltonian system on the state space (x_1, x_2) of the plant using various initial conditions along the line $x_2 = 0$.

It should be apparent that any section of the state space can be "covered" by characteristics given a sufficient number of initial points by the algorithm.

Recall the Hamiltonian system also solves for $V(x)$ and its derivatives as well. Therefore, the value function over the entire region can be estimated by using interpolation methods between the characteristics. Also, since in this case $u(t) = p_2(t)$, a numerical solution for the feedback control can be found as well. Figure 11 shows the graphs of both functions.

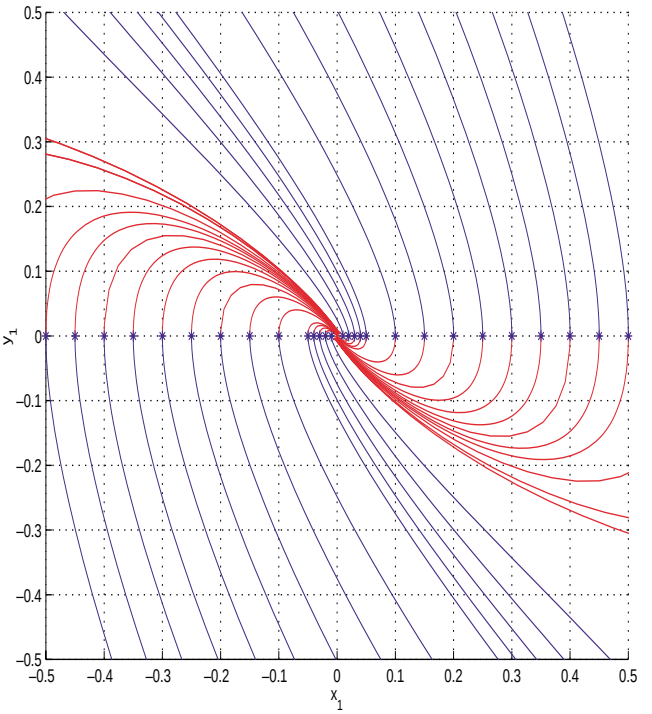

FIG. 10. *Trajectories of Hamiltonian around the origin.*

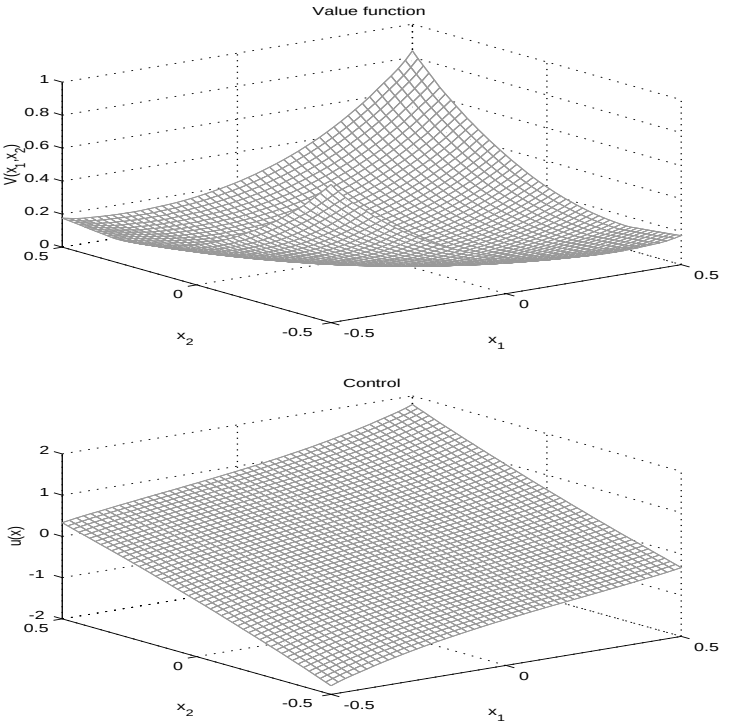

FIG. 11. *$V(x)$ and $u(x)$ for optimal control problem.*

7. Conclusions. There is a need for numerical methods which approximate solutions to the special types of equations which arise in nonlinear control theory. This paper presents an algorithm which calculates an open-loop solution to these Hamilton–Jacobi type equations for points sufficiently close to the origin.

A NEW LAGRANGIAN METHOD FOR TIME-DEPENDENT INVISCID FLOW COMPUTATION*

C. Y. LOH† AND W. H. HUI‡

Abstract. This paper presents a new Lagrangian approach for the two-dimensional (2-D) time-dependent Euler equations. It may be considered as a sequel to the authors' previous Lagrangian approaches for steady supersonic flow computations [C. Y. Loh and W. H. Hui, *J. Comput. Phys.*, 89 (1990), pp. 207–240; W. H. Hui and C. Y. Loh, *J. Comput. Phys.*, 103 (1992), pp. 450–464; W. H. Hui and C. Y. Loh, *J. Comput. Phys.*, 103 (1992), pp. 465–471; C. Y. Loh and M. S. Liou, *J. Comput. Phys.*, 104 (1993), pp. 150–161; C. Y. Loh and M. S. Liou, *SIAM J. Sci. Comput.*, 15 (1994), pp. 1038–1058; C. Y. Loh and M. S. Liou, *J. Comput. Phys.*, 113 (1994), pp. 224–248]. The theoretical background and the intrinsic flow coordinates as well as the Lagrangian conservation form are introduced based on the concept of *material functions* (or *path functions*). A TVD scheme of the Godunov type is chosen to describe the numerical procedure. Several examples are then given to justify the claimed advantages of the new methodology, namely, (a) any contact discontinuities are crisply solved and (b) grids are automatically and accurately generated following pathlines.

1. Introduction.

It is well known that there exist two self-contained general formulations of studying fluid flow: the Eulerian formulation observes flow at fixed locations whereas the Lagrangian formulation does so following fluid particles.

Most of the existing work uses the Eulerian formulation in which the computational cells are fixed in space, while fluid particles move across cell interface. It is this convective flux that causes severe numerical diffusion in the numerical solutions using Eulerian formulation. Indeed, contact discontinuities or slip lines are smeared badly and shocks are also smeared, albeit somewhat better than contact discontinuities. Moreover, the smearing of contact increases with time and distance as a result of continuous mixing of fluid particles. This process exhibits the nature of Eulerian formulation. It cannot be stopped by simply reducing the artificial damping of the numerical scheme. In [1], it is estimated, for example, for a second-order scheme, the smearing is in the order of $O(n^{1/3})$, where n is the number of time steps. Higher order schemes such as piecewise parabolic method (PPM) and essentially nonoscillatory (ENO) may have better performance, but the process still exists as a result of the fundamental nature of the Eulerian approach. Special treatments or numerical fixes, such as artificial compression, steeper reconstruction, and subcell resolution [1], were then introduced in association with higher order schemes (PPM, ENO, etc.). For many problems, great improvements are achieved. However, these numerical fixes either have side-effects or are not always reliable. Since the sixties, the primary efforts of computational fluid dynamics (CFD) algorithm researchers have been concentrated

on developing better (more robust, accurate, and efficient) ways to deal with this convective flux. Although great progresses have been made, numerical diffusion still exists, causing inaccuracy, and is even more difficult to handle in multidimensional flow problems.

Computational cells in the Lagrangian formulation, on the other hand, are literally fluid particles. Consequently, there is no convective flux across cell boundaries and the numerical diffusion is thus minimized. Fundamentally, Lagrangian formulation is ideal for crisp contact resolution. In addition, flow physics is closely followed in a Lagrangian approach and the numerical scheme may benefit from it. The most famous Lagrangian method in use at the present time is the arbitrary Lagrangian–Eulerian method (ALE) [2]. The ALE begins with the first principles of flow physical laws, and the grid nodes are advanced in space and time according to their corresponding velocities. Most modern Lagrangian methods follow the same idea of using staggered grids with velocities at nodes and other quantities at cell centers. For any Lagrangian approach, however, in some cases (e.g., vortical flow with roll-up) the very essence of allowing computational cells to exactly follow the fluid particles can result in cell distortion so severe that the grid lines cross one another and cause the failure of the numerical process. To prevent this from happening, the ALE makes a step back to the Eulerian phase by using continuous rezoning.

Along the line of Lagrangian approach, recently, Hui and van Roessel [3] and van Roessel and Hui [4] developed a new idea in reformulating the Euler equations of gas dynamics and Navier–Stokes equations and thus laid the foundation of a new Lagrangian description for fluid dynamics. They utilize three material functions, M^1, M^2, M^3, to replace the conventional particle labels x_0, y_0, z_0 (typically, the initial position of the particle) as independent variables; then the fourth independent variable τ turns out to have the same dimension as time, which they term the *Lagrangian time*. A *material function* or *path function* [5] is defined as a function that remains constant along a fluid particle path. In the case of steady flow, the material functions become identical to stream functions [4] and their number reduces from three to two. The following is a brief account of their derivation for two-dimensional (2-D) unsteady inviscid flows. The purpose is to show the existence of the new coordinate system. Tensor notations are used for precise and compact presentation.

The derivation begins with an attempt to eliminate the continuity equation. In Cartesian coordinates $x^1 - x^2$ (standing for the usual $x - y$), let $x^0 = t$ be the time of motion, v^0=1, v^i, $i = 1, 2$, the x^1 and x^2 components of velocity (namely, u, v), and ρ the density. Then, the continuity equation can be written as

$$(\rho v^i)_{,i} = 0, \quad i = 0, 1, 2.$$

The material functions $M^i(x^0, x^1, x^2),\ i = 1, 2$, are defined as functions satisfying the following equations:

$$\epsilon^{ijk} K(M^1, M^2) \frac{\partial M^1}{\partial x^j} \frac{\partial M^2}{\partial x^k} = \rho v^i, \quad i, j, k = 0, 1, 2, \tag{1}$$

where ϵ^{ijk} is the permutation symbol and $K(M^1, M^2)$ is a function related to the Jacobian by

$$\frac{\rho}{K} = \frac{\partial(M^1, M^2)}{\partial(x^1, x^2)}. \tag{2}$$

Equation (2) is obtained by setting $i = 0$ in (1). By substituting (1) in the continuity equation, it is observed that the continuity equation is identically satisfied and thus can be eliminated:

$$(\rho v^i)_{,i} = \epsilon^{ijk} \frac{\partial}{\partial x^i} \left[K \frac{\partial M^1}{\partial x^j} \frac{\partial M^2}{\partial x^k} \right] = 0, \quad i, j, k = 0, 1, 2.$$

Rewrite (1) using $I, J, K = 0, 1, 2$ in place of i, j, k:

$$v^I = \frac{K}{\rho} \epsilon^{IJK} \frac{\partial M^1}{\partial x^J} \frac{\partial M^2}{\partial x^K},$$

$M^i, i = 1, 2$, are readily verified to be material functions since

$$\frac{DM^i}{Dt} = v^I \frac{\partial M^i}{\partial x^I} = \frac{K}{\rho} \epsilon^{IJK} \frac{\partial M^i}{\partial x^I} \frac{\partial M^1}{\partial x^J} \frac{\partial M^2}{\partial x^K} = 0. \tag{3}$$

Now, consider $M^i, i = 1, 2$, as new independent variables and choose a third one, M^0, in such a way that the new Jacobian remains the same as before,

$$\frac{\partial(M^0, M^1, M^2)}{\partial(x^0, x^1, x^2)} = \frac{\partial(M^1, M^2)}{\partial(x^1, x^2)} = \frac{\rho}{K}.$$

Then, there are totally three new independent variables $M^i, i = 0, 1, 2$. The inverse transformation provides

$$\frac{\partial x^i}{\partial M^0} = \frac{K}{\rho} \epsilon^{ijk} \frac{\partial M^1}{\partial x^j} \frac{\partial M^2}{\partial x^k}, \quad i, j, k = 0, 1, 2.$$

From (1), the above relations result in

$$v^i = \frac{\partial x^i}{\partial M^0}, \quad i = 1, 2; \qquad v^0 = 1 = \frac{\partial x^0}{\partial M^0} = \frac{\partial t}{\partial M^0}.$$

In other words, M^0 plays a role as time. It is thus termed the Lagrangian time and denoted by τ. τ is indeed a physical time. Following a fluid particle, τ differs from t only by a constant and may be considered as the time individually specified for this fluid particle. The material derivative now reduces to

$$\frac{D}{Dt} = v^i \frac{\partial}{\partial x^i} = \frac{\partial x^i}{\partial \tau} \frac{\partial}{\partial x^i} = \frac{\partial}{\partial \tau}. \tag{4}$$

Equation (4) shows that the new coordinate system (τ, M^1, M^2) is truly Lagrangian. By now, the existence of the new Lagrangian coordinate system is justified.

The major difference between the new and conventional Lagrangian formulations lies in the choice of fluid particle labels. In the conventional Lagrangian description of fluid motion, fluid particle labels x_0, y_0, and z_0 being the independent variables are often chosen from the initial fluid particle positions (e.g., in ALE [2]). In contrast, the new Lagrangian description is characterized by employing material functions (or stream functions in the steady flow case) as fluid particle labels. It turns out that by so doing, an intrinsic flow coordinate is established and a direct and exact relation between flow physics (velocity) and flow geometry—the compatibility equation is found, while such relation is only expressed approximately and implicitly in the conventional Lagrangian formulation (such as the Lagrangian phase of ALE [2]). When

written in conservation form, this relation becomes a geometrical conservation law. As a consequence of the new Lagrangian formulation, we are able to use an unsplit, nonstaggered grid, and to utilize the well-established modern high resolution shock-capturing schemes.

In general, it is observed that the new Lagrangian approach possesses the following features compared to its Eulerian counterpart:

- A computational cell is literally a fluid particle; consequently physics is closely followed.
- Contact discontinuity resolution is crisp and never becomes smeared.
- Grids are automatically generated following particle pathlines or streamlines. The geometrical conservation law assures the correct deformation of each grid cell.
- On the other hand, as in any (pure, nonrezoned) Lagrangian approach, the numerical procdure may fail when the computational cells are highly distorted and grid line crossing occurs (e.g., when vortical roll-up occurs).

Currently our research on the new Lagrangian approach is mostly concentrated in applying finite difference approach in the steady supersonic flow regime. The present authors [6, 7, 8] first put forward a Lagrangian conservation form and applied a Godunov/TVD scheme in 2-D steady supersonic flow computation. In the meantime, they also successfully apply a random choice method [9] for the 2-D supersonic flow problems. In [8], they developed a shock cell splitting technique to exactly locate the shock, which was recently further improved by LePage and Hui [10]. Loh and Liou [11, 12] applied the finte difference and random choice methods for 2-D real gas problems. Recently, they [13, 14] extended the TVD scheme to solve three-dimensional (3-D) supersonic flow problems and obtained interesting results.

In this paper, we report our research on the Lagrangian approach for 2-D unsteady inviscid flow, which includes the new Lagrangian formulation, the corresponding conservation form, and the TVD numerical scheme. The contents are organized in the following way. In section 2, the new conservation forms for 2-D unsteady flows are derived. Section 3 is devoted to the numerical method applied in the new Lagrangian approach. In section 4, several typical numerical results are presented to show the advantages of the new methodology. Finally the paper is concluded in section 5.

2. Lagrangian conservation form for 2-D unsteady flows. The new Lagrangian coordinates may be considered as the *intrinsic* flow coordinates, which is analogous to the intrinsic (or natural) coordinates for a spatial curve in differential geometry. From the viewpoint of numerical computation, we are more interested in the conservation form of the governing equations. Although such a Lagrangian conservation form can be derived via the first principles of physics, we prefer a derivation based on applying coordinate transformation to the Euler equations (5). By so doing, the compatibility equations, which provide geometrical conservation laws for grid deformation, are directly available. The coordinate transformations from Cartesian variables (t, x, y) to Lagrangian variables (τ, ξ, η) (hereafter, M^1, M^2 are replaced by ξ, η, respectively) lead to a *compact* form of the Euler equations under the new system. The Eulerian conservation laws for 2-D unsteady flows are

$$\frac{\partial \mathbf{E}}{\partial t} + \frac{\partial \mathbf{F}}{\partial x} + \frac{\partial \mathbf{G}}{\partial y} = 0, \tag{5}$$

where

$$\mathbf{E} = \begin{pmatrix} \rho \\ \rho u \\ \rho v \\ \rho e \end{pmatrix}, \qquad \mathbf{F} = \begin{pmatrix} \rho u \\ \rho u^2 + p \\ \rho uv \\ (\rho e + p)u \end{pmatrix}, \qquad \mathbf{G} = \begin{pmatrix} \rho v \\ \rho uv \\ \rho v^2 + p \\ (\rho e + p)v \end{pmatrix}.$$

As usual, t, u, v, ρ, and p are, respectively, time, the Cartesian components of flow velocity, density, and pressure of the fluid obeying the γ-law; the special total energy

$$e = \frac{1}{2}(u^2 + v^2) + \frac{1}{(\gamma - 1)}\frac{p}{\rho}.$$

Note that the γ-law is not a condition for converting (5) into a Lagrangian form but is a convenient choice since it is set in our Riemann solver. Let $\mathbf{r} = (x, y)^T$, $\mathbf{V} = (u, v)^T$ denote the Cartesian coordinates and the fluid velocity, respectively. Then,

$$\mathbf{V} = \frac{D\mathbf{r}}{Dt} = \frac{\partial \mathbf{r}}{\partial \tau}. \tag{6}$$

Furthermore, we define the following Lagrangian quantities:

$$\mathbf{T} = (U, V)^T = \frac{\partial \mathbf{r}}{\partial \xi}, \qquad \mathbf{S} = (X, Y)^T = \frac{\partial \mathbf{r}}{\partial \eta}. \tag{7}$$

These quantities represent the lateral displacement gradients of a fluid particle (or a quadrilateral computational cell). Note that they should not be confused with the lower case flow velocities (u, v) and coordinates (x, y). We also define

$$W = \frac{\partial t}{\partial \xi}, \qquad Z = \frac{\partial t}{\partial \eta}. \tag{8}$$

Then the Jacobian matrix of the transformation is

$$J = \frac{\partial(t, x, y)}{\partial(\tau, \xi, \eta)} = \begin{pmatrix} \partial t/\partial \tau & \partial t/\partial \xi & \partial t/\partial \eta \\ \partial x/\partial \tau & \partial x/\partial \xi & \partial x/\partial \eta \\ \partial y/\partial \tau & \partial y/\partial \xi & \partial y/\partial \eta \end{pmatrix} = \begin{pmatrix} 1 & W & Z \\ u & U & X \\ v & V & Y \end{pmatrix}. \tag{9}$$

Notice that

$$\frac{\partial W}{\partial \tau} = \frac{\partial}{\partial \tau}\left(\frac{\partial t}{\partial \xi}\right) = \frac{\partial}{\partial \xi}\left(\frac{\partial t}{\partial \tau}\right) = 0, \qquad \frac{\partial Z}{\partial \tau} = \frac{\partial}{\partial \tau}\left(\frac{\partial t}{\partial \eta}\right) = \frac{\partial}{\partial \eta}\left(\frac{\partial t}{\partial \tau}\right) = 0.$$

In other words, W and Z are independent of τ during marching forward in time. For simplicity, we let $W = Z = 0$ identically. The Jacobian matrix J is now reduced to

$$J = \begin{pmatrix} 1 & 0 & 0 \\ u & U & X \\ v & V & Y \end{pmatrix}, \tag{10}$$

and its determinant becomes

$$|J| = \begin{vmatrix} U & X \\ V & Y \end{vmatrix}. \tag{11}$$

Equation (11) denotes the volume ratio during the change of independent variables. Subsequently,

$$K = \rho|J| = \rho \begin{vmatrix} U & X \\ V & Y \end{vmatrix} \tag{12}$$

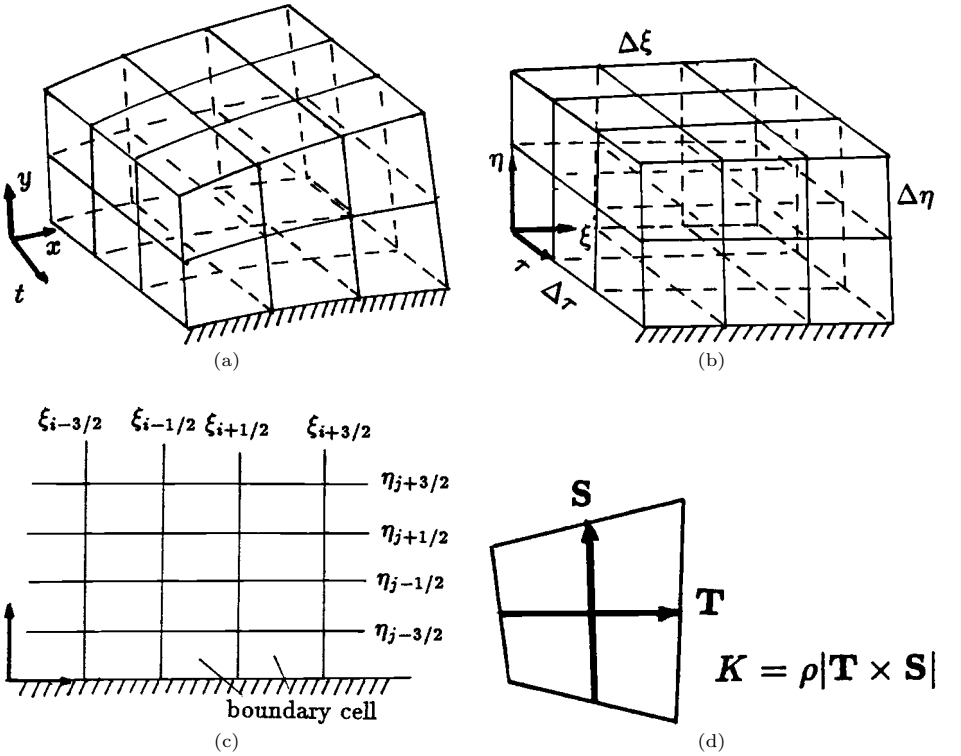

FIG. 1. *Physical and computational space-time domains.* (a) *Physical domain,* (b) *computational domain,* (c) *cell layout on a typical* $\xi - \eta$ *plane,* (d) *mass flux of a cell.*

is the mass flux (Figure 1(d)). The function K thus derived is identical to the 2-D definition of (2). From (12), $|J| = K/\rho$, and the Jacobian matrix of the inverse transformation

$$J^{-1} = \frac{\partial(\tau,\xi,\eta)}{\partial(t,x,y)} = \begin{pmatrix} \partial\tau/\partial t & \partial\tau/\partial x & \partial\tau/\partial y \\ \partial\xi/\partial t & \partial\xi/\partial x & \partial\xi/\partial y \\ \partial\eta/\partial t & \partial\eta/\partial x & \partial\eta/\partial y \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 \\ u & U & X \\ v & V & Y \end{pmatrix}^{-1} \tag{13}$$

$$= \frac{\rho}{K} \begin{pmatrix} \frac{K}{\rho} & 0 & 0 \\ J_{21} & Y & -X \\ J_{31} & -V & U \end{pmatrix},$$

where

$$J_{21} = -\begin{vmatrix} u & X \\ v & Y \end{vmatrix}, \qquad J_{31} = -\begin{vmatrix} u & U \\ v & V \end{vmatrix}.$$

Equation (13) provides all the partial derivatives $\frac{\partial}{\partial t}$, $\frac{\partial}{\partial x}$, and $\frac{\partial}{\partial y}$ that are needed in converting the Eulerian conservation form (5) into a new Lagrangian conservation form with (τ, ξ, η) as the independent variables:

$$\frac{\partial}{\partial t} = \frac{\partial}{\partial \tau} + \frac{\rho}{K} J_{21} \frac{\partial}{\partial \xi} + \frac{\rho}{K} J_{31} \frac{\partial}{\partial \eta},$$

$$\frac{\partial}{\partial x} = \frac{\rho}{K} Y \frac{\partial}{\partial \xi} - \frac{\rho}{K} V \frac{\partial}{\partial \eta},$$

$$\frac{\partial}{\partial y} = -\frac{\rho}{K} X \frac{\partial}{\partial \xi} + \frac{\rho}{K} U \frac{\partial}{\partial \eta}.$$

Now, corresponding to (3), it can easily be confirmed that the material derivatives of ξ and η vanish,

$$\frac{D\xi}{Dt} = \frac{D\eta}{Dt} = 0,$$

and that ξ and η are truly material functions or path functions.

After some algerbraic manipulation, (5) is transformed into a new Lagrangian conservation form with independent variables (τ, ξ, η)

$$\frac{\partial \mathbf{E_l}}{\partial \tau} + \frac{\partial \mathbf{F_l}}{\partial \xi} + \frac{\partial \mathbf{G_l}}{\partial \eta} = 0, \tag{14}$$

where the subscript l stands for Lagrangian form and

$$\mathbf{E_l} = \begin{pmatrix} K \\ Ku \\ Kv \\ Ke \end{pmatrix}, \qquad \mathbf{F_l} = \begin{pmatrix} 0 \\ Yp \\ -Xp \\ -J_{21}p \end{pmatrix}, \qquad \mathbf{G_l} = \begin{pmatrix} 0 \\ -Vp \\ Up \\ -J_{31}p \end{pmatrix}.$$

Moreover, from (7), we have the following compatibility conditions between the τ-derivatives, ξ-derivatives, and η-derivatives of $\mathbf{r}$:

$$\frac{\partial \mathbf{T}}{\partial \tau} = \frac{\partial \mathbf{V}}{\partial \xi}, \qquad \frac{\partial \mathbf{S}}{\partial \tau} = \frac{\partial \mathbf{V}}{\partial \eta}. \tag{15}$$

Equation (15) represents the geometrical deformation of the computational cells (fluid particles) and is hence called the geometrical conservation law. It provides the exact relations between flow physics (velocity) and geometry and marks the major difference between the new Lagrangian approach and a conventional one. A conventional Lagrangian approach (such as ALE) employs interpolation to march forward and to achieve grid deformation. Such relations between flow velocity and cell geometry, of course, exist but are not required explicitly.

By combining the Lagrangian physical conservation laws (14) and the geometrical conservation laws (15), we achieve a complete set of the new Lagrangian conservation form (for brevity the subscript l is dropped off):

$$\frac{\partial \mathbf{E}}{\partial \tau} + \frac{\partial \mathbf{F}}{\partial \xi} + \frac{\partial \mathbf{G}}{\partial \eta} = 0, \tag{16}$$

where

$$\mathbf{E} = \begin{pmatrix} e_1 \\ e_2 \\ e_3 \\ e_4 \\ e_5 \\ e_6 \\ e_7 \\ e_8 \end{pmatrix} \equiv \begin{pmatrix} K \\ Ku \\ Kv \\ Ke \\ U \\ V \\ X \\ Y \end{pmatrix}, \quad \mathbf{F} = \begin{pmatrix} f_1 \\ f_2 \\ f_3 \\ f_4 \\ f_5 \\ f_6 \\ f_7 \\ f_8 \end{pmatrix} \equiv \begin{pmatrix} 0 \\ Yp \\ -Xp \\ -J_{21}p \\ -u \\ -v \\ 0 \\ 0 \end{pmatrix}, \quad \mathbf{G} = \begin{pmatrix} g_1 \\ g_2 \\ g_3 \\ g_4 \\ g_5 \\ g_6 \\ g_7 \\ g_8 \end{pmatrix} \equiv \begin{pmatrix} 0 \\ -Vp \\ Up \\ -J_{31}p \\ 0 \\ 0 \\ -u \\ -v \end{pmatrix}.$$

We note here that in the conventional Lagrangian formulation, including ALE, the Euler equations of gas dynamics have never been written in conservation form (divergence form), except in the special case of one-dimensional (1-D) flow.

At first glance, the Lagrangian equation system (16) seems to have four more equations to solve than (5). A closer investigation shows that there is no need to solve the first equation, it only states that mass flux K is constant all the time along a pathline. Only seven equations need to be solved. The last four equations stand for a dynamic flow-adapting grid generation-deformation procedure. Their counterpart in an Eulerian approach (such as the finite volume method) is the grid generation in the presence of general solid bodies and walls. The solution turns out to be a straight forward step in the numerical approach as described in the next section and costs little overhead (generally, less than 5%) in the CPU time consumption.

Regarding the hyperbolicity of the system (16), after careful investigation, it turns out that the system (16) is only *weakly* hyperbolic [22], in contrast to the hyperbolicity of the original Euler equations (5). In other words, in system (16), all 8 eigenvalues are real but only 7 (instead of 8) linearly independent eigenvectors can be found. Let α and β be the directional cosines of any directions in the $\xi-\eta$ plane, $\alpha^2+\beta^2=1$, and define $\alpha'=\alpha\xi_x+\beta\xi_y$, $\beta'=\alpha\eta_x+\beta\eta_y$, where, from (13), $\xi_x=Y/|J|$, $\xi_y=-X/|J|$, $\eta_x=-V/|J|$, $\eta_y=U/|J|$. Then, the eigenvalues of the system (16) are $\lambda_1=0$, $\lambda_\pm=\pm a(\alpha'^2+\beta'^2)^{1/2}$, where λ_1 has a multiplicity of 6 and a is the local speed of sound. With these eigenvalues, from (13), the local CFL number ν for marching in the computational space is

$$\nu=\frac{(\gamma p\rho)^{1/2}}{K}\max\left[\frac{(V^2+Y^2)^{1/2}}{\Delta\xi},\frac{(U^2+X^2)^{1/2}}{\Delta\eta}\right]\Delta\tau\le 1,$$

when the flow is continuous. In the presence of discontinuity, the above eigenvalue analysis is no longer valid, local shock speeds from the Riemann solvers are required instead, and the expression for a local CFL number becomes very complicated.

3. Numerical approach. The Lagrangian conservation form derived in the above section provides a formulation for applying various numerical methods in the flow computations. In principle, all the existing numerical methods that are appropriate for the Eulerian formulation are appropriate for the new Lagrangian one as well. We shall choose to give brief descriptions to the Godunov/TVD schemes, since it is one of the most popular schemes in gas dynamics computation and is easy to apply.

The space-time physical domain and computational domain in the $\tau-\xi-\eta$ space are respectively illustrated in Figures 1(a) and 1(b). A physical cell in the $x-y$ plane marching along its pathline corresponds to a rectangle cell in the $\xi-\eta$ plane marching in the τ direction in the computational space $\tau-\xi-\eta$. The superscript k refers to the marching time step number and the subscripts i and j refer to the cell index number on a time plane $\tau=$ const. The time step $\Delta\tau^k=\tau^{k+1}-\tau^k$ is uniform for all i and j but is always chosen to satisfy the CFL stability condition. The mesh divides the computational domain into cuboid control volumes or cells which in ξ and η directions are centered at $(\tau^k,\,\xi_i,\,\eta_j)$ and have heights $\Delta\xi_i=\xi_{i+1/2}-\xi_{i-1/2}$ and $\Delta\eta_j=\eta_{j+1/2}-\eta_{j-1/2}$ (for all k). Unless otherwise stated we shall use uniform cell width $\Delta\xi_i$ for all i and $\Delta\eta_j$ for all j (Figure 1(c)).

In the physical space (t,x,y) a cuboid cell marching in (τ,ξ,η) space corresponds to a fluid particle marching along its path tube with step Δt ($\Delta t=\Delta\tau$). The fluid particle is bounded by four path surfaces $\xi=\xi_{i\pm1/2}$ and $\eta=\eta_{j\pm1/2}$ around it. Initially, any curvilinear coordinate mesh on the $x-y$ plane surface may be used as

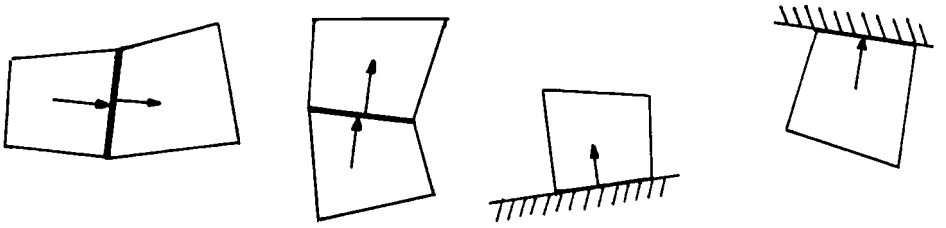

FIG. 2. (a) *Left and right states for* 1*-D local Riemann solver;* (b) *right or left state for a local boundary Riemann solver.*

the $\xi - \eta$ coordinate mesh and the initial $\mathbf{T}$ and $\mathbf{S}$ can be determined from (7) as part of the initial condition. A solid wall is always a path surface (material surface) and hence a coordinate surface.

The Godunov scheme [15, 16] for (16) is derived by applying the divergence theorem to the cuboid cell (i, j, k). The result is

$$\mathbf{E}_{i,j}^{k+1} = \mathbf{E}_{i,j}^{k} - \frac{\Delta\tau^k}{\Delta\xi_i}\,(\mathbf{F}_{i+1/2,j}^{k+1/2} - \mathbf{F}_{i-1/2,j}^{k+1/2}) - \frac{\Delta\tau^k}{\Delta\eta_j}\,(\mathbf{G}_{i,j+1/2}^{k+1/2} - \mathbf{G}_{i,j-1/2}^{k+1/2}), \tag{17}$$

$$i = 1, 2, \ldots, m, \qquad j = 1, 2, \ldots, n,$$

where the notation for the cell average of any quantity f is

$$f_{i,j}^{k} = \frac{1}{\Delta\xi_i \Delta\eta_j} \int_{\xi_{i-1/2}}^{\xi_{i+1/2}} \int_{\eta_{j-1/2}}^{\eta_{j+1/2}} f(\tau^k, \xi, \eta)\, d\xi\, d\eta \tag{18}$$

and the notation for time τ average of f is

(19)

$$f_{i+1/2,j}^{k+1/2} = \frac{1}{\Delta\tau^k} \int_{\tau^k}^{\tau^{k+1}} f(\tau, \xi_{i+1/2}, \eta_j)\, d\tau, \qquad f_{i,j+1/2}^{k+1/2} = \frac{1}{\Delta\tau^k} \int_{\tau^k}^{\tau^{k+1}} f(\tau, \xi_i, \eta_{j+1/2})\, d\tau.$$

In (17), ideally, the cell-interface fluxes $\mathbf{F}_{i+1/2,j}^{k+1/2}$ and $\mathbf{G}_{i,j+1/2}^{k+1/2}$ for the cell (i, j) would be obtained from the self-similar solution of a local 2-D Riemann problem formed by the average constant state $\mathbf{Q}_{i,j} = (u, v, p, \rho)_{i,j}^T$ of the cell (i, j) and those of its adjacent cells. Unfortunately, due to its complexity, the exact solution to a general 2-D Riemann problem is not yet available. On the other hand, it is known that a monotone difference scheme to a general conservation form converges to the physically relevant entropy-satisfying solution. In particular, Crandall and Majda [17] establish the rigorous convergence for dimensional splitting algorithms when each step is approximated by a monotone difference scheme (such as the Godunov scheme) for a single conservation law of multidimension. We shall extend and apply the dimensional splitting in the Godunov scheme for the hyperbolic system of conservation laws (16).

When applying the dimension-splitting technique in the Godunov scheme (17), one only needs to solve a regular 1-D Riemann problem formed by two adjacent constant states, say, $\mathbf{Q}_{i,j}$ and $\mathbf{Q}_{i+1,j}$ in the normal direction of the interface (Figure 2(a)). For a high resolution TVD scheme, nonlinear interpolation is employed across the interface line to reconstruct the flow variables at both sides of the interface before applying the local 1-D Riemann solver. At a solid wall, a boundary Riemann problem

is solved, which consists of Riemann data that are a mirror image with respect to the wall (Figure 2(b)).

The numerical procedure of the Godunov/TVD scheme can now be summarized as follows:

(i) Initiation. Assume the initial conditions of a flow problem are given at $t = 0$ ($\tau = 0$) in the $x - y$ plane. Then an appropriate $\xi - \eta$ coordinate mesh is laid on the $x-y$ plane (for instance, we take ξ and η equal to the arc length of their corresponding coordinate lines on $x - y$ plane), with $\xi = \xi_0, \xi_1, \xi_2, \ldots, \xi_m$, $\eta = \eta_0, \eta_1, \eta_2, \ldots, \eta_n$, and the curve $\xi = \xi_0$ (or $\eta = \eta_0$) coinciding with the body surface if there is a solid wall (Figure 1(a)). Hence $\mathbf{T}^0$, $\mathbf{S}^0$ as well as the flow variable $\mathbf{Q}^0 = (u^0, v^0, p^0, \rho^0)^T$ are known on $x - y$ plane as initial conditions. Subsequently, $\mathbf{E}^0_{i,j}$, $i = 1, 2, \ldots, m$, $j = 1, 2, \ldots, n$, are available. For example, if we choose ξ, η to be the respective arc lengths of x- and y-coordinate lines then, from (7), $\mathbf{T}^0 = (1, 0)^T$, $\mathbf{S}^0 = (0, 1)^T$, and $\mathbf{E}^0$ follows from its expressions in (16).

(ii) Evaluate cell interface fluxes, and update e_5, e_6, e_7, e_8. With all $\mathbf{E}^k_{i,j}$ and $\mathbf{Q}^k_{i,j}$ known at step k ($k = 0, 1, 2, \ldots$), the $\mathbf{Q}$ data is first upgraded or reconstructed via a monotonic upstream-centered scheme for conservation laws (MUSCL) TVD procedure by nonlinear interpolation. This upgrading is performed in a dimension-by-dimension way. For example, in the ξ direction, let f be any of the above physical variables u, v, p, or ρ, then, instead of assuming a uniform state in the cells (i, j) and $(i + 1, j)$, we assume linearly distributed states and use linear extrapolation to determine cell interface flow variables $f_r = f_{i+1,j} - .5(f_{i+2,j} - f_{i+1,j})\phi(r^+)$ with $r^+ = (f_{i+1,j} - f_{i,j})/(f_{i+2,j} - f_{i+1,j})$ and $f_l = f_{i,j} + .5(f_{i,j} - f_{i-1,j})\phi(r^-)$ with $r^- = (f_{i+1,j} - f_{i,j})/(f_{i,j} - f_{i-1,j})$, where $\phi(r) = \max(0, \min(1, r))$ is the minmod flux limiter and subscripts r and l correspond to right and left states, respectively. They are then projected on the normal direction of the cell interface (Figure 2(a)) and used as the input to the the local Riemann solvers. To obtain the normal direction of an interface, say, between cells $(i + 1, j)$ and (i, j), the directional vector of this interface is first obtained by taking the average of the unit vectors of $\mathbf{S}_{i+1,j}$ and $\mathbf{S}_{i,j}$ and its normal vector follows in a straightforward way. At a solid wall, of course, its normal direction is chosen as the normal to the wall. New cell interface flow variables $\mathbf{V}^{k+1/2}_{i\pm1/2,j}$ or $\mathbf{V}^{k+1/2}_{i,j\pm1/2}$ and $p^{k+1/2}_{i\pm1/2,j}$ or $p^{k+1/2}_{i,j\pm1/2}$ are obtained as the results of these Riemann solvers. Then fluxes $\mathbf{F}$ and $\mathbf{G}$ are calculated from their expressions in (16). In order to do so, we first update $\mathbf{T}^k_{i,j}$ and $\mathbf{S}^k_{i,j}$ to $\mathbf{T}^{k+1}_{i,j}$ and $\mathbf{S}^{k+1}_{i,j}$:

$$\begin{pmatrix} U^{k+1}_{i,j} \\ V^{k+1}_{i,j} \end{pmatrix} = \mathbf{T}^{k+1}_{i,j} = \mathbf{T}^k_{i,j} + \frac{\Delta\tau^k}{\Delta\xi_i}\,(\mathbf{V}^{k+1/2}_{i+1/2,j} - \mathbf{V}^{k+1/2}_{i-1/2,j}), \tag{20}$$

$$\begin{pmatrix} X^{k+1}_{i,j} \\ Y^{k+1}_{i,j} \end{pmatrix} = \mathbf{S}^{k+1}_{i,j} = \mathbf{S}^k_{i,j} + \frac{\Delta\tau^k}{\Delta\eta_j}\,(\mathbf{V}^{k+1/2}_{i,j+1/2} - \mathbf{V}^{k+1/2}_{i,j-1/2}). \tag{21}$$

Thus the updating of U, V, X, and Y (i.e., e_5, e_6, e_7, e_8) is completed. With these newly updated U, V, X, Y and the pressures $p^{k+1/2}_{i\pm1/2,j}$ or $p^{k+1/2}_{i,j\pm1/2}$ from the local Riemann solvers, flux components f_2, f_3, f_4 and g_2, g_3, g_4 are readily available according to their expressions in (16). For example, for the cell (i, j), f_4, the fourth component of $\mathbf{F}$ at the interface between cells $(i + 1, j)$ and (i, j), is evaluated as

$$-p^{k+1/2}_{i+1/2,j} \begin{vmatrix} u^{k+1/2}_{i+1/2,j} & Y^{k+1}_{i,j} \\ v^{k+1/2}_{i+1/2,j} & X^{k+1}_{i,j} \end{vmatrix}.$$

(iii) Use (17) to update e_2, e_3, e_4 and advance by one step (e_1 requires no updating).

(iv) Decode $\mathbf{E}_{i,j}^{k+1}$ to get $\mathbf{Q}_{i,j}^{k+1}$. For simplicity, all the i, j, k superscripts and subscripts are dropped. From (12) and the expression of $\mathbf{E}$ in (16),

$$\rho = \frac{K}{(e_5 e_8 - e_6 e_7)}, \qquad u = \frac{e_2}{K}, \qquad v = \frac{e_3}{K}, \qquad p = (\gamma - 1)\rho \left[\frac{e_4}{K} - .5(u^2 + v^2)\right].$$

Now the numerical procedure for advancing one time step is completed. To march forward further, one goes back to (ii) and repeats (ii)–(iv). The loop from (ii) to (iv) is self-sustained when marching in the $\tau - \xi - \eta$ computational space. However, if a grid in the physical $x - y$ plane is required for plotting a curve or contours, one may

(v) Generate grid points (coordinates of cell centers) along pathlines

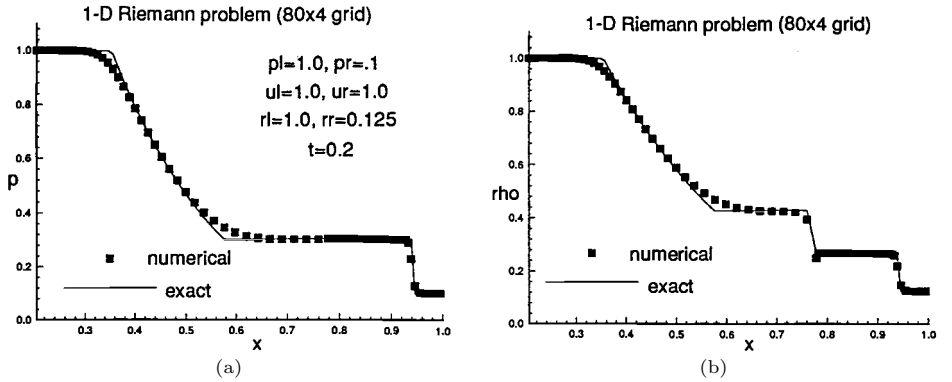
$$x_{i,j}^{k+1} = x_{i,j}^{k} + \frac{1}{2}\Delta\tau^k (u_{i,j}^{k} + u_{i,j}^{k+1}), \qquad y_{i,j}^{k+1} = y_{i,j}^{k} + \frac{1}{2}\Delta\tau^k (v_{i,j}^{k} + v_{i,j}^{k+1}).$$

Each grid point represents the center of a fluid particle (a computational cell). Note that unlike the conventional Lagrangian approach (e.g., ALE), these new x, y coordinates are not fed back to, as they are not used in, the computational process. Again, unlike any conventional Lagrangian methods using staggered grids, our approach does not need a staggered grid and the information of the positions of cell corners is never required.

An interesting feature of the time-dependent Lagrangian approach is that the entire physical domain of computation may move along with the main flow and keep deforming its shape. It plays a role as a moving viewing window. One can always adjust the viewing window so that it becomes relatively motionless. For this purpose, only a few more lines in the Fortran code are needed. For instance, assume the main flow directs from left to right, we wait until the leftmost column of cells moves over a distance of about the average cell size, then a new column of cells is injected as the new leftmost column. To avoid increasing the number of cells, the rightmost column of cells, which is exiting the viewing window, is removed. In section 4, this technique is applied to examples 2 and 3.

4. Typical numerical results. In this section, the new Lagrangian approach is tested for accuracy and robustness on several numerical examples. $\gamma = 1.4$ is used for all the cases. The numerical results are then compared to exact solutions or experimental results whenever they are available, or to the numerical results by other Eulerian approaches. Example 4 is also chosen for convergence test or validation. In all the examples, a modest grid is used to demonstrate that the Lagrangian approach is capable of catching all the flow features even with a coarse grid, except when convergence test is carried out.

The first example is indeed a 1-D Riemann problem but is numerically solved as a 2-D problem. The initial data is chosen from the well-known Sod's shock tube problem, namely, $(u_l, v_l, p_l, \rho_l) = (1.0, 0, 1.0, 1.0)$, $(u_r, v_r, p_r, \rho_r) = (1.0, 0, 0.1, 0.125)$, where the subscripts l and r denote left and right states, respectively. A grid of 80×4 with $\Delta x = \Delta y = 0.01$ is employed in the computation. Since the flow is uniform in y direction, only 4 grid points are used in this direction. The computed pressure p and density ρ at time $t = 0.2$ are shown in Figure 3, where the corresponding exact solutions are also plotted for comparison. It is observed that our numerical results agree well with the exact solutions. While a shock is resolved in about two points, the contact discontinuity remains almost absolutely sharp, as claimed in section 1. Note



(a) (b)

FIG. 3. *Comparison of numerical solutions and exact solutions for a* 1*-D Riemann problem,* (a) *pressure and* (b) *density distributions along* x *direction.*

that in the density plot, there is a little dip-down (glitch) after the contact, which is a common phenomenon for Lagrangian approach (see, e.g., [23]).

The next example is a genuine 2-D problem—a steady supersonic flow of Mach numer 2.9 past a ramp channel. The steady state is achieved by time marching until the flow variables do not change with time. At the bottom, a ramp of 10.94° locates at $x = 0.5$ (Figure 4), while the top wall is a horizontal straight line. The height of the physical domain is 1.0 at the inlet, and initially, the domain length is chosen to be 3.0. As mentioned in section 3, we apply the motionless viewing window technique, the size and shape of the window change slightly with time-marching. A grid of 90×40 with $\Delta x = 0.032$ and $\Delta y = 0.025$ is employed. A $\Delta t = .001$ is chosen as the marching time step size. For this oblique shock and shock reflection problem, there exists a steady state exact solution. The free stream state is given as $(u, v, p, \rho) = (2.9, 0, 1/1.4, 1.0)$; the state downstream of the oblique shock is evaluated to be $(u, v, p, \rho) = (2.6193, 0.50632, 1.5282, 1.7)$, with a shock angle of 29°; while the state after shock reflection is $(u, v, p, \rho) = (2.4015, 0, 2.934, 2.6872)$. Since the flow is supersonic, all the flow variables are specified at the inlet as boundary conditions. At the outlet, boundary condition is simply the extrapolation condition.

In Figure 4(a) the Lagrangian grid is seen deformed with the flow and becomes condensed when the fluid is compressed. In Figure 4(b) the isobars and the shock reflection is clearly displayed. Figures 4(c) and 4(d) show, respectively, pressure plots along the bottom wall and the top wall; along with the corresponding exact solutions. The numerical solutions agree well with the exact ones. Figure 4(e) displays the density distribution along y direction at the domain exit. The plot is seen in good agreement with the exact solution except there are "glitches" at the top and bottom walls, since solid walls represent contacts.

In the third example, we consider a supersonic flow with a subsonic pocket—the problem of supersonic flow past a channel with a ramp segment. The total length of the physical domain is 3.3 with height at inlet 1.0. As shown in Figure 5, a ramp of 15° is located at the bottom wall between $x = 0.5$ and $x = 1$, the rest of the top and bottom walls are horizontal flat lines [18, 19]. When a Mach 1.8 flow passes through the channel, an oblique shock, a Mach stem, shear layers, and reflected shocks are generated as shown in Figure 5. Again a modest grid of 90×40 cells is used in the computation. To test if the steady state is reached, the computation was first carried to $t = 8$ and then to $t = 18$. The computed flow is found only slightly changed from $t = 8$ to $t = 18$. The contours and plots in Figures 5 and 6 are based on the

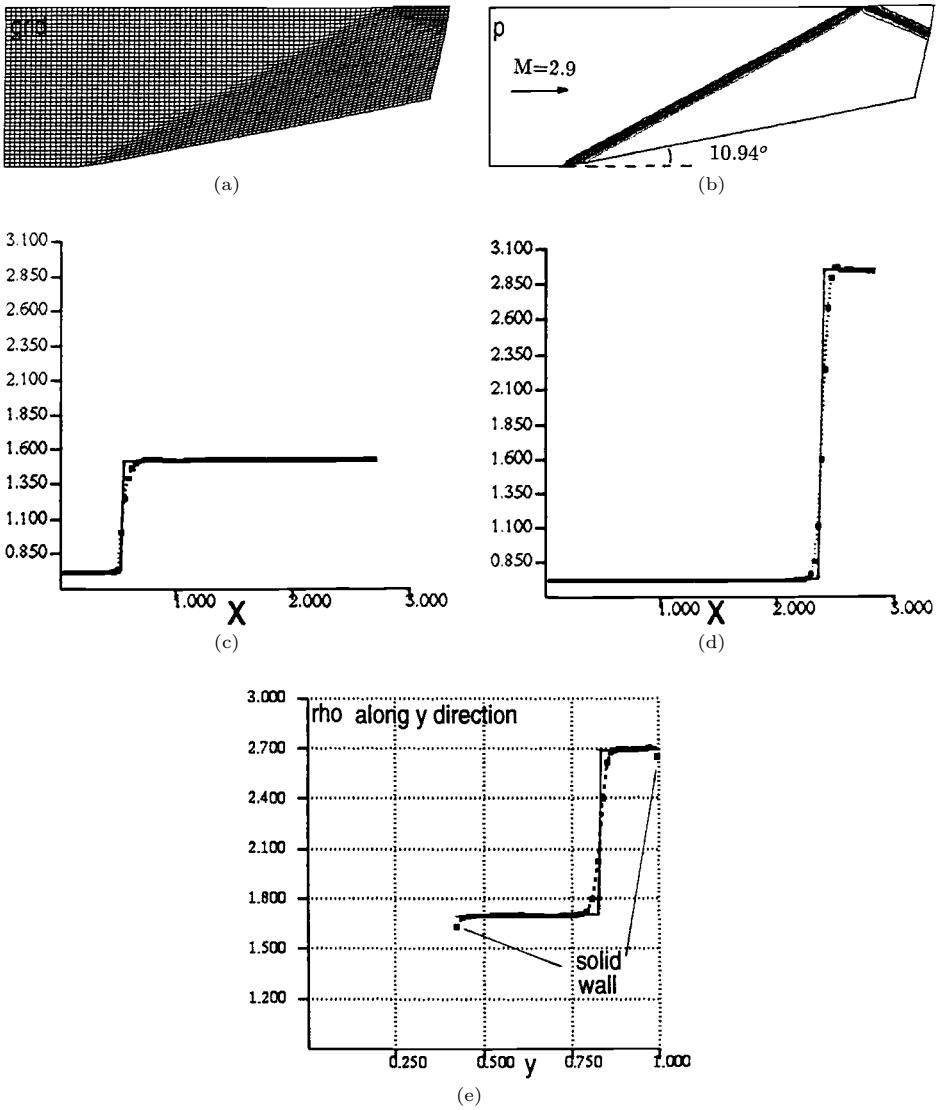


FIG. 4. *Supersonic flow of Mach* 2.9 *past a ramp channel. The ramp angle is* 10.94°. (a) *The deformed Lagrangian grid (when flow becomes steady),* (b) *isobars (*40 *levels between* max. *and* min. *pressure values),* (c) *pressure distribution along bottom wall,* (d) *pressure distribution along top wall, and* (e) *density distribution at domain exit; solid lines denote the exact solutions. numerical results at $t = 18$. In Figure 5, the grid formed according to the flow, the isobars and the isomachs are illustrated. A notch at the upper right corner of the physical domain is due to the slow-down of the flow downstream of the Mach stem, where the flow becomes subsonic with a Mach number as low as 0.65. Although the grid is relatively crude, all the flow features are clearly displayed: the Mach stem is about 20% of the domain height, the oblique and reflected shocks, and particularly the shear layers stemming out from the triple point. The quality of the shear layers is seen comparable to that of a finer grid in Eulerian formulation (see, e.g., [18, 19]). In Figure 6, pressure and Mach number distributions along the top and the bottom

walls are plotted. When passing across a shock, these plots show crisp resolutions of 2 to 3 points. They agree well with the results by the Eulerian method (e.g., [19]).

The fourth example is the Mach reflection of a shock wave from a wedge [20]. A vertical plane shock of Mach 1.3 travels over a wedge of 25° and generates Mach reflection as shown in Figure 7. The isobars, isomachs, and grids at $t = 1.2$ are displayed. They agree well with the experimental result [20]. In particular, the

contactline (shear layers) stemming from the triple point is clearly seen from the isomach contours. In this case, a grid of 150×60 is employed with $\Delta x = \Delta y = 0.01$, $\Delta t = 0.002$. The initial state is $\mathbf{Q^0} = (p^0, u^0, v^0, \rho^0)^T = (1/1.4, 0, 0, 1)^T$ and the flow state at the left end is $\mathbf{Q}_i = (1.2893, 0.44231, 0, 1.5157)^T$. We also run the problem with a given CFL number ν according to the expression at the end of section 2, instead of a fixed Δt. Although the numerical process does not blow up for ν up to 0.9, the output isomachs are noisy with wiggles. The results are improved and clean when ν is reduced to 0.5 or less. At $\nu = 0.5$, 360 time steps are marched to reach $t = 1.2$ and CPU time is considerably saved as compared to the case with fixed $\Delta t = 0.002$.

The present example is also chosen to go through a convergence test (validation) for the new Lagrangian approach. For this purpose, double grid (300×120) and quadruple grid (600×240) are used and the same code is run with appropriate half and quarter time step sizes, respectively, to $t = 1.2$. Figures 7(d) and 7(e) demonstrate the corresponding isomachs of the two runs, they look almost identical except that the denser grid yields a sharper picture. In addition, they all agree well with the isomachs in Figure 7(b) and the convergence of the numerical approach is justified.

The last example is an interesting implosion/explosion problem. A numerical study of this problem has been carried out in [21]. A typical implosion/explosion problem is depicted in Figure 8(a). Consider a square duct of infinite length. Inside the duct, initially separated by a diaphragm, an inner square contains a gas of different state from the outer one. The centers of these two squares coincide (Figure 8(a)). At $t = 0$, the diaphragm is ruptured, and the inner and outer gases begin to interact with

each other. The implosion/explosion problem may be regarded as a 2-D version of the shock tube problem with four surrounding walls. However, due to higher dimension, the flow pattern is much more complicated. In our test, we choose the inner state $\mathbf{Q}_i$ and outer state $\mathbf{Q}_o$ as follows: $(u_i, v_i, p_i, \rho_i) = (0, 0, 0.14, 0.125)$, $(u_o, v_o, p_o, \rho_o) = (0, 0, 1.0, 1.0)$. Initially, a uniform grid of 60×60 is laid as shown in Figure 8(a) with grid size $\Delta x = \Delta y = 0.01$. Two computation runs are carried out to $t = 0.6$. The first one runs with a fixed CFL number $\nu = 0.7$ and it takes 1060 time steps to reach $t = 0.6$. The second one runs with a fixed time step $\Delta t = 0.0005$, taking only 600 steps and less CPU time. In this case, it is more advantageous to march with a constant time step size. Figure 8(b) illustrates how the grid is deformed with the flow from $t = 0.05$ to $t = 0.6$ with an increment of $\Delta = 0.05$. Soon after time $t = 0.6$ (step 12) the computation stops due to severe cell deformation and the consequent gridline crossing. An indication of the failure is that the determinant of transformation $|J|$ in (11) passes through 0 and becomes negative, rendering the transformation invalid. Figure 9(a) and 9(b) display, respectively, the isobars and isopycnics at different time steps. Steps 1–12 correspond to the same steps in Figure 8(b). Since the pressure of $\mathbf{Q}_i$ is lower at the beginning, a shock appears in the inner region. It propagates and contracts to the center. At the four corners of the shock, triple points and embedded shocks are generated as observed from step 1, Figure 9(a). Later on, very complicated flow patterns are developed. From Figure 9(b), it is seen that the contact stays in the center area but keeps changing its shape and reducing its encircled area slowly and steadily. The contact can be located by comparing the contours at the same step in Figures 9(a) and 9(b). The Mach numbers in the domain range from 0 to about 0.3. The present problem is a typical one of low Mach number flow.

In Figure 10, pressure and density distributions along the centerline in x-direction are plotted. In general, shocks are resolved in 2–4 points and the contacts are almost absolutely sharp, which is a well-known major advantage of the Lagrangian approach. Qualitatively the contours in Figure 9(a) and 9(b) are comparable to those from [21], except the 2-D shocks look thicker due to the crude grid. In contrast, a grid of 359×359 points is employed in [21] to achieve high resolution. In Figure 10(b), the numerical density value dips down slightly across a contact, as other examples do in the present paper (see also, e.g., [23]).

Finally, regarding the CPU time consumption, it somewhat slightly depends on the newton iterations in the local Riemann solvers (i.e., flow complexity). Typically on a CRAY-YMP without vectorization, CPU time consumption per cell per time step is $120\mu s$. With appropriate vectorization, it is expected to be a few times faster.

5. Concluding remarks. In this paper, with the concept of material functions (path functions), we successfully introduce the new Lagrangian formulation in conservation form for time-dependent inviscid flows and its numerical procedure based on the standard Godunov/TVD numerical schemes. Various numerical examples are presented to demonstrate the capability and robustness of the new Lagrangian approach in handling unsteady or steady, supersonic or subsonic inviscid flow computations.

Compared to the Eulerian approach, the new Lagrangian approach possesses the following features:

(i) Flow physics is closely followed, and contact discontinuity resolution is crisp and never becomes smeared.

(ii) Grids are automatically generated following particle pathlines. The geometrical conservation law assures the correct deformation of each grid cell.

A possible extra advantage is some enhancement of shock resolution since the

Lagrangian TVD scheme changes its upwind direction automatically according to the flow, playing a role as a rotating upwind scheme.

Compared to the conventional Lagrangian approach (such as the Lagrangian phase of ALE), the new Lagrangian formulation puts the Euler equations in divergence form, making it possible to use an unsplit, nonstaggered grid. In other words, it provides an intrinsic coordinate system and a direct and exact relation between flow physics and grid geometry—the geometrical conservation laws, which allows proper analysis and easy application of modern high resolution shock capturing schemes and subsequently may yield better results.

On the other hand, it shares with any conventional Lagrangian method the same difficulty for flows where fluid particles experience servere distortion, resulting in gridline crossing and failure. In ALE [2], the gridline curdling is remedied by rezoning—a step back to the Eulerian phase. In the new Lagrangian approach, a remedy to gridline crossing is under investigation and will be reported in the future.

GRADIENT-PARTICLE SOLUTIONS OF FOKKER–PLANCK EQUATIONS FOR NOISY DELAY BIFURCATIONS*

R. KUSKE†

Abstract. A gradient particle method is used to compute probability densities for processes with delay bifurcations that are sensitive to very small noise. The method is particularly useful for computing the probability density in the transition region, where asymptotic approximations may not be valid. For a one-dimensional steady bifurcation problem and a two-dimensional FitzHugh–Nagumo model, we solve the Fokker–Planck equation (FPE) and compare the results with direct simulations and asymptotic approximations.

1. Introduction.

Certain dynamical systems are very sensitive to noise, such as models of chemical kinetics [1], [2], neuron firing [2], [3], chaotic wave mode interactions [4], and lasers [5]. The deterministic dynamics of these systems, described by systems of ordinary differential equations (ODEs), can change substantially when very small noise is introduced. The probability density for the process describes the sensitivity of the process to noise. It can be used to find a variety of properties of the stochastic process, including time and location of state transitions and moments. Even though the probability density function holds all of the information for the stochastic process, much of the previous work on noisy nonlinear dynamics does not attempt to compute or approximate it. This is because it can be difficult to find the probability density when the underlying dynamical system is complicated and the noise is small.

In general, the goal is to find $p(\mathbf{x}, t)$, the probability that the process takes the value $\mathbf{x}$ at a given time t. Given a system of stochastic differential equations (SDEs) describing the process,

$$d\mathbf{x} = \mathbf{a}(\mathbf{x}, \mathbf{t})dt + \sqrt{2}\epsilon d\mathbf{W} \quad (\epsilon \text{ is a constant}), \tag{1.1}$$

with $\mathbf{W}$ a vector of independent Brownian motions, the probability density $p(\mathbf{x}, t)$ satisfies the partial differential equation (PDE),

$$\frac{\partial p}{\partial t} = \epsilon^2 \nabla^2 p - \nabla \cdot (\mathbf{a}p), \tag{1.2}$$

known as the Fokker–Planck equation (FPE) [6]. Note that the white noise in the SDEs corresponds to the diffusion in (1.2), while the drift $\mathbf{a}(\mathbf{x}, \mathbf{t})$ describes the convection. In this paper, we consider problems in which a slow variation of a control parameter through a critical point results in a delay in the transition between states for the underlying noiseless dynamics ((1.1) with $\epsilon = 0$). This delay can be changed significantly by very small noise (e.g., $0 < \epsilon \leq 10^{-4}$). This is discussed in detail in section 2.

There are several issues to consider in trying to find a solution to (1.2). For small noise ($\epsilon \ll 1$) it is expected that $p(\mathbf{x}, t)$ has large gradients, as is typical of solutions of problems with small diffusion. Then one might look for an asymptotic approximation, rather than a numerical solution. However, in the problems we study in this paper, the probability density has large gradients in some regions of space or time but not in others. Then an asymptotic approach may not be uniformly applicable. Therefore a numerical solution is necessary both to validate the asymptotic approximation where it is correct, and to provide a solution when the asymptotic approximation breaks down. The asymptotic expansions for (1.2) are discussed in detail in [7]. In this paper we focus on numerical solutions for the probability density and illustrate their complementary relationship to the asymptotic results.

A variety of numerical methods can be considered for solving (1.2). For very small diffusion, grid-based numerical methods can introduce numerical diffusion which obscures the effects of the small noise. Since the main purpose of the calculation is to determine the effect of the small noise, an appropriate method must sufficiently resolve the solution. In the applications we consider in this paper the diffusion coefficient in the Fokker–Planck equation is 10^{-8} or smaller. Under these circumstances, adapting or refining the mesh could be expensive or impractical.

Another approach is to find the probability density from simulations of (1.1), which avoids the issue of numerically solving (1.2). While this is a direct and intuitive way to find $p(\mathbf{x}, t)$ given the SDE (1.1), a very large number of simulations is necessary to obtain a smooth result for the density function. The number of simulations necessary can increase with the dimension of $\mathbf{x}$, and it also depends on the concentration of the density. We discuss the various methods further in the context of the application of section 2.

In this paper we use a gradient-particle method (GPM) to find the probability densities from (1.2) for problems with noisy delay bifurcations. Even with very small noise, the concentration and the gradient of the probability density function for these processes can vary significantly. The GPM incorporates the natural idea of simulation of (1.1) into the numerical solution of (1.2) so that the effects of the noise are not obscured and the result for the density is smooth.

In section 2 we give a description of a one-dimensional problem which illustrates why GPMs are appropriate for this problem. In section 3 we outline the algorithm, which uses ideas from [8] and [9]. In section 4 we compare the GPM results for the one-dimensional problem of section 2 with results from direct simulation (DS) and the asymptotic method of [7]. In section 5 we compute the probability density function for the noisy FitzHugh–Nagumo model and compare the GPM results with DS and the asymptotic results. In this paper we focus on the computational issues in finding the probability density function, and refer the reader to [7] for a complete discussion of the complementary asymptotic methods. A brief outline of the asymptotic approach is given in the appendix.

2. Motivation for the GPM. A description of a simple example of a delay bifurcation illustrates the important issues. The deterministic problem is

$$\frac{dy}{dt} = cy - y^3. \tag{2.1}$$

This equation was studied in [10] as a canonical model of the delay of a steady bifurcation. We summarize the results. If the control or bifurcation parameter, c, is a constant, there are two steady state solutions: $y = 0$ for all c and $y = \sqrt{c}$ for $c > 0$.

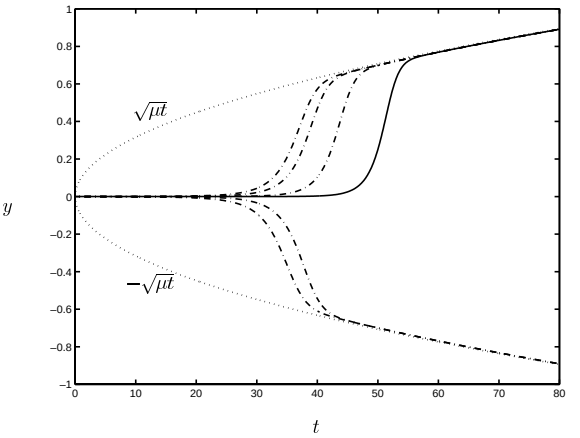

FIG. 2.1. *The solution of* (2.2) *for* $\epsilon = 0$ *and* $\epsilon = 10^{-4}$. *The solid line is the deterministic solution of* (2.2) *with* ($\epsilon = 0$), *and the dash-dotted lines are five realizations of the solution of* (2.2) *with* $\epsilon = 10^{-4}$. *In both cases the initial condition was* $y(0) = 10^{-6}$ *and* $\mu = .01$. *Note that the noisy solution makes the transition to a solution near* $\pm\sqrt{\mu t}$ *much sooner than the deterministic solution does; that is, the delay of the transition is reduced in the presence of noise.*

The solution $y = \sqrt{c}$ is stable for $c > 0$. That is, there is a steady bifurcation from the zero solution to the solution $y = \sqrt{c}$ at the critical parameter value $c = 0$.

Now consider $c = \mu t$ for $0 < \mu \ll 1$. When the system is subcritical, ($\mu t < 0$), $y(t)$ decays exponentially. As t increases so that $t > 0$, $y(t)$ remains small for a long interval of time. For $\sqrt{\mu t} = O(1)$, $y(t)$ grows rapidly, approaching $y(t) \sim \sqrt{\mu t}$. This is known as a delay bifurcation, since the solution does not immediately increase rapidly as the coefficient μt varies slowly through the critical point $\mu t = 0$. This behavior can be seen from the exact solution of (2.1).

Now we consider the effect of noise on the delay bifurcation. Previous studies have considered the reduction of the delay with the addition of sinusoidal oscillations [10]. Numerical simulations of

$$dy = (\mu t y - y^3)dt + \sqrt{2}\epsilon dW, \tag{2.2}$$

where W is standard Brownian motion, demonstrate that the delay is reduced with the addition of noise [11], even though $\epsilon = 10^{-4}$ (see Figure 2.1). The simulations of Figure 2.1 show that the noisy dynamics are close to the deterministic dynamics, except during the transition from $y \ll 1$ to $y \sim \pm\sqrt{\mu t}$. These simulations suggest that the probability density function is sharply peaked about either $y = 0$ or $y = \pm\sqrt{\mu t}$, except in the transition region. This variation suggests that the concentration of the probability density function changes significantly over time.

A quantitative description of the delay can be obtained by considering the FPE for the probability density $p(y, t)$, defined as

$$p(y, t)dy = \text{ P}(y(t) \in (y, y + dy) \text{ at time } t), \tag{2.3}$$

for the process $y(t)$ described in (2.2). For $\epsilon \neq 0$ we look for the solution of

$$p_t = \epsilon^2 p_{yy} - ((\mu t y - y^3)p)_y = 0, \quad p(0) = p_0(y). \tag{2.4}$$

An asymptotic approximation can be made for this density when the random dynamics are close to the deterministic dynamics [7], but from the few typical realizations in

Figure 2.1, that leaves a significant region (in this case between $t = 30$ and $t = 50$) in which this approximation may fail. Therefore we are especially interested in computing $p(y,t)$ in this transition region. As mentioned in the introduction, $p(y,t)$ gives the probability that the process has made the transition from $y \sim 0$ to $y \sim \pm\sqrt{\mu t}$ at time t and can be used to compute moments of the process $y(t)$ or the expected time until this transition is made [7].

In section 4 we use a GPM to compute the probability density function for this one-dimensional example of a delay bifurcation. In section 5 we extend this method to a two-dimensional model, the FitzHugh–Nagumo model. There the noise also reduces the time of a delay bifurcation. We have several reasons for using GPMs which follow from the discussion above.

1. The diffusion in the FPE is very small for the cases of interest, that is, $\epsilon \ll 1$. (In particular, $\epsilon \leq .0001$ in this paper.) Insufficiently resolved grid-based methods give numerical diffusion which swamps the diffusion due to the noise.

2. The probability density has steep gradients in some regions in space and time and not in others. This is due to the fact that the noisy dynamics follow the deterministic dynamics closely except in the transition region. Outside of the transition region the gradients are large, but within this region the gradients are no longer large. This variation in shape, and the transition of the process itself, could make adaptive methods expensive. Such a method would require frequent regridding, based on some prior knowledge given by analysis or preprocessing or on monitoring the evolution of the solution at each step.

3. A straightforward simulation method involving only direct simulation of the SDE would require a large number of realizations in order to resolve the probability density in all regions of space and time of interest. The natural idea of simulating the stochastic motion by solving the SDE (1.1) is incorporated in the GPM. It requires many fewer realizations than the DS method since both particle positions and gradients are computed. We compare the GPM results to the DS results in sections 4 and 5.

3. The method. We outline the GPM for computing the probability density function $p(\mathbf{x},\mathbf{t})$ for the process described by (1.1). Here $\mathbf{x}$ and $\mathbf{a}(\mathbf{x},t)$ are vectors (in one and two dimensions for the applications in this paper) and $d\mathbf{W}$ is a vector of independent white noise processes. Then the probability density satisfies the Fokker–Planck equation (1.2) with initial condition $p(\mathbf{x},0) = p_0(\mathbf{x})$. In one dimension $\mathbf{x} = x$ and $\mathbf{a}(\mathbf{x},t) = a(x,t)$, and the equation for $p_x(x,t)$ is

$$(p_x)_t = \epsilon^2 \frac{\partial^2 p_x}{\partial x^2} - (a p_x)_x - a_{xx} p - a_x p_x. \tag{3.1}$$

In two dimensions we use the notation of the application in section 5, taking $\mathbf{x} = (u,v)$, $\mathbf{g} = (g_1, g_2) \equiv (p_u, p_v)$, and $\mathbf{a} = (a_1, a_2)$ and differentiating (1.2),

$$\begin{aligned} \frac{\partial}{\partial t}\begin{pmatrix} g_1 \\ g_2 \end{pmatrix} &= \epsilon^2 \nabla^2 \begin{pmatrix} g_1 \\ g_2 \end{pmatrix} - \frac{\partial}{\partial u}\left[a_1 \begin{pmatrix} g_1 \\ g_2 \end{pmatrix}\right] - \frac{\partial}{\partial v}\left[a_2 \begin{pmatrix} g_1 \\ g_2 \end{pmatrix}\right] \\ &\quad - \begin{bmatrix} (a_1)_u & (a_2)_u \\ (a_1)_v & (a_2)_v \end{bmatrix} \begin{pmatrix} g_1 \\ g_2 \end{pmatrix} - \begin{pmatrix} (a_1)_{uu} + (a_2)_{vu} \\ (a_1)_{uv} + (a_2)_{vv} \end{pmatrix} p. \end{aligned} \tag{3.2}$$

These equations are similar to those in [8], where the convection-diffusion equation for a chemical concentration in an incompressible flow was solved with GPMs. The main difference between [8] and this application is that the equation for the gradient

in this paper involves both ∇p and p itself, while the equation for the gradient in [8] involves only the derivatives of p. This is because the flow was incompressible ($\nabla \cdot \mathbf{a} = 0$) for the convection-diffusion equation studied in [8]. This is not true for (1.1) in general, and, in particular, $\nabla \cdot \mathbf{a} \neq 0$ for the delay bifurcation applications which we study here. It follows that there is a reconstruction of p from ∇p in each time step. A similar reconstruction was required in [9] for the solution of a reaction-diffusion system using a gradient random walk method. We outline the steps of the algorithm, pointing out differences and similarities to [8] and [9]. Both [8] and [9] contain excellent discussions of GPMs and comparisons with previous work in deterministic and random particle methods. We do not repeat their discussion here but mention a few alternative approaches at the end of this section.

The algorithm is based on the observation that both the particle motion and the evolution of the gradient vectors contribute to changes in ∇p and thus in p as well [8]. Specifically, in (3.1) the terms $\epsilon^2(p_x)_{xx} - (ap_x)_x$ correspond to changes in concentration due to the motion of the particles as described by (1.1). The terms $-a_{xx}p - a_x p_x$ give the changes in shape due to the evolution of p_x. Similarly in the two-dimensional case, the terms $\epsilon^2\nabla^2(g_j) - \nabla \cdot (\mathbf{a}g_j)$ for $j = 1, 2$ are due to the motion of the particles, and the remaining terms on the right-hand side of (3.2) describe changes in the gradient vectors. The motion of the particles is obtained by solving (1.1).

One additional note is that the probability densities described above are defined on an infinite domain. However, the probability densities are exponentially small outside a bounded region. Therefore we compute on a rectangular region which contains all but the tails of the probability density whose mass is essentially zero and set $p(\mathbf{x}, t) = 0$ on the boundary of this region.

THE ALGORITHM:

Initial conditions: To each of N particles assign position vectors $\mathbf{x}_k$, the probability density $p_k \equiv p_0(\mathbf{x}_k)$ from the initial condition, and gradient vectors $\mathbf{g}_k \equiv \nabla p_k$ for $k = 1, \ldots, N$.

At each time step:

1. Find the new position of the particles by solving (1.1). In this paper a second order weak explicit scheme for SDEs [12] was used. Since the coefficient of the noise is a constant, the scheme simplifies considerably,

$$\mathbf{x}(t + \Delta t) = \mathbf{x}(t) + \frac{1}{2}(\mathbf{a}(\mathbf{z}(t + \Delta t), t + \Delta t) + \mathbf{a}(\mathbf{x}(t), t))\Delta t + \epsilon\sqrt{2\Delta t}v_n,$$

$$\mathbf{z}(t + \Delta t) = \mathbf{x}(t) + \mathbf{a}(\mathbf{x}(t), t)\Delta t + \epsilon\sqrt{2\Delta t}v_n, \tag{3.3}$$

where v_n is a standard normal random variable, generated at the nth time step.

2. Evolve the gradient vectors using the remaining terms from the equation. For the one-dimensional example, $g_k = (p_x)_k$ and $(g_k)_t = -a_{xx}p_k - a_x g_k$, and a_{xx} and a_x are evaluated at x_k. In two dimensions the equation is

$$\frac{\partial \mathbf{g}_k}{\partial t} = -\begin{bmatrix} (a_1)_u & (a_2)_u \\ (a_1)_v & (a_2)_v \end{bmatrix} \begin{pmatrix} g_{1k} \\ g_{2k} \end{pmatrix} - \begin{pmatrix} (a_1)_{uu} + (a_2)_{vu} \\ (a_1)_{uv} + (a_2)_{vv} \end{pmatrix} p_k. \tag{3.4}$$

This step is similar to one used in [8], but there is an extra term involving p_k that was not present in the applications studied in [8], as discussed above. A second order Runge–Kutta method was used to advance $\mathbf{g}_k$.

Note that this step is not present in the method used for reaction-diffusion equations in [9] and [13]. Instead changes in the shape of the density were obtained by either creating or destroying particles, depending on the sign of terms analogous to the right-hand side of (3.4). In this paper the number of particles is constant throughout the computation, and changes in the shape of the density enter through the evolution of the gradient computed in this step.

3. Reconstruct p_k from its gradient vector $\mathbf{g}_k$. In one dimension this is accomplished by computing $\hat{\mathbf{g}}_k = (p_k)_x \Delta x_k$, then sorting the particles and approximating the integral of $\mathbf{g}_k$ with a sum of the $\hat{\mathbf{g}}_k$'s to get p_k.

In two dimensions, using $\mathbf{x}_k = (u_k, v_k)$, we find it convenient to compute $\tilde{\mathbf{g}}_k = \nabla p_k \Delta u \Delta v$. Then $\nabla p(u, v, t)$ is determined on a lattice with points given by (u_j, v_m), for $j = 1, \ldots, N_u$, $m = 1, \ldots, N_v$, as follows:

$$\begin{pmatrix} p_u(u_j, v_m, t) \\ p_v(u_j, v_m, t) \end{pmatrix} = \sum_{k=1}^{N} \tilde{\mathbf{g}}_k(t) \delta_{\mathbf{x}}((u_k - u_j), (v_k - v_m)). \tag{3.5}$$

Here $\delta_{\mathbf{x}}$ approximates the two-dimensional Dirac delta function, using the piecewise linear hat function as in [8],

$$\begin{aligned} &\delta_{\mathbf{x}}((u - u_j), (v - v_m)) \\ &= \frac{1}{\Delta u \Delta v} \max\left(0, 1 - \frac{|u - u_j|}{\Delta u}\right) \max\left(0, 1 - \frac{|v - v_m|}{\Delta v}\right). \end{aligned} \tag{3.6}$$

Then $p(u, v, t)$ is obtained using the method outlined in [8], by solving two Poisson's equations. Note that this reconstruction must be performed at every time step since the evolution equation for the gradient, as in (3.4), depends on p. Briefly, the reconstruction of $p(u, v, t)$ is computed on the rectangle $a \le u \le b$, and $c \le v \le d$,

$$\begin{aligned} &\nabla^2 \phi = p_u, \quad \phi(a, v) = \phi(b, v) = \phi_v(u, c) = \phi_v(u, d) = 0, \\ &\nabla^2 \psi = p_v, \quad \psi_u(a, v) = \psi_u(b, v) = \psi(u, c) = \psi(u, d) = 0, \\ &p(u, v, t) = \phi_u + \psi_v + \text{ constant}. \end{aligned} \tag{3.7}$$

Here the rectangle is sufficiently large so that $p(u, v, t)$ is essentially zero on the boundaries. This reconstruction method is discussed in [8]. As noted there, we found that this reconstruction gives a nonnegative result for the density. The constant in (3.7) was chosen in order to properly normalize $p(x, y, t)$ for any t, so that the integral over space of the density is 1. We found that this constant approached zero as the number of points in the reconstruction lattice was increased and was negligible as compared to the maximum of the density function.

In [9] the reconstruction step used a method similar to random vortex methods [14]. The method suggested by Anderson [15] uses Poisson's formula to obtain a point-gradient formulation for the recovery of $p(u, v, t)$. This method is expensive, but fast multipole methods of [16] can be used to reduce the computation time. Some smoothing problems were encountered in [9] in using the fast multipole methods. Since we found the implementation straightforward and the method (3.7) sufficiently fast we used the method of [8]. As noted there, this reconstruction method does introduce some errors when the gradients are very large. In our problem these errors are apparent in the tails of the density, but they did not affect the bulk of the density. These effects are discussed further in the following sections. We used the *fishpack* subroutines [17] to solve (3.7).

In the next sections we illustrate the use of particle methods for these applications and compare the results with other methods. We have not explored all possibilities for optimizing run time. Higher order methods could be used to solve (1.1), which could introduce some savings even though these methods require that additional random variables be generated at each time step [12]. Higher order methods could also be used to evolve $\mathbf{g}_k$. We also found that adaptive initial placement of the particles, based on experience with the solution, could be used to reduce the number of particles necessary for resolution. However, we did not pursue this further than trying a few different initial placements of particles for each case. Future work could explore these time saving steps and compare this reconstruction method with that of [15] for the noisy delay bifurcation problems described here.

4. The one-dimensional model of a steady bifurcation. First we give the results for the probability density for the one-dimensional steady delay bifurcation example as discussed in section 2. The equation for $p(y,t)$ is given by

$$p_t = \epsilon^2 p_{yy} - ((\mu t y - y^3)p)_y, \tag{4.1}$$

$$p(0) = p_0(y). \tag{4.2}$$

As an initial condition, we take

$$p_0(y) = \frac{1}{\sqrt{2\pi\epsilon^2}} \exp\left(-\frac{(y-y_0)^2}{2\epsilon^2}\right). \tag{4.3}$$

As discussed above, y decays exponentially for $t < 0$. Then starting with (4.3) is the same as taking an initial condition at $t < 0$ so that $y(0) < \epsilon$ and the noise dominates the dynamics at the critical point $t = 0$. The figures compare computations of $p(y,t)$ using 10,000 and 15,000 particles in the GPM with $p(y,t)$ obtained from a DS of the SDE (2.2). The results at $t = 36$ are also compared with an asymptotic approximation which is valid through a part of the transition region, as discussed in detail in [7], and summarized in the appendix.

In Figure 4.1(a), we see good agreement between all methods, noting that the direct simulation with 60,000 realizations (particles) has statistical errors, while the GPM method gives a much smoother solution. In Figure 4.1(b) this difference is even more obvious. Figure 4.1 shows that the GPM can be used to compute the probability density through the transition region and gives the probability density before and after this transition has occurred (mean transition time is shown to be $t \approx 28$ in [7] for this case). Specifically, Figure 4.1(a) shows the probability density while the process is still concentrated around $y = 0$. Figure 4.1(b) shows the density within the time interval in which the process makes the transition from $y \ll 1$ to $|y| \sim \sqrt{\mu t}$, and Figure 4.1(c) shows the density at a time when the transition is likely to have occurred. Thus the GPM result is valid throughout the transition interval, which is a longer time range than the validity interval for the asymptotic approximation. The reconstruction of the density from its gradient provides the smoothing which gives good results even though the GPM uses only 10,000 particles, as compared to the nonsmooth results from the DS of the particle motion, using 60,000 particles. Even though the GPM requires additional computations of the evolution of the gradients and the reconstruction of $p(y,t)$ from $p_y(y,t)$, the computation times for the GPM with 10,000 particles and the DS with 60,000 particles are comparable (overnight on a Pentium II workstation to compute to $t = 40$). Note that the time step can not be too large, in order to keep computational errors below the noise level.

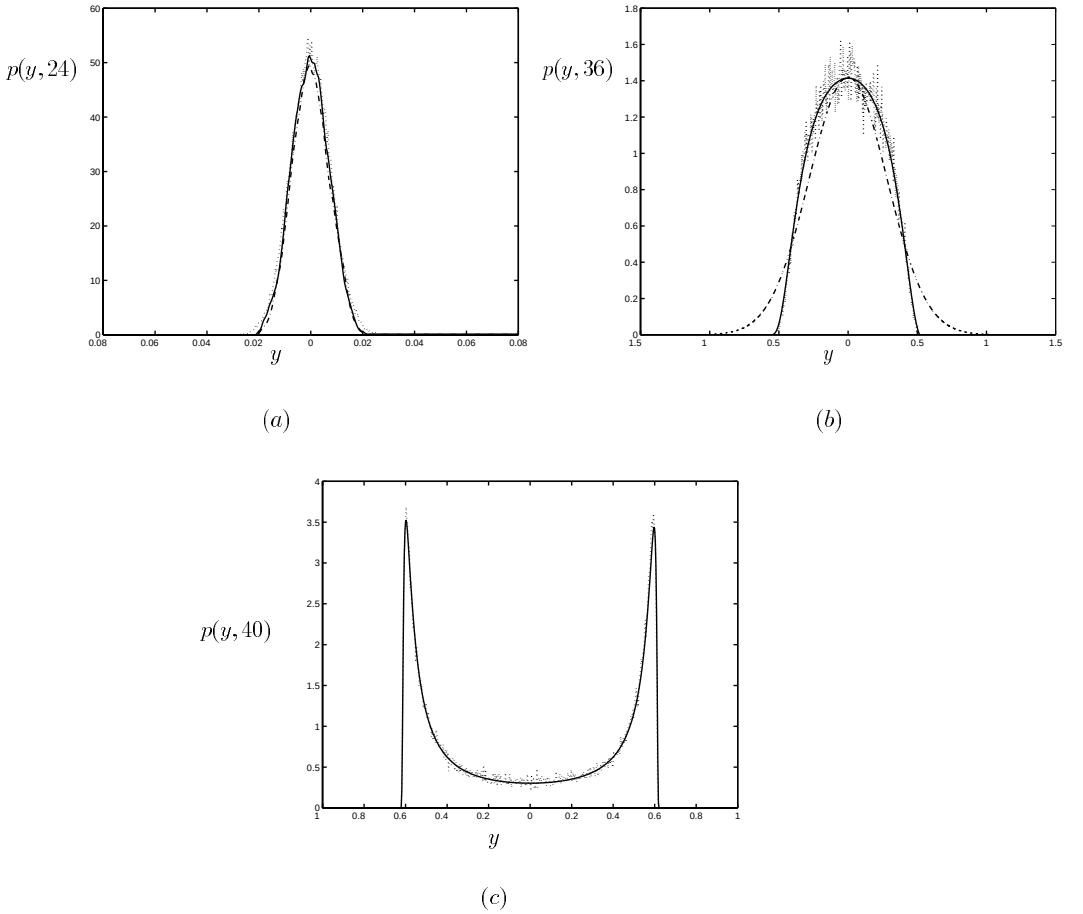

FIG. 4.1. *Comparison of results for the density at* $t = 24$, $t = 36$, *and* $t = 40$, *with* $\mu = .01$ *and* $\epsilon = 10^{-4}$ *and initial condition* (4.3). (a) *The solid line is the GPM solution with* 10,000 *particles, the dash-dotted line is the GPM solution for* 15,000 *particles, and the dotted line is the result from the DS of* (2.2) *with* 60,000 *realizations (particles). Although it is not shown, the asymptotic approximation of* [7] *is in good agreement with all of these results.* (b) *The solid line is the GPM solution with* 10,000 *particles and the dotted line is the result for DS of* (2.2) *with* 60,000 *realizations (particles). The dash-dotted line is the asymptotic (Gaussian-type) approximation, which does not capture the behavior of the tails for this value of* t, *when the density is less concentrated.* (c) *The solid line is the GPM solution with* 10,000 *particles, and the dotted line is the result from the DS of* (2.2) *with* 60,000 *particles. The numerical results are in good agreement as far as location and general shape of the density, but the DS results are not smooth.*

Recalling that the density $p(y,t)$ is reconstructed from $p_y(y,t)$ at each step in the GPM method, one might expect that errors in the reconstruction can feedback into the computation. We found that these errors could be significant, especially in the transition zone. Then the gradient is not large, except near $y = \pm\sqrt{\mu t}$, where the density function drops off sharply. The reconstruction errors for $p(y,t)$ near $y = \pm\sqrt{\mu t}$ can appear in the computation near this sharp gradient in the density function. By decreasing the time-step and using a sufficiently fine grid, we reduced this error substantially. For example, for times before the transition ($t < 28$) we used a time step of $\Delta t = .0005$, in order to keep the errors of the computations ($O(\Delta t^2)$) well below the noise level ($\epsilon = 10^{-4}$). If we computed until $t = 40$ with this same Δt

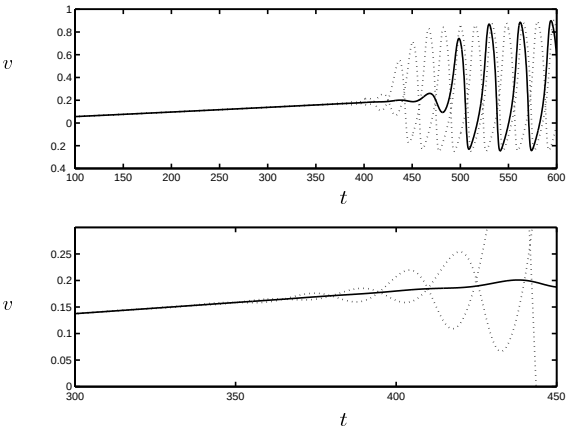

FIG. 5.1. *The solid line is the solution of v from* (5.1) *with $\epsilon = 0$, while the dotted line is the solution for v from* (5.1) *with $\epsilon = 10^{-5}$, $a = .2$, $b = .05$, $\gamma = .4$, and $I(t) = \mu t$ with $\mu = .001$. The bottom figure is an enlargement of the top figure. The bifurcation point for the problem when I is constant is $I_c \approx 273$. Then it is clear that there is a delay in the transition from steady to oscillatory behavior, but the delay is reduced when small noise is present.*

we would eventually see errors in the tails of the density which were approximately 5–10% of the peak of the density. To avoid these reconstruction errors, we reduced the size of the time step through the transition region. For $28 < t < 32$ we used $\Delta t = .00025$, but for $t > 32$ we found the computation increasingly sensitive to reconstruction errors. When we used $\Delta t = .0001$ for $32 < t < 36$ and $\Delta t = .00001$ for $36 < t < 40$, we found an error in the tails that was approximately 3–4% of the height of the peak of the density. By using $\Delta t = .00001$ for $32 < t < 36$ and $\Delta t = .000005$ for $36 < t < 40$, we reduced this error, as shown in Figure 4.1(c).

5. The two-dimensional model: FitzHugh–Nagumo. Next we consider the two-dimensional model of FitzHugh–Nagumo [2], [18],

$$du = b(v - \gamma u)dt,$$

$$dv = (-f(v) - u + I(t))dt + \sqrt{2}\epsilon dW, \tag{5.1}$$

$$f(v) = v(v-1)(v-a), \tag{5.2}$$

where a, b, and γ are physical parameters. This is a reduced model of the propagation of neural impulses in the giant axon of a squid, with v the potential difference across the membrane of the axon, and u the recovery current. $I(t)$ is an applied current and plays the role of the bifurcation parameter. When I is constant, there is a Hopf bifurcation at $I = I_c$; for $I < I_c$ the stable solution is constant, while for $I > I_c$ the stable solution is periodic. Figure 5.1 shows that there is delay in the bifurcation from constant to periodic behavior as the applied current $I(t) = \mu t$ is increased slowly ($\mu \ll 1$). In the realizations with small noise ($\epsilon = 10^{-5}$ in Figure 5.1) this delay is significantly reduced. Only the solution for v is shown in Figure 5.1, since the variable u is virtually slaved to v. That is, the behavior of u follows that of v, with a time lag. Then a transition to oscillatory behavior in v is followed by a transition to oscillatory behavior in u. Since the noise causes a reduction in the delay until the transition to the oscillatory state, we anticipate that the gradient of the probability density varies significantly in the transition region. The probability density for this process satisfies

(1.2) with $a_1 = b(v - \gamma u)$ and $a_2 = -f(v) - u + I(t)$ so that

$$\frac{\partial p}{\partial t} = \epsilon^2 \nabla^2 p - ((b(v - \gamma u)p)_u - ((-f(v) - u + I(t))p)_v. \tag{5.3}$$

We determine $p(u, v, t)$ using the GPM and compare to the results from the direct simulation of (5.1) and the asymptotic approximation of [7], summarized in the appendix. In the computations the initial condition was

$$p(u, v, t_0) = p_{asymp}(u, v, t_0), \tag{5.4}$$

where $p_{asymp}(u, v, t_0)$ is the asymptotic approximation to the density obtained in [7] and $t_0 > 0$ is some time before the transition time. This choice of initial condition is justified by the dynamics of the system. For a typical realization, as shown in Figure 5.1, the stochastic and deterministic behavior are close until t approaches the transition time.The asymptotic approximation and the numerical computations agree for t below the transition interval, which Figure 5.1 suggests is $t < 370$ for the parameter values used there. We verified this agreement by starting at different initial times $t_0 < 350$ with initial conditions of the type (5.4). As expected, the asymptotic approximation is valid until large values of t where the probability function is less concentrated around the deterministic dynamics.

The use of the initial condition (5.4) also illustrates the complementary nature of the asymptotic approximation and the computational method; the asymptotic approximation is used as an initial condition at t_0 before the transition time, and then the computational method is used to find the probability density in the transition region, where the validity of the asymptotic method is suspect. This is a very practical reduction of the amount of computation necessary, since the computational method does not perform as well as the asymptotic method for values of t_0 before the transition time, where the density function has large gradients. The computation time is significantly reduced, since the computations are done for $t > t_0 > 0$, rather than for all $t > 0$.

In Figure 5.2 we compare the results from GPM and the asymptotic method of [7] for $t = 375$ and the same parameter values as in Figure 5.1. These figures show good agreement between the two methods. This is expected, since the process has not reached the expected transition time (calculated as $t \approx 383$ in [7]), and the density is still concentrated around the deterministic behavior. In Figure 5.3 we compare the GPM and asymptotic method for $t = 390$ and $t = 410$ for the same parameter values as in Figure 5.2, and in Figure 5.4 we compare the results from the GPM and asymptotic method for a different value of $\mu = .003$. In both of these cases the results are compared for times before and after the transition to oscillatory behavior. Again good agreement is seen for the location of the concentration of the density and the shape of the peak. The shape and location of the density is consistent with the simulations and the dynamics of (5.1). The density remains centered around the deterministic dynamics, but the variable v makes the transition to the oscillatory state first, so that the density is less concentrated about the deterministic value of v. The gradients are larger in the variable u since u follows v with a time lag. That is, the gradients in u are also decreasing but not as fast as in the v direction.

Errors in the reconstruction of p can accumulate in our computations, since the reconstruction must be carried out at each time step, and the result for p is used in the evolution of the gradient vectors (3.4) at the following time step. The computations in [8] did not have this accumulation of error, since the concentration (analogous

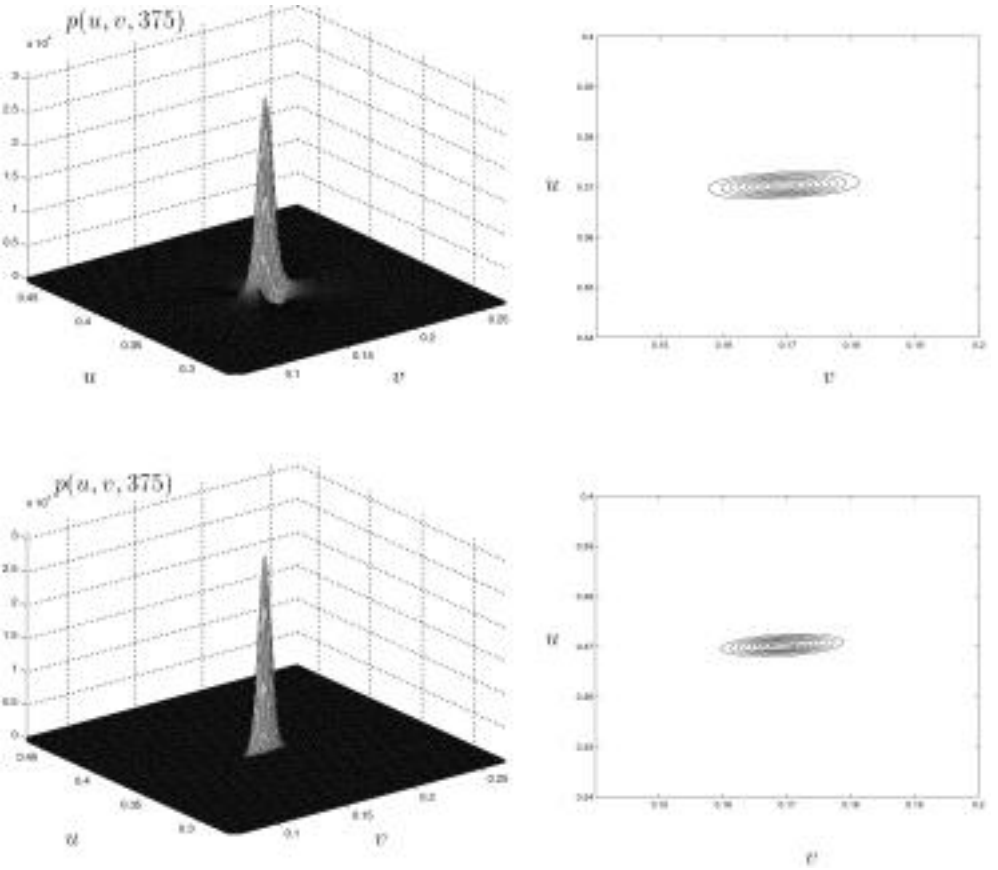

FIG. 5.2. *Comparison of the probability density $p(u, v, t)$ computed with the GPM of this paper (top row) with the asymptotic result from* [7] *(bottom row). The parameter values are the same as in Figure* 5.1*, and $\epsilon = 10^{-5}$. The left column is the surface plot, and the right column is the corresponding contour plot. Good agreement in both location and shape is obtained from the two methods. Note that this is for a time before the transition has occurred.*

to $p(u, v, t)$) did not appear in the equation for the gradient (see section 3). There is some oscillation in the tails of the numerical result which is especially evident at $t = 410$ in Figure 5.3 and $t = 145$ in Figure 5.4. There the contour line at the base of the peak is irregularly shaped (not elliptic). This is due to the reconstruction process, which has difficulty resolving the very steep gradients. We found an increased effect of these errors when $|p_u|$ is much larger than $|p_v|$, which is far into the transition zone. Since this p is reconstructed from ∇p at every time step, these errors can accumulate over long computation times, as is required for these computations. As in the one-dimensional problem of section 4, these errors can be reduced by decreasing the time step and adjusting the reconstruction lattice. We chose the lattice and time step so that the computations would not take longer than 10–20 hours on a Pentium II workstation, times which are comparable to direct simulation times. As in the one-dimensional example, we took $\Delta t = .0005$ for times before the transition. As the density began to spread out, we reduced the time step to $\Delta t = .0001$, and the errors in the tails were reduced by a few percent of the maximum height of the density. The largest reconstruction lattice that we used was 512×256, and the smallest time

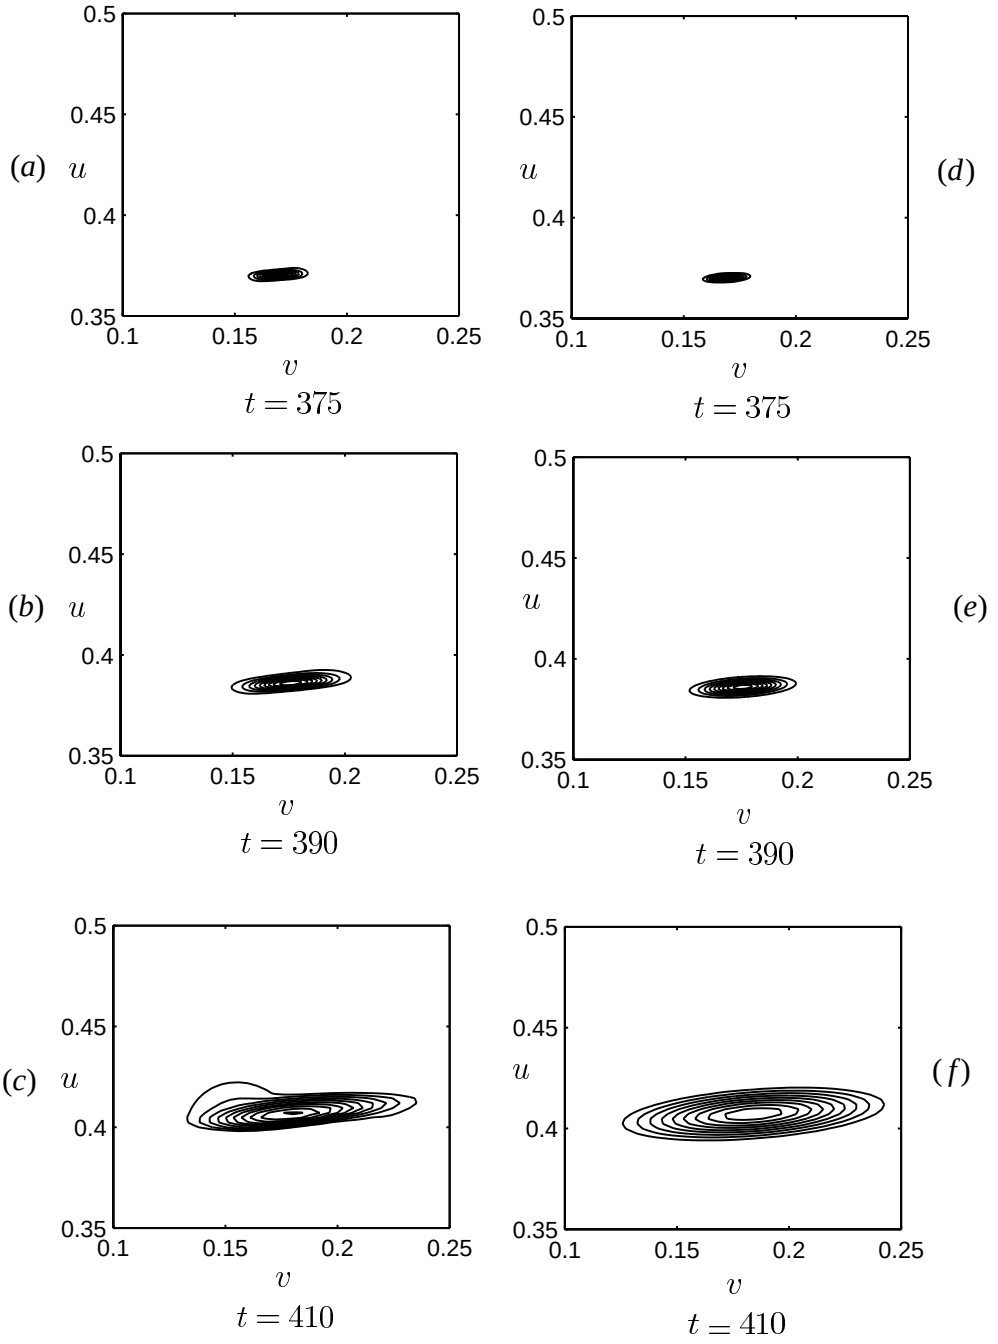

FIG. 5.3. *Comparison of the contour plots for* $p(u, v, t)$ *for the asymptotic result* [7] *with GPM results for* $t = 375, t = 390, t = 410$. *The parameters are the same as in Figure* 5.2. *The* (a)–(c) *are the results from the GPM. The* (d)–(f) *are the asymptotic results.*

step was .00001. Even with these extreme cases the error in the tails of the density (approximately 2–3% of the peak of the density) was not completely eliminated. In

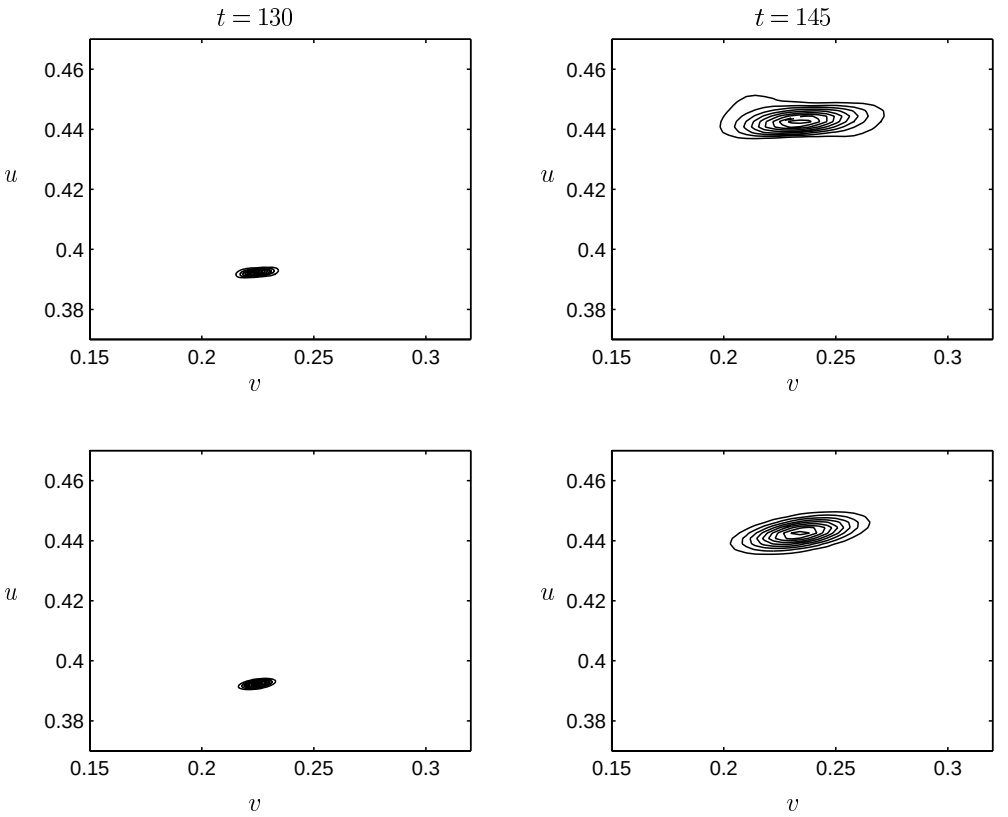

FIG. 5.4. *Comparison of the contour plots for $p(u, v, t)$ for the asymptotic result* [7] *with GPM results for the parameter values $\epsilon = 10^{-5}$, $a = .2$, $b = .05$, $\gamma = .4$, and $I(t) = \mu t$ with $\mu = .003$. The plots are compared for times before ($t = 130$) and after ($t = 145$) the transition. Again there is a large change in the shape of the density. Accumulation of reconstruction errors is reduced as described in the text. The top row are the results from the GPM. The bottom row are the asymptotic results.*

this application we found it more effective to reduce the errors by using the asymptotic approximation for an initial condition at larger values of t, where the approximation is still valid and agrees with the computation. (For Figure 5.3 we used (5.4) with $t_0 = 390$, and for Figure 5.4 we used (5.4) with $t_0 = 135$.) This adjustment reduces the computing time and the accumulation of error. The resulting reduction of the error can be seen in comparing Figures 5.3 ($\mu = .001$) and 5.4 ($\mu = .003$). In Figure 5.4, the parameter μ is larger ($\mu = .003$) and the transition occurs at a faster rate. Then the probability density after the transition is obtained from computing over a shorter time interval, and we found less accumulation of reconstruction errors for $\mu = .003$.

In Figure 5.5 we compare the results for $p(u, v, t)$ from solving (5.3) with a GPM and from the DS of (5.1). The results from the DS use 80,000 realizations, while the GPM uses 10,000 particles. The statistical errors in the DS are increasingly evident as time increases since the density is spreading out. An increasing number of realizations would be necessary to properly approximate the density for later times. The results for the GPM method are smooth, and the number of particles is sufficient for resolving the peak in the density. Other solutions were obtained using a larger number of particles in the GPM, but they gave essentially the same results.

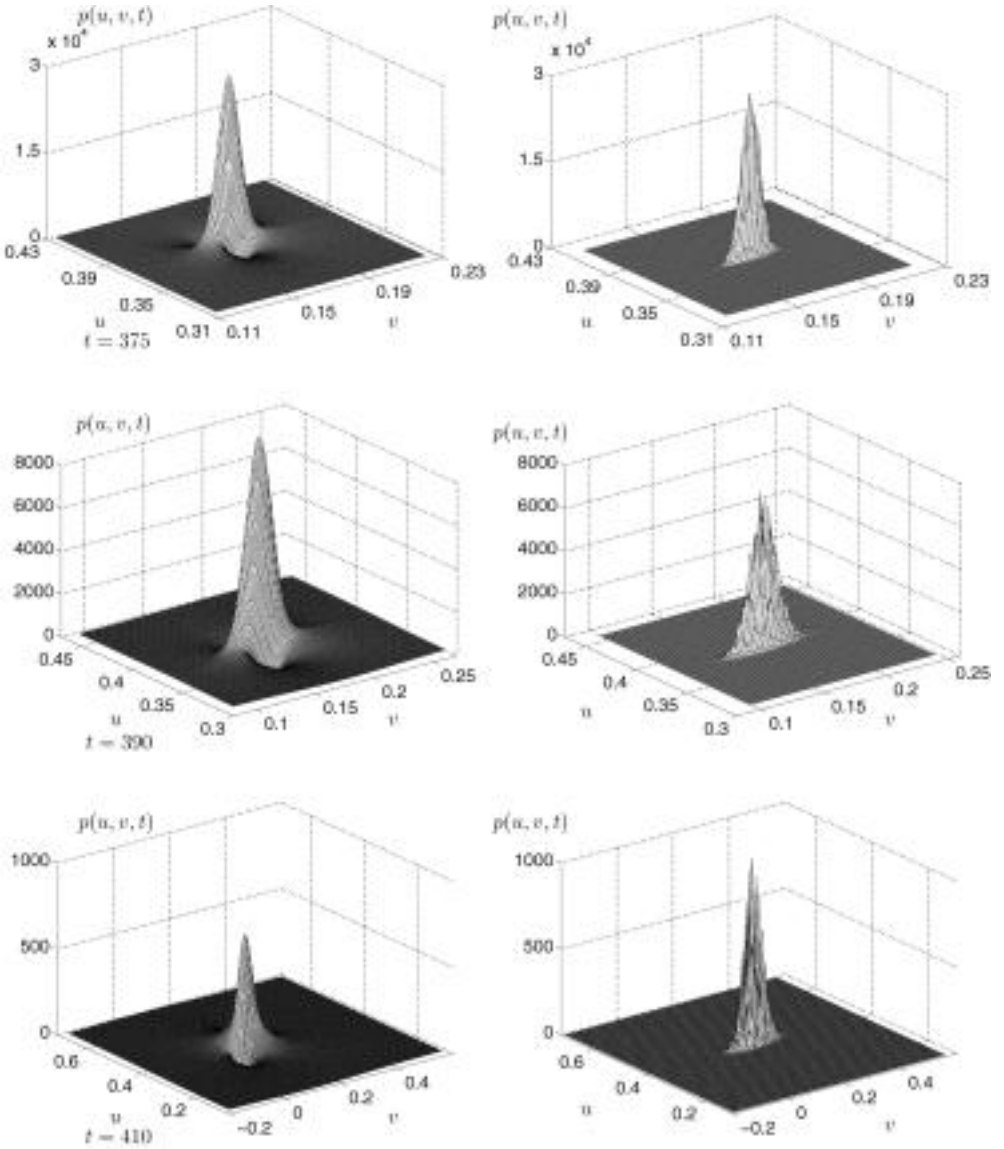

FIG. 5.5. *Comparison of* $p(u, v, t)$ *computed as the solution of* (5.3) *with the GPM (left column) using* 10,000 *particles and computed by DS of* (5.1) *(right column) using* 80,000 *realizations (particles) for* $t = 375$, $t = 390$, *and* $t = 410$. *The parameters are the same as in Figures* 5.2 *and* 5.3. *Note the different scales of the plots, which indicate that the density is less concentrated for increasing time. As time increases, the results of the DS get increasingly rough, which indicates that an increasing number of realizations is necessary to obtain an approximation for* $p(u, v, t)$. *Here* $a = .2$, $b = .05$, *and* $\gamma = .4$, $\mu = .001$, *and* $\epsilon = 10^{-5}$.

In Figure 5.6 we compare the results for the marginal density

$$p(v,t) = \int_{-\infty}^{\infty} p(u,v,t)du. \tag{5.5}$$

The dynamics of v indicate the transition time since the transition in u follows that of

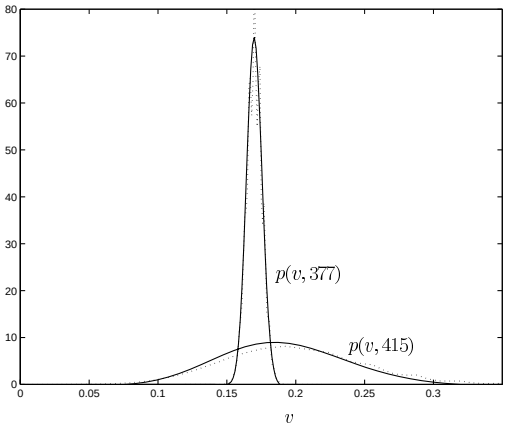

FIG. 5.6. *Comparison of the marginal density $p(v,t)$ obtained by the DS of* (5.1) (80,000 *realizations*) *and the GPM for $t = 377$ and $t = 415$. Here $a = .2$, $b = .05$, $\gamma = .4$, $\mu = .001$, and $\epsilon = 10^{-5}$.*

v. Therefore $p(v,t)$ itself may be used to determine when the transition has occurred, as in [7]. Figure 5.6 compares the results for the marginal density, using $p(u,v,t)$ for the GPM and the DS of (2.2). Note that even with the extra step of smoothing, that is, integration in u, the results from the DS do not give a smooth result for the marginal density.

6. Conclusion. A gradient particle method is used to solve FPEs for noisy delay bifurcations. The solution of the FPE gives the time-dependent probability density function for the stochastic process.

In these problems, a delay in the transition between states occurs in the deterministic dynamics when a bifurcation parameter varies slowly through the bifurcation point. This delay is reduced by the presence of noise, even if it is very small. The probability density gives a complete description of the process, and in particular it describes the transition of the process. Since there is considerable variation in the gradient of the density, numerical methods must be used to solve the FPE, yielding results which are complementary to those obtained asymptotically. The small diffusion of the cases of interest (very small noise) and the variation in the concentration of the density suggest that the GPMs are practical methods for computing the solution to the FPE. These methods incorporate simulation of the noisy process (motion of the particles) with the evolution of the gradients of the probability density. The reconstruction of the density from its gradient introduces a smoothing so that fewer realizations are necessary than in computing the density with a direct simulation.

We compute probability densities through the transition regions and compare the GPM results to asymptotic results and direct simulations. The GPMs yield satisfactory results throughout the transition regions, where the asymptotic method is no longer valid and yield results which are much smoother than those obtained with direct simulation. Some caution must be used in applying the GPMs, since the density must be reconstructed from its gradient at each time step and errors can accumulate over long time periods. These errors can be reduced by adjusting the time step and reconstruction grid, and by using the asymptotic approximation as an "initial condition," which reduces the length of the time of computation.

Appendix. The asymptotic method. We give a brief summary of the asymptotic method of [7] which was used to approximate the probability densities in sections 4 and 5. The asymptotic method is based on a Gaussian-type ansatz for the form of the probability density. With this ansatz the problem is reduced to solving a system of ODEs.

For the one-dimensional example of section 4, the ansatz for $p(y,t)$ is

$$p(y,t) \sim C\left[\frac{1}{2}\sqrt{g(t)}e^{-(y-|F(t)|-\frac{2\epsilon}{\sqrt{g_n}})^2\frac{g(t)}{2\epsilon^2}} + \frac{1}{2}\sqrt{g(t)}e^{-(y+|F(t)|-\frac{2\epsilon}{\sqrt{g_n}})^2\frac{g(t)}{2\epsilon^2}}\right]. \tag{A.1}$$

Here $F(t)$ is the solution of the deterministic problem (2.1) for $c = \mu t$, $g(t)$ is a function to be determined, and C is a normalization constant. By substituting (A.1) into the FPE (2.4) and using a perturbation expansion about $\epsilon = 0$, an ODE for $g(t)$ is found at leading order

$$-\frac{g'(t)}{2} = g^2 + (\mu t - 3F^2(t))g. \tag{A.2}$$

This equation has the solution

$$g(t) = \frac{e^{-2Q}}{2\int_0^t e^{-2Q(t')}dt' + c_g} \equiv \frac{g_n(t)}{2\int g_n(t')dt'}, \tag{A.3}$$
$$Q(t) = \int^t \mu t' - 3F^2(t')dt', \quad c_g = \text{constant},$$

and the result can be substituted in (A.1) to give an asymptotic approximation to $p(y,t)$.

The idea behind (A.1) is that the density is approximately Gaussian, centered around the deterministic dynamics given by $F(t)$. The concentration of the density varies in time, with $\epsilon^2/g(t)$ playing the role of a time-dependent variance. When the function $g(t)$ is very small, the variance is large and the Gaussian-type approximation is no longer valid. This point was discussed in section 4, where the asymptotic approach fails when the density is less concentrated in the transition region (see Figure 4.1(b)). Note that the ansatz (A.1) is actually a linear combination of two Gaussian-type densities since there are two possible deterministic solutions, $y = \pm|F(t)|$, symmetric about $y = 0$.

Similarly, for the two-dimensional example of section 5, one can make the ansatz

$$p(u,v,t) \sim C\exp\left[-\frac{g(t)}{2\epsilon^2}(v-V(t))^2 - \frac{h(t)}{\epsilon^2}(u-U(t))(v-V(t)) - \frac{k(t)}{2\epsilon^2}(u-U(t))^2\right.$$
$$\left. + \frac{q(t)}{\epsilon}(v-V(t)) + \frac{r(t)}{\epsilon}(u-U(t)) + s(t)\right]. \tag{A.4}$$

Here $(U(t),V(t))$ is the deterministic solution to (5.1) with $\epsilon = 0$. Substitution of (A.4) into (5.3) yields a system of coupled ODEs for $g(t)$, $h(t)$, $k(t)$, $q(t)$, and $r(t)$, and $s(t)$, which depend on $U(t)$ and $V(t)$ and describe the time-dependent concentration of the density. This system can be solved numerically, and the solution is substituted into (A.4) to give an asymptotic approximation for $p(u,v,t)$.

Acknowledgment. The author would like to thank Christoph Börgers for many helpful discussions.

ASYMPTOTIC-NUMERICAL STUDY OF SUPERSENSITIVITY FOR GENERALIZED BURGERS' EQUATIONS*

MARC GARBEY† AND HANS G. KAPER‡

Abstract. This article addresses some asymptotic and numerical issues related to the solution of Burgers' equation, $-\varepsilon u_{xx}+u_t+uu_x = 0$ on $(-1,1)$, subject to the boundary conditions $u(-1) = 1+\delta$, $u(1) = -1$, and its generalization to two dimensions, $-\varepsilon\Delta u+u_t+uu_x+uu_y = 0$ on $(-1,1)\times(-\pi,\pi)$, subject to the boundary conditions $u|_{x=1} = 1+\delta$, $u|_{x=-1} = -1$, with 2π periodicity in y. The perturbation parameters δ and ε are arbitrarily small positive and independent; when they approach 0, they satisfy the asymptotic order relation $\delta = O_s(\mathrm{e}^{-a/\varepsilon})$ for some constant $a \in (0,1)$.

The solutions of these convection-dominated viscous conservation laws exhibit a transition layer in the interior of the domain, whose position as $t \to \infty$ is supersensitive to the boundary perturbation. Algorithms are presented for the computation of the position of the transition layer at steady state. The algorithms generalize to viscous conservation laws with a convex nonlinearity and are scalable in a parallel computing environment.

1. Introduction.

In this article we address some asymptotic and numerical issues related to the solution of Burgers' equation,

$$-\varepsilon u_{xx} + u_t + uu_x = 0 \quad \text{on } (-1,1), \quad u(-1) = 1+\delta, \quad u(1) = -1, \tag{1.1}$$

and its generalization to two dimensions,

$$-\varepsilon\Delta u + u_t + uu_x + \beta uu_y = 0 \quad \text{on } (-1,1)\times(-\pi,\pi), \quad u|_{x=-1} = 1+\delta, \quad u|_{x=1} = -1. \tag{1.2}$$

In the latter case, we assume periodicity (period 2π) in the second coordinate (y). The perturbation parameters δ and ε are arbitrarily small positive; they are independent, but when they approach 0, they satisfy the asymptotic order relation

$$\delta = O_s(\mathrm{e}^{-a/\varepsilon}) \quad \text{as } \delta, \varepsilon \downarrow 0 \tag{1.3}$$

for some constant $a \in (0,1)$ which does not depend on δ or ε. This asymptotic relation implies that δ is transcendentally small (in the sense of asymptotic analysis) compared

with ε, but δ dominates $e^{-1/\varepsilon}$ as $\varepsilon \downarrow 0$. (See [1, 2, 3, 4, 5] for definitions and basic concepts of asymptotic analysis.)

If $\varepsilon = 0$, the solution of (1.1) develops a shock (discontinuity) in finite time, even when the initial data are smooth [6, 7]. The perturbation introduced by a nonzero ε models the presence of viscosity, which tends to smooth the discontinuity [8, 9]. Instead of a shock, one has a transition layer—a region of rapid variation, which extends over a distance $O(\varepsilon)$ as $\varepsilon \downarrow 0$. The position of the transition layer varies with time, and its eventual location at steady state is extremely sensitive to the boundary data. In fact, even the transcendentally small perturbation δ leads to a measurable (that is, order one) effect on the eventual location of the transition layer. This phenomenon, known as *supersensitivity*, was first observed by Lorentz [10]. It has been studied extensively for Burgers' equation and more general viscous conservation laws in one dimension by Kreiss and Kreiss [11], Kreiss [12], Laforgue and O'Malley [13, 14, 15, 16, 17, 18], and Reyna and Ward [19, 20, 21].

An example from combustion theory shows that supersensitivity is of more than mathematical significance. A simple model of flame propagation in gaseous fuels involves a system of two coupled convection-diffusion equations, one for the temperature of the mixture, another for the concentration of the reaction-limiting component in the mixture [22, section 3.2]. If one ignores exponentially small perturbations in the data, one finds that the Lewis number $\mathcal{L}$, which is a measure for the ratio of heat and mass transfer in the mixture, has no effect on the location of the combustion front. Yet, numerical computations show that this location is very sensitive—in fact, supersensitive—to the value of $\mathcal{L}$.

Although the phenomenon of supersensitivity is fairly well understood theoretically, at least for one-dimensional problems, the numerical solution of such problems still poses formidable challenges, especially in more than one dimension. The methods that have been proposed in the numerical literature for singularly perturbed boundary-value problems (see, for example, [23]) tend to focus on uniform approximations or finite elements with special features, not on the supersensitive dependence of the transition layer on the boundary data. On the other hand, the algorithms we propose are designed specifically to capture the phenomenon of supersensitivity. They use the fact that the solution approaches a certain profile as the perturbation parameters approach zero and focus on the computation of the corrections.

Our ultimate goal is to develop algorithms for multidimensional problems that are, first of all, suitable for long-time integration, so stable steady states can be computed with confidence; second, extremely accurate in space, so the eventual location of transition layers can be predicted with accuracy; and third, scalable in a multiprocessing environment, so large-scale problems can be solved in a reasonable length of time. Although we discuss only Burgers' equation and its generalization to two dimensions, the algorithms are not restricted by the special form of the nonlinearity.

In section 2 we consider Burgers' equation. We propose a simple algorithm that effectively captures the supersensitive location of the transition layer at steady state. We stress the importance of the regions outside the transition layer, where the solution does not yet deviate appreciably from the boundary values. In section 3 we address the generalized Burgers' equation in two dimensions. We show through a formal asymptotic analysis that the location of the transition layer may vary in the direction of periodicity (y), but the transition layer is essentially flat, and only its average position (averaged over y) depends supersensitively on the small parameters. We then develop an algorithm that effectively approximates the transition layer.

2. One-dimensional case. We begin by considering (1.1),

$$-\varepsilon u_{xx} + u_t + uu_x = 0 \quad \text{on } (-1,1), \quad u(-1) = 1+\delta, \quad u(1) = -1. \tag{2.1}$$

As shown by Laforgue and O'Malley [16], the solution approaches a certain profile function as $\varepsilon \downarrow 0$,

$$u(x,t) = -\tanh\eta + \mathrm{e}^{-a/\varepsilon} u_1(\eta,\sigma) + \cdots, \tag{2.2}$$

where

$$\eta = \frac{x - x^*(\sigma)}{\varepsilon}, \quad \sigma = t\mathrm{e}^{-a/\varepsilon}. \tag{2.3}$$

The hyperbolic tangent incorporates a transition layer centered at x^*, which connects the limiting values ± 1 at $\mp\infty$. Note that these limiting values are transcendentally close to the prescribed boundary values $1+\delta$ and -1 of u at -1 and 1. The position of the transition layer varies on a transcendentally slow time scale; if $\delta = 2b\mathrm{e}^{-a/\varepsilon}$, its limit as $\sigma \to \infty$ is

$$x^*_{\mathrm{as}} = 1 - a + \varepsilon \ln b. \tag{2.4}$$

The important points to observe are that, first, the solution u approaches a certain profile function as $\varepsilon \downarrow 0$; second, the accurate determination of the steady-state position of the transition layer requires long-term integration; and, third, a transcendentally small perturbation of the boundary data has a measurable effect on the location of the transition layer.

The asymptotic analysis has been generalized to more general nonlinearities by Laforgue and O'Malley [17, 18] and Reyna and Ward [19], with similar results. One finds a limiting profile, which generalizes the hyperbolic tangent function, and a transition layer which moves on a transcendentally slow time scale to a steady-state position. This position depends supersensitively on the boundary perturbation. Whenever this situation arises, appropriate variants of the following algorithms can be developed.

2.1. Spatial approximation. To approximate the solution in space, we use a domain decomposition method with two nonoverlapping subdomains, where the interface is located approximately at the center of the transition layer; an adaptive pseudospectral method on each subdomain; and collocation based on Tchebychev polynomials, where the collocation points are concentrated in the transition layer. The algorithm is standard and has been described elsewhere [24, 25, 26, 27, 28]; we summarize it here only for completeness.

Let $x^* \in (-1,1)$ denote the (approximate) position of the center of the transition layer; x^* varies in time (t), but since t enters only as a parameter in the discussion of the spatial approximation, we do not write it explicitly. We decompose,

$$\Omega_1 = (-1, x^*), \quad \Omega_2 = (x^*, 1), \tag{2.5}$$

and map each of the subdomains Ω_1 and Ω_2 linearly onto $(-1,1)$,

$$g_1 : y \in (-1,1) \mapsto x = g_1(y) = -1 + \tfrac{1}{2}(x^*+1)(y+1) \in \Omega_1,$$

$$g_2 : y \in (-1,1) \mapsto x = g_2(y) = 1 - \tfrac{1}{2}(1-x^*)(1-y) \in \Omega_2.$$

The restrictions of u to Ω_1 and Ω_2 exhibit boundary layer behavior near x^*. The point $x = x^*$ corresponds to $y = 1$ under g_1 and to $y = -1$ under g_2. To concentrate the collocation points near x^*, we define a one-parameter family of nonlinear mappings of the interval $(-1, 1)$ onto itself,

$$f_1(\cdot\,,\alpha) : s \in (-1,1) \mapsto y = f_1(s,\alpha) = 1 - (4/\pi)\arctan\left(\alpha \tan \tfrac{1}{4}(1-s)\pi\right) \in (-1,1),$$

$$f_2(\cdot\,,\alpha) : s \in (-1,1) \mapsto y = f_2(s,\alpha) = -1 + (4/\pi)\arctan\left(\alpha \tan \tfrac{1}{4}(s+1)\pi\right) \in (-1,1).$$

If the parameter α is small, f_1 concentrates points near 1 and f_2 concentrates points near -1. Concentrating points near critical points is the computational analog of coordinate stretching in asymptotic analysis. The choice of α can be optimized by means of a priori estimates [24, 25]; we usually take $\alpha = \varepsilon^{1/2}$ [27]. The composite maps,

$$h_i(\cdot\,;\alpha) = g_i(\cdot\,) \circ f_i(\cdot\,,\alpha), \quad i = 1, 2,$$

are one-to-one from $(-1, 1)$ onto Ω_i; we denote their inverses by $h_i^{-1}(\cdot\,;\alpha)$, $i = 1, 2$.

We look for the solution of (2.1) by approximating locally on each of the subdomains Ω_1 and Ω_2 and imposing C^1 continuity at x^*. If U denotes the global approximation, then

$$U(x) = U_i(x) \quad \text{for } x \in \Omega_i, \quad U \in C^1([-1,1]).$$

The local approximations consist of finite sums of Tchebychev polynomials,

$$U_i(x) = \sum_{j=0}^{N-1} a_{ij} T_j(h_i^{-1}(x;\alpha)), \quad x \in \Omega_i,\ i = 1,2; \quad T_j(\cos\theta) = \cos(j\theta), \quad \theta = \pi/N.$$

2.2. Integration for times of order one. For short-time integration it suffices to combine a one-step forward Euler approximation with an implicit treatment of the second-order spatial derivative and an explicit treatment of the nonlinear term.

Starting with an approximate solution $U^0 = U(\cdot\,, t_0)$ at time t_0, we identify the point $x^* = x^*(t_0)$ with the location of the zero of U^0, partition the domain in two subdomains, and select the collocation points. Fixing this configuration temporarily, we compute a sequence $\{U^n : n = 1, 2 \ldots\}$ of successive approximations U^n using the algorithm

$$-\varepsilon D^2 U^n + \frac{U^n - U^{n-1}}{\Delta t} + U^{n-1} D U^{n-1} = 0, \quad n = 1, 2, \ldots. \tag{2.6}$$

The symbol D represents the pseudospectral differentiation operator in physical space [29]. The time step Δt is constant, so U^n is the approximate solution of the boundary-value problem (1.1) at $t_0 + n\Delta t$. The algortithm (2.6) is nonconservative.

When the location of the zero of U^n has moved over a distance ε, we suspend the algorithm (2.6). We shift x^* to the current location of the zero, reconfigure the partition, update the collocation points, replace U^0 by the values at the new collocation points (using interpolation if necessary), and continue the algorithm (2.6). We repeat this process until the steady state is reached. The change in the location of the zero of the computed approximation becomes smaller as time progresses, so the same collocation configuration serves for longer and longer time intervals.

The algorithm (2.6) requires the solution of U^n from the equation

$$AU^n = U^{n-1} + (\Delta t)U^{n-1}DU^{n-1}. \tag{2.7}$$

The matrix A, which is order $2N-1$, has a block structure,

$$A = \begin{pmatrix} A_1 & b_1 & \\ a_1^{\rm t} & c & b_2^{\rm t} \\ & a_2 & A_2 \end{pmatrix}.$$

A_1 and A_2 are square matrices of order $N-1$; a_1, a_2, b_1, and b_2 vectors of length $N-1$; c is a constant. The center row accounts for the C^1 continuity at the interface. This block structure allows a solution of the system (2.7) in two parallel processes from opposite ends. The matrix A does not change as long as the collocation configuration is frozen. However, its condition number increases with the number of collocation points. This increase puts a lower limit on the values of δ one can handle in practice.

Table 1 gives the location of the transition layer at steady state, x^*_∞, computed with the algorithm (2.6) with $N = 39$ collocation points in each subdomain and a time step $\Delta t = 0.02$. The number $x^*_{\rm as} = 1 - \varepsilon \ln(2/\delta)$, which is an asymptotic estimate of x^* (see (2.4)), is given for comparison. The initial conditions were usually obtained by linear interpolation from the boundary data, but variations were made to test the answers. The lower limit on ε is determined by the fact that the computation time for the algorithm (2.6) increases as ε decreases. In subsection 2.4 we discuss an algorithm suitable for long-time integration.

Table 2 shows the impact of grid refinement (the number of collocation points, N) on the value of x^*_∞.

2.3. Neglecting viscosity. In supersensitive boundary-value problems, the solution in the "tails" on either side of the transition layer is exponentially close to the prescribed boundary values, so the viscous term is exponentially small there. It is therefore tempting to assume that one can sacrifice some accuracy in the computation of the viscous term during the transient phase and still find the position of the transition layer at steady state with a high degree of accuracy.

An extreme form of this assumption underlies the approach where one constructs a first approximation by ignoring the viscous term altogether. Using a conservative

finite-difference scheme, such as Godunov, one constructs the entropy solution of the inviscid conservation law ($\varepsilon = 0$) and takes this as a first approximation. One then constructs higher order uniform approximations, for example, by means of a heterogeneous domain-decomposition method, using either a different numerical scheme to solve the full viscid problem in the interior of the transition layer or some other approximation of the viscous equation.

The χ method introduced by Brezzi, Canuto, and Russo [30] is a more sophisticated nonlinear adaptive scheme based on the same assumption. Here, one replaces the boundary-value problem by

$$-\varepsilon\chi(u_{xx}) + u_t + (f(u))_x = 0 \text{ on } (-1,1), \quad u(-1,t) = 1+\delta,\ u(1,t) = -1, \tag{2.8}$$

where $\chi \equiv \chi_{\sigma,\tau}$ is a smooth monotone function, $\chi(s) = 0$ if $|s| \le \sigma$, and $\chi(s) = s$ if $|s| \ge \sigma + \tau$ for some positive numbers σ and τ. This method has been applied to Burgers' equation [31] and the incompressible Navier–Stokes equations [32]. However, we claim that the χ method cannot accurately predict the ultimate position of the transition layer, at least for Burgers' equation on a finite interval with Dirichlet data. This claim is supported by the following observations.

Consider the results quoted in [31, Table II]. With few exceptions, they involve relatively large values of σ (σ is called δ in [31]); in fact, σ is typically greater than $\varepsilon^{-1/2}$ (ε is called ν in [31]) by one or two orders of magnitude. The viscous term is therefore always neglected, unless u_{xx} is of the same order as $\varepsilon^{-1/2}$; that is, the viscous term is neglected everywhere except in the transition layer. If the χ method gave the correct position of the transition layer at steady state, then the same would certainly be the case when we simply multiply the viscous term by a smooth function of position, whose support is of order one and includes the transition layer. After all, in the latter case we account for the viscous term over a much broader region. These arguments lead us to consider the boundary-value problem

$$-\varepsilon H(x)u_{xx} + u_t + uu_x = 0 \text{ on } (-1,1), \quad u(-1,t) = 1+\delta,\ u(1,t) = -1, \tag{2.9}$$

instead of the boundary-value problem (2.8). Here, H is a smooth cutoff function,

$$H(x) = \begin{cases} \frac{1}{2}\left(1 + \tanh(\alpha(x - x^*(t) + \beta))\right), & x < x^*(t), \\ \frac{1}{2}\left(1 + \tanh(\alpha(-x + x^*(t) + \beta))\right), & x > x^*(t). \end{cases} \tag{2.10}$$

We use a numerical approximation of $x^*(t)$ and choose the parameters α and β so

$$H(x) = 1 \text{ if } |x - x^*(t)| < \tfrac{1}{2}\beta, \quad H(x) = 0 \text{ if } |x - x^*(t)| > \tfrac{3}{2}\beta$$

to within machine accuracy ($1 \cdot 10^{-15}$). The algorithm (2.6) leads to the solution of U^n from the equation

$$-\varepsilon H D^2 U^n + \frac{U^n - U^{n-1}}{\Delta t} + U^{n-1} D u^{n-1} = 0, \quad n = 1, 2, \ldots. \tag{2.11}$$

The results given in Table 3 (computed for $\varepsilon = 0.1$ and $\delta = 1.0 \cdot 10^{-2}$, with $\alpha = 200$) show that the algorithm (2.11) can give incorrect results for the position of the transition layer at steady state. (The correct value is $x^*_\infty = 0.47486$; see Table 1.) The position of the shock freezes too early during the transient phase. The actual moment of freezing depends on the size of the zone to the left of the transition layer (where $H \equiv 0$). The result improves as β increases, but for $\beta = 0.8$ the algorithm

TABLE 3
Location of the transition layer at steady state computed with the χ method.

β	0.1	0.2	0.3	0.4	0.5	0.6	0.7
x^*_∞	0.0056	0.0110	0.0174	0.0384	0.0923	0.1067	0.1565

fails to converge. (The position of the transition layer keeps oscillating between the regions where $H \equiv 1$ and $H \equiv 0$.) On the other hand, if we include the missing part of the viscous term explicitly and use the algorithm

(2.12)
$$-\varepsilon H D^2 U^n - \varepsilon(1-H)D^2 U^{n-1} + \frac{U^n - U^{n-1}}{\Delta t} + U^{n-1} D u^{n-1} = 0, \quad n = 1, 2, \ldots,$$

instead of (2.11), we retrieve the correct position of the transition layer at steady state. This result demonstrates clearly that, when the problem is supersensitive, it is not advisable to neglect the viscous term, even when that term is exponentially small.

Note that the modified algorithm (2.13) treats the second-order derivative explicitly in the region where $H \equiv 0$ and implicitly in the region where $H \equiv 1$. The idea of using a cutoff function to construct a composite algorithm is described in detail in our article [28]. The procedure offers a very general tool for the design of heterogeneous domain decompositions in the framework of a finite-difference approximation. However, since the algorithm (2.13) is based on a Tchebyshev pseudospectral approximation, the partially explicit treatment of the viscous term forces a severe constraint on the time step that cannot be circumvented. For example, with $\varepsilon = 0.1$ and $N = 49$ collocation points per subdomain, the time step must be 10 times smaller than the time step for the algorithm (2.6). The algorithm (2.13) is therefore certainly not practical for long-time integration.

2.4. Long-time integration. The explicit treatment of the nonlinear term in the algorithm (2.6) imposes a severe constraint on the time step (CFL condition). The algorithm is therefore not suitable for long-time integration. The alternative approach commonly taken is to use a fully implicit scheme in combination with a Newton algorithm [33]. However, an implicit scheme can be expensive and is certain to increase interprocessor communication in a multiprocessing environment. If the solution of the viscous conservation law is close to a certain profile function, as is the case for Burgers' equation, at least after an initial transient, the following algorithm offers a more efficient alternative.

We start the integration of (2.1) at $t = t_0$, say, when we have an approximate profile with a transition layer centered at x^*. We construct the function u_0,

$$u_0(x) = -\tanh \frac{x - x^*}{2\varepsilon}, \tag{2.13}$$

which satifies Burgers' equation exactly, and look for a solution u of the form

$$u(x,t) = u_0(x) + \delta v(x,t). \tag{2.14}$$

Then v must satisfy the nonlinear boundary-value problem

$$-\varepsilon v_{xx} + v_t + u_0 v_x + u_0' v + \delta v v_x = 0 \quad \text{on } (-1,1),$$

$$v(-1,t) = \delta^{-1}(1 + \delta - u_0(-1)), \quad v(1,t) = \delta^{-1}(-1 - u_0(1)).$$

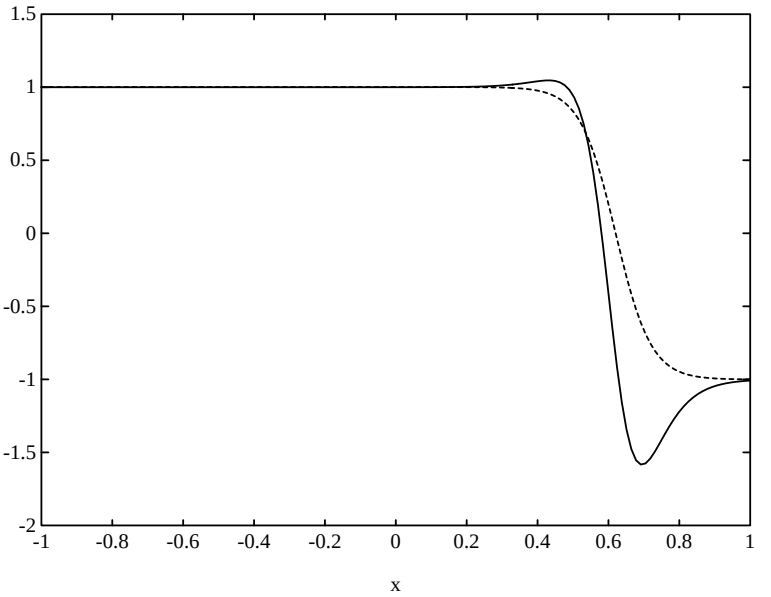

FIG. 1. *The profile function u_0 (dashed line) and the computed solution $U(\cdot\,,t)$ at some time t (solid line); $\varepsilon = 0.05$, $\delta = 1 \cdot 10^{-3}$.*

We integrate this boundary-value problem for $t > t_0$, using the algorithm

(2.15)
$$-\varepsilon D^2 V^n + \frac{V^n - V^{n-1}}{\Delta t} + u_0 DV^n + u_0' V^n = -\delta V^{n-1} DV^{n-1}, \quad n = 1, 2, \ldots,$$

and define an approximation U of u for $t > t_0$,

(2.16)
$$U(x,t) = u_0(x) + \delta V(x,t), \quad t > t_0.$$

We proceed with the integration as long as the supremum of $U(\cdot\,,t) - u_0$ remains of the order of δ. When this criterion is no longer met, at $t = t_1$, say, we suspend the integration, identify the point x^* with the location of the center of the transition layer at t_1, update the profile function u_0, and continue the integration beyond t_1. We repeat the procedure until the steady state is reached. Figure 1 shows a profile function u_0 and the computed solution $U(\cdot\,,t)$ at some time t. Note that the former is monotone, the latter is not.

The algorithm (2.16) is very similar to (2.6). The spatial approximation is handled with the same domain-decomposition method, so the structure of the resulting linear system is the same as in (2.7). But the constraint on the time step is relaxed by a factor δ. With the algorithm (2.16) we can integrate the boundary-value problem for values of ε as small as 0.01, down to δs of the order of 10^{-6}, using time steps that are typically 50 times larger than with the algorithm (2.6). Table 4 gives some results for x_∞^*, computed with the algorithm (2.16), with $N = 39$ collocation points in each subdomain.

