The resulting refined subdomain mesh for one subdomain and the corresponding solution (the deformation mapping φ) is shown in Figure 12. (The deformation is taken to be larger than the range of validity of the linear elasticity equations for visualization purposes.) As in the PLTMG examples, the refinement performed by MC is confined primarily to the given region, with some refinement into adjacent regions due to the closure algorithm which maintains conformity and shape regularity. The four problems are solved completely independently by the sequential adaptive code MC. This decomposition approach is especially effective for this particular problem due to the structure of the object, which leads to very weak couplings between the deformations of the individual letters, and due to the fact that the spectral bisection algorithm happens to decomposes the mesh close to the boundaries of the letters.

2.4. A 3D nonlinear elliptic system arising in gravitation. The fourth and final example involves the use of MC to solve a coupled nonlinear elliptic system in R^3, namely, the elliptic constraints in the Einstein equations (cf. [38]):

$$\hat{\gamma}^{ab}\hat{D}_a\hat{D}_b\phi = \frac{1}{8}\hat{R}\phi - \frac{1}{8}\phi^{-7}(\hat{A}^*_{ab} + (\hat{l}W)_{ab})^2 + \frac{1}{12}(\mathrm{tr}K)^2\phi^5 - 2\pi\hat{\rho}\phi^{-3}, \tag{2.6}$$

$$\hat{D}_b(\hat{l}W)^{ab} = \frac{2}{3}\phi^6\hat{D}^a\mathrm{tr}K + 8\pi\hat{j}^a. \tag{2.7}$$

The unknowns are the "conformal factor" ϕ and the vector potential W^b. The $(\hat{l}W)^{ab}$ operator above is a certain symmetrized gradient operator for tensors:

$$(\hat{l}W)^{ab} = \hat{D}^aW^b + \hat{D}^bW^a - \frac{2}{3}\hat{\gamma}^{ab}\hat{D}_cW^c. \tag{2.8}$$

The Einstein summation convention is used above, so that all repeated symbols in products imply a sum over that index. The gradient operator $\hat{D}^a$ is covariant, meaning that its application requires the use of Christoffel symbols due to the curvilinear nature of the coordinate system required to represent the underlying domain manifold. The Christoffel symbols are formed with respect to an underlying background metric $\hat{\gamma}^{ab}$, so that the left-hand side of the first equation for the conformal factor ϕ is essentially a covariant Laplace operator.

To use MC to calculate the initial bending of space and time around two massive black holes separated by a fixed distance by solving the above constraint equations, we place two spherical objects in space, the first object having unit radius (after appropriate normalization), the second object having radius 2, separated by a distance of 20. Infinite space is truncated with an enclosing sphere of radius 100. (This outer boundary may be moved further from the objects to improve the accuracy of boundary condition approximations.) Physically reasonable functions for remaining parameters

appearing in the equations are used to completely specify the problem (cf. [16] for details).

We then generate an initial (coarse) mesh of tetrahedra inside the enclosing sphere, exterior to the two spherical objects within the enclosing sphere. The mesh is generated by adaptively bisecting an initial mesh consisting of an icosahedron volume filled with tetrahedra. The bisection procedure simply bisects any tetrahedron which touches the surface of one of the small spherical objects. When a reasonable approximation to the surface of the spheres is obtained, the tetrahedra completely inside the small spherical objects are removed, and the points forming the surfaces of the small spherical objects are projected to the spherical surfaces exactly. This projection involves solving a linear elasticity problem (nearly identical to the problem solved in Example 3 above), together with the use of a shape-optimization-based smoothing procedure. The smoothing procedure locally optimizes the following shape measure function for a given d-simplex s, in an iterative fashion, similar to the approach taken in [4]:

$$\eta(s,d) = \frac{2^{2(1-\frac{1}{d})} 3^{\frac{d-1}{2}} |s|^{\frac{2}{d}}}{\sum_{0 \le i < j \le d} |e_{ij}|^2}.$$

The quantity $|s|$ represents the (possibly negative) volume of the d-simplex s, and $|e_{ij}|$ represents the length of the edge that connects vertex i to vertex j in the simplex. For $d = 2$, this is the shape-measure used in [4], with a slightly different normalization. For $d = 3$, this is the shape-measure given in [18], again with a slightly different normalization. Unlike Laplace smoothing, this local shape optimization approach is guaranteed to improve the shape of elements locally at each step, and always maintains a mesh of simplices with positive volumes.

The initial coarse mesh in Figures 13 and 14, generated using the procedure described above, has 31786 tetrahedral elements and 5809 vertices. As in the previous examples, we partition the domain into four subdomains (shown in Figures 15 and 16 with approximately equal error using the recursive spectral bisection algorithm described in section 3 below. The four subdomain problems are then solved independently by MC, starting from the complete coarse mesh and coarse mesh solution. The mesh is adaptively refined in each subdomain until a mesh with roughly 50000 vertices is obtained (yielding subdomains with about 250000 simplices each).

The resulting refined subdomain meshes are shown in Figures 17 and 18. As in the previous examples, the refinement performed by MC is confined primarily to the given region, with some refinement into adjacent regions due to the closure algorithm which maintains conformity and shape regularity. The four problems are solved completely independently by the sequential adaptive code MC. One component of the solution (the conformal factor ϕ) of the elliptic system is depicted in Figure 19 (the subdomain zero solution) and in Figure 20 (the subdomain two solution).

3. Computational considerations.

3.1. A spectral bisection algorithm. In this section we describe the algorithm we use for partitioning the coarse mesh so that each subregion has approximately equal error. This algorithm is a variant of the recursive spectral bisection algorithm [11, 27, 31]. While this particular mesh partitioning algorithm is one of the more expensive of the choices that we could make, we emphasize that it is used in our algorithm *only once*, and it is only used on a very small coarse grid problem. As

a result, the initial partitioning cost is much smaller than the solve time for a single subdomain problem (see Tables 1 and 2 below).

Let $\mathcal{T}$ denote a triangulation of the domain Ω with triangular elements $t_i \in \mathcal{T}$, $1 \le i \le N$, and let e_i denote the a posteriori error estimate for t_i,

$$e_i \approx \|\nabla(u - u_h)\|^2_{t_i}.$$

Define the $N \times N$ symmetric, positive semidefinite M-matrix A by

$$A_{ij} = \begin{cases} -1, & i \neq j \text{ and } t_i \text{ and } t_j \text{ share a common edge,} \\ 0, & i \neq j \text{ and } t_i \text{ and } t_j \text{ do not share a common edge,} \\ s_i, & i = j,\ s_i = -\sum_{k \neq i} A_{ik}, \end{cases}$$

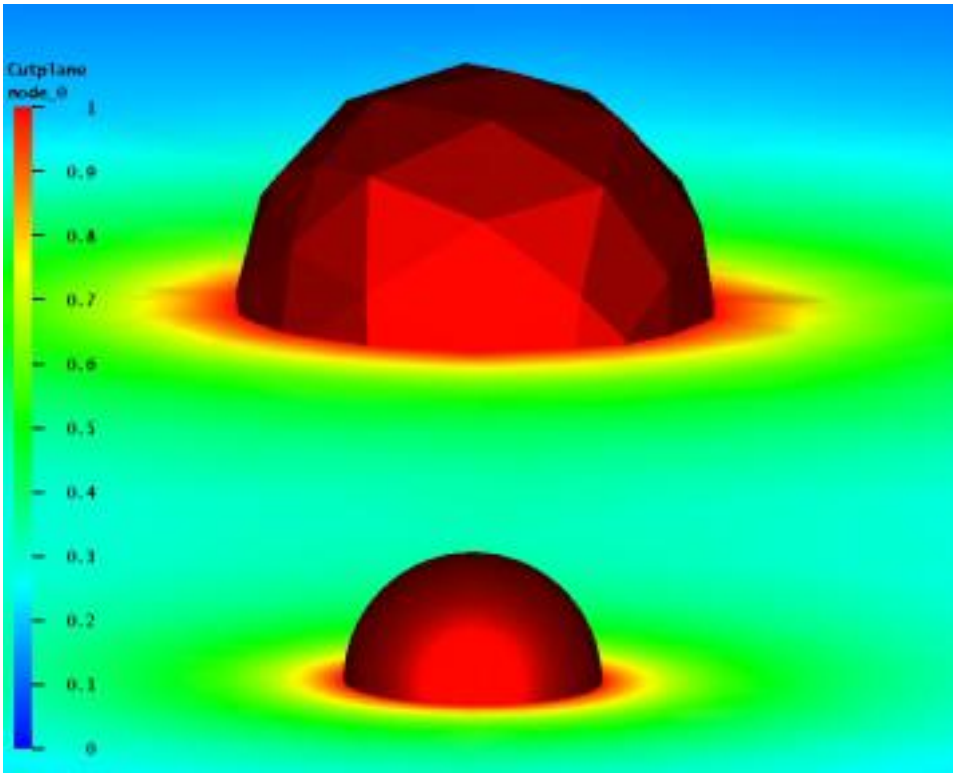

FIG. 19. *The conformal factor ϕ from the adapted subdomain* 1 *solve.*

and the positive diagonal matrix D by

$$D_{ii} = e_i / e_{max},$$

where

$$e_{max} = \max_i e_i.$$

A typical row of A will have three nonzero off-diagonal elements and $A_{ii} = 3$; this is the so-called *discrete Laplacian* for the dual graph for the triangulation. (The triangles themselves are the nodes of the dual graph, and the edges are defined by the adjacency relation.) We consider the generalized eigenvalue problem

$$A\psi = \lambda D\psi. \tag{3.1}$$

Our approach is standard; by construction, the smallest eigenvalue for (3.1) is $\lambda_1 = 0$ and $\psi_1 = (1, 1, \ldots, 1)^t$. Our interest is in the second eigenvector ψ_2, known as the Fiedler vector.

Let $\mathcal{S}^+$ and $\mathcal{S}^-$ denote the index sets corresponding to positive and nonpositive components of ψ_2. Then from the orthogonality relation

$$\psi_1^t D\psi_2 = 0$$

we have

$$\sum_{i\in\mathcal{S}^+} e_i\psi_{2,i} = -\sum_{i\in\mathcal{S}^-} e_i\psi_{2,i}.$$

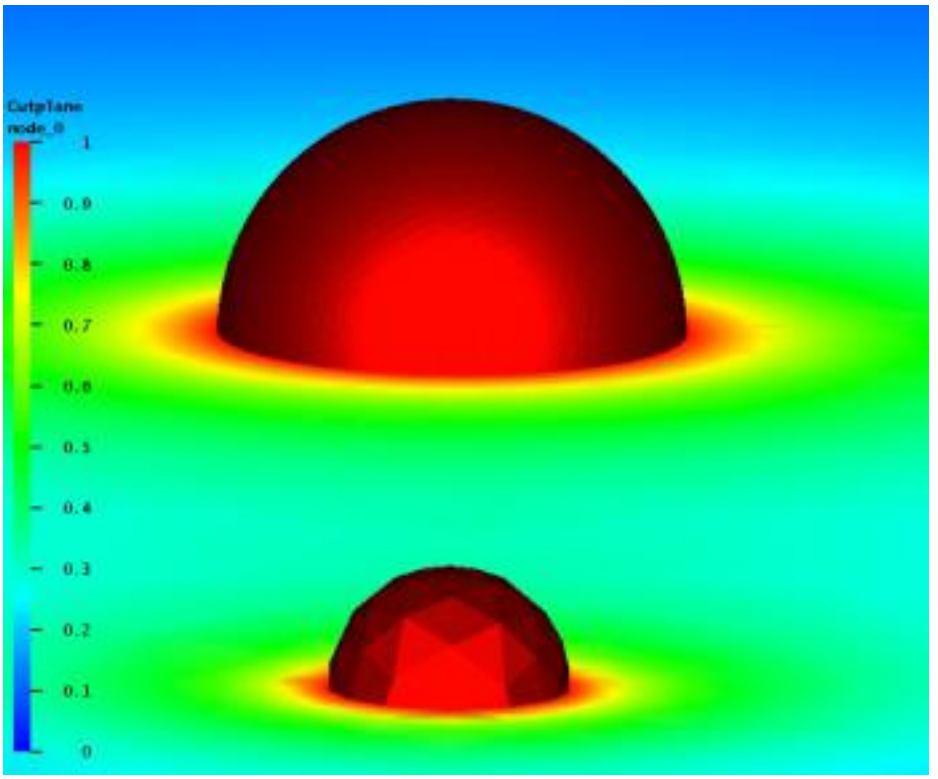

FIG. 20. *The conformal factor ϕ from the adapted subdomain* 3 *solve.*

This indicates that the total error for the two groups of triangles is approximately balanced (and would be exactly balanced if all entries of ψ_2 were ± 1). Using this observation as motivation, to construct a partition of the elements we first find a permutation of the elements $\{p_i\}$ such that

$$\psi_{2,i} \leq \psi_{2,j} \quad \text{if and only if} \quad p_i < p_j.$$

We then find the index k which provides the best partition of the form

$$\sum_{p_i \leq k} e_i \approx \sum_{p_i > k} e_i. \tag{3.2}$$

Often this partition is very close to the partition based on $\mathcal{S}^{\pm}$. This is similar to the strategy suggested by Chan, Ciarlet, and Szeto [11].

As usual, we apply this approach recursively, at each level dividing each group of elements into two smaller groups by solving an eigenvalue problem of the type (3.1) restricted to that group of elements. Thus after k steps, we have created a partition of the elements into 2^k groups of roughly equal error.

We now briefly describe some details of our procedure for computing the second eigenvector of (3.1). Our procedure is essentially just a classical Rayleigh quotient iteration [25], modified both to bias convergence to λ_2, and to account for the fact that the linear systems arising in the inverse iteration substep are solved (approximately) by an iterative process. To simplify notation and avoid multiple subscripts, we let $\phi_k \approx \psi_2$, where k now denotes the iteration index.

We suppose that we have a current iterate ϕ_k which satisfies

$$\phi_k^t D\phi_k = 1 \qquad \text{and} \qquad \psi_1^t D\phi_k = 0. \tag{3.3}$$

Using ϕ_k we compute the approximate eigenvalue $\sigma_k \approx \lambda_2$ from the Rayleigh quotient

$$\sigma_k = \phi_k^t A \phi_k$$

and form the residual vector

$$r_k = \sigma_k D\phi_k - A\phi_k.$$

Note that by construction $\psi_1^t r_k = \phi_k^t r_k = 0$. Next, we approximately solve the linear system

$$(A - \theta_k \sigma_k D)\tilde{\delta}_k = r_k, \tag{3.4}$$

where $0 \le \theta_k \le 1$ is chosen to try to insure $0 \le \theta_k \sigma_k \le \lambda_2$. A simple strategy such as $\theta_k = 1 - 2^{-k}$ is often effective (although, of course, offers no guarantees). From $\tilde{\delta}_k$, we form the vector δ_k satisfying

$$\delta_k^t D\delta_k = 1 \qquad \text{and} \qquad \psi_1^t D\delta_k = \phi_k^t D\delta_k = 0.$$

The inverse iteration step uses a conservative shift policy in order to strongly bias the calculation in favor of convergence to the desired second eigenvector. The residual appears as right-hand side, since this system is to be solved by iteration rather than by direct Gaussian elimination. In this circumstance only a few iterations are used, and the effect is mainly to attenuate unwanted eigenvectors rather than "blow up" the desired eigenvector. For our iterative method, we use a conjugate gradient procedure with symmetric Gauss–Seidel preconditioner. So far, this has proven to be simple and effective, but the issue of the most efficient solver in this context is presently open.

Finally, we solve the 2×2 eigenvalue problem

$$\hat{A}v = \lambda v,$$

where

$$\hat{A} = \begin{pmatrix} \phi_k^t \\ \delta_k^t \end{pmatrix} A \begin{pmatrix} \phi_k & \delta_k \end{pmatrix}.$$

If $v = (\alpha, \beta)^t$ is an eigenvector corresponding to the smaller eigenvalue, we form

$$\tilde{\phi}_{k+1} = \alpha\phi_k + \beta\delta_k,$$

and then ϕ_{k+1} is formed from $\tilde{\phi}_{k+1}$ by imposing conditions (3.3). The use of this subspace-iteration–like calculation rather than a simple eigenvector update provides a second means to bias the overall Rayleigh quotient iteration towards convergence to ψ_2. It also compensates to some extent for the loss in convergence rate due to the conservative shift policy and incomplete solution of (3.4) by iteration.

This completes the description of a single Rayleigh quotient iteration. Note that continually imposing orthogonality conditions with respect to ψ_1 is mathematically unnecessary, but is important in practice because this direction is reintroduced by roundoff error. Without systematically and continually excluding this eigenvector, the Rayleigh quotient iteration could easily converge to ψ_1.

3.2. Load balancing. Partitioning the domain to achieve approximately equal error in each subregion is not really the optimal approach. The optimal strategy is to partition the domain such that each subregion requires equal *work* for the ensuing calculation, and the errors are approximately equal in each element of the global composite mesh. Estimating the work is problematic for many reasons, among them:

- The cost of function evaluations and numerical integration used in computing matrices, right-hand sides, and a posteriori error estimates might vary significantly in various regions. Moreover, the number of such quadratures depends on the number of elements, and the number of instances when such assembly steps are required.
- The number of iterations of Newton's method for nonlinear systems and linear iterative methods for linear systems may vary slightly from problem to problem, even though all are derived from the same continuous problem. Because the number of iterations is usually small, the percentage change in the work can be quite large (e.g., 3 rather than 2 multigrid cycles represents a 50% increase in the work for that part of the computation). It should also be clear that such small differences are difficult to predict in advance of the actual calculation. The cost per iteration will also vary due to differing orders of the problems.
- The cost of grid management (refining, unrefining, moving the mesh points, and maintaining the relevant data structures) will vary with the number of elements involved and the particular mix of tasks.
- The number of major iterations through the adaptive feedback loop may differ from problem to problem, even if the final meshes all have about the same number of unknowns.

Creating subregions of approximately equal error for the initial partition really amounts to the fragile assumption that this corresponds to approximately equal work for each processor. Although one can hope that more sophisticated models of work will lead to improvement, it seems certain that the overall flexibility and complexity of current adaptive solvers will still make this aspect of the initial load balancing phase problematic.

On the positive side, despite all the dangers mentioned above, our load balancing procedure using a posteriori error estimates has empirically been observed to be much better than one might at first expect, at least for the classes of problems we address. For example, in Table 1, we give the overall execution times (in seconds) for the two PLTMG example calculations described in section 2 (examples 1 and 2 in sections 2.1 and 2.2, respectively). These times are for an SGI Octane 195mhz R10000, using the f77 compiler options -O -32.

In Table 2, we give the execution times (in seconds) for the two MC example calculations described in section 2 (examples 3 and 4 in sections 2.3 and 2.4, respectively). These times are for a single 195Mhz R10000 processor of an SGI Octane, using the IRIX C compiler with optimization -O2. While the numbers of vertices and elements in the subdomain meshes of the 3D UCSD example are similar to the two PLTMG examples, there are actually three unknowns at each vertex (the three displacement degrees of freedom), so the discrete problem sizes are triple the number of vertices.

The initialization times in both tables includes generating a coarse mesh from the geometry description, solving the coarse mesh problem, computing a posteriori error estimates, and partitioning the domain. The initialization was done on one processor.

Global test solution	422	—

The times for each of the subproblems include all aspects of the adaptive feedback loop, including matrix and right-hand side assembly, solution of linear and nonlinear systems, a posteriori error estimation, and adaptive refinement and mesh smoothing. In Table 1, this also includes some relatively inexpensive clean-up performed by PLTMG, mainly removing unwanted parts of each mesh and solution in preparation for creating the global composite mesh. (These calculations are not performed by MC and do not appear in the timing figures in Table 2.)

The postprocessing costs given in Table 1 for the PLTMG implementation includes the creation of a global conforming mesh and forming an initial guess for the solution on that mesh using the procedures described in section 4.1. In our present code, this is also done on one processor. In contrast, the MC implementation does not form a global problem; this is justified to some extent in section 4.3. The global test solution costs listed in Table 2 for the first MC example reflects the cost of solving the entire problem sequentially on one processor without decomposition. (The refined black hole subdomain problems were so large that it was not possible to solve a single global problem on an SGI Octane with roughly four times the number of simplices of each subdomain problem.) What is interesting to note is that the overhead required to decompose the problem is amortized by the gain due to the reduced subproblem sizes; solving the subproblems sequentially is actually faster than solving the global problem. In other words, if the solution quality of the decomposition algorithm is reliable, then the decomposition algorithm actually reduces the sequential solution time when viewed purely as a sequential algorithm. Note that if the decomposition algorithm is used in conjunction with solvers with less favorable complexities than the $O(N \log N)$ complexities in PLTMG and MC, then the decomposition algorithm would show an even larger gain over solving the global problem.

From Tables 1 and 2 we see that although the mix of calculations was different for each subproblem, the overall times do not vary too much. And since these problems were solved completely independently, there was no time spent in communication between processors, synchronization, etc. Thus to some extent, the time potentially

saved by not having the processor communicate during the bulk of the computation offsets the time potentially lost by imperfect load balancing. The potential flow problem has a smaller initialization time than the convection-diffusion problem, mainly due to the smaller size of its coarse mesh problem (221 vertices compared to 1368). The solution times for the subspace problems are larger, due mainly to the facts that the potential flow problem is nonlinear and involves a Newton iteration, and it has more expensive coefficient function evaluations in the assembly phases and the a posteriori error estimates. In the 3D examples, the black hole calculation has a much larger initialization time than the elasticity problem due to the size of the initial coarse mesh (159 vertices compared with 5,809 vertices).

3.3. Scalability. We now consider some aspects of the scalability of our procedure. Let N_c denote in the size of the coarse grid problem (number of elements or grid points). Let N_f denote the target size of the global fine grid problem, p denote the number of processors, and N_p denote the target problem size for each of the processors.

We have, approximately,

$$N_p \approx N_c + \frac{N_f - N_c}{p}. \tag{3.5}$$

Relation (3.5) does not take into account the fact that the processor given the task of refining subregion Ω_i will refine some elements *not* in Ω_i. This will occur mainly near the interface boundaries of Ω_i, where the mesh will be graded in a smooth fashion from the smaller elements of Ω_i to larger elements that cover the remainder of Ω. Such grading is necessary to maintain a conforming, shape regular mesh. In a typical situation, one would expect this to be an effect of order $O(N_p^{1/2})$ in 2D, and of order $(N_p^{2/3})$ in 3D. Nevertheless, in practical situations, choosing $N_p > N_c + (N_f - N_c)/p$ is generally needed to achieve a fine grid problem size of N_f.

It seems clear that generally one should have

$$N_c \gg p. \tag{3.6}$$

A requirement like (3.6) is important to give the partitioning algorithm enough flexibility to construct regions of approximately equal error. For example, in the extreme case where the number of elements and the number of processors are equal, then the only partition is to provide one element to each processor, regardless of the error. This would likely result in a very uneven distribution of the error and poor performance of our adaptive refinement strategy.

It also is important to have

$$N_p \gg N_c. \tag{3.7}$$

This will marginalize the cost of redundant computations. For example, if $N_p = 2N_c$, then one could expect that about half of the computation on each processor would be redundant, which is a significant fraction of the total cost. By solving the problem on the entire domain, using a coarse mesh in all but one subregion, we are in effect substituting computation for communication. This trade-off will be most effective in situations where N_p is much larger than N_c (e.g., $N_p > 10N_c$) so that the redundant computation represents a small fraction of the total cost.

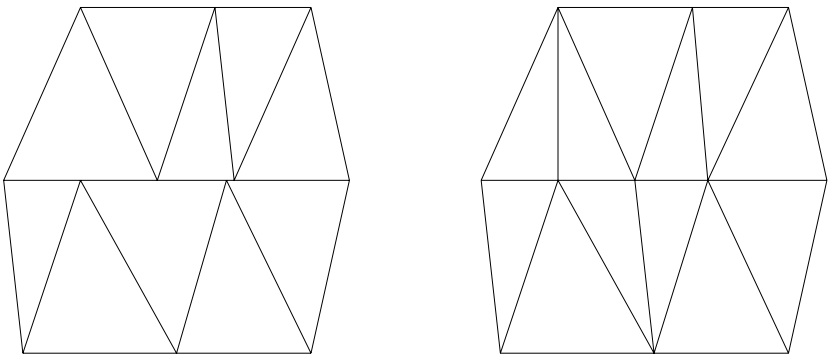

FIG. 21. *Nonmatching interface, shown on the left, is made conforming by refining elements and adjusting vertex locations. The resulting conforming interface is shown on the right.*

Taken together (3.5)–(3.7) indicate that for good performance, the difficulty of the problem must in some sense scale in proportion to the number of processors. That is, "simple" problems with only a few significant features that need to be resolved through refinement can most efficiently be solved using a few processors. Such problems could be handled on a small network of powerful workstations. Using our procedure effectively with, say, $p = 128$, would require a more difficult problem which could be decomposed into at least 128 regions, with most including some interesting behavior to resolve.

4. The global solution. In this section we discuss some options for combining the independent calculations to form a global composite mesh and solution.

4.1. Conforming meshes and global smoothing. In PLTMG, we have implemented an option where the independently generated meshes are glued together to form a global conforming mesh. We begin by simply deleting unwanted parts of the mesh from each of the independently solved problems. The union of the remaining submeshes forms a global mesh. Mesh points on the interfaces are restricted to move only along the interface during mesh smoothing phases of the independent solution process, so the overall geometry of the subregions remains conforming. However, along the interfaces the meshes will generally be nonmatching, leading to a global nonconforming triangulation, as shown in Figure 21. This mesh is made globally conforming through a combination of the refinement of triangles with boundary edges on the interface, and adjusting the locations of some interface vertices. The result is a matching grid along the interface and a globally conforming triangulation. These alternatives are illustrated in Figure 21. Once the mesh is globally conforming, local mesh improvement routines of PLTMG (e.g., edge swapping and mesh smoothing) can be employed to improve the shape regularity of the elements as needed.

We remark that the element sizes on both sides of an interface should be approximately equal if the load balancing algorithm is working properly, so that this gluing process, although technically complicated in terms of data structures and implementation, is both simple and natural at a more abstract level.

If one uses a refined element tree data structure for the refinement process [3, 5], as in previous versions of PLTMG, then this procedure is greatly simplified, since each independent problem starts from the same element tree. A simple postprocessing step

can enforce equal (and hence conforming) levels of refinement for elements sharing an interface edge. Also, if mesh smoothing is disallowed for vertices on the interface, the post processing is further simplified, since each interface vertex created during the independent solution process will be exactly the midpoint of the edge it refines. Assuming the refinement levels are approximately the same on both sides of an interface, it is likely that most vertices along an interface from one independent problem will have matching counterparts on the other side of the interface from another independent problem. Furthermore, the locations of nonmatching vertices cannot be arbitrary, but must lie, e.g., at midpoints of unrefined edges. Such additional constraints, if present in the refinement algorithm, greatly simplify the algorithm for rendering a conforming mesh.

In any event, once a conforming mesh is created, a solution on the globally refined mesh can be defined as follows. For vertices not on the interface, we use the solution from the independent problem corresponding to that region. For vertices on the interface, the solution is defined by a simple averaging of the solutions from the relevant independent problems. This procedure seems adequate if the resulting solution is to serve only as an initial guess for a subsequent global solution technique. However, one could conceive of more sophisticated and more accurate procedures. For example, one could assemble and solve a problem for the interface values, holding all other values fixed. This results in a low-dimensional system consisting mainly of tridiagonal blocks, with some interblock coupling due to so-called *cross points*. One could also include points adjacent or near to the interfaces as well, yielding larger, but still easily solved systems of equations.

In our present code, all postprocessing is done on one processor, following the solution phase. There are several ways one could make this parallel. For example, one could initially have several processors each glue together the results from two subproblems. These larger pieces then could be combined (in parallel) to make composite meshes arising from four subproblems. Continuing in this fashion leads to an overall algorithm with logarithmic complexity. However, we prefer a simple alternative strategy in which some processors solve subproblems while other processors simultaneously postprocess results from earlier computations.

An example is given in Table 3. Here we assume that the domain is partitioned into 16 subproblems ($P_1 - P_{16}$) to be distributed among four processors. Rather than provide four problems to each processor, we provide five problems to three of the processors and only one to the fourth. After solving its subproblem, this processor then begins the task of postprocessing the previously computed solutions. We remark that the cost of postprocessing a problem is usually less than one-third the cost of solving it. Indeed it was much smaller in both examples given in Table 1. This ratio was assumed for convenience in this illustration; in practice, one might assign Processor 0 several subproblems before switching to postprocessing calculations.

To compute the global solution, one can of course simply assemble and solve the global problem on a single processor. This was the choice made in PLTMG, but it was made mainly to maximize the use of the existing code, rather than for reasons of efficiency. More in keeping with the overall strategy of parallel processing, there are a variety of standard domain decomposition approaches that could be applied in this situation, both with and without overlap. The relevant decomposition and communication channels can be based on the same partitioning used to create the independent problems, which greatly simplifies the implementation. One could also apply parallel multigrid or another parallel iterative method to this situation. Here

the parallel multigrid method of Mitchell [20, 21, 22] seems particularly appropriate. In any event, by creating a good initial guess from the solutions of the independent problems, very little work (e.g., few iterations) should be required to compute the global solution.

4.2. Mortar elements. In the 3D case, producing a global conforming mesh is much more problematic, in that face matching simply through bisection is not achievable as it is in the 2D case. This is a well-known problem, and impacts adaptive tetrahedral subdivision algorithms based on octasection of tetrahedra [39, 24, 9]. We consider two approaches for dealing with this difficultly in the present context. The first of these is the mortar elements, which is discussed here; the second approach is described in the next section.

One approach for making a global solution from subdomain solutions on nonconforming subdomains is to simply use the global nonconforming mesh and establish weak continuity of the solution on the interface using so-called *mortar elements* [8, 7]. Although originally developed as a technique to couple spectral and finite element methods, it can be used to couple finite element discretizations which are conforming within subdomains but have nonmatching meshes at the interfaces of the subdomains.

To keep the discussion simple, suppose that there are only two subregions with a single interface Γ. Let $u_h^{(1)}$ and $u_h^{(2)}$ denote the approximate solutions for the two subregions. Rather than forcing the mesh along the interface to become conforming, we impose continuity of the computed solution weakly, as

$$\int_\Gamma (u_h^{(1)} - u_h^{(1)})\phi \, dx = 0 \quad \text{for all } \phi \in \mathcal{V}, \tag{4.1}$$

where $\mathcal{V}$ is some suitably chosen mortar space. See [8, 7, 1, 6] for details on the selection of $\mathcal{V}$. When assembled, the resulting system of linear equations will have the classic saddle point structure

$$\begin{pmatrix} A_1 & 0 & B_1 \\ 0 & A_2 & B_2 \\ B_1^t & B_2^t & 0 \end{pmatrix} \begin{pmatrix} U_1 \\ U_2 \\ \Lambda \end{pmatrix} = \begin{pmatrix} R_1 \\ R_2 \\ 0 \end{pmatrix}, \tag{4.2}$$

where, as usual, A_i correspond to individual subregions and B_i corresponds to the coupling of the subregions through the mortar space $\mathcal{V}$. The space $\mathcal{V}$ plays the role of

Lagrange multipliers in the saddle point problem, and the element of $\mathcal{V}$ corresponding to the solution of (4.2) has a physical interpretation in terms of an approximation to the normal component of ∇u on Γ.

From its structure, it is clear that one may apply classical domain decomposition techniques to the solution of (4.2) (and the more general case of many subregions). All of the information related to each subdomain is already present on the processor responsible for adaptively creating that portion of the composite mesh. Communication between processors is necessary for coupling through the mortar elements, but as usual, the required information is related to the solution and the structure of the mesh only along the interface, generally a small amount of data in comparison with the size of the subdomains.

4.3. Overlapping decompositions and interior estimates. The simplest way to form a global solution is not to form one, meaning that the subdomain solutions themselves are taken to be the final discrete solution represented subdomainwise. To evaluate the solution at any point $x \in \bar{\Omega}$, one simply must determine which subdomain contains the point x and then fetch the solution value from the particular subdomain. While this approach seems naive, some recent [37] and not so recent [23, 28, 29] theoretical results actually support this.

The principle idea underlying the results in [37] is that while elliptic problems are globally coupled, this global coupling is essentially a "low-frequency" coupling, and can be handled on a mesh which is much coarser than that required for approximation accuracy considerations. This idea has been exploited for example in [19, 36], and is, in fact, why the construction of a coarse problem in overlapping domain decomposition methods is the key to obtaining convergence rates which are independent of the number of subdomains (cf. [35]).

The key results in [37] for our purposes are the following a priori and a posteriori error estimates. To explain, let Ω_k be the collection of disjoint subregions of the domain Ω defined by the weighted spectral bisection algorithm of the previous section, and let Ω_k^0 to be an extension of the disjoint Ω_k, such that $\Omega_k \subset\subset \Omega_k^0$, and so that the sizes of the overlap regions $\Omega_i^0 \bigcap \Omega_j^0$ are on the order of the sizes of the regions Ω_k. Under some reasonable assumptions about the approximation properties of a finite element space S_0^h defined over Ω (existence of superapproximation, inverse, and trace inequalities), the following a priori error estimate holds for the global Galerkin solution u_h to a Poisson-like linear elliptic equation:

$$\|u - u_h\|_{H^1(\Omega_k)} \leq C \left(\inf_{v \in S_0^h} \|u - v\|_{H^1(\Omega_k^0)} + \|u - u_h\|_{L^2(\Omega)} \right),$$

and the following a posteriori error estimate holds (where $\eta(u_h)$ is a locally computable jump function):

$$\|u - u_h\|_{H^1(\Omega_k)} \leq C \left(\|h\eta(u_h)\|_{L^2(\Omega_k^0)} + \|u - u_h\|_{L^2(\Omega)} \right).$$

The a priori result states that the error in the global Galerkin solution u_h restricted to a subdomain Ω_k can be bounded by the error in the best approximation from the finite element space S_0^h measured only over the extended subdomain Ω_k^0, plus a higher-order global term (the global L^2-norm of the error). In the context of the algorithm in this paper, if the global coarse mesh is quasi-uniform and shape regular with element diameter H, and if we assume that $u \in H^2(\Omega)$, then standard

interpolation theory and L^2-lifting can be used to bound the global term by an $O(H^2)$ factor. Moreover, if the mesh produced by adaptivity in the extended subdomain Ω_k^0 is again quasi-uniform and shape regular, but now has element diameter h, then the local term can be bounded using standard interpolation theory by an $O(h)$ factor. If our adaptive method respects the relationship $h = O(H^2)$ between the coarse and refined regions, then asymptotically the global term based on the much coarser mesh outside Ω_k^0 does not pollute the accuracy of the adapted solution in the subdomain Ω_k. A similar argument can be applied in the less regular case of $u \in H^{1+\alpha}(\Omega)$.

The a posteriori estimate states that the error in the global Galerkin solution restricted to a subdomain Ω_k can be estimated in terms of a (computable) jump function $\eta(\cdot)$ over the extended subdomain Ω_k^0, plus a higher-order term (the global L^2-norm of the error). Through the same argument above, this means that asymptotically, the global error can be controlled by the local computable jump function estimate in each subdomain, so that reliable a posteriori error estimates can be computed in isolation from the other subdomains.

The a priori and a posteriori estimates from [37] outlined above were derived for self-adjoint linear problems in the plane, and as a result they do not apply directly to the examples presented in this paper (nonlinear scalar problems and elliptic systems in both 2D and 3D). Moreover, the local refinement strategy described here tends to produce very little overlap of the extended subdomains Ω_k^0, violating one of the key assumptions in [37], and we do not explicitly enforce a refinement limitation such as $h = O(H^2)$. However, the estimates in [37] indicate that this approach will likely provide a very good initial approximation to an overlapping domain decomposition procedure for solving the final global problem, and in an ideal situation (certain classes of elliptic problems with large subdomain overlap), it might be possible to skip the global solution altogether.

FLEXIBLE CONJUGATE GRADIENTS*

YVAN NOTAY†

Abstract. We analyze the conjugate gradient (CG) method with preconditioning slightly variable from one iteration to the next. To maintain the optimal convergence properties, we consider a variant proposed by Axelsson that performs an explicit orthogonalization of the search directions vectors. For this method, which we refer to as *flexible* CG, we develop a theoretical analysis that shows that the convergence rate is essentially independent of the variations in the preconditioner as long as the latter are kept sufficiently small. We further discuss the real convergence rate on the basis of some heuristic arguments supported by numerical experiments. Depending on the eigenvalue distribution corresponding to the fixed reference preconditioner, several situations have to be distinguished. In some cases, the convergence is as fast with truncated versions of the algorithm or even with the standard CG method, whereas quite large variations are allowed without too much penalty. In other cases, the flexible variant effectively outperforms the standard method, while the need for truncation limits the size of the variations that can be reasonably allowed.

Key words. iterative methods for linear systems, acceleration of convergence, preconditioning

1. Introduction.

As is well known, the conjugate gradient (CG) method combined with a suitable preconditioning is a choice method to solve large sparse $n \times n$ linear systems

$$A\,\mathbf{u} \;=\; \mathbf{b} \tag{1.1}$$

whose coefficient matrix A is symmetric and positive definite (e.g., [4, 9, 19, 21]). Ideally, a preconditioner is a symmetric and positive definite matrix B such that solving a system

$$B\,\mathbf{x} \;=\; \mathbf{y} \tag{1.2}$$

is relatively cheap, whereas the eigenvalues of $B^{-1}A$ are nicely clustered, favoring a rapid convergence.

Now, as preconditioning techniques become more sophisticated and apply to a wider class of problems, it is not unusual that the solution of (1.2) itself requires solving one or more subproblems for which, again, the preconditioned CG method is best suited. Although, from a theoretical point of view, it is more comfortable to assume that the system (1.2) is nevertheless solved accurately, in practice, the overall efficiency of the scheme may then critically depend on the ability to allow loose stopping criteria for the inner iterative solutions. In this case, the preconditioning step seen by the outer process is no longer $\mathbf{x} = B^{-1}\,\mathbf{y}$, but is

$$\mathbf{x} \;=\; \mathcal{B}(\mathbf{y}), \tag{1.3}$$

where $\mathcal{B}$ is a mapping from $\mathcal{R}^n$ to $\mathcal{R}^n$, in general nonlinear.

Early observation has indeed been made by Golub and Overton [17, 18] that the convergence rate of the outer CG process could be maintained even with very

loose accuracy for the inner iterations. Unfortunately, much less is known from a theoretical point of view. An interesting analysis has been recently developed by Golub and Ye [20], but, as will be seen in section 3, the bound derived there tends to strongly overestimate nonlinearities effects. On the other hand, some insight can be gained by reexamining the studies on CG in the presence of errors [22, 23, 31, 26], letting the parameter governing the size of the errors be much larger than the roundoff unit considered in these works. However, only heuristic conclusions can be derived on this basis, and the latter display that the method may lose part of its efficiency when the extremal eigenvalues of $B^{-1}A$ are well separated.

In [4, p. 549], Axelsson proposed a variant of the CG algorithm that is specifically designed to accommodate variable preconditioners (see also Algorithm 5.3 in [8]). This algorithm automatically truncates to standard CG when using a fixed symmetric and positive definite preconditioner, whereas, in the general case, optimal convergence property in A-norm is preserved at the price of performing a full orthogonalization of the search direction vectors (with respect to the $(\cdot, A\,\cdot)$ inner product). Although this method is a particular case of the generalized CG (GCG) algorithm developed in [1, 2, 3, 7], we refer to it as *flexible* CG (FCG).[1]

Similar to any method not based on a short recurrence, FCG has to be combined in practice with a truncation or a restart strategy. In this respect, it is interesting to note that with maximal truncation one recovers the steepest descent algorithm, whereas adding one orthogonality constraint delivers an implementation of the usual CG method, in fact the one observed in [20] to be the most stable with respect to variations in the preconditioner.

Concerning the theoretical analysis, the results in the latter paper prove fast convergence only when the perturbations are below some given threshold, and the analysis fails otherwise. One may then resort to the general results on GCG with variable preconditioning [4, 7], which prove the well definiteness of the method and its convergence under rather weak assumptions on $\mathcal{B}$. However, the proved speed of convergence is clearly much too pessimistic in the case of FCG; see section 3 for details. On the other hand, from a practical point of view, no discussion seems available on which restart or truncation strategy is advisable, and on which benefit can be hoped by using this flexible variant instead of the standard CG algorithm.

In the present paper, we aim at filling these gaps. We first propose in section 2 a mixed truncation–restart strategy that combines the advantages of both pure truncation and pure restart. We next consider in section 3 individual steps of FCG and prove a bound on the decrease of the error between two successive steps that tends to the optimal bound as $\mathcal{B} \to B^{-1}$, while allowing quite large variations in the preconditioner. We further consider in section 4 several successive steps of the untruncated algorithm and show that there exists a matrix $\widehat{B}$ such that $\mathcal{B}(\mathbf{y}) = \widehat{B}\,\mathbf{y}$ for all vectors $\mathbf{y}$ to which $\mathcal{B}$ is effectively applied during these steps. Moreover, when $\mathcal{B}$ is close to some symmetric and positive definite matrix B^{-1}, the spectrum of $\widehat{B}\,A$ is only a slight perturbation of that of $B^{-1}A$. Finally, we discuss in section 5 the effects of truncation and compare FCG with the standard CG algorithm in view of some illustrative numerical examples. Our conclusions are summarized in section 6.

Concerning the use of variable preconditioning in combination with other methods for the outer iterations, we refer the reader to the literature: Chebyshev and Richardson iterations are considered in [16, 17, 18], the Uzawa algorithm is analyzed

[1] *Generalized* CG mostly refers to methods designed to solve unsymmetric systems, whereas the specific variant considered here solely permits the use of variable preconditioners in CG.

in [15], and a flexible variant of GMRES is discussed in [28, 34] (see also [29]).

Notation. Throughout this paper, A and B are $n \times n$ symmetric and positive definite matrices, and $\lambda_1 \leq \lambda_2 \leq \cdots \leq \lambda_n$ are the eigenvalues of $B^{-1}A$ in increasing order, whereas

$$\kappa = \frac{\lambda_n}{\lambda_1} \tag{1.4}$$

is the spectral condition number.

For any symmetric and positive definite matrix matrix C, $\|\cdot\|_C$ is the C-norm, that is, the norm associated with the $(\cdot, C\,\cdot)$ inner product: $\|\mathbf{v}\|_C = \sqrt{(\mathbf{v},\, C\,\mathbf{v})}$ for all $\mathbf{v}$. When G is a matrix, $\|G\|_C$ is the matrix norm induced by this vector norm: $\|G\|_C = \max_{\mathbf{z}\neq 0} (\|G\,\mathbf{z}\|_C / \|\mathbf{z}\|_C)$.

2. Algorithm and basic properties. We recall below (Algorithm 2.1) the method referred to as FCG in the introduction, that is, Algorithm 5(a) from [4, p. 549] or Algorithm 5.3 from [8]. As already stated, the main difference with standard CG lies in the explicit orthogonalization of the search direction vectors $\mathbf{d}_i$; more precisely, $\mathbf{d}_i$ is orthogonalized with respect to $(\cdot, A\,\cdot)$ against the m_i previous vectors, where $\{m_i\}_{i=0,1,\ldots}$ is a sequence of truncation parameters. The untruncated version corresponds to $m_i = i$ for all i, whereas the natural choice for m_i would be $m_i = \min(i,\, m_{\max})$ (pure truncation) or sequences like $m_i = 0, 1, \ldots, m_{\max}, 0, 1 \ldots, m_{\max}$, which would mean restarting the (untruncated) algorithm at each $m_{\max}+1$ iteration. However, as we discuss below, one should avoid using m_i less than 1 for any $i > 0$. This observation leads to the mixed truncation–restart strategy advised in Algorithm 2.1, which we generally observed to be more cost efficient than pure truncation (see section 5.3). In Algorithm 2.1 this specific truncation–restart strategy will be referred to as FCG($m_{\max}$).

ALGORITHM 2.1 (FCG).
Flexible Conjugate Gradient

- *Initialization*

$$\begin{aligned} \mathbf{u}_0 &\quad \text{arbitrary} \\ \mathbf{r}_0 &= \mathbf{b} - A\,\mathbf{u}_0 \end{aligned}$$

- *Iteration* $(i = 0, 1, \ldots)$

$$\begin{aligned} \mathbf{w}_i &= \mathcal{B}(\mathbf{r}_i) \\ \mathbf{d}_i &= \mathbf{w}_i - \sum_{k=i-m_i}^{i-1} \frac{(\mathbf{w}_i,\, A\,\mathbf{d}_k)}{(\mathbf{d}_k,\, A\,\mathbf{d}_k)}\,\mathbf{d}_k \\ \mathbf{u}_{i+1} &= \mathbf{u}_i + \frac{(\mathbf{d}_i, \mathbf{r}_i)}{(\mathbf{d}_i,\, A\,\mathbf{d}_i)}\,\mathbf{d}_i \\ \mathbf{r}_{i+1} &= \mathbf{r}_i - \frac{(\mathbf{d}_i, \mathbf{r}_i)}{(\mathbf{d}_i,\, A\,\mathbf{d}_i)}\,A\,\mathbf{d}_i \end{aligned}$$

Advised truncation strategy (FCG($m_{\max}$)):
$m_0 = 0;\ m_i = \max\big(1,\, \mathrm{mod}(i,\, m_{\max}+1)\big) \quad (i > 0)$
$m_{\max}$: *nonnegative integer.*

Assuming A symmetric and positive definite and $0 \leq m_{i+1} \leq m_i + 1$ for all i, it is easy to prove that (see [4, 7])

$$(\mathbf{d}_k,\, A\,\mathbf{d}_j) = 0 \quad \text{for all } j,\, k \text{ such that } i - m_i \leq j < k \leq i, \tag{2.1}$$

$$(\mathbf{r}_k,\, \mathbf{d}_j) = 0 \quad \text{for all } j,\, k \text{ such that } i - m_i \leq j < k \leq i + 1 \tag{2.2}$$

and that, letting $\mathbf{u} = A^{-1}\,\mathbf{b}$,

$$\|\mathbf{u} - \mathbf{u}_{i+1}\|_A \;=\; \min_{\mathbf{d} \in \mathrm{span}\{\mathbf{d}_{i-m_i},\, \ldots,\, \mathbf{d}_i\}} \|\mathbf{u} - \mathbf{u}_{i-m_i} - \mathbf{d}\|_A. \tag{2.3}$$

If $m_i = i$ (no truncation), these are the optimality properties satisfied by the standard CG method. Moreover, when $\mathcal{B} \equiv B^{-1}$ is a symmetric and positive definite matrix, it can be proved that the recursion defining $\mathbf{d}_i$ automatically truncates because $(\mathbf{w}_i,\, A\,\mathbf{d}_k) = 0$ for all $k < i - 1$. Algorithm 2.1 simplifies then to a particular implementation of the standard CG method, in fact, one of the variants discussed in the early works on CG [24, 27]. This variant is also referred to as inexact preconditioned CG (IPCG) in [20], because there it is observed to be the most stable with respect to variations in the preconditioner. Note, however, that it requires computing one more inner product per iteration than the standard algorithm described in most textbooks (e.g., [4, 9, 19, 21]). In the remainder of this paper, we use "standard CG" to refer to the latter algorithm, whereas the alternative implementation offered by Algorithm 2.1 with $m_{\max} = 1$ will be referred to as FCG(1).

Note that our motivation to propose a strategy in which m_i is never less than 1 originates in this close relation between FCG and CG. Indeed, we then have the guarantee that one will recover the usual CG convergence when $\mathcal{B}$ is a fixed preconditioner, whereas something would irremediably be lost with the pure restart that results when setting $m_i = 0$ for some $i > 0$.

3. Convergence analysis. Equation (2.3) proves that the error measured in the A-norm cannot increase, but it says nothing about the convergence rate. In [4, 7], it is proved that

$$\frac{\|\mathbf{u} - \mathbf{u}_{i+1}\|_A}{\|\mathbf{u} - \mathbf{u}_i\|_A} \;\leq\; \sqrt{1 - \left(\frac{\delta_2}{\delta_1}\right)^2}, \tag{3.1}$$

where

$$\delta_1 = \max_{\mathbf{v} \neq 0} \frac{(\mathbf{v},\, \mathcal{B}(\mathbf{v}))}{(\mathbf{v},\, A^{-1}\,\mathbf{v})}, \qquad \delta_2 = \min_{\mathbf{v} \neq 0} \sqrt{\frac{(\mathcal{B}(\mathbf{v}),\, A\,\mathcal{B}(\mathbf{v}))}{(\mathbf{v},\, A^{-1}\,\mathbf{v})}}.$$

In this analysis, the requirements on $\mathcal{B}$ are thus quite weak, but, unfortunately, the proved speed of convergence is likely to be much too pessimistic. This is easily seen by inspecting the case $\mathcal{B} \equiv B^{-1}$. Then, $\delta_1 = \lambda_n$, $\delta_2 = \lambda_1$, and (3.1) writes

$$\frac{\|\mathbf{u} - \mathbf{u}_{i+1}\|_A}{\|\mathbf{u} - \mathbf{u}_i\|_A} \;\leq\; \sqrt{1 - \kappa^{-2}}, \tag{3.2}$$

whereas the best available bound on the "local" decrease of the error is

$$\frac{\|\mathbf{u} - \mathbf{u}_{i+1}\|_A}{\|\mathbf{u} - \mathbf{u}_i\|_A} \;\leq\; \frac{\kappa - 1}{\kappa + 1}. \tag{3.3}$$

By way of comparison, for $\kappa = 9$, the latter results prove $\|\mathbf{u}-\mathbf{u}_{i+1}\|_A \leq 0.8\,\|\mathbf{u}-\mathbf{u}_i\|_A$, whereas (3.2) yields only $\|\mathbf{u}-\mathbf{u}_{i+1}\|_A \leq 0.994\,\|\mathbf{u}-\mathbf{u}_i\|_A$.

Except for very well conditioned problems, the bound (3.1) is therefore of little help to understand the real effects of the nonlinearities in $\mathcal{B}$. In the following theorem, we also bound the "local" decrease of the error, but with an expression that tends to (3.3) as $\mathcal{B} \to B^{-1}$.

THEOREM 3.1. *Let A, B be $n\times n$ symmetric and positive definite matrices and $\mathcal{B}$ a mapping from $\mathcal{R}^n$ to $\mathcal{R}^n$. Let $\mathbf{b}$, $\mathbf{u}_0$ be vectors of $\mathcal{R}^n$, and let $\{\mathbf{r}_i\}_{i=0,1,\ldots}$, $\{\mathbf{d}_i\}_{i=0,1,\ldots}$, $\{\mathbf{u}_i\}_{i=1,2,\ldots}$ be the sequences of vectors generated by applying Algorithm 2.1 to A, $\mathcal{B}$, $\mathbf{b}$, and $\mathbf{u}_0$ with some given sequence of nonnegative integer parameters $\{m_i\}_{i=0,1,\ldots}$.*

If, for any i,

$$\frac{\|\mathcal{B}(\mathbf{r}_i) - B^{-1}\,\mathbf{r}_i\|_B}{\|B^{-1}\,\mathbf{r}_i\|_B} \;\leq\; \varepsilon_i \;<\; 1, \tag{3.4}$$

then

$$\frac{\|\mathbf{u}-\mathbf{u}_{i+1}\|_A}{\|\mathbf{u}-\mathbf{u}_i\|_A} \;\leq\; \sqrt{1-\frac{4\,\kappa\,(1-\varepsilon_i)^2}{(\kappa+\varepsilon_i^2(\kappa-1)+(1-\varepsilon_i)^2)^2}} \;\leq\; \frac{\kappa\,\frac{1+\varepsilon_i}{1-\varepsilon_i}\,\frac{\left(1+\varepsilon_i^2\right)^2}{1-\varepsilon_i^2}-1}{\kappa\,\frac{1+\varepsilon_i}{1-\varepsilon_i}\,\frac{(1+\varepsilon_i^2)^2}{1-\varepsilon_i^2}+1}. \tag{3.5}$$

Proof. Clearly, by (2.3), for any real α,

$$\|\mathbf{u}-\mathbf{u}_{i+1}\|_A \;\leq\; \|\mathbf{u}-\mathbf{u}_i-\alpha\,\mathcal{B}(\mathbf{r}_i)\|_A \;=\; \|\mathbf{r}_i-\alpha\,A\,\mathcal{B}(\mathbf{r}_i)\|_{A^{-1}}.$$

Then let $\mathbf{t}_i = B^{-1}\,\mathbf{r}_i - \mathcal{B}(\mathbf{r}_i)$. One has

$$(\mathbf{t}_i,\,A\,\mathbf{t}_i) \;=\; \frac{(\mathbf{t}_i,\,A\,\mathbf{t}_i)}{(\mathbf{t}_i,\,B\,\mathbf{t}_i)}\,(\mathbf{t}_i,\,B\,\mathbf{t}_i) \;\leq\; \lambda_n\,\varepsilon_i^2\,(\mathbf{r}_i,\,B^{-1}\,\mathbf{r}_i),$$

whereas

$$|\,\big((I-\alpha\,A\,B^{-1})\mathbf{r}_i,\,\mathbf{t}_i\big)\,| \;\leq \|\mathbf{t}_i\|_B\,\|B^{-1}\,(I-\alpha\,A\,B^{-1})\mathbf{r}_i\|_B \;\leq\; \varepsilon_i\,\beta\,(\mathbf{r}_i,\,B^{-1}\,\mathbf{r}_i),$$

where $\beta = \|I-\alpha\,A\,B^{-1}\|_{B^{-1}} = \max(|1-\alpha\,\lambda_1|,\,|1-\alpha\,\lambda_n|)$. Hence, for $\alpha \geq 0$,

$$\begin{aligned}\|\mathbf{r}_i-\alpha\,A\,\mathcal{B}(\mathbf{r}_i)\|_{A^{-1}}^2 &= \|(I-\alpha\,A\,B^{-1})\mathbf{r}_i\|_{A^{-1}}^2 + 2\,\alpha\,\big((I-\alpha\,A\,B^{-1})\mathbf{r}_i,\,\mathbf{t}_i\big) + \alpha^2\,\|\mathbf{t}_i\|_A \\ &\leq \big(\mathbf{r}_i,\,(I-\alpha\,B^{-1}\,A)A^{-1}(I-\alpha\,A\,B^{-1})\,\mathbf{r}_i\big) \\ &\quad + \big(2\,\alpha\,\beta\,\varepsilon_i+\alpha^2\,\lambda_n\,\varepsilon_i^2\big)\;\;\big(\mathbf{r}_i,\,B^{-1}\,\mathbf{r}_i\big)\,.\end{aligned}$$

Clearly, the right-hand side of the latter inequality cannot be larger than $(1-\eta_i)\|\mathbf{u}-\mathbf{u}_i\|_A^2 = (1-\eta_i)(\mathbf{r}_i,\,A^{-1}\,\mathbf{r}_i)$ if the matrix

$$(1-\eta_i)\,A^{-1} \;-\; (I-\alpha\,B^{-1}\,A)A^{-1}(I-\alpha\,A\,B^{-1}) \;-\; \big(2\,\alpha\,\beta\,\varepsilon_i+\alpha^2\,\lambda_n\,\varepsilon_i^2\big)\;B^{-1}$$

is nonnegative definite. This holds if and only if

$$-\alpha^2\,\lambda^2 \;+\; \big(2\,\alpha-2\,\alpha\,\beta\,\varepsilon_i-\alpha^2\,\lambda_n\,\varepsilon_i^2\big)\;\lambda \;-\; \eta_i \;\geq 0 \quad \text{for all } \lambda \in \sigma\left(B^{-1}A\right). \tag{3.6}$$

Consider now

$$\alpha = 2\,\left(\tfrac{\lambda_n+\varepsilon_i^2(\lambda_n-\lambda_1)}{1-\varepsilon_i}+(1-\varepsilon_i)\,\lambda_1\right)^{-1}.$$

One has $0 < \alpha \leq 2(\lambda_n + \lambda_1)^{-1}$ and therefore $\beta = 1 - \alpha\,\lambda_1$, yielding

$$2\,\alpha - 2\,\alpha\,\beta\,\varepsilon_i - \alpha^2\,\lambda_n\,\varepsilon_i^2 \;=\; \alpha\,(2\,(1-\varepsilon_i) + \alpha\,\varepsilon_i\,(2\lambda_1 - \varepsilon_i\,\lambda_n)) \;=\; \alpha^2\,(\lambda_n + \lambda_1).$$

Hence, the sum of the roots of the polynomial in the left-hand side of (3.6) is just $(\lambda_n + \lambda_1)$; (3.6) therefore holds for $\eta_i = \lambda_1\,\lambda_n\,\alpha^2$, since these two roots are then precisely equal to λ_1 and λ_n, respectively; the left inequality (3.5) readily follows. To prove the right one, note that

$$\frac{\kappa\,(1-\varepsilon_i)^2}{\left(\kappa + \varepsilon_i^2(\kappa-1) + (1-\varepsilon_i)^2\right)^2} \;=\; \frac{\kappa\,\frac{1+\varepsilon_i}{1-\varepsilon_i}\,\frac{\left(1+\varepsilon_i^2\right)^2}{1-\varepsilon_i^2}}{\left(\kappa\,\frac{1+\varepsilon_i}{1-\varepsilon_i}\,\frac{(1+\varepsilon_i^2)^2}{1-\varepsilon_i^2} \;+\; \frac{(1+\varepsilon_i^2)(1-2\,\varepsilon_i)}{(1-\varepsilon_i)^2}\right)^2}$$

whereas $\frac{(1+\varepsilon_i^2)(1-2\,\varepsilon_i)}{(1-\varepsilon_i)^2} \leq 1$ holds since $(1-2\,\varepsilon_i) + \varepsilon_i^2\,(1-2\,\varepsilon_i) \leq 1 - 2\,\varepsilon_i + \varepsilon_i^2$. ∎

We now comment on the assumption (3.4), which will also be used in the next section. It will require that the relative error for the approximate solution of (1.2) is less than ε_i in the B-norm. This latter norm is the most natural if a fixed number of inner CG iterations is performed with B as system matrix, since standard analysis will then result in a bound on this measure of the error. Even when the stopping criterion for the inner iterations is based on the relative residual error, it remains that the error in B-norm is guaranteed to decrease monotonically. Further, in practice, it often happens that all relative measures of the error decrease more or less similarly. Hence, *on average*, one may expect ε_i to be close to the user prescribed tolerance. In this respect, note that we do not require ε_i to be less than 1 at *each* iteration. Thus, even from a purely theoretical point of view, it is not necessary to use a tolerance on the relative residual error that is small enough to guarantee some uniform bound on ε_i.

Now, one should remember that, in general, inner iterations will not be performed directly to solve $B\,\mathbf{x} = \mathbf{y}$, but rather will be involved in some subproblem(s) whose solution is needed for the computation of $\mathbf{x}$. Then an analysis is required to check that a small error for this (these) subproblem(s) cannot be magnified and result in a large global error on $\mathbf{x}$. Of course, such an analysis is application dependent and lies therefore outside the scope of the present paper.

Finally, it is interesting to compare our bound (3.5) with the one recently obtained by Golub and Ye [20, Theorem 3.6]. This comparison is possible because they measure the errors with a criterion similar to (3.4), which is even identical when $\mathcal{B}$ is defined by inner CG iterations with B as the system matrix. However, they consider *two* successive steps of FCG(1) (referred to as IPCG), and their bound, for $\varepsilon \to 0$, tends to the standard bound for two CG iterations. The latter is of course better than the bound for the two steepest descent iterations, and our result therefore cannot compete for small ε. Nevertheless, as seen in Figure 1, Golub–Ye analysis strongly overestimates perturbations effects, so that our bound becomes better for ε larger than approximately 0.05.

4. Equivalent linear operator. The analysis of inexact preconditioning is intrinsically difficult because $\mathcal{B}$ is in general nonlinear and therefore cannot be represented in standard matrix form. Indeed, it would be too restrictive to assume $\mathcal{B}(\mathbf{x}+\mathbf{y}) = \mathcal{B}(\mathbf{x}) + \mathcal{B}(\mathbf{y})$ for any $\mathbf{x}$, $\mathbf{y}$. However, we do not in fact need a matrix representation of $\mathcal{B}(\mathbf{x})$ valid for any $\mathbf{x}$: Our interest is restricted to the vectors $\mathbf{r}_0$, $\mathbf{r}_1$, ... to which $\mathcal{B}$ is effectively applied during the course of the iterations. Moreover, to

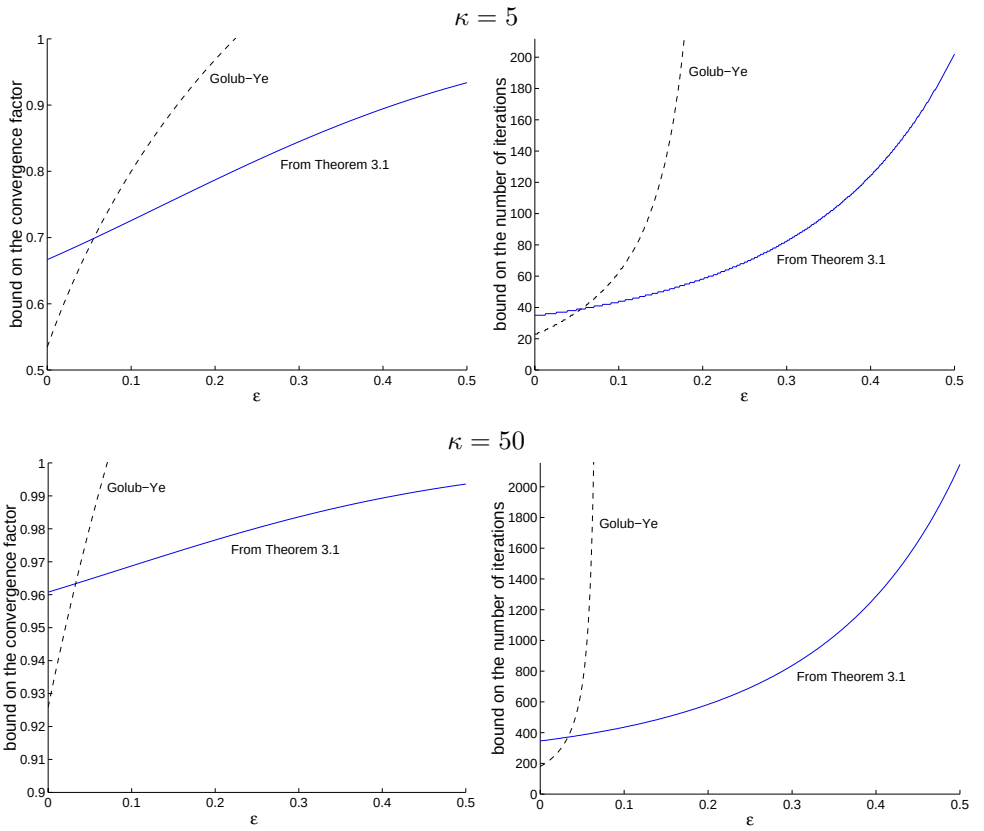

FIG. 1. *Left: convergence factor as estimated by* (3.5) *(solid line) and by Golub–Ye analysis (dashed line). Right: corresponding bound on the number of iterations to reduce the relative error in A-norm by* 10^{-6}.

analyze $\|\mathbf{u} - \mathbf{u}_{i+1}\|$ in view of (2.3), it is not useful to know something about $\mathcal{B}(\mathbf{r}_j)$ for all j. We have only to find a matrix $\widehat{B}_{i,\ell}$ such that

$$\mathcal{B}(\mathbf{r}_j) \;=\; \widehat{B}_{i,\ell}\,\mathbf{r}_j \qquad \text{for } j = i-\ell,\ldots,i \tag{4.1}$$

with $\ell \le m_i$.

It is rather obvious that such a matrix exists as long as the vectors $\mathbf{r}_{i-\ell}, \ldots, \mathbf{r}_i$ are linearly independent (there are even infinitely many possibilities if $\ell + 1 < n$). When using a fixed preconditioner, it is known that this linear independence holds because $(\mathbf{r}_j, B^{-1}\mathbf{r}_k) = 0$ for all $j \neq k$. In the general case, the linear independence is easily proved as soon as Theorem 3.1 (or (3.1)) applies to guarantee $\|\mathbf{r}_i\|_{A^{-1}} < \|\mathbf{r}_{i-1}\|_{A^{-1}} < \cdots < \|\mathbf{r}_{i-\ell}\|_{A^{-1}}$. Indeed, if $\sum_{k=j}^{i} \xi_k \mathbf{r}_k = 0$ with $\xi_j \neq 0$ for some $j \ge i-\ell$, one should have $(\mathbf{r}_j, \mathbf{d}_j) = 0$ (since by (2.2) $(\mathbf{r}_k, \mathbf{d}_j) = 0$ for $k = j+1, \ldots, i$). But this would imply $\mathbf{r}_{j+1} = \mathbf{r}_j$ (see Algorithm 2.1), and this stagnation contradicts the assumption that the error is strictly decreasing.

Now, to gain a further insight, one has to analyze how close the eigenvalues of $\widehat{B}_{i,\ell}A$ are to those of the "target" preconditioned system matrix $B^{-1}A$. This is the purpose of the next theorem. For technical reasons, we assume $m_i = i$ for all i; that is, we limit the analysis to the untruncated version of Algorithm 2.1. We believe that

this is not too severe a limitation because, as discussed below, one should expect from the theorem more qualitative than quantitative insight.

THEOREM 4.1. *Let the assumptions of Theorem* 3.1 *hold, and assume in addition that* $m_i = i$ *for all* i *in Algorithm* 2.1. *Let* i, ℓ *be some nonnegative integers such that* $\ell \leq i$. *For* $j = i - \ell, \ldots, i$, *let*

$$\mathbf{t}_j \;=\; B^{-1}\,\mathbf{r}_j - \mathcal{B}(\mathbf{r}_j), \tag{4.2}$$

and let ε, γ_t, *and* γ_r *be such that*

$$\frac{\|\mathbf{t}_j\|_B}{\|B^{-1}\,\mathbf{r}_j\|_B} \leq \varepsilon, \tag{4.3}$$

$$\frac{|(\mathbf{t}_j,\, B\,\mathbf{t}_k)|}{\|\mathbf{t}_j\|_B\,\|\mathbf{t}_k\|_B} \leq \gamma_t, \qquad k = j+1, \ldots, i, \tag{4.4}$$

$$\frac{|(\mathbf{t}_j,\, \mathbf{r}_k)|}{\|\mathbf{t}_j\|_B\,\|B^{-1}\,\mathbf{r}_k\|_B} \leq \gamma_r, \qquad k = j+1, \ldots, i. \tag{4.5}$$

If

$$\widehat{\varepsilon} \;=\; \varepsilon\sqrt{\frac{1+\gamma_t\,\ell}{1-\varepsilon\,\gamma_r\,\ell}} \;<\; 1, \tag{4.6}$$

then there exists a matrix $\widehat{B}_{i,\ell}$ *satisfying*

$$\widehat{B}_{i,\ell}\,\mathbf{r}_j \;=\; \mathcal{B}(\mathbf{r}_j), \qquad j = i-\ell, \ldots, i, \tag{4.7}$$

and such that, noting $W(C)$ *the field of value of the matrix* C, *one has*

$$W\left(A^{1/2}\widehat{B}_{i,\ell}A^{1/2}\right) \;\subset\; \left\{\overline{\lambda}\in\mathcal{C} \;:\; \left|\frac{\overline{\lambda}}{\lambda}-1\right| \leq \widehat{\varepsilon} \text{ for } \lambda \in W\left(A^{1/2}B^{-1}A^{1/2}\right)\right\} \tag{4.8}$$

and

$$\sigma\left(\widehat{B}_{i,\ell}\,A\right) \;\subset\; \bigcup_{k=1}^{n}\mathcal{D}_k, \tag{4.9}$$

where

$$\mathcal{D}_k \;=\; \left\{\overline{\lambda}\in\mathcal{C} \;:\; \left|\overline{\lambda}-\lambda_k\right| \leq \widehat{\varepsilon}\,\lambda_n\right\} \tag{4.10}$$

is the disk of radius $\widehat{\varepsilon}\,\lambda_n$ *centered at the* k*th eigenvalue of* $B^{-1}A$. *Moreover, if* s *such disks form a connected domain isolated from the remainder, there are precisely* s *eigenvalues in this domain.*

Finally, letting $\mathbf{z}_k$ *be an eigenvector of* $A^{1/2}\,B^{-1}\,A^{1/2}$ *associated with eigenvalue* λ_k, *there holds*

$$\left|\frac{\left(\mathbf{z}_k,\, A^{1/2}\,\widehat{B}_{i,\ell}\,A^{1/2}\,\mathbf{z}_k\right)}{(\mathbf{z}_k,\,\mathbf{z}_k)} - \lambda_k\right| \;\leq\; \widehat{\varepsilon}\,\lambda_k. \tag{4.11}$$

Proof. With (4.3), one easily sees that Theorem 3.1 applies, and therefore that $\mathbf{r}_{i-\ell}, \ldots, \mathbf{r}_i$ are linearly independent as shown above. There exists then a unique $n \times n$ matrix $\widehat{B}_{i,\ell}$ satisfying (4.7) and

$$\widehat{B}_{i,\ell}\,\mathbf{v} \;=\; B^{-1}\,\mathbf{v} \qquad \text{for all } \mathbf{v}:\ (\mathbf{v},\, B^{-1}\mathbf{r}_j) = 0,\ j = i-\ell, \ldots, i. \tag{4.12}$$

Let $E = \widehat{B}_{i,\ell} - B^{-1}$. First, (4.9) and the subsequent assertion on the localization of the eigenvalues follow from a standard result of perturbation theory [35, p. 88] if $\|A^{1/2}\,E\,A^{1/2}\|_2 \leq \widehat{\varepsilon}\,\lambda_n$. Now,

$$\begin{aligned}
\|A^{1/2}\,E\,A^{1/2}\|_2^2 &= \max_{\mathbf{z}\neq 0} \frac{(\mathbf{z},\, A^{1/2}\,E^T\,A\,E\,A^{1/2}\,\mathbf{z})}{(\mathbf{z},\,\mathbf{z})} \\
&= \max_{\mathbf{z}\neq 0} \frac{(E\,\mathbf{z},\, A\,E\,\mathbf{z})}{(\mathbf{z},\, A^{-1}\,\mathbf{z})} \\
&\leq \lambda_n^2\ \max_{\mathbf{z}\neq 0} \frac{(E\,\mathbf{z},\, B\,E\,\mathbf{z})}{(\mathbf{z},\, B^{-1}\,\mathbf{z})}
\end{aligned}$$

and (4.9) holds if

$$\max_{\mathbf{z}\neq 0} \sqrt{\frac{(E\,\mathbf{z},\, B\,E\,\mathbf{z})}{(\mathbf{z},\, B^{-1}\,\mathbf{z})}} \;=\; \|B\,E\|_{B^{-1}} \;\leq\; \widehat{\varepsilon}. \tag{4.13}$$

Likewise, letting $\mathbf{v} = A^{1/2}\mathbf{z}$,

$$\frac{(\mathbf{z},\, A^{1/2}\,\widehat{B}_{i,\ell}\,A^{1/2}\,\mathbf{z})}{(\mathbf{z},\,\mathbf{z})} \;=\; \frac{(\mathbf{v},\, \widehat{B}_{i,\ell}\,\mathbf{v})}{(\mathbf{v},\, A^{-1}\,\mathbf{v})} \;=\; \frac{(\mathbf{v},\, B^{-1}\,\mathbf{v})}{(\mathbf{v},\, A^{-1}\,\mathbf{v})}\left(1 + \frac{(\mathbf{v},\, E\,\mathbf{v})}{(\mathbf{v},\, B^{-1}\,\mathbf{v})}\right),$$

and, noting that $\frac{(\mathbf{v},\, B^{-1}\,\mathbf{v})}{(\mathbf{v},\, A^{-1}\,\mathbf{v})} \in [\lambda_1,\, \lambda_n] = W\left(A^{1/2}B^{-1}A^{1/2}\right)$, we have that (4.8) follows if (4.13) holds since

$$\max_{\mathbf{v}\neq 0} \frac{|(\mathbf{v},\, E\,\mathbf{v})|}{(\mathbf{v},\, B^{-1}\,\mathbf{v})} \;\leq\; \max_{\mathbf{v}\neq 0} \frac{\|\mathbf{v}\|_{B^{-1}}\,\|B\,E\,\mathbf{v}\|_{B^{-1}}}{\|\mathbf{v}\|_{B^{-1}}^2} \;=\; \|B\,E\|_{B^{-1}}. \tag{4.14}$$

Further, noting that $\mathbf{v}_k = A^{1/2}\,\mathbf{z}_k$ satisfies $A^{-1}\,\mathbf{v}_k = \lambda_k^{-1}\,B^{-1}\,\mathbf{v}_k$, one has

$$\begin{aligned}
\left|\frac{\left(\mathbf{z}_k,\, A^{1/2}\,\widehat{B}_{i,\ell}\,A^{1/2}\,\mathbf{z}_k\right)}{(\mathbf{z}_k,\,\mathbf{z}_k)} - \lambda_k\right| &= \frac{|\left(\mathbf{z}_k,\, A^{1/2}\,E\,A^{1/2}\,\mathbf{z}_k\right)|}{(\mathbf{z}_k,\,\mathbf{z}_k)} \\
&= \frac{|\,(\mathbf{v}_k,\, E\,\mathbf{v}_k)\,|}{(\mathbf{v}_k,\, A^{-1}\,\mathbf{v}_k)} \\
&= \lambda_k\ \frac{|\,(\mathbf{v}_k,\, E\,\mathbf{v}_k)\,|}{(\mathbf{v}_k,\, B^{-1}\,\mathbf{v}_k)},
\end{aligned}$$

showing with (4.14) that (4.11) also holds when (4.13) is satisfied.

Hence we are left with proving (4.13). In this view, note first that by (4.12) we may restrict the maximum in the left-hand side of (4.13) to vectors of the form $\mathbf{z} = \sum_{k=i-\ell}^{i} \xi_k \mathbf{r}_k$. Let then, for $j_0 = 1, \ldots, \ell+1$,

$$y_{j_0} \;=\; \|\mathbf{r}_{j_0+i-\ell-1}\|_{B^{-1}}\,\xi_{j_0+i-\ell-1}$$

and set $y = \begin{pmatrix} y_1 & y_2 & \dots & y_{\ell+1} \end{pmatrix}^T$. Note that, for $i - \ell \le k \le i$, $E\,\mathbf{r}_k = \widehat{B}_{i,\ell}\,\mathbf{r}_k - B^{-1}\,\mathbf{r}_k = -\mathbf{t}_k$, one has

$$\frac{(E\,\mathbf{z},\, B\,E\,\mathbf{z})}{(\mathbf{z},\, B^{-1}\,\mathbf{z})} \;=\; \frac{y^T\,G\,y}{y^T\,H\,y},$$

where G, H are the symmetric $(\ell+1) \times (\ell+1)$ matrices with components

$$G_{j_0k_0} = \frac{(\mathbf{t}_j,\, B\,\mathbf{t}_k)}{\|\mathbf{r}_j\|_{B^{-1}}\,\|\mathbf{r}_k\|_{B^{-1}}},$$
$$H_{j_0k_0} = \frac{(\mathbf{r}_j,\, B^{-1}\,\mathbf{r}_k)}{\|\mathbf{r}_j\|_{B^{-1}}\,\|\mathbf{r}_k\|_{B^{-1}}}$$

(letting $j = j_0 + i - \ell - 1$ and $k = k_0 + i - \ell - 1$).

Now, (4.3) and (4.4) straightforwardly yield $G_{j_0j_0} \le \varepsilon^2$ and $G_{j_0k_0} \le \varepsilon^2\,\gamma_t$ for $k_0 \ne j_0$. Hence, the largest eigenvalue of G is bounded by

$$\lambda_{\max}(G) \;\le\; \|G\|_\infty \;\le\; \varepsilon^2\,(1 + \gamma_t\,\ell).$$

Concerning H, we note that $H_{j_0j_0} = 1$ for all j_0, whereas, when $k > j$,

$$(\mathbf{r}_k,\, B^{-1}\,\mathbf{r}_j) \;=\; (\mathbf{r}_k,\, \mathcal{B}(\mathbf{r}_j)\,) + (\mathbf{r}_k,\, \mathbf{t}_j) \;=\; (\mathbf{r}_k,\, \mathbf{t}_j)$$

because $\mathcal{B}(\mathbf{r}_j)$ is a linear combination of $\mathbf{d}_0$, $\mathbf{d}_1$, …, $\mathbf{d}_j$, and (2.2) applies therefore to show $(\mathbf{r}_k,\, \mathcal{B}(\mathbf{r}_j)\,) = 0$.[2] One then readily obtains with (4.5) that $|H_{k_0j_0}| = |H_{j_0k_0}| \le \varepsilon\,\gamma_r$ for $k_0 > j_0$. The Gerschgorin theorem then yields

$$\lambda_{\min}(H) \;\ge\; 1 - \varepsilon\,\gamma_r\,\ell.$$

$\frac{y^T\,G\,y}{y^T\,H\,y} \le \widehat{\varepsilon}^{\,2}$ and therefore the required result readily follows. ∎

Note that, with (2.3), Theorem 4.1 yields

$$\frac{\|\mathbf{u} - \mathbf{u}_{i+1}\|_A}{\|\mathbf{u} - \mathbf{u}_{i-\ell}\|_A} \;\le\; \min_{\substack{\mathcal{P}_{\ell+1}\text{pol. of degree }(\ell+1)\\ \mathcal{P}_{\ell+1}(0)=1}} \left\|\mathcal{P}_{\ell+1}\left(A^{1/2}\,\widehat{B}_{i,\ell}\,A^{1/2}\right)\right\|. \tag{4.15}$$

A bound on the convergence rate can then be deduced by selecting shifted Chebyshev polynomials for which, thanks to (4.8), we may apply Eiermann analysis based on the field of value [14, Theorem 1]. Clearly, the resulting bound on the asymptotic convergence factor will tend to the usual bound $\frac{\sqrt{\kappa}-1}{\sqrt{\kappa}+1}$ as $W(A^{1/2}\widehat{B}_{i,\ell}A^{1/2})$ gets closer to $[\lambda_1,\, \lambda_n]$, that is, for ε "sufficiently small."

We did not pursue this direction, however, because the requirements on ε would be too stringent and no longer compatible with our general goal of allowing loose accuracy for the inner solutions. Indeed, in theory, we can only say about γ_t and γ_r that they do not exceed 1 by virtue of the Cauchy–Schwarz inequality (with respect to the $(\cdot,\, B\,\cdot)$ inner product). Hence, for realistic ε, the theoretical bound on $\widehat{\varepsilon}$ grows quickly with the number of iterations, even if in practice γ_t and γ_r are both expected to be small, because we act in a very large space and the error vectors $\mathbf{t}_j$ have at first sight no serious reason to be aligned in one preferred direction.

[2] This is the technical detail that motivates the restriction to the untruncated version of Algorithm 2.1.

Theorem 4.1 is also too pessimistic when it requires no truncation, whereas FCG(1) or even standard CG is observed to be quite robust in practice; see, e.g., [17, 18, 20]. This is not completely surprising if one takes into account the general analysis of perturbed CG sequences [22, 23, 31, 26], which indeed display that the *linear* convergence properties of the method are essentially preserved, at least when such perturbations are tiny. Extrapolating these conclusions to larger perturbations gives then a heuristic explanation of the observed robustness.

Now, fast convergence is often possible only on account of the so-called *superlinear* convergence of CG. This arises when the condition number is relatively large, but with a good separation of the extremal eigenvalues, so that interesting bounds on the convergence can nevertheless be proved by selecting polynomials that vanish exactly at these isolated eigenvalues [6, 32]. Since (4.9) and (4.11) show that the spectrum of $\widehat{B}_{i,\ell}A$ is only a slight perturbation of that of $B^{-1}A$,[3] we expect a similar superlinear convergence when applying untruncated FCG, even if, here again, trying to prove this rigorously would lead to too stringent requirements on ε.

Concerning truncated FCG, however, we cannot put forward in this context the heuristic argument above based on the general results about perturbed CG sequences. Indeed, detailed analysis reveals that these superlinear bounds are then essentially unreliable, especially when the perturbations are not that small [26]. Hence, we rather expect a big difference between truncated and untruncated versions when the extremal eigenvalues are well separated.

5. Numerical results. Theorem 3.1 delivers a bound that, at first order in ε, corresponds to the usual bound for the steepest descent in which the condition number is magnified by a factor $\frac{1+\varepsilon}{1-\varepsilon}$. As this does not take into account global convergence effects, this is clearly much too pessimistic for (sufficiently) small ε when using FCG(m) with $m > 0$. On the other hand, attempts to improve the analysis as in Theorem 4.1 or in [20] lead to too stringent requirements on ε.

We therefore resorted to numerical tests to further assess the real convergence rate. In section 5.1, we conducted very simple experiments with artificial examples to investigate to what extent the number of iterations can be realistically estimated by making the substitution $\kappa \to \kappa\frac{1+\varepsilon}{1-\varepsilon}$ in the standard bounds for the CG method with a fixed preconditioner. On the other hand, in sections 5.2 and 5.3, we considered more realistic computations, aiming principally at comparing FCG with standard CG while assessing the real effects of truncation.

5.1. Some artificial experiments. Here, we let $A = \mathrm{diag}(\lambda_i)$ with

Case 1: $\lambda_i = 1 + \kappa\,\frac{i-1}{n-1}$, $\kappa = 5$, $i = 1, \ldots, n$;
Case 2: $\lambda_i = 1 + \kappa\,\frac{i-1}{n-1}$, $\kappa = 50$, $i = 1, \ldots, n$;
Case 3: $\lambda_1 = 10^{-2}$, $\lambda_i = 1 + \kappa_2\,\frac{i-2}{n-2}$, $\kappa_2 = 10$, $i = 2, \ldots, n$.

We further set $B = I$ and consider two kinds of perturbations for the "solution" of $I\,\mathbf{w}_i = \mathbf{r}_i$:

(a) $\mathbf{w}_i = \mathbf{r}_i + \varepsilon\,\frac{\|\mathbf{r}_i\|}{\|\mathbf{f}\|}\,\mathbf{f}$, the components of $\mathbf{f}$ being pseudorandom numbers uniformly distributed in $[-1, 1]$;
(b) $\mathbf{w}_i$ computed from inner CG iterations with the zero vector as initial approximation, $B = I$ as system matrix, and ε as prescribed accuracy on the relative residual error (which is also equal to the relative error measured in

[3] The eigenvalues of $\widehat{B}_{i,\ell}A$ satisfy $\lambda_k(\varepsilon) = \frac{\left(\mathbf{z}_k,\, A^{1/2}\,\widehat{B}_{i,\ell}\,A^{1/2}\,\mathbf{z}_k\right)}{(\mathbf{z}_k,\,\mathbf{z}_k)} + \mathcal{O}\left(\varepsilon^2\right)$; see [35, p. 69].

the B-norm); since $B = I$, this inner CG process is nontrivial only if one uses a "preconditioner" C such that $C^{-1}B \neq I$, and we actually selected C defined by $C = \mathrm{diag}(c_i)$ with $c_i^{-1} = 1 + 10\,\frac{i-1}{n-1}$ (hence $\kappa(C^{-1}B) = 10$).

For Cases 1 and 2, the heuristic estimate of the number of iterations is

$$k_\delta \;=\; \mathrm{int}\left[\frac{1}{2}\,\sqrt{\kappa\tfrac{1+\varepsilon}{1-\varepsilon}}\,\ln\frac{2}{\delta}\right] + 1, \tag{5.1}$$

where δ is the prescribed accuracy on the relative error measured in the A-norm. For Case 3, we have to take into account that the first eigenvalue is isolated. A heuristic estimate is then obtained by multiplying κ_2 by $\frac{1+\varepsilon}{1-\varepsilon}$ in the appropriate bound, which gives [6, 26]

$$k_\delta \;=\; \mathrm{int}\left[\frac{1}{2}\sqrt{\kappa_2\tfrac{1+\varepsilon}{1-\varepsilon}}\left(\ln\frac{2}{\delta} + \ln\frac{\lambda_2}{\lambda_1}\right)\right] \;+\; \mathrm{int}\left[\sqrt{\kappa_2\tfrac{1+\varepsilon}{1-\varepsilon}} + 1\right] \;+\; 1. \tag{5.2}$$

We made tests with both truncated and untruncated FCG, using in each case $n = 10^4$, $\delta = 10^{-6}$, a pseudorandom right-hand side, and the zero vector as initial approximation. It turned out that, for both Cases 1 and 2, there was almost no difference between FCG(1) and the untruncated version, so we report in Table 1 the results for FCG(1) only. On the other hand, for Case 3, truncated versions converged much more slowly, so we report the results for the untruncated version only; in other cases the comparison with the heuristic estimate (5.2) is meaningless anyway (truncated and untruncated versions are compared further in section 5.3). Besides, we also report the total number of inner iterations for the choice (b), where $\mathbf{w}_i$ is generated by performing inner CG iterations; the number given for $\varepsilon = 1$ is then the number of CG iterations when A is directly preconditioned by C.

One sees that the heuristic estimates predict relatively well the actual convergence, although they cannot pretend in any way to be *upper bounds* on the number of

iterations. In concrete applications, the optimal ε will clearly depend on the overhead involved by outer iterations, and it is therefore difficult to define a general rule. The sensitivity to variations in the preconditioner is somewhat higher when the condition number is relatively large, but such effects seem very slight, at least on these examples. We therefore do not necessarily confirm that ε should be kept proportional to $\kappa^{-1/2}$ as advised in [20].

5.2. A problem with no separated eigenvalues. We consider the linear systems resulting from the finite element discretization of the linear elasticity equations. The aim is to compute the displacement at each gridpoint. Thus, in three dimensions, there are three unknowns per gridpoint, one for each component. If these unknowns are ordered separately, the system matrix presents the 3×3 block structure

$$A = \begin{pmatrix} A_{xx} & A_{xy} & A_{xz} \\ A_{yx} & A_{yy} & A_{yz} \\ A_{zz} & A_{zy} & A_{zz} \end{pmatrix}.$$

A is then known to be spectrally equivalent to its block diagonal part [5, 10]; thus we select

$$B = \begin{pmatrix} A_{xx} & & \\ & A_{yy} & \\ & & A_{zz} \end{pmatrix}.$$

B is itself easily preconditioned, because each diagonal block is similar to a weakly anisotropic discrete Laplace operator. Using more particularly the finite element scheme described in [10], these blocks are even symmetric M-matrices, allowing an appropriate use of incomplete factorization methods (e.g., [4, 13]). This preconditioner of B can serve as is to precondition A [10, 30], but there are some (potential) advantages in using an inner–outer iterative scheme [5], because A is much denser than B; hence it is worth trying to keep the number of multiplications by A to a minimum.

For the numerical test, we consider more particularly the mining stability problem referred to as "Stope" in [11], which is discretized on a $40 \times 40 \times 40$ regular grid by means of the finite element scheme described in [10]. The numerically computed smallest eigenvalues of $B^{-1}A$ are $0.301, 0.326, 0.369, \ldots$, and the largest ones (in decreasing order) are $1.98, 1.91, 1.79, \ldots$. Thus, $\kappa = 6.58$ and there are no isolated eigenvalues.

We report in Table 2 the number of (outer) iterations necessary to reduce the relative residual error below 10^{-6} whenever using the zero vector as an initial approximation; ε is the tolerance used for the inner iterations, the stopping test being also based on the relative residual error and checked independently for each of the three systems $A_{xx}\,\mathbf{w}_x = \mathbf{r}_x$, $A_{yy}\,\mathbf{w}_y = \mathbf{r}_y$, $A_{zz}\,\mathbf{w}_z = \mathbf{r}_z$ (note for completeness that these diagonal blocks were preconditioned by the dynamic relaxed block ILU algorithm from [25]); we also indicate the values taken by the heuristic estimate (5.1).

One may observe a nice agreement between these numerical results and our previous conclusions: As long as the inner solutions remain reasonably accurate, the standard CG algorithm and FCG($m_{\max}$) behave similarly and deliver a convergence close to that of the method with exact preconditioning. Note, however, that for very inaccurate inner solutions, FCG tends to be more stable than CG, and it seems to still obey the rule that the condition number is just multiplied by $\frac{1+\varepsilon}{1-\varepsilon}$. As this stabilization is already obtained for FCG(1), we recommend its use for problems with

TABLE 2
Results for the problem with no separated eigenvalues.

ε	10^{-6}	10^{-3}	10^{-2}	10^{-1}	$\frac{1}{7}$	$\frac{1}{4}$	$\frac{1}{3}$	$\frac{1}{2}$

Estimate (5.1)	19	19	19	21	22	24	26	33

this type of eigenvalue distribution. Practitioners may be satisfied with the standard CG algorithm, but for a fairly small overhead (one more inner product computation per iteration) FCG(1) allows the inner solutions to be still less accurate and therefore cheaper.

5.3. A problem with well-separated extremal eigenvalues. To generate a simple example in which $B^{-1}A$ has isolated eigenvalues, we apply a very basic additive Schwarz preconditioning scheme (e.g., see [12] and the references therein) to a problem from [33], namely, the linear system resulting from the five-point approximation of

$$-\partial_x\, a\, \partial_x\, u - \partial_y\, a\, \partial_y\, u = f$$

in the unit square, with homogeneous Dirichlet boundary conditions on the bottom boundary and homogeneous Neumann boundary conditions elsewhere, and with $a = f = 100$ in the box $\left(\frac{1}{4}, \frac{1}{4}\right) \times \left(\frac{1}{4}, \frac{1}{4}\right)$ and $a = 1$, $f = 0$ elsewhere; we use a uniform grid of mesh size $h = \frac{1}{160}$.

The partitioning is based on a division of the domain (that is, the unit square) in 4×2 subdomains with internal boundaries located at $x = \frac{1}{4}$, $x = \frac{1}{2}$, $x = \frac{3}{4}$, and $y = \frac{1}{2}$. Since we want to simulate numerical difficulties that may be unavoidable in other contexts, we deliberately omit the coarse grid correction and consider minimal overlap; that is, the unknowns for each subdomain are just those corresponding to the gridpoints effectively located in the subdomain or on its boundary.

Letting B be the preconditioner corresponding to exact subdomain solves, we have that the numerically computed smallest eigenvalues of $B^{-1}A$ are $0.207\,10^{-3}$, 0.0486, 0.698, ..., and the largest ones (in decreasing order) are 4.00, 2.08, 2.00, ... Hence, $\kappa = 1.9\,10^4$, which is much too large to obtain a satisfactory convergence without the superlinear convergence effects mentioned at the end of section 4.

We report in Table 3 the number of (outer) iterations necessary to reduce the relative residual error below 10^{-6} whenever we use the zero vector as an initial approximation; ε is again the tolerance for the inner subdomain solves, also verified with respect to the relative residual error; for these solves, we used the standard MILU preconditioning without fill-in [4, 13].

The results for both FCG(1) and the untruncated version (FCG(∞)) just confirm our expectation from the previous discussions. The good news is that satisfactory convergence for fairly moderate accuracy of the inner solutions is already restored with reasonable values of $m_{\max}$. We do not discuss which couple (ε, $m_{\max}$) is most effective because this heavily depends on the context, for instance on the quality of the preconditioner for the inner iterations. Note, however, that we programmed the orthogonalization of $\mathbf{d}_i$ in a classical Gram–Schmidt fashion, so that the communication cost per iteration is essentially independent of $m_{\max}$; the tradeoff between increasing $m_{\max}$ or decreasing ε to achieve a given convergence can thus be analyzed by

TABLE 3
Numbers of iteration for the problem with small isolated eigenvalues; Tr–FCG ($m_{\max}$) refers to Algorithm 2.1 with $m_i = \min(i, m_{\max})$.

ε	10^{-6}	10^{-3}	10^{-2}	10^{-1}	$\frac{1}{7}$	$\frac{1}{4}$	$\frac{1}{3}$	$\frac{1}{2}$

Tr–FCG(20)	62	80	83	87	90	94	95	105

comparing the cost of the inner solves with that of local vector operations. Which convergence one should target is difficult to predict, but, as a general rule, it seems reasonable to admit only a moderate deterioration of the convergence from the "ideal" case with exact preconditioning. Indeed, inner–outer iterative processes are primarily motivated by the high cost of outer iterations, for instance, the communication cost in the present example. (Would it not be the case, one probably should skip inner iterations and use one application of the corresponding preconditioner instead.)

For the sake of completeness, we also performed some runs using Algorithm 2.1 with a pure truncation strategy (Tr–FCG($m_{\max}$)). Clearly, the additional work with respect to FCG($m_{\max}$) does not pay off since the convergence is nearly the same in all cases, whereas FCG($2\,m_{\max}$) is much faster despite a similar cost per iteration. We also tested a pure restart approach, but we did not succeed in obtaining a useful convergence. This is not surprising since, even with a fixed preconditioner, pure restarting has a disastrous effect with this kind of eigenvalue distribution.

6. Conclusions. When one is willing to use inexact preconditioning, one should distinguish two types of problems.

For problems with a regular distribution of the eigenvalues, for which the fast convergence is due to a nice condition number, inexact preconditioning may be used quite safely, even with very loose stopping criteria for the inner iterations. It is not necessary to use a method much more costly than the standard CG algorithm, but FCG(1) brings still more stability at the price of a fairly small overhead.

The situation is more tricky when a relatively fast convergence depends on "superlinear" effects in connection with a good separation of the extremal eigenvalues. A convergence close to that of the ideal case with exact preconditioning can still be obtained with FCG($m_{\max}$), but at the price of increasing $m_{\max}$ while decreasing the accuracy requirements for the inner solutions. Hence, one will not be able to use stopping criteria as loosely as in the preceding case, and the FCG process itself will be more costly.

These considerations also tell us that whenever using inner–outer iterative schemes, improving the basic preconditioner always brings some additional benefit. For instance, removing small isolated eigenvalues not only accelerates the convergence with exact preconditioning, but also indirectly allows a decrease in the cost of inner

solutions.

Generally speaking, we feel that coupled inner–outer iterations can be efficient when at least either the global preconditioner or the one used for the inner solutions is a highly effective. Indeed, in the former case, the CG process will be very stable, allowing quite loose stopping criteria for the inner iterations. On the other hand, in the latter case, it is relatively cheap to prevent stability problems by requiring a high accuracy for the inner solutions. These considerations also show that when both preconditioners are of medium quality, then coupled inner–outer iterations are not necessarily advisable.

Acknowledgments. My interest in variable preconditioning originates from private discussions with O. Axelsson and his coworkers M. Neytcheva and B. Polman. I also thank R. Blaheta and R. Kohut who provided the code that generates the matrix for the first test example. Mark Embree provided me with some interesting remarks, pointing out the possible use of Eiermann results. Magolu Monga-Made informed me of reference [20] as soon as it appeared.

A THIRD-ORDER SEMIDISCRETE CENTRAL SCHEME FOR CONSERVATION LAWS AND CONVECTION-DIFFUSION EQUATIONS*

ALEXANDER KURGANOV† AND DORON LEVY‡

Abstract. We present a new third-order, semidiscrete, central method for approximating solutions to multidimensional systems of hyperbolic conservation laws, convection-diffusion equations, and related problems. Our method is a high-order extension of the recently proposed second-order, semidiscrete method in [A. Kurgonov and E. Tadmor, *J. Comput Phys.*, 160 (2000) pp. 241–282].

The method is derived independently of the specific piecewise polynomial reconstruction which is based on the previously computed cell-averages. We demonstrate our results by focusing on the new third-order central weighted essentially nonoscillatory (CWENO) reconstruction presented in [D. Levy, G. Puppo, and G. Russo, *SIAM J. Sci. Comput.*, 21 (1999), pp. 294–322]. The numerical results we present show the desired accuracy, high resolution, and robustness of our method.

Key words. hyperbolic systems, convection-diffusion equations, central difference schemes, high-order accuracy, nonoscillatory schemes, weighted essentially nonoscillatory reconstruction.

1. Introduction.

Numerical methods for approximating solutions of hyperbolic conservation laws,

$$\frac{\partial}{\partial t}u(x,t) + \frac{\partial}{\partial x}f(u(x,t)) = 0, \tag{1.1}$$

and of the related convection-diffusion equations,

$$\frac{\partial}{\partial t}u(x,t) + \frac{\partial}{\partial x}f(u(x,t)) = \frac{\partial}{\partial x}Q[u(x,t), u_x(x,t)], \tag{1.2}$$

have attracted much attention in recent years (see, e.g., [6, 35] and the references therein). Here, $u(x,t)$ is a conserved quantity, $f(u)$ is a nonlinear convection flux, and $Q(u,u_x)$ is a dissipation flux satisfying the (weak) parabolicity condition, $\frac{\partial}{\partial s}Q(u,s) \geq 0\ \forall u, s$. In the most general case $u = (u_1, \ldots, u_n)$ is an n-vector in a $d+1$-dimensional space, $(x,t) = (x_1, \ldots, x_d, t)$, and f and Q are vector-functions.

In this paper, we focus on the class of *central schemes*, all of which can be viewed as an extension of the well-known Lax–Friedrichs (LxF) scheme [5]. The first-order LxF method enjoys the major advantage of simplicity over the upwind schemes (e.g., the Godunov scheme [7]): no (approximate) Riemann solvers or characteristic decompositions are involved in its construction, and therefore, its realization for complicated

multidimensional systems is rather simple. At the same time, the LxF scheme suffers from excessive numerical dissipation, which causes a poor (smeared) resolution of discontinuities and rarefaction waves.

A second-order, nonoscillatory central scheme was first introduced by Nessyahu and Tadmor in [30]. Since then, the Nessyahu–Tadmor (NT) scheme was further extended to higher orders of accuracy [28] (also see [3, 19]), as well as to the multidimensional systems (1.1), in [1] and [12] (also see [18, 20, 21, 22]).

The main ingredient in the construction of the NT method is a second-order, nonoscillatory, monotonic upstream schemes for conservation laws (MUSCL)-type [17], piecewise linear interpolant (instead of the piecewise constant one employed in the LxF scheme) in combination with the exact solver for the time evolution. This approach allows us to significantly improve the resolution of nonsmooth solutions to hyperbolic conservation laws, (1.1), while retaining the main advantage of the LxF scheme—*simplicity*.

Unfortunately, applying the fully discrete NT scheme (or its higher-order extensions) to the second-order convection-diffusion equations, (1.2), does not provide the desired resolution of discontinuities (see, e.g., [14, 15, 16]). This loss of resolution occurs due to the accumulation of excessive numerical dissipation, which is typical of fully discrete central schemes with small time-steps $\Delta t \sim (\Delta x)^2$ (see [16] for details).

To circumvent this difficulty, a second-order *semidiscrete* central scheme was introduced by Kurganov and Tadmor in [16]. This scheme has smaller dissipation than the NT scheme and, unlike the fully discrete central schemes, it can be efficiently used with time-steps as small as required by the CFL stability restriction due to the diffusion term.

The basic idea in the construction of the second-order semidiscrete scheme was to use more accurate information about the *local* speed of propagation of the discontinuities. One was then able to derive a nonstaggered semidiscrete central method, by first integrating over nonequally spaced control volumes, out of which a new piecewise linear interpolant was reconstructed and finally projected on its cell-averages (without evolving in time). The final step was first introduced in [10], in a somewhat different context of transforming staggered methods into nonstaggered methods.

In this paper we extend the results of [16] by introducing a new *third-order, semidiscrete, central scheme*. Our new scheme is derived in a general form which is independent of the reconstruction step, as long as the reconstructed interpolant is sufficiently accurate and nonoscillatory. In particular, we use the new third-order central weighted essentially nonoscillatory (CWENO) reconstruction proposed in [21]. This reconstruction provides a third-order accurate interpolant which is built from the given cell-averages such that it is nonoscillatory in the essentially nonoscillatory (ENO) sense (see [9, 32]). This interpolant is written as a convex combination of two one-sided linear functions and one centered parabola. In smooth regions this convex combination guarantees the desired third-order accuracy. It automatically switches to a second-order, one-sided, linear reconstruction in the presence of large gradients. Such weighted essentially non-oscillatory (WENO) reconstructions were first introduced in the upwind framework, [11, 27], after which they were extended to the central framework [19, 20, 21, 22]. A different approach to creating a high-order (ENO-type) method which does not require Riemann solvers was suggested in [26].

This paper is organized as follows. We start in section 2 with a brief overview of central schemes for conservation laws. In particular we focus in section 2.1 on the CWENO reconstruction which we use as the building block for our third-order

method below.

We then proceed to construct our new third-order scheme. First, we deal with the fully discrete, one-dimensional (1D) setup in section 3. This new fully discrete scheme is sketched in (3.7). We give only the required details that are necessary to fulfill our final goal, namely, to derive the semidiscrete scheme.

With the fully discrete scheme, (3.7), we are ready to approach the semidiscrete limit in section 4.1. Our new third-order, one-dimensional, semidiscrete scheme is then summarized in (4.5). This scheme is written in a general form which is independent of the reconstruction step and can also be combined with any appropriate ODE solver for carrying out the time evolution. In section 4.2 we then extend our semidiscrete scheme to multidimensional hyperbolic and (degenerate) parabolic problems.

We end by presenting several numerical examples in section 5, in which we approximate solutions to hyperbolic conservation laws as well as to convection-diffusion equations. Our new method is shown to enjoy the expected high accuracy as well as the robustness and the simplicity of the entire family of central schemes.

2. Central schemes for conservation laws. We briefly overview the framework of central schemes for conservation laws. Consider the 1D system (1.1). To approximate its solutions, we introduce a spatial scale, Δx, and integrate over the cell $I(x) := \{\xi \mid |\xi - x| \le \Delta x/2\}$,

$$\bar{u}_t + \frac{1}{\Delta x}\left[f\left(\left(x+\frac{\Delta x}{2},t\right)\right) + f\left(u\left(x-\frac{\Delta x}{2},t\right)\right)\right] = 0. \tag{2.1}$$

Here and below, $\bar{u}$ denotes the average of u over I,

$$\bar{u}(x,t) := \frac{1}{\Delta x}\int_{I(x)} u(\xi,t)d\xi.$$

Introducing a time scale, Δt, integrating in time from t to $t+\Delta t$, and sampling (2.1) at the cells $[x_j, x_{j+1}]$, we obtain

$$\bar{u}^{n+1}_{j+1/2} = \bar{u}^{n}_{j+1/2} - \frac{1}{\Delta x}\int_{\tau=t^n}^{t^{n+1}} \left[f(u(x_{j+1},\tau)) - f(u(x_j,\tau))\right] d\tau, \tag{2.2}$$

where $x_j := j\Delta x$, $t^n := n\Delta t$, $u^n_j := u(x_j,t^n)$, and $\bar{u}^n_j := \bar{u}(x_j,t^n)$. Assuming that at time $t = t^n$ we have computed the cell-averages of the approximate solution, $\{\bar{u}^n_j\}$, we would like to utilize (2.2) to compute the cell-averages at the next time level, $t^{n+1} = t^n + \Delta t$. To that extent, we introduce a piecewise-polynomial reconstruction,

$$u(x,t^n) \approx \sum_j P_j(x)\chi_j(x), \tag{2.3}$$

where $\chi_j(x)$ is the characteristic function of the cell $I_j := I(x_j)$, and $P_j(x)$ is a polynomial which is reconstructed from the computed cell-averages, $\{\bar{u}^n_j\}$. The degree of the polynomial depends on the desired order of accuracy of the method. Having such an approximation to $u(x,t^n)$, (2.3), we can easily compute the right-hand side (RHS) of (2.2). The first term, $\bar{u}^n_{j+1/2}$, equals

$$\bar{u}^n_{j+1/2} = \int_{x_j}^{x_{j+1/2}} P_j(x)dx + \int_{x_{j+1/2}}^{x_{j+1}} P_{j+1}(x)dx.$$

For a sufficiently small time-step, Δt, the solution of (1.1) subject to the initial data (2.3), prescribed at time $t = t^n$, will remain smooth at some neighborhood of the grid points x_j for $t \in [t^n, t^{n+1}]$. Hence, the integrals on the RHS of (2.2) can be approximated using a sufficiently accurate quadrature, which is determined by the overall desired accuracy of the method. The values at the intermediate times which will be required in the quadrature can be predicted either by a Taylor expansion or using a Runge–Kutta method (consult [3, 19, 28, 30]).

For example, a piecewise-constant reconstruction, $P_j(x) = \bar{u}_j^n$, and a first-order quadrature,

$$\int_{t^n}^{t^{n+1}} f(u(t))dt \sim \Delta t f(\bar{u}^n),$$

will result in the staggered-LxF scheme (with $\lambda := \Delta t/\Delta x$ denoting the mesh ratio),

$$\bar{u}_{j+1/2}^{n+1} = \frac{\bar{u}_{j+1}^n + \bar{u}_j^n}{2} - \lambda(f(\bar{u}_{j+1}^n) - f(\bar{u}_j^n)).$$

A piecewise linear reconstruction, $P_j(x) = \bar{u}_j^n + (u_x)_j^n(x - x_j)$, with a second-order quadrature in time (such as the midpoint rule), results in the NT scheme. Applying nonlinear limiters on the discrete slopes, $(u_x)_j^n$, will prevent oscillations (for details, see [30]).

To obtain a third-order central scheme, one should use a third-order, piecewise parabolic reconstruction together with a more accurate quadrature in time, e.g., Simpson's quadrature rule (see [28] for details).

Remarks.

1. *Robustness.* In order to reconstruct a nonoscillatory interpolant, one typically is required to use nonlinear limiters. These limiters decrease the order of accuracy of the method at extrema and by that they play a stabilizing role (e.g., see [17, 28, 30, 35]).

2. *Numerical dissipation and time step.* When using fully discrete central schemes to approximate solutions of convection-diffusion equations, (1.2), the stability restriction enforces small time-steps, $\Delta t \sim (\Delta x)^2$. That is why the numerical dissipation is accumulated and we do not obtain high resolution of discontinuities (see [16] for details).

This problem can be avoided by using semidiscrete schemes instead of the fully-discrete schemes. Such a second-order, central, semidiscrete scheme was introduced in [16]. In this paper we develop a third-order, central, semidiscrete scheme with small numerical dissipation, which can be used efficiently with the small time-steps required due to the second-order operators.

3. *Upwind schemes.* Sampling (2.1) at the cells I_j will result in upwind schemes. Here, one remains with the discontinuities along the interfaces and is bound to solve the Riemann problems there, or at least to approximate their solutions. In the scalar, 1D case this can be easily accomplished, but the Riemann problem has no known solution in the general case of systems and/or several space dimensions.

This is the reason why central schemes can be considered as universal methods for solving hyperbolic conservation laws: Riemann solvers are not involved in their construction and, moreover, since (2.2) can be carried out componentwise, no characteristic decomposition is required.

2.1. CWENO reconstruction. The first 1D, third-order central scheme in [28] implemented the nonoscillatory piecewise parabolic reconstruction proposed by Liu

and Osher in [25]. Since then, a variety of simpler reconstructions has appeared in the literature. Among these, we would like to mention the central-ENO reconstruction in [3] and the central-WENO (CWENO) reconstruction in [19] and [21], which was extended to the two-dimensional (2D) setup in [20] and [22].

Our new third-order semidiscrete method which we develop in section 3 and section 4 below can be integrated with any third-order, nonoscillatory reconstruction. In our numerical simulations presented in section 5, we will use the method recently presented in [21], of which we will now give a brief overview.

In each cell I_j we reconstruct a quadratic polynomial as a convex combination of three polynomials $P_{\rm L}(x), P_{\rm R}(x)$, and $P_{\rm C}(x)$,

$$P_j(x) = w_{\rm L}P_{\rm L}(x) + w_{\rm R}P_{\rm R}(x) + w_{\rm C}P_{\rm C}(x), \tag{2.4}$$

with positive weights $w_i \geq 0 \forall i \in \{{\rm C}, {\rm R}, {\rm L}\}$ and $\sum_i w_i = 1$. The polynomials $P_{\rm L}(x), P_{\rm R}(x)$ correspond to left and right one-sided linear reconstructions, respectively, while $P_{\rm C}(x)$ is a parabola, centered around x_j.

The linear functions, $P_{\rm R}(x)$ and $P_{\rm L}(x)$, are uniquely determined by requiring them to conserve the one-sided cell-averages ($\bar{u}^n_j, \bar{u}^n_{j+1}$ and $\bar{u}^n_j, \bar{u}^n_{j-1}$, respectively) as

$$P_{\rm R}(x) = \bar{u}^n_j + \frac{\bar{u}^n_{j+1} - \bar{u}^n_j}{\Delta x}(x - x_j), \quad P_{\rm L}(x) = \bar{u}^n_j + \frac{\bar{u}^n_j - \bar{u}^n_{j-1}}{\Delta x}(x - x_j). \tag{2.5}$$

The centered parabola, $P_{\rm C}(x)$, is chosen so as to satisfy

$$P_{\rm EXACT}(x) = c_{\rm L}P_{\rm L}(x) + c_{\rm R}P_{\rm R}(x) + (1 - c_{\rm L} - c_{\rm R})P_{\rm C}(x) \tag{2.6}$$

with constants c_i's. Here, $P_{\rm EXACT}(x)$ is the unique parabola that conserves the three-cell-averages, $\bar{u}^n_{j-1}, \bar{u}^n_j$, and $\bar{u}^n_{j+1}$, which is given by

$$P_{\rm EXACT}(x) = u^n_j + u'_j(x - x_j) + \frac{1}{2}u''_j(x - xj)^2. \tag{2.7}$$

The approximations to the point-values of $u(x_j, t^n), u_x(x_j, t^n)$, and $u_{xx}(x_j, t^n)$ are denoted by u^n_j, u'_j, u''_j and are given by

$$u^n_j = \bar{u}^n_j - \frac{1}{24}(\bar{u}^n_{j+1} - 2\bar{u}^n_j + \bar{u}^n_{j-1}),$$
$$u'_j = \frac{\bar{u}^n_{j+1} - \bar{u}^n_{j-1}}{2\Delta x}, \qquad u''_j = \frac{\bar{u}^n_{j-1} - 2\bar{u}^n_j + \bar{u}^n_{j+1}}{\Delta x^2}.$$

In [21] it was shown that every symmetric selection of the constants c_i's in (2.6) will provide the desired third-order accuracy. For example, by taking $c_{\rm L} = c_{\rm R} = 1/4$, (2.5)–(2.7) yield

$$P_{\rm C}(x) = \bar{u}^n_j - \frac{1}{12}(\bar{u}^n_{j+1} - 2\bar{u}^n_j + \bar{u}^n_{j-1})$$
$$+\frac{\bar{u}^n_{j+1} - \bar{u}^n_{j-1}}{2\Delta x}(x - x_j) + \frac{\bar{u}^n_{j+1} - 2\bar{u}^n_j + \bar{u}^n_{j-1}}{\Delta x^2}(x - x_j)^2.$$

In smooth regions, the coefficients w_i of the convex combination in (2.4) are chosen to guarantee the maximum order of accuracy (in this particular case, order three), but in the presence of a discontinuity they are automatically switched to the best

one-sided stencil (which generates the least oscillatory reconstruction). The weights are taken as

$$w_i = \frac{\alpha_i}{\sum\limits_m \alpha_m}, \quad \text{where} \quad \alpha_i = \frac{c_i}{(\epsilon + IS_i)^p}, \qquad i, m \in \{\text{C}, \text{R}, \text{L}\}, \tag{2.8}$$
$$c_{\text{L}} = c_{\text{R}} = 1/4, \qquad c_{\text{C}} = 1/2.$$

The constant ϵ guarantees that the denominator does not vanish and is taken as $\epsilon = 10^{-6}$. The value of p may be chosen to provide the highest accuracy in smooth areas and to ensure the nonoscillatory nature of the solution near the discontinuities (consult [11]; see also [19, 21]). In [11] the value $p = 2$ was empirically selected, and here we use the same p in most of the examples presented below. Finally, the smoothness indicators, IS_i, are defined as

$$IS_i = \sum_{l=1}^{2} \int_{x_{j-1/2}}^{x_{j+1/2}} (\Delta x)^{2l-1} (P_i^{(l)}(x))^2 dx.$$

A direct computation then results in

$$IS_{\text{L}} = (\bar{u}_j^n - \bar{u}_{j-1}^n)^2, \qquad IS_{\text{R}} = (\bar{u}_{j+1}^n - \bar{u}_j^n)^2, \tag{2.9}$$
$$IS_{\text{C}} = \frac{13}{3}(\bar{u}_{j+1}^n - 2\bar{u}_j^n + \bar{u}_{j-1}^n)^2 + \frac{1}{4}(\bar{u}_{j+1}^n - \bar{u}_{j-1}^n)^2.$$

It is easy to see that in the presence of large gradients, this reconstruction switches to one of the second-order one-sided linear reconstructions, P_{R} or P_{L}. For more details we refer to [21].

3. The fully discrete one-dimensional construction. In this section we present the new third-order method in the fully discrete framework. Since we are mainly interested in deriving the semidiscrete scheme, we will concentrate only on the details which are required for that task. The scheme we derive here is a third-order extension of the fully discrete second-order scheme presented in [16].

Following [16], we would like to augment the integration over the Riemann fans by more accurate information about the *local* speed of wave propagation. We start by assuming that in every cell, I_j, we have reconstructed a piecewise polynomial interpolant, $P_j(x, t^n)$, from the previously computed cell-averages, $\{\bar{u}_j^n\}$. Then, an upper bound on the speed of propagation of discontinuities at the cell boundaries, $x_{j+1/2}$, is given by

$$a_{j+1/2}^n = \max_{u \in \mathcal{C}(u_{j+1/2}^-, u_{j+1/2}^+)} \rho\Big(\frac{\partial f}{\partial u}(u)\Big), \tag{3.1}$$

where $\rho(A)$ denotes the spectral radius of a matrix A, i.e., $\rho(A) := \max_i |\lambda_i(A)|$ with $\lambda_i(A)$ being its eigenvalues. We denote by $u_{j+1/2}^+$ and $u_{j+1/2}^-$ the left and right intermediate values of $u(x, t^n)$ at $x_{j+1/2}$, i.e.,

$$u_{j+1/2}^+ := P_{j+1}(x_{j+1/2}, t^n), \quad u_{j+1/2}^- := P_j(x_{j+1/2}, t^n),$$

and by $\mathcal{C}(u_{j+1/2}^-, u_{j+1/2}^+)$ a curve in phase space that connects $u_{j+1/2}^-$ and $u_{j+1/2}^+$ via the Riemann fan.

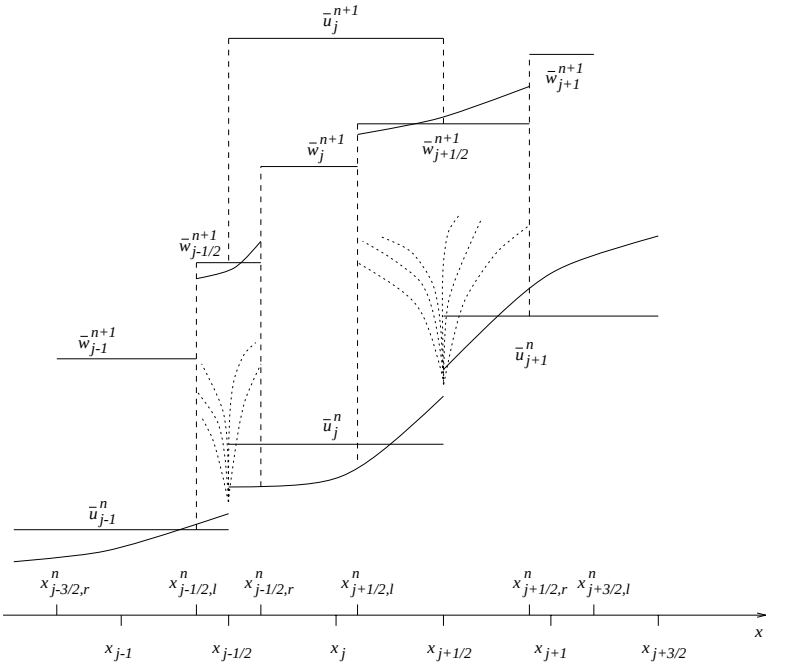

FIG. 3.1. *Modified central differencing.*

Remark. In most practical applications, these local maximal speeds can be easily evaluated. For example, in the genuinely nonlinear or linearly degenerate case one finds that (3.1) reduces to

$$a_{j+1/2}^n := \max\left\{\rho\Big(\frac{\partial f}{\partial u}(u_{j+1/2}^-)\Big), \rho\Big(\frac{\partial f}{\partial u}(u_{j+1/2}^+)\Big)\right\}. \tag{3.2}$$

Given the piecewise polynomial interpolant at time t^n, $\{P_j(x,t^n)\}$, and the local speeds of propagation, $\{a_{j+1/2}^n\}$, we construct the fully discrete, central method in two steps, which are schematically described in Figure 3.1. First, we integrate over the control volumes, $[x_{j-1/2,l}^n, x_{j-1/2,r}^n]\times[t^n,t^{n+1}]$, $[x_{j-1/2,r}^n, x_{j+1/2,l}^n]\times[t^n,t^{n+1}]$, and $[x_{j+1/2,l}^n, x_{j+1/2,r}^n]\times[t^n,t^{n+1}]$, obtaining $\bar{w}_{j-1/2}^{n+1}$, $\bar{w}_j^{n+1}$, and $\bar{w}_{j+1/2}^{n+1}$, respectively. Due to the finite speed of propagation, the points $x_{j+1/2,l}^n$ and $x_{j+1/2,r}^n$,

$$x_{j+1/2,l}^n := x_{j+1/2} - a_{j+1/2}^n\Delta t, \quad x_{j+1/2,r}^n := x_{j+1/2} + a_{j+1/2}^n\Delta t,$$

separate between smooth and nonsmooth regions. That is, the solution of (1.1) subject to the piecewise polynomial initial data prescribed at time $t = t^n$ may be nonsmooth only inside the intervals $[x_{j+1/2,l}^n\,,\, x_{j+1/2,r}^n]$ for $t\in[t^n,t^{n+1})$.

In the second step, we repeat the nonoscillatory reconstruction (this time on a nonuniformly spaced grid) and project the obtained reconstruction on the original, uniform grid, ending up with the cell-averages at the next time level t^{n+1}, $\{\bar{u}_j^{n+1}\}$. This last step does not involve time integration and was introduced in the context of changing staggered methods into nonstaggered methods in [10].

We now turn to the detailed description of this algorithm. Assume that the

piecewise polynomial reconstruction in cell I_j at time t^n is of the form

$$P_j(x,t^n) = A_j + B_j(x-x_j) + \frac{1}{2}C_j(x-x_j)^2. \tag{3.3}$$

Then a direct computation of the integrals over the control volumes, $[x^n_{j+1/2,l}, x^n_{j+1/2,r}]\times[t^n,t^{n+1}]$ and $[x^n_{j-1/2,r}, x^n_{j+1/2,l}]\times[t^n,t^{n+1}]$, yields

$$\begin{aligned}\bar{w}^{n+1}_{j+1/2} &= \frac{A_j+A_{j+1}}{2} + \frac{\Delta x - a^n_{j+1/2}\Delta t}{4}(B_j - B_{j+1})\\ &+ \left(\frac{\Delta x^2}{16} - \frac{a^n_{j+1/2}\Delta t\Delta x}{8} + \frac{(a^n_{j+1/2}\Delta t)^2}{12}\right)(C_j + C_{j+1})\\ &- \frac{1}{2a^n_{j+1/2}\Delta t}\left\{\int_{t^n}^{t^{n+1}}\Big[f(u(x^n_{j+1/2,r},t))dt - f(u(x^n_{j+1/2,l},t))\Big]\,dt\right\},\end{aligned} \tag{3.4}$$

and

$$\begin{aligned}\bar{w}^{n+1}_{j} &= A_j + \frac{\Delta t}{2}(a^n_{j-1/2} - a^n_{j+1/2})B_j\\ &+ \left[\frac{(\Delta x)^2}{24} - \frac{\Delta t\Delta x}{12}(a^n_{j-1/2}+a^n_{j+1/2})\right.\\ &\qquad\left. + \frac{(\Delta t)^2}{6}\Big((a^n_{j-1/2})^2 - a^n_{j-1/2}a^n_{j+1/2} + (a^n_{j+1/2})^2\Big)\right]C_j\\ &- \frac{1}{\Delta x - \Delta t(a^n_{j-1/2}+a^n_{j+1/2})}\left\{\int_{t^n}^{t^{n+1}}\Big[f(u(x^n_{j+1/2,l},t))dt\right.\\ &\qquad\left. - f(u(x^n_{j-1/2,r},t))\Big]\,dt\right\},\end{aligned} \tag{3.5}$$

respectively. To complete these computations, one should approximate the flux integrals on the RHS of (3.4) and (3.5) using, e.g., Simpson's quadrature as described in section 2.

At this stage, the approximate cell-averages, $\{\bar{w}^{n+1}_{j+\frac{1}{2}}, \bar{w}^{n+1}_j\}$, realize the solution at $t=t^{n+1}$ over a nonuniform grid, which is oversampled by twice the number of the original cells at $t=t^n$. To convert these nonuniform averages back into the original grid, we proceed along the lines of [10].

First, from the cell-averages, $\bar{w}^{n+1}_{j+\frac{1}{2}}$, $\bar{w}^{n+1}_j$, given by (3.4)–(3.5), we reconstruct a third-order, piecewise polynomial, nonoscillatory interpolant (e.g., the CWENO interpolant described in section 2.1), which we will denote by $\tilde{w}^{n+1}_{j+1/2}(x)$ and $\tilde{w}^{n+1}_j(x)$, respectively. In fact, we do not need any high-order reconstruction $\tilde{w}^{n+1}_j(x)$ since it will be averaged out (consult Figure 3.1).

We note in passing that even for a nonuniform grid data, the CWENO interpolant can be written explicitly (in the spirit of section 2.1), but these details are irrelevant for the semidiscrete scheme, which will be described in section 4. At that point, all we need is to assume that such a reconstruction exists and that for all j it takes the form

$$\begin{aligned}\tilde{w}^{n+1}_{j+1/2}(x) &= \tilde{A}_{j+1/2} + \tilde{B}_{j+1/2}(x-x_{j+1/2}) + \frac{1}{2}\tilde{C}_{j+1/2}(x-x_{j+1/2})^2,\\ \tilde{w}^{n+1}_{j}(x) &= \bar{w}^{n+1}_j,\end{aligned} \tag{3.6}$$

in the nonsmooth region $(x^n_{j+1/2,l}, x^n_{j+1/2,r})$ and in the smooth region $(x^n_{j-1/2,r}, x^n_{j+1/2,l})$, respectively. Given (3.4), (3.5), and (3.6), we conclude by computing the new cell-averages at time t^{n+1} according to

$$\begin{aligned}\bar{u}_j^{n+1} &= \frac{1}{\Delta x}\left[\int_{x_{j-1/2}}^{x^n_{j-1/2,r}} \tilde{w}^{n+1}_{j-1/2}(x)dx + \int_{x^n_{j-1/2,r}}^{x^n_{j+1/2,l}} \tilde{w}^{n+1}_{j}(x)dx + \int_{x^n_{j+1/2,l}}^{x_{j+1/2}} \tilde{w}^{n+1}_{j+1/2}(x)dx\right]\\ &= \lambda a^n_{j-1/2}\tilde{A}_{j-1/2} + \left[1-\lambda(a^n_{j-1/2}+a^n_{j+1/2})\right]\bar{w}_j^{n+1} + \lambda a^n_{j+1/2}\tilde{A}_{j+1/2}\\ &\quad + \frac{\lambda\Delta t}{2}\left((a^n_{j-1/2})^2\tilde{B}_{j-1/2} - (a^n_{j+1/2})^2\tilde{B}_{j+1/2}\right)\\ &\quad + \frac{\lambda(\Delta t)^2}{6}\left((a^n_{j-1/2})^3\tilde{C}_{j-1/2} + (a^n_{j+1/2})^3\tilde{C}_{j+1/2}\right).\end{aligned} \tag{3.7}$$

Remark. The third-order reconstruction (3.6) is necessary in order to guarantee the overall third-order accuracy, since simple averaging over $[x_{j-\frac{1}{2}}, x_{j+\frac{1}{2}}]$ (without reconstruction) reduces the order of the resulting scheme (see [10]).

4. The semidiscrete scheme. We are now ready to derive our main result, which is the new third-order, semidiscrete, central scheme. First, we describe our ideas in the 1D framework and then we extend them to multidimensional problems.

4.1. 1D problems. We start with the derivation of the third-order semidiscrete scheme for 1D (systems of) hyperbolic conservation laws. Using the fully discrete scheme obtained in section 3, the semidiscrete approximation can be directly written as the limit

$$\frac{d}{dt}\bar{u}_j(t) = \lim_{\Delta t\to 0}\frac{\bar{u}_j^{n+1}-\bar{u}_j^n}{\Delta t}. \tag{4.1}$$

Substituting (3.7) into (4.1) results in

$$\begin{aligned}\frac{d\bar{u}_j}{dt} = \lim_{\Delta t\to 0}\Bigg\{ &\frac{1}{\Delta x}a^n_{j-1/2}\tilde{A}_{j-1/2} - \frac{1}{\Delta x}(a^n_{j-1/2}+a^n_{j+1/2})\bar{w}_j^{n+1}\\ &+\frac{1}{\Delta x}a^n_{j+1/2}\tilde{A}_{j+1/2} + \frac{1}{\Delta t}(\bar{w}_j^{n+1}-\bar{u}_j^n)\Bigg\}.\end{aligned} \tag{4.2}$$

In the limit as $\Delta t\to 0$, all the Riemann fans have zero widths and therefore,

$$\tilde{A}_{j+1/2} = \bar{w}^{n+1}_{j+1/2}, \qquad \tilde{A}_{j-1/2} = \bar{w}^{n+1}_{j-1/2}. \tag{4.3}$$

Using (3.3) we can also obtain

$$\begin{aligned}u(x^n_{j+1/2,r},t) &\to P_{j+1}(x_{j+1/2},t)\\ &= A_{j+1} - \frac{\Delta x}{2}B_{j+1} + \frac{(\Delta x)^2}{8}C_{j+1} =: u^+_{j+1/2}(t),\\ u(x^n_{j+1/2,l},t) &\to P_j(x_{j+1/2},t)\\ &= A_j + \frac{\Delta x}{2}B_j + \frac{(\Delta x)^2}{8}C_j =: u^-_{j+1/2}(t).\end{aligned} \tag{4.4}$$

Finally, plugging (3.4), (3.5), and (4.3) into (4.2) we compute the time limit explicitly, ending up with our new semidiscrete scheme,

$$\frac{d\bar{u}_j}{dt} = -\frac{1}{2\Delta x}\left[f(u^+_{j+1/2}(t)) + f(u^-_{j+1/2}(t)) - f(u^+_{j-1/2}(t)) - f(u^-_{j-1/2}(t))\right]$$

$$+\frac{a_{j+1/2}(t)}{2\Delta x}\left[u^+_{j+1/2}(t)-u^-_{j+1/2}(t)\right]-\frac{a_{j-1/2}(t)}{2\Delta x}\left[u^+_{j-1/2}(t)-u^-_{j-1/2}(t)\right], \tag{4.5}$$

with local speeds $a_{j+1/2}(t)$, e.g.,

$$a_{j+1/2}(t):=\max\left\{\rho\Big(\frac{\partial f}{\partial u}(u^-_{j+1/2}(t))\Big),\rho\Big(\frac{\partial f}{\partial u}(u^+_{j+1/2}(t))\Big)\right\}.$$

Remarks.

1. We would like to emphasize that the scheme (4.5) was derived independently of any specific piecewise-quadratic reconstruction. If one wants, e.g., to use the CWENO reconstruction described in section 2.1, then the values of A_j, B_j, and C_j in (4.4) are

$$\begin{aligned}
A_j&=\bar u^n_j-\frac{w_{\rm C}}{12}(\bar u^n_{j+1}-2\bar u^n_j+\bar u^n_{j-1}),\\
B_j&=\frac{1}{\Delta x}\left[w_{\rm R}(\bar u^n_{j+1}-\bar u^n_j)+w_{\rm C}\frac{\bar u^n_{j+1}-\bar u^n_{j-1}}{2}+w_{\rm L}(\bar u^n_j-\bar u^n_{j-1})\right],\\
C_j&=2w_{\rm C}\frac{\bar u^n_{j-1}-2\bar u^n_j+\bar u^n_{j+1}}{\Delta x^2},
\end{aligned}$$

where $w_{\rm L}, w_{\rm C}$, and $w_{\rm R}$ are defined in (2.8).

2. Our third-order scheme, (4.5), admits the conservative form

$$\frac{d\bar u_j}{dt}=-\frac{H_{j+1/2}(t)-H_{j-1/2}(t)}{\Delta x}, \tag{4.6}$$

with the numerical flux

$$\begin{aligned}
H_{j+1/2}(t):=&\frac{f(u^+_{j+1/2}(t))+f(u^-_{j+1/2}(t))}{2}\\
&-\frac{a_{j+1/2}(t)}{2}\left[u^+_{j+1/2}(t)-u^-_{j+1/2}(t)\right].
\end{aligned} \tag{4.7}$$

This scheme is a natural generalization of the second-order semidiscrete scheme from [16]. Moreover, the second-order scheme has exactly the same form, (4.6)–(4.7); the only difference is in the more accurate computation of the intermediate value $u^+_{j+1/2}(t)$ and $u^-_{j+1/2}(t)$. It is interesting to note that also the fully discrete, staggered, second- and third-order central schemes have the same structure (see [28]).

3. Similar to the case of the second-order scheme [16], the nonoscillatory property of the piecewise parabolic reconstruction, (3.3), will guarantee the nonoscillatory nature of our semidiscrete scheme. But unlike the piecewise linear reconstruction utilized in the second-order method, a piecewise parabolic reconstruction can be only essentially nonoscillatory. This means that, in principle, such a reconstruction may increase the total variation of the computed piecewise constant solution. Our numerical examples, however, demonstrate that the growth of the total variation is always bounded. Such desirable behavior of bounded total variation in the context of central-WENO schemes was already observed in [23].

4. We would like to stress once again the simplicity of our new method, which does not require any (approximate) Riemann solver or any use of the characteristic variables—the reconstruction of piecewise polynomial interpolant, (3.3), is carried

out *componentwise*. In particular, unlike the standard central schemes, but similar to the second-order semidiscrete method in [16], our method is based on one grid (and not on staggering between two grids). This can be a big advantage (compared with the traditional central schemes) when dealing with boundary conditions and complex geometries.

5. Finally, similar to the second-order semidiscrete scheme [16], the third-order scheme, (4.6)–(4.7), boils down in the scalar linear case to an upwind scheme. In the nonlinear, *scalar*, case, this is a finite volume scheme based on a local LxF (Rusanov) monotone flux. Since we derived our method as a central Godunov-type scheme, our result also naturally holds for systems (including multi-dimensional systems as shown below).

Next, let us consider the general convection-diffusion equation, (1.2). Similar to the case of the second-order semidiscrete scheme [16], operator splitting is not needed. We can apply our third-order semidiscrete scheme, (4.6)–(4.7), to the (degenerate) parabolic equation, (1.2), in a straightforward manner. This results in the scheme

$$\frac{d\bar{u}_j}{dt} = -\frac{H_{j+1/2}(t) - H_{j-1/2}(t)}{\Delta x} + Q_j(t). \tag{4.8}$$

Here, $H_{j+1/2}(t)$ is our numerical convection flux, (4.7), and $Q_j(t)$ is a high-order approximation to the diffusion term, $Q(u, u_x)_x$. In the examples below we use the fourth-order central differencing of the form

$$\begin{aligned} Q_j(t) = \frac{1}{12\Delta x}\Big[&- Q(u_{j+2}(t), (u_x)_{j+2,j}) + 8Q(u_{j+1}(t), (u_x)_{j+1,j}) \\ &-8Q(u_{j-1}(t), (u_x)_{j-1,j}) + Q(u_{j-2}(t), (u_x)_{j-2,j})\Big], \end{aligned} \tag{4.9}$$

where

$$\begin{aligned} (u_x)_{j+2,j} &:= \frac{1}{12\Delta x}\Big[25u_{j+2}(t) - 48u_{j+1}(t) + 36u_j - 16u_{j-1}(t) + 3u_{j-2}(t)\Big], \\ (u_x)_{j+1,j} &:= \frac{1}{12\Delta x}\Big[3u_{j+2}(t) + 10u_{j+1}(t) - 18u_j + 6u_{j-1}(t) - u_{j-2}(t)\Big], \\ (u_x)_{j-1,j} &:= \frac{1}{12\Delta x}\Big[u_{j+2}(t) - 6u_{j+1}(t) + 18u_j - 10u_{j-1}(t) - 3u_{j-2}(t)\Big], \\ (u_x)_{j-2,j} &:= \frac{1}{12\Delta x}\Big[-3u_{j+2}(t) + 16u_{j+1}(t) - 36u_j + 48u_{j-1}(t) - 25u_{j-2}(t)\Big], \end{aligned} \tag{4.10}$$

and $\{u_j(t)\}$ are point-values of the reconstructed polynomials, (3.3), i.e., $u_j(t) = P_j(x_j, t)$.

4.2. Multidimensional extensions. Without loss of generality, let us consider the 2D (system of) convection-diffusion equations,

$$u_t + f(u)_x + g(u)_y = Q^x(u, u_x, u_y)_x + Q^y(u, u_x, u_y)_y, \tag{4.11}$$

where the case $Q^x \equiv Q^y \equiv 0$ corresponds to the 2D pure hyperbolic problem.

Suppose that we have computed an approximate solution to (4.11) at some time t and have reconstructed a 2D piecewise polynomial, third-order, ENO interpolant over the uniform spatial grid, $(x_j, y_k) = (j\Delta x, k\Delta y)$.

Following [16], the 2D extension of our third-order semidiscrete scheme, (4.8),(4.7), can be written in the following form:

$$\frac{d\bar{u}_{j,k}}{dt} = -\frac{H^x_{j+1/2,k}(t) - H^x_{j-1/2,k}(t)}{\Delta x} - \frac{H^y_{j,k+1/2}(t) - H^y_{j,k-1/2}(t)}{\Delta y} + Q^x_{j,k}(t) + Q^y_{j,k}(t). \tag{4.12}$$

Here, $H^x_{j+1/2,k}(t)$ and $H^y_{j,k+1/2}(t)$ are x- and y-numerical convection fluxes, respectively (they can be viewed as a generalization of the 1D flux, (4.7)),

$$\begin{aligned} H^x_{j+1/2,k}(t) &:= \frac{f(u^+_{j+1/2,k}(t)) + f(u^-_{j+1/2,k}(t))}{2} \\ &\quad - \frac{a^x_{j+1/2,k}(t)}{2}\left[u^+_{j+1/2,k}(t) - u^-_{j+1/2,k}(t)\right], \\ H^y_{j,k+1/2}(t) &:= \frac{g(u^+_{j,k+1/2}(t)) + g(u^-_{j,k+1/2}(t))}{2} \\ &\quad - \frac{a^y_{j,k+1/2}(t)}{2}\left[u^+_{j,k+1/2}(t) - u^-_{j,k+1/2}(t)\right]. \end{aligned} \tag{4.13}$$

The numerical fluxes, (4.13), are expressed in terms of the intermediate values, $u^{\pm}_{j+1/2,k}(t)$, $u^{\pm}_{j,k+1/2}(t)$, which are obtained from the piecewise polynomial reconstruction. The local speeds, $a^x_{j+1/2,k}(t)$ and $a^y_{j,k+1/2}(t)$, are computed, e.g., by

$$\begin{aligned} a^x_{j+1/2,k}(t) &:= \max\left\{\rho\Big(\frac{\partial f}{\partial u}(u^-_{j+1/2,k}(t))\Big), \rho\Big(\frac{\partial f}{\partial u}(u^+_{j+1/2,k}(t))\Big)\right\}, \\ a^y_{j,k+1/2}(t) &:= \max\left\{\rho\Big(\frac{\partial g}{\partial u}(u^-_{j,k+1/2}(t))\Big), \rho\Big(\frac{\partial g}{\partial u}(u^+_{j,k+1/2}(t))\Big)\right\}. \end{aligned} \tag{4.14}$$

Finally, $Q^x_{j,k}(t)$ and $Q^y_{j,k}(t)$ are high-order, central differencing approximations to the diffusion terms $Q^x(u, u_x, u_y)_x$ and $Q^y(u, u_x, u_y)_y$.

Remarks.

1. We would like to emphasize that the problem of constructing a 2D, third-order, nonoscillatory interpolant is highly nontrivial. Several essentially 2D reconstructions were proposed in [20, 21, 22]. Alternatively, one can use 1D CWENO reconstruction, direction by direction, in order to compute the intermediate values $u^{\pm}_{j+1/2,k}(t)$ and $u^{\pm}_{j,k+1/2}(t)$.

Following is the recipe for the computation of $u^-_{j+1/2,k}$ (the computation of other intermediate values can be carried out in a similar way):

$$u^-_{j+1/2,k} = w_{\text{L}} P^k_{\text{L}}(x_{j+1/2}) + w_{\text{R}} P^k_{\text{R}}(x_{j+1/2}) + w_{\text{C}} P^k_{\text{C}}(x_{j+1/2}), \tag{4.15}$$

where the P's are the polynomials introduced in section 2.1,

$$\begin{aligned} P^k_{\text{R}}(x) &= \bar{u}_{j,k} + \frac{\bar{u}_{j+1,k} - \bar{u}_{j,k}}{\Delta x}(x - x_j), \\ P^k_{\text{L}}(x) &= \bar{u}_{j,k} + \frac{\bar{u}_{j,k} - \bar{u}_{j-1,k}}{\Delta x}(x - x_j), \end{aligned}$$

(4.16)
$$P^k_{\rm C}(x) = \bar u_{j,k} - \frac{1}{12}(\bar u_{j+1,k} - 2\bar u_{j,k} + \bar u_{j-1,k}) - \frac{1}{12}(\bar u_{j,k+1} - 2\bar u_{j,k} + \bar u_{j,k-1}) + \frac{\bar u_{j+1,k} - \bar u_{j-1,k}}{2\Delta x}(x - x_j) + \frac{\bar u_{j+1,k} - 2\bar u_{j,k} + \bar u_{j-1,k}}{\Delta x^2}(x - x_j)^2.$$

The weights, $w_{\rm L}, w_{\rm R}, w_{\rm C}$, which are given by (2.8), are based on the smoothness indicators in (2.9).

Note that the only difference between this reconstruction and the 1D reconstruction, (2.4)–(2.9), is an additional term in $P^k_{\rm C}(x)$, $-\frac{1}{12}(\bar u_{j,k+1} - 2\bar u_{j,k} + \bar u_{j,k-1})$, which corresponds to the second derivative in the y direction and guarantees the third-order accuracy of the computed intermediate values. This "dimension by dimension" approach was implemented in Example 5 below.

2. It is straightforward to extend the 2D scheme, (4.12), to more space dimensions. In particular, the dimension-by-dimension approach is a very simple and promising approach for multidimensional problems.

5. Numerical examples. We conclude the paper with a number of numerical examples. Here, in order to retain the overall high accuracy, the semidiscrete scheme is combined with a high-order, stable ODE solver to complete the spatio-temporal discretization. Numerically, we observed that a variety of explicit methods provides satisfactory results in the context of our semidiscrete scheme.

For the inviscid problems (Examples 1, 2, 3, and 5), we used the third-order total variation diminishing (TVD) Runge–Kutta-type method introduced by Shu and Osher in [33]. However, if we apply this time-integration method or any other standard Runge–Kutta-type method to (degenerate) parabolic problems, the time-step can be very small due to their strict stability restrictions.

To overcome this difficulty, we used (in Examples 4 and 5) the third-order ODE solver (called DUMKA3) by Medovikov [29]. This explicit method has larger stability domains (compared with the standard Runge–Kutta methods), which allow larger time-steps. In practice, DUMKA3 works as fast as implicit methods (see [29] for details).

We abbreviate our third-order semidiscrete scheme by SD3, which will be combined with the third-order TVD Runge–Kutta-type method (RK3) or with DUMKA3.

Example 1: Linear accuracy test. Consider the scalar linear hyperbolic equation

$$u_t + u_x = 0, \qquad x \in [0, 2\pi], \tag{5.1}$$

augmented with the smooth initial data, $u(x,0) = \sin x$, and periodic boundary conditions. This simple problem admits a global classical solution, which was computed at time $T = 1$ with a varying number of grid points, N.

In Table 5.1 we check the accuracy of our third-order semidiscrete scheme, SD3, coupled with the RK3 ODE solver. Clearly, this is a high-order method. The asymptotic convergence rate seems to be better than three, which is similar to the superconvergence observed in [27].

The error is measured in terms of the pointwise values,

$$\|\tilde u - u\|_{L^1} := \Delta x \sum_j |\tilde u_j(T) - u(x_j, T)|, \quad \|\tilde u - u\|_{L^\infty} := \max_j |\tilde u_j(T) - u(x_j, T)|.$$

TABLE 5.1
Accuracy test for the linear advection problem (5.1)*; the errors at* $T = 1$.

N	L^1-error	Rate	L^∞-error	Rate

1280	3.044e-07	4.00	5.732e-07	4.96

Here, $\tilde{u}$ is an approximate solution, which is realized by its values at the grid points, x_j,

$$\tilde{u}_j(T) = P_j(x_j, T),$$

where the P_j's are the piecewise parabolic interpolants, (3.3), constructed at the final time $t = T$.

Example 2: The Burgers equation. In this example we approximate solutions to the inviscid Burgers equation,

$$u_t + \left(\frac{u^2}{2}\right)_x = 0, \qquad x \in [0, 2\pi], \tag{5.2}$$

augmented with the smooth initial data, $u(x, 0) = 0.5 + \sin x$, and periodic boundary conditions.

The unique entropy solution of (5.2) develops a shock discontinuity at the critical time $T_c = 1$. Table 5.2 shows the L^1- and L^∞-norms of the errors at the preshock time $T = 0.5$, when the solution is still smooth. Once again, our results indicate that the method is a high-order method also when implemented for nonlinear problems.

In Figures 5.1 and 5.2 we present the approximate solutions at the postshock time $T = 2$, when the shock is well developed. The essentially nonoscillatory nature of our scheme can be clearly observed.

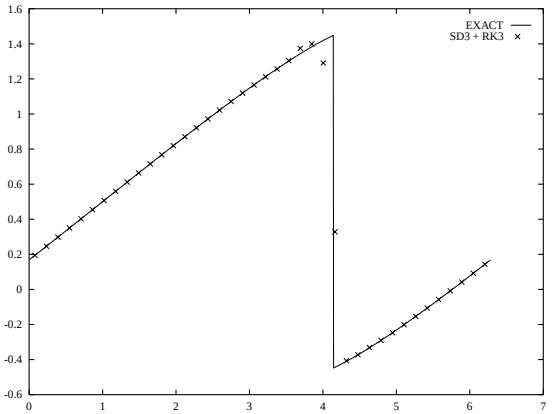

FIG. 5.1. *The Burgers equation,* (5.2)*;* $T = 2$*,* $N = 40$.

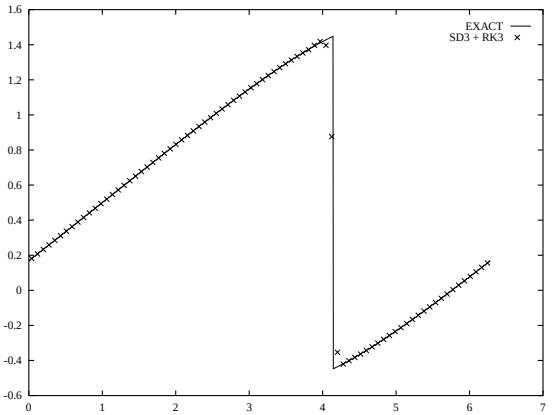

FIG. 5.2. *The Burgers equation,* (5.2)*;* $T = 2$*,* $N = 80$.

Example 3: Euler equations of gas dynamics. Let us consider the 1D Euler system

$$\frac{\partial}{\partial t}\begin{bmatrix} \rho \\ m \\ E \end{bmatrix} + \frac{\partial}{\partial x}\begin{bmatrix} m \\ \rho u^2 + p \\ u(E+p) \end{bmatrix} = 0, \qquad p = (\gamma - 1) \cdot \left(E - \frac{\rho}{2}u^2\right),$$

where ρ, u, $m = \rho u$, p, and E are the density, velocity, momentum, pressure, and total energy, respectively. We solve this system subject to Sod's Riemann initial data, proposed in [34],

$$\vec{u}(x,0) = \begin{cases} \vec{u}_L = (1,0,2.5)^T, & x < 0, \\ \vec{u}_R = (0.125,0,0.25)^T, & x > 0. \end{cases}$$

The approximations to the density, velocity, and pressure obtained by the SD3 scheme with the RK3 time discretization are presented in Figures 5.3–5.8. The coefficient p in the smoothness indicator, (2.8)–(2.9), was taken as 0.6, which seems to be the optimal value in this specific example. WENO-type schemes do require a parameter tuning in order to reduce the amplitude of the oscillations. Formally, this does not affect the order of accuracy of the method (in certain ranges of the parameters).

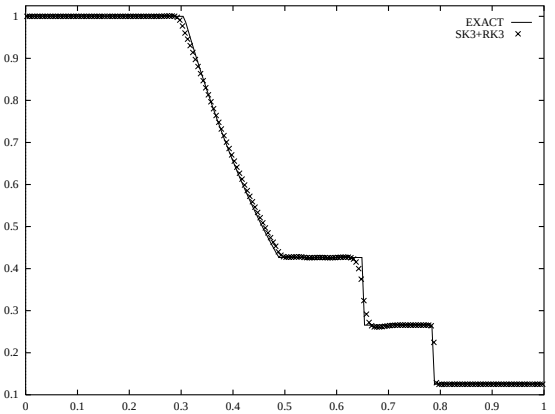

FIG. 5.3. *Sod problem*—density. $N = 200$, $T = 0.1644$.

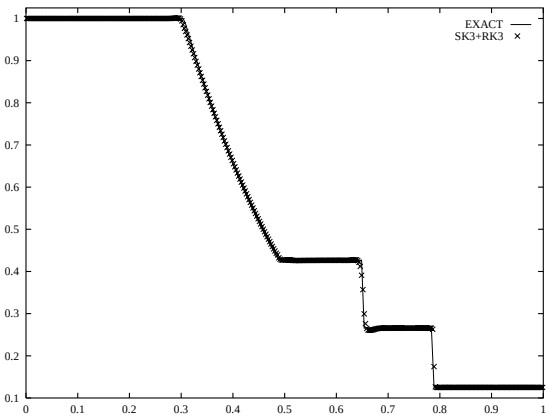

FIG. 5.4. *Sod problem*—density. $N = 400$, $T = 0.1644$.

We would like to stress again that our SD3 scheme does not employ the characteristic decomposition. To improve the resolution of the contact discontinuity, which is always smeared while the solution to the system of Euler equations is computed by the central method, we implemented the artificial compression method (ACM) by Harten [8]. In the context of central schemes, the ACM can be implemented as a corrector step to the componentwise approach (see [30] for details).

Example 4: Convection-diffusion equations—the Buckley–Leverett model. In this example we solve the 1D Buckley–Leverett equation,

$$u_t + f(u)_x = \varepsilon(\nu(u)u_x)_x, \quad \varepsilon\nu(u) \geq 0, \tag{5.3}$$

which can be viewed as a prototype model for the two-phase flow in oil reservoirs. Typically, $\nu(u)$ vanishes at some values of u, and thus (5.3) is a degenerate parabolic equation. Specifically, we take

$$f(u) = \frac{u^2}{u^2 + (1-u)^2}, \quad \nu(u) = 4u(1-u), \quad \varepsilon = 0.01,$$

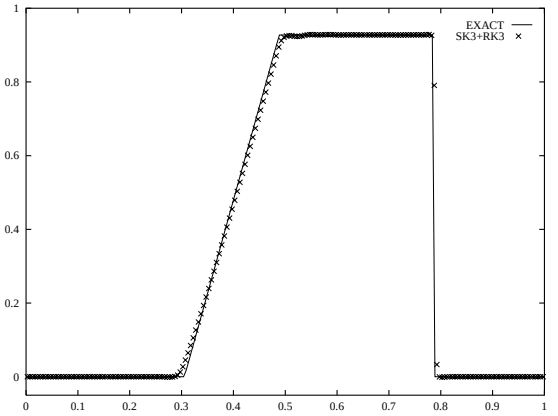

FIG. 5.5. *Sod problem*—velocity. $N = 200$, $T = 0.1644$.

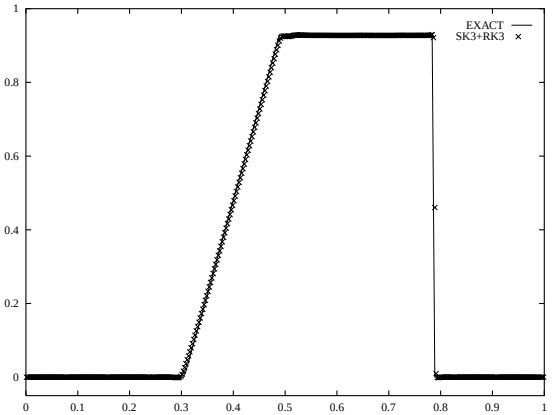

FIG. 5.6. *Sod problem*—velocity. $N = 400$, $T = 0.1644$.

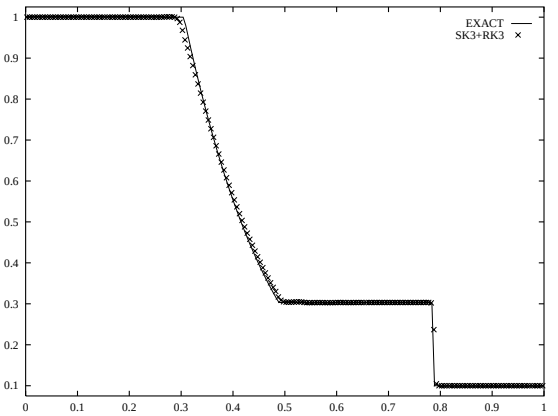

FIG. 5.7. *Sod problem*—pressure. $N = 200$, $T = 0.1644$.

and consider the initial value problem with the Riemann initial data,

$$u(x,0) = \begin{cases} 0, & 0 \le x < 1 - \frac{1}{\sqrt{2}}, \\ 1, & 1 - \frac{1}{\sqrt{2}} \le x \le 1. \end{cases} \tag{5.4}$$

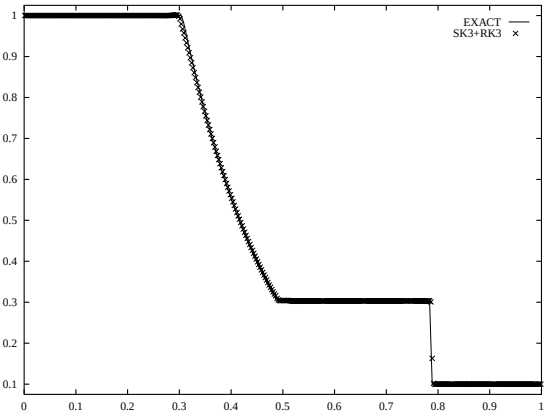

FIG. 5.8. *Sod problem*—pressure. $N = 400$, $T = 0.1644$.

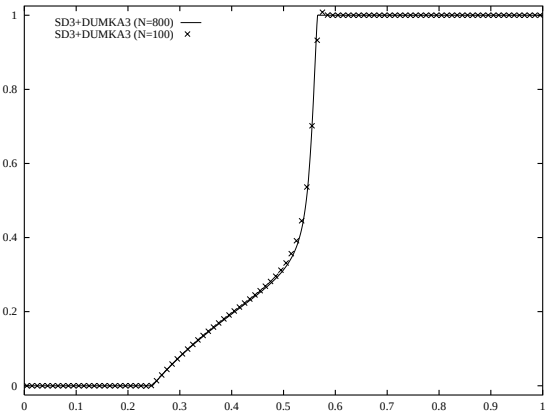

FIG. 5.9. *Buckley–Leverett model,* (5.3)–(5.4). $T = 0.2$.

The numerical solution to this problem, obtained by the SD3 scheme augmented with the DUMKA3 ODE solver, is presented in Figure 5.9.

The model, (5.3), becomes more complicated by adding the effects of gravitation. These effects can be obtained, e.g., by taking

$$f(u) = \frac{u^2}{u^2 + (1-u)^2}(1 - 5(1-u)^2), \tag{5.5}$$

which is nonmonotone on the interval $u \in [0, 1]$.

The numerical solution to this initial value problem is shown in Figure 5.10. Note that the exact solution to problem (5.3)–(5.4) is not available, but our solutions seem to converge to the physically relevant solutions in both cases—with gravitation and without it.

Example 5: Incompressible Euler and Navier–Stokes equations. In this example we consider 2D viscous and inviscid incompressible flow governed by the Navier–Stokes ($\nu > 0$) and Euler ($\nu = 0$) equations,

$$\vec{u}_t + (\vec{u} \cdot \nabla)\vec{u} + \nabla p = \nu \Delta \vec{u}. \tag{5.6}$$

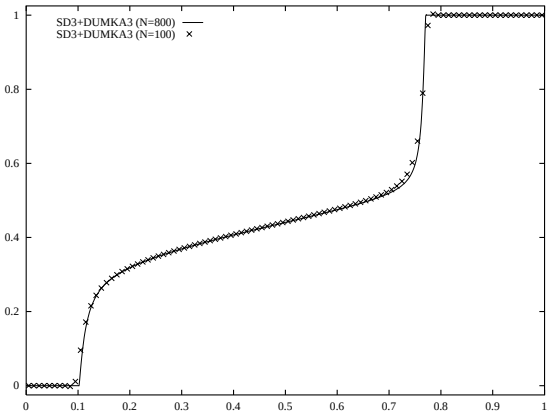

FIG. 5.10. *Buckley–Leverett model,* (5.3)–(5.4)*, including the gravitational effect,* (5.5)*.* $T = 0.2$.

Here, p denotes the pressure, and $\vec{u} = (u, v)$ is the two-component divergence-free velocity field satisfying

$$u_x + v_y = 0. \tag{5.7}$$

In the 2D case (5.6) admits an equivalent scalar formulation in terms of the vorticity,

$$\omega_t + (u\omega)_x + (v\omega)_y = \nu\Delta\omega, \tag{5.8}$$

where $\omega := v_x - u_y$. The incompressibility, (5.7), implies that (5.8) can be written in an equivalent conservative form,

$$\omega_t + f(\omega)_x + g(\omega)_y = \nu\Delta\omega, \tag{5.9}$$

with a *global* convection flux, $(f, g) := (u\omega, v\omega)$. A second-order, fully discrete, staggered, central scheme was used to solve the 2D vorticity equations in [24]. This scheme was proved to satisfy a maximum principle for the vorticity. (For an equivalent scheme in the velocity formulation, see [13].)

When applied to (5.9), our 2D, third-order, semidiscrete scheme, (4.12)–(4.14), takes the form

$$\begin{aligned}\frac{d\bar{\omega}_{j,k}}{dt} = &-\frac{H^x_{j+1/2,k}(t) - H^x_{j-1/2,k}(t)}{\Delta x}\\ &-\frac{H^y_{j,k+1/2}(t) - H^y_{j,k-1/2}(t)}{\Delta y} + \nu Q_{j,k}(t),\end{aligned} \tag{5.10}$$

with the numerical convection fluxes,

$$\begin{aligned}H^x_{j+1/2,k}(t) = &\frac{u_{j+1/2,k}(t)}{2}\left[\omega^+_{j+1/2,k}(t) + \omega^-_{j+1/2,k}(t)\right]\\ &-\frac{a^x_{j+1/2,k}(t)}{2}\left[\omega^+_{j+1/2,k}(t) - \omega^-_{j+1/2,k}(t)\right],\\ H^y_{j,k+1/2}(t) = &\frac{v_{j,k+1/2}(t)}{2}\left[\omega^+_{j,k+1/2}(t) + \omega^-_{j,k+1/2}(t)\right]\\ &-\frac{a^y_{j,k+1/2}(t)}{2}\left[\omega^+_{j,k+1/2}(t) - \omega^-_{j,k+1/2}(t)\right],\end{aligned} \tag{5.11}$$

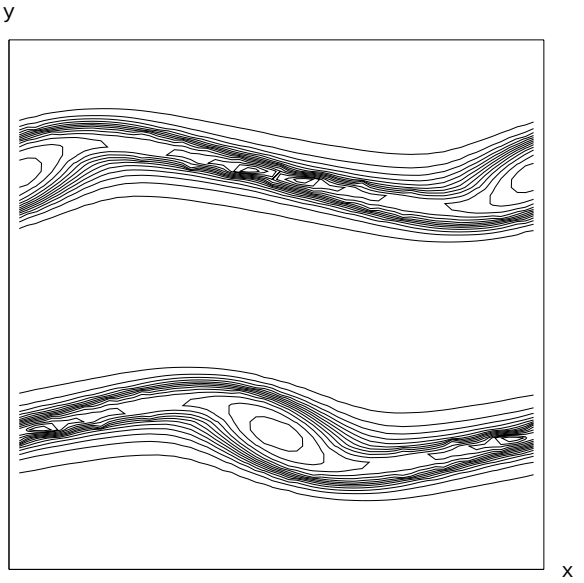

FIG. 5.11. *Incompressible Euler equations; third-order method;* $T = 4$, 64×64 *grid.*

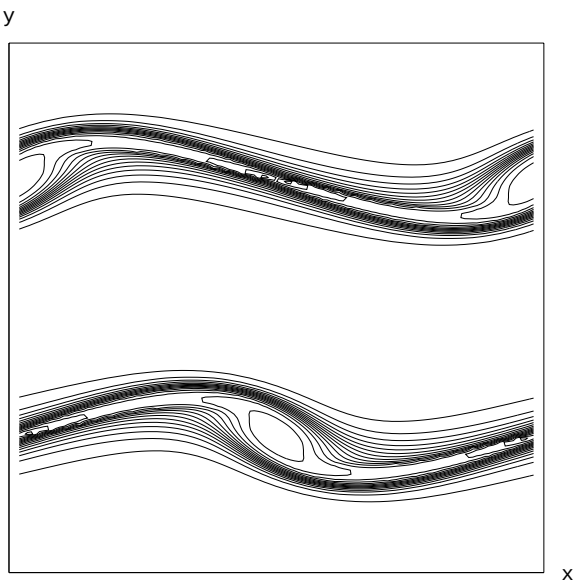

FIG. 5.12. *Incompressible Euler equations; third-order method;* $T = 4$, 128×128 *grid.*

and the local speeds,

$$a^x_{j+1/2,k}(t) := |u_{j+1/2,k}(t)|, \qquad a^y_{j,k+1/2}(t) := |v_{j,k+1/2}(t)|. \tag{5.12}$$

To approximate the linear viscosity, $\Delta\omega$, we used the fourth-order central differencing,

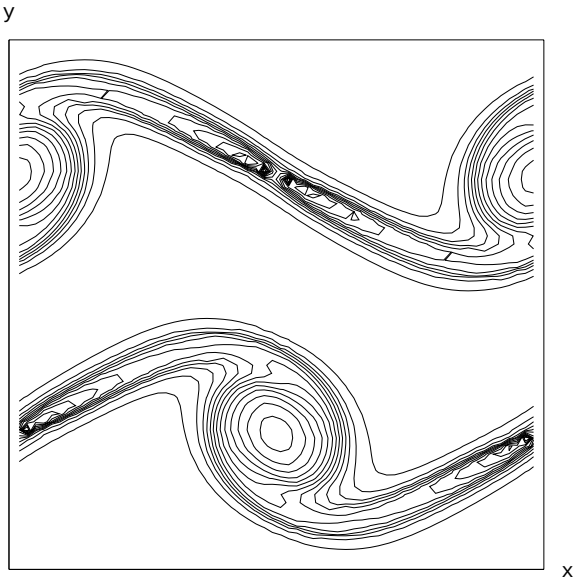

FIG. 5.13. *Incompressible Euler equations; third-order method;* $T = 6$, 64×64 *grid.*

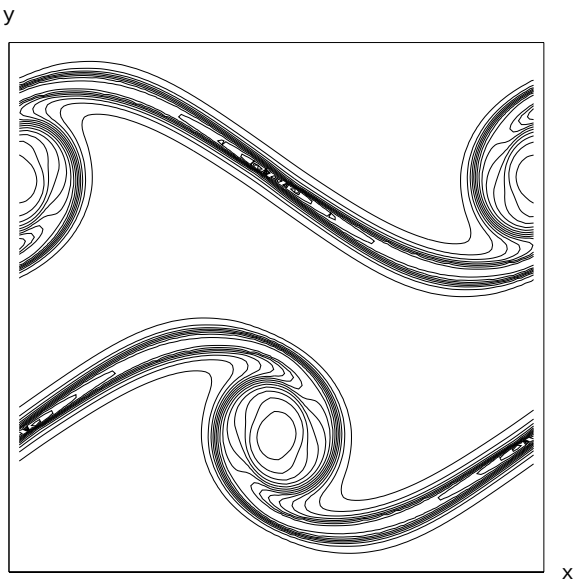

FIG. 5.14. *Incompressible Euler equations; third-order method;* $T = 6$, 128×128 *grid.*

$$Q_{j,k}(t) = \frac{-\omega_{j+2,k}(t) + 16\omega_{j+1,k}(t) - 30\omega_{j,k}(t) + 16\omega_{j-1,k}(t) - \omega_{j-2,k}(t)}{12\Delta x^2} + \frac{-\omega_{j,k+2}(t) + 16\omega_{j,k+1}(t) - 30\omega_{j,k}(t) + 16\omega_{j,k-1}(t) - \omega_{j,k-2}(t)}{12\Delta y^2}. \tag{5.13}$$

To compute the intermediate values of the vorticity, we use the "dimension by dimension" approach described in section 4.2: we reconstruct the corresponding CWENO

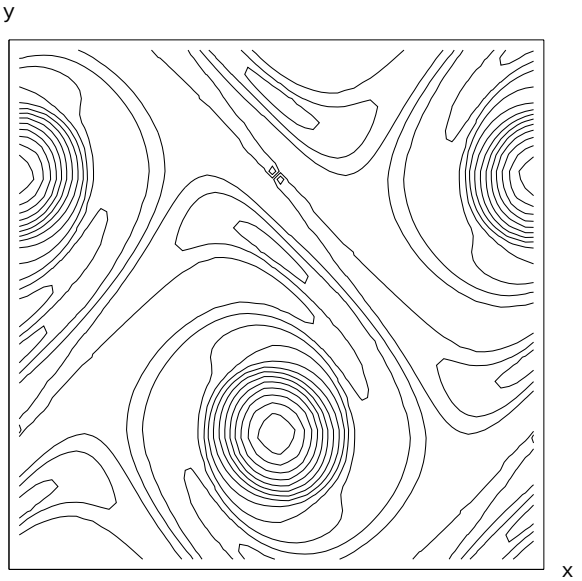

FIG. 5.15. *Incompressible Euler equations; third-order method;* $T = 10$, 64×64 *grid.*

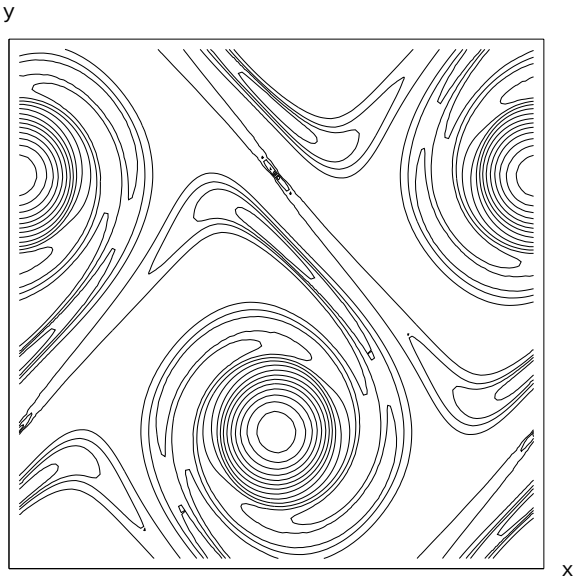

FIG. 5.16. *Incompressible Euler equations; third-order method;* $T = 10$, 128×128 *grid.*

interpolants in the x- and y-directions to obtain the values of $\omega^{\pm}_{j+1/2,k}$ and $\omega^{\pm}_{j,k+1/2}$.

Another important point in the incompressible computations is that in every time-step one has to recover the velocities, $\{u_{j,k}, v_{j,k}\}$, from the known values of the vorticity, $\{\omega_{j,k}\}$. This can be done in many different ways (consult, e.g., [24] and the references therein). Here we have used a stream-function, ψ, such that $\triangle\psi = -\omega$, which is obtained by solving the nine-points Laplacian, $\triangle\psi_{j,k} = -\omega_{j,k}(t)$. This provides the values of the stream-function with fourth-order accuracy. Its gradient,

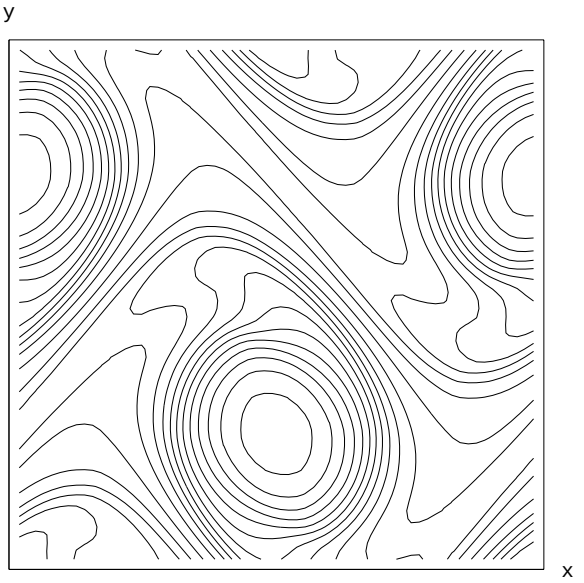

FIG. 5.17. *Incompressible Euler equations; second-order method;* $T = 10$, 64×64 *grid.*

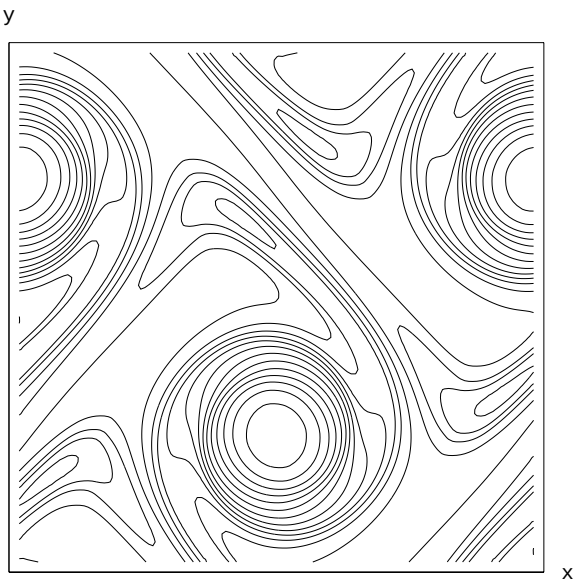

FIG. 5.18. *Incompressible Euler equations; second-order method;* $T = 10$, 128×128 *grid.*

$\nabla\psi$, then recovers the velocity field,

$$u_{j,k}(t) = \frac{-\psi_{j,k+2} + 8\psi_{j,k+1} - 8\psi_{j,k-1} + \psi_{j,k-2}}{12\Delta y},$$
$$v_{j,k}(t) = \frac{\psi_{j+2,k} - 8\psi_{j+1,k} + 8\psi_{j-1,k} - \psi_{j-2,k}}{12\Delta x}. \tag{5.14}$$

Remarks.

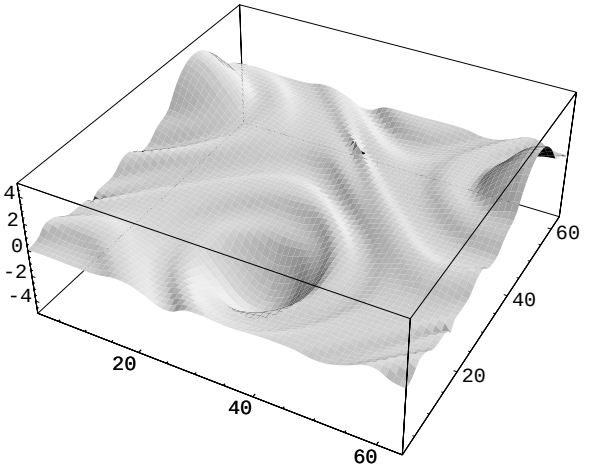

FIG. 5.19. *Incompressible Euler equations; third-order method;* $T = 10$, 64×64 *grid.*

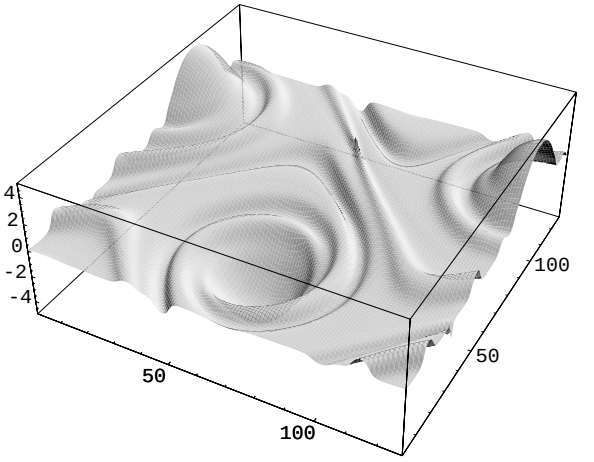

FIG. 5.20. *Incompressible Euler equations; third-order method;* $T = 10$, 128×128 *grid.*

1. Observe that in this way we retain the discrete incompressibility, namely, the discrete velocities computed in (5.14) satisfy

$$\frac{-u_{j+2,k} + 8u_{j+1,k} - 8u_{j-1,k} + u_{j-2,k}}{12\Delta x} + \frac{-v_{j,k+2} + 8v_{j,k+1} - 8v_{j,k-1} + v_{j,k-2}}{12\Delta y} = 0.$$

2. The point-values of the vorticity, which are required for using the nine-points Laplacian, were computed from its cell-averages using the "dimension by dimension" recipe, (4.15)–(4.16).

Finally, the intermediate values of velocities can be computed, e.g., using fourth-order averaging,

$$\begin{aligned} u_{j+1/2,k}(t) &= \frac{-u_{j+2,k}(t) + 9u_{j+1,k}(t) + 9u_{j,k}(t) - u_{j-1,k}(t)}{16}, \\ v_{j,k+1/2}(t) &= \frac{-v_{j,k+2}(t) + 9v_{j,k+1}(t) + 9v_{j,k}(t) - v_{j,k-1}(t)}{16}. \end{aligned} \tag{5.15}$$

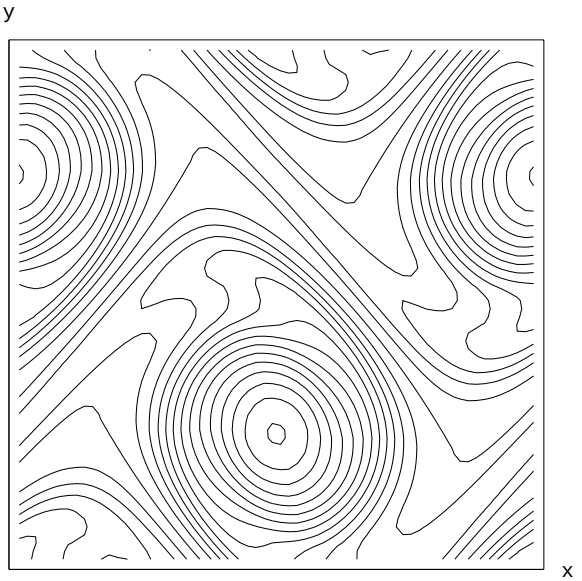

FIG. 5.21. *Incompressible Navier–Stokes equations; third-order method;* $T = 10$, 64×64 *grid.*

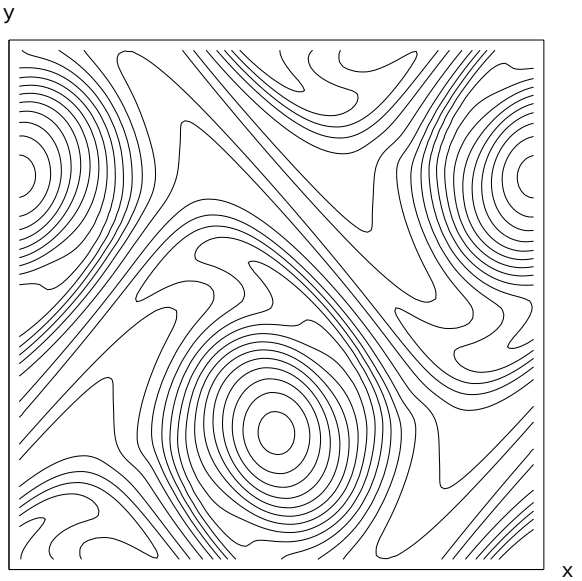

FIG. 5.22. *Incompressible Navier–Stokes equations; third-order method;* $T = 10$, 128×128 *grid.*

We start our numerical experiments by checking the accuracy of our scheme, (5.10)–(5.15), augmented with the DUMKA3 time discretization. We consider the Navier–Stokes equations, (5.6)–(5.7) with $\nu = 0.05$, subject to the smooth periodic initial data (taken from [4]),

$$u(x, y, 0) = -\cos(x)\sin(y), \qquad v(x, y, 0) = \sin(x)\cos(y). \tag{5.16}$$

The exact solution to this problem is simply an exponential decay of the initial data,

TABLE 5.3

given by

$$u(x,y,t) = -\cos(x)\sin(y)e^{-2\nu t}, \qquad v(x,y,t) = \sin(x)\cos(y)e^{-2\nu t}.$$

The approximate solution with a different number of grid points was computed at time $t = 2$. The errors, measured in terms of vorticity in the L^∞-, L^1-, and L^2-norms are shown in Table 5.3.

Next, the third-order semidiscrete scheme, (5.10)–(5.15), was implemented for the periodic double shear-layer model problem taken from [2]. First, we solve the Euler equations, (5.6)–(5.7) with $\nu = 0$, subject to the $(2\pi, 2\pi)$-periodic initial data,

$$u(x,y,0) = \begin{cases} \tanh(\frac{1}{\rho}(y - \pi/2)), & y \le \pi, \\ \tanh(\frac{1}{\rho}(3\pi/2 - y)), & y > \pi, \end{cases} \qquad v(x,y,0) = \delta \cdot \sin(x). \tag{5.17}$$

Here, the "thick" shear-layer width parameter, ρ, is taken as $\frac{\pi}{15}$ and the perturbation parameter $\delta = 0.05$.

The numerical results at times $T = 4, 6, 10$ with $N = 64 \times 64$ and $N = 128 \times 128$ grid points are presented in Figures 5.11 through 5.16 and 5.19 through 5.20. In order to compare the quality of the results obtained with our new method to previous results, we plot in Figures 5.17 and 5.18 the results obtained for the same double shear-layer problem with the second-order central scheme proposed in [24]. Compared with the second-order method, the new third-order method can resolve the large gradients better. Since we are using only an essentially nonoscillatory reconstruction, some oscillations are created with the third-order method (and not with the "fully" nonoscillatory second-order method).

Finally, we solve the Navier–Stokes equations, (5.6)–(5.7) with $\nu = 0.01$, augmented with the "thick" shear-layer periodic initial data, (5.17).

The numerical results at time $T = 10$ with $N = 64 \times 64$ and $N = 128 \times 128$ grid points are presented in Figures 5.21–5.24.

Acknowledgment. The authors would like to thank Professors S. Karni and R. S. Krasny for helpful comments.

A MODIFIED FRACTIONAL STEP METHOD FOR THE ACCURATE APPROXIMATION OF DETONATION WAVES*

CHRISTIANE HELZEL†, RANDALL J. LEVEQUE‡, AND GERALD WARNECKE†

Abstract. The numerical approximation of combustion processes may lead to numerical difficulties, which are caused by different time scales of the transport part and the reactive part of the model equations. Here we consider a modified fractional step method that overcomes this difficulty on standard test problems and allows the use of a mesh width and time step determined by the nonreactive part, without precisely resolving the very small reaction zone. High-resolution Godunov methods are employed and the structure of the Riemann solution is used to determine where burning should occur in each time step. The modification is implemented in the software package CLAWPACK. Numerical results for 1D and 2D detonation waves are shown, including a detonation wave diffracting around a corner.

1. Introduction.

We consider hyperbolic systems of conservation laws with source term which arise in the modeling of combustion processes. Here the source term describes a chemical reaction, i.e., a burning process which leads to a production or reduction of physical quantities inside the domain considered. Under appropriate smoothness assumptions the differential form of a system of conservation laws with source term is given as

$$q_t + \sum_{i=1}^{d} f_i(q)_{x_i} = \psi(q), \tag{1.1}$$

where the physical states $q(x,t)$, the fluxes f_i, and the source ψ are vector-valued functions and d is the space dimension.

If the time scale of the ordinary differential equation (ODE) $q_t = \psi(q)$ for the source term is orders of magnitude smaller than the time scale of the homogeneous conservation law $q_t + \sum_{i=1}^{d} f_i(q)_{x_i} = 0$, then the problem is said to be *stiff*. Here we consider a combustion problem, where the chemical reaction, i.e., the burning process, may be much faster than the gas flow.

We restrict our considerations to numerical solutions which are computed by using a fractional step method, in which we alternate between solving the homogeneous conservation law and the ODEs for the reactions. Furthermore, we solve the homogeneous conservation law by using a high-resolution version of the Godunov scheme,

which is implemented in CLAWPACK [18]. It is known that the numerical solutions of conservation laws with stiff source terms may be erroneous, for instance, with discontinuities that propagate at the wrong speed and with nonphysical states. These purely numerical problems are caused by the smearing effect of the conservation law solver. A conservative scheme for solving the homogeneous conservation law leads to smeared-out shock profiles while discontinuities are still moving with the correct speed. In a fractional step scheme this smearing effect may lead to an activation of the very fast process described by the source term. This can produce totally nonphysical solutions. Colella, Majda, and Roytburd [11] have observed nonphysical speeds for a simplified combustion problem. LeVeque and Yee [23] have studied incorrect propagation speeds of a contact discontinuity in the numerical solution of an advection equation with a stiff nonlinear source term.

In order to avoid these problems one could use adaptive mesh refinement or front tracking schemes, see, e.g., Bourlioux [9], LeVeque and Shyue [22], Jeltsch and Klingenstein [16]. Using a sufficiently fine mesh it is always possible to avoid nonphysical solutions since the fractional step method is convergent to the relevant solution. Note that a sufficient spatial resolution is as important as a temporal resolution; see [23].

However, resolution of the fine scale is what one really would like to avoid, if one is not interested in the detailed structure of the detonation wave. Therefore some authors, e.g., Pember [25] or Berkenbosch [7] considered the question of whether it is possible to obtain an accurate numerical solution of a stiff hyperbolic system of conservation laws with source term using time and space steps controlled only by the nonstiff part, i.e., without fully resolving the effect of the stiff source term. With such an *underresolved scheme* one would hope to approximate the global solution structure, e.g., the correct propagation speed of a detonation wave.

Note that this approach is not appropriate if one is interested in processes arising on the scale of the reaction zone, i.e., inside the reaction zone, which we do not want to resolve in the stiff case. A correct approximation of pulsating detonation waves or cellular structures can therefore not be obtained by our modified solver. In order to get such results, one has to resolve the reaction zone.

For the combustion problem, the nonphysical numerical solution that is obtained, if the chemical reaction is not resolved on the grid, is a weak detonation wave usually moving with a speed of one mesh cell per time step. Pember [25] postulated that a necessary condition for such a spurious solution to occur in the numerical calculation could be that the temperature of the post detonation state of the approximated spurious weak detonation wave is higher than the ignition temperature. Therefore, this nonphysical numerical solution can be suppressed if the ignition temperature is high enough. In Berkenbosch [7] the dependency of the numerical solution on the ignition temperature is analyzed in much more detail; see also Berkenbosch, Kaasschieter, and Klein [8]. They also show that the critical ignition temperature needed to get an appropriate approximation of the correct strong detonation wave is lower if a high-resolution scheme for the homogeneous conservation law is used in the fractional step scheme. Based on this observation Berkenbosch [7] and Berkenbosch, Kaasschieter, and Klein [8] suggest using a suitable ignition temperature. A similar change of the ignition temperature was also described by Ton; see [28].

Another possibility to approximate shocks as sharp discontinuities (at least in 1D approaches) is supplied by using the Glimm scheme, which was introduced in [14]. This scheme uses the exact values of the Riemann problem at a randomly chosen point inside every mesh cell. The good performance of the Glimm scheme used in

a fractional step approach to solve the reactive Euler equations is demonstrated in Colella, Majda, and Roytburd [11]. A projection step that eliminates intermediate states which are not in equilibrium was introduced by Sjögreen and Engquist [26] and was tested for 1D and 2D problems. The idea of calculating values at randomly chosen points was recently also used by Bao and Jin [2], [3] in a different way. They replaced the ignition temperature by a uniformly distributed random variable inside the interval of the temperature of the completely unburnt state and the completely burnt state.

In Ben-Artzi [4] and Falcovitz and Ben-Artzi [13] the authors considered the approximation of a Chapman–Jouguet (CJ) detonation wave by using an unsplit second order scheme which is based on the solution of generalized Riemann problems. Their scheme was not intended to resolve the stiffness of the problem. Instead it was constructed in a way that should better approximate the coupling between the fluid dynamical and the chemical equations. For the example used in those papers the ignition temperature is above the critical temperature which is needed for a second order fractional step scheme to approximate the correct detonation front. Their numerical results show that the detonation wave is reasonably approximated if an explicit scheme is used to calculate the reduction of unburnt gas, whereas the use of an implicit scheme leads to the unphysical weak detonation wave.

Here we discuss a modification of the fractional step scheme for the approximation of underresolved detonation waves which gives promising numerical resolution for all appropriate ignition temperatures. It turns out that one can get all the information required for this modification from the structure of the Riemann problems occurring in the discretization. We believe that this approach could also give more insight into the numerical problems occurring when solving conservation laws with stiff source terms.

2. The 1D combustion problem.

2.1. The reactive Euler equations. For modeling the combustion process we use the reactive Euler equations as described, for instance, in [12], [15], [20]. We make use of the following basic assumptions. There are only the two chemical states: burnt gas and unburnt gas. The unburnt gas is converted to burnt gas via an irreversible, exothermic chemical reaction described by the function $K(T)$. The reaction rate $K(T)$ depends on the temperature T via an *Arrhenius law* modeled by

$$K(T) = K_0 \exp\left(-E^+/T\right), \tag{2.1}$$

where K_0 is the rate constant and E^+ is the activation energy; see, for instance, Oran and Boris [24]. The reaction rate is negligible for low temperature values and grows exponentially fast if the temperature is high enough. Sometimes this reaction rate is replaced by a discrete *ignition temperature kinetics model* of the form

$$K(T) = \begin{cases} 1/\tau_0 & : \quad T \geq T_{ign}, \\ 0 & : \quad T < T_{ign}, \end{cases} \tag{2.2}$$

where T_{ign} is the ignition temperature and τ_0 is the time scale of the chemical reaction. Note that $1/\tau_0$ roughly corresponds to K_0 in (2.1). In a stiff calculation, where we do not want to resolve the reaction zone, the discrete ignition temperature kinetics model is a reasonable approximation of the Arrhenius law. Therefore, we will first restrict our considerations to this simplified reaction rate. Later we will show that

our modified scheme can also be applied to the more general form of the Arrhenius law (2.1).