3. Two-dimensional case. Next, we consider Burgers' equation generalized to two dimensions,

(3.1)

$$-\varepsilon\Delta u + u_t + uu_x + \beta u u_y = 0 \quad \text{on } (-1,1)\times(-\pi,\pi), \quad u|_{x=-1} = 1+\delta, \quad u|_{x=1} = -1.$$

We assume periodicity in y (period 2π). The perturbation δ may vary with y; its Fourier expansion is

$$\delta \equiv \delta(y) = \delta_0 \sum_{k\in\mathbf{Z}} \eta_k \mathrm{e}^{iky}. \tag{3.2}$$

The coefficients η_k, as well as the prefactor δ_0, are independent of y. The prefactor δ_0 is arbitrarily small positive and defined in such a way that $\eta_0 = 1$ and $\eta_k = O(1)$ as $\delta_0 \downarrow 0$ for $k = \pm 1, \pm 2, \ldots$. The order relation (1.3) between δ and ε, which must hold uniformly in y, implies that

$$\delta_0 = O_s(\mathrm{e}^{-a/\varepsilon}) \quad \text{as } \delta_0, \varepsilon \downarrow 0 \tag{3.3}$$

for some $a \in (0,1)$. We show in section 3.1 that, under these conditions, the *average* position of the transition layer (averaged over y) depends supersensitively on the small parameters ε and δ_0. In section 3.2 we briefly review the spatial approximation. Section 3.3 is devoted to the integration procedure.

3.1. Profile function. The algorithm we propose for the solution of the boundary-value problem (3.1) is again based on the assumption that the solution is close to a known profile function. Our goal in this section is to show that, under the conditions given above, the profile function is asymptotically independent of y and again given to leading order by the hyperbolic tangent, as in (2.2).

We introduce the constant $x^* \in (0,1)$ such that $x^* \sim 1 - \varepsilon \ln(2/\delta_0)$ as $\varepsilon \downarrow 0$. We define the function u_0,

$$u_0(x) = -\tanh \frac{x - x^*}{2\varepsilon}, \tag{3.4}$$

and look for a profile function u of the form

$$u(x,y) = u_0(x) + v(x,y). \tag{3.5}$$

Because $-\varepsilon u_0'' + u_0 u_0'$, v must satisfy the differential equation

$$-\varepsilon\Delta v + u_0 v_x + u_0' v + \beta u_0 v_y + v v_x + \beta v v_y = 0, \tag{3.6}$$

together with the boundary conditions

$$v|_{x=-1} = \delta - \delta_0, \quad v|_{x=1} = 0. \tag{3.7}$$

The linearized equation,

$$\ell(v) \equiv -\varepsilon\Delta v + u_0 v_x + u_0' v + \beta u_0 v_y = 0, \tag{3.8}$$

has a solution, $\ell(u_0') = 0$, so we reduce the order by substituting

$$v = u_0' w. \tag{3.9}$$

Then w must satisfy the equation

$$-\varepsilon\Delta w - u_0 w_x + \beta u_0 w_y = 0, \tag{3.10}$$

together with the boundary conditions

$$w|_{x=-1} = (\delta - \delta_0)/u_0'(-1), \quad w|_{x=1} = 0. \tag{3.11}$$

We estimate w by means of the coefficients in its Fourier expansion,

$$w(x,y) = \sum_{k\in\mathbf{Z}} w_k(x)\mathrm{e}^{iky}. \tag{3.12}$$

The leading coefficient w_0 is the solution of the boundary-value problem

$$-\varepsilon w_0'' - u_0 w_0' = 0 \quad \text{on } (-1,1), \quad w_0(-1) = 0, \quad w_0(1) = 0, \tag{3.13}$$

so $w_0 = 0$. Note that this result is a direct consequence of the fact that we have defined x^* in terms of the average δ_0 in (3.4); any other definition leads to an inhomogeneous boundary-value problem, whose solution w_0 does not vanish.

The remaining coefficients w_k, $k = \pm1, \pm2, \ldots$, are found from the boundary-value problem

$$-\varepsilon w_k'' - u_0 w_k' + (\varepsilon k^2 + i\beta k u_0) w_k = 0, \quad w_k(-1) = \delta_0\eta_k, \quad w_k(1) = 0. \tag{3.14}$$

This is a classical turning-point problem, as u_0 changes sign in the interval $(-1,1)$. The asymptotic behavior of w_k as $\varepsilon \downarrow 0$ can be found by the method described in [3, section 3.E],

$$w_k(x) \sim \left[c_k\mathrm{e}^{i\beta kx} + \left(1 - c_k\mathrm{e}^{-i\beta k}\right)\mathrm{e}^{-(1+x)/\varepsilon} + \left(0 - c_k\mathrm{e}^{i\beta k}\right)\mathrm{e}^{-(1-x)/\varepsilon}\right] w_k(-1). \tag{3.15}$$

The coefficient c_k is such that the functional

$$\mathcal{L}[w] = \frac{1}{2}\int_{-1}^{1} \left[\varepsilon w'^2 + (\varepsilon k^2 + i\beta k u_0) w^2\right] \exp\left(\frac{1}{\varepsilon}\int_0^x u_0(\xi)\,\mathrm{d}\xi\right)\,\mathrm{d}x \tag{3.16}$$

has a critical point at $w = w_k$,

$$\frac{\partial\mathcal{L}[w_k]}{\partial c_k} = 0. \tag{3.17}$$

Notice that the differential equation (3.14) is the Euler equation of the functional $\mathcal{L}$; the Neumann boundary conditions $w_k'(\pm1) = 0$ are the natural boundary conditions associated with $\mathcal{L}$.

Obviously, finding an explicit expression for c_k is out of the question. The best we can aim for is an asymptotic expansion as $\varepsilon \downarrow 0$, and even here we must resort to computational assistance. Using the symbolic manipulation language MAPLE, we find

$$c_k \sim \frac{\mathrm{e}^{-(x^*+1)/\varepsilon}}{(1+\beta^2)\varepsilon^2 k^2}\mathrm{e}^{-i\beta k(1+2x^*)} \quad \text{as } \varepsilon \downarrow 0. \tag{3.18}$$

The first term in the brackets in (3.16) represents the regular part of the asymptotic behavior of w_k, which dominates in the interior; the remaining two terms represent the singular part, which dominates near the endpoints of the interval. Since we are interested in the transition layer, which is located in the interior, we ignore the singular part and take only the regular part, $w_k(x) \sim c_k w_k(-1)\mathrm{e}^{i\beta kx}$. That is, we take

$$v_k(x) \sim \frac{\delta_0\eta_k \mathrm{e}^{-(1+x^*)/\varepsilon}}{(1+\beta^2)\varepsilon^2 k^2}\,\frac{u_0'(x)}{u_0'(-1)}\,\mathrm{e}^{i\beta k(1-2x^*+x)} \quad \text{as } \varepsilon \downarrow 0. \tag{3.19}$$

If we use the asymptotic approximation

$$\frac{u_0'(x)}{u_0'(-1)} = \frac{1-\tanh^2((x-x^*)/(2\varepsilon))}{1-\tanh^2((-1-x^*)/(2\varepsilon))} \sim \frac{1-\tanh^2((x-x^*)/(2\varepsilon))}{4\mathrm{e}^{-(1+x^*)/\varepsilon}},$$

we obtain the asymptotic expression

$$v_k(x) \sim \frac{\delta_0\eta_k}{4(1+\beta^2)\varepsilon^2 k^2}\,\mathrm{e}^{i\beta k(1-2x^*+x)}\left(1-\tanh^2\frac{x-x^*}{2\varepsilon}\right). \tag{3.20}$$

This result implies that the Fourier series of v, as well as those of v_x and v_y, converge. Furthermore, $\|v\|_\infty$ and $\|v_y\|_\infty$ are $O(\delta_0\varepsilon^{-2})$.

Finding the asymptotic behavior of $\|v_x\|_\infty$ is less obvious. It follows from (3.16) that $w_k'(x) \sim c_k\mathrm{e}^{i\beta kx}$ as $\varepsilon \downarrow 0$, at least for x in the interior of the domain. Therefore, $v_k'(x) = (u_0'w_k)'(x) \sim (u_0''w_k)(x) \sim \varepsilon^{-1}(u_0'w_k)(x) = \varepsilon^{-1}v_k(x)$. Hence, $\|v_x\|_\infty = O(\delta_0\varepsilon^{-3})$ as $\delta_0, \varepsilon \downarrow 0$.

Since $\delta_0 = O_s(\mathrm{e}^{-a/\varepsilon})$ for some $a \in (0,1)$, we have $\delta_0\varepsilon^{-p} = O_s(\mathrm{e}^{-a'/\varepsilon})$ $(p = 2,3)$ for any $a' \in (0,a)$, so any solution v of (3.8) which satisfies the boundary conditions (3.7) is transcendentally small. The residue $vv_x + \beta v v_y$, which was ignored in the transition from the nonlinear equation (3.6) to the linear equation (3.8) is likewise transcendentally small and, in fact, $O(\delta_0^2\varepsilon^{-5})$, so we also have an a posteriori justification for the linearization.

These arguments motivate the choice of u_0, which depends only on x, as the profile function in the design of the numerical algorithms for (3.2).

3.2. Spatial approximation. The spatial approximation is again based on a domain decomposition with two nonoverlapping subdomains on either side of the y-averaged location of the center of the transition layer. On each subdomain we use an adaptive pseudospectral method in the x direction and a finite-difference method in the y direction. The pseudospectral method is the same as in the one-dimensional case; it uses Tchebychev polynomial collocation with N_x collocation points.

Since the transition layer is close to a plane parallel to the x axis, there is no need to resort to an adaptive grid in the y direction. For our numerical experiments we chose a regular grid with mesh width $h = 2\pi/N_y$ and a sixth-order central finite-difference approximation of u_{yy} and u_y. The choice may seem inconsistent with the

spectral approximation in the x direction; a more obvious choice would be a Fourier approximation in the y direction. Theoretically, the finite-difference approximation in the y direction restricts the accuracy of the approximation for a regular problem ($\varepsilon = O_s(1)$) to sixth order, less than the accuracy guaranteed by the pseudospectral approximation in the x direction. However, as the transition layer is close to a plane parallel to the x axis, it is relatively easy to keep the numerical error in the finite-difference approximation of the term εu_{yy} smaller than the numerical error in the pseudospectral approximation of the term εu_{xx} with a moderate number of discretization points N_y. There is, therefore, no need to use a better approximation, like the Fourier approximation, for the term εu_{yy}. Furthermore, the spectral radius of D_y^2 is smaller with sixth-order finite differences than with Fourier differentiation. This difference implies an additional advantage for a finite-difference approximation when the y derivatives are treated explicitly [34].

3.3. Integration for times of order one. We extend the Euler scheme (2.6) to two dimensions as follows:

(3.21)
$$-\varepsilon D_x^2 U^n + \frac{U^n - U^{n-1}}{\Delta t} = \varepsilon D_y^2 U^{n-1} + U^{n-1} D_x U^{n-1} + \beta U^{n-1} D_y U^{n-1}, \quad n = 1, 2, \ldots.$$

Here, D_x is the pseudospectral differential operator with Tchebychev polynomials, D_y the finite-difference operator with sixth-order central finite differences.

The algorithm (3.21) has several features that make it readily parallelizable. First, the approximations $D_y U^{n-1}$ and $D_y^2 U^{n-1}$ are taken explicitly, so the variable y is only a parameter. Second, because we are using finite-difference approximations, we have only local data dependencies. This latter point especially offers a significant advantage over a spectral method, which uses global interpolation.

Table 5 shows the results for the boundary-value problem (3.1) with $\beta = 1$, $\varepsilon = 0.1$ and piecewise constant boundary data with $\delta_0 = 1.0 \cdot 10^{-2}$,

(3.22)
$$u(-1, y) = \begin{cases} 1.01 - \Delta\delta & \text{if } -\pi \le y < -\frac{1}{2}\pi, \\ 1.01 + \Delta\delta & \text{if } -\frac{1}{2}\pi \le y < \frac{1}{2}\pi, \\ 1.01 - \Delta\delta & \text{if } \frac{1}{2}\pi \le y < \pi. \end{cases}$$

The algorithm (3.21) was applied with $N_x = 39$ collocation points per subdomain in the x direction and $N_y = 32$ interpolation points in the y direction. The table gives the y-averaged location of the transition layer at steady state, $\langle x_\infty^* \rangle$, as well as the maximum deviation of the center of the transition layer from its y-averaged location, Δx^*; that is, $x_\infty^*(y)$ varies between $\langle x_\infty^* \rangle - \Delta x^*$ and $\langle x_\infty^* \rangle + \Delta x^*$. These results show that the algorithm (3.21) is extremely effective for the boundary-value problem. As $\Delta\delta$ increases, Δx^* grows approximately linearly with $\Delta\delta$. The graph of $U - u_0$ maintains its overall shape, so its width (which measures Δx^*) varies in proportion to its height (which measures $\|U - u_0\|_\infty$). The numerical results therefore indicate also that $\|U - u_0\|_\infty$ grows approximately linearly with $\Delta\delta$. This conclusion matches the results of the asymptotic analysis in section 3.1, in particular (3.20), where it was shown that v_k is proportional to η_k.

Results for a much harder case are presented in Table 6. The parameters β and ε are fixed as before, $\beta = 1$ and $\varepsilon = 0.1$, but this time the data at the left boundary are sharply peaked at the midpoint,

(3.23)
$$u(-1, y) = 1.005 + (\Delta\delta) \mathrm{e}^{-20(1-\cos y)}, \quad -\pi < y < \pi.$$

The algorithm (3.21) was again applied with $N_x = 39$ collocation points per subdomain in the x direction and $N_y = 32$ interpolation points in the y direction. The table gives, in addition to the values of $\langle x^*_\infty \rangle$ and Δx^*, the asymptotic value $x^*_{\text{as}} = 1 - \varepsilon \ln(2/\delta_0)$. The average location of the transition layer is predicted very well by the asymptotics. Again, the maximum deviation Δx^* grows with $\Delta\delta$, although not linearly as in the case of the step boundary data (3.22).

Table 7 shows the impact of grid refinement (the number of collocation points per subdomain, N_x, and the number of discretization points, N_y) on the computed value of $x^*_\infty(y)$ for the problem with boundary data (3.22), $\Delta\delta = 0.01$.

An obvious way to parallelize the algorithm (3.21) is to partition the interval $(-\pi, \pi)$ into subintervals of equal length $2\pi/N_y$ and map this partition onto a ring of processors. Thus, one can achieve high speedups on a Paragon using nonblocking communications. If each processor covers at least four mesh points in the y direction, only nearest-neighbor communication is needed. Table 8 gives ample evidence that the algorithm (3.21) is highly scalable; doubling the number of processors with the problem size results in almost identical CPU times.

Additional parallelism can be introduced by decomposing the domain in the x

TABLE 8
CPU time for $1,000$ *time steps on the Paragon XP/S as a function of the number of processors* (P) *and the size of the problem (measured by* N_y*);* $N_x = 49$.

N_y	$P=1$	$P=2$	$P=4$	$P=8$	$P=16$

direction. However, our experience with a similar algorithm for combustion problems indicates a potentially significant decrease (as much as 70%) in the efficiency of the algorithm [35].

In general, the algorithm (3.21) is very well adapted to the quasi-one-dimensional structure of the transition layer. The algorithm predicts the location of the transition layer at steady state with a significant accuracy. The time step is of the same order of magnitude as for the one-dimensional analogue (2.6).

3.4. Long-time integration. The algorithm (3.21) needs to be modified for long-time integration. We distinguish between the cases $\beta = 0$ and $\beta \neq 0$.

If $\beta = 0$, we use an algorithm similar to the one described in section 2.4. We start the integration of (3.1) at $t = t_0$, say. We identify the point x^* with the location of the zero of the approximation U of u, averaged over y, at $t = t_0$ and define the profile function u_0 as in (3.4),

$$u_0(x) = -\tanh \frac{x - x^*}{2\varepsilon}. \tag{3.24}$$

Then we integrate the nonlinear boundary-value problem

$$-\varepsilon \Delta v + v_t + u_0 v_x + u_0' v + \delta_0 \varepsilon^{-2} v v_x = 0 \quad \text{on } (-1,1) \times (-\pi, \pi)$$

forward in time, subject to the boundary conditions

$$v|_{x=-1} = \delta_0^{-1} \varepsilon^2 (1 + \delta - u_0(-1)), \quad v|_{x=1} = \delta_0^{-1} \varepsilon^2 (-1 - u_0(1)),$$

using the algorithm

$$-\varepsilon D_x^2 V^n + \frac{V^n - V^{n-1}}{\Delta t} + u_0 D_x V^n + u_0' V^n = \varepsilon D_y^2 V^{n-1} - \delta_0 \varepsilon^{-2} V^{n-1} D_x V^{n-1} \tag{3.25}$$

for $n = 1, 2, \ldots$. We define the approximation U of u,

$$U(x, y, t) = u_0(x) + \delta_0 \varepsilon^{-2} V(x, y, t), \tag{3.26}$$

and integrate as long as the supremum of $U(\cdot\,, \cdot\,, t) - u_0$ remains of the order of $\delta_0 \varepsilon^{-2}$. When this criterion is no longer met, at $t = t_1$, say, we suspend the integration, identify the point x^* with the location of the center of the transition layer (averaged over y), and update the profile function u_0. We repeat the procedure until the steady state is reached.

The time step for the algorithm (3.25) is limited by the (explicit) term $\varepsilon D_y^2 V^{n-1}$, $\Delta t < c(2\pi/N_y)^2/\varepsilon$, for some constant $c < \frac{1}{2}$. This limitation is not too severe, as ε is

TABLE 9
Location of the transition layer at steady state; boundary data (3.28).

$\Delta\delta$	$\langle x^*_\infty \rangle$	Δx^*
$1.0 \cdot 10^{-6}$	0.7099	$< 1.0 \cdot 10^{-4}$
$1.0 \cdot 10^{-5}$	0.7099	$< 1.0 \cdot 10^{-4}$
$1.0 \cdot 10^{-4}$	0.7101	$3.9 \cdot 10^{-3}$
$0.5 \cdot 10^{-3}$	0.7122	$1.9 \cdot 10^{-2}$
$1.0 \cdot 10^{-3}$	0.7162	$3.0 \cdot 10^{-2}$

very small and the variation of the solution in the y direction is exponentially small, so N_y need not be large.

If $\beta \neq 0$, the situation becomes more complicated. One can, of course, extend the algorithm (3.25) trivially by incorporating the convective term in the right member,

$$-\varepsilon D_x^2 V^n + \frac{V^n - V^{n-1}}{\Delta t} + u_0 D_x V^n + u_0' V^n \tag{3.27}$$
$$= \varepsilon D_y^2 V^{n-1} - \delta_0 \varepsilon^{-2} V^{n-1} D_x V^{n-1} - \beta u_0 D_y V^{n-1} - \beta \delta_0 \varepsilon^{-2} V^{n-1} D_y V^{n-1}$$

for $n = 1, 2, \ldots$. Representative results obtained in this way for the boundary-value problem (3.1) with $\beta = 1$ and $\varepsilon = 0.02$ are given in Table 9. The boundary data are again piecewise constant, as in Table 5, but with $\delta_0 = 1.0 \cdot 10^{-6}$,

$$u(-1, y) = \begin{cases} 1 + 1.0 \cdot 10^{-6} - \Delta\delta & \text{if } -\pi \leq y < -\frac{1}{2}\pi, \\ 1 + 1.0 \cdot 10^{-6} + \Delta\delta & \text{if } -\frac{1}{2}\pi \leq y < \frac{1}{2}\pi, \\ 1 + 1.0 \cdot 10^{-6} - \Delta\delta & \text{if } \frac{1}{2}\pi \leq y < \pi. \end{cases} \tag{3.28}$$

The algorithm (3.27) was applied with $N_x = 39$ collocation points per subdomain in the x direction and only $N_y = 16$ interpolation points in the y direction. We observe that the average location of the transition layer does not change appreciably as long as $\Delta\delta$ is of the same order as the average perturbation δ_0. As $\Delta\delta$ increases, the perturbation is no longer small compared with δ_0, and the asymptotic results of section 3.1 do not necessarily apply. Indeed, Δx^* does not appear to vary linearly with $\Delta\delta$, as was the case in Table 6.

A graphical representation of the computed solution U and its deviation from the profile function, $U - u_0$, for the case $\Delta\delta = 1.0 \cdot 10^{-3}$ are given in Figure 2 (contour lines of U at steady state) and Figures 3 and 4 (perspective drawings of U and the difference $U - u_0$ at steady state). The data for these figures were taken after 2,500,000 time steps ($\Delta t = 0.4$).

The results are quite good, but for long-time integration one would do better by looking for v in terms of its Fourier coefficients v_k and adopting an implicit scheme in the y direction. Thus, the constraint on the time step becomes the same as in the one-dimensional case. The algorithm would be of the following type:

$$-\varepsilon D_x^2 V_k^n + \frac{V_k^n - V_k^{n-1}}{\Delta t} + u_0 D_x V_k^n + (i\beta k u_0 + \varepsilon k^2) V_k^n + u_0' V^n = -\delta_0 \varepsilon^{-2} W_k^{n-1} \tag{3.29}$$

for $n = 1, 2, \ldots$; D_y is the matrix of differentiation with respect to y in Fourier space, and W_k is some approximation to the kth Fourier coefficient of $vv_x + \beta v v_y$.

EXPLICIT ALGORITHMS FOR A NEW TIME DEPENDENT MODEL BASED ON LEVEL SET MOTION FOR NONLINEAR DEBLURRING AND NOISE REMOVAL*

ANTONIO MARQUINA† AND STANLEY OSHER‡

Dedicated to the memory of Emad Fatemi

Abstract. In this paper we formulate a time dependent model to approximate the solution to the nonlinear total variation optimization problem for deblurring and noise removal introduced by Rudin and Osher [*Total variation based image restoration with free local constraints*, in Proceedings IEEE Internat. Conf. Imag. Proc., IEEE Press, Piscataway, NJ, (1994), pp. 31–35] and Rudin, Osher, and Fatemi [*Phys. D*, 60 (1992), pp. 259–268], respectively. Our model is based on level set motion whose steady state is quickly reached by means of an explicit procedure based on Roe's scheme [*J. Comput. Phys.*, 43 (1981), pp. 357–372], used in fluid dynamics. We show numerical evidence of the speed of resolution and stability of this simple explicit procedure in some representative 1D and 2D numerical examples.

Key words. image restoration, total variation norm, upwind schemes, nonlinear diffusion, level set motion

1. Introduction.

Classical algorithms for image deblurring and/or denoising have been mainly based on least squares, Fourier series, and other $\mathcal{L}^2$-norm approximations, and consequently, the results are liken to be contaminated by Gibbs's phenomena (*ringing*) and/or smearing near edges. Their computational advantage comes from the fact that the classical algorithms are linear; thus, fast solvers are widely available. However, the effect of the restoration is not local in space. Other bases of orthogonal functions have been introduced in order to get rid of those problems, e.g., compactly supported wavelets, but Gibbs's phenomenon (*ringing*) and/or smearing are/is still present for these linear procedures.

The total variation (TV) deblurring and denoising models are based on a variational problem with constraints using the TV norm as a nonlinear nondifferentiable functional. The formulation of these models was first given by Rudin, Osher, and Fatemi in [19] for the denoising model and Rudin and Osher in [18] for the denoising and deblurring case. The main advantage is that their solutions preserve edges very well, but there are computational difficulties. Indeed, in spite of the fact that the variational problem is convex, the Euler–Lagrange equations are nonlinear and ill-conditioned. Linear semi-implicit fixed-point procedures devised by Vogel and Oman (see [26]), and interior-point primal-dual implicit quadratic methods by Chan, Golub,

and Mulet (see [6]), were introduced to solve the models. Those methods give good results when treating pure denoising problems, but the methods become highly ill-conditioned for the deblurring and denoising case where the computational cost is very high and parameter dependent. Furthermore, those methods also suffer from the undesirable *staircase effect*, namely the transformation of smooth regions (*ramps*) into piecewise constant regions (*stairs*).

In this paper we present a very simple time dependent model constructed by evolving the Euler–Lagrange equation of the Rudin–Osher optimization problem, multiplied by the magnitude of the gradient of the solution. The two main analytic features of this formulation are the following: (1) the level contours of the image move quickly to the steady solution and (2) the presence of the gradient numerically regularizes the mean curvature term in a way that preserves and enhances edges and kills noise through the nonlinear diffusion acting on small scales. We use the entropy-violating Roe scheme [16] for the convective term and central differencing for the regularized mean curvature diffusion term. This makes a very simple, stable, explicit procedure, computationally competitive compared with other semi-implicit or implicit procedures. We show numerical evidence of the power of resolution and stability of this explicit procedure in some representative 1D and 2D numerical examples, consisting of noisy and blurred signals and images. (We use Gaussian white noise and Gaussian blur.) We have observed in our experiments that our algorithm shows a substantially reduced staircase effect.

2. Deblurring and denoising. A recording device or a camera would record a signal or image so that (1) the recorded intensity of a small region is related to the true intensities of a neighborhood of the pixel through a degradation process usually called *blurring* and (2) the recorded intensities are contaminated by random noise.

To fix our ideas we restrict the discussion to $\mathbb{R}^2$. An image can be interpreted as either a real function defined on Ω, a bounded and open domain of $\mathbb{R}^2$ (for simplicity we will assume Ω to be the unit square henceforth), or as a suitable discretization of this continuous image. Our interest is to restore an image which is contaminated with noise and blur in such a way that the process should recover the edges of the image.

Let us denote by u_0 the observed image and u the real image. A model of blurring comes from the degradation of u through some kind of averaging. Indeed, u may be blurred through the application of a kernel: $k(x, s, y, r)$ by means of

$$v_0(x, y) = \int_\Omega u(s, r)\, k(x, s, y, r)\, ds\, dr, \tag{2.1}$$

and we denote this operation by $v_0 = k * u$. The model of degradation we assume is

$$k * u + n = u_0, \tag{2.2}$$

where n is Gaussian white noise, i.e., the values n_i of n at the pixels i are independent random variables, each with a Gaussian distribution of zero mean and variance σ^2. We will use the *signal to noise ratio* of the signal u to measure the level of noise, defined as

$$SNR = \frac{||u - \overline{u}||_{\mathcal{L}^2}}{\sigma},$$

where $\overline{u}$ is the mean of the signal u, i.e., the ratio of the standard deviation of the signal over the standard deviation of the noise. If the kernel k is translation-invariant, i.e.,

there is a function $j(x,y)$ (also called a kernel) such that $k(x,s,y,r) = j(x-s,y-r)$ and the blurring is defined as a "superposition" of js,

$$v_0(x,y) = (j*u)(x,y) = \int_\Omega u(s,r)\, j(x-s,y-r)\, ds\, dr, \tag{2.3}$$

and this isotropic blurring is called *convolution*. Otherwise, if the kernel k is not translation-invariant we call this blurring *anisotropic*. For the sake of simplicity, we suppose that the blurring is coming from a convolution, through a kernel function j such that $j*u$ is a compact integral operator. Typically, j has the following properties, $j(x,y) \geq 0$, $j(x,y) \to 0$, as $(x^2+y^2)^{1/2}$ goes to ∞ and $\int_{\mathbb{R}^2} j(x,y)\, dx\, dy = 1$. For any $\alpha > 0$ the so-called *heat kernel*, defined as

$$j(x,y) = \frac{1}{4\pi\alpha}\, e^{-(x^2+y^2)/4\alpha}, \tag{2.4}$$

is an important example that we will use in our numerical experiments.

The main advantage of the convolution is that if we take the Fourier transform of (2.3) we get

$$\hat{v}_0(k,l) = \hat{j}(k,l)\hat{u}(k,l); \tag{2.5}$$

then, to solve the model (2.2) with $k = j$, we take Fourier transform and we arrive at

$$\hat{j}(k,l)\hat{u}(k,l) + \hat{n}(k,l) = \hat{u_0}(k,l). \tag{2.6}$$

To recover $u(x,y)$, we need to deconvolve, i.e., we have to divide (2.6) by $\hat{j}(k,l)$ and apply the inverse Fourier transform. This procedure is generally very ill-posed. Indeed, j is usually smooth and $\hat{j}(k,l) \to 0$ rapidly as $(k^2+l^2)^{1/2}$ goes to ∞; thus, large frequencies in u_0 get amplified considerably. The function u_0 is generally piecewise smooth with jumps in the function values and derivatives; thus, the Fourier method approximation gives global error estimates of order $O(h)$ (see [11]) and suffers from Gibbs's phenomenon. Discrete direct methods dealing with the linear integral equation (2.6) have been designed by different authors (see [13] and references therein).

One way to make life easier is to consider a variational formulation of the model that regularizes the problem. Our objective is to estimate u from statistics of the noise, blur, and some a priori knowledge of the image (smoothness, existence of edges). This knowledge is incorporated into the formulation by using a functional R that measures the quality of the image u, in the sense that smaller values of $R(u)$ correspond to better images. The process, in other words, consists in the choice of the best quality image among those matching the constraints imposed by the statistics of the noise together with the blur induced by j.

The usual approach consists in solving constrained optimization problem

$$\begin{aligned} &\min_u R(u) \\ &\text{subject to } ||j*u-u_0||^2_{\mathcal{L}^2} = |\Omega|\,\sigma^2, \end{aligned} \tag{2.7}$$

since $n = u_0 - j*u$ and $E(\int_\Omega n^2\, dx) = |\Omega|\,\sigma^2$ ($E(X)$ denotes the expectation of the random variable X) imply that $||j*u-u_0||^2_{\mathcal{L}^2} = \int_\Omega (j*u-u_0)^2\, dx \approx |\Omega|\sigma^2$.

Examples of regularization functionals that can be found in the literature are $R(u) = \|\Delta u\|_{\mathcal{L}^2}, \|\nabla u\|_{\mathcal{L}^2}$, where ∇ is the gradient and Δ is the Laplacian; see [22, 8].

The main disadvantage of using these functionals is that they do not allow discontinuities in the solution, therefore, the edges can not be satisfactorily recovered.

In [19], the *TV norm* is proposed as a regularization functional for the image restoration problem:

$$TV(u) = \int_\Omega |\nabla u|\, dx = \int_\Omega \sqrt{u_x^2 + u_y^2}\, dx. \tag{2.8}$$

The TV norm does not penalize discontinuities in u, and thus allows us to recover the edges of the original image. There are other functionals with similar properties introduced in the literature for different purposes (see, for instance, [7, 5, 25, 2]). The restoration problem can be thus written as

$$\begin{aligned} &\min_u \int_\Omega |\nabla u|\, dx \\ &\text{subject to } \frac{1}{2}\Big(\int_\Omega (j * u - u_0)^2\, dx - |\Omega|\,\sigma^2\Big) = 0. \end{aligned} \tag{2.9}$$

Its Lagrangian is

$$\int_\Omega |\nabla u|\, dx + \frac{\lambda}{2}\Big(\int_\Omega (j * u - u_0)^2\, dx - |\Omega|\,\sigma^2\Big), \tag{2.10}$$

and its Euler–Lagrange equations, with homogeneous Neumann boundary conditions for u, are

$$0 = -\nabla \cdot \left(\frac{\nabla u}{|\nabla u|}\right) + \lambda\,(j * (j * u - u_0)), \tag{2.11}$$

$$0 = \frac{1}{2}\left(\int_\Omega (j * u - u_0)^2\, dx - |\Omega|\,\sigma^2\right). \tag{2.12}$$

There are known techniques (see [3]) for solving the constrained optimization problem (2.9) by exploiting solvers for the corresponding unconstrained problem whose Euler–Lagrange equations are (2.11) for λ fixed. Therefore, for the sake of clarity, we will assume the Lagrange multiplier λ to be known throughout the exposition. For $\nu = \frac{1}{\lambda}$, we can then write the equivalent unconstrained problem as

$$\min_u \int_\Omega \left(\nu\,|\nabla u| + \frac{1}{2}\,(j * u - u_0)^2\right) dx \tag{2.13}$$

and its Euler–Lagrange equation in the more usual form:

$$0 = -\nabla \cdot \left(\frac{\nabla u}{|\nabla u|}\right) + \lambda\, j * (j * u - u_0). \tag{2.14}$$

We call (2.14) the *nonlinear deconvolution model*. The linear deconvolution model would be

$$0 = -\Delta u + \lambda\, j * (j * u - u_0). \tag{2.15}$$

that comes from the Euler–Lagrange equation of the corresponding unconstrained problem with the norm $R(u) = \|\nabla u\|_{\mathcal{L}^2}$.

Since (2.14) is not well defined at points where $\nabla u = 0$, due to the presence of the term $1/|\nabla u|$, it is common to slightly perturb the TV functional to become

$$\int_\Omega \sqrt{|\nabla u|^2 + \beta}\, dx, \tag{2.16}$$

where β is a small positive parameter, or

$$\int_\Omega |\nabla u|_\beta\, dx, \tag{2.17}$$

with the notation ($x \in \mathbb{R}$, $v \in \mathbb{R}^2$)

$$|x|_\beta = \sqrt{x^2 + \beta}, \quad |v|_\beta = \sqrt{|v|^2 + \beta}. \tag{2.18}$$

3. The time dependent model. Vogel and Oman and Chan, Golub, and Mulet devised direct methods to approximate the solution to the Euler–Lagrange equation (2.14) with an a priori estimate of the Lagrange multiplier and homogeneous Neumann boundary conditions. Those methods work well for denoising problems, but the removal of blur becomes very ill-conditioned with a user-dependent choice of parameters. However, stable explicit schemes are preferable when the steady state is quickly reached because the choice of parameters is almost user-independent. Moreover, the programming for our algorithm is quite simple compared to the implicit inversions needed in the above mentioned methods.

Usually, time dependent approximations to the ill-conditioned Euler–Lagrange equation (2.14) are inefficient. This is because a very small time step is required when a simple explicit scheme is used. This is the case with the following formulation due to Rudin, Osher, and Fatemi (see [19]) and Rudin and Osher (see [18]):

$$u_t = -\lambda\, j * (j * u - u_0) + \nabla \cdot \left(\frac{\nabla u}{|\nabla u|} \right) \tag{3.1}$$

with $u(x, y, 0)$ given as initial data (they used as initial guess the original blurry and noisy image u_0) and homogeneous Neumann boundary conditions, i.e., $\frac{\partial u}{\partial n} = 0$ on the boundary of the domain. As t increases, we approach a restored version of our image, and the effect of the evolution should be edge detection and enhancement and smoothing at small scales to remove the noise. This solution procedure is a parabolic equation with time as an evolution parameter and resembles the gradient-projection method of Rosen (see [17]). In this formulation we assume an a priori estimate of the Lagrange multiplier, in contrast with the dynamic change of λ supposed in the Rosen method (see section 6 for details). Equation (3.1) moves each level curve of u normal to itself with normal velocity equal to the curvature of the level surface divided by the magnitude of the gradient of u (see [23, 15, 20]). The constraints are included in the λ-term, and they are needed to prevent distortion and to obtain a nontrivial steady state.

However, this evolution procedure converges very slowly to its steady state since the parabolic term is singular for small gradients. In fact, an ad hoc rule of thumb would indicate that the timestep Δt and the space stepsize Δx need to be related by

$$\frac{\Delta t}{\Delta x^2} \leq c\, |\Delta u|, \tag{3.2}$$

for fixed $c > 0$, for stability. This restriction called the Courant–Friedrichs–Lewy restriction (CFL for short) is what we shall relax. These issues are well documented in numerous experiments. In order to avoid these difficulties, we propose a new time dependent model that accelerates the movement of level curves of u and regularizes the parabolic term in a nonlinear way. In order to regularize the parabolic term we multiply the whole Euler–Lagrange equation (2.14) by the magnitude of the gradient and our time evolution model reads as follows:

$$u_t = -|\nabla u|\,\lambda\, j * (j * u - u_0) + |\nabla u|\,\nabla \cdot \left(\frac{\nabla u}{|\nabla u|}\right). \tag{3.3}$$

We use as initial guess the original blurry and noisy image u_0 and homogeneous Neumann boundary conditions as above, with an a priori estimate of the Lagrange multiplier. Since this model does not increase the total variation of the initial guess, the above choice is reasonable for slightly blurred and noisy images. When the blur is strong we can use as initial guess some regularized linear deconvolution of the blurry and noisy image. In our case we propose the solution of (2.15) with a linear Lagrange multiplier that matches the noise using a fast solver. We have used this choice for the 1D case when strong blur is present (the 2D case is a work in progress). Our current 2D numerical experiments use u_0 as initial guess. The effect of this reformulation, (i.e., preconditioning) is positive in various aspects:

1. The effect of the regularizing term means that the movement of level curves of u is pure mean curvature motion (see [15]).
2. The total movement of level curves goes in the direction of the zeros of $j*u-u_0$ regularized by the anisotropic diffusion introduced by the curvature term.
3. The problem for the denoising case is well-posed in the sense that there exists a maximum principle that determines the solution (see [15]).
4. There are simple explicit schemes, such as Roe's scheme, applied to the convective term and central differencing used for the regularized second order term that behave stably with a CFL restriction of the form

$$\frac{\Delta t}{\Delta x^2} < c$$

   for a fixed number $c > 0$.
5. This procedure is more *morphological* (see [1]) in the pure denoising case; i.e., it operates mainly on the level sets of u and u_0. This is easily seen if we replace u by $h(u)$ and u_0 by $h(u_0)$ with $h' > 0$. Then, (3.3) is invariant, except that $u - u_0$ gets replaced by $(h(u) - h(u_0))/h'(u)$.
6. The numerical steady state reached with this model when the singular term is regularized is different from the one obtained by the TV model, allowing smoother ramps, and thus reducing the staircase effect.
7. Explicit schemes can also be applied for the "anisotropic blurring" case.

The anisotropic diffusion introduced in this model is a nonlinear way to discriminate scales of computation. This never occurs with a linear model, (e.g. the linear deconvolution model), because in this case we would have the linear heat equation with constant diffusion. Thus, our model (3.3) can be seen as a convection-diffusion equation with *morphological* convection and anisotropic diffusion. Items 1, 2, and 5 above are desirable properties of any image processing algorithm; i.e., operations should be performed on the *level contours* of the image. This yields contrast invariant results, and this is the basis for the rigorous analysis performed in [1].

4. Explicit numerical schemes for the 1D model. The 2D model described before is more regular than the corresponding 1D model because the 1D original optimization problem is barely convex. For the sake of understanding the numerical behavior of our schemes, we also discuss the 1D model. The Euler–Lagrange equation in the 1D case reads as follows:

$$0 = -\left(\frac{u_x}{|u_x|}\right)_x + \lambda\, j * (j * u - u_0). \tag{4.1}$$

This equation can be written either as

$$0 = -\left(\frac{u_x}{|u_x|_\beta}\right)_x + \lambda\, j * (j * u - u_0), \tag{4.2}$$

using the small regularizing parameter $\beta > 0$ introduced at the end of the previous section, or

$$0 = -\delta(u_x) u_{xx} + \lambda\, j * (j * u - u_0), \tag{4.3}$$

using the δ-function.

The Rudin–Osher–Fatemi model (ROF model) in terms of the δ-function will read as follows:

$$u_t = -\lambda\, j * (j * u - u_0) + \delta(u_x)\, u_{xx}. \tag{4.4}$$

Our model in 1D will be

$$u_t = -|u_x|\, \lambda\, j * (j * u - u_0) + \frac{\beta}{\beta + u_x^2}\, u_{xx}, \tag{4.5}$$

where $\beta > 0$ is the small regularizing parameter. The parameter $\beta > 0$ in this model is estimated from the local amount of noise. We have found for our model, through our numerical experiments in 1D and 2D, that β can be estimated as the standard deviation of the noise. We have found, through our numerical experiments, that this regularization of the second order term removes spurious oscillations near discontinuities.

We can also state our model in terms of the δ function as

$$u_t = -|u_x|\, \lambda\, j * (j * u - u_0) + |u_x|\, \delta(u_x)\, u_{xx}, \tag{4.6}$$

where a convolution of the δ function must be used in practice. The intensity of this kind of convolution decides which scale the diffusion term is acting. In this paper, we always approximate δ by

$$\delta(z) \approx \beta \cdot (z^2 + \beta)^{-3/2} \tag{4.7}$$

in order to be consistent with the regularization used for the absolute value function (2.18). Consistency in this case means that the derivative of the regularized absolute value function must be equal to the regularized sign function, and the derivative of the above must be equal to the regularized delta function.

A radical way to make the coefficient of u_{xx} nonsingular is to solve the evolution model:

$$u_t = -\frac{1}{\delta(u_x)}\, \lambda\, j * (j * u - u_0) + u_{xx}. \tag{4.8}$$

This model works in such a manner that away from extrema we have a large multiplier of $-j * (j * u - u_0)$ and at extrema it is just the heat equation.

These evolution models are initialized with the blurry and noisy signal u_0 and homogeneous Neumann boundary conditions, and with a prescribed Lagrange multiplier for slightly blurred and noisy signals. If the signal is strongly blurred, then we propose to use an initial guess, u_{00}, which is the solution of the *linear deconvolution model* equation (2.15) with a linear Lagrange multiplier that matches the noise and allows an increase in total variation of the signal.

We estimated $\lambda > 0$ near the maximum value such that the explicit scheme is stable under appropriate CFL restrictions (see below), provided β is chosen to be the standard deviation of the noise.

In order to convince the reader about the speed and programming simplicity of our model, we shall give the details of the first order scheme for the 1D pure denoising model, i.e.,

$$u_t = -|u_x|\,\lambda\,(u - u_0) + \frac{\beta}{\beta + u_x^2}\,u_{xx}. \tag{4.9}$$

Let u_j^n be the approximation to the value $u(x_j, t_n)$, where $x_j = j\Delta x$ and $t_n = n\Delta t$. Then the scheme for the problem (4.9) will be

$$\frac{u_j^{n+1} - u_j^n}{\Delta t} = -|ug_j|\,\lambda\,(u_j^n - u_0(x_j)) + \frac{\beta}{\beta + g_j^2}\,\frac{u_{j+1}^n - 2u_j^n + u_{j-1}^n}{\Delta x^2}, \tag{4.10}$$

where

$$g_j = \frac{u_{j+1}^n - u_{j-1}^n}{2\Delta x}$$

and ug_j is the upwind gradient, i.e.,

$$ug_j = \frac{u_j^n - u_{j-1}^n}{\Delta x}$$

if $g_j(u_j^n - u_0(x_j)) > 0$ and

$$ug_j = \frac{u_{j+1}^n - u_j^n}{\Delta x}$$

if $g_j(u_j^n - u_0(x_j)) < 0$

Our general explicit scheme has the following features:

1. We use central differencing for u_{xx}.
2. The convolution operator j is computed by evolving the heat equation $u_t = u_{xx}$ with the explicit Euler method in time and central differencing in space with a CFL restriction $\frac{\Delta t}{\Delta x^2} < 0.25$, corresponding to an $\epsilon > 0$ of the 1D heat kernel,

$$j(x) = \frac{1}{2\sqrt{\pi\epsilon}}\,e^{-x^2/4\epsilon}, \tag{4.11}$$

in order to ensure homogeneous Neumann boundary conditions. We note that we may compute the convolution operator through a direct convolution with a discrete approximation of the kernel j (*point spread function* (PSF). In

order to make convolution faster the FFT can be used, provided we consider periodic signals and therefore the convolution operator is cyclic. However, the reader should be aware that most of the available FFT packages are designed such that the signals are enlarged with zero values. For the sake of computational efficiency and consistency with homogeneous Neumann boundary conditions a work in progress is to convolve, using the *fast cosine transform*, enlarging the signal with the mirror image.

3. We use upwind Roe differencing (see [16, 10]), checking the direction of propagation by computing the sign of the derivative of the coefficient of $j*(j*u-u_0)$ with respect to u_x times the sign of this term. Indeed, for our evolution model (4.5) it is enough to check the sign of $u_x \cdot j*(j*u-u_0)$. For the model (4.8) we get the same direction of propagation as before. We note that there is no notion of "entropy condition satisfying" discontinuities in image processing; thus we omit the usual "entropy-fix" applied to the Roe solver in this work.
4. The CFL condition depends on λ and β.

Indeed, the parabolic term in our model (4.5) gives a CFL restriction

$$\frac{\Delta t}{\Delta x^2} \leq \frac{\beta + u_x^2}{2\beta}, \tag{4.12}$$

and the convection term gives

$$\frac{\Delta t}{\Delta x} \leq c\,\lambda \sqrt{1 + \frac{\beta}{u_x^2}} \tag{4.13}$$

for fixed c. These restrictions are reasonable at local extrema and near edges, compared with the parabolic CFL restriction that corresponds to the reaction-diffusion ROF model (4.4):

$$\frac{\Delta t}{\Delta x^2} \leq \frac{1}{2\delta(u_x)}, \tag{4.14}$$

which is too stiff along flat regions or at local extrema. The CFL restriction coming from the convection term in the radical model (4.8) is better but also unfortunate:

$$\frac{\Delta t}{\Delta x} \leq \frac{\beta}{3|u_x|(\beta + u_x^2)^{1/2}}. \tag{4.15}$$

Thus, our model is more convenient from this point of view.

5. Explicit numerical schemes for the 2D model. We can express our 2D model in terms of explicit partial derivatives as

$$u_t = -\sqrt{u_x^2 + u_y^2}\;\lambda\, j*(j*u-u_0) + \frac{u_{xx}(u_y^2+\beta) - 2u_{xy}u_xu_y + u_{yy}(u_x^2+\beta)}{u_x^2+u_y^2+\beta}, \tag{5.1}$$

using u_0 as initial guess and homogeneous Neumann boundary conditions (i.e., absorbing boundary). We only consider in this paper slightly blurred images, therefore this choice of the initial guess is reasonable.

We remark that the above regularization of the curvature term is consistent with one used in our 1D model, i.e., for $u_y = 0$ we get (4.5).

The parameter β is the standard deviation of the noise and it is chosen to be very small for a pure deblurring problem. Then, the Lagrange multiplier $\lambda > 0$ is chosen as large as possible subject to the above mentioned CFL restriction $\frac{\Delta t}{\Delta x^2} < c$.

Let u_{ik}^n be the approximation to the value $u(x_i, y_k, t_n)$, where $x_i = i\Delta x$, $y_k = k\Delta y$, and $t_n = n\Delta t$, where Δx, Δy, and Δt are the spatial stepsizes and the time stepsize, respectively. We define the quantities $v_0 = j * u_0$ and $w_{ik}^n = j * j * (u_{ik}^n)$. We point out that we used for j the convolution with the 2D heat kernel, (2.4), in our experiments, aproximated by evolving the 2D heat equation $u_t = u_{xx} + u_{yy}$ by means of the explicit Euler method in time and central differencing in space. Then our first order scheme reads as follows:

$$\frac{u_{ik}^{n+1} - u_{ik}^n}{\Delta t} = -\sqrt{ug_{ik}^{x\ 2} + ug_{ik}^{y\ 2}}\ \lambda\,(w_{ik}^n - v_0(x_i, y_k)) + s_{ik}^n, \tag{5.2}$$

where the second order term is defined by

$$s_{ik}^n := 0 \tag{5.3}$$

if $g_{ik}^{x\ 2} + g_{ik}^{y\ 2} < \beta$ and

$$s_{ik}^n := \frac{g_{ik}^{xx}\, g_{ik}^{y\ 2} - 2g_{ik}^{xy} g_{ik}^x g_{ik}^y + g_{ik}^{yy} g_{ik}^{x\ 2}}{g_{ik}^{x\ 2} + g_{ik}^{y\ 2}} \tag{5.4}$$

otherwise, where

$$g_{ik}^x = \frac{u_{i+1,k}^n - u_{i-1,k}^n}{2\Delta x}, \tag{5.5}$$

$$g_{ik}^y = \frac{u_{i,k+1}^n - u_{i,k-1}^n}{2\Delta y}, \tag{5.6}$$

$$g_{ik}^{xx} = \frac{u_{i+1,k}^n - 2u_{ik}^n + u_{i-1,k}^n}{\Delta x^2}, \tag{5.7}$$

$$g_{ik}^{yy} = \frac{u_{i,k+1}^n - 2u_{ik}^n + u_{i,k-1}^n}{\Delta y^2}, \tag{5.8}$$

$$g_{ik}^{xy} = \frac{u_{i+1,k+1}^n - u_{i-1,k+1}^n - u_{i+1,k-1}^n + u_{i-1,k-1}^n}{2\Delta x \Delta y}; \tag{5.9}$$

ug_{ik}^x is the upwind gradient in the x-direction, i.e.,

$$ug_{ik}^x = \frac{u_{ik}^n - u_{i-1,k}^n}{\Delta x} \tag{5.10}$$

if $g_{ik}^x(w_{ik}^n - v_0(x_i, y_k)) > 0$; and

$$ug_{ik}^x = \frac{u_{i+1,k}^n - u_{ik}^n}{\Delta x} \tag{5.11}$$

if $g^x_{ik}(w^n_{ik} - v_0(x_i, y_k)) < 0$; and ug^y_{ik} is the upwind gradient in the y-direction, i.e.,

$$ug^y_{ik} = \frac{u^n_{ik} - u^n_{i,k-1}}{\Delta y} \tag{5.12}$$

if $g^y_{ik}(w^n_{ik} - v_0(x_i, y_k)) > 0$ and

$$ug^y_{ik} = \frac{u^n_{i,k+1} - u^n_{ik}}{\Delta y} \tag{5.13}$$

if $g^y_{ik}(w^n_{ik} - v_0(x_i, y_k)) < 0$.

A very simple way to extend this scheme to get high order accuracy is to follow Shu–Osher prescription (see [21]). Thus, we consider a method of lines, using an explicit high order Runge–Kutta method in time and using a method of spatial ENO reconstruction (see [24, 9, 21, 12]), of the same order, for the convection term, applied on every time substep.

We have tested the Van Leer second order MUSCL (defined in [24]) spatial reconstruction using the **minmod** function as slope-limiter together with classical second order Runge–Kutta method and the third order PHM spatial reconstruction as in [12], using as slope-limiter the **harmod** function, consisting of the harmonic mean of the lateral slopes when they have the same sign and zero when they have different sign, together with the third order Shu–Osher Runge–Kutta method of [21]. We have found that these explicit methods are stable and give high accuracy under the same CFL restrictions as the first order scheme.

As a sample we shall describe the second order MUSCL method. Since the Runge–Kutta methods used here are linear combination of first order explicit Euler timesteps, it is enough to formulate one Euler step (in fact, in this case it is Heun's method which is the arithmetic mean of two Euler timesteps). Following the notation used above we have

$$\frac{u^{n+1}_{ik} - u^n_{ik}}{\Delta t} = -\sqrt{rug^x_{ik}{}^2 + rug^y_{ik}{}^2}\ \lambda\,(w^n_{ik} - v_0(x_i, y_k)) + s^n_{ik}, \tag{5.14}$$

where the reconstructed upwind gradients rug^x_{ik} and rug^y_{ik} are computed in the following way. We reconstruct the left x-gradient in (x_i, y_k) from the linear function

$$pl(x) := m_{i-1}(x - x_{i-1/2}) + \frac{u^n_{ik} - u^n_{i-1,k}}{\Delta x}, \tag{5.15}$$

where

$$m_{i-1} = \operatorname{minmod}(g^{xx}_{i-1,k}, g^{xx}_{i,k}) \tag{5.16}$$

computed in x_i, i.e.,

$$gl^x_i := pl(x_i), \tag{5.17}$$

where the *minmod* function is defined as

$$\operatorname{minmod}(r, s) := \frac{1}{2}\,\min(|r|, |s|)\,(\operatorname{sgn}(r) + \operatorname{sgn}(s)), \tag{5.18}$$

sgn being the sign function. Analogously, we have the reconstructed right x-gradient, gr^x_i, as

$$gr^x_i := pr(x_i), \tag{5.19}$$

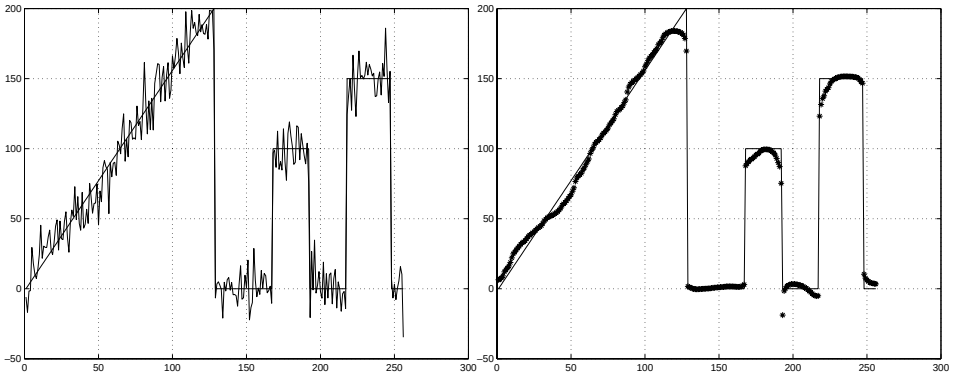

FIG. 6.1. *Left: original vs. noisy* 1D *image. Right: original vs. recovered* 1D *image.*

where

$$pr(x) := m_i(x - x_{i+1/2}) + \frac{u^n_{i+1,k} - u^n_{i,k}}{\Delta x}, \tag{5.20}$$

where

$$m_i = \text{minmod}(g^{xx}_{i,k}, g^{xx}_{i+1,k}). \tag{5.21}$$

Then the reconstructed upwind gradient in the x-direction is defined from the mean value

$$gm^x_i := \frac{gl^x_i + gr^x_i}{2} \tag{5.22}$$

as

$$rug^x_{ik} = gl^x_i \tag{5.23}$$

if $gm^x_i(w^n_{ik} - v_0(x_i, y_k)) > 0$ and

$$rug^x_{ik} = gr^x_i \tag{5.24}$$

if $gm^x_i(w^n_{ik} - v_0(x_i, y_k)) < 0$. The procedure in the y-direction is similar.

6. Numerical experiments. In this section, we perform some numerical experiments in 1D and 2D.

We have used 1D signals with values in the range $[0, 255]$. Figure 6.1 (left) represents the original signal vs. the noisy signal with $SNR \approx 5$. Figure 6.1 (right) represents the original signal vs. the recovered signal after 80 iterations with first order scheme with CFL number 0.25. The estimated $\lambda = 0.05$ was computed as a value near the maximum allowed for stability, using the explicit Euler method in time. We have used $\beta = 15$ in this experiment in order to achieve the appropriate amount of diffusion at small scales and this value corresponds to the standard deviation of the noise. Let us observe the very reduced *staircase effect*, compared with the usual one obtained with either fixed-point iterative methods or nonlinear primal-dual methods (see [4]).

In order to show the power of reduction of the *staircase effect* with our model we apply our explicit procedure to a very unusual noisy signal, proposed by Chambolle

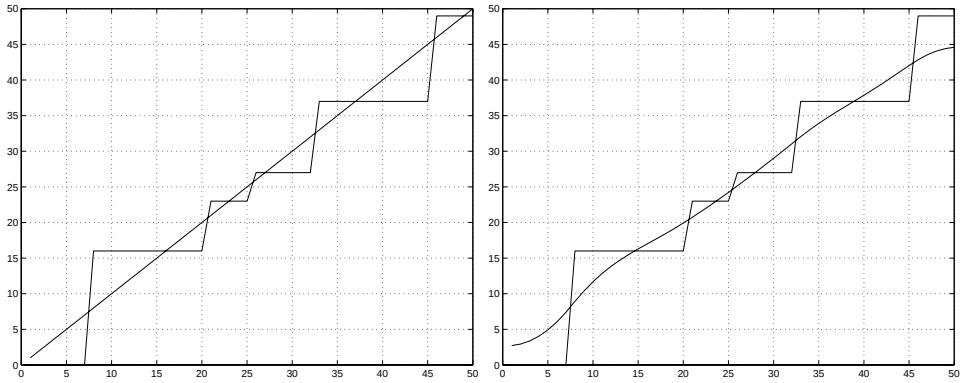

FIG. 6.2. *Left: original ramp* 1D *signal vs. staircased noisy* 1D *signal. Right: noisy signal vs. recovered* 1D *signal.*

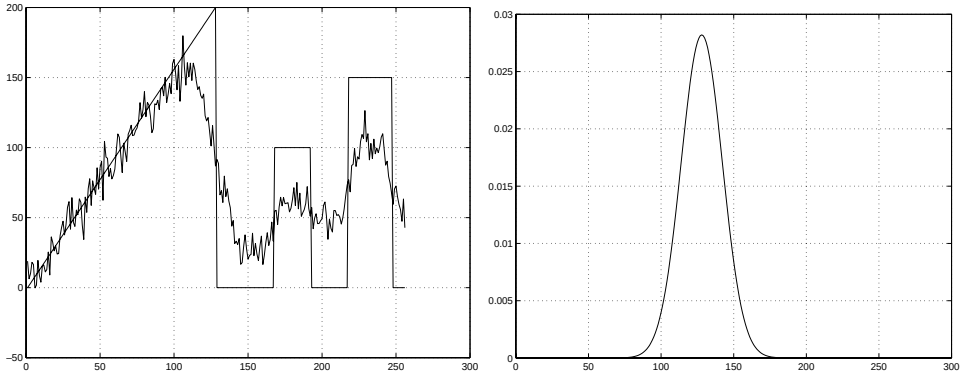

FIG. 6.3. *Left: original vs. blurry and noisy* 1D *signal. Right:* 1D *PSF.*

and Lions in [5]. The original signal we want to recover is simply the function $u(x) = x, x \in [0, 50]$, and the noise has turned it into a piecewise constant nondecreasing function. The standard deviation of the noise is approximately $\sigma \approx 3.5$, (see Figure 5 in [5]). The signal of Figure 6.2 (left) represents the original ramp signal versus the staircased noisy signal with $\sigma = 3.5$. The signal of Figure 6.2 (right) represents the noisy signal versus the recovered signal after 80 iterations with our first order scheme for CFL number 0.25. We use $\beta = \sigma$ and the estimated Lagrange multiplier is $\lambda = 0.005$.

We note that for the above 1D pure denoising problems we always use the noisy signal as initial guess.

However, in the following experiment where strong blur is present we use a different choice. Figure 6.3 (left) represents the original signal vs. the strongly blurred and noisy signal with $\epsilon = 50$ (as in (4.11)), and $SNR \approx 5$. The aproximation to the PSF of the corresponding Gaussian blur is represented in Figure 6.3 (right). We solve the linear deconvolution model (2.15) by using a Lagrange multiplier equal to 1, using the Matlab FFT package, which uses homogeneous periodic boundary conditions. Figure 6.4 (left) represents computed solution vs. the blurry and noisy signal. The linear deconvolved signal u_{00} appears to be an oscillatory approximation to a smooth function. Edges are not apparent with this somewhat denoised result. The denoising is

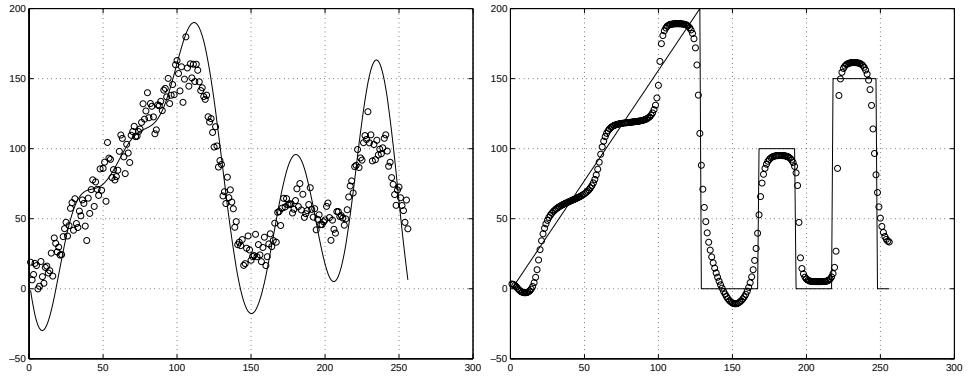

FIG. 6.4. *Left: computed linear deconvolution* u_{00} *vs. blurry and noisy* 1D *signal. Right: original vs. recovered* 1D *signal.*

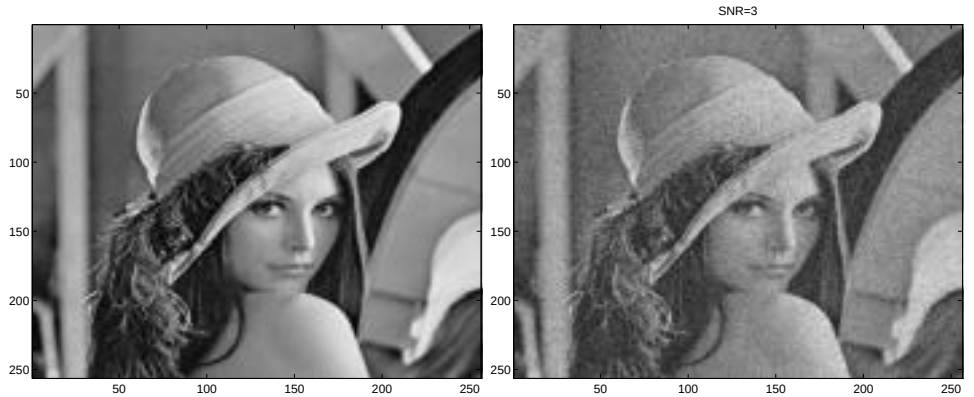

FIG. 6.5. *Left: original image. Right: noisy image, SNR*≈ 3.

due to the regularization effect of the chosen $\lambda = 1$ that matches the noise. Moreover, the total variation of u_{00} is substantially larger than the signal u_0. Then we use our model, using u_{00} as initial guess (u_0 in the equation!), and after 200 iterations with first order scheme with CFL number 0.1, we get the signal represented in Figure 6.4 (right). We use $\beta = 9$, which corresponds to the standard deviation of the noise. The estimated $\lambda = 4.5$ was computed as a value near the maximum allowed for stability. We also observe a reduced *staircase effect*. We performed many other experiments with 1D signals, obtaining similar results.

All our 2D numerical experiments were performed on the original image (Figure 6.5 (left)) with 256×256 pixels and dynamic range in $[0, 255]$.

The third order scheme we used in our 2D experiments was based on the third order Runge–Kutta introduced by Shu and Osher (see [21]) to evolve in time with a third order spatial approximation based on the PHM reconstruction introduced in [12].

Our first 2D experiment was made on the noisy image, see Figure 6.5 (right), with a SNR which is approximately 3. Details of the approximate solutions using the Chan–Golub–Mulet primal-dual method and our time dependent model using the third order Roe's scheme (described above) are shown in Figure 6.6. We used $\lambda \approx 0.0713$ and we perform 50 iterations with $\Delta t/\Delta x^2 = 0.1$. We used the same estimated λ as the

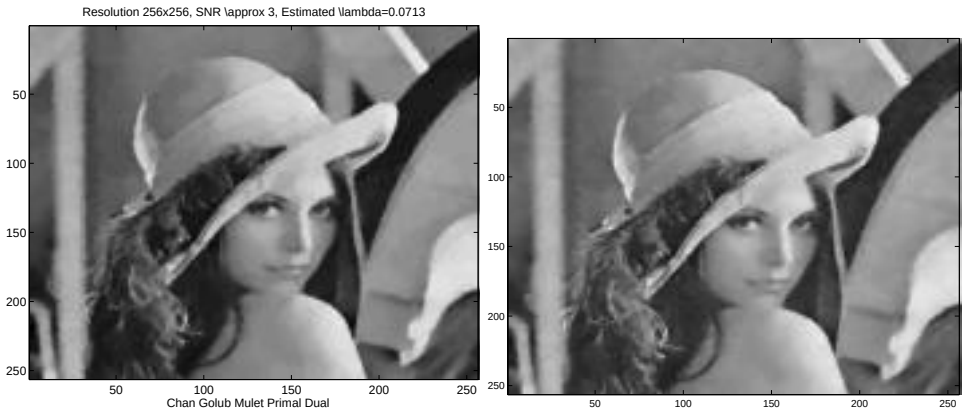

FIG. 6.6. *Left: image obtained by the Chan–Golub–Mulet primal-dual method. Right: image obtained by our time evolution model, with* 50 *timesteps,* $\Delta t/\Delta x^2 = 0.1$, $\beta = 14$, *and* $\lambda = 0.0713$.

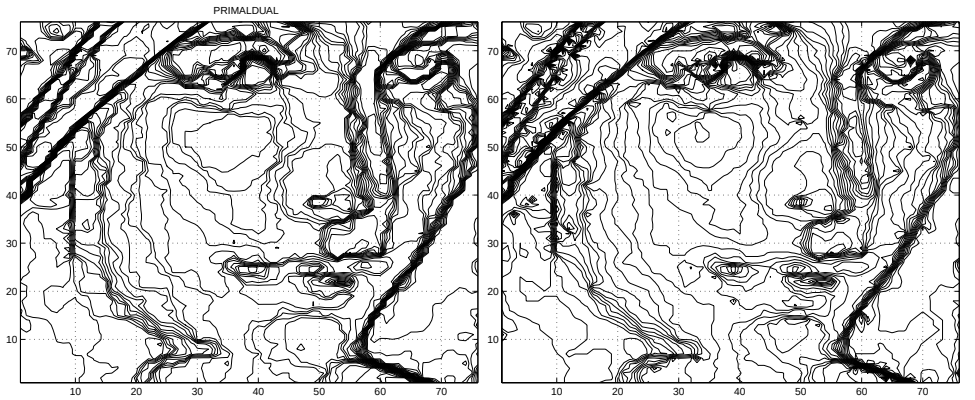

FIG. 6.7. *Left: isointensity contours of part of the image obtained by the primal-dual method. Right: isointensity contours of part of the image obtained by our time evolution model.*

one used for the primal-dual method, and we observed that this value corresponds to a value near the largest we allowed for stability under the timestep restriction. We use $\beta = 14$ which is the standard deviation of the noise corresponding to a signal to noise ratio $SNR = 3$. We also remark that the third order Runge–Kutta method used enhances the diffusion at small scales. The contour plots are shown in Figure 6.7. The numerical steady state obtained with our model is smoother than the one obtained for the TV model, which appears to be staircased. This is because numerically our approximation of the convection term involves hyperbolic upwind ideas.

Our second 2D experiment is a pure deblurring problem. Figure 6.8 (left), corresponds to the original image blurred with Gaussian blur, where $\alpha = 5$ as in (2.4). We remark that we computed the convolution operator j by evolving the 2D heat equation with explicit Euler method in time and central differencing in space with a CFL number of 0.125 in order to ensure homogeneous Neumann boundary conditions. In Figure 6.8 (right), we represent the approximation using our third order Roe's scheme, where we perform 50 iterations with a CFL restriction $\Delta t/\Delta x^2 = 0.1$. We have used $\lambda = 1.5$ (near the maximum value that allows stability for the above CFL restriction) and $\beta = 0.01$, which is small since no noise is present. The isointen-

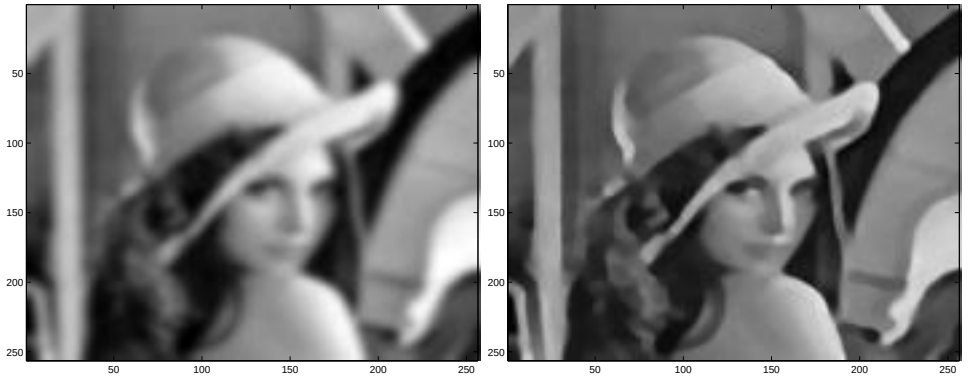

FIG. 6.8. *Left: image blurred with Gaussian blur with* $\alpha = 5$. *Right: image restored with our model, using third order Roe's scheme with* 50 *timesteps and* $\Delta t/\Delta x^2 = 0.1$.

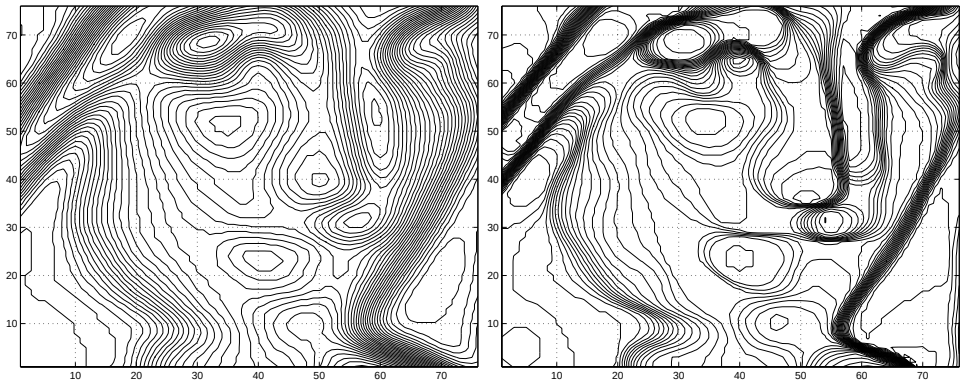

FIG. 6.9. *Left: isointensity contours of part of the blurred image. Right: isointensity contours of part of the image restored by using our time evolution model.*

sity contours showed in Figure 6.9 make clear the edge enhancement obtained through our algorithm.

Our 2D critical experiment was performed on the slightly blurred and noisy image represented in Figure 6.10 (left), with Gaussian blur where $\alpha = 5$ as in (2.4) and $SNR \approx 5$.

We have used $\beta = 7$ (the standard deviation of the noise), and $\lambda = 1.5$, near the largest value allowing stability. We performed 50 iterations with a CFL restriction $\Delta t/\Delta x^2 = 0.1$ using our third order Roe's scheme, obtaining the approximation represented in Figure (6.10, right). Let us observe the denoising and deblurring effect in the isointensity contours picture represented in Figure (6.11).

Finally, we shall include the convergence history of the 1D pure denoising problem experiment presented above. In Figure 6.12 we represent the semilog plot of the $\mathcal{L}^2$-norm of the differences between consecutive iterates vs. the number of iterations and the plot of the evolution of the total variation of the solution. We observe "superlinear" convergence along the first third of the evolution and linear convergence along the remainder. We have obtained similar convergence histories for 1D deblurring and denoising problems. We pointed out that all our experiments were performed with a constant timestep and thus, the computational cost is very low compared with the

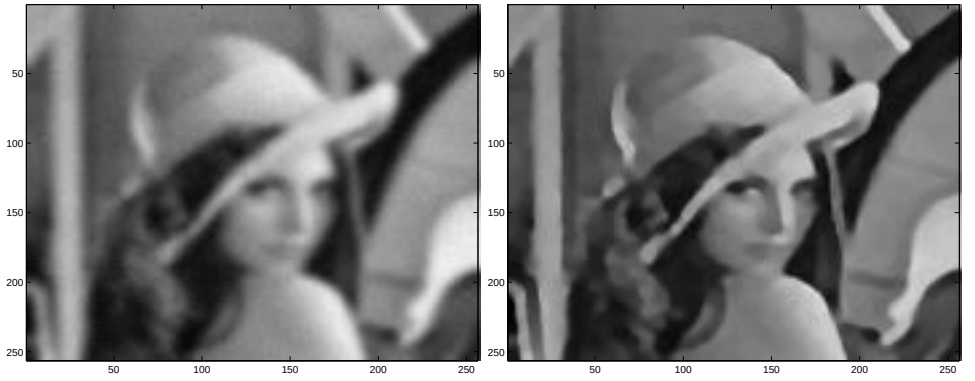

FIG. 6.10. *Left: image blurred with Gaussian blur with* $\alpha = 5$ *and noisy with* $SNR \approx 10$. *Right: image restored with our model, using third order Roe's scheme with* 50 *timesteps and* $\Delta t/\Delta x^2 = 0.1$.

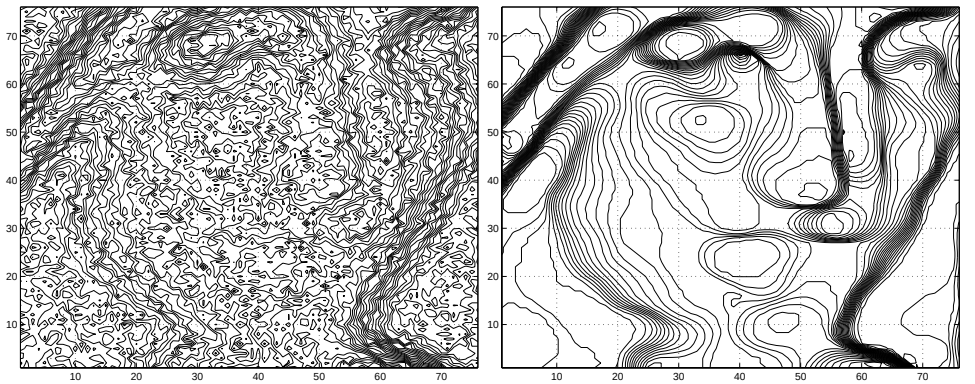

FIG. 6.11. *Left: isointensity contours of part of the blurred and noisy image. Right: isointensity contours of part of the image restored by using our time evolution model.*

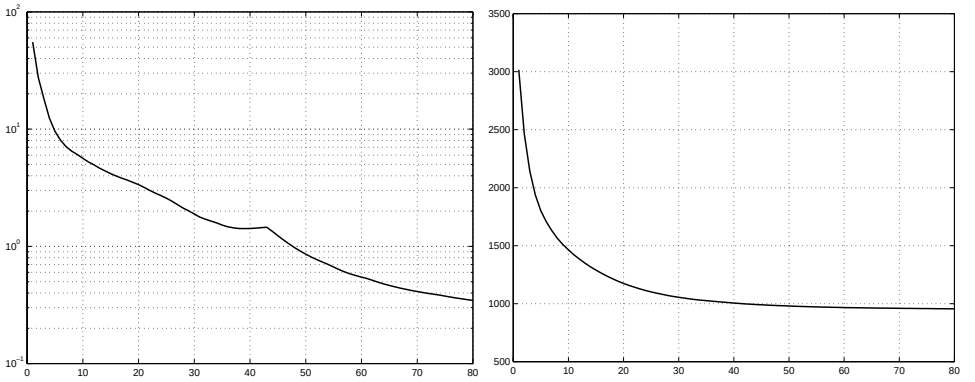

FIG. 6.12. *Left: semilog differences of iterates vs. number of iterations for the pure denoising problem. Right: total variation vs. number of iterations.*

semi-implicit methods. These usually require one third of the number of iterations we needed, but every step of the semi-implicit method requires about five iterations of the preconditioned conjugate gradient method to invert.

7. Concluding remarks. We presented a new time dependent model to solve the nonlinear TV model for noise removal and deblurring together with a very simple explicit algorithm based on Roe's scheme of fluid dymamics. The numerical algorithm is stable with a reasonable CFL restriction, it is easy to program, and it converges quickly to the steady state solution, even for deblurring and denoising problems. The algorithm is fast and efficient since no inversions are needed for deblurring problems with noise. Our time dependent model is based on level set motion that makes the procedure *morphological* and appears to satisfy a maximum principle in the pure denoising case, using as initial guess the noisy image. We also have numerical evidence (through our numerical tests) of this stability in the deblurring case.

SCHUR-TYPE METHODS FOR SOLVING LEAST SQUARES PROBLEMS WITH TOEPLITZ STRUCTURE*

HAESUN PARK† AND LARS ELDÉN‡

Abstract. We give an overview of fast algorithms for solving least squares problems with Toeplitz structure, based on generalization of the classical Schur algorithm, and discuss their stability properties. In order to obtain more accurate triangular factors of a Toeplitz matrix as well as accurate solutions for the least squares problems, methods based on corrected seminormal equations (CSNE) can be used. We show that the applicability of the generalized Schur algorithm is considerably enhanced when the algorithm is used in conjunction with CSNE.

Several numerical tests are reported, where different variants of the generalized Schur algorithm and CSNE are compared for their accuracy and speed.

1. Introduction.

We consider the linear least squares (LS) problem

$$\min_x \|Tx - b\|_2, \tag{1.1}$$

where $T \in \mathbf{R}^{m\times n}$, $m \geq n$, is a Toeplitz matrix with $\operatorname{rank}(T) = n$,

$$T = \begin{pmatrix} t_0 & t_{-1} & & \cdots & t_{-n+1} \\ t_1 & t_0 & t_{-1} & & \vdots \\ \vdots & t_1 & t_0 & \ddots & \\ \vdots & & t_1 & \ddots & t_{-1} \\ \vdots & & & \ddots & t_0 \\ \vdots & & & & t_1 \\ \vdots & & & & \vdots \\ t_{m-1} & & & & t_{m-n} \end{pmatrix},$$

and $b \in \mathbf{R}^m$ is an arbitrary vector (b is arbitrary in the sense that neither $[T\ b]$ nor $[b\ T]$ is Toeplitz). Although the results presented in this paper apply for complex Toeplitz problems as well, we will restrict the discussion to real cases for simplicity. Throughout this paper, the notation T will denote an $m \times n$ real Toeplitz matrix.

‡Department of Mathematics, Linköping University, S–581 83 Linköping, Sweden (laeld@math.liu.se).

It is well known that the LS problem (1.1) can be solved using the QR decomposition of the matrix T,

$$T = Q \begin{pmatrix} R \\ 0 \end{pmatrix}, \tag{1.2}$$

where $Q \in \mathbf{R}^{m \times m}$ is orthogonal and $R \in \mathbf{R}^{n \times n}$ is upper triangular. To denote the upper triangular factor R for T in (1.2), we will use the notation

$$R = \mathrm{qr}(T). \tag{1.3}$$

The QR decomposition can be computed in $O(mn^2)$ flops (floating point operations, 1 flop $\approx$ 1 addition and 1 multiplication) in general, using, e.g., Householder transformations (see, e.g., [19, Chap. 5]). For a Toeplitz matrix T, several fast algorithms of $O(mn)$ flops exist. The first such algorithm was developed by Sweet [42] taking advantage of the Toeplitz structure and it was improved by Bojanczyk, Brent, and de Hoog [9]. The algorithm due to Chun, Kailath, and Lev-Ari [12] takes advantage of the displacement structure of Toeplitz matrices and it is essentially the same as the algorithm in [9]. It can be shown ([12] and sections 2.1–2.2 in the present paper) that these algorithms are generalizations of a classical algorithm by Schur [21, 36, 37]. In [29], Nagy modified the algorithm presented in [12] to produce R^{-1} instead of R factor in the QR decomposition. He also showed how to compute the vector $Q^T b$ directly instead of computing the full Q factor. For a fast algorithm which is not related to the Schur algorithm but is based on lattice structure and inner product, see [14].

In section 5.2 we will demonstrate that for large Toeplitz LS problems, fast algorithms based on the generalized Schur algorithm are significantly faster than the standard algorithm from LAPACK [2] which is based on Householder transformations. However, the stability properties of the fast algorithms are inferior to those of the standard algorithm [29, 10, 40, 32]. In this paper, we will present several modifications and enhancements that make the fast algorithm more accurate and reliable and investigate stability properties of these fast algorithms that are based on the generalized Schur algorithm. Then several fast Schur-type algorithms are compared by experimentation to identify fast and accurate practical algorithms for Toeplitz LS problems.

Recently, we showed [32] that the accuracy of the upper triangular factor R computed by the generalized Schur algorithm is comparable to that of R computed as the Cholesky factor of $T^T T$, and therefore it is worse than that computed from the stable QR decomposition algorithms such as the Householder or Givens methods. We also showed that in many cases it is possible to *improve the accuracy of R factor* computed by the generalized Schur algorithm by postprocessing the R factor using corrected seminormal equations (CSNE) [5, 3].

Given the upper triangular factor R in the QR decomposition of T, the LS problem (1.1) can be solved using the seminormal equations (SNE)

$$R^T R x = T^T b. \tag{1.4}$$

The SNE method is not recommended in general [5] due to the possible loss of numerical accuracy. However, the SNE method has the advantage that it does not require the Q factor from the QR decomposition (1.2) of T. In addition, when one step of iterative refinement is applied to the SNE (1.4), we obtain the CSNE method, and the accuracy of the solution can be greatly improved [5]. In fact, in all of the existing fast

Toeplitz QR decomposition algorithms, the Q factor is computed based on the similar recursion that is used for computing the R factor, and the orthogonality and accuracy of the Q factor can be poor. It is important to note, however, that the analysis of the SNE and CSNE methods in [5] assumes that R is computed by a backward stable method (e.g., Householder transformations). If R is inaccurately computed, then the applicability of these methods may be severely restricted as shown in [3, sect. 6.6.5].

The rest of the paper is organized as follows. In section 2, the generalization of the Schur algorithm is summarized and several ways for solving Toeplitz LS problems are shown utilizing the generalized Schur algorithm and displacement structure of the LS problems. In section 3, a new forward error analysis for the generalized Schur algorithm is given. Some variants for applying the corrected seminormal equations for improving stability of the fast algorithms are discussed in section 4. Then in section 5, numerical test results comparing computational speed and accuracy of several fast algorithms are presented.

2. Generalized Schur algorithm. In this section, we first review the displacement representation and the generalized Schur algorithm. Then we show that the algorithm can be used for solving the Toeplitz LS problem in several different ways.

Suppose a symmetric positive definite matrix $K \in \mathbf{R}^{n\times n}$ can be represented as

$$K = \sum_{i=1}^{q} U_i^T U_i - \sum_{i=q+1}^{d} U_i^T U_i, \tag{2.1}$$

where $U_i \in \mathbf{R}^{n\times n}$, $1 \le i \le d$, are upper triangular *Toeplitz* matrices. This is called the *displacement representation* of K, and the *displacement rank* is defined to be the minimum value of d that allows such representation [12, 27]. The matrix K that satisfies (2.1) can also be represented as

$$K - Z_n K Z_n^T = \sum_{i=1}^{q} x^{(i)} {x^{(i)}}^T - \sum_{i=q+1}^{d} x^{(i)} {x^{(i)}}^T, \tag{2.2}$$

where Z_n is the lower shift matrix with ones on the first subdiagonal and zeros elsewhere, and the vectors $x^{(i)}$ are related to the matrices U_i by $U_i = \mathrm{up}(x^{(i)})$ [26], [12, Lemma 1], where

$$\mathrm{up}\begin{pmatrix} u_1 \\ u_2 \\ \vdots \\ u_n \end{pmatrix} = \begin{pmatrix} u_1 & u_2 & u_3 & \cdots & \cdots & u_n \\ & u_1 & u_2 & u_3 & \cdots & u_{n-1} \\ & & u_1 & u_2 & \ddots & \\ & & & \ddots & \ddots & \vdots \\ & & & & u_1 & u_2 \\ & & & & & u_1 \end{pmatrix}.$$

According to (2.2), $\mathrm{rank}(K - Z_n K Z_n^T) = d$, which explains the terms displacement structure and displacement rank. A survey of theory and applications of the displacement concept is given in [27], and generalizations are presented in [25].

When K is a symmetric positive definite Toeplitz matrix, it has a displacement representation with $q = 1$ and $d = 2$, and the Cholesky decomposition $K = U^T U$ can be computed by the well-known, original *Schur algorithm* [21, 36, 37]. The relation between the displacement representation and the Schur algorithm is discussed in [24].

The generalized Schur algorithm, summarized in section 2.1, is a fast procedure for computing the upper triangular factor of structured matrices that have a displacement representation. In general, the Cholesky decomposition of a symmetric positive definite matrix $K \in \mathbf{R}^{n\times n}$ with the displacement representation (2.1) can be computed in $O(dn^2)$ flops by a generalization of the Schur algorithm. The algorithm can be used in the following several ways for computing the solution of the LS problem (1.1) with Toeplitz structure:

(1) When $[T\ b]$ (or $[b\ T]$) is Toeplitz, as in linear prediction, the generalized Schur algorithm can be used to compute the triangular factor of $[T\ b]$

$$\begin{pmatrix} R & w \\ 0 & \kappa \end{pmatrix} = \mathrm{qr}([T\ b]), \tag{2.3}$$

where $w \in \mathbf{R}^{n\times 1}$ and $\kappa \in \mathbf{R}$. Then the LS solution is obtained by solving the system $Rx = w$ (a slight modification is needed when $[b\,T]$ is Toeplitz). This method does not require the orthogonal factor.

(2) When T is Toeplitz and $[T\,b]$ is not Toeplitz, the generalized Schur algorithm can be used to compute the triangular factor $R = \mathrm{qr}(T)$ of T. To solve the LS problem, either $Q^T b$ needs to be computed, where Q is the orthogonal factor in the QR decomposition of T [29], or the method of seminormal equations can be used, which does not require the orthogonal factor [3, sect. 6.6.5].

(3) Even when T is Toeplitz but $[T\ b]$ is not Toeplitz, the generalized Schur algorithm can be applied to compute the upper triangular factor of $[T\ b]$ or $[b\ T]$ using a certain displacement representation as shown in section 2.2. Then the LS solution can be obtained by solving a triangular system as in (1) above. No orthogonal factor is needed in this case.

2.1. The generalized Schur algorithm. The generalized Schur algorithm can be derived in many ways. In [9, 12], [27, sect. 3.1], the derivation is based on the *generator* for the displacement representation. Here we prefer to utilize the representation (2.1), since it allows us to use downdating perturbation theory for the error analysis.

We describe the details of the algorithm using a case with $q = 2$ and $d = 4$. The starting point for the derivation is that (2.1) can also be written

$$K = S^T \Lambda S,$$

where

$$S = \begin{pmatrix} U_1 \\ U_2 \\ U_3 \\ U_4 \end{pmatrix}, \qquad \Lambda = \begin{pmatrix} I_n & 0 & 0 & 0 \\ 0 & I_n & 0 & 0 \\ 0 & 0 & -I_n & 0 \\ 0 & 0 & 0 & -I_n \end{pmatrix},$$

and I_n denotes the $n \times n$ identity matrix. Now assume that we can find a matrix $\Theta \in \mathbf{R}^{4n\times 4n}$ that satisfies

$$\Theta^T \Lambda \Theta = \Lambda \tag{2.4}$$

such that

$$\Theta S = \begin{pmatrix} U \\ 0 \\ 0 \\ 0 \end{pmatrix}, \tag{2.5}$$

$$S \equiv \begin{pmatrix} U_1 \\ U_2 \\ U_3 \\ U_4 \end{pmatrix} = \begin{pmatrix} \alpha_1 & \alpha_2 & \alpha_3 & \alpha_4 \\ & \alpha_1 & \alpha_2 & \alpha_3 \\ & & \alpha_1 & \alpha_2 \\ & & & \alpha_1 \\ 0 & \beta_2 & \beta_3 & \beta_4 \\ & 0 & \beta_2 & \beta_3 \\ & & 0 & \beta_2 \\ & & & 0 \\ 0 & \gamma_2 & \gamma_3 & \gamma_4 \\ & 0 & \gamma_2 & \gamma_3 \\ & & 0 & \gamma_2 \\ & & & 0 \\ 0 & \delta_2 & \delta_3 & \delta_4 \\ & 0 & \delta_2 & \delta_3 \\ & & 0 & \delta_2 \\ & & & 0 \end{pmatrix}, \qquad S' = \begin{pmatrix} U_1' \\ U_2' \\ U_3' \\ U_4' \end{pmatrix} = \begin{pmatrix} \alpha_1 & \alpha_2 & \alpha_3 & \alpha_4 \\ & \alpha_1' & \alpha_2' & \alpha_3' \\ & & \alpha_1' & \alpha_2' \\ & & & \alpha_1' \\ 0 & 0 & \beta_3' & \beta_4' \\ & 0 & 0 & \beta_3' \\ & & 0 & 0 \\ & & & 0 \\ 0 & 0 & \gamma_3' & \gamma_4' \\ & 0 & 0 & \gamma_3' \\ & & 0 & 0 \\ & & & 0 \\ 0 & 0 & \delta_3' & \delta_4' \\ & 0 & 0 & \delta_3' \\ & & 0 & 0 \\ & & & 0 \end{pmatrix}.$$

FIG. 2.1. *Annihilation of the second diagonals of* U_i, $2 \le i \le 4$, *where* $\alpha_i, \beta_i, \gamma_i, \delta_i \in \mathbf{R}$.

where U is upper triangular. Then

$$K = S^T \Lambda S = (\Theta S)^T \Lambda (\Theta S) = U^T U, \tag{2.6}$$

which gives a Cholesky factor of K.

We will now describe how Θ can be constructed as a product of Givens and hyperbolic transformations. For Givens transformations (rotations) and hyperbolic transformations, see, e.g., [20, Chap. 5 and Chap. 12.5]. It is crucial for the accuracy of the Schur algorithm to use "stabilized" variants of hyperbolic transformations; see [8, 39, 41, 29, 10, 40, 32].

By premultiplying S by a sequence of Givens or hyperbolic transformations, selected elements can be annihilated. Let $n = 4$, and define S as in Figure 2.1. First, we apply Givens rotations J_1 and J_2 in the (2,5) and the (9,13) planes, to annihilate β_2 and δ_2, respectively. Due to the Toeplitz structure of each U_i, the same rotations J_1 and J_2 annihilate the entire first superdiagonals in U_2 and U_4, respectively, when applied in appropriate planes, without any extra computation. Next, by a stabilized hyperbolic transformation H_1 in the (2,9) plane, we can annihilate the modified element in the location of γ_2 and annihilate the entire first superdiagonal of the third block without any extra computation. After these steps, we obtain S' shown in Figure 2.1. Due to the structures of U_2', U_3', and U_4', the second row of U_1' will not be modified any further and this becomes the second row of the final matrix U. Since each U_i' has the necessary Toeplitz structure, we can continue the same procedure, now working with the 2×2 submatrices. In general, after $n - 1$ such steps we have obtained an upper triangular matrix U shown in (2.5).

Note that the Givens transformations are applied between blocks 1 and 2, or between blocks 3 and 4, and elementary (two-by-two) hyperbolic transformations are applied between blocks 1 and 3. All Givens transformations J_i and hyperbolic transformations H_i used in this procedure satisfy

$$J_i^T \Lambda J_i = \Lambda, \qquad H_i^T \Lambda H_i = \Lambda,$$

ALGORITHM 1.
Given the displacement representation $K = \sum_{i=1}^{q} U_i^T U_i - \sum_{i=q+1}^{d} U_i^T U_i$, this generalized Schur algorithm computes the Cholesky factor U for K.

(1) $U(1, 1:n) := U_1(1, 1:n)$
(2) **for** $k = 1 : n-1$
(a) $r_1(k : n-1) := U(k, k : n-1)$
(b) $(*$ Update blocks $2, 3, \ldots, q$ to block 1 $*)$
for $i = 2 : q$,
$[r_1(k),\ c,\ s] := \text{givens}(r_1(k), u_{(i)}(k))$
$$\begin{pmatrix} r_1^T(k+1 : n-1) \\ u_{(i)}^T(k+1 : n-1) \end{pmatrix} := \begin{pmatrix} c & s \\ -s & c \end{pmatrix} \begin{pmatrix} r_1^T(k+1 : n-1) \\ u_{(i)}^T(k+1 : n-1) \end{pmatrix}$$
end
(c) $(*$ Update blocks $q+2, \ldots, d$ to block $q+1$ $*)$
for $i = q+2 : d$,
$[u_{(q+1)}(k),\ c,\ s] := \text{givens}(u_{(q+1)}(k), u_{(i)}(k))$
$$\begin{pmatrix} u_{(q+1)}^T(k+1 : n-1) \\ u_{(i)}^T(k+1 : n-1) \end{pmatrix} := \begin{pmatrix} c & s \\ -s & c \end{pmatrix} \begin{pmatrix} u_{(q+1)}^T(k+1 : n-1) \\ u_{(i)}^T(k+1 : n-1) \end{pmatrix}$$
end
(d) $(*$ Downdate block $q+1$ from block 1 $*)$
$[r_b(k),\ c,\ s] := \text{shyp}(r_1(k), u_{(q+1)}(k))$
$$\begin{pmatrix} r_b^T(k+1 : n-1) \\ u_{(q+1)}^T(k+1 : n-1) \end{pmatrix} := \begin{pmatrix} 1 & 0 \\ -c & s \end{pmatrix} \begin{pmatrix} 1/s & -c/s \\ 0 & 1 \end{pmatrix} \begin{pmatrix} r_1^T(k+1 : n-1) \\ u_{(q+1)}^T(k+1 : n-1) \end{pmatrix}$$
(e) $U(k+1, k+1 : n) := r_b(k : n-1)$
end

and therefore the product Θ of all these matrices satisfies (2.4). It now follows from (2.6) that the matrix U is the Cholesky factor of K. The algorithm for arbitrary q and d is analogous and is summarized in Algorithm 1, where the function $\text{givens}(x, y)$ returns $\sqrt{x^2 + y^2}$ and the cosine and sine pair $[c,\ s]$ such that

$$\begin{pmatrix} c & s \\ -s & c \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} \sqrt{x^2 + y^2} \\ 0 \end{pmatrix}. \tag{2.7}$$

Similarly, the function $\text{shyp}(x, y)$ returns $\sqrt{x^2 - y^2}$ and the cosine and sine pair $[c,\ s]$ of the stabilized hyperbolic transformations. For details, see [1, 32].

2.2. Displacement representations. We now show the displacement representations for several cases which allow us to utilize the generalized Schur algorithm for solving Toeplitz LS problems:

Case 1: $K = T^T T$;

Case 2: $K_a = [T\ b]^T [T\ b]$, where $[T\ b]$ is not Toeplitz;

Case 3: $K_b = [b\ T]^T [b\ T]$, where $[b\ T]$ is not Toeplitz.

For all cases, we will assume that the Cholesky factor of the matrix K exists. However, in Case 2 we can allow the last diagonal element in the Cholesky factor of K_a to be equal to zero. This situation occurs when the LS problem (1.1) is consistent.

Suppose U is the Cholesky factor for T^TT,

$$T^TT = U^TU, \tag{2.8}$$

and T and U are partitioned as

$$T = \begin{pmatrix} t_0 & f_r^T \\ f_c & T_0 \end{pmatrix} = \begin{pmatrix} T_0 & l_c \\ l_r^T & t_{m-n} \end{pmatrix}, \tag{2.9}$$

where $T_0 \in \mathbf{R}^{(m-1)\times(n-1)}$ is a Toeplitz submatrix of T, $f_r, l_r \in \mathbf{R}^{(n-1)\times 1}$, and $f_c, l_c \in \mathbf{R}^{(m-1)\times 1}$, and

$$U = \begin{pmatrix} u_{11} & u_r^T \\ 0 & U_b \end{pmatrix} = \begin{pmatrix} U_t & u_c \\ 0 & u_{nn} \end{pmatrix}, \tag{2.10}$$

where $U_b, U_t \in \mathbf{R}^{(n-1)\times(n-1)}$ are upper triangular and $u_r, u_c \in \mathbf{R}^{(n-1)\times 1}$. Using these partitionings, the relation (2.8) can be written in two different ways,

$$\begin{pmatrix} t_0^2 + f_c^Tf_c & t_0f_r^T + f_c^TT_0 \\ t_0f_r + T_0^Tf_c & f_rf_r^T + T_0^TT_0 \end{pmatrix} = \begin{pmatrix} u_{11}^2 & u_{11}u_r^T \\ u_{11}u_r & u_ru_r^T + U_b^TU_b \end{pmatrix}, \tag{2.11}$$

and

$$\begin{pmatrix} T_0^TT_0 + l_r{l_r}^T & T_0^Tl_c + t_{m-n}l_r \\ {l_c}^TT_0 + t_{m-n}{l_r}^T & {l_c}^Tl_c + t_{m-n}^2 \end{pmatrix} = \begin{pmatrix} U_t^TU_t & U_t^Tu_c \\ u_c^TU_t & u_c^Tu_c + u_{nn}^2 \end{pmatrix},$$

from which we get

$$\begin{aligned} u_ru_r^T + U_b^TU_b - U_t^TU_t &= (f_rf_r^T + T_0^TT_0) - (T_0^TT_0 + l_rl_r^T) \\ &= f_rf_r^T - l_rl_r^T. \end{aligned} \tag{2.12}$$

For Case 1,

$$\begin{aligned} T^TT - Z_nT^TTZ_n^T &= \begin{pmatrix} u_{11}^2 & u_{11}u_r^T \\ u_{11}u_r & u_ru_r^T + U_b^TU_b \end{pmatrix} - \begin{pmatrix} 0 & 0 \\ 0 & U_t^TU_t \end{pmatrix} \\ &= \begin{pmatrix} u_{11}^2 & u_{11}u_r^T \\ u_{11}u_r & u_ru_r^T + U_b^TU_b - U_t^TU_t \end{pmatrix}, \end{aligned}$$

where Z_n is the lower shift matrix of order n. Using (2.12) we now obtain

$$T^TT - Z_nT^TTZ_n^T = \begin{pmatrix} u_{11} \\ u_r \end{pmatrix}\begin{pmatrix} u_{11} \\ u_r \end{pmatrix}^T + \begin{pmatrix} 0 \\ f_r \end{pmatrix}\begin{pmatrix} 0 \\ f_r \end{pmatrix}^T - \begin{pmatrix} 0 \\ u_r \end{pmatrix}\begin{pmatrix} 0 \\ u_r \end{pmatrix}^T - \begin{pmatrix} 0 \\ l_r \end{pmatrix}\begin{pmatrix} 0 \\ l_r \end{pmatrix}^T. \tag{2.13}$$

From (2.11), u_{11} and u_r can be computed as

$$u_{11} = (t_0^2 + f_c^Tf_c)^{1/2}, \qquad u_r = (1/u_{11})(T_0^Tf_c + t_0f_r).$$

By an inductive argument, we can now give a displacement representation of the form (2.1).

PROPOSITION 2.1 (see [12]). *Assume that $T \in \mathbf{R}^{m\times n}$, $m \geq n$, is a Toeplitz matrix partitioned as in* (2.9) *and* $\operatorname{rank}(T) = n$, *and that T^TT has the Cholesky factor U, partitioned as in* (2.10). *Then we have*

$$U^TU = U_1^TU_1 + U_2^TU_2 - U_3^TU_3 - U_4^TU_4,$$

where

$$U_1 = \mathrm{up}\begin{pmatrix} u_{11} \\ u_r \end{pmatrix}, \quad U_2 = \mathrm{up}\begin{pmatrix} 0 \\ f_r \end{pmatrix}, \quad U_3 = \mathrm{up}\begin{pmatrix} 0 \\ u_r \end{pmatrix}, \quad U_4 = \mathrm{up}\begin{pmatrix} 0 \\ l_r \end{pmatrix}.$$

For Case 2, a displacement representation for $K = [T\ b]^T[T\ b]$ can be derived in several different ways. We present one simple expression which can easily be obtained based on the above displacement representation for T^TT. Let

$$Z_{n+1} = \begin{pmatrix} Z_n & 0 \\ e_n^T & 0 \end{pmatrix} \in \mathbf{R}^{(n+1)\times(n+1)}$$

be the lower shift matrix of order $n+1$. Then

$$[T\ b]^T[T\ b] - Z_{n+1}[T\ b]^T[T\ b]{Z_{n+1}}^T = \begin{pmatrix} T^TT - Z_nT^TTZ_n^T & T^Tb - Z_nT^TTe_n \\ b^TT - e_nT^TTZ^T & b^Tb - e_n^TT^TTe_n \end{pmatrix}. \tag{2.14}$$

A rank 2 matrix of the form

$$\begin{pmatrix} O_{n\times n} & y \\ y^T & \alpha \end{pmatrix}, \qquad \text{where} \qquad y \in \mathbf{R}^{n\times 1}, \tag{2.15}$$

can be represented as a product of two rank 2 matrices as follows:

$$\begin{pmatrix} O_{n\times n} & y \\ y^T & \alpha \end{pmatrix} = \begin{pmatrix} y & y \\ \beta & \gamma \end{pmatrix}\begin{pmatrix} y^T & \beta \\ -y^T & -\gamma \end{pmatrix}, \quad \text{where} \quad \beta = \frac{\alpha+1}{2}, \quad \gamma = \frac{\alpha-1}{2}. \tag{2.16}$$

Combining (2.13) and (2.16), and the fact that the Cholesky factor U for T^TT is the same as the submatrix $R(1:n, 1:n)$ of the Cholesky factor R for $[T\ b]^T[T\ b]$, we have the following result.

PROPOSITION 2.2. *Assume that $T \in \mathbf{R}^{m\times n}$, $m \geq n$, is Toeplitz, $[T\ b] \in \mathbf{R}^{m\times(n+1)}$ is not Toeplitz, and $[T\ b]^T[T\ b]$ has the Cholesky factor R. Then R satisfies*

$$R^TR = \sum_{i=1}^{3} R_i^TR_i - \sum_{i=4}^{6} R_i^TR_i,$$

where

$$R_1 = \mathrm{up}\begin{pmatrix} u_{11} \\ u_r \\ 0 \end{pmatrix}, \quad R_2 = \mathrm{up}\begin{pmatrix} 0 \\ f_r \\ 0 \end{pmatrix}, \quad R_3 = \mathrm{up}\begin{pmatrix} y \\ \beta \end{pmatrix},$$

$$R_4 = \mathrm{up}\begin{pmatrix} 0 \\ u_r \\ 0 \end{pmatrix}, \quad R_5 = \mathrm{up}\begin{pmatrix} 0 \\ l_r \\ 0 \end{pmatrix}, \quad R_6 = \mathrm{up}\begin{pmatrix} y \\ \gamma \end{pmatrix},$$

$y = T^Tb - Z_nT^TTe_n$, $\beta = (\alpha+1)/2$, $\gamma = (\alpha-1)/2$, *and* $\alpha = b^Tb - e_n^TT^TTe_n$.

For Case 3, once the Cholesky factor

$$R_0 = \begin{pmatrix} \kappa & w^T \\ 0 & G \end{pmatrix}, \qquad \text{where} \qquad \kappa \in \mathbf{R}, \qquad w \in \mathbf{R}^{n\times 1}, \qquad G \in \mathbf{R}^{n\times n}, \tag{2.17}$$

of $K_b = [b\ T]^T[b\ T]$ is computed, then the Cholesky factor R for $[T\ b]$ can be easily obtained by using a product J of n Givens rotations to triangularize $\begin{pmatrix} w^T & \kappa \\ G & 0 \end{pmatrix}$ as

$$R = J \begin{pmatrix} w^T & \kappa \\ G & 0 \end{pmatrix}. \tag{2.18}$$

We will derive two different displacement representations that can be used in combination with the generalized Schur algorithm when $K_b = [b\ T]^T[b\ T]$. First, partition Z_{n+1} as

$$Z_{n+1} = \begin{pmatrix} 0 & 0 \\ e_1 & Z_n \end{pmatrix}.$$

Then

$$[b\ T]^T[b\ T] - Z_{n+1}[b\ T]^T[b\ T]Z_{n+1}^T = \begin{pmatrix} b^Tb & b^TT \\ T^Tb & M \end{pmatrix}, \tag{2.19}$$

where

$$M = T^TT - Z_nT^TTZ_n^T - e_1b^Tbe_1^T - e_1b^TTZ_n^T - Z_nT^Tbe_1^T.$$

Letting

$$Z_nT^Tb = \begin{pmatrix} 0 \\ g \end{pmatrix}, \qquad g \in \mathbf{R}^{(n-1)\times 1},$$

we have

$$M = \begin{pmatrix} u_{11}^2 - b^Tb & u_{11}u_r^T - g^T \\ u_{11}u_r - g & f_rf_r^T - l_rl_r^T \end{pmatrix}. \tag{2.20}$$

The following result now follows from (2.13), (2.19), and (2.20).

PROPOSITION 2.3. *Assume that $T \in R^{m\times n}$, $m \geq n$, is Toeplitz, that $[b\ T] \in R^{m\times(n+1)}$ is not Toeplitz, and that $[b\ T]^T[b\ T]$ has the Cholesky factor R_0. Then R_0 satisfies*

$$R_0^TR_0 = \sum_{i=1}^{3} R_i^TR_i - \sum_{i=4}^{6} R_i^TR_i,$$

where

$$R_1 = \mathrm{up}\begin{pmatrix} \sqrt{b^Tb} \\ T^Tb/\sqrt{b^Tb} \end{pmatrix}, \quad R_2 = \mathrm{up}\begin{pmatrix} 0 \\ \beta \\ u_{11}u_r - g \end{pmatrix}, \quad R_3 = \mathrm{up}\begin{pmatrix} 0 \\ 0 \\ f_r \end{pmatrix},$$

$$R_4 = \mathrm{up}\begin{pmatrix} 0 \\ T^Tb/\sqrt{b^Tb} \end{pmatrix}, \quad R_5 = \mathrm{up}\begin{pmatrix} 0 \\ \gamma \\ u_{11}u_r - g \end{pmatrix}, \quad R_6 = \mathrm{up}\begin{pmatrix} 0 \\ 0 \\ l_r \end{pmatrix},$$

$\beta = (u_{11}^2 - b^Tb + 1)/2$, and $\gamma = (u_{11}^2 - b^Tb - 1)/2$.

Now we present another displacement representation that allows us to compute the submatrix G of R_0 by Algorithm 1. Let the matrix G and the vector w of (2.17) be partitioned as

$$\begin{pmatrix} w^T \\ G \end{pmatrix} = \begin{pmatrix} w_1 & w_b^T \\ g_{11} & g_r^T \\ 0 & G_b \end{pmatrix} = \begin{pmatrix} w_t^T & w_n \\ G_t & g_c \\ 0 & g_{nn} \end{pmatrix}, \tag{2.21}$$

ALGORITHM 2.
Given a Toeplitz matrix T of full column rank, and a vector b, this algorithm solves the LS problem $\min_x \|Tx - b\|_2$.

(1) Compute κ, w, and $[g_{11}\ g_r^T]$ of (2.17) and (2.21).
(2) Define the matrices $G_i,\ i = 1, \ldots, 6$, from (2.23), (2.24), and compute G by Algorithm 1.
(3) Transform the matrix $\begin{pmatrix} w^T & \kappa \\ G & 0 \end{pmatrix}$ to upper triangular form by a sequence of n Givens rotations:

$$J \begin{pmatrix} w^T & \kappa \\ G & 0 \end{pmatrix} = \begin{pmatrix} R & c \\ 0 & \kappa' \end{pmatrix}.$$

(4) Solve $Rx = c$.

where $G_b, G_t \in \mathbf{R}^{(n-1)\times(n-1)}$, $g_r, g_c, w_b, w_t \in \mathbf{R}^{(n-1)\times 1}$, and $g_{11}, g_{nn}, w_1, w_n \in \mathbf{R}$. Then

$$G^T G - Z_n G^T G Z_n^T = \begin{pmatrix} g_{11}^2 & g_{11} g_r^T \\ g_{11} g_r & g_r g_r^T + G_b^T G_b - G_t^T G_t \end{pmatrix}.$$

Using the same technique as in Case 1, we then obtain

$$g_r g_r^T + G_b^T G_b - G_t^T G_t = f_r f_r^T + w_t w_t^T - l_r l_r^T - w_b w_b^T. \tag{2.22}$$

The above results are summarized in Proposition 2.4.

PROPOSITION 2.4. *Under the same assumptions as those in Proposition* 2.3*, the submatrix G of the Cholesky factor*

$$R_0 = \begin{pmatrix} \kappa & w^T \\ 0 & G \end{pmatrix}$$

of $[b\ T]^T[b\ T]$ satisfies

$$G^T G = \sum_{i=1}^{3} G_i G_i^T - \sum_{i=4}^{6} G_i G_i^T,$$

where

$$G_1 = \mathrm{up}\begin{pmatrix} g_{11} \\ g_r \end{pmatrix}, \quad G_2 = \mathrm{up}\begin{pmatrix} 0 \\ f_r \end{pmatrix}, \quad G_3 = \mathrm{up}\begin{pmatrix} 0 \\ w_t \end{pmatrix}, \tag{2.23}$$

$$G_4 = \mathrm{up}\begin{pmatrix} 0 \\ g_r \end{pmatrix}, \quad G_5 = \mathrm{up}\begin{pmatrix} 0 \\ l_r \end{pmatrix}, \quad G_6 = \mathrm{up}\begin{pmatrix} 0 \\ w_b \end{pmatrix}. \tag{2.24}$$

To be able to use Algorithm 1 here, first we must compute κ, the vector w, and the first row of G. This can be done efficiently in $O(n)$ operations; see, e.g., [20, Chap. 4]. The pre- and postprocessing that is needed in this case is summarized in Algorithm 2.

We have shown the displacement representations to utilize the generalized Schur algorithm. Note that the displacement representation and displacement rank are

TABLE 2.1
Complexity of the algorithms in flops.

	Total	Preproc.	Gen. Schur	Postproc.	Tri. system solve
Prop. 2.1, SNE	$2mn + 7n^2$	mn	$6n^2$	mn	n^2
Prop. 2.1, CSNE	$4mn + 8n^2$	mn	$6n^2$	$3mn$	$2n^2$
Prop. 2.2	$3mn + 10.5n^2$	$3mn$	$10n^2$	–	$0.5n^2$
Prop. 2.3	$2mn + 12.5n^2$	$2mn$	$10n^2$	$2n^2$	$0.5n^2$
Prop. 2.4	$2mn + 12.5n^2$	$2mn$	$10n^2$	$2n^2$	$0.5n^2$

highly dependent on the structure of the matrix. The displacement rank is not preserved under permutations. For example, when Π is a permutation matrix, the displacement rank of $(T\Pi)^T(T\Pi)$ is not 4 any more, unless $T\Pi$ is also Toeplitz. Also the displacement rank refers to the rank of the matrix $K - ZKZ^T$ *in general*: when T is already upper triangular and Toeplitz, the displacement rank of T^TT is only 1, rather than 4.

The computational complexity of the algorithm for solving the Toeplitz LS problems using each of the displacement representation is summarized in Table 2.1. In the table, the preprocessing refers to the computations to be done to obtain the vectors to be involved in the generalized Schur algorithm. The postprocessing refers to those involved after the triangular factor is obtained, before any triangular system is solved. In the algorithms based on Proposition 2.1, where only the upper triangular matrix U is computed using the generalized Schur algorithm, the LS problem is solved using the SNE and CSNE approach [3, sect. 6.6.5]. In the operation counts we have assumed that the Toeplitz matrix times vector operations are performed by the standard algorithm, requiring mn flops. The complexity of the generalized Schur algorithm with the displacement rank d is $2(d-1)n^2$.

3. Forward error analysis. The forward error analysis given in [32] for the case $q = 2$ and $d = 4$ applies also to the general case. We briefly repeat[1] the derivation from [32] for the special case

$$K = T^TT = U^TU = U_1^TU_1 + U_2^TU_2 - U_3^TU_3 - U_4^TU_4 \tag{3.1}$$

and then derive better results using new perturbation theory according to Chang, Paige, and Stewart [11]. The problem of computing the Cholesky decomposition of a matrix K, based on its displacement representation (3.1), can be considered as that of performing a sequence of updates and downdates, and the analysis of [39] is applicable.

Assume that the computations are performed in a floating point system with unit roundoff μ (see, e.g., [20, p. 61]). Using the error analysis of stabilized hyperbolic transformations [8, 39], it can be shown [32] that the computed matrix $\bar{U}$ satisfies

$$J\begin{pmatrix} U_1 \\ U_2 \\ 0 \\ 0 \end{pmatrix} = \begin{pmatrix} \bar{U} \\ 0 \\ U_3 \\ U_4 \end{pmatrix} + E, \qquad \|E\|_F \le C\mu\|U\|_F + O(\mu^2), \tag{3.2}$$

[1]For simplicity we here omit the treatment of errors in the computation of the elements of U_1 and U_3; see [32].

for some exactly orthogonal matrix J, where C is a polynomial of low degree[2] in the dimensions of T and the displacement rank d. From (3.2) we get

$$\bar{U}^T\bar{U} = U_1^TU_1 + U_2^TU_2 - U_3^TU_3 - U_4^TU_4 + E_c,$$

where

$$\|E_c\|_F \le 2\|E\|_F \,\|\,(\,\bar{U} \quad U_3 \quad U_4\,)\,\|_F + O(\mu^2).$$

Using (3.2) we have $\|\,(\,\bar{U} \quad U_3 \quad U_4\,)\,\|_F \le \|\,(\,U_1 \quad U_2\,)\,\|_F + \|E\|_F$, and since the elements of U_1 and U_2 are from U and T, respectively, we can estimate

$$\|E_c\|_F \le C\mu\,\|U\|_2^2 + O(\mu^2) = C\mu\|T\|_2^2 + O(\mu^2).$$

We can now use the new perturbation result for the Cholesky decomposition [11] to estimate the forward error. First define $W_U \in \mathbf{R}^{n(n+1)/2\times n(n+1)/2}$ as the lower triangular matrix

$$W_U = \begin{pmatrix}
2u_{11} & & & & & & & & & & \\
u_{12} & u_{11} & & & & & & & & & \\
 & 2u_{12} & 2u_{22} & & & & & & & & \\
u_{13} & & & u_{11} & & & & & & & \\
 & u_{13} & u_{23} & u_{12} & u_{22} & & & & & & \\
 & & & 2u_{13} & 2u_{23} & 2u_{33} & & & & & \\
\cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & & & & \\
u_{1n} & & & & & & & u_{11} & & & \\
 & u_{1n} & u_{2n} & & & & & u_{12} & u_{22} & & \\
 & & & u_{1n} & u_{2n} & u_{3n} & & u_{13} & u_{23} & u_{33} & \\
 & & & & & & \cdot & \cdot & \cdot & \cdot & \cdot \\
 & & & & & & & 2u_{1n} & 2u_{2n} & 2u_{3n} & \cdot & 2u_{nn}
\end{pmatrix}, \tag{3.3}$$

and put

$$D = \operatorname{diag}(1, \underbrace{\sqrt{2}, 1}_{2}, \ldots, \underbrace{\sqrt{2}, \ldots, \sqrt{2}, 1}_{j}, \ldots, \underbrace{\sqrt{2}, \ldots, \sqrt{2}, 1}_{n}) \in \mathbf{R}^{n(n+1)/2\times n(n+1)/2}.$$

THEOREM 3.1. *Let T and U be defined as in Proposition* 2.1*, and assume that the condition number of T is is not too large* [11]*. Then the approximation $\bar{U}$ computed using the generalized Schur algorithm satisfies*

$$\frac{\|\bar{U} - U\|_F}{\|U\|_2} \le C\mu\kappa_c(T^TT) + O(\mu^2), \tag{3.4}$$

where $\kappa_c(T^TT)$ is the Cholesky condition number [11]

$$\kappa_c(T^TT) = \|(DW_U)^{-1}\|_2\,\|T^TT\|_2^{1/2},$$

which can be bounded as

$$\frac{1}{2}\kappa_2(T) \le \kappa_c(T^TT) \le \frac{1}{\sqrt{2}}\kappa_2^2(T). \tag{3.5}$$

[2]Each occurrence of C will denote a different polynomial.

The theorem is valid also if we take into account the errors in the computation of the elements of U_1 and U_3; cf. [32].

In (3.5), $\kappa_2(A)$ is the usual condition number, measured in the matrix 2-norm [20, p. 57]. It is demonstrated in [11] (see also section 5) that there are matrices T for which $\kappa_c(T^TT)$ is close to the lower bound and others for which $\kappa_c(T^TT)$ is close to the upper bound. Thus, the error estimate (3.4) shows that although the upper triangular factor U is computed by Algorithm 1 without forming T^TT, the error in the computed $\bar{U}$ may in some cases be as large as if it had been computed as the Cholesky factor of T^TT. This is interesting, considering that nowhere in the algorithm was T^TT explicitly formed.

Obviously analogous results can be derived for the general case

$$K = \sum_{i=1}^{q} U_i^T U_i - \sum_{i=q+1}^{d} U_i^T U_i,$$

provided that $\|U_i\|_F$, $i = q+1, \ldots, d$, can be bounded in terms of $\|K\|_F$. In the special case when $K = T$ is a symmetric, positive definite Toeplitz matrix (the displacement rank is 2), we have

$$\frac{\|\bar{U} - U\|_F}{\|U\|_2} \leq C\mu\kappa_c(T) + O(\mu^2),$$

which is the same as for the Cholesky algorithm. In fact, it has been shown in [7] (see also [40]) that in this special case the Schur algorithm is stable even if ordinary "unstabilized" hyperbolic transformations are used.

The error analysis must be modified somewhat for $K_a = [T\ b]^T[T\ b]$. Let the Cholesky decomposition of K_a be

$$K_a = \begin{pmatrix} U^T & 0 \\ z^T & \rho \end{pmatrix} \begin{pmatrix} U & z \\ 0 & \rho \end{pmatrix},$$

where ρ may be equal to zero, and let $V = (U\ z)$. Then the error estimate for $\bar{V}$ becomes

$$\frac{\|\bar{V} - V\|_F}{\|V\|_2} \leq C\mu\hat{\kappa}_c(K_a) + O(\mu^2),$$

where $\hat{\kappa}_c(K_a)$ is a slightly modified condition number,

$$\hat{\kappa}_c(K_a) = \|\hat{W}_U^{-1}\|_2 \|V\|_2^{1/2},$$

and $\hat{W}_U$ is defined by

$$\hat{W}_U = \begin{pmatrix} DW_U & 0 \\ S & U \end{pmatrix}, \quad S = \begin{pmatrix} z_1 & & & & & & & & \\ & z_1 & z_2 & & & & & & \\ & & & z_1 & z_2 & z_3 & & & \\ & & & & & & \cdots & & \\ & & & & & & & z_1 & z_2 & \cdots & z_n \end{pmatrix}.$$

Note that the perturbation of the upper triangular factor U still satisfies the bound (3.5). It is interesting to be able to bound the perturbation of the right-hand side z

separately. Using the same technique as in [11, p. 461], the perturbation of z can be shown to be bounded essentially by $\kappa_2^2(T)$ (cf. the bound (3.5) for κ_c).

A similar analysis can also be made for the algorithms based on Propositions 2.3 and 2.4 for the generalized Schur algorithm applied to $K_b = [b\ T]^T[b\ T]$, and the accuracy will depend on the condition number $\kappa_c(K_b)$. However, when the LS problem is almost consistent, then K_b is very ill-conditioned, and in the extreme case when b is in the range $R(T)$, then K_b is singular. Therefore, the algorithm based on Proposition 2.3 can give large errors, which makes it unsuitable for least squares problems. In the next section we will show that we can modify Algorithm 2 (which is based on Proposition 2.4), using CSNE to refine the upper triangular matrix, in such a way that this algorithm will give accurate results even for almost consistent systems.

4. Improving accuracy by CSNE. In this section we will describe a method based on CSNE which was originally designed [5] for computing the solution of the LS problem when only the R factor in the QR decomposition is available. First, we discuss block downdating using CSNE, and then we describe the application of CSNE block downdating for Toeplitz LS problems. For applying CSNE to Algorithm 1, see [32].

4.1. CSNE for block downdating. Let $A = \begin{pmatrix} H \\ \tilde{A} \end{pmatrix} \in \mathbf{R}^{m\times n}$ with $m \geq n$, where $H \in \mathbf{R}^{k\times n}$, with $k \leq n$. Assume that $\operatorname{rank}(A) = n$. Given the QR decomposition

$$A = Q \begin{pmatrix} R \\ 0 \end{pmatrix},$$

where $Q \in \mathbf{R}^{m\times m}$ is orthogonal and R is upper triangular, the block downdating that we will apply in the next section is to find the upper triangular factor $\tilde{R}$ in the QR decomposition of $\tilde{A}$, using R and A only as data, in no more than $O(mn + n^2)$ flops. The downdating problem for $k = 1$ has been studied in [1, 4, 18, 20, 31, 35, 38] and block downdating for $k > 1$ in [34, 15, 30]. Perturbation and error analysis are given in [38, 16, 17, 39].

Block downdating can be performed by first computing the matrix $Q_1 \in \mathbf{R}^{n\times k}$ from the triangular system $R^TQ_1 = H^T$, the Cholesky factor $\Gamma \in \mathbf{R}^{k\times k}$ of the matrix $I - Q_1^TQ_1$, and then computing the downdated upper triangular factor $\tilde{R}$ as a block in the QR decomposition

$$\begin{pmatrix} Q_1 & R \\ \Gamma & 0 \end{pmatrix} = P \begin{pmatrix} I_k & \hat{H} \\ 0 & \tilde{R} \end{pmatrix},$$

where P is orthogonal. This is the generalization of the LINPACK downdating algorithm [16]. The method of CSNE for LS problems can be applied to the block downdating problem. This is due to the fact that the matrix Γ can be computed as the R factor in the QR decomposition of the residual matrix in the LS problem

$$\min_V \left\| \begin{pmatrix} I_k \\ 0 \end{pmatrix} - AV \right\|_F, \tag{4.1}$$

and we can apply the method of CSNE to (4.1). For details, see [15, 17].

When the matrix A is available in the product form,

$$A = W^TX,$$

ALGORITHM 3. BLOCK DOWNDATING BY CSNE FOR A MATRIX IN PRODUCT FORM. Given the upper triangular factor R for A, $X(= WA)$, and only the first k columns of the orthogonal matrix W, downdate the first k rows of A from R, giving $\tilde{R}$.

(1) Compute Q_1, V, and F from

$$(a)\ R^T Q_1 = X^T W_1, \qquad (b)\ RV = Q_1, \qquad (c)\ F := W_1 - XV.$$

(2) (a) Update Q_1, V, and F:

$$R^T \delta Q_1 = X^T F, \qquad Q_1 := Q_1 + \delta Q_1,$$
$$R\delta V = \delta Q_1, \qquad F := F - X\delta V.$$

(b) Compute the R factor of F to determine Γ:

$$\Gamma = \mathrm{qr}(F).$$

(3) Triangularize $\begin{pmatrix} Q_1 & R \\ \Gamma & 0 \end{pmatrix}$ by a product of Givens rotations P :

$$\begin{pmatrix} I_k & \hat{H} \\ 0 & \tilde{R} \end{pmatrix} := P \begin{pmatrix} Q_1 & R \\ \Gamma & 0 \end{pmatrix}.$$

where $W \in \mathbf{R}^{m\times m}$ is an orthogonal matrix partitioned as

$$W = (\, W_1 \quad W_2 \,), \qquad W_1 \in \mathbf{R}^{m\times k},$$

and $X \in \mathbf{R}^{m\times n}$, the matrix A does not need to be computed explicitly for block downdating. This is because the LS problem

$$\min_V \|W_1 - XV\|_F$$

is equivalent to (4.1) [32]. The block downdating algorithm with CSNE for this case is summarized in Algorithm 3, which will be used in the next subsection.

4.2. CSNE for Algorithm 2. In this subsection, we show how the CSNE method for block downdating can be used to refine the matrix G obtained from Algorithm 2. For this purpose, we rewrite (2.22) as

$$\hat{G}^T \hat{G} = G_t^T G_t + w_t w_t^T + f_r f_r^T, \tag{4.2}$$
$$G_b^T G_b = \hat{G}^T \hat{G} - H^T H, \tag{4.3}$$

where $H^T = (\, l_r \quad g_r \quad w_b \,) \in \mathbf{R}^{(n-1)\times 3}$. Suppose we have $\hat{G}$ from Algorithm 2 (it is easy to see that $\hat{G}$ can be obtained as a byproduct of the algorithm at no extra cost). From (2.22), (2.9), and (2.21), we have

$$\hat{G} = \mathrm{qr}(X), \qquad X = \begin{pmatrix} f_r^T \\ T_0 \\ l_r^T \end{pmatrix} \in \mathbf{R}^{(m+1)\times(n-1)}, \tag{4.4}$$

and the matrix G_b is obtained by downdating the block H from $\hat{G}$. Note that g_r^T and w_b^T are from the first two rows in the upper triangular factor of the matrix $[b\ T]$. We

ALGORITHM 4. SOLUTION OF TOEPLITZ LS PROBLEM USING CSNE REFINEMENT. Given the matrix T and a right-hand side b, solve the LS problem $\min_x \|Tx - b\|_2$.

(1) Compute κ, w, G, and $\hat{G}$ using steps 1–3 of Algorithm 2.
(2) Compute the first three columns of the matrix W (no computation needed for the first column).
(3) Let X be defined by (4.4), and compute refined G_b by downdating the first three rows of $A = W^T X$ using Algorithm 3.
(4) Perform steps 3 and 4 of Algorithm 2.

can find an orthogonal matrix, $\hat{W}^T$, which transforms the first two columns of $[b\ T]$ to upper triangular form, and, accordingly, the first two rows into

$$\begin{pmatrix} \kappa & w_1 & w_b^T \\ 0 & g_{11} & g_r^T \end{pmatrix}.$$

Then H consists of the first three rows of the matrix A defined as

$$A \equiv W^T X = \begin{pmatrix} 0 & 1 \\ \hat{W}^T & 0 \end{pmatrix} \begin{pmatrix} f_r^T \\ T_0 \\ l_r^T \end{pmatrix}.$$

Now, we can apply the CSNE block downdating algorithm considering A as the data matrix for the triangular factor $\hat{G}$ and solve

$$\min_V \left\| \begin{pmatrix} I_3 \\ 0 \end{pmatrix} - AV \right\|_F. \tag{4.5}$$

This problem is equivalent to (cf. subsection 4.1)

$$\min_V \|W_1 - XV\|_F, \qquad W = (W_1\ W_2), \qquad W_1 \in \mathbf{R}^{(m+1)\times 3}. \tag{4.6}$$

Note that the first column of W_1 is $e_{m+1} \in \mathbf{R}^{(m+1)\times 1}$, which is the $(m+1)$th unit vector. The above derivation is summarized in Algorithm 4.

According to Theorem 3.1, the accuracy of the matrix G computed by Algorithm 2 depends on the condition number of G, which may be ill-conditioned even if R (and, equivalently, T) is well-conditioned.

However, in the CSNE method, it is the condition number of $\hat{G}$ defined by (4.2) that determines the final accuracy [17, 32]. We will now demonstrate that if T is well-conditioned, then $\hat{G}$ is well-conditioned, even if G is ill-conditioned. Let $\sigma_i(R)$ denote the singular values of R, and assume that they are ordered $\sigma_1(R) \geq \sigma_2(R) \geq \cdots \geq \sigma_n(R)$.

From (2.18) we see that the upper triangular factor in the QR decomposition of

$$G_0 = \begin{pmatrix} w_t^T \\ G_t \end{pmatrix}$$

is equal to the $(n-1) \times (n-1)$ principal submatrix of R. Therefore, using theory for eigenvalues of symmetric matrices [20, Chap. 8.1], we get

$$\sigma_1(G_0) \leq \sigma_1(R), \quad \sigma_{n-1}(G_0) \geq \sigma_n(R). \tag{4.7}$$

Furthermore, since $\hat{G}^T\hat{G} = G_0^T G_0 + f_r f_r^T$, the smallest singular value of $\hat{G}$ satisfies

$$\sigma_{n-1}(\hat{G}) \geq \sigma_{n-1}(G_0). \tag{4.8}$$

The vector f_r^T is part of the first row of T, which implies

$$\|f_r\|_2 \leq \sigma_1(R),$$

and, using [20, Thm. 8.1.8], we can deduce

$$\sigma_1^2(\hat{G}) \leq \sigma_1^2(G_0) + \|f_r\|_2^2 \leq 2\sigma_1^2(R). \tag{4.9}$$

Combining (4.7)–(4.9), we have

$$\kappa_2(\hat{G}) \leq \sqrt{2}\,\kappa_2(R) = \sqrt{2}\,\kappa_2(T). \tag{4.10}$$

The accuracy of the matrix $\hat{G}$ computed by Algorithm 2 depends essentially on the condition number of $\hat{G}$ and not on that of G [39, 17, 32]. Therefore, if T is well-conditioned, then $\hat{G}$ will be accurately computed by Algorithm 2. Since $\hat{G}$ is accurate, Algorithm 4 will produce an accurate approximation of G [17, 32], which, finally, will lead to an accurate LS solution. In cases where $\hat{G}$ is well-conditioned and T is ill-conditioned, Algorithm 4 will still give a good approximation of G. However, if T is ill-conditioned with three or more small singular values (relative to the largest singular value), this cannot happen because then $\hat{G}$ has at least one small singular value.

5. Numerical tests. In this section, we present test results for the purpose of comparing the accuracy and speed of the various algorithms for Toeplitz LS problems.

5.1. Comparison of accuracy. We have performed numerical tests in MATLAB with IEEE double precision floating point arithmetic with unit round off $\mu \approx 10^{-16}$. The accuracy of the LS solutions computed from the following algorithms are compared:

- Algorithm Cyb: The Q and R factors for T are computed by Cybenko's algorithm [14].
- Algorithm Sq: The R factor and $Q^T b$ are computed by the generalized Schur algorithm as in [29].
- Algorithm Ssne: The R factor is computed by the generalized Schur algorithm (Algorithm 1) and then the solution is computed from the SNE, $R^T R x = T^T b$, cf. [6].
- Algorithm Scsne: The R factor is computed by the generalized Schur algorithm (Algorithm 1) and then the solution is computed from the CSNE.
- Algorithm Rcsne: The R factor is computed by the Toeplitz matrix triangularization algorithm presented in [32] (Algorithm C in that paper, which refines the R factor from Algorithm 1 by CSNE), and then the solution is computed from the CSNE.
- Algorithm Gcsne: The solution vector x is computed by Algorithm 4 presented in this paper.

The relative forward error in the computed solution x,

$$\frac{\|x_c - x\|_2}{\|x_c\|_2},$$

for each method is presented, where x_c is a vector with all of its components equal to $1/\sqrt{n}$. The right-hand-side vector b is computed from $b := Tx_c$. We also made a number of test runs with data where the residual in the LS problem was nonzero. The results were very similar to those that we report here.

An estimate of the backward error was also computed as

$$\begin{aligned} e_b &:= \min\left\{\frac{\|r\|_2}{\|x\|_2}, \sigma_{min}([T\ F])\right\} \\ &= \min\{\|E\|_F : \|(T+E)x - b\|_2 = \min_{x'} \|(T+E)x' - b\|_2\}, \end{aligned}$$

where

$$r = b - Tx, \qquad F = \frac{\|r\|_2}{\|x\|_2}(I - rr^T),$$

and σ_{min} is the smallest singular value of the matrix $[T\ F]$, as in [44]. The relative backward error is then defined as

$$r_b = \frac{e_b}{\|T\|_F}.$$

Test I. The matrix $T \in \mathbf{R}^{5\times 4}$ is similar to that in [33],

$$T = \begin{pmatrix} 1 & 2 & 3 & 1/\epsilon \\ 2 & 1 & 2 & 3 \\ 3 & 2 & 1 & 2 \\ 4 & 3 & 2 & 1 \\ 1/\epsilon & 4 & 3 & 2 \end{pmatrix},$$

and $\epsilon = 10^{-1-i}$, $i = 1, 2, \ldots, 9$, are chosen so that the matrix becomes progressively more ill-conditioned, with condition number $\kappa_2(T)$ ranging from 95 to $9 \cdot 10^9$. The condition number $\kappa_c(T^TT)$ is close to $\kappa_2^2(T)$. The results are presented in Figure 5.1. For reference, we also give the errors obtained by solving the LS problem using Householder transformations.

Test II. In this test, where

$$T = \begin{pmatrix} 1 & t & t & t & \cdots & t \\ 0 & 1 & t & t & \cdots & t \\ 0 & 0 & 1 & t & \cdots & t \\ \vdots & & & \ddots & \ddots & \vdots \\ & & & & 1 & t \\ 0 & \cdots & & & & 1 \end{pmatrix} \in \mathbf{R}^{50\times 50},$$

the algorithms are applied ignoring the fact that the matrix is already triangular. The parameter t was chosen as $t = \epsilon^{-1/4}$ where ϵ is the same as that in Test I. The condition number $\kappa_2(T)$ varied from $4 \cdot 10^3$ to $4 \cdot 10^9$. In this test the dimension of the matrix is too large to allow for the computation of κ_c within reasonable time. The results are shown in Figure 5.2.

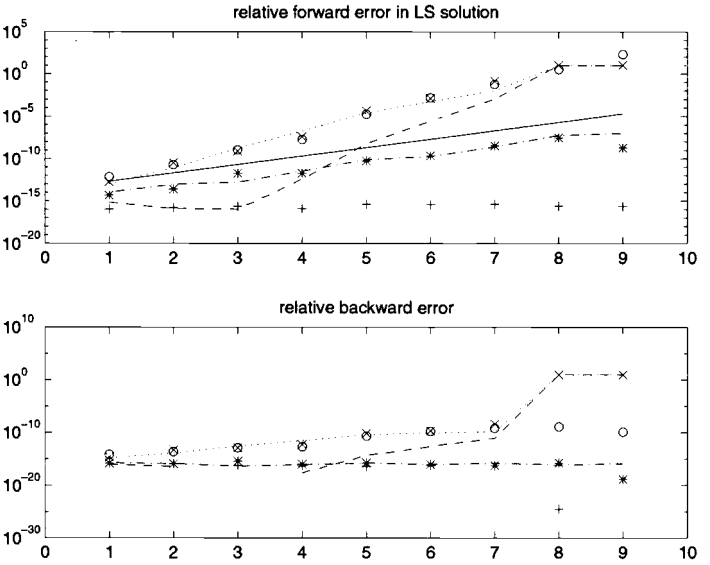

FIG. 5.1. *Test* I. *Relative forward and backward errors for the different algorithms. The following symbols are used: o (Cyb),* $\times$ *(Sq), dotted (Ssne), dashed (Scsne),* $+$ *(Rcsne), dashed-dotted (Gcsne),* $*$ *(Householder). In the upper graph, the solid line represents* $10\mu\kappa_2(T)$*, which can be considered as a reasonable error level for a backward stable algorithm. Note that parts of some curves are missing in the lower plot because the backward error was estimated to be zero. In cases when Algorithm* 1 *broke down, we assigned the value* 10 *to the relative error.*

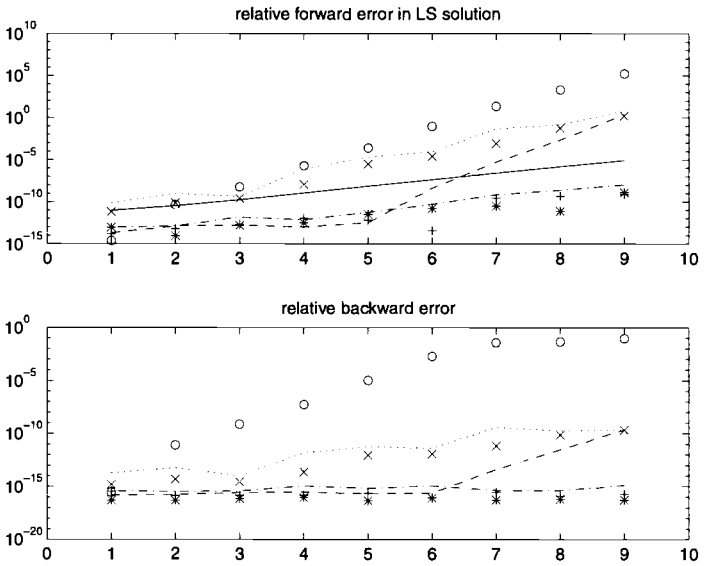

FIG. 5.2. *Test* II.

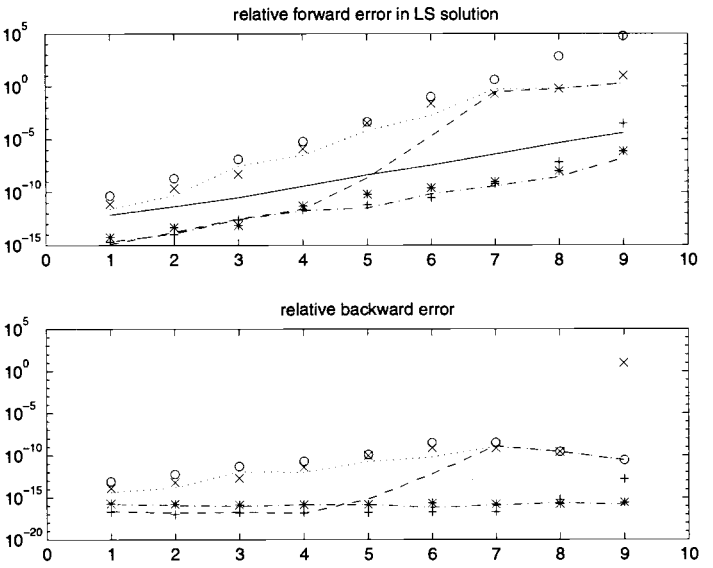

FIG. 5.3. *Test* III.

Test III. This test matrix is a modification of an example from [28]. A set of data was generated as

$$x_n = x(n\Delta t) = \sum_{j=1}^{9} A_j \exp(-\alpha n \Delta t)\cos(\omega_j n \Delta t) + \epsilon r_n,$$

where

$$\begin{aligned} A_j &= j/10, && j = 1, \ldots, 9, \\ \alpha &= \pi/50, && \Delta t = 0.5, \\ \omega_j &= \begin{cases} j\pi/5, & j = 1,2,3,4,5,6,8,9, \\ 7.95\pi/5, & j = 7, \end{cases} \end{aligned}$$

r_n is taken from a normal distribution, $r_n \in N(0,1)$, and ϵ is the same as that in Test I. The matrix $T \in \mathbf{R}^{59\times 19}$ was constructed from $T_{ij} = x_{i-j+19}$. For small values of ϵ, it has one singular value considerably smaller than the rest, and the condition number $\kappa_2(T)$ varied from 340 to $2 \cdot 10^{10}$. In most cases $\kappa_c(T^T T)$ was close to $\kappa_2(T)$. The results are shown in Figure 5.3.

Test IV.

$$T = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 \\ t & 1 & 0 & 0 & 0 \\ 0 & t & 1 & 0 & 0 \\ 0 & 0 & t & 1 & 0 \\ 0 & 0 & 0 & t & 1 \end{pmatrix} \in \mathbf{R}^{5\times 5},$$

where $t = -\log_{10}(\epsilon) + 0.1$ and ϵ is the same as that in Test I. Here $\kappa_2(T)$ varied from 75 to $1 \cdot 10^5$, and $\kappa_c(T^T T)$ was close to $\kappa_2(T)$. The results are shown in Figure 5.4.

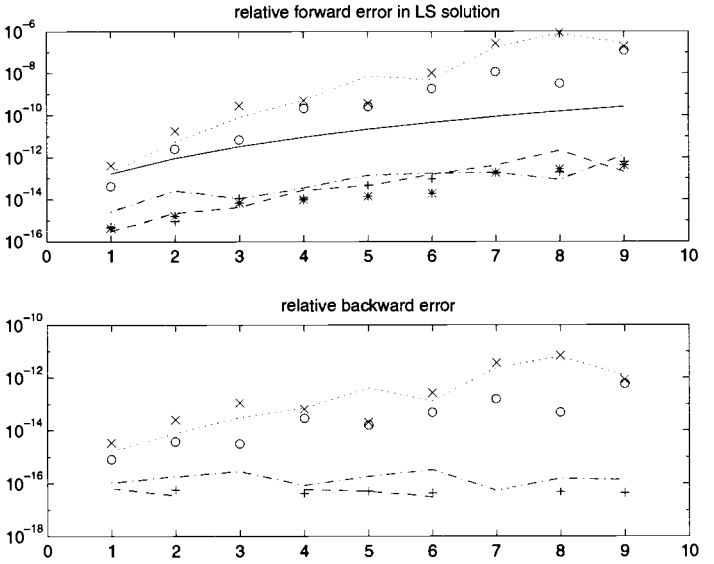

FIG. 5.4. *Test* IV.

Test V. This test matrix is modified from an example in [23]. The matrix is

$$T = \begin{pmatrix} 3 & 2 & 1 & 1 & 2 & 3 \\ 4 & 3 & 2 & 1 & 1 & 2 \\ 5 & 4 & 3 & 2 & 1 & 1 \\ 6 & 5 & 4 & 3 & 2 & 1 \\ 7 & 6 & 5 & 4 & 3 & 2 \\ 8 & 7 & 6 & 5 & 4 & 3 \\ 9 & 8 & 7 & 6 & 5 & 4 \end{pmatrix} + \epsilon * P \in \mathbf{R}^{7\times 6},$$

where P is a random Toeplitz matrix and $\epsilon = 10^{-1-i}$, $i = 1, 2, \ldots, 8$. For $\epsilon = 0$, T is singular, and for the values of ϵ that we chose, $\kappa_2(T)$ varied from $6 \cdot 10^3$ to $8 \cdot 10^{10}$. $\kappa_c(T^T T)$ was much larger than $\kappa_2(T)$. The results are shown in Figure 5.5.

5.2. Comparison of speed. In Table 5.1 we summarize the computational complexity of the algorithms. We give the number of multiplications for computing the LS solution. The fast algorithm by Cybenko [14] is based on the inner products and projections as in a lattice algorithm for linear prediction [13] and it is quite different from any of the other fast algorithms mentioned for the Toeplitz matrix QR decomposition. For a comparison of the complexities of these algorithms, see Nagy [29]. By using the fast Fourier transform it is possible to perform the matrix-vector multiplications for a Toeplitz matrix in $O((m+n)\log(m+n))$ operations (see, e.g., [43, pp. 206–209]), thus reducing the operation count considerably for large n. In the table we have not taken this into account. Of course, on modern computers more factors than operation counts are important for the overall efficiency of algorithms, e.g., the possibility of pipelining vector operations and to parallelize the computations. This will be investigated in our future research.