The value τ_0 in (2.1) must be seen in relation to the time scale of the convective part of our problem. Further we assume that the burnt and unburnt gases are ideal gases with the same ratio of specific heats γ and temperature $T = p/\rho\mathcal{R}$, where $\mathcal{R}$ is the specific gas constant. Finally we ignore the effects of diffusion. Using all of these assumptions we get the model equations

$$\rho_t + (\rho u)_x = 0 \qquad \text{conservation of mass,} \tag{2.3}$$

$$(\rho u)_t + (\rho u^2 + p)_x = 0 \qquad \text{conservation of momentum,} \tag{2.4}$$

$$E_t + (u(E+p))_x = 0 \qquad \text{conservation of energy,} \tag{2.5}$$

$$(\rho Z)_t + (\rho u Z)_x = -K(T)\rho Z \qquad \text{continuity equation for the unburnt gas,} \tag{2.6}$$

as a combination of the Euler equations with the kinetics model. The variable Z is the mass fraction of unburnt gas, where $Z = 1$ describes the unburnt state and $Z = 0$ the completely burnt state. The other variables are as usual the total density of burnt and unburnt gas ρ, the velocity u, the pressure p, and the total energy E. The total energy is calculated via the equation of state

$$E = \frac{p}{\gamma - 1} + \frac{1}{2}\rho u^2 + q_0 \rho Z, \tag{2.7}$$

where q_0 is the heat release and the term $q_0\rho Z$ is the chemical energy. Note that by using (2.3), (2.6) is equivalent to

$$Z_t + uZ_x = -K(T)Z. \tag{2.8}$$

There are two combustion processes which are associated with the reactive Euler equations, namely, detonations and deflagrations. Here we restrict our considerations to the approximation of detonation processes; see, for instance, Courant and Friedrichs [12], Godlewski and Raviart [15], or Berkenbosch [7] for a characterization of these processes. We will consider the special case of a CJ detonation wave, which is the detonation wave that occurs most frequently in practice.

The solution structure that can be derived from the reactive Euler equations was originally considered by Zel'dovich, von Neumann, and Döring and is therefore called a *ZND structure*. The detonation process is initiated by a shock. Through this shock, pressure, density, and temperature are raised instantaneously. If the temperature of the unburnt gas becomes greater than the ignition temperature, then the combustion is initiated. Through the combustion process, pressure and density are decreased; see Figure 1. For numerical experiments it is useful to start with such an exact ZND structure as initial data. In this case the exact traveling wave solution and especially the exact propagation speed of the detonation wave can be calculated.

We say that the reactive Euler equations for approximating a detonation wave are *stiff* if the reaction zone is small relative to the mesh size $\triangle x$, in which case the ZND structure cannot be resolved on the grid. This is consistent with the characterization of stiffness given in the introduction because the time scale of the chemical reaction τ_0 is proportional to the length of the reaction zone. In this case the time step appropriate for the fluid dynamics is also insufficient to resolve the kinetics.

2.2. Numerical solutions by using the fractional step method. We use a fractional step method to calculate the numerical solution, e.g., we split the calculation

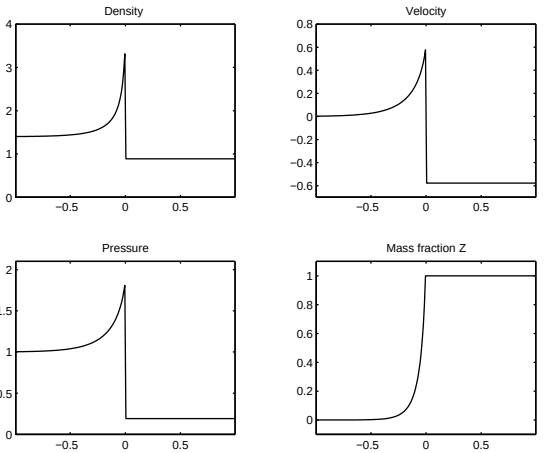

FIG. 1. *ZND structure of a CJ detonation wave.*

of (1.1) into the subproblems

$$q_t + f(q)_x = 0, \tag{2.9}$$

$$q_t = \psi(q) \tag{2.10}$$

and alternate between evolving these numerically. Let $L_{CL}^{\triangle t}$ denote an approximate solution operator of the conservation law (2.9) and $L_{ODE}^{\triangle t}$ be an approximate solution operator of the ODE (2.10), each over a time step of length $\triangle t$. Then the numerical solution at time step t_{n+1} is calculated from the numerical solution at time t_n via the relation

$$Q^{n+1} = L_{ODE}^{\triangle t} L_{CL}^{\triangle t} Q^n.$$

Here, we will restrict our considerations to this "Godunov splitting" scheme, but the results can also be extended to other fractional step methods, e.g., the Strang splitting scheme. See, for instance, LeVeque [20] for more details on fractional step methods. We use a high-resolution version of the Godunov scheme with an exact Riemann solver for solving the system of conservation laws. The solution of the Riemann problem for the nonreactive two-component Euler equations, i.e., the solution of (2.3)–(2.6) with $K(T) = 0$ and piecewise constant initial values, is very similar to the solution of the Riemann problem for the Euler equations. The solution theory of this frequently-used Riemann problem is well known; see, e.g., Smoller [27] or Kröner [17]. This solution consists of constant states separated by three waves, where the 2-wave is always a contact discontinuity. The quantities u and p are Riemann invariants of the 2-wave, thus they are constant across the contact discontinuity. The 1- and the 3-wave are shock or rarefaction waves. Further it is known that the characteristic speed of the contact discontinuity is equal to u. The mass fraction of unburnt gas in the homogeneous part of (2.8) is advected with the speed u, i.e., with the speed of the contact discontinuity. Therefore the mass fraction of unburnt gas in a Riemann problem is equal to Z_l everywhere to the left of the contact discontinuity and equal to Z_r everywhere to the right-hand side of this 2-wave. Different iterative schemes for solving the Riemann problem for the Euler equations were developed, for instance, the Chorin

algorithm [10]. The latter can easily be extended to solving the Riemann problem of the nonreactive two-component Euler equations. It was used in our calculations.

The second step in the fractional step scheme consists in solving the ODE for the source term. The assumption that $K(T)$ is constant is permissible for the ignition temperature kinetics model (2.2). Therefore, the ODE $Z_t = -K(T)Z$ can be solved exactly. We get the solution

$$Z_j^{n+1} = \exp\left(-K(\overline{T}_j^n)\triangle t\right)\overline{Z}_j^n,$$

where $\overline{Z}_j^n$ and $\overline{T}_j^n$ are the values after one time step $\triangle t$ of the conservation law solver. We consider the following test problem of a CJ detonation wave moving with speed one.

Example 1. The initial values consist of totally burnt gas on the left-hand side and totally unburnt gas on the right-hand side. The density, velocity, and pressure of the burnt gas are given by $\rho_b = 1.4$, $u_b = 0$, $p_b = 1$, and $Z_b = 0$. It is then possible to calculate the values for the unburnt state so that the states are connected by a CJ detonation wave moving with speed 1. We find that $\rho_u = 0.887565$, $u_u = -0.577350$, and $p_u = 0.191709$. The mass fraction of unburnt gas is $Z_u = 1$, which means that there is only unburnt gas. Further we can calculate the states within the reaction zone. The other parameters are set to $\gamma = 1.4$, $\mathcal{R} = 1$, and $q_0 = 1$.

For our first set of tests we use the discrete ignition temperature kinetics reaction rate model (2.2). The time scale of the chemical reaction τ_0 as well as the ignition temperature T_{ign} vary in the numerical calculations considered. We consider two values of τ_0 for our experiments: $\tau_0 = 10^{-6}$, in which case the problem is stiff on all grids we consider, and the nonstiff case $\tau_0 = 0.1$. In Figure 1 the ZND structure is shown for the nonstiff case, and these values are also used as initial data. The temperature is increased by the shock. The wave propagates to the right into unburnt gas and the temperature directly behind the fluid dynamical shock is called the *von Neumann temperature*, T_{vN}. The ignition temperature has to be higher than T_u, i.e., higher than the temperature of the unburnt gas, and lower or equal to T_{vN}. In our example the von Neumann temperature is $T_{vN} = 0.545918$ and the temperature of the unburnt gas is $T_u = 0.21598$. Note that the same initial value problem was considered in LeVeque [20] where some preliminary results with this approach were presented.

Now we set $\tau_0 = 10^{-6}$ and $T_{ign} = 0.22$, i.e., the problem is stiff and the temperature is only slightly higher than the temperature of the unburnt gas. In this case the fractional step scheme produces a nonphysical solution, a discontinuity which is propagating with a speed of one mesh cell per time step as mentioned in the introduction; see Figure 2.

This phenomenon has been studied by several authors, see, for instance, [8], [9], [11], [13], and it is well understood that it is caused by the numerical diffusion of the conservation law solver feeding into the fractional step method. For understanding this purely numerical problem we consider one time step using the fractional step method to approximate a detonation wave in a very stiff case, i.e., the reaction zone is much smaller than the width of one mesh cell. For this stiff case the Riemann problem, consisting of totally unburnt gas at the right-hand side and totally burnt gas at the left-hand side, would be a reasonable approximation of the ZND structure. Now we apply one time step of the Godunov scheme to this Riemann problem. The solution structure of the Riemann problem considered is indicated in Figure 3.

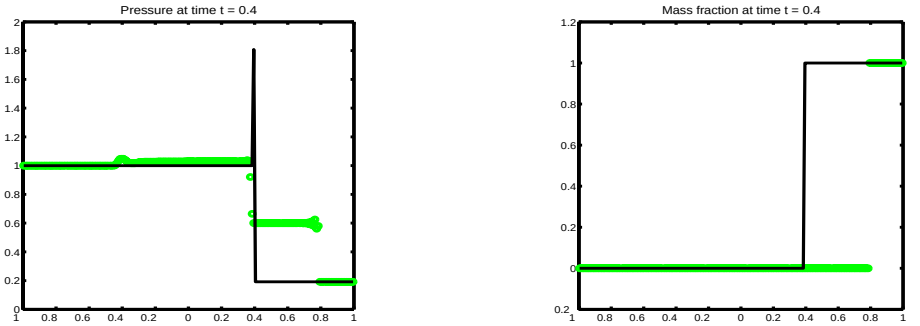

FIG. 2. *Exact* (− − −) *and numerical* (ooo) *solution using the classical fractional step method, with high-resolution Godunov scheme. Parameter values:* $\tau_0 = 10^{-6}$, $T_{ign} = 0.22$, $\triangle x = 0.01$, *and* $\triangle t = 0.005$, *giving a Courant number between* 0.5 *and* 1.

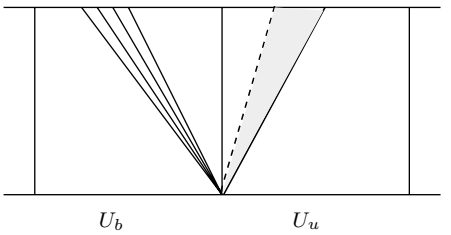

FIG. 3. *Structure of the Riemann solution for the reactive Euler equations. From left to right:* 1*-rarefaction wave,* 2*-contact discontinuity,* 3*-shock; left state: completely burnt gas, right state: unburnt gas.*

The rightmost wave (3-wave) is a shock moving into the unburnt gas. The 2-wave denoted by a dashed line is the contact discontinuity separating burnt gas to the left from initially unburnt gas to the right. However, the shock increases the temperature of the unburnt gas in the region between the 3-wave and 2-wave (the shaded region in Figure 3). The temperature is now greater than T_{ign} and this gas will burn. In the stiff case it burns completely during this time step.

The incorrect propagation speed in the fractional step method arises from the fact that the structure shown in Figure 3 is first averaged over the grid cells to create new piecewise constant states before the reaction terms are applied. As a result the entire grid cell to the right in Figure 3 obtains a single averaged temperature. If this is greater then T_{ign} then *all* the unburnt gas in this cell burns during the reaction step, including the gas to the right of the 3-wave. This causes the interface between burnt and unburnt gas to advance by one full grid cell. See [23] for more details. The closer T_{ign} is to T_u the more likely this is to happen. If T_{ign} is considerably larger than T_u, then in some steps the full cell will burn and in other steps nothing will burn, and the average speed could still come out close to correct. Furthermore, if the ignition temperature is high enough then an unphysical intermediate state (for instance in pressure) lower than the value of the completely burnt state can not be obtained. This has been investigated by Berkenbosch [7]; see also [8].

2.3. Modification of the fractional step method. We have seen that the nonphysical solutions are a consequence of smearing the reaction zone before burning. Using this observation we construct a modification of the fractional step scheme which

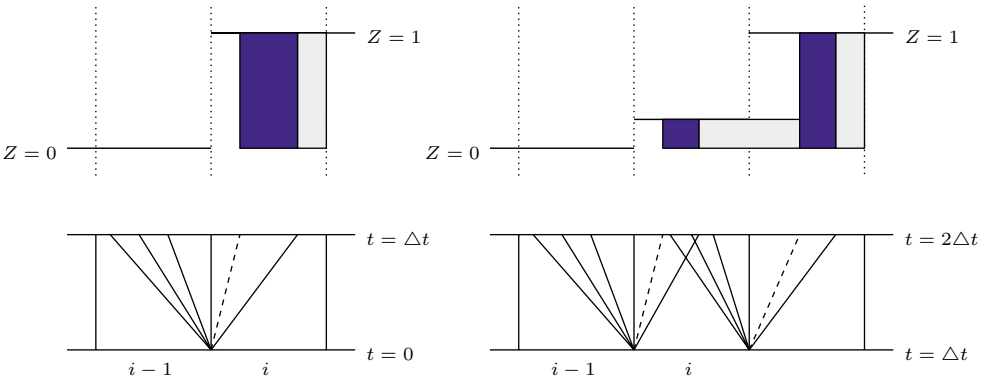

FIG. 4. *Modification of the scheme along the smeared-out reaction front in the stiff case. Left: first time step; right: second time step.*

eliminates those combustion processes which are purely a consequence of the smearing effects. First we consider the stiff case, in which the exact reaction zone is smaller than one mesh cell and the reactions take place very fast.

Again considering the situation which is shown in Figure 3, we should allow a reaction only between the shock and the contact discontinuity in the first time step, because only there do sufficiently high temperature and unburnt gas coexist. The essential idea of our approach is to apply the ODE solver only in the region where burning should occur. In the first time step this is easy, but after one time step we do expect some smearing of the correct shock location and hence a nonphysical "average" temperature in at least one grid cell. Now we want to interpret the cell average in a different way. As shown in Figure 4 the piecewise constant initial values for the second time step contain one mesh cell i, where the mass fraction of unburnt gas Z has a value with $0 < Z < 1$. The average of the temperature in cell i might be higher than the ignition temperature, but more correctly the burnt gas in cell i has a temperature higher than T_{ign} and the unburnt gas has a temperature lower than T_{ign}.

In the stiff case the reaction takes place very fast and during one time step the whole portion of the gas which was heated up by the shock has already burnt. Therefore we interpret the gas flow described by the homogeneous conservation law in the second time step as a transport of the unburnt gas. A reaction can only take place if this unburnt gas is ignited by a shock. This modification is described in Figure 4. The shaded areas indicate the mass fraction of unburnt gas after the transport by the homogeneous conservation law. Only in the dark shaded area a reaction is initiated. We make use of the fact that a rarefaction wave, such as the one generated between cells i and $i + 1$, cannot increase the temperature of the unburnt gas. In consequence there is no reaction to the right of the 3-shock in cell i even though the *average* value of the temperature might be higher than T_{ign}. The solution structure could also consist of a 1-shock and a 3-shock. In this case we allow a reaction between these two waves.

The temperature as well as the pressure can only be increased by a shock. We observe that along the smeared-out reaction front the Riemann problems occurring in each time step for solving the homogeneous conservation law have a 3-shock if the combustion front moves from left to right.

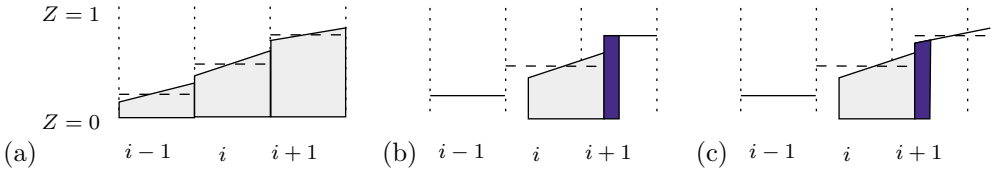

FIG. 5. *Description of the modification using the high-resolution wave propagation algorithm.*

On the other hand, a mesh cell may also lie within the reaction zone. If the temperature in a mesh cell is higher than the ignition temperature and there is still unburnt gas but no shock wave is coming into this mesh cell that will further increase the temperature there, then this cell belongs to the (smeared-out) reaction zone. In this case we allow the burning process in the whole mesh cell; i.e., we use the classical fractional step method.

For our example of a CJ detonation wave moving from the left- to the right-hand side, we can easily determine whether a mesh cell belongs to the smeared-out shock or to the reaction zone and, hence, whether the burning process in the stiff case should take place between shock and contact discontinuity, or in the whole mesh cell by only considering the 3-wave. If the 3-wave is a shock, then we allow the burning process only between the shock and contact discontinuity, and if the 3-wave is a rarefaction wave, then we allow the burning process in the whole mesh cell.

By using a second order finite volume scheme, sharper results can be obtained in which discontinuities are smeared-out over fewer mesh cells than when using first order schemes. Nevertheless, in combination with a fractional step scheme, the same numerical problems occur for both first and second order approximations of the conservation laws if the source term is not treated carefully. Note that the numerical results which are shown in Figure 2 were calculated with a high-resolution Godunov scheme to approximate the convective part. The same nonphysical solution would be obtained using the first order Godunov scheme. For our improved numerical calculations we have combined the high-resolution wave propagation algorithm from CLAWPACK, which is described in LeVeque [21], with the modification of the fractional step scheme described above.

The high-resolution method is based on using piecewise linear reconstruction in place of piecewise constant functions. Slopes are chosen based on nearby solution values, and limiters are applied to avoid spurious oscillations. For all calculations shown in this paper we used the monotonized-centered limiter, proposed by van Leer [29] and given explicitly in [21] in the context of CLAWPACK. Other standard limiters, e.g., minmod or superbee, which are also available in CLAWPACK were also tested and gave comparable results. Figure 5(a) shows the piecewise linear reconstruction of Z in three grid cells. From the structure of the Riemann problem we know that discontinuities in Z are propagated at the speed of the contact discontinuity. In the high-resolution method each piecewise linear structure is propagated at the local fluid speed and then averaged onto the grid; see [21]. With combustion, we again wish to apply burning only to the unburnt gas lying between a shock and contact where the temperature has been raised above the ignition temperature. This is illustrated in Figure 5(b) and (c) for the case where such a shock arises from the Riemann problem between cells i and $i+1$ and moves into cell $i+1$ at a speed greater than the contact speed. Hence, it is the unburnt gas initially in cell $i+1$ which now burns, as indicated by the dark shaded region in each figure. In Figure 5(b) we simply use the cell average

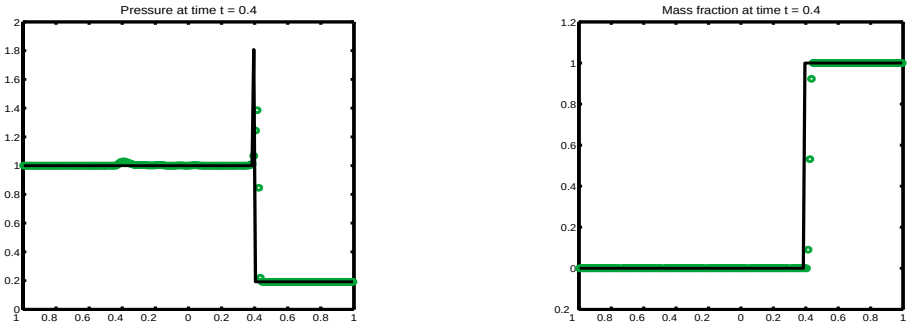

FIG. 6. *Exact and numerical solution using the modification, with high-resolution Godunov scheme. Parameter values:* $\tau_0 = 10^{-6}$ *and* $T_{ign} = 0.22$, $\triangle x = 0.01$, $\triangle t = 0.005$ *giving a Courant number between* 0.5 *and* 1.

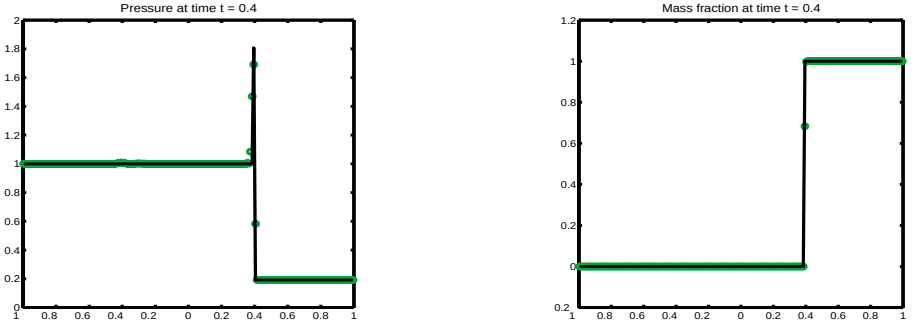

FIG. 7. *Exact and numerical solution using the modification, with high-resolution Godunov scheme. Parameter values:* $\tau_0 = 10^{-6}$ *and* $T_{ign} = 0.54$, $\triangle x = 0.01$, $\triangle t = 0.005$ *giving a Courant number between* 0.5 *and* 1.

Z_{i+1} to determine how much gas burns. This is easier to implement than the more accurate procedure indicated in Figure 5(c), where the piecewise linear structure in cell $i + 1$ is used to determine the amount that burns. Both have been tested in one dimension but we have found very little difference in the observed accuracy. Consequently, we have used the simpler approach of Figure 5(b) in the 2D extension presented below.

Figure 6 shows the numerical solution of the stiff problem with low ignition temperature using the modification which was described above. One should compare with Figure 2 where the same problem was solved by using the classical fractional step method. In Figure 7 the stiff problem was solved with our modification for a case with a higher ignition temperature, near the von Neumann temperature, in order to show that we get a good approximation of the detonation wave for all possible ignition temperatures.

In the nonstiff case the fractional step method gives a good approximation of the detonation wave, since for this case the two time scales fit together; see LeVeque [20] for a numerical calculation. This is consistent with our modification of the stiff case in the following sense. In the nonstiff case most of the mesh cells with $0 < Z < 1$ belong to the reaction zone and therefore a reaction should take

TABLE 1

Numerical propagation speed, calculated taking (2.11)*, using the classical fractional step method* ($S_{fs,1}$ *or* $S_{fs,2}$) *and the modified method* ($S_{mod,1}$ *or* $S_{mod,2}$) *with first-order and high-resolution versions of the Godunov scheme for different ignition temperatures* (T_{ign}) *and different time scales* τ_0*. The numerical propagation speed is given for the time* $t = 0.4$*. For all calculations we used the mesh width* $\triangle x = 0.01$ *and a time step* $\triangle t = 0.005$ *giving a Courant number between* 0.5 *and* 1*.*

	10^{-6}	0.40	1.078079	1.043682	1.102789	1.052685
	10^{-6}	0.54	1.025647	1.004062	1.056581	1.007961

place in the whole mesh cell. Now, in contrast to the stiff case, the gas that was heated by the shock did not entirely burn in one time step. Note that this was our main motivation for the modification along the smeared-out reaction front in the stiff case. Therefore, in the nonstiff case we do not restrict a reaction to the region between the shock and contact discontinuity only. Only in the mesh cell where the totally unburnt gas is first heated up by a shock do we need to make an exception. There the reaction should be restricted to the area behind the shock because only there we have a sufficiently high temperature. The numerical results which where obtained with this modification are very similar to those obtained by the classical fractional step method, which is already adequate for the nonstiff case, as seen in Table 1. Note that the approximation of the nonstiff case is also consistent with the transition between the stiff and the nonstiff method which is described below.

Table 1 contains different values for the numerical propagation speed $S^{n\triangle t}$ of the mass fraction of unburnt gas calculated by the formula

$$S^{n\triangle t} = \frac{\triangle x}{n\triangle t} \cdot \sum_{i=-\infty}^{\infty} (Z_i^0 - Z_i^n). \tag{2.11}$$

$S^{n\triangle t}$ is the averaged numerical propagation speed of the detonation wave at time $n\triangle t$, which was calculated via an approximation of the equal area rule; see Berkenbosch [7]. Both a nonstiff and a stiff case are considered with different values of T_{ign}. The correct value of the propagation speed is equal to one in all cases. The index of S in Table 1 further specifies the numerical scheme which was used for the calculation as well as the order. All values of the numerical propagation speed are given for the time $n\triangle t = 0.4$, which corresponds to the time step of the numerical approximations shown in Figure 2 as well as Figures 6 and 7.

Table 1 shows that the classical fractional step scheme gives a good approximation of the stiff problem if the ignition temperature T_{ign} is high enough. This was studied by Berkenbosch in [7] and Berkenbosch, Kaasschieter, and Klein in [8]. With the modified fractional step scheme we always get a more accurate approximation of the shock speed and maintain reasonable accuracy even in the stiff case.

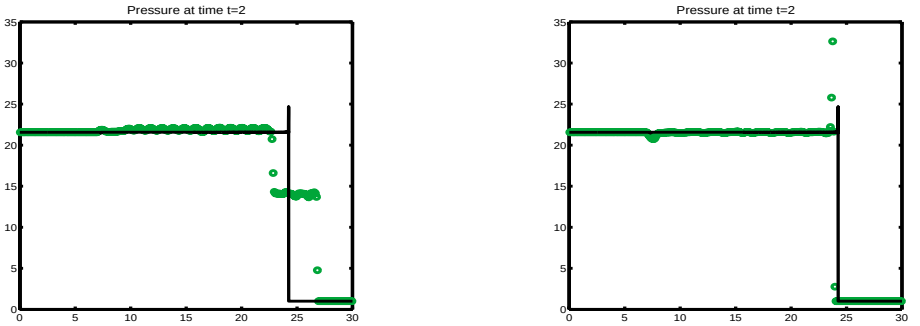

FIG. 8. *Resolved* (− − −) *and underresolved* (ooo) *approximation of the pressure for Example 2. For the resolved calculation we used the mesh width* $\triangle x = 0.0025$*, and for the underresolved calculation we used* $\triangle x = 0.1$*. The classical fractional step scheme gives an unphysical solution (left); the modified fractional step scheme gives an accurate approximation (right).*

In our next example we apply our modified fractional step scheme to the approximation of a stiff detonation wave for which the reaction is modeled by the Arrhenius law (2.1).

Example 2. We consider the reactive Euler equations with the reaction rate law (2.1). The unburnt state is given by $\rho_u = 1$, $u_u = 0$, $p_u = 1$. For the heat release, we used the value $q_0 = 25$ and the activation energy is set to $E^+ = 25$. Furthermore, the ratio of specific heats is set to $\gamma = 1.4$. The unburnt state is connected to the burnt state by a CJ detonation wave. The physical quantities of the completely burnt state are $\rho_b = 1.6812$, $u_b = 2.8867$, $p_b = 21.5672$. The CJ detonation wave has the speed $s_{CJ} = 7.1247$. Initially the discontinuity is located at the point $x = 10$. We use the rate constant $K_0 = 164180$.

Figure 8 shows numerical results of the pressure for underresolved calculations of the detonation wave described in Example 2. The solid line is the reference solution which was calculated on a very fine mesh. Our modified fractional step scheme, which can be applied in the same way as described for the ignition temperature kinetics model, approximates the correct propagation speed of the detonation wave, whereas the usual fractional step scheme again leads to an unphysical weak detonation wave followed by a nonreactive shock.

In order to approximate the transition between the stiff and the nonstiff case on those mesh cells which approximate the smeared-out leading shock of a detonation wave in an appropriate way, we limit the amount of the mass fraction of unburnt gas, which is converted to burnt gas during one time step, from above by $(\triangle Z_i)_{max} = \text{area } Z_i$, where Z_i is the cell average of the mass fraction of unburnt gas and area specifies the part of the mesh cell, where the source term should be applied in a stiff calculation. In the 1D case this part of the mesh cell is given by $\text{area} = \frac{(s-c)\triangle t}{\triangle x}$, where s is the speed of the shock and c is the propagation speed of the contact discontinuity. This implies that along the smeared-out leading shock of a detonation wave, *at most* the whole mass fraction of unburnt gas between shock and contact discontinuity would completely burn. In the nonstiff case the reduction of the mass fraction of unburnt gas due to the ODE for the source term equation applied to the whole cell average will in general be less than $(\triangle Z_i)_{max}$, and our modified fractional step scheme automatically switches to the classical fractional step scheme along the smeared-out leading shock of a detonation wave. The same criteria can be applied to calcula-

tions which use the Arrhenius law (2.1). However, for this reaction rate equation the reaction rate and also the length of the reaction zone depends on the temperature. Therefore, especially in multidimensional examples, the problem can include stiff and nonstiff regions depending on the temperature. We will consider such a problem in section 3.

3. The 2D combustion problem. Now we consider the modification of the scheme for 2D reactive Euler equations, i.e., for the system of equations

$$\rho_t + (\rho u)_x + (\rho v)_y = 0, \tag{3.1}$$

$$(\rho u)_t + \left(\rho u^2 + p\right)_x + (\rho uv)_y = 0, \tag{3.2}$$

$$(\rho v)_t + (\rho uv)_x + \left(\rho v^2 + p\right)_y = 0, \tag{3.3}$$

$$E_t + (u(E+p))_x + (v(E+p))_y = 0, \tag{3.4}$$

$$(\rho Z)_t + (\rho uZ)_x + (\rho vZ)_y = -\rho K(T)Z. \tag{3.5}$$

Here u is the velocity of the gas in x-direction and v is the y-component of the velocity. The equation of state is in the 2D case

$$E = \frac{p}{\gamma - 1} + \frac{1}{2}\rho(u^2 + v^2) + q_0\rho Z.$$

Again we want to use a fractional step scheme for approximating the solution. As in the 1D case we have to apply a modification in order to avoid both nonphysical propagation speeds of the combustion front and wrong intermediate states. For the solution of the homogeneous conservation law we used the high-resolution version of the Godunov scheme implemented in CLAWPACK [18]. The method is based on solving 1D Riemann problems at each cell boundary as well as taking transverse directions into consideration. The part of the flux across a cell boundary which is propagated in the transverse direction is calculated via the tangential Riemann problem based on a Roe linearization; see LeVeque [21]. This improves the stability and accuracy of the scheme.

3.1. Modification of the 2D fractional step method. As we have already mentioned, the 2D version of the Godunov scheme is based on solving 1D Riemann problems in the x- as well as in the y-direction. Therefore, we can use the same modification as in the 1D case; i.e., in the stiff case along the reaction front a reaction will only be possible between the shock and contact discontinuity. This modification is indicated in Figure 9, where we assume the case of a 3-shock.

Now we also want to consider the influence of the transverse propagation. This means that parts of the shaded areas in Figure 9 are propagated into other mesh cells. Here we only want to consider the propagation in the y-direction of the reaction area calculated by a Riemann problem in x-direction. From the transverse Riemann solver we can get a decomposition of each wave into a linear combination of eigenvectors of the Jacobian matrix of the flux functions in the tangential direction. These subwaves are moving upwards or downwards with the speeds μ^i corresponding to the eigenvalues of the Jacobian matrix of the form $\mu^1 = v - c$, $\mu^2 = v$, $\mu^3 = v + c$; see [21].

The most accurate possibility for calculating the transverse propagation of the area where a reaction is supposed to take place would require calculating the temperature for all the subwaves corresponding to the area behind a shock along the reaction zone. If the temperature is higher than the ignition temperature, then the

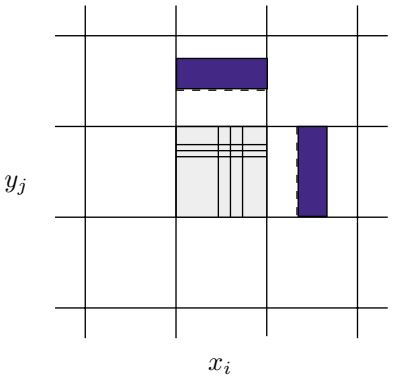

FIG. 9. *Structure of the modification of the normal Riemann problem in x direction between the states $q(x_i, y_j)$ and $q(x_{i+1}, y_j)$ as well as for the Riemann problem in y direction between the states $q(x_i, y_j)$ and $q(x_i, y_{j+1})$ used in the stiff case.*

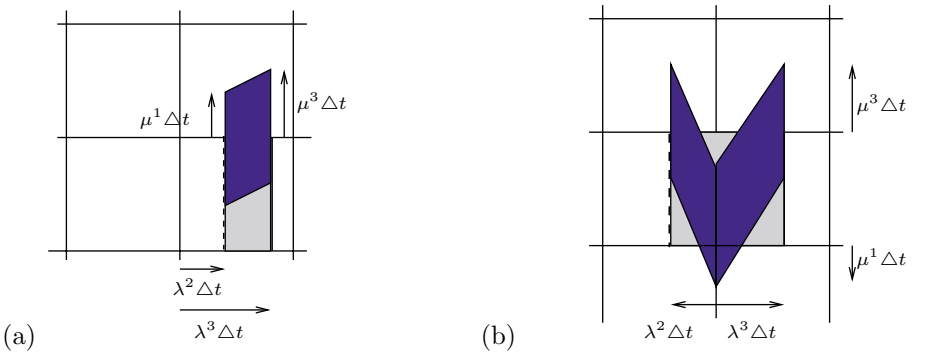

FIG. 10. *Two different possibilities for the transverse modification. The dark shaded regions are the cell portions where a reaction takes place for a Riemann problem in the x-direction with transverse modification.*

area between the shock and contact discontinuity should be propagated in the transverse direction. Such a modification would be quite expensive. For the transverse propagation, it is also not necessary to decouple every wave separately. Instead of decoupling each wave, only the left- and right-going flux differences have to be considered. Therefore, we have used the simplified transverse propagation of cell areas where a reaction takes place as indicated in Figure 10 which only uses the transverse speeds μ^1 and μ^3. If both of these eigenvalues have the same sign, then the area which is propagated in the y direction is equal to the trapezoid with a height equal to the distance between shock and contact discontinuity and the sides $|\mu^1 \triangle t|$ and $|\mu^3 \triangle t|$. This is shown in Figure 10(a) for the case where all eigenvalues are positive. In the case where $\mu^1 < 0$ and $\mu^3 > 0$, we would have a triangular portion corresponding to μ^1, which is moving into the cell below, and another triangular portion moving into the cell above, which corresponds to the eigenvalue μ^3. Figure 10(b) shows yet another possibility: the transverse propagation of the reaction area consisting of a left-going contact discontinuity and a right-going 3-shock assuming also that the eigenvalues μ^1 and μ^3 have different signs.

3.2. Approximation of a radialsymmetric CJ detonation wave. We restrict our considerations to the stiff case where the fractional step scheme may have numerical problems. First we want to note that also in the 2D case the usual fractional step scheme without modification leads to a good approximation if the ignition temperature is high enough. This was observed by Berkenbosch, Kaasschieter, and Klein [8] for 1D and 2D combustion waves.

Example 3. For our numerical computations we consider a radially symmetric CJ detonation wave. The initial values consist of totally burnt gas inside of a circle with radius 0.3 and totally unburnt gas everywhere outside of this circle. Furthermore, the unburnt and burnt states are chosen in a way analogous to the 1D case, i.e., $\rho_b = 1.4$, $\rho_u = 0.887565$, $p_b = 1$, $p_u = 0.191709$, $Z_b = 0$, $Z_u = 1$, $u_b = 0$, $u_u = -0.577350\cos\alpha$, $v_b = 0$, $v_u = -0.577350\sin\alpha$, where α is the angle in polar coordinates. The ignition temperature is set to $T_{ign} = 0.26$.

For this radially symmetric problem it is possible to get more insight into the structure of the solution by comparing the solution calculated with a 2D algorithm and the numerical solution of the 1D system of reactive Euler equations with an additional source term for the radial symmetry. The 1D reactive Euler equations for a radially symmetric problem are

$$\rho_t + (\rho\hat{u})_r = -\frac{1}{r}\rho\hat{u},$$

$$(\rho\hat{u})_t + (\rho\hat{u}^2 + p)_r = -\frac{1}{r}\rho\hat{u}^2,$$

$$E_t + (\hat{u}(E+p))_r = -\frac{1}{r}\hat{u}(E+p),$$

$$Z_t + \hat{u}Z_r = -K(T)Z,$$

where $\hat{u} = u\cos(\alpha) + v\sin(\alpha)$ is the speed in radial direction and $r = \sqrt{x^2 + y^2}$ is the distance from the center. Now we can use the 1D fractional step scheme with the modification for the stiff source term to get an approximation along any radial slice of the 2D combustion wave. The 1D system is solved on a very fine grid ($\triangle x = 0.00025$) so that the numerical solution is assumed to be an accurate approximation of the exact solution. The numerical solutions of the 1D reference problem are plotted as solid lines in Figures 14–16. The scatter plots of the 2D solutions are obtained by plotting the value on each mesh cell as a function of r, i.e. the distance to the center of symmetry.

In the 2D case we have the additional effect that also the gas flow ahead of the combustion front increases the temperature slightly. For simplicity, we are not interested in this effect for the moment. Therefore, we have to choose the ignition temperature higher than the temperature occurring just ahead of the combustion front during the time interval considered.

Figures 11 and 12 as well as the scatter plots Figures 14 and 15 show the numerical calculations at different time steps obtained using the modified fractional step scheme. Here the combustion front moves with the correct speed and, furthermore, the circular geometry is resolved well on the grid.

For contrast, in Figure 13 contour plots of the pressure and mass fraction of unburnt gas are shown, calculated by using the classical fractional step scheme at the

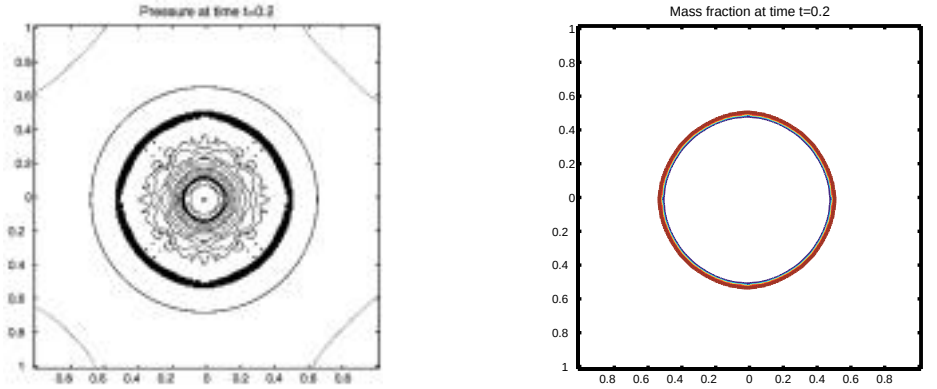

FIG. 11. *Contour plot of pressure and mass fraction of unburnt gas at time* $t = 0.2$ *using the modification with high-resolution Godunov scheme,* $T_{ign} = 0.26$, $\tau_0 = 10^{-6}$, $\triangle x = \triangle y = 0.01$, $CFL \leq 0.75$.

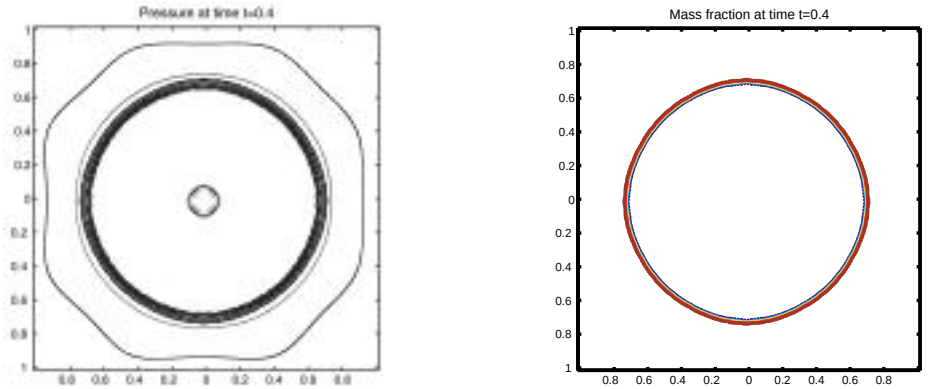

FIG. 12. *Contour plot of pressure and mass fraction of unburnt gas at time* $t = 0.4$ *using the modification with high-resolution Godunov scheme,* $T_{ign} = 0.26$, $\tau_0 = 10^{-6}$, $\triangle x = \triangle y = 0.01$, $CFL \leq 0.75$.

later time. The scatter plots in Figure 16 show that the combustion front moves too fast and there is an unphysical intermediate state for the pressure. Moreover, the front does not remain circular.

Finally, Table 2 shows some numerical order of convergence results. For the numerical approximation of this discontinuous solution the expected order of convergence is between 0.5 and 1; see [19]. With our modified fractional step scheme we could achieve such a convergence order without resolving the reaction zone. Although our numerical solution shows the typical von Neumann peak behind the shock front, we get a relatively large error in the region which approximates the very small reaction zone. This might be a reason why the experimental order of convergence for the variables which contain a peak is lower than the order of convergence for the mass fraction of unburnt gas, which in the stiff case only contains a discontinuity.

The transition between the stiff and the nonstiff case is done in a manner analogous to what was described for the 1D case in section 2.3. Now the maximal rate of reduction (area) of the mass fraction of unburnt gas in those mesh cells which approximate the leading shock wave of the detonation is calculated using all normal and transverse Riemann problems which have an influence on the mesh cell.

3.3. Approximation of a diffracting detonation wave. As a final example, we consider a more interesting and challenging 2D problem, a CJ detonation wave

which is diffracting around a 90 degree corner. We use the reactive Euler equations with the Arrhenius reaction rate law (2.1). For this example the temperature behind the leading shock wave will vary, which causes a change of the reaction rate. We can therefore test our stiff solver as well as the transition between the stiff and the nonstiff approach. Resolved calculations for a similar problem were considered by Xu, Aslam, and Stewart [30] and Aslam and Stewart [1]. The solution of this problem depends strongly on the activation energy and the reaction rate constant. In order to decrease the reaction zone length and make the problem more stiff, we used a larger reaction rate constant than in [30]. We also increased the activation energy in order to obtain the solution structure for our more stiff problem.

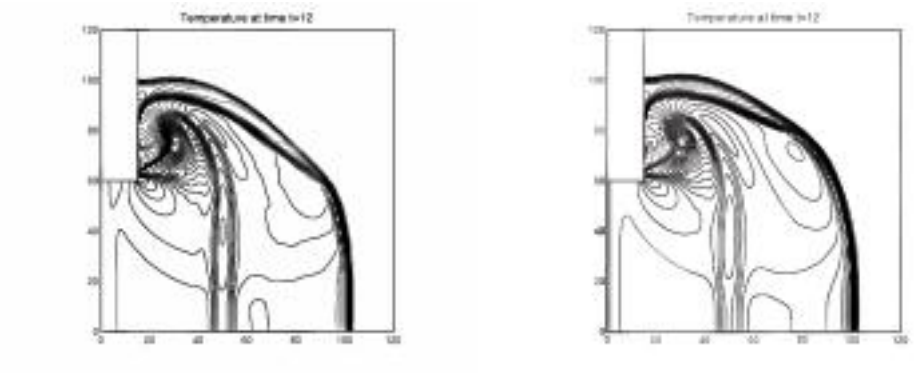
The computational domain is $[0, 120] \times [0, 120]$. There is a solid wall in the upper-left corner of the domain for $x \leq 15$ and $y \geq 60$. Initially unburnt gas is in the region $x > 14$. This unburnt state is given by $\rho_u = 1$, $u_u = 0$, $v_u = 0$, and $p_u = 1$. The ratio of specific heat is $\gamma = 1.4$, the heat release is $q_0 = 25$, the activation energy is $E^+ = 35$, and the reaction rate constant is given as $K_0 = 120$. The unburnt state is again connected by a CJ detonation wave to the burnt state, the half-reaction zone length of this CJ detonation wave is about 0.5.

First we consider a resolved approximation using the adaptive mesh refinement algorithm of AMRCLAW [5], [6]. On the finest discretization level, which is used along the leading shock of the detonation wave, the half-reaction zone length is resolved by 16 mesh points. A 3840×3840 grid would be required to achieve this same resolution on a uniform grid. Contour plots of the temperature as well as of the mass fraction of unburnt gas are given in Figure 17.

As the detonation wave moves around the corner, the leading shock weakens, which decreases the temperature behind the shock. When the shock becomes weak enough, it will no longer raise the temperature above the ignition point. Then we get a nonreactive shock traveling vertically followed by a region in which the temperature is high relative to the initial unburnt state but the reaction rate is still negligible. Some distance behind this shock the gas burns via a deflagration wave. This region can be seen in the plot of the temperature; see Figure 17(a).

The shock which is traveling in the horizontal direction is still strong enough to ignite a reaction and remains a CJ detonation wave with the constant speed $s_{CJ} = 7.1247$. At some point along the curved shock front there is a transition between the detonation wave traveling horizontally and the shock-deflagration structure traveling vertically. Our goal in this set of experiments is to demonstrate that on underresolved grids the modified method approximates the correct structure better than the classical fractional step method.

Figures 18–20 show underresolved calculations of this problem. When the shock becomes weaker and the temperature behind the shock becomes lower, the reaction rate behind the shock decreases. In the mesh cells which approximate the leading shock front we will therefore also switch from the stiff to the nonstiff solver. Our modified fractional step scheme, used for the plots on the left-hand side, gives a more accurate approximation of the transition of the solution structure from a detonation wave to a nonreactive shock followed by a deflagration wave. The modified approach on the 120×120 grid (Figure 18(a)) gives a representation of this structure that is at least as good as what is seen with the classical method on the 240×240 grid (Figure 19(b)). The modified scheme on the 240×240 grid gives comparable results as the fractional step scheme on the 480×480 grid (compare Figure 19(a)



(a) (b)

and Figure 20(b)). Finally the modified scheme on the 480×480 grid produces a very accurate approximation as can be seen by comparing Figure 20(a) with the resolved calculation in Figure 17(a).

For lower or higher values of the activation energy, the point at which the shock structure changes from a reactive to a nonreactive shock moves. If the activation energy is low enough then the shock which is diffracting around the corner may remain strong enough to ignite a reaction and remain a detonation wave everywhere. The reaction rate constant also has an influence on the solution structure. For a larger rate constant the reaction behind the curved shock becomes stronger and the length of the reaction zone becomes smaller. Additional experiments with our method (not shown here) have confirmed that it is robust and yields the correct structure on underresolved grids also in other cases.

4. Conclusions. If stiff source terms are not treated carefully, then the numerical method can produce unphysical solutions even if the scheme is stable. We have considered these numerical difficulties for a combustion problem. If one is not interested in a calculation of the physical processes inside the very small reaction zone but instead wants to determine more global features, e.g., the propagation speed of a detonation wave, then it would be preferable to use a scheme which does not have to resolve the very stiff source term. Here we have shown how the classical fractional step scheme can be modified to give an accurate approximation for the model combustion problem. In section 2 we gave a heuristic motivation of a modification of the fractional step method which was described in that section and extended to 2D problems in section 3.

Our modified fractional step scheme needs information about the structure of the Riemann solution in order to determine the mesh cells over which the leading shock of a detonation wave is smeared. Furthermore, the distance between the shock and contact discontinuity in these mesh cells is required. This information will automatically be provided by an exact Riemann solver as we have described. The distance between the shock and contact discontinuity determines the part of a mesh cell where the source term will be applied in a stiff calculation. For 2D calculations this area depends on all Riemann problems which have an influence to the mesh cell, including the Riemann problems which are solved in order to obtain the fluxes in the transverse direction. However, this further information can be obtained with less effort than the calculation of the change of the cell average due to the solution of the homogeneous problem. Moreover, the modified treatment of the source term is only necessary in those mesh cells which approximate the smeared-out leading shock, e.g., in about three mesh cells for the calculation of the 1D example. Therefore, our modification requires only slightly more effort than the classical fractional step scheme and permits the use of much coarser underresolved grids.

AN EFFICIENT LINEAR SOLVER FOR NONLINEAR PARAMETER IDENTIFICATION PROBLEMS*

YEE LO KEUNG† AND JUN ZOU‡

Abstract. In this paper, we study some efficient numerical methods for parameter identifications in elliptic systems. The proposed numerical methods are conducted iteratively and each iteration involves only solving positive definite linear algebraic systems, although the original inverse problems are ill-posed and highly nonlinear. The positive definite systems can be naturally preconditioned with their corresponding block diagonal matrices. Numerical experiments are presented to illustrate the efficiency of the proposed algorithms.

Key words. parameter identifications, elliptic problems, positive definite

1. Introduction.

The purpose of this paper is to investigate some numerical methods for efficiently identifying the unknown coefficient q in the following elliptic problem:

$$-\nabla \cdot (q\nabla u) = f \quad \text{in} \quad \Omega; \quad u = 0 \quad \text{on} \quad \Gamma. \tag{1.1}$$

The identifying process is carried out in a way that the solution u matches its observation data z optimally either in the L^2-norm or in the H^1-norm. Here Ω can be any bounded domain in R^d, $d = 1, 2$, or 3, with piecewise smooth boundary Γ and $f \in H^{-1}(\Omega)$ is given. Practically, we are often asked to recover the parameter $q(x)$ using the observed data z of the solution u. About the data z we are interested in the following two cases:

(a) the measurement of the gradient of u is available,

(b) the measurement of the solution u itself is available.

For parameter identifications, Itô and Kunisch proposed a hybrid method in [11, 12, 13] which combines the output least squares and the equation error formulation within the mathematical framework given by the augmented Lagrangian technique and incorporates a regularization term of the H^2-seminorm of the parameters to be recovered. Chen and Zou [5] and Keung and Zou [14] generalized the method to the case which allows the identifying coefficients to be discontinuous by using the regularization of bounded variations and they provided the rigorous theoretical justifications of the method and its finite element approximation. Independently, Chan and Tai [3, 4, 18] considered also the regularization of bounded variations and did numerous experiments on the performance of the augmented Lagrangian method for identifying highly discontinuous parameters.

The primary approach we are interested in here is based on the following energy-

norm least squares formulation of the aforementioned parameter identifying problem:

$$\text{(P1)} \quad \begin{cases} \text{minimize} & J(q,v) = \frac{1}{2}\int_\Omega q\,|\nabla v - \nabla z|^2 dx + \beta\, N(q) \\ \text{subject to} & (q,v) \in K \times V \quad \text{and} \quad e(q,v) = 0 \end{cases}$$

in case (a) or on the following L^2-norm least squares formulation:

$$\text{(P2)} \quad \begin{cases} \text{minimize} & J(q,v) = \frac{1}{2}\int_\Omega |v - z|^2 dx + \beta\, N(q) \\ \text{subject to} & (q,v) \in K \times V \quad \text{and} \quad e(q,v) = 0 \end{cases}$$

in case (b). Here $V = H_0^1(\Omega)$ and K is a constrained set given by

$$K = \big\{ q \in L^1(\Omega); \quad N(q) < \infty \ \text{ and } \ \alpha_1 \le q(x) \le \alpha_2 \quad \text{almost everywhere (a.e.) in } \Omega \big\}$$

with α_1 and α_2 being two positive constants. $N(q)$ is a regularization term with a weighted coefficient $\beta > 0$. $e(\cdot,\cdot)$ is an operator from $K \times V$ into V defined by the residual equation of (1.1) (in the weak sense):

$$(\nabla e(q,v), \nabla\phi) = (q\nabla v, \nabla\phi) - (f,\phi) \quad \forall\,(q,v) \in K \times V, \quad \phi \in V, \tag{1.2}$$

where $(\cdot,\cdot)$ denotes the duality pairing between $H^{-1}(\Omega)$ and $H_0^1(\Omega)$, which is the extension of the inner product in $L^2(\Omega)$. It is useful to remark that $e(q,v)$ is convex with respect to each variable.

The intention of this paper is to investigate some efficient and easy-to-implement method for the preceding parameter identifications. We know that the regularization of bounded variations, i.e., $N(q) = |q|_{BV(\Omega)}$, is very effective in recovering discontinuous parameters, but it also adds a big difficulty to the numerical resolution process. Namely, one has to solve a nearly singular and indefinite nonlinear minimization system of the form

$$-\beta\nabla \cdot \frac{\nabla q}{\sqrt{|\nabla q|^2 + \varepsilon}} + c(q) = g$$

at each iteration, where ε is the smoothing parameter introduced to smooth the BV-norm term in numerical implementations and $c(q)$ is a linear function of q, which causes the indefiniteness of the system; see [3, 4, 5, 14, 18]. It seems there are very few iterative methods which are known to be globally convergent for solving such a troublesome system. We refer to Chan and Mulet [2], Dobson and Vogel [8], and the references therein for some fixed point methods and their global convergence results when $c(q)$ is not too complicated.

In this paper, instead of the BV-norm regularization we are going to utilize the H^1- or piecewise H^1-norm regularization. We will see that the H^1-norm regularization performs perfectly for identifying smooth coefficients as expected. In fact, our experience indicates that it can also give rise to satisfactory results in most discontinuous coefficient cases. But in the cases where the location of the discontinuities of the identifying coefficients is available, we can achieve much more accurate recoveries even for the coefficients with high discontinuities by using the piecewise H^1-norm regularization. The location of the discontinuities of parameters may be known in some applications or can be identified first by some existing simple algorithms. As we will show later on, with the H^1- or piecewise H^1-norm regularization, each iteration of our algorithms involves only solving linear positive definite algebraic systems, which can be solved by the well-known GMRES iteration with guaranteed convergence [9]. Moreover, the positive definite systems may be preconditioned by their

natural block diagonal matrices, which are very cheap and easy to implement. The numerical experiments will also show that these preconditioners are effective.

The problems (P1) and (P2) will be solved by the augmented Lagrangian method which enables us to relax the residual constraint $e(q,u)=0$ and enhance the convexity of the objective functional. For the purpose we introduce the augmented Lagrangian functional $\mathcal{L}_r : K \times V \times V \to R$ by

$$\mathcal{L}_r(q,v;\mu) = J(q,v) + (\nabla\mu, \nabla e(q,v)) + \frac{r}{2}\|\nabla e(q,v)\|^2_{L^2(\Omega)}, \tag{1.3}$$

where $r \geq 0$ is some given constant.

Following the same arguments as we used in [5] we have the following.

THEOREM 1.1. *$(q^*, v^*) \in K \times V$ is a solution of the minimization problem* (P1) *or* (P2) *if and only if there exists a $\lambda^* \in V$ such that $(q^*, v^*, \lambda^*) \in K \times V \times V$ is a saddle-point of the augmented Lagrangian $\mathcal{L}_r : K \times V \times V \to R$, namely,*

$$\mathcal{L}_r(q^*, v^*; \mu) \leq \mathcal{L}_r(q^*, v^*; \lambda^*) \leq \mathcal{L}_r(q, v; \lambda^*) \quad \forall\, (q,v,\mu) \in K \times V \times V. \tag{1.4}$$

Remark 1.1. We refer to [5] for the proof of similar results as stated in Theorem 1.1 for the TV-regularization, and [12, 13] for other quadratic regularizations.

2. Discretization and augmented Lagrangian algorithms. We now consider the finite element discretization of the augmented Lagrangian $\mathcal{L}_r$ and derive a discrete saddle-point problem.

Let Ω be a polyhedral domain in R^d, $d = 1, 2$, or 3, and $\{\mathcal{T}^h\}_{h>0}$ be a family of regular triangulations (cf. Ciarlet [7]) of the domain Ω with simplicial elements. Denote by V_h the standard piecewise linear finite element space over the triangulation $\mathcal{T}^h$ and

$$\overset{\circ}{V}_h = V_h \cap H_0^1(\Omega), \quad K_h = K \cap V_h.$$

The standard nodal basis functions of $\overset{\circ}{V}_h$ and V_h are denoted as $\{\phi_i\}_{i=1}^{N_0}$ and $\{\phi_i\}_{i=1}^{N}$, respectively.

We define a discrete version of the operator $e(\cdot,\cdot) : K \times V \to V$ as follows:

For any $(q_h, v_h) \in K_h \times \overset{\circ}{V}_h$, $e_h(q_h, v_h) \in \overset{\circ}{V}_h$ is the solution of the system

$$(\nabla e_h(q_h, v_h),\ \nabla\phi) = (q_h \nabla v_h,\ \nabla\phi) - (f, \phi) \quad \forall\, \phi \in \overset{\circ}{V}_h. \tag{2.1}$$

Then we introduce a discrete augmented Lagrangian L_r from $K_h \times \overset{\circ}{V}_h \times \overset{\circ}{V}_h$ to R:

$$L_r(q_h, v_h; \mu_h) = J_h(q_h, v_h) + (\nabla\mu_h,\ \nabla e_h(q_h, v_h)) + \frac{r}{2}\|\nabla e_h(q_h, v_h)\|^2_{L^2(\Omega)} \tag{2.2}$$

with

$$J_h(q_h, v_h) = \frac{1}{2}\int_\Omega q_h |\nabla v_h - \nabla z|^2 dx + \beta \int_\Omega |\nabla q_h|^2\ dx$$

in the case (a) and

$$J_h(q_h, v_h) = \frac{1}{2}\int_\Omega |v_h - z|^2 dx + \beta \int_\Omega |\nabla q_h|^2\ dx$$

in the case (b).

Applying the arguments as we used in [5], we obtain the following.

THEOREM 2.1. *For any $r \geq 0$, there exists at least a saddle-point for the discrete augmented Lagrangian $L_r : K_h \times \overset{\circ}{V}_h \times \overset{\circ}{V}_h \to R$. Moreover, each saddle-point $(q_h^*, v_h^*, \lambda_h^*)$ of L_0 is also a saddle-point of L_r for any $r > 0$.*

We apply the algorithm of the following Uzawa type to find the saddle-points of the discrete augmented Lagrangian L_r defined in (2.2).

UZAWA ALGORITHM. Given $\lambda^0 \in \overset{\circ}{V}_h$. Then for $n \geq 0$, determine the pair $\{q^n, u^n\} \in K_h \times \overset{\circ}{V}_h$ such that

$$L_r(q^n, u^n; \lambda^n) = \min \left\{ L_r(p, v; \lambda^n) \quad \forall\, (p, v) \in K_h \times \overset{\circ}{V}_h \right\} \tag{2.3}$$

and then compute λ^{n+1} by

$$\lambda^{n+1} = \lambda^n + \rho_n \, e_{_h}(q^n, u^n). \tag{2.4}$$

This Uzawa algorithm was proved in [5] to be convergent globally as long as $0 < \rho_n < r$. Earlier proofs of such global convergence of the Uzawa algorithms with different quadratic regularizations can be found in [15] and the references therein. The major cost of the algorithm is solving (2.3), a coupled system with q^n and u^n as unknowns. In our implementations, we will use the following alternative iteration for solving (2.3).

MODIFIED UZAWA ALGORITHM. Given $\lambda^0 \in \overset{\circ}{V}_h$ and $q^0 \in K_h$. Set $n = 1$.

1. Set $k = 1$ and $q^{n,0} = q^{n-1}$.

2. Compute $u^{n,k} \in \overset{\circ}{V}_h$ by solving

$$L_r(q^{n,k-1}, u^{n,k}; \lambda^{n-1}) = \min_{v_h \in V_h^0} L_r(q^{n,k-1}, v_h; \lambda^{n-1}), \tag{2.5}$$

and then compute $q^{n,k} \in V_h$ by solving

$$L_r(q^{n,k}, u^{n,k}; \lambda^{n-1}) = \min_{p_{_h} \in V_h} L_r(p_{_h}, u^{n,k}; \lambda^{n-1}). \tag{2.6}$$

Compute $q^{n,k} = \max\{\alpha_1, \min\{q^{n,k}, \alpha_2\}\}$.
If $\|q^{n,k} - q^{n,k-1}\| \leq$ tolerance, set $u^n = u^{n,k}$ and $q^n = q^{n,k}$, GOTO **3**;
Otherwise set $k = k + 1$, GOTO **2.**

3. Compute λ^n by

$$\lambda^n = \lambda^{n-1} + \frac{3}{4}\, r \, e_{_h}(q^n, u^n). \tag{2.7}$$

Set $n = n + 1$, GOTO **1.**

We will show in the next section that solving the minimization problems (2.5) and (2.6) is equivalent to solving two linear positive definite systems.

2.1. Positive definite systems: Energy-norm case. From the modified Uzawa algorithm we see that the major cost in each iteration of Step 2 is to solve the minimization problems (2.5) and (2.6). We next show that (2.5) and (2.6) are equivalent to two positive definite systems and thus can be solved using the GMRES iteration [16, 17], and more efficiently solved by the preconditioned GMRES

method with their corresponding block diagonal symmetric positive definite matrices as preconditioners.

We first need to derive Gâteaux derivatives of the augmented Lagrangian functional $L_r(q,u;\lambda)$. For the function $e_h(q_h,u_h)$, we can easily see its derivative with respect to q_h, denoted as $e'_h(q_h,u_h)p_h$ at direction $p_h \in V_h$, is a finite element function in $\overset{\circ}{V}_h$ and solves the equation

$$(\nabla e'_h(q_h,u_h)p_h,\nabla\phi) = (p_h\nabla u_h,\nabla\phi) \quad \forall\,\phi\in\overset{\circ}{V}_h, \tag{2.8}$$

while its derivative with respect to u_h, denoted as $e'_h(q_h,u_h)w_h$ at direction $w_h \in\overset{\circ}{V}_h$, is a finite element function in $\overset{\circ}{V}_h$ and solves the equation

$$(\nabla e'_h(q_h,u_h)w_h,\nabla\phi) = (q_h\nabla w_h,\nabla\phi) \quad \forall\,\phi\in\overset{\circ}{V}_h. \tag{2.9}$$

Note from above that for the sake of notation, we distinguish between the directional derivatives of $e_h(q_h,u_h)$ with respect to q_h and u_h only by the direction notation, i.e., depending only on whether we use p_h or w_h. Using these derivatives of $e_h(q_h,u_h)$, we can immediately obtain the Gâteaux derivatives of the augmented Lagrangian functional $L_r(q,u;\lambda)$. Its derivative with respect to u_h at direction w_h is

$$\begin{aligned} &L'_r(q_h,u_h;\lambda_h)w_h\\ &= (q_h\,(\nabla u_h-\nabla z),\nabla w_h) + (\nabla\lambda_h,\nabla e'_h(q_h,u_h)w_h)\\ &\quad + r\,(\nabla e_h(q_h,u_h),\nabla e'_h(q_h,u_h)w_h)\\ &= (q_h\,(\nabla u_h-\nabla z),\nabla w_h) + (q_h\,\nabla\lambda_h,\nabla w_h) + r\,(q_h\,\nabla e_h(q_h,u_h),\nabla w_h), \end{aligned} \tag{2.10}$$

while its derivative with respect to q_h at direction p_h is

$$\begin{aligned} &L'_r(q_h,u_h;\lambda_h)p_h\\ &= \frac{1}{2}\int_\Omega p_h\,|\nabla u_h-\nabla z|^2\,dx + \beta\,(\nabla q_h,\nabla p_h) + (\nabla\lambda_h,\nabla e'_h(q_h,u_h)p_h)\\ &\qquad + r\,(\nabla e_h(q_h,u_h),\nabla e'_h(q_h,u_h)p_h)\\ &= \frac{1}{2}\int_\Omega p_h\,|\nabla u_h-\nabla z|^2\,dx + \beta\,(\nabla q_h,\nabla p_h) + (p_h\,\nabla u_h,\nabla\lambda_h)\\ &\qquad + r\,(p_h\,\nabla u_h,\nabla e_h(q_h,u_h)). \end{aligned} \tag{2.11}$$

Now combining the formula (2.10) and the definition of $e_h(\cdot,\cdot)$, we can find the solution $u^{n,k}$ in (2.5), together with $e_h(q^{n,k-1},u^{n,k})$ as follows:

Find $(u^{n,k},e_h(q^{n,k-1},u^{n,k})) \equiv (u_h,e_h)\in\overset{\circ}{V}_h\times\overset{\circ}{V}_h$ such that

$$(q^{n,k-1}\,\nabla u_h,\nabla w_h) + r\,(q^{n,k-1}\,\nabla e_h,\nabla w_h) = (q^{n,k-1}\,\nabla(z-\lambda^{n-1}),\nabla w_h), \tag{2.12}$$

$$(\nabla e_h,\nabla\phi_h) - (q^{n,k-1}\,\nabla u_h,\nabla\phi_h) = -(f,\phi_h) \tag{2.13}$$

$\forall w_h\in\overset{\circ}{V}_h$ and $\phi_h\in\overset{\circ}{V}_h$. Similarly, the solution $q^{n,k}$ in (2.6) can be solved together with $e_h(q^{n,k},u^{n,k})$:

Find $(q^{n,k},e_h(q^{n,k},u^{n,k})) \equiv (q_h,e_h)\in V_h\times\overset{\circ}{V}_h$ such that

$$\beta\,(\nabla q_h,\nabla p_h) + r\,(\nabla e_h,p_h\nabla u^{n,k}) = -g_k(p_h), \tag{2.14}$$

$$(\nabla e_h,\nabla\phi_h) - (q_h\,\nabla u^{n,k},\nabla\phi_h) = -(f,\phi_h) \tag{2.15}$$

$\forall p_h \in V_h$ and $\phi_h \in \overset{\circ}{V}_h$. Here $g_k(p_h)$ is given by

$$g_k(p_h) = \frac{1}{2}\int_\Omega p_h\,|\nabla(u^{n,k}-z)|^2 dx + (p_h\,\nabla u^{n,k}, \nabla\lambda^{n-1}).$$

Next we show that the linear systems (2.12)–(2.13) and (2.14)–(2.15) are both positive definite. To see this, we introduce

$$\mathbf{A} = (a_{ij}), \quad \mathbf{B} = (b_{ij}), \quad \mathbf{\Lambda} = (\Lambda_j), \quad \mathbf{F} = (f_j)$$

with

$$a_{ij} = (q^{n,k-1}\nabla\phi_i, \nabla\phi_j), \quad b_{ij} = (\nabla\phi_i, \nabla\phi_j)$$

and

$$\Lambda_j = (q^{n,k-1}\nabla(z-\lambda^{n-1}), \nabla\phi_j), \quad f_j = (f, \phi_j)$$

for $i, j = 1, 2, \ldots, N_0$. Then (2.12)–(2.13) can be written as follows:

$$\mathbf{A}\mathbf{u} + r\,\mathbf{A}\mathbf{e} = \mathbf{\Lambda}, \quad \mathbf{B}\mathbf{e} - \mathbf{A}\mathbf{u} = -\mathbf{F},$$

or equivalently

$$(\mathbf{B} + r\mathbf{A})\,\mathbf{e} = \mathbf{\Lambda} - \mathbf{F}, \quad \mathbf{A}\,\mathbf{u} = \mathbf{B}\,\mathbf{e} + \mathbf{F}, \tag{2.16}$$

where $\mathbf{u}$ and $\mathbf{e}$ are the coefficient vectors of u_h and e_h in terms of the basis $\{\phi_i\}_{i=1}^{N_0}$, respectively. These two equations are both symmetric positive definite and can be solved by the conjugate gradient methods, or more efficiently by PCG method with the standard domain decomposition type preconditioners [1].

In an analogous manner, we introduce the following notation for the system (2.14)–(2.15):

$$\mathbf{Q} = (q_{ij}), \quad \mathbf{N} = (n_{ij}), \quad \mathbf{G} = (g_k(\phi_j))$$

with

$$q_{ij} = (\nabla\varphi_i, \nabla\varphi_j), \quad n_{ij} = (\varphi_i\nabla u^{n,k}, \nabla\phi_j)$$

for $i, j = 1, 2, \ldots, N$. Then (2.14)–(2.15) can be written as follows:

$$\beta\,\mathbf{Q}\,\mathbf{q} + r\,\mathbf{N}\,\mathbf{e} = -\mathbf{G}, \quad \mathbf{B}\,\mathbf{e} - \mathbf{N}^\top\,\mathbf{q} = -\mathbf{F}.$$

By eliminating $\mathbf{e}$, we can easily show that the system has a unique solution pair $(\mathbf{q}, \mathbf{e})$. For implementation, we write the system as

$$\begin{pmatrix} r\,\mathbf{B} & -r\,\mathbf{N}^\top \\ r\,\mathbf{N} & \beta\,\mathbf{Q} \end{pmatrix} \begin{pmatrix} \mathbf{e} \\ \mathbf{q} \end{pmatrix} = \begin{pmatrix} -r\,\mathbf{F} \\ -\mathbf{G} \end{pmatrix}. \tag{2.17}$$

If we let $\mathbf{A}_2$ be the coefficient matrix of the above system, and $\mathbf{D}_2$ be the block diagonal matrix of $\mathbf{A}_2$, then we can easily verify that

$$(\mathbf{e}^\top, \mathbf{q}^\top)\mathbf{A}_2 \begin{pmatrix} \mathbf{e} \\ \mathbf{q} \end{pmatrix} = r\,\mathbf{e}^\top\mathbf{B}\,\mathbf{e} + \beta\,\mathbf{q}^\top\mathbf{Q}\,\mathbf{q} = (\mathbf{e}^\top, \mathbf{q}^\top)\,\mathbf{D}_2 \begin{pmatrix} \mathbf{e} \\ \mathbf{q} \end{pmatrix} > 0$$

for any nonzero pair $(\mathbf{q}, \mathbf{e})$. Therefore $\mathbf{A}_2$ is positive definite, and so (2.17) can be solved using the GMRES iterative method, or more efficiently solved using the preconditioned GMRES method. A natural choice of the preconditioner matrix for $\mathbf{A}_2$ is $\mathbf{D}_2^{-1}$, with

$$\mathbf{D}_2 = \begin{pmatrix} r\,\mathbf{B} & \\ & \beta\,\mathbf{Q} \end{pmatrix}, \tag{2.18}$$

which is independent of the number of iterations and so is very cheap and easy to implement.

2.2. Positive definite systems: L^2-norm case. In the L^2-norm case, we can similarly obtain the Gâteaux derivative of the augmented Lagrangian functional with respect to u_h and q_h as in section 2.1. The derivative with respect to u_h at direction w_h is

$$L_r'(q_h, u_h; \lambda_h)w_h = (u_h - z, w_h) + (q_h\,\nabla\lambda_h, \nabla w_h) + r\,(q_h\,\nabla e_h(q_h, u_h), \nabla w_h), \tag{2.19}$$

while its derivative with respect to q_h at direction p_h is

$$L_r'(q_h, u_h; \lambda_h)p_h = \beta\,(\nabla q_h, \nabla p_h) + (p_h\,\nabla u_h, \nabla\lambda_h) + r\,(p_h\,\nabla u_h, \nabla e_h(q_h, u_h)). \tag{2.20}$$

Now combining the formula (2.19) and the definition of $e_h(\cdot,\cdot)$, we can find the solution $u^{n,k}$ in (2.5), together with $e_h(q^{n,k-1}, u^{n,k})$, as follows:

Find $(u^{n,k}, e_h(q^{n,k-1}, u^{n,k})) \equiv (u_h, e_h) \in \overset{\circ}{V}_h \times \overset{\circ}{V}_h$ such that

$$(u_h, w_h) + r\,(q^{n,k-1}\,\nabla e_h, \nabla w_h) = (z, w_h) - (q^{n,k-1}\,\nabla\lambda^{n-1}, \nabla w_h), \tag{2.21}$$

$$(\nabla e_h, \nabla\phi_h) - (q^{n,k-1}\,\nabla u_h, \nabla\phi_h) = -(f, \phi_h) \tag{2.22}$$

$\forall w_h \in \overset{\circ}{V}_h$ and $\phi_h \in \overset{\circ}{V}_h$.

We next show that (2.21)–(2.22) is a positive definite system. To see this, we introduce

$$\mathbf{A} = (a_{ij}), \quad \mathbf{B} = (b_{ij}), \quad \mathbf{M} = (m_{ij}), \quad \mathbf{H} = (h_j), \quad \mathbf{F} = (f_j)$$

with

$$a_{ij} = (q^{n,k-1}\nabla\phi_i, \nabla\phi_j), \quad b_{ij} = (\nabla\phi_i, \nabla\phi_j), \quad m_{ij} = (\phi_i, \phi_j)$$

and

$$h_j = (z, \phi_j) - (q^{n,k-1}\nabla\lambda^{n-1}, \nabla\phi_j), \quad f_j = (f, \phi_j),$$

for $i, j = 1, 2, \ldots, N_0$. Then (2.21)–(2.22) can be written as follows:

$$\mathbf{M}\mathbf{u} + r\,\mathbf{A}\mathbf{e} = \mathbf{H}, \quad \mathbf{B}\mathbf{e} - \mathbf{A}\mathbf{u} = -\mathbf{F},$$

or equivalently,

$$\begin{pmatrix} r\,\mathbf{B} & -r\,\mathbf{A} \\ r\,\mathbf{A} & \mathbf{M} \end{pmatrix} \begin{pmatrix} \mathbf{e} \\ \mathbf{u} \end{pmatrix} = \begin{pmatrix} -r\,\mathbf{F} \\ \mathbf{H} \end{pmatrix}.$$

Let $\mathbf{A}_3$ be the coefficient matrix of the above system and $\mathbf{D}_3$ be the block diagonal matrix of $\mathbf{A}_3$; then we can see that $\mathbf{A}_3$ is positive definite as

$$(\mathbf{e}^\top, \mathbf{u}^\top)\mathbf{A}_3 \begin{pmatrix} \mathbf{e} \\ \mathbf{u} \end{pmatrix} = r\,\mathbf{e}^\top \mathbf{B}\,\mathbf{e} + \mathbf{u}^\top \mathbf{M}\,\mathbf{u} = (\mathbf{e}^\top, \mathbf{u}^\top)\mathbf{D}_3 \begin{pmatrix} \mathbf{e} \\ \mathbf{u} \end{pmatrix} > 0$$

for any nonzero pair $(\mathbf{q}, \mathbf{e})$. Thus the system can be solved by the GMRES method. Another way to solve the system is to first eliminate $\mathbf{u}$ and solve the symmetric positive definite system $(\mathbf{B} + r\mathbf{A}\mathbf{M}^{-1}\mathbf{A})\mathbf{e} = -\mathbf{F} + \mathbf{A}\mathbf{M}^{-1}\mathbf{H}$ for $\mathbf{e}$ and then substitute $\mathbf{e}$ back to the system. Note that if we use the lumped mass scheme to approximate the mass matrix $\mathbf{M}$, then $\mathbf{M}$ is a diagonal matrix. This simplification keeps the same accuracy of approximation as we calculate $\mathbf{M}$ exactly (cf. Hoffmann–Zou [10]).

On the other hand, combining the formula (2.20) and the definition of $e_{_h}(\cdot,\cdot)$, we know that the solution $q^{n,k}$ in (2.6) satisfies the same equation as (2.17) but with $g_k(\phi_j)$ replaced by

$$\int_\Omega \varphi_i\, \nabla u^{n,k} \cdot \nabla \lambda^{n-1}\, dx\ .$$

3. Regularization with piecewise H^1 seminorms. In some applications, the location of the discontinuities of the identifying parameters may be available, either achieved technically or obtained by some simple numerical methods. In this case, we propose to use the piecewise H^1-seminorm regularization to obtain a more accurate recovery for the highly discontinuous parameters.

For simplicity, let us assume that the coefficient $q(x)$ has jumps only across the interface Γ between two subdomains Ω_1 and Ω_2 of Ω, namely,

$$q(x) = \begin{cases} q_1(x), & x \in \Omega_1, \\ q_2(x), & x \in \Omega_2, \end{cases}$$

with $\bar{\Omega} = \bar{\Omega}_1 \cup \bar{\Omega}_2$. The corresponding residual equation (1.2) becomes

$$(\nabla e(q,v), \nabla\phi) = (q\nabla v, \nabla\phi) - \left\{ \int_\Gamma \left[q \frac{\partial u}{\partial \mathbf{n}} \right] \phi + (f, \phi) \right\} \quad \forall\, (q,v) \in K \times V, \quad \phi \in V.$$

Here $\left[q\frac{\partial u}{\partial \mathbf{n}}\right]$ is the jump of the flux $q\frac{\partial u}{\partial \mathbf{n}}$ across the interface Γ, which is given and in fact vanishes in many real applications. We assume that Γ is a piecewise line segment ($d = 2$) or a polygon ($d = 3$). In other cases the finite element discretization needs to be taken care of very technically (cf. Chen–Zou [6]). Let $\mathcal{T}^h$ be a triangulation of Ω with all the finite elements aligning with the interface Γ and $\tilde{V}_h$ be the standard piecewise linear finite element space, respectively, in Ω_1 and Ω_2, namely, with piecewise linear functions which are continuous both in Ω_1 and Ω_2 but probably having jumps across Γ. We define the discrete constrained set to be $\tilde{K}_h = K \cap \tilde{V}_h$.

Now we can reformulate the augmented Lagrangian functional $\mathcal{L}_r$ in (1.3) by replacing the regularization term $N(q)$ there by

$$\tilde{N}(q) = \beta \int_{\Omega_1} |\nabla q_1|^2\, dx + \beta \int_{\Omega_2} |\nabla q_2|^2\, dx.$$

And in this case the discrete constrained set is defined to be $\tilde{K}_h = K \cap \tilde{V}_h$, and the discrete augmented Lagrangian functional L_r in (2.2) is now defined on $\tilde{K}_h \times \overset{\circ}{V}_h \times \overset{\circ}{V}_h$

and has the same form as (2.2) but with the regularization terms in $J_h(q_h, v_h)$ replaced by $\tilde{N}(q_h)$.

All the derivations in sections 2.1–2.2 can be carried over with only minor notational changes. The resulting linear algebraic systems from (2.5) and (2.6) are still all positive definite as we showed in sections 2.1–2.2.

4. Numerical experiments. We now show some numerical experiments on the proposed method for parameter identifications. We apply the modified Uzawa algorithm for the identification of the coefficients in the following test problems:

$$-\frac{d}{dx}\Big(q(x)\frac{d}{dx}u(x)\Big) = f(x), \quad x \in (0,1), \tag{4.1}$$

$$u(0) = 0, \quad u(1) = 0 \tag{4.2}$$

and

$$-\nabla \cdot (q(x,y)\nabla u) + c(x,y)u = f(x,y), \quad (x,y) \in \Omega, \tag{4.3}$$

$$u(x,y) = 0, \quad (x,y) \in \partial\Omega, \tag{4.4}$$

where $\Omega = (0,1) \times (0,1)$. In our implementations, the interval $(0,1)$ is divided into N uniformly distributed subintervals of length $h = 1/N$, the domain $(0,1) \times (0,1)$ is triangulated uniformly into triangular elements with horizontal and vertical edges of length $h = 1/N$.

Most parameters required in the algorithm are attached in each figure. The error $\mathcal{E}$ shown is the relative L^2-norm error between the exact parameter $q(x)$ to be identified and the numerically identified parameter q_h. The numerically recovered q_h shown throughout this section are the result obtained at the 5th iteration, i.e., $n = 5$, in the modified Uzawa algorithm. The augmented Lagrangian coefficient r and the initial guess of the Lagrangian multiplier λ^0 are always set to be 1 and 0, and the finite element mesh size h to be $1/80$ unless otherwise specified. The lower and upper bounds α_1 and α_2 in the constrained set K are taken to be 0.5 and 20.0, respectively. The tolerance is taken to be 10^{-6}, i.e., $\|q^{n,k} - q^{n,k-1}\|_\infty \le 10^{-6}$.

To generate the noisy observation data, we will always take the following form:

$$\nabla z^\delta(x) = \nabla z + \delta\,\mathrm{rand}(x)$$

in case (a) or

$$z^\delta(x) = z + \delta\,\mathrm{rand}(x)$$

in case (b), where $\mathrm{rand}(x)$ is a uniformly distributed random (vector-valued in (a)) function in $[-1,1]$, δ is the noise level parameter. Then in our implementations, we replace all previously appeared ∇z and z by ∇z^δ and z^δ, respectively.

4.1. Energy-norm case. We first show some results for the energy-norm case.

Example 1. We take the observed data z as

$$z(x) = u(q)(x) = \sin(2\pi x)$$

with the coefficient $q(x)$ as

$$q(x) = 3 + 2x^2 - 2\sin(2\pi x).$$

Figures 1 and 2 show the exact solution $q(x)$ (the solid line in Figure 1 but dashed line in Figure 2) and the numerically identified solution $q_h(x)$ (the "o" line in Figure

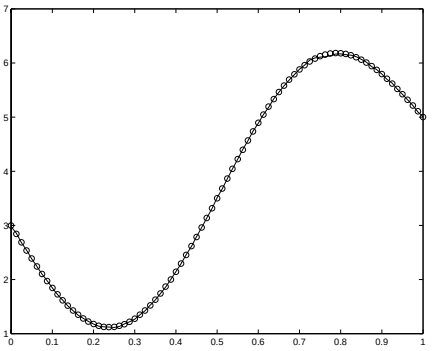

FIG. 1: $q_h^0 = 5.0, \beta = 10^{-5}, \delta = 1\%, \mathcal{E}$=0.0025.

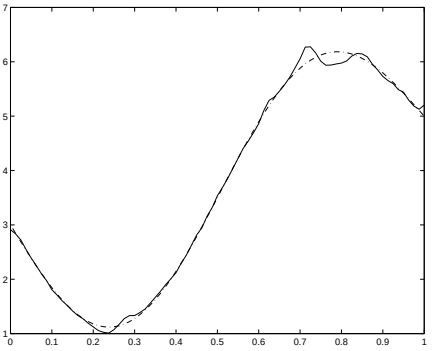

FIG. 2: $q_h^0 = 5.0, \beta = 10^{-5}, \delta = 10\%, \mathcal{E}$=0.021.

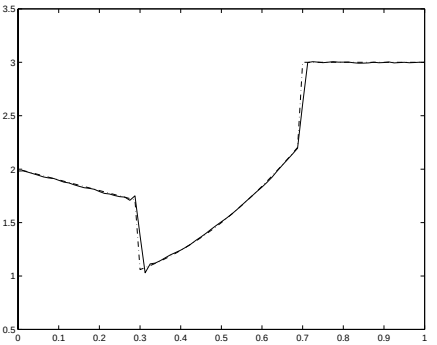

FIG. 3: $q_h^0 = 5.0, \beta = 5 \times 10^{-5}, \delta = 1\%, \mathcal{E}$=0.026.

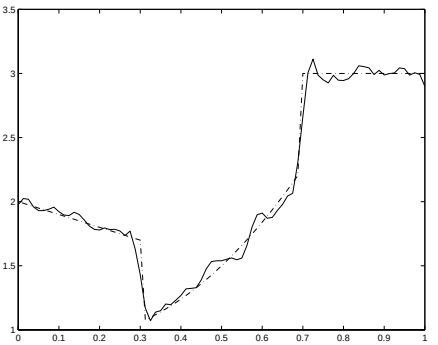

FIG. 4: $q_h^0 = 5.0, \beta = 10^{-5}, \delta = 10\%, \mathcal{E}$=0.031.

1 but solid line in Figure 2) with the noise level $\delta = 1\%$ and $\delta = 10\%$, respectively. Note that the initial guess $q_h^0 = 5.0$ is not a good initial guess at all, but the numerical method converges very stably and fast. Figures 1 and 2 are the results obtained at the 5th iteration ($n = 5$). As the numerical algorithm is a globally convergent algorithm, one can take the initial q_h^0 much worse than $q_h^0 = 5.0$, say, $q_h^0 = 50.0$, and still obtain the same accurate recovery. This is true for all examples shown in this section.

Example 2. We take the observed data z as

$$z(x) = u(q)(x) = \sin(\pi x)$$

with the discontinuous coefficient $q(x)$ as

$$q(x) = \begin{cases} 2 - x, & x \in [0,\ 0.3], \\ 1 - x + 4x^2, & x \in (0.3,\ 0.7), \\ 3, & x \in [0.7,\ 1]. \end{cases}$$

Figures 3 and 4 show the exact solution $q(x)$ (the dashed line) and the numerically identified solution $q_h(x)$ (the solid line) with the noise level $\delta = 1\%$ and 10%, respectively.

Example 3. We take the observed data z as

$$z(x, y) = u(q)(x, y) = \sin(\pi x)\sin(\pi y)$$

and the coefficient $q(x, y)$ as

$$q(x, y) = 1 + 6x^2 y(1 - y).$$

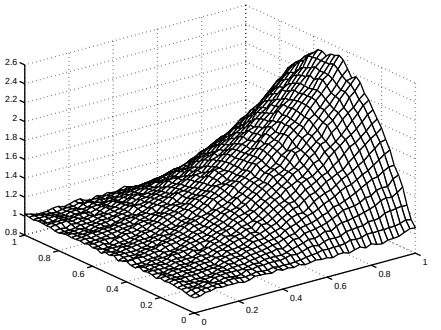

FIG. 5: $q_h^0 = 5.0, \beta = 10^{-5}, \delta = 1\%, \mathcal{E}$=0.025.

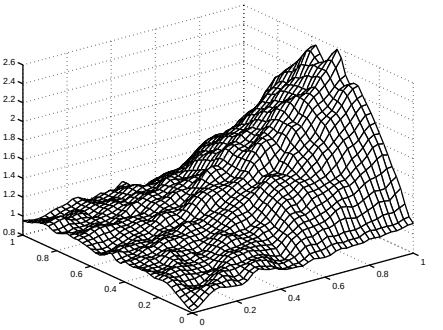

FIG. 6: $q_h^0 = 5.0, \beta = 10^{-4}, \delta = 10\%, \mathcal{E}$=0.079.

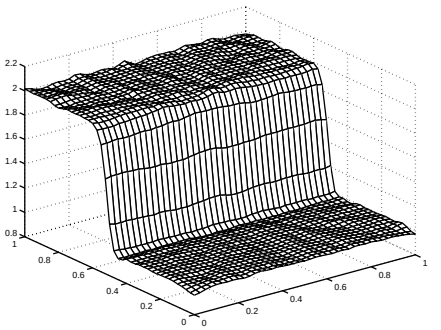

FIG. 7: $q_h^0 = 5.0, \beta = 10^{-5}, \delta = 1\%, \mathcal{E}$=0.049.

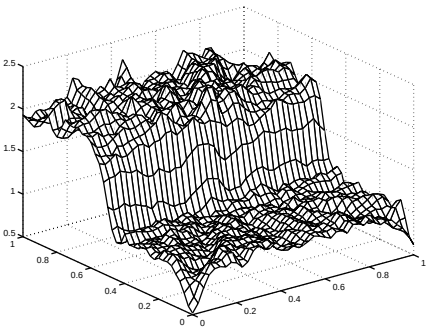

FIG. 8: $q_h^0 = 5.0, \beta = 10^{-5}, \delta = 10\%, \mathcal{E}$=0.069.

Figures 5–6 show the numerically identified solution $q_h(x, y)$ with $h = 1/40$ and the noise level $\delta = 1\%$ and $\delta = 10\%$, respectively.

Example 4. We take the observed data z as

$$z(x) = u(q)(x, y) = \sin(\pi x) \sin(\pi y)$$

with a discontinuous coefficient $q(x, y)$ as

$$\begin{cases} q(x, y) = 1, & y \in [0,\ 0.5], \\ q(x, y) = 2, & y \in (0.5, 1]. \end{cases}$$

Figures 7–8 show the numerically identified solution $q_h(x, y)$ with $h = 1/40$, and the noise level $\delta = 1\%$ and $\delta = 10\%$, respectively.

4.2. L^2-norm case. In this subsection, we show some numerical experiments on the proposed method with the L^2-norm formulation for the identification of the coefficient $q(x)$ in the test problems (4.1)–(4.2) and (4.3)–(4.4). The L^2-norm formulation assumes that the observation data is available via the pointwise function values, not the gradient values as in the energy-norm case. Note that the behavior of the gradient of a function is more essential for knowing the changes of a function than the function values, so in general we cannot expect the same nice performance in the current case as in the energy-norm case.

Example 5. The observed data z and the coefficient $q(x)$ are the same as in Example 1. Figure 9 shows the exact solution $q(x)$ (the dashed line) and the numerically identified solution $q_h(x)$ (the solid line) with the noise level $\delta = 1\%$.

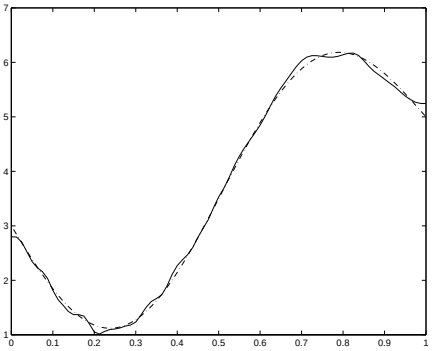

FIG. 9: $q_h^0 = 3.0, \beta = 10^{-7}, \delta = 1\%, \mathcal{E}$=0.018.

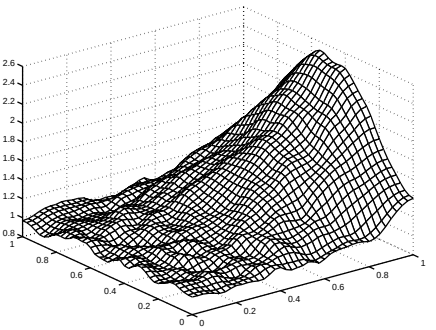

FIG. 10: $q_h^0 = 5.0, \beta = 10^{-6}, \delta = 1\%, \mathcal{E}$=0.031.

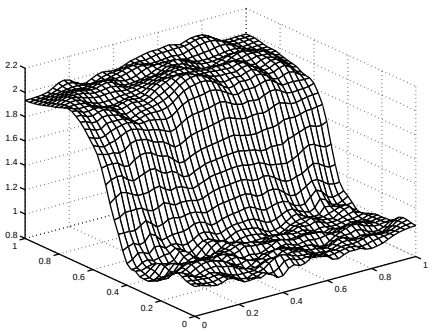

FIG. 11: $q_h^0 = 5.0, \beta = 10^{-6}, \delta = 1\%, \mathcal{E}$=0.091.

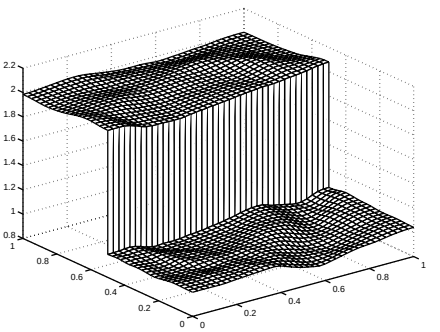

FIG. 12: $q_h^0 = 5.0, \gamma = 10^{-4}, \delta = 10\%, \mathcal{E}$=0.018.

Example 6. The observed data z and the discontinuous coefficient $q(x)$ are taken to be the same as in Example 3. Figure 10 shows the numerical solution $q_h(x, y)$ with $h = 1/40$ and the noise level $\delta = 1\%$.

Example 7. The observed data z and the discontinuous coefficient $q(x)$ are taken to be the same as in Example 4. Figure 11 shows the numerically identified solution $q_h(x, y)$ with $h = 1/40$ and the noise level $\delta = 1\%$; the recovery seems acceptable but not very satisfactory.

If the location of the discontinuity of the parameter $q(x)$ is available, then we can achieve much better identification by using the piecewise H^1-seminorm regularization (see section 3). Figure 12 is the numerically identified results using piecewise H^1-seminorm regularization with the noise level $\delta = 10\%$ and $h = 1/40$. Compared with

Figure 11, where the noise level is only $\delta = 1\%$, we can see that the numerical results using piecewise H^1-seminorm regularization are much more satisfactory.

4.3. GMRES iteration. As stated in the modified Uzawa algorithm, we have to eventually solve two minimization problems (2.5) and (2.6) at each iteration of step 2. But we have shown in sections 2.1–2.2 that these two problems are both equivalent to solving two positive definite systems. In this section we take the energy-norm formulation as an example and present some detailed numerical performance of the Uzawa algorithm using the GMRES method to solve the nonsymmetric but positive definite system (2.17). From the GMRES theory we know this system can be solved by GMRES with guaranteed convergence. However, when discretization mesh size is very fine, (2.17) is large and still expensive to solve, especially in two and three dimensions. So good preconditioners are needed. Fortunately we have a cheap and natural preconditioner available, i.e., M^{-1}. Here M is the block diagonal coefficient matrix

$$M = \begin{pmatrix} rB & 0 \\ 0 & \beta Q \end{pmatrix} \tag{4.5}$$

of (2.17). We are going to demonstrate some numerical experiments and compare the results using GMRES with or without preconditioning.

In our implementation, the stopping criterion of all GMRES or preconditioned GMRES iteration for a system $Ax = b$ is taken to be 10^{-6}, i.e.,

$$\frac{\|b - Ax\|}{\|b\|} < 10^{-6}.$$

The system $Mx = c$ involved in the preconditioned GMRES is always solved by the backward and forward substitutions using the LU factorization of M, i.e., $M = LU$. Note that the two diagonal block matrices B and Q of the preconditioner M are both symmetric and positive definite, in fact they are the stiffness matrices arising from the finite element discretization of the simple Laplacian operator, so the preconditioner M is unchanged in the whole outer (Uzawa iteration) and inner (GMRES) iterations. Thus the LU factorization of M needs to be done only once for all, namely, it can be done before we start the Uzawa algorithm.

We remark that the matrix Q used in the preconditioner M is a singular matrix, so the upper triangular matrix U of the LU factorization may have zeros on its diagonal. In this case, we add 10^{-10} (for $d = 1$) and 10^{-6} (for $d = 2$) to those diagonal entries with magnitudes less than 10^{-10}.

Another way to avoid the singularity of the matrix Q is to replace the seminorm $\int_\Omega |\nabla q|^2 \, dx$ by the full-norm $\int_\Omega (|\nabla q|^2 + q^2) \, dx$ as the regularization term. In this case,

$$Q = (q_{ij}), \quad q_{ij} = (\nabla \varphi_i, \nabla \varphi_j) + (\varphi_i, \varphi_j)$$

and the preconditioner $\tilde{M}$ formed as in (4.5) is always nonsingular.

In the following examples, we will demonstrate the effectiveness of the preconditioner M and the effect of seminorm and full-norm regularizations, by showing the number of GMRES iterations performed.

In each table below,

(a) is the total number of GMRES solvers used when the number of the outer-loop iteration of the modified Uzawa algorithm is $n = 5$;

(b) represents the average number of iterations within one GMRES solver, i.e., the total number of iterations accumulated in all GMRES iterations divided by the number given in (a).

Example 8. The observed data z and the exact coefficient $q(x)$ are taken to be the same as in Example 1. Results by using H^1-seminorm and full-norm regularizations with or without preconditioning are shown in Tables 4.1 and 4.2.

For all the examples given in this section, the graphs of the numerically identified solution $q_h(x)$ are similar to the ones we have shown in section 4.1, so we do not present them here again. From Tables 4.1–4.2, we see that the numbers of GMRES solvers performed (column (a)) are approximately the same with different mesh sizes, which means the convergence of the algorithm is almost *independent of* finite element mesh sizes; this seems to be a surprising observation. When considering the average number of iterations within one GMRES solver (column (b)), the one with preconditioning seems to have much fewer iterations, and this averaged number of iterations seems to be asymptotically constant. This indicates the preconditioners we used are almost optimal, namely, the numbers of the iterations of the preconditioned GMRES required to reach the stopping criteria are independent of the finite element mesh sizes. So the advantage of the preconditioning is more obvious when the problem sizes are larger. We can see such conclusion more evidently when we compare the results in Tables 4.1–4.2 and Tables 4.3–4.4 for the one-dimensional problems with the results in Tables 4.5–4.6 and Tables 4.7–4.8 for the two-dimensional problems.

The above observations are true for all other examples shown below.

Example 9. We take the observed data z and the true parameter $q(x)$ (discontinuous) to be the same as in Example 2. Results using H^1-seminorm and full-norm regularizations with or without preconditioning are shown in Tables 4.3 and 4.4.

Example 10. We take the observed data z and the true coefficient $q(x, y)$ to be

A STRUCTURAL DIAGNOSIS OF SOME IC ORDERINGS*

ROBERT BRIDSON† AND WEI-PAI TANG‡

Abstract. We present a novel analysis of the potential effectiveness of a matrix ordering for the incomplete Cholesky factorization (IC) in terms of just the sparsity structure. By looking at the structure of the approximate inverse implicitly created by IC we can help to explain the success of reverse Cuthill–McKee orderings, the problems IC(0) has under red-black orderings that disappear when extra fill is included, and where fill must be added to make fill-reducing orderings such as minimum degree effective.

Key words. ordering, incomplete factorization, incomplete Cholesky, preconditioner, sparse matrix, graph theory

1. Introduction.

The incomplete LU factorization (ILU) class of preconditioners has proven to be very competitive. However, like any algorithm that involves factoring a matrix into triangular parts (exactly or only approximately), the ordering of the rows and columns can have a crucial effect. The issue of how best to choose that ordering is an important area of research continuing up to today [1, 3, 4, 5, 6, 8, 9].

A natural first choice for an ordering might be the best fill-reducing ordering available—maybe a minimum degree variant or some kind of nested dissection. This follows the intuition that if there are less fill entries to drop, then the incomplete factorization will be more accurate.

However, it often turns out that envelope orderings like reverse Cuthill–McKee (RCM) orderings do better despite allowing more fill, at least for level-of-fill based incomplete factorizations and for fairly symmetric problems (e.g., see [1] for discussion of highly nonsymmetric matrices). Another puzzling observation is that red-black orderings usually give poor performance for ILU(0) but competitive performance for higher levels of fill.[1] These and many other orderings were considered in depth in [8], but the reasons for the varying performance are still not clear. Other papers have since further explored the effect of ordering on ILU, usually with a view toward explaining (and minimizing) the typical tradeoff between parallelism and convergence speed, but have generally stuck to model PDE problems on uniform rectangular grids [6, 9].

The following analysis provides some justification for these phenomena that works with the sparsity structure of the matrix, without considering the numerical values. The new results may be used as a guide for the construction of high-quality orderings,

[1]Gene Golub has recently suggested that ILU shouldn't be applied directly to a red-black ordered matrix, but rather to the Schur complement formed after diagonal scaling and pre-elimination of the red nodes; our analysis could then be applied to the structure and ordering of the Schur complement.

particularly in the common case where matrix entries may change from solution to solution but the sparsity structure and ordering stay the same.

We restrict our attention to symmetric positive definite matrices A with an incomplete Cholesky factorization $\bar{L}\bar{L}^T$ approximating the exact factorization LL^T. Our analysis is purely structural, however, so the results are equally applicable to matrices with symmetric structure only and whose ILU factors have identical structure after transposition, as is the case with ILU(k). Extensions to the fully unsymmetric case are possible, but we have yet to find satisfying, intuitive results there.

2. Inverse structure. The goal of an incomplete factorization is that the application of the preconditioner is close to the application of the true inverse of A. In other words, we want $(\bar{L}\bar{L}^T)^{-1}$ close to A^{-1}, viewing IC as a kind of implicit approximate inverse. This study focuses on just what the sparsity structure of the matrix can tell us; for orderings that consider numerical values, see, for example, [3, 4, 5, 6, 9].

One obvious desirable property for the incomplete factorization is that $(\bar{L}\bar{L}^T)^{-1}$ at least should have the same nonzero structure as A^{-1} (e.g., fully dense for irreducible matrices, such as those arising from elliptic PDEs). If $(\bar{L}\bar{L}^T)^{-1}$ is constrained to have zeros where A^{-1} has nonnegligible entries, the approximation cannot be good—the required coupling between nodes is absent.

Before proceeding, we will introduce some graph theory notation (see [10, 11] for more details). The (directed) graph of an $n \times n$ matrix B is a graph with vertices $1, \ldots, n$, and an arc $i \to j$ if and only if $B_{ij} \neq 0$. We will just write B instead of "the graph of B" where it is clear. A dipath is an ordered set $\langle i_1, i_2, \ldots, i_p \rangle$ such that $i_1 \to i_2$, $i_2 \to i_3$, $\ldots$, and $i_{p-1} \to i_p$, often written as $i_1 \to i_2 \to \cdots \to i_p$ or simply $i_1 \rightsquigarrow i_p$. The transitive closure of a graph $\mathcal{G}$ is a graph $\mathcal{G}^*$ on the same vertices but with an arc $i \to j$ in $\mathcal{G}^*$ whenever $i \rightsquigarrow j$ in $\mathcal{G}$.

In [11] the nonzero structure of the inverse of a matrix, assuming no fortuitous cancellation, is characterized in terms of its graph: the structure of B^{-1} is the transitive closure of B. In other words, $(B^{-1})_{ij} \neq 0$ if and only if there is a dipath $i \rightsquigarrow j$ in B.

We can immediately determine the structure of A^{-1} then. Assuming A is connected, and making use of its symmetric structure, there is a dipath between any two nodes. Hence A^{-1} is completely dense (first shown in [7]). We are thus interested in having $(\bar{L}\bar{L}^T)^{-1}_{ij} \neq 0$ for all i, j. Observe that

$$(\bar{L}\bar{L}^T)^{-1}_{ij} = \sum_{k=1}^{n} (\bar{L}^{-1})_{ki} (\bar{L}^{-1})_{kj}.$$

Thus $(\bar{L}\bar{L}^T)^{-1}_{ij} \neq 0$ if and only if there is some k such that $k \rightsquigarrow i$ and $k \rightsquigarrow j$ in $\bar{L}$ (assuming no fortuitous cancellation). Notice that since $\bar{L}$ is lower triangular, $u \to v$ in $\bar{L}$ implies that $u \geq v$, and so similarly $u \rightsquigarrow v$ implies $u \geq v$ (and in fact the nodes on the dipath are monotonically decreasing). Therefore it is necessary that $n \rightsquigarrow i$ monotonically for all i since no $k > n$—and this is clearly sufficient too, since then $n \rightsquigarrow i$ and $n \rightsquigarrow j$ for all i, j, which implies $(\bar{L}\bar{L}^T)^{-1}_{ij} \neq 0$ for all i, j.

Thus $(\bar{L}\bar{L}^T)^{-1}$ is fully dense if and only if node $n-1$ is adjacent to n (in $\bar{L}$), node $n-2$ is adjacent to the set $\{n-1, n\}$, node $n-3$ is adjacent to $\{n-2, n-1, n\}$, etc. Imagine selecting the ordering (the labelling of the nodes) in reverse order: choosing which node will be n, then which will be $n-1$, etc. Recall that a graph traversal is a step-by-step selection of the graph's nodes such that at each step, the next node selected is adjacent to some previously selected node. Then what we have follows.

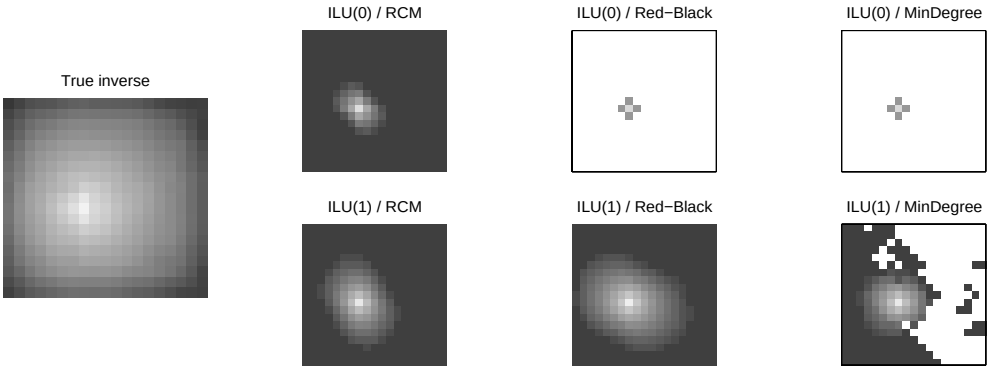

FIG. 2.1. *True inverse and implicit approximate inverses for IC*(0) *and IC*(1) *of the* 5*-point Laplacian under different orderings. Lighter grey indicates larger entries, except that pure white indicates exact zeros.*

THEOREM 2.1. *The implicit approximate inverse* $(\bar{L}\bar{L}^T)^{-1}$ *is fully dense if and only if the ordering is a "reversed graph traversal" (RGT) of* $\bar{L}$*, labelling the root* n*, the next node visited* $n-1$*, then the next one* $n-2$*, and so on.*

For IC(0), where the structure of $\bar{L}$ is the same as the structure of the lower triangle of A, we then are looking for a reversed graph traversal of A. A prime example of this is RCM ordering, where a pseudoperipheral node is chosen as the root, a special breadth-first traversal is made from the root, and the ordering is taken by reversing the traversal so that the root is numbered n.

Parenthetically, this helps to explain why ILU can often give faster convergence than an (explicit) approximate inverse with the same number of nonzeros. A nonfactored sparse approximate inverse is by definition far from dense—for an elliptic PDE this means that the preconditioner can't resolve low-frequency components of the error and is bound to have slow convergence. Factored sparse approximate inverses may have a dense product, but under more restrictive conditions than ILU: the last row/column of the lower/upper triangular factors, respectively, must be dense, which is often not the case.

Another result concerns red-black ordering on a 5-point grid. For IC(0) this is far from being an RGT—every black node is numbered higher than all its neighbors (which are red), and so there are no dipaths leading to a black node. However, for IC(1) each black node is connected in $\bar{L}$ to the eight nearest black nodes, and assuming the usual row-ordering of the black nodes, this does give an RGT. This is one reason why red-black orderings are competitive only at higher fill levels.

Unless special measures are taken, minimum degree, nested dissection, and similar orderings are typically not RGTs for low fill ILU. Figure 2.1 shows an example from a 5-point Laplacian on a 31×31 square grid. Each plot is of a column of the implicit approximate inverse (or the true inverse) appropriately matched to the PDE's domain—i.e., a 31^2 column vector reshaped into a grid function on the 31×31 mesh. These are in essence discretized views of "slices" of the Green's function or its IC approximations. The shading of the squares shows how big the nonzero entries are. It's clear that even if the numerical factorization were optimal, red-black ordered IC(0) and the displayed low fill minimum degree ordered preconditioner must have serious difficulties, whereas the RCM ordered factorization and red-black ordered ILU(1) at least have the structural potential to be very effective.

FIG. 2.2. *An example ordering on a* 7×7 *grid that is both a nested dissection and an RGT.*

However, orderings like minimum degree and nested dissection sometimes can give RGTs for low fill ILU. In particular, on square grids it is easy to determine a nested dissection that is an RGT as well—Figure 2.2 gives an example for a 7×7 grid. The key point is that each separator is itself ordered as an RGT with its root adjacent to the highest numbered node from the highest level separator possible. In this way there always exists a path in the underlying graph between any node and node n that does not pass through a lower numbered node than the starting node—in fact, a monotonic path that goes along the separators.

3. Inverse factor structure. For an even better simulation of the application of $A^{-1} = L^{-T}L^{-1}$, one could demand that the structure of the inverses of the incomplete factors match those of the true factors. Our intuition is that this will allow increased global coupling; it can be seen as an intermediate step between the full coupling of the exact factorization and the weakest global coupling discussed in the previous section.

Requiring that $\bar{L}^{-1}$ is as full as L^{-1} is a stronger condition than requiring just that $\bar{L}^{-T}\bar{L}^{-1}$ is as full as A^{-1}, and so this narrows down which graph traversals can be used. In particular, we will observe that this condition is not satisfied by RGT nested dissection orderings with low fill-in, providing some explanation of why they are typically still not as effective as other orderings.

Recall that a depth-first search is a graph traversal where at each step the next node to be visited is chosen to be adjacent to the most recently visited node possible. The subgraph induced by the edges linking each successive node (the child) to the most recently visited adjacent node (its parent) is the associated depth-first search tree.

Define a deepening search to be a topological (or post-order) traversal of a depth-first search tree, i.e., a traversal of a depth-first search tree beginning at the root and visiting each parent node before any of its children. Alternatively put, at each step of a deepening search consider the connected components of unvisited nodes, and select a node from any of those components that is adjacent to the most recently visited node possible for that component. (A depth-first search is a particular type of deepening search.) This leads to the following result.

THEOREM 3.1. *Assume that there is no numerical cancellation and that the structure of the lower triangle of* A *is a subset of the structure of* $\bar{L}$*, which is in turn a subset of the structure of the exact lower triangular factor* L*. Then the structure of* $\bar{L}^{-1}$ *matches the structure of* L^{-1} *if and only if* A *has been ordered according to a reversed deepening search (RDS) of* $\bar{L}$*. In particular, any RDS of* A *fulfills this condition.*

Proof. Recall that the structure of the inverse B^{-1} of some matrix B is given by the transitive closure of the graph of B, which is the same as the transitive closure of the transitive reduction of B [11]. Since the structure of $\bar{L}$ is a subset of the structure

of L, the structure of $\bar{L}^{-1}$ is a subset of the structure of L^{-1}, and is equal to it if and only if $\bar{L}$ contains the transitive reduction of L.

Further recall that the transitive reduction of L is the elimination tree of A [12]. Thus a necessary and sufficient condition for the result is that $\bar{L}$ contain the elimination tree of A.

Note that augmenting the structure of A with any subset of edges from L (i.e., adding "nonzeros" that are actually numerically zero) does not effect the structures of its triangular factors, and hence also does not effect its elimination tree. Thus we can simplify our argument by considering the structure of A augmented with the edges from $\bar{L}$ and $\bar{L}^T$, denoted by $\bar{A}$, instead of A. The necessary and sufficient condition is then reduced to $\bar{A}$ containing its own elimination tree.

Let $E(i)$ denote the set of nodes reachable from i through paths in $\bar{A}$ using only nodes $\{1, \ldots, i-1\}$, or in other words, the nodes reachable from i after all higher numbered nodes have been removed from the graph of $\bar{A}$. Partition each $E(i)$ according to the connected components it induces in the graph of $\bar{A}$, giving subsets $E_1(i), \ldots, E_{f(i)}(i)$.[2] Thus each $E_k(i)$ is a set of nodes numbered less than i that induces a connected subgraph of $\bar{A}$, with at least one node adjacent to i.

As characterized in [2], for example, the nonzeros in row i of L^{-1} correspond to the set $E(i)$. Observe that the elimination tree, the transitive reduction of L^{-1}, has an edge between i and the highest numbered node in each $E_k(i)$, by the following reasoning. Certainly these edges must be contained in the transitive reduction, since there is no equivalent path to them in L^{-1}: L^{-1} is triangular, so there can't be a path from i to the highest numbered node going through lower numbered nodes. These edges also suffice to give the full transitive closure, since it is clear that for each such edge (i, j) with $j = \max(E_k(i))$, we have $E(j) = E_k(i) \setminus \{j\}$, so inductively a path using just these exists from i to any node in $E(i)$.

Therefore, the necessary and sufficient condition becomes that, for each i, there is an edge in $\bar{A}$ from i to each of $\max(E_1(i)), \ldots, \max(E_{f(i)}(i))$. Imagine visiting the nodes in reverse order, starting at n and ending at 1. The condition means that within a connected component of unvisited nodes, the next node to visit must be a neighbor of the most recently visited node adjacent to the component. In other words, the condition is simply that the ordering must be an RDS of $\bar{L}$ (and the associated depth-first search tree is the elimination tree, consisting of the edges between each i and $\max(E_1(i)), \ldots, \max(E_{f(i)}(i))$.

Finally, observe that, barring numerical cancellation, adding more fill to $\bar{L}$ cannot reduce the structure of its inverse. Thus if the ordering is an RDS of the original A, i.e., of an IC(0) factor, then any higher fill incomplete factorizations $\bar{L}\bar{L}^T$ must satisfy the condition. □

An example of an RDS ordering that has already been investigated for ILU (and shown to be fairly effective) is the spiral ordering of [8]. This illustrates a special case of RDS orderings, where the associated depth-first search tree is actually a Hamiltonian path (i.e., it doesn't branch at all) and so the subdiagonal of A is all nonzero, which guarantees that L^{-1} will be a fully dense lower-triangular matrix.

Although RCM orderings are always RGT orderings, they typically are not RDS orderings, at least for low fill IC. However, it should be noted that by rearranging each level set appropriately, they may always be converted into RDS orderings—perhaps at the expense of increasing the envelope, but that is generally inconsequential in

[2] These may be called eliminated elements at step i of a complete factorization, and would correspond to the quotient nodes adjacent to i in the quotient graph [10].

modern sparse matrix packages for iterative methods.

On the other hand, although we observed in the previous section that separator-based fill-reducing orderings such as nested dissection can be made into RGT orderings by reordering separators, it is in general impossible to similarly convert them to RDS orderings. Lower-level separators generally are adjacent to higher-level ones at the wrong places, namely, the middle nodes rather than an end node. This may help to explain why these orderings, even if they are RGTs, generally perform poorly with low fill.[3]

4. Conclusion. The two theorems in this paper provide some understanding of already observed phenomena—the robust performance of RCM orderings, etc. However, we look forward to a constructive use in designing more effective orderings (and fill patterns) for IC. It certainly seems likely that any ordering considered today can be made into an RGT either by adding extra fill or reordering separators, for example, and many can be further made into an RDS. Alhough this is no guarantee of a good quality preconditioner, this at least removes structural impediments and paves the way for an effective incomplete numerical factorization.

Acknowledgments. We would like to thank the anonymous referees for their helpful suggestions in refocusing and clarifying the paper and for some instructive references.

ASSESSMENT OF A HIGH RESOLUTION CENTERED SCHEME FOR THE SOLUTION OF HYDRODYNAMICAL SEMICONDUCTOR EQUATIONS*

A. MARCELLO ANILE†, NIKOLAOS NIKIFORAKIS‡, AND ROSA M. PIDATELLA†

Abstract. Hydrodynamical models are suitable to describe carrier transport in submicron semiconductor devices. These models have the form of nonlinear systems of hyperbolic conservation laws with source terms, coupled with Poisson's equation. In this article we examine the suitability of a high resolution centered numerical scheme for the solution of the hyperbolic part of these extended models, in one space dimension. Because of the lack of physically significant exact analytical solutions, the method is assessed against a benchmark for the system of compressible, unsteady Euler equations with source terms, which has an exact solution; the latter is shown to be nearly identical to the numerical one. The method is then used to solve the extended hydrodynamical model (EM) based on the maximum entropy closure recently introduced by Anile, Romano, and Russo, simulating a ballistic diode $n^+ - n - n^+$, which models a metal oxide semiconductor field effect transistor (MOSFET) channel. Results are presented for the reduced- and full-equation EM formulation at steady state, for an initially discontinuous electron density at the junctions. Transient results show the evolution of highly nonlinear waves emanating from the neighborhood of the junctions.

1. Introduction.

Enhanced functional integration in modern electron devices requires an accurate modeling of energy transport in semiconductors in order to describe high-field phenomena such as hot-electron propagation, impact ionization, and heat generation in the bulk material. Furthermore, when using compound semiconductors for high frequency applications, usually one deals with multivalley band structures and in these cases the transfer of carriers from one valley to the other must also be modeled. The standard drift-diffusion models cannot cope with high-field phenomena because they do not comprise energy as a dynamical variable. Also they do not incorporate dynamical transfer of carriers from one valley to the other and this renders them ill-suited for simulating time dependent high frequency phenomena. Therefore, generalizations of the drift-diffusion equations have been sought which would incorporate energy as a dynamical variable and which also could treat time dependent high frequency phenomena. Because of their mathematical similarity to the equations of compressible fluid flow, these models are called hydrodynamical models. Semiconductor hydrodynamical models are obtained from the infinite hierarchy of moment equations of the semiclassical Boltzmann transport equation (BTE) by a suitable truncation procedure. This requires making suitable assumptions on (i) choosing the appropriate moments, (ii) closing the hierarchy of moment equations by finding appropriate expressions for the $N + 1$ order moment in terms of the previous

ones, and (iii) modeling the production terms on the right-hand side of the moment equations which arise from the moments of the collision terms in the BTE.

Various closure assumptions have been made for the semiconductor transport moment systems, leading to various classes of hydrodynamical models, e.g., [12, 9, 19, 18]. However, these various closure assumptions are, at best, only phenomenological and lack a consistent physical and mathematical justification.

Lately a closure assumption based on the maximum entropy principle of extended thermodynamics [28, 24] or, equivalently, the method of exponential closures [21] has been applied, in the parabolic band approximation, to the semiconductor moment equations, leading to a semiconductor hydrodynamical model free from phenomenological assumptions and enjoying important mathematical properties such as hyperbolicity [5, 4, 6, 8].

With this closure the distribution function used to calculate the higher order moments is assumed to be the one which maximizes the entropy under the constraints of the given set of moments. The resulting constitutive equations for various moments have been compared with the results obtained by Monte Carlo (MC) simulations in [7, 29] and are very encouraging in support of the maximum entropy ansatz. In these models the production terms are modeled by means of a fitting of the MC data for both homogeneous and inhomogeneous doped semiconductors.

1.1. Previous work on steady-state model integrations. Apart from the usual balance equations for carrier density, momentum, and energy, these extended models (EMs) comprise evolution equations for the heat flux and shear stress. The resulting system is hyperbolic in a suitable domain of the space of variables.

In the stationary case, by neglecting the viscous stresses and linearizing the heat flux equation for small temperature gradients (Maxwellian iteration) one obtains an extension of the Fourier law which includes also a convective term, which we call the Anile and Pennisi (AP) model [5]. When the convective term in the constitutive equation for the heat flow is (incorrectly) neglected, one obtains the model of Blotekjaer [12] and Baccarani and Wordeman [9] (BBW), which is often used in industrial simulation studies. Gardner, Jerome, and Rose [16] and Gardner [17] numerically integrated the BBW model for a benchmark case study (1-dimensional (1D) quasiballistic $n^+ - n - n^+$ diode). They discretized the system of equations by using either central differences (if the flow is everywhere subsonic) or the second upwind method (for transonic flow). The discretized system is then linearized by using Newton's method with a damping factor. In this way Gardner [17] was able to show evidence for an electron shock wave in the diode. A method similar to Gardner's was used by Anile, Maccora, and Pidatella [3] in order to solve the AP model with viscosity included. Gardner's results were also recovered within their approach. A similar approach has been used by Benvenuti, Coughran, and Pinto [10] in order to solve coupled thermal hydrodynamical models, using a Galerkin-type formulation.

Another approach which has been used in order to find the steady state for the BBW or AP model (in 1D and 2D) is that of using an artificial time method and mixed finite element space discretization. The ensuing time dependent numerical solutions are evolved until steady state is reached [27].

1.2. Previous work on time dependent calculations. The above approaches have dealt with the steady-state system of equations. For several practical applications one has to account for dynamic processes like self-heating of the device, coupling with mechanical effects, etc. This requires that at least the time derivatives in the particle and energy balance equations be reinstated. For recent advanced applications, such

as microwave power generation and optoelectronics, the remaining time derivatives in the momentum and energy-flux equations have to be taken into account.

Numerical solutions of various unsteady semiconductor hydrodynamical models have been presented in various articles. The hyperbolic part of the simpler BBW model coincides with the Euler hydrodynamical equations; shock capturing schemes have been adopted for its solution [15], achieving the stationary solutions as the limit of the time dependent one.

Lately Gruzinskis et al. [18] have applied finite difference methods to solve their hydrodynamical formulation which has a phenomenological closure and obtained wave-like solutions.

Blokhin and Iordanovich [11] have presented numerical solutions for the AP model using a flux vector splitting method, marching the algorithm to steady state.

Similar results have been presented in [31], again for the AP equations, using the Nessyahu–Tadmor (NT) scheme [32] for the convective step, which has the advantage over upwind-based schemes that it does not require the knowledge of the characteristic speeds of the system, which are not known analytically in this case. In their paper Romano and Russo [31] recovered the results obtained by Fatemi, Jerome, and Osher [15] in the case of the BBW model. Further work using the NT scheme was carried out by Anile, Romano, and Russo [7] in order to obtain the steady state for the 1D quasiballistic diode by marching in time the unsteady algorithm.

Since there are no known nontrivial analytical solutions of the EMs against which to compare the numerical results, confidence on the numerical results is enhanced by utilizing other unrelated numerical schemes or by solving mathematically similar problems with known solutions from other disciplines. This motivated recent work on kinetic schemes [2] (which gave results identical to those obtained with the NT scheme, although at a higher computational cost) as well as the work presented in this article.

2. Rationale for the current numerical approach. Our intention is to ultimately perform accurate multidimensional calculations of the full time dependent EMs equations to simulate the behavior of realistic devices (bipolar junction transistor (BJT), MOSFET, resonant diodes, etc.) in both transient and steady-state regimes. In this context accuracy means being able to capture small scale wave features (e.g., related to Gunn-type oscillations), as well as the bulk behavior. In this article we have considered the case of a 1D quasiballistic $n^+ - n - n^+$ diode, which is used as a benchmark problem for models of submicron electron devices, since the salient features of its behavior are understood. The modeling of a realistic device of this kind because of the discontinuous doping profile introduces strong gradients in the initial electron density at the junctions. The subsequent evolution of the system gives rise to nonlinear waves, before reaching a steady state. This implies that we must use methods which do not suffer from excess numerical diffusion or spurious oscillations in the vicinity of steep gradients. Also, although there are "source terms," the conservation properties of the hyperbolic left-hand side must be maintained. These requirements point us to the *high resolution* family of methods (see, for example, the textbooks by Hirsch [22], LeVeque [26], or Toro [33]) and in particular to those who lend themselves to be combined readily with computational techniques like adaptive mesh refinement (AMR) and modern computer architectures (such as massively parallel computers (MPP)). A typical method of this family offers a conservative discretization, low numerical diffusion, and no spurious oscillations near steep gradients.

High resolution *upwind* methods are most suitable for the numerical solution of systems of hyperbolic conservation laws because they introduce characteristic informa-

tion (regarding the local directionality of the flow) in the evaluation of the numerical fluxes. A great number of upwind high resolution schemes use the solution of the Riemann problem to evaluate the intercell fluxes. However, when the solution of the Riemann problem is not known, it is possible to construct *centered* schemes which do not compromise the qualities of the high resolution family, albeit at a small loss of "sharpness" of the solution.

The solution is updated by evaluating a finite volume formula derived by considering the integral form of the conservation laws. In particular, for a 1D system of the form

$$\mathbf{U}_t + \mathbf{F}(\mathbf{U})_x = 0, \tag{2.1}$$

where $\mathbf{U}$ and $\mathbf{F}(\mathbf{U})$ are the vectors of the conserved variables and the fluxes, respectively, and the equivalent integral formulation

$$\oint [\mathbf{U}dx + \mathbf{F}(\mathbf{U})dt] = 0, \tag{2.2}$$

the resulting update formula is (see [34])

$$\mathbf{U}_i^{n+1} = \mathbf{U}_i^n + \frac{\Delta t}{\Delta x}[\mathbf{F}_{i-1/2} - \mathbf{F}_{i+1/2}], \tag{2.3}$$

where $\mathbf{U}_i^{n+1}$ and $\mathbf{U}_i^n$ are the solutions at the next and current time-levels, $n+1$ and n, respectively. $\mathbf{F}_{i-1/2}$, $\mathbf{F}_{i+1/2}$ are the numerical fluxes[1] at the interfaces of the computational cells of the discretized space; see Figure 2.1. For a given cell width, Δx, and timestep, Δt, the values of the numerical fluxes need to be evaluated in formula (2.3) in order to compute the conserved variables at the next time-level.

To this end centered schemes can be constructed using a nonlinear combination of a good second (or higher) order scheme with a first order monotone scheme.

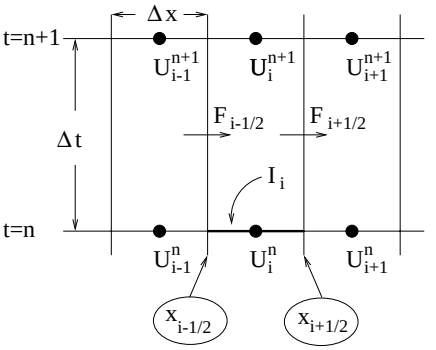

FIG. 2.1. *Geometrical representation of the finite volume update formula.*

2.1. The slope limiter centered scheme. The centered method we use for the calculations presented in this article, namely the slope limiter centered (SLIC) scheme [33], uses a version of the second order MUSCL–Hancock [36] (where MUSCL stands for monotone upstream-centered scheme for conservation laws) and the first-order centered (FORCE) scheme [33]. Since the scheme has been presented elsewhere, we summarize below only its main points, and in particular the ones necessary for our discussion.

[1]The numerical fluxes are approximations to the physical fluxes.

The MUSCL–Hancock approach achieves a second order extension of Godunov's first order scheme by reconstructing the data as piecewise linear functions in every cell. The left and right cell boundary extrapolated values for cell i

$$\mathbf{U}_i^L = \mathbf{U}_i^n - \frac{1}{2}\Delta_i, \qquad \mathbf{U}_i^R = \mathbf{U}_i^n + \frac{1}{2}\Delta_i$$

(where Δ_i is a slope vector), are evolved in time by half a timestep as linear combinations of the conserved variables and the fluxes:

$$\mathbf{U}_i^{Lnew} = \mathbf{U}_i^L + \frac{1}{2}\frac{\Delta t}{\Delta x}[\mathbf{F}(\mathbf{U}_i^L) - \mathbf{F}(\mathbf{U}_i^R)],$$
$$\mathbf{U}_i^{Rnew} = \mathbf{U}_i^R + \frac{1}{2}\frac{\Delta t}{\Delta x}[\mathbf{F}(\mathbf{U}_i^L) - \mathbf{F}(\mathbf{U}_i^R)].$$

However, the intercell fluxes are evaluated using the FORCE scheme, instead of using the solution of the Riemann problem. FORCE is a result of a combination of the Lax–Friedrichs and the Richtmyer schemes (see [33] and references therein). In particular, the flux at the interface of two states U_L, U_R is

$$F_{i+1/2}^{force} \equiv F_{i+1/2}^{force}(U_L, U_R) = 0.5\left[F_{i+1/2}^{LF}(U_L, U_R) + F_{i+1/2}^{Ri}(U_L, U_R)\right]. \tag{2.4}$$

In the above expressions, the first order Lax–Friedrichs flux, F^{LF}, is given by

$$F_{i+1/2}^{LF} \equiv F_{i+1/2}^{LF}(U_L, U_R) = 0.5\,[F(U_L) + F(U_R)] + 0.5\frac{\Delta x}{\Delta t}[U_L + U_R].$$

The second order Richtmyer scheme (which computes a numerical flux by first defining an intemediate state) is

$$U_{i+1/2}^{Ri} \equiv U_{i+1/2}^{Ri}(U_L, U_R) = 0.5(U_L + U_R) + 0.5\frac{\Delta t}{\Delta x}[F(U_L) - F(U_R)],$$

setting $F^{Ri} = F(U_{i+1/2}^{Ri})$.

The resulting scheme is second order accurate in space and time, so to avoid spurious oscillations in the vicinity of steep gradients, the slopes Δ_i are replaced by limited slopes $\bar{\Delta}_i$, using slope limiter functions. For a detailed exposition of the scheme, the slope limiter functions, and validation problems, see the textbook by Toro [33].

An advantage of the scheme is that every flux component is "limited" independently, using the appropriate conserved variable. This is of paramount importance because normally a single function is used to limit all components; since there is no formal theory on the selection of these functions, this can compromise the performance of the scheme, especially if one flux is continuous at a point in space and time, while another is discontinuous at the same point. Even if a suitable global function is empirically found, this will have to be changed if the equations are altered.

From the above discussion it is evident that once a skeleton algorithm for the scheme is coded, any system of hyperbolic conservation laws can be solved simply by typing the vectors of the conserved variables and the fluxes. For our purposes this is very important because the effects of altering the terms in the conservation laws on the physics of the problem can be readily investigated. For example, in this article we solve the full as well as the reduced EM semiconductor equations; see the following sections.

Also, because the scheme uses a conventional finite volume update formula on a conventional computational mesh, it can be implemented in existing computer program for 2D extensions with or without source terms, as explained in the next section.

2.2. Fractional steps. The equations for our problem are of the form

$$\frac{\partial \mathbf{U}}{\partial t} + \frac{\partial \mathbf{F}(\mathbf{U})}{\partial x} = \mathbf{S}(\mathbf{U}), \tag{2.5}$$

coupled with the Poisson equation

$$\frac{\partial^2 \Phi}{\partial x^2} = S_1. \tag{2.6}$$

We adopt the method of fractional steps to evaluate (2.5) and (2.6), where the homogeneous hyperbolic part

$$\frac{\partial \mathbf{U}}{\partial t} + \frac{\partial \mathbf{F}}{\partial \mathbf{U}} = 0$$

is solved using SLIC (with initial and boundary conditions as specified for the complete system), and then we evaluate the remaining ordinary differential equation

$$\frac{\partial \mathbf{U}}{\partial t} = S(\mathbf{U})$$

and the Poisson equation (2.6) using conventional techniques (e.g., Runge–Kutta and tridiagonal matrix solver). Calling R the relaxation step operator, C the convection step operator, and P the Poisson operator, and assuming that the numerical schemes used are at least second order accurate, a Strang splitting [30] which maintains this level of accuracy is

$$\mathbf{U}^{n+1} = R(\Delta t/2)P(\Delta t/2)C(\Delta t)P(\Delta t/2)R(\Delta t/2)\mathbf{U}^n.$$

The accuracy of this splitting and the performance of SLIC for arbitrary source-term driven flow is evaluated using a combustion problem which has an exact solution.

3. A validation case study. The scheme has been validated in open literature only for homogeneous systems of equations [33]. Before attempting to implement the semiconductor equations, we validate the scheme against exact solutions of the compressible unsteady Euler equations with source terms using a simplified combustion problem described in some detail by Clarke [13]. It considers flow generated by the action of source terms and is rich in wave structures similar to the ones anticipated in the unsteady evolution of electron flow in semiconductor devices. The governing equations are of the form

$$\mathbf{U}_t + \mathbf{F}(\mathbf{U})_x = \mathbf{S}(\mathbf{U}),$$

where the vectors $\mathbf{U}$, $\mathbf{F}(\mathbf{U})$, and $\mathbf{S}(\mathbf{U})$ are

$$\mathbf{U} = \begin{bmatrix} \rho \\ \rho u \\ E \end{bmatrix}, \qquad \mathbf{F}(\mathbf{U}) = \begin{bmatrix} \rho u \\ \rho u^2 + p \\ (E+p)u \end{bmatrix}, \qquad \mathbf{S}(\mathbf{U}) = \begin{bmatrix} G \\ F \\ H \end{bmatrix}. \tag{3.1}$$

The right-hand sides G, F, and H represent general sources of mass, momentum, and energy, while the last two can be written as functions of G:

$$F = uG, \qquad H = (E + p/\rho)G.$$

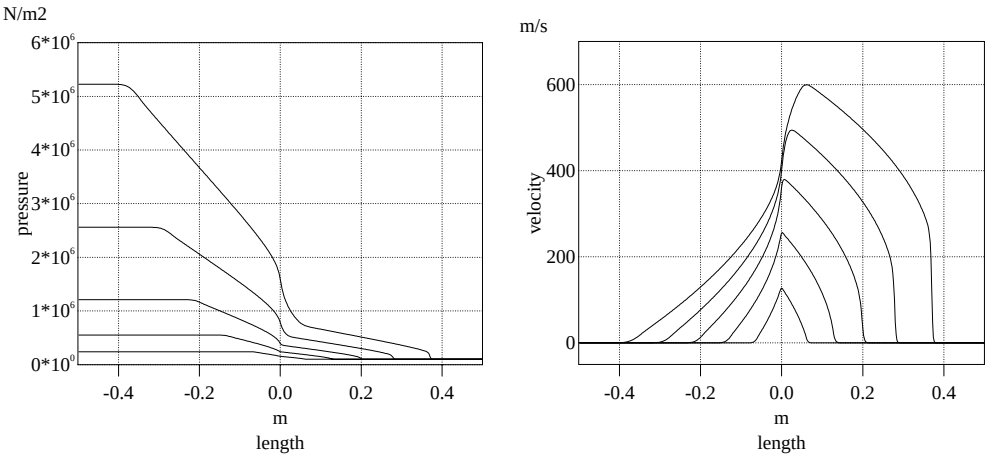

FIG. 3.1. *Superimposed numerical (using SLIC) profiles for pressure and velocity at different times, showing the evolution of the flow for the combustion problem formulated in section* 3. *An expansion wave propagates to the left in a region of increasing pressure, while a compression wave propagates to the right, eventually turning to a shock wave. Sonic flow is observed at the middle of the domain.*

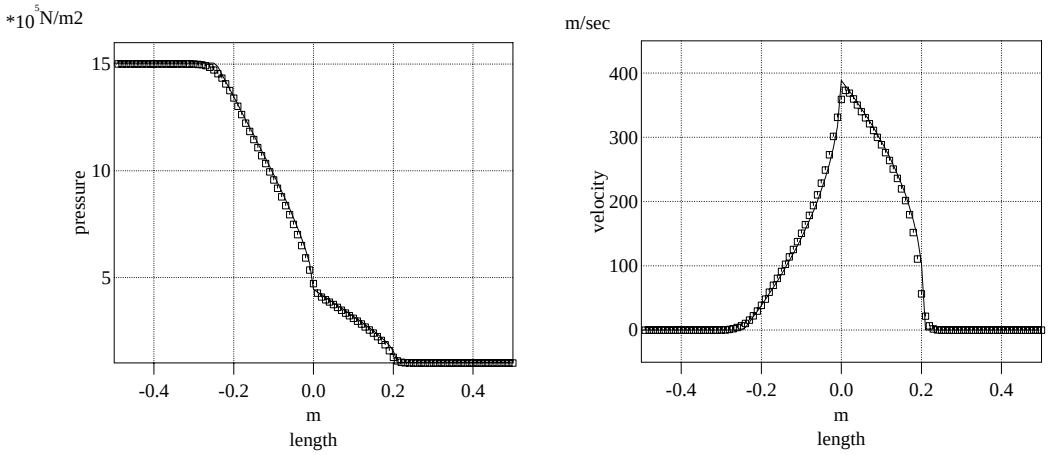

FIG. 3.2. *Superimposed exact (line) and numerical (points) solutions using SLIC for the combustion problem formulated in section* 3.

An exact solution can be derived if the source term G is chosen to be such that

$$(aG/\rho) = \bar{G} = \text{ const. in } x < 0, \text{ and } \bar{G} = 0 \text{ in } x > 0.$$

Part of the exact solution can be found in the paper by Clarke and Toro [14]. Initially pressure is one atmosphere, $u = 0$, and $a = a_0$, while the values of the constants are $a_0 = 330\text{m/sec}$ and $\bar{G} = 1294301.0\text{m/sec}^2$.

Profiles of pressure and velocity at different times, mapping the evolution of the flow, are shown in Figure 3.1; these results were obtained using SLIC. The source-driven flow is isentropic up to the time of shock formation ($t = (4a_0)/((\gamma + 1)\bar{G})$) at the head of the wave propagating to the right. Sonic flow conditions appear at $x = 0$ at $t = (4a_0)/((3 - \gamma)\bar{G})$.

Salient features of interest in the context of scheme validation are the rising pressure and the expansion wave in the left (source-filled) part of the domain and the propagating pressure wave in the right part of the domain, which steepens to form a shock wave. An interesting feature of this problem is that the flow "chokes" in the middle of the domain when sonic conditions appear, as indicated by the velocity curves which reach a limit at $x = 0$ and cusp to the right of the domain.

The accuracy of the method and the correct coupling of the hyperbolic and source-term module is demonstrated in Figure 3.2, which shows superimposed exact (lines) and numerical (points) results at $t = 0.505 \times 10^{-3}$; the two solutions are nearly identical.

4. Semiconductor equations. The EMs which we consider here were formulated by Anile, Romano, and Russo [7, 6]. The equations are of the form

$$\mathbf{U}_t + \mathbf{F}(\mathbf{U})_x = \mathbf{S}(\mathbf{U}),$$

where the vectors $U, F(U)$, and $S(U)$ are

$$\mathbf{U} = \begin{bmatrix} n \\ nv \\ nv^2 + 3p/m_* \\ \frac{2}{3}nv^2 + \sigma/m_* \\ nv^3 + 5vp/m_* + 2\sigma v/m_* + 2q/m_* \end{bmatrix}, \tag{4.1}$$

$$\mathbf{F}(\mathbf{U}) = \begin{bmatrix} nv \\ nv^2 + p/m_* + \sigma/m_* \\ nv^3 + 5vp/m_* + 2\sigma v/m_* + 2q/m_* \\ \frac{2}{3}nv^3 + \frac{4}{3}vp/m_* + \frac{7}{3}v\sigma/m_* + \frac{8}{15}q/m_* \\ nv^4 + 5p^2/n(m_*)^2 + 7\sigma p/n(m_*)^2 + \frac{32}{5}qv/m_* + \\ \qquad v^2(8p/m_* + 5\sigma/m_*) + \frac{148}{25}q^2/m_* p \end{bmatrix}, \tag{4.2}$$

$$\mathbf{S}(\mathbf{U}) = \begin{bmatrix} 0 \\ -nv/\tau_p - neE/m_* \\ -2(W - W_0)/m_*\tau_W - 2nevE/m_* \\ -1/m_*\tau_\sigma(nv^2 + \sigma/m_*) - 4nevE/3/m_* \\ -1/\tau_q(nv^3 + 5vp/m_* + 2\sigma v/m_* + 2q/m_*) \\ \qquad -eE/m_*(3nv^2 + 5p/m_* + 2\sigma/m_*) \end{bmatrix}. \tag{4.3}$$

Depending on the strength of the electric field, some of the nonlinear terms in the deviation from local thermal equilibrium can be neglected, as well as the anisotropic stresses. Thereby one obtains the following set of equations, which we refer to as the reduced EM. In this case the vectors $\mathbf{U}$, $\mathbf{F}(\mathbf{U})$, and $\mathbf{S}(\mathbf{U})$ are

$$\mathbf{U} = \begin{bmatrix} n \\ nv \\ 3p/m_* \\ 2q/m_* \end{bmatrix}, \tag{4.4}$$

$$\mathbf{F}(\mathbf{U}) = \begin{bmatrix} nv \\ p/m_* \\ 2q/m_* \\ 5p^2/n(m_*)^2 \end{bmatrix}, \tag{4.5}$$

$$\mathbf{S}(\mathbf{U}) = \begin{bmatrix} 0 \\ -nv/\tau_p - neE/m_* \\ -2(W - W_0)/m_*\tau_W - 2nevE/m_* \\ -1/\tau_q(2q/m_*) - 5eEp/(m_*)^2 \end{bmatrix}. \tag{4.6}$$

We remark that for the reduced model the interpretation of q is not that of heat flux but of total energy flux.

In both cases we solve Poisson's equation:

$$\varepsilon \frac{\partial^2 \Phi}{\partial x^2} = -e(N_D - N_A - n), \qquad E = -\frac{\partial \Phi}{\partial x}. \tag{4.7}$$

Here n is the electron density, v is the electron velocity, p is the electron fluid pressure, m_* is the effective electron mass (taken to be 0.32 me), σ is the anisotropic stress, q is the heat flux, τ_p is the relaxation time for momentum, τ_w is the relaxation time for energy, τ_σ stands for anisotropic stresses, τ_q is the relaxation time for the energy flux, e is the absolute value of the electron charge, E is the electric field, W is the energy density, $W = (1/2)m_*v^2 + (3/2)K_BT$, and W_0 is the thermal equilibrium energy density.

In both cases the relaxation times are obtained as functions of energy W from fitting to MC simulation for the same benchmark device (see [29]). The reduced model resembles strongly the so-called energy-transport models obtained from the semiclassical BTE by a Chapman–Enskog-like procedure [1].

5. A benchmark case study. As a test problem we consider a ballistic diode $n^+ - n - n^+$, which models a MOSFET channel. The diode is made of silicon, and the bulk temperature is supposed to be 300°K. The n^+ regions are 0.1μm long and the channel length L_c we consider is 0.4μm. The doping profile is $N_D^+ = 1. \times 10^{18}$ cm^{-3}, $N_D = 0.01 \times 10^{18}$ cm^{-3}.

For the electron effective mass in the approximation of parabolic band we use $m_* = 0.32\ m_e$, where m_e is the electron mass [35]. The silicon dielectric constant is given by $\epsilon = \epsilon_r\epsilon_0$, where ϵ_r =11.7 is the relative dielectric constant and $\epsilon_0 = 8.85 \times 10^{-12} F/m$ μm is the dielectric constant of vacuum.

The initial electron temperature is the lattice temperature $T_0 = 300$°K, and the charges are at rest. A bias voltage of 1 volt is applied and this determines a charge flux in the semiconductor.

Solutions for the full and the reduced formulation of the equations are shown in this section. In both cases all of the variables are assumed to be initially constant across the computational domain, save for the density of the electrons, which varies discontinuously at the junctions

$$T(x,0) = 300°\text{K}, \quad v(x,0) = 0, \quad q(x,0) = 0, \quad \sigma(x,0) = 0.$$

The initial density profile is the doping profile, which is an inverted top hat. The total length of the device is $L = L_c + 0.2\mu$m. Transmissive boundary conditions are

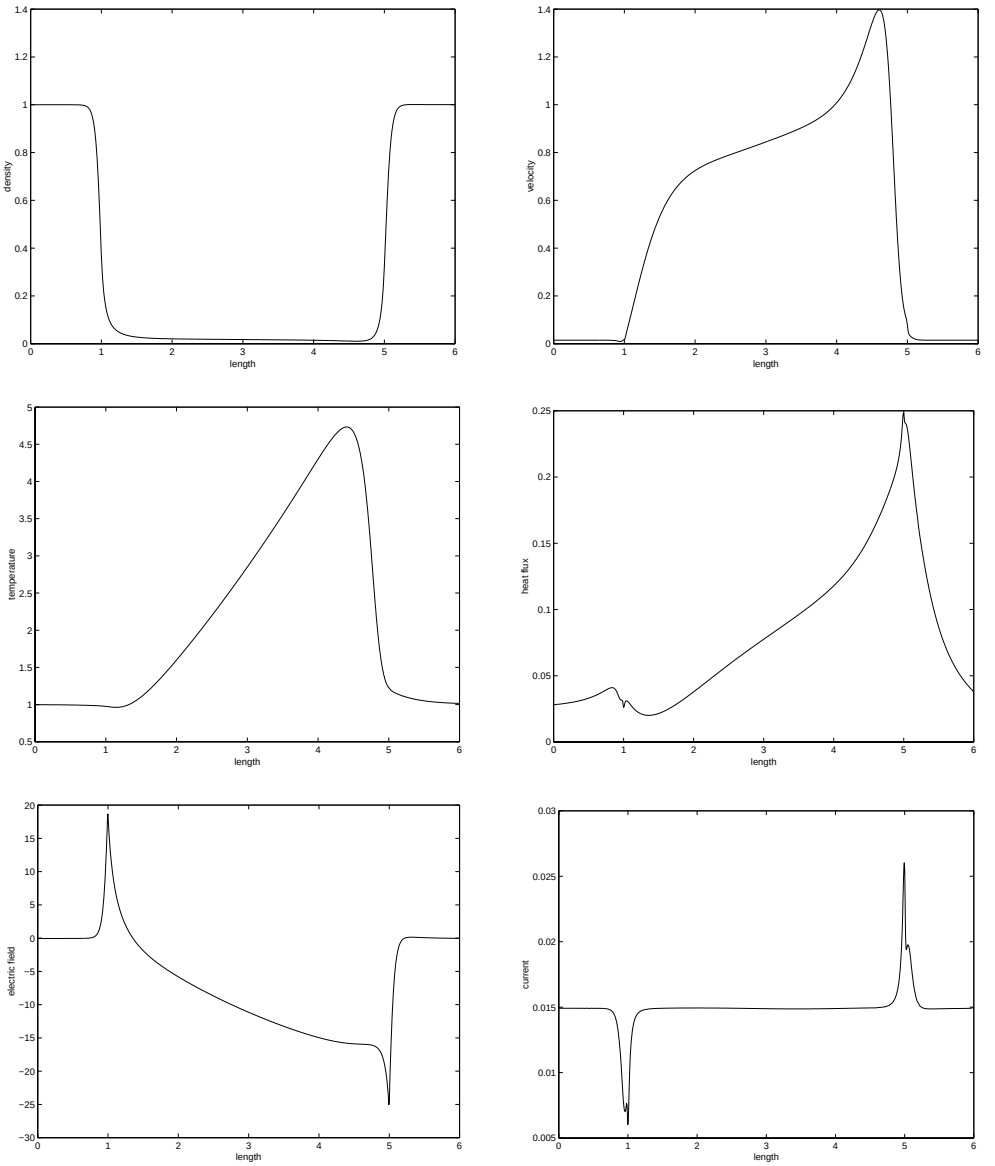

FIG. 5.1. *Numerical solutions using SLIC method solving the reduced model* $n^+ - n - n^+$ *diode formulation. The initial density distribution was discontinuous at the location of the junctions.*

applied at both ends of the computational domain. The boundary conditions for the Poisson's equation are

$$e\Phi(x_{left}) = K_B T ln(N_D/n_i), \quad e\Phi(x_{right}) = K_B T ln(N_D/n_i) + eV_{bias},$$

where n_i =1.45$\times$ 10^{10}cm^{-3} is the intrinsic concentration.

The system is left to evolve, preserving time accuracy, until steady state is reached (results shown at $t = 5$ picoseconds). The hyperbolic and the source terms are allowed to evolve at different timesteps, which are, however, matched at the end of every iteration. In this way the lower timestep of the source terms does not burden

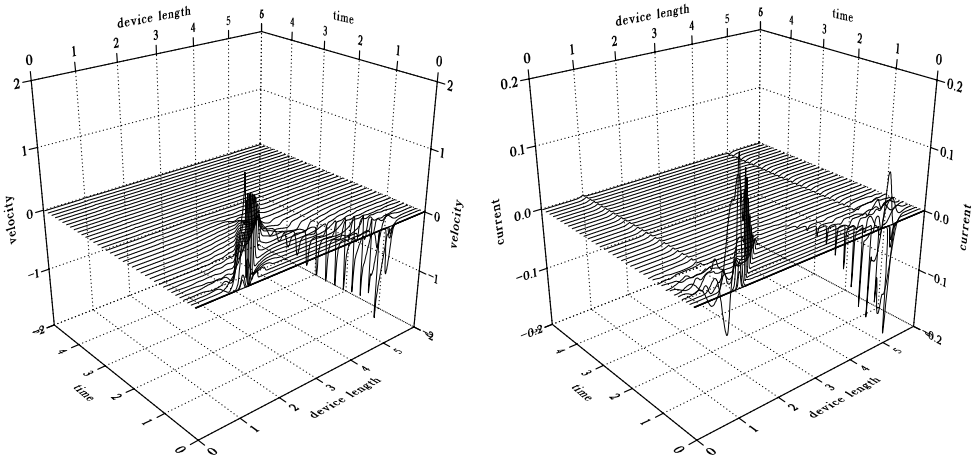

FIG. 5.2. *SLIC method solving the full EM for zero bias (discontinuous initial density). After the initial waves attenuate, velocity reaches a steady-state value of nearly zero (compared with the initial magnitude of the waves), while there is evidence of a small value of current at the location of the junctions.*

the speed of execution of the complete code. It should be noted here that apart from the efficiency issue, marching any method for hyperbolic conservation laws at a timestep smaller than the optimum one, as dictated by the Courant–Friedrichs–Levy (CFL) condition, significantly increases the truncation error of the calculation, which manifests as excessive numerical diffusion.

The thickness of the junctions is of importance to the calculations because, as we will demonstrate in a future communication, it affects some of the salient features in the steady-state profiles of the primitive variables. In any case, the method allows one to vary the junction thickness down to the width of a computational cell, i.e., a genuine discontinuous profile of the initial density, which can match the true physical width of a real device where the doping is obtained by epitaxial growth (and not by ion diffusion). To the best of our knowledge, in all other published results the junctions are smeared over several computational cells and therefore, the resulting simulations apply only to the cases in which the initial profile is obtained by some sort of diffusion.

5.1. Reduced EM calculations. The qualitative behavior of the solutions is the same as for the "energy transport" models studied by several researchers [1, 27, 25] under steady-state conditions. The new feature of our approach is that we use a method suitable for hyperbolic systems with source terms, and in this particular case study we evolved the solution as an unsteady problem marched to steady state, preserving time as well as space accuracy. Therefore, our code could be used to investigate the transient behavior of the system from an academic and an engineering point of view. The results of the simulations are shown in Figure 5.1; the initial doping profile is discontinuous at the junctions and the qualitative behavior of the fields is what is expected on physical grounds. Similar results have been obtained where the initial doping is smoothed with a convolution or hyperbolic tangent. In these latter cases the results have been compared with those obtained by a direct solution of the stationary equations using mixed finite elements [37]; the two sets of results agree completely within computer arithmetic. It appears that the current is

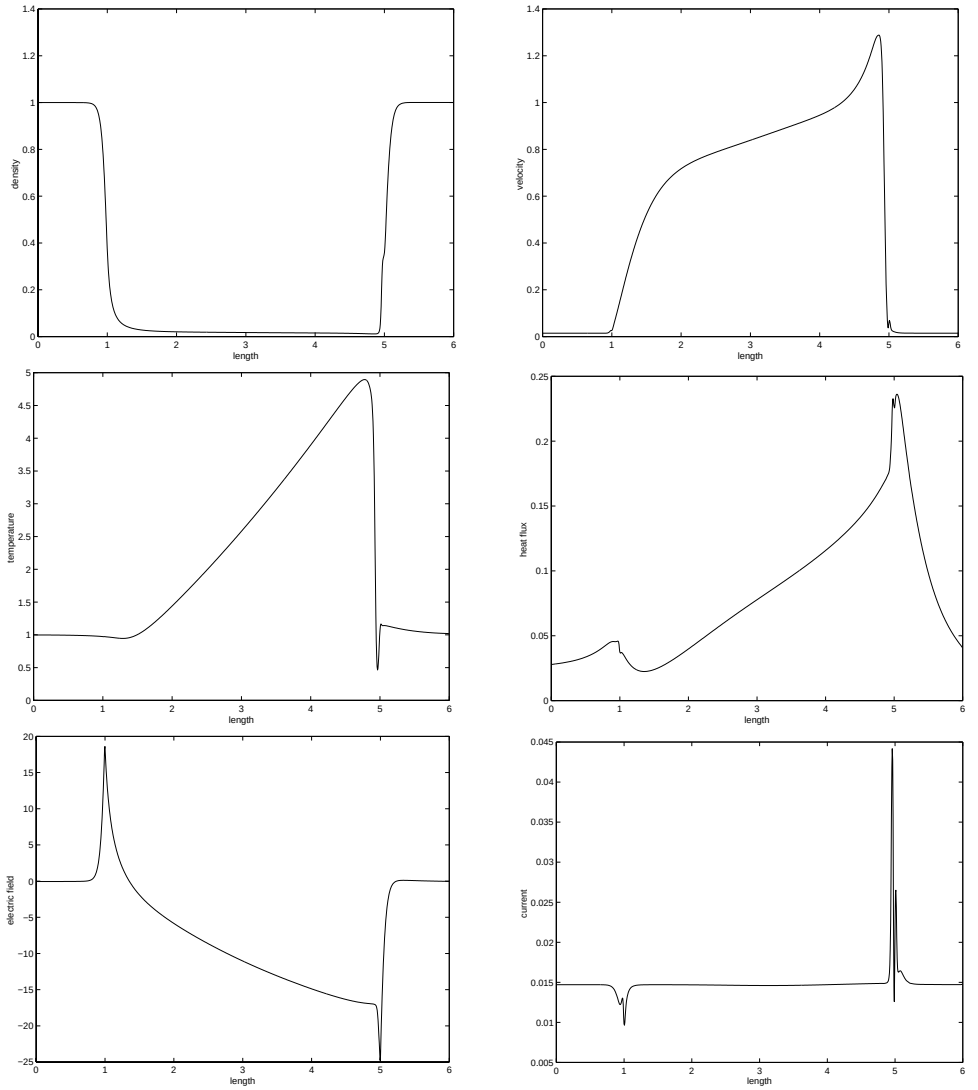

FIG. 5.3. *SLIC method solving the full EM for* 1 *volt bias (discontinuous initial density); steady-state profiles for various physical variables.*

not exactly constant in the vicinity of the junctions. Previous studies have shown that the magnitude of the error is related to the order of accuracy of the method and, consequently, to the width of the computational cells, i.e., the error can be decreased by using a method of higher order of accuracy. Alternatively, for a given order of accuracy, the error can be decreased by increasing the number of computational cells. The error apparent from Figure 5.1 is of the same order as for similar second order methods and tends to vanish as the number of computational cells increases.

5.2. Full EM calculations. The full system of equations was integrated at a zero and a finite-value bias. The former can be used to calculate the junction capacitance and the voltage across the junction. Also, since the velocity and current must go to zero, it also serves as an indication of the accuracy of the numerical model.

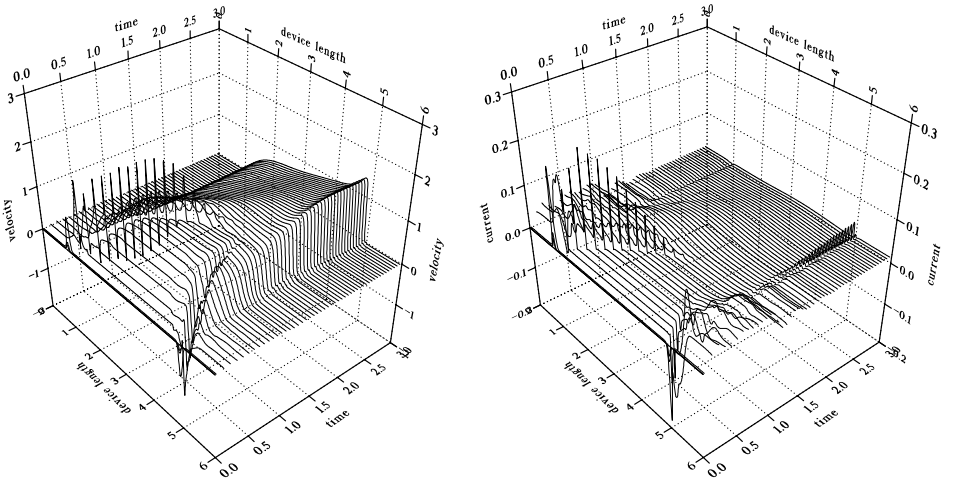

FIG. 5.4. *SLIC method solving the full EM for* 1 *V bias (discontinuous initial density); transient profiles for velocity and current.*

The evolution of the field can be seen in Figure 5.2; electrons expand in both directions of the channel, creating electron waves which reach steady state by $t = 3$ picoseconds. There are no oscillations present in the velocity field, as was reported in the paper by Fatemi, Jerome, and Osher [15]. There is, however, a residual value of current at the location of the junctions, albeit of an order of magnitude smaller than the maximum value reached during this test.

A bias of 1 volt was then applied across the device. Figure 5.3 shows the distribution of the variables at steady state (t=5 picoseconds), while results as a function of time are shown in Figure 5.4. The steady-state plots show no spurious oscillations near steep gradients of the field variables. The small unphysical negative velocity usually observed in the region of the left junction is absent from these calculations. The "bump" usually observed in the vicinity of the right junction is just visible, but not pronounced; initial results suggest that its magnitude and spacial extent is a function of the initial thickness of the junction (the wider the junction, the more pronounced the bump is).

The time-evolution plots show that during the initial stages of the evolution, the strong shock waves (emanating from the locations of the initial density discontinuities) propagate from the junctions towards the middle of the channel. At approximately t =1.5 they begin to attenuate; the wave propagating from the left adds to the constant increase of the velocity in the middle of the channel, to form the "ramp" of the steady-state velocity profile, while the one from the right contributes to the formation of the pronounced "spike." The evolution of the latter coincides with the formation of a spike in the current distribution, which persists even after steady state has been reached. If the transient behavior is to be studied in detail, the existence of these strong shock waves necessitates the use of TVD methods.

These results compare favorably to the ones presented in the paper by Anile and Muscato [4], where a direct solution of the steady-state equations is reached using a method similar to Gardner's [17]. A similar calculation for the transients has been performed by Jerome and Shu [23], albeit for a different model (Baccarani and Wordeman [9]) using an essentially nonoscillatory (ENO) scheme. In both case stud-

ies nonlinear waves arise, but detailed comparison is not meaningful because of the substantial differences in the models.

By comparing the results of the reduced model and of the full model with the same physical and computational parameters, we notice that they differ only slightly (the reduced model shows a higher velocity peak and a lower energy peak), but otherwise the bulk features are essentially the same. Therefore, since the full model presents a more significant computational challenge (in terms of the singularities arising from the nonlinearity and the added computational expense), the reduced model can be used for parametric studies, and once the relevant parameters have been estimated, more detailed simulations can be carried out using the full model.

6. Conclusions. A second order scheme for the solution of hyperbolic conservation laws, namely SLIC, has been implemented to solve the extended hydrodynamical semiconductor equations. Other conventional methods have been used to evaluate the source terms and the Poisson equation which is coupled with this system. The scheme is second order accurate in space and time, and it belongs to the high-resolution class of methods. As it is expected from schemes of this class, it is conservative, monotone, and it can resolve discontinuous solutions over very few computational cells.

Our motivation to use this scheme stems from its low computational cost, ease of implementation, and lack of arbitrary, user-adjusted parameters. The current implementation has an automatic selection of the optimum timestep, so that every iteration remains as close as possible to the scheme's stability limit, thus reducing truncation errors and keeping the CPU time as low as possible. Test problems which have an exact solution show that SLIC retains these qualities when used for the integration of a system as complex as the extended hydrodyamical semiconductor equations. Because the scheme does not have user-adjusted parameters and it does not need a special computational stencil, it can be used for multidimensional discretizations on domains of arbitrary geometry and can also be used in conjuction with adaptive mesh refinement software without any implementation complications.

The latest developments in semiconductor technology for ultrafast phenomena in electron devices require new approaches for their numerical simulation. In this article we have implemented a method used in other disciplines which deal with highly nonlinear phenomena and have shown that it is effective in accurately capturing the transient evolution of the electron flow to steady state in a submicron diode.

A LEGENDRE SPECTRAL GALERKIN METHOD FOR THE BIHARMONIC DIRICHLET PROBLEM*

BERNARD BIALECKI† AND ANDREAS KARAGEORGHIS‡

Abstract. A Legendre spectral Galerkin method is presented for the solution of the biharmonic Dirichlet problem on a square. The solution and its Laplacian are approximated using the set of basis functions suggested by Shen, which are linear combinations of two Legendre polynomials. A Schur complement approach is used to reduce the resulting linear system to one involving the approximation of the Laplacian of the solution on the two vertical sides of the square. The Schur complement system is solved by a preconditioned conjugate gradient method or the Cholesky method. The total cost of the algorithm is $O(N^3)$. Numerical results demonstrate the spectral convergence of the method.

1. Introduction.

The aim of this work is to propose a Legendre spectral Galerkin method for the solution of the biharmonic Dirichlet problem. This problem has been the subject of several studies in recent years. Our work is related to the papers of Shen [7] and Bjørstad and Tjøstheim [3], whose approach is based on the standard variational formulation of the fourth order differential equation. Our approach is based on the mixed method of Ciarlet and Raviart [4] which gives rise to a variational formulation for two second order differential equations. A similar approach has been recently applied in the Legendre spectral collocation solution of the same problem [2].

The formulation of the biharmonic Legendre spectral Galerkin problem and the method of solution are similar to those developed in [5] for the finite element Galerkin method with piecewise Hermite bicubics.

In this study we consider the biharmonic Dirichlet problem

$$\Delta^2 u = f \text{ in } \Omega, \qquad u = \partial u/\partial n = 0 \text{ on } \partial\Omega, \tag{1.1}$$

where Δ denotes the Laplacian, $\Omega = (-1,1)\times(-1,1)$, $\partial\Omega$ is the boundary of Ω, and $\partial/\partial n$ is the outward normal derivative on $\partial\Omega$.

We set $v = \Delta u$ and discretize a coupled pair of Poisson's equations in u and v using a Galerkin method with polynomials of degree $\leq N$. Employing a Schur complement approach, we reduce the Galerkin problem to a Schur complement system involving an approximation to v on the two vertical sides of $\partial\Omega$ and an auxiliary Galerkin problem for a related biharmonic problem with v, instead of $\partial u/\partial n$, specified on the two vertical sides of $\partial\Omega$. The Schur complement system with a symmetric positive definite matrix is solved by the preconditioned conjugate gradient (PCG) method

or the Cholesky method. A preconditioner for PCG is obtained from the Galerkin problem for a related biharmonic problem with v instead of $\partial u/\partial n$ specified on the two horizontal sides of $\partial\Omega$. We conjecture that the preconditioner is spectrally equivalent to the Schur complement matrix. The cost of multiplying the Schur complement matrix by a vector is $4N^2 + O(N)$ and the cost of solving a linear system with the preconditioner is $O(N)$. With the number of PCG iterations equal to $c \log N$, the dominant cost of solving the Schur complement system is $c4N^2 \log N$. The solution of the auxiliary Galerkin problem is obtained at a cost $2N^3 + O(N^2)$ using separation of variables and the solution of a simple eigenvalue problem which reduces to two symmetric eigenvalue problems with tridiagonal matrices. Hence the dominant cost of our PCG algorithm is $2N^3 + c4N^2 \log N$. The dominant cost of our Cholesky algorithm is $8N^3/3$. Both algorithms are well suited for parallel implementation since many of their steps involve independent matrix-vector multiplications. Numerical results demonstrate the spectral convergence rate of the approximations to u and v in the maximum norm.

In section 2 we introduce two polynomial spaces, the corresponding basis functions, and Galerkin matrices. We also discuss the solution of the linear system corresponding to a one-dimensional biharmonic problem. The spectral Galerkin biharmonic problem and its solution are discussed in sections 3 and 4, respectively. Numerical results are presented in section 5 and concluding remarks are given in section 6.

2. Preliminaries. For an integer $N \geq 2$, let

$$P_N^0 = \{p \in P_N : p(\pm 1) = 0\},$$

where P_k denotes the set of polynomials of degree $\leq k$ on $(-1, 1)$. (Note that the dimensions of P_N and P_N^0 are $N + 1$ and $N - 1$, respectively.) Following (2.7) of [7], we introduce the basis $\{\phi_k\}_{k=2}^N$ for P_N^0 with

$$\phi_k(x) = \frac{1}{\sqrt{4k-2}}[L_{k-2}(x) - L_k(x)], \qquad k = 2, \ldots, N,$$

where $L_k(x)$ is the kth degree Legendre polynomial normalized by $\int_{-1}^1 L_k^2(x)\,dx = 2/(2k+1)$. Augmenting the basis $\{\phi_k\}_{k=2}^N$ for P_N^0 by

$$\phi_0(x) = \frac{\sqrt{6}}{2}L_0(x), \qquad \phi_1(x) = \frac{3\sqrt{10}}{2}L_1(x), \tag{2.1}$$

we obtain the basis $\{\phi_k\}_{k=0}^N$ for P_N.

With $(p, q) = \int_{-1}^1 (pq)(x)\,dx$, we introduce the Galerkin matrices

$$A = [(\phi_i', \phi_k')]_{i,k=2}^N, \qquad B = [(\phi_i, \phi_k)]_{i,k=2}^N, \tag{2.2}$$

$$A_t = [(\phi_i', \phi_k')]_{i=2,k=0}^{N,1}, \qquad B_t = [(\phi_i, \phi_k)]_{i=2,k=0}^{N,1}, \tag{2.3}$$

and

$$B_s = [(\phi_i, \phi_k)]_{i,k=0}^1, \tag{2.4}$$

where i and k are the row and column indices, respectively. It follows from Lemma 2.1 in [7] that

$$A = I_{N-1}, \qquad B = \begin{bmatrix} \times & & \times & & & & \\ & \times & & \times & & & \\ \times & & \times & & \times & & \\ & \ddots & & \ddots & & \ddots & \\ & & \times & & \times & & \times \\ & & & \times & & \times & \\ & & & & \times & & \times \end{bmatrix}, \tag{2.5}$$

where I_k is the $k \times k$ identity matrix and the symbols $\times$ denote the only nonzero matrix coefficients. The matrix B is clearly symmetric and positive definite.

Since $\phi_k(\pm 1) = 0$, $k = 2, \ldots, N$, and $\phi_0'' = \phi_1'' = 0$, using integration by parts and the orthonormality of the Legendre polynomials we obtain

$$A_t = O, \qquad B_t = \begin{bmatrix} 1 & 0 \\ 0 & 1 \\ 0 & 0 \\ \vdots & \vdots \\ 0 & 0 \end{bmatrix}, \qquad B_s = \begin{bmatrix} 3 & 0 \\ 0 & 15 \end{bmatrix}. \tag{2.6}$$

For $\lambda > 0$ consider the linear system

$$\begin{aligned} R_{11}\,[\vec{u}, \vec{v}]^T + R_{12}\,[v_0, v_1]^T &= \left[\vec{g}, \vec{f}\right]^T, \\ R_{21}\,[\vec{u}, \vec{v}]^T + R_{22}[v_0, v_1]^T &= [g_0, g_1]^T, \end{aligned} \tag{2.7}$$

where

$$\vec{u} = [u_2, \ldots, u_N]^T, \qquad \vec{v} = [v_2, \ldots, v_N]^T,$$

$$\vec{g} = [g_2, \ldots, g_N]^T, \qquad \vec{f} = [f_2, \ldots, f_N]^T,$$

$$R_{11} = \begin{bmatrix} B + \lambda I_{N-1} & \lambda B \\ O & B + \lambda I_{N-1} \end{bmatrix}, \tag{2.8}$$

and

$$R_{12} = \begin{bmatrix} \lambda B_t \\ B_t \end{bmatrix}, \qquad R_{21} = \begin{bmatrix} B_t^T, \lambda B_t^T \end{bmatrix}, \qquad R_{22} = \lambda B_s. \tag{2.9}$$

Assume that N is even and introduce the vectors

$$\vec{u}^{(0)} = [u_2, u_4, \ldots, u_N]^T, \qquad \vec{u}^{(1)} = [u_3, u_5, \ldots, u_{N-1}]^T.$$

For $i = 0, 1$, let the vectors $\vec{v}^{(i)}$, $\vec{g}^{(i)}$, and $\vec{f}^{(i)}$ be defined in a similar way. Since B in (2.5) consists of two tridiagonal matrices B_0 and B_1 and since B_s in (2.6) is diagonal, (2.7) splits into two systems

$$\begin{aligned} A_i \left[\vec{u}^{(i)}, \vec{v}^{(i)}\right]^T + \vec{p} v_i &= \left[\vec{g}^{(i)}, \vec{f}^{(i)}\right]^T, \\ \vec{q} \left[\vec{u}^{(i)}, \vec{v}^{(i)}\right]^T + d_i v_i &= g_i \end{aligned} \tag{2.10}$$

for $i = 0, 1$, where

$$A_i = \begin{bmatrix} B_i + \lambda I_{N/2-i} & \lambda B_i \\ O & B_i + \lambda I_{N/2-i} \end{bmatrix} \tag{2.11}$$

and

$$\vec{p} = [\lambda, 0, \ldots, 0, 1, 0, \ldots, 0]^T, \quad \vec{q} = [1, 0, \ldots, 0, \lambda, 0, \ldots, 0], \quad d_0 = 3\lambda, \quad d_1 = 15\lambda. \tag{2.12}$$

It can be shown that the matrix in (2.10) is nonsingular. Moreover, A_i is nonsingular since $B_i + \lambda I_{N/2-i}$ is positive definite. Solving the first equation of (2.10) for $[\vec{u}^{(i)}, \vec{v}^{(i)}]$ and substituting it into the second equation of (2.10), we obtain

$$v_i = (g_i - \vec{s}^{(i)}[\vec{g}^{(i)}, \vec{f}^{(i)}]^T)/\delta_i, \tag{2.13}$$

where

$$\vec{s}^{(i)} = \vec{q} A_i^{-1}, \quad \delta_i = d_i - \vec{s}^{(i)}\vec{p}. \tag{2.14}$$

The vector $\vec{s}^{(i)}$ and the number δ_i can be computed with costs $O(N)$ and $O(1)$, respectively. Once the number v_i of (2.13) has been evaluated at cost $O(N)$, $\vec{u}^{(i)}$ and $\vec{v}^{(i)}$ of (2.10) can be obtained with cost $O(N)$ by solving two systems with the same tridiagonal positive definite matrix $B_i + \lambda I_{N/2-i}$. Therefore, the cost of solving (2.7) is $O(N)$.

Throughout the paper we use the symbol $\otimes$ to denote the tensor product of matrices and the tensor product of function spaces. Let I, J, K, and L be finite sets of increasing indices. Without loss of generality we assume

$$I = \{1, \ldots, M_1\}, \quad K = \{1, \ldots, N_1\}, \quad J = \{1, \ldots, M_2\}, \quad L = \{1, \ldots, N_2\}.$$

Then the matrix-vector form of

$$z_{i,j} = \sum_{k \in K} c^{(1)}_{i,k} \sum_{l \in L} c^{(2)}_{j,l} w_{k,l}, \quad i \in I, \quad j \in J, \tag{2.15}$$

is

$$\vec{z} = (C_1 \otimes C_2)\vec{w}, \tag{2.16}$$

where

$$C_1 = (c^{(1)}_{i,k})_{i \in I, k \in K}, \quad C_2 = (c^{(2)}_{j,l})_{j \in J, l \in L},$$

and

$$\vec{z} = [z_{1,1}, \ldots, z_{1,M_2}, \ldots, z_{M_1,1}, \ldots, z_{M_1,M_2}]^T,$$
$$\vec{w} = [w_{1,1}, \ldots, w_{1,N_2}, \ldots, w_{N_1,1}, \ldots, w_{N_1,N_2}]^T.$$

3. Biharmonic spectral Galerkin problem. Introducing $v = \Delta u$ in (1.1), we obtain the coupled problem (see Figure 1)

$$\begin{aligned} -\Delta u + v = 0 \text{ in } \Omega, \quad u = 0 \text{ on } \partial\Omega, \quad \partial u/\partial n = 0 \text{ on } \partial\Omega, \\ -\Delta v = -f \text{ in } \Omega. \end{aligned} \tag{3.1}$$

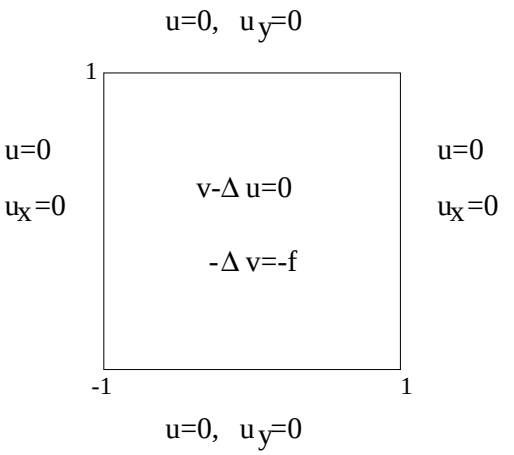

FIG. 1. *Coupled problem* (3.1).

The weak form of (3.1), obtained using Green's formula, is

$$\int_\Omega \nabla u \nabla \eta \, d\Omega + \int_\Omega v\eta \, d\Omega = 0, \qquad \eta \in H^1(\Omega),$$
$$\int_\Omega \nabla v \nabla \delta \, d\Omega = -\int_\Omega f\delta \, d\Omega, \qquad \delta \in H_0^1(\Omega).$$

Let

$$X_N = \{w \in P_N \otimes P_N : w(\alpha,\beta) = 0, \alpha,\beta = \pm 1\}, \qquad X_N^0 = P_N^0 \otimes P_N^0.$$

The corner conditions $w(\alpha,\beta) = 0$, $\alpha,\beta = \pm 1$, in the definition of X_N are motivated by the fact that

$$v(\alpha,\beta) = u_{xx}(\alpha,\beta) + u_{yy}(\alpha,\beta) = 0, \qquad \alpha,\beta = \pm 1.$$

The Legendre spectral Galerkin problem for (3.1) consists of finding $U \in X_N^0$ and $V \in X_N$ such that

$$\int_\Omega \nabla U \nabla \eta \, d\Omega + \int_\Omega V\eta \, d\Omega = 0, \qquad \eta \in X_N, \tag{3.2}$$

$$\int_\Omega \nabla V \nabla \delta \, d\Omega = -\int_\Omega f\delta \, d\Omega, \qquad \delta \in X_N^0. \tag{3.3}$$

THEOREM 3.1. *There exist unique $U \in X_N^0$ and $V \in X_N$ satisfying* (3.2)–(3.3).

Proof. Since in (3.2)–(3.3) the number of constraints is equal to the number of degrees of freedom, we assume that $f = 0$ and show that $U = V = 0$. Taking $\eta = V$ in (3.2) and $\delta = U$ in (3.3), we obtain

$$\int_\Omega \nabla U \nabla V \, d\Omega + \int_\Omega V^2 \, d\Omega = 0, \qquad \int_\Omega \nabla V \nabla U \, d\Omega = 0,$$

which gives $\int_\Omega V^2 \, d\Omega = 0$, $V = 0$. With $V = 0$ and $\eta = U$, (3.2) becomes $\int_\Omega \nabla U \nabla U \, d\Omega = 0$, which implies $U = 0$ by the Poincaré inequality. ∎

Using the basis functions $\{\phi_k\}_{k=0}^N$ of section 2 for $U \in X_N^0$ and $V \in X_N$, we have

$$U(x,y) = \sum_{k=2}^{N}\sum_{l=2}^{N} u_{k,l}\phi_k(x)\phi_l(y) \tag{3.4}$$

and

$$V(x,y) = \sum_{k=2}^{N}\sum_{l=2}^{N} v_{k,l}\phi_k(x)\phi_l(y) + \sum_{k=2}^{N}\sum_{l=0}^{1} v_{k,l}\phi_k(x)\phi_l(y) + \sum_{k=0}^{1}\sum_{l=2}^{N} v_{k,l}\phi_k(x)\phi_l(y), \tag{3.5}$$

where we used properties of ϕ_0 and ϕ_1 of (2.1) in the derivation of (3.5). Corresponding to (3.4) and (3.5) we introduce the vectors

$$\vec{u} = [u_{2,2}, \ldots, u_{2,N}, \ldots, u_{N,2}, \ldots, u_{N,N}]^T, \tag{3.6}$$

$$\vec{v} = [v_{2,2}, \ldots, v_{2,N}, \ldots, v_{N,2}, \ldots, v_{N,N}]^T, \tag{3.7}$$

$$\vec{v}_h = [v_{2,0}, v_{2,1}, \ldots, v_{N,0}, v_{N,1}]^T, \tag{3.8}$$

$$\vec{v}_v = [v_{0,2}, \ldots, v_{0,N}, v_{1,2}, \ldots, v_{1,N}]^T. \tag{3.9}$$

Substituting (3.4), (3.5) into (3.2)–(3.3), taking $\eta = \phi_i(x)\phi_j(y)$, $i,j = 2,\ldots,N$, $\delta = \phi_i(x)\phi_j(y)$, $i,j = 2,\ldots,N$, $\eta = \phi_i(x)\phi_j(y)$, $i = 2,\ldots,N$, $j = 0,1$, $\eta = \phi_i(x)\phi_j(y)$, $i = 0,1$, $j = 2,\ldots,N$, and using (2.15), (2.16), (2.2)–(2.6), we obtain, respectively,

$$\begin{gathered}
(I_{N-1}\otimes B + B\otimes I_{N-1})\vec{u} + (B\otimes B)\vec{v} + (B\otimes B_t)\vec{v}_h + (B_t\otimes B)\vec{v}_v = \vec{0},\\
(I_{N-1}\otimes B + B\otimes I_{N-1})\vec{v} + (I_{N-1}\otimes B_t)\vec{v}_h + (B_t\otimes I_{N-1})\vec{v}_v = \vec{f},\\
(I_{N-1}\otimes B_t^T)\vec{u} + (B\otimes B_t^T)\vec{v} + (B\otimes B_s)\vec{v}_h + (B_t\otimes B_t^T)\vec{v}_v = \vec{0},\\
(B_t^T\otimes I_{N-1})\vec{u} + (B_t^T\otimes B)\vec{v} + (B_t^T\otimes B_t)\vec{v}_h + (B_s\otimes B)\vec{v}_v = \vec{0},
\end{gathered} \tag{3.10}$$

where

$$\vec{f} = [f_{2,2}, \ldots, f_{2,N}, \ldots, f_{N,2}, \ldots, f_{N,N}]^T \tag{3.11}$$

and

$$f_{i,j} = -\int_\Omega f\phi_i(x)\phi_j(y)\,d\Omega.$$

Using the N-point Gauss–Legendre quadrature in the x and y coordinates, with nodes $\{\xi_k\}_{k=1}^N$ and weights $\{w_k\}_{k=1}^N$, we approximate $\vec{f}$ by

$$\vec{f} \approx -(CD\otimes CD)\left[f(\xi_1,\xi_1), \ldots, f(\xi_1,\xi_N), \ldots, f(\xi_N,\xi_1), \ldots, f(\xi_N,\xi_N)\right]^T, \tag{3.12}$$

where C and D are given by

$$C = [\phi_i(\xi_k)]_{i=2,k=1}^{N,N}, \qquad D = \text{ diag } (w_1, \ldots, w_N).$$

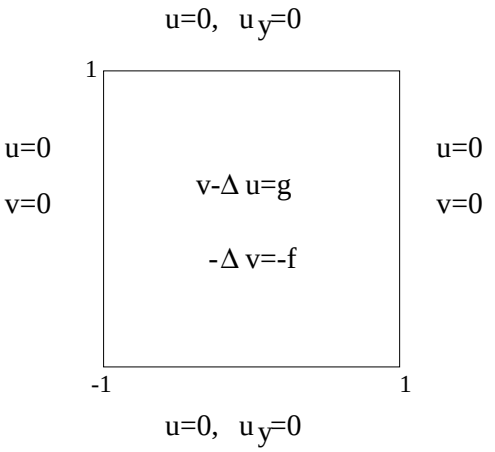

FIG. 2. *Auxiliary problem* (4.1).

The computation of the right-hand side of (3.12) requires $O(N^3)$ operations. The vector $\vec{f}$ can be also approximated in a slightly different and more efficient way using the approach described in [6].

Equations (3.10) can be written as

$$\begin{aligned} S_{11}\left[\vec{u},\vec{v},\vec{v}_h\right]^T + S_{12}\vec{v}_v &= \left[\vec{0},\vec{f},\vec{0}\right]^T, \\ S_{21}\left[\vec{u},\vec{v},\vec{v}_h\right]^T + S_{22}\vec{v}_v &= \vec{0}, \end{aligned} \tag{3.13}$$

where

$$S_{11} = \begin{bmatrix} I_{N-1}\otimes B + B\otimes I_{N-1} & B\otimes B & B\otimes B_t \\ O & I_{N-1}\otimes B + B\otimes I_{N-1} & I_{N-1}\otimes B_t \\ I_{N-1}\otimes B_t^T & B\otimes B_t^T & B\otimes B_s \end{bmatrix}, \tag{3.14}$$

$$S_{12} = \begin{bmatrix} B_t\otimes B \\ B_t\otimes I_{N-1} \\ B_t\otimes B_t^T \end{bmatrix}, \tag{3.15}$$

$$S_{21} = \begin{bmatrix} B_t^T\otimes I_{N-1}, B_t^T\otimes B, B_t^T\otimes B_t \end{bmatrix}, \tag{3.16}$$

$$S_{22} = B_s\otimes B. \tag{3.17}$$

In the remainder of the paper we describe an algorithm for solving (3.13) assuming that $\vec{f}$ or its approximation is given.

4. Solving the biharmonic linear system.

4.1. Inverse of S_{11}. The matrix S_{11} of (3.14) arises in the spectral Galerkin method for the auxiliary problem (see Figure 2)

$$\begin{aligned} -\Delta u + v = g \text{ in } \Omega, \quad u = 0 \text{ on } \partial\Omega, \quad \partial u/\partial n = 0 \text{ on } \partial\Omega_h, \\ -\Delta v = -f \text{ in } \Omega, \quad v = 0 \text{ on } \partial\Omega_v, \end{aligned} \tag{4.1}$$

where $\partial\Omega_h$ is the union of the horizontal sides of $\partial\Omega$ and $\partial\Omega_v$ is the union of the vertical sides of $\partial\Omega$. The weak form of (4.1) is

$$\int_\Omega \nabla u \nabla \eta \, d\Omega + \int_\Omega v\eta \, d\Omega = \int_\Omega g\eta \, d\Omega, \qquad \eta \in H^1(\Omega), \qquad \eta = 0 \text{ on } \partial\Omega_v,$$
$$\int_\Omega \nabla v \nabla \delta \, d\Omega = -\int_\Omega f\delta \, d\Omega, \qquad \delta \in H_0^1(\Omega).$$

The spectral Galerkin problem for (4.1) consists of finding $U \in X_N^0$ and $V \in P_N^0 \otimes P_N$ such that

$$\int_\Omega \nabla U \nabla \eta \, d\Omega + \int_\Omega V\eta \, d\Omega = \int_\Omega g\eta \, d\Omega, \qquad \eta \in P_N^0 \otimes P_N,$$
$$\int_\Omega \nabla V \nabla \delta \, d\Omega = -\int_\Omega f\delta \, d\Omega, \qquad \delta \in X_N^0. \tag{4.2}$$

LEMMA 4.1. *The matrix S_{11} of (3.14) is nonsingular.*

Proof. It can be shown, using an approach similar to the proof of Theorem 3.1, that (4.2) has a unique solution. ∎

Since B of (2.2) is symmetric, it is orthogonally similar to a diagonal matrix, that is, there exist real $Z = (z_{i,j})_{i,j=2}^N$ and real

$$\Lambda = \operatorname{diag}(\lambda_2, \ldots, \lambda_N) \tag{4.3}$$

such that

$$Z^T Z = I_{N-1}, \qquad Z^T B Z = \Lambda. \tag{4.4}$$

It follows from the structure of B in (2.5) that the computation of Λ and Z satisfying (4.3) and (4.4) reduces to solving two symmetric eigenvalue problems with tridiagonal matrices. With the use of the QR algorithm for evaluating eigenvalues and the inverse iteration for evaluating the corresponding eigenvectors, Λ and Z can be precomputed with cost $O(N^2)$. Moreover, the coefficients of Z are such that

$$z_{i,j} = 0 \quad \text{if} \quad i + j \text{ is odd}. \tag{4.5}$$

Let

$$W = \begin{bmatrix} Z \otimes I_{N-1} & O & O \\ O & Z \otimes I_{N-1} & O \\ O & O & Z \otimes I_2 \end{bmatrix}. \tag{4.6}$$

Then using (3.14) and (4.4), we obtain

$$W^T S_{11} W = G,$$

where

$$G = \begin{bmatrix} I_{N-1} \otimes B + \Lambda \otimes I_{N-1} & \Lambda \otimes B & \Lambda \otimes B_t \\ O & I_{N-1} \otimes B + \Lambda \otimes I_{N-1} & I_{N-1} \otimes B_t \\ I_{N-1} \otimes B_t^T & \Lambda \otimes B_t^T & \Lambda \otimes B_s \end{bmatrix}. \tag{4.7}$$

Since W is orthogonal, it follows that

$$S_{11}^{-1} = W G^{-1} W^T. \tag{4.8}$$

Let the vectors $\vec{u}$, $\vec{v}$, $\vec{v}_h$, and $\vec{f}$ have the forms given in (3.6), (3.7), (3.8), and (3.11), respectively, and let

$$\vec{g} = [g_{2,2}, \ldots, g_{2,N}, \ldots, g_{N,2}, \ldots, g_{N,N}]^T, \qquad \vec{g}_h = [g_{2,0}, g_{2,1}, \ldots, g_{N,0}, g_{N,1}]^T. \tag{4.9}$$

In the following, the vectors $\vec{u}'$, $\vec{v}'$, $\vec{v}'_h$, $\vec{f}'$, $\vec{g}'$, and $\vec{g}'_h$ have the same forms as $\vec{u}$, $\vec{v}$, $\vec{v}_h$, $\vec{f}$, $\vec{g}$, and $\vec{g}_h$, respectively. The components of the primed vectors are denoted by the primed letters corresponding to the unprimed vectors. For example,

$$\vec{u}' = [u'_{2,2}, \ldots, u'_{2,N}, \ldots, u'_{N,2}, \ldots, u'_{N,N}]^T, \qquad \vec{v}'_h = [v'_{2,0}, v'_{2,1}, \ldots, v'_{N,0}, v'_{N,1}]^T.$$

Consider the computation of

$$[\vec{u}', \vec{v}', \vec{v}'_h]^T = G^{-1}[\vec{g}', \vec{f}', \vec{g}'_h]^T. \tag{4.10}$$

It follows from (4.7) that (4.10) is equivalent to the system

$$\begin{aligned}
(I_{N-1} \otimes B + \Lambda \otimes I_{N-1})\vec{u}' + (\Lambda \otimes B)\vec{v}' + (\Lambda \otimes B_t)\vec{v}'_h &= \vec{g}', \\
(I_{N-1} \otimes B + \Lambda \otimes I_{N-1})\vec{v}' + (I_{N-1} \otimes B_t)\vec{v}'_h &= \vec{f}', \\
(I_{N-1} \otimes B_t^T)\vec{u}' + (\Lambda \otimes B_t^T)\vec{v}' + (\Lambda \otimes B_s)\vec{v}'_h &= \vec{g}'_h,
\end{aligned}$$

which, from (4.3), becomes

$$\begin{aligned}
R_{11}^{(k)} \left[\vec{u}'_{k,\cdot}, \vec{v}'_{k,\cdot}\right]^T + R_{12}^{(k)} \left[v'_{k,0}, v'_{k,1}\right]^T &= \left[\vec{g}'_{k,\cdot}, \vec{f}'_{k,\cdot}\right]^T, \\
R_{21}^{(k)} \left[\vec{u}'_{k,\cdot}, \vec{v}'_{k,\cdot}\right]^T + R_{22}^{(k)} [v'_{k,0}, v'_{k,1}]^T &= [g'_{k,0}, g'_{k,1}]^T
\end{aligned} \tag{4.11}$$

for $k = 2, \ldots, N$, where the $R_{ij}^{(k)}$ are given by (2.8), (2.9) with λ replaced by λ_k, and

$$\vec{u}'_{k,\cdot} = [u'_{k,2}, \ldots, u'_{k,N}]^T, \qquad \vec{v}'_{k,\cdot} = [v'_{k,2}, \ldots, v'_{k,N}]^T,$$

$$\vec{g}'_{k,\cdot} = [g'_{k,2}, \ldots, g'_{k,N}]^T, \qquad \vec{f}'_{k,\cdot} = [f'_{k,2}, \ldots, f'_{k,N}]^T.$$

Since B is positive definite, it follows from the second equation in (4.4) that Λ is positive definite and hence, by (4.3), $\lambda_k > 0$, $k = 2, \ldots, N$. Clearly (4.11) is of the same form as (2.7) with λ replaced by λ_k. Hence it follows from the discussion in section 2 that $[\vec{u}', \vec{v}', \vec{v}'_h]^T$ of (4.10) can be computed with cost $O(N^2)$. Also it follows from (2.13) that in the special case of $\vec{g}' = \vec{f}' = \vec{0}$, $\vec{v}'_h$ of (4.10) can be obtained with cost $O(N)$.

4.2. Description of the algorithm. Since S_{11} is nonsingular (see Lemma 4.1), eliminating $[\vec{u}, \vec{v}, \vec{v}_h]^T$ from (3.13), and using (4.8), (4.6), we obtain

$$S\vec{v}_v = -S_{21}WG^{-1} \left[\vec{0}, (Z^T \otimes I_{N-1})\vec{f}, \vec{0}\right]^T, \tag{4.12}$$

where S is the $2(N-1) \times 2(N-1)$ Schur complement matrix given by

$$S = S_{22} - S_{21}S_{11}^{-1}S_{12}. \tag{4.13}$$

(S is the Schur complement of S_{11} in $\left[\begin{smallmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{smallmatrix}\right]$.) It also follows from (3.13), (4.8), and (4.6) that

$$[\vec{u}, \vec{v}, \vec{v}_h]^T = WG^{-1}\{[\vec{0}, (Z^T \otimes \vec{f}, \vec{0})] - W^T S_{12}\vec{v}_v\}. \tag{4.14}$$

Using (4.12), (4.14), and (4.6) we arrive at the following algorithm for solving (3.13).

ALGORITHM.

Step 1. Compute $\vec{f}' = (Z^T \otimes I_{N-1})\vec{f}$.

Step 2. Compute $[\vec{u}', \vec{v}', \vec{v}_h']^T = G^{-1}[\vec{0}, \vec{f}', \vec{0}]^T$.

Step 3. Compute $\vec{r} = -S_{21}[\vec{u}, \vec{v}, \vec{v}_h]^T$, where $\vec{u} = (Z \otimes I_{N-1})\vec{u}'$, $\vec{v} = (Z \otimes I_{N-1})\vec{v}'$, $\vec{v}_h = (Z \otimes I_2)\vec{v}_h'$.

Step 4. Solve $S\vec{v}_v = \vec{r}$ for $\vec{v}_v$.

Step 5. Compute $\vec{g}' = (Z^T \otimes I_{N-1})\vec{g}$, $\vec{f}'' = (Z^T \otimes I_{N-1})\vec{f}$, $\vec{g}_h' = (Z^T \otimes I_2)\vec{g}_h$, where $[\vec{g}, \vec{f}, \vec{g}_h]^T = S_{12}\vec{v}_v$.

Step 6. Compute $[\vec{g}'', \vec{f}''', \vec{g}_h'']^T = [\vec{0}, \vec{f}', \vec{0}]^T - [\vec{g}', \vec{f}'', \vec{g}_h']^T$.

Step 7. Compute $[\vec{u}', \vec{v}', \vec{v}_h']^T = G^{-1}[\vec{g}'', \vec{f}''', \vec{g}_h'']^T$.

Step 8. Compute $\vec{u} = (Z \otimes I_{N-1})\vec{u}'$, $\vec{v} = (Z \otimes I_{N-1})\vec{v}'$,$\vec{v}_h = (Z \otimes I_2)\vec{v}_h'$.

It follows from (4.5) that the cost of Step 1 is $N^3 + O(N^2)$ and the cost of Step 8 is $2N^3 + O(N^2)$. However, if the approximation to $v = \Delta u$ is not required, then the cost of Step 8 is only $N^3 + O(N^2)$. It follows from the discussion in section 4.1 that the costs of Steps 2 and 7 are $O(N^2)$ each. Clearly, the cost of Step 6 is also $O(N^2)$.

Let $\vec{u}$, $\vec{v}$, and $\vec{v}_h$ be of the forms given in (3.6), (3.7), and (3.8), respectively, and let, for $k = 2, \ldots, N$,

$$\vec{u}_{k,\cdot} = [u_{k,2}, \ldots, u_{k,N}]^T, \qquad \vec{v}_{k,\cdot} = [v_{k,2}, \ldots, v_{k,N}]^T.$$

Then it follows from (3.16) and (2.6) that

$$S_{21}[\vec{u}, \vec{v}, \vec{v}_h]^T = [\vec{u}_{2,\cdot}, \vec{u}_{3,\cdot}]^T + [B\vec{v}_{2,\cdot}, B\vec{v}_{3,\cdot}]^T + [v_{2,0}, v_{2,1}, 0, \ldots, 0, v_{3,0}, v_{3,1}, 0, \ldots, 0]^T. \tag{4.15}$$

Hence the cost of Step 3 is $O(N^2)$.

Let $\vec{v}_v$, $\vec{f}$, and $\vec{g}$, $\vec{g}_h$ be of the forms given in (3.9), (3.11), and (4.9), respectively. Let

$$\vec{v}_v^{(0)} = [v_{0,2}, \ldots, v_{0,N}]^T, \qquad \vec{v}_v^{(1)} = [v_{1,2}, \ldots, v_{1,N}]^T, \tag{4.16}$$

and let, for $k = 2, \ldots, N$,

$$\vec{f}_{k,\cdot} = [f_{k,2}, \ldots, f_{k,N}]^T, \qquad \vec{g}_{k,\cdot} = [g_{k,2}, \ldots, g_{k,N}]^T.$$

Then it follows from (3.15) and (2.6) that for

$$[\vec{g}, \vec{f}, \vec{g}_h] = S_{12}\vec{v}_v, \tag{4.17}$$

we have

$$\vec{g}_{2,\cdot} = B\vec{v}_v^{(0)}, \quad \vec{g}_{3,\cdot} = B\vec{v}_v^{(1)}, \qquad \vec{f}_{2,\cdot} = \vec{v}_v^{(0)}, \quad \vec{f}_{3,\cdot} = \vec{v}_v^{(1)}, \qquad \vec{f}_{k,\cdot} = \vec{g}_{k,\cdot} = \vec{0}, \quad k = 4, \ldots, N, \tag{4.18}$$

$$g_{2,0} = v_{0,2}, \quad g_{2,1} = v_{0,3} \qquad g_{3,0} = v_{1,2}, \quad g_{3,1} = v_{1,3}, \qquad g_{k,0} = g_{k,1} = 0, \quad k = 4, \ldots, N. \tag{4.19}$$

Hence the cost of Step 5 is $O(N^2)$.

In the next subsection we discuss in more detail Step 4.

4.3. Solving systems with S.

THEOREM 4.1. *The matrix S of* (4.13) *is symmetric and positive definite.*

Proof. For $n = 1, 2$, and arbitrary

$$\vec{v}_v^{(n)} = [v_{0,2}^{(n)}, \ldots, v_{0,N}^{(n)}, v_{1,2}^{(n)}, \ldots, v_{1,N}^{(n)}]^T, \tag{4.20}$$

using (4.13), we obtain

$$(S\vec{v}_v^{(1)}, \vec{v}_v^{(2)})_{R^{2N-2}} = (S_{22}\vec{v}_v^{(1)}, \vec{v}_v^{(2)})_{R^{2N-2}} - (S_{21}S_{11}^{-1}S_{12}\vec{v}_v^{(1)}, \vec{v}_v^{(2)})_{R^{2N-2}}. \tag{4.21}$$

Let

$$\vec{u}^{(n)} = [u_{2,2}^{(n)}, \ldots, u_{2,N}^{(n)}, \ldots, u_{N,2}^{(n)}, \ldots, u_{N,N}^{(n)}]^T, \tag{4.22}$$

$$\vec{v}^{(n)} = [v_{2,2}^{(n)}, \ldots, v_{2,N}^{(n)}, \ldots, v_{N,2}^{(n)}, \ldots, v_{N,N}^{(n)}]^T, \tag{4.23}$$

$$\vec{v}_h^{(n)} = [v_{2,0}^{(n)}, v_{2,1}^{(n)}, \ldots, v_{N,0}^{(n)}, v_{N,1}^{(n)}]^T$$

be such that

$$S_{11}[\vec{u}^{(n)}, \vec{v}^{(n)}, \vec{v}_h^{(n)}]^T + S_{12}\vec{v}_v^{(n)} = \vec{0}. \tag{4.24}$$

Existence and uniqueness of $\vec{u}^{(n)}$, $\vec{v}^{(n)}$, and $\vec{v}_h^{(n)}$ follow from the nonsingularity of S_{11} (see Lemma 4.1). Then (4.21), (4.24), (3.17), and (3.16) give

$$\begin{aligned}(S\vec{v}_v^{(1)}, \vec{v}_v^{(2)})_{R^{2N-2}} &= (S_{22}\vec{v}_v^{(1)}, \vec{v}_v^{(2)})_{R^{2N-2}} + (S_{21}[\vec{u}^{(1)}, \vec{v}^{(1)}, \vec{v}_h^{(1)}]^T, \vec{v}_v^{(2)})_{R^{2N-2}} \\ &= ((B_s \otimes B)\vec{v}_v^{(1)}, \vec{v}_v^{(2)})_{R^{2N-2}} + ((B_t^T \otimes I_{N-1})\vec{u}^{(1)}, \vec{v}_v^{(2)})_{R^{2N-2}} \\ &\quad + ((B_t^T \otimes B)\vec{v}^{(1)}, \vec{v}_v^{(2)})_{R^{2N-2}} + ((B_t^T \otimes B_t)\vec{v}_h^{(1)}, \vec{v}_v^{(2)})_{R^{2N-2}}.\end{aligned} \tag{4.25}$$

Equation (4.24) is the matrix-vector form of the spectral Galerkin problem

$$\begin{aligned}\int_\Omega \nabla U^{(n)} \nabla \eta \, d\Omega + \int_\Omega V^{(n)} \eta \, d\Omega = 0, \quad \eta \in P_N^0 \otimes P_N, \\ \int_\Omega \nabla V^{(n)} \nabla \delta \, d\Omega = 0, \quad \delta \in X_N^0,\end{aligned} \tag{4.26}$$

where

$$U^{(n)}(x, y) = \sum_{k=2}^{N} \sum_{l=2}^{N} u_{k,l}^{(n)} \phi_k(x) \phi_l(y), \tag{4.27}$$

$$V^{(n)}(x, y) = V_i^{(n)}(x, y) + V_h^{(n)}(x, y) + V_v^{(n)}(x, y), \tag{4.28}$$

and

$$V_i^{(n)}(x, y) = \sum_{k=2}^{N} \sum_{l=2}^{N} v_{k,l}^{(n)} \phi_k(x) \phi_l(y), \tag{4.29}$$

$$V_h^{(n)}(x, y) = \sum_{k=2}^{N} \sum_{l=0}^{1} v_{k,l}^{(n)} \phi_k(x) \phi_l(y), \tag{4.30}$$

$$V_v^{(n)}(x,y) = \sum_{k=0}^{1}\sum_{l=2}^{N} v_{k,l}^{(n)}\phi_k(x)\phi_l(y). \tag{4.31}$$

Since $V_i^{(2)} + V_h^{(2)} \in P_N^0 \otimes P_N$ and $U^{(1)} \in X_N^0$, it follows from (4.28) and (4.26) that

$$\begin{aligned}\int_\Omega V^{(1)}V^{(2)}\,d\Omega &= \int_\Omega V^{(1)}V_v^{(2)}\,d\Omega + \int_\Omega V^{(1)}\left(V_i^{(2)} + V_h^{(2)}\right)d\Omega \\ &= \int_\Omega V^{(1)}V_v^{(2)}\,d\Omega - \int_\Omega \nabla U^{(1)}\nabla\left(V^{(2)} - V_v^{(2)}\right)d\Omega \\ &= \int_\Omega V_i^{(1)}V_v^{(2)}\,d\Omega + \int_\Omega V_h^{(1)}V_v^{(2)}\,d\Omega + \int_\Omega V_v^{(1)}V_v^{(2)}\,d\Omega + \int_\Omega \nabla U^{(1)}\nabla V_v^{(2)}\,d\Omega.\end{aligned} \tag{4.32}$$

Using (4.29), (4.31), (2.15), (2.16), (2.3), and (2.2) we have

$$\begin{aligned}\int_\Omega V_i^{(1)}V_v^{(2)}\,d\Omega &= \int_\Omega \left[\sum_{k=2}^{N}\sum_{l=2}^{N} v_{k,l}^{(1)}\phi_k(x)\phi_l(y)\right]\left[\sum_{i=0}^{1}\sum_{j=2}^{N} v_{i,j}^{(2)}\phi_i(x)\phi_j(y)\right]d\Omega \\ &= \sum_{i=0}^{1}\sum_{j=2}^{N}\left[\sum_{k=2}^{N}\int_{-1}^{1}\phi_i(x)\phi_k(x)\,dx\sum_{l=2}^{N}\int_{-1}^{1}\phi_j(y)\phi_l(y)\,dy v_{k,l}^{(1)}\right]v_{i,j}^{(2)} \\ &= ((B_t^T \otimes B)\vec{v}^{(1)}, \vec{v}_v^{(2)})_{R^{2N-2}}.\end{aligned} \tag{4.33}$$

In a similar way, using (4.30), (4.31), (4.27), (2.15), (2.16), and (2.2)–(2.4), we obtain

$$\int_\Omega V_h^{(1)}V_v^{(2)}\,d\Omega = ((B_t^T \otimes B_t)\vec{v}_h^{(1)}, \vec{v}_v^{(2)})_{R^{2N-2}}, \tag{4.34}$$

$$\int_\Omega V_v^{(1)}V_v^{(2)}\,d\Omega = ((B_s \otimes B)\vec{v}_v^{(1)}, \vec{v}_v^{(2)})_{R^{2N-2}}, \tag{4.35}$$

$$\int_\Omega \nabla U^{(1)}V_v^{(2)}\,d\Omega = ((B_t^T \otimes I_{N-1})\vec{u}^{(1)}, \vec{v}_v^{(2)})_{R^{2N-2}}. \tag{4.36}$$

Hence, it follows from (4.25) and (4.32)–(4.36) that

$$(S\vec{v}_v^{(1)}, \vec{v}_v^{(2)})_{R^{2N-2}} = \int_\Omega V^{(1)}V^{(2)}\,d\Omega, \tag{4.37}$$

which implies

$$(S\vec{v}_v^{(1)}, \vec{v}_v^{(2)})_{R^{2N-2}} = (S\vec{v}_v^{(2)}, \vec{v}_v^{(1)})_{R^{2N-2}}, \qquad \vec{v}_v^{(1)}, \vec{v}_v^{(2)} \in R^{2N-2}.$$

This proves the symmetry of S.

For $\vec{v}_v^{(1)} = \vec{v}_v^{(2)}$, (4.37) gives

$$(S\vec{v}_v^{(1)}, \vec{v}_v^{(1)})_{R^{2N-2}} = \int_\Omega [V^{(1)}]^2\,d\Omega.$$

This and the linear independence of the basis functions in $V^{(1)}$ of (4.28)–(4.31) show that S is positive definite. □

It follows from Theorem 4.1 that the PCG method is a good candidate for solving a linear system with S. Therefore, in the following, we discuss the matrix-vector multiplication involving S, the selection of a preconditioner, and the solution of a linear system with this preconditioner.

It follows from (4.13) that in order to multiply by S, we have to multiply by S_{22} and $S_{21}S_{11}^{-1}S_{12}$. Assume that N is even. Let $\vec{v}_v$ and $\vec{v}_v^{(0)}$, $\vec{v}_v^{(1)}$ be as in (3.9) and (4.16), respectively. Then it follows from (3.17) and (2.6) that

$$S_{22}\vec{v}_v = [3B\vec{v}_v^{(0)}, 15B\vec{v}_v^{(1)}]^T. \tag{4.38}$$

Using (4.17)–(4.19), (4.8), (4.10), (4.15), (4.6), (4.5), and (4.11) it can be shown that

$$S_{21}S_{11}^{-1}S_{12}\vec{v}_v = [\vec{u}_{2,\cdot}, \vec{u}_{3,\cdot}]^T + [B\vec{v}_{2,\cdot}, B\vec{v}_{3,\cdot}]^T + [v_{2,0}, v_{2,1}, 0, \ldots, 0, v_{3,0}, v_{3,1}, 0, \ldots, 0]^T, \tag{4.39}$$

where

$$[\vec{u}_{2,\cdot}, \vec{v}_{2,\cdot}, v_{2,0}, v_{2,1}]^T = \sum_{k=1}^{N/2} z_{2,2k}^2 [R^{(2k)}]^{-1} [B\vec{v}_v^{(0)}, \vec{v}_v^{(0)}, v_{0,2}, v_{0,3}]^T, \tag{4.40}$$

$$[\vec{u}_{3,\cdot}, \vec{v}_{3,\cdot}, v_{3,0}, v_{3,1}]^T = \sum_{k=1}^{N/2-1} z_{3,2k+1}^2 [R^{(2k+1)}]^{-1} [B\vec{v}_v^{(1)}, \vec{v}_v^{(1)}, v_{1,2}, v_{1,3}]^T, \tag{4.41}$$

$$R^{(k)} = \begin{bmatrix} R_{11}^{(k)} & R_{12}^{(k)} \\ R_{21}^{(k)} & R_{22}^{(k)} \end{bmatrix},$$

and $R_{ij}^{(k)}$ are given by (2.8), (2.9) with λ replaced by λ_k. We next analyze (4.40). The analysis of (4.41) is similar. Introducing

$$[\vec{u}^{(2k)}, \vec{v}^{(2k)}, v_0^{(2k)}, v_1^{(2k)}]^T = [R^{(2k)}]^{-1} [B\vec{v}_v^{(0)}, \vec{v}_v^{(0)}, v_{0,2}, v_{0,3}]^T$$

and using (4.40), we obtain

$$[\vec{u}_{2,\cdot}, \vec{v}_{2,\cdot}]^T = \sum_{k=1}^{N/2} z_{2,2k}^2 [R_{11}^{(2k)}]^{-1} \left\{ [B\vec{v}_v^{(0)}, \vec{v}_v^{(0)}]^T - R_{12}^{(2k)} [v_0^{(2k)}, v_1^{(2k)}]^T \right\}, \tag{4.42}$$

$$v_{2,j} = \sum_{k=1}^{N/2} z_{2,2k}^2 v_j^{(2k)}, \qquad j = 0, 1.$$

Further, (2.8) and (4.4) imply that

$$[R_{11}^{(2k)}]^{-1} = (I_2 \otimes Z) D_{2k}^{-1} (I_2 \otimes Z^T),$$

where

$$D_{2k} = \begin{bmatrix} \Lambda + \lambda_{2k} I_{N-1} & \lambda_{2k}\Lambda \\ O & \Lambda + \lambda_{2k} I_{N-1} \end{bmatrix}.$$

Hence (4.42) becomes

$$[\vec{u}_{2,\cdot}, \vec{v}_{2,\cdot}]^T = (I_2 \otimes Z) \left\{ D_0 [Z^T B \vec{v}_v^{(0)}, Z^T \vec{v}_v^{(0)}]^T - \sum_{k=1}^{N/2} z_{2,2k}^2 \left(v_0^{(2k)} \vec{p}^{(2k)} + v_1^{(2k)} \vec{q}^{(2k)} \right) \right\}, \tag{4.43}$$

where

$$D_0 = \sum_{k=1}^{N/2} z_{2,2k}^2 D_{2k}^{-1}, \qquad [\vec{p}^{(2k)}, \vec{q}^{(2k)}] = D_{2k}^{-1} (I_2 \otimes Z^T) R_{12}^{(2k)}. \tag{4.44}$$

The presence of B in (4.38), $I_2 \otimes Z$ in (4.43), and (4.4) suggest that we introduce

$$\hat{S} = (I_2 \otimes \Lambda^{-1/2} Z^T) S (I_2 \otimes Z \Lambda^{-1/2}), \quad \hat{r} = (I_2 \otimes \Lambda^{-1/2} Z^T) \vec{r}, \quad \hat{v}_v = (I_2 \otimes \Lambda^{1/2} Z^T) \vec{v}_v, \tag{4.45}$$

and solve the system

$$\hat{S} \hat{v}_v = \hat{r} \tag{4.46}$$

instead of $S\vec{v}_v = \vec{r}$. This approach for computing $\vec{v}_v$ involves one additional multiplication by $I_2 \otimes \Lambda^{-1/2} Z^T$ to obtain $\hat{r}$ and one additional multiplication by $I_2 \otimes Z\Lambda^{-1/2}$ to recover $\vec{v}_v$ from $\hat{v}_v$. However, multiplication of a vector by $\hat{S}$ takes only $4N^2 + O(N)$ operations provided that additional diagonal matrices related to D_0, D_1, and additional vectors related to $\vec{p}^{(2k)}$, $\vec{q}^{(2k)}$, $k = 1, \ldots, N/2$, $\vec{p}^{(2k+1)}$, $\vec{q}^{(2k+1)}$, $k = 1, \ldots, N/2 - 1$, are precomputed with cost $O(N^2)$. (Here D_1 and $\vec{p}^{(2k+1)}$, $\vec{q}^{(2k+1)}$ are counterparts of D_0 and $\vec{p}^{(2k)}$, $\vec{q}^{(2k)}$ for (4.41).)

In the remainder of this section we select a preconditioner for $\hat{S}$ and discuss the solution of a linear system with this preconditioner. First, to select the preconditioner for S of (4.13), we consider the linear system

$$\begin{aligned} (I_{N-1} \otimes B + B \otimes I_{N-1}) \vec{u} + (B \otimes B) \vec{v} + (B_t \otimes B) \vec{v}_v &= \vec{0}, \\ (I_{N-1} \otimes B + B \otimes I_{N-1}) \vec{v} + (B_t \otimes I_{N-1}) \vec{v}_v &= \vec{0}, \\ (B_t^T \otimes I_{N-1}) \vec{u} + (B_t^T \otimes B) \vec{v} + (B_s \otimes B) \vec{v}_v &= \vec{g}_v, \end{aligned} \tag{4.47}$$

where

$$\vec{g}_v = [g_{0,2}, \ldots, g_{0,N}, g_{1,2}, \ldots, g_{1,N}]^T.$$

Note that the matrix in (4.47) is the same as S_{11} of (3.14) but with the roles of the x and y coordinates interchanged. The matrix of (4.47) arises in the spectral Galerkin method for the auxiliary problem (see Figure 3)

$$\begin{aligned} -\Delta u + v = g \text{ in } \Omega, \quad u = 0 \text{ on } \partial\Omega, \qquad \partial u / \partial n = 0 \text{ on } \partial\Omega_v, \\ -\Delta v = -f \text{ in } \Omega, \quad v = 0 \text{ on } \partial\Omega_h, \end{aligned} \tag{4.48}$$

which only differs from (4.1) in the roles of the x and y coordinates. Equations (4.47) can be written as

$$\begin{aligned} P_{11} [\vec{u}, \vec{v}]^T + P_{12} \vec{v}_v &= \vec{0}, \\ P_{21} [\vec{u}, \vec{v}]^T + P_{22} \vec{v}_v &= \vec{g}_v, \end{aligned} \tag{4.49}$$

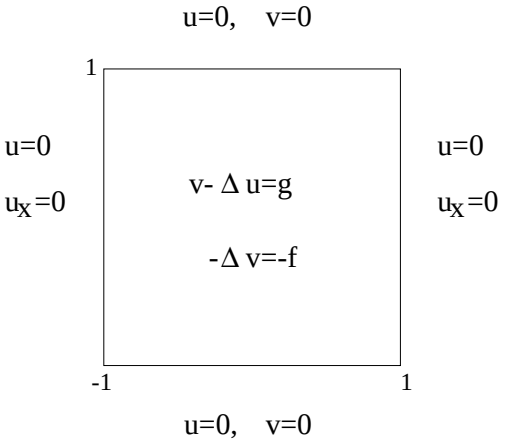

FIG. 3. *Auxiliary problem* (4.48).

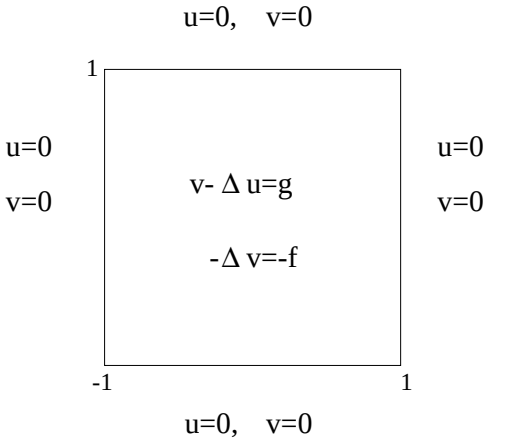

FIG. 4. *Decoupled problem* (4.52).

where

$$P_{11} = \begin{bmatrix} I_{N-1} \otimes B + B \otimes I_{N-1} & B \otimes B \\ O & I_{N-1} \otimes B + B \otimes I_{N-1} \end{bmatrix}, \tag{4.50}$$

and

$$P_{12} = \begin{bmatrix} B_t \otimes B \\ B_t \otimes I_{N-1} \end{bmatrix}, \quad P_{21} = \begin{bmatrix} B_t^T \otimes I_{N-1}, B_t^T \otimes B \end{bmatrix}, \quad P_{22} = \begin{bmatrix} B_s \otimes B \end{bmatrix}. \tag{4.51}$$

The matrix P_{11} arises in the spectral Galerkin method for the decoupled problem (see Figure 4)

$$\begin{aligned} -\Delta u + v &= g \text{ in } \Omega, \quad u = 0 \text{ on } \partial\Omega, \\ -\Delta v &= -f \text{ in } \Omega, \quad v = 0 \text{ on } \partial\Omega. \end{aligned} \tag{4.52}$$

The weak form of (4.52) is

$$\int_\Omega \nabla u \nabla \eta \, d\Omega + \int_\Omega v\eta \, d\Omega = \int_\Omega g\eta \, d\Omega, \qquad \eta \in H_0^1(\Omega),$$

$$\int_\Omega \nabla v \nabla \delta \, d\Omega = -\int_\Omega f\delta \, d\Omega, \qquad \delta \in H_0^1(\Omega),$$

and the spectral Galerkin problem consists of finding $U, V \in X_N^0$ such that

$$\begin{aligned} \int_\Omega \nabla U \nabla \eta \, d\Omega + \int_\Omega V\eta \, d\Omega &= \int_\Omega g\eta \, d\Omega, \qquad \eta \in X_N^0, \\ \int_\Omega \nabla V \nabla \delta \, d\Omega &= -\int_\Omega f\delta \, d\Omega, \qquad \delta \in X_N^0. \end{aligned} \tag{4.53}$$

LEMMA 4.2. *The matrix P_{11} of (4.50) is nonsingular.*

Proof. It is easy to show that (4.53) has a unique solution. ∎

Since P_{11} is nonsingular, eliminating $[\vec{u}, \vec{v}]^T$ from (4.49), we obtain

$$P\vec{v}_v = \vec{g}_v, \tag{4.54}$$

where the $2(N-1) \times 2(N-1)$ Schur complement matrix

$$P = P_{22} - P_{21}P_{11}^{-1}P_{12}. \tag{4.55}$$

(P is the Schur complement of P_{11} in $\left[\begin{smallmatrix} P_{11} & P_{12} \\ P_{21} & P_{22} \end{smallmatrix}\right]$.)

THEOREM 4.2. *The matrix P is symmetric and positive definite.*

Proof. Proof of this theorem is similar to that of Theorem 4.1. For $n = 1, 2$, and arbitrary $\vec{v}_v^{(n)}$ of the form (4.20), let $\vec{u}^{(n)}$ of the form (4.22) and $\vec{v}^{(n)}$ of the form (4.23) be such that

$$P_{11}[\vec{u}^{(n)}, \vec{v}^{(n)}]^T + P_{12}\vec{v}_v^{(n)} = \vec{0}. \tag{4.56}$$

Then (4.55), (4.56), and (4.51) give

$$\begin{aligned} (P\vec{v}_v^{(1)}, \vec{v}_v^{(2)})_{R^{2N-2}} &= (P_{22}\vec{v}_v^{(1)}, \vec{v}_v^{(2)})_{R^{2N-2}} + (P_{21}[\vec{u}^{(1)}, \vec{v}^{(1)}]^T, \vec{v}_v^{(2)})_{R^{2N-2}} \\ &= ((B_s \otimes B)\vec{v}_v^{(1)}, \vec{v}_v^{(2)})_{R^{2N-2}} + ((B_t^T \otimes I_{N-1})\vec{u}^{(1)}, \vec{v}_v^{(2)})_{R^{2N-2}} \\ &\quad + ((B_t^T \otimes B)\vec{v}^{(1)}, \vec{v}_v^{(2)})_{R^{2N-2}}. \end{aligned} \tag{4.57}$$

Equation (4.56) is the matrix-vector form of the spectral Galerkin problem

$$\begin{aligned} \int_\Omega \nabla U^{(n)} \nabla \eta \, d\Omega + \int_\Omega V^{(n)}\eta \, d\Omega = 0, \quad \eta \in X_N^0, \\ \int_\Omega \nabla V^{(n)} \nabla \delta \, d\Omega = 0, \quad \delta \in X_N^0, \end{aligned} \tag{4.58}$$

where $U^{(n)}(x, y)$ is of the from (4.27),

$$V^{(n)}(x, y) = V_i^{(n)}(x, y) + V_v^{(n)}(x, y), \tag{4.59}$$

and $V_i^{(n)}(x, y)$, $V_v^{(n)}(x, y)$ are of the forms (4.29), (4.31), respectively. Since $V_i^{(2)}, U^{(1)} \in X_N^0$, it follows from (4.59) and (4.58) that

$$\begin{aligned} \int_\Omega V^{(1)}V^{(2)} \, d\Omega &= \int_\Omega V^{(1)}V_v^{(2)} \, d\Omega + \int_\Omega V^{(1)}V_i^{(2)} \, d\Omega \\ &= \int_\Omega V^{(1)}V_v^{(2)} \, d\Omega - \int_\Omega \nabla U^{(1)} \nabla \left(V^{(2)} - V_v^{(2)}\right) d\Omega \\ &= \int_\Omega V_i^{(1)}V_v^{(2)} \, d\Omega + \int_\Omega V_v^{(1)}V_v^{(2)} \, d\Omega + \int_\Omega \nabla U^{(1)} \nabla V_v^{(2)} \, d\Omega. \end{aligned} \tag{4.60}$$

TABLE 1
$\kappa_2(\hat{P}^{-1/2}\hat{S}\hat{P}^{-1/2})$ *and* $\kappa_2(\hat{S}_i)$, $i = 1, 2, 3, 4$.

N	16	32	64	128
$\kappa_2(\hat{P}^{-1/2}\hat{S}\hat{P}^{-1/2})$	1.65	1.67	1.68	1.68
$\kappa_2(\hat{S}_1)$	28.68	104.91	400.84	1566.64
$\kappa_2(\hat{S}_2)$	24.39	90.99	350.59	1375.56
$\kappa_2(\hat{S}_3)$	13.93	53.43	209.14	827.35
$\kappa_2(\hat{S}_4)$	13.57	52.54	206.82	820.78

Hence, it follows from (4.57), (4.60), (4.33), (4.35), and (4.36) that

$$(P\vec{v}_v^{(1)}, \vec{v}_v^{(2)})_{R^{2N-2}} = \int_\Omega V^{(1)}V^{(2)}\, d\Omega,$$

which implies the symmetry and positive definiteness of P. □

We take P of (4.55) as a preconditioner for S and

$$\hat{P} = (I_2 \otimes \Lambda^{-1/2}Z^T)P(I_2 \otimes Z\Lambda^{-1/2})$$

as a preconditioner for $\hat{S}$ of (4.45). For arbitrary $\vec{g}_v$, the solution of (4.54) can be obtained by solving (4.49) for $\vec{v}_v$. Equivalently, we compute $\vec{v}_h$ of

$$[\vec{u}, \vec{v}, \vec{v}_h]^T = S_{11}^{-1}[\vec{0}, \vec{0}, \vec{g}_h]^T.$$

(Note that the roles of the x and y coordinates are interchanged, that is, for $k = 2, \ldots, N$, the components $g_{k,0}$, $g_{k,1}$ of $\vec{g}_h$ are equal to the components $g_{0,k}$, $g_{1,k}$ of $\vec{g}_v$ and the components $v_{0,k}$, $v_{1,k}$ of $\vec{v}_v$ are equal to the components $v_{k,0}$, $v_{k,1}$ of $\vec{v}_h$.) It follows from (4.8), (4.6), and the discussion in section 4.1 of the special case of (4.10) that the cost of solving a linear system with $\hat{P}$ is $O(N)$.

With the preconditioner $\hat{P}$, the convergence rate of the PCG method applied to a linear system with $\hat{S}$ depends on $\kappa_2(\hat{P}^{-1/2}\hat{S}\hat{P}^{-1/2})$, where, for a symmetric and positive definite matrix M, $\kappa_2(M) = \lambda_{max}(M)/\lambda_{min}(M)$. A careful analysis shows that $\hat{S}$ splits into four symmetric positive definite matrices $\hat{S}_i$, $i = 1, 2, 3, 4$, and $\hat{P}$ splits into four positive definite diagonal matrices $\hat{P}_i$, $i = 1, 2, 3, 4$. ($\hat{S}_i$, $\hat{P}_i$, $i = 1, 2$, are of order $N/2 \times N/2$ and $\hat{S}_i$, $\hat{P}_i$, $i = 3, 4$, are of order $(N/2-1) \times (N/2-1)$.) Since our preconditioning of $\hat{S}$ by $\hat{P}$ is equivalent to preconditioning each $\hat{S}_i$ by $\hat{P}_i$, we have

$$\kappa_2(\hat{P}^{-1/2}\hat{S}\hat{P}^{-1/2}) = \max_{i=1,2,3,4} \lambda_{max}(\hat{P}_i^{-1/2}\hat{S}_i\hat{P}_i^{-1/2}) / \min_{i=1,2,3,4} \lambda_{min}(\hat{P}_i^{-1/2}\hat{S}_i\hat{P}_i^{-1/2}).$$

This last formula was used to compute $\kappa_2(\hat{P}^{-1/2}\hat{S}\hat{P}^{-1/2})$ numerically for several values of N. Based on the results presented in Table 1, we conjecture that $\kappa_2(\hat{P}^{-1/2}\hat{S}\hat{P}^{-1/2})$ is bounded from above by a positive constant which is independent of N while $\kappa(\hat{S}_i)$, $i = 1, 2, 3, 4$, grows quadratically with N.

Since the matrix $\hat{S}$ of (4.45) is symmetric and positive definite, the system (4.46), equivalently the corresponding systems with $\hat{S}_i$, $i = 1, 2, 3, 4$, can also be solved by Cholesky's method. The columns of $\hat{S}$, equivalently the columns of $\hat{S}_i$, $i = 1, 2, 3, 4$, can be obtained using (4.38) and (4.39) with one component of $\vec{v}_v$ equal to 1 and all remaining components equal to 0. All four matrices $\hat{S}_i$ can be formed with cost $N^3/2 + O(N^2)$ and factored out with cost $N^3/6 + O(N^2)$. Clearly, the cost of the solution stage is $O(N^2)$.

4.4. Cost and memory requirements of the algorithm. We now discuss the cost and memory requirements of solving (3.13) using the algorithm of section 4.2.

The preprocessing stage consists of computing

Λ, Z of (4.3), (4.4) using the LAPACK [1] routines dsteqr and dstein;

$\vec{s}^{(i)}$, δ_i of (2.14) and the factorization of $B_i + \lambda I_{N/2-i}$ for $\lambda = \lambda_k$, $k = 2, \ldots, N$, and $i = 0, 1$;

the diagonal matrices related to D_0, D_1 and the vectors related to $\vec{p}^{(2k)}$, $\vec{q}^{(2k)}$, $k = 1, \ldots, N/2$, $\vec{p}^{(2k+1)}$, $\vec{q}^{(2k+1)}$, $k = 1, \ldots, N/2 - 1$, (cf. (4.44)).

The cost of these computations is $O(N^2)$ and the memory requirements are $11N^2/2$.

In the case of the Cholesky method for solving (4.46), the preprocessing stage also includes the computation of the matrices $\hat{S}_i$, $i = 1, 2, 3, 4$, and their factorizations. The cost of these computations is $2N^3/3$ and the memory requirements are N^2.

From the discussions in sections 4.2 and 4.3, it follows that the cost of the remaining portion of the PCG algorithm for finding $\vec{u}$ is

$$2N^3 + (\text{number of PCG iterations}) \times 4N^2, \tag{4.61}$$

where $4N^2$ is the cost of one PCG iteration. We select $\vec{0}$ as the initial guess for the PCG method. Our numerical tests indicate that the number of PCG iterations should be an integer multiple of $\log N$ if the accuracy of the PCG algorithm is to be comparable with that of the Cholesky algorithm. Hence the total cost of the PCG algorithm for finding $\vec{u}$ is given by (4.61) with the second term dominating the first one for small values of N.

The cost of the remaining portion of the Cholesky algorithm for finding $\vec{u}$ is $2N^3$ which gives the total cost $8N^3/3$ of this algorithm.

The memory requirements for the remaining portions of the PCG and Cholesky algorithms are $3N^2$.

For both the PCG and Cholesky algorithms, the additional cost of computing the vector $\vec{v}$ in Step 8 is $N^3 + O(N^2)$.

5. Numerical results. We solved (1.1) with

$$f(x, y) = 128\pi^4[\cos(4\pi x)\cos(4\pi y) - \sin^2(2\pi x)\cos(4\pi y) - \cos(4\pi x)\sin^2(2\pi y)].$$

The exact solution of this problem, which was also considered by Shen [7] and Bjørstad and Tjøstheim [3], is $u = \sin^2(2\pi x)\sin^2(2\pi y)$.

Our PCG and Cholesky algorithms were implemented in Fortran 77 and numerical experiments were carried out on an IBM RS6000 (processor type: Power PC 604/100MHz), for which the LINPACK TPP benchmark in MFLOPS is 56.4.

The number of PCG iterations in Step 4 of our PCG algorithm was taken to be $3 \log N$. In Table 2 we present the maximum absolute error in u and $v = \Delta u$ on a uniform $(0.02) \times (0.02)$ grid for different values of N. Comparable errors were obtained for the Cholesky algorithm. The exponential convergence achieved is shown in Figure 5 where we present the graph of the logarithm of the maximum absolute error versus N.

Following the format of Table 3 in [7], in Table 3 we present the CPU times in seconds (excluding preprocessing times) for computing $\vec{u}$ by the PCG and Cholesky algorithms. The preprocessing times are given separately in parentheses. As expected from the discussion in section 4.4, preprocessing for the Cholesky algorithm takes

TABLE 2
Maximum absolute error for numerical example.

N	16	20	24	28	32	128	512
$\|u-U\|_\infty$	0.21(−1)	0.22(−3)	0.13(−5)	0.34(−8)	0.51(−11)	0.30(−12)	0.62(−12)
$\|v-V\|_\infty$	0.60(+1)	0.77(−1)	0.53(−3)	0.15(−5)	0.23(−8)	0.93(−10)	0.12(−9)

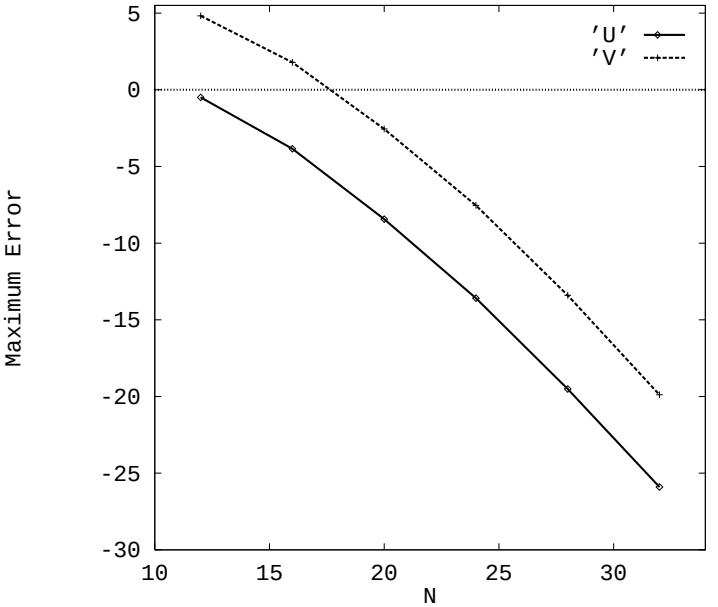

FIG. 5. *Logarithm of the maximum absolute error versus N.*

TABLE 3
Execution time for PCG and Cholesky algorithms.

N	16	32	64	128	512
PCG: CPU(Pre-P)	0.0096 (0.0012)	0.034 (0.012)	0.176 (0.076)	1.076 (0.44)	54.840 (24.844)
Chol: CPU (Pre-P)	0.0072 (0.0052)	0.026 (0.020)	0.134 (0.116)	0.892 (0.70)	48.224 (40.674)

more time than preprocessing for the PCG algorithm, whereas the CPU time for the Cholesky algorithm is smaller than the CPU time for the PCG algorithm. Also, for large values of N the total execution time (CPU + Pre-P) for the PCG algorithm is smaller than that for the Cholesky algorithm.

6. Concluding remarks. As shown in (3.9) of [7], the Legendre spectral Galerkin method based on the standard weak form

$$\int_\Omega \Delta u \Delta \eta \, d\Omega = \int_\Omega f\eta \, d\Omega, \qquad \eta \in H_0^2(\Omega),$$

of (1.1) leads to the linear system

$$(I_{N-3} \otimes B + 2C \otimes C + B \otimes I_{N-3})\vec{u} = \vec{f}, \tag{6.1}$$

where B and C are the Galerkin matrices corresponding to the derivatives of order zero and two in the space $\{p \in P_N^0 : p'(\pm 1) = 0\}$. Shen [7] solves (6.1) using a

capacitance matrix approach with the auxiliary matrix

$$I_{N-3} \otimes B + 2C \otimes C + \tilde{B} \otimes I_{N-3}.$$

The matrix $\tilde{B}$, a modification of B, is such that C and $\tilde{B}$ commute and hence diagonalization in the x direction is possible. The capacitance matrix of [7], which is neither symmetric nor positive definite, is formed explicitly and then factored out using Gauss elimination. The cost of Shen's algorithm is $4N^3 + O(N^2)$ and this count does not include formation and factorization of the capacitance matrix. Both formation and factorization require $O(N^3)$ operations, where the constant multiple of N^3 is not given in [7].

In [3], Bjørstad and Tjøstheim solve (6.1) using the Sherman–Morrison formula with the auxiliary matrix

$$I_{N-3} \otimes B + 2C \otimes C + C^2 \otimes I_{N-3}.$$

Their counterpart of our Schur complement matrix S is symmetric and it is preconditioned by another symmetric matrix. Numerical tests indicate that both matrices are positive definite. The dominant cost of the PCG algorithm of [3] is given by (4.61), where $4N^2$ should be replaced with $24N^2$ [8]. The cost of the Cholesky algorithm in [3] is $16N^3/3 + O(N^2)$.

It follows from section 4.4 that our algorithms, based on discretizing the coupled problem (3.1), are more efficient with respect to operation counts. Our Schur complement matrices S of (4.13) and P of (4.55) are closely related to boundary value problems (3.1), (4.1), and (4.48), (4.52), respectively. This allows us to prove that they are both symmetric and positive definite. Moreover, if required, we also obtain an approximation to $v = \Delta u$ with an additional cost of $N^3 + O(N^2)$.

The algorithms of [3] and [7] were developed for the fourth order problem of the form

$$\Delta^2 u - \beta \Delta u + \alpha u = f \text{ in } \Omega, \qquad u = \partial u/\partial n = 0 \text{ on } \partial\Omega, \tag{6.2}$$

where α and β are nonnegative constants. Our approach, based on introducing $v = \Delta u$, and the corresponding PCG and Cholesky algorithms generalize, with the same dominant costs, to (6.2). In this more general case, the blocks S_{11}, S_{12} of (3.14), (3.15) are to be replaced, respectively, by

$$S_{11} = \begin{bmatrix} I_{N-1} \otimes B + B \otimes I_{N-1} & B \otimes B & B \otimes B_t \\ -\beta(B \otimes B) & (I_{N-1} + \alpha B) \otimes B + B \otimes I_{N-1} & (I_{N-1} + \alpha B) \otimes B_t \\ I_{N-1} \otimes B_t^T & B \otimes B_t^T & B \otimes B_s \end{bmatrix},$$

$$S_{12} = \begin{bmatrix} B_t \otimes B \\ B_t \otimes (I_{N-1} + \alpha B) \\ B_t \otimes B_t^T \end{bmatrix}.$$

Similarly, A_i of (2.11) and $\vec{p}$ of (2.12) are to replaced with

$$A_i = \begin{bmatrix} B_i + \lambda I_{N/2-i} & \lambda B_i \\ -\beta\lambda B_i & (1 + \alpha\lambda) B_i + \lambda I_{N/2-i} \end{bmatrix},$$

$$\vec{p} = [\lambda, 0, \ldots, 0, 1 + \alpha\lambda, 0, \ldots, 0]^T.$$

The new matrix A_i reduces to a block tridiagonal matrix with 2×2 blocks.

Our approach allows also for an efficient treatment of some other boundary conditions, such as $u = \Delta u = 0$ on $\partial\Omega$ or $u = 0$ on $\partial\Omega$, $\partial u/\partial n = 0$ on the horizontal sides of $\partial\Omega$ and $\Delta u = 0$ on the vertical sides of $\partial\Omega$. In fact, as discussed in section 4.1, the last set of boundary conditions gives rise to a linear system with matrix S_{11} of (3.14) and hence its solution, for the approximation to u, can be obtained at a cost of only $2N^3 + O(N^2)$.

ALGEBRAIC MULTIGRID BASED ON ELEMENT INTERPOLATION (AMGe)*

M. BREZINA†, A. J. CLEARY‡, R. D. FALGOUT‡, V. E. HENSON‡, J. E. JONES‡, T. A. MANTEUFFEL†, S. F. MCCORMICK†, AND J. W. RUGE†

Abstract. We introduce AMGe, an algebraic multigrid method for solving the discrete equations that arise in Ritz-type finite element methods for partial differential equations. Assuming access to the element stiffness matrices, we have that AMGe is based on the use of two local measures, which are derived from global measures that appear in existing multigrid theory. These new measures are used to determine local representations of algebraically "smooth" error components that provide the basis for constructing effective interpolation and, hence, the coarsening process for AMG. Here, we focus on the interpolation process; choice of the coarse "grids" based on these measures is the subject of current research. We develop a theoretical foundation for AMGe and present numerical results that demonstrate the efficacy of the method.

Key words. algebraic multigrid, finite elements, interpolation weights

1. Introduction.

Computer simulations play an increasingly important role in scientific investigations. Indeed, as experimentation becomes more expensive, impracticable, or even proscribed, scientists are turning more and more to numerical simulation. Modern simulation packages are extremely complex, with components spanning many disciplines (e.g., hydrodynamics, radiation transport, structures, thermodynamics, chemistry, and electromagnetics). Also, the problems are frequently posed in multimaterial regimes, with contact surfaces, interpenetrability constraints, and intricate geometries. As a result, codes are being developed to solve complex multiphysics problems on highly resolved, unstructured grids. Such large-grid simulations require the efficient union of massively parallel computing with scalable numerical algorithms such as multigrid (see, e.g., [2]).

An especially effective method for many of the problems that arise in these applications is algebraic multigrid (AMG) [5, 4, 6, 20, 17, 19, 18]. AMG is a method for solving matrix equations that is based on multigrid concepts, but constructs the coarsening process in an algebraic way that requires no explicit knowledge of the geometry. It examines the matrix entries to determine a sequence of smaller matrix

problems that serve as coarse-level equations. AMG also determines associated inter-level transfer operators (restriction and prolongation), then solves the original matrix equation in a multigrid-like process based on these automatically constructed components. AMG has been shown to be well suited for solving unstructured grid problems and to work well over a wide variety of applications (see, e.g., [10]).

It has been applied successfully to M-matrix problems where the so-called strength of connection is easily measured (this measure is used to determine which variables are strongly representative of the errors left by relaxation, so that they can be used to construct the coarse levels). It also applies well to scalar problems that depart substantially from M-matrix discretizations. However, for problems where strength of connection is not easily measured, AMG is not effective without certain problem-specific modifications or careful parameter tuning. For such cases, there is no systematic AMG approach that has proven effective in any kind of general context. There are still other problems (e.g., thin-body elasticity on unstructured grids) for which AMG and other iterative methods in general have failed to achieve full optimality (i.e., convergence factors bounded uniformly in the size of the problem). The goal of our research is to develop a more robust AMG for solving these difficult problems.

This paper introduces an AMG method for solving partial differential equations discretized by Ritz-type finite element methods. As a departure from standard AMG, where only the operator matrix is required, this approach assumes access to element stiffness matrices. We thus refer to it as AMGe (AMG henceforth refers to the standard scheme). This new approach is based on the use of either of two measures (derived from global measures used in existing theory) to determine algebraically "smooth" error and to construct effective interpolation. AMGe uses a minimization principle based on the *element interpolation* scheme first introduced in [16]. Other multigrid methods, using minimization principles for constructing energetically stable intergrid transfer operators, have recently appeared in [23, 24, 12].

Some notation and the key ideas behind AMG are summarized in the next section. (Nevertheless, we assume that the reader is familiar with AMG methods and terminology. For more details, see [10] and [18].) In particular, we discuss the notion of *strength of dependence* and its role in defining the basic AMG components. In section 3, we define a heuristic based on two *global measures* and establish a corresponding two-level convergence result. We "localize" these measures in section 4 and describe how they can be used to compute the interpolation operator for AMGe. We also discuss the relationship between the local and global measures in subsection 4.3. Section 5 contains numerical results supporting the theory and demonstrating the efficacy of the approach. Concluding remarks are made in section 6.

2. Preliminaries. We begin this section by describing notation. Capital italic Roman letters (A, B, P, R) denote matrices and bold lowercase Roman and Greek letters denote vectors ($\mathbf{u}, \mathbf{v}, \boldsymbol{\varepsilon}$). The ith component of the vector $\mathbf{q}$ is denoted by q_i. Other lowercase letters denote scalars, while capital calligraphic letters denote sets and spaces ($\mathcal{C}, \mathcal{F}, \mathcal{S}$), with the singular exception that $\mathcal{A}$ is used to denote finite element stiffness matrices. We define the A-inner product by $\langle \cdot,\ \cdot \rangle_A := \langle A\cdot,\ \cdot \rangle$, where $\langle \cdot,\ \cdot \rangle$ is the standard Euclidean inner product, and the A-norm (also called the energy norm) by $\|\cdot\|_A := \langle \cdot,\ \cdot \rangle_A^{1/2}$.

Assume that we are given an $n \times n$ symmetric positive definite matrix A expressed as the sum of a given set of finite element stiffness matrices: $A = \sum_{\alpha \in \mathcal{T}} \mathcal{A}_\alpha$, where $\mathcal{T}$ is the set of finite elements used to discretize the problem and each $\mathcal{A}_\alpha$ is symmetric positive semidefinite. We do not assume access to a spatial grid or the ability to create

new finite element stiffness matrices.

We seek the solution $\mathbf{u} \in \mathbb{R}^n$ to the linear system

$$A\mathbf{u} = \mathbf{f} \tag{2.1}$$

for a given $\mathbf{f} \in \mathbb{R}^n$. Standard iterative schemes, like Gauss–Seidel and Krylov space methods, tend to converge slowly for large-scale problems of this type that arise from partial differential equations. The difficulty is that smooth error components are typically attenuated very slowly by these simple processes, because they are based on local properties (i.e., local connections in A). Multigrid methods attempt to correct this limitation by representing the smooth errors on increasingly coarser, and, therefore, more global levels.

To describe how system (2.1) could be solved by a multilevel method, let P be an $n \times n_c$ *interpolation* or *prolongation* matrix that transfers level n_c corrections to level n, with $n_c < n$. P could be determined *geometrically* by, say, linear interpolation (cf. [7]) when $\mathbb{R}^{n_c}$ and $\mathbb{R}^n$ represent grids whose nodal positions are accessible. P could instead be determined *algebraically* by so-called operator interpolation (cf. [1]), which is based on the entries of A. In any event, we choose P^T as the *restriction* matrix that transfers level n residuals to level n_c. The two-grid method for solving (2.1) is then defined as follows:

(2.2a) Relax ν_1 times on $A\mathbf{u} = \mathbf{f}$.

(2.2b) Correct $\mathbf{u} \leftarrow \mathbf{u} + P(P^TAP)^{-1}P^T(\mathbf{f} - A\mathbf{u})$.

(2.2c) Relax ν_2 times on $A\mathbf{u} = \mathbf{f}$.

Note the use of P^TAP in correction step (2.2b). This so-called Galerkin coarse-grid operator, together with the use of P^T as the restriction operator, amounts to a *variational* form of multigrid. When A is symmetric, the correction step minimizes the energy norm of the fine-grid error over all possible corrections from the range of P (cf. [7]). To solve (2.1) in practice, one would use a multilevel method that recursively applies algorithm (2.2) to solve the linear system involving P^TAP in correction step (2.2b).

Further examination of (2.2) reveals that relaxation and coarse-grid correction must be chosen to complement each other: An error not reduced by one must be reduced by the other. In this paper, we fix the choice of relaxation, then determine interpolation. The relaxation we choose is a simple pointwise method, like Richardson, damped Jacobi, or Gauss–Seidel, that satisfies the following heuristic:

H1: *Error in the direction of an eigenvector associated with a large eigenvalue is rapidly reduced by relaxation, while error in the direction of an eigenvector associated with a small eigenvalue is reduced by a factor that may approach* 1 *as the eigenvalue approaches* 0.

An error that is not rapidly reduced by relaxation is called *algebraically smooth*. The actual character of algebraically smooth error depends on the operator and the type of relaxation, but it loosely means that the residual is small when compared with the error itself (we will be more precise about this shortly). This does not mean that the error is smooth in any geometric sense. Thus, an error at a point may be very different from the errors at neighboring points, yet it might be difficult to reduce the error by relaxation. Such is the case for anisotropic problems, where an algebraically smooth error that pointwise Gauss–Seidel relaxation cannot effectively

reduce can be geometrically oscillatory in the direction of small coefficients of the differential equation. In any case, the interpolation matrix, P, must be defined so that an algebraically smooth error is effectively eliminated in step (2.2b) and the coarse-grid equations, which involve $P^T AP$, are amenable to solution.

2.1. AMG. To define the multigrid components in AMG, we use the following heuristic (cf. [5, **?**, 18]) based on special properties of M-matrices:

H2: *Smooth error varies slowest in the direction of strong dependence.*

Here, we say that *unknown i strongly depends on unknown j* if

$$-a_{i,j} \geq \theta \max_{k \neq i} \{-a_{i,k}\} \quad \text{for some fixed } \theta \in (0,1). \tag{2.3}$$

Thus, strong dependence is characterized by matrix coefficients that are large in the sense of (2.3). A typical choice for parameter θ is 0.25.

Although AMG was developed with M-matrices in mind, in practice it is not limited to this class of problems. However, the standard method does rely on **H2**, and our sense of strong dependence may not be suitable for many important classes of problems. For example, one simple problem with which standard AMG has difficulty is the Poisson equation on a rectangular grid, discretized with bilinear quadrilateral elements, where the fine-grid elements are stretched to a 10:1 aspect ratio. This yields the coefficient stencil

$$\begin{bmatrix} -1 & -3.9 & -1 \\ 1.9 & 8 & 1.9 \\ -1 & -3.9 & -1 \end{bmatrix}. \tag{2.4}$$

In (2.4), it is not readily apparent from the size of the off-diagonal entries that the direction of strongest dependence is vertical. Since **H2** is used to define all the AMG components, and it requires a clear understanding of strong dependence, AMG can exhibit degraded performance (see Table 5.2). For this simple case, slow convergence of AMG can be ameliorated by simply tuning its parameters (e.g., setting $\theta = 0.5$) or by more elaborate algorithmic "fixes" (e.g., *iterative weight interpolation* [10] or geometric/algebraic interpolation methods [11, 9, 8]). Another approach is to replace **H2** by a heuristic that leads to a more robust AMG algorithm. Exploring this possibility, as we begin to do in the next section, is the primary aim of this paper.

3. Global measures and convergence bounds. This paper takes a slightly different approach, using a heuristic based not on M-matrices, but on the eigenvectors of A. In a two-grid scheme, coarse-grid correction will completely eliminate error in Range (P), the range of the interpolation operator. To complement the action of relaxation, which satisfies **H1**, the interpolation matrix must satisfy the following heuristic:

H3: *Interpolation must be able to approximate an eigenvector with error bound proportional to the size of the associated eigenvalue.*

To make **H3** more rigorous, define $Q : \mathbb{R}^n \to \mathbb{R}^n$ to be a convenient projection onto Range (P), that is,

$$Q = PR \tag{3.1}$$

for some restriction operator $R : \mathbb{R}^n \to \mathbb{R}^{n_c}$ such that $RP = I_c$, the identity on $\mathbb{R}^{n_c}$. The specific form for Q (and, hence, R) will not become important until section 4.

For any vector $\mathbf{e} \in \text{Range}\,(P)$, we have $Q\mathbf{e} = \mathbf{e}$. Thus, $I - Q$ can be used to measure the defect of interpolation. With this in mind, we now define two measures of how well **H3** is satisfied:

$$M_1(Q, \mathbf{e}) := \frac{\langle (I-Q)\mathbf{e},\ (I-Q)\mathbf{e}\rangle}{\langle A\mathbf{e},\ \mathbf{e}\rangle}, \tag{3.2}$$

$$M_2(Q, \mathbf{e}) := \frac{\langle A(I-Q)\mathbf{e},\ (I-Q)\mathbf{e}\rangle}{\langle A\mathbf{e},\ A\mathbf{e}\rangle}. \tag{3.3}$$

Measure M_2 was used in the early multigrid theory [15, 13, 14] to establish optimal convergence of the V-cycle algorithm under full regularity assumptions on the associated partial differential equation. Measure M_1 was introduced in [4] and used more recently to establish convergence, independent of the coarse-grid size, of a two-level method for linear elasticity [22]. It is also an essential ingredient of the regularity-free multilevel theory found in [3]. We develop the relevant two-grid theory here for both measures so that we can tailor the results to our needs.

It has not been our practice to use diagonal conditioning of A in standard AMG. Such a scaling generally changes the nature of smooth errors. Since current schemes at some point rely on a premise of how a smooth error behaves (e.g., that it is locally constant), then diagonal scaling can make it more difficult for AMG to handle. However, no such premise of smoothness is made anywhere in AMGe. Thus, in the remainder of this paper, we are free to assume for convenience that matrix A has been scaled so that its diagonal is the identity. For a general symmetric positive-definite matrix with diagonal $D \neq I$, this can be assured by a diagonal scaling that replaces A by $D^{-1/2}AD^{-1/2}$. Note that this transformation must be considered in the representation of A as a sum of local stiffness matrices, but this is just a straightforward rescaling of the variables. This scaling does, however, bear on the practicality of our results because we analyze AMG based on Richardson iteration, which is not generally a good smoother for matrices that have widely varying diagonal entries. Thus, if diagonal scaling is not used, then in general it would be wise to use a relaxation scheme like damped Jacobi and adjust measures M_1 and M_2 accordingly.

Our theory assumes that either M_1 or M_2 is bounded uniformly in $\mathbf{e} \in \mathbb{R}^n \backslash \{\mathbf{0}\}$. To see how this assumption relates to **H3**, suppose that $\mathbf{e}$ is an eigenvector of A corresponding to a small eigenvalue. Then, for M_1 or M_2 to be bounded, since the denominators of the two measures are small, the numerators must also be small. Thus, Q must accurately interpolate eigenvectors belonging to small eigenvalues. On the other hand, if $\mathbf{e}$ is an eigenvector of A corresponding to a large eigenvalue, then the denominators of the two measures are large, so the numerators may be large. Thus, Q need not accurately interpolate eigenvectors belonging to large eigenvalues.

We now prove convergence results based on M_1 or M_2 for two-level algorithm (2.2).

LEMMA 3.1. *Let Q be any projection onto* Range (P). *Assume that either of the following two approximation properties are satisfied for some constant K:*

$$M_1(Q, \mathbf{e}) \leq K \quad \forall \mathbf{e} \in \mathbb{R}^n \backslash \{\mathbf{0}\}, \tag{3.4}$$

$$M_2(Q, \mathbf{e}) \leq K \quad \forall \mathbf{e} \in \mathbb{R}^n \backslash \{\mathbf{0}\}. \tag{3.5}$$

If $\mathbf{e} \neq 0$ is A-orthogonal to Range (P), *then*

$$\frac{1}{K} \leq \frac{\|A\mathbf{e}\|^2}{\langle A\mathbf{e},\ \mathbf{e}\rangle} \leq \|A\|. \tag{3.6}$$

Proof. The upper bound in (3.6) follows easily from the definition of the matrix norm. To prove the lower bound, note that Range (Q) = Range (P). Hence, if $\mathbf{e}$ is A-orthogonal to Range (P), then

$$\langle A\mathbf{e},\ Q\mathbf{v}\rangle = 0 \quad \forall \mathbf{v} \in \mathbb{R}^n. \tag{3.7}$$

First, assume that (3.4) holds. From (3.7) and the Cauchy–Schwarz inequality, we have

$$\begin{aligned}\langle A\mathbf{e},\ \mathbf{e}\rangle &= \langle A\mathbf{e},\ (I-Q)\mathbf{e}\rangle \\ &\le \|A\mathbf{e}\|\,\|(I-Q)\mathbf{e}\| \\ &\le \|A\mathbf{e}\|\,\langle A\mathbf{e},\ \mathbf{e}\rangle^{1/2}\,K^{1/2}.\end{aligned}$$

The lower bound in (3.6) now follows by dividing through by $\langle A\mathbf{e},\ \mathbf{e}\rangle\,K^{1/2}$ and squaring the result.

Now, assume that (3.5) holds. From (3.7) and the Cauchy–Schwarz inequality, we have

$$\begin{aligned}\langle A\mathbf{e},\ \mathbf{e}\rangle &\le \langle A\mathbf{e},\ \mathbf{e}\rangle + \langle AQ\mathbf{e},\ Q\mathbf{e}\rangle \\ &= \langle A\mathbf{e},\ \mathbf{e}\rangle - \langle A\mathbf{e},\ Q\mathbf{e}\rangle - \langle AQ\mathbf{e},\ \mathbf{e}\rangle + \langle AQ\mathbf{e},\ Q\mathbf{e}\rangle \\ &= \langle A(I-Q)\mathbf{e},\ (I-Q)\mathbf{e}\rangle \\ &\le \|A\mathbf{e}\|^2\,K.\end{aligned}$$

The lower bound in (3.6) now follows by dividing through by $\langle A\mathbf{e},\ \mathbf{e}\rangle\,K$. ∎

Denote the A-orthogonal projection onto the Range (P) by S. Thus,

$$S := P(P^TAP)^{-1}P^TA. \tag{3.8}$$

The error propagation matrix for the coarse-grid correction step (2.2b) is $I-S$. A Richardson iteration with step-size parameter $s = \omega/\|A\|$, $\omega \in (0,2)$, has the error propagation matrix $G = I - sA$. If we choose $(\nu_1,\nu_2) = (0,1)$ in (2.2), then the associated error propagation matrix for this simple two-grid scheme is $G(I-S)$. The following theorem analyzes its convergence by bounding its error propagation matrix in the A-norm. Convergence results for other values of (ν_1,ν_2) then follow naturally [14].

Analogous multilevel results can be found in [15, 13, 14] for approximation property (3.5), and in [3, 21] for (3.4) under the additional assumption of *energetic stability of interpolation*, a sufficient condition for which is that $\|P(P^TP)^{-1}P^T\|_A$ be bounded uniformly on all levels.

THEOREM 3.2. *Assume that either approximation property* (3.4) *or* (3.5) *is satisfied for some constant* K. *Then*

$$\|G(I-S)\|_A \le \left(1 - \frac{\omega(2-\omega)}{K\,\|A\|}\right)^{1/2}. \tag{3.9}$$

Proof. First note that (3.6) implies $K \ge 1/\|A\| \ge \omega(2-\omega)/\|A\|$, so that (3.9) makes sense. We have

$$\begin{aligned}\langle AG\mathbf{e},\ G\mathbf{e}\rangle &= \langle A\mathbf{e},\ \mathbf{e}\rangle - 2s\,\langle A\mathbf{e},\ A\mathbf{e}\rangle + s^2\,\langle A^2\mathbf{e},\ A\mathbf{e}\rangle \\ &\le \langle A\mathbf{e},\ \mathbf{e}\rangle - \frac{\omega(2-\omega)}{\|A\|}\,\langle A\mathbf{e},\ A\mathbf{e}\rangle.\end{aligned}$$

Replacing $\mathbf{e}$ with $(I-S)\mathbf{e}$ and applying the result in Lemma 3.1 yields

$$\begin{aligned}\|G(I-S)\mathbf{e}\|_A^2 &\leq \langle A(I-S)\mathbf{e},\ (I-S)\mathbf{e}\rangle - \frac{\omega(2-\omega)}{\|A\|}\|A(I-S)\mathbf{e}\|^2 \\ &\leq \left(1-\frac{\omega(2-\omega)}{K\|A\|}\right)\|\mathbf{e}\|_A^2 . \qquad \square\end{aligned}$$

Notice that the bound on the convergence factor approaches 1 as K becomes large. Conversely, smaller K yields a smaller bound on the convergence factor. Our aim is to determine P so that, for some appropriate Q, either (3.4) or (3.5) is satisfied for a reasonably small K.

We also remark that the above results can be generalized to apply when (2.1) is a consistent system with symmetric positive semidefinite matrix A. Measures M_1 and M_2 must be restricted to $\mathbf{e} \notin \text{Null}(A)$. A finite bound K in (3.4) or (3.5) then implies that interpolation is exact for $\mathbf{e} \in \text{Null}(A)$, which in turn implies that the correction step involves a consistent system. A zero initial guess and relaxation using a polynomial method like Richardson iteration ensures that the approximate solution remains orthogonal to Null(A).

4. Interpolation using local measures. Quantities M_1 and M_2 are global measures of the quality of interpolation. Our intent is to use these measures to determine an effective strategy for constructing interpolation in AMG, but it is not practical to do this globally. In this section, we discuss an approach for localizing these measures for linear systems (2.1) that arise from finite element discretizations.

Recall that A is given as the sum of finite element stiffness matrices: $A = \sum_{\alpha\in\mathcal{T}} \mathcal{A}_\alpha$. Now, we do not assume access to an underlying spatial grid. However, we can construct an artificial grid based on the graph associated with A, with vertices $\mathcal{G} := \{1, 2, \ldots, n\}$ and edges $\mathcal{E} := \{(i,j) \ : \ a_{ij} \neq 0 \ \text{ for } i \neq j\}$. Grid point (vertex) $i \in \mathcal{G}$ is associated with unknown u_i.

We first define the point set of an element:

$$\mathcal{M}_\alpha := \left\{ j \ : \ \boldsymbol{\varepsilon}_j^T \mathcal{A}_\alpha \boldsymbol{\varepsilon}_j \neq 0 \right\}, \tag{4.1}$$

where $\boldsymbol{\varepsilon}_j$ is the canonical basis vector associated with unknown j. Next, define the neighborhood of grid point i as the set of elements and set of points

$$\mathcal{T}_i := \{\alpha \in \mathcal{T} : \boldsymbol{\varepsilon}_i^T \mathcal{A}_\alpha \boldsymbol{\varepsilon}_i \neq 0\}, \tag{4.2}$$

$$\mathcal{N}_i := \cup_{\alpha\in\mathcal{T}_i} \mathcal{M}_\alpha, \tag{4.3}$$

respectively (see Figure 4.1). Define the local matrices on neighborhood i by

$$A_i = \sum_{\alpha\in\mathcal{T}_i} \mathcal{A}_\alpha. \tag{4.4}$$

We also assume that a coarse grid has been selected; that is, the points in $\mathcal{G}$ have been partitioned into coarse-grid points $\mathcal{C}$ and fine-grid points $\mathcal{F}$ such that $\mathcal{C} \cup \mathcal{F} = \mathcal{G}$ and $\mathcal{C} \cap \mathcal{F} = \emptyset$. We now seek the $n \times n_c$ interpolation matrix P, where $n_c = |\mathcal{C}|$, that interpolates from the coarse-grid points $\mathcal{C}$ to the entire grid $\mathcal{G}$.

Two conflicting goals drive the construction of P. The first is to minimize the bound on measure M_1 or M_2, while the second is to control the sparsity of the coarse-grid system involving P^TAP. Focusing on the second goal first, we assume that

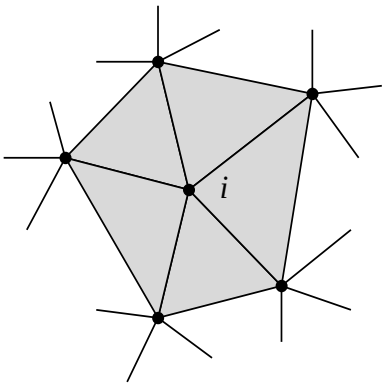

FIG. 4.1. *Local neighborhoods.*

the coarse-grid points interpolate to themselves exactly; that is, P restricted to $\mathcal{C}$ is the identity, while fine-grid points interpolate only from coarse-grid points in their neighborhood, that is, from $\mathcal{C}_i := \mathcal{N}_i \cap \mathcal{C}$.

To make the construction more clear, suppose that the rows and columns of A have been arranged so that the fine-grid points come first, followed by the coarse-grid points. We may then write A in block form as follows:

$$A = \begin{bmatrix} A_{ff} & A_{fc} \\ A_{cf} & A_{cc} \end{bmatrix}. \tag{4.5}$$

In this context, the interpolation matrix has the block form

$$P = \begin{bmatrix} P_{fc} \\ I_c \end{bmatrix}. \tag{4.6}$$

Alternatively, we may define the projection

$$Q = \begin{bmatrix} 0 & P_{fc} \\ 0 & I_c \end{bmatrix}, \tag{4.7}$$

which implies the choice of $R = [0, I_c]$ as the restriction in (3.1).

In what follows, we develop a strategy for constructing the rows of P_{fc}, that is, the rows of Q corresponding to each point $i \in \mathcal{F}$, which we denote

$$\mathbf{q}_i^T := \boldsymbol{\varepsilon}_i^T Q. \tag{4.8}$$

Restricting interpolation to a neighborhood of coarse-grid points is equivalent to choosing

$$\mathbf{q}_i \in \mathcal{Z}_i := \{\mathbf{v} \in \mathbb{R}^n \ : \ v_j = 0 \text{ for } j \notin \mathcal{C}_i\}. \tag{4.9}$$

We now localize measures M_1 and M_2 by defining

$$M_{i,1}(Q, \mathbf{e}) := \frac{\langle \boldsymbol{\varepsilon}_i \boldsymbol{\varepsilon}_i^T (I - Q)\mathbf{e},\ \boldsymbol{\varepsilon}_i \boldsymbol{\varepsilon}_i^T (I - Q)\mathbf{e} \rangle}{\langle A_i \mathbf{e},\ \mathbf{e} \rangle}, \tag{4.10}$$

$$M_{i,2}(Q, \mathbf{e}) := \frac{\langle A_i \boldsymbol{\varepsilon}_i \boldsymbol{\varepsilon}_i^T (I - Q)\mathbf{e},\ \boldsymbol{\varepsilon}_i \boldsymbol{\varepsilon}_i^T (I - Q)\mathbf{e} \rangle}{\langle A_i \mathbf{e},\ A_i \mathbf{e} \rangle} \tag{4.11}$$

for any $\mathbf{e} \notin \text{Null}(A_i)$. Notice for $i \in \mathcal{C}$ that $M_{i,1} = M_{i,2} = 0$, while for $i \in \mathcal{F}$ the above measures depend only on the ith row of Q, which is to be chosen in $\mathcal{Z}_i$. To emphasize this dependence, when the meaning is clear we write

$$M_{i,1}(\mathbf{q_i}, \mathbf{e}) = \frac{\langle (\boldsymbol{\varepsilon}_i - \mathbf{q_i})^T \mathbf{e},\ (\boldsymbol{\varepsilon}_i - \mathbf{q_i})^T \mathbf{e} \rangle}{\langle A_i \mathbf{e},\ \mathbf{e} \rangle}, \tag{4.12}$$

$$M_{i,2}(\mathbf{q_i}, \mathbf{e}) = \frac{\langle (\boldsymbol{\varepsilon}_i - \mathbf{q_i})^T \mathbf{e},\ (\boldsymbol{\varepsilon}_i - \mathbf{q_i})^T \mathbf{e} \rangle}{\langle A_i \mathbf{e},\ A_i \mathbf{e} \rangle} \tag{4.13}$$

for $\mathbf{q_i} \in \mathcal{Z}_i$ and $\mathbf{e} \notin \text{Null}(A_i)$. (Recall that A has unit diagonal.)

Heuristic **H3**, as applied to these local measures, now relates interpolation accuracy to local eigenvectors of A_i. This makes it practical to use $M_{i,1}$ and $M_{i,2}$ to compute interpolation. Since we wish to make these local measures small, interpolation is defined so that the $\mathbf{q}_i$ in (4.8) is the arg min (that is, the argument that attains the minimum) of one of the following min-max problems:

$$K_{i,p} := \min_{\mathbf{q_i} \in \mathcal{Z}_i} \max_{\mathbf{e} \notin \text{Null}(A_i)} M_{i,p}(\mathbf{q_i}, \mathbf{e}) \tag{4.14}$$

for $p = 1$ or 2. Note that if there exists a $\mathbf{q_i} \in \mathcal{Z}_i$ that yields $K_{i,p} < \infty$, then $\mathbf{q_i}$ satisfies the constraint

$$(\boldsymbol{\varepsilon}_i - \mathbf{q_i})^T \mathbf{e} = 0 \quad \forall \mathbf{e} \in \text{Null}(A_i).$$

Thus, min-max problem (4.14) can be restated as the constrained min-max problem

$$\begin{aligned} K_{i,p} &= \min_{\mathbf{q_i} \in \mathcal{Z}_i} \max_{\mathbf{e} \perp \text{Null}(A_i)} M_{i,p}(\mathbf{q_i}, \mathbf{e}) \\ &\text{subject to} \quad (\boldsymbol{\varepsilon}_i - \mathbf{q_i})^T \mathbf{e} = 0 \quad \forall \mathbf{e} \in \text{Null}(A_i) \end{aligned} \tag{4.15}$$

for $p = 1$ or 2. The next two subsections focus on solving these min-max problems. In section 4.3, we relate the local measures to the global measures.

4.1. Computing interpolation by fitting eigenvectors. One way to compute the $\mathbf{q}_i$ in (4.14) or (4.15) is to "fit" the eigenvectors of A_i, as quantified in the following theorem.

THEOREM 4.1. *Suppose we have computed the eigendecomposition*

$$A_i V_i = V_i \Lambda_i, \quad V_i^T V_i = I. \tag{4.16}$$

The columns of V_i are the orthonormalized eigenvectors of A_i, and Λ_i is the diagonal matrix formed from the corresponding eigenvalues. Assume that this eigen-decomposition is ordered to distinguish between zero eigenvalues and positive eigenvalues (that form the diagonal matrix Λ_{i+}):

$$V_i = \begin{bmatrix} V_{i0} & V_{i+} \end{bmatrix}, \quad \Lambda_i = \begin{bmatrix} 0 & 0 \\ 0 & \Lambda_{i+} \end{bmatrix}. \tag{4.17}$$

Then min-max *problem* (4.15) *is equivalent to the following constrained least-squares problem:*

$$\min_{\mathbf{q}_i} \left\| \Lambda_{i+}^{-p/2} V_{i+}^T (\boldsymbol{\varepsilon}_i - \mathbf{q}_i) \right\|^2 \quad \textit{subject to} \quad V_{i0}^T (\boldsymbol{\varepsilon}_i - \mathbf{q}_i) = 0 \tag{4.18}$$

for $p = 1$ or 2.

Proof. Note that the null-space constraint in (4.15) is equivalent to that in (4.18). Assume first that $\mathbf{q}_i$ satisfies (4.15) with $p = 1$. Since $\mathbf{e} \perp \text{Null}(A_i)$, we can write $\mathbf{e} = V_{i+}\Lambda_{i+}^{-1/2}\mathbf{w}$, which yields

$$\min_{\mathbf{q}_i \in \mathcal{Z}_i} \max_{\mathbf{e} \perp \text{Null}(A_i)} M_{i,1}(\mathbf{q}_i, \mathbf{e}) = \min_{\mathbf{q}_i \in \mathcal{Z}_i} \max_{\mathbf{w}} \frac{\left\| (\boldsymbol{\varepsilon}_i - \mathbf{q}_i)^T V_{i+}\Lambda_{i+}^{-1/2}\mathbf{w} \right\|^2}{\|\mathbf{w}\|^2}$$
$$= \min_{\mathbf{q}_i \in \mathcal{Z}_i} \left\| \Lambda_{i+}^{-1/2} V_{i+}^T (\boldsymbol{\varepsilon}_i - \mathbf{q}_i) \right\|^2 .$$

Assume now that $\mathbf{q}_i$ satisfies (4.15) with $p = 2$. Writing $\mathbf{e} = V_{i+}\Lambda_{i+}^{-1}\mathbf{w}$, we then have

$$\min_{\mathbf{q}_i \in \mathcal{Z}_i} \max_{\mathbf{e} \perp \text{Null}(A_i)} M_{i,2}(\mathbf{q}_i, \mathbf{e}) = \min_{\mathbf{q}_i \in \mathcal{Z}_i} \max_{\mathbf{w}} \frac{\left\| (\boldsymbol{\varepsilon}_i - \mathbf{q}_i)^T V_{i+}\Lambda_{i+}^{-1}\mathbf{w} \right\|^2}{\|\mathbf{w}\|^2}$$
$$= \min_{\mathbf{q}_i \in \mathcal{Z}_i} \left\| \Lambda_{i+}^{-1} V_{i+}^T (\boldsymbol{\varepsilon}_i - \mathbf{q}_i) \right\|^2 . \qquad \square$$

Computing the interpolation weights $\mathbf{q}_i$ using (4.18) requires eigendecomposition (4.16), which is not the most efficient method. We introduce a simpler approach in the next subsection. However, we include this notion of fitting eigenvectors because it is useful for understanding the basic principles involved in selecting interpolation.

4.2. A more practical algorithm for computing interpolation. Here we describe a practical algorithm for determining when (4.14) or (4.15) has a (unique) solution for $i \in \mathcal{F}$, and for computing Q when a solution does exist. One important consequence of this characterization is its update property: Whenever the solution with the current interpolatory set does not exist, we can add points to $\mathcal{C}_i$ and test again for solvability without redoing all of the computation.

Assume first that grid point $i \in \mathcal{F}$ has a neighborhood, as depicted in Figure 4.1, consisting of n_i points in set $\mathcal{N}_i$, with n_f fine-grid points and n_c coarse-grid points in C_i. Next, order the unknowns and equations of matrix A_i so that unknown i is first, followed by the other fine-grid points, with the coarse-grid points last. The neighborhood matrix and its square can then be written as

$$A_i = \begin{bmatrix} A_{ff}^{(1)} & A_{fc}^{(1)} \\ A_{cf}^{(1)} & A_{cc}^{(1)} \end{bmatrix} \quad \text{and} \quad A_i^2 = \begin{bmatrix} A_{ff}^{(2)} & A_{fc}^{(2)} \\ A_{cf}^{(2)} & A_{cc}^{(2)} \end{bmatrix},$$

respectively, and $\boldsymbol{\varepsilon}_i$ becomes $\boldsymbol{\varepsilon}_1$.

In the remainder of this subsection, we drop the subscript i whenever the meaning is clear. Set $\mathcal{Z}_i$ restricted to the neighborhood becomes

$$\mathcal{Z} := \{\mathbf{e} \in \mathbb{R}^{n_i} \ : \ e_j = 0 \ \forall j \notin C_i\} .$$

We can then interpret (4.15) with $p = 1$ or 2 as the problem of determining a vector $\mathbf{q} \in \mathcal{Z}$ that minimizes $\max_{\mathbf{e} \notin \text{Null}(A_i)} M_{i,p}(\mathbf{q}, \mathbf{e})$ subject to the constraint

$$(\boldsymbol{\varepsilon}_1 - \mathbf{q})^T \mathbf{e} = 0 \qquad \forall\, \mathbf{e} \in \text{Null}(A_i) = \text{Null}(A_i^2).$$

That is, we require

$$\boldsymbol{\varepsilon}_1 - \mathbf{q} \in \text{Range}\,(A_i) = \text{Range}\left(A_i^2\right). \tag{4.19}$$

Our first concern is the existence of such a vector $\mathbf{q}$. For this, we let $\hat{\boldsymbol{\varepsilon}}_1 \in \mathbb{R}^{n_f}$ denote the first canonical basis vector of length n_f.

LEMMA 4.2. *There exists* $\mathbf{q} \in \mathcal{Z}$ *such that* $\boldsymbol{\varepsilon}_1 - \mathbf{q} \in \text{Range}\,(A_i^p)$ *if and only if*

$$\hat{\boldsymbol{\varepsilon}}_1 \in \text{Range}\left(A_{ff}^{(p)}\right),$$

with $p = 1$ *or* 2.

Proof. Assume that $\hat{\boldsymbol{\varepsilon}}_1 \in \text{Range}\left(A_{ff}^{(p)}\right)$ so that

$$\hat{\boldsymbol{\varepsilon}}_1 = A_{ff}^{(p)} \hat{\boldsymbol{\delta}}_1$$

for some $\hat{\boldsymbol{\delta}}_1 \in \mathbb{R}^{n_f}$. Then

$$A_i^p \boldsymbol{\delta} := \begin{bmatrix} A_{ff}^{(p)} & A_{fc}^{(p)} \\ A_{cf}^{(p)} & A_{cc}^{(p)} \end{bmatrix} \begin{pmatrix} \hat{\boldsymbol{\delta}}_1 \\ 0 \end{pmatrix} = \boldsymbol{\varepsilon}_1 - \mathbf{q} \ \in \text{Range}\,(A_i^p)\,,$$

and $\mathbf{q} \in \mathcal{Z}$.

Conversely, suppose there exists $\mathbf{q} \in \mathcal{Z}$ such that $\boldsymbol{\varepsilon}_1 - \mathbf{q} \in \text{Range}\,(A_i^p)$; that is, there exists $\boldsymbol{\delta}$ such that

$$\boldsymbol{\varepsilon}_1 - \mathbf{q} = A_i^p \boldsymbol{\delta}.$$

This, in turn, implies that

$$\hat{\boldsymbol{\varepsilon}}_1 = \left[A_{ff}^{(p)},\ A_{fc}^{(p)}\right] \boldsymbol{\delta} \ \in \text{Range}\left(\left[A_{ff}^{(p)},\ A_{fc}^{(p)}\right]\right).$$

The proof will be completed by demonstrating that

$$\text{Range}\left(\left[A_{ff}^{(p)},\ A_{fc}^{(p)}\right]\right) = \text{Range}\left(A_{ff}^{(p)}\right).$$

This is certainly true if $A_{ff}^{(p)}$ is nonsingular. Assume otherwise, and let $\hat{\boldsymbol{\delta}}$ be a nonzero vector in $\text{Null}(A_{ff}^{(p)})$. Then

$$\left\langle \begin{bmatrix} A_{ff}^{(p)} & A_{fc}^{(p)} \\ A_{cf}^{(p)} & A_{cc}^{(p)} \end{bmatrix} \begin{pmatrix} \hat{\boldsymbol{\delta}} \\ 0 \end{pmatrix},\ \begin{pmatrix} \hat{\boldsymbol{\delta}} \\ 0 \end{pmatrix} \right\rangle = 0.$$

Since A_i^p is symmetric positive semidefinite, then 0 is an extreme value of $\langle A_i^p \mathbf{e},\ \mathbf{e}\rangle$, which implies that the vector $(\hat{\boldsymbol{\delta}},\ 0)^T$ is an eigenvector of A_i^p with eigenvalue 0. In other words, $(\hat{\boldsymbol{\delta}},\ 0)^T \in \text{Null}(A_i^p)$, which implies that

$$\text{Null}(A_{ff}^{(p)}) = \text{Null}(A_{cf}^{(p)}),$$

which, in turn, implies that

$$\text{Range}\left(A_{ff}^{(p)}\right) = \text{Range}\left(\left(A_{cf}^{(p)}\right)^T\right) = \text{Range}\left(A_{fc}^{(p)}\right),$$

and the lemma is proved. ∎

Rewriting (4.19), we want $\boldsymbol{\delta} \in \mathbb{R}^{n_i}$ such that

$$\boldsymbol{\varepsilon}_1 - \mathbf{q} = A_i^p \boldsymbol{\delta}$$

for some $\mathbf{q} \in \mathcal{Z}$. By the proof of Lemma 4.2, the set of all such $\boldsymbol{\delta}$ is

$$Y^{(p)} := \left\{ \boldsymbol{\delta} \in \mathbb{R}^{n_i} \ : \ \left[A_{ff}^{(p)},\ A_{fc}^{(p)} \right] \boldsymbol{\delta} = \hat{\boldsymbol{\varepsilon}}_1 \right\}.$$

If $Y^{(p)}$ is empty, then the constraint in (4.15) cannot be satisfied and $K_{i,p} = \infty$. In this case, more points must be added to C_i for (4.15) to have a solution. If $Y^{(p)}$ is not empty, then any $\boldsymbol{\delta} \in Y^{(p)}$ can be written as $\boldsymbol{\delta} = \boldsymbol{\delta}^* + \boldsymbol{\gamma}$, where $\boldsymbol{\delta}^*$ is a particular element of $Y^{(p)}$ and $\boldsymbol{\gamma} \in \text{Null}([A_{ff}^{(p)},\ A_{fc}^{(p)}])$. From the proof of Lemma 4.2, we may choose $\boldsymbol{\delta}^* = (\hat{\boldsymbol{\delta}}_1,\ 0)^T$, where $A_{ff}^{(p)} \hat{\boldsymbol{\delta}}_1 = \hat{\boldsymbol{\varepsilon}}_1$. We now show that

$$\boldsymbol{\varepsilon}_1 - \mathbf{q}^* = A_i^p \boldsymbol{\delta}^*$$

yields the unique solution to (4.14) or (4.15).

THEOREM 4.3. *If $\hat{\boldsymbol{\varepsilon}}_1 \notin$ Range $(A_{ff}^{(p)})$, then $K_{i,p} = \infty$. If $\hat{\boldsymbol{\varepsilon}}_1 = A_{ff}^{(p)} \hat{\boldsymbol{\delta}}_1$, then the unique solution of* (4.14) *is given by*

$$\mathbf{q}^* = \begin{pmatrix} 0 \\ -A_{cf}^{(p)} \hat{\boldsymbol{\delta}}_1 \end{pmatrix} \in \mathcal{Z}, \tag{4.20}$$

and $K_{i,p} = \langle \hat{\boldsymbol{\varepsilon}}_1, \hat{\boldsymbol{\delta}}_1 \rangle$ for $p = 1$ or 2.

Proof. The first statement follows from Lemma 4.2. To prove the second, let $\boldsymbol{\delta}^* = (\hat{\boldsymbol{\delta}}_1,\ 0)^T$. Using the substitution

$$\boldsymbol{\varepsilon}_1 - \mathbf{q} = A^{(p)} \boldsymbol{\delta}$$

with $\boldsymbol{\delta} \in Y^{(p)}$, we can rewrite (4.14) as

$$\begin{aligned} \min_{\mathbf{q} \in \mathcal{Z}} \max_{\mathbf{e} \notin \text{Null}(A_i^p)} \frac{\langle (\boldsymbol{\varepsilon}_1 - \mathbf{q})^T \mathbf{e},\ (\boldsymbol{\varepsilon}_1 - \mathbf{q})^T \mathbf{e} \rangle}{\langle A_i^p \mathbf{e},\ \mathbf{e} \rangle} &= \min_{\boldsymbol{\delta} \in Y^{(p)}} \langle A_i^p \boldsymbol{\delta}, \boldsymbol{\delta} \rangle \\ &= \min_{\boldsymbol{\gamma} \in \text{Null}([A_{ff}^{(p)},\ A_{fc}^{(p)}])} \langle A_i^p (\boldsymbol{\delta}^* + \boldsymbol{\gamma}),\ (\boldsymbol{\delta}^* + \boldsymbol{\gamma}) \rangle . \end{aligned} \tag{4.21}$$

Any solution of (4.21) is characterized by $\boldsymbol{\gamma}^* \in \text{Null}([A_{ff}^{(p)},\ A_{fc}^{(p)}])$ such that

$$\langle A_i^p (\boldsymbol{\delta}^* + \boldsymbol{\gamma}^*),\ \boldsymbol{\gamma} \rangle = 0 \qquad \forall\, \boldsymbol{\gamma} \in \text{Null}([A_{ff}^{(p)},\ A_{fc}^{(p)}]); \tag{4.22}$$

that is,

$$A_i^p (\boldsymbol{\delta}^* + \boldsymbol{\gamma}^*) \in \text{Range} \left(\begin{bmatrix} A_{ff}^{(p)} \\ A_{cf}^{(p)} \end{bmatrix} \right). \tag{4.23}$$

But $\boldsymbol{\gamma}^* = 0$ satisfies (4.22) by construction of $\boldsymbol{\delta}^*$, which proves that (4.20) solves (4.14).

To prove uniqueness, suppose there are two such solutions to (4.22), say, $\boldsymbol{\delta}^*$ and $\boldsymbol{\beta}^*$. Then

$$A_i^p (\boldsymbol{\delta}^* - \boldsymbol{\beta}^*) = \begin{bmatrix} A_{ff}^{(p)} \\ A_{cf}^{(p)} \end{bmatrix} \hat{\mathbf{w}}$$

for some $\hat{\mathbf{w}} \in \mathbb{R}^{n_f}$. Since both $\boldsymbol{\delta}^*$ and $\boldsymbol{\beta}^*$ are in $Y^{(p)}$, we have $\hat{\mathbf{w}} \in \text{Null}(A_{ff}^{(p)})$. From Lemma 4.2, we have $\text{Null}(A_{ff}^{(p)}) = \text{Null}(A_{cf}^{(p)})$, which implies that $A_i^p(\boldsymbol{\delta}^* - \boldsymbol{\beta}^*) = 0$ and that $\mathbf{q}^*$ is unique.

Finally, substituting $\boldsymbol{\delta}^*$ into (4.21) yields

$$K_{i,p} = \langle A_i^p \boldsymbol{\delta}^*,\ \boldsymbol{\delta}^* \rangle = \left\langle \hat{\boldsymbol{\varepsilon}}_1,\ \hat{\boldsymbol{\delta}}_1 \right\rangle,$$

which completes the proof. ∎

A practical algorithm for determining Q is as follows:

For $p = 1$, set

$$A_{ff}^{(1)} = A_{ff}, \qquad A_{cf}^{(1)} = A_{cf}.$$

For $p = 2$, set

$$A_{ff}^{(2)} = A_{ff}^2 + A_{fc}A_{cf}, \qquad A_{cf}^{(2)} = A_{cf}A_{ff} + A_{cc}A_{cf}.$$

Perform a QR factorization on $A_{ff}^{(p)}$ using Householder reflections and column pivoting to detect rank deficiency. If

$$A_{ff}^{(p)} \hat{\boldsymbol{\delta}}_1 = \hat{\boldsymbol{\varepsilon}}_1$$

has a solution, then set

$$\mathbf{q}^* = \begin{pmatrix} 0 \\ -A_{cf}^{(p)} \hat{\boldsymbol{\delta}}_1 \end{pmatrix}$$

and $K_{i,p} = \langle \hat{\boldsymbol{\varepsilon}}_1,\ \hat{\boldsymbol{\delta}}_1 \rangle$; otherwise, set $K_{i,p} = \infty$.

4.3. Local-global measure. This subsection shows that if $M_{i,1}$ or $M_{i,2}$ is bounded for every $i \in \mathcal{F}$, then the global measure M_1 is also bounded.

THEOREM 4.4. *Let $p = 1$ or 2 and assume that the local approximation property*

$$M_{i,p}(Q, \mathbf{e}) \le K_{i,p} \quad \forall \mathbf{e} \in \mathbb{R}^n \tag{4.24}$$

holds for some $K_{i,p}$ and all $i \in \mathcal{F}$. Then global approximation property (3.4) *is also satisfied with*

$$K = \max_{\alpha \in \mathcal{T}} \sum_{i \in \mathcal{M}_\alpha \cap \mathcal{F}} K_{i,p} \left\| A_i \right\|^{p-1}. \tag{4.25}$$

Proof. We have

$$\begin{aligned}
\langle (I-Q)\mathbf{e},\ (I-Q)\mathbf{e} \rangle &= \sum_{i \in \mathcal{F}} \left\langle \boldsymbol{\varepsilon}_i \boldsymbol{\varepsilon}_i^T (I-Q)\mathbf{e},\ \boldsymbol{\varepsilon}_i \boldsymbol{\varepsilon}_i^T (I-Q)\mathbf{e} \right\rangle \\
&\le \sum_{i \in \mathcal{F}} K_{i,p} \left\langle A_i^p \mathbf{e},\ \mathbf{e} \right\rangle \\
&\le \sum_{i \in \mathcal{F}} K_{i,p} \left\| A_i \right\|^{p-1} \left\langle A_i \mathbf{e},\ \mathbf{e} \right\rangle \\
&= \sum_{\alpha \in \mathcal{T}} \langle A_\alpha \mathbf{e},\ \mathbf{e} \rangle \sum_{i \in \mathcal{M}_\alpha \cap \mathcal{F}} K_{i,p} \left\| A_i \right\|^{p-1} \\
&\le K \sum_{\alpha \in \mathcal{T}} \langle A_\alpha \mathbf{e},\ \mathbf{e} \rangle \\
&= K \left\langle A\mathbf{e},\ \mathbf{e} \right\rangle. \qquad \blacksquare
\end{aligned}$$

Straightforward application of the above techniques can be used to bound M_2 in terms of $M_{i,2}$. However, the resulting bounds on M_2 can be much larger than the maximum value of $M_{i,2}$. While this may not be sharp, it is simple to construct an example where M_2 is much larger than the largest $M_{i,2}$ and, hence, much larger than M_1. In this case, using M_2 to estimate convergence could lead to the erroneous conclusion that the resulting two-level method is slow to converge.

The local measure bounds, $K_{i,p}$, can be used as a diagnostic tool: Theorem 4.4 shows that they contribute to the bound K used to establish convergence in Theorem 3.2. While neither measure provides a sharp bound when the algorithm exhibits a small convergence factor, they can provide a warning: If $K_{i,p}$ is large for some i, it may be profitable to reexamine the choice of the coarse grid, perhaps adding more grid points to $\mathcal{C}$.

As an alternative to increasing the size of $\mathcal{C}$, we could respond to large values of $K_{i,p}$ locally by increasing the size of the neighborhood. Define the set $\mathcal{N}_i^{(k)}$ of *kth removed neighbors* recursively by letting $\mathcal{N}_i^{(1)} := \mathcal{N}_i$ and

$$\mathcal{N}_i^{(\ell+1)} := \cup_{j \in \mathcal{N}_i^{(\ell)}} \mathcal{N}_j. \tag{4.26}$$

Then interpolation could be allowed from the set $\mathcal{C}_i := \mathcal{N}_i^{(k)} \cap \mathcal{C}$, which are the coarse-grid points connected to point i by a path of length k in the graph of A. While this would yield more accurate interpolation, the complexity of $P^T AP$ would certainly increase.

5. Numerical results. We apply the element interpolation methods numerically to two illustrative examples: a Poisson equation discretized on stretched quadrilaterals and a plane-stress cantilever beam. We compare our numerical results with the *bounds* predicted by our theory and demonstrate the improved robustness of the new methods over AMG.

For each problem, we first present results for AMG to show that our usual approach breaks down. For standard AMG, which we now refer to as AMG1, parameter θ defining the cutoff for strong connections is set to 0.25. The interpolation formula is that found in [18] (see (5.10) and (6.4) there). For the stretched grid problem, two variants of AMG are presented that restore convergence (although these fixes will be shown to be ineffective in the elasticity problem). The first, called AMG2, uses a more restrictive definition of strong connections by taking $\theta = 0.50$. The second variant (AMG3) returns to $\theta = 0.25$ but uses iterative weight interpolation [10].

For comparison, we also include a method presented in [9, 8], since they report results for both anisotropic Poisson problems and 2D elasticity. In those articles two basic methods are described, each with a user-specified parameter θ_1. The one we include (referred to in [8] as method II, with $\theta_1 = 0$, and called the Chang–Wong–Fu (CWF) method here) appears to be the most robust of their methods overall. There are two main differences between our standard AMG algorithm and theirs. The first is that their strong connections are determined by absolute value, while we consider only connections of the "right" sign (i.e., the opposite sign from that of the diagonal entry) to be strong. (As with standard AMG, they take $\theta = 0.25$.) The second difference is the use of a modified interpolation formula. As with standard AMG, interpolation to a point i is derived by writing the corresponding residual equation in terms of the error, making some approximations for those terms defined at points not used in interpolation, and solving for e_i to obtain the weights. Unlike standard AMG, these approximations use weighted averages based on absolute values of the matrix

entries and incorporate some geometric ideas based on the assumption that the size of matrix entries diminishes with the distance between grid points. A seemingly minor modification is that, for weak (small) connections j with no connection to set the interpolation points, the approximation is made that $e_j = e_i$ if $\text{sign}(a_{ij}) = -\text{sign}(a_{ii})$ or $e_j = -e_i$ if $\text{sign}(a_{ij}) = \text{sign}(a_{ii})$. Variants of their methods include modifications to restriction and the definition of the coarse-grid operator. However, the algorithm we test reduces to the standard Galerkin formulation. That is, restriction is defined as the transpose of interpolation, and the coarse-grid operator is taken as the product of restriction, the fine-grid matrix, and interpolation. The coarsening method they describe is simply the Ruge–Stüben two-pass coarsening scheme [18] using the modified definition of strong connections. For testing their method, we use our AMG coarsening code with strong connections determined by absolute value.

The only difference here between AMGe and the AMG variants described above is that we use the element interpolation method in AMGe to construct the interpolation operators. Thus, the coarse grids are selected in the same way that they are in AMG. The possibility of using the AMGe measures to determine coarsening is a topic of current research. Three different definitions are considered for interpolation: AMG, local measure 1 (AMGe1), and local measure 2 (AMGe2).

In the multilevel algorithm, we construct "coarse element stiffness matrices" $A_{c,\alpha}$ as follows:

$$A_{c,\alpha} = P^T A_\alpha P. \tag{5.1}$$

To reduce computational complexity and storage costs, we combine coarse elements that operate on the same points by summing them. That is, we define

$$\mathcal{M}_{c,\alpha} := \left\{ j \ : \ \boldsymbol{\varepsilon}_j^T A_{c,\alpha} \boldsymbol{\varepsilon}_j \neq 0 \right\} \tag{5.2}$$

and, when $\mathcal{M}_{c,\alpha} = \mathcal{M}_{c,\beta}$, we combine $A_{c,\alpha}$ and $A_{c,\beta}$ to form a single coarse-element stiffness matrix.

To conform to the theory, the linear systems for the AMGe tests are scaled so that the diagonal is the identity. That is, we actually solve $\hat{A}\hat{\mathbf{u}} = \hat{\mathbf{f}}$, where $\hat{A} = D^{-1/2} A D^{-1/2}$, $\hat{\mathbf{u}} = D^{1/2}\mathbf{u}$, and $\hat{\mathbf{f}} = D^{-1/2}\mathbf{f}$. Our initial experiments use $V(0,1)$ cycles based on damped Jacobi with step size $s = 1/2$. In the examples below, $\|A\|$ is between 2.5 and 3.0 so that $\frac{1}{\|A\|} \leq s \leq \frac{2}{\|A\|}$. For AMG, we use the original unscaled matrix A.

Equation (3.9) in Theorem 3.2 yields a bound on the convergence factor given by

$$\rho \leq 1 - \frac{4 - \|A\|}{4K}, \tag{5.3}$$

where K is the bound on either M_1 or M_2. As we will see, this bound is very pessimistic. Replacing K from (4.25) by $K_p = \max_i K_{i,p}$ yields a somewhat more realistic but still pessimistic estimate for the convergence factor. These estimates are included in the numerical results below.

5.1. Stretched quadrilateral. Consider the stretched quadrilateral problem introduced in section 2, which consists of a Poisson equation on a rectangular grid discretized with $n_x \times n_y$ bilinear quadrilateral elements. The fine-grid elements have a 10:1 aspect ratio, yielding the stencil in (2.4). The boundary conditions are Dirichlet, which are eliminated from the matrix during discretization.

TABLE 5.1
Two-level and V-cycle asymptotic convergence factors for the stretched quadrilateral problem.

	Two-Level				Multilevel			
Size	AMG1	AMG2	AMG3	CWF	AMG1	AMG2	AMG3	CWF
64×64	0.80	0.12	0.09	0.91	0.81	0.14	0.09	0.91
128×128	0.80	0.12	0.10	0.92	0.81	0.14	0.10	0.91

In Table 5.1, we present results of tests with AMG and its variants for the stretched-grid Poisson problem. Both two-level and V-cycle results are given. In all cases, (1,1) V-cycles are used, with C/F-ordered Gauss–Seidel relaxation. For AMG1, convergence is much worse than the two-level factors of 0.06 and V-cycle factors of 0.10 that we would get on unstretched grids. AMG2 and AMG3 both improve convergence greatly, nearly restoring the results that would be obtained in the uniform case.

The AMG variants each produced a semicoarsened grid for the first coarsening. Away from boundaries, AMG1 used a six-point interpolation stencil of the form

$$P_{\text{AMG}} = \begin{bmatrix} 0.084 & 0.332 & 0.084 \\ & * & \\ 0.084 & 0.332 & 0.084 \end{bmatrix}. \tag{5.4}$$

Both AMG2 and AMG3 produced two-point interpolation away from boundaries, so that weights of 0.5 were obtained for the north and south points. Here, the difference between these two methods lies in the interpolation stencils near boundaries.

In geometric multigrid, this anisotropic situation is often treated by semicoarsening, that is, by choosing coarse-grid points along each vertical line. Interpolation is then performed only in the y direction. The typical interpolation weights used in geometric semicoarsening do not involve corner points, so smaller weights intuitively make more sense here. In fact, it can be shown that, for this problem, smaller corner weights (up to a point) generally produce better two-level results. Since performance is very sensitive to these weights, small changes in the algorithm can affect convergence greatly. For example, in the code AMG1R5 that is widely available to the public, in computing the interpolation operator, weak connections are treated in a manner similar to strong connections. For this problem, this modification gives corner weights of 0.0052 and results in two-level and V-cycle factors of 0.33 and 0.54, respectively.

Poor performance of the CWF method is primarily due to the grid chosen. Using their modified definition of strong connections, all off diagonals in stencil (2.4) are considered strong. This results in standard coarsening (coarsening by a factor of 2 in each grid direction), not semicoarsening. It is well known that such a coarse grid cannot be used effectively for this problem without additional modifications to the algorithm, such as line relaxation. It is interesting to note that, as the grid becomes "unstretched," the connections to the left and right become smaller, and proper semicoarsening results. If semicoarsening were used in conjunction with the CWF interpolation, two-level results of 0.33 would be obtained. This is still far from the results reported for anisotropic problems in [8]. In that paper, however, simple five-point finite difference stencils are used, so that M-matrices result, and connections to the east and west actually do become small as the grid is stretched. AMG and the

variants used here would also have no problem with such discretizations. It should be noted that the coarse grids we obtain may not be those that would be obtained with the algorithm as they have implemented it, and in fact appear to be coarser in most of their test problems, given the larger grid complexities they report. Nevertheless, the grids chosen satisfy the criteria they present.

The point here is not that particular fixes exist for this specific problem. There is no shortage of variations of the AMG algorithm: Each works well for some specific cases but can break down for others. Our goal is instead to obtain robust AMG methods that are much more difficult to break. This goal is the motive for the development of AMGe.

In the AMGe tests, the AMG coarsening algorithm used for all three methods again produces semicoarsened grids, and the interpolation formulas for AMGe1 and AMGe2 are as follows:

$$P_{\mathrm{AMGe1}} = \begin{bmatrix} 0.007 & 0.486 & 0.007 \\ & * & \\ 0.007 & 0.486 & 0.007 \end{bmatrix}, \tag{5.5}$$

$$P_{\mathrm{AMGe2}} = \begin{bmatrix} 0.003 & 0.494 & 0.003 \\ & * & \\ 0.003 & 0.494 & 0.003 \end{bmatrix}. \tag{5.6}$$

The stencils at boundaries are similar. Note that interpolation for these algorithms also involve corner points, since these are considered strong connections, but the associated weights for AMGe1 and AMGe2 are much smaller than for AMG. The large element aspect ratio effectively decouples each vertical line of grid points from the others.

The experimental results for AMG1, AMGe1, and AMGe2 are presented in Table 5.2. Two grid sizes, 64×64 and 128×128, are used. For better comparison with the theory, two changes were made to the solution method. First, we used (1,0) V-cycles, as opposed to the (1,1) V-cycles reported in the previous table. In addition, relaxation has been changed from C/F Gauss–Seidel to a Richardson iteration with a relaxation parameter $\omega = 0.5$. For each grid, we show asymptotic convergence factors for AMG1, AMGe1, and AMGe2. Factors are shown for both two-level and multilevel cases. For the two-level case, we show the bound on the convergence factor corresponding to using (4.25) in Theorem 3.2 for M_1. This is computed using $\|A\| = 2.97$ and $K_1 = 2.68$. As expected, the bound is very pessimistic. We also show the convergence factor (labeled "estimate") that would result from substituting $K_1 = \max_i K_{i,1} = 1.34$ and $K_2 = \max_i K_{i,2} = 2.0$ for (4.25) in Theorem 3.2. This provides a somewhat improved but still very pessimistic value for the convergence factor. This behavior is typical of most multigrid theory, where results often substantially exceed theoretical estimates.

The key observation to be made from the data in Table 5.2 is that both AMGe1 and AMGe2 produce substantial improvement over AMG for stretched quadrilaterals. For this problem, AMG2 and AMG3 described above would produce results similar to AMGe1 and AMGe2. Such techniques, however, tend to be somewhat ad hoc, and are not based on theoretical considerations. As such, we cannot determine in advance whether such treatments will be useful for a given problem. By contrast, we expect AMGe1 and AMGe2 to perform well in more general problems involving high aspect

TABLE 5.2

Estimate		0.81	0.87	–	–	–

ratios, so they should find wide applicability for problems based on unstructured grids having thin domains or regions.

5.2. Plane-stress cantilever beam. Consider the 2D linear elasticity equations

$$u_{xx} + \frac{1-\nu}{2}u_{yy} + \frac{1+\nu}{2}v_{xy} = f_1,$$
$$v_{yy} + \frac{1-\nu}{2}v_{xx} + \frac{1+\nu}{2}u_{xy} = f_2,$$

where u and v are displacements in the x and y directions, respectively. We take $\nu = 4/7$ for the tests. The problem, depicted in Figure 5.1, has free boundaries, except on the left where $u = v = 0$. We discretize with bilinear finite elements on a uniform rectangular mesh with spacing h in both directions (square elements).

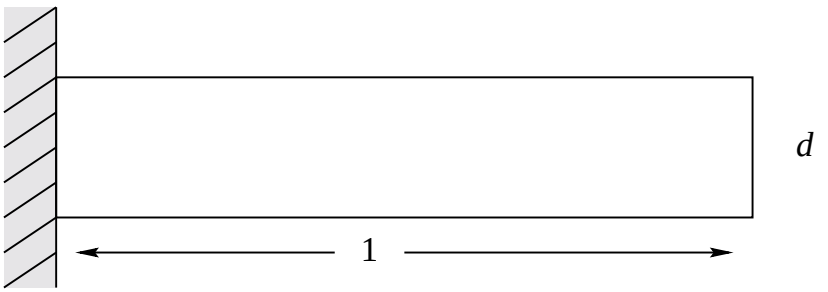

FIG. 5.1. *Plane-stress cantilever beam problem.*

Again, before testing the element-based methods, we present results for the AMG1, AMG2, AMG3, and CWF methods of the previous section. AMG1, AMG2, and AMG3 are applied in a separate fashion (the so-called unknown approach [18]) in which connections between u and v are completely ignored in the determination of strong connections and computation of interpolation weights. Such an approach has been shown to produce good results for the elasticity problem on the unit square when full Dirichlet boundary conditions are used, although it degrades with the number of free sides allowed (cf. [10]). As in [8], the CWF method does not differentiate between the two unknowns. (It should be noted that, in comparison with the AMG1R5 code in that paper, AMG was also applied in a "scalar" fashion. Not unexpectedly, it did not perform well since AMG1R5 was designed for scalar problems and there is really no local relationship between pointwise values of errors in u and errors in v, even when these errors are smooth.)

TABLE 5.3
Two-level and V-cycle asymptotic convergence factors for four methods for the plane-stress problem.

1/4	0.58	0.57	0.51	0.98	0.97	0.95	0.98	0.98
1/8	0.90	0.90	0.87	0.99	0.99	0.98	0.99	0.99
1/16	0.98	0.98	0.98	0.99	0.98	0.98	0.99	0.99
1/32	0.98	0.99	0.98	0.99	0.99	0.99	0.99	0.98
1/64	0.99	0.99	0.99	0.99	0.98	0.98	0.98	0.98

Results are presented in Table 5.3. Several different thicknesses are used for the beam, ranging from a square cross section, $d = 1$, to a very thin beam, $d = 1/64$. As before, (1,1) V-cycles were used with C/F Gauss–Seidel relaxation. The factors shown were obtained after 100 cycles. (With such poor convergence factors, it generally takes many iterations to reach the asymptotic state.) Note that there is little difference between convergence factors for AMG1, AMG2, and AMG3, although AMG3 with iterative weight interpolation shows a slight advantage. For this problem, the $u - u$ and $v - v$ stencils each resemble the anisotropic stencils for the Poisson problem (with the first stretched in x and the second in y), but with grids that are less stretched. Thus, the "fixes" do not improve much on the basic algorithm, as they did for the stretched-grid Poisson problem. Note that two-level factors are nearly constant until d is reduced to below 1/2, at which convergence degrades sharply. V-cycle factors, while somewhat acceptable for large d, degrade even more quickly than two-level factors as the domain becomes thinner. With all three AMG variants, on the finest grid, u is semicoarsened in x while v is semicoarsened in y for all d used. Thus, for all $d > 1/64$, interpolation computed on the finest level does not change. This indicates strongly that the problem is not that interpolation accuracy for smooth components is affected, but that such smooth components must be interpolated *more* accurately as d is reduced. In fact, it can be shown that the energy norm relative to the Euclidean norm of the smoothest components decreases to zero with d, which by standard variational multigrid theory (see section 3) suggests that interpolation must become increasingly more accurate.

For this problem, the interpolation scheme in the CWF method gives very slow convergence. Even two-level factors are large for $d = 1$, indicating that the local interpolation accuracy is not sufficient. Since quite good results for the 2D elasticity problem were presented in [8], some explanation for the behavior of the method here is warranted. As noted earlier, the CWF method does not differentiate between u and v, and, for example, u at a point can interpolate from a combination of u and v values at surrounding points. With such interpolation, however, some minimal conditions must be met before reasonable convergence could be expected. With discretizations of scalar differential operators, away from Dirichlet boundaries, the matrix generally has zero row sums, so that the constant is in the local null space of the operator. Since the smoothest grid functions are locally constant, these must be interpolated exactly, which in turn requires interpolation weights at each point to sum to 1. Similarly, in the elasticity problem, away from fixed boundaries the $u - u$, $u - v$, $v - u$, and $v - v$

TABLE 5.4

Bound	–	0.97	–	–	–	–
Estimate	–	0.87	0.97	–	–	–

connections at each point also sum to zero, so that separate independent constants in u and v are in the local null space of the operator. For these components to be interpolated exactly, the $u - u$ and $v - v$ interpolation weights both must sum to 1, while the $u-v$ and $v-u$ weights both must sum to zero. Loss of any of these conditions can severely degrade convergence. Now, one thing to note is that the tests in [8] use finite differences and full Dirichlet boundary conditions. In the finite difference case, the $u - v$ and $v - u$ connections are smaller relative to the maximum connection, and are considered weak, thus keeping interpolation completely separate for u and v, at least on the finest grid. In the finite element case here, connections from u to v and v to u are considered strong. By itself, this is not bad. In fact, when full Dirichlet conditions are used with the finite element discretization, the CWF method gives a two-level convergence factor of 0.33 for the $d = 1$ problem. Along free boundaries, however, it was found that different geometric assumptions applied to positive and negative cross connections resulted in a loss of one-row sum for the $u-u$ interpolation weights and zero-row sum for the $u - v$ and $v - u$ weights, resulting in the uniformly poor convergence found.

In the AMGe tests, we use the geometric coarsening strategy of doubling the element size in both directions until there is only one element in the y direction, then doubling the element size in the x direction only. For the multilevel results, we coarsen until $h_x = 2h_y$. Such a grid is not admissible with the other AMG algorithms presented, so a direct comparison of the effect of using the different interpolation formulas on the same grid is not practical here. (Actually, a modification of iterative weight interpolation could be used and would yield results comparable with those previously obtained.) However, it is instructive to include results of AMG where linear interpolation is actually used on these uniform grids. This method then becomes a geometric multigrid algorithm, which we call GMG.

Experimental results from three methods are shown in Table 5.4, using (0,1) V-cycles based on Jacobi sweeps with relaxation parameter $\omega = 0.5$. This should be kept in mind when comparing results with the AMG tests of Table 5.3, since (1,1) V-cycles were used there. The theoretical bounds and estimates suggest extremely slow convergence for AMGe1 and AMGe2 (when applied to AMG, they do not indicate that AMG will converge at all). In fact, however, both AMGe1 and AMGe2 achieve substantial improvement, especially for the two-level algorithm, where they greatly exceed predictions. The bound is based on $\|A\| = 2.50$ and $K_1 = 12.25$, while the predictions are based on $\max_i K_{i,1} = 2.84$ and $\max_i K_{i,2} = 8.31$.

Note that the GMG method, which is basically the best that the AMG methods using separate interpolation can aspire to, also shows the same type of degradation as the AMG methods, although less severe. That is, two-level results are stable until d becomes small, then worsen. V-cycle results degrade faster, although they stabilize due to the artificial limitation on the coarsest grid used. This limitation was not present in the AMG tests. In fact, coarser grids could have been used here, which would result in much worse convergence factors if we were to continue with the same interpolation and relaxation schemes. For further coarsening in the x direction, smoothing of pointwise relaxation would suffer as the grid aspect ratios worsen, so "group" relaxation (here equivalent to y-line relaxation) would be needed to maintain efficiency. We did not consider this group relaxation option or its implications on our theory because the focus here is on the interpolation process.

Two observations are significant: The two-level performance of AMGe1 and AMGe2 is generally independent of the beam thickness until $d = h_x$, where even greater improvement occurs; and the multilevel performance of AMGe1 and AMGe2 improves steadily as the beam becomes thinner. This is in direct contrast to the AMG and GMG results obtained, demonstrating the effectiveness of the new interpolation methods.

While this paper concentrates on the effect of the new interpolation method, it should be kept in mind that there are other techniques that may be applied to enhance performance of the algorithm. For instance, the multilevel experiments shown here focused on Jacobi relaxation and a (0,1) V-cycle. The relaxation method and its parameters can be chosen differently. For example, the multilevel AMGe1 case with $d = 1/4$ shows a convergence factor of 0.65 in Table 5.4. A Jacobi (1,1) V-cycle improves this factor to 0.58, while a (1,1) F-cycle (see [14]) attains a convergence factor of 0.31. Nearly identical results, 0.65 for V(0,1), 0.56 for V(1,1), and 0.33 for $F(1,1)$, are obtained if the Jacobi relaxation is replaced by nodal Gauss–Seidel with symmetric CF relaxation, which sweeps over the C points followed by the F points on the downward leg of the V-cycle, and over the F points followed by the C points on the upward leg. Another possibility is the use of a single multigrid V(1,1) cycle as a preconditioner for a conjugate gradient iteration. Applied to the plane-stress problem using the nodal relaxation described above, this yields convergence factors ranging from 0.16 to 0.26 per conjugate gradient iteration.

For both sets of experiments, AMGe interpolation achieves significant improvement over conventional AMG performance. We believe that further improvement is possible using more sophisticated coarse-grid selection. We observe that local measures $M_{i,1}$ and $M_{i,2}$ carry a great deal of information about the nature of the underlying problem and its discretization, and we should be able to exploit this information to determine more effective coarse grids.

6. Conclusions. For any multigrid method to work, errors that remain after relaxation must be well approximated by the range of interpolation. Since algebraic multigrid does not rely on geometric information, its fundamental challenge is to construct coarse grids and interpolation operators that approximate these errors. The core of this challenge is to determine errors that cannot be effectively reduced by local processing.

Two local measures were introduced here to quantify how well the coarsening processes determine algebraically smooth error, and they were used to construct new interpolation operators. Experimental data for two representative test problems confirm that these operators produce an AMGe algorithm whose convergence rates for

these cases are substantially better than standard AMG.

Current research focuses on using these measures in AMGe also to assess the ability of coarse-grid points to represent the necessary error components, that is, to determine *which* points are best suited to be on the coarse grid. Combined with the improved interpolation operator, this may lead to very efficient AMGe algorithms for a much wider range of problems than is currently available.

COLLOCATION METHODS FOR THE COMPUTATION OF PERIODIC SOLUTIONS OF DELAY DIFFERENTIAL EQUATIONS*

K. ENGELBORGHS†, T. LUZYANINA†‡, K. J. IN 'T HOUT§, AND D. ROOSE†

Abstract. In this paper we investigate collocation methods for the computation of periodic solutions of autonomous delay differential equations (DDEs). Periodic solutions are found by solving a periodic two-point boundary value problem, which is an infinite-dimensional problem for DDEs, in contrast to the case of ordinary differential equations. We investigate three collocation methods based on piecewise polynomials. We discuss computational issues and show numerical orders of convergence using an extensive number of tests. We compare our numerical results with known theoretical convergence results for initial value problems for DDEs. In particular, we show how superconvergence at the mesh points can be lost or recovered depending on the DDE model under consideration and on the choice of collocation discretization. We end with a brief discussion of adaptive mesh selection.

Key words. delay differential equations, periodic solutions, collocation methods

AMS subject classifications. 65J15, 65P05

1. Introduction.

This paper deals with collocation methods for the computation of periodic solutions to autonomous *delay differential equations* (DDEs),

$$\frac{\mathrm{d}x(t)}{\mathrm{d}t} = f(x(t), x(t-\tau)), \tag{1.1}$$

with one (constant) delay $\tau > 0$ and $f : \mathbb{R}^n \times \mathbb{R}^n \to \mathbb{R}^n$. For the sake of convenience we restrict ourselves to one-delay DDEs, but generalization to multiple delays is straightforward.

Let $C := C([-\tau, 0], \mathbb{R}^n)$ be the vector space of continuous functions mapping the interval $[-\tau, 0]$ into $\mathbb{R}^n$. For $s \in \mathbb{R}$, denote by $x_s \in C$ the segment of a solution x to (1.1) defined by

$$x_s(\theta) = x(s+\theta), \ \ \theta \in [-\tau, 0].$$

C is the state space for (1.1), that is, for any given s the solution segment x_s uniquely determines, via (1.1), the values $x(t)$ for all $t \geq s$. Consequently, any periodic solution

to (1.1) can be found as the solution of the following *two-point boundary value problem* (BVP),

$$\left\{\begin{array}{l} \frac{\mathrm{d}x(t)}{\mathrm{d}t} = f(x(t), x(t-\tau)),\ t \in [0,T], \\ x_0 = x_T, \\ p(x,T) = 0, \end{array}\right. \tag{1.2}$$

where T denotes the (unknown) period and $p(x,T) = 0$ represents a suitable phase condition to remove translational invariancy.

Observe that the boundary condition $x_0 = x_T$ in (1.2) concerns a condition in an *infinite-dimensional* space, namely, C. This is clearly in contrast with the analogous problem for the case of ordinary differential equations (ODEs, i.e., (1.1) without a delay argument $x(t-\tau)$), where the boundary condition applies in a *finite-dimensional* space, $\mathbb{R}^n$.

In [22] the convergence of numerical simulations to stable periodic solutions was considered. In [27] a shooting approach is used, based on a combination of [16] and [26], for solving problem (1.2). This approach has been used to study a number of specific applications of DDEs [14, 13] and has been shown to be reasonably efficient.

The approach we follow in this paper is to solve the BVP (1.2) by the well-known collocation method. Collocation methods are popular methods for the numerical solution of BVPs for systems of ODEs. The widely used COLSYS/COLNEW [1, 6] and AUTO [12] software packages employ collocation with piecewise polynomials to approximate the solutions to BVPs for ODEs.

In this paper, our main aim is to study, by means of numerical experiments, a number of related collocation schemes for (1.2) with respect to their (observed) convergence orders and efficiency. In section 2 we distinguish between two kinds of BVPs for DDEs and discuss theoretical convergence results from the literature. In section 3 we outline the general setting relevant to collocation methods. In section 4 we review known convergence results concerning the numerical solution of IVPs for DDEs, which we will compare with the outcomes of our numerical experiments for the periodic BVP (1.2). This comparison is motivated by the fact that in the case of ODEs the same convergence orders are valid for similar discretizations of IVPs and BVPs, respectively. Next, in section 5 we explain the collocation variants that we investigate. In section 6 we describe the test models which we use, and we present our actual numerical results in section 7. Section 8 contains conclusions.

2. Two kinds of BVPs. A general two-point BVP for delay differential equations (1.1) may be formulated as (cf., e.g., [18, 24])

$$\left\{\begin{array}{l} \frac{\mathrm{d}x(t)}{\mathrm{d}t} = f(x(t), x(t-\tau)),\ t \in [0,T], \\ b(x_0, x_T) = 0, \end{array}\right. \tag{2.1}$$

where $b : C \times C \to C$ and $T > 0$ are given. However, in the current literature on the numerical solution of BVPs for DDEs (or more general functional differential equations), see, e.g., [5, 8, 3, 9, 30, 25] and [2, section 11.7], one invariably encounters BVPs for (1.1) of the form

$$\left\{\begin{array}{l} \frac{\mathrm{d}x(t)}{\mathrm{d}t} = f(x(t), x(t-\tau)),\ t \in [0,T], \\ x(\theta) = \phi(\theta),\ \theta \in [-\tau, 0), \\ b(x(0), x(T)) = 0. \end{array}\right. \tag{2.2}$$

Here, an initial function $\phi \in C$ is given, a discontinuity in the solution at $t = 0$ is allowed, and $b : \mathbb{R}^n \times \mathbb{R}^n \to \mathbb{R}^n$ specifies a boundary condition in the finite-dimensional space $\mathbb{R}^n$. We note that both kinds of BVPs, (2.1) and (2.2), may contain additional conditions and corresponding free parameters (cf. $p(x, T) = 0$ and T in (1.2)). In [24] problem (2.1) is called Halanay's boundary value problem, whereas (2.2) is called a BVP with finite defect.

The existing literature on the numerical solution of BVPs for DDEs seems to be mainly targeted towards problems of the kind (2.2), which arise, among others, in control applications. In particular, a convergence result for piecewise polynomial collocation for the problem (2.2) is proven in [4]. We are not aware of theoretical convergence results on the numerical solution of problems of the kind (2.1) which cannot be reduced to the BVP (2.2) (and are not based on approximations by truncated Fourier series as in [11, 10, 33]). Note that, in general, periodic solutions of (1.1) cannot be found as solutions to BVPs of the form (2.2).

3. Preliminaries. Below, we give our basic notations and the general setting relevant to collocation methods.

Let Π be a *mesh*, i.e., a collection of *mesh points* $0 = t_0 < t_1 < \cdots < t_L = T$ which partition the interval $[0, T]$. Set $h_i := t_{i+1} - t_i$ for $i = 0, \ldots, L-1$. Denote by π_m the set of all (vector-valued) polynomials of degree not exceeding m. We will approximate a solution x to (1.1) on the interval $[0, T]$ by an element from the following space of piecewise polynomials:

$$S_m(\Pi) := \{u \in C([0, T], \mathbb{R}^n) : u|_{[t_i, t_{i+1}]} \in \pi_m,\ i = 0, \ldots, L-1\}.$$

Clearly, $\dim S_m(\Pi) = n \times (L \times m + 1)$. Note that $u \in S_m(\Pi)$ is continuous but not necessarily continuously differentiable (at the mesh points).

Let

$$X(\Pi) := \bigcup_{i=0}^{L-1} X_i$$

with

$$X_i := \{c_{i,l} := t_i + c_l h_i,\ l = 1, \ldots, m\}$$

be a given set of (so-called) *collocation points* in $[0, T]$ based on the given, fixed set of *collocation parameters* $\{c_l\}$ with $0 \le c_1 < c_2 < \cdots < c_m \le 1$. Then the idea of a *collocation method* for approximating a solution to the DDE (1.1) is to find a function $u : [-\tau, T] \to \mathbb{R}^n$, the so-called *collocation solution*, such that (a) its restriction to $[0, T]$ belongs to $S_m(\Pi)$, (b) for $i = 0, \ldots, L-1$ its restriction to $[t_i, t_{i+1}]$ satisfies system (1.1) on the (finite) set X_i, and (c) it fulfills the relevant initial or boundary value condition.

For $i = 0, \ldots, L-1$ the collocation solution can be represented on subinterval $[t_i, t_{i+1}]$ as

$$u(t) = \sum_{j=0}^{m} u(t_{i+\frac{j}{m}}) P_{i,j}(t), \tag{3.1}$$

where

$$P_{i,j}(t) = \prod_{r=0, r\neq j}^{m} \frac{t - t_{i+\frac{r}{m}}}{t_{i+\frac{j}{m}} - t_{i+\frac{r}{m}}},\ j = 0, \ldots, m \tag{3.2}$$

are Lagrange polynomials and

$$t_{i+\frac{j}{m}} := t_i + \frac{j}{m}h_i,\ j = 1, \ldots, m-1$$

are so-called *representation points* (between the mesh points $t_{i+\frac{0}{m}} = t_i$ and $t_{i+\frac{m}{m}} = t_{i+1}$). Thus the collocation solution u is completely determined on $[0, T]$ by the vectors $u_{i+\frac{j}{m}} := u(t_{i+\frac{j}{m}})$, $i = 0, \ldots, L-1$, $j = 0, \ldots, m-1$, and $u_L = u(t_L)$.

4. Initial value problems. In this section we consider the initial value problem (IVP)

$$\begin{cases} \frac{\mathrm{d}x(t)}{\mathrm{d}t} = f(x(t), x(t-\tau)),\ t \in [0, T], \\ x_0 = \phi, \end{cases} \tag{4.1}$$

where $\phi \in C$ is a given initial function.

Even if both f and ϕ are arbitrarily smooth, a solution x to (4.1) may have a discontinuity in its first derivative at $t = 0$. This is because, in general,

$$\left.\frac{\mathrm{d}\phi(\theta)}{\mathrm{d}\theta}\right|_{\theta=0^-} \neq f(\phi(0), \phi(-\tau)).$$

Due to the presence of the delayed term $x(t-\tau)$ in (4.1), the discontinuity at $t = 0$ is propagated forward in time. However, the discontinuity is smoothed as time increases, and a discontinuity in the $(k+1)$st derivative of x, in general, appears at $t = k\tau$, $k = 0, 1, 2, \ldots$. In a numerical procedure for IVPs (4.1) it is important to include some of these so-called breaking points $t = k\tau$, $k = 0, 1, 2, \ldots$, in the mesh to avoid a reduction in the order of accuracy.

The theory concerning the numerical solution of IVPs for DDEs is well developed. Below, several main results on the convergence behavior of collocation methods in the case of the IVP (4.1) are collected. In particular, these deal also with collocation methods that are based on the well-known *Gauss–Legendre* collocation parameters $\{c_l\}$, i.e., the roots of the mth degree Gauss–Legendre polynomial transformed to $[0, 1]$.

The collocation method as outlined in section 3 consists of solving successively for $i = 0, \ldots, L-1$ the following system of equations for u restricted to $[t_i, t_{i+1}]$:

$$\frac{\mathrm{d}u(c_{i,l})}{\mathrm{d}t} = \begin{cases} f(u(c_{i,l}), \phi(c_{i,l}-\tau)) \text{ when } c_{i,l} - \tau \leq 0, \\ f(u(c_{i,l}), u(c_{i,l}-\tau)) \text{ when } c_{i,l} - \tau > 0 \end{cases} \tag{4.2}$$

for $l = 1, \ldots, m$, where $u(0) = \phi(0)$. The derivative of u in (4.2) has to be interpreted such that if $c_{i,l} = t_i$ it denotes the right-hand derivative at t_i, whereas if $c_{i,l} = t_{i+1}$, it stands for the left-hand derivative at t_{i+1}.

For ease of presentation, we assume in the rest of this section that all breaking points in $[0, T]$ are included in the mesh Π and, further, that f, ϕ are both arbitrarily smooth. We set $h := \max_i(h_i)$ and let $\|\cdot\|$ denote a given, fixed norm on $\mathbb{R}^n$.

The first theorem is a standard convergence result.

THEOREM 4.1. *Let x be the exact solution to* (4.1), *and let u be a corresponding collocation solution as described in section* 3 *and above. Then the following estimate holds:*

$$\max_{t\in[0,T]} \|u(t) - x(t)\| = \mathcal{O}(h^m) \quad (h \downarrow 0). \tag{4.3}$$

If $\{c_l\}$ are the Gauss–Legendre collocation parameters, then the above estimate can be sharpened to

$$\max_{t\in[0,T]} \|u(t) - x(t)\| = \mathcal{O}(h^{m+1}) \quad (h \downarrow 0). \tag{4.4}$$

The following result deals with the special case where the mesh Π is such that for each $i < L$ with $t_i \geq \tau$ the subinterval $[t_i, t_{i+1}]$ is mapped by $t \mapsto t - \tau$ exactly onto a (previous) subinterval $[t_k, t_{k+1}]$ with $0 \leq k < i$. A mesh with this property is called a *constrained mesh*.

THEOREM 4.2. *Let x be the exact solution to* (4.1)*, and let u be a corresponding collocation solution, as described in section* 3 *and above, based on a constrained mesh Π. If $\{c_l\}$ are the Gauss–Legendre collocation parameters, then the following estimate is valid:*

$$\max_{i=0,\ldots,L} \|u(t_i) - x(t_i)\| = \mathcal{O}(h^{2m}) \quad (h \downarrow 0). \tag{4.5}$$

The above result can be found in [7, 17]. It means that *superconvergence* at the mesh points, a well-known phenomenon in the case of both IVPs and BVPs for ODEs, also occurs in the case of IVPs for DDEs under an appropriate choice of Π.

The result of Theorem 4.2 can be obtained for more general meshes Π when one considers application of alternative interpolation procedures in the past, instead of using the relevant local collocation polynomial. We state convergence theorems for two alternative types of interpolation procedures, where we leave the detailed (interpolation) formulas to section 5.1. We assume that the ratios h_{i+1}/h_i are uniformly bounded from below and above by fixed positive real numbers. We further assume that, near a breaking point, the support points for the two interpolation procedures below are all taken on one side of the breaking point.

Let $q \geq 1$ be a given fixed integer. The first theorem below deals with the case of polynomial interpolation with respect to the mesh points for approximating the delayed term $x(t - \tau)$ (cf. (5.9)).

THEOREM 4.3. *Let x be the exact solution to* (4.1)*, and let u be a corresponding collocation solution, where in* (4.2) *the quantity $u(c_{i,l} - \tau)$ is replaced by the value of the polynomial of degree q at $t = c_{i,l} - \tau$ that interpolates u at $q + 1$ mesh points t_j in the neighborhood of t. If $\{c_l\}$ are the Gauss–Legendre collocation parameters, then the following estimates hold:*

$$\max_{i=0,\ldots,L} \|u(t_i) - x(t_i)\| = \mathcal{O}(h^{\min(2m,q+1)}) \quad (h \downarrow 0), \tag{4.6}$$

$$\max_{t\in[0,T]} \|u(t) - x(t)\| = \mathcal{O}(h^{\min(m+1,q+1)}) \quad (h \downarrow 0). \tag{4.7}$$

Theorem 4.3 follows from common estimation arguments. If the above polynomial interpolation procedure is used with $q = 2m-1$, superconvergence at the mesh points is obtained for (in essence) arbitrary meshes.

The next theorem deals with the case of *equistage* interpolation [20, 21] for approximating the delayed term (cf. (5.10)). At present, a satisfactory convergence analysis for this procedure, relevant to arbitrary meshes, is not known. A first result was obtained in [21].

THEOREM 4.4. *Let x be the exact solution to* (4.1)*, and let u be a corresponding collocation solution, where in* (4.2) *the quantity $u(c_{i,l} - \tau)$ is replaced by the value of*

the equistage polynomial of degree q at $t = c_{i,l} - \tau$ that interpolates u at $q+1$ points $c_{j,l}$ in the neighborhood of t. If $\{c_l\}$ are the Gauss–Legendre collocation parameters, then (4.7) *holds, and* (4.6) *holds under a model assumption on* Π *(see* [21]*).*

Result (4.6) follows from a direct application of the convergence theorem proved in [21]. The result concerning (4.7) can be shown using well-known arguments.

We remark that if the mesh is constrained, then the collocation process described in Theorem 4.4 reduces to the original collocation process, as in this case equistage interpolation is not actually performed. Thus, in this case Theorems 4.1, 4.2 apply.

5. Computation of periodic solutions. In this section we explain in detail the collocation variants that we consider. We also discuss the structure of the linear system which needs to be solved in each Newton iteration and describe adaptive mesh selection.

5.1. Outline of the collocation variants. For our numerical method, it is convenient to consider instead of BVP (1.2) a transformed BVP that is obtained from (1.2) after scaling time by the factor T^{-1},

$$\left\{ \begin{array}{l} \frac{\mathrm{d}x(t)}{\mathrm{d}t} = Tf(x(t), x(t - \frac{\tau}{T})), \ \ t \in [0,1], \\ x_0 = x_1, \\ p(x,T) = 0. \end{array} \right. \tag{5.1}$$

Recall that T is unknown and will be determined during computations. In the following we assume that $\tau < T$. We set $\bar{\tau} = \tau T^{-1}$. Note that a periodic solution to (1.1) is arbitrarily smooth for all times (if f is arbitrarily smooth). Therefore no time points have to be included in the mesh a priori; cf. section 4.

A collocation solution u to the transformed BVP (5.1), corresponding to a mesh Π on $[0,1]$ and collocation parameters $\{c_l\}$, is determined (cf. section 3) in terms of the unknowns

$$u_{i+\frac{j}{m}} = u(t_{i+\frac{j}{m}}), \ i = 0, \ldots, L-1, \ j = 0, \ldots, m-1, \text{ and } u_L = u(t_L)$$

by the *collocation equations*

$$\frac{\mathrm{d}u(c_{i,l})}{\mathrm{d}t} = \left\{ \begin{array}{l} Tf(u(c_{i,l}), u(c_{i,l} - \bar{\tau} + 1)) \text{ when } c_{i,l} - \bar{\tau} < 0, \\ Tf(u(c_{i,l}), u(c_{i,l} - \bar{\tau})) \text{ when } c_{i,l} - \bar{\tau} \geq 0 \end{array} \right. \tag{5.2}$$

for $i = 0, \ldots, L-1$, $l = 1, \ldots, m$. Here, the same convention on the derivative of u holds as in the case of (4.2).

Clearly, for BVP (1.2) the initial function, x_0, is not known beforehand. However, the periodic boundary condition is linear, and in constructing (5.2) we have used this fact in order to eliminate directly the numerical unknowns corresponding to times $t < 0$. We did not eliminate u_0 (because its value is used to determine u in $[0, t_1]$), so we still need to require

$$u_0 = u_L, \tag{5.3}$$

together with the phase condition

$$p(u,T) = 0. \tag{5.4}$$

In order to solve the combined nonlinear system (5.2), (5.3), (5.4), we apply Newton iteration. Write $c = c_{i,l}$ and

$$\tilde{c} = \left\{ \begin{array}{ll} c - \bar{\tau} + 1 & \text{when } c - \bar{\tau} < 0, \\ c - \bar{\tau} & \text{when } c - \bar{\tau} \geq 0. \end{array} \right. \tag{5.5}$$

Let integer k be such that $t_k \le \tilde{c} < t_{k+1}$. Then (5.2) assumes the form

$$\sum_{j=0}^{m} u_{i+\frac{j}{m}} P'_{i,j}(c) = Tf\left(\sum_{j=0}^{m} u_{i+\frac{j}{m}} P_{i,j}(c), \sum_{j=0}^{m} u_{k+\frac{j}{m}} P_{k,j}(\tilde{c})\right), \tag{5.6}$$

where $P'_{i,j}$ denotes the derivative of $P_{i,j}$. After linearization of (5.6) with respect to u, T we obtain

$$\begin{aligned} &\textstyle\sum_{j=0}^{m} P'_{i,j}(c)\Delta u_{i+\frac{j}{m}} - f(u(c),u(\tilde{c}))\Delta T - TA_0(u(c),u(\tilde{c}))\sum_{j=0}^{m} P_{i,j}(c)\Delta u_{i+\frac{j}{m}} \\ &-TA_1(u(c),u(\tilde{c}))\left(\textstyle\sum_{j=0}^{m} P_{k,j}(\tilde{c})\Delta u_{k+\frac{j}{m}} + \left(\sum_{j=0}^{m} u_{k+\frac{j}{m}} P'_{k,j}(\tilde{c})\right)\frac{\tau}{T^2}\Delta T\right) \\ &\qquad = -\left(\textstyle\sum_{j=0}^{m} u_{i+\frac{j}{m}} P'_{i,j}(c) - Tf(u(c),u(\tilde{c}))\right), \end{aligned} \tag{5.7}$$

where

$$u(c) = \textstyle\sum_{j=0}^{m} u_{i+\frac{j}{m}} P_{i,j}(c),\ u(\tilde{c}) = \sum_{j=0}^{m} u_{k+\frac{j}{m}} P_{k,j}(\tilde{c})$$

and

$$A_0(\xi,\eta) = \frac{\partial f}{\partial \xi}(\xi,\eta),\ A_1(\xi,\eta) = \frac{\partial f}{\partial \eta}(\xi,\eta).$$

Note that (5.6) is, through $\tilde{c}$, in general nondifferentiable with respect to T whenever $t_k = \tilde{c}$. We have (arbitrarily) chosen the right-hand derivative when this occurs. The nondifferentiability can reduce the asymptotic quadratic convergence of the Newton iteration. However, since periodic solutions have continuous derivatives, we did not expect nor encountered problems in our test cases.

We also deal with two variants to the above collocation scheme. Here, the value of the collocation solution at $\tilde{c}$ ("in the past"),

$$u(\tilde{c}) = \sum_{j=0}^{m} u_{k+\frac{j}{m}} P_{k,j}(\tilde{c}), \tag{5.8}$$

is replaced, in (5.6), by the value of an interpolating polynomial of (fixed) degree $q = k_1 + k_2$ constructed through $q+1$ mesh points in the neighborhood of $\tilde{c}$,

$$u(\tilde{c}) \to \sum_{j=k-k_1}^{k+k_2} u(t_j) Q_{k,j}(\tilde{c}), \tag{5.9}$$

or, by the value of an interpolating polynomial defined according to equistage interpolation (see [20], [21]),

$$u(\tilde{c}) \to \sum_{j=k-k_1}^{k+k_2} u(c_{j,l}) R_{k,j,l}(\tilde{c}), \tag{5.10}$$

where

$$Q_{k,j}(t) = \prod_{r=k-k_1, r\neq j}^{k+k_2} \frac{t-t_r}{t_j - t_r}, \qquad R_{k,j,l}(t) = \prod_{r=k-k_1, r\neq j}^{k+k_2} \frac{t-c_{r,l}}{c_{j,l} - c_{r,l}}. \tag{5.11}$$

Integers k_1, k_2 are chosen such that the points t_j and $c_{j,l}$ lie centered around the value $\tilde{c} \in [t_k, t_{k+1}]$. Remark that, if the mesh points or collocation points used in (5.9), (5.10), (5.11) have indices outside $0,\dots,L$, they are appropriately substituted using "periodic continuation" of Π and u (as in (5.5)).

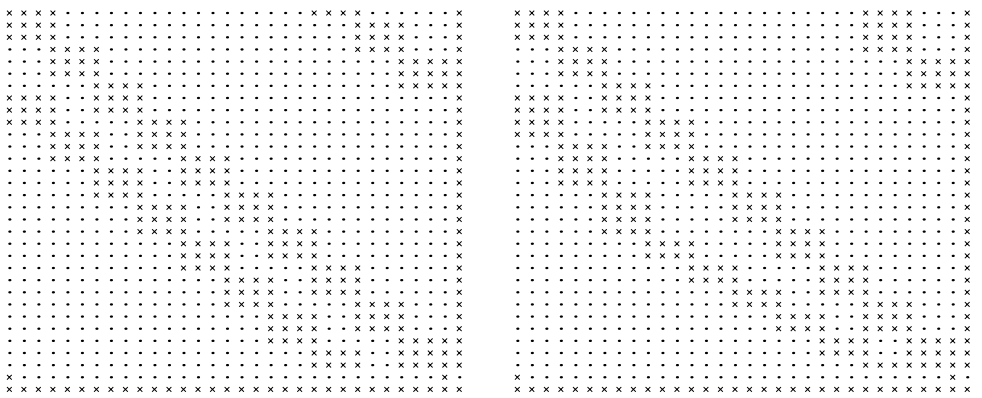

FIG. 1. *Structure of the matrix arising in the Newton iteration in the case of method* (5.3), (5.4), (5.6) *and model* (6.3) *using a uniform mesh (left) and a nonuniform mesh (right) with* $L = 10$ *and collocation polynomials of degree* $m = 3$ *(*$n = 1$*,* $\tau = 1$*,* $T \approx 4.0964$*). Zero elements are indicated by dots* $(\cdot)$ *and nonzero elements by crosses* $(\times)$*.*

5.2. Linear system structure. Figure 1 visualizes the structure of two matrices corresponding to two cases of the system of linear equations (5.7), (5.3), (5.4), which defines the Newton iteration. These matrices contain a (large) $mLn \times (mL+1)n$ block filled with two (circular) bands. This block is bordered by one column and $n+1$ rows. The extra column contains derivatives with respect to the period; n extra rows contain condition (5.3), and one extra row arises because of the phase condition (5.4).

The diagonal band is itself a concatenation of $mn \times (m+1)n$ blocks. The off-diagonal band is a consequence of the delay term, its circularity is due to the (eliminated) periodicity condition. When the mesh is equidistant (uniform), the off-diagonal band lies at a fixed distance from the diagonal band. This distance is approximately equal to $\bar{\tau}$ of the total matrix size. When the mesh is nonuniform, this distance varies (see Figure 1 (right)).

In the case of ODEs, the linear system can be solved with a band solver. Then the band size is proportional to the system size n and the (polynomial) degree m but it does not depend on the number of intervals L. For DDEs this is no longer possible. For moderate values of m, n, and L the linear system can be solved with a direct method as we did in our tests. Efficiency could be increased using, e.g., a chord-Newton method, in which case the Jacobian is not recomputed (and factored) in every iteration but remains fixed during a number of iterations.

Figure 2 shows the structure of the matrices corresponding to the linearized system of equations for the collocation variants defined by the replacements (5.9) and (5.10), respectively. As can be seen, both variants yield an increase in the size of the bandwidth of the off-diagonal band, approximately by a factor q.

We conclude this subsection by noticing that the technique of condensation of parameters (cf. [2]) cannot be applied in our case except for the collocation variant based on (5.9) because its interpolation procedure in the past uses approximations only at the mesh points.

5.3. Adaptive mesh selection. Adaptive mesh selection for BVPs for ODEs is achieved by equidistributing the integral

$$K = \int_0^1 |x^{(m+1)}(Ts)|^{\frac{1}{m+1}} ds$$

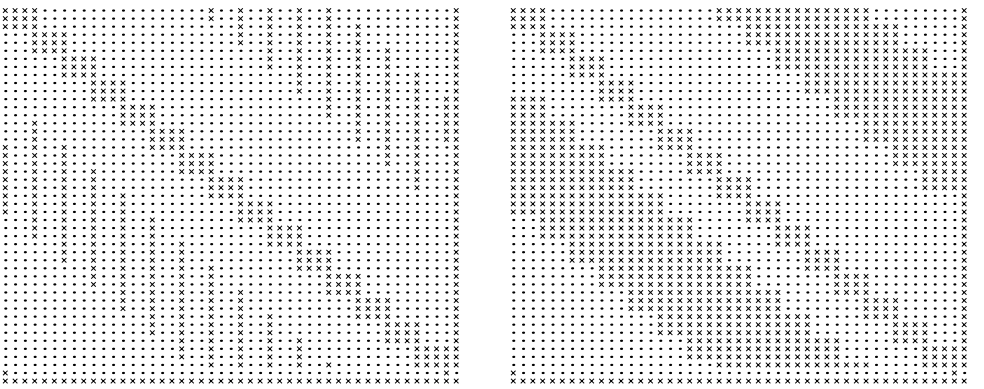

FIG. 2. *Structure of the matrices arising in the Newton iteration in the case of collocation variants based on* (5.9) *(left) and* (5.10) *(right) for model* (6.1) *using a uniform mesh with* $L = 15$*, collocation polynomials of degree* $m = 3$*, and* $q = 5$ *(*$n = 1$*,* $\tau = 2$*,* $T \approx 5.3918$*). Zero elements are indicated by dots* $(\cdot)$*, and nonzero elements by crosses* $(\times)$*.*

over the mesh intervals

$$\int_{t_i}^{t_{i+1}} |x^{(m+1)}(Ts)|^{\frac{1}{m+1}} ds = \frac{1}{L} K, \ i = 0, \ldots, L-1, \tag{5.12}$$

where $x(t)$ is scalar and $|\cdot|$ is the absolute value; see, e.g., [12, 2].

The new mesh points, t_i, satisfying (5.12) are determined using an approximation of $x^{(m+1)}$ obtained from the current mesh and collocation solution u.

Formula (5.12) is based on the error estimate

$$|x(tT) - u(t)| = C h_i^{m+1} \max_{s \in [t_i, t_{i+1}]} |x^{(m+1)}(Ts)| + \mathcal{O}(h^{m+2}), \ t \in [t_i, t_{i+1}], \tag{5.13}$$

when using Gauss–Legendre collocation points. Formula (5.13) is proven for BVPs for ODEs using a Green's function [31]. The use of a Green's function can be extended to BVPs of finite defect (2.2) (see [5] which includes a discussion of its changed smoothness properties) but the approach is not applicable to the "infinite-dimensional" BVP (2.1). Hence the validity of (5.13) remains an important open question in our situation.

Our numerical tests (see section 7.2), however, indicate that formula (5.13) remains valid for the periodic BVP (1.2). We subsequently implemented and tested the strategy (5.12) as implemented in AUTO on the models considered in this paper. These tests resulted in a desirable decrease in error for difficult profiles (compared to the use of a uniform mesh with the same number of mesh points) but in an increase in error for rather easy profiles (i.e., profiles without steep gradients). The latter phenomenon (which did not disappear even for very fine meshes) was, after a number of tests, removed by changing the discretization formula used for (5.12) in AUTO to the trapezium rule. The scheme then showed both a (small) decrease in error for easy profiles and an (even larger than before) decrease in error for difficult profiles. We conclude with the formulae for the latter variant.

Based on the old mesh points, t_i, and the piecewise constant $u^{(m)}$, let

$$d_i = \frac{u^{(m)}(\xi_{i+1}) - u^{(m)}(\xi_i)}{\frac{1}{2}(t_{i+1} - t_{i-1})}, \ i = 0, \ldots, L,$$

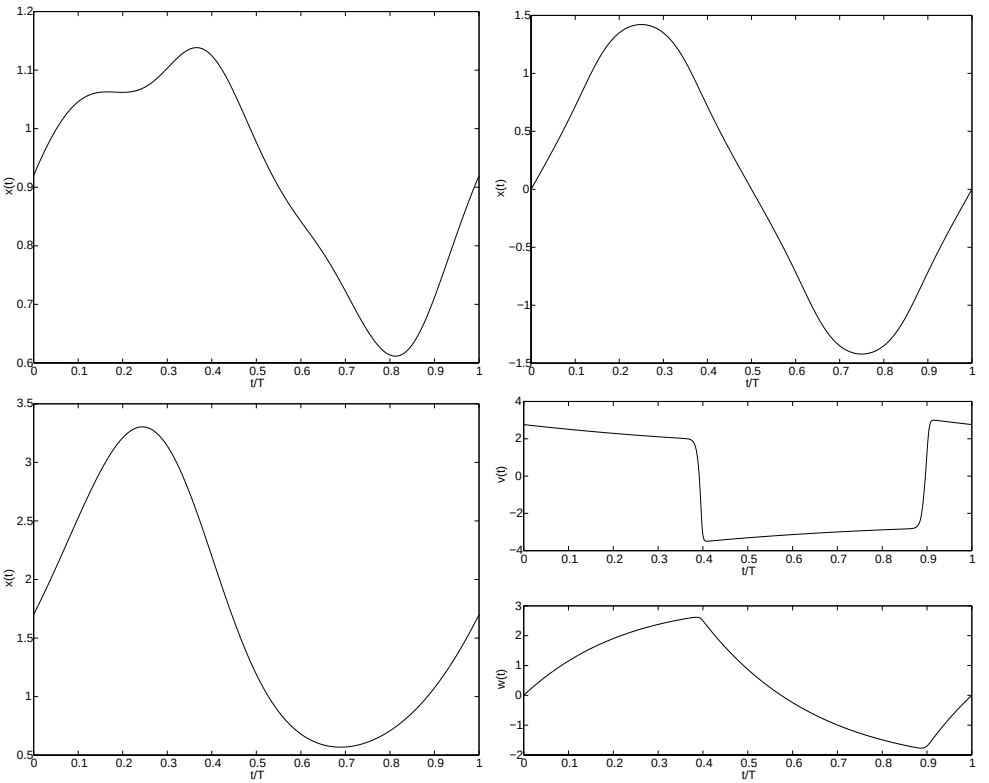

FIG. 3. *The periodic solutions under consideration: model* 1 *(upper left),* 2 *(upper right),* 3 *(lower left), and* 4 *(lower right).*

where $\xi_i \in (t_{i-1}, t_i)$, $\xi_{i+1} \in (t_i, t_{i+1})$ are chosen arbitrarily and where "periodic continuation" is used for d_0 and d_L. We approximate

$$S(t) = \int_0^t |x^{(m+1)}(Ts)|^{\frac{1}{m+1}} ds$$

by $\tilde{S}(t)$ at the old mesh points using $\tilde{S}(t_0) = 0$ and

$$\tilde{S}(t_{i+1}) = \tilde{S}(t_i) + (t_{i+1} - t_i)\frac{|d_i|^{\frac{1}{m+1}} + |d_{i+1}|^{\frac{1}{m+1}}}{2},\ i = 1, \ldots, L-1,$$

and assume $\tilde{S}$ is linear between mesh points. If u is not scalar, $\tilde{S}$ is computed for each component as above and then summed over all components. The new t_i's are now easily selected from the monotonically increasing $\tilde{S}$ by linear interpolation such that $t_0 = 0$ and $\tilde{S}(t_{i+1}) - \tilde{S}(t_i) = \Delta\tilde{S} = \frac{\tilde{S}(1)}{L},\ i = 1, \ldots, L-1$.

6. Test models. In this section we formulate the models we considered to test the collocation methods described in section 5. The periodic solution profiles (scaled to the interval $[0, 1]$) are displayed in Figure 3.

Model 1. The following equation is a model for the regeneration of white blood cells [15, 19] and is usually referred to as the Mackey–Glass equation,

$$\frac{dx}{dt} = ax(t) + b\frac{x(t-\tau)}{1 + x^c(t-\tau)}, \tag{6.1}$$

where a, b, c, τ are given parameters. For $a = -1$, $b = 1.74$, $c = 10$, $\tau = 2$ we computed an unstable periodic solution with period $T \approx 5.3918$.

Model 2. The scalar DDE

$$\frac{dx}{dt} = \alpha x(t-1)\frac{1+x^2(t-1)}{1+x^4(t-1)} \tag{6.2}$$

was studied analytically (see, e.g., [23, 28, 32]) and numerically [16, 11, 27]. It was proven that at $\alpha = \pi/2$ a family of periodic solutions bifurcates from the zero solution and that stable periodic solutions of period $T = 4$ exist whenever $\alpha > \pi/2$. Here we consider such a stable periodic solution at $\alpha = 2$.

Model 3. This is the well-known delayed logistic equation

$$\frac{dx}{dt} = (\lambda - x(t-1))x(t); \tag{6.3}$$

cf., e.g., [18, 22]. We computed a stable periodic solution at $\lambda = 1.7$ with $T \approx 4.0964$.

Model 4. The following system models recurrent neural feedback [29, 10],

$$\begin{cases} \frac{dv}{dt} = h(v(t)) - w(t) + I(v(t-\tau)), \\ \frac{dw}{dt} = \rho\,(v(t) + a - bw(t)) \end{cases} \tag{6.4}$$

with

$$\begin{cases} h(v) = v - v^3/3, \\ I(v) = \mu\,(v - v_0), \\ v_0 = \text{a real root of } h(v) - (v+a)/b. \end{cases}$$

This system exhibits a stable spiked periodic solution for parameter values $a = 0.7$, $b = 0.8$, $\rho = 0.08$, $\tau = 25$, $v_0 \approx -1.1994$, and $\mu = -2$ with $T \approx 50.7326$.

7. Results. In this section we discuss our numerical results. For a given mesh Π we compute (approximations of) the *continuous error* E_C and the *discrete error* E_I, defined by

$$E_C = \max_{t\in[0,1]} \|x(Tt) - u(t)\|, \; E_I = \max_{i=0,\ldots,L} \|x(Tt_i) - u(t_i)\|,$$

where x denotes the exact periodic solution, u denotes a collocation solution, and $\|\cdot\|$ is the Euclidean norm. To this purpose, we first computed a reference solution for x, using $L = 1000$ subintervals. Next, we compared the reference solution to u (for $L = 10, \ldots, 200$) at a very fine mesh in order to compute E_C, and at (only) the mesh points in order to compute E_I. As a phase condition, we fixed the value of one component of the solution at $t_0 = 0$. We show observed orders of convergence and the results of adaptive mesh selection.

7.1. Numerical order results. In this subsection the mesh points are always taken equidistant, i.e., $h_i = h$ for $i = 0, \ldots, L-1$.

First we concentrate on the collocation method (5.3), (5.4), (5.6). Figure 4 shows the evolution of E_C and E_I for collocation solutions with $m = 4$ as h goes to zero using equidistant collocation points (collocation parameters $\{c_l\} = \{\frac{1}{8}, \frac{3}{8}, \frac{5}{8}, \frac{7}{8}\}$) (left) and Gauss–Legendre collocation points (right). We have approximated the slope of the graph of the continuous error E_C by means of a least squares fit on (all) the results for $L = 100, \ldots, 200$. Table 1 summarizes the obtained convergence orders

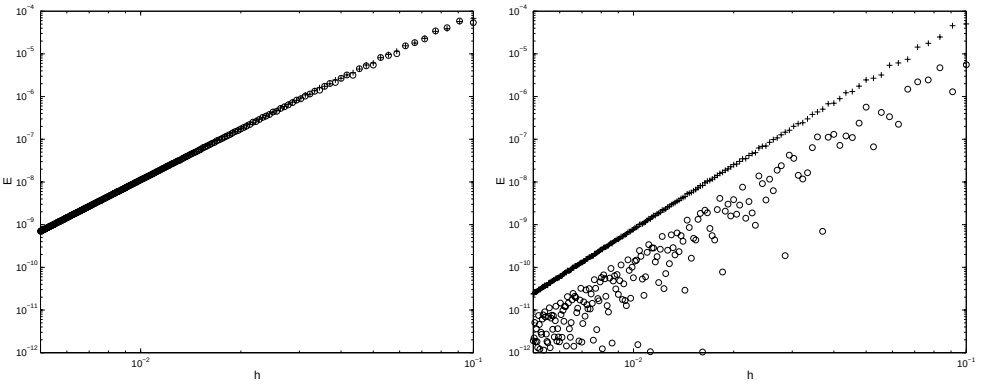

FIG. 4. *Evolution of $E_C(+)$ and E_I ($\circ$) in the case of Model* 1 *and the collocation method* (5.3), (5.4), (5.6) *with $m = 4$ using equidistant (left) and Gauss–Legendre (right) collocation points.*

TABLE 1

Approximations to the orders of convergence of E_C in the case of Models 1–3 *and the collocation method* (5.3), (5.4), (5.6) *for $L = 100, \ldots, 200$ using equidistant (left) and Gauss–Legendre (right) collocation points.*

4	4.003	4.017	4.033	4	5.003	4.990	4.927

of E_C for $m = 2, 3, 4$. Clearly, an $\mathcal{O}(h^m)$ versus $\mathcal{O}(h^{m+1})$ convergence behavior is apparent. For odd m, a numerical convergence behavior of $\mathcal{O}(h^{m+1})$ is also found in the case of equidistant collocation points. This feature seems to be a consequence of the specific choice of the collocation parameters and it disappears if they are not chosen symmetrically with respect to 1/2. The table clearly shows agreement with the result of Theorem 4.1 for IVPs for DDEs (and with results for BVPs of the form (2.2), see [5, 8]).

Superconvergence at mesh points is not present in the E_I curve of Figure 4 (right). According to Theorem 4.2 it is recovered in the case of IVPs for DDEs for constrained meshes. The special situation that mesh points get mapped into mesh points (and collocation points into collocation points) by the delay depends, for BVPs, both on the model and the mesh [2]. More specifically, it occurs when $k\tau = lT$ with k and l integer and (equidistant) mesh points with L a multiple of k. This is the case for Model 2 where $4\tau = T$ whenever L is a multiple of 4. During computations, this relation holds only approximately as T is computed with finite accuracy. Nevertheless we observe numerical superconvergence; see Figure 5 (left). We further observe that, when the period and the delay are not commensurate, E_I is generally smaller whenever L is such that $\frac{\tau}{T}L$ is near an integer number (that is, whenever L is a multiple of k and $\frac{\tau}{T} \approx \frac{l}{k}$ for some k, l); see Figure 5 (right).

We now consider the two variants of the collocation method (5.3), (5.4), (5.6) where, instead of using the collocation solution in the past, the interpolation formula (5.9) or (5.10) is applied. Figure 6 shows the evolution of E_C and E_I when $u(\tilde{c})$ is replaced by the value of an interpolating polynomial of degree $q = 2m - 1$ through $q + 1$ mesh points t_j according to (5.9) (left), or through $q + 1$ collocation points $c_{j,l}$ according to (5.10) (right). The obtained convergence orders for E_I in the case

Left: superconvergence of E_I when L is a multiple of* 4 *(E_I indicated as a $\diamond$). Right: greater accuracy for E_I when $\frac{\tau}{T}L \approx 31.003$ (1), $\frac{\tau}{T}L \approx 20.994$ (2), $\frac{\tau}{T}L \approx 10.009$ (3).*

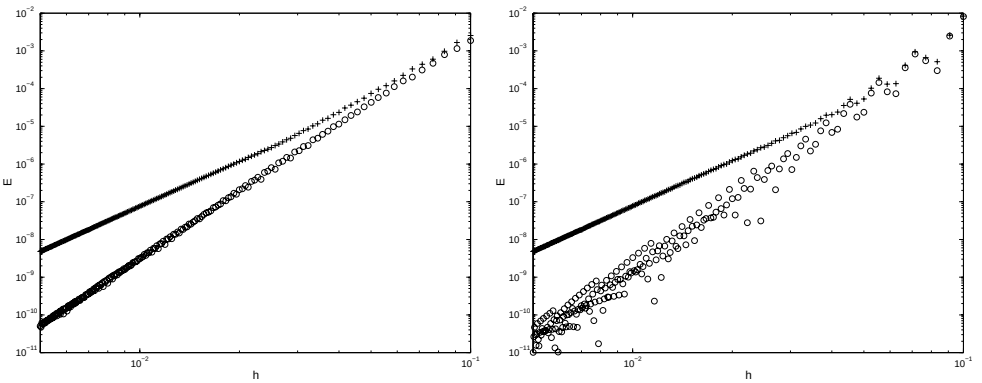

FIG. 6. *Evolution of $E_C(+)$ and E_I ($\circ$) for Model* 3 *based on collocation variants* (5.9) *(left) and* (5.10) *(right) with $m = 3$, $q = 2m - 1$, and Gauss–Legendre collocation points.*

of the variant based on (5.9) are summarized in Table 2. In both cases, we observe superconvergence behavior for E_I, which is in agreement with Theorems 4.3, 4.4. Further, if h is sufficiently small, both variants have essentially the same continuous error E_C as the original collocation method; cf. Figures 5 (right) and 6.

Though, for E_I, $\mathcal{O}(h^{2m})$ is the maximum order of convergence, we observed that, for the collocation variants, E_I can be further decreased for small h by choosing $q > 2m - 1$. This is illustrated in Figure 7 (compare left to right for points where L is not a multiple of 4).

7.2. Adaptive mesh selection. When the mesh is uniform, formula (5.13) implies that the error is locally proportional to the $(m+1)$-st derivative of the solution profile. This correspondence is clearly visible in Figure 8 and was observed in several other tests as well.

On profiles without steep gradients (Figure 3, Models 1–3) little benefit can be expected from an adapted mesh in comparison with a uniform mesh. However, as mentioned in section 5.3, AUTO's adaptive mesh selection can, at times, increase the

error for the case of DDEs. This unfavorable feature does not disappear as h goes to zero; see Figure 9 (top). Instead, it was (almost completely) removed by slightly changing the scheme as described in section 5.3. We might also note that we did not observe this feature in a small number of tests on periodic solutions of ODEs.

The periodic solution of model 4 exhibits steep gradients and we successfully used adaptive mesh selection to decrease the errors significantly. Here too, the variant described in section 5.3 gives better results (see Figure 9 (bottom)). The evolution, for this example, of both E_C and E_I versus L is shown in Figure 10. Note that an increase of more than three orders of accuracy is gained by adapting the mesh compared to the accuracy using a uniform mesh with the same number of intervals and thus the same number of unknowns in the Newton procedure.

As a last remark, we note that when adaptive mesh selection is applied in the case of Model 4 and the collocation variants based on (5.9) or (5.10), errors decrease compared to uniform meshes but not as much as in Figure 10. Also, no superconvergence was visible within the range of intervals computed.

We conclude that our numerical results indicate for the collocation method (5.3), (5.4), (5.6) the validity of formula (5.13) and approach (5.12) combined with the need for a (small) change in their discretization used in a practical implementation.

8. Conclusions. Collocation, based on piecewise polynomials, is considerably successful in the numerical solution of (periodic) BVPs for systems of ODEs. It is, e.g., used in the software packages COLSYS/COLNEW [1, 6] and AUTO [12]. In this paper we investigated the use of collocation methods for computing periodic solutions to DDEs.

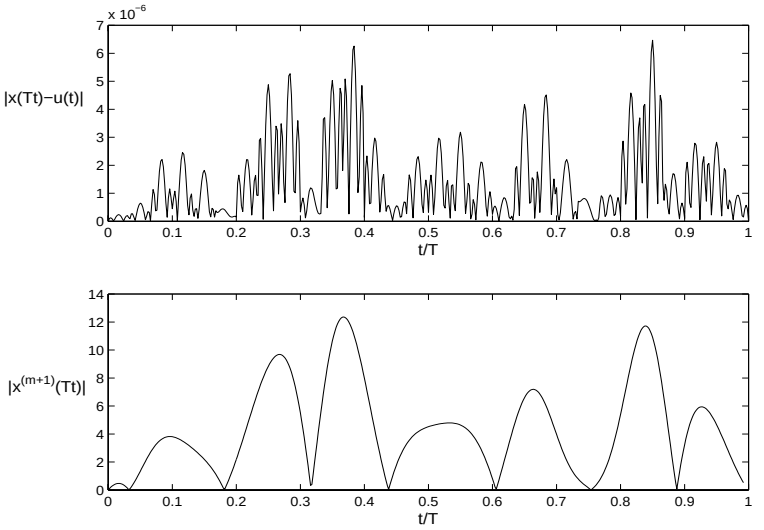

FIG. 8. *Correspondence of the error* $|x(Tt) - u(t)|$ *and the* $(m+1)$*th derivative,* $|x^{(m+1)}(Tt)|$*, of a collocation solution for Model* 1 *using* $m = 3$*,* $L = 30$*, a uniform mesh, and Gauss–Legendre collocation points.*

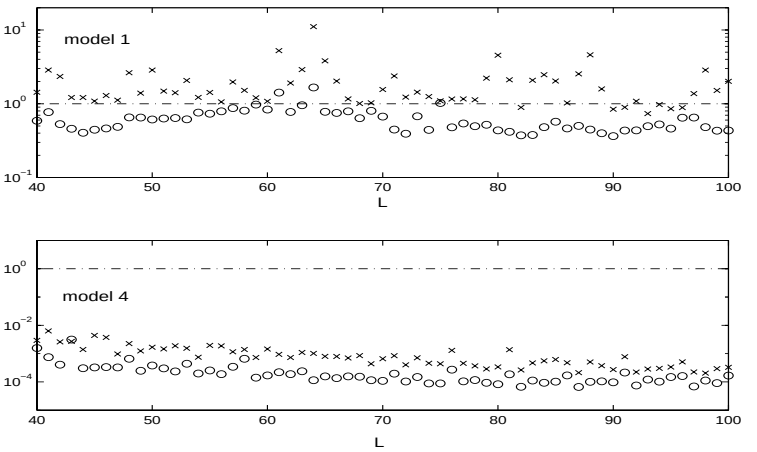

FIG. 9. *Ratio* $E_C^{\text{adapted}}(L)/E_C^{\text{uniform}}(L)$ *versus* L *using AUTO's adaptive mesh selection* $(\times)$*, respectively the variant described in section* 5.3*,* $(\circ)$ *for* $L = 40, \ldots, 100$*. Here,* $m = 3$ *and Gauss–Legendre collocation points are used to compute the collocation solutions for Model* 1 *(upper part) and Model* 4 *(lower part).*

We studied three collocation methods, two of which are based on alternative interpolation procedures for approximating the delayed term. The presence of the delayed term influences the structure of the linear system to be solved in the Newton iteration and thus affects the efficiency of the collocation method. Based on an extensive set of numerical tests we obtained information on the order of convergence and its dependence on the collocation discretization. We show how these results correspond with known convergence results for IVPs for DDEs. In particular, we show when superconvergence at mesh points is lost and/or recovered. We end with a brief discussion of adaptive mesh selection.

INDEX CONCEPTS FOR LINEAR MIXED SYSTEMS OF DIFFERENTIAL-ALGEBRAIC AND HYPERBOLIC-TYPE EQUATIONS*

MICHAEL GÜNTHER† AND YVONNE WAGNER‡

Abstract. For many technical systems, the use of a refined network modeling approach leads to hyperbolic-type initial-boundary value problems of partial differential-algebraic equations (PDAEs). The boundary conditions of these systems are governed by time-dependent differential-algebraic equations (DAEs) that couple the PDAE system with the network elements that are modeled by DAEs in time only. In order to classify these systems, we extend some index notions that have already been introduced to treat parabolic-type problems. A perturbation index is considered that reflects the sensitivity of the mixed system to slight perturbations in the right-hand side of the PDAEs, as well as in the input signals of the DAE systems and initial values. In order to make an a posteriori analysis of semidiscretization in space and time, we introduce additionally a space and a method of lines (MOL) index. Here one is especially interested in whether the semidiscretized systems properly reflect the properties of the underlying systems. We will show that these indices may detect an artificial sensitivity with respect to perturbations, e.g., if the semidiscretization does not consider the information transport along the characteristics.

Key words. refined network models, coupled systems of partial differential-algebraic equations and differential-algebraic equations, perturbation, space and method of line index, semidiscretization with respect to space and time

1. Introduction.

In technical simulation of time-dependent processes today's industrial software is based on a network approach [14]. In the case of so-called *compact* network elements only topology, and no spatial dimension, is considered; the network equations are given by systems of differential-algebraic equations (DAEs). However, if coupling and second order effects become more important, the spatial distribution can no longer be neglected; the network approach has to be extended to cope with so-called *distributed* elements that are mainly described by partial differential equations (PDEs) in space and time. For example, chemical engineering plants are simulated which consist of both compact and distributed network elements such as heat exchangers [23]. Parameter models can lead to PDEs with DAE systems as boundary conditions [13]. In electric network analysis, the network equations describing the compact network elements such as capacitors and resistors are completed by the telegrapher's equations for transmission lines to model the interconnections more accurately [8]. The use of elastic connections leads to a flexible part in the network equations of multibody system dynamics [22]. Whereas chambers in gas flow networks are described by DAE and ODE models, the connecting pipes are governed by the Euler equations [19].

In many of the applications mentioned above one has to deal with hyperbolic-type initial-boundary value problems of partial differential-algebraic equations (PDAEs). The boundary conditions of these systems are governed by time-dependent DAEs that couple the PDAE system with the network DAEs for the compact elements.

The aim of this paper is to classify such mixed systems by generalizing the index concept for DAE systems. The DAE index concept has turned out to give insight into the solution properties, as well as into the numerical problems to be expected when solving these systems, for example, how to obtain consistent initial data if there are hidden constraints [20]. For this purpose, Martinson and Barton [17] have generalized the differential time index to PDAE systems that are regarded as abstract Cauchy problems in any direction in the independent variable space. Generalizations of index concepts to linear PDAE systems have recently been proposed by Campbell and Marzalek [6], and Lucht, Strehmel, and Eichler-Liebenow [16], with a main focus on parabolic systems. Though these concepts do not take care of general boundary conditions that arise in our case, some of them can be adapted to the hyperbolic-type case with DAE boundary conditions.

There are different properties that are demanded (or wished) from an index: First, it would be interesting to know some structural properties of the system before its numerical solution, for example, the sensitivity of the analytical solution to small perturbations in the initial data and/or input signals. Second, estimates are required for the impact of semidiscretization in space or time on the index of the semidiscretized system: Does the semidiscretized system properly reflect the behavior of the underlying mixed system, for example, the information transport along the characteristics? Or do we detect an artificial smoothing or coarsening effect?

The paper is organized as follows. In section 2 we specify the system to be examined. We will restrict our investigations to linear hyperbolic-type PDAEs of first order in one space dimension. The boundary conditions are generally given as differential-algebraic equations and may be coupled with network equations for the compact elements.

In section 3 we will define appropriate index concepts, adjusting and extending the concepts introduced in [6, 16] to our hyperbolic case. In order to cope with the effects of semidiscretization in space and time, different indices have been proposed. The spatial index is transferred from the linear parabolic case; by a Laplace transformation the time variable is eliminated and a DAE-BVP is obtained. The time index which is based on a Fourier expansion of the solution is replaced by a MOL index derived by an upwind semidiscretization of the space variable using the characteristic formulation. Finally, a perturbation index is considered which reflects the sensitivity of the mixed system with respect to perturbations in the right-hand side of the PDAE equations, in the initial and boundary data. Energy estimates are used to obtain results for the perturbation index.

Section 4 treats two benchmark problems in detail: a PDAE model for a heat exchanger, and a mixed model for a single transmission line with voltage source and capacitor as terminating elements. We discuss the impact of semidiscretization in time or space on the index of the resulting approximate DAE (ADAE) system. The first example shows that the application of different Rothe methods, where — in contrast to the classical method of lines — semidiscretization is made with respect to time to obtain a boundary value problem in space alone, may lead to different indices for the semidiscretized system, higher than the perturbation index. For the latter example the perturbation and MOL index will allow insights into whether the properties of the system are correctly reflected by the ADAE system: if the information in the characteristic formulation is not adequately used, the semidiscretized system may show a spurious sensitivity with respect to perturbations.

2. Linear mixed systems of DAEs and hyperbolic-type PDAEs. In the following we will consider hyperbolic-type initial-boundary value problems of PDAEs often occurring in a refined network approach. The boundary conditions are governed by time-dependent DAEs that may couple the PDAE system with the network DAEs for those compact elements linked with the PDAE system.

We motivate different levels of abstraction by two examples. The first comes from interconnected electrical network simulation, the second is a mathematical model for a countercurrent heat exchanger.

The signal propagation in a transmission line can be characterized by the telegrapher's equations

$$Au_t + Bu_x + Cu = 0 \quad \text{with} \quad A = \begin{bmatrix} 0 & L \\ C & 0 \end{bmatrix},\ B = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix},\ C = \begin{bmatrix} 0 & R \\ G & 0 \end{bmatrix} \tag{2.1}$$

with $u(x,t) = [U(x,t), I(x,t)]^\top$ denoting line voltage $U(x,t)$ with respect to ground, and line current $I(x,t)$. The coefficients R, L, G, and C are the resistance, inductance, conductance, and capacitance per unit length. This first order system of PDEs is initialized by a set of initial values $u(x,0) = g(x)$, $x \in [0,1]$. If we do not neglect any effects, R, L, G and $C > 0$ holds. Thus (2.1) defines a conservation law with source term, a linear hyperbolic PDE system with two waves traveling to the left and right, respectively.

Depending on the terminating elements that link the transmission line to the electrical networks, we can distinguish two levels of mathematical models:

- *Level* 1*a: PDE system with purely time-dependent boundary conditions.*
  If we use two purely time-dependent sources that fix the boundary conditions, for example, voltage source $V(t)$ at the left and current source $J(t) \equiv 0$ (for an open end) at the right end of the transmission line, we get a hyperbolic initial-boundary value problem. The corresponding boundary conditions for (2.1) then read as follows:

  $$U(0,t) - V(t) = 0, \qquad I(1,t) = 0. \tag{2.2}$$

  A network description for this system is given in Figure 2.1.
- *Level* 1*b: PDE system with DAE boundary conditions.*
  However, if the right end is closed by a capacitor with capacitance C_1, the boundary conditions of system (2.1) are now given by DAEs in time

  $$U(0,t) - V(t) = 0, \qquad C_1 U_t(1,t) - I(1,t) = 0, \tag{2.3}$$

  with line voltage and current at both ends as the only unknowns. Consider now the case where the transmission line is coupled with other electrical networks. If, for example, the voltage source is driven by the node voltage of a JL cutset[1] [10] (see Figure 2.2) the boundary conditions are now DAE systems in time with line voltage and currents, as well as network variables z_1 and $z_2 := I_L$ of the coupled systems as unknowns:

  $$U(0,t) - z_1 = 0, \tag{2.4a}$$
  $$C_1 U_t(1,t) - I(1,t) = 0, \tag{2.4b}$$

[1]Let an electrical network be cut into two parts. If the network elements connected to cut nodes consist only of current sources (J) and inductors (L), the circuit is said to contain a JL cutset. Hence the left circuit of Figure 2.2 is the generic case for circuits containing JL cutsets.

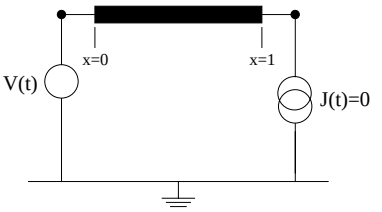

FIG. 2.1. *Transmission line driven by voltage source at the left end and open right end.*

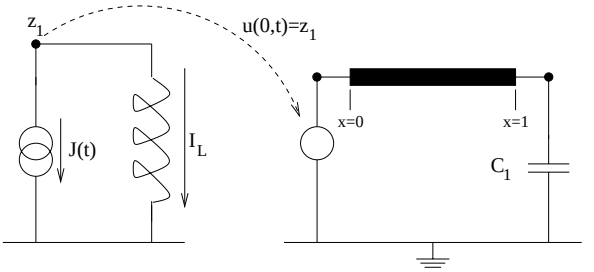

FIG. 2.2. *VC loop with transmission line. The voltage source is driven by JL cutset.*

$$z_2 + J(t) = 0, \tag{2.4c}$$

$$L_{ind}\dot{z}_2 - z_1 = 0. \tag{2.4d}$$

The next example describes a model for a countercurrent heat exchanger used in process simulation.

A plain scheme for a countercurrent heat exchanger is illustrated in Figure 2.3 where two fluids are flowing in the opposite direction and exchange heat through a metal layer. The mathematical model is derived using energy balances under simplifying assumptions:

$$u_t + Bu_x + Cu = 0\,, \qquad u(x,0) = g(x)\,, \tag{2.5}$$

where $u(x,t) = (T_1, T_2, T_m)^\top$, $x \in [0, L]$, $t \in [0, T]$, and

$$B = \begin{pmatrix} v_1 & 0 & 0 \\ 0 & -v_2 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \qquad C = \begin{pmatrix} \frac{v_1\alpha_1 A_1}{Ln_1 C_{p_1}} & 0 & -\frac{v_1\alpha_1 A_1}{Ln_1 C_{p_1}} \\ 0 & \frac{v_2\alpha_2 A_2}{Ln_2 C_{p_2}} & -\frac{v_2\alpha_2 A_2}{Ln_2 C_{p_2}} \\ -\frac{\alpha_1 A_1}{mC_{p_m}} & -\frac{\alpha_2 A_2}{mC_{p_m}} & \sum_{i=1}^{2} \frac{\alpha_i A_i}{mC_{p_m}} \end{pmatrix}$$

with fluid temperature $T_i(x,t)$, metal temperature $T_m(x,t)$, fluid velocity v_i, heat transfer area A_i, heat transfer coefficients α_i, length of the heat exchanger L, mass of the heat exchanger m, molar quantity flux n_i, heat capacity of the metal C_{p_m}, and molar heat capacity of the fluid C_{p_i}, $i = 1, 2$. For a more detailed description, see [23].

As before, different levels can be distinguished for the system (2.5) with respect to boundary conditions:

- *Level 2a: PDAE system with purely time-dependent boundary conditions.* System (2.5) together with boundary conditions

$$u^1(0,t) = s_1(t), \quad u^2(1,t) = s_2(t) \tag{2.6}$$

defines an initial-boundary value problem of PDAEs.

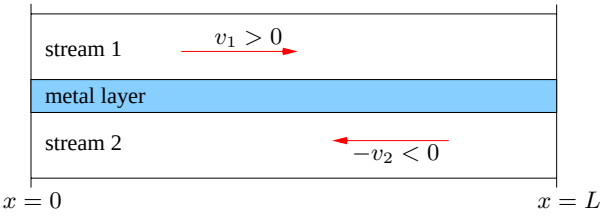

FIG. 2.3. *Countercurrent heat exchanger.*

- *Level 2b: PDAE system with DAE boundary conditions.*
  Correspondingly, system (2.5) together with DAE boundary conditions, e.g.,

$$\begin{aligned} u^1(0,t) &= s_1(t)\,, \\ \dot{z}(t) + u^2(1,t) &= s_2(t)\,, \\ z(t) &= s_3(t)\,, \end{aligned} \tag{2.7}$$

  yields an initial-boundary value problem of PDAEs with DAEs as boundary conditions that may be linked with the network variables z of the coupled networks.

With these examples in mind, we now define a general first order linear PDAE system of dimension n_u as

$$\mathcal{F}(u, u_t, u_x, f) := Au_t + Bu_x + Cu - f = 0, \quad x \in [0,1], \quad t \in [0,T], \tag{2.8a}$$

with consistent initial values

$$u(x,0) = g(x). \tag{2.8b}$$

Note that we define the system on closed intervals of definition, forcing initial and boundary data to fulfill the PDAE equations analogous to the DAE case. If at least one of the matrices A and B is singular, system (2.8a) is called partial differential-algebraic. In order to guarantee the hyperbolicity of this system of first order, we further assume A regular and $A^{-1}B$ real diagonalizable. Otherwise it would be possible to obtain parabolic or elliptic parts. For example, consider (2.1) with $L = G = 0$. Then there are two cases to distinguish: For $R = 0$ the system can be transformed to the elliptic Laplace equation $I_{xx} = 0$, and for $R \neq 0$ we get the parabolic heat equation $RCu_t - u_{xx} = 0$. As a consequence, different boundary and/or initial values would have to be prescribed. These effects are avoided by the above assumption. Thus, the DAE part consists of $n_u - m$, $m = \dim \ker B$, physical boundary conditions of Dirichlet type for the PDAE system, and n_z network equations for the compact parts of the system of the following mixed type:

$$\begin{aligned} &\mathcal{R}(u(0,t), u_t(0,t), u(1,t), u_t(1,t), z(t), \dot{z}(t), s) \\ &:= R_1 \begin{bmatrix} u_t(0,t) \\ u_t(1,t) \\ \dot{z}(t) \end{bmatrix} + R_2 \begin{bmatrix} u(0,t) \\ u(1,t) \\ z(t) \end{bmatrix} - s(t) = 0 \end{aligned} \tag{2.8c}$$

with the vector of network variables $z \in \mathbb{R}^{n_z}$, $z(0) = z_0$ and the matrices $R_1, R_2 \in \mathbb{R}^{(n_u - m + n_z) \times (2n_u + n_z)}$. We assume that the DAE part fulfills the rank condition $\operatorname{rank}(\lambda R_1 + R_2) = n_z + n_u - m$ for at least one $\lambda \in \mathbb{C}$ and that the boundary conditions are consistent with the initial values.

System (2.8a) can be rewritten into characteristic form

$$w_t + \Lambda w_x + \widetilde{C} w = \widetilde{f}, \tag{2.9a}$$

where $w = X^{-1}u$, $\widetilde{C} := X^{-1}A^{-1}CX$, $\widetilde{f} := X^{-1}A^{-1}f$ with the matrix X of eigenvectors and the matrix $\Lambda = \operatorname{diag}(\lambda_1, \ldots, \lambda_{n_u})$ of eigenvalues of $A^{-1}B$. The initial conditions (2.8b) now read

$$w(x,0) = X^{-1}g(x), \tag{2.9b}$$

and the boundary conditions

$$\widetilde{R}_1 \begin{bmatrix} w_t(0,t) \\ w_t(1,t) \\ \dot{z}(t) \end{bmatrix} + \widetilde{R}_2 \begin{bmatrix} w(0,t) \\ w(1,t) \\ z(t) \end{bmatrix} - s(t) = 0 \tag{2.9c}$$

with $\widetilde{R}_i = R_i \cdot \operatorname{diag}(X, X, I_{n_z})$, $i = 1, 2$. In the following we shall see that it is often important to consider the characteristic formulation.