In Figure 5.6, the actual gain in speed up from using the fast algorithms is illustrated. Here we have used the fast, FFT-based matrix-vector multiplication. The

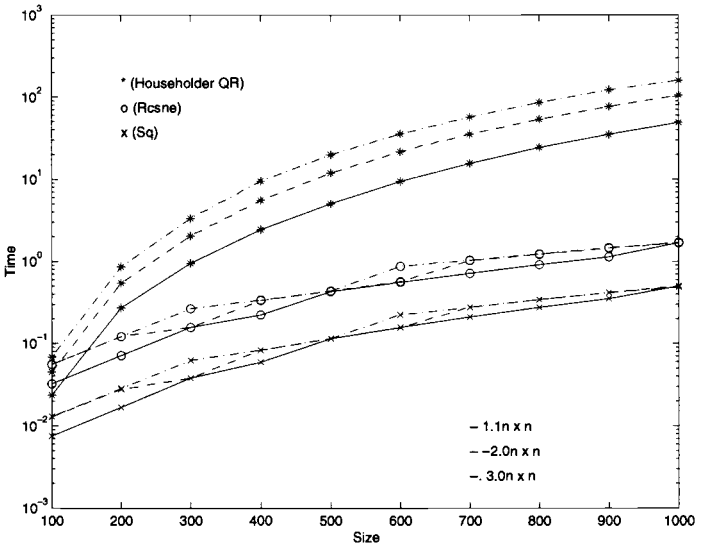

FIG. 5.6. *Execution time in seconds (on SGI Power Challenge) for solving LS problems with* $m \times n$ *Toeplitz matrix, with* $m = 1.1n$ *(solid line),* $m = 2n$ *(dashed line), and* $m = 3n$ *(dash dot line).*

tests were performed on an SGI Power Challenge in the Department of Computer Science and Engineering at the University of Minnesota in Minneapolis. Each output is an average of 20 runs and the test Toeplitz matrices were generated by specifying the first row and the first column, using random numbers. The matrices with column dimensions of $n = 100i$ with $i = 1, 2, \ldots, 10$ were tested. Also for each column dimension n, three different row dimensions of $1.1n$, $2n$, and $3n$ were used. We compared the Householder QR decomposition method with BLAS3 and the two fast algorithms, Algorithm Sq which is the fastest according to the floating operation count and Algorithm Rcsne which is the most accurate. As we can see in Figure 5.6, the gain in speed from using the fast algorithms is significant even for small problems. From the smallest problems of size 110×100, Algorithm Sq was already faster than the Householder QR by a factor of over 3. Then for the problems of size 3000×1000, Algorithm Sq and Algorithm Rcsne were faster than the Householder QR by factors of over 330 and 100, respectively. This test results show that the fast algorithms for Toeplitz LS problems are indeed faster than the slow counterpart in actual implementation.

6. Conclusions and remarks. We have studied fast direct algorithms for the solutions of Toeplitz LS problems. According to our numerical test results, algorithms Cyb, Sq, and Ssne consistently give higher errors than the others, even for relatively well-conditioned problems. For the Sq algorithm, the error estimate (3.4) (cf. also [32]) shows that the accuracy of R may depend on $\kappa_2^2(T)$, and therefore in general it is not accurate enough to qualify as a QR decomposition method. Even if we have no error analysis for the computation of $Q^T b$, its accuracy seems to be comparable to that of R. Since in algorithm Ssne both the computation of R and the solution of the SNE depend on $\kappa_2^2(T)$, this method is not expected to be more accurate than Algorithm Sq.

For well-conditioned problems the Scsne algorithm is about as accurate as the Rcsne and new algorithms. However, as is indicated in the error analysis for Algorithm 1 (see (3.4)), for more ill-conditioned problems, the R factor given by Algorithm 1 is not accurate enough for the assumptions of the theory in [5], [3, sect. 6.6.5] to hold. Therefore, for ill-conditioned problems, the CSNE method cannot make up for the imprecision of R, and the Scsne algorithm is not as accurate as the Rcsne and Gcsne algorithms.

By refining the R factor before the CSNE method is applied to the solution of the LS problem, the Rcsne method works better for more ill-conditioned problems than the Scsne algorithm. The Gcsne algorithm is similar to the Rcsne method in that the computed R factor is refined by the CSNE method. We have tested the fast algorithms on random data and numerous other difficult test problems, and the Rcsne and Gcsne algorithms consistently outperformed the others. However, if the matrix T is ill-conditioned with several small singular values (relative to the largest), then CSNE refinement of the R factor may not work well.

Based on our numerical experience, we expect that a hybrid method that avoids CSNE refinement of the upper triangular matrix in well-conditioned cases might be an accurate and less expensive alternative. Note that if the CSNE step is skipped in the new algorithm, then the operation count is reduced to $2mn + 12.5n^2$. A hybrid method can also be based on Scsne and Rcsne, which estimates the conditioning of R produced by Algorithm 1 and refines it (as in Rcsne) if necessary. More research is needed for testing the choice of tolerances and for implementing the algorithm for larger problems before such a method can be considered a reliable and robust algorithm in practice.

Recently Gu [22] published an algorithm for Toeplitz LS problems, based on the fact that a Toeplitz matrix is a Cauchy-like matrix. However, the operation count for that method is considerably higher than for the methods in the present paper.

Our current research also involves the comparison of the direct fast methods and the iterative methods for the Toeplitz LS problems. The iterative methods are promising since the Toeplitz matrix-vector multiplication can be performed by the FFT and also they do not use the recursions that the fast direct methods rely on. The possibility of circulant preconditioners may improve the speed further to make the iterative methods as fast as or faster than the fast direct methods.

LOCALLY ADAPTED TETRAHEDRAL MESHES USING BISECTION*

DOUGLAS N. ARNOLD†, ARUP MUKHERJEE‡, AND LUC POULY§

Abstract. We present an algorithm for the construction of locally adapted conformal tetrahedral meshes. The algorithm is based on bisection of tetrahedra. A new data structure is introduced, which simplifies both the selection of the refinement edge of a tetrahedron and the recursive refinement to conformity of a mesh once some tetrahedra have been bisected. We prove that repeated application of the algorithm leads to only finitely many tetrahedral shapes up to similarity, and we bound the amount of additional refinement that is needed to achieve conformity. Numerical examples of the effectiveness of the algorithm are presented.

Key words. bisection, tetrahedral meshes, adaptive refinement, similarity classes, finite elements

1. Introduction.

The generation of locally adapted conforming tetrahedral meshes is an important component of many modern algorithms, for example, in the finite element solution of partial differential equations. Typically, such meshes are produced by starting with a coarse tetrahedral mesh, selecting certain elements for refinement, somehow refining those elements and others as necessary to maintain conformity, and then possibly repeating this process one (or more than one) time. In this paper we present a simple algorithm for this purpose, and we analyze its behavior. In particular, we consider the question of the shape of tetrahedra that may arise from repeated application of our algorithm and show in section 4 that only a fixed finite number of dissimilar tetrahedra ever arise. A fortiori, the tetrahedral shape cannot degenerate as the mesh is refined in the sense that all the solid angles of all the descendants remain bounded below by a positive constant depending on the tetrahedra in the initial mesh.

The basic refinement step in our algorithm is tetrahedral bisection as in Figure 1. When bisecting a tetrahedron, a particular edge—called the *refinement edge*—is selected for the new vertex. As new tetrahedra are constructed in the course of generating an adapted mesh, their refinement edges must be selected carefully; otherwise element shapes may degenerate. A key aspect of any bisection algorithm is the selection of the refinement edge.

To refine a given conforming mesh we first bisect those tetrahedra that have been selected for refinement. This will usually lead to a nonconforming mesh (a mesh in which neighboring elements do not meet face-to-face). We then apply a recursive procedure to further refine until a conforming mesh is produced. Since it is not obvious

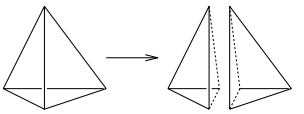

FIG. 1. *Bisection of a single tetrahedron.*

that this procedure will terminate in finitely many steps, in section 3 we provide a rigorous proof that this is the case and establish bounds on the number of steps.

Besides bisection, tetrahedra may be subdivided by octasection. This approach has been studied by Zhang [13] and Ong [10] to obtain uniformly refined meshes. However, octasection cannot be used alone to produce locally adapted conforming meshes. Motivated by work in two dimensions, where local quadrisection has been successfully combined with bisection to obtain conformity (cf., for example, Bank's code PLTMG [2]), Bey [4] has studied the use of local octasection combined with a variety of supplemental refinement strategies which are used to obtain conformity. By contrast, bisection can be used alone to create locally refined conforming meshes, which adds to the simplicity of its implementation. A further advantage of bisection over octasection is that it potentially allows finer control over mesh size. If an error indicator flags an element for refinement, with bisection the element can be divided to reduce its volume by a factor of 2, 4, ... , as required, while with octasection it is not possible to reduce element volume by a factor less than 8.

A number of other authors have proposed bisection-based algorithms for the refinement of tetrahedral meshes. In the pioneering paper [3], Bänsch presented an algorithm for local tetrahedral mesh refinement and discussed element shape degeneration. Although our algorithm appears quite different from Bänsch's, it is essentially equivalent, as we shall discuss in section 2. Another paper which influenced our work is that of Maubach [7]. Maubach considered the question of assigning refinement edges to successive bisections of a single simplex in an arbitrary number of dimensions. His algorithm cannot be easily applied to generate conforming adapted meshes, except for quite special initial meshes. For successive refinement of a single tetrahedron, we establish the precise relationship between our method and his in section 4. We show that his method generates only finitely many similarity classes of simplices (in n dimensions), and from this we deduce the same result for our algorithm. Liu and Joe [6] also study local refinement by bisection. Their algorithm, which is relatively complicated to state and to analyze, is in fact closely related to Bänsch's and therefore to ours. The relationship is discussed in section 2. Liu and Joe [5] prove that their algorithm generates only finitely many similarity classes, although their bound exceeds our sharp one by a large factor. A quite different approach to tetrahedral bisection has been pursued by Rivara [11] and Rivara and Levin [12]. They always use the longest edge of a tetrahedron as the refinement edge. In two dimensions, this approach leads to a finite number of similarity classes, although the number may be arbitrarily large, depending on the initial triangle [1]. As far as we know, the question of finiteness of similarity classes or even of element degeneration for longest edge bisection remains open in three dimensions.

A new aspect of our work is a data structure, which we name *marked tetrahedron*, used to store a geometric tetrahedron together with information necessary to choose its refinement edge and that of its descendants. This data structure is small—it contains just a little additional information beyond the vertices of the tetrahedron—

and it allows us to describe the bisection algorithm simply. Moreover, the marked tetrahedron data structure is useful for insuring mesh conformity. Any conforming tetrahedral mesh can be marked to yield a conforming mesh of marked tetrahedra, and therefore our algorithm does not require any restriction on the initial mesh.

2. Bisection of a single tetrahedron. In this section we describe the marked tetrahedron data structure and present the algorithm `BisectTet`. `BisectTet` bisects a marked tetrahedron by introducing a new vertex at the midpoint of the refinement edge and joining it to the two vertices of the original tetrahedron that do not lie on the refinement edge. It also marks the children (for use in further refinement).

To define a *marked tetrahedron* we introduce some terminology. For a tetrahedron τ, let $\mathcal{V}(\tau)$, $\mathcal{E}(\tau)$, and $\mathcal{F}(\tau)$ denote the set of its vertices, edges, and faces, respectively. For $\varphi \in \mathcal{F}(\tau)$, $\mathcal{E}(\varphi)$ denotes the edges contained in φ. Once a particular edge has been specified as the refinement edge of τ, the two faces that intersect at the refinement edge are called its *refinement faces*. For a marked tetrahedron we specify not only the refinement edge, but also a particular edge of each of the two nonrefinement faces. These are called the *marked edges* of these faces, and we take the refinement edge itself as the marked edges of the two refinement faces. Each marked tetrahedron is also assigned a boolean *flag*. The flag is always unset unless the marked edges of the four faces are all coplanar (we call this a *planar* marked tetrahedron), in which case the flag may or may not be set.

More precisely, a marked tetrahedron τ is a 4-tuple

$$\big(\mathcal{V}(\tau), r_\tau, (m_\varphi)_{\varphi\in\mathcal{F}(\tau)}, f_\tau\big),$$

where

$\mathcal{V}(\tau)$ is a set of four noncoplanar points in $\mathbb{R}^3$, the vertices of τ;
$r_\tau \in \mathcal{E}(\tau)$ is the refinement edge of τ;
$m_\varphi \in \mathcal{E}(\varphi)$ is the marked edge of φ, with $m_\varphi = r_\tau$ if $r_\tau \subset \varphi$;
$f_\tau \in \{0, 1\}$ is the flag, with $f_\tau = 0$ if τ is not planar.

Each marked nonrefinement edge of a marked tetrahedron is either adjacent or opposite to the refinement edge. Thus, we can classify marked tetrahedra into types as follows (cf. Figure 2).

- Type P, planar: the marked edges are coplanar. A type P tetrahedron is further classified as type P_f or type P_u, according to whether its flag is set or not, respectively.
- Type A, adjacent: the marked edges intersect the refinement edge, but are not coplanar.
- Type O, opposite: the marked edges of the nonrefinement faces do not intersect the refinement edge. In this case, a pair of opposite edges are marked in the tetrahedron: one as the refinement edge, and the other as the marked edge of the two nonrefinement faces intersecting there.
- Type M, mixed: the marked edge of just one of the nonrefinement faces intersects the refinement edge.

When a tetrahedron τ is bisected to create children τ_1 and τ_2, a face $\varphi \in \mathcal{F}(\tau_i)$ is called an *inherited face* if $\varphi \in \mathcal{F}(\tau)$, a *cut face* if $\varphi \subsetneqq \varphi'$ for some $\varphi' \in \mathcal{F}(\tau)$, and a *new face* otherwise. Each child has one inherited face, two cut faces, and one new face, which is common to both children. Cf. Figure 3. We are now ready to state `BisectTet`.

ALGORITHM $\{\tau_1, \tau_2\} =$ `BisectTet`(τ)
input: A marked tetrahedron τ

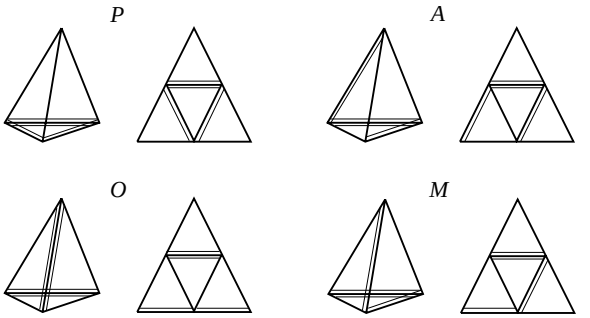

FIG. 2. *The four types of marked tetrahedra: P, A, O, and M. Each marked edge is indicated by a double line and the refinement edge is marked for both faces containing it. Each tetrahedron is shown in three dimensions and cut open and unfolded into two dimensions.*

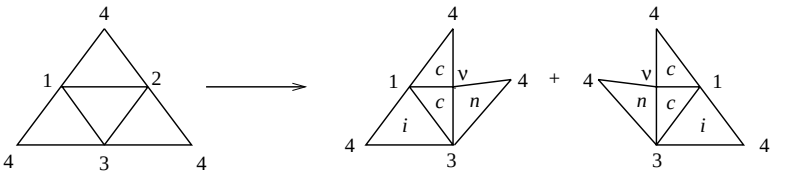

FIG. 3. *Typical bisection of a tetrahedron with the new vertex marked ν, cut faces marked c, inherited faces marked i, and new face marked n.*

output: Marked tetrahedra τ_1 and τ_2

1. Bisect τ by joining the midpoint of its refinement edge to each of the two vertices not lying on the refinement edge. This defines $\mathcal{V}(\tau_i)$ for $i = 1$ and 2.

Mark the faces of the children as follows.

2. The inherited face inherits its marked edge from the parent, and this marked edge is the refinement edge of the child.

3. On the cut faces of the children mark the edge opposite the new vertex with respect to the face.

4. The new face is marked the same way for both children. If the parent is type P_f, the marked edge is the edge connecting the new vertex to the new refinement edge. Otherwise it is the edge opposite the new vertex.

5. The flag is set in the children if and only if the parent is type P_u.

The algorithm is illustrated in Figure 4. Note that the tetrahedra τ_1 and τ_2 output by `BisectTet` will be of the same type. Figure 5 summarizes the relation between the input tetrahedron type and the output tetrahedra type. Note that types M and O are never output.

We close this section by relating the algorithm just described to those of Bänsch [3] and Liu and Joe [5], [6]. The relationship to the work of Maubach [7] will be treated in section 4. Bänsch used a slightly different system for marking a tetrahedron. Namely he associated to each face of the tetrahedron a unique marked edge. He assumes that at least one edge is marked in both faces containing it, and he calls such an edge a *global refinement edge*. This allows the possibility that a tetrahedron has two global refinement edges. Bänsch is not explicit in how such a tetrahedron is bisected. Presumably an arbitrary selection of one of the global refinement edges is made. Assuming such a selection, there is a direct correspondence between Bänsch's marking

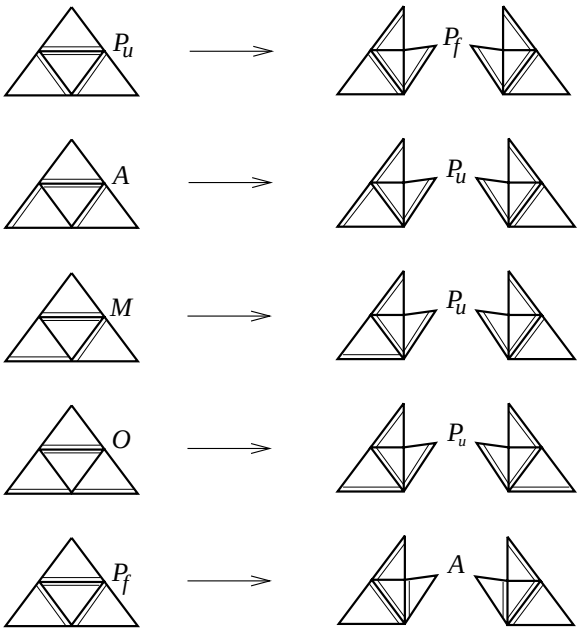

FIG. 4. *Bisection rules for marked tetrahedra.*

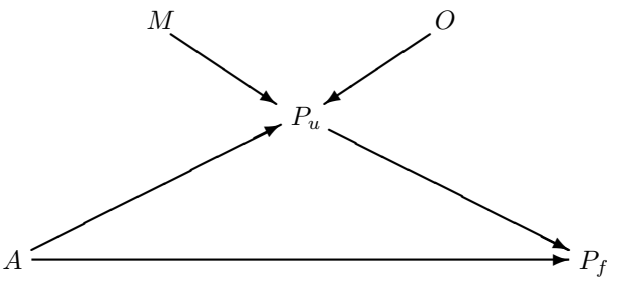

FIG. 5. *The types of tetrahedra produced by* `BisectTet`.

and ours. Bänsch refers to a tetrahedron of type A as red, one of type P as black, and does not explicitly name tetrahedra of type O or M. Our marking also involves a flag which for planar tetrahedra may be either set or unset. Bänsch addresses the same situation by referring to the parent of the tetrahedron: he singles out black tetrahedra with black parents for special treatment. These are precisely our tetrahedra of type P_f. For each type of tetrahedron Bänsch furnishes a picture showing how it should be refined. The algorithm thus described is, via the correspondences just presented, precisely equivalent to `BisectTet`. In this sense, `BisectTet` may be thought of as a convenient reformulation of Bänsch's algorithm.

The relationship to the work of Liu and Joe is less direct. In [5] they present an algorithm for the repeated bisection of an arbitrary tetrahedron. For this they introduce a special tetrahedron with a specific ordering of its vertices. The special tetrahedron and its descendants are always bisected using the longest edge as the refinement edge. They show that, for this particular tetrahedron, the mesh of nth

generation descendants is conforming and contains only one similarity class, which, in fact, depends only on n mod 3. To bisect an arbitrary tetrahedron, they choose an ordering for its vertices and use this to define a unique affine isomorphism with the special tetrahedron. The descendants of the arbitrary tetrahedron are then given as the inverse images of the descendants of the special tetrahedron under this transformation. Liu and Joe prove that the descendants fall into at most 168 distinct similarity classes and give a lower bound for a measure of their shape.

To draw the connection with `BisectTet`, we mark Liu and Joe's special tetrahedron with vertices p_0, p_1, p_2, and p_3, defined in their paper, so that $\overline{p_1p_2}$ is the refinement edge and $\overline{p_1p_3}$ and $\overline{p_2p_3}$ are the other marked edges. This is a planar marking, and we leave the flag unset, so that the special tetrahedron is marked to be type P_u. It can then be verified that applications of `BisectTet` to this marked tetrahedron and its descendants always bisect the longest edge. Indeed, for the first three generations this can be computed explicitly, and it turns out that at the third generation all of the descendants are similar to original special tetrahedron and correspondingly marked, so the bisection of the longest edge continues. Thus, for the special tetrahedron with appropriate marking, Liu and Joe's algorithm coincides with `BisectTet`. For an arbitrary tetrahedron with a selected ordering of its vertices we may use the affine isomorphism of the previous paragraph to transfer the marking from the special tetrahedron, and then we again have equivalence between the algorithm of Liu and Joe and the algorithm `BisectTet`. To summarize, given an arbitrary tetrahedron and an ordering of its vertices, we can determine a marking of this tetrahedron of type P_u, so that our algorithm and Liu and Joe's algorithm for repeated bisection of the tetrahedron are equivalent. In this sense the algorithm of [5] is equivalent to the special case of `BisectTet` applied to a tetrahedron of type P_u and its descendants. As a consequence we may apply our results from section 4 below to deduce that the descendants in fact fall into at most 36 similarity classes.

As remarked by the authors themselves, the question of how the algorithm of [5] can be applied to create a locally refined conforming mesh is far from obvious. This is the subject of [6]. The final algorithm, `QLRB`, which incorporates other algorithms called `BISECT1`, `BISECT2`, `TRANBIS`, `NEWTYPE`, `REFINE`, and `PREBISECT`, is far too complicated to describe here. We are not able to ascertain the precise relationship with `BisectTet` and the algorithm `LocalRefine` presented in the next section, although there are clearly points of similarity. In particular, the tetrahedron classes DD, DSS1, DSS2, and DSS3 introduced in [6] directly correspond to our types O, P, A, and M, respectively. In our analysis of `LocalRefine` in the next section we prove a termination theorem, Theorem 3.1. This is in fact the exact analogue of Theorem 3.1 for `QLRB` of [6].

3. A locally adaptive mesh refinement procedure. In many applications, such as adaptive finite element computations, one wishes to construct a sequence of nested conforming meshes which are adapted to a given criterion. A key step is the construction of a conforming refinement of a given conforming mesh, in which a selected subset of elements has been refined. In this section we describe an algorithm based on `BisectTet` to accomplish this.

Before stating the algorithm we fix some terminology. A *mesh* $\mathcal{T}$ of a domain Ω in $\mathbb{R}^3$ is a set of closed tetrahedra with disjoint interiors and union $\bar{\Omega}$. The *vertex set* of $\mathcal{T}$ is $\mathcal{V}(\mathcal{T}) = \bigcup\{\mathcal{V}(\tau) : \tau \in \mathcal{T}\}$. The *edge set* $\mathcal{E}(\mathcal{T})$ and the *face set* $\mathcal{F}(\mathcal{T})$ are defined similarly. A mesh is *conforming* if the intersection of two distinct tetrahedra is either a common face, a common edge, a common vertex, or empty. If $\tau \in \mathcal{T}$ and

$\nu \in \mathcal{V}(\mathcal{T})$, we say that ν is a *hanging node* of τ if $\nu \in \tau \setminus \mathcal{V}(\tau)$. A mesh is conforming if no tetrahedron in it has a hanging node and every face of every tetrahedron in the mesh either belongs to the boundary or is a face of another tetrahedron in the mesh. A mesh is *marked* if each tetrahedron in it is marked. A marked conforming mesh is *conformingly-marked* if each face has a unique marked edge (that is, when a face is shared by two tetrahedra, the marked edge is the same for both). Given an arbitrary conforming mesh the following marking procedure yields a conformingly-marked mesh. Strictly order the edges of the mesh in an arbitrary but fixed manner, for example, by length with a well-defined tie-breaking rule. Then choose the maximal edge of each tetrahedron as its refinement edge and the maximal edge of each face as its marked edge. Unset the flag on all tetrahedra. (The assumption that the coarse mesh has no flagged tetrahedra will be used in the analysis below.)

We now state the main algorithm of this section.

ALGORITHM $\mathcal{T}' = \texttt{LocalRefine}\ (\mathcal{T}, \mathcal{S})$

input: conformingly-marked mesh $\mathcal{T}$ and $\mathcal{S} \subset \mathcal{T}$

output: conformingly-marked mesh $\mathcal{T}'$

1. $\bar{\mathcal{T}} = \texttt{BisectTets}(\mathcal{T}, \mathcal{S})$
2. $\mathcal{T}' = \texttt{RefineToConformity}(\bar{\mathcal{T}})$

The algorithm in the first step, `BisectTets`, is trivial; we simply bisect each tetrahedron in $\mathcal{S}$:

$$\texttt{BisectTets}(\mathcal{T}, \mathcal{S}) = (\mathcal{T} \setminus \mathcal{S}) \cup \bigcup_{\tau \in \mathcal{S}} \texttt{BisectTet}(\tau).$$

In the second step, we perform further refinement as necessary to obtain a conforming mesh:

ALGORITHM $\mathcal{T}' = \texttt{RefineToConformity}(\mathcal{T})$

input: marked mesh $\mathcal{T}$

output: marked mesh $\mathcal{T}'$ without hanging nodes

1. set $\mathcal{S} = \{\tau \in \mathcal{T} \mid \tau \text{ has a hanging node}\}$
2. if $\mathcal{S} \neq \emptyset$ then
   $\bar{\mathcal{T}} = \texttt{BisectTets}(\mathcal{T}, \mathcal{S})$
   $\mathcal{T}' = \texttt{RefineToConformity}(\bar{\mathcal{T}})$
3. else
   $\mathcal{T}' = \mathcal{T}$

The recursion in the Algorithm `RefineToConformity` could conceivably continue forever. Moreover, even if the recursion terminates, the output mesh may not be conforming (a mesh without hanging nodes can nonetheless be nonconforming; cf. Figure 6). However, we shall prove that the recursion does terminate in the application of `RefineToConformity` in Algorithm `LocalRefine`, and that the resulting output mesh is conformingly-marked. Moreover, we shall bound the amount of refinement which can occur before termination. To state this result precisely, we consider an initial marked mesh $\mathcal{T}_0$ and set $\mathcal{Q}_0 = \mathcal{T}_0$, and $\mathcal{Q}_{k+1} = \texttt{BisectTets}(\mathcal{Q}_k, \mathcal{Q}_k)$, $k = 0, 1, \ldots$. Thus $\mathcal{Q}_1$ consists of all children of tetrahedra in the initial mesh, $\mathcal{Q}_2$ all grandchildren, etc. We assign *generation* k to all tetrahedra in $\mathcal{Q}_k$.

THEOREM 3.1. *Let $\mathcal{T}_0$ be a conformingly-marked mesh with no flagged tetrahedra. For $k = 0, 1, \ldots$, choose $\mathcal{S}_k \subset \mathcal{T}_k$ arbitrarily, and set $\mathcal{T}_{k+1} = \texttt{LocalRefine}(\mathcal{T}_k, \mathcal{S}_k)$. Then for each k, the application of* `RefineToConformity` *from within* `LocalRefine` *terminates producing a conformingly-marked mesh, and each tetrahedron in $\mathcal{T}_k$ has a generation of at most $3k$. Moreover, if the maximum generation of a tetrahedron in*

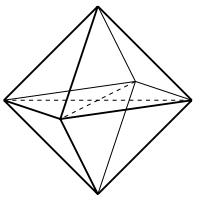

FIG. 6. *A nonconforming mesh without hanging nodes (the barycenter is* not *a vertex of the mesh).*

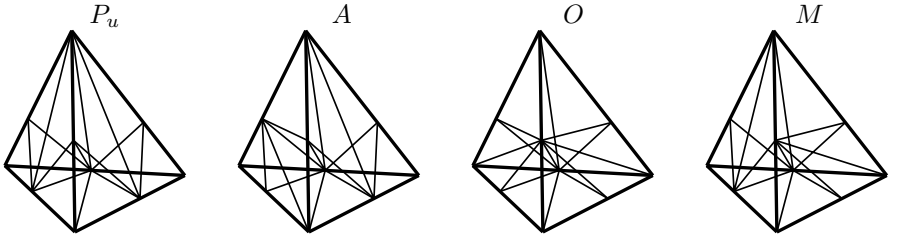

FIG. 7. *The meshes obtained via three applications of* `BisectTet` *beginning with a tetrahedra of type* P_u, A, O, *and* M.

$\mathcal{T}_k$ *is less than* $3m$ *for some integer* m, *then the maximum generation of a tetrahedron in* $\mathcal{T}_{k+1}$ *is less than or equal to* $3m$.

For the proof of the theorem, we need a classification of the edges that arise from repeated bisection of an unflagged marked tetrahedron τ. Let $\mathcal{Q}_0^\tau = \{\tau\}$ and define the meshes $\mathcal{Q}_k^\tau$ in analogy to the definition of the $\mathcal{Q}_k$ above (so $\mathcal{Q}_k^\tau$ contains all descendants of τ of generation k). We define $\mathcal{E}_k(\tau) = \mathcal{E}(\mathcal{Q}_{3k}^\tau)$ and refer to these as the edges of generation k. Thus the edges of generation 0 are exactly the edges of τ itself, and, referring to Figure 7, we verify that the edges of generation 1 are precisely the following 25 line segments:

- the line segment connecting the midpoint of the refinement edge to the midpoint of the opposite edge;
- for each face, the line segment connecting the midpoint of the marked edge to the opposite vertex;
- for each face, the two line segments connecting the midpoint of the marked edge to the midpoints of the two nonmarked edges;
- for each edge, its two children.

LEMMA 3.2. *Let* τ *be an unflagged marked tetrahedron. Then for* $k = 1, 2, \ldots$, *the mesh* $\mathcal{Q}_{3k}^\tau$, *consisting of all descendants of* τ *of generation* $3k$, *is conformingly-marked. If* τ *is of type* P_u, *then all the tetrahedra in* $\mathcal{Q}_{3k}^\tau$ *are of type* P_u, *and otherwise all the tetrahedra in* $\mathcal{Q}_{3k}^\tau$ *are of type* A.

Proof. It is clear from Figure 7 that $\mathcal{Q}_3^\tau$ is conforming. Moreover, the definition of `BisectTet` insures $\mathcal{Q}_3^\tau$ is conformingly-marked (because whenever a face is introduced, it is marked identically in the tetrahedra containing it). From the diagram in Figure 5, we see that tetrahedra in $\mathcal{Q}_3^\tau$ are all either type P_u or type A, depending on whether τ is type P_u. This verifies the lemma in case $k = 1$.

If $\tau' \in \mathcal{Q}_3^\tau$, then the mesh of third generation descendants of τ' is, by the same argument, conformingly-marked and uniformly of type P_u or A. Because $\mathcal{Q}_3^\tau$ is it-

TABLE 1
The types of tetrahedra and generation of edges occurring in the meshes $\mathcal{Q}_k$.

Generations of tetrahedra	Types of tetrahedra		Generations of edges
0	P_u	nonplanar	0
1	P_f	P_u	0,1
2	A	P_f	0,1
3	P_u	A	1
4	P_f	P_u	1,2
5	A	P_f	1,2
6	P_u	A	2
⋮	⋮	⋮	⋮
$3k$	P_u	A	k
$3k+1$	P_f	P_u	$k, k+1$
$3k+2$	A	P_f	$k, k+1$
$3(k+1)$	P_u	A	$k+1$

self conformingly-marked, the mesh obtained by combining all these meshes is again conformingly-marked, verifying the lemma in case $k = 2$. By induction we obtain the result for all k. □

If τ' is a generation $3k$ descendant of an unflagged marked tetrahedron τ, then, by definition, all of the edges of τ' have generation k. The next lemma determines the generations of the edges of descendants of generation $3k+1$ and $3k+2$.

LEMMA 3.3. *Let τ be an unflagged marked tetrahedron and τ' a descendant of τ of generation $3k+1$ or $3k+2$. Then the edges of τ' all have generation k or $k+1$.*

Proof. The tetrahedron τ' is either a child or a grandchild of an unflagged tetrahedron of generation $3k$. From Figure 7, it is easy to see that every edge of a child or a grandchild of an unflagged tetrahedron is either an edge of that tetrahedron or an edge of one of its great grandchildren. Thus each edge of τ' is an edge of a tetrahedron whose generation is either $3k$ or $3k+3$. □

Returning to Theorem 3.1, we easily deduce the following proposition from the preceding lemmas.

PROPOSITION 3.4. *Let $\mathcal{T}_0$ be a conformingly-marked mesh with no flagged tetrahedra, and let $\mathcal{Q}_k$ denote the mesh of all descendants of generation k of tetrahedra in $\mathcal{T}_0$. Then the types of tetrahedra and the generation of edges of occurring in $\mathcal{Q}_k$ are as shown in Table* 1. *Moreover, the meshes $\mathcal{Q}_{3k}$ are conformingly-marked.*

Proof of Theorem 3.1. The proof will proceed in several steps. We use the terminology *descendant mesh of $\mathcal{T}_0$* to refer to any mesh that can arise from $\mathcal{T}_0$ by repeated application of `BisectTet`.

Step 1. If $\mathcal{T}$ is any descendant mesh of $\mathcal{T}_0$ which has maximal tetrahedron generation $3k$, then the application of `BisectTets` in step 2 of `RefineToConformity`($\mathcal{T}$) returns a mesh which again has maximal tetrahedron generation $3k$.

Proof. We refer to Table 1 to see that all the edges of tetrahedra in $\mathcal{T}$ are of most generation k. Now if a tetrahedron in $\mathcal{T}$ has a hanging node, then the edge of the tetrahedron on which the hanging node lies must have generation $k-1$ or less (since its children are also edges in the mesh and so have generation k or less). Hence, again with reference to the table, a tetrahedron with a hanging node has generation strictly less than $3k$. That is, the set $\mathcal{S}$ defined in step 1 of `RefineToConformity` consists of tetrahedra of generation less than $3k$. Consequently the mesh output from `BisectTets` in step 2 of `RefineToConformity`, again has maximal tetrahedron generation $3k$.

Step 2. If $\mathcal{T}$ is any descendant mesh of $\mathcal{T}_0$ which has maximal tetrahedron gener-

ation $3k$, then every mesh constructed in the recursive application of the algorithm `RefineToConformity`$(\mathcal{T})$ has maximal tetrahedron generation $3k$ and, moreover, the algorithm terminates.

Proof. Indeed new tetrahedra are only introduced by the application of `BisectTets` in step 2 of `RefineToConformity`, so the generation bound follows from the previous step. Since there are only finitely many tetrahedra of generation $3k$, the algorithm must terminate.

Step 3. Each tetrahedron in $\mathcal{T}_k$ has generation at most $3k$.

Proof. The proof is by induction on k, with the case $k = 0$ being the obvious final step. By the induction hypothesis, $\mathcal{T}_{k-1}$ consists of tetrahedra of generation at most $3k - 3$. Hence, the mesh $\bar{\mathcal{T}}$ output from `BisectTets` in step 1 of `LocalRefine`$(\mathcal{T}_{k-1}, \mathcal{S}_{k-1})$ has maximum tetrahedron generation $3k - 2 \le 3k$, and the result follows from the preceding claim.

Step 4. The output mesh is conformingly-marked.

Proof. This follows easily from the fact that the output mesh is a descendant of a conformingly-marked mesh and has no hanging nodes.

Step 5. The last sentence of the theorem follows directly from step 2. ∎

4. Similarity classes. In [7] Maubach presented an algorithm, which we refer to as `BisectSimplex`, for the bisection of an arbitrary n-simplex in $\mathbb{R}^n$. After recalling this algorithm, we shall show that in the special case $n = 3$, it is essentially equivalent to `BisectTet`, when `BisectTet` is restricted to tetrahedra of types A and P as input. Define a *tagged simplex* in $\mathbb{R}^n$ as an ordered pair, $\mathfrak{t} = \big((x_0, x_1, \dots, x_n), d\big)$, where $(x_0, x_1, \dots, x_n)$ is an ordered $(n+1)$-tuple of points in general position in $\mathbb{R}^n$ (the vertices of the simplex), and $d \in \{1, 2, \dots, n\}$ is a *tag* ($\overline{x_0 x_d}$ is the refinement edge of $\mathfrak{t}$). With this terminology, Maubach's algorithm may be stated as follows.

ALGORITHM $\{\mathfrak{t}^{(1)}, \mathfrak{t}^{(2)}\} =$ `BisectSimplex`$(\mathfrak{t})$

input: tagged n-simplex $\mathfrak{t}$

output: tagged n-simplices $\mathfrak{t}^{(1)}$ and $\mathfrak{t}^{(2)}$.

1. set $d' = \begin{cases} d-1, & d > 1 \\ n, & d = 1 \end{cases}$
2. create the new vertex $z = \frac{1}{2}(x_0 + x_d)$
3. set $\mathfrak{t}^{(1)} = \big((x_0, x_1, \dots, x_{d-1}, z, x_{d+1}, ..., x_n), d'\big)$
4. set $\mathfrak{t}^{(2)} = \big((x_1, x_2, \dots, x_d, z, x_{d+1}, ..., x_n), d'\big)$

We now define a correspondence between tagged simplices in $\mathbb{R}^3$ and marked tetrahedra of types P and A, and we show that repeated application of either `BisectTet` or `BisectSimplex` to the same geometric tetrahedron yields the same sequence of descendant tetrahedra. Let $\mathcal{T}_T$ be the set of all tagged 3-simplices and $\mathcal{T}_M$ be the set of all marked tetrahedra; also, let $\mathcal{T}_a \subset \mathcal{T}_M$ denote the set of marked tetrahedra of type A or P. Define a mapping $\mathcal{F} : \mathcal{T}_T \to \mathcal{T}_M$ as follows.

For $\mathfrak{t} = \big((x_0, x_1, x_2, x_3), d\big) \in \mathcal{T}_T$, set $\mathcal{F}(\mathfrak{t}) = (\mathcal{V}(\tau), r_\tau, m_\varphi, f_\tau)$ with $\mathcal{V}(\tau) = \{x_0, x_1, x_2, x_3\}$ and

$$r_\tau = x_0 x_1, \quad m_\varphi = \begin{cases} \overline{x_0 x_3} & \text{if } \varphi = x_0 x_2 x_3, \\ \overline{x_1 x_3} & \text{if } \varphi = x_1 x_2 x_3, \end{cases} \quad f_\tau = 1 \quad \text{if } d = 1;$$

$$r_\tau = x_0x_2, \quad m_\varphi = \begin{cases} \overline{x_0x_1} & \text{if } \varphi = x_0x_1x_3, \\ \overline{x_1x_2} & \text{if } \varphi = x_1x_2x_3, \end{cases} \quad f_\tau = 0 \quad \text{if } d = 2;$$

$$r_\tau = x_0x_3, \quad m_\varphi = \begin{cases} \overline{x_0x_2} & \text{if } \varphi = x_0x_1x_2, \\ \overline{x_1x_3} & \text{if } \varphi = x_1x_2x_3, \end{cases} \quad f_\tau = 0 \quad \text{if } d = 3.$$

Note that $\mathcal{F}(\mathfrak{t})$ has type P_f, P_u, or A, when $d = 1$, 2, or 3, respectively. Consequently, $\mathcal{F}(\mathcal{T}_T) \subset \mathcal{T}_a$. In fact, we have the following proposition.

PROPOSITION 4.1. *The mapping $\mathcal{F}$ maps $\mathcal{T}_T$ onto $\mathcal{T}_a$ and is precisely 2 to 1.*

Proof. Given a marked tetrahedron $\tau = (\{v_0, v_1, v_2, v_3\}, r_\tau, m_\varphi, f_\tau) \in \mathcal{T}_a$, we define two tagged 3-simplices in its preimage under $\mathcal{F}$ as follows.

If τ has type A, we assume, without loss of generality, that its refinement and nonrefinement edges are $\overline{v_0v_1}$ and $\{\overline{v_0v_2}, \overline{v_1v_3}\}$, respectively. To get the first tagged simplex, set $d = 3$ and choose $x_0 = v_0$ and $x_d = v_1$ (the end points of the refinement edge). Set $x_1 = v_3$ (the second endpoint of the marked nonrefinement edge containing x_d) and $x_2 = v_2$. To obtain the second tagged simplex, we reverse x_0 and x_3 and x_1 and x_2. Thus, the two tagged 3-simplices corresponding to the given marked tetrahedron are $\big((v_0, v_3, v_2, v_1), 3\big)$ and $\big((v_1, v_2, v_3, v_0), 3\big)$. It is straightforward to check that $\mathcal{F}$ maps each of these tagged simplices to τ and that these are the only preimages of τ under $\mathcal{F}$. The argument is similar in the cases of τ of type P_u or P_f. In the P_u case, we take the numbering so that the refinement and marked nonrefinement edges are $\overline{v_0v_1}$ and $\{\overline{v_0v_2}, \overline{v_1v_2}\}$, respectively, and find the two preimages $\big((v_0, v_2, v_1, v_3), 2\big)$ and $\big((v_1, v_2, v_0, v_3), 2\big)$. In the P_f case with refinement and marked nonrefinement edges $\overline{v_0v_1}$ and $\{\overline{v_0v_2}, \overline{v_1v_2}\}$, the preimages are $\big((v_0, v_1, v_3, v_2), 1\big)$ and $\big((v_1, v_0, v_3, v_2), 1\big)$. ∎

The following theorem exhibits the relation between the algorithms `BisectTet` and `BisectSimplex`.

THEOREM 4.2. *The following diagram commutes.*

$$\begin{array}{ccc} \mathcal{T}_T & \xrightarrow{\ \mathcal{F}\ } & \mathcal{T}_M \\ \Big\downarrow{\scriptstyle \texttt{BisectSimplex}} & & \Big\downarrow{\scriptstyle \texttt{BisectTet}} \\ \mathcal{T}_T \times \mathcal{T}_T & \xrightarrow{\ \mathcal{F}\times\mathcal{F}\ } & \mathcal{T}_M \times \mathcal{T}_M \end{array}$$

Proof. Suppose $\mathfrak{t} = \big((x_0, x_1, x_2, x_3), 3\big) \in \mathcal{T}_T$, and $\{\mathfrak{t}^{(1)}, \mathfrak{t}^{(2)}\} \in \mathcal{T}_T \times \mathcal{T}_T$ is produced by `BisectSimplex`($\mathfrak{t}$). Then $\mathfrak{t}^{(1)} = \big((x_0, x_1, x_2, z), 2\big)$ with $z = (x_0 + x_3)/2$, and so $\mathcal{F}(\mathfrak{t}^{(1)})$ yields the marked tetrahedron $(\{x_0, x_1, x_2, z\}, \overline{x_0x_2}, \{\overline{x_0x_1}, \overline{x_1x_2}\}, 0)$. (Here, only the markings for the nonrefinement faces of the tetrahedron are specified in m_φ with the convention that the given edges are marked for the nonrefinement face containing them.) On the other hand, $\mathcal{F}(\mathfrak{t}) = (\{x_0, x_1, x_2, x_3\}, \overline{x_0x_3}, \{\overline{x_0x_2}, \overline{x_1x_3}\}, 0)$ which is a tetrahedron of type A, and one of the marked tetrahedra produced by applying `BisectTet` to this tetrahedron is $\mathcal{F}(\mathfrak{t}^{(1)})$. A similar verification is easily carried out for the other cases. ∎

Theorem 4.2 implies that if `BisectSimplex` is applied m times to a tagged 3-simplex, the images under the mapping $\mathcal{F}$ of the 2^m descendents are exactly the descendents obtained by applying `BisectTet` m times to the image under $\mathcal{F}$ of the parent. The following corollary is thus immediate.

COROLLARY 4.3. *The 2^m geometric 3-simplices obtained by applying the algorithm* `BisectSimplex` *m times to $\mathfrak{t} \in \mathcal{T}_T$ are exactly the same as those obtained by applying* `BisectTet` *m times to $\mathcal{F}(\mathfrak{t})$.*

Our next goal is a bound on the number of similarity classes produced by repeated application of algorithm `BisectSimplex`. (Two simplices are said to belong to the same similarity class if one can be transformed to the other via a dilation and a rigid motion.) This will be based on the following technical result from [7]. (Theorem 4.1 of [7] states this result in less generality, but the same proof applies to the statement given here.)

LEMMA 4.4. *Let $\mathfrak{t}'$ be a descendent of the tagged n-simplex*

$$\mathfrak{t} = \big((0, e_1, e_1 + e_2, \dots, e_1 + e_2 + \cdots + e_n), n\big)$$

obtained via k applications of `BisectSimplex`*, where $\mathcal{B} = \{e_1, e_2, \dots, e_n\}$ is an arbitrary basis of $\mathbb{R}^n$. Define integers $q \geq 0$ and $r \in \{0, \dots, n-1\}$ by $k = qn + r$. Let $(x_0, x_1, \dots, x_n)$ be the ordered vertices of $\mathfrak{t}'$ and define $y_i = x_i - x_0$ for $i = 1, 2, \dots, n$. Then, there exist two linear mappings π and R from $\mathbb{R}^n$ to $\mathbb{R}^n$ such that $\{\pi(e_1), \pi(e_2), \dots, \pi(e_n)\}$ is a permutation of the basis vectors of $\mathcal{B}$, and $R(e_i) = \pm e_i$, $1 \leq i \leq n$, with*

$$y_i = \left(\frac{1}{2}\right)^q \alpha_i R\pi \sum_{j=1}^{i} e_j, \qquad 1 \leq i \leq n,$$

where

$$\alpha_i = \begin{cases} 1, & 1 \leq i \leq n - r, \\ \frac{1}{2}, & n - r + 1 \leq i \leq n. \end{cases}$$

THEOREM 4.5. *The number of similarity classes of n-simplices produced by the repeated application of* `BisectSimplex` *is bounded by $nn!2^{n-2}$.*

Proof. Without loss of generality we may assume that the initial simplex has tag n, because an arbitrary tagged simplex is a descendant of such a simplex. For example, $\big((x_0, x_1, x_2, \dots, x_n), n-1\big)$ is a child of $\big((x_0, x_1, x_2, \dots, 2x_n - x_0), n\big)$. Moreover we may translate so that the first vertex is at the origin, and thus the initial simplex can be taken to be of the form $\mathfrak{t}$ assumed in the lemma.

From this immediately get an upper bound of $nn!2^n$ similarity classes for the descendants, since there are $n!$ possibilities for the permutations π, 2^n possibilities for the reflections R, and exactly n different vectors α_i. Noting that two different reflections, R and $-R$, give n-simplices in the same similarity class, the bound can be reduced by a factor of 2 to $nn!2^{n-1}$. To prove the theorem it suffices to reduce this by another factor of 2, which we shall do by showing that each n-simplex produced is a translate of another.

Using the notations introduced in Lemma 4.4 and noting that q does not play a role in the count for the number of similarity classes of tetrahedra, we will assume $q = 0$ without any loss of generality. Define the mappings $\hat{\pi} : \mathbb{R}^n \to \mathbb{R}^n$ and $\hat{R} : \mathbb{R}^n \to \mathbb{R}^n$ by

$$\hat{\pi}(e_j) = \begin{cases} \pi(e_{n-r+1-j}), & 1 \leq j \leq n - r, \\ \pi(e_j), & n - r + 1 \leq j \leq n, \end{cases} \tag{1}$$

$$\hat{R}\pi\,(e_j) = \begin{cases} -R\pi(e_j), & 1 \leq j \leq n - r, \\ R\pi(e_j), & n - r + 1 \leq j \leq n, \end{cases} \tag{2}$$

for $j \in \{1, 2, \dots, n\}$. Note that $\hat{\pi}$ is a permutation and $\hat{R}$ a reflection relative to $\mathcal{B}$. The ordered set $(0, y_1, y_2, \dots, y_n)$ represents the vertices of the tagged n-simplex $\mathfrak{t}'$. Denote the ordered set of vertices of another tagged n-simplex $\hat{\mathfrak{t}}$ by $(0, \hat{y}_1, \hat{y}_2, \dots, \hat{y}_n)$ with $\hat{y}_i = \alpha_i \hat{R}\hat{\pi} \sum_{j=1}^{i} e_i$ for $1 \le i \le n$. Let $\Phi : \mathbb{R}^n \to \mathbb{R}^n$ be the translation defined by

$$\Phi(x) = x - R\pi \sum_{j=1}^{n-r} e_j = x - y_{n-r}.$$

Then $\Phi(0) = -R\pi \sum_{j=1}^{n-r} e_j$ and

$$\Phi(y_i) = \begin{cases} -R\pi \sum\limits_{j=i+1}^{n-r} e_j, & 1 \le i < n-r, \\ 0, & i = n-r, \\ -\frac{1}{2} R\pi \sum\limits_{j=1}^{n-r} e_j + \frac{1}{2} R\pi \sum\limits_{j=n-r+1}^{i} e_j, & n-r+1 \le i \le n. \end{cases}$$

Using (1), (2), and the definition of $\hat{y}_i$, we get $\Phi(0) = \hat{y}_{n-r}$ and

$$\Phi(y_i) = \begin{cases} \hat{y}_{n-r-i}, & 1 \le i < n-r, \\ 0, & i = n-r, \\ \hat{y}_i, & n-r+1 \le i \le n. \end{cases}$$

Thus, $\mathfrak{t}'$ is related to $\hat{\mathfrak{t}}$ via the translation Φ as desired. □

For $n = 2$ the bound of four similarity classes furnished by the theorem is easily seen to be sharp. For $n = 3$, the bound is 36. By direct computation on a particular tetrahedron we have verified that the bound of 36 is sharp. (For example, if $\mathfrak{t} = \big((v_0, v_1, v_2, v_3), 3\big)$, where $v_0 = (0, 0, 0)$, $v_1 = (23, 0, 0)$, $v_2 = (7, 0, 11)$, and $v_3 = (17, 5, 33)$, then the upper bound of 36 is attained at the sixth generation.) Maubach [8] has announced a proof that the bound of $nn!2^{n-2}$ is sharp for all n.

In view of Proposition 4.1 and Theorem 4.2, the above result applies to bisection of marked tetrahedra of types A and P: repeated application of `BisectTet` starting from such a marked tetrahedron will produce at most 36 similarity classes. Since one application of `BisectTet` to a tetrahedron of type O or M produces children of type P_u, the repeated bisection of such a tetrahedron will produce at most 72 similarity classes of tetrahedra. In particular, for an arbitrary initial mesh of marked tetrahedra, only finitely many similarity classes will arise in its descendant meshes.

5. Examples. In this section, we give some examples of adapted tetrahedral meshes generated using `LocalRefine`. A coarse initial mesh $\mathcal{T}_0$ is chosen and the meshes $\mathcal{T}_k$ are generated using $\mathcal{T}_k = \texttt{LocalRefine}(\mathcal{T}_{k-1}, \mathcal{S}_{k-1})$ as in section 3 with different criteria being used to determine the sets $\mathcal{S}_k$ in each example.

Example 1. The first example is adapted from Maubach [7]. Let $\mathcal{T}_0$ be the subdivision of the cube $[0, 1]^3$ into six congruent tetrahedra. We choose the longest edge of each face as its marked edge. It can easily be verified that all six tetrahedra are of type A and they belong to the same similarity class. Let

$$\mathcal{H} = \left\{ (x, y, z) \in \mathbb{R}^3 \middle| \left(x - \frac{1}{2}\right)^2 + \left(y - \frac{1}{2}\right)^2 + \left(z - \frac{1}{2}\right)^2 = \frac{1}{16} \text{ with } x \ge \frac{1}{2} \right\}$$

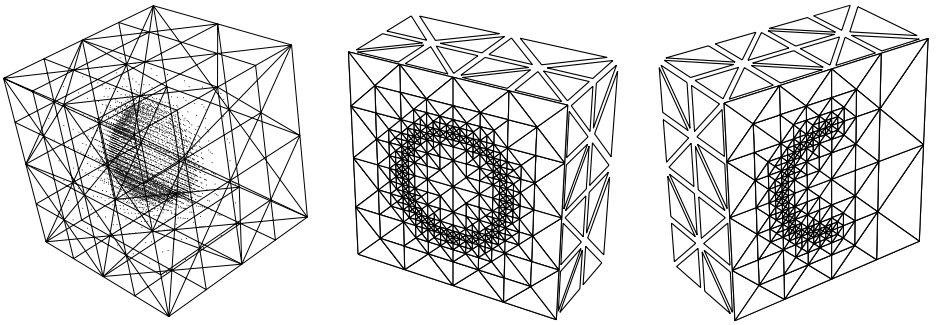

FIG. 8. *The mesh $\mathcal{T}_{16}$ of Example* 1. *The first view shows the vertices of the mesh, the second a cut along the plane $x = 1/2$, and the third a cut along the plane $y = 1/2$.*

be a hemisphere embedded in the cube. We choose $\mathcal{S}_{k-1} = \{\tau \in \mathcal{T}_{k-1} | \tau \cap \mathcal{H} \neq \emptyset\}$, so that we attempt to adapt the meshes to the hemisphere $\mathcal{H}$. Figure 8 shows different views of $\mathcal{T}_{16}$ having 25,448 tetrahedra. The local adaptivity around $\mathcal{H}$ is clear.

The algorithm `LocalRefine` has been incorporated into a code for solving second order elliptic boundary value problems (cf. [9]). Error estimators are used to determine the sets $\mathcal{S}_k$ in the code, leading to refinement in regions where the gradient of the solution changes rapidly.

Example 2. This example is a test problem for which the exact solution is known to be

$$u_{\text{ex}} = (x^2 - x)(y^2 - y)(z^2 - z)e^{-100[(x-1/4)^2+(y-1/4)^2+(z-1/4)^2]},$$

and $\mathcal{T}_0$ was taken to be a subdivision of $[0,1]^3$ having 96 tetrahedra. The problem was solved using piecewise linear finite elements, and a full multigrid solver based on the sequence of adaptively defined meshes. Note that u_{ex} varies very rapidly near the point $(1/4, 1/4, 1/4)$, and has relatively slow variation in other parts of the domain. This behavior is captured well by the adaptive mesh refinement process, as seen in $\mathcal{T}_6$ pictured in Figure 9.

Figure 10 shows a log-log plot of the errors in energy and L^2 norms against $\mathcal{V}(\mathcal{T})^{-1/3}$, which is an indicator of mesh size for locally refined meshes, using both adaptive and uniform refinement. (Lines with slopes 1 and 2 are shown for easy comparison.) Using uniform refinement, the finest mesh has 68,705 vertices and a relative percentage energy error of approximately 15.85% while the maximum number of vertices using adaptive refinement are 62,738 and the corresponding relative percentage energy error is 4.95%.

Example 3. As a final example, we consider a problem that arose in numerical relativity concerning compatible initial metric data for the collision of two black holes. This involves a nonlinear elliptic boundary value problem which we solve with piecewise linear finite elements, an outer Newton iteration, and an inner multigrid iteration based on the sequence of adapted meshes. For details, see [9]. The domain consists of a ball about the origin of radius $64\sqrt{3}$ minus two disjoint balls of radius $\sqrt{3}/2$ and $\sqrt{3}$ centered at $(0, 0, -2\sqrt{3})$ and $(0, 0, 2\sqrt{3})$, respectively. Beginning with the mesh $\mathcal{T}_0$ containing 585 vertices and 2,982 tetrahedra the code produced an adapted mesh $\mathcal{T}_5$ with 63,133 vertices and 346,084 tetrahedra. In Figures 11 and 12, which is a zoom of the previous figure, we show results computed on the intermediate mesh $\mathcal{T}_3$ with

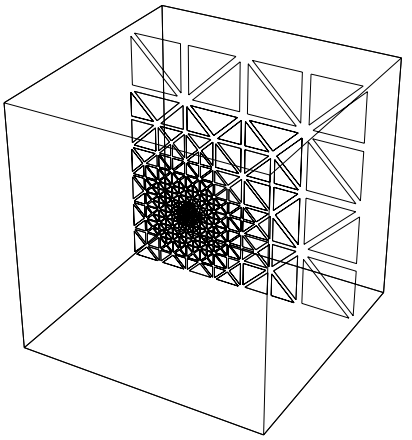

FIG. 9. *Cut along the the plane* $x = 1/4$ *of* $\mathcal{T}_6$ *of Example* 2 *(there are* 11,418 *tetrahedra and* 2,116 *vertices in the mesh).*

13,899 vertices and 75,300 tetrahedra.

The figures show a contour plot of the solution on the plane $x = y$ (the plot shade is keyed to the value of the solution). This is easier to interpret in the color version, which can be found in [9]. The intersections of the tetrahedra with the plane are shown slightly shrunken to improve visibility. Also shown are the mesh edges which intersect the boundary. Next, Figure 13 gives evidence of the mesh quality in the initial and final meshes. The shape measure used is the ratio of the circumscribed to inscribed spheres, scaled so that an equilateral tetrahedron has shape measure one. The first histogram shows that in the initial mesh more than 80% of elements have measure less than 2, while the worst elements have quality around 3.5. In the final mesh, 72% of the elements have measure less than 2, while 84% have measure less than 2.5, and the worst elements have measure about 5.4.

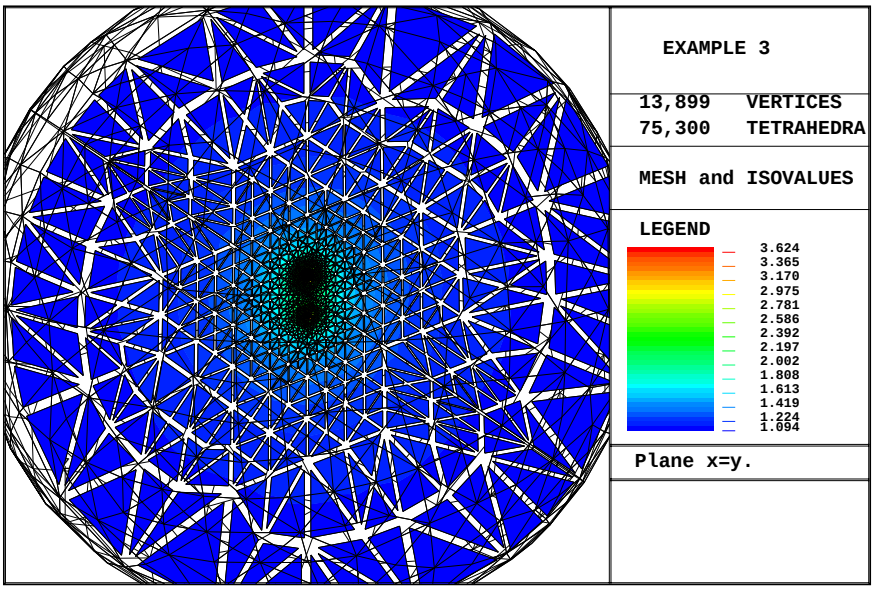

FIG. 11. *Solution to a binary black hole problem.*

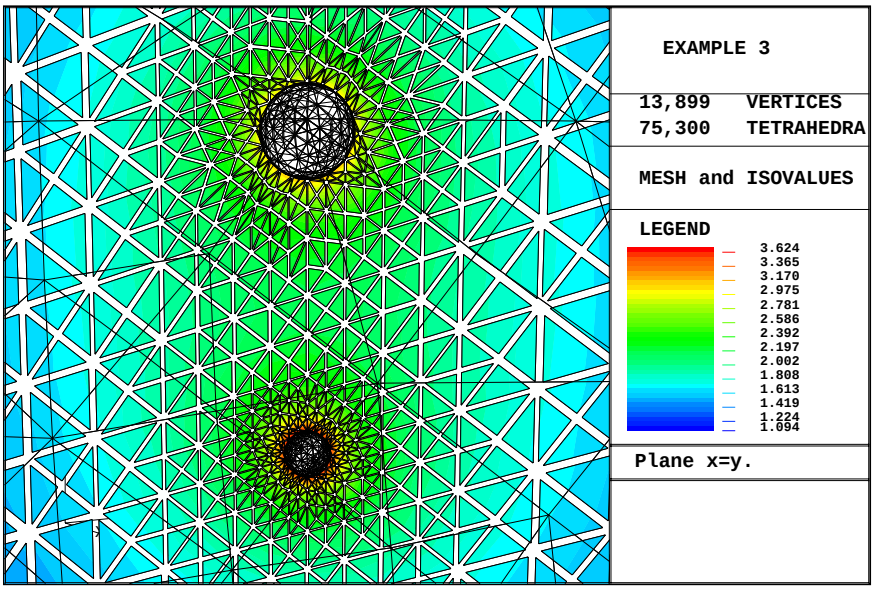

FIG. 12. *Solution to a binary black hole problem, zoom.*

Finally, Figure 14 shows a plot of the total CPU time for the solution of the boundary value problem including the mesh refinement, error estimation, outer iteration, and the multigrid solve on a 1993 DEC 3000 model 500 with a single 150 MHz Alpha processor versus number of mesh vertices. The plot clearly shows that the computation time is very nearly proportional to the number of vertices in the mesh.

6. Conclusion. In section 2 we introduced the notion of a marked tetrahedron, and presented algorithm `BisectTet` for the bisection of a marked tetrahedron into two children. We discussed its relation which other algorithms in the literature. In section 3 we showed how, beginning with an arbitrary conforming tetrahedral mesh, the algorithm `BisectTet` can be applied to create locally refined conforming tetrahedral meshes, and we bounded the amount of additional refinement that might be required to obtain conformity. In the following section we showed that repeated application of `BisectTet` to a given tetrahedron and its descendants generates at most 36 or 72 dissimilar tetrahedra in all (depending on the marking of the original tetrahedron). In doing so, we showed that for some markings `BisectTet` is, in a certain specific sense, equivalent to the three-dimensional case of Maubach's algorithm for repeated bisection of n-simplices, and for this algorithm we showed that at most $n\,n!2^{n-2}$ dissimilar simplices are created. We closed the paper with numerical examples of the performance of the algorithm.

A FINITE-VOLUME METHOD FOR THE MAXWELL EQUATIONS IN THE TIME DOMAIN*

C.-D. MUNZ†, R. SCHNEIDER‡, AND U. VOß‡

Abstract. A finite-volume scheme for the Maxwell equations is proposed using collocated nonorthogonal curvilinear grid arrangements, with the advantage that all components of the electric and magnetic field are stored at the same computational location and time. It is based on construction principles of high-resolution schemes for hyperbolic conservation laws and takes into account the local wave propagation. The implementation of boundary conditions based on the characteristic theory is described. A new divergence correction technique is proposed to preserve locally the charge conservation. This is important if the Maxwell solver is used within an electromagnetic particle-in-cell (PIC) code. The accuracy and efficiency of this finite-volume framework is demonstrated with problems of electromagnetic wave propagation and of the self-consistent motion of charged particles.

Key words. Maxwell–Lorentz equations, particle-in-cell method, divergence correction techniques

1. Introduction.

The traditional techniques in computational electromagnetics (CEM) for solving the Maxwell equations in the time domain rely on finite-differences and are called finite-difference time domain (FDTD) methods. One basic approach has been developed by Yee [37]. Here, a so-called staggered grid is used, where approximate values of the components of electromagnetic fields are calculated at different locations, e.g., at different faces and at the center of the grid zones. This staggering stabilizes the explicit central differences. Usually, these schemes are formulated staggered in time also, i.e., the electric and the magnetic fields are given at different time levels t_n and $t_{n+1/2}$. Originally, the staggered finite-difference scheme has been formulated by Yee for Cartesian coordinates and has been extended to structured boundary-fitted grids by Holland [15]. A review of FDTD schemes for the Maxwell equations and their applications has been given by Taflove [32]. Approximating an integral formulation of Maxwell equations based on the Stokes theorem, Weiland [36], and Madsen and Ziolkowski [18, 19] proposed staggered finite-volume schemes for general grids which reduce to the Yee algorithm in the Cartesian case. The main advantage of the staggered approach is that it combines second-order accuracy in space and time with a short stencil of the difference quotients. The disadvantages are that the field components are not given at the same points in space and time, resulting in a complicated data structure. Grid refinement techniques in regions of steep gradients are cumbersome.

In this paper, we consider the finite-volume approach on a collocated grid, where all field components as well as charge and current density are stored at the same computational location. The Maxwell equations are formulated as a system of con-

servation laws and are integrated component-by-component over each grid cell to achieve evolution equations for integral values. These values change in time due to fluxes through the grid zone interfaces. Mohammadian, Shankar, and Hall [22] approximated the conservation formulation by a classical second-order accurate method, the Lax–Wendroff method. The intention of this paper is to consider high-resolution schemes for hyperbolic conservation laws that take into account the direction of the local wave propagation. (For a review see [17], [25].) By that fact, they succeed to combine both robustness at strong gradients and high-order accuracy. They are dissipative but prevent the increase of numerical damping in time by the compressive nonlinear behavior (see, e.g., [23, 25]). Very recently, several authors proposed Maxwell solvers based on construction principles of the high-resolution schemes. Shang [26] and Shang and Gaitonde [27] used dimensional splitting and applied the high-resolution techniques in each one-dimensional sweep. This approach is restricted to second-order accuracy and to structured boundary-fitted grids. Cioni, Fezoui, and Steve [4] proposed a finite-volume/finite-element method. In both approaches the basic building block of the flux calculation is formulated as a generalization of the Steger–Warming flux splitting algorithm [30].

We propose in this paper a finite-volume Maxwell solver for curvilinear nonorthogonal coordinates without using dimensional splitting. The local wave propagation between adjacent grid zones is determined by the solution of Riemann problems. This has been proposed by Godunov [10] for the Euler equations and is usually called Godunov method. In the case of the Maxwell equations with constant permitivity and magnetic permeability and for a Cartesian grid this method and the flux-splitting method become identical to the original characteristic-based Courant–Isaacson–Rees scheme [7]. We prefer in this context the Godunov approach for two reasons: First, this approach gives a clear picture and may be an obvious starting point for how to extend the algorithm to nonhomogeneous media with discontinuous permitivity and magnetic permeability. Second, the difficulties arising in a proper implementation of the boundary conditions can be circumvented applying the Godunov idea. For that, fictitious boundary grid cells are introduced and the values of the physical variables in these cells are defined in such a way that the physical flux at the boundary is approximated correctly. To get high-order accuracy the solution inside each grid zone has to be reconstructed from its integral approximate values. We compare numerical results of total variation diminishing (TVD) interpolation scheme (see, e.g., [23, 17]) with those using the essentially nonoscillatory (ENO) interpolation of Harten and Osher [12] up to fifth-order accuracy in both time and space.

Studying kinetic phenomena of charge particles in plasma physics, the numerical solution of the Maxwell–Lorentz equations has to be computed, where the Maxwell solver is used as one part of a complex simulation program. An attractive numerical method to solve this time-dependent nonlinear Maxwell–Lorentz problem is the particle-in-cell (PIC) approach based on particle-mesh techniques [2, 14]. The basic idea of this PIC method can be summarized as follows: The electromagnetic fields obtained by the numerical solution of the Maxwell equations are interpolated to the actual locations of the charged particles, representing the considered plasma. According to the Lorentz force the charged particles are redistributed and the new phase space coordinates are determined by solving numerically the usual laws of dynamics. To close the chain of self-consistent interplay the particles have to be located with respect to the computational grid in order to determine the new charge and current density which act as sources for the Maxwell equations in the following iteration cy-

cle. It is a well known fact, that the different steps within the PIC treatment of charged particles introduce numerical errors and, consequently, charge conservation is not guaranteed exactly or at least approximately on this discrete level of approximation. Hence, sophisticated and appropriate correction methods have to be applied to obtain physically relevant results from the numerical solution. In the present work a new divergence correction technique to preserve locally the charge conservation is formulated in the framework of the considered high-resolution schemes.

2. The Maxwell equations.

2.1. The classical form. The time-dependent Maxwell equations are usually formulated as

$$\partial_t \mathbf{E} - c^2 \nabla \times \mathbf{B} = -\frac{\mathbf{j}}{\epsilon_0}\,, \tag{2.1a}$$

$$\partial_t \mathbf{B} + \nabla \times \mathbf{E} = 0\,, \tag{2.1b}$$

$$\nabla \cdot \mathbf{E} = \frac{\rho}{\epsilon_0}\,, \tag{2.1c}$$

$$\nabla \cdot \mathbf{B} = 0\,, \tag{2.1d}$$

where $\mathbf{E}, \mathbf{B}, \rho$, and $\mathbf{j}$ denote the electric field, the magnetic induction, the charge, and the current density, respectively. For sake of clarity as well as with respect to our special purposes we consider a finite domain in a homogeneous medium where the permitivity and the magnetic permeability are constant and set equal to one. The electric and magnetic field constants in vacuum are related to the speed of light according to $\epsilon_0 \mu_0 c^2 = 1$.

It is well known that if the charge conservation equation

$$\partial_t \rho + \nabla \cdot \mathbf{j} = 0 \tag{2.2}$$

is valid for all times and if the initial data for $\mathbf{E}$ and $\mathbf{B}$ satisfy (2.1c) and (2.1d), respectively, then these relations also hold for all times. This follows directly from (2.1a), (2.1b) and the fact that the divergence of the curl of any (differentiable) vector-field equals zero. The evolution equations (2.1a), (2.1b) are hyperbolic and the Cauchy problem describing initial data in the whole space is well-posed. In practical calculations a bounded computational domain must be dealt with and boundary values have to be prescribed. These boundary conditions and their proper numerical implementation have to be based on the characteristic theory and are described in section 3.4.

2.2. The conservation form. The Maxwell equations (2.1a), (2.1b) may be written as a system of linear evolution equations

$$\partial_t \mathbf{u} + \mathcal{K}_1 \partial_{x_1} \mathbf{u} + \mathcal{K}_2 \partial_{x_2} \mathbf{u} + \mathcal{K}_3 \partial_{x_3} \mathbf{u} = \mathbf{q}(\mathbf{u}), \tag{2.3}$$

where $\mathbf{u}$ is the vector of the electric field and magnetic induction

$$\mathbf{u} = (E_1, E_2, E_3, B_1, B_2, B_3)^{\mathrm{T}},$$

and the 6×6 matrices $\mathcal{K}_i$ are defined as

$$\mathcal{K}_i = \begin{pmatrix} \mathbf{0} & -c^2 \mathcal{M}_i \\ \mathcal{M}_i & \mathbf{0} \end{pmatrix}, \quad i = 1, 2, 3, \tag{2.4}$$

with

$$\mathcal{M}_1 = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & -1 \\ 0 & 1 & 0 \end{pmatrix}, \ \mathcal{M}_2 = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ -1 & 0 & 0 \end{pmatrix}, \ \mathcal{M}_3 = \frac{1}{x_2^\kappa} \begin{pmatrix} 0 & -1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}. \tag{2.5}$$

We consider the Maxwell equations for Cartesian coordinates $\mathbf{x} = (x_1, x_2, x_3) = (x, y, z)$ as well as cylindrical coordinates $\mathbf{x} = (x_1, x_2, x_3) = (z, r, \phi)$. The parameter κ in (2.5) allows a switch between both coordinate systems, namely, $\kappa = 0$ for Cartesian and $\kappa = 1$ for cylindrical coordinates. The right-hand side $\mathbf{q}$ of (2.3) contains the current density and terms introduced by the geometry and is given by

$$\mathbf{q}(\mathbf{u}) = -\frac{1}{\epsilon_0} \left(j_1, j_2, j_3, 0, 0, 0\right)^T + \frac{\kappa}{x_2} \left(c^2 B_3, 0, 0, -E_3, 0, 0\right)^T. \tag{2.6}$$

Since the matrices $\mathcal{K}_i$ are constant, the Maxwell equations may be written in conservation form,

$$\partial_t \mathbf{u} + \partial_{x_1} \mathbf{f}_1(\mathbf{u}) + \partial_{x_2} \mathbf{f}_2(\mathbf{u}) + \partial_{x_3} \mathbf{f}_3(\mathbf{u}) = \mathbf{q}(\mathbf{u}), \tag{2.7}$$

with $\mathbf{f}_i(\mathbf{u}) = \mathcal{K}_i \mathbf{u}$, $i = 1, 2, 3$, which is the basis for the construction of finite-volume methods. The new aspect in this formulation is that the differential operator is considered as the divergence applied component-by-component to the physical fluxes $\mathbf{f}_i(\mathbf{u})$.

2.3. The constrained formulation. Numerical methods in the time domain are usually based on the evolution equations (2.1a), (2.1b) only. But, in the numerical approximation the relations (2.1c) and (2.1d) are, in general, not preserved exactly. Due to approximation errors the discrete divergence of the discrete curl operator may be nonzero:

$$\widetilde{\nabla} \cdot \left(\widetilde{\nabla} \times\right) = O(h^k), \tag{2.8}$$

where $\widetilde{\nabla}\cdot, \widetilde{\nabla}\times$ denote the discrete divergence and curl, respectively, h denotes some typical space increment, and k denotes some order. In pure field calculations where the charge conservation equation (2.2) is satisfied exactly, this seems not to be a severe problem, because this defect does not drastically increase in time and falsify the results [24, 4]. A quite different situation occurs when the Maxwell solver is applied as one part of a PIC code for the self-consistent simulation of charged particles. In the PIC approach the charge and current density are assigned to the grid points applying special interpolation schemes (see, e.g., [2, 14]). The motion of the particles is obtained by solving the Lorentz equations numerically. Both steps introduce numerical errors and a discrete analogue of the charge conservation equation (2.2) is not guaranteed exactly or even with a defect of the order $O(h^k)$. Since only the current density is used for the numerical field calculation based on (2.1a), (2.1b), the consistency of $\nabla \cdot \mathbf{E}$ with the charge density ρ may be lost. One way to get physically relevant results is to introduce sophisticated particle motion and current density approximations (see, e.g., [35]) and charge and current density assignment [9] to the numerically caused lack in (2.2). Another possibility to achieve consistency is to impose the divergence conditions (2.1c), (2.1d) directly by the introduction of correcting potentials [2].

Here, we follow the approach of Assous et al. [1] and introduce Lagrange multipliers which may be considered potentials correcting the electric field and the magnetic

induction. This constrained formulation reads as

$$\partial_t \mathbf{E} - c^2 \nabla \times \mathbf{B} + c^2 \nabla \phi = -\frac{\mathbf{j}}{\epsilon_0}\,, \tag{2.9a}$$

$$\partial_t \mathbf{B} + \nabla \times \mathbf{E} + \nabla p = 0\,, \tag{2.9b}$$

$$\nabla \cdot \mathbf{E} = \frac{\rho}{\epsilon_0}\,, \tag{2.9c}$$

$$\nabla \cdot \mathbf{B} = 0\,, \tag{2.9d}$$

where ϕ and p denote the potentials to meet the conditions (2.1c), (2.1d). Assuming that $\mathbf{E}$ and $\mathbf{B}$ satisfy the correct boundary conditions we require homogeneous Dirichlet boundary conditions on p and ϕ:

$$\begin{array}{l} \phi(\mathbf{x},t)=0 \\ p(\mathbf{x},t)=0 \end{array} \qquad \text{for } \mathbf{x} \in \Gamma \text{ and all } t, \tag{2.10}$$

where Γ denotes the boundary of the domain G. If the conservation equation (2.2) for ρ and $\mathbf{j}$ is satisfied, then (2.9) is equivalent to (2.1). This becomes obvious by applying the divergence to (2.9a), (2.1b) and using (2.2) which results in Laplace equations for ϕ and p. On account of the boundary conditions (2.10) this directly yields $\phi \equiv 0$ and $p \equiv 0$.

3. The finite-volume approach.

3.1. Integral formulation and discretization. A finite-volume scheme approximates the conservation equations (2.7) integrated over the grid cells. In the following we restrict ourselves to two space dimensions and assume that $\mathbf{E}$ and $\mathbf{B}$ do not depend on x_3. We consider a structured boundary-fitted grid, where the physical area G is covered by quadrilateral grid zones $V_{ij} : G = \bigcup_{ij} V_{ij}$. Integrating the system (2.7) component-by-component over the space-time volume $V_{ij} \times [t_n, t_{n+1}]$ and applying Gauß's theorem to the integral over the divergence of the flux components one obtains

$$\mathbf{u}_{ij}^{n+1} = \mathbf{u}_{ij}^{n} - \frac{1}{|V_{ij}|} \int_{t_n}^{t_{n+1}} \oint_{\partial V_{ij}} \mathcal{F}(\mathbf{u})\, \mathbf{n}_{ij}\, dS\, dt + \frac{1}{|V_{ij}|} \int_{t_n}^{t_{n+1}} \int_{V_{ij}} \mathbf{q}(\mathbf{u})\, dV\, dt. \tag{3.1}$$

Here, $\mathbf{u}_{ij}^n$ denotes the cell average of $\mathbf{u}$ over the cell V_{ij} with area $|V_{ij}|$ at time t_n:

$$\mathbf{u}_{ij}^{n} = \frac{1}{|V_{ij}|} \int_{V_{ij}} \mathbf{u}(\mathbf{x}, t_n)\, dV, \tag{3.2}$$

$\mathcal{F}(\mathbf{u})$ denotes the 6×2 flux matrix $(\mathbf{f}_1(\mathbf{u}), \mathbf{f}_2(\mathbf{u}))$, and $\mathbf{n}_{ij} \in \mathbb{R}^2$ denotes the outwards directed normal at the boundary ∂V_{ij} of grid cell V_{ij}. As sketched out in Figure 1, the boundary of a quadrilateral grid cell is given by $\partial V_{ij} = \sum_{\beta=1}^{4} S_{ij,\beta}$ and the line integral in (3.1) can be replaced by

$$\oint_{\partial V_{ij}} \mathcal{F}(\mathbf{u})\, \mathbf{n}_{ij}\, dS = \sum_{\beta=1}^{4} \int_{S_{ij,\beta}} \mathcal{F}(\mathbf{u})\, \mathbf{n}_{ij,\beta}\, dS, \tag{3.3}$$

where $\mathbf{n}_{ij,\beta} = ((n_1)_{ij,\beta}, (n_2)_{ij,\beta})^{\mathrm{T}}$ denotes the outwards directed unit normal at the edge $S_{ij,\beta}$. The integral equations (3.1) establish exact evolution equations for the mean values of the solution.

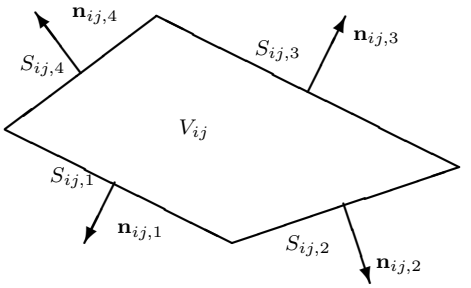

FIG. 1. *Quadrilateral grid zone V_{ij} with boundary ∂V_{ij} and outwards directed normals $\mathbf{n}_{ij,\beta}$.*

A finite-volume scheme is a direct approximation of the integral formulation (3.1) and is usually written in the form

$$\mathbf{u}_{ij}^{n+1} = \mathbf{u}_{ij}^{n} - \frac{\Delta t}{|V_{ij}|} \sum_{\beta=1}^{4} \mathbf{G}_{ij,\beta}^{n} + \Delta t \mathbf{q}_{ij}^{n+1/2}, \tag{3.4}$$

where the so-called numerical flux $\mathbf{G}_{ij,\beta}$ is an approximation of the physical flux $\mathcal{F}(\mathbf{u})$ through the boundary segment $S_{ij,\beta}$:

$$\mathbf{G}_{ij,\beta}^{n} \approx \frac{1}{\Delta t} \int_{t_n}^{t_{n+1}} \int_{S_{ij,\beta}} \mathcal{F}(\mathbf{u}) \mathbf{n}_{ij,\beta} \, dS \, dt. \tag{3.5}$$

The vector $\mathbf{q}_{ij}^{n+1/2}$ approximates the source terms averaged over V_{ij} and the time interval $[t_n, t_{n+1}]$. The main task in the context of finite-volume schemes is to find a suitable numerical flux (3.5) as a function of the averaged quantities. This is described in the next section. As indicated by the superscript "n" of the numerical flux in (3.4) we are interested in an explicit approximation using the values at the old time level t_n.

For the approximation of the source term we apply in the following a splitting method as proposed by Marchuk [20]. In each time step, first the homogeneous Maxwell equations are solved neglecting the term $\mathbf{q}_{ij}^{n+\frac{1}{2}}$ in (3.4). The values obtained are then used as initial values for the numerical solution of the system of ordinary differential equations

$$\partial_t \mathbf{u} = \mathbf{q}(\mathbf{u}) \tag{3.6}$$

introducing the sources into the scheme. To solve (3.6) a standard ordinary differential equation solver may be chosen. We remark, that if the source step (3.6) as well as the Maxwell step (3.4) are solved accurately up to second-order in time, then the so-called Strang splitting should be applied to preserve the overall second-order accuracy of the algorithm (see [20, 31]). Here, the order of the different steps is changed in each time cycle.

3.2. The numerical flux calculation. The finite-volume method is completely defined by specifying the numerical fluxes (3.5). First, the integral over the boundary

segments has to be approximated. In the following, we restrict ourselves for the sake of simplicity to second-order accuracy and use the midpoint rule,

$$\mathbf{G}^n_{ij,\beta} = |S_{ij,\beta}|\,((n_1)_{ij,\beta}\,\mathcal{K}_1 + (n_2)_{ij,\beta}\,\mathcal{K}_2)\;\mathbf{u}(\mathbf{x}_{MP,\beta}, t_n), \tag{3.7}$$

where $\mathbf{x}_{MP,\beta}$ denotes the midpoint of edge β. Clearly, a higher order accurate numerical quadrature formula has to be chosen for higher order schemes. Next, an appropriate approximation of the solution at this midpoint has to be calculated. Here, we follow the ideas of Godunov [10] who developed this method for the equations of gas dynamics. During the last years, the Godunov method has been successfully applied to other systems of conservation laws. For a review, we refer to the excellent book of LeVeque [17]. Assuming the approximation to be piecewise constant at time level t_n and equal to the integral values in each grid zone, the local wave propagation at the point $\mathbf{x}_{\mathrm{MP},\beta}$ into normal direction is determined by the break-up of the discontinuity at the grid interface $S_{ij,\beta}$. Information about this is provided by the local solution of a Riemann problem which is an initial-value problem of the form

$$\partial_t \mathbf{u} + \mathcal{C}_{ij,\beta}\,\partial_\zeta \mathbf{u} = 0, \tag{3.8}$$

$$\mathbf{u}(\zeta, 0) = \begin{cases} \mathbf{u}_l & \text{for } \zeta < 0, \\ \mathbf{u}_r & \text{for } \zeta > 0, \end{cases} \tag{3.9}$$

with

$$\mathcal{C}_{ij,\beta} = (n_1)_{ij,\beta}\,\mathcal{K}_1 + (n_2)_{ij,\beta}\,\mathcal{K}_2. \tag{3.10}$$

The values $\mathbf{u}_l$ and $\mathbf{u}_r$ are the states in the grid zone (i, j) and its neighbor cell according to the value of β. The flux at $\zeta = 0$, generated by the solution of the Riemann problem and multiplied by the length $|S_{ij,\beta}|$ is then defined to be the numerical flux (3.7) of the Godunov scheme.

The solution of the Riemann problem (3.8), (3.9) is obtained by the theory of characteristics and is briefly summarized in the following. The matrix $\mathcal{C}_{ij,\beta}$ has the three different, double-valued real eigenvalues

$$\lambda_1 = \lambda_2 = -c, \qquad \lambda_3 = \lambda_4 = 0, \qquad \lambda_5 = \lambda_6 = c \tag{3.11}$$

and a complete set of right eigenvectors $\mathbf{r}^1, \ldots, \mathbf{r}^6$, which may be written as columns of the matrix

$$\mathcal{R} = \left(\mathbf{r}^1, \ldots, \mathbf{r}^6\right) = \begin{pmatrix} bc & 0 & a & 0 & -bc & 0 \\ -ac & 0 & b & 0 & ac & 0 \\ 0 & c & 0 & 0 & 0 & -c \\ 0 & -b & 0 & a & 0 & -b \\ 0 & a & 0 & b & 0 & a \\ 1 & 0 & 0 & 0 & 1 & 0 \end{pmatrix}, \tag{3.12}$$

with $a := (n_1)_{ij,\beta}, b := (n_2)_{ij,\beta}$. The corresponding left eigenvectors $\mathbf{l}^1, \ldots, \mathbf{l}^6$ are the rows of the matrix

$$\mathcal{R}^{-1} = \left(\mathbf{l}^1, \ldots, \mathbf{l}^6\right)^{\mathrm{T}} = \frac{1}{2c} \begin{pmatrix} b & -a & 0 & 0 & 0 & c \\ 0 & 0 & 1 & -bc & ac & 0 \\ 2ac & 2bc & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 2ac & 2bc & 0 \\ -b & a & 0 & 0 & 0 & c \\ 0 & 0 & -1 & -bc & ac & 0 \end{pmatrix}. \tag{3.13}$$

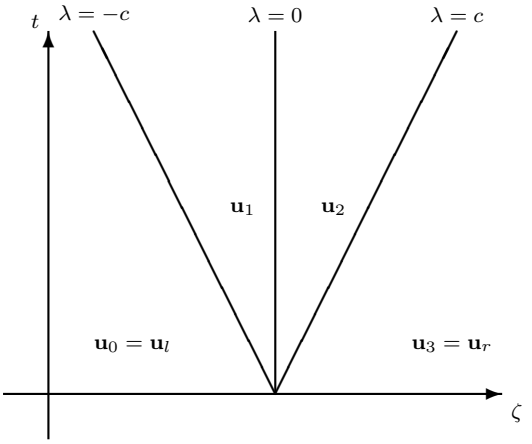

FIG. 2. *(ζ, t)-diagram of the exact solution of the Riemann problem. The solution consists of four constant states $\mathbf{u}_l, \mathbf{u}_1, \mathbf{u}_2$, and $\mathbf{u}_r$ separated by the characteristics.*

Figure 2 shows the (ζ, t)-diagram of the exact solution of the Riemann problem. It consists of four constant states separated by the three characteristics. The intermediate constant states are given by

$$\mathbf{u}_1 = \mathbf{u}_l + \sum_{j=1}^{2} \alpha_j \mathbf{r}^j = \mathbf{u}_r - \sum_{j=0}^{3} \alpha_{6-j} \mathbf{r}^{6-j}, \tag{3.14}$$

$$\mathbf{u}_2 = \mathbf{u}_l + \sum_{j=1}^{4} \alpha_j \mathbf{r}^j = \mathbf{u}_r - \sum_{j=0}^{1} \alpha_{6-j} \mathbf{r}^{6-j}, \tag{3.15}$$

with coefficients

$$\alpha_j = \mathbf{l}_j(\mathbf{u}_r - \mathbf{u}_l), \quad j = 1, \ldots, 6. \tag{3.16}$$

The numerical flux can now be calculated as

$$\mathbf{G}^n_{ij,\beta} = |S_{ij,\beta}|\, \mathcal{C}_{ij,\beta} \mathbf{u}_1 = |S_{ij,\beta}|\, \mathcal{C}_{ij,\beta} \mathbf{u}_2, \tag{3.17}$$

which can be shown in a straightforward manner using the definitions (3.10), (3.14), and (3.15).

We remark that (3.17) can be rewritten in several forms. In the context of this paper we prefer the flux-vector splitting form given by

$$\mathbf{G}^n_{ij,\beta} = |S_{ij,\beta}| \left(\mathcal{C}^+_{ij,\beta} \mathbf{u}_l + \mathcal{C}^-_{ij,\beta} \mathbf{u}_r \right), \tag{3.18}$$

with

$$\mathcal{C}^{\pm}_{ij,\beta} = \frac{1}{2} \left(\mathcal{C}_{ij,\beta} \pm |\mathcal{C}_{ij,\beta}| \right), \tag{3.19}$$

where the absolute value, $|\mathcal{C}_{ij,\beta}|$, is defined with the aid of the diagonalized matrix according to

$$|\mathcal{C}_{ij,\beta}| = \mathcal{R}\ \mathrm{diag}(c, c, 0, 0, c, c)\ \mathcal{R}^{-1} \tag{3.20}$$

with $\mathcal{R}$ and $\mathcal{R}^{-1}$ given by (3.12) and (3.13), respectively. In this formulation the total flux is decomposed into a flux to the "right" associated with $\mathcal{C}^{+}_{ij,\beta}$, having nonnegative eigenvalues only, and a flux to the "left" associated with $\mathcal{C}^{-}_{ij,\beta}$, having nonpositive eigenvalues only (see [30]). The first matrix acts on $\mathbf{u}_l$, while the other acts on $\mathbf{u}_r$, taking into account the correct domain of influence.

All these considerations are valid only if it is guaranteed that the waves generated at different grid zone interfaces do not interact. This leads to a CFL time step restriction in the form $c\frac{\Delta t}{h} \leq 1$, where h denotes the smallest length of a grid zone. For a Cartesian grid and for smooth solutions the finite-volume scheme defined in this way agrees with the Courant–Isaacson–Rees scheme [7], which is based on the characteristic form of the equations. The Godunov scheme may be considered as an extension of this scheme to general grids. Since the direction of the wave propagation is taken into account, this numerical scheme is inherently very robust and able to resolve steep gradients without generating spurious oscillations. However, it is only of first-order accuracy in both space and time and introduces too much numerical dissipation for practical calculations. In the following section this lack is removed by an extension of the scheme to higher order accuracy.

3.3. Higher order accuracy. To get higher order accuracy in space the reconstruction from the approximate integral values has to be improved. This idea has been proposed by van Leer [34] and is called MUSCL approach. In the following, we restrict ourselves to a piecewise linear reconstruction, which establishes second-order accuracy. Two extensions of the MUSCL approach to boundary-fitted grids are shortly described.

The first extension has been proposed by Durlofsky, Engquist, and Osher [8] for triangular grid cells. It can be adapted to quadrilateral grids in a straightforward way. The linear representation of each component $w \in \{E_1, E_2, E_3, B_1, B_2, B_3\}$ is given by the truncated Taylor expansion

$$w^n(\mathbf{x}) = w^n_{ij} + (\mathbf{x} - \mathbf{x}_{ij}) \cdot \widetilde{\nabla} w^n_{ij} \qquad \text{for } \mathbf{x} \in V_{ij}, \tag{3.21}$$

where $\mathbf{x}_{ij}$ denotes the barycenter of cell (i,j) and $\widetilde{\nabla} w^n_{ij}$ an approximation of the gradient of component w in cell (i,j) at time t_n. To approximate this gradient, the field averages of the cell under consideration and of two of its neighbors are linearly interpolated (see Figure 3). $\widetilde{\nabla}^{(1)} w^n_{ij}$ is the gradient of the plane through $(\mathbf{x}_{ij}, \mathbf{u}^n_{ij}), (\mathbf{x}_{i+1,j}, \mathbf{u}^n_{i+1,j})$, and $(\mathbf{x}_{i,j+1}, \mathbf{u}^n_{i,j+1})$. Similarly, $\widetilde{\nabla}^{(2)} w^n_{ij}$ is obtained using $\mathbf{u}^n_{ij}; \mathbf{u}^n_{i,j+1}$ and $\mathbf{u}^n_{i-1,j}$; $\widetilde{\nabla}^{(3)} w^n_{ij}$ using $\mathbf{u}^n_{ij}, \mathbf{u}^n_{i-1,j}$, and $\mathbf{u}^n_{i,j-1}$; and $\widetilde{\nabla}^{(4)} w^n_{ij}$ using $\mathbf{u}^n_{ij}, \mathbf{u}^n_{i,j-1}$, and $\mathbf{u}^n_{i+1,j}$ and the coordinates of the corresponding barycenters (see Figure 3). To avoid spurious oscillations near steep gradients the one in this set with the smallest norm is used in (3.21). For more details see [8].

To enhance the time accuracy a truncated Taylor expansion also in t is used where the necessary approximation of the time derivative of $\mathbf{u}$ at time t_n is replaced by approximations of the space derivatives according to the differential equations

$$\mathbf{u}^{n+\frac{1}{2}}(\mathbf{x}) = \mathbf{u}^n(\mathbf{x}) - \frac{\Delta t}{2}\left(\mathcal{K}_1 \widetilde{\partial}_{x_1} \mathbf{u}^n + \mathcal{K}_2 \widetilde{\partial}_{x_2} \mathbf{u}^n\right), \tag{3.22}$$

where $\widetilde{\partial}_{x_1} \mathbf{u}$ and $\widetilde{\partial}_{x_2} \mathbf{u}$ denote the approximations of the space derivatives as calculated in (3.21).

This technique for enhancing the accuracy with respect to time has first been used in the Lax–Wendroff scheme (see, e.g., [17]) and, hence, is often called Lax–Wendroff

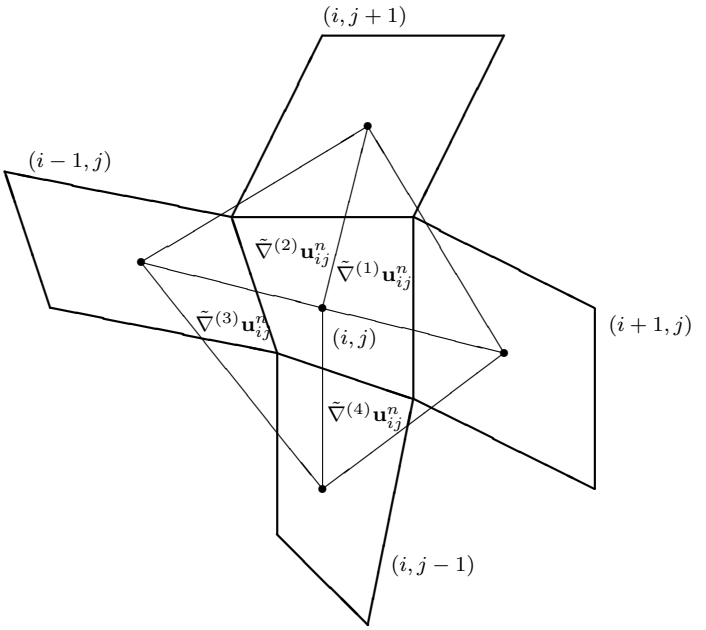

FIG. 3. *Candidates for slope calculation in the ansatz of Durlofsky et al.*

procedure. The values of the interpolation polynomials at the midpoint of a side face from both sides are then used as data of the Riemann problem (3.8), (3.9) to determine the numerical flux. However, the application of the Durlofsky, Engquist, and Osher ansatz to quadrilateral cells makes use of the structure of the grid only with regard to data administration.

The second ansatz, proposed by Colella in [6], refers to more information about the grid structure. He proposed a two-dimensional MUSCL scheme without splitting, also extended to boundary-fitted coordinates requiring the existence of a smooth coordinate mapping $(\xi, \eta) \mapsto (x, y)$ between the coordinate space and the physical space with a rectangular mesh in the coordinate space (ξ, η). Here, the slope is assumed to be constant in each component along the lines $\xi = \text{const.}$ and $\eta = \text{const.}$ These constant vectors are denoted by $\widetilde{\mathbf{u}_\xi}$ and $\widetilde{\mathbf{u}_\eta}$. To avoid spurious oscillations near steep gradients the slopes have to be calculated carefully. One possibility is to compare the left and right difference quotients and to take that one with the smaller absolute value if their signs coincide. For different signs the slope is set equal to zero. This is the Minmod limiting procedure:

$$\widetilde{\mathbf{u}_\xi} = \text{Minmod}\left(\frac{\mathbf{u}_{i+1,j} - \mathbf{u}_{ij}}{\|\mathbf{x}_{i+1,j} - \mathbf{x}_{ij}\|}, \frac{\mathbf{u}_{ij} - \mathbf{u}_{i-1,j}}{\|\mathbf{x}_{ij} - \mathbf{x}_{i-1,j}\|}\right), \tag{3.23}$$

$$\widetilde{\mathbf{u}_\eta} = \text{Minmod}\left(\frac{\mathbf{u}_{i,j+1} - \mathbf{u}_{ij}}{\|\mathbf{x}_{i,j+1} - \mathbf{x}_{ij}\|}, \frac{\mathbf{u}_{ij} - \mathbf{u}_{i,j-1}}{\|\mathbf{x}_{ij} - \mathbf{x}_{i,j-1}\|}\right). \tag{3.24}$$

Further appropriate slope calculations are reviewed, e.g., in [17], [23]. All procedures have the TVD property which guarantees for one-dimensional scalar problems that the total variation of the solution does not increase in time. The values $\mathbf{u}^n_{i\pm,j}, \mathbf{u}^n_{i,j\pm}$

at the cell's boundary are obtained by a one-dimensional setting (see [34]) for each direction separately:

$$\mathbf{u}^n_{i\pm,j} = \mathbf{u}^n_{ij} \pm \frac{|\mathbf{x}_{ij} - \mathbf{x}_{i\pm\frac{1}{2},j}|}{2}(\widetilde{\mathbf{u}_\xi})^n_{ij}, \tag{3.25}$$

$$\mathbf{u}^n_{i,j\pm} = \mathbf{u}^n_{ij} \pm \frac{|\mathbf{x}_{ij} - \mathbf{x}_{i,j\pm\frac{1}{2}}|}{2}(\widetilde{\mathbf{u}_\eta})^n_{ij}, \tag{3.26}$$

where $\mathbf{x}_{i\pm\frac{1}{2},j}$ and $\mathbf{x}_{i,j\pm\frac{1}{2}}$ denote the midpoints of the boundary segments. For the temporal extrapolation

$$\mathbf{u}^{n+1/2}_{i\pm,j} = \mathbf{u}^n_{i\pm,j} + \frac{\Delta t}{2}(\widetilde{\mathbf{u}_t})_{ij}, \tag{3.27}$$

$$\mathbf{u}^{n+1/2}_{i,j\pm} = \mathbf{u}^n_{i,j\pm} + \frac{\Delta t}{2}(\widetilde{\mathbf{u}_t})_{ij} \tag{3.28}$$

via the Lax–Wendroff procedure now the equations transformed onto the (ξ, η) curved coordinate system

$$\mathbf{u}_t + \frac{(y_\eta \mathcal{A}\mathbf{u} - x_\eta \mathcal{B}\mathbf{u})_\xi}{\det J} + \frac{(-y_\xi \mathcal{A}\mathbf{u} + x_\xi \mathcal{B}\mathbf{u})_\eta}{\det J} = 0 \tag{3.29}$$

have to be used to replace the time derivatives by space derivatives. Here, x_ξ, x_η, y_ξ, and y_η denote the partial derivatives of the transformation with respect to ξ and η and $\det J$ denotes the determinant of the Jacobi matrix of the transformation.

These second-order TVD schemes are quite robust but introduce some clipping of extrema. Harten and Osher [12] succeeded to construct a higher order ENO reconstruction of the solution. The ENO interpolation procedure minimizes numerical oscillations near strong gradients by using data from the smoothest part of the solution. First, a table of divided differences is calculated and a searching algorithm determines which portion of the surrounding solution is smoothest. The stencils of the interpolation polynomial chosen are allowed to shift to this region—away from the larger differences. For more details we refer to [11, 12]. Also to get higher than second-order accuracy in time the application of the Lax–Wendroff procedure seems to be no longer favorable because space derivatives of higher order occur which also have to be approximated in an appropriate way. A more convenient possibility is to use a Runge–Kutta time approximation as proposed by Shu and Osher [28]. A third-order Runge–Kutta scheme, eg., is given by

$$\begin{aligned} u^{(1)} &= u^{(n)} + \Delta t L(u^{(n)}), \\ u^{(2)} &= \frac{3}{4}u^{(n)} + \frac{1}{4}u^{(1)} + \frac{1}{4}\Delta t L(u^{(1)}), \\ u^{(n+1)} &= \frac{1}{3}u^{(n)} + \frac{2}{3}u^{(2)} + \frac{2}{3}\Delta t L(u^{(2)}), \end{aligned} \tag{3.30}$$

where L denotes the spatial approximation, and $u^{(1)}$, $u^{(2)}$ the intermediate steps.

3.4. Implementation of boundary conditions. The Maxwell equations form a system of hyperbolic equations and hence boundary conditions and their implementation are only well-posed if they take into account the wave propagation as given by the theory of characteristics. In the presented finite-volume approach this is established again using the solution of the Riemann problem. At the grid cells adjacent

to the boundaries of the computational domain initial-boundary-value problems instead of Riemann problems have to be solved locally. Our goal is to reformulate these initial-boundary-value problems as Riemann problems. For that, first fictitious grid zones are introduced around the computational domain, called dummy grid cells. Then in these grid zones values for the physical variables are specified in such a way that the solution of the Riemann problem at the boundary yields the proper physical conditions.

For this, we need the solution of the Riemann problem (3.8), (3.9) at $\zeta = 0$. As there occur vanishing eigenvalues, the boundary $\zeta = 0$ coincides with the characteristic curve separating the two intermediate states $\mathbf{u}_1$ and $\mathbf{u}_2$ according to (3.14) and (3.15), respectively. The value $\mathbf{u}_0 = (E_{1,0}, E_{2,0}, \ldots, B_{3,0})^{\mathrm{T}}$ of the Riemann solution $\mathbf{u}$ at $\zeta = 0$ can be defined to be $\mathbf{u}_1$ or $\mathbf{u}_2$, which does not affect the flux calculation (3.17). For symmetry reasons we define $\mathbf{u}_0$ to be the arithmetic average of $\mathbf{u}_1$ and $\mathbf{u}_2$. With $\mathbf{n} = (a, b, 0)^{\mathrm{T}}$ the outer normal at the boundary, $\mathbf{u}_0$ is given by

$$\mathbf{u}_0 = \frac{1}{2} \begin{pmatrix} E_{1,r} + E_{1,l} + bc(B_{3,r} - B_{3,l}) \\ E_{2,r} + E_{2,l} - ac(B_{3,r} - B_{3,l}) \\ E_{3,r} + E_{3,l} - bc(B_{1,r} - B_{1,l}) + ac(B_{2,r} - B_{2,l}) \\ B_{1,r} + B_{1,l} - \frac{b}{c}(E_{3,r} - E_{3,l}) \\ B_{2,r} + B_{2,l} + \frac{a}{c}(E_{3,r} - E_{3,l}) \\ B_{3,r} + B_{3,l} + \frac{b}{c}(E_{1,r} - E_{1,l}) - \frac{a}{c}(E_{2,r} - E_{2,l}) \end{pmatrix}. \tag{3.31}$$

Considering, for instance, a boundary on the left-hand side of the computational domain, (3.31) has to be solved for the dummy state $\mathbf{u}_l$. First, we remark that there exists no uniquely determined solution. Rather, there are an infinite number of possibilities to define the dummy state $\mathbf{u}_r$. This arbitrariness reflects the fact that in the dummy cell the characteristic variables corresponding to waves which do not enter the computational domain have no influence on the solution at the boundary. These arbitrary values in the dummy cells also do not affect the numerical values because the characteristic-based flux calculation automatically picks out the proper information. Secondly, boundary conditions can not be imposed independently of the state inside the last cell of the computational domain. This reflects the fact that the part of characteristic information at the boundary, which is transported from the last cell inside the domain to the boundary, must coincide with the values prescribed there. For physical relevant boundary conditions, however, the latter is automatically met.

The main advantage of the outlined technique is that imposing the boundary conditions concerns only the dummy cells and can be managed in a first step of the calculation cycle. Then the discrete equations can be solved without any further modification in the whole computational domain, leading to a highly vectorizable algorithm. Furthermore, the exchange of boundary values necessary for parallelization based on domain decomposition can be handled in a similar way. In the following we discuss the boundary conditions for perfect electrical conducting surfaces, for symmetry, irradiation of electromagnetic energy into the domain, and for open boundaries which are introduced to limit artificially the computational domain. In the latter case, waves should propagate out of the domain without generating reflections. All boundary conditions are formulated for the case of curvilinear coordinates.

First, we consider the boundary condition of a perfect conducting wall, where the fields cannot penetrate into the surface. In this case the physical boundary conditions

read as

$$\mathbf{n} \times \mathbf{E}_0 = 0, \qquad \mathbf{n} \cdot \mathbf{B}_0 = 0. \tag{3.32}$$

These conditions lead to

$$aE_{2,0} - bE_{1,0} = 0, \qquad E_{3,0} = 0, \qquad aB_{1,0} + bB_{2,0} = 0. \tag{3.33}$$

For a given state $\mathbf{u}_r$ or $\mathbf{u}_l$, the other one has to be defined in such a way that the relations (3.33) are valid at the boundary. In the case, where $\mathbf{u}_r$ is given, a possible choice for $\mathbf{u}_l$ is

$$\begin{aligned} E_{1,l} = -E_{1,r}, \quad E_{2,l} = -E_{2,r}, \quad E_{3,l} = -E_{3,r}, \quad B_{3,l} = B_{3,r}, \\ B_{1,l} = (b^2 - a^2)B_{1,r} - 2abB_{2,r}, \\ B_{2,l} = (a^2 - b^2)B_{2,r} - 2abB_{1,r}. \end{aligned} \tag{3.34}$$

Now we assume that the boundary of interest is an axis of symmetry which does not coincide with lines parallel to the x_1- or x_2-axis. At this axis the following conditions

$$E_{3,0} = 0, \qquad \mathbf{n} \cdot \mathbf{E}_0 = 0 \tag{3.35}$$

and

$$B_{3,0} = 0, \qquad \mathbf{n} \cdot \mathbf{B}_0 = 0 \tag{3.36}$$

hold. As mentioned above, these conditions are not sufficient to find a solution for the fictitious grid zones from (3.31). With the choice

$$E_{3,l} = -E_{3,r}, \qquad B_{3,l} = -B_{3,r}, \tag{3.37}$$

however, the values of the other components of the electromagnetic fields in the dummy grid cells are obtained from (3.31) resulting in

$$E_{1,l} = (b^2 - a^2)E_{1,r} - 2abE_{2,r}, \quad E_{2,l} = (a^2 - b^2)E_{2,r} - 2abE_{1,r}, \tag{3.38a}$$

$$B_{1,l} = (b^2 - a^2)B_{1,r} - 2abB_{2,r}, \quad B_{2,l} = (a^2 - b^2)B_{2,r} - 2abB_{1,r}. \tag{3.38b}$$

Another situation occurs when the electrical device is driven by external fields irradiated at certain scheduled edges of the device. Since there exist two outgoing characteristics which transport information from the computational domain to the boundary two compatibility conditions have to be satisfied by the boundary conditions at $\zeta = 0$. Considering a left boundary, those are the characteristics associated with the negative eigenvalues and hence the first two components of the characteristic variable $\mathbf{v} = \mathcal{R}^{-1}\mathbf{u}$ have to satisfy

$$v_{1,0} = cB_{3,0} + bE_{1,0} - aE_{2,0} = cB_{3,r} + bE_{1,r} - aE_{2,r}, \tag{3.39}$$

$$v_{2,0} = E_{3,0} - cbB_{1,0} + caB_{2,0} = E_{3,r} - cbB_{1,r} + caB_{2,r}. \tag{3.40}$$

Therefore only two of the three values of the subsystems E_1, E_2, B_3 and B_1, B_2, E_3 can be prescribed. Assuming that the third component of the electric field and magnetic induction is not imposed explicitly, a possible choice is

$$B_{3,l} = B_{3,r}, \qquad E_{1,l} = 2E_{1,0} - E_{1,r}, \qquad E_{2,l} = 2E_{2,0} - E_{2,r} \tag{3.41}$$

and

$$E_{3,l} = E_{3,r}, \qquad B_{1,l} = 2B_{1,0} - B_{1,r}, \qquad B_{2,l} = 2B_{2,0} - B_{2,r}. \tag{3.42}$$

Open boundaries are conditions motivated by numerical simulations and necessary to limit artificially the computational domain. A criterion of an open or nonreflecting boundary has been formulated by Hedstrom [13]: No wave should travel into the computational domain which means that the amplitudes of incoming waves are constant with respect to time. Incoming and outgoing traveling waves can be easily identified by the use of characteristic variables as proposed by Thompson [33]. Considering a left boundary as before, the incoming waves are those associated with the positive eigenvalues. Then, the open boundary condition reads as

$$\partial_t v_{5,0} = \partial_t v_{6,0} = 0, \tag{3.43}$$

for all t, whereas the equations for the other four characteristic variables remain unchanged.

In the first step we calculate the physical solution at the boundary. The transformation back to the conserved variables $\mathbf{u} = \mathcal{R}\mathbf{v}$ shows that the solution satisfying (3.43) at the boundary is the solution of the Riemann problem

$$\partial_t \mathbf{u} + \mathcal{C}^- \partial_\zeta \mathbf{u} = 0, \tag{3.44}$$

$$\mathbf{u}(\zeta, 0) = \begin{cases} \mathbf{u}_l & \zeta < 0, \\ \mathbf{u}_r & \zeta > 0, \end{cases} \tag{3.45}$$

with $\mathcal{C}^-$ given by (3.19). This Riemann problem can be solved, yielding $\mathbf{u}_0 = \mathbf{u}_r$, as $\mathcal{C}^-$ has only nonpositive eigenvalues. Now we have the physical solution on the boundary as in the examples before, with the only difference, that the value on the boundary depends on the actual value inside the computational domain.

In the second step, now we proceed as before. Inserting the solution $\mathbf{u}_0 = \mathbf{u}_r$ into (3.31) gives $\mathbf{u}_l = \mathbf{u}_r$ as a possible choice for the dummy cells. We remark that this can be regarded as a special case of irradiation. The values of two characteristic quantities at the boundary have to remain constant, but the constant is not known. Depending on the outgoing information $\mathbf{u}_r$, the correct information is irradiated so that the outgoing information is "neutralized." We further emphasize that the proposed boundary treatment is based on the physical transport of information by its construction. As an upwind scheme the presented finite-volume approach models properly the physical transport and therefore the arbitrarily prescribed values have no influence on the numerical solution.

4. Numerical results. Typical test examples for Maxwell solvers are transverse magnetic (TM) and transverse electric (TE) waves, for which exact solutions are available (see [16]). In this case the Maxwell equations are homogeneous, i.e., $\mathbf{j} \equiv 0$ in (2.6). For the following TM problem we consider the computational domain $G = \{(x, y) |\ 0 \le x \le x_0, 0 \le y \le y_0\}$. The initial data are given by

$$E_3(\mathbf{x}, 0) = E_0 \sin(ax) \sin(by) \tag{4.1}$$

with

$$a = \frac{m\pi}{x_0}, \qquad b = \frac{n\pi}{y_0}, \tag{4.2}$$

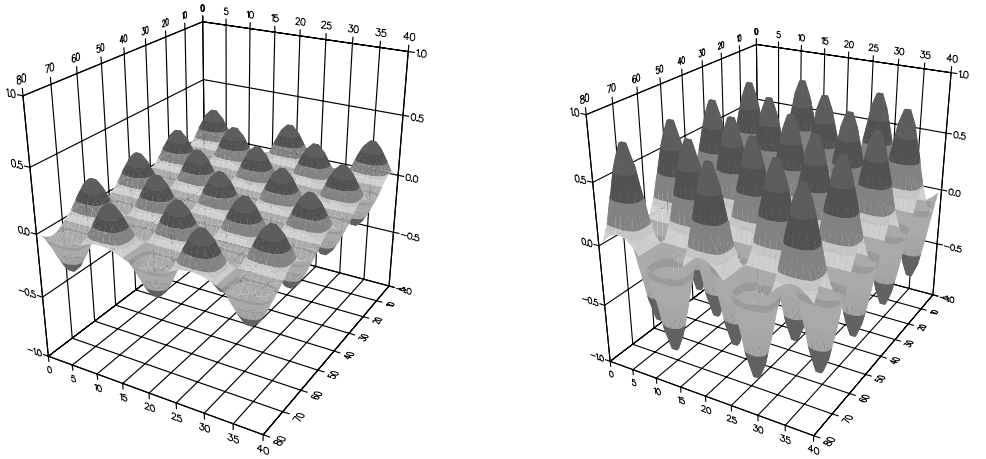

FIG. 4. *Numerical results for a TM wave calculation with $m = 8$ and $n = 5$. The plots show the spatial distribution of the component E_3 at $t = 75ns$ (left) and $t = 150ns$ (right).*

where $\frac{m}{2}$ and $\frac{n}{2}$ is the number of waves in x and y direction, respectively. All other components of $\mathbf{u}$ are set equal to zero everywhere. The exact solution of this initial-value problem is given by the solution of a wave equation for E_3, B_1 and B_2, and $E_1 \equiv E_2 \equiv B_3 \equiv 0$.

In the following we first show numerical results for a regular Cartesian grid with constant space increments, surrounded by a perfect conducting wall. Here, the computational domain G with $x_0 = 80\,\mathrm{m}$, $y_0 = 40\,\mathrm{m}$ is discretized by a grid of 80×40 grid zones. An overview of the numerical solution for this initial value problem is given in Figure 4 for $E_0 = 1\mathrm{V/m}$, $m = 8$, and $n = 5$. The temporal evolution of E_3 is depicted at the time $t = 75\,\mathrm{ns}$ (left) and $t = 150\,\mathrm{ns}$ (right), corresponding to 28 and 56 time steps, respectively.

A first glimpse of the ability of the different finite-volume schemes to capture these TM waves becomes obvious considering slices parallel to the x and y axis, respectively, at $y_0 = 20$ (upper part) and $x_0 = 40$ (lower part) in Figure 5. The plots show results at time $t = 75\,\mathrm{ns}$ (left) and $t = 150\,\mathrm{ns}$ (right). The first-order scheme $(_{+++})$ has already damped the oscillations nearly up to a constant at the time $t = 150\mathrm{ns}$. For practical calculations a first-order method seems not to be appropriate. The second-order TVD-MUSCL scheme clearly reproduces the shape of the wave but reduces the amplitude approximately by a factor 0.5 during the calculation. The slope calculation is based on Sweby's flux limiter function with $k = 1.5$ (see, e.g., [17, 23]). The clipping of extrema can clearly be seen at $t = 75\,\mathrm{ns}$. The ENO-reconstruction of third-order accuracy produces much better results. The form of the wave as well as the amplitude are reproduced very well. To get a more quantitative picture of the approximation quality of the different methods the L^2 error is calculated as a function of time. This error averaged over the whole time interval is listed in Table 1 for the E_3, B_1, and B_2 component.

A serious problem of many electromagnetic field calculations is the accurate resolution of high frequency waves. Here, the ability of the numerical method to capture waves accurately with a small number of grid points is important, especially, in multidimensional calculations to reduce memory requirement and computer time. Due to the reduction of the numerical damping the high-order methods are superior. In the

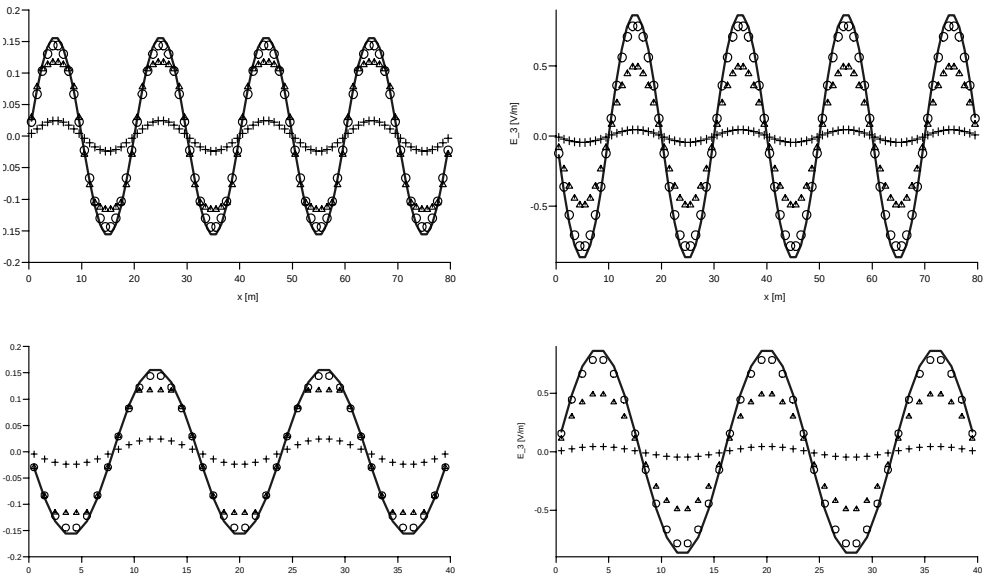

FIG. 5. *Comparison of numerical results for a TM wave calculation with $m = 8$ and $n = 5$ at $t = 75ns$ (left) and $t = 150ns$ (right). The upper plots show the slice of the E_3 component at $y_0 = 20\,m$, the lower plots show the slice at $x_0 = 40\,m$; the exact solution is plotted by a solid line, first-order and second-order TVD and third-order ENO schemes are plotted by "+ + +," "ΔΔΔ," and "o o o," respectively.*

following we study this behavior comparing a second-order TVD with higher order ENO schemes. For a specified value of the error we determine how many grid points per wavelength are necessary for the different methods to keep this bound. These numbers are listed in Table 2 used to capture the waves with a given error. For example, the first column in this table indicates that, using the fifth-order ENO instead of the second-order TVD scheme, the number of grid zones can be reduced by a factor of more than four in each space dimension, i.e., the number of grid zones in a three-dimensional calculation can be decreased by a factor 64. These results clearly indicate that if a numerical solution with a very small error should be obtained, then a high order accurate method is favorable. Especially for three-dimensional calculations, with a high-oscillating solution, this is important because the memory requirement can be drastically reduced. Of course, the computational effort increases with better accuracy. Not only differences of higher order have to be evaluated and compared but also the order of the Runge–Kutta method used for the time approximation has to be increased. If larger errors are tolerable the efficiency of the high-order accurate approximation is lower. For tolerable 10% error the difference in the number of grid

zones is a factor two only. But using a first-order method at about five times more grid zones must be used as with the second-order accurate method.

The implementation for nonorthogonal grids has been tested on the grid shown in Figure 6. The computational domain $G = \{(x, y)|0 \leq x \leq 50\text{m}, 0 \leq y \leq 50\text{m}\}$ is covered by a distorted grid with large cells next to very small ones. The results for the same TM problem as sketched out above are shown in Figure 7. The comparison between the exact (upper plots) and the numerical results (lower plots) at time $t = 90\,\text{ns}$ (left) and $t = 180\,\text{ns}$ (right) (corresponding to 180 and 360 time steps, respectively)

Method of Durlofsky, Engquist, and Osher [8]

indicates that the necessary approximations of the normals at the cells edges do not at all affect the structure of the solution. The results shown in this figure are obtained using the scheme proposed by Colella [6]. When applying the scheme of Durlofsky, Engquist, and Osher [8] the results look quite similar. In order to compare the two schemes in more detail the L^2 norm of the difference between exact and numerical solution is plotted as a function of time in Figure 8. The time averaged L^2 norm, given in Table 3, leads to an experimental order of convergence (EOC) which is quite similar for both schemes and about 1.7.

Due to the clipping phenomenon of the TVD schemes the value two is not completely obtained. In essence, the approach of Colella in [6] as well as the one of Durlofsky, Engquist, and Osher in [8] for gradient approximation in boundary-fitted

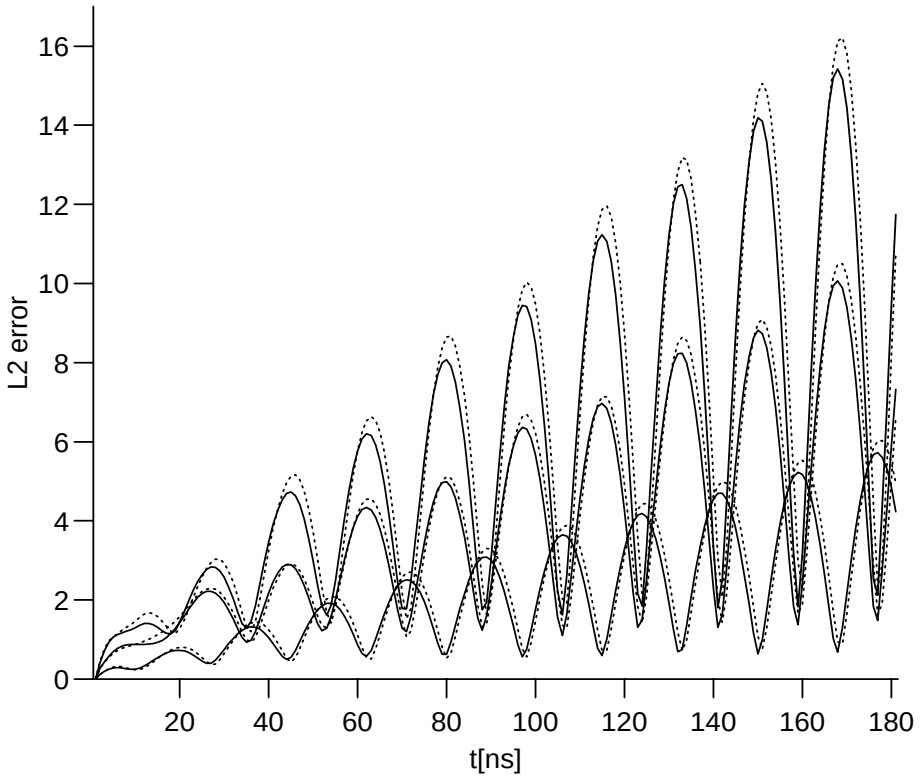

FIG. 8. *Comparison of the L^2 error of the schemes based on the slope calculation of Colella (solid line) and of Durlofsky, Engquist, and Osher (dotted line). coordinates are powerful and efficient and have a sufficient accuracy for practical applications.

Simultaneously checking the numerical treatment of open boundary and energy irradiation conditions, we consider the radiation field of a simple two-dimensional dipole located at the origin of the (x, y)-plane. The finite-size computational domain for this problem consisting of a quarter ring with an inner and outer radius r_i and r_o, respectively, is shown in the upper part of Figure 9. At r_i the theoretical result of the dipole field

$$\begin{aligned} B_{1,0}(t) &= \frac{E_0}{c}\frac{y}{r_i}\psi(r_i, t), \\ B_{2,0}(t) &= -\frac{E_0}{c}\frac{x}{r_i}\psi(r_i, t), \\ \psi(r_i, t) &= \sin(\omega t)J_1(kr_i) - \cos(\omega t)Y_1(kr_i) \end{aligned} \tag{4.3}$$

is irradiated, where J_1 and Y_1 are Bessel functions of first and second kind, E_0 is fixed to $-19,54V/m$, and the frequency $\omega = 0,628/ns$ and the wave number k are related according to $\omega = ck$. Open boundary conditions are imposed at r_o while symmetric boundary conditions are necessary at the axes. The contour plot seen in Figure 9 is a snapshot of the numerical B_2 field at $t = 30$ ns, clearly indicating that no visible

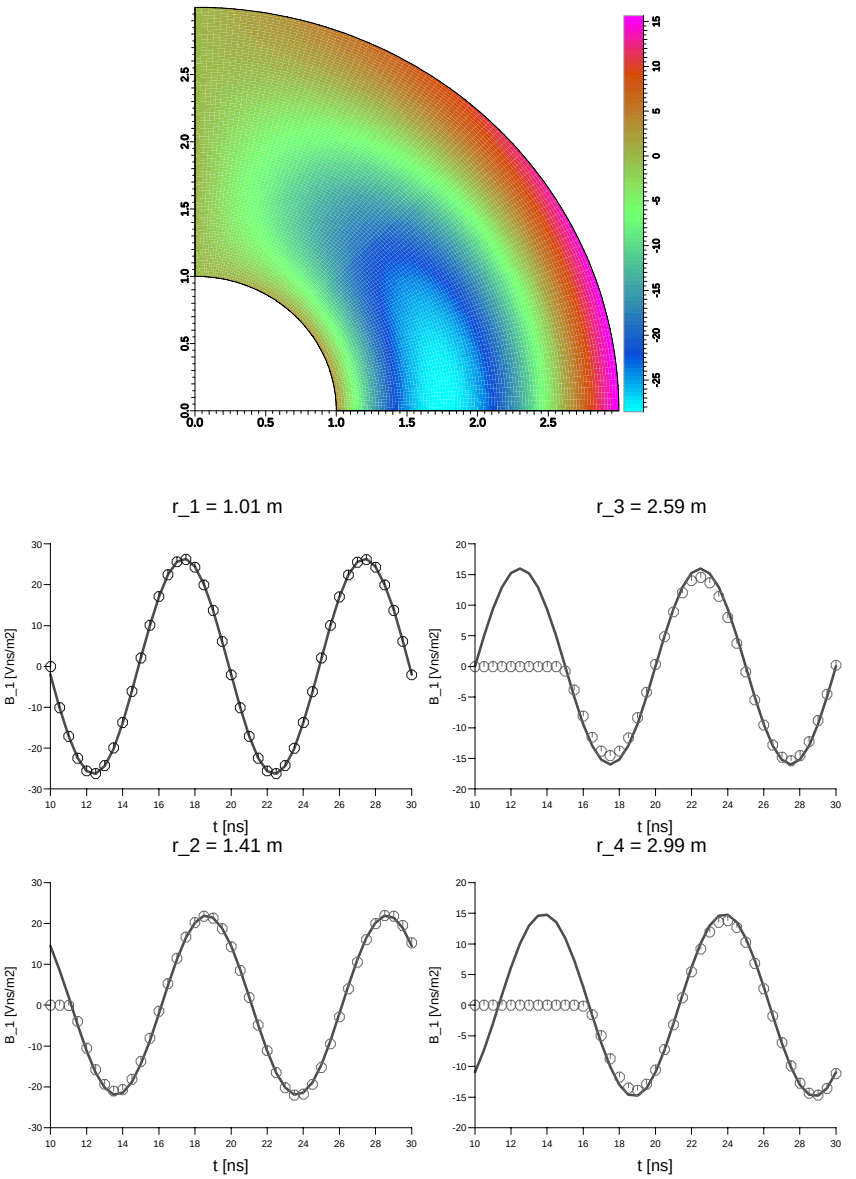

FIG. 9. *The contour plot shows the spatial distribution of the numerical and exact B_2 dipol field solution right and left of the bisector of the angle of the first quadrant, respectively, at $t = 30$ ns. A quantitative comparison between the exact solution (solid lines) and the numerical result (open circles) of the B_1 field component at four different fixed points is depicted in the lower plot.*

wave reflection occurs at the truncated numerical domain at r_o. By scanning the time variation of the B_1 component at four fixed space points ($r_1 = 1.01\,\mathrm{m}$, $r_2 = 1.41\,\mathrm{m}$, $r_3 = 2.59\,\mathrm{m}$, $r_4 = 2.99\,\mathrm{m}$) lying at the bisector of the angle of the first quadrant, the exact solution (solid lines) and numerical approximation (open circles) reveal the high quality and accuracy of the applied methods.

5. Numerical approximation of the constrained formulation. In this section we investigate a modification of the proposed finite-volume methods to enforce the divergence condition (2.1c). We restrict ourselves to describe the correction of the electric field, as the errors in charge conservation do only affect the electrical field. For the magnetic induction, where no influence of source terms occurs, the accuracy of the finite-volume method was sufficient in all our calculations.

One basic approach has been proposed by Boris [3], who applied a correction potential after the fields have been advanced. This may be formulated as a direct approximation of the constrained formulation which is fully implicit in time with respect to the Lagrange multiplier, while the other part is not changed. The implicit part can be reformulated as an elliptic equation for the potential whose numerical solution needs a lot of computational effort. This technique may also be appropriate for the correction of the magnetic field. Other correction techniques have been proposed by Marder [21] and within a finite-element framework by Assous et al. [1] and Starke [29].

In the following we propose a new technique: we approximate the hyperbolic-elliptic system (2.9a), (2.9c) by the strictly hyperbolic problem

$$\partial_t \mathbf{E} - c^2 \nabla \times \mathbf{B} + c^2 \nabla \phi = -\frac{\mathbf{j}}{\epsilon_0}, \tag{5.1a}$$

$$\frac{1}{\gamma^2} \partial_t \phi + \nabla \cdot \mathbf{E} = \frac{\rho}{\epsilon_0}, \tag{5.1b}$$

where an artificial coupling of both equations is introduced by adding the term $\partial_t \phi / \gamma^2$ to the elliptic equation (2.9c). As a hyperbolic system, this system requires initial conditions also for ϕ which are imposed setting $\phi = 0$ initially. The system (5.1) can be written together with (2.1b) as a hyperbolic evolution equation in the form (2.3) but now with the vector

$$\mathbf{u} = (E_1, E_2, E_3, B_1, B_2, B_3, \phi)^{\mathrm{T}}, \tag{5.2}$$

and modified matrices $\mathcal{K}_i, i = 1, 2, 3$. The eigenvalues of these matrices are

$$\lambda_1 = -c\gamma, \quad \lambda_{2/3} = -c, \quad \lambda_4 = 0, \quad \lambda_{5/6} = c, \quad \lambda_7 = c\gamma, \tag{5.3}$$

written in increasing order. By this, the hyperbolic-elliptic problem has been replaced by a hyperbolic system. For the defect $d = \nabla \cdot E - \rho/\epsilon_0$ a wave equation

$$d_{tt} - \gamma^2 c^2 \triangle d = (\rho_t + \nabla \cdot \mathbf{j})_t \tag{5.4}$$

with initial values

$$d(\mathbf{x}, 0) = \nabla \cdot \mathbf{E}_0(x) - \frac{\rho(\mathbf{x}, 0)}{\epsilon_0} \qquad \forall\, \mathbf{x} \in \Omega, \tag{5.5}$$

$$d_t(\mathbf{x}, 0) = \rho_t(\mathbf{x}, 0) + \nabla \cdot \mathbf{j}(\mathbf{x}, 0) \qquad \forall\, \mathbf{x} \in \Omega \tag{5.6}$$

holds. This means that the errors in Gauß's law (2.1c) do not spread out with infinite speed but with finite speed $c\gamma$, where the parameter γ is assumed to be larger than one. Here, we adopted the idea of Chorin [5] to couple the velocity equations of incompressible fluid flow with the divergence-free constraint of the velocity field which is called the method of artificial compression. The physical interpretation in this context is that the pressure waves propagate as acoustic waves with large but finite artificial speed. We remark that the artificial coupling of the Maxwell equations

and Gauß's law will give the proper stationary solution, if the method converges, because ϕ_t/γ^2 vanishes and Gauß's law is satisfied according to (5.1b). The Lagrange multiplier ϕ then equals zero.

The system (5.1) combined with the evolution equation for the magnetic field (2.1b) may be approximated by an explicit high-resolution scheme in a similar way to that proposed in section 3. But, the CFL condition now reads as

$$\gamma c \frac{\Delta t}{h} \leq 1, \tag{5.7}$$

where h denotes the smallest length of a grid zone. If γ is chosen to be much larger than one, this CFL-condition (5.7) becomes a severe restriction of the time step size. But usually the numerical charge errors are small and the transport of these errors to the boundary of the computational domain at a rate near the speed of light should be sufficient to avoid their increase in time. It is well known that in PIC calculations for relevant technical devices usually the divergence correction via a correction potential is carried out after a couple of time steps only. Nevertheless, to get the possibility of an efficient solution for larger values of γ, we split up the system (5.1), (2.1b) into the evolutionary Maxwell equations (2.3) and

$$\partial_t \mathbf{E} + c^2 \nabla \phi = 0, \tag{5.8}$$

$$\partial_t \phi + \gamma^2 \nabla \cdot \mathbf{E} = \gamma^2 \frac{\rho}{\epsilon_0}, \tag{5.9}$$

which contains all the terms involved by the Lagrange multiplier. Recasted as a system of evolution equations it has the form

$$\partial_t \mathbf{w} + \mathcal{K}_1' \partial_{x_1} \mathbf{w} + \mathcal{K}_2' \partial_{x_2} \mathbf{w} + \mathcal{K}_3' \partial_{x_3} \mathbf{w} = \mathbf{g} \tag{5.10}$$

with the vector $\mathbf{w} = (E_1, E_2, E_3, \phi)^{\mathrm{T}}$ and $\mathbf{g} = (0, 0, 0, \gamma^2 \frac{\rho}{\epsilon_0})^{\mathrm{T}}$. The matrices $\mathcal{K}_1'$ and $\mathcal{K}_2'$ have the eigenvalues

$$\lambda_1 = -c\gamma, \quad \lambda_2 = \lambda_3 = 0, \quad \lambda_4 = c\gamma. \tag{5.11}$$

After this preliminary remark, it is obvious that a high-resolution finite-volume scheme can be constructed in the same way as given in section 3.

The advantage of the splitting approach is, first, that the Maxwell solver without modifications can be applied and, second, that a subcycling for the correction step procedure can easily be introduced. According to the value of γ smaller time steps may be chosen in the correction part to satisfy (5.7). Several correction steps are performed within one sweep solving the Maxwell equations.

For numerical purposes also boundary conditions on ϕ have to be added. To have a meaningful correction technique, open boundary conditions have to be imposed on d. This is done by using the initial values $d = 0$ all outside the computational domain. This yields $\phi_t = 0$ outside the computational domain, and together with the initial condition $\phi(\mathbf{x}, 0) = 0$ resulting again in $\phi(\mathbf{x}, t) = 0$ on the boundary.

The numerical results for the following artificial but comprehensive test problem, where the initial fields at time $t = 0$ are set equal to zero in the whole computational domain

$$\mathbf{E}_0(\mathbf{x}) = 0, \qquad \mathbf{B}_0(\mathbf{x}) = 0 \qquad \forall \mathbf{x} \in \mathbf{G}, \tag{5.12}$$

demonstrate the quality of this new correction approach. The charge and current density are prescribed in such a way, that the charge conservation equation (2.2) is violated:

$$\begin{aligned} &\mathbf{j}(\mathbf{x},t)=0 \\ &\rho(\mathbf{x},t)=\rho_0 \sin(\omega t)\delta(\mathbf{x}-\mathbf{x}_0) \end{aligned} \qquad \forall(\mathbf{x},t) \tag{5.13}$$

with some constant ρ_0 and frequency ω. The exact solution of this problem is given by the electric field of a source located at $\mathbf{x}_0$ oscillating with the frequency ω. Solving this problem with a Maxwell solver based on the hyperbolic evolution equations (2.1a), (2.1b) without any divergence correction, we would obtain the trivial solution $\mathbf{E} \equiv 0, \mathbf{B} \equiv 0$ as the charge density does not enter the numerical procedure.

Numerical results for $G = \{(x,y), 0 \le x \le 50\,\mathrm{m}, 0 \le y \le 50\,\mathrm{m}\}$ are presented in Figure 10. The upper picture shows the divergence of the electric field at time $t = 5\,\mathrm{ns}$. Around $x_0 = 25\,\mathrm{m}, y_0 = 25\,\mathrm{m}$ the divergence has a peak whose exact height is 1. It is clearly visible that the divergence errors are transported to the boundary of the computational domain. A quantitative comparison between the exact and numerically obtained maximum of $\nabla \cdot \mathbf{E}$ as a function of time is seen in the lower part of Figure 10. Aside from the exact solution, results for $\gamma = 30$ and $\gamma = 20$ are shown. These results show clearly that the method gives the desired correction of the electrical field and is able to follow the oscillating of the source.

A further numerical result obtained from the area of PIC applications is depicted in Figure 11 and shows explicitly the importance of the correction of the electrical field. Here, an electron beam is emitted within a small area at the cathode ($x = 0$) and accelerated to the anode ($x = 0.1m$) under the action of a constant external field $E_1 = -2\frac{MV}{m}$. The anode-cathode gap of this simple diode configuration coincides with the computational domain discretized by a grid of 100×100 grid zones. The snapshots of the noncorrected (left) as well as the corrected (right) electron distribution and the E_1 component of the electrical filed are recorded at time $t = 10ns$, where the beam has already reached a stationary (steady) state.

In the case where no correction procedure is applied (left), the electron distribution reveals constriction and filamentation of the beam while nonphysically gradients are observed in the electrical field both as a consequence of numerical errors in charge conservation. The situation is drastically improved toward physical reliance (right) performing the proposed hyperbolic correction with $\gamma = 3$. For this electron beam example the hyperbolic correction technique is checked against the standard correction potential approach yielding comparable overall agreement. Furthermore, a gain of a factor of four in CPU time is obtained choosing the hyperbolic instead of the usual elliptic correction approach.

6. Conclusions. The finite-volume approach to solve numerically the Maxwell equations is an interesting alternative to finite-difference and finite-element schemes. With the finite-element approach it shares the flexibility of the grid so that computational domains with complicated geometries can be handled. The finite-volume schemes proposed in this paper are based on TVD and ENO-schemes for hyperbolic conservation laws and known to be very robust even in the vicinity of steep gradients. Hence, these methods are favorable for all classes of problems where fields undergo strong changes. Due to the construction principle to take into account the local wave propagation they may be considered as a natural extension of the method of characteristics.

For Cartesian grids the standard finite-difference schemes need less computational

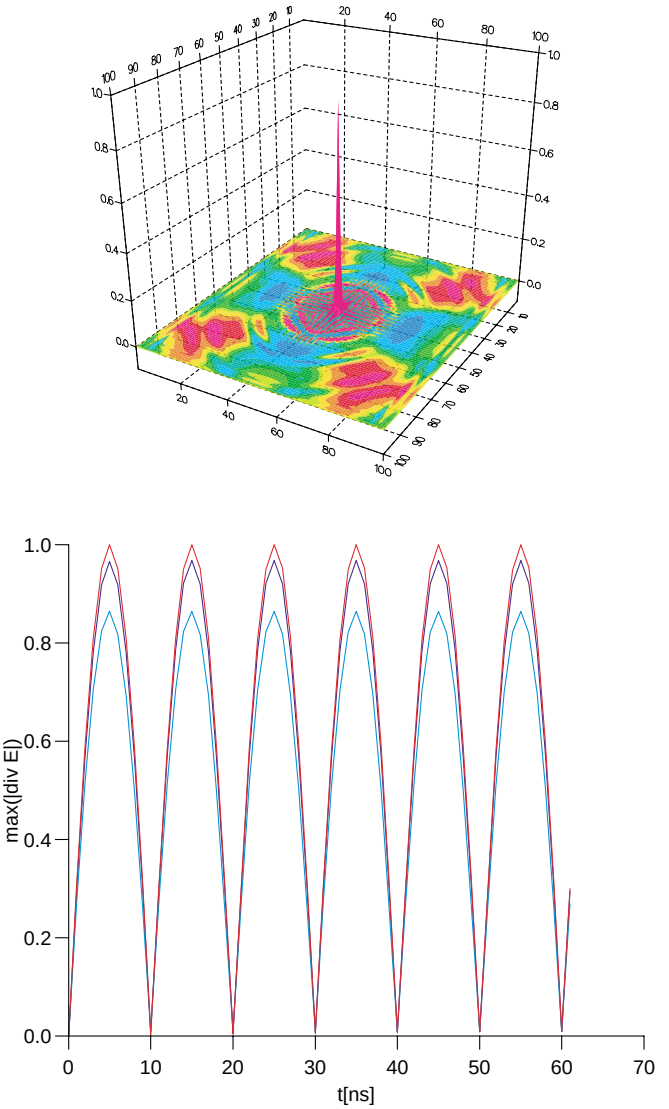

FIG. 10. *The upper picture shows the absolute value of* $\nabla \cdot \mathbf{E}$ *at* $t = 5\,ns$. *A quantitative comparison between the exact and numerically obtained maximum of* $\nabla \cdot \mathbf{E}$ *as function of time is seen in the lower part of the figure. effort. For the Yee scheme [37] the effort is at about a factor of three less, compared with a second-order accurate TVD scheme. Hence, for problems with simple geometries and without strong gradients in the solution the finite-difference methods seem to be superior. Their extensions to more general grids using the "staggered" finite-volume approach [18, 19, 36] require also less computational effort than the characteristics based approach on a collocated grid. But besides their robustness a further advantage of our approach is the possibility to increase the order of accuracy without loosing their robustness by use of sophisticated ENO interpolation schemes combined with Runge–Kutta time stepping procedures. For calculations on a Carte-

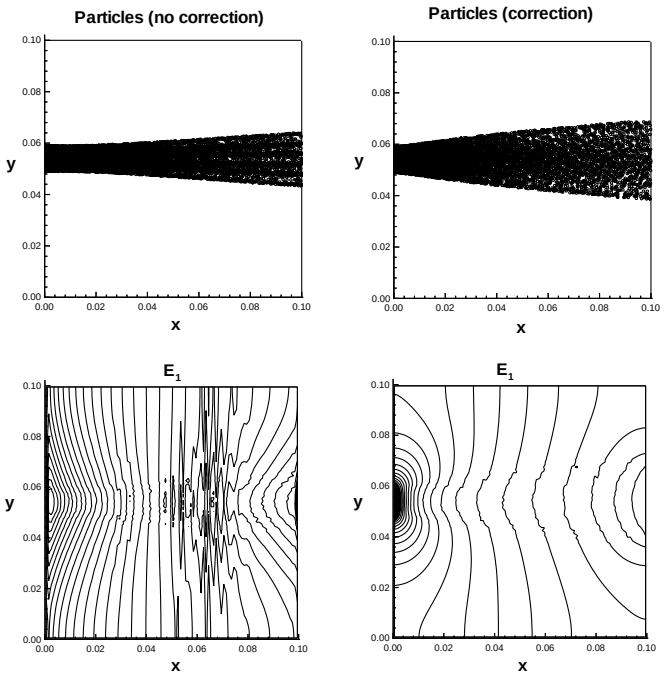

FIG. 11. *A typical finite-volume PIC application to a self-consistent beam simulation for a simple diode configuration demonstrates clearly the importance and consequence of electrical field correction. The charge conservation is enforced by the hyperbolic correction technique with* $\gamma = 3$.

sian grid we demonstrated the possibility of reducing significantly the number of grid cells by higher order accurate methods while the resolution of waves is preserved. Especially, in three-dimensional calculations this fact is interesting to save storage as well as computer time. Of course, the ENO interpolation needs more computational effort, especially for curvilinear grids, and the third- or fourth-order accurate schemes may be of practical interest only.

A class of problems where our finite-volume Maxwell solver seems to be very attractive is the self-consistent simulation of the motion of charged particles. Especially in the case where the Maxwell solver is one part of an electromagnetic PIC code, the fields have to be calculated at the particle locations. A staggering in space and time needs additional interpolation which usually increases the approximation errors. A new correction method for the electric field enforcing the validity of Gauß's law is formulated in the finite-volume framework, which seemed to be very important in the context of PIC calculations.

COMPARISON OF HIGH-ACCURACY FINITE-DIFFERENCE METHODS FOR LINEAR WAVE PROPAGATION*

DAVID W. ZINGG†

Abstract. This paper analyzes a number of high-order and optimized finite-difference methods for numerically simulating the propagation and scattering of linear waves, such as electromagnetic, acoustic, and elastic waves. The spatial operators analyzed include compact schemes, noncompact schemes, schemes on staggered grids, and schemes which are optimized to produce specific characteristics. The time-marching methods include Runge–Kutta methods, Adams–Bashforth methods, and the leapfrog method. In addition, the following fully-discrete finite-difference methods are studied: a one-step implicit scheme with a three-point spatial stencil, a one-step explicit scheme with a five-point spatial stencil, and a two-step explicit scheme with a five-point spatial stencil. For each method, the number of grid points per wavelength required for accurate simulation of wave propagation over large distances is presented. The results provide a clear understanding of the relative merits of the methods compared, especially the trade-offs associated with the use of optimized methods. A numerical example is given which shows that the benefits of an optimized scheme can be small if the waveform has broad spectral content.

Key words. finite-difference methods, wave propagation, electromagnetics, acoustics, Maxwell equations

Introduction. Numerical simulation can play an important role in the context of engineering design and in improving our understanding of complex systems. The simulation of wave phenomena, including electromagnetic, elastic, and acoustic waves, is an area of active research. Lighthill [24] and Taflove [40] discuss the prospects for computational aeroacoustics and electromagnetics, respectively. The computational requirements for accurate simulations of the propagation and scattering of waves can be high, particularly if the size of the geometry under study is much larger than the wavelength. Consequently, there has been considerable recent effort directed towards improving the efficiency of numerical methods for simulating wave phenomena.

In electromagnetics, the most popular approach to the numerical solution of the time-domain Maxwell equations for numerous applications has been the algorithm of Yee [50], which was named the finite-difference time-domain (FDTD) method by Taflove [41]. This algorithm combines second-order centered differences on a staggered grid in space with second-order staggered leapfrog time marching. Its main attributes are its very low cost per grid node and lack of dissipative error. Yee's method is often applied using Cartesian grids, with a special treatment of curved boundaries [20]. Extension to curvilinear grids was carried out by Fusco [11]. Madsen and Ziolowski [28] put the method into a finite-volume framework applicable to unstructured grids. Vinokur and Yarrow [47, 48] developed a related finite-surface method with advantages at boundaries and grid singularities.

Other methods which have been successfully applied to the time-domain Maxwell equations include the upwind Lax–Wendroff approach used by Shankar, Mohamma-

dian, and Hall [38], the characteristic-based fractional-step method of Shang [36], and the finite-element method of Cangellaris, Lin, and Mei [5]. Although all of these second-order methods have been used with a great deal of success, they are efficient only for geometries of moderate electrical size, on the order of 20 wavelengths or less. For wave propagation over longer distances, the grid resolution requirements of second-order methods can become excessive, leading to impractical CPU and memory requirements. This has motivated the development of higher-order methods which produce smaller errors for a given grid resolution, such as the extension of Yee's method to fourth-order in space [40] and the methods of Liu [25], Shang and Gaitonde [37], Zingg et al. [52, 55, 18, 19], Petropoulos [31], Turkel and Yefet [44], and Young, Gaitonde, and Shang [51], many of which use staggered grids.

In seismology, the need for higher-order methods has been recognized for some time. Alford, Kelly, and Boore [2], Marfurt [29], Dablain [9], and Sei [34] present higher-order algorithms for the elastic wave equation. Similarly, higher-order finite-difference methods have been developed for acoustic applications by Gottlieb and Turkel [13], Cohen and Joly [8], and Davis [10], for example.

It can be advantageous to modify the coefficients of a potentially higher-order method, thereby lowering the order of accuracy, to produce reduced errors over a range of wavenumbers. We refer to such schemes as optimized schemes [52]. This approach was first proposed by Vichnevetsky and De Schutter [45] and later studied in more detail by Holberg [16] and Lele [23]. Haras and Ta'asan [15] and later Kim and Lee [21] further refined the optimization technique used by Lele. The papers by Holberg and Lele spawned a number of optimized schemes, including those presented by Hu, Hussaini, and Manthey [17], Lockard, Brentner, and Atkins [27], Sguazzero, Kindelan, and Kamel [35], Tam [42], Tam and Webb [43], Zingg and Lomax [53], and Zingg, Lomax, and Jurgens [52, 55]. See Wells and Renaut [49] for a discussion of several of these schemes in the context of computational aeroacoustics.

In addition to the accuracy of the interior differencing scheme, there are several other important issues in simulating wave phenomena. High-order and optimized methods often have a large spatial stencil which cannot be used near boundaries. This necessitates the use of numerical boundary schemes which must be suitably accurate relative to the interior scheme [14] and stable. These can be difficult to obtain, and this represents a significant obstacle to the use of higher-order methods. Recent progress is reported by Olsson [30] and Carpenter, Gottlieb, and Abarbanel [6, 7]. Zingg and Lomax [54] present a fifth-order numerical boundary scheme which produces a stable scheme in conjunction with sixth-order centered differences. An improved version, which is stable for curvilinear grids, is given by Jurgens and Zingg [19]. Another important consideration is the boundary condition at the outer boundary of the domain, which inevitably causes spurious reflection. As a result of recent developments in this area, such as perfectly matched absorbing layers [1, 4, 12, 32, 57], such reflections can be substantially reduced. Consequently, the numerical errors introduced by the interior differencing scheme are often dominant, and the choice of the interior scheme is critical to the efficient simulation of wave phenomena.

An efficient discretization of a partial differential equation governing a linear wave phenomenon reliably maintains the numerical error below an acceptable threshold, which is problem dependent, at the lowest possible cost. The cost includes processing time and memory, although development cost can be considered as well. Numerical errors arise from both the spatial and the temporal discretization. They include both phase and amplitude errors, which depend on the wavenumber, the grid spacing,

the Courant number, and the direction of propagation relative to the grid. The dependence of the phase speed on the wavenumber results in numerical dispersion [46], while the amplitude error results in numerical dissipation. The dependence of these errors on the direction of wave propagation relative to the grid leads to numerical anisotropy. Fourier analysis provides a straightforward means of calculating these errors [46, 26]. Although this simplified analysis excludes errors associated with nonuniform grids and boundaries, it is a very useful tool for scheme evaluation and development. Good performance under the conditions of Fourier analysis, i.e., uniform grids and periodic boundary conditions, is a necessary condition for good performance under more general conditions.

Through Fourier analysis, one can calculate the phase and amplitude error of a given method as a function of the wavenumber. However, this information can be difficult to interpret. A more useful approach used by Lockard, Brentner, and Atkins [27] is to plot the grid resolution in terms of grid points per wavelength (PPW) required to maintain global phase and amplitude errors below a specified threshold as a function of the distance of propagation expressed in terms of the number of wavelengths traveled. This is not only an excellent metric for scheme development and comparison, but it also provides useful information for applying the methods to specific problems.

In this paper, we study and compare the grid resolution requirements of several high-order and optimized schemes, including spatial discretizations, time-marching methods, and combined time-space discretizations. Emphasis is on schemes requiring under 30 PPW for accurate simulations with propagation distances of up to 200 wavelengths. The purpose is twofold. First, the results can aid in the evaluation and application of high-accuracy methods and are especially helpful in clarifying the behavior of optimized schemes. Second, the framework presented can be used in the assessment of new methods.

Finite-difference schemes compared. In this section, we present the various finite-difference schemes in the context of the linear advection equation given by

$$\frac{\partial u}{\partial t} + a\frac{\partial u}{\partial x} = 0, \tag{1}$$

where u is a scalar quantity propagating with speed a, which is real and positive. The schemes under study can be divided into two distinct groups. In the first group, the spatial and temporal discretizations are independent, i.e., a discretization is applied to the spatial derivative to produce a system of ordinary differential equations (ODEs), which is solved numerically using a time-marching method. Hence we first study spatial discretizations and time-marching methods separately and later consider specific combinations. The spatial difference operators are approximations to $\partial/\partial x$. The time-marching methods are presented as applied to a scalar ODE of the form

$$\frac{du}{dt} = f(u,t). \tag{2}$$

The second group of methods involves the simultaneous discretization of space and time; there is no intermediate semidiscrete form. These are presented as applied to (1) itself. The coefficients of all of the schemes studied are given in the appendix.

The methods can also be classified as dissipative or nondissipative. A spatial discretization is nondissipative, i.e., produces no amplitude error, if it is skew symmetric. When combined with certain time-marching methods, such as the leapfrog

method, the resulting full discretization is nondissipative, that is, the amplitude of the solution will neither grow nor decay except in the presence of boundaries. Combined space-time discretizations can be nondissipative as well. This is generally a useful property in that it is consistent with the physics in preserving certain energy norms. Thus nondissipative schemes are widely used with great success, especially in solving the Maxwell equations. However, dissipative schemes can be effective as well, as long as the numerical dissipation is carefully controlled. For example, in the scheme of Zingg, Lomax, and Jurgens [55], the dissipative error is smaller than the phase error for all wavenumbers. Therefore, any mode for which the numerical dissipation is excessive already suffers from excessive phase error. Dissipative schemes have the advantage that high-frequency spurious waves, arising from boundaries, for example, are damped [13]. Furthermore, dissipative schemes can, at least in principle, be applied to nonlinear problems.

Spatial difference operators. On a uniform grid with $x_j = j\Delta x$ and $u_j = u(x_j)$, compact centered-difference schemes of up to tenth order can be represented by the following formula:

$$\begin{aligned} &\beta(\delta_x u)_{j-2} + \alpha(\delta_x u)_{j-1} + (\delta_x u)_j + \alpha(\delta_x u)_{j+1} + \beta(\delta_x u)_{j+2} \\ &= \frac{1}{2\Delta x}\left[\frac{c}{3}(u_{j+3} - u_{j-3}) + \frac{b}{2}(u_{j+2} - u_{j-2}) + a(u_{j+1} - u_{j-1})\right], \end{aligned} \tag{3}$$

where $(\delta_x u)_j$ is an approximation to $\partial u/\partial x$ at node j. These schemes produce no amplitude error. Noncompact schemes of up to sixth order are obtained with $\beta = \alpha = 0$.

Haras and Ta'asan [15] revisited the compact schemes of Lele [23] based on (3) using a more sophisticated optimization procedure. They developed tridiagonal schemes ($\beta = 0$) and tridiagonal schemes with a five-point stencil ($\beta = c = 0$) as well. In each case, Haras and Ta'asan present several methods which result from different parameters in the optimization procedure. In the comparisons below, we will include only those schemes which are best according to our criterion, i.e., those schemes which require the fewest grid points per wavelength for accurate wave propagation over a distance of 200 wavelengths.

The spatial operator of Zingg, Lomax, and Jurgens [52, 55] is noncompact with a seven-point stencil. The operator is divided into a skew-symmetric part given by

$$(\delta_x^a u)_j = \frac{1}{\Delta x}\left[a_3\left(u_{j+3} - u_{j-3}\right) + a_2\left(u_{j+2} - u_{j-2}\right) + a_1\left(u_{j+1} - u_{j-1}\right)\right] \tag{4}$$

and a symmetric part given by

$$(\delta_x^s u)_j = \frac{1}{\Delta x}\left[d_3\left(u_{j+3} + u_{j-3}\right) + d_2\left(u_{j+2} + u_{j-2}\right) + d_1\left(u_{j+1} + u_{j-1}\right) + d_0 u_j\right]. \tag{5}$$

The symmetric part provides dissipation of spurious high-wavenumber components of the solution. The magnitude of the dissipative component is chosen such that the amplitude error produced is less than the phase error. [52, 55] include a maximum-order scheme and an optimized scheme. The optimized scheme was designed to minimize the maximum phase and amplitude errors for waves resolved with at least 10 PPW. It is superior for distances of travel of up to 330 wavelengths. Hence we do not consider the maximum-order scheme here. Tam and Webb [43] have also developed an optimized scheme based on the skew-symmetric operator given in (4).

Lockard, Brentner, and Atkins [27] present an optimized upwind-biased noncompact spatial difference operator based on an eight-point stencil. It can be written in the form

$$(\delta_x u)_j = \frac{1}{\Delta x} \sum_{m=-4}^{3} a_m u_{j+m}. \tag{6}$$

The operator is optimized for waves resolved with at least 7 PPW and provides excellent accuracy up to about 340 wavelengths of travel. Note that this operator can also be written as the sum of a skew-symmetric and a symmetric operator. A nine-point stencil is required for systems of equations with wave speeds of opposite sign.

Differencing schemes on staggered grids are well suited to problems in which the time derivative of one variable depends on the spatial derivative of the other, and vice-versa. This is the case for the time-domain Maxwell equations or the Euler equations linearized about a reference state with zero velocity, for example. Centered staggered differencing schemes of up to sixth order can be written in the form

$$(\delta_x u)_j = \frac{1}{\Delta x} \left[b_1 \left(u_{j+1/2} - u_{j-1/2} \right) + b_2 \left(u_{j+3/2} - u_{j-3/2} \right) + b_3 \left(u_{j+5/2} - u_{j-5/2} \right) \right]. \tag{7}$$

Time-marching methods. There are many considerations involved in selecting a time-marching method, including efficiency, i.e., accuracy per unit computational effort, stability, and memory use. Since wave propagation problems are generally not particularly stiff, explicit methods are appropriate. Thus the Adams–Bashforth and Runge–Kutta families are suitable candidates. Although other methods, such as predictor-corrector methods, can be used, we analyze only a few popular options, as well as some recently introduced methods.

Since a large portion of the computational effort is generally associated with evaluation of the derivative function, one can approximately assess the efficiency of a time-marching method by accounting for the number of derivative function evaluations per time step. Runge–Kutta methods require one derivative function evaluation per stage. Zingg and Chisholm [56] have shown that for linear ODEs with constant coefficients, Runge–Kutta methods of up to sixth order can be derived with a number of stages equal to the order. However, the memory requirements of the methods of orders five and six are high. For nonlinear ODEs and linear ODEs with nonconstant coefficients, six stages are required for fifth-order accuracy and seven stages for sixth-order accuracy [22].

An alternative approach is to use low-storage multistage methods which are high-order for homogeneous linear ODEs but second-order otherwise [55]. Haras and Ta'asan [15] and Zingg, Lomax, and Jurgens [52, 55] present five- and six-stage methods of this type, respectively. For example, when applied to (2), the six-stage method of Zingg, Lomax, and Jurgens [52, 55] is given by

$$\begin{aligned}
u^{(1)}_{n+\alpha_1} &= u_n + h\alpha_1 f_n, \\
u^{(2)}_{n+\alpha_2} &= u_n + h\alpha_2 f^{(1)}_{n+\alpha_1}, \\
u^{(3)}_{n+\alpha_3} &= u_n + h\alpha_3 f^{(2)}_{n+\alpha_2}, \\
u^{(4)}_{n+\alpha_4} &= u_n + h\alpha_4 f^{(3)}_{n+\alpha_3},
\end{aligned} \tag{8}$$

$$u_{n+\alpha_5}^{(5)} = u_n + h\alpha_5 f_{n+\alpha_4}^{(4)},$$
$$u_{n+1} = u_n + h f_{n+\alpha_5}^{(5)},$$

where $h = \Delta t$ is the time step, $t_n = nh$, $u_n = u(t_n)$, and

$$f_{n+\alpha}^{(k)} = f(u_{n+\alpha}^{(k)}, t_n + \alpha h).$$

The five-stage method of [15] is analogous. In their maximum-order form (for homogeneous ODEs), these methods are not stable for pure central (skew-symmetric) differencing in space. Consequently, Haras and Ta'asan modify the coefficients of the five-stage scheme to produce stability, while Zingg, Lomax, and Jurgens [52, 55] add a dissipative (symmetric) component to their spatial operator, as given in (5).

Adams–Bashforth methods require only one derivative function evaluation per time step, and thus can be more efficient than Runge–Kutta methods of equal order. Since they are *multistep* methods, however, they require extra storage. Furthermore, Adams–Bashforth methods of order higher than four have extremely restrictive stability bounds. Thus the time-marching methods we consider here are the fourth-order Adams–Bashforth method, the low-storage fourth-order Runge–Kutta method for linear ODEs given by Zingg and Chisholm [56], and the low-storage five- and six-stage methods described above. In terms of stability and Fourier error analysis, the fourth-order Runge–Kutta method of [56] is identical to the classical fourth-order Runge–Kutta method. With respect to memory requirements, the fourth-order Adams–Bashforth method requires five memory locations per dependent variable, while the other methods considered require only two.

A natural choice of time-marching method for use with staggered spatial differencing is the second-order staggered leapfrog method, given by

$$u_{n+1} = u_n + h f_{n+1/2}. \tag{9}$$

When used with a nondissipative spatial scheme, as in the FDTD method, the resulting fully-discrete operator produces no amplitude error. Furthermore, the staggered leapfrog method generally produces a leading phase error, which can offset the phase lag usually produced by centered spatial differences. At specific Courant numbers and angles of propagation, the perfect-shift property[1] can be obtained, leading to exact propagation for all wavenumbers. Although this has little practical significance, fully-discrete methods which possess this property are generally most accurate when used near the perfect-shift conditions.

Simultaneous space-time discretizations. The scheme of Davis [10] is a nondissipative implicit scheme with a three-point spatial stencil. When applied to the linear advection equation, it is given by

$$a_0 u_j^{n+1} + a_1 u_{j-1}^{n+1} + a_2 u_{j+1}^{n+1} = b_0 u_j^n + b_1 u_{j-1}^n + b_2 u_{j+1}^n \tag{10}$$

with $a_0 = b_0$, $a_1 = b_2$, and $a_2 = b_1$, where $u_j^n = u(x_j, t_n)$. Being implicit, this scheme requires more computational expense than explicit schemes. However, it achieves fourth-order accuracy in time and space with a three-point spatial stencil.

The scheme of Gottlieb and Turkel [13] is an extension of the Lax–Wendroff approach to fourth-order in space, remaining second-order in time. It is an explicit

[1] This refers to the situation when the error from the spatial discretization precisely cancels that from the temporal discretization.

one-step scheme but requires a five-point stencil. When applied to the linear advection equation, it is given by

$$u_j^{(1)} = u_j^n + \frac{ah}{6\Delta x}(u_{j+2}^n - 8u_{j+1}^n + 7u_j^n),$$
$$u_j^{n+1} = \frac{1}{2}(u_j^n + u_j^{(1)}) + \frac{ah}{12\Delta x}(-u_{j-2}^{(1)} + 8u_{j-1}^{(1)} - 7u_j^{(1)}). \tag{11}$$

The two-stage form is motivated by nonlinear problems. This method is dissipative and has received considerable use in nonlinear problems. The justification for having a lower order of accuracy in time than in space is based on the idea that the system is at least mildly stiff. Hence the time-step restriction based on the parasitic modes, i.e., the stability limit, is often much more stringent than that for the driving modes, i.e., the accuracy limit. Note, however, that many wave propagation problems are not stiff at all.

It is straightforward to extend this approach to fourth-order in time without increasing the stencil. For example, one can derive the following dissipative one-step fourth-order method:

$$u_j^{n+1} = u_j^n - ah(\delta_x^{(4)}u)_j^n + \frac{h^2a^2}{2}(\delta_{xx}^{(4)}u)_j^n - \frac{h^3a^3}{6}(\delta_{xxx}^{(2)}u)_j^n + \frac{h^4a^4}{24}(\delta_{xxxx}^{(2)}u)_j^n, \tag{12}$$

where $\delta_x^{(4)}$ is a fourth-order centered difference approximation to a first derivative, $\delta_{xx}^{(4)}$ is a fourth-order centered difference approximation to a second derivative, $\delta_{xxx}^{(2)}$ is a second-order centered difference approximation to a third derivative, and $\delta_{xxxx}^{(2)}$ is a second-order centered approximation to a fourth derivative. All of the operators on the right-hand side require a five-point stencil, as follows:

$$(\delta_x^{(4)}u)_j = \frac{1}{12\Delta x}\left(u_{j-2} - 8u_{j-1} + 8u_{j+1} - u_{j+2}\right),$$
$$(\delta_{xx}^{(4)}u)_j = \frac{1}{12\Delta x^2}\left(-u_{j-2} + 16u_{j-1} - 30u_j + 16u_{j+1} - u_{j+2}\right),$$
$$(\delta_{xxx}^{(2)}u)_j = \frac{1}{2\Delta x^3}\left(-u_{j-2} + 2u_{j-1} - 2u_{j+1} + u_{j+2}\right),$$
$$(\delta_{xxxx}^{(2)}u)_j = \frac{1}{\Delta x^4}\left(u_{j-2} - 4u_{j-1} + 6u_j - 4u_{j+1} + u_{j+2}\right). \tag{13}$$

This scheme is quite complicated to apply in multidimensions. Hence we will consider a simpler scheme which is fourth-order in time and space, the following nondissipative two-step explicit scheme:

$$u_j^{n+1} = u_j^{n-1} - 2ah(\delta_x^{(4)}u)_j^n - \frac{h^3a^3}{3}(\delta_{xxx}^{(2)}u)_j^n, \tag{14}$$

where $\delta_x^{(4)}$ and $\delta_{xxx}^{(2)}$ are given in (13) above. Related methods for the second-order wave equation are presented by Cohen and Joly [8] and Shubin and Bell [39].

Fourier error analysis. Consider the linear convection equation, (1), on an infinite domain. A solution initiated by a harmonic function with wavenumber κ is

$$u(x,t) = f(t)e^{i\kappa x}, \tag{15}$$

where $f(t)$ satisfies the ODE

$$\frac{df}{dt} = -ia\kappa f. \tag{16}$$

If the spatial derivative is approximated by a finite-difference formula, then the ODE becomes

$$\frac{df}{dt} = -ia\kappa^* f, \tag{17}$$

where κ^* is the modified wavenumber. For example, the modified wavenumber associated with the spatial operator given in (3) is obtained from

$$\kappa^* \Delta x = \frac{a\sin(z) + (b/2)\sin(2z) + (c/3)\sin(3z)}{1 + 2\alpha\cos(z) + 2\beta\cos(2z)}, \tag{18}$$

where $z = \kappa\Delta x$, i.e., $z = 2\pi/\text{PPW}$. The numerical phase speed, a^*, is the speed at which a harmonic function propagates numerically. It is related to the modified wavenumber by

$$\frac{a^*}{a} = \frac{\kappa^*}{\kappa}. \tag{19}$$

The dependence of a^* on κ introduces numerical dispersion. For the spatial operator given in (4) and (5), the modified wavenumber is obtained from

$$\begin{aligned} i\kappa^*\Delta x = {} & d_0 + 2(d_1\cos\kappa\Delta x + d_2\cos 2\kappa\Delta x + d_3\cos 3\kappa\Delta x) \\ & + 2i(a_1\sin\kappa\Delta x + a_2\sin 2\kappa\Delta x + a_3\sin 3\kappa\Delta x). \end{aligned} \tag{20}$$

The real part of the modified wavenumber determines the phase (or dispersive) error, while the imaginary part determines the amplitude (or dissipative) error.

The accuracy of a time-marching method can be assessed through the characteristic polynomial of the ODE resulting from application of the time-marching method to the following ODE:

$$\frac{df}{dt} = \lambda f. \tag{21}$$

The accuracy analysis is based on the principal root of the characteristic polynomial, denoted by $\sigma(\lambda h)$, which is an approximation to $e^{\lambda h}$. In order to assess the accuracy of time-marching methods for wave propagation, we consider only pure imaginary values of λ, i.e., $\lambda = i\omega$ with ω real. The normalized local amplitude and phase errors are determined from $\sigma(\lambda h)$, as follows:

$$er_a = |\sigma| - 1, \tag{22}$$

$$er_p = -\frac{\phi}{\omega h} + 1, \tag{23}$$

where $\phi = \arctan(\sigma_i/\sigma_r)$, and σ_r and σ_i are the real and imaginary parts of σ. Equation (16) is in the form of (21) with $\lambda = i\omega = -ia\kappa$. Substituting $\omega = -a\kappa$ into (23), we obtain

$$er_p = \frac{\phi}{zC} + 1, \tag{24}$$

where $\sigma = \sigma(-izC)$, and $C = ah/\Delta x$ is the Courant number. To analyze a time-marching method in combination with a spatial discretization, $\sigma = \sigma(-i\kappa^*\Delta x C)$,

where κ^* is the modified wavenumber associated with the spatial operator. For simultaneous space-time discretizations, the complex amplification factor is calculated directly by substituting a solution of the form $u(x,t) = \sigma^n e^{i\kappa x}$ into the fully discrete operator [3].

Our criterion for comparing schemes is based on the magnitude of the global amplitude and phase errors, which are

$$\begin{aligned} Er_a &= \left||\sigma|^N - 1\right| \\ &= \left||\sigma|^{PPWn_w/C} - 1\right|, \end{aligned} \tag{25}$$

$$\begin{aligned} Er_p &= N|\omega h - \phi| \\ &= n_w \left|\frac{PPW\phi}{C} + 2\pi\right|, \end{aligned} \tag{26}$$

where $N = PPWn_w/C$ is the number of time steps and n_w is the number of wavelengths traveled. Using these formulas with an accurate time-marching method and a very small Courant number gives the errors for the spatial operator alone; the time advance is effectively exact. In the results section, the various methods are compared in terms of the PPW required to keep both global phase and amplitude errors below 0.1 as a function of the number of wavelengths traveled. This error threshold is, of course, arbitrary and corresponds to that used by Lockard, Brentner, and Atkins [27]. The relative performance of the methods is similar for other choices, and thus our conclusions are independent of the specific value of the error threshold. For some schemes, especially optimized schemes, the error does not increase monotonically with the nondimensional wavenumber z. Hence the error can actually become larger as the grid resolution is increased. In such cases, we use the value of PPW for which all higher values of PPW also satisfy the error threshold.

Since practical problems involve multidimensional systems of equations, the use of one-dimensional scalar analysis requires some justification. A hyperbolic system of equations is diagonalizable with real eigenvalues, or wave speeds. These wave speeds can vary significantly. Consequently, the effective Courant number for the different waves can also vary significantly. A nonuniform grid further contributes to the variation in the Courant number. For the fastest wave, the Courant number must be sufficiently small such that the scheme is both accurate and stable. For the slower waves, the Courant number is then much smaller. A scheme which produces poor accuracy at low Courant numbers is thus inappropriate for such problems. This situation can arise if a scheme relies on cancellation of time and space errors to achieve high accuracy. For example, several schemes which combine the spatial and temporal discretization produce the perfect-shift property at specific Courant numbers. Often this perfect cancellation of temporal and spatial errors is achieved at a Courant number of unity. For such schemes, the error *increases* as the Courant number is reduced since the temporal error decreases and no longer cancels the spatial error. Hence it is important to assess schemes over a range of Courant numbers. Note that this is not an issue with schemes which combine a high-accuracy spatial discretization with a high-accuracy time-marching method. Since such schemes generally do not rely on cancellation to achieve high accuracy, the error does not increase as the Courant number is reduced.

The situation is similar in multidimensions. For most spatial discretizations, the error is largest for waves propagating at 0 or 90 degrees to the grid [46, 23, 53]. The

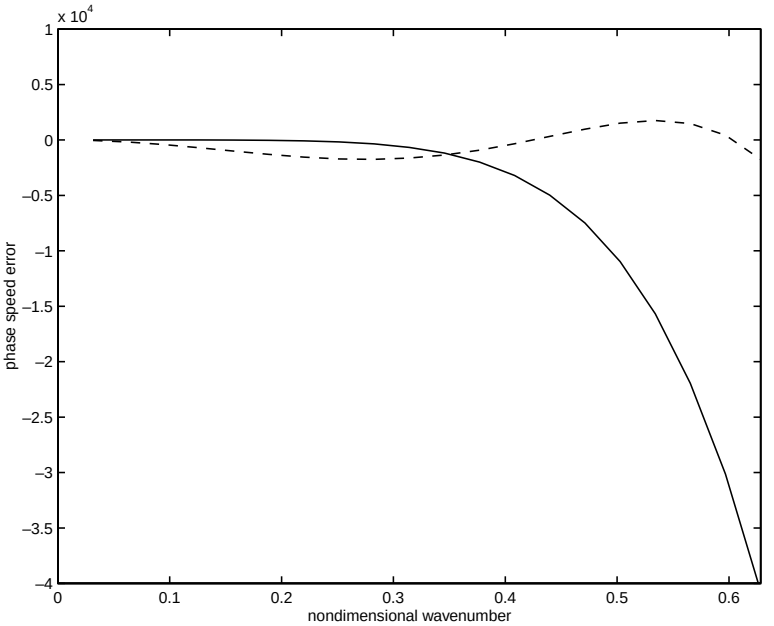

FIG. 1. *Phase speed error for the maximum-order (—) and optimized (- - -) schemes of Zingg, Lomax, and Jurgens* [55].

error from the time-marching method is isotropic. Therefore, if there is no cancellation of spatial and temporal errors, the one-dimensional analysis is conservative. In contrast, if a scheme relies on such cancellation, then the error at arbitrary angles of propagation can be much higher than that in one dimension. For example, a scheme with the perfect shift property at a Courant number of unity in one dimension can produce large errors at the same Courant number in multidimensions and can even be unstable. This occurs because the spatial error is anisotropic while the temporal error is isotropic. Hence they cannot cancel at all angles. Fortunately, this situation can be revealed by a one-dimensional analysis as long as a wide range of Courant numbers is considered. As the Courant number tends to zero, so does the temporal error, and only the spatial error remains. Hence the one-dimensional analysis at a low Courant number can represent the worst case for some schemes, since there is no cancellation of temporal and spatial errors. This is confirmed by the results presented below.

Before proceeding to the results, we briefly discuss the concept of an optimized scheme, using the schemes of Zingg, Lomax, and Jurgens [55] as an example. Figure 1 shows the phase speed error for the maximum-order and optimized spatial discretizations given in [55] for a nondimensional wavenumber z between 0 and $\pi/5$, i.e., for waves resolved with at least 10 PPW. This optimized scheme trades increased errors at low wavenumbers in return for greatly reduced errors for $0.4 \leq z \leq \pi/5$. The idea is to extend the range of wavenumbers for which the scheme is sufficiently accurate. Note that, for the optimized scheme, the error at $z = 0.29$ (22 PPW) is very close to that at $z = \pi/5$ (10 PPW). Consequently, there is no benefit in increasing the grid resolution from 10 PPW to 22 PPW. If a grid resolution of 10 PPW is insufficient for a given propagation distance, then greater than 22 PPW will be required. This explains the sudden jumps in the grid resolution requirements of optimized schemes which will be seen below.

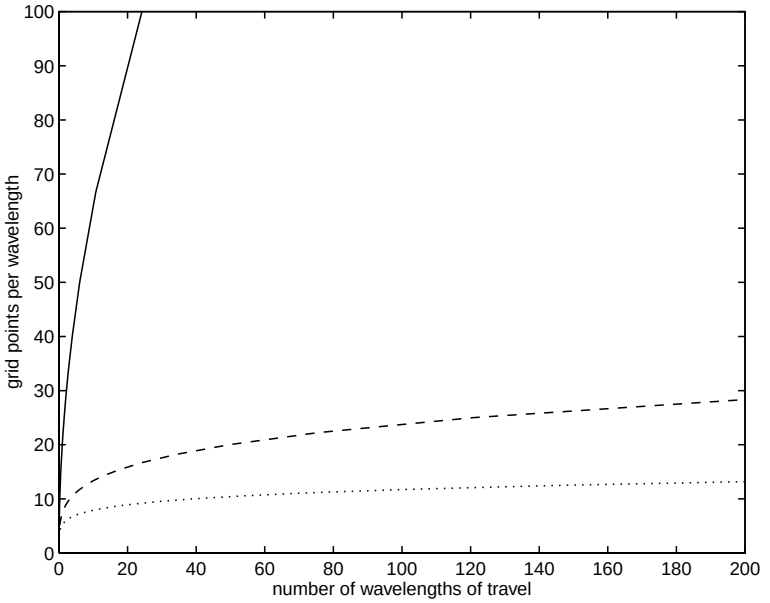

FIG. 2. *Grid resolution requirements for second-order (—), fourth-order (- - -), and sixth-order (· · ·) noncompact centered spatial differences.*

Results.

Spatial difference operators. In this section, we consider the errors produced by the spatial operators alone. The figures show the PPW required to keep both global phase and amplitude errors below 0.1 as a function of the number of wavelengths traveled. Figure 2 shows the grid resolution requirements for second-, fourth-, and sixth-order noncompact centered difference schemes. Since these spatial operators are nondissipative, the grid resolution requirements are determined from the global phase error. The requirements of the second-order scheme are clearly excessive. While more accurate second-order discretizations are available, such as the FDTD scheme or the upwind leapfrog scheme [33], none of these meets our criterion of 30 PPW for 200 wavelengths of travel except under specific conditions.

The PPW requirements for compact centered difference schemes of up to tenth order are shown in Figure 3. The tenth-order scheme requires the solution of a pentadiagonal system of equations. The remaining schemes lead to tridiagonal systems. The compact schemes are considerably more accurate than the noncompact schemes of equivalent order.

We next demonstrate the tradeoffs associated with optimization, using the tridiagonal five-point operators ($\beta = c = 0$) of Haras and Ta'asan as an example. Figure 4 shows the behavior of three different optimized schemes given in [15] as well as the maximum-order scheme which can be obtained using this operator, which is sixth-order. Note the presence of sudden jumps in the grid resolution requirements of the optimized schemes. These are associated with the fact that for an optimized scheme the error does not increase monotonically with increasing wavenumber, as discussed earlier. Their location is dependent on the error threshold used. Reducing the error allowed moves the jumps to the left. With the present error threshold, the scheme denoted "A" is superior up to a distance of travel of about 60 wavelengths. Scheme B

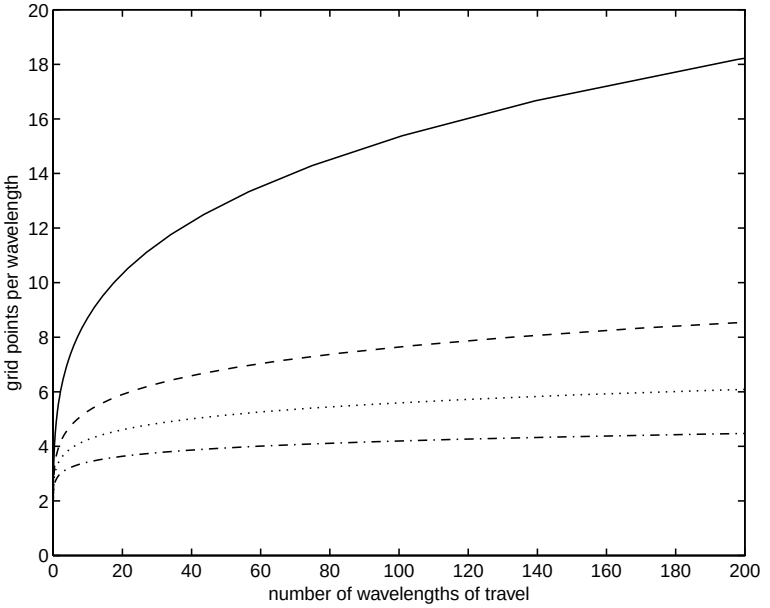

FIG. 3. *Grid resolution requirements for fourth-order (——), sixth-order (- - -), eighth-order (· · ·), and tenth-order (— · —) compact centered spatial differences.*

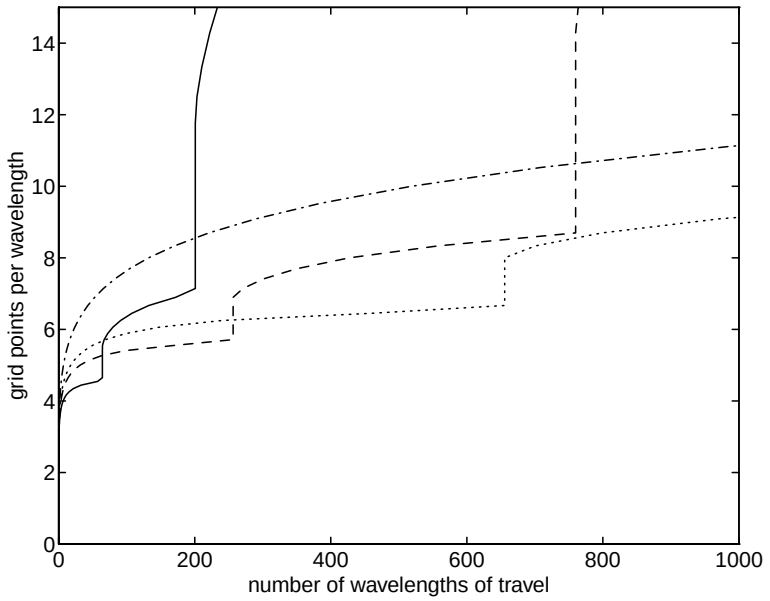

FIG. 4. *Grid resolution requirements for the tridiagonal spatial operators with* 5*-point right-hand stencil of Haras and Ta'asan* [15]: *scheme A (——), scheme B (- - -), scheme C (· · ·), sixth-order scheme (— · —).*

is superior for distances up to 250 wavelengths while scheme C is preferable for even longer distances. Such behavior is typical of optimized schemes. Aggressive optimization (as in the case of scheme A) leads to excellent performance for small distances

of travel but poor performance for longer distances. In this paper we concentrate on distances of travel up to 200 wavelengths. Hence we consider only scheme B further.

Figure 5 shows the PPW required by the optimized schemes of Haras and Ta'asan for distances of travel up to 200 wavelengths. In each case, the best scheme presented by Haras and Ta'asan for this distance of travel is shown, as discussed above. The pentadiagonal scheme requires about 3.7 PPW for 200 wavelengths of travel while the tridiagonal seven-point scheme requires 4.5 and the tridiagonal five-point scheme requires 5.7. The computational effort is roughly proportional to PPW^{d+1}, where d is the number of dimensions, since the number of grid nodes is proportional to PPW^d, and the additional factor of PPW is associated with the decrease in the time step required to maintain a constant Courant number as PPW is increased, i.e., $N = PPWn_w/C$. Therefore the increased cost per grid node of the pentadiagonal scheme is not justified. However, the tridiagonal seven-point scheme is more efficient than the tridiagonal five-point scheme.

The noncompact optimized schemes of Lockard, Brentner, and Atkins [27], Zingg, Lomax, and Jurgens [55], and Tam and Webb [43] are compared with sixth-order centered differences in Figure 6. For the scheme of Lockard, Brentner, and Atkins [27], the PPW requirements are determined by the amplitude error. For the scheme of Zingg, Lomax, and Jurgens [55], the phase and amplitude errors produce roughly equivalent grid resolution requirements over this distance. Since Tam and Webb's scheme [43] is nondissipative, its PPW requirements are determined by the phase error. The figure shows that Tam and Webb's scheme [43] has been optimized for fairly small distances of travel, leading to excellent performance for less than roughly 14 wavelengths of travel. The scheme of Lockard, Brentner, and Atkins [27] requires roughly 8 PPW for 200 wavelengths of travel while that of Zingg, Lomax, and Jurgens [55] requires over 9 PPW.

Figure 7 shows the PPW requirements of the staggered spatial operators. In each case, the staggered schemes are much more accurate than their nonstaggered counterparts of equivalent order. The grid requirements of the second-order scheme are again excessive. However, when used with staggered leapfrog time marching (the FDTD scheme), better results can be obtained. Also shown in Figure 7 is an optimized scheme with $b_3 = 103/19200$, $b_2 = -1315/19200$, and $b_1 = 22630/19200$, which produces excellent performance for up to 200 wavelengths of travel.

Time-marching methods. Figures 8 and 9 show the amplitude and phase errors produced by the four time-marching methods under consideration. The five- and six-stage methods shown are the maximum-order versions rather than the optimized methods, which are discussed in the next subsection. In order to account for the number of stages in the Runge–Kutta methods, the errors are plotted versus $\omega h/p$, where p is the number of stages. Hence the errors shown are for approximately equal computational effort. Since the time step of a p-stage scheme is thus p times larger than that of a single-stage scheme, the amplitude error shown is $|\sigma|^{1/p} - 1$.

The figures show that the phase errors produced by these methods are larger than the amplitude errors. Each increase in the order of the Runge–Kutta method produces an increase in accuracy even though the extra work has been accounted for. The fourth-order Adams–Bashforth method is much more accurate than the fourth-order Runge–Kutta method per unit cost. It produces the lowest amplitude error of the methods considered and phase error comparable to the five-stage Runge–Kutta method.

In order to compare time-marching methods properly, one must consider the

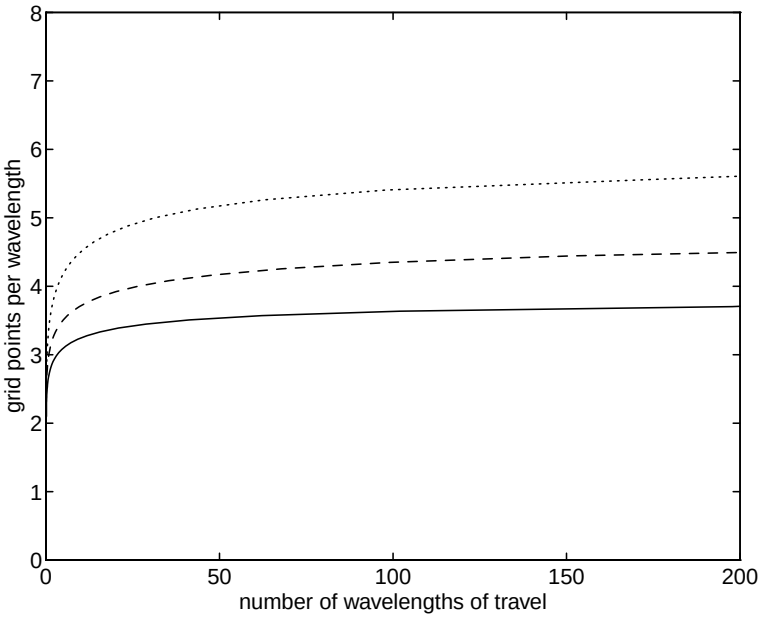

FIG. 5. *Grid resolution requirements for the spatial operators of Haras and Ta'asan* [15]: *pentadiagonal operator with seven-point right-hand stencil (——), tridiagonal operator with seven-point right-hand stencil (- - -), tridiagonal operator with five-point right-hand stencil (· · ·).*

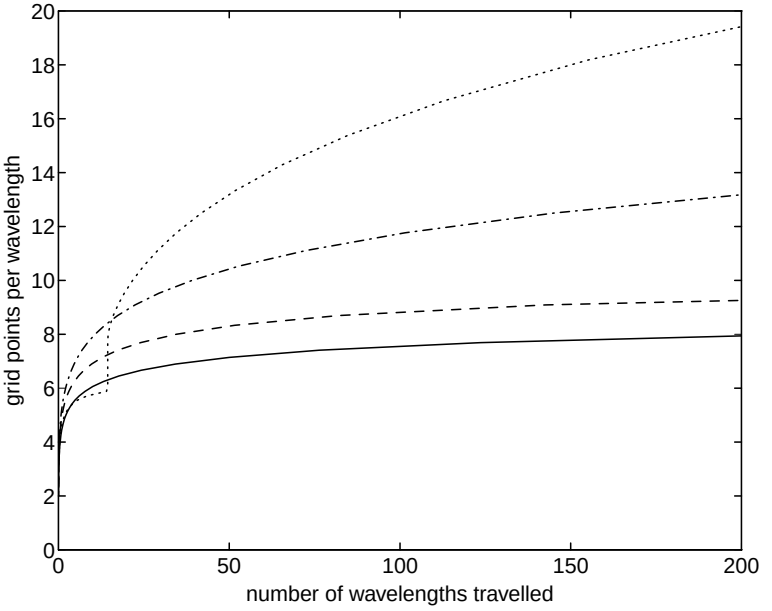

FIG. 6. *Grid resolution requirements for the spatial operators of Lockard, Brentner, and Atkins* [27] *(——), Zingg, Lomax, and Jurgens* [55] *(- - -), Tam and Webb* [43] *(· · ·), and sixth-order centered differences (— · —).*

spatial discretization to be used. For each combination of a spatial discretization and a time-marching method, there is a Courant number which minimizes the computational

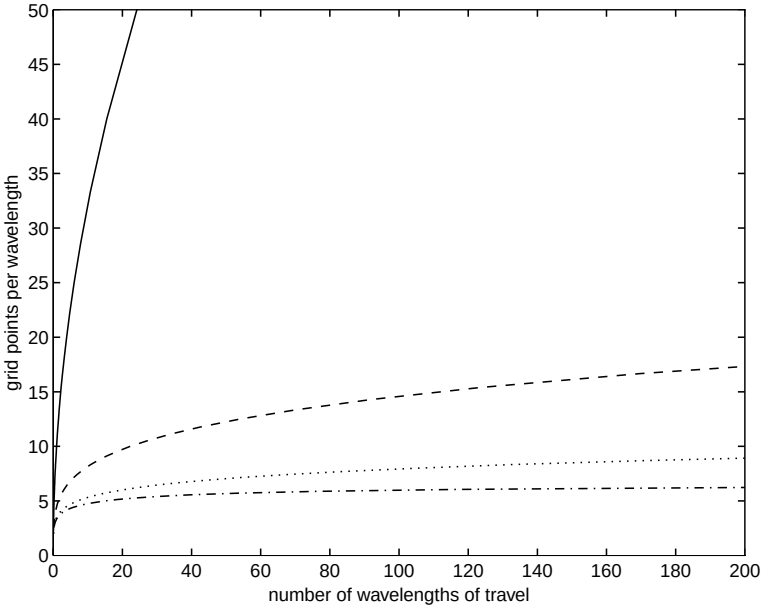

FIG. 7. *Grid resolution requirements for second-order (——), fourth-order (- - -), sixth-order (· · ·), and optimized (— · —) centered spatial differences on a staggered grid.*

work to achieve a given standard of accuracy for a specified distance of travel. The computational work is proportional to the product of the number of derivative function evaluations and the work per function evaluation. The former is given by $pN = pPPWn_w/C$, while the latter is proportional to the number of grid nodes, PPW^d, where p is again the number of stages (which gives the number of function evaluations per time step for the schemes under consideration) and d the number of dimensions. Hence the computational work for a given distance of travel, n_w, is proportional to

$$F = \frac{p}{C} PPW^{d+1}. \tag{27}$$

For example, with fourth-order centered differences in space the optimum Courant number for the fourth-order Runge–Kutta method in two dimensions (determined by trial and error) is about 1.25 for 200 wavelengths of travel and global errors less than 0.1. With this spatial operator, the optimum Courant number for the Adams–Bashforth method is determined by its stability bound, which for pure imaginary λ is roughly 0.43. With fourth-order centered differences in two dimensions, the resulting Courant number is about 0.21. The value of F produced at this Courant number is slightly higher than that produced using the fourth-order Runge–Kutta method at its optimum Courant number. Since the fourth-order Runge–Kutta method also requires less memory than the fourth-order Adams–Bashforth method, it is clearly the preferred method for use with fourth-order centered differences in space.

With sixth-order centered differences in space, the comparison changes. The optimum Courant number for the fourth-order Runge–Kutta method is reduced to roughly 2/3 while that for the fourth-order Adams–Bashforth method remains stability limited, leading to a Courant number of roughly 0.19. In this case, the value of F produced by the Adams–Bashforth method is less than 80% of that for the Runge–Kutta method. Thus the comparison is more complicated, as one must weigh

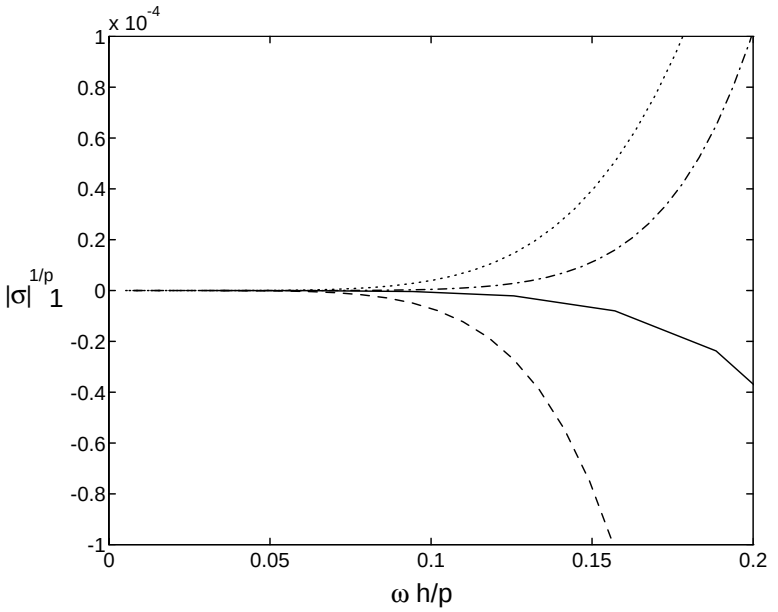

FIG. 8. *Amplitude error produced by the fourth-order Adams–Bashforth method (——), the fourth-order Runge–Kutta method (- - -), the five-stage Runge–Kutta method (· · ·), and the six-stage Runge–Kutta method (— · —).*

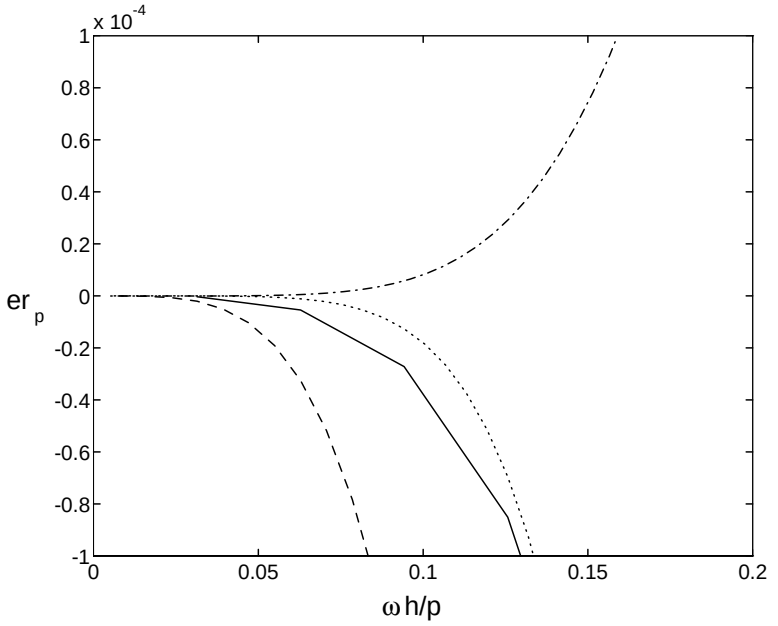

FIG. 9. *Phase error produced by the fourth-order Adams–Bashforth method (——), the fourth-order Runge–Kutta method (- - -), the five-stage Runge–Kutta method (· · ·), and the six-stage Runge–Kutta method (— · —).*

the increased efficiency of the Adams–Bashforth method against the reduced memory requirements of the Runge–Kutta method.

The difficulty with the maximum-order five- and six-stage Runge–Kutta methods

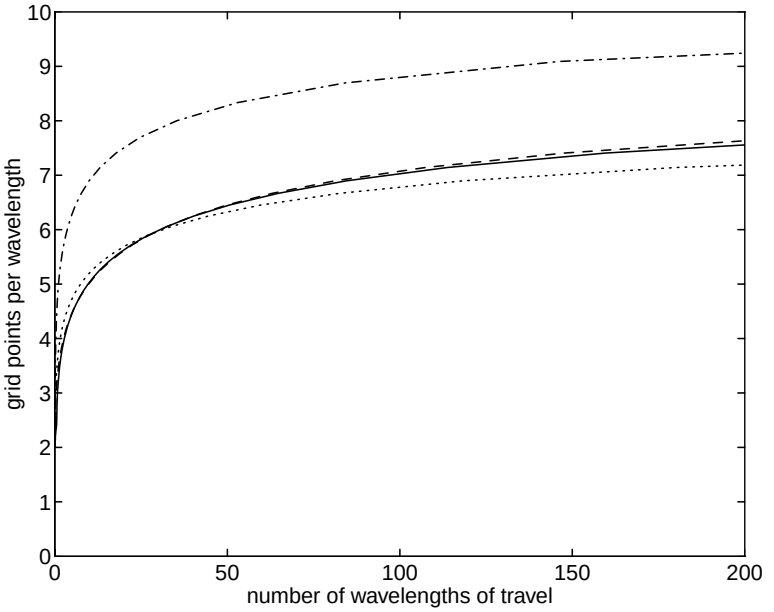

FIG. 10. *Grid resolution requirements for the spatial and temporal operators of Haras and Ta'asan* [15] *at a Courant number of* 0.9: *pentadiagonal operator with seven-point right-hand stencil (——), tridiagonal operator with seven-point right-hand stencil (- - -), tridiagonal operator with five-point right-hand stencil (· · ·); spatial and temporal operators of Zingg, Lomax, and Jurgens* [55] *at a Courant number of* 1 *(— · —).*

is that they are unstable for pure imaginary λ, as shown in Figure 8. We consider these schemes further below.

Combined space-time discretizations. Haras and Ta'asan modified the coefficients of the five-stage Runge–Kutta method to produce stability for pure imaginary λ while maintaining second-order accuracy and optimized error behavior. The methods are designed for $C = 0.9$. Figure 10 shows the grid resolution requirements of the three spatial operators of Haras and Ta'asan compared in Figure 5 in combination with their five-stage time-marching method at a Courant number of 0.9. All three schemes require between 7 and 8 PPW for 200 wavelengths of travel. The advantage of the more accurate spatial operators has been lost. Either a lower Courant number or a more accurate time-marching method should be used.

As a result of the dissipation in the spatial operator, the six-stage time-marching method of Zingg, Lomax, and Jurgens [55] is stable up to a Courant number a little greater than unity in two dimensions. The grid requirements for the combined space-time discretization at a Courant number of unity are shown in Figure 10. Comparison with Figure 6 shows that the time-marching method introduces very little error compared to the spatial differencing. Tam and Webb [43] use an optimized four-step Adams–Bashforth method in conjunction with their spatial operator. It produces little error for Courant numbers less than about 0.3. In both cases, optimization of the time-marching method has a much smaller impact than optimization of the spatial operator.

Figure 11 shows the PPW requirements of the fourth-order staggered spatial difference operator combined with staggered leapfrog time marching. As the Courant number is increased from 0.001 to 0.1, the PPW requirements decrease, since the

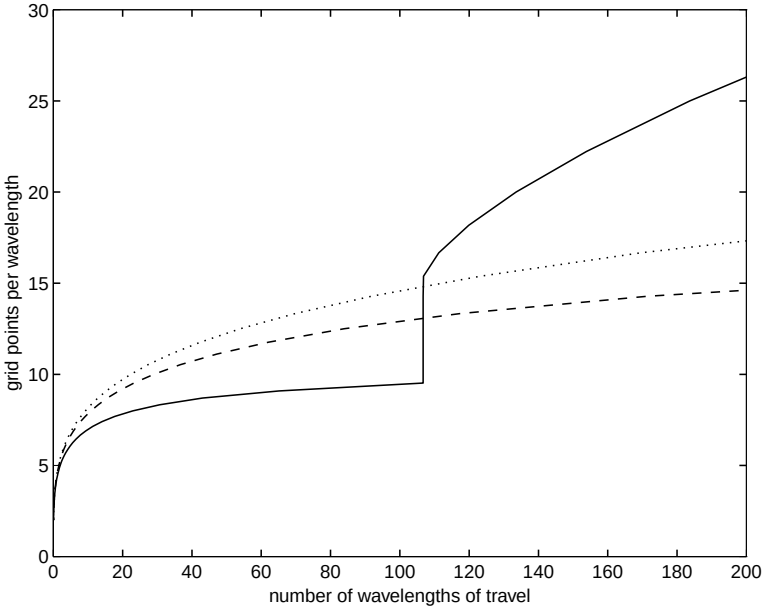

FIG. 11. *Grid resolution requirements for fourth-order centered differences on a staggered grid coupled with staggered leapfrog time marching at Courant numbers of* 0.2 *(——),* 0.1 *(- - -), and* 0.001 *(· · ·).*

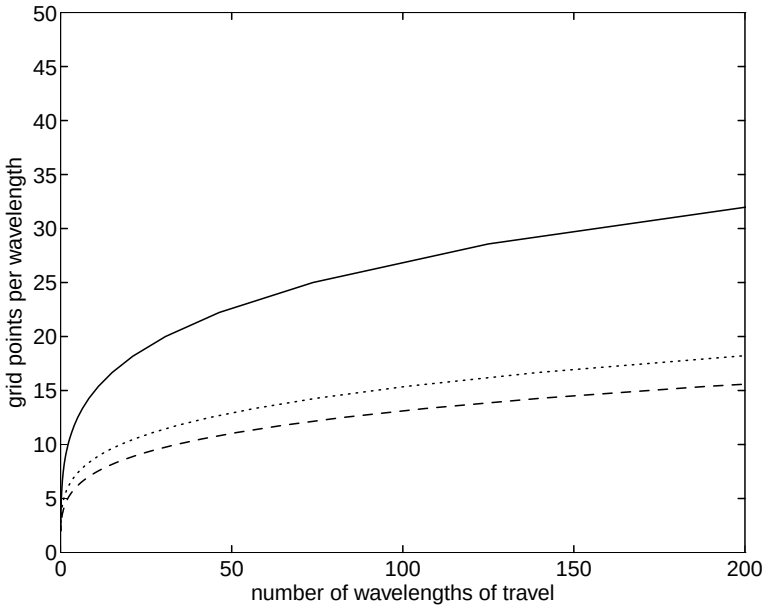

FIG. 12. *Grid resolution requirements for the scheme of Davis* [10] *at Courant numbers of* 3 *(——),* 1.5 *(- - -), and* 0.01 *(· · ·).*

error from the time-marching method is of opposite sign to that of the spatial operator. However, as the Courant number is further increased, the error from the second-order time-marching method begins to dominate. Excellent performance for

200 wavelengths of travel is obtained for Courant numbers up to 0.1.

Results for the method of Davis [10] are shown in Figure 12. Since the method is nondissipative, the PPW requirements are determined from the phase error. This scheme is unconditionally stable. For Courant numbers under 1.5, less than 19 PPW are required for 200 wavelengths of travel. While this is quite good, much better than many schemes, it is not sufficient to justify the additional computational effort associated with an implicit scheme.

Figure 13 shows the grid resolution requirements for the Gottlieb–Turkel scheme, which is stable up to a Courant number of 2/3 in one dimension. This scheme is very robust and has received extensive use in nonlinear applications. Since the method is only second-order in time, high accuracy is obtained only for Courant numbers less than about 0.13. Less than 29 PPW are required to propagate a wave 200 wavelengths with Courant numbers below this value. Although the cost per grid node is reasonably low, these PPW requirements are too high for efficient simulation over such distances.

Finally, the grid requirements of the nondissipative two-step explicit scheme, (14), are shown in Figure 14. This scheme is stable up to a Courant number of unity in one dimension. It has the perfect shift property at this Courant number. The phase error increases as the Courant number is reduced. Less than 29 PPW are required for all stable Courant numbers. Since it provides reasonably low error at Courant numbers up to unity, this scheme has a very low cost per grid node, substantially lower than the Gottlieb–Turkel scheme. However, the PPW requirements are again much higher than some of the other schemes considered.

A numerical example. In this section, we present a numerical simulation of the propagation and reflection of an electromagnetic wave which demonstrates the applicability of the previous analysis in multidimensional cases using nonuniform curvilinear grids. Further details, including the treatment of the boundary conditions, are available in [19]. The governing equations are the transverse magnetic set of the two-dimensional time-domain Maxwell equations. The simulation consists of a pulsed plane wave incident on a perfectly-conducting cylinder. A grid containing 5,400 nodes is shown in Figure 15. Figure 16 shows a snapshot of the electric field intensity computed on a grid with 21,600 nodes using the maximum-order version of the method of Zingg, Lomax, and Jurgens [52, 55]. The dashed contours indicate negative values of the electric field intensity. This solution is visually indistinguishable from that computed using the same method on a grid with 16 times as many nodes, which is used as a baseline to estimate numerical errors. The reflected wave has not yet reached the outer boundary, so spurious reflections are not an issue.

Figures 17 and 18 show the L_2 norm of the numerical error versus the number of grid nodes and the CPU effort, respectively. Four methods are included, the maximum-order (MO) and optimized (O10) schemes of Zingg, Lomax, and Jurgens [52, 55], as well as second- (C2) and fourth-order (C4) centered differences. The second- and fourth-order difference schemes are combined with fourth-order Runge–Kutta time marching and include a very small amount of artificial dissipation for stability. These figures show that the higher-order and optimized methods lead to substantial reductions in both memory and CPU time. The relative grid resolution requirements of the methods are consistent with the predictions obtained from Fourier analysis. Furthermore, the results show that the increased cost per grid node of the higher-order methods is insignificant compared to the reduction in grid resolution required. The benefits of the optimized scheme over the maximum-order scheme are fairly modest due to the nature of the waveform, which is a Gaussian and thus has

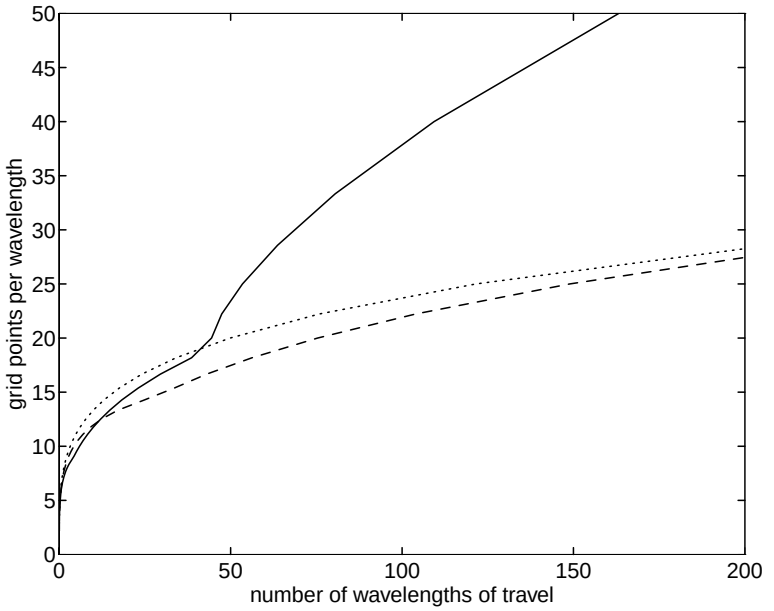

FIG. 13. *Grid resolution requirements for the scheme of Gottlieb and Turkel* [13] *at Courant numbers of* 0.2 *(——),* 0.13 *(- - -), and* 0.01 *(· · ·).*

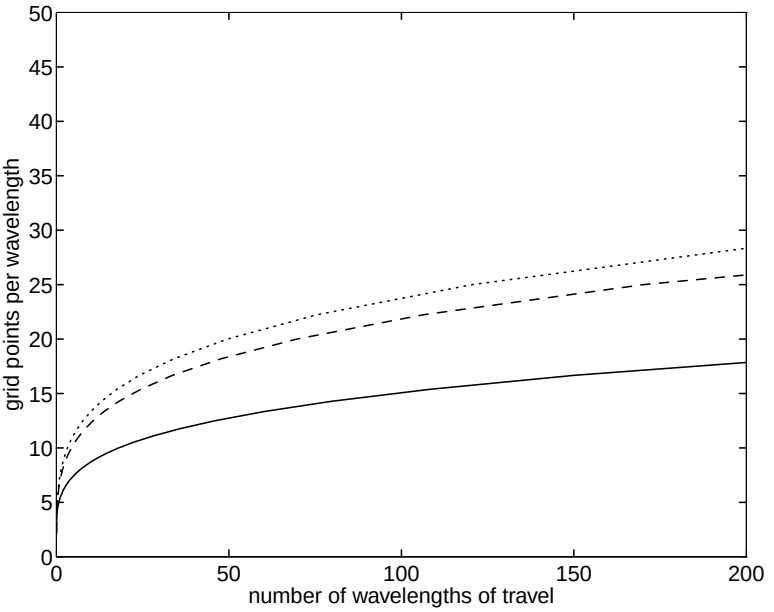

FIG. 14. *Grid resolution requirements for the two-step explicit scheme* (10) *at Courant numbers of* 0.9 *(——),* 0.5 *(- - -), and* 0.01 *(· · ·).*

considerable low-wavenumber content.

Discussion and conclusions. Fourier analysis shows that optimized schemes can provide a significant advantage over their maximum-order counterparts. How-

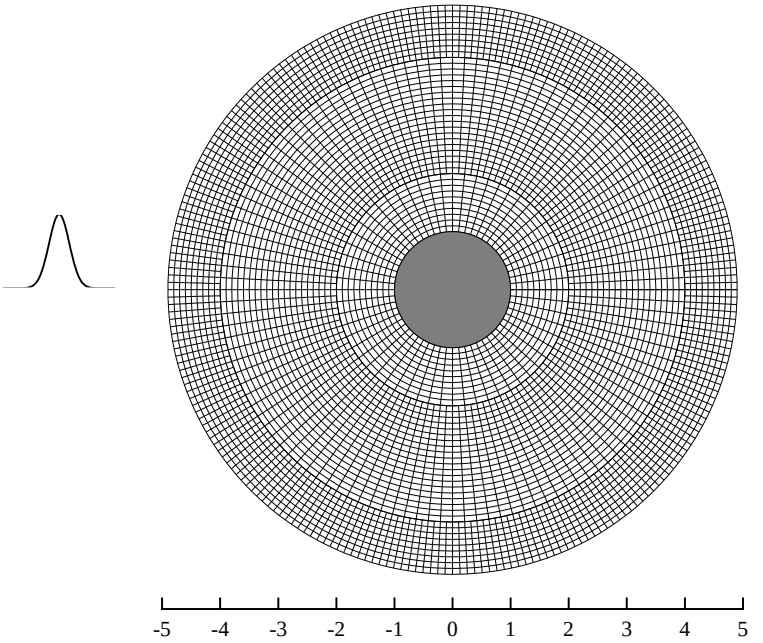

FIG. 15. *Grid for the perfectly-conducting cylinder.*

ever, if optimized too aggressively, they perform poorly for longer distances of travel. Furthermore, if a waveform has significant low wavenumber content, as in the case of a Gaussian pulse, the benefits of an optimized scheme can be minimal, and maximum-order schemes can even be superior. The spatial operators of Haras and Ta'asan [15], Lockard, Brentner, and Atkins [27], and Zingg, Lomax, and Jurgens [52, 55] all provide adequate accuracy for 200 wavelengths of travel. The selection of a time-marching method is not quite as critical, since the computational work varies linearly with the time-step size. Consequently, the cost of reducing the time step is much less than the

cost of reducing the PPW, and, furthermore, has no memory implications. Adams–Bashforth and low-storage Runge–Kutta methods can be used, with the latter often preferable because of their reduced memory requirements.

For appropriate problems, such as those involving electromagnetic waves or acoustic waves in a quiescent medium, staggered spatial schemes perform very well. These can be combined with either a high-order time-marching method or the staggered leapfrog method. In the latter case, a low Courant number should be used. For large propagation distances, higher-order time-marching methods are more efficient.

The grid requirements of the explicit fourth-order methods involving simultaneous space-time discretization are reasonably low considering the low cost of these schemes, especially the two-step explicit scheme. This suggests that sixth-order and optimized extensions of these schemes are worthy of investigation.

Based on the results presented, it is clear that high-order and optimized finite-difference methods will play an important role in the simulation of high-frequency linear wave phenomena. Several of the methods studied have the potential to substantially reduce the computational requirements for accurate simulations, including both CPU time and memory. The choice of an optimization strategy can be correlated with a specific distance of propagation. Among the various optimized schemes of Haras and Ta'asan, for example, specific choices can be made if the propagation distance can be estimated. This suggests the use of optimized schemes which are specifically tailored to the spectral content and distance of propagation of a given simulation. In addition to providing a useful reference for scheme evaluation and comparison, our results can be used as a basis for selecting an appropriate grid resolution when applying these schemes.

Appendix. The following are the coefficients of the finite-difference schemes studied. The number of significant figures given is based on the number given in the cited references.

The spatial operator of Haras and Ta'asan is given in (3). The schemes shown in Figure 4 have $\beta = c = 0$. The remaining coefficients are

Scheme A:

$$\begin{aligned} \alpha &= 0.3534620453, \\ a &= 1.566965775, \\ b &= 0.1399583152; \end{aligned}$$

Scheme B:

$$\begin{aligned} \alpha &= 0.3461890571, \\ a &= 1.5633098070, \\ b &= 0.1290683071; \end{aligned}$$

Scheme C:

$$\begin{aligned} \alpha &= 0.3427812069, \\ a &= 1.5614141543, \\ b &= 0.124148259. \end{aligned}$$

In Figure 5, the pentadiagonal seven-point scheme has

$$\alpha = 0.5801818925,$$

$$\begin{aligned}\beta &= 0.0877284887,\\ a &= 1.3058941939,\\ b &= 0.9975884963,\\ c &= 0.0323380724.\end{aligned}$$

The tridiagonal seven-point scheme has

$$\begin{aligned}\alpha &= 0.3904091387,\\ \beta &= 0,\\ a &= 1.5638887738,\\ b &= 0.2348222711,\\ c &= -0.0178927675.\end{aligned}$$

The tridiagonal five-point operator is scheme B above.

In Figure 6, the scheme of Lockard, Brentner, and Atkins is the average of two schemes with the following coefficients, as defined in (6):

$$\begin{aligned}a_{-4} &= 0.0207860419,\\ a_{-3} &= -0.1500704734,\\ a_{-2} &= 0.5234309723,\\ a_{-1} &= -1.34207332539,\\ a_0 &= 0.574548248808,\\ a_1 &= 0.4090357053658,\\ a_2 &= -0.035657169508\end{aligned}$$

and

$$\begin{aligned}a_0 &= 0,\\ a_1 &= -a_{-1} = 0.763289242273,\\ a_2 &= -a_{-2} = -0.160631393818,\\ a_3 &= -a_{-3} = 0.019324515121.\end{aligned}$$

The optimized scheme of Zingg, Lomax, and Jurgens [52, 55] is given by (4) and (5) with the following coefficients:

$$\begin{aligned}a_1 &= 0.75996126,\\ a_2 &= -0.15812197,\\ a_3 &= 0.018760895,\\ d_0 &= 0.1,\\ d_1 &= -0.076384622,\\ d_2 &= 0.032289620,\\ d_3 &= -0.0059049989.\end{aligned}$$

Tam and Webb's scheme is obtained from (4) with (coefficients are from [42])

$$\begin{aligned}a_1 &= 0.770882380518,\\ a_2 &= -0.166705904415,\\ a_3 &= 0.0208431427703.\end{aligned}$$

The five-stage Runge–Kutta method shown in Figures 8 and 9 has the following characteristic polynomial:

$$\sigma(\lambda h) = 1 + \lambda h + \frac{(\lambda h)^2}{2} + \frac{(\lambda h)^3}{6} + \frac{(\lambda h)^4}{24} + \frac{(\lambda h)^5}{120}.$$

The six-stage method is obtained from (8) with $\alpha_5 = 1/2$, $\alpha_4 = 1/3$, $\alpha_3 = 1/4$, $\alpha_2 = 1/5$, $\alpha_1 = 1/6$, leading to the following characteristic polynomial:

$$\sigma(\lambda h) = 1 + \lambda h + \frac{(\lambda h)^2}{2} + \frac{(\lambda h)^3}{6} + \frac{(\lambda h)^4}{24} + \frac{(\lambda h)^5}{120} + \frac{(\lambda h)^6}{720}.$$

The characteristic polynomial of the optimized five-stage Runge–Kutta method of Haras and Ta'asan used in Figure 10 is

$$\sigma(\lambda h) = 1 + \lambda h + \frac{(\lambda h)^2}{2} + 0.166407(\lambda h)^3 + 0.0409525(\lambda h)^4 + 0.0074510(\lambda h)^5.$$

The optimized temporal operator of Zingg, Lomax, and Jurgens [52, 55] is obtained from (8) with the following coefficients:

$$\begin{aligned} \alpha_1 &= 0.168850, \\ \alpha_2 &= 0.197348, \\ \alpha_3 &= 0.250038, \\ \alpha_4 &= 0.333306, \\ \alpha_5 &= 0.5. \end{aligned}$$

The resulting characteristic polynomial is

$$\begin{aligned} \sigma(\lambda h) = 1 + \lambda h + \frac{(\lambda h)^2}{2} + 0.16665295(\lambda h)^3 + 0.041669557(\lambda h)^4 \\ + 0.0082233848(\lambda h)^5 + 0.0013885169(\lambda h)^6. \end{aligned}$$

The scheme of Davis is obtained from (10) with

$$\begin{aligned} a_0 &= b_0 = -2(C-2)(C+2), \\ a_1 &= b_2 = (C-1)(C-2), \\ a_2 &= b_1 = (C+1)(C+2), \end{aligned}$$

where $C = ah/\Delta x$ is the Courant number.

HIGH-ORDER TOTAL VARIATION-BASED IMAGE RESTORATION*

TONY CHAN†, ANTONIO MARQUINA‡, AND PEP MULET‡

Abstract. The total variation (TV) denoising method is a PDE-based technique that preserves edges well but has the sometimes undesirable *staircase effect*, namely, the transformation of smooth regions (*ramps*) into piecewise constant regions (*stairs*). In this paper we present an improved model, constructed by adding a nonlinear fourth order diffusive term to the Euler–Lagrange equations of the variational TV model. Our technique substantially reduces the staircase effect, while preserving sharp jump discontinuities (edges). We show numerical evidence of the power of resolution of this novel model with respect to the TV model in some 1D and 2D numerical examples.

Key words. image denoising, total variation, fourth order PDE

1. Introduction.

The degradation of an image is usually unavoidable during its acquisition and at the early stages of its processing, and it renders the later phases difficult and inaccurate. The classical algorithms for image denoising have been mainly based on least squares, and, consequently, their outputs may be contaminated by Gibbs phenomena and do not approximate images containing edges well. To overcome this difficulty a technique based on the minimization of the total variation (TV) norm is proposed in [12]. This technique preserves edges well, but the images resulting from the application of this technique in the presence of noise are often piecewise constant; thus the finer details in the original image may not be recovered satisfactorily, and *ramps* (affine regions) will give *stairs* (piecewise constant regions); see Figure 8.2. In this paper we present an improved model, constructed by adding a nonlinear fourth order diffusive term to the Euler–Lagrange equations of the variational TV model. This technique substantially reduces the staircase effect, while preserving sharp jump discontinuities (edges).

The paper is organized as follows. In section 2, we describe the original TV model and the nonlinear equations associated with it. In section 3, we describe the staircase effect caused by the TV model and briefly review several techniques proposed in the literature to deal with it. In section 4 we aim to reduce the staircase effect by using a variational formulation for the denoising problem with a functional obtained by adding a nonlinear second order term to the TV functional. In the next section we analyze the fourth order nonlinear Euler–Lagrange equation associated with the latter variational problem in the 1D case and notice that their discretizations can be ill-posed. We then propose to drop the term that might cause the ill-posedness, thus deviating from the variational formulation to obtain the nonlinear fourth order diffusion equation that we propose in this paper. We next present a fixed point scheme for the solution of

this nonlinear equation. In section 6, a straightforward 2D extension of the 1D PDE is explored and more sophisticated possibilities are hinted at. We comment on the choice of parameters in section 7. Finally, in section 8, we discuss some numerical techniques to solve the problem and present numerical experiments comparing the results of the TV denoising technique and the new model.

2. TV denoising. An image can be interpreted as either a real function defined on Ω, a bounded and open domain of $\mathbb{R}^2$ (for simplicity we will assume Ω to be the unit square henceforth), or as a suitable discretization of this continuous image.

Our interest is to restore an image which is contaminated with noise in such a way that the process should recover the edges of the image. Let us denote by z the observed image and by u the real image. The model of degradation we assume is $u + n = z$, where n is a Gaussian white noise; i.e., the values n_i of n at the pixels i are independent random variables, each with a Gaussian distribution of zero mean and variance σ^2.

Our objective is to estimate u from statistics of the noise and some a priori knowledge of the image (smoothness, existence of edges). This knowledge is incorporated into the formulation by using a functional R that measures the quality of the image u in the sense that smaller values of $R(u)$ correspond to better images. The process, in other words, consists in the choice of the best quality image among those matching the constraints imposed by the statistics of the noise.

The usual approach consists in solving the following constrained optimization problem:

$$\begin{aligned} &\min_u R(u) \\ &\text{subject to } ||u - z||^2_{\mathcal{L}^2} = |\Omega|\sigma^2, \end{aligned} \tag{2.1}$$

since $n = z - u$ and $E(\int_\Omega n^2) = |\Omega|\sigma^2$ ($E(X)$ denotes the expectation of the random variable X) give that $||u - z||^2_{\mathcal{L}^2} = \int_\Omega (u - z)^2 \approx |\Omega|\sigma^2$. There are known techniques (see [3]) for solving the constrained optimization problem (2.1) by exploiting solvers for the corresponding unconstrained problem. Therefore, for the sake of clarity, we will assume the Lagrange multiplier λ associated with (2.1) to be known throughout the exposition. For $\alpha = \frac{1}{\lambda}$, we can then write the equivalent unconstrained problem for image denoising

$$\min_u \alpha R(u) + \frac{1}{2}\|u - z\|^2_{\mathcal{L}^2}. \tag{2.2}$$

Here α represents the trade-off between smoothness and fidelity to the original data.

Examples of regularization functionals that can be found in the literature are $R(u) = \|u\|_{\mathcal{L}^2}, \|\Delta u\|_{\mathcal{L}^2}, \|\nabla u\|_{\mathcal{L}^2} = \left(\int_\Omega |\nabla u|^2\right)^{\frac{1}{2}}$, where ∇ is the gradient, $|\nabla u| = \sqrt{u_x^2 + u_y^2}$, and Δ is the Laplacian; see [13, 10]. The main disadvantage of using these functionals is that they do not allow discontinuities in the solution; therefore the edges cannot be satisfactorily recovered.

In [12], the TV is proposed as the regularization functional for the image restoration problem:

$$TV(u) = \int_\Omega |\nabla u|.$$

The TV functional does not penalize discontinuities in u and thus allows us to recover the edges of the original image. The restoration problem can be thus written as

$$\min_u \int_\Omega \left(\alpha |\nabla u| + \frac{1}{2}(u-z)^2 \right). \tag{2.3}$$

The functional of problem (2.3) is strictly convex, coercive, and lower semicontinuous, but it is not differentiable. Therefore the optimality conditions cannot be stated with the usual gradient but with a subgradient. Nevertheless, to overcome this technical difficulty it is common to slightly perturb the TV functional to become

$$\int_\Omega \sqrt{|\nabla u|^2 + \beta},$$

where β is a small positive parameter, or

$$\int_\Omega |\nabla u|_\beta,$$

with the notation ($x \in \mathbb{R}$, $v \in \mathbb{R}^2$)

$$|x|_\beta = \sqrt{x^2 + \beta}, \quad |v|_\beta = \sqrt{|v|^2 + \beta}. \tag{2.4}$$

In [1] it is shown that the solutions of the perturbed problems

$$\min_u \int_\Omega \left(\alpha |\nabla u|_\beta + \frac{1}{2}(u-z)^2 \right) \tag{2.5}$$

converge to the solution of (2.3) when $\beta \to 0$. The Euler–Lagrange equation of (2.5) is

$$0 = -\alpha \nabla \cdot \left(\frac{\nabla u}{|\nabla u|_\beta} \right) + u - z, \tag{2.6}$$

with homogeneous Neumann boundary conditions.

3. The staircase effect. The image restoration model based on the TV tends to yield piecewise constant images, i.e., "blocky" images. Whereas this is certainly useful for many applications, it can be a serious drawback for many others. In particular, when applying this denoising technique to an affine image degraded with noise, the result will invariably be a "staircase," thus creating oversharpening at smooth transitions; see Figure 8.2a.

To prevent the TV oversharpening, one could penalize jumps more. This can be achieved by taking second derivatives into account: intuitively, in discrete form, the first derivative at a height 1 jump of a step function is $\frac{1}{h}$, whereas the second derivative is $\frac{1}{h^2} \gg \frac{1}{h}$ when $h \approx 0$. Somehow, the TV functional does not distinguish between jumps and smooth transitions; therefore we want to analyze functionals that take into account second order derivatives. Successful application of functionals with second (or higher) order derivatives can be found in the works by Geman and Reynolds [9] and Chambolle and Lions [6]. In [4], Blomgren, Chan, and Mulet propose a "TV-H^1 interpolation" approach that avoids the use of second order derivatives to address the staircase problem of the TV technique.

We briefly review the inf-convolution technique of Chambolle and Lions and refer the reader to [6] for further information. Chambolle and Lions propose to use as a

regularizing functional the inf-convolution of the TV functional F_1, and a functional based on second order derivatives

$$F_2 = \alpha \int_\Omega |d^2 u|,$$

where d^2u is the second differential of u and α is a parameter that balances F_1 and F_2. The problem can then be written as finding $u = u_1 + u_2$ such that

$$(u_1, u_2) = \operatorname*{argmin}_{u_1, u_2} F_1(u_1) + F_2(u_2)$$
$$\text{subject to } \frac{1}{2}(\|u_1 + u_2 - z\|_{\mathcal{L}^2} - \sigma^2) = 0.$$

In other words, this method decomposes u into a sum of a smooth function u_2 and a function u_1 that contains the jumps, so that the corresponding Euler–Lagrange equations are solved by u_1, u_2.

4. A second order functional for staircase reduction. In this section we perform a qualitative study of image denoising models aiming to reduce the staircase effect and consisting in the solution of variational problems

$$\min_u R(u) + \frac{1}{2}\|u - z\|^2_{\mathcal{L}^2}, \tag{4.1}$$

where

$$R(u) = \int_\Omega f(\nabla u, \mathcal{L}(u)) \tag{4.2}$$

for a real function f and an elliptic operator $\mathcal{L}(u)$. Note that in (4.1) we have included α in the functional $R(u)$. The latter functionals should retain the good properties of the TV functional near the "true" edges and penalize "wrong" edges created in regions which "should" be smooth. The naïve choice of, e.g.,

$$\int_\Omega (\alpha |\nabla u|_\beta + \mu(\mathcal{L}(u))^2) \tag{4.3}$$

results in a high global penalization of jumps that smooths the data excessively. Bearing this in mind, we consider an *adaptive* functional, in which the action of the second order term is lessened where the gradient is large:

$$\int_\Omega (\alpha |\nabla u|_\beta + \mu \Phi(|\nabla u|)(\mathcal{L}(u))^2), \tag{4.4}$$

where Φ is a real function that indicates the presence of edges in the sense that its value approaches 0 when the gradient $|\nabla u|$ is large, i.e., near edges.

The motivation for the choice of this precise form for the additional second order term is that it is quadratic in $\mathcal{L}(u)$; hence, the numerical treatment is easier than merely choosing $|\mathcal{L}(u)|$. The additional complexity caused by the term $\Phi(|\nabla u|)$ in (4.4) does not render it much more complicated than (4.3), for this equation is already nonquadratic.

A family of functions that meet the above requirements is

$$\Phi(x) = 1/(\sqrt{x^2 + \gamma})^p, \quad p > 0, \tag{4.5}$$

which can be written more compactly as $1/|x|^p_\gamma$, using the notation introduced in (2.4). A balance between the two differential terms of (4.4) can be achieved by the choice of exponent $p = 3$, for then both depend on the scale h as $\mathcal{O}(\frac{1}{h})$, thus making the functional $R(u)$ independent of the scale h: intuitively,

$$\alpha|\nabla u|_\beta + \mu\frac{\mathcal{L}(u)^2}{|\nabla u|^p_\gamma} \approx \mathcal{O}(h^{-1}) + \frac{\mathcal{O}((\frac{1}{h^2})^2)}{\mathcal{O}(\frac{1}{h^p})} \approx \mathcal{O}(h^{-1}) + \mathcal{O}(h^{p-4}),$$

which gives $p = 3$, by equating the exponents of both terms. With this choice of exponent, the functional in (4.4) now reads

$$\int_\Omega \left(\alpha|\nabla u|_\beta + \mu\frac{\mathcal{L}(u)^2}{|\nabla u|^3_\gamma}\right), \tag{4.6}$$

and the denoising variational problem is thus

$$\min_u \int_\Omega \left(\alpha|\nabla u|_\beta + \mu\frac{\mathcal{L}(u)^2}{|\nabla u|^3_\gamma} + \frac{1}{2}(u-z)^2\right). \tag{4.7}$$

Furthermore, concerning the energy of monotone 1D signals, let us consider a function u that is monotone on $[x_i, x_{i+1}]$, $0 = x_1 < \cdots < x_{n+1} = 1$; then its TV is $\sum_{i=1}^n |u(x_{i+1}) - u(x_i)|$. Applying this to $u_1 = \chi_{(\frac{1}{2},1)}$ and $u_2 = x$, we get $TV(u_1) = TV(u_2) = 1$. Let us examine the second term of the energy in (4.6) for the natural choice $\mathcal{L}(u) = u''$. Since $u_2' = 1$ and $u_2'' = 0$, the contribution of the second order term is null; therefore the energy of u_2 is α. A suitable discretization of $I_2 = \int_0^1 \frac{(u'')^2}{((u')^2+\gamma)^{\frac{3}{2}}}$ for $u = u_1$ gives $I_2 \approx h\frac{(\frac{1}{h^2})^2}{(\frac{1}{h^2}+\gamma)^{\frac{3}{2}}} = \frac{1}{(1+\gamma h^2)^{\frac{3}{2}}} \to 1$ when $h \to 0$. The energy, computed from (4.7), of u_1 is then $\alpha + \mu \cdot 1 = \alpha + \mu$; therefore, it is bigger than the energy of u_2. Thus, this functional "prefers ramps to stairs."

The functionals in (4.6) are not convex; therefore some good mathematical properties of (strictly) convex functionals, as uniqueness of solutions, are not present. Use of nonconvex functionals in the image processing field can be found in [9, 14, 2].

5. The 1D model. For the reasonable choice of $\mathcal{L}(u) = u''$, the Euler–Lagrange equation for the 1D denoising variational problem (4.7) reads:

$$\begin{aligned} 0 &= (\kappa_2 u'')'' - (\kappa_1^* u')' + u - z, \\ \kappa_1^* &= \frac{\alpha}{|u'|_\beta} - 3\mu\frac{(u'')^2}{|u'|^5_\gamma}, \\ \kappa_2 &= \frac{2\mu}{|u'|^3_\gamma}, \end{aligned} \tag{5.1}$$

where the natural boundary conditions, obtained by integration by parts, are

$$u'(x) = (\kappa_2(u')u'')'(x) = 0, x = 0, 1.$$

In this 1D case the latter boundary conditions can be simplified to

$$u'(x) = u'''(x) = 0, x = 0, 1. \tag{5.2}$$

The coefficient κ_2 is strictly positive, whereas κ_1^* may be negative. This can be problematic when solving discretizations of these equations, for then it may cause

numerical difficulties due to the lack of maximum principles for this fourth order equation. Near the jump discontinuities of u, κ_2 becomes $O(h^3)$ and κ_1^* is about $O(h)$, where h is the spatial step-size of the representation of u. Thus the second order term dominates the equation, and therefore the positivity of the coefficient κ_1^* is an unavoidable requirement to prevent the increasing in the TV of u that would otherwise make the solution of (5.1) ill-conditioned. Therefore, we introduce a regularization, consisting in redefining κ_1^* to be $\kappa_1 = \frac{\alpha}{|u'|_\beta} > 0$, which can be interpreted as adding a *nonlinear viscosity* to the original equation. To recap, the regularized equations that we propose are

$$\begin{aligned} 0 &= (\kappa_2 u'')'' - (\kappa_1 u')' + u - z, \\ \kappa_1 &= \frac{\alpha}{|u'|_\beta}, \\ \kappa_2 &= \frac{2\mu}{|u'|_\gamma^3}, \end{aligned} \tag{5.3}$$

with boundary conditions given by (5.2). Note that if $\alpha = 0$ we still have a fourth order anisotropic diffusion equation with denoising effect.

This regularization makes the equation satisfy a local maximum principle in the sense that suitable discretizations give positive definite frozen Jacobians. Near the jumps the model approaches the TV model, since the coefficient $\kappa_2 = \frac{2\mu}{|u'|_\gamma^3}$ of the additional fourth order term behaves as $\mathcal{O}(h^3)$. Furthermore, (5.3) can be regarded as adding the fourth order nonlinear term $(\kappa_2 u'')''$ to the Euler–Lagrange equations (2.6). It is worthwhile to point out that, due to the lack of symmetry, (5.3) is not the Euler–Lagrange equation of any variational problem.

For the numerical solution of (5.3), we could consider the steady-state solution of the time evolving equation

$$u_t = -(\kappa_2 u_{xx})_{xx} + (\kappa_1 u_x)_x - u + z, \tag{5.4}$$

where u is now a function of t and x. The time evolution equation is parabolic since κ_2 is strictly positive, and we know that the constant coefficient parabolic equation

$$u_t = -a\, u_{xxxx} + b\, u_{xx} - u + z, \tag{5.5}$$

with $a > 0$ and initial data in $\mathcal{L}^2$, is a well-posed problem (see [11, p. 271]). Equation (5.4) is, of course, much more complicated than (5.5), but this can serve as a model to understand the local behavior of the linear equation obtained after freezing the coefficients of (5.4).

In our case, we have nonlinear coefficients that change with u' so that time marching procedures are usually stiff and inefficient, as practice has shown in that kind of problem. The CFL stability restriction for explicit schemes (see [11]) requires the time step to be $\mathcal{O}(h^4)$, which precludes their use in any realistic computation.

The *lagged diffusivity fixed point* iteration has proven lately to be a quite popular linearization method for solving the TV restoration problem; see [15]. In the same fashion, we can consider an iterative procedure that aims to converge to a solution of (5.3), starting from the initial approximation $u_0 = z$ and solving for u^{n+1} the following the linear fourth order elliptic equation at every step:

$$0 = (\kappa_2(u_n) u''_{n+1})'' - (\kappa_1(u_n) u'_{n+1})' + u_n - z, \quad n = 0, 1 \ldots. \tag{5.6}$$

Remark 1. We have observed in our experiments that our model with $\alpha = 0$ and sound choices of μ, i.e.,

$$\begin{aligned} 0 &= (\kappa_2 u'')'' + u - z, \\ \kappa_2 &= \frac{2\mu}{|u'|_\gamma^3}, \end{aligned}$$

can be used for denoising purposes. It recovers sharp edges and does not produce staircasing, but it may create artificial nonnull gradients at flat regions and some overshooting that do not appear for sufficiently big α, since those features then have a TV penalty.

6. The 2D model. In the 2D case there are many possible choices for the elliptic operator $\mathcal{L}(u)$. One could choose the *directional Laplacian*

$$\mathcal{L}(u) = \left(\frac{\nabla u}{|\nabla u|}\right)^T H(u) \left(\frac{\nabla u}{|\nabla u|}\right) = \frac{u_{xx}u_x^2 + 2u_{xy}u_x u_y + u_{yy}u_y^2}{u_x^2 + u_y^2},$$

where $H(u)$ denotes the Hessian matrix of u. However, the Euler–Lagrange equations for the isotropic Laplacian $\mathcal{L}(u) = \Delta u = u_{xx} + u_{yy}$ are easier to tackle numerically; therefore we will restrict ourselves to treat this case in this paper.

With the latter choices of elliptic operator, the Euler–Lagrange equation of (4.7) is the following:

$$\begin{aligned} 0 &= \Delta(\kappa_2 \Delta u) - \nabla \cdot (\kappa_1^* \nabla u) + u - z, \\ \kappa_1^* &= \frac{\alpha}{|\nabla u|_\beta} - 3\mu \frac{(\Delta u)^2}{|\nabla u|_\gamma^5}, \\ \kappa_2 &= \frac{2\mu}{|\nabla u|_\gamma^3}, \\ 0 &= \frac{\partial u}{\partial n}, \\ 0 &= \frac{\partial\big(\kappa_2 \Delta u\big)}{\partial n}, \end{aligned} \tag{6.1}$$

where n is the outward unit normal vector to the boundary.

The same stability issues as in the 1D case apply here. We drop the negative term in κ_1 to add appropriate artificial viscosity to (6.1). Thus, the resulting equations are

$$\begin{aligned} 0 &= \Delta(\kappa_2 \Delta u) - \nabla \cdot (\kappa_1 \nabla u) + u - z, \\ \kappa_1 &= \frac{\alpha}{|\nabla u|_\beta}, \\ \kappa_2 &= \frac{2\mu}{|\nabla u|_\gamma^3}, \end{aligned} \tag{6.2}$$

with the same boundary conditions as in (6.1).

As in the 1D case, we could use the fixed point scheme

$$0 = \Delta(\kappa_2(u_n)\Delta u_{n+1}) - \nabla \cdot (\kappa_1(u_n)\nabla u_{n+1}) + u_{n+1} - z, \tag{6.3}$$

solving at each iteration a linear fourth order elliptic equation. Nevertheless, in our experiments we have found that it does not show a strongly stable convergence behavior in the sense that the norm of the right-hand side of (6.2) does not decrease

monotonically towards 0. However, a suitable modification of it has shown smoother convergence in our experiments. The modified scheme consists in solving equation (6.3) for $\hat{u}_{n+1}$ and then underrelaxing by setting u_{n+1} to be the average $\frac{1}{2}(u_n + \hat{u}_{n+1})$, i.e.,

$$\begin{aligned} &\Delta(\kappa_2(u_n)\Delta\hat{u}_{n+1}) - \nabla\cdot(\kappa_1(u_n)\nabla\hat{u}_{n+1}) + \hat{u}_{n+1} = z, \\ &u_{n+1} = \frac{u_n + \hat{u}_{n+1}}{2}. \end{aligned} \tag{6.4}$$

Underrelaxation is a classical procedure used to avoid weak instability.

The same issues as in the 1D model about using (6.2) with $\kappa_1 = 0$ apply here as well.

7. Choice of parameters. We comment briefly on the choice of the various parameters in the algorithm described above. The easiest parameter to choose is β. If d is the dynamic range of the image (i.e., u takes values from the interval $[0, d]$), then we recommend from our experience using $\beta = 10^{-5}d^2$, so β scales properly with the term $|\nabla u|^2$ that appears in (2.4). For the same scaling reasons and to get a satisfactory removal of staircasing, we strongly recommend $\gamma = d^2$, i.e., $\gamma = 1$ if the picture takes values in $[0, 1]$.

The other two parameters, α, μ, are more complicated to choose. We describe now a heuristic procedure that has proven to be quite successful in our experiments. We make the usual assumption that the noise variance σ^2 is known, as is, e.g., the setting of [12].

We have observed that the fixed point scheme ((5.6) in 1D and (6.4) in 2D) with $\kappa_1 = 0$ converges nicely for μ less than some threshold value μ_0, but it gives oscillations of the norm of the equations and bad conditioning of the frozen Jacobians for μ sufficiently bigger than μ_0 ($\mu > 1.5\mu_0$, say). We recommend selecting $\mu = \mu_0$ and then adjusting α so that u matches the noise variance, i.e., $\|u - z\|^2_{\mathcal{L}^2} = \sigma^2$. This matching can be accomplished by using the techniques of [3] or by taking into account that $\|u_\alpha - z\|_{\mathcal{L}^2}$ typically is an increasing function of α, where u_α is the solution of the problem for that α.

8. Numerical results. In this section, we perform some numerical experiments in 1D and 2D with the new model. Throughout this section, the parameters are chosen as described in section 7 so that a match of the noise level is achieved. The linear PDEs in (5.6) and (6.4) are discretized by standard forward differences, except that a wider stencil is used for the computation of κ_2. This discretization is obtained by applying standard forward differences to the smoothed image $g * u$, where

$$g = G^{(k)} = G *^{(k)} \cdots * G, \quad G = \frac{1}{4}\begin{bmatrix} 1 & 2 & 1 \end{bmatrix},$$

in the 1D case and

$$g = G^{(k)} = G *^{(k)} \cdots * G, \quad G = \frac{1}{8}\begin{bmatrix} 0 & 1 & 0 \\ 1 & 4 & 1 \\ 0 & 1 & 0 \end{bmatrix}, \tag{8.1}$$

in the 2D case. This technique is inspired by [5] and results in the expression

$$\kappa_2 = \frac{2\mu}{|\nabla(g * u)|^3_\gamma} = \frac{2\mu}{|(\nabla g) * u|^3_\gamma}. \tag{8.2}$$

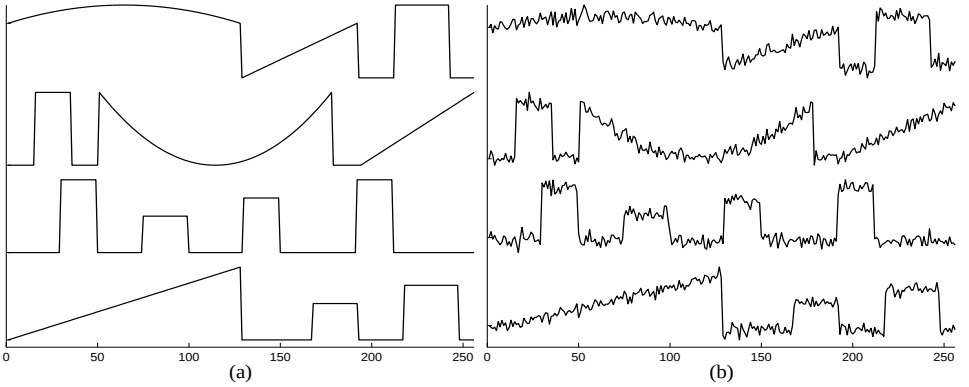

FIG. 8.1. (a) *Original* 1*D images;* (b) *noisy* 1*D images, SNR*≈ 5.

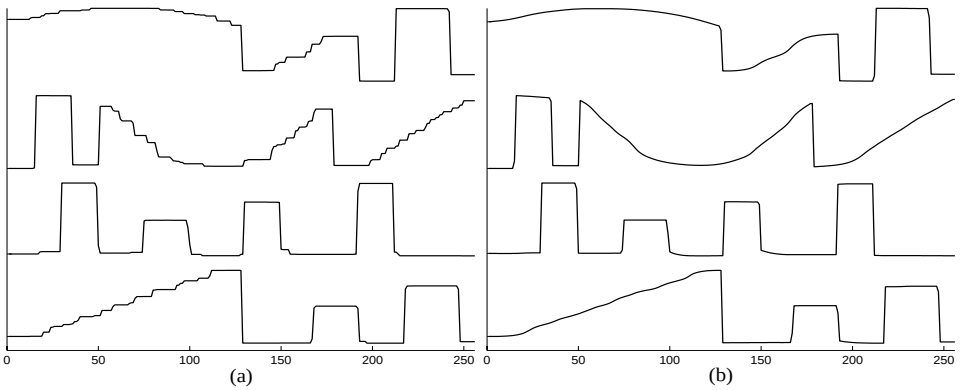

FIG. 8.2. (a) *Results of TV restoration;* (b) *results of our model.*

We have observed that using standard differences for the computation of κ_2, i.e., $k = 0$ in (8.2), does not give convergent schemes.

The resulting systems of linear equations (with symmetric and positive definite matrices) are solved by Gaussian elimination in 1D and the conjugate gradient method preconditioned by SSOR in 2D.

In the first experiment we compare the result of the restoration using the new model with the result of the constrained TV restoration for a number of test 1D images, including piecewise constant, piecewise linear, and piecewise parabolic 1D images. The original 1D images are shown in Figure 8.1a, and the (artificially) degraded 1D images in Figure 8.1b. The results of the TV denoising method are shown in Figure 8.2a. We show in Figure 8.2b, right, the result of our model. We make a final comparison by overlaying the original, TV restoration and the results of our model for some of the test 1D images, and we show it in Figure 8.3. We observe that the results obtained by the new model have sharp gradients at the "true" edges but smooth transitions at ramps, whereas the TV model shows the typical staircase effect.

In the next experiment, we compare the results of our model to Chambolle–Lions's inf-convolution approach. In Figure 8.4a, we plot several solutions of our model for some μ's differing by power of 2 factors from the parameter $\mu = 13.89$ selected by our algorithm. We point out that the solution corresponding to $\mu = 27.78$ (topmost

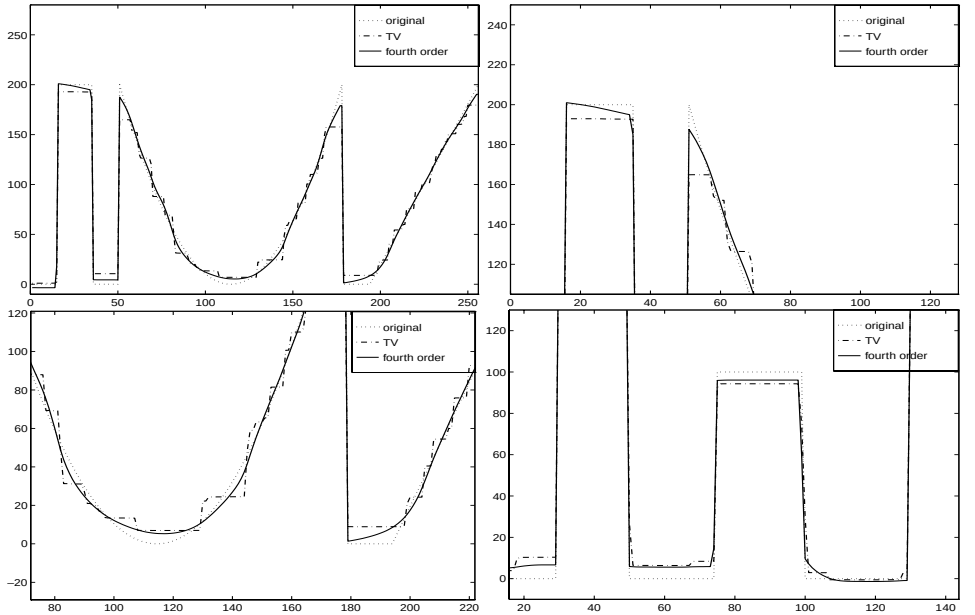

FIG. 8.3. *Details of comparison of TV denoising and our model.*

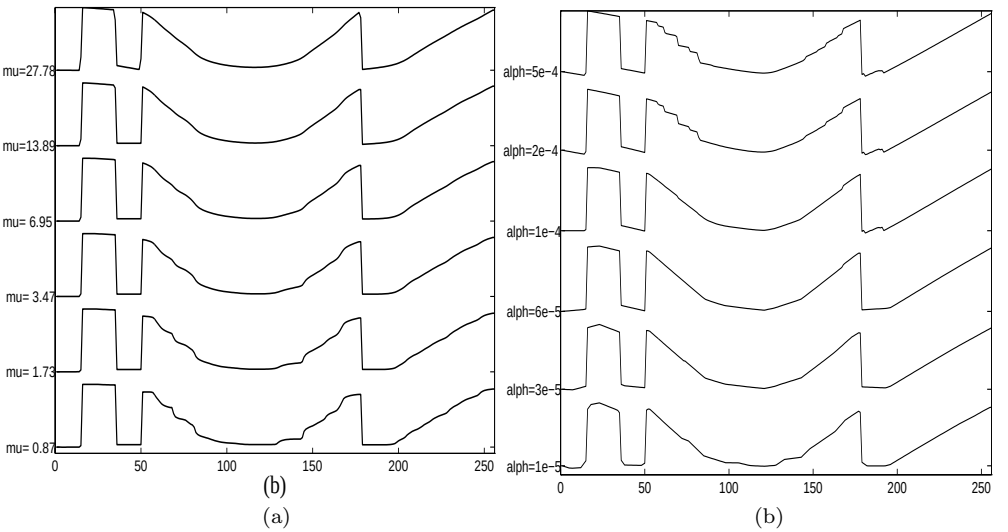

FIG. 8.4. *Comparison of our model and* inf*-convolution models for several parameters.*

one) does not match the noise level due to the nature of the selection procedure for μ expounded in section 7. In Figure 8.4b, we display some solutions of the inf-convolution technique for the values of the parameter $\alpha = 2^{-16}, 2^{-15}, \ldots, 2^{-11}$, where a match with the noise level has been enforced in our algorithms. The conclusion we can draw from this experiment is that the model we present in this paper is quite less sensitive to the parameter choice than the inf-convolution approach, since, for the same range of variation of the parameter that controls the intensity of the fourth order term of the equation (μ in our model and α in Chambolle–Lions'), our results look

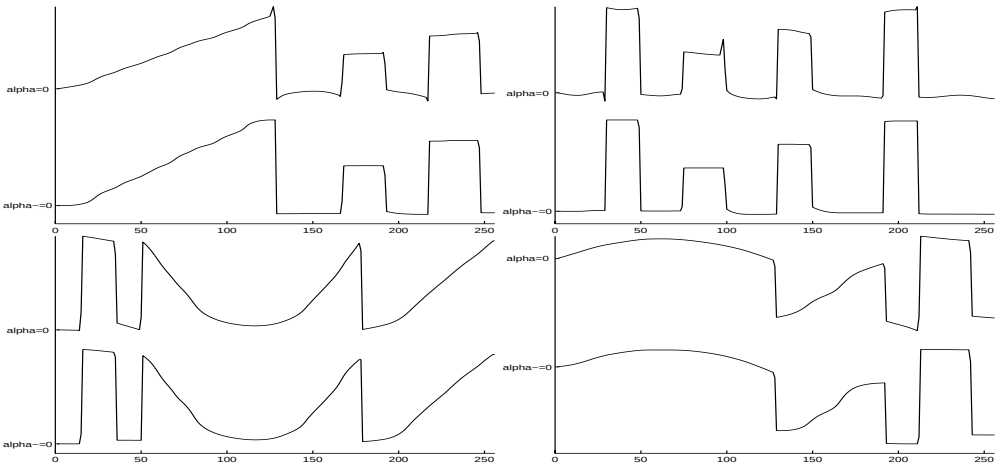

FIG. 8.5. *Comparison of our model with* $\alpha = 0$ *and* $\alpha \neq 0$.

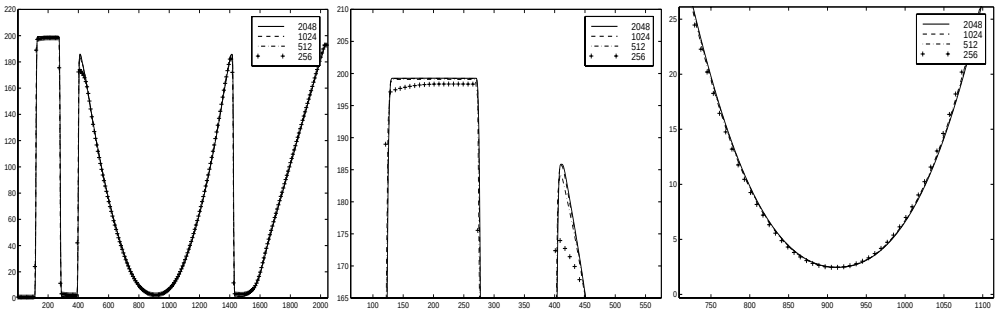

FIG. 8.6. *Details of comparison of solutions for* 256, 512, 1024, 2048 *grid points.*

much more uniform. Furthermore, our results exhibit no staircasing in the topmost three and sharp edges in all plots, whereas the best visual result of the inf-convolution technique, corresponding to $\alpha = 2^{-14} \approx 6 \times 10^{-5}$, does not contain staircasing, but some spurious gradients have been created in zones that should be flat. Actually, for $\mu = 0.87$ (at the bottom, $\mu = \frac{1}{16} \times 13.89$) only a mild staircase effect appears in the results of our model. Furthermore, the heuristics applied to the choice of the parameter μ explained in section 7 apparently give good results.

In Figure 8.5 we compare the results of our model with $\alpha = 0$ and $\alpha \neq 0$. This comparison backs the statements in Remark 1.

In the next experiment we analyze the dependence of the solution of the new model with respect to the grid size. For this, we use the signal that appears in the second place from the top of Figure 8.1a, whose size is $256 = 2^8$. We interpolate it to sizes $2^9, \ldots, 2^{15}$ and apply our model, with the parameters chosen as in the first experiment, to each of these interpolated signals as "noisy data" z. We overlay some of these solutions in Figure 8.6 and plot in Figure 8.7 the 2-, 1-, and ∞-norms of the difference of each solution with the solution at the finest grid. The errors thus computed behave as $\mathcal{O}(h^p)$, where $p \approx 1.5$ for the 2-norm, $p \approx 1$ for the 1- and ∞-norms. As can be seen from the pictures, the difference between these signals is very small, which seems to suggest that the PDE that we propose is well-posed.

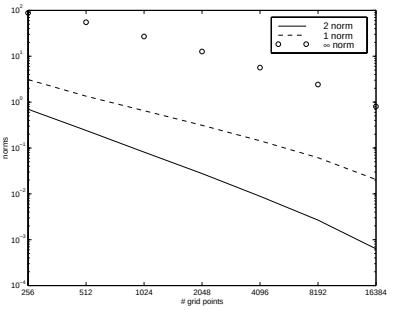

FIG. 8.7. *Plot of the* 1-, 2-, *and* ∞*-norms of the error between the solution of our scheme in a fine grid of* 2^{15} *points to the solutions in coarser grids of* $2^8, \ldots, 2^{14}$ *points.*

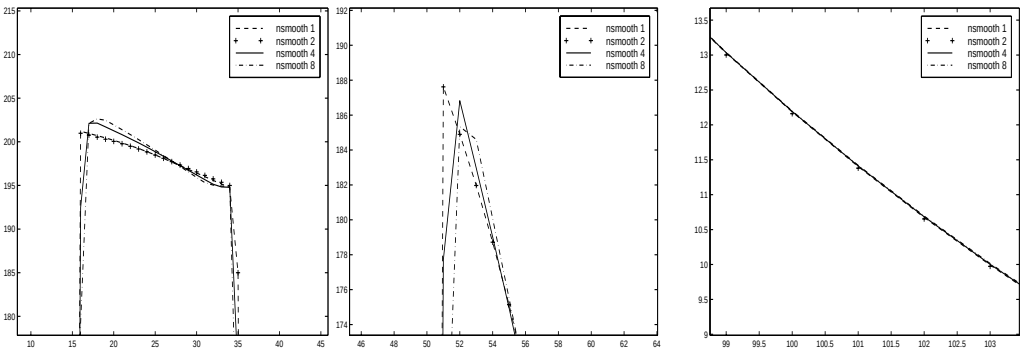

FIG. 8.8. *Details of comparison of solutions for degree of smoothing* $k = 1, 2, 4, 8$.

FIG. 8.9. *Left: original image. Right: noisy image, SNR* ≈ 4.

We analyze in the next experiment the dependence of the solution of our new model on the degree of smoothing k for the calculation of κ_2. We solve the denoising problem using convolution kernels given by (8.1) with $k = 1, 2, 4, 8$ and with optimal parameters for the noisy signal of the previous experiment. The results are overlayed in Figure 8.8 and suggest that the impact of smoothing is very little: it is imperceptible in smooth zones and edges are captured quite independently of the degree of smoothing.

The image of Figure 8.9 is used in the 2D experiment. The SNR of the noisy image is approximately 4. Details of the solutions of the denoising problems by TV and our model are shown in Figure 8.10. The contour plots of these details are shown

FIG. 8.10. *Left: image obtained by TV restoration model. Right: image obtained by our model.*

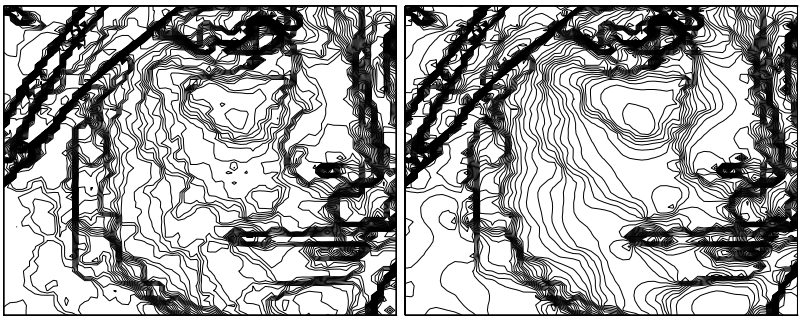

FIG. 8.11. *Left: contours of part of the image obtained by TV restoration model. Right: contours of part of the image obtained by new restoration model.*

in Figure 8.11. We can deduce from these contours that the image obtained by the new model is significantly smoother at smooth regions than the one obtained by the TV model, while the "true" edges are preserved similarly by both models. Furthermore, we can see from the contours of the TV restoration that it contains many regions of constant gray level, whereas the new model tends to preserve some small details better, thus giving the restored image a less cartoon-like aspect.

9. Concluding remarks. The main advantage of the fourth order PDE model that we have presented in this paper with respect to the original TV model is that it allows smooth transitions without penalizing sharp edges. It also shows significant robustness to the choice of the parameter μ. A disadvantage of the new model is that it has two parameters instead of one, although some heuristics have been applied to choose the additional parameter μ (see section 7). Another disadvantage is that the mathematical problem is much more challenging. In principle, the uniqueness of the solution of the nonlinear fourth order PDE that we propose is not ensured. Nevertheless, we have observed that for sound choices of the parameter μ, the fixed point method that we use to solve this equation converges to the same solution, regardless of the initial approximation. However, although this fixed point scheme has shown significant convergence robustness in our experiments, it does not show the monotonic decay of the norm of the equation that appears when applied to the TV restoration problem (see [8]). We will pursue more sophisticated and faster alternatives to this method in our future research.

A ROBUST ALGORITHM FOR OPTIMIZATION WITH GENERAL EQUALITY AND INEQUALITY CONSTRAINTS*

XIN-WEI LIU† AND YA-XIANG YUAN†

Abstract. An algorithm for general nonlinearly constrained optimization is presented, which solves an unconstrained piecewise quadratic subproblem and a quadratic programming subproblem at each iterate. The algorithm is robust since it can circumvent the difficulties associated with the possible inconsistency of QP subproblem of the original SQP method. Moreover, the algorithm can converge to a point which satisfies a certain first-order necessary optimality condition even when the original problem is itself infeasible, which is a feature of Burke and Han's methods [*Math. Programming*, 43 (1989), pp. 277–303]. Unlike Burke and Han's methods, our algorithm does not introduce additional bound constraints. The algorithm solves the same subproblems as the Han–Powell SQP algorithm at feasible points of the original problem. Under certain assumptions, it is shown that the algorithm coincides with the Han–Powell method when the iterates are sufficiently close to the solution. Some global convergence results are proved and locally superlinear convergence results are also obtained. Preliminary numerical results are reported.

Key words. SQP algorithm, constrained optimization, convergence

1. Introduction.

We consider the optimization problem with general equality and inequality constraints

$$\min f(x) \tag{1.1}$$

$$\text{subject to (s.t.) } c_i(x) = 0, \quad i \in E, \tag{1.2}$$

$$c_i(x) \geq 0, \quad i \in I, \tag{1.3}$$

where $f(x) : R^n \to R$ and $c_i(x) : R^n \to R (i \in E \cup I)$ are continuously differentiable functions, $E = \{1, 2, \ldots, m_e\}$, $I = \{m_e + 1, \ldots, m\}$, m_e and m are two positive integers, and $m \geq m_e$.

SQP algorithms for constrained optimization are iterative and generate a new approximate to the solution by the procedure

$$x^+ = x + sd, \tag{1.4}$$

where x is the current point, d is a search direction which minimizes a quadratic model subject to linearized constraints, and s is the step-length along the direction such as [8, 13, 21]. For $k \geq 1$, the original SQP method developed by Wilson, Han, and Powell solves the following QP subproblem

$$\min g_k^T d + \frac{1}{2} d^T B_k d \tag{1.5}$$

$$\text{s.t. } c_i(x_k) + \nabla c_i(x_k)^T d = 0, \quad i \in E, \tag{1.6}$$

$$c_i(x_k) + \nabla c_i(x_k)^T d \geq 0, \quad i \in I, \tag{1.7}$$

at the kth iterate, where $g_k = \nabla f(x_k)$ is the gradient of the objective function and B_k is an estimate of the Hessian of the Lagrangian function

$$L(x, \lambda) = f(x) - \sum_{i=1}^{m} \lambda_i c_i(x), \tag{1.8}$$

and $(\lambda_1, \lambda_2, \ldots, \lambda_m)^T$ is a multiplier vector approximation.

Because of its nice convergence properties (for example, see [8, 13, 14] and [1]), the SQP method has been attracting the attention of many researchers. It has been extended to problems other than optimization [12, 20].

The requisite consistency of the linearized constraints of the QP subproblem (1.5)–(1.7) is a serious limitation of the SQP method. Within the framework of the SQP method, Powell suggests solving a modified subproblem at each iterate (see [13, 19]):

$$\min\ g_k^T d + \frac{1}{2} d^T B_k d + \frac{1}{2}\delta_k (1-\mu)^2 \tag{1.9}$$

$$\text{s.t. } \mu c_i(x_k) + \nabla c_i(x_k)^T d = 0, \quad i \in E, \tag{1.10}$$

$$\mu_i c_i(x_k) + \nabla c_i(x_k)^T d \geq 0, \quad i \in I, \tag{1.11}$$

where

$$\mu_i = \begin{cases} 1, & c_i(x_k) > 0 \\ \mu, & c_i(x_k) \leq 0 \end{cases}$$

and $0 \leq \mu \leq 1$, $\delta_k > 0$ is a penalty parameter. With some other technique, the computational investigation provided by Schittkowski [17, 18] shows that this modification works very well.

A simple example presented by Burke and Han [3] and Burke [2] indicates this approach may not be the best one. Assume there are two constraints on R:

$$c_1(x) = 1 - e^x = 0, \tag{1.12}$$

$$c_2(x) = x = 0, \tag{1.13}$$

with any objective function $f(x)$ on R. For any infeasible point $x \neq 0$, the linearized constraints are inconsistent, and the only solution of the modified constraints (1.10)–(1.11) is $\mu = 0$ and $d = 0$. Although this example is too specialized to make a general claim, it shows that the problem caused by the inconsistency of the linearized constraints can not always be solved by using (1.10)–(1.11).

Based on a trust region strategy, Fletcher [6, 7] developed the Sl_1QP method for (1.1)–(1.3). Fletcher's approach solves the following QP subproblem at the kth iteration:

$$\min\ g_k^T d + \frac{1}{2} d^T B_k d + \delta_k ||(c(x_k) + \nabla c(x_k)^T d)_-||_1 \tag{1.14}$$

$$\text{s.t. } ||d||_\infty \leq \beta_k, \tag{1.15}$$

where $c(x_k) = (c_1(x_k), \ldots, c_m(x_k))^T$, $(c(x_k) + \nabla c(x_k)^T d)_- \in R^m$ with

$$(c_i(x_k) + \nabla c_i(x_k)^T d)_- = c_i(x_k) + \nabla c_i(x_k)^T d, \quad i \in E, \tag{1.16}$$

$$(c_i(x_k) + \nabla c_i(x_k)^T d)_- = \min(0, c_i(x_k) + \nabla c_i(x_k)^T d), \quad i \in I, \tag{1.17}$$

δ_k is a penalty parameter, β_k is a positive constant. It has been shown that under certain assumptions the search direction generated by (1.14)–(1.15) is locally identical to that by (1.5)–(1.7).

Burke and Han [3] show that Fletcher's approach is still incomplete. One of the reasons is that the search direction may point away from the optimal point.

Similar to the method of Sahba [16], Burke and Han [3] and Burke [2] present an approach to overcome difficulties associated with the inconsistency of the QP subproblem (1.5)–(1.7). Their methods are also similar to the methods of Powell [13] and Fletcher [6, 7]. A feature different from the other methods is that even when (1.1)–(1.3) is itself infeasible their methods can converge to a point which meets a certain first-order necessary optimality condition. However, Burke and Han's method is conceptual.

In this paper, we describe an implementable algorithm which is a modification to the SQP method. Our motivation is to explore further techniques for overcoming the inconsistency of the QP subproblem to derive an efficient reliable SQP algorithm. The line search direction of our algorithm consists of two directions: one is computed by solving a special nonsmooth l_1QP subproblem that depends on only active constraints defined by an active technique; another is obtained by solving a simplified QP problem which is always feasible even when the QP subproblem of the standard SQP method is infeasible. Our algorithm is a generalization of the algorithm presented by Liu and Yuan [10], which is also similar to Burke and Han's method [3]. However, unlike their method, we do not introduce additional bound constraints. Our algorithm obtains a direction which can be a nonzero descent direction of the merit function even if (1.5)–(1.7) is infeasible. At a feasible point of (1.1)–(1.3), the algorithm solves the same subproblem as (1.5)–(1.7). Moreover, under certain assumptions, our algorithm generates the same iterates as the Han–Powell method. Some global convergence results are proved and locally superlinear convergence is derived.

Our algorithm can be easily combined with the trust region approach. Thus, the algorithm can be extended to a trust region algorithm for optimization with general constraints.

The paper is organized as follows. We present our algorithm in section 2. The stationary properties of the algorithm are given in section 3. In section 4 some global convergence results are proved. We discuss the local properties of the algorithm in section 5. In section 6, some preliminary numerical results are reported.

2. The algorithm. Define the penalty function associated with (1.1)–(1.3),

$$\phi(x, r) = f(x) + r||c(x)_-||, \tag{2.1}$$

where $||\cdot||$ is any given convex norm on R^m, $r > 0$ is a penalty parameter, and $c(x)_- \in R^m$ with

$$c_i(x)_- = c_i(x), \quad i \in E, \tag{2.2}$$

$$c_i(x)_- = \min(0, c_i(x)), \quad i \in I. \tag{2.3}$$

It is straightforward to see that $||c(x)_-|| = 0$ if and only if x is a feasible point of (1.1)–(1.3). If the norm $||\cdot||$ is the l_1 norm, (2.1) is the l_1 exact penalty function, which is also a merit function employed by Han [8] and Powell [13, 14]. Throughout this paper if the norm is not specified, it is the same as that used in (2.1).

Define the index sets

$$I_k = \{i \in I : c_i(x_k) \le 0\}, \tag{2.4}$$

$$\bar{I}_k = \{i \in I : c_i(x_k) > 0\}, \tag{2.5}$$

$$J_k = I_k \cup E. \tag{2.6}$$

These index sets are related to the current iterate x_k and can be identified easily. Under some assumptions, we will show that J_k tends to be the index set of the active constraints of (1.1)–(1.3).

Our algorithm solves two subproblems at each iterate: one is an unconstrained piecewise quadratic subproblem (see [13, 21]), and the other is a quadratic programming subproblem. At the kth iteration the unconstrained subproblem has the following form:

$$\min_{d \in R^n} \psi_k(d) = \frac{1}{2} d^T B_k d + r_k ||(c_{J_k}(x_k) + \nabla c_{J_k}(x_k)^T d)_-||, \tag{2.7}$$

where B_k positive definite is an estimate of the Lagrangian Hessian of (1.1)–(1.3), $c_{J_k}(x_k) \in R^{|J_k|}$ is a vector whose components are $c_i(x_k)(i \in J_k)$, $|J_k|$ is the cardinality of the index set J_k, and r_k is the penalty parameter. Let d_{k1} be the solution of (2.7). If x_k is feasible, we have $d_{k1} = 0$. If $d_{k1} \neq 0$, d_{k1} is a descent direction of $\phi(x_k, r_{k+1})$ for sufficiently large r_{k+1}. Moreover, there is a $\tau_k \in (0, 1]$ such that $c_i(x_k) + \delta \nabla c_i(x_k)^T d_{k1} \geq 0$ for all $\delta \in [0, \tau_k]$ and $i \in \bar{I}_k$. In fact, we can let $\tau_k = \min\{1, \hat{\tau}_k\}$, where

$$\hat{\tau}_k = \min\{-c_i(x_k)/(\nabla c_i(x_k)^T d_{k1}) : \quad i \in \bar{I}_k \text{ and } \nabla c_i(x_k)^T d_{k1} < 0\}. \tag{2.8}$$

Let $\hat{c}_i(x_k) = c_i(x_k) + \nabla c_i(x_k)^T \tau_k d_{k1}$ for $i \in \bar{I}_k$. We generate d_{k2} by solving the QP subproblem

$$\min\ g_k^T d + \frac{1}{2} d^T B_k d \tag{2.9}$$

$$\text{s.t. } \nabla c_i(x_k)^T d = 0, \quad i \in E, \tag{2.10}$$

$$\nabla c_i(x_k)^T d \geq 0, \quad i \in I_k, \tag{2.11}$$

$$\hat{c}_i(x_k) + \nabla c_i(x_k)^T d \geq 0, \quad i \in \bar{I}_k, \tag{2.12}$$

and let $d_k = \tau_k d_{k1} + d_{k2}$ be the search direction. It will be shown that d_k is a descent direction for the penalty function where the penalty parameter is updated automatically. Therefore, (2.1) can be employed as a merit function to force the global convergence of the algorithm.

The updating of penalty parameter for the SQP approach is important. In order to obtain the global convergence, Han [8] and Powell [13] require that

$$r \geq ||\lambda_k||_\infty \tag{2.13}$$

for all $k \geq 1$, where λ_k is an estimate of the Lagrangian multiplier vector at x_k. However, (2.13) is generally replaced by some updating procedure when practically implementing an SQP algorithm because we do not know any information about the multiplier vector of (1.8). Similar to Powell [13] and Burke and Han [3], a penalty parameter updating procedure is employed in our algorithm. Since d_{k2} is not related to the constraint violation, the object of updating the penalty parameter is to force d_{k1} to be a descent direction of (2.1). Thus, at the kth iteration we let r_k remain unchanged if d_{k1} is a descent direction; otherwise, r_k is increased in the following way:

$$r_{k+1} = \max\left\{2r_k + \rho, \quad \frac{g_k^T d_{k1} + d_{k1}^T B_k d_{k1}}{||(c_{J_k})_-|| - ||(c_{J_k} + \nabla c_{J_k}^T d_{k1})_-||}\right\}, \tag{2.14}$$

where ρ is a positive number.

Now we can state our algorithm as follows.

ALGORITHM 2.1 (a robust algorithm for optimization).

Step 1 [Step 0.] Given the initial approximate x_0, an $n\times n$ symmetric positive definite matrix B_0, an initial penalty parameter $r_0 > 0$, and some positive scalars ρ, β and μ, where $\beta < 1$ and $\mu < \frac{1}{2}$; $k = 0$;

If the stopping criterion is satisfied, stop;
Solve subproblem (2.7) *to generate d_{k1} and subproblem* (2.9)–(2.12) *to generate d_{k2};*

Step 2. *Update penalty parameter. If*

$$g_k^T d_{k1} + \frac{1}{2} d_{k1}^T B_k d_{k1} + r_k(||(c_{J_k}(x_k) + \nabla c_{J_k}(x_k)^T d_{k1})_-|| - ||(c_k(x_k))_-||) \le 0, \tag{2.15}$$

let $r_{k+1} = r_k$; Otherwise, r_k is updated by (2.14).

Step 3. $d_k = \tau_k d_{k1} + d_{k2}$. Select the smallest positive integer s such that

$$\phi(x_k + \beta^s d_k, r_{k+1}) - \phi(x_k, r_{k+1}) \le \mu\beta^s(g_k^T d_k + r_{k+1}(||(c(x_k) + \nabla c(x_k)^T d_k)_-|| - ||(c(x_k))_-||)). \tag{2.16}$$

Let $t_k = \beta^s$ and $x_{k+1} = x_k + t_k d_k$;

Step 4. Generate B_{k+1}. Set $k = k + 1$ and goto Step 1.

The stopping criterion is not given in the algorithm. Generally, $||d_k||_2 = 0$ can be used as the stopping criterion. Since no assumption on regularity of the constraints is made, it is possible that d_k does not tend to zero for $k \to \infty$. Thus, we use the condition $||x_{k+1} - x_k||_2 = 0$ as the stopping criterion. In practical implementation, a positive tolerance number will be introduced.

Algorithm 2.1 is similar to the methods proposed by Burke and Han [3] and Burke [2]. Since no additional bound constraints are employed, the algorithm can be implemented in the same way as SQP algorithms.

It should be noted that our algorithm solves the same subproblem as (1.5)–(1.7) at a feasible point of (1.1)–(1.3).

Two examples presented by Burke and Han [3] can help us to understand the above algorithm and the differences between our algorithm and Burke and Han's methods.

Example 2.2. The constraint function $c : R \to R^2$ has the form

$$c(x) = \begin{pmatrix} 1 - e^x \\ x \end{pmatrix} \tag{2.17}$$

and $m_e = m = 2$. The norm is the l_1 norm.

For this problem, (2.7) has the form

$$\min_{d\in R} \quad \frac{1}{2} B_k d^2 + r_k(|1 - e^x - e^x d| + |x + d|). \tag{2.18}$$

For any $x_k = x \neq 0$, by direct calculations, $d_{k2} = 0$ and

$$d_{k1} = \begin{cases} e^{-x} - 1 \text{ or } -\frac{r_k}{B_k}(e^x + 1) & \text{if } x > 0, \\ \frac{r_k}{B_k}(e^x + 1) \text{ or } -x & \text{if } x < 0, \\ = 0 & \text{if } x = 0. \end{cases} \tag{2.19}$$

It is easily found that d_{k1} has the following properties:

$$d_{k1} \begin{cases} > 0 & \text{for } x < 0, \\ < 0 & \text{for } x > 0, \\ = 0 & \text{for } x = 0. \end{cases} \tag{2.20}$$

From (2.20), it is easy to see that our algorithm will converge to the solution $x = 0$ from any starting point.

Example 2.3. The constraint function $c : R \to R^2$ is given by

$$c(x) = \begin{pmatrix} -x^2 - 1 \\ -x \end{pmatrix} \tag{2.21}$$

and $m_e = 0$, $m = 2$. Any problem with $c(x)$ as its constraint is infeasible as $c_1(x) = -x^2 - 1 = 0$ has no solution. Let the norm be the l_1 norm.

For constraints (2.21), we have that

$$d_{k1} = \begin{cases} \max\left(-\frac{2r_k}{B_k}x,\ -\frac{x^2+1}{2x}\right) & \text{if } x < 0, \\ -x,\ -\frac{x^2+1}{2x},\ -\frac{r_k(2x+1)}{B_k} \text{ or } -\frac{2r_k}{B_k}x & \text{if } 0 < x < 1, \\ -x,\ -\frac{x^2+1}{2x},\ -\frac{r_k}{B_k} \text{ or } -\frac{r_k}{B_k}(2x+1) & \text{if } x > 1, \\ \max\left(-\frac{3r_k}{B_k},\ -1\right) & \text{if } x = 1, \\ 0 & \text{if } x = 0, \end{cases} \tag{2.22}$$

and

$$d_{k2} \begin{cases} = 0 & \text{if } x < 0, \\ \le 0 & \text{if } x \ge 0. \end{cases} \tag{2.23}$$

Thus, the search direction generated by our algorithm always points toward the origin, of which the image under c is the closest point to R^2_+ for the l_1 norm.

Algorithm 2.1 can also solve the problem (8.1) of Burke and Han [3] successfully since $d_{k2} = 0$ and d_{k1} directs to the optimal solution for any iteration point $x \neq 0$.

3. Stationary properties of the algorithm. Examples 2.2 and 2.3 display some properties of Algorithm 2.1. These properties are favorable in practice because much information, such as consistency for (1.1)–(1.3), is not known beforehand. Since no restrictions are imposed on the constraint functions, a cluster point of the sequence generated by our algorithm can be one of three different types of points. Similar to Yuan [23], we give their definitions and their stationary properties.

DEFINITION 3.1. *$x \in R^n$ is called*

(1) *a strong stationary point of* (1.1)–(1.3) *if x is feasible and there exists a vector $\lambda = (\lambda_1, \lambda_2, \ldots, \lambda_m)^T \in R^m$ such that*

$$g(x) - \sum_{i=1}^{m} \lambda_i \nabla c_i(x) = 0, \tag{3.1}$$

$$\lambda_i \ge 0, \quad \lambda_i c_i(x) = 0, \qquad i \in I; \tag{3.2}$$

(2) *an infeasible stationary point of* (1.1)–(1.3) *if x is infeasible and*

$$\min_{d \in R^n} ||(c(x) + \nabla c(x)^T d)_-|| = ||(c(x))_-||; \tag{3.3}$$

(3) *a singular stationary point of* (1.1)–(1.3) *if* x *is feasible and there exists an infeasible sequence* $\{v_k\}$ *converging to* x *such that*

$$\lim_{k\to\infty} \frac{\min_{d\in R^n} ||(c(v_k) + \nabla c(v_k)^T d)_-||}{||(c(v_k))_-||} = 1. \tag{3.4}$$

Definition 3.1 is related to our algorithm closely. It should be noted that there are some differences between our definition and that of [23], for example, the definition on the singular stationary point.

A strong stationary point defined above is precisely a $K-T$ point of (1.1)–(1.3). If $||(c(x_k))_-|| = 0$ and $d_{k2} = 0$, by the first-order $K-T$ condition of (2.9)–(2.12), x_k is a strong stationary point of (1.1)–(1.3).

Throughout this report, we make the following assumption.

Assumption 3.2. (1) $f(x)$ and $c_i(x)$, $i \in E \cup I$, are twice continuously differentiable functions; (2) the approximation B_k of the Lagrangian Hessian is positive definite and there exists two positive constants M_1 and M_2 such that

$$M_1||d||_2^2 \le d^T B_k d \le M_2||d||_2^2 \tag{3.5}$$

holds for all $d \in R^n$ and all $k \ge 1$.

LEMMA 3.3. *The following statements hold:*

(i) *If* (3.3) *holds at* x_k, *then* $d = 0$ *solves* (2.7) *uniquely;*

(ii) *if* $\{x_k\}$ *and* $\{r_k\}$ *are bounded, then* $\{d_{k1}\}$ *is also bounded.*

Proof. (i) For any $d \ne 0$, by (3.3), there exists $t > 0$ sufficiently small such that

$$\begin{aligned} \psi_k(td) &= (1/2)t^2 d^T B_k d + r_k||(c_{J_k}(x_k) + \nabla c_{J_k}(x_k)^T (td))_-|| \\ &= (1/2)t^2 d^T B_k d + r_k||(c(x_k) + \nabla c(x_k)^T (td))_-|| \\ &\ge (1/2)t^2 d^T B_k d + r_k||(c(x_k))_-|| > \psi_k(0). \end{aligned} \tag{3.6}$$

Because $\psi_k(d)$ is convex, we can see that $d = 0$ is the unique solution of (2.7).

(ii) The definition of d_{k1} shows that

$$\begin{aligned} \psi_k(0) &\ge \psi_k(d_{k1}) \\ &\ge (1/2)M_1||d_{k1}||_2^2 + r_k||(c_{J_k}(x_k) + \nabla c_{J_k}(x_k)^T d_{k1})_-|| \\ &\ge (1/2)M_1||d_{k1}||_2^2. \end{aligned} \tag{3.7}$$

Therefore,

$$||d_{k1}||_2^2 \le (2/M_1)\psi_k(0) = (2/M_1)r_k||(c(x_k))_-||. \qquad \square \tag{3.8}$$

LEMMA 3.4. *If* $x \in R^n$ *is an infeasible stationary point or a singular stationary point as defined above, then there exist* $\lambda_0 \ge 0$ *and* $\lambda \in R^m$ *such that the first-order necessary optimality condition*

$$\lambda_0 g(x) - \sum_{i=1}^{m} \lambda_i \nabla c_i(x) = 0, \tag{3.9}$$

$$\lambda_i \ge 0, \quad i \in I, \tag{3.10}$$

holds.

Proof. Suppose that $d(x)$ minimizes the unconstrained problem

$$\min_{d\in R^n} \frac{1}{2}d^T Bd + ||(c(x) + \nabla c(x)^T d)_-|| \tag{3.11}$$

at the iteration point x, where B is any positive definite matrix. Then, the first-order optimality condition at x gives that

$$Bd + \nabla c(x)\mu(x) = 0, \tag{3.12}$$

$$\mu(x) \in \partial||u||\big|_{u=(c(x)+\nabla c(x)^T d)_-}, \tag{3.13}$$

where $\mu(x) \in R^m$. It follows directly from (3.13) that $(\mu(x))_i \le 0$ for $i \in I$.

If x is an infeasible stationary point, similar to the proof of Lemma 3.3, we have that $d(x) = 0$. Let $\lambda_0 = 0$ and $\lambda_i = -(\mu(x))_i$, which gives (3.9).

Now suppose that x is a singular stationary point, $\{x_k : k \in K\}$ is a subsequence, and $x_k \to x$ for $k \to \infty (k \in K)$. Suppose that $d(x_k)$ is a solution of (3.11) at x_k; then (3.12)–(3.13) holds at x_k and

$$\begin{aligned}\min_{d\in R^n} ||(c(x_k) + \nabla c(x_k)^T d)_-|| - ||(c(x_k))_-|| \\ \le -\frac{1}{2}d(x_k)^T Bd(x_k) \le 0.\end{aligned} \tag{3.14}$$

Combining (3.4), we have

$$\lim_{k\to\infty, k\in K} \frac{d(x_k)^T Bd(x_k)}{||c(x_k)_-||} = 0. \tag{3.15}$$

Thus, for $k \in K$,

$$\lim_{k\to\infty} ||d(x_k)|| = 0. \tag{3.16}$$

It follows from (3.16) and (3.12) that

$$\lim_{k\to\infty, k\in K} \nabla c(x_k)\mu(x_k) = 0. \tag{3.17}$$

Because $||\mu(x_k)||_0 \le 1$ for all k (where $||\cdot||_0$ is the dual norm of $||\cdot||$), there is a cluster point $\mu^* \in R^m$ with $(\mu^*)_i \le 0$ for $i \in I$. We see that (3.9) holds if we let $\lambda_0 = 0$ and $\lambda_i = -(\mu^*)_i$ for $i \in E \cup I$. This completes our proof. □

4. Global convergence. First we show that if our algorithm stops after finite many iterations, the last iterate point must be a strong stationary point or an infeasible stationary point of (1.1)–(1.3).

LEMMA 4.1. *Suppose that d_{k1} is a solution of* (2.7) *and d_{k2} solves* (2.9)–(2.12). *If $d_{k1} = 0$ and $d_{k2} = 0$, then x_k is either a strong stationary point or an infeasible stationary point of* (1.1)–(1.3).

Proof. If $d_{k1} = 0$ and $d_{k2} = 0$, it follows from the first-order Kuhn–Tucker condition of (2.9)–(2.12) that there exists $\lambda_k \in R^m$ such that

$$g_k - \nabla c(x_k)\lambda_k = 0, \tag{4.1}$$

$$(\lambda_k)_i c_i(x_k) = 0 \quad \text{for } i \in \bar{I}_k, \tag{4.2}$$

$$(\lambda_k)_i \ge 0 \quad \text{for } i \in I. \tag{4.3}$$

If $||(c(x_k))_-|| = 0$, then by (4.1)–(4.3) and Definition 3.1(1), x_k is a strong stationary point of (1.1)–(1.3).