Example 1 (transmission line). The telegrapher's equations (2.1) rewritten in characteristic form (2.9) are given by

$$w(x,t) = X^{-1}u(x,t) \quad \text{with} \quad X = \begin{bmatrix} -\sqrt{\frac{L}{C}} & \sqrt{\frac{L}{C}} \\ 1 & 1 \end{bmatrix} \quad \text{and} \tag{2.10a}$$

$$\Lambda = \begin{bmatrix} \frac{-1}{\sqrt{LC}} & 0 \\ 0 & \frac{1}{\sqrt{LC}} \end{bmatrix}, \quad \widetilde{C} = \frac{1}{2}\begin{bmatrix} \frac{R}{L} + \frac{G}{C} & \frac{R}{L} - \frac{G}{C} \\ \frac{R}{L} - \frac{G}{C} & \frac{R}{L} + \frac{G}{C} \end{bmatrix}, \quad \widetilde{f} = 0. \tag{2.10b}$$

The boundary conditions (2.3) of level 1b, for example, now read

$$\underbrace{\begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & -C_1\sqrt{L/C} & C_1\sqrt{L/C} \end{bmatrix}}_{\widetilde{R_1}} \cdot \begin{bmatrix} w_t(0,t) \\ w_t(1,t) \end{bmatrix}$$

$$+ \underbrace{\begin{bmatrix} -\sqrt{L/C} & \sqrt{L/C} & 0 & 0 \\ 0 & 0 & -1 & -1 \end{bmatrix}}_{\widetilde{R_2}} \cdot \begin{bmatrix} w(0,t) \\ w(1,t) \end{bmatrix} = \begin{bmatrix} V(t) \\ 0 \end{bmatrix}. \tag{2.10c}$$

Example 2 (countercurrent heat exchanger). The mathematical model for the countercurrent heat exchanger (2.5) is already formulated in characteristic form, with boundary conditions of either level 2a or 2b.

Since we analyze linear systems, smooth solutions can be obtained provided that the inhomogenity $f(x,t)$, consistent initial data $g(x)$, and input signals $s(t)$ are smooth enough, according to the structure of system (2.8a) and the type of boundary conditions (2.8c). The index concepts are introduced in the following section to classify these properties.

3. Index concepts. Before introducing index concepts for linear mixed systems of DAEs and hyperbolic-type PDAEs, we first review the index concept for linear systems of DAEs of the form

$$A\dot{u} + Cu = f(t), \tag{3.1}$$

where $A, C \in \mathbb{R}^{n\times n}$, $\dot{u}, u \in \mathbb{R}^n$, $f : I \to \mathbb{R}^n$, and I is a subinterval of $\mathbb{R}$. See, for example, [3, 14] for more details.

3.1. Linear DAEs. If the matrix pencil $\{A, C\}$ is regular, i.e., $\det(\lambda A + C) \not\equiv 0$ for at least one $\lambda \in \mathbb{C}$, it can be transformed into Kronecker normal form

$$\{PAQ, PCQ\} = \left\{ \begin{bmatrix} I & 0 \\ 0 & N \end{bmatrix}, \begin{bmatrix} M & 0 \\ 0 & I \end{bmatrix} \right\}$$

with regular matrices $P, Q \in \mathbb{R}^{n\times n}$, $M \in \mathbb{R}^{k\times k}$, $k \leq n$, and a nilpotent matrix $N \in \mathbb{R}^{(n-k)\times(n-k)}$. N belongs to the eigenvalue 0 of A and is of nilpotency ν_a, i.e., ν_a is the smallest number such that $N^{\nu_a} = 0$, but $N^{\nu_a - 1} \neq 0$. With the variable transformation

$$\begin{bmatrix} y \\ z \end{bmatrix} = Q^{-1}u, \qquad \begin{bmatrix} \eta(t) \\ \chi(t) \end{bmatrix} = Pf(t)$$

into differential variables $y \in \mathbb{R}^k$ and algebraic variables $z \in \mathbb{R}^{n-k}$, the transformation of the matrix pencil corresponds to a decoupling of (3.1) into an explicit ODE and a nilpotent part:

$$\dot{y} = \eta(t) - My, \tag{3.2a}$$

$$N\dot{z} = \chi(t) - z. \tag{3.2b}$$

One has to perform $\nu_a - 1$ differentiations to solve for the nilpotent part:

$$z = \sum_{i=0}^{\nu_a - 1} (-1)^i N^i \chi^{(i)}(t), \tag{3.3}$$

and a last differentiation yields an explicit ODE for z. The solution behavior of system (3.1) differs from standard ODE theory in the following ways:

- The solution has to fulfill an algebraic constraint, since $z(0)$ is fixed by χ and its higher derivatives at the initial time point. Especially, consistent initial values have to be found.
- The system is sensitive with respect to perturbations. Take as example a signal noise, modeled by the input signal $\delta(t)$ that is added to $\chi(t)$: although δ may be very small, its higher derivatives may be arbitrarily large. A severe amplification of perturbations may occur for problems with nilpotency $\nu_a \geq 2$.

These analytical results suggest that no severe numerical problems arise for $\nu_a \leq 1$: the algebraic constraint is explicitly given; hence implicit numerical integration schemes for stiff systems, which contain a solver for nonlinear equations, are suitable to treat these problems. Additionally, no amplification of round-off errors is to be expected since the system is not sensitive with respect to perturbations.

However, severe numerical problems arise for systems with nilpotency $\nu_a \geq 2$: there are hidden algebraic constraints, which may be resolved by an unstable differentiation process. Regarding perturbations from round-off errors, the numerical solution will include terms of order $\delta/h^{\nu_a - 1}$, where h is the small time step.

Since the value of ν_a defines the behavior of the system (3.1), both in a theoretical and a numerical respect, ν_a is called the *algebraic index* of system (3.1). Additionally, the observations made above motivate two different points of view.

Differential index: To obtain an explicit differential system instead of the linear-implicit system (3.1), we had to differentiate the nilpotent part (3.2b). Since numerical differentiation is an unstable procedure, the number of differentiation steps needed to get an explicit ODE system is a measure for the numerical problems to be expected

when solving systems of type (3.1). Hence the minimum number of differentiations required is called the *differential index* ν_d of the linear-implicit linear system (3.1).

Perturbation index: We have seen that derivatives of the perturbation enter the solution of (3.1). This observation leads to a new kind of index, which measures the sensitivity of the solution with respect to perturbations in the equations: The linear-implicit system (3.1) has *perturbation index* ν_p if derivatives of perturbations up to degree ν_p enter the derivative of the solution.

All index notions are equivalent in the case of linear DAE systems: $\nu_a = \nu_p = \nu_d$. Hence we just speak of *the* DAE index for a linear DAE system throughout this paper.

Remark 1. In the nonlinear case, both definitions for the differential and perturbation index can be generalized in a straightforward way; see [7, 11] for technical details. However, the differential and perturbation index may differ arbitrarily for nonlinear systems [4].

In the following sections, we will apply and extend the index concept introduced in [6, 16] for parabolic-type PDAEs to linear mixed systems of DAEs and hyperbolic-type PDAEs. However, the time index, which needs periodic boundary conditions, is replaced by a MOL index based on an upwind semidiscretization. The *spatial index* and *MOL index* will measure the sensitivity of the system with respect to slight perturbations in the initial data and input signals, respectively. These index concepts are a measure for the sensitivity of the ADAE system after semidiscretization with respect to space and time. The *perturbation index* aims at the sensitivity of the system in both space and time.

3.2. A spatial index. The theory for the spatial index can be directly transferred from the approach for parabolic systems. We apply the Laplace transformation as described in [16] to (2.8a). If a componentwise growth condition

$$|u(x,t)| \le Ke^{ct}, \quad K, c \in \mathbb{R}, \qquad K > 0,$$

for u is fulfilled, u can be transformed into

$$U_\xi(x) = \int_0^\infty e^{-\xi t} u(x,t)\, dt, \quad \xi \in \mathbb{C}, \quad \operatorname{Re}\xi > c.$$

If the growth conditions holds for u_t, f, s, and z, too, this transformation leads to

$$BU'_\xi(x) + (A\xi + C)U_\xi(x) = F_\xi(x) + Ag(x)$$

for (2.8a) and to

$$[R_1\xi + R_2] \begin{bmatrix} U_\xi(0) \\ U_\xi(1) \\ Z_\xi \end{bmatrix} = S_\xi + R_1 \begin{bmatrix} g(0) \\ g(1) \\ z_0 \end{bmatrix}$$

for the boundary conditions (2.8c), where $F_\xi(x), S_\xi, Z_\xi$ are the Laplace-transforms of $f(x,t), s(t), z(t)$, respectively.

For the ODE case, B regular, the spatial index ν_S is defined to be zero. Else, if B is singular, we get a BVP-DAE system where we define the spatial index ν_S as the algebraic index of the matrix pencil $\{B, A\xi + C\}$. Here, we have to bear in mind that in the previous chapter we defined the algebraic index for a real-valued matrix pencil, whereas $\{B, A\xi + C\}$ is a polynomial matrix pencil. However, the index can be defined analogously for matrix elements of any field. In our case, as we assumed A

regular, it is not possible to obtain a spatial index > 1. Looking at the characteristic formulation (2.9a) and considering the matrix pencil $\{\Lambda, I\xi + \widetilde{C}\}$, we immediately get $\nu_S = 0$ for Λ regular and $\nu_S = 1$ for Λ singular for $\operatorname{Re}\xi$ sufficiently large.

Example 3 (transmission line). For the transmission line system (2.1) we have a regular matrix Λ in (2.10a), and hence space index $\nu_S = 0$ for either boundary conditions (2.3) or (2.4).

Example 4 (countercurrent heat exchanger). Consider the two stream countercurrent heat exchanger (2.5) with boundary conditions (2.6) of level 2a. We apply the Laplace transformation $u \longrightarrow U_\xi$ to (2.5) and obtain

$$BU'_\xi(x) + (\xi I + C)U_\xi(x) = g(x).$$

The boundary conditions transform equivalently into

$$\begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} U_\xi(0) + \begin{bmatrix} 0 & 0 & 0 \\ 0 & 1 & 0 \end{bmatrix} U_\xi(1) = \begin{bmatrix} \int_0^\infty e^{-\xi t} s_1(t)dt \\ \int_0^\infty e^{-\xi t} s_2(t)dt \end{bmatrix}.$$

The resulting DAE-BVP has index 1, since B is a singular diagonal matrix and $\xi I + C$ is regular with positive entries on the diagonal. This is what we would expect considering the underlying PDE. This system can be solved for U_ξ, and the final solution u is obtained by back transformation.

3.3. A MOL index. In [6, 16] definitions for a modal and time index are given in the context of parabolic PDAEs of type

$$Au_t + Du_{xx} + Cu = f \tag{3.4}$$

with homogeneous boundary conditions. It is possible to expand u in orthogonal eigenfunctions $\sin k\pi x$ of the operator d^2/dx^2,

$$u(x,t) = \sum_{k=1}^{\infty} u_k(t) \sin k\pi x,$$

fulfilling the same boundary conditions as the above system. With the Galerkin principle, the $u_k(t)$ decouple and the DAEs for $u_k(t)$ can be solved independently. This approach is not applicable if an additional first order term Bu_x arises in (3.4).

However, in system (2.8) we have to face this case. Additionally, we cannot assume homogeneous, or more generally, periodic boundary conditions for first order hyperbolic systems. Hence we propose a MOL index rather than a time index to measure the sensitivity of system (2.8) with respect to time: the following index definition is not based on an expansion of the PDAE solution in orthogonal eigenfunctions, but on a semidiscretization with respect to space that is applied to the characteristic formulation (2.9) of the system.

In order to reflect properly the information flow in the system, we use first order approximations of w_x in the different upwind directions. We use a uniform grid $\Omega_h = \{x_k : \ x_k = kh, \ k = 0, 1, \ldots, N, \ h = 1/N\}$. Introducing the discrete vector $W^h(t) = [w_0^h(t)^\top, w_1^h(t)^\top, \ldots, w_N^h(t)^\top]^\top$ with $w_k^h(t) \approx w(t, x_k)$, $k = 0, 1, \ldots, N$, we can define the following ADAE system in the unknown W:

$$\dot{w}_j^{h,i} + \sum_{k=1}^{n_u} c_{ik} w_j^{h,k} + \left\{ \begin{array}{ll} \frac{\lambda_i}{h}\left[w_j^{h,i} - w_{j-1}^{h,i}\right] & \text{if } \lambda_i > 0 \\ \frac{\lambda_i}{h}\left[w_{j+1}^{h,i} - w_j^{h,i}\right] & \text{if } \lambda_i < 0 \\ 0 & \text{if } \lambda_i = 0 \end{array} \right\} = f^i(x_j, t) \tag{3.5a}$$

for $i = 1, \ldots, n_u$, $j = 1, \ldots, N-1$. The numerical boundary conditions at the outflows are given by

$$\dot{w}_N^{h,i} + \sum_{k=1}^{n_u} c_{ik} w_N^{h,k} + \frac{\lambda_i}{h}\left[w_N^{h,i} - w_{N-1}^{h,i}\right] = f^i(x_N, t) \tag{3.5b}$$

for $\lambda_i > 0$ and

$$\dot{w}_0^{h,i} + \sum_{k=1}^{n_u} c_{ik} w_0^{h,k} + \frac{\lambda_i}{h}\left[w_1^{h,i} - w_0^{h,i}\right] = f^i(x_0, t) \tag{3.5c}$$

for $\lambda_i < 0$. The system is completed by the physical boundary conditions (2.9c)

$$\widetilde{R}_1 \begin{bmatrix} \dot{w}_0^h(t) \\ \dot{w}_N^h(t) \\ \dot{z}^h(t) \end{bmatrix} + \widetilde{R}_2 \begin{bmatrix} w_0^h(t) \\ w_N^h(t) \\ z^h(t) \end{bmatrix} - s(t) = 0. \tag{3.5d}$$

Note that $z^h(t)$ is also indexed by h since we get different approximate solutions $z^h(t)$ for different h due to the coupling with $W^h(t)$.

DEFINITION 3.1. *System* (3.5) *defines a family* $\{F_N\}_{N\in\mathbb{N}_0}$ *of linear DAE systems with solution* $[W^h(t), z^h(t)]^\top$ *with index* ν_N. *We shall take the MOL index* ν_T *of the PDAE* (2.8) *to be* ν_N *for* N *sufficiently large, provided* ν_N *does not change for all* $N > N_0$ *with some* $N_0 \in \mathbb{N}_0$.

Example 5 (transmission line). Using the results of Example 1, we obtain with

$$M = (m)_{ij} = \delta_{i+1,j} - \delta_{i,j}, \quad i = 1, \ldots, N, \quad j = 1, \ldots, N+1,$$

and $c_1 = R/L + G/C$, $c_2 = R/L - G/C$ the DAE system

$$\begin{bmatrix} \dot{w}_0^{h,1} \\ \vdots \\ \dot{w}_{N-1}^{h,1} \end{bmatrix} - \frac{1}{h\sqrt{LC}} M \begin{bmatrix} w_0^{h,1} \\ \vdots \\ w_N^{h,1} \end{bmatrix} + \frac{1}{2}\left(c_1 \begin{bmatrix} w_0^{h,1} \\ \vdots \\ w_{N-1}^{h,1} \end{bmatrix} + c_2 \begin{bmatrix} w_0^{h,2} \\ \vdots \\ w_{N-1}^{h,2} \end{bmatrix} \right) = 0, \tag{3.6a}$$

$$\begin{bmatrix} \dot{w}_1^{h,2} \\ \vdots \\ \dot{w}_N^{h,2} \end{bmatrix} + \frac{1}{h\sqrt{LC}} M \begin{bmatrix} w_0^{h,2} \\ \vdots \\ w_N^{h,2} \end{bmatrix} + \frac{1}{2}\left(c_2 \begin{bmatrix} w_1^{h,1} \\ \vdots \\ w_N^{h,1} \end{bmatrix} + c_1 \begin{bmatrix} w_1^{h,2} \\ \vdots \\ w_N^{h,2} \end{bmatrix} \right) = 0, \tag{3.6b}$$

$$\sqrt{L/C}\left[w_0^{h,2}(t) - w_0^{h,1}(t)\right] = V(t) \tag{3.6c}$$

$$C_1\sqrt{L/C}\left[\dot{w}_N^{h,2}(t) - \dot{w}_N^{h,1}(t)\right] - \left[w_N^{h,1}(t) + w_N^{h,2}(t)\right] = 0 \tag{3.6d}$$

in $W^h(t)$. Obviously, this system has index one independent of h, which yields the MOL index $\nu_T = 1$. Correspondingly, the system with boundary conditions (2.4) has MOL index $\nu_T = 2$.

Example 6 (countercurrent heat exchanger). Consider again the model for the countercurrent heat exchanger (2.5) with boundary conditions (2.6) and (2.7), respectively, of levels 2a and 2b. The system is already in characteristic form. The

ADAE (3.5a)–(3.5c) now reads

$$\dot{u}_j^{h,1} + \frac{v_1}{h}\left[u_j^{h,1} - u_{j-1}^{h,1}\right] + \frac{v_1\alpha_1 A_1}{Ln_1 C_{p_1}}\left[u_j^{h,1} - u_j^{h,3}\right] = 0, \quad j = 1, \ldots, N,$$

$$\dot{u}_j^{h,2} - \frac{v_2}{h}\left[u_{j+1}^{h,2} - u_j^{h,2}\right] + \frac{v_2\alpha_2 A_2}{Ln_2 C_{p_2}}\left[u_j^{h,2} - u_j^{h,3}\right] = 0, \quad j = 0, \ldots, N-1,$$

$$\dot{u}_j^{h,3} + \frac{\alpha_1 A_1}{mC_{p_m}}\left[u_j^{h,3} - u_j^{h,1}\right] + \frac{\alpha_2 A_2}{mC_{p_m}}\left[u_j^{h,3} - u_j^{h,2}\right] = 0, \quad j = 0, \ldots, N,$$

together with either

$$u_0^{h,1} = s_1(t), \qquad u_N^{h,2} = s_2(t)$$

for the boundary conditions (2.6) of level 2a or

$$u_0^{h,1} = s_1(t), \quad \dot{z}^h + u_N^{h,2} = s_2(t), \quad z^h = s_3(t)$$

for boundary conditions (2.7) of level 2b. Thus we have $\nu_T = 1$ in the first and $\nu_T = 2$ in the latter case.

3.4. The perturbation index. Let $[u, z]^\top$ be the (reference) solution of the PDAE system (2.8a)–(2.8c) with consistent initial values $u(x, 0) = g(x)$ and $z(0) = z_0$. To investigate the sensitivity of this solution with respect to initial values, input signals, and inhomogenities, we apply perturbations $\delta(x, t)$ and $\mu(t)$ to the right-hand sides of (2.8a) and (2.8c). The corresponding perturbed solution is denoted by $[\hat{u}, \hat{z}]^\top$ with consistent perturbed initial values $\hat{u}(x, 0) = \hat{g}(x)$ and $\hat{z}(0) = \hat{z}_0$. The aim is to obtain estimates for the sensitivity of the solution. As we are especially interested in the influence of perturbations in the time-dependent boundary conditions, we will consider the PDAE as an evolution problem.

We consider first the telegrapher's equations (2.1) which are coupled with a network without inductors and voltage sources: the DAE boundary conditions (2.8c) then read

$$\widetilde{C}\dot{z} + \widetilde{G}z + P\begin{bmatrix} I(0,t) \\ -I(1,t) \end{bmatrix} = V(t) \tag{3.8}$$

with a positive-definite, symmetric capacitance matrix $\widetilde{C}$, a conductance matrix $\widetilde{G}$, an incidence matrix P that assembles the current contributions from the transmission lines at the respective nodes, and the coupling condition

$$\begin{bmatrix} U(0,t) \\ U(1,t) \end{bmatrix} = P^\top z$$

for the boundary node voltages. Due to the linearity of the systems, $[\bar{u}, \bar{z}]^\top := [\hat{u} - u, \hat{z} - z]^\top$ is now the solution of (2.1), (3.8) with δ and μ as inhomogenities for the initial values $\bar{u}(x, 0) = \bar{g}(x) := \hat{g}(x) - g(x)$ and $\bar{z}(0) = \bar{z}_0 = \hat{z}_0 - z_0$.

To get an estimate for $\bar{u}$, we consider the inner product of the PDE with $[\bar{I}, \bar{U}]^\top$. Integration over $(0, 1)$ with respect to x and integration by parts yield

$$\bar{U}(\cdot,t)\bar{I}(\cdot,t)\Big|_0^1 + \frac{1}{2}\frac{d}{dt}\Big[(L\bar{I},\bar{I}) + (C\bar{U},\bar{U})\Big] + (R\bar{I},\bar{I}) + (G\bar{U},\bar{U}) + (\bar{I},\delta_1) + (\bar{U},\delta_2) = 0$$

with $(\cdot,\cdot)$ denoting the inner product in $L^2(0,1)$. Using the coupling condition and $P^\top P = I$, the first term can be replaced by

$$\frac{1}{2}\frac{d}{dt}\left[\bar{z}^\top \widetilde{C}\bar{z}\right] + \bar{z}^\top \widetilde{G}\bar{z} - \bar{z}^\top \mu(t).$$

Integrating over $(0,t)$, we get with $C, L > 0$ and $\widetilde{C}$ positive definite the estimate

$$\rho(t) := \|\bar{U}(\cdot,t)\|_{L^2}^2 + \|\bar{I}(\cdot,t)\|_{L^2}^2 + \|\bar{z}(t)\|_2^2 \tag{3.9}$$

$$\leq \text{ const } \left(\rho(0) + \int_0^t \left(\|\mu(\tau)\|_2^2 + \|\delta(\cdot,\tau)\|_{L^2}^2 + \rho(\tau)\right) d\tau\right). \tag{3.10}$$

Here $\|\cdot\|_2$ denotes the Euclidian norm on $\mathbb{R}^n$, and $\|u(\cdot,t)\|_{L^2}^2 := (u(\cdot,t),u(\cdot,t))$ the norm associated to the inner product. By Gronwall's lemma we end up with

$$\max_{t\in[0,T]} \|u(\cdot,t) - \hat{u}(\cdot,t)\|_{L^2} + \max_{t\in[0,T]} \|z(t) - \hat{z}(t)\|_2 \tag{3.11}$$

$$\leq \text{ const} \left(\|g - \hat{g}\|_{L^2} + \|z_0 - \hat{z}_0\|_2 + \max_{t\in[0,T]} \left(\|\mu(t)\|_2 + \|\delta(\cdot,t)\|_{L^2}\right)\right).$$

Generalizing this estimate, a perturbation index can be defined similar to the definition in [6] as follows.

DEFINITION 3.2. *If there exists for all $t \in [0,T]$ an estimate for the reference solution $[u,z]^\top$ with initial values $[g(x),z_0]^\top$ of system* (2.8a)–(2.8c) *of the type*

$$||u - \hat{u}||_{C([0,T],L^2)} + ||z - \hat{z}||_{C([0,T])} \tag{3.12}$$

$$\leq \Gamma \left\{ ||g - \hat{g}||_{H^{q_2}} + ||z_0 - \hat{z}_0||_2 + \left(\|\mu\|_{C^{p_2}([0,T])} + \|\delta\|_{C^{p_1}([0,T],H^{q_1})}\right)\right\},$$

where $[\hat{u},\hat{z}]^\top$ denotes the corresponding perturbed solution with perturbations $[\delta(x,t),\mu(t)]^\top$, then the perturbation index ν_P is defined by

$$\nu_P = 1 + \min\left\{\max(p_1+q_1, p_2, q_2)\middle|\ (3.12) \text{ holds for } (p_1,q_1,p_2,q_2)\right\}.$$

The used norms are given by

$$||\delta||_{C^{p_1}([0,T],H^{q_1})} := \max_{t\in[0,T]} \sqrt{\int_0^1 \sum_{i=0}^{p_1}\sum_{k=0}^{q_1} \left\| \frac{\partial^{i+k}\delta(x,t)}{\partial t^i \partial x^k}\right\|_2^2 dx},$$

$$||g||_{H^{q_2}} := \sqrt{\int_0^1 \sum_{k=0}^{q_2} \left\| \frac{d^k g(x)}{dx^k}\right\|_2^2 dx},$$

$$||\mu||_{C^{p_2}([0,T])} := \max_{t\in[0,T]} \sqrt{\sum_{i=0}^{p_2} \left\| \frac{d^i \mu(t)}{dt^i}\right\|_2^2}.$$

Remark 2.

- Γ is a nonzero constant independent of δ, μ, and $g - \hat{g}$. The constant depends only on A, B, C, R_1, R_2, and T.

- The perturbations and the respective consistent initial data have to be smooth enough to guarantee the existence of the norms on the right-hand side of (3.12).

Even for a hyperbolic system with purely time-dependent boundary conditions we can get perturbation index greater than one, where the analytical solution depends on derivatives of both initial values and input signals.

Example 7. Consider again telegrapher's equations of Example 1 in characteristic form with $L = C = 1$, $R = G = 0$, boundary conditions

$$\begin{bmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix} \cdot \begin{bmatrix} w_t(0,t) \\ w_t(1,t) \end{bmatrix} + \begin{bmatrix} 1 & 0 & 1 & 0 \\ 0 & 1 & 0 & 1 \end{bmatrix} \cdot \begin{bmatrix} w(0,t) \\ w(1,t) \end{bmatrix} = s(t),$$

and consistent initial values $w(x,0) = g(x)$. The analytical solution in $[0,1]^2$ reads

$$w^1(x,t) = \begin{cases} g_1(x+t), & 0 \le x+t \le 1, \\ s_1(x+t-1) - g_1(x+t-1), & \\ -\dot{s}_2(x+t-1) - \dot{g}_2(2-(x+t)), & 1 \le x+t \le 2, \end{cases}$$

$$w^2(x,t) = \begin{cases} g_2(x-t), & t \le x \le 1, \\ s_2(t-x) - g_2(1-t+x), & x \le t \le 1, \end{cases}$$

which yields an estimate of type (3.12) with $q_2 = p_2 = 1$ for the trivial solution as a reference, when neglecting disturbances in the inhomogenity.

For systems with purely time-dependent boundary conditions we state in the following lemma an estimate depending on the inhomogenity f and the initial conditions g, which extends the energy estimate results for Cauchy problems of symmetric hyperbolic systems [21].

LEMMA 3.3. *Consider system* (2.9a)

$$u_t + \Lambda u_x + Cu = f(x,t), \quad x \in [0,1], \quad t \in [0,T] \tag{3.13}$$

with $\Lambda = diag(\lambda_1, \dots, \lambda_r, 0, \dots, 0)$, $\lambda_i > 0$ *for* $1 \le i \le l$ *and* $\lambda_i < 0$ *for* $l+1 \le i \le r$, *initial condition* $u(x,0) = g(x)$ *and boundary conditions of type* (2.8c). *One obtains the following estimate for the solution* $u \in C([0,T], L^2)$ *for the system* (3.13), (2.8c)

$$||u(\cdot,t)||_{C([0,T],L^2)} \le \Gamma \left(||g||_{L^2} + ||f||_{C([0,T],L^2)} + ||\chi||_{C([0,T])} \right),$$

with $\chi = (\chi_1, \dots, \chi_r)^\top$, Γ *constant and the physical boundaries defined by*

$$u_i(0,t) = \chi_i(t), \quad i = 1, \dots, l, \text{ respectively, } u_i(1,t) = \chi_i(t), \quad i = l+1, \dots, r. \tag{3.14}$$

Proof. Integrating the inner product of (3.13) with u over the region $R_t = \{(\tau, x) |\, 0 \le \tau \le t,\, x \in [0,1]\}$ in the t-x-plane gives

$$\begin{aligned} \|u(\cdot,t)\|_{L^2}^2 = &\int_{R_t} (-2u^\top Cu + 2u^\top f) dx\, d\tau + ||g||_{L^2}^2 \\ &+ \int_0^t [u(0,\tau)^\top \Lambda u(0,\tau) - u(1,\tau)^\top \Lambda u(1,\tau)] d\tau\,. \end{aligned}$$

As C is constant, we find $-2u^\top Cu \le Ku^\top u$ with a constant $K > 0$; additionally, the expression with the inhomogenity f is estimated by

$$2u^\top f \le u^\top u + f^\top f\,.$$

In order to insert the boundary conditions, Λ is split:

$$u(0,\tau)^\top \Lambda u(0,\tau) = \sum_{k=1}^{l} \lambda_k \chi_k(\tau)^2 + \sum_{k=l+1}^{r} \lambda_k u_k(0,\tau)^2\,, \qquad \text{respectively,}$$

$$u(1,\tau)^\top \Lambda u(1,\tau) = \sum_{k=1}^{l} \lambda_k u_k(1,\tau)^2 + \sum_{k=l+1}^{r} \lambda_k \chi_k(\tau)^2\,.$$

Due to the different signs the following inequality holds with $M_1 := K + 1$:

$$\|u(\cdot,t)\|_{L^2}^2 \le M_1 \int_0^t \|u(\cdot,\tau)\|_{L^2}^2 d\tau + ||g||_{L^2}^2 + T \max_{0\le\tau\le t} \Big(\max_k |\lambda_k| \cdot ||\chi(\tau)||_2^2 + ||f(\cdot,\tau)||_{L^2}^2 \Big).$$

With $M_2 := \max\{1, T, T \max_{k=1,\dots,r} |\lambda_k|\}$ Gronwall's lemma yields

$$\|u(\cdot,t)\|_{L^2}^2 \le \left(||g||_{L^2}^2 + \max_{0\le\tau\le t} \Big(||\chi(\tau)||_2^2 + ||f(\cdot,\tau)||_{L^2}^2 \Big) \right) \cdot M_2 e^{M_1 T}, \tag{3.15}$$

and we obtain with $\Gamma := \sqrt{M_2 e^{M_1 T}}$ the desired inequality of the above lemma. ∎

COROLLARY 1. *If only physical boundaries $\chi_k(t)$, $k = 1,\dots,r$, appear, then the perturbation index ν_P is one higher than the degree of the highest derivative of the boundary data fulfilling an estimate*

$$||u(\cdot,t) - \hat{u}(\cdot,t)||_{L^2} \le \Gamma \left(||g - \hat{g}||_{L^2} + ||\delta||_{C([0,T];L^2)} + ||\mu||_{C^q([0,T])} \right)$$

with the norms of Lemma 3.3*, i.e., $\nu_P = q+1$. ν_P then corresponds to the DAE index of the boundary conditions.*

Example 8 (transmission line). Consider now the telegrapher's equations for a single transmission line given in (2.1) with both boundary conditions (2.3) and (2.4) of level 1b. Neglecting the anyway regularizing source term, line resistance R and conductance G, the system perturbed with $\delta(x,t)$ at the right-hand sides of (2.1) and $\mu(t)$ at the right-hand sides of (2.4) and (2.3), respectively, can be solved analytically for $t \in [0,1]$; see the appendix. For simplicity, we have fixed $C = L = 1$, and thus normalized the wave speed to 1. For system (2.1), (2.4) we get an estimate of type (3.12) with $(p_1, q_1, p_2, q_2) = (0,0,1,0)$, and the perturbation index is 2. The system is only sensitive with respect to perturbations in the input signals. For system (2.1), (2.3) the index reduces to 1.

Example 9 (countercurrent heat exchanger). Analyzing again the model for the countercurrent heat exchanger (2.5), we get with Corollary 1 that for purely time-dependent boundary conditions (2.6) the perturbation index is one, whereas the index-2 boundary conditions (2.7) yield a perturbation index two.

4. Benchmark examples. The index concepts derived in section 3 are now applied to the two previously introduced benchmark examples from chemical and electrical engineering.

On the one hand, the countercurrent heat exchanger model is already in characteristic form. Not surprisingly, semidiscretization with respect to space leads to ADAE systems with an index indicated by the perturbation and MOL index. Thus we will focus on the connection between spatial index and the ADAE systems obtained after semidiscretization with respect to time.

On the other hand, the higher sensitivity with respect to input signals in the transmission line model cannot be resolved by a horizontal MOL, which always will

lead to ODE systems. Therefore we will concentrate on the connection between MOL index and the ADAE systems obtained after semidiscretization with respect to space.

Then an interesting point in both cases will be the comparison between the perturbation index and the different indices mentioned above.

4.1. Countercurrent heat exchanger. First consider system (2.5) with boundary conditions (2.6) of level 2a. The perturbation and MOL index of this system are both equal to one, as shown in Examples 6 and 9.

The following subsection compares the spatial index and the DAE index of the approximative system obtained after application of some Rothe method, where — in contrast to the classical method of lines — semidiscretization is made with respect to time to obtain a boundary value problem in space alone. As the perturbation index measures the sensitivity of the original system with respect to boundary and initial values, the ADAE should have the same property.

Using the implicit Euler scheme as time discretization with $N+1$ grid points $t_j = j\tau$ in the horizontal MOL, we also have to solve a DAE of index one ($u_j^\tau(x)$ denotes the numerical approximation for $u(x,t_j)$):

$$\tau \begin{bmatrix} 0 & & & \\ & B & & \\ & & \ddots & \\ & & & B \end{bmatrix} \begin{bmatrix} {u_0^\tau}'(x) \\ {u_1^\tau}'(x) \\ \vdots \\ {u_N^\tau}'(x) \end{bmatrix} + \begin{bmatrix} I & & & & \\ -I & I+\tau\cdot C & & & \\ & -I & \ddots & & \\ & & \ddots & \ddots & \\ & & & -I & I+\tau\cdot C \end{bmatrix} \begin{bmatrix} u_0^\tau(x) \\ u_1^\tau(x) \\ \vdots \\ u_N^\tau(x) \end{bmatrix} = \begin{bmatrix} g(x) \\ 0 \\ \vdots \\ 0 \end{bmatrix}$$

with boundary values

$$\begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} u_j^\tau(0) + \begin{bmatrix} 0 & 0 & 0 \\ 0 & 1 & 0 \end{bmatrix} u_j^\tau(1) = \begin{bmatrix} s_1(j\tau) \\ s_2(j\tau) \end{bmatrix}.$$

For the implicit Euler scheme, the DAE index of the approximative system coincides with the spatial and perturbation index.

However, considering the explicit Euler scheme

$$\tau \begin{bmatrix} 0 & & & \\ B & 0 & & \\ & \ddots & \ddots & \\ & & B & 0 \end{bmatrix} \begin{bmatrix} {u_0^\tau}'(x) \\ {u_1^\tau}'(x) \\ \vdots \\ {u_N^\tau}'(x) \end{bmatrix} + \begin{bmatrix} I & & & \\ -I+\tau\cdot C & \ddots & & \\ & \ddots & I & \\ & & -I+\tau\cdot C & I \end{bmatrix} \begin{bmatrix} u_0^\tau(x) \\ u_1^\tau(x) \\ \vdots \\ u_N^\tau(x) \end{bmatrix} = \begin{bmatrix} g(x) \\ 0 \\ \vdots \\ 0 \end{bmatrix},$$

we obtain index $N+1$ because of the influence of the initial conditions. Thus, the index of the ADAE system in x does not always coincide with the spatial and perturbation

index. Such a behavior has to be avoided. Anyway, the explicit Euler method is not suitable for a time discretization, as the boundary values cannot be chosen freely.

Generally, the problems due to DAE boundary values are not well reflected using any Rothe method, i.e., the index would be the same regardless of applying (2.6) or (2.7).

4.2. VC loop with transmission line. Our next benchmark example arises from network theory. We consider the telegrapher's equations for a single transmission line given in (2.1) with both boundary conditions (2.3) and (2.4) (level 1b).

If the transmission line is skipped, we know from network theory that the DAE system has index three and two if the voltage source of the VC loop is driven by a JL cutset and a time-dependent voltage source, respectively; see [10].

In Examples 5 and 8 we have seen that both perturbation and MOL index for the corresponding systems with transmission lines is two and one, respectively, — the inclusion of transmission lines has a regularizing effect.

However, index three and two, respectively, may be obtained for the ADAE after semidiscretizations with respect to space, if the information in the characteristics is not adequately used. This will be shown in the following.

4.2.1. Semidiscretization with respect to space: Characteristic form. In a first step, we consider on a uniform grid Ω^h different semidiscretizations with respect to space which are based on system (2.10) in characteristic form. With the notation of Example 5, central differences lead to

$$\dot{\bar{w}}^h + (\Lambda \otimes \widetilde{M})w^h + (\widetilde{C} \otimes I_{N-1})\bar{w}^h = 0 \quad \text{with} \tag{4.1a}$$

$$\widetilde{M} = (\widetilde{m})_{ij} = \frac{1}{2h} \cdot (\delta_{i+2,j} - \delta_{i,j}), \quad i = 1, \dots, N-1, \quad j = 1, \dots, N+1,$$

and the Kronecker product $F \otimes G$ of two matrices $F \in \mathbb{R}^{n\times r}$ and $G \in \mathbb{R}^{s\times m}$ given by $F \otimes G := (f_{ij} \cdot G) \in \mathbb{R}^{ns\times rm}$. Using the abbreviations $\bar{w}^h = [\bar{w}^{h,1}, \bar{w}^{h,2}]^\top$, $\bar{w}^{h,i} = [w_1^{h,i}, \dots, w_{N-1}^{h,i}]^\top$ for $i = 1, 2$, the vector of approximate unknowns w^h is given by $w^h = [w_0^{h,1}, \bar{w}^{h,1}, w_N^{h,1}, w_0^{h,2}, \bar{w}^{h,2}, w_N^{h,2}]^\top$. The system is completed by the physical boundary conditions (3.6c), (3.6d) and by appropriate numerical boundary conditions: for example, upwind at the boundaries yields

$$\dot{w}_0^{h,1} - \frac{1}{\sqrt{LC}h}\left(w_1^{h,1} - w_0^{h,1}\right) + \frac{1}{2}\left(c_1 w_0^{h,1} + c_2 w_0^{h,2}\right) = 0, \tag{4.1b}$$

$$\dot{w}_N^{h,2} + \frac{1}{\sqrt{LC}h}\left(w_N^{h,2} - w_{N-1}^{h,2}\right) + \frac{1}{2}\left(c_2 w_N^{h,1} + c_1 w_N^{h,2}\right) = 0. \tag{4.1c}$$

Obviously, the index is one. One could also think of linear finite element approximations $\widetilde{w}^h(x,t)$ to $w^h(x,t)$ that are constructed according to the characteristics by fixing the solution at the respective inflow boundary:

$$\widetilde{w}^{h,1}(x,t) = \frac{1}{2}\left(I^h(1,t) - \frac{1}{\sqrt{L/C}}U^h(1,t)\right)\varphi_N + \sum_{k=0}^{N-1} w_k^{h,1}(t)\varphi_k(x) \tag{4.2a}$$

$$\widetilde{w}^{h,2}(x,t) = \frac{1}{2}\left(I^h(0,t) + \frac{1}{\sqrt{L/C}}U^h(0,t)\right)\varphi_0 + \sum_{k=1}^{N} w_k^{h,2}(t)\varphi_k(x). \tag{4.2b}$$

Then Galerkin applied to (2.9), (2.10a), (2.10b), together with the physical boundary conditions

$$U^h(0,t) - V(t) = 0, \qquad C_1 \cdot U_t^h(1,t) - I^h(1,t) = 0 \tag{4.3}$$

at the transmission line ends, and the coupling conditions

$$\widetilde{w}^{2,h}(1,t) = \frac{1}{2}\left(I^h(1,t) + \frac{U^h(1,t)}{\sqrt{L/C}}\right), \ \widetilde{w}^{1,h}(0,t) = \frac{1}{2}\left(I^h(0,t) - \frac{U^h(0,t)}{\sqrt{L/C}}\right) \tag{4.4}$$

at the remaining outflow boundaries, defines a linear DAE system in the unknowns $w_0^{1,h}, w_1^{1h} \ldots, w_{N-1}^{1,h}, w_1^{2,h}, w_2^{2,h}, \ldots, w_N^{2,h}, U^h(0,t), U^h(1,t), I^h(0,t), I^h(1,t)$. One can show that this system has index one independent of h.

4.2.2. Semidiscretization with respect to space: Noncharacteristic form. The situation is quite different if semidiscretization with respect to space is applied to the original formulation (2.1), (2.3). Central differences now yield index two for some exceptional values of the discretization parameter h, but index one is assured for h being small enough. This behavior is well known for ADAE systems arising from MOLs applied to PDAEs [1, 5].

However, things may be even worse: let us investigate the use of so-called RLGC companion network models [2], which corresponds to the use of central differences with staggered grids applied to (2.1), (2.3):

$$L\begin{bmatrix} \dot{I}_{1/2}^h \\ \vdots \\ \dot{I}_{N-1/2}^h \end{bmatrix} + R\begin{bmatrix} I_{1/2}^h \\ \vdots \\ I_{N-1/2}^h \end{bmatrix} + \frac{1}{h}\begin{bmatrix} -1 & 1 & & \\ & \ddots & \ddots & \\ & & -1 & 1 \end{bmatrix}\begin{bmatrix} U_0^h \\ \vdots \\ U_N^h \end{bmatrix} = 0, \tag{4.5a}$$

$$C\begin{bmatrix} \dot{U}_0^h \\ \vdots \\ \dot{U}_N^h \end{bmatrix} + G\begin{bmatrix} U_0^h \\ \vdots \\ U_N^h \end{bmatrix} + \frac{1}{h}\begin{bmatrix} -2 & 2 & & & & \\ & -1 & 1 & & & \\ & & \ddots & \ddots & & \\ & & & -1 & 1 & \\ & & & & -2 & 2 \end{bmatrix}\begin{bmatrix} I_0^h \\ I_{1/2}^h \\ \vdots \\ I_{N-1/2}^h \\ I_N \end{bmatrix} = 0, \tag{4.5b}$$

with $U_l^h(t)$, $I_l^h(t)$ numerical approximations for $U(x,t)$, $I(x,t)$ at the points (lh,t).

Together with the boundary conditions

$$U_0^h - V(t) = 0, \tag{4.5c}$$

$$C_1\dot{U}_N^h - I_N^h = 0 \tag{4.5d}$$

the ADAE (4.5) has index two for all $C, L, C_1 > 0$ and $R, G \geq 0$ independent of h: boundary condition (4.5d) is equivalent to

$$I_N^h = \frac{1}{C/C_1 + 2/h}\left(\frac{2}{h}I_{N-1/2}^h - GU_N^h\right),$$

which defines $\dot{I}_N^h$ after one differentiation in terms of $I_{N-1/2}^h, I_N^h, U_{N-1}^h, U_N^h$. However, one differentiation of (4.5c) is necessary to obtain

$$I_0^h = I_{1/2}^h + \frac{h}{2}\left(C\dot{V}(t) + GV(t)\right),$$

and a second differentiation is necessary to get an explicit ODE for I_0. Thus I_0^h, the current through the voltage source, is an index-2 variable, as for a VC loop without transmission lines. It can be shown that linear finite elements applied to the original formulation (2.1), (2.3) have the same deregularizing effect: they also yield index-2 ADAE systems for all discretization parameters [9].

Inspecting the VC loop, we have seen that a model refinement based on including transmission lines effects may regularize DAE network equations of higher index. Using semidiscretization with respect to space, the MOL approach converts this mixed system of PDEs and DAEs into an ADAE system in time only. To reflect the physical properties of the original PDAE network model, the ADAE system should neither be more nor less sensitive, and the regularizing effect should be kept. However, semidiscretization may deregularize a regularizing PDE model, if the method of lines approach is not consistent with the information flow along characteristics.

5. Conclusion. We have extended some of the index concepts for parabolic PDAEs with homogeneous boundary conditions to hyperbolic-type initial-boundary value problems of linear PDAEs, where the boundary conditions are governed by linear time-dependent DAEs. To investigate the impact of semidiscretization in space and time, we introduced a space and a MOL index for an a posteriori analysis. However, the DAE index of the approximative system obtained after a particular semidiscretization may be different. The properties of the underlying mixed system were described by a perturbation index, which reflects the sensitivity of the original system with respect to slight perturbations in the right-hand side of the PDAE, as well as in the input signals and initial values.

By inspecting interconnected electrical circuits and a heat exchanger as examples arising in applications, we have seen that these index notions give insight into the properties of the mixed PDAE/DAE system and the DAE systems obtained after semidiscretization: the spatial and MOL index give hints for the sensitivity of the ADAEs with respect to input signals and data. These properties should be consistent with the behavior of the original system described by the perturbation index. The ADAEs should be neither more nor less sensitive, though the latter might facilitate the numerical solution of the ADAE system; however, the obtained solution could be physically incorrect. On the other hand, a spurious sensitivity of the ADAE system detected by an index larger than the MOL index might indicate that the semidiscretization with respect to space is not appropriate.

The analysis of mixed DAEs and hyperbolic-type PDAEs using index concepts provided helpful information. In order to give reliable recipes for the numerical treatment of coupled DAE and hyperbolic-type PDAE systems, further investigations should aim at a more closed theory for the different index notions and extend the analysis to nonlinear systems.

Appendix. Perturbed VC loop with transmission lines. Fixing $R = G = 0$ and $C = L = 1$, systems (2.1), (2.4) and (2.1), (2.3) perturbed with $\delta(x,t)$ at the right-hand sides of (2.1), and $\mu(t)$ at the right-hand sides of (2.4) and (2.3), respectively, can be solved analytically for $t \in [0,1]$.

For system (2.1), (2.4) we get

$$\text{(A.1a)} \qquad \begin{bmatrix} U(x,t) \\ I(x,t) \end{bmatrix} = \underbrace{\begin{bmatrix} -1 & 1 \\ 1 & 1 \end{bmatrix}}_{T} \cdot \begin{bmatrix} w^1(x,t) \\ w^2(x,t) \end{bmatrix}$$

with the characteristic variables w^1 and w^2.

1. $1 \le x+t \le 2$:

$$w^1(x,t) = w_0^2(2-(x+t)) - \exp\left(\frac{1-(x+t)}{C_1}\right)(w_0^1(1) - w_0^2(1))$$
$$- \int_0^{(x+t)-1} \exp\left(\frac{(1+\tau)-(x+t)}{C_1}\right)\left[\frac{\mu_2(\tau)}{C_1} + \frac{2}{C_1}\left(w_0^2(1-\tau)\right.\right.$$
$$\left.\left. + \int_0^{\tau} \widetilde{\delta}_2(\xi + (1-\tau), \xi)\, d\xi\right)\right] d\tau + \int_0^{(x+t)-1} \widetilde{\delta}_2(\tau + 2 - (x+t), \tau)\, d\tau$$
$$+ \int_0^{1-x} \widetilde{\delta}_1(1-\tau, \tau + (x+t) - 1)\, d\tau. \tag{A.1b}$$

2. $0 \le x+t \le 1$:

$$w^1(x,t) = w_0^1(x+t) + \int_x^{x+t} \widetilde{\delta}_1(\xi, (x+t) - \xi)\, d\xi. \tag{A.1c}$$

3. $0 \le x-t \le 1$:

$$w^2(x,t) = w_0^2(x-t) + \int_0^{t} \widetilde{\delta}_2(\xi + (x-t), \xi)\, d\xi. \tag{A.1d}$$

4. $0 \le t-x \le 1$:

$$w^2(x,t) = \mu_4(t-x) + \mu_1(t-x) + L_{ind}(\dot{\mu}_3(t-x) - \dot{J}(t-x)) + w_0^1(t-x)$$
$$+ \int_0^{t-x} \widetilde{\delta}_1(\xi, (t-x) - \xi)\, d\xi + \int_{t-x}^{t} \widetilde{\delta}_2(\tau - (t-x), \tau)\, d\tau. \tag{A.1e}$$

The network variables are given by

$$z = L_{ind}(\dot{\mu}_3(t) - \dot{J}(t)) + \mu_4(t), \qquad I_L = \mu_3(t) - J(t). \tag{A.1f}$$

Here we have used the transformed source term $\widetilde{\delta}(x,t) = T^{-1}\delta(x,t)$ and the transformed initial values

$$\begin{bmatrix} w_0^1(x) \\ w_0^2(x) \end{bmatrix} = T^{-1} \begin{bmatrix} U(x,0) \\ I(x,0) \end{bmatrix}.$$

For system (2.1), (2.3) equation (A.1f) can be skipped, and (A.1e) is transformed to

$$w^2(x,t) = V(t-x) + \mu_1(t-x) + w_0^1(t-x)$$
$$+ \int_0^{t-x} \widetilde{\delta}_1(\xi, (t-x) - \xi)\, d\xi + \int_{t-x}^{t} \widetilde{\delta}_2(\tau - (t-x), \tau)\, d\tau.$$

Acknowledgments. The authors thank P. Rentrop and B. Simeon for valuable suggestions, as well as M. Arnold and S. Campbell for helpful discussions. We are indebted to the referees for helpful comments leading to an improved version of the paper.

IMMERSED INTERFACE METHODS FOR NEUMANN AND RELATED PROBLEMS IN TWO AND THREE DIMENSIONS*

AARON L. FOGELSON† AND JAMES P. KEENER†

Abstract. We develop and apply a finite-difference method to discretize the Laplacian operator with Neumann boundary conditions on an irregular domain using a regular Cartesian grid. The method is an extension of the immersed interface method developed by LeVeque and Li [*SIAM J. Numer. Anal.*, 31 (1994) 1019–1044]. With careful selection of stencils, the method is second order accurate and produces a matrix that is stable (diagonally semidominant). The method is illustrated on several two-dimensional problems and one three-dimensional problem.

Key words. Neumann problems, immersed interface, Cartesian grid, stability

1. Introduction.

In this paper we discuss Cartesian-grid finite-difference methods for discretizing the Laplacian with Neumann boundary conditions specified on one or more curves or surfaces. The methods use special but compact stencils (i.e., 3 by 3 in two dimensions, 3 by 3 by 3 in three dimensions); they are second order accurate; and we give sufficient conditions that guarantee their stability. Even when these sufficient conditions are not met, the methods perform stably in our applications. We give a systematic procedure for selecting the stencils which can easily be implemented using look-up tables.

Cartesian-grid finite-difference methods are traditionally thought to be inappropriate for handling Neumann conditions on general curves or surfaces (see, e.g., [16]). The difficulty is this: on the one hand, first order one-sided difference approximations to the normal derivative combined with a standard five-point (in two dimensions) scheme for the Laplacian at interior points yields a stable but first order method [3]. On the other hand, traditional second order one-sided approximations to the normal derivative yield improved accuracy but at the cost of possible instability and a wide difference stencil [16]. The popularity of finite-element methods [4] and boundary-fitted grid methods [17] for such problems stems largely from their perceived superiority in handling this kind of boundary condition. But finite-element methods and boundary-fitted grid methods involve substantially more complicated data structures than do Cartesian-grid methods. The complicated data structures increase the complexity and cost of many parts of the solution process, especially the linear algebra, and complicate as well graphical display of the results. For these reasons, it is desirable to seek methods based on Cartesian grids that are easier to use.

The starting point for the derivation of the methods discussed here is the immersed interface method introduced by LeVeque and Li [7] for handling diffusion problems with discontinuous diffusion coefficients (see also [8, 11, 9, 10]). For our problems, the

physical domain is embedded in a larger rectangular domain, the partial differential equation(s) are extended to the rectangular domain, and a simple Cartesian grid is placed over the full domain. A standard discretization of the Laplacian is used at "regular" points of the grid for which the grid point and its immediate neighbors all lie on the same side of the boundary curves or surfaces. Special stencils are used at the remaining "irregular" points. In [7], LeVeque and Li use continuity and jump conditions at the interface across which the diffusion coefficient is discontinuous in order to simplify the truncation error that results when points on both sides of the interface are used to construct a discrete Laplacian. The equations for the stencil coefficients follow from this simplified expression. The present work is distinguished from that of LeVeque and Li by its use of Neumann boundary conditions instead of interface conditions, and by its careful exploration of the optimal choice of stencil to achieve stability as well as second order accuracy. We give detailed specifications of how to best choose a stencil in both two and three dimensions. These specifications are easily coded in terms of look-up tables making the method only slightly more expensive than standard schemes on rectangular grids with rectilinear boundaries aligned with the grid.

In a series of papers, Mayo and coworkers [12, 13, 14, 15] present an alternative approach to solving certain elliptic problems in irregular regions. It involves solving an integral equation on the domain boundary and using a standard discretization of the Laplacian on a Cartesian grid placed over a rectangle in which the irregular region is embedded. Later we briefly describe this approach, indicate how it is different from the method of this paper, and discuss some of the relative advantages and disadvantages of the two approaches.

The contents of the remainder of this paper are as follows: In section 2 we give a detailed derivation of the system of equations that the coefficients of the approximate two-dimensional Laplacian must satisfy at irregular points of the grid to achieve overall second order accuracy. In section 3, we discuss additional considerations in choosing the stencil to ensure stability, and arrive at a precise specification of how to make this choice. Section 4 concerns derivation of the coefficient equations for the three-dimensional Laplacian and stencil selections. In section 5, we apply the two-dimensional formulas to the heat equation in a number of contexts and numerically verify the stability and second order accuracy of the method. In section 6, we illustrate the three-dimensional method by solving the Poisson equation in a region bounded between an ellipsoid and a sphere.

As mentioned above, this project began as an effort to extend the ideas of LeVeque and Li's immersed interface method to handle Neumann conditions on irregular boundaries, and the derivation of our stencil equations is carried out in that spirit. But as we show in section 3, stable second order stencils often can be chosen using only grid points interior to the original physical domain. Hence, the method can be used as a purely interior-point method without reference to the grid points in the extended domain. Alternatively, it can be used in the spirit of the original derivation making use of grid points throughout the rectangular domain. Both approaches are illustrated below and we discuss why one approach or the other might be preferred in a given situation.

2. Derivation of the methods. We are interested in solving Poisson's equation

$$-\beta \Delta v(\mathbf{x}) \;=\; f(\mathbf{x}) \tag{2.1}$$

or the heat equation

$$v_t(\mathbf{x},t) = \beta\Delta v(\mathbf{x},t) + f(\mathbf{x},t) \tag{2.2}$$

in a two-dimensional region Ω^+. We assume v satisfies Neumann boundary condition

$$\beta\frac{\partial v}{\partial n} \;=\; g \tag{2.3}$$

at points of $\Gamma = \partial\Omega^+$. We adopt the convention throughout this paper that $\mathbf{n}$ is the unit normal vector which points *out* of the region Ω^+, so that $g > 0$ corresponds to a flux into Ω^+. We assume that Γ is at least piecewise smooth. We embed Ω^+ in a rectangular region Ω and define $\Omega^- = \Omega \setminus \overline{\Omega^+}$. We extend v to all of Ω by requiring that in Ω^-, v satisfy

$$-\beta\Delta v \;=\; f(\mathbf{x}) \tag{2.4}$$

in the case of Poisson's equation or

$$v_t = \beta\Delta v + f(\mathbf{x},t) \tag{2.5}$$

in the case of the heat equation. The extended source function $f(\mathbf{x})$ is assumed to be continuous in Ω. (If an analytic expression for f on the full rectangle is not available, then the extension of f to $(x,y) \in \Omega^-$ can be defined, for example, as the value of f at the point of Γ closest to (x,y) times a rapidly decaying function of the distance of (x,y) from Γ.) We require that v be continuous along Γ and that (2.3) be satisfied at points $(x,y) \in \Gamma$ when the derivatives are interpreted as one-sided ones involving values of v only on $\Omega^+ \cup \Gamma$. These conditions can be written as

$$[v] \;\equiv\; v^+ \;-\; v^- = 0 \tag{2.6}$$

and

$$\beta\frac{\partial v}{\partial n}^+ \;=\; g. \tag{2.7}$$

Here, and throughout this paper, the notation f^+ and f^- indicate limiting values of f at points of Γ with the limits taken entirely within Ω^+ or Ω^-, respectively. We also impose conditions on v or its derivatives on the boundary of the embedding rectangle Ω in order that v be uniquely determined (at least to within an additive constant) in all of Ω. We note that because of the continuity of v and the source term across Γ, the Laplacian of v is also continuous across Γ:

$$[\Delta v] \;\equiv\; (\Delta v)^+ \;-\; (\Delta v)^- = 0. \tag{2.8}$$

In this paper we describe a method for solving each of the above problems in two or three spatial dimensions. For now, we consider the problems in a *two-dimensional* region Ω. To determine an approximate solution to our problem, we place a uniform rectangular mesh with meshspace h over the region Ω and we seek to approximate (2.1) and (2.4) or (2.2) and (2.5) at each point of the mesh. We use a Crank–Nicolson time discretization in (2.2) and (2.5). We approximate the Laplacian in (2.1), (2.2), (2.4), or (2.5) by the standard five-point discrete Laplacian

$$\Delta^h u_{j_1,j_2} \;\equiv\; h^{-2}\left\{u_{j_1,j_2-1} + u_{j_1-1,j_2} + u_{j_1+1,j_2} + u_{j_1,j_2+1} - 4u_{j_1,j_2}\right\} \tag{2.9}$$

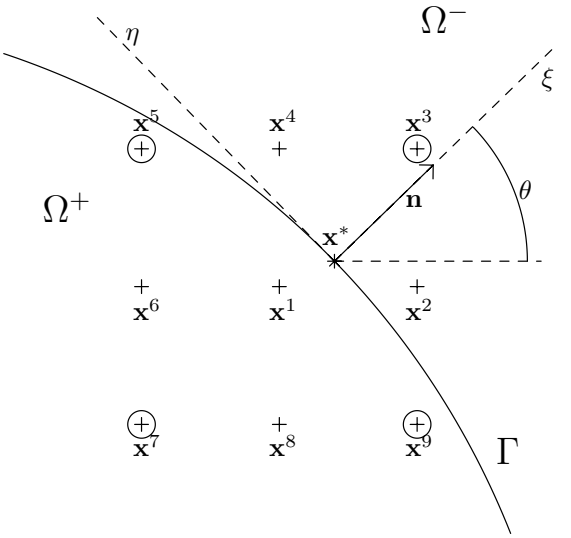

FIG. 2.1. *Layout near irregular point: Labeling of potential stencil points and definition of* (ξ, η) *coordinate system.*

at points $(j_1 h, j_2 h)$ for which all the points involved in this definition are on the same side of the "interface" Γ. Such points are called "regular points." This approximation to the Laplacian is, of course, second order.

Points of the mesh which are close to the interface and for which points of the standard stencil lie on both sides of the interface are called "irregular points." Our immediate goal is to derive a suitable approximation to the Laplacian at each irregular point. Because the size of the irregular region is roughly a dimension less than that of the domain, it suffices that the approximate Laplacian at such points be first order.

Consider an irregular point $\mathbf{x}^P = (j_1 h, j_2 h) \in \Omega^+$ and imagine that the interface Γ cuts through the mesh as indicated in Figure 2.1. (Point $\mathbf{x}^P$ is shown as $\mathbf{x}^1$ in the figure.) Let $\mathbf{x}^*$ be a point on the curve Γ close to $\mathbf{x}^P$ and such that the curve is smooth at $\mathbf{x}^*$. Since v is smooth in Ω^+, $\Delta v(\mathbf{x}^P) = \Delta v(\mathbf{x}^*)^+ + O(h)$, so it suffices to approximate $\Delta v(\mathbf{x}^*)^+$ to within $O(h)$. We approximate $\Delta v(\mathbf{x}^*)^+$ by a linear combination of values of v at the nine mesh points marked by a plus sign in Figure 2.1. Let K denote the set of indices of these nine points, $K^+ \subseteq K$ be the indices of those points which are in $\Omega^+ \cup \Gamma$, and $K^- \subseteq K$ be the indices of those points which are in Ω^-. Then we seek to determine a set of coefficients γ_k for $k \in K$ and a value C, so that $\sum_{k \in K} \gamma_k v(\mathbf{x}_k) - C$ is an $O(h)$ approximation to $\Delta v(\mathbf{x}^*)^+$. As is shown below, we generally need to have six nonzero γ_k in order to achieve an $O(h)$ approximation. In accordance with the size of the coefficients in the usual discretization (2.9) of the Laplacian, we expect that the magnitude of the nonzero γ_k is $O(h^{-2})$. The truncation error in using this approximation is

$$T^* = \Delta v(\mathbf{x}^*)^- - \sum_{k \in K^+} \gamma_k v(\mathbf{x}_k) - \sum_{k \in K^-} \gamma_k v(\mathbf{x}_k) + C. \tag{2.10}$$

For each $k \in K^+$, we expand $v(\mathbf{x}_k)$ in a Taylor series about $\mathbf{x}^*$ using limits of function

values from Ω^+. For each $k \in K^-$ we find a similar expansion using limits of function values from Ω^-. Before doing these expansions, it is useful to introduce a local change of coordinates near the point $\mathbf{x}^*$. As shown in Figure 2.1, θ is the angle between the positive x-direction and the normal $\mathbf{n}$ to the curve Γ pointing out of the region Ω^+. We introduce new orthogonal coordinates (ξ, η) by the equations

$$x - x^* = \xi \cos\theta - \eta \sin\theta, \tag{2.11}$$

$$y - y^* = \xi \sin\theta + \eta \cos\theta. \tag{2.12}$$

Note that $(\xi, \eta) = (0, 0)$ corresponds to the point $\mathbf{x}^*$. The curve Γ is assumed to be described locally near $\mathbf{x}^*$ by the relation $\xi = \chi(\eta)$. Note that $\chi(0) = 0$ and $\chi'(0) = 0$. We also write $\mathbf{x}_k = (\xi_k, \eta_k)$ to express the mesh points in terms of the new coordinates. In these new coordinates, we find Taylor series expansions for $k \in K^+$,

$$v(\mathbf{x}_k) = v^+ + v^+_\xi \xi_k + v^+_\eta \eta_k + \frac{1}{2} v^+_{\xi\xi} {\xi_k}^2 + v^+_{\xi\eta} \xi_k \eta_k + v^+_{\eta\eta} {\eta_k}^2 + O(h^3), \tag{2.13}$$

and for $k \in K^-$,

$$v(\mathbf{x}_k) = v^- + v^-_\xi \xi_k + v^-_\eta \eta_k + \frac{1}{2} v^-_{\xi\xi} {\xi_k}^2 + v^-_{\xi\eta} \xi_k \eta_k + v^-_{\eta\eta} {\eta_k}^2 + O(h^3). \tag{2.14}$$

We have truncated these expansions after the second order terms because this suffices if our expectation that $\gamma_k = O(h^{-2})$ is correct. When we substitute (2.13) and (2.14) into the expression (2.10) for T^*, we get an expression for T^* in terms of the twelve quantities $v^\pm$, $v^\pm_\xi$, $v^\pm_\eta$, $v^\pm_{\xi\xi}$, $v^\pm_{\xi\eta}$, and $v^\pm_{\eta\eta}$. We use the continuity conditions on v across Γ along with the given boundary conditions on Γ to express the Ω^+ quantities v^+, v^+_ξ, v^+_η, $v^+_{\xi\xi}$, $v^+_{\xi\eta}$, and $v^+_{\eta\eta}$ in terms of the Ω^- quantities v^-, v^-_ξ, v^-_η, $v^-_{\xi\xi}$, $v^-_{\xi\eta}$, and $v^-_{\eta\eta}$, and thus obtain an expression for T^* entirely in terms of Ω^- quantities. To this end, we express the interface conditions (2.6), (2.7), and (2.8) in terms of the local coordinate description of Γ:

$$v(\chi(\eta), \eta)^+ = v(\chi(\eta), \eta)^-, \tag{2.15}$$

$$v_\xi(\chi(\eta), \eta)^+ - \chi'(\eta) v_\eta(\chi(\eta), \eta)^+ = \frac{(1 + {\chi'}^2)^{1/2}}{\beta} g, \tag{2.16}$$

and

$$v_{\xi\xi}(\chi(\eta), \eta)^+ + v_{\eta\eta}(\chi(\eta), \eta)^+ = v_{\xi\xi}(\chi(\eta), \eta)^- + v_{\eta\eta}(\chi(\eta), \eta)^-. \tag{2.17}$$

In converting (2.7) to (2.16), we have used the fact that the outward unit normal to Γ is

$$\frac{1}{(1 + {\chi'}^2)^{1/2}} \begin{pmatrix} 1 \\ -\chi'(\eta) \end{pmatrix}.$$

We obtain additional relations between Ω^+ and Ω^- quantities by differentiating relations (2.15) and (2.16) with respect to η. Differentiating (2.15) with respect to η gives

$$(v_\xi \chi' + v_\eta)^+ = (v_\xi \chi' + v_\eta)^-. \tag{2.18}$$

Differentiating this again with respect to η yields

$$(v_{\xi\xi}\chi'^2 + 2v_{\xi\eta}\chi' + v_\xi\chi'' + v_{\eta\eta})^+ = (v_{\xi\xi}\chi'^2 + 2v_{\xi\eta}\chi' + v_\xi\chi'' + v_{\eta\eta})^-. \tag{2.19}$$

Differentiating (2.16) with respect to η gives

$$v^+_{\xi\xi}\chi' + v^+_{\xi\eta} - v^+_{\xi\eta}(\chi')^2 - v^+_{\eta\eta}\chi' - v^+_\eta\chi'' = \frac{(1 + \chi'^2)^{1/2}}{\beta}g' + \frac{\chi'\chi''}{\beta(1 + \chi'^2)^{1/2}}g. \tag{2.20}$$

We are interested in these relations at the point $\mathbf{x}^* = (\chi(0), 0)$. Setting $\eta = 0$ in (2.15)–(2.20), and recalling that $\chi(0) = 0$ and $\chi'(0) = 0$, we obtain the six relations

$$v^+ = v^-, \tag{2.21}$$

$$v^+_\xi = \frac{g}{\beta}, \tag{2.22}$$

$$v^+_\eta = v^-_\eta, \tag{2.23}$$

$$v^+_{\xi\xi} + v^+_{\eta\eta} = v^-_{\xi\xi} + v^-_{\eta\eta}, \tag{2.24}$$

$$v^+_{\xi\eta} - \chi''v^+_\eta = \frac{g'}{\beta}, \tag{2.25}$$

$$v^+_\xi\chi'' + v^+_{\eta\eta} = v^-_\xi\chi'' + v^-_{\eta\eta}. \tag{2.26}$$

Here, all quantities are evaluated at $\eta = 0$.

It is helpful to express relations (2.21)–(2.26) in a more compact form. We define V and $G \in \mathbb{R}^6$ by

$$V = (v,\ v_\xi,\ v_\eta,\ v_{\xi\xi}\ v_{\xi\eta}, v_{\eta\eta})^T \tag{2.27}$$

and

$$G = \left(0,\ \frac{g}{\beta},\ 0,\ 0,\ \frac{g'}{\beta},\ 0\right)^T. \tag{2.28}$$

Then (2.21)–(2.26) can be written as

$$A^+\,V^+ = A^-\,V^- + G, \tag{2.29}$$

where the 6×6 matrices A^+ and A^- are defined by

$$A^+ = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 1 \\ 0 & 0 & -\chi'' & 0 & 1 & 0 \\ 0 & \chi'' & 0 & 0 & 0 & 1 \end{bmatrix} \tag{2.30}$$

and

$$A^- = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & \chi'' & 0 & 0 & 0 & 1 \end{bmatrix}. \tag{2.31}$$

Since the matrix A^+ is nonsingular for any value of the curvature χ'', we can write

$$V^+ = (A^+)^{-1}A^-V^- + (A^+)^{-1}G. \tag{2.32}$$

We can now use this relation to express the truncation error defined by (2.10) in terms only of Ω^- quantities. In terms of the local (ξ, η) coordinate system, the truncation error at $\mathbf{x}^*$ is

$$T^* = v^+_{\xi\xi} + v^+_{\eta\eta} - \sum_{k\in K^+} \gamma_k v(\mathbf{x}_k) - \sum_{k\in K^-} \gamma_k v(\mathbf{x}_k) + C. \tag{2.33}$$

We let

$$Z_k = \left(1,\ \xi_k,\ \eta_k,\ \frac{1}{2}\xi_k^2,\ \xi_k\eta_k, \frac{1}{2}\eta_k^2\right)^T, \tag{2.34}$$

and

$$W = (0,\ 0,\ 0,\ 1,\ 0, 1)^T. \tag{2.35}$$

Then, using the Taylor series expansions (2.13) and (2.14) in (2.33), we get

$$T^* = W^TV^+ - \sum_{k\in K^+} \gamma_k Z_k^T V^+ - \sum_{k\in K^-} \gamma_k Z_k^T V^- + C + O(h^3)\max|\gamma_k|. \tag{2.36}$$

Since we anticipate that $|\gamma_k| = O(h^{-2})$, we expect that this last term is $O(h)$. Using (2.17) and (2.32), we can express T^* entirely in terms of Ω^- function values:

$$\begin{aligned} T^* = &\left\{ W^TV^- - \sum_{k\in K^+} \gamma_k Z_k^T \left[(A^+)^{-1}A^-V^-\right] - \sum_{k\in K^-} \gamma_k Z_k^T V^- \right\} \\ &+ \left(C - \sum_{k\in K^+} \gamma_k Z_k^T (A^+)^{-1}G \right) + O(h^3)\max|\gamma_k|. \end{aligned} \tag{2.37}$$

We want to choose the coefficients $\{\gamma_k\}$ so that the bracketed term in (2.37) vanishes for all vectors $V^- \in \mathbb{R}^6$ and to then choose C so that the term within ( ) vanishes. With these choices, $T^* = O(h)$. Clearly it suffices that the bracketed term vanish for each of the six standard basis vectors for $\mathbb{R}^6$. This gives us a system of six linear equations for the unknown γ_k, and so, in general, we need six nonzero γ_k, and therefore a six-point stencil, to obtain an $O(h)$ approximation. The six equations are

$$0 = \sum_{k\in K^+} \gamma_k + \sum_{k\in K^-} \gamma_k, \tag{2.38}$$

$$0 = \sum_{k\in K^+} \gamma_k \left\{ \frac{1}{2}\chi''({\eta_k}^2 - {\xi_k}^2) \right\} + \sum_{k\in K^-} \gamma_k \xi_k, \tag{2.39}$$

$$0 = \sum_{k\in K^+} \gamma_k \{\eta_k + \chi'' \xi_k \eta_k\} + \sum_{k\in K^-} \gamma_k \eta_k, \tag{2.40}$$

$$2 = \sum_{k\in K^+} \gamma_k {\xi_k}^2 + \sum_{k\in K^-} \gamma_k {\xi_k}^2, \tag{2.41}$$

$$0 = \sum_{k\in K^-} \gamma_k \xi_k \eta_k, \tag{2.42}$$

$$2 = \sum_{k\in K^+} \gamma_k {\eta_k}^2 + \sum_{k\in K^-} \gamma_k {\eta_k}^2. \tag{2.43}$$

In addition,

$$C = \sum_{k\in K^+} \gamma_k \{a_k + b_k\}, \tag{2.44}$$

where

$$a_k = \frac{1}{\beta}\, g\left[\xi_k - \frac{1}{2}\chi''({\eta_k}^2 - {\xi_k}^2)\right] \tag{2.45}$$

and

$$b_k = \frac{1}{\beta}\, g' \xi_k \eta_k. \tag{2.46}$$

This same approach can be used to handle Robin boundary conditions

$$\beta \frac{\partial v^+}{\partial n} + \alpha v^+ = g \qquad (\beta \neq 0) \tag{2.47}$$

instead of the Neumann conditions (2.7). In this case, the jump conditions can again be written in the form of (2.29). The matrix A^- and the vector G are the same as before, and the matrix A^+ is

$$A^+ = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ \frac{\alpha}{\beta} & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 1 \\ \frac{\alpha}{\beta} & 0 & -\chi'' & 0 & 1 & 0 \\ 0 & \chi'' & 0 & 0 & 0 & 1 \end{bmatrix}. \tag{2.48}$$

Since A^+ is again nonsingular, one can express V^+ in terms of V^- and therefore express the truncation error (2.36) entirely in terms of V^-. One obtains a system of six equations for the γ_k analogous to the system (2.38)–(2.43) above.

3. Stencil selection. We now face the issue of how to select the "best" stencil. While a criterion for "best" is not completely settled, here we seek a stencil whose coefficients satisfy the above equations and also satisfy the Gerschgorin sufficient conditions for stability. A matrix with entries a_{ij} satisfies the Gerschgorin stability conditions if

$$\sum_{j,j\neq i} |a_{ij}| \leq |a_{ii}| \tag{3.1}$$

and $a_{ii} \leq 0$. If this is the case, the eigenvalues of the matrix are guaranteed to lie in the left half of the complex plane, assuring only nonpositive real parts. It also follows in this case that the scheme satisfies a discrete maximum principle. In this problem we know from (2.38) that the row sum is zero, so the stability condition is that all noncentral γ's (i.e., other than the central point of the grid) must be positive. Thus, in what follows, we seek stencils for which the above equations hold and the noncentral γ's are positive.

Before we proceed further, we note that the grid points are numbered as

$$\begin{matrix} 5 & 4 & 3 \\ 6 & 1 & 2 \\ 7 & 8 & 9 \end{matrix} \tag{3.2}$$

so that the central point has label 1, the upper right corner is 3, and so on (see Figure 2.1). The Gerschgorin stability conditions can then be expressed

$$\gamma_1 < 0 \quad \text{and} \quad \gamma_{\mathrm{k}} \geq 0 \quad \text{for} \quad \mathrm{k} \neq 1. \tag{3.3}$$

Using the numbering just introduced, a six-point stencil is uniquely identified by five numbers (since the central point 1 is always assumed to be part of the stencil). For the remainder of this discussion, we define $\mathbf{x}^* = (x, y)$ to be the *closest* point on the boundary to the center of the stencil which we take to be at $(0, 0)$. We consider (x, y) in the unit square $0 \leq x \leq 1, 0 \leq y \leq 1$. (In essence we have set $h = 1$ for this analysis.)

We now make our first observation.

THEOREM 3.1. *With exactly one exterior point in the stencil, the system of equations* (2.38)–(2.43) *is singular.*

To show this, note that if we multiply (2.41) by $\frac{1}{2}\chi''$ and (2.43) by $-\frac{1}{2}\chi''$ and add both of these to (2.39), we find

$$0 \;=\; \sum_{k\in K^-} \gamma_k \left\{ \xi_k + \frac{1}{2}\chi''({\eta_k}^2 - {\xi_k}^2) \right\}, \tag{3.4}$$

which we use to replace (2.39). Now observe that both (2.41) and (3.4) have nonzero terms only for exterior grid points, and so, if there is only one exterior grid point, there are two equations with five zero coefficients, and the system of equations is singular.

The consequence of this is that if there is only one exterior point, one should use a standard five-point scheme, either the usual scheme 2468 (if 3, 5, 7, or 9 is missing) or the diagonal scheme 3579 (if 2, 4, 6, or 8 is missing).

Henceforth we assume that there are at least two exterior grid points, and to be specific we take them to be points 2 and 3. Now we make our second observation.

THEOREM 3.2. *With two exterior grid points and four interior grid points in the stencil, the coefficients for the exterior points are zero.*

This follows easily by observing that with two exterior grid points, (2.42) and (3.4) are a two by two system of linear equations which has only the trivial solution.

The problem is now simplified to looking at four-point interior schemes (which we call, simply, four-point schemes, and identify with three numbers, say, 568). There are twenty possible four-point interior schemes, giving a bewildering array of possibilities. However, we can immediately eliminate four of these schemes from further consideration, as follows.

THEOREM 3.3. *The four-point schemes with three adjacent points* (*schemes* 456, 567, 678, 789) *do not meet the Gerschgorin stability criterion for* χ'' *below some positive number.*

The proof of this follows from a direct calculation. For example, for the 678 scheme, one can calculate that

$$\gamma_7 = \frac{-2(x^2+y^2)^2 - (x+y)(x-y)^2 + 2\chi''(x^2+y^2)^{3/2}(2x^2+x+y+2y^2)}{xy(2x^2+x+y+2y^2) - \chi''(x^2+y^2)^{3/2}(1+2y)(1+2x)}. \tag{3.5}$$

It follows that for this scheme, γ_7 is negative in the range $0 < x \le 1,\ 0 < y \le 1$ if $\chi'' \le \frac{\sqrt{2}}{3}$. Similar statements can be made for the other schemes.

The primary consequence of this is that there are *no* acceptable four-point schemes when there are five grid points which are exterior to the domain. If there are five exterior points, then χ'' is likely to be negative. If, in fact, the boundary arc is described locally by the parabolic arc $\xi = \frac{1}{2}\chi''\eta^2$, then to have five exterior points χ'' must be negative. In this situation, therefore, if there are five exterior grid points, all possible four point schemes fail the Gerschgorin criterion. Thus, for the remainder of this discussion, we restrict our attention to a domain for which there are never more than four grid points that are exterior to the domain. With this further restriction we now have *only* sixteen schemes to evaluate. Later we discuss what to do if, in fact, a situation arises in which there are five exterior grid points.

We begin our search by looking at the region in which a particular scheme satisfies the Gerschgorin criterion. In this regard, the best of the sixteen schemes is the four-point scheme 579. For this scheme we calculate that

$$\gamma_5 = \frac{(x^2+y^2)^2 + 2x^2y - \chi''(x^2+y+y^2)(x^2+y^2)^{3/2}}{(x+y)D}, \tag{3.6}$$

$$\gamma_7 = \frac{2xy - \chi''(x^2+y^2)^{3/2}}{D}, \tag{3.7}$$

$$\gamma_9 = \frac{(x^2+y^2)^2 + 2xy^2 - \chi''(x^2+x+y^2)(x^2+y^2)^{3/2}}{(x+y)D}, \tag{3.8}$$

where $D = (x^2+y^2)(x+y) + 2xy - \chi''(x^2+y^2)^{3/2}(x+y+1)$. It is apparent that these three coefficients are positive if $\chi'' < 0$, suggesting that this is a good candidate for a useful scheme. Indeed it is a good scheme, but with limited usefulness. This limitation is because this scheme is admissible only when points 5 and 9 are both interior to the domain, a consideration that we address below.

A similar restriction applies to the second "obvious" good guess, 468. Here,

$$\gamma_6 = \frac{2(x^2-y^2) - 2\chi''(x^2+y^2)^{3/2}}{2x(x^2+y^2) + x^2 - y^2 - \chi''(x^2+y^2)^{3/2}(2x+1)} \tag{3.9}$$

with similar formulas for γ_4 and γ_8. Clearly, with $\chi'' = 0$, $\gamma_6 > 0$ provided $x > y$. In fact, all three coefficients are positive provided $x > y$ and $\chi'' \geq 0$. However, for any value of χ'', there are subregions of the square $0 < x < 1,\ 0 < y < 1$ for which the Gerschgorin criterion fails, so that this scheme is also not universally useful.

The disadvantage of the 579 and 468 schemes is that they are useful only if no more than three grid points are exterior to the domain. Schemes which are potentially more useful are those with a smaller footprint, including 457, 467, 568, 578, 679, and 689. (The symmetric partner of 457, which is 279, is not considered here because the point 2 is assumed to be exterior to the domain.) All of these schemes allow for four grid points exterior to the domain. One quickly determines that of these, 457 and 467 are essentially useless, as they satisfy the Gerschgorin criterion in only a small region of the unit square.

The schemes 568 and 578 have identical regions of the unit square in which the Gerschgorin criterion holds. The region is determined by $\gamma_6 > 0$, where γ_6 is given by

$$\gamma_6 = \frac{-2(x^2+y^2)^2 + x^3 + 5x^2y - xy^2 - y^3 + \chi''(x^2+y^2)^{3/2}(2x^2 - x - 1 - y + 2y^2)}{x(x+y)(2x^2+x+2y^2) - \chi''(x^2+y^2)^{3/2}(2x+1)(2x+1+2y)}. \tag{3.10}$$

The schemes 679 and 689 are the symmetric partners of 568 and 578 and so have symmetric regions in which they satisfy the Gerschgorin criterion.

At this point, we have identified a number of schemes that satisfy the Gerschgorin criterion in certain subregions of the unit square, but this does not help to decide if these schemes are useful without additional information about the location of the grid points relative to the boundary of the domain. Thus far, the number χ'' has been used solely as a parameter, but it also contains information about the boundary arc. If we now assume that the boundary arc is well approximated by the parabolic arc $\xi = \frac{1}{2}\chi''\eta^2$, then we can subdivide the unit square into regions in which each footprint is permitted. The boundary of these subregions are the 5 curves in the unit square for which the boundary arc $\xi = \frac{1}{2}\chi''\eta^2$ exactly intersects one of the grid points 2, 4, 5, 8, or 9. For example, the curve for gridpoint 4 is given by

$$2(x^2 - y + y^2)\sqrt{x^2+y^2} + \chi'' x^2 = 0, \tag{3.11}$$

and similar expressions are easily obtained for the other grid points. A plot of these five curves is shown in Figure 3.1(a) for $\chi'' = -0.3$, and Figure 3.1(b) shows similar plots for $\chi'' = 0.3$. The exact boundaries of the different regions shown change for different values of χ'', but the qualitative nature of the regions is as shown here. For example, to the right of the curve 4, the grid point 4 is exterior to the domain so a four-point stencil containing point 4 cannot be used.

Now that the unit square is divided into regions for which different footprints are possible, we must decide which of the possible schemes also satisfy the Gerschgorin criterion.

Figure 3.2 shows the further subdivisions of the unit square on which different schemes satisfy the Gerschgorin stability criterion. These regions are denoted by the number of possible schemes. For example, in the regions denoted 5a or 5b, there are 5 schemes that are permitted. In Table 3.1, the acceptable schemes for each of the subregions are listed, both for the case $\chi'' \leq 0$ and $\chi'' > 0$. The columns to the right of the double vertical line are acceptable only when $\chi'' > 0$. Note that schemes 459 and 489 have only an admissible range for $\chi'' > 0$. Region 0 is the region in which

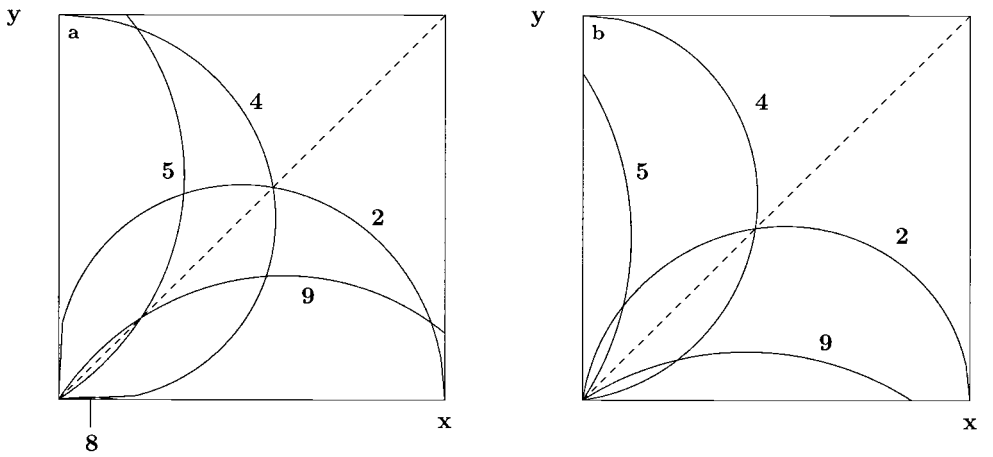

FIG. 3.1. *Geometric curves for cases* (a) $\chi'' = -0.3$ *and* (b) $\chi'' = 0.3$. *For each* $I \in \{2, 4, 5, 8, 9\}$, *curve* I *bounds the subregion of the unit square with the property that if the closest boundary point* (x, y) *is in that subregion, and if the boundary is described locally by the parabolic arc* $\xi = \frac{1}{2}\chi''\eta^2$, *then stencil point* I *is an interior point.*

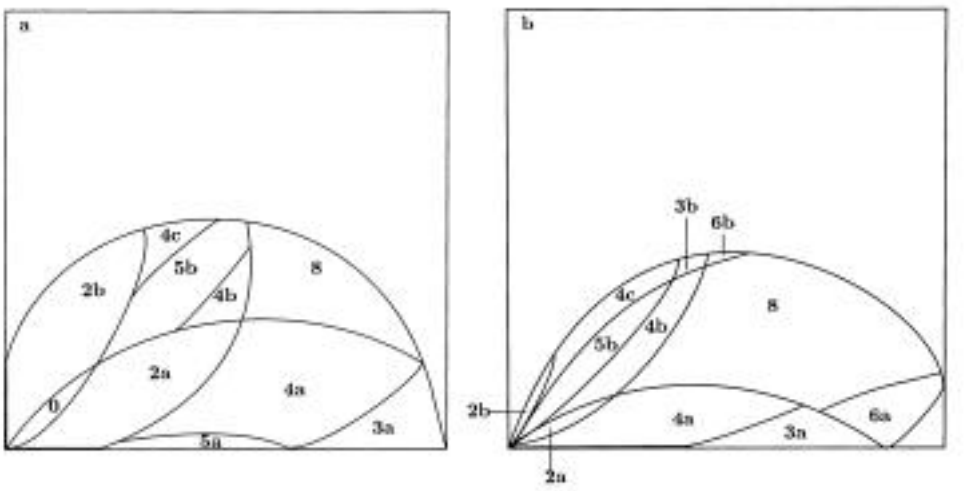

FIG. 3.2. *Gerschgorin regions and covering schemes for* (a) $\chi'' = -0.3$ *and* (b) $\chi'' = 0.3$. *The region labels correspond to those in Table* 3.1. *In the unlabeled regions, a standard five-point scheme is acceptable.*

there are five exterior grid points and for which, therefore, there are no admissible four-point schemes. This region exists only if $\chi'' < 0$.

The challenge is to find the smallest set of admissible schemes that covers the domain. Scanning through the table, one sees that for $\chi'' \leq 0$, three schemes are necessary for this purpose. For example, the three schemes 568, 689, and 468 cover the domain. This is not a unique covering set, as 578 and 568 can be freely interchanged, as can 679 and 689. This covering set is valid for $\chi'' \leq 0$ but not for $\chi'' > 0$. In Table 3.2 are listed the minimal covering sets as a function of χ''.

Provided there are no more than four exterior points, an easy computational strategy for determining a scheme that satisfies the Gerschgorin stability criterion is evident. First, if $\chi'' \leq 0$, try the scheme 568 (as that covers the most area), and if this fails try 468 if point 4 is in the domain interior, or 689 if point 9 is in the domain interior. If $\chi'' > 0$, first, if point 9 is in the domain interior, try 579 as this covers the most area. If this fails, then 468 is most likely to succeed. The schemes 568 and 689 cover small regions and so are less likely to be needed, but are necessary to produce a complete cover. Note that there are two ways to reject a scheme when pursuing this strategy. First, it may not be possible to find a solution to the linear system (2.38)–(2.43) for a given stencil. Second, the solution may not satisfy the Gerschgorin stability condition. In any case, one of the above choices of stencils is guaranteed to lead to a solvable system whose solution does satisfy the Gerschgorin condition.

It remains to address the question of what to do if an interior irregular point occurs with 5 exterior points in its stencil. When this happens, the above discussion does not apply, and furthermore, we have found no schemes with three interior points that satisfy the Gerschgorin condition. The two canonical situations in which such an irregular point arises are illustrated in Figure 3.3. In part (a), the boundary curve has high local curvature and the mesh is not fine enough to resolve this curvature. A finer mesh should be used. In part (b), the curvature is small and yet there are 5 exterior points. One way to deal with this situation is to shift slightly the entire mesh relative to the domain of interest. Another possibility, discussed below in the context of solution of the heat equation, is to make use of both interior and exterior points

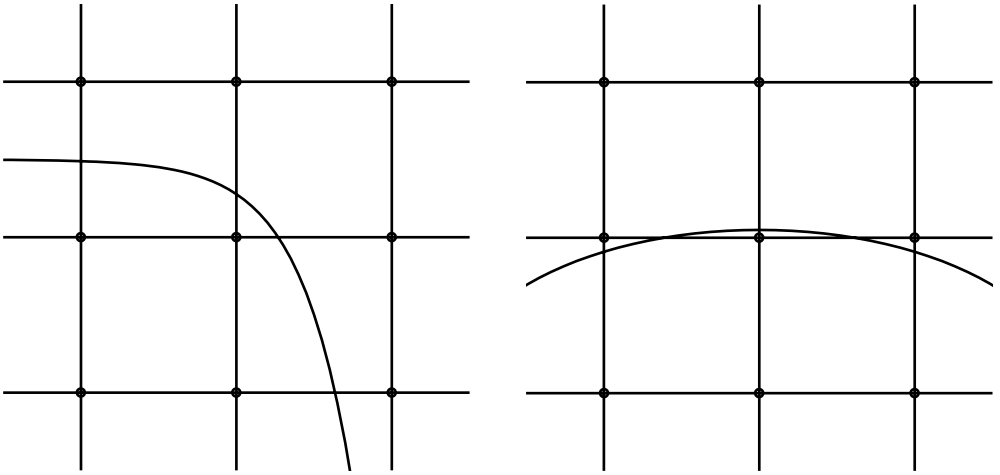

FIG. 3.3. *Situations in which there are five exterior points.*

for the stencil.

4. Three-dimensional problems. The extension of the above ideas to three-dimensional problems is straightforward, although there are a number of unresolved issues.

The derivation of the coefficient equations for the approximation to the Laplacian at irregular points follows the same arguments used in the two-dimensional case. We determine the point $\mathbf{x}^*$ on the boundary about which to make the local expansion. We introduce a new local orthogonal coordinate system (ξ, η_1, η_2), taking $(\xi, \eta_1, \eta_2) = (0, 0, 0)$ to correspond to the point $\mathbf{x}^*$. The surface is assumed to be described locally by the relationship $\xi = \chi(\eta_1, \eta_2)$. We denote $\frac{\partial \chi}{\partial \eta_j} = \chi_j$ and $\frac{\partial^2 \chi}{\partial \eta_j \partial \eta_k} = \chi_{jk}$ for $j = 1, 2, k = 1, 2$. We suppose that the coordinate system is chosen to be the principal coordinate system for the surface so that $\chi(0,0) = \chi_1(0,0) = \chi_2(0,0) = \chi_{12}(0,0) = 0$. The numbers $\chi_{11}(0,0)$ and $\chi_{22}(0,0)$ are the principal curvatures and the surface has the local representation $\xi = \frac{1}{2}\chi_{11}(0,0)\eta_1^2 + \frac{1}{2}\chi_{22}(0,0)\eta_2^2$.

The quantities that must be continuous across the boundary are v; $v_\xi \chi_j + v_{\eta_j}$ for $j = 1, 2$; $v_{\xi\xi}\chi_j\chi_k + v_{\xi\eta_k}\chi_j + v_\xi \chi_{jk} + v_{\xi\eta_j}\chi_k + v_{\eta_j\eta_k}$ for $(j,k) = (1,1), (1,2), (2,2)$; and $(v_{\xi\xi} + v_{\eta_1\eta_1} + v_{\eta_2\eta_2})$. The Neumann boundary condition (2.3) contributes the three equations

$$(v_\xi - v_{\eta_1}\chi_1 - v_{\eta_2}\chi_2)^+ = \frac{(1 + \chi_1^2 + \chi_2^2)^{1/2}\, g}{\beta}, \tag{4.1}$$

(4.2)

$$\begin{aligned}\big(v_{\xi\xi}\chi_j + v_{\xi\eta_j} - v_{\xi\eta_1}\chi_1\chi_j - v_{\eta_1\eta_2}\chi_1 - v_{\eta_1}\chi_{1j} - v_{\xi\eta_2}\chi_2\chi_j - v_{\eta_2\eta_j}\chi_2 - v_{\eta_2}\chi_{2j}\big)^+ \\ = \frac{\partial}{\partial \eta_j}\left((1 + \chi_1^2 + \chi_2^2)^{1/2}\, \frac{g}{\beta}\right)\end{aligned}$$

for $j = 1, 2$, which gives us a total of ten conditions relating limiting values at $\mathbf{x}^*$ from Ω^+ to those from Ω^-. We define the vector

$$V = (v, v_\xi, v_{\eta_1}, v_{\eta_2}, v_{\xi\xi}, v_{\xi\eta_1}, v_{\eta_1\eta_1}, v_{\xi\eta_2}, v_{\eta_2\eta_2}, v_{\eta_1\eta_2})^T$$

and write the resulting system of equations in matrix form as

$$A^+V^+ = A^-V^- + G, \tag{4.3}$$

where

$$A^+ = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & \chi_{11} & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & \chi_{22} & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 1 & 0 & 1 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & -\chi_{11} & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & -\chi_{22} & 0 & 0 & 0 & 1 & 0 & 0 \end{bmatrix}. \tag{4.4}$$

The first seven rows of A^- are identical to those of A^+, and the last three rows of A^- are all zero. It is not difficult to determine that

$$(A^+)^{-1}A^- = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & -\chi_{11}-\chi_{22} & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & \chi_{11} & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & \chi_{11} & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & \chi_{22} & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & \chi_{22} & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix}. \tag{4.5}$$

Finally, with

$$W = (0,0,0,0,1,0,1,0,1,0)^T, \qquad Z_k = (1,\xi,\eta_1,\eta_2,\frac{1}{2}\xi^2,\xi\eta_1,\frac{1}{2}\eta_1^2,\xi\eta_2,\frac{1}{2}\eta_2^2,\eta_1\eta_2)_k^T,$$

we require that

$$W = \sum_{k\in K^+} \gamma_k \left[(A^+)^{-1}A^-\right]^T Z_k + \sum_{k\in K^-} \gamma_k Z_k \tag{4.6}$$

as our system of equations for determining the coefficients γ_k. These equations simplify somewhat if we premultiply (4.6) with the matrix

$$T = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 1 & 0 & 0 & \chi_{11}+\chi_{22} & 0 & -\chi_{11} & 0 & -\chi_{22} & 0 \end{bmatrix}, \tag{4.7}$$

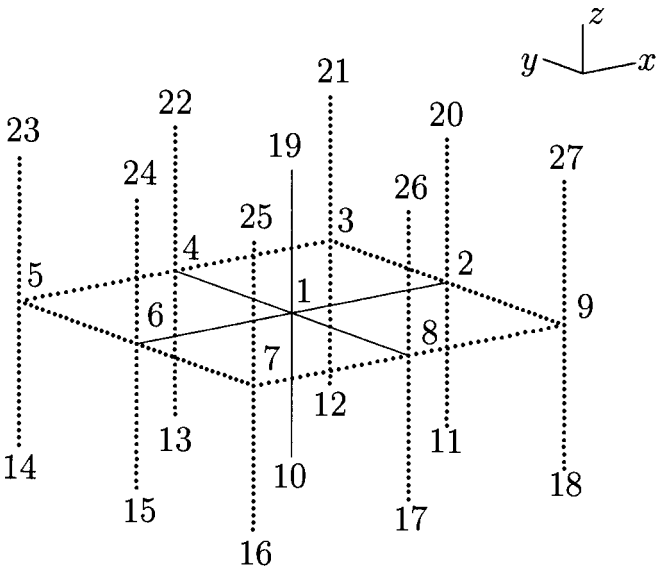

FIG. 4.1. *Labeling of potential stencil points for three-dimensional calculations.*

and then the equations take the form

$$TW = \sum_{k \in K^+} \gamma_k BZ_k \; + \; \sum_{k \in K^-} \gamma_k TZ_k, \tag{4.8}$$

where $BZ = (1, \eta_1 + \xi\eta_1\chi_{11}, \eta_2 + \xi\eta_2\chi_{22}, \frac{1}{2}\xi^2, \frac{1}{2}\eta_1^2, \frac{1}{2}\eta_2^2, \eta_1\eta_2, 0, 0, 0)^T$, $TZ = (1, \eta_1, \eta_2, \frac{1}{2}\eta_1^2, \frac{1}{2}\eta_2^2, \eta_1\eta_2, \xi\eta_1, \xi\eta_2, \xi + \frac{1}{2}\chi_{11}(\xi^2 - \eta_1^2) + \frac{1}{2}\chi_{22}(\xi^2 - \eta_2^2))^T$, and $TW = (0, 0, 0, 2, 2, 2, 0, 0, 0, 0)^T$.

There are now a number of simple consequences of this calculation, analogous to the two-dimensional case.

THEOREM 4.1. *With less that three exterior points, this system of equations is singular.*

With less than three exterior points, there is certain to be a "standard" seven-point scheme that can, and should, be used.

THEOREM 4.2. *Any scheme with exactly seven interior points has* $\gamma_k = 0$ *for the three exterior points.*

Now we face the difficult issue of choosing three-dimensional stencils that satisfy the Gerschgorin stability criterion. We assume that there are at least three exterior grid points and we seek seven-point stencils consisting entirely of interior points. We use a nomenclature similar to the two-dimensional nomenclature to identify the grid points with a number between 1 and 27. This grid nomenclature, depicted in Figure 4.1, assigns the numbers 1 through 9 to the points in the $z = 0$ plane exactly as in the two-dimensional case. In the plane $z = -h$, add 9 to the corresponding point at $z = 0$ and in the plane $z = h$ add 18 to the corresponding point at $z = 0$.

Next we simplify the problem slightly by assuming that the boundary surface is locally planar, having $\chi_{11} = \chi_{22} = 0$. Notice that in the limit of small grid size, the weights γ_j are independent of curvature, so there is no loss of accuracy in the limit $h \to 0$.

We assume that the boundary surface passes through the first octant (so that point 21 is certain to be an exterior point). Using a numerical search, we have found that all (admissible) points in the first octant can be covered by 45 seven-point stencils. These schemes are generated by the following 8 stencils:

1. 2 4 5 7 8 10 (6),
2. 6 8 9 10 11 13 (6),
3. 5 6 8 9 10 12 (3),
4. 5 7 9 10 11 26 (6),
5. 6 7 8 9 10 13 (6),
6. 2 6 7 8 10 13 (6),
7. 6 7 9 10 13 15 (6),
8. 6 7 8 9 13 18 (6).

Each of these stencils is used to generate additional stencils by reflections in the planes $x = y$, $x = z$, and $y = z$. The number in parentheses following the stencil indicates the total number of stencils generated by this group action. Seven of the stencils generate six separate stencils and one generates only three stencils because it is symmetric about the plane $x = y$.

With these stencils it is possible to find a scheme that satisfies the Gerschgorin stability criterion for any planar boundary surface that intersects the first octant. While this list of stencils covers the range of possibilities, it is not known if this is the minimal list.

5. Two-dimensional heat equation. We apply the formulas derived in section 2 to the two-dimensional heat equation in a variety of domains Ω^+ each of which is contained within the unit square Ω. For each application, the boundary $\Gamma = \partial\Omega^+$ consists of the union of one or more circles, and we assume that Neumann boundary conditions hold along each circle. These calculations were done before the analysis of sufficient conditions for obtaining Gerschgorin stability was complete, and so a somewhat different strategy for choosing the stencil was used. This strategy usually, but not always, led to our choosing a stencil which satisfies the Gerschgorin condition. The occasional failure to satisfy this condition seems to have had no detrimental effects. This suggests that the Gerschgorin condition is not necessary for stability, at least in this context.

We discretize time into steps of size k and place a uniform spatial grid with meshspace h over Ω. We denote by $u^n_{j_1,j_2}$ the numerical solution at grid point $\mathbf{x}_{j_1,j_2} = (j_1h, j_2h)$ at time $t_n = nk$, and we denote by $\mathbf{u}^n$ the vector of grid values of the numerical solution ordered in some specified way (typically row-by-row ordering is used). We use the Crank–Nicolson time-discretization, and so, in each timestep, we have a linear system of the form

$$\left(I - \frac{\beta k}{2}A\right)\mathbf{u}^{n+1} \;=\; \left(I + \frac{\beta k}{2}A\right)\mathbf{u}^n \;+\; \mathbf{C}, \tag{5.1}$$

where the coefficient matrix A is an approximation to the Laplacian determined by the approach of section 2. Thus, if $\mathbf{x}_{j_1,j_2}$ is a regular point, the corresponding row of A consists of the coefficients from the standard five-point approximation to the Laplacian, while if $\mathbf{x}_{j_1,j_2}$ is an irregular point, the corresponding row of A typically contains six nonzero coefficients determined by solving (2.38)–(2.43) and by defining a correction term C_{j_1,j_2} if necessary. In (5.1), the vector $\mathbf{C}$ contains these correction terms in the same order as the unknowns $u^n_{j_1,j_2}$ appear in $\mathbf{u}^n$. Recall that the correction term is nonzero only in the case of inhomogeneous Neumann conditions, and is easily calcu-

lated from (2.44) once the corresponding coefficients γ_k have been determined. Since the main issue is computing the γ_k, we assume for now that homogeneous Neumann conditions hold, and therefore we drop reference to $\mathbf{C}$.

The formulas derived in section 2 for determining the coefficients γ_k ensure that the local truncation error at each irregular point be $O(h)$. Because there are many possible choices of which six points of the nine-point stencil to use, there is still a lot of freedom left in the choice of γ_k. For these calculations we set satisfying the Gerschgorin stability condition as a goal in choosing the stencil points. Since we are using the Crank–Nicolson time-discretization, achieving this goal would ensure the stability of our calculations. In our attempt to satisfy the Gerschgorin condition (3.3), we adopted the following rule for choosing the γ_k: For the six stencil points, we use the five points of the standard stencil numbered as in Figure 2.1, and one of the corner points (circled in the figure) of the nine-point stencil. We consider each of the corner points in turn, rejecting a corner point if the corresponding system of six equations (2.38)–(2.43) for the γ_k is not solvable, or if the resulting γ_k fail to give a diagonally-dominant matrix A. We accept as the sixth point the first corner point for which the diagonal dominance condition does hold, and we use the corresponding γ_k in A.

In all of our numerical tests, we have not encountered a case where all four choices of corner points result in unsolvable systems, and we find only very rarely that all four sets of potential γ_k calculated from the corner points fail to satisfy the sufficient condition for stability. In these cases, use of one of these sets of γ_k does not cause any apparent instability.

To test the accuracy of our method, we construct a problem for which an exact analytic solution is available. Let $r_0 < 1/2 \le r_1$, and consider the radially symmetric heat equation

$$v_t(r,t) \;=\; \beta \frac{1}{r}(r v_r(r,t))_r \tag{5.2}$$

in the annulus $r_0 < r < r_1$ for $t > 0$, with $v(r_1,t) = 0$ and $v_r(r_0,t) = 0$ for $t > 0$, and $v(r,0) = b(r)$ for $r_0 < r < r_1$. This problem has the solution

$$v^{ex}(r,t) = \sum_{m=1}^{p} A_m \left\{ J_0(\lambda_m r) Y_0(\lambda_m r_1) - J_0(\lambda_m r_1) Y_0(\lambda_m r) \right\} e^{-{\lambda_m}^2 \beta t}, \tag{5.3}$$

provided that the initial function $b(r)$ is given by

$$b(r) = \sum_{m=1}^{p} A_m \left\{ J_0(\lambda_m r) Y_0(\lambda_m r_1) - J_0(\lambda_m r_1) Y_0(\lambda_m r) \right\}. \tag{5.4}$$

Here, J_0 and Y_0 are Bessel functions of order 0, and λ_m satisfies $J_1(\lambda r_0) Y_0(\lambda r_1) - J_0(\lambda r_1) Y_1(\lambda r_0) \;=\; 0$. We measure r from the center of the unit square $\Omega = [0,1] \times [0,1]$; we let $\Omega^+ = \Omega \cap \{r :\; r_0 < r\}$, $\Omega^- = \Omega \setminus \overline{\Omega^+}$, $\Gamma = \{r :\; r = r_0\}$; and we use our numerical method to solve the problem

$$v_t(\mathbf{x},t) \;=\; \beta \Delta v(\mathbf{x},t) \tag{5.5}$$

for $\mathbf{x} \in \Omega^+$ and $t > 0$, with boundary conditions $\frac{\partial v}{\partial n}(\mathbf{x},t) \;=\; 0$ for $\mathbf{x} \in \Gamma$ and $t > 0$, $v(\mathbf{x},t) \;=\; v^{ex}(\mathbf{x},t)$ for $\mathbf{x} \in \partial\Omega$ and $t > 0$, and initial condition $v(\mathbf{x},0) \;=\; b(r)$ for $\mathbf{x} \in \Omega^+$. To provide initial data for the numerical solution in all of Ω, we extend $b(r)$

to the disc $\Omega^- = \{r < r_0\}$ as the constant value $b(r_0)$. We used $r_0 = 0.25$, $r_1 = 1.25$, and $p = 5$ in (5.3)–(5.4) and performed numerical experiments with stepsizes $h = 0.02$ or $h = 0.01$ and timesteps $k = 0.1h$. The results, given in Table 5.1, involve various error norms computed using grid points in Ω^+ and clearly show that the method is second order accurate for this problem.

The second problem we consider involves two disjoint circles contained within the unit square Ω (see Figure 5.1). The region of interest Ω^+ is the portion of the unit square outside of the two circles. The union of the interiors of the two circles is Ω^-, and Γ is the union of the circles. We are interested in solving the heat equation in Ω^+ with no-flux boundary conditions on both circles and along the left, right, and bottom boundaries of Ω and a prescribed nonzero flux along the top boundary of Ω. This flux is constant over much of the top boundary, and drops smoothly to zero as the top corners are approached. In Figure 5.1, we show contour plots at selected times in a computation performed on an 80×80 grid. Observe that the contour lines intersect

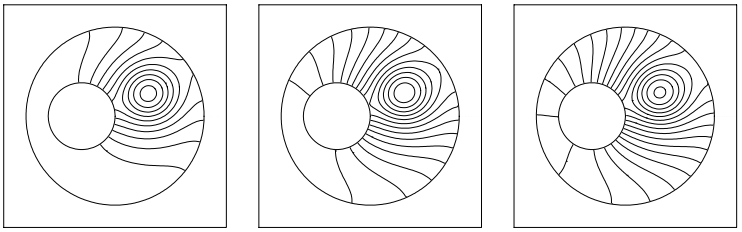

FIG. 5.2. *Contour plots of solution to heat equation at selected times. Homogeneous Neumann conditions on circles. Source between circles.*

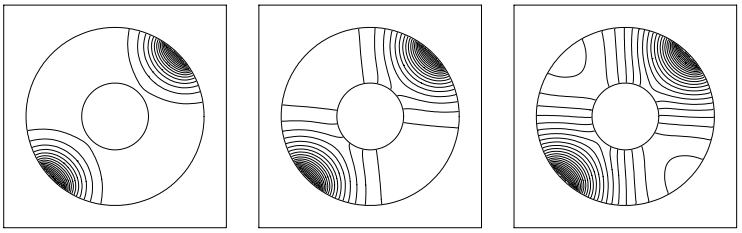

FIG. 5.3. *Contour plots of solution to heat equation at selected times. Inhomogeneous Neumann conditions on circles.*

the circles orthogonally. The contours inside the circle are physically meaningless; only those in Ω^+ are of interest. We compared the discrete integral of the solution over the region Ω^+ with the time integral of the flux and found excellent agreement.

The third problem involves heat flow in a region Ω^+ between two circles, so the two parts of Γ have curvatures of different sign. No-flux boundary conditions are imposed on both circles and there is a steady source term with circular support centered to the right and above the inner circle. Figure 5.2 shows contour plots from the solution of this problem using a 128×128 grid on the unit square. For clarity we show only contour lines within Ω^+. The boundary of the unit square is outside the region of interest and so the boundary conditions there have no physical meaning. For these calculations we applied homogeneous Dirichlet conditions along these boundaries. Again we see that the solution contours intersect the circles orthogonally.

In Figure 5.3, we show contour plots from a problem with inhomogeneous Neumann conditions on portions of Γ. Again the physical domain Ω^+ is the region between two circles. On the inner circle, homogeneous Neumann conditions are applied. On the outer circle, inhomogeneous Neumann conditions (2.3) hold with

$$\begin{aligned} g(s) \;=\; & 5 * \left\{ \tanh\left(100 r_2 \left(\Theta - \frac{3\pi}{16}\right)\right) - \tanh\left(100 r_2 \left(\Theta - \frac{5\pi}{16}\right)\right)\right\} \\ & + \; 5 * \left\{ \tanh\left(100 r_2 \left(\Theta - \frac{19\pi}{16}\right)\right) - \tanh\left(100 r_2 \left(\Theta - \frac{21\pi}{16}\right)\right)\right\}, \end{aligned}$$

where $r_2 = 0.4$ is the radius of the outer circle and $s = r_2\Theta$ is arclength. So the flux is approximately 5 over the angular intervals $(\frac{3\pi}{16}, \frac{5\pi}{16})$ and $(\frac{19\pi}{16}, \frac{21\pi}{16})$ and 0 elsewhere. The correction term C_{j_1,j_2} given by (2.44) is nonzero only for irregular points adjacent to these portions of Γ. Convergence studies for the problems in Figures 5.2 and 5.3 show second order convergence.

The last example in this section involves solution of the heat equation in the region shown in Figure 5.4. Again Ω is the unit square and this time periodic boundary

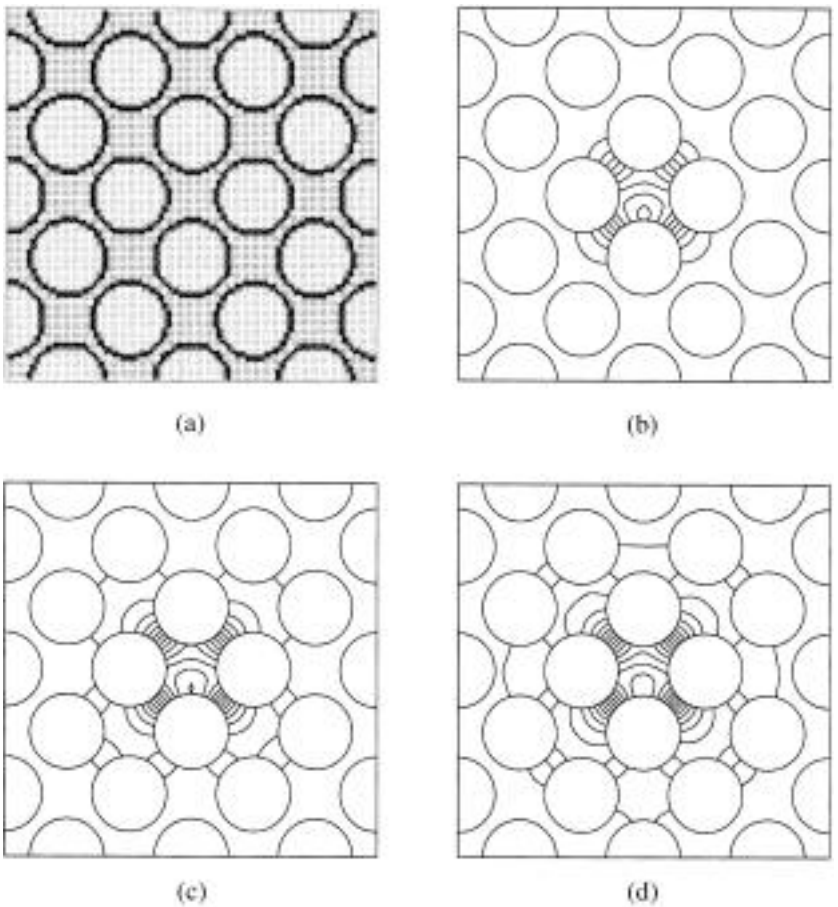

FIG. 5.4. (a) *Locations of irregular points.* (b)–(d) *Contour plots of solution to heat equation at selected times. Homogeneous Neumann conditions on circles. Source near domain center.*

conditions are imposed along its edges. The physical domain is that part of Ω exterior to all of the circles shown. Homogeneous Neumann conditions are imposed on each of the circles, and there is a source term located just below the center of the domain. Figure 5.4(a) shows the distribution of regular and irregular points for a 100×100 grid. In Figure 5.4(b)–(d), we show contours of the solution as it evolves and heat diffuses from the source through the gaps between the circular obstacles. In Figure 5.5, we show a perspective plot of the solution at a particular time. We have postprocessed the solution by setting its value to zero at points outside the physical domain.

To carry out a convergence study of our method applied to this problem, we performed calculations on grids with $h = 0.02$, 0.01, 0.005, and 0.0025, and with timestep $k = 0.1h$. In Table 5.2, we show the relative differences between each of the 0.02, 0.01, and 0.005 computations and the 0.0025 computation. There are several aspects of these results that should be noted. There is only a factor of 2 improvement between the $h = 0.02$ and $h = 0.01$ results, but an almost order of magnitude improvement between the $h = 0.01$ and $h = 0.005$ results. The first probably reflects the fact that with $h = 0.02$ and even $h = 0.01$, a relatively large part of the grid consists of irregular points. In fact, in the $h = 0.02$ version of Figure

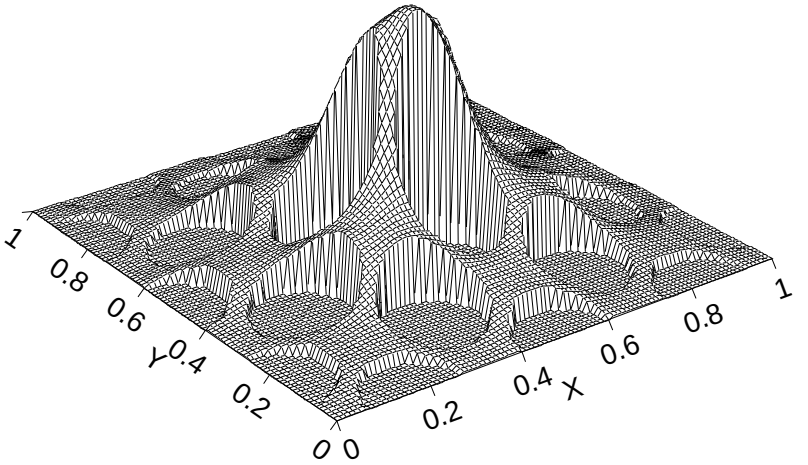

FIG. 5.5. *Perspective plot of solution to heat equation at same time as in* (d) *in preceding figure.*

TABLE 5.2
Errors for problem with many circles.

h	$\|\ \|_\infty$	$\|\ \|_1$	$\|\ \|_2$
0.02	0.238E-01	0.173E-01	0.166E-01
0.01	0.993E-02	0.803E-02	0.787E-02
0.005	0.130E-02	0.822E-03	0.820E-03

5.4(a) (not shown), there are no regular points in the narrow spaces between adjacent circles. Yet with a further reduction of h to 0.005, the results seem to "catch-up," so there is about a factor of 16 reduction in error from $h = 0.02$ to $h = 0.005$. We also think that it is noteworthy that even with $h = 0.02$, the errors were only 1–2%. We think these results suggest that this method may be quite useful for studying diffusion in porous media.

6. Three-dimensional Poisson equation. We apply the formulas described in section 4 to solve the Poisson equation in the region shown in Figure 6.1(a). For this problem the region Ω^+ is bounded on the outside by a sphere and on the inside by an ellipsoid. Homogeneous Neumann conditions hold on both of these surfaces. A source is distributed over a region of Ω^+ above the ellipsoid, and a sink of equal magnitude is distributed over the symmetric region below the ellipsoid. In Figure 6.1(b) are shown iso-surfaces of the solution obtained on a 64^3 grid with equal spacing in all coordinate directions. While the problem set-up is symmetric about an axis through the ellipsoid and sphere centers, the numerical method was not modified in any way to exploit this symmetry.

7. Conclusions. We have shown that Cartesian-grid finite-difference methods can be used very effectively to solve elliptic and parabolic equations with Neumann boundary conditions on general boundary curves or surfaces. The methods we discuss involve modifications to the finite-difference stencil at points near the boundary, and we described the results of a careful exploration of how these modifications should be made in order to achieve second order accuracy and stability. While the exploration itself was tedious, the results of it are easy to use in that we have specified exactly which choices of stencil work in each of a number of circumstances. This can be

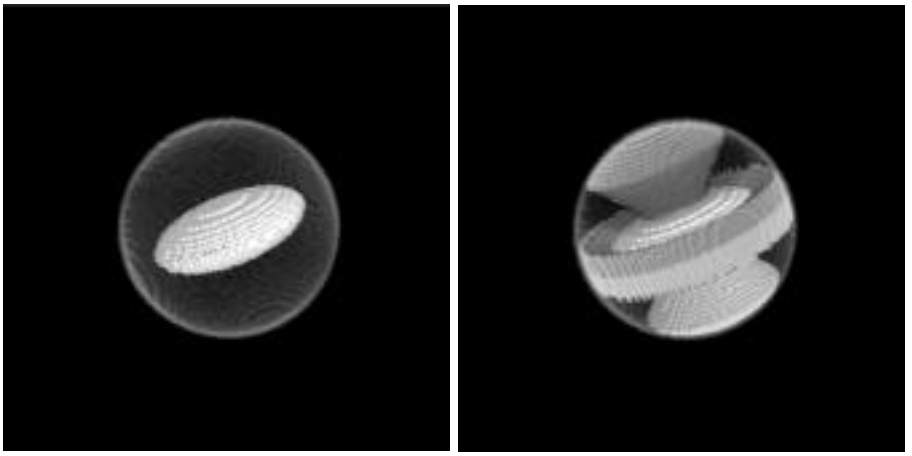

FIG. 6.1. (a) *Domain for three-dimensional calculation is bounded by sphere and ellipsoid.* (b) *Level surfaces of solution of three-dimensional Poisson equation.*

implemented simply in terms of look-up tables. Our approach works for both two-dimensional and three-dimensional problems as we illustrated through a variety of numerical examples.

One issue that we are still working on concerns iterative solution of the discrete system. For the two-dimensional heat-equation applications, line SOR or a very simple multigrid method was used. Even though the restriction and prolongation steps of this multigrid method did not take the boundary into account, the multigrid method was several times faster than line SOR. Perhaps incorporating information about the boundary into these steps, as in [1], will further improve the rate of convergence. Another issue that arises when a Galerkin formulation is used to define the coarse grid operators is whether it is important that the coarse grid operators inherit the Gerschgorin stability condition from the fine grid operator. We have preliminary evidence that by choosing appropriate operator-determined prolongation and restriction operators [2, 18] we can indeed preserve the Gerschgorin condition on coarse grids, and that this leads to a very effective multigrid method. When complete, this will be reported in a separate paper.

As mentioned in the introduction, Mayo and coworkers developed an alternative approach to solving certain elliptic problems in irregular regions. For the Laplace equation with Dirichlet boundary conditions their approach makes use of an integral representation of the solution in terms of an unknown double layer potential times a kernel derived from the fundamental solution to the Laplace equation. An integral equation on the domain boundary is solved to determine the double layer potential. As in our method, the irregular domain is embedded in a larger rectangular domain and a Cartesian grid is placed over the rectangle. The integral representation is used to define boundary values on the edges of the rectangle, to define a nonsmooth extension of the solution to the entire rectangle, and to determine the jumps in the extended function and its derivatives across the boundary of the irregular domain. A standard five-point formula for the discrete Laplacian is used at all points of the grid. For "regular" points, the truncation error made in setting the discrete Laplacian to 0 is order h^2. For "irregular" points, Taylor series manipulations combined with jump

conditions expressed in terms of the double layer potential and its derivatives are used to derive a correction term m such that the standard discrete Laplacian at the irregular point equals the true Laplacian there plus the correction term plus additional terms of order h or higher. Since the true solution is harmonic, the truncation error made in setting the discrete Laplacian equal to the correction term is equal to these additional terms. A standard fast Poisson solver for rectangular domains is then used to solve the algebraic system consisting of the equations obtained by setting the discrete Laplacian equal to 0 at regular points and to the correction term m at irregular points. For Poisson's equation, a particular solution to the differential equation is first determined without regard to boundary conditions and then the above procedure is used to solve Laplace's equation with modified boundary conditions. The preliminary step of finding the particular solution involves another discrete Poisson solve on the rectangle. In [12, 13, 14, 15], solution of the Dirichlet problem is discussed in detail and it is said that similar techniques can be used for the Neumann problem but, in fact, the details of this are not spelled out.

There are some similarities and many differences between the approach of Mayo et al. and that described in our paper. Both use Taylor series expansions and jump conditions to modify the standard discrete Laplacian at irregular points. Mayo's approach makes use of potential theory and the solution of an integral equation to derive the jump conditions; our's uses purely local information obtained from the differential equation and local continuity and boundary conditions. Mayo's approach has the advantage of using the standard discrete Laplacian for which (i) stability is well understood and (ii) there are fast solvers available. Our's modifies the difference stencil and so requires a new analysis of stability (as above) and rules out the use of conventional fast solvers. The latter would be a major disadvantage if not for the possibility of developing appropriate multigrid methods for these systems. As indicated earlier, this development is under way and preliminary results are very encouraging. The approach of Mayo et al. makes essential use of an accurate solution to an integral equation. Obtaining this solution, whether by a Nystrom method with trapezoidal rule quadrature as in [12, 13] or with a fast multipole method as in [15], is the dominant computational cost of the method and requires implementation of a lot of machinery not required in our approach. More importantly though, the approach of Mayo et al. is limited to problems with a known fundamental solution and fast solver. It is therefore not generalizable to variable coefficient or anisotropic diffusion problems which are important, for example, in exploring the mechanical or electrical-conduction properties of biological tissues. This generalization should be relatively straightforward with our method.

In this paper, we have limited discussion of our method to Poisson's equation and the heat equation. There are also extensions of the method that will make it useful on a wider class of problems. The method has been combined with advections algorithms [6] to produce methods for solving advection-diffusion equations in regions of complex shape. Preliminary results with the combined algorithm show second order convergence. This advection-diffusion code is being applied to study continuum models of platelet aggregation. Other applications include propagation of action potentials in a realistic, bidomain model of the intact heart, for which it is necessary to solve the Poisson equation in an irregular domain [5]. Other methodological extensions which are being explored are multigrid solvers and local mesh refinement.

Acknowledgments. The authors are very grateful to Randy LeVeque and Zhilin Li for many helpful discussions during the early stages of this work and to David Eyre

for helping produce the three-dimensional figures.

BLENDING FINITE-DIFFERENCE AND VORTEX METHODS FOR INCOMPRESSIBLE FLOW COMPUTATIONS*

M. L. OULD-SALIHI†, G.-H. COTTET†, AND M. EL HAMRAOUI†

Abstract. We describe and illustrate numerical procedures that combine grid and particle solvers for the solution of the incompressible Navier–Stokes equations. These procedures include vortex in cell (VIC) and domain decomposition schemes. Numerical comparisons with pure finite-difference methods demonstrate the effectiveness of these techniques for various flow geometries, bounded or unbounded.

Key words. vortex methods, finite-difference methods, Navier–Stokes equations, domain decomposition methods

1. Introduction.

The idea of coupling finite-difference and particle methods is rather common in the field of Navier–Stokes and kinetic equations. The motivation for using particles is to reduce the dimensionality of the phase space and to deal in an elegant and robust way with the transport terms in the equations, while grid solvers can rely on fast Fourier transform (FFT) to evaluate the fields at a minimal numerical cost.

In plasma simulations, grid techniques are indeed the usual way to compute the fields that move the particles. For incompressible flow calculations, however, the common wisdom is that grid solvers not only go against the Lagrangian features of vortex methods, but they also cannot retain the subgrid information that particles carry with them.

The goal of this paper is to show that, when used with the appropriate tools, particle-grid methods combine accuracy, speed, and robustness and provide an efficient alternative to other high-order methods for a number of high Reynolds flows. This point will be made by direct comparisons with centered finite-difference, both from the accuracy and CPU time points of view. As a matter of fact, we believe that direct comparisons of vortex methods with other types of methods, although not very common in the literature, should be done in a systematic way in order to demonstrate their usefulness in computational fluid dynamics (CFD).

We will be concerned with two types of particle-grid techniques. In the first type, the particles and the grid are used in the same computational domain to deal with different aspects of the flow equations. Typically, particles solve the transport equations and the grid can be used to compute the velocity. The diffusion and the vorticity boundary conditions can be solved by either method. These methods are in the spirit of the vortex in cell (VIC) method pioneered by Christiansen [3]. They retain the key feature of particle methods; namely, the advection part of the equation is dealt with in a Lagrangian fashion and reduces to a set of differential equations. As a result, the stability of the vorticity transport and stretching equations is not constrained by classical CFL conditions. As for vortex-blob methods, the time step

*Received by the editors February 1, 1999; accepted for publication (in revised form) May 23, 2000; published electronically December 5, 2000.

†LMC-IMAG, Université Joseph Fourier, B.P. 53, 38041 Grenoble Cédex 9, France (cottet@imag.fr).

is determined as a function of the maximum strain in the flow (typically a fraction of the inverse of the vorticity maximum). We will see that they can take advantage of high-order interpolation formulas for optimal particle-grid transfers.

In the second kind of method, the computational domain is split into several subdomains where different solvers are used. The coupling between the methods then has to be done within the framework of domain decomposition techniques and is most easily designed with overlapping subdomains. These methods have been proposed in [4]. The developments we propose here take advantage of high-order regridding of the particles in the overlapping zone. The gain that can be expected from this type of technique in the simulation of complex flows around obstacles is to combine the flexibility of grid and particle methods, respectively, near the solid boundaries and in the wake.

The outline of the paper is as follows. In section 2 we recall the principles of particle-grid assignment and interpolation, which are essential in all particle-grid techniques. Section 3 is devoted to VIC methods. We define these methods for 2D and 3D, ideal as well as viscous, flows and illustrate them on several classic 2D and 3D test cases with strong vortex–wall interactions. In section 4 we focus on particle-grid domain decomposition. We recall the key features of these methods and show that the principles of the method can be indifferently applied to the case when the finite-difference solver is used on a velocity-pressure or velocity–vorticity formulation of the Navier–Stokes equations. The method is then illustrated in the case of a flow over a backward-facing step and the wake of a cylinder. Finally, in section 5 we draw some conclusions on the suitability of particle-grid techniques for the simulation of complex 3D flows.

2. Particle-grid operators. All methods combining grids and particles rely heavily on the ability one has to transfer quantities such as vorticity and velocity between these two types of discretization. These transfers are most simply done by interpolation. Assume that we are given a distribution of particles located at x_p carrying circulations Γ_p, and thus a vorticity field is given by $\omega(x) = \sum_p \Gamma_p \delta(x - x_p)$. If ϕ_i is a basis of functions associated with the grid, a natural formula to assign vorticity values to the grid is

$$\omega_i = \frac{1}{V_i} \sum_p \Gamma_p \phi_i(x_p), \tag{1}$$

where V_i is the volume of the grid cell centered at x_i. Conversely, grid quantities, like velocities, are interpolated at particle locations with the formula

$$u_p = \sum_i u_i \phi_i(x_p). \tag{2}$$

In practice the grid often is deduced from a uniform Cartesian grid through a mapping given by explicit formulas (this is true, in particular, when one wishes to use finite-difference-type grid solvers, which is the case we have in mind). By using the same mapping formulas for the particles, one is led back to the case of a translation invariant grid, with grid size ε, and $V_i = \varepsilon^d$ (d is the dimension). The basis (ϕ_i) then reduces to a single kernel ϕ by the formula $\phi_i(x) = \phi(\frac{x - x_i}{\varepsilon})$, where ε is the grid size. Moreover, ϕ can be chosen as a tensor product of 1D kernels, and from now on we will focus on 1D kernels.

A class of kernels is given by successive convolutions of the top-hat filter χ with support in $[-1/2, 1/2]$. This gives kernels of increasing smoothness, which spread

the circulation of one particle onto an increasing number of points. To evaluate the accuracy of a given kernel it is customary to consider its conservation properties. Conservation of the total circulation, as measured by the particles and the grid, reads

$$\sum_i \omega_i V_i = \sum_p \Gamma_p.$$

It is clearly requires that the kernel ϕ satisfies

$$\sum_i \phi\left(\frac{x - x_i}{\varepsilon}\right) \equiv 1. \tag{3}$$

Conservation of linear and angular impulse, respectively, then requires that

$$\sum_i x_i \phi\left(\frac{x - x_i}{\varepsilon}\right) \equiv x, \tag{4}$$

$$\sum_i x_i^2 \phi\left(\frac{x - x_i}{\varepsilon}\right) \equiv x^2. \tag{5}$$

It is readily seen that these properties imply that the interpolation formulas will be of orders one, two, and three, respectively. Fourier analysis [23] gives simple criteria to determine the accuracy of a given kernel. Let g be the Fourier transform of ϕ:

$$g(k) = \int_{-\infty}^{+\infty} \phi(x) \varepsilon^{-ikx} dx.$$

One can show that ϕ yields an interpolation formula of order m (that is, it conserves the moments up to $m - 1$) if the following two conditions hold simultaneously:

$$k \to g(k) - 1 \text{ has a zero of order } m \text{ at } k = 0, \tag{6}$$

$$k \to g(k) \text{ has zeros of order } m \text{ at all } k = 2\pi n \qquad (n \neq 0). \tag{7}$$

Since the Fourier transform of χ is given by

$$g(k) = \frac{\sin(\pi k)}{\pi k},$$

this criterion clearly shows that χ is of order 1, while $\chi \star \chi$ and all the following kernels are second order.

In practice, the requirement one must have on the kernel accuracy very much depends on what is to be done on the grid. In a VIC calculation, where vorticity values on the grid are used only to compute the velocity, one can tolerate a certain level of dissipation in the assignment, and second-order formulas can give sufficient accuracy. However, if vorticity on the grid is directly used in the vorticity equation to solve for the diffusion or in a vorticity boundary condition, for instance, the numerical dissipation induced by these formulas can affect the overall performance of the method. In this case it is advisable to use higher-order formulas. All our calculations use the

following third-order kernel first proposed by Monaghan [20] in the context of smooth particle hydrodynamics (SPH) calculations:

$$\phi(x) = \begin{cases} 0 & \text{if } |x| > 2, \\ \frac{1}{2}(2-|x|)^2(1-|x|) & \text{if } 1 \le |x| \le 2, \\ 1 - \frac{5x^2}{2} + \frac{3|x|^3}{2} & \text{if } |x| \le 1. \end{cases} \tag{8}$$

The theoretical order of accuracy of a given kernel is actually obtained only insofar as the particles are able to represent a smooth function. Thus, besides the order of the interpolation kernel, another important factor in the accuracy of particle-grid schemes is the regularity of the particle distribution. Vortex-grid and vortex-blob methods are no different from this point of view. In the high Reynolds flows that we examine, the particles are likely to undergo severe distortions. Some cures can be proposed to maintain a minimal accuracy in the particle-grid transfers. One is to implement the formula (1) with a volume value deduced from the particles through the formula

$$V_i = \sum_p v_p \phi_i(x_p), \tag{9}$$

where v_p are the volumes of the particles. This formula has the effect of compensating for a local lack or excess of particles, because a constant vorticity field grid assignment with the formula (9) recovers the exact value, no matter how distorted the particles are. One may also process the weights of the particles in order to recover the correct vorticity values on the particles, along the same lines as in the iterative method proposed in the context of vortex-blob methods by Beale [1]. However, it is possible to maintain regularity in the particle distribution at almost no cost and with no discernible numerical dissipation (see [9]) by frequently regridding the particles. This has the effect of maintaining a good accuracy for the interpolation formulas. In all the vortex calculations shown in this paper, the same kernel (8) will be used for both the particle-grid transfers and for regridding the particles on regular locations.

3. VIC methods. Let us first recall the velocity–vorticity formulation of the incompressible Navier–Stokes equations

$$\frac{\partial \omega}{\partial t} + (u \cdot \nabla)\omega - (\omega \cdot \nabla)u - \sigma \Delta \omega = 0, \tag{10}$$

$$u = \nabla \times \psi, \tag{11}$$

$$-\Delta \psi = \omega. \tag{12}$$

This system has to be supplemented with initial and boundary conditions. Here we are interested in methods where grid and particle solvers coexist in the same computational domain. One important motivation for using Navier–Stokes vortex solvers lies in their robust and accurate treatment of the advection terms in (10): The vortex solution to (10) consists of moving vortices with their local velocities and updating their circulations to account for stretching and diffusion, and no explicit computation of the convection term $(u \cdot \nabla)\omega$ is required. On the other hand, grid solves can take advantage of FFT and fast Poisson solvers to compute velocity fields in (11)–(12).

In the early 1970s, grid Poisson solvers were actually the only way to do vortex simulations with more than a thousand particles. The advent of fast summation techniques has allowed completely grid-free simulations using up to a million particles, but in regular bounded geometries grid-based velocity solvers still offer a significant speed-up, unless particles occupy a very small part of the domain.

A typical VIC algorithm in two dimensions consists of the following sequence:

- Assign circulations to the grid with formula (1),
- solve (12) for the stream function on the grid with the desired boundary condition,
- compute grid velocities by finite differences,
- interpolate velocities on particles and move particles.

In this algorithm, most of the CPU time is devoted in the interpolation formulas involved in the particle-grid operators. A typical CPU time for the computation of the velocities on two million particles with the same number of grid points is a few seconds on a DEC workstation in three dimensions. To give an idea of the savings over a fast multipole algorithm in a vortex-blob method, from the figures given in [24] we can extrapolate that the same number of particles would require with these methods more than an hour of CPU time.

In a viscous code, it is also possible to solve for the diffusion on the grid. After the assignment step one computes $\Delta\omega$ on the grid by finite differences and then interpolates this quantity on the particles before updating their circulation. One must be aware that this scheme is not conservative. A conservative variant can be obtained with a finite-element formulation (see [6]). However, our simulations show that, when regridding, we maintain enough regularity in the particle distribution so the lack of conservation is not noticeable.

In the case where the grid is used for the diffusion, also it must handle a vorticity boundary condition to supplement (10) and translate the desired velocity boundary condition. One may either use an influence matrix technique to derive exact, at the grid level, vorticity boundary conditions, or rely on Taylor expansions to derive approximate boundary conditions, accurate to a given order. There has been in the last years extensive work in this direction. We refer in particular to [22, 11] and the references therein. We now illustrate these techniques on three flow examples: the 2D driven cavity, vortex dipoles, and vortex rings.

3.1. Driven cavity flow. In the VIC method implemented here, the diffusion is solved on the grid. It is compared with a finite-difference scheme using a centered second-order approximation of the advection and diffusion terms. When used together with fourth-order Runge–Kutta time stepping, this scheme does not suffer any cell Reynolds number limitations and is linearly stable under a convection CFL condition. We have implemented several other finite-difference schemes, in particular Arakawa and a fourth-order compact scheme [12]. We have observed that, when used with sufficient resolution, these schemes give very close results. When insufficiently resolved, all centered schemes ultimately lead to instabilities. The second-order scheme has been chosen in view of its simplicity and low CPU cost.

Concerning the vorticity boundary condition, we have implemented Thom's first-order formula, various second-order formulas, and Briley's fourth-order formulas. Here again we have observed that the difference between second- and fourth-order formulas was very marginal. (These formulas, however, clearly outperform Thom's formulas.) We have finally chosen the following second-order scheme: velocities at the interior grid points are computed from the stream function and at the boundary using the

TABLE 1
Run parameters and CPU times with VIC and finite-difference methods for various Reynolds numbers and resolutions.

CPU time for VIC scheme	5	16	32

velocity boundary conditions; then second-order one-sided finite differences are used to compute the vorticity at the boundary, which yields the Dirichlet boundary conditions used in the diffusion solver. The same vorticity boundary condition is used in the VIC method.

The finite-difference method used a fourth-order Runge–Kutta time stepping. This is actually necessary for the centered scheme to be stable [12] under a CFL condition. As for VIC method, it does not impose on the time step any stability constraint from the treatment of the convection term. In our simulations with the VIC method, we used second-order Runge–Kutta time stepping.

Due to the explicit treatment of the diffusion, for both methods the time step also must satisfy a diffusion CFL. In practice, for high Reynolds number flows, this last stability condition is far less drastic than the advective CFL condition. As a result, in most cases of interest the VIC code could be run with bigger time steps than the finite-difference code. Table 1 summarizes some typical run resolution and CPU times for a given simulation time on a Sun Sparc station. Due to the interpolation steps, each iteration of the VIC code requires slightly more computational time than the finite-difference code, but for Reynolds numbers beyond 10,000, the bigger time steps used in the VIC code lead to substantial CPU savings. Another nice feature of the VIC method is that it is insensitive to the lack of smoothness of the flow, whereas centered finite difference may become unstable when used without sufficient resolution if sharp vorticity gradients develop.

Figure 1 shows the vorticity contours obtained with the VIC and the finite-difference method for 256^2 and 512^2 resolutions.

The Reynolds number is 10,000, and the velocity profile at the top boundary has a parabolic profile. At the lower resolution, the two methods diverge from each other in the transient stage before reaching the same quasi-steady-state regime. As we refine the resolution, both methods converge toward the same solution. This is confirmed by looking at the vorticity profile on the first diagonal (Figure 2). The 256^2 resolution is enough in the VIC code to obtain converged results for a large time behavior. At this resolution it yields a sevenfold speed-up over the finite-difference method.

This CPU gain makes affordable large time simulations at higher Reynolds numbers. Figure 3 shows successive stages of the vorticity field in a driven cavity at a Reynolds number of 10^5, with 1024^2 grid points. (In this calculation, as in all our VIC simulations, we used the same mesh size for the grid and the particles.) The same resolution would have required a CPU time 17 times larger with the finite-difference method. (However, it is fair to mention that, due to the proliferation of small scales at this Reynolds number, it is virtually impossible to obtain converged

results; these simulations only convey qualitative information, such as the number of eddies.) Demonstrations of this simulation can be downloaded from the World Wide Web site www-lmc.imag.fr/lmc-edp/Georges-Henri.Cottet/vortex.html.

3.2. Dipole-wall interaction. In the calculations we now show, the diffusion and vorticity boundary conditions are computed on the particles and the grid is used only to compute the velocity. The particle diffusion solver is a particle strength exchange (PSE) scheme [10]; that is, particles exchange vorticity among them through

$$\frac{d\omega_p}{dt} = \sigma\varepsilon^{-2}\sum_q v_q(\omega_q - \omega_p)\Lambda_\varepsilon(x_p - x_q).$$

In the above formula, v_q are the volumes of the particles (typically h^d when particles are initialized on a uniform mesh with mesh size h) and Λ is a kernel satisfying appropriate second-order moment conditions.

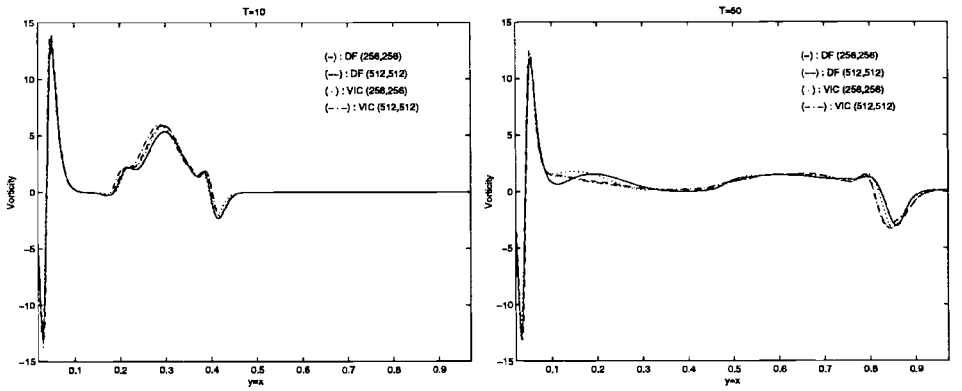

FIG. 2. *Vorticity profiles along the line* $x_1 = x_2$ *in a driven cavity at a Reynolds number of* 10^4.

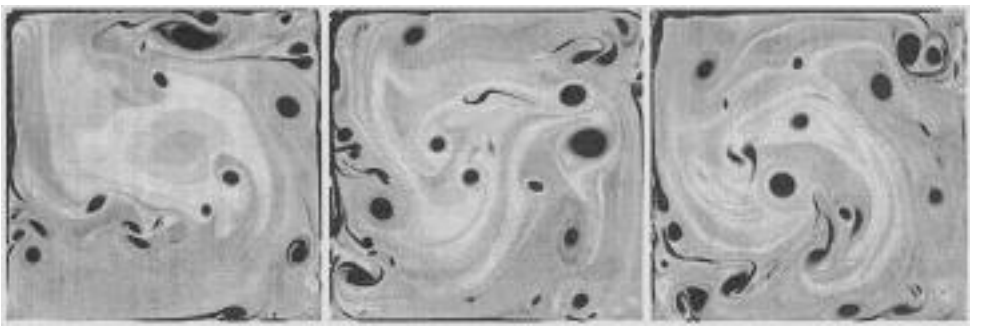

FIG. 3. *Successive stages of the evolution of the driven cavity at a Reynolds number of* 10^5. *VIC method using* 1024^2 *particles.*

This diffusion scheme is used in a viscous splitting algorithm with a Neumann vorticity boundary condition translating the no-slip condition at the wall. This algorithm is described in [5, 16]. It consists of first doing a time step of the PSE scheme, then evaluating the slip $u \cdot \tau$ at the wall. Finally, the diffusion step is repeated with a vorticity flux equal to $-u \cdot \tau / \delta t$. This last step is solved by means of integral equations.

This scheme has been applied successfully in various geometries [15, 17]. However, to our knowledge there has not been any direct comparison in terms of CPU time and accuracy of this method with grid-based schemes. On the basis of the results for the driven cavity, we have chosen to compare the VIC method with a second-order centered finite-difference scheme with fourth-order Runge–Kutta time stepping and the second-order vorticity boundary condition described above for the driven cavity problem.

Figure 4 shows a comparison of the results given by the VIC and finite-difference codes at a Reynolds number of 800. The initial condition is a Lamb dipole with circulation $\Gamma = 6.83$. The boundary conditions are periodic in the direction parallel to the wall. At the top boundary we assume no through flow and zero vorticity. The resolution is $\Delta x = 0.027$ for both simulations. Due to the advection CFL, the time step for the finite-difference scheme is five times smaller than for the VIC code. The results are in good agreement, although as time goes on the VIC solution seems to go slightly faster than the finite-difference solution.

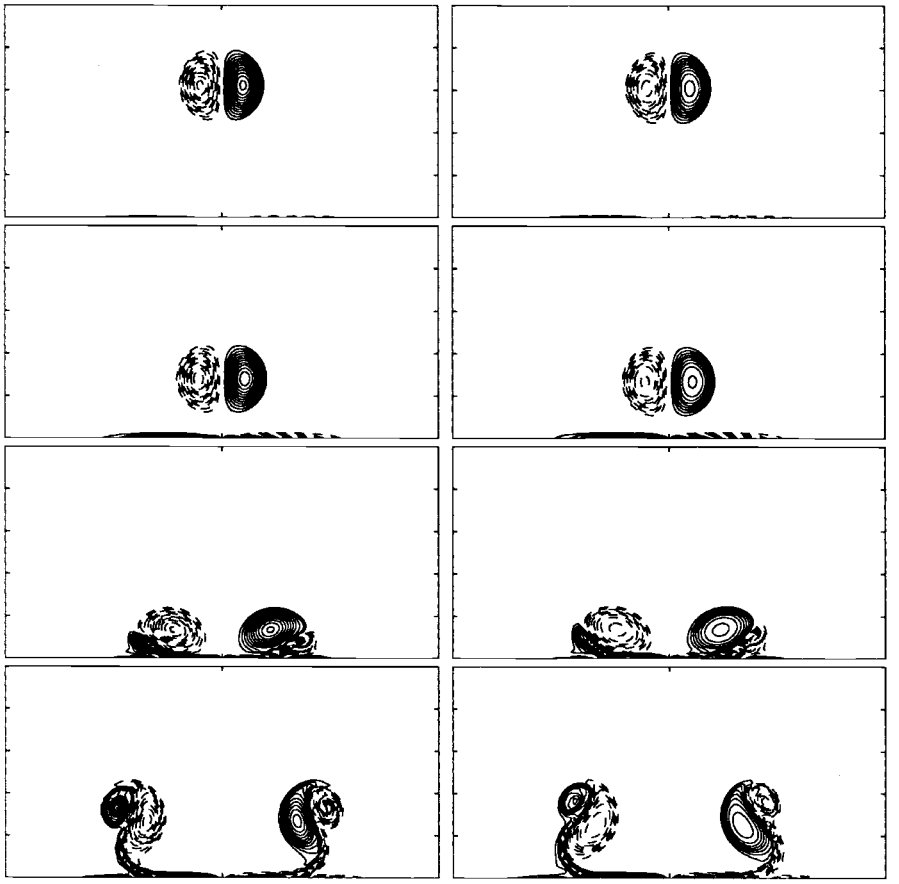

FIG. 4. *Contours of vorticity for a vortex dipole impinging a wall at times* $2, 4, 6, 8$. *Left column: finite-difference method,* $\Delta t = .02$*; right column: vortex method,* $\Delta t = 0.1$.

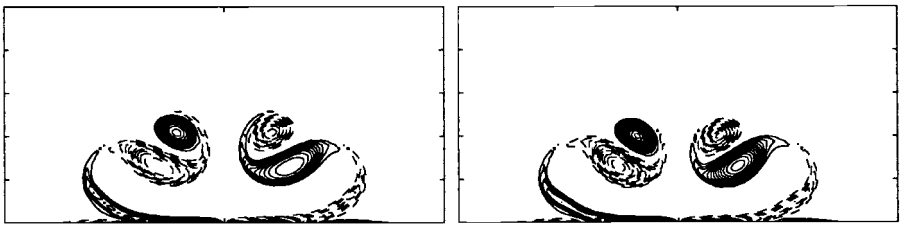

FIG. 5. *Contours of vorticity for a vortex dipole impinging a wall at time* 10. *Reynolds number* 800*, vortex method. Left picture:* $\Delta x = .027$*,* $\Delta t = .1$*; right picture:* $\Delta x = 0.0135$*,* $\Delta t = .05$.

Figure 5 is a refinement study at a later time for the VIC method (the resolution and time steps have been divided by a factor of 2), which shows that the VIC results in Figure 4 can be considered as nearly converged results.

Finally, Figure 6 is a VIC simulation at a Reynolds number of 1600. The resolution has been increased to $\Delta x = 0.0195$, but the time step has been kept equal to 0.1. For the same resolution, the finite-difference method would have required a time step 10 times smaller. Compared with the former case, the lower viscous dis-

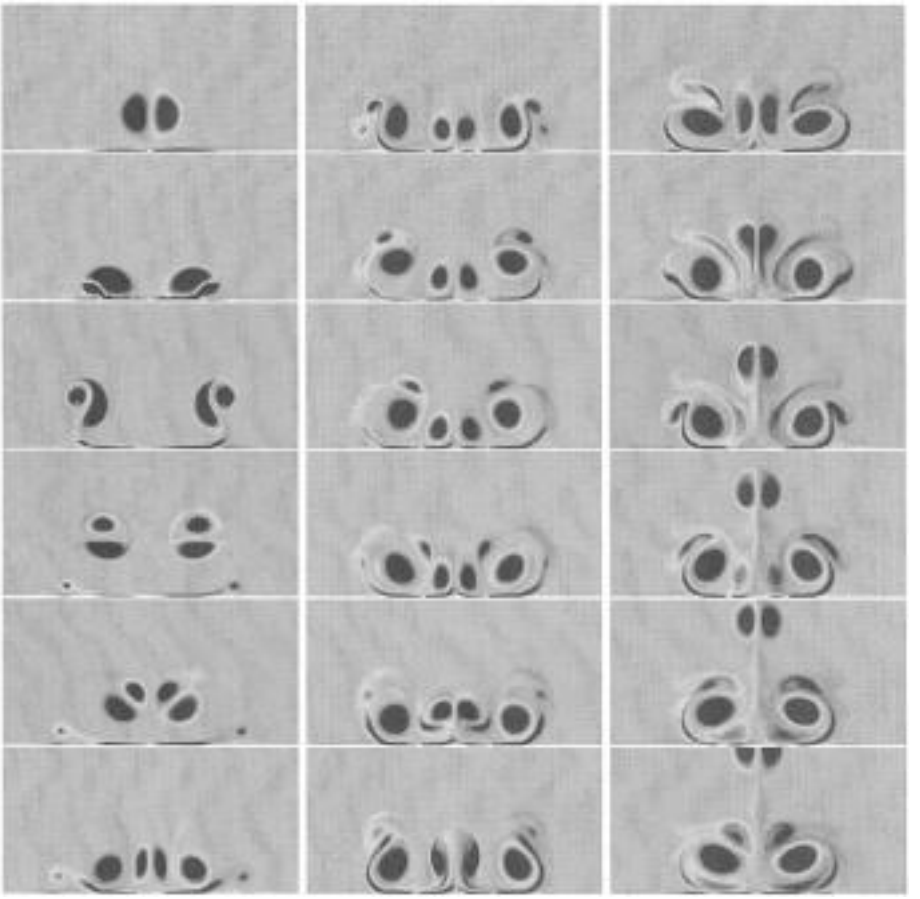

FIG. 6. *Vortex dipole impinging a wall by a VIC method with* $\Delta x = .0195$, $\Delta t = .1$. *Reynolds number of* 1600.

sipation yields larger circulations in the secondary vorticity produced at the wall. The resulting new dipole therefore gets enough circulation to eject itself from the wall.

These results are in good agreement with the results of Orlandi [21], however, with the same delay as noticed for the Reynolds 800 case.

It is interesting to note that, although first order in time, the vorticity flux boundary conditions give a satisfactory accuracy even when used with large time steps. By contrast, we have found that the vorticity boundary conditions given by Thom's formula, which is first-order accurate in space, failed to give acceptable results for this type of flow where it is crucial to capture accurately the sharp vorticity gradients produced at the boundary.

3.3. Ring-wall interactions. Here we consider the 3D counterpart of the dipole calculations just seen. Let us first describe how to extend the VIC schemes described in section 3.2 to three dimensions. First we must discretize the stretching term $(\omega \cdot \nabla)u$ appearing in the vorticity equation. One way is to obtain velocity derivatives by finite difference on the grid, then to interpolate these values at the particle locations. Particle vorticities are then updated, as in a grid-free vortex method,

by solving

$$\frac{d\omega_p}{dt} = [\nabla u(x_p)]\omega_p.$$

Another possibility, which we have elected in our calculations, is based on the conservative form $\mathrm{div}(\omega : u)$ of the stretching term. The idea is to multiply grid values of vorticity and velocity. The tensor $\omega_i u_j$ is then differentiated on the grid, and its divergence is finally interpolated on the particles to update their circulations. This last option has the advantage of being conservative at the grid level, even when the vorticity field is not exactly divergence-free. To avoid numerical dissipation in this procedure, we have used a fourth-order finite-difference formula for the divergence to compute the stretching term on the grid.

The second point that needs to be clarified is the extension to three dimensions of the vorticity flux boundary condition used in the 2D vortex schemes. One needs boundary conditions for each vorticity component. For no-slip velocity, the normal component of the vorticity must clearly vanish. For the components parallel to the wall, we adopt the same viscous-splitting point of view as in the 2D case and write for them a Neumann vorticity boundary condition to cancel the slip in the orthogonal direction of the wall. We refer to [6] for a more detailed account of this technique and a proof that it does not violate the divergence-free constraints for the vorticity.

As explained in [21], the features of the vorticity equation in three dimensions imply some important differences between the ring-wall and the dipole-wall interactions. These differences are noticeable particularly when the ring hits the wall with an angle. In this case the lower part of the ring is subject, as it approaches the wall, to intense stretching, which has the effect of pumping its circulation, which then feeds the upper part of the ring, causing it to rebound. We have chosen for these simulations the same parameter as in [25]: The angle is 38.5 degrees, the computational box is $[0,1]^2 \times [0,1/2]$ with periodic boundary conditions in the directions parallel to the wall $z = 0$, no slip at the wall, and no through flow and zero vorticity at the top boundary. The ring has radius $R = 1/8$ with a Gaussian core of radius equal to $0.4R$. At time zero it is located at a distance 0.25 of the bottom wall. The Reynolds number, based on the ring circulation, is 1400.

Particles were initialized and remeshed on a regular 128^3 grid. The same grid resolution was used for the computation of the velocity field. This resolution is roughly the same as in [25] (these authors used $129 \times 91 \times 97$ grid points, with grid refinement in the normal direction of about a factor of 2 near the wall). At the last stage of the computation considered here, there were about 900,000 particles (which means that the vorticity occupied roughly half of the computational domain).

Figure 7 shows the contours of the y-component of the vorticity in the symmetry (x, z) plane together with isosurfaces of the vorticity magnitude (for clarity, only half of the surfaces are shown) at times 24, 40, and 64. These results are in excellent agreement with the results of [25]. At this resolution the time steps used in the finite-difference and vortex methods are of the same order, and the goal of this example mostly was to demonstrate the ability of vortex methods to perform accurate direct numerical simulations of complex vortex-wall interactions. Quantitative comparisons with spectral methods for homogeneous turbulent flows and Crow instabilities are presented elsewhere [8].

4. Particle-grid domain decomposition. We now describe numerical techniques in which grid and particles are used in different subdomains of the computational domain. These techniques are rather natural: Vortex methods are attractive

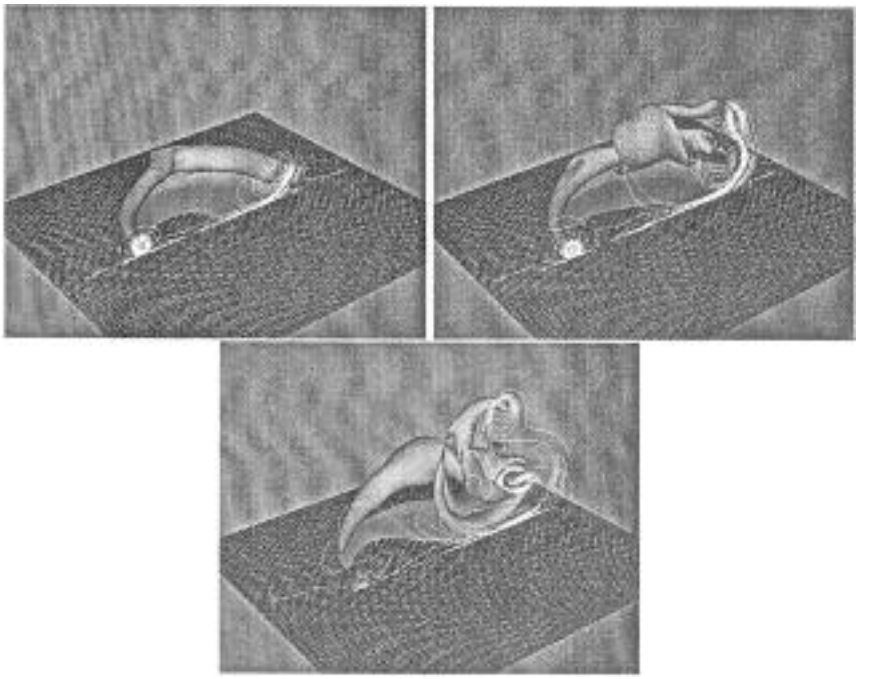

FIG. 7. *Vortex ring hitting a wall at an angle of* 38.5 *degrees. Contours of the vorticity component perpendicular to the symmetry plane, and isosurfaces of vorticity magnitude at times* 24, 40, *and* 64 *(from left to right, top to bottom).*

particularly in flow regions where the vorticity is confined to areas of small dimension and do not need to model far-field conditions, whereas grid-based methods offer more flexibility in dealing with boundary conditions at solid walls, in particular because using the velocity-pressure formulation is allowed.

4.1. Design. Particle-grid domains have been formalized for the first time in [4]. Note that at this time there was no clear understanding of how to accurately implement no-slip boundary conditions in vortex methods, which was a strong motivation for coupling vortex methods with grid techniques near obstacles. The method described in this reference is based on the velocity–vorticity formulation of the equations in the whole domain, but as we will see it extends readily to the case when a velocity-pressure formulation is chosen in the finite-difference subdomain.

As stressed in [4], for a clear-cut particle-grid domain decomposition algorithm, it is important to separate the kinematic and kinetic parts of the flow equations. They correspond to equations of a different nature and thus require different interface conditions.

Without loss of generality, we will assume no-slip boundary conditions and a domain decomposition as sketched in Figure 8. Ω_1 and Ω_2 are, respectively, the finite-difference and vortex domains. Important ingredients in the method will be the overlapping of Ω_1 and Ω_2 and the fact that there exists a domain Ω_2' including Ω_2 such that particles and grid coexist in $\Omega_1 \cap \Omega_2'$. The precise role played by Ω_2' and the geometrical constraints imposed on the width of the overlapping will appear in the discussion below.

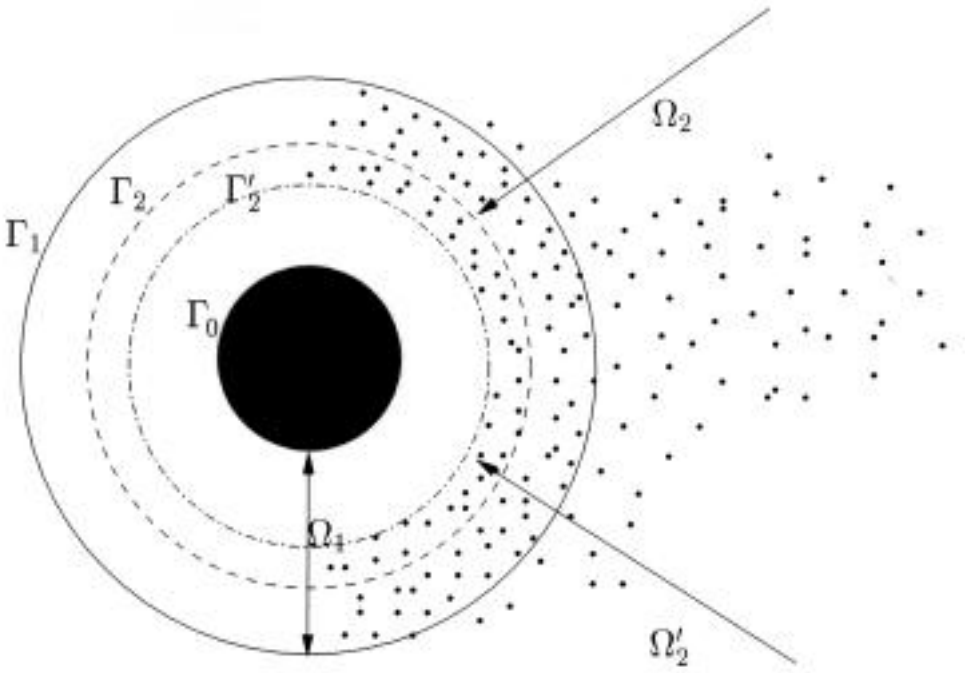

FIG. 8. *Particle-grid domain decomposition with overlapping.*

Let us mention that an alternative approach, without overlapping, has been proposed in [13]. This method, however, does not clearly indicate the interface conditions on which it relies and its consistency is not obvious.

Let us first consider the case when the velocity–vorticity formulation is used in both domains. At each time step—or substep in a Runge–Kutta scheme—one has to solve the elliptic equation $-\Delta\psi = \omega$ in each subdomain with the appropriate boundary conditions. While on Γ_0 the no-through-flow condition gives a homogeneous Dirichlet boundary condition, on Γ_1 and Γ_2 these boundary conditions are part of the calculations. A popular and efficient way to determine them is the Schwarz alternating method. In our case, it is slightly modified to take into account that different solvers are used in the two subdomains: a finite-difference solver and an integral one, given by the Poincaré identity, in the vortex zone. Note that, unlike for the bounded flows considered in the previous section, a VIC approach would not be appropriate in Ω_2, as it would not retain the ability of vortex methods to exactly satisfy the far-field condition. One iteration of the Schwarz algorithm proceeds as follows.

1. Solve $-\Delta\psi = \omega$ in Ω_1 by finite differences with $\psi = 0$ on Γ_0 and $\psi = a$ on Γ_1.
2. Compute $b = \psi$ and $c = \partial\psi/\partial n$ on source points on Γ_2.
3. Evaluate

$$\psi = \int_{\Omega_2} G(x-y)\omega(y)\,dy + \int_{\Gamma_2} G(x-y)c(y)\,dy + \int_{\Gamma_2} \frac{\partial G}{\partial \nu}(x-y)b(y)\,dy$$

on grid points of Γ_1, where ω is the vortex-blob solution in Ω_2 and G is the Green function $G(x) = \log|x|/2\pi$, to get new values of a on Γ_1.

Once the stream function, and thus the velocity, is known on both subdomains, we can describe how to update the vorticity. While the vortex method is always based on explicit time discretization of the equations, one may consider finite-difference solvers using either an explicit or implicit treatment of the diffusion. However, for the Reynolds numbers we are interested in, the time step is always limited by the advective CFL condition, and explicit diffusion solvers do not yield any additional stability constraints, so we will discard the option of implicit schemes.

To simplify the discussion we will consider the case of a forward Euler time discretization in both domains. To advance from time t_n to time t_{n+1}, explicit finite-difference solvers require only the knowledge at time t_n of the vorticity at the grid points on the boundary, assuming a second-order stencil, or a higher-order method with one-sided finite differences near the boundaries. We have already indicated in section 3 how to deal with the no-slip boundary on Γ_0. Since $\Gamma_1 \subset \Omega_2$, it is natural to obtain boundary values there by assigning vorticity values available at that time on particles of Ω_2, provided Ω_2 contains all the particles contributing to this assignment: If ε is the grid size and the interpolation kernel is given by (8), this means that $d(\Gamma_1, \Gamma_2) \geq 3\varepsilon$. Conversely, to update the circulations of the particles in Ω_2 one needs the circulations at time t_n of the particles in this domain surrounded by a layer of size at least $u_{\max}\Delta t + \rho$, where ρ is the width of the kernel used in the PSE scheme (of the order of the grid size ε). This dictates the geometrical constraints that have to be fulfilled by Ω_2 and Ω_2': One must have $d(\Gamma_2, \Gamma_2') \geq u_{\max}\Delta t + \rho$. In practice the various boundaries are separated by distances that are fractions of the body size, and these constraints are satisfied easily. To update the circulations of the particles in Ω_2, one finally interpolates grid values on the particles in $\Omega_2' - \Omega_2$ and includes these particles into the vortex scheme.

Note that the scheme just described is nothing but an extension of what would be done if a finite-difference scheme was used in both domains Ω_1 and Ω_2. In some sense the particles in $\Omega_2' - \Omega_2$ play the role of the outer grid points that would be needed in a finite-difference solver.

In summary, the algorithm proceeds as follows, assuming a forward Euler time stepping in both subdomains: Given a vorticity field ω^n known on the grid in Ω_1 and on particles in Ω_2,

- compute the stream function on Γ_1 and Γ_2 and its normal derivative on Γ_1, using the Schwarz alternating method;
- deduce velocity values on the grid and on particles in Ω_2;
- interpolate grid values of ω^n on particles in $\Omega_2' - \Omega_2$, and assign particle circulations to grid points on Γ_1;
- update vorticity in both domains to obtain ω^{n+1}.

In our calculations, this scheme is extended to a fourth-order Runge–Kutta time discretization in both domains.

The consistency of the interface conditions just described clearly relies on the ability of the particles in $\Omega_2' \cap \Omega_1$ to transfer vorticity between the two subdomains. This is achieved by periodically regridding particles in Ω_2' and by using high-order interpolation formulas like those described in section 2.

Let us mention that very similar ingredients can be used to design particle–particle domain decomposition methods. In this case, vortex methods are used in all subdomains, but they correspond to different mesh resolutions. We refer to [6, 7] for details.

We now turn to the case when a velocity-pressure formulation is used in the finite-difference domain. We have chosen in our simulations a second-order projection

technique that is a straight-forward extension, based on a second-order Runge–Kutta time advancing scheme, of Chorin's classical projection method [2]. For the sake of simplicity, as in the velocity–vorticity case, we will describe the domain decomposition method assuming a forward Euler discretization. In this case, starting from a divergence-free velocity u^n the projection method consists in computing

$$R^n = -(u^n \cdot \nabla)u^n + \sigma \Delta u^n \tag{13}$$

then

$$u^{n+1} = u^n + \Delta t(R^n + \nabla p^n). \tag{14}$$

The pressure p^n is adjusted to make u^{n+1} divergence-free and to satisfy the appropriate boundary condition for the normal component:

$$\Delta p^n = -\text{div } R^n \text{ in } \Omega_1, \tag{15}$$

$$\frac{\partial p^n}{\partial \nu} = -R^n \cdot \nu + \frac{u^{n+1} - u^n}{\Delta t} \cdot \nu \text{ on } \partial\Omega_1. \tag{16}$$

This system requires the knowledge of $u^{n+1} \cdot \nu$ on Γ_1. It may be obtained again by a Schwarz alternating method: Each Schwarz iteration consists of solving (15), (16), then evaluating the velocity on Γ_2 with (14), and finally using the Poincaré identity in Ω_2 to obtain new values for $u^{n+1} \cdot \nu$ on Γ_1.

One step of the complete algorithm, still in the case of a forward Euler scheme, proceeds as follows, starting from u^n in Ω_1 and ω^n in Ω_2:

- compute the particle velocities in Ω_2 with the Poincaré formula;
- differentiate u^n on the grid in Ω_1 and interpolate grid vorticity values on particles in $\Omega_2' - \Omega_2$;
- update particles in Ω_2 to get ω^{n+1};
- compute G^n, then $u^{n+1} \cdot \nu$ on Γ_1 through (14)–(16) and the Schwarz method, and finally u^{n+1}.

For a Runge–Kutta scheme, these steps have to be repeated at each substep.

Another type of particle-grid coupling method with overlapping has been proposed in [14]. The main difference with the method of [4] used here is that particle velocities are computed using a Biot–Savart law involving both particles and grid points. We believe that this approach is more expensive, since the Biot–Savart solver, even in the most efficient implementations of fast solvers, is significantly slower than a finite-difference one in simple geometries (in our calculations the number of grid points was always larger than the number of particles, even for a wake extending far downstream). Moreover, mixing grid points and particles in the same quadrature formula requires adjusting their volumes in the interface zone, which introduces some technical complications.

4.2. Numerical results. We have selected here a few results that illustrate the main features of the method. A more systematic study of particle-grid domain decomposition can be found in [18].

Our first example is to demonstrate that the interface conditions, although combining solvers of a different nature, maintain a smooth transfer of vorticity. Figure 9 shows the vorticity in a flow over a backward-facing step at a Reynolds number of 355. In the bottom picture, the finite-difference zone surrounds the top and bottom limits of the channel. The interface Γ_2 with particle is shown by a dotted line.

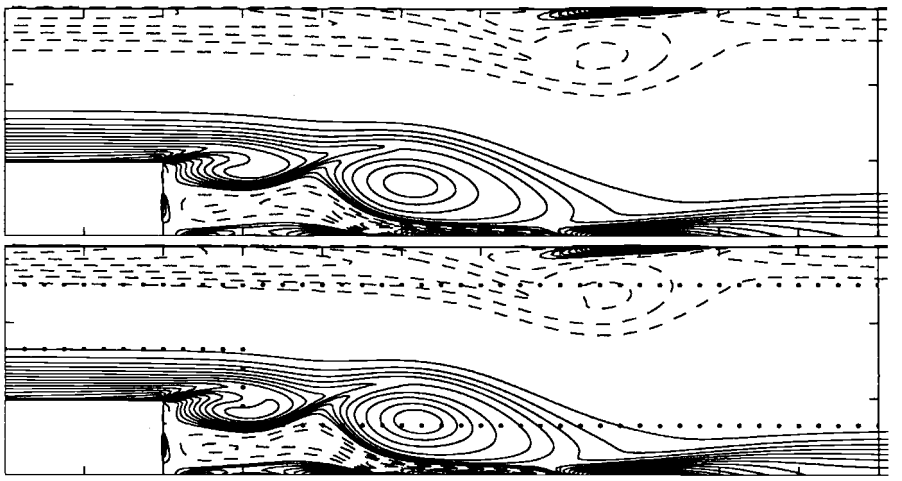

FIG. 9. *Vorticity contours for a flow over a backward-facing step at a Reynolds number of* 355. *Top picture: finite-difference calculation; bottom picture: particle-grid domain decomposition. The bullets materialize the interface.*

As a comparison, the top picture shows the results of a calculation using the finite-difference solver everywhere. The results are almost identical. Although the interface cuts through several recirculation zones with sharp vorticity gradients, no oscillations in the vorticity are discernible. Particles and grid have the same mesh size equal to 3% of the height of the step. This results in about 30,000 discretization points.

We now focus on flows past a cylinder. This is a good prototype of an unbounded flow producing complex dynamics near the boundary and it is well documented. In all our calculations the cylinder had a unit radius, and the velocity at infinity was equal to 1. The finite-difference domain extended to $r = 2$. The finite-difference method was a second-order centered scheme written in polar coordinates. The vortex and finite-difference schemes used fourth-order Runge–Kutta time stepping. In all cases the grid resolution in the finite-difference and vortex domains were identical.

We have first compared the particle-grid domain decomposition with a finite-difference method using an artificial boundary condition at the outer boundary. Both methods are based on a velocity–vorticity formulation of the flow equations. Figure 10 shows the vorticity on the cylinder at time 5, and the velocity profile on the symmetry axis behind the cylinder, for a Reynolds number of 550. The finite-difference domain extended to $r = 7$. One can observe that the vorticity values are almost identical, while the velocity profiles for late times differ in the wake due to the artificial boundary condition used in the finite-difference solver.

Figure 11 is concerned with a Reynolds number of 3000. It shows the vorticity contours obtained by the particle-grid domain decomposition method at times 3.2 and 8.4. Figure 12 shows the drag history. These results are in excellent agreement with the results of Koumoutsakos and Leonard [15]. The finite-difference method used 120×620 grid points on a polar grid extending to two times the radius of a cylinder. The number of particles at time 8 was about 36,000. At that time, the vorticity support extends to about $r = 7.1$, which means that a pure finite-difference method with the same resolution would have needed more than 720 grid points in the radial direction, and thus about four times more computational elements than the domain decomposition method. This example, although in a case where the vorticity is fairly

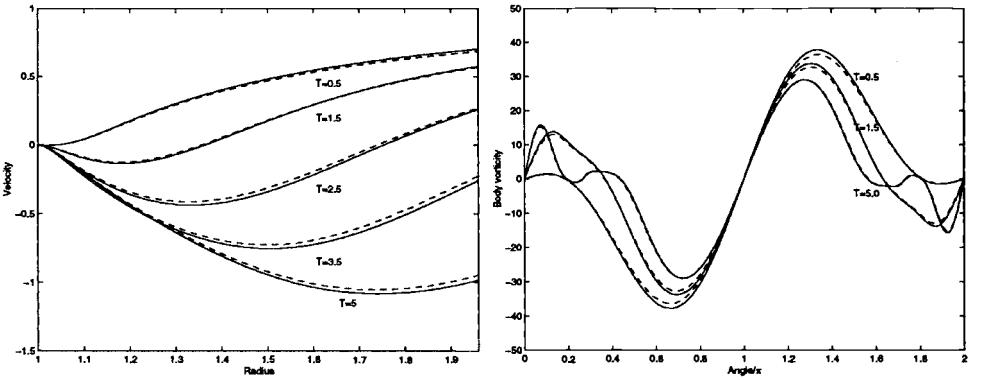

FIG. 10. *Flow past a cylinder at Reynolds* 550. *Vorticity values on the cylinder (right picture) and velocity in the back of the cylinder (left picture). Solid line: particle-grid domain decomposition; dashed line: finite-difference method.*

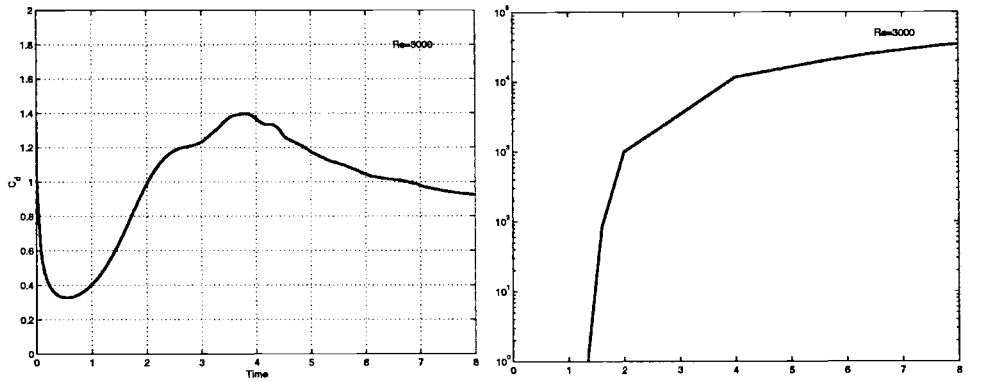

FIG. 12. *Flow past a cylinder at Reynolds number* 3000 *by a particle-grid domain decomposition. Drag history and number of particles.*

confined, illustrates the potential savings that the particle-grid method offers.

Our last examples are concerned with a particle-grid domain decomposition using a velocity-pressure formulation in the finite-difference domain. Figure 13 is a compar-

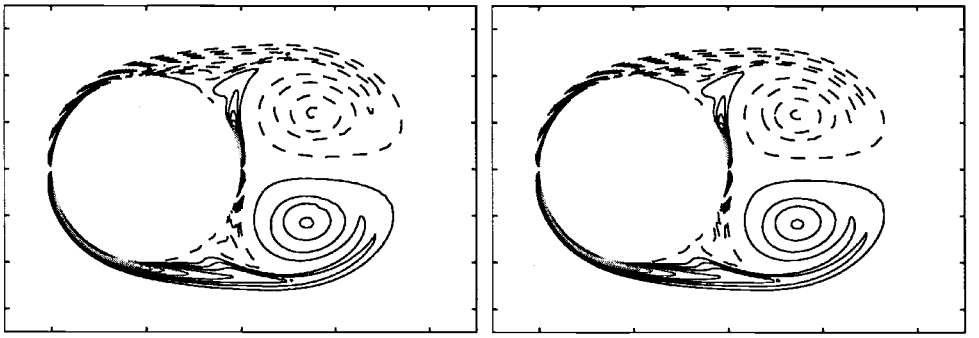

FIG. 13. *Vorticity contours for flow past a cylinder at Reynolds number* 1000. *Particle-grid domain decomposition based on a velocity–pressure formulation (left picture) and a velocity–vorticity formulation (right picture) in the finite-difference at time* $T = 6$.

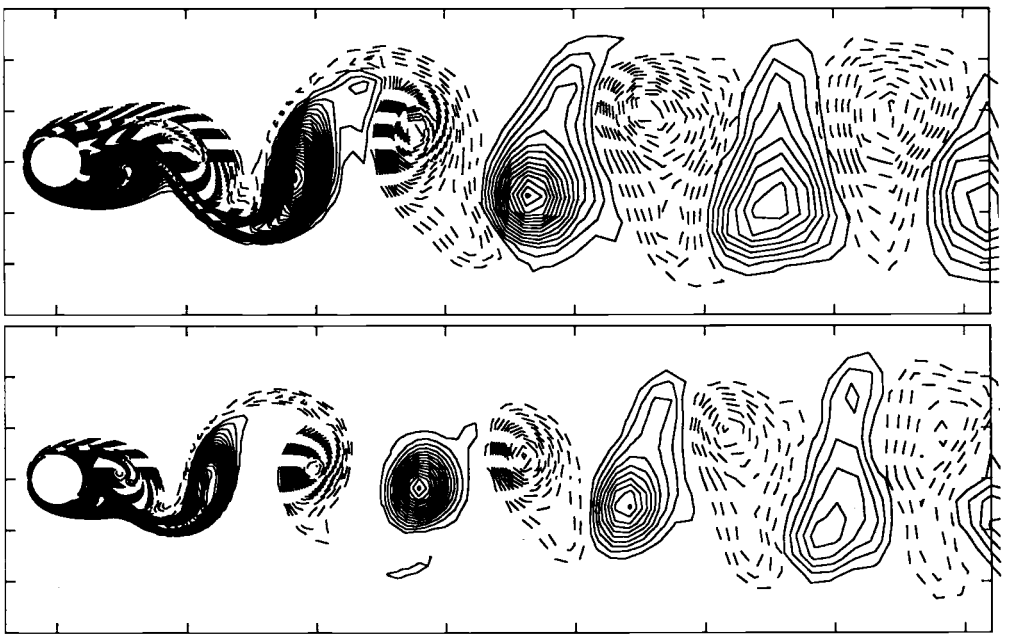

FIG. 14. *Karman streets behind a cylinder at Reynolds number of* 150 *(top picture) and* 300 *(bottom picture).*

ison of this technique with the domain-decomposition method based on a velocity–vorticity formulation in both domains at a Reynolds number of 1000. The vorticity contours are almost identical, which shows that combining different solvers based on different formulations of the equations does not introduce new difficulties, provided the interface conditions are written in a consistent way.

Finally, we now consider the case of a developed wake behind a cylinder. This is clearly the case where the vortex method is able to yield the most savings, as it uses computational elements only in the support of the vorticity and does not require any far-field artificial boundary condition. The finite-difference domain extended in this case to a six times the radius of a cylinder and the vortex domain started at three times

the radius of a cylinder. We have used a grid resolution with exponential stretching in the radial direction in both domains. The finite-difference domain extended to six times the radius of a cylinder and the vortex domain started at three times the radius of a cylinder. The vortex method used variable-size blobs with an exponential grid stretching in the radial direction (see [6, 7]). Figure 14 shows the Karman street obtained for Reynolds numbers of 150 and 300 at some late times. In the latter case the finite-difference grid used in the domain was 17,000 points, and the number of particles at the end of the simulation was slightly less than 12,000. The Strouhal numbers measured from these computations were, respectively, 0.183 and 0.208, in excellent agreement with the experimental values found by Williamson [26]. Note that, due to the loose resolution away from the cylinder, the far wake is obviously not accurately captured beyond about 10 diameters. However, this does not affect the computations of the forces on the body. In this case the particle-grid domain decomposition can be considered as a way to provide a good artificial boundary condition for the finite-difference solver for a limited cost.

5. Conclusion and future plans. We have presented a class of methods that combine grid-based and vortex schemes. High-order interpolation formulas are the key ingredients to transfer information between the two solvers at low cost and with minimal numerical dissipation.

VIC methods, where the grid essentially is used to compute the velocity fields and to take advantage of FFT-based fast Poisson solvers, provide robust and accurate solvers for flows in simple geometries. These features make them an attractive alternative to high-order grid-based methods, whenever it is crucial to compute complex dynamics on large time scales without numerical dissipation.

In two dimensions, stratified geophysical flows are good prototypes of such flows that could benefit from vortex methods. In three dimensions there are a number of flows in simple geometries that still lack accurate descriptions at high Reynolds numbers, in particular due to the time-step limitations that are in general implied by fine grids. Concerning 3D flows, work is underway to gain from classical homogeneous turbulence problems further insight into the effects at a subgrid level of the interpolations involved in grid-particle interpolations.

From another perspective, although vortex methods have proved that they are efficient in the simulation of complex vortex-wall interactions in two and three dimensions, particle-grid domain decomposition methods may be viewed as a more flexible tool, in particular in three dimensions when the grid solver near the obstacle is based on a velocity-pressure formulation. On the other hand, for 3D flows, it seems that pure finite-difference solvers still suffer from a dilemma between accuracy and stability. The numerical dissipation produced by upwind high-order schemes makes them inappropriate for large eddy simulations. Centered schemes do not have this difficulty, but they are very sensitive to grid regularity and to outflow boundary conditions [19]. Numerical schemes using vortex methods in the wake may be able to improve these aspects of current finite-difference solvers.

NUMERICAL SOLUTION OF THE TIME-DOMAIN MAXWELL EQUATIONS USING HIGH-ACCURACY FINITE-DIFFERENCE METHODS*

H. M. JURGENS† AND D. W. ZINGG†

Abstract. High-accuracy finite-difference schemes are used to solve the two-dimensional time-domain Maxwell equations for electromagnetic wave propagation and scattering. The high-accuracy schemes consist of a seven-point spatial operator coupled with a six-stage Runge–Kutta time-marching method. Two methods are studied, one of which produces the maximum order of accuracy and one of which is optimized for propagation distances smaller than roughly 300 wavelengths. Boundary conditions are presented which preserve the accuracy of these schemes when modeling interfaces between different materials. Numerical experiments are performed which demonstrate the utility of the high-accuracy schemes in modeling waves incident on dielectric and perfect-conducting scatterers using Cartesian and curvilinear grids. The high-accuracy schemes are shown to be substantially more efficient, in both computing time and memory, than a second-order and a fourth-order method. The optimized scheme can lead to a reduction in error relative to the maximum-order scheme, with no additional expense, especially when the number of wavelengths of travel is large.

Key words. computational electromagnetics, finite-difference schemes, wave propagation, phase error, Maxwell's equations

1. Introduction.

Numerical simulation of the propagation and scattering of electromagnetic waves has a wide range of applications in science and engineering, including antennas, microwave circuits, high-speed digital interconnects, all-optical devices, and many more [23]. The appropriate numerical algorithm for such simulations is dependent on the nature of the system being modeled. For geometries of low electrical size, i.e., spanning at most a few wavelengths, the method of moments is an efficient technique. However, scaling arguments presented by Petropoulos [18] show that this approach quickly becomes impractical as the electrical size increases. Geometries of moderate electrical size can be handled effectively using several available numerical methods for solving the Maxwell equations in the time domain. For such simulations, the geometric flexibility of the finite-element method can compensate for its relative inefficiency for hyperbolic equations. More efficient methods, which are effective for propagation distances on the order of 10 or 20 wavelengths, include the finite-difference methods of Yee [28] and Shang [20] and the finite-volume method of Mohammadian, Shankar, and Hall [16]. However, for propagation distances greater than 20 wavelengths, these methods, which are second-order accurate, typically require excessive grid densities with correspondingly large computational requirements.

The limitations of second-order methods in simulating wave phenomena have led to the development and application of higher-order and optimized finite-difference methods in several fields, including acoustics [13, 24] and seismology [10], as well as electromagnetics [12, 21, 25, 27, 29, 31, 34]. Higher-order methods offer increased accuracy for a given node density at the expense of increased cost per node. Optimized

schemes sacrifice the order of accuracy in return for low error over an increased range of wavenumbers. Fourier analysis provides a simple means of analyzing the phase and amplitude errors of finite-difference methods [14, 26, 31, 34]. Several high-order and optimized schemes were compared by Zingg [30] using this approach. Zingg showed that one of the optimized compact schemes developed by Haras and Ta'asan [6] is capable of accurate simulations involving 200 wavelengths of travel with less than 4 grid points per wavelength. This scheme requires the solution of a pentadiagonal system of equations in each coordinate direction. The optimized noncompact schemes of Lockard, Brentner, and Atkins [15] and Zingg, Lomax, and Jurgens [34, 35] require less than 10 grid points per wavelength for 200 wavelengths of travel with a much lower cost per node. Numerical experiments are required to determine the relative efficiencies of these methods in a practical context.

In order to avoid the use of a very small time step, the accuracy of the time-marching method should be comparable to that of the spatial operator. For simulating wave phenomena, Runge–Kutta and Adams–Bashforth methods are natural candidates, with the former generally preferred due to their low memory requirements. For linear ordinary differential equations with constant coefficients, Runge–Kutta methods of up to fourth order require only two memory locations per dependent variable [31]. Five- and six-stage methods with the same memory requirement have been proposed by Haras and Ta'asan [6] and Zingg, Lomax, and Jurgens [34, 35].

The need for stable and accurate numerical boundary schemes presents a major obstacle in the application of high-order finite-difference methods. Since long propagation distances are generally associated with multiple interactions with media interfaces, the numerical boundary schemes can have a significant impact on the overall accuracy of a simulation, and hence on the relative accuracy of various methods. Progress in the development of numerical boundary schemes was reported in [4, 17, 33]. Another important consideration in the application of high-order methods is the choice of gridding strategy. Uniform Cartesian grids were used, for example, by Taflove and co-workers [23], while body-fitted curvilinear grids were favored by Shankar, Mohammadian, and Hall [22] and others. The Cartesian approach produces two significant advantages in the interior of the domain. Virtually all numerical methods are most accurate on a uniform grid. In addition, the need to deal with the metrics of a curvilinear coordinate transformation leads to a substantial penalty in terms of both speed and memory. On the other hand, it is extremely difficult to develop stable and accurate boundary treatments for higher-order methods on Cartesian grids. Furthermore, some geometries, such as a curved surface with a thin coating, are not well suited to Cartesian grids. Clearly, the choice of a gridding strategy is problem dependent.

A further issue in the development of numerical methods for the time-domain Maxwell equations is the need to truncate the domain, which inevitably leads to spurious reflections. Boundary conditions based on locally one-dimensional characteristic splitting generally produce excessive reflection. Thus, development of nonreflecting boundary conditions for hyperbolic problems has been an active area of research for many years. Important contributions have been made by Engquist and Majda [5], Bayliss and Turkel [2], Berenger [3], and Petropoulos, Zhao, and Cangellaris [19].