Suppose that $||(c(x_k))_-|| \neq 0$. We want to prove that (3.3) holds for x_k. If it is not the case, then there exist $\tilde{d}_k \neq 0$ and $0 < \tau_k \leq 1$ such that

$$\min_{d \in R^n} ||(c(x_k) + \nabla c(x_k)^T d)_-|| = ||(c(x_k) + \nabla c(x_k)^T \tilde{d}_k)_-|| < ||(c(x_k))_-|| \tag{4.4}$$

and

$$||(c(x_k) + \nabla c(x_k)^T (\tau_k \tilde{d}_k))_-|| = ||(c_{J_k}(x_k) + \nabla c_{J_k}(x_k)^T (\tau_k \tilde{d}_k))_-||. \tag{4.5}$$

Let $\hat{d}_k = \tau_k \tilde{d}_k$; then it follows that

$$r_k(||(c_{J_k}(x_k))_-|| - ||(c_{J_k}(x_k) + \nabla c_{J_k}(x_k)^T \hat{d}_k)_-||) \leq \frac{1}{2} \hat{d}_k^T B_k \hat{d}_k. \tag{4.6}$$

Define

$$t_0 = \frac{r_k}{2} \frac{||(c_{J_k}(x_k))_-|| - ||(c_{J_k}(x_k) + \nabla c_{J_k}(x_k)^T \hat{d}_k)_-||}{\hat{d}_k^T B_k \hat{d}_k}; \tag{4.7}$$

then by (4.6), $0 < t_0 \leq \frac{1}{4}$ and

$$\begin{aligned} &\psi_k(t_0 \hat{d}_k) - \psi_k(d_{k1}) \\ &\quad \leq \frac{1}{2} t_0^2 \hat{d}_k^T B_k \hat{d}_k + r_k t_0 \{||(c_{J_k}(x_k) + \nabla c_{J_k}(x_k)^T \hat{d}_k)_-|| - ||(c_{J_k}(x_k))_-||\} \\ &\quad \leq \frac{3}{4} t_0 \tau_k r_k \{||(c(x_k) + \nabla c(x_k)^T \tilde{d}_k)_-|| - ||(c(x_k))_-||\} < 0, \end{aligned} \tag{4.8}$$

which gives a contradiction. □

The following result shows that the line search procedure is well defined in the algorithm.

LEMMA 4.2. *Suppose that at least one of d_{k1} and d_{k2} is nonzero; then τ_k is defined by* (2.8). *Then $\tau_k d_{k1} + d_{k2}$ is a descent direction of the penalty function* (2.1) *and the line search condition* (2.17) *is well defined.*

Proof. Let $q(x) = ||c(x)_-||$; then by Lemma 4.1 of Burke and Han [4],

$$q'(x; d) \leq ||(c(x) + \nabla c(x)^T d)_-|| - ||c(x)_-||. \tag{4.9}$$

Define $d_k = \tau_k d_{k1} + d_{k2}$; then

$$\phi'(x_k, r_{k+1}; d_k) \leq g_k^T d_k + r_{k+1}(||(c(x_k) + \nabla c(x_k)^T d_k)_-|| - ||c(x_k)_-||). \tag{4.10}$$

By (2.9)–(2.12) and the convexity of the norm,

$$\begin{aligned} &||(c(x_k) + \nabla c(x_k)^T d_k)_-|| - ||c(x_k)_-|| \\ &\quad \leq \tau_k(||(c_{J_k}(x_k) + \nabla c_{J_k}(x_k)^T d_{k1})_-|| - ||c(x_k)_-||). \end{aligned} \tag{4.11}$$

Thus,

$$\begin{aligned} \phi'(x_k, r_{k+1}; d_k) &\leq g_k^T d_{k2} + \tau_k \{g_k^T d_{k1} \\ &\quad + r_{k+1}(||(c_{J_k}(x_k) + \nabla c_{J_k}(x_k)^T d_{k1})_-|| - ||c(x_k)_-||)\}. \end{aligned} \tag{4.12}$$

It follows from Step 2 of the algorithm that

$$\phi'(x_k, r_{k+1}; d_k) \leq -\frac{1}{2} d_{k2}^T B_k d_{k2} - \frac{1}{2}\tau_k d_{k1}^T B_k d_{k1} < 0. \tag{4.13}$$

Now we prove that the line search condition (2.17) is well defined. By the mean value theorem, for any $t > 0$, there exists $\alpha \in (0, t)$ such that

$$f(x_k + td_k) - f(x_k) = tg(x_k + \alpha d_k)^T d_k. \tag{4.14}$$

Similarly there exist $\alpha_i \in (0, t)$ such that

$$c_i(x_k + td_k) - c_i(x_k) = t\nabla c_i(x_k + \alpha_i d_k)^T d_k. \tag{4.15}$$

Define $A_k = (\nabla c_1(x_k + \alpha_1 d_k), \nabla c_2(x_k + \alpha_2 d_k), \ldots, \nabla c_m(x_k + \alpha_m d_k))$; then

$$\begin{aligned}\phi(x_k + td_k, r_{k+1}) - \phi(x_k, r_{k+1}) &\leq tg(x_k + \alpha d_k)^T d_k \\ &\quad + tr_{k+1}(||(c(x_k) + A_k^T d_k)_-|| - ||c(x_k)_-||).\end{aligned} \tag{4.16}$$

Since

$$||(c(x_k) + A_k^T d_k)_-|| - ||(c(x_k) + \nabla c(x_k)^T d_k)_-|| \leq ||(A_k - \nabla c(x_k))^T d_k||, \tag{4.17}$$

it follows from the first part of the proof that there always exists a sufficiently small $t_0 > 0$ such that for all $t \in (0, t_0)$, $\alpha \in (0, t)$,

$$\begin{aligned}&(g(x_k + \alpha d_k) - g_k)^T d_k + r_{k+1}(||(A_k - \nabla c(x_k))^T d_k||) \\ &\quad + (1 - \mu)(g_k^T d_k + r_{k+1}(||(c(x_k) + \nabla c(x_k)^T d_k)_-|| - ||c(x_k)_-||)) < 0,\end{aligned} \tag{4.18}$$

which completes the proof. □

Assumption 4.3. $\{x_k\}$ and $\{d_k\}$ are uniformly bounded.

The assumption on $\{x_k\}$ is common in analyses on convergence of the algorithms. Since the objective function (2.9) is coercive, and $d = 0$ is feasible for (2.10)–(2.12), d_{k2} is bounded. If $r_k \to \infty$, in place of (2.7), we use the following subproblem:

$$\min \frac{1}{2} d^T B_k d + r_k ||(c_{J_k}(x_k) + \nabla c_{J_k}(x_k)^T d)_-|| \tag{4.19}$$

$$\text{s.t. } ||d||_2 \leq R, \tag{4.20}$$

where $R > 0$ is a constant, and all analyses still hold since the norm is convex.

If $r_k \to \infty$, by Lemma 4.2 of [23], $\lim_{k\to\infty} ||c(x_k)_-||$ exists.

LEMMA 4.4. *If $r_k \to \infty$ and $\lim_{k\to\infty} ||c(x_k)_-|| \neq 0$, then there exists a convergent subsequence of $\{x_k\}$ which converges to an infeasible stationary point of* (1.1)–(1.3).

Proof. Let S be the set of the accumulation points of $\{x_k\}$. If the lemma is not true, for any $x \in S$, $||c(x)_-|| \neq 0$ and (3.3) does not hold. Thus, there exists a $v > 0$ such that for k large enough,

$$\min_{||d||_2 \leq \delta} ||(c(x_k) + \nabla c(x_k)^T d)_-|| \leq ||c(x_k)_-|| - v, \tag{4.21}$$

where δ is a positive constant.

Let $\hat{d}_k$ be a vector such that $\|\hat{d}_k\| \leq \delta$ and that

$$||(c(x_k) + \nabla c(x_k)^T \hat{d}_k)_-|| = \min_{||d||_2 \leq \delta} ||(c(x_k) + \nabla c(x_k)^T d)_-||. \tag{4.22}$$

The fact that $\|\hat{d}_k\| \leq \delta$,

$$||(c_{J_k}(x_k) + \nabla c_{J_k}(x_k)^T \hat{d}_k)_-|| \leq ||(c(x_k) + \nabla c(x_k)^T \hat{d}_k)_-||, \tag{4.23}$$

$r_k \to \infty$, and that d_{k1} solves (2.7) implies that inequality

$$\begin{aligned} &g_k^T d_{k1} + \frac{1}{2} d_{k1}^T B_k d_{k1} + r_k(||(c_{J_k}(x_k) + \nabla c_{J_k}(x_k)^T d_{k1})_-|| - ||(c(x_k))_-||) \\ &\leq g_k^T d_{k1} + \frac{1}{2} \hat{d}_k^T B_k \hat{d}_k + r_k(||(c_{J_k}(x_k) + \nabla c_{J_k}(x_k)^T \hat{d}_k)_-|| - ||(c(x_k))_-||) \\ &\leq g_k^T d_{k1} + \frac{1}{2} M\delta^2 - r_k v < 0 \end{aligned} \tag{4.24}$$

holds for all sufficiently large k, which contradicts the parameter updating procedure. □

Similarly, we have the following result.

LEMMA 4.5. *If $r_k \to \infty$ and $\lim_{k\to\infty} ||c(x_k)_-|| = 0$, then there exists a convergent subsequence of $\{x_k\}$ which converges to a singular stationary point of* (1.1)–(1.3).

Proof. Let x be any accumulation point of $\{x_k\}$. Then x is a feasible point of (1.1)–(1.3). The condition $r_k \to \infty$ implies that there exists an infinite subsequence $\{x_k : k \in \mathcal{K}\}$ such that $||(c(x_k))_-|| \neq 0$ for $k \in \mathcal{K}$.

If the result is not true, then for any convergent subsequence $\{x_k : k \in \tilde{K}\}(\tilde{K} \subset \mathcal{K})$, (3.4) does not hold. Hence, there exists a positive number v such that (4.21) holds. Similar to Lemma 4.4, the proof can be completed. □

The above two lemmas imply that r_k is bounded if no subsequence of $\{x_k\}$ converges to an infeasible stationary point or a singular stationary point of (1.1)–(1.3).

LEMMA 4.6. *Suppose that $r_k = r$ (r is a positive constant) for all k large enough, $\{x_k\}$ is an infinite sequence, and $\{x_k : k \in \hat{K}\}$ is a convergent subsequence. Then $d_k \to 0$ for $k \in \hat{K}$ and $k \to \infty$.*

Proof. We proceed by contradiction. Without loss of generality, assume that $r_k = r$ for all k.

Suppose that there exist an infinite subset $K' \subset \hat{K}$ and a positive constant η such that $||d_k||_2 \geq \eta$ for $k \in K'$. By Lemma 4.2, there exists $\hat{\eta} > 0$ such that

$$\nabla_t \phi(x_k + td_k, r)|_{t=0} \leq -\hat{\eta} < 0. \tag{4.25}$$

Thus, there exists a constant $\sigma > 0$ and sufficiently small $t_k > 0$ such that for $k \in K'$,

$$\phi(x_k + t_k d_k, r) \leq \phi(x_k, r) - \sigma. \tag{4.26}$$

The above inequality implies that

$$\Sigma_{k\in K'}(\phi(x_k + t_k d_k, r) - \phi(x_k, r)) \leq -\Sigma_{k\in K'}\sigma = -\infty, \tag{4.27}$$

which is a contradiction. This completes the proof. □

In the following theorem, we assume that (d_{k2}, λ_k) is a Kuhn–Tucker pair of (2.9)–(2.12) at x_k, where $\lambda_k \in R^m$ is a Lagrange multiplier vector associated with d_{k2}.

THEOREM 4.7. *Suppose that $\{x_k\}$ is an infinite sequence generated by the algorithm, $\{r_k\}$ and $\{\lambda_k\}$ are bounded, and $\{x_k : k \in \hat{K}\}$ is a subsequence converging to x^*. If $||c(x^*)_-|| = 0$, then x^* is a strong stationary point of* (1.1)–(1.3).

Proof. Since (d_{k2}, λ_k) is a Kuhn–Tucker pair of (2.9)–(2.12) at x_k, we have

$$g_k + B_k d_{k2} - \nabla c(x_k)\lambda_k = 0, \tag{4.28}$$

$$(\lambda_k)_i \nabla c_i(x_k)^T d_{k2} = 0 \text{ for } i \in I_k, \tag{4.29}$$

$$(\lambda_k)_i(\hat{c}_i(x_k) + \nabla c_i(x_k)^T d_{k2}) = 0 \text{ for } i \in \bar{I}_k, \tag{4.30}$$

$$(\lambda_k)_i \geq 0 \text{ for } i \in I, \tag{4.31}$$

and (2.10)–(2.12) hold. Moreover, (d_{k1}, μ_{J_k}) satisfies that

$$B_k d_{k1} + r_k \nabla c_{J_k}(x_k)\mu_{J_k} = 0, \tag{4.32}$$

$$\mu_{J_k} \in \partial ||u|| \big|_{u=(c_{J_k}(x_k)+\nabla c_{J_k}(x_k)^T d_{k1})_-}, \tag{4.33}$$

where $\mu_{J_k} \in R^{|J_k|}$ is a vector with $(\mu_{J_k})_i (i \in J_k)$ as its components. It follows from (4.33) that $(\mu_{J_k})_i \leq 0$ for $i \in I_k$. Thus, we have

$$g_k + B_k d_k - \nabla c(x_k)u_k = 0, \tag{4.34}$$

$$(u_k)_i(c_i(x_k) + \nabla c_i(x_k)^T d_k) = 0 \text{ for } i \in \bar{I}_k, \tag{4.35}$$

$$(u_k)_i \geq 0 \text{ for } i \in I, \tag{4.36}$$

where

$$(u_k)_i = (\lambda_k)_i - r_k \tau_k (\mu_{J_k})_i \quad \text{for } i \in J_k, \tag{4.37}$$

and

$$(u_k)_i = (\lambda_k)_i \quad \text{for } i \in \bar{I}_k. \tag{4.38}$$

Let $\mathcal{I}(x^*) = \{i : i \in I_k \text{ for infinitely many } k \in \hat{K}\}$, $I(x^*) = \{i \in I : c_i(x^*) = 0\}$. Then $I(x^*) \supset \mathcal{I}(x^*)$.

By (4.33), $||\mu_{J_k}||_0 \leq 1$, where $||\cdot||_0$ is the dual norm of $||\cdot||$ defined by (2.1). Then it follows from Lemma 4.6 that there exists a cluster point $u^* \in R^m$ of $\{u_k\}$ such that

$$g(x^*) - \nabla c(x^*)u^* = 0, \tag{4.39}$$

$$(u^*)_i c_i(x^*) = 0 \text{ for } i \in I, \tag{4.40}$$

with $(u^*)_i \geq 0$ for $i \in I$. □

The condition on λ_k is not restrictive. The boundedness of $\{r_k\}$ implies that (2.15) holds for sufficiently large k. Thus, by (4.32)–(4.33) and (4.28), we have

$$r_k \geq ((\nabla c(x_k)^T d_{k1})^T \lambda_k)/||\nabla c(x_k)^T d_{k1}|| \tag{4.41}$$

for sufficiently large k. On the other hand, if we suppose the Mangasarian–Fromovitz condition holds at x^*, it can be proved that λ_k is bounded.

It should be noted that the above convergence results do not rely on any linear independence assumption of the gradients of the constraints. Thus, the algorithm may terminate at some iteration, which is not a Kuhn–Tucker point of (1.1)–(1.3), even if the penalty parameter is bounded. A simple example will demonstrate this case.

Example 4.8. Consider the problem

$$\min\ y_1 + (1/2)y_2^2 \tag{4.42}$$

$$\text{s.t. } (1/2)y_1^2 = 0, \tag{4.43}$$

$$y_1 + y_2^3 - 3/2 = 0. \tag{4.44}$$

Let the penalty parameter $r = 1$; the algorithm will terminate at $(1, 0)$, which is not a Kuhn–Tucker point of (4.42)–(4.44).

5. Local convergence. To study local convergence properties of the algorithm, we make the following assumption.

Assumption 5.1. (1) $x_k \to x^*$, where x^* is a Kuhn–Tucker point of (1.1)–(1.3); (2) let $I^* = \{i \in I : c_i(x^*) = 0\}$; $\nabla c_i(x^*)(i \in E \cup I^*)$ are linearly independent; (3) $r_k = r$ for $k \geq \hat{k}$, where $r > 0$ is a constant, and $\hat{k}$ is a sufficiently large positive integer.

The definitions of (2.4)–(2.5) imply that for infinitely many k, there exists a small $\epsilon > 0$ such that $c_i(x_k) \geq \epsilon$ for $i \in \bar{I}_k$. Thus, by Assumption 4.3 and (2.8), we have $\tau_k \geq \tau_0$ for infinitely many k, where $\tau_0 > 0$ is a constant.

For sufficiently large k, by definitions of (2.4)–(2.5), $\bar{I}_k \supseteq \bar{I}_{k+1}$. Thus, $I_k = I^*$ for sufficiently large k. Moreover, under Assumption 5.1, it follows from (3.8) that $||d_{k1}||_2 \to 0$ for $k \to \infty$. Therefore, $\tau_k \to 1$ for sufficiently large k.

LEMMA 5.2. *Under Assumption* 5.1, *suppose that* d_{k1} *is a solution of* (2.7) *at the point* x_k; *then there exists a sufficiently large* k', *such that for* $k \geq k'$,

$$(c_{J_k}(x_k) + \nabla c_{J_k}(x_k)^T d_{k1})_- = 0. \tag{5.1}$$

Proof. The first-order necessary condition of (2.7) imply that (4.32)–(4.33) hold and $||\mu_{J_k}||_0 \leq 1$ with $||\cdot||_0$ being the dual norm of $||\cdot||$ defined by (2.1). If at the kth iteration $(c_{J_k}(x_k) + \nabla c_{J_k}(x_k)^T d_{k1})_- \neq 0$, then $||\mu_{J_k}||_0 = 1$.

Define $p_k = ||B_k d_{k1} + r_k \nabla c_{J_k}(x_k)\mu_{J_k}||_2$ and $J^* = E \cup I^*$. If for sufficiently large k, $(c_{J_k}(x_k) + \nabla c_{J_k}(x_k)^T d_{k1})_- \neq 0$, then it follows from Lemma 4.6 and the equivalence of the norm that

$$\begin{aligned} p_k &= ||r_k \nabla c_{J^*}(x^*)\mu_{J_k}||_2 + O(||x_k - x^*||_2) + O(||d_{k1}||_2) \\ &\geq r_k ||\mu_{J_k}||_2 / ||\nabla c_{J^*}(x^*)^+||_2 + o(1) \\ &\geq c_0 r_k ||\mu_{J_k}||_0 / ||\nabla c_{J^*}(x^*)^+||_2 + o(1) \\ &\geq c_0 r / (2||\nabla c_{J^*}(x^*)^+||_2), \end{aligned} \tag{5.2}$$

where $\nabla c_{J^*}(x^*) \in R^{n \times |J^*|}$ is a matrix with $\nabla c_i(x^*)$ $(i \in J^*)$ as its volume vectors, $\nabla c_{J^*}(x^*)^+$ is its generalized inverse matrix, and $c_0 > 0$ is a constant. Equation (5.2) contradicts (4.32). This completes our proof. □

The above lemma shows that there exists a sufficient large integer k_0, such that for $k \geq k_0$, the piecewise quadratic subproblem (2.7) is equivalent to the following quadratic programming problem:

$$\min\ \frac{1}{2} d^T B_k d \tag{5.3}$$

$$\text{s.t. } c_i(x_k) + \nabla c_i(x_k)^T d = 0, \quad i \in E, \tag{5.4}$$

$$c_i(x_k) + \nabla c_i(x_k)^T d \geq 0, \quad i \in I_k. \tag{5.5}$$

Assumption 5.3. Suppose that λ^* is a Lagrangian multiplier vector associated with x^*: (1) The strict complementarity condition holds at (x^*, λ^*); (2) $\nabla^2 L(x^*, \lambda^*)$ is positive definite for all nonzero d in the null space $\{d : \ \nabla c_i(x^*)^T d = 0, \ \ i \in E \cup I^*\}$, where $L(x, \lambda)$ is defined as (1.8).

It follows from Assumption 5.3 that (x^*, λ^*) is an isolated Kuhn–Tucker pair of (1.1)–(1.3). If the conditions in Assumption 5.3 hold, then for sufficiently large k, d_{k1} derived by (5.3)–(5.5) is a solution of the problem

$$\min \ \frac{1}{2} d^T B_k d \tag{5.6}$$

$$\text{s.t. } c_i(x_k) + \nabla c_i(x_k)^T d = 0 \quad \text{for } i \in E \cup I^*, \tag{5.7}$$

and d_{k2} generated by (2.9)–(2.12) solves

$$\min \ g_k^T d + \frac{1}{2} d^T B_k d \tag{5.8}$$

$$\text{s.t. } \nabla c_i(x_k)^T d = 0 \quad \text{for } i \in E \cup I^*. \tag{5.9}$$

Let $\nabla c_{J^*}(x_k)$ be an $n \times |J^*|$ matrix with $\nabla c_i(x_k)(i \in J^*)$ as its components. By direct calculations, it follows from (5.6)–(5.7) that

$$d_{k1} = -B_k^{-1} \nabla c_{J^*}(x_k)(\nabla c_{J^*}(x_k)^T B_k^{-1} \nabla c_{J^*}(x_k))^{-1} c_{J^*}(x_k), \tag{5.10}$$

and by (5.8)–(5.9),

$$\begin{aligned} d_{k2} = {} & B_k^{-1} \nabla c_{J^*}(x_k)(\nabla c_{J^*}(x_k)^T B_k^{-1} \nabla c_{J^*}(x_k))^{-1} \nabla c_{J^*}(x_k)^T B_k^{-1} g_k \\ & - B_k^{-1} g_k. \end{aligned} \tag{5.11}$$

Thus, $d_{k1} + d_{k2}$ is a solution of the problem

$$\min \ g_k^T d + \frac{1}{2} d^T B_k d \tag{5.12}$$

$$\text{s.t. } c_i(x_k) + \nabla c_i(x_k)^T d = 0 \quad \text{for } i \in J^*. \tag{5.13}$$

The above discussion can be stated as the following lemma.

LEMMA 5.4. *If the conditions in Assumptions* 5.1 *and* 5.3 *hold, then there exists a sufficiently large* k_1, $k_1 \geq k_0$, *such that for* $k \geq k_1$, *the algorithm generates identical directions with the Han–Powell method.*

By Lemma 5.4 and the related results of the *SQP* method (for example, see [1] and [22]), the superlinear convergence of the algorithm is a direct result.

LEMMA 5.5. *Suppose that the conditions in Assumption* 5.3 *hold. If*

$$\lim_{k \to \infty} \frac{||P^*(B_k - \nabla^2 L(x^*, \lambda^*))d_k||_2}{||d_k||_2} = 0, \tag{5.14}$$

where P^* *is a projection matrix on the null space* $\{d : \ \nabla c_i(x^*)^T d = 0, \ \ i \in E \cup I^*\}$; *then*

$$\lim_{k \to \infty} \frac{||x_k + d_k - x^*||}{||x_k - x^*||} = 0. \tag{5.15}$$

A superlinear convergence step may be truncated due to the nonsmoothness of the merit function, which is known as "the Marotos effect" (for example, see [22, 24]). In order to avoid this difficulty, the second-order correction technique is considered by Mayne and Polak [11], Coleman and Conn [5], Fletcher [7], and so on. For our problem, when $||c_{J_k}(x_k)|| \leq \epsilon$ (ϵ is a prescribed number), we solve the subproblem

$$\min_{d \in R^n} \frac{1}{2} d^T B_k d + r_k ||(c_{J_k}(x_k + d_k) + \nabla c_{J_k}(x_k)^T d)_-|| \tag{5.16}$$

to generate the second-order correction step $\tilde{d}_k$. The algorithm with the second-order correction technique is presented, which is a modification to Algorithm 2.1.

ALGORITHM 5.6.

Step 1 [Step 0.] Given $x_0 \in R^n$, $B_0 \in R^{n \times n}$, $r_0 > 0$, $0 < \mu < \frac{1}{2}$, $0 < \beta < 1$, $\rho > 0$, ϵ_0, ϵ_1, ϵ_2, $\epsilon_3 > 0$, $k := 0$.

Generate J_k *and* $\bar{I}_k$ *by* (2.4)–(2.6), *solve* (2.7) *giving* d_{k1};
Calculate τ_k *by* (2.8); *Solve* (2.9) *giving* d_{k2}; $d_k = \tau_k d_{k1} + d_{k2}$;
If $||d_k|| \leq \epsilon_0$, *stop;*
If $||c_{J_k}(x_k)|| \leq \epsilon_1$ *solve* (5.16) *giving* $\tilde{d}_k$; *else* $\tilde{d}_k = 0$.

Step 2. $r_{k+1} := r_k$ *if* (2.15) *holds, otherwise compute* r_{k+1} *by* (2.14).

Step 3. $s = 0, 1, 2, \ldots$; *If*

$$\phi(x_k + \beta^s d_k + \beta^{2s} \tilde{d}_k, r_{k+1}) - \phi(x_k, r_{k+1}) \leq \mu \beta^s (g_k^T d_k + r_{k+1}(||(c(x_k) + \nabla c(x_k)^T d_k)_-|| - ||(c(x_k))_-||)). \tag{5.17}$$

Let $t_k = \beta^s$ *and* $x_{k+1} = x_k + t_k d_k + t_k^2 \tilde{d}$.

Step 4. If $||x_{k+1} - x_k|| \leq \epsilon_3$, *stop.*

Step 5. Compute the values of $f(x)$, $c(x)$, $\nabla f(x)$, *and* $\nabla c(x)$ *at* x_{k+1};
Generate B_{k+1}; $k := k + 1$ *and goto Step* 1.

Similar to the above discussion on Lemmas 5.2 and 5.4, and to the analyses in [11, 22, 24], we have the following result.

THEOREM 5.7. *Under Assumptions* 5.1 *and* 5.3, *suppose that* (5.14) *holds,* $\epsilon_i = 0 (i = 0, 1, 2, 3)$, *and* $\{x_k\}$ *is an infinite sequence generated by Algorithm* 5.6. *Then*

$$\lim_{k \to \infty} \frac{||x_k + d_k + \tilde{d}_k - x^*||}{||x_k - x^*||} = 0, \tag{5.18}$$

and there exists a sufficiently large k_2 *such that for* $k \geq k_2$, $t_k = 1$. *Thus,* $\{x_k\}$ *converges Q-superlinearly.*

6. Numerical results. A FORTRAN subroutine was programmed to test our algorithm. Our experiments were done on an SGI indigo workstation at the State Key Laboratory of Scientific and Engineering Computing, Chinese Academy of Sciences, Beijing.

The norm in (2.1) is selected to be the l_∞ norm. We solve the piecewise quadratic subproblem (2.7) by reformulating it as follows:

$$\min \frac{1}{2} w^T Q_k w + p_k^T w \tag{6.1}$$

$$\text{s.t. } y - \nabla c_i(x_k)^T d \geq c_i(x_k) \quad \text{for } i \in E, \tag{6.2}$$

$$y + \nabla c_i(x_k)^T d \geq -c_i(x_k) \quad \text{for } i \in J_k, \tag{6.3}$$

where $Q_k = \begin{pmatrix} B_k & \\ & 0 \end{pmatrix} \in R^{(n+1)\times(n+1)}$, $w = \begin{pmatrix} d \\ y \end{pmatrix} \in R^{n+1}$, $p_k = \begin{pmatrix} 0 \\ r_k \end{pmatrix} \in R^{n+1}$. Problem (6.1)–(6.3) is a convex quadratic programming problem, which is, in our algorithm, solved by Powell's subroutine ZQPCVD [15]. The second-order correction subproblem (5.16) is solved similarly.

The first test problem that we solved is taken from [16]:

$$\min x_1 x_2 \tag{6.4}$$

$$\text{s.t.} -\sin(x_1) \geq 0, \tag{6.5}$$

$$\cos(x_1) \geq 0, \tag{6.6}$$

$$-x_1^2 - x_2^2 + \pi/2 \geq 0, \tag{6.7}$$

$$x_1 + \pi \geq 0, \tag{6.8}$$

$$x_2 + \pi/2 \geq 0, \tag{6.9}$$

and the standard starting point is $x_0 = (0, 5)^T$. Sahba's algorithm terminates at the point $x^* = (0, -1.25331)^T$, which is an approximate Kuhn–Tucker point and not the approximate minimum point of (6.4)–(6.9). The other test problems are from Hock and Schittkowski [9].

In our implementation of the algorithm, a small positive tolerance number ϵ is introduced and the index sets

$$I_k(\epsilon) = \{i \in I : c_i(x_k) \leq \epsilon\}, \tag{6.10}$$

$$\bar{I}_k(\epsilon) = \{i \in I : c_i(x_k) > \epsilon\}, \tag{6.11}$$

$$J_k(\epsilon) = I_k(\epsilon) \cup E \tag{6.12}$$

are employed instead of (2.4)–(2.6).

For each problem, the standard initial point is used. We choose initial parameters $\mu = 0.1$, $\beta = 0.5$, $\rho = 1$, and $\epsilon_i = 10^{-6}$ for $i = 0, 1, 2, 3$. The choice of the initial penalty parameter is scale dependent and $r_0 = 1$ is chosen for our test problems. The initial Lagrangian Hessian estimate $B_0 = I$ and B_k is updated by the damped BFGS formula (see [14]):

$$B_{k+1} = B_k - \frac{B_k s_k s_k^T B_k}{s_k^T B_k s_k} + \frac{y_k y_k^T}{s_k^T y_k}, \tag{6.13}$$

where

$$y_k = \begin{cases} \hat{y}_k, & \hat{y}_k^T s_k \geq 0.2 s_k^T B_k s_k, \\ \theta_k \hat{y}_k + (1-\theta_k) B_k s_k, & \text{otherwise}, \end{cases} \tag{6.14}$$

and $\hat{y}_k = g_{k+1} - g_k + (\nabla c(x_{k+1}) - \nabla c(x_k))\lambda_k$, $s_k = x_{k+1} - x_k$, $\theta_k = 0.8 s_k^T B_k s_k / (s_k^T B_k s_k - s_k^T \hat{y}_k)$, λ_k is a multiplier associated with (2.9)–(2.12).

The test problems are also solved by Powell's subroutine VMCWD, which is a very successful algorithm for many nonlinear programming problems. The error tolerance for VMCWD is 10^{-8}.

The subroutine VMCWD failed to solve Sahba's problem (6.4)–(6.9) since the constraints seem to be inconsistent after the first iteration. The numerical results given by our algorithm are presented in Table 1, where $R - KT$ and $R - CV$ represent the l_2 norms of the gradient of the Lagrangian and the violation of the constraints,

TABLE 1

respectively. The algorithm terminates at the approximate minimum point of (6.4)–(6.9).

Some numerical results for equality constrained optimization problems have been reported in Liu and Yuan [10]. It has been noticed that our algorithm can overcome the difficulties associated with the linear dependence of the gradients of the constraints, since an unconstrained subproblem is solved at each iterate.

The numerical results for other test problems are listed in Table 2. The problems are numbered in the same way as in Hock and Schittkowski [9]. For example, "HS43" is problem 43 in Hock and Schittkowski [9]. NI, NF, and NG represent the numbers of iterations, function, and gradient calculations, respectively.

The numerical results show that our algorithm is comparable to VMCWD. However, our algorithm requires slightly more function evaluations.

MODELING MICROSTRUCTURE EVOLUTION USING GRADIENT-WEIGHTED MOVING FINITE ELEMENTS*

ANDREW KUPRAT†

Abstract. Microstructure evolution, where grain boundaries evolve by mean curvature motion, is modeled in three dimensions (3-D) using gradient-weighted moving finite elements (GWMFE). To do this, we modify and extend an existing 2-D GWMFE code to create a new code GRAIN3D which makes the 3-D microstructure modeling possible. The right-hand side term which drives the GWMFE motion can be viewed as surface tension forces, that is, as the negative gradient of the surface integral of a constant energy density μ on the triangular interfacial grid. Extensions to the method include equations for the motion of tetrahedra that are conformally attached to the moving piecewise linear triangular facets which represent the GWMFE discretization of the evolving grain boundaries. We present some new regularization terms which control element quality, as well as preventing element collapse in the simulation. New capabilities for changing the mesh topology are used to keep the grid edge lengths below a maximum allowable length $h_{\max}$ and to mimic actual changes in the physical topology, such as collapse and disappearance of individual grains. Validating runs are performed on some test cases that can be analytically solved, including collapse of a spherical grain and the case of columnar microstructure. In the spherical collapse case, the GWMFE method appears to have an error in the surface area collapse rate $-\frac{dA}{dt}$ which is $\mathcal{O}((\Delta\theta)^2)$, where $\Delta\theta$ is a measure of the angular resolution of the mesh. Finally, a run is presented where a true 3-D microstructure (possessing triple lines and quadruple points in the interior and triple points on the exterior boundaries) is evolved to a "2-D" columnar microstructure and finally evolved down to a single grain.

Key words. microstructure evolution, motion by mean curvature, gradient-weighted moving finite elements, unstructured tetrahedral meshes, deforming grids, changing grid topology, front-tracking

1. Introduction.

Under close examination, a sample of metal (such as copper or aluminum used in semiconductor manufacture) possesses a microstructure wherein the sample is decomposed into separate grains. The atoms in individual grains exist in a crystal lattice and the lattice orientations of adjacent grains differ. The boundary surfaces between grains are thus areas of lattice misalignment and effectively possess an excess energy per unit grain boundary area. In the simplest approximation, this excess energy density is a constant μ per unit area for all grain boundaries. When the sample is heated, the grain boundaries become mobile and grain growth takes place. The motion resulting from the desire to minimize surface energy is *mean curvature motion* where the normal velocity of a point on a grain boundary is proportional to the mean curvature at that point [19]. Thus the grain boundaries move as if they are under the influence of a driving force proportional to the mean curvature, with motion opposed by a frictional force proportional to normal velocity (as if the grain boundaries are immersed in a uniform, isotropic viscous medium).

Approaches to mean curvature motion and/or grain growth modeling have included 2-D front-tracking models [5]; Surface Evolver, a popular energy gradient descent method [2]; level sets [23]; vertex methods [6, 9]; and gradient-weighted moving finite elements (GWMFE) [1, 3, 4, 15]. 2-*D front tracking models* have been the workhorse of grain growth modeling—they have been used in many research articles and are particularly successful in the case of thin films, where the microstructure is for the most part columnar. *Surface Evolver* is a widely used code available over the web which allows the user to interactively reduce the surface energies of arbitrary surface configurations. Constant surface energy leads to mean curvature motion, but much more general energies and motions are possible. The method uses an explicit step where mesh points are advanced along either the energy gradient descent direction or the conjugate gradient direction. *Level set methods* have the advantage of automatically resolving certain types of topological changes that occur during grain evolution such as *self-pinchoff* where a single grain divides into two or more grains. However, when three or more grains intersect at a point (*triple* or *quadruple* point) or on a curve (*triple line*), the standard level set formulation fails and a nontrivial increase in algorithmic complexity is necessary to correctly model the evolution of these points of intersection [21, 25]. *Vertex methods* consider points of maximum grain intersection (triple or quadruple points) and assume the curves between these points are straight lines. These methods may produce valid statistical results on large collections of grains but cannot hope to compute detailed grain shapes.

Moving finite elements (MFE) [1, 14, 16] is a standard Galerkin finite element method of computing the solution $u(\mathbf{x}, t)$ of a time-dependent PDE

$$u_t = F(\mathbf{x}, t, u, \nabla u, \ldots),$$

with the additional novel feature that the Galerkin formalism is used to compute domain velocities for the computational grid points in addition to determining the time derivative of u at the grid points. Because this method would frequently overconcentrate computational nodes in the steep portions of the graph of u, it was necessary to devise GWMFE which deemphasized the importance of node placement in high-gradient regions by multiplying the PDE residual by the gradient-weighting factor $\frac{1}{\sqrt{1+|\nabla u|^2}} \leq 1$. It turns out that GWMFE can be viewed as a nonweighted method when the independent variables are taken to be the nodal positions on the graph of u, the residual is taken to be the norm of errors in u_t in the direction normal to the graph of u, and the inner product integrals are taken over the surface area of the graph. In fact, GWMFE is naturally seen to be a method for evolving a surface *without* the restriction that the surface be the graph of a function u and is thus a very natural way to compute mean curvature motion. Examples of GWMFE applied to normal motion by mean curvature are given in [15, 4]; other examples of GWMFE computations involving mean curvature are given in [12, 13, 18]. Other GWMFE computations and an exposition of the method from a somewhat different viewpoint are given in the now standard book by Baines [1].

Recently, we took the 2-D version of GWMFE used in [4], which represents evolving surfaces by piecewise linear triangular elements, and incorporated it into a new code GRAIN3D which extended its capabilities so that general microstructure evolution could be simulated. Specifically, a program called LaGriT [8] was used to produce 3-D models of metallic microstructure which consisted of a domain $\Omega \subseteq \mathbb{R}^3$ partitioned into grains, each of which were composed of hundreds of tetrahedra. The triangular interfaces between the grains were extracted from the 3-D model and evolved by

GRAIN3D using the GWMFE algorithm. Additional equations of motions were devised for the "extra" vertices in the 3-D model that were interior to the grains and not on the grain boundaries. Motions were determined solely by the requirement that the tetrahedra remain well-shaped (i.e., have a low aspect ratio) as the surfaces to which they are conformally attached deform under mean curvature motion. Finally, grid topology-change software was written to maintain to some degree a roughly constant spacing between grid points as the mesh deforms and to make possible physically significant topology changes, such as the collapse and disappearance of certain grains during the course of evolution.

The new capability of supporting a system of tetrahedra that is conformally attached to the moving triangular surfaces will be crucial in the future when we use these volume elements to compute ambient quantities throughout Ω (such as temperature). This will allow more detailed simulations where the medium's resistance to grain boundary movement is not assumed uniform. (Note, for example, that grain boundary mobility in fact strongly depends on temperature [19].)

In section 2, we review GWMFE from a surface evolution point of view. We present a detailed derivation of how the GWMFE right-hand side integral involving curvature is evaluated and show that this integral can be seen as the negative gradient, with respect to the nodal position vector $\mathbf{x} = (x_i, y_i, z_i)$ of the surface integral of a constant energy per unit area μ on the discretized interfaces. In section 3, we review regularization terms necessary for the GWMFE method to work efficiently, and we introduce a right-hand regularization term involving a quality force that controls element quality as well as preventing element collapse in the simulation. We also present a regularization force that prevents excessive stretching of elements, derived from a small artificial surface energy associated with each triangular facet. In section 4, we introduce additional equations for moving tetrahedra conformally attached to the GWMFE triangular interface mesh. In section 5, we touch on grid maintenance operations necessary to keep grid edge lengths below a maximum allowable $h_{\max}$. In section 6, we describe *recoloring* operations necessary to perform important topological changes in the microstructure simulation, such as the collapse and disappearance of individual grains. In section 7, we compare numerical solutions computed by GRAIN3D to analytic solutions for the cases of spherically symmetric grain collapse and columnar microstructures. In section 8, we show a numerical example where GRAIN3D evolves a truly 3-D microstructure.

2. Mean curvature motion and GWMFE.

2.1. Review of method. We use GWMFE [3, 4, 15] to move a multiply connected network of piecewise linear triangles for the modeling of deformation of 3-D grains. In one model of metallic grain growth [19], interface surfaces obey the simple equation

$$v_n = \mu K,$$

where v_n is the normal velocity of the interface, K is the curvature, and μ is the product of the excess energy per unit area and the mobility of the grain boundary. K is the sum of principle curvatures, i.e., twice the mean curvature. In this paper, we assume that μ is constant, i.e., it does not depend on the choice of materials on either side of the interface, nor does it depend on the orientation of the interface. We represent interfaces as parametrized surfaces:

$$\mathbf{x}(s_1, s_2) = \sum_{\text{nodes } j} \alpha_j(s_1, s_2)\mathbf{x}_j.$$

Here, (s_1, s_2) is the surface parametrization, the sum is over the N interface nodes, $\alpha_j(s_1, s_2)$ is the piecewise linear basis function (hat function) which is unity at node j and zero at all other interface nodes, and $\mathbf{x}_j = (x_j^1, x_j^2, x_j^3) \in \mathbb{R}^3$ is the vector position of node j.

We have that

$$\dot{\mathbf{x}}(s_1, s_2) = \sum_j \alpha_j(s_1, s_2)\dot{\mathbf{x}}_j,$$

is the velocity of the surface at the point $\mathbf{x}(s_1, s_2)$ (based upon linear interpolation of node velocities) and

$$v_n = \dot{\mathbf{x}}(s_1, s_2) \cdot \hat{\mathbf{n}} \quad (\hat{\mathbf{n}} \text{ is local surface normal}).$$

So

$$v_n = \sum_j (\hat{\mathbf{n}}\alpha_j) \cdot \dot{\mathbf{x}}_j. \tag{1}$$

In effect, we have that the $3N$ basis functions for v_n are $n_k\alpha_j$, where $\hat{\mathbf{n}} = (n_1, n_2, n_3)$. These basis functions are discontinuous piecewise linear, since the n_k are piecewise constant.

The GWMFE method is to minimize

$$\int (v_n - \mu K)^2 \, dS \tag{2}$$

over all possible values for the derivatives $\dot{\mathbf{x}}_i$. (The integral is over the surface area of the interfaces.) We thus obtain

$$\begin{aligned} 0 &= \frac{1}{2}\frac{\partial}{\partial \dot{x}_i^k} \int (v_n - \mu K)^2 \, dS, \quad 1 \le k \le 3, \quad 1 \le i \le N \\ &= \int (v_n - \mu K) n_k \alpha_i \, dS. \end{aligned}$$

Using (1), we obtain a system of $3N$ ODEs:

$$\left[\int \hat{\mathbf{n}}\hat{\mathbf{n}}^T \alpha_i \alpha_j \, dS \right] \dot{\mathbf{x}}_j = \int \mu K \hat{\mathbf{n}} \alpha_i \, dS,$$

or

$$\mathbf{C}(\mathbf{x})\dot{\mathbf{x}} = \mathbf{g}(\mathbf{x}), \tag{3}$$

where $\mathbf{x} = (x_1^1, x_1^2, x_1^3, x_2^1, \ldots, x_N^3)^T = (\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_N)^T$ is the $3N$-vector containing the x, y, and z coordinates of all N interface nodes, $\mathbf{C}(\mathbf{x})$ is the matrix of inner products of basis functions, and $\mathbf{g}(\mathbf{x})$ is the right-hand side of inner products involving surface curvature. Since $\hat{\mathbf{n}}\hat{\mathbf{n}}^T$ is a 3×3 matrix, it is clear that $\mathbf{C}(\mathbf{x})$ has a 3×3 block structure.

The ODEs are solved with an implicit second order backwards difference variable time-step ODE solver [3]. We use generalized minimal residual (GMRES) iteration [22] with block-diagonal preconditioner to solve the linear equations arising from the Newton's method. (A more complex and robust choice of iterative method and preconditioner is used in [24] to solve systems involving indefinite Jacobians that arise when GWMFE is applied to problems involving convection.) The ODEs are scaled so that the variation of the x_j^k values is $\mathcal{O}(1)$ and the truncation error η (i.e., the maximum acceptable estimated error made in the x_j^k every time step) is usually set to 10^{-3}.

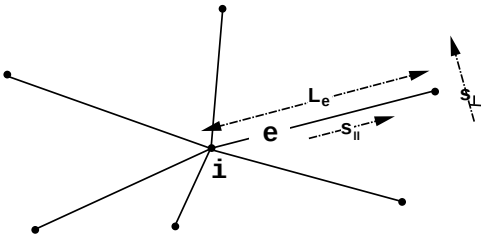

FIG. 1. *Definition of some quantities around node i, edge e.*

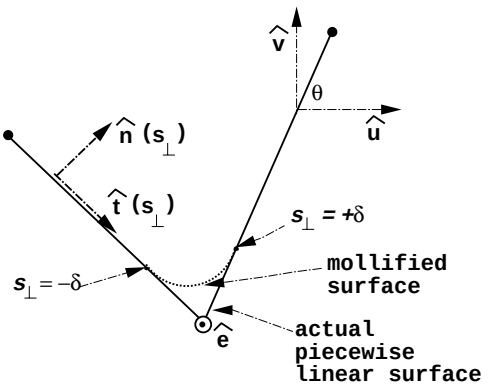

FIG. 2. *Cross-sectional view of grid. Edge e is orthogonal to page.*

2.2. Evaluation of right-hand side curvature term. The right-hand side term due to curvature,

$$\int \mu K \hat{\mathbf{n}} \alpha_i \, dS,$$

requires special consideration because on a piecewise linear manifold K is actually a distribution which is zero in the interiors of the triangles and infinite on the edges. Evaluation of this term is undertaken by mollifying (smoothing) the manifold in a small neighborhood (within a small distance δ) of the edges and then showing that $\int K \hat{\mathbf{n}} \alpha_i \, dS$ on the δ-mollified manifold tends to a limit as $\delta \to 0$ which is independent of the mollification process. This mollification interpretation is extensively explained in section 2.6 of [15], sections 2.3 and 4.10 in [3] (for 1-D), and sections 3.3 and 6.4 in [4]. For completeness we include a derivation here. Indeed, referring to Figure 1, we consider one of the edges e emanating from node i and we let $s_{||}$ be the arclength parameter running parallel to the edge and $s_\perp$ be the arclength parameter corresponding to movement on the manifold perpendicular to the edge. The length of the edge is L_e. In Figure 2, we show the intersection of the surface with a plane orthogonal to the edge e. The intersection yields a smoothed curve (due to the mollification of the surface). We assume the mollified region runs from $s_\perp = -\delta$ to $s_\perp = +\delta$. The intersection curve has tangent $\hat{\mathbf{t}}(s_\perp)$ which varies smoothly between $\hat{\mathbf{t}}(-\delta)$ and $\hat{\mathbf{t}}(+\delta)$. $\hat{\mathbf{n}}(s_\perp)$ is the normal to the surface, which smoothly varies between $\hat{\mathbf{n}}(-\delta)$ and $\hat{\mathbf{n}}(+\delta)$. We define $\hat{\mathbf{u}}$, $\hat{\mathbf{v}}$ to be unit vectors in the plane with $\hat{\mathbf{u}} \times \hat{\mathbf{v}} = \hat{\mathbf{e}}$ (the unit vector parallel

to e). θ is defined as the angle that $\hat{\mathbf{t}}(s_\perp)$ makes with $\hat{\mathbf{u}}$. Now we write

$$\begin{aligned}\int \mu K\hat{\mathbf{n}}\alpha_i \, dS &= \mu \sum_{\substack{\text{edges } e \\ \text{with } i\in e}} \int_0^{L_e} \left(\int_{-\delta}^{\delta} K\hat{\mathbf{n}}\alpha_i \, ds_\perp \right) ds_{||} \\ &\approx \mu \sum_{\substack{\text{edges } e \\ \text{with } i\in e}} \left(\int_0^{L_e} \alpha_i(s_{||}) \, ds_{||} \right) \left(\int_{-\delta}^{\delta} \frac{d\theta}{ds_\perp} \hat{\mathbf{n}} \, ds_\perp \right).\end{aligned}$$

That is, the right-hand side curvature inner product at node i is the sum of contributions from edges e incident on i. In the 2δ-wide strip near edge e, $\alpha_i(s_{||}, s_\perp)$ is nearly a piecewise linear function of only $s_{||}$ which is 1 at $s_{||} = 0$ and 0 at $s_{||} = L_e$. This means that the first integral evaluates to $\frac{1}{2}L_e$. The curvature K of the mollified surface is $\frac{d\theta}{ds_\perp}$ since there is no curvature parallel to edge e in the unmollified surface (and hence no curvature in this direction for the mollified surface as well). Now

$$\begin{aligned}\int_{-\delta}^{\delta} \frac{d\theta}{ds_\perp} \hat{\mathbf{n}} \, ds_\perp &= \int_{\theta(-\delta)}^{\theta(\delta)} \hat{\mathbf{n}} \, d\theta \\ &= \int_{\theta(-\delta)}^{\theta(\delta)} (-\sin\theta\hat{\mathbf{u}} + \cos\theta\hat{\mathbf{v}}) \, d\theta \\ &= \cos\theta\hat{\mathbf{u}} + \sin\theta\hat{\mathbf{v}} \Big|_{\theta(-\delta)}^{\theta(\delta)} \\ &= \hat{\mathbf{t}}(\delta) - \hat{\mathbf{t}}(-\delta).\end{aligned}$$

So we obtain as $\delta \to 0$ that

$$\int \mu K\hat{\mathbf{n}}\alpha_i \, dS = \mu \sum_{\substack{\text{edges } e \\ \text{with } i\in e}} \frac{1}{2} L_e(\hat{\mathbf{t}}_e^{(1)} + \hat{\mathbf{t}}_e^{(2)}),$$

where $\hat{\mathbf{t}}_e^{(1)}$, $\hat{\mathbf{t}}_e^{(2)}$ are unit normals in the piecewise linear surface which are both orthogonal to e. $\hat{\mathbf{t}}_e^{(1)}$ points into one triangle sharing e, and $\hat{\mathbf{t}}_e^{(2)}$ points into the other triangle sharing e. Now we can rewrite this sum as a sum over the triangles incident on i:

$$\int \mu K\hat{\mathbf{n}}\alpha_i \, dS = \mu \sum_{\substack{\text{triangles } k \\ \text{with } i\in k}} \frac{1}{2} \big(L_k^{(1)}\hat{\mathbf{t}}_k^{(1)} + L_k^{(2)}\hat{\mathbf{t}}_k^{(2)}\big),$$

where for each triangle k, $L_k^{(1)}$ is the length of one of the edges bordering k that contains i, $\hat{\mathbf{t}}_k^{(1)}$ is the inward normal to that edge, and $L_k^{(2)}$, $\hat{\mathbf{t}}_k^{(2)}$ are the corresponding quantities for the other edge. (See Figure 3.)

Interestingly, since $\sum_{j=1}^{3} L_k^{(j)}\hat{\mathbf{t}}_k^{(j)} = 0$ (again, see Figure 3 for the definition of $L_k^{(3)}$, $\hat{\mathbf{t}}_k^{(3)}$), we have

$$\begin{aligned}\int \mu K\hat{\mathbf{n}}\alpha_i \, dS &= -\mu \sum_{\substack{\text{triangles } k \\ \text{with } i\in k}} \frac{1}{2} L_k^{(3)}\hat{\mathbf{t}}_k^{(3)} \\ &= -\nabla_{\mathbf{x}_i} \left(\sum_{\substack{\text{triangles } k \\ \text{with } i\in k}} \mu A_k \right),\end{aligned}$$

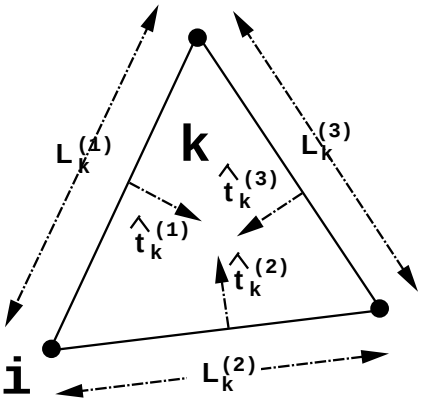

FIG. 3. *Definition of quantities around node i, triangle k.*

where A_k is the area of triangle k. If we attribute an energy of μ per unit area to the surface, then this becomes

$$\int \mu K \hat{\mathbf{n}} \alpha_i \, dS = -\nabla_{\mathbf{x}_i} E, \tag{4}$$

where

$$E = \sum_{\text{triangles } k} \mu A_k \tag{5}$$

is the total energy of the surface. This shows that the node-concentrated right-hand side force on the ith node is derivable from the negative gradient, with respect to the node position variables $\mathbf{x}_i = (x_i, y_i, z_i)$ of the surface integral of an assumed constant surface energy density of μ in our GWMFE manifold. This mirrors the physical model where mean curvature motion was derived under the assumption that the mechanism of grain growth is minimization of excess surface energy proportional to the surface integral of μ. This negative gradient force on the ith node is exactly that which would be given by a "surface tension" of magnitude μ in the planar triangular cells of our GWMFE manifold, as pointed out in [15, 4].

We note here that the form (4)–(5) for the right-hand side PDE driving terms makes conceivable computations where $\mu = \mu(\hat{\mathbf{n}})$, that is, where μ depends on the direction of the normal at the surface. In this case, one need only loop through triangles in the mesh and evaluate the quantities (4)–(5) using the orientation-dependent μ. If μ depends strongly on $\hat{\mathbf{n}}$, faceting of the surface can occur [7].

3. Regularization. In [15] it is shown how (3) represents a balance of forces on the moving GWMFE surface. The right-hand side represents driving forces from the PDE, and the left-hand side represents viscosity forces that resist these driving forces; all these forces are taken to be concentrated at the nodes. In practice, certain grid configurations can cause $\mathbf{C}(\mathbf{x})$ to be nearly singular, so that there exist essentially undamped node motions that lead to chaotic grid behavior and collapse of the time step. To alleviate this, Carlson and Miller [4] added a term (a left-hand side regularizing force) that was of the form $\mathbf{C}_1(\mathbf{x})\dot{\mathbf{x}}$ so that the total matrix $(\mathbf{C} + \mathbf{C}_1)(\mathbf{x})$ was positive definite.

In addition certain grid behaviors are possible, such as the collapse to zero of the inscribed radius of a very thin or large aspect ratio triangle, which has no physical

significance (i.e., which does not affect the shape of the surface) but which causes a catastrophic loss of time step and run termination. To alleviate these problems, small regularizing forces are added to the right-hand side of (3). The form of these forces differs from those used in [4].

3.1. Left-hand side grid viscosity forces. Suppose a node i and its neighboring nodes are all nearly coplanar. More precisely, suppose that there exists a plane P (spanned by $\hat{\mathbf{u}}$ and $\hat{\mathbf{v}}$) such that $\mathbf{x}_i$ and each member of $\{\mathbf{x}_j \mid \text{nodes } i \text{ and } j \text{ share an edge}\}$ have normal distance $\leq \eta$ to this plane. Then, since the local truncation error tolerance is η, computationally this situation is indistinguishable from the case where $\mathbf{x}_i$ and all the $\mathbf{x}_j$ exactly lie in the same plane. In this case, it is apparent that one could alter $\dot{\mathbf{x}}_i$ (or $\mathbf{x}_i$) by a plane vector $a\hat{\mathbf{u}} + b\hat{\mathbf{v}}$ without altering the normal velocity (or the shape) of the surface in the neighborhood of node i. Since (3) is derived from (2), which is a minimization that is unaffected by these additional node motions for node i, we conclude that $\mathbf{C}(\mathbf{x})$ nearly annihilates the 2-D subspace corresponding to the in-plane motions of node i. If this degeneracy or near-degeneracy is not remedied, the motion of node i will not be smooth, if it is defined at all, and the time step will decrease greatly. (This describes a *planar*-type degeneracy at node i; there are also possible *crease*-type geometrical degeneracies in which the manifold has a straight crease through node i, as in the straight ridge of a roof. See section 3.1 of [15] or section 2.4 of [4] for a further discussion and for a derivation of the following grid viscosity forces for GWMFE. Also see Chapters 6 and 7 of [1].)

To remedy such degeneracies, we add the small grid viscosity force

$$\epsilon_1 \left[\int \mathbf{I}_3 (\nabla_{\mathbf{s}} \alpha_i \cdot \nabla_{\mathbf{s}} \alpha_j) \, dS \right] \dot{\mathbf{x}}_j \equiv \mathbf{C}_1(\mathbf{x}) \dot{\mathbf{x}} \tag{6}$$

to the left-hand side of (3). Here $\mathbf{I}_3$ represents the 3×3 identity matrix, which indicates that grid viscosity is isotropic in that it treats independently and identically the x, y, and z components of the velocities $\dot{\mathbf{x}}_j$. ϵ_1 is a small number, and the gradient $\nabla_{\mathbf{s}}$ is with respect to the tangential coordinate system of the surface. We now show (6) is equal to

$$\epsilon_1 \nabla_{\dot{\mathbf{x}}_i} \frac{1}{2} \int ||\nabla_{\mathbf{s}} \dot{\mathbf{x}}||^2 \, dS. \tag{7}$$

Here $\nabla_{\dot{\mathbf{x}}_i}$ is the gradient with respect to the node velocity $\dot{\mathbf{x}}_i$ and $\dot{\mathbf{x}} = \sum \dot{\mathbf{x}}_j \alpha_j(\mathbf{s})$ is interpolated grid velocity. $\nabla_{\mathbf{s}} \dot{\mathbf{x}}$ is the gradient with respect to surface measure of interpolated grid velocity and, hence, it is a 3×2 matrix. $||\nabla_{\mathbf{s}} \dot{\mathbf{x}}||^2$ is the sum of squares of the six components (i.e., the Froebenius norm). To show (7), we have that

$$\begin{aligned}
\nabla_{\dot{\mathbf{x}}_i} \frac{1}{2} \int ||\nabla_{\mathbf{s}} \dot{\mathbf{x}}||^2 \, dS &= \nabla_{\dot{\mathbf{x}}_i} \frac{1}{2} \int \Big|\Big|\nabla_{\mathbf{s}} \sum_k \dot{\mathbf{x}}_k \alpha_k\Big|\Big|^2 \, dS \\
&= \nabla_{\dot{\mathbf{x}}_i} \frac{1}{2} \int \sum_k \sum_j (\dot{\mathbf{x}}_k \cdot \dot{\mathbf{x}}_j)(\nabla_{\mathbf{s}} \alpha_k \cdot \nabla_{\mathbf{s}} \alpha_j) \, dS \\
&= \int \sum_j \dot{\mathbf{x}}_j (\nabla_{\mathbf{s}} \alpha_i \cdot \nabla_{\mathbf{s}} \alpha_j) \, dS \\
&= \sum_j \left[\int \mathbf{I}_3 (\nabla_{\mathbf{s}} \alpha_i \cdot \nabla_{\mathbf{s}} \alpha_j) \, dS \right] \dot{\mathbf{x}}_j.
\end{aligned}$$

Thus, our regularization force is, for each node, the velocity gradient of a velocity potential and the effect of this force is to reduce $\int ||\nabla_{\mathbf{s}}\dot{\mathbf{x}}||^2\ dS$, a measure of the nonuniformity of the interpolated velocity field.

Using arguments in [3], ϵ_1 is chosen in the range

$$.25\eta^2 \leq \epsilon_1 \leq 25\eta^2, \tag{8}$$

so that the effect of the regularization term dominates only when $\mathbf{x}_i$ and the neighboring $\mathbf{x}_j$ are within η of an exact plane. If the graph is not nearly planar in this sense, the left-hand side will be dominated by $\mathbf{C}(\mathbf{x})\dot{\mathbf{x}}$, which represents viscous node resistance arising from the minimization principle (2).

3.2. Right-hand side triangle quality force. Minimization of (2) does not prevent the collapse of triangles in the moving grid; if triangle collapse (i.e., shrinking to zero of inscribed radius) is allowed to occur, the numerical run will have to be terminated. To prevent triangle collapse, a right-hand side regularizing quality force is added of the form

$$-\epsilon_2 \nabla_{\mathbf{x}_i} Q^{\text{tri}}, \tag{9}$$

where Q^{tri} is a dimensionless quality energy:

$$Q^{\text{tri}} = \sum_{\text{triangles k}} Q_k^{\text{tri}} = \sum_{\text{triangles k}} \left[\frac{(L_k^{(1)})^2 + (L_k^{(2)})^2 + (L_k^{(3)})^2}{A_k} \right]^2, \tag{10}$$

where the $L_k^{(i)}$ are edge lengths for triangle k and A_k is the area. Q_k^{tri} has a minimal value of $Q_{\text{eql}}^{\text{tri}} = 48$ for an equilateral triangle and gets larger as the aspect ratio of the triangle gets larger. That is, poorly shaped triangles have poor quality and a large quality energy. Q_k^{tri} is dimensionless and is thus independent of the scale of the triangle k. However, the force $-\nabla_{\mathbf{x}_i} Q_k^{\text{tri}}$ is not scale invariant and its magnitude increases as the scale is decreased. We can thus choose ϵ_2 to be equal to a value such that $-\nabla_{\mathbf{x}_i} Q_k^{\text{tri}}$ dominates for small triangles with shortest altitude $\leq \eta$. This will prevent triangle collapse. Indeed, for triangle k (assuming the nomenclature of Figure 3), we have that

$$\begin{aligned}
-\nabla_{\mathbf{x}_i}\epsilon_2 Q_k^{\text{tri}} &= -\epsilon_2 \nabla_{\mathbf{x}_i} \left(\frac{\sum_{j=1}^3 (L_k^{(j)})^2}{A_k} \right)^2 \\
&= -2\epsilon_2 \frac{\sum_{j=1}^3 (L_k^{(j)})^2}{A_k} \left(\frac{2\sum_{j=1}^3 L_k^{(j)} \nabla_{\mathbf{x}_i} L_k^{(j)}}{A_k} - \frac{\sum_{j=1}^3 (L_k^{(j)})^2}{A_k} \frac{\nabla_{\mathbf{x}_i} A_k}{A_k} \right) \\
&= -2\epsilon_2 Q_k^{\text{tri}} \left(\frac{2(L_k^{(1)} \nabla_{\mathbf{x}_i} L_k^{(1)} + L_k^{(2)} \nabla_{\mathbf{x}_i} L_k^{(2)})}{\sum_{j=1}^3 (L_k^{(j)})^2} - \frac{\nabla_{\mathbf{x}_i} A_k}{A_k} \right) \\
&= 2\epsilon_2 Q_k^{\text{tri}} \left(-\frac{2L_k^{(1)}}{||L_k||^2} \nabla_{\mathbf{x}_i} L_k^{(1)} - \frac{2L_k^{(2)}}{||L_k||^2} \nabla_{\mathbf{x}_i} L_k^{(2)} + \frac{\hat{\mathbf{t}}_k^{(3)}}{h_k^{(3)}} \right),
\end{aligned}$$

where $h_k^{(3)}$ is the altitude of the vertex $\mathbf{x}_i$ above the opposite edge in triangle k and $||L_k||^2$ is the square of the l_2 norm of the edge lengths. Since $-\nabla_{\mathbf{x}_i} L_k^{(1)}$ and $-\nabla_{\mathbf{x}_i} L_k^{(2)}$ are unit vectors directed along the edges in triangle k that originate at $\mathbf{x}_i$,

we have that the first two terms represent tension forces of magnitudes $4\epsilon_2 Q_k^{\text{tri}} \frac{L_k^{(1)}}{||L_k||^2}$ and $4\epsilon_2 Q_k^{\text{tri}} \frac{L_k^{(2)}}{||L_k||^2}$, respectively, which act along edges that attract node $\mathbf{x}_i$ to its neighboring nodes in triangle k. Since $\hat{\mathbf{t}}_k^{(3)}$ is a unit vector pointing normally towards node $\mathbf{x}_i$ from the edge opposite $\mathbf{x}_i$, the third term represents a repulsive force of magnitude $\frac{2\epsilon_2 Q_k^{\text{tri}}}{h_k^{(3)}}$ that prevents triangle collapse. The quality force thus causes a node to be attracted along edges and repelled along altitudes. It is zero only for the case of an equilateral triangle. If the triangle is nonequilateral, there will be a node with a shortest altitude that will feel a net repulsion from the opposite edge. If the triangle shape becomes very distorted, the node will feel a repulsive force that is arbitrarily larger than the attractive forces directed along the edges.

Assuming the case of distorted, nonequilateral triangles with shortest altitude at $\mathbf{x}_i$, we wish the dominant repulsive force be comparable to the "physically justified" driving force arising from the PDE, $-\nabla_{\mathbf{x}_i} \int \mu \, dS$, when the shortest altitude of the triangle is of order η. Thus, referring to (5), we set

$$\begin{aligned} \frac{2\epsilon_2 Q_k^{\text{tri}}}{h_k^{(3)}} &= || - \nabla_{\mathbf{x}_i} \mu A_k || \\ &= \frac{\mu L_k^{(3)}}{2}, \end{aligned}$$

so that

$$\epsilon_2 = \frac{\mu L_k^{(3)} h_k^{(3)}}{4 Q_k^{\text{tri}}}.$$

Since we are assuming $Q_k^{\text{tri}} > Q_{\text{eql}}^{\text{tri}}$ and $L_k^{(3)} > h_k^{(3)} = \mathcal{O}(\eta)$, to obtain an order of magnitude estimate for ϵ_2 we insert the trial values $Q_k^{\text{tri}} = 10 \; Q_{\text{eql}}^{\text{tri}}$ and $h_k^{(3)} = \eta$ (which implies that roughly $L_k^{(3)} = 6 \, \eta$). This leads to

$$\epsilon_2 = 3 \times 10^{-3} \, \mu \eta^2. \tag{11}$$

Certainly with $Q_k^{\text{tri}} = 10 \; Q_{\text{eql}}^{\text{tri}}$ we have that the repulsive force along the triangle altitude dominates, as assumed. If $Q_k^{\text{tri}} > 10 \; Q_{\text{eql}}^{\text{tri}}$, for triangles with shortest altitude of order η (or larger than η for sufficiently distorted triangles) the "quality force" is stronger than the physical tension force. This means that large aspect ratio triangles are prevented from forming or are "locked up," prevented from attaining an even worse shape. In practice, these needle-shaped triangles make up a small amount of the surface area of the computational interface surfaces and do not significantly affect the accuracy of the computed solutions. If $Q_k^{\text{tri}} < 10 \; Q_{\text{eql}}^{\text{tri}}$, the quality force is weaker and for Q_k^{tri} approaching $Q_{\text{eql}}^{\text{tri}}$ we have that the attractive forces along edges begin to cancel the repulsive force until at $Q_k^{\text{tri}} = Q_{\text{eql}}^{\text{tri}}$ there is no force whatsoever. Thus the force (9)–(10) *does* allow for the collapse of triangles *if they remain perfectly equilateral* during collapse. However, in practice, there is always some asymmetry in the computational runs, and so (9) with choice (11) is indeed effective at preventing triangle collapse. In fact, ϵ_2 is chosen to be somewhat less than the estimate (11) since we have found that the choice of ϵ_2 (and of the other regularization coefficients ϵ_i in this paper) is not critical and we can err on the side of introducing *less* artificial regularization forces.

3.3. Right-hand side perimeter-dependent surface energy. The opposite of grid collapse is excessive stretching of triangular elements. If edges exceed a certain maximum acceptable edge length $h_{\max}$, then the GWMFE method is running on too coarse a discretization, degrading accuracy of the results. Even if the initial grid has all edges $\leq h_{\max}$ in length without explicit intervention, it is quite possible that some edges exceed $h_{\max}$ in length after some grid evolution. To discourage excessive grid stretching, we add a right-hand side surface energy that is proportional to the perimeter of the triangles:

$$\begin{aligned} -\nabla_{\mathbf{x}_i}\epsilon_3 E^{\text{perim}} &= -\nabla_{\mathbf{x}_i}\left(\epsilon_3 \sum_{\text{triangles k}} E_k^{\text{perim}}\right) \\ &= -\nabla_{\mathbf{x}_i}\left(\epsilon_3 \sum_{\text{triangles k}} (L_k^{(1)} + L_k^{(2)} + L_k^{(3)})A_k\right). \end{aligned} \tag{12}$$

This corresponds to an artificial energy density $\mu_3 \equiv \epsilon_3 p_k$, where $p_k = L_k^{(1)} + L_k^{(2)} + L_k^{(3)}$ is the triangle perimeter. This force grows in strength as the perimeter gets large, and thus excessive stretching of individual elements will be avoided. Since it is highly likely that most edges will be near $h_{\max}$ in length, the artificial energy density will constantly be affecting the solution, introducing errors throughout the grid. (This is as opposed to the triangle quality force which will only affect the solution near "hot spots" where the grid has "thin" elements nearing collapse.) Errors in surface velocities due to (12) will be roughly $\mathcal{O}(\mu_3/\mu)$ throughout the grid, so we want this quantity to be less than some tolerance. On our $\mathcal{O}(1)$ grid, η represents a tolerance on fractional error in node position. It is reasonable to also take this as fractional error in surface velocity, and so using $\mu_3 \approx \epsilon_3(3h_{\max})$, we obtain

$$\epsilon_3 \lesssim \frac{\eta\mu}{3h_{\max}}. \tag{13}$$

4. Enlargement of system to move noninterface nodes. System (3) is integrated using a second-order implicit variable time step ODE solver [3]. However, it gives velocities of the interface nodes only ($\dot{\mathbf{x}} = (\,\dot{x}_j^k\,)_{,1\leq l\leq N}^{,1\leq k\leq 3}$), and so the system must be enlarged to include velocities for M interior nodes that are not part of the interface. That is, we extend $\mathbf{x}$ to

$$\mathbf{x} = \begin{pmatrix} \mathbf{x}_{interface} \\ \mathbf{x}_{interior} \end{pmatrix},$$

where $\mathbf{x}_{interface} = (\,x_j^k\,)_{,1\leq l\leq N}^{,1\leq k\leq 3}$, and $\mathbf{x}_{interior} = (\,x_j^k\,)_{,N+1\leq l\leq N+M}^{,1\leq k\leq 3}$. With this extension, we enlarge system (3) to be order $N+M$.

Since interface physics only tells us how to evolve the N interface nodes, we must "artificially" construct the extra elements in the enlarged $\mathbf{C}(\mathbf{x})$, $\mathbf{g}(\mathbf{x})$ to allow for orderly (tetrahedra orientation preserving) evolution of the mesh. That is, given a physically meaningful method of evolving the triangular interfaces, we are free to develop auxiliary equations for moving the tetrahedra (some of which are conformally attached to the triangular interfaces) with the only requirements being that these equations lead to efficient solution of the system (3) and that they maintain positive orientation of tetrahedra.

A natural choice for the additional equations is to generalize the left-hand side regularization force (6) to viscously damp volume grid motions, and to generalize the right-hand side quality force (9)–(10) to seek well-shaped tetrahedra.

4.1. Volume grid viscosity force. To the left-hand side of (3), we add the following contribution:

$$\epsilon_4 \left[\int \mathbf{I}_3 (\nabla \tilde{\alpha}_i \cdot \nabla \tilde{\alpha}_j)\, dV \right] \dot{\mathbf{x}}_j \equiv \mathbf{C}_4(\mathbf{x}) \dot{\mathbf{x}}. \tag{14}$$

Here, $\nabla \tilde{\alpha}_j = \nabla \tilde{\alpha}_j(\mathbf{x})$ is a piecewise linear hat function defined for $\mathbf{x} \in \mathbb{R}^3$. $\tilde{\alpha}_j$ is 1 on the jth node in the tetrahedral mesh and zero on all other nodes. $\nabla \tilde{\alpha}_j$ is the gradient of $\tilde{\alpha}_j$ over the tetrahedra (i.e., $\nabla = \nabla_{\mathbf{x}}$, where $\mathbf{x} \in \mathbb{R}^3$.) The integral is taken over the whole volume domain $\Omega \subseteq \mathbb{R}^3$ which has been partitioned into tetrahedra. This is a generalization of the surface grid viscosity term (6). Similar to (6)–(7), (14) is easily seen to be equal to

$$\epsilon_4 \nabla_{\dot{\mathbf{x}}_i} \frac{1}{2} \int ||\nabla \dot{\mathbf{x}}||^2 \, dV, \tag{15}$$

where $\dot{\mathbf{x}} = \sum_j \dot{\mathbf{x}}_j \tilde{\alpha}_j(\mathbf{x})$ is interpolated volume mesh velocity. As in the case of surface grid viscosity, the effect of (14) is to reduce nonuniformities in volume grid velocity. So, for example, if a collection of noninterface nodes were surrounded by a set of interface nodes all moving at constant velocity $\mathbf{a}$, the solution of the system

$$\begin{aligned} \mathbf{C}_4 \, \dot{\mathbf{x}} &= 0, \\ \dot{\mathbf{x}}_i &= \mathbf{a} \quad \text{at interface nodes} \end{aligned}$$

would be $\dot{\mathbf{x}} = \mathbf{a}$ at noninterface nodes as well. This is clear, since in this case $\int ||\nabla \dot{\mathbf{x}}||^2 \, dV$ is zero and is thus minimized.

To choose a suitable value for ϵ_4, we compare (6) and (14) and arrange for these terms to be roughly of the same order. Suppose node i is on the interfacial triangular network. We choose ϵ_4 so that the diagonal elements of the matrices $\mathbf{C}_1$ and $\mathbf{C}_4$ are roughly the same. That is,

$$\epsilon_4 \int \nabla \tilde{\alpha}_i \cdot \nabla \tilde{\alpha}_i \, dV \approx \epsilon_1 \int \nabla_{\mathbf{s}} \alpha_i \cdot \nabla_{\mathbf{s}} \alpha_i \, dS.$$

If we assume that the altitudes of the volume elements sharing node i are about the same magnitude as the altitudes of the surface elements sharing node i, then the integrands of the two integrals are roughly the same. Thus we should have

$$\begin{aligned} \epsilon_4 &\approx \epsilon_1 \int \nabla_{\mathbf{s}} \alpha_i \cdot \nabla_{\mathbf{s}} \alpha_i \, dS \Big/ \int \nabla \tilde{\alpha}_i \cdot \nabla \tilde{\alpha}_i \, dV \\ &\approx \epsilon_1 \int_{|\mathbf{x}-\mathbf{x}_i| \le h} dS \Big/ \int_{|\mathbf{x}-\mathbf{x}_i| \le h} dV \\ &= \frac{3}{4} \frac{1}{h} \epsilon_1, \end{aligned}$$

where h is the length of a typical edge in the mesh near node i. We approximate h by $h_{\max}$, since in practice many edges are at (or near) the longest allowed edge length in the computation. Thus, using (8), we arrive at the guideline,

$$.2\eta^2 / h_{\max} \le \epsilon_4 \le 20\eta^2 / h_{\max}. \tag{16}$$

4.2. Volume quality force. Similar to section 3.2, to prevent tetrahedral collapse and inversion as the mesh evolves, to the right-hand side of (3) we add the tetrahedral quality force

$$-\epsilon_5 \nabla_{\mathbf{x}_i} Q^{\text{tet}}, \tag{17}$$

where Q^{tet} is the dimensionless quality energy

$$Q^{\text{tet}} = \sum_{\text{tets } p} Q_p^{\text{tet}} = \sum_{\text{tets } p} \frac{\sum_{n=1}^{6} (L_p^{(n)})^2 \sum_{n=1}^{4} (A_p^{(n)})^2}{V_p^2}, \tag{18}$$

where the $L_p^{(n)}$ are the edge lengths, the $A_p^{(n)}$ are the face areas, and V_p is the volume of tetrahedron p. Q_p is a dimensionless quality measure which has the minimal value $Q_{\text{eql}}^{\text{tet}} = 324$ if p is a regular (equilateral) tetrahedron but approaches infinity if p has a worsening aspect ratio. We note that Q_k^{tri} (10) and Q_p^{tet} are both equivalent to $||L||^2||\frac{1}{H}||^2$, the square of the l_2 norm of the edge lengths of the element multiplied by the square of the l_2 norm of the inverse altitudes of the element. They are thus dimensionless element quality measures which are extremely smooth (i.e., require no square root evaluations).

The argument for setting ϵ_5 is similar to that for setting ϵ_2. Suppose one face k of a nearly collapsed tetrahedron p is on an interface. Suppose node i is on this face. We choose ϵ_5 so the force on this node due to the quality force begins to dominate for small nonregular tetrahedra with shortest altitude $\leq \eta$. Analogous to the triangle quality force of section 3.2, node i is attracted along the edges of tetrahedron p emanating from the node (terms involving $\nabla_{\mathbf{x}_i} L_p^{(n)}$), node i is attracted along the altitudes of the faces emanating from the node (terms involving $\nabla_{\mathbf{x}_i} A_p^{(n)}$), and node i is repelled along the altitude from the face opposite the node (the term involving $\nabla_{\mathbf{x}_i} V_p$). The quality force is zero only for the case of a regular tetrahedron. If the tetrahedron is nonregular, there will be a node with a shortest altitude that will feel a net repulsion from the opposite face. If the tetrahedron shape becomes very distorted, the node will feel a repulsive force that is arbitrarily larger than the attractive forces directed along the edges and faces. So assuming that the shortest altitude (and hence greatest quality force) occurs at $\mathbf{x}_i$, we have

$$\begin{aligned} -\epsilon_5 \nabla_{\mathbf{x}_i} Q_p^{\text{tet}} &= -\epsilon_5 \nabla_{\mathbf{x}_i} \frac{\sum_{n=1}^{6} (L_p^{(n)})^2 \sum_{n=1}^{4} (A_p^{(n)})^2}{V_p^2} \\ &\approx 2\epsilon_5 \frac{\sum_{n=1}^{6} (L_p^{(n)})^2 \sum_{n=1}^{4} (A_p^{(n)})^2}{V_p^2} \frac{\nabla_{\mathbf{x}_i} V_p}{V_p} \\ &= \frac{2\epsilon_5 Q_p^{\text{tet}}}{h_p^i} \hat{\mathbf{t}}_p^i, \end{aligned}$$

where h_p^i is the altitude of point $\mathbf{x}_i$ above the opposite face in tetrahedron p, and $\hat{\mathbf{t}}_p^i$ is a unit vector pointing along the altitude (towards $\mathbf{x}_i$). As in section 3.2, we wish the magnitude of this force to be equal to the magnitude of the physical force $-\nabla_{\mathbf{x}_i} \mu A_k$ due to surface tension over the interface triangle k of tetrahedron p. Again using the nomenclature of Figure 3, we have

$$\frac{2\epsilon_5 Q_p^{\text{tet}}}{h_p^i} = || - \nabla_{\mathbf{x}_i} \mu A_k || = \frac{\mu L_k^{(3)}}{2}.$$

So

$$\epsilon_5 = \frac{\mu L_k^{(3)} h_p^i}{4 Q_p^{\text{tet}}}.$$

To obtain an order of magnitude estimate for ϵ_5, we insert the trial values $Q_p^{\text{tet}} = 10\, Q_{\text{eql}}^{\text{tet}}$ and $h_p^i = \eta$, which implies that roughly $L_k^{(3)} = 5\,\eta$ (see below). This leads to

$$\epsilon_5 \approx 4 \times 10^{-4} \mu \eta^2. \tag{19}$$

We justify the assignment $L_k^{(3)}/h_p^i = 5$ when $Q_p^{\text{tet}} = 10\, Q_{\text{eql}}^{\text{tet}}$ as follows. We assume face k is roughly equilateral (the force in section 3.2 presuming to have prevented poor aspect ratio triangles on the interface). So say $L_k^{(1)} = L_k^{(2)} = L_k^{(3)} = L$. But we are assuming tetrahedron p has a short altitude h_p^i at node $\mathbf{x}_i$ pointing away from interface triangle k into the volume. Given the classification of nearly degenerate tetrahedra in [11, p. 286], tetrahedron p either has a single short edge at $\mathbf{x}_i$ or no short edges at all. In both cases, a rough calculation shows $L/h_p^i \approx 5$ when $Q_p^{\text{tet}} = 10\, Q_{\text{eql}}^{\text{tet}}$. The remarks at the end of section 3.2 (which discuss the cases $Q < 10$ and $Q > 10$ for triangles) are analogously true here for tetrahedra. Again, these are only order of magnitude estimates which are adequate for setting regularization force coefficients.

4.3. Tetrahedron lock-up. The grid forces acting on tetrahedra move the grid by (1) acting to minimize nonuniformities in grid velocity, and (2) acting to continually improve grid element aspect ratios. The artificial grid forces have the effect of necessarily overriding physically justified node movement when it is necessary to prevent inversion of tetrahedra. For instance, if a tetrahedron p has all 4 nodes on an interface, the motion given by (3) might cause the tetrahedron to invert, especially if the interface changes its sense of curvature. By adding the quality force (17) and (18), the tetrahedron will lock up when the shortest altitude is close to η and will be prevented from inverting. The effect of this on the simulation is acceptable with regard to accuracy since the lock up of a small number of tetrahedra simply removes a small fraction of numerical degrees of freedom from the simulation. The effect is further reduced if the locked up tetrahedra are effectively removed by merge and swap operations mentioned in the next section.

4.4. Equation summary. After adding regularization and tetrahedral dynamics terms to (3), the complete system of ODEs that we solve in our implementation of GWMFE is

$$\left[\int \left(\hat{\mathbf{n}}\hat{\mathbf{n}}^T \alpha_i \alpha_j + \mathbf{I}_3 \epsilon_1 (\nabla_{\mathbf{s}} \alpha_i \cdot \nabla_{\mathbf{s}} \alpha_j) \right) dS \; + \; \int \mathbf{I}_3 \epsilon_4 (\nabla \tilde{\alpha}_i \cdot \nabla \tilde{\alpha}_j)\, dV \right] \dot{\mathbf{x}}_j$$

$$= \int \mu K \hat{\mathbf{n}} \alpha_i \, dS \; - \; \nabla_{\mathbf{x}_i} (\epsilon_2 Q^{\text{tri}} + \epsilon_3 E^{\text{perim}} + \epsilon_5 Q^{\text{tet}}) \, , \quad 1 \le i \le N + M. \tag{20}$$

Here the system has been written as $N + M$ 3-vector equations, one associated with each of the N interface nodes and M interior nodes. The left-hand side is an implied

sum over all the nodes j in the mesh. The "artificial" terms involving $\epsilon_1, \ldots, \epsilon_5$ and guidelines for setting $\epsilon_1, \ldots, \epsilon_5$ are explained in (6), (8), (9)–(11), (12), (13), (14), (16), (17)–(19). For the left-hand side, if either i or j is not an interface node, then the surface integral is not defined and does not contribute to the left-hand side. On the right-hand side of (20), if i is not an interface node, then only the term involving Q^{tet} is defined and contributes to the right-hand side.

5. Grid maintenance operations. As the surfaces move and grains deform, mesh maintenance and mesh optimization tools are used to ensure good element quality and to ensure grid edges do not stretch beyond the allowable maximum length $h_{\max}$. Primitive grid operations provided by periodic calls to LaGriT, the Los Alamos Grid Toolbox [8], provide a basis for mesh maintenance and optimization. The *merge* primitive accepts as input lists of pairs of neighboring nodes: merge candidate nodes and survivor nodes. If the merge is completed, only one of the pair survives and the mesh connectivity is repaired to reflect that one node has been deleted. Before the merge takes place, LaGriT verifies that the merge will not cause tetrahedra to become inverted and that the node types and surface constraints of the survivor and merged nodes will lead to a legal merge. The *refine* primitive used in these simulations adds nodes at the midpoints of selected edges. LaGriT sets the node type and surface constraints of the added nodes by determining if the added node is in the interior, on a material interface, or on an exterior boundary. The grid connectivity is repaired to include the new elements created by connecting the new node to the other vertices of the elements which contained the refined edge. Depending on what is desired by the user, the *recon* primitive swaps connections to either improve a measure of the geometric quality of the elements (closely related to Q_p^{tet} in (18)) or to maximize the number of elements satisfying the familiar "Delaunay" criterion.

The three primitives, refine, merge, and recon, are combined into the LaGriT grid optimization operation called *massage*. (Massage is similar to the algorithm presented in [10].) Massage accepts three arguments: a creation edge length, an annihilation edge length, and a damage tolerance. (In our numerical runs, we set these three tolerances to .3, .3, and .01, respectively.) Refinement is carried out such that no edge in the grid has length greater than the creation edge length. The refine primitive is invoked using a version of an algorithm due to Rivara [20]. In the algorithm, an edge marked for refinement is placed on a stack. The algorithm then checks that the elements containing the marked edge have no other edges longer than the marked edge. If longer edges are encountered, they are placed on the stack ahead of the marked edge. The process continues recursively. The refinement candidates are then popped off the stack and refined, resulting in a refinement pattern proceeding from the longest edges to the shortest; this pattern is desirable since it usually does not degrade element quality. Massage may attempt to merge pairs of points only if the resulting grid has no edge length greater than the annihilation length. The damage tolerance specifies the amount of change to the shape of a material interface that is permissible. If a node that sits on a material interface is merged out, the interface will become flatter at that point. If the distance from the merged node's original position to its projected position on the flattened interface is greater than the damage tolerance, the merge will not be allowed. Since *merge* and (less commonly) *refine* can produce poorly shaped tetrahedra, then *recon* is used to restore well-shaped elements.

6. Mesh response to grain topology changes: Recoloring. As grain boundaries move, topology changes must be detected and the mesh must be modified to

reflect these topological changes. The topology changes are detected by assembling and monitoring the rate of change of sets of topological components. To detect grain collapse, we assemble sets of connected elements of the same material. For interface surface collapse we assemble sets of connected interface triangles between two materials; for boundary surface detachment, we assemble sets of connected boundary triangles that lie on a given boundary surface; for triple line collapse where a line is surrounded by three or more materials, we assemble sets of connected edges. We monitor the rate of collapse of these sets, and when a collapse or detachment is imminent, the mesh is adjusted. We identify a neighborhood that completely surrounds the collapsing feature and assign a new material to the elements in this neighborhood. We refer to this as *recoloring*. Ideally, the encroaching material that is accumulating most rapidly is chosen to be the new material, but in this first version of our algorithm, the new material is chosen randomly from a list of viable adjacent materials. Soon after the material reassignment, the curvature driven interface motion will effectively straighten the interfaces. Figure 4 is a schematic of three types of topological change. The first frame in each sequence shows the event as it is detected by GRAIN3D; the dotted line demarcates the neighborhood to receive a new material assignment. The second frame shows the mesh just after the material reassignment, and the third frame shows the mesh after the interfaces have straightened. A further topological change, self-pinchoff, where a grain intersects itself and splits into two pieces, is yet to be incorporated in GRAIN3D.

7. Comparison against known solutions. To gauge the accuracy of the GWMFE method, we set up two types of test cases with analytically known collapse rates: spherical collapse and columnar grains.

7.1. Sphericallly symmetric collapse. The collapse of a spherical grain is easily solvable analytically and provides our first test of the accuracy of GWMFE. Assuming that a sphere is collapsing with normal velocity equal to the curvature (i.e., the *sum* of principle curvatures), we have

$$\frac{dr}{dt} = K = -\frac{2}{r}.$$

So

$$\begin{aligned}\frac{dA}{dt} &= \frac{d(4\pi r^2)}{dt} \\ &= 8\pi r \frac{dr}{dt} \\ &= -16\pi.\end{aligned}$$

The rate of change of surface areas is thus constant and is thus a convenient quantity to use for comparison with a numerical GWMFE solution. In Figure 5 we show the initial grid for a 42-node polyhedral representation of the sphere and then at $t = 0.04$. In Figure 6, we do the same for a 162-node sphere. The highest resolution case of a 642-node sphere is not shown. For each case, the triangles on the surface of the sphere are visible. Edges from tetrahedra conformally attached to the outside of the sphere are visible as well. Of course, tetrahedra within the sphere are not visible. Each surface point on the sphere is placed at exactly radius 0.5. We ran the code with $\mu = 1$, $\eta = 10^{-3}$, $h_{\max} = 0.3$, $\epsilon_1 = 5\eta^2$, $\epsilon_2 = 10^{-4}\eta^2\mu$, $\epsilon_3 = \eta\mu/h_{\max}$, $\epsilon_4 = 5\eta^2/h_{\max}$, and $\epsilon_5 = 10^{-4}\eta^2\mu$. In Figures 7–9, we display results for these cases

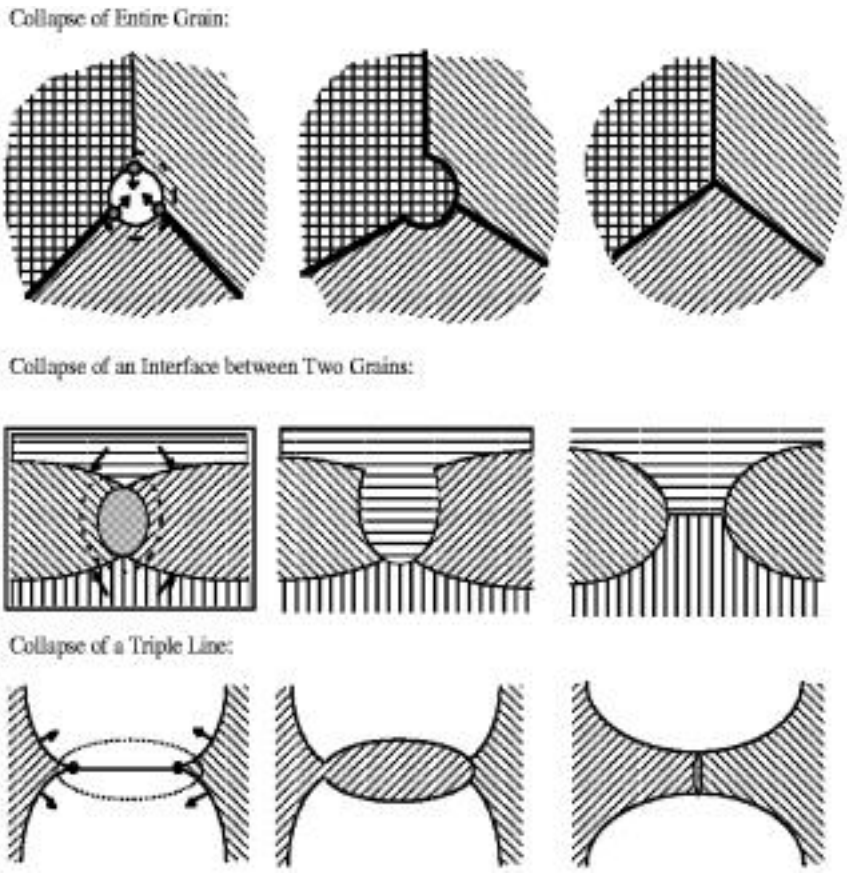

FIG. 4. *Topological collapse detection and resolution by GRAIN3D.*

showing computed graphs of $\frac{dA}{dt}$ vs. t and A vs. t (each dot signifies a time step) and compare them against the analytical results. Note that we apparently converge to the correct $-\frac{dA}{dt}$ as the number of nodes is increased. Also note that at $t = 0$, each numerical solution starts with a surface area less than the exact area π due to the flatness of the triangular facets. As can be seen, this initial surface area deficit is essentially maintained unchanged as the sphere collapses. Hence, errors introduced by the numerical solution seem to be less than errors introduced by simply discretizing the initial condition!

Of course, near the terminal time $t = \frac{\pi}{16\pi} = 0.0625$, we have that the numerical solution for these three cases deviates from the analytic solution. Near the terminal time, the tetrahedra inside the sphere have been collapsed to the point that the shortest altitudes approach η and the tetrahedral quality force (17)–(18) takes over and stops the collapse. If this were a grain growth simulation run, the topology change software would have recolored the collapsing tetrahedra to the color of the surrounding medium close to the terminal time. However, by turning off the recoloring algorithm, we are able to see how the tetrahedral quality force eventually will dominate if no corrective topological change is taken.

To get a better idea of the accuracy of the *pure* GWMFE method without regularization, we reran these three cases with $\mu = 1$, $\eta = 10^{-3}$, $h_{\max} = 0.3$, $\epsilon_1 = .001\eta^2$,

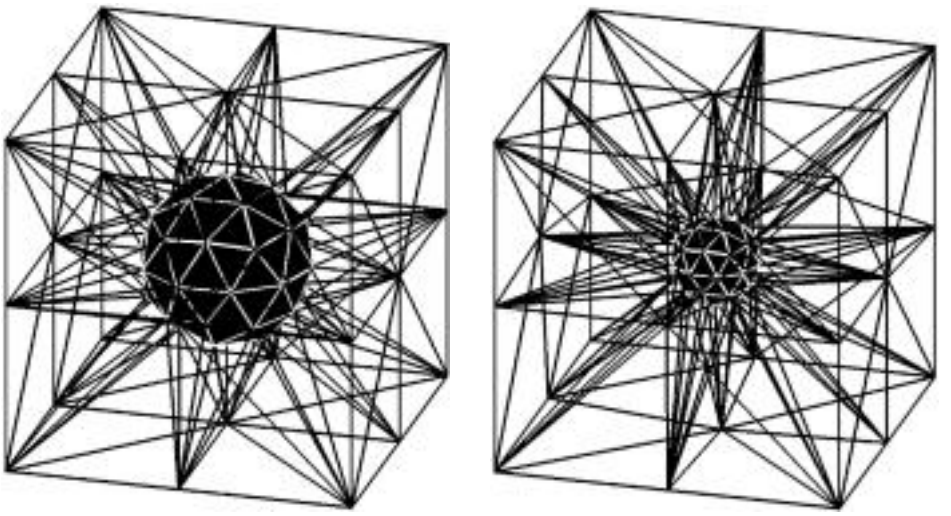

FIG. 5. *Initial* 162*-node sphere (with attached tetrahedra) and at* $t = 0.04$.

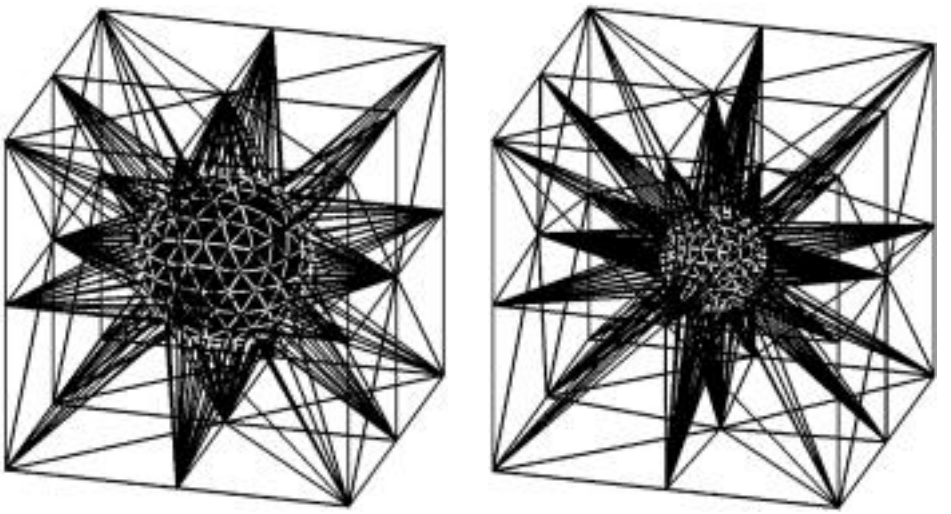

FIG. 6. *Initial* 162*-node sphere (with attached tetrahedra) and at* $t = 0.04$.

$\epsilon_2 = 0$, $\epsilon_3 = 0$, $\epsilon_4 = .001\eta^2/h_{\max}$, and $\epsilon_5 = 0$, which represent zero right-hand side regularization forces and left-hand side internodal viscosities far smaller than recommended. We plotted $-\frac{dA}{dt}$ for these three cases against the theoretical collapse rate in Figure 10. These simulations abruptly end when the terminal time is reached in the absence of counterbalancing tetrahedral quality forces. It is apparent from this figure that the error in $-\frac{dA}{dt}$ is constant over each run, and that the error is cut by roughly a factor of 4 when one increases the number of nodes from 42 (Case 1) to 162 (Case 2), and then the error drops by a factor of four when the number of nodes is increased again from 162 to 642 (Case 3). Since Case 2 represents a refinement which reduces by a factor of 2 the spacing h between nodes on the initial polyhedron (as compared to the 42-noded polyhedron of Case 1), and since Case 3 represents a further refinement

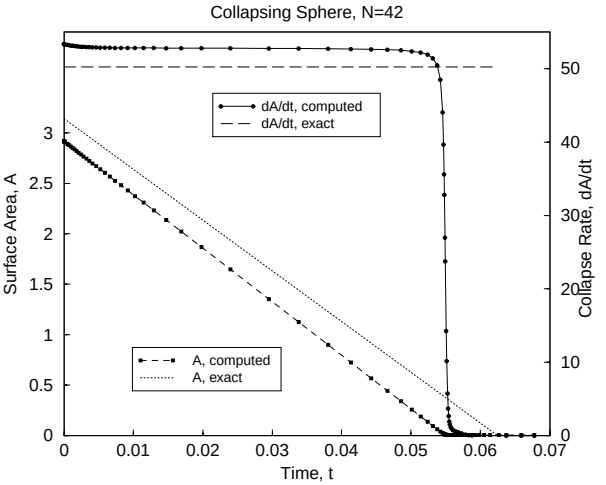

FIG. 7. *Results for* 42*-node sphere run.*

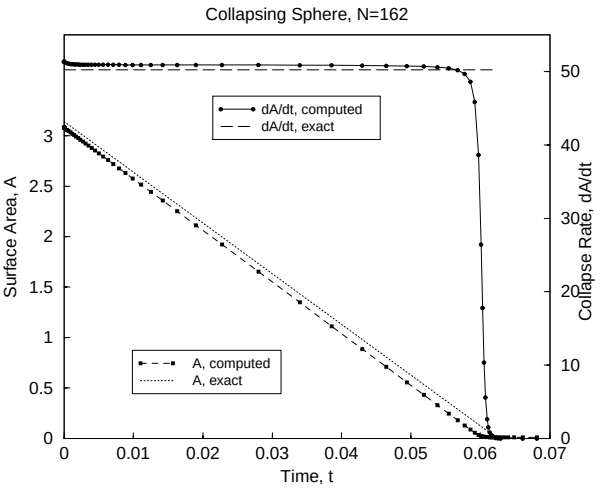

FIG. 8. *Results for* 162*-node sphere run.*

and halving of h, it is tempting to say the error in $-\frac{dA}{dt}$ as computed by the pure GWMFE method is $\mathcal{O}(h^2)$. However, as $t \to 0.0625$, we have that $h \to 0$, but the error remains constant. Instead, consider the Gauss map $\hat{\mathbf{n}} : M \mapsto S^2$ which maps each point $\mathbf{x}$ on a surface M to the unit outward normal $\hat{\mathbf{n}}(\mathbf{x})$ of the surface at $\mathbf{x}$. We define $\Delta\theta$ to be the distance between mapped grid points on the unit sphere. Then at all times for these three numerical test runs, the error in $-\frac{dA}{dt}$ using GWMFE appears to be $\mathcal{O}\big((\Delta\theta)^2\big)$. Thus, it would appear that high accuracy of the GWMFE solution depends on good *angular* resolution of the discretized surface.

The grid maintenance operations in section 5 (which are used in more complex microstructures such as that in section 8) strive to maintain a maximum edge length $h_{\max}$ rather than a coarsest angular resolution $\Delta\theta$. Given the statements of the last paragraph, this implies that small grains in the computations involving grid maintenance operations will have a relatively coarser angular discretization and will suffer

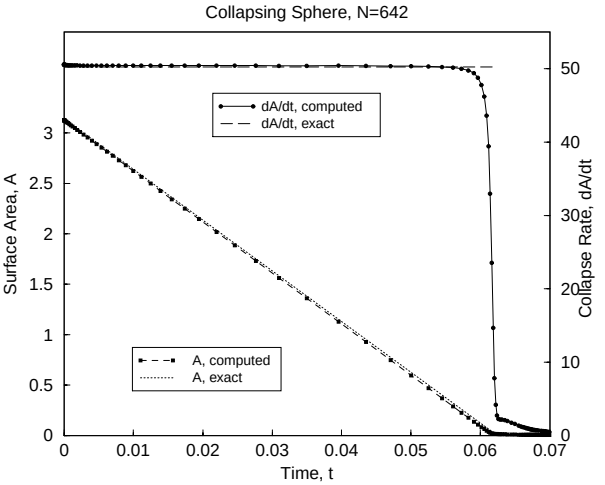

FIG. 9. *Results for* 642*-node sphere run.*

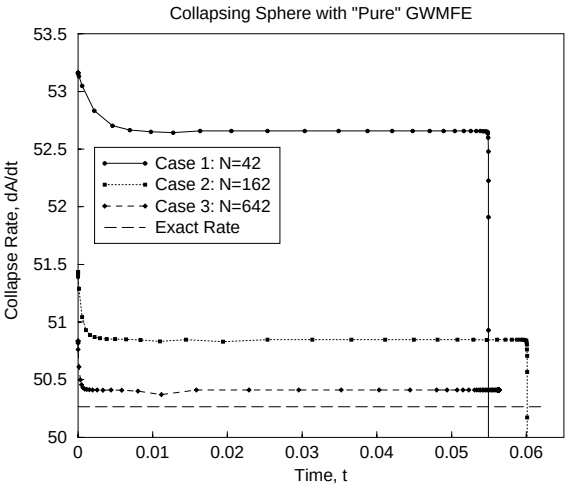

FIG. 10. *Results for nonregularized GWMFE.*

larger computational errors than larger grains. This is somewhat unavoidable, however, since in practical computations grains must be coarsened just prior to collapse.

7.2. Columnar microstructures. Our second set of test cases involve columnar microstructures which are arbitrary 2-D collections of grains that are extended into 3-D to be right cylinders. These microstructures do not possess curvature in 3-D, and thus are amenable to a 2-D analysis.

In 2-D, microstructures moving under curvature driven motion also obey Von Neumann's law [17], which states that for an interior grain G surrounded by n neighbors $G_1, G_2, \ldots, G_n$, the rate of area growth of G is

$$\frac{dA}{dt} = \mu \frac{\pi}{3}(n-6). \tag{21}$$

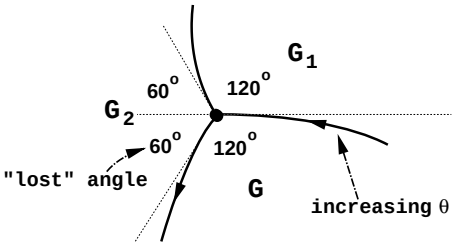

FIG. 11. *Loss of angle at triple point.*

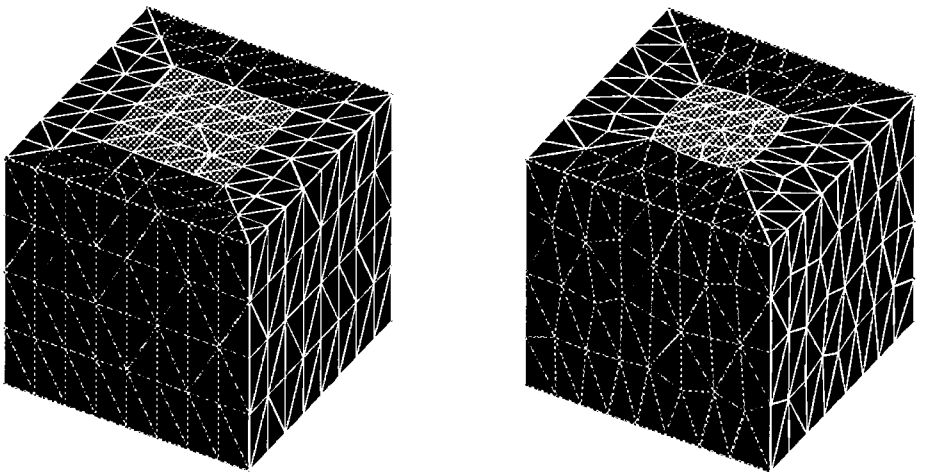

FIG. 12. *Initial* 16*-node columnar microstructure and at* $t = 0.2$. *The term* 16*-node refers to the number of nodes bounding top surface of internal grain.*

This is easily derived as follows. We have that

$$\frac{dA}{dt} = -\int_{\partial G} v_n \, ds,$$

where v_n is normal inward velocity, and the integral is taken over the arclength of the boundary of G. Since $v_n = \mu K$,

$$\begin{aligned}\frac{dA}{dt} &= -\int_{\partial G} \mu K \, ds \\ &= -\mu \int_{\partial G} \frac{d\theta}{ds} \, ds \\ &= -\mu \int_{\partial G} d\theta.\end{aligned}$$

$\int_{\partial G} d\theta$ is not 2π if $n > 0$, since at each triple point junction, there is a 60° loss of angle due to the 120°–120°–120° equilibrium angle condition (Figure 11) that exists at triple points resulting from the necessity of force balance of surface tension at the triple point. The interior grain G has n such triple points. We thus obtain (21).

In Figure 12 we show the initial grid for a five grain columnar microstructure with the axis running top to bottom. A central square-columnar grain G (light in

color) is surrounded by four trapezoidal-columnar grains G_1, G_2, G_3, G_4 (darker in color). The area A of the top surface of the central grain is $1 \times 1 = 1$, while the total top area of all five grains put together is $2 \times 2 = 4$. GRAIN3D was run on this initial microstructure using the same parameter values as in the regularized run of section 7.1. Nodes on the exterior planes were allowed to slide on the planes, nodes on exterior edges were allowed to slide on the edges, and the eight corner nodes were fixed. For this run, each of the four interfaces between the four surrounding grains (i.e., $G_1 \cap G_2$, $G_2 \cap G_3$, $G_3 \cap G_4$, and $G_4 \cap G_1$) was associated with and pinned to a vertical exterior edge.

Figure 12 also shows the evolved microstructure, as computed by GRAIN3D, at $t = 0.2$. The grains have remained columnar and the top surface of the central grain has shrunk. The four triple points on the top surface have adopted the correct 120°–120°–120° angle at this time. In Figure 13, we see computed and exact curves for $-\frac{dA}{dt}$ vs. t and A vs. t, where we have used (21) with $n = 4$ to obtain the "exact" value $-\frac{dA}{dt} = \frac{2\pi}{3}$. (We have called this run N = 16, since A is bounded by 16 computational nodes.) For this run, the computed and exact A vs. t are virtually identical. For most of the run, the computed and exact values for $-\frac{dA}{dt}$ are virtually indistinguishable. At the beginning of the run there is a "blip," where $-\frac{dA}{dt}$ is significantly higher than the theoretical value of $\frac{2\pi}{3}$. We attribute this to the state of the four triple points in the initial data. These four triple points are 90°–135°–135° in the initial data, which is not the 120°–120°–120° force balance equilibrium that should exist. Thus the initial blip represents rapid relaxation to the force balance state; essentially the code has accepted "incorrect" initial data (with forces not in balance at the triple points) and relaxed it to an acceptable state on a rapid time scale. The final blip in $-\frac{dA}{dt}$ occurs near the terminal time $t = \frac{3}{2\pi}$ when the central grain has been reduced to an extremely thin column, by which time the recoloring algorithm would have changed the topology, had it been activated. This blip is not surprising since the slender grain carries with it virtually no energy (due to its vanishingly small surface area), and therefore errors present (i.e., due to the nonphysical regularization forces) may well be magnified at this advanced stage.

In Figure 14, we see $-\frac{dA}{dt}$ vs. t and A vs. t for an $N = 32$ geometry (i.e., at twice the grid density of the one pictured in Figure 12). The initial anomalously high $-\frac{dA}{dt}$ blip is shorter lived, and the final blip at the terminal time has disappeared.

A study of "pure" GWMFE error (with regularization turned off) is impossible for this problem. It was possible in the highly symmetrical sphere collapse problem of section 7.1, but in this problem, which exhibits less symmetry and which has changing triple point angles, the regularization forces play a crucial role in preserving the positivity of all triangle areas and tetrahedral volumes throughout the computation.

8. Numerical example with 3-D microstructure. In this section, we show how GRAIN3D evolves a truly 3-D microstructure to steady-state, successfully maintaining mesh quality and performing necessary topological changes during the course of the calculation. In Figure 15(a), we show an initial five grain microstructure provided by the LaGriT tetrahedral mesh generator. We evolve the mesh with GRAIN3D, using the same regularization parameters as in the previous regularization runs. The nodes are allowed to slide on the external surfaces, as in section 7.2. Every $\Delta t_{\text{massage}} = 0.04$ time units, the mesh topology is massaged: edges that are too long are bisected, unneeded nodes are eliminated, and connections are swapped if necessary. Whenever we detect that a topological component is about to collapse (such as a grain, a grain-grain interface, or a triple line) in the next $\Delta t_{\text{collapse}} = 0.002$ time

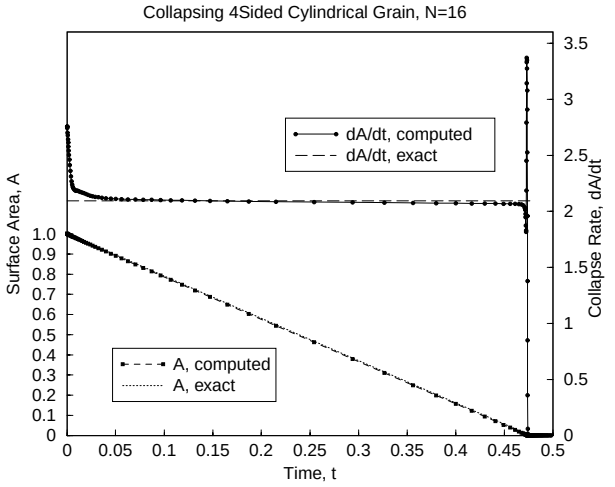

FIG. 13. *Results for* 16*-node run.*

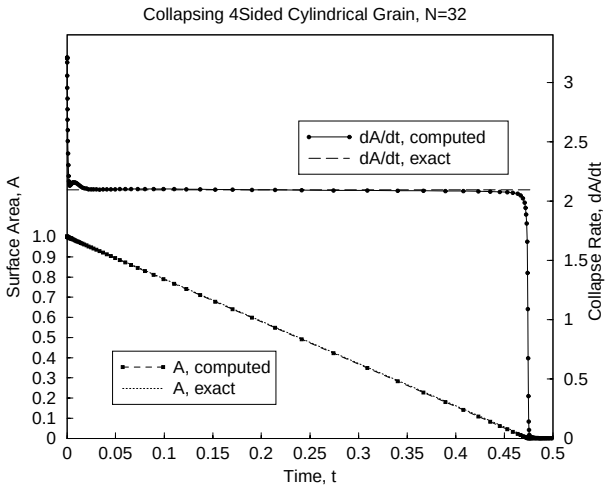

FIG. 14. *Results for* 32*-node run.*

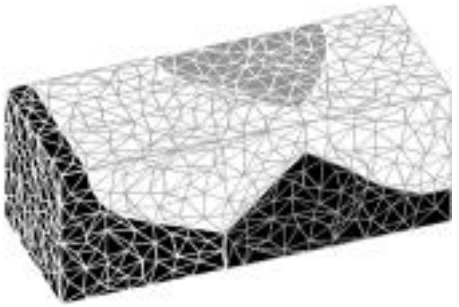
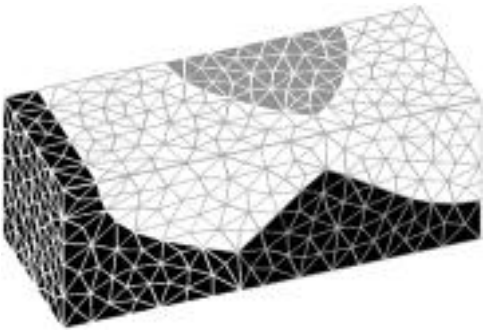
units, we call the recoloring algorithm to effectively perform the necessary topological change.

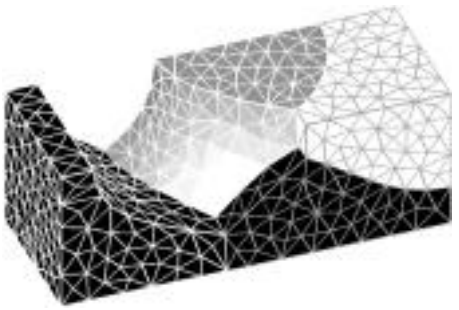
The massage algorithm is called immediately after $t = 0.00$, and the regularization forces (especially perimeter dependent surface energy (12)) fatten the elements, so by $t = 0.02$ (Figure 15(b)), the mesh is much improved. In 15(c), we have made one grain graphically transparent to reveal triples lines and quadruple points. At $t = 0.20$ (15(d)), the invisible grain has shrunk. At $t = 0.30$ (15(e)), the invisible grain has detached from the rear wall. In 15(f), the invisible grain is near collapse. By 15(g), the grain has been eliminated by the recoloring algorithm. This figure also shows a small rear grain about to collapse. In 15(i) this grain has collapsed and we are down to three grains. In fact, the microstructure is now columnar (the axis runs front to back) and would be perfectly well modeled by a 2-D front tracking code, such as that described in [5]. At $t = 1.50$ (15(j)), the light colored grain has disappeared, leaving



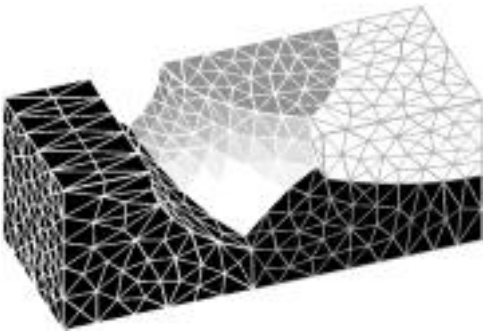
(a) $t = 0.00$. Initial grid is from LaGriT.



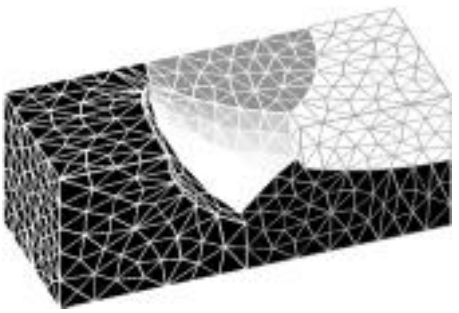
(b) $t = 0.02$. Grid improved by regularization and massage.



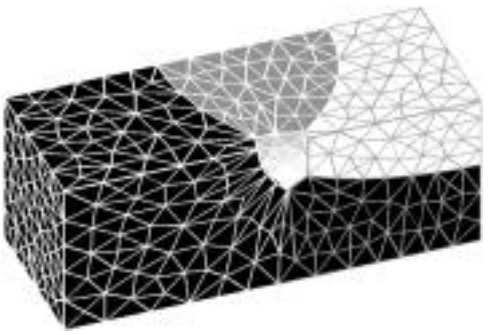
(c) $t = 0.02$. Grid with grain graphically removed for illustration.



(d) $t = 0.02$. Invisible grain has shrunk.



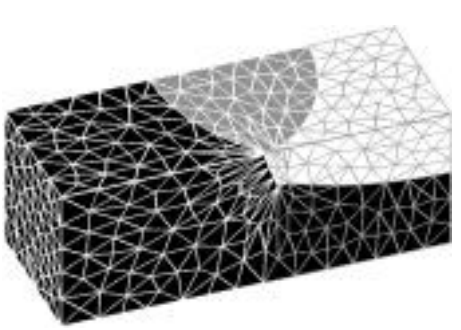
(e) $t = 0.30$. Invisible grain has detached from rear wall.



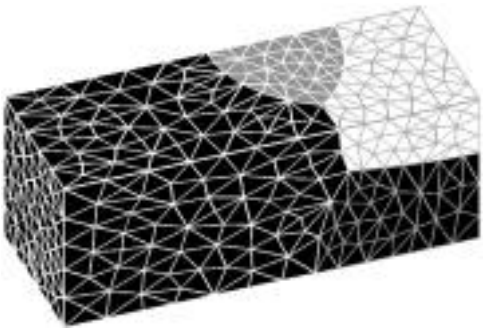
(f) $t = 0.45$. Invisible grain about to collapse.

FIG. 15 (a)–(f). *Grain evolution time sequence computed by GRAIN3D.*

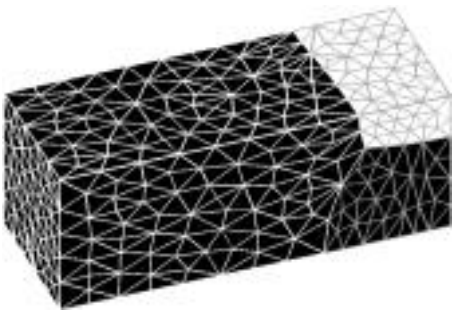
a collapsing circular-columnar grain and a larger complementary grain. At $t = 1.75$ (15(k)), the circular-columnar grain has collapsed, leaving the entire computational domain covered by a single grain. Evidence of the grain collapse is visible in that the grid is somewhat finer in the bottom right-hand corner. Finally, at $t = 1.80$ (15(l)), massage and regularization have coarsened the grid in the vicinity of the last collapsed grain. Of course, the difference between the grids at $t = 1.75$ and $t = 1.80$ is



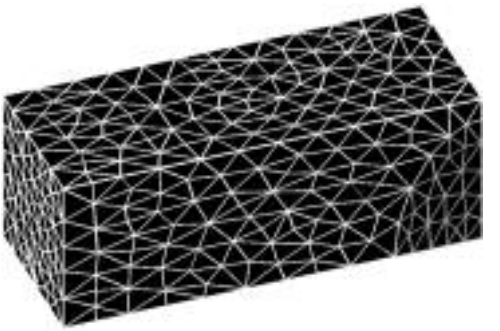
(g) $t = 0.47$. Invisible grain has collapsed.



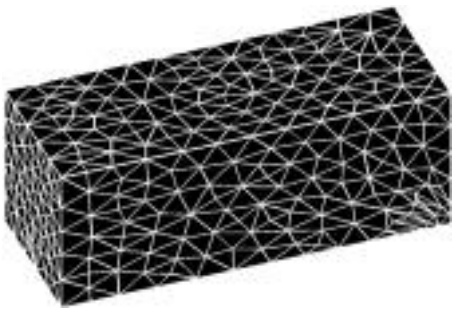
(h) $t = 0.80$. Surface triple points draw apart.



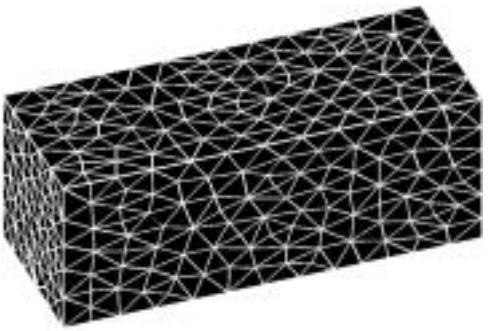
(i) $t = 1.10$. A second grain has collapsed. The microstructure is now 2-D.



(j) $t = 1.50$. A third grain has collapsed.



(k) $t = 1.75$. Fourth grain has collapsed. One grain left.



(l) $t = 1.80$. Grid improved by regularization and massage.

FIG. 15 (g)–(l). *Grain evolution time sequence computed by GRAIN3D.*

purely nonphysical—the grain is the same, but the grid is different. The run is truly completed at $t = 1.75$ when the microstructure evolution has ceased, but it isn't until $t = 1.80$ that the grid has settled down.

Acknowledgments. The author would like to acknowledge the invaluable support of the rest of the Los Alamos T-1 Grain Growth team: Denise George helped with enhancements to LaGriT, Tinka Gammel generated the initial microstructure used in section 8, Neil Carlson (now with Motorola, Inc.) provided assistance with his

GWMFE2DS code, and Galen Straub provided necessary motivation and resources. I also thank the referees for their detailed comments and corrections.

AN APPROXIMATION TO MISCIBLE FLUID FLOWS IN POROUS MEDIA WITH POINT SOURCES AND SINKS BY AN EULERIAN–LAGRANGIAN LOCALIZED ADJOINT METHOD AND MIXED FINITE ELEMENT METHODS*

HONG WANG†, DONG LIANG‡, RICHARD E. EWING§, STEPHEN L. LYONS¶, AND GUAN QIN¶

Abstract. We develop an Eulerian–Lagrangian localized adjoint method (ELLAM)-mixed finite element method (MFEM) solution technique for accurate numerical simulation of coupled systems of partial differential equations (PDEs), which describe complex fluid flow processes in porous media. An ELLAM, which was shown previously to outperform many widely used methods in the context of linear convection-diffusion PDEs, is presented to solve the transport equation for concentration. Since accurate fluid velocities are crucial in numerical simulations, an MFEM is used to solve the pressure equation for the pressure and Darcy velocity. This minimizes the numerical difficulties occurring in standard methods for approximating velocities caused by differentiation of the pressure and then multiplication by rough coefficients.

The ELLAM-MFEM solution technique significantly reduces temporal errors, symmetrizes the governing transport equation, eliminates nonphysical oscillation and/or excessive numerical dispersion in many simulators, conserves mass, and treats boundary conditions accurately. Numerical experiments show that the ELLAM-MFEM solution technique simulates miscible displacements of incompressible fluid flows in porous media accurately with fairly coarse spatial grids and very large time steps, which are one or two orders of magnitude larger than the time steps used in many methods. Moreover, the ELLAM-MFEM solution technique can treat large mobility ratios, discontinuous permeabilities and porosities, anisotropic dispersion in tensor form, and point sources and sinks.

Key words. characteristic methods, Eulerian–Lagrangian methods, miscible fluid flows in porous media with wells, numerical simulation of convection-diffusion equations, reservoir simulation, subsurface contaminant transport

1. Introduction.

Many difficult problems arise in the numerical simulation of complex fluid flow processes in reservoir simulation, subsurface contaminant transport and remediation, and other applications. The mathematical models used to describe these fluid flow processes are coupled systems of nonlinear partial differential equations (PDEs), which are basically convection/diffusion types with convection being the dominant process. Due to the nonlinearity and couplings of these PDEs, the moving steep fronts present in the solutions of these PDEs, the singularities of the solutions at the point sources and sinks (e.g., injection and production wells), and the

enormous size of field-scale applications, the numerical treatment of these systems often encounters severe difficulties.

Let $c(\mathbf{x},t)$ be the concentration of an invading fluid, and let $p(\mathbf{x},t)$ and $\mathbf{u}(\mathbf{x},t)$ be the pressure and Darcy velocity of the total fluid mixture. The mass conservation equation for the fluid mixture incorporated with the incompressibility condition, Darcy's law, and the mass conservation equation for the invading fluid lead to the following coupled system of PDEs [3, 15], which models the miscible displacement of one incompressible fluid by another in a porous medium reservoir Ω over a time period of $[0,T]$:

$$\begin{aligned} \nabla\cdot\mathbf{u} &= q, && \mathbf{x}\in\Omega, \quad t\in[0,T], \\ \mathbf{u} &= -\frac{\mathbf{K}}{\mu(c)}(\nabla p-\rho g\nabla d), && \mathbf{x}\in\Omega, \quad t\in[0,T], \end{aligned} \tag{1.1}$$

$$\phi\frac{\partial c}{\partial t}+\nabla\cdot(\mathbf{u}c-\mathbf{D}(\mathbf{x},\mathbf{u})\nabla c)=\bar{c}q, \quad \mathbf{x}\in\Omega, \quad t\in[0,T]. \tag{1.2}$$

In many cases, the thickness of the medium is significantly smaller than its length and width. Hence, it is reasonable to average the medium properties vertically and to assume $\Omega\subset\mathbb{R}^2$ with a nonuniform local elevation. In (1.1)–(1.2), $\mathbf{x}:=(x,y)$. The dependent variables are the pressure $p(\mathbf{x},t)$ and the Darcy velocity $\mathbf{u}(\mathbf{x},t):=(u_x(\mathbf{x},t),u_y(\mathbf{x},t))$ of the fluid mixture, where $u_x(\mathbf{x},t)$ and $u_y(\mathbf{x},t)$ are the x and y components of $\mathbf{u}$, respectively, and the volumetric concentration $c(\mathbf{x},t)$ of the invading fluid. $\mathbf{K}(\mathbf{x})$ is the 2×2 permeability tensor of the medium, $\mu(c)$ is the concentration-dependent viscosity of the fluid mixture, which is determined by some mixing rule

$$\mu(c)=\mu(0)[(1-c)+M^{\frac{1}{4}}c]^{-4}, \tag{1.3}$$

where M is the mobility ratio between the resident and injected fluids, and $\mu(0)$ is the viscosity of resident fluid (oil). ρ is the density of the fluid mixture, g is the magnitude of gravitational acceleration, $d(\mathbf{x})$ is the reservoir depth, $q(\mathbf{x},t)$ is the external source/sink term that accounts for the effect of injection and production wells, $\phi(\mathbf{x})$ is the porosity of the medium, $\mathbf{D}$ is the diffusion-dispersion tensor

$$\mathbf{D}(\mathbf{x},\mathbf{u}):=\phi(\mathbf{x})d_m\,\mathbf{I}+\frac{d_l}{|\mathbf{u}|}\begin{pmatrix} u_x^2 & u_xu_y \\ u_xu_y & u_y^2 \end{pmatrix}+\frac{d_t}{|\mathbf{u}|}\begin{pmatrix} u_y^2 & -u_xu_y \\ -u_xu_y & u_x^2 \end{pmatrix}, \tag{1.4}$$

where d_m is the molecular diffusion coefficient, $\mathbf{I}$ is the 2×2 identity tensor, and d_l and d_t are the longitudinal and transverse dispersivities, respectively. $\bar{c}(\mathbf{x},t)$ is either the specified concentration of the injected fluid at injection wells or $\bar{c}(\mathbf{x},t)=c(\mathbf{x},t)$ is the resident concentration at production wells.

In reservoir simulation, the boundary $\Gamma:=\partial\Omega$ is typically impermeable. Consequently, the associated boundary conditions are given by

$$\begin{aligned} \mathbf{u}\cdot\mathbf{n} &= 0, && (\mathbf{x},t)\in\Gamma\times[0,T], \\ (\mathbf{D}\nabla c)\cdot\mathbf{n} &= 0, && (\mathbf{x},t)\in\Gamma\times[0,T]. \end{aligned} \tag{1.5}$$

In addition, the systems (1.1)–(1.2) also need an initial condition for the concentration

$$c(\mathbf{x},0)=c_0(\mathbf{x}), \quad \mathbf{x}\in\Omega. \tag{1.6}$$

The combination of the first equation in (1.1) and that in (1.5) leads to the following compatibility condition that must be imposed on the data:

$$\int_\Omega q(\mathbf{x},t)d\mathbf{x}=0, \quad t\in[0,T]. \tag{1.7}$$

Equation (1.7) states that for an incompressible flow with an impermeable boundary, the amount of injected fluid should be equal to the amount that is produced. In addition, (1.1) with the no-flow boundary condition (1.5) can only determine the pressure $p(\mathbf{x}, t)$ up to an additive constant for all the time $t \in [0, T]$. However, this indeterminacy is of no consequence since $\mathbf{u}$ is uniquely determined by Darcy's law, and only $\mathbf{u}$ (not p) is needed in (1.2).

2. State of the art in numerical approximations. The principal variable of physical interest in (1.1)–(1.2) is the concentration $c(\mathbf{x}, t)$. In reservoir simulation, it indicates how much of the reservoir is swept by solvent, or equivalently, how much oil is recovered. In subsurface contaminant transport, it shows the movement of the concerned solute in groundwater porous medium flows, which one wants to determine. Because the magnitude of the diffusion-dispersion tensor $\mathbf{D}$ is often much smaller than that of the Darcy velocity $\mathbf{u}$, (1.2) for c is a strongly convection-dominated PDE with small diffusion and dispersion terms indicated by the size of the coefficients d_m, d_l, and d_t in (1.4). Moreover, (1.1)–(1.2) are a coupled system of PDEs which is typically defined on a very large physical domain.

2.1. Numerical methods for elliptic pressure PDEs. One important issue in the simulation of porous medium flows is the manner in which the Darcy velocity $\mathbf{u}$ is calculated. Since the convection and diffusion-dispersion terms in (1.2) are governed by the Darcy velocity, accurate approximation to the concentration c requires an accurate approximation to the Darcy velocity $\mathbf{u}$. However, the properties of the porous medium (e.g., $\mathbf{K}$) often change abruptly with sharp changes in lithology. The viscosity $\mu(c)$ also changes rapidly across fluid interfaces. These sharp changes are accompanied by large changes in the pressure gradient which, in a compensatory fashion, yield a fairly smooth Darcy velocity $\mathbf{u}$. Standard finite difference or finite element methods (FDMs, FEMs, respectively) solve (1.1) for the pressure p, which is not necessarily smooth due to the impact of the rough coefficients. The resulting p is then differentiated numerically and then multiplied by a possibly rough coefficient to determine the Darcy velocity $\mathbf{u}$. Therefore, these methods generate a rough and often inaccurate velocity $\mathbf{u}$, which then reduces the accuracy of the approximation to (1.2). Mixed finite element methods (MFEMs) [6, 24] approximate both p and $\mathbf{u}$ from the system (1.1) simultaneously, yield an accurate velocity field $\mathbf{u}$, and conserve mass. MFEMs have been successfully applied in reservoir simulation [15, 27].

2.2. Numerical methods for convection-diffusion PDEs. Standard FDMs or FEMs tend to generate solutions with severe nonphysical oscillations. In industrial applications, upstream weighting techniques are commonly used to stabilize the numerical approximations in large-scale simulators. However, these methods produce excessive numerical dispersion and spurious effects related to the grid orientation [15]. Two general classes of improved methods can be identified from the literature: the Eulerian methods that use the standard temporal discretization and the characteristic methods that carry out the temporal discretization by a characteristic tracking.

Most Eulerian methods are based on upstream weighting techniques. The optimal test function methods [2, 10] attempt to minimize the spatial error and yield an upstream bias in the resulting schemes. Some Eulerian methods [5] try to reduce the overall truncation error by using a nonzero spatial error to cancel temporal errors. The streamline diffusion FEMs [20, 21] add a numerical diffusion only in the direction of streamlines with no crosswind diffusion introduced. However, an a priori choice of the free parameter in the methods is not clear and is heavily problem de-

pendent. The total variation diminishing methods (TVD), essentially nonoscillatory (ENO) methods, and other high resolution methods [11, 14, 18, 29] are well suited for nonlinear hyperbolic conservation laws and resolve shock discontinuities in the solutions without excessive smearing or spurious oscillations. These methods were extended to solve convection-diffusion PDEs [9].

Because of the hyperbolic nature of convective transport, many characteristic methods have been developed for solving convection-diffusion PDEs [4, 13, 23, 30]. Traditional forward tracking or moving mesh methods advance the grids following the characteristics and greatly reduce temporal errors. But they often severely distort the evolving grids and greatly complicate the solution procedures. The modified method of characteristics (MMOC) [13] tracks the characteristics backward from a fixed grid at the current time step and, hence, avoids the grid distortion problems present in forward tracking methods. The MMOC symmetrizes and stabilizes the convection-diffusion PDEs, greatly reduces temporal errors and so allows for large time steps in a simulation without loss of accuracy, and eliminates the excessive numerical dispersion and grid orientation effects present in many Eulerian methods [15, 27]. However, MMOC and many other characteristic methods fail to conserve mass and have difficulties in treating general boundary conditions.

2.3. Numerical approximations to the systems (1.1)–(1.2). The combination of close couplings and nonlinearities of the governing PDEs, the singularities of the solutions due to the effect of injection and production wells, the moving steep fronts present in the solutions of the governing PDEs, the use of large grid-spacings, and the convection-diffusion feature of the governing PDEs often generate spurious numerical artifacts and inaccurate approximations to the systems. A blind linearization with little regard to the properties of the governing PDEs or the solutions can result in extremely large, ill-conditioned, nonlinear discrete algebraic systems. These issues, if not treated carefully, may destroy the usefulness of the simulation.

Fully explicit methods are computationally local and are very efficient per time step, but they often require extremely fine spatial grids and time steps and result in enormous amounts of overall computations in numerical simulations [15, 31]. Fully coupled and fully implicit methods solve all of the coupled nonlinear PDEs simultaneously in an implicit fashion, and they are unconditionally stable. There has been development of fully implicit FDM or FEM simulators for three phase flows, for steam flooding, and for compositional models [15, 27]. However, these methods are computationally expensive per time step and introduce excessive numerical diffusion and reduced accuracy with large time steps [15, 31]. IMPES methods, which solve (1.1) *implicitly* for *pressure* and (1.2) *explicitly* for *saturation* (or concentration), provide variations to fully explicit methods to obtain better stability without increasing complexity too much. However, for difficult nonlinearities, IMPES methods are often forced to use extremely small time steps which lead to significantly compromised computational efficiency [15].

Douglas, Ewing, and Wheeler [12] presented and analyzed an efficient sequential linearization technique for the miscible displacement of one incompressible fluid by another in a porous medium. In the procedure, an MFEM was used to solve (1.1) for the pressure and Darcy velocity and a Galerkin FEM was used to solve (1.2) for the concentration. However, the use of a Galerkin FEM may generate numerical solutions with severe oscillation. Russell generalized the work in [13] and introduced the MMOC into the Society of Petroleum Engineers (SPE) literature [25] for solving (1.2) in miscible displacement of incompressible fluids in reservoir simulation, where

the pressure equation (1.1) was solved by a biquadratic FEM. Subsequently, Ewing, Russell, and Wheeler in [12] and Russell in [25] combined the ideas and proposed an improved MMOC-MFEM sequential solution technique in the numerical simulation of the miscible displacement of incompressible fluid flows in porous media [16], in which the MMOC was used to solve (1.2) and an MFEM was employed to solve (1.1). The use of an MFEM for the pressure equation yields accurate Darcy velocity fields that conserve mass, while the application of MMOC allows large time steps to be used in the solution of the transport equation without loss of accuracy and eliminates the numerical dispersion and grid orientation effects that are among the major difficulties presented in large-scale reservoir simulators [15, 27].

3. An ELLAM scheme for the transport equation (1.2). The ELLAM was introduced by Celia et al. [8] for solving (one-dimensional constant-coefficient) convection-diffusion PDEs. The ELLAM formalism provides a general characteristic solution procedure for convection-dominated PDEs and a consistent framework for conserving mass and treating general boundary conditions. The ELLAM techniques symmetrize these PDEs, generate accurate numerical solutions even if large time steps are used, and eliminate nonphysical oscillations, numerical dispersion, and grid orientation artifacts. Thus, the ELLAM framework overcomes the principal shortcomings of the previous characteristic methods while maintaining their numerical advantages. In this section, we present an ELLAM scheme for the transport equation (1.2) under the assumption that the Darcy velocity $\mathbf{u}$ is known. An ELLAM-MFEM sequential solution technique for the coupled systems (1.1)–(1.2) will be described in section 5.

3.1. A reference equation. We define a partition of the interval $[0, T]$ by

$$0 =: t_0^c < t_1^c < \cdots < t_n^c < \cdots < t_{N-1}^c < t_N^c := T \quad \text{and} \quad \Delta t_n^c := t_n^c - t_{n-1}^c. \tag{3.1}$$

In the ELLAM framework, we choose the test functions $z(\mathbf{x}, t)$ to be continuous and piecewise smooth on the space-time strip $\Omega \times (t_{n-1}^c, t_n^c]$. We allow them to be discontinuous in time at time t_{n-1}^c so that the ELLAM scheme can be decoupled in time. This in turn permits us to focus on the development of the scheme on the current time interval $[t_{n-1}^c, t_n^c]$ only and to define the test functions by constant extension along the characteristics as we should see below. We refer readers to [1, 8, 31] for details. Multiplying (1.2) by these test functions $z(\mathbf{x}, t)$, and integrating the resulting equation over the space-time strip $\Omega \times (t_{n-1}^c, t_n^c]$, we obtain the following space-time weak formulation for (1.2):

$$\begin{aligned} &\int_\Omega \phi(\mathbf{x}) c(\mathbf{x}, t_n^c) z(\mathbf{x}, t_n^c)\, d\mathbf{x} + \int_{t_{n-1}^c}^{t_n^c} \int_\Omega \nabla z(\mathbf{y}, \theta) \cdot \mathbf{D}(\mathbf{y}, \mathbf{u}(\mathbf{y}, \theta)) \nabla c(\mathbf{y}, \theta)\, d\mathbf{y} d\theta \\ &\quad - \int_{t_{n-1}^c}^{t_n^c} \int_\Omega c(\mathbf{y}, \theta) \left[\phi(\mathbf{y}) \frac{\partial z(\mathbf{y}, \theta)}{\partial \theta} + \mathbf{u}(\mathbf{y}, \theta) \cdot \nabla z(\mathbf{y}, \theta) \right] d\mathbf{y} d\theta \\ &\quad = \int_\Omega \phi(\mathbf{x}) c(\mathbf{x}, t_{n-1}^c) z(\mathbf{x}, t_{n-1}^{c,+})\, d\mathbf{x} + \int_{t_{n-1}^c}^{t_n^c} \int_\Omega \bar{c}(\mathbf{y}, \theta) q(\mathbf{y}, \theta) z(\mathbf{y}, \theta)\, d\mathbf{y} d\theta, \end{aligned} \tag{3.2}$$

where $z(\mathbf{x}, t_{n-1}^{c,+}) := \lim_{t \to t_{n-1}^c,\ t > t_{n-1}^c} z(\mathbf{x}, t)$ to take into account the fact that $z(\mathbf{x}, t)$ is discontinuous in time at time t_{n-1}^c. We replace the dummy variables $\mathbf{x}$ and t in the space-time integrals in (3.2) by $\mathbf{y}$ and θ, and we reserve $\mathbf{x}$ for the point in Ω at time t_n^c or t_{n-1}^c for later convenience.

Different splittings of the adjoint equation of (1.2) are studied in the ELLAM framework. It is shown [8] that the test functions should be chosen to satisfy the adjoint equation of (1.2) to reflect the hyperbolic nature of (1.2):

$$\phi(\mathbf{y})\ \frac{\partial z(\mathbf{y},\theta)}{\partial \theta} + \mathbf{u}(\mathbf{y},\theta)\cdot\nabla z(\mathbf{y},\theta) = 0, \quad \mathbf{y}\in\overline{\Omega}, \quad \theta\in[t_{n-1}^c, t_n^c]. \tag{3.3}$$

Thus, the test functions $z(\mathbf{y},\theta)$ should be constant along the characteristics $\mathbf{y} = \mathbf{r}(\theta;\mathbf{x},t_n^c)$, defined by the initial-value problem of the differential equation

$$\frac{d\mathbf{r}}{d\theta} = \frac{\mathbf{u}(\mathbf{r},\theta)}{\phi(\mathbf{r})} \quad \text{and} \quad \mathbf{r}(\theta;\bar{\mathbf{x}},\bar{t})\Big|_{\theta=\bar{t}} = \bar{\mathbf{x}}. \tag{3.4}$$

For any $(\mathbf{y},\theta)\in\Omega\times[t_{n-1}^c,t_n^c]$, there exists an $\mathbf{x}\in\Omega$ such that $\mathbf{y}=\mathbf{r}(\theta;\mathbf{x},t_n^c)$. We apply the Euler formula at time t_n^c to evaluate the source and sink term in (3.2) to obtain

$$\begin{aligned}
&\int_{t_{n-1}^c}^{t_n^c}\int_\Omega \bar{c}(\mathbf{y},\theta)q(\mathbf{y},\theta)z(\mathbf{y},\theta)\ d\mathbf{y}d\theta \\
&\quad= \int_\Omega\int_{t_{n-1}^c}^{t_n^c} \bar{c}(\mathbf{r}(\theta;\mathbf{x},t_n),\theta)q(\mathbf{r}(\theta;\mathbf{x},t_n),\theta)z(\mathbf{x},t_n)\left|\frac{\partial\mathbf{r}(\theta;\mathbf{x},t_n^c)}{\partial\mathbf{x}}\right| d\theta d\mathbf{x} \\
&\quad= \Delta t_n^c\int_\Omega \bar{c}(\mathbf{x},t_n^c)q(\mathbf{x},t_n^c)z(\mathbf{x},t_n^c)d\mathbf{x} + E_q(\bar{c},z),
\end{aligned} \tag{3.5}$$

where $|\frac{\partial\mathbf{r}(\theta;\mathbf{x},t_n^c)}{\partial\mathbf{x}}| = 1+\mathcal{O}(t_n^c-\theta)$ is the Jacobian of the transformation from $\mathbf{x}$ to $\mathbf{y}=\mathbf{r}(\theta;\mathbf{x},t_n^c)$, and $E_q(\bar{c},z)$ is the local truncation error term.

Likewise, we evaluate the diffusion-dispersion term in (1.2) to obtain

$$\begin{aligned}
&\int_{t_{n-1}^c}^{t_n^c}\int_\Omega \nabla z(\mathbf{y},\theta)\cdot\mathbf{D}(\mathbf{y},\mathbf{u}(\mathbf{y},\theta))\nabla c(\mathbf{y},\theta)\ d\mathbf{y}d\theta \\
&\qquad= \Delta t_n^c\int_\Omega \nabla z(\mathbf{x},t_n^c)\cdot\mathbf{D}(\mathbf{x},\mathbf{u}(\mathbf{x},t_n^c))\nabla c(\mathbf{x},t_n^c)\ d\mathbf{x} + E_{\mathbf{D}}(c,z),
\end{aligned} \tag{3.6}$$

where $E_{\mathbf{D}}(c,z)$ is the local truncation error term.

Substituting (3.5) and (3.6) into (3.2), we obtain a reference equation

$$\begin{aligned}
&\int_\Omega \phi(\mathbf{x})c(\mathbf{x},t_n^c)z(\mathbf{x},t_n^c)\ d\mathbf{x} + \Delta t_n^c\int_\Omega \nabla z(\mathbf{x},t_n^c)\cdot\mathbf{D}(\mathbf{x},\mathbf{u}(\mathbf{x},t_n^c))\nabla c(\mathbf{x},t_n^c)\ d\mathbf{x} \\
&= \int_\Omega \phi(\mathbf{x})c(\mathbf{x},t_{n-1}^c)z(\mathbf{x},t_{n-1}^{c,+})\ d\mathbf{x} + \Delta t_n^c\int_\Omega \bar{c}(\mathbf{x},t_n^c)\ q(\mathbf{x},t_n^c)z(\mathbf{x},t_n^c)\ d\mathbf{x} + E(c,z),
\end{aligned} \tag{3.7}$$

where

$$\begin{aligned}
E(c,z) := \ &\int_{t_{n-1}^c}^{t_n^c}\int_\Omega c(\mathbf{y},\theta)\ \left[\phi(\mathbf{y})\ \frac{\partial z(\mathbf{y},\theta)}{\partial\theta} + \mathbf{u}(\mathbf{y},\theta)\cdot\nabla z(\mathbf{y},\theta)\right]\ d\mathbf{y}d\theta \\
&-E_{\mathbf{D}}(c,z) + E_q(\bar{c},z).
\end{aligned} \tag{3.8}$$

3.2. An ELLAM scheme. We present an ELLAM scheme for (1.2). In reservoir simulations, the physical domain is typically a rectangular domain or a finite union of rectangular domains. For simplicity, we assume $\Omega := (a_x,b_x)\times(a_y,b_y)$ and define a tensor-product spatial partition

$$\begin{aligned}
a_x =: \ & x_0^c < x_1^c < \cdots < x_i^c < \cdots < x_{I-1}^c < x_I^c \ := b_x, \\
a_y =: \ & y_0^c < y_1^c < \cdots < y_j^c < \cdots < y_{J-1}^c < y_J^c \ := b_y.
\end{aligned} \tag{3.9}$$

We define the trial and test function spaces to be the space of continuous and piecewise bilinear polynomials on the partition (3.9). Namely,

$$S^c(\Omega) := M^c_{0,1}[a_x, b_x] \otimes M^c_{0,1}[a_y, b_y], \tag{3.10}$$

where

$$\begin{aligned} M^c_{\alpha,\beta}[a_x, b_x] &:= \Big\{ v \in C^\alpha[a_x, b_x] \;\Big|\; v|_{[x^c_{i-1}, x^c_i]} \in P_\beta[x^c_{i-1}, x^c_i],\ i = 1, \ldots, I \Big\}, \\ M^c_{\alpha,\beta}[a_y, b_y] &:= \Big\{ v \in C^\alpha[a_y, b_y] \;\Big|\; v|_{[y^c_{j-1}, y^c_j]} \in P_\beta[y^c_{j-1}, y^c_j],\ j = 1, \ldots, J \Big\}. \end{aligned} \tag{3.11}$$

Here, $C^0[a, b]$ denotes the space of continuous functions on $[a, b]$ and $P_\beta[a, b]$ is the space of univariate polynomials of degree less than or equal to β, restricted to the interval $[a, b]$.

If we assume that the Darcy velocity $\mathbf{u}(\mathbf{x}, t^c_n)$ in (1.2) is known, then the ELLAM scheme is defined as follows: Find $c(\mathbf{x}, t^c_n) \in S^c(\Omega)$ such that

$$\begin{aligned} &\int_\Omega \phi(\mathbf{x}) c(\mathbf{x}, t^c_n) z(\mathbf{x}, t^c_n)\, d\mathbf{x} + \Delta t^c_n \int_\Omega \nabla z(\mathbf{x}, t^c_n) \cdot \mathbf{D}(\mathbf{x}, \mathbf{u}(\mathbf{x}, t^c_n)) \nabla c(\mathbf{x}, t^c_n)\, d\mathbf{x} \\ &\quad = \int_\Omega \phi(\mathbf{x}) c(\mathbf{x}, t^c_{n-1}) z(\mathbf{x}, t^{c,+}_{n-1})\, d\mathbf{x} + \Delta t^c_n \int_\Omega \bar{c}(\mathbf{x}, t^c_n)\, q(\mathbf{x}, t^c_n) z(\mathbf{x}, t^c_n)\, d\mathbf{x} \\ &\qquad\qquad \forall z(\mathbf{x}, t^c_n) \in S^c(\Omega). \end{aligned} \tag{3.12}$$

Remark 3.1. By using a characteristic tracking, the ELLAM scheme (3.12) symmetrizes the transport PDE (1.2), significantly reduces temporal errors and so generates accurate solutions even if large time steps are used in numerical simulations, and yields a 9-banded, symmetric, and positive-definite coefficient matrix. Furthermore, the ELLAM scheme conserves mass [8, 26], i.e.,

$$\int_\Omega \phi(\mathbf{x}) c(\mathbf{x}, t^c_n) d\mathbf{x} = \int_\Omega \phi(\mathbf{x}) c(\mathbf{x}, t^c_{n-1}) d\mathbf{x} + \int_{t^c_{n-1}}^{t^c_n} \int_\Omega \bar{c}(\mathbf{x}, t) q(\mathbf{x}, t) d\mathbf{x} dt, \tag{3.13}$$

which is of essential importance in applications.

Remark 3.2. Because $c(\mathbf{x}, t^c_n), z(\mathbf{x}, t^c_n) \in S^c(\Omega)$ are standard piecewise bilinear functions at time t^c_n, in (3.12) all the terms except the first one on the right-hand side are standard integrals in FEMs and can be evaluated in a fairly standard way. In the first term on the right-hand side, the value of $c(\mathbf{x}, t^c_{n-1})$ is known from the solution at the previous time step t^c_{n-1}. However, the test functions $z(\mathbf{x}, t^{c,+}_{n-1}) := \lim_{t \to t^c_{n-1},\ t > t^c_{n-1}} z(\mathbf{x}, t) = z(\tilde{\mathbf{x}}, t^c_n)$, where $\tilde{\mathbf{x}} = \mathbf{r}(t^c_n; \mathbf{x}, t^c_{n-1})$ is the point at the head of the characteristic that corresponds to $\mathbf{x}$ at the foot. The evaluation of this term becomes much more challenging in multiple dimensions, due to the multidimensional deformation of each cell $[x^c_{i-1}, x^c_i] \times [y^c_{j-1}, y^c_j]$ on which the test functions are defined as the geometry is backtracked from time step t^c_n to time step t^c_{n-1}.

The most practical approach for evaluating this term is to use a forward tracking algorithm proposed by Russell and Trujillo [26]. In this algorithm, an integration quadrature is enforced at time step t^c_{n-1} with respect to the fixed spatial grids (3.9) on which $c(\mathbf{x}, t^c_{n-1})$ is defined, and the difficult evaluation is the test function $z(\mathbf{x}, t^{c,+}_{n-1})$. Rather than backtracking the geometry and estimating the test functions by mapping the deformed geometry onto the fixed grids (3.9), discrete quadrature points chosen on the fixed grids at time step t^c_{n-1} can be tracked forward to time step t^c_n, where evaluation of $z(\mathbf{x}, t^c_n)$ is straightforward. Because the forward tracking algorithm

is used only to evaluate the first term on the right-hand side of (3.12), it has no effect on the solution grids (3.9) or the data structure of the discrete system for (3.12). Therefore, the forward tracking algorithm used here does not suffer from the complication of distorted grids, which complicates many forward tracking algorithms.

Remark 3.3. For a general velocity field $\mathbf{u}(\mathbf{x}, t)$, one cannot solve the initial-value problem (3.4) analytically to track characteristics. Hence, numerical quadratures (e.g., Euler or Runge–Kutta methods) were previously used to track characteristics in the ELLAM schemes for linear transport PDEs where $\mathbf{u}(\mathbf{x}, t)$ is assumed to be a known smooth function [1, 17, 31]. However, in the current circumstances, the velocity field $\mathbf{u}(\mathbf{x}, t)$ is given as a Raviart–Thomas MFEM solution to (1.1) (refer to section 4), which is only piecewise (cell-by-cell) smooth. Therefore, numerical quadratures would generate an inaccurate characteristic tracking, which in turn affects the accuracy of the solutions of the ELLAM schemes. In applications, within each cell the porosity $\phi(\mathbf{x})$ is constant and $u_x(\mathbf{x}, t_n^c)$ (or $u_y(\mathbf{x}, t_n^c)$) is linear (or constant) in the x direction and constant (or linear) in the y direction. Therefore, we can solve the problem (3.4) analytically to track the characteristics on a cell-by-cell basis [17, 19, 28]. In this way, we also minimize the effect of the well singularities on the characteristic tracking.

Remark 3.4. In the MMOC, which is a typical representative of many previous characteristic methods, (1.2) is rewritten in a nonconservative form

$$\phi \frac{\partial c}{\partial t} + \mathbf{u} \cdot \nabla c - \nabla \cdot (\mathbf{D}(\mathbf{x}, \mathbf{u}) \nabla c) = (\bar{c} - c) q, \quad \mathbf{x} \in \Omega, \quad t \in [0, T], \tag{3.14}$$

where the first equation in (1.1) has been used to get $(\nabla \cdot \mathbf{u})\ c = c\ q$.

Then the first two terms on the left-hand side of (3.14) are combined to form one term through a characteristic tracking [13]

$$\begin{aligned} &\phi(\mathbf{x}) \frac{\partial c(\mathbf{x}, t_n^c)}{\partial t} + \mathbf{u}(\mathbf{x}, t_n^c) \cdot \nabla c(\mathbf{x}, t_n^c) \\ &\quad = \sqrt{\phi^2(\mathbf{x}) + |\mathbf{u}(\mathbf{x}, t_n^c)|^2}\ \frac{dc(\mathbf{r}(t; \mathbf{x}, t_n^c), t)}{dt}\bigg|_{t = t_n^c} \\ &\quad \approx \phi(\mathbf{x}) \frac{c(\mathbf{x}, t_n^c) - c(\mathbf{x}^*, t_{n-1}^c)}{\Delta t_n^c}, \end{aligned} \tag{3.15}$$

where

$$\mathbf{x}^* := \mathbf{x} - \frac{\mathbf{u}(\mathbf{x}, t_n^c)}{\phi(\mathbf{x})} \Delta t_n^c. \tag{3.16}$$

Substituting (3.15) for the first two terms on the left-hand side of (3.14) and integrating the resulting equation against any test functions $v(\mathbf{x}) \in S^c(\Omega)$, one obtains the following MMOC scheme [13, 16] for (3.14):

$$\begin{aligned} &\int_\Omega \phi(\mathbf{x})\ \frac{c(\mathbf{x}, t_n^c) - c(\mathbf{x}^*, t_{n-1}^c)}{\Delta t_n^c}\ v(\mathbf{x}) d\mathbf{x} \\ &\qquad + \int_\Omega \nabla v(\mathbf{x}) \cdot \mathbf{D}(\mathbf{x}, \mathbf{u}(\mathbf{x}, t_n^c)) \nabla c(\mathbf{x}, t_n^c)\ d\mathbf{x} \\ &\quad = \int_\Omega (\bar{c}(\mathbf{x}, t_n^c) - c(\mathbf{x}, t_n^c))\ q(\mathbf{x}, t_n^c) v(\mathbf{x})\ d\mathbf{x} \qquad \forall v(\mathbf{x}, t_n^c) \in S^c(\Omega). \end{aligned} \tag{3.17}$$

Although by (1.5) $\mathbf{u}(\mathbf{x}, t) \cdot \mathbf{n}(\mathbf{x})|_\Gamma = 0$, there might be some $\mathbf{x} \in \Omega$, which is close to Γ, such that the corresponding $\mathbf{x}^*$ determined by (3.16) runs out of the domain

Ω. This leads to implementational and analytical difficulties in the application of the MMOC. In contrast, in the ELLAM scheme (3.12) the tracking algorithm is carried out by solving the problem (3.4) analytically on a cell-by-cell basis. Since the numerical Darcy velocity $\mathbf{u}$ satisfies the no-flow boundary condition, the characteristic tracking never runs out of the domain Ω and so avoids this difficulty. This is an additional advantage of the ELLAM scheme.

4. An MFEM for the pressure equation (1.1). Because they yield an accurate velocity field $\mathbf{u}$ for porous medium flows and conserve mass, MFEMs have been widely applied in porous medium flow problems [27]. In this section, we briefly describe an MFEM for the pressure system (1.1).

4.1. Preliminary notations. Let $L^2(\Omega)$ be the standard function space of all the Lebesgue square integrable functions on Ω. Then we define the Sobolev spaces

$$
\begin{aligned}
H^1(\Omega) &:= \left\{ v(\mathbf{x}) \;\middle|\; \frac{\partial v(x,y)}{\partial x},\ \frac{\partial v(x,y)}{\partial y} \in L^2(\Omega) \right\}, \\
L_0^2(\Omega) &:= \left\{ v(\mathbf{x}) \in L^2(\Omega) \;\middle|\; \int_\Omega v(\mathbf{x}) d\mathbf{x} = 0 \right\}, \\
H(\mathrm{div};\Omega) &:= \left\{ \mathbf{v}(\mathbf{x}) \in (L^2(\Omega))^2, \nabla \cdot \mathbf{v} \in L^2(\Omega) \right\} \\
H_0(\mathrm{div};\Omega) &:= \left\{ \mathbf{v}(\mathbf{x}) \in H(\mathrm{div};\Omega) \;\middle|\; \mathbf{v}(\mathbf{x}) \cdot \mathbf{n}(\mathbf{x}) = 0,\ \mathbf{x} \in \Gamma \right\}.
\end{aligned} \tag{4.1}
$$

Multiplying the second equation in (1.1) by $\mu(c)\ \mathbf{K}^{-1}(\mathbf{x})$ yields

$$
\mu(c(\mathbf{x},t))\mathbf{K}^{-1}(\mathbf{x})\ \mathbf{u}(\mathbf{x},t) + \nabla p(\mathbf{x},t) = \rho\ g\ \nabla d(\mathbf{x}), \quad \mathbf{x} \in \Omega, \quad t \in [0,T]. \tag{4.2}
$$

Integrating (4.2) against any test functions $\mathbf{v} \in H_0(\mathrm{div};\Omega)$ and applying the divergence theorem to the ∇p term, we obtain the first equation in (4.2). Then integrating the first equation in (1.1) against any test functions $w(\mathbf{x}) \in L_0^2(\Omega)$, we obtain the second equation in the following system:

$$
\begin{aligned}
\int_\Omega \mu(c)\ \mathbf{K}^{-1}\ \mathbf{u} \cdot \mathbf{v}\ d\mathbf{x} - \int_\Omega p\ \nabla \cdot \mathbf{v}\ d\mathbf{x} &= \int_\Omega \rho\ g\ \nabla d \cdot \mathbf{v}\ d\mathbf{x}, \\
\int_\Omega w\ \nabla \cdot \mathbf{u}\ d\mathbf{x} &= \int_\Omega q(\mathbf{x},t)\ w\ d\mathbf{x} \\
\forall \mathbf{v}(\mathbf{x}) \in H_0(\mathrm{div};\Omega) \quad & \forall w(\mathbf{x}) \in L_0^2(\Omega), \quad t \in [0,T].
\end{aligned} \tag{4.3}
$$

Equation (4.3) is a saddle-point problem which has been proven [6] to have a unique solution $(\mathbf{u}(\mathbf{x},t), p(\mathbf{x},t)) \in H_0(\mathrm{div};\Omega) \times L_0^2(\Omega)\ \forall\ t \in [0,T]$.

4.2. An MFEM for (1.1). We define the following space-time partition for the pressure system (1.1):

$$
\begin{aligned}
0 =: &\ t_0^p < t_1^p < \cdots < t_m^p < \cdots < t_{M-1}^p < t_M^p && := T, \\
a_x =: &\ x_0^p < x_1^p < \cdots < x_k^p < \cdots < x_{K-1}^p < x_K^p && := b_x, \\
a_y =: &\ y_0^p < y_1^p < \cdots < y_l^p < \cdots < y_{L-1}^p < y_L^p && := b_y.
\end{aligned} \tag{4.4}
$$

At each time step t_m^p, we define the trial and test function spaces to be the lowest order Raviart–Thomas MFEM space on the partition (4.4)

$$
\begin{aligned}
S^p(\Omega) &:= \Big(M^p_{0,1}[a_x,b_x]\times M^p_{-1,0}[a_y,b_y]\Big)\times\Big(M^p_{-1,0}[a_x,b_x]\times M^p_{0,1}[a_y,b_y]\Big),\\
S^p_0(\Omega) &:= \Big\{\mathbf{v}(\mathbf{x})\in S^p(\Omega)\ \Big|\ \mathbf{v}(\mathbf{x})\cdot\mathbf{n}(\mathbf{x})=0,\quad \mathbf{x}\in\Gamma\Big\},\\
W^p(\Omega) &:= M^p_{-1,0}[a_x,b_x]\times M^p_{-1,0}[a_y,b_y],\\
W^p_0(\Omega) &:= \left\{v(\mathbf{x})\in W^p(\Omega)\ \Big|\ \int_\Omega v(\mathbf{x})d\mathbf{x}=0\right\},
\end{aligned}
\tag{4.5}
$$

with

$$
\begin{aligned}
M^p_{\alpha,\beta}[a_x,b_x] &:= \Big\{v\in C^\alpha[a_x,b_x]\ \Big|\ v|_{[x^p_{k-1},x^p_k]}\in P_\beta[x^p_{k-1},x^p_k],\ k=1,\dots,K\Big\},\\
M^p_{\alpha,\beta}[a_y,b_y] &:= \Big\{v\in C^\alpha[a_y,b_y]\ \Big|\ v|_{[y^p_{l-1},y^p_l]}\in P_\beta[y^p_{l-1},y^p_l],\ l=1,\dots,L\Big\}.
\end{aligned}
\tag{4.6}
$$

Here, $C^{-1}[a,b]$ is the space of piecewise continuous functions. $C^0[a,b]$ and $P_\beta[a,b]$ are defined in (3.11).

If we assume that $c(\mathbf{x},t_m^p)$ is known, an MFEM for the pressure equation (1.1) can be formulated as follows: Find $\mathbf{u}(\mathbf{x},t_m^p)\in S^p(\Omega)$ and $p(\mathbf{x},t_m^p)\in W_0^p(\Omega)$ such that

$$
\begin{aligned}
\int_\Omega \mu(c(\mathbf{x},t_m^p))\ \mathbf{K}^{-1}\ \mathbf{u}(\mathbf{x},t_m^p)\cdot\mathbf{v}\ d\mathbf{x}&\\
-\int_\Omega p(\mathbf{x},t_m^p)\ \nabla\cdot\mathbf{v}\ d\mathbf{x} &= \int_\Omega \rho\ g\ \nabla d\cdot\mathbf{v}\ d\mathbf{x}\quad \forall\mathbf{v}(\mathbf{x})\in S^p(\Omega),\\
\int_\Omega w\ \nabla\cdot\mathbf{u}(\mathbf{x},t_m^p)\ d\mathbf{x} &= \int_\Omega q(\mathbf{x},t_m^p)\ w\ d\mathbf{x}\quad \forall w(\mathbf{x})\in W_0^p(\Omega).
\end{aligned}
\tag{4.7}
$$

Remark 4.1. In the pressure system (1.1), the sharp changes of the permeability tensor $\mathbf{K}(\mathbf{x})$ and the viscosity coefficient $\mu(c)$ across fluid interfaces often lead to large changes in the pressure gradient which, in a compensatory fashion, yield a fairly smooth Darcy velocity $\mathbf{u}$. By approximating both p and $\mathbf{u}$ from system (1.1) simultaneously, MFEMs generate more accurate Darcy velocities than standard FDMs or FEMs. Moreover, they conserve mass. Furthermore, the MFEM approximations to the Darcy velocity $\mathbf{u}(\mathbf{x},t_m^p)$ are particularly suited for the semianalytical characteristic tracking used in the ELLAM scheme (3.12) and guarantee that the tracking stays within the physical domain (refer to Remarks 3.3 and 3.4).

Remark 4.2. While they possess various numerical advantages, MFEMs generate an indefinite coefficient matrix for the discrete algebraic system and are more expensive to solve than standard FDMs or FEMs. Moreover, the MFEM function spaces for p and $\mathbf{u}$ must be chosen carefully, so that they satisfy the inf-sup stability condition. Extensive research has been conducted on the efficient solution of MFEM discrete systems and on the development of various generalized MFEM spaces [7]. Furthermore, an additional numerical difficulty for the MFEMs for porous medium flows is the effect of the singular source and sink terms $q(\mathbf{x},t)$ in (4.7) (see [15, 27]).

5. An ELLAM-MFEM sequential solution technique for the systems (1.1)–(1.2). Because of the couplings and nonlinearities of the PDEs in the systems (1.1)–(1.2), the effect of the point sources and sinks, the use of large grid-spacings, and the convection-diffusion feature of (1.2), fully coupled and fully implicit methods are commonly used in large-scale simulators for the systems (1.1)–(1.2). However, they are computationally expensive per time step and introduce excessive numerical diffusion

and greatly reduced accuracy with large time steps. Since its introduction by Douglas, Ewing, and Wheeler [12], the MFEM sequential solution technique has proven to be an efficient procedure for the simulation of miscible fluid flow processes in porous media. The MMOC-MFEM solution technique proposed by Ewing, Russell, and Wheeler [16] eliminates the possible nonphysical oscillations in the MFEM sequential techniques and allows larger time steps to be used in the simulation of the systems (1.1)–(1.2). However, the MMOC-MFEM sequential method fails to conserve mass and has difficulties in treating boundary conditions (recall Remark 3.4).

In this section, we present an ELLAM-MFEM solution technique for the systems (1.1)–(1.2), in which we use the ELLAM scheme (3.12) for (1.2) and the MFEM (4.7) for the pressure system (1.1). In the miscible displacement of incompressible fluid flow processes in a porous medium reservoir, the Darcy velocity field $\mathbf{u}(\mathbf{x}, t)$ often changes less rapidly than the concentration, even if characteristics are taken into account. Therefore, it is appropriate to use coarser spatial grids and time steps (4.4) for the pressure system (1.1) than the spatial grids (3.9) and time steps (3.1) for (1.2). We assume that the spatial grids (3.9) and the time steps (3.1) are obtained by subdividing the spatial grids and the time steps (4.4). Namely, there exist

$$
\begin{array}{l}
0 =: N_0 < N_1 < \cdots < N_m < \cdots < N_{M-1} < N_M := N, \\
0 =: I_0 \ < I_1 \ < \cdots < I_k \ < \cdots < I_{K-1} \ < I_K \ := I, \\
0 =: J_0 \ < J_1 \ < \cdots < J_l \ < \cdots < J_{L-1} \ < J_L \ := J,
\end{array} \tag{5.1}
$$

such that

$$
t^c_{N_m} = t^p_m, \quad x^c_{I_k} = x^p_k, \quad y^c_{J_l} = y^p_l, \quad 0 \le m \le M,\ 0 \le k \le K,\ 0 \le l \le L. \tag{5.2}
$$

For $n = N_{m-1}+1, N_{m-1}+2, \ldots, N_m$, the concentration time step t^c_n relates to the pressure time steps by $t^p_{m-1} < t^c_n \le t^p_m$. Thus, we require a velocity approximation for the ELLAM scheme (3.12) based on $\mathbf{u}(\mathbf{x}, t^p_m)$ and earlier values. We define a velocity approximation by an extrapolation

$$
\begin{aligned}
(E\mathbf{u})(\mathbf{x}, t^c_n) \ &:= \left(1 + \frac{t^c_n - t^p_{m-1}}{t^p_{m-1} - t^p_{m-2}}\right)\mathbf{u}(\mathbf{x}, t^p_{m-1}) - \frac{t^c_n - t^p_{m-1}}{t^p_{m-1} - t^p_{m-2}}\mathbf{u}(\mathbf{x}, t^p_{m-2}), \\
&\qquad n = N_{m-1}+1, N_{m-1}+2, \ldots, N_m, \quad m = 2, 3, \ldots, M, \\
(E\mathbf{u})(\mathbf{x}, t^c_n) \ &:= \mathbf{u}(\mathbf{x}, 0), \quad n = 1, 2, \ldots, N_1, \quad m = 1.
\end{aligned} \tag{5.3}
$$

Equivalently, the first equation in (5.3) can be rewritten as

$$
\begin{aligned}
(E\mathbf{u})(\mathbf{x}, t^c_n) \ &:= \ \frac{t^p_m - t^c_n}{t^p_m - t^p_{m-1}}\mathbf{u}(\mathbf{x}, t^p_{m-1}) + \frac{t^c_n - t^p_{m-1}}{t^p_m - t^p_{m-1}}(E\mathbf{u})(\mathbf{x}, t^p_m), \\
&\qquad n = N_{m-1}+1, N_{m-1}+2, \ldots, N_m, \quad m = 2, 3, \ldots, M,
\end{aligned} \tag{5.4}
$$

where $(E\mathbf{u})(\mathbf{x}, t^p_m)$ is evaluated by (5.3) with $t^c_n = t^p_m$ or $n = N_m$.

We are now in a position to present an ELLAM-MFEM sequential decoupling and linearization solution technique for the coupled systems (1.1)–(1.2).

Initialization:
for $m = 0$ and $n = 0$ **do**

A1: Define $c(\mathbf{x}, 0)$ to be the L^2-projection of $c_0(\mathbf{x})$, which is given in (1.6), to the finite element subspace $S^c(\Omega)$: find $c(\mathbf{x}, 0) \in S^c(\Omega)$, such that

$$\int_\Omega c(\mathbf{x}, 0)v(\mathbf{x})d\mathbf{x} = \int_\Omega c_0(\mathbf{x})v(\mathbf{x})d\mathbf{x} \quad \forall v(\mathbf{x}) \in S^c(\Omega). \tag{5.5}$$

A2: With $c(\mathbf{x}, 0)$ obtained from (5.5), find $\mathbf{u}(\mathbf{x}, 0) \in S^p(\Omega)$ and $p(\mathbf{x}, 0) \in W_0^p(\Omega)$, such that

$$\begin{aligned} &\int_\Omega \mu(c(\mathbf{x}, 0))\ \mathbf{K}^{-1}\ \mathbf{u}(\mathbf{x}, 0) \cdot \mathbf{v}\ d\mathbf{x} \\ &\qquad -\int_\Omega p(\mathbf{x}, 0)\ \nabla \cdot \mathbf{v}\ d\mathbf{x} \quad = \quad \int_\Omega \rho\ g\ \nabla d \cdot \mathbf{v}\ d\mathbf{x} \quad \forall \mathbf{v}(\mathbf{x}) \in S^p(\Omega), \\ &\qquad \int_\Omega w\ \nabla \cdot \mathbf{u}(\mathbf{x}, 0)\ d\mathbf{x} \quad = \quad \int_\Omega q(\mathbf{x}, 0)\ w\ d\mathbf{x} \quad \forall w(\mathbf{x}) \in W_0^p(\Omega). \end{aligned} \tag{5.6}$$

end do
for $m = 1, 2, \ldots, M$ **do**

B1: **for** $n = N_{m-1} + 1, N_{m-1} + 2, \ldots, N_m$ **do**
—Find $c(\mathbf{x}, t_n^c) \in S^c(\Omega)$, such that for $(E\mathbf{u})(\mathbf{x}, t_n^c)$ given in (5.3)

$$\begin{aligned} &\int_\Omega \phi(\mathbf{x})c(\mathbf{x}, t_n^c)z(\mathbf{x}, t_n^c)\ d\mathbf{x} + \Delta t_n^c \int_\Omega\ \nabla z(\mathbf{x}, t_n^c) \cdot \mathbf{D}(\mathbf{x}, (E\mathbf{u})(\mathbf{x}, t_n^c))\nabla c(\mathbf{x}, t_n^c)\ d\mathbf{x} \\ &= \int_\Omega \phi(\mathbf{x})c(\mathbf{x}, t_{n-1}^c)z(\mathbf{x}, t_{n-1}^{c,+})\ d\mathbf{x} + \Delta t_n^c \int_\Omega \bar{c}(\mathbf{x}, t_n^c)\ q(\mathbf{x}, t_n^c)z(\mathbf{x}, t_n^c)\ d\mathbf{x} \\ &\qquad\qquad \forall \mathbf{z}(\mathbf{x}, t_n^c) \in S^c(\Omega). \end{aligned} \tag{5.7}$$

end do

B2: Since $t_{N_m}^c = t_m^p$ and $c(\mathbf{x}, t_m^p) = c(\mathbf{x}, t_{N_m}^c)$ is obtained from (5.7) with $n = N_m$, solve the following equation for $\mathbf{u}(\mathbf{x}, t_m^p) \in S^p(\Omega)$ and $p(\mathbf{x}, t_m^p) \in W_0^p(\Omega)$:

$$\begin{aligned} &\int_\Omega \mu(c(\mathbf{x}, t_m^p))\ \mathbf{K}^{-1}\ \mathbf{u}(\mathbf{x}, t_m^p) \cdot \mathbf{v}\ d\mathbf{x} \\ &\qquad -\int_\Omega p(\mathbf{x}, t_m^p)\ \nabla \cdot \mathbf{v}\ d\mathbf{x} \quad = \quad \int_\Omega \rho\ g\ \nabla d \cdot \mathbf{v}\ d\mathbf{x} \quad \forall \mathbf{v}(\mathbf{x}) \in S^p(\Omega), \\ &\qquad \int_\Omega w\ \nabla \cdot \mathbf{u}(\mathbf{x}, t_m^p)\ d\mathbf{x} \quad = \quad \int_\Omega q(\mathbf{x}, t_m^p)\ w\ d\mathbf{x} \quad \forall w(\mathbf{x}) \in W_0^p(\Omega). \end{aligned} \tag{5.8}$$

end do

Remark 5.1. The ELLAM-MFEM solution technique inherits all the numerical advantages of the ELLAM schemes for linear transport PDEs and the MMOC-MFEM sequential method, while overcoming the shortcomings of the MMOC-MFEM method. It significantly reduces the temporal errors and thus generates accurate numerical solutions even if very large time steps Δt_n^c are used. It symmetrizes (1.2) and yields a symmetric and positive-definite coefficient matrix with a condition number of $\mathcal{O}(1 + |\mathbf{D}|\Delta t_n^c/h_c^2)$, where

$$\begin{aligned} h_c &:= \min_{\{i=1,\ldots,I;\ j=1,\ldots,J\}} \{\Delta x_c := x_i^c - x_{i-1}^c,\ \Delta y_c := y_j^c - y_{j-1}^c\}, \\ h_p &:= \min_{\{k=1,\ldots,K;\ l=1,\ldots,L\}} \{\Delta x_p := x_k^p - x_{k-1}^p,\ \Delta y_p := y_l^p - y_{l-1}^p\}. \end{aligned} \tag{5.9}$$

Remark 5.2. The MFEM (4.7) has an indefinite symmetric coefficient matrix with a condition number of $\mathcal{O}(h_p^{-2})$. Hence, it is much more expensive to solve than the ELLAM scheme (3.12), even if preconditioning techniques are used. On the other hand, by utilizing the flow property that the Darcy velocity field $\mathbf{u}$ changes less rapidly than the concentration c, the ELLAM-MFEM (as well as the MFEM-based and the MMOC-MFEM) solution technique allows much coarser spatial grids and time steps for the pressure system (1.1) to be used in a simulation without loss of accuracy. The application of the coarser spatial grids for the pressure reduces the size of the coefficient matrix and therefore its condition number, while the use of coarser time steps reduces the number of times the MFEM (4.7) needs to be solved. In this way, the ELLAM-MFEM sequential technique further enhances the computational efficiency.

Remark 5.3. The ELLAM-MFEM solution technique could be iterated at each pressure time step t_m^p. This would use the computed Darcy velocity $\mathbf{u}(\mathbf{x}, t_m^p)$ from (5.8) to replace the extrapolated Darcy velocity $(E\mathbf{u})(\mathbf{x}, t_m^p)$ in (5.4) in computing $(E\mathbf{u})(\mathbf{x}, t_n^c)$. Then the new velocity $(E\mathbf{u})(\mathbf{x}, t_n^c)$ would be used in the step B1. The present sequential procedure would be considered the first iteration. This was not attempted in this study. An iterated ELLAM-MFEM sequential solution procedure will probably be needed in more complicated applications.

6. Numerical experiments. In this section, we apply the ELLAM-MFEM solution technique to a variety of two-dimensional miscible displacement problems of one incompressible fluid by another in porous media to examine its performance. The test runs include problems with large mobility ratios, anisotropic dispersion in tensor form, discontinuous permeabilities and porosities, and point sources and sinks. In the numerical experiments, we tried to choose test problems with reported data and results in the literature, to justify that the ELLAM-MFEM solution technique generates correct solutions, and to have some approximate comparisons of the ELLAM-MFEM technique with other widely used methods in terms of the spatial grids and time steps used in order to generate comparable solutions.

The numerical experiments simulated miscible displacement within a horizontal reservoir of a thickness of one unit over a period of 10 years (3600 days) for one-quarter of a regular five-spot pattern with injection and production wells at the corners. The spatial domain is $\Omega = (0, 1000) \times (0, 1000)$ ft^2, the time period $[0, T] = [0, 3600]$ days, and the viscosity of the oil is $\mu(0) = 1.0$ cp. The injection well is located at the upper-right corner $(1000, 1000)$ of the domain with an injection rate of $q = 30$ ft^2/day and an injection concentration of $\bar{c} = 1.0$. The production well is located at the lower-left corner $(0, 0)$ with a production rate of $q = 30$ ft^2/day. The initial concentration is $c_0(x, y) = 0$. In the numerical simulation, we use a fairly coarse uniform spatial grid of $\Delta x^c = \Delta y^c = \Delta x^p = \Delta y^p = 50$ ft in both x and y directions, although we understand that a simulation on a nonuniform partition with finer cells around wells probably generate more accurate solutions and our simulator allows such a partition. We also take an extremely large time step of $\Delta t^c = \Delta t^p = 360$ days (*one year*). In contrast, in the numerical results reported previously in the literature, the time steps were chosen from *a few days* for FDM or FEM simulators to about *a month* for MMOC-based simulators [16, 15, 25].

Test 1. We assume that the porous medium is homogeneous and isotropic. The permeability coefficients (diagonal entries of $\mathbf{K}$) are given by $k_x = k_y = 80$ md, and the porosity of the medium is specified as $\phi = 0.1$. Furthermore, we assume that the mobility ratio between the resident and injected fluids is $M = 1$ and that the physical diffusion-dispersion term is given by $D_m := \phi\, d_m = 1.0$ ft^2/day, $D_l := \phi\, d_l = 0.0$ ft,

FIG. 1. *The concentration of the invading component in Test* 1 *at* 3 *and* 10 *years.*

and $D_t := \phi\ d_t = 0.0$ ft. Namely, only molecular diffusion is present. This example has been widely used in testing the performance of a simulator since the qualitative behavior of its numerical simulation is understood fairly well.

The surface and contour plots for the concentration of the invading fluid at $t =$ 3 years (1080 days) are presented in Figure 1 (a) and (b). The contours of the concentration are a family of concentric circles, which are physically reasonable due to the following reasons: (i) Mobility ratio $M = 1$ implies that the fluid has a constant viscosity $\mu(c) = \mu(0)$. (ii) Together with the facts that $\mathbf{K}$ is a constant tensor and that the reservoir is horizontal, we see that the Darcy velocity $\mathbf{u}$ is actually radial. (iii) Only the molecular diffusion, which is isotropic, is present. In fact, since the model does not include any permeability/viscosity variations or mechanical dispersion effects, any fingering phenomenon, if it happened, would be due to numerical errors and not to the modeling of any physics. Because of the effect of the no-flow boundary conditions and the production wells, the invading fluid moves faster along the diagonal (flow direction) of the reservoir with no fingering phenomena present. This was observed from the surface and contour plots, Figure 1 (c) and (d), of the concentration of the invading fluid at $t = 10$ years (3600 days). These results demonstrate that even

though extremely large time steps have been used in the simulation, the ELLAM-MFEM simulator still generates accurate and physically reasonable solutions.

To investigate the mass conservation property of the ELLAM-MFEM solution technique, we calculate the mass balance error numerically. We divide the difference of the left-hand and right-hand sides of (3.13) by the mass $\int_\Omega \phi(\mathbf{x})c(\mathbf{x}, t_n^c)d\mathbf{x}$ at the time t_n^c. At the production well, $\bar{c}(\mathbf{x}, t) = c(\mathbf{x}, t)$. We use a trapezoidal quadrature to evaluate the temporal integral. In the 10-year simulation, the mass balance error is 1.99×10^{-4}. With a refined time step of $\Delta t/10$, the mass balance error is reduced to 2.05×10^{-5}. To indicate the accuracy of the ELLAM-MFEM solution technique, we compare the numerical solution with the solution obtained with a refined grid of $\Delta t/10$ and $\Delta x/2 = \Delta y/2$. The difference in the L^∞- and L^1-norms is 5.71×10^{-2} and 4.88×10^{-3}, respectively.

Test 2. We consider a simulation with an adverse mobility ratio of $M = 41$ and an anisotropic dispersion in tensor form. The physical diffusion-dispersion term is given by $D_m := \phi\ d_m = 0.0$ ft^2/day, $D_l := \phi\ d_l = 5.0$ ft, and $D_t := \phi\ d_t = 0.5$ ft. The permeability and porosity of the medium are taken to be the same as in Test 1. Equations (1.1)–(1.2) were derived via a volume-averaging mechanism and hold only on a macroscopic scale, so they do not model physical behavior on a pore-volume scale. Nevertheless, by including differences in longitudinal versus transverse dispersion levels (which can be viewed as a macroscopic reflection of the microscopic mechanism), (1.1)–(1.2) should model the corresponding (microscopic) behavior of the flow in the form of a macroscopic fingering phenomenon due to varying flow velocities. The macroscopic fingering phenomenon should propagate and grow in a manner akin to viscous fingering on a smaller scale. We refer readers to [15] for detailed descriptions on these concepts.

The surface and contour plots for the concentration of the invading fluid at $t = 3$ years (1080 days) and 10 years (3600 days) are presented in Figure 2 (a)–(b) and (c)–(d), respectively. Due to the effect of the large adverse mobility ratio $M = 41$, the viscosity $\mu(c)$ given by the expression (1.3) changes rapidly across the steep fluid interface. Consequently, the Darcy velocity $\mathbf{u}$ has a rapid change across the fluid interface. Moreover, the large differences in longitudinal versus transverse dispersion levels force the fluid flow to move much faster along the diagonal direction (flow direction) from the injection well to the production well. The concentration front moves much faster in the diagonal direction than it did when only the molecular diffusion term was present.

Test 3. We consider the numerical simulation of a miscible displacement in a porous medium with discontinuous permeabilities, which is often encountered in many field applications. In the example run, we use the same data as in Test 2, with an exception that $k_x = k_y = 80$ md is specified on the subdomain $\Omega_L := (0, 1000) \times (0, 500)$ (the lower half of the domain Ω) and that $k_x = k_y = 20$ md is given on the subdomain $\Omega_U := (0, 1000) \times (500, 1000)$ (the upper half of the domain Ω). The surface and contour plots for the concentration of the invading fluid at $t = 3$ years (1080 days) and 10 years (3600 days) are presented in Figure 3 (a)–(b) and (c)–(d), respectively.

From Figure 3 (a)–(b), we see that the concentration front initially moves faster in the vertical direction than in the horizontal direction, because the subdomain Ω_L has a larger permeability and, thus, a larger Darcy velocity than the subdomain Ω_U. Once the invading fluid reaches Ω_L, it starts to move much faster in the horizontal direction on Ω_L than on Ω_U due to the same reason.

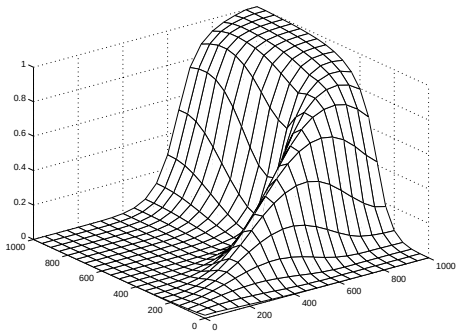
(d) *Contour plot at* $t = 10$ *years.*

FIG. 2. *The concentration of the invading component in Test* 2 *at* 3 *and* 10 *years.*

Test 4. We consider a simulation in a porous medium with piecewise structures. On the subdomain $\Omega_I := (150, 550) \times (150, 550)$, we specify that the permeability of the medium is $k_x = k_y = 25$ md, that the porosity of the medium is $\phi = 0.09$, and that the physical diffusion-dispersion term is $D_m := \phi\ d_m = 0.0$ ft^2/day, $D_l := \phi\ d_l = 4.5$ ft, and $D_t := \phi\ d_t = 0.45$ ft. On the subdomain $\Omega_O := \Omega - \Omega_I$, we specify that the permeability of the medium is $k_x = k_y = 80$ md, that the porosity of the medium is $\phi = 0.1$, and that the physical diffusion-dispersion term is $D_m := \phi\ d_m = 0.0$ ft^2/day, $D_l := \phi\ d_l = 5.0$ ft, and $D_t := \phi\ d_t = 0.5$ ft. The mobility ratio is still given as $M = 41$. The surface and contour plots for the concentration of the invading fluid at $t = 3$ years (1080 days) and 5 years (1800 days) are presented in Figure 4 (a)–(d), while the corresponding plots at $t = 7$ years (2520 days) and 10 years (3600 days) are presented in Figure 4 (e)–(h).

From these numerical results, we have the following observations: (i) The ELLAM-MFEM sequential solution technique can simulate fluid flows in porous media with fairly complex structures, and generates accurate and physically reasonable solutions even though a fairly coarse spatial grid and an extremely large time step are used in the simulation that in turn implies significantly improved computational efficiency.



(a) *Surface plot at* $t = 3$ *years.*

(ii) Comparing these results with those in Test 2, we see that if one has a choice, one should put the production well in a low permeability zone to increase the area swept by the injected fluid. This illustrates how the results of numerical simulations could help the decision making in the petroleum reservoir industry. (iii) A very important technique in enhanced oil recovery is the use of polymers in flooding processes to alter the permeability of the reservoir porous medium to allow the fluid to flow in certain ways. Since the polymers are highly viscous, they can be used to selectively block or reduce the permeabilities of certain pores or flow regions to direct the fluid flow in a manner to optimize the hydrocarbon recovery. Test 4 could also serve as a demonstration for this technique. In this case, one can view that the original fluid and porous medium properties are given as in Test 2. By injecting some polymers in some ways, one alters the properties of the medium to those given in this test. By comparing the corresponding results in Figures 2 and 4, we see that the injected fluid in Figure 4 swept a larger area, which in turn implies a larger output. Since a major cost in the petroleum industry is the cost of drilling (injection and production) wells, these results show the effect of enhanced oil recovery.

7. Summary and conclusions. We develop an ELLAM-MFEM sequential solution technique for miscible fluid flows in porous media with injection and production wells (point sources and sinks), in which we use an ELLAM to solve the transport equation for concentration and an MFEM to solve the pressure equation for the pressure and Darcy velocity. The ELLAM-MFEM solution technique significantly reduces the temporal truncation errors, and thus generates accurate numerical solutions even if fairly coarse spatial grids and very large time steps are used. It symmetrizes the transport equation and greatly reduces or eliminates nonphysical oscillation and/or excessive numerical dispersion present in many large-scale simulators that are widely used in industrial applications. In this manner, the ELLAM-MFEM solution technique has a greatly improved computational efficiency over many other methods. Furthermore, the ELLAM-MFEM solution technique conserves mass and treats boundary conditions accurately, and therefore overcomes all the shortcomings of the MMOC-MFEM method while maintaining its numerical advantages.

Previous numerical experiments [1, 31] showed that the ELLAM often outperformed many widely used methods, such as the upwind FDM, various Galerkin and Petrov–Galerkin FEMs [2, 5, 10], the streamline diffusion FEMs [20, 21], and the MUSCL and minmod schemes [11, 14, 18, 29] in the context of linear transport PDEs. The present numerical experiments illustrate that the ELLAM-MFEM solution technique can simulate miscible displacements of incompressible fluid flows in porous media accurately with fairly coarse spatial grids as well as very large time steps, which are much larger than the time steps used in the MMOC-MFEM sequential solution procedure and one or two orders of magnitude larger than those used in many large-scale simulators. The ELLAM-MFEM technique can treat large mobility ratios, discontinuous permeabilities and porosities, anisotropic dispersion in tensor form, and point sources and sinks.

FOURIER ANALYSIS OF GMRES(m) PRECONDITIONED BY MULTIGRID*

ROMAN WIENANDS†, CORNELIS W. OOSTERLEE†, AND TAKUMI WASHIO‡

Abstract. This paper deals with convergence estimates of GMRES(m) [Saad and Schultz, *SIAM J. Sci. Statist. Comput.*, 7 (1986), pp. 856–869] preconditioned by multigrid [Brandt, *Math. Comp.*, 31 (1977), pp. 333–390], [Hackbusch, *Multi-Grid Methods and Applications*, Springer, Berlin, 1985]. Fourier analysis is a well-known and useful tool in the multigrid community for the prediction of two-grid convergence rates [Brandt, *Math. Comp.*, 31 (1977), pp. 333–390], [Stüben and Trottenberg, in *Multigrid Methods*, Lecture Notes in Math. 960, K. Stüben and U. Trottenberg, eds., Springer, Berlin, pp. 1–176]. This analysis is generalized here to the situation in which multigrid is a preconditioner, since it is possible to obtain the whole spectrum of the two-grid iteration matrix. A preconditioned Krylov subspace acceleration method like GMRES(m) implicitly builds up a minimal residual polynomial. The determination of the polynomial coefficients is easily possible and can be done explicitly since, from Fourier analysis, a simple block-diagonal two-grid iteration matrix results. Based on the GMRES(m) polynomial, sharp theoretical convergence estimates can be obtained which are compared with estimates based on the spectrum of the iteration matrix. Several numerical scalar test problems are computed in order to validate the theoretical predictions.

Key words. Fourier analysis, multigrid, restarted GMRES

1. Introduction.

Nowadays, it has become popular to study the convergence of multilevel methods and to use them in combination with a Krylov subspace acceleration method, in other words, to use multilevel methods as a preconditioner. Often the cycling in a hierarchy of grids is simplified compared to standard multigrid cycling; i.e., the multiplicative cycling between the fine and coarse grids is replaced by an additive (simultaneous) cycling. It is then necessary to use this additive method as a preconditioner to obtain a converging method even for simple problems. Recently, standard (multiplicative) multigrid solvers [1], [8] have been used as preconditioners as well. This application of standard multigrid is beneficial in situations where standard multigrid alone does not converge fully satisfactorily, because certain error frequencies are not reduced well enough. This occurs mainly when complicated PDEs are solved. In general, it is difficult to construct *robust* multigrid solvers for large classes of problems. From this point of view, it makes sense to increase the class of problems for which proven efficient multigrid solvers exist by accelerating (standard) multigrid by a Krylov subspace method. Among many other papers, this approach has been presented in [11], where a symmetric multigrid method was accelerated by CG, in [3] for problems with fine level structures, in [13] for linear singularly perturbed problems, and in [14] for nonlinear problems.

Here, we theoretically analyze one combined solution method, restarted GMRES, GMRES(m), preconditioned by multigrid. We derive quantitative convergence results. The basis for the theoretical convergence estimates is Fourier analysis, which

is a well-known tool for obtaining two-grid convergence factors (see [1], [19]). The typical use of the two-grid Fourier analysis in a multigrid context is that the spectral radius is obtained theoretically. It is the basis for asymptotic multigrid convergence estimates [19]. Two-grid Fourier analysis transforms a two-grid iteration matrix into a block-diagonal matrix from which more information about the spectrum is easily obtained. Fourier analysis uses unitary basis transformations to simplify the representation of the two-grid iteration matrix. It is therefore suitable for the estimate of the multigrid preconditioned GMRES(m) convergence since unitary transformations do not affect the convergence behavior of GMRES [15]. A preconditioned Krylov subspace acceleration method like GMRES(m) implicitly builds up a minimal residual polynomial. The determination of the polynomial coefficients is easily possible and can be done explicitly, since a block-diagonal matrix results with the help of the Fourier analysis.

In this paper, we restrict ourselves to standard problems coming from linear scalar PDEs discretized with finite differences on uniform Cartesian grids and we keep the multigrid method simple. For example, we restrict ourselves to point smoothers combined with standard grid coarsening and analyze the effect of Krylov subspace acceleration for anisotropic diffusion problems and for problems with mixed derivatives, although it is known that other (more expensive) smoothers or other coarsening strategies are appropriate remedies for the poor convergence of such equations. In this way we gain insight in the behavior of the combination of multigrid and GMRES(m).

In section 2 a multigrid preconditioner is presented and the rigorous two-grid Fourier analysis (see [19], [20]) is repeated briefly for 3D problems. The information on the multigrid preconditioner obtained is used in section 3, where different ways to analyze GMRES(m) preconditioned by multigrid are discussed.

There are actually two types of Fourier analysis available in the multigrid community. The first one is the analysis called "rigorous analysis" here, since it explicitly takes boundary conditions into account and discrete eigenfunctions are related to the discrete mesh size. Discrete sine functions are the basis in case Dirichlet boundary conditions are considered [19]. This analysis is, however, restricted to model situations, i.e., to symmetric problems and standard multigrid components. The second possibility is known as local mode analysis [1]. Exponential functions are the basis for the analysis. A discretization at domain boundaries cannot be taken into account. This analysis can be used for a wider range of PDEs and multigrid components. Local mode two-grid analysis and its generalization to multigrid preconditioned GMRES(m) is explained in section 4. Several numerical tests compare the theoretical convergence estimates with the actual numerical convergence.

For symmetric equations it is possible to construct a symmetric multigrid cycle and to apply CG as Krylov subspace acceleration method. We will not do this in section 3 because CG cannot be applied to the unsymmetric multigrid solvers MG-RB (multigrid solver based on pre- and post-smoothing by red-black Gauss–Seidel relaxation) from section 2 and MG-FF (multigrid solver based on pre- and post-smoothing by lexicographical Gauss–Seidel relaxation) from section 4. Furthermore, we are dealing with unsymmetric equations in sections 4.2 and 4.3. However, the analysis as described in section 3 carries over to an acceleration by CG in a straightforward manner. (See also the first remark in section 4.1.)

Furthermore, a relation to other techniques in which (multistage) parameters for smoothing methods, or acceleration parameters for coarse grid corrections [4], are optimized is presented in section 4.3. Such approaches can easily be viewed in the

framework of Krylov subspace acceleration.

The multigrid purist may not like the approach presented here with multigrid viewed as a preconditioner. It is, of course, also possible to try to construct an optimal multigrid method for each separate problem. For the purist, the analysis might give an indication as to how far his present method is from an optimal multigrid solution method. In other words, if an additional acceleration of the convergence is found by the Fourier analysis of multigrid preconditioned GMRES(m), it must also be possible to tune one of the multigrid components, so that multigrid as a stand alone solver is improved.

2. Rigorous Fourier analysis of multigrid. The Poisson equation, a simple test problem, is chosen to explain the possibilities of convergence estimates by Fourier analysis for multigrid. We apply the standard 5-point discretization on a square ($d = 2$) and the 7-point discretization on a cube ($d = 3$) with Dirichlet boundary conditions using a uniform mesh with meshsize $h = 1/n$:

$$\begin{aligned} A_h u_h(\boldsymbol{x}) = -\Delta_h u_h(\boldsymbol{x}) = b_h(\boldsymbol{x}) \quad &\text{on } \Omega_h = (0,1)^d \cap G_h, \\ u_h(\boldsymbol{x}) = 0 \quad &\text{on } \Gamma_h = ([0,1]^d \setminus \Omega_h) \cap G_h, \end{aligned} \tag{1}$$

with $G_h := \{\boldsymbol{x} = h\boldsymbol{j},\ \boldsymbol{j} \in \mathbb{Z}^d\}$. Equation (1), in stencil notation, looks like

$$A_h u_h(\boldsymbol{x}) = \sum_{\boldsymbol{\kappa} \in J} a_{\boldsymbol{\kappa}} u_h(\boldsymbol{x} + \boldsymbol{\kappa} h) = b_h(\boldsymbol{x}) \ \text{ on } \Omega_h, \tag{2}$$

with $J = \{(-1,0,0),(1,0,0),(0,-1,0),(0,1,0),(0,0,-1),(0,0,1),(0,0,0)\}$ ($d = 3$). We combine stencil, operator, and matrix notation. Multigrid is commonly explained with operators (see, for example, [19], [1]), whereas Krylov subspace methods are often described with matrices. An operator is denoted by a subscript "h" (K_h, Δ_h, M_h^{2h}, etc.) and the corresponding Fourier matrix representation is denoted by a tilde ($\widetilde{K}$, $\widetilde{M}$ etc.).

A well-known efficient multigrid method (see [19], [20]) for problem (1) consists of a red-black Gauss–Seidel smoothing method (GS-RB), full weighting of residuals to obtain the right-hand side on the coarse grids, bi- or tri-linear interpolation (in 2D and 3D, respectively) of corrections from coarse to fine grids, and the coarse grid discretization of the PDE on a grid with meshsize $2h$ in each direction. We call this method the red-black multigrid solver or MG-RB.

For the d-dimensional problem (1) and MG-RB, it is possible to apply rigorous two-grid Fourier analysis, as it was presented for 2D problems in [19] and used for 3D (Poisson-type) problems in [20]. We repeat the 3D analysis in some detail here.

The existence of the basis of discrete eigenfunctions

$$\begin{aligned} \varphi_h^{k,\ell,m}(x,y,z) &= \sin k\pi x \sin \ell\pi y \sin m\pi z, \\ \text{with } \ k,\ell,m &= 1,\ldots,n-1 \ \ ((x,y,z) = \boldsymbol{x} \in \Omega_h) \end{aligned} \tag{3}$$

for the operator (1) is crucial for the 3D discrete Fourier analysis. The scaled basis functions $\varphi_h^{k,\ell,m}(\boldsymbol{x})$ generate the space of all grid functions, $F(\Omega_h)$, and are orthogonal with respect to the discrete inner product on Ω_h:

$$(v_h, w_h) := h^3 \sum_{\boldsymbol{x} \in \Omega_h} v_h(\boldsymbol{x})\, w_h(\boldsymbol{x}) \quad \text{with } v_h, w_h \in F(\Omega_h).$$

The discrete solution u_h and the current approximation u_j can be represented by linear combinations of the basis functions $\varphi_h^{k,\ell,m}(\boldsymbol{x})$. The same holds for the error $v_{j-1} = u_{j-1} - u_h$ before and $v_j = u_j - u_h$ after the jth two-grid cycle. The error v_{j-1} is transformed by a two-grid cycle as follows:

$$v_j = M_h^{2h}\, v_{j-1} \quad \text{with} \quad M_h^{2h} = S_h^{\nu_2} K_h^{2h} S_h^{\nu_1} = S_h^{\nu_2}(I_h - I_{2h}^h(\Delta_{2h})^{-1} I_h^{2h}\Delta_h) S_h^{\nu_1}, \tag{4}$$

where S_h is the smoothing operator, ν_1 and ν_2 indicate the number of pre- and post-smoothing iterations, K_h^{2h} is the coarse grid correction operator, Δ_{2h} the discretization of the operator on a $2h$ coarse grid, I_{2h}^h and I_h^{2h} are transfer operators from coarse to fine grids, and vice versa.

In case of standard multigrid coarsening ($H = 2h$) in 3D, it is convenient to divide $F(\Omega_h)$ into a direct sum of (at most) eight-dimensional subspaces, the *2h-harmonics* [20]:

$$\begin{aligned} E_h^{k,\ell,m} = \operatorname{span}\Big[&\varphi_h^{k,\ell,m}, \varphi_h^{n-k,n-\ell,n-m}, \varphi_h^{n-k,\ell,m}, \varphi_h^{k,n-\ell,n-m}, \varphi_h^{k,n-\ell,m}, \\ &\varphi_h^{n-k,\ell,n-m}, \varphi_h^{k,\ell,n-m}, \varphi_h^{n-k,n-\ell,m}\Big] \quad \text{for} \quad k,\ell,m = 1,\ldots,\frac{n}{2}. \end{aligned} \tag{5}$$

This distinction is motivated by the observation that the *low-frequency* harmonic $\varphi_h^{k,\ell,m}$ ($1 \le k,\ell,m \le \frac{n}{2}$) is also visible on the coarse grid Ω_{2h}, whereas the (at most) seven corresponding *high-frequency* harmonics coincide (up to their sign) with $\varphi_h^{k,\ell,m}$. If one, two, or three of the indices equal $n/2$, the dimension of $E_h^{k,l,m}$ is four, two, or one, respectively. The coarse grid correction operator K_h^{2h} leaves the (at most) eight-dimensional spaces of *2h-harmonics* $E_h^{k,\ell,m}$ with an arbitrary $k,\ell,m = 1,\ldots,\frac{n}{2}$ invariant; see [20]:

$$K_h^{2h} \;:\; E_h^{k,\ell,m} \to E_h^{k,\ell,m} \quad k,\ell,m = 1,\ldots,\frac{n}{2}\,.$$

This is a consequence of the following relations of the transfer and discretization operators:

$$\begin{aligned} \Delta_h \quad &: \quad \operatorname{span}\,[\varphi_h^{k,\ell,m}] \to \operatorname{span}\,[\varphi_h^{k,\ell,m}], \\ I_h^{2h} \quad &: \quad E_h^{k,\ell,m} \to \operatorname{span}\,[\varphi_{2h}^{k,\ell,m}], \\ \Delta_{2h}^{-1} \quad &: \quad \operatorname{span}\,[\varphi_{2h}^{k,\ell,m}] \to \operatorname{span}\,[\varphi_{2h}^{k,\ell,m}], \\ I_{2h}^h \quad &: \quad \operatorname{span}\,[\varphi_{2h}^{k,\ell,m}] \to E_h^{k,\ell,m}. \end{aligned}$$

Because of this invariance property, the corresponding matrix representation of K_h^{2h} with respect to the spaces $E_h^{k,\ell,m}$ leads to a block-diagonal matrix $\widetilde{K}$:

$$\widetilde{K} := \Big[\widehat{K}(k,\ell,m)\Big]_{k,\ell,m=1,\ldots,\frac{n}{2}} \triangleq K_h^{2h} \quad \text{with} \quad \widehat{K}(k,\ell,m) \triangleq K_h^{2h}|_{E_h^{k,\ell,m}}.$$

The same invariance property is true for the GS-RB relaxation, $S_h = S_h^{BLACK} \cdot S_h^{RED}$ [20], where S_h^{RED} and S_h^{BLACK} are the partial step operators, leading to a matrix $\widetilde{S}$:

$$\widetilde{S} := \Big[\widehat{S}(k,\ell,m)\Big]_{k,\ell,m=1,\ldots,\frac{n}{2}} \triangleq S_h \quad \text{with} \quad \widehat{S}(k,\ell,m) \triangleq S_h|_{E_h^{k,\ell,m}}.$$

Hence, M_h^{2h} is orthogonally equivalent to a block matrix $\widetilde{M}$ consisting of (at most) 8×8 blocks (see [19], [20]):

$$\widetilde{M} := \Big[\widehat{M}(k,\ell,m)\Big]_{k,\ell,m=1,\ldots,\frac{n}{2}} \stackrel{\wedge}{=} M_h^{2h} \quad \text{with} \quad \widehat{M}(k,\ell,m) \stackrel{\wedge}{=} M_h^{2h}|_{E_h^{k,\ell,m}}.$$

The tilde $\widetilde{\ }$ indicates the *Fourier matrix representation* of the related operator. By M we denote the matrix representation of the multigrid operator M_h^{2h}, and by A we denote the matrix representation of Δ_h with respect to the Euclidean basis. We have

$$\widetilde{M} = UMU^{-1} \tag{6}$$

with a unitary matrix U. Eight consecutive rows of U are given by the $(n-1)^3$-dimensional orthogonal eigenvectors of A related to the eigenfunctions from (5):

$$\begin{aligned} &\varphi^{k,\ell,m},\ \varphi^{n-k,n-\ell,n-m},\ \varphi^{n-k,\ell,m},\ \varphi^{k,n-\ell,n-m},\ \varphi^{k,n-\ell,m},\ \varphi^{n-k,\ell,n-m}, \\ &\varphi^{k,\ell,n-m},\ \varphi^{n-k,n-\ell,m} \quad \text{for} \quad k,\ell,m = 1,\ldots,\frac{n}{2}, \quad \text{with, for example,} \\ &\varphi^{k,\ell,m} = (\ \sin k\pi h \sin \ell\pi h \sin m\pi h, \ldots, \sin k\pi(1-h)\sin \ell\pi(1-h)\sin m\pi(1-h)\ )^T. \end{aligned} \tag{7}$$

Using discrete Fourier frequencies $\boldsymbol{\theta} = \pi h(k,\ell,m)$ $(k,\ell,m = 1,\ldots,n-1)$, this gives

$$A\,\varphi^{k,\ell,m} = \lambda(\boldsymbol{\theta},h)\,\varphi^{k,\ell,m} \quad \text{with} \quad \lambda(\boldsymbol{\theta},h) = \sum_{\boldsymbol{\kappa}\in J} a_{\boldsymbol{\kappa}} \cos(\boldsymbol{\theta}\boldsymbol{\kappa}). \tag{8}$$

The dimension of $\widetilde{M}$ is given by $(n/2-1)^3\cdot 8 + 3(n/2-1)^2\cdot 4 + 3(n/2-1)\cdot 2 + 1\cdot 1 = (n-1)^3$ due to the dimensions of the $2h$-*harmonics* (5). The representation of $\widehat{M}(k,\ell,m) = \widehat{S}^{\nu_2}(k,\ell,m)\cdot\widehat{K}(k,\ell,m)\cdot\widehat{S}^{\nu_1}(k,\ell,m)$ $(k,\ell,m = 1,\ldots,\frac{n}{2})$ is obtained by straightforward generalization of the 2D case in [19]. From the block matrices $\widehat{M}(k,\ell,m)$, we obtain the two-grid convergence factor by

$$\rho_F := \rho(\widetilde{M}) = \max_{1\le k,\ell,m\le \frac{n}{2}} \rho(\widehat{M}(k,\ell,m)). \tag{9}$$

It is the asymptotic two-grid convergence which is a theoretical estimate of the multigrid convergence. Furthermore, it is possible to determine the whole spectrum and thus the eigenvalue distribution of $\widetilde{M}$ by calculating all eigenvalues of $\widehat{M}(k,\ell,m)$ for $k,\ell,m = 1,\ldots,\frac{n}{2}$. We use this distribution in section 3 for the analysis of the convergence of the multigrid preconditioned GMRES(m) method.

The *smoothing factor* μ_F is based on the ideal coarse grid correction operator Q_h^{2h} from [19] which annihilates the low-frequency error components and leaves the high-frequency components unchanged. Q_h^{2h} is a projection operator onto the space of high frequencies represented by a block-diagonal matrix $\widetilde{Q}$ consisting of (at most) 8×8 diagonal blocks: $\widehat{Q} = \mathrm{diag}(0,1,1,1,1,1,1,1)$. This leads to the following definition of the smoothing factor [19]:

$$\mu_F := \rho(\widetilde{S}^{\nu_2}\widetilde{Q}\widetilde{S}^{\nu_1}) = \rho(\widetilde{Q}\widetilde{S}^{\nu_1+\nu_2}) = \max_{1\le k,\ell,m\le \frac{n}{2}} \rho(\widehat{Q}\widehat{S}(k,\ell,m)^{\nu_1+\nu_2}). \tag{10}$$

The smoothing factor indicates the smoothing effect of the relaxation method under consideration. μ_F is a realistic estimate of the two-grid convergence factor ρ_F as long as the ideal coarse grid correction operator is a good approximation of K_h^{2h}.

2.1. Fourier results for multigrid. In [23] it was shown that an overrelaxation parameter ($\omega > 1$) improves the smoothing properties of GS-RB (leading to ω-GS-RB) and therefore improves the convergence of MG-RB for d-dimensional Poisson-type equations. The extra computational work for performing the overrelaxation in the smoother is worthwhile if $d = 3$. With the 3D Fourier two-grid and smoothing analysis explained above, we are able to estimate this convergence improvement for (1) very accurately; see Table 1. The average numerical convergence rate ρ_h^{mg} from MG-RB (after 100 multigrid iterations) is compared to ρ_F in Table 1. The number of multigrid levels used is 5, 6, and 6, respectively, for the 32^3, 64^3, and 96^3 problems.

In [23] it was shown furthermore that ω-GS-RB also improves the convergence factor of the 2D anisotropic diffusion equation,

$$A_h u_h(\boldsymbol{x}) = \frac{1}{h^2}\begin{bmatrix} & -1 & \\ -\varepsilon & 2\varepsilon+2 & -\varepsilon \\ & -1 & \end{bmatrix} u_h(\boldsymbol{x}) = b_h(\boldsymbol{x}) \ \text{ on } \Omega_h, \tag{11}$$
$$u_h(\boldsymbol{x}) = 0 \quad \text{on } \Gamma_h.$$

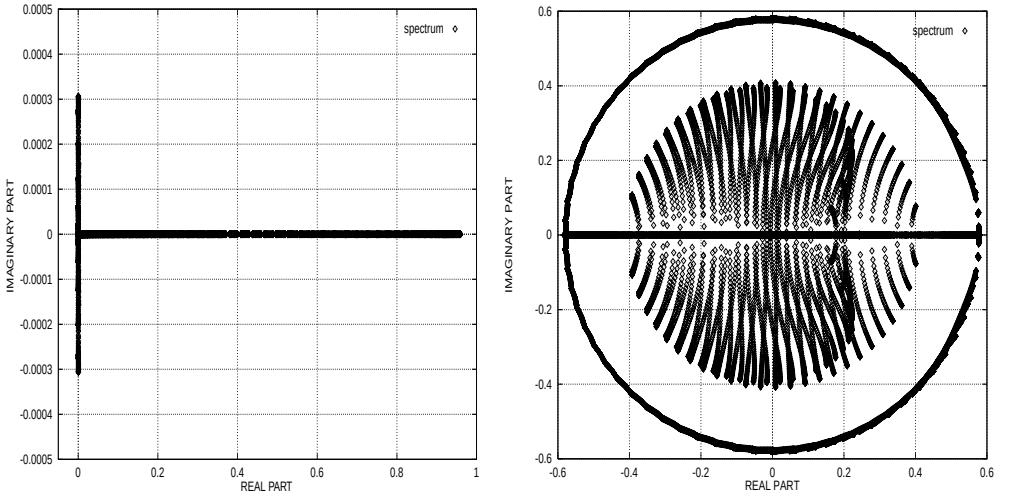
For moderate values of ε, like $100 \geq \varepsilon \geq 0.01$, the extra computational work pays off. Anisotropic problems can be solved with line smoothers in the multigrid process [19], by which much better convergence rates are obtained. However, line smoothers cannot be applied to unstructured grids in a straightforward way and their parallelization can be expensive. Here, we investigate the possibility to improve a multigrid method with a point smoother for moderate anisotropies with GMRES(m) acceleration. (Results are presented in the next sections.)

The rigorous Fourier analysis also applies for (11). In 2D we have to deal with (at most) four-dimensional $2h$-harmonics (see (5)) and therefore $\widetilde{M}$ consists of (at most) 4×4 blocks [19]. We perform numerical tests with $\varepsilon = 0.1$ and $\varepsilon = 0.01$. In both cases a large overrelaxation parameter (ω_{opt}=1.41, 1.76) has to be selected (for these values, see [23]) to obtain an impressive multigrid convergence improvement. The numerical multigrid convergence rates ρ_h^{mg} and the Fourier values μ_F and ρ_F are shown in Table 2. The W-cycle with $\nu_1 = \nu_2 = 1$ (W(1,1)) is chosen with seven multigrid levels for problem (11) discretized on a 128×128 grid.

TABLE 2
W(1,1)-cycle multigrid convergence ρ_h^{mg}, predicted convergence ρ_F, and smoothing factor μ_F for the 2D anisotropic diffusion equation, $h = 1/128$.

	$\omega = 1.0$			$\omega = \omega_{opt}$		
ε	ρ_h^{mg}	ρ_F	μ_F	ρ_h^{mg}	ρ_F	μ_F
$\varepsilon = 0.1$	0.679	0.682	0.682	0.193	0.210	0.219
$\varepsilon = 0.01$	0.957	0.960	0.960	0.566	0.583	0.590

In Figure 1, we show the effect of an overrelaxation parameter $\omega = 1.76$ on the eigenvalue distribution of the two-grid iteration matrix for the anisotropic ($\varepsilon = 0.01$) diffusion problem. In contrast to the almost real-valued spectrum for $\omega = 1.0$, which is uniformly distributed on the interval $[0.0, 0.960]$, we find complex eigenvalues clustered around the origin and uniformly distributed on a circle by the overrelaxation.



1 (a). $\omega = 1.0$ 1 (b). $\omega = 1.76$

FIG. 1. *Eigenvalue spectra of the red-black two-grid 2D anisotropic diffusion solver from rigorous Fourier analysis;* $\nu_1 = \nu_2 = 1, \varepsilon = 0.01, h = 1/128$. (*Note the different scaling of the axes in Figure* 1 (a).)

From the comparison of the predicted convergence rates ρ_F and the numerically obtained ρ_h^{mg}, it is clear that the two-grid Fourier analysis provides excellent quantitative estimates for the actual multigrid convergence of MG-RB for Poisson-type equations. These results encourage the following considerations concerning Fourier analysis of the multigrid preconditioned GMRES(m).

3. Fourier analysis of GMRES(m) preconditioned by multigrid. In this section we discuss two approaches for the analysis of GMRES(m) preconditioned by multigrid. For both approaches it is crucial that the discrete Fourier analysis uses unitary basis transformations (6) which simplify the representation of the multigrid iteration matrix.

We consider the linear system related to (2),

$$Au = b. \tag{12}$$

A two-grid (or more generally, a multigrid) cycle for solving (12) is described by the following matrix splitting:

$$Cu_j + (A - C)u_{j-1} = b, \tag{13}$$

where u_j represents a new and u_{j-1} a previous approximation. This formulation is equivalent to

$$u_j = u_{j-1} + C^{-1}(b - Au_{j-1}), \qquad r_j = (I - AC^{-1})r_{j-1}, \tag{14}$$

with r_j, r_{j-1} the residual vectors and $I - AC^{-1}$ represents the two-grid (multi-grid) iteration matrix.

The multigrid method (13) considered was described in the previous section. It is used as a *right preconditioner* for GMRES(m). The parameter m represents the number of search vectors stored after which the GMRES(m) algorithm will restart. GMRES(m) searches for a solution u_j in the following subspace:

$$\begin{aligned} C(u_j - u_{j-m}) &\in \operatorname{span}[r_{j-m}, (AC^{-1})r_{j-m}, \ldots, (AC^{-1})^{m-1}r_{j-m}] \\ &=: K^m(AC^{-1}, r_{j-m}), \end{aligned} \tag{15}$$

where $K^m(AC^{-1}, r_{j-m})$ is the Krylov subspace. It selects a new approximation u_j by minimizing the corresponding residual r_j in the L_2-norm

$$\min_{C(u_j - u_{j-m}) \in K^m(AC^{-1}, r_{j-m})} ||b - Au_j||_2. \tag{16}$$

Any element w in the affine subspace $u_{j-m} + C^{-1}K^m(AC^{-1}, r_{j-m})$ (see (14), (15)) can be represented by

$$w = u_{j-m} + C^{-1}(\alpha_1 r_{j-m} + \alpha_2 AC^{-1}r_{j-m} + \cdots + \alpha_m (AC^{-1})^{m-1} r_{j-m}). \tag{17}$$

By substituting (17) into the residual equation, we obtain

$$\begin{aligned} r_w &= b - Aw \\ &= r_{j-m} - \alpha_1 AC^{-1} r_{j-m} - \alpha_2 (AC^{-1})^2 r_{j-m} - \cdots - \alpha_m (AC^{-1})^m r_{j-m} \\ &= P_m(AC^{-1}) r_{j-m}, \end{aligned} \tag{18}$$

where P_m is an mth order polynomial defined by $P_m(\lambda) = 1 - \sum_{k=1}^{m} \alpha_k \lambda^k$. Comparing (16) and (18), we see that the L_2-norm of r_j satisfies the following minimization property:

$$||r_j||_2 = \min\{||P_m(AC^{-1})r_{j-m}||_2 \ \mid \ P_m \in \mathbb{P}_m\}, \tag{19}$$

where $\mathbb{P}_m$ denotes the set of all polynomials of degree at most m with $P_m(0) = 1$.

Since we are interested in the convergence of multigrid preconditioned GMRES with a restart after m iterations, we consider the residuals $r_m, r_{2m}, \ldots, r_{i \cdot m}$. This leads to the following definition of the reduction factors ρ_i for a *complete* ith iteration, consisting of m multigrid preconditioned GMRES(m) steps:

$$\rho_i := \left[\left(\frac{||r_{i \cdot m}||_2}{||r_0||_2} \right)^{1/m} \right]^{1/i}.$$

In subsection 3.1, we review estimates for ρ_i which are based on an analysis of the spectrum σ of AC^{-1} (see [5], [6], [15], [16], [17]). In general, these estimates exhibit a qualitative character, and concrete values are rarely found in the literature because the spectrum is usually not available. However, with the Fourier analysis these estimates can be calculated explicitly since the spectrum is easily obtained if multigrid is used as a preconditioner. In subsection 3.2 we introduce a sharper estimate, which is based on an analysis of the GMRES(m) polynomial.

3.1. Analysis with the spectrum of the iteration matrix. The usual way to analyze the convergence of GMRES is to exploit information about the spectrum of the iteration matrix AC^{-1}. If we compare the error transformation (4) and the residual transformation (14) by a two-grid cycle, the Fourier matrix $\widetilde{M}$ (6) is related to the two-grid iteration matrix $I - AC^{-1}$ via the identity

$$\widetilde{M} = UA^{-1}(I - AC^{-1})AU^{-1} \Longleftrightarrow \widetilde{M} = I - UC^{-1}AU^{-1}, \tag{20}$$

with the unitary matrix U from (6). With (20) we have

$$UAC^{-1}U^{-1} = I - UAU^{-1}\widetilde{M}(UAU^{-1})^{-1} = I - \widetilde{A}\widetilde{M}\widetilde{A}^{-1}. \tag{21}$$

$\widetilde{A}$ and $\widetilde{A}^{-1}$ are diagonal matrices since the rows of U are eigenvectors of A (see (7) and section 2). This means that $UAC^{-1}U^{-1}$ is a block-diagonal matrix which consists of (at most) 8×8 blocks in the 3D case and of (at most) 4×4 blocks in the 2D case. The eigenvalues of these block matrices are easily calculated.

We are dealing with positive real iteration matrices AC^{-1} (due to the multigrid preconditioner), so the symmetric part of AC^{-1} is positive definite. It is shown in [6], [5] that GMRES(m) always converges for this type of matrices. More generally, it is sufficient that the *field of values* of the iteration matrix $\{\bar{x}^T AC^{-1}x/\bar{x}^T x : x \in \mathbb{C}^{(n-1)^d}\}$ lies in an open half-plane $\{z : \mathrm{Re}(e^{-i\theta}z) > 0\}$. This is called the *half-plane condition* [12]. In particular the following error bound can be established for any restart parameter m and iteration index i [6]:

$$||r_{i\cdot m}||_2 \leq (1 - \alpha/\beta)^{m/2}||r_{(i-1)m}||_2, \tag{22}$$

with $\alpha = (\,\lambda_{min}(\frac{1}{2}(AC^{-1}+(AC^{-1})^T))\,)^2$ and $\beta = \lambda_{max}(\,(AC^{-1})^T AC^{-1}\,)$. Using (22), we obtain

$$||r_{i\cdot m}||_2 \leq (1 - \alpha/\beta)^{i\cdot m/2}||r_0||_2 \quad \Longrightarrow \quad \rho_i \leq (1 - \alpha/\beta)^{1/2} =: \rho_{hpc} < 1. \tag{23}$$

In general, the m- and i-independent value ρ_{hpc} is not a realistic quantitative estimate of ρ_i, but the residual bound from (23) is an important qualitative result because it ensures the convergence of GMRES(m) for all m.

Next, we discuss considerations on the convergence of GMRES(m) from [15], [16], [17], which are also based on the spectrum of the iteration matrix. From (19) it follows that

$$||r_{i\cdot m}||_2 \leq ||P_m(AC^{-1})||_2\,||r_{(i-1)m}||_2 \quad \text{for all} \quad P_m \in \mathbb{P}_m. \tag{24}$$

Suppose that all eigenvalues of AC^{-1} are located in an ellipse $E(c, d, a)$ which excludes the origin. c denotes the center, d the focal distance, and a the major semi-axis. Then it is known [17] that the absolute value of the polynomial

$$t_m(z) := T_m\Big(\frac{c}{d} - \frac{1}{d}\,z\Big)/T_m\Big(\frac{c}{d}\Big) = T_m(\widehat{z})/T_m\Big(\frac{c}{d}\Big) \quad \text{with} \quad z,\,\widehat{z} := \Big(\frac{c}{d} - \frac{1}{d}\,z\Big) \in \mathbb{C}$$

is small on the spectrum of AC^{-1}. Here, T_m represents the Chebychev polynomial of degree m of the first kind which is given by the three-term recurrence relation

$$T_0(\widehat{z}) = I\,, \quad T_1(\widehat{z}) = \widehat{z}\,, \quad T_{m+1}(\widehat{z}) = 2T_m(\widehat{z}) - T_{m-1}(\widehat{z}) \quad \text{for} \quad m \geq 1.$$

If AC^{-1} is diagonalizable, $AC^{-1} = XDX^{-1}$; then (24) yields

$$||r_{i\cdot m}||_2 \leq ||t_m(AC^{-1})||_2 \, ||r_{(i-1)m}||_2 \leq \left[||t_m(AC^{-1})||_2\right]^i \, ||r_0||_2 \tag{25}$$

$$\leq \left[||X||_2 \, ||X^{-1}||_2 \max_{\lambda_j \in \sigma} |t_m(\lambda_j)|\right]^i \, ||r_0||_2 \tag{26}$$

$$\leq \left[\kappa_2(X)\, T_m\left(\frac{a}{d}\right) / T_m\left(\frac{c}{d}\right)\right]^i \, ||r_0||_2, \tag{27}$$

where $\kappa_2(X)$ denotes the spectral condition number of the transformation matrix X (see [16], [17]). Inequality (27) uses the fact that the maximum modulus of a complex analytical function is attained on the boundary of the domain, which is due to Liouville's theorem [16]. Heuristically, we expect this inequality to be sharp if the interior of the ellipse $E(c, d, a)$ is well covered by the spectrum σ. Using (25) and (27), we obtain the following well-known estimates [16], [17] for ρ_i:

$$\rho_i \leq N_m^E \leq (\kappa_2(X))^{1/m} \, T_m^E, \tag{28}$$

$$\text{with} \quad N_m^E := (||t_m(AC^{-1})||_2)^{1/m} \quad \text{and} \quad T_m^E := \left(T_m\Big(\frac{a}{d}\Big)/T_m\Big(\frac{c}{d}\Big)\right)^{1/m}. \tag{29}$$

T_m^E can be further approximated by

$$T_m^E = \left(\frac{\left(\frac{a}{d} + \sqrt{(\frac{a}{d})^2 - 1}\right)^m + \left(\frac{a}{d} + \sqrt{(\frac{a}{d})^2 - 1}\right)^{-m}}{\left(\frac{c}{d} + \sqrt{(\frac{c}{d})^2 - 1}\right)^m + \left(\frac{c}{d} + \sqrt{(\frac{c}{d})^2 - 1}\right)^{-m}}\right)^{1/m} \approx \frac{a + \sqrt{a^2 - d^2}}{c + \sqrt{c^2 - d^2}}. \tag{30}$$

Approximation (30) is sharp if $a \gg d$ and $c \gg d$ or $m \gg 1$ holds. The first inequality is fulfilled if the ellipse $E(c, d, a)$ tends to a circle which means that the focal distance d becomes very small compared to a (in our tests it is usually sufficient if approximately $a \geq 2d$). In all cases considered, the multigrid preconditioner ensures that the spectrum σ is clustered around 1, which means that the second inequality is satisfied. If (30) is sharp due to a circular shape of σ or due to a large m, T_m^E is independent of the restart parameter m. In this case, it is difficult to further accelerate the multigrid method. A large Krylov subspace (15) does not lead to additional acceleration.

The main drawback of the estimates (28) for the reduction factors ρ_i is their i-independence. The relative amount of residual decrease from early GMRES cycles compared to later ones depends on both the matrix and the initial residual. The reduction by early cycles may be very different from the reduction by later ones. More precisely, the estimates from (28) are based on the worst previous residual that is possible due to the definition of the matrix norm $||A||_2 := \sup\{||Ar||_2/||r||_2 : r \in \mathbb{C}^{(n-1)^d}\}$. Thus, in general they cannot be expected to be sharp approximations for large i because $r_{(i-1)m}$ can be completely different from the worst residual since many iterations have already been performed and the worst search directions have already been removed from the current approximation $u_{(i-1)m}$ by GMRES(m). Furthermore, $\kappa_2(X)$ can be very large if the iteration matrix AC^{-1} is far from normal. But it is found in [12] that the condition number $\kappa_2(X)$ is not always relevant for the convergence of GMRES. In [17] it is stated that (28) is an asymptotic result and that the actual residual norm should behave like T_m^E without $\kappa_2(X)$. Therefore, the explicit values for T_m^E are also given in subsection 3.3 and compared with the asymptotic numerical convergence results. However, T_m^E is a heuristic estimate for $\rho_{i \gg 1}$ and not an upper bound like N_m^E.

3.2. Analysis with the GMRES-polynomial. To obtain a quantitative result for the convergence of GMRES(m), we present a second approach to estimate ρ_i, which explicitly depends on the iteration index i. In this way, it is possible to take the benefits of the previous iterations into account, in contrast to the above estimates. An initial residual r_0 is prescribed, and the GMRES(m)-polynomials P_m^i are explicitly determined for every i. The choice of r_0 does not influence the average reduction factor for $i \gg 1$ in which we are interested.

For any unitary matrix U, and in particular for U from (6), we have $||r_{i\cdot m}||_2 = ||Ur_{i\cdot m}||_2$. In order to find the coefficients α_k^i $(k = 1, \ldots, m)$ of the GMRES(m)-polynomials P_m^i, the following function f is minimized:

$$\begin{aligned} f(\alpha_1^i, \ldots, \alpha_m^i) :=& \Big(UP_m^i(AC^{-1})r_{(i-1)m}, UP_m^i(AC^{-1})r_{(i-1)m} \Big) \\ =& \Big(P_m^i(UAC^{-1}U^{-1})Ur_{(i-1)m}, P_m^i(UAC^{-1}U^{-1})Ur_{(i-1)m} \Big) \\ =& \sum_{l,k=1}^{m} \alpha_l^i \alpha_k^i \Big((UAC^{-1}U^{-1})^l Ur_{(i-1)m}, (UAC^{-1}U^{-1})^k Ur_{(i-1)m} \Big) \\ &+ 2\sum_{l=1}^{m} \alpha_l^i \Big((UAC^{-1}U^{-1})^l Ur_{(i-1)m}, Ur_{(i-1)m} \Big). \end{aligned}$$

The α_k^i are obtained by solving the following linear system of equations:

$$\begin{aligned} \frac{\partial f}{\partial \alpha_l^i} =& 2\sum_{k=1}^{m} \alpha_k^i \Big((UAC^{-1}U^{-1})^l Ur_{(i-1)m}, (UAC^{-1}U^{-1})^k Ur_{(i-1)m} \Big) \\ &+ 2\Big((UAC^{-1}U^{-1})^l Ur_{(i-1)m}, Ur_{(i-1)m} \Big) = 0 \quad \text{for } l = 1, \ldots, m. \end{aligned} \tag{31}$$

In (21) it is seen that the argument $UAC^{-1}U^{-1} = I - \widetilde{A}\widetilde{M}\widetilde{A}^{-1}$ of the GMRES(m)-polynomials P_m^i has a simple block structure. Therefore, due to the sparse structure of $(UAC^{-1}U^{-1})^l$ $(l = 1, \ldots, m)$, the solution of the linear system (31) is easily computed for every complete iteration i, as soon as the previous transformed residual $Ur_{(i-1)m}$ is given. We prescribe right-hand side $b = 0$ and a randomly chosen initial approximation Uu_0, which yield a transformed initial residual $Ur_0 = -\widetilde{A}Uu_0$. More precisely, we select an initial solution $u_0 = \sum_{k,\ell,m=1}^{n-1} \beta(k,\ell,m)\varphi^{k,\ell,m}$, where the amplitudes $\beta(k,\ell,m)$ of the eigenvectors are randomly chosen. Hence, we get

$$Uu_0 = \Big(\beta(1,1,1), \beta(n-1,n-1,n-1), \ldots, \beta\Big(\frac{n}{2}, \frac{n}{2}, \frac{n}{2}\Big) \Big)^T;$$

see (7). From Ur_0 it is possible to evaluate the α_k^1 by solving (31) for $i = 1$. This gives

$$Ur_m = P_m^1(UAC^{-1}U^{-1})Ur_0.$$

It follows that $Ur_{i\cdot m}$ is easily calculated for every i. This leads to the definition of an average reduction factor ρ_i^U obtained by the Fourier analysis:

$$\rho_i^U := \left[\left(\frac{||Ur_{i\cdot m}||_2}{||Ur_0||_2} \right)^{1/m} \right]^{1/i}. \tag{32}$$

A straightforward way to compute ρ_i^U is to run GMRES(m) directly for the prescribed residual r_0 and the transformed matrix $UACU^{-1}$. However, it turns out (see subsection 4.3) that an explicit calculation of the coefficients α_k^i $(k = 1, \ldots, m)$ of the GMRES(m)-polynomials gives an interesting insight into the behavior of GMRES(m).

In most of the tests, presented in the next subsection, ρ_i^U becomes constant for $i \geq 20$. Thus, ρ_{20}^U is expected to match numerical reference values very well and, in particular, to be sharper than the estimates from subsection 3.1.

3.3. Fourier results of multigrid preconditioned GMRES(m). Here, we investigate the quality of the theoretical considerations by comparing them to the numerical convergence of the multigrid preconditioned GMRES(m) method for the test problems from subsection 2.1. We compare the average accelerated multigrid convergence rate, ρ_h^{acc}, from numerical experiments with the theoretical prediction $\rho_{i=20}^U$, the heuristic estimate T_m^E, and the upper bound N_m^E. Insight into the behavior of the acceleration method is gained by considering different combinations of the relaxation parameter ω and the GMRES(m) restart parameter m.

In order to make sure that the asymptotic convergence behavior is observed, we present ρ_h^{acc} after 40 or after 100 multigrid preconditioned GMRES(m) iterations. These numbers of iterations match $\rho_{i=20}^U$ for $m = 2$ and for $m = 5$, respectively. However, the numerical convergence stabilizes much earlier and often the asymptotic values are obtained after only a few complete iterations.

The results for the 3D Poisson equation with right-hand side $b_h(\boldsymbol{x}) = 0$ and initial guess $u_0 = (1, \ldots, 1)^T$ are presented in Table 3. We observe that $\rho_{i=20}^U$ and T_m^E provide accurate predictions of ρ_h^{acc} for different overrelaxation parameters ω. The upper bound N_m^E becomes sharper with increasing m as T_m^E and N_m^E coincide for large m, because the condition number $\kappa_2(X)$ cancels out (see (28)). Comparing Tables 1 and 3, we observe a satisfactory convergence improvement for $\omega = 1$. If overrelaxation is selected, the benefits of the GMRES(m) acceleration are small and the convergence cannot be improved significantly by using a larger Krylov space (15). This behavior is expected from the spectral picture in Figure 2. The ellipses become more orbital (note the different scaling of the axes) with the overrelaxation so that approximation (30) gets sharper.

TABLE 3

W(1,1)-cycle multigrid preconditioned GMRES(m) convergence ρ_h^{acc} and convergence estimates $\rho_{i=20}^U$, T_m^E, N_m^E for the 3D Poisson equation, $h = 1/32$.

Relaxation parameter	Acc. MG-RB, $m = 2$				Acc. MG-RB, $m = 5$			
	ρ_h^{acc}	$\rho_{i=20}^U$	T_m^E	N_m^E	ρ_h^{acc}	$\rho_{i=20}^U$	T_m^E	N_m^E
$\omega = 1.0$	0.085	0.090	0.091	0.186	0.070	0.072	0.074	0.115
$\omega = 1.1$	0.045	0.054	0.055	0.133	0.042	0.045	0.047	0.082
$\omega = 1.15$ [23]	0.050	0.054	0.056	0.129	0.045	0.049	0.055	0.077

Similar statements hold for the 2D anisotropic diffusion equation, where right-hand side $b_h(\boldsymbol{x}) = 0$ and initial guess $u_0 = (1, \ldots, 1)^T$ are chosen, as in the 3D case. Theoretical predictions $\rho_{i=20}^U$ match very well with ρ_h^{acc}, as can be seen from Table 4. In most cases the same observation can be made for the values T_m^E and ρ_h^{acc}. N_m^E is not a good approximation for ρ_h^{acc} but it improves with increasing m. If we choose an optimal overrelaxation parameter for $\varepsilon = 0.1$ and $\varepsilon = 0.01$, it is not really possible to further accelerate the ω-MG-RB method due to the circular shape of the corresponding spectrum σ shown in Figure 3. For the same reason further

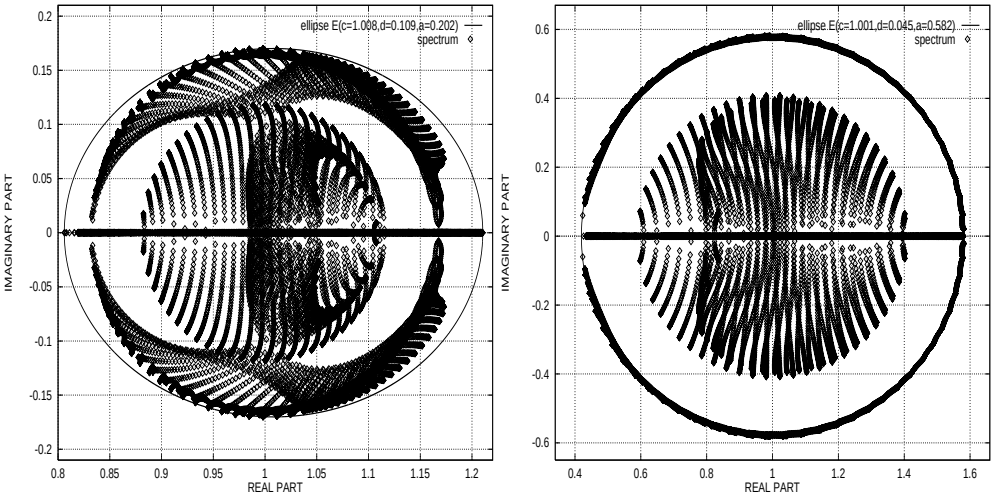
$m = 5$	0.723	0.740	0.763	1.054	0.566	0.579	0.580	1.182

improvement cannot be achieved by a larger Krylov space. For $\omega = 1.0$ a satisfactory convergence improvement can be observed comparing Table 2 and Table 4.

As mentioned before, the Fourier analysis for multigrid is based on $\widetilde{M} = I - UC^{-1}AU^{-1}$ (see (20)), the *error* reduction in a two-grid algorithm, whereas Krylov methods minimize the *residual* norm and are based on AC^{-1}. Thus, we have for the corresponding spectra: $\sigma(AC^{-1}) = 1 - \sigma(\widetilde{M})$ (compare Figure 1 (b) and Figure 3 (b)). As a consequence the iteration matrices AC^{-1} are always positive real here because the spectrum of the multigrid iteration matrix $\sigma(\widetilde{M})$ is mainly clustered around the origin. In particular $\rho(\widetilde{M}) = \rho_F < 1$ holds because the multigrid preconditioner is already a convergent method. Thus, any eigenvalue of AC^{-1} lies in the right half-plane and we have $\rho_{hpc} < 1$.

Remark. In this connection it is interesting to note that the *residual* reduction norm $||\widetilde{A}\widetilde{M}\widetilde{A}^{-1}||_2$ decreases with an increasing number of post-relaxations ν_2 in contrast to the *error* reduction norm $||\widetilde{M}||_2$ which decreases with an increasing ν_1 [19]. According to this observation, one should choose similar values for ν_1 and ν_2 and prefer $\nu_1 \geq \nu_2$ to $\nu_1 \leq \nu_2$ when multigrid is selected as a solver [19]. The reversed



3 (a). $\varepsilon = 0.1$, $\omega = 1.41$ 3 (b). $\varepsilon = 0.01$, $\omega = 1.76$

FIG. 3. *Eigenvalue spectra of the red-black two-grid* $2D$ *anisotropic diffusion solver from Fourier analysis;* $\nu_1 = \nu_2 = 1$, $h = 1/128$.

statement (prefer $\nu_1 \leq \nu_2$ to $\nu_1 \geq \nu_2$) holds if we apply multigrid as a preconditioner for a Krylov acceleration technique.

From Tables 3 and 4, it follows that a significant acceleration of the ω-MG-RB method with the help of GMRES(m) is possible if $\omega = 1.0$. This acceleration is observed if we compare the numerical results ρ_h^{mg} and ρ_h^{acc} from subsections 2.1 and 3.3 and if we compare the Fourier estimates ρ_F and $\rho_{i=20}^U$. If, in some sense, an *optimal multigrid method* is selected by using the optimal overrelaxation parameter, a further improvement is almost impossible.

$\rho_{i=20}^U$ can be considered as a quantitative value which is found to be close to the numerical convergence rate ρ_h^{acc}. The heuristic estimate T_m^E gives good insight into the asymptotic convergence behavior, whereas N_m^E is too pessimistic an approximation in general. The qualitative value ρ_{hpc} is important for theoretical purposes, but it doesn't help in choosing between solution methods. In most cases ρ_{hpc} is close to 1 and far away from ρ_h^{acc}.

4. Local mode analysis of multigrid preconditioned GMRES(m). The Fourier analysis as presented in section 2 is restricted to model operators A_h, for which the discrete functions (3) form a basis of eigenfunctions. Furthermore, it is not possible to apply this analysis for multigrid methods based on Gauss–Seidel relaxations with a lexicographical ordering of the grid points (GS-LEX). The eigenfunctions (3) are no longer invariant under the GS-LEX operators. Instead they are intermixed, which leads to a full matrix $\widetilde{S}$. For a general linear operator A_h with constant or frozen coefficients it is, however, possible to use the *local mode Fourier analysis* [1] for analyzing multigrid methods based on GS-LEX as the smoother. The theoretical foundations (for example, presented in [18], [2]) for the local mode analysis are not as straightforward as they are for the analysis from section 2. Basically the local mode analysis is valid if the influence of a domain boundary is negligible [2]. Often, this requirement can be satisfied by performing extra local boundary relaxation. In practice, the local mode (or infinite grid) two-grid and smoothing analysis gives satisfactory

sharp estimates of the actual multigrid convergence.

Instead of considering the finite domain with discrete eigenfunctions (3) of A_h an infinite domain $\overline{\Omega}_h := \{\boldsymbol{x} = (j_x h, j_y h, j_z h) : j_x, j_y, j_z \in \mathbb{Z}\}$ is considered with continuous eigenfunctions

$$\phi_h(\boldsymbol{\theta}, \boldsymbol{x}) = e^{i\boldsymbol{x}\boldsymbol{\theta}/h} = e^{i\boldsymbol{j}\boldsymbol{\theta}} = e^{i(j_x\theta_x + j_y\theta_y + j_z\theta_z)}, \tag{33}$$

where the Fourier frequencies $\boldsymbol{\theta} = (\theta_x, \theta_y, \theta_z)$ vary continuously in $\mathbb{R}^3$. The corresponding eigenvalues are given by $\lambda(\boldsymbol{\theta}, h) = \sum_{\boldsymbol{\kappa}\in J} a_{\boldsymbol{\kappa}} e^{i\boldsymbol{\theta}\boldsymbol{\kappa}}$ (see (8)). Fourier components with $|\boldsymbol{\theta}| := \max\{|\theta_x|, |\theta_y|, |\theta_z|\} \geq \pi$ are not visible on $\overline{\Omega}_h$, since they coincide with components $e^{i\boldsymbol{j}\hat{\boldsymbol{\theta}}}$ where $\hat{\boldsymbol{\theta}} = \boldsymbol{\theta} (\mathrm{mod}\, \pi)$. Therefore, the Fourier space

$$\boldsymbol{\varepsilon}^h = \mathrm{span}\{e^{i\boldsymbol{j}\boldsymbol{\theta}} : \boldsymbol{\theta} \in \Theta = (-\pi, \pi]^3\}$$

contains any infinite grid function on $\overline{\Omega}_h$ [19]. As in the discrete Fourier analysis, we divide the Fourier space $\boldsymbol{\varepsilon}^h$ into eight-dimensional subspaces $\boldsymbol{\varepsilon}^h_{\boldsymbol{\theta}}$, which consist of one low-frequency harmonic ($\boldsymbol{\theta} \in \Theta^l := (-\pi/2, \pi/2]^3$) and seven corresponding high-frequency harmonics ($\boldsymbol{\theta} \in \Theta^h := \Theta \backslash \Theta^l$) (5):

$$\boldsymbol{\varepsilon}^h_{\boldsymbol{\theta}} = \mathrm{span}[\phi(\boldsymbol{\theta}^{\alpha_x\alpha_y\alpha_z}, \boldsymbol{x}) = e^{i\boldsymbol{j}\boldsymbol{\theta}^{\alpha_x\alpha_y\alpha_z}} : \alpha_x, \alpha_y, \alpha_z \in \{0, 1\}], \quad \text{with } \boldsymbol{x} \in \overline{\Omega}_h,$$
$$\boldsymbol{\theta}^{000} \in \Theta^l, \text{ and } \boldsymbol{\theta}^{\alpha_x\alpha_y\alpha_z} = (\theta_x - \alpha_x \mathrm{sign}(\theta_x)\pi, \theta_y - \alpha_y \mathrm{sign}(\theta_y)\pi, \theta_z - \alpha_z \mathrm{sign}(\theta_z)\pi).$$

These spaces $\boldsymbol{\varepsilon}^h_{\boldsymbol{\theta}}$ of $2h$-harmonics are invariant under the coarse grid correction operator K_h^{2h} (4) and also under a GS-LEX relaxation operator. In order to obtain a well-defined two-grid operator we replace the Fourier space $\boldsymbol{\varepsilon}^h$ by a slightly shrunk subspace $\tilde{\boldsymbol{\varepsilon}}^h$ such that $(A_h)^{-1}$ exists and also $(A_{2h})^{-1}$ can be reasonably defined on the coarser grid, as in [19]:

$$\tilde{\boldsymbol{\varepsilon}}^h = \boldsymbol{\varepsilon}^h \backslash \bigcup_{\boldsymbol{\theta}\in\Psi} \boldsymbol{\varepsilon}^h_{\boldsymbol{\theta}} \quad \text{with} \quad \Psi := \{\boldsymbol{\theta} : \lambda(\boldsymbol{\theta}, h) = 0 \text{ or } \lambda(2\boldsymbol{\theta}, 2h) = 0\}.$$

Hence, we have a well-defined operator M_h^{2h} (4) on $\tilde{\boldsymbol{\varepsilon}}^h$ with the invariance property

$$M_h^{2h} : \boldsymbol{\varepsilon}^h_{\boldsymbol{\theta}} \longrightarrow \boldsymbol{\varepsilon}^h_{\boldsymbol{\theta}} \quad \text{with} \quad \boldsymbol{\theta} \in \tilde{\Theta}^l := \Theta^l \backslash \Psi,$$

equivalent to a block-diagonal matrix $\widetilde{M}$. The spectral radius $\rho(\widetilde{M})$ of the corresponding Fourier matrix is determined similarly as in the previous Fourier analysis (9):

$$\rho_F := \rho(\widetilde{M}) = \sup_{\boldsymbol{\theta}\in\tilde{\Theta}^l} \rho(\widehat{M}(\boldsymbol{\theta})) \quad \text{with} \quad \widehat{M}(\boldsymbol{\theta}) \triangleq M_h^{2h}|_{\boldsymbol{\varepsilon}^h_{\boldsymbol{\theta}}}. \tag{34}$$

We consider operators with $\Psi = \{(0, 0, 0)\}$, which is an ellipticity requirement [2]. Then, it is possible to keep the suprenum (34) finite by an appropriate choice of the transfer operators I_h^{2h} and I_{2h}^h [9].

The whole spectrum is obtained similarly as in section 2. We, however, always observe a spectrum from a discrete mesh, whereas we have a continuously defined set of eigenfunctions (33) in order to get h-independent upper bounds for the convergence rates.

The definition of the smoothing factor (10) carries over from the rigorous analysis. The coarse grid correction operator is replaced by an ideal operator Q_h^{2h} which is orthogonally equivalent to a block matrix $\widetilde{Q}$ with blocks $\widehat{Q} = \mathrm{diag}(0, 1, 1, 1, 1, 1, 1, 1)$.

$$\mu_F := \rho(\widetilde{S}_2^{\nu_2}\widetilde{Q}\widetilde{S}_1^{\nu_1}) = \rho(\widetilde{Q}\widetilde{S}_1^{\nu_1}\widetilde{S}_2^{\nu_2}) = \sup_{\boldsymbol{\theta}\in\tilde{\Theta}^l} \rho(\widehat{Q}\widehat{S}_1(\boldsymbol{\theta})^{\nu_1}\widehat{S}_2(\boldsymbol{\theta})^{\nu_2}) \quad \text{with} \quad \widehat{S}_*(\boldsymbol{\theta}) \triangleq S_h^*|_{\boldsymbol{\varepsilon}^h_{\boldsymbol{\theta}}}.$$

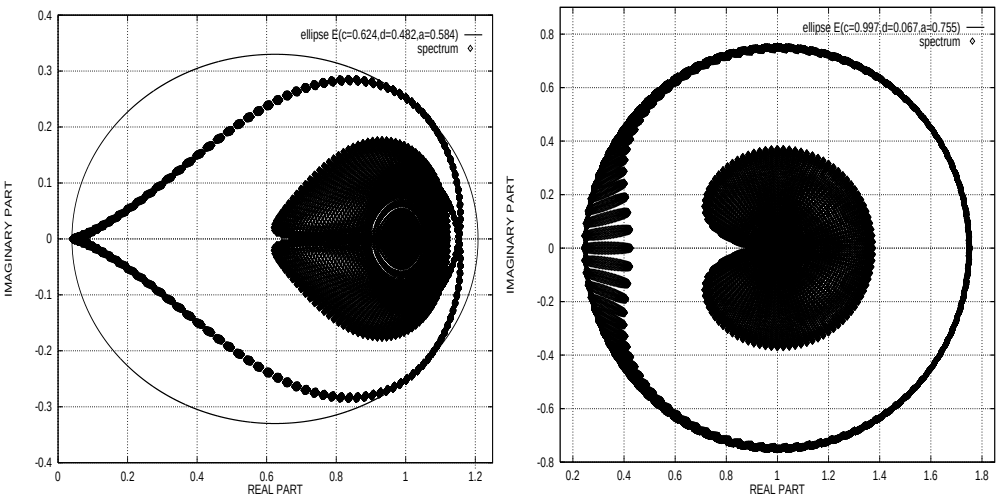
From the local mode analysis, the analytical values $\rho_{i=20}^U$, T_m^E, N_m^E, and ρ_{hpc} for the multigrid preconditioned GMRES(m) method are obtained by straightforward modifications of the definitions (32), (29), and (23) taken from the rigorous case.

4.1. Results for Poisson-type equations. The first example of the local-mode Fourier analysis of multigrid preconditioned GMRES(m) deals again with the anisotropic diffusion equation (2). We analyze the difference in convergence between performing two smoothing iterations ($\nu_1 = \nu_2 = 1$) of the forward lexicographical point Gauss–Seidel (GS-fLEX) method, and one iteration of GS-fLEX and one iteration of backward lexicographical point Gauss–Seidel (GS-bLEX). The other multigrid components are identical to the previously introduced multigrid method MG-RB. In the following, we call these multigrid methods MG-FF and MG-FB, which stand for multigrid forward forward and multigrid forward backward, respectively.

Local mode analysis gives sharp quantitative predictions for the multigrid convergence of MG-FF and MG-FB for the 2D anisotropic diffusion equation with $\varepsilon = 0.1$ and $\varepsilon = 0.01$, as can be seen in Table 5. In the anisotropic case, it is also beneficial to introduce an overrelaxation parameter for these lexicographical smoothers leading to ω-MG-FF and ω-MG-FB. The improvement is less impressive than for ω-MG-RB from [23], even if the optimal overrelaxation parameter ($\omega_{opt} = 1.40$ for $\varepsilon = 0.1, \omega_{opt} = 1.75$, or $\varepsilon = 0.01$) is selected (see Table 5).

In contrast to ω_{opt}-MG-FF (and ω_{opt}-MG-RB), it is possible to further accelerate ω_{opt}-MG-FB significantly by GMRES(m). This can be observed by comparing Table 5 and Table 6 and can be explained as follows. If A is a symmetric matrix, then MG-FB results in an *A-symmetric iteration matrix* due to the construction of the coarse grid correction (FW as the restriction and bilinear interpolation as the prolongation

operator) and the two relaxations which are adjoint to each other [8]. This means that the multigrid iteration matrix M is symmetric with respect to the A-induced inner product $(\,.\,,\,.\,)_A := (A\,.\,,\,.\,)$ (see, for example, [10]). The spectrum of the iteration matrix is real-valued, and uniformly distributed on the interval $[\lambda_{min}, \lambda_{max}]$. This feature is maintained if ω_{opt} is introduced, whereas for ω_{opt}-MG-FF an acceleration by GMRES(m) is not possible because the spectrum becomes orbital. This behavior of ω-MG-FF can be observed in Figure 4, where the spectra of the iteration matrices for $\omega = 1.0$ and $\omega = 1.75$ are shown for $\varepsilon = 0.01$. For other applications it is found in [10] that a symmetrization is not beneficial if Bi-CGstab [21] is used as the Krylov subspace acceleration method.



4 (a). $\omega = 1.0$ 4 (b). $\omega = 1.75$

FIG. 4. *Eigenvalue spectra of the MG-FF two-grid 2D anisotropic diffusion solver from local mode analysis;* $\varepsilon = 0.01, h = 1/128$. (*Note the different scaling of the axes in Figure* 4(a).)

Remark. For A-symmetric matrices it is possible to use the CG iteration as the acceleration method, in which the residual is minimized in the A-norm instead of the 2-norm (see (16)). The asymptotic convergence rate for the preconditioned CG iteration is given by the well-known formula [16]

$$\rho_{cg} := \Big(\min_{P\in\mathbb{P}_m} \max_{\lambda_j\in[\lambda_{min},\lambda_{max}]} |P(\lambda_j)| \Big)^{1/m} = \left(\max_{\lambda_j\in[\lambda_{min},\lambda_{max}]} \frac{T_m(1+2\frac{\lambda_{min}-\lambda_j}{\lambda_{max}-\lambda_{min}})}{T_m(1+2\frac{\lambda_{min}}{\lambda_{max}-\lambda_{min}})} \right)^{1/m}$$
$$= \left(2/T_m\left(\frac{\lambda_{max}+\lambda_{min}}{\lambda_{max}-\lambda_{min}}\right) \right)^{1/m} \le 2\frac{\sqrt{\kappa}-1}{\sqrt{\kappa}+1} \qquad \text{with} \quad \kappa := \kappa_A(AC^{-1}) = \frac{\lambda_{max}}{\lambda_{min}}.$$

If we consider the definition T_m^E (29) for a real-valued spectrum $\sigma \subset [\lambda_{min}, \lambda_{max}]$, then the ellipse $E(c,d,a)$ deteriorates to a line. In particular we have $a = d = (\lambda_{max} - \lambda_{min})/2$ and $c = \lambda_{min} + a$, which leads to $T_m^E = (T_m(\frac{a}{a})/T_m(\frac{c}{a}))^{1/m} = \rho_{cg}$ (see (29), (30)). As the iteration matrix is A-symmetric, we find $\kappa_A(X) = 1$, where $\kappa_A(X)$ denotes the condition number of the transformation matrix X (26) with respect to the A-norm. In general, this does not imply that $\kappa_2(X) = 1$, but $\kappa_2(X)$ cancels out of (28) for large m. It can be expected that GMRES(m) has a similar asymptotic convergence as CG.

TABLE 7
Multigrid and multigrid preconditioned GMRES(m) convergence (different m) for the 3D Poisson equation and forward and backward lexicographical Gauss–Seidel smoothers.

Solution method	Grid 32^3	Grid 64^3	Grid 96^3	Fourier values
MG-FF	0.25	0.26	0.26	$\rho_F = 0.266$
Acc. MG-FF, $m = 2$	0.22	0.22	0.22	$\rho^U_{i=20} = 0.233$
Acc. MG-FF, $m = 5$	0.22	0.21	0.21	$\rho^U_{i=20} = 0.233$
MG-FB	0.29	0.29	0.29	$\rho_F = 0.294$
Acc. MG-FB, $m = 2$	0.098	0.10	0.10	$\rho^U_{i=20} = 0.121$
Acc. MG-FB, $m = 5$	0.086	0.085	0.086	$\rho^U_{i=20} = 0.099$

The analytical prediction $\rho^U_{i=20}$ shows a sharp quantitative character again, and the estimate T^E_m gives a reliable indication of the average accelerated convergence rate presented in Table 6. N^E_m is an interesting quantity for large m. For the 3D Poisson equation also, the multigrid convergence of MG-FF and MG-FB is similar. The convergence estimate ρ_F is 0.266 for MG-FF and 0.294 for MG-FB, whereas the spectra are completely different (as in 2D). It can be seen from Table 7 that the convergence rates with and without GMRES(m) are h-independent. Table 7 shows that very satisfactory convergence rates are obtained by the Krylov subspace acceleration of MG-FB. Moreover, due to the symmetry, we can predict the convergence rate of the accelerated MG-FB accurately from ρ_{cg} for different m.

Remark. With this knowledge, a symmetrization of the red-black multigrid Poisson solver is performed by doing the post-smoothing in black-red order. Indeed, the iteration matrix is A-symmetric, but the asymptotic convergence factor ρ_F increases to 0.440, which is also the value for MG-RB with only one smoothing step (see, for example, [7]). In this case the nonsymmetric multigrid iteration matrix leads to much better convergence factors with and without Krylov acceleration.

4.2. Results for a problem with mixed derivative. Next, we discuss an unsymmetric equation where reasonable smoothing properties can be achieved with point smoothers, but the coarse grid correction turns out to be problematic in combination with standard coarsening [19]. This equation is tackled in order to demonstrate that GMRES can also be applied to overcome coarse grid difficulties. We investigate the 2D differential equation with a mixed derivative $-\Delta u - \tau u_{xy} = b$ discretized by the $O(h^2)$ 9-point operator

$$A_h u_h(\boldsymbol{x}) = \frac{1}{h^2} \begin{bmatrix} \frac{\tau}{4} & -1 & -\frac{\tau}{4} \\ -1 & 4 & -1 \\ -\frac{\tau}{4} & -1 & \frac{\tau}{4} \end{bmatrix} u_h(\boldsymbol{x}) = b_h(\boldsymbol{x}) \quad \text{on} \quad \Omega_h.$$

It is no longer elliptic if $|\tau| = 2$ and the efficiency of all previously considered multigrid methods (MG-RB, MG-FF, MG-FB) deteriorates for $|\tau| \to 2$ (see, for example, Table 8 and [19]). This behavior can be explained if we perform a simplified two-grid analysis where only the very low Fourier frequencies along the characteristic direction of the differential operator (first differential approximation (FDA) [22]) are considered. The transfer operators act almost as identities for very low-frequency harmonics and no reduction of amplitudes can be achieved by the Gauss–Seidel relaxation. Thus, we obtain the following two-grid amplification factor (see (4)):

$$\rho^{FDA}(\boldsymbol{\theta}) := 1 - \frac{\lambda(\boldsymbol{\theta}, h)}{\lambda(2\boldsymbol{\theta}, 2h)} \quad \text{for } |\boldsymbol{\theta}| := \max\{|\theta_1|, |\theta_2|\} \longrightarrow 0. \tag{35}$$

TABLE 8
Multigrid and two-grid convergences ρ_h^{mg} and ρ_h^{tg}, predicted convergence ρ_F, and smoothing factor μ_F for the τ-problem, MG-FB, $h = 1/64$.

$\tau = -1.90$				$\tau = -1.99$			
ρ_h^{mg}	ρ_h^{tg}	ρ_F	μ_F	ρ_h^{mg}	ρ_h^{tg}	ρ_F	μ_F
0.747	0.654	0.662	0.499	0.839	0.730	0.745	0.518

TABLE 9
Multi- and two-grid preconditioned GMRES(m) convergence factors ρ_h^{acc} and $\rho_h^{acc}(tg)$ and estimates $\rho_{i=20}^U$, T_m^E for the τ-problem, $h = 1/64$.

Acc.	$\tau = -1.90$				$\tau = -1.99$			
MG-FB	ρ_h^{acc}	$\rho_h^{acc}(tg)$	$\rho_{i=20}^U$	T_m^E	ρ_h^{acc}	$\rho_h^{acc}(tg)$	$\rho_{i=20}^U$	T_m^E
$m = 2$	0.420	0.333	0.372	0.373	0.533	0.404	0.415	0.463
$m = 5$	0.370	0.287	0.302	0.304	0.472	0.348	0.354	0.378

The Fourier symbol $\lambda(\boldsymbol{\theta}, h)$ of the differential operator reads as follows:

$$\begin{aligned}\lambda(\boldsymbol{\theta}, h) &= \frac{1}{h^2}\Big(4 - 2\cos(\theta_1) - 2\cos(\theta_2) + \frac{\tau}{2}\cos(\theta_1 - \theta_2) - \frac{\tau}{2}\cos(\theta_1 + \theta_2)\Big) \\ &= \frac{1}{h^2}\Big(\theta_1^2 + \theta_2^2 + \frac{\tau}{4}(\,(\theta_1 + \theta_2)^2 - (\theta_1 - \theta_2)^2\,) - \frac{\theta_1^4 + \theta_2^4}{12} \\ &\qquad + \frac{\tau}{48}(\,(\theta_1 - \theta_2)^4 - (\theta_1 + \theta_2)^4\,) + \mathrm{O}(|\boldsymbol{\theta}|^6)\Big),\end{aligned}$$

where Taylor's expansion is used. If $\tau \longrightarrow \pm 2$ the characteristic frequencies are given by $\theta_2 = \mp\theta_1$. This gives

$$\begin{aligned}&\lambda(\boldsymbol{\theta}, h) = \frac{1}{h^2}\Big((2 \mp \tau)\theta_1^2 - \Big(\frac{1}{6} \mp \frac{\tau}{3}\Big)\theta_1^4 + \mathrm{O}(\theta_1^6)\Big) \\ \Longrightarrow\quad &\rho^{FDA}(\boldsymbol{\theta}) = 1 - \frac{4}{16} = 0.75 \quad \text{for } |\boldsymbol{\theta}| \longrightarrow 0 \text{ and } \tau \longrightarrow \pm 2.\end{aligned}$$

For $\tau = -1.99$ and MG-FB, this limiting value of 0.75 is almost obtained by the predicted two-grid factor ρ_F and also by the numerically obtained ρ_h^{tg}; see Table 8. The multigrid convergence ρ_h^{mg} increases further since the coarse grid problem occurs on all coarser grids (actually six grids are used).

One way to handle the coarse grid problem is to change the smoother to the more expensive ILU-type relaxation [19], which also takes care of the problematic low-frequency error components. A second way is to replace the grid coarsening by a nonstandard coarsening technique. We keep the point Gauss–Seidel smoother with standard grid coarsening and solve this problem by the Krylov subspace acceleration of MG-FB. In Table 9, a significant improvement of the multigrid convergence due to the acceleration is observed even with a small Krylov subspace. The two-grid convergence $\rho_h^{acc}(tg)$ is very well predicted by $\rho_{i=20}^U$ and T_m^E.

Comparing the accelerated two-grid and multigrid convergences from Table 9, it is expected that it is possible to further improve ρ_h^{acc} by incorporating the Krylov acceleration into the multigrid cycle and to apply it also on the coarse grids as in [14].

4.3. Further results and extensions. Here, we present a relation between Krylov subspace acceleration and a coarse grid correction acceleration as presented for the convection-diffusion equation in [4] and a relation between Krylov subspace acceleration and optimal (multistage) overrelaxation in a smoothing method.

A standard upwind discretization of a convection-dominated ($0 < \epsilon \ll 1$) convection-diffusion equation

$$-\epsilon\Delta u(\boldsymbol{x}) + (\, a_1(\boldsymbol{x})u(\boldsymbol{x})\,)_x + (\, a_2(\boldsymbol{x})u(\boldsymbol{x})\,)_y = b(\boldsymbol{x}), \tag{36}$$

with a rotating convection term ($a_1(\boldsymbol{x}) = -\sin(\pi x)\cos(\pi y)$, $a_2(\boldsymbol{x}) = \sin(\pi y)\cos(\pi x)$), is another well-known equation with a problematic coarse grid correction (see [4], [8]). A similar FDA analysis, as in the previous section, shows that characteristic low frequency error components, that are constant along the characteristics of the advection operator, are not reduced efficiently on coarse grids [4]. The different scaling of convection $(\, a_1(\boldsymbol{x})/h, a_2(\boldsymbol{x})/h\,)$ and diffusion ϵ/h^2 is not approximated properly on the $2h$-grid which leads to a limiting two-grid convergence factor of 0.5 [4]. It is shown in [14] that the problems with rotating convection direction can be solved efficiently by a Krylov subspace acceleration of multigrid (also on the coarser grids of the multigrid preconditioner). In [4] an improved multigrid method is designed for this problem where the residuals in the kth two-grid cycle are overweighted by optimized acceleration parameters η_k. This means that the FDA error amplification factor after the mth cycle is given by the following polynomial (see (35) and [4]):

$$\rho_m^{FDA}(\boldsymbol{\theta}) = \prod_{k=1}^{m} (\, 1 - \eta_k \zeta(\boldsymbol{\theta})\,) \quad \text{with} \quad \zeta(\boldsymbol{\theta}) = \frac{\lambda(\boldsymbol{\theta}, h)}{\lambda(2\boldsymbol{\theta}, 2h)}.$$

The two methods are related. The FDA analysis can also be performed for the argument of the GMRES(m)-polynomials (21). It yields that the block matrix $UAC^{-1}U$ is dominated by $\zeta(\boldsymbol{\theta})$ for very low characteristic frequencies $\boldsymbol{\theta}$. We can construct an initial solution u_0 (necessary to calculate the GMRES(m)-polynomials explicitly; see subsection 3.2), which consists only of characteristic error components and freezes the discretization operator at a fixed (but arbitrary) point $\boldsymbol{x}$. All resulting GMRES(m)-polynomials P_m^i are almost identical for $i \geq 20$. Therefore, always the same coefficients α_k^i ($k = 1, \ldots, m$) are found. Thus, it is possible to identify ρ_m^{FDA} with P_m^i for $i \geq 20$ and we can express the coefficients α_k^i ($i \geq 20$) by the η_k, for example,

$$\alpha_1^i = -\eta_1 \quad \text{for} \quad m = 1\,, \quad \alpha_1^i = -(\eta_1 + \eta_2)\,,\ \alpha_2^i = \eta_1\eta_2 \quad \text{for} \quad m = 2. \tag{37}$$

The above considerations are confirmed by test calculations where such relations as from (37) are established for $i \geq 20$ and also for larger m. For problem (36), for example, we find

$$\alpha_1^i = -1.33 \quad \text{for} \quad m = 1\,, \quad \alpha_1^i = -2.82\,,\ \alpha_2^i = 1.88 \quad \text{for} \quad m = 2,$$

which matches exactly with the reference values η_k; see [4]. We see from this heuristic consideration that an optimal tuning of the coarse grid correction is implicitly done by the Krylov subspace acceleration.

Similarly it is possible to find optimal overrelaxation parameters for smoothing methods, like Jacobi or GS-RB, if the coarse grid correction acts as the optimal operator Q_h^{2h} from sections 2 and 4. For example, consider the multistage Jacobi relaxation for the 2D Poisson equation for which the smoothing operator is given by the polynomial

$$S_h = \prod_{k=1}^{m} (\, I_h - \omega_k \Delta_h/4\,). \tag{38}$$

The corresponding smoothing factor for the multistage relaxation S_h from (38) can be minimized analytically, yielding the optimal ω_k, which are knots of Chebychev polynomials [19]. If we select an initial approximation which consists only of high frequency error components, it is possible to identify S_h with the GMRES(m)-polynomials P_m^i (for $i \geq 20$) as the coarse grid correction leaves the high frequency components almost unchanged. A similar comparison of coefficients ω_k and α_k can be performed as described above for η_k and α_k (37). The related α_k^i, calculated by the analysis from subsection 3.2, match with the optimal ω_k for $i \geq 20$ very well.

For more complicated equations (or smoothing procedures) it is, in general, not possible to determine optimal overrelaxation parameters analytically, but the analysis is easily applicable and the α_k^i can be determined. As an example we consider the discrete biharmonic equation $\Delta_h \Delta_h u_h = b_h$ which is sometimes transformed into a system of two Poisson-type equations in order to achieve better smoothing properties [1]. Here we keep the scalar forth order problem and apply a multistage version of a GS-RB smoothing method

$$S_h^{msRB} = \prod_{k=1}^{m} (I_h - \omega_k (I_h - S_h^{BLACK} \cdot S_h^{RED})),$$

where the multistage parameters ω_k are obtained by an evaluation of the related α_k^i ($i \geq 20$). It can be seen in Table 10 that it is possible to obtain satisfactory smoothing rates also for the scalar biharmonic equation.

TABLE 10

Multistage red-black Gauss–Seidel relaxation parameters and smoothing rate for the biharmonic equation.

	α_1	α_2	α_3	μ_F	$(\mu_F)^{1/m}$
$m = 1$	-1.39			0.501	0.501
$m = 2$	-3.17	2.20		0.152	0.390
$m = 3$	-4.81	7.13	-3.30	0.050	0.369

Finally, it can be concluded that the Krylov subspace acceleration implicitly improves the coarse grid correction or the relaxation procedure, if one of these multigrid components clearly hampers the overall multigrid convergence. Furthermore, the analysis from subsection 3.2 is an easy tool to obtain good overrelaxation parameters for different (and also difficult) problems.

5. Conclusions. In this paper we have presented a way to obtain sharp quantitative convergence estimates for GMRES(m) preconditioned by multigrid on the basis of Fourier analysis. For all the cases considered the estimates are accurate compared to measured numerical convergence of the multigrid preconditioned GMRES(m) method.

It has been shown that it is not easily possible to further accelerate multigrid methods which are optimally tuned with, for example, overrelaxation parameters. In other situations, however, very satisfactory convergence improvement is achieved with the Krylov subspace acceleration. The possibilities for the subspace acceleration of multigrid are not only available in the case of isolated eigenvalues from the multigrid preconditioner, but they depend also on the shape of the spectrum. A spectrum resulting from the preconditioner with a circular shape is not appropriate for an acceleration with the method presented. For a fair comparison one should take the additional work for the Krylov subspace acceleration into account. This, however,

is not the main issue in this paper. The acceleration is, in general, cheap compared to the multigrid method. The proposed acceleration is, of course, also applicable to situations in which it is not easy to tune a multigrid method.

ADAPTIVE BOUNDARY ELEMENT METHODS BASED ON COMPUTATIONAL SCHEMES FOR SOBOLEV NORMS*

O. STEINBACH†

Abstract. Multilevel methods are applied to compute local and global Sobolev norms arising in adaptive boundary element methods. Combining this approach with an approximate computation of an error function we construct efficient and reliable a posteriori error estimators for arbitrary boundary element solutions related to either a Dirichlet or Neumann boundary value problem.

Key words. adaptivity, boundary element methods, error estimation, multilevel methods

1. Introduction.

Multilevel methods (see, for example, [2, 3, 9, 13, 14, 20, 22, 23]) were originally designed for an efficient solution of numerical schemes related to elliptic boundary value problems, in particular, finite and boundary element methods. In fact, multilevel methods are often used to construct almost optimal preconditioners to be used in iterative methods, i.e., we refer to BPX-type preconditioners first considered in [3, 22]. The numerical analysis of such an approach is essentially based on multilevel representations of equivalent norms in certain Sobolev spaces; see, for example, [14]. In a recent paper by Oswald [15] it was shown that the Sobolev norm in $H^{-1/2}(\Gamma)$ allows an equivalent multilevel representation using piecewise constant trial functions. In this paper we will use this equivalent multilevel approximation to define local and global a posteriori error indicators needed in adaptive boundary element methods. A related approach is to derive a posteriori error estimators using hierarchical basis techniques; see, e.g., [1, 16] for finite elements, [11] for boundary elements, or [12] for a coupling of finite and boundary elements.

For the design of adaptive boundary element methods, it is necessary to estimate and localize the error. This is more complicated, as in finite element methods, since the boundary integral operators involved are, in general, nonlocal. Residual-based error estimators for Galerkin boundary element methods were considered, for example, in [4, 7, 17, 21]. The challenge there is the localization of the Sobolev norm, in particular for the Dirichlet boundary value problem where the related boundary integral operator is of order minus one, and to prove reliability of the resulting local error indicators [8]. Since residual-based error estimators require the evaluation of the residual inside certain quadrature formulae (see, for example, [4]), for some applications these methods may be time consuming and therefore become inefficient; see [18].

In [18, 19] we considered an alternative approach to approximate the error function of an arbitrary given boundary element solution for both the Dirichlet and Neumann boundary value problem. This method is based on a truncated Neumann series

to solve a second kind boundary integral equation. In [18, 19] we analyzed the convergence of these Neumann series in appropriate energy norms to get reliability and efficiency for the resulting global error estimators. To get local error indicators, we used the local contributions of the energy norm. However, in this case we could prove the efficiency of the local error indicators only. Moreover, the use of energy norms induced by boundary integral operators, in particular by the single layer potential, seems not to be satisfactory with respect to the computational costs.

In this paper we describe a new approach to compute and to localize Sobolev norms by means of multilevel methods. These methods are almost optimal with respect to the amount of work. Therefore, in comparison with the approach described in [18, 19], we get a more efficient algorithm as it will be seen in the numerical example. Moreover, when using a multilevel norm instead of an energy norm, we can prove also reliability of the resulting global and local error estimator.

While in this paper we consider multilevel methods to compute Sobolev norms of an approximated error function, one can use such an approach even to compute and localize Sobolev norms of the residual. This modification is straightforward and will not be considered here.

The rest of the paper is organized as follows. In section 2 we recall the definition and basic properties of multilevel operators and derive a local representation of an equivalent Sobolev norm in $H^{-1/2}(\Gamma)$. The approximation of the error function in case of a Dirichlet boundary value problem is described in section 3, where we apply the results of section 2 to construct local and global error indicators. Section 4 is devoted to the same topics in the case of a Neumann boundary value problem. In section 5 we give a general adaptive boundary element algorithm for the solution of Dirichlet or Neumann boundary values problems. Some numerical examples for the two-dimensional Laplacian are given in section 6, i.e., we compare the proposed new approach with an uniform approach as well as with an adaptive algorithm based on the energy norm as considered in [18, 19].

2. Computational schemes for Sobolev norms. Let $\Omega \subset \mathbb{R}^n$ $(n = 2, 3)$ be a bounded domain with Lipschitz boundary $\Gamma = \partial\Omega$. For a family of regular boundary element meshes Γ_{h_j} $(j = 1, \ldots, J)$ of mesh size h_j and consisting of N_j boundary elements $\Gamma_{j,k}$ $(k = 1, \ldots, N_j)$ we define a nested sequence of trial spaces Z_j of piecewise constant basis functions $\psi_{j,k}$ $(k = 1, \ldots, N_j; j = 1, \ldots, J)$, i.e.,

$$Z_1 \subset Z_2 \subset \cdots \subset Z_J \subset H^{-1/2}(\Gamma).$$

Let Q_j denote the L^2 Galerkin projection onto Z_j defined by

$$\langle Q_j w, \tau \rangle_{L^2(\Gamma)} = \langle w, \tau \rangle_{L^2(\Gamma)} \quad \text{for all } \tau \in Z_j. \tag{2.1}$$

Set $Q_0 = 0$. Then there hold the following relations for $k = 1, \ldots, J$:

$$Q_k Q_\ell = Q_\ell Q_k = Q_\ell \quad \text{for } \ell \le k, \tag{2.2}$$

$$(Q_k - Q_{k-1})Q_\ell = 0 \quad \text{for } \ell < k, \tag{2.3}$$

$$(Q_k - Q_{k-1})^2 = Q_k - Q_{k-1}, \tag{2.4}$$

$$(Q_k - Q_{k-1})(Q_\ell - Q_{\ell-1}) = 0 \quad \text{for } k \neq \ell. \tag{2.5}$$

In fact, (2.3)–(2.5) are simple consequences of (2.2) [22].

For $s \in \mathbb{R}$ and $w \in Z_J$ we define the multilevel operator

$$A^{(s)} w = \sum_{j=1}^{J} h_j^{-2s} \cdot (Q_j - Q_{j-1}) w \,. \tag{2.6}$$

From [15, Theorem 2] it is known that there hold the spectral equivalence inequalities

$$c_1||w||^2_{H^{-1/2}(\Gamma)} \leq \langle A^{(-\frac{1}{2})}w, w\rangle_{L^2(\Gamma)} \leq c_2 J^2||w||^2_{H^{-1/2}(\Gamma)} \quad \text{for all } w \in Z_J \tag{2.7}$$

with positive constants c_1 and c_2 independent of $w \in Z_J$ and $J \geq 1$.

While we can use the operator $A^{(-1/2)}$ to compute an equivalent Sobolov norm in $H^{-1/2}(\Gamma)$ (this is due to (2.7)) we need to compute local norms to be used in the mesh refinement of adaptive boundary element methods. This will be based on the following result which is a consequence of (2.4) and (2.5); see also [22].

PROPOSITION 2.1. *Let $A^{(s)}$ be defined as in* (2.6) *for some $s \in \mathbb{R}$. Then there holds*

$$A^{(s)} = A^{(s/2)} \cdot A^{(s/2)}.$$

Proof. A simple computation shows that

$$\begin{aligned} A^{(s/2)} \cdot A^{(s/2)} &= \sum_{k=1}^{J} h_k^{-s}(Q_k - Q_{k-1}) \cdot \sum_{\ell=1}^{J} h_\ell^{-s}(Q_\ell - Q_{\ell-1}) \\ &= \sum_{k=1}^{J}\sum_{\ell=1}^{J} h_k^{-s} h_\ell^{-s}(Q_k - Q_{k-1})(Q_\ell - Q_{\ell-1}) \\ &= \sum_{k=1}^{J} h_k^{-2s}(Q_k - Q_{k-1}) = A^{(s)} \end{aligned}$$

due to (2.4) and (2.5). ∎

As a conclusion of (2.7) and Proposition 2.1 we get that

$$||A^{(-1/4)}w||^2_{L^2(\Gamma)} = \langle A^{(-1/2)}w, w\rangle_{L^2(\Gamma)} \quad \text{for all } w \in Z_J \tag{2.8}$$

is an equivalent Sobolev norm in $H^{-1/2}(\Gamma)$. Moreover, we can localize (2.8) by

$$||A^{(-1/4)}w||^2_{L^2(\Gamma)} = \sum_{k=1}^{N_J} ||A^{(-1/4)}w||^2_{L^2(\Gamma_{J,k})} \quad \text{for all } w \in Z_J. \tag{2.9}$$

The computation of $A^{(-1/4)}w$ for $w \in Z_J$ via (2.6) requires the solution of the variational problems (2.1) for all $j = 1, \ldots, J$, i.e., the inversion of the Gram matrices G_j defined by $G_j[k,\ell] = \langle \psi_{j,k}, \psi_{j,\ell}\rangle_{L^2(\Gamma)}$ for $k, \ell = 1, \ldots, N_j; j = 1, \ldots, J$. Since we are using piecewise constant trial functions $\psi_{j,k}$ the Gram matrices G_j are just diagonal matrices, and therefore the computation of G_j^{-1} and thus of $Q_j w$ is trivial.

3. An error estimator for the Dirichlet problem. Let $\Omega \subset \mathbb{R}^n$ $(n = 2, 3)$ with Lipschitz boundary $\Gamma = \partial\Omega$. For the numerical solution of the Dirichlet boundary value problem

$$Lu(x) = 0 \quad \text{for } x \in \Omega, \qquad u(x) = g(x) \quad \text{for } x \in \Gamma \tag{3.1}$$

with an elliptic and self-adjoint second-order partial differential operator L we consider the boundary integral equation

$$(Vt)(x) = \left(\frac{1}{2}I + K\right) g(x) \quad \text{for } x \in \Gamma \tag{3.2}$$

with the standard notations for the single layer potential V and the double layer potential K,

$$(Vt)(x) = \int_\Gamma U^*(x,y)t(y)ds_y, \qquad (Ku)(x) = \int_\Gamma u(y)T^*(x,y)ds_y.$$

Here, $U^*(x,y)$ is the fundamental solution of the partial differential operator L, $T^*(x,y) = T_y U^*(x,y)$, and $t(y) = T_y u(y)$, where T_y is the conormal derivative operator corresponding to L.

Let $Z_h := Z_I$ be a trial space of piecewise constant basis functions as introduced in the previous section for some $1 \le I < J$. The Galerkin variational formulation of (3.2) reads to find $t_h \in Z_h$ such that

$$\langle Vt_h, \tau_h \rangle_{L^2(\Gamma)} = \left\langle \left(\frac{1}{2}I + K\right) g, \tau_h \right\rangle_{L^2(\Gamma)} \quad \text{for all } \tau_h \in Z_h. \tag{3.3}$$

It is well known (see, for example, [10]) that the variational problem (3.3) is uniquely solvable and that there holds the a priori error estimate

$$||t - t_h||_{H^{-1/2}(\Gamma)} \le c \cdot \inf_{\tau_h \in Z_h} ||t - \tau_h||_{H^{-1/2}(\Gamma)} \le c \cdot h^{s+\frac{1}{2}} \cdot ||t||_{H^s(\Gamma)} \tag{3.4}$$

if $t \in H^s(\Gamma)$ and $s \le 1$.

The design of adaptive boundary element methods is in general based on global and local a posteriori estimators for the error

$$e_h(x) := (t - t_h)(x) \quad \text{for } x \in \Gamma. \tag{3.5}$$

The use of residual based error estimators requires the computation of

$$r_h(x) := (Ve_h)(x) = \left(\frac{1}{2}I + K\right) g(x) - (Vt_h)(x) \quad \text{for } x \in \Gamma. \tag{3.6}$$

Due to the equivalence inequalities

$$c_1 \cdot ||r_h||^2_{H^{1/2}(\Gamma)} \le ||e_h||^2_{H^{-1/2}} \le c_2 \cdot ||r_h||^2_{H^{1/2}(\Gamma)}$$

one can use $||r_h||^2_{H^{1/2}(\Gamma)}$ to derive both local and global error indicators, i.e., one has to localize an equivalent Sobolev norm in $H^{1/2}(\Gamma)$; see [4, 8]. However, numerical examples in [4, 18] indicate that a residual-based approach to constructing error estimators may lead to unstable and, with respect to computing times, inefficient algorithms. In [18] we proposed an alternative approach to estimate the error (3.5) by solving a second kind boundary integral equation via a truncated Neumann series. The resulting approximation of the error (3.5) can be done with high accuracy, but the computation of global and local error indicators now has to be done in a equivalent Sobolev norm in $H^{-1/2}(\Gamma)$. In [18] we used the energy norm induced by the single layer potential V to compute the global error estimator as well as some local indicators. Although, for the example considered, the approach in [18] was more efficient compared with the method described in [4] and an uniform refinement, the amount of work to compute the energy norm was not satisfactory. Therefore, we consider in this paper an alternative approach to compute both the global and local error indicators appearing in [18] by an equivalent Sobolev norm based on multilevel trial spaces as described in

section 2. Moreover, we also get reliability of local error indicators when using this multilevel approach.

Let $t_h \in Z_h$ be an arbitrary boundary element approximation for $t \in H^{-1/2}(\Gamma)$, for example, we may take the Galerkin solution of (3.3) but any other discretization scheme such as collocation may be used also. Then we can define an approximate solution of the boundary value problem (3.1) by

$$u_h(\widetilde{x}) = \int_\Gamma U^*(\widetilde{x},y)t_h(y)ds_y - \int_\Gamma g(x)T^*(\widetilde{x},y)ds_y \quad \text{for } \widetilde{x} \in \Omega. \tag{3.7}$$

Applying T_x for $x \in \Gamma$ and taking the limit $\Omega \ni \widetilde{x} \to x \in \Gamma$, (3.7) defines a computable function

$$\widetilde{t}(x) = \left(\frac{1}{2}I + K'\right) t_h(x) + (Dg)(x) \quad \text{for } x \in \Gamma \tag{3.8}$$

almost everywhere where K' is the adjoint double layer potential operator and D is the hypersingular integral operator,

$$(K't)(x) = \int_\Gamma T_x U^*(x,y)t(y)ds_y, \quad (Du)(x) = -T_x \int_\Gamma u(x)T_y U^*(x,y)ds_y.$$

It was shown in [18, Lemma 1] that the error (3.5) is then a solution of the second kind boundary integral equation

$$\left(\frac{1}{2}I - K'\right)(t - t_h)(x) = (\widetilde{t} - t_h)(x) \quad \text{for } x \in \Gamma. \tag{3.9}$$

Let $||\cdot||_V$ denote the energy norm in $H^{-1/2}(\Gamma)$ induced by the single layer potential. Then (see [18, Theorem 1])

$$\left\| \left(\frac{1}{2}I + K'\right) w \right\|_V \le c_K \cdot ||w||_V \quad \text{for all } w \in H^{-1/2}(\Gamma) \quad \text{with } c_K < 1. \tag{3.10}$$

Therefore we can compute the error (3.5) by the Neumann series

$$e_h(x) = \sum_{\ell=0}^{\infty} (\frac{1}{2}I + K')^\ell (\widetilde{t} - t_h)(x) \quad \text{for } x \in \Gamma.$$

Using a truncated Neumann series, i.e., for a fixed $q \ge 0$, we may compute the approximate error function

$$e_h^{(q)}(x) = \sum_{\ell=0}^{q} \left(\frac{1}{2}I + K'\right)^\ell e_h^{(0)}(x), \quad e_h^{(0)}(x) = (\widetilde{t} - t_h)(x), \tag{3.11}$$

and derive global and local error indicators from $||e_h^{(q)}||^2_{H^{-1/2}(\Gamma)}$ or an equivalent norm. From (3.11) using (3.10) we conclude the equivalence inequalities

$$\frac{1}{1 + c_K^{q+1}} \, ||e_h^{(q)}||_V \le ||e_h||_V \le \frac{1}{1 - c_K^{q+1}} \, ||e_h^{(q)}||_V. \tag{3.12}$$

For a numerical realization of the successive approximation (3.11) we introduce a trial space $Z_J := Z_{\tilde{h}}$ of dimension N_J with $Z_h \subset Z_{\tilde{h}}$ and compute

$$e_{\tilde{h}}^{(q)}(x) = \sum_{\ell=0}^{q} \left[Q_{\tilde{h}} \left(\frac{1}{2} I + K' \right) \right]^{\ell} e_{\tilde{h}}^{(0)}(x), \quad e_{\tilde{h}}^{0}(x) = Q_{\tilde{h}}(\widetilde{t} - t_h)(x), \tag{3.13}$$

where $Q_{\tilde{h}}$ is the L^2 Galerkin projection onto $Z_{\tilde{h}}$ as defined in (2.1).

Hence, using the energy norm induced by the single layer potential, a global a posteriori error estimator is given by

$$\eta^{(q)} := ||e_{\tilde{h}}^{(q)}||_V. \tag{3.14}$$

Combining the equivalence inequalities (3.12) with the approximation error of $Q_{\widetilde{h}}$ in $H^{-1/2}(\Gamma)$ we get the following result.

THEOREM 3.1 (see [18, Theorem 3.3]). *Let $\eta^{(q)}$ as defined in* (3.14). *Then,*

$$\frac{1}{1 + c_K^{q+1}} \left\{ \eta^{(q)} - c \cdot q \cdot \widetilde{h}^{1/2} ||e_h^{(0)}||_{L^2(\Gamma)} \right\} \leq ||e_h||_V \leq \frac{1}{1 - c_K^{q+1}} \left\{ \eta^{(q)} + c \cdot q \cdot \widetilde{h}^{1/2} ||e_h^{(0)}||_{L^2(\Gamma)} \right\}.$$

We note that, due to our construction, the trial spaces Z_j form a nested sequence

$$Z_1 \subset \cdots \subset Z_I = Z_h \subset \cdots \subset Z_J = Z_{\tilde{h}},$$

therefore we can apply all results from section 2, in particular, we may define the global error estimator

$$\widetilde{\eta}^{(q)} = \sqrt{\langle A^{-1/2} e_{\tilde{h}}^{(q)}, e_{\tilde{h}}^{(q)} \rangle_{L^2(\Gamma)}} \tag{3.15}$$

which is equivalent to $\eta^{(q)}$ as defined in (3.14) and therefore to $||e_h||_V$. Moreover, due to (2.9) we can define local error indicators

$$\widetilde{\eta}_k^{(q)} := ||A^{-1/4} e_{\tilde{h}}^{(q)}||_{L^2(\Gamma_{I,k})} \tag{3.16}$$

satisfying

$$[\widetilde{\eta}^{(q)}]^2 = \sum_{k=1}^{N_I} [\widetilde{\eta}_k^{(q)}]^2.$$

Hence, the local error indicators defined by (3.16) satisfy the equivalence inequalities

$$c_1 \cdot \sqrt{\sum_{k=1}^{N_I} [\widetilde{\eta}_k^{(q)}]^2} \leq ||e_h||_V \leq c_2 \cdot \sqrt{\sum_{k=1}^{N_I} [\widetilde{\eta}_k^{(q)}]^2}. \tag{3.17}$$

The local error indicators (3.16) are local contributions of the global Sobolev norm (2.8) which is an equivalent norm in $H^{-1/2}(\Gamma)$. Moreover, the global error estimator (3.15) can be derived from all local indicators. Hence we get reliability and efficiency for both global and local error indicators. Note that we are localizing a Sobolev norm in $H^{-1/2}(\Gamma)$ to get a posteriori error estimators for the Dirichlet problem. When using a residual-based approach one has to localize a Sobolev norm in $H^{1/2}(\Gamma)$. This can be done, for example, by a window technique as described in [17], by a direct localization of the Sobolev–Slobodeckii norm in $H^{1/2}(\Gamma)$ (see [8]), or by local indicators of Babuška–Rheinboldt type [4, 7].