This paper presents the implementation and validation of the high-order and optimized finite-difference methods presented in [34, 35] for the solution of the time-domain Maxwell equations. The objective is to demonstrate the efficiency of these methods on nontrivial sample problems. The methods combine a noncompact spatial

operator with a seven-point stencil and a low-storage six-stage time-marching method. Two methods are studied, one of which produces the maximum order of accuracy and one of which is optimized for propagation distances less than roughly 300 wavelengths. In the next section, the Maxwell equations are presented in generalized curvilinear coordinates. The two finite-difference methods, including both spatial and temporal operators, are then presented. This is followed by a description of the treatment of interfaces and boundaries, including dielectric interfaces, perfect conductors, and domain boundaries. The two methods are applied to a number of test problems involving the propagation and scattering of electromagnetic waves. In order to demonstrate the efficiency of the present methods, the computational requirements are compared with two other methods, one fourth order in space, the other second order.

2. Governing equations. In two dimensions, Maxwell's equations decouple into two sets, the transverse magnetic (TM) and the transverse electric (TE) equations. Without any loss of physics, we consider only the TM set. We restrict our attention to linear, isotropic, perfect dielectric materials with constant properties, no charge density, and no current sources. Under these conditions, the TM equations can be written in the following form:

$$\frac{\partial \mathbf{Q}}{\partial t} + \mathbf{A}\frac{\partial \mathbf{Q}}{\partial x} + \mathbf{B}\frac{\partial \mathbf{Q}}{\partial y} = \mathbf{0}. \tag{2.1}$$

The vector of unknowns is given by

$$\mathbf{Q} = \begin{bmatrix} D_z \\ B_x \\ B_y \end{bmatrix}, \tag{2.2}$$

where D_z is the z component of the electric flux density, B_x and B_y are the x and y components of the magnetic flux density, and the two matrices are

$$\mathbf{A} = \begin{bmatrix} 0 & 0 & -\dfrac{1}{\mu} \\ 0 & 0 & 0 \\ -\dfrac{1}{\varepsilon} & 0 & 0 \end{bmatrix}, \qquad \mathbf{B} = \begin{bmatrix} 0 & \dfrac{1}{\mu} & 0 \\ \dfrac{1}{\varepsilon} & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}; \tag{2.3}$$

μ is the magnetic permeability and ε is the electric permittivity. The constitutive relations are $\mathbf{D} = \varepsilon\mathbf{E}$ and $\mathbf{B} = \mu\mathbf{H}$, where $\mathbf{E}$ is the electric field intensity and $\mathbf{H}$ is the magnetic field intensity. In our tests, we assume a nondimensional form of the equations where, in free space, $\varepsilon = \mu = 1$. Note that the divergence relations are not explicitly enforced. However, numerous tests with the numerical methods studied in this paper show that the divergence of the magnetic field remains of the order of the truncation error for all time.

When numerically modeling electromagnetic fields, it is often the case that the geometry of the problem lends itself to a more generalized coordinate system than Cartesian. A method that allows the independent variables of the partial differential equations to be transformed into a uniformly spaced computational domain was given in [1]. The two-dimensional TM form of Maxwell's curl equations can be expressed in a generalized coordinate system using the following transformation:

$$\xi = \xi(x, y), \qquad \eta = \eta(x, y). \tag{2.4}$$

This allows the Cartesian coordinates to be transformed into curvilinear coordinates in such a way that a curvilinear grid will map to a uniform and square computational space with $\Delta\xi = \Delta\eta = 1$. The mapping is usually defined by assigning integer curvilinear coordinate values to each node in the grid and calculating the metrics of the transformation numerically. The transformed equations can be written in the following form:

$$\frac{\partial \mathbf{Q}}{\partial t} + \hat{\mathbf{A}}\frac{\partial \mathbf{Q}}{\partial \xi} + \hat{\mathbf{B}}\frac{\partial \mathbf{Q}}{\partial \eta} = \mathbf{0}, \tag{2.5}$$

where the two matrices are

$$\hat{\mathbf{A}} = \begin{bmatrix} 0 & \frac{1}{\mu}\frac{\partial \xi}{\partial y} & -\frac{1}{\mu}\frac{\partial \xi}{\partial x} \\ \frac{1}{\varepsilon}\frac{\partial \xi}{\partial y} & 0 & 0 \\ -\frac{1}{\varepsilon}\frac{\partial \xi}{\partial x} & 0 & 0 \end{bmatrix}, \qquad \hat{\mathbf{B}} = \begin{bmatrix} 0 & \frac{1}{\mu}\frac{\partial \eta}{\partial y} & -\frac{1}{\mu}\frac{\partial \eta}{\partial x} \\ \frac{1}{\varepsilon}\frac{\partial \eta}{\partial y} & 0 & 0 \\ -\frac{1}{\varepsilon}\frac{\partial \eta}{\partial x} & 0 & 0 \end{bmatrix}. \tag{2.6}$$

Extension to spatially variable material properties requires the use of a strong-conservation-law form of the equations, as discussed in [11].

3. Numerical method. Our aim is to solve for the total electric and magnetic field components by approximating Maxwell's equations using finite-difference methods. The finite-difference schemes used consist of a seven-point spatial operator in conjunction with an explicit six-stage time-marching method. These high-accuracy methods were originally presented by Zingg, Lomax, and Jurgens [35], and an extensive description of the methods, including an error and stability analysis, can be found in [34].

The spatial operator is made up of two parts, an antisymmetric or central-difference operator,

$$(\delta_x^a u)_j = \frac{1}{\Delta x}[a_1(u_{j+1} - u_{j-1}) + a_2(u_{j+2} - u_{j-2}) + a_3(u_{j+3} - u_{j-3})], \tag{3.1}$$

and a symmetric operator,

$$(\delta_x^s u)_j = \frac{1}{\Delta x}[d_0 u_j + d_1(u_{j+1} + u_{j-1}) + d_2(u_{j+2} + u_{j-2}) + d_3(u_{j+3} + u_{j-3})]. \tag{3.2}$$

The operator described by (3.1) has a maximum formal order which varies as Δx^6 when $a_1 = \frac{3}{4}$, $a_2 = -\frac{3}{20}$, and $a_3 = \frac{1}{60}$. The operator described by (3.2) has a maximum formal order which varies as Δx^5 when $d_1 = -\frac{3}{4}d_0$, $d_2 = \frac{3}{10}d_0$, and $d_3 = -\frac{1}{20}d_0$. The symmetric operator is used to add a small amount of numerical dissipation to the scheme. We use a value of $d_0 = \frac{1}{10}$. A characteristic splitting is used when the operator is applied to a hyperbolic system of equations. For example, in order to approximate the term $\mathbf{A}\frac{\partial \mathbf{Q}}{\partial x}$, the scheme is applied as follows:

$$\mathbf{A}\left(\frac{\partial \mathbf{Q}}{\partial x}\right)_j = \mathbf{A}(\delta_x^a \mathbf{Q})_j + |\mathbf{A}|(\delta_x^s \mathbf{Q})_j \tag{3.3}$$

at any interior node j. Note that $|\mathbf{A}| = \mathbf{X}|\Lambda|\mathbf{X}^{-1}$, where $\mathbf{X}$ is the matrix of right eigenvectors of $\mathbf{A}$, and Λ is the matrix of eigenvalues of $\mathbf{A}$. The method is applied in a similar way in order to approximate the y-derivatives of the field values.

The time-marching method, when applied to the ordinary differential equation $\frac{du}{dt} = f(u,t)$, can be written as

$$
\begin{aligned}
u^{(1)}_{n+\alpha_1} &= u_n + h\alpha_1 f_n, \\
u^{(2)}_{n+\alpha_2} &= u_n + h\alpha_2 f^{(1)}_{n+\alpha_1}, \\
u^{(3)}_{n+\alpha_3} &= u_n + h\alpha_3 f^{(2)}_{n+\alpha_2}, \\
u^{(4)}_{n+\alpha_4} &= u_n + h\alpha_4 f^{(3)}_{n+\alpha_3}, \\
u^{(5)}_{n+\alpha_5} &= u_n + h\alpha_5 f^{(4)}_{n+\alpha_4}, \\
u_{n+1} &= u_n + h f^{(5)}_{n+\alpha_5},
\end{aligned}
\tag{3.4}
$$

where $h = \Delta t$ is the time step, $t_n = nh$, $u_n = u(t_n)$, and $f^{(k)}_{n+\alpha} = f(u^{(k)}_{n+\alpha}, t_n + \alpha h)$. Setting $\alpha_5 = \frac{1}{2}$ gives a method that is second-order accurate. Additionally setting $\alpha_4 = \frac{1}{3}$, $\alpha_3 = \frac{1}{4}$, $\alpha_2 = \frac{1}{5}$, and $\alpha_1 = \frac{1}{6}$ gives the method with the highest formal order for linear homogeneous ordinary differential equations, which is sixth-order accurate. For inhomogeneous and nonlinear ordinary differential equations, it is second-order accurate. Two memory locations are required per dependent variable. The stability region for this method was shown in [34].

The above operators contain coefficients that can be determined in a number of ways. We have already described the operators in which the coefficients are determined by maximizing the formal order (referred to as the maximum-order (MO) operator). Zingg, Lomax, and Jurgens [34, 35] presented an additional method, in which the coefficients are determined by specifying that the phase and amplitude errors of the operators are minimized for waves which are resolved by the computational grid with at least 10 points per wavelength (referred to as the optimized operator or O10). The coefficients for this optimized scheme can be found in the appendix.

These schemes have a number of useful properties. First, the amplitude error is less than the phase error for all wavenumbers [34]. Hence any wavenumber components that are excessively damped also have excessive phase error. Second, the time-marching method produces significantly smaller errors than the spatial discretization. Hence the phase and amplitude errors are virtually independent of the Courant number (for Courant numbers less than unity). This contrasts with some other schemes that are accurate only within a narrow range of Courant numbers. Similarly, the present schemes do not require that the direction of wave propagation be aligned with the grid. The errors are largest for propagation angles of zero and 90 degrees. Hence the one-dimensional analysis given in [34] gives an upper bound on the error.

4. Interface and boundary treatment. In order to simulate the scattering of electromagnetic waves off of materials which have differing dielectric properties, each region is modeled as a distinct numerical domain. These domains are then coupled using the appropriate physical boundary conditions. This procedure allows the grids for each region to be generated independently, which is useful since the resolution of the grid is dependent on the material properties of the domain. Three separate boundary types are considered, an interface between two dielectric regions, the boundary between a dielectric and a perfect conductor, and the far-field boundary which is located at the outer region of the domain. At the interface between two dielectric media and at the surface of a perfect conductor, a locally one-dimensional characteristic formulation of the governing equations is used [8]. Using this approach,

characteristic variables can be found that represent incoming and outgoing waves along lines normal to the interface. For example, if we consider a boundary that lies at the right side of the domain on a line of constant x, the incoming waves are associated with $\mathbf{A}^-$ and the outgoing waves with $\mathbf{A}^+$, where

$$\mathbf{A}^{\pm} = \frac{\mathbf{A} \pm |\mathbf{A}|}{2} \tag{4.1}$$

and $|\mathbf{A}|$ is defined after (3.3). Similar expressions can be found for boundaries that lie on lines of constant y and for boundaries in curvilinear coordinates. For the curvilinear case, the incoming and outgoing waves will be associated with $\hat{\mathbf{A}}^{\pm}$ and $\hat{\mathbf{B}}^{\pm}$. When calculating spatial derivatives near boundaries and interfaces, flux-vector splitting is used. Regular fifth-order one-sided and upwind-biased schemes are used for the outgoing waves, while the following numerical boundary scheme (NBS) is used for the incoming waves:

$$\begin{aligned}(\delta_x u)_1 &= \frac{1}{60\Delta x}[-3u_0 - 119u_1 + 255u_2 - 240u_3 + 155u_4 - 57u_5 + 9u_6],\\ (\delta_x u)_2 &= \frac{1}{60\Delta x}[9u_0 - 66u_1 + 70u_2 - 60u_3 + 75u_4 - 34u_5 + 6u_6].\end{aligned} \tag{4.2}$$

The above NBS is a modified version of the one presented by Zingg, Lomax, and Jurgens [34, 35], which was found to be unstable on some curvilinear grids.

4.1. Dielectric interfaces. On the interface between two dielectrics the following conditions must hold:

$$E_t^{(1)} = E_t^{(2)}, \tag{4.3}$$

$$H_t^{(1)} = H_t^{(2)}, \tag{4.4}$$

$$D_n^{(1)} = D_n^{(2)}, \tag{4.5}$$

$$B_n^{(1)} = B_n^{(2)}. \tag{4.6}$$

The superscripts refer to the field values in materials (1) and (2). Note that these relations assume that there is no surface current flowing along the interface and that there is no surface charge density present at the interface. In the TM case, the electric intensity and electric flux density vectors point out of the x-y plane, and thus (4.5) holds automatically and (4.3) simplifies to

$$E_z^{(1)} = E_z^{(2)}. \tag{4.7}$$

Consider a body-fitted grid which ensures that the interface between different materials will lie on a ξ = constant curve. The grid is constrained to be orthogonal near the body, thus η = constant curves are normal to the interface. In this example, we assume that the positive ξ direction points from region (1) to region (2). Figure 1 shows an example of such a body-fitted coordinate system. We can generalize this example to different cases in curvilinear coordinates and to Cartesian coordinates quite easily. There are six unknown values which need to be stored on the interface: $D_z^{(1)}$, $D_z^{(2)}$, $B_x^{(1)}$, $B_x^{(2)}$, $B_y^{(1)}$, and $B_y^{(2)}$. The fields are extrapolated to the interface using a sixth-order method (see the appendix). The characteristic variables are then calculated from

$$w_+^{(1)} = Z^{(1)} D_z^{(1)} + B_t^{(1)} \tag{4.8}$$

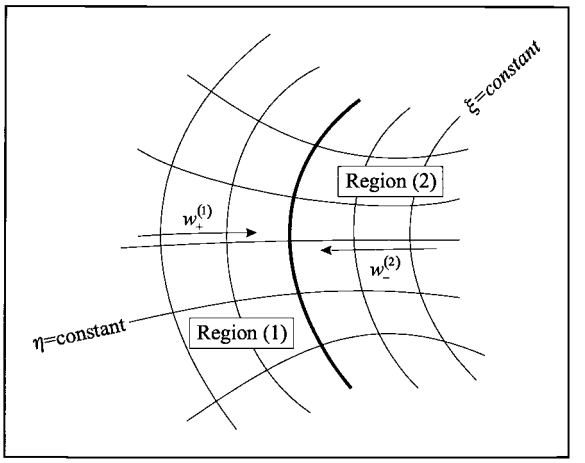

FIG. 1. *Example of a body-fitted grid showing the characteristic variables associated with the outgoing waves.*

and

$$w_-^{(2)} = Z^{(2)} D_z^{(2)} - B_t^{(2)}, \tag{4.9}$$

where $Z = (\mu/\varepsilon)^{1/2}$ is the intrinsic impedance of the medium. Note that

$$B_t = \frac{\dfrac{\partial \xi}{\partial y} B_x - \dfrac{\partial \xi}{\partial x} B_y}{\left[\left(\dfrac{\partial \xi}{\partial x} \right)^2 + \left(\dfrac{\partial \xi}{\partial y} \right)^2 \right]^{1/2}} \tag{4.10}$$

is the component of $\mathbf{B}$ tangent to a $\xi =$ constant curve, and

$$B_n = \frac{\dfrac{\partial \xi}{\partial x} B_x + \dfrac{\partial \xi}{\partial y} B_y}{\left[\left(\dfrac{\partial \xi}{\partial x} \right)^2 + \left(\dfrac{\partial \xi}{\partial y} \right)^2 \right]^{1/2}} \tag{4.11}$$

is the component of $\mathbf{B}$ normal to a $\xi =$ constant curve. This gives two equations for the unknown values $D_z^{(1)}$, $D_z^{(2)}$, $B_t^{(1)}$, and $B_t^{(2)}$. Note that the quantities extrapolated depend on the orientation of the local (ξ, η) coordinate system at the interface. Combining these with the jump conditions, we obtain

$$D_z^{(1)} = \frac{w_+^{(1)} + \dfrac{\mu^{(1)}}{\mu^{(2)}} w_-^{(2)}}{Z^{(1)} \left(1 + \dfrac{Z^{(1)}}{Z^{(2)}} \right)}, \tag{4.12}$$

$$D_z^{(2)} = \frac{\varepsilon^{(2)}}{\varepsilon^{(1)}} D_z^{(1)}, \tag{4.13}$$

$$B_t^{(1)} = \frac{Z^{(1)} w_+^{(1)} - \mu^{(1)} c^{(2)} w_-^{(2)}}{Z^{(1)} + Z^{(2)}}, \tag{4.14}$$

$$B_t^{(2)} = \frac{\mu^{(2)}}{\mu^{(1)}} B_t^{(1)}. \tag{4.15}$$

The variable $c = (\varepsilon\mu)^{-1/2}$ is the propagation speed. The normal component of the magnetic flux density is single valued on the interface, as shown by (4.6), and is determined by averaging the two values obtained by extrapolation. The values of B_x and B_y are determined from B_n and B_t using (4.10) and (4.11).

The above interface treatment was closely examined in [32]. The error introduced at interfaces is of the same order of magnitude as that introduced in the interior using the high-accuracy schemes. Both the interior discretization and the interface treatment, including the NBS (4.2), contribute to the overall error, with the relative contribution depending on the distance between interfaces.

4.2. Perfect conductors. At the interface between a dielectric material and a perfect conductor, the physical boundary conditions given in the above section must be modified. If, for example, region (2) is a perfect conductor—that is, having an infinite conductivity—then all the field values inside the region must be zero. Using this fact, and the four relations given in the above section, one obtains the following boundary conditions at the surface of a perfect conductor:

$$E_t = 0, \tag{4.16}$$

$$H_t = J_s, \tag{4.17}$$

$$D_n = 0, \tag{4.18}$$

$$B_n = 0. \tag{4.19}$$

In general, there will always be a finite current density, J_s, on the surface of a perfect conductor, but we have assumed a zero surface charge density. For the TM case, the third condition is automatically satisfied since the electric flux density points out of the plane, and the first condition sets its magnitude to zero, i.e., $D_z = 0$. The tangential component of the magnetic flux density, and thus the surface current, is found by extrapolating the fields to the surface and then calculating the outgoing characteristic variable. For example, if the surface of the perfect conductor lies along a grid line of constant ξ, with ξ increasing as the boundary is approached, then w_+ is determined from (4.8). Since $D_z = 0$, (4.8) gives

$$B_t = w_+, \tag{4.20}$$

where B_t is defined by (4.10). The Cartesian components of the magnetic flux density are determined using this value and the fact that $B_n = 0$.

4.3. Far-field boundaries. To model the problem of waves moving out into free space, the numerical domain must be artificially truncated. There is a considerable body of literature on the subject of far-field boundary conditions which tries to minimize the spurious reflection introduced when a disturbance propagates out of the numerical domain [2, 3, 5, 19, 23, 24]. There are many papers, such as [9], that discuss the merits of different types of far-field conditions.

We implement a modified version of the radiating boundary condition introduced by Bayliss and Turkel [2], which was found to be the best method of those tested by

Hixon, Shih, and Mankbadi [9]. This method truncates the domain by using a far-field radiation condition which only allows disturbances to propagate in the outward direction. The condition is applied by enforcing the following partial differential equation on the boundary region of the domain:

$$\left(\frac{1}{c}\frac{\partial}{\partial t}+\frac{\partial}{\partial r}+\frac{a}{2r}\right)\begin{bmatrix} D_z \\ B_x \\ B_y \end{bmatrix}=\mathbf{0}. \tag{4.21}$$

When $a = 1$ the operator given in [2] is recovered, which is $O(r^{-5/2})$. Using the operator with this value of a results in the numerical schemes becoming unstable for some curvilinear grids. We use a value of $a = 3$, which results in a stable and accurate method. The numerical domain is split into two regions, one of which contains the total electromagnetic field and one of which contains only the scattered field (see, for example, [23]). We store the scattered field on ghost-points which lie outside the domain, and the total field at all other nodes. To approximate the spatial derivatives in Maxwell's equations where the computational stencil will overlap the ghost-point region, the incident field is added to the scattered field at the necessary nodes in this region. When calculating the spatial derivatives for the radiation condition, the incident field is subtracted from the total field at the necessary nodes in the interior domain.

5. Results and discussion.

5.1. Dielectric square. We first simulate the scattering of a pulsed plane wave off of a dielectric square. Figure 2 shows an example grid as well as the geometry of the problem. The domain is square, with x and y ranging from 0 to 1, and the dielectric is located in the center of this region, at $0.4 \le x \le 0.6$, $0.4 \le y \le 0.6$. The permittivity of the dielectric is four times that of the free space region. The wavespeed in free space is normalized to one, resulting in a wavespeed of one-half in the dielectric. The domain is discretized using a Cartesian grid, in which $\Delta x = \Delta y$, and the grid density in the interior of the dielectric is twice that of free space. Results are obtained for a Gaussian pulse incident upon the dielectric square at an angle of 45°. The incident electric field is given by

$$E_z(x,y,t)=\exp\left[-\frac{1}{2\sigma^2}\left(x\cos\frac{\pi}{4}+y\sin\frac{\pi}{4}+\frac{1}{2}-t\right)^2\right] \tag{5.1}$$

with $\sigma = 0.03$. For all test cases, the time step is chosen in order to give a Courant number of unity in free space. This results in a value of Δt equal to the Δx value of the free space domain. As a result of both the wave speed and the grid spacing inside the dielectric being one half the values found outside the dielectric, the Courant number will also have a value of unity inside the dielectric. This ensures that the spatial resolution inside the dielectric is matched with that found in free space, since the width of the pulse will narrow as it slows down. Because of this, the errors will not be as localized to the interior of the dielectric as they were in the tests performed in section 5.1 of [11], where the grid resolution was kept constant over the entire domain. The better grid resolution inside the dielectric also allows for an accurate simulation of a narrower pulse. Note, however, that the accuracy of the high-accuracy finite-difference schemes is equally good at Courant numbers less than unity. Spurious reflections are not an issue for this case because the incident field is imposed along

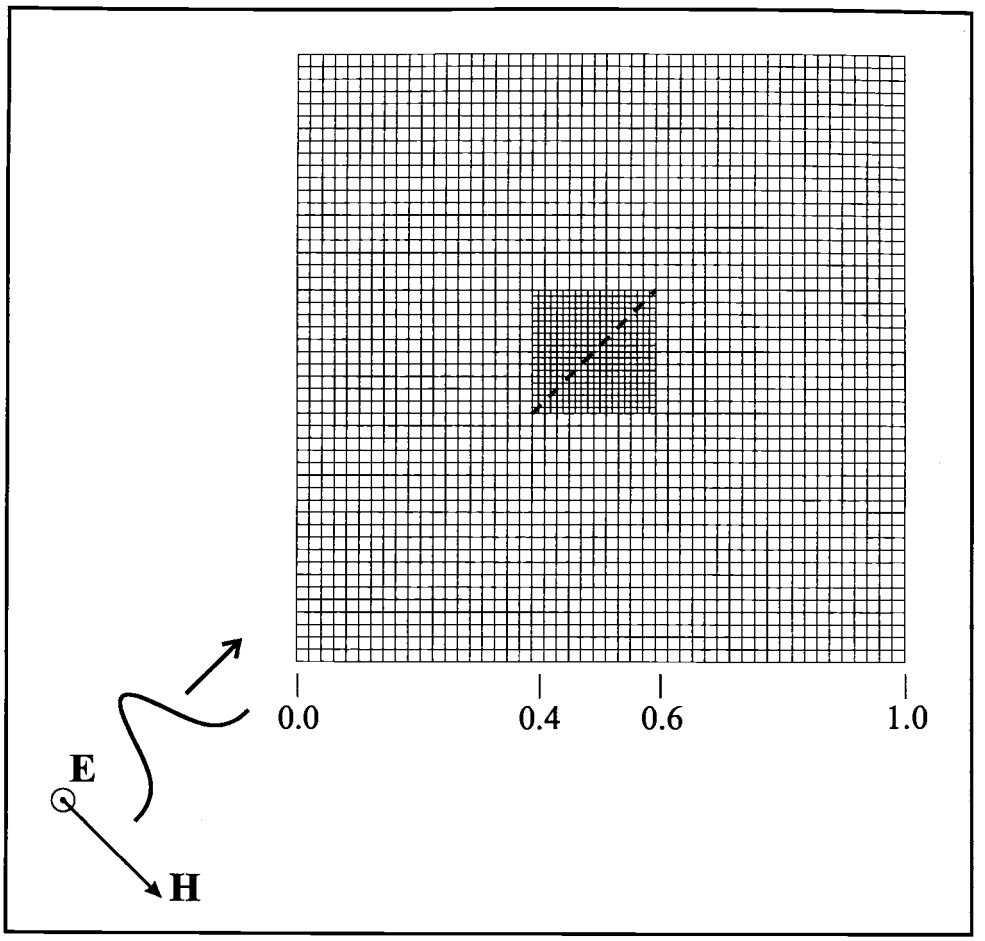

FIG. 2. *Example grid showing pulsed plane wave with Gaussian cross-section incident at* 45° *on a dielectric square.*

the entire outer boundary, and the simulation is not run long enough for the reflected pulse to reach the outer boundary.

For this simulation the interfaces between the different materials lie along lines in the Cartesian grid. The jump conditions discussed in section 4.1 can be used to obtain the field values along grid lines that cross the interfaces. In order to obtain the field unknowns along the interface at nodes inside the dielectric, which do not have a corresponding node outside the dielectric, interpolation and extrapolation of values from neighboring interface nodes are used. The interpolation and extrapolation schemes can be found in the appendix. Note that the extrapolation scheme and the noncentered interpolation schemes are used for the nodes near the corners of the dielectric. The corners must also be treated as special cases. It is only necessary to store the field values at the corner nodes for the free space part of the domain since the values in the interior of the dielectric are never used during the simulation. These values are obtained by taking the average value of the results of interpolating the field values along the x and y grid lines which intersect the corner node. Again, the relevant inerpolation schemes can be found in the appendix. Note that the presence of the

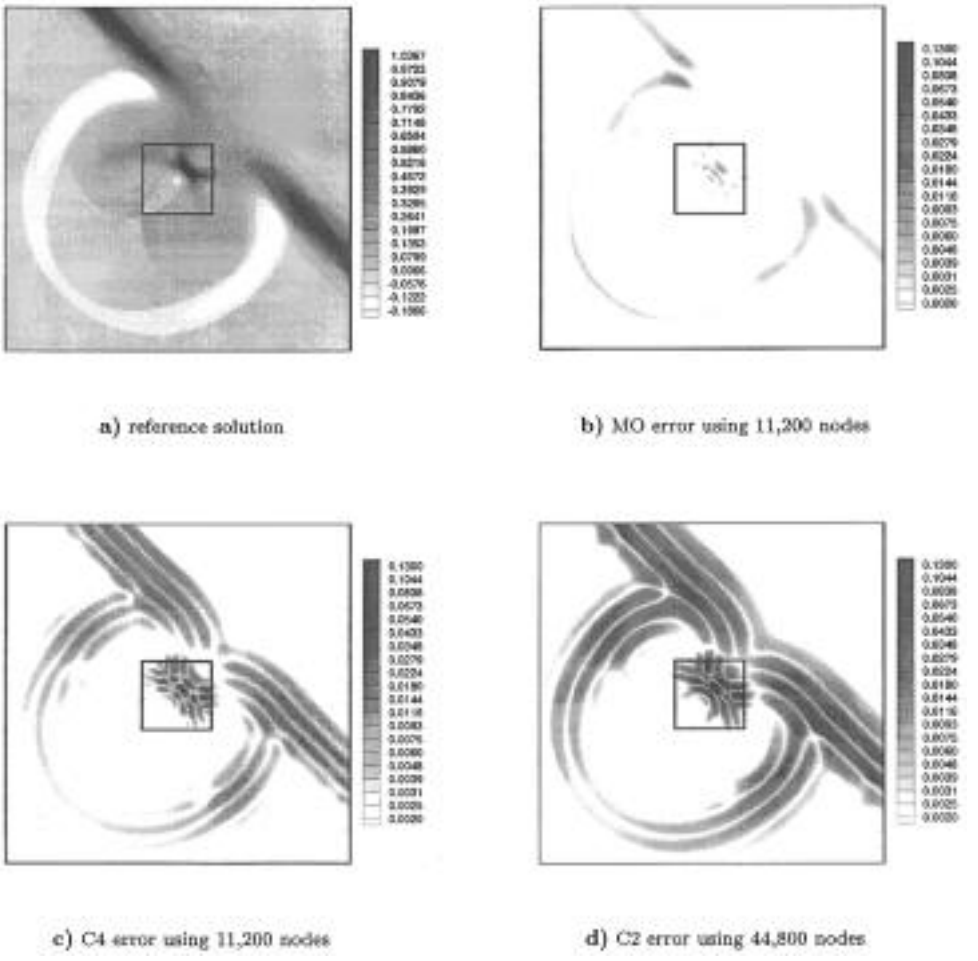

FIG. 3. *Contour plots of electric field intensity and errors in electric field intensity.* (a) *Reference solution,* (b) *MO error using* 11,200 *nodes,* (c) *C4 error using* 11,200 *nodes, and* (d) *C2 error using* 44,800 *nodes.*

singularity in the neighborhood of the corners introduces a low-order error locally. The finite-difference scheme can be modified locally to account for the singularity, but our results will show that the high-accuracy methods produce significant error reduction without implementing such a strategy.

In addition to the MO and O10 schemes described here, results are presented for second-order centered differences in space combined with fourth-order Runge–Kutta time marching (C2) and fourth-order centered differences in space combined with fourth-order Runge–Kutta time marching (C4).

Contour plots of the absolute value of the error in the electric field intensity at $t = 1.4$ are shown for three different cases in Figure 3. Figure 3(a) shows the electric field intensity for a reference solution calculated using the MO scheme on a grid with 179,200 nodes. The error obtained using the MO scheme on a grid with 11,200 nodes is shown in Figure 3(b). Note that the contour levels grow exponentially, and the error is extremely small. Plots of the errors obtained using method C4 on the grid with

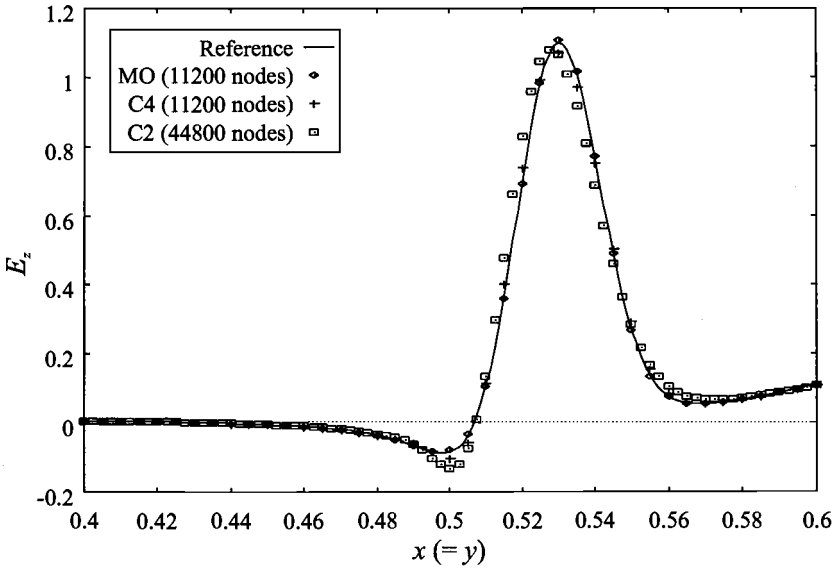

FIG. 4. *Electric field intensity across diagonal of dielectric square.*

11,200 nodes and method C2 on a grid with 44,800 nodes are shown in Figures 3(c) and (d), respectively. The errors obtained using method C4 are much larger than those obtained using the MO scheme, and even greater errors are evident in the C2 results, which are computed on a grid with four times as many nodes.

The electric field intensity along the diagonal of the dielectric square is shown in Figure 4 for the reference solution, the MO scheme on a grid with 11,200 nodes, the C4 scheme on a grid with 11,200 nodes, and the C2 scheme on a grid with 44,800 nodes. The results for the MO scheme lie very close to the reference solution. The C4 results are also fairly accurate, but there are some discernible deviations from the reference solution near the maximum and minimum field values. The solution obtained using C2 deviates considerably from the reference values.

Figure 5 compares the L_2 norm of the error in the electric field intensity, normalized by the number of nodes in the numerical domain, versus the number of nodes, for the C2, C4, MO, and O10 schemes. The errors are determined by considering the results obtained from a simulation on the highly resolved grid as an accurate reference solution. Since the number of nodes is inversely proportional to the mesh spacing squared, the C2 and C4 schemes display roughly second- and fourth-order convergence, respectively. This indicates that the effect of the corner singularity is not large. The MO and O10 schemes, which are formally second order as a result of the time-marching method, produce fourth-order accuracy over the range shown. However, our emphasis here is not on the asymptotic error behavior but on the grid density required to achieve specified error levels. The high-accuracy schemes show a significant advantage in this regard.

Figure 6 plots the error as a function of the computer time needed to obtain the solution. All schemes are implemented in a consistent manner. Hence computing time is an objective measure of cost, and similar relative performance is expected across computing platforms. It is clear that the high-accuracy schemes (MO and O10) are more efficient than the C4 and C2 schemes. To obtain the accuracy of the MO and

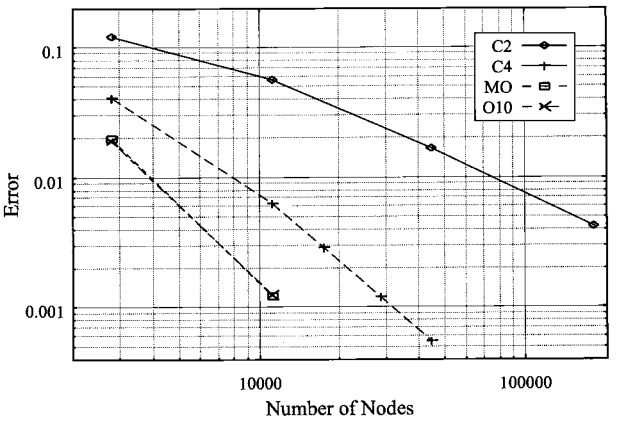

FIG. 5. L_2 *norm of the error in the electric field intensity for the dielectric square case, as a function of the number of nodes in the grid.*

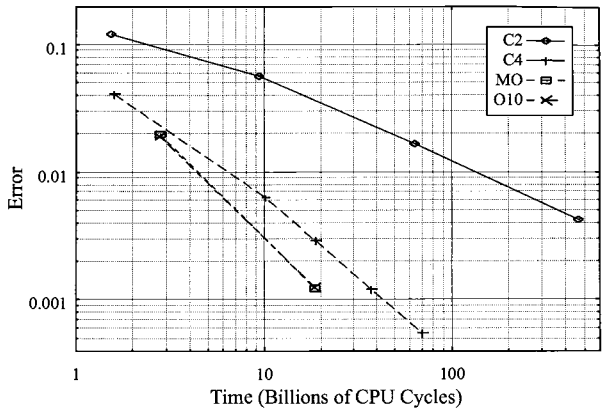

FIG. 6. L_2 *norm of the error in the electric field intensity for the dielectric square case, as a function of the CPU cycles necessary to complete simulation.*

O10 methods on a grid with 11,200 nodes, the C4 scheme needs to be run on a grid with 2.5 times as many grid nodes, requiring twice as much CPU time. The results obtained using C2 on a grid with 16 times as many nodes gives an error which is about 3.5 times as large as that obtained by the MO scheme, taking about 25 times longer to run. Even though the high-accuracy schemes take longer to run per grid node per time step, this is easily offset by the fact that smaller errors can be obtained by using a grid with far fewer nodes, and, as a result, a larger time step. The savings in memory is a direct result of using a grid with fewer nodes. The savings in both time and memory will be even more evident in three dimensions.

For the above cases the optimized method (O10) gives the same results as the MO scheme. This is primarily due to the nature of the Gaussian pulse, which has significant low wavenumber content. The majority of the Fourier components of the pulse have wavenumbers that give a value of $\kappa\Delta x < 0.35$ on the grid with 11,200 nodes. These are resolved more accurately by the MO scheme.

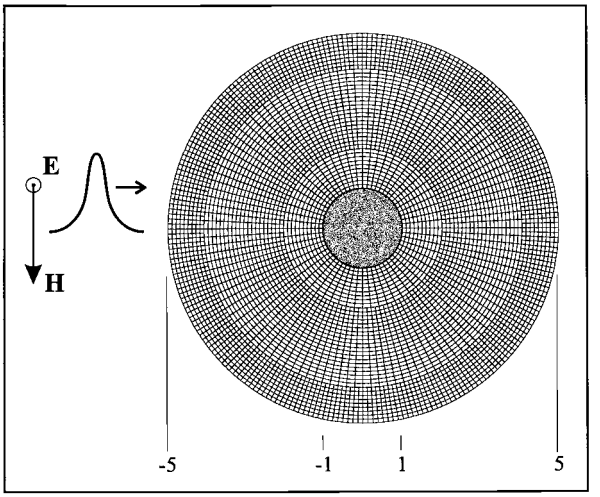

FIG. 7. *Example grid showing pulsed plane wave with Gaussian cross-section incident on a perfectly conducting cylinder.*

5.2. Perfectly conducting cylinder. We now consider an example using a curvilinear grid which consists of a waveform incident on a perfectly conducting cylinder. Figure 7 shows the geometry of the problem. The cylinder has a radius of unity, and the outer limit of the numerical domain is at $r = 5$. The speed at which a wave travels in free space is again normalized to unity. The waveform enters the domain from the left. The simulations described in section 5.2 of [12] are improved by modifying the grids so they are made up of three distinct zones. These grids, an example of which is shown in Figure 7, limit the widening of individual cells as one moves away from the scatterer, which allows the modeling of narrower pulses. This is a result of doubling the resolution of the grid, in the θ direction, whenever the value of r is doubled. This ensures that the waves are evenly resolved over the entire computational domain. The zones in the domain are allowed to overlap slightly in order to avoid the use of boundary operators where they interface. Interpolation must be used in order to obtain the field values at nodes that do not have corresponding nodes in the zone being overlapped. The interpolation schemes are described in the appendix. The grids are generated in order to obtain cells that have an aspect ratio close to 1 near the perfect conductor. When the aspect ratio deviates too much from this value, it is difficult to find boundary schemes that are stable and accurate for the high-accuracy methods. For all the tests, the time step is chosen so that the Courant number falls in the range 0.5 to 1.0. The grid metrics are calculated numerically using the same antisymmetric operator used in the calculation of the spatial derivatives of the electromagnetic fields. It should be emphasized that such a grid, i.e., one that produces a small range of Courant numbers, is not required in order to demonstrate the efficiency of the high-accuracy schemes, as shown in [12]. We have generated the grid in this manner simply to show that it can easily be done and to avoid a simulation in which the numerical errors are introduced primarily in one region of the grid.

5.2.1. Gaussian incident pulse. Consider a pulsed plane wave with a Gaussian cross-section incident on the cylinder. The incident electric field intensity is given by

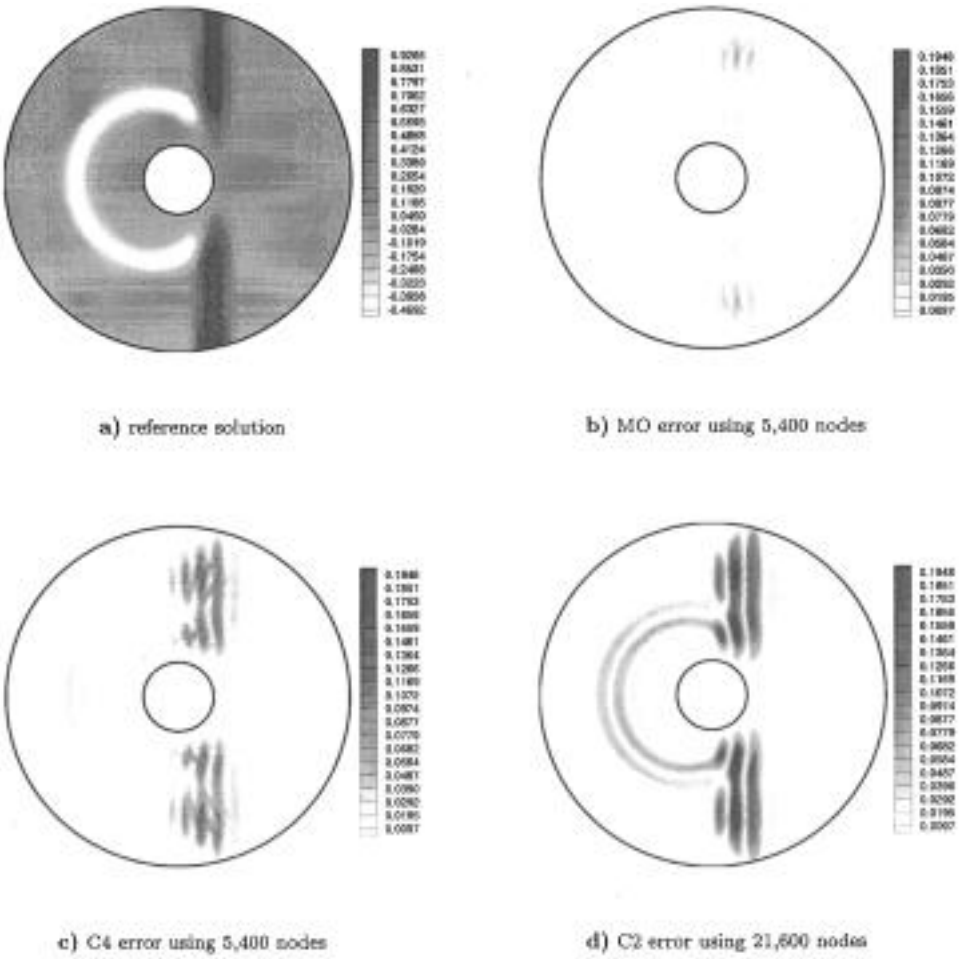

FIG. 8. *Contour plots of electric field intensity and errors in electric field intensity.* (a) *Reference solution,* (b) *MO error using* 5,400 *nodes,* (c) *C4 error using* 5,400 *nodes, and* (d) *C2 error using* 21,600 *nodes.*

$$E_z(x,y,t) = \exp\left[-\frac{1}{2\sigma^2}\left(x+\frac{15}{2}-t\right)^2\right] \tag{5.2}$$

with $\sigma = 0.3$, and the simulation is run until $t = 8.5$. Figure 8(a) shows a contour plot of the electric field intensity for a reference solution calculated using the MO scheme on a grid with 345,600 nodes. The absolute value of the error obtained using the MO scheme on a grid with 5,400 nodes is shown in Figure 8(b). Even though this grid is fairly coarse, the errors are seen to be very small. Plots of the errors obtained using method C4 on the grid with 5,400 nodes and method C2 on a grid with 21,600 nodes are shown in Figures 8(c) and (d), respectively. Both of these solutions show significant deviations from the reference solution.

The electric field intensity along the x-axis, behind the perfect conductor, is shown in Figure 9. In this region, the solution is not visible in Figure 8(a) and is very sensitive to numerical errors. The reference solution, the results from the MO

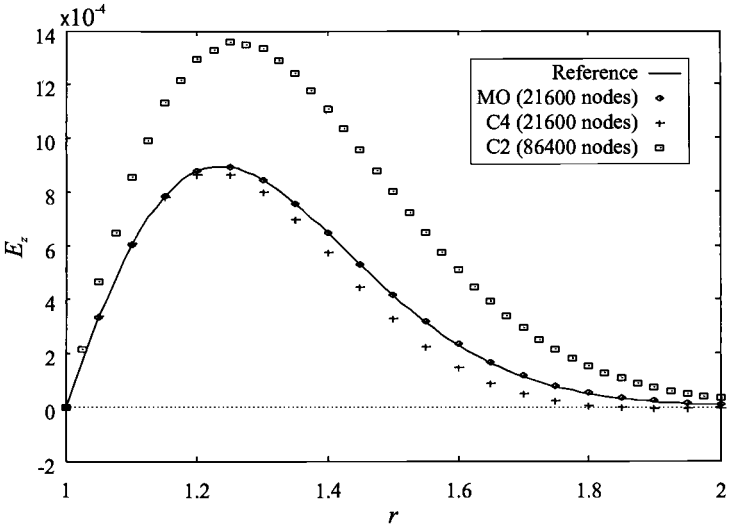

FIG. 9. *Electric field intensity along a radial line behind the perfectly conducting cylinder for an incident pulse with a Gaussian cross-section.*

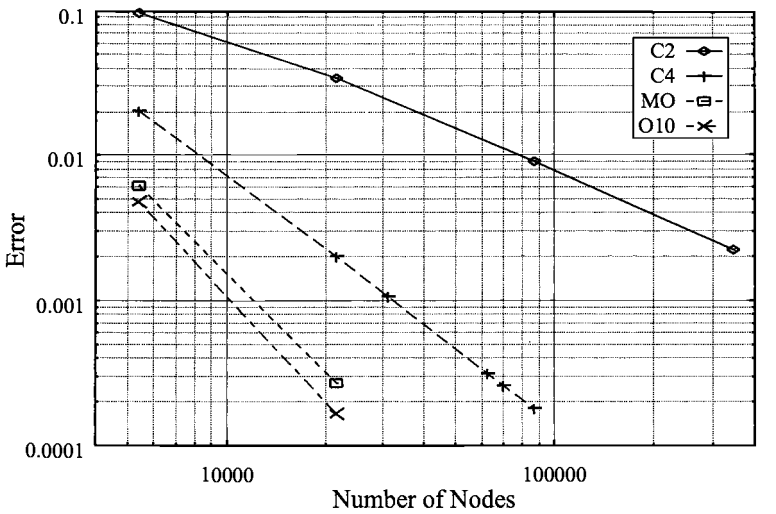

FIG. 10. L_2 *norm of the error in the electric field intensity as a function of the number of nodes in the grid for a pulsed plane wave incident on the perfectly conducting cylinder.*

scheme on a grid having 21,600 nodes, the results from the C4 scheme on a grid with 21,600 nodes, and the results from the C2 scheme on a grid with 86,400 nodes are all shown. The solution obtained using the MO scheme is very accurate. Using the same grid, the C4 method produces a solution that deviates significantly from the reference solution. The solution obtained by using C2 on a grid with four times as many nodes is not adequate for engineering purposes.

Figure 10 shows the normalized L_2 norm of the errors in the electric field intensity as a function of the number of nodes in the grid, and Figure 11 shows the error as a function of the CPU usage. The error value for each test is calculated using a reference

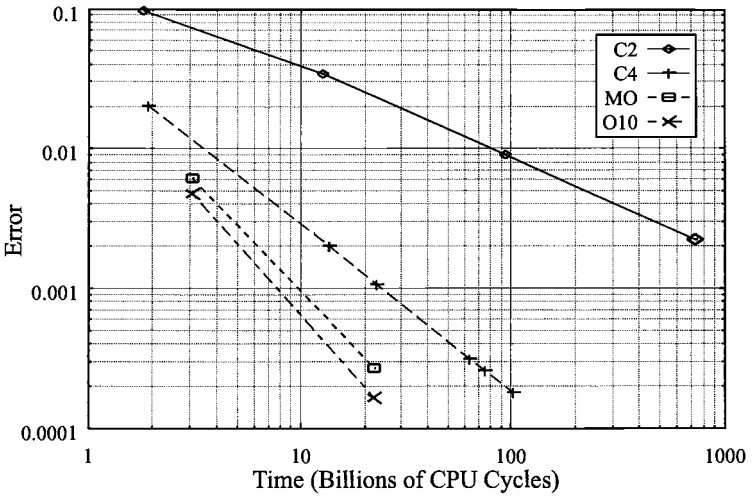

FIG. 11. L_2 *norm of the error in the electric field intensity as a function of the number of CPU cycles it takes to complete the simulation for a pulsed plane wave incident on the perfectly conducting cylinder.*

solution obtained using the MO scheme on a highly resolved grid. The trends shown in these figures are very similar to those obtained for the dielectric square case. To attain the same error level as the MO scheme used on a grid with 21,600 nodes, the C4 scheme must use about 3.25 times as many nodes and takes about 3.4 times as long to complete the simulation. Even when using a grid with 345,600 nodes, the C2 method does not produce a solution that can compare with those computed by the high-accuracy methods on a grid with 21,600 nodes. The O10 scheme is seen to produce slightly better results than the MO scheme when using the same grid. For example, on the grid with 21,600 nodes, the O10 scheme results in an error that is 61% of that obtained using the MO scheme, with no additional CPU expense.

5.2.2. Cosine incident wave. In this section, simulations of a cosine plane wave incident on the perfectly conducting cylinder are presented. The existence of an analytical solution for a plane harmonic electromagnetic wave incident upon a perfectly conducting circular cylinder is well known and can be found in, for example, [7]. The incident electric field intensity is given by

$$E_z(x, y, t) = \cos \kappa(x - t) \tag{5.3}$$

with $\kappa = 2\pi$. A shaded contour plot of the analytical solution for the total electric field intensity is shown in Figure 12.

Figure 13 compares the errors as a function of the number of nodes in the grids. Figure 14 plots these errors as a function of the CPU time needed to complete the simulations. These plots again show the superior efficiency of the high-accuracy methods. The second-order method produces significant errors for all three of the grids. The fourth-order method needs to use the most resolved grid to generate a solution with acceptable accuracy, which can be produced by the high-accuracy methods on a grid with four times fewer nodes. Figure 15 shows the electric field intensity along a radial line directly behind the scatterer for the analytical, fourth-order, and MO solutions. The numerical solutions were obtained on a grid with 21,600 nodes. The solution ob-

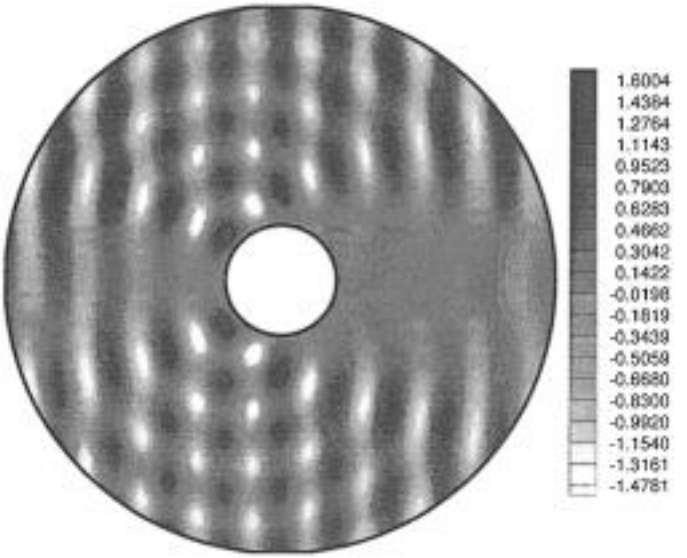

FIG. 12. *Electric field intensity for cosine wave, with* $\kappa = 2\pi$*, incident on a perfectly conducting cylinder.*

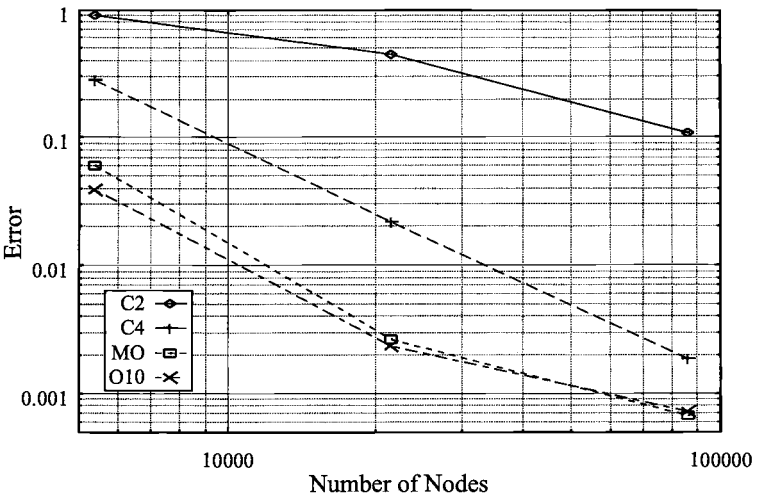

FIG. 13. L_2 *norm of the error in the electric field intensity as a function of the number of nodes in the grid for a cosine wave, with* $\kappa = 2\pi$*, incident on the perfectly conducting cylinder.*

tained using the MO method is considerably more accurate than that obtained using the fourth-order method.

The optimized scheme does not show significant improvement over the maximum-order scheme in the above tests because of the relatively short distance of travel for the waves being considered. To test longer distances of travel (in terms of wavelength) a highly resolved grid with 345,600 nodes is used, and incident waves with much higher wavenumbers are modeled. With $\kappa = 8\pi$, the wave is resolved with 10 to 20 PPW and travels 32 wavelengths during the simulation. For this case, the optimized method produces an error that is about 40% of that produced by the MO scheme. With

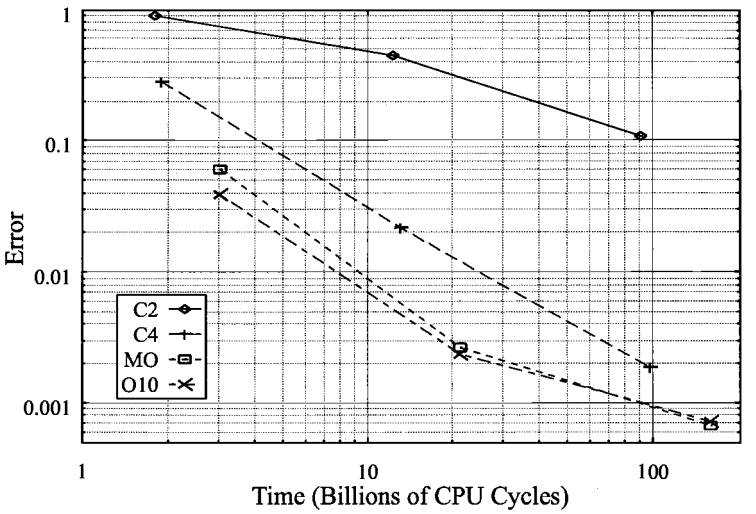

FIG. 14. L_2 *norm of the error in the electric field intensity as a function of the CPU time necessary to complete the simulation for a cosine wave, with* $\kappa = 2\pi$, *incident on the perfectly conducting cylinder.*

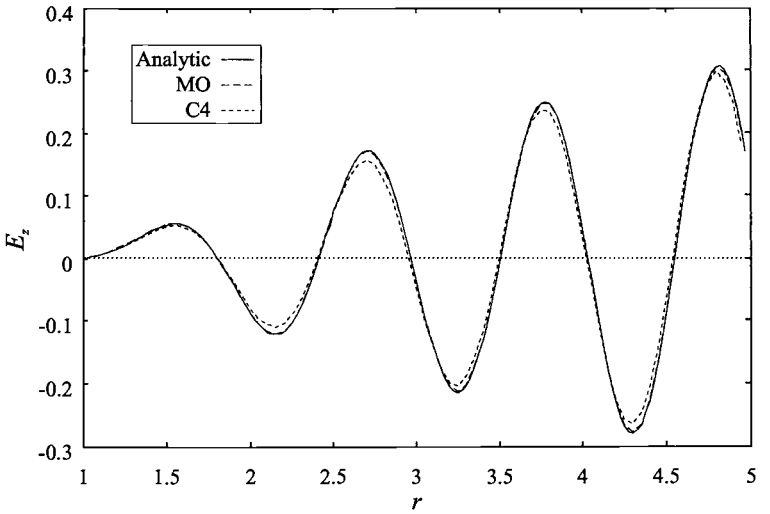

FIG. 15. *Electric field intensity along a radial line behind the perfectly conducting cylinder for an incident cosine wave with* $\kappa = 2\pi$.

$\kappa = 10\pi$, the resolution is 8 to 16 PPW, and the distance of travel is 40 wavelengths. For this wavenumber, the optimized method produces an error that is about 25% of that produced by the maximum-order scheme. This shows that the benefits of the optimized scheme increase as the number of wavelengths traveled between reflections increases.

6. Conclusions. Two high-accuracy finite-difference schemes have been used to solve the two-dimensional time-domain Maxwell equations to simulate electromagnetic wave propagation and scattering. The schemes have successfully modeled perfectly

conducting and dielectric scatterers on Cartesian and curvilinear grids. The high-accuracy methods have been shown to be more efficient than classical second-order and fourth-order methods in terms of computing time and memory. The optimized scheme can produce some error reduction relative to the maximum-order scheme with no additional expense, especially when the number of wavelengths of travel is large. Overall, the results demonstrate that these methods are an efficient option for simulating the propagation and scattering of high-frequency electromagnetic waves.

Appendix. The following are the coefficients of the optimized scheme:

$$a_1 = 0.759961, \quad a_2 = -0.158122, \quad a_3 = 0.0187609,$$
$$d_0 = 0.1, \quad d_1 = -0.0763846, \quad d_2 = 0.0322896, \quad d_3 = -0.005905,$$
$$\alpha_1 = 0.168850, \quad \alpha_2 = 0.197348, \quad \alpha_3 = 0.250038, \quad \alpha_4 = 0.333306, \quad \alpha_5 = 0.5.$$

The following are the extrapolation and interpolation schemes used along interfaces:

$$u_j = 6u_{j+1} - 15u_{j+2} + 20u_{j+3} - 15u_{j+4} + 6u_{j+5} - u_{j+6},$$
$$u_{j+1/2} = (3u_{j-2} - 25u_{j-1} + 150u_j + 150u_{j+1} - 25u_{j+2} + 3u_{j+3})/256,$$
$$u_{j+1/2} = (-7u_{j-1} + 105u_j + 210u_{j+1} - 70u_{j+2} + 21u_{j+3} - 3u_{j+4})/256,$$
$$u_{j+1/2} = (63u_j + 315u_{j+1} - 210u_{j+2} + 126u_{j+1} - 45u_{j+4} + 7u_{j+5})/256,$$
$$u_j = \frac{3}{4}(u_{j-1} + u_{j+1}) - \frac{3}{10}(u_{j-2} + u_{j+2}) + \frac{1}{20}(u_{j-3} + u_{j+3}).$$

The following can be used to calculate the absolute value of the flux Jacobians and the split flux Jacobians, for example, $|\hat{\mathbf{A}}| = |\hat{\mathbf{J}}(\xi)|$ and $\hat{\mathbf{B}}^{\pm} = \hat{\mathbf{J}}^{\pm}(\eta)$:

$$|\hat{\mathbf{J}}(k)| = \begin{bmatrix} c|\nabla k| & 0 & 0 \\ 0 & c\frac{1}{|\nabla k|}\left(\frac{\partial k}{\partial y}\right)^2 & c\frac{1}{|\nabla k|}\frac{\partial k}{\partial x}\frac{\partial k}{\partial y} \\ 0 & -c\frac{1}{|\nabla k|}\frac{\partial k}{\partial x}\frac{\partial k}{\partial y} & c\frac{1}{|\nabla k|}\left(\frac{\partial k}{\partial x}\right)^2 \end{bmatrix},$$

$$\hat{\mathbf{J}}^{\pm}(k) = \frac{1}{2}\begin{bmatrix} \pm c|\nabla k| & \frac{1}{\mu}\frac{\partial k}{\partial y} & -\frac{1}{\mu}\frac{\partial k}{\partial x} \\ \frac{1}{\varepsilon}\frac{\partial k}{\partial y} & \pm c\frac{1}{|\nabla k|}\left(\frac{\partial k}{\partial y}\right)^2 & \mp c\frac{1}{|\nabla k|}\frac{\partial k}{\partial x}\frac{\partial k}{\partial y} \\ -\frac{1}{\varepsilon}\frac{\partial k}{\partial x} & \mp c\frac{1}{|\nabla k|}\frac{\partial k}{\partial x}\frac{\partial k}{\partial y} & \pm c\frac{1}{|\nabla k|}\left(\frac{\partial k}{\partial x}\right)^2 \end{bmatrix},$$

where

$$|\nabla k| = \sqrt{\left(\frac{\partial k}{\partial x}\right)^2 + \left(\frac{\partial k}{\partial y}\right)^2}.$$

The following are the local characteristic variables in the ξ (use $k = \xi$) and η (use $k = \eta$) directions:

$$w_+ = ZD_z + \left(\frac{\partial k}{\partial y}B_x - \frac{\partial k}{\partial x}B_y\right) \Big/ |\nabla k|,$$

$$w_- = ZD_z - \left(\frac{\partial k}{\partial y}B_x - \frac{\partial k}{\partial x}B_y\right) \Big/ |\nabla k|.$$

SUPERCONVERGENT DEFERRED CORRECTION METHODS FOR FIRST ORDER SYSTEMS OF NONLINEAR TWO-POINT BOUNDARY VALUE PROBLEMS*

MARNIX VAN DAELE† AND JEFF R. CASH‡

Abstract. Iterated deferred correction is a widely used approach to the numerical solution of first order systems of nonlinear two-point boundary value problems. Normally the orders of accuracy of the various methods used in a deferred correction scheme differ by 2, and, as a direct result, each time a deferred correction is applied the order of the overall scheme is increased by a maximum of 2. In this paper we consider the construction of mono-implicit Runge–Kutta (MIRK) methods where an increase of four orders of accuracy is obtained for each deferred correction. We develop a very powerful yet rather straightforward theory which allows us to identify the appropriate Runge–Kutta formulae for inclusion in such schemes. In particular, we will focus on the construction of pairs of MIRK formulae of order 4 and 8 which will allow this superconvergence to be realized. We will further show that it is possible to derive formulae of this type for which high order interpolants and accurate error estimates are readily available.

Key words. deferred correction, mono-implicit Runge–Kutta formula, superconvergence, stability, two-point boundary value problems

1. Introduction.

In this paper we will be concerned with the numerical solution of the first order system of nonlinear two-point boundary value problems

$$\frac{dy}{dx} = f(x,y), \quad a \le x \le b, \quad g(y(a), y(b)) = 0. \tag{1.1}$$

A widely used technique for the solution of such problems is iterated deferred correction. A single step of a typical deferred correction scheme based on implicit Runge–Kutta formulae can be defined as follows.

Let ϕ_i, ϕ_j be two Runge–Kutta formulae of order i and j, respectively, where $i < j$. Consider the algorithm defined by

$$\phi_i(\eta) = 0, \tag{1.2}$$

$$\phi_i(\bar{\eta}) = -\phi_j(\eta). \tag{1.3}$$

Here η is the solution of the Runge–Kutta formula of order i while $\bar{\eta}$ denotes the (more accurate) solution of the deferred correction scheme (1.3). Then, providing that ϕ_i and ϕ_j have certain special properties, the deferred correction scheme defined by (1.2), (1.3) is of order j. There is a nice heuristic argument for this approach which goes as follows. Let η be the $O(h^i)$ approximation obtained from $\phi_i(\eta) = 0$, and let η^* be the $O(h^j)$ approximation corresponding to $\phi_j(\eta^*) = 0$. We could in principal compute $\bar{\eta}$ from $\phi_i(\bar{\eta}) = \phi_i(\eta^*)$. Of course we cannot do this in practice because the

right-hand side of this expression is unknown. However, it can be estimated in the following way:

$$\begin{aligned}\phi_i(\eta^*) &= \phi_i(\eta^*) - \phi_j(\eta^*) \\ &\approx \phi_i(\eta) - \phi_j(\eta) \\ &= -\phi_j(\eta),\end{aligned}$$

which gives (1.3). The important question now is what are the conditions under which

$$\|\bar{\eta} - y\| = O(h^j), \tag{1.4}$$

where y is the true solution of (1.1).

Algorithms of this type based on mono-implicit Runge–Kutta (MIRK) methods have been derived in [7], [8], [9], while deferred correction schemes based on Lobatto formulae are developed in [1]. Two codes TWPBVP and ACDC which implement deferred correction schemes are available from NETLIB and from the web page of one of the authors.[1] The first of these codes is based on MIRK formulae, while the second uses Lobatto formulae with continuation.

A somewhat similar defect correction approach has been given by Schild [18]. His investigation started from the observation that Gaussian collocation is an excellent algorithm for the numerical solution of two-point boundary value problems but that the effort required to compute the collocation spline grows rapidly with order. Schild proposed to implement Gaussian collocation via defect correction. Whereas our approach uses only formulae of order 4 and 8, the Schild defect correction scheme uses Gaussian formulae of orders $2, 4, 6$, and 8. In this way Schild's defect correction algorithm typically reduces the error by a factor of $O(h^2)$ per iteration. The question of whether an order 2 starting formula would be more robust than an order 4 formula for difficult problems, where a good initial mesh and solution is hard to find, and whether the complete sequence of orders $2, 4, 6$, and 8 gives better a posteriori error estimates than just orders 4 and 8 is still an open question which is certainly worthy of further investigation.

In what follows we will consider the rather more general deferred correction scheme

$$\phi(\eta) = 0, \tag{1.5}$$

$$\phi(\bar{\eta}) = \psi(\eta)\,. \tag{1.6}$$

A general framework for proving accuracy results for deferred correction schemes of the form (1.5), (1.6) was given in an influential paper by Skeel [19]. In what follows we present his main theorem.

Consider the approximate numerical solution of (1.1) on a mesh

$$\pi : a = x_1 < x_2 < \cdots < x_{N+1} = b.$$

Denote by Δy the restriction of the continuous solution $y(x)$ to the finite grid π. Then we have the following theorem.

THEOREM 1.1. *Let ϕ be a stable numerical method, and assume that the following conditions hold for the deferred correction scheme* (1.5), (1.6):

(i) $\|\eta - \Delta y\| = O(h^p)$,

[1] http://www.ic.ac.uk/~jcash/BVP_software

(ii) $\|\psi(\Delta y) - \phi(\Delta y)\| = O(h^{r+p})$,

(iii) $\psi(\Delta w) = O(h^r)$

for arbitrary functions w having at least r continuous derivatives. Here $\|.\|$ is a suitable finite norm defined in [19], *and h is the maximum grid spacing. If $\phi(\bar{\eta}) = \psi(\eta)$, then*

$$\|\bar{\eta} - \Delta y\| = O(h^{r+p})\,.$$

The feature that is common to all of the deferred correction schemes that have been derived so far is that $r = 2$ and for these schemes the order of accuracy is increased by 2 for each application of the deferred correction. See also [16]. In [1] a sufficient condition to achieve this increase in accuracy was given and this was basically that the Runge–Kutta formulae ϕ_i and ϕ_j should be symmetric and that they should be written in a special way that is appropriate for boundary value problems. This condition is, of course, straightforward to satisfy. The main reason why it is hard to get more than two orders of accuracy improvement per iteration is the difficulty in satisfying condition (iii) for $r > 2$.

The purpose of the present paper is to address the question of whether it is possible to choose ϕ_i and ϕ_j so that we can achieve $r > 2$ while maintaining the efficiency of the deferred correction scheme. We will call deferred correction schemes with $r > 2$ superconvergent, and, in particular, we will investigate the minimum number of stages required to obtain superconvergent MIRK schemes. By focussing on pairs of MIRK formulae of order 4 and 8 we will show that it is possible to achieve this superconvergence and that the resulting deferred correction schemes have potential advantages over some other deferred correction schemes that have been derived.

2. MIRK methods. A special class of MIRK formulae for the numerical solution of stiff initial value problems was first proposed in [10]. These formulae were derived as reflections of standard explicit Runge–Kutta methods, and as a result their order and stability were easy to determine. A rather more general class of MIRK formulae was derived in [2], [11] for initial value problems and in [12] for boundary value problems. The analysis of these schemes was simplified considerably by the work of Enright and Muir [13], who introduced MIRK formulae as a particular class of what they called parameterized IRK methods. These formulae can be written in the general form

$$y_{n+1} = y_n + h \sum_{i=1}^{s} b_i\, f(x_n + c_i\, h,\, Y_i), \tag{2.1}$$

$$Y_i = (1 - v_i)\, y_n + v_i\, y_{n+1} + h \sum_{j=1}^{s} x_{ij}\, f(x_n + c_j\, h,\, Y_j), \qquad i = 1, \ldots, s\,. \tag{2.2}$$

Hence, an s-stage parameterized IRK method is completely determined by the tableau $(b,\, X,\, c,\, v)$, denoted as

$$\begin{array}{c|c|cccc} c_1 & v_1 & x_{11} & x_{12} & \ldots & x_{1s} \\ c_2 & v_2 & x_{21} & x_{22} & \ldots & x_{2s} \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ c_s & v_s & x_{s1} & x_{s2} & \ldots & x_{ss} \\ \hline & & b_1 & b_2 & \ldots & b_s \end{array} \tag{2.3}$$

If we compare this representation with that of a general IRK method in terms of its Butcher tableau $(c,\, A,\, b)$ [4], it is easy to verify that the relationship $A = X + v.b^T$

holds. For all methods to be derived in this paper, we will assume that the row-sum condition holds, i.e., $A.e = X.e + v = c$, where e is the s-vector with unit entries. By imposing the restriction that X (or X after a rearrangement of its rows and columns) is a strictly lower triangular matrix, one obtains MIRK methods, and it is exactly this property of X which characterizes MIRK methods. This characterization of MIRK formulae in terms of the matrix X considerably helps in their derivation and shows clearly their special structure. We illustrate this by considering the well-known Clippinger–Dimsdale formula [17, p. 160].

$$\begin{array}{c|ccc} 0 & 0 & 0 & 0 \\ \frac{1}{2} & \frac{5}{24} & \frac{1}{3} & -\frac{1}{24} \\ 1 & \frac{1}{6} & \frac{2}{3} & \frac{1}{6} \\ \hline & \frac{1}{6} & \frac{2}{3} & \frac{1}{6} \end{array} \tag{2.4}$$

At first sight there is nothing remarkable about this formula. However, it is clear that it can be rewritten in the form

$$y_{n+1} - y_n = \frac{h}{6}(k_1 + 4k_2 + k_3), \tag{2.5}$$

where

$$k_1 = f(x_n, y_n), k_2 = f\left(x_{n+\frac{1}{2}}, \frac{y_n + y_{n+1}}{2} - \frac{h}{8}(k_3 - k_1)\right), k_3 = f(x_{n+1}, y_{n+1}). \tag{2.6}$$

Note that (2.5) and (2.6) are a representation of (2.4) in its "eliminated" form (i.e., where the internal stages Y_i ,$i = 1, 2, \ldots s$, have been eliminated). In the algorithmic realization of our deferred correction algorithms, it is the eliminated forms of the MIRK formulae that are used throughout so that the only unknowns in each mesh interval are y_n and y_{n+1}. If we now introduce the notation used in (2.3), we can rewrite (2.4) as

$$\begin{array}{c|cc|ccc} 0 & 0 & & 0 & 0 & 0 \\ 1 & 1 & & 0 & 0 & 0 \\ \frac{1}{2} & \frac{1}{2} & & \frac{1}{8} & -\frac{1}{8} & 0 \\ \hline & & & \frac{1}{6} & \frac{1}{6} & \frac{2}{3} \end{array} \tag{2.7}$$

This can now be identified from (2.7) as a MIRK formula since the matrix X is strictly lower triangular. In [3] several results concerning the order and stability of MIRK methods have been established. Among the more important of these results are the following theorems.

THEOREM 2.1. *An s-stage pth order MIRK method satisfies $p \leq s + 1$.*

THEOREM 2.2. *The stage order of a MIRK method is 3 at most.*

THEOREM 2.3. *For the test equation $y' = \lambda y$, $y(x_0) = y_0$ one can write $y_n = R(\lambda h)^n y_0$, where $R(z) = P(e - v, z)/P(-v, z)$ with $P(w, z) = 1 + z\, b^T.(I - z\, X)^{-1}.w = 1 + \sum_{i=1}^{s} z^i\, b^T.X^{i-1}.w$.*

MIRK methods have not been widely used so far for the numerical solution of initial value problems. This is due primarily to the fact that if the nonlinear algebraic

equations arising from the application of a MIRK formula are solved using some form of Newton iteration, then the coefficient matrix of the Newton scheme is a polynomial in the Jacobian matrix. Furthermore, stability problems may also arise, as explained in [20]. However, the situation for boundary value problems is quite different. If the MIRK formulae for the solution of (1.1) are written in a deferred correction framework, then the deferred corrections $\psi(\eta)$ are explicit and thus cheap to compute. Furthermore, the linear algebra cost of computing $\bar{\eta}$ from (1.3) is relatively small, and the required stability properties of the underlying formulae are maintained. This in turn means that algorithms for local error estimation and mesh changing are relatively cheap, and this makes deferred correction methods based on MIRK formulae very competitive with other algorithms for the solution of (1.1).

3. Deferred correction with MIRK methods. As we have mentioned in the previous section, all deferred correction methods which have so far been used for the solution of two-point boundary value problems increase the order by 2 for each deferred correction. The reason why higher increases in the order of accuracy have not been obtained is because of the difficulty of satisfying condition (iii) of Theorem 1.1. In this section we examine the possibility of increasing the order of accuracy by 4 for each iteration. This problem has also been looked at in the context of initial value problems in [20], [21], and many of the ideas contained in these two papers will be important in what follows. Before we start our analysis we wish to remark that our derivation holds not only for MIRK methods but also for any paramaterized Runge–Kutta method.

Let ϕ be a MIRK method of order p, and define $\psi := \phi - \phi^*$, where ϕ^* corresponds to a MIRK method of order $p^* > p$. (We will systematically denote the quantities that relate to ϕ^* with a *-superscript : s^*, a^*_{ij}, b^*_i, c^*_i, ...) The formula $\phi(\Delta\eta)$ can then be written as

$$\phi(\eta)_{n+1} := \frac{1}{h}\,(\eta_{n+1} - \eta_n) - \sum_{i=1}^{s} b_i\, f(x_n + c_i\, h,\, Y_i)\,.$$

To analyze the conditions of Theorem 1.1, we write down the B-series expansions for ϕ and ϕ^*. We therefore rewrite $\phi(\eta)_{n+1}$ as

$$\begin{aligned} g_i &= (1 - v_i)\,\eta_n + v_i\,\eta_{n+1} + \sum_{j=1}^{s} x_{ij}\,k_j, \\ k_i &= h\,f(x_n + c_i\,h,\, g_i), \\ \phi(\eta)_{n+1} &= \frac{\eta_{n+1} - \eta_n - \sum_{i=1}^{s} b_i\,k_i}{h}. \end{aligned}$$

Now if $g_i = B(\boldsymbol{g_i},\, \eta_n)$, $k_i = B(\boldsymbol{k_i},\, \eta_n)$, $\eta_{n+1} = B(\boldsymbol{\eta_{n+1}}, \eta_n)$, and $h\,\phi(\eta)_{n+1} = B(\boldsymbol{\phi_{n+1}},\, \eta_n)$ are all B-series, then Corollary 12.7 in [14] allows us to transcribe these formulas for each labelled tree $t = [t_1 \cdots t_m]$ as

$$\begin{cases} \boldsymbol{g_i}(t) = v_i\,\boldsymbol{\eta_{n+1}}(t) + \displaystyle\sum_{j=1}^{s} x_{ij}\,\boldsymbol{k_j}(t), \\ \boldsymbol{k_i}(t) = \rho(t)\,\boldsymbol{g_i}(t_1)\,\boldsymbol{g_i}(t_2)\cdots\boldsymbol{g_i}(t_m), \\ \boldsymbol{\phi_{n+1}}(t) = \boldsymbol{\eta_{n+1}}(t) - \displaystyle\sum_{j=1}^{s} b_j\,\boldsymbol{k_j}(t) \end{cases}$$

with $\boldsymbol{g_i}(\emptyset) = 1$, $\boldsymbol{k_i}(\tau) = 1$, and $\boldsymbol{\phi_{n+1}}(\emptyset) = 1$.

For condition (i) of Theorem 1.1, it follows from $\phi(\eta)_{n+1} = 0$ that $\boldsymbol{\phi_{n+1}}(t) = 0$ for all t, such that

$$\begin{cases} \boldsymbol{g_i}(t) = \sum_{j=1}^{s} (v_i\, b_j + x_{ij})\, \boldsymbol{k_j}(t), \\ \boldsymbol{k_i}(t) = \rho(t)\, \boldsymbol{g_i}(t_1)\, \boldsymbol{g_i}(t_2) \cdots \boldsymbol{g_i}(t_m), \\ \boldsymbol{\eta_{n+1}}(t) = \sum_{j=1}^{s} b_j\, \boldsymbol{k_j}(t). \end{cases}$$

Let $y_n(h) = B(\boldsymbol{y_n}, \eta_n)$ be the true solution of $y' = f(x, y)$, $y(x_n) = \eta_n$; then $\boldsymbol{y_n}(t) = 1$ for all t, and the well-known order conditions up to order p are obtained by comparing the coefficients of the B-series $B(\boldsymbol{y_n}, \eta_n)$ and $B(\boldsymbol{\eta_{n+1}}, \eta_n)$.

Condition (ii) of Theorem 1.1 analogously describes that ϕ^* has order p^*.

For the third condition of Theorem 1.1, we replace η by an arbitrary function w and the corresponding B-series $B(\boldsymbol{\eta_{n+1}}, \eta_n)$ by $B(\boldsymbol{w_{n+1}}, \eta_n)$. Condition (iii) then leads to

$$\sum_{j=1}^{s} b_j\, \boldsymbol{k_j}(t) - \sum_{j=1}^{s^*} b_j^*\, \boldsymbol{k_j^*}(t) = 0 \tag{3.1}$$

for all t with $\rho(t) \le r$, whereby

$$\begin{cases} \boldsymbol{g_i}(t) = v_i\, \boldsymbol{w_{n+1}}(t) + \sum_{j=1}^{s} x_{ij}\, \boldsymbol{k_j}(t), \\ \boldsymbol{k_i}(t) = \rho(t)\, \boldsymbol{g_i}(t_1)\, \boldsymbol{g_i}(t_2) \cdots \boldsymbol{g_i}(t_m), \end{cases} \qquad i = 1, \ldots, s,$$

$$\begin{cases} \boldsymbol{g_i^*}(t) = v_i^*\, \boldsymbol{w_{n+1}}(t) + \sum_{j=1}^{s^*} x_{ij}^*\, \boldsymbol{k_j^*}(t), \\ \boldsymbol{k_i^*}(t) = \rho(t)\, \boldsymbol{g_i^*}(t_1)\, \boldsymbol{g_i^*}(t_2) \cdots \boldsymbol{g_i^*}(t_m), \end{cases} \qquad i = 1, \ldots, s^*.$$

We thus find for all trees t with $\rho(t) \le 4$

$$\sum_{j=1}^{s} b_j\, \boldsymbol{k_j}(\tau) = 1,$$

$$\sum_{j=1}^{s} b_j\, \boldsymbol{k_j}([\tau]) = 2\, b^T.v\, \boldsymbol{w_{n+1}}(\tau) + 2\, b^T.X.e,$$

$$\sum_{j=1}^{s} b_j\, \boldsymbol{k_j}([\tau^2]) = 3\, b^T.v^2\, \boldsymbol{w_{n+1}}(\tau)^2 + 6\, b^T.(v\, X.e)\, \boldsymbol{w_{n+1}}(\tau) + 3\, b^T.(X.e)^2,$$

$$\sum_{j=1}^{s} b_j\, \boldsymbol{k_j}([_2\tau]_2) = 3\, b^T.v\, \boldsymbol{w_{n+1}}([\tau]) + 6\, b^T.X.v\, \boldsymbol{w_{n+1}}(\tau) + 6\, b^T.X^2.e,$$

$$\sum_{j=1}^{s} b_j\, \boldsymbol{k_j}([\tau^3]) = 4\, b^T.v^3\, \boldsymbol{w_{n+1}}(\tau)^3 + 12\, b^T.(v^2\, X.e)\, \boldsymbol{w_{n+1}}(\tau)^2$$

$$
\begin{aligned}
&\qquad +12\,b^T.(v\,(X.e)^2)\,\boldsymbol{w_{n+1}}(\tau) + 4\,b^T.(X.e)^3,\\
\sum_{j=1}^{s} b_j\,\boldsymbol{k_j}([\tau[\tau]_2) &= 4\,b^T.v^2\,\boldsymbol{w_{n+1}}(\tau)\,\boldsymbol{w_{n+1}}([\tau]) + 4\,b^T.(v\,X.e)\,\boldsymbol{w_{n+1}}([\tau])\\
&\qquad +8\,[b^T.(X.e\,X.v) + b^T.(v\,X^2.e)]\,\boldsymbol{w_{n+1}}(\tau)\\
&\qquad +8\,b^T.(v\,X.v)\,\boldsymbol{w_{n+1}}(\tau)^2 + 8\,b^T.(X.e\,X^2.e),\\
\sum_{j=1}^{s} b_j\,\boldsymbol{k_j}([{}_2\tau^2]_2) &= 4\,b^T.v\,\boldsymbol{w_{n+1}}([\tau^2]) + 12\,b^T.X.v^2\,\boldsymbol{w_{n+1}}(\tau)^2\\
&\qquad +24\,b^T.X.(v\,X.e)\,\boldsymbol{w_{n+1}}(\tau) + 12\,b^T.X.(X.e)^2,\\
\sum_{j=1}^{s} b_j\,\boldsymbol{k_j}([{}_3\tau]_3) &= 4\,b^T.v\,\boldsymbol{w_{n+1}}([{}_2\tau]_2) + 12\,b^T.X.v\,\boldsymbol{w_{n+1}}([\tau]) + 24\,b^T.X^2.v\,\boldsymbol{w_{n+1}}(\tau)\\
&\qquad +4\,b^T.X^3.e.
\end{aligned}
$$

If condition (3.1) has to be fulfilled for any B-series $\boldsymbol{w_{n+1}}$ and for any method ϕ of order p and any method ϕ^* of order p^*, where $p^* \geq p \geq r$, we obtain an extra set of conditions. If we assume that both ϕ and ϕ^* have stage order at least 1 and we take into account that the order conditions up to order r are fulfilled, then we must have that $r \leq \max\{i|E_i = 0\}$, where

$$
\begin{aligned}
&E_1 := 0,\\
&E_2 := |b^T.v - b^{*T}.v^*|,\\
&E_3 := |b^T.v^2 - b^{*T}.v^{*2}| + |b^T.(c\,v) - b^{*T}.(c^*\,v^*)| + |b^T.X.v - b^{*T}.X^*.v^*|,\\
&E_4 := |b^T.v^3 - b^{*T}.v^{*3}| + |b^T.(c\,v^2) - b^{*T}.(c^*\,v^{*2})| + |b^T.(c^2\,v) - b^{*T}.(c^{*2}\,v^*)|\\
&\qquad +|b^T.X.v^2 - b^{*T}.X^*.v^{*2}| + |b^T.X^2.v - b^{*T}.X^{*2}.v^*|\\
&\qquad +|b^T.(v\,X.v) - b^{*T}.(v^*\,X^*.v^*)| + |b^T.(c\,X.v) - b^{*T}.(c^*\,X^*.v^*)|\\
&\qquad +|b^T.(X.c\,v) - b^{*T}.(X^*.c^*\,v^*)| + |b^T.X.(c\,v) - b^{*T}.X^*.(c^*\,v^*)|,\\
&E_5 := \cdots.
\end{aligned}
\tag{3.2}
$$

It is of interest to note that for a general MIRK method the stage order equations read

$$
kX.c^{k-1} = c^k - v, \qquad k = 1, 2, \ldots, q, \tag{3.3}
$$

whereas (3.2) involves $X.v$ rather than $X.c$. To really use the stage order conditions in this analysis we would need to choose $c = v$ and $c^* = v^*$. We will see later that this is indeed the choice we make.

The expressions E_i can be generalized: each E_i ($i \geq 2$) contains all strings of i elements of which b^T and v are the first and last ones. In between is a permutation with replacement of 3 in groups of $i - 2$ from the set $\{c, v, X\}$.

We thus find that, while the value of r in condition (iii) is 1 in general, it can be raised to 2 or even higher. In [5], [6], where symmetric methods are used, the value $r = 2$ is obtained since for all symmetric methods $b^T.v = 1/2$. Symmetry is, however, not necessary for $r = 2$. The above result also shows that convergence can be accelerated if some extra conditions are satisfied. We call such methods superconvergent.

Of course, the question of how to satisfy the conditions (3.2) still remains. For the case $q = 4$, for example, there are 13 extra conditions. It would seem that these

conditions will significantly increase the number of stages required by the method. Some of these conditions can be eliminated if one uses methods with high stage order, but most of them remain to be fulfilled. There is, however, one important case for which (3.2) imposes no extra conditions: indeed, if $c = v$ and $c^* = v^*$, then all expressions which appear in (3.2) are fixed numbers since they are order conditions (re-expressed in terms of X). If $c = v$ and $c^* = v^*$, the value $r = p$ is thus obtained automatically. In the following section, we will investigate the existence of deferred correction schemes based on MIRK methods for which $c = v$. We further restrict ourselves to symmetric methods, a natural choice in the context of BVPs.

The conditions of symmetry for a Runge–Kutta method are well known and can be expressed as follows: if x_n and x_{n+1} and y_n and y_{n+1} are swapped, and if h is replaced by $-h$, then the original method is obtained. The MIRK formula tableau is a particularly convenient representation for the investigation of symmetry. The condition for symmetry comes down to the requirement that there must exist a permutation σ of the stages such that for each stage Y_i there exists a stage $Y_{\sigma(i)}$ for which $c_{\sigma(i)} = 1 - c_i$, $v_{\sigma(i)} = 1 - v_i$, and $x_{\sigma(i)\sigma(j)} = -x_{ij}$.

4. Superconvergent deferred correction schemes based on symmetric MIRK methods with $c = v$. It was shown in the previous section that, in the quest for superconvergent deferred correction schemes, there are some important advantages to be gained by making the particular choice $v = c$. In what follows we will refer to formulae with this particular choice as MIRKA formulae. As was shown in the previous section, the superconvergence conditions for MIRKA formulae reduce to standard order conditions. The main result that we will give in this section is a lower bound on the number of stages of symmetric MIRKA methods of a given (even) order.

A MIRK formula is conveniently characterized by the properties of its X matrix. Hence in what follows we will develop a framework to derive high order MIRKA formulae in terms of the elements x_{ij}.

Stage order. If $c = v$, then stage order q is obtained if and only if

$$C(q) \ : X.c^{k-1} = \frac{1}{k}\,(c^k - c)\,, \qquad k = 1, \ldots, q\,.$$

In particular, the row-sum condition $A.e = c$ means $X.e = (0, 0, \ldots, 0)^T$.

We now investigate the relationship between the order p and the minimum number of stages s of a MIRKA formula. The situation for $s = 1$ is very straightforward.

The implicit midpoint rule is a symmetric MIRKA formula with only one stage and is of order 2. Its tableau is

(4.1)

$\frac{1}{2}$	$\frac{1}{2}$	0
		1

For higher values of p (p must be even because we are only considering symmetric formulae) we have the following theorem.

THEOREM 4.1. *A symmetric MIRKA formula of order $p \geq 4$ requires at least $s = 2\,p - 5$ stages.*

This theorem relies on the following lemmas, which are straightforward to prove.

LEMMA 4.2. *The stability function of a MIRKA formula is given by*

$$R(h) = \frac{1 + h - h\,S(h)}{1 - h\,S(h)} = 1 + \frac{h}{1 - h\,S(h)},$$

where $S(h) = b^T.(I - h\,X)^{-1}.c = \sum_{i=0}^{s}(b^T.X^i.c)\,h^i$,

Since $R(h)$ is an approximation to $\exp(h)$, it follows that $S(h) \approx \frac{1}{2} + \frac{1}{h} - \frac{1}{2}\coth\frac{h}{2}$.

LEMMA 4.3. *If* $S(h) = \frac{1}{2} + \frac{1}{h} - \frac{1}{2}\coth\frac{h}{2} + \mathcal{O}(h^{2\,l+1})$, *then* $R(h) = \exp(h) + \mathcal{O}(h^{2\,l+3})$.

LEMMA 4.4. *For a symmetric nonconfluent s-stage MIRK formula, one has* $X^{s'} = O$, *where* $s' = \lfloor\frac{s+1}{2}\rfloor$ *and where* O *is the matrix of appropriate size with zero entries.*

With the help of these lemmas, we can now prove Theorem 4.1.

Proof. Suppose we are looking for a symmetric formula of order $p \geq 4$. Then, according to Lemma 4.3, we must have

$$S(h) - \left(\frac{1}{2} + \frac{1}{h} - \frac{1}{2}\coth\frac{h}{2}\right) = \mathcal{O}(h^{p-1})\,,$$

which means that, since $\frac{1}{h} - \frac{1}{2}\coth\frac{h}{2}$ is odd, $S(h)$ must be a polynomial of degree $p-3$ at least and according to Lemma 4.2, X^{p-3} does not vanish. From Lemma 4.4 it follows that

$$p - 3 < s' = (s+1)/2.$$

This now gives the result that

$$\begin{cases} s \geq 2\,p - 4 & \text{if } s \text{ is even,} \\ s \geq 2\,p - 5 & \text{if } s \text{ is odd.} \end{cases} \qquad \square$$

For $p = 4$ it follows that $s = 3$ stages is sufficient, as is demonstrated by the Lobatto formula (2.7). In order to find higher order methods, it is standard practice to reduce the number of order equations by making various simplifying assumptions. One possibility is to choose the stage order to be as high as possible. This is the approach that we will adopt in this paper, and in what follows we will consider only MIRKA methods with stage-order 3. We now give a lemma which will help in the construction of symmetric MIRKA methods of this type.

LEMMA 4.5. (i) *If a symmetric MIRKA method is nonconfluent, then stage order* 3 *implies that* $c_3 = 1/2$ *(which means that s will be odd);* (ii) *the fourth and fifth stages can only have order of consistency at most* 3, *while the sixth and seventh stages have order of consistency (stage order) at most* 5, *and so on.*

For $p = 6$ and $p = 8$ the minimum number of stages is given by Theorem 4.1 as 7 and 11, respectively. In the next section we will investigate these two cases. First, we will show that $p = 8$ can only be achieved with at least 13 stages. We will construct such a family of methods with 13 stages, and we will show that it is possible (i) to add an 8th order interpolant and (ii) to add an embedded method of order 6 with a 6th order interpolant. Second, we will use some ideas from the case $p = 8$ to show that $p = 6$ can be obtained with seven stages.

5. The construction of symmetric MIRKA methods. In this section we consider the derivation of an order 8 method using the classical approach of Butcher.

5.1. Order 8 methods. It is well known that, if the stage order conditions are satisfied ad infinitum, the only order conditions that remain to be satisfied are the quadrature conditions. These take the form

$$b^T.c^k = \frac{1}{k+1}, \qquad k = 0,\,1,\,\ldots\,.$$

However, it is also well known that the stage order of MIRK methods is bounded by 3. In order to minimize the number of remaining order conditions, we will try to construct methods for which the stage order reaches the maximum value. If this is done, it follows that, apart from the quadrature conditions, there are 26 order conditions left. We will see later that the minimum number of stages for a symmetric MIRKA method of order 8 is 13, and this leads us to consider the scheme A given in the appendix.

We will choose $b_3 = b_4 = 0$ to reduce the effect of low stage order for stages 3, 4, and 5. It is clear that in this case x_{ij} $(1 \le j \le 3)$ can be expressed in terms of c_i and x_{ij} $(4 \le j < i)$.

We note that the matrix X contains 2 by 2 matrices of the form

$$\begin{pmatrix} x_{ij} & x_{i,j+1} \\ -x_{i,j+1} & -x_{ij} \end{pmatrix} = \frac{y_{ij}}{2} \begin{pmatrix} 1 & -1 \\ 1 & -1 \end{pmatrix} + \frac{z_{ij}}{2} \begin{pmatrix} 1 & 1 \\ -1 & -1 \end{pmatrix} = y_{ij}\, Y + z_{ij}\, Z,$$

where $y_{ij} = x_{ij} - x_{i,j+1}$ and $z_{ij} = x_{ij} + x_{i,j+1}$. The matrices Y and Z appearing on the right-hand side of this identity are very easy to work with when considering powers of X. This is first because they are nilpotent, and second, we have the identities $ZYZ = Z$ and $YZY = Y$. This motivates us to work with the y and z variables instead of the x variables. To complete this transformation we also need to define $z_{i3} = x_{i3}$.

We now constrain all stages to have order of consistency 5, except stages 3, 4, and 5, which have order of consistency 3. (This is the maximum that we can achieve for these stages).

These extra conditions imply that all coefficients in the upper seven stages are constants or are expressed in terms of c_4 and c_6. In the last six stages, some degrees of freedom are left and we let the undetermined variables be y_{86}, z_{86}, $y_{10,6}$, $y_{10,8}$, $z_{10,6}$, $z_{10,8}$, $y_{12,6}$, $y_{12,8}$, $y_{12,10}$, $z_{12,6}$, $z_{12,8}$, and $z_{12,10}$.

If the conditions that are to be satisfied by the different stages are written in terms of the y_{ij} and z_{ij} variables, it can be shown that for $i = 2, 3, \ldots, 6$,

$$y_{2i,j} = \mathcal{Y}^{[0]}_{2i,j} + \sum_{k=3}^{i-1} \mathcal{Y}^{[k]}_{j}\, y_{2i,2k}\,, \qquad j = 1,\, 4\,, \tag{5.1}$$

$$z_{2i,j} = \mathcal{Z}^{[0]}_{2i,j} + \sum_{k=3}^{i-1} \mathcal{Z}^{[k]}_{j}\, z_{2i,2k}, \qquad j = 1,\, 3,\, 4\,, \tag{5.2}$$

where the $\mathcal{Y}$ and $\mathcal{Z}$ coefficients depend only on the elements of the vector c.

Due to the above choices, many of the remaining conditions are automatically satisfied. Indeed, the choices made allow us to state that, for example, all order conditions associated with trees of the form $[\tau^i[\tau^3]_2$ and $[\tau^i[\tau^4]_2$ (i.e., in the expression for the order equation the matrix A appears only once) are automatically satisfied.

We now need to satisfy the 14 remaining conditions. We first re-express these conditions in terms of X instead of A since this will make the equations easier to work with. Thus, for example, we have the conditions

$$b^T.X.c^i = -\frac{i}{2\,(i+1)\,(i+2)}\,, \tag{5.3}$$

which still remain to be satisfied for $i = 5$ and $i = 6$. However, these conditions are not independent of each other. Defining

$$\begin{cases} Y_1 = b_6\, y_{61} + b_8\, y_{81} + b_{10}\, y_{10,1} + b_{12}\, y_{12,1}, \\ Y_4 = b_6\, y_{64} + b_8\, y_{84} + b_{10}\, y_{10,4} + b_{12}\, y_{12,4}, \\ Y_6 = b_8\, y_{86} + b_{10}\, y_{10,6} + b_{12}\, y_{12,6}, \\ Y_8 = b_{10}\, y_{10,8} + b_{12}\, y_{12,8}, \\ Y_{10} = b_{12}\, y_{12,10}, \end{cases}$$

the conditions (5.3) can be rewritten as $E_i = 0$, where

$$E_i := Y_1 + \sum_{j=2}^{5} (c_{2\,j}^i - (1 - c_{2\,j})^i)\, Y_{2\,j} + \frac{i}{2\,(i+1)\,(i+2)}\,.$$

It can then immediately be shown that

$$\sum_{i=0}^{n} (-1)^i \binom{n}{i} E_{2\,n-i} = 0\,.$$

Using the identities

$$(1-1)^n = \sum_{i=0}^{n} (-1)^i \binom{n}{i} = 0$$

and

$$x^n\,(x-1)^n = \sum_{i=0}^{n} (-1)^i \binom{n}{i} x^{2\,n-i} = \sum_{i=0}^{n} (-1)^i \binom{n}{i} (1-x)^{2\,n-i}\,,$$

it follows that

$$\sum_{i=0}^{n} (-1)^i \binom{n}{i} \left(x^{2\,n-i} - (1-x)^{2\,n-i}\right) = 0\,.$$

From this last term we obtain the expression

$$x^{n+2}\,(1-x)^n - x^n\,(1-x)^{n+2} = x^n\,(1-x)^n\,(2\,x-1) = \sum_{i=0}^{n} (-1)^i \binom{n}{i} (2\,x^{2\,n+1-i} - x^{2\,n-i}),$$

and after integration between 0 and 1 we have

$$\begin{aligned} 0 &= \sum_{i=0}^{n} (-1)^i \binom{n}{i} \left(\frac{2}{2\,n+2-i} - \frac{1}{2\,n+1-i} \right) \\ &= \sum_{i=0}^{n} (-1)^i \binom{n}{i} \frac{2\,n-i}{(2\,n+1-i)\,(2\,n+2-i)}\,. \end{aligned}$$

This shows that $E_6 = 0$ is automatically satisfied if $E_5 = 0$ is satisfied. We can thus impose the equivalent condition $E_5 - E_6 = 0$:

$$\sum_{i=3}^{5} Y_{2\,i}\, c_{2\,i}\, (1 - c_{2\,i})\, (c_{2\,i}^4 - (1 - c_{2\,i})^4) = -\frac{1}{168}. \tag{5.4}$$

To satisfy the remaining 13 conditions, we use the fact that

$$w_j = X\,c^j - \frac{1}{j+1}(c^{j+1} - c)\,, \qquad j = 3,\, 4, \tag{5.5}$$

has three nonzero components, and we replace every order condition of the form $b^T.M.X.c^j = \cdots$ (where M is any product of $C = \mathrm{diag}(c_1, \ldots, c_s)$ and X matrices) by $b^T.M.w_j = 0$.

This leads to the following five conditions:

$$0 = Y_4, \tag{5.6}$$

$$0 = \sum_{i=2}^{5} Y_{2\,i}\, z_{2\,i,3}, \tag{5.7}$$

$$0 = \sum_{i=3}^{5} Y_{2\,i}\, z_{2\,i,4}, \tag{5.8}$$

$$0 = \sum_{i=2}^{6} b_{2\,i}\ (2\,c_{2\,i} - 1)\ z_{2\,i,3}, \tag{5.9}$$

$$0 = \sum_{i=3}^{6} b_{2\,i}\ (2\,c_{2\,i} - 1)\ z_{2\,i,4}. \tag{5.10}$$

Due to the structure of (5.2), (5.9)–(5.10) can be rewritten as

$$\alpha(c_4,\, c_6)\, Z_6 + \alpha(c_4,\, c_8)\, Z_8 + \alpha(c_4,\, c_{10})\, Z_{10} = \frac{2 - 7\,c_4 + 7\,c_4^2}{2520}, \tag{5.11}$$

$$\beta(c_6)\, Z_6 + \beta(c_8)\, Z_8 + \beta(c_{10})\, Z_{10} = \frac{1}{2520} \tag{5.12}$$

in terms of the variables Z_6, Z_8, and Z_{10}, where

$$\begin{cases} Z_6 = b_8\,(1 - 2\,c_8)\, z_{86} + b_{10}\,(1 - 2\,c_{10})\, z_{10,6} + b_{12}\,(1 - 2\,c_{12})\, z_{12,6}, \\ Z_8 = b_{10}\ (1 - 2\,c_{10})\, z_{10,8} + b_{12}\,(1 - 2\,c_{12})\, z_{12,8}, \\ Z_{10} = b_{12}\,(1 - 2\,c_{12})\, z_{12,10}\,. \end{cases}$$

The equations (5.4) and (5.6) form a system of two equations in the three unknowns Y_6, Y_8, and Y_{10}. We can solve this system for Y_6 and Y_8 in terms of Y_{10} to give

$$Y_6 = -\frac{1}{\alpha(c_8,\, c_6)\,(1 - 2\,c_6)}\ \left[\frac{1 - 7\,c_8 + 7\,c_8^2}{840} + \alpha(c_8,\, c_{10})\,(1 - 2\,c_{10})\, Y_{10}\right], \tag{5.13}$$

$$Y_8 = -\frac{1}{\alpha(c_6,\, c_8)\,(1 - 2\,c_8)}\ \left[\frac{1 - 7\,c_6 + 7\,c_6^2}{840} + \alpha(c_6,\, c_{10})\,(1 - 2\,c_{10})\, Y_{10}\right], \tag{5.14}$$

where $\alpha(c,\, d) = d\,(1 - d)\,(c - d)\,(1 - c - d)$.

Substituting these results into (5.7) and (5.8), the following two relations are obtained:

$$\frac{7\,c_4^2 - 7\,c_4 + 2}{5040} = \alpha(c_4,\, c_6)\, Y_{10}\, z_{10,6} + \alpha(c_4,\, c_8)\, Y_{10}\, z_{10,8} - \frac{\alpha(c_4,\, c_6)}{\alpha(c_6,\, c_8)\,(1 - 2\,c_8)}\, Q\, z_{86}, \tag{5.15}$$

$$\frac{1}{5040} = \beta(c_6)\, Y_{10}\, z_{10,6} + \beta(c_8)\, Y_{10}\, z_{10,8} - \frac{\beta(c_6)}{\alpha(c_6,\, c_8)\,(1 - 2\,c_8)}\, Q\, z_{86}, \tag{5.16}$$

where $Q = \frac{1 - 7\,c_6 + 7\,c_6^2}{840} + \alpha(c_6,\, c_{10})\,(1 - 2\,c_{10})\, Y_{10}$ and $\beta(c) = c\,(1 - c)\,(1 - 2\,c)^2$.

From the above, it follows that solutions can exist only for $Y_{10} \neq 0$, i.e., $b_{12} \neq 0$. This implies that if stage order three is assumed, at least 13 stages are needed!

Although this result is somewhat disappointing, there are actual advantages in considering 13 stages. First, now that we know we cannot choose $b_{12} = 0$, we are able to choose $b_6 = 0$. It now follows that, for a method of order 8, the four remaining variables of the b-vector can be uniquely determined in terms of the c-values. Further, we can also raise the order of consistency of the lower six stages from 5 to 7. This in turn allows us to construct an eighth order interpolant $u_8(x)$. For reasons of symmetry, we could impose, for example, the following conditions on a polynomial of degree nine:

$$\begin{aligned}
&u_8(x_n) = y_n, \qquad u_8(x_n + h) = y_{n+1},\\
&u_8'(x_n) = k_1, \qquad u_8'(x_n + h) = k_2,\\
&u_8'(x_n + c_{2i}\,h) = f(x_n + c_{2i}\,h,\, u_8(x_n + c_{2i}\,h)) = k_{2i}, \qquad i = 4,\, 5,\, 6,\\
&u_8'(x_n + (1 - c_{2i})\,h) = f(x_n + (1 - c_{2i})\,h,\, u_8(x_n + (1 - c_{2i})\,h)) = k_{2i+1}\,, i = 4,\, 5,\, 6.
\end{aligned}$$

Raising the order of consistency of the last six stages from 5 to 6 means that (5.1) also holds for $j = 6$. (We are now left with $y_{10,8}$, $y_{12,8}$, and $y_{12,10} \neq 0$ as free y-coefficients.) It also follows that (5.4) is automatically satisfied. From (5.6) one obtains relation (5.14) between Y_8 and Y_{10}. If no further conditions are imposed, then we have the following procedure for obtaining an 8th order method.

- The system (5.15)–(5.16) can be solved for $Y_{10}\, z_{10,6}$ and $Y_{10}\, z_{10,8}$ in terms of Y_{10} and z_{86}.
- The system (5.11)–(5.12) can then be solved for Z_6 and Z_8 in terms of Z_{10}.

If we now analyze the construction process, we can conclude that we have constructed a family of methods which, apart from c_4, c_6, c_8, c_{10}, and c_{12}, still has four free parameters: $y_{12,10}$ ($\neq 0$), $z_{12,10}$, z_{86}, and either $y_{10,8}$ or $y_{12,8}$.

However, the interpolant requires that the order of consistency of the last six stages is raised from 6 to 7. This means that (5.2) also holds for $j = 6$ ($z_{10,8}$, $z_{12,8}$, and $z_{12,10}$ are the remaining free z-coefficients). Due to the structure of (5.2), the equations can be solved as follows.

- The system (5.15)–(5.16) is linear in Y_{10} and $Y_{10}\, z_{10,8}$. Solving this system, we can thus fix Y_{10} and $z_{10,8}$ in terms of the c-values.
- The system (5.11)–(5.12) can be solved for Z_8 and Z_{10} in terms of the c-values.
- Y_8 is determined by Y_{10} in (5.14). As a consequence, $y_{12,8}$ is a function of $y_{10,8}$ or vice versa.

In this way we have constructed a family of methods which, apart from c_4, c_6, c_8, c_{10}, and c_{12}, still has one free parameter: either $y_{10,8}$ or $y_{12,8}$. It follows from earlier

analysis that all of these methods will have the same stability function, which is

$$R_2(h) = \frac{N_2(h)}{D_2(h)} = \frac{1 + \frac{h}{2} + \frac{h^2}{12} - \frac{h^4}{720} + \frac{h^6}{30240}}{1 - \frac{h}{2} + \frac{h^2}{12} - \frac{h^4}{720} + \frac{h^6}{30240}}\,.$$

For IVPs the combination of (2.7), for which the stability function is given by

$$R_1(h) = \frac{N_1(h)}{D_1(h)} = \frac{1 + \frac{h}{2} + \frac{h^2}{12}}{1 - \frac{h}{2} + \frac{h^2}{12}},$$

and any of these 8th order methods leads to an unstable scheme since the stability function [20] is given by

$$\begin{aligned} R(h) &= \frac{[D_1(h) - D_2(h)]\, R_1(h) + N_2(h)}{D_1(h)} \\ &= \frac{1 - \frac{h^2}{12} + \frac{h^4}{144} + \frac{h^5}{720} - \frac{h^7}{30240}}{\left(1 - \frac{h}{2} + \frac{h^2}{12}\right)^2}. \end{aligned}$$

For BVPs, however, the stability function [6] is given by

$$R(h,\, n) = R_1(h)^n \,\left[R_1(h) + (n+1)\,(R_2(h) - R_1(h))\right],$$

where

$$R_2(h) - R_1(h) = \frac{\frac{h^5}{720} - \frac{h^7}{30240}}{\left(1 - \frac{h}{2} + \frac{h^2}{12}\right)\,\left(1 - \frac{h}{2} + \frac{h^2}{12} - \frac{h^4}{720} + \frac{h^6}{30240}\right)}.$$

Note now that

$$\lim_{h\to\infty} R(h,\, n) = 1\,,$$

i.e., the stability function is bounded for all values of h. We give the coefficients of our 8th order formula in section A of the appendix.

We now construct an embedded MIRK method $(\hat{b},\, X,\, c,\, c)$ of order 6. To do so, we note that apart from the quadrature conditions, three conditions remain to be satisfied: namely,

$$\hat{b}^T.X.X.c^3 = \frac{1}{240}, \qquad \hat{b}^T.(c\,X).c^3 = -\frac{1}{24}, \qquad \hat{b}^T.X.c^4 = -\frac{1}{15}\,.$$

It is clear that these conditions are satisfied if $\hat{b}_3 = 0 = \hat{b}_4$. In order to have a method of order 6, we need at least three nonzero $\hat{b}$-coefficients, and therefore it follows that there are 6th order embedded methods with nine stages. Due to the fact that all of the stages with nonzero $\hat{b}$-weight have order of consistency 5 at least, it follows that these embedded methods have an interpolant $u_6(x)$ of order 6. This can be realized by imposing the conditions

$$\begin{aligned} &u_6(x_n) = y_n, \qquad u_6(x_n + h) = y_{n+1}, \\ &u_6'(x_n) = k_1, \qquad u_6'(x_n + h) = k_2, \\ &u_6'(x_n + c_{2i}\,h) = f(x_n + c_{2i}\,h,\, u_6(x_n + c_{2i}\,h)) = k_{2\,i}, \qquad i = 3,\, 4, \\ &u_6'(x_n + (1 - c_{2i})\,h) = f(x_n + (1 - c_{2i})\,h,\, u_6(x_n + (1 - c_{2i})\,h)) = k_{2\,i+1}, \quad i = 3,\, 4. \end{aligned}$$

The $\hat{b}$ coefficients for the embedded formula are given in section B of the appendix.

5.2. Order 6 methods. We use the same approach as was followed in the previous section to construct methods of order 6 with seven stages. We propose a scheme of the form

$$\begin{array}{c|c|ccccccc}
0 & 0 & & & & & & & \\
1 & 1 & 0 & & & & & & \\
\frac{1}{2} & \frac{1}{2} & \frac{1}{8} & -\frac{1}{8} & & & & & \\
c_4 & c_4 & x_{41} & x_{42} & x_{43} & & & & \\
1-c_4 & 1-c_4 & -x_{42} & -x_{41} & -x_{43} & 0 & & & \\
c_6 & c_6 & x_{61} & x_{62} & x_{63} & x_{64} & x_{65} & & \\
1-c_6 & 1-c_6 & -x_{62} & -x_{61} & -x_{63} & -x_{65} & -x_{64} & 0 & \\
\hline
 & & b_1 & b_1 & b_3 & b_4 & b_4 & b_6 & b_6
\end{array}$$

which has stage order 3, and for which the last two stages have order of consistency 5. All x-variables can thus be expressed in terms of c_4 and c_6 only. We choose the same $c_i s$ as were used with the 8th order formula. In this case the x variables are exactly the same as those appearing in the 8th order formula because we impose the same stage order conditions on both formulae. If this is done, there are three nonquadrature conditions that remain to be satisfied. It turns out that all of these three conditions are satisfied if

$$b_3 = -32\, c_4^2\, (1-c_4)^2\, b_4\,. \tag{5.17}$$

The three quadrature conditions together with (5.17) gives a system which uniquely determines the four b-coefficients. In this way we have constructed a two-parameter family (c_4 and c_6) of symmetric mono-implicit methods of order 6 which have $c = v$ and have seven stages. The coefficients of this 6th order formula are given in section C in the appendix.

6. Computational aspects. In order to compare the computational effort required by the superconvergent deferred correction algorithm described in this paper with that required by a standard deferred correction method such as TWPBVP, we first recall exactly how the code TWPBVP is implemented. The classical deferred correction approach on which the code TWPBVP is based is as follows:

$$\begin{aligned}
&\phi_4(\eta) = 0,\\
&\phi_4(\bar{\eta}) = -\phi_6(\eta),\\
&\phi_4(\bar{\bar{\eta}}) = -\phi_6(\eta) - \phi_8(\bar{\eta}).
\end{aligned} \tag{6.1}$$

Here the vector solutions η, $\bar{\eta}$, and $\bar{\bar{\eta}}$ are of order 4, 6, and 8, respectively. We note, in particular, that since (6.1) is not superconvergent, it is not possible to compute the 8th order solution before the 6th order one is computed. Once $\bar{\eta}$ and $\bar{\bar{\eta}}$ have been computed, we can determine whether or not an accuracy requirement of the form

$$\|\bar{\eta} - \bar{\bar{\eta}}\| < Tol \tag{6.2}$$

is satisfied, where Tol is the requested tolerance. If (6.2) is satisfied, then the solution $\bar{\bar{\eta}}$ is accepted as the final solution, and if not, a remeshing is carried out. The particular remeshing algorithm used in TWPBVP is one which seeks to equidistribute the deferred correction term

$$\phi_8(\bar{\eta}). \tag{6.3}$$

In the case of superconvergent schemes, however, the situation is quite different. Now the deferred correction scheme can be regarded as having the form (6.1), where the third stage is

$$\phi_4(\bar{\bar{\eta}}) = -\bar{\phi}_8(\eta). \tag{6.4}$$

Note, in particular, that both the deferred correction terms in this modified superconvergent scheme depend only on the 4th order solution η. Furthermore, the only role of the $\bar{\eta}$ term is as an error estimate, and this particular aspect of the algorithm has some important consequences. The most important of these is the fact that $\bar{\eta}$ and $\bar{\bar{\eta}}$ can be computed independently of each other. Indeed, in a parallel environment these two terms can be computed at the same time. This means that in the linear case we can solve for the error estimate without knowing either $\bar{\eta}$ or $\bar{\bar{\eta}}$. This is done in the following way. From the last two equations of the deferred correction scheme we have

$$\phi_4(\bar{\bar{\eta}} - \bar{\eta}) = \phi_6(\eta) - \bar{\phi}_8(\eta). \tag{6.5}$$

Thus the revised algorithm for the linear case now is

$$\begin{aligned} \phi_4(\eta) &= 0, \\ \phi_4(\bar{\bar{\eta}} - \bar{\eta}) &= \phi_6(\eta) - \bar{\phi}_8(\eta). \end{aligned} \tag{6.6}$$

Having computed the error estimate $\bar{\bar{\eta}} - \bar{\eta}$ from (6.6), we now see if it satisfies the error criterion (6.2). If it does, then we accept the current grid as the final one and compute the solution $\bar{\bar{\eta}}$ on this grid using the first equation of (6.1) together with (6.4). If the error estimate (6.2) is not satisfied, then we remesh using an algorithm based on the equidistribution of $\phi_6(\eta) - \bar{\phi}_8(\eta)$. The saving in computational effort results from the fact that we do not need to compute $\bar{\bar{\eta}}$ until the error estimate is satisfied. Ideally we would like to be able to extend this algorithm to the nonlinear case, but we have been unable to do this.

The computational effort per iteration for the two schemes is rather similar. Both require the solution of the 4th order formula

$$\phi_4(\eta) = 0 \tag{6.7}$$

initially. The standard scheme (6.1) then requires 14 function evaluations to compute the deferred correction terms while the modified scheme requires 13. The relative performance of the two algorithms is, however, very problem dependent due to their complicated structure. In particular, it depends on the number of iterations required to solve $\phi_4(\eta) = 0$, the relative cost of the linear algebra compared with that of function evaluations, and the relative accuracies of the 6th and 8th order formulae in the deferred correction schemes. However, to give some idea of the relative performance we consider the following two problems.

PROBLEM 1 (see [15]). *The solution has a boundary layer of width $O(\sqrt{\epsilon})$ at $x = 0$.*

$$\epsilon y'' - y = 0, \quad y(0) = 1, \quad y(1) = 0.$$

The exact solution is $y(x) = (\exp(-x/\sqrt{\epsilon}) - \exp((x-2)/\sqrt{\epsilon}))/(1 - \exp(-2/\sqrt{\epsilon}))$.

PROBLEM 2 (see [15]). *The solution has a corner layer at $x = 0.745$.*

$$\epsilon y'' + (y')^2 = 1, \quad y(0) = 1 + \epsilon \ln\cosh(-0.745/\epsilon), \quad y(1) = 1 + \epsilon \ln\cosh(0.255/\epsilon).$$

The exact solution is $y(x) = 1 + \epsilon \ln \cosh(x - 0.745)/\epsilon)$.

In Tables 6.1 and 6.2 we give the results obtained for the numerical solution of these two problems using a tolerance of 10^{-8}. As we explained in the previous section, there are some arbitrary parameters to be chosen in our 8th order formula. In our code we chose $y_{12,8} = 0.1$, c_4=0.2, $c_6 = 0.25$, c_8=0.3, c_{10}=0.85, and $c_{12} = 0.6$, and the complete formula is given in the appendix.

TABLE 6.1
Results for Problem 1.

		TWPBVP			NEW	
ε	N	Time	Mesh err	N	Time	Mesh err
10^{-1}	7	.01	0.1d-8	28	.03	0.3d-13
10^{-2}	25	.03	0.3d-10	24	.02	0.2d-9
10^{-3}	35	.05	0.9d-9	35	.04	0.1d-9
10^{-4}	68	.06	0.7d-11	51	.05	0.2d-10
10^{-5}	52	.05	0.8d-9	45	.05	0.2d-8
10^{-6}	64	.10	0.5d-10	84	.07	0.3d-9
10^{-7}	90	.21	0.7d-11	101	.15	0.3d-9

The headings in the tables can be explained as follows. "N" indicates the number of mesh subintervals in the final mesh for each problem. "Time" denotes the run time in seconds. "Mesh err" is the maximum error that results from comparing the order 8 solution (computed at the mesh points) with the analytic solution. Under "NEW" we list the results obtained using the superconvergent scheme derived in section 5, while "TWPBVP" indicates the results obtained using the code TWPBVP.f obtained from NETLIB.

TABLE 6.2
Results for Problem 2.

		TWPBVP			NEW	
ε	N	Time	Mesh err	N	Time	Mesh err
10^{-1}	44	.13	0.42d-11	26	.09	0.4d-9
10^{-2}	51	.31	0.43d-10	63	.49	0.4d-8
10^{-3}	598	11.1	0.11d-10	94	9.4	0.4d-9

As can be seen from the two tables, the results obtained are quite comparable. Neither algorithm is consistently better than the other, and what these results indicate is that the superconvergent scheme is competitive with the widely used code TWPBVP.f. Also it is important to recall that the superconvergent scheme has associated with it an 8th order interpolant whereas the code TWPBVP.f has no interpolant. This makes it possible for the superconvergent scheme to provide a continuous solution, and this is an important advantage over previously derived MIRK schemes.

Finally, we wish to summarize the main points that have been achieved in this paper. The first important point that we have demonstrated is the possibility of obtaining superconvergence. In particular, we have derived an algebraic criterion for superconvergence and shown by some practical examples that this is actually achieved in practice. In addition, we have derived a framework which will allow us to derive high order MIRK methods. It is interesting to note that the original 8th order MIRK formula derived by Singhal took more than 40 pages of algebra to derive. The framework that we have derived makes the derivation of 8th order MIRK formulae very straightforward. We have not in any way optimized our 8th

order formula, and this is something worth doing in the future. In addition, we have derived a superconvergent MIRK formula with an 8th order interpolant. This has solved a very difficult outstanding problem since previous papers have derived only interpolants of order 4 and 6. Since our basic algorithm is of order 8, it is clear that it is an 8th order interpolant that is required. Finally, we remark that the theory of superconvergence developed in this paper is sufficiently general to be applicable to large classes of parameterized Runge–Kutta methods. We plan to investigate the extension of these ideas to other classes of Runge–Kutta methods in the future.

Appendix. In section A we give the MIRKA formula of order 8 in 13 stages. The $\hat{b}$ coefficients of the embedded method of order 6 are given in section B. In section C we present the MIRKA formula of order 6 in seven stages.

A. The 8th order MIRKA method. An 8th order formula in 13 stages is of the form

$$
\begin{array}{c|c|cccccccccccc}
0 & 0 & & & & & & & & & & & & \\
1 & 1 & 0 & & & & & & & & & & & \\
\frac{1}{2} & \frac{1}{2} & \frac{1}{8} & -\frac{1}{8} & & & & & & & & & & \\
c_4 & c_4 & x_{41} & x_{42} & x_{43} & & & & & & & & & \\
1-c_4 & 1-c_4 & -x_{42} & -x_{41} & -x_{43} & 0 & & & & & & & & \\
c_6 & c_6 & x_{61} & x_{62} & x_{63} & x_{64} & x_{65} & & & & & & & \\
1-c_6 & 1-c_6 & -x_{62} & -x_{61} & -x_{63} & -x_{65} & -x_{64} & 0 & & & & & & \\

$x_{12,2} = \frac{-349408852772543}{17343030480562500} + \frac{3}{400}\, y_{12,8}, x_{12,3} = \frac{15647244464}{53086359375} x_{12,4} = \frac{-3470436703}{1539011780460} + \frac{63}{176}\, y_{12,8},$
$x_{12,5} = \frac{367646969159}{1539011780460} - \frac{63}{176}\, y_{12,8}, x_{12,6} = \frac{719445043186076}{1202352953484375} - \frac{224}{275}\, y_{12,8},$
$x_{12,7} = \frac{358555969186076}{1202352953484375} + \frac{224}{275}\, y_{12,8}, x_{12,8} = \frac{-702597274}{1308047895} + \frac{1}{2}\, y_{12,8}, x_{12,9} = \frac{-702597274}{1308047895.0} - \frac{1}{2}\, y_{12,8},$
$x_{12,10} = \frac{-168424068}{536350969}, x_{12,11} = \frac{-25336068}{536350969}.$

B. The 6th order embedded MIRKA method. The three nonzero $\hat{b}$ coefficients for the 6th order embedded formula are

$$\hat{b_1} = \frac{1431859}{17459442},$$
$$\hat{b_6} = \frac{10346336}{52378326},$$
$$\hat{b_8} = \frac{11547250}{52378326}.$$

C. The 6th order MIRKA method. The b coefficients for the 6th order formula appearing in section 5.2 are

$$b_1 = \frac{6623}{79920},$$
$$b_3 = \frac{18944}{239760},$$
$$b_4 = \frac{-23125}{239760},$$
$$b_6 = \frac{37888}{79920}.$$

The c_i and $x_{i,j}$ coefficients are the same as in section A.

Acknowledgments. The authors are grateful to two anonymous referees whose suggestions greatly improved the presentation of this paper.

FAST SOLUTION OF THE RADIAL BASIS FUNCTION INTERPOLATION EQUATIONS: DOMAIN DECOMPOSITION METHODS*

R. K. BEATSON†, W. A. LIGHT‡, AND S. BILLINGS§

Abstract. In this paper we consider domain decomposition methods for solving the radial basis function interpolation equations. There are three interwoven threads to the paper. The first thread provides good ways of setting up and solving small- to medium-sized radial basis function interpolation problems. These may occur as subproblems in a domain decomposition solution of a larger interpolation problem. The usual formulation of such a problem can suffer from an unfortunate scale dependence not intrinsic in the problem itself. This scale dependence occurs, for instance, when fitting polyharmonic splines in even dimensions. We present and analyze an alternative formulation, available for all strictly conditionally positive definite basic functions, which does not suffer from this drawback, at least for the very important example previously mentioned. This formulation changes the problem into one involving a strictly positive definite symmetric system, which can be easily and efficiently solved by Cholesky factorization. The second section considers a natural domain decomposition method for the interpolation equations and views it as an instance of von Neumann's alternating projection algorithm. Here the underlying Hilbert space is the reproducing kernel Hilbert space induced by the strictly conditionally positive definite basic function. We show that the domain decomposition method presented converges linearly under very weak nondegeneracy conditions on the possibly overlapping subdomains. The last section presents some algorithmic details and numerical results of a domain decomposition interpolatory code for polyharmonic splines in 2 and 3 dimensions. This code has solved problems with 5 million centers and can fit splines with 10,000 centers in approximately 7 seconds on very modest hardware.

1. Introduction.

One of the most basic problems in approximation theory is to construct an approximation to data specified at m distinct points $x_1, \ldots, x_m$ in $\mathcal{R}^n$. A simple approach consists of choosing m functions and then looking for the unique combination of these functions which interpolates the data at the given points. For this process to be successful, the set of functions chosen must be linearly independent over the set of interpolation points $x_1, \ldots, x_m$. If the functions are $u_1, \ldots, u_m$, then this is equivalent to the matrix $\big(u_j(x_i)\big)$ being invertible. To implement this program, the user must make a choice of the functions $u_1, \ldots, u_m$. However, it is sometimes more natural to specify not the actual basis to be used, but rather the subspace given by $\text{span}\{u_1, \ldots, u_m\}$. This is the approach we intend to study. We consider interpolants of the form

$$s = p + \sum_{j=1}^{m} \lambda_j \Phi(\cdot, x_j). \tag{1.1}$$

Here $X = \{x_1, \ldots, x_m\}$ is a given set of distinct centers, p is a polynomial of total degree at most $k-1$, and Φ is a mapping from $\mathcal{R}^n \times \mathcal{R}^n \to \mathcal{R}$. Because there are more parameters than data, we impose the further conditions that the coefficient vector λ satisfies

$$\sum_{j=1}^{m} \lambda_j q(x_j) = 0 \tag{1.2}$$

for all polynomials q of degree at most $k-1$. The related interpolation problem follows.

PROBLEM 1.1. *Given distinct nodes $X = \{x_1, \ldots, x_m\} \subset \mathcal{R}^n$ unisolvent with respect to the polynomials of degree at most $k-1$, and a vector $d \in \mathcal{R}^m$, find a function s of the form specified by* (1.1) *and* (1.2)*, satisfying the interpolation conditions*

$$s(x_i) = d_i, \qquad 1 \le i \le m.$$

Let π_{k-1} denote the subspace of $C(\mathcal{R}^n)$ consisting of all polynomials of total degree $k-1$, and let $\{p_1, p_2, \ldots, p_\ell\}$ be a basis for π_{k-1}. Then the corresponding system of equations is often written in matrix terms as

$$\begin{pmatrix} \mathsf{A} & \mathsf{P} \\ \mathsf{P}^T & \mathsf{O} \end{pmatrix} \begin{pmatrix} \lambda \\ c \end{pmatrix} = \begin{pmatrix} d \\ 0 \end{pmatrix}, \tag{1.3}$$

in which

$$\mathsf{A}_{ij} = \Phi(x_i, x_j), \qquad i, j = 1, \ldots, m, \tag{1.4}$$

and

$$\mathsf{P}_{ij} = p_j(x_i), \qquad i = 1, \ldots, m, \quad j = 1, \ldots, \ell. \tag{1.5}$$

Note that in this system, and throughout the paper, we use the symbol O to represent the zero matrix of appropriate size, while the symbol 0 is used for the zero vector/scalar.

The above setting covers natural spline interpolation in $\mathcal{R}$ and interpolation by radial basis functions in $\mathcal{R}^n$. In the latter case, the function Φ has the form $\Phi(x, y) = \phi(|x-y|)$ for $x, y \in \mathcal{R}^n$, where $\phi : \mathcal{R} \to \mathcal{R}$, and $|\cdot|$ is the Euclidean norm in $\mathcal{R}^n$. This case is of considerable practical importance. Problem 1.1 is known to have a unique solution for many choices of Φ. To discuss these results we will need the following definition.

DEFINITION 1. *A symmetric function $\Phi : \mathcal{R}^n \times \mathcal{R}^n \to \mathcal{R}$ is strictly conditionally positive definite of order k on $\mathcal{R}^n$ if for all sets $X = \{x_1, \ldots, x_m\} \subset \mathcal{R}^n$ of distinct points, and all vectors $\lambda \in \mathcal{R}^m$ satisfying the orthogonality condition* (1.2)*, the quadratic form*

$$\lambda^T \mathsf{A} \lambda = \sum_{i,j=1}^{m} \lambda_i \lambda_j \Phi(x_i, x_j)$$

is positive whenever $\lambda \neq 0$.

The paper of Micchelli [11] showed that the interpolation system (1.3) is invertible whenever the function $\Phi(x, y) = \phi(|x-y|)$ is strictly conditionally positive definite of

order k, and X is unisolvent for π_{k-1}.[1] Earlier work in a similar vein can be found in Schoenberg [21]. It is worth noting that if a function Φ is conditionally positive definite of order k, then it is also conditionally positive definite of order k' for any $k' \geq k$, and so there is some flexibility over the choice of the parameter k.

For radial basis function interpolation, the most popular choices of the function Φ are strictly conditionally positive definite, notably the multiquadrics and the polyharmonic splines. These interpolation methods are popular for a number of reasons. First, the interpolant depends only on the radial distance between the interpolation points. This feature makes radial basis function interpolation suitable for treating unstructured data—particular data which does not fall on, or close to, the points of some rectangular or regular triangular grid. Such data is often described as scattered. We have already indicated that in practical cases, the types of geometry for which the interpolant is not specified uniquely are extremely simple. For example, interpolation by thin-plate splines in $\mathcal{R}^2$ requires only that the nodes must not lie on a line. With a scattered data set, one can almost guarantee that this condition will be satisfied. This is in sharp contrast to the situation for polynomial interpolation, where the conditions on the data sets required in order that a unique interpolant exists get progressively more complex as the number of interpolation points increases. Furthermore, all the radial basis function interpolants in use have the feature that they minimize a seminorm. Sometimes (as is the case with polyharmonic spline interpolants—see below) the seminorm can be seen to force the interpolant to be the "smoothest" interpolant in some sense. This smoothness property can actually be seen in graphical representations of the interpolant and is akin to the smoothness experienced when interpolating by a low degree polynomial spline in $\mathcal{R}$.

Despite the many nice features of radial basis function interpolation, early workers in the field encountered significant computational difficulties. A small part of these difficulties was due to the computing equipment available at the time, but the major problem was that system (1.3) led to an very ill-conditioned system of equations with a full matrix. We refer the reader to [1] for quotes concerning these difficulties. Further discussion of the ill-conditioning can be found in [10]. In [12] lower bounds on the condition number were given, which showed the poor conditioning of the matrix of system (1.3) as a function of the minimum separation between the interpolation points. It is clear that direct solution methods are not feasible for large data sets. Therefore, a number of iterative methods have been proposed, of which [1] and [4] are recent examples.

This paper focuses on various aspects of the numerical solution of interpolation problems using interpolants of the type described in (1.1). Our prime objective is to present a method for large problems with many, many nodes. However, we will also need good methods for small subproblems that occur naturally in our solution strategy. Two questions arise immediately. First, is (1.1) the best way of couching the interpolation problem, or are there other bases for the finite-dimensional space

$$\mathcal{S} = \left\{ p + \sum_{j=1}^{m} \lambda_j \Phi(\cdot, x_j) : \textstyle\sum_{j=1}^{m} \lambda_j q(x_j) = 0 \text{ for all } q \in \pi_{k-1} \right\}$$

which are numerically superior? Second, once we have decided on a suitable choice of basis, what solver do we use for the linear system generated by this basis?

[1] A suitably modified statement holds when X is not unisolvent for π_{k-1}.

In section 2 we investigate the choice of a basis. We have a number of objectives in this section. First, we do not want to work with a spanning set for $\mathcal{S}$ which is "overspecified" in the sense that it consists of more functions than the dimension of $\mathcal{S}$. Second, we would like the basis to have some natural link to the problem. Third, many of the problems which come within our remit have a certain natural feature—that of scale independence. We want a basis for $\mathcal{S}$, and certainly a method of solution which possesses this same scale independence. Let us be a bit more precise.

DEFINITION 2. *Consider an interpolation method $L_{X,d}$ defined for some suitable class of finite subsets of points $X \subset \mathcal{R}^n$ and data values d. The interpolation method $L_{X,d}$ will be called scale independent if for all suitable sets of interpolation points X and data values d, the interpolant s fitted at the points X to data values d, and the interpolant s^h fitted at the scaled points hX to the unscaled data values d, are related by $s^h(h\,\cdot) = s$.*

As an example, consider the polyharmonic spline interpolants, corresponding to the strictly conditionally positive definite function of order $k+1$,

$$\Phi(x,y) = (-1)^{k+1}|x-y|^{2k}\ln|x-y| \qquad \text{for } x, y \in \mathcal{R}^n.$$

If n is even, then the interpolant corresponding to strict conditional positive definiteness of order $k' = k + (n/2)$, $p \in \pi_{k'-1}$ and sums of shifts of Φ, minimizes the seminorm

$$|g|^2 = \int_{\mathcal{R}^n} \sum_{|\alpha|=k'} \binom{k'}{\alpha} \left(D^\alpha g\right)^2 dx$$

over all suitably smooth interpolating functions.[2] This condition, and the scaling of derivatives, clearly implies that polyharmonic spline interpolation is scale independent. However, we shall see that the numerical methods commonly used for fitting such splines are not scale independent. This is because the chosen basis, or spanning set, behaves badly with respect to scale. We will propose a basis which behaves much better with respect to scale, and which will be very useful for the direct solution of small- to moderately-sized radial basis function interpolation problems.

One particular application for our basis is the direct solution of subproblems arising in a domain decomposition code for large problems. This is the subject of section 4. We wish to suggest that the domain decomposition iterative method of solving a linear system is an effective strategy for the systems considered here. Section 3 introduces a form of the domain decomposition algorithm. This may be viewed as multiplicative Schwarz, or as the alternating projection algorithm of von Neumann [13]. The main benefits of the latter viewpoint are that there is a lot of information available about the convergence of the alternating algorithm and the fact that in favorable circumstances the rate of convergence is linear. We will establish linear convergence of our domain decomposition method, and give some theoretical estimates of the rate, based on the idea of an angle between two subspaces in a Hilbert space.

The description of the domain decomposition method in section 3 is quite general and abstract. In section 4 we present some details of the functioning domain decomposition code and some numerical results.

We conclude this introduction with some remarks about notation. The sign $|\cdot|$ appears frequently throughout the paper and has a number of different meanings. For

[2]It should be clear to the discerning reader that a number of technicalities have been omitted here. Furthermore, it is not really necessary to impose the restriction that n is even, but we wanted to keep the discussion simple.

example, if $x \in \mathcal{R}^n$, then $|x|$ means the Euclidean norm of x. If α is a nonnegative multi-integer, that is, $\alpha \in \mathcal{Z}_+^n$, then $|\alpha|$ is the "length" of α—the sum of its coordinates. Frequent use will be made of the subspace π_{k-1} of $C(\mathcal{R}^n)$ consisting of all algebraic polynomials of total degree at most $k-1$.

2. Alternative bases for the interpolation problem. If the data values $d_1, \ldots, d_m$ are given on $x_1, \ldots, x_m \in \mathcal{R}^n$, then the radial basis function interpolant we seek is a function drawn from the subspace

$$\mathcal{S} = \left\{ s : s = p + \sum_{j=1}^{m} \lambda_j \phi(|\cdot - x_j|) : \ p \in \pi_{k-1}, \lambda_1, \ldots, \lambda_m \in \mathcal{R} \right.$$
$$\left. \text{and } \sum_{j=1}^{m} \lambda_j q(x_j) = 0 \text{ for all } q \in \pi_{k-1} \right\}.$$

Because the interpolation problem is well posed when Φ is strictly conditionally positive definite of order k, it must be that this space has dimension m. An alternative approach is therefore to develop a basis consisting of only m functions. The first results in this direction were obtained by Sibson and Stone [23], who used the thin-plate spline radial basic function $\Phi(x,y) = |x-y|^2 \log |x-y|$ together with linear polynomials in $\mathcal{R}^2$. As pointed out in the introduction, this choice of radial basic function is a very popular one that has been very successful in applications. In this section we present an alternative approach which is simple to follow both conceptually and numerically and can be carried out for any of the radial basis functions in common usage. It will turn out that our approach is equivalent to that of Sibson and Stone in the case of thin-plate splines in $\mathcal{R}^2$.

The technical fact on which our approach is based is that every basic function which is strictly conditionally positive definite of some order generates a reproducing kernel Hilbert space. That is, there is a Hilbert space $\mathcal{H}$ consisting of continuous functions on $\mathcal{R}^n$ and such that for each $x \in \mathcal{R}^n$ the mapping $f \mapsto f(x)$ for $f \in \mathcal{H}$ is bounded. It then follows easily from the Riesz representation theorem that there is a unique kernel $K : \mathcal{R}^n \times \mathcal{R}^n \to \mathcal{R}$ with the following properties.

(i) $K(x,y) = K(y,x)$ for all $x, y \in \mathcal{R}^n$.
(ii) $K(\cdot, x) \in \mathcal{H}$ for all $x \in \mathcal{R}^n$.
(iii) K is strictly positive definite. That is, for any choice of points $x_1, \ldots, x_m \in \mathcal{R}^n$ and numbers $\lambda_1, \ldots, \lambda_m \in \mathcal{R}$, $\sum_{i,j=1}^{m} \lambda_i \lambda_j K(x_i, x_j) \geq 0$, with equality only when $\boldsymbol{\lambda} = 0$.
(iv) $f(y) = \langle f, K(\cdot, y) \rangle$ for all $f \in \mathcal{H}$ and $y \in \mathcal{R}^n$.

Some other results about reproducing kernels help us in our analysis. Once Φ is given, and the degree of conditional positive definiteness is known, it is possible to write down the reproducing kernel for $\mathcal{H}$ explicitly. To do this we must first make a choice about how to define $\mathcal{H}$. Suppose Φ is strictly conditionally positive definite of order k on $\mathcal{R}^n$. Let $\dim(\pi_{k-1}) = \ell$, and let $\{x_1, \ldots, x_\ell\} \subset \mathcal{R}^n$ be a set of points which is unisolvent with respect to π_{k-1}. The conditional positive definiteness of Φ allows us to define a seminorm $|\cdot|$, with $\mathcal{H}$ then being the set of all functions for which this seminorm is finite. The seminorm has kernel π_{k-1}. The seminorm is modified into a norm simply by choosing an appropriate norm on π_{k-1} and adding it to the seminorm. We always make the choice

$$\|f\|^2 = \sum_{i=1}^{\ell} \big(f(x_i)\big)^2 + |f|^2 \qquad \text{for } f \text{ in } \mathcal{H}.$$

Let $p_1, \ldots, p_\ell$ be the Lagrange basis for π_{k-1} with respect to the points $x_1, \ldots, x_\ell$. That is, the p_j are chosen such that $p_j(x_i)$ is 1 if $i = j$ and is zero otherwise, $1 \le i, j \le \ell$. Then the reproducing kernel K is given by

$$\begin{aligned} K(x,y) = \Phi(x,y) &- \sum_{j=1}^{\ell} p_j(y)\Phi(x,x_j) - \sum_{i=1}^{\ell} p_i(x)\Phi(x_i,y) \\ &+ \sum_{i=1}^{\ell}\sum_{j=1}^{\ell} p_i(x)p_j(y)\Phi(x_i,x_j) + \sum_{i=1}^{\ell} p_i(x)p_i(y) \quad \text{for } x, y \in \mathcal{R}^n. \end{aligned} \tag{2.1}$$

Here we have tried to give a very rapid sketch of matters which are peripheral to our concerns in this paper. Full details may be found in [8]. Our reason for giving a little of the detail here is that we need the following observations. First, it is easily calculated from (2.1) that $K(\cdot, x_j) = p_j$ for $j = 1, \ldots, \ell$. Second, because of the form of the induced inner product in $\mathcal{H}$ (see (3.1)), $p_1, \ldots, p_\ell$ are an orthonormal basis for π_{k-1}. This follows from the observation that

$$\langle p_\mu, p_\nu \rangle = \sum_{i=1}^{\ell} p_\nu(x_i)p_\mu(x_i)$$

for $\nu, \mu = 1, \ldots, \ell$. Let $P : C(\mathcal{R}^n) \to \pi_{k-1}$ be defined by $Pf = \sum_{j=1}^{\ell} f(x_j)p_j$ for each $f \in C(\mathcal{R}^n)$. The above remarks then show that

$$Pf = \sum_{j=1}^{\ell} f(x_j)p_j = \sum_{j=1}^{\ell} \langle f, K(\cdot, x_j)\rangle p_j = \sum_{j=1}^{\ell} \langle f, p_j\rangle p_j,$$

and so P is the orthogonal projection from $\mathcal{H}$ onto π_{k-1}. It is now possible to compress (2.1) significantly:

$$K = (I \otimes I - P \otimes I)(I \otimes I - I \otimes P)\,\Phi + \sum_{j=1}^{\ell} p_j \otimes p_j. \tag{2.2}$$

The operator $P \otimes I + I \otimes P - P \otimes P$ is the Boolean sum $(P \otimes I) \oplus (I \otimes P)$. The radial basis interpolant defined in (1.1) and (1.2) can be expressed in the form $s = \sum_{j=1}^{m} \mu_j K(\cdot, x_j)$ as long as the interpolation points $x_1, \ldots, x_m$ are assumed to contain the set $x_1, \ldots, x_\ell$ which is unisolvent for π_{k-1}. This allows us to immediately achieve our first objective: $\{K(\cdot, x_1), \ldots, K(\cdot, x_m)\}$ is a basis for the subspace $\mathcal{S}$, and the interpolant $s = \sum_{j=1}^{m} \mu_j K(\cdot, x_j)$ is specified by the equations

$$\sum_{j=1}^{m} \mu_j K(x_i, x_j) = f_i, \quad 1 \le i \le m. \tag{2.3}$$

The matrix K with elements

$$\mathsf{K}_{ij} = K(x_i, x_j) \quad \text{for } 1 \le i, j \le m \tag{2.4}$$

is positive definite, and so (2.3) gives a potentially very attractive alternative to (1.3) for solving the interpolation equations. Table 1 compares the conditioning of the matrix K with that of the matrix

$$\mathsf{B} = \begin{pmatrix} \mathsf{A} & \mathsf{P} \\ \mathsf{P}^T & \mathsf{O} \end{pmatrix} \tag{2.5}$$

TABLE 1

Two-norm condition numbers of various matrices corresponding to different formulations of the thin-plate spline interpolation problem. The model problem is on a uniform grid including corners of the unit square with interpoint spacing h along each edge.

Spacing h	Conventional matrix B	Reproducing kernel matrix K	Homogeneous matrix C
1/8	3.5158(3)	1.8930(4)	7.5838(3)
1/16	3.8938(4)	2.6514(5)	1.1086(5)
1/32	5.1363(5)	4.0007(6)	1.6864(6)
1/64	7.6183(6)	6.2029(7)	2.6264(7)

TABLE 2

Two-norm condition numbers of various matrices corresponding to different formulations of the thin-plate spline interpolation problem. The model problem is on a uniform 5×5 grid in $[0, \alpha]^2$.

Scale parameter α	Conventional matrix B	Reproducing kernel matrix K	Homogeneous matrix C
0.001	2.4349(8)	8.4635(8)	5.4938(2)
0.01	2.4364(6)	8.4640(6)	5.4938(2)
0.1	2.5179(4)	8.5134(4)	5.4938(2)
1.0	3.6458(2)	1.3660(3)	5.4938(2)
10	1.8742(6)	1.2609(3)	5.4938(2)
100	1.1520(11)	1.1396(5)	5.4938(2)
1000	3.4590(15)	1.1386(7)	5.4938(2)

of the usual system (1.3), in which the monomials are used as a basis for the polynomials. Also included is a comparison with a different formulation of the interpolation problem to be developed later. The comparison is over sets of uniformly distributed points in $[0, 1]^2$, using the radial basis function $\phi(r) = r^2 \log r$ with the order of conditional positive definiteness equal to 2. In this table an entry of the form $d_0.d_1d_2d_3(e)$, with d_0, d_1, d_2, d_3 decimal digits, represents the number $d_0.d_1d_2d_3 \times 10^e$. It can be seen that the conditioning of the matrices corresponding to all three approaches is roughly the same, when the problem is posed on the unit square. However, the spectrum of the matrix K of (2.4) and also of the matrix (2.5) are affected by the scale of the problem. For example, Table 2 shows calculated condition numbers for the matrices B of (2.5), the matrix K of (2.4), and the matrix C of the different formulation to be developed later (see Theorem 2.4). These matrices correspond to different ways of casting the interpolation problem. The model problem considered is thin-plate spline interpolation on a uniform 5×5 grid in $[0, \alpha]^2$ with interpoint spacing of $\alpha/4$. The table shows the effect of varying the scale parameter α.

Recall from the introduction that the problem itself is scale independent, so that the scale dependence displayed in Table 2 is not intrinsic to the problem. Rather, it is a consequence of the approach taken to the solving the interpolation system. Some years ago Newsam [15] pointed out to one of us that in the case of the usual interpolation system (1.3) the problem is that the matrix A and the matrix P (using the monomial basis for π_{k-1}) scale differently. We will see later that a similar phenomena is happening in the reproducing kernel setting.

If the solution function we seek is scale independent, then the supplying of data at $hx_1, \ldots, hx_m$, $h > 0$, instead of $x_1, \ldots, x_m$ ought not to change the numerical difficulty of the fitting task. The ideal situation would be if K were homogeneous, that is, if for all $h > 0$ and $x, y \in \mathcal{R}^n$, there were some number $\gamma > 0$ such that $K(hx, hy) = h^\gamma K(x, y)$. This would have the effect that the eigenvalues of the scaled interpolation problem would be scaled versions of the eigenvalues of the unscaled interpolation

matrix. Thus, conditioning and eigenvalue clustering would be unaffected by changes of scale. We investigate this possibility next.

LEMMA 2.1. *Let $x_1, \ldots, x_\ell \in \mathcal{R}^n$ be unisolvent with respect to π_{k-1}. Let $p_1, \ldots, p_\ell$ in π_{k-1} be such that $p_i(x_j)$ is 1 if $i = j$ and is zero otherwise, $1 \le i, j \le \ell$. Define $T : C(\mathcal{R}^n \times \mathcal{R}^n) \to C(\mathcal{R}^n \times \mathcal{R}^n)$ by*

$$(Tg)(x,y) = g(x,y) - \sum_{i=1}^{\ell} g(x_i,y)p_i(x) - \sum_{j=1}^{\ell} g(x,x_j)p_j(y) + \sum_{i=1}^{\ell}\sum_{j=1}^{\ell} p_i(x)p_j(y)g(x_i,x_j)$$

for $x, y \in \mathcal{R}^n$ and $g \in C(\mathcal{R}^n \times \mathcal{R}^n)$. Then T annihilates any function g of the form $g(x,y) = p(x-y)$ with $p \in \pi_{2k-1}$.

Proof. It will suffice to establish the result in the case $p(x) = p_\alpha(x) = x^\alpha$, where $x \in \mathcal{R}^n$ and $\alpha \in \mathcal{Z}_+^n$ with $|\alpha| < 2k$. The binomial theorem provides constants a_β, $\beta \in \mathcal{Z}_+^n$, $0 \le \beta \le \alpha$ such that

$$p(x-y) = \sum_{0\le\beta\le\alpha} a_\beta x^{\alpha-\beta}y^\beta = \sum_{0\le\beta\le\alpha} a_\beta p_{\alpha-\beta}(x)p_\beta(y), \quad x, y \in \mathcal{R}^n.$$

Define $g_{\alpha\beta}$ by $g_{\alpha\beta}(x,y) = p_{\alpha-\beta}(x)p_\beta(y)$. Then,

$$Tp_\alpha = \sum_{0\le\beta\le\alpha} a_\beta T g_{\alpha\beta}. \tag{2.6}$$

Now recall the operator $P : C(\mathcal{R}^n) \to \pi_{k-1}$ given by $Pf = \sum_{j=1}^{\ell} f(x_j)p_j$. Then

$$\begin{aligned} Tg_{\alpha\beta} &= g_{\alpha\beta} - (Pp_{\alpha-\beta})\,p_\beta - p_{\alpha-\beta}Pp_\beta + Pp_{\alpha-\beta}Pp_\beta \\ &= (p_{\alpha-\beta} - Pp_{\alpha-\beta}) \otimes (p_\beta - Pp_\beta)\,. \end{aligned}$$

Now since $|\alpha| \le 2k-1$, it follows that either $|\beta| \le k-1$ or $|\alpha-\beta| \le k-1$ in (2.6). Because the operator $I - P$ annihilates π_{k-1}, the result follows. ∎

THEOREM 2.2. *Let the symmetric function $\Phi \in C(\mathcal{R}^n \times \mathcal{R}^n)$ be such that $\Phi(hx, hy) = h^\lambda \Phi(x,y) + q_h(x-y)$ for all $h > 0$ and $x, y \in \mathcal{R}^n$, where $\lambda \in \mathcal{R}$ and $q_h \in \pi_{2k-1}$. Let $x_1, \ldots, x_\ell$ be a unisolvent set of points with respect to π_{k-1}, and let $p_1, \ldots, p_\ell$ be the associated Lagrange basis for π_{k-1}: $p_i(x_j) = \delta_{ij}$, $1 \le i, j \le \ell$, where δ_{ij} is the Kronecker delta. Define the symmetric function $H : \mathcal{R}^n \times \mathcal{R}^n \to \mathcal{R}$ by*

$$H(x,y) = \Phi(x,y) - \sum_{i=1}^{\ell} p_i(x)\Phi(x_i,y) - \sum_{j=1}^{\ell} p_j(y)\Phi(x,x_j) + \sum_{i=1}^{\ell}\sum_{j=1}^{\ell} p_i(x)p_j(y)\Phi(x_i,x_j) \quad \text{for } x, y \in \mathcal{R}^n.$$

For $h > 0$, let H^h be defined in the same way except using points $hx_1, \ldots, hx_\ell$ and the associated Lagrange basis for π_{k-1}, $p_1^h, \ldots, p_\ell^h$. Then $H^h(hx, hy) = h^\lambda H(x,y)$ for all $x, y \in \mathcal{R}^n$.

Proof. From the definition

$$H^h(x,y) = \Phi(x,y) - \sum_{i=1}^{\ell} p_i^h(x)\Phi(hx_i,y) - \sum_{j=1}^{\ell} p_j^h(y)\Phi(x,hx_j) + \sum_{i=1}^{\ell}\sum_{j=1}^{\ell} p_i^h(x)p_j^h(y)\Phi(hx_i,hx_j).$$

Hence,

$$H^h(hx,hy) = \Phi(hx,hy) - \sum_{i=1}^{\ell} p_i^h(hx)\Phi(hx_i,hy) - \sum_{j=1}^{\ell} p_j^h(hy)\Phi(hx,hx_j) + \sum_{i=1}^{\ell}\sum_{j=1}^{\ell} p_i^h(hx)p_j^h(hy)\Phi(hx_i,hx_j).$$

Clearly $p_j^h(hx) = p_j(x)$ for all $x \in \mathcal{R}^n$ and $1 \le j \le \ell$. Thus,

$$H^h(hx,hy) = h^\lambda \left\{ \begin{array}{l} \Phi(x,y) - \displaystyle\sum_{i=1}^{\ell} p_i(x)\Phi(x_i,y) - \sum_{j=1}^{\ell} p_j(y)\Phi(x,x_j) \\ \qquad\qquad + \displaystyle\sum_{i=1}^{\ell}\sum_{j=1}^{\ell} p_i(x)p_j(y)\Phi(x_i,x_j) \end{array} \right\} + (Tv)(x,y),$$

where $v(x,y) = q_h(x-y)$ for some $q_h \in \pi_{2k-1}$, and T is as in Lemma 2.1. By that lemma, $Tv = 0$ and so $H^h(hx,hy) = h^\lambda H(x,y)$ for all $h > 0$ and $x, y \in \mathcal{R}^n$. ∎

We now give an application of Theorem 2.2 to the popular polyharmonic splines.

COROLLARY 2.3. *The function Φ defined by $\Phi(x,y) = (-1)^{k+1}|x-y|^{2k}\ln|x-y|$ is strictly conditionally positive definite of order k' for any $k' \ge k+1$. The corresponding function H satisfies $H^h(hx,hy) = h^{2k}H(x,y)$ for all $x, y \in \mathcal{R}^n$.*

Proof. The conditional positive definiteness can be found in Micchelli [11]. It follows that the reproducing kernel K, and hence the kernel H, are built using points $x_1, \ldots, x_m \in \mathcal{R}^n$ which are unisolvent with respect to $\pi_{k'-1}$. Furthermore,

$$\begin{aligned} \Phi(hx,hy) = (-1)^{k+1}|hx-hy|^{2k}\ln|hx-hy| &= (-1)^{k+1}h^{2k}|x-y|^{2k}\left(\ln|x-y| + \ln h\right) \\ &= h^{2k}\Phi(x,y) + (-1)^{k+1}h^{2k}|x-y|^{2k}\ln h \\ &= h^{2k}\Phi(x,y) + q_h(x-y), \end{aligned}$$

where $q_h \in \pi_{2k} \subset \pi_{2k'-1}$. Theorem 2.2 now applies and $H^h(hx,hy) = h^{2k}H(x,y)$. ∎

The problem with the reproducing kernel matrix is now clearly highlighted. We can write

$$K^h(x,y) = H^h(x,y) + \sum_{i=1}^{\ell} p_i^h(x)p_i^h(y) \quad \text{for } x, y \in \mathcal{R}^n. \tag{2.7}$$

In many cases the H^h function scales at a rate controlled by the basis function with which it is associated. As we just saw in Corollary 2.3, in the thin-plate case with

$\phi(r) = (-1)^{k+1} r^{2k} \ln r$, the kernel H^h scales as a function of h^{2k}. The last term $\sum_{i=1}^{\ell} p_i^h(x) p_i^h(y)$ does not scale at all. Consequently, the general position is that the reproducing kernel is made up of two pieces which scale in fundamentally different ways.

An alternative approach consists of trying to use $\{H(\cdot, x_j)\}_{j=1}^{m}$ as a basis for $\mathcal{S}$. This is, of course, doomed to failure, because we somehow need the terms $\sum_{i=1}^{\ell} p_i^h(x) p_i^h(y)$ which differentiate between K and H. Indeed, one simply checks that $H(\cdot, x_j) = 0$ for $j = 1, \ldots, \ell$. Consequently, we choose as a potential basis the functions $\{p_1, \ldots, p_\ell, H(\cdot, x_{\ell+1}), \ldots, H(\cdot, x_m)\}$. To solve the interpolation problem using this basis we must find $c_1, \ldots, c_\ell, \gamma_{\ell+1}, \ldots, \gamma_m$ such that

$$\sum_{j=1}^{\ell} c_j p_j(x_i) + \sum_{j=\ell+1}^{m} \gamma_j H(x_i, x_j) = d_i, \quad i = 1, \ldots, m.$$

This system of equations has some special structure which we now investigate. First, from the remark above that $H(\cdot, x_j) = 0$ for $1 \le j \le \ell$ and symmetry, it follows in particular that $H(x_i, x_j) = 0$ for $1 \le i \le \ell$ and all j. Thus our system of equations can be written

$$\begin{pmatrix} \mathsf{I} & \mathsf{O} \\ \mathsf{E}^T & \mathsf{C} \end{pmatrix} \begin{pmatrix} c \\ \gamma \end{pmatrix} = d, \tag{2.8}$$

where I is the $\ell \times \ell$ identity, C is the matrix $\big(H(x_i, x_j)\big)_{i,j=\ell+1}^{m}$, E^T is the $(m-\ell) \times \ell$ matrix $\big(p_j(x_i)\big)_{i=\ell+1, j=1}^{m, \ \ell}$, and c, γ, d are the vectors $(c_1, \ldots, c_\ell)^T$, $(\gamma_{\ell+1}, \ldots, \gamma_m)^T$, and $(d_1, \ldots, d_m)^T$, respectively.

THEOREM 2.4. *The matrix* $\mathsf{C} = \big(H(x_i, x_j)\big)_{i,j=\ell+1}^{m}$ *is strictly positive definite.*

Proof. As before, define $P : C(\mathcal{R}^n) \to \pi_{k-1}$ by $Pf = \sum_{j=1}^{\ell} f(x_j) p_j$. Then P is a projection onto π_{k-1}. Furthermore, from (2.2),

$$\begin{aligned} PK(\cdot, x_j) &= \left[(P \otimes I)\, K\right](\cdot, x_j) \\ &= \left[(P \otimes I)\,(I \otimes I - P \otimes I)\,(I \otimes I - I \otimes P)\,\Phi\right](\cdot, x_j) + \sum_{i=1}^{\ell} p_i(x_j) P p_i. \end{aligned}$$

Because $P \otimes I$ is a projection, $(P \otimes I)\,(I \otimes I - P \otimes I) = 0$ and so $PK(\cdot, x_j) = \sum_{i=1}^{\ell} p_i(x_j) p_i$. This calculation shows that for $j = \ell + 1, \ldots, m$,

$$H(\cdot, x_j) = K(\cdot, x_j) - \sum_{i=1}^{\ell} p_i(x_j) p_i = K(\cdot, x_j) - PK(\cdot, x_j). \tag{2.9}$$

Now let $v = (v_{\ell+1}, \ldots, v_m) \in \mathcal{R}^{m-\ell}$. Then,

$$\begin{aligned} v^T \mathsf{C} v &= \sum_{i,j=\ell+1}^{m} v_i v_j H(x_i, x_j) \\ &= \sum_{i,j=\ell+1}^{m} v_i v_j \big\langle H(\cdot, x_i), K(\cdot, x_j) \big\rangle \end{aligned}$$

$$
\begin{aligned}
&= \sum_{i,j=\ell+1}^{m} v_i v_j \big\langle H(\cdot,x_i), H(\cdot,x_j) + PK(\cdot,x_j)\big\rangle \\
&= \sum_{i,j=\ell+1}^{m} v_i v_j \left\{ \big\langle H(\cdot,x_i), H(\cdot,x_j)\big\rangle + \big\langle H(\cdot,x_i), PK(\cdot,x_j)\big\rangle \right\} \\
&= \sum_{i,j=\ell+1}^{m} v_i v_j \left\{ \big\langle H(\cdot,x_i), H(\cdot,x_j)\big\rangle + \big\langle K(\cdot,x_i) - PK(\cdot,x_i), PK(\cdot,x_j)\big\rangle \right\} \\
&= \sum_{i,j=\ell+1}^{m} v_i v_j \big\langle H(\cdot,x_i), H(\cdot,x_j)\big\rangle = \left\| \sum_{j=\ell+1}^{m} v_j H(\cdot,x_j) \right\|^2 \geq 0.
\end{aligned}
$$

In the second line we have used the reproducing property of K; in the third line we have used (2.9); and in the last line we have used the fact that $K(\cdot,x_j) - PK(\cdot,x_j)$ is orthogonal to polynomials of degree at most $k-1$. Furthermore, by the linear independence of $\{K(\cdot,x_j)\}_{j=1}^{m}$ and the fact that $K(\cdot,x_j) = p_j$, $1 \leq j \leq \ell$, the functions $\{H(\cdot,x_j), j = \ell+1, \ldots, m\}$ are linearly independent in the Hilbert space. Hence, $\sum_{j=\ell+1}^{m} v_j H(\cdot,x_j)$ is nonzero unless $v = 0$. It follows that $v^T \mathsf{C} v > 0$ unless $v = 0$ and so C is strictly positive definite. □

To summarize, we have shown that using a basis of the Lagrange polynomials, $\{p_j\}_{j=1}^{\ell}$, supplemented by the functions $\{H(\cdot,x_j) : \ell+1 \leq j \leq m\}$ casts the interpolation problem, Problem 1.1, in the form of (2.8) in which C is a strictly positive definite, symmetric matrix. One way to solve this system is as follows. First "solve" for the coefficients of the Lagrange polynomials setting $c = (d_1, \ldots, d_\ell)^T$. Next substitute the value for c back into the second row of the partitioned system (2.8), obtaining with $d^* = (d_{\ell+1}, \ldots, d_m)^T$ the equation

$$\mathsf{C}\gamma = d^* - \mathsf{E}^T c = \begin{pmatrix} -\mathsf{E}^T & \mathsf{I} \end{pmatrix} d.$$

In this system the right-hand side $\begin{pmatrix} -\mathsf{E}^T & \mathsf{I} \end{pmatrix} d$ is cheap to calculate as each row of E^T has at most ℓ nonzero entries. Once the right-hand side is calculated, the system can be efficiently solved for γ via Cholesky decomposition of C followed by forward and back substitution. This of course takes approximately half the operations of any Gauss elimination routine that does not exploit symmetry, such as might be applied to the usual system (1.3). Also, throughout this whole process one needs to store only E^T and the lower triangle of C, so that the method is efficient in storage as well as operations.

We conclude this section with a brief exploration of the connection between our work and that of Sibson and Stone [23]. Sibson and Stone examined the radial basis function $\phi(r) = r^2 \ln r$ supplemented by linear ploynomials, using data specified at points of $\mathcal{R}^2$. An extension of their approach to general dimension d, and general order k of polynomial, is as follows. Pre- and postmultiply the usual system

$$\begin{pmatrix} \mathsf{A} & \mathsf{P} \\ \mathsf{P}^T & \mathsf{O} \end{pmatrix} \begin{pmatrix} \lambda \\ c \end{pmatrix} = \begin{pmatrix} d \\ 0 \end{pmatrix} \tag{2.10}$$

by an $m \times (m-\ell)$ matrix Q whose columns span the orthogonal complement of the column space of P. This implies in particular that Q has full rank. Then any $\lambda \in \mathcal{R}^m$ satisfying $\mathsf{P}^T\lambda = 0$ can be uniquely expressed in the form $\lambda = \mathsf{Q}\gamma$, where $\gamma \in \mathcal{R}^{m-\ell}$. Thus, the constraints on λ are automatically satisfied, and we need only solve the

unconstrained system $\mathsf{A}\mathsf{Q}\gamma + \mathsf{P}c = d$. Premultiplying by Q^T gives

$$(\mathsf{Q}^T\mathsf{A}\mathsf{Q})\gamma = \mathsf{Q}^T d. \tag{2.11}$$

Observe that for any $u \in \mathcal{R}^{m-\ell}$ with $u \neq 0$, $u^T\left(\mathsf{Q}^T\mathsf{A}\mathsf{Q}\right)u = (\mathsf{Q}u)^T\,\mathsf{A}\,(\mathsf{Q}u) > 0$, since Q has full rank and Φ is strictly conditionally positive definite of order k. Hence, $\mathsf{Q}^T\mathsf{A}\mathsf{Q}$ is a strictly positive definite, symmetric matrix. Therefore, (2.11) uniquely specifies γ and $\lambda = \mathsf{Q}\gamma$. Note also that (2.11) can be rewritten as

$$0 = \mathsf{Q}^T\left(d - \mathsf{A}\mathsf{Q}\gamma\right) = \mathsf{Q}^T\left(d - \mathsf{A}\lambda\right).$$

Hence, $d - \mathsf{A}\lambda$ is in the column space of P, and there is a unique c such that

$$\mathsf{P}c = d - \mathsf{A}\lambda.$$

Thus, we may solve the interpolation problem, Problem 1.1, in the following way.

- Choose an $m \times (m-\ell)$ matrix Q whose columns span the orthogonal complement of the column space of P.
- Find γ by solving the $(m-\ell) \times (m-\ell)$ system (2.11), for example, via Cholesky factorization.
- Set $\lambda = \mathsf{Q}\gamma$.
- Find the polynomial from π_{k-1} interpolating to the following residual function

$$r = d - \sum_{j=1}^{m} \lambda_j \Phi(x, x_j),$$

  at the nodes $\{x_1, \ldots, x_\ell\}$.

A possible choice for Q is

$$\mathsf{Q} = \begin{pmatrix} -p_1(x_{\ell+1}) & -p_1(x_{\ell+2}) & -p_1(x_{\ell+3}) & \ldots & -p_1(x_m) \\ \vdots & \vdots & \vdots & & \vdots \\ -p_\ell(x_{\ell+1}) & -p_\ell(x_{\ell+2}) & -p_\ell(x_{\ell+3}) & \ldots & -p_\ell(x_m) \\ 1 & 0 & 0 & \ldots & 0 \\ 0 & 1 & 0 & \ldots & 0 \\ \vdots & & \ddots & & \vdots \\ 0 & 0 & 0 & \ldots & 1 \end{pmatrix}.$$

This choice of Q is clearly of full rank. Also, we claim that the columns of Q are orthogonal to the columns of P, that is, $\mathsf{P}^T\mathsf{Q} = \mathsf{O}$. Since each row of P^T is of the form $\big(q(x_1), \ldots, q(x_m)\big)$, for some $q \in \pi_{k-1}$, a typical element of $\mathsf{P}^T\mathsf{Q}$ has the form

$$q(x_{\ell+i}) - \sum_{j=1}^{\ell} q(x_j)p_j(x_{\ell+i}) = q(x_{\ell+i}) - q(x_{\ell+i}) = 0,$$

by the properties of the Lagrange basis.

For the particular choice of Q given above, the matrix C in (2.8) obtained via homogenizing the reproducing kernel turns out to be identical with the matrix $\mathsf{Q}^T\mathsf{A}\mathsf{Q}$ obtained via the generalized Sibson and Stone approach.

Powell [16], in the setting of thin-plate splines in $\mathcal{R}^2$, and building on the Sibson and Stone approach, proposes a different choice of Q. His choice is based upon a Householder QR factorization of P.

Our choice of Q reduces the operation count for the setup of the lower triangle of the $\mathsf{Q}^T\mathsf{A}\mathsf{Q}$, and the modified right-hand side $\mathsf{Q}^T d$. When the iterative solution of the large system requires solution of a large number of different small systems, the accumulated setup cost can be a considerable part of the overall cost of a solve. A further convenience of our choice of Q is that it does not intermix the terms $\Phi(\cdot, x_j)$ as much. In certain situations this can allow one to curtail Cholesky back substitutions early, thus saving additional operations.

3. Convergence and the alternating algorithm. This section discusses the convergence of a domain decomposition method for solving the interpolation equations. In the language of the domain decomposition literature the method analyzed is a multiplicative Schwarz type method. It can be viewed equally well as an instance of the von Neumann alternating projection algorithm. We will show that the method presented converges linearly under very weak assumptions on the choice of the subdomains.

The key to the analysis is to view the algorithm as a sequence of orthogonal projections onto overlapping subspaces. Such an approach is standard in the domain decomposition literature [24, 2] and in the analysis of the von Neumann alternating algorithm [13, 14, 25]. In the radial basis function literature, related Hilbert space ideas are used to advantage by Madych and Nelson [9], Faul and Powell [4], Schaback [18, 19] and Schaback and Wendland [20]. After completing this work we learned of some work on different projection methods by Wenz [26].

As was already emphasized in the previous section, interpolation problems involving translates of a basic function can be solved with the aid of the reproducing kernel $K : \mathcal{R}^n \times \mathcal{R}^n \to \mathcal{R}$. It has been known for some time now that this reproducing kernel can be used to define an inner product on a suitable space of continuous functions. It is not necessary for us to operate at the full level of generality of this result. We can simply suppose that f and g mapping $\mathcal{R}^n \to \mathcal{R}$ have the form

$$f = \sum_{i=1}^{m} a_i K(\cdot, x_i) \quad \text{and} \quad g = \sum_{j=1}^{m} b_j K(\cdot, x_j).$$

Define

$$\langle f, g \rangle = \sum_{i,j=1}^{m} a_i b_j K(x_i, x_j). \tag{3.1}$$

There are a number of minor observations at this point. First of all, there is no loss of generality in our requirement that f and g are both linear combinations of $K(\cdot, x_1), \ldots, K(\cdot, x_m)$. If this is not the case, then one simply coalesces the sets on which f and g are based, and sets the appropriate coefficients amongst the a_i and b_j to zero. Second, the symmetry of the reproducing kernel produces the symmetry of the inner product. Third, since K is a reproducing kernel, the matrix $\big(K(x_i, x_j)\big)_{i,j=1}^{m}$ is positive definite. In all cases of interest to us this matrix is, in fact, strictly positive definite,[3] and so $\langle \cdot, \cdot \rangle$ defines an inner product on the set

$$\left\{ \sum_{j=1}^{m} a_j K(\cdot, x_j) : m \in \mathcal{N}, a_1, \ldots, a_m \in \mathcal{R}, x_1, \ldots, x_m \text{ are distinct points of } \mathcal{R}^n \right\}.$$

[3]For some discussion of what can happen in the exceptional cases, see Shapiro [22, p. 71].

Let $\mathcal{H}$ denote the completion of this space with respect to our inner product. In all cases of interest to us, $\mathcal{H} \subset C(\mathcal{R}^n)$, and so we shall assume this throughout what follows.

Throughout this section we will employ the following notation. Given a finite set of distinct points in $\mathcal{R}^n$, $X = \{x_1, \ldots, x_m\}$, we will use the symbol $\mathcal{X}$ to denote the subspace of functions in $\mathcal{H}$ "carried" by X. That is,

$$\mathcal{X} = \left\{ f \in \mathcal{H} : f = \sum_{x \in X} \lambda_x K(\cdot, x), \text{ where } \lambda_x \in \mathcal{R} \right\}.$$

This notation will chiefly be employed with sets of points X or Y, and corresponding sets of functions $\mathcal{X}$ and $\mathcal{Y}$. All these sets will on occasion carry integer subscripts.

Given such a finite set of distinct points $X \subset \mathcal{R}^n$ we consider interpolation problems of the following form:

Given $f \in \mathcal{H}$, find the element of $\mathcal{X}$ that interpolates to f on X.

One version of the domain decomposition method is to let $X_1, X_2, \ldots, X_k$ be subsets of X, such that $\cup_{i=1}^k X_i = X$. Given $f \in \mathcal{H}$, we let $P_i f$, $i = 1, \ldots, k$, denote the function from $\mathcal{X}_i$ that interpolates to f on X_i. Thus,

$$P_i f = \sum_{x \in X_i} \lambda_x K(\cdot, x) \quad \text{and} \quad (P_i f)(y) = f(y) \quad \text{for all } y \in X_i.$$

The domain decomposition algorithm now generates the sequence of residual vectors $\{f_{nk+r}\}$, where $n \in \mathcal{N}_0$ and $r = 1, 2, \ldots, k$ via the relationships

$$f_0 = f \text{ and } f_{nk+r} = f_{nk+r-1} - P_r f_{nk+r-1}.$$

The corresponding sequence of approximations $\{s_{nk+r}\}$ is generated via the relationships

$$s_0 = 0 \text{ and } s_{nk+r} = s_{nk+r-1} + P_r f_{nk+r-1}.$$

The next two results identify interpolation on a subset as the orthogonal projection onto the function space "carried" by that subset. They are key observations utilized by Faul and Powell [4] and Schaback and Wendland [20].

LEMMA 3.1. *Let X be a finite set of distinct points in $\mathcal{R}^n$. Let $f \in \mathcal{H}$ be such that $f(x) = 0$ for all $x \in X$. Let $g \in \mathcal{X}$. Then $\langle f, g \rangle = 0$.*

Proof. Let $X = \{x_1, \ldots, x_m\}$ and $g = \sum_{j=1}^m a_j K(\cdot, x_j)$. First suppose that f has the form $f = \sum_{j=1}^n b_j K(\cdot, x_j)$, where $n \geq m$. Set $a_{m+1} = \cdots = a_n = 0$. Then

$$\begin{aligned} \langle f, g \rangle &= \sum_{i,j=1}^{n} a_i b_j K(x_i, x_j) \\ &= \sum_{i=1}^{m} a_i \sum_{j=1}^{n} b_j K(x_i, x_j) \\ &= \sum_{i=1}^{m} a_i f(x_i) = 0. \end{aligned}$$

If $f \in \mathcal{H}$ does not have the form above, then we can find a sequence $\{h_\ell\} \subset \mathcal{H}$ such that each h_ℓ has the form $h_\ell = \sum_{j=1}^{n_\ell} b_{j\ell} K(\cdot, x_j)$ and $\langle f - h_\ell, f - h_\ell \rangle \to 0$ as $\ell \to \infty$. The above calculations show that

$$\langle h_\ell, g \rangle = \sum_{i=1}^{m} a_i h_\ell(x_i).$$

Since the point evaluation functionals lie in $\mathcal{H}^*$ (because $\mathcal{H}$ is a reproducing kernel Hilbert space) it follows that $h_\ell(x_i) \to 0$ as $\ell \to \infty$ for $i = 1, \ldots, m$. Hence,

$$\langle f, g \rangle = \lim_{\ell \to \infty} \langle h_\ell, g \rangle = \sum_{i=1}^{m} a_i \lim_{\ell \to \infty} h_\ell(x_i) = 0. \qquad \square$$

COROLLARY 3.2. *Let X be a finite set of distinct points of $\mathcal{R}^n$, and let $\mathcal{X} = \left\{ f \in \mathcal{H} : f = \sum_{x \in X} \lambda_x K(\cdot, x), \text{ where } \lambda_x \in \mathcal{R} \right\}$ be the space "carried" by X. Then*

$$\mathcal{X}^\perp = \{ f \in \mathcal{H} : f(x) = 0 \text{ for all } x \in X \}.$$

Furthermore, let P denote the operator defined by interpolation from $\mathcal{X}$ at the nodes in X. Then P is the orthogonal projection from $\mathcal{H}$ onto $\mathcal{X}$.

Proof. That functions $f \in \mathcal{H}$ zero everywhere on X are in $\mathcal{X}^\perp$ follows directly from Lemma 3.1. In the other direction if f is nonzero at a point $y \in X$, then consider the function $g := K(\cdot, y) \in \mathcal{X}$. By an argument similar to that of the lemma we find $\langle f, g \rangle = f(y) \neq 0$. Hence $f \notin \mathcal{X}^\perp$. This establishes the first claim of the corollary.

Now turn to the second claim. From the interpolation conditions, $f - Pf$ is zero at every point of $x \in X$. Hence, by the lemma $f - Pf$ is orthogonal to $\mathcal{X}$. The second claim now follows from the characterization of the orthogonal projection of $f \in \mathcal{H}$ onto a closed subspace $\mathcal{G}$ of $\mathcal{H}$, as the unique $g \in \mathcal{G}$ such that the error $f - g$ is orthogonal to $\mathcal{G}$. $\square$

It is now possible to understand the domain decomposition algorithm as a version of the alternating projection algorithm of von Neumann [13, 14] or the Kacmarz procedure [6]. Each operator P_i in the domain decomposition algorithm is, in fact, the orthogonal projection from $\mathcal{H}$ onto the subspace

$$\mathcal{X}_i = \left\{ f \in \mathcal{H} : f = \sum_{x \in X_i} \lambda_x K(\cdot, x), \text{ where } \lambda_x \in \mathcal{R} \right\}.$$

If we define $Q_i = I - P_i$, then Q_i is the orthogonal projection onto $\mathcal{X}_i^\perp$, and ℓ complete cycles of the domain decomposition algorithm computes $(Q_k \cdots Q_1)^\ell f$.

The convergence of the alternating algorithm is well understood in terms of the angles between these subspaces $\mathcal{X}_i^\perp$.

DEFINITION 3. *Let $\mathcal{U}_1$ and $\mathcal{U}_2$ be closed subspaces of a Hilbert space $\mathcal{H}$ with $\mathcal{U} = \mathcal{U}_1 \cap \mathcal{U}_2$. Then the angle α between $\mathcal{U}_1$ and $\mathcal{U}_2$ is given by*

$$\cos \alpha = \sup \left\{ \langle u, v \rangle : u \in \mathcal{U}_1 \cap \mathcal{U}^\perp, v \in \mathcal{U}_2 \cap \mathcal{U}^\perp \text{ and } \|u\|, \|v\| \leq 1 \right\}.$$

The following theorem of Smith, Solmon, and Wagner [25] then shows that the alternating algorithm usually converges linearly.[4]

[4]It is well known that the rate estimate of Theorem 3.3 is often pessimistic. However, our interest at this point is to guarantee linear convergence, rather than to obtain the best rate. Rate estimates for the alternating algorithm which are often improvements on the estimate of Theorem 3.3 can be found in [5, 7].

THEOREM 3.3. *Let $Q_1, \ldots, Q_k$ be orthogonal projections onto closed subspaces $\mathcal{U}_1, \ldots, \mathcal{U}_k$ in a Hilbert space $\mathcal{H}$. Let $\mathcal{U} = \cap_{i=1}^k \mathcal{U}_i$. Let $Q : \mathcal{H} \to \mathcal{U}$ be the orthogonal projection onto $\mathcal{U}$, and let α_j be the angle between $\mathcal{U}_j$ and $\mathcal{A}_{j+1} = \cap_{i=j+1}^k \mathcal{U}_j$. Then for any $f \in \mathcal{H}$,*

$$\left\| (Q_k \cdots Q_1)^\ell f - Qf \right\|^2 \leq c^{2\ell} \left\| f - Qf \right\|^2,$$

where

$$c^2 \leq 1 - \Pi_{j=1}^{k-1} \sin^2 \alpha_j.$$

Of course it is possible that the angle between some pair $\mathcal{U}_j$ and A_{j+1} may be zero so that $c = 1$, thus denying us the chance of verifying convergence. However, we will soon see that for our application some very weak conditions on the intersections of the node sets are sufficient to rule out this possibility.

DEFINITION 4. *Let $X_1, \ldots, X_k$ be nonempty subsets of $\mathcal{R}^n$ and let $Y_j = \cup_{i=j}^k X_i$, $j = 1, \ldots k$. The sets $X_1, \ldots, X_k$ will be called* weakly distinct *if for each $j = 1, \ldots, k-1$, $X_j \neq Y_j$ and $Y_{j+1} \neq Y_j$.*

Note that if each X_j has a point which belongs only to it, and to no other X_i, then the sets $X_1, \ldots, X_k$ are weakly distinct.

LEMMA 3.4. *Let $X_1, \ldots, X_k$ be finite subsets of $\mathcal{R}^n$, and let $Y_j = \cup_{i=j}^k X_i$, $j = 1, \ldots, k$. Then,*

(i) *$\mathcal{Y}_j^\perp = \cap_{i=j}^k \mathcal{X}_i^\perp$ for $j = 1, \ldots, k$.*

(ii) *If the sets $X_1, \ldots, X_k$ are weakly distinct, then the subspaces $\mathcal{X}_j^\perp \cap \mathcal{Y}_j$ and $\mathcal{Y}_{j+1}^\perp \cap \mathcal{Y}_j$ contain nonzero functions for $j = 1, \ldots, k-1$.*

Proof. First,

$$\begin{aligned}
\bigcap_{i=j}^k \mathcal{X}_i^\perp &= \bigcap_{i=j}^k \{f \in \mathcal{H} : f(x) = 0 \text{ for all } x \in X_i\} \\
&= \left\{ f \in \mathcal{H} : f(x) = 0 \text{ for all } x \in \bigcup_{i=j}^k X_i \right\} \\
&= \left\{ f \in \mathcal{H} : f = \sum_{x \in Y_j} \theta_x K(\cdot, x) : \theta_x \in \mathcal{R} \right\}^\perp \\
&= \mathcal{Y}_j^\perp.
\end{aligned}$$

This shows the first claim of the lemma.

Since $X_1, \ldots, X_k$ are weakly distinct, there is a point $z \in Y_j$ such that $z \notin X_j$. Now consider an element $u \in \mathcal{Y}_j$ of the form

$$u = \sum_{x \in X_j} \theta_x K(\cdot, x) + K(\cdot, z).$$

We claim there is a choice of the θ_x's such that $u \in \mathcal{X}_j^\perp$. In order that $u \in \mathcal{X}_j^\perp$, we have to satisfy the equations

$$\sum_{x \in X_j} \theta_x K(a, x) = -K(a, z) \text{ for all } a \in X_j.$$

Since the matrix $\big(K(a,x)\big)_{a,x\in X_j}$ is invertible, this set of equations has a unique solution for $\{\theta_x : x \in X_j\}$. The corresponding u is nontrivial since the coefficient of $K(\cdot,z)$ in its expansion is 1. The proof that $\mathcal{Y}_{j+1}^{\perp} \cap \mathcal{Y}_j$ contains a nonzero function is similar and will be omitted. ∎

THEOREM 3.5. *Let $f \in \mathcal{H}$ and let $X_1, \ldots, X_k$ be weakly distinct finite subsets of $\mathcal{R}^n$. Set $Y_j = \cup_{i=j}^{k} X_i$, $j = 1, \ldots, k$. Let $Q : \mathcal{H} \to \mathcal{Y}_1^{\perp}$ be the orthogonal projection onto $\mathcal{Y}_1^{\perp}$. Let f_ℓ be the element of $\mathcal{H}$ obtained by applying ℓ complete cycles of the domain decomposition algorithm to f on $X_1, \ldots, X_k$. Then there exists a number $0 \le c < 1$ such that*

$$\|f_\ell - Qf\|^2 \le c^{2\ell}\|f - Qf\|^2 \le c^{2\ell}\|f\|^2, \qquad \ell = 1, 2, \ldots .$$

Proof. We know from our earlier discussion that $f_\ell = (Q_k \cdots Q_1)^\ell f$, where $Q_i : \mathcal{H} \to \mathcal{X}_i^{\perp}$ is the orthogonal projection. An application of Theorem 3.3 shows that

$$\left\|(Q_k \cdots Q_1)^\ell f - Qf\right\|^2 \le c^{2\ell}\|f - Qf\|^2, \qquad \ell = 1, 2, \ldots ,$$

where c may be estimated in terms of the angles between subspaces.

It remains to show that $c < 1$. In the notation of Theorem 3.3, this involves examining α_j, the angle between the subspaces $\mathcal{U}_j = \mathcal{X}_j^{\perp}$ and $\mathcal{A}_{j+1} = \cap_{i=j+1}^{k} \mathcal{X}_i^{\perp}$. A critical ingredient of this analysis is the orthogonal complement of the intersection of these two spaces, namely the subspace

$$\mathcal{B}_j = \left(\mathcal{X}_j^{\perp} \bigcap \left(\bigcap_{i=j+1}^{k} \mathcal{X}_i^{\perp}\right)\right)^{\perp} = \left(\bigcap_{i=j}^{k} \mathcal{X}_i^{\perp}\right)^{\perp}.$$

In Lemma 3.4 it was shown that $\mathcal{Y}_j^{\perp} = \big(\cap_{i=j}^{k} \mathcal{X}_i^{\perp}\big)$ for $j = 1, \ldots, k$. It follows that $\mathcal{A}_{j+1} = \mathcal{Y}_{j+1}^{\perp}$ and $\mathcal{B}_j = \mathcal{Y}_j$. Lemma 3.4 also guarantees that the subspaces $\mathcal{X}_j^{\perp} \cap \mathcal{Y}_j$ and $\mathcal{Y}_{j+1}^{\perp} \cap \mathcal{Y}_j$ contain nonzero elements. Now suppose that $\cos\alpha_j = 1$. That is,

$$\sup\big\{\langle u, v\rangle : u \in \mathcal{X}_j^{\perp} \cap \mathcal{Y}_j, v \in \mathcal{Y}_{j+1}^{\perp} \cap \mathcal{Y}_j, \|u\|, \|v\| \le 1\big\} = 1.$$

For the purposes of the convergence of the algorithm, we can consider ourselves to be working in the finite-dimensional space spanned by f and the elements of $\{K(\cdot, y) : y \in Y_1\}$. Hence, by compactness, we can find elements $u^* \in \mathcal{X}_j^{\perp} \cap \mathcal{Y}_j$ and $v^* \in \mathcal{Y}_{j+1}^{\perp} \cap \mathcal{Y}_j$ with $\|u^*\| = \|v^*\| = 1$ such that $\langle u^*, v^*\rangle = 1$. By the condition for equality in the Cauchy–Schwarz inequality, it follows that $u^* = v^*$. Thus, $u^* \in \mathcal{X}_j^{\perp} \cap \mathcal{Y}_{j+1}^{\perp} = \mathcal{Y}_j^{\perp}$. However, u^* is also in $\mathcal{Y}_j$. Hence $u^* = 0$. This contradicts the fact that $\|u^*\| = 1$, and so $\sin\alpha_j \ne 0$ for $j = 1, \ldots, k$. ∎

We now complement the analysis of Theorem 3.5 by showing how to calculate the angles between subspaces employed in the estimate of the constant c and in the alternative estimates of [5, 7].

Recall from the proof of Theorem 3.5 that α_j is the angle between $\mathcal{X}_j^{\perp}$ and $\mathcal{Y}_{j+1}^{\perp}$. The following result can be found in [3].

LEMMA 3.6. *Let $\mathcal{U}$, $\mathcal{V}$ be closed subspaces of a Hilbert space $\mathcal{H}$. Then the angle between $\mathcal{U}$ and $\mathcal{V}$ is the same as the angle between $\mathcal{U}^{\perp}$ and $\mathcal{V}^{\perp}$.*

This allows us to compute the α_j as the angle between

$$\mathcal{X}_j = \left\{ f \in \mathcal{H} : f = \sum_{x \in X_j} \lambda_x K(\cdot, x) \right\}$$

and

$$\mathcal{Y}_{j+1} = \left\{ f \in \mathcal{H} : f = \sum_{y \in Y_{j+1}} \lambda_y K(\cdot, y) \right\}.$$

Relabeling if necessary, we enumerate X_j as $\{x_1, \ldots, x_{m_2}\}$ and Y_{j+1} as $\{x_{m_1+1}, \ldots, x_{m_3}\}$, where $1 \le m_1 < m_2 \le m_3$. This enumeration is made so that $X_j \cap Y_{j+1} = \{x_{m_1+1}, \ldots, x_{m_2}\}$. We now work entirely in the finite-dimensional Hilbert space

$$\mathcal{H} = \left\{ \sum_{j=1}^{m_3} \lambda_j K(\cdot, x_j) : \lambda_j \in \mathcal{R}, j = 1, \ldots, m_3 \right\}.$$

We adopt the ";" notation for stacking rows of partitioned vectors. Then any vector $\boldsymbol{\lambda} \in \mathcal{R}^{m_3}$ of coefficients can be partitioned into $\boldsymbol{\lambda} = (\boldsymbol{\lambda}_1; \boldsymbol{\lambda}_2; \boldsymbol{\lambda}_3)$, where $\boldsymbol{\lambda}_1 \in \mathcal{R}^{m_1}$, $\boldsymbol{\lambda}_2 \in \mathcal{R}^{m_2-m_1}$, and $\boldsymbol{\lambda}_3 \in \mathcal{R}^{m_3-m_2}$. The corresponding partitioning of the matrix $\mathsf{K} = \left(K(x_i, x_j)\right)_{i,j=1}^{m_3}$ is

$$\begin{array}{c} \begin{array}{ccc} m_1 & m_2 - m_1 & m_3 - m_2 \end{array} \\ \begin{pmatrix} \mathsf{D}_1 & \mathsf{E}_1 & \mathsf{F}_1 \\ \mathsf{C}_2 & \mathsf{D}_2 & \mathsf{E}_2 \\ \mathsf{B}_3 & \mathsf{C}_3 & \mathsf{D}_3 \end{pmatrix} \begin{array}{c} m_1 \\ m_2 - m_1 \\ m_3 - m_2 \end{array} \end{array}.$$

Also the inner product defined in (3.1) of two functions u, v in $\mathcal{H}$ is $\mu^T \mathsf{K} \nu$, where μ and ν are the coefficient vectors of u and v with respect to the reproducing kernel basis.