4. An error estimator for the Neumann problem. Now we consider instead of (3.1) the Neumann boundary value problem

$$Lu(x) = 0 \quad \text{for } x \in \Omega, \qquad (T_x u)(x) = f(x) \quad \text{for } x \in \Gamma. \tag{4.1}$$

Note that f has to satisfy the compatibility condition

$$\int_\Gamma f(x)v(x)ds_x \;=\; 0 \quad \text{for all } v \in \mathcal{K}, \tag{4.2}$$

where $\mathcal{K}$ is the solution space of the homogeneous Neumann boundary value problem,

$$\mathcal{K} \;:=\; \left\{ v \in H^1(\Omega) \;:\; Lv = 0 \text{ in } \Omega, T_x v = 0 \text{ on } \Gamma \right\}, \tag{4.3}$$

and that the solution of (4.1) is unique only modulo $\mathcal{K}$.

Let us denote

$$H_0^{1/2}(\Gamma) \;:=\; \{ v \in H^{1/2}(\Gamma) \;:\; \langle v, w \rangle_{L^2(\Gamma)} = 0 \quad \text{for all } w \in \mathcal{K} \}. \tag{4.4}$$

For the numerical solution of (4.1) we may consider the hypersingular boundary integral equation

$$(Du)(x) \;=\; \left(\frac{1}{2} I - K' \right) f(x) \quad \text{for } x \in \Gamma, \tag{4.5}$$

where the boundary integral operators are defined as in the previous section. If f satisfies (4.2), then there exists a unique solution $u \in H_0^{1/2}(\Gamma)$ satisfying (4.5). Let

$$W_h \;=\; \operatorname{span}\{\varphi_k\}_{k=1}^M \subset H_0^{1/2}(\Gamma) \tag{4.6}$$

be a boundary element trial space of continuous and piecewise linear splines with respect to a triangulation $\Gamma_h = \Gamma_{h_I}$ for some $1 \le I < J$; see section 2. The Galerkin formulation of (4.5) reads to find $u_h \in W_h$ such that

$$\langle Du_h, v_h \rangle_{L^2(\Gamma)} \;=\; \left\langle \left(\frac{1}{2} I - K' \right) f, v_h \right\rangle_{L^2(\Gamma)} \qquad \text{for all } v_h \in W_h. \tag{4.7}$$

It is well known that there exists a unique solution $u_h \in W_h$ of (4.7) satisfying the error estimate

$$||u - u_h||_{H^{1/2}(\Gamma)} \;\le\; c \cdot \inf_{v_h \in W_h} ||u - v_h||_{H^{1/2}(\Gamma)} \;\le\; c \cdot h^{s-\frac{1}{2}} \cdot ||u||_{H^s(\Gamma)} \tag{4.8}$$

if $u \in H^s(\Gamma)$ and $s \le 2$. It was shown in [19] that the error

$$e_h(x) \;=\; (u - u_h)(x) \in H_0^{1/2}(\Gamma) \tag{4.9}$$

is a solution of the second kind boundary integral equation

$$\left(\frac{1}{2} I + K \right) (u - u_h)(x) \;=\; (\widetilde{u} - u_h)(x) \quad \text{for } x \in \Gamma, \tag{4.10}$$

where $\widetilde{u}$ is given as

$$\widetilde{u}(x) \;=\; (Vf)(x) + \left(\frac{1}{2} I - K \right) u_h(x) \quad \text{for } x \in \Gamma.$$

Let $P_{\mathcal{K}} : H^{1/2} \to H_0^{1/2}(\Gamma)$. Then we can compute an approximate error function by the truncated Neumann series

$$e_h^{(q)} = \sum_{\ell=0}^{q} \left[P_{\mathcal{K}} \left(\frac{1}{2} I - K \right) \right]^{\ell} P_{\mathcal{K}} (\widetilde{u} - u_h)(x) \quad \text{for } x \in \Gamma \tag{4.11}$$

for some $q \geq 0$ to be used as an error estimator for (4.9); see [19] for details. As in the case of the Dirichlet problem we introduce a trial space $W_{\tilde{h}}$ with $W_h \subset W_{\tilde{h}}$ to realize the successive approximation (4.11), i.e., we compute

$$\widetilde{e}_h^{(q)} = \sum_{\ell=0}^{q} \left[\hat{Q}_{\tilde{h}} P_{\mathcal{K}} \left(\frac{1}{2} I - K \right) \right]^{\ell} \hat{Q}_{\tilde{h}} P_{\mathcal{K}} (\widetilde{u} - u_h)(x) \quad \text{for } x \in \Gamma, \tag{4.12}$$

where $\hat{Q}_{\tilde{h}}$ is now the L^2 Galerkin projection onto $W_{\tilde{h}}$. We have to assume that $\hat{Q}_{\tilde{h}} : H^1(\Gamma) \to W_{\tilde{h}} \subset H^1(\Gamma)$ is bounded. To ensure this for adaptively refined meshes we need to formulate some additional mesh restrictions [5]. For example, when using piecewise linear trial functions on a curve, the mesh ratio of neighbored elements has to be bounded by 4; see [5, Theorem 2].

Based on the approximated error function (4.12) we can compute a global error estimator by

$$\widetilde{\eta}^{(q)} = ||\widetilde{e}_h^{(q)}||_D, \tag{4.13}$$

where we used the energy norm induced by the hypersingular integral operator D.

THEOREM 4.1 (see [19, Theorem 3.1]). *Let $\widetilde{\eta}^{(q)}$ as defined in* (4.13). *Then,*

$$\frac{1}{1 + c_K^{q+1}} \left\{ \eta^{(q)} - c \cdot q \cdot \widetilde{h}^{1/2} ||\widetilde{e}_h^{(0)}||_{L^2(\Gamma)} \right\} \leq ||\widetilde{e}_h||_D \leq \frac{1}{1 - c_K^{q+1}} \left\{ \eta^{(q)} + c \cdot q \cdot \widetilde{h}^{1/2} ||\widetilde{e}_h^{(0)}||_{L^2(\Gamma)} \right\}.$$

For the computation of all global and local error indicators we consider the case $n = 2$ first. Since the energy norm induced by the hypersingular integral operator of the Laplace equation is spectrally equivalent to any other norm in $H_0^{1/2}(\Gamma)$ it is sufficient to consider the norm induced by the hypersingular integral operator of the Laplacian only. Moreover, for the boundary integral operators related to the Laplace operator it is known that there holds

$$\langle Du, v \rangle_{L^2(\Gamma)} = \left\langle V \frac{d}{ds} u, \frac{d}{ds} v \right\rangle_{L^2(\Gamma)} \quad \text{for all } u, v \in H_0^{1/2}(\Gamma).$$

Since $\widetilde{e}_h^{(q)} \in W_{\tilde{h}}$ we get that $\frac{d}{ds} \widetilde{e}_h^{(q)} =: w_{\tilde{h}}^{(q)} \in Z_{\tilde{h}}$, where $Z_{\tilde{h}}$ is the trial space of piecewise constant splines as introduced in the previous section. Therefore,

$$||\widetilde{e}_h^{(q)}||_D^2 = \langle D \widetilde{e}_h^{(q)}, \widetilde{e}_h^{(q)} \rangle_{L^2(\Gamma)} = \langle V w_{\tilde{h}}^{(q)}, w_{\tilde{h}}^{(q)} \rangle_{L^2(\Gamma)}.$$

Since the single layer potential operator $V : H^{-1/2}(\Gamma) \to H^{1/2}(\Gamma)$ is positive definite and bounded, we conclude that

$$c_1 \cdot ||w_{\tilde{h}}^{(q)}||_{H^{-1/2}(\Gamma)}^2 \leq ||\widetilde{e}_h^{(q)}||_D^2 \leq c_2 \cdot ||w_{\tilde{h}}^{(q)}||_{H^{-1/2}(\Gamma)}^2,$$

and hence it is sufficient to compute and localize an equivalent Sobolev norm in $H^{-1/2}(\Gamma)$ for $w_{\tilde{h}}^{(q)} \in Z_{\tilde{h}}$.

For $n = 3$ we can apply a similar approach. Using (see [6])

$$\begin{aligned}\langle Du, v\rangle_{L_2(\Gamma)} &= \frac{1}{4\pi}\int_\Gamma\int_\Gamma \frac{1}{|x-y|}\vec{\mathrm{curl}}_\Gamma u(x)\cdot\vec{\mathrm{curl}}_\Gamma v(x)ds_x ds_y \\ &= \sum_{i=1}^{3}\langle V(\vec{\mathrm{curl}}_\Gamma u)_i, (\vec{\mathrm{curl}}_\Gamma v)_i\rangle_{L_2(\Gamma)},\end{aligned}$$

the energy norm induced by the hypersingular integral operator for the Laplacian can be written again as energy norm induced by the single layer potential. Then we can follow the same ideas as described above for each component of $\vec{\mathrm{curl}}_\Gamma \widetilde{e}_h^{(q)}$.

5. Adaptive boundary element schemes. Now we are in a position to describe an adaptive boundary element method for the numerical solution of either the Dirichlet boundary value problem (3.1) or the Neumann boundary value problem (4.1) by means of the Galerkin formulation (3.3) or (4.7), respectively.

The adaptive boundary element algorithm reads as follows:

1. For a given boundary element mesh Γ_h compute either a boundary element solution t_h of (3.3) (Dirichlet) or $u_h \in W_h$ of (4.7) (Neumann).
2. Compute the approximate error functions $\widetilde{e}_h^{(q)}$ for some $q \geq 0$ by means of the truncated Neumann series (3.11) (Dirichlet) or (4.12) (Neumann).
3. In case of the Neumann problem (n=2) compute $w_{\tilde{h}}^{(q)} = \frac{d}{ds}\widetilde{e}_h^{(q)} \in Z_{\tilde{h}}$.
4. Compute $v_{\tilde{h}} = A^{(-\frac{1}{4})}\widetilde{e}_h^{(q)}$ (Dirichlet) or $v_{\tilde{h}} = A^{(-\frac{1}{4})}w_{\tilde{h}}^{(q)}$ (Neumann, n=2) via the multilevel representation (2.6).
5. Compute all local error indicators $\widetilde{\eta}_k^{(q)} = ||v_{\tilde{h}}||_{L^2(\Gamma_{I,k})}$ and the global error estimator $\widetilde{\eta}^{(q)} = \sqrt{\sum_{k=1}^{N_I}[\widetilde{\eta}_k^{(q)}]^2}$. Stop, if a required accuracy is reached.
6. Refine all boundary elements Γ_k, where

$$\widetilde{\eta}_k^{(q)} \geq \theta \cdot \max_{1\leq\ell\leq\widetilde{N}} \widetilde{\eta}_\ell^{(q)}$$

is satisfied with some appropriate chosen refinement parameter $\theta \in [0, 1]$.

For the Neumann problem and $n = 3$ some slight modifications in steps 3 and 4 as described in the previous section are needed.

6. Numerical results. As a numerical example we consider for both the Dirichlet and Neumann boundary value problem the two-dimensional Laplace equation, where Ω is the L shaped domain described by the nodes $(0, 0)$, $(0.25, 0)$, $(0.25, 0.25)$, $(-0.25, 0.25)$, $(-0.25, -0.25)$, and $(0, -0.25)$.

Let Z_h and W_h denote the boundary element spaces of piecewise constant and piecewise linear trial functions, respectively. Then we define $Z_{\tilde{h}}$ by piecewise constant basis functions and $W_{\tilde{h}}$ by piecewise linear ones where the mesh size in both cases is $\tilde{h} = h/8$, i.e., we apply three additional refinement steps to construct the underlying boundary element mesh $\Gamma_{\tilde{h}}$ from Γ_h.

In both examples we have chosen $q = 0$ in the truncated Neumann series (3.11) and (4.12), respectively. While the corresponding error functions $\widetilde{e}_h^{(0)}$ already define equivalent error estimators, the constants in the equivalence inequalities and therefore

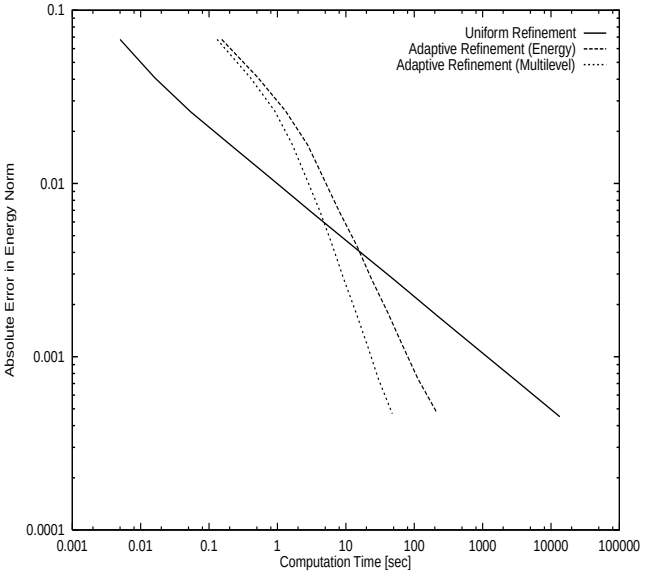

FIG. 1. *Uniform vs. adaptive refinement, Dirichlet problem.*

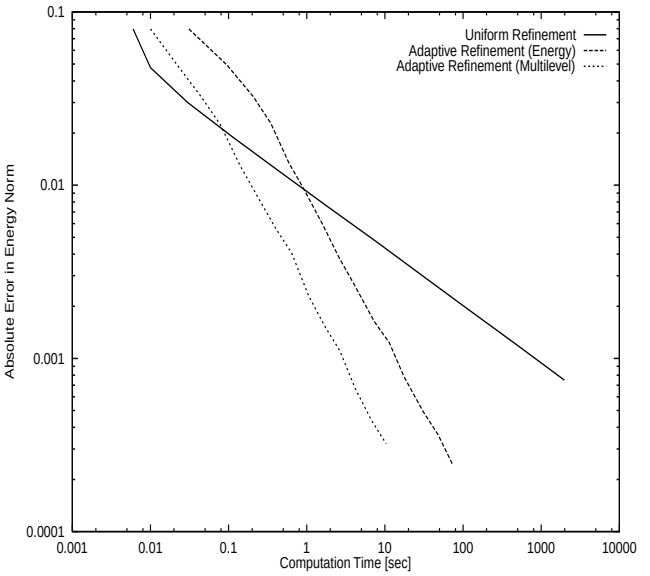

FIG. 2. *Uniform vs. adaptive refinement, Neumann problem.*

the accuracy of the error estimator can be improved when using some $q > 0$; see [18] for a more detailed discussion on this.

6.1. Dirichlet problem. For the Dirichlet boundary value problem the boundary data are given in such a way that the solution is

$$u(x) = u(r,\varphi) = r^{2/3} \sin\left(\frac{2}{3}\varphi\right) \tag{6.1}$$

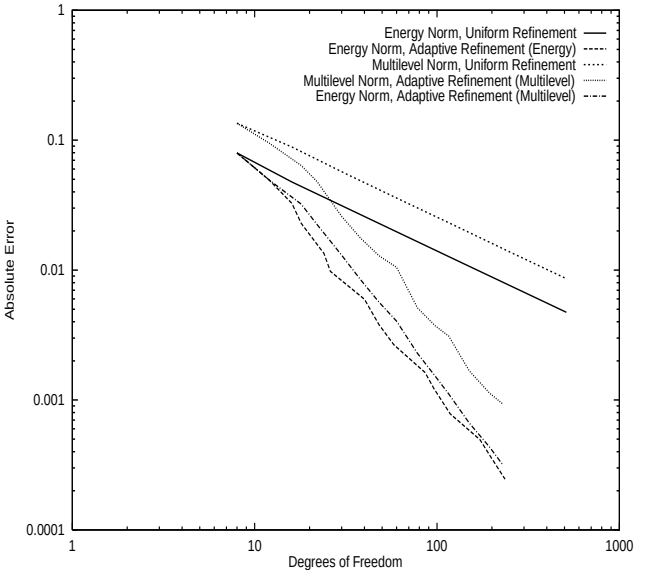

FIG. 3. *Errors for adaptive refinement, Neumann problem.*

TABLE 1
Errors for uniform refinement, Neumann problem.

N	$\|\|u-u_h\|\|_D$	Order	$\|\|A^{-\frac{1}{4}}\frac{d}{ds}(u-u_h)\|\|_{L^2}$	Order
8	7.98 –2		1.35 –1	
16	4.77 –2	0.74	8.86 –2	0.61
32	3.00 –2	0.67	5.47 –2	0.70
64	1.89 –2	0.67	3.44 –2	0.67
128	1.19 –2	0.67	2.17 –2	0.66

512	4.73 –3	0.67	8.59 –3	0.66

when using polar coordinates. In this case we get $t \in H^\sigma(\Gamma)$ with $\sigma < \frac{1}{6}$ for the solution t of the boundary integral equation (3.2). Therefore, in case of an uniform refinement the expected rate of convergence is $\frac{2}{3}$ when measuring the error $t-t_h$ in an equivalent norm in $H^{-1/2}(\Gamma)$; see (3.4). In Table 2 we give the results when using the energy norm $||\cdot||_V$ induced by the single layer potential V and the multilevel norm (2.9). In the case of a regular solution $t \in H^1(\Gamma)$ the expected order of convergence is supposed to be $\frac{3}{2}$. To improve the order of convergence we used the adaptive boundary element algorithm as described in section 5 with the refinement parameter $\theta = 0.05$. The results are given in Figure 4, for comparison we give also the error curves when using the energy norm $||\cdot||_V$ to compute all local and global error indicators; see [18]. Note that the energy error of the solution based on the multilevel approach converges even faster than using the adaptive approach based on the energy norm. On the other hand we can notify the norm equivalence as stated in the theory. Note that *adaptive refinement (energy)* marks the use of the adaptive refinement strategy based on local error indicators computed by the energy norm while *adaptive refinement (multilevel)* describes the results in case of the multilevel computation of the local indicators.

One motivation for the use of multilevel methods in the computation of local and global Sobolev norms was the expected efficiency due to the minimal amount of work

TABLE 2
Errors for uniform refinement, Dirichlet problem.

N	$\|\|t - t_h\|\|_V$	Order	$\|\|A^{-\frac{1}{4}}(t - t_h)\|\|_{L^2}$	Order
8	6.79 –2		1.16 –1	
16	4.08 –2	0.72	7.94 –2	0.55

256	6.74 –3	0.65	1.31 –2	0.62
512	4.30 –3	0.65	8.48 –3	0.63

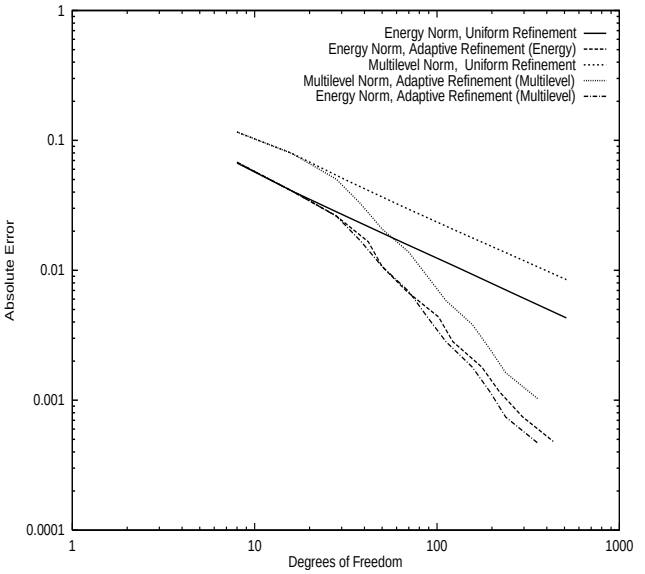

FIG. 4. *Errors for adaptive refinement, Dirichlet problem.*

involved in the computation of Sobolev norms. Therefore we give a comparison of the computing times in Figure 1, where we consider an uniform refinement, an adaptive strategy based on the energy norm [18] and the algorithm based on the multilevel norm as proposed in this paper. Note that in the uniform case the computing time includes the discretization and solution process at one level only, while in the adaptive algorithms the total computing time includes discretization, solution, and error estimation over all previous mesh levels. As expected from the theory the amount of work of the multilevel approach is less than the method based on the energy norm while both algorithms produce almost the same adaptive boundary element mesh.

6.2. Neumann problem. In case of a Neumann boundary value problem for the Laplace equation the boundary conditions are given in such a way that the solution is

$$u(x) \;=\; u(r,\varphi) \;=\; r^{2/3}\;\cos\left(\frac{2}{3}\varphi\right). \tag{6.2}$$

In this case we get $u \in H^{\rho}(\Gamma)$ with $\rho < \frac{7}{6}$ for the solution of (4.5). Hence, the order of convergence is about $\frac{2}{3}$ when measuring the error in an equivalent Sobolev norm in

$H^{1/2}(\Gamma)$; this is well documented numerically in Table 1 when using both the energy norm $||\cdot||_D$ and the multilevel norm (2.9).

For a regular solution $u \in H^2(\Gamma)$ the expected rate of convergence is about $\frac{3}{2}$. Hence, using the adaptive algorithm as described in section 5 with $\theta = 0.25$ we can improve the order of convergence to get almost the optimal behavior. This is documented for both the energy and the multilevel norm in Figure 3. In addition to the results based on the multilevel approach we also give the results for the adaptive algorithm based on the energy norm [19]; see Figure 2.

OPTIMAL DECOMPOSITION OF THE DOMAIN IN SPECTRAL METHODS FOR WAVE-LIKE PHENOMENA*

CARL ERIK WASBERG† AND DAVID GOTTLIEB‡

Abstract. A strategy for determining the optimal number of grid points and subdomains in a spectral method with domain decomposition on a serial computer is presented. The rapidly growing computational cost for large numbers of grid points in each subdomain is balanced against the exponential convergence for spectral approximation of smooth functions, and the optimum is found as the number of grid points and subdomains that gives the minimal computational cost for a given accuracy. The typical length scale of the problem is found to influence the number of subdomains but not the number of grid points within each subdomain.

Key words. domain decomposition, spectral methods

1. Introduction.

Domain decomposition methods have been extensively used for numerical simulations involving spectral methods, as they can offer more flexibility in treating complicated domains as well as computational savings. In fact, when applied to incompressible flows, the spectral element method [16], based on domain decomposition, seems to be the method of choice. The application of domain decomposition spectral methods to hyperbolic equations has been considered, e.g., by Kopriva [12], Kopriva and Kolias [14], and Quarteroni [17]. The advent of parallel computers has made multidomain methods very popular.

In this paper we consider spectral Chebyshev collocation methods with domain decomposition applied to problems whose solutions display wave-like behavior. By wave-like we mean that the structure is mostly homogeneous over the whole computational domain, or at least that the spatial resolution requirements are the same throughout. This does not necessarily exclude situations with, e.g., boundary layers, if suitable coordinate transformations are applied in the areas where fine structure is expected. Such an approach leads also to natural load-balancing in parallel implementations, as the computational complexity will be similar for all subdomains. The analysis in this paper extends to complex geometries, as long as the domain can be built up by transformed squares, or three-dimensional (3-D).

Our main subject is to find the number of subdomains, d, and number of grid points per subdomain, N, in each spatial direction that gives a solution of given accuracy with minimal computational work. Numerical experiments illustrating this problem can by found, e.g., in [10, 11, 15, 19]. Our approach is based on models for the error and for the complexity of the algorithm as functions of these domain decomposition parameters.

We assume that the total accuracy of an algorithm can be estimated by the spatial approximation accuracy, i.e., that other tasks such as time-stepping or implicit

solutions can be done sufficiently accurately. An error estimate for the approximation of sine waves is used, and the desired spatial resolution determines the highest wavenumber it is required to resolve. The approximation error decays exponentially in N (see section 2), so using more points in each subdomain increases the accuracy substantially. Of course, the number of waves that each subdomain "sees" decreases linearly with the number of subdomains.

For a given numerical algorithm, the computational work can be estimated experimentally by timing or theoretically through operation counts. The computational work in a spectral method scales with some power of the number of points in each subdomain, and this growth is usually faster than the growth with an increasing number of subdomains. (See the algorithm examples in section 5.) Thus, it is computationally cheaper to use many subdomains with few points in each subdomain, provided that the required accuracy can be achieved. Our models of computational work do not include costs of memory access (e.g., the use of cache), which could introduce discontinuities in the work functions. We note only that the tensor-product structure of the basis functions in spectral methods and the use of matrix multiplication for evaluation of spatial derivatives facilitate efficient use of cache. Serial machines are considered in this paper, while some issues arising in parallel computations are treated in [5].

Given the models for accuracy and work, we obtain optimal values for the domain decomposition parameters N and d, depending on the required accuracy. The optimal values represent the balance between the high accuracy of a large number of points in each subdomain and the computational gain of many subdomains with fewer points in each. We do the analysis for quite general work functions, and we show examples in sections 5 and 6 of how given algorithms fit into this framework.

The paper is organized as follows. We start with a brief introduction to spectral collocation methods with Chebyshev polynomials in section 2. In section 3 we introduce the models for the error and for the computational work. The problem of minimizing the work for a given accuracy is analyzed in section 4, and the results are discussed and related to algorithm examples in section 5. In section 6, the theoretical results are compared with results of numerical experiments of function approximation and PDE-solution. Finally, we comment on the relation to high-order finite difference methods in section 7 before summing up with the conclusions in section 8.

2. Chebyshev collocation methods. Spectral methods are based on representing the numerical solution on a form that can be differentiated analytically to produce good approximations to the spatial derivatives. The representations used in the early spectral methods were truncated Fourier series, but polynomial expansions have become widely used. In spectral collocation methods, the expansion coefficients are determined from discrete transforms, i.e., they are based only on the values of the numerical solution at discrete points. The resulting representation interpolates the numerical solution at these points.

In more than one spatial dimension, the basis functions are tensor products of the one-dimensional (1-D) ones, and each direction can be scaled or mapped to change the form of the computational domain. In the following, we briefly review some basic theory for Chebyshev spectral methods that can be found, e.g., in the book by Canuto et al. [3].

The Chebyshev polynomial of order k can be written as a cosine function with a change of variable:

$$T_k(x) = \cos(k \arccos x), \qquad k = 0, 1, 2, \ldots, \tag{2.1}$$

and the Chebyshev polynomials are orthogonal in the weighted function space $L^2_w(-1,1)$, with the weight function

$$w(x) = (1-x^2)^{-1/2}. \tag{2.2}$$

The discrete Chebyshev coefficients of a function $v(x)$, defined on $[-1,1]$, with respect to the collocation points

$$x_j = \cos \pi j/N, \qquad j = 0,1,\ldots,N, \tag{2.3}$$

are defined by

$$\widetilde{v}_k = \frac{2}{N\bar{c}_k} \sum_{j=0}^{N} \frac{1}{\bar{c}_j} v(x_j) T_k(x_j), \quad k = 0,1,\ldots,N, \tag{2.4}$$

where $\bar{c}_k = 1$, $k = 1,\ldots,N-1$, $\bar{c}_0 = \bar{c}_N = 2$. Equation (2.4) gives the transformation from the physical space of point values to the spectral space of coefficients. The inverse transformation is the interpolating function

$$I_N v(x) = \sum_{k=0}^{N} \widetilde{v}_k T_k(x). \tag{2.5}$$

An error estimate involving derivatives up to order l can be found in the norm of the weighted Sobolev space $H^l_w(-1,1)$:

$$\|v - I_N v\|_{H^l_w(-1,1)} \le C N^{2l-m} \|v\|_{H^m_w(-1,1)}, \qquad m \ge 1, \quad 0 \le l \le m, \tag{2.6}$$

when $v \in H^m_w(-1,1)$. If $v(x)$ is smooth, then m in (2.6) can be chosen arbitrarily large, with the result that the approximation error decays faster than any algebraic power of N as $N \to \infty$. The approximation is then said to be exponentially or spectrally accurate. An attractive aspect of using the Chebyshev polynomials is that simple expressions for the polynomials and the collocation points are available because of the relation (2.1) to cosine functions, and the transform (2.4) and the evaluation of (2.5) at the collocation points (2.3) can be carried out by fast Fourier transforms (FFTs) for suitable even values of N.

Approximate spatial derivatives can be calculated by differentiating the interpolating function (2.5). The coefficients $\widetilde{v}'_k$ for the derivative are given by

$$\begin{aligned} \widetilde{v}'_N = 0, \qquad & \widetilde{v}'_{N-1} = 2N\widetilde{v}_N, \\ \bar{c}_k \widetilde{v}'_k = \widetilde{v}'_{k+2} + 2(k+1)\widetilde{v}_{k+1}, \qquad & k = 0,1,\ldots,N-2. \end{aligned} \tag{2.7}$$

The differentiation operation can also be expressed as $\mathbf{u}_x = D\mathbf{u}$, where $\mathbf{u}$ is the vector of function values at the collocation points and $\mathbf{u}_x$ is the vector of approximate values for the derivative at the same points. From the description given above about calculating coefficients for the derivative, it is clear that the derivative operator can be written $D = T^{-1}\widetilde{D}T$, where T is the transformation (2.4) from physical space to spectral space, $\widetilde{D}$ is the derivative matrix in spectral space, and T^{-1} is the evaluation of (2.5) at the collocation points with the new coefficients. For small values of N, it is usually more efficient to form the derivative matrix D explicitly and calculate the derivative by matrix/vector multiplication than to use FFTs for the operations T and T^{-1}. The crossover point depends heavily on the computer architecture and the

implementation details. It was found to be around $N = 64$ in the calculations on a CRAY X-MP in [20], while calculations on scalar computers would give smaller numbers. We refer to [4] for a discussion with several timing examples.

This review has concentrated on the spatial approximation properties. Time-dependent PDEs can be solved using the method of lines. This means that the spatial derivatives are approximated as described above, and the resulting semidiscrete problem

$$\mathbf{u}_t = \mathbf{f}(\mathbf{u}), \qquad \mathbf{u} = (u(x_0), \ldots, u(x_N))^T \tag{2.8}$$

is solved by a standard method for systems of ordinary differential equations [9]. Explicit Runge–Kutta methods are used in the example presented in section 6.2, with boundary conditions applied at the end of each time-step.

With explicit time-integration methods, and also many implicit methods, there is a stability restriction on the allowable time-steps, depending on the operator $\mathbf{f}$ in (2.8). For linear and quasi-linear systems, the maximum explicit time-steps with Chebyshev collocation are $O(1/N^2)$ for first-order problems and $O(1/N^4)$ for second-order problems. Explicit time-integration is therefore usually too expensive for nonperiodic problems involving second derivatives.

3. Models for accuracy and computational work. The Chebyshev expansion of a sine function with k wavelengths in the interval $[-1, 1]$ is

$$\sin(k\pi x) = \sum_{n=0}^{\infty} a_n T_n(x), \qquad -1 \le x \le 1, \tag{3.1a}$$

with (Galerkin) expansion coefficients [8, Eq. (3.41)] (or from [1, Eq. (9.1.21)])

$$\begin{aligned} a_n &= \frac{2}{\pi c_n} \int_{-1}^{1} \sin(k\pi x)\, T_n(x)\, w(x)\, dx \\ &= \frac{2}{c_n} J_n(k\pi) \sin(n\pi/2), \qquad n = 0, 1, \ldots, \end{aligned} \tag{3.1b}$$

where $c_0 = 2$, $c_n = 1$ $(n > 0)$, and J_n is the Bessel function of the first kind of order n. Since $J_n(k\pi) \to 0$ exponentially fast as n increases beyond $k\pi$, the estimated truncation error $E(N, k)$ of an N-term Chebyshev expansion of $\sin(k\pi x)$ is given by the upper bound of the coefficient a_N, i.e.,

$$E(N, k) = 2J_N(k\pi), \qquad N > k\pi.$$

Using the asymptotic form (as $\nu \to \infty$) [1, Eq. (9.3.1)]

$$J_\nu(x) \sim \frac{1}{\sqrt{2\pi\nu}} \left(\frac{ex}{2\nu}\right)^\nu,$$

we obtain the estimate

$$E(N, k) = \sqrt{\frac{2}{\pi N}} \left(\frac{e\pi k}{2N}\right)^N. \tag{3.2}$$

The error estimate can also be used for a collocation method, since the interpolation error is asymptotically of the same order as the truncation error. Figure 3.1 shows the estimate (3.2) compared with the measured maximum error for approximation of the

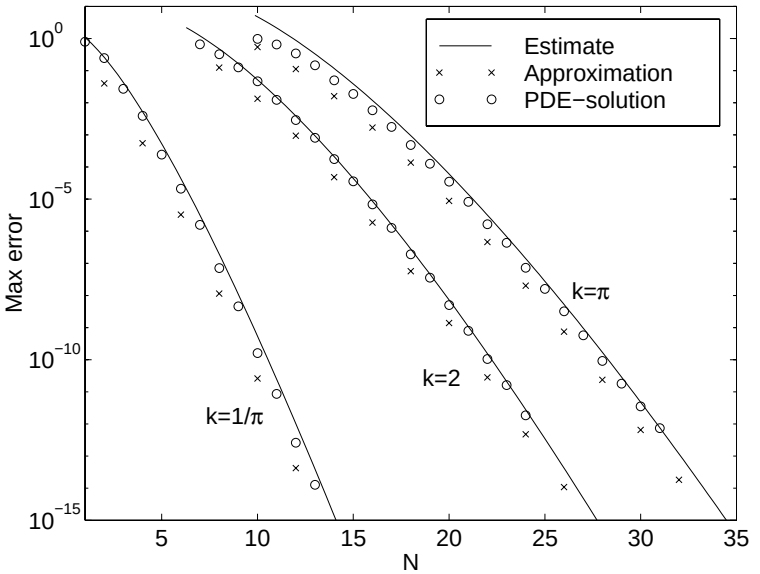

FIG. 3.1. *Estimated* (3.2) *and numerically measured* 1*-domain Chebyshev collocation approximation error for the function* $\sin(kx)$*,* $-1 \le x \le 1$*, with* $k = 1/\pi, 2, \pi$*, compared with the errors in the solution of the* 2*-D advection problem* (6.1) *with the same wavenumbers in the initial and boundary conditions.*

function $\sin(k\pi x)$ for $k = 1/\pi, 2, \pi$ and the maximum error of the solution of the two-dimensional (2-D) advection equation (see section 6.2) with the same wavenumbers in the initial and boundary conditions. While the error estimate is too conservative by factors between 4 and 20 in the approximation case, we note that the estimated values of N for a given accuracy are still generally only 1 grid point error away from the measured values. In the PDE-examples, the error estimates are within a factor of 2 grid point errors of the measured errors for the majority of the data.

For a Legendre expansion, an expression similar to (3.2) can be obtained using [8, Eq. (3.45)] instead of (3.1).

If the computational domain is divided into d subdomains in each spatial direction, the wavenumber on each subdomain becomes k/d, and the new error function is

$$E(N, k, d) = \sqrt{\frac{2}{\pi N}} \left(\frac{e\pi k}{2dN} \right)^N. \tag{3.3}$$

In higher dimensions, N is the number of grid points in each spatial direction in each subdomain.

We assume that the computational work required to solve the problem in question is given by a function $W(N, d)$. The simplest of the models we consider in this paper is

$$W(N, d) = C d^r N^\alpha, \qquad \alpha > r \ge 1. \tag{3.4a}$$

The condition $\alpha > r$ ensures that it is computationally cheaper to increase the total number of points by using more subdomains than by increasing the number of

points within each subdomain. If this was not the case, the single domain approach would be preferred because of the spectral accuracy property. Motivation for domain decomposition would then have to come from aspects other than those considered in this analysis, e.g., parallelization, geometry considerations, or the need for local grid refinement.

Lower order terms in the work function may become significant for small values of N. As an example, evaluation of derivatives in 3-D by matrix multiplication requires $O(N^4)$-operations on each subdomain, while, e.g., adding up derivatives in different directions for all the grid points in a subdomain is an $O(N^3)$-operation. We therefore consider also work functions on the form

$$W(N,d) = Cd^r(N^\alpha + \beta N^{\alpha-1}), \qquad \alpha > r \geq 1, \quad \beta > 0. \tag{3.4b}$$

For larger values of N, it may be more efficient to apply FFTs instead of matrix multiplication for the transformations between the physical and spectral space. In that case the work function includes a logarithmic term:

$$W(N,d) = Cd^r N^{\alpha-1} \log_2 N, \qquad \alpha - 1 > r \geq 1. \tag{3.4c}$$

Examples of the parameters r and α in given algorithms are given in section 5.

We can now formulate the problem described in the introduction more precisely.

PROBLEM 1. *Minimize $W(N,d)$ under the constraint*

$$E(N,k,d) = e^{-\varepsilon}. \tag{3.5}$$

As $\varepsilon = -\ln E$, the values of ε would be in the range between 4 ($E = 1.8 \cdot 10^{-2}$, low accuracy) and 30 ($E = 9.4 \cdot 10^{-14}$, close to standard double precision machine accuracy). The problem is analyzed in the next section for the different work functions given by (3.4a)–(3.4c).

4. Analysis. Combining the error function (3.3) and the constraint (3.5) gives the following expression for the number of subdomains, d:

$$d = \frac{e\pi k}{2N} \left(\frac{2}{\pi N}\right)^{\frac{1}{2N}} e^{\varepsilon/N}. \tag{4.1}$$

This is used in the analysis below to eliminate d from the work functions. For each of the three work functions (3.4a)–(3.4c), examples of the optimal number of points per subdomain and the optimal number of points per wavelength for different values of the parameters r and α are shown in Figures 4.1 and 4.2.

Case (a). Inserting (4.1) into the simple work function (3.4a) and setting $\frac{\partial W}{\partial N} = 0$ gives the following relation for the optimal number of points in each subdomain:

$$(\alpha - r)N = r\varepsilon + \frac{r}{2}\left(1 - \ln\frac{\pi N}{2}\right). \tag{4.2}$$

Thus the optimal N is approximately given by

$$N_{\text{opt}} \approx \frac{r\varepsilon}{\alpha - r} \tag{4.3}$$

and plotted for different values of r and α in Figures 4.1 and 4.2.

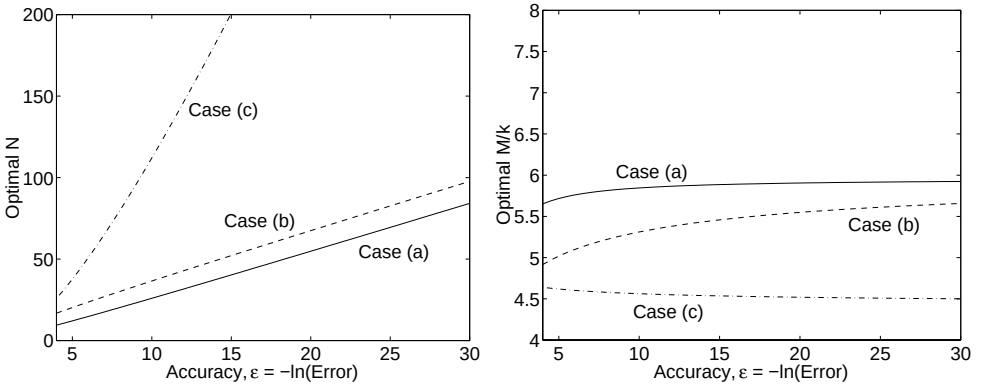

FIG. 4.1. *Optimal number of points in each subdomain (left) and optimal total number of points per wavelength (right) as functions of the accuracy for the different work functions* (3.4) *for* $r = 3$, $\alpha = 4$.

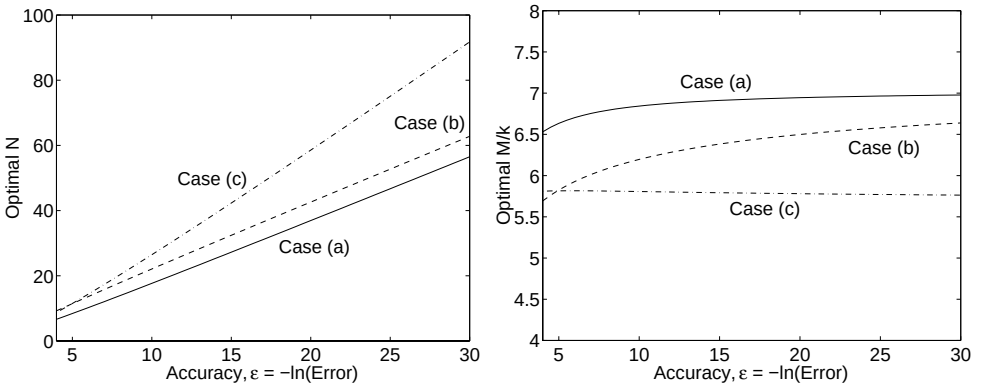

FIG. 4.2. *Optimal number of points in each subdomain (left) and optimal total number of points per wavelength (right) as functions of the accuracy for the different work functions* (3.4) *for* $r = 4$, $\alpha = 6$.

Using (4.1), the total number of grid points is

$$M = dN = \frac{e\pi k}{2}\left(\frac{2}{\pi N}\right)^{\frac{1}{2N}} e^{\varepsilon/N},$$

so by using the approximate N_{opt} from (4.3), we obtain

$$M_{\text{opt}} = d_{\text{opt}} N_{\text{opt}} \approx \frac{1}{2}\pi e^{\alpha}\left(\frac{2(\alpha - r)}{\pi r \varepsilon}\right)^{\frac{\alpha - r}{2r\varepsilon}} k.$$

The result is that the optimal total number of points per wavelength, M_{opt}/k, is increasing very slowly with the accuracy ε, as shown in Figures 4.1 and 4.2.

Case (b). Inserting (4.1) into the work function (3.4b), including a lower order term, and setting $\frac{\partial W}{\partial N} = 0$, gives the relation

$$(\alpha - r)N^2 + (\beta(\alpha - 1 - r) - r\varepsilon)\, N + (N + \beta)\frac{r}{2}\left(\ln\frac{\pi N}{2} - 1\right) - r\varepsilon\beta = 0. \tag{4.4}$$

Compared with the results from the previous section, the effect of the lower order term is slightly higher values of N_{opt}, as shown in Figures 4.1 and 4.2 (with $\beta = 16$ in (4.4)). This means that the spectral accuracy property is more dominant, and more efficient approximations are done in each subdomain. As a consequence the optimal total number of points per wavelength is lower.

Case (c). Inserting (4.1) into the work function (3.4c) including a logarithmic term, and setting $\frac{\partial W}{\partial N} = 0$, gives the relation

$$(\alpha - 1 - r)N + \frac{N}{\ln N} = r\varepsilon + \frac{r}{2}\left(1 - \ln\frac{\pi N}{2}\right). \tag{4.5}$$

Because of the slower growth of the work with N than in the previous cases, N_{opt} is higher. As explained for in Case (b), this gives a lower optimal total number of points per wavelength. These effects are also illustrated in Figures 4.1 and 4.2.

5. Discussion.

Algorithm examples. A spectral element method for the steady Stokes problem

$$\begin{aligned} -\nabla^2\mathbf{u} + \nabla p &= \mathbf{f} \quad \text{in } \Omega, \\ -\nabla\cdot\mathbf{u} &= 0 \quad \text{in } \Omega, \\ \mathbf{u} &= \mathbf{0} \quad \text{on } \partial\Omega \end{aligned} \tag{5.1}$$

is analyzed in [6], including serial work estimates. The algorithm is based on the iterative solution of a Poisson problem by a preconditioned conjugate gradient method. For a discretization in $\mathbf{R}^s$ using d elements in each direction and polynomial order N in each direction within each element, each iteration has a computational complexity of $O(d^s N^{s+1})$, and the number of conjugate gradient iterations is estimated to be of order dN. The solution of the Stokes problem is then obtained by the Uzawa iterative procedure involving an outer conjugate gradient loop that converges in $O(1)$ iterations, leaving the total complexity of the algorithm to be $O(d^{s+1}N^{s+2})$ in s spatial dimensions. This corresponds to $r = s + 1$, $\alpha = s + 2$ in the work functions (3.4a) or (3.4b). The results shown in Figure 4.1 consequently cover the 2-D version of this algorithm.

As another algorithm example, we consider the solution of a hyperbolic system in s spatial dimensions

$$\mathbf{u}_t + \sum_{i=1}^{s} A_i \mathbf{u}_{x_i} = 0 \tag{5.2}$$

with suitable initial and boundary conditions for $\mathbf{u}(\mathbf{x}, t)$. Details of solution of the Euler equations can be found, e.g., in [2, 13]. These algorithms use explicit time-integration, with time-steps proportional to $1/dN^2$. With $O(d^s N^{s+1})$-operations at each time-step, the total work for integrating one time-unit is $O(d^{s+1}N^{s+3})$, corresponding to $r = s + 1$, $\alpha = s + 3$ in the work functions (3.4a) or (3.4b). The results shown in Figure 4.2 therefore illustrate this algorithm in 3-D.

An iteration-by-subdomain method for domain decomposition is described in [18]. For an elliptic problem $Au = f$ (e.g., the Poisson problem), the problem is solved on each subdomain by an iterative method with preconditioning, and for the best preconditioners the number of iterations is independent of N. This gives $O(N^{s+1})$ work per subdomain for each of the d^s subdomains. The number of iterations in the outer iteration-by-subdomain loop is also independent of N but proportional to d.

TABLE 5.1

Factors to multiply by sigma = −ln(Error) to estimate the optimal N for an algorithm with work function $W(N,d) = Cd^{s+1}N^{s+q}$. N is the number of points in each direction in each subdomain, d is the number of subdomains in each direction, and s is the spatial dimension.

	1-D	2-D	3-D
$q = 2$	2	3	4
$q = 3$	1	3/2	2

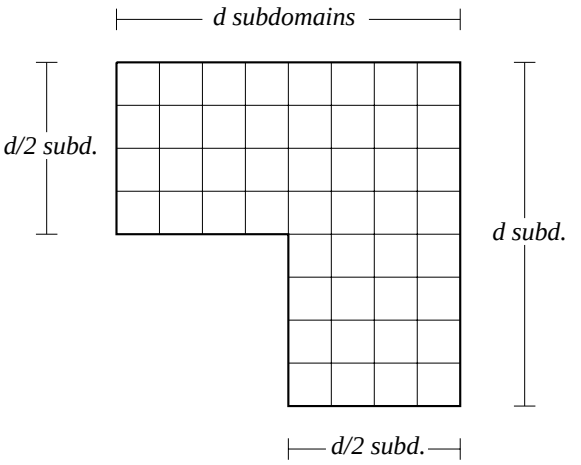

FIG. 5.1. *An L-shaped domain with 3/4 d^2 subdomains.*

This gives a total complexity of $O(d^{s+1}N^{s+1})$, i.e., $r = \alpha$ in the notation used in our work functions. As discussed in section 3, the choice of domain decomposition parameters in such a case is not covered by the analysis in this paper.

Conversely, in the discussion of the iteration-by-subdomain method for hyperbolic problems [17], Quarteroni gives the computational complexity in 1-D as $O(d^2N^3)$, because in this case effective preconditioners for the solution at each subdomain by implicit time-integration are not found. A generalization to s spatial dimensions gives an $O(d^{s+1}N^{s+2})$-algorithm, as in the spectral element example discussed above.

Dimension dependency. In most cases the work function depends on the number of spatial dimensions, s, as

$$W(N,d) = Cd^{s+p}N^{s+q}, \qquad p \geq 0, \quad q > p, \tag{5.3}$$

which gives

$$N_{\text{opt}} \approx \frac{s+p}{q-p}\varepsilon$$

in Case (a). We have seen examples of $p = 1$ and $q = 2, 3$ in the algorithms discussed above. The value of $\frac{s+p}{q-p}$ in these cases is given in Table 5.1 for 1, 2, and 3 spatial dimensions, to show how the estimates of optimal N vary with the number of dimensions.

Complex geometries. The analysis in this paper extends to topologically nonrectangular geometries, as illustrated by the L-shaped domain in Figure 5.1. From the description of wave-like behavior in the introduction, we have (possibly after a mapping) a homogeneous smallest-length scale all through the domain, and the highest

number of waves to be approximated on each subdomain is as before k/d in each direction. Therefore, the accuracy estimate (3.3) is still valid. The number of subdomains in this example is $3/4\ d^2$, and since our analysis is independent of the constant factor in the work functions, it also applies in this case.

Differentiation algorithms. Calculation of derivatives is carried out on most current computer architectures more efficiently by matrix multiplication than by the use of FFTs when the number of grid points in the differentiation direction is less than 32. Figures 4.1 and 4.2 and Table 5.1 show that the optimal N can be less than 32 for a wide range of accuracies and work functions not involving the logarithmic term, but higher values of N may be optimal when very high accuracy is required in two or three dimensions, leaving FFTs as the method of choice.

Total number of points per wavelength. In all the cases analyzed above, the total number of points per wavelength (M/k) approaches constant values when the accuracy is increased.

Optimal balancing of subdomains and points in each subdomain. The analysis shows that the optimal number of points in each subdomain is independent of the wavenumber k, and Figures 4.1 and 4.2 show that it depends almost linearly on the accuracy ε for a given work function $W(N, d)$. As the optimal total number of points per wavelength varies slowly only with ε, the optimal number of subdomains is approximately inversely proportional to ε.

6. Numerical results.

6.1. An approximation example. The Chebyshev collocation approximation to the function $\sin(2\pi^2 x)$ on $-1 \le x \le 1$ is calculated. Matrix multiplication is used to calculate Chebyshev coefficients, and the work function is approximately proportional to dN^2. However, actual timing of the calculations shows that the work is expressed more accurately by $Cd(N^2 + 4N)$, i.e., using the work function from Case (b), with $\beta = 4$.

Maximum approximation error is measured by evaluating the Chebyshev interpolant at a fixed set of equidistant points. The typical tendency is illustrated in Figure 6.1. Many subdomains are most efficient for low accuracy, while high accuracy requires fewer subdomains with more points in each. More detailed results are given in Table 6.1, where the most efficient choices of parameters are marked with boxes around N. For each d and E, the table entry is chosen as the N giving an error closest to E on a logarithmic scale. To find the "most efficient" of two pairs of (N, d) when one of them requires more calculation time but yields higher accuracy, we have considered straight lines between the data points closest to the required accuracy, as drawn in Figure 6.1.

The results in Table 6.1 can be compared with the theoretical optimal values, found by solving (4.2) or (4.4), with $r = 1$, $\alpha = 2$, and ε for the required accuracy to obtain N, and then by inserting this N and ε into (4.1) for the number of subdomains d. The theoretical optimal values of N and d for the three different accuracies are shown in Table 6.2, and the agreement is good for the work function of Case (b) with $\beta = 4$.

6.2. A PDE example. The PDE

$$u_t + u_x + u_y = 0, \qquad 0 < x < 2, \quad 0 < y < 2, \quad t > 0, \tag{6.1a}$$

with initial and boundary conditions

$$u(x, y, 0) = \sin(k\pi x + k\pi y), \qquad 0 < x < 2, \quad 0 < y < 2, \tag{6.1b}$$

$$u(x, 0, t) = \sin\left(k\pi(x - t) - k\pi t\right), \qquad 0 < x < 2, \quad t > 0, \tag{6.1d}$$

with $k = 5\pi/\sqrt{2}$, is integrated to $t = 2$. The spatial discretization is Chebyshev collocation, while a high-order explicit time-integration scheme (Butcher's sixth-order Runge–Kutta method [9]) is used to eliminate time discretization errors. Timing and accuracy results are given in Table 6.3, where the most efficient choices of parameters are marked with boxes around N. Practically identical results are obtained with the initial function $u_0(x, y) = \sin(k\pi x) \cdot \sin(k\pi y)$, which does not represent a plane wave.

The time-steps are proportional to $1/dN^2$, and as the calculation of derivatives at each time-step involves matrix products of complexity $O(N^3)$ per subdomain, the

number of operations for integration up to a given time is $O(d^3N^5)$. As in the previous example, the actual CPU-time indicates that lower order terms should be included, as seen from Figure 6.2. Using (3.4b) from Case (b) with $\alpha = 4$ and $\beta = 16$ gives a better estimate of the computational work, and the corresponding predictions for N_{opt} and d_{opt} are given in Table 6.4. The predicted optimal values using Case (b) with $\beta = 16$ are close to the experimental results, as there are small differences in efficiency between the best choices of (N, d).

7. Relation to finite difference methods. In some of the cases considered in the previous sections both the theoretical analysis and the numerical experiments give quite small optimal numbers of points in each subdomain. The resulting methods are comparable to high-order finite difference methods, except that the grid points are not uniformly distributed. It is therefore natural to ask whether a finite difference method would be more efficient. Spectral methods are better when high accuracy is required, but in which range is this valid?

To indicate how the efficiency of finite difference methods and spectral methods compare, the first derivative of the function $\sin(\pi^2 x)$ is calculated on the interval $-1 \le x \le 1$. As examples of high-order finite difference schemes we have used the standard fourth-order (FD4) and sixth-order (FD6) centered schemes given, e.g., in [7]. A complication with finite difference schemes is that special operators that reduce the accuracy have to be constructed at and near the boundaries.

Figure 7.1 shows the efficiency and the grid point requirements for these finite difference methods compared with single-domain and multidomain Chebyshev collocation methods. When more than the lowest accuracies are required, the finite difference methods must be of very high order to compete with the spectral methods.

These results are based on derivative approximation and do not include the larger numerical dispersion and diffusion errors in finite difference methods for wave propagation problems. Conversely, the time-step restrictions for explicit time-integration are less severe for finite differences.

Figure 7.2 shows that for the solution of the advection problem

$$\begin{aligned} u_t + u_x &= 0, \qquad 0 < x < 2, \quad t > 0, \\ u(x,0) &= \sin(\pi^2 x), \qquad u(0,t) = -\sin(\pi^2 t), \end{aligned} \tag{7.1}$$

the fourth-order finite difference method is more efficient than the spectral method only for accuracy between two and three digits or less. The time-integration in this example is done by the standard fourth-order Runge–Kutta method [9], and the time-steps are chosen as the most efficient stable values for each method ($3/N$ for FD4 and $6/dN^2$ for the spectral methods).

8. Conclusions. We have presented a strategy for choosing the optimal number of subdomains and grid points in each subdomain in a Chebyshev domain decompo-

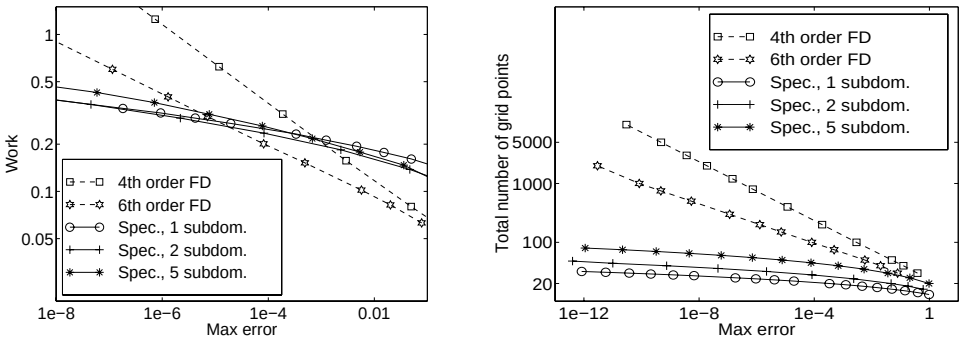

FIG. 7.1. *Approximation of the derivative of the function* $\sin(\pi^2 x)$ *by finite difference and spectral Chebyshev collocation methods. Left: Work (CPU-time) as a function of the max error. Right: The total number of grid points as a function of the max error.*

sition method. It is assumed that the solution is mainly homogeneous throughout the domain, such that a global smallest length scale can be decided a priori. This corresponds to the highest wavenumber to be resolved in the calculations.

The accuracy of the method is derived from properties of spectral approximation, and the computational work to obtain a required accuracy is minimized for work functions of different form, where the work grows faster with increased resolution within each subdomain than with increasing number of subdomains.

These considerations lead to a standard minimization problem, and the results can be summarized as follows:

- The optimal number of points in each subdomain, N_{opt}, is in the simplest case linearly proportional to the negative logarithm of the required accuracy. This optimal number N_{opt} is independent of the complexity (the number of waves) of the problem.
- The optimal number of subdomains increases with the complexity of the problem and is approximately inversely proportional to the negative logarithm of the required accuracy.
- The optimal total number of points per wavelength is slowly varying only with the required accuracy and approaches constant values for high accuracies.

Acknowledgments. The first author thanks Professor Knut S. Eckhoff for initiating the study of this problem and Professor David A. Kopriva for stimulating discussions.

HALF-SPACE ANALYSIS OF THE DEFECT-CORRECTION METHOD FOR FROMM DISCRETIZATION OF CONVECTION*

BORIS DISKIN† AND JAMES L. THOMAS‡

Abstract. A novel, comprehensive, discrete, half-space analysis for the defect-correction method has been developed. This analysis plays the same role for nonelliptic-problem solvers as the full-space Fourier mode analysis plays for elliptic-problem solvers. Numerical simulations confirm the accuracy of the half-space analysis. The following important findings about the defect-correction method applied to the Fromm discretization of the two-dimensional convection equation are reported:

1. The initial convergence rate of the defect-correction method is principally a function of the relative accuracy of the operators involved in the defect-correction iterations.
2. The asymptotic convergence rate is about 0.5 per defect-correction iteration.
3. If the driver operator is first-order accurate, then the initial convergence rates may be slow. The number of iterations required to get into the asymptotic convergence regime or/and to converge the algebraic error below the discretization-error level can be proportional to $h^{-1/3}$. This h-dependent delay is a multidimensional phenomenon—it cannot be observed in one-dimensional problems, and it disappears in the case of close alignment between the grid and the convection equation characteristic.
4. If the driver operator is second-order accurate, the defect-correction solver demonstrates the asymptotic convergence rate from the very beginning. Only one defect-correction iteration is required to converge algebraic error substantially below the discretization-error level.

Key words. half-space analysis, convection equation, Fromm discretization, defect-correction method

1. Introduction.

The subject of this paper is the analysis of the convergence properties of the defect-correction method for the Fromm discretization of the scalar constant-coefficient convection equation. This problem is rather simple, but past experience has shown that many important aspects relevant to more general problems can be well captured in such simple models. In the last decade, the defect-correction technique introduced in [2] has been used extensively in computational fluid dynamics (CFD), often in conjunction with multigrid, for convection-diffusion, Euler, and Navier–Stokes problems (see, e.g., [1, 7, 8, 11, 12, 13, 14, 15, 16, 17]). Usually, the efficiency was quite satisfactory. Sometimes, however, fast convergence was observed only after several slowly convergent initial iterations. The analysis of the defect-correction method reported in this paper was motivated by the search for an explanation of convergence properties of existing practical CFD solvers [13, 15].

Although the defect-correction method has been used to solve complicated nonlinear problems, the analytical tool usually applied to confirm experimental findings was the full-space Fourier mode analysis of a related constant-coefficient problem (see,

e.g., [8, 14]). This approach is well justified for *elliptic* problems, where the full-space Fourier analysis is known to provide an accurate prediction of the asymptotic convergence rate. The asymptotic convergence rate is especially important in elliptic problems because it provides the upper bound for the convergence rates throughout the solution process.

In *nonelliptic* problems, a good asymptotic convergence rate is often observed in contrast to a pessimistic forecast provided by the modified (zero-mode exclusion) full-space Fourier mode analysis (see [8, 18]). The full-space analysis fails to predict the asymptotic convergence rate correctly because it does not take boundary conditions into account. For nonelliptic problems, accounting for the inflow boundary conditions becomes very important because solution values in the interior, far away from the boundary, are strongly affected by the boundary conditions.

Another problem associated with nonellipticity is the fact that convergence rates in several *initial* iterations might be quite slow. Note that the modified full-space Fourier mode analysis can still be used to estimate the slowest possible (but not asymptotic) convergence rate, while the asymptotic rate can be found by an eigenvalue matrix analysis (see [8]). However, none of these (full-space Fourier and eigenvalue) analyses can predict the *number* of slow initial iterations preceding establishment of the asymptotic convergence rate.

The analysis proposed in this paper for the defect-correction method is a half-space analysis. Generally, this half-space analysis plays the same role for nonelliptic-problem solvers as the full-space Fourier mode analysis plays for elliptic-problem solvers. Applications of this analysis are not limited to the defect-correction method. (See [5] for an application of the half-space analysis to a multigrid method.) This analysis considers difference operators on the half-space including the inflow boundary. The inflow boundary conditions are represented by one Fourier component at a time. In this way, the original multidimensional problem is translated into a one-dimensional (1D) discrete problem, where the frequency of the boundary Fourier component is considered as a parameter.

The half-space analysis is able to precisely explain many phenomena observed in solving nonelliptic equations and provides a close prediction of the actual solution behavior. It predicts the convergence rate for each iteration and the asymptotic convergence rate. It can be easily adjusted to analyze a global effect of *any* discretization of the inflow boundary conditions. If necessary, it can take into account the influence of the discretized outflow boundary conditions; this is important for applications of this analysis to convection-diffusion and strongly anisotropic problems.

Although we consider only a two-dimensional (2D) problem, the half-space analysis can be extended to three dimensions. In this case, a 2D Fourier component represents the inflow boundary conditions. The resulting 1D discrete problem includes two frequency parameters.

The material in the paper is presented in 10 sections. The model problem is formulated in section 2 and is followed by a brief explanation of the defect-correction procedure in section 3. In section 4, the notion of *penetration distance* is introduced and its role in defining approximation accuracy in discretized nonelliptic problems is discussed. The applicability, complexity, and interrelation of different types of analysis are discussed in section 5. A simplified, but very useful, version of the half-space analysis is presented and applied in section 6. In this version, the difference operators involved in defect-correction iterations are replaced with their first differential approximations. Such an analysis provides a qualitative estimate of the convergence for an

arbitrary defect-correction scheme. A novel, comprehensive, *discrete* half-space analysis for the defect-correction method with the first-order driver is introduced in section 7. Section 8 refers to a standard 1D matrix analysis for estimating the asymptotic convergence rate and the convergence rate upper bound for the 2D defect-correction iterations. Results of numerical tests with the defect-correction method employing the first-order driver for the Fromm scheme are collected in section 9. Section 10 presents numerical results for the defect-correction method with a second-order driver.

2. Model problem. The model problem studied in this paper is the 2D constant-coefficient convection equation

$$LU \equiv \Big(\bar{b}\cdot\nabla\Big)U = F(x,y), \tag{2.1}$$

where $\bar{b} = (b_1, b_2)$ is a given vector. Without loss of generality one can assume $b_1^2 + b_2^2 = 1$.

The solution $U(x,y)$ is a differentiable function defined on the layer $(x,y) \in [0,1] \times (-\infty, +\infty)$. In this paper, we deal mostly with the homogeneous equation $F(x,y) \equiv 0$. Exceptions when nonzero right-hand-side (source) functions $F(x,y)$ are considered will be emphasized specifically.

Let ϕ be the nonalignment angle, i.e., the angle between the vector $\bar{b}$ and the positive direction of the x axis; $t = \tan\phi = b_2/b_1$ is the nonalignment parameter. For simplicity, we assume $b_1 \geq b_2 \geq 0$ and, therefore, $1 \geq t \geq 0$. Then, (2.1) can be rewritten as

$$\partial_\xi U = F(x,y), \tag{2.2}$$

where $\xi = b_1 x + b_2 y$ is a variable along the characteristic of (2.1). For subsequent use, we also define the cross-characteristic variable ($\perp$ to the characteristic) $\eta = -b_2 x + b_1 y$.

The equation is supplied with Dirichlet boundary conditions at the inflow boundary $x = 0$:

$$U(0,y) = g(y), \tag{2.3}$$

where $g(y)$ is a given function.

This problem is discretized on the 2D Cartesian grid with uniform mesh size h in both x and y directions. Let u_{i_1,i_2} be a discrete approximation to the solution $U(x,y)$ at the point $(x,y) = (i_1 h, i_2 h)$. Then, the second-order accurate discretization corresponding to the Fromm scheme is defined as

$$\begin{aligned}
L^h u_{i_1,i_2} &\equiv \tfrac{1}{4h}\Big(b_1\Big(u_{i_1+1,i_2} + 3u_{i_1,i_2} - 5u_{i_1-1,i_2} + u_{i_1-2,i_2}\Big) \\
&\qquad + b_2\Big(u_{i_1,i_2+1} + 3u_{i_1,i_2} - 5u_{i_1,i_2-1} + u_{i_1,i_2-2}\Big)\Big) = f_{i_1,i_2}, \\
L^h u_{N,i_2} &\equiv \tfrac{1}{2h}\Big(b_1\Big(3u_{N,i_2} - 4u_{N-1,i_2} + u_{N-2,i_2}\Big) \\
&\qquad + b_2\Big(3u_{N,i_2} - 4u_{N,i_2-1} + u_{N,i_2-2}\Big)\Big) = f_{N,i_2}, \\
& i_1 = 1,2,\ldots,N-1, \qquad N = 1/h, \\
& u_{0,i_2} = g(i_2 h), \qquad u_{-1,i_2} = g'(i_2 h).
\end{aligned} \tag{2.4}$$

The discrete scheme (2.4) in the interior is upwind biased but not a pure upstream scheme, because the operator at the point (i_1, i_2) requires the solution values at the downstream points $(i_1 + 1, i_2)$ and $(i_1, i_2 + 1)$ are required. As shown in [8], this discretization is well suited for solution by the defect-correction method. The outflow boundary conditions at $i_1 = N$ are discretized by the second-order upwind scheme. The discretization of the right-hand-side function is $f_{i_1,i_2} = F(i_1 h, i_2 h)$. Function $g'(y)$ is an additional numerical boundary condition. In model problems where the exact solution $U(x, y)$ is known, one can define $g'(y) = U(-h, y)$. This (artificial) discretization of the inflow boundary conditions was chosen due to its simplicity; it provides the same discretization stencil for operator (2.4) at all inner grid points. Any other locally defined discrete boundary conditions (e.g., given values of u_{0,i_2} and the first-order upstream discretization at $i_1 = 1$) can be considered as well.

3. Defect-correction schemes. Let the target discrete problem be

$$L^h u_{i_1,i_2} = f_{i_1,i_2}, \tag{3.1}$$

where L^h is a target discretization of the convection operator (e.g., (2.4)) and let L^h_d be an easily solvable discretization of the same convection operator. One possible candidate is the first-order upwind discretization

$$\begin{aligned} L^h_d u_{i_1,i_2} &= \frac{1}{h}\Big(b_1\Big(u_{i_1,i_2} - u_{i_1-1,i_2}\Big) + b_2\Big(u_{i_1,i_2} - u_{i_1,i_2-1}\Big)\Big), \\ u_{0,i_2} &= g(i_2 h). \end{aligned} \tag{3.2}$$

This scheme is stable in downstream marching. In the case of a layer domain, the marching of this scheme requires an implicit line-by-line rather than a simple pointwise passage.

Let $\tilde{u}_{i_1,i_2}$ be the current solution approximation. Then the improved approximation $\bar{u}_{i_1,i_2}$ is calculated in the following two steps:

1. The correction v_{i_1,i_2} is calculated by marching operator L^h_d with a right-hand side represented by the residual of (3.1) computed for the current approximation $\tilde{u}_{i_1,i_2}$. The inflow boundary conditions for v are initialized with the zero values.

$$L^h_d v_{i_1,i_2} = f_{i_1,i_2} - L^h \tilde{u}_{i_1,i_2}. \tag{3.3}$$

2. The current approximation is corrected

$$\bar{u}_{i_1,i_2} = \tilde{u}_{i_1,i_2} + v_{i_1,i_2}. \tag{3.4}$$

The operator L^h_d is called the *driver* operator. If the iteration converges, steps (3.3) and (3.4) can be repeated until the desired accuracy is reached.

4. Penetration distance and discretization accuracy. In several papers (e.g., [8, 15]), authors studying the defect-correction method for nonelliptic problems observed a slow convergence or even a divergence in some common error norms for the initial iterations and good asymptotic convergence rates afterward. This behavior is different from that observed in solving elliptic problems by the defect-correction method, where the asymptotic convergence rate is the slowest one. The analysis in this paper shows that this nonelliptic feature is explained by some properties associated with the cross-characteristic interaction (e.g., dissipation and/or dispersion)

in the operators involved in the defect-correction iterations. Specifically, this cross-characteristic interaction and the frequency of an incoming component define the *penetration distance* (also termed "survival distance" in [6]) of this component. The penetration distance is the distance from the inflow boundary in which the discrete solution of the homogeneous problem reasonably approximates the continuous one (i.e., the discretization error is substantially smaller than the solution). The ratio of penetration distances of the operators L^h and L_d^h is an important factor in determining the number of defect-correction sweeps required to reach the asymptotic convergence regime.

Nonellipticity introduces a new issue into the standard discretization analysis common for elliptic operators. The discretization error of a discrete elliptic operator defined on a grid with mesh size h regarding a given component with frequency ω is defined by (1) the operator's approximation order p and (2) the component's normalized frequency ωh. For nonelliptic operators, the main factor is (3) the penetration distance d of this component, which is a function of p, ωh, and ω, namely,

$$d = d\Big(\omega(\omega h)^p\Big). \tag{4.1}$$

In homogeneous nonelliptic problems, the discrete operator does not yield a reasonable solution approximation beyond some $O(d)$ neighborhood of the inflow boundary. A discretization shows accuracy of order p (i.e., the discretization error is reduced by factor 2^p when the mesh size h is refined to $h/2$) if and only if the penetration distance of the incoming component is comparable with (or exceeds) the characteristic size of the domain. Of course, the penetration distance of a given incoming component increases on finer grids (i.e., on the grids with smaller mesh sizes). The grid on which the penetration distance approaches the characteristic size of the domain can be considered the coarsest grid for resolving this component.

In the solution of the homogeneous differential problem (2.1)–(2.3), all the incoming components are translated along the characteristics without changing their phases and amplitudes. However, on any grid which does not align with the characteristic, the discretization unavoidably introduces some dissipation and dispersion errors by cross-characteristic interaction. A quantitative measure of this numerical cross-characteristic interaction is the coefficient of the largest cross-characteristic derivative appearing in the first differential approximation (FDA) (see [19, 20]) to the operator under consideration. Briefly, the first differential approximation (also called modified equation) to a difference operator on a grid with mesh size h is the Taylor expansion of this difference operator truncated to the first items including the least nonzero power of h. The penetration distance is limited by the cross-characteristic interaction in the discrete scheme.

5. Different types of analysis: Applicability, complexity, and interrelation. In the defect-correction method solving elliptic problems, the main mechanism of convergence is damping of error components. In nonelliptic problems, there is another very important convergence mechanism: the downstream transport of the error components. In the presence of this additional mechanism, the accuracy is first achieved near the inflow boundary and then propagated into the interior of the domain. This downstream transport mechanism also explains the observed establishment of a good asymptotic convergence rate after slowly convergent initial iterations as follows: The components with the large amplification factors (which are responsible for the initial slowness) are eventually streamed out of the domain. The error

components that approximate the eigencomponents of the discrete target operator determine the asymptotic convergence. When the target discrete operator approximates the differential operator, these latter error components become characteristic components. In general, the *characteristic components* are components that are much smoother in the characteristic direction than in other directions.

The recognition of this additional convergence mechanism urges modifications in the standard analysis developed for elliptic problems. Basically, one can distinguish four types of analysis applied to nonelliptic problems: (1) a matrix analysis, (2) a modified zero-mode-exclusion full-space Fourier mode analysis, (3) a simplified half-space analysis of the FDA, and (4) the discrete half-space analysis proposed in this paper. The quality of an analysis applied to nonelliptic problems is determined by how well the analysis handles the characteristic components.

5.1. Matrix analysis. The most general and precise analysis is the matrix analysis. (See examples in [7, 8].) This analysis considers the difference operators without assumptions about the solution and boundary conditions. It can be applied to variable-coefficient problems as well. This analysis was found very useful for analyzing 1D problems. However, the enormous computational complexity of this analysis makes it not viable for multidimensional problems.

5.2. Modified full-space Fourier mode analysis. The modified full-space Fourier mode analysis is a modification of the standard full-space Fourier mode analysis excluding from the consideration all the characteristic modes. (See [18] and the bibliography therein.) It is the simplest and most popular type of analysis (e.g., see applications in [8, 14]). This analysis deals with the full-space Fourier components. It estimates only the amplification (damping) factor. Its inherent disadvantage is the inability to take the influence of the inflow boundary into account. This explains its failure in predicting the asymptotic convergence rate and describing the downstream transport phenomenon. However, initial slow convergence rates are often caused by noncharacteristic components for which the solution of the driver operator does not approximate well the target-operator solution. Therefore, the modified full-space analysis provides a good upper bound for the convergence rate. Note that it can also be useful for analyzing the effect of source functions.

5.3. FDA half-space analysis. The FDA half-space analysis is a relatively simple and efficient tool for analyzing the effect of the inflow boundary. (See examples of applications of this analysis in [3, 6, 10, 20] and also section 6 below.) The first differential approximations are considered on the half-space including the inflow boundary. The boundary conditions are represented by one Fourier mode at a time. The FDA analysis provides a good *qualitative* description of the downstream error transport phenomenon. It can also provide an estimate of the number of iterations required to get into the asymptotic convergence regime. This analysis focuses on characteristic components and, therefore, considers homogeneous problems. Note that a combination of the FDA analysis with the modified full-space analysis can provide a good insight for nonhomogeneous problems as well. The disadvantages of this analysis are the inability to provide quantitative estimates, to analyze the effect of different boundary condition discretizations, and to address the asymptotic convergence rate.

5.4. Discrete half-space analysis. The discrete half-space analysis considers the discretizations in their exact form rather than their differential approximation, while the boundary data are represented by a Fourier component. This analysis translates the original multidimensional problem into a 1D discrete problem, where

the frequency of the boundary Fourier component is considered as a parameter. To regularize the half-space problem, the solution is not allowed to grow faster than a polynomial function. This tool is very accurate (and cumbersome at the same time). It can be used to explain in detail many phenomena observed in solving nonelliptic equations and provides a close prediction of the actual solution behavior.

The solution obtained in the discrete half-space analysis has two different representation forms: (1) away from the boundary, the solution is defined as a linear combination of a finite number of analytical components; this region is called the *analytical representation region*; (2) in the region adjacent to the inflow boundary, the solution is defined pointwise; this zone is referred to as the *pointwise representation region*. In each defect-correction iteration, the pointwise representation region penetrates by one mesh size into the interior. By using these representations, the computational complexity of the analysis becomes much less than that associated with the 1D matrix analysis. In the asymptotic regime, when the pointwise representation zone covers all the domain, this analysis becomes a discrete 1D matrix analysis of the multidimensional problem.

The discrete half-space analysis provides a *quantitative* description of the approximate solution obtained at any stage of the defect correction solver. It predicts the convergence rate for each iteration and the asymptotic convergence rate. It can be easily adjusted to analyze a global effect of *any* local discretization of the inflow boundary conditions. This adjustment can be done just by widening the initial pointwise representation region at the inflow boundary. If necessary, the analysis can take into account the influence of the discretized outflow boundary conditions; in this case, it is exact for the constant-coefficient problems on a layer. Generally, this discrete half-space analysis treats completely both mechanisms of convergence, damping and downstream transport of errors, associated with nonelliptic problem solvers. It plays the same role for nonelliptic-problem solvers as the full-space Fourier mode analysis plays for elliptic-problem solvers.

6. Half-space analysis of first differential approximations. In this section, the FDA half-space analysis is applied to provide a qualitative description of penetration distances of the operators involved in defect-correction iterations. This analysis shows that if the operators L^h and L_d^h have different approximation orders, then efficiency of the defect-correction method is actually grid dependent. Grid dependence means that the maximal number of sweeps which might be required to reach the asymptotic convergence rate (or to reduce the algebraic error to the discretization-error level) on fine grids is larger than on coarse grids or vice versa. This phenomenon relates to the fact that some *characteristic* components are poorly approximated by the driver operator. In other cases, when the operators L^h and L_d^h have the same approximation order (see section 10), efficiency of the defect-correction method is optimal and grid independent.

Let L^h be an accurate discretization with respect to a particular incoming component. To approximate the solution of the operator L^h by solving some less accurate operator L_d^h (with a correspondingly shorter penetration distance), one has to iterate L_d^h as many times as needed to attain accuracy up to the L^h penetration distance. The required number of iterations depends on N, where N is the number of grid points in the characteristic direction. To be precise, the number of iterations is proportional to $N^{\frac{p-r}{p+1}}$, where p and r are the approximation orders of operators L^h and L_d^h, respectively. Below we derive the predicted dependence for a particular case where $p = 2$ and $r = 1$.

The target operator L^h approximates the differential operator L from (2.1) with second-order accuracy; therefore

$$\mathrm{FDA}\Big(L^h\Big) = \partial_\xi - C_2 h^2 \Big(\partial_{\eta\eta\eta} + \partial_\xi B^2(\partial_\xi, \partial_\eta)\Big),$$

where η is defined in section 2, $B^2(\partial_\xi, \partial_\eta)$ is a linear combination of second-order derivatives with respect to ξ and η, and C_2 is a constant. For a characteristic component u (in terms of which $\partial_\eta u \gg \partial_\xi u$), this approximation is simplified to

$$\mathrm{FDA}\Big(L^h\Big) \approx \partial_\xi - C_2 h^2 \partial_{\eta\eta\eta}. \tag{6.1}$$

Let the driver operator L_d^h have the first-order approximation accuracy. Then its FDA taken for the characteristic components is

$$\mathrm{FDA}\Big(L_d^h\Big) \approx \partial_\xi - C_1 h \partial_{\eta\eta}, \tag{6.2}$$

where, for a stable scheme, C_1 is a *positive* constant.

As in [3] and [6], the half-space analysis for the FDAs to the operators L^h and L_d^h presented in this section is focused on approximating the characteristic components. The analysis considers the discretizations of the homogeneous equation (2.1) on the half space $\{(x, y) : x \geq 0,\ -\infty < y < \infty\}$ with boundary conditions (at $x = 0$) being represented by the Fourier mode $e^{i\omega y}$. The purpose of this analysis is to estimate the penetration distance as a function of the frequency ω of the incoming Fourier component and the mesh size h.

For the driver operator, we seek a bounded differentiable function $\phi(x, y)$ satisfying the following equation and boundary condition:

$$\partial_\xi \phi - C_1 h \partial_{\eta\eta} \phi = 0, \qquad \phi(0, y) = e^{i\omega y}. \tag{6.3}$$

The exact solution to (6.3) can be written as

$$\phi = e^{C_1 h \beta^2 \xi + \beta \eta},$$

where $\beta = a + ib$ is a complex number with a and b satisfying the system of the algebraic equations

$$\begin{cases} C_1 h(a^2 - b^2)t + a = 0, \\ 2C_1 h a b t + b = \omega\sqrt{1 + t^2}. \end{cases}$$

From the system, $a = O(h)$ and $b = \omega\sqrt{1 + t^2} + O(h^2)$. Therefore, the leading term of the bounded solution to (6.3) is

$$\phi \sim e^{-C_1 h(1+t^2)\omega^2 \xi + i\omega\eta\sqrt{1+t^2}}. \tag{6.4}$$

The factor $e^{\sqrt{1+t^2}(i\omega\eta)}$ represents the exact solution of the continuous problem, while the factor $e^{-C_1 h(1+t^2)\omega^2 \xi}$ is the influence of the numerical cross-characteristic interaction. In the case of the first-order driver, this is a dissipation which damps the amplitude. From (6.4), one can conclude that the penetration distance along the characteristic direction ξ at which this damping becomes $O(1)$ is proportional to $r^{(1)} = \frac{1}{\omega(\omega h)}$. In a similar way, one can derive the penetration distance of a second-order scheme, which is proportional to $r^{(2)} = \frac{1}{\omega(\omega h)^2}$. For even-order schemes, the

numerical cross-characteristic interaction usually affects the *phase* of the incoming component rather than the amplitude.

If the penetration distances $r^{(1)}$ and $r^{(2)}$ exceed the characteristic size of the domain, then fast initial convergence in the defect-correction method is expected because any errors including the errors at the region adjacent to the inflow boundary are swept out of the domain—to first-order accuracy on the first sweep and to the second-order accuracy on the second sweep. On the other hand, if $r^{(1)}$ does not exceed the characteristic size of the domain, errors adjacent to the inflow boundary are swept downstream only a fraction of the domain size. Multiple sweeps are required to sweep errors out of the domain, as

$$N_{\text{sweeps}} \sim \frac{R}{r^{(1)}}, \tag{6.5}$$

where R is a characteristic size of the domain ($R = \sqrt{1+t^2}$ in our problem). This consideration implies that in the case, when the second-order accuracy of the target operator is just attained, $r^{(2)} \approx R$, the number of iterations is estimated as

$$N_{\text{sweeps}} \sim \begin{cases} (R/h)^{\frac{1}{3}} & \text{for} \quad \omega = O\Big(R^{-\frac{1}{3}} h^{-\frac{2}{3}}\Big), \\ (R\omega)^{\frac{1}{2}} & \text{for} \quad h = O\Big(R^{-\frac{1}{2}} \omega^{-\frac{3}{2}}\Big). \end{cases} \tag{6.6}$$

This h dependence was first mentioned in [4]. In many practical calculations, it can hardly be noticed. Note that this h-dependence disappears in the case of close alignment ($t \approx 0$) because the coefficients C_1 (6.2) and C_2 (6.1) are proportional to t (see examples in section 9.1). However, a careful choice of data in the numerical experiments allows us to observe this behavior (section 9). This h dependence is most prominent in the problems associated with boundary information propagating to great distances—aeroacoustics or electromagnetics, for example.

7. Discrete half-space analysis for defect-correction method with first-order driver. This section presents the discrete half-space analysis for the defect-correction method solving the Fromm discretization (2.4) with the first-order driver (DC1) (3.2). The goal of this analysis is the comparison of (1) the exact solution of the differential problem, (2) the exact solution of the discrete problem, and (3) the approximate solutions at different stages of the defect-correction solver. All the results reported in sections 9.2, 9.3, and 10 below have been obtained by means of this analysis.

7.1. Exact solutions and discretization error. Let the exact solution of the problem (2.2) and (2.3) have the form $U(x,y) = e^{i(\omega_1 x + \omega_2 y)}$; then the differential problem can be rewritten as

$$\partial_\xi U(x,y) = i\beta_\xi e^{i(\omega_1 x + \omega_2 y)}, \qquad U(0,y) = e^{i\omega_2 y},$$

where $\beta_\xi = b_1\omega_1 + b_2\omega_2$ is the characteristic frequency ($\beta_\xi \approx 0$ for characteristic components).

The discrete counterpart is

$$L^h u_{i_1,i_2} = i\beta_\xi e^{i(\Omega_1 i_1 + \Omega_2 i_2)}, \qquad u_{0,i_2} = e^{i\Omega_2 i_2}, \qquad u_{-1,i_2} = e^{i(-\Omega_1 + \Omega_2 i_2)}, \tag{7.1}$$

where L^h is the target discrete operator and $\Omega_1 = \omega_1 h$ and $\Omega_2 = \omega_2 h$ are normalized frequencies.

We seek a solution of the discrete problem in the form

$$u_{i_1,i_2} = \phi_{i_1} e^{i\Omega_2 i_2}. \tag{7.2}$$

Then the problem (7.1) can be reformulated for ϕ_{i_1} as

$$a_{-2}\phi_{i_1-2} + a_{-1}\phi_{i_1-1} + a_0\phi_{i_1} + a_1\phi_{i_1+1} = \sqrt{1+t^2}hi\beta_\xi e^{i\Omega_1 i_1}, \tag{7.3}$$

$$\phi_0 = 1, \qquad \phi_{-1} = e^{-i\Omega_1}, \tag{7.4}$$

where

$$a_{-2} = \tfrac{1}{4},\ a_{-1} = -\tfrac{5}{4},\ a_0 = \tfrac{3}{4} + \tfrac{t}{4}\Big(e^{-i2\Omega_2} - 5e^{-i\Omega_2} + 3 + e^{i\Omega_2}\Big),\ a_1 = \tfrac{1}{4}. \tag{7.5}$$

The solution to (7.3) and (7.4) is given by

$$\phi_{i_1} = W_0 e^{i\Omega_1 i_1} + \Big(1 - W_0\Big)\Big(C_0 r_0^{i_1} + C_1 r_1^{i_1}\Big), \tag{7.6}$$

where r_0 and r_1 are the roots of the cubic equation

$$a_{-2} + a_{-1}r + a_0 r^2 + a_1 r^3 = 0,$$

satisfying to $|r| \le 1$,

$$W_0 = \frac{\sqrt{1+t^2}hi\beta_\xi}{a_{-2}e^{-i2\Omega_1} + a_{-1}e^{-i\Omega_1} + a_0 + a_1 e^{i\Omega_1}},$$

$$C_0 = \frac{r_0\Big(r_1 - e^{i\Omega_1}\Big)}{e^{i\Omega_1}\Big(r_1 - r_0\Big)}, \qquad C_1 = \frac{r_1\Big(r_0 - e^{i\Omega_1}\Big)}{e^{i\Omega_1}\Big(r_0 - r_1\Big)}.$$

We avoid here considering in detail the exceptional cases where either the denominator in the expression for W_0 turns out to be zero or $r_0 = r_1$. In these cases, the form of the solution (7.6) remains the same, while W_0 and/or $C_j (j = 0, 1)$ might become some linear functions of i_1.

Thus, the discretization error is calculated as

$$\begin{aligned} U\Big(i_1 h, i_2 h\Big) - u_{i_1,i_2} &= \Big[e^{i\Omega_1 i_1} - \phi_{i_1}\Big] e^{i\Omega_2 i_2} \\ &= \Big(1 - W_0\Big)\Big[e^{i\Omega_1 i_1} - C_0 r_0^{i_1} - C_1 r_1^{i_1}\Big] e^{i\Omega_2 i_2}. \end{aligned} \tag{7.7}$$

7.2. DC1 iteration. Let the boundary data be represented by a discrete Fourier mode $e^{i\Omega_2 i_2}$. Recall that the solution obtained in the discrete half-space analysis has two different representation forms: (1) Away from the boundary, the solution is defined as a collection of a finite number of analytical components; this region is called the *analytical representation region*. (2) In the region adjacent to the inflow boundary, the solution is defined pointwise; this zone is referred to as the *pointwise representation region*. The analysis is most efficient in problems where the initial analytical representation region covers most of the domain.

7.2.1. Analytical representation region. In the analytical representation region, the approximate solution to (7.1) is defined as a linear combination of analytical components; each component has the general form

$$P(i_1)q^{i_1}e^{i\Omega_2 i_2}, \tag{7.8}$$

where $P(i_1)$ is a complex-coefficient polynomial of i_1 and q ($|q| \le 1$) is the base of the given component. The polynomial part $P(i_1)$ will be referred to as the *amplitude* of the component $q^{i_1}e^{i\Omega_2 i_2}$. The initial approximation and the source function are assumed to be a finite collection of analytical components in the form (7.8). Many reasonable initial approximations satisfy this assumption: (1) zero approximation has no analytical components; (2) solution of the driver equation provides one analytical component; (3) the solution interpolated from a coarse grid in the framework of a two-grid solver is represented by several analytical components. The analytical representation at any stage of the defect-correction solver contains this finite collection plus the eigencomponent of the driver operator. To define this eigencomponent, the action of the driver operator on the component $q^{i_1}e^{i\Omega_2 i_2}$ is considered.

$$L_d^h\Big(q^{i_1}e^{i\Omega_2 i_2}\Big) \equiv \frac{d_{-1}q^{i_1-1} + d_0 q^{i_1}}{h\sqrt{1+t^2}}e^{i\Omega_2 i_2}, \tag{7.9}$$

where

$$d_{-1} = -1, \qquad d_0 = 1 + t\Big(1 - e^{-i\Omega_2}\Big). \tag{7.10}$$

Then the *driver-operator eigencomponent* which solves the equation

$$L_d^h\Big(q^{i_1}e^{i\Omega_2 i_2}\Big) = 0 \tag{7.11}$$

is the component with the base $q_d = -d_{-1}/d_0$.

7.2.2. Pointwise representation region. In most cases, the interior analytical approximation does not satisfy the discrete inflow boundary conditions, and an adjustment is needed in the neighborhood of the inflow boundary. This adjustment is given by an additional *pointwise* component

$$\begin{cases} B_{i_1}e^{i\Omega_2 i_2}, & 0 < i_1 \le N_0, \\ 0 & \text{otherwise}, \end{cases}$$

where B_{i_1} is a complex-valued vector of the length N_0. The segment $0 < i_1 \le N_0$ is the pointwise representation region and the vector B_{i_1} is called *the pointwise amplitude*. The role of the pointwise component is to correct the analytic representation in the pointwise region so that the combined approximate solution satisfies the inflow boundary conditions. In each DC1 iteration, N_0 increases by 1. (The size of the increment is determined by the length of the upwind part in the driver-operator discretization stencil.) The inflow boundary condition implementation used in the model problem (2.4) implies $N_0 = 0$. Analyzing more practical boundary conditions employing a modified stencil near the inflow boundary would be similarly done just requiring initial $N_0 > 0$.

7.2.3. Iteration. At any stage of the defect-correction iteration the solution approximation can be represented as

$$\tilde{u}_{i_1,i_2} = Q(i_1)e^{i\Omega_2 i_2}, \qquad Q(i_1) = \begin{cases} \sum\limits_j P_j(i_1)q_j^{i_1} + B_{i_1}, & 1 \le i_1 \le N_0, \\ \sum\limits_j P_j(i_1)q_j^{i_1}, & N_0 < i_1, \end{cases} \tag{7.12}$$

where $P_j(i_1)q_j^{i_1}e^{i\Omega_2 i_2}$ are the analytical components and $B_{i_1}e^{i\Omega_2 i_2}$ is the pointwise component.

The DC1 iteration consists of the two main computational blocks: (1) calculating residuals of the target operator (7.1) and (2) computing corrections by solving the driver operator with the right-hand-side function given by the target-operator residuals. The response in a DC1 iteration of each computational block to an input analytical component $v_{i_1,i_2} = P(i_1)q^{i_1}e^{i\Omega_2 i_2}$ and to the pointwise component is analyzed below. An example of the DC1 iteration analysis for the homogeneous equation (7.1) ($\beta_\xi = 0$) and the zero initial approximation can be found in [10].

Computing residual for analytical component. The residual function calculated for v_{i_1,i_2} is the same component $q^{i_1}e^{i\Omega_2 i_2}$, of course, with different amplitude $R(i_1)$. The amplitude $R(i_1)$ of the residual of v_{i_1,i_2} is calculated as

$$R(i_1) = \Lambda - \tfrac{1}{h\sqrt{1+t^2}}\Big[\, a_{-2}q^{-2}P(i_1-2) + a_{-1}q^{-1}P(i_1-1) + a_0P(i_1) + a_1qP(i_1+1)\Big], \tag{7.13}$$

where if $q^{i_1}e^{i\Omega_2 i_2}$ is a right-hand-side component of (7.1) ($q = e^{i\Omega_1}$), then $\Lambda = i\beta_\xi$; otherwise $\Lambda = 0$. Coefficients $a_j (j = -2, -1, 0, 1)$ are defined in (7.5).

Computing residual for pointwise component. Recall that the pointwise component corrects the analytical representation in the pointwise representation region. So the values B_{-1} and B_0 are given by the difference between boundary conditions (7.4) and the values calculated from analytical representation at points $i_1 = -1$ and $i_1 = 0$. Let N_0 be the current inner boundary for the pointwise representation region ($B_{i_1} = 0$ for $i_1 > N_0$) and an extended inner boundary be $N_0' = N_0 + 2$. Then the pointwise residual function is computed in the following way:

$$R_{i_1}^{\mathrm{pt}} = -\frac{1}{h\sqrt{1+t^2}} \begin{cases} a_{-2}B_{i_1-2} + a_{-1}B_{i_1-1} + a_0B_{i_1} + a_1B_{i_1+1}, & 1 \le i_1 \le N_0' \\ 0 & \text{otherwise.} \end{cases}$$

Correction to analytical component. Correction to the analytical component is a combination of the input component $C(i_1)q^{i_1}e^{i\Omega_2 i_2}$ and the driver-operator eigencomponent. The amplitude $C(i_1)$ of the correction to the analytical component v_{i_1,i_2} is calculated using the equation

$$d_{-1}q^{-1}C(i_1-1) + d_0C(i_1) = h\sqrt{1+t^2}R(i_1) \tag{7.14}$$

derived from (3.3), where the coefficients d_{-1} and d_0 are defined in (7.10). If v_{i_1,i_2} is not an eigencomponent for the driver operator ($q \ne q_d = -d_{-1}/d_0$), then the power of the polynomial $C(i_1)$ is the same as the power of the polynomial $R(i_1)$; otherwise the power of $C(i_1)$ is higher.

To satisfy the zero inflow boundary condition at $i_1 = 0$ that accompanies the correction equation, one must complete the correction with the driver-operator eigencomponent $D_0 q_d^{i_1} e^{i\Omega_2 i_2}$ with the amplitude

$$D_0 = -C(0).$$

Correction to pointwise component. The correction $C_{i_1}^{\mathrm{pt}}$ to the pointwise component is calculated from the following system of linear equations:

$$\begin{cases} C_{N_0'}^{\mathrm{pt}} = 0, \\ d_{-1} C_{i_1}^{\mathrm{pt}} + d_0 C_{i_1+1}^{\mathrm{pt}} = h\sqrt{1+t^2} R_{i_1+1}^{\mathrm{pt}}, \qquad 0 < i_1 < N_0'. \end{cases} \tag{7.15}$$

The amplitude D_1 of the accompanying driver-operator eigencomponent is computed as

$$D_1 = -\frac{h\sqrt{1+t^2} R_1^{\mathrm{pt}} - d_0 C_1^{\mathrm{pt}}}{d_{-1}}.$$

New amplitudes for analytical component, pointwise component, and driver-operator eigencomponent. The new amplitude $\tilde{P}(i_1)$ of the analytical component v_{i_1,i_2} is calculated as

$$\tilde{P}(i_1) = P(i_1) + C(i_1).$$

The corrected pointwise amplitude $\tilde{B}_{i_1}$ and the new boundary $\tilde{N}_0$ of the pointwise representation region are

$$\tilde{B}_{i_1} = B_{i_1} + C_{i_1}^{\mathrm{pt}}, \qquad \tilde{N}_0 = N_0 + 1.$$

The amplitude $D(i_1)$ of the driver-operator eigencomponent is also changed to $\tilde{D}(i_1)$ as follows:

$$\tilde{D}(i_1) = D(i_1) + D_0 + D_1.$$

7.3. Discretization of outflow boundary conditions. The discretization of the outflow boundary conditions can be taken into account as well. This is important for analyzing convection-diffusion and strongly anisotropic problems where resolution of the outflow boundary layer is of high priority. Discretized outflow boundary conditions usually imply some special discretization stencil different from that in the interior. To incorporate this feature into the analysis one can simply introduce another pointwise representation zone near the outflow boundary. In other words, an additional pointwise component makes the half-space analysis absolutely precise for all the constant-coefficient problems on a layer. This modified analysis was used in numerical experiments (sections 9.2, 9.3, and 10). The difference between the basic version (without taking outflow boundary conditions into account) and the modified version was extremely small, dropping below the computer round-off error on grids with $h \le 2^{-8}$. In the discretization accuracy tests (section 9.1), the influence of the discretized outflow boundary conditions was ignored.

7.4. Algebraic error. The *algebraic error* function, which is the difference between the exact (u_{i_1,i_2}) and approximate $(\tilde{u}_{i_1,i_2})$ solutions of the discrete target problem, is given by

$$\tilde{u}_{i_1,i_2} - u_{i_1,i_2} = \Big[Q(i_1) - \Big(W_0 e^{i\Omega_1 i_1} + (1 - W_0)(C_0 r_0^{i_1} + C_1 r_1^{i_1}) \Big) \Big] e^{i\Omega_2 i_2}, \tag{7.16}$$

where $\tilde{u}_{i_1,i_2}$ and u_{i_1,i_2} are defined in (7.12) and (7.2), respectively.

8. 1D matrix analysis. The 1D matrix analysis, applied to the problem (7.3)–(7.4), vastly simplifies analyzing the original multidimensional problem (2.4). This 1D matrix analysis predicts well both the asymptotic and the worst possible convergence rates of the multidimensional defect-correction solver. An $N\times N$ residual amplification matrix, $\mathbf{G_r}$, of the defect-correction iteration is constructed,

$$\bar{\mathbf{r}}^{\text{new}} = \mathbf{G_r}\bar{\mathbf{r}}^{\text{old}},$$

where the N-dimensional vectors $\bar{\mathbf{r}}^{\text{old}}$ and $\bar{\mathbf{r}}^{\text{new}}$ are residuals of (7.3) before and after the iteration, respectively.

The amplification of the residual can be bounded either by the spectral radius of $\mathbf{G_r}$ ($\rho(\mathbf{G_r})$) or by the L_2-norm of the matrix $\mathbf{G_r}$ ($||\mathbf{G_r}||_2 = \sqrt{\rho(\mathbf{G_r^*}\mathbf{G_r})}$). The spectral radius, $\rho(\mathbf{G_r})$, is usually associated with the asymptotic convergence rate, i.e., the rate corresponding to a large number of iterations. The L_2-norm ($||\mathbf{G_r}||_2$) indicates the "worst" possible convergence rate.

9. Numerical tests.

9.1. Verification of analytical predictions: Discretization accuracy test. A discretization is considered to have ϵ accuracy on a grid with mesh size h with respect to a given solution $U(x,y)$ of the differential problem if the following inequality holds

$$\frac{\|u_{i_1,i_2} - U(i_1h, i_2h)\|}{\|U\|} \le \epsilon, \tag{9.1}$$

where u_{i_1,i_2} is the exact discrete solution.

For characteristic components, the discretization accuracy is related with the penetration distance of this component in the discrete solution. Let the exact solution $U(x,y) = e^{i(\omega_1 x+\omega_2 y)}$ of the differential problem (2.2), (2.3) be a characteristic component, i.e., $\omega_1 + t\omega_2 \approx 0$. Below, the penetration distances of this component in the operators involved in the DC1 iterations are approximately calculated from the asymptotic solution of the half-space problem associated with each operators' FDA.

The FDA to the target second-order-accurate discrete operator (2.4) is given by

$$\text{FDA}\Big(L^h\Big) = b_1\partial_x + b_2\partial_y - \frac{h^2}{12}\Big(b_1\partial_{xxx} + b_2\partial_{yyy}\Big).$$

For characteristic components, it becomes

$$\text{FDA}\Big(L^h\Big) = \partial_\xi - \frac{h^2}{12\Big(1+t^2\Big)^2}\Big(-t^3+t\Big)\partial_{\eta\eta\eta}, \tag{9.2}$$

where the nonalignment parameter t and the characteristic variables ξ and η have been defined in section 2. Notice that when $t \approx 1$ the coefficient of the third derivative with respect to η vanishes in the FDA and the next term (the fourth derivative) becomes important.

The asymptotic solution $u(\xi,\eta)$ of the problem

$$\partial_\xi u - \frac{h^2}{12\Big(1+t^2\Big)^2}\Big(-t^3+t\Big)\partial_{\eta\eta\eta}u = 0, \qquad u\Big|_{x=0} = e^{i\omega_2 y}, \tag{9.3}$$

can be found as

$$u(\xi,\eta) = e^{\frac{\xi}{r_2}+i\omega_2\sqrt{1+t^2}\eta}, \tag{9.4}$$

where

$$r_2 = \frac{-i12\sqrt{1+t^2}}{\omega_2\Big(\omega_2 h\Big)^2\Big(-t^3+t\Big)} \tag{9.5}$$

and $|r_2|$ is the normalized penetration distance for the operator L^h in the characteristic (ξ) direction. Then the discretization error of L^h, defined as $\mathrm{DE}(L^h)$, can be estimated as

$$\mathrm{DE}(L^h) = e^{i(\omega_1 x+\omega_2 y)}\Big(1-e^{-\frac{\xi}{r_2}}\Big).$$

Thus, this discretization is estimated to have the accuracy ϵ for $U(x,y)$ on the distance δ (measured along the characteristic) from the boundary if the following inequality holds:

$$\Big|1-e^{-\frac{\xi}{r_2}}\Big| \le \epsilon \qquad \text{for} \quad \xi \le \delta. \tag{9.6}$$

Note, that ϵ defines the *relative* error; hence, $0 \le \epsilon \le 1$, and $\epsilon \approx 1$ indicates very poor accuracy. For operator (2.4), the penetration distance of the ϵ-accuracy is estimated from (9.6) as

$$\delta_2 = |r_2| \arccos(1-\epsilon^2/2). \tag{9.7}$$

The first differential approximation to the first-order-accurate driver operator (3.2) taken for the characteristic components is given by

$$\mathrm{FDA}\Big(L_d^h\Big) = \partial_\xi - \frac{h}{2\Big(1+t^2\Big)^{3/2}}\Big(t^2+t\Big)\partial_{\eta\eta}.$$

The normalized penetration distance in the ξ direction is

$$r_1 = \frac{2\sqrt{1+t^2}}{\omega_2\Big(\omega_2 h\Big)\Big(t^2+t\Big)} \tag{9.8}$$

and the ϵ-accuracy penetration distance is

$$\delta_1 = -r_1 \ln(1-\epsilon). \tag{9.9}$$

We perform the first test to validate the discrete half-space analysis without incorporating outflow boundary conditions from section 7 and analytical expressions (9.7) and (9.9) for penetration distances of characteristic components. We calculate penetration distances of $\epsilon = 0.01$ accuracy for different values of t and ω_2 for the target and driver operators (2.4) and (3.2). Our aim is to compare the following distances from the boundary (measured in mesh sizes along the x direction):

- the distances calculated by formulas (9.7) and (9.9) ($\delta_a^{(j)} = \delta_j/\big(h\sqrt{1+t^2}\big)$, $j = 1, 2$);

TABLE 9.1
Penetration distances (in mesh sizes) of the 1% accuracy.

t	ω_2	1%-Accuracy penetration distances					
		Target operator			Driver operator		
		$\delta_a^{(2)}$	$\delta_A^{(2)}$	$\delta_N^{(2)}$	$\delta_a^{(1)}$	$\delta_A^{(1)}$	$\delta_N^{(1)}$
0.2	2π	> 256	> 256	256	139.034	139	139

	10π	225.456	181	181	0.927	0	0
	16π	55.043	35	35	0.362	0	0

- the distances obtained from the L^h discretization-error formula (7.7), $\delta_A^{(2)}$, and analogously derived discretization-error formula for L_d^h, $\delta_A^{(1)}$;
- the distances computed in direct numerical simulations ($\delta_N^{(j)}$).

In analytical calculations, the exact solution of the differential problem (2.1) and (2.3) is always assumed to be $e^{i\omega_2(-tx+y)}$. In direct numerical simulations the exact solution has been chosen to be $\sin(\omega_2(-tx+y))$. The numerical distance is considered to be m if the L_∞ norm of the relative discretization error on the $(m+1)$th vertical line is greater than 0.01. The simulation grid is 257×257. If in analytical calculations the result exceeds 256 (i.e., the penetration distance covers all the domain), it has been set to > 256. Table 9.1 contains the test results. The two obvious conclusions are as follows.

1. The discrete half-space analysis is actually precise even without incorporating outflow boundary conditions. In all the tests, the results predicted by this analysis and obtained in real numerical calculations coincide.
2. The estimates (9.7) and (9.9) of the penetration distances are accurate, especially for the first-order operator or for small nonalignment angles ($t \le 0.6$). Some deterioration in predicting the second-order operator penetration distances for nearly diagonal alignment is explained by the fact that the penetration distance in the case of 45° angle of nonalignment ($t = 1$) is determined by the *third-order term*, which is not taken into account in calculating r_2. Nevertheless, the estimate (9.7) seems to be reliable for predicting the key property—whether the penetration distance is comparable with (or larger than) the characteristic size of the domain.

9.2. Convergence in different regimes. The discrete problem (2.4) approximating homogeneous differential equation (2.2) on the layer $(x, y) \in [0, 1] \times (-\infty, +\infty)$ was solved. The inflow boundary conditions $g(y) = e^{i\omega_2 y}$ and $g'(y) = e^{i(-\omega_1 h + \omega_2 y)}$ were derived from the assumption that $U(x, y) = e^{i(\omega_1 x + \omega_2 y)}$ $(\omega_1 + t\omega_2 = 0)$ is the desired solution of the differential equation (2.2). The problem is reduced to the 1D

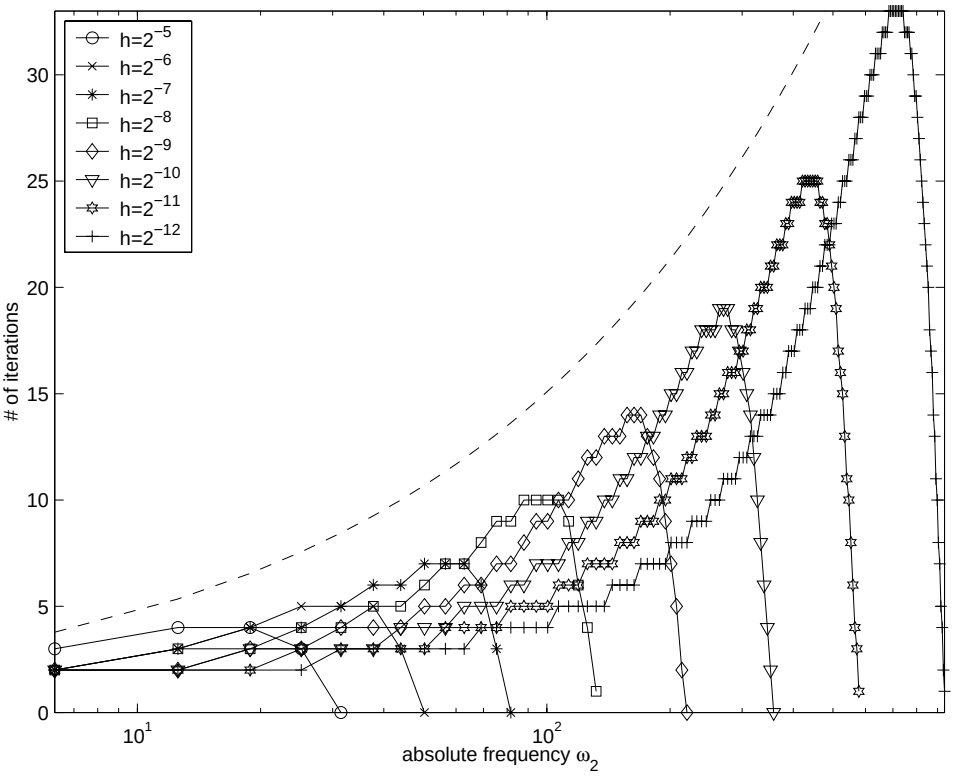

FIG. 9.1. *Algebraic-to-discretization error convergence for DC*1: *Dependence on the incoming frequency* ω_2 *and the mesh size* h.

problem (7.3)–(7.4) with outflow boundary conditions at $i_1 = N$ given by

$$b_{-2}\phi_{N-2} + b_{-1}\phi_{N-1} + b_0\phi_N = 0, \tag{9.10}$$

where

$$\begin{aligned} b_{-2} &= \tfrac{1}{2}, \\ b_{-1} &= -2, \\ b_0 &= \tfrac{3}{2} + \tfrac{t}{2}\Big(e^{-i2\Omega_2} - 4e^{-i\Omega_2} + 3\Big). \end{aligned} \tag{9.11}$$

The numerical experiments with the DC1 algorithm were performed following recipes incorporating the outflow boundary conditions, given in section 7.2. As noted earlier, this 1D analysis provides the exact simulation of the DC1 iterations performed for the 2D problem.

The tests were performed on the uniform grids with $h = 2^{-5}, 2^{-6}, \ldots, 2^{-12}$. The nonalignment angle was the same in all the tests ($t = 0.5$). The absolute (not normalized) value of the incoming frequency was varied from $\omega_2 = 2\pi$ with increment 2π. The initial approximation for the DC1 method was always obtained from the solution of the driver operator. The tests on each grid were stopped when one DC1 iteration succeeded to converge the L_2 norm of the algebraic error below the L_2 norm of the discretization error. The results of the tests are collected in Figure 9.1.

For any given inflow content, there is the worst grid on which the required number of iterations is maximal. With further grid refinement, the initial convergence rates become faster and eventually just two DC1 iterations are needed to converge the algebraic error below the discretization-error level.

One can distinguish three convergence regimes with respect to the relative accuracy of the target and driver operators. In the discussion below, the penetration distances are estimated as large or small with respect to the characteristic size of the domain.

Fast convergence regime—large penetration distance in the driver operator. For very smooth inflow boundary conditions, the solutions of both the target and the driver operators accurately approximate the true solution of the differential problem. Convergence rates are fast from the very beginning. Four DC1 iterations at most are needed to converge the algebraic errors to the discretization-accuracy level. This regime is established when the driver operator attains at least 40% accuracy ($\epsilon = 0.4$) over the entire domain. In this regime, the minimal number of required iterations is two, as expected.

Slow convergence regime—large penetration distance in the target operator, small penetration distance in the driver operator. This regime is established for the range of inflow boundary conditions, for which the target operator is accurate while the driver equation does not approximate the differential equation on a large part of the domain, i.e., the driver-operator penetration distance is substantially shorter than the characteristic size of the domain. The initial convergence rates are slow, and many iterations are required to converge the algebraic errors. The maximal number of iterations required to converge the algebraic error below the discretization-error level increases in a good accordance with FDA estimate (6.6). This regime is actually the most important one, from the consideration that it describes the convergence on grids minimally sufficient for accurate target-operator approximations of the true differential solution. Generally, the maximal number of iterations is required for the incoming components with about 50% accuracy ($\epsilon = 0.5$) provided by the target operator. This accuracy is not practical. Section 9.3 presents numerical experiments with more accurate approximations.

Fast convergence regime—small penetration distance in the target operator. The third regime where the initial convergence is fast again is established for relatively high-frequency inflow contents. In this regime, neither the target nor the driver operator is accurate.

The estimate (6.6) for the maximal number of iterations can be adjusted for the second regime by incorporating (9.7) and the assumption $\delta_2 = R$ as

$$N_{\text{sweeps}} \approx \frac{t+t^2}{2} \begin{cases} h^{-\frac{1}{3}} \left(\frac{12 \arccos(1-\frac{\epsilon^2}{2})}{t-t^3} \right)^{\frac{2}{3}}, \\ \omega_2^{\frac{1}{2}} \left(\frac{12 \arccos(1-\frac{\epsilon^2}{2})}{t-t^3} \right)^{\frac{1}{2}}. \end{cases} \tag{9.12}$$

This estimate is a counterpart to (6.6) with the target operator attaining the ϵ accuracy over the characteristic size of the domain. Substituting for the value of $\epsilon = 0.5$ observed in the numerical experiments in the second regime to (9.12) yields the dashed line in Figure 9.1; the variation of the maximal number of iteration is characterized well.

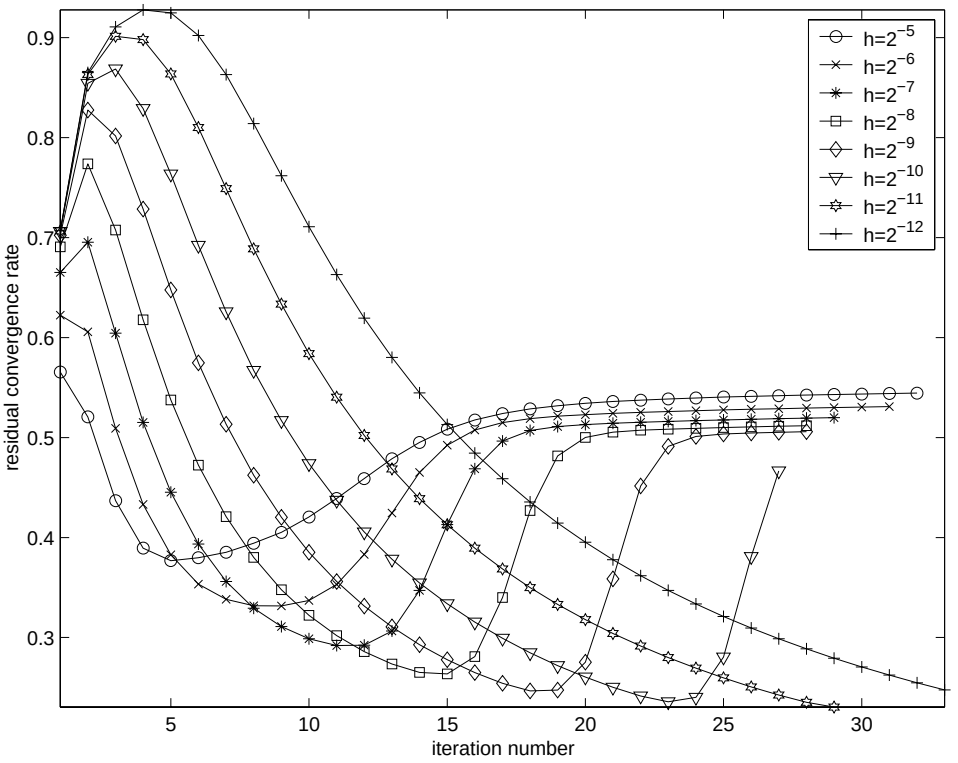

FIG. 9.2. *Residual convergence rate history for DC*1.

9.3. Grid-dependent convergence. Eight tests were performed on the same grids with the same nonalignment angle ($t = 0.5$) as in the previous section. The frequencies, ω_2, of the inflow Fourier components on different grids were chosen to provide the target-operator penetration distance to coincide with the characteristic size of the domain ($\delta_2 = \sqrt{1+t^2}$). The penetration distance was computed by the formula (9.7) for the 5% accuracy ($\epsilon = 0.05$), which is representative of the accuracy required in practice. The initial approximation for the defect-correction method was again obtained from the solution of the driver operator. Figure 9.2 depicts the residual convergence rate history in the experiments performed. The convergence rate in a DC1 iteration was defined as the ratio of the L_2 norms of the residual after and before the iteration. In each test, the last iteration shown on the Figure 9.2 corresponded to the approximate solution with the L_2 norm of the target-operator residual less than 10^{-10}. Figure 9.3 exhibits the ratios between the L_2 norms of the algebraic and discretization errors observed in the same experiments. In this figure, the solid horizontal line designates algebraic error equal to the discretization error. The first qualitative conclusion is obvious: the convergence of DC1 iterations is grid dependent, i.e., more iterations are required on finer grids to get into the asymptotic convergence regime and/or to converge the algebraic error below the discretization error level.

The quantitative characteristics of the experiments are collected in Table 9.2. The column $\omega_2 h$ shows the normalized frequency of the inflow boundary Fourier component having the unity penetration distance for 5% accuracy on the uniform grid with mesh size h. The columns $\rho(G_r)$ and $\|G_r\|_2$ exhibit the asymptotic convergence rate and the

worst possible convergence rate, respectively, both calculated by 1D matrix analysis described in section 8. The DC1 iteration process was considered to have reached the asymptotic convergence regime when an iteration convergence rate became less than the asymptotic convergence rate ($\rho(G_r)$) on the given grid. The number of iterations required to reach the asymptotic convergence regime is shown in the column labeled "Asympt. delay." The column marked "Alg. error" demonstrates the number of DC1 iterations required to converge the algebraic error below the discretization error level. The last column, marked "Estimated N_{sweeps}," is the number of sweeps calculated from (9.12) for $\epsilon = 0.05$.

The fast asymptotic convergence rate predicted by the 1D matrix analysis and confirmed in the numerical tests is not a surprise. It was observed by many researchers

that the asymptotic convergence rate of the defect-correction solver for (2.4) is about 0.5 per iteration. In [8], the authors emphasized that the asymptotic convergence rate deteriorates for the central and the pure upwind target discretizations.

The bound $\|G_r\|_2$ is not very sharp in the presented tests. The full-space Fourier analysis (eliminating the characteristic components from the consideration) gives a similar estimate (see [8]). This similarity suggests that to observe this "worst" behavior one should test nonhomogeneous problems or consider special initial approximations.

The numerical tests corroborate the conclusion derived from the half-space analysis that the number of DC1 iterations required to obtain the asymptotic convergence rate or to have the algebraic error smaller than the discretization error might grow on fine grids. The quantitative prediction that the growth is proportional to $h^{-\frac{1}{3}}$, i.e., the number of the iterations is doubled when the grid becomes eight times larger (mesh size h is replaced with $h/8$), has also been confirmed with a good accuracy (see Table 9.2). The crude estimate (9.12) is a good indicator of the h-dependent delay in convergence. A smarter choice of the initial approximation (e.g., the initial approximation interpolated from the solution on a coarser grid) can shorten somewhat this delay on each given grid, but the qualitative behavior remains the same: the number of required defect-correction iterations grows as $h^{-\frac{1}{3}}$ in passing to finer grids.

There are several ways to change the algorithm in order to make its convergence grid independent:

1. The first possibility, studied in section 10, is to apply a driver of the same approximation order as the target operator.
2. The second way is to use a predictor-corrector technique for solving the target operator. This method suggests some marching along the flow direction. Preliminary numerical tests indicate that if the marching is possible (there are no recirculation zones), then the predictor-corrector method demonstrates the optimal efficiency.
3. The third method is a semicoarsening multigrid algorithm which employs the coarse-grid operators closely approximating the *characteristic-component FDA* of the target operator (see [9]).

10. Defect-correction method with second-order driver. In this section, the defect-correction algorithm with the second order driver (DC2) is presented. The driver operator which is the second-order accurate upwind discretization is accompanied with the same inflow boundary condition as the target operator (2.4).

$$
\begin{aligned}
L_d^h u_{i_1,i_2} = \frac{1}{2h}\Big(& b_1\Big(3u_{i_1,i_2} - 4u_{i_1-1,i_2} + u_{i_1-2,i_2}\Big) \\
& + b_2\Big(3u_{i_1,i_2} - 4u_{i_1,i_2-1} + u_{i_1,i_2-2}\Big)\Big), \\
i_1 = 1, 2, \ldots, N, & \\
u_{0,i_2} = g(i_2 h),\ & u_{-1,i_2} = g'(i_2 h).
\end{aligned}
\tag{10.1}
$$

The discretization scheme (10.1) is stable. This scheme may be considered as a target scheme by itself. In extension to convection-diffusion equation, however, purely upwind schemes do not possess the advantage of a one-shot solution and the accuracy considerations become dominant. The Fromm scheme (2.4) is about four times more accurate than the scheme (10.1).

We tested the DC2 iterations for the same test cases as in section 9.3. The results confirm that the DC2 solver is optimally efficient on all the grids. The convergence in DC2 iterations is grid independent. Convergence rates faster than 0.5 per iteration are obtained from the very beginning. The DC2 solver requires only one sweep to reduce the algebraic error substantially below the level of discretization accuracy.

The efficiency demonstrated by DC2 solver indicates that the second-order driver would be preferable for solving high-order operators by defect-correction method. On the other hand, implementation of second-order drivers in practical problems is not straightforward. For example, in solving discretized multidimensional hyperbolic systems of equations where downstream marching is impossible, first-order schemes are considered to be much easier to solve than second-order schemes. Nevertheless, the opportunity for employing the second-order driver should always be carefully considered.

11. Conclusions. This paper presented a novel, comprehensive, discrete, half-space analysis for a defect-correction method solving the Fromm discretization of the 2D convection equation. This analysis is precise for constant-coefficient problems on layers and can be easily generalized to the convection-diffusion and strongly anisotropic problems. The half-space analysis plays the same role for nonelliptic problem solvers as the full-space Fourier mode analysis plays for elliptic problem solvers; in nonelliptic problems, it accounts for both the damping and the downstream transport of errors. The analytical solution on the half-space is defined as a combination of a finite number of analytical components and a pointwise component. The analytical components represent the solution away from the boundary. The role of the pointwise component is to correct the analytic representation in the region adjacent to the boundary so that the combined approximate solution satisfies the inflow boundary conditions. Any locally discretized inflow boundary conditions can be considered in the framework of this analysis. In each DC1 iteration the pointwise representation region penetrates in the interior by one mesh size. By using these representations, the computational complexity of the analysis becomes much less than that associated with the 1D matrix analysis. In the asymptotic regime, when the pointwise representation zone covers all the domain, this analysis becomes a discrete 1D matrix analysis of the multidimensional problem. The discrete half-space analysis was found to be an accurate and very efficient tool for predicting actual solution behavior.

The following important findings about the analyzed defect-correction method were reported:

1. The initial convergence rate of the defect-correction method is principally a function of the relative accuracy of the driver and target operators, as reasoned by the penetration distances for characteristic components.
2. The asymptotic convergence rate of the defect-correction method is about 0.5 per iteration.
3. The efficiency of the defect-correction method with the first-order driver is grid dependent. The maximal number of iterations required to reach the discretization accuracy or to obtain the asymptotic convergence rate can be proportional to $h^{-\frac{1}{3}}$, corresponding to the characteristic error components with the target-operator penetration distances approximately equal to (and the driver-operator penetration distances substantially less than) the characteristic size of the domain.
4. Using the second-order driver in the defect-correction iterations eliminates this h-dependence and results in an optimally efficient solver.

COMPACT CENTRAL WENO SCHEMES FOR MULTIDIMENSIONAL CONSERVATION LAWS*

DORON LEVY†, GABRIELLA PUPPO‡, AND GIOVANNI RUSSO§

Abstract. We present a new third-order central scheme for approximating solutions of systems of conservation laws in one and two space dimensions. In the spirit of Godunov-type schemes, our method is based on reconstructing a piecewise-polynomial interpolant from cell-averages which is then advanced exactly in time.

In the reconstruction step, we introduce a new third-order, *compact*, central weighted essentially nonoscillatory (CWENO) reconstruction, which is written as a convex combination of interpolants based on different stencils. The heart of the matter is that one of these interpolants is taken as a suitable quadratic polynomial, and the weights of the convex combination are set as to obtain third-order accuracy in smooth regions. The embedded mechanism in the WENO-like schemes guarantees that in regions with discontinuities or large gradients, there is an automatic switch to a one-sided second-order reconstruction, which prevents the creation of spurious oscillations.

In the one-dimensional case, our new third-order reconstruction is based on an extremely compact *three*-point stencil. Analogous compactness is retained in more space dimensions. The accuracy, robustness, and high-resolution properties of our scheme are demonstrated in a variety of one- and two-dimensional problems.

1. Introduction.

We are concerned with multidimensional systems of hyperbolic conservation laws of the form

$$u_t + \nabla_x \cdot f(u) = 0, \qquad x \in \mathbb{R}^d, \quad u = (u_1, \ldots, u_n). \tag{1.1}$$

Methods for approximating solutions to (1.1) have attracted a lot of attention in recent years (see [5], [11], [25], and the references therein).

In this work we focus on Godunov-type schemes, where one first reconstructs a piecewise-polynomial interpolant which is then advanced exactly in time according to (1.1) and finally projected on its cell-averages. Generally, one can divide Godunov-type schemes into two subclasses—*upwind methods* and *central methods*.

In *upwind schemes*, one first reconstructs a polynomial in every cell, which is then used to compute a new cell-average in the same location in the next time step. This procedure requires solving Riemann problems at the discontinuous interfaces. For high-order methods, instead of analytically solving the resulting Riemann problems,

one typically implements approximate Riemann solvers or some form of flux splitting. For systems of conservation laws, or in the demanding context of more space dimensions, this procedure turns out to be more intricate as such Riemann solvers do not exist. The essentially nonoscillatory (ENO) methods by Harten are the prototype of high-order methods (see [6], [23], and the references therein). A recent review of ENO and weighted essentially nonoscillatory (WENO) methods can be found in [22].

Central schemes, on the other hand, are based on averaging over the Riemann fans, a procedure which is typically done by staggering between two grids. They require no Riemann solvers, no projection along characteristic directions, and no flux splitting. Therefore, all that one has to do in order to solve a problem is to supply the flux function. They are more simple when compared with upwind schemes.

The major difference between different central methods is in the reconstruction step, where one computes a piecewise-polynomial interpolant from the previously computed cell-averages.

The prototype of central schemes is the Lax–Friedrichs [4] scheme which is based on a piecewise-constant interpolant. Even though it is very robust, it is only first-order accurate and, moreover, it suffers from excessive numerical dissipation. A second-order central method was proposed by Nessyahu and Tadmor in [20]. This method is based on a MUSCL-like [10] piecewise linear interpolant and nonlinear limiters which prevent spurious oscillations (see [21] for a different approach). A variety of extensions to these methods were suggested. The one-dimensional third-order method of Liu and Tadmor [19] is based on the third-order reconstruction by Liu and Osher in [17]. For the two-dimensional method, see [1] and [8].

A first step for importing the high-order reconstructions that were derived in the upwind framework was taken in [2]. There, the ENO method was transformed into the central setup, and a new *mostly centered stencil* was shown to produce the least oscillatory results. The next step was taken in the one-dimensional case in [13], where a new *central weighted nonoscillatory* (CWENO) reconstruction was introduced. This CWENO method is based on the upwind WENO methods by [18] and [7], in which an interpolant is written as a convex combination of several reconstructions which are based on different stencils. These methods include an internal switch which is designed such as to provide the maximum possible accuracy in smooth regions, while automatically switching to a more robust one-sided stencil in the presence of discontinuities and large gradients. The one-dimensional CWENO method was extended to two space dimensions in [15] and [16]. For a numerical study of the behavior of the total variation for the CWENO scheme, see [14].

In this paper we present a new, compact CWENO reconstruction. This new reconstruction is based on defining a suitable quadratic function which is added to linear interpolants in such a way as to obtain third-order accuracy in smooth regions (in one and two space dimensions). In regions with discontinuities or large gradients, the weights are automatically changed so that they switch to a one-sided second-order linear reconstruction. This reconstruction turns out to be extremely compact; in the one-dimensional case, e.g., the reconstruction is based on a three-point stencil.

The structure of this paper is as follows: We start in section 2 with a brief overview of central schemes for conservation laws in one and two space dimensions.

We then proceed to present our new, compact, third-order CWENO reconstruction in section 3. The idea of introducing a quadratic reconstruction is first presented in the one-dimensional framework and then extended to two space dimensions.

We end in section 4 where we demonstrate our new method in several test cases.

First, the accuracy tests (both in one-dimensional and two-dimensional cases) show the third-order accuracy of the method. We then solve the one-dimensional system of the Euler equations of gas dynamics for a few test problems and we illustrate the behavior of the scheme in scalar two-dimensional cases. In particular, we would like to stress that in our numerical results we observe a very robust and nonoscillatory behavior of the weights, which can be related to the overall robustness and accuracy properties of our new method.

2. Central schemes for conservation laws. In this section we give a brief overview of central schemes for approximating solutions to hyperbolic conservation laws in one and two space dimensions. For further details we refer the reader to [25], [8], [13], and the references therein.

Starting in the one-dimensional case, we seek numerical solutions of the Cauchy problem

$$\begin{cases} u_t + f(u)_x = 0, \\ \\ u(x, t{=}0) = u_0(x). \end{cases} \tag{2.1}$$

For simplicity, we introduce a uniformly spaced grid in the (x,t) space, where the mesh spacings are denoted by $h := \Delta x$ and $k := \Delta t$, respectively. We denote by $\bar{u}_j^n$ the numerical approximation of the cell average in the cell $I_j := [x_{j-1/2}, x_{j+1/2}]$ at time $t^n = nk$, where $x_j = jh$. The finite-difference method will approximate the cell-averages at time t^{n+1} based on their values at time t^n.

We start by reconstructing at time t^n a piecewise-polynomial conservative interpolant from the known cell-averages, $\bar{u}_j^n$, i.e.,

$$P_u(x, t^n) := \sum_j R_j(x)\chi_j, \tag{2.2}$$

where χ_j is the characteristic function of the interval I_j and $R_j(x)$ is a polynomial defined in I_j. It is here, in the reconstruction step, where the accuracy and nonoscillatory requirements enter. Different central methods will be typically based on different reconstructions.

The reconstruction, $P_u(x, t^n)$, is then evolved exactly in time (integrating (2.1)), and then projected on staggered cells, in order to compute the cell average at $I_{j+1/2}$. With this procedure we obtain

$$\bar{u}_{j+1/2}^{n+1} = \bar{u}_{j+1/2}^n + \frac{1}{h}\int_{t^n}^{t^{n+1}} [f(P_u(x_j, \tau)) - f(P_u(x_{j+1}, \tau))]\, d\tau. \tag{2.3}$$

Based on the reconstruction, (2.2), the first term on the right-hand side (RHS) of (2.3) can be explicitly computed,

$$\bar{u}_{j+1/2}^n = \frac{1}{h}\int_{x_j}^{x_{j+1}} P_u(x, t^n)\, dx.$$

In order to compute the second integral on the RHS of (2.3), namely the integral in time over the fluxes, one should observe that due to the staggering, up to a suitable Courant–Friedrichs–Lewy (CFL) condition, these integrals involve only smooth functions, and hence can be approximated by a sufficiently smooth quadrature. A second-order method can be obtained, e.g., using the midpoint rule in time (see [20]).

Simpson's rule for the quadrature in time will provide fourth-order accuracy (which will naturally be sufficient also for a third-order method).

The quadratures for the time integrals of the fluxes require the *prediction* of point-values of the function in several points in the interval $[t^n, t^{n+1}]$. One possible approach is to use a Taylor expansion based on (2.1). Such an approach was used, e.g., in [20] and [19]. In order to avoid the technical complications involved in the Taylor series (in particular with high-order methods, and when dealing with systems of equations), one can alternatively use a Runge–Kutta (RK) method directly on (2.1) to predict the required values in later times. By using the *natural continuous extension* (NCE) of RK schemes [26], the value of the flux at the nodes of the quadrature formula can be computed with a single RK step. Such a method is simpler compared with the Taylor expansion method, but it does require another reconstruction: the reconstruction of the point values of the derivatives of the fluxes at time t^n which are then used as the input to the RK solver (see [2] and [13] for more details).

The simplicity of central schemes manifests itself when turning to deal with systems of equations. Basically, the algorithm that was described in the scalar case repeats itself componentwise. Based on the type of the reconstruction, when solving systems of equations, there can even be simplifications over a purely componentwise extension of the scalar scheme. These can be found, e.g., in section 3.3 below.

The extension to two space dimensions is straightforward: We consider

$$u_t + f(u)_x + g(u)_y = 0, \tag{2.4}$$

subject to the initial condition, $u(x, y, t{=}0) = u_0(x, y)$. Here, Δx and Δy will denote the spatial mesh spacings, while Δt denotes the spacing in time. The two-dimensional cells are now $I_{i,j} = [x_{i-1/2}, x_{i+1/2}] \times [y_{j-1/2}, y_{j+1/2}]$.

Following the general methodology, we wish to construct the cell-averages, $\bar{u}^{n+1}_{j,k}$, based on the cell-averages at time t^n. First, we construct a two-dimensional interpolant which reads

$$P_u(x, y, t^n) = \sum_{i,j} R_{i,j}(x, y)\chi_{i,j}, \tag{2.5}$$

with $\chi_{i,j}$ being the characteristic function of the cell $I_{i,j}$ and $R_{i,j}(x, y)$ a polynomial of a suitable degree. An exact evolution in time of the interpolant (2.5) which is projected on its cell-averages now reads (compare with (2.3))

(2.6)

$$\begin{aligned}\bar{u}^{n+1}_{i+1/2,j+1/2} = \bar{u}^{n}_{i+1/2,j+1/2} &+ \frac{1}{\Delta x \Delta y}\int_{t^n}^{t^{n+1}}\int_{y=y_j}^{y_{j+1}} [f(P_u(x_i, y, \tau)) - f(P_u(x_{i+1}, y, \tau)]\, dy d\tau \\ &+ \frac{1}{\Delta x \Delta y}\int_{t^n}^{t^{n+1}}\int_{x=x_i}^{x_{i+1}} [f(P_u(x, y_j, \tau)) - f(P_u(x, y_{j+1}, \tau)]\, dx d\tau.\end{aligned}$$

The staggered cell-average at time t^n can be directly computed by

$$\bar{u}^n_{i+1/2,j+1/2} = \frac{1}{\Delta x \Delta y}\int_{x_i}^{x_{i+1}}\int_{y_j}^{y_{j+1}} P_u(x, y, t^n)\, dy dx.$$

Analogously to the one-dimensional case, the flux integrals on the RHS of (2.6) can be approximated using a quadrature rule in time. This can be coupled with a quadrature

rule for the line integrals in space. Here it is necessary to avoid quadrature points at which the fluxes may not be smooth. The details can be found, e.g., in [15] and [16] (see also [8]).

3. A compact third-order CWENO reconstruction.

3.1. The one-dimensional framework. In this section we derive our new CWENO reconstruction in one space dimension. The two-dimensional extension will follow in section 3.2.

We first note that in the absence of large gradients, we obtain third-order accuracy if we choose for the reconstruction the *optimal* polynomial

$$P_j(x) = P_{\text{OPT},j}(x),$$

where $P_{\text{OPT},j}(x)$ is the parabola that interpolates the data $\bar{u}^n_{j-1}, \bar{u}^n_j, \bar{u}^n_{j+1}$ in the sense of cell-averages to enforce conservation:

$$\int_{x_{j+l-1/2}}^{x_{j+l+1/2}} P_{\text{OPT},j}(x)\,dx = \bar{u}^n_{j+l}, \qquad l = -1, 0, 1.$$

These conditions determine $P_{\text{OPT},j}(x)$ completely, namely,

$$P_{\text{OPT},j}(x) = u^n_j + u'_j(x - x_j) + \frac{1}{2}u''_j(x - x_j)^2, \tag{3.1}$$

with

$$u^n_j = \bar{u}^n_j - \frac{1}{24}(\bar{u}^n_{j+1} - 2\bar{u}^n_j + \bar{u}^n_{j-1}),$$
$$u'_j = \frac{\bar{u}^n_{j+1} - \bar{u}^n_{j-1}}{2\Delta x}, \qquad u''_j = \frac{\bar{u}^n_{j-1} - 2\bar{u}^n_j + \bar{u}^n_{j+1}}{\Delta x^2}.$$

However, when discontinuities or large gradients occur, this reconstruction would be oscillatory. Therefore, following the WENO methodology [18], [7], [13], we construct an ENO interpolant as a convex combination of polynomials which are based on different stencils. Specifically, in the cell I_j we write

$$P_j(x) = \sum_i w^j_i P^j_i(x), \quad \sum_i w^j_i = 1, \quad w_i \geq 0, \quad i \in \{\text{L}, \text{C}, \text{R}\}, \tag{3.2}$$

where P_{L} and P_{R} are linear functions based on a left stencil and a right stencil, respectively, and P_{C} is a quadratic polynomial. In order to simplify the notations, we will omit the upper index j, remembering that the weights and the three polynomials change from cell to cell.

Conservation requires that $P_{\text{R}}(x)$ will interpolate the cell-averages

$$\int_{x_{j-1/2}}^{x_{j+1/2}} P_{\text{R}}(x)dx = \Delta x\,\bar{u}^n_j, \qquad \int_{x_{j+1/2}}^{x_{j+3/2}} P_{\text{R}}(x)dx = \Delta x\,\bar{u}^n_{j+1},$$

which, in turn, results with

$$P_{\text{R}}(x) = \bar{u}^n_j + \frac{\bar{u}^n_{j+1} - \bar{u}^n_j}{\Delta x}(x - x_j). \tag{3.3}$$

Similarly, for the left interpolant we have

$$P_{\mathrm{L}}(x) = \bar{u}_j^n + \frac{\bar{u}_j^n - \bar{u}_{j-1}^n}{\Delta x}(x - x_j). \tag{3.4}$$

All that is left is to reconstruct a centered polynomial, P_{C}, such that the convex combination, (3.2), will be third-order accurate in smooth regions. It must, therefore, satisfy

$$P_{\mathrm{OPT}}(x) = C_{\mathrm{L}}P_{\mathrm{L}}(x) + C_{\mathrm{R}}P_{\mathrm{R}}(x) + C_{\mathrm{C}}P_{\mathrm{C}}(x), \quad \sum_i C_i = 1, \quad i \in \{\mathrm{L}, \mathrm{C}, \mathrm{R}\}, \tag{3.5}$$

where $C_{\mathrm{L}}, C_{\mathrm{C}}$, and C_{R} are constants. Due to the staggering between every two consecutive steps of the central method, our reconstruction should provide half-cell averages which are third-order accurate. A straightforward calculation shows that *any* symmetric choice of constants C_i in (3.5) provides the desired accuracy. In particular, for the specific choice of $C_{\mathrm{L}} = C_{\mathrm{R}} = 1/4$, (3.3)–(3.5) yield

$$\begin{aligned} P_{\mathrm{C}}(x) &= 2P_{\mathrm{OPT}}(x) - \frac{1}{2}(P_{\mathrm{R}}(x) + P_{\mathrm{L}}(x)) = \bar{u}_j^n - \frac{1}{12}(\bar{u}_{j+1}^n - 2\bar{u}_j^n + \bar{u}_{j-1}^n) \\ &\quad + \frac{\bar{u}_{j+1}^n - \bar{u}_{j-1}^n}{2\Delta x}(x - x_j) + \frac{\bar{u}_{j+1}^n - 2\bar{u}_j^n + \bar{u}_{j-1}^n}{\Delta x^2}(x - x_j)^2. \end{aligned} \tag{3.6}$$

In order to complete the reconstruction of $P_j(x)$ in (3.2), it is left to compute the weights w_i. Following [7] and [13], we write

$$w_i = \frac{\alpha_i}{\sum_k \alpha_k}, \qquad \alpha_i = \frac{C_i}{(\varepsilon + IS_i)^p}, \qquad i, k \in \{\mathrm{L}, \mathrm{C}, \mathrm{R}\}. \tag{3.7}$$

The constants C_is in (3.7) are chosen to be the same as in (3.5), i.e., $C_{\mathrm{L}} = C_{\mathrm{R}} = 1/4$, while $C_{\mathrm{C}} = 1/2$.

The *smoothness indicators*, IS_i, are responsible for detecting large gradients or discontinuities and to automatically switch to the stencil that generates the least oscillatory reconstruction in such cases. Once again, we follow [7] and [13] and define in each cell I_j the three smoothness indicators, IS_i, as

$$IS_i = \sum_{l=1}^{2} \int_{x_{j-1/2}}^{x_{j+1/2}} h^{2l-1}(P_i^{(l)}(x))^2 dx, \qquad i \in \{\mathrm{L}, \mathrm{C}, \mathrm{R}\}. \tag{3.8}$$

A direct computation, based on (3.3), (3.4), and (3.6), yields

$$\begin{aligned} IS_{\mathrm{L}} &= (\bar{u}_j^n - \bar{u}_{j-1}^n)^2, \qquad IS_{\mathrm{R}} = (\bar{u}_{j+1}^n - \bar{u}_j^n)^2, \\ IS_{\mathrm{C}} &= \frac{13}{3}(\bar{u}_{j+1}^n - 2\bar{u}_j^n + \bar{u}_{j-1}^n)^2 + \frac{1}{4}(\bar{u}_{j+1}^n - \bar{u}_{j-1}^n)^2. \end{aligned} \tag{3.9}$$

The constant ε is taken to prevent the denominator from vanishing. Furthermore, its value has to satisfy two requirements, namely,

(i) $\varepsilon + h^2 u_x^2 \gg |IS - h^2 u_x^2|$ in smooth regions,

(ii) $\varepsilon \ll IS$ near discontinuities.

The first condition guarantees that, on smooth regions, the weights are basically equal to the constants that provide high accuracy. The second condition guarantees that in the presence of a discontinuity, the weights of the parabola and of one of the one-sided

linear reconstructions will be practically zero, and we will be left with the other one-sided linear reconstruction. Hence, our third-order method automatically switches to a second-order method in the presence of large gradients, which is exactly what makes it so robust as will be evident in our numerical computations presented below.

The constant p weights the departure from smoothness. We used the value $p = 2$. For a discussion about its choice, see [7] and [13].

A second, nonoscillatory reconstruction is required for the flux derivative. It is natural to adapt the reconstruction that we used for the half-cell averages also to the reconstruction of the point-values of the flux derivative. Here, however, the interpolation requirements will be in the sense of point-values instead of cell-averages. Once again, a direct computation shows that any symmetric choice of constants will provide the desired accuracy, and it will only be natural to use the same constants, C_is, that were used in (3.5). This is simpler than the case of [13] where we had to use different sets of constants for the two different reconstructions (the reconstruction of the half-cell averages and the reconstruction of the point-values of the flux derivative at the center of the cells).

Remarks.

1. We would like to emphasize that our new method is based on adding the parabola P_{C} into the convex combination which is the heart of our nonoscillatory reconstruction. Our numerical simulations showed that the freedom we have in selecting the constants C_i has no influence on the properties of the method. It is easy to prove that we obtain third-order accuracy regardless of the smoothness of the weights, as long as they are symmetric. Of course this is mainly of theoretical interest, since it is very unlikely that only a smooth departure from symmetry is maintained if the weights are not smooth.
2. By extending our new ideas, one can modify our previous CWENO method presented in [13] in order to obtain a fifth-order, central, nonoscillatory scheme. This can be done by simply adding a fourth-order polynomial for the computation of the point-values.
3. Our new reconstruction is equivalent to limiting with the minimum slope instead of slope zero in the presence of a discontinuity. Hence, it is based on a second-order reconstruction close to shocks, unlike the scheme of [19] which can be only first-order accurate in such regions.
4. In the one-dimensional case, the additional parabola is needed only for the accurate recovery of the point-values. In the two-dimensional framework, however, the equivalent additional parabola will be required also for the accurate reconstruction of the fractional cell-averages.

3.2. A two-dimensional extension. We extend the ideas of section 3.1 to the two-dimensional framework. This extension is straightforward and is based on reconstructing an interpolant as a convex combination of four one-sided, piecewise-linear interpolants, and a centered, quadratic interpolant, in order to get the desired third-order accuracy in smooth regions.

Following these ideas, the reconstruction in the cell I_{ij}, can be written as

$$P_{i,j}(x,y) = \sum_k w_k^{i,j} P_k^{i,j}(x,y), \qquad k \in \{\mathrm{NE}, \mathrm{NW}, \mathrm{SE}, \mathrm{SW}, \mathrm{C}\}, \tag{3.10}$$

with $\sum_k w_k^{i,j} = 1$, and $w_k^{i,j} \geq 0$. Here, P_{NE}, P_{NW}, P_{SE}, and P_{SW} are the one-sided linear reconstructions, and P_{C} is a centered quadratic reconstruction (see Figure 3.1). As in

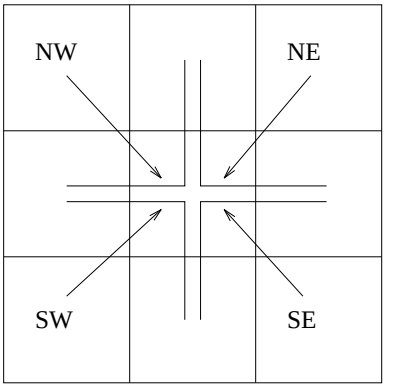

FIG. 3.1. *The two-dimensional stencil.*

the one-dimensional case, we will simplify our notations by omitting the superscripts, remembering that both the weights and the polynomials change from cell to cell.

Clearly, in analogy with the one-dimensional case, (3.3)–(3.4), the four linear reconstructions are given by

$$
\begin{aligned}
P_{\text{NE}}(x,y) &= \bar{u}^n_{i,j} + \frac{\bar{u}^n_{i+1,j} - \bar{u}^n_{i,j}}{\Delta x}(x - x_i) + \frac{\bar{u}^n_{i,j+1} - \bar{u}^n_{i,j}}{\Delta y}(y - y_j),\\
P_{\text{NW}}(x,y) &= \bar{u}^n_{i,j} + \frac{\bar{u}^n_{i,j} - \bar{u}^n_{i-1,j}}{\Delta x}(x - x_i) + \frac{\bar{u}^n_{i,j+1} - \bar{u}^n_{i,j}}{\Delta y}(y - y_j),\\
P_{\text{SW}}(x,y) &= \bar{u}^n_{i,j} + \frac{\bar{u}^n_{i,j} - \bar{u}^n_{i-1,j}}{\Delta x}(x - x_i) + \frac{\bar{u}^n_{i,j} - \bar{u}^n_{i,j-1}}{\Delta y}(y - y_j),\\
P_{\text{SE}}(x,y) &= \bar{u}^n_{i,j} + \frac{\bar{u}^n_{i+1,j} - \bar{u}^n_{i,j}}{\Delta x}(x - x_i) + \frac{\bar{u}^n_{i,j} - \bar{u}^n_{i,j-1}}{\Delta y}(y - y_j).
\end{aligned}
\tag{3.11}
$$

The centered polynomial, $P_{\text{C}}(x,y)$, is taken such as to satisfy

$$
P_{\text{OPT}}(x,y) = \sum_k C_k P_k(x,y), \quad \sum_k C_k = 1, \qquad k \in \{\text{NE}, \text{NW}, \text{SE}, \text{SW}, \text{C}\}.
\tag{3.12}
$$

Here, P_{OPT} is the quadratic polynomial based on a nine-point stencil, centered around $I_{i,j}$, which is given by (see [12])

$$
\begin{aligned}
P_{\text{OPT}}(x,y) = {} & u^n_{i,j} + u'_{i,j}(x - x_i) + u^{\backslash}_{i,j}(y - y_j) + u^{\wedge}_{i,j}(x - x_i)(y - y_j)\\
& + \frac{1}{2}u''_{i,j}(x - x_i)^2 + \frac{1}{2}u^{\prime\prime}_{i,j}(y - y_j)^2,
\end{aligned}
\tag{3.13}
$$

where

$$
\begin{aligned}
u^n_{i,j} &= \bar{u}_{i,j} - \frac{1}{24}\left((\Delta x)^2 u''_{i,j} + (\Delta y)^2 u^{\prime\prime}_{i,j}\right),\\
u'_{i,j} &= \frac{\bar{u}^n_{i+1,j} - \bar{u}^n_{i-1,j}}{2\Delta x}, \qquad u^{\backslash}_{i,j} = \frac{\bar{u}^n_{i,j+1} - \bar{u}^n_{i,j-1}}{2\Delta y},\\
u''_{i,j} &= \frac{\bar{u}^n_{i+1,j} - 2\bar{u}^n_{i,j} + \bar{u}^n_{i-1,j}}{\Delta x^2}, \qquad u^{\prime\prime}_{i,j} = \frac{\bar{u}^n_{i,j+1} - 2\bar{u}^n_{i,j} + \bar{u}^n_{i,j-1}}{\Delta y^2},\\
u^{\wedge}_{i,j} &= \frac{\bar{u}^n_{i+1,j+1} + \bar{u}^n_{i-1,j-1} - \bar{u}^n_{i+1,j-1} - \bar{u}^n_{i-1,j+1}}{4\Delta x \Delta y}.
\end{aligned}
\tag{3.14}
$$

Unlike the one-dimensional case, not every symmetric selection of the constants C_ks will provide a third-order reconstruction for the quarter cell-averages. Here, a straightforward computation shows that in order to satisfy the accuracy requirements, we must take $C_{\rm NE} = C_{\rm NW} = C_{\rm SW} = C_{\rm SE} = 1/8$. Hence, $C_{\rm C} = 1/2$, and (3.12) implies

$$\begin{aligned} P_{\rm C}(x,y) &= 2P_{\rm OPT}(x,y) - \frac{1}{4}\Big[P_{\rm NE}(x,y) + P_{\rm NW}(x,y) + P_{\rm SW}(x,y) + P_{\rm SE}(x,y)\Big] \\ &= u^n_{i,j} + u'_{i,j}(x-x_i) + u^{\backprime}_{i,j}(y-y_j) + 2u^{\wedge}_{i,j}(x-x_i)(y-y_j) \\ &\quad + u''_{i,j}(x-x_i)^2 + u^{\backprime\backprime}_{i,j}(y-y_j)^2, \end{aligned} \tag{3.15}$$

where for this formula

$$u^n_{i,j} = \bar{u}^n_{i,j} - \frac{1}{12}\Big[(\Delta x)^2 u''_{i,j} + (\Delta y)^2 u^{\backprime\backprime}_{i,j}\Big].$$

All that remains is to determine the weights $w^{i,j}_k$ in (3.10). Once again, we write

$$w^{i,j}_k = \frac{\alpha^{i,j}_k}{\sum_l \alpha^{i,j}_l}, \qquad \alpha^{i,j}_k = \frac{C^{i,j}_k}{(\varepsilon + IS^{i,j}_k)^p}, \qquad k,l \in \{{\rm NE}, {\rm NW}, {\rm SE}, {\rm SW}, {\rm C}\}.$$

The constants C_k are the same constants that were used to reconstruct the centered parabola in (3.12). The constants ε and p play the same role as in the one-dimensional case. At this point, to simplify the notations we assume that the mesh spacings are equal in the x and y directions, i.e., $\Delta x = \Delta y = h$. We can then follow [15] and define the smoothness indicators, $IS^{i,j}_k$, as

(3.16)

$$IS^{i,j}_k = \sum_{|\alpha|=1,2} \int_{x_{i-h/2}}^{x_{i+h/2}} \int_{y_{j-h/2}}^{y_{j+h/2}} h^{2(|\alpha|-1)} (D^\alpha P_k)^2, \qquad k \in \{{\rm NE}, {\rm NW}, {\rm SE}, {\rm SW}, {\rm C}\}.$$

If $\Delta x \neq \Delta y$, then only a trivial enhancement to (3.16) is required. For the four one-sided linear reconstructions, which can all be written as

$$P_k = \hat{u}_k + \hat{u}'_k(x-x_i) + \hat{u}^{\backprime}_k(y-y_j), \qquad k \in \{{\rm NE}, {\rm NW}, {\rm SE}, {\rm SW}\},$$

with suitable reconstructed point-values and first derivatives, a direct computation of (3.16) results with

$$IS_k = h^2[(\hat{u}')^2 + (\hat{u}^{\backprime})^2]. \tag{3.17}$$

The centered smoothness indicator, $IS_{\rm C}$, which corresponds to the centered quadratic reconstruction, $P_c(x,y)$, (3.15), is given by

$$IS_{\rm C} = h^2\left[(u')^2 + (u^{\backprime})^2\right] + \frac{h^4}{3}\left[13(u'')^2 + 14(u^{\wedge})^2 + 13(u^{\backprime\backprime})^2\right]$$

(the discrete derivatives are given by (3.14)).

3.3. A note on systems. Almost nothing changes when turning to deal with systems. The reconstruction that was described in the previous sections directly transforms to systems and is performed componentwise. The only relatively subtle issue is the computation of the smoothness indicators.

In our previous work [13], we have suggested several approaches for the computation of the smoothness indicators. Three different options were suggested: the first is to allow every component to have a strictly individual behavior, namely, to allow a different stencil with different smoothness indicators to each component. In the second approach, we designed *global smoothness indicators* such as to force every component to adjust even when the discontinuity is in a different component. The last approach was to use external information about the system. For example, in the Euler equations of gas dynamics, one expects both shocks and contact discontinuities to occur in the density. Hence, all stencils can be tuned according to this component.

Our results in [13] showed that the best approach is the one which was based on the *global smoothness indicators*. It requires no additional information on the system, it produced less oscillatory results compared with the individual smoothness indicators for each component, and it was the simplest to implement.

In the one-dimensional case, e.g., the global smoothness indicators are given by (compare with (3.8))

$$IS_k = \frac{1}{d}\sum_{r=1}^{d}\frac{1}{\|\bar{u}_r\|_2}\left(\sum_{l=1}^{2}\int_{x_{j-1/2}}^{x_{j+1/2}} h^{2l-1}\left(P_{k,r}^{(l)}\right)^2\,dx\right), \quad k\in\{\text{L},\text{C},\text{R}\}. \tag{3.18}$$

Here the kth polynomial in the rth component is denoted by $P_{k,r}$, and d is the number of equations. The scaling factor $\|\bar{u}_r\|_2$ is defined as the L^2 norm of the cell-averages of the rth component of u,

$$\|\bar{u}_r\|_2 = \left(\sum_{\text{all } j}|\bar{u}_{j,r}|^2 h\right)^{1/2}.$$

The numerical examples performed for systems, appearing in section 4, were carried out with the global smoothness indicators.

4. Examples. We present numerical tests in one and two space dimensions, in which we demonstrate the accuracy, robustness, and high-resolution properties of our new method.

Following our previous works [2], [13], [15], and [16], in all our numerical examples we integrate in time using a two-step RK method with natural continuous extension, which was presented in [26], with a fixed time step.

The time step is determined by imposing that the Courant number is a given fraction of the maximum Courant number determined by linear stability analysis. The Courant number is defined by

$$C = \frac{\lambda}{\max_j \rho_j},$$

where ρ_j denotes the spectral radius of the matrix $f'(u_j)$ computed on the initial condition, and $\lambda = \Delta t/\Delta x$ is the mesh ratio.

The linear stability analysis carried out in [3] yields a Courant number $C = 3/7$ for the one-dimensional case. We remark that the stencil used in [3] was different than

the one that we use, and therefore linear stability should be repeated for the compact scheme in order to obtain a sharp estimate on the maximum Courant number.

Example 1: *Accuracy tests.* Our first example checks the accuracy of our new method in several one- and two-dimensional test cases. In all of the one-dimensional tables, the norms of the errors are given by

$$\begin{aligned} L^1 - \text{error}: &\quad ||\text{Error}||_1 = \textstyle\sum_{j=1}^{N} |u(x_j, t^n) - u_j^n| h, \\ L^\infty - \text{error}: &\quad ||\text{Error}||_\infty = \max_{1 \le j \le N} |u(x_j, t^n) - u_j^n|. \end{aligned}$$

Analogous expressions hold for the two-dimensional norms.

1. *Linear advection:* This test estimates the convergence rate at large times. We solve $u_t + u_x = 0$, subject to the initial data $u(x, t=0) = \sin(\pi x)$ and to periodic boundary conditions on $[-1, 1]$. The integration time was taken as $T = 10$.
   In Table 4.1, we show the results obtained for this test problem with $\epsilon = 10^{-2}$. We clearly see a third-order convergence rate in both L^1 and L^∞ norms. We also show in Table 4.2 the results obtained for the same example with $\epsilon = 10^{-4}$. Note that in order to observe high-order accuracy, a higher value of ϵ is required compared to the one used by the purely parabolic reconstruction (see [7] and [13]).
   Compared with Table 4.1, the errors are larger, and the convergence rate is not as regular as before. This is mainly due to the fact that for a very small value of ε, condition (i) is not satisfied until the grid spacing Δx becomes very small. Note that, at variance with CWENO based on piecewise parabolic reconstruction, here a small deviation of the weights from their optimal constant value results in a degradation of the order of accuracy of the reconstruction.
2. *Linear advection with oscillatory data:* This test is used to detect deteriorations of accuracy due to oscillations in the parameters that control the selection of the stencil (for details see [2] and the references therein). Once again, the equation is $u_t + u_x = 0$, subject to the oscillatory initial data $u(x, t=0) = \sin^4(\pi x)$ and to periodic boundary conditions on $[-1, 1]$. Here, the integration time is taken as $T = 1$ and $\epsilon = 10^{-4}$.
   The results of this test are displayed in Table 4.3 and confirm the third-order accuracy of the method with no deteriorations in its accuracy.
3. *Burgers equation:* We solve the Burgers equation $u_t + (0.5u^2)_x = 0$, subject to the initial data $u(x, t=0) = 1 + 0.5\sin(\pi x)$ and to periodic boundary conditions on $[-1, 1]$. The integration time is $T = .33$, and $\epsilon = 10^{-4}$. Here, a shock develops at $T = 2/\pi$. Note that here the maximum speed of propagation is $f'(u) = 3/2$. Thus we use $\lambda = .66 * 3/7 \simeq 2/3\lambda_{\max}$.
   Table 4.4 shows the results we obtained which verify the third-order accuracy of the method also for nonlinear problems.
   The result of the computation for time $T = 1.5$ is shown in Figure 4.1.
4. *Two-dimensional linear advection:* Finally, we implemented our method for the two-dimensional linear advection problem, $u_t + u_x + u_y = 0$. The initial condition is taken as $u(x, t=0) = \sin^2(\pi x)\sin^2(\pi y)$, and we impose periodic boundary conditions on $[0, 1]^2$. The errors and the estimated convergence rate are computed at time $T = 1$.
   In Table 4.5 we present the results obtained when the weights are taken as constants (3.12). Table 4.6 shows the results obtained with the fully nonlinear

TABLE 4.1
Linear advection, $T = 10$, $u_0(x) = \sin(\pi x)$, $\epsilon = 10^{-2}$; *Courant number* $C = 0.9C_{max}$, $C_{max} = 3/7$.

scheme, where the weights of the reconstruction include also the oscillatory indicators. With constant weights our method is third-order as expected, while with nonconstant weights, there seems to be a better convergence rate. A careful study of the tables shows, however, that this better convergence rate is mainly due to larger errors on the coarser grids.

we solve the Euler equations of gas dynamics,

$$\frac{\partial}{\partial t}\begin{pmatrix}\rho\\ m\\ E\end{pmatrix} + \frac{\partial}{\partial x}\begin{pmatrix} m\\ \rho u^2 + p\\ u(E+p)\end{pmatrix} = 0, \qquad p = (\gamma - 1)\cdot\left(E - \frac{\rho}{2}u^2\right),$$

where the variables ρ, u, $m = \rho u$, p, and E denote the density, velocity, momentum,

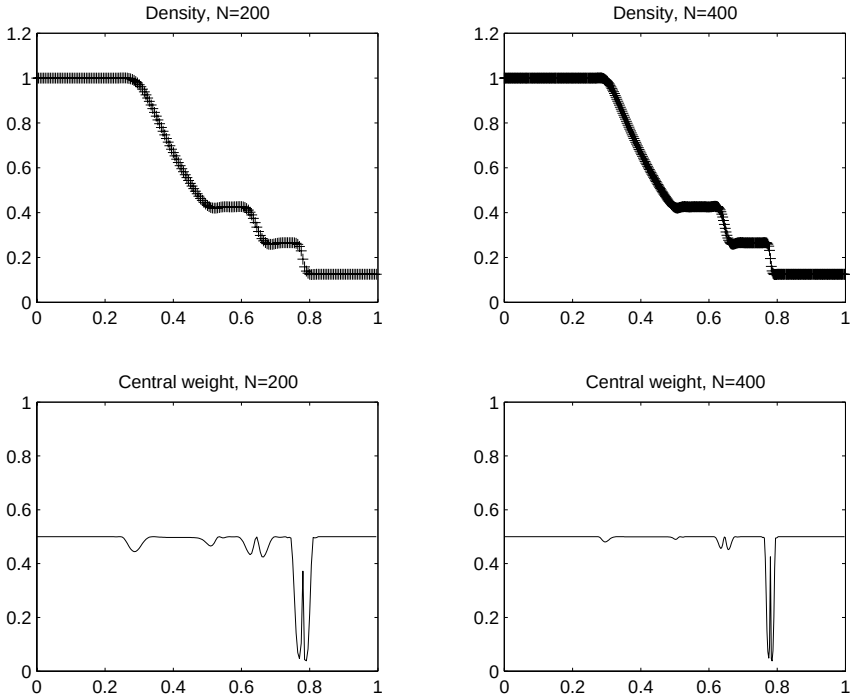

FIG. 4.2. *Euler equations of gas dynamics—Sod's initial data,* $\lambda = 0.1$, $T = 0.16$.

pressure, and total energy, respectively. We use two sets of initial data:

1. Shock tube problem with Sod's initial data [24],

$$\begin{cases} (\rho_l, m_l, E_l) = (1, 0, 2.5), & x < 0.5, \\ (\rho_r, m_r, E_r) = (0.125, 0, 0.25), & x > 0.5. \end{cases}$$

2. Shock tube problem with Lax's initial data [9],

$$\begin{cases} (\rho_l, m_l, E_l) = (0.445, 0.311, 8.928), & x < 0.5, \\ (\rho_r, m_r, E_r) = (0.5, 0, 1.4275), & x > 0.5. \end{cases}$$

We integrate the equations up to time $T = 0.16$, using $\epsilon = 10^{-4}$. In Figure 4.2 we show the density components for Sod's initial data, and in Figure 4.3 we show the equivalent plot for Lax's initial data. In both figures we also present the weight of the central stencil at the final time. All the results are given for 200 and 400 grid points. Following [20], we pick $\lambda = .1$. Note that the maximum characteristic speed for Sod's problem is roughly 2.5, while for the Lax problem the maximum propagation speed is $\simeq 5$. Since our scheme has a Courant number no larger than .5, we see that $\lambda = .1$ is actually the maximum value compatible with stability.

It is interesting to compare the behavior of the central weight of the new method to the behavior of the central weight of the original CWENO method [13]. Here, the weights are much smoother compared with the weights in [13]. The accuracy and stability properties of the method can be related to the smoothness of the nonlinear weights involved (see [2]).

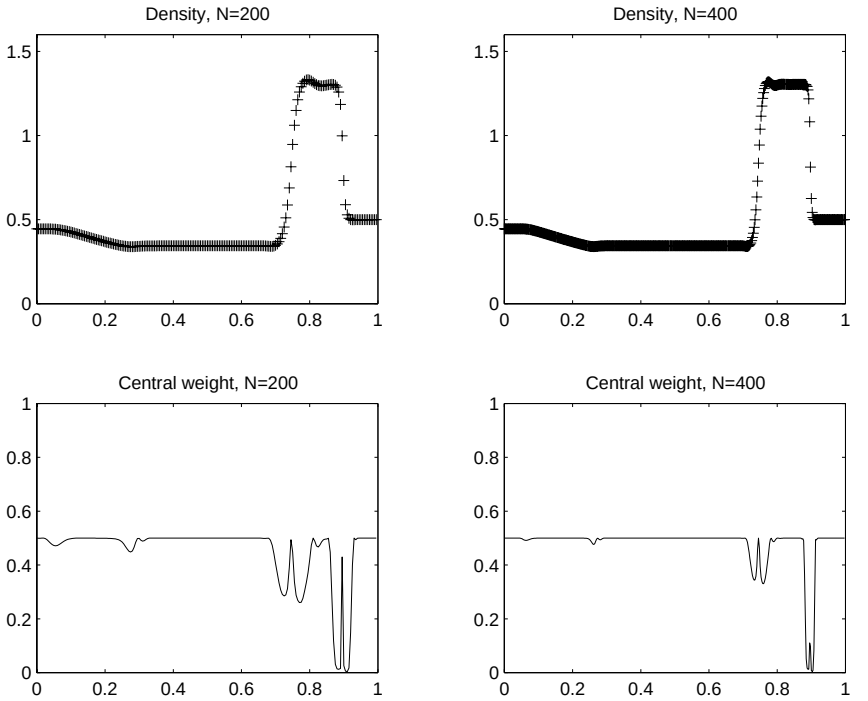

FIG. 4.3. *Euler equations of gas dynamics—Lax's initial data,* $\lambda = 0.1$, $T = 0.16$.

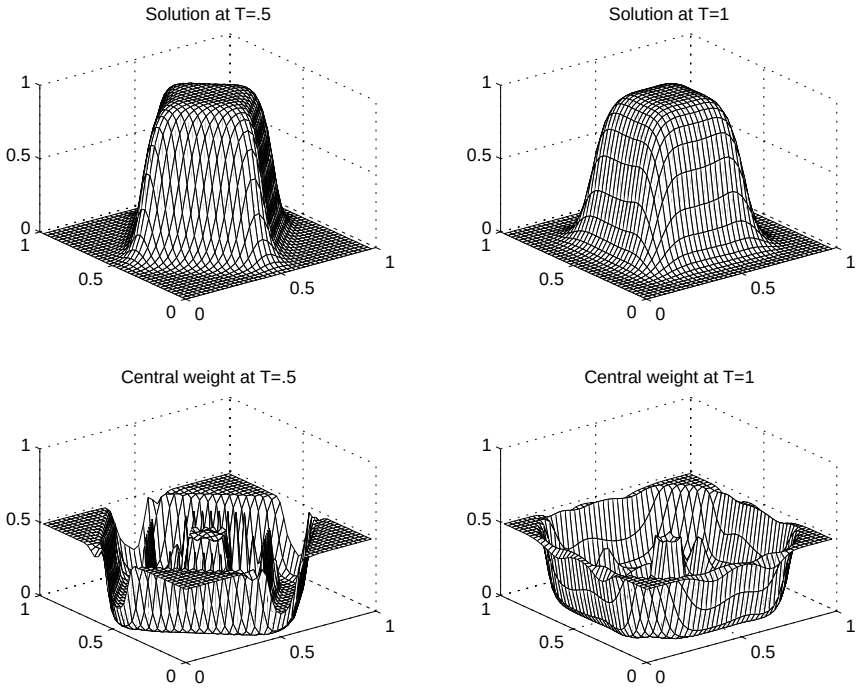

FIG. 4.4. *Linear rotation,* $\lambda = 0.425$, $N = 40$.

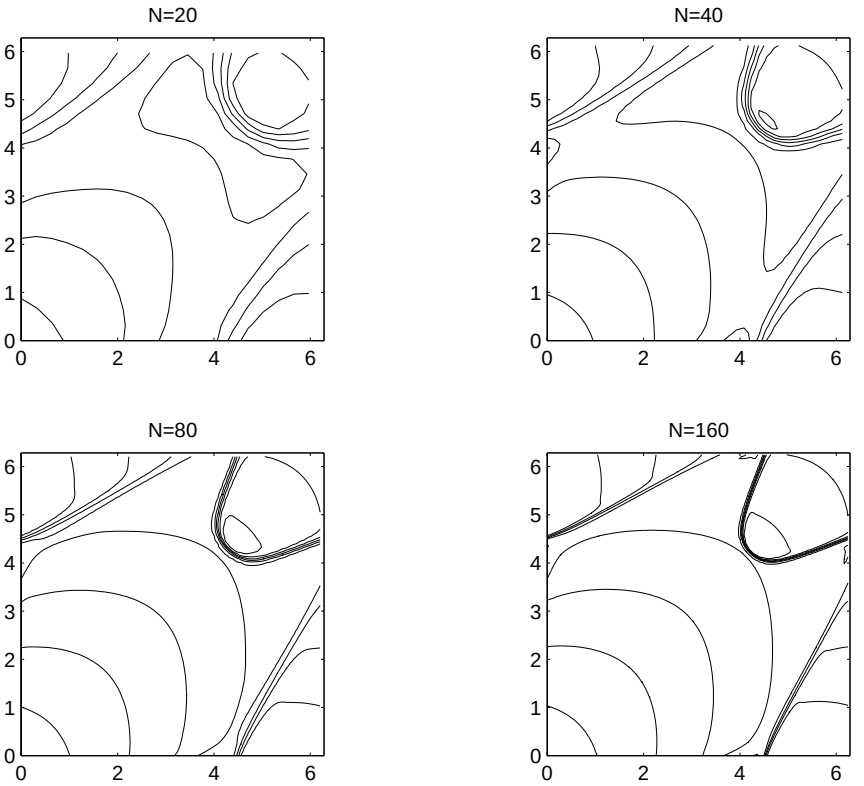

FIG. 4.5. *Two-dimensional Burgers equation,* $\lambda = 0.425$, $T = 1.5$.

Example 3*: Two-dimensional problems.*

1. *Linear rotation:* Following [15], we consider a linear rotation of a square patch on $[0,1]^2$, with initial condition $u_0(x,y) = 1$ for $\{|x - 1/2| \leq 1/2\} \times \{|y - 1/2| \leq 1/2\}$ and zero elsewhere. In Figure 4.4 we display the solution after a rotation of $\pi/4$ and of $\pi/2$. As before, the value of ϵ is taken as 10^{-4}. There are no spurious oscillations. We also show the corresponding central weight. As expected, this weight is zero in regions where the solution has steep gradients, and that is exactly the property that prevents spurious oscillations from developing. Even though we are dealing with linear waves, the resulting resolution is relatively good. Due to the compactness of the stencil, when the slopes are not sharp, they are not identified as discontinuities. This can be observed in the plots of the central weight, which returns to its constant value (1/2) on the slope.
2. *Two-dimensional—Burgers equation:* We end by solving the two-dimensional Burgers equation, $u_t + (u^2/2)_x + (u^2/2)_y = 0$, subject to the initial data $u(x, t = 0) = \sin^2(\pi x)\sin^2(\pi y)$ and periodic boundary conditions on $[0,1]^2$. Here also $\epsilon = 10^{-4}$. In Figure 4.5 we present the solution obtained at time $T = 1.5$ with different mesh spacings. One can easily notice that the shocks are well resolved and there are no spurious oscillations.

CONSTRUCTION AND ANALYSIS OF OPTIMAL HIERARCHIC MODELS OF BOUNDARY VALUE PROBLEMS ON THIN CIRCULAR AND SPHERICAL GEOMETRIES*

MARK AINSWORTH† AND MARK ARNOLD‡

Abstract. A sequence of optimal hierarchic models is derived for stationary heat conduction on the following laminated domains: a flat plate, a circular arch, and a spherical shell. An a priori bound is presented, which is evaluated explicitly in the homogeneous case on each domain. Computational examples are given, which illustrate the theoretical results. Furthermore, in the case of a spherical shell, the hierarchic models are compared numerically to models obtained using polynomial approximation in the radial direction, and it is found that the hierarchic models are both more accurate than the polynomial ones and provide more robust convergence with respect to the shell thickness.

Key words. hierarchic models, thin domains, dimensional reduction

1. Introduction.

Dimensional reduction of boundary value problems posed on thin domains has a long history in the mathematical modelling of physical problems, as illustrated, for instance, in [12, 15]. Traditionally, the derivation of the models is based on physical intuition and practical experience, with little attention paid to bounding the accuracy of the resulting models. Hierarchic modelling [27, 28] provides an effective and systematic framework for modelling problems on thin domains by reducing the dimension of the resulting boundary value problem. Original work was carried out in this area by Vogelius and Babuska [27, 28] for stationary heat conduction on flat, laminated plates. They derived a sequence of models, each capturing more modes of variation in the thickness of the plate of the true solution, designed to be optimally accurate when the thickness of the plate was small. In [27], a priori error bounds were derived giving the order of accuracy as the thickness of the plate tends to zero. This work has been subsequently applied to several areas; in particular, hierarchic models of thin domains have been derived for nonlinear problems [13, 14], elasticity [8, 22], Stokes flow [6], and Helmholtz equations [5, 17, 18]. For an overview of hierarchic modelling of thin domains, see [22] and the references therein.

The treatment of flat plates is well understood thanks to the efforts of [27, 28]. One notable feature of this work is the realization that the selection of the functions to be used in constructing the dimensionally reduced models has a significant impact on the accuracy of the reduced model. However, for curved geometries such as circular arches and spherical shells, most practitioners have based the models on a family of polynomial functions in the radial direction. In particular, we mention the work of Cho and Oden [7, 8] in the context of linear elastic shells, Shen [23, 24] for Helmholtz's equation on polar and cylindrical geometries, and Surana and Abusaleh [25] and

Surana and Bose [26]. The results presented in these sources show the efficiency of basing models on the use of polynomials. Here, we adopt a different approach, more akin to the original investigations of Vogelius and Babuska [27, 28] and attempt to obtain the optimal family of dimensionally reduced models. It is found that the optimal family of functions depends on the thickness of the domain in a nontrivial manner. This renders the derivation of a priori error bounds more difficult since the dependence of the optimal family on the thickness means that certain constants now depend on the thickness. An approach is presented that allows the constants to be computed *explicitly*, and furthermore, the analysis makes no assumptions on the thickness being small. A by-product of the analysis is sharper bounds for the flat plates already analyzed in [27, 28], along with sharp new results for circular arches and spherical shells that have not been studied hitherto.

Numerical examples are presented, supporting and verifying the theory. It is also shown that the computational cost associated with using the optimal models is essentially identical to the cost of simply using polynomials. However, numerical evidence is presented showing that the accuracy of the optimal models can be orders of magnitude superior to the simple polynomial based models. The numerical results also indicate that the optimal family is significantly more robust in the case when the domains are relatively thick.

1.1. Dimensional reduction on a spherical shell. Consider the steady state temperature distribution $u(r,\boldsymbol{\theta})$, where $\boldsymbol{\theta}=(\theta,\phi)$, in a thin spherical cap of average radius $R>0$:

$$\Omega=\{(r,\boldsymbol{\theta}):(1-\epsilon)R<r<(1+\epsilon)R,\boldsymbol{\theta}\in\omega\}\,,$$

where ω is a simply-connected portion of the surface of a sphere, with Lipschitz boundary $\partial\omega$. The physical principles determining the temperature distribution are as follows.

1. Conservation of energy:

$$\boldsymbol{\nabla}\cdot\boldsymbol{q}=0 \text{ in } \Omega, \tag{1}$$

where $\boldsymbol{q}=\boldsymbol{q}(r,\boldsymbol{\theta})$ is the heat flux.

2. Constitutive equation (Fourier's law):

$$\boldsymbol{q}=-\mathcal{K}\boldsymbol{\nabla}u \text{ in } \Omega, \tag{2}$$

where $\mathcal{K}$ is the thermal conductivity tensor.

3. Boundary conditions.

(a) Prescribed heat fluxes on top and bottom surfaces:

$$\pm\hat{\boldsymbol{e}}_r\cdot\boldsymbol{q}=-f^{\pm}(\boldsymbol{\theta}) \text{ on } \Omega_{\pm}, \tag{3}$$

where

$$\Omega_{\pm}=\{(r,\boldsymbol{\theta})\in\Omega:r=(1\pm\epsilon)R\}$$

and $\hat{\boldsymbol{e}}_r$ is the unit vector in the radial direction.

(b) Prescribed temperature:

$$u=0 \text{ on } \Gamma, \tag{4}$$

where Γ is the lateral boundary

$$\Gamma=\{(r,\boldsymbol{\theta}):(1-\epsilon)R<r<(1+\epsilon)R,\boldsymbol{\theta}\in\partial\omega\}\,.$$

For the geometry of the sphere, the following relations assume the particular form.

1. Conservation of energy:

$$\frac{1}{r^2}\frac{\partial}{\partial r}(r^2 q_r) + \frac{1}{r}\bar{\boldsymbol{\nabla}}' \cdot \boldsymbol{q}' = 0, \tag{5}$$

where the heat flux is written as

$$\boldsymbol{q} = \boldsymbol{q}' + q_r \hat{\boldsymbol{e}}_r; \boldsymbol{q}' = q_\theta \hat{\boldsymbol{e}}_\theta + q_\phi \hat{\boldsymbol{e}}_\phi$$

and the divergence operator on the surface of the unit sphere is given by

$$\bar{\boldsymbol{\nabla}}' \cdot \boldsymbol{q}' = \frac{1}{\sin\theta}\frac{\partial}{\partial\theta}\sin\theta q_\theta + \frac{1}{\sin\theta}\frac{\partial}{\partial\phi}q_\phi. \tag{6}$$

2. Constitutive relation: The conductivity tensor is assumed to have the form

$$\boldsymbol{q}' = -k_1\left(\frac{r-R}{\epsilon R}\right)\mathcal{K}'(\boldsymbol{\theta})\frac{1}{r}\bar{\boldsymbol{\nabla}}' u, \tag{7}$$

$$q_r = -k_2\left(\frac{r-R}{\epsilon R}\right)\frac{\partial u}{\partial r}, \tag{8}$$

where

$$\bar{\boldsymbol{\nabla}}' u = \frac{\partial u}{\partial\theta}\hat{\boldsymbol{e}}_\theta + \frac{1}{\sin\theta}\frac{\partial u}{\partial\phi}\hat{\boldsymbol{e}}_\phi. \tag{9}$$

The determination of the true solution of the boundary value problem represented by (1)–(4) generally entails a considerable degree of complexity, especially if the domain is of laminated construction, meaning that the coefficients k_1, k_2 are only piecewise continuous. Typically, one must resort to an approximate numerical method to obtain a sufficiently accurate solution. However, if the domain is very thin ($\epsilon \ll 1$), then one experiences difficulties even with a numerical approach owing to the anisotropy of the domain.

A standard approach to such problems posed on thin domains consists of replacing the full (three-)dimensional problem by a dimensionally reduced model posed in fewer (two) dimensions over the mid-surface ω. The dimensionally reduced model is generally an elliptic system (rather than a scalar problem) with the unknowns corresponding to weighted averages of the true solution u through the thickness. The equations satisfied by the averages derive from the physical model (1)–(4) as follows.

Let $\psi \in L^\infty(-1,1)$ be a given function to be selected later and consider a weighted average of the solution u_ψ defined by

$$u_\psi(\boldsymbol{\theta}) = \int_{(1-\epsilon)R}^{(1+\epsilon)R} \psi\left(\frac{r-R}{\epsilon R}\right) k_1\left(\frac{r-R}{\epsilon R}\right) u(r,\boldsymbol{\theta})\, dr.$$

It then follows that

$$\mathcal{K}'(\boldsymbol{\theta})\bar{\boldsymbol{\nabla}}' u_\psi(\boldsymbol{\theta}) = \mathcal{K}'(\boldsymbol{\theta})\int_{(1-\epsilon)R}^{(1+\epsilon)R} \psi\left(\frac{r-R}{\epsilon R}\right) k_1\left(\frac{r-R}{\epsilon R}\right)\bar{\boldsymbol{\nabla}}' u\, dr$$

and applying the constitutive relation (7) leads to

$$\mathcal{K}'(\boldsymbol{\theta})\bar{\boldsymbol{\nabla}}' u_\psi(\boldsymbol{\theta}) = -\int_{(1-\epsilon)R}^{(1+\epsilon)R} \psi\left(\frac{r-R}{\epsilon R}\right)\boldsymbol{q}'(r,\boldsymbol{\theta}) r dr.$$

Consequently,

$$-\bar{\boldsymbol{\nabla}}' \cdot \left(\mathcal{K}'(\boldsymbol{\theta}) \bar{\boldsymbol{\nabla}}' u_\psi(\boldsymbol{\theta}) \right) = \int_{(1-\epsilon)R}^{(1+\epsilon)R} \psi\left(\frac{r-R}{\epsilon R} \right) \bar{\boldsymbol{\nabla}}' \cdot \boldsymbol{q}'(r, \boldsymbol{\theta}) r dr$$

and by conservation of energy (5), one obtains

$$\bar{\boldsymbol{\nabla}}' \cdot \left(\mathcal{K}'(\boldsymbol{\theta}) \bar{\boldsymbol{\nabla}}' u_\psi(\boldsymbol{\theta}) \right) = \int_{(1-\epsilon)R}^{(1+\epsilon)R} \psi\left(\frac{r-R}{\epsilon R} \right) \frac{\partial}{\partial r}(r^2 q_r) dr.$$

Integrating by parts and inserting the boundary conditions (3) reveals that

$$\begin{aligned} -\bar{\boldsymbol{\nabla}}' \cdot \left(\mathcal{K}'(\boldsymbol{\theta}) \bar{\boldsymbol{\nabla}}' u_\psi(\boldsymbol{\theta}) \right) &= (1+\epsilon)^2 R^2 \psi(1) f^+(\boldsymbol{\theta}) + (1-\epsilon)^2 R^2 \psi(-1) f^-(\boldsymbol{\theta}) \\ &\quad + \frac{1}{\epsilon R} \int_{(1-\epsilon)R}^{(1+\epsilon)R} \psi'\left(\frac{r-R}{\epsilon R} \right) r^2 q_r dr, \end{aligned}$$

where $\psi' = d\psi(s)/ds$. The constitutive relation (8) allows the final term to be rewritten as

$$-\frac{1}{\epsilon R} \int_{(1-\epsilon)R}^{(1+\epsilon)R} \psi'\left(\frac{r-R}{\epsilon R} \right) k_2\left(\frac{r-R}{\epsilon R} \right) \frac{\partial u}{\partial r} r^2 dr.$$

In conclusion, we have shown that the average u_ψ satisfies

$$\begin{aligned} -\bar{\boldsymbol{\nabla}}' \cdot \left(\mathcal{K}' \bar{\boldsymbol{\nabla}}' u_\psi(\boldsymbol{\theta}) \right) + \frac{1}{\epsilon R} \int_{(1-\epsilon)R}^{(1+\epsilon)R} \psi'\left(\frac{r-R}{\epsilon R} \right) k_2\left(\frac{r-R}{\epsilon R} \right) \frac{\partial u}{\partial r} r^2 dr \\ = R \left[\psi(1) f_\epsilon^+(\boldsymbol{\theta}) + \psi(-1) f_\epsilon^-(\boldsymbol{\theta}) \right], \end{aligned} \tag{10}$$

where

$$f_\epsilon^\pm = R(1 \pm \epsilon)^2 f^\pm.$$

Obviously, the boundary condition (4) implies that

$$u_\psi = 0 \text{ on } \partial\omega. \tag{11}$$

1.2. Simplest reduced model. The simplest dimensionally reduced model consists of selecting ψ to be a constant function, e.g., $\psi \equiv 1$. In this case, (10) reduces to the single scalar equation for $\alpha_0(\boldsymbol{\theta})$:

$$-\bar{\boldsymbol{\nabla}}' \cdot \left(\mathcal{K}' \bar{\boldsymbol{\nabla}}' \alpha_0 \right) = R(f_\epsilon^+(\boldsymbol{\theta}) + f_\epsilon^-(\boldsymbol{\theta})) \text{ in } \omega \tag{12}$$

subject to $\alpha_0 = 0$ on $\partial\omega$, where α_0 denotes the average

$$\alpha_0(\boldsymbol{\theta}) = u_\psi(\boldsymbol{\theta}) = \int_{(1-\epsilon)R}^{(1+\epsilon)R} k_1\left(\frac{r-R}{\epsilon R} \right) u(r, \boldsymbol{\theta}) dr.$$

Obviously, one is particularly interested in the accuracy of this dimensionally reduced model approximating the original full three-dimensional model. In [3] it was shown that, for $\epsilon \ll 1$, the error $e = u - \alpha_0$ is bounded by

$$\begin{aligned} |||e|||^2 \le \frac{2}{3}\epsilon \int_\omega R \sin\theta (f^e(\boldsymbol{\theta}))^2 d\theta d\phi \\ + 2\epsilon \int_\omega R \sin\theta (f^o(\boldsymbol{\theta}))^2 d\theta d\phi, \end{aligned} \tag{13}$$

where $D_\epsilon = \sqrt{\frac{1-\epsilon}{1+\epsilon}}$,

$$f^e = \frac{1}{2}\left(f_\epsilon^+ + \sqrt{\frac{1+\epsilon}{1-\epsilon}} f_\epsilon^-\right), \quad f^o = \frac{1}{2}\left(f_\epsilon^+ - \sqrt{\frac{1+\epsilon}{1-\epsilon}} f_\epsilon^-\right), \tag{14}$$

and $|||\cdot|||$ denotes the energy norm (defined later). This bound justifies the choice $\psi \equiv 1$ since as the thickness ϵ of the shell approaches 0, the accuracy of the model is improved. However, the question arises of what can be done if the accuracy for a finite ϵ is not acceptable.

1.3. Higher order models. The natural route to obtaining a more sophisticated model consists of including further weighted averages of the true solution in the reduced approximation. Let $\{\psi_l\}_{l=0}^\infty \in L_\infty(-1,1)$ be given functions to be selected later and consider a model based on the weighted averages

$$u_l(\boldsymbol{\theta}) = \int_{(1-\epsilon)R}^{(1+\epsilon)R} \psi_l\left(\frac{r-R}{\epsilon R}\right) k_1\left(\frac{r-R}{\epsilon R}\right) u(r,\boldsymbol{\theta}) dr \ , \ l = 0, \ldots, N.$$

The weighted averages satisfy (10). However, it is worthwhile to consider first how the averages are used to reconstruct an approximation u_N of the solution u of the original three-dimensional problem. The approximation u_N is sought in the form

$$u_N(r,\boldsymbol{\theta}) = \sum_{l=0}^N \alpha_l(\boldsymbol{\theta}) \psi_l\left(\frac{r-R}{\epsilon R}\right), \tag{15}$$

where the coefficients $\{\alpha_l\}_{l=0}^N$ are determined by the condition that u_N satisfy

$$\int_{(1-\epsilon)R}^{(1+\epsilon)R} (u(r,\boldsymbol{\theta}) - u_N(r,\boldsymbol{\theta})) \psi_l\left(\frac{r-R}{\epsilon R}\right) k_1\left(\frac{r-R}{\epsilon R}\right) dr = 0$$

for $l = 0, 1, \ldots, N$. Rearranging these equations leads to the conclusion that

$$\begin{aligned}
&\sum_{l=0}^N \alpha_l(\boldsymbol{\theta}) \int_{(1-\epsilon)R}^{(1+\epsilon)R} \psi_l\left(\frac{r-R}{\epsilon R}\right) \psi_m\left(\frac{r-R}{\epsilon R}\right) k_1\left(\frac{r-R}{\epsilon R}\right) dr \\
&= \int_{(1-\epsilon)R}^{(1+\epsilon)R} \psi_m\left(\frac{r-R}{\epsilon R}\right) k_1\left(\frac{r-R}{\epsilon R}\right) u(r,\boldsymbol{\theta}) dr \\
&= u_{\psi_m}(\boldsymbol{\theta})
\end{aligned}$$

for $m = 0, 1, \ldots, N$. Furthermore, by performing a change of variable, it follows that

$$u_{\psi_m}(\boldsymbol{\theta}) = \epsilon R \sum_{l=0}^N A_{ml} \alpha_l(\boldsymbol{\theta}), \tag{16}$$

where

$$\begin{aligned}
A_{ml} &= \frac{1}{\epsilon R} \int_{(1-\epsilon)R}^{(1+\epsilon)R} k_1\left(\frac{r-R}{\epsilon R}\right) \psi_l\left(\frac{r-R}{\epsilon R}\right) \psi_m\left(\frac{r-R}{\epsilon R}\right) dr \\
&= \int_{-1}^1 k_1(z) \psi_m(z) \psi_l(z) dz.
\end{aligned}$$

If the functions $\{\psi_l\}_{l=0}^N$ are linearly independent, then the matrix $\boldsymbol{A}$ is symmetric and positive definite since the coefficient k_1 is nonnegative.

Thanks to (15)–(16), it is possible to dispense with the weighted averages $\{u_{\psi_m}\}_{m=0}^N$ entirely and instead work with the coefficients $\{\alpha_l\}_{l=0}^N$ directly. In fact, inserting (15)–(16) into (10) leads to an elliptic system for the unknown functions $\{\alpha_l\}_{l=0}^N$:

$$-\epsilon R\bar{\boldsymbol{\nabla}}'\cdot\left(\mathcal{K}'\boldsymbol{A}\bar{\boldsymbol{\nabla}}'\boldsymbol{\alpha}\right)+\frac{1}{\epsilon R}\boldsymbol{B}\boldsymbol{\alpha}=\boldsymbol{f}_\epsilon, \tag{17}$$

where $\boldsymbol{B}$ is the matrix with entries

$$\begin{aligned}B_{ml}&=\int_{(1-\epsilon)R}^{(1+\epsilon)R}k_2\left(\frac{r-R}{\epsilon R}\right)\psi_m'\left(\frac{r-R}{\epsilon R}\right)\psi_l'\left(\frac{r-R}{\epsilon R}\right)r^2dr\\&=\int_{-1}^{1}k_2(z)\psi_m'(z)\psi_l'(z)(1+\epsilon z)^2dz\end{aligned}$$

and $\boldsymbol{f}_\epsilon$ is the load vector with entries

$$[\boldsymbol{f}_\epsilon]_m=R\left[\psi_m(1)f_\epsilon^+(\boldsymbol{\theta})+\psi_m(-1)f_\epsilon^-(\boldsymbol{\theta})\right].$$

The boundary condition $\boldsymbol{\alpha}=\boldsymbol{0}$ on $\partial\omega$ follows in a similar fashion from (11).

The coefficients are uniquely determined as the solution of the elliptic system (17) once the functions $\{\psi_l\}_{l=0}^N$ to be used in the weighted averages have been chosen. The purpose of the present work is as follows:

1. to determine a principle for the selection of the functions $\{\psi_l\}_{l=0}^N$ that are optimal in a certain sense,
2. to develop explicit a priori estimates for the accuracy of the resulting dimensionally reduced model.

2. Dimensional reduction. In the introduction we considered the problem given by (1)–(4) posed on a spherical cap. In our analysis we will consider more generally the physical problem given by (1)–(4) posed on a flat plate and a circular arch. The next section is devoted to presenting a general framework incorporating these cases.

2.1. General framework. The variational form of the problem (1)–(4) for each of the domains under consideration is

$$\text{find } u\in V \text{ such that } B_\epsilon(u,v)=F_\epsilon(v)\ \forall v\in V, \tag{18}$$

where V is the space

$$V=\{v\in H^1(\Omega):v=0 \text{ on } \partial\omega\},$$

and the bilinear form $B_\epsilon(u,v):V\times V\to\mathbb{R}$, and load functional $F_\epsilon(v):V\to\mathbb{R}$ are given for each domain as follows.

1. Flat plate:

$$\begin{aligned}\Omega&=\{(\boldsymbol{x}',z):\boldsymbol{x}'\in\omega,-\epsilon<z<\epsilon\},\\\Omega_\pm&=\{(\boldsymbol{x}',z):z=\pm\epsilon\},\\\Gamma&=\{(\boldsymbol{x}',z):-\epsilon<z<\epsilon,\boldsymbol{x}'\in\omega\},\\B_\epsilon(u,v)&=\int_\omega\int_{-1}^1\left\{\frac{k_2(z)}{\epsilon}\frac{\partial u}{\partial z}\frac{\partial v}{\partial z}+\epsilon k_1(z)\left(\boldsymbol{\nabla}'u\right)^T\mathcal{K}'\boldsymbol{\nabla}'v\right\}dz\,d\boldsymbol{x}',\\F_\epsilon(v)&=\int_\omega d\boldsymbol{x}'(f^+(\boldsymbol{x}')v(\boldsymbol{x}',1)+f^-(\boldsymbol{x}')v(\boldsymbol{x}',-1)),\end{aligned}$$

where

$$\bar{\boldsymbol{\nabla}}' = \frac{\partial}{\partial x}\hat{\boldsymbol{e}}_x + \frac{\partial}{\partial y}\hat{\boldsymbol{e}}_y.$$

2. Circular arch:

$$\Omega = \{(\hat{r}, \theta) : \theta \in \omega, R(1-\epsilon) < \hat{r} < R(1+\epsilon)\};$$

$\Gamma, \Omega_\pm$ are as they are for the spherical shell except that ω is now a section of a circle with end points $\partial\omega$.

$$B_\epsilon(u,v) = \int_\omega \int_{-1}^{1} \left\{ \frac{k_2(r)(1+\epsilon r)}{\epsilon} \frac{\partial u}{\partial r}\frac{\partial v}{\partial r} + \frac{k_1(r)\epsilon}{1+\epsilon r} (\bar{\boldsymbol{\nabla}}' u)^T \mathcal{K}' \bar{\boldsymbol{\nabla}}' v \right\} dr\, d\theta,$$

$$F_\epsilon(v) = \int_\omega R d\theta (f^+(\theta)(1+\epsilon)v(\theta,1) + f^-(\theta)(1-\epsilon)v(\theta,-1)),$$

$$\bar{\boldsymbol{\nabla}}' = \frac{\partial}{\partial\theta}\hat{\boldsymbol{e}}_{\boldsymbol{\theta}}.$$

3. Spherical shell:

$$\Omega = \{(\hat{r}, \theta, \phi) : (\theta, \phi) \in \omega, R(1-\epsilon) < \hat{r} < R(1+\epsilon)\},$$

$$\begin{aligned} B_\epsilon(u,v) = \int_\omega & R\sin(\theta) d\theta d\phi \int_{-1}^{1} dr \\ & \times \left\{ \frac{k_2(r)(1+\epsilon r)^2}{\epsilon} \frac{\partial u}{\partial r}\frac{\partial v}{\partial r} + \epsilon k_1(r) \left(\bar{\boldsymbol{\nabla}}' u\right)^T \mathcal{K}' \left(\bar{\boldsymbol{\nabla}}' v\right) \right\}, \\ F_\epsilon(v) = \int_\omega & R^2 \sin(\theta) d\theta d\phi \\ & \left\{ f^+(\theta,\phi)(1+\epsilon)^2 v(\theta,\phi,1) + f^-(\theta,\phi)(1-\epsilon)^2 v(\theta,\phi,-1) \right\}, \\ \bar{\boldsymbol{\nabla}}' = & \frac{\partial}{\partial\theta}\hat{\boldsymbol{e}}_{\boldsymbol{\theta}} + \frac{1}{\sin\theta}\frac{\partial}{\partial\phi}\hat{\boldsymbol{e}}_{\boldsymbol{\phi}}. \end{aligned}$$

In general, the bilinear form B_ϵ and linear functional F_ϵ are of the form

$$B_\epsilon(u,v) = \int_\omega d\boldsymbol{\theta} \int_{-1}^{1} dr \left\{ \frac{a(1+\epsilon r)}{\epsilon} \frac{\partial u}{\partial r}\frac{\partial v}{\partial r} + \epsilon b(1+\epsilon r) \left(\bar{\boldsymbol{\nabla}}' u\right)^T \mathcal{K}' \bar{\boldsymbol{\nabla}}' v \right\} \tag{19}$$

and

$$F_\epsilon(v) = \int_\omega (f_\epsilon^+(\boldsymbol{\theta}) v(\boldsymbol{\theta}, 1) + f_\epsilon^-(\boldsymbol{\theta}) v(\boldsymbol{\theta}, -1)) d\boldsymbol{\theta}, \tag{20}$$

where $\boldsymbol{\theta}$ represents the mid-surface coordinates for each of the three cases [10]: (x, y) for flat plates, (θ) for circular arches, and (θ, ϕ) for spherical shells; where $f_\epsilon^\pm$ represents $f^\pm$ for plates, $f^\pm R(1 \pm \epsilon)$ for arches, and $f^\pm R(1 \pm \epsilon)^2$ for shells; and where $d\boldsymbol{\theta}$ represents $d\boldsymbol{x}'$ for plates, $d\theta$ arches, and $R\sin(\theta) d\theta d\phi$ for spherical shells.

The energy norm is defined by

$$|||v|||^2 = B_\epsilon(v, v),$$

and a weighted space is defined by

$$L^2_M(\omega) = \{u : \|u\|_{L^2_M(\omega)} < \infty\}$$

and equipped with the norm

$$\|u\|^2_{L^2_M(\omega)} = \int_\omega M(\boldsymbol{\theta})|u(\boldsymbol{\theta})|^2 d\boldsymbol{\theta},$$

where, in the cases of the circular arch and flat plate, the weight $M(\boldsymbol{\theta}) \equiv 1$, while for spherical shells $M(\boldsymbol{\theta}) = R\sin\theta$.

2.2. Simple dimensionally reduced models. In [3], the accuracy of the simplest dimensionally reduced model was studied in detail. The dimensionally reduced problem for the unknown coefficient function $\alpha_0(\boldsymbol{\theta})$, obtained for spherical shells in (12), is similar in the case of circular arches and flat plates [3]:

$$\begin{aligned} -2\epsilon\bar{b}\bar{\boldsymbol{\nabla}}' \cdot \left(\mathcal{K}'\bar{\boldsymbol{\nabla}}'\alpha_0\right) &= f^+_\epsilon + f^-_\epsilon \text{ in } \omega, \\ \alpha_0 &= 0 \text{ on } \partial\omega, \end{aligned}$$

where

$$\bar{b} = \frac{1}{2}\int_{-1}^{1} k_1(z)dz.$$

The error in the simple dimensionally reduced models is bounded in each case by the following.

1. Homogeneous flat plate [2, 4]:

$$|||e|||^2 \le \frac{\epsilon}{6}\|f^+ + f^-\|^2_{L^2_M(\omega)} + \frac{\epsilon}{2}\|f^+ - f^-\|^2_{L^2_M(\omega)}.$$

2. Homogeneous circular arch (Theorem 3.2 in [3]):

$$|||e|||^2 \le \frac{1}{12}\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)\|f^+_\epsilon + f^-_\epsilon\|^2_{L^2_M(\omega)} + \frac{1}{4}\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)\|f^+_\epsilon - f^-_\epsilon\|^2_{L^2_M(\omega)}.$$

3. Homogeneous spherical shell (Theorem 3.4 in [3]):

$$\begin{aligned} |||e|||^2 \le \epsilon &\left(-\frac{1}{\epsilon^3}\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)(D_\epsilon - \epsilon + 1) + \frac{1}{\epsilon^2}(D_\epsilon + 1)^2\right)\|f^e\|^2_{L^2_M(\omega)} \\ +\epsilon &\left(\frac{1}{\epsilon^3}\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)(D_\epsilon + \epsilon - 1) + \frac{1}{\epsilon^2}(D_\epsilon - 1)^2\right)\|f^o\|^2_{L^2_M(\omega)}, \end{aligned}$$

which leads to the result already quoted in (13) since the terms in parentheses tend to 2/3 and 2 as $\epsilon \to 0$.

These bounds show that, in general, as the thickness of the domain becomes small ($\epsilon \to 0$), the accuracy of the simple models derived under the assumption $u \approx u_0$ is improved. However, it is worth bearing in mind that the bounds are valid for all ϵ, not necessarily small.

A key step [3] in developing these bounds consists of a representation for the error $B(u - u_0, v)$ in terms of Peano-type kernels: K^e_0, K^o_0,

$$B(u - u_0, v) = \int_\omega d\boldsymbol{\theta}\int_{-1}^{1} dr\,(f^e(\boldsymbol{\theta})K^e_0(r) + f^o(\boldsymbol{\theta})K^o_0(r))\,\frac{\partial v}{\partial r}, \tag{21}$$

where K_0^e, K_0^o satisfy the orthogonality condition

$$\int_{-1}^{1} \frac{1}{a} K_0^e K_0^o dr = 0.$$

Here, and in what follows, we work exclusively with the scaled bilinear form and omit the subscript ϵ on $B(u,v)$ and $F(v)$. The particular form of the kernels for homogeneous materials, $k_1 = k_2 = 1$, along with the corresponding data f^e, f^o, are given in each case by the following.

1. Flat plates:

$$K_0^e = z; K_0^o = 1,$$
$$f^e = \frac{1}{2}(f^+ + f^-); f^o = \frac{1}{2}(f^+ - f^-). \tag{22}$$

2. Circular arches:

$$K_0^e = \frac{1}{\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)} \left(2\ln\left(\frac{1+\epsilon r}{1-\epsilon}\right) - \ln\left(\frac{1+\epsilon}{1-\epsilon}\right)\right); K_0^o = 1,$$
$$f^e = \frac{1}{2}(f_\epsilon^+ + f_\epsilon^-); f^o = \frac{1}{2}(f_\epsilon^+ - f_\epsilon^-). \tag{23}$$

3. Spherical shells:

$$K_0^e = \frac{1}{2}\left(1 - \sqrt{\frac{1-\epsilon}{1+\epsilon}} + r\left(1 + \sqrt{\frac{1-\epsilon}{1+\epsilon}}\right)\right),$$
$$K_0^o = \frac{1}{2}\left(1 + \sqrt{\frac{1-\epsilon}{1+\epsilon}} + r\left(1 - \sqrt{\frac{1-\epsilon}{1+\epsilon}}\right)\right); \tag{24}$$

f^e, f^0 are defined in (14).

A similar technique will be employed in the forthcoming analysis, where the error term of the higher order models, $B(u-u_N, v)$, is expressed in terms of higher order kernels K_N^e, K_N^o orthogonal with respect to the weighted inner product $\int_{-1}^{1} \frac{1}{a} K_N^e K_N^o dr$.

3. Determination of the hierarchy of dimensionally reduced models. This section is concerned with selecting the functions $\{\psi_l\}$ to be used in developing more sophisticated dimensionally reduced models of the original three-dimensional boundary value problems. First, we define the space V_N from which our dimensionally reduced approximation will be sought to be

$$V_N = \left\{ v \in V : v = \sum_{i=0}^{N} \beta_i^e(\boldsymbol{\theta})\psi_i^e(r) + \sum_{i=1}^{N} \beta_i^o(\boldsymbol{\theta})\psi_i^o(r),\ \beta_i^{e,o} \in H_0^1(\omega) \right\}. \tag{25}$$

Further, we also introduce the space $\mathcal{H}^{2N}$ with which we shall express the regularity required of the data f^e, f^o, defined by

$$\mathcal{H}^{2N} = \{\beta : A^N \beta \in L_M^2(\omega) : A^k \beta \in H_0^1(\omega), k = 0, \ldots, N-1\},$$

where $H_0^1(\omega)$ is the usual Sobolev space [1], and A is the operator

$$A[v] = -\bar{\boldsymbol{\nabla}}' \cdot \left(\mathcal{K}' \bar{\boldsymbol{\nabla}}' v\right), \tag{26}$$

with domain and range satisfying

$$L^2(\omega) \supseteq \mathcal{D}(A) \to L^2_M(\omega).$$

Remark. It can be seen that the condition $A^k\beta \in H^1_0(\omega)$ in the definition of $\mathcal{H}^{2N}$ imposes a severe restriction on the data. If the data does not satisfy these compatibility requirements, then the convergence rates given later in this section will not be attained and boundary layers [9, 29] will be formed. In practice, this means that the solution will be hard to approximate using dimensional reduction in the neighborhood of the boundary. In this eventuality one would employ a hybrid model whereby the dimensionally reduced models of the current work would be employed in the interior of the domain and coupled to a three-dimensional model near the boundary. See [19, 20, 21] for further details on boundary layers in plate models and their resolution.

We now state and prove a general result concerning how the basis functions $\{\psi_i\}_{i=0}^{\infty}$ should be selected and give the corresponding bound in the energy norm.

THEOREM 3.1. *Let V_N be the subspace*

$$V_N = \left\{ v \in V : v = \sum_{i=0}^{N} \alpha_i^e \psi_i^e + \alpha_i^o \psi_i^o,\ \alpha_i^{e,o} \in H^1_0(\omega) \right\},$$

where the functions $\{\psi_N^e, \psi_N^o\}_{N=0}^{\infty}$ are defined recursively as follows:

$$\psi_0^e(r) = \left(\int_{-1}^{1} b dr \right)^{-1}, \psi_0^o(r) = 0$$

and

$$a \frac{d\psi_N}{dr}^{\{e,o\}} = K_{N-1}^{\{e,o\}}, \int_{-1}^{1} b\psi_N^{\{e,o\}} = 0, \quad N = 1, 2, \ldots.$$

If the data satisfy $f^e, f^o \in \mathcal{H}^{2N}$, then there exists $u_N \in V_N$ such that for all $v \in V$

$$B(u - u_N, v) = \epsilon^{2N} \int_{\omega} d\boldsymbol{\theta} \int_{-1}^{1} dr \left(A^N f^e(\boldsymbol{\theta}) K_N^e(r) + A^N f^o(\boldsymbol{\theta}) K_N^o(r) \right) \frac{\partial v}{\partial r}, \tag{27}$$

where the kernels $\{K_N^e, K_N^o\}_{N=0}^{\infty}$ are defined by (22)–(24) if $N = 0$ and

$$Q(K_N^{\{e,o\}}) = K_{N-1}^{\{e,o\}}, \tag{28}$$

$$K_N^{\{e,o\}}(1) = 0 = K_N^{\{e,o\}}(-1) \tag{29}$$

for $N = 1, 2, \ldots$ with

$$Q = a \frac{d}{dr} \frac{1}{b} \frac{d}{dr}.$$

Proof. Let $u_N \in V_N$ be given by

$$u_N = \sum_{i=0}^{N} \alpha_i^e \psi_i^e + \alpha_i^o \psi_i^o,$$

where each $\alpha_i^{e,o} \in H_0^1(\omega)$ satisfies

$$\alpha_i^{\{e,o\}} = \epsilon^{2i-1} A^{i-1} f^{\{e,o\}}, \qquad i = 0, \ldots, N.$$

The condition $\alpha_i^{e,o} \in H_0^1(\omega)$ is required in order for the homogeneous boundary conditions on $\partial\omega$ to be satisfied, and it is ensured by the compatibility conditions imposed on the data to be in the space $\mathcal{H}^{2N}$.

First, we prove the result for the case when either f^e or f^o vanishes. The result in the case $N = 0$ is stated in (21) and we proceed to prove the general case by induction. Thus, assume (27) holds for $N = k$. Then, from (19),

$$\begin{aligned} B(u - u_{k+1}, v) &= B(u - u_k, v) - B(\alpha_{k+1}\psi_{k+1}, v) \\ &= \epsilon^{2k} \int_\omega d\boldsymbol{\theta} A^k f(\boldsymbol{\theta}) \int_{-1}^1 dr K_k \frac{\partial v}{\partial r} \\ &\quad - \int_\omega d\boldsymbol{\theta} \int_{-1}^1 dr \left(\alpha_{k+1} \frac{a}{\epsilon} \frac{d\psi_{k+1}}{dr} \frac{\partial v}{\partial r} + \epsilon b \psi_{k+1} (\bar{\boldsymbol{\nabla}}' \alpha_{k+1})^T \mathcal{K}' \bar{\boldsymbol{\nabla}}' v \right). \end{aligned} \tag{30}$$

Inserting $a d\psi_{k+1}/dr = K_k(r)$ and $\alpha_{k+1} = \epsilon^{2k+1} A^k f$ results in the lowest order terms in (30) cancelling, and we are left with

$$\begin{aligned} B(u - u_{k+1}, v) &= -\epsilon^{2k+2} \int_\omega d\boldsymbol{\theta} \int_{-1}^1 dr b \psi_{k+1} (\bar{\boldsymbol{\nabla}}' A^k f)^T \mathcal{K}' \bar{\boldsymbol{\nabla}}' v \\ &= \epsilon^{2k+2} \int_\omega d\boldsymbol{\theta} \bar{\boldsymbol{\nabla}}' \cdot \left(\mathcal{K}' \bar{\boldsymbol{\nabla}}' A^k f \right) \int_{-1}^1 dr b \psi_{k+1} v \\ &= -\epsilon^{2k+2} \int_\omega d\boldsymbol{\theta} A^{k+1} f \int_{-1}^1 dr b \psi_{k+1} v \\ &= -\epsilon^{2k+2} \int_\omega d\boldsymbol{\theta} A^{k+1} f \int_{-1}^1 dr \frac{dK_{k+1}}{dr} v, \end{aligned} \tag{31}$$

where the last line follows, since

$$a \frac{d\psi_i}{dr} = K_{i-1} = a \frac{d}{dr} \frac{1}{b} \frac{dK_i}{dr}, \qquad i = 1, 2, \ldots,$$

so that, due to (29), and the fact from Theorem 3.1

$$\int_{-1}^1 b \psi_N^{\{e,o\}} = 0,$$

we obtain

$$b\psi_i = \frac{dK_i}{dr}, \qquad i = 1, 2, \ldots.$$

The result then follows for $N = k+1$ at once by integrating (31) by parts with respect to r using the fact that K_{k+1} vanishes at ± 1. The general case when both f^o and f^e are present follows from linearity. □

Now as in (21), it is useful to express the error in terms of kernels K_N^o, K_N^e orthogonal in the weighted inner product $\int_{-1}^1 \frac{1}{a} K_N^e K_N^o dr$. It will now be proved that if the kernels K_N^e, K_N^o are selected as in Theorem 3.1, then they are indeed orthogonal in the weighted inner product.

LEMMA 3.1. *Let K_N^e, K_N^o be selected as in Theorem* 3.1*; then*

$$\int_{-1}^{1} \frac{K_N^e K_N^o}{a} dr = 0 \quad \forall\ N \in \mathbb{N}.$$

Proof. In [3] the kernels K_0^e, K_0^o in (22)–(24) were selected so that, if expanded in terms of the eigenfunctions of Q, that is,

$$K_0^e = \sum_{m=1}^{\infty} \alpha_m^e \phi_m, K_0^o = \sum_{m=1}^{\infty} \alpha_m^o \phi_m,$$

where ϕ_m are the eigenfunctions of Q, then

$$\alpha_m^e \alpha_m^o = 0.$$

Hence by direct calculation using (28)–(29),

$$\begin{aligned}\int_{-1}^{1} \frac{K_N^e K_N^o}{a} dr &= \int_{-1}^{1} \frac{1}{a} Q^{-N} K_0^e Q^{-N} K_0^o dr \\ &= \int_{-1}^{1} \frac{1}{a} \left(\sum_{m=1}^{\infty} \lambda_m^{-N} \alpha_m^e \phi_m \right) \left(\sum_{n=1}^{\infty} \lambda_n^{-N} \alpha_n^o \phi_n \right) dr \\ &= \sum_{m=1}^{\infty} \frac{\alpha_m^e \alpha_m^o}{\lambda_m^{2N}} \\ &= 0\end{aligned}$$

since $\alpha_m^e \alpha_m^o = 0$. ∎

The main result concerning the accuracy of the dimensionally reduced models can now be given.

THEOREM 3.2. *Suppose $f^e, f^o \in \mathcal{H}^{2N}$, and V_N be defined as in Theorem* 3.1*; let A be given as in* (26)*; and let a be given in* (19)*. Then*

$$\begin{aligned}\inf_{u_N \in V_N} |||u - u_N|||^2 \le \epsilon^{4N+1} \Bigg(&\|A^N f^e\|^2_{L^2_M(\omega)} \int_{-1}^{1} dr \frac{(K_N^e)^2}{a} \\ &+ \|A^N f^o\|^2_{L^2_M(\omega)} \int_{-1}^{1} dr \frac{(K_N^o)^2}{a} \Bigg),\end{aligned} \tag{32}$$

where K_N^e, K_N^o are given in Theorem 3.1.

Proof. Let u_N be the function constructed in Theorem 3.1. Then from (27), for $v \in V$,

$$B(u - u_N, v) = \epsilon^{2N+\frac{1}{2}} \int_{\omega} d\boldsymbol{\theta} \int_{-1}^{1} \frac{dr}{a^{\frac{1}{2}}} \left(A^N f^e(\boldsymbol{\theta}) K_N^e(r) + A^N f^o(\boldsymbol{\theta}) K_N^o(r) \right) \frac{a^{\frac{1}{2}}}{\epsilon^{\frac{1}{2}}} \frac{\partial v}{\partial r}.$$

Applying the Cauchy–Schwarz inequality and squaring, one arrives at

$$\begin{aligned}&|B(u - u_N, v)|^2 \\ &\le \epsilon^{4N+1} \int_{\omega} d\boldsymbol{\theta} \int_{-1}^{1} \frac{dr}{a} \left(A^N f^e(\boldsymbol{\theta}) K_N^e(r) + A^N f^o(\boldsymbol{\theta}) K_N^o(r) \right)^2 |||v|||^2.\end{aligned}$$

Choosing $v = u - u_N$, dividing both sides by $|||u - u_N|||^2$, and applying Lemma 3.1 gives the result claimed. ∎

In the above analysis, the model order N was the same for both odd and even components u_N^o, u_N^e of the approximation u_N. Occasionally, due to symmetries in the data, it is worthwhile using differing model orders N_o, N_e for the odd and even modes. The corresponding error bound is then as follows.

COROLLARY 3.3. *Let V_{N_e,N_o} denote the subspace*

$$V_{N_e,N_o} = \left\{ v \in V : v = \sum_{i=0}^{N_e} \alpha_i^e \psi_i^e + \sum_{i=0}^{N_o} \alpha_i^o \psi_i^o,\ \alpha_i^{e,o} \in H_0^1(\omega) \right\}$$

and suppose $f^e, f^o \in \mathcal{H}^{2N}$. Then there exists $u_{N_{e,o}} \in V_{N_e,N_o}$ such that

$$\inf_{u_{N_{e,o}} \in V_{N_e,N_o}} |||u - u_{N_{e,o}}|||^2 \le \epsilon^{4N_e+1} \left(\|A^{N_e} f^e\|^2_{L^2_M(\omega)} \int_{-1}^{1} dr \frac{(K^e_{N_e})^2}{a} \right) + \epsilon^{4N_o+1} \left(\|A^{N_o} f^o\|^2_{L^2_M(\omega)} \int_{-1}^{1} dr \frac{(K^o_{N_o})^2}{a} \right).$$

Proof. Due to linearity, if differing orders are used, then

$$B(u - u_{N_{e,o}}, v) = \int_\omega d\boldsymbol{\theta} \int_{-1}^{1} \frac{dr}{a^{\frac{1}{2}}} \left(\epsilon^{2N_e+\frac{1}{2}} A^{N_e} f^e(\boldsymbol{\theta}) K^e_{N_e}(r) + \epsilon^{2N_o+\frac{1}{2}} A^{N_o} f^o(\boldsymbol{\theta}) K^o_{N_o}(r) \right) \frac{a^{\frac{1}{2}}}{\epsilon^{\frac{1}{2}}} \frac{\partial v}{\partial r}.$$

The result then follows from the Cauchy–Schwarz inequality, and the fact that Lemma 3.1 clearly holds when differing model orders are used, so that $K^o_{N_o}, K^e_{N_e}$ are orthogonal with respect to the $1/a$ weighted inner product. ∎

4. Evaluating the constant of approximation. The error bound in Theorem 3.2 is of the form

$$\inf_{u_N \in V_N} |||u - u_N|||^2 \le \epsilon^{4N+1} C(\epsilon, N, f^e, f^o),$$

where $C(\epsilon, N, f^e, f^o)$ is a constant which depends on ϵ, the model order N, and the data f^e, f^o. It is essential to determine the dependence of the constant C on the thickness ϵ. For flat plates, as considered by Vogelius and Babuska [27], it was shown that C is independent of ϵ. However, in general C depends on ϵ in a nontrivial way. The purpose of this section is to present a technique whereby the constant can actually be evaluated completely. This strengthens the analysis of [27], but more significantly, exhibits the dependence on ϵ explicitly for the more general geometries under consideration here. Furthermore, it is not assumed that ϵ is necessarily small, and the bounds are therefore valid for thick domains.

First, an abstract result is presented, which gives an expression for the constant of approximation in terms of an infinite series involving the eigenvalues of the operator Q defined in Theorem 3.1.

THEOREM 4.1. *Let $f^e, f^o \in \mathcal{H}^{2N}$, and V_N be defined as in Theorem* 3.1. *Then*

$$\inf_{u_N \in V_N} |||u - u_N|||^2 \le \epsilon^{4N+1} \left\{ \left(\sum_{m=1}^{\infty} \frac{(\alpha_m^e)^2}{\lambda_m^{2N}} \right) \|A^N f^e\|^2_{L^2_M(\omega)} + \left(\sum_{m=1}^{\infty} \frac{(\alpha_m^o)^2}{\lambda_m^{2N}} \right) \|A^N f^o\|^2_{L^2_M(\omega)} \right\}, \tag{33}$$

where α_m^o, α_m^o *are given by*

$$\alpha_m^{e,o} = \int_{-1}^{1} \frac{K_0^{e,o}\phi_m}{a} ds$$

and where $\{\lambda_m\phi_m\}_{m=0}^{\infty}$ *are the eigensolutions of* Q.

Proof. Let u_N be constructed as in Theorem 3.1 and define

$$C(\epsilon, N) = \int_{-1}^{1} \frac{(K_N)^2}{a} dr$$

where we omit the subscripts e, o, since the analysis is identical for both the odd and even cases. In order to evaluate C explicitly, we recall the recurrence relation from Theorem 3.1:

$$QK_N = K_{N-1}; K_N(\pm 1) = 0 \ , \ N = 1, \ldots, \tag{34}$$

where

$$Q = a\frac{d}{dr}\frac{1}{b}\frac{d}{dr},$$

and K_0 is defined in (22)–(24). The solution of this differential equation is given by

$$K_N(r) = \int_{-1}^{1} \frac{G(r,s)K_{N-1}(s)}{a(s)} ds,$$

where G is the Green function written in the form [16]

$$G(r,s) = \sum_{m=1}^{\infty} \frac{\phi_m(r)\phi_m(s)}{\lambda_m}$$

and ϕ_m, λ_m are the eigensolutions of the Sturm–Liouville problem

$$\frac{d}{dr}\frac{1}{b}\frac{d\phi_m}{dr} + \frac{\lambda_m}{a}\phi_m = 0, \qquad \phi_m(\pm 1) = 0,$$

normalized so that

$$\int_{-1}^{1} \frac{\phi_m\phi_n}{a} dr = \delta_{mn}. \tag{35}$$

Consequently,

$$K_N(r) = \int_{-1}^{1} ds \frac{K_{N-1}(s)}{a(s)} \left(\sum_{m=1}^{\infty} \frac{\phi_m(r)\phi_m(s)}{\lambda_m} \right). \tag{36}$$

Expanding $K_0 = \sum_{n=1}^{\infty} \alpha_n\phi_n$ and using the recurrence relation (34), we obtain

$$\begin{aligned} K_1 &= \int_{-1}^{1} ds \frac{K_0(s)}{a(s)} \left(\sum_{m=1}^{\infty} \frac{\phi_m(r)\phi_m(s)}{\lambda_m} \right) \\ &= \int_{-1}^{1} ds \sum_{n=1}^{\infty} \frac{\alpha_n\phi_n(s)}{a(s)} \left(\sum_{m=1}^{\infty} \frac{\phi_m(r)\phi_m(s)}{\lambda_m} \right) \\ &= \sum_{n=1}^{\infty} \frac{\alpha_n\phi_n(r)}{\lambda_n} \end{aligned}$$

on recalling (35). Similarly, by repeated application of (36), we conclude

$$K_N = \sum_{m=1}^{\infty} \frac{\phi_m}{\lambda_m} \int_{-1}^{1} ds \frac{\phi_m(s)}{a(s)} \left(\sum_{n=1}^{\infty} \frac{\alpha_n \phi_n(s)}{\lambda_n^{N-1}} \right) = \sum_{m=1}^{\infty} \frac{\alpha_m \phi_m(r)}{\lambda_m^N}. \tag{37}$$

It follows from (35) that the constant C in the error bound is given by

$$\int_{-1}^{1} ds \frac{K_N^2}{a} = \int_{-1}^{1} \frac{1}{a} \left(\sum_{m=1}^{\infty} \frac{\alpha_m \phi_m(r)}{\lambda_m^N} \right)^2 = \sum_{m=1}^{\infty} \frac{\alpha_m^2}{\lambda_m^{2N}}. \tag{38}$$

The result now follows directly from Theorem 3.2. □

The general error bound obtained in Theorem 4.1 will now be evaluated for the three cases of a homogeneous flat plate, a homogeneous circular arch, and a homogeneous spherical shell.

4.1. Homogeneous flat plate.

THEOREM 4.2. *Let $f^e, f^o \in \mathcal{H}^{2N}$, and V_N be defined as in Theorem* 3.1. *Then*

$$\inf_{u_N \in V_N} |||u - u_N|||^2 \leq \left(\frac{\epsilon}{\pi}\right)^{4N+1} \frac{4}{\pi} \left\{ \zeta(4N+2) \|A^N f^e\|^2_{L^2(\omega)} + \zeta\left(4N+2, -\tfrac{1}{2}\right) \|A^N f^o\|^2_{L^2(\omega)} \right\},$$

where $\zeta(n)$ represents the Riemann–Zeta function [11]

$$\zeta(n) = \sum_{i=1}^{\infty} \frac{1}{i^n}$$

and where $\zeta(n, w)$ represents the generalized Riemann–Zeta function [11]

$$\zeta(n, w) = \sum_{i=1}^{\infty} \frac{1}{(i+w)^n}.$$

Remark. Note that the above result and the ones that follow in this section show that if ϵ is sufficiently small, then exponential rates of convergence are obtained for compatible data. In fact, the method converges, as $N \to \infty$, for all values of ϵ, and for a proof of this for flat plates, see Vogelius and Babuska [28].

The proof of Theorem 4.2 follows at once from the two special cases presented in the following lemmas.

LEMMA 4.1. *Let $f^e, f^o \in \mathcal{H}^{2N}$, and V_N be defined as in Theorem* 3.1. *If $f^+ = f^-$ (so that $f^o = 0$), then*

$$\inf_{u_N \in V_N} |||u - u_N|||^2 \leq \left(\frac{\epsilon}{\pi}\right)^{4N+1} \frac{4}{\pi} \zeta(4N+2) \|A^N f^e\|^2_{L^2(\omega)}. \tag{39}$$

Proof. It is merely necessary to calculate the quantities appearing in the bounds of Theorem 4.1. Expanding $K_0^e = s$ in terms of the eigenfunctions ϕ_m, where $\phi_m = \sin m\pi$, and $\lambda_m = (m\pi)^2$, we obtain

$$\alpha_m^e = \frac{2}{\pi m} (-1)^{m+1}.$$

Hence (33) becomes

$$\begin{aligned}\sum_{m-1}^{\infty}\frac{(\alpha_m^e)^2}{\lambda_m^{2N}} &= \frac{4}{\pi^2}\sum_{m=1}^{\infty}\frac{1}{m^2\lambda_m^{2N}}\\ &= \frac{4}{\pi^2}\sum_{m=1}^{\infty}\frac{1}{m^2}\frac{1}{(m\pi)^{4N}}\\ &= \frac{4}{\pi^{4N+2}}\sum_{m=1}^{\infty}\frac{1}{m^{4N+2}}\\ &= \frac{4}{\pi^{4N+2}}\zeta(4N+2).\end{aligned}$$

Hence, after substituting this result into Theorem 3.1, the lemma follows. ∎

The procedure which has just been used to obtain a bound in the case of symmetric data may be carried out similarly for the case of antisymmetric data to obtain the following lemma.

LEMMA 4.2. *Let $f^e, f^o \in \mathcal{H}^{2N}$, and V_N be defined as in Theorem* 3.1. *Then if $f^+ = -f^-$ (so that $f^e = 0$),*

$$\inf_{u_N\in V_N}|||u-u_N|||^2 \le \frac{4}{\pi}\left(\frac{\epsilon}{\pi}\right)^{4N+1}\zeta\left(4N+2,-\frac{1}{2}\right)\|A^N f^o\|^2_{L^2(\omega)}. \tag{40}$$

Proof. As before we need to expand K_0^o in terms of $\{\phi_m\}$, and from our earlier analysis we know that if we transform K_0^o onto $(0,1)$ and expand in a half-range Fourier sine series, then

$$\alpha_m^o = \frac{2}{\pi m}(1+(-1)^{m+1})$$

and therefore

$$\begin{aligned}K_0^o(\hat{r}) &= \frac{2}{\pi}\sum_{m=1}^{\infty}\frac{(1+(-1)^{n+1})\phi_m(\hat{r})}{m}\\ &= \frac{4}{\pi}\sum_{m=1}^{\infty}\frac{\phi_{2m-1}(\hat{r})}{2m-1}.\end{aligned}$$

Hence, from (37),

$$K_N^o(\hat{r}) = \frac{4}{\pi}\sum_{m=1}^{\infty}\frac{\phi_{2m-1}(\hat{r})}{\lambda_{2m-1}^N(2m-1)}$$

so that

$$\begin{aligned}\|K_N^o(r)\|^2_{L^2(-1,1)} &= 2\|K_N^o(\hat{r})\|^2_{L^2(0,1)}\\ &= 2\frac{16}{\pi^2}\int_0^1\left(\phi^2_{2m-1}ds\right)\sum_{m=1}^{\infty}\frac{1}{\lambda^{2N}_{2m-1}(2m-1)^2}\\ &= \frac{16}{\pi^2}\sum_{m=1}^{\infty}\frac{1}{\lambda^{2N}_{2m-1}(2m-1)^2}\end{aligned}$$

since $\int_0^1 \phi_m \phi_n ds = \frac{1}{2}\delta_{mn}$. But $\lambda_m = (\frac{m\pi}{2})^2$ for the rescaled problem and hence we arrive at

$$\begin{aligned}\|K_N^o\|_{L^2}^2 &= \frac{16}{\pi^2}\sum_{m=1}^{\infty}\frac{1}{(\frac{2m-1}{2})^{4N}\pi^{4N}(2m-1)^2}\\ &= \frac{4}{\pi^{4N+2}}\sum_{m=1}^{\infty}\frac{1}{(m-\frac{1}{2})^{4N+2}}\\ &= \frac{4}{\pi^{4N+2}}\zeta\left(4N+2,-\frac{1}{2}\right). \qquad \square\end{aligned}$$

The proof of Theorem 4.2 follows directly from Lemmas 4.1 and 4.2.

4.2. Homogeneous circular arch.

THEOREM 4.3. *Let $f^e, f^o \in \mathcal{H}^{2N}$, and V_N be defined as in Theorem* 3.1. *Then for the arch problem we have*

$$\inf_{u_N\in V_N}|||u-u_N|||^2 \le \left(\frac{1}{2\pi}\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)\right)^{4N+1}\frac{4}{\pi}\left\{\zeta(4N+2)\|A^N f^e\|_{L^2(\omega)}^2 + \zeta\left(4N+2,-\frac{1}{2}\right)\|A^N f^o\|_{L^2(\omega)}^2\right\}.$$

Proof. The result can be obtained by applying Theorem 4.1. However, by a change of variable, the result for circular arches can be derived from that for flat plates. To show this, recall that the bilinear form for arches is given by

$$B(u,v) = \int_\omega\int_{-1}^1\left\{\frac{(1+\epsilon r)}{\epsilon}\frac{\partial u}{\partial r}\frac{\partial v}{\partial r} + \frac{\epsilon}{1+\epsilon r}(\bar{\boldsymbol{\nabla}}' u)^T\mathcal{K}'\bar{\boldsymbol{\nabla}}' v\right\}dr\,d\theta.$$

Then, making the substitution

$$t = \frac{2}{\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)}\left(\ln(1+\epsilon r) - \ln(1-\epsilon) - \frac{1}{2}(\ln(1+\epsilon) - \ln(1-\epsilon))\right)$$

we arrive at

$$B(u,v) = \int_\omega\int_{-1}^1\left\{\frac{2}{\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)}\frac{\partial u}{\partial t}\frac{\partial v}{\partial t} + \frac{\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)}{2}(\bar{\boldsymbol{\nabla}}' u)^T\mathcal{K}'\bar{\boldsymbol{\nabla}}' v\right\}dt\,d\theta.$$

It can now be seen that the $B(u,v)$ in this case is equivalent to $B(u,v)$ in the flat plate case, except that now we have $\frac{1}{2}\ln(\frac{1+\epsilon}{1-\epsilon})$ instead of ϵ. Therefore the functions which optimally capture the variation in the thickness of the true solution in this case will be polynomials in t, that is, in $\ln(1+\epsilon r)$. As a consequence of this equivalence to the flat plate case, one can easily obtain formulae for arches by referring to the formulae for plates and replacing ϵ by $\frac{1}{2}\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)$. $\square$

Remark. It can be seen from the above formula that exponential convergence is obtained for $\frac{1}{2\pi}\ln\left(\frac{1+\epsilon}{1-\epsilon}\right) < 1$, that is, $\epsilon < \tanh(2\pi) \approx 0.996$. So for arches, the bound promises exponential convergence for practically the whole range of values of the thickness (if the data is sufficiently compatible).

4.3. Homogeneous spherical shells. In order to derive the bound in the energy norm we estimate the weighted L_2 norms of K_N^o,K_N^e separately and then combine them as in Theorem 4.1 to obtain an overall bound. From earlier, we know that the eigensolutions $\lambda_m\phi_m$ of the equation

$$-(\epsilon r+1)^2\frac{d^2\phi_m}{dr^2}=\lambda\phi_m,\qquad \phi_m(\pm1)=0,\qquad m=1,2,\ldots,$$

are given by

$$\phi_m(r)=\left(\frac{2\epsilon(1+\epsilon r)}{\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)}\right)^{\frac12}\sin\left(\frac{m\pi\ln\left(\frac{1+\epsilon r}{1-\epsilon}\right)}{\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)}\right),$$

$$\lambda_m=\epsilon^2\left(\left(\frac{m\pi}{\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)}\right)^2+\frac14\right).$$

One may proceed as in the case of flat plates and circular arches by using the eigenfunctions and eigenvalues to evaluate the weighted L_2 norm of K_N^e, K_N^o. Using the expressions for the weighted L_2 norm of the kernels K_N^o, K_N^e we can now state and prove a result concerning the convergence rate for dimensional reduction on a spherical shell.

THEOREM 4.4. *Let $f^e, f^o \in \mathcal{H}^{2N}$, and V_N be defined as in Theorem* 3.1. *Then*

$$\inf_{u_N\in V_N}|||u-u_N|||^2\le\frac{4}{\pi(1+\epsilon)}\left(\frac{1}{2\pi}\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)\right)^{4N+1}\times\left\{\zeta\left(4N+2,-\frac12\right)\|A^Nf^o\|^2_{L^2_M(\omega)}+\zeta(4N+2)\|A^Nf^e\|^2_{L^2_M(\omega)}\right\}.$$

Before commencing with the proof, two lemmas are stated and proved, from which the proof of the theorem will immediately follow.

LEMMA 4.3. *Let K_N^o be as in Theorem* 3.1 *and a be as in* (19). *Then*

$$\left\|\frac{K_N^o}{a^{\frac12}}\right\|^2_{L^2(-1,1)}\le\frac{4}{\pi(1+\epsilon)}\left(\frac{1}{2\epsilon\pi}\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)\right)^{4N+1}\zeta\left(4N+2,-\frac12\right).$$

Proof. Now it can be shown that (see [3]) if K_0^o is expanded in terms of the eigenfunctions of Q in the form

$$K_0^o=\sum_{m=1}^{\infty}\alpha_m^o\phi_m,$$

then

$$\alpha_m^o=4\pi m\left(\frac{2\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)}{\epsilon(1-\epsilon)}\right)^{\frac12}D_\epsilon\left(\frac{1+(-1)^{m+1}}{\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)^2+4\pi^2m^2}\right)$$

$$=\frac{m}{\pi}\left(\frac{2\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)}{\epsilon(1+\epsilon)}\right)^{\frac12}\left(\left\{\frac{1+(-1)^{m+1}}{(m^2+\sigma^2)}\right\}\right),$$

where $\sigma = \frac{1}{2\pi}\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)$ and $D_\epsilon = \sqrt{\frac{1-\epsilon}{1+\epsilon}}$.

Hence, substituting in the value of α_m^o into (38) one obtains

$$\begin{aligned}\left\|\frac{K_N^o}{a^{\frac{1}{2}}}\right\|^2_{L^2(-1,1)} &= \sum_{m=1}^{\infty}\frac{(\alpha_m^o)^2}{\lambda_m^{2N}}\\ &= \frac{2}{\pi^2\epsilon(1+\epsilon)}\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)\sum_{m=1}^{\infty}\frac{((-1)^{m+1}+1)^2m^2}{(m^2+\sigma^2)^2\lambda_m^{2N}}. \qquad (41)\end{aligned}$$

Recalling that

$$\lambda_m = \frac{\epsilon^2\pi^2}{\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)^2}(m^2+\sigma^2), \qquad (42)$$

and substituting into (41), one obtains

$$\begin{aligned}&\left\|\frac{K_N^o}{a^{\frac{1}{2}}}\right\|^2_{L^2(-1,1)} \qquad (43)\\ &= \frac{2}{\pi^2\epsilon(1+\epsilon)}\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)\left(\frac{1}{\epsilon\pi}\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)\right)^{4N}\sum_{m=1}^{\infty}\frac{((-1)^{m+1}+1)^2m^2}{(m^2+\sigma^2)^{2N+2}}\\ &= \frac{2}{\pi(1+\epsilon)}\left(\frac{1}{\epsilon\pi}\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)\right)^{4N+1}\sum_{m=1}^{\infty}\frac{4(2m-1)^2}{((2m-1)^2+\sigma^2)^{2N+2}}\\ &= \frac{4}{\pi(1+\epsilon)}\left(\frac{1}{2\epsilon\pi}\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)\right)^{4N+1}\sum_{m=1}^{\infty}\frac{(m-\frac{1}{2})^2}{\left((m-\frac{1}{2})^2+\left(\frac{\sigma}{2}\right)^2\right)^{2N+2}}\\ &\le \frac{4}{\pi(1+\epsilon)}\left(\frac{1}{2\epsilon\pi}\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)\right)^{4N+1}\sum_{m=1}^{\infty}\frac{1}{(m-\frac{1}{2})^{4N+2}}. \qquad (44)\end{aligned}$$

Hence, one arrives at the estimate

$$\left\|\frac{K_N^o}{a^{\frac{1}{2}}}\right\|^2_{L^2(-1,1)} \le \frac{4}{\pi(1+\epsilon)}\left(\frac{1}{2\epsilon\pi}\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)\right)^{4N+1}\zeta\left(4N+2,-\frac{1}{2}\right),$$

which is the result stated in the lemma. □

LEMMA 4.4. *Let K_N^e be as in Theorem* 3.1 *and a be as in* (19). *Then*

$$\left\|\frac{K_N^e}{a^{\frac{1}{2}}}\right\|^2_{L^2(-1,1)} \le \frac{4}{\pi(1+\epsilon)}\left(\frac{1}{2\epsilon\pi}\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)\right)^{4N+1}\zeta(4N+2).$$

Proof. It can be shown that if $K_0^e = \sum_{m=1}^{\infty}\alpha_m^e\phi_m$, then

$$\alpha_m^e = \frac{m}{\pi}\left(\frac{2\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)}{\epsilon(1+\epsilon)}\right)^{\frac{1}{2}}\left\{\frac{(-1)^m+1}{(m^2+\sigma^2)}\right\}. \qquad (45)$$

Using this expression for α_m^e and reasoning as before, one obtains

$$
\begin{aligned}
(46)\qquad & \left\| \frac{K_N^e}{a^{\frac{1}{2}}} \right\|^2_{L^2(-1,1)} \\
&= \sum_{m=1}^{\infty} \frac{(\alpha_m^e)^2}{\lambda_m^{2N}} \\
&= \frac{2}{\pi^2 \epsilon(1+\epsilon)} \ln\left(\frac{1+\epsilon}{1-\epsilon}\right) \sum_{m=1}^{\infty} \frac{((-1)^m+1)^2 m^2}{\left(m^2+\sigma^2\right)^2 \lambda_m^{2N}} \\
&= \frac{2}{\pi^2 \epsilon(1+\epsilon)} \ln\left(\frac{1+\epsilon}{1-\epsilon}\right) \left(\frac{1}{\epsilon\pi} \ln\left(\frac{1+\epsilon}{1-\epsilon}\right)\right)^{4N} \sum_{m=1}^{\infty} \frac{4(2m)^2}{\left((2m)^2+\sigma^2\right)^{2N+2}} \\
&= \frac{2}{\pi(1+\epsilon)} \left(\frac{1}{\epsilon\pi} \ln\left(\frac{1+\epsilon}{1-\epsilon}\right)\right)^{4N+1} \frac{1}{2^{4N}} \sum_{m=1}^{\infty} \frac{m^2}{\left(m^2+\left(\frac{\sigma}{2}\right)^2\right)^{2N+2}} \\
&= \frac{4}{\pi(1+\epsilon)} \left(\frac{1}{2\epsilon\pi} \ln\left(\frac{1+\epsilon}{1-\epsilon}\right)\right)^{4N+1} \sum_{m=1}^{\infty} \frac{m^2}{\left(m^2+\left(\frac{\sigma}{2}\right)^2\right)^{2N+2}} \\
&\le \frac{4}{\pi(1+\epsilon)} \left(\frac{1}{2\epsilon\pi} \ln\left(\frac{1+\epsilon}{1-\epsilon}\right)\right)^{4N+1} \sum_{m=1}^{\infty} \frac{1}{m^{4N+2}} \\
(47)\qquad &= \frac{4}{\pi(1+\epsilon)} \left(\frac{1}{2\epsilon\pi} \ln\left(\frac{1+\epsilon}{1-\epsilon}\right)\right)^{4N+1} \zeta(4N+2),
\end{aligned}
$$

which is the result stated in the lemma. ∎

The proof of Theorem 4.4 follows directly from Lemma 4.3, Lemma 4.4, and Theorem 3.2.

Remark. Note that the error bound in Theorem 4.4 is identical to that of arches in Theorem 4.3 except for a factor of $(1+\epsilon)^{-1}$.

5. Numerical examples. In this section, the optimal functions to be used to construct the dimensionally reduced models in the case of circular arches and spherical shells will be given explicitly. The functions are then used to construct the subspace $V_N \subset V$ defined in (25). The dimensionally reduced approximation of the problem

$$u \in V : B(u,v) = F(v) \quad \forall v \in V$$

consists of seeking the solution

$$u_N^* \in V_N : B(u_N^*, v_N) = F(v_N) \quad \forall v_N \in V_N.$$

This results in the following elliptic system, in one dimension less than the original problem

$$(48)\qquad -\epsilon \bar{\boldsymbol{B}} \nabla' \cdot \mathcal{K} \nabla' \boldsymbol{\alpha} + \frac{1}{\epsilon} \bar{\boldsymbol{A}} \boldsymbol{\alpha} = \boldsymbol{c}^+ f_\epsilon^+ + \boldsymbol{c}^- f_\epsilon^- \quad \text{in } \omega$$

subject to $\boldsymbol{\alpha} = \boldsymbol{0}$ on $\partial\omega$, where

$$(49)\qquad \bar{B}_{jk} = \int_{-1}^{1} b \psi_j \psi_k dr, \ \bar{A}_{jk} = \int_{-1}^{1} a \frac{d\psi_j}{dr} \frac{d\psi_k}{dr} dr,$$

$$(50)\qquad \boldsymbol{\alpha} = (\alpha_0, \ldots, \alpha_N)^T; \boldsymbol{c}_j^{\pm} = \psi_j(\pm 1),$$

with the approximation given by

$$u_N = \boldsymbol{\alpha}^T \Psi,$$

where $\Psi = (\psi_0, \ldots, \psi_N)^T$.

In general, the solution u_N^* will differ from the function u_N constructed in Theorem 3.1. However, the standard property of the Galerkin method means that

$$|||u - u_N^*||| \leq |||u - v_N||| \quad \forall v_N \in V_N$$

and as a consequence

$$|||u - u_N^*||| \leq \inf_{u_N \in V_N} |||u - u_N|||.$$

The approximation theoretic results of the foregoing sections find immediate application in obtaining bounds for the accuracy of the dimensionally reduced approximation u_N^*.

The optimal functions will now be used in the resolution of some simple illustrative problems in order to verify the theoretical results concerning the rates of convergence. Occasionally, the odd and even model orders N_o and N_e will differ, as in Corollary 3.3, and the model order is then written as a pair (N_e, N_o).

5.1. Flat plates.

5.1.1. Selection of optimal functions. It follows from Theorem 3.1 that $\psi_0^e = 1/2$, and that the functions $\psi_N^{e,o}$ for $N = 1, 2, \ldots$, for a flat plate are given by

$$\frac{d\psi_N^{e,o}}{dr} = K_{N-1}^{e,o}, \int_{-1}^{1} \psi_N^{e,o} dr = 0,$$

where $K_0^e = r$, $K_0^o = 1$, and $K_N^{e,o}$ for $N = 1, 2, \ldots$ are given by

$$\frac{d^2 K_N^{e,o}}{dr^2} = K_{N-1}^{e,o}, K_N^{e,o}(\pm 1) = 0, \quad N = 1, 2, \ldots.$$

From these relations, it is easy to show that K_N^e and K_N^o are odd and even polynomials, respectively, and consequently ψ_N^e and ψ_N^o are even and odd polynomials, respectively. Since it is not the exact basis functions themselves but the space spanned by them that is crucial in order to obtain the approximation properties given earlier in the paper, we have freedom to choose the polynomial basis used. In the numerical results that follow, the basis used was $\psi_0^e = 1, \psi_1^o = r$, and

$$\psi_i^e = \int_{-1}^{r} P_{2i-1}(s) ds, \quad i = 1, 2, \ldots, \; \psi_i^o = \int_{-1}^{r} P_{2i-2}(s) ds, \quad i = 2, 3, \ldots,$$

where P_i is the Legendre polynomial of degree i. The matrices $\bar{\boldsymbol{A}}, \bar{\boldsymbol{B}}$ can be calculated explicitly with this choice of basis, with entries given by

$$\bar{A}_{ij}^{plate} = \frac{2}{2i-1} \delta_{ij},$$

and

$$\bar{B}_{ii}^{plate} = \frac{1}{(2i-1)^2} \left(\frac{2}{2i+1} + \frac{2}{2i-3} \right),$$

$$\bar{B}_{i,i+2}^{plate} = \frac{-2}{(2i-1)(2i+1)(2i+3)},$$

$$\bar{B}_{i,i-2}^{plate} = \frac{-2}{(2i-5)(2i-3)(2i-1)},$$

with the remaining entries vanishing.

5.1.2. Numerical example for a flat plate. We approximate the flat plate problem with domain and flux given by

$$\begin{aligned}\Omega &= (-1,1)\times(-\epsilon,\epsilon),\\ f^+ &= -\pi e^{-\pi\epsilon}\sin(\pi x),\\ f^- &= \pi e^{\pi\epsilon}\sin(\pi x).\end{aligned}$$

For this problem the true solution is given by $e^{-\pi y}\sin(\pi x)$. Note that

$$\begin{aligned}f^e &= \pi(e^{\pi\epsilon}-e^{-\pi\epsilon})\sin(\pi x),\\ f^o &= -\pi(e^{\pi\epsilon}+e^{-\pi\epsilon})\sin(\pi x).\end{aligned}$$

With the aid of Corollary 3.3 the error is bounded by

$$\begin{aligned}|||u-u_N|||^2 &\le \epsilon^{4N_e+1}C(N_e)\|A^{N_e}f^e\|^2_{L^2(\omega)}\\ &\quad +\epsilon^{4N_o+1}C(N_o)\|A^{N_o}f^o\|^2_{L^2(\omega)}.\end{aligned}\tag{51}$$

Now

$$\begin{aligned}\|A^{N_e}f^e\|^2_{L^2(\omega)} &= \|\pi^{2N_e+1}2\sinh(\pi\epsilon)\sin(\pi x)\|^2_{L^2(\omega)} = 4\pi^{4N_e+2}\sinh^2(\pi\epsilon),\\ \|A^{N_o}f^o\|^2_{L^2(\omega)} &= \|\pi^{2N_o+1}2\cosh(\pi\epsilon)\sin(\pi x)\|^2_{L^2(\omega)} = 4\pi^{4N_o+2}\cosh^2(\pi\epsilon).\end{aligned}$$

Substituting these into (51), this bound can then be rewritten as

$$\begin{aligned}|||u-u_N|||^2 &\le 4\pi^{4N_e+2}\epsilon^{4N_e+1}C(N_e)\sinh^2(\pi\epsilon)\\ &\quad +4\pi^{4N_o+2}\epsilon^{4N_o+1}C(N_o)\cosh^2(\pi\epsilon).\end{aligned}\tag{52}$$

The overall convergence rate will be governed by the lowest order term in (52). Note that $\sinh^2(\pi\epsilon)=O(\epsilon^2)$, and this will affect the order of convergence when the lowest order term is the even one (that is, where $N_o > N_e$). So when $N_o \le N_e$, (52) predicts ϵ^{4N_o+1} in the bound, but when $N_o > N_e$, (52) predicts ϵ^{4N_e+3}. As can be seen from Figure 1, these predicted results are attained. Vogelius and Babuska [27] found bounds in the flat plate case of the form

$$|||u-u_N|||^2 \le C(u,N)\epsilon^{4N+1}.$$

This bound takes no account of symmetries in the data that lead to higher rates of convergence than $O(\epsilon^{4n+1})$ suggested here. Schwab (e.g., [19, 20, 22]) has split the problem into odd and even components and shows that in the case of even data, a rate of ϵ^{4N_e+1} is obtained, which agrees with the bound stated in Theorem 4.2.

5.2. Circular arches.

5.2.1. Selection of optimal functions. It follows from Theorem 3.1 that

$$\psi_0^e = \frac{1}{2\epsilon}\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)$$

and that the functions $\psi_N^{e,o}$ for $N=1,2,\ldots$, for a circular arch are given by

$$(1+\epsilon r)\frac{d\psi_N^{e,o}}{dr} = K_{N-1}^{e,o}, \int_{-1}^{1}\frac{1}{1+\epsilon r}\psi_N^{e,o}\,dr = 0,$$

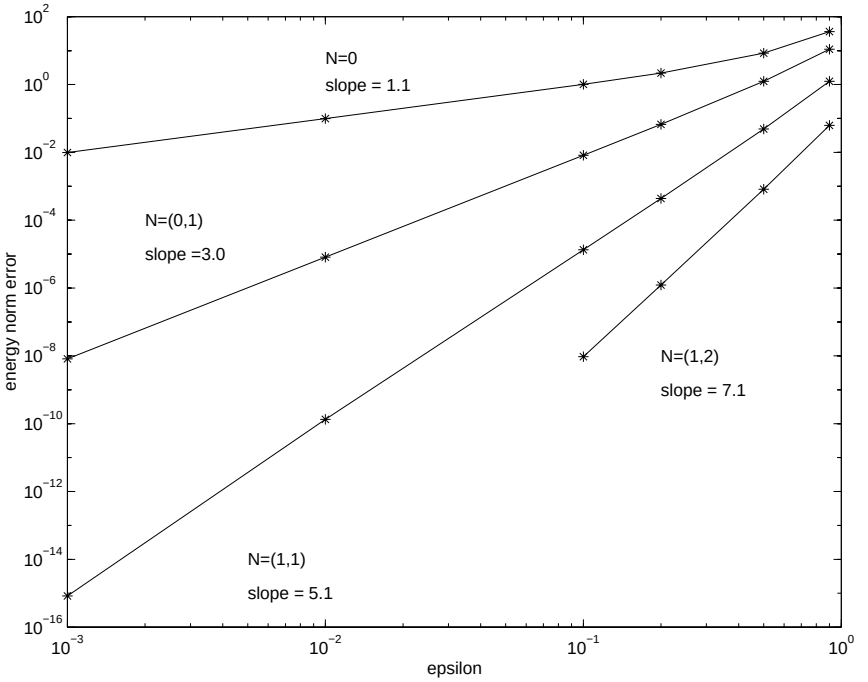

FIG. 1. *Convergence rates for the flat plate problem.*

where K_0^e, K_0^o are as in (23), and $K_N^{e,o}$ for $N = 1, 2, \ldots$ are given by

$$(1+\epsilon r)\frac{d}{dr}(1+\epsilon r)\frac{dK_N^{e,o}}{dr} = K_{N-1}^{e,o}, K_N^{e,o}(\pm 1) = 0, \quad N = 1, 2, \ldots.$$

From these relations, it is easy to show that a basis spanning the same space as the solutions to the above relations is given by the following logarithmic polynomial basis:

$$\psi_0^e = 1; \psi_1^o = \frac{2}{\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)}\left(\ln(1+\epsilon r) - \frac{1}{2}\left(\ln(1+\epsilon) + \ln(1-\epsilon)\right)\right),$$

and

$$\psi_i^e = \int_{-1}^{t} P_{2i-1}(s)ds, \ i = 1, 2, \ldots,$$
$$\psi_i^o = \int_{-1}^{t} P_{2i-2}(s)ds, \ i = 2, 3, \ldots,$$

where

$$t = \frac{2}{\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)}\left(\ln(1+\epsilon r) - \frac{1}{2}\left(\ln(1+\epsilon) + \ln(1-\epsilon)\right)\right) \tag{53}$$

and P_i is the Legendre polynomial of degree i. Now

$$\bar{A}_{ij} = \int_{-1}^{1}(1+\epsilon r)\frac{d\psi_i}{dr}\frac{d\psi_j}{dr}dr,$$

and so with t as in (53), one obtains

$$\bar{A}_{ij} = \frac{2\epsilon}{\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)} \int_{-1}^{1} \frac{d\psi_i}{dt} \frac{d\psi_j}{dt} dt.$$

Hence, with the above choice of basis

$$\begin{aligned} \bar{A}^{arch}_{ij} &= \frac{2\epsilon}{\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)} \frac{2}{2i-1} \delta_{ij} \\ &= \frac{2\epsilon}{\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)} \bar{A}^{plate}_{ij}, \end{aligned}$$

which is the same as for flat plates but with an ϵ dependent scaling. Similarly,

$$\bar{B}^{arch} = \frac{1}{2\epsilon} \ln\left(\frac{1+\epsilon}{1-\epsilon}\right) \bar{B}^{plate}.$$

5.2.2. Numerical examples for a circular arch. We illustrate in this section that the convergence rates predicted in Theorem 4.3 are attained for arches using the optimal basis functions. We use the following annular domain with which to verify our theory:

$$\Omega = (0, \pi) \times (1 - \epsilon, 1 + \epsilon).$$

The results in Theorem 4.3 are verified using data with various symmetries to illustrate each of the possibilities.

1. Symmetric data: $f^+_\epsilon = f^-_\epsilon = x(\pi - x)$. Theorem 4.3 predicts that

$$|||u - u_N|||^2 \leq \left(\frac{1}{2\pi} \ln\left(\frac{1+\epsilon}{1-\epsilon}\right)\right)^{4N+1} \zeta(4N+2) \|\triangle^N f^e\|^2_{L^2(\omega)},$$

   where N is the even model order. In particular, the odd basis functions have no effect on the accuracy of the approximation since $f^o = 0$ and there is no odd component of the error term. Since $f_e \in \mathcal{H}^2$ we would not expect to obtain the rate $\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)^{4N+1}$ for values of N larger than 1. The results are given in Figure 2. As can be seen the convergence rate for even model orders $N = 0, 1$ are $\ln\left(\frac{1+\epsilon}{1-\epsilon}\right), \ln\left(\frac{1+\epsilon}{1-\epsilon}\right)^5$, respectively, as predicted, while the full rate is not attained for $N = 2$.
2. Antisymmetric data: $f^+_\epsilon = -f^-_\epsilon = x\pi(x^2 - \pi^2) + x^3(\pi - x)$. Theorem 4.3 predicts that

$$|||u - u_N\|^2 \leq \left(\frac{1}{2\pi} \ln\left(\frac{1+\epsilon}{1-\epsilon}\right)\right)^{4N+1} \frac{4}{\pi} \zeta\left(4N+2, -\frac{1}{2}\right) \|\triangle^N f^o\|^2_{L^2(\omega)},$$

   where N is the odd model order. In particular, the even basis functions now have no effect on the accuracy of the approximation since $f^e = 0$ and there is no even component of the error term. Since $f_o \in \mathcal{H}^4$ we would not expect to observe the rate $\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)^{4N+1}$ for values of N greater than 2. The results are shown in Figure 3, where it is seen that the convergence rate for odd model orders $N = 1, 2$ are $\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)^5, \approx \ln\left(\frac{1+\epsilon}{1-\epsilon}\right)^9$, respectively, as predicted.

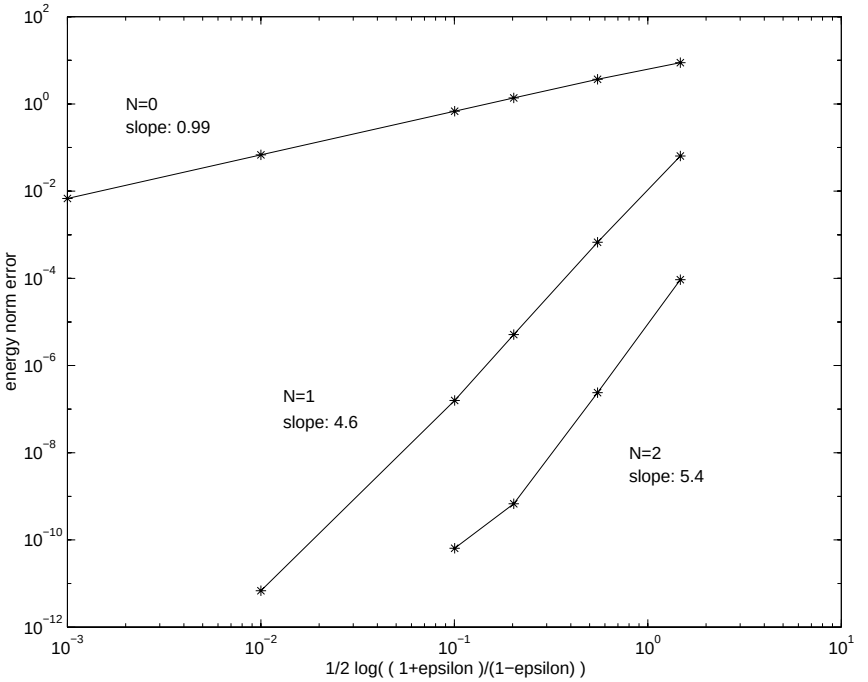

FIG. 2. *Convergence rates for* $f_\epsilon^+ = f_\epsilon^- = x(\pi - x)$ *for even model order* $N_e = 0, 1, 2$. *The gradients of each line are given in brackets below the model order. The results show that as* N_e *is increased from* 0 *to* 1, *the rate of convergence increases from* $\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)$ *to* $\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)^5$ *as predicted in the theory. For* $N_e = 2$ *there is a degradation in the expected convergence rate due to the limited compatibility of the data.*

3. Unsymmetric data: $f_\epsilon^+ = x(\pi - x), f_\epsilon^- = 0$. From (32), it can be seen that there are two parts to the error,

$$\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)^{4N_e+1} \|\triangle^{N_e} f^e\|^2_{L^2(\omega)}, \ln\left(\frac{1+\epsilon}{1-\epsilon}\right)^{4N_o+1} \|\triangle^{N_o} f^o\|^2_{L^2(\omega)},$$

so that merely adding an odd basis function (so that $N_o = N_e + 1$) will not increase the convergence rate: both an odd and an even function need to be added to increase the rate of convergence. The constant of approximation, however, should decrease if only an odd function is added as then the error term has only an even part. Results are given in Figure 4. As can be seen, the numerical results support the theory, since the convergence rate for (0,1) and (1,2) is the same as for $N = 0$ and $(1, 1)\big(\approx \ln\left(\frac{1+\epsilon}{1-\epsilon}\right), \ln\left(\frac{1+\epsilon}{1-\epsilon}\right)^5\big)$, respectively.

5.3. Spherical shells. It follows from Theorem 3.1 that the functions ψ_N, for $N = 1, 2, \ldots$, for a spherical shell are given by

$$(1 + \epsilon r)^2 \frac{d\psi_N^{e,o}}{d\psi} = K_{N-1}^{e,o}, \int_{-1}^{1} \psi_N^{e,o} dr = 0,$$

where K_0^e, K_0^o are as in (24), and $K_N^{e,o}$ for $N = 1, 2, \ldots$ are given by

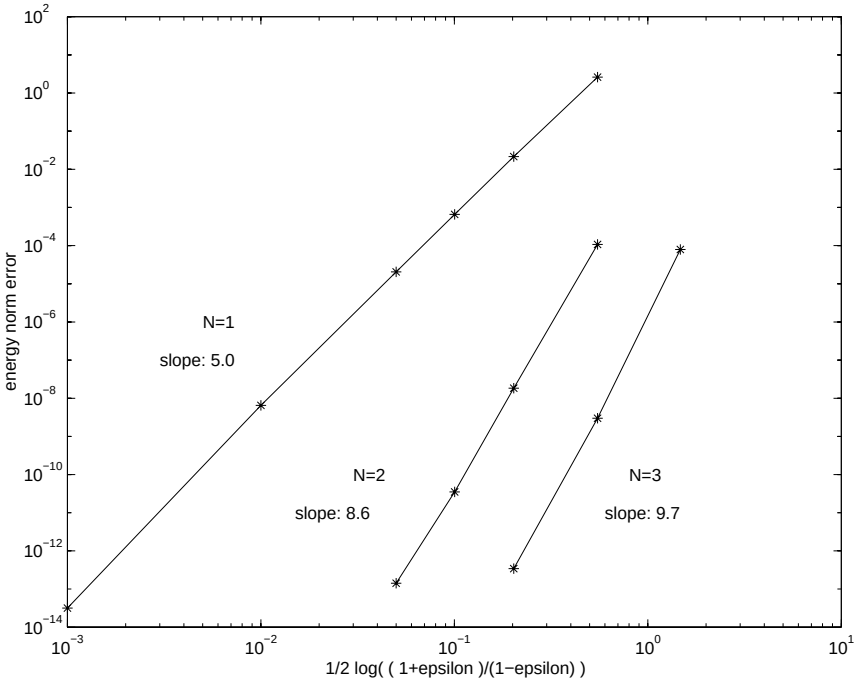

FIG. 3. *Convergence rates for* $f_\epsilon^+ = -f_\epsilon^- = x\pi(x^2-\pi^2) + x^3(\pi - x)$ *for odd model order* $N_o = 1, 2, 3$. *The gradients of each line are given in brackets below the model order. The results show that as* N_o *is increased from* 1 *to* 2, *the rate of convergence increases from* $\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)^5$ *to* $\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)^9$ *as predicted in the theory. For* $N_o = 3$ *there is a degradation in the convergence rate due to the limited compatibility of the data.*

$$(1+\epsilon r)^2 \frac{d^2 K_N^{e,o}}{dr^2} = K_{N-1}^{e,o}; K_N^{e,o}(\pm 1) = 0, \quad N = 1, 2, \ldots.$$

For $N = 0$, ψ_0^e is a constant. For $N > 0$, the solutions to this problem are of the form

$$\psi_N^e = \sum_{j=1}^{N} c_j \frac{(\ln(1+\epsilon r))^{j-1}}{1+\epsilon r} + \sum_{j=0}^{N} d_j (\ln(1+\epsilon r))^j,$$
$$\psi_N^o = \sum_{j=1}^{N} \tilde{c}_j \frac{(\ln(1+\epsilon r))^{j-1}}{1+\epsilon r} + \sum_{j=0}^{N-1} \tilde{d}_j (\ln(1+\epsilon r))^j.$$

For very small values of ϵ, these functions are practically linearly dependent, leading to numerical difficulties. Therefore, a different basis, spanning the same space, is employed:

$$\psi_j^e = \left(\ln\left(\frac{1+\epsilon r}{1-\epsilon}\right)\right)^j, \qquad j = 0, 1, 2 \ldots,$$
$$\psi_j^o = \frac{r}{1+\epsilon r}\left(\ln\left(\frac{1+\epsilon r}{1-\epsilon}\right)\right)^{j-1}, \qquad j = 1, 2, \ldots.$$

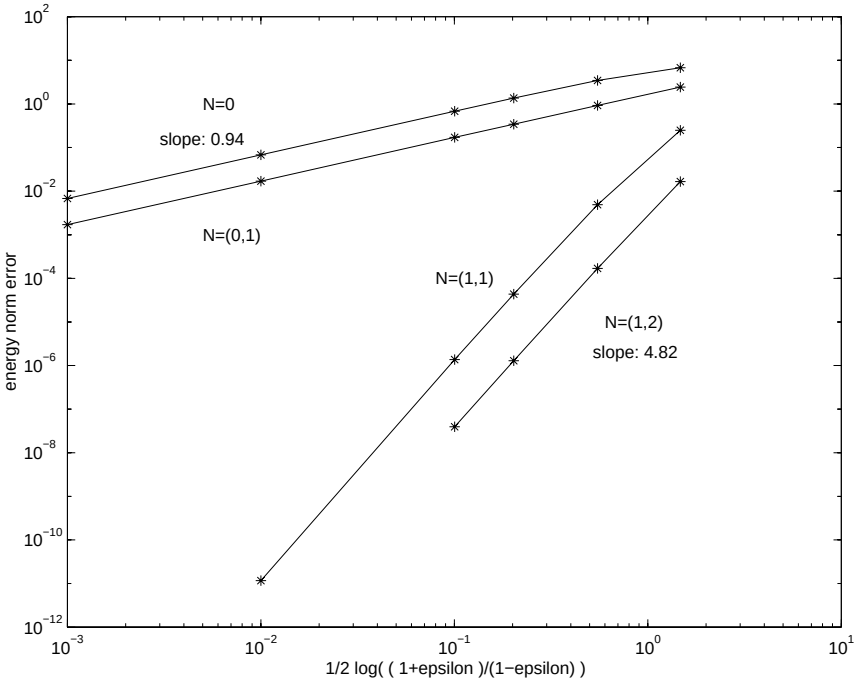

FIG. 4. *Convergence rates for* $f_\epsilon^+ = x(\pi - x), f_\epsilon^- = 0$ *for model orders* $0, (0,1), (1,1), (1,2)$. *The gradients of each line are given in brackets below the model order. The results show that if only* N_o *is increased (so that* $N_o = N_e + 1$*), then there is no increase in the convergence rate.*

5.3.1. Numerical examples. We present numerical results for a problem posed on a complete spherical shell with the following data:

$$f^+ = \left(2(1+\epsilon) - \frac{3}{(1+\epsilon)^4}\right)\sin^2(\theta)\sin(2\phi),$$
$$f^- = -\left(2(1-\epsilon) - \frac{3}{(1-\epsilon)^4}\right)\sin^2(\theta)\sin(2\phi).$$

With this choice of data the true solution u is given by

$$u = (r^2 + r^{-3})\sin^2(\theta)\sin(2\phi).$$

For model orders $N = 0, 1$ (that is, 0,(1,1)) we expect convergence rates in the thickness to be $\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)^{4N+1}$. It can be seen in Figure 5 that this is indeed the case. For the intermediate model orders, there is more rapid convergence than expected, and to see how this happens one has to examine the error term for the constant through the thickness model. By a rearrangement of (21) it can be seen that

$$B(u - u_0, v)$$
$$= \int_\omega d\boldsymbol{\theta} \int_{-1}^{1} dr \frac{r}{2}((1+\epsilon)^2 f^+ + (1-\epsilon)^2 f^-) + \frac{1}{2}((1+\epsilon)^2 f^+ - (1-\epsilon)^2 f^-).$$

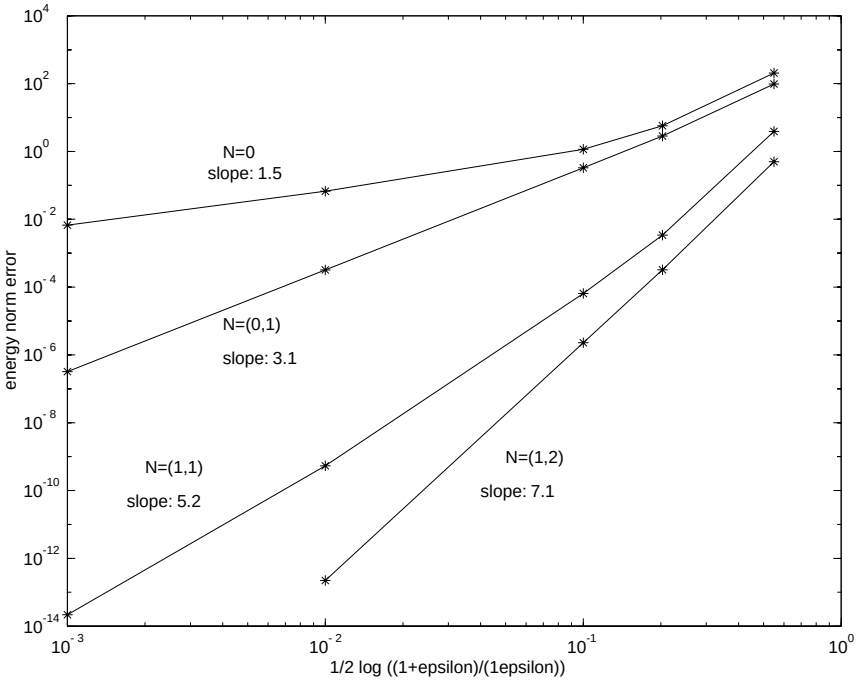

FIG. 5. *Convergence rates for the shell problem using the optimal functions. It can be seen that each time a new function is added to the approximation the convergence rates increase by approximately* $\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)^2$.

Now the function ψ_1^o eliminates the $((1+\epsilon)^2 f^+ - (1-\epsilon)^2 f^-)$ term from $B(u-u_0, v)$. Noting that

$$\begin{aligned}
&(1+\epsilon)^2 f^+ + (1-\epsilon)^2 f^- \\
&= \left(2((1+\epsilon)^3 - (1-\epsilon)^3) - 3\left(\frac{1}{(1+\epsilon)^2} - \frac{1}{(1-\epsilon)^2}\right)\right)\sin^2(\theta)\sin(2\phi) \\
&= \left(2(3\epsilon + \epsilon^3) - \frac{12\epsilon}{(1+\epsilon)^2(1-\epsilon)^2}\right)\sin^2(\theta)\sin(2\phi) \\
&= \epsilon\left(3 + \epsilon^2 - \frac{4\epsilon}{(1+\epsilon)^2(1-\epsilon)^2}\right)\sin^2(\theta)\sin(2\phi) \\
&= O(\epsilon)
\end{aligned}$$

and

$$\begin{aligned}
&(1+\epsilon)^2 f^+ - (1-\epsilon)^2 f^- \\
&= \left(2((1+\epsilon)^3 + (1-\epsilon)^3) - 3\left(\frac{1}{(1+\epsilon)^2} + \frac{1}{(1-\epsilon)^2}\right)\right)\sin^2(\theta)\sin(2\phi) \\
&= \epsilon\left((2+6\epsilon^2) - \frac{6(1+\epsilon^2)}{(1+\epsilon)^2(1-\epsilon)^2}\right)\sin^2(\theta)\sin(2\phi) \\
&= O(1),
\end{aligned}$$

it can be seen that we are left with an $O(\epsilon)$ term, which then produces the high-order convergence rate ϵ^2 in the energy norm. Similarly, this process continues so that

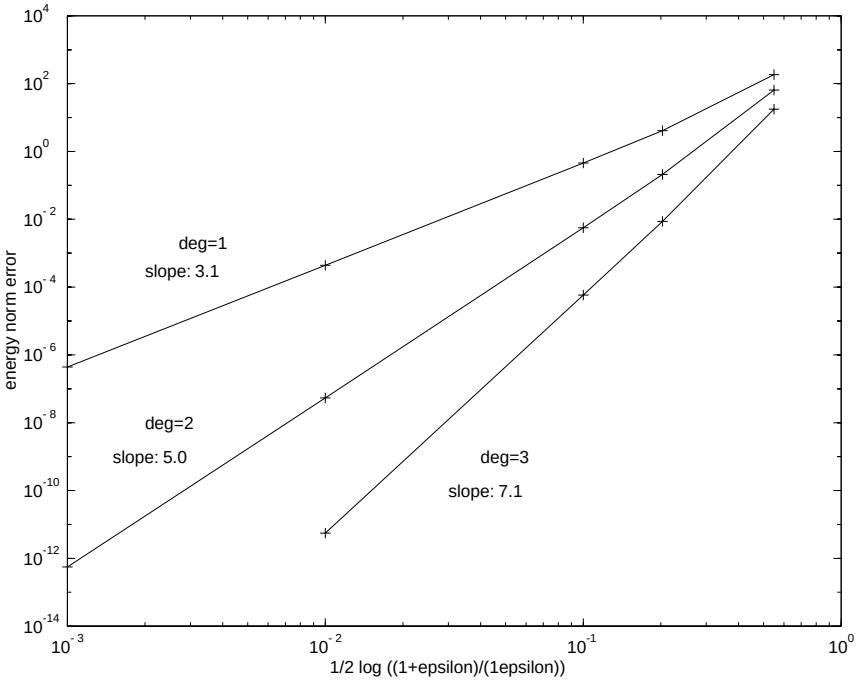

FIG. 6. *A plot showing the convergence rates for an integrated Legendre basis. It can be seen that the convergence rates in* $\ln\left(\frac{1+\epsilon}{1-\epsilon}\right)$ *are approximately the same as for the optimal basis.*

model order (1,2) has convergence of $O(\epsilon^7)$ rather than $O(\epsilon^5)$, as might be expected at first sight.

5.4. Comparison of optimal functions with polynomials. Previous work on dimensional reduction for spherical and cylindrical geometries has involved the use of polynomials in the radial direction. Surana and Abusaleh [25] and Surana and Bose [26] have recommended the use of polynomials in the thickness direction for heat conduction problems on both homogeneous and composite shells, Shen [24] has used polynomials in the radial direction for a Helmholtz problem on a spherical shell, and Cho and Oden [7, 8] have used polynomials to approximate in the radial direction in an elasticity problem on a cylindrical shell. In this section, we compare the error measured in the energy norm for the optimal functions $\{\psi_i\}$ derived earlier with polynomials for heat conduction on a homogeneous spherical shell.

Figures 6 and 7 show the error for the optimal functions compared with polynomials. For model order 0 both methods will be the same since both bases start with the constant function, but for higher model orders, then the constant $C(N)$ is smaller for the optimal functions for both "thin" and "thick" shells. The convergence rates with respect to the thickness are roughly equal for both bases as would be expected since for $\epsilon \ll 1$ the optimal functions behave approximately as polynomials. However, for relatively thick domains, the performance of the optimal functions derived here is superior to that of polynomials. It is worth observing that the cost of using the optimal functions is essentially the same as the cost of a polynomial basis, but the performance is more robust for thick domains.

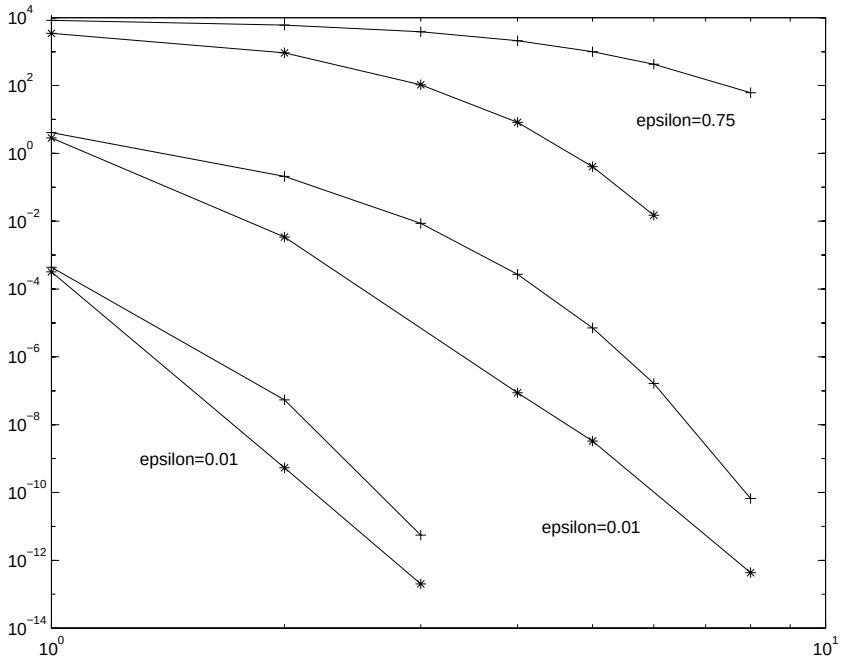

FIG. 7. *A comparison between the convergence rates for the optimal basis and the integrated Legendre basis as the model order (degree for polynomials) increases (for* $\epsilon = 0.75, 0.2, 0.01$*). The plots for the integrated Legendre basis are marked with "+" signs, where the optimal basis is marked with asterisks. It can be seen that the optimal basis is more accurate in each case.*

SCHUR COMPLEMENT SYSTEMS IN THE MIXED-HYBRID FINITE ELEMENT APPROXIMATION OF THE POTENTIAL FLUID FLOW PROBLEM*

J. MARYŠKA†, M. ROZLOŽNÍK‡, AND M. TŮMA†

Abstract. The mixed-hybrid finite element discretization of Darcy's law and continuity equation describing the potential fluid flow problem in porous media leads to a symmetric indefinite linear system for the pressure and velocity vector components. As a method of solution the reduction to three Schur complement systems based on successive block elimination is considered. The first and second Schur complement matrices are formed eliminating the velocity and pressure variables, respectively, and the third Schur complement matrix is obtained by elimination of a part of Lagrange multipliers that come from the hybridization of a mixed method. The structural properties of these consecutive Schur complement matrices in terms of the discretization parameters are studied in detail. Based on these results the computational complexity of a direct solution method is estimated and compared to the computational cost of the iterative conjugate gradient method applied to Schur complement systems. It is shown that due to special block structure the spectral properties of successive Schur complement matrices do not deteriorate and the approach based on the block elimination and subsequent iterative solution is well justified. Theoretical results are illustrated by numerical experiments.

1. Introduction.

Let Ω be a bounded domain in $\mathcal{R}^3$ with a Lipschitz continuous boundary $\partial\Omega$. The potential fluid flow in saturated porous media can be described by the velocity $\mathbf{u}$ using Darcy's law and by the continuity equation for incompressible flow

$$\mathbf{A}\mathbf{u} = -\nabla p, \quad \nabla \cdot \mathbf{u} = q, \tag{1.1}$$

where p is the piezometric potential (fluid pressure), $\mathbf{A}$ is a symmetric and uniformly positive definite second rank tensor of the hydraulic resistance of medium with $[\mathbf{A}(\mathbf{x})]_{ij} \in L^\infty(\Omega)$ for all $i, j \in \{1, 2, 3\}$, and q represents the density of potential sources in the medium. The boundary conditions are given by

$$p = p_D \quad \text{on} \quad \partial\Omega_D, \quad \mathbf{u} \cdot \mathbf{n} = u_N \quad \text{on} \quad \partial\Omega_N, \tag{1.2}$$

where $\partial\Omega = \overline{\partial\Omega_D} \cup \overline{\partial\Omega_N}$ are such that $\partial\Omega_D \neq \emptyset$, $\partial\Omega_D \cap \partial\Omega_N = \emptyset$, and $\mathbf{n}$ is the outward normal vector defined (almost everywhere) on the boundary $\partial\Omega$.

Assume that the domain Ω is a polyhedron and it is divided into a collection of subdomains such that every subdomain is a trilateral prism with vertical faces and

general nonparallel bases (see, e.g., [11], [14], or [15]). We will denote the discretization of the domain Ω by $\mathcal{E}_h$ and assume an uniform regular mesh with the discretization parameter h. Denote also the collection of all faces of elements $e \in \mathcal{E}_h$ which are not adjacent to the boundary $\partial\Omega_D$ by $\Gamma_h = \cup_{e\in\mathcal{E}_h}\partial e - \partial\Omega_D$ and introduce the set of interior faces $int(\Gamma_h) = \Gamma_h - \partial\Omega_N$.

We consider the following low-order finite element approximation. Let

$$\mathbf{RT}^0(e) = \left\{\mathbf{v}^e;\ \mathbf{v}^e(\mathbf{x}) = \sum_{j=1}^{5} \nu_j \mathbf{v}_j^e(\mathbf{x})\ \forall \mathbf{x} = (x_1, x_2, x_3) \in e\right\} \tag{1.3}$$

be the space spanned by the linearly independent basis functions $\mathbf{v}_j^e(\mathbf{x}),\ j = 1, \ldots, 5$ defined on the element $e \in \mathcal{E}_h$ in the form

$$\mathbf{v}_j^e(\mathbf{x}) = k_j^e \begin{pmatrix} 0 \\ 0 \\ x_3 - \alpha_{j3}^e \end{pmatrix},\ j = 1, 2, \quad \mathbf{v}_j^e(\mathbf{x}) = k_j^e \begin{pmatrix} x_1 - \alpha_{j1}^e \\ x_2 - \alpha_{j2}^e \\ \beta_j^e x_3 - \alpha_{j3}^e \end{pmatrix},\ j = 3, 4, 5, \tag{1.4}$$

and such that they are orthonormal with respect to the set of functionals

$$\mathcal{F}_k(\mathbf{v}_j^e) = \int_{f_k^e} \mathbf{n}_k^e \cdot \mathbf{v}_j^e dS = \delta_{jk},\ j, k = 1, \ldots, 5. \tag{1.5}$$

Here f_k^e denotes the kth face of the element $e \in \mathcal{E}_h$ and $\mathbf{n}_k^e = (n_{k,1}^e, n_{k,2}^e, n_{k,3}^e)$ is the outward normal vector with respect to the face f_k^e. The velocity function $\mathbf{u}$ will then be approximated by vector functions linear on every element $e \in \mathcal{E}_h$ from the Raviart–Thomas space

$$\mathbf{RT}_{-1}^0(\mathcal{E}_h) = \left\{\mathbf{v}_h \in \mathbf{L}^2(\Omega);\ \mathbf{v}_h|^e \in \mathbf{RT}^0(e) \quad \forall e \in \mathcal{E}_h\right\}, \tag{1.6}$$

where $\mathbf{v}_h|^e$ denotes the restriction of a function $\mathbf{v}_h$ onto the element $e \in \mathcal{E}_h$. Further denote the space of constant functions on each element $e \in \mathcal{E}_h$ by $M^0(e)$ and denote the space of constant functions on each face $f \in \Gamma_h$ by $M^0(f)$. The piezometric potential p will be approximated by the space which consists of elementwise constant functions

$$M_{-1}^0(\mathcal{E}_h) = \{\phi_h \in L^2(\Omega);\ \phi_h|^e \in M^0(e) \quad \forall e \in \mathcal{E}_h\}, \tag{1.7}$$

where $\phi_h|^e$ is the restriction of a function ϕ_h onto element $e \in \mathcal{E}_h$. The Lagrange multipliers coming from the hybridization of a method will be approximated by the space of all functions constant on every face from Γ_h,

$$M_{-1}^0(\Gamma_h) = \{\mu_h \in L^2(\Omega);\ \Gamma_h \to R;\ \mu_h|^f \in M^0(f) \quad \forall f \in \Gamma_h\}. \tag{1.8}$$

Here $\mu_h|^f$ denotes the restriction of a function μ_h onto the face $f \in \Gamma_h$. Analogously we introduce the spaces $M_{-1}^0(\partial\Omega_D)$ and $M_{-1}^0(\partial\Omega_N)$ as the spaces of functions constant on every face from $\cup_{e\in\mathcal{E}_h}\partial e \cap \partial\Omega_D$ and $\Gamma_h \cap \partial\Omega_N$, respectively. The detailed description of the spaces that we use can be found in [14] (see also [11] or [15]).

The Raviart–Thomas approximation of the mixed-hybrid formulation for the problem (1.1), and (1.2) reads as follows (see [4]):

Find $(\mathbf{u}_h, p_h, \lambda_h) \in \mathbf{RT}^0_{-1}(\mathcal{E}_h) \times M^0_{-1}(\mathcal{E}_h) \times M^0_{-1}(\Gamma_h)$ such that

$$\sum_{e\in\mathcal{E}_h} \{(\mathbf{A}\mathbf{u}_h, \mathbf{v}_h)_{0,e} - (p_h, \nabla\cdot\mathbf{v}_h)_{0,e} + \langle\lambda_h, \mathbf{n}^e\cdot\mathbf{v}_h\rangle_{\partial e\cap\Gamma_h}\}$$

$$= \langle p_{D,h}, \mathbf{n}^e\cdot\mathbf{v}_h\rangle_{\partial e\cap\partial\Omega_D} \quad \forall \mathbf{v}_h \in \mathbf{RT}^0_{-1}(\mathcal{E}_h), \tag{1.9}$$

$$-\sum_{e\in\mathcal{E}_h} (\nabla\cdot\mathbf{u}_h, \phi_h)_{0,e} = -(q_h, \phi_h)_{0,\Omega} \quad \forall \phi_h \in M^0_{-1}(\mathcal{E}_h), \tag{1.10}$$

$$\sum_{e\in\mathcal{E}_h} \langle\mathbf{n}^e\cdot\mathbf{u}_h, \mu_h\rangle_{\partial e} = \langle u_{N,h}, \mu_h\rangle_{\partial e\cap\partial\Omega_N} \quad \forall \mu_h \in M^0_{-1}(\Gamma_h), \tag{1.11}$$

where $p_{D,h}$ and $u_{N,h}$ are approximations to the functions p_D and u_N on the spaces $M^0_{-1}(\partial\Omega_D)$ and $M^0_{-1}(\partial\Omega_N)$, respectively, and where the function q is approximated by $q_h \in M^0_{-1}(\mathcal{E}_h)$. For other details we refer to [14] or [11].

Further denote by $NE = |\mathcal{E}_h|$ the number of elements, by $NIF = |int(\Gamma_h)|$ the number of interior interelement faces, and the number of faces with the prescribed Neumann boundary conditions in the discretization by $NNC = |\partial\Omega_N|$. Let $e_i \in \mathcal{E}_h$, $i = 1, \ldots, NE$, be some numbered ordering of the set of prismatic elements and f_k, $k = 1, \ldots, NIF + NNC$, be the ordering of the set of non-Dirichlet faces from Γ_h. For every element $e_i \in \mathcal{E}_h$ we denote by NIF_{e_i} the number of interior interelement faces and by NNC_{e_i} the number of faces with Neumann boundary conditions imposed on the element e_i. Let the finite-dimensional space $\mathbf{RT}^0_{-1}(\mathcal{E}_h)$ be spanned by $NA = 5 \times NE$ linearly independent basis functions $\mathbf{v}_j$, $j = 1, \ldots, NA$ from the definition (1.6), let the space $M^0_{-1}(\mathcal{E}_h)$ be spanned by NE linearly independent basis functions ϕ_i, $i = 1, \ldots, NE$, and finally the space $M^0_{-1}(\Gamma_h)$ be spanned by $NIF+NNC$ linearly independent basis functions μ_k, $k = 1, \ldots, NIF + NNC$. From this Raviart–Thomas approximation we obtain the system of linear algebraic equations in the form

$$\begin{pmatrix} A & B & C \\ B^T & & \\ C^T & & \end{pmatrix} \begin{pmatrix} u \\ p \\ \lambda \end{pmatrix} = \begin{pmatrix} q_1 \\ q_2 \\ q_3 \end{pmatrix}, \tag{1.12}$$

where $u = (u_1, \ldots, u_{NA})^T$, $p = (p_1, \ldots, p_{NE})^T$, $\lambda = (\lambda_1, \ldots, \lambda_{NIF+NNC})^T$ are unknowns, the symmetric positive definite matrix block $A \in \mathcal{R}^{NA,NA}$ is given by the terms $(\mathbf{A}\mathbf{v}_i, \mathbf{v}_j)_{0,\Omega}$, the outdiagonal block $B \in \mathcal{R}^{NA,NE}$ by $-(\nabla\cdot\mathbf{v}_i, 1)_{0,e_j}$, and the block $C \in \mathcal{R}^{NA,NIF+NNC}$ by $\langle\mathbf{n}_k\cdot\mathbf{v}_i, 1\rangle_{f_k}$. Here $\mathbf{n}_k$ is the outward normal vector to with respect to the face $f_k \in \Gamma_h$ (see [11] and [14]).