Now let $u \in \mathcal{X}_j \cap (\mathcal{X}_j \cap \mathcal{Y}_{j+1})^\perp$. Then u has a coefficient vector of the form $(\boldsymbol{\mu}_1; \boldsymbol{\mu}_2; \mathbf{0})$ because $u \in \mathcal{X}_j$. However, since $u \in (\mathcal{X}_j \cap \mathcal{Y}_{j+1})^\perp$ we have $u(x_i) = 0$, $i = m_1 + 1, \ldots, m_2$. Hence, u satisfies interpolation equations of the form $\mathsf{K}(\boldsymbol{\mu}_1; \boldsymbol{\mu}_2; \mathbf{0}) = (\boldsymbol{a}; \mathbf{0}; \boldsymbol{b})$, which imply

$$\mathsf{C}_2 \boldsymbol{\mu}_1 + \mathsf{D}_2 \boldsymbol{\mu}_2 = \mathbf{0}.$$

Since D_2 is invertible, $\boldsymbol{\mu}_2 = -\mathsf{D}_2^{-1} \mathsf{C}_2 \boldsymbol{\mu}_1$. Thus any element $u \in \mathcal{X}_j \cap (\mathcal{X}_j \cap \mathcal{Y}_{j+1})^\perp$ has coefficient vector $(\boldsymbol{\mu}_1; \boldsymbol{\mu}_2; \mathbf{0})$, where

$$\begin{pmatrix} \boldsymbol{\mu}_1 \\ \boldsymbol{\mu}_2 \end{pmatrix} = \begin{pmatrix} \mathsf{I} \\ -\mathsf{D}_2^{-1} \mathsf{C}_2 \end{pmatrix} \boldsymbol{\mu}_1,$$

$\boldsymbol{\mu}_1 \in \mathcal{R}^{m_1}$, $\boldsymbol{\nu}_2 \in \mathcal{R}^{m_2-m_1}$, and I is the $m_1 \times m_1$ identity. Note in particular that the matrix on the right of the equation above has full rank.

In our computation of the angle between $\mathcal{X}_j$ and $\mathcal{Y}_{j+1}$, we need to restrict attention to $u \in \mathcal{X}_j$ with $\|u\| = 1$. Now,

$$\begin{aligned} \|u\|^2 &= \begin{pmatrix} \boldsymbol{\mu}_1^T & \boldsymbol{\mu}_2^T & \mathbf{0}^T \end{pmatrix} \begin{pmatrix} \mathsf{D}_1 & \mathsf{E}_1 & \mathsf{F}_1 \\ \mathsf{C}_2 & \mathsf{D}_2 & \mathsf{E}_2 \\ \mathsf{B}_3 & \mathsf{C}_3 & \mathsf{D}_3 \end{pmatrix} \begin{pmatrix} \boldsymbol{\mu}_1 \\ \boldsymbol{\mu}_2 \\ \mathbf{0} \end{pmatrix} \\ &= \boldsymbol{\mu}_1^T \begin{pmatrix} I & \left(-\mathsf{D}_2^{-1} \mathsf{C}_2\right)^T \end{pmatrix} \begin{pmatrix} \mathsf{D}_1 & \mathsf{E}_1 \\ \mathsf{C}_2 & \mathsf{D}_2 \end{pmatrix} \begin{pmatrix} \mathsf{I} \\ -\mathsf{D}_2^{-1} \mathsf{C}_2 \end{pmatrix} \boldsymbol{\mu}_1 \\ &= \boldsymbol{\mu}_1^T \left(\mathsf{D}_1 - \mathsf{E}_1 \mathsf{D}_2^{-1} \mathsf{C}_2\right) \boldsymbol{\mu}_1 \\ &= \boldsymbol{\mu}_1^T \left(\mathsf{D}_1 - \mathsf{C}_2^T \mathsf{D}_2^{-1} \mathsf{C}_2\right) \boldsymbol{\mu}_1 \, . \end{aligned}$$

The matrix $\left(\begin{smallmatrix}\mathsf{D}_1 & \mathsf{E}_1\\ \mathsf{C}_2 & \mathsf{D}_2\end{smallmatrix}\right)$ is the interpolation matrix for the set X_j and so is strictly positive definite and symmetric. Since $\begin{pmatrix}\mathsf{I} & (-\mathsf{D}_2^{-1}\mathsf{C}_2)^T\end{pmatrix}$ is of full rank we can write $\|u\|^2 = \boldsymbol{\mu}_1^T\mathsf{G}_1\boldsymbol{\mu}_1$, where G_1 is strictly positive definite and symmetric. Let the Cholesky decomposition of G_1 be $\mathsf{L}_1\mathsf{L}_1^T$. Then $\|u\|^2 = \boldsymbol{\mu}_1^T\mathsf{L}_1\mathsf{L}_1^T\boldsymbol{\mu}_1$. Letting $\boldsymbol{\gamma}_1 = \mathsf{L}_1^T\boldsymbol{\mu}_1$ gives $\|u\|^2 = \boldsymbol{\gamma}_1^T\boldsymbol{\gamma}_1$.

Similar arguments show that if $v \in \mathcal{Y}_{j+1}\cap(\mathcal{X}_j \cap \mathcal{Y}_{j+1})^\perp$, then v has coefficient vector $(\mathbf{0};\boldsymbol{\nu}_2;\boldsymbol{\nu}_3)$. Furthermore, $\|v\|^2$ can be realized via the expression $\|v\|^2 = \boldsymbol{\gamma}_3^T\boldsymbol{\gamma}_3 = \boldsymbol{\nu}_3\mathsf{L}_3\mathsf{L}_3^T\boldsymbol{\nu}_3$, where $\mathsf{L}_3\mathsf{L}_3^T$ is the Cholesky decomposition of the matrix

$$\begin{pmatrix}\left(-\mathsf{D}_2^{-1}\mathsf{E}_2\right)^T & \mathsf{I}\end{pmatrix}\begin{pmatrix}\mathsf{D}_2 & \mathsf{E}_2\\ \mathsf{C}_3 & \mathsf{D}_3\end{pmatrix}\begin{pmatrix}-\mathsf{D}_2^{-1}\mathsf{E}_2\\ \mathsf{I}\end{pmatrix} = \mathsf{D}_3 - \mathsf{C}_3\mathsf{D}_2^{-1}\mathsf{C}_3^T.$$

Thus the calculation of the cosine of the angle between $\mathcal{X}_j$ and $\mathcal{Y}_{j+1}$ involves finding the supremum over vectors $\boldsymbol{\gamma}_1 \in \mathcal{R}^{m_1}$ and $\boldsymbol{\gamma}_3 \in \mathcal{R}^{m_3-m_2}$ with $\|\boldsymbol{\gamma}_1\|_2 = \|\boldsymbol{\gamma}_3\|_2 = 1$ of the expression

$$\begin{aligned}\mu^T\mathsf{K}\nu &= \boldsymbol{\mu}_1^T\begin{pmatrix}\mathsf{I} & \left(-\mathsf{D}_2^{-1}\mathsf{C}_2\right)^T & \mathsf{O}\end{pmatrix}\begin{pmatrix}\mathsf{D}_1 & \mathsf{E}_1 & \mathsf{F}_1\\ \mathsf{C}_2 & \mathsf{D}_2 & \mathsf{E}_2\\ \mathsf{B}_3 & \mathsf{C}_3 & \mathsf{D}_3\end{pmatrix}\begin{pmatrix}\mathsf{O}\\ -\mathsf{D}_2^{-1}\mathsf{E}_2\\ \mathsf{I}\end{pmatrix}\boldsymbol{\nu}_3\\ &= \boldsymbol{\mu}_1^T\begin{pmatrix}\mathsf{I} & \left(-\mathsf{D}_2^{-1}\mathsf{C}_2\right)^T & \mathsf{O}\end{pmatrix}\begin{pmatrix}-\mathsf{E}_1\mathsf{D}_2^{-1}\mathsf{E}_2+\mathsf{F}_1\\ \mathsf{O}\\ -\mathsf{C}_3\mathsf{D}_2^{-1}\mathsf{E}_2+\mathsf{D}_3\end{pmatrix}\boldsymbol{\nu}_3\\ &= \boldsymbol{\mu}_1^T(\mathsf{F}_1 - \mathsf{E}_1\mathsf{D}_2^{-1}\mathsf{E}_2)\boldsymbol{\nu}_3\\ &= \boldsymbol{\gamma}_1^T\mathsf{L}_1^{-1}(\mathsf{F}_1 - \mathsf{E}_1\mathsf{D}_2^{-1}\mathsf{E}_2)\left(\mathsf{L}_3^T\right)^{-1}\boldsymbol{\gamma}_3.\end{aligned}$$

We have therefore established the following result.

THEOREM 3.7. *Adopt the notation prior to the theorem. Then the cosine of the angle between* $\mathcal{X}_j^\perp$ *and* $\cap_{i=j+1}^k\mathcal{X}_i^\perp$ *is given by the* ℓ_2 *norm of the matrix* $\mathsf{L}_1^{-1}(\mathsf{F}_1 - \mathsf{E}_1\mathsf{D}_2^{-1}\mathsf{E}_2)\left(\mathsf{L}_3^T\right)^{-1}$.

An easy adjustment needs to be made to the above theorem if there is no overlap between the sets X_j and Y_{j+1}. In this case, we write the block matrix as

$$\mathsf{K} = \begin{pmatrix}\mathsf{D}_1 & \mathsf{F}_1\\ \mathsf{B}_3 & \mathsf{D}_3\end{pmatrix},$$

and find that the angle between the subspaces $\mathcal{X}_j$ and $\mathcal{Y}_{j+1}$ is the ℓ_2 norm of the matrix $\mathsf{L}_1^{-1}\mathsf{F}_1(\mathsf{L}_3^T)^{-1}$, where $\mathsf{L}_1\mathsf{L}_1^T = \mathsf{D}_1$ and $\mathsf{L}_3\mathsf{L}_3^T = \mathsf{D}_3$.

4. Numerical results of a domain decomposition code. In this section we will briefly discuss some aspects of the implementation and performance of a domain decomposition interpolation code employing some of the previous mathematics. As in section 3, it will be convenient to denote a finite set of distinct points by X and the space of functions "carried" by that set by $\mathcal{X}$.

We list below what we see as the essential ingredients of a domain decomposition code for fitting a globally supported radial basis function by interpolation.

Essential ingredients for a domain decomposition interpolatory fitter.

(i) A method for subdividing space.

(ii) An efficient and scale independent method for solving small interpolation subproblems. The solutions to the small problems will be used to precondition, or approximately solve, the large problem.

(iii) A fast method for computing the action of the large interpolation matrices that occur at various scales.
(iv) An outer iteration.

The method for subdividing space of item (i) above will be used to form the subdomains. Currently we are using a point ordering related to a balanced nD-tree [17] to subdivide space into rectangular boxes. Given that the solution of the large system is to be built upon the solution of many small systems, the need for item (ii) above is clear. This need is filled by, and indeed partly motivated, section 2 of this paper. All matrix iterative methods of which we are aware require at least one matrix-vector product per iteration. Therefore, a prerequisite for the overall method to achieve convergence in $\mathcal{O}(N)$, or $\mathcal{O}(N \log N)$, operations is that a single matrix-vector product costs at most $\mathcal{O}(N)$ or $\mathcal{O}(N \log N)$ operations. Thus, for large interpolation problems with globally supported radial basis functions, item (iii) in the list above, a fast way of computing the action of the interpolation matrix on a vector is absolutely essential. Fortunately, such fast evaluators are becoming available for more and more functions Φ. Item (iv) of the list consists of any suitable means of updating the current approximation to the interpolant using the current residuals and quantities derived from the residuals by interpolation on subdomains. It may be as simple as incrementing the current approximation to the interpolant by an approximate interpolant to the current residual.

A simplified two-level code built upon the parts specified in the ingredients list is given below. The method described is a variant of additive Schwarz as opposed to the multiplicative Schwarz method analyzed in section 3.

A simplified domain decomposition interpolation code.

INPUT

Input the finite node set X, the right-hand side f, and the desired accuracy ϵ.

SETUP

(1) Subdivide space (that is, X) into overlapping subdomains $\{X_j : j = 1, \ldots, m\}$. For each subdomain classify some points as inner points and some as outer, such that the union of all the inner points is the whole node set.
(2) Choose a coarse grid $Y^{(2)}$ containing some points from each inner subdomain.
(3) Form and factor the matrices required to solve the radial basis function (RBF) interpolation problems on the subdomains. Throughout, r_g, s_g, λ_g and c_g will denote the current residual, the current approximation to the interpolant and parameters of the current approximation to the interpolant at the finest, or global, level.
(5) $r_g \leftarrow f$, $s_g \leftarrow 0$, $\lambda_g \leftarrow 0$, and $c_g \leftarrow 0$.

ITERATIVE SOLUTION

(1) **while** $\|r_g\| > \epsilon$
(2) $\lambda \leftarrow 0$. λ is the coefficient vector of the fine level correction.

(3) **for** $j = 1$ **to** m
(4) Set the coefficients λ_i corresponding to inner points of X_j to the coefficients of the interpolant from the spline space $\mathcal{X}_j$ to $r_g|_{X_j}$.
(5) **end for**
(6) Correct λ to be orthogonal to π_{k-1}.
(7) $s_1 \leftarrow \sum \lambda_j \Phi(\cdot, x_j)$.
(8) Evaluate the residual $r_1 \leftarrow r_g - s_1$ at the coarse grid points.
(9) Interpolate to r_1 at the coarse grid points $Y^{(2)}$ using a spline s_2 (including the polynomial part) from $\mathcal{Y}^{(2)}$.
(10) $s_g \leftarrow s_g + s_1 + s_2$.
(11) Reevaluate the global residuals $r_g \leftarrow f - s_g$ at all the points of X.
(12) **end while**

Clearly there are many choices here. For example, one can use a multiplicative Schwarz (block Gauss–Seidel) like update, rather than the additive Schwarz (block Jacobi) like update of the coefficient vector λ. The analysis of section 3 guarantees that such a multiplicative Schwarz updated version will converge. Note for the analysis to apply one must at step 4 of the iterative solution update all the λ_i's corresponding to $\mathcal{X}_j$, not just those for inner points. As is well known [24], an advantage of additive Schwarz is that it is easier to parallelize as the changes to blocks of coefficient vectors can be made in parallel. Furthermore, in our application, the evaluation of the residuals, typically performed with a variant of the fast multipole method, is also easily parallelized.

Other choices occur in the evaluation of the residuals. There is usually more than one applicable fast evaluation algorithm, and even when the overall fast evaluation algorithm is fixed, there are many detailed implementation decisions to make. Another possibility is to view the forming of the correction function $s_1 + s_2$ as the action of a preconditioning matrix B on the current residual vector r_g. It is then natural to employ some matrix iterative method, for example GMRES, in the outer iteration. Furthermore, for really large data sets one clearly employs more than two levels.

A single pass through the main while loop of the iterative process sketched above can be viewed as a linear process on the input residuals. Therefore, one can represent the process as a mapping $r_g \to \mathsf{R} r_g$. The convergence of the iteration will then be characterized by the spectral radius of this *residual matrix* R. Numerical experiments show that if coarse grid correction is absent, then even with subdomain overlap, the spectral radius of R can be large. Further, these experiments show that the eigenvectors corresponding to the largest magnitude eigenvalue typically represent a low frequency oscillation. Correction by interpolation at coarse grid points can be expected to damp out such low frequency oscillations. Experiments involving calculation of the spectral radius of R, with coarse grid correction, show that this expectation is realized. Specifically calculations of the spectral radius of R have been performed for small model problems and the thin-plate spline in two dimensions. The results are tabulated in Table 3. They show that, as expected, the spectral radius of R is generally small and becomes smaller as the amount of overlap, or the size of the correction grid, is increased.

TABLE 3

Spectral radius of the residual matrix for four subdomains and various values of overlap and correction size. The grids are all uniform subdivisions of the unit square. The interpolant considered is the thin-plate spline.

Correction grid	Fine grid	Number of overlap rows/columns		
		2	3	4
3×3	10×10	1.391(-1)	9.152(-2)	5.290(-2)
	20×20	1.769(-1)	1.463(-1)	1.355(-1)
	40×40	3.338(-1)	1.823(-1)	1.755(-1)
4×4	10×10	5.606(-2)	4.186(-2)	3.374(-2)
	20×20	2.479(-1)	5.758(-2)	5.145(-2)
	40×40	6.975(-1)	1.556(-1)	6.404(-2)

TABLE 4

Performance of the current C domain decomposition implementation. The table gives times in seconds to fit the Franke 1 *function until the residual is of magnitude less than* 1.0×10^{-6}. *All computations were carried out using doubles (*64 *bit reals). The node sets were randomly distributed in* $[0,1]^2$ *and the timings performed on a generic machine with an Intel Celeron processor running at* 450 *MHz.*

Number of nodes	Number of level 1 iterations	Time taken in seconds
10,000	8	7.0
20,000	8	17.5
40,000	6	35.5
80,000	6	105.7
160,000	7	407.8

The current C implementation is specialized to fitting 2- and 3-dimensional polyharmonic splines. This was due mostly to the suitability of these splines for some large geophysical and image processing problems motivating our work. A subsidiary reason was that we had in place fast evaluation codes for these functions. However, the ideas and the mathematics of the previous sections apply in the much more general setting of interpolants based upon sums of translates of any strictly conditionally positive definite function Φ. Furthermore, fast evaluation schemes are now being developed for a wide variety of basic functions. Thus we expect the domain decomposition approach to have wide applicability. The existing code has been successfully used to fit data sets of up to 5 million points in 2 dimensions, and up to 250,000 points in 3 dimensions. It is being steadily improved in sophistication, speed, and memory footprint.

The $\mathcal{O}(N^2)$ storage requirements, and $\mathcal{O}(N^3)$ operation counts of direct methods, imply that direct solution of problems with greater than 10,000 centers will be very time consuming, even on very well-endowed machines. Indeed, as late as 1992, many authors have commented on the impracticality of direct, or even iterative, solution of such large RBF interpolation problems. See the quotes in [1]. Bearing this history in mind, the timings in Table 4 are highly satisfactory. They are for interpolation to the

Franke 1 function

$$F^{(1)}(\xi,\eta) = \frac{3}{4}\exp\left(-\frac{(9\xi-2)^2+(9\eta-2)^2}{4}\right) + \frac{3}{4}\exp\left(-\frac{(9\xi+1)^2}{49} - \frac{9\eta+1}{10}\right)$$
$$+ \frac{1}{2}\exp\left(-\frac{(9\xi-7)^2+(9\eta-3)^2}{4}\right) - \frac{1}{5}\exp\left(-(9\xi-4)^2-(9\eta-7)^2\right).$$

To the best of our knowledge these timings are superior at the time of writing to those achieved by any competing RBF fitting code. The closest competitors in terms of performance on large problems are the preconditioned GMRES iterative methods discussed in [1]. These are slower but much easier to implement. Numerical experience with the domain decomposition code seems to indicate an approximately $\mathcal{O}(N \log N)$ complexity.

Acknowledgment. We are grateful to Tim Mitchell of the University of Canterbury for his careful efforts in coding various versions of the method.

PRECONDITIONERS FOR ILL-CONDITIONED TOEPLITZ SYSTEMS CONSTRUCTED FROM POSITIVE KERNELS*

DANIEL POTTS† AND GABRIELE STEIDL‡

Abstract. In this paper, we are interested in the iterative solution of ill-conditioned Toeplitz systems generated by continuous nonnegative real-valued functions f with a finite number of zeros. We construct new w-circulant preconditioners without explicit knowledge of the generating function f by approximating f by its convolution $f * K_N$ with a suitable positive reproducing kernel K_N. By the restriction to positive kernels we obtain positive definite preconditioners. Moreover, if f has only zeros of even order $\leq 2s$, then we can prove that the property $\int_{-\pi}^{\pi} t^{2k} K_N(t)\,\mathrm{d}t \leq CN^{-2k}$ $(k = 0, \ldots, s)$ of the kernel is necessary and sufficient to ensure the convergence of the PCG method in a number of iteration steps independent of the dimension N of the system. Our theoretical results were confirmed by numerical tests.

1. Introduction.

In this paper, we are concerned with the iterative solution of sequences of "mildly" ill-conditioned Toeplitz systems

$$\boldsymbol{A}_N \boldsymbol{x}_N = \boldsymbol{b}_N\,,$$

where $\boldsymbol{A}_N \in \mathbb{C}^{N,N}$ are positive definite Hermitian Toeplitz matrices generated by a continuous nonnegative function f which has only a finite number of zeros. Often these systems are obtained by discretization of continuous problems (partial differential equation, integral equation with weakly singular kernel) and the dimension N is related to the grid parameter of the discretization. For further applications, see [12] and the references therein.

Iterative solution methods for Toeplitz systems, in particular the conjugate gradient method (CG method), have attained much attention during the last years. The reason for this is that the essential computational effort per iteration step, namely, the multiplication of a vector with the Toeplitz matrix $\boldsymbol{A}_N$, can be reduced to $\mathcal{O}(N \log N)$ arithmetical operations by fast Fourier transforms (FFTs). However, the number of iteration steps depends on the distribution of the eigenvalues of $\boldsymbol{A}_N$. If we allow the generating function f to have isolated zeros, then the condition numbers of the related Toeplitz matrices grow polynomial with N and the CG method converges very slowly [8, 28, 45]. Therefore, the real task consists in the construction of suitable preconditioners $\boldsymbol{M}_N$ of $\boldsymbol{A}_N$ so that the number of iteration steps of the corresponding preconditioned CG method (PCG method) becomes independent of N. Here it is useful to recall a result of Axelsson [1, p. 573] relating the spectrum of the coefficient matrix to the number of iteration steps to achieve a prescribed precision.

THEOREM 1.1. *Let $\boldsymbol{A}$ be a positive definite Hermitian (N,N)-matrix which has p and q isolated large and small eigenvalues, respectively:*

$$0 < \lambda_1 \le \lambda_2 \le \cdots \le \lambda_q < a \le \lambda_{q+1} \le \cdots \le \lambda_{N-p} \le b < \lambda_{N-p+1} \le \lambda_{N-p+2} \le \cdots \le \lambda_N \quad (0 < a < b < \infty).$$

Let $\lceil x \rceil$ denote the smallest integer $\ge x$. Then the CG method for the solution of $\boldsymbol{A}\boldsymbol{x} = \boldsymbol{b}$ requires at most

$$n = \left\lceil \left(\ln \frac{2}{\tau} + \sum_{k=1}^{q} \ln \frac{b}{\lambda_k} \right) \Big/ \ln \frac{1 + (\frac{a}{b})^{1/2}}{1 - (\frac{a}{b})^{1/2}} \right\rceil + p + q$$

iteration steps to achieve precision τ, i.e.,

$$\frac{||\boldsymbol{x}_n - \boldsymbol{x}||_A}{||\boldsymbol{x}_0 - \boldsymbol{x}||_A} \le \tau \ ,$$

where $||\boldsymbol{x}||_A := \sqrt{\bar{\boldsymbol{x}}' \boldsymbol{A}\, \boldsymbol{x}}$ and where $\boldsymbol{x}_n$ denotes the numerical solution after n iteration steps.

In literature two kinds of preconditioners were mainly exploited, namely banded Toeplitz matrices and matrices arising from a matrix algebra $\mathcal{A}_{O_N} := \{\bar{\boldsymbol{O}}'_N(\operatorname{diag} \boldsymbol{d})\boldsymbol{O}_N : \boldsymbol{d} \in \mathbb{C}^N\}$, where $\boldsymbol{O}_N$ denotes a unitary matrix.

For another approach by multigrid methods see, for example, [23].

Various banded Toeplitz preconditioners were examined [10, 5, 40, 36, 41]. It was proved that the corresponding PCG methods converge in a number of iteration steps independent of N. However, there is the significant constraint that the cost per iteration of the proposed procedure should be upper-bounded by $\mathcal{O}(N \log N)$. This implies some conditions on the growth of the bandwidth of the banded Toeplitz preconditioners [41].

The above constraint is trivially fulfilled if we chose preconditioners from matrix algebras, where the unitary matrix $\boldsymbol{O}_N$ has to allow an efficient multiplication with a vector in $\mathcal{O}(N \log N)$ arithmetical operations. Up to now, the only preconditioners of the matrix algebra class which ensure the desired convergence of the corresponding PCG method are the preconditioners proposed in [31, 25]. Unfortunately, the construction of these preconditioners requires the explicit knowledge of the generating function f.

Extensive examinations were done with natural and optimal Tau preconditioners [6, 3]. Only for sufficiently smooth functions, where the necessary smoothness depends on the order of the zeros of f, the natural Tau preconditioners become positive definite and lead to the desired location of the eigenvalues of the preconditioned matrices. The optimal Tau preconditioner is in general a bad choice if f has zeros of order > 2 (cf. [6]).

In this paper, we combine our approach in [31] with the approximation of f by its convolution with a reproducing kernel K_N. The kernel approach was given in [15] for positive generating functions. Interesting tests with B-spline kernels were performed by Chan, Tso, and Sun in [14]. The advantage of the kernel approach is that it does not require the explicit knowledge of the generating function. However, for our theoretical proofs we need some knowledge about the location of the zeros of the generating function f. See the remarks at the end of this section. We restrict our attention to positive kernels. This ensures that our preconditioners are positive

definite. Suppose that f has only zeros of even order $\leq 2s$. Then we prove that under the *moment condition*

$$\int_{-\pi}^{\pi} t^{2k} K_N(t)\,\mathrm{d}t \leq CN^{-2k} \quad (k = 0, \ldots, s)$$

on the kernels K_N, the eigenvalues of $\boldsymbol{M}_N^{-1}\boldsymbol{A}_N$ are contained in some interval $[a, b]$ $(0 < a \leq b < \infty)$ except for a fixed number (independent of N) of eigenvalues falling into $[b, \infty)$ so that PCG converges in $\mathcal{O}(1)$ steps.

Note that the above kernel property with $s = 1$ implies for sufficiently smooth f the Jackson result

$$||f - K_N * f||_\infty \leq N^{-2}\omega(f^{(2)}, 1/N)\,,$$

where ω denotes the modulus of continuity. On the other hand, the classical saturation result of Korovkin [29, 21] states that we cannot expect a convergence speed of $||f - K_N * f||_\infty$ better than N^{-2} even in the presence of very regular functions f.

This paper is organized as follows: In section 2, we introduce our w-circulant positive definite preconditioners. We show how the corresponding PCG method can be implemented with only $\mathcal{O}(N)$ arithmetical operations per step more than the original CG method. Section 3 is concerned with the location of the eigenvalues of the preconditioned matrices. We will see that under some assumptions on the kernel the number of CG iterations is independent of N. Special kernels as Jackson kernels and B-spline kernels are considered in section 5. In section 6, we sketch how our ideas can be extended to (real) symmetric Toeplitz matrices with trigonometric preconditioners and to doubly symmetric block Toeplitz matrices with Toeplitz blocks (BTTB matrix). Finally, section 7 contains numerical results.

After sending our manuscript to the *SIAM Journal of Scientific Computing*, R. H. Chan informed us that his group produced results similar to those in our preprint. See [16], and for a refined version, see [17]. The construction of circulant preconditioners of Chan et al. is only based on Jackson kernels and the proofs are different from ours. By a trick (see [16, Theorem 4.2]), which can also be applied to our w-circulant preconditioners, the authors need no knowledge about the location of the zeros of f.

2. Preconditioners from kernels. Let $C_{2\pi}$ denote the Banach space of 2π-periodic real-valued continuous functions with norm

$$\|f\|_\infty := \max_{x\in[-\pi,\pi]} |f(x)|\,.$$

We are interested in the solution of Hermitian Toeplitz systems

$$\boldsymbol{A}_N\boldsymbol{x} = \boldsymbol{b}, \quad \boldsymbol{A}_N = \boldsymbol{A}_N(f) := (a_{j-k})_{j,k=0}^{N-1}, \tag{2.1}$$

$$a_k = a_k(f) := \frac{1}{2\pi}\int_0^{2\pi} f(x)\,\mathrm{e}^{-\mathrm{i}kx}\,\mathrm{d}x$$

generated by a nonnegative function $f \in C_{2\pi}$ which has only a finite number of zeros. By [10], the matrices $\boldsymbol{A}_N(f)$ are positive definite such that (2.1) can be solved by the CG method. Unfortunately, since the generating function $f \in C_{2\pi}$ has zeros, the related Toeplitz matrices are asymptotically ill-conditioned and the CG method converges very slowly. To accelerate the convergence of the CG method, we are looking

for suitable preconditioners of $\boldsymbol{A}_N$, where we do not suppose the explicit knowledge of the generating function f. To reach our aim, we use reproducing kernels. This method was originally proposed for Toeplitz matrices arising from positive functions $f \in C_{2\pi}$ in [15].

In [14] Chan, Tso, and Sun showed by numerical tests that preconditioners from special kernels related to B-splines can improve the convergence of the CG method also if $f \geq 0$ has zeros of various order. A theoretical proof of R. H. Chan's results was open up to now.

In this paper, we restrict our attention to even trigonometric polynomials

$$K_N(x) := c_{N,0} + 2 \sum_{k=1}^{N-1} c_{N,k} \cos kx \,, \quad c_{N,k} = a_k(K_N) \,. \tag{2.2}$$

If

$$\frac{1}{2\pi} \int_0^{2\pi} K_N(x) dx = c_{N,0} = 1 \tag{2.3}$$

and $K_N \geq 0$, then K_N is called a *positive* (trigonometric) *kernel*. As main examples of such kernels, we consider generalized Jackson polynomials and B-spline kernels in section 4. For $f \in C_{2\pi}$, let f_N denote the *convolution of f with K_N*, i.e.,

$$f_N(x) = (f * K_N)(x) := \frac{1}{2\pi} \int_0^{2\pi} f(t) K_N(x-t) \, \mathrm{d}t, \tag{2.4}$$

or equivalently, in the Fourier domain

$$f_N(x) = \sum_{k=-(N-1)}^{N-1} a_k(f) c_{N,k} \, \mathrm{e}^{\mathrm{i}kx} \,. \tag{2.5}$$

We consider so-called *reproducing kernels* K_N $(N \in \mathbb{N})$ with the property that

$$\lim_{N \to \infty} \|f - f_N\|_\infty = 0 \tag{2.6}$$

for all $f \in C_{2\pi}$.

We chose grids G_N $(N \in \mathbb{N})$ consisting of equispaced nodes

$$x_{N,l} := w_N + \frac{2\pi l}{N} \quad \left(l = 0, \ldots, N-1; \, w_N \in \left[0, \frac{2\pi}{N} \right) \right) \tag{2.7}$$

such that $f(x_{N,l}) \neq 0$ for all $l = 0, \ldots, N-1$. Note that the choice of the grids requires some preliminary information about the location of the zeros of f. By a trick (cf. [16]) this restriction can be neglected if we accept some more outliers. We consider matrices of the form

$$\boldsymbol{M}_N(f) := \boldsymbol{W}_N \boldsymbol{F}_N \boldsymbol{D}_N(f) \bar{\boldsymbol{F}}_N \bar{\boldsymbol{W}}_N \tag{2.8}$$

with

$$\boldsymbol{F}_N := \frac{1}{\sqrt{N}} \left(\mathrm{e}^{-2\pi \mathrm{i} jk/N} \right)_{j,k=0}^{N-1} \,, \quad \boldsymbol{W}_N := \operatorname{diag} \left(\mathrm{e}^{-\mathrm{i}k w_N} \right)_{k=0}^{N-1},$$

$$\boldsymbol{D}_N(f) \, = \, \operatorname{diag} \left(f(x_{N,l}) \right)_{l=0}^{N-1}.$$

Obviously, the matrices $\boldsymbol{M}_N$ can be written as

$$\boldsymbol{M}_N(f) = \begin{pmatrix} \tilde{a}_0 & \tilde{a}_{N-1}\,\mathrm{e}^{\mathrm{i}Nw_N} & \cdots & \tilde{a}_1\,\mathrm{e}^{\mathrm{i}Nw_N} \\ \tilde{a}_1 & \tilde{a}_0 & & \\ \vdots & & \ddots & \vdots \\ \tilde{a}_{N-1} & \cdots & \cdots & \tilde{a}_0 \end{pmatrix}$$

with

$$\tilde{a}_k = \tilde{a}_k(f) := \frac{1}{N}\sum_{l=0}^{N-1} f(x_{N,l})\ \mathrm{e}^{-ikw_N}\ \mathrm{e}^{-2\pi\mathrm{i}kl/N}\,. \tag{2.9}$$

These are $(\mathrm{e}^{\mathrm{i}Nw_N})$-*circulant matrices* (see [20]). In particular, we obtain circulant matrices for $w_N = 0$ and skew-circulant matrices for $w_N = \frac{\pi}{N}$.

As preconditioners for (2.1), we suggest matrices of the form

$$\boldsymbol{M}_N := \boldsymbol{M}_N(f_N) \tag{2.10}$$

with suitable positive reproducing kernels K_N. By (2.5), the construction of these preconditioners requires only the knowledge of the Toeplitz matrices $\boldsymbol{A}_N$. It is not necessary to know the generating function f explicitly. However, for the theoretical results in this paper, we must have some information about the location of the zeros of f. Note that by a trick in [16] this information is also superfluous. Here we point out that the auxiliary nontrivial problem of finding some crucial analytic properties of the generating function f has been treated and partially solved in [40].

Moreover, our preconditioners have the following desirable properties.

1. Since $f \geq 0$ with a finite number of zeros and K_N is a positive kernel, it follows by (2.4) that $f_N > 0$. Thus, the matrices $\boldsymbol{M}_N(f_N)$ are positive definite.
2. In the following section, we will prove that under certain conditions on the kernels K_N, the eigenvalues of $\boldsymbol{M}_N^{-1}\boldsymbol{A}_N$ are bounded from below by a positive constant independent of N and that the number of isolated eigenvalues of $\boldsymbol{M}_N^{-1}\boldsymbol{A}_N$ is independent of N. Then, by Theorem 1.1, the number of PCG steps to achieve a fixed precision is independent of N.
3. By construction (2.8), the multiplication of $\boldsymbol{M}_N$ with a vector requires only $\mathcal{O}(N\log N)$ arithmetical operations by using FFT techniques. By a technique presented in [26] it is possible to implement a PCG method with preconditioner $\boldsymbol{M}_N$ which takes only $\mathcal{O}(N)$ instead of $\mathcal{O}(N\log N)$ arithmetical operations per iteration step more than the original CG method with respect to $\boldsymbol{A}_N$.

3. Eigenvalues of $\boldsymbol{M}_N^{-1}\boldsymbol{A}_N$. In this section, we prove that under certain assumptions on the kernels K_N the eigenvalues of $\boldsymbol{M}_N^{-1}\boldsymbol{A}_N$ are bounded from below by a positive constant independent of N and that the number of isolated eigenvalues of $\boldsymbol{M}_N^{-1}\boldsymbol{A}_N$ is independent of N. For the proof of our main result, we need some preliminary lemmas.

LEMMA 3.1. *Let $p \in C_{2\pi}$ be a nonnegative function which has only a finite number of zeros. Let $h \in C_{2\pi}$ be a positive function with*

$$h_{\min} := \min_{x\in[0,2\pi]} h(x)\,, \quad h_{\max} := \max_{x\in[0,2\pi]} h(x)\,.$$

Then, for $f := ph$ and any $N \in \mathbb{N}$, the eigenvalues of $\boldsymbol{A}_N^{-1}(p)\boldsymbol{A}_N(f)$ lie in the interval $[h_{\min}, h_{\max}]$.

The proof can be found, for example, in [5, 10, 31]. A more sophisticated version for $f, g \in L^1$ was proved in [38, 37].

LEMMA 3.2. *Let p be a real-valued nonnegative trigonometric polynomial of degree $\le s$. Let $N \ge 2s$. Then at most $2s$ eigenvalues of $\boldsymbol{M}_N(p)^{-1}\boldsymbol{A}_N(p)$ differ from 1.*

Proof. For arbitrary $f \in C_{2\pi}$ with pointwise convergent Fourier series, we obtain by replacing $f(x_{N,l})$ in (2.9) by the Fourier series of f at $x_{N,l}$

$$\begin{aligned}
\tilde{a}_k &= \frac{1}{N} \sum_{l=0}^{N-1} \sum_{j\in\mathbb{Z}} a_j \, \mathrm{e}^{\mathrm{i}jx_{N,l}} \, \mathrm{e}^{-2\pi\mathrm{i}lk/N} \, \mathrm{e}^{-\mathrm{i}kw_N} \\
&= \sum_{j=0}^{N-1} a_j \, \mathrm{e}^{-\mathrm{i}w_N k} \, \mathrm{e}^{\mathrm{i}w_N j} \left(\frac{1}{N} \sum_{l=0}^{N-1} \mathrm{e}^{-2\pi\mathrm{i}lk/N} \, \mathrm{e}^{2\pi\mathrm{i}lj/N} \right) \\
&\quad + \sum_{j=0}^{N-1} \sum_{r\in\mathbb{Z}\setminus\{0\}} a_{j+rN} \mathrm{e}^{-\mathrm{i}w_N k} \, \mathrm{e}^{\mathrm{i}w_N (j+rN)} \left(\frac{1}{N} \sum_{l=0}^{N-1} \mathrm{e}^{-2\pi\mathrm{i}lk/N} \, \mathrm{e}^{2\pi\mathrm{i}lj/N} \right) \\
&= a_k \quad + \sum_{r\in\mathbb{Z}\setminus\{0\}} a_{k+rN} \, \mathrm{e}^{\mathrm{i}w_N rN} \, .
\end{aligned}$$

This is well known as *aliasing effect*. Then it follows that

$$\boldsymbol{A}_N(f) = \boldsymbol{M}_N(f) - \boldsymbol{B}_N(f) \, , \tag{3.1}$$

where

$$\boldsymbol{B}_N(f) := (b_{j-k}(f))_{j,k=0}^{N-1} \, , \quad b_k(f) := \sum_{r\in\mathbb{Z}\setminus\{0\}} a_{k+rN}(f) \, \mathrm{e}^{\mathrm{i}w_N rN}.$$

We consider $f = p$. Since p is of degree smaller than $s \le \frac{N}{2}$, we have that $b_k(p) = 0$ for $|k| \le N - 1 - s$. Consequently, $\boldsymbol{B}_N(p)$ is of rank $\le 2s$. Now the assertion follows by (3.1). ∎

In what follows, we restrict our attention to Toeplitz matrices having a nonnegative generating function $f \in C_{2\pi}$ with a zero of even order $2s$ ($s \in N$) at $x = 0$.

We use the trigonometric polynomial

$$p_s(x) := (2 - 2\cos x)^s \; = \; \left(2 \sin \frac{x}{2}\right)^{2s} \; = \; \sum_{k=0}^{s} \alpha_k \cos kx \quad (s \ge 1) \tag{3.2}$$

of degree s which also has a zero of order $2s$ at $x = 0$.

The convergence of our PCG method is related to the behavior of the grid functions

$$q_{s,N}(x) := \frac{p_{s,N}(x)}{p_s(x)} \quad (x \in G_N) \, , \tag{3.3}$$

where $p_{s,N}(x) := (p_s * K_N)(x)$. More precisely, for the proof of our main theorem, we need that $\{q_{s,N}(x)\}_{N\in\mathbb{N}}$ is bounded for all $x \in G_N$ from above and below by positive constants independent of N. This will be the content of the following lemmas.

First, we see that the above property follows immediately for all grid points $x \in G_N$ having some distance independent of N from the zero of f.

LEMMA 3.3. *Let G_N be defined by (2.7) with $w_N \neq 0$. Let $\{K_N\}_{N\in\mathbb{N}}$ be a sequence of positive even reproducing kernels, and let $q_{s,N}$ be given by (3.3). Then, for $x_N \in G_N \cap [a,b]$ ($[a,b] \subset (0,2\pi)$) and for every $\varepsilon > 0$ there exists $N(\varepsilon)$ such that*

$$1 - \varepsilon \leq q_{s,N}(x_N) \leq 1 + \varepsilon$$

for all $N \geq N(\varepsilon)$.

Proof. Since $x_N \in [a,b]$ ($N \in \mathbb{N}$) for some $a > 0, b < 2\pi$, we have that

$$p_s(x_N) \geq \min\{p_s(a), p_s(b)\} > 0\,.$$

Further, we obtain by (2.6) that for every $\varepsilon > 0$ there exists $N(\varepsilon)$ such that

$$|p_s(x) - p_{s,N}(x)| \leq \varepsilon \min\{p_s(a), p_s(b)\} \quad (x \in [0, 2\pi))$$

for all $N \geq N(\varepsilon)$. By rewriting (3.3) in the form

$$q_{s,N}(x_N) \;=\; 1 + \frac{p_{s,N}(x_N) - p_s(x_N)}{p_s(x_N)}$$

we obtain the assertion. ∎

By Lemma 3.3, it remains to consider the sequences $\{q_{s,N}(x_N)\}_{N\in\mathbb{N}}$ for $x_N \in G_N$ with $x_N \to 0$ for $N \to \infty$ or with $x_N \to 2\pi$ for $N \to \infty$. Since both cases require the same ideas, we consider $x_N \in G_N$ with

$$\lim_{N\to\infty} x_N \;=\; 0\,.$$

The existence of a lower bound of $\{q_{s,N}(x_N)\}_{N\in\mathbb{N}}$ does not also require additional properties of the kernel K_N.

LEMMA 3.4. *Let G_N be defined by (2.7) with $w_N \neq 0$. Let $\{K_N\}_{N\in\mathbb{N}}$ be a sequence of positive even reproducing kernels, and let $q_{s,N}$ be given by (3.3). Then, for $x_N \in G_N$ with $\lim_{N\to\infty} x_N = 0$, there exists a constant $\alpha > 0$ independent of N such that*

$$\alpha \leq q_{s,N}(x_N).$$

Proof. By definition of $q_{s,N}$ and $p_{s,N}$, we have that

$$q_{s,N}(x_N) = \frac{1}{2\pi} \int_0^{2\pi} \frac{p_s(t)}{p_s(x_N)}\, K_N(x_N - t)\,\mathrm{d}t$$

and since $p_s \geq 0$ and $K_N \geq 0$, we obtain for $x_N < \pi$ that

$$q_{s,N}(x_N) \geq \frac{1}{2\pi} \int_{x_N}^{\pi} \frac{p_s(t)}{p_s(x_N)}\, K_N(x_N - t)\,\mathrm{d}t\,.$$

The polynomial p_s is monotonely increasing on $[0,\pi]$. Thus

$$q_{s,N}(x_N) \geq \frac{1}{2\pi} \int_{x_N}^{\pi} K_N(x_N - t)\,\mathrm{d}t\,.$$

Since K_N is even and fulfills (2.3), we get for any sequence $x_N \in G_N$ ($x_N < \pi$) with $\lim_{N\to\infty} x_N = 0$ that

$$q_{s,N}(x_N) \geq \frac{1}{2\pi} \int_0^{\pi - x_N} K_N(t)\,\mathrm{d}t \geq \text{const}\,. \qquad ∎$$

It remains to examine if

$$q_{s,N}(x_N) = \frac{p_{s,N}(x_N)}{p_s(x_N)} \le \beta$$

for any $x_N \in G_N$ with $\lim_{N\to\infty} x_N = 0$. Here the "moment property" comes into play.

LEMMA 3.5. *Let G_N $(n \in \mathbb{N})$ be defined by (2.7) with*

$$0 < w \le w_N N \le \tilde{w} < 2\pi\,. \tag{3.4}$$

Let $\{K_N\}_{N\in\mathbb{N}}$ be a sequence of positive even kernels, and let $q_{s,N}$ $(s \ge 1)$ be given by (3.3). Then there exists a constant $\beta < \infty$ independent of N such that

$$q_{s,N}(x_N) \le \beta$$

for all $x_N \in G_N$ with $\lim_{N\to\infty} x_N = 0$ if and only if K_N fulfills the "moment property"

$$\int_{-\pi}^{\pi} t^{2k} K_N(t)\,dt = \mathcal{O}(N^{-2k}) \quad (k = 0, \dots, s)\,. \tag{3.5}$$

Note that the restriction (3.4) on the grids G_N means that we have for any $x_N \in G_N$ that $w/N \le x_N$.

Proof. Since $\sin^2 x \le x^2$ for all $x \in \mathbb{R}$, we obtain by (3.2) that

$$p_s(x) \le x^{2s} \quad (x \in \mathbb{R})\,. \tag{3.6}$$

Similarly, we have for any fixed $0 \le y \le \pi/2$ that

$$\sin^2 x \ge \left(\frac{2}{\pi}\,\frac{\frac{\pi}{2} - y}{\frac{\pi}{2} + y}\right)^2 x^2 \quad \left(x \in \left[-\frac{\pi}{2} - y, \frac{\pi}{2} + y\right]\right)$$

and hence

$$p_s(x) \ge \left(\frac{2}{\pi}\right)^{2s} \left(\frac{\frac{\pi}{2} - y}{\frac{\pi}{2} + y}\right)^{2s} x^{2s} \qquad (x \in [-\pi - 2y, \pi + 2y])\,. \tag{3.7}$$

Using (3.6), we conclude by $K_N \ge 0$ that

$$\begin{aligned} p_{s,N}(x) &= \frac{1}{2\pi} \int_{-\pi}^{\pi} p_s(x - t)\, K_N(t)\,\mathrm{d}t \\ &\le \frac{1}{2\pi} \int_{-\pi}^{\pi} (x - t)^{2s}\, K_N(t)\,\mathrm{d}t \\ &= \frac{1}{2\pi} \sum_{k=0}^{2s} \binom{2s}{k} (-1)^k x^{2s-k} \int_{-\pi}^{\pi} t^k\, K_N(t)\,\mathrm{d}t \quad (x \in [-\pi, \pi)) \end{aligned}$$

and since K_N is even

$$p_{s,N}(x) \le \frac{1}{2\pi} \sum_{k=0}^{s} \binom{2s}{2k} x^{2s-2k} \int_{-\pi}^{\pi} t^{2k}\, K_N(t)\,\mathrm{d}t\,.$$

Let K_N satisfy (3.5). Then

$$p_{s,N}(x) \le \frac{c}{2\pi} \sum_{k=0}^{s} \binom{2s}{2k} x^{2s-2k} N^{-2k}\,.$$

By (3.4), we have for any grid sequence $x_N \in G_N$ that $x_N \geq w/N$. Consequently,

$$p_{s,N}(x_N) \leq C\, x_N^{2s}\,.$$

By (3.7) this implies that there exists $\beta < \infty$ independent of N so that $q_{s,N}(x_N) \leq \beta$.

On the other hand, we see by (3.7) with $y := \pi/4$ that

$$\begin{aligned} p_{s,N}(x) &= \frac{1}{2\pi}\int_{-\pi}^{\pi} p_s(x-t)K_N(t)\,\mathrm{d}t \\ &\geq \frac{1}{2\pi}\left(\frac{2}{3\pi}\right)^{2s}\sum_{k=0}^{s}\binom{2s}{2k}x^{2s-2k}\int_{-\pi}^{\pi} t^{2k}K_N(t)\,\mathrm{d}t \qquad \left(x \in \left[-\frac{\pi}{2},\frac{\pi}{2}\right]\right)\,. \end{aligned}$$

By definition of G_N, there exists a grid sequence $\{x_N\}_{N\in\mathbb{N}}$ so that x_N approaches zero as N^{-1} $(N \to \infty)$. Assume that K_N does not fulfill (3.5). Then we obtain for the above sequence that $p_{s,N}(x_N) \geq c\,N^{-2s+\varepsilon}$ $(\varepsilon > 0)$, while we have by (3.6) that $p_s(x_N) = \mathcal{O}(N^{-2s})$. Thus $q_{s,N}(x_N)$ cannot be bounded from above. This completes the proof. □

By Lemmas 3.3–3.5, we obtain that for grids G_N defined by (2.7) and (3.4) and for even positive reproducing kernels with (3.5) there exist

$$\begin{aligned} 0 < \alpha &:= \inf\{q_{s,N}(x) : x \in G_N; N \in \mathbb{N}\}, \\ \infty > \beta &:= \sup\{q_{s,N}(x) : x \in G_N; N \in \mathbb{N}\}. \end{aligned} \tag{3.8}$$

Now we can prove our main theorem.

THEOREM 3.6. *Let $\{\boldsymbol{A}_N(f)\}_{N\in\mathbb{N}}$ be a sequence of Toeplitz matrices generated by a nonnegative function $f \in C_{2\pi}$ which has only a zero of order $2s$ $(s \in \mathbb{N})$ at $x = 0$. Let the grids G_N be defined by* (2.7) *and* (3.4). *Assume that $\{K_N\}_{N\in\mathbb{N}}$ is a sequence of even positive reproducing kernels satisfying* (3.5). *Finally, let $\boldsymbol{M}_N(f_N)$ be defined by* (2.10). *Then we have the following results:*

(i) *The eigenvalues of $\boldsymbol{M}_N(f_N)^{-1}\boldsymbol{A}_N(f)$ are bounded from below by a positive constant independent of N.*

(ii) *For $N \geq 2s$, at most $2s$ eigenvalues of $\boldsymbol{M}_N(f_N)^{-1}\boldsymbol{A}_N(f)$ are not contained in the interval $[\frac{h_{\min}}{\beta\, h_{\max}}, \frac{h_{\max}}{\alpha\, h_{\min}}]$. Here α, β are given by* (3.8) *and $h_{\min}, h_{\max}$ are defined as in Lemma* 3.1, *where $h := f/p_s$.*

Proof. 1. To show (ii), we consider the Rayleigh quotient

$$\frac{\bar{\boldsymbol{u}}'\,\boldsymbol{A}_N(f)\,\boldsymbol{u}}{\bar{\boldsymbol{u}}'\,\boldsymbol{M}_N(f_N)\,\boldsymbol{u}} \;=\; \frac{\bar{\boldsymbol{u}}'\,\boldsymbol{A}_N(f)\,\boldsymbol{u}}{\bar{\boldsymbol{u}}'\,\boldsymbol{A}_N(p_s)\,\boldsymbol{u}}\;\frac{\bar{\boldsymbol{u}}'\,\boldsymbol{A}_N(p_s)\,\boldsymbol{u}}{\bar{\boldsymbol{u}}'\,\boldsymbol{M}_N(f_N)\,\boldsymbol{u}} \quad (\boldsymbol{u} \neq \boldsymbol{o}_N)\,. \tag{3.9}$$

By Lemma 3.1, we have that

$$\frac{\bar{\boldsymbol{u}}'\,\boldsymbol{A}_N(f)\,\boldsymbol{u}}{\bar{\boldsymbol{u}}'\,\boldsymbol{A}_N(p_s)\,\boldsymbol{u}} \in [h_{\min}, h_{\max}]$$

and thus, since the second factor on the right-hand side of (3.9) is positive,

$$h_{\min}\,\frac{\bar{\boldsymbol{u}}'\,\boldsymbol{A}_N(p_s)\,\boldsymbol{u}}{\bar{\boldsymbol{u}}'\,\boldsymbol{M}_N(f_N)\,\boldsymbol{u}} \;\leq\; \frac{\bar{\boldsymbol{u}}'\,\boldsymbol{A}_N(f)\,\boldsymbol{u}}{\bar{\boldsymbol{u}}'\,\boldsymbol{M}_N(f_N)\,\boldsymbol{u}} \;\leq\; h_{\max}\,\frac{\bar{\boldsymbol{u}}'\,\boldsymbol{A}_N(p_s)\,\boldsymbol{u}}{\bar{\boldsymbol{u}}'\,\boldsymbol{M}_N(f_N)\,\boldsymbol{u}}\,. \tag{3.10}$$

By Lemma 3.2, we know that

$$\boldsymbol{A}_N(p_s) \;=\; \boldsymbol{M}_N(p_s) \;+\; \boldsymbol{R}_N(2s)$$

with a matrix $\boldsymbol{R}_N(2s)$ of rank $2s$ and consequently

$$\frac{\bar{\boldsymbol{u}}'\,\boldsymbol{A}_N(f)\,\boldsymbol{u}}{\bar{\boldsymbol{u}}'\,\boldsymbol{M}_N(f_N)\,\boldsymbol{u}} \;\le\; h_{\max}\,\frac{\bar{\boldsymbol{u}}'\,\boldsymbol{M}_N(p_s)\,\boldsymbol{u}}{\bar{\boldsymbol{u}}'\,\boldsymbol{M}_N(f_N)\,\boldsymbol{u}} \;+\; \frac{\bar{\boldsymbol{u}}'\,h_{\max}\boldsymbol{R}_N(2s)\,\boldsymbol{u}}{\bar{\boldsymbol{u}}'\,\boldsymbol{M}_N(f_N)\,\boldsymbol{u}}\,,$$

and

$$\frac{\bar{\boldsymbol{u}}'\,(\boldsymbol{A}_N(f)-h_{\max}\boldsymbol{R}_N(2s))\,\boldsymbol{u}}{\bar{\boldsymbol{u}}'\,\boldsymbol{M}_N(f_N)\,\boldsymbol{u}} \;\le\; h_{\max}\,\frac{\bar{\boldsymbol{u}}'\,\boldsymbol{M}_N(p_s)\,\boldsymbol{u}}{\bar{\boldsymbol{u}}'\,\boldsymbol{M}_N(f_N)\,\boldsymbol{u}}\,.$$

Since K_N and p_s are nonnegative, we obtain by (2.4) and by definition of h that

$$h_{\min}\,p_{s,N}(x) \;\le\; f_N(x) \;\le\; h_{\max}\,p_{s,N}(x) \quad x\in[0,2\pi]\,.$$

This implies by definition of $\boldsymbol{M}_N(f_N)$ that

$$\frac{\bar{\boldsymbol{u}}'\,(\boldsymbol{A}_N(f)-h_{\max}\boldsymbol{R}_N(2s))\,\boldsymbol{u}}{\bar{\boldsymbol{u}}'\,\boldsymbol{M}_N(f_N)\,\boldsymbol{u}} \;\le\; \frac{h_{\max}}{h_{\min}}\,\frac{\bar{\boldsymbol{u}}'\,\boldsymbol{M}_N(p_s)\,\boldsymbol{u}}{\bar{\boldsymbol{u}}'\,\boldsymbol{M}_N(p_{s,N})\,\boldsymbol{u}}$$

and further by (3.3), (3.8) and since $0<\alpha\le\beta<\infty$ that

$$\frac{\bar{\boldsymbol{u}}'\,(\boldsymbol{A}_N(f)-h_{\max}\boldsymbol{R}_N(2s))\,\boldsymbol{u}}{\bar{\boldsymbol{u}}'\,\boldsymbol{M}_N(f_N)\,\boldsymbol{u}} \;\le\; \frac{h_{\max}}{\alpha\,h_{\min}}$$

for all $\boldsymbol{u}\ne\boldsymbol{o}_N$. Assume that $\boldsymbol{R}_N(2s)$ has s_1 positive eigenvalues. Then, by properties of the Rayleigh quotient and by Weyl's theorem [24, p. 184] at most s_1 eigenvalues of $\boldsymbol{M}_N(f_N)^{-1}\boldsymbol{A}_N(f)$ are larger than $\frac{h_{\max}}{\alpha\,h_{\min}}$. Similarly, we obtain by consideration of the left-hand inequality of (3.10) that at most $2s-s_1$ eigenvalues of $\boldsymbol{M}_N(f_N)^{-1}\boldsymbol{A}_N(f)$ are smaller than $\frac{h_{\min}}{\beta\,h_{\max}}$.

2. To show (i), we rewrite (3.9) as

$$\frac{\bar{\boldsymbol{u}}'\,\boldsymbol{A}_N(f)\,\boldsymbol{u}}{\bar{\boldsymbol{u}}'\,\boldsymbol{M}_N(f_N)\,\boldsymbol{u}} \;=\; \frac{\bar{\boldsymbol{u}}'\,\boldsymbol{A}_N(f)\,\boldsymbol{u}}{\bar{\boldsymbol{u}}'\,\boldsymbol{A}_N(p_s)\,\boldsymbol{u}}\;\frac{\bar{\boldsymbol{u}}'\,\boldsymbol{M}_N(p_s)\,\boldsymbol{u}}{\bar{\boldsymbol{u}}'\,\boldsymbol{M}_N(f_N)\,\boldsymbol{u}}\;\frac{\bar{\boldsymbol{u}}'\,\boldsymbol{A}_N(p_s)\,\boldsymbol{u}}{\bar{\boldsymbol{u}}'\,\boldsymbol{M}_N(p_s)\,\boldsymbol{u}} \quad (\boldsymbol{u}\ne\boldsymbol{o}_N)\,.$$

As in the first part of the proof, we see that this implies

$$\frac{\bar{\boldsymbol{u}}'\,\boldsymbol{A}_N(f)\,\boldsymbol{u}}{\bar{\boldsymbol{u}}'\,\boldsymbol{M}_N(f_N)\,\boldsymbol{u}} \;\ge\; \frac{h_{\min}}{\beta\,h_{\max}}\;\frac{\bar{\boldsymbol{u}}'\,\boldsymbol{A}_N(p_s)\,\boldsymbol{u}}{\bar{\boldsymbol{u}}'\,\boldsymbol{M}_N(p_s)\,\boldsymbol{u}}\,.$$

Consequently, it remains to show that there exists a constant $0<c<\infty$ such that

$$\frac{\bar{\boldsymbol{u}}'\,\boldsymbol{A}_N(p_s)\,\boldsymbol{u}}{\bar{\boldsymbol{u}}'\,\boldsymbol{M}_N(p_s)\,\boldsymbol{u}} \;\ge\; \frac{1}{c}\,.$$

By (3.1), this is equivalent to

$$1 \;+\; \frac{\bar{\boldsymbol{u}}'\,\boldsymbol{B}_N(p_s)\,\boldsymbol{u}}{\bar{\boldsymbol{u}}'\,\boldsymbol{A}_N(p_s)\,\boldsymbol{u}} \;\le\; c\,.$$

By the special structure of $\boldsymbol{B}_N(p_s)$ and $\boldsymbol{A}_N(p_s)$, assertion (i) follows as in the proof of Theorem 4.3 in [3]. This completes the proof. □

By the following theorem, the "moment property" (3.5) of the kernel is also *necessary* to obtain good preconditioners.

THEOREM 3.7. *Let $\{\boldsymbol{A}_N(f)\}_{N\in\mathbb{N}}$ be a sequence of Toeplitz matrices generated by a nonnegative function $f \in C_{2\pi}$ which has only a zero of order $2s$ ($s \in \mathbb{N}$) at $x = 0$. Let the grids G_N be defined by* (2.7) *and* (3.4). *Assume that $\{K_N\}_{N\in\mathbb{N}}$ is a sequence of even positive reproducing kernels which do not fulfill* (3.5). *Finally, let $\boldsymbol{M}_N(f_N)$ be defined by* (2.10). *Then, for arbitrary $\varepsilon > 0$ and arbitrary $c \in \mathbb{N}$, there exist $N(\varepsilon, c)$ such that for all $N \geq N(\varepsilon, c)$ at least c eigenvalues of $\boldsymbol{M}_N(f_N)^{-1}\boldsymbol{A}_N(f)$ are contained in $(0, \varepsilon)$.*

The proof follows again the lines of the fundamental paper of Di Benedetto [3, Theorem 5.4]. We include the short proof with respect to our background.

Proof. By the proof of Theorem 3.6, we have for all $\boldsymbol{u} \neq \boldsymbol{o}$ that

$$\frac{\bar{\boldsymbol{u}}'\,\boldsymbol{A}_N(f)\,\boldsymbol{u}}{\bar{\boldsymbol{u}}'\,\boldsymbol{M}_N(f_N)\,\boldsymbol{u}} \;\leq\; \frac{h_{\max}}{h_{\min}}\,\frac{\bar{\boldsymbol{u}}'\,\boldsymbol{A}_N(p_s)\,\boldsymbol{u}}{\bar{\boldsymbol{u}}'\,\boldsymbol{M}_N(p_{s,N})\,\boldsymbol{u}}\,.$$

Hence it remains to show that $\boldsymbol{M}_N(p_{s,N})^{-1}\boldsymbol{A}_N(p_s)$ has an arbitrary number of eigenvalues in $(0, \varepsilon)$ for N sufficiently large. By (3.2) and [32, Theorem 3.1], we have that

$$\begin{aligned}
\boldsymbol{T}_{N+2s-2} &:= \boldsymbol{S}^I_{N+2s-2}\,\mathrm{diag}\left(\left(2\,\sin\frac{j\pi}{2(N+2s-1)}\right)^{2s}\right)_{j=1}^{N+2s-2}\boldsymbol{S}^I_{N+2s-2}\\
&= \boldsymbol{S}^I_{N+2s-2}\,\mathrm{diag}\left(\sum_{k=0}^{s}\alpha_k\cos\frac{jk\pi}{N+2s-1}\right)_{j=1}^{N+2s-2}\boldsymbol{S}^I_{N+2s-2}\\
&= \frac{1}{2}\,\mathrm{stoep}(2\alpha_0,\,\ldots\,,\alpha_s,0,\,\ldots\,,0) \;-\; \frac{1}{2}\,\mathrm{shank}(\alpha_2,\,\ldots\,,\alpha_s,0,\,\ldots\,,0)\,,
\end{aligned}$$

where $\boldsymbol{S}^I_{N-1} := (2/N)^{1/2}(\sin\frac{(j+1)(k+1)\pi}{N})_{j,k=0}^{N-2}$ is an orthogonal matrix and where $\mathrm{stoep}\,\boldsymbol{a}'$ and $\mathrm{shank}\,\boldsymbol{a}'$ denote the symmetric Toeplitz matrix and the persymmetric Hankel matrix with first row $\boldsymbol{a}'$, respectively. Deleting the first $s-1$ and the last $s-1$ rows and columns of $\boldsymbol{T}_{N+2s-2}$ we obtain $\boldsymbol{A}_N(p_s)$. Thus, we have by Courant's minimax theorem for the eigenvalues $\lambda_1(\boldsymbol{A}_N(p_s)) \leq \cdots \leq \lambda_N(\boldsymbol{A}_N(p_s))$ of $\boldsymbol{A}_N(p_s)$ that

$$\lambda_j(\boldsymbol{A}_N(p_s)) \leq \lambda_{j+2s-2}(\boldsymbol{T}_{N+2s-2}) = \left(2\,\sin\frac{j+2s-2}{2(N+2s-1)}\right)^{2s} \leq \left(\frac{j+2s-2}{N+2s-1}\right)^{2s}.$$

The later result is due to a technique of Bini and Capovani [7, Proposition 4.2]. Consider $\boldsymbol{A}_N(p_s) - t\boldsymbol{M}_N(p_{s,N})$. For $t = 0$, this matrix has positive eigenvalues, while we have for arbitrary $\varepsilon > 0$ that

$$\begin{aligned}
\lambda_j(\boldsymbol{A}_N(p_s) - \varepsilon\,\boldsymbol{M}_N(p_{s,N})) &\leq \lambda_j(\boldsymbol{A}_N(p_s)) \;-\; \varepsilon\,\lambda_{\min}(\boldsymbol{M}_N(p_{s,N}))\\
&\leq \left(\frac{j+2s-2}{N+2s-1}\right)^{2s} \;-\; \varepsilon\,p_{s,N}(w_N)\\
&= N^{-2s}\left(\left(\frac{j+2s-2}{1+\frac{2s-1}{N}}\right)^{2s} \;-\; \varepsilon\,\frac{p_{s,N}(w_N)}{N^{2s}}\right).
\end{aligned}$$

Since K_N does not fulfill (3.5), we have by Lemma 3.5 that

$$\lim_{N\to\infty}\frac{p_{s,N}(w_N)}{N^{2s}} = \infty\,.$$

Thus, for $j \leq c$ independent of N and for sufficiently large $N \geq N(\varepsilon, c)$ the values $\lambda_j(\boldsymbol{A}_N(p_s) - \varepsilon \boldsymbol{M}_N(p_{s,N}))$ become negative. The eigenvalues of $\boldsymbol{A}_N(p_s) - t\,\boldsymbol{M}_N(p_{s,N})$ are continuous functions of t. Since the smallest c eigenvalues pass from a positive value for $t = 0$ to a negative value for $t = \varepsilon$, there exist $\varepsilon_1, \ldots, \varepsilon_c \in (0, \varepsilon)$ such that $\boldsymbol{A}_N(p_s) - \varepsilon_j \boldsymbol{M}_N(p_{s,N})$ has eigenvalue zero. This is equivalent to the fact that $\boldsymbol{M}_N(p_{s,N})^{-1}\boldsymbol{A}_N(p_s)$ has an eigenvalue $\varepsilon_j \in (0, \varepsilon)$, and we are done with the proof. □

The generalization of the above results for generating functions with different zeros of even order

$$f(x) \;=\; (x - y_1)^{2s_1} \ldots (x - y_m)^{2s_m} \tilde{f}(x) \quad (\tilde{f} > 0)$$

is straightforward (see [18]). By applying the polynomial

$$p(x) := \prod_{i=1}^{m} p_{s_i}(x - y_i)$$

instead of p_s and following the above lines, we can show that for grids G_N of the form (2.7) with $x_{N,l} \neq y_i$ $(l = 0, \ldots, N-1;\ i = 1, \ldots, m)$ and for kernels K_N fulfilling (3.5) with $s := \max\{s_j : j = 1, \ldots, m\}$, there exist constants $0 < \alpha \leq \beta < \infty$ such that for all $x \in G_N$

$$\alpha \leq \frac{(p * K_N)(x)}{p(x)} \leq \beta\,.$$

4. Jackson polynomials and *B*-spline kernels. In this section, we consider concrete positive reproducing kernels K_N with property (3.5).

The *generalized Jackson polynomials* of degree $\leq N - 1$ are defined by

$$J_{m,N}(x) = \lambda_{m,N} \left(\frac{\sin(nx/2)}{\sin x/2} \right)^{2m} \qquad (m \in \mathbb{N})\,,$$

where $n := \lfloor \frac{N-1}{m} \rfloor + 1$ and where $\lambda_{m,N}$ is determined by (2.3) [22, p. 203]. It is well known [22, p. 204] that the generalized Jackson polynomials $J_{m,N}$ are even positive reproducing kernels which satisfy property (3.5) for

$$m \geq s + 1\,.$$

In particular, $J_{1,N}$ is the *Fejér kernel* which is related to the optimal circulant preconditioner [19, 15]. However, the Fejér kernel does not fulfill (3.5) for $s \geq 1$ such that we cannot expect a fast convergence of our PCG method if f has a zero of order ≥ 2. Our numerical tests confirm this result.

By Theorem 3.6, the generalized Jackson polynomials $K_N = J_{m,N}$ with $m \geq s+1$ can be used for the construction of preconditioners. Note that preconditioners related to Jackson kernels were also suggested in [39]. However, the construction of the Fourier coefficients of $J_{m,N}$ seems to be rather complicated. See also [10]. Therefore we prefer the following B-spline kernels.

The "B-spline kernels" were introduced by Chan, Tso, and Sun in [14]. The authors showed by numerical tests that preconditioners from B-spline kernels of certain order seem to be good candidates for the PCG method. Applying the results of the previous section, we are able to show the theoretical reasons for these results, at least for the positive B-spline kernels.

Let $\chi_{[0,1)}$ denote the characteristic function of $[0,1)$. The *cardinal B-splines* N_m $(m \geq 1)$ *of order* m are defined by

$$N_1 := \chi_{[0,1)}\,,\ N_{m+1} := \int_0^1 N_1(t)\ N_m(\cdot - t)\ \mathrm{d}t$$

and their centered version by

$$M_m := N_m\left(\cdot + \frac{m}{2}\right)\ .$$

Note that M_m is an even function with $\operatorname{supp} M_m = [-\frac{m}{2}, \frac{m}{2}]$ and that

$$\int_{-\infty}^{\infty} M_m(t)\ \mathrm{e}^{-\mathrm{i}xt}\ \mathrm{d}t = \left(\operatorname{sinc}\frac{x}{2}\right)^m\ , \tag{4.1}$$

where

$$\operatorname{sinc} x := \begin{cases} \dfrac{\sin x}{x}, & x \neq 0\ , \\ 1, & x = 0\ . \end{cases}$$

Let the *B-spline kernels* $B_{m,N}$ be defined by [14]

$$B_{m,N}(x) := 1 + \frac{2}{M_{2m}(0)} \sum_{k=1}^{N-1} M_{2m}\left(\frac{mk}{N}\right)\ \cos kx\ .$$

Note that $B_{1,N}$ again coincides with the Fejér kernel.

For the construction of the preconditioner, it is important that the Fourier coefficient $c_{N,k} = M_{2m}(\frac{mk}{N})/M_{2m}(0)$ can be computed in a simple way, for example, by applying a simplified version of de Boor's algorithm [9, p. 54].

By (4.1), it is easy to check that $B_{m,N}$ is a dilated, 2π-periodized version of $(\operatorname{sinc}\frac{x}{2})^{2m}$, i.e.,

$$B_{m,N}(x) = \frac{N}{m}\ \frac{1}{M_{2m}(0)}\ \sum_{r\in\mathbb{Z}} \left(\operatorname{sinc}\ \left(\frac{N}{m}\left(\frac{x+2\pi r}{2}\right)\right)\right)^{2m}\ . \tag{4.2}$$

Thus

$$B_{m,N} \geq 0 \quad (m \in \mathbb{N})\ .$$

Moreover, we obtain similar to the generalized Jackson polynomials the following lemma.

LEMMA 4.1. *The B-spline kernels* $B_{m,N}$ *satisfy* (3.5) *if and only if* $m \geq s+1$.

Proof. By (4.2), we obtain that

$$\begin{aligned}
\int_{-\pi}^{\pi} t^{2k}\, B_{m,N}(t)\,\mathrm{d}t &= \frac{N}{m}\ \frac{1}{M_{2m}(0)} \int_{-\pi}^{\pi} t^{2k} \sum_{r\in\mathbb{Z}} \left(\operatorname{sinc}\ \left(\frac{N}{m}\left(\frac{t+2\pi r}{2}\right)\right)\right)^{2m}\ \mathrm{d}t \\
&\leq \frac{N}{m}\ \frac{1}{M_{2m}(0)} \int_{-\infty}^{\infty} t^{2k} \left(\frac{\sin\left(\frac{N}{m}\frac{t}{2}\right)}{\frac{N}{m}\frac{t}{2}}\right)^{2m}\ \mathrm{d}t \\
&= \frac{2}{M_{2m}(0)} \int_{-\infty}^{\infty} \left(\frac{2mu}{N}\right)^{2k} \left(\frac{\sin u}{u}\right)^{2m}\ \mathrm{d}u \\
&\leq c\, N^{-2k} \int_{-\infty}^{\infty} u^{2k-2m}\,\mathrm{d}u \leq C\, N^{-2k}
\end{aligned}$$

for $m \geq k+1$. Thus, for $m \geq s+1$ the kernels $B_{m,N}$ satisfy property (3.5).

On the other hand, we have that

$$\begin{aligned}\int_{-\pi}^{\pi} t^{2k}\, B_{m,N}(t)\,\mathrm{d}t &\geq \frac{N}{m}\,\frac{1}{M_{2m}(0)}\int_{-\pi}^{\pi} t^{2k}\left(\frac{\sin\frac{N}{m}\left(\frac{t}{2}\right)}{\frac{N}{m}\left(\frac{t}{2}\right)}\right)^{2m}\mathrm{d}t\\ &= \frac{2}{M_{2m}(0)}\int_{-N\pi/(2m)}^{N\pi/(2m)}\left(\frac{2mu}{N}\right)^{2k}\left(\frac{\sin u}{u}\right)^{2m}\mathrm{d}u\\ &= \frac{2\,(2m)^{2k}}{M_{2m}(0)}\,N^{-2k}\int_{-N\pi/(2m)}^{N\pi/(2m)}\frac{(\sin u)^{2m}}{u^{2m-2k}}\,\mathrm{d}u\,.\end{aligned}$$

If $m \leq k$, then the last integral is not bounded for $N \to \infty$. Thus, for $m \leq s$, the kernel $B_{m,N}$ does not fulfill property (3.5). ∎

By Theorem 3.6, the B-spline kernels $K_N = B_{m,N}$ with $m \geq s+1$ produce good preconditioners.

5. Generalizations of the preconditioning technique. In this section, we sketch how our preconditioners can be generalized to (real) symmetric Toeplitz matrices and to BTTB matrices. We will do this in a very short way since both cases do not require new ideas. However, we have to introduce some notation to understand the numerical tests in section 7.

Symmetric Toeplitz matrices. First, we suppose in addition to section 2 that the Toeplitz matrices $\boldsymbol{A}_N \in \mathbb{R}^{N,N}$ are symmetric, i.e., the generating function $f \in C_{2\pi}$ is even. Note that in this case, the multiplication of a vector with $\boldsymbol{A}_N$ can be realized using *fast trigonometric transforms* instead of FFTs (see [32]). In this way, complex arithmetic can be completely avoided in the iterative solution of (2.1). This is one of the reasons to look for preconditioners of type (2.8), where the Fourier matrix $\boldsymbol{F}_N$ is replaced by trigonometric matrices corresponding to fast trigonometric transforms. In practice, four discrete sine transforms (DST I–IV) and four discrete cosine transforms (DCT I–IV) were applied (see [46]). Any of these eight trigonometric transforms can be realized with $\mathcal{O}(N \log N)$ arithmetical operations (see, for example, [2, 44]). Likewise, we can define preconditioners with respect to any of these transforms. In this paper, we restrict our attention to the DST–II and DCT–II, which are determined by the following transform matrices:

$$\begin{aligned}\text{DCT–II}: \quad \boldsymbol{C}_N^{II} &:= \left(\frac{2}{N}\right)^{1/2}\left(\varepsilon_j^N\,\cos\,\frac{j(2k+1)\pi}{2N}\right)_{j,k=0}^{N-1} \in \mathbb{R}^{N,N},\\ \text{DST–II}: \quad \boldsymbol{S}_N^{II} &:= \left(\frac{2}{N}\right)^{1/2}\left(\varepsilon_{j+1}^N\,\sin\,\frac{(j+1)(2k+1)\pi}{2N}\right)_{j,k=0}^{N-1} \in \mathbb{R}^{N,N},\end{aligned}$$

where $\varepsilon_k^N := 2^{-1/2}$ $(k = 0, N)$ and $\varepsilon_k^N := 1$ $(k = 1, \ldots, N-1)$. Similar to (2.10), (2.8), we introduce the preconditioners (see [31])

$$\begin{aligned}\mathrm{DCT-II}: \qquad \boldsymbol{M}_N(f_N, \boldsymbol{C}_N^{II}) &:= (\boldsymbol{C}_N^{II})'\,\mathrm{diag}\left(f_N\left(\frac{l\pi}{N}\right)\right)_{l=0}^{N-1}\boldsymbol{C}_N^{II},\\ \mathrm{DST-II}: \qquad \boldsymbol{M}_N(f_N, \boldsymbol{S}_N^{II}) &:= (\boldsymbol{S}_N^{II})'\,\mathrm{diag}\left(f_N\left(\frac{l\pi}{N}\right)\right)_{l=1}^{N}\boldsymbol{S}_N^{II}\,.\end{aligned} \tag{5.1}$$

We recall that for the construction of these preconditioners no explicit knowledge of the generating function is required. Since f is even, the grids G_N are simply chosen as

$G_N := \{x_{N,l} := \frac{l\pi}{N} : l = 0, \dots, N-1\}$ and $G_N := \{x_{N,l} := \frac{(l+1)\pi}{N} : l = 0, \dots, N-1\}$ for the DCT–II and the DST–II preconditioners, respectively. If $f(x_{N,l}) \neq 0$ ($l = 0, \dots, N$), then we can prove Theorem 3.6 with respect to the preconditioners (5.1) in a completely similar way. We have only to replace the decomposition (3.1) by

$$\boldsymbol{A}_N(f) = \boldsymbol{M}_N(f, \boldsymbol{C}_N^{II}) - \operatorname{shank}(a_1, \dots, a_{N-1}, 0),$$
$$\boldsymbol{A}_N(f) = \boldsymbol{M}_N(f, \boldsymbol{S}_N^{II}) + \operatorname{shank}(a_1, \dots, a_{N-1}, 0)$$

for the DCT–II and for the DST–II, respectively. See also [31].

Remark. Let

$$\mathcal{A}_{O_N} := \{\bar{\boldsymbol{O}}_N'(\operatorname{diag} \boldsymbol{d})\boldsymbol{O}_N : \boldsymbol{d} \in \mathbb{R}^N\}$$

denote the matrix algebra with respect to the unitary matrix $\boldsymbol{O}_N$. Then the *optimal preconditioner* $\boldsymbol{M}_N \in \mathcal{A}_{O_N}$ *of* $\boldsymbol{A}_N$ *in* $\mathcal{A}_{O_N}$ is defined by

$$||\boldsymbol{M}_N - \boldsymbol{A}_N||_F = \min\{||\boldsymbol{P} - \boldsymbol{A}_N||_F : \boldsymbol{P} \in \mathcal{A}_{O_N}\},$$

where $\|\cdot\|_F$ denotes the Frobenius norm. As mentioned in the previous section, the optimal preconditioner in $\mathcal{A}_{F_N}$ coincides with our preconditioner (2.10) defined with respect to the Fejér kernel $B_{1,N}$ and with $w_N = 0$ in (2.7). It is easy to check (see [33]) that the optimal preconditioner in $\mathcal{A}_{O_N}$, where $\boldsymbol{O}_N \in \{\boldsymbol{C}_N^{IV}, \boldsymbol{S}_N^{IV}\}$, is equal to our preconditioner $\boldsymbol{M}_N(f_N, \boldsymbol{O}_N)$ in (5.1) defined with respect to $\boldsymbol{O}_N$ and with respect to the Fejér kernel. Unfortunately, the Fejér kernel preconditioners do not lead to a fast convergence of the PCG method if the generating function f of $\boldsymbol{A}_N$ has a zero of order $2s \geq 2$.

In contrast to these results, the optimal preconditioners in $\mathcal{A}_{O_N}$ with $\boldsymbol{O}_N$ defined by the DCT I–III or by the DST I–III do not coincide with the corresponding Fejér kernel preconditioner $\boldsymbol{M}_N(f_N, \boldsymbol{O}_N)$ in (5.1). In literature [6, 3], so-called optimal Tau preconditioners were of special interest. Using our notation, optimal Tau preconditioners are the optimal preconditioners with respect to the DST–I as unitary transform. The optimal Tau preconditioner realizes a fast convergence of the PCG method if the generating function f of $\boldsymbol{A}_N$ has only zeros of order $2s \leq 2$ [6].

Block Toeplitz matrices with Toeplitz blocks. Next we are interested in the solution of BTTB matrices. The construction of preconditioners with the help of reproducing kernels was applied to well-conditioned block Toeplitz systems in [27]. Following these lines, we generalize our univariate construction to ill-conditioned block Toeplitz systems with Toeplitz blocks. In the next section we will present good numerical results also for the block case. However, in general, it is not possible to prove the convergence of PCG in a number of iteration steps independent of N. Here we refer to [34].

Note that as in the univariate case there exist banded block Toeplitz preconditioners with banded Toeplitz blocks which ensure a fast convergence of the corresponding PCG method [35]. See also [4, 30].

We consider systems of linear equations

$$\boldsymbol{A}_{M,N}\boldsymbol{x} = \boldsymbol{b},$$

where $\boldsymbol{A}_{M,N}$ denotes a positive *definite doubly symmetric block Toeplitz matrix with Toeplitz blocks* (BTTB matrix), i.e.,

$$\boldsymbol{A}_{M,N} := (\boldsymbol{A}_{r-s})_{r,s=0}^{M-1} \quad \text{with} \quad \boldsymbol{A}_r := (a_{r,j-k})_{j,k=0}^{N-1}$$

and $a_{r,j} = a_{|r|,|j|}$. We assume that the matrices $\boldsymbol{A}_{M,N}$ are generated by a real-valued 2π-periodic continuous even function in two variables, i.e.,

$$a_{j,k} := \frac{1}{4\pi^2} \int_0^{2\pi} \int_0^{2\pi} \varphi(s,t)\, \mathrm{e}^{-\mathrm{i}(sj+tk)}\, \mathrm{d}s\, \mathrm{d}t\,.$$

Note that the multiplication of a vector with a BTTB matrix requires only $\mathcal{O}(MN \log(MN))$ arithmetical operations (see [33]). We define our so-called "*level*-2" *preconditioners* by

$$\begin{aligned}
\boldsymbol{M}_{M,N}(\varphi_{M,N}, \boldsymbol{C}_M^{II} \otimes \boldsymbol{C}_N^{II}) &:= (\boldsymbol{C}_M^{II} \otimes \boldsymbol{C}_N^{II})'\ \mathrm{diag}\left(\mathrm{col}\left(\varphi_{M,N}\left(\frac{r\pi}{M}, \frac{j\pi}{N}\right)\right)_{j,k=0}^{N-1,M-1}\right) \\
&\quad \times (\boldsymbol{C}_M^{II} \otimes \boldsymbol{C}_N^{II})\,, \\
\boldsymbol{M}_{M,N}(\varphi_{M,N}, \boldsymbol{S}_M^{II} \otimes \boldsymbol{S}_N^{II}) &:= (\boldsymbol{S}_M^{II} \otimes \boldsymbol{S}_N^{II})'\ \mathrm{diag}\left(\mathrm{col}\left(\varphi_{M,N}\left(\frac{r\pi}{M}, \frac{j\pi}{N}\right)\right)_{j,k=1}^{N,M}\right) \\
&\quad \times (\boldsymbol{S}_M^{II} \otimes \boldsymbol{S}_N^{II})\,, \qquad (5.2)
\end{aligned}$$

with $\varphi_{M,N} = \varphi * K_{M,N}$ and $K_{M,N}(x,y) := K_M(x) K_N(y)$. Here col: $\mathbb{R}^{N,M} \to \mathbb{R}^{MN}$ is defined by

$$\mathrm{col}\,(x_{j,k})_{j=0,k=0}^{N-1,M-1} := (x_r)_{r=0}^{MN-1} \quad \text{with} \quad x_{kN+j} := x_{j,k}\,.$$

6. Numerical examples. In this section, we confirm our theoretical results by various numerical examples. The fast computation of the preconditioners and the PCG method were implemented in MATLAB, where the C programs for the fast trigonometric transforms were included by cmex. The algorithms were tested on a Sun SPARCstation 20.

As transform length we choose $N = 2^n$ and as right-hand side $\boldsymbol{b}$ of (2.1) the vector consisting of N entries "1". The PCG method started with the zero vector and stopped if $\|\boldsymbol{r}^{(j)}\|_2 / \|\boldsymbol{r}^{(0)}\|_2 < 10^{-7}$, where $\boldsymbol{r}^{(j)}$ denotes the residual vector after j iterations.

We restrict our attention to preconditioners (2.10) and (5.1) constructed from B-spline kernels $K_N = B_{m,N}$. The following tables (Tables 1–6) show the number of iterations of the corresponding PCG method to achieve a fixed precision. The first row of each table contains the exponent n of the transform length $N = 2^n$ in the univariate case and the block length N in the block Toeplitz case. The kernels are listed in the first column and the applied unitary transform are listed in the second column of each table. Here $\boldsymbol{F}_N^w := \boldsymbol{W}_N \boldsymbol{F}_N$ with $\boldsymbol{W}_N := \mathrm{diag}(\,\mathrm{e}^{-\mathrm{i}k\pi/N})_{k=0}^{N-1}$, i.e., $w_N := \pi/N$ in (2.7). For comparison, the second row of each table contains the number of PCG steps with preconditioner $\boldsymbol{M}_N(f)$ defined by (2.8). These preconditioners, which can be constructed only if the generating function f is known, were examined in [31].

We begin with symmetric ill-conditioned Toeplitz matrices $\boldsymbol{A}_N(f)$ arising from the generating functions

(i) (see [13, 14, 33]): $f(x) := x^2 \quad (x \in [-\pi, \pi))$.

(ii) (see [3, 10, 11, 14, 31, 36]): $f(x) := x^4 \quad (x \in [-\pi, \pi))$.

Tables 1 and 2 present the number of iteration steps with different preconditioners.

As expected, for $f(x) = x^2$ it is not sufficient to choose a preconditioner based on the Fejér kernel $K_N = B_{1,N}$ and for $f(x) = x^4$ it is not sufficient to choose a preconditioner based on the cubic B-spline kernel $K_N = B_{2,N}$ in order to keep the number of iterations independent of N.

$B_{1,N}$	$\boldsymbol{F}_N^w$	8	15	23	36	61	153	390	> 800	> 800
$B_{1,N}$	$\boldsymbol{C}_N^{II}$	8	13	20	32	53	129	319	> 800	> 800
$B_{1,N}$	$\boldsymbol{S}_N^{II}$	8	16	24	38	65	158	402	> 800	> 800
$B_{2,N}$	$\boldsymbol{F}_N$	9	9	11	11	13	15	18	22	27
$B_{2,N}$	$\boldsymbol{F}_N^w$	9	9	10	10	13	14	17	20	26
$B_{2,N}$	$\boldsymbol{C}_N^{II}$	8	8	9	9	9	11	13	14	16
$B_{2,N}$	$\boldsymbol{S}_N^{II}$	10	10	10	11	13	14	18	19	22
$B_{3,N}$	$\boldsymbol{F}_N$	9	11	11	12	12	12	13	15	14
$B_{3,N}$	$\boldsymbol{F}_N^w$	9	9	10	10	12	12	13	13	13
$B_{3,N}$	$\boldsymbol{C}_N^{II}$	8	9	9	9	9	9	10	10	9
$B_{3,N}$	$\boldsymbol{S}_N^{II}$	10	10	12	12	14	14	14	15	16

On the other hand, we have a similar convergence behavior for the different unitary transforms. This is no surprise for $\boldsymbol{F}_N^w$ and for $\boldsymbol{S}_N^{II}$. However, for $\boldsymbol{F}_N$ and for $\boldsymbol{C}_N^{II}$, the corresponding grids G_N contain the zero of f, namely, $x_{N,0} = 0$. This was excluded in Theorem 3.6. In our numerical tests it seems to play no rule that a grid point meets the zero of f.

TABLE 4
$\varphi(s,t) = s^2 + t^2 + s^2 t^2 \quad (s,t \in [-\pi, \pi))$.

$K_{N,N}$	$\boldsymbol{O}_N$	8	16	32	64	128	256	512
φ	$\boldsymbol{S}_N^{II}$	8	9	9	10	10	10	10
$B_{1,N,N}$	$\boldsymbol{S}_N^{II}$	10	12	14	16	20	26	36
$B_{2,N,N}$	$\boldsymbol{S}_N^{II}$	10	10	11	11	11	11	11
$B_{3,N,N}$	$\boldsymbol{S}_N^{II}$	10	10	11	11	11	11	11

Our next example in Table 3 confirms our theoretical results for the function

(iii) $f(x) = (x^2 - 1)^2$

with zeros of order 2 at $x = \pm 1$.

Finally, let us turn to BTTB matrices $\boldsymbol{A}_{N,N}$. In our examples, the matrices $\boldsymbol{A}_{N,N}$ are generated by the functions

(iv) (see [4]): $\varphi(s,t) = s^2 + t^2 + s^2\, t^2 \quad (s,t \in [-\pi, \pi))$.

(v) (see [30, 31]): $\varphi(s,t) = s^2\, t^4 \quad (s,t \in [-\pi, \pi))$.

(vi) (see [30, 31]): $\varphi(s,t) = (s^2 + t^2)^2 \quad (s,t \in [-\pi, \pi))$.

These matrices are ill-conditioned and the CG method without preconditioning, with Strang-type–preconditioning or with optimal trigonometric preconditioning, converges very slow (see [30, 33, 4]). Our preconditioning (5.2) leads to the number of iterations in Tables 4–6. Here $B_{k,N,N}(x,y) := B_{k,N}(x)\, B_{k,N}(y)$.

In [34], we proved that the number of iteration steps of PCG is independent of N in Example (iv) and we explained the convergence behavior of PCG for the other examples. To our knowledge, at the present time there does not exist a faster PCG

method if the generating function φ is unknown.

Note that by [42, 43] any multilevel preconditioner is not optimal in the sense that a cluster cannot be proper [45].

Summary. We suggested new positive definite w-circulant preconditioners for sequences of Toeplitz systems with polynomial increasing condition numbers. The construction of our preconditioners is based on the convolution of the generating function with positive reproducing kernels and, by working in the Fourier domain, does not require the explicit knowledge of the generating function. As our main result we proved that the quality of the preconditioner depends on a "moment property" of the corresponding kernel which is related to the order of the zeros of the generating function. This explains, e.g., why optimal circulant preconditioners arising from convolutions with the Fejér kernels fail to be good preconditioners if the generating function has zeros of order ≥ 2.

A NOTE ON PARALLEL MATRIX INVERSION*

ENRIQUE S. QUINTANA†, GREGORIO QUINTANA†, XIAOBAI SUN‡, AND ROBERT VAN DE GEIJN§

Dedicated to G. W. Stewart on the occasion of his 60th birthday

Abstract. We present one-sweep parallel algorithms for the inversion of general and symmetric positive definite matrices. The algorithms feature simple programming and performance optimization while maintaining the same arithmetic cost and numerical properties of conventional inversion algorithms. Our experiments on a Cray T3E-600 and a Beowulf cluster demonstrate high performance of implementations for distributed memory parallel computers.

Key words. matrix inversion, Gauss–Jordan elimination, parallel computers

1. Introduction.

Despite the inexpedience of matrix inverse, as Higham summarizes in [13], "there are situations in which a matrix inverse must be computed." Examples arise in statistics [4, section 7.5], [15, section 2.3], [16, p. 342], [3]; in numerical integrations in superconductivity computations [12]; and in stable subspace computation in control theory [17]. The recent years have seen increasing interest in parallel solutions of large-scale applications [3, 7, 9]. Inversion algorithms for general full nonsingular matrices are mostly based on the availability of a complete LU factorization. The algorithm used by LINPACK [8] and LAPACK [2] proceeds as follows.

(1) LU factorization with partial pivoting, $PA = LU$, where P is a permutation matrix, and U, $L \in \Re^{n \times n}$ are upper triangular and unit lower triangular matrices, respectively.
(2) Triangular inversion of U (forward substitution).
(3) Triangular (system) solve for X: $XL = U^{-1}$ (backward substitution).
(4) Back permutation of columns, $A^{-1} = XP$.

The algorithm allows the inverse to be computed *in-place*, that is, the computed inverse overwrites the input matrix to be inverted. It sweeps three times across the array that houses the involved matrices for LU factorization, triangular inversion, and triangular solve. The algorithm is effective on uniprocessor computers and shared memory parallel computers. A parallel version of the algorithm is implemented in ScaLAPACK [6]. We present in this paper our study of inversion algorithms via Gauss–Jordan elimination (GJE) for general square matrices and a related algorithm for symmetric positive definite (SPD) matrices. Specifically, we show that these algorithms are more suitable for parallel computers with physically distributed

FIG. 1. MATLAB *code for matrix inversion via GJE. By also executing the steps on the right, pivoting is added.*

memory.

Matrix inversion using GJE is, in essence, a reordering of the computation performed by matrix inversion methods using Gaussian elimination (LU factorization) and hence requires the same arithmetic cost. Many classic references to inversion methods can be found in [13, 14]. Nevertheless, computation arrangements for matrix inversion via GJE (instead of a system solve with multiple right-hand sides) are rarely presented in the literature. A nonblocked parallel version of the in-place GJE-based inversion algorithm presented later is given in [10]. An in-place procedure for inversion of positive definite matrices is given by Bauer and Reinsch [5].

In Figure 1 we describe in MATLAB language a LEVEL-2 basic linear algebra subprogram (BLAS), in-place inversion algorithm via GJE for a general square matrix. The fact that the sweeps over the intermediate triangular matrices L and U are computationally eluded has multiple advantages in parallel computations, as we will describe in sections 5 and 6.

The rest of the paper is organized as follows. In section 2 we present an inversion algorithm via GJE with partial pivoting. The relation of this algorithm with traditional multistage algorithms is given in section 3. The approach is extended to SPD matrices in section 4. In section 5 we discuss parallel implementation issues. In section 6 we present performance results for our parallel implementations of the algorithm. Concluding remarks can be found in the final section.

2. An inversion algorithm via Gauss–Jordan elimination. Recall how to invert an $n \times n$ matrix A by creating an augmented system $\left(\begin{array}{c|c} A & B \end{array}\right)$ with $B = I_n$, the $n \times n$ identity matrix, and performing Gauss–Jordan elimination on this augmented system:

for $k = 1, n$

Partition $\left(\begin{array}{c|c} A & B \end{array}\right) \rightarrow \left(\begin{array}{c|c|c||c|c|c} I_{k-1} & a_{01} & A_{02} & B_{00} & 0 & 0 \\ \hline 0 & \alpha_{11} & a_{12}^T & b_{10}^T & 1 & 0 \\ \hline 0 & a_{21} & A_{22} & B_{20} & 0 & I_{n-k} \end{array}\right)$

Update $\left(\begin{array}{c|c||c} A & B \end{array}\right) \leftarrow$

$$\left(\begin{array}{c|c|c||c|c|c} I_{k-1} & 0 & A_{02}+u_{01}a_{12}^T & B_{00}+u_{01}b_{10}^T & u_{01}=-a_{01}/\alpha_{11} & 0 \\ \hline 0 & 1 & a_{12}^T/\alpha_{11} & b_{10}^T/\alpha_{11} & 1/\alpha_{11} & 0 \\ \hline 0 & 0 & A_{22}+l_{21}a_{12}^T & B_{20}+l_{21}b_{10}^T & l_{21}=-a_{21}/\alpha_{11} & I_{n-k} \end{array}\right)$$

endfor

Magically, upon completion B has been overwritten by A^{-1}.

2.1. An in-place algorithm. After k steps of the above algorithm, it suffices to store only the first k columns of B and the last $n-k$ columns of A. Thus, an algorithm that overwrites A with A^{-1} is given by:

Partition $A = \left(\begin{array}{c||c} A_L & A_R \end{array}\right)$ and $B = \left(\begin{array}{c||c} B_L & B_R \end{array}\right)$, where initially $A_R = A$ and $B_R = I_n$.

for $k = 1, n$

Partition $\left(\begin{array}{c||c} B_L & A_R \end{array}\right) \rightarrow \left(\begin{array}{c||c|c} B_{00} & a_{01} & A_{02} \\ \hline b_{10}^T & \alpha_{11} & a_{12}^T \\ \hline B_{20} & a_{21} & A_{22} \end{array}\right)$, where B_{00} is square.

Update $\left(\begin{array}{c||c} B_L & A_R \end{array}\right) \leftarrow$

$$\left(\begin{array}{c|c||c} B_{00}+u_{01}b_{10}^T & u_{01}=-a_{01}/\alpha_{11} & A_{02}+u_{01}a_{12}^T \\ \hline b_{10}^T/\alpha_{11} & 1/\alpha_{11} & a_{12}^T/\alpha_{11} \\ \hline B_{20}+l_{21}b_{10}^T & l_{21}=-a_{21}/\alpha_{11} & A_{22}+l_{21}a_{12}^T \end{array}\right)$$

endfor

Upon entering the loop $\left(\begin{array}{c||c} B_L & A_R \end{array}\right)$ equals A and after its completion it equals A^{-1}.

The above update can also be accomplished by the *rank*-1 *update*

$$\left(\begin{array}{c||c} B_L & A_R \end{array}\right) \leftarrow \left(\begin{array}{c|c||c} B_{00} & 0 & A_{02} \\ \hline 0 & 0 & 0 \\ \hline B_{20} & 0 & A_{22} \end{array}\right) + \frac{1}{\alpha_{11}} \left(\begin{array}{c} -a_{01} \\ \hline 1 \\ \hline -a_{21} \end{array}\right) \left(\begin{array}{c|c||c} b_{10}^T & 1 & a_{12}^T \end{array}\right).$$

The entire computation is in the rank-1 update at a cost of $2n^2$ floating point operations (flops) per iteration for a total cost of $2n^3$ flops. A compact MATLAB code is given in Figure 1.

2.2. A blocked algorithm. A blocked variant of the above algorithm can be developed in a straightforward fashion:

Partition $A = \left(\begin{array}{c||c} A_L & A_R \end{array}\right)$ and $B = \left(\begin{array}{c||c} B_L & B_R \end{array}\right)$, where initially $A_R = A$ and $B_R = I_n$.

for $k = 1, n$ in steps of b

Partition $\left(\begin{array}{c||c} B_L & A_R \end{array}\right) \rightarrow \left(\begin{array}{c||c|c} B_{00} & A_{01} & A_{02} \\ \hline B_{10} & A_{11} & A_{12} \\ \hline B_{20} & A_{21} & A_{22} \end{array}\right)$, where B_{00} is square and A_{11} is $b \times b$.

Update

$$\left(\begin{array}{c||c} B_L & A_R \end{array}\right) \leftarrow \left(\begin{array}{c|c||c} B_{00} & 0 & A_{02} \\ \hline 0 & 0 & 0 \\ \hline B_{20} & 0 & A_{22} \end{array}\right) + \left(\begin{array}{c} -A_{01}A_{11}^{-1} \\ \hline A_{11}^{-1} \\ \hline -A_{21}A_{11}^{-1} \end{array}\right) \left(\begin{array}{c|c||c} B_{10} & I_b & A_{12} \end{array}\right)$$

endfor

The benefit of the blocked algorithm is that most of the computation is now in a matrix-matrix multiply (rank-k update) which allows high performance to be achieved in a portable fashion.

2.3. Adding pivoting. As for the LU factorization, in order to improve stability for general square nonsingular matrices, it is necessary to include row pivoting in the algorithm. To add pivoting to our nonblocked algorithm, before the update step, the row with the largest absolute value among elements of α_{11} and a_{21} is swapped with the kth row. If the augmented system is taken to equal $\left(\begin{array}{c||c} A & B \end{array}\right)$ with $B = P^T$ instead, we can guarantee that after $k-1$ steps *and after swapping the rows for the current step* the system looks like

$$\left(\begin{array}{c|c|c||c|c|c} I_{k-1} & a_{01} & A_{02} & B_{00} & 0 & 0 \\ \hline 0 & \alpha_{11} & a_{12}^T & b_{10}^T & 1 & 0 \\ \hline 0 & a_{21} & A_{22} & B_{20} & 0 & P_{n-k} \end{array}\right),$$

where P_{n-k} is some permutation matrix determined by future iterations of the loop. The usual update step then proceeds. This time, $A^{-1}P^T$ is computed, so that it is necessary to complete the process by permuting the columns of the result: $A^{-1} = (A^{-1}P^T)P$. Figure 1 shows how pivoting can be added to the MATLAB code.

Likewise, pivoting is added to the above blocked algorithm by changing the body of the loop to

Partition (as before)

Compute $P\left(\begin{array}{c} A_{11} \\ \hline A_{21} \end{array}\right) \rightarrow \left(\begin{array}{c} L_{11} \\ \hline L_{21} \end{array}\right) U_{11}$ (LU factorization with pivoting)

Swap $\left(\begin{array}{c|c||c} B_{10} & A_{11} & A_{12} \\ \hline B_{20} & A_{21} & A_{22} \end{array}\right) \leftarrow P \left(\begin{array}{c|c||c} B_{10} & A_{11} & A_{12} \\ \hline B_{20} & A_{21} & A_{22} \end{array}\right)$

Update (as before)

There are a number of ways to compute the update. As for the unblocked algorithm, a final permutation of the columns is required.

The update in the blocked algorithm is equivalent to the update

$$\begin{aligned} \left(\begin{array}{c||c} B_L & A_R \end{array}\right) \leftarrow & \left(\begin{array}{c|c||c} B_{00} & 0 & A_{02} \\ \hline 0 & 0 & 0 \\ \hline B_{20} & 0 & A_{22} \end{array}\right) \\ & + \left(\begin{array}{c} -A_{01}U_{11}^{-1} \\ \hline U_{11}^{-1} \\ \hline -L_{21} \end{array}\right) \left(\begin{array}{c|c||c} L_{11}^{-1}B_{10} & L_{11}^{-1} & L_{11}^{-1}A_{12} \end{array}\right), \end{aligned} \tag{2.1}$$

where L_{11}, L_{21}, and U_{11} are as computed by the LU factorization with partial pivoting of the corresponding part of A. Here $-A_{01}U_{11}^{-1}$, $L_{11}^{-1}B_{10}$, and $L_{11}^{-1}A_{21}$ are computed using triangular solves rather than matrix inversion. Forming $A_{11}^{-1} = U_{11}^{-1}L_{11}^{-1}$ can be accomplished as in the traditional matrix inversion algorithm. Computing the update in this fashion has the benefit that since explicit use of A_{11}^{-1} is avoided, stability of the algorithm should be similar to that exhibited by the traditional approach. We elaborate on this next.

3. Relation with multistage algorithms. The explicit use of A_{11}^{-1} in the blocked algorithm with pivoting should raise eyebrows. In [18], we show that the

numerical stability of the overall algorithm is only mildly affected by the use of the inverse, with stability deteriorating as a function of the algorithmic block size b. By using instead the variant that updates the matrix given in (2.1) these instabilities can be avoided.

Consider yet another alternative for computing A^{-1}:

(1) LU factorization with partial pivoting, $PA = LU$.
(2) Triangular inversion of U.
(3) Triangular inversion of L.
(4) Multiplication of triangular matrices $X = U^{-1}L^{-1}$.
(5) Back permutation of columns, $A^{-1} = XP$.

For simplicity we ignore pivoting and give blocked algorithms for the four remaining stages in Figure 2. If one picks the block size b to be equal at each step of the algorithms, it becomes clear that all four algorithms can be implemented by merging the loops. Critical to this observation is the fact that the different algorithms update four different quadrants of the matrix. Once the four loops have been merged into one loop, a number of intermediate computations can be eliminated leaving only the computations in the boxes in Figure 2. In Figure 3 we show that these computations are exactly the updates of the nine submatrices as given in (2.1). The same conclusion holds when pivoting is added.

We conclude that the algorithm based on (2.1) is equivalent to this multistage algorithm and thus shares its stability properties. In [13] it is shown that the traditional approach and this alternative multistage algorithm are essentially equally stable.

4. SPD matrix inversion. The techniques described above can be used to derive a blocked algorithm for SPD matrix inversion.

Let A be SPD. Then its inverse can be computed by first computing its Cholesky factor L, where $A = LL^T$, after which $A^{-1} = L^{-T}L^{-1}$. Naturally, this can be accomplished in three stages: (1) Compute the Cholesky factorization, (2) invert the lower triangular matrix L, and (3) multiply $A^{-1} = L^{-1^T}L^{-1}$. By putting all these stages together, a one-sweep algorithm can be derived: Partition the current matrix $A^{(k)}$, the original matrix A, and the factor L like

$$A^{(k)} = \left(\begin{array}{c||c} A_{TL}^{(k)} & \star \\ \hline\hline A_{BL}^{(k)} & A_{BR}^{(k)} \end{array}\right), \quad A = \left(\begin{array}{c||c} A_{TL} & \star \\ \hline\hline A_{BL} & A_{BR} \end{array}\right), \text{ and } L = \left(\begin{array}{c||c} L_{TL} & 0 \\ \hline\hline L_{BL} & L_{BR} \end{array}\right),$$

where the $\star$ indicates the symmetric part not to be updated and $A_{TL}^{(k)}$, A_{TL}, and L_{TL} are $k \times k$. Repartition

$$A^{(k)} = \left(\begin{array}{c||c} A_{TL}^{(k)} & \star \\ \hline\hline A_{BL}^{(k)} & A_{BR}^{(k)} \end{array}\right) = \left(\begin{array}{c||c|c} A_{00} & \star & \star \\ \hline\hline A_{10} & A_{11} & \star \\ \hline A_{20} & A_{21} & A_{22} \end{array}\right),$$

and consider the update

$$A^{(k+b)} = \left(\begin{array}{c||c} A_{TL}^{(k+b)} & \star \\ \hline\hline A_{BL}^{(k+b)} & A_{BR}^{(k+b)} \end{array}\right) = \left(\begin{array}{c|c||c} A_{00} + \hat{L}_{10}^T\hat{L}_{10} & \star & \star \\ \hline\hline L_{11}^{-T}\hat{L}_{10} & L_{11}^{-T}L_{11}^{-1} & \star \\ \hline A_{20} - L_{21}\hat{L}_{10} & L_{21} & A_{22} - L_{21}L_{21}^T \end{array}\right),$$

where L_{11} equals the Cholesky factor of A_{11}, $L_{21} = A_{21}L_{11}^{-T}$ and $\hat{L}_{10} = L_{11}^{-1}A_{10}$. This

update maintains the state

$$A^{(k)} = \left(\begin{array}{c\|c} A_{TL}^{(k)} & \star \\ \hline A_{BL}^{(k)} & A_{BR}^{(k)} \end{array}\right) = \left(\begin{array}{c\|c} L_{TL}^{-T}L_{TL}^{-1} & \star \\ \hline L_{BL}L_{TL}^{-1} & A_{BR} - L_{BL}L_{BL}^{T} \end{array}\right).$$

Note that once $k = n$, $A^{(k)} = A^{-1}$, which is the desired result.

5. Parallel implementation. Sadly, the above described algorithms yield no real performance benefits on a sequential computer. The primary reason is that on sequential architectures the individual stages of the traditional algorithm lend themselves well to optimization. On distributed memory parallel architectures, the story is different.

All three stages of the traditional approach suffer from load-imbalance when executed on distributed memory parallel architectures: During the LU factorization, the active part of the matrix shrinks from an $n \times n$ matrix to a 1×1 matrix as the computation unfolds. For the inversion of U, initially the active matrix is 1×1, eventually expanding to $n \times n$. In addition, the computation only acts on the upper triangular portion of the matrix. During the computation of the solution X to $XL = U^{-1}$, the active matrix expands from $1 \times n$ to $n \times n$. While cyclic wrapping of the matrices helps load-balance, there is still a considerable performance hit. Similar issues affect the three stages for inverting an SPD matrix.

The blocked algorithm presented in the previous section does not suffer the same fate: The bulk of the computation is in the rank-k update given in section 2.2 which parallelizes almost perfectly. Indeed, the computation required for the GJE-based inversion algorithm is almost identical to the sequence of rank-k updates used to implement highly efficient parallel matrix-matrix multiplication algorithms [1, 11, 19]. Cyclic wrapping of the matrix is not even necessary for load-balance! Even when the inversion is part of a larger computation and wrapping is desirable, excellent performance can be achieved, as we will show in the next section. For inverting an

SPD matrix, wrapping is still needed since only the lower triangular part of the matrix is updated.

6. Experimental results. We present results for three parallel implementations of algorithms for inversion of a general matrix and one for inversion of an SPD matrix. `SL_IGEP` is part of ScaLAPACK [6] and implements the traditional inversion algorithm via LU factorization; `SL_IGJEP` was coded using ScaLAPACK parallel BLAS kernels (PBLAS). It implements a blocked GJE algorithm with the algorithmic block size limited by the distribution block size. All operations required to update the current column panel are performed within a single column of processors. A second implementation of the blocked GJE algorithm, `PLA_IGJEP`, was coded using PLAPACK [20]. In this implementation the current column panel is redistributed so that all processors participate when the unblocked algorithm is used to update that panel. This results in better load-balance during this stage of the algorithm and simplifies the coding when the algorithmic block size is to be larger than the distribution block size. While `SL_IGJEP` represents a basic implementation of the algorithm, `PLA_IGJEP` includes a number of optimizations, some of which cannot be (easily) implemented using ScaLAPACK. `PLA_ISPD` implements a parallel blocked one-sweep algorithm for the inversion of SPD matrices.

Performance results are given for two different distributed memory architectures using 64-bit real arithmetic, the Cray T3E-600 (300 MHz), and a Beowulf cluster. The Cray T3E-600 consists of DEC Alpha EV5 with 128 Mbytes of RAM each, interconnected via a three-dimensional toroidal interconnect. The Beowulf cluster consists of Intel Pentium-II (300 MHz) processors running on a 66 MHz Intel Atlanta motherboard with 128 Mbytes of RAM each, and interconnected via a 1Gbps Myrinet switch.

We used ScaLAPACK available from Netlib (version 1.6) with the MPIBLACS precompiled for Cray T3E[1] and Linux. The PLAPACK version, implemented using an alpha release of PLAPACK R2.0, is also MPI-based. Optimized sequential BLASs were used to attain high performance locally on each processor. The sequential BLAS routine `gemm` delivers 400–450 Mflop/s (millions of flops per second) on a single processor of the Cray T3E and 175–200 Mflop/s on one Pentium-II (300 MHz) processor. We report performance of the inverse routines measuring Mflop/s per processor using the established operation count of $2n^3$ flops for inversion of a general $n \times n$ matrix and n^3 flops for inversion of an SPD matrix.

In Figure 4, we show that very respectable performance is attained on both architectures using 32 processors. Algorithmic and distribution block sizes of 48 and 32 were used for `SL_IGEP` and `SL_IGJEP` on the T3E and cluster, respectively. As expected, `SL_IGJEP` outperforms `SL_IGEP` since it incurs less communication and exhibits better load-balance. For `PLA_IGJEP` we report performance when algorithmic and distribution block sizes are both equal to those used for ScaLAPACK (`PLA_IGJEP_48_48` and `PLA_IGJEP_32_32`). We also show that better performance is attained when a smaller distribution block size and larger algorithmic block size is used (`PLA_IGJEP_24_96` and `PLA_IGJEP_16_64`). The larger algorithmic block size allows local matrix-matrix multiplication to attain higher performance, which explains the asymptotically better performance attained by `PLA_IGJEP_24_96`. The smaller distribution block size yields

[1]The Cray Scientific library provides a version of ScaLAPACK that uses the *shmem* library for communication. For a fair comparison between `PLA_IGJEP` and `SL_IGJEP`, we chose the MPI-based version of ScaLAPACK. Only for small matrices is the shmem-based version of ScaLAPACK noticeably faster than the MPI-based version.

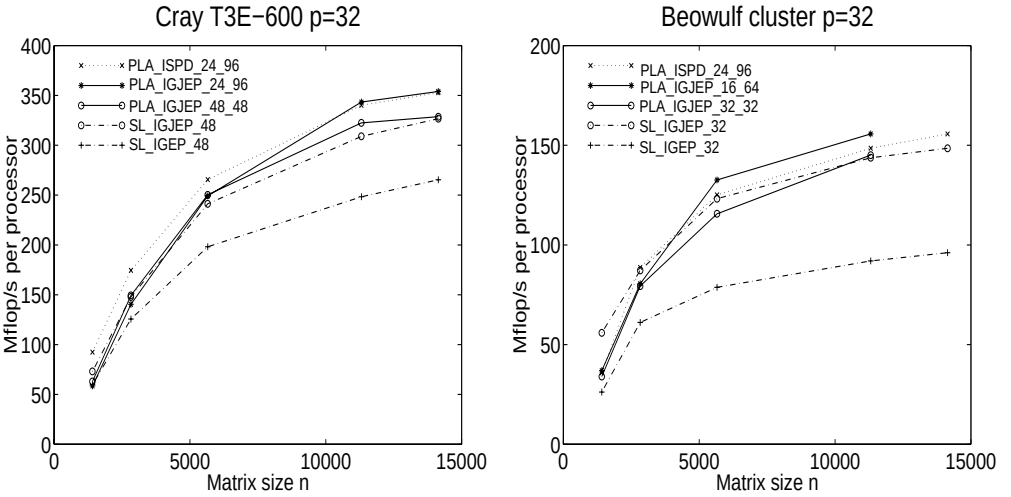

FIG. 4. *Mflop/s per processor on the Cray T3E-600 (left) and the Beowulf cluster (right).*

better load-balance. For smaller problems, the additional cost of redistributing the current column panel results in a reduction in performance relative to the ScaLAPACK implementation. Finally, in Figure 4 (left) we report performance of the SPD inversion routine using an algorithmic block size of 96/64 and distribution block size of 24/16 (`PLA_ISPD_24_96` and `PLA_ISPD_16_64`). In Figure 4 (right) we present similar performance results for the Beowulf cluster.

We do not present scalability results for these algorithms since scalability is clearly at least as good at that of parallel implementations for the individual stages of the traditional algorithm, which themselves are known to have very good scalability properties. For details, see [18].

7. Concluding remarks. We have described matrix inversion via Gauss–Jordan elimination for general matrices and a related algorithm for SPD matrices. The approaches present the same arithmetic cost as the conventional inversion algorithms while maintaining their numerical properties. Our matrix inversion algorithms render simple programming and performance optimization, which are especially appropriate for parallel computers with distributed memory. The experimental results on a Cray T3E-600 and a Beowulf cluster show that very high performance is attained by the parallel Gauss–Jordan inversion algorithm for general matrices and the parallel one-sweep inversion algorithm for SPD matrices.

Implementations are available at http://www.cs.utexas.edu/users/plapack/inverse/.

ON THE COMPUTATION OF THE RANK-ONE CONVEX HULL OF A FUNCTION*

ERNESTO ARANDA† AND PABLO PEDREGAL†

Abstract. We report on several numerical experiments where the rank-one convexification of an energy density is computed. The explicit examples cover a whole spectrum of typical situations one may encounter. One of those is especially relevant for the computation of microstructures in crystalline solids.

Key words. laminates, maximum number of levels, rank-one convex hull

1. Introduction.

The relevance of different types of convex hulls for vector variational problems is by now well established [23], [50]. One of the main driving forces that has led the effort in examining nonconvex vector variational problems has been the analysis of phase transitions in crystalline solids where symmetry is the main cause for this lack of convexity [3], [4]. In such situations, highly oscillatory minimizing sequences represent optimal behavior from an energetic point of view, and this in turn reflects rather accurately the configurations observed in experiments (the so-called microstructures), so that this energetic explanation seems to be the clue to understanding the behavior of such nonlinear materials. As can be easily inferred, the numerical analysis and simulation of such nonconvex vector variational problems has also received a lot of attention: [6], [7], [8], [9], [10], [11], [12], [13], [14], [15], [16], [17], [18], [19], [20], [24], [25], [26], [28], [29], [30], [31], [34], [35], [36], [37], [38], [39], [40], [41], [42], [44], [45], [46], [51]. In particular, the computation and approximation of the above-mentioned convex hulls can be considered as a first step toward the simulation of more complex examples with nonaffine boundary conditions [2], [34], [52]. In the present paper, we would like to explain our efforts in computing, from a practical point of view, the rank-one convex hull of a function and its meaning with respect to oscillatory behavior for vector, nonconvex variational problems.

Stable equilibrium configurations of hyperelastic materials are minimizers of the energy functional

$$I(u) = \int_\Omega \varphi(\nabla u(x))\, dx,$$

where $\Omega \subset \mathbf{R}^2$ is a regular domain and $u : \Omega \to \mathbf{R}^2$ represents a deformation of the body. As such, u must verify several additional restrictions which are not relevant to our discussion. Under a global condition of place, we require $u = u_0$ all over $\partial\Omega$. The direct method [23], [50] to show optimal solutions of the previous variational principle relies on the property of weak lower semicontinuity of I,

$$u_j \rightharpoonup u \quad \text{implies} \quad I(u) \leq \liminf_{j\to\infty} I(u_j),$$

where weak convergence takes place on a suitable Sobolev space. This convenient property is in turn equivalent to the quasi-convexity of the energy density $\varphi : \mathbf{M} \to \mathbf{R}$, where $\mathbf{M}$ designates the space of 2×2 matrices [43]. Such φ is said to be quasi-convex if

$$\varphi(F) \leq \frac{1}{|T|}\int_T \varphi(F + \nabla v(x))\, dx$$

for all matrices F, all test fields $v \in W^{1,\infty}(T)$, and some domain T. This condition requires, under affine boundary conditions determined by the matrix F, that this affine deformation all over Q has less (or equal) energy than any other admissible deformation. When an energy density φ does not enjoy the quasi-convexity property, as is the case of crystalline materials, highly oscillatory behavior is expected in many circumstances. In such cases the analysis of the corresponding variational problem proceeds, examining a relaxed formulation where the integrand φ is replaced by its quasi-convexification $Q\varphi$:

$$Q\varphi(F) = \inf\left\{\frac{1}{|T|}\int_T \varphi(F + \nabla v(x))\, dx : v = 0 \text{ on } \partial\Omega\right\}.$$

T can be any domain since this infimum does not depend on this choice. A typical relaxation theorem says that, under technical assumptions, the infimum of both variational problems, the one with integrand φ and the one with density $Q\varphi$, are the same [21]. Moreover, the computation of this quasi-convex hull, as indicated above, can be considered as the first step towards the numerical analysis of the original nonconvex variational problem [48], [49].

The difficulties attached to understanding quasi-convexity and the quasi-convex hull are so great that some other intimately connected convex hulls have been introduced. In particular, rank-one convexity for a function φ requires the usual convexity inequality

$$\varphi(tA + (1-t)B) \leq t\varphi(A) + (1-t)\varphi(B), \quad t \in [0,1],$$

only when the difference matrix $A-B$ is of rank one. It turns out that quasi-convexity implies rank-one convexity, and this is not hard to see. But the converse is not true in general [53]. Nonetheless, in most of the explicit examples and experiments known, replacing the quasi-convex hull by its rank-one convex counterpart produces good results. In fact, minimizing sequences that arise from the rank-one convex hull of an energy density (the so-called laminates) provides configurations with a remarkable degree of accuracy both qualitative and quantitative. For these reasons we will restrict our attention to the rank-one convex hull in this work.

In a previous paper [1], we proposed to approximate the rank-one convex hull of a function by exploiting the structure of laminates [22], [47] and obtained an estimate of the type

$$0 \leq \varphi^{(L)}(F) - R\varphi(F) \leq C\lambda^L, \quad C > 0, \quad 0 < \lambda < 1,$$

where L indicates a precise level of approximation to the rank-one convexification of φ, $R\varphi$, and the constants C and λ are independent of L (see section 2). This time we would like to complete that analysis by trying to compute, from a practical

perspective, the approximations to $R\varphi$ indicated by $\varphi^{(L)}$. We have adapted to our situation an optimization algorithm based on the "simulated annealing" process, and we test such a procedure with several typical examples. The first one is the minimum of two quadratic functions where the location of the minima for both quadratics makes the approximation scheme different. This example was explicitly computed in closed form in [32] by using Fourier techniques. Since the structure of oscillations hidden in the nonconvexity of this example is rather simple, our analysis focuses on comparing the degree of precision for different situations. Our second example corresponds to the Ericksen–James energy [27]

$$\varphi(F) = \phi(F^T F),$$

where for $C = (c_{ij})$ the Cauchy–Green tensor

$$\phi(C) = \kappa_1(\operatorname{tr} C - 2 - \delta^2)^2 + \kappa_2(c_{12}^2 - \delta^2)^2 + \kappa_3(c_{11} - 1)^2.$$

κ_i and δ are given, positive constants. This test energy exhibits most of the relevant features that real energy densities for crystalline materials have, namely, frame indifference (this is elementary to check)

$$\varphi(F) = \varphi(RF) \quad \text{for all rotations } R,$$

and two potential wells: if

$$F_0^{\pm} = \mathbf{1} \pm \delta e_1 \otimes e_2,$$

then $\varphi(F_0^{\pm}) = 0$ and $\varphi > 0$ otherwise. By putting together these two pieces of information we conclude that the zero set of φ, K is the disjoint union of two wells

$$K = SO(2)F_0 \cup SO(2)F_0^{-1}.$$

Our simulations make an attempt to compute and approximate $R\varphi(F)$ for a selection of F's and to determine the underlying laminates. In this case, because of the relevance of this example with respect to real materials, we depict the information recorded in such laminates in the form of oscillations, as shown in Figure 1.

Finally, our third example is the remarkable four-matrix configuration where an infinite order laminate is involved [5], [54]. In this situation, our main concern was to detect computationally the structure of the laminates and how computations evolved as we let the number of levels increase. We discover some interesting numerical facts that speak about the complexity of computing the rank-one convexification of a function because of the global nature of the underlying optimization problem. Our pictures for this example show the best computed laminates constrained in the maximum number of levels allowed. In the sequence of pictures in Figures 2–4 the last level has been colored differently.

The paper has three more sections. We first describe the algorithm and make some observations of a technical nature. Next, we precisely describe the three above situations analyzed by using the algorithm. We make some final remarks in section 4.

2. Description of the algorithm. Our algorithm tries to compute the approximated rank-one convex hull of a function as described in [1]. Specifically, if $\varphi : \mathbf{M}^{m\times N} \to \mathbf{R}$ is a continuous function satisfying the technical assumptions

$$c(|A|^p - 1) \le \varphi(A) \le C(1 + |A|^p), \quad p > N, \quad C > c > 0,$$

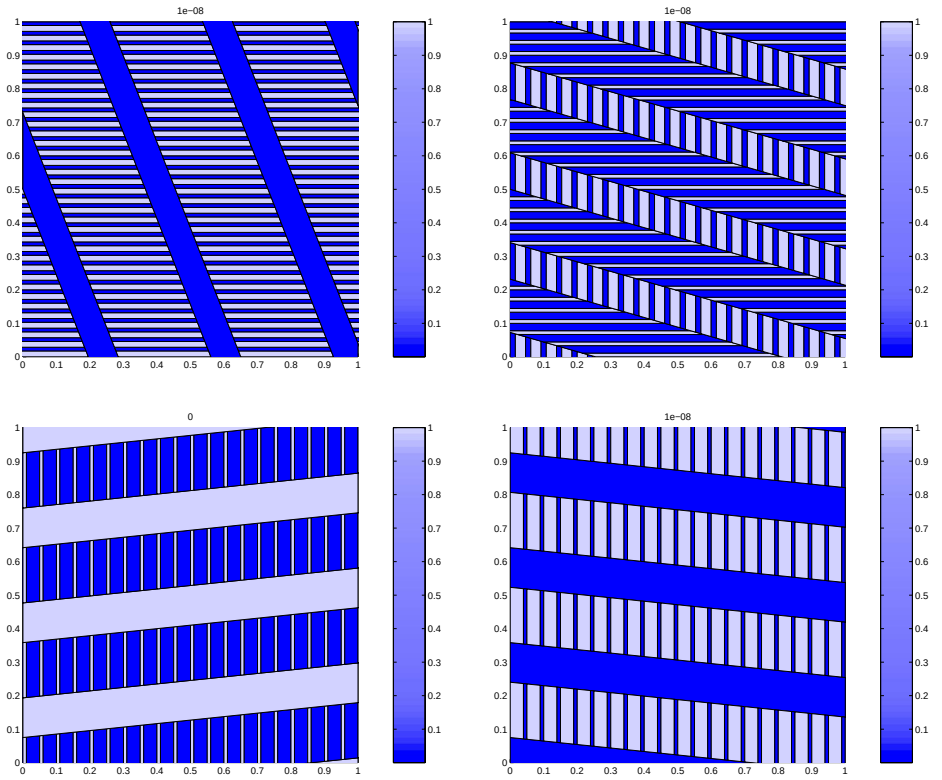

FIG. 1.

its approximated rank-one convex hull of order L is given by

$$\varphi_\epsilon^{(L)}(F) = \inf\left\{\sum_i t_i\varphi(F_i) : \{(t_i, F_i)\} \text{ verifies the } (H_\epsilon^L) \text{ condition and has barycenter } F\right\}. \tag{2.1}$$

Here, $\epsilon > 0$ is meant to designate a realistic measure of accuracy in our actual computations, and the (H_ϵ^L) conditions are defined as follows.

DEFINITION 2.1. *A set of pairs $\{(t_i, F_i)\}_{1\le i\le l}$, where $t_i > 0$, $\sum_i t_i = 1$, $F_i \in \mathbf{M}$, is said to satisfy the (H_ϵ^L) condition, $\epsilon \ge 0$, if*

(i) *the only set of pairs satisfying the (H_ϵ^0) is $\{(1, F)\}$;*

(ii) *for $L > 0$, there exist*

  (a) *$\{(s_j, Z_j)\}_{1\le j\le k}$ satisfying the (H_ϵ^{L-1}) condition, $k \le L-1$;*

  (b) *matrices A_j, $|A_j| = 1$ with $\operatorname{rank}(A_j) = 1$;*

  (c) *nonnegative numbers α_j, β_j such that either $\alpha_j = 0$ or else $\alpha_j > \epsilon$ and the same for β_j*

such that all the matrices $Z_j + \alpha_j A_j$ and $Z_j - \beta_j A_j$ belong to the set $\{F_i\}_{1\le i\le l}$ and for every fixed i, $1 \le i \le l$,

$$t_i = \sum_{Z_j+\alpha_j A_j = F_i} s_j \frac{\alpha_j}{\alpha_j+\beta_j} + \sum_{Z_j-\beta_j A_j = F_i} s_j \frac{\beta_j}{\alpha_j+\beta_j}.$$

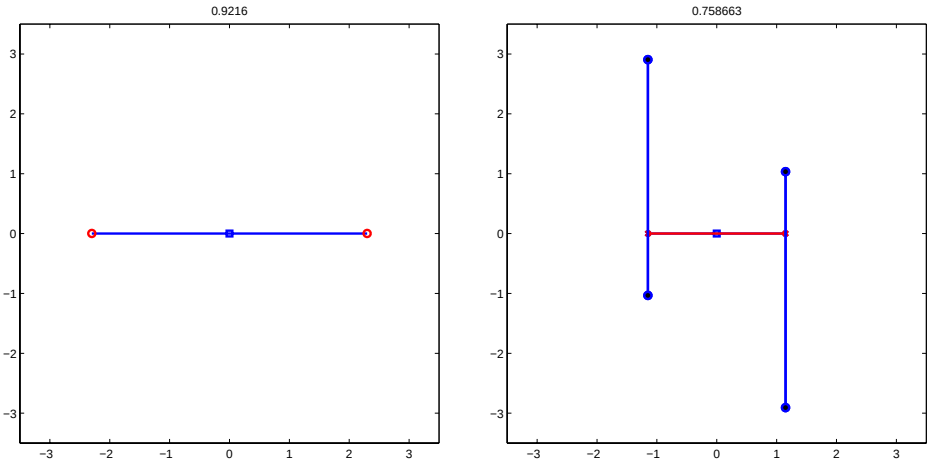

FIG. 2.

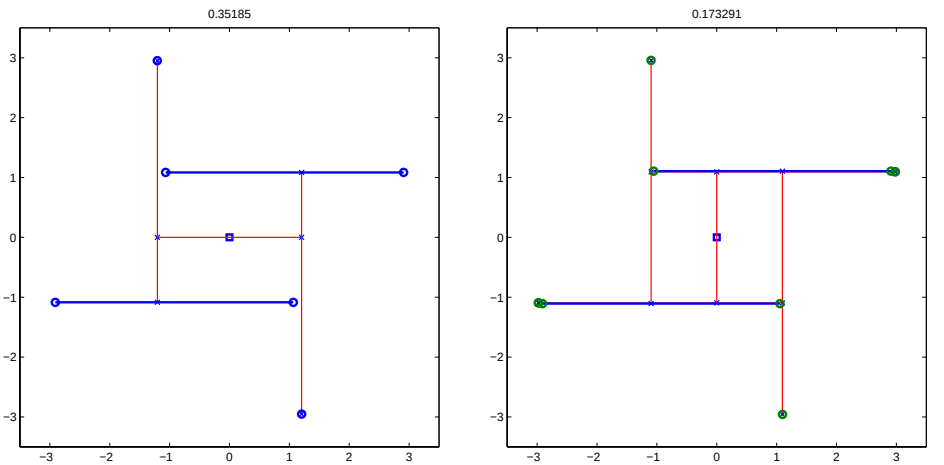

FIG. 3.

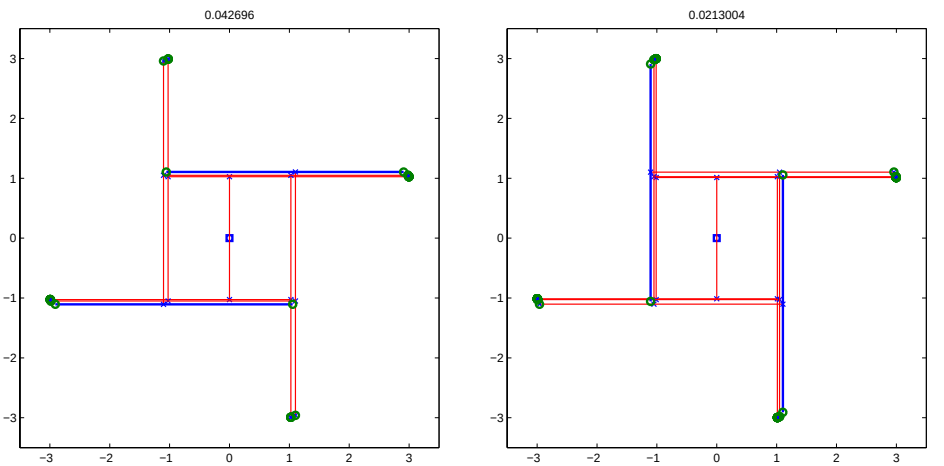

FIG. 4.

This definition differs from the typical (H_L) condition [22], [47] in a formal way. We found this format more convenient for our purposes.

The algorithm we present approximates $\varphi_\epsilon^{(L)}(F)$ by trying to find one optimal (H_ϵ^L) condition with barycenter F according to (2.1). In practice, we have to deal with and construct (H_ϵ^L) conditions. In order to generate one of these, we rely on the basic building block of these conditions. Starting from one arbitrary matrix Y, we choose a rank-one direction (eventually a null-direction) A, normalized in some reasonable way, along which we decompose Y by fixing two distances, $x_1 \geq \epsilon$ and $x_2 \geq \epsilon$, from Y along A:

$$Y_1 = Y + x_1 A, \quad Y_2 = Y - x_2 A.$$

If

$$\lambda_i = \frac{x_j}{x_1 + x_2}, \quad j \neq i,$$

then it is trivial to check

$$Y = \lambda_1 Y_1 + \lambda_2 Y_2, \quad Y_1 - Y_2, \text{ rank-one.}$$

(H_ϵ^L) conditions are built by applying recursively this decomposition to all of the matrices obtained. Starting from the first moment F and choosing A, x_1, x_2 as above, we find (F_1, λ_1), (F_2, λ_2). Applying this same decomposition to each F_i, we would find

$$(F_{11}, \lambda_1\lambda_{11}), (F_{12}, \lambda_1\lambda_{12}), (F_{21}, \lambda_2\lambda_{21}), (F_{22}, \lambda_2\lambda_{22}).$$

This set of pairs would make up an (H_ϵ^2) condition. If we keep doing these decompositions with all of the F_{ij}, we would end up with an (H_ϵ^3) condition, and so on. The parameters that determine one of such (H_ϵ^L) conditions are the rank-one matrices A and the associated distances x_1, x_2.

In the case of 2×2 matrices, rank-one directions can be determined by two angles α, β in the interval $[0, \pi)$ in the form

$$M = (\cos\alpha_1, \sin\alpha_1) \otimes (\cos\alpha_2, \sin\alpha_2).$$

Rank-one matrices are recorded in a vector α. On the other hand, the distances associated to such rank-one matrices are recorded in a vector x. If we are interested in approximating $\varphi_\epsilon^L(F)$, (H_ϵ^L) conditions can be specified by a vector, α, that generates rank-one matrices, and a corresponding vector x of associated distances. Namely, matrices and weights in the (H_ϵ^L) condition are obtained recursively by putting

$$\begin{aligned} F_{2i-1} &= F_{i-1} + x_{2i-1} M_i, \quad F_{2i} = F_{i-1} - x_{2i} M_i, \\ \lambda_{2i-1} &= \lambda_{i-1} \frac{x_{2i}}{x_{2i-1} + x_{2i}}, \quad \lambda_{2i} = \lambda_{i-1} \frac{x_{2i-1}}{x_{2i-1} + x_{2i}} \end{aligned}$$

for $1 \leq i \leq 2^L - 1$, $\lambda_0 = 1$, $F_0 = F$, where $\epsilon \leq x \leq D$ for some constant D. The energy associated to such a laminate would be

$$E(\alpha, x) = \sum_{i=2^L-1}^{2^{L+1}-2} \lambda_i \varphi(F_i).$$

It is this function E whose global minimum, and vectors where it is taken on, we are interested in.

In order to tackle the global optimization problem we are faced with, we have adopted a scheme where the roles of α and x are different. Indeed, we have used for α a discretization of equidistant nodes in the interval $[0, \pi)$, generating a set of discrete rank-one directions Γ_h, where h is the distance between nodes in $[0, \pi)$. The optimization procedure goes alternatively from optimizing on x for given α, and optimizing on α for given x. For the first part, we have used an algorithm of limited memory [7], [8] which is a quasi-Newton algorithm that approximates the hessian of the objective function by limited-memory matrices. For the second part, we have employed the simulated annealing technique in order to find the best configuration of rank-one matrices from the discrete set of possibilities Γ_h, in some instances improving the optimal solution thus obtained by an easy corrector procedure. Because of the nature of our problem, the initialization of the algorithm is a delicate point. In some instances one can simply try to decompose matrices in the best way using only one level at a time. However, this scheme will not produce nontrivial decompositions starting from the barycenter in the case of the four well. It is when we allow two or more levels that we are able to move away from a delta centered at the first moment. In some cases, several thousands of initial guesses were necessary in order to initialize the algorithm in a convenient way. This feature actually shows how complex and tricky these computations may become.

3. Numerical examples. As announced in the introduction, we will be concerned with three quite different situations, and we use our algorithm to make computations.

For the first one we take

$$\varphi : \mathbf{M} \to \mathbf{R}, \quad \varphi(A) = \min\{|A - M|^2, |A|^2\},$$

where M is a given matrix. The quasi-convexification (which in this case coincides with the rank-one convexification) of this type of examples was explicitly computed in [32]. Namely, one has to distinguish two cases depending on the rank of M. If it is one, the quasi-convexification equals the usual convexification. If it is two, the quasi-convexification is given explicitly by

$$Q\varphi(A) = \begin{cases} |A|^2, & |A - M|^2 - |A|^2 \geq g/2, \\ |A - M|^2, & |A - M|^2 - |A|^2 \leq -g/2, \\ |A|^2 - \frac{1}{2g}\left(|A|^2 - |A - M|^2 + \frac{g}{2}\right)^2, & ||A - M|^2 - |A|^2| \leq g/2. \end{cases}$$

When the rank of M is one, $g = 2|M|^2$, while in the case of rank two, $g = 2\sigma_0$, where σ_0 represents the greatest of the eigenvalues of the matrix $M^T M$. In both cases, the rank-one convexification is achieved by $\varphi^{(1)}$ one-level decompositions.

The experiments performed on this family of examples correspond to four different choices for M, two in the rank-one case and two in the rank-two case. Namely,

$$M_1 = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}, \quad M_2 = \left(\cos\frac{\pi}{5}, \sin\frac{\pi}{5}\right) \otimes \left(\cos\frac{\pi}{3}, \sin\frac{\pi}{3}\right),$$
$$M_3 = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}, \quad M_4 = \begin{pmatrix} 2 & 1 \\ 1/2 & 1/2 \end{pmatrix}.$$

For each one of the corresponding densities, we have computed $\varphi_h^{(1)}$, the approximation to $\varphi_\epsilon^{(1)}$ provided by our algorithm, over a set of matrices Δ_k uniformly distributed over the cube $[-D, D]^4$, and then we have examined the error

$$\left\|\varphi_h^{(1)} - R\varphi\right\|_{\infty,\Delta_k} = \max\left\{\left|\varphi_h^{(1)}(A) - R\varphi(A)\right| : A \in \Delta_k\right\}.$$

These errors are presented in Tables 1 and 2. The parameter $N = \pi/h$ is a measure of the fineness of the discretization of rank-one directions, as explained in the preceding section.

TABLE 1

TABLE 2

	M_2	M_4
$N = 2$	$0.86372827 \times 10^{-1}$	0.36354086
$N = 6$	$0.19029316 \times 10^{-8}$	$0.33946668 \times 10^{-9}$
$N = 12$	$0.19029316 \times 10^{-8}$	$0.58557923 \times 10^{-8}$

We notice that the approximation is better for the rank-one case, and that the error depends on how close M, or its projection over the set of rank-one matrices, is to the discrete set of rank-one directions Γ_h.

We have also observed, even in this simple setting, the difficulties associated to local minima. For example, for the density corresponding to M_2, the matrix

$$A = \begin{pmatrix} 1 & -1/2 \\ -1 & 1/2 \end{pmatrix}$$

is such that $\varphi(A) = 2.5$ while $R\varphi(A) = 2.49978037599552$. Even if we let $N = 12$, the algorithm does not lower the energy, and only when $N = 20$ does the best energy have an error of 0.22×10^{-10} over the rank-one convexification.

The second situation we have examined concerns the Ericksen–James energy density

$$\varphi(F) = \phi(F^T F), \quad \phi(C) = \kappa_1(\operatorname{tr} C - 2 - \delta^2)^2 + \kappa_2(c_{12}^2 - \delta^2)^2 + \kappa_3(c_{11} - 1)^2,$$

where $\kappa_i, \delta > 0$ are constants. This function enjoys the frame indifference property, and its zero set, $K = \{\varphi = 0\}$, has the structure of two potential wells

$$K = SO_2F_0 \cup SO_2F_0^{-1}, \quad F_0^{\pm 1} = \mathbf{1} \pm \delta e_1 \otimes e_2.$$

We are especially interested in computing the rank-one convexification of φ for matrices F that may support stress free microstructures $R\varphi(F) = 0$. These matrices F, as well as the compatibility of wells, reciprocal twins, and laminates supported in K, are very well known [4], [50].

The visualization of our experiments has been implemented by showing the structure of layers within layers for different levels of approximation. In order to represent the states for the gradients of a minimizing sequence, we have used a color function

$$\psi(F) = \frac{\left|F^T F - F_0^T F_0\right|}{\left|F^T F - F_0^T F_0\right| + \left|F^T F - (F_0^{-1})^T F_0^{-1}\right|},$$

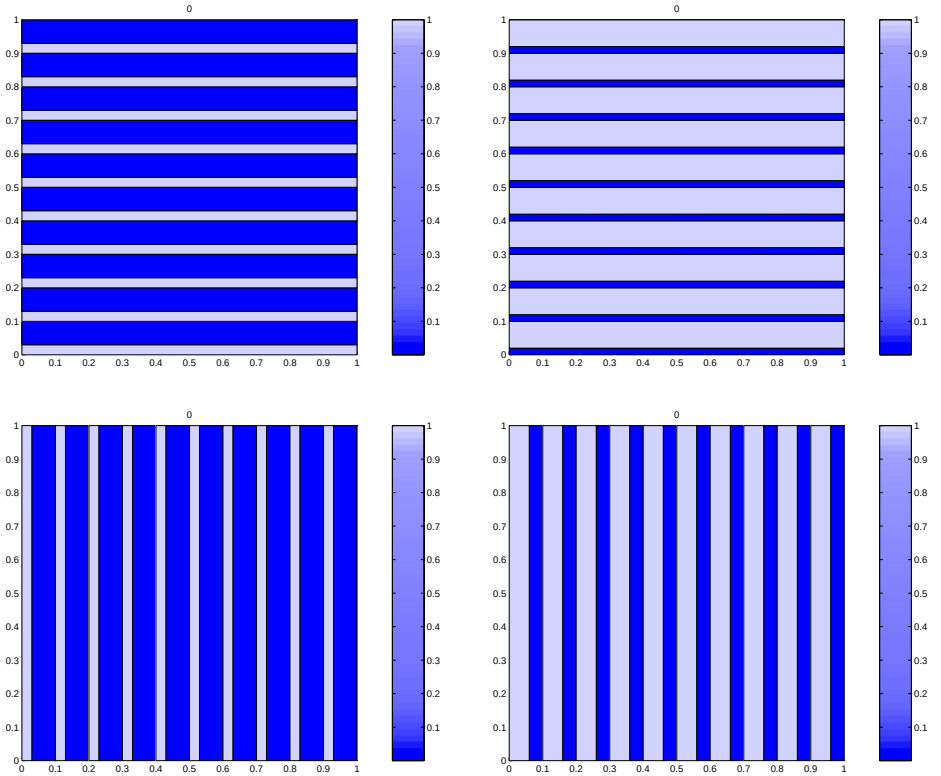

FIG. 5.

which takes on the value 1 if F belongs to $SO_2F_0^{-1}$, and its value is 0 if F lies on the other well SO_2F_0. We have also utilized the computed normals for the laminates in order to depict the oscillatory behavior which would be associated to such minimizing sequences. The width of layers is indicated by the weights on the associated laminate. We stick to the notation

$$U^i_{\lambda,t} = (1-\lambda)Q_tR_iF_0 + \lambda Q_tF_0^{-1}, \quad t \in [0, 2\pi], \quad i = 1, 2, \quad \lambda \in [0, 1], \tag{3.1}$$

where

$$Q_t = \begin{pmatrix} \cos t & -\sin t \\ \sin t & \cos t \end{pmatrix}, \quad R_1 = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}, \quad R_2 = \frac{1}{1+\delta^2}\begin{pmatrix} 1-\delta^2 & -2\delta \\ 2\delta & 1-\delta^2 \end{pmatrix}.$$

R_2 represents the reciprocal twin. Our experiments take place on the domain $\Omega = (0,1)^2$ with $\kappa_1 = 10$, $\kappa_2 = 3$, $\kappa_3 = 1$, and $\delta = 1$.

The first experiments deal with several situations where the uniqueness of the underlying laminate is known [50]. According to the above notation, we consider affine boundary values given by the matrices

$$U^1_{0.3,0},\ U^1_{0.8,\pi/5},\ U^2_{0.3,0},\ U^1_{0.6,\pi/7}.$$

The computed laminates are shown in Figure 5, while computed values of the energy and volume fractions are contained in Table 3.

TABLE 3

	$U^1_{0.3,0}$	$U^1_{0.8,\pi/5}$	$U^2_{0.3,0}$	$U^1_{0.6,\pi/7}$
φ	9.17280	5.32480	4.05720	5.29920
E	0.43×10^{-19}	0.13×10^{-10}	0.19×10^{-17}	0.45×10^{-10}
λ	0.3	0.19999970	0.3	0.60000094

We are aware that if the matrix chosen as the underlying barycenter does not admit a decomposition as in (3.1), then a surprising nonuniqueness for the underlying microstructure occurs. Indeed, many laminates of the form

$$(1-\mu)(1-\lambda)\delta_{\hat{Q}F_0} + (1-\mu)\lambda\delta_{\hat{Q}F_0^{-1}} + \mu(1-\lambda)\delta_{F_0^{-1}} + \mu\lambda\delta_{F_0}$$

for

$$\hat{Q} = \frac{1}{1+\delta^2(1-2\lambda)^2}\begin{pmatrix} 1-\delta^2(1-2\lambda)^2 & -2\delta(1-2\lambda) \\ 2\delta(1-2\lambda) & 1-\delta^2(1-2\lambda)^2 \end{pmatrix},$$

for different choices of μ and λ, can be found for the same barycenter [50]. If we take

$$U = \begin{pmatrix} 4/5 & 1/2 \\ -2/5 & 1 \end{pmatrix}, \tag{3.2}$$

which corresponds to taking $\mu = 1/2$, $\lambda = 3/4$, and

$$\hat{Q} = \begin{pmatrix} 3/5 & 4/5 \\ -4/5 & 3/5 \end{pmatrix},$$

the associated laminate is the one in Figure 6(a). However, this particular microstructure has not been obtained in our numerous experiments, but rather different laminates (with zero energy) for the same underlying affine deformation given by U in (3.2) have been computed. The one in Figure 6(b) is associated to the convex combination

$$(1-\lambda)(1-\mu)\delta_{F_0} + (1-\lambda)\mu\delta_{R_2^T F_0^{-1}} + \lambda(1-\sigma)\delta_{\overline{Q}F_0} + \lambda\sigma\delta_{\overline{Q}F_0^{-1}},$$

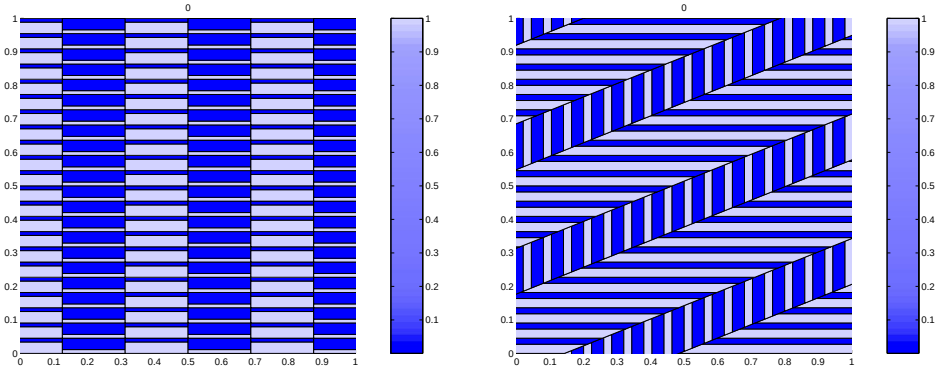
where

$$\lambda = \frac{1}{\sqrt{21}-3}, \quad \mu = \frac{2}{5}, \quad \sigma = \frac{7-\sqrt{21}}{4},$$
$$\overline{Q} = \begin{pmatrix} \sqrt{21}/5 & 2/5 \\ -2/5 & \sqrt{21}/5 \end{pmatrix}, \quad m_1 = \frac{1}{\sqrt{29}}\begin{pmatrix} -2 \\ 5 \end{pmatrix}.$$

m_1 is the normal to the interface between $(1-\mu)F_0 + \mu R_2^T F_0^{-1}$ and $(1-\sigma)\overline{Q}F_0 + \sigma\overline{Q}F_0^{-1}$, while $m_2 = (1,0)$ is the normal between F_0 and $R_2^T F_0^{-1}$, and $m_3 = (1,0)$ is the one corresponding to $\overline{Q}F_0$ and $\overline{Q}F_0^{-1}$. Table 4 shows the computed values for all these parameters.

We have also found laminates with the same barycenter U in (3.2) supported in three matrices [4]

$$(1-\lambda_i)Q_{s_i}F_0^{-1} + \lambda_i(1-\mu_i)Q_{t_i}F_0 + \lambda_i\mu_i Q_{t_i}F_0^{-1}, \quad i = 1,2,$$



(a) (b)

FIG. 6.

where

$$\lambda_1 = \frac{17}{42} + \frac{4}{105}\sqrt{85}, \quad \lambda_2 = \frac{17}{49} + \frac{5}{196}\sqrt{85},$$
$$\mu_1 = 5 - \frac{\sqrt{85}}{2}, \quad \mu_2 = \frac{8}{3} - \frac{4}{15}\sqrt{85},$$
$$\cos s_1 = \frac{56}{97} - \frac{17}{485}\sqrt{85}, \quad \cos s_2 = \frac{56}{97} + \frac{17}{485}\sqrt{85},$$
$$\sin s_1 = \frac{68}{97} + \frac{14}{485}\sqrt{85}, \quad \sin s_2 = \frac{68}{97} - \frac{14}{485}\sqrt{85},$$
$$\cos t_1 = \frac{9}{85}\sqrt{85}, \quad \cos t_2 = -\frac{2}{85}\sqrt{85},$$
$$\sin t_1 = \frac{2}{85}\sqrt{85}, \quad \sin t_1 = \frac{9}{85}\sqrt{85}.$$

Figure 7 and Table 5 show the approximated minimizing gradients and computed numerical values. Finally, Figure 1 corresponds to other different microstructures associated to the same affine underlying deformation.

TABLE 4

λ	0.63191385	m_1	$(-0.37141829, 0.92846565)$

σ	0.60432472	m_3	$(0.00002523, 1)$

Our last situation refers to the example with four matrices, none of which is rank-one related to the other three. Despite this fact, nontrivial infinite order laminates are supported in this set of four matrices. This is one of those examples that must be tested for any new way of computing laminates and rank-one convex hulls of functions. We will consider the particular configuration with

$$A_1 = \begin{pmatrix} -3 & 0 \\ 0 & -1 \end{pmatrix}, \quad A_2 = \begin{pmatrix} 1 & 0 \\ 0 & -3 \end{pmatrix},$$
$$A_3 = \begin{pmatrix} 3 & 0 \\ 0 & 1 \end{pmatrix}, \quad A_4 = \begin{pmatrix} -1 & 0 \\ 0 & 3 \end{pmatrix},$$

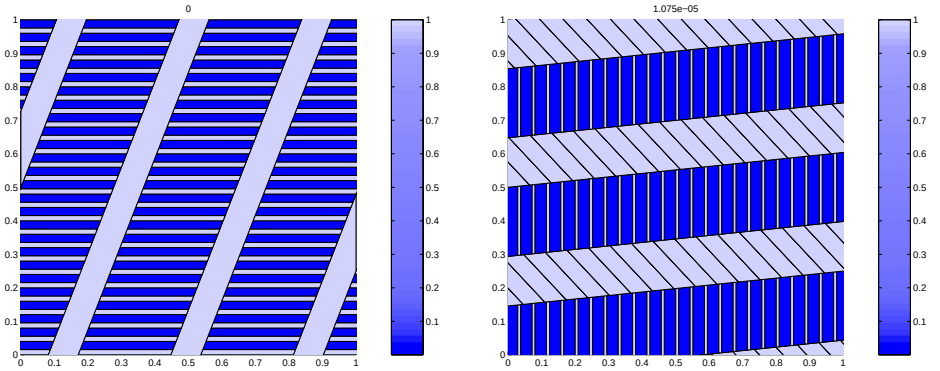

FIG. 7.

TABLE 5

λ_1	0.24402617	λ_2	0.41786234
μ_1	0.39022623	μ_2	0.20813357
E_1	0.14×10^{-8}	E_2	1.07×10^{-5}

and the integrand $\varphi : \mathbf{M}^{2\times 2} \to \mathbf{R}$ given by

$$\varphi(A) = 10^{-4} \prod_{i=1}^{4} |A - A_i|^2 .$$

If

$$B_1 = \begin{pmatrix} -1 & 0 \\ 0 & -1 \end{pmatrix}, \quad B_2 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix},$$
$$B_3 = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}, \quad B_4 = \begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix},$$

then it is well known (see the above references) that the rank-one convexification of φ vanishes within the square $B_1B_2B_3B_4$ and that this value can only be achieved by an infinite order laminate. From a numerical point of view, we would like to see if our algorithm is capable of capturing the successive approximated (H^L) conditions. Since in this situation we are interested not so much in the structure of the underlying minimizing gradients as in the structure of the approximated (H^L) conditions, we will draw these in the two-dimensional subspace of diagonal matrices rather than representing deformation gradients in the reference configuration.

One of the main difficulties in computing optimal (H^L) conditions is the fact that knowing the optimal such configuration for L does not help in finding the one for $L+1$. Indeed, in many cases these are surprisingly unrelated. In what follows we will identify points in the plane (x, y) with diagonal matrices

$$\begin{pmatrix} x & 0 \\ 0 & y \end{pmatrix}.$$

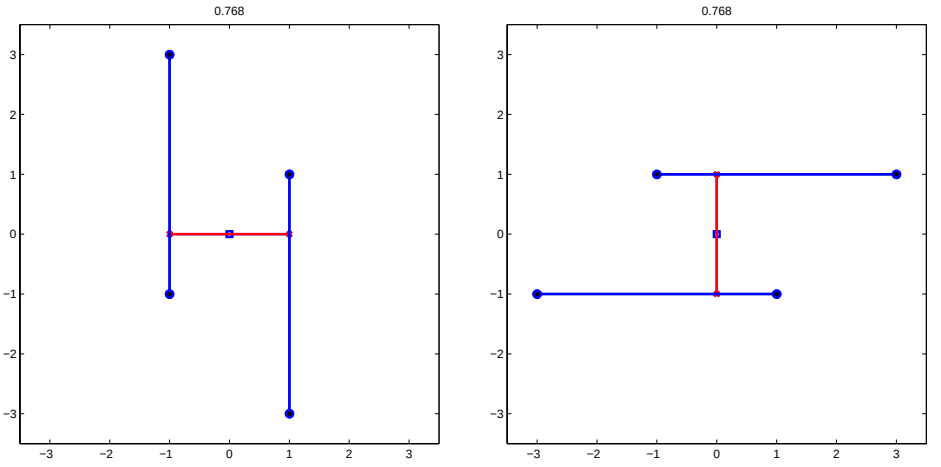

FIG. 8.

We will start by examining optimal (H^L) conditions with first moment the zero matrix, but before we do that we believe it is instructive to describe the basic idea on the construction of the infinite order laminate which yields a vanishing value for the rank-one convexification of φ. We will describe the situation taking as barycenter B_1, but then it can immediately be adapted to other matrices. Indeed, it is a matter of checking the decompositions that follow, making sure that they are made along rank-one matrices, and using them in a recursive manner:

$$B_1 = \frac{1}{2}A_1 + \frac{1}{2}B_2, \quad B_2 = \frac{1}{2}A_2 + \frac{1}{2}B_3,$$
$$B_3 = \frac{1}{2}A_3 + \frac{1}{2}B_4, \quad B_4 = \frac{1}{2}A_4 + \frac{1}{2}B_1.$$

Then

$$B_1 = \frac{1}{2}A_1 + \frac{1}{2}\left(\frac{1}{2}A_2 + \frac{1}{2}B_3\right),$$
$$B_1 = \frac{1}{2}A_1 + \frac{1}{2}\left(\frac{1}{2}A_2 + \frac{1}{2}\left(\frac{1}{2}A_3 + \frac{1}{2}B_4\right)\right)$$
$$\cdots$$

If we keep doing these decompositions, we build an infinite order laminate supported on the four matrices A_i, and hence the rank-one convexification of φ on B_1 vanishes. The same is true for any matrix in the square $B_1B_2B_3B_4$, as pointed out above, and also for the segments $[A_i, B_i]$, $i = 1, 2, 3, 4$.

Figure 8 shows the expected (in the sense of the recursive decompositions given above) (H^2) conditions

$$(0,0) = \frac{1}{2}(1,0) + \frac{1}{2}(-1,0)$$
$$= \frac{1}{2}\left[\frac{3}{4}(1,1) + \frac{1}{4}(1,-3)\right] + \frac{1}{2}\left[\frac{3}{4}(-1,-1) + \frac{1}{4}(-1,3)\right],$$

or

$$(0,0) = \frac{1}{2}(0,1) + \frac{1}{2}(0,-1)$$
$$= \frac{1}{2}\left[\frac{3}{4}(-1,1) + \frac{1}{4}(3,1)\right] + \frac{1}{2}\left[\frac{3}{4}(1,-1) + \frac{1}{4}(-3,-1)\right],$$

both with energy $E = 0.768$. Our experiments yield a slight variation on these decompositions. We see in Figure 2 that the optimal (H^1) has not been taken as a starting point for the best (H^2) condition. This in turn is slightly different from the one shown in Figure 8. The computed matrices are

$$(1.1493, 1.03359), (1.1493, -2.9066), (-1.1493, 2.9066), (-1.1493, -1.0335)$$

with an energy value slightly better $E = 0.75866$. In Figure 3, optimal structures of level three and four ($L = 3$ and $L = 4$, respectively) obtained by our algorithm have been drawn. The values for the energy are $E_3 = 0.35185$ and $E_4 = 0.17329$, respectively. They are again better than the ones corresponding to the limit laminate (see Table 6). It is also interesting to notice that the support of optimal (H^L) conditions tends to the zero set, $K = \{A_i\}$, of φ as L increases. This can be seen in the supports for the computed optimal (H^3) and (H^4) conditions

$$K_3 = \{(1.2042, -2.9511), (-1.2042, 2.9511), (-2.9094, -1.0851),$$
$$(2.9094, 1.0851), (1.0646, -1.0851), (-1.0646, 1.0851)\},$$
$$K_4 = \{(-2.9793, -1.0951), (1.0960, -2.9589), (2.9088, 1.1063), (-2.9088, -1.1063),$$
$$(-1.0960, 2.9589), (2.9793, 1.0951), (-1.0545, 1.1063), (1.0545, -1.1063)\}.$$

For a greater number of levels, this trend is maintained. Optimal values of the energy are a bit better than the expected values, while the matrices in the support tend to the wells of φ. In Figure 4, we show the optimal (H^6) and (H^7) conditions.

TABLE 6

Expected	Computed
$E_2 = 0.768$	$E_2 = 0.75866$
$E_3 = 0.384$	$E_3 = 0.35185$
$E_4 = 0.192$	$E_4 = 0.17329$
$E_5 = 0.096$	$E_5 = 0.08578$
$E_6 = 0.048$	$E_6 = 0.04269$
$E_7 = 0.024$	$E_7 = 0.0213$

Similar results have been obtained for matrices located over the boundary of the square $B_1B_2B_3B_4$. Figure 9 shows computed optimal (H^5) conditions for some of those matrices.

So far, the experiments have shown a clear similarity with the expected result. For matrices in the interior of the square mentioned in the last paragraph this is not so. For instance, let us focus on $(1/2, 1/2)$. Up to level four ($L = 4$), one would expect a structure similar to (see Figure 10(a))

$$\left(\frac{1}{2}, \frac{1}{2}\right) = \frac{3}{4}\left(\frac{1}{2}, 1\right) + \frac{1}{4}\left(\frac{1}{2}, -1\right)$$
$$= \frac{3}{4}\left[\frac{5}{8}(-1,1) + \frac{3}{8}(3,1)\right] + \frac{1}{4}\left[\frac{7}{8}(1,-1) + \frac{1}{8}(-3,-1)\right]$$

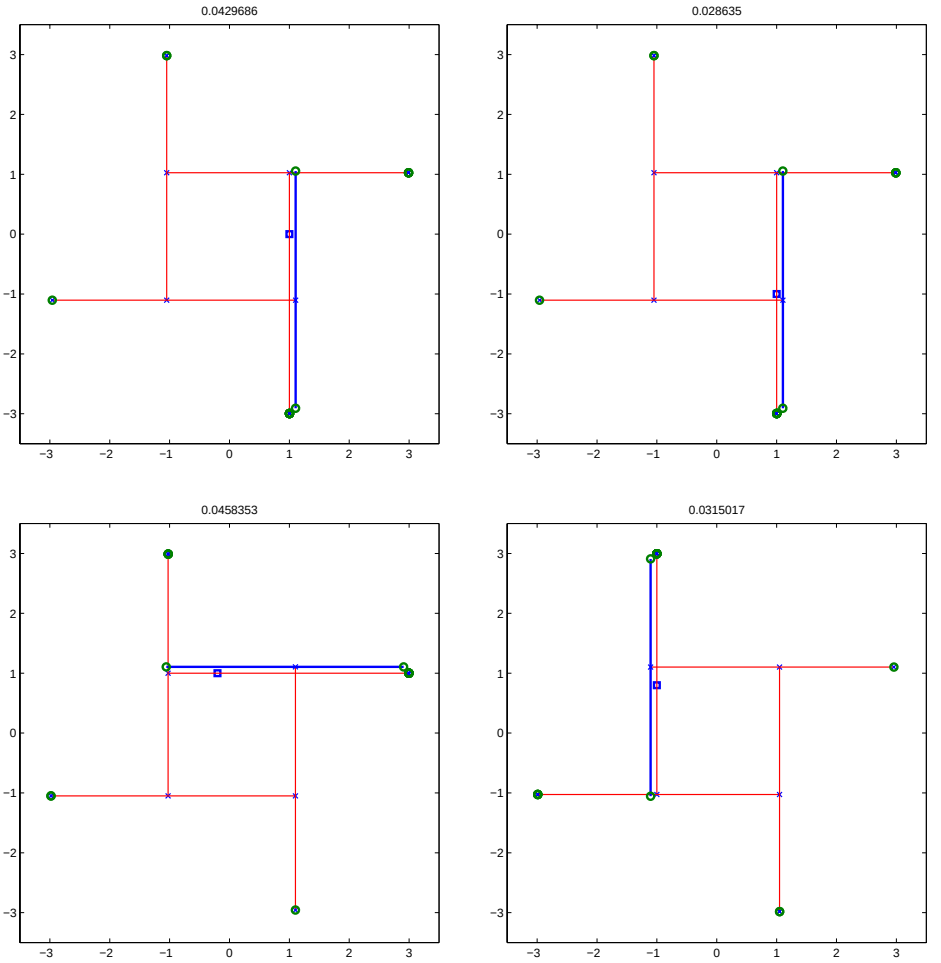

FIG. 9.

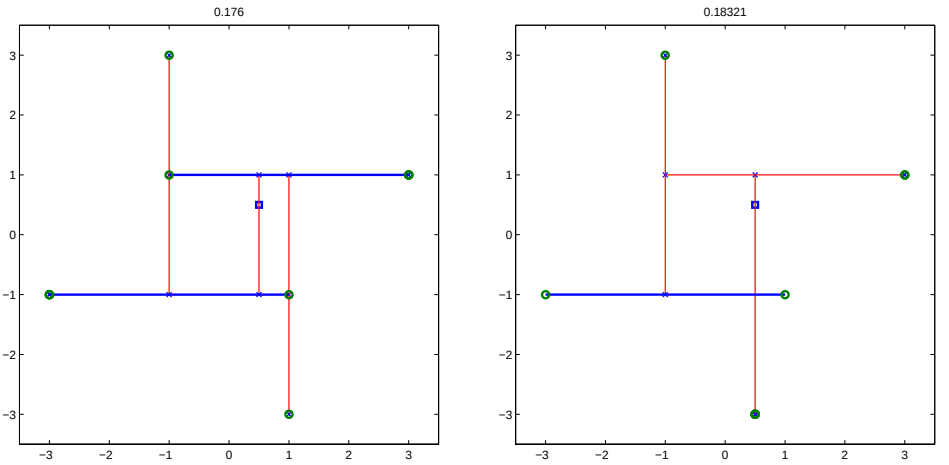
$$
\begin{aligned}
&= \frac{15}{32}\left[\frac{1}{2}(-1,-1)+\frac{1}{2}(-1,3)\right]+\frac{7}{32}\left[\frac{1}{2}(1,1)+\frac{1}{2}(1,-3)\right]\\
&\quad+\frac{9}{32}(3,1)+\frac{7}{32}(-3,-1)\\
&= \frac{15}{64}\frac{1}{2}(1,-1)+\frac{7}{64}\frac{1}{2}(-1,1)+\frac{15}{64}(-1,3)+\frac{7}{64}(1,-3)\\
&\quad+\left(\frac{7}{32}+\frac{15}{128}\right)(-3,-1)+\left(\frac{9}{32}+\frac{7}{128}\right)(3,1).
\end{aligned}
$$

However, we found that the decomposition (Figure 10(b))

$$
\begin{aligned}
\left(\frac{1}{2},\frac{1}{2}\right) &= \frac{7}{8}\left(\frac{1}{2},1\right)+\frac{1}{8}\left(\frac{1}{2},-3\right)\\
&= \frac{7}{8}\left[\frac{5}{8}(-1,1)+\frac{3}{8}(3,1)\right]+\frac{1}{8}\left(\frac{1}{2},-3\right)
\end{aligned}
$$



(a) (b)

FIG. 10.

$$= \frac{35}{64}\left[\frac{1}{2}(-1,-1)+\frac{1}{2}(-1,3)\right]+\frac{21}{64}(3,1)+\frac{1}{8}\left(\frac{1}{2},-3\right)$$
$$= \frac{35}{128}\frac{1}{2}(1,-1)+\frac{35}{128}\frac{1}{2}(-1,3)+\frac{35}{128}(-3,-1)+\frac{21}{64}(3,1)+\frac{1}{8}\left(\frac{1}{2},-3\right)$$

is the best one up to three levels, and only from four levels on the expected decomposition beats the last one. The numerical values are in Table 7, and the optimal structures are in Figure 11. This deviation from expected structures is more clear as we move toward the boundary of the square. In some cases one needs to let up to five levels of decomposition in order to see the expected structure for the limit optimal laminate. For instance, for the matrix $(8/10, 8/10)$ one must go up to seven levels.

TABLE 7

Expected	Computed
$E_2 = 0.704$	$E_2 = 0.509254$
$E_3 = 0.352$	$E_3 = 0.30375$
$E_4 = 0.176$	$E_4 = 0.15801$
$E_5 = 0.08$	$E_5 = 0.07837$

4. Final remarks. We would like to make some comments on the algorithm used to implement the numerical experiments in this paper.

It is important to notice that the number of variables involved exponentially increases with the number of levels L, thus making the computations unfeasible for large values of L. On the other hand, the main estimate in [1] ensures that the error reduces exponentially with L as well, so that there is no need, in principle, to use many different levels in real computations. Nonetheless, it would be interesting to have error estimates in approximating φ^L by our algorithm. Since the computation of $\varphi^L(A)$ is essentially a global optimization problem, there is no standard way of measuring how far we are from the real global optimum. An attempt in this direction

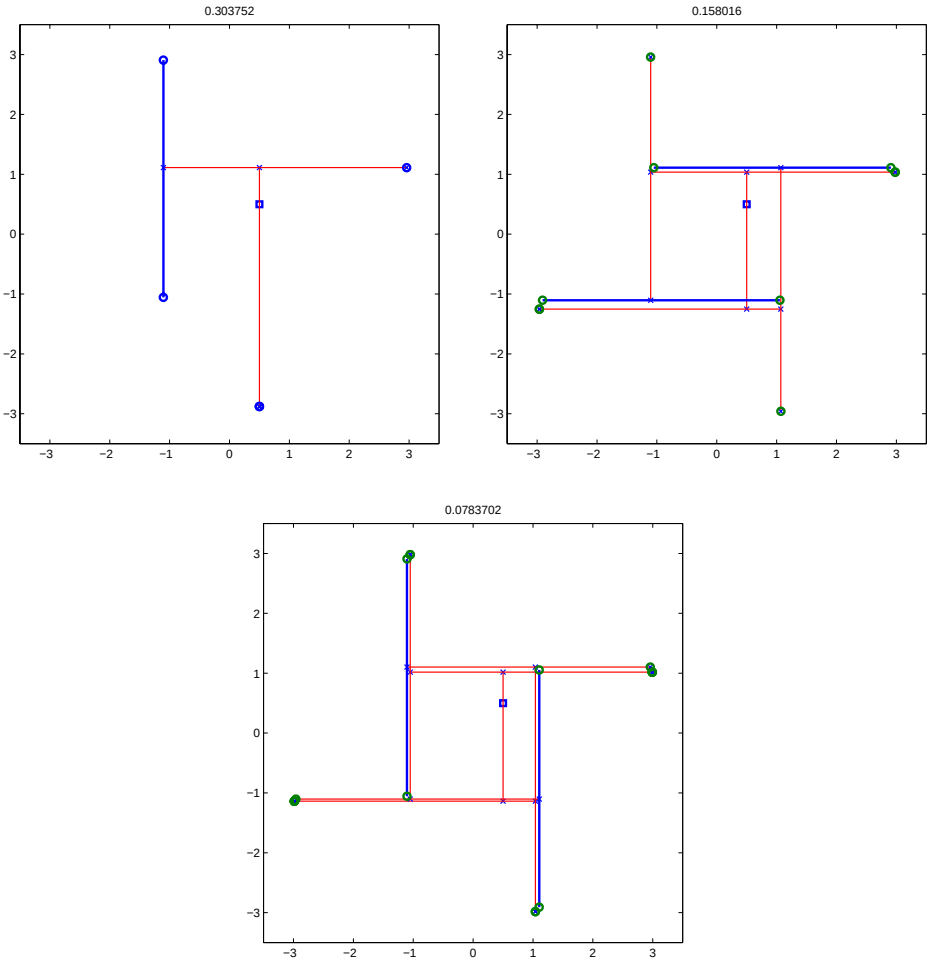


FIG. 11.

is made in [24], [25], [26]. In many cases we cannot be sure if we are even close to the optimum sought, although in our examples that seems to be the case. In most of the practical algorithms utilized for global optimization problems (like simulated annealing) several parameters must be tuned for good results. In our case, only the situation with the four matrices required fine adjustments when the number of levels increased beyond a certain point. The most delicate point was the choice of the initial guess to start out the algorithm, in order to avoid local minima. This is again a typical difficulty of these methods. Finally, it is important to point out that the continuity of the density φ turns out to be vital for good results, which, on the other hand, must not be surprising. We tried the algorithm with the example [33]

$$\varphi(A) = \begin{cases} 1 + |A|^2, & A \neq 0, \\ 0, & A = 0, \end{cases}$$

and most of the time the algorithm does not go out of a trivial configuration as could be easily anticipated.

A MOVING MESH METHOD FOR ONE-DIMENSIONAL HYPERBOLIC CONSERVATION LAWS*

JOHN M. STOCKIE†, JOHN A. MACKENZIE‡, AND ROBERT D. RUSSELL§

Abstract. We develop an adaptive method for solving one-dimensional systems of hyperbolic conservation laws that employs a high resolution Godunov-type scheme for the physical equations, in conjunction with a moving mesh PDE governing the motion of the spatial grid points. Many other moving mesh methods developed to solve hyperbolic problems use a fully implicit discretization for the coupled solution-mesh equations, and so suffer from a significant degree of numerical stiffness. We employ a semi-implicit approach that couples the moving mesh equation to an efficient, explicit solver for the physical PDE, with the resulting scheme behaving in practice as a two-step predictor-corrector method. In comparison with computations on a fixed, uniform mesh, our method exhibits more accurate resolution of discontinuities for a similar level of computational work.

Key words. moving mesh, adaptivity, equidistribution, shock capturing, hyperbolic conservation laws, finite volume methods

1. Introduction.

In this paper, we present an adaptive algorithm for computing solutions to one-dimensional systems of hyperbolic conservation laws. We consider problems of the form

$$\boldsymbol{q}_t + \boldsymbol{f}(\boldsymbol{q})_x = 0, \tag{1.1a}$$

$$\boldsymbol{q}(x,0) = \boldsymbol{q}_0(x), \tag{1.1b}$$

where $\boldsymbol{q}(x,t) \in \mathbb{R}^m$ is an m-vector, $a \le x \le b$, and $t \ge 0$. The system is "hyperbolic" in the sense that the Jacobian matrix $\partial \boldsymbol{f}/\partial \boldsymbol{q}$ has real eigenvalues and is diagonalizable with m linearly independent eigenvectors. Such problems are characterized by moving discontinuities (i.e., fronts or shocks) that separate regions of flow where the solution is smooth. The major challenge in solving hyperbolic systems numerically is to capture the discontinuous solutions with sufficient accuracy while also keeping the computational cost within acceptable limits.

The vast majority of numerical methods for solving hyperbolic problems have been developed for fixed, uniform grids. An important class of such methods is based on the Godunov scheme [16], which is a first order, finite volume method that employs the exact solution to local Riemann problems at cell interfaces to enhance the resolution of discontinuities. Accuracy can be further improved by using higher order variants, such as the flux- and slope-limiter methods reviewed in [28, 31], and computational cost is

reduced by linearizing the equations and solving approximate Riemann problems in each cell instead.

The discontinuities that are characteristic of hyperbolic problems typically move in time, and so the solution at a particular point in space can change very rapidly (see Figure 1.1). As a result, computations on a fixed, uniform spatial mesh can require that the time step be extremely small in order to reduce the error arising from the time variation in the solution at points near the front. On the other hand, it is possible to take a much larger time step when the solution is smooth and does not exhibit such large variation from one mesh point to the next. In principle, therefore, it is desirable to employ a nonuniform mesh that is sparse in regions where the solution is smooth and more concentrated near discontinuities. Since the steep fronts are not stationary, it is attractive to allow the mesh points to move in time so that fine grid resolution can be maintained near discontinuities, thereby attaining a balance between accuracy and efficiency.

There has been some success in solving hyperbolic problems on adaptive spatial meshes, starting with Harten and Hyman [17] who demonstrated how to extend a Godunov scheme to handle moving grids in one dimension. They employed a static regridding technique, in which the solution and mesh are evolved separately, with the mesh points updated in each time step to explicitly track discontinuities. Another static refinement strategy that has proven very successful, especially for higher dimensional problems, is the adaptive mesh refinement method [3] in which the mesh is refined locally based on some measure of the solution error using Cartesian subgrids. Biswas, Flaherty, and Arney [4] combined both mesh movement and local mesh refinement in a finite element framework.

In contrast with static refinement techniques is the second major class of adaptive methods based on dynamic refinement, in which one explicitly derives an equation governing the spatial mesh, which moves mesh points naturally to where they are most needed. The mesh equation is often derived from an *equidistribution principle*, which attempts to equally distribute some measure of solution error over the spatial domain. This approach was used to solve one-dimensional hyperbolic problems in [30] and [11], employing a flux splitting method for discretizing the physical PDE. The major disadvantage to this technique is that the coupling between the solution and mesh equations is nonlinear, often requiring a Newton iteration in each time

step, which can be very costly. This problem is further exacerbated by the dense clustering of mesh points near discontinuities, which degrades the convergence of the iteration.

In many moving mesh methods it has been found necessary to introduce an additional artificial viscosity term of the form $\mu \boldsymbol{q}_{xx}$ into (1.1), and solve the resulting parabolic system instead. This approach has been taken in connection with spatial discretizations based on finite differences [23, 29, 12], finite elements [15, 22], and collocation [19]. However, even with the viscous regularization, there are still convergence problems associated with taking the hyperbolic limit $\mu \to 0$ that can seriously degrade performance [15].

In this work, we propose an adaptive method that combines the flexibility and accuracy afforded by a dynamically moving mesh with the increased shock resolution capability of a Godunov-type scheme. The resulting method has the potential to reduce the cost of the moving mesh component of the algorithm significantly by eliminating the need for such a high concentration of grid points near discontinuities. We employ the moving mesh PDE (MMPDE) approach of Huang, Ren, and Russell [18] in which the number of grid points is constant and the points move throughout the domain, subject to a time-dependent PDE. The main difference from many of the other moving grid methods mentioned earlier is that the MMPDE incorporates a temporal smoothing term which improves the performance of the solution-mesh iteration.

For the physical PDE, we use the wave propagation method introduced by LeVeque [21] and implemented in the software package CLAWPACK [20]. The resulting method is similar to that of Chen [9], wherein a Godunov scheme was coupled with an MMPDE in a fully implicit time discretization based on the method of lines. However, we construct a more efficient semi-implicit scheme (similar to that developed in [29] for parabolic problems) that behaves as an explicit, predictor-corrector step for the test problems considered here. Furthermore, our method satisfies a discrete conservation principle which may not be the case for implicit discretizations based on a straightforward method-of-lines approach (see [14, 9, 12]). Our strategy is based on the principle that there is no reason to solve the physical PDE and mesh equation with the same spatial discretization or to the same level of accuracy, since they are equations of different type (one hyperbolic, one parabolic) and have fundamentally different interpretations (one physical, and the other an artificial construct).

We begin in section 2 with a description of the numerical method, including details of the wave propagation scheme for the hyperbolic conservation law, the discretization of the moving mesh equation, and the iteration that couples the two together. Section 3 presents several possible monitor functions that are designed specifically to resolve discontinuous solutions and shows how a monitor function can be generalized for systems of conservation laws where multiple fronts arise. In section 4, numerical tests are performed on several problems encompassing both scalar conservation laws and systems, to demonstrate the accuracy, efficiency, and robustness of the moving mesh method. Throughout this paper two major issues of concern are choosing a monitor function that is tailored to capturing discontinuous flow features, and temporal smoothing for controlling mesh motion.

2. The numerical method.

2.1. The physical PDE: Godunov's method on a moving mesh. We first describe the finite volume discretization of the hyperbolic conservation law (1.1a) on a

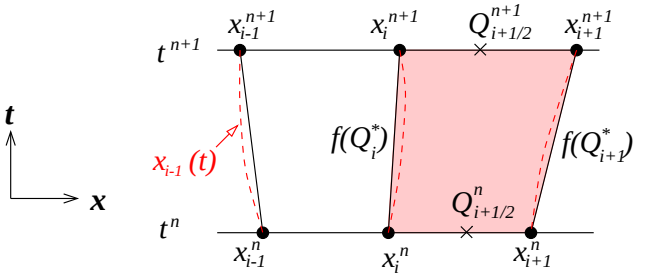

FIG. 2.1. *A computational cell on an adaptive spatial mesh. The dashed lines show the actual, curved, grid trajectories, which are approximated by straight lines in the xt-plane.*

nonuniform, moving mesh derived by Fazio and LeVeque in [13].[1] Consider a sequence of times t^n for $n = 0, 1, \ldots$, where the time steps $\Delta t^n = t^{n+1} - t^n$ need not be equal. Suppose that the spatial domain $[a, b]$ is subdivided using a set of points which move in time and are parameterized by $x_i(t) = x(\xi_i, t)$, where $\xi_i = \frac{i}{N}$ are the equally spaced computational coordinates, and

$$a \equiv x_0 < x_1(t) < x_2(t) < \cdots < x_{N-1}(t) < x_N \equiv b.$$

Figure 2.1 depicts a typical computational cell with grid points evolving from time level t^n to $t^{n+1} = t^n + \Delta t^n$, and with $x_i^n = x_i(t^n)$. In the following discussion, we develop the method in terms of the scalar quantity q to simplify notation, although the results extend easily to vectors.

In the *Godunov scheme* [16], the solution is assumed to be piecewise constant on each subinterval $[x_i, x_{i+1}]$, and the discrete solution is taken to represent the average value of the actual solution along the lower cell boundary,

$$Q_{i+1/2}^n = \frac{1}{\Delta x_{i+1/2}^n} \int_{x_i^n}^{x_{i+1}^n} q(s, t^n)\, ds, \tag{2.1}$$

where $\Delta x_{i+1/2}^n = x_{i+1}^n - x_i^n$ is the local mesh spacing. We then integrate the conservation law (1.1a) across the computational cell to obtain the formula

$$\kappa_{i+1/2}^{n+1} Q_{i+1/2}^{n+1} = \kappa_{i+1/2}^n Q_{i+1/2}^n - \frac{\Delta t^n}{\Delta \xi}\Big[(f(Q_{i+1}^*) - \dot{x}_{i+1}^n Q_{i+1}^*) - (f(Q_i^*) - \dot{x}_i^n Q_i^*)\Big], \tag{2.2}$$

where $\Delta \xi = \frac{1}{N}$ and $\kappa_{i+1/2}^n \doteq \Delta x_{i+1/2}^n / \Delta \xi$. The numerical flux $f(Q_i^*)$ is an approximation of the actual flux along the left slanted boundary of the cell and is computed using the solution to the local Riemann problem arising at the interface between the constant states $Q_{i-1/2}^n$ and $Q_{i+1/2}^n$. The intermediate state, Q_i^*, is actually the solution to the Riemann problem that lies along the straight-line characteristic $(x - x_i^n)/(t - t^n) = \dot{x}_i^n$. Here, we have assumed that the time derivative $\dot{x}_i = \partial x(\xi_i, t)/\partial t$ is constant over the time interval $[t^n, t^{n+1}]$, so that the edges of the cell are straight lines. The main

[1] Fazio and LeVeque used a simple moving mesh strategy for the Euler equations in which the contact line is tracked explicitly and a piecewise uniform mesh is fit to either side of the discontinuity. Our moving mesh approach is designed to capture discontinuities naturally as part of the solution process and is therefore much more flexible.

difference between this and Godunov's scheme on a fixed mesh is the appearance of additional $\dot{x}$ terms in (2.2) that arise due to the movement of the mesh points.

The method in the form (2.2) is nonconservative but can be modified to get a conservative discretization. Again assuming $\dot{x}_i$ is constant in a cell, we can use $x_i^{n+1} = x_i^n + \Delta t^n \dot{x}_i^n$ to obtain

$$\kappa_{i+1/2}^n Q_{i+1/2}^n = \kappa_{i+1/2}^{n+1} Q_{i+1/2}^n - \frac{\Delta t^n}{\Delta \xi}(\dot{x}_{i+1}^n - \dot{x}_i^n) Q_{i+1/2}^n.$$

Substituting this expression into (2.2) yields the discrete system

$$\begin{aligned}\kappa_{i+1/2}^{n+1} Q_{i+1/2}^{n+1} = \kappa_{i+1/2}^{n+1} Q_{i+1/2}^n - \frac{\Delta t^n}{\Delta \xi}\Big[&(f(Q_{i+1}^*) - \dot{x}_{i+1}^n (Q_{i+1}^* - Q_{i+1/2}^n)) \\ &- (f(Q_i^*) - \dot{x}_i^n (Q_i^* - Q_{i+1/2}^n))\Big].\end{aligned} \tag{2.3}$$

The advantage to this form is that the quantity $\sum_i \kappa_{i+1/2}^n Q_{i+1/2}^n$ is conserved with n and constant states Q are preserved.

For reasons which will become clear shortly, we write the Godunov scheme in *wave propagation form*:

$$Q_{i+1/2}^{n+1} = Q_{i+1/2}^n - \frac{\Delta t^n}{\kappa_{i+1/2}^{n+1} \Delta \xi}\left(\mathcal{A}^+ \Delta Q_i^n + \mathcal{A}^- \Delta Q_{i+1}^n\right) \tag{2.4}$$

with

$$\begin{aligned}\mathcal{A}^+ \Delta Q_i^n &= f(Q_{i+1/2}^n) - f(Q_i^*) - \dot{x}_i^n (Q_{i+1/2}^n - Q_i^*), \qquad \text{and} \\ \mathcal{A}^- \Delta Q_i^n &= f(Q_i^*) - f(Q_{i-1/2}^n) - \dot{x}_i^n (Q_i^* - Q_{i-1/2}^n).\end{aligned}$$

Here, $\mathcal{A}^+ \Delta Q_i^n$ is the right-going flux difference from solving the Riemann problem between $Q_{i-1/2}^n$ and $Q_{i+1/2}^n$ and models the combined effect on the cell average $Q_{i+1/2}^n$ of waves entering from the left edge. Similarly, $\mathcal{A}^- \Delta Q_{i+1}^n$ is the left-going flux difference from the Riemann problem between $Q_{i+1/2}^n$ and $Q_{i+3/2}^n$ and models the combined effect of all waves entering the cell from the right.

The Godunov scheme can be very expensive, particularly for systems of conservation laws, where the Riemann problem at each cell interface requires the solution of a nonlinear system of equations. In practice, it is possible to solve the Riemann problem approximately based on the linearized system

$$\boldsymbol{q}_t + A \cdot \boldsymbol{q}_x = 0 \tag{2.5}$$

with A an $m \times m$ matrix. The well-known approximate Riemann solver of Roe [25] is the solution to such a linearization and yields a set of m wave speeds λ_i^p and jumps $\mathcal{W}_i^p$ across each wave for $p = 1, \ldots, m$. Using the wave decomposition from the Roe solver, we can write

$$\mathcal{A}^+ \Delta Q_i = \sum_{p=1}^m (\widetilde{\lambda}_i^p)^+ \mathcal{W}_i^p, \tag{2.6a}$$

$$\mathcal{A}^- \Delta Q_i = \sum_{p=1}^m (\widetilde{\lambda}_i^p)^- \mathcal{W}_i^p, \tag{2.6b}$$

where $(\widetilde{\lambda}_i^p)^+ = \max(0, \widetilde{\lambda}_i^p)$, $(\widetilde{\lambda}_i^p)^- = \min(0, \widetilde{\lambda}_i^p)$, and $\widetilde{\lambda}_i^p = \lambda_i^p - \dot{x}_i^n$ are "shifted" wave speeds, incorporating the influence of the moving mesh. One of the major advantages of using this type of finite volume formulation is the natural way in which mesh motion is incorporated into the discrete equations, appearing only in the wave speeds. This should be contrasted with other methods based on finite differences that explicitly introduce terms of the form $q_x\dot{x}$, which can lead to problems with stability unless discretized carefully [23].

Godunov's method is only first order accurate in space, and so it suffers from a high degree of artificial dissipation which leads to significant smearing of the sharp fronts as the solution is evolved. To increase the accuracy of the discretization, one can use a high resolution flux correction (see [13, 21] for details).

Because the scheme is explicit in time, stability requires the time step to satisfy the *Courant–Friedrichs–Levy (CFL) condition* $\nu \leq 1$, where the CFL number is

$$\nu = \Delta t \max_{i,p} \left\{ \left| \frac{(\widetilde{\lambda}_i^p)^+}{\Delta x_{i+1/2}} \right|, \left| \frac{(\widetilde{\lambda}_{i+1}^p)^-}{\Delta x_{i+1/2}} \right| \right\}. \tag{2.7}$$

This inequality requires that the time step be small enough that waves from neighboring cells do not intersect.

It is important to distinguish the difference between the CFL condition for a moving mesh method and that arising from a *fixed* nonuniform grid, which is the same as (2.7) except that $\widetilde{\lambda}_i^p$ is replaced by the unshifted wave speeds λ_i^p. On a fixed mesh, $\Delta x_{i+1/2}$ can be very small, leading to a very strict global requirement on the time step. In contrast, the moving mesh method allows for a much less restrictive CFL condition when the shifted wave speeds are close to zero; i.e., provided that mesh points move at approximately the same speed as solution discontinuities, $\dot{x}_i \approx \lambda_i^p$. The possibility of relaxing the global CFL restriction for explicit calculations on nonuniform meshes is one of the major advantages of using a moving mesh for hyperbolic problems.

2.2. The MMPDE. Now we consider the mesh computation and for this formulate a moving mesh PDE that is based on an equidistribution principle. Following [18], we require that the transformation $x(\xi, t)$ from physical to computational coordinates satisfy

$$\int_a^{x(\xi,t)} M(s,t)\, ds = \xi \cdot \int_a^b M(s,t)\, ds. \tag{2.8}$$

The function $M(x,t) > 0$ is called the *monitor function* and can be the most important component of the adaptive mesh algorithm. In principle, M can be any appropriately chosen measure of the numerical error in the solution of the physical PDE. However, an advantage of the moving mesh approach is that M can be chosen to capitalize on some underlying property of the solution (for example, self-similarity or scaling invariance [5]). This is a feature that can be exploited in order to place mesh points precisely where they are needed in order to achieve optimal accuracy.

It is possible to discretize the integral form (2.8) directly, leading to a set of algebraic equations for the mesh locations which can be extremely difficult to solve efficiently when coupled with the physical PDE. Instead we take the MMPDE approach used by Huang, Ren, and Russell [18], wherein a PDE describing the moving mesh points is obtained by taking the time derivative of (2.8) and introducing temporal smoothing. There are a large number of possible MMPDEs, one being MMPDE4

of [18]:[2]

$$\frac{\partial}{\partial \xi}\left(M\frac{\partial \dot{x}}{\partial \xi}\right) = -\frac{1}{\tau}\frac{\partial}{\partial \xi}\left(M\frac{\partial x}{\partial \xi}\right). \tag{2.9}$$

The parameter τ can be thought of as the time scale over which the mesh relaxes towards equidistribution.

A commonly used form of M is the arclength monitor function

$$M = \sqrt{1+|q_x|^2}. \tag{2.10}$$

The corresponding centered finite difference approximation at cell midpoints is

$$M_{i+1/2} = \sqrt{1+\left|\frac{\overline{Q}_{i+1}-\overline{Q}_i}{x_{i+1}-x_i}\right|^2}, \tag{2.11}$$

where $\overline{Q}_i = (Q_{i+1/2}\Delta x_{i-1/2} + Q_{i-1/2}\Delta x_{i+1/2})/(\Delta x_{i+1/2} + \Delta x_{i-1/2})$ is a weighted average of cell-centered solution values, located at cell edges. Notice that M is largest where the solution changes most rapidly, and as a result the mesh equation (2.9) serves to concentrate grid points in regions with large solution gradients.

It is well known that some sort of smoothing of the mesh is required in order to maintain reasonable accuracy in the computation of a solution on an adaptive mesh. Rather than smoothing the mesh itself, a commonly applied technique in the moving mesh framework is to replace the monitor function in the equations above by a regularized version $\widetilde{M}$ given by

$$\widetilde{M}_{i+1/2} = \sqrt{\sum_{k=i-i_p}^{i+i_p} M_{k+1/2}^2 \left(\frac{\gamma_s}{1+\gamma_s}\right)^{|k-i|} \Bigg/ \sum_{k=i-i_p}^{i+i_p} \left(\frac{\gamma_s}{1+\gamma_s}\right)^{|k-i|}}. \tag{2.12}$$

$\widetilde{M}_{i+1/2}$ can be thought of as a weighted average of the neighboring $2i_p+1$ values of M (with weighting factors determined by the parameter $\gamma_s > 0$) that serves to eliminate local oscillatory or nonsmooth behavior that may arise from solving the MMPDE.

We discretize the MMPDE using centered finite differences in space, yielding

$$M_{i+1/2}\left(\dot{x}_{i+1}-\dot{x}_i\right) - M_{i-1/2}\left(\dot{x}_i-\dot{x}_{i-1}\right) = -\frac{E_i}{\tau}, \tag{2.13a}$$

where E_i is a centered approximation to the term on the right-hand side of (2.9) given by

$$E_i = M_{i+1/2}\left(x_{i+1}-x_i\right) - M_{i-1/2}\left(x_i-x_{i-1}\right). \tag{2.13b}$$

Since the monitor function depends on the solution values $Q_{i+1/2}$, the discrete physical equation (2.4) and (2.13a) form a coupled, nonlinear system of equations to be solved in each time step. In one-dimensional problems, it is common to employ a fully implicit time discretization and solve the resulting system of stiff ODEs using a package such as DASSL [24]. In two dimensions this procedure becomes very costly, and other approaches are needed (see [6], for example). We wish to construct a time-stepping procedure that preserves the conservation properties of the physical PDE, an issue addressed in the following section.

[2]Another MMPDE, MMPDE6, performs better for problems in which there are viscous shocks [22] or blow-up [5]. Its success is attributable to a certain scaling invariance property. However, we have found in numerical experiments that MMPDE6 is unsuitable for solving hyperbolic problems, which may be related to some alternate form of scaling invariance.

2.3. Time integration. Here we describe an algorithm for solving the discrete equations (2.4) and (2.13). By itself, the wave propagation scheme is explicit, but when coupled with the mesh equation, the system becomes implicit due to the dependence of the mesh equation on Q through the monitor function.

In our experience, a straightforward explicit discretization in time will lead to instabilities, and therefore some form of implicit time differencing is required (see also [23, 15]). Intuitively, it is easy to see the need for some form of iteration: if we were to employ a fully explicit algorithm, basing the mesh locations on the solution for the previous time step, then grid points can lag behind the solution, leading to serious violations of the CFL condition. However, a fully implicit scheme, wherein the coupled nonlinear system is solved in each time step, is far too expensive for practical calculations. Our method is similar to the fully explicit, predictor-corrector step constructed in [29], except that the step is iterated. Our aim in constructing a scheme is to leave the solution step for the physical PDE unaltered, so that we can employ the conservative, high resolution algorithms in CLAWPACK, and build around it a fixed point iteration on the mesh.

We propose the following algorithm.

Moving Mesh Algorithm

1. *Let* $n = 0$.
2. *Given an initial solution* Q^0 *at time* $t = t^0$*, equidistribute the mesh exactly using a discretization of the exact equidistribution principle* $(Mx_\xi)_\xi = 0$ *(corresponding to* $\tau = 0$*).*
3. *Step the solution to time level* $n+1$ *using the following iteration:*
   (a) *Let* $m = 0$*. Take a guess at the new mesh positions using* $x_i^{n+1,0} = x_i^n + \Delta t^n \dot{x}_i^n$*, unless this leads to mesh crossings, in which case we take the conservative guess* $x_i^{n+1,0} = x_i^n$*.*
   (b) *Use* CLAWPACK *to obtain an initial guess* $Q^{n+1,0}$ *for the solution at time level* $n+1$ *using the mesh* $x_i^{n+1,0}$*.* CLAWPACK *returns an adaptively-chosen time step* Δt^n *which is used for the remainder of the iteration.*
   (c) *Iterate on* m*:*
      i. *Compute the raw and smoothed monitor function values,* $M_{i+1/2}$ *and* $\widetilde{M}_{i+1/2}$*, and the quantity* E_i *from* (2.13b)*, all based on the current solution iterate* $Q_{i+1/2}^{n+1,m}$*.*
      ii. *Employ a Crank–Nicolson discretization of* (2.13a) *for updating the mesh:*

$$\widetilde{M}_{i+1/2}^{n+1,m}(x_{i+1}^{n+1,m+1} - x_i^{n+1,m+1}) - \widetilde{M}_{i-1/2}^{n+1,m}(x_i^{n+1,m+1} - x_{i-1}^{n+1,m+1})$$

$$= \widetilde{M}_{i+1/2}^{n+1,m}(x_{i+1}^n - x_i^n) - \widetilde{M}_{i-1/2}^{n+1,m}(x_i^n - x_{i-1}^n) - \frac{\Delta t^n}{2\tau}\left[E_i^{n+1,m} + E_i^n\right],$$

      for which a tridiagonal system is solved for the unknowns $x_i^{n+1,m+1}$*.*
      iii. *Use* CLAWPACK *to obtain the new solution approximation* $Q_i^{n+1,m+1}$*, using mesh positions* $x_i^{n+1,m+1}$*, mesh velocities* $\dot{x}_i^{n+1} = (x_i^{n+1,m+1} - x_i^n)/\Delta t^n$*, and a CFL restriction of* $\nu \le 0.9$*.*
      iv. *If* $\|x^{n+1,m+1} - x^{n+1,m}\|_1 > TOL$*, then increment* m*, and go to step* 3(c)(i)*.*

4. *Once the iteration has converged, increment n and begin a new time step in step* 3.

Some of the key aspects of the algorithm worth noting are that

- the physical PDE is integrated explicitly in time using a conservative method;
- the convergence tolerance is applied on the mesh only;
- there is only a single parameter (the temporal smoothing, τ) needed to control the mesh motion;
- because the physical PDE is solved using the general purpose solver CLAWPACK, the method is easy to generalize to other problems.

These features combine together to yield a method that to our knowledge is distinct from any other adaptive approach that has appeared in the literature.

3. Monitor functions for resolving discontinuities. The monitor function should in principle be chosen so that it represents some measure of the error in the computed solution in an appropriate norm. At points where the error is large, M should also be large so that mesh points will tend to concentrate in those areas where higher resolution is needed. While solution arclength (2.10) concentrates mesh points where the solution has large gradients and gives excellent results for many parabolic problems, we have found that it is inappropriate for hyperbolic equations. Particularly when high resolution Godunov schemes are used, computed discontinuous flow features can be very steep, and so the MMPDE may drive more points than necessary into the neighborhood of these discontinuities. Several investigations have already been made into how the arclength monitor function can be modified to avoid excessive clustering of points and so control the conditioning of the mesh equation [10, 1, 22]. Our objective in this section is to obtain regularized variants of the arclength monitor, which are still large where discontinuities arise, but not so large that they over-resolve steep layers.

One way to modify the arclength monitor function so as to balance the number of points inside and outside a steep internal layer is to introduce a "regularizing factor" α in the following manner:[3]

$$M = \sqrt{1 + \frac{1}{\alpha}\,|q_x|^2}. \tag{3.1}$$

The factor α allows one to reduce the magnitude of the monitor function in situations where $|q_x|$ is very large, thereby avoiding over-resolution of steep layers, while also ensuring that M still retains a significant peak near these discontinuities. Beckett and Mackenzie [1] applied this type of regularization in the context of singularly perturbed boundary value problems, and using a monitor function based on curvature, $M = 1 + \frac{1}{\alpha}|q_{xx}|^{1/m}$. Taking α to be any constant greater than one in (3.1) will tend to move points out of a steep front into regions where the solution is smooth. However, if we are to construct a monitor function that will give reasonably consistent results for shocks of arbitrary steepness, then α will have to depend on the solution.

A scaling of the arclength function using the maximum solution value (with $\alpha \propto \max_x |q|^2$) was applied in [11] to eliminate large variations in the solution components

[3]Note that the monitor functions $M = \sqrt{\alpha + |q_x|^2}$ and $M = \sqrt{1 + |q_x|^2/\alpha}$ give identical results because of the invariance of MMPDE4 in (2.9) under the scaling $M \mapsto cM$, where c is a constant. MMPDE6, incidentally, is not invariant under this scaling.

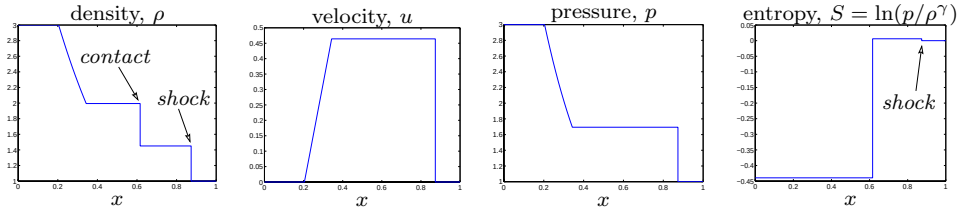

FIG. 3.1. *Plots of density, velocity, pressure, and entropy for a solution to the Euler equations. In each plot, the rarefaction wave is on the left, the shock on the right, and the contact line lies in between.*

for systems of conservation laws. This monitor will still over-resolve discontinuous fronts, and so we consider instead a scaling based on the maximum derivative value,

$$\alpha = \alpha^{max} \doteq \max_x |q_x|^2/\beta, \tag{3.2}$$

where the parameter $\beta > 1$ controls the concentration of mesh points. A related regularization, used in [1], scaled the derivative term in (3.1) by its average value over the domain using

$$\alpha = \alpha^{avg} \doteq \frac{1}{|b-a|} \int_a^b |q_x|^2 \, dx. \tag{3.3}$$

The advantage to this type of monitor function is that there is no free parameter needed for mesh control.

3.1. Generalization to systems of equations. The discussion of monitor functions thus far has been restricted to the case where the unknown function is a scalar. The definition extends naturally to systems of equations in which $\boldsymbol{q}$ is an m-vector. Perhaps the most obvious approach is to replace the absolute value $|q_x|$ with the vector 2-norm $\|\boldsymbol{q}\|$ in (3.1). However, in problems such as the Euler equations of gas dynamics, the solution components can take on values that differ widely in magnitude, in which case it makes no sense to weight the individual components equally. Furthermore, shocks are characterized by jumps in all three components, whereas contact lines appear as discontinuities in the density only, as pictured in Figure 3.1. As a result shocks are weighted more heavily in the calculation of the monitor function and contact lines are essentially ignored. This is undoubtedly what limits the accuracy of contact line resolution in other moving mesh computations such as those reported in [8, 22].

In order to obtain a monitor function that is better able to capture all discontinuous flow features, some form of rescaling must be performed on the solution components. Dorfi and Drury [11] used a weighted 2-norm of the solution in which each component $q^{(j)}$ is scaled by a factor $\alpha^{(j)} \approx \max_x |q^{(j)}|^2$, and as a result the contribution of each component to the monitor function is the same.

Rather than using a simple scaled vector norm, we construct two distinct monitor functions, one tailored to recognizing shocks and one to contact lines, and scale each separately. Since the velocity, u, is discontinuous only across shocks, a natural choice for constructing a "shock monitor" is the following:

$$M^s = \sqrt{1 + \beta \left(\frac{|u_x|}{\max_x |u_x|} \right)^2}, \tag{3.4}$$

although pressure could equally well be used in place of velocity. We choose to regularize the monitor function using α^{max}, since then the maximum magnitude of M is independent of the shock steepness or the magnitude of the velocity component. It is then possible to normalize the monitor functions so that different discontinuities are given equal weight, something which is not possible with the averaged regularization parameter α^{avg}.

In a similar manner, we construct a "contact monitor" function defined in terms of the entropy $S = \ln(p/\rho^\gamma)$ as

$$M^c = \sqrt{1 + \beta \left(\frac{|S_x|}{\max_x |S_x|} \right)^2}. \tag{3.5}$$

While the entropy is discontinuous across both shocks and contact lines (see Figure 3.1) and so is not an ideal choice for a contact monitor, entropy typically has a much smaller jump across a shock than a contact line. Therefore, (3.5) should still be a good measure of the location of contact discontinuities.

The moving mesh algorithm requires a single monitor function, which we define using the simple convex combination

$$M^{cs} = \theta M^c + (1 - \theta) M^s. \tag{3.6}$$

In all numerical simulations performed herein, we weight the two classes of discontinuity equally and take $\theta = \frac{1}{2}$. The resolution of the shock and contact line is fairly insensitive to the choice β in (3.4) and (3.5) provided it is taken large enough, and in practice a value of $\beta = 100$ has proven to give satisfactory results.

4. Numerical results. In this section, we will focus on three test problems: the inviscid Burgers equation; the Buckley–Leverett equation (which is distinguished by a nonconvex flux function); and the Euler equations of gas dynamics (a system of three hyperbolic conservation laws). We evaluate the various monitor functions introduced in section 3 by comparing accuracy and computational cost. We also investigate the importance of the temporal smoothing parameter τ appearing in the moving mesh equation and whether there are any particular issues associated with solving problems that have discontinuous solutions. The solution quality and algorithm performance are much less sensitive to the level of spatial smoothing, and so we fix the parameters $i_p = 4$ and $\gamma_s = 2$ in (2.12) for the remainder.

Computational costs are reported as CPU times in seconds measured on a Sun SPARCstation-20, and in all of our simulations the overhead cost associated directly with computing the mesh amounted to at most 25% of the total CPU time. As a result, any differences in total cost between the fixed and moving mesh results can be attributed primarily to differences in the time step in conjunction with any additional moving mesh iterations required in each time step.

Errors are reported relative to an "exact" solution which is actually a finely resolved numerical approximation obtained from a fixed mesh computation with $N = 2500$. An appropriate norm for measuring errors in discontinuous solutions is the L^1-norm, which we approximate using the formula

$$\|Q - q\|_1 = \sum_{i=1}^{N} \left| Q_{i+1/2} - q(x_{i+1/2}) \right| \cdot \Delta x_{i+1/2},$$

where Q is the computed solution and q the exact solution.

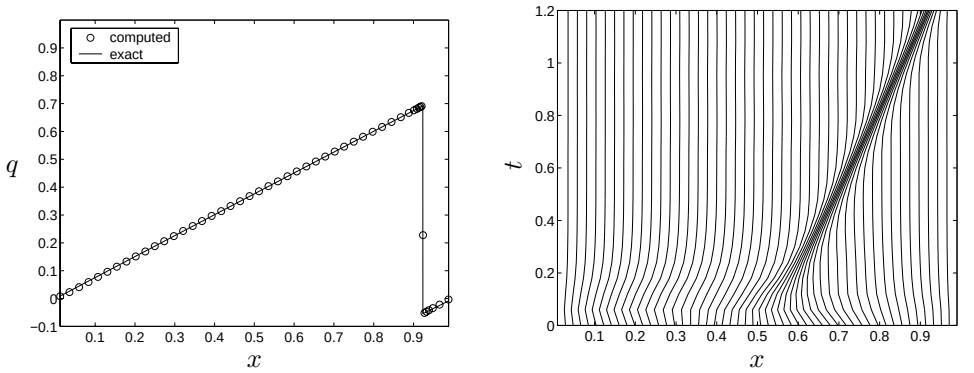

FIG. 4.1. *Moving mesh solution to Burgers's equation at time $t = 1.2$ sec. On the left is the solution and on the right are the mesh contours (α^{avg}, $\tau = 0.05$, $N = 50$).*

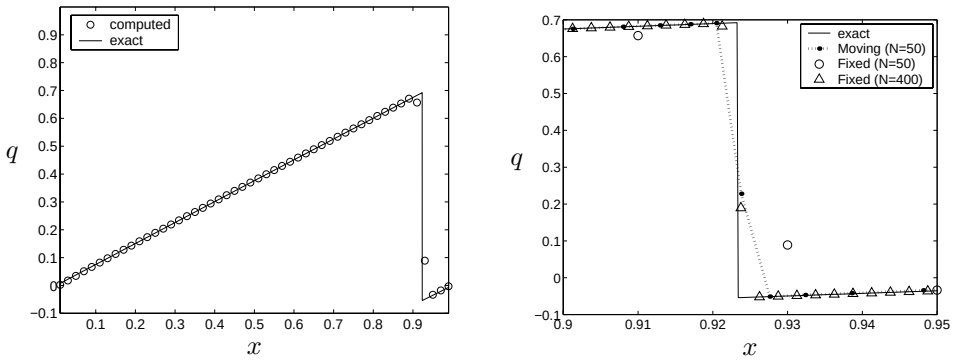

FIG. 4.2. *Fixed mesh solution with $N = 50$ points (left) and a blow-up of various fixed and moving mesh calculations in the neighborhood of the shock (right).*

4.1. Inviscid Burgers equation. Our first test of the moving mesh method is the inviscid Burgers equation

$$q_t + \left(\frac{1}{2}q^2\right)_x = 0 \tag{4.1}$$

for $0 \le x \le 1$, and $t \ge 0$, with periodic boundary conditions and an initial solution profile given by $q_0(x) = \sin(2\pi x) + \frac{1}{2}\sin(\pi x)$. The solution propagates to the right, steepening until the *singularity time* $t_s = 64/(129\pi) \approx 0.15792$, at which point a shock forms.

The solution up to time $t = 1.2$ is displayed in Figure 4.1 for a moving mesh calculation with $N = 50$, $\tau = 0.05$, and regularization parameter α^{avg}, while the fixed grid solution with the same number of mesh points is given in Figure 4.2 for comparison. It is evident that the moving mesh computation yields considerably better shock resolution than the fixed mesh method because of the clustering of mesh points near the shock. The ability of the mesh to capture and follow the moving shock is demonstrated by the mesh contour plot in Figure 4.1.

A more quantitative comparison of solution errors is afforded by Table 4.1, which lists the L^1 error in the solution for various fixed and moving mesh calculations. The

TABLE 4.1

Comparison of various fixed and moving grid solutions for Burgers's equation. The NT column reports the number of time steps and $\mathcal{R}$ the mesh racing factor. The arclength computation flagged with a "∗" experienced difficulties with stability of the mesh equation which accounts for the exceptionally large CPU time.

Description	*CPU time*	*NT*	L^1 *error*	$\mathcal{R}$
Fixed mesh:

$N = 400$	7.36	562	0.0007	
Moving mesh ($\tau = 0.1$)*:*				
α^{max}, $N = 50$	1.66	185	0.0017	0.104
α^{avg}, $N = 50$	1.58	172	0.0013	0.101
α^{avg}, $N = 100$	4.84	331	0.0005	0.056
Arclength monitor ($N = 50$)*:*				
$\tau = 0.2$	2.67	323	0.0015	0.022
∗ $\tau = 0.1$	31.20	4256	0.0016	0.001

moving mesh calculations with 50 grid points are as accurate as for a fixed mesh with 200 points, and they require less CPU time.

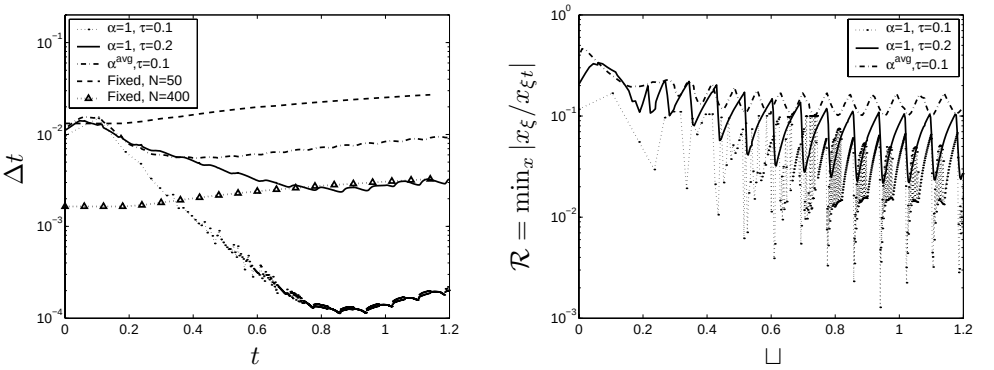
For the computations using regularization parameters α^{avg} and α^{max}, the number of iterations in each time step is at most 2. Therefore, the major factor determining the efficiency of the method is the CFL condition (2.7) arising from the physical PDE. The time steps in the moving mesh calculations are considerably larger than that which would be allowed on a fixed mesh with a similar level of refinement near the shock. This is illustrated by the time step plots in Figure 4.3(a), which correspond to a 400-point fixed mesh and a moving grid with α^{avg}. However, the improvement is not as dramatic as we might have expected from (2.7) because the shifted wave speeds are never exactly zero. It is not possible to constrain mesh points to lie always along the front since they must periodically enter the shock layer from the right and leave from the left, as seen in Figure 4.1. This phenomenon, known as *"mesh racing,"*[4] is unavoidable in r-adaptive methods for which mesh points are not explicitly added or removed throughout the adaptation procedure.

The connection between mesh racing and the CFL number (2.7) can be made more apparent by considering two mesh trajectories, x_{i-1} and x_i, that lie along a shock as pictured in Figure 4.4. The mesh point x_i continues moving along the shock, and so the wave speed is $\lambda \approx \dot{x}_i$. The local CFL number corresponding to the mesh point x_{i-1} is then given by

$$\nu_{i-1/2} = \frac{|\lambda - \dot{x}_{i-1}|\Delta t}{x_i - x_{i-1}} \approx \frac{|\dot{x}_i - \dot{x}_{i-1}|}{\Delta\xi} \cdot \frac{\Delta\xi}{x_i - x_{i-1}} \cdot \Delta t \approx \Delta t \Big/ \left|\frac{x_\xi}{x_{\xi t}}\right|. \tag{4.2}$$

Consequently, when mesh racing occurs, there is an accompanying stability constraint on the time step that is determined by the *"mesh racing factor,"* $\mathcal{R} \doteq \min_x |x_\xi / x_{\xi t}|$. Table 4.1 and Figure 4.3(b) both show that smaller values of $\mathcal{R}$ (associated with clustering of grid points and large mesh curvature) correspond to reductions in the time step. More careful investigation shows that this correlation between time step and mesh racing factor persists for all moving mesh calculations.

[4]While not standardized in the literature, the term "mesh racing" has been used in the past by K. Miller.



(a) Time step. *(b) Mesh racing factor.*

FIG. 4.3. *Plots of the time step (left) and mesh racing factor* $\mathcal{R} = \min_x |x_\xi / x_{\xi t}|$ *(right) for several fixed and moving mesh calculations. The moving mesh computations with arclength and* α^{avg} *monitor functions (with* $N = 50$*) demonstrate that smaller time steps correspond to smaller values of* $\mathcal{R}$*.*

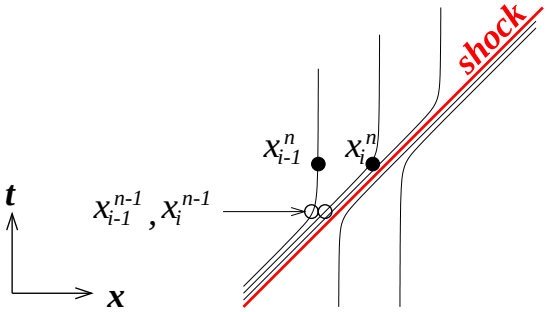


FIG. 4.4. *A plot of moving mesh trajectories in the* $x - t$ *plane, depicted in the neighborhood of a discontinuity, denoted by the thick gray line. Mesh racing is illustrated, in which two mesh trajectories lying along the shock,* x_{i-1} *and* x_i*, diverge from each other between one time level and the next.*

Temporal smoothing plays a central role in the performance of the algorithm and the resolution of discontinuous solution features. The primary influence of the parameter τ is to smooth the mesh trajectories, or in other words, to lessen the mesh "curvature," $x_{\xi t}$. Hence, temporal smoothing is integrally connected to mesh racing. Too much smoothing prevents the moving mesh algorithm from recognizing a discontinuity at all, resulting in a mesh that is nearly uniform. On the other hand, too little smoothing can lead to mesh racing, excessively small time steps, and difficulties with convergence of the solution-mesh iteration. Table 4.2 displays the CPU time and errors for several values of τ, from which it is evident that the algorithm can be quite sensitive to the level of smoothing.

The temporal smoothing parameter can also be interpreted as a time scale over which the grid relaxes towards equidistribution. Consequently, a secondary effect of temporal smoothing is a slight time delay in the mesh motion. This is manifested in Figure 4.1 as a higher concentration of mesh points at the trailing edge of the shock.

TABLE 4.2
Comparison of various fixed and moving grid solutions for Burgers's equation (α^{avg}, $N = 50$). The NT column reports the number of time steps and $\mathcal{R}$ the mesh racing factor. The arclength computation marked with a "∗" experienced difficulty with stability of the mesh equation.

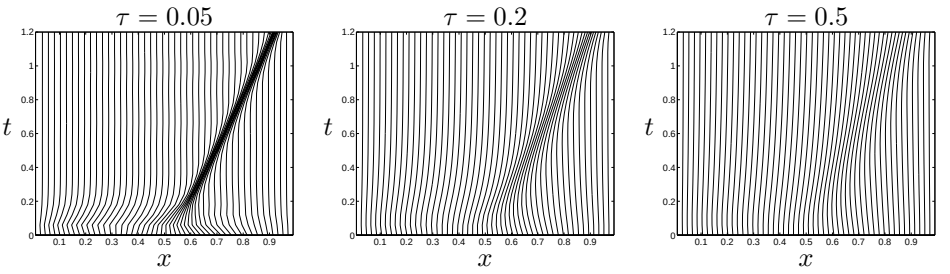

FIG. 4.5. *Mesh trajectories for various temporal smoothing parameters (α^{avg}, $N = 50$).*

A tangible connection can be made between mesh racing and the level of temporal smoothing, based on the analysis of moving mesh methods performed by Smith and Stuart [26] for a general class of time-dependent scalar PDEs. In this work, the authors derive the following bounds on the mesh derivatives in terms of τ and $\bar{M} \doteq \max_x(M)$:

$$|x_{\xi t}| \leq \frac{\bar{M}^2}{\tau} \qquad \text{and} \qquad x_\xi \geq \frac{1}{\bar{M}},$$

which can be combined to obtain a bound on the mesh racing factor,

$$\mathcal{R} \geq \frac{\tau}{\bar{M}^3}. \tag{4.3}$$

While this is only a lower bound on $\mathcal{R}$, it does suggest that our strategy of combining temporal smoothing with a regularized monitor function serves to control mesh racing. This is particularly evident in the case of the α^{max} regularization, for which M is bounded by a constant and, in fact, $\mathcal{R} \geq \tau/\beta^{3/2}$. Referring to the contour plots in Figure 4.5 and the entries in Table 4.2, τ clearly does have a mollifying influence on the mesh curvature and hence also on mesh racing.

We now move on to a discussion of the choice of monitor function. Using solution arclength for problems with steep fronts, the mesh equation is known to become ill-conditioned as the viscosity, and hence also the front thickness, go to zero [15], causing mesh points to cluster in the layer. The results in Table 4.1 demonstrate that the arclength monitor requires a higher value of τ to control the mesh behavior, and the iteration diverges even when τ is as large as 0.1. As long as the temporal smoothing is taken large enough the arclength results are comparable to that for other monitor functions, although the accuracy suffers somewhat because of the time lag in the mesh motion. However, as we will see later in computations with the Euler equations, arclength can introduce severe ill-conditioning in the mesh equation, so we do not advocate its use for hyperbolic problems.

TABLE 4.3

Comparison of moving grid calculations for Burgers's equation based on the method of lines ($N = 50$, $\tau = 0.05$). The columns NT and NJAC give the number of time steps and number of Jacobian evaluations, respectively.

Description	*CPU time*	*NT*	*NJAC*	L^1 *error*
Inviscid Burgers, α^{max}	15.70	1264	221	0.0063

$\mu = 10^{-4}$	14.70	830	79	0.0039
$\mu = 10^{-5}$	32.90	1523	214	0.0036

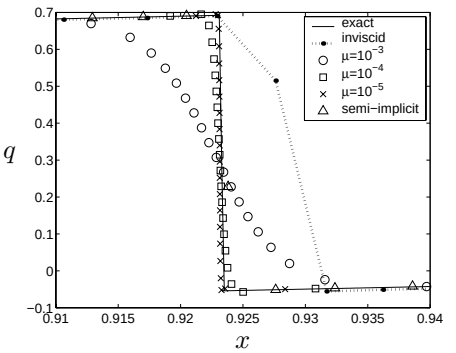

FIG. 4.6. *Close-up of the solution to the viscous and inviscid Burgers equation at time $t = 1.2$ using a fully implicit method of lines approach. Our semi-implicit moving mesh solution is shown for comparison purposes.*

We close with a brief comparison to other more common moving mesh approaches, and report on simulations for which the physical and mesh PDEs are discretized implicitly in time using a method of lines approach. The resulting nonlinear system is solved using the backward difference formula (BDF) solver DASSL [24] with error tolerances $atol = rtol = 10^{-6}$. We employ two different spatial discretizations: the first being a centered finite difference approximation of the viscous Burgers equation with the viscosity $\mu \to 0$, and the second a Godunov scheme for the inviscid problem. The CPU times and errors are listed in Table 4.3, from which it is easy to see the significant increase in cost required for a fully implicit method. The close-up plots of the solution near the shock in Figure 4.6 indicate the clustering together of points as the layer steepens, with CPU times demonstrating the corresponding increase in difficulty of solving the mesh equation.

These difficulties can only be expected to worsen for hyperbolic problems which have no natural dissipative mechanism to control the mesh. In fact, the inviscid Burgers computation fails to converge at all using the arclength monitor function, and so an alternate monitor had to be employed. Using the α^{max} regularization we were able to compute the solution pictured in Figure 4.6. While the L^1 error is only slightly larger in comparison to the other computations, there is clearly a significant error in the shock speed. This points to a serious drawback in using a straightforward method of lines approach for hyperbolic problems: namely, that the resulting discretization may not be conservative. This is one of our main motivations for constructing a semi-implicit algorithm using an explicit, conservative step in the physical solution.

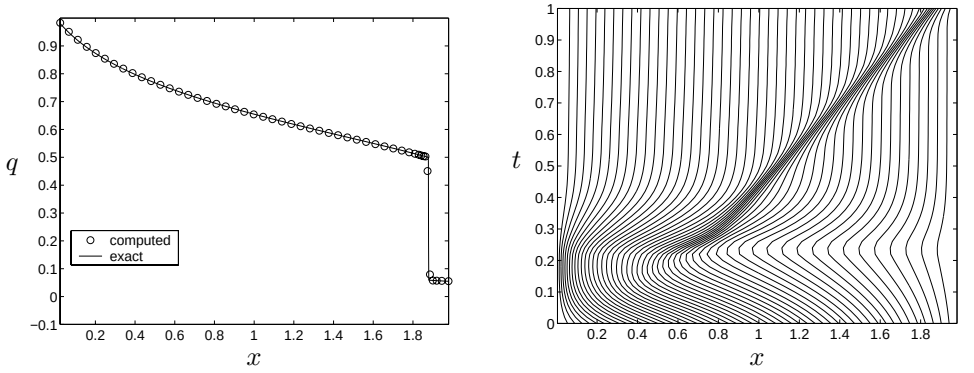

FIG. 4.7. *Moving mesh solution to the Buckley–Leverett equation (α^{max}, $\tau = 0.05$, $N = 50$).*

4.2. Buckley–Leverett equation. We next consider the scalar Buckley–Leverett problem which has been used to describe the one-dimensional flow of two immiscible fluids in a porous medium, neglecting capillary pressure and gravity. This may be used to model gas and oil in a reservoir, for which the equations take the form of a scalar conservation law (1.1a), where q is the fluid saturation (water volume/pore volume) and the flux function is

$$f(q) = \frac{q^2}{q^2 + 0.5(1-q)^2}. \tag{4.4}$$

The solution is obtained on the interval $x \in [0, 1]$, with initial and boundary conditions

$$q(x, 0) = \frac{1}{1 + 10x}, \qquad q(0, t) = 1, \qquad q(1, t) = \frac{1}{11},$$

corresponding to an "oil recovery" scenario where water is pumped into the reservoir at $x = 0$ and oil is forced out at $x = 1$. In contrast with Burgers's equation, the Buckley–Leverett flux function $f(q)$ is nonconvex, which leads to difficulties with some numerical schemes and so serves as an excellent test of a numerical method.

The solution to time $t = 1.0$ sec is shown for a moving mesh in Figure 4.7 and the corresponding fixed mesh simulation in Figure 4.8. Again, the adaptive mesh does an excellent job of capturing and following the discontinuity, and it resolves the shock layer much more accurately than the fixed mesh method with the same number of points.

4.3. Euler equations. The Euler equations describing the evolution of an inviscid, compressible, polytropic gas in one dimension are

$$\frac{\partial}{\partial t}\begin{bmatrix} \rho \\ \rho u \\ e \end{bmatrix} + \frac{\partial}{\partial x}\begin{bmatrix} \rho u \\ \rho u^2 + p \\ u(e+p) \end{bmatrix} = 0, \tag{4.5}$$

where ρ is the density, u the velocity, p the pressure, $e = \frac{p}{\gamma - 1} + \frac{1}{2}\rho u^2$ the internal energy, and γ the ratio of specific heats ($\gamma = 1.4$ for air). The system (4.5) is in the form of a conservation law (1.1a) with $q = (\rho, \rho u, e)^T$ and $f(q) = qu + (0, p, pu)^T$. We

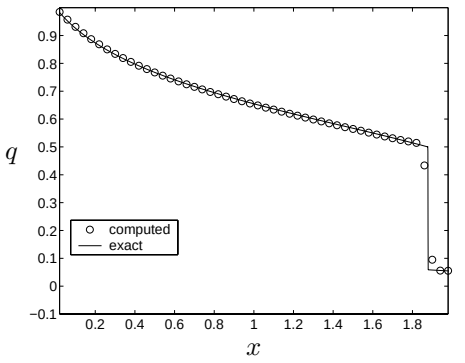

FIG. 4.8. *Fixed mesh solution to the Buckley–Leverett equation ($N = 50$).*

consider Sod's classical shock tube problem [27] which has the initial conditions

$$q(x,0) = \begin{cases} (1.0, 0.0, 2.5) & \text{if } 0 \le x < 0.5, \\ (0.125, 0.0, 0.25) & \text{if } 0.5 \le x \le 1, \end{cases}$$

and reflecting boundary conditions at $x = 0$ and $x = 1$.

In contrast with the Burgers or Buckley–Leverett problems of the previous sections (in which the initial data are smooth), the selection of an appropriate initial mesh is of particular importance here because the initial conditions are discontinuous. In order to allow mesh points to concentrate on or near initial discontinuities, the data must be smoothed over some finite width. We therefore replace jumps in each component of the initial data with smoothed, hyperbolic tangent profiles of the form

$$\widetilde{q}(x) = q_L + \frac{1}{2}(q_R - q_L)\left(1 + \tanh\left(\frac{x - x_c}{\epsilon}\right)\right), \tag{4.6}$$

where q_L and q_R are the left and right jump states, $x = x_c$ is the location of the discontinuity, and ϵ is the smoothing width. Reasonable mesh distributions are obtained when points are exactly equidistributed (i.e., $\tau = 0$) with a smoothing width of $\epsilon \approx 0.005$. The resulting nonlinear system of equations is solved using a fixed point iteration starting from an equally spaced mesh, and in order to improve the convergence of the iteration we use a continuation procedure in which ϵ is gradually decreased from 0.1 to 0.005. The iteration proceeds until the difference between mesh locations for successive iterates goes to zero, and then the resulting mesh and solution data are used as the initial conditions in the numerical scheme.

The performance of the moving mesh algorithm with the arclength monitor function was much worse than for Burgers's equation, requiring an excessively large value of τ for stability. We therefore consider only regularized monitor functions, and begin with $M = \sqrt{1 + \|\boldsymbol{q}_x\|_2^2/\alpha}$, based on a straightforward 2-norm of the solution components, with $\alpha = \int \|\boldsymbol{q}_x\|_2^2 \, dx$. The computed density and mesh contour plot are displayed in Figure 4.9, from which we see that the moving mesh solution provides much better resolution of the shock and rarefaction wave than the fixed mesh algorithm (shown in Figure 4.10). However, the contact discontinuity is not detected at all, and consequently, the resolution of the contact line is no better than for a fixed

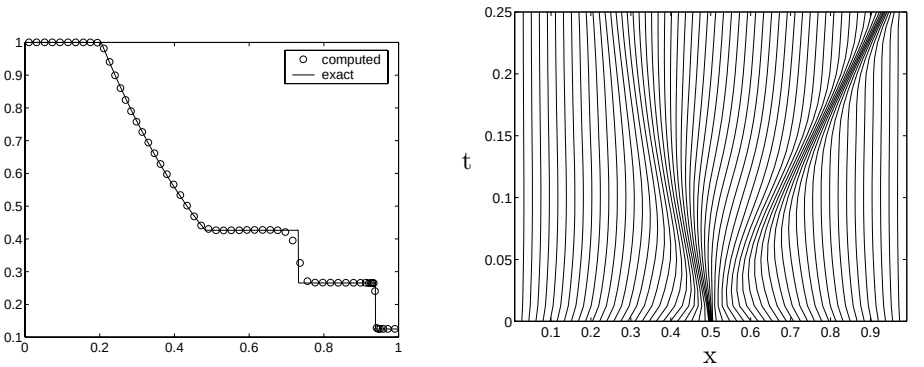

FIG. 4.9. *Moving mesh solution (left: density component; right: mesh contours) for the Euler equations, with monitor function based on the* 2*-norm* (α^{avg}, $\tau = 0.005$, $N = 60$).

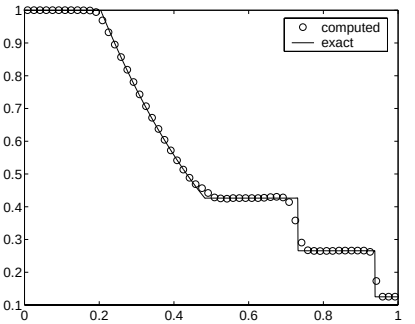

FIG. 4.10. *Fixed mesh solution for the Euler equations with* $N = 60$.

mesh. These qualitative observations are supported by the L^1 error values reported in Table 4.4.

We next demonstrate the effectiveness of the monitor functions tailored specifically to resolving individual elementary waves. The mesh computed with the shock and contact monitor functions, M^s and M^c from (3.4) and (3.5), respectively, are pictured in Figure 4.11. Clearly, both do an excellent job of capturing their corresponding discontinuity, although the errors in Table 4.4 demonstrate the loss in accuracy suffered when only one of the two discontinuous flow features is resolved. Furthermore, the computational time is increased, due primarily to reductions in time step from local CFL violations near the discontinuity that is not being adequately resolved.

The results computed with the monitor function M^{cs} are displayed in Figure 4.12. While the solution is not as sharp at the individual fronts as the solution obtained with each monitor function individually, the averaged monitor function does capture both discontinuities and improves the overall accuracy in the solution relative to the fixed mesh method. The resolution of the contact line is especially good considering the difficulties in resolving this class of wave that are reported for other moving mesh methods (e.g., [12, 22]). It is also important to mention here that we have made no effort to optimize the efficiency of the moving mesh component of the code, and it is certain that considerable gains in CPU time can still be made.

While it is difficult to perform an indepth comparison of accuracy and CPU time

TABLE 4.4
Comparison of various fixed and moving grid solutions for the Euler equations.

Description	*CPU time*	*NT*	L^1 *error*	$\mathcal{R}$
Fixed grid:				
$N = 60$	0.82	56	0.0047	
$N = 120$	2.03	98	0.0026	
$N = 240$	6.60	179	0.0013	
$N = 480$	21.19	339	0.0006	
Moving grid ($N = 60$, $\tau = 0.005$)*:*				
α^{avg} (M based on $\|q_x\|_2^2$)	5.46	152	0.0032	0.0123
Moving grid ($N = 60$, $\tau = 0.005$, α^{max})*:*				
$M = M^c$	5.03	103	0.0041	0.0145
$M = M^s$	4.50	117	0.0043	0.0136
$M = M^{cs}$	3.32	80	0.0026	0.0150

with other moving mesh results reported in the literature, we can still make some general comments. When compared to other methods (e.g., [14, 2, 22]), even those that employ fully implicit time-stepping, our moving mesh scheme requires at most the same number of time steps for a comparable level of accuracy. If we then take into account the added cost of evaluating and inverting the Jacobian matrix in implicit methods, our scheme is much cheaper. Furthermore, in the case of the Euler equations, we observe a significant improvement in the resolution of contact lines.

5. Conclusions. We have developed an adaptive method for solving one-dimensional hyperbolic conservation laws that is accurate and efficient. This is despite the fact that difficulties identified with solving parabolic problems on moving meshes in the literature (namely, mesh racing and ill-conditioning of the solution-mesh iteration) are exacerbated for hyperbolic problems due in large part to the absence of a natural dissipative mechanism in the physical equations.

The method is based on the existing fast, wave propagation algorithms implemented in the software package CLAWPACK. The accuracy of our results derives from our combining the high resolution, Godunov-type scheme for the physical equations with a moving mesh PDE that uses a monitor function specifically designed to capture solution discontinuities. Numerical results demonstrate the efficacy of the method in comparison with fixed mesh computations and other moving mesh results reported in

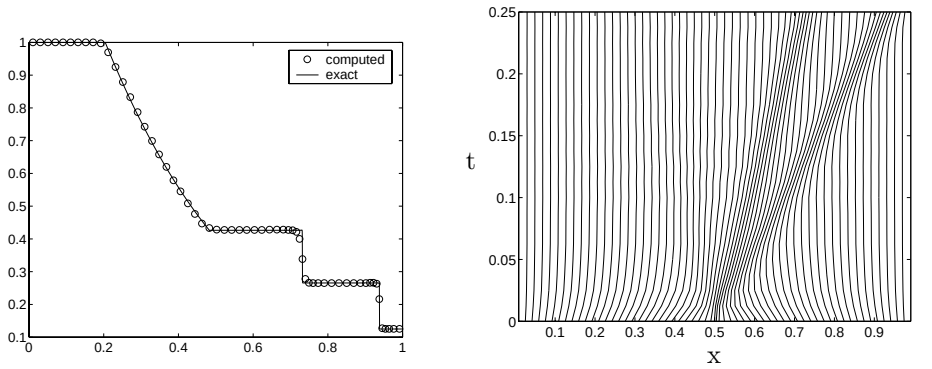

FIG. 4.12. *Moving mesh solution computed with the discontinuity-adaptive monitor function* M^{cs} *(*$\tau = 0.005$*,* $N = 60$*).*

the literature, particularly as regards resolution of contact discontinuities.

The efficiency of our solution algorithm stems primarily from our construction of a semi-implicit iteration for the solution and mesh, which behaves as a two- or three-step predictor-corrector method for the test problems considered here. This should be compared with other moving mesh algorithms, which typically employ a fully implicit time discretization for the coupled solution-mesh system that iterates both solution and mesh to convergence. The rapid convergence of the iteration is aided by a combination of a discontinuity-adaptive monitor function that avoids over-resolving sharp fronts with temporal smoothing that mollifies the effects of mesh racing. The temporal smoothing parameter τ is the only free parameter required in the moving mesh algorithm. However, the level of smoothing required varies between problems, and so this is one area where further work is required. It is likely that performance can be enhanced by allowing τ to depend on the solution throughout a given computation.

We have come to two fundamental conclusions regarding adaptive solution of hyperbolic problems. First, the arclength monitor function, which is the one most commonly used in moving mesh computations, is not appropriate for hyperbolic problems, where high concentrations of mesh points near discontinuous solution features can cause the mesh equations to become ill-conditioned. Second, temporal smoothing is essential for controlling mesh racing, which can otherwise cause serious CFL violations and further degrade the solution-mesh iteration.

We are not advocating r-adaptive methods as a panacea for all hyperbolic problems, particularly because of the proven success of static refinement methods such as adaptive mesh refinement (AMR) [3]. However, we have shown that there is considerable advantage to be gained by some degree of dynamic mesh movement, and so an optimal "overall" solution strategy is likely to derive from a combination of grid movement (r-refinement) and grid subdivision (h-refinement).

The most obvious extension of this work is to higher dimensional problems where multiple shock interactions pose particular challenges for mesh adaptation. The CLAWPACK code has already proven very effective for problems on nonuniform stationary grids in two dimensions, and so our next step will be to generalize the wave propagation scheme to a moving grid. When used in combination with the variational approach for two-dimensional moving meshes developed in Cao, Huang, and Russell [7], our discontinuity-adaptive monitor function should exhibit similar advan-

tages in higher dimensions.

There is also a need for further theoretical work on the behavior of the nonlinear system of equations for the solution and mesh. It is our hope that an analysis for hyperbolic problems (perhaps in the context of the scalar advection equation) will provide insight into the importance of both the monitor function and temporal smoothing, and their relationship to the phenomenon of mesh racing.

LOCKING AND RESTARTING QUADRATIC EIGENVALUE SOLVERS*

KARL MEERBERGEN†

Abstract. This paper studies the solution of quadratic eigenvalue problems by the quadratic residual iteration method. The focus is on applications arising from finite-element simulations in acoustics. One approach is the shift-and-invert Arnoldi method applied to the linearized problem. When more than one eigenvalue is wanted, it is advisable to use locking or deflation of converged eigenvectors (or Schur vectors). In order to avoid unlimited growth of the subspace dimension, one can restart the method by purging unwanted eigenvectors (or Schur vectors). Both locking and restarting use the partial Schur form. The disadvantage of this approach is that the dimension of the linearized problem is twice that of the quadratic problem. The quadratic residual iteration and Jacobi–Davidson methods directly solve the quadratic problem. Unfortunately, the Schur form is not defined, nor are locking and restarting. This paper shows a link between methods for solving quadratic eigenvalue problems and the linearized problem. It aims to combine the benefits of the quadratic and the linearized approaches by employing a locking and restarting scheme based on the Schur form of the linearized problem in quadratic residual iteration and Jacobi–Davidson. Numerical experiments illustrate quadratic residual iteration and Jacobi–Davidson for computing the linear Schur form. It also makes a comparison with the shift-and-invert Arnoldi method.

Key words. quadratic eigenvalue problem, linearization, Schur factorization, Davidson, shift-and-invert Arnoldi, deflation, purging

1. Introduction.

This paper studies the solution of the quadratic eigenvalue problem

$$Ku + i\omega Cu - \omega^2 Mu = 0, \qquad u \neq 0, \tag{1.1}$$

where K, C, and M have dimension $n \times n$ and M is symmetric positive definite. The scalar ω is called an eigenvalue, u is a corresponding eigenvector, and (ω, u) is an eigenpair. This problem arises from the finite-element simulation of damped acoustic problems, where K is the stiffness matrix and is symmetric positive (semi)definite, M is the mass matrix and is symmetric positive definite, and C is the damping matrix and is symmetric and sometimes complex. The condition number of M is usually relatively small, since M is the discretization of the continuous identity operator. Typically, K, C, and M are large (of the order of 10,000 or more unknowns) and sparse. In engineering applications, the eigenvalue ω is complex. The real part is the resonance frequency, while the imaginary part represents the exponential damping of the eigenmode. In applications, all the eigenvalues in a frequency range are wanted; this is a few tens to a few hundreds of eigenpairs.

The problem (1.1) can be "linearized" into

$$\begin{bmatrix} K & 0 \\ 0 & M \end{bmatrix} \begin{pmatrix} u \\ \omega u \end{pmatrix} = \omega \begin{bmatrix} -iC & M \\ M & 0 \end{bmatrix} \begin{pmatrix} u \\ \omega u \end{pmatrix}, \tag{1.2}$$

†Free Field Technologies, 16 place de l'Université, 1348 Louvain-la-Neuve, Belgium (karl.meerbergen@fft.be).

which we also denote as $Ax = \omega Bx$ with

$$A = \begin{bmatrix} K & 0 \\ 0 & M \end{bmatrix} \quad \text{and} \quad B = \begin{bmatrix} -iC & M \\ M & 0 \end{bmatrix}. \tag{1.3}$$

(See [21, Chapter X] and [31] for alternatives.) Note that for acoustic finite-element applications, A is symmetric positive (semi)definite and B is (in general) complex symmetric. Since M is nonsingular, this problem has $2n$ finite eigenvalues. When C is purely imaginary, $Ax = \omega Bx$ is a Hermitian problem, so all eigenvalues are real. In general, C has a real component, and hence complex eigenvalues are present. When C is real, then the spectrum is symmetric with respect to the imaginary axis: indeed, if (ω, u) satisfies (1.1) and C is real, then $(-\bar{\omega}, \bar{u})$ is also an eigenpair. Note that when $C = 0$, the spectral transformation block Lanczos method [7] is a very robust and efficient solver.

In the literature, methods have been proposed for solving (1.1) and (1.2). The linearized problem can be solved by the shift-and-invert Arnoldi method [21, 18]. This method computes the eigenpairs of the shift-and-invert transformation $(A - \sigma B)^{-1}B$, where σ is called the shift. Alternatively, the rational Krylov method [20] or the Jacobi–Davidson method [27] may be used. The advantage of the linearized approach is that existing methods and software can be used. A disadvantage is that the dimension is doubled.

Methods have been developed for directly tackling (1.1). They solve a sequence of linear systems

$$(K + i\sigma C - \sigma^2 M)y = r, \tag{1.4}$$

where σ may change at each iteration. When a direct method is used for solving (1.4), a matrix factorization on each iteration is inevitable. Neumaier [19] and Huitfeldt and Ruhe [9] propose methods that use a fixed σ. This allows the same factorization to be used for several iterations. Another approach is the Jacobi–Davidson method [26, 28, 32] for the quadratic problem. The methods that we study build a subspace. For reasons of computational cost and memory, the subspace dimension is limited. When this limit has been reached without convergence of the sought-after eigenvalues, the method needs to be restarted. The concept of restarting eigenvalue solvers is very well understood for linear problems. See the recent work for the Arnoldi method [29, 11, 16], the Jacobi–Davidson method [5], and the rational Krylov method [20, 3]. When more than one eigenvalue is wanted, it is usually advisable to lock the converged eigenpairs. This is proposed for subspace iteration [30], Arnoldi's method [11], Jacobi–Davidson [5], and rational Krylov [20]. Both restarting and locking use the partial Schur form.

The purpose of this paper is the development of reliable deflation and restarting in methods that solve the quadratic problem (1.1). The problem is that the Schur form is not defined for quadratic problems. We give a definition and show that this Schur form does not always exist. Therefore, we propose using the Schur form of the linearized problem (1.2).

We also want to stress that all theory in this paper can be extended to the m degree polynomial case with $m > 2$. The polynomial problem

$$A_0 u + \lambda A_1 u + \cdots + \lambda^m A_m u = 0$$

can be solved by linearization into

$$\begin{bmatrix} A_0 & & & \\ & I & & \\ & & \ddots & \\ & & & I \end{bmatrix} \begin{pmatrix} u \\ \lambda u \\ \lambda^2 u \\ \vdots \\ \lambda^{m-1} u \end{pmatrix} = \lambda \begin{bmatrix} -A_1 & -A_2 & \cdots & -A_m \\ I & & & \\ & \ddots & & \\ & & I & \end{bmatrix} \begin{pmatrix} u \\ \lambda u \\ \lambda^2 u \\ \vdots \\ \lambda^{m-1} u \end{pmatrix}.$$

The paper is organized as follows. In section 2, we present the quadratic residual iteration method for solving (1.1) and prove a relationship with a modification of the generalized Davidson method for the solution of the linearized problem (1.2). In section 3, we use the theory developed in section 2 to link the Jacobi–Davidson methods for (1.1) and (1.2). In section 4, the notion of partial Schur form is extended to quadratic eigenvalue problems, and the theory of section 2 is used to efficiently compute an approximate partial Schur form of the linearized problem by orthogonal projection of the quadratic problem. In section 5, a deflation or locking technique is proposed for the linearized problem, and in section 6, we discuss restarting the linearized problem by purging Schur vectors. In section 7, we explain which vectors we use to expand the subspace when we want to compute a partial Schur form of the linearized problem. Section 8 presents a practical algorithm that is illustrated by numerical examples including one from applications. In section 9, we compare quadratic residual iteration and Jacobi–Davidson for computing a partial Schur form. In section 10, we compare the shift-and-invert Arnoldi method with quadratic residual iteration and Jacobi–Davidson. Finally, we summarize the main conclusions in section 11. Throughout the paper, $\|\cdot\|$ is used for the 2-norm of matrices and vectors and $\|\cdot\|_F$ for the Frobenius norm.

2. Quadratic residual iteration. In this section, we derive a relationship between methods for solving (1.1) and (1.2). All conclusions assume exact arithmetic. For results on the backward error and condition of the linearized problem we refer to Tisseur [31]. For the linearized problem, we consider the generalized Davidson method [15] (which formally covers the Jacobi–Davidson method [27, 17]) and for the quadratic problem we consider the residual iteration method [19] with subspace projection. We also discuss the Jacobi–Davidson variant for this problem. This section is devoted to the development of a relationship between the two approaches. Therefore, we also define a modified Davidson technique for the linearized problem (1.2) which is shown to produce the same results as the quadratic residual iteration on (1.1).

The generalized Davidson method for the linearized problem is described by the following algorithm [15]. The ω_k's form the sequence of Ritz values, and the σ_k's are chosen shifts.

ALGORITHM 2.1 (generalized Davidson method).

1. *Given* $v_1 \in \mathbf{C}^{2n}$ *with* $\|v_1\| = 1$.
2. *For* $k = 1, 2, \ldots$ *do*
   - 2.1. *Let* $\mathcal{V}_k = [v_1, \ldots, v_k]$.
   - 2.2. *Compute the projection matrices* $A_k = \mathcal{V}_k^* A \mathcal{V}_k$, *and* $B_k = \mathcal{V}_k^* B \mathcal{V}_k$.
   - 2.3. *Compute the eigenpair* (ω_k, z_k) *of interest of* $A_k z = \omega B_k z$.
   - 2.4. *Compute the corresponding Ritz vector* $x_k = \mathcal{V}_k z_k$.
   - 2.5. *Compute the corresponding residual* $r_k = Ax_k - \omega_k B x_k$.
   - 2.6. *Solve the linear system* $(A - \sigma_k B) y_k = r_k$.
   - 2.7. *Orthonormalize* y_k *against* $v_1, \ldots, v_k$ *into* v_{k+1}.

This algorithm consists of a sequence of Cayley transformations

$$y_k = (A - \sigma_k B)^{-1}(A - \omega_k B)x_k \tag{2.1}$$

and a projection step for computing the approximate eigenpair. The Cayley transform aims to improve the approximation of eigenvalues near σ_k. For projection methods, approximate eigenpairs are called Ritz pairs. The approximate eigenvalue is a Ritz value, and the approximate eigenvector a Ritz vector. The small eigenvalue problem in step 2.3 is usually solved by the QZ method [6]. We select the eigenpair of interest, e.g., corresponding to the eigenvalue nearest σ_k. When the linear system in step 2.6 is solved by an iterative method, Algorithm 2.1 is the generalized Davidson method. In Davidson's method, one usually employs $\sigma_k = \omega_k$ and step 2.6 is executed approximately [1], or one can use the Jacobi–Davidson method (see section 3). This choice of σ_k leads to quadratic convergence. The generalized Davidson method does not exploit the special structure of eigenvectors of (1.2). Clearly, it is sufficient to compute the first n components of the eigenvectors and then construct the remaining components. The following algorithm is a modification of the generalized Davidson method that uses the first n components only.

ALGORITHM 2.2 (modified Davidson method).

1. *Given* $v_1 \in \mathbf{C}^n$ *with* $\|v_1\| = 1$.
2. *For* $k = 1, 2, \ldots$ *do*
   - 2.1. *Let* $V_k = [v_1, \ldots, v_k]$ *and* $\mathcal{V}_{2k} = \begin{pmatrix} V_k & 0 \\ 0 & V_k \end{pmatrix}$.
   - 2.2. *Compute the projection matrices* $A_{2k} = \mathcal{V}_{2k}^* A \mathcal{V}_{2k}$, *and* $B_{2k} = \mathcal{V}_{2k}^* B \mathcal{V}_{2k}$.
   - 2.3. *Compute the eigenpair* (ω_k, z_k) *of interest of* $A_{2k}z = \omega B_{2k}z$.
   - 2.4. *Compute the corresponding Ritz vector* $x_k = \mathcal{V}_{2k} z_k$.
   - 2.5. *Compute the corresponding residual* $r_k = Ax_k - \omega_k B x_k$.
   - 2.6. *Solve the linear system* $(A - \sigma_k B)y_k = r_k$.
   - 2.7. *Orthonormalize the first* n *components of* y_k *against* $v_1, \ldots, v_k$ *into* v_{k+1}.

Alternatively, one could select the last n components of y_k in step 2.7. As we shall see, there is no advantage in exact arithmetic. The basis vectors satisfy the projection equation

$$A\mathcal{V}_{2k} - B\mathcal{V}_{2k}H_{2k} = \mathcal{F}_{2k}$$

with projection matrix $H_{2k} = B_{2k}^{-1} A_{2k}$ and with residual term $\mathcal{F}_{2k}$ satisfying $\mathcal{V}_{2k}^* \mathcal{F}_{2k} = 0$. The projection equation is frequently used in section 4.

The quadratic residual iteration is now discussed.

ALGORITHM 2.3 (quadratic residual iteration).

1. *Given* $v_1 \in \mathbf{C}^n$ *with* $\|v_1\| = 1$.
2. *For* $k = 1, 2, \ldots$ *do*
   - 2.1. *Let* $V_k = [v_1, \ldots, v_k]$.
   - 2.2. *Compute the projection matrices* $K_k = V_k^* K V_k$, $C_k = V_k^* C V_k$, *and* $M_k = V_k^* M V_k$.
   - 2.3. *Compute the eigenpair* (ω_k, z_k) *of interest of* $K_k z + i\omega C_k z - \omega^2 M_k z = 0$.
   - 2.4. *Compute the corresponding Ritz vector* $u_k = V_k z_k$.
   - 2.5. *Compute the corresponding residual* $r_k = Ku_k + i\omega_k C u_k - \omega_k^2 M u_k$.
   - 2.6. *Solve the linear system* $(K + i\sigma_k C - \sigma_k^2 M)y_k = r_k$.
   - 2.7. *Orthonormalize* y_k *against* $v_1, \ldots, v_k$ *into* v_{k+1}.

The algorithm is very similar to Algorithms 2.1 and 2.2, but instead of a regular Cayley transform, a quadratic Cayley transform

$$y_k = (K + i\sigma_k C - \sigma_k^2 M)^{-1}(K + i\omega_k C - \omega_k^2 M)u_k \tag{2.2}$$

is employed. The small eigenvalue problem at step 2.3 is solved by a method for solving quadratic eigenvalue problems, e.g., Newton's method, or by solving the corresponding linearized problem.

In the following, we derive a relationship between Algorithms 2.2 and 2.3. The main operations in these algorithms are the Cayley transform and the projection step.

Cayley transformation. On each iteration, the subspace is expanded by the Cayley transformation applied to a Ritz vector. Here we establish a relationship between the Cayley transforms (2.1) and (2.2) applied to a vector with a special structure.

LEMMA 2.1. *Let A and B be defined by* (1.3) *and*

$$\begin{pmatrix} x \\ y \end{pmatrix} = (A - \sigma B)^{-1}(A - \omega B) \begin{pmatrix} u \\ \omega u \end{pmatrix}. \tag{2.3}$$

Then

$$x = (K + i\sigma C - \sigma^2 M)^{-1}(K + i\omega C - \omega^2 M)u \qquad \text{and} \qquad y = \sigma x. \tag{2.4}$$

Proof. Write (2.3) as

$$\begin{aligned} \begin{bmatrix} K + i\sigma C & -\sigma M \\ -\sigma M & M \end{bmatrix} \begin{pmatrix} x \\ y \end{pmatrix} &= \begin{bmatrix} K + i\omega C & -\omega M \\ -\omega M & M \end{bmatrix} \begin{pmatrix} u \\ \omega u \end{pmatrix} \\ &= \begin{pmatrix} (K + i\omega C - \omega^2 M)u \\ 0 \end{pmatrix}. \end{aligned}$$

The last row readily produces $y = \sigma x$. Substituting this in the first row leads to the first statement in (2.4). This proves the lemma. ∎

Projection. The projection used in Algorithm 2.2 produces the same Ritz pairs as the projection in Algorithm 2.3 if the V_k's are the same.

LEMMA 2.2. *If the projection of* (1.1) *on* Range(V) *produces the Ritz pair* (ω, u), *then the projection of* (1.2) *on*

$$\mathcal{V} = \text{Range}\left(\begin{pmatrix} V & 0 \\ 0 & V \end{pmatrix}\right)$$

produces the Ritz pair

$$\left(\omega, \begin{pmatrix} u \\ \omega u \end{pmatrix}\right). \tag{2.5}$$

Proof. The projection of (1.2) on $\mathcal{V}$ is

$$\begin{aligned} &\begin{pmatrix} V & 0 \\ 0 & V \end{pmatrix}^* \begin{bmatrix} K & 0 \\ 0 & M \end{bmatrix} \begin{pmatrix} V & 0 \\ 0 & V \end{pmatrix} \begin{pmatrix} z \\ t \end{pmatrix} \\ &= \omega \begin{pmatrix} V & 0 \\ 0 & V \end{pmatrix}^* \begin{bmatrix} -iC & M \\ M & 0 \end{bmatrix} \begin{pmatrix} V & 0 \\ 0 & V \end{pmatrix} \begin{pmatrix} z \\ t \end{pmatrix}. \end{aligned}$$

This leads to $V^*KVz = \omega(-iV^*CVz + V^*MVt)$ and $t = \omega z$. This implies that $V^*(K + i\omega C - \omega^2 M)Vz = 0$, which is the projection of (1.1) on Range(V). This completes the proof. ∎

The theory can now be used for establishing the following relationship.

THEOREM 2.3. *Suppose that v_1 is the same for Algorithms* 2.2 *and* 2.3. *When $k \leq n$, both algorithms produce the same Ritz pairs.*

Proof. The proof is given by induction. Suppose that we use an initial vector v_1 for Algorithms 2.2 and 2.3. Suppose that the theorem is true at the end of iteration $k-1$, i.e., V_k is the same for both algorithms. Following Lemma 2.2, Algorithm 2.3 produces (ω, u), and Algorithm 2.2 produces $(\omega, \begin{pmatrix} u \\ \omega u \end{pmatrix})$. Finally, following Lemma 2.1, x_k is the same for both algorithms, so both produce the same v_{k+1}. This implies that V_{k+1} is equal in both algorithms, from which the proof follows. ∎

An important question is how much better is the subspace generated by Algorithm 2.2 than Algorithm 2.1. Let $\begin{pmatrix} u \\ \omega u \end{pmatrix}$ be a Ritz vector, and let $\begin{pmatrix} y \\ \sigma y \end{pmatrix}$ be the result of the Cayley transformation. In Algorithm 2.2, we add both $\begin{pmatrix} y \\ 0 \end{pmatrix}$ and $\begin{pmatrix} 0 \\ y \end{pmatrix}$ to the subspace. When $\sigma \neq 0$, this is mathematically equivalent to adding $\begin{pmatrix} y \\ \sigma y \end{pmatrix}$ and $\begin{pmatrix} y \\ -\sigma y \end{pmatrix}$, since both vector pairs have the same span. The first vector is the result of the Cayley transform

$$\begin{pmatrix} y \\ \sigma y \end{pmatrix} = (A - \sigma B)^{-1}(A - \omega B) \begin{pmatrix} u \\ \omega u \end{pmatrix}.$$

The first vector tries to improve the eigenvector components corresponding to the eigenvalues near σ. When $C = 0$, then the second vector is

$$\begin{pmatrix} y \\ -\sigma y \end{pmatrix} = (A + \sigma B)^{-1}(A + \omega B) \begin{pmatrix} u \\ -\omega u \end{pmatrix},$$

i.e., tries to improve the eigenvectors corresponding to eigenvalues nearest $-\sigma$. In general, however, $\begin{pmatrix} y \\ -\sigma y \end{pmatrix}$ does not have a particular meaning. When $\|C\|$ is small, this vector may help finding eigenvalues near $-\sigma$.

Stopping criterion. Usually, iterative eigenvalue solvers use a stopping criterion based on the residual. If $Ax - \lambda Bx = r$, then (λ, x) is an exact eigenpair of the perturbed problem $(A + E)x = \lambda Bx$ with $Ex = -r$. So $\|r\|/\|x\|$ is a measure of the backward error. A relationship between the residual and the forward error on the eigenvalues is given by the Bauer–Fike theorem [21, Theorem 3.6].

THEOREM 2.4 (Bauer–Fike). *Consider an $n \times n$ matrix G that has n independent eigenvectors. Let λ be an eigenvalue of G, and let (μ, x) be an approximate eigenpair with residual $r = Gx - \mu x$ and $\|x\| \neq 0$. Then*

$$|\lambda - \mu| \leq \kappa \|r\|/\|x\|,$$

where κ is the condition number of the matrix of eigenvectors.

The residual for the linearized problem with Ritz pair (2.5) becomes

$$r_L = A \begin{pmatrix} u \\ \omega u \end{pmatrix} - \omega B \begin{pmatrix} u \\ \omega u \end{pmatrix} = \begin{pmatrix} r_P \\ 0 \end{pmatrix}$$

with $r_P = Ku + i\omega Cu - \omega^2 Mu$. The first component of r_L is the quadratic residual, so the 2-norm of both residuals is equal. So, for quadratic problems, the residual can also be regarded as a backward error. Note, however, that the Ritz vectors, u and $\begin{pmatrix} u \\ \omega u \end{pmatrix}$, have a different norm. In order to use the Bauer–Fike theorem, consider the residual $B^{-1}Ax - \omega x$, which becomes

$$\begin{aligned} B^{-1}A \begin{pmatrix} u \\ \omega u \end{pmatrix} - \omega \begin{pmatrix} u \\ \omega u \end{pmatrix} &= \begin{bmatrix} -iC & M \\ M & 0 \end{bmatrix}^{-1} \begin{pmatrix} Ku + i\omega Cu - \omega^2 Mu \\ 0 \end{pmatrix} \\ &= \begin{pmatrix} 0 \\ M^{-1}Ku + i\omega M^{-1}Cu - \omega^2 u \end{pmatrix}. \end{aligned}$$

So the error between the exact eigenvalue λ and an approximation ω can be bounded by

$$|\omega - \lambda| \leq \kappa \|M^{-1}\| \frac{\|Ku + i\omega Cu - \omega^2 Mu\|}{\|u\|\sqrt{1+|\omega|^2}},$$

where κ is the condition number of the matrix of eigenvectors of $B^{-1}A$, and the denominator is the norm of the Ritz vector.

Accuracy of the Cayley transform. A comment is in order on the solution of the linear system

$$(K + i\sigma C - \sigma^2 M)y = (K + i\omega C - \omega^2 M)u \equiv r_P.$$

When we use a linear system solver, we have a residual s so that

$$(K + i\sigma C - \sigma^2 M)y = (K + i\omega C - \omega^2 M)x - s.$$

When a direct method is used, $\|s\|$ is usually of the order of machine precision times $\|r_P\|$ and the quadratic Cayley transform can be considered as exact. When an iterative solver is used, $\|s_k\| \leq \tau \|r_P\|$ with τ as the relative residual tolerance. The smaller τ is, the more expensive the iterative solver is. We therefore want to choose the tolerance not too small. There is a relationship with the linear problem, since

$$\begin{bmatrix} K + i\sigma C & -\sigma M \\ -\sigma M & M \end{bmatrix} \begin{pmatrix} y \\ \sigma y \end{pmatrix} = \begin{bmatrix} K + i\omega C & -\omega M \\ -\omega M & M \end{bmatrix} \begin{pmatrix} u \\ \omega u \end{pmatrix} - \begin{pmatrix} s \\ 0 \end{pmatrix}.$$

When iterative solvers are used for computing the linear Cayley transform in eigenvalue solvers, we talk about the inexact Cayley transform [14, 13, 10, 17]. Two elements play a role in the convergence of an inexact Cayley transform iteration method. The first one is the convergence for an exact Cayley transformation, and the second one is the accuracy of the linear system solver, τ. When τ is not too large, the convergence is as fast as for $\tau = 0$. We give an example in section 8.3.

Cayley transform and shift-and-invert. A problem arises when $\sigma = \omega$ in the Cayley transformation. Since $y = (A - \omega B)^{-1}(A - \omega B)x = x$, no new direction is added to the subspace. When the Cayley transform is computed exactly, e.g., with a direct linear solver (in practice, we have a small backward error on the solution of the linear system), then

$$y \equiv (A - \sigma B)^{-1}(A - \omega B)x = x + (\sigma - \omega)(A - \sigma B)^{-1}Bx. \tag{2.6}$$

The matrix $(A - \sigma B)^{-1}B$ is called the shift-and-invert transformation [21] or the spectral transformation [4]. The use of the Cayley transform or the spectral transformation in a projection method is equivalent since both add the same direction orthogonal to x to the subspace. The advantage of the shift-and-invert transform is that the transformation still works when $\sigma = \omega$. When an iterative solver is used, it is usually advantageous to use the Cayley transform instead of shift-and-invert [10, 17].

For the quadratic eigenvalue problem, the shift-and-invert transformation is defined as follows. The Cayley transform can be rewritten as

$$\begin{aligned} y &\equiv (K + i\sigma C - \sigma^2 M)^{-1}(K + i\omega C - \omega^2 M)u \\ &= u + (\omega - \sigma)(K + i\sigma C - \sigma^2 M)^{-1}(iC - (\omega + \sigma)M)u. \end{aligned}$$

The shift-and-invert transformation is defined as

$$(K + i\sigma C - \sigma^2 M)^{-1}(iC - (\omega + \sigma)M) \tag{2.7}$$

and can also be used when $\sigma = \omega$.

3. The Jacobi–Davidson method. The Jacobi–Davidson method is an alternative to the shift-and-invert transformation when an iterative linear solver is used and $\sigma = \omega$.

The combination of the Newton method applied to the set of nonlinear equations

$$\begin{aligned} Ax - \omega Bx &= 0, \\ x^*x &= 1 \end{aligned}$$

in ω and x and the generalized Davidson method (Algorithm 2.1) is called the Jacobi–Davidson method [27, 26]. It adds the x component of the solution of the Newton iteration to a subspace and computes Ritz pairs by projection. The algorithm for the linear problem (1.2) is the same as Algorithm 2.1 except for the transformation in step 2.6. Instead, a "correction equation" is solved. Let (ω, x) be a Ritz pair; then the subspace is expanded with y satisfying

$$\left(I - \frac{Bxx^*}{x^*Bx}\right)(A - \omega B)\left(I - \frac{xx^*}{x^*x}\right)y = (A - \omega B)x. \tag{3.1}$$

The solution y is computed by an iterative method with a suitable preconditioner if available. For the quadratic problem (1.1), the Jacobi–Davidson method is Algorithm 2.3 where step 2.6 is replaced by

$$\begin{aligned} &\left(I - \frac{(-iC + 2\omega M)uu^*}{u^*(-iC + 2\omega M)u}\right)(K + i\omega C - \omega^2 M)\left(I - \frac{uu^*}{u^*u}\right)v \\ &\qquad = (K + i\omega C - \omega^2 M)u, \end{aligned} \tag{3.2}$$

where (ω, u) is a Ritz pair [26, 32]. This can be derived from one Newton iteration on (1.1) and $u^*u = 1$.

The Jacobi–Davidson method is strongly related to the Davidson method. When we require that $y \perp x$, we can rewrite (3.1) as

$$\begin{aligned} (A - \omega B)y - \epsilon Bx &= (A - \omega B)x \\ \text{or} \quad y &= x + \epsilon(A - \omega B)^{-1}Bx, \end{aligned} \tag{3.3}$$

where ϵ is so that $y \perp x$ [27]. Note the resemblance with (2.6). When y is added to the subspace, the new direction v_{k+1} is independent of ϵ, since x is in the subspace. We can write y also as

$$y = (A - \omega B)^{-1}(A - (\omega - \epsilon)B)x.$$

We immediately see the connection with the generalized Davidson method, where the pole (σ) is now ω and the zero (ω) is now $\omega + \epsilon$. It is shown in [17] that $\omega + \epsilon$ is the harmonic Ritz value with target ω. The value ϵ converges to zero when ω converges to an eigenvalue [27].

Similarly, with $v \perp u$, (3.2) can be rewritten as

$$\begin{aligned} (K + i\omega C - \omega^2 M)v - \eta(-iC + 2\omega M)u &= (K + i\omega C - \omega^2 M)u, \\ v &= u + \eta(K + i\omega C - \omega^2 M)^{-1}(-iC + 2\omega M)u, \end{aligned} \tag{3.4}$$

where η is so that $v \perp u$. Note the resemblence with (2.7) for $\sigma = \omega$.

In section 2, we showed the equivalence of the modified Davidson method in Algorithm 2.2 and quadratic residual iteration in Algorithm 2.3. The following lemma

shows that, when step 2.6 is replaced by the solution of the Newton correction equations (3.1) and (3.2), respectively, the subspace V is expanded in the same way for both Algorithms 2.2 and 2.3.

LEMMA 3.1. *Let (ω, u) be a Ritz pair for* (1.1), *and assume $\epsilon \neq 0$. Let $x = \begin{pmatrix} u \\ \omega u \end{pmatrix}$, and let $y = \begin{pmatrix} y_1 \\ y_2 \end{pmatrix}$ be the solution of* (3.1). *Then $(\eta/\epsilon)y_1$ is a solution of* (3.2).

Proof. Assume that $y \perp x$ and rewrite (3.3) as

$$\begin{bmatrix} K + i\omega C & -\omega M \\ -\omega M & M \end{bmatrix} \begin{pmatrix} y_1 \\ y_2 \end{pmatrix} - \epsilon \begin{bmatrix} -iC & M \\ M & 0 \end{bmatrix} \begin{pmatrix} u \\ \omega u \end{pmatrix} = \begin{bmatrix} K + i\omega C & -\omega M \\ -\omega M & M \end{bmatrix} \begin{pmatrix} u \\ \omega u \end{pmatrix}$$

or

$$\begin{aligned} (K + i\omega C)y_1 - \omega M y_2 - \epsilon(-iC + \omega M)u &= Ku + i\omega Cu - \omega^2 Mu, \\ -\omega M y_1 + M y_2 - \epsilon M u &= 0, \end{aligned}$$

from which $y_2 = \omega y_1 + \epsilon u$. This gives

$$(K + i\omega C - \omega^2 M)y_1 - \epsilon(-iC + 2\omega M)u = Ku + i\omega Cu - \omega^2 Mu,$$

which looks like (3.4). The only difference is that $\eta \neq \epsilon$. Since $(\eta/\epsilon)y_1$ and v in (3.4) have the same component orthogonal to u, $(\eta/\epsilon)y_1$ satisfies (3.2). This gives the proof of the lemma. ∎

Finally, it is important to note that the projections used in (3.1) and (3.2) can also be used for $\sigma \neq \omega$. An example is given in [12, section 3.3.6]. However, when the linear systems are solved exactly (e.g., using a direct linear solver), there is no advantage in doing this. The search space V_k will be expanded with the same direction. This is discussed in more detail in [10, (6.3) and (6.4)] and [17]. When an iterative solver is used, the projections may help speed up the convergence of the iterative solvers, since the projection may remove a small eigenvalue of the matrix in the linear system. An example is given in section 9.

4. The Schur factorization. Methods for solving linear eigenvalue problems use the Schur factorization when more than one eigenvalue needs to be computed. The reasons are that a set of $2n$ independent Schur vectors always exists in contrast with the eigenvectors, Schur bases are orthogonal, and they can easily be used for locking and restarting purposes as we will discuss in the coming sections. This section is devoted to the Schur factorization for the linear problem and the quadratic problem. We show some properties of the Schur factorization of the linear problem and define one for the quadratic problem. We also show that the quadratic Schur form may not exist. Therefore, we suggest the use of the Schur form of the linearized problem.

4.1. Linear problems. When B is invertible, the Schur form or Schur factorization of $Ax = \lambda Bx$ is defined by

$$B^{-1}AX = XS \qquad \Leftrightarrow \qquad AX = BXS, \tag{4.1}$$

where X is an $n \times n$ unitary matrix and S is an $n \times n$ upper triangular matrix with the eigenvalues on the main diagonal. The columns of X are the Schur vectors, and S is the Schur matrix. The Schur form (4.1) can be computed by the QR method

applied to $B^{-1}A$ or the QZ method applied to the pair (A, B) [6]. Using the QR method assumes a nonsingular B and the formation of $B^{-1}A$. One could avoid this computation by using the generalized Schur form computed by the QZ method. This complicates the notation, but the concept is very similar. In this paper, we use the Schur form from (4.1) computed by the QR method.

A partial Schur form of order p with $1 \leq p \leq n$ is defined by

$$AX_p = BX_pS_p,$$

where $X_p \in \mathbf{C}^{n\times p}$ has orthonormal columns and $S_p \in \mathbf{C}^{p\times p}$ is upper triangular with eigenvalues of $Ax = \lambda Bx$ on the main diagonal.

When A and B are large and sparse, the QR method is not suitable for computing a partial Schur form. One usually employs a projection method, i.e., approximate Schur vectors $\mathcal{U}_k$ are computed in the subspace spanned by the (orthonormal) columns of the matrix $\mathcal{V}_k$ so that

$$A\mathcal{U}_k - B\mathcal{U}_kS_k = \mathcal{F}_k, \tag{4.2}$$

where $\mathcal{U}_k = \mathcal{V}_kX_k$ and $\mathcal{F}_k$ is a residual term. Using the concept of orthogonal projection, i.e., we force $\mathcal{V}_k^*\mathcal{F}_k = 0$, we find that X_k and S_k satisfy the $k \times k$ Schur problem

$$A_kX_k - B_kX_kS_k = 0 \quad \text{with} \quad A_k = \mathcal{V}_k^*A\mathcal{V}_k \ \text{ and } \ B_k = \mathcal{V}_k^*B\mathcal{V}_k, \tag{4.3}$$

which can easily be solved by the QR method on $H_k = B_k^{-1}A_k$. We call (4.2) the *approximate partial Schur form.*

We can describe an orthogonal projection method in terms of $\mathcal{U}_k$ instead of $\mathcal{V}_k$ since both form an orthonormal basis for the same subspace. The use of the Schur basis instead of $\mathcal{V}_k$ makes it easier to lock and restart as we shall see later. After the kth iteration we thus have (4.2) with $\mathcal{U}_k^*\mathcal{F}_k = 0$. In the $k+1$st iteration, a new vector v_{k+1} is added and a new projection matrix H_{k+1} is computed so that

$$A\begin{pmatrix} \mathcal{U}_k & v_{k+1} \end{pmatrix} - B\begin{pmatrix} \mathcal{U}_k & v_{k+1} \end{pmatrix} H_{k+1} = \mathcal{F}_{k+1}$$

with $(\mathcal{U}_k \quad v_{k+1})^*\mathcal{F}_{k+1} = 0$. Note that the basis $(\mathcal{U}_k \quad v_{k+1})$ has the Schur vectors in the front, which is useful for locking as we shall discuss in section 5. In practice, we never compute $\mathcal{U}_k$ at each iteration. Instead, we store $\mathcal{V}_k$ and X_k. Only X_k needs to be computed, which is much cheaper.

4.2. Quadratic problems. The existence of a partial Schur form is guaranteed for the linearized problem (1.2):

$$\begin{bmatrix} K & 0 \\ 0 & M \end{bmatrix} \begin{pmatrix} U_{2k} \\ Y_{2k} \end{pmatrix} = \begin{bmatrix} -iC & M \\ M & 0 \end{bmatrix} \begin{pmatrix} U_{2k} \\ Y_{2k} \end{pmatrix} S_{2k}, \tag{4.4}$$

with U_{2k}, $Y_{2k} \in \mathbf{C}^{n\times 2k}$, and S_{2k} a $2k \times 2k$ upper triangular matrix. Note that U_{2k} does not need to be of full rank. For example, when $C = 0$ and (ω, u) is an eigenpair, $(-\omega, u)$ is also one. The corresponding U matrix is $U_2 = (\alpha u \quad \beta u)$ for some constants α and β which has rank smaller than two.

We define the partial quadratic Schur form as

$$KW_{2k} + iCW_{2k}T_{2k} - MW_{2k}T_{2k}^2 = 0, \tag{4.5}$$

where $W_{2k} \in \mathbf{C}^{n\times 2k}$ has orthonormal columns and $T_{2k} \in \mathbf{C}^{2k\times 2k}$ is upper triangular with the eigenvalues on its main diagonal. The following lemma shows a condition for which a partial quadratic Schur form exists.

LEMMA 4.1. *If U_{2k} from* (4.4) *has full rank, then a partial Schur form* (4.5) *of* (1.1) *exists.*

Proof. From (4.4), it follows that $Y_{2k} = U_{2k}S_{2k}$ and

$$KU_{2k} + iCU_{2k}S_{2k} - MU_{2k}S_{2k}^2 = 0. \tag{4.6}$$

Consider the QR factorization $W_{2k}Z_{2k} = U_{2k}$, where $W_{2k} \in \mathbf{C}^{n\times 2k}$ has orthonormal columns and $Z_{2k} \in \mathbf{C}^{2k\times 2k}$ is upper triangular. Define the upper triangular matrix $T_{2k} = Z_{2k}S_{2k}Z_{2k}^{-1}$. Then (4.5) is satisfied. ∎

We propose computing (4.4) instead of (4.5), since this Schur form is guaranteed to exist. Due to the relationship between the quadratic problem and its linearization and the corresponding solvers, we can use quadratic residual iteration for building the subspace and computing Ritz pairs.

On the kth iteration, we project the linearized problem (1.2) on the subspace with basis

$$\mathcal{V}_{2k} = \begin{bmatrix} V_k & 0 \\ 0 & V_k \end{bmatrix} \tag{4.7}$$

for computing the Schur basis, where the Schur vectors have the form

$$\mathcal{U}_{2k} = \begin{pmatrix} U_{2k} \\ Y_{2k} \end{pmatrix} = \begin{bmatrix} V_k & 0 \\ 0 & V_k \end{bmatrix} \begin{pmatrix} X_1 \\ X_2 \end{pmatrix}. \tag{4.8}$$

With $K_k = V_k^*KV_k$, $C_k = V_k^*CV_k$, and $M_k = V_k^*MV_k$, this projection gives

$$\begin{bmatrix} K_k & \\ & M_k \end{bmatrix} \begin{pmatrix} X_1 \\ X_2 \end{pmatrix} = \begin{bmatrix} -iC_k & M_k \\ M_k & \end{bmatrix} \begin{pmatrix} X_1 \\ X_2 \end{pmatrix} S_{2k}, \tag{4.9}$$

from which $X_2 = X_1S_{2k}$. Hence, the approximate partial Schur form is

$$\begin{bmatrix} K & \\ & M \end{bmatrix} \begin{pmatrix} U_{2k} \\ U_{2k}S_{2k} \end{pmatrix} - \begin{bmatrix} -iC & M \\ M & \end{bmatrix} \begin{pmatrix} U_{2k} \\ U_{2k}S_{2k} \end{pmatrix} S_{2k} = \begin{pmatrix} F_{2k} \\ 0 \end{pmatrix}$$

and

$$KU_{2k} + iCU_{2k}S_{2k} - MU_{2k}S_{2k}^2 = F_{2k}. \tag{4.10}$$

Note that (even with $F_{2k} = 0$) (4.10) is not a partial quadratic Schur factorization since U_{2k} does not have orthogonal columns and is not guaranteed to have full rank.

As mentioned before, we can use the Schur basis $\mathcal{U}_{2k}$ instead of $\mathcal{V}_{2k}$. Instead of adding one vector at the $k+1$st iteration, we now add two vectors to the basis, so the basis at iteration $k+1$ becomes

$$\begin{pmatrix} \mathcal{U}_{2k} & \begin{pmatrix} v_{k+1} & 0 \\ 0 & v_{k+1} \end{pmatrix} \end{pmatrix}.$$

Using (4.8), we can rewrite this as

$$\begin{bmatrix} V_k & v_{k+1} & 0 & 0 \\ 0 & 0 & V_k & v_{k+1} \end{bmatrix} \begin{pmatrix} X_1 & 0 & 0 \\ 0 & 1 & 0 \\ X_2 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix}.$$

It is thus sufficient to store V_k, v_{k+1} and X_1, X_2 to represent the basis.

For the computation of the Schur form of the linearized problem, we need $H_{2k} = B_{2k}^{-1} A_{2k}$. This is cheaply computed and in a numerically stable way: let

$$B_{2k} = \begin{bmatrix} -iC_k & M_k \\ M_k & 0 \end{bmatrix} \quad \text{and} \quad A_{2k} = \begin{bmatrix} K_k & \\ & M_k \end{bmatrix}.$$

Then $H_{2k} = B_{2k}^{-1} A_{2k}$ can be computed as follows.

ALGORITHM 4.1 (computation of $H_{2k} = B_{2k}^{-1} A_{2k}$). *Compute* $H_{2k} = \begin{bmatrix} 0 & I \\ M_k^{-1} K_k & iM_k^{-1} C_k \end{bmatrix}$, *where the action of* M_k^{-1} *is performed using the Cholesky factorization* $M_k = L_k L_k^*$ *with* L_k *lower triangular. The matrix* $M_k = V_k^* M V_k$ *is well conditioned since* M *is positive definite and has a small condition number.*

5. Locking. Locking of converged eigenvalues is widely used in linear eigenvalue calculations [30, 11, 20, 5]. We first explain the idea of locking for linear problems and then apply this to the quadratic problem (1.2).

5.1. Linear problems. The idea of locking is as follows. Suppose that, at the kth iteration, the Schur factorization is reordered so that we have the decomposition

$$A \begin{pmatrix} \mathcal{U}_q & \mathcal{U}_{k-q} \end{pmatrix} - B \begin{pmatrix} \mathcal{U}_q & \mathcal{U}_{k-q} \end{pmatrix} \begin{bmatrix} S_q & S_{q,k-q} \\ 0 & S_{k-q} \end{bmatrix} = \begin{pmatrix} \mathcal{F}_q & \mathcal{F}_{k-q} \end{pmatrix}, \tag{5.1}$$

with $\|\mathcal{F}_q\|$ smaller than the convergence tolerance. We consider the first q Ritz values and corresponding Schur vectors as converged. In fact, we assume that $\mathcal{F}_q = 0$. The first q Schur vectors $\mathcal{U}_q$ and the Schur matrix S_q are fixed or "locked" in the subsequent iterations, i.e., when new directions are added to the subspace and the Schur vectors are recomputed, the locked vectors are not changed. On the $k+1$st iteration, after the addition of v_{k+1}, we have a new basis $(\mathcal{U}_q \quad \mathcal{V}_{k-q+1}) = (\mathcal{U}_q \quad \mathcal{U}_{k-q} \quad v_{k+1})$, and, after projection, we have the projection equation

$$A \begin{pmatrix} \mathcal{U}_q & \mathcal{V}_{k-q+1} \end{pmatrix} - B \begin{pmatrix} \mathcal{U}_q & \mathcal{V}_{k-q+1} \end{pmatrix} \begin{bmatrix} H_q & H_{q,k-q+1} \\ H_{k-q+1,q} & H_{k-q+1} \end{bmatrix} = \begin{pmatrix} \mathcal{G}_q & \mathcal{G}_{k-q+1} \end{pmatrix} \tag{5.2}$$

with $(\mathcal{U}_q \quad \mathcal{V}_{k-q+1})^* (\mathcal{G}_q \quad \mathcal{G}_{k-q+1}) = 0$, and with the projection matrix

$$\begin{bmatrix} H_q & H_{q,k-q+1} \\ H_{k-q+1,q} & H_{k-q+1} \end{bmatrix} = B_k^{-1} A_k \quad \text{and} \tag{5.3a}$$

$$A_k = \begin{pmatrix} \mathcal{U}_q & \mathcal{V}_{k-q+1} \end{pmatrix}^* A \begin{pmatrix} \mathcal{U}_q & \mathcal{V}_{k-q+1} \end{pmatrix}, \tag{5.3b}$$

$$B_k = \begin{pmatrix} \mathcal{U}_q & \mathcal{V}_{k-q+1} \end{pmatrix}^* B \begin{pmatrix} \mathcal{U}_q & \mathcal{V}_{k-q+1} \end{pmatrix}. \tag{5.3c}$$

Since $\|F_q\|$ is small, we can replace the projection matrix by

$$\begin{bmatrix} S_q & H_{q,k-q+1} \\ & H_{k-q+1} \end{bmatrix}$$

without making a big error. This is deflation or locking. The error made is given by the following theorem.

THEOREM 5.1. *Let*

$$\mathcal{U}_q^* A \mathcal{U}_q - \mathcal{U}_q^* B \mathcal{U}_q S_q = 0, \tag{5.4}$$

$$A\mathcal{U}_q - B\mathcal{U}_q S_q = \mathcal{F}_q, \tag{5.5}$$

and let $(\mathcal{U}_q \quad \mathcal{V}_{k-q+1})$ *have orthonormal columns. Then, with the definition of* (5.3),

$$\left\| \begin{bmatrix} H_q & H_{q,k-q+1} \\ H_{k-q+1,q} & H_{k-q+1} \end{bmatrix} - \begin{bmatrix} S_q & H_{q,k-q+1} \\ 0 & H_{k-q+1} \end{bmatrix} \right\|_F \leq \|B_k^{-1}\| \|\mathcal{V}_{k-q+1}^* \mathcal{F}_q\|_F.$$

Proof. We drop the subscripts for $\mathcal{U}_q$ and $\mathcal{V}_{k-q+1}$. From (5.3), it follows that

$$\begin{aligned} \mathcal{U}^* A\mathcal{U} - \mathcal{U}^* B\mathcal{U} H_q - \mathcal{U}^* B\mathcal{V} H_{k-q+1,q} &= 0, \\ \mathcal{V}^* A\mathcal{U} - \mathcal{V}^* B\mathcal{U} H_q - \mathcal{V}^* B\mathcal{V} H_{k-q+1,q} &= 0. \end{aligned}$$

From (5.4) and (5.5), we have that

$$\begin{aligned} \mathcal{U}^* B\mathcal{U}(S_q - H_q) - \mathcal{U}^* B\mathcal{V} H_{k-q+1,q} &= 0, \\ \mathcal{V}^* B\mathcal{U}(S_q - H_q) - \mathcal{V}^* B\mathcal{V} H_{k-q+1,q} &= -\mathcal{V}^* \mathcal{F}_q. \end{aligned}$$

This gives the linear system

$$\left(\begin{pmatrix} \mathcal{U} & \mathcal{V} \end{pmatrix}^* B \begin{pmatrix} \mathcal{U} & \mathcal{V} \end{pmatrix} \right) \begin{pmatrix} S_q - H_q \\ H_{k-q+1,q} \end{pmatrix} = \begin{pmatrix} 0 \\ -\mathcal{V}^* \mathcal{F}_q \end{pmatrix},$$

which implies that

$$\|S_q - H_q\|_F^2 + \|H_{k-q+1,q}\|_F^2 \leq \left\| \left(\begin{pmatrix} \mathcal{U} & \mathcal{V} \end{pmatrix}^* B \begin{pmatrix} \mathcal{U} & \mathcal{V} \end{pmatrix} \right)^{-1} \right\|_2^2 \|\mathcal{V}^* \mathcal{F}_q\|_F^2.$$

This completes the proof. ∎

The projection equation can now be decomposed as

$$\begin{aligned} A \begin{pmatrix} \mathcal{U}_q & \mathcal{V}_{k-q} \end{pmatrix} - B \begin{pmatrix} \mathcal{U}_q & \mathcal{V}_{k-q+1} \end{pmatrix} \begin{bmatrix} S_q & H_{q,k-q+1} \\ 0 & H_{k-q+1} \end{bmatrix} \\ = \begin{pmatrix} \mathcal{F}_q & \mathcal{F}_{k-q+1} \end{pmatrix}. \end{aligned} \tag{5.6}$$

The new Schur vectors must have the form

$$\begin{pmatrix} \mathcal{U}_q & \mathcal{V}_{k-q+1} \end{pmatrix} \begin{bmatrix} I & 0 \\ 0 & Z_{k-q+1} \end{bmatrix}.$$

By multiplying (5.6) on the right by $\left(\begin{smallmatrix} I & 0 \\ 0 & Z_{k-q+1} \end{smallmatrix}\right)$, it follows that with $\mathcal{U}_{k-q+1} = \mathcal{V}_{k-q+1} Z_{k-q+1}$

$$\begin{aligned} A \begin{pmatrix} \mathcal{U}_q & \mathcal{U}_{k-q+1} \end{pmatrix} - B \begin{pmatrix} \mathcal{U}_q & \mathcal{U}_{k-q+1} \end{pmatrix} \begin{bmatrix} S_q & H_{q,k-q+1} Z_{k-q+1} \\ & S_{k-q+1} \end{bmatrix} \\ = \begin{pmatrix} \mathcal{F}_q & \mathcal{F}_{k-q+1} Z_{k-q+1} \end{pmatrix}, \end{aligned}$$

where $H_{k-q+1} Z_{k-q+1} = Z_{k-q+1} S_{k-q+1}$ is the Schur form of H_{k-q+1}. This allows us to compute Z_{k-q+1} and S_{k-q+1}.

5.2. Quadratic problems. Locking in quadratic residual iteration can be performed via the linearized problem. The mathematics in the last section remains, but two vectors instead of only one are added at each iteration. It is also important to note that it is not necessary to store $\mathcal{U}_{2k}$, but only V_k, X_{2k}, and S_{2k}. Locking then corresponds to locking the first q columns of X_{2k} and S_{2k}.

6. Restarting. The number of basis vectors, k, grows as the algorithms proceed. In practice, this number is limited by storage and computational costs for the Gram–Schmidt orthogonalization. It is possible that convergence to the desired eigenpairs has not occurred when this limit is reached. One way to solve this problem is to reduce the dimension of the subspace by throwing away the uninteresting part. This is called purging.

6.1. Linear problems. We can keep the locked Schur vectors as well as the Schur vectors of interest in the subspace and throw away those we are not interested in. This idea was used for restarting the block Arnoldi method [24], the implicitly restarted Arnoldi method [11, 16], the Jacobi–Davidson method [5], and the rational Krylov method [20, 3]. The main idea is to reorder the Schur form so that unwanted Schur vectors are moved toward the end of the matrix of Schur vectors and to cut the Schur factorization after the pth column. So

$$A \begin{pmatrix} \mathcal{U}_p & \mathcal{U}_{k-p} \end{pmatrix} - B \begin{pmatrix} \mathcal{U}_p & \mathcal{U}_{k-p} \end{pmatrix} \begin{bmatrix} S_p & S_{p,k-p} \\ 0 & S_{k-p} \end{bmatrix} = \begin{pmatrix} \mathcal{F}_p & \mathcal{F}_{k-p} \end{pmatrix}$$

is reduced to

$$A\mathcal{U}_p - B\mathcal{U}_p S_p = \mathcal{F}_p$$

by purging the last $k-p$ Schur vectors. This equation can be expanded by adding new vectors.

In practice, the Schur vectors are computed from the projected Schur form (4.3) as $\mathcal{U}_k = \mathcal{V}_k X_k$ by decomposing $X_k = \begin{pmatrix} X_p & X_{k-p} \end{pmatrix}$ and by using $\mathcal{V}_p = \mathcal{V}_k X_p$ as the new basis.

6.2. Quadratic problems. We want to reduce the approximate Schur form

$$A \begin{pmatrix} U_{2k} \\ U_{2k} S_{2k} \end{pmatrix} - B \begin{pmatrix} U_{2k} \\ U_{2k} S_{2k} \end{pmatrix} S_{2k} = \begin{pmatrix} F_{2k} \\ 0 \end{pmatrix}$$

to

$$A \begin{pmatrix} U_{2p} \\ U_{2p} S_{2p} \end{pmatrix} - B \begin{pmatrix} U_{2p} \\ U_{2p} S_{2p} \end{pmatrix} S_{2p} = \begin{pmatrix} F_{2p} \\ 0 \end{pmatrix}$$

by chopping off the last $2k-2p$ columns of U_{2k} and S_{2k}. This is not possible since the new basis must have the form

$$\mathcal{Y}_{2p} = \begin{bmatrix} W_p & 0 \\ 0 & W_p \end{bmatrix} \begin{pmatrix} Z_{11} & Z_{12} \\ Z_{21} & Z_{22} \end{pmatrix}.$$

We can, however, keep the first p columns of U_{2k}, denoted by U_p, as follows. Consider the QR factorization $U_p = W_p T_p$, where W_p has orthonormal columns and T_p is upper triangular. Let $Z_{11} = T_p$ and $Z_{21} = T_p S_p$ with S_p as the upper left $p \times p$ submatrix of S_{2p}. The remaining blocks Z_{12} and Z_{22} must be chosen so that

$$\begin{pmatrix} T_p & Z_{12} \\ T_p S_p & Z_{22} \end{pmatrix} \tag{6.1}$$

is square and unitary. The last p columns do not represent Schur vectors but are necessary to keep the basis in the form (4.7).

In practice, we proceed as follows.

ALGORITHM 6.1.

1. *Let the first p columns of $U_{2k} = V_k X_1$ be U_p and let $U_p = V_k X_{11}$.*
2. *Compute the QR factorization $X_{11} = QT_p$.*
3. *Decompose*

$$\begin{pmatrix} X_1 \\ X_2 \end{pmatrix} = \begin{pmatrix} X_{11} & X_{12} \\ X_{21} & X_{22} \end{pmatrix}$$

with $X_{11}, X_{21} \in \mathbf{C}^{k\times p}$ and $X_{12}, X_{22} \in \mathbf{C}^{k\times 2k-p}$.
4. *Apply Q*

$$\begin{pmatrix} Q^*X_1 \\ Q^*X_2 \end{pmatrix} = \begin{pmatrix} T_p & Q^*X_{12} \\ T_pS_p & Q^*X_{22} \end{pmatrix}.$$

Remove the last $2k-2p$ columns of X_1 and X_2.
5. *Orthogonalize this matrix to get* (6.1).

Note that the first p columns of $\mathcal{Y}_{2p}$ are the same as those of $\mathcal{U}_{2k}$. When the first q columns of $\mathcal{U}_{2k}$ are locked Schur vectors and $q \le p$, then

$$A\mathcal{Y}_{2p} - B\mathcal{Y}_{2p}\begin{bmatrix} S_q & H_{q,2p-q} \\ 0 & H_{2p-q} \end{bmatrix} = \begin{pmatrix} \mathcal{F}_q & \mathcal{G}_{2p-q} \end{pmatrix},$$

where the lower left block in the Schur matrix is forced to be zero. (See Theorem 5.1.)

7. Building the Schur factorization. We have discussed how to compute an approximate partial Schur form by projection on a subspace and how to use the partial Schur form for restarting purposes and for locking eigenvectors (or Schur vectors). We still have to discuss which vectors will be added to the subspace. Instead of building a basis of eigenvectors in the subspace Range(V_k), we can build a partial Schur form. A Schur form always exists, while the eigendecomposition does not. Moreover, Schur vectors are orthogonal, which is in favor of the numerical stability of the method. In this section, we discuss how we can expand a partial Schur form.

7.1. Linear problems. The Jacobi–Davidson QR (JDQR) and Jacobi–Davidson QZ (JDQZ) methods [5] for solving linear eigenvalue problems compute the partial Schur form $A\mathcal{U}_k = B\mathcal{U}_k S_k$ column by column. Decompose the partial Schur form into

$$A\begin{pmatrix} \mathcal{U}_{k-1} & x \end{pmatrix} = B\begin{pmatrix} \mathcal{U}_{k-1} & x \end{pmatrix}\begin{bmatrix} S_{k-1} & s \\ & \omega \end{bmatrix}.$$

In order to simplify the notation, we use S to denote S_{k-1} and $\mathcal{U}$ for $\mathcal{U}_{k-1}$. Define $\mathcal{Q}$ so that $\mathcal{Q}^*B\mathcal{U} = I$. As a result, $I - B\mathcal{U}Q^*$ is a projector that maps $B\mathcal{U}$ to zero. Also note that $B\mathcal{U}\mathcal{Q}^*(A-\omega B)x = B\mathcal{U}s$. We will discuss later how to choose $\mathcal{Q}$. Since $(I - \mathcal{U}\mathcal{U}^*)x = x$, we can consider (ω, x) as an eigenpair of

$$(I - B\mathcal{U}\mathcal{Q}^*)A(I - \mathcal{U}\mathcal{U}^*)x = \omega(I - B\mathcal{U}\mathcal{Q}^*)B(I - \mathcal{U}\mathcal{U}^*)x. \tag{7.1}$$

Note the resemblance with the Jacobi–Davidson correction equation in (3.1). Suppose $\mathcal{U}$ and S are already computed and we wish to compute x, s, and ω. Suppose an approximation for (ω, x) is available that satisfies the approximate Schur factorization

$$A\begin{pmatrix} \mathcal{U} & x \end{pmatrix} - B\begin{pmatrix} \mathcal{U} & x \end{pmatrix}\begin{bmatrix} S & s \\ & \omega \end{bmatrix} = \begin{pmatrix} 0 & r \end{pmatrix},$$

with $\mathcal{Q}^*r = 0$. We want to compute an improvement by using the Cayley transform on (7.1). The Cayley transform y is solved from the system

$$(I - B\mathcal{U}\mathcal{Q}^*)(A - \sigma B)(I - \mathcal{U}\mathcal{U}^*)y = (I - B\mathcal{U}\mathcal{Q}^*)(A - \omega B)(I - \mathcal{U}\mathcal{U}^*)x.$$

Since $\mathcal{U}^*x = 0$ and assuming that $\mathcal{U}^*y = 0$, we get

$$(I - B\mathcal{U}\mathcal{Q}^*)(A - \sigma B)y = (I - B\mathcal{U}\mathcal{Q}^*)r, \tag{7.2}$$

and so

$$(A - \sigma B)y = r + B\mathcal{U}z, \tag{7.3}$$

where $z = \mathcal{Q}^*(A - \sigma B)y$ is chosen so that $\mathcal{U}^*y = 0$. If $A - \sigma B$ is invertible, the solution can be written as

$$y = (A - \sigma B)^{-1}B\mathcal{U}z + (A - \sigma B)^{-1}r.$$

Since $(A - \sigma B)^{-1}B\mathcal{U} = \mathcal{U}(S - \sigma I)^{-1}$,

$$y = \mathcal{U}\tilde{z} + (A - \sigma B)^{-1}r, \tag{7.4}$$

where $\tilde{z}$ is such that $y \perp \mathcal{U}$. The second term in the right-hand side can be considered as the Cayley transform for the Schur vector x.

7.2. Quadratic problems. In quadratic residual iteration, we want to expand the subspace by the first n components of y without explicitly solving a linear system with $A - \sigma B$. With U denoting U_{k-1}, recall from $\mathcal{U}_k = \left(\begin{smallmatrix} U_k \\ U_k S_k \end{smallmatrix}\right)$ that $\mathcal{U} = \left(\begin{smallmatrix} U \\ US \end{smallmatrix}\right)$ and $x = \left(\begin{smallmatrix} u \\ Us + \omega u \end{smallmatrix}\right)$. Decompose $r = \left(\begin{smallmatrix} r_1 \\ r_2 \end{smallmatrix}\right)$, and then from $r = (A - \omega B)x - B\mathcal{U}s$, we derive

$$\begin{aligned} r_1 &= Ku + i\omega Cu - \omega^2 Mu + iCUs - \omega MUs - MUSs, \\ r_2 &= 0. \end{aligned}$$

Note that r_1 is the last column of the approximate partial Schur factorization

$$K \begin{pmatrix} U & u \end{pmatrix} + iC \begin{pmatrix} U & u \end{pmatrix} \begin{bmatrix} S & s \\ & \omega \end{bmatrix}$$
$$-M \begin{pmatrix} U & u \end{pmatrix} \begin{bmatrix} S & s \\ & \omega \end{bmatrix}^2 = \begin{pmatrix} 0 & r_1 \end{pmatrix}.$$

With $y = \left(\begin{smallmatrix} y_1 \\ y_2 \end{smallmatrix}\right)$, (7.3) becomes

$$(K + i\sigma C)y_1 - \sigma My_2 = r_1 - iCUz + MUSz \tag{7.5a}$$
$$-\sigma My_1 + My_2 = MUz. \tag{7.5b}$$

Decompose $\mathcal{Q} = \left(\begin{smallmatrix} Q_1 \\ Q_2 \end{smallmatrix}\right)$; then $\mathcal{Q}^*r = 0 = Q_1^*r_1$ and

$$z = \begin{pmatrix} Q_1 \\ Q_2 \end{pmatrix}^* \begin{pmatrix} (K + i\sigma C)y_1 - \sigma My_2 \\ -\sigma My_1 + My_2 \end{pmatrix}.$$

By multiplying (7.5b) by σ and adding to (7.5a), we get

$$\begin{aligned} (K + i\sigma C - \sigma^2 M)y_1 &= r_1 + (-iCU + MU(S + \sigma I))z \\ -\sigma My_1 + My_2 &= MUz, \end{aligned} \tag{7.6}$$

with, similarly,

$$z = \begin{pmatrix} Q_1 \\ Q_2 - \sigma Q_1 \end{pmatrix}^* \begin{pmatrix} (K + i\sigma C - \sigma^2 M)y_1 \\ -\sigma M y_1 + M y_2 \end{pmatrix}.$$

The dependence on y_2 disappears when $Q_2 = \sigma Q_1$. Equation (7.4) becomes

$$\begin{aligned} y_1 &= U\tilde{z} + (K + i\sigma C - \sigma^2 M)^{-1} r_1, \\ y_2 &= US\tilde{z} + \sigma(K + i\sigma C - \sigma^2 M)^{-1} r_1 \end{aligned}$$

and shows that y_1 and y_2 point in the same direction orthogonal to U. In a projection method, it is only this direction that matters, so it is sufficient to add y_1 to the subspace. By rearranging (7.6) we obtain

$$(I - (-iCU + MU(S + \sigma I))Q_1^*)(K + i\sigma C - \sigma^2 M)y_1 = r_1,$$

where we still have the condition that $\mathcal{U}^* y = 0$. Since $\tilde{z}$ is determined by this condition but since $\mathcal{U}\tilde{z}$ does not contribute to the expansion of the subspace, we can just as well use the orthogonality condition $U^* y_1 = 0$, which produces another $\tilde{z}$ but produces the same component of y_1 orthogonal to U. This also produces y_2 with the same direction orthogonal to U.

In practice we solve the equation

$$(I - PQ^*)(K + i\sigma C - \sigma^2 M)(I - ZZ^*)y_1 = r_1 \tag{7.7}$$

by an iterative method with $P = iCU - MU(S + \sigma I)$ and $ZT = U$, the QR factorization of U. We still have to make a choice of Q. When U and S are computed by orthogonal projection within quadratic residual iteration or Jacobi–Davidson, the obvious choice is $Q = ZR$ since $Z^* r_1 = 0$, where R is chosen so that $Q^* P = I$. The problem is that PQ^* is an oblique projector and is not guaranteed to exist. A more robust choice is $Q = PR$, but then we first must orthogonalize r_1 against the columns of Q. In our numerical experiments we used $Q = ZR$.

8. Algorithm and numerical examples. The first two examples are easily generated and are included to allow the reader to reproduce the results. The last example is the numerical simulation of poro-elastic material and is less easily reproduced. This is added to illustrate the method on a more realistic problem.

The algorithm that we use for the computation of Ritz pairs is the following one. It uses locking of converged Schur vectors and purging for restarting purposes. On each iteration, the Schur basis of the projected linearized problem is computed. The basis vectors are obtained by Gram–Schmidt orthogonalization with reorthogonalization [2]. The major work lies in the solution of the linear system in step 2.10 and the Gram–Schmidt orthogonalization in step 2.11. When the number of vectors becomes large, the operations on the small scale linearized problem may also become significant. We allow σ to be chosen differently at each iteration. When a direct linear solver is used, however, we prefer to keep σ unchanged for a number of iterations in order to avoid a factorization on each iteration.

ALGORITHM 8.1. *In this algorithm, k is the actual dimension of the subspace, q is the number of locked Schur vectors, satisfying $\|KU_q e_j + iCU_q S_q e_j - MU_q S_q^2 e_j\| \leq$ TOL for $j = 1, \ldots, q$, where $\left\|\begin{pmatrix} U_q \\ U_q S_q \end{pmatrix}\right\| = 1$, p is the dimension after a restart, and m is the maximum subspace dimension.*

1. *Given* $v_1 \in \mathbf{C}^n$ *with* $\|v_1\| = 1$.
   Let $k = 1$ *and* $q = 0$.
2. *Until* $q \geq$ *number of wanted eigenvalues:*
   2.1. *Compute the* k*th row and column of* $K_k = V_k^* K V_k$, $C_k = V_k^* C V_k$, *and* $M_k = V_k^* M V_k$.
   2.2. *Compute* H_{2k} *by Algorithm* 4.1.
   2.3. *Map* H_{2k} *in the Schur basis:*

$$H_{2k} = \begin{pmatrix} X_1 & 0 & 0 \\ 0 & 1 & 0 \\ X_2 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix}^* H_{2k} \begin{pmatrix} X_1 & 0 & 0 \\ 0 & 1 & 0 \\ X_2 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix}.$$

   2.4. *Compute the Schur form* $H_{2k}\binom{X_1}{X_2} = \binom{X_1}{X_2} S_{2k}$, *where the first* q *Schur vectors are locked.*
   2.5. *Order the Schur form so that the main diagonal elements of* S_{2k} *nearest* σ *are in the upper left position.*
   2.6. *For* $j = q + 1$ *to* k*:*
      2.6.1. *Compute the* j*th column of* $R_k = KV_kX_1 + iCV_kX_1S_{2k} - MV_kX_1S_{2k}^2$.
      2.6.3. *If* $\|R_k e_j\| \leq$ TOL, *then* $q = q + 1$.
      Else Go to 2.7.
      End for
   2.7. *If* $k \geq m$, *then*
      2.7.2. *Compute the QR factorization* $X_1 = Q_k T_k$.
      2.7.3. *Compute the basis vectors* $V_p = V_k Q_p$.
      2.7.4. *Update the Schur vectors:* $X_1 = T_p$ *and* $X_2 = Q_p^* X_2$.
      2.7.5. *Add columns to* X_1 *and* X_2 *so that they have appropriate size and form an orthonormal basis* (*see Algorithm* 6.1).
      2.7.6. *Update:* $K_p = Q_p^* K_k Q_p$, $C_p = Q_p^* C_k Q_p$, $M_p = Q_p^* M_k Q_p$.
   2.8. *Increase the subspace dimension* $k = k + 1$.
   2.9. *Select a pole* σ.
   2.10. *Solve the linear system* $(K + i\sigma C - \sigma^2 M)w = R_k e_{q+1}$.
   2.11. *Orthogonalize* w *against* $v_1, \ldots, v_k$ *by Gram–Schmidt into* v_{k+1}.

For our examples, K, C, and M are real symmetric matrices, so, in step 2.1 it is sufficient to compute the kth column. The subspace is expanded by a quadratic Cayley transform applied to a Schur vector. When an iterative solver is used, we can expand the subspace by solving the correction equation (3.2) instead of the Cayley linear system in step 2.10, and we also take into account the locked Schur vectors by employing (7.7), where Z also contains the last (unlocked) Schur vector and Q is the corresponding left-hand side basis. (See sections 9 and 10 for examples.)

8.1. A "linear" problem. For the first example, M is the identity matrix, C is zero, and K is the diagonal matrix with $1^2, 2^2, \ldots, n^2$ on its main diagonal for $n = 1000$. The 10 eigenvalues nearest zero are $\pm j$ for $j = 1, \ldots, 5$, and the corresponding eigenvectors are e_j for the eigenvalue $\pm j$, where e_j is the jth identity vector. Note that the Schur form, defined by (4.5), does not exist, but it does exist for the linearized problem. Incidentally, the linearized problem has $2n$ eigenvectors. We can solve this problem by the spectral transformation Lanczos method [4] since $C = 0$, but we want to illustrate that the algorithm is able to compute linearly dependent eigenvectors of the quadratic eigenvalue problem.

We computed the 10 eigenvalues nearest zero by the use of Algorithm 8.1 with a fixed pole $\sigma = 0$ and $m = 30$ iteration vectors. The initial vector v_1 was $1/\sqrt{n}$ everywhere. All the eigenvalues were computed within 20 iterations to a tolerance (TOL) of 10^{-7}. When only $m = 17$ vectors are used and we compress the dimension to $p = 15$, then before the first restart, 8 eigenvalues have converged. For the convergence of the remaining two eigenvalues, two restarts are required. In total, this corresponds to 20 iterations, which is exactly the same number as for the run with $m = 30$ vectors. This shows that the purging of the Ritz values far away from the pole σ does not necessarily slow down the convergence. A similar result was shown for the implicitly restarted Arnoldi method [16] and for the implicitly filtered rational Krylov method [3].

8.2. A simple quadratic problem. We use the same K and M as for the previous example, but now $C = \alpha I$ with $\alpha = 0.1$. We again computed the 10 eigenvalues nearest zero. We used the same parameters as for the previous example, i.e., $m = 17$, $p = 15$, $\sigma = 0$, and a tolerance of 10^{-7}. The eigenvalues of this example and the previous one are related as follows.

LEMMA 8.1. *Let $u \neq 0$, and let $Ku + i\omega Cu - \omega^2 Mu = 0$; then there is an eigenvalue λ of $Kv = \lambda^2 Mv$ so that*

$$|\lambda - \omega| \leq |\omega| \|M^{-1}\|^{1/2} \frac{\|Cu\|}{u^* Mu}.$$

Proof. Let L be so that $M = L^* L$. Define $v = Lu$ so that

$$\begin{aligned} Ku - \omega^2 Mu &= -i\omega Cu, \\ L^{-*} K L^{-1} v - \omega^2 v &= -i\omega L^{-*} Cu. \end{aligned}$$

The proof follows from the Bauer–Fike theorem (Theorem 2.4) with $\kappa = 1$, since $L^{-*} K L^{-1}$ is Hermitian. Note that $\|L^{-*}\| = \|M^{-1}\|^{1/2}$. ∎

Since $\|C\| = 0.1$ the eigenvalues lie close to those of the previous example. Therefore, the convergence is very similar. It took 20 iterations to compute the ten Ritz values. The first ten Ritz values are given by Table 8.1.

TABLE 8.1
Ritz values for the example in section 8.2.

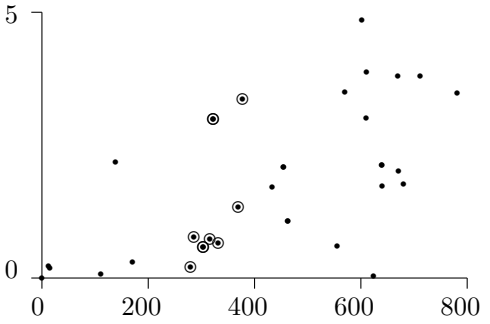

FIG. 8.1. *The eigenvalues of the acoustic simulation of a poro-elastic material between* 0 *and* 800 *Hz are shown as dots. The Ritz values computed by Algorithm* 8.1 *are denoted as circles. Only eight circles are shown, since there are two pairs of double eigenvalues. Notice the different scales for real and imaginary axes.*

8.3. Acoustic simulation of poro-elastic material. This example is related to the acoustic simulation of a $0.4m \times 0.4m \times 0.06m$ sample made of a poro-elastic material. The material is modelled using a two-phase Biot model accounting for kinematic and mechanical interactions between the (elastic) skeleton and the pore (acoustic) fluid [23, 25]. The following material properties have been selected: for the skeleton, the Young modulus is $140000N/m^2$, the Poisson ratio is $0.35(-)$, and the density is $1300kg/m^3$. The pore fluid has density $1.225kg/m^3$, the sound speed is $340m/s$, the porosity is $0.95(-)$, the flow resistivity is $5000Ns/m^4$, the Biot factor is $1(-)$, the fluid bulk modulus is $141600N/m2$, and the tortuosity is $1.2(-)$. The discrete finite-element model relies on a *u-w* formulation [25], where skeleton displacement components (u) and relative fluid displacement components (weighted by the local porosity) (w) are selected as nodal variables. The finite-element mesh has 324 nodes and 192 HEXA8 elements. The total number of degrees of freedom is 1944.

We used Algorithm 8.1 with $m = 30$, $p = 15$, and the number of wanted Ritz values 10. The first pole was 300. A new pole σ was selected after every 10 iterations, as

$$\sigma = \min_{j \geq q+1} \{\mu = \mathrm{Re}((\omega_j + \omega_{j+1})/2), |\omega_j - \mu| \geq 10\},$$

where q is the number of converged Ritz values so that the pole is never close to a Ritz value. This prevents the matrix factorization of almost singular matrices. The tolerance for the eigenvalue problem was $\mathrm{TOL} = 10^{-5}$. (This tolerance is relatively large, since the initial residual norm $\|r_P\|$ is of the order 1.)

The results are obtained by a direct and an iterative method for solving the linear system in step 2.12 of Algorithm 8.1. The direct solver is the package ME47 from the Harwell Subroutine Library (HSL) [8]. The iterative solver is GMRES [22]. The linear systems are solved with a relative residual tolerance $\tau = 10^{-2}$ and $\tau = 10^{-4}$, i.e., $(K + i\sigma C - \sigma^2 M)w = r_P + s$ and $\|s\| \leq \tau \|r_P\|$, where s is the residual of the linear system and $r_P = R_k e_{q+1}$ is the quadratic residual of the Ritz pair. The real part $K - \sigma^2 M$ was used as preconditioner, where the HSL package MA47 was used for the solution of the corresponding linear system. The preconditioner is perhaps not very advisable for practical computations, but this example shows that an iterative method can be used. Recall from section 2 that the quadratic Cayley transform need not be computed very accurately for fast convergence.

The eigenvalues and computed Ritz values are displayed in Figure 8.1. The iterative solver for $\tau = 10^{-2}$ required between 21 and 27 iterations to attain the required

residual tolerance. From the numerical results in Table 8.2, it can be seen that about the same number of Ritz values have converged after 40 iterations, independent of the choice of linear solver. From the 40th iteration on, there is a significantly different convergence behavior. Quadratic residual iteration requires 46 iterations when a direct linear solver is used and 59 iterations when the iterative solver with $\tau = 10^{-2}$ is used. Note that the relative residual tolerance $\tau = 10^{-2}$ for GMRES is quite large. Accurate solves are not necessary. With $\tau = 10^{-4}$, the convergence speed is the same as when a direct linear system solver is used, but the cost per iteration is higher than when $\tau = 10^{-2}$.

TABLE 8.2
Number of converged Ritz pairs for some iteration numbers when a direct and iterative linear solver are used. τ is the relative residual tolerance of the iterative method.

Iteration	Number of converged Ritz values		
	Direct	Iterative $\tau = 10^{-2}$	Iterative $\tau = 10^{-4}$
10	1	1	1
20	3	3	4

50		9	
59		10	

9. Jacobi–Davidson for the quadratic eigenvalue problem. In this section, we compare the Jacobi–Davidson method with quadratic residual iteration. The only difference from Algorithm 8.1 is in step 2.12, where we solve the correction equation (3.2) instead of computing a Cayley transformation. Since we compute more than one eigenpair, we also add the locked Schur vectors to this basis, i.e., we solve a problem of the form (7.7), where Z spans the $q+1$ first columns of $V_k X_1$ and Q the first $q+1$ columns of $iC(V_k X_1) - M(V_k X_1)(S_{2k} + \sigma I)$.

We now compare the following methods for the application from section 8.3. The purpose is to compute the ten eigenvalues nearest 300.

QRI-D. Quadratic residual iteration with a direct linear solver. The solver used is ME47 from HSL. The pole changes every ten iterations. The first pole is 300.

QRI-G. Quadratic residual iteration with GMRES(30) as linear solver, preconditioned by the direct solver MA47 from HSL for $K - \sigma^2 M$. The pole σ changes every ten iterations. The first pole is 300.

QRI-GP. Quadratic residual iteration with GMRES(30) applied to (7.7), with Z and Q defined as above, preconditioned by MA47. The pole σ changes every ten iterations. The first pole is 300.

QJD. Jacobi–Davidson, where the linear systems are solved by GMRES(30) preconditioned by MA47. For the first ten iterations, the pole was kept constant to 300. From the eleventh iteration on, the pole $\sigma = \omega$ and changes each iteration. The preconditioner changes every ten iterations, so we factorize only a few times.

TABLE 9.1
The number of linear solves for the different algorithms.

Method	Linear solver tolerance τ	Direct linear solves	Eigensolver iterations
QRI-D	—	**45**	46
QRI-G	10^{-2}	**1412**	58
QRI-G	10^{-3}	1545	48

QRI-G	10^{-6}	2998	47
QRI-G	10^{-8}	4130	47
QRI-GP	10^{-2}	**1432**	57
QRI-GP	10^{-3}	1499	47
QRI-GP	10^{-4}	1739	46
QRI-GP	10^{-6}	2318	46
QRI-GP	10^{-8}	3503	45
QJD	10^{-2}	—	—
QJD	10^{-3}	—	—
QJD	10^{-4}	**1469**	33
QJD	10^{-6}	2208	27
QJD	10^{-8}	2918	25

Table 9.1 contains results for the methods listed above for different values of the tolerance of the linear solver. The bold values give the minimum number of linear solves for each method. Clearly, QRI-D is much faster than any other method, but this is because the linear systems with $K + i\sigma C - \sigma^2 M$ are solved exactly. Note, however, that a direct solver for complex linear systems is used while the other methods use a direct solver for real matrices. Let us concentrate on the results obtained with GMRES. The preconditioner is the real part of $K + i\sigma C - \sigma^2 M$, which is in this case $K - \sigma^2 M$. Note that the factorization cost is about the same for all methods since factorization is only performed every ten outer iterations. For QRI-G and QRI-GP, the linear systems need not be solved very accurately to obtain fast convergence. It is remarkable that the number of outer iterations is much larger for the optimal cases. For $\tau = 10^{-6}$ and $\tau = 10^{-8}$ the linear systems are solved more accurately than necessary, since the number of outer iterations does not change significantly. Using a larger τ gives roughly the same number of outer iterations, but less global work. Also note that QRI-GP is more efficient than QRI-G when τ is smaller. We also tried QRI-G with $\sigma \equiv \omega$ as for QJD, but then GMRES stagnates rather quickly. Without the projections in the correction equation (3.2), the matrix of the linear system has an eigenvalue near zero that hinders the convergence. The projections filter away this eigenvalue. For small τ, QJD is definitely faster than any other algorithm. For large τ, QJD stagnates after the locking of the first Ritz value. The first and second eigenvalue form a double one at $303.624 + 0.589i$, and it seems to be difficult to find the second of the double eigenvalue when τ is large. A more important danger arises in the following situation. When we use $\tau = 10^{-8}$ and change the pole after the 6th iteration instead of after the 10th, the Ritz value is $\omega \simeq 303.624 + 0.589i$ and QJD tries to improve the corresponding Ritz vector by solving (7.7). The problem is that there is an eigenvalue at $303.624 + 0.589i$ with multiplicity two, while only one eigenvector is filtered away by the projector $I - ZZ^*$. This means that the linear system is still nearly singular and GMRES stagnates.

10. Shift-and-invert Arnoldi for the linearized problem. The most widely used method in applications is probably the shift-and-invert Arnoldi method applied to the linearized problem (1.2). This method is criticized because it doubles the

size of the problem, leading to an increase in storage cost for the iteration vectors $\mathcal{V}_k$ and in the overall computational cost. The shift-and-invert transformation, $y = (A - \sigma B)^{-1}Bx$, however, can be efficiently computed by the solution of the block structured linear system

$$(A - \sigma B)y = Bx,$$
$$\begin{bmatrix} K + i\sigma C & -\sigma M \\ -\sigma M & M \end{bmatrix} \begin{pmatrix} y_1 \\ y_2 \end{pmatrix} = \begin{pmatrix} -iCx_1 + Mx_2 \\ Mx_1 \end{pmatrix}.$$

By multiplying the last row by σ and adding to the first row, we get

$$\begin{bmatrix} K + i\sigma C - \sigma^2 M & 0 \\ -\sigma M & M \end{bmatrix} \begin{pmatrix} y_1 \\ y_2 \end{pmatrix} = \begin{pmatrix} -iCx_1 + M(x_2 + \sigma x_1) \\ Mx_1 \end{pmatrix},$$

from which

$$y_1 = (K + i\sigma C - \sigma^2 M)^{-1}(-iCx_1 + M(x_2 + \sigma x_1)),$$
$$y_2 = x_1 + \sigma y_1.$$

This requires the matrix factorization of $K + i\sigma C - \sigma^2 M$ as in the solution of the quadratic problem.

The Arnoldi method does not produce Ritz vectors that satisfy (2.5) exactly, so the relationship between Algorithms 2.2 and 2.3 is lost. On the other hand, there is a link with Algorithm 2.1, since in exact arithmetic and with the exact linear solves the Davidson method produces the same subspace as the shift-and-invert Arnoldi method when σ is fixed. The major difference between Algorithms 2.1 and 2.3 lies in the construction of the subspaces. In the Algorithms 2.2 and 2.3, the subspace is expanded so that the two components from the Cayley transform applied to a Ritz vector are added. Both algorithms are designed to improve one Ritz vector at a time. In the Arnoldi method, all Ritz vectors converge together.

This is illustrated by the following example. Consider the example from section 8.3. We performed 30 steps of Arnoldi's method applied to $(A - \sigma B)^{-1}B$ starting with a random initial vector. The left-hand picture in Figure 10.1 shows the residual norms $\rho_j = \|Ax_j - BX_jS_j\|$ of the six Ritz values nearest $\sigma = 300$ as a function of the iteration number. The Ritz values nearest σ converge faster, where $X_j = [x_1, \ldots, x_j]$ denote the first j Schur vectors and S_j denotes the corresponding Schur matrix. Most of the Ritz values have decreasing residuals from the first to the last iteration. The central picture shows the results of 30 iterations of quadratic residual iteration. We used Algorithm 8.1 without a restart. We consider a Ritz value as converged when the residual norm $\rho_j = \|r_P\| = \|(KU_j + iCU_jS_j - MU_jS_j^2)e_j\|$ is smaller than the convergence tolerance, 10^{-7}. The horizontal dashed line indicates the tolerance TOL used by Algorithm 8.1 in step 2.3.6. Two different kinds of convergence behavior can be observed. The residual norm of the third Ritz value (dotted line) makes a significant decrease during the convergence of the first and the second. This looks like the convergence behavior of the Arnoldi method. The other Ritz values show a completely different behavior. Each time a Ritz value has converged, it is locked and another Ritz value is targeted and starts converging. This is very clear from the dashed convergence curves. The residuals decrease at the beginning, but most of them stagnate until a new eigenpair is targeted. Peaks in the curves indicate a Ritz value that starts converging to another eigenvalue.

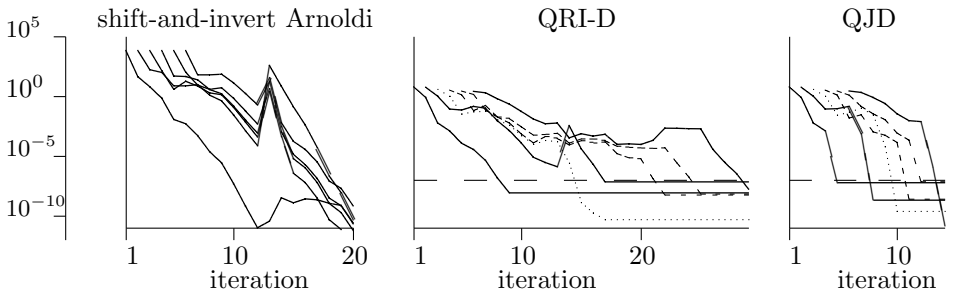

FIG. 10.1. *Convergence behavior of shift-and-invert Arnoldi, quadratic residual iteration (QRI-D), and Jacobi–Davidson (QJD) for the problem from section* 8.3. *The lines show the evolution of* $\rho_j = \|(KU_j + iCU_jS_j - MU_jS_j^2)e_j\|$ *of the six Ritz values nearest* σ.

The tolerance TOL plays an important role in the overall convergence speed. In the example mentioned above, Arnoldi requires 21 iterations for finding six eigenvalues with the required accuracy when TOL$= 10^{-7}$ and quadratic residual iteration 28 iterations. When TOL$= 10^{-4}$ instead, Arnoldi's method requires only 18 iterations, but quadratic residual requires no more than 14. This illustrates that we cannot make a decision on which method is the best.

The right-hand picture shows the results for the Jacobi–Davidson method preconditioned with $K + i\sigma C - \sigma^2 M$ with $\sigma = 300$ and linear solver tolerance $\tau = 10^{-5}$. The first three iterations used a fixed pole $\sigma = 300$, and then $\sigma = \omega$, while the preconditioner is computed once for $\sigma = 300$. The picture shows quadratic convergence for the Ritz values. The algorithm converges in 13 iterations but requires 118 complex linear solves, while less than 30 for the other two algorithms. Stagnation is not as pronounced as for the QRI-D method.

The quadratic residual iteration method has some advantages. First, the modified Davidson framework (Algorithm 2.2) uses a larger subspace than the Davidson approach (Algorithm 2.1) constructed by adding two vectors per iteration step to the subspace. This may lead to some minor gain in convergence speed. The potential gain is in the storage of the iteration vectors. Often, however, one stores the matrices KV_k, MV_k, and CV_k in order to calculate the residuals more efficiently or the projection matrices K_k, M_k, and C_k, and then the advantage is lost. In our implementation, these additional vectors are not stored.

11. Conclusions. In this paper, we have shown there is a close connection between solution methods for the quadratic eigenvalue problem and its linearized form. Solution methods that solve the quadratic problem without linearization appear to be equivalent to methods that solve the linearized problem by projection on a larger subspace. The Jacobi–Davidson correction equation for the linearized problem is connected to the correction equation of the quadratic problem.

If direct linear system solvers are used for the Cayley transform, the gain of the residual iteration method is small compared to the shift-and-invert Arnoldi method. The Gram–Schmidt orthogonalization cost is significantly lower due to the smaller dimension. When the vectors KV_k, CV_k, and MV_k are not stored, about half of the memory is needed, but otherwise the memory consumption is higher than for the shift-and-invert Arnoldi method. The convergence of the Arnoldi method is not focused on a single eigenvalue, but all eigenvalues start converging from the beginning. The quadratic method targets one eigenvalue, which may lead to a fast local

convergence, but a slow global convergence. Therefore, we suggest the use of the shift-and-invert Arnoldi method when direct linear system solvers are used. However, as the last example illustrates, when the convergence tolerance is large, quadratic residual iteration is faster. If iterative linear system solvers are used, we suggest the use of quadratic residual iteration or the Jacobi–Davidson method for the quadratic problem in conjunction with a deflation and restarting scheme based on the linearized case. It is important to note that none of the discussed methods can be flagged as optimal: there are always situations for which one method outperforms the other.

Finally, we want to stress that a practical code should use a block version, i.e., a number of Cayley transforms is applied to more than one Ritz vector at a time. This allows us to compute multiple or clustered eigenvalues more efficiently and may improve the reliability of the method since more than one eigenvalue is targeted simultaneously. When Jacobi–Davidson is used, some care with the choice of poles σ is in order when multiple eigenvalues are expected, since this may lead to the solution of nearly singular linear systems.

Acknowledgments. The author thanks Jennifer Scott, Nick Gould, and Iain Duff from the Rutherford Appleton Laboratory and Françoise Tisseur from the University of Manchester for helpful comments that improved the presentation of the paper. We are also grateful to Jean-Pierre Coyette from Free Field Technologies for the matrices of the acoustic simulation of a poro-elastic material. The author also thanks the referee for suggestions that improved the comparisons between the various methods.

KRYLOV SUBSPACE ESTIMATION*

MICHAEL K. SCHNEIDER† AND ALAN S. WILLSKY†

Abstract. Computing the linear least-squares estimate of a high-dimensional random quantity given noisy data requires solving a large system of linear equations. In many situations, one can solve this system efficiently using a Krylov subspace method, such as the conjugate gradient (CG) algorithm. Computing the estimation error variances is a more intricate task. It is difficult because the error variances are the diagonal elements of a matrix expression involving the inverse of a given matrix. This paper presents a method for using the conjugate search directions generated by the CG algorithm to obtain a convergent approximation to the estimation error variances. The algorithm for computing the error variances falls out naturally from a new estimation-theoretic interpretation of the CG algorithm. This paper discusses this interpretation and convergence issues and presents numerical examples. The examples include a 10^5-dimensional estimation problem from oceanography.

1. Introduction.

The goal of finite-dimensional linear least-squares estimation is to estimate an l-dimensional random vector x with a linear function of another m-dimensional random vector y so as to minimize the mean squared error [11, Chapter 4]. That is, one minimizes $\mathrm{E}[\|x-\hat{x}(y)\|^2]$ over $\hat{x}(y)$ to find the linear least-squares estimate (LLSE).

Write the relationship between x and y as $y = z+n$, where n is noise, uncorrelated with x, and

$$z = Cx \tag{1.1}$$

for a matrix C reflecting the type of measurements of x. In the Bayesian framework, x, z, and n have known means and covariances. The covariance matrices are denoted by Λ_x, Λ_z, and Λ_n, respectively, and, without loss of generality, the means are assumed to be zero. The LLSE of x given y is

$$\hat{x}(y) = \Lambda_x C^T \Lambda_y^{-1} y, \tag{1.2}$$

where $\Lambda_y = \Lambda_z + \Lambda_n = C\Lambda_x C^T + \Lambda_n$ is the covariance of y.

Direct computation of $\hat{x}(y)$ is difficult if x and y are of high dimension. In particular, the work in this paper was motivated by problems in which x represents a spatially distributed phenomenon and y represents measurements encountered in applications ranging from image processing to remote sensing. For example, when x and y represent natural images, they typically consist of $256 \times 256 = 65536$ pixels.

In problems from physical oceanography, the dimensions of x and y are typically upwards of 10^5 and 10^4, respectively (e.g., see [7]). Furthermore, in applications such as remote sensing in which the measurement sampling pattern is highly irregular, Λ_z is typically a full matrix that is far from Toeplitz. This prevents one from solving the linear system (1.2) by spectral or sparse matrix methods. However, Λ_y often has a considerable amount of structure. For example, the covariance, Λ_x, of the full spatial field, is often either Toeplitz or well-approximated by a very sparse matrix in an appropriate basis, such as a local cosine basis [12]. The measurement matrix C is often sparse, and the noise covariance Λ_n is often a multiple of the identity. Thus, multiplying vectors by Λ_y is often efficient, and an iterative method for solving linear systems that makes use of multiplications by Λ_y, such as a Krylov subspace method, could be used to compute $\hat{x}(y)$.

For linear least-squares estimation problems, one is interested not only in computing the estimates but also some portion of the estimation error covariance matrix. The covariance of the estimation error,

$$\Lambda_{e_x}(y) = \Lambda_x - \Lambda_x C^T \Lambda_y^{-1} C \Lambda_x, \tag{1.3}$$

is the difference between the prior covariance and the error reduction. The terms on the diagonal of this matrix are the estimation error variances, the quantities most sought after for characterizing the errors in the linear estimate. A natural question to ask is whether a Krylov subspace method for computing the linear estimate $\hat{x}(y)$, such as the method of conjugate gradients (CG), could be adapted for computing portions of the error covariance matrix. This paper presents an interpretation of CG in the context of linear least-squares estimation that leads to a new algorithm for computing estimation error variances.

Many researchers in the geosciences have used CG for computing LLSEs. In particular, Bennett, Chua, and Leslie [1, 2, 3] and da Silva and Guo [4] use CG for computing LLSEs of atmospheric variables. The structures of these estimation problems are very similar to the ones considered here. In particular, the quantities to be estimated, x, are spatially varying processes, and the measurement matrices, C, are sparse. However, they do not consider using a Krylov subspace method for the computation of error variances. We not only propose such a method in this paper but also provide a detailed convergence analysis.

Paige and Saunders [13] and Xu et al. [19, 20, 21, 22] have developed Krylov subspace methods for solving statistical problems that are closely related to linear least-squares estimation. The LSQR algorithm of Paige and Saunders solves a regression problem and can compute approximations to the standard errors. The regression problem is a more general version of linear least-squares estimation in which a prior model is not necessarily specified. In the special case of linear least-squares estimation, the standard errors of the regression problem are the estimation error variances. Thus, LSQR can compute approximations to the error variances. The novelty of our work is that it focuses specifically on linear least-squares estimation and takes advantage of the structure inherent in many prior models for image processing problems. In particular, many such prior models imply a covariance of the data, $\Lambda_y = \Lambda_z + \Lambda_n$, in which the signal covariance matrix, Λ_z, has eigenvalues that decay rapidly to zero and the noise covariance matrix, Λ_n, is a multiple of the identity. Such properties are exploited by our algorithm. These assumptions were also made in the work of Xu, Kailath, et al. for signal subspace tracking. For that problem, one is interested in computing the dominant eigenvectors and eigenvalues of Λ_z. Although computing

the dominant eigenvectors and eigenvalues of Λ_z is sufficient to compute an approximation to the estimation error variances, it is not necessary. We do not explicitly compute eigenvectors or eigenvalues. This provides us with the opportunity to exploit preconditioning techniques in a very efficient manner.

Section 2 discusses our interpretation of CG as used to compute LLSEs. This naturally leads to the presentation of a new iterative algorithm for computing estimation error variances. Section 3 proposes two alternative stopping criteria. The main convergence result is presented in section 4. Techniques for accelerating convergence, including preconditioned and block algorithmic forms, are discussed in section 5. The main convergence result is proved in section 6. Finally, section 7 illustrates the proposed techniques with various numerical examples.

2. The estimation algorithm. The primary difficulty in computing the LLSE $\hat{x}(y)$ in (1.2) is the large dimension of the data y. The signal in the data, however, typically lies in a much lower dimensional subspace. One can take advantage of this fact to compute an approximation to $\hat{x}(y)$ by computing, instead of $\hat{x}(y)$, the LLSE of x given a small number of linear functionals of the data, $p_1^T y, p_2^T y, \ldots, p_k^T y$. For a particular sequence of linearly independent linear functionals, $p_1^T, p_2^T, \ldots, p_k^T$, let $\hat{x}_k(y)$ denote the LLSE of x given $p_1^T y, p_2^T y, \ldots, p_k^T y$. If most of the signal components in y lie in the span of $p_1, p_2, \ldots, p_k$, then the estimate $\hat{x}_k(y)$ approximates $\hat{x}(y)$. In this case, the covariance of the error in the estimate $\hat{x}_k(y)$, $\Lambda_{e_x,k}(y) \triangleq \mathrm{Cov}(x - \hat{x}_k(y))$, approximates the optimal error covariance, $\Lambda_{e_x}(y) \triangleq \mathrm{Cov}(x - \hat{x}(y))$.

The principal novelty of the algorithm we propose in this paper is the use of linear functionals that form bases for Krylov subspaces. The use of Krylov subspaces for solving linear algebra problems is not new, but the application of Krylov subspaces to the computation of error covariances is new. A Krylov subspace of dimension k, generated by a vector s and the matrix Λ_y, is the span of $s, \Lambda_y s, \ldots, \Lambda_y^{k-1} s$ and is denoted by $\mathcal{K}(\Lambda_y, s, k)$ [8, section 9.1.1]. The advantage of using linear functionals that form bases for Krylov subspaces is twofold. One reason is theoretical. Specifically, one can consider the behavior of the angles between $\mathcal{K}(\Lambda_y, s, k)$ and the dominant eigenvectors, u_i, of Λ_y: $\arcsin \|(I - \pi_k)u_i\|/\|u_i\|$, where π_k is the orthogonal projection onto $\mathcal{K}(\Lambda_y, s, k)$. As noted in [16], these angles are rapidly decreasing as k increases. Thus, linear functionals from Krylov subspaces will capture most of the dominant components of the data. Another reason for using functionals from Krylov subspaces is computational. As discussed in the introduction, the structure of Λ_y in many problems is such that multiplying a vector by Λ_y is efficient. A consequence of this fact is that one can generate bases for the Krylov subspaces efficiently.

The specific linear functionals used in this paper are the search directions generated by standard CG for solving a linear system of equations involving the matrix Λ_y. The conjugate search directions, $p_1, \ldots, p_k$, form a basis for $\mathcal{K}(\Lambda_y, s, k)$ and are Λ_y-conjugate [8, section 10.2]. The Λ_y-conjugacy of the search directions implies that $\mathrm{Cov}(p_i^T y, p_j^T y) = \delta_{ij}$; so, these linear functionals of the data are white. Thus, we can draw the novel conclusion that CG whitens the data. The whiteness of the linear functionals of the data allows one to write

$$\hat{x}_k(y) = \sum_{j=1}^{k} \left(\Lambda_x C^T p_i\right) p_i^T y, \tag{2.1}$$

$$\Lambda_{e_x,k}(y) = \Lambda_x - \sum_{j=1}^{k} \left(\Lambda_x C^T p_i\right) \left(\Lambda_x C^T p_i\right)^T, \tag{2.2}$$

which follows from $\mathrm{Cov}(p_1^T y, \ldots, p_k^T y) = I$.[1] One can now write recursions for the estimates and error variances in terms of the quantities $b_{y,k} = \Lambda_x C^T p_k$. We call these the *filtered backprojected* search directions because the prior covariance matrix Λ_x typically acts as a low-pass filter and C^T is a backprojection (as the term is used in tomography) since C is a measurement matrix. In terms of the $b_{y,k}$, the recursions have the following form:

$$\hat{x}_k(y) = \hat{x}_{k-1}(y) + b_{y,k} p_k^T y, \tag{2.3}$$

$$(\Lambda_{e_x,k}(y))_{ii} = (\Lambda_{e_x,k-1}(y))_{ii} - ((b_{y,k})_i)^2, \tag{2.4}$$

with initial conditions

$$\hat{x}_0(y) = 0, \tag{2.5}$$

$$(\Lambda_{e_x,0}(y))_{ii} = (\Lambda_x)_{ii}, \tag{2.6}$$

where $i = 1, \ldots, l$. Unfortunately, the vectors $p_1, p_2, \ldots$ generated by standard CG are not Λ_y-conjugate to a reasonable degree of precision because of the numerical properties of the method.

The numerical difficulties associated with standard CG can be circumvented using a Lanczos iteration, combined with some form of reorthogonalization, to generate the conjugate search directions [8, sections 9.1 and 9.2]. The Lanczos iteration generates a sequence of vectors according to the following recursion:

$$\alpha_k = q_k^T \Lambda_y q_k, \tag{2.7}$$

$$h_k = \Lambda_y q_k - \alpha_k q_k - \beta_k q_{k-1}, \tag{2.8}$$

$$\beta_{k+1} = \|h_k\|, \tag{2.9}$$

$$q_{k+1} = \frac{h_k}{\beta_{k+1}}, \tag{2.10}$$

which is initialized by setting q_1 equal to the starting vector s, $q_0 = 0$, and $\beta_1 = 0$. The Lanczos vectors, $q_1, q_2, \ldots$, are orthonormal and such that

$$\begin{bmatrix} q_1 & q_2 & \cdots & q_k \end{bmatrix}^T \Lambda_y \begin{bmatrix} q_1 & q_2 & \cdots & q_k \end{bmatrix} \tag{2.11}$$

is tridiagonal $\forall k$. Let $T_{y,k}$ denote this tridiagonal matrix, and let $L_{y,k}$ denote the lower bidiagonal Cholesky factor. Then, the vectors defined by

$$\begin{bmatrix} p_1 & p_2 & \cdots & p_k \end{bmatrix} = \begin{bmatrix} q_1 & q_2 & \cdots & q_k \end{bmatrix} L_{y,k}^{-T} \tag{2.12}$$

are equal, up to a sign, to the conjugate search directions generated by CG in exact arithmetic. That $L_{y,k}$ is lower bidiagonal allows one to use a simple one-step recursion to compute the p_i from the q_i. Note also that the $b_{y,k} = \Lambda_x C^T p_i$ can be computed easily in terms of a recursion in $\Lambda_x C^T q_i$. These latter quantities are available since the computation of q_{k+1} requires the product $\Lambda_y q_k = C(\Lambda_x C^T) q_k + \Lambda_n q_k$.

One of the main advantages to using the Lanczos iteration followed by the Cholesky factorization is that one can use a variety of reorthogonalization schemes to ensure

[1] Specifically, (2.1) and (2.2) follow from (1.2) and (1.3) with the substitution of I for Λ_y and $p_1^T C, \ldots, p_k^T C$ for the rows of C.

that the Lanczos vectors remain orthogonal and, in turn, that the associated conjugate search directions are Λ_y-conjugate. The simplest scheme is full orthogonalization [5, section 7.4]. This just recomputes h_k as

$$h_k := h_k - \begin{bmatrix} q_1 & \cdots & q_k \end{bmatrix} \begin{bmatrix} q_1 & \cdots & q_k \end{bmatrix}^T h_k \tag{2.13}$$

between the steps in (2.8) and (2.9). This is typically sufficient to ensure orthogonality among the q_i. However, one can also use more complicated schemes that are more efficient such as selective orthogonalization [15]. A discussion of the details can be found in [18, Appendix B]. We have found that the type of orthogonalization used does not significantly affect the quality of the results.

Although one must use an orthogonalization scheme in conjunction with the Lanczos iteration, the added complexity is not prohibitive. Specifically, consider counting the number of floating point operations (flops) required to perform k iterations. We will assume that full orthogonalization is used and that the number of flops required to multiply vectors by Λ_y is linear in either the dimension m of the data or the dimension l of the estimate. Then, the only contribution to the flop count that is second order or higher in k, l, and m is from the orthogonalization, $2mk^2$. For comparison, consider a direct method for computing the error variances that uses Gaussian elimination to invert the symmetric positive definite Λ_y. The flop count is dominated by the elimination, which requires $m^3/3$ flops [8, p. 146]. Thus, our algorithm typically provides a gain if $k < m/6$. For many estimation problems, a reasonable degree of accuracy is attained for $k \ll m$. Some examples are given in section 7.

A summary of the steps outlined above to compute an approximation to the optimal linear least-squares estimate and associated estimation error variances is as follows.

ALGORITHM 2.1.

1. *Initialize* $\hat{x}_0(y) = 0$, $(\Lambda_{e_x,0}(y))_{ii} = (\Lambda_x)_{ii}$ *for* $i = 1, \ldots, l$.
2. *Generate a random vector* s *to initialize the Lanczos iteration.*
3. *At each step* k,
   (a) *compute the conjugate search direction* p_k *and filtered backprojection* $b_{y,k}$ *using a reorthogonalized Lanczos iteration, and*
   (b) *update*

$$\hat{x}_k(y) = \hat{x}_{k-1}(y) + b_{y,k} p_k^T y, \tag{2.14}$$

$$(\Lambda_{e_x,k}(y))_{ii} = (\Lambda_{e_x,k-1}(y))_{ii} - ((b_{y,k})_i)^2 \quad \text{for } i = 1, \ldots, l. \tag{2.15}$$

3. Stopping criteria. A stopping criterion is needed to determine when a sufficient number of iterations has been run to obtain an adequate approximation to the error variances. Two alternative stopping criteria are proposed in this section. The first is a simple scheme that we have found works well. However, there is no systematic method for setting the parameters of the criterion to guarantee that a specified level of accuracy is achieved. The second stopping criterion is a more complicated scheme for which one can establish bounds on the approximation error. However, the criterion tends to be overly conservative in establishing the number of iterations needed to achieve a specified level of accuracy.

3.1. Windowed-maximal-error criterion. Under this first criterion, the algorithm stops iterating after k steps if

$$\tau_{k,\varepsilon_{\min}} \triangleq \max_{k-K_{\text{win}} \le j \le k} \max_i \frac{((b_{y,j})_i)^2}{\max((\Lambda_{e_x,k}(y))_{ii}, \varepsilon_{\min})} < \varepsilon_{\text{tol}}, \tag{3.1}$$

where K_{win}, $\varepsilon_{\min}$, and ε_{tol} are parameters. This criterion guarantees that no components of the error variances have been altered over the last $K_{\text{win}}+1$ iterations by more than ε_{tol} relative to the current approximation to the error variances. The motivation for this criterion is the theorem in section 4 which implies that the vectors $b_{y,k}$, representing the contribution to error reduction from $p_k^T y$, get smaller as k increases. However, this behavior is not always monotone; so, the criterion takes into account gains over a window of the last few iterations.

3.2. Noiseless-estimation-error criterion. The second stopping criterion examines how well the Krylov subspace at the kth step, $\mathcal{K}(\Lambda_y, s, k-1)$, captures the significant components of the signal z, as defined in (1.1). The motivation for such a criterion is the convergence analysis of section 4. A portion of the analysis examines the optimal error covariance for estimating z from y, $\Lambda_{e_z}(y)$, and its relation to the optimal error covariance for estimating z from $p_1^T y, \ldots, p_k^T y$, $\Lambda_{e_z,k}(y)$. The implication is that as $\Lambda_{e_z,k}(y) - \Lambda_{e_z}(y)$ gets smaller, the difference between $\Lambda_{e_x,k}(y)$ and $\Lambda_{e_x}(y)$ also decreases, albeit possibly at a slower rate. So, a relatively small difference between $\Lambda_{e_z,k}(y)$ and $\Lambda_{e_z}(y)$ implies a relatively small difference between $\Lambda_{e_x,k}(y)$ and $\Lambda_{e_x}(y)$. This fact motivates the interest in efficiently computable bounds for $\Lambda_{e_z,k}(y) - \Lambda_{e_z}(y)$. One such bound can be written, as follows, in terms of the error covariance for the noiseless estimation problem of estimating x from z.

PROPOSITION 3.1. *Suppose $\Lambda_n = \sigma^2 I$ for $\sigma^2 > 0$. Let $\Lambda_{e_z,k}(z)$ be the optimal estimation error covariance for estimating z from $p_1^T z, \ldots, p_k^T z$. Then, the difference between the error covariance for estimating z from y and z from $p_1^T y, \ldots, p_k^T y$ is bounded by*

$$\Lambda_{e_z,k}(y) - \Lambda_{e_z}(y) \le \Lambda_{e_z,k}(z) + f_k f_k^T, \tag{3.2}$$

where

$$\|f_k\|^2 \le \|\Lambda_z p_{k-1}\|^2 + \|\Lambda_z p_k\|^2 + \|\Lambda_z p_{k+1}\|^2 + \|\Lambda_z p_{k+2}\|^2. \tag{3.3}$$

Proof. The proof makes use of the Lanczos vectors q_i discussed at the end of section 2. The Lanczos vectors are useful because they form bases for the Krylov subspaces, and they tridiagonalize both Λ_y and Λ_z since $\Lambda_n = \sigma^2 I$, by assumption. Since the Lanczos vectors tridiagonalize Λ_y, $q_i^T y$ is correlated with $q_j^T y$ if and only if i and j differ by at most one. Let $\Lambda_{r_z,k+1}(y)$ denote the error reduction obtained from estimating z with $q_{k+2}^T y, q_{k+3}^T y, \ldots$. Furthermore, let $\Lambda^{\perp}_{r_z,k+1}(y)$ denote the error reduction obtained from estimating z with the random variable formed by making $q_{k+1}^T y$ uncorrelated with $q_i^T y$ for $i \ne k+1$. Then,

$$\Lambda_{e_z}(y) - \Lambda_{e_z,k}(y) = \Lambda_{r_z,k+1}(y) + \Lambda^{\perp}_{r_z,k+1}(y). \tag{3.4}$$

Since y is simply a noisy version of z, $\Lambda_{r_z,k+1}(y) \le \Lambda_{r_z,k+1}(z)$, where $\Lambda_{r_z,k+1}(z)$ is the error reduction obtained from estimating z with $q_{k+2}^T z, q_{k+3}^T z, \ldots$. Furthermore, $\Lambda_{r_z,k+1}(z) \le \Lambda_{e_z,k}(z)$ because $\Lambda_{e_z}(z) = 0$ and $q_i^T z$ is uncorrelated with $q_j^T z$ if i and j differ by more than one. Combining the last two inequalities with (3.4) yields

$$\Lambda_{e_z,k}(y) - \Lambda_{e_z}(y) \le \Lambda_{e_z,k}(z) + \Lambda^{\perp}_{r_z,k+1}(y). \tag{3.5}$$

The matrix $\Lambda^{\perp}_{r_z,k+1}(y)$ in (3.5) is bounded above by the optimal error reduction for estimating z from $q_k^T y$, $q_{k+1}^T y$, and $q_{k+2}^T y$ since $\Lambda^{\perp}_{r_z,k+1}(y)$ is the error reduction

for an estimator that is linear in these three functionals of y. Furthermore, $\Lambda^{\perp}_{r_z,k+1}(y)$ is bounded above by the optimal error reduction for estimating z from $p_{k-1}^T y, \ldots, p_{k+2}^T y$ since q_k, q_{k+1}, and q_{k+2} are linear combinations of $p_{k-1}, \ldots, p_{k+2}$. Now, write the rank-one matrix $\Lambda^{\perp}_{r_z,k+1}(y)$ as $f_k f_k^T$. Then, the latter bound on $\Lambda^{\perp}_{r_z,k+1}(y)$ implies (3.3). □

Although Proposition 3.1 provides a bound on $\|f_k\|^2$, the argument in the proof suggests that the bound is very weak. Recall from the proof that $f_k f_k^T = \Lambda^{\perp}_{r_z,k+1}(y)$, the error reduction obtained for estimating z from the random variable formed by making $q_{k+1}^T y$ uncorrelated with $q_k^T y$ and $q_{k+2}^T y$. Both q_k and q_{k+2}, as vectors from a Krylov subspace generated by Λ_y, are such that $q_k^T y$ and $q_{k+2}^T y$ are significantly correlated with z. Thus, making $q_{k+1}^T y$ uncorrelated with $q_k^T y$ and $q_{k+2}^T y$ will often significantly reduce the correlation of the resulting quantity with z. As a result, $\Lambda^{\perp}_{r_z,k+1}(y)$ is typically much smaller than the error reduction for estimating z from $q_{k+1}^T y$ alone, which, in turn, is smaller than the right-hand side of (3.3). Thus, the bound on $\|f_k\|^2$ is weak, and $\Lambda_{e_z,k}(z)$, the dominant term in (3.2), could be used alone as the basis of a stopping criterion.

One of the main advantages of the bound in Proposition 3.1 is that the diagonal elements of $\Lambda_{e_z,k}(z)$ are easily computable. As discussed in the proof of Proposition 3.1, the Lanczos vectors $q_1, q_2, \ldots$ generated by Algorithm 2.1 not only tridiagonalize Λ_y; they also tridiagonalize Λ_z:

$$\begin{bmatrix} q_1 & q_2 & \cdots & q_k \end{bmatrix}^T \Lambda_z \begin{bmatrix} q_1 & q_2 & \cdots & q_k \end{bmatrix} = T_{z,k}. \tag{3.6}$$

Let $L_{z,k}$ be the lower bidiagonal Cholesky factor of $T_{z,k}$, and let the vectors $r_1, r_2, \ldots$ be defined by

$$\begin{bmatrix} r_1 & r_2 & \cdots & r_k \end{bmatrix} = \begin{bmatrix} q_1 & q_2 & \cdots & q_k \end{bmatrix} L_{z,k}^{-T}. \tag{3.7}$$

Then, the linear functionals of the signal $r_1^T z, r_2^T z, \ldots$ are white. So, a simple recursion can be used to compute $\Lambda_{e_z,k}(z)$:

$$(\Lambda_{e_z,k}(z))_{ii} = (\Lambda_{e_z,k-1}(z))_{ii} - ((b_{z,k})_i)^2 \tag{3.8}$$

with the initialization

$$(\Lambda_{e_z,0}(z))_{ii} = (\Lambda_z)_{ii}, \tag{3.9}$$

where $i = 1, \ldots, m$ and $b_{z,k} = \Lambda_z r_k$. Note that $b_{z,k}$ can be computed without an additional multiplication by Λ_z since Algorithm 2.1 computes $\Lambda_z q_i$. The computations for calculating $\Lambda_{e_z,k}(z)$ are summarized as follows.

ALGORITHM 3.2.

1. *Initialize* $(\Lambda_{e_z,0}(z))_{ii} = (\Lambda_z)_{ii}$.
2. *At each iteration* k*:*
   (a) *compute* $b_{z,k}$ *using* q_k *and the one-step recursion specified by* $L_{z,k}^T$*, and*
   (b) *update*

$$(\Lambda_{e_z,k}(z))_{ii} = (\Lambda_{e_z,k-1}(z))_{ii} - ((b_{z,k})_i)^2. \tag{3.10}$$

Stopping Algorithm 2.1 when a function of $(\Lambda_{e_z,k}(z))_{ii}$ falls below some threshold has a variety of advantages and disadvantages. Although it may appear that one of the main disadvantages is the requirement that Λ_n must be a multiple of the identity,

this is not the case. There is an extension to the nonwhite case that makes use of preconditioning ideas, as discussed in section 5. In fact, the main disadvantage stems from the bound in Proposition 3.1 being based on the noiseless estimation problem (i.e., $\Lambda_n = 0$). If Λ_n is not small, the bound may not be tight. Thus, a stopping criterion based on $\Lambda_{e_z,k}(z)$ may be conservative in determining the number of iterations needed to guarantee a specified level of accuracy. On the other hand, the bound is easy to compute and provides a good indication of the fraction of error reduction that has been attained by a specific iteration.

4. The main convergence result. In this section, we state the main convergence result. It establishes a bound on the rate at which the approximation to the error variances, in exact arithmetic, converges to the optimal estimation error variances. The result leads naturally to a consideration of the two acceleration techniques discussed in the next section. The proof of the main result is left for section 6.

Establishing the convergence result requires making a few assumptions concerning the estimation problem and starting vector for the algorithm. The first is that the starting vector s in Algorithm 2.1 is a zero-mean Gaussian random vector. This assumption is needed to guarantee the independence of uncorrelated components of s. The covariance matrix of s, Λ_s, is assumed to equal Λ_y or to be proportional to the identity. As regards the estimation problem for the purposes of this section, Λ_n is not necessarily a multiple of the identity. However, we do assume that Λ_y and Λ_z have the same eigenvectors $u_1, u_2, \ldots, u_m$ and that the corresponding eigenvalues $\lambda_{y,1} \geq \lambda_{y,2} \geq \cdots \geq \lambda_{y,m}$ and $\lambda_{z,1} \geq \lambda_{z,2} \geq \cdots \geq \lambda_{z,m}$ satisfy the inequality, $\lambda_{z,i}/\lambda_{y,i} \leq \bar{\lambda}_i/\sigma^2$ for some $\sigma^2 > 0$ and sequence $\bar{\lambda}_i$. Note that both of these statements would hold for $\bar{\lambda}_i = \lambda_{z,i}$ if Λ_n were $\sigma^2 I$. The conditions are stated this generally because Λ_n may not be a multiple of the identity if some of the preconditioning techniques of section 5.1 are used. We also assume that the eigenvalues of Λ_y are distinct and have a relative separation $(\lambda_{y,i} - \lambda_{y,i+1})/(\lambda_{y,i+1} - \lambda_{y,m})$ that is bounded below by a constant $\lambda_{\text{sep}} > 0$. Furthermore, the $\lambda_{y,i}$ are assumed to decrease slowly enough (not faster than a geometric decay) that one can find constants $\zeta > 0$ and $0 < \Gamma < 1$ of reasonable magnitude (ζ not much larger than $\|\Lambda_y\|$) for which $1/(\lambda_{y,k}\gamma^k) < \zeta\Gamma^k$, where

$$\gamma \triangleq 1 + 2\left(\lambda_{\text{sep}} + \sqrt{\lambda_{\text{sep}} + \lambda_{\text{sep}}^2}\right). \tag{4.1}$$

This last assumption is a very weak assumption that is almost never violated. All of these assumptions concerning the estimation problem are not restrictive because they can be guaranteed using appropriate preconditioning techniques, as described in section 5. The assumptions are summarized as follows.

Assumptions.

1. The starting vector s in Algorithm 2.1 is a zero-mean Gaussian random vector, and $\Lambda_s = \Lambda_y$ or $\Lambda_s \propto I$.
2. There exist constants $\zeta > 0$ and $0 < \Gamma < 1$ such that $1/(\lambda_{y,k}\gamma^k) < \zeta\Gamma^k$.
3. Λ_y and Λ_z have the same eigenvectors.
4. There exist a constant $\sigma^2 > 0$ and a sequence $\bar{\lambda}_i$ such that $\lambda_{z,i}/\lambda_{y,i} \leq \bar{\lambda}_i/\sigma^2$.
5. There exists a constant $\lambda_{\text{sep}} > 0$ such that $(\lambda_{y,i} - \lambda_{y,i+1})/(\lambda_{y,i+1} - \lambda_{y,m}) \geq \lambda_{\text{sep}} > 0$.

These assumptions lead to the main convergence result, as stated next in Theorem 4.1. The theorem consists of two bounds, one concerning the error variances for estimating x, and one concerning the error variances for estimating only the measured

components of x, $z = Cx$. Two bounds are given because one may need fewer iterations to obtain a good estimate of z than of x. Moreover, the rate of convergence of the error variance for estimating z is of interest since z is often a subsampled version of x.[2]

THEOREM 4.1. *If Assumptions* 1–5 *hold, then*

(4.2)
$$\sum_{j=1}^{m}(\Lambda_{e_x,k}(y) - \Lambda_{e_x}(y))_{jj} \leq \frac{\|s\|^2\zeta\eta\|\Lambda_x\|\|\Lambda_y\|}{\sigma^2(1-\frac{1}{\gamma^2})(1-\frac{1}{\sqrt[4]{\gamma}})}\gamma^{-k/4} + \frac{\|\Lambda_x\|}{\sigma^2}\sum_{i=k}^{m-1}(i-k+4)\bar{\lambda}_{\lfloor\frac{i}{4}\rfloor}$$

and

$$\sum_{j=1}^{m}(\Lambda_{e_z,k}(y) - \Lambda_{e_z}(y))_{jj} \leq \frac{\|s\|^2\zeta\eta\|\Lambda_y\|}{(1-\frac{1}{\gamma^2})(1-\frac{1}{\sqrt{\gamma}})}\gamma^{-k/2} + \sum_{i=k}^{m-1}(i-k+4)\min\left(\frac{\bar{\lambda}_{\lfloor\frac{i}{4}\rfloor}\lambda_{z,\lfloor\frac{i}{4}\rfloor}}{\sigma^2}, \bar{\lambda}_{\lfloor\frac{i}{4}\rfloor}\right), \tag{4.3}$$

where γ *is given by* (4.1) *and* η *is a random variable whose statistics depend only on* λ_{sep}, γ, *and* Γ.

The bounds in Theorem 4.1 provide a characterization of the difference between the optimal error variances and the computed approximation. The bounds are a sum of two terms. The first terms on the right-hand sides of (4.2) and (4.3) characterize how well the Krylov subspaces have captured the dominant components of Λ_y. The bigger λ_{sep} is, the larger γ is, and the smaller the first terms in (4.2) and (4.3) become. Thus, the more separated the eigenvalues (as measured by λ_{sep}) are, the better the algorithm will perform. The second term is a sum of bounds $\bar{\lambda}_i$ on the ratio of eigenvalues $\lambda_{z,i}/\lambda_{y,i}$. The sum is over those $\bar{\lambda}_i$ corresponding to eigenvectors of Λ_z that are not well captured by the Krylov subspaces at step k. Note that the sum is over the more rapidly decreasing $\bar{\lambda}_i\lambda_{z,i}$ in (4.3).

The bounds are useful principally for two reasons. First, they indicate how the errors will scale as s, σ^2, $\|\Lambda_x\|$, $\|\Lambda_y\|$, and the eigenvalues of Λ_z change. In particular, note that the only dependence on the starting vector s is through the norm $\|s\|$. Thus, the performance of the algorithm does not depend strongly on s. Second, the bounds indicate that the rate of convergence can be increased by transforming the estimation problem in order to make γ big enough so that the second terms in (4.2) and (4.3) dominate. Such transformations are discussed next in section 5.1.

5. Techniques for improving convergence properties. This section presents two different techniques for improving the convergence properties of the proposed algorithm for computing error variances. These techniques can be used to guarantee convergence in the case that a given estimation problem violates any of the assumptions of Theorem 4.1. One can also use these techniques to increase γ so as to improve the theoretical convergence rates.

5.1. Preconditioning. In the estimation context, preconditioning consists of determining an invertible transformation B such that estimating x from the transformed data By can be theoretically done more efficiently by the proposed algorithm

[2]That the two bounds differ is a consequence of the fact that, for a given number of iterations k, we are not computing the best k linear functionals of the data for estimating x.

than estimating x directly from y. This will be the case if the covariances of the transformed data, $B\Lambda_y B^T$, and of the transformed signal, $B\Lambda_z B^T$, satisfy Assumptions 3 and 5 of Theorem 4.1 but Λ_y and Λ_z do not. The convergence properties will also be improved if γ for the transformed problem is higher than for the untransformed problem. The principal novelty of the preconditioning approaches described here is that they focus on these particular goals, which are very different than those of standard CG preconditioning and differ significantly from those of preconditioning for eigenvector algorithms [17, Chapter 8]. Although the goals of the preconditioning discussed here are different than for standard CG, the implementation details are very similar. In particular, explicit specification of a transformation B is not necessarily required for preconditioning techniques because preconditioning can be implemented in such a way that only multiplications by $B^T B$ are needed instead of multiplications by B and B^T.

There are three different implementations of preconditioning, each of which is mathematically equivalent in exact arithmetic. Symmetric preconditioning simply consists of applying the Krylov subspace algorithm to estimating x from $By = BCx + Bn$. Essentially, x is estimated given linear functionals from Krylov subspaces $\mathcal{K}(B\Lambda_y B^T, Bs, k)$ applied to By. There are also left and right preconditioning techniques. The following discussion focuses on right preconditioning, and analogous statements can be made concerning left preconditioning. Right preconditioning differs from symmetric preconditioning in that it involves estimating x given linear functionals from the Krylov subspaces $\mathcal{K}(\Lambda_y B^T B, s, k)$ applied to $B^T By$. Note that this is equivalent to the estimation performed in the case of symmetric preconditioning. Although $\Lambda_y B^T B$ is not symmetric, it is self-adjoint with respect to the $B^T B$ inner product. As in Algorithm 2.1, we do not compute the conjugate search directions for the preconditioned estimation problem using a standard preconditioned CG iteration. Instead, we use Lanczos iterations that compute a series of $B^T B$-conjugate vectors that tridiagonalize $B^T B\Lambda_y B^T B$, as follows:

$$\alpha_k = t_k^T \Lambda_y t_k, \tag{5.1}$$

$$h_k = \Lambda_y t_k - \alpha_k q_k - \beta_k q_{k-1}, \tag{5.2}$$

$$d_k = B^T B h_k, \tag{5.3}$$

$$\beta_{k+1} = \sqrt{d_k^T h_k}, \tag{5.4}$$

$$q_{k+1} = \frac{h_k}{\beta_{k+1}}, \tag{5.5}$$

$$t_{k+1} = \frac{d_k}{\beta_{k+1}}, \tag{5.6}$$

where $t_1 = B^T Bs$, $q_1 = s$, $q_0 = 0$, and $\beta_1 = 0$. The q_k are the $B^T B$-conjugate Lanczos vectors that tridiagonalize $B^T B\Lambda_y B^T B$, and the $t_k = B^T Bq_k$ tridiagonalize Λ_y. This latter tridiagonal matrix can be factored, as in Algorithm 2.1, to compute the Λ_y-conjugate search directions p_k. The only difference is that the t_k replace the q_k in (2.11) and (2.12). Moreover, one can compute the filtered backprojected search directions $b_{y,k} = \Lambda_x C^T p_k$ as a by-product. Overall, the steps of the preconditioned Krylov subspace algorithm are the same as those in Algorithm 2.1 except that a preconditioned Lanczos iteration replaces the normal Lanczos iteration. Note that the Lanczos method for tridiagonalizing a left-preconditioned system is the same as the generalized Lanczos algorithm for solving generalized eigenvalue problems [14,

section 15.11]. What follows are some examples of preconditioners in squared up form, B^TB, that one can consider using in various contexts.

One choice for a preconditioner when the noise covariance Λ_n is not a multiple of the identity but is invertible is to choose $B^TB = \Lambda_n^{-1}$. This choice of preconditioner will effectively shape the noise covariance to be a multiple of the identity. The transformed data covariance, $B\Lambda_yB^T$, and signal covariance, $B\Lambda_zB^T$, will then satisfy Assumption 3. Multiplying a vector by Λ_n^{-1} is often easy because Λ_n is often diagonal.

If the noise covariance is, or has been transformed to be, a multiple of the identity, one can consider preconditioners that will maximally separate the eigenvalues of Λ_y. Such preconditioners can guarantee that the transformed data covariance, $B\Lambda_yB^T$, satisfies Assumption 5 and can increase γ to improve the bounds in Theorem 4.1. Note that such preconditioning will do little to change the bound $\bar{\lambda}_i$ on $\lambda_{z,i}/\lambda_{y,i}$ in Assumption 4 because the preconditioner will transform both $\lambda_{z,i}$ and $\lambda_{y,i}$. The ideal preconditioner would simply operate on the spectrum of Λ_y and force a geometric decay in the eigenvalues to the noise level σ^2. The geometric decay guarantees a constant relative separation in the eigenvalues as measured by the ratio in Assumption 5. However, operating on the spectrum is difficult because one doesn't know the eigendecomposition of Λ_y. When the rows of C are orthogonal (which is often the case in the applications mentioned in the introduction) and the eigendecomposition of Λ_x is known, one practical preconditioner is the following. Let Λ_p be a matrix whose eigenvectors are the same as those of Λ_x and whose eigenvalues decay geometrically. Then, let the preconditioner be given by $B^TB = C\Lambda_pC^T$. Although this preconditioner has worked well in practice, as described in section 7, we have no theoretical results concerning the properties of the transformed estimation problem.

One can use extensions of each of the stopping criteria of section 3 in conjunction with preconditioning; however, the preconditioner must satisfy certain assumptions for the extension of the noiseless-estimation stopping criterion of section 3.2 to be used. What follows is a discussion of the extension and the underlying assumptions concerning the preconditioner for the right-preconditioned case. Recall that the discussion in section 3.2 assumes that the noise covariance is a multiple of the identity. This assumption ensures that the Lanczos vectors tridiagonalize both Λ_y and Λ_z so that one can compute $\Lambda_{e_z,k}(z)$ efficiently. Now, suppose one is using a preconditioning transformation B. Let $\Lambda_{n'} = \Lambda_n - (B^TB)^{-1}$. Assume that $\Lambda_{n'}$ is positive semidefinite so that it is a valid covariance matrix. Let n' be a random vector with covariance $\Lambda_{n'}$ and uncorrelated with z. Then, $z' = z + n'$ has covariance $\Lambda_{z'} = \Lambda_z + \Lambda_{n'}$. One can compute $\Lambda_{e_z,k}(z')$ efficiently because the t_k in (5.1)–(5.6) tridiagonalize both Λ_y and $\Lambda_{z'}$. For $\Lambda_{e_z,k}(z')$ to be useful, the pseudosignal z' should not have any significant components not in z. Note that an example of a preconditioner satisfying the above two assumptions is given by $B^TB = \Lambda_n^{-1}$. For this preconditioner, $\Lambda_{n'} = 0$; so, $\Lambda_{e_z,k}(z) = \Lambda_{e_z,k}(z')$. Thus, one can use $\Lambda_{e_z,k}(z')$ as part of a stopping criterion in conjunction with preconditioning provided that the preconditioner satisfies the two assumptions outlined above.

5.2. Using multiple starting vectors. Another technique for improving convergence properties in the case where Λ_y has repeated eigenvalues is to use a block form of Algorithm 2.1. Block Krylov subspace algorithms have been developed for other computations, particularly eigendecompositions [8, section 9.2.6]. The principal novelty of the algorithm we present here is the application to estimation.

Now consider the subspace spanned by the columns of

$$\begin{bmatrix} S & \Lambda_y S & \Lambda_y^2 S & \cdots & \Lambda_y^{k-1} S \end{bmatrix}, \tag{5.7}$$

where S is an $m \times r$ matrix of independent identically distributed random starting vectors whose marginal statistics satisfy the restrictions for Algorithm 2.1 starting vectors. Denote this subspace by $\mathcal{K}(\Lambda_y, S, k)$. Then, one can consider forming $m \times r$ matrices $P_1, \ldots, P_k$ whose columns form bases for $\mathcal{K}(\Lambda_y, S, k)$ and which satisfy $P_i^T \Lambda_y P_j = \delta_{ij} I$. As for the single starting vector case in section 2, the LLSE of x given the random vectors $P_1^T y, \ldots, P_k^T y$ and the associated error variances can be computing using a recursion:

$$\hat{x}_k(y) = \hat{x}_{k-1}(y) + B_{y,k} P_k^T y, \tag{5.8}$$

$$(\Lambda_{e_x,k}(y))_{ii} = (\Lambda_{e_x,k-1}(y))_{ii} - \sum_{j=1}^{r} ((B_{y,k})_{ij})^2, \tag{5.9}$$

with initial conditions

$$\hat{x}_0(y) = 0, \tag{5.10}$$

$$(\Lambda_{e_x,0}(y))_{ii} = (\Lambda_x)_{ii}, \tag{5.11}$$

where $i = 1, \ldots, l$ and $B_{y,k} = \Lambda_x C^T P_k$.

The P_i and $B_{y,i}$ can be computed using a reorthogonalized block Lanczos algorithm [8, section 9.2.6]. The block Lanczos iteration generates, according to the following recursions, a sequence of orthogonal matrices Q_i that are orthogonal to each other:

$$A_k = Q_k^T \Lambda_y Q_k, \tag{5.12}$$

$$H_k = \Lambda_y Q_k - Q_k A_k - Q_{k-1} R_k, \tag{5.13}$$

$$Q_{k+1} R_{k+1} = H_k \quad \text{(QR factorization of } H_k\text{)}, \tag{5.14}$$

where Q_1 and R_1 are a QR factorization of the starting matrix S, and $Q_0 = 0$. The Q_i block tridiagonalize Λ_y; so, one can write

$$\begin{bmatrix} Q_1 & \cdots & Q_k \end{bmatrix}^T \Lambda_y \begin{bmatrix} Q_1 & \cdots & Q_k \end{bmatrix} = T_{y,k}, \tag{5.15}$$

where $T_{y,k}$ is a block tridiagonal matrix. Let $L_{y,k}$ be the lower block bidiagonal Cholesky factor of $T_{y,k}$. Then, the P_i are defined by

$$\begin{bmatrix} P_1 & \cdots & P_k \end{bmatrix} \triangleq \begin{bmatrix} Q_1 & \cdots & Q_k \end{bmatrix} L_{y,k}^{-T}. \tag{5.16}$$

Thus, the P_i can be computed from the Q_i using a one-step recursion. Moreover, the $B_i = \Lambda_x C^T P_i$ can be computed as a by-product, as with a single starting vector.

As for the single starting vector case in section 2, the block Lanczos iteration must be combined with some form of reorthogonalization. Unlike the previous case, however, there are not as many methods for reorthogonalizing the block Lanczos iteration. Full orthogonalization is very common and is the method we have used. This simply recomputes H_k as

$$H_k := H_k - \begin{bmatrix} Q_1 & \cdots & Q_k \end{bmatrix} \begin{bmatrix} Q_1 & \cdots & Q_k \end{bmatrix}^T H_k \tag{5.17}$$

between steps (5.12) and (5.13).

The algorithm is summarized as follows.

ALGORITHM 5.1.

1. *Initialize* $\hat{x}_0(y) = 0$, $(\Lambda_{e_x,0}(y))_{ii} = (\Lambda_x)_{ii}$ *for* $i = 1, \ldots, l$.
2. *Generate a random* $m \times r$ *matrix* S *to initialize the block Lanczos iteration.*
3. *At each step* k,
   (a) *compute the block of search directions* P_k *and filtered backprojections* $B_{y,k}$ *using a reorthogonalized block Lanczos iteration, and*
   (b) *update*

$$\hat{x}_k(y) = \hat{x}_{k-1}(y) + B_{y,k} P_k^T y, \tag{5.18}$$

$$(\Lambda_{e_x,k}(y))_{ii} = (\Lambda_{e_x,k-1}(y))_{ii} - \sum_{j=1}^{r} ((B_{y,k})_{ij})^2 \quad \text{for } i = 1, \ldots, l. \tag{5.19}$$

The advantage of using the block form is that there may be small angles between the subspaces $\mathcal{K}(\Lambda_y, S, k)$ and multiple orthogonal eigenvectors of Λ_y associated with the same repeated eigenvalue, even in exact arithmetic. This is because each of the columns of S may have linearly independent projections onto the eigenspace associated with a repeated eigenvalue. The following theorem establishes convergence rates for the block case when there may be repeated eigenvalues. It is an extension of Theorem 4.1 to the block case. The proofs of both theorems are very similar, so the proof of Theorem 5.2 is omitted.[3]

THEOREM 5.2. *Suppose the following.*

1. *There exists a constant* $\lambda_{\text{sep},r} > 0$ *such that* $(\lambda_{y,i} - \lambda_{y,i+r})/(\lambda_{y,i+r} - \lambda_{y,m}) \geq \lambda_{\text{sep},r}$.
2. *There exist constants* $\zeta > 0$ *and* $0 < \Gamma < 1$ *such that* $1/(\lambda_{y,i}\gamma_r^i) < \zeta\Gamma^i$, *where*

$$\gamma_r \triangleq 1 + 2\left(\lambda_{\text{sep},r} + \sqrt{\lambda_{\text{sep},r} + \lambda_{\text{sep},r}^2}\right). \tag{5.20}$$

3. Λ_y *and* Λ_z *have the same eigenvectors.*
4. *There exist a constant* $\sigma^2 > 0$ *and a sequence* $\bar{\lambda}_i$ *such that* $\lambda_{z,i}/\lambda_{y,i} \leq \bar{\lambda}_i/\sigma^2$.
5. $(\lambda_{y,i} - \lambda_{y,i_+})/(\lambda_{y,i_+} - \lambda_{y,m})$ *is bounded away from zero, where* i_+ *is the index of the next smallest distinct eigenvalue of* Λ_y *after* i, *and then,*

$$\sum_{j=1}^{m} (\Lambda_{e_x,k}(y) - \Lambda_{e_x}(y))_{jj} \leq \frac{\eta \|\Lambda_x\| \|\Lambda_y\|}{\sigma^2 (1 - \frac{1}{\gamma_r^2})(1 - \frac{1}{\sqrt[4]{\gamma_r}})} \gamma_r^{-k/4} + \frac{\|\Lambda_x\|}{\sigma^2} \sum_{i=k}^{m-1} (i - k + 4) \bar{\lambda}_{\lfloor \frac{i}{4} \rfloor} \tag{5.21}$$

and

$$\sum_{j=1}^{m} (\Lambda_{e_z,k}(y) - \Lambda_{e_z}(y))_{jj} \leq \frac{\eta \|\Lambda_y\|}{(1 - \frac{1}{\gamma_r^2})(1 - \frac{1}{\sqrt{\gamma_r}})} \gamma_r^{-k/2} + \sum_{i=k}^{m-1} (i - k + 4) \min\left(\frac{\bar{\lambda}_{\lfloor \frac{i}{4} \rfloor} \lambda_{z,\lfloor \frac{i}{4} \rfloor}^2}{\sigma^2}, \bar{\lambda}_{\lfloor \frac{i}{4} \rfloor} \right), \tag{5.22}$$

where the statistics of the random variable η *depend on the starting matrix* S.

There are two key differences between the statements of Theorems 4.1 and 5.2. The first addresses the possibility of repeated eigenvalues. Specifically, the bounds in

[3] A proof may be found in [18, Appendix A].

Theorem 5.2 depend on the eigenvalue separation through $\lambda_{\text{sep},r}$, which measures the relative separation between eigenvalues whose indices differ by r. Thus, the proposition establishes a convergence rate in the case where there may be groups of up to r repeated or clustered eigenvalues. The second key difference is that the bounds in Theorem 5.2 may have a strong dependence on the starting matrix. This contrasts with the bounds in Theorem 4.1 which depend on the starting vector s only through the norm $\|s\|$. However, our numerical results have not indicated that the block algorithm's performance depends strongly on the starting matrix S.

One can use natural extensions of the preconditioning techniques and either of the stopping criteria of section 3 with Algorithm 5.1. Thus, Algorithm 5.1 is a simple replacement for Algorithm 2.1 that can be used to obtain better convergence properties when Λ_y has repeated eigenvalues.

6. Convergence analysis. The bounds in Theorem 4.1 are proved in this section in several steps. The first few steps place bounds on the norms of the filtered backprojected conjugate search directions, $\|\Lambda_x C^T p_i\|$ and $\|C\Lambda_x C^T p_i\|$. The bounds are proved using Saad's convergence theory for the Lanczos algorithm [16]. These bounds are stated in terms of an extremum of independent random variables. The extremum arises because the starting vector affects the angles between the Krylov subspaces and the dominant components of Λ_y. However, we prove that the extremum is part of a sequence of extrema that are converging in probability to a finite random variable (η in Theorem 4.1). Thus, the starting vector has no strong effect on the quality of the approximation to the error variances. This result is the principal novelty of our convergence analysis. After establishing the convergence of the extrema, we prove Theorem 4.1.

6.1. Bounds on the filtered backprojected search directions. One is interested in bounding the norms of the filtered backprojected search directions because the quality of the approximation to the error variances depends on the norms as follows:

$$\sum_{j=1}^{l}(\Lambda_{e_x,k}(y) - \Lambda_{e_x}(y))_{jj} = \sum_{i=k+1}^{l} \|\Lambda_x C^T p_i\|^2, \tag{6.1}$$

$$\sum_{j=1}^{l}(\Lambda_{e_z,k}(y) - \Lambda_{e_z}(y))_{jj} = \sum_{i=k+1}^{l} \|C\Lambda_x C^T p_i\|^2. \tag{6.2}$$

PROPOSITION 6.1. *Write the conjugate search directions in the basis of eigenvectors of Λ_y as follows:*

$$p_i = \upsilon_{i,1} u_1 + \cdots + \upsilon_{i,m} u_m. \tag{6.3}$$

Then

$$\|\Lambda_x C^T p_i\|^2 \le \|\Lambda_x\| \sum_{j=1}^{m} \lambda_{z,j} \upsilon_{i,j}^2, \tag{6.4}$$

and

$$\|C\Lambda_x C^T p_i\|^2 = \sum_{j=1}^{m} \lambda_{z,j}^2 \upsilon_{i,j}^2. \tag{6.5}$$

Proof. $\|\Lambda_x C^T p_i\|^2 \le \|\Lambda_x\| \|\Lambda_x^{1/2} C^T p_i\|^2 = \|\Lambda_x\| \sum_{j=1}^m \lambda_{z,j} \upsilon_{i,j}^2$. This proves the first inequality. The second inequality follows from Parseval's theorem. ∎

As we now show, one can bound the coefficients $\upsilon_{i,j}$ in terms of $\|(I-\pi_i)u_j\|/\|\pi_i u_j\|$, where π_i is the operator that produces the orthogonal projection onto $\mathcal{K}(\Lambda_y, s, i)$ with respect to the standard inner product.

PROPOSITION 6.2. *Write* $p_i = \upsilon_{i,1}u_1 + \cdots + \upsilon_{i,m}u_m$ *as in Proposition* 6.1. *Then*

$$|\upsilon_{i+1,j}| \le \frac{\|\Lambda_y\|^{1/2}}{\lambda_{y,j}} \frac{\|(I-\pi_i)u_j\|}{\|\pi_i u_j\|}. \tag{6.6}$$

Proof. Note that

$$\begin{aligned} \lambda_{y,j}|\upsilon_{i+1,j}| &= |p_{i+1}^T \Lambda_y u_j| \\ &= |p_{i+1}^T \Lambda_y \pi_i u_j + p_{i+1}^T \Lambda_y (I-\pi_i) u_j| \\ &= |p_{i+1}^T \Lambda_y (I-\pi_i) u_j| \end{aligned} \tag{6.7}$$

since p_{i+1} is Λ_y-conjugate to vectors in the range of π_i. Thus, $\lambda_{y,j}|\upsilon_{i+1,j}| \le \|\Lambda_y p_{i+1}\| \cdot \|(I-\pi_i)u_j\| \le \|\Lambda_y\|^{1/2} \|(I-\pi_i)u_j\|$ because of the Cauchy–Schwarz inequality and the fact that p_{i+1} is Λ_y-normal. The inequality in (6.6) then follows from $\|\pi_i u_j\| \le 1$. ∎

The bound in Proposition 6.2 can be refined. In particular, a theorem due to Saad [16, Theorem 1] implies the following result concerning the ratio $\|(I-\pi_i)u_j\|/\|\pi_i u_j\|$, which we state without proof.

THEOREM 6.3. *Let* γ *be defined by* (4.1), *and let* K_j *be defined by*

$$K_j \triangleq \begin{cases} \prod_{k=1}^{j-1} \frac{\lambda_{y,k}-\lambda_{y,m}}{\lambda_{y,k}-\lambda_{y,j}} & \text{if } j \ne 1, \\ 1 & \text{if } j = 1. \end{cases} \tag{6.8}$$

Then

$$\frac{\|(I-\pi_i)u_j\|}{\|\pi_i u_j\|} \le \frac{2K_j}{\gamma^{i-j}} \frac{1}{\|\pi_1 u_j\|}. \tag{6.9}$$

Recall, from the definition of angles between subspaces given in section 2, that $\|(I-\pi_i)u_j\|/\|\pi_i u_j\|$ is the tangent of the angle between the Krylov subspace $\mathcal{K}(\Lambda_y, s, i)$ and the eigenvector u_j. Theorem 6.3 bounds the rate at which these angles decrease as the subspace dimension i increases. The bound has three components. The rate of decay is γ, the relative separation between eigenvalues as defined in (4.1). The constant in the numerator, $2K_j$, depends on the eigenvalues according to (6.8). The numerator, $\|\pi_1 u_j\|$, is the norm of the projection of the starting vector, s, onto u_j. The primary importance of the theorem is that it establishes the decay rate γ.

One can refine the bound in Proposition 6.2 by splitting the coefficients $\upsilon_{i,j}$ into two groups: those that are getting small by Proposition 6.2 and Theorem 6.3 and those that may be large but do not significantly affect $\|\Lambda_x C^T p_i\|$ because the corresponding eigenvalues of Λ_z are small. This idea leads to the following proposition.

PROPOSITION 6.4.

$$\|\Lambda_x C^T p_{i+1}\|^2 \le 4\|\Lambda_x\|\|\Lambda_y\| \sum_{j=1}^{\lfloor \frac{i}{4} \rfloor - 1} K_j^2 \frac{1}{\gamma^{2(i-j)} \|\pi_1 u_j\|^2} \frac{\lambda_{z,j}}{\lambda_{y,j}^2} + \|\Lambda_x\| \sum_{j=\lfloor \frac{i}{4} \rfloor}^{\infty} \frac{\lambda_{z,j}}{\lambda_{y,j}}, \tag{6.10}$$

and

$$\|C\Lambda_x C^T p_{i+1}\|^2 \le 4\|\Lambda_y\| \sum_{j=1}^{\lfloor \frac{i}{4} \rfloor - 1} K_j^2 \frac{1}{\gamma^{2(i-j)}\|\pi_1 u_j\|^2} \frac{\lambda_{z,j}^2}{\lambda_{y,j}^2} + \sum_{j=\lfloor \frac{i}{4} \rfloor}^{\infty} \frac{\lambda_{z,j}^2}{\lambda_{y,j}}. \tag{6.11}$$

Proof. The first term in each of (6.10) and (6.11) follows immediately from Propositions 6.1 and 6.2 and Theorem 6.3. The second term follows from Proposition 6.1 and the fact that $p_{i+1}^T \Lambda_y p_{i+1} = \sum_{j=1}^m \lambda_{y,j} v_{i+1,j}^2 = 1$. ∎

The first terms in the bounds of Proposition 6.4 may get large if $1/(\gamma^i \|\pi_1 u_j\|^2)$ or K_j are not well behaved. However, the standing assumptions concerning the eigenvalues of Λ_y, Λ_z, and Λ_s imply that K_j and $1/(\gamma^i \|\pi_1 u_j\|^2)$ are bounded by quantities of a reasonable magnitude, as we now show.

6.2. Convergence of infinite products and extrema of independent sequences. The main result regarding the convergence of infinite products and extrema of independent sequences is the following.

PROPOSITION 6.5. *Let $F_i(v)$, $i = 1, 2, \ldots$, be a sequence of functions such that*

1. *$1 - F_i(v)$ is a cumulative distribution function, i.e., right-continuous and monotonically increasing from zero to one;*
2. *for every interval $[V, \infty)$ over which $1 - F_i(v)$ are positive, there exist a constant $A(V)$ and an absolutely summable sequence $\bar{F}_i(V)$ such that $F_i(V) \le \bar{F}_i(V) \le A(V) < 1$ $\forall i$; and*
3. *$\lim_{v \to \infty} \sum_{i=1}^{\infty} F_i(v) = 0$.*

Then, $F(v) = \prod_{i=1}^{\infty}(1 - F_i(v))$ is a distribution function. Moreover, $F(v)$ is positive over every interval such that $1 - F_i(v)$ is positive $\forall i$.

Proof. For $F(v)$ to be a distribution function, it must be right-continuous and monotonically increasing from zero to one.

Consider the interval $[V, \infty)$. Now, $\sum_{i=1}^{I} \log(1 - F_i(v))$ is right-continuous for each I since each $F_i(v)$ is right-continuous. Furthermore,

$$\begin{aligned} \left| \log(F(v)) - \sum_{i=1}^{I} \log(1 - F_i(v)) \right| &= \left| \sum_{i=I+1}^{\infty} \log(1 - F_i(v)) \right| \le \left| \sum_{i=I+1}^{\infty} \log(1 - \bar{F}_i(V)) \right| \\ &= \left| \sum_{i=I+1}^{\infty} \sum_{j=1}^{\infty} \frac{\bar{F}_i^j(V)}{j} \right| \le \left| \sum_{i=I+1}^{\infty} \frac{\bar{F}_i(V)}{1 - A(V)} \right|. \end{aligned} \tag{6.12}$$

Since $\bar{F}_i(V)$ is absolutely summable, $\sum_{i=1}^{I} \log(1 - F_i(v))$ converges to $\log(F(v))$ uniformly for $v \in [V, \infty)$. Thus, $\log(F(v))$ and, in turn, $F(v)$ are right-continuous.

That $F(v)$ is monotonic follows from the monotonicity of the $1 - F_i(v)$. Now, $\lim_{v \to -\infty} F(v) = 0$ since $\lim_{v \to -\infty}(1 - F_1(v)) = 0$. Moreover,

$$\lim_{v \to \infty} \log(F(v)) \ge \lim_{v \to \infty} \sum_{i=1}^{\infty} \frac{-F_i(v)}{1 - A(V)} = 0, \tag{6.13}$$

where V is such that $1 - F_i(v)$ is positive over $[V, \infty)$ $\forall i$. So, $\lim_{v \to \infty} F(v) = 1$.

Furthermore, if $1 - F_i(v)$ is positive $\forall i$ over an interval $[V, \infty)$, then

$$\log(F(v)) \ge \sum_{i=1}^{\infty} \frac{-\bar{F}_i(V)}{1 - A(V)} > -\infty. \tag{6.14}$$

Hence, $F(v)$ is positive over every interval such that $1 - F_i(v)$ is positive $\forall i$. □

A particular example of such a sequence of functions $F_i(v)$ satisfying the assumptions of Proposition 6.5 is

$$F_i(v) = \begin{cases} 1, & v < 0, \\ (1-v)^i, & 0 \le v \le 1, \\ 0, & v > 1. \end{cases} \tag{6.15}$$

Thus, any product of numbers converging geometrically fast towards one is bounded away from zero, and the product is continuously varying from zero to one as the geometric rate changes from one to zero. This fact is used in the proof of the following proposition, which bounds the constants K_j.

PROPOSITION 6.6. *There exists a function $K(v)$ which is continuous and monotonically decreasing from infinity to one as v ranges from zero to infinity and satisfies*

$$K_j \le K(\lambda_{\text{sep}}). \tag{6.16}$$

Proof.

$$\begin{aligned} \frac{1}{K_j} &= \prod_{k=1}^{j-1} \frac{\lambda_{y,k} - \lambda_{y,j}}{\lambda_{y,k} - \lambda_{y,m}} \\ &\ge \prod_{k=1}^{j-1} \left(1 - \left(\frac{1}{1 + \lambda_{\text{sep}}} \right)^k \right), \end{aligned} \tag{6.17}$$

where the inequality follows from Assumption 5. By Proposition 6.5, the product is monotonically decreasing to a limit as j tends to infinity. The limit is a continuous function of λ_{sep} that varies monotonically from zero to one as λ_{sep} increases from zero to infinity. Denote the limit by $1/K(\lambda_{\text{sep}})$. Then, $K_j \le K(\lambda_{\text{sep}})$, as desired. □

The bound on $1/(\gamma^i \|\pi_1 u_j\|^2)$ is stochastic because $\pi_1 = s^T/\|s\|$, where s is the starting vector. By Assumption 1, one can write $\|\pi_1 u_j\|^2 = \lambda_{s,j}|w_j|^2/\|s\|^2$, where $\lambda_{s,j}$ are eigenvalues of Λ_s and w_j are independent, zero-mean, unit variance Gaussian random variables. Thus,

$$\frac{1}{\gamma^i \|\pi_1 u_j\|^2} \le \|s\|^2 \max_{1 \le k \le m} \frac{1}{\lambda_{s,k} \gamma^k |w_k|^2} \tag{6.18}$$

for $m \ge i \ge j$. Suppose that the $\lambda_{y,k}$ satisfy

$$\frac{1}{\lambda_{y,k} \gamma^k} < \zeta \Gamma^k \tag{6.19}$$

for constants $\zeta > 0$ and $0 < \Gamma < 1$. Then, (6.19) holds for $\lambda_{s,k}$ for the same ζ and Γ if $\Lambda_s = \Lambda_y$ and for a different ζ and $\Gamma = 1/\gamma$ if $\Lambda_s \propto I$. Let

$$\mu_k = \max_{1 \le j \le k} \frac{\Gamma^j}{|w_j|^2}. \tag{6.20}$$

The quantity μ_k is an extremum of an independent, nonidentically distributed sequence of random variables. Bounding the rate at which extrema grow is a classic problem in statistics [10]. The following result states that the μ_k do not grow without bound but converge in probability.

PROPOSITION 6.7. *Suppose $w_1, w_2, w_3, \ldots$ is an independent sequence of zero-mean, unit variance Gaussian random variables. Let μ_k be as in* (6.20). *Then, the μ_k converge in probability to a finite-valued random variable.*

Proof. First, we show the μ_k converge in distribution.

$$\mathrm{P}\{\mu_k \le M\} = \prod_{i=1}^{k} \mathrm{P}\left\{|w_i| \ge \sqrt{\frac{\Gamma^i}{M}}\right\}. \tag{6.21}$$

Let

$$F_i(M) = \mathrm{P}\left\{|w_i| \ge \sqrt{\frac{\Gamma^i}{M}}\right\}. \tag{6.22}$$

Then

$$F_i(M) \le \sqrt{\frac{2}{\pi}}\sqrt{\frac{\Gamma^i}{M}}, \tag{6.23}$$

which satisfies the conditions of Proposition 6.5. Thus, $\lim_{k\to\infty} \mathrm{P}\{\mu_k \le M\} = F(M)$ for some distribution function F.

To show that the μ_k converge in probability, consider the following. For $n > k$ and $\varepsilon > 0$,

$$\mathrm{P}\{\mu_n - \mu_k > \varepsilon\} = \int \mathrm{P}\{\mu_n > \varepsilon + v | \mu_k = v\} dG_k(v), \tag{6.24}$$

where G_k is the distribution of μ_k. Now

$$\begin{aligned} \mathrm{P}\{\mu_n > \varepsilon + v | \mu_k = v\} &= \mathrm{P}\left\{\max_{1\le j\le n-k+1} \frac{\Gamma^j}{|w_j|^2} > \frac{\varepsilon + v}{\Gamma^{k-1}}\right\} \\ &\le 1 - F\left(\frac{\varepsilon + v}{\Gamma^{k-1}}\right). \end{aligned} \tag{6.25}$$

Let V be such that $1 - F(V) < \varepsilon/2$, and let N be such that

$$1 - F\left(\frac{\varepsilon + v}{\Gamma^{k-1}}\right) < \frac{\varepsilon}{2} \quad \text{for } k \ge N. \tag{6.26}$$

For $n > k \ge N$,

$$\begin{aligned} \int \mathrm{P}\{\mu_n > \varepsilon + v | \mu_k = v\} dG_k(v) &= \int_0^V \mathrm{P}\{\mu_n > \varepsilon + v | \mu_k = v\} dG_k(v) \\ &\quad + \int_V^\infty \mathrm{P}\{\mu_n > \varepsilon + v | \mu_k = v\} dG_k(v) \\ &\le \int_0^V \frac{\varepsilon}{2} dG_k(v) + \int_V^\infty dG_k(v) < \varepsilon. \end{aligned} \tag{6.27}$$

Thus, the μ_k satisfy the Cauchy criterion and converge in probability to a random variable whose distribution function is F [6, pp. 226–227]. □

6.3. Proof of Theorem 4.1. The results of the preceding two subsections combine to form a proof of Theorem 4.1 as follows.

Proof. By Propositions 6.4 and 6.6,

$$\sum_{j=1}^{m}(\Lambda_{e_x}(p_1^T y,\dots,p_k^T y))_{jj}-(\Lambda_{e_x}(y))_{jj}=\sum_{i=k+1}^{m}\|\Lambda_x C^T p_i\|^2 \tag{6.28}$$
$$\le 4\|\Lambda_x\|\|\Lambda_y\|\|s\|^2K^2(\lambda_{\mathrm{sep}})\zeta\mu_m\sum_{i=k}^{m-1}\sum_{j=1}^{\lfloor\frac{i}{4}\rfloor-1}\frac{\lambda_{z,j}}{\lambda_{y,j}^2}\frac{1}{\gamma^{(i-2j)}}+\|\Lambda_x\|\sum_{i=k}^{m-1}\sum_{j=\lfloor\frac{i}{4}\rfloor}^{m}\frac{\lambda_{z,j}}{\lambda_{y,j}},$$

and

$$\sum_{j=1}^{m}(\Lambda_{e_z}(p_1^T y,\dots,p_k^T y))_{jj}-(\Lambda_{e_z}(y))_{jj}=\sum_{i=k+1}^{m}\|\Lambda_x C^T p_i\|^2 \tag{6.29}$$
$$\le 4\|\Lambda_y\|\|s\|^2K^2(\lambda_{\mathrm{sep}})\zeta\mu_m\sum_{i=k}^{m-1}\sum_{j=1}^{\lfloor\frac{i}{4}\rfloor-1}\frac{\lambda_{z,j}^2}{\lambda_{y,j}^2}\frac{1}{\gamma^{(i-2j)}}+\sum_{i=k}^{m-1}\sum_{j=\lfloor\frac{i}{4}\rfloor}^{m}\frac{\lambda_{z,j}^2}{\lambda_{y,j}}.$$

By Assumptions 4 and 2, $\lambda_{z,j}/\lambda_{y,j}\le\bar{\lambda}_j/\sigma^2$ and $\bar{\lambda}_j/(\gamma^j\lambda_{y,j})\le\xi$ for a constant ξ. Moreover, $\lambda_{z,i}/\lambda_{y,j}\le 1$, in general. Thus

$$\sum_{j=1}^{m}(\Lambda_{e_x}(p_1^T y,\dots,p_k^T y))_{jj}-(\Lambda_{e_x}(y))_{jj}=\sum_{i=k+1}^{m}\|\Lambda_x C^T p_i\|^2 \tag{6.30}$$
$$\le\frac{4\|\Lambda_x\|\|\Lambda_y\|\|s\|^2K^2(\lambda_{\mathrm{sep}})\zeta\mu_m\xi}{\sigma^2(1-\frac{1}{\gamma^2})}\sum_{i=k}^{m-1}\frac{1}{\gamma^{i/4}}+\frac{\|\Lambda_x\|}{\sigma^2}\sum_{i=k}^{m-1}(i-k+4)\bar{\lambda}_{\lfloor\frac{i}{4}\rfloor},$$

and

$$\sum_{j=1}^{m}(\Lambda_{e_z}(p_1^T y,\dots,p_k^T y))_{jj}-(\Lambda_{e_z}(y))_{jj}=\sum_{i=k+1}^{m}\|C\Lambda_x C^T p_i\|^2 \tag{6.31}$$
$$\le\frac{4\|\Lambda_y\|\|s\|^2K^2(\lambda_{\mathrm{sep}})\zeta\mu_m}{(1-\frac{1}{\gamma^2})}\sum_{i=k}^{m-1}\frac{1}{\gamma^{i/2}}+\sum_{i=k}^{m-1}(i-k+4)\min\left(\frac{\bar{\lambda}_{\lfloor\frac{i}{4}\rfloor}\lambda_{z,\lfloor\frac{i}{4}\rfloor}}{\sigma^2},\bar{\lambda}_{\lfloor\frac{i}{4}\rfloor}\right).$$

The increasing μ_m converge in probability to a random variable μ by Proposition 6.7. Equations (4.2) and (4.3) follow immediately from (6.30) and (6.31). ∎

The analysis presented here predicts actual convergence behaviors, as illustrated next with the numerical examples in section 7.

7. Numerical examples. The following numerical examples illustrate the actual performance of the algorithm in relation to the theory of the previous sections. There are four different examples. Each one illustrates a different aspect of the theory. The estimation problems in each of the examples is different. The breadth of estimation problems provides a glimpse at the range of applicability of the Krylov subspace estimation algorithm. For each of the following problems, full orthogonalization was used, except as noted.

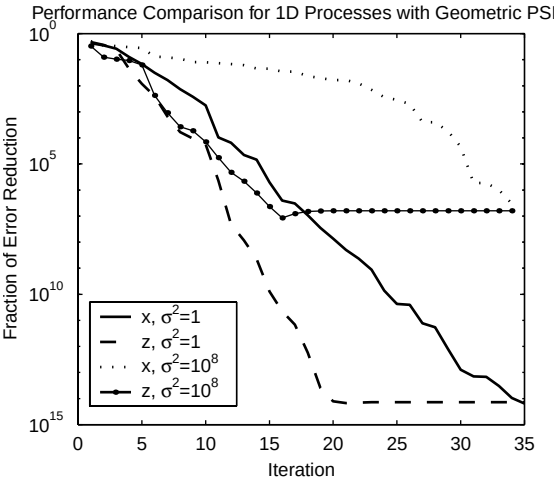

FIG. 7.1. *The four curves plotted here show the convergence behaviors when computing error variances for estimating two different quantities in two slightly different estimation problems. One of the quantities to be estimated is a* 1*-D process,* x*, and the other is a subsampled version of the same process,* z*. Both quantities are estimated from measurements consisting of* z *embedded in additive noise. The only difference between the two estimation problems is the variance of the noise,* σ^2*, which is* 1 *in one case and* 10^{-8} *in the other. The curves indicate that convergence is slower for lower* σ^2 *and for estimating* x*, as predicted by Theorem* 4.1.

The results in Figure 7.1 illustrate the relationship between the actual performance of the algorithm and that predicted by Theorem 4.1. The estimation problem consists of estimating 1024 samples of a stationary process, x, on a 1-D torus from 512 consecutive point measurements, y. The power spectral density (PSD) of x has a geometric decay, $S_{xx}(\omega) \propto (0.3)^{|\omega|}$, and is normalized so that the variance of x is one. Depicted in Figure 7.1 are the fractions of error reduction obtained for estimating x,

$$\frac{\sum_{i=1}^{l}(\Lambda_{e_x,k}(y) - \Lambda_{e_x}(y))_{ii}}{\sum_{i=1}^{l}(\Lambda_x - \Lambda_{e_x}(y))_{ii}}, \tag{7.1}$$

and z,

$$\frac{\sum_{i=1}^{l}(\Lambda_{e_z,k}(y) - \Lambda_{e_z}(y))_{ii}}{\sum_{i=1}^{l}(\Lambda_z - \Lambda_{e_z}(y))_{ii}}, \tag{7.2}$$

where $\Lambda_n = \sigma^2 I$ for $\sigma^2 = 1$ and $\sigma^2 = 10^{-8}$. Note that the numerators in (7.1) and (7.2) are the terms bounded in Theorem 4.1 and that the denominators are independent of the iteration index, k. The reference values $\Lambda_{e_x}(y)$ and $\Lambda_{e_z}(y)$ are computed using direct methods in MATLAB. The numerical errors in these direct methods tend to dominate after several iterations especially for $\sigma^2 = 10^{-8}$. Note that the eigenvalues of Λ_x and Λ_z satisfy $\lambda_{x,i} \geq \lambda_{z,i} \geq \lambda_{x,l-m+i}$ as a consequence of Cauchy's interlace theorem [9, Theorem 4.3.15] and the rows of the measurement matrix C being orthogonal. Since the PSD (collection of eigenvalues) display a two-sided geometric decay, Λ_z and, in turn, $\Lambda_y = \Lambda_z + \sigma^2 I$ may have eigenvalue multiplicities of order two. However, the plots show a geometric rate of convergence consistent with a geometrical decay of Λ_y despite the fact that the block form of the algorithm is not used. A block form is not necessary because roundoff error will introduce components of the

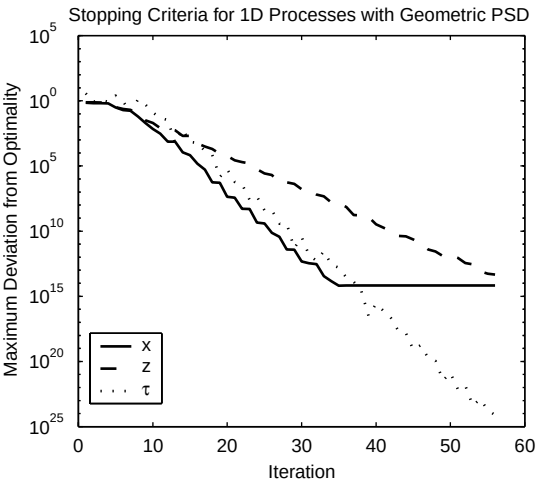

FIG. 7.2. *The results plotted here indicate how the computable quantities making up the two stopping criteria of section* 3 *relate to the difference between the computed approximation to the error covariance for estimating* x *at iteration* k *and the optimal error covariance,* $\Lambda_{e_x,k}(y) - \Lambda_{e_x}(y)$. *The solid line is the maximal difference between the computed and optimal error variances for estimating* x, $\max_i(\Lambda_{e_x,k}(y) - \Lambda_{e_x}(y))_{ii}$. *Each of the other two curves plot the quantities making up the two stopping criteria. The dashed line is the maximal error variance for estimating* z, $\max_i(\Lambda_{e_z,k}(z))_{ii}$, *and the dotted line is the maximum change made to the error variances at the current iteration,* $\tau_{k,0}$, *as defined in* (3.1) *for* $K_{\text{win}} = 0$.

eigenvectors of Λ_y into the Krylov subspaces that are not present in the starting vector [15, p. 228]. Note also that, as suggested by Theorem 4.1, the rate of convergence is faster for the error variances at measurement locations, i.e., for estimates of z, than away from measurement locations, i.e., for estimates of all of x. The theorem also suggests that convergence is slower for smaller σ^2, which is evident in Figure 7.1. Thus, Theorem 4.1 accurately predicts convergence behavior.

Figure 7.2 depicts how the two stopping criteria relate to the difference between the computed approximation to the error covariance for estimating x at iteration k and the optimal error covariance, $\Lambda_{e_x,k}(y) - \Lambda_{e_x}(y)$. The process to be estimated is the same one previously described. The measurement locations are chosen randomly. At any given location, the chance that there is a measurement is 50% and is independent of there being a measurement at any other sample point. The measurement noise covariance matrix is a diagonal matrix whose elements vary according to the following triangle function:

$$(\Lambda_n)_{ii} = \begin{cases} 9\frac{i-1}{\lfloor m/2 \rfloor - 1} + 1 & \text{for } 1 \le i \le \lfloor m/2 \rfloor, \\ 9\frac{m-i}{m - \lfloor m/2 \rfloor - 1} + 1 & \text{for } \lfloor m/2 \rfloor + 1 \le i \le m. \end{cases} \tag{7.3}$$

A whitening preconditioner, Λ_n^{-1}, is used. The figure contains plots of the maximal difference between the computed and optimal error variances for estimating x, $\max_i(\Lambda_{e_x,k}(y) - \Lambda_{e_x}(y))_{ii}$. There are also plots of the two quantities making up each of the two stopping criteria. One is of the maximal error variance for estimating z, $\max_i(\Lambda_{e_z,k}(z))_{ii}$, and the other is of the maximum change made to the error variances at the current iteration, $\tau_{k,0}$, as defined in (3.1). Note that $\Lambda_{e_z,k}(z)$ is a bound on $\Lambda_{e_x,k}(y) - \Lambda_{e_x}(y)$, but that the rates of convergence of these two quantities are different. The $\tau_{k,0}$, on the other hand, are more erratic but decrease at a rate close

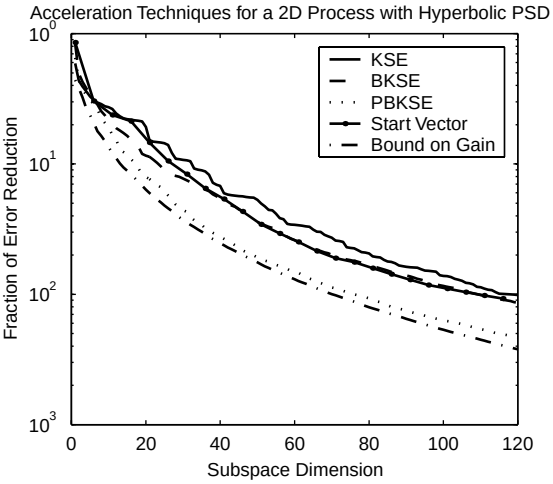

FIG. 7.3. *The results plotted here indicate that various acceleration techniques can be used to achieve nearly optimal performance. The curves depict the fraction of error reduction for estimating x for different methods of choosing linear functionals of the data. The figure shows the results for the standard Krylov subspace estimation algorithm (KSE), a block form with a block size of* 2 *(BKSE), and a preconditioned block form (PBKSE), also with a block size of* 2*. For comparison, the figure shows two additional curves. One (Start Vector) is of the results for Algorithm* 2.1 *modified to start with a linear combination of the first* 60 *eigenvectors of Λ_y. The other (Bound on Gain) is of the fraction of error reduction attained by using the optimal linear functionals of the data.*

to $\Lambda_{e_x,k}(y) - \Lambda_{e_x}(y)$. Stopping when $\tau_{k,\varepsilon_{\min}}$ falls below a threshold has been the most successful criterion because the $\tau_{k,\varepsilon_{\min}}$ give a good indication of the rate of decrease of $\max_i(\Lambda_{e_x,k}(y) - \Lambda_{e_x}(y))_{ii}$. However, stopping when $\max_i(\Lambda_{e_z,k}(z))_{ii}$ falls below a threshold is a preferable criterion when the noise intensity is small primarily because $\max_i(\Lambda_{e_z,k}(z))_{ii}$ provides a tight bound on $\max_i(\Lambda_{e_x,k}(y) - \Lambda_{e_x}(y))_{ii}$.

A comparison among various techniques to accelerate convergence is provided in Figure 7.3. The estimation problem consists of estimating a stationary random field, x, on a 32×32 toroidal grid from point measurements, y, of equal quality taken over one 32×16 rectangle. The PSD of x is proportional to $1/(|\omega| + 1)^3$ and is normalized so that the variance of x is one. The measurement noise covariance matrix Λ_n is $4I$. The plots are of the fraction of error reduction attained for estimating x, as defined by (7.1), versus the Krylov subspace dimensions. Both a right-preconditioned and a block form are considered. The preconditioner has the form $C\Lambda_p C^T$, as described in section 5.1. A simple block algorithm (BKSE) with a block size of 2 does not do much better than the standard algorithm (KSE). However, a preconditioned block form (PBKSE) requires considerably fewer iterations to achieve a given level of accuracy than the standard algorithm. The error reduction attained by using the optimal linear functionals of the data is also plotted in Figure 7.3. The performance of PBKSE is close to the optimal performance. Figure 7.3 also shows the results of an experiment to determine whether one can gain much by picking a good starting vector. A starting vector with components in each of the first 60 eigenvectors of Λ_y was used to start a run. The results are plotted in Figure 7.3 and are comparable to those of BKSE, indicating that one does not gain much by picking a good starting vector. That the choice of starting vector should have little impact on the results is a consequence of Proposition 6.7.

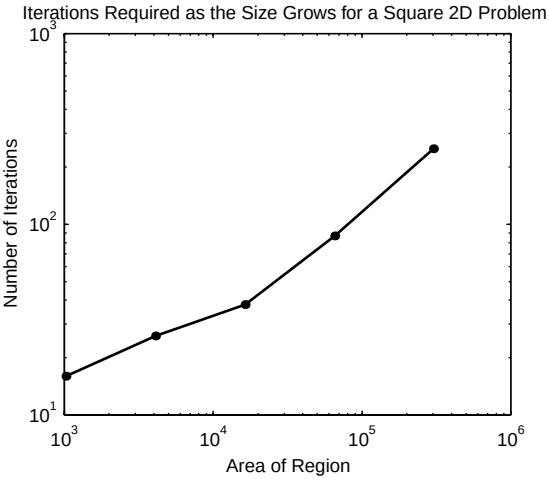

FIG. 7.4. *The number of iterations required for a practical* 2*-D problem of interest is not very large and grows no more than linearly with the area of the region of interest.*

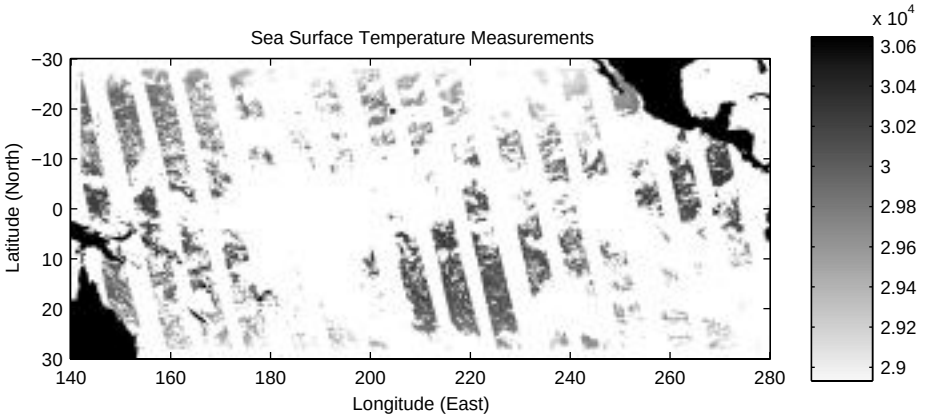

FIG. 7.5. *These data are satellite measurements of sea surface temperature. Measurements are taken only along satellite tracks with no obscuring cloud cover.*

Lastly, Figure 7.4 shows how the number of iterations grows with the region size for the problem of estimating deviations from mean sea surface temperature, x, from the satellite data, y, in Figure 7.5 [7]. The temperature deviations are estimated on a rectangular grid and are assumed to be stationary with a Gaussian-shaped covariance function. The width of the Gaussian is 60 pixels, and the height is 9×10^4. The measurements are very scattered because they exist only along the satellite tracks where there is no obscuring cloud cover (see Figure 7.5). The measurement noise covariance Λ_n is $400I$. Figure 7.4 shows how the number of iterations needed to satisfy $\tau_{k,10^{-2}} < 10^{-2}$ for $K_{\text{win}} = 8$ grows as a region of interest grows. Note that the measurement density in these regions varies from approximately $10 - 20\%$. The growth in the number of iterations is less than linear as the area of the region grows. One expects this behavior because one should need an increasing number of linear functionals as the region grows, but the growth should be no more than linear in the

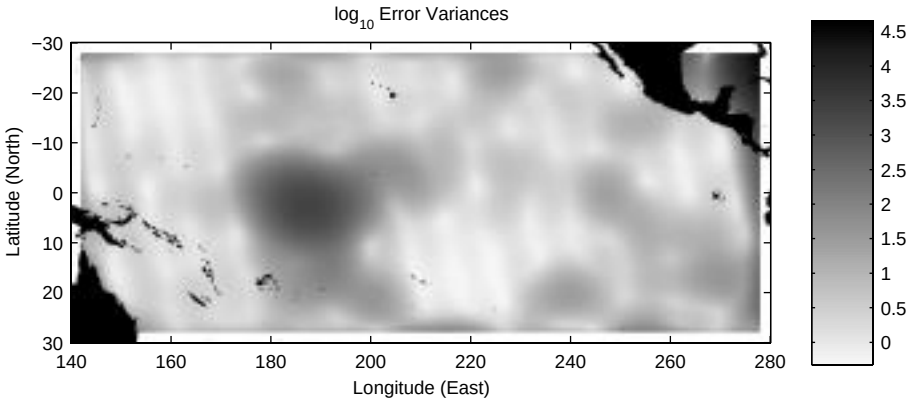

FIG. 7.6. *The Krylov subspace estimation algorithm generated these error variances on a* 1/6*-degree grid.*

area, provided that the process is stationary (as it is in this case). Figure 7.6 shows the error variances for estimating sea surface temperature given all 42,298 measurements in Figure 7.5. A selective orthogonalization scheme was used to generate this result [18, Appendix B]. Although the number of iterations is growing with problem size, the number of iterations needed for this moderately large 320,400-dimensional estimation problem is 249. That only a relatively small number of iterations was used indicates that the algorithm has found a very low-rank but very good estimator. Hence, the algorithm described here can be used to solve high-dimensional, practical problems with relatively few iterations.

8. Conclusion. In this paper, a statistical interpretation of CG has been used to derive a Krylov subspace estimation algorithm. The algorithm computes a low-rank approximation to the linear least-squares error reduction term which can be used to recursively compute LLSEs *and* error variances. An analysis of the convergence properties explains behaviors of the algorithm. In particular, convergence is more rapid at measurement locations than away from them when there are scattered point measurements. Furthermore, the analysis indicates that a randomly generated vector is a good starting vector. The theory also suggests preconditioning methods for accelerating convergence. Preconditioning has been found to increase the rate of convergence in those cases where convergence is not already rapid.

The low-rank approximation to the error reduction term is a very useful statistical object. The computation of estimates and error variances is just one application. Another is the simulation of Gaussian random processes. Simulation typically requires the computation of the square root of the covariance matrix of the process, a potentially costly procedure. However, the Krylov subspace estimation algorithm can be adapted to generate a low-rank approximation to the square root of the covariance matrix. Yet another application is the fusion of existing estimates with those generated by additional data. The resulting fusion algorithm can also be used as the engine of a Kalman filtering routine, thereby allowing the computation of estimates of quantities evolving in time. This is the subject of ongoing research.

Acknowledgments. The authors wish to thank Jacob White, Gilbert Strang, and Hamid Krim for helpful discussions, Paul Fieguth for his insight and for providing the sea surface temperature data, and the reviewers for their thoughtful suggestions.

ON THE APPROXIMATION OF OPTIMAL STOPPING PROBLEMS WITH APPLICATION TO FINANCIAL MATHEMATICS*

MICHAEL D. MARCOZZI†

Abstract. The determination of the value function associated with a given reward and stochastic process represents an important class of stochastic control problem. In particular, the expectations of such processes may be represented as solutions of variational inequalities of evolutionary type typically characterized by their high number of degrees of freedom, unbounded domains, and lack of "natural" boundary conditions. In this paper, we introduce two methodologies for computing the value function of optimal stopping associated with general stochastic processes. Our results are implemented utilizing finite elements and are validated using problems taken from financial mathematics.

Key words. optimal stopping, variational inequalities, mathematical finance, option pricing

1. Introduction.

We consider in this paper the outcome of making a decision based upon present information pertaining to a random process X_t relative to which there exist two possibilities at each moment of time $t > 0$: exit the process or continue on. We remark that the two decisions are generally not equally favorable but depend on efficiencies represented by a given reward function $g(\xi) \geq 0$. The issue is then to decide whether future gains will outweigh the loss due to stopping at the present moment or due to future unfavorable moves. Since the process on which these decisions are based is random, it is not possible to know at the time if the decision will turn out to be optimal. We therefore consider determining a stopping strategy which provides the best result "in the long run"; that is, which optimizes the expectation relative to the reward function. Such a scenario constitutes an optimal stopping problem. More specifically, if X_t is an Itô diffusion on $\mathbb{R}^n$ starting at $X_0 = x \in \mathbb{R}^n$ and g is continuous, we seek a stopping time τ^* such that

$$\mathbb{E}\left[g(X_{\tau^*})\right] = \sup_{\tau} \mathbb{E}\left[g(X_\tau)\right]$$

and the corresponding optimal expected reward

$$g^*(x) = \mathbb{E}\left[g(X_{\tau^*})\right],$$

where the supremum is taken over all stopping times τ for $\{X_t\}$ and $\mathbb{E}$ denotes the expectation with respect to the probability law associated with the process X_t.

The determination of the value function associated with a given reward g and stochastic process X_t represents an important class of stochastic control problem. When early stopping is anticipated, the value function may be approximated either through dynamic programming algorithms or their associated variational inequality. Indeed, traditionally, dynamic programming algorithms (i.e., approximating Markov

*Received by the editors December 10, 1999; accepted for publication (in revised form) July 26, 2000; published electronically January 31, 2001.
http://www.siam.org/journals/sisc/22-5/36464.html
†Department of Mathematical Sciences, University of Nevada, Las Vegas, NV 89154-4020 (marcozzi@nevada.edu).

chains, lattice techniques) have been developed by formally applying an explicit first-order accurate in time, second-order accurate in space finite difference approximation scheme to the Feynman–Kac partial differential equation. For single sources of uncertainty, dynamic programming has remained popular due more to its pedagogical simplicity than its computational efficiency.

The main difficulty toward implementing dynamic programming algorithms for multiple noise processes has largely stemmed from their inherent computational inefficiencies. That is, the discretization of the diffusion generator produces stiff systems which are more efficiently handled through implicit methods, possibly utilizing adaptive mesh refinement and time stepping techniques. However, precisely because they are based on explicit time stepping strategies, dynamic programming algorithms enjoy the feature that boundary information may be inherently propagated from the initial condition, thereby making any explicit statement of boundary conditions redundant, at the cost of possibly excessively large mesh sizes (a problem particularly acute for processes in higher dimensions). This has led, in particular, to the naïve belief that general so-called field equation methods (e.g., finite difference, finite element) are unsuitable for stopping problems. Indeed, while a few recent attempts have been made to apply field equation methods to some stopping problems involving two sources of uncertainty, these attempts have led exclusively to formulations which are neither well-posed in a mathematical sense nor may they be generalized.

The fundamental issue in applying field equation methods for computing the value function associated with a stopping process lies in the development of appropriate computationally viable formulations. To this end, we show that one poses restrictions of the original problem on a sequence of exhausting approximating domains such that boundary conditions are inferred from the reward function. Using these calculations as a benchmark, this paper also introduces an entirely new *implicit* formulation wherein boundary conditions are *not* employed. In particular, we note that this new "natural (no) boundary condition" formulation has the potential to reduce the size of the computational domain (thereby reducing the associate size of the discretization) by eliminating error introduced by the artificial boundary condition, a feature particularly important for multiple noise processes.

As an application, we consider stopping problems derived from financial mathematics. To this end, we note that a vanilla American option is a contract to buy or sell a prescribed asset (which follows a diffusion process) for a predetermined amount (the exercise price) up until a specified time in the future (the expiration date). The purpose of option pricing is to determine the present value of the option and its (expected) optimal exercise time. Options which may only be exercised at the expiration date are known as European. As represented by Black and Scholes [9] and Merton [42], the value of an option formally equates to the value of a portfolio consisting of a position in a safe asset, typically a money-market account, and the risky assets on which the option is written. The determination of the investment distribution which eliminates arbitrage opportunities in a risk-neutral measure is a stochastic control (stopping) problem and dictates the value of the portfolio and consequently the option.

The outline of this paper is as follows: in section 2, we detail the mathematical formulation of the stopping problem and the representation of the (deterministic) value function as the solution to a variational inequality. The interpretation of the mathematical framework in a financial context is presented. We introduce in section 3 two new methodologies for approximating the associated value functions. Estimates

are presented for a backward Euler finite element scheme which quantify the quality of the approximations. Finally, section 4 validates each method's performance for a number of problems arising in finance. To this end, we consider valuing options written on multiple (up to three) assets as well as an option written on a foreign currency acting within a stochastic interest rate global economy.

2. Stochastic equation; definition of the economy. We consider in section 2.1 the mathematical formulation of the stopping problem and the representation of its (deterministic) value function as the solution to a variational inequality. In section 2.2, we present a brief discussion of the mathematical framework vis-à-vis its financial context. Our intent here is to relate the assumptions necessary for the well-posedness of the variational formulation to those required for there to be unique existence of the option valuation problem.

2.1. Variational characterization of the stopping problem. In the following, we consider m independent exogenous sources of uncertainty represented in the model by the m-dimensional Brownian motion $\{B_t\}_{t\geq 0}$ defined on the probability space $(\Omega, \mathcal{F}, \mathbb{P})$. Here we assume that $\mathcal{F} = \{\mathcal{F}_t\}_{t\geq 0}$ denotes the standard augmentation of the natural filtration associated with $\{B_t\}_{t\geq 0}$. We suppose that the state variable $X_t \in \mathbb{R}^n$ evolves according to the Itô process

$$dX_s = b(X_s, s)\, ds + \sigma(X_s, s)\, dB_s, \quad s > t\,, \tag{2.1a}$$

$$X_t = x\,, \tag{2.1b}$$

such that x is deterministic. We make the following additional assumptions.

(**A1**) The drift vector $b : \mathbb{R}^n \times [0,\infty) \to \mathbb{R}^n$ is C^1 and has bounded derivatives.

(**A2**) The dispersion matrix $\sigma : \mathbb{R}^n \times [0,\infty) \to \mathbb{R}^{n\times m}$ is $C^{2,1}$, bounded, and has bounded derivatives.

(**A3**) The coercivity condition holds; that is, there exists a constant $\eta > 0$ such that

$$\xi^T\, a\, \xi \geq \eta\, \|\xi\|^2$$

for all $\xi \in \mathbb{R}^m$ and each $(x,t) \in \mathbb{R}^n \times (0,\infty)$. The $(n\times n)$-matrix $a(x,t) := \sigma(x,t)\,\sigma(x,t)^T$ is known as the diffusion matrix.

In particular, the functions b and σ satisfy the global Lipschitz condition

$$\|b(x,t) - b(y,t)\| + \|\sigma(x,t) - \sigma(y,t)\| \leq c\, \|x - y\|$$

for every $0 \leq t < \infty$, $x \in \mathbb{R}^n$, $y \in \mathbb{R}^n$, and for some constant $c > 0$, which then suffices to ensure that there exists a unique t-continuous strong solution of (2.1) (e.g., [35]). Formally, the characteristic operator $\mathcal{A}$ associated with (2.1) is given by

$$\mathcal{A}f := -\frac{1}{2}\sum_{i,j} \frac{\partial}{\partial x_i}\left(a_{ij}\frac{\partial f}{\partial x_j}\right) + \sum_j a_j \frac{\partial f}{\partial x_j}\,, \tag{2.2a}$$

where

$$a_j = \sum_i \frac{\partial a_{ij}}{\partial x_i} - b_j\ ;\ j = 1, \ldots, n\,. \tag{2.2b}$$

Associated with the flow (2.1), the decision variable (i.e., stopping time) θ, and the constraint ψ, the (expected) cost function is defined as

$$J_t^x(\theta) = \mathbb{E}_{\mathbb{P}}\left[\exp\left(-\int_t^\theta a_0(X_s, s)\, ds\right)\psi(X_\theta, \theta)\right] \tag{2.3a}$$

and the stopping problem is defined as

$$u(x,t) = \sup_{\theta \in \mathcal{T}_{[t,T]}} J_t^x(\theta)\,, \tag{2.3b}$$

where $T < \infty$ represents the (time) horizon and $\mathcal{T}_{[t,T]}$ the set of stopping times in $[t,T]$. The cost (or reward) function associated with (2.3) is

$$\exp\left(-\int_t^\theta a_0(X_s, s)\, ds\right)\psi(X_\theta, \theta),$$

where the exponential term may be interpreted as an actualization of the (final) reward.

In order to characterize the deterministic valuation function (2.3) as the solution of a variational inequality, we introduce the weighted Sobolev spaces $W^{m,p,\mu}$; the space of functions $u \in L^p(\mathbb{R}^n, e^{-\mu|x|}\,dx)$ whose weak derivatives of all orders $\leq m$ belong to $L^p(\mathbb{R}^n, e^{-\mu|x|}\,dx)$, where m denotes a nonnegative integer, $1 \leq p \leq \infty$, and $0 < \mu < \infty$. We equip $W^{m,p,\mu}$ with the norm

$$\|u\|_{m,p,\mu} = \left\{\sum_{k \leq m} \int_{\mathbb{R}^n} |D^k u(x)|^p \cdot e^{-\mu|x|}\, dx\right\}^{1/p}.$$

If $\mathcal{X}$ is equipped with norm $\|\cdot\|_{\mathcal{X}}$, the space $L^p([0,T];\mathcal{X})$ consists of the set of measurable functions $g : [0,T] \to \mathcal{X}$ such that $\int_{[0,T]} \|g(t)\|_{\mathcal{X}}^p\, dt < \infty$. Subject to the additional assumption

(**A4**) the constraint $\psi \in L^p([0,T]; W^{2,p,\mu})$, where $p > (n/2) + 1$, is nonnegative and bounded,

we consider the following (strong) variational inequality. Determine $u \in L^2([0,T]; H^1_{loc})$ $\cap\, L^p([0,T]; W^{2,p,\mu})$, $\partial u/\partial t \in L^2([0.T]; L^2_{loc}) \cap L^p([0,T]; W^{0,p,\mu})$ such that

$$\frac{\partial u}{\partial t} - \mathcal{A}\, u - a_0 u \geq 0, \qquad u \geq \psi\,, \tag{2.4a}$$

$$\left\{\frac{\partial u}{\partial t} - \mathcal{A}\, u - a_0 u\right\} \cdot \{u - \psi\} = 0\,, \tag{2.4b}$$

where

$$u(x,T) = \psi(x,T) \tag{2.4c}$$

for all $x \in \mathbb{R}^n$. Supposing (A1)–(A4), that a_0 satisfies (A1), and that $\partial\psi/\partial t - \mathcal{A}\psi - a_0\psi \in L^p([0,T]; W^{0,p,\mu})$, there exists a unique solution to (2.4) represented by (2.3) for all p sufficiently large and μ sufficiently small (cf. [8] for the case $a_0 \in \mathbb{R}$; see also [32], [38], [24]). In particular, it follows from the Sobolev embedding theorem

that $u(\cdot,t) \in C^0$ for all $t \in [0,T)$. For $n = 1$, the solution u may be seen to be infinitely smooth on the continuation region and C^1 globally (cf. [48]). The current assumptions are not strict. We note that the boundedness imposed in (A4) is a formal restriction and may be circumvented by the process indicated in the following paragraph. Subsequently, all examples in what follows may be considered to lie within the present framework.

Practically, the solution u may be realized as the limit of a (pointwise) convergent sequence obtained through approximating (2.4) on bounded exhausting domains. That is, let $\{\Omega_k\}$ denote an increasing sequence of bounded open domains for which $\cup \Omega_k = \mathbb{R}^n$ and $\Psi \in L^p([0,T]; W^{2,p,\mu})$ a regularization of ψ such that $\widetilde{\psi} := \psi - \Psi \to 0$ as $\|x\| \to \infty$. Of course, one may consider as a special case that $\Psi = \psi$, but this is not required and consequently $\widetilde{\psi}$ does not necessarily vanish on $\partial\Omega_k$. We consider $\widetilde{u}_k := u_k - \Psi$, where u_k approximates $u - \psi$ on Ω_k and $\widetilde{u}_k|_{\partial\Omega_k} \equiv \widetilde{\psi}|_{\partial\Omega_k}$, by construction. In particular, there exists a unique $\widetilde{u}_k \in L^2([0,T]; H^1_{\widetilde{\psi}}(\Omega_k) \cap H^2(\Omega_k))$, $\partial\widetilde{u}_k/\partial t \in L^2([0,T]; L^2(\Omega_k))$ such that

$$\frac{\partial \widetilde{u}_k}{\partial t} - \mathcal{A}\,\widetilde{u}_k - a_0 \widetilde{u}_k \geq \widetilde{f} \ \text{ almost everywhere (a.e.) on } \ \Omega_k \times [0,T)\ ;\ \widetilde{u}_k \geq \widetilde{\psi} \ \text{ on } \ \overline{\Omega}_k \times [0,T]\,, \tag{2.5a}$$

$$\left\{ \frac{\partial \widetilde{u}_k}{\partial t} - \mathcal{A}\,\widetilde{u}_k - a_0 \widetilde{u}_k - \widetilde{f} \right\} \cdot \left\{ \widetilde{u}_k - \widetilde{\psi} \right\} = 0 \ \text{ a.e. on } \ \Omega_k \times [0,T)\,, \tag{2.5b}$$

where $\widetilde{f} = -\partial\widetilde{\psi}/\partial\, t + \mathcal{A}\widetilde{\psi} + a_0\widetilde{\psi}$ and

$$\widetilde{u}_k(x,T) = \widetilde{\psi}(x,T) \tag{2.5c}$$

for all $x \in \Omega_k$, where $H^1_{\widetilde{\psi}}(\Omega_k) := \{v \in H^1(\Omega_k) \mid v = \widetilde{\psi} \text{ on } \partial\Omega_k\ \}$. It follows then for any compact set $\overline{G} \subset \mathbb{R}^n$ that

$$\max_{t\in[0,T]} \|u(x,t) - u_k(x,t)\|_{L^\infty(\overline{G})} \to 0 \ \text{ as } \ k \to \infty \tag{2.6}$$

(cf. [8], proof of Theorem 3.19 and section 3.4.9 or [32], Proposition 4.1 in the case $\operatorname{supp}\{\widetilde{\psi}\} \subseteq \Omega_k$ for k sufficiently large). The result (2.6) may be intuitively understood in that the asymptotic behavior (that is, $\widetilde{u}_k|_{\partial\Omega_k}$) cannot "appreciably" affect the solution in any fixed bounded region within a finite interval of time (n.b. the behavior of the Green's function; cf. also [23]).

Remark. It is precisely this result which justifies the essentially arbitrarily prescribed boundary information associated with the approximation (2.5) in use exclusively throughout the literature for multidimensional state spaces ($n > 1$) and single dimensional state spaces ($n = 1$) when the asymptotic behavior of the value function is not readily apparent. That is, generalizing the above, we see that *any* well-posed problem on Ω_k yields the estimate (2.6) and so suffices as an approximation to (2.4) *provided* that k is taken sufficiently large and the validity of the approximation is considered on the compact region $\overline{G}$ only. Indeed, in Barles, Daher, and Romano [5] the influence of the artificial boundary data $\widetilde{u}_k|_{\partial\Omega_k}$, which is noted to be local near $\partial\Omega_k$, is attributed to "boundary-layer" effects, presupposing an advection dominated region, which is not the case. This effect is, in fact, the natural consequence of the restriction of the problem from $\mathbb{R}^n$ to Ω_k and is essentially a purely local influence confined to a neighborhood of $\partial\Omega_k$.

The starting point for most applications typically assumes that the problem is posed on a bounded domain. For example, in Clarke and Parrot [15], Dirichlet data is utilized along one axis and Neumann data (set to vanish) along a second. Barles, Daher, and Romano [5] examine both Dirichlet and Neumann data for a single state variable application. Generally, the ad hoc nature of the boundary information causes the ill-posedness of the formulation such as in the studies by Zvan, Forsyth, and Vetzal [51] and Haber, Schönbucher, and Wilmott [28] involving two state variables and the one-dimensional studies of Dewynne and Wilmott [21] and Das [19]. In a footnote in Amin and Bordurtha [1] (referring to a problem to be considered in section 4 and justifying the need for a lattice type implementation which does not employ explicit boundary information), it is stated that "even if such a partial differential equation can be derived, the boundary conditions are extremely complicated with three state variables. In fact, no attempts have been made to numerically solve three state partial differential equations in the finance literature." We remark that all of the above cited studies may be formulated within the present unifying framework.

2.2. Economic context. In an economic context, we consider $(n-1)$ risky processes X_t within a given market; a_0 representing the rate of return from the nth asset which is supposed "risk-free," such as a U.S. government bond or money-market account, ψ a contract which specifies a payoff at the exercise time, and T the expiration date of the contract. The purpose of option pricing is to determine the "fair" value (and expected exercise time) of the contingent claim (cf. [3], [43], [34], [7]). Of course, the ability to value a claim lies within the assumptions imposed upon the economy. In particular, we require (cf. [6]) the following conditions.

- *Equivalent martingale measure.* An equivalent martingale measure is a measure $\mathbb{Q}$ equivalent to $\mathbb{P}$, under which the discounted securities (that is, normalized by one of the asset within the market) are all $\mathbb{Q}$-martingales.
- *Arbitrage-free.* A market is arbitrage-free if there exists no "wealth" process (self-financing trading strategy) having zero initial value which generates a "risk-free" profit (that is, a positive expectation under the $\mathbb{P}$ equivalent "risk-free" measure $\mathbb{Q}$).
- *Completeness.* A market is complete if any possible derivative claim can be "hedged" by trading with a "self-financing" portfolio of securities (that is, the value process lies within the span of the securities).

The ability to value options is predicated on the following result (cf. [29], [20]):

1. A market is arbitrage-free if and only if there exists an equivalent martingale measure $\mathbb{Q}$.
2. A market is complete if and only if it is arbitrage-free and the measure $\mathbb{Q}$ is unique.

From a mathematical perspective, there exists a unique value for a derivative security if and only if there exists a unique equivalent martingale measure $\mathbb{Q}$. In order to represent the unique "fair" value of the derivative security, the expectation (2.3) is necessarily considered with respect to the $\mathbb{P}$-equivalent measure $\mathbb{Q}$. In a financial context, a portfolio consisting of positions in the $n-1$ risky assets and the riskless security may be constructed to "replicate" (hedge) the behavior of the derivative security (the value process) in such a manner that an investor cannot secure a profit starting out with no investment in the market. Put another way, an investor cannot make a profit without incurring some risk (this means that the market is arbitrage-free). Martingales are necessary for there to be no arbitrage and hedging results in unique prices.

With respect to the above, we note that coercivity (A3) and the regularity assumptions (A1), (A2), and (A4) provide for the unique existence of an equivalent martingale measure through a Girsanov transformation and consequently for market completeness. These same arguments are essential for the well-posedness of (2.4) and consequently allow for the valuation of options through variational techniques.

In a complete market it is possible to define the so-called market price of risk γ_t as the change in drift associated with Girsanov's transformation from the measure $\mathbb{P}$ to $\mathbb{Q}$. In general, γ_t is dependent only on the traded assets X_t and time t, not on the underlying derivative security valuation u. As such, under the $\mathbb{Q}$-measure, an asset is tradable if and only if its market price of risk is zero. In this case, all (normalized) tradable assets in the economy have the same growth rate as the money-market account (and consequently it is not possible to generate a risk-free profit). It is for this reason that the $\mathbb{Q}$-measure is said to be risk-neutral or arbitrage-free. Financially, γ_t represents the return (per unit of risk) above the risk-free rate; an investor expects to be compensated for the uncertainty associated with his investment. By specifying a particular measure, such as the one which minimizes inherent risk, variational techniques may be used as well in incomplete markets, although in this case there is in general no unique option valuation (cf. [36]).

3. Approximation of the stopping problem. Standard results for the approximation of variational problems on bounded domains are utilized to construct an approximating sequence for the stopping problem (2.4) on unbounded domains via the exhausting sequence of restrictions (2.5). We implement this procedure as method (i) below. Clearly, any convergence realized beyond the estimate (2.6) will rely on the quality of the artificial boundary conditions imposed upon the frontier of Ω_k. In order to avoid this difficulty, we introduce a so-called natural (or no) boundary condition approximation. This constitutes method (ii) below. In section 3.1 we introduce the weak formulation of (2.5) followed in section 3.2 by an implicit differencing in time, finite element approximation in space. A pointwise approximating sequence is constructed in section 3.3 for (2.4) on $\overline{G}$. Estimates are provided which quantify the quality of the approximation.

3.1. Weak formulation on bounded domains. We introduce now the (weak) variational form of (2.5). Formally, we consider a class of so-called *test* functions v such that $v \geq \widetilde{\psi}$. It follows then from (2.5a) that for a given t

$$\left\{ \frac{\partial \widetilde{u}_k}{\partial t} - \mathcal{A}\,\widetilde{u}_k - a_0 \widetilde{u}_k - \widetilde{f} \right\} \cdot \left\{ v - \widetilde{\psi} \right\} \geq 0\,. \tag{3.1a}$$

Subtracting (2.5b) from (3.1a), we obtain

$$\left\{ \frac{\partial \widetilde{u}_k}{\partial t} - \mathcal{A}\,\widetilde{u}_k - a_0 \widetilde{u}_k - \widetilde{f} \right\} \cdot \{ v - \widetilde{u}_k \} \geq 0\,. \tag{3.1b}$$

The weak form of (2.5) then follows by integrating (3.1b) over Ω_k and applying the Green's formula in the usual manner (e.g., [8], [38], [49]). For simplicity, we suppose $a_{ij} \in \mathbb{R}$, then for each $t \in (0,T)$, $u, v \in H^1(\Omega_k)$, we define

$$a_k(t;u,v) := \frac{1}{2} \sum \int_{\Omega_k} a_{ij}\, \frac{\partial u}{\partial x_j}\, \frac{\partial v}{\partial x_i}\, dx + \sum \int_{\Omega_k} a_j\, \frac{\partial u}{\partial x_j}\, v\, dx + \int_{\Omega_k} a_0\, u\, v\, dx$$

and

$$b_k(t;u,v) := \sum \int_{\partial \Omega_k} a_{ij}\, \frac{\partial u}{\partial x_j}\, v\, n_i\, dx\,,$$

where n_i denotes the ith component of the outward unit normal vector to $\partial\Omega_k$. In what follows we denote the $L^2(\Omega_k)$ inner product by $(\cdot,\cdot)$ and recall that $H^{2,1}(\Omega_k \times (0,T)) := \{v \mid v_{x_i}, v_{x_{ij}}, v_t \in L^2\}$. The two formulations below differ solely in the manner in which boundary information is inherited from (2.4) by (2.5).

(i) *Constraint as boundary condition.* We consider here that $\operatorname{supp}\{\widetilde{\psi}\} \subseteq \Omega_k$ (in which case $\widetilde{u}_k|_{\partial\Omega_K} = 0$) for all k sufficiently large. In this case, the solution $\widetilde{u}_k \in \overset{\circ}{K}_t := \{v \in H^{2,1}(\Omega_k \times (0,T)) \,|\, v \geq \widetilde{\psi} \text{ a.e. in } \Omega_k \times (0,T);\ v = 0 \text{ a.e. on } \partial\Omega_k \times (0,T)\}$ of (2.5) is equivalently a solution to the evolutionary variational inequality

$$\left(\frac{\partial \widetilde{u}_k}{\partial t}, v\right) - a_k(t; \widetilde{u}_k, v) \geq \left(\widetilde{f}, v\right) \quad \text{a.e. in } t\,, \tag{3.2a}$$

such that

$$\widetilde{u}_k(x,T) = \widetilde{\psi}(x,T) \ \text{ on } \ \Omega_k \tag{3.2b}$$

for all $v \in \overset{\circ}{K}_t$. The equation (3.2) is the statement of (2.5) in weak form. The application of $\widetilde{u}_k|_{\partial\Omega_k} = 0$ represents a so-called (essential) artificial boundary condition for (3.2) or (2.5) relative to (2.4). We remark that the quality of the regularization Ψ affects the efficiency of this implementation through the Dirichlet condition.

(ii) *Natural (no) boundary condition.* Supposing that $\widetilde{u}_k \in K_t := \{v \in H^{2,1}(\Omega_k \times (0,T)) \,|\, v \geq \widetilde{\psi} \text{ a.e. in } \Omega_k \times (0,T)\}$ is a solution of (2.5), it is equivalently a solution of the variational inequality

$$\left(\frac{\partial \widetilde{u}_k}{\partial t}, v\right) - a_k(t; \widetilde{u}_k, v) - b_k(t; \widetilde{u}_k, v) \geq \left(\widetilde{f}, v\right) \quad \text{a.e. in } t\,, \tag{3.3a}$$

such that

$$\widetilde{u}_k(x,T) = \widetilde{\psi}(x,T) \ \text{ on } \ \Omega_k \tag{3.3b}$$

for all $v \in K_t$. Note that here the boundary conditions are formally represented by allowing $x \in \Omega_k \to x_o \in \partial\Omega_k$ such that $\partial u/\partial t - \mathcal{A}u - a_0 u - \widetilde{f} \to 0$; that is, by considering one-sided derivatives in $\mathcal{A}$ on $\partial\Omega_k$. Indeed, *no* explicit boundary information is transmitted by this condition.

We label this approach as "natural" in that boundary information is not imposed in the space of test functions K_t. Nor is boundary information transmitted through the variational equation (3.3a). In particular, we require only a growth constraint on the solution which is enforceable on the finite domain Ω_k, for all k sufficiently large, by the well-posedness of the formulation (3.3) alone. This "trivial (no)" boundary condition has important ramifications relative to the numerical implementation of the scheme (cf. section 4).

3.2. Discretization on bounded domains. When, for a given fixed k, the constraint is imposed as an artificial boundary condition in (2.5) (that is, when $\widetilde{u}_k|_{\partial\Omega_k} = 0$), numerical methods for the approximation of $\widetilde{u}_k$ are well known (cf. [27], [26], [14], [17]). As such, we now consider the approximation of the evolutionary variational inequality (2.5) by (implicit) semidiscretization. To this end, we let $\Delta t = T/M$, for some positive integer M, $t_m = m \cdot \Delta t$, and define the sequence $\{\widetilde{u}_k^m\}$, $\widetilde{u}_k^m \in V_k$, by recurrence starting with

$$\widetilde{u}_k^M = \widetilde{\psi}\,, \tag{3.4a}$$

where, for $m = 1, \ldots, M-1$,

$$-\left(\frac{1}{\Delta t}\widetilde{u}_k^m, v\right) - a_k(t_m; \widetilde{u}_k^m, v) - \iota \cdot b_k(t_m; \widetilde{u}_k^m, v) \geq \left(\widetilde{f} - \frac{1}{\Delta t}\widetilde{u}_k^{m+1}, v\right) \tag{3.4b}$$

for all $v \in V_k$, where $\iota = 0$, $V_k = \overset{\circ}{K} := \{v \in H^2(\Omega_k) \,|\, v \geq \widetilde{\psi} \text{ in } \Omega_k \,;\, v = 0 \text{ on } \partial\Omega_k\}$ and $\iota = 1$, $V_k = K := \{v \in H^2(\Omega_k) \,|\, v \geq \widetilde{\psi} \text{ in } \Omega_k\}$ when approximating (3.1) and (3.2), respectively. In particular, we note that for each $1 \leq m < M$, the relation (3.4b) is a stationary variational inequality which is known to be uniquely solvable in the case $V_k = \overset{\circ}{K}$, for all Δt sufficiently small (and, by transformation, for all Δt). Allowing piecewise continuation on the interval $[m\,\Delta t, (m+1)\,\Delta t)$ and imposing the constraint at the boundary, it can be shown in addition that the solution $\widetilde{u}_k^m$ converges weakly to $\widetilde{u}_k$ in $H^{2,1}(\Omega_k \times (0,T))$ (cf. [8], [26]).

In order to obtain a fully discrete approximation of (3.2) (resp., (3.3)), we let $\{S_h\}$ denote a family of finite-dimensional subspaces of $H_0^1(\Omega_k) \cap H^2(\Omega_k)$ (resp., $H^2(\Omega_k)$) such that $\{\phi_{h,1}, \phi_{h,2}, \ldots, \phi_{h,N}\}$ forms a basis for S_h. For definiteness, we suppose that Ω_k is rectangular and that S_h consists of piecewise linear (componentwise) functions on a quasi-uniform rectangular "triangulation" of Ω_k with mesh size (length of the longest side) h. Letting $\mathcal{N}_h$ denote the set of nodes of the space S_h (i.e., the set of all vertices), we define

$$K_h = \{v_h \in S_h \mid \text{ for all } b \in \mathcal{N}_h\,,\ v_h(b) \geq \widetilde{\psi}(b)\}\,.$$

In general, the set K_h is not contained in either $\overset{\circ}{K}$ or K. Replacing V_k with K_h, we obtain the following discretization in space and time of (3.4). Determine the sequence $\{\widetilde{u}_h^m\}$, $\widetilde{u}_h^m \in K_h$, by recurrence starting with

$$\widetilde{u}_h^M = \widetilde{\psi}\,, \tag{3.5a}$$

where, for $m = 1, \ldots, M-1$,

$$-\left(\frac{1}{\Delta t}\widetilde{u}_h^m, v\right) - a_k(t_m; \widetilde{u}_h^m, v) - \iota \cdot b_k(t_m; \widetilde{u}_h^m, v) \geq \left(\widetilde{f} - \frac{1}{\Delta t}\widetilde{u}_h^{m+1}, v\right) \tag{3.5b}$$

for all $v \in K_h$, where $\iota = 0$ (resp., $\iota = 1$) for the fully discrete approximation of (3.2) (resp., (3.3)). In particular, we have the representations

$$\widetilde{u}_h^m = \sum_{i=1}^{N} u_i(t) \cdot \phi_{h,i}(x) \tag{3.6a}$$

and

$$v = \sum_{i=1}^{N} v_i \cdot \phi_{h,i}(x)\,, \tag{3.6b}$$

where $u_i(t)$ and v_i are elements of $\mathbb{R}$. Substituting (3.6) into (3.5), we obtain the sequence (one for each m) of linear complimentary problems for $u^m = (u_1(t_m), u_2(t_m), \ldots, u_N(t_m))$ and $v = (v_1, v_2, \ldots, v_N)$: determine the sequence $\{u^m\}$ by recurrence such that

$$u^M = \widetilde{\psi}(b, t_M) \text{ for all } b \in \mathcal{N}_h, \tag{3.7a}$$

where

$$v \cdot A\, u^m \geq v \cdot F^{m+1} \tag{3.7b}$$

for $m = 1, \ldots, M-1$ (cf. [16], [39]). Here, $A = (A_{ij})$ such that

$$A_{ij} = -\frac{1}{\Delta t}(\phi_{h,i}, \phi_{h,j}) - (\nabla\phi_{h,i} \cdot e_i, \nabla\phi_{h,j} \cdot e_j) - \iota \cdot (\nabla\phi_{h,i} \cdot n_i, \phi_{h,j})\,,$$

$$F^{m+1} = \widetilde{f} - B\, u^{m+1}\,,$$

where $B = (B_{ij})$,

$$B_{ij} = \frac{1}{\Delta t}(\phi_{h,i}, \phi_{h,j})\,,$$

and e_i and n_i denote the ith component of the unit coordinate and unit outward normal vectors, respectively.

In particular, the sequence $\{\widetilde{u}_h^m\}$ constitutes an implicit Euler finite element approximation of $\widetilde{u}_k$ utilizing regular n-rectangles of type 1 (and globally of class C^0), where the rectangular partitions are hierarchical and consist of quasi-uniform elements parameterized by h (cf. [14], [27], [26]). The quality of the approximation (3.5) to (3.2), for fixed k, is known to satisfy the estimate

$$\max_{t\in[0,T]} \|\widetilde{u}_k - \widetilde{u}_h^m\|_{L^\infty(\Omega_k)} \leq \mathcal{O}(l + h^{2-\epsilon}) \tag{3.8}$$

for any $\epsilon > 0$ and all $l := \Delta t$, h sufficiently small (cf. [27]). The estimate (3.8) is a statement that the finite element discretization (3.5) is first-order accurate in time and second-order accurate in space over Ω_k.

3.3. Discrete approximation on unbounded domains. The approximating methods (i) and (ii) are then defined by considering the pointwise limit on $\overline{G}$ of the sequence $\widetilde{u}_h^m$ for $\iota = 0$ and 1, respectively, as $k \to \infty$. More precisely, for a given k, a finite element approximation $\widetilde{u}_{h_k}^m$ is constructed which satisfies (3.7) for a specific time/mesh size l_k and h_k. By induction, the approximation $\widetilde{u}_{h_{k+1}}^m$ is constructed with $\Omega_k \subset \Omega_{k+1}$, $l_k > l_{k+1}$, and $h_k > h_{k+1}$. Letting $u_{h_k}^m := \widetilde{u}_{h_k}^m|_{\overline{G}} + \Psi|_{\overline{G}}$, the *diagonalizing* sequence $\{u_{h_k}^m\}$ approximating the solution u of (2.4) is now fully specified on $\overline{G}$. Combining (3.8) with (2.6), it then follows that

$$\max_{t\in[0,T]} \|u(x,t) - u_{h_k}^m(x,t)\|_{L^\infty(\overline{G})} \leq \mathcal{O}(l_k + h_k^{2-\epsilon}) + o(\Pi_k^{-1}) \;\text{ as }\; k \to \infty \tag{3.9}$$

for any $\epsilon > 0$, where $\overline{G} \subset \Omega_k$ denotes the (fixed) so-called *approximation* domain and $\Pi_k := \mathrm{diam}\{\Omega_k\}$ is the diameter of the *computational* domain Ω_k. Clearly, the first term in the estimate bounds the time discretization error, the second bounds the space discretization error, and the third bounds the error due to the truncation of the domain. We note (cf. section 4) (a) that asymptotic performance may *only* be realized on the approximating region $\overline{G}$ and not over the entire computational domain Ω_k, (b) the futility of refining a mesh relative to a fixed computational domain, and (c) the detriment of stipulating a time/mesh sizing l_k and h_k without refining Π_k. The practices (a)–(c) are utilized exclusively in the literature (e.g., [25], [5]). Relative to method (ii), we remark that it is not known if (3.3) or its finite element approximation

(3.5) is solvable. However, we verify the estimate (3.9) in this case computationally in the next section.

Remark. We note that in Jaillet, Lamberton, and Lapeyre [32], Zhang [50], and Barles, Daher, and Romano [5], for example, the estimate (2.6) and a finite difference analogue of (3.8) relative to (3.2) are obtained. The estimate (3.9) addresses the more general case where l_k, $h_k \to 0$ *and* $\Pi_k \to \infty$. In particular, each of the cited works develops a "localization" of the expectation (cf. (2.3)) onto a bounded domain (that is, the diffusion is absorbed on $\partial\Omega_k$), the value function being then characterized as the solution to a variational problem such that $\widetilde{u}_k|_{\partial\Omega} = 0$ (for fixed k). This approach fails to develop the local approximation to u on $\overline{G}$ through the construction of the sequence $\{u^m_{h_k}\}$. In this context, the localization employed by method (ii) would be consistent with a specific reflected diffusion imposed on Ω_k.

4. Computational results. In order to validate the estimate (3.9), and consequently verify the convergence and efficiency of the proposed methods, we consider as an application a variety of optimal stopping problems derived from mathematical finance. To this end, we value options written on multiple assets (e.g., stocks) as well as an option written on a foreign currency. In section 4.1 we present the specifics of implementing the proposed methods. In section 4.2 we discuss case related details and summarize our general conclusion.

Since analytic solutions do not generally exist for optimal stopping problems, numerical methods are necessitated. In terms of approximating the value function of a stopping process, we remark that dynamic programming based algorithms have typically been employed, particularly in the single state space case when boundary information may be ignored (so-called lattice methods) without any great computational cost (cf. [25]). When the time horizon is known to be realized (e.g., European options), Monte Carlo and Quasi-Monte Carlo methods have been shown to be effective in higher dimensions (cf. [44], [10]). Recently, attempts at combining these two approaches have lead to dynamic programming simulation based techniques (cf. [12]). These appear attractive when possible early exit times are limited to a "small" set.

4.1. Numerical implementation. In the following, we solve the discretization (3.7) by projected successive-over-relaxation (SOR) (cf. [18]). Projection methods have been shown to be efficient solvers for (3.7) (cf. [11], [40], [30], [37]). An introductory treatment of finite elements and projected SOR can be found in [49], for example. Additionally, we note that for most numerical implementations it is not actually necessary to introduce the intermediate function $\widetilde{u}_k$ and the formulation (2.5). One simply constructs an approximation for $u|_{\Omega_k}$ directly; it is not necessary to introduce the regularization Ψ and consider that the Dirichlet data vanish on the computational boundary $\partial\Omega_k$. This is the procedure utilized unless otherwise noted. In the exceptional cases, we approximate $\widetilde{u}_k$ via (2.5) and determine $u|_{\Omega_k} = \widetilde{u}_k + \Psi$ assuming $\Psi = \psi$ and consequently that $u_k|_{\partial\Omega_k} = 0$ (cf. section 3.3).

Relative to the implementation of method (i) and the imposition of Dirichlet boundary data, the array A and vector F^{m+1} from (3.7) are constructed (assembled) and then the values of the discrete solution (overwrite) are set equal to the constraint Ψ at each boundary node. Method (ii) is implemented such that no overwriting occurs. In the single state variable case and a finite difference setting, method (ii) would be analogous to employing a second-order central differencing scheme for space discretization at the interior nodes and a second-order one-sided differencing scheme at the boundary nodes.

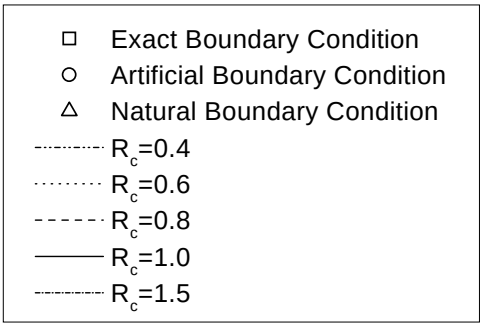

FIG. 1. *Figure index. Note: R_c is the radius of the computational domain in the maximum norm.*

When early exercise (stopping) is not anticipated (e.g., European options), comparisons will be made to the analytic solution where possible. In the case of early stopping (e.g., American options), or when analytic solutions are not available for processes which run to completion, we will compute solutions anticipated to be at least two orders of magnitude more accurate than the approximations and utilize these as benchmarks (the validity of this approach will be evidenced by the realized convergence rates) (cf. (III) below).

In order to computationally validate the estimate (3.9), we fix $l_k/h_k^2 = \beta$, where we choose for computational purposes $\beta = 1$, a sufficiently small constant (as verified by the asymptotic behavior obtained). As such, we expect to achieve asymptotic convergence as $k \to \infty$; that is, as $h_k \to 0$ and $\Pi_k \to \infty$. Note that the choice of β effects the relative performance (accuracy) of the method.

The approximation and computational domains were constructed as n-squares with (maximum norm) radius, R_a and R_c, respectively. The center of G and Ω_k were aligned. In particular, the radius $R_a = 0.1$ for all computations. Mesh spacing was uniform (that is, $\Delta x_i = \Delta x_j = \Delta x$) such that $h_k = \Delta x$.

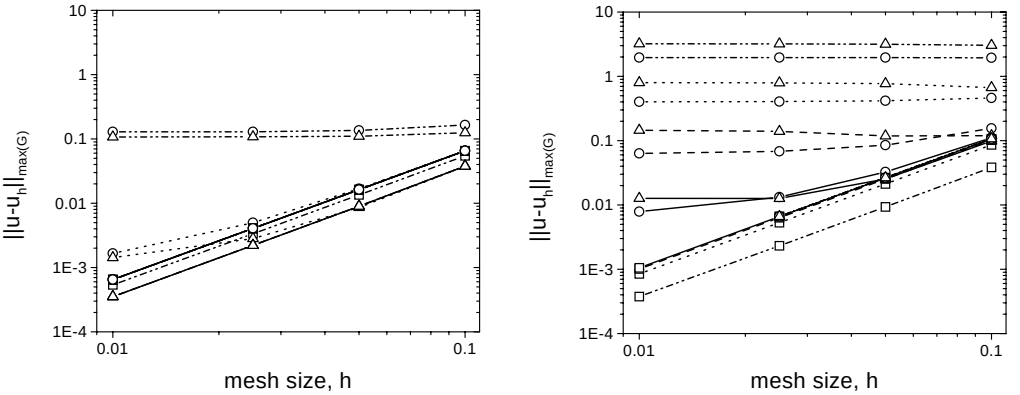
Computations were performed on a variety of platforms, the most powerful of which was a PIII 500MHz machine. The largest mesh size considered contained on the order of 36,000 nodes. The multivariate normal probabilities utilized for the multiple asset analytical solutions were computed using a double precision archived implementation of the code presented in [46].

4.2. Asymptotic analysis. The following formulations are provided in the so-called risk neutral measure $\mathbb{Q}$, designating complete markets and unique option prices (cf. section 2.2). We remark that the process (2.1) is fully specified by its drift and volatility, whereas the options themselves are uniquely determined by their payoff attributes represented by the function ψ in (2.3). Figure 1 provides the key which is utilized in all subsequent graphics.

(I) *European put option on the minimum of n-assets.* In this case, the logarithm of each stock's price is represented by a component of the diffusion X_t, the discounting factor a_0 and drifts b_j are taken to be the (fixed) risk-free rate of return $r \in \mathbb{R}$, and the payoff is defined such that

$$\psi(X_T, T) = \max\Big\{E - \min\left[e^{X_1}, e^{X_2}, \ldots, e^{X_n}\right], 0\Big\},$$

where E denotes the exercise price of the option. The constraint utilized for the



a. Single asset. *b. Two assets.*

FIG. 2. *European put option on the minimum of n assets.*

European options was the depreciated payoff

$$\psi(X_t, t) = \max\left\{E \cdot e^{-r\,(T-t)} - \min\left[e^{X_1}, e^{X_2}, \ldots, e^{X_n}\right], 0\right\}.$$

In the case of a single asset, the European put price is given by the celebrated Black–Scholes formula. For the two asset case, the Black–Scholes formula is generalized in Stultz [47]. The stochastic process (2.1) was defined such that $\sigma_{ii} = 0.3$, $\sigma_{ij} = 0$ $(i \neq j)$, $r = 0.1$, $T = 1.0$, while for the payoff we assumed $E = 100$. The center of the computational grid (and of G) was taken to be $\ln(E)$ in the single asset case and $(\ln(E), \ln(E))$ in the two asset case.

Figure 2 presents the convergence of methods (i) and (ii) on the approximating domain $\overline{G}$ for the one $(n = 1)$ and two $(n = 2)$ asset European cases. As European options do not exercise early, the variational inequality (2.5) reduces to a standard parabolic partial differential equation in this case. Computationally, when a European option is implemented as a variational inequality, the constraint would not be expected to enter into the projected SOR algorithm (thus, the problem would implicitly be solved as a parabolic partial differential equation). Indeed, we found that solving the equations via projected SOR, as opposed to SOR, resulted in slightly larger computed errors. The exception to this was the method (ii) formulation of the single asset put, which converged for significantly smaller computational domains in the variational setting (when projected SOR was employed), as opposed to a partial differential equation formulation (solved by SOR). The variational formulation (projected SOR) values are recorded in Figure 2 in the single asset case.

(II) *Call option on the minimum of n-assets.* As with the put, here we take the logarithm of each stock's price to be a component of the diffusion X_t, the discounting factor a_0 and drifts b_j again taken to be the risk-free rate of return r, and the payoff defined such that

$$\psi(X_T, T) = \max\Big\{\min\left[e^{X_1}, e^{X_2}, \ldots, e^{X_n}\right] - E, 0\Big\},$$

where E denotes the exercise price of the option. In this case, the time evolving constraint is the payoff

$$\psi(X_t, t) = \max\left\{\min\left[e^{X_1}, e^{X_2}, \ldots, e^{X_n}\right] - E, 0\right\}.$$

Calls, as defined here, do not exercise early. For a single asset, the sum of the European call plus the depreciated exercise price of the option equates to the European put price added to the asset's value; a principle known as put-call parity. For multiple assets, a variety of call options valuations are derived in Johnson [33] (cf. also [47]).

We found it necessary in the single asset case ($n = 1$) to run computations for the function $\widetilde{u}_k$ and to compute $u|_{\partial\Omega_k} = \widetilde{u}_k + \Psi$ (rather than calculate $u|_{\partial\Omega_k}$ directly, cf. section 4.1) in order to make method (ii) stable. We note that by (A4) we require the payoff function ψ to have bounded growth. Therefore, it is not surprising that we needed to compute $\widetilde{u}_k$ as per (2.5) rather than $u|_{\partial\Omega_k}$ directly. By contrast (and perhaps surprisingly), we were able to compute $u|_{\partial\Omega_k}$ directly for the multiple asset cases ($n = 2, 3$ trials), which afforded significant coding simplifications.

Figure 3 pertains to the convergence of the approximations on $\overline{G}$ to the analytic European call value for up to three assets. Here the stochastic process and payoff are defined by $\sigma_{ii} = 0.3$, $\sigma_{ij} = 0$ $(i \neq j)$, $r = 0.1$, $T = 1.0$, $E = 100$, and the computational grid centered about $\ln(E)$ in each component. As with the European put on a single asset, we utilized the variational inequality setting (i.e., projected SOR) only in the case of the call on a single asset for method (ii), convergence being obtained without the use of the constraint (that is, with SOR) for suitably large computational domains. The method (ii) implementation for calls on multiple assets ($n > 1$) was always stable (for any mesh and computational sizes) without the use of the constraint (the results represented in Figure 3). As with the European puts, utilizing the constraint for the European call options on multiple assets (that is, projected SOR as opposed to SOR) generally resulted in slightly larger computed errors.

(III) *Put option on the geometric average of n-assets.* As above, the logarithm of each stock's price is represented by a component of the diffusion X_t and the discounting factor a_0 and drifts b_j are taken to be the risk-free rate of return r. The payoff in this case is defined to be

$$\psi(X_T, T) = \max\left\{E - \left(e^{X_1} \cdot e^{X_2} \cdot \ldots \cdot e^{X_n}\right)^{1/n}, 0\right\},$$

the constraint for a European option is given by the depreciated payoff

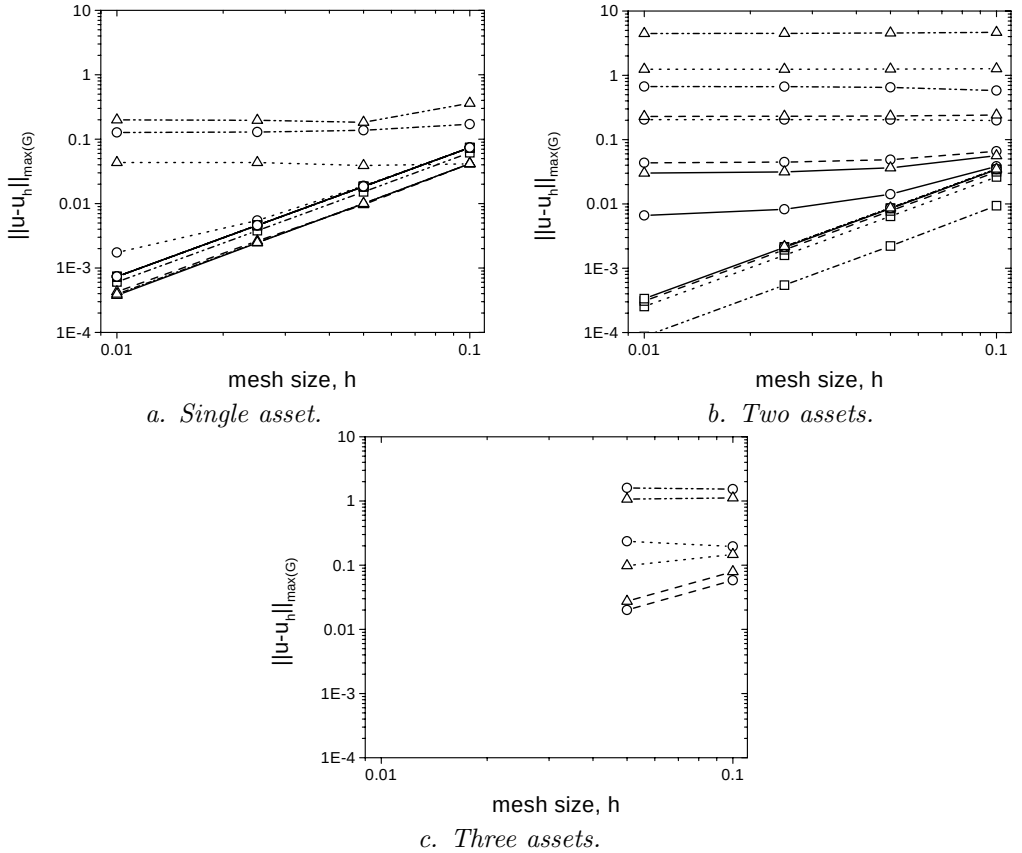
$$\psi(X_t, t) = \max\left\{E \cdot e^{-r\,(T-t)} - \left(e^{X_1} \cdot e^{X_2} \cdot \ldots \cdot e^{X_n}\right)^{1/n}, 0\right\},$$

while for an American option it is

$$\psi(X_t, t) = \max\left\{E - \left(e^{X_1} \cdot e^{X_2} \cdot \ldots \cdot e^{X_n}\right)^{1/n}, 0\right\},$$

where E again denotes the exercise price of the option. Unlike the previous cases, no analytic solution exists here for the European ($n > 1$) or American options (any $n > 0$). However, by introducing the process $Y_t = X_1 + X_2 + \cdots + X_n$ such that $\psi(Y_t) = \max\{E - e^{Y_t/n}, 0\}$, we are able to value these options by numerically approximating $4(Y_t)$, which has only a single source of uncertainty (that is, by solving the single state variable variational inequality for Y_t). The computed solutions for $4(Y_t)$ were then utilized as benchmarks for both the European and American cases when solved according to methods (i) and (ii) (with $h = 0.001$).

Figure 4 presents convergence results for the European case and Figure 5 the analogous results for the American case for up to three assets ($n \leq 3$), where $\sigma_{ii} = 0.3$, $\sigma_{ij} = 0$ $(i \neq j)$, $r = 0.1$, $T = 1.0$, and $E = 100$, and again the computational



a. Single asset. *b. Two assets.*

c. Three assets.

FIG. 3. *European call option on the minimum of n assets.*

grid was centered about $\ln(E)$ per coordinate axis. Note that the European put on the geometric average of a single asset is provided in Figure 2(a). We remark that the presence of the free boundary appears to upset the stability of the method (ii) implementation in the single asset American case for "small" computational domain sizes. (Again, for "larger" computational domain sizes, this was not a problem.) This occurrence was not present for the multiple asset ($n > 1$) tests.

(IV) *Option on a foreign currency.* Here, we denote the (stochastic) instantaneous risk-free rate of return at time t within the domestic economy by $a_0 = X_1$, the foreign economy by X_2, and the logarithm of the cross-currency exchange rate by X_3. It follows then that the payoff of a put on a foreign currency is given by

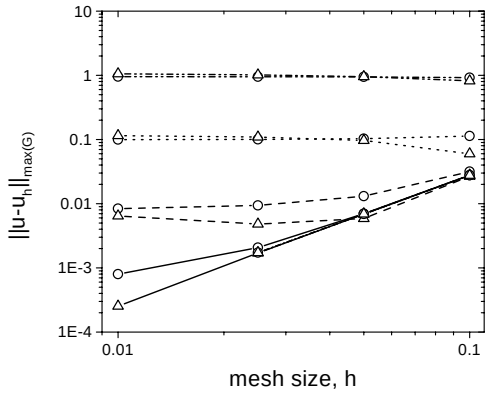
$$\psi(X_T, T) = \max\{E - e^{X_3}, 0\},$$

such that in the European case the time varying constraint is specified as

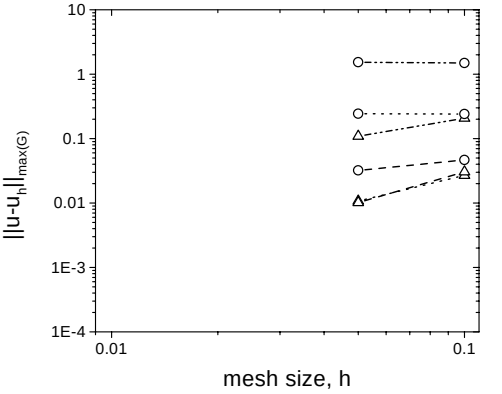
$$\psi(X_t, t) = \begin{cases} \max\{E - e^{X_3}, 0\} & \text{if } X_1 < 0, \\ \max\{E \cdot e^{-X_1 (T-t)} - e^{X_3}, 0\} & \text{if } X_1 \geq 0, \end{cases}$$

and by

$$\psi(X_t, t) = \max\{E - e^{X_3}, 0\},$$



a. Two assets.



b. Three assets.

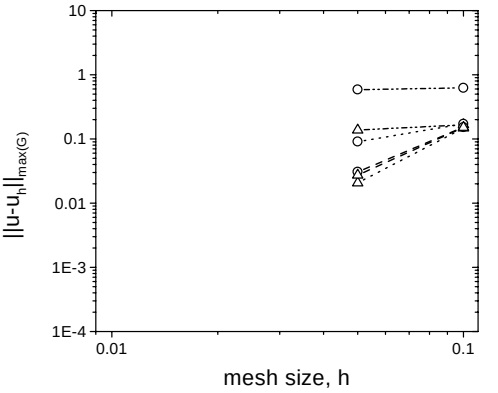
b. Two assets.



c. Three assets.

FIG. 5. *American put option on the geometric average of n assets.*

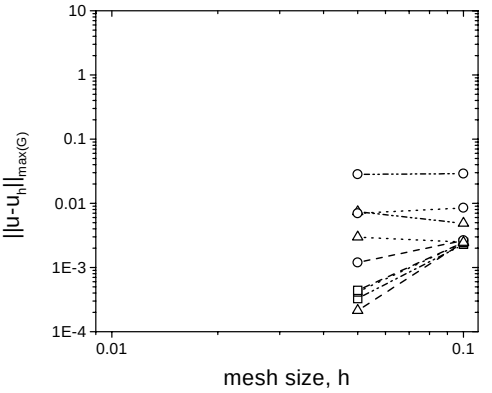


FIG. 6. *European put option on a foreign currency.*

in the American case, where E is the exercise price of the option. The specific model utilized is introduced in Choi and Marcozzi [13]. The general model for American options on a foreign currency under stochastic interests rates was first developed in Amin and Jarrow [2], which includes an analytic solution applicable to the European case specified here. The convergence results for the approximation schemes of section 3 are presented in Figure 6 for the European option. In particular, we suppose

$$\sigma = \begin{bmatrix} 0.05 & 0.005 & 0.005 \\ 0.005 & 0.05 & 0.005 \\ 0.03 & 0.03 & 0.3 \end{bmatrix}$$

in addition to taking $b_1 = 0.005$, $b_2 = 0.005 - \sum_{i=1}^{3} \sigma_{2i}\sigma_{3i}$, $b_3 = X_1 - X_2 - \sum_{i=1}^{3} \sigma_{3i}^2/2$, an exercise price of $E = 1$, and a duration of $T = 1$.

We note that for a computational mesh radius of $R_c = 0.8$ and a mesh size of $h = 0.05$, we obtained a computed solution utilizing method (i) of $u_k = 0.114450$ at $(0.05, 0.05, 0)$, the center of the computational domain. This compares to the analytic value of $u = 0.114477$, for a difference of 0.02%. We remark by way of comparison that the two-step discrete formulation in Amin and Bordurtha [1] was never demonstrated to have attained asymptotic convergence nor an accuracy greater than possibly 2–10% in spite of having employed a mesh of up to 2.6 million nodes (versus about 36,000 nodes for the present computations) and a graded time step (which significantly reduced the number of nodes). For the corresponding American option, we obtained a value of 0.117160, or only approximately 2% greater than for the European case.

We summarize the following points.

1. Method (ii) demonstrates the feasibility (and desirability) of solving evolutionary partial differential equations and variational inequalities on unbounded regions by implicit time discretization without the use of explicit boundary information. For European options written on a single asset ($n = 1$), we did, however, find it preferable to actually employ a variational inequality format and projected SOR when using method (ii).
2. The estimate (3.9) appears valid for method (ii) as well as method (i). In all tests, both methods converged at the anticipated asymptotic rate and realized comparable accuracies on the fixed approximation domain for suitably large computational domains. Conversely, for both methods (i) and (ii), and in

all cases considered, mesh refinement without suitably large computational domains resulted in no improvement of accuracy.

3. It appears that method (ii) becomes increasingly more efficient relative to method (i) as the number of state variables (the dimension n) increases; that is, method (ii) reaches its asymptotic limit with smaller computational domains. Indeed, in almost all cases tested involving three sources of uncertainty, method (ii) was able to obtain comparable accuracies to method (i) while simultaneously employing significantly fewer nodes in the mesh, the generality of this conclusion being predicated, however, on the particular choice of the constraint employed.
4. In the case of early stopping involving calculations employing a uniform mesh (or without an adaptive mesh strategy to locate the free boundary), the use of a smaller computational domain coupled with finer mesh sizing (relative to the nonearly stopping case) seems optimal. This may prove to be a necessary approach as adaptive mesh strategies for complicated free surfaces in dimensions greater than two may not be practical to implement. Conversely, when early stopping occurs, some form of adaptive meshing or local mesh refinement appears necessary in order to achieve asymptotic convergence rates and accuracies. We remark that this has consequences relative to the efficiency of projected solvers.

With the exception of dynamic programming (e.g., lattice) methods, which can be developed as a special case of variational techniques (cf. [23], [31]), there exist *no* alternative methodologies for determining the value function when continuous early exercise is allowed. Additionally, because lattice techniques rely on explicit time discretization and do not employ explicit boundary conditions, they are inherently less efficient than variational methods, particularly as greater accuracy is sought. With the exception of example (IV) above, we note that no existing benchmark computations exist at this time with which to compare the performance of the proposed methods. Ongoing research indicates that so-called *hp*-methods, featuring relatively large mesh sizing and adaptive time stepping (cf. [4], [45], [22]), and high performance computing appear to hold particular potential for multiple state variables applications. The present framework may also be extended to include path dependent processes (cf. [41]). Finally, this paper validates the asymptotic efficiency of methods (i) and (ii) for computing the value functions associated with general optimal stopping problems through their field equation representations.

SYMPLECTIC BALANCING OF HAMILTONIAN MATRICES*

PETER BENNER†

Abstract. We discuss the balancing of Hamiltonian matrices by structure preserving similarity transformations. The method is closely related to balancing nonsymmetric matrices for eigenvalue computations as proposed by Osborne [*J. ACM*, 7 (1960), pp. 338–345] and Parlett and Reinsch [*Numer. Math.*, 13 (1969), pp. 296–304] and implemented in most linear algebra software packages. It is shown that isolated eigenvalues can be deflated using similarity transformations with symplectic permutation matrices. Balancing is then based on equilibrating row and column norms of the Hamiltonian matrix using symplectic scaling matrices. Due to the given structure, it is sufficient to deal with the leading half rows and columns of the matrix. Numerical examples show that the method improves eigenvalue calculations of Hamiltonian matrices as well as numerical methods for solving continuous-time algebraic Riccati equations.

1. Introduction.

The eigenvalue problem for *Hamiltonian matrices*

$$H = \begin{bmatrix} A & G \\ Q & -A^T \end{bmatrix}, \tag{1.1}$$

where $A, G, Q \in \mathbb{R}^{n\times n}$ and G, Q are symmetric, plays a fundamental role in many algorithms of control theory and other areas of applied mathematics as well as computational physics and chemistry. Computing the eigenvalues of Hamiltonian matrices is required, e.g., when computing the $\mathcal{H}_\infty$–norm of transfer matrices (see, e.g., [9, 10]), when calculating the stability radius of a matrix [14, 30], when computing response functions [23], and when performing many other calculations. Hamiltonian matrices are also closely related to *continuous-time algebraic Riccati equations* (CARE) of the form

$$0 = Q + A^T X + XA - XGX \tag{1.2}$$

with A, G, Q as in (1.1): $X \in \mathbb{R}^{n\times n}$ is a symmetric solution matrix. Many numerical methods for solving (1.2) are based on computing certain invariant subspaces of the related Hamiltonian matrices; see, e.g., [20, 22, 27, 29]. For a detailed discussion of the relations of Hamiltonian matrices and CARE (1.2) we refer to [19].

In eigenvalue computations, matrices and matrix pencils are often preprocessed using a *balancing* procedure as described in [24, 26] for a general matrix $A \in \mathbb{R}^{n\times n}$. First, A is permuted via similarity transformations in order to isolate eigenvalues, i.e., a permutation matrix $P \in \mathbb{R}^{n\times n}$ is computed such that

$$P^T A P = \begin{bmatrix} T_1 & X & Y \\ 0 & Z & W \\ 0 & 0 & T_2 \end{bmatrix}, \tag{1.3}$$

where $T_1 \in \mathbb{R}^{p\times p}$ and $T_2 \in \mathbb{R}^{q\times q}$ are upper triangular matrices. Then a diagonal matrix

$$D := \begin{bmatrix} I_p & 0 & 0 \\ 0 & D_Z & 0 \\ 0 & 0 & I_q \end{bmatrix}, \qquad D_Z := \operatorname{diag}(d_{p+1}, \ldots, d_{n-q}),$$

is computed such that rows and columns of $D_Z^{-1} Z D_Z$ are as close in norm as possible. That is, balancing consists of a permutation step and a scaling step. In the scaling step, the rows and columns of a matrix are scaled, which usually leads to a decrease of the matrix norm. This preprocessing step often improves the accuracy of computed eigenvalues significantly; *isolated eigenvalues* (i.e., those contained in T_1 and T_2) are even computed without roundoff error.

Unfortunately, applying this balancing strategy to a Hamiltonian matrix H as given in (1.1) will in general destroy the Hamiltonian structure. This is no problem if the subsequent eigenvalue algorithm does not preserve or use the Hamiltonian structure. But during the past fifteen years, several structure preserving methods for the Hamiltonian eigenproblem have been suggested. In particular, the square-reduced method [32], the Hamiltonian QR algorithm (if in (1.1), $\operatorname{rank} G = 1$ or $\operatorname{rank} Q = 1$) [13], the recently proposed algorithm based on a symplectic URV-like decomposition [7], or the implicitly restarted symplectic Lanczos method of [5] for large sparse Hamiltonian eigenproblems are appropriate choices for developing subroutines for library usage and raise the need for a symplectic balancing routine. Similarity transformations by symplectic matrices preserve the Hamiltonian structure. Thus, in order to balance a Hamiltonian matrix and to preserve its structure, the required permutation matrix and the diagonal scaling matrix should in general be symplectic—only in very special cases can these goals be achieved by nonsymplectic similarity transformations, e.g., if $A = 0$ in (1.1).

In section 2 we will give some necessary background. Isolating eigenvalues of Hamiltonian matrices without destroying the structure can be achieved using symplectic permutation matrices. This will be the topic of section 3. How to equilibrate rows and norms of Hamiltonian matrices in a similar way as proposed in [26] using symplectic diagonal scaling matrices will be presented in section 4. When invariant subspaces, eigenvectors, or solutions of algebraic Riccati equations are the target of the computations, some postprocessing steps are required. These and some other applications of the proposed symplectic balancing method are discussed in section 5. Some numerical examples on the use of the proposed balancing strategy for eigenvalue computation and the numerical solution of algebraic Riccati equations are given in section 6.

2. Preliminaries. The following classes of matrices will be employed in what follows.

DEFINITION 2.1. *Let*

$$J := J_n := \begin{bmatrix} 0 & I_n \\ -I_n & 0 \end{bmatrix}, \tag{2.1}$$

where I_n is the $n\times n$ identity matrix. If the size of the matrix is clear from the context, we leave off the subscript.

(a) *A matrix $H \in \mathbb{R}^{2n\times 2n}$ is* Hamiltonian *if $(HJ)^T = HJ$. The Lie algebra of Hamiltonian matrices in $\mathbb{R}^{2n\times 2n}$ is denoted by $\mathcal{H}_{2n}$.*

(b) *A matrix* $\mathcal{H} \in \mathbb{R}^{2n\times 2n}$ *is* skew-Hamiltonian *if* $(HJ)^T = -HJ$. *The Jordan algebra of skew-Hamiltonian matrices in* $\mathbb{R}^{2n\times 2n}$ *is denoted by* $\mathcal{SH}_{2n}$.

(c) *A matrix* $S \in \mathbb{R}^{2n\times 2n}$ *is* symplectic *if* $SJS^T = J$ *or, equivalently,* $S^TJS = J$. *The Lie group of symplectic matrices in* $\mathbb{R}^{2n\times 2n}$ *is denoted by* $\mathcal{S}_{2n}$.

(d) *A matrix* $U \in \mathbb{R}^{2n\times 2n}$ *is* unitary symplectic *if* $U \in \mathcal{S}_{2n}$ *and* $UU^T = I_{2n}$. *The compact Lie group of unitary symplectic matrices in* $\mathbb{R}^{2n\times 2n}$ *is denoted by* $\mathcal{US}_{2n}$.

Observe that every $H \in \mathcal{H}_{2n}$ has the block representation given in (1.1).

In [12], an important relation between symplectic and Hamiltonian matrices is proved.

PROPOSITION 2.2. *Let* $S \in \mathbb{R}^{2n\times 2n}$ *be nonsingular. Then* $S^{-1}HS$ *is Hamiltonian for all* $H \in \mathcal{H}_{2n}$ *if and only if* $S^TJS = \alpha J$ *for some* $\alpha \in \mathbb{R} \setminus \{0\}$.

This result shows that, in general, similarity transformations that preserve the Hamiltonian structure have to be symplectic up to scaling with a real scalar.

The following proposition shows that the structure of $2n \times 2n$ orthogonal symplectic matrices permits them to be represented as a pair of $n \times n$ matrices. Hence, the arithmetic cost and storage for accumulating orthogonal symplectic matrices can be halved.

PROPOSITION 2.3 (see [25]). *An orthogonal matrix* $U \in \mathbb{R}^{2n\times 2n}$ *is symplectic if and only if it takes the form* $U = \left[\begin{smallmatrix} U_1 & U_2 \\ -U_2 & U_1 \end{smallmatrix}\right]$, *where* $U_i \in \mathbb{R}^{n\times n}$, $i = 1, 2$.

We have the following well-known property of the spectra of Hamiltonian matrices (see, e.g., [19, 22] and the references given therein).

PROPOSITION 2.4. *The spectrum of a real Hamiltonian matrix* H, *denoted by* $\sigma(H)$ *is symmetric with respect to the imaginary axis, i.e., if* $\lambda \in \sigma(H)$, *then* $-\lambda \in \sigma(H)$. *The spectrum of* $H \in \mathcal{H}_{2n}$ *can therefore be partitioned as*

$$\sigma(H) = \{\lambda_1, \ldots, \lambda_k\} \cup \{-\lambda_1, \ldots, -\lambda_k\} \cup \{\pm\lambda_{k+1}, \ldots, \pm\lambda_n\} =: \Delta \cup (-\Delta) \cup \Delta_0,$$

where $Re(\lambda_j) > 0$, $j = 1, \ldots, k$, *and* $Re(\lambda_j) = 0$, $j = k+1, \ldots, n$.

In many applications, $\Delta_0 = \emptyset$. Note that the multiplicities of the eigenvalues collected in Δ_0 play an essential role for the existence of structured Schur forms for Hamiltonian matrices as outlined below.

Real Schur forms play an important role when solving eigenvalue problems for nonsymmetric matrices. For Hamiltonian matrices, Schur forms should be computed in a structure-preserving way.

DEFINITION 2.5. (a) *Let* $\hat{H} \in \mathcal{H}_{2n}$. *If* $\hat{H}$ *has the form*

$$\hat{H} = \begin{bmatrix} \hat{A} & \hat{G} \\ 0 & -\hat{A}^T \end{bmatrix}, \tag{2.2}$$

where $\hat{A} \in \mathbb{R}^{n\times n}$ *is in real Schur form (quasi-upper triangular) and* $\hat{G} = \hat{G}^T$, *then* $\hat{H}$ *is* real Hamiltonian quasi-triangular.

(b) *If* $H \in \mathcal{H}_{2n}$ *and there exists* $U \in \mathcal{US}_{2n}$ *such that* $\hat{H} = U^THU$ *is real Hamiltonian quasi-triangular, then* $\hat{H}$ *is in* real Hamiltonian Schur form *and* U^THU *is called a* Hamiltonian Schur decomposition.

DEFINITION 2.6. *A subspace* $\mathcal{V} \subset \mathbb{R}^{2n}$ *is called* isotropic *if* $x^TJy = 0$ *for all* $x, y \in \mathcal{V}$. *It is called* Lagrangian *if it is isotropic and maximal, i.e., if it is not contained in a larger isotropic subspace* $\mathcal{W} \subset \mathbb{R}^{2n}$.

If a Hamiltonian Schur decomposition exists such that $\hat{H}$ is as is (2.2), then U can be chosen such that $\sigma(\hat{A})$ is contained in the closed right half plane. Moreover, the first n columns of the orthogonal symplectic matrix U in the Hamiltonian Schur

decomposition span a Lagrangian H-invariant subspace. Using the notation from Proposition 2.4, if $\Delta_0 = \emptyset$ and $\sigma(\hat{A}) = -\Delta$, then we say that this H-invariant subspace is *c-stable*. That is, if it exists, the c-stable H-invariant subspace corresponds to the n eigenvalues of H in the open left half plane.

Most of the structure-preserving methods for the Hamiltonian eigenproblem, i.e., those using symplectic (similarity) transformations, rely on the following result. For Hamiltonian matrices with no purely imaginary eigenvalues this result was first stated in [25], while in its full generality as given below it has been proved in [21].

THEOREM 2.7. *Let $H \in \mathcal{H}_{2n}$, and let $i\alpha_1, \ldots, i\alpha_\ell$ be its pairwise distinct nonzero purely imaginary eigenvalues. Furthermore, let the associated H-invariant subspaces be spanned by the columns of $U_k \in \mathbb{R}^{2n\times p_k}$, $k = 1, \ldots, \ell$. Then the following are equivalent.*

(i) *There exists $S \in \mathcal{S}_{2n}$ such that $S^{-1}HS$ is real Hamiltonian quasi-triangular.*
(ii) *There exists $U \in \mathcal{US}_{2n}$ such that U^THU is in real Hamiltonian Schur form.*
(iii) *$U_k^H J_n U_k$ is congruent to J_{p_k} for all $k = 1, \ldots, \ell$.*

Note that from Theorem 2.7 it follows that purely imaginary eigenvalues of $H \in \mathcal{H}_{2n}$ (if any) must have even algebraic multiplicity in order for the Hamiltonian Schur form of H to exist.

3. Isolating eigenvalues by symplectic permutations. Let P denote any $n \times n$ permutation matrix. It is easy to see that symplectic permutation matrices have the form

$$P_s = \begin{bmatrix} P & 0 \\ 0 & P \end{bmatrix}. \tag{3.1}$$

With matrices of type (3.1) it is possible to transform a Hamiltonian matrix to the form

$$\tilde{H} = P_s H P_s = \left[\begin{array}{ccc|ccc} A_{11} & A_{12} & A_{13} & G_{11} & G_{12} & G_{13} \\ 0 & A_{22} & A_{23} & G_{12}^T & G_{22} & 0 \\ 0 & 0 & A_{33} & G_{13}^T & 0 & 0 \\ \hline 0 & 0 & Q_{13} & -A_{11}^T & 0 & 0 \\ 0 & Q_{22} & Q_{23} & -A_{12}^T & -A_{22}^T & 0 \\ Q_{13}^T & Q_{23}^T & Q_{33} & -A_{13}^T & -A_{23}^T & -A_{33}^T \end{array}\right] \begin{array}{l} \}p \\ \}n-p-q =: r \\ \}q \\ \}p \\ \}n-p-q = r \\ \}q \end{array}, \tag{3.2}$$
$$\underbrace{}_{p}\ \underbrace{}_{r}\ \underbrace{}_{q}\ \underbrace{}_{p}\ \underbrace{}_{r}\ \underbrace{}_{q}$$

where A_{11}, A_{33} are upper triangular and either $Q_{13} = 0$ or $G_{13} = 0$. The existence of such a P_s will be proved in a constructive way later by Algorithm 3.4, which transforms a Hamiltonian matrix to the form given in (3.2). From a Hamiltonian matrix having the form (3.2) a total of $2(p+q)$ eigenvalues of H can be read off directly as seen by the following result.

LEMMA 3.1. *Let $H \in \mathcal{H}_{2n}$ and $p, q, r \in \mathbb{N}_0$ with $r = n - p - q$, where H is of the form* (3.2) *and either $G_{13} = 0$ or $Q_{13} = 0$. Then there exists a permutation matrix $P \in \mathbb{R}^{2n\times 2n}$ such that*

$$T = P^THP = \begin{bmatrix} T_1 & Y & Z \\ 0 & H_{22} & W \\ 0 & 0 & T_2 \end{bmatrix}, \tag{3.3}$$

where $T_1, T_2 \in \mathbb{R}^{(p+q)\times(p+q)}$ are upper triangular with

$$\sigma(T_1) = \sigma(-T_2) \tag{3.4}$$

and

$$H_{22} = \begin{bmatrix} A_{22} & G_{22} \\ Q_{22} & -A_{22}^T \end{bmatrix} \tag{3.5}$$

is a $2r \times 2r$ *Hamiltonian submatrix of* H.

Proof. Let H be as in (3.2) and

$$P_1 := \left[\begin{array}{ccc|ccc} 0 & I_p & 0 & 0 & 0 & 0 \\ 0 & 0 & I_r & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & I_q \\ \hline 0 & 0 & 0 & 0 & I_p & 0 \\ 0 & 0 & 0 & I_r & 0 & 0 \\ I_q & 0 & 0 & 0 & 0 & 0 \end{array}\right]. \tag{3.6}$$

Then

$$P_1^T H P_1 = \left[\begin{array}{cc|cc|cc} -A_{33}^T & Q_{13}^T & Q_{23}^T & -A_{23}^T & -A_{13}^T & Q_{33} \\ G_{13}^T & A_{11} & A_{12} & G_{12} & G_{11} & A_{13} \\ \hline 0 & 0 & A_{22} & G_{22} & G_{12}^T & A_{23} \\ 0 & 0 & Q_{22} & -A_{22}^T & -A_{12}^T & Q_{23} \\ \hline 0 & 0 & 0 & 0 & -A_{11}^T & Q_{13} \\ 0 & 0 & 0 & 0 & G_{13} & A_{33} \end{array}\right]. \tag{3.7}$$

Define

$$\Pi_m := \begin{bmatrix} & & 1 \\ & \diagup & \\ 1 & & \end{bmatrix} \in \mathbb{R}^{m \times m}. \tag{3.8}$$

If $G_{13} = 0$, then set $P_2 := \operatorname{diag}(\Pi_q, I_p, I_r, I_r, \Pi_p, I_q)$. Otherwise ($Q_{13} = 0$), set

$$P_2 := \left[\begin{array}{cc|cc|cc} 0 & \Pi_q & & & & \\ I_p & 0 & & & & \\ \hline & & I_r & 0 & & \\ & & 0 & I_r & & \\ \hline & & & & 0 & \Pi_p \\ & & & & I_q & 0 \end{array}\right].$$

Thus, $T := P_2^T P_1^T H P_1 P_2$ has the desired form. The relation (3.4) follows from

$$\begin{bmatrix} 0 & I_p \\ -I_q & 0 \end{bmatrix}^{-1} \begin{bmatrix} -A_{11}^T & Q_{13} \\ G_{13} & A_{33} \end{bmatrix} \begin{bmatrix} 0 & I_p \\ -I_q & 0 \end{bmatrix} = - \begin{bmatrix} -A_{33}^T & Q_{13}^T \\ G_{13}^T & A_{11} \end{bmatrix}^T. \qquad \square$$

Lemma 3.1 is merely of theoretical interest and demonstrates that in order to solve the Hamiltonian eigenvalue problem, we can proceed by working only with H_{22}. But the transformations we have used in the proof are, in general, not symplectic. If we want to compute invariant subspaces, eigenvectors, and/or the Hamiltonian Schur form given in Theorem 2.7, we can transform the Hamiltonian matrix in (3.2) such that it has Hamiltonian Schur form in rows and columns $1, \ldots, p+q$ and $n+1, \ldots, n+p+q$. But this cannot, in general, be accomplished using only symplectic permutation matrices of the form (3.1). Therefore, we need another class of transformation matrices.

DEFINITION 3.2. *A matrix $P_J \in \mathbb{R}^{2n\times 2n}$ is called a* J-permutation matrix *if*
(a) *it is symplectic, i.e., $P_J^T J P_J = J$,*
(b) *$(P_J)_{j,k} \in \{-1, 0, 1\}$ for $j,k = 1,\ldots,2n$, and*
(c) *each row and column have exactly one nonzero entry.*

As $P_J \in \mathcal{US}_{2n}$, it is clear that a similarity transformation by a J-permutation matrix preserves the Hamiltonian structure. In analogy to standard permutations, similarity transformations with P_J can be performed without floating point operations. Moreover, they can be represented by a signed integer vector IP of length n, where $\mathtt{IP}(k) = \pm j$, $k = 1,\ldots,n$, $j = 1,\ldots,2n$, if rows and columns k, j are to be interchanged while the sign indicates if the corresponding entry in P_J is $+1$ or -1. The entries of P_J in rows $n+1$ to $2n$ can be deduced from IP and Proposition 2.3. Furthermore, symplectic permutation matrices as given in (3.1) are J-permutation matrices.

LEMMA 3.3. *For any $H \in \mathcal{H}_{2n}$ having the form* (3.2)*, there exists a J-permutation matrix P_J such that*

$$\hat{H} \;=\; P_J^T H P_J \;=\; \left[\begin{array}{cc|cc} \hat{A}_{11} & \hat{A}_{12} & \hat{G}_{11} & \hat{G}_{12} \\ 0 & \hat{A}_{22} & \hat{G}_{12}^T & \hat{G}_{22} \\ \hline 0 & 0 & -\hat{A}_{11}^T & 0 \\ 0 & \hat{Q}_{22} & -\hat{A}_{12}^T & -\hat{A}_{22}^T \end{array}\right] \begin{array}{l} \}p+q \\ \}n-p-q=r \\ \}p+q \\ \}n-p-q=r \end{array}, \tag{3.9}$$

where $\hat{A}_{11}$ is upper triangular and, with the notation in (3.2)*,*

$$\hat{A}_{22} \;=\; A_{22}, \qquad \hat{G}_{22} \;=\; G_{22}, \qquad \hat{Q}_{22} \;=\; Q_{22}.$$

Proof. Let a Hamiltonian matrix H be given as in (3.2). We need a J-permutation matrix only in the first step. Let

$$P_1 \;:=\; \left[\begin{array}{ccc|ccc} I_p & 0 & 0 & 0 & 0 & 0 \\ 0 & I_r & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & I_q \\ \hline 0 & 0 & 0 & I_p & 0 & 0 \\ 0 & 0 & 0 & 0 & I_r & 0 \\ 0 & 0 & -I_q & 0 & 0 & 0 \end{array}\right].$$

Obviously, P_1 is a J-permutation matrix and

$$H_1 \;:=\; P_1^T H P_1 \;=\; \left[\begin{array}{ccc|ccc} A_{11} & A_{12} & -G_{13} & G_{11} & G_{12} & A_{13} \\ 0 & A_{22} & 0 & G_{12}^T & G_{22} & A_{23} \\ -Q_{13}^T & -Q_{23}^T & -A_{33}^T & A_{13}^T & A_{23}^T & -Q_{33} \\ \hline 0 & 0 & 0 & -A_{11}^T & 0 & Q_{13} \\ 0 & Q_{22} & 0 & -A_{12}^T & -A_{22}^T & Q_{23} \\ 0 & 0 & 0 & G_{13}^T & 0 & A_{33} \end{array}\right].$$

Now assume $G_{13} = 0$. Set $P_2 := \operatorname{diag}(\tilde{P}_2, \tilde{P}_2)$, where

$$\tilde{P}_2 \;:=\; \left[\begin{array}{ccc} 0 & I_p & 0 \\ 0 & 0 & I_r \\ I_q & 0 & 0 \end{array}\right].$$

Then

$$H_2 \;:=\; P_2^T H_1 P_2 \;=\; \left[\begin{array}{ccc|ccc} -A_{33}^T & -Q_{13}^T & -Q_{23}^T & -Q_{33} & A_{13}^T & A_{23}^T \\ 0 & A_{11} & A_{12} & A_{13} & G_{11} & G_{12} \\ 0 & 0 & A_{22} & A_{23} & G_{12}^T & G_{22} \\ \hline 0 & 0 & 0 & A_{33} & 0 & 0 \\ 0 & 0 & 0 & Q_{13} & -A_{11}^T & 0 \\ 0 & 0 & Q_{22} & Q_{23} & -A_{12}^T & -A_{22}^T \end{array}\right].$$

We thus obtain the form (3.9) by another similarity transformation with

$$P_3 := \operatorname{diag}(\Pi_q,\, I_p,\, I_r,\, \Pi_q,\, I_p,\, I_r),$$

where Π_q is defined in (3.8). For the other case, i.e., $Q_{13} = 0$, set

$$\tilde{P}_2 \;=\; \left[\begin{array}{ccc} I_p & 0 & 0 \\ 0 & 0 & I_r \\ 0 & I_q & 0 \end{array}\right],$$

and $P_2 := \operatorname{diag}(\tilde{P}_2,\, \tilde{P}_2)$, $P_3 := \operatorname{diag}(I_p,\, \Pi_q,\, I_r,\, I_p,\, \Pi_q,\, I_r)$.

In both cases, $\hat{P} := P_1 P_2 P_3$ is a J-permutation matrix and $\hat{H} := \hat{P}^T H \hat{P}$ is a Hamiltonian matrix having the desired form (3.9). □

In order to isolate eigenvalues, it is sufficient to restrict ourselves to symplectic permutations. But having computed the form (3.2), it is possible that there are still isolated eigenvalues in H_{22}. Applying the same procedure used to isolate eigenvalues in H to H_{22}, we can transform H_{22} to the form (3.2). This process can then be repeated until no more isolated eigenvalues are found. Accumulating all permutations in a symplectic permutation matrix P_s of the form (3.1) results in a similarity transformation

$$\tilde{H} = P_s^T H P_s \tag{3.10}$$

$$= \left[\begin{array}{ccccc|ccccc} A_{11} & \dots & A_{1,t} & \dots & A_{1,s} & G_{11} & \dots & G_{1,t} & \dots & G_{1,s} \\ 0 & \ddots & \vdots & & \vdots & \vdots & & \vdots & \diagup & 0 \\ \vdots & \ddots & A_{t,t} & \dots & A_{t,s} & G_{1,t}^T & \dots & G_{t,t} & 0 & \vdots \\ \vdots & & \ddots & \ddots & \vdots & \vdots & \diagup & 0 & & \vdots \\ 0 & \dots & \dots & 0 & A_{s,s} & G_{1,s}^T & 0 & \dots & \dots & 0 \\ \hline 0 & \dots & \dots & 0 & Q_{1,s} & -A_{11}^T & 0 & \dots & \dots & 0 \\ \vdots & & 0 & \diagup & \vdots & \vdots & \ddots & \ddots & & \vdots \\ \vdots & 0 & Q_{t,t} & \dots & Q_{t,s} & -A_{t,s}^T & \dots & -A_{t,t}^T & \ddots & \vdots \\ 0 & \diagup & \vdots & & \vdots & \vdots & & \vdots & \ddots & 0 \\ Q_{1,s}^T & \dots & Q_{t,s}^T & \dots & Q_{s,s} & -A_{1,s}^T & \dots & -A_{t,s}^T & \dots & -A_{s,s}^T \end{array}\right] \begin{array}{l} \}p_1 \\ \}p_2 + \ldots + p_{t-1} \\ \}p_t \\ \}p_{t+1} + \ldots + p_{s-1} \\ \}p_s \\ \}p_1 \\ \}p_2 + \ldots + p_{t-1} \\ \}p_t \\ \}p_{t+1} + \ldots + p_{s-1} \\ \}p_s \end{array}.$$

Here, $A_{j,j} \in \mathbb{R}^{p_j \times p_j}$, $j = 1, \ldots, s$, $j \neq t$, are upper triangular and for $j = 1, \ldots, t-1$, either $Q_{j,s-j+1} = 0$ or $G_{j,s-j+1} = 0$ and the Hamiltonian submatrix

$$H_{t,t} = \left[\begin{array}{cc} A_{t,t} & G_{t,t} \\ Q_{t,t} & -A_{t,t}^T \end{array}\right] \tag{3.11}$$

has no isolated eigenvalues. If we now define $p := \sum_{j=1}^{t-1} p_j$, $q := \sum_{j=t+1}^{s} p_j$, then we can partition $\tilde{H}$ in (3.10) as in (3.2). Then the first step in the proof of Lemma 3.1 can be performed to obtain the form (3.7). Just the block-structure of the upper left and lower right diagonal blocks in (3.7) is more complicated. But it is still possible to bring them to upper triangular form using repeatedly the same sequence of permutations used in the proof of Lemma 3.1. This shows that $2(p+q)$ eigenvalues of the Hamiltonian matrix can be read off directly from (3.10) and that $\tilde{H}$ is permutationally similar to

$$\begin{bmatrix} \tilde{T}_1 & \tilde{Y} & \tilde{Z} \\ 0 & H_{t,t} & \tilde{W} \\ 0 & 0 & \tilde{T}_2 \end{bmatrix} = \begin{bmatrix} \blacksquare & \square & \square \\ & \square & \square \\ & & \blacksquare \end{bmatrix}.$$

Further, we have $H_{t,t} \in \mathbb{R}^{2r \times 2r}$, where now $r := p_t = n - p - q$, and

$$\sigma(H) = \sigma(H_{t,t}) \cup \bigcup_{\substack{j=1 \\ j \neq t}}^{s} \sigma(A_{j,j}) \cup \bigcup_{\substack{j=1 \\ j \neq t}}^{s} \sigma(-A_{j,j}^T). \tag{3.12}$$

If only eigenvalues are required, we can continue working only with $H_{t,t}$. If also eigenvectors and/or invariant subspaces are required, the similarity transformations used to solve the reduced-order eigenproblem for $H_{t,t}$ have to be applied to the whole matrix $\tilde{H}$. In that case, $\tilde{H}$ should be transformed to the form given in (3.9). Partitioning $\tilde{H}$ from (3.10) as in (3.2), we can perform the first step of the proof of Lemma 3.3 with the J-permutation matrix P_1. The subsequent steps to achieve upper triangular form in the first $p+q$ rows and columns then have to be performed for each of the first $t-1$ block columns, distinguishing the cases $Q_{j,s-j+1} = 0$ or $G_{j,s-j+1} = 0$ for $j = 1, \ldots, t-1$.

A procedure to transform a Hamiltonian matrix H to the form in (3.10) is given in the following algorithm. Note that in the given algorithm, $p_j = 1$ for all $j = 1, \ldots, s$, $j \neq t$.

ALGORITHM 3.4.

Input: *Matrices $A, G, Q \in \mathbb{R}^{n \times n}$, where $Q = Q^T$, $G = G^T$, defining a Hamiltonian matrix $H \in \mathbb{R}^{2n \times 2n}$.*

Output: *A symplectic permutation matrix P_s; matrices A, G, Q with $G = G^T$, $Q = Q^T$ defining a Hamiltonian matrix $H = P_s^T H P_s$ having the form (3.10); integers $i_l = p_1 + \cdots + p_{t-1} + 1 = p + 1$ and $i_h = i_l + p_t = n - q$.*

$P_s = I_{2n}$
$i_l = 1, \quad i_h = n$
$\tilde{i}_l = 0, \quad \tilde{i}_h = n$
`WHILE` $(i_l \neq \tilde{i}_l)$ `AND` $(i_h \neq \tilde{i}_h)$
  $\tilde{i}_l = i_l, \quad \tilde{i}_h = i_h$
  $i = i_h$
  `WHILE` $(i > i_l)$ `AND` $(i_h = \tilde{i}_h)$
    $\tilde{i}_h = i_h$
    $r = \sum_{\substack{j=i_l \\ j \neq i}}^{i_h} |a_{ij}| + \sum_{j=i_l}^{i_h} |g_{ij}|$

```
        IF (r = 0) THEN
            P̃ = I_n + e_i e_{i_h}^T + e_{i_h} e_i^T − e_i e_i^T − e_{i_h} e_{i_h}^T
            A = P̃^T A P̃,      G = P̃^T G P̃,      Q = P̃^T Q P̃
            P = P · diag(P̃, P̃)
            i_h = i_h − 1
        END IF
        i = i − 1
    END WHILE
    i = i_l
    WHILE (i < i_h) AND (i_l = ĩ_l)
        ĩ_l = i_l
        c = Σ_{j=i_l, j≠i}^{i_h} |a_ji| + Σ_{j=i_l}^{i_h} |q_ji|
        IF (c = 0) THEN
            P̃ = I_n + e_i e_{i_l}^T + e_{i_l} e_i^T − e_i e_i^T − e_{i_l} e_{i_l}^T
            A = P̃^T A P̃,      G = P̃^T G P̃,      Q = P̃^T Q P̃
            P = P · diag(P̃, P̃)
            i_l = i_l + 1
        END IF
        i = i + 1
    END WHILE
  END WHILE
END
```

In each execution of the outer `WHILE`-loop, we first search a row isolating an eigenvalue. If such a row is found, we look for a column isolating an eigenvalue. In this fashion it can be guaranteed that at the end, there are no more isolated eigenvalues, although we always only touch the first n rows and columns of the Hamiltonian matrix.

In an actual implementation one would of course never form the permutation matrices explicitly but store the relevant information in an integer vector. Multiplications by permutation matrices are realized by swapping the data contained in the rows or columns to be permuted; for details, see, e.g., [3].

It is rather difficult to give a complete account of the cost of Algorithm 3.4. If there are no isolated eigenvalues, the algorithm requires $4n^2 - 2n$ floating point additions and $2n$ comparisons as opposed to $8n^2 - 4n$ additions and $4n$ comparisons for the unstructured permutation procedure from [26] as implemented in the LAPACK subroutine xGEBAL [3] when applied to $H \in \mathbb{R}^{2n\times 2n}$. The worst case for Algorithm 3.4 would be that in each execution of the outer `WHILE`-loop, an isolated eigenvalue is found in the last execution of the second inner `WHILE`-loop. In that case, the cost consists of $4n^3/3 + n^2 + O(n)$ floating point additions, $n^2 + n$ comparisons, and moving $2n^2 + 2n$ floating point numbers. But in this worst-case analysis, all eigenvalues are isolated such that after permuting, there is nothing left to do, and the Hamiltonian matrix is in Hamiltonian Schur form. A worst-case study for xGEBAL shows that the permutation part requires $8n^3/3 - 2n^2 + O(n)$ additions, $2n^2 + n$ comparisons, and moving $4n^2 + 2n$ floating point numbers. We can therefore conclude that Algorithm 3.4 is about half as expensive as the procedure proposed in [26] applied to a Hamiltonian matrix.

4. Symplectic scaling. Suppose now that we have transformed the Hamiltonian matrix to the form (3.10). Since all subsequent transformations are determined from $H_{t,t}$, the scaling parameters to balance $H_{t,t}$ now have to be chosen such that the rows and columns of $H_{t,t}$ (instead of $\tilde{H}$) are as close in norm as possible.

In order to simplify notation, in what follows we will call the Hamiltonian matrix again H. Let H_{off} be the off-diagonal part of H, i.e.,

$$H_{\text{off}} = H - \operatorname{diag}(H).$$

We may without loss of generality assume that none of the rows and columns of H_{off} vanishes identically. Otherwise, we could isolate another pair of eigenvalues.

Now we want to scale H such that the norms of its rows and columns are close in norm. As noted before, employing the technique of Parlett and Reinsch [26] destroys the Hamiltonian structure. Diagonal scaling has thus to be performed using a symplectic diagonal matrix D_s. Such a matrix must have the form,

$$D_s = \begin{bmatrix} D & 0 \\ 0 & D^{-1} \end{bmatrix}, \tag{4.1}$$

where $D \in \mathbb{R}^{n\times n}$ is a nonsingular diagonal matrix.

Let us at first note an obvious result for Hamiltonian matrices. Here and in what follows we will use the *colon notation* (see, e.g., [16]) $H(:,k)$, $H(j,:)$ to indicate the kth column and jth row, respectively, of a matrix H.

LEMMA 4.1. *Let $H \in \mathbb{R}^{2n\times 2n}$ be a Hamiltonian matrix. Then for all $p \geq 1$ and for all $i = 1,\ldots,n$,*

$$\|H(:,i)\|_p = \|H(n+i,:)^T\|_p, \tag{4.2}$$

$$\|H(i,:)^T\|_p = \|H(:,n+i)\|_p, \tag{4.3}$$

i.e., the p-norm of the ith column equals the norm of the $(n+i)$th row and the norm of the ith row equal the norm of the $(n+i)$th column.

Proof. The result is obvious by noting that $\|x\|_p = (\sum_{k=1}^{2n} |x_k|^p)^{\frac{1}{p}}$ for $x \in \mathbb{R}^{2n}$ and by observing that from the structure of Hamiltonian matrices, we have

$$\begin{aligned} H(:,i) &= [a_{1,i}, a_{2,i}, \ldots, a_{n,i}, q_{1,i}, q_{2,i}, \ldots, q_{n,i}]^T, \\ H(n+i,:) &= [q_{i,1}, q_{i,2}, \ldots, q_{i,n}, -a_{1,i}, -a_{2,i}, \ldots, -a_{n,i}], \end{aligned}$$

and, furthermore, $q_{ij} = q_{ji}$ for all $1 \leq i,j \leq n$. Equation (4.3) follows analogously by noting that $g_{ij} = g_{ji}$ for all $1 \leq i,j \leq n$. ∎

We can now conclude that it is sufficient to equilibrate the norms of the first n rows and columns of a $2n \times 2n$ Hamiltonian matrix by using a consequence of Lemma 4.1.

COROLLARY 4.2. *Let $H \in \mathbb{R}^{2n\times 2n}$ be a Hamiltonian matrix. Then for all $p \geq 1$ and for all $i = 1,\ldots,n$,*

$$\|H(:,i)\|_p = \|H(i,:)\|_p \iff \|H(:,n+i)\|_p = \|H(n+i,:)\|_p.$$

Since a similarity transformation with any diagonal matrix does not affect the diagonal elements of the transformed matrix, it is in the following sufficient to consider H_{off}. We will employ the notation

$$\begin{aligned} h_i &:= H_{\text{off}}(:,i) \;=\; i\text{th column of } H_{\text{off}}, \\ h^i &:= H_{\text{off}}(i,:)^T \;=\; \text{transpose of the } i\text{th row of } H_{\text{off}}. \end{aligned}$$

In what follows, we will for convenience use $p = 1$. The results also hold for any other p-norm. From a computational point of view it is also reasonable to use the 1–norm since its computation does not involve any floating point multiplications, and, furthermore, reducing the norm of H in one norm usually implies also a reduction in the other norms.

Equilibrating $\|h_i\|_1$ and $\|h^i\|_1$ can now be achieved in a similar way as in the Parlett–Reinsch method. If β denotes the base of the floating point arithmetic and σ_i is any signed integer, then they compute β^{σ_i} closest to the real scalar

$$\delta_i = \sqrt{\|h^i\|_1/\|h_i\|_1}.$$

Thus, with $D^{(i)} = I_{2n} + (\delta_i - 1)e_i e_i^T$ and $\hat{H} = (D^{(i)})^{-1} H D^{(i)}$, it follows that $\|\hat{h}^i\|_1 = \|\hat{h}_i\|_1$. But if $\delta_i \neq 1$, $\hat{H}$ is in general no longer Hamiltonian. Unfortunately, using the symplectic diagonal matrix

$$D_s^{(i)} = \begin{bmatrix} D_i & 0 \\ 0 & D_i^{-1} \end{bmatrix},$$

where $D_i = I_n + (\delta_i - 1)e_i e_i^T$, and computing

$$\tilde{H} = (D_s^{(i)})^{-1} H D_s^{(i)}, \tag{4.4}$$

we obtain

$$\|\tilde{h}_i\|_1 \;=\; \|\hat{h}_i\|_1 - \delta_i|q_{ii}| + \delta_i^2|q_{ii}|, \qquad \|\tilde{h}^i\|_1 \;=\; \|\hat{h}^i\|_1 - \frac{1}{\delta_i}|g_{ii}| + \frac{1}{\delta_i^2}|g_{ii}| \tag{4.5}$$

and thus in general, $\|\tilde{h}_i\|_1 \neq \|\tilde{h}^i\|_1$.

Nevertheless, equilibrating the 1-norms of h_i and h^i can be achieved by requiring $\|\tilde{h}_i\|_1 = \|\tilde{h}^i\|_1$ and solving the resulting quartic equation

$$\delta_i(\|h_i\|_1 - |q_{ii}|) + \delta_i^2|q_{ii}| \;=\; \frac{1}{\delta_i}(\|h^i\|_1 - |g_{ii}|) + \frac{1}{\delta_i^2}|g_{ii}|. \tag{4.6}$$

It remains to show that (4.6) has a positive solution.

THEOREM 4.3. *Let $H \in \mathbb{R}^{2n\times 2n}$ be a Hamiltonian matrix, and denote its off-diagonal part by H_{off}. Assume that none of the rows and columns of H_{off} vanishes identically. Then there exists a unique real number $\delta_i > 0$ such that for $\tilde{H}$ as in* (4.4) *we have*

$$\|\tilde{h}_i\|_1 = \|\tilde{h}^i\|_1 = \|\tilde{h}_{n+i}\|_1 = \|\tilde{h}^{n+i}\|_1.$$

Proof. Solutions of (4.6) are nonzero solutions of

$$0 = |q_{ii}|\delta_i^4 + (\|h_i\|_1 - |q_{ii}|)\delta_i^3 + (|g_{ii} - \|h^i\|_1)\delta_i - |g_{ii}| =: p(\delta_i), \tag{4.7}$$

where $p(t) = \sum_{k=0}^{4} a_k t^k$. Recalling that $g_{ii} = (h^i)_{n+i}$, $q_{ii} = (h_i)_{n+i}$, the coefficients of the polynomial p satisfy

$$\begin{aligned} a_0 &= -|g_{ii}| \;\le\; 0, \qquad a_1 \;=\; |g_{ii}| - \|h^i\|_1 \;\le\; 0, \qquad a_2 \;=\; 0, \\ a_3 &= \|h_i\|_1 - |q_{ii}| \;\ge\; 0, \qquad a_4 \;=\; |q_{ii}| \ge 0. \end{aligned}$$

Since there is at most one change of sign in the coefficients of the polynomial p, Descartes' rule of signs shows that there is at most one positive zero of p. So if

there exists a positive solution of (4.6), it is unique. By assumption, $\|h_i\|_1 \neq 0$ and $\|h^i\|_1 \neq 0$. Therefore, either $a_0 < 0$ or $a_1 < 0$ (as g_{ii} is part of h^i), and either $a_3 > 0$ or $a_4 > 0$ (as q_{ii} is part of h_i). Thus, we know that p is a polynomial of degree at least 3 with positive leading coefficient, and hence $\lim_{t\to\infty} p(t) = +\infty$.

On the other hand, if $g_{ii} \neq 0$, then $p(0) < 0$, and, using the mean value theorem, it follows that there exists a positive zero of p. If $g_{ii} = 0$, then $t = 0$ is a zero of p and $a_1 < 0$. The third order polynomial $q(t) = a_4t^3 + a_3t^2 + a_1$ has a positive zero because of the mean value theorem and $q(0) = a_1 < 0$ as well as $\lim_{t\to\infty} q(t) = +\infty$. Thus, by $p(t) = tq(t)$, p has again at least one positive zero, and hence (4.6) has at least one positive real solution regardless of the value of g_{ii}. On the other hand, it was already observed that there is at most one such solution, and we can conclude that there exists a unique $\delta_i > 0$ solving (4.6) whence $\|\tilde{h}_i\|_1 = \|\tilde{h}^i\|_1$.

The other equalities follow immediately from Corollary 4.2. □

Computing the exact value of δ_i that is needed to equilibrate the ith and $(n+i)$th rows and columns would require the solution of the fourth-order equation (4.6). Since the diagonal similarity transformations are to be chosen from the set of machine numbers, it is sufficient to find the machine number β^{σ_i} closest to δ_i. This can be done similarly to the computation in the general case as proposed in [26] and as implemented in the Fortran 77 subroutines BALANC from EISPACK [15] or in its successor xGEBAL from LAPACK [3]. That is, starting with $\delta_i = 1$, the quantities in (4.5) are evaluated and compared. If $\|\tilde{h}_i\|_1 < \|\tilde{h}^i\|_1$, then this is repeated for $\delta_i = \beta^k$, $k = 1, 2, \ldots$ until $\|\tilde{h}_i\|_1 > \|\tilde{h}^i\|_1$. Otherwise, if $\|\tilde{h}_i\|_1 > \|\tilde{h}^i\|_1$, then we use $\delta_i = \beta^{-k}$, $k = 1, 2, \ldots$ until $\|\tilde{h}_i\|_1 < \|\tilde{h}^i\|_1$. This is achieved by the following algorithm.

ALGORITHM 4.4.

Input: *Hamiltonian matrix $H \in \mathcal{H}_{2n}$ having no isolated eigenvalues, β = base of floating point arithmetic.*

Output: *Diagonal matrix $D_s \in \mathcal{S}_{2n}$, H is overwritten by $D_s^{-1}HD_s \in \mathcal{H}_{2n}$ with row and column norms equilibrated as far as possible.*

$D_s = I_{2n}$
FOR $k = 1, 2, \ldots$ until convergence,
  FOR $i = 1, \ldots, n$,
    $\delta = 1$
    $c = \|h_i\|_1$, $q_a = |h_{n+i,i}|$, $c_a = c - q_a$,
    $r = \|h^i\|_1$, $g_a = |h_{i,n+i}|$, $r_a = r - g_a$,
    WHILE $c < r$
      $c_a = \beta c_a$, $q_a = \beta^2 q_a$, $c = c_a + q_a$,
      $r_a = r_a/\beta$, $g_a = g_a/\beta^2$, $r = r_a + g_a$,
      $\delta = \beta\delta$,
    END WHILE
    IF $\delta = 1$ THEN
      WHILE $r < c$
        $c_a = c_a/\beta$, $q_a = q_a/\beta^2$, $c = c_a + q_a$,
        $r_a = \beta(r_a - g_a)$, $g_a = \beta^2 g_a$, $r = r_a + g_a$,
        $\delta = \delta/\beta$,
      END WHILE
    END IF
    $D_i = I + (\delta - 1)e_ie_i^T$, $D_s = D_s\mathrm{diag}\left(D_i,\, D_i^{-1}\right)$,
    $H = \mathrm{diag}\left(D_i^{-1},\, D_i\right) \cdot H \cdot \mathrm{diag}\left(D_i,\, D_i^{-1}\right)$,

```
    END FOR i
  END FOR k
END
```

One execution of the outer FOR-loop of Algorithm 4.4 can be considered as a sweep. The algorithm is terminated if, for a whole sweep, all $D_i = I_n$. Usually, the row and column norms are approximately equal after very few sweeps. Afterwards, the iteration makes only very limited progress. Therefore, Parlett and Reinsch propose a modification in [26] that, translated to our problem, becomes the following.

Let δ_i be determined by the two inner WHILE*-loops of Algorithm* 4.4*, and compute*

$$c_i = \delta_i(\|h_i\|_1 - |q_{ii}|) + \delta_i^2|q_{ii}|, \qquad r_i = \frac{1}{\delta_i}(\|h^i\|_1 - |g_{ii}|) + \frac{1}{\delta_i^2}|g_{ii}|. \tag{4.8}$$

If $(c_i + r_i) < \gamma(\|h_i\|_1 + \|h^i\|_1)$ (where γ is a given positive constant), then compute D_i as in Algorithm 4.4*. Otherwise, set $D_i = I_n$.*

For $\gamma = 1$, the behavior is essentially the same as for Algorithm 4.4. (In a few cases, Algorithm 4.4 increases $\|h_i\|_1 + \|h^i\|_1$, which cannot happen if $\gamma = 1$.) For γ slightly smaller than one, a step is skipped if it would produce an insubstantial reduction of $\|h_i\|_1 + \|h^i\|_1$.

In an actual computation, the similarity transformations with the D_i's can be applied directly to the blocks A, G, and Q of the Hamiltonian matrix without forming the Hamiltonian matrix itself. Thus, each similarity transformation can be performed using only $4n - 4$ multiplications. When the standard (not structure-preserving) scaling procedure from [26] is applied to H, each similarity transformation requires $4n - 2$ multiplications. (Recall that in Algorithm 4.4, two rows and columns are equilibrated at a time, while only one row and column are treated in each step of the inner FOR-loop of the standard procedure.)

The number of sweeps required to converge is similar to that for the general case since the theory derived in [26] requires only the assumption of similarity transformations with diagonal matrices and that in step i of each sweep, the ith rows and columns are equilibrated as far as possible with $\delta_i = \beta^{\sigma_i}$. But this is accomplished by Algorithm 4.4. Moreover, if δ_i is taken as the exact solution of (4.6), the convergence of the sequence of similarity transformations to a stationary point can be proved as in [24, 17]. That is, if $\delta_i^{(k)}$ is the solution of (4.6) in sweep k, then $\lim_{k\to\infty} \delta_i^{(k)} = 1$ for all $i = 1, \ldots, n$, and hence, in the limit, H is a balanced Hamiltonian matrix.

Note that here each sweep has length n, while in the standard balancing algorithm one has to go through each row/column pair of the matrix, and thus each sweep has length $2n$. Thus, the computational cost for scaling a $2n \times 2n$ Hamiltonian matrix by Algorithm 4.4, assuming k_1 sweeps are required, is $4n^2k_1 + O(k_1n)$ as opposed to $8n^2k_2 + O(k_2n)$ for the standard scaling procedure as given in [26] with assumed k_2 sweeps required for convergence. In general, $k_1 \approx k_2$ such that the structure-preserving scaling strategy is about half as expensive as the standard procedure. These flop counts are based on the assumption that the cost for determining the δ_i can be considered as small ($O(1)$) compared to the similarity transformations.

Remark 4.5. In [18] it is proposed to solve the matrix balancing problem using a convex programming approach. To compare the complexity of this approach to that of Algorithm 4.4, suppose that Algorithm 4.4 terminates after k_1 sweeps with

$|\,\|h_i\|_1 - \|h^i\|_1\,| < \mu_i$. For the matrix H to be balanced, let

$$\mathcal{E} := \{(i,j) \in \{1,\ldots,n\} \times \{1,\ldots,n\} \mid i \neq j,\ \ h_{ij} \neq 0\},$$

$\tau = \sum_{(i,j)\in\mathcal{E}} |h_{ij}|$, and $h_{\min} = \min\{|h_{ij}|\,|\,(i,j) \in \mathcal{E}\}$. Assume that $\sum_{i=1}^{n} \mu_i^2 =: \mu^2$ and $\mu < e\tau$. (Here, $e = \exp(1)$.) Then Theorem 5 in [18] states that the complexity of computing a diagonal matrix Y with positive diagonal entries such that the rows and columns of $Y^{-1}HY$ are balanced with the same accuracy as achieved by Algorithm 4.4 is $O(n^4 \ln(\frac{ne\tau}{\mu} \ln \frac{\tau}{h_{\min}}))$. From numerical experience, it can be assumed that $k_1 = O(1)$ with respect to n. Hence, Algorithm 4.4 can be considered to be of complexity $O(n^2)$. This complexity is clearly superior to that of the convex programming approach which is still the case if $k_1 = O(n)$.

Algorithm 4.4 requires a careful implementation to guard against over- and underflow due to a very large/small δ_i. Here, we can use the bounds discussed in [26] and implemented in LAPACK subroutine xGEBAL [3]; we just have to take into account that in each step we scale by $\beta^{\pm 2}$ rather than β as in xGEBAL.

5. Backtransformation, ordering of eigenvalues, and applications. So far we have considered only the problem of computing the eigenvalues of a Hamiltonian matrix. In order to compute eigenvectors, invariant subspaces, and the solutions of algebraic Riccati equations, we have to transform the Hamiltonian matrix to real Schur form. As we are considering structure-preserving methods, the goal is to transform the Hamiltonian matrix to real Hamiltonian Schur form as given in Theorem 2.7(a)—if it exists.

Assume that we have applied Algorithm 3.4 to the Hamiltonian matrix and obtained a symplectic permutation matrix P_s such that $P_s^T H P_s$ has the form given in (3.10). Then, we have applied a J-permutation P_J to the permuted Hamiltonian matrix such that its rows and columns numbered $1,\ldots,p+q,\ n+1,\ldots,n+p+q$ are in Hamiltonian Schur form, i.e., $P_J^T P_s^T H P_s P_J$ has the form given in (3.9). (From Lemma 3.3 we know that such a P_J exists.) Next, we have applied Algorithm 4.4 to the Hamiltonian submatrix $H_{t,t} \in \mathcal{H}_{2r}$ from (3.11) and obtained a diagonal matrix $D = \operatorname{diag}\left(D_t, D_t^{-1}\right) \in \mathcal{S}_{2r}$. Let

$$D_s \;=\; \begin{bmatrix} I_{p+q} & 0 & 0 & 0 \\ 0 & D_r & 0 & 0 \\ 0 & 0 & I_{p+q} & 0 \\ 0 & 0 & 0 & D_r^{-1} \end{bmatrix}.$$

Then

$$\hat{H} \;:=\; D_s^{-1} P_J^T P_s^T H P_s P_j D_s \;=\; \begin{bmatrix} \hat{A}_{11} & \hat{A}_{12} & \hat{G}_{11} & \hat{G}_{12} \\ 0 & \hat{A}_{22} & \hat{G}_{12}^T & \hat{G}_{22} \\ 0 & 0 & -\hat{A}_{11}^T & 0 \\ 0 & \hat{Q}_{22} & -\hat{A}_{12}^T & -\hat{A}_{22}^T \end{bmatrix},$$

where $\hat{A}_{11} \in \mathbb{R}^{(p+q)\times(p+q)}$ is upper triangular and the Hamiltonian submatrix $\hat{H}_{22} := \left[\begin{smallmatrix} \hat{A}_{22} & \hat{G}_{22} \\ \hat{Q}_{22} & -\hat{A}_{22}^T \end{smallmatrix}\right]$ has no isolated eigenvalues and its rows and columns are equilibrated by Algorithm 4.4. Now assume that the Hamiltonian Schur form of $\hat{H}_{22}$ exists and that we have computed $U_{22} = \left[\begin{smallmatrix} \hat{U}_{22} & -\hat{V}_{22} \\ \hat{V}_{22} & \hat{U}_{22} \end{smallmatrix}\right] \in \mathcal{US}_{2r}$, transforming $\hat{H}_{22}$ into real Hamiltonian

Schur form. Set

$$U := \begin{bmatrix} I_{p+q} & 0 & 0 & 0 \\ 0 & \hat{U}_{22} & 0 & -\hat{V}_{22} \\ 0 & 0 & I_{p+q} & 0 \\ 0 & \hat{V}_{22} & 0 & \hat{U}_{22} \end{bmatrix}$$

and $S := P_s P_J D_s U$. Then $H_1 := S^{-1} H S$ is real Hamiltonian quasi-triangular and $S \in \mathcal{S}_{2n}$. The first n columns of S span a Lagrangian H-invariant subspace. In most applications, the c-stable H-invariant subspace is desired. Let us assume the method used to transform $\hat{H}_{22}$ to Hamiltonian Schur form chooses U_{22} such that the first r columns of U_{22}, i.e., the columns of $\left[\begin{smallmatrix} \hat{U}_{22} \\ \hat{V}_{22} \end{smallmatrix}\right]$, span the $\hat{H}_{22}$-invariant subspace of choice. But there is no guarantee that the isolated eigenvalues in $\hat{A}_{11}$ are the desired ones. In that case, we have to reorder the Hamiltonian Schur form in order to move the undesired eigenvalues to the lower right block of $\hat{H}$ and the desired ones to the upper left block. Assume that we want to compute the Lagrangian H-invariant subspace corresponding to a set $\Lambda = \{\lambda_1 \ldots, \lambda_n\} \subset \sigma(H)$, which is closed under complex conjugation. (Note that this is a necessary condition in order to obtain a Lagrangian invariant subspace [2].) Using the standard reordering algorithm for the real Schur form of an $n \times n$ nonsymmetric matrix as given in [16, 31], we can find an orthogonal matrix $\tilde{U}_\Lambda$ such that with the orthogonal symplectic matrix $U_\Lambda = \operatorname{diag}(\tilde{U}_\Lambda, \tilde{U}_\Lambda)$ we have that

$$H_2 := U_\Lambda^T H_1 U_\Lambda = \begin{bmatrix} \tilde{A}_{11} & \tilde{A}_{12} & \tilde{G}_{11} & \tilde{G}_{12} \\ 0 & \tilde{A}_{22} & \tilde{G}_{12}^T & \tilde{G}_{22} \\ 0 & 0 & -\tilde{A}_{11}^T & 0 \\ 0 & 0 & -\tilde{A}_{12}^T & -\tilde{A}_{22}^T \end{bmatrix} \begin{matrix} \}n-k \\ \}k \\ \}n-k \\ \}k \end{matrix}, \tag{5.1}$$

where A_{11}, A_{22} are quasi-upper triangular, and that

$$\Lambda = \sigma(\tilde{A}_{11}) \cup \sigma(-\tilde{A}_{22}^T), \qquad -\Lambda = \sigma(\tilde{A}_{22}) \cup \sigma(-\tilde{A}_{11}^T). \tag{5.2}$$

Therefore, we have to swap the eigenvalues in $\tilde{A}_{22}$ and $-\tilde{A}_{22}^T$. Note that the eigenvalues to be reordered are among the isolated eigenvalues and hence are real. This implies that $\tilde{A}_{22}$ is upper triangular. The reordering can be achieved analogously to the reordering of eigenvalues in the real Schur form as given in [16, 31]. The following procedure uses this standard reordering in order to swap eigenvalues within $\tilde{A}_{22}$ (and $-\tilde{A}_{22}^T$) and requires rotations working exclusively in rows and columns n and $2n$ in order to exchange eigenvalues from $\tilde{A}_{22}$ with eigenvalues from $-\tilde{A}_{22}^T$. Assume $(H_2)_{n,n} = (\tilde{A}_{22})_{kk} = -\lambda_n$. Then $(H_2)_{2n,2n} = (-\tilde{A}_{22}^T)_{kk} = \lambda_n$. Let $\left[\begin{smallmatrix} c_{\lambda_n} & -s_{\lambda_n} \\ s_{\lambda_n} & c_{\lambda_n} \end{smallmatrix}\right]$ be a 2×2 Givens rotation matrix that annihilates the second component of $\left[\begin{smallmatrix} \tilde{g}_{nn} \\ -2\lambda_n \end{smallmatrix}\right]$, where $\tilde{g}_{nn} = (H_2)_{n,2n} = (\tilde{G}_{22})_{kk}$. Define

$$U_{\lambda_n} := I_{2n} + (c-1)(e_n e_n^T + e_{2n} e_{2n}^T) + s(e_{2n} e_n^T - e_n e_{2n}^T).$$

Then U_{λ_n} is a symplectic Givens rotation matrix acting in planes n and $2n$, and

$$U_{\lambda_n}^T H_2 U_{\lambda_n} = \left[\begin{array}{ccc|ccc} \tilde{A}_{11} & \tilde{A}_{12} & \bar{a}_{1,n} & \tilde{G}_{11} & \tilde{G}_{12} & \bar{g}_{1n} \\ 0 & \tilde{A}_{22} & \vdots & \tilde{G}_{12}^T & \tilde{G}_{22} & \vdots \\ 0 & 0 & \lambda_n & \bar{g}_{1n} & \cdots & \bar{g}_{nn} \\ \hline 0 & 0 & 0 & -\tilde{A}_{11}^T & 0 & 0 \\ 0 & 0 & 0 & -\tilde{A}_{12}^T & -\tilde{A}_{22}^T & 0 \\ 0 & 0 & 0 & -\bar{a}_{1,n} & \cdots & -\lambda_n \end{array}\right] \begin{matrix} \}n-k \\ \}k-1 \\ \}1 \\ \}n-k \\ \}k-1 \\ \}1 \end{matrix}.$$

Here, the bar indicates elements changed by the similarity transformation.

The next step is now to move λ_n up in the upper diagonal block using again the standard ordering subroutine such that we obtain again the form given in (5.1), just $\tilde{A}_{11} \in \mathbb{R}^{(n-k+1)\times(n-k+1)}$, and again the relations (5.2) hold. This procedure has now to be repeated until $k = 0$ and $\Lambda = \sigma(\hat{A}_{11})$.

Remark 5.1. If the Hamiltonian matrix has the form $H = \left[\begin{smallmatrix} A & BB^T \\ C^TC & -A^T \end{smallmatrix}\right]$, which corresponds to a linear system $\dot{x} = Ax + Bu$, $y = Cx$, with (A, B) stabilizable and (C, A) detectable (see, e.g., [19, 29]), then each isolated eigenvalue in (5.1) given by the diagonal elements of $\tilde{A}_{11}$ has negative real part. Otherwise, these eigenvalues are unstable or undetectable and cannot be stabilized/detected. Therefore, if we have not mixed up blocks by the J-permutation matrix P_J (i.e., in Algorithm 3.4, $i_h = n$) and the c-stable H-invariant subspace is required, no reordering is necessary.

Remark 5.2. When solving algebraic Riccati equations using any approach based on the Hamiltonian eigenproblem, the symplectic balancing strategy proposed here is often not enough to minimize errors caused by ill-scaling. This is due to the effect that for a balanced Hamiltonian matrix $H = \left[\begin{smallmatrix} A & G \\ Q & -A^T \end{smallmatrix}\right]$ we may still have $\|Q\| \gg \|G\|$, which can cause large errors when computing invariant subspaces [28]. Therefore, another symplectic scaling using a similarity transformation with $\operatorname{diag}(\sqrt{\rho}I_n, \frac{1}{\sqrt{\rho}}I_n) \in \mathcal{S}_{2n}$, $\rho \in \mathbb{R}$, should be applied to H in order to achieve $\|A\| \approx \|G\| \approx \|Q\|$ as far as possible; see [4] for details and a discussion of several heuristic strategies to achieve this.

Remark 5.3. Everything derived so far for Hamiltonian matrices can be applied in the same way to skew-Hamiltonian matrices. If $N \in \mathcal{SH}_{2n}$, then $N = \left[\begin{smallmatrix} A & G \\ Q & A^T \end{smallmatrix}\right]$ with $G = -G^T$, $Q = -Q^T$. The skew-Hamiltonian structure is again preserved under symplectic similarity transformations. Hence, isolating eigenvalues, reordering, etc., can be achieved in the same way as for Hamiltonian matrices as all considered transformations do not depend on the signs in the matrix blocks A, G, Q but only on the distinction zero/nonzero when isolating eigenvalues and on the absolute values of the entries when equilibrating rows and norms. Note that Algorithm 4.4 even simplifies quite a lot for *real* skew-Hamiltonian matrices. As $q_{ii} = g_{ii} =$ for all $i = 1, \ldots, n$, the scaling factor δ_i can be computed as in the general balancing algorithm for nonsymmetric matrices because in (4.5) we obtain $\|\tilde{h}_i\|_1 = \|\tilde{h}^i\|_1$.

Eigenvalues of skew-Hamiltonian matrices as well as a skew-Hamiltonian Schur form can be computed in a numerically strong backward stable way by Van Loan's method [32]. It is advisable to balance skew-Hamiltonian matrices using the proposed strategies prior to applying this algorithm.

Remark 5.4. We have considered so far only real Hamiltonian and skew-Hamiltonian matrices. Isolating eigenvalues and equilibrating rows and columns for complex (skew-)Hamiltonian matrices can be achieved in exactly the same way. A structure-preserving, numerically backward stable (and hence numerically strong backward stable [11]) method for solving the complex (skew-)Hamiltonian eigenproblem has recently been proposed [8]. The proposed symplectic balancing method can (and should) also be used prior to applying this algorithm.

6. Numerical examples. We have tested the symplectic balancing strategy for eigenvalue computations. The computations were done in MATLAB[1] version 5.2 with machine precision $\varepsilon \approx 2.2204 \times 10^{-16}$. Algorithms 3.4 and 4.4 were implemented as

[1] MATLAB is a trademark of The MathWorks, Inc.

MATLAB functions. We used the modified algorithm as suggested by (4.8), where we set $\gamma = 0.95$ as suggested in [26] and as implemented in the LAPACK subroutine xGEBAL [3]. The eigenvalues of the balanced and the unbalanced Hamiltonian matrix were computed by the square-reduced method using a MATLAB function `sqred`, which implements the explicit version of the square-reduced method (see [32]).

We also tested the effects of symplectic balancing for the numerically backward stable, structure-preserving method for the Hamiltonian eigenvalue problem presented in [7]. Like the square-reduced method, this algorithm uses the square of the Hamiltonian matrix. But it avoids forming the square, explicitly using a symplectic URV-type decomposition of the Hamiltonian matrix.

As reference values we used the eigenvalues computed by the unsymmetric QR algorithm with Parlett–Reinsch balancing as implemented in the LAPACK expert driver routine DGEEVX [3], applied to the Hamiltonian matrix and using quadruple precision.

Moreover, we tested the effects of balancing when solving algebraic Riccati equations with the structure-preserving multishift method presented in [1] for the examples from the benchmark collection [6]. We only present some of the most intriguing results.

Example 6.1 (see [6, Example 6]). The system data come from an optimal control problem for a J-100 jet engine as a special case of a multivariable servomechanism problem. The resulting Hamiltonian matrix $H \in \mathbb{R}^{60\times 60}$ has eight isolated eigenvalues: triple eigenvalues at ± 20.0 and simple eigenvalues at ± 33.3.

Algorithm 3.4 returns $i_l = 5$ and $i_h = 30$, and for the permuted Hamiltonian matrix we have

$$\begin{aligned} H_{1:i_l-1,1:i_l-1} &= \operatorname{diag}(-33.3,\ -20.0,\ -20.0,\ -20.0\,), \\ H_{n+1:n+i_l-1,n+1:n+i_l-1} &= \operatorname{diag}(\,33.3,\ 20.0,\ 20.0,\ 20.0\,). \end{aligned}$$

Next, the Hamiltonian submatrix

$$H_{22} \;=\; \begin{bmatrix} H_{5:30,5:30} & H_{5:30,35:60} \\ H_{35:60,5:30} & -H_{5:30,5:30}^T \end{bmatrix}$$

is scaled using Algorithm 4.4. After six sweeps, we obtain the balanced Hamiltonian matrix H_b. We have $\|H\|_2 = 1.44 \times 10^8$ and $\|H_b\|_2 = 6.54 \times 10^2$; that is, we have decreased the 2-norm of the matrix used in the subsequent eigenvalue computation by more than five orders of magnitude. If the eigenvalues are computed by the square-reduced method applied to the unbalanced Hamiltonian matrix, the triplet of isolated eigenvalues is returned as a pair of conjugate complex eigenvalues with relative errors $\approx 4.06 \times 10^{-11}$ and a simple eigenvalue with relative error $\approx 3.96 \times 10^{-11}$. For the simple eigenvalue at 33.3, the relative error is $\approx 7.7 \times 10^{-15}$. For the balanced version, these eigenvalues are returned with full accuracy since they are not affected by roundoff errors. The relative errors for the other (not isolated) eigenvalues are given in Figure 6.1, where we use the relative distance of the computed eigenvalues to those computed by DGEEVX as an estimate of the real relative error.

Figure 6.1 only contains the relative errors for the eigenvalues with positive real parts as `sqred` returns the eigenvalues as exact plus-minus pairs. The "+" for the 26th eigenvalue is missing as the computed relative error for the balanced version is zero with respect to machine precision. The eigenvalues are ordered by increasing absolute values. From Figure 6.1, the increasing accuracy for decreasing ratio $\|H\|_2/|\lambda|$ is

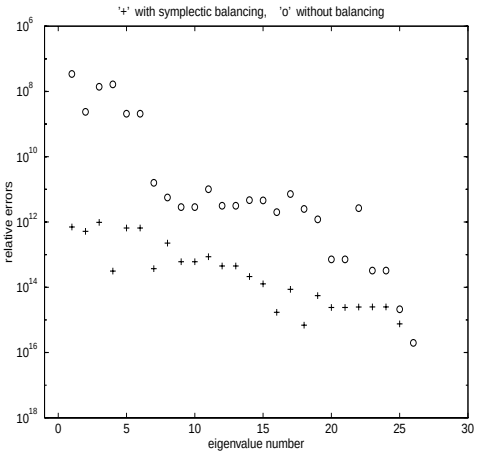

FIG. 6.1. *Square-reduced method.*

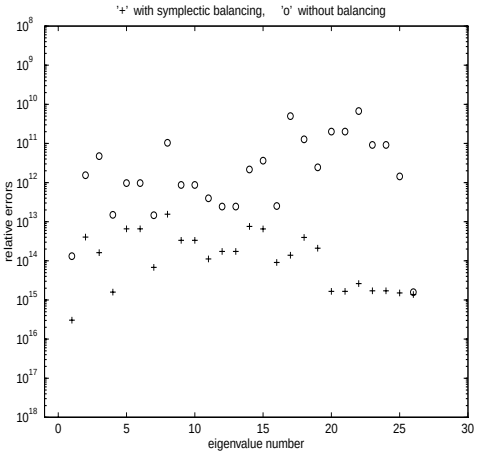

FIG. 6.2. *Symplectic URV + periodic QR.*

obvious—with or without balancing. All computed eigenvalues of the balanced matrix are more accurate than for the unbalanced one. The increase in accuracy is more significant for the eigenvalues of smaller magnitude. This reflects the decrease of the ratios $\|H\|_2/|\lambda|$, which more or less determines the accuracy of the computed eigenvalues; see [32]. The decrease factor for $\|H\|_2$ is about 5×10^{-6}. The accuracy for the eigenvalues of smaller magnitude increases by almost the same factor.

From Figure 6.2 we see that symplectic balancing also improves the eigenvalues computed by the method proposed in [7]. As the method does not suffer from the $\|H\|_2/|\lambda|$ perturbation, the accuracy for all computed eigenvalues is similar. Also note that in the unbalanced version, the isolated eigenvalues are computed with a relative accuracy ranging from 7.0×10^{-14} to 1.2×10^{-15}.

Using the balanced matrix in order to solve algebraic Riccati equations by the multishift method as described in [1], we obtain the following results. If the multishift method is applied to the unbalanced data, the computed solution yields a residual

$$r_F := \|Q + A^T X + XA - XGX\|_F \tag{6.1}$$

of size 1.5×10^{-6}, while using the balanced Hamiltonian matrix we get $r_F = 8.1 \times 10^{-10}$. This shows that numerical methods for solving algebraic Riccati equations can be substantially improved by employing balancing.

Example 6.2 (see [6, Example 13]). The Hamiltonian matrix is defined as in (1.1) with

$$A = \begin{bmatrix} 0 & 0.4 & 0 & 0 \\ 0 & 0 & 0.345 & 0 \\ 0 & -0.524 \cdot \tau & -0.465 \cdot \tau & 0.262 \cdot \tau \\ 0 & 0 & 0 & -\tau \end{bmatrix}, \qquad \begin{aligned} G &= \tau^2 e_4 e_4^T, \\ Q &= \operatorname{diag}(1,\ 0,\ 1,\ 0), \end{aligned}$$

where $\tau = 10^6$ and e_4 denotes the fourth unit vector. After four sweeps of Algorithm 4.4, $\|H\|_2$ is reduced from 10^{12} to 1.5×10^6. The accuracy of the computed eigenvalues did not improve significantly, but for the stabilizing solution of the algebraic Riccati equation, the Frobenius norm of the residual as defined in (6.1) dropped from $r_F = 5.4 \times 10^{-11}$ to $r_F = 1.8 \times 10^{-15}$.

7. Concluding remarks. We have seen that isolated eigenvalues of a real Hamiltonian matrix can be deflated using similarity transformations with symplectic permutation matrices, the deflated problem can be scaled in order to reduce the norm of the deflated Hamiltonian matrix and to equilibrate its row and column norms, and the remaining (not isolated) eigenvalues then can be determined by computing the eigenvalues of the deflated, balanced Hamiltonian submatrix. If invariant subspaces are required, then we can use J-permutation matrices and a symplectic reordering strategy in order to obtain the desired invariant subspaces. The same method can be applied in order to balance skew-Hamiltonian and complex (skew-)Hamiltonian matrices.

Numerical examples demonstrate that symplectic balancing can significantly improve the accuracy of eigenvalues of Hamiltonian matrices as well as the accuracy of solutions of the associated algebraic Riccati equations computed by structure-preserving methods.

Final remark and acknowledgments. The work presented in this article continues preliminary results derived in [4]. The author would like to thank Ralph Byers, Heike Faßbender, and Volker Mehrmann for helpful suggestions.

STRUCTURE-PRESERVING METHODS FOR COMPUTING EIGENPAIRS OF LARGE SPARSE SKEW-HAMILTONIAN/HAMILTONIAN PENCILS*

VOLKER MEHRMANN† AND DAVID WATKINS‡

Abstract. We study large, sparse generalized eigenvalue problems for matrix pencils, where one of the matrices is Hamiltonian and the other is skew-Hamiltonian. Problems of this form arise in the numerical simulation of elastic deformation of anisotropic materials, in structural mechanics, and in the linear quadratic control problem for partial differential equations. We develop a structure-preserving skew-Hamiltonian, isotropic, implicitly restarted shift-and-invert Arnoldi algorithm (SHIRA). Several numerical examples demonstrate the superiority of SHIRA over a competing unstructured method.

Key words. skew-Hamiltonian/Hamiltonian pencil, generalized eigenvalue problem, quadratic eigenvalue problem, implicitly restarted Arnoldi method, Lamé equations, classical mechanics, linear quadratic control, algebraic Riccati equation

1. Introduction.

In this paper we study the numerical computation of a small number of eigenvalues (and the associated eigenvectors) of large-scale generalized eigenvalue problems having a certain structure that arises frequently in applications. A $2n \times 2n$ real matrix pencil

$$\alpha\mathcal{N} - \beta\mathcal{H} = \alpha \begin{bmatrix} F_1 & G_1 \\ H_1 & F_1^T \end{bmatrix} - \beta \begin{bmatrix} F_2 & G_2 \\ H_2 & -F_2^T \end{bmatrix}, \tag{1.1}$$

where $G_1 = -G_1^T$, $H_1 = -H_1^T$, $G_2 = G_2^T$, and $H_2 = H_2^T$, is called a *skew-Hamiltonian/Hamiltonian* pencil or, more briefly, an *SHH* pencil. Throughout this paper we will assume that $\mathcal{N}$ and $\mathcal{H}$ are large and sparse. Several examples of applications that give rise to large, sparse generalized eigenvalue problems with SHH pencils are given in section 2.

The reason for the terminology is simply this: matrices the form of $\mathcal{N}$ and $\mathcal{H}$ in (1.1) are called *skew-Hamiltonian* and *Hamiltonian*, respectively. If

$$J = \begin{bmatrix} 0 & I_n \\ -I_n & 0 \end{bmatrix}, \tag{1.2}$$

where I_n is the $n \times n$ identity matrix, then skew-Hamiltonian matrices satisfy $(\mathcal{N}J)^T = -(\mathcal{N}J)$ and Hamiltonian matrices satisfy $(\mathcal{H}J)^T = \mathcal{H}J$.

An SHH pencil and, in particular, its spectrum have considerable structure. The eigenvalues occur in quadruplets $(\lambda, \bar{\lambda}, -\lambda, -\bar{\lambda})$ or in real or purely imaginary pairs $(\lambda, -\lambda)$ [24, 25, 26]. The objective of this paper is to develop algorithms that preserve and exploit this structure. The payoffs are more efficient and more accurate algorithms. In some cases, preservation of the structure is crucial to the stable solution of a problem.

Typical applications require the few eigenvalues that are smallest in magnitude or closest to the imaginary axis. To achieve this we must apply transformations that have the effect of shifting the desired eigenvalues to the periphery of the spectrum, so that they can be computed efficiently by Krylov subspace methods, e.g., Arnoldi or Lanczos, possibly with implicit restarts. This is a standard procedure in methods for large sparse eigenvalue problems, [33, 39]. What is special to this paper is that our transformations and our Krylov subspace methods respect the structure of the problem.

Our approach requires that the skew-Hamiltonian matrix $\mathcal{N}$ be presented as a product in the special form

$$\mathcal{N} = \mathcal{Z}_1\mathcal{Z}_2, \quad \text{where} \quad \mathcal{Z}_2^T J = \pm J\mathcal{Z}_1, \tag{1.3}$$

with $\mathcal{Z}_1$ and $\mathcal{Z}_2$ sparse. This allows us to transform the pencil $\alpha\mathcal{N} - \beta\mathcal{H}$ to a standard eigenvalue problem $\alpha I - \beta\mathcal{W} = \alpha I - \beta\mathcal{Z}_1^{-1}\mathcal{H}\mathcal{Z}_2^{-1}$, in which the matrix $\mathcal{W} = \mathcal{Z}_1^{-1}\mathcal{H}\mathcal{Z}_2^{-1}$ turns out to be Hamiltonian.

This procedure is analogous to the technique by which a symmetric pencil $A - \lambda B$, with B positive definite, is transformed to a standard eigenvalue problem using a Cholesky decomposition $B = LL^T$. Because of the symmetry of the decomposition, the matrix $L^{-1}AL^{-T}$ inherits the symmetry of A. In the current context, if we introduce the skew-symmetric "inner product" $\langle x, y\rangle_J = y^T Jx$, we find that a matrix is Hamiltonian if and only if it is skew-symmetric with respect to this J-inner product, i.e., $\langle Hx, y\rangle_J = -\langle x, Hy\rangle_J$ for all $x, y \in \mathbf{R}^{2n}$. The relationship between $\mathcal{Z}_1$ and $\mathcal{Z}_2$ given in (1.3) implies that $\mathcal{Z}_2$ is (plus or minus) the adjoint of $\mathcal{Z}_1$ with respect to the J-inner product, i.e., $\langle \mathcal{Z}_1 x, y\rangle_J = \pm\langle x, \mathcal{Z}_2 y\rangle_J$ for all $x, y \in \mathbf{R}^{2n}$. Thus the decomposition $\mathcal{N} = \mathcal{Z}_1\mathcal{Z}_2$ is a symmetric, Cholesky-like decomposition of $\mathcal{N}$. Consequently, $\mathcal{W} = \mathcal{Z}_1^{-1}\mathcal{H}\mathcal{Z}_2^{-1}$ inherits the J-skew symmetry of $\mathcal{H}$; that is, $\mathcal{W}$ is Hamiltonian.

We discuss two approaches that make different transformations of the Hamiltonian operator $\mathcal{W}$. The first maps $\mathcal{W}$ to a skew-Hamiltonian operator, from which the eigenvalues can be extracted by an implicitly restarted Arnoldi (IRA) method that has been modified to preserve the structure. For this approach we provide numerical results demonstrating its effectiveness. The second approach maps $\mathcal{W}$ to a symplectic operator by a generalized Cayley transform. The desired eigenvalues can then be extracted by an implicitly restarted symplectic Lanczos method. We only outline this approach and discuss its advantages and disadvantages.

2. Applications. The need to solve SHH generalized eigenvalue problems arises in many applications. The best-known example is the linear quadratic optimal control problem for descriptor systems, where the pencil typically has the particular form

$$\alpha \begin{bmatrix} E & 0 \\ 0 & E^T \end{bmatrix} - \beta \begin{bmatrix} A & -BB^T \\ C^TC & -A^T \end{bmatrix}, \tag{2.1}$$

with B of size $n \times m$, C of size $p \times n$, and $m << n, p << n$; see [3, 4, 26]. Large sparse problems of this type arise, for example, in the control of semidiscretized parabolic partial differential equations [18, 31, 32].

Here the skew-Hamiltonian matrix can be written in factored form as

$$\mathcal{N} = \mathcal{Z}_1\mathcal{Z}_2 = \begin{bmatrix} E & 0 \\ 0 & I \end{bmatrix} \begin{bmatrix} I & 0 \\ 0 & E^T \end{bmatrix}, \tag{2.2}$$

with $\mathcal{Z}_2^T J = J\mathcal{Z}_1$.

The application that we will discuss in detail in this paper arises from quadratic eigenvalue problems of the form

$$\lambda^2 Mx + \lambda Gx + Kx = 0, \tag{2.3}$$

where $M = M^T$ is positive definite, $K = K^T$, and $G = -G^T$.

Large sparse eigenvalue problems of this form arise, for example, in finite element discretization in structural analysis [35] and in the elastic deformation of anisotropic materials [19, 21, 34]. In these applications M is a mass matrix, and $-K$ is a stiffness matrix. Depending on the applications, different parts of the spectrum are of interest; typically, one is interested in the eigenvalues with smallest real part or the eigenvalues smallest or largest in modulus.

At first glance the quadratic eigenvalue problem (2.3) and the SHH generalized eigenvalue problem (1.1) seem not to have much in common. However, it is well known that the eigenvalues of (2.3) occur in quadruplets $(\lambda, \bar{\lambda}, -\lambda, -\bar{\lambda})$ or real or purely imaginary pairs $(\lambda, -\lambda)$ [20], just as they do for (1.1). The reason for this similarity is that (2.3) can be "linearized" to have the form (1.1). This can be done in several different ways. For example, if we make the substitution

$$y = \lambda Mx \tag{2.4}$$

in (2.3) and rewrite the substitution as $\lambda x - M^{-1}y = 0$, we obtain the SHH generalized eigenvalue problem

$$\lambda\mathcal{N}z - \mathcal{H}z = \lambda \begin{bmatrix} I & G \\ 0 & I \end{bmatrix} \begin{bmatrix} y \\ x \end{bmatrix} - \begin{bmatrix} 0 & -K \\ M^{-1} & 0 \end{bmatrix} \begin{bmatrix} y \\ x \end{bmatrix} = 0. \tag{2.5}$$

Since $\mathcal{N}$ is invertible, the pencil $\lambda\mathcal{N} - \mathcal{H}$ is regular, i.e., $\det(\lambda\mathcal{N} - \mathcal{H})$ does not vanish identically.

The skew-Hamiltonian matrix $\mathcal{N}$ can be written in factored form as

$$\mathcal{N} = \mathcal{Z}_1\mathcal{Z}_2 = \begin{bmatrix} I & \frac{1}{2}G \\ 0 & I \end{bmatrix} \begin{bmatrix} I & \frac{1}{2}G \\ 0 & I \end{bmatrix}, \tag{2.6}$$

with $\mathcal{Z}_2^T J = J\mathcal{Z}_1$. We note that $\mathcal{Z}_1 = \mathcal{Z}_2$ is a skew-Hamiltonian square root of $\mathcal{N}$.

A second approach is to use the substitution

$$y = \lambda x \tag{2.7}$$

in (2.3) and rewrite the substitution as $\lambda Mx - My = 0$. This yields the SHH generalized eigenvalue problem

$$\lambda\mathcal{N}z - \mathcal{H}z = \lambda \begin{bmatrix} M & G \\ 0 & M \end{bmatrix} \begin{bmatrix} y \\ x \end{bmatrix} - \begin{bmatrix} 0 & -K \\ M & 0 \end{bmatrix} \begin{bmatrix} y \\ x \end{bmatrix} = 0. \tag{2.8}$$

In this case the skew Hamiltonian matrix $\mathcal{N}$ can be written in factored form as

$$\mathcal{N} = \mathcal{Z}_1\mathcal{Z}_2 = \begin{bmatrix} I & \frac{1}{2}G \\ 0 & M \end{bmatrix} \begin{bmatrix} M & \frac{1}{2}G \\ 0 & I \end{bmatrix}, \tag{2.9}$$

with $\mathcal{Z}_2^T J = J\mathcal{Z}_1$. This linearization has also been discussed in the context of Lanczos-like algorithms for quadratic eigenvalue problems in [14].

An approach that is intermediate to the previous two uses the Cholesky factorization $M = LL^T$ and the substitution

$$y = \lambda L^T x \tag{2.10}$$

in (2.3) to obtain the SHH generalized eigenvalue problem

$$\lambda\mathcal{N}z - \mathcal{H}z = \lambda \begin{bmatrix} L & G \\ 0 & L^T \end{bmatrix} \begin{bmatrix} y \\ x \end{bmatrix} - \begin{bmatrix} 0 & -K \\ I & 0 \end{bmatrix} \begin{bmatrix} y \\ x \end{bmatrix} = 0. \tag{2.11}$$

The skew-Hamiltonian matrix $\mathcal{N}$ can be written in the factored form

$$\mathcal{N} = \mathcal{Z}_1\mathcal{Z}_2 = \begin{bmatrix} I & \frac{1}{2}G \\ 0 & L^T \end{bmatrix} \begin{bmatrix} L & \frac{1}{2}G \\ 0 & I \end{bmatrix}, \tag{2.12}$$

with $\mathcal{Z}_2^T J = J\mathcal{Z}_1$.

It turns out that all three of these linearizations give rise to the same Hamiltonian operator $\mathcal{W} = \mathcal{Z}_1^{-1}\mathcal{H}\mathcal{Z}_2^{-1}$, so which one we use is just a matter of convenience.

If the matrix K is nonsingular, the substitution (2.7) together with the equivalent equation $Ky = \lambda Kx$ leads to the Hamiltonian/skew-Hamiltonian generalized eigenvalue problem

$$\lambda \begin{bmatrix} 0 & -M \\ K & 0 \end{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix} - \begin{bmatrix} K & G \\ 0 & K \end{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix} = 0. \tag{2.13}$$

We prefer not to use this linearization. If K is nearly singular, as is typically the case in practice, then the matrix pencil in (2.13) is close to a singular pencil [11].

Other linearizations that have been used are

$$\lambda \begin{bmatrix} I & 0 \\ G & M \end{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix} - \begin{bmatrix} 0 & I \\ -K & 0 \end{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix} = 0 \tag{2.14}$$

or, equivalently,

$$\lambda \begin{bmatrix} I & 0 \\ 0 & M \end{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix} - \begin{bmatrix} 0 & I \\ -K & -G \end{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix} = 0, \tag{2.15}$$

which are both obtained with the substitution (2.7). Neither (2.14) nor (2.15) is SHH. Although, in particular, (2.15) seems attractive, since the matrix $\left[\begin{smallmatrix} I & 0 \\ 0 & M \end{smallmatrix}\right]$ is Hermitian positive definite, it is still preferable to use an SHH linearization, which reflects the structure of the spectrum. Since we construct methods that respect this structure also in finite arithmetic, the computed eigenvalues will be the exact eigenvalues of a perturbed SHH pencil. Thus the computed eigenvalues will occur in quadruplets, as they should. See the perturbation analysis in [3, 7, 8, 9]. Furthermore, the comparison of the perturbation theory for quadratic eigenvalue problems and the related linearization, as it has been analyzed in [41], show that even numerically backward stable methods that do not respect the special structure of the eigenvectors of the quadratic eigenvalue problem in its linearization may be unstable.

Surveys of numerical methods for the quadratic eigenvalue problem (in various forms) have been given in [23, 37, 38]. In particular, the Lanzcos and Arnoldi methods

[17, 29, 33] as well as the Jacobi–Davidson iterations [36] are compared. Simultaneous iteration methods for quadratic eigenvalue problems have been studied in [13, 28, 38].

Some of the methods can be directly applied to the quadratic problem, while others only work for the linearizations. The major difference between the direct solution of the quadratic problem and its linearizations is that in order to solve the projected problems and to use implicit restarts, one needs some kind of generalized Schur form for the problem. Such a form is not known for quadratic problems, while for matrix pencils this is the generalized Schur form [17], and for SHH pencils there is a structured generalized form that was analyzed in [24, 25]. Numerical methods for its computation have been derived in [3, 4].

3. Rational transformations of Hamiltonian matrices. If the skew-Hamiltonian matrix $\mathcal{N}$ in the SHH pencil $\alpha\mathcal{N} - \beta\mathcal{H}$ is invertible and given in the factored form $\mathcal{N} = \mathcal{Z}_1\mathcal{Z}_2$ with $\mathcal{Z}_2^T J = \pm J\mathcal{Z}_1$, then the pencil is equivalent to the pencil

$$\alpha I - \beta\mathcal{W} := \alpha I - \beta\mathcal{Z}_1^{-1}\mathcal{H}\mathcal{Z}_2^{-1}. \tag{3.1}$$

As we explained in the introduction, $\mathcal{W}$ is again Hamiltonian. Hence we can consider first transformations of Hamiltonian matrices, and then apply these to SHH pencils by rewriting them in terms of the original data.

Suppose we want to find the eigenvalues of $\mathcal{W}$ that lie nearest to some target value λ_0. The standard transformation for this purpose is $(\mathcal{W} - \lambda_0 I)^{-1}$, which, however, fails to preserve the structure. Each eigenvalue near λ_0 is related to eigenvalues near $\bar{\lambda}_0$, $-\lambda_0$, and $-\bar{\lambda}_0$. If we are to hope to preserve the structure, we must extract all four of these eigenvalues together. Thus we should also bring $(\mathcal{W} - \bar{\lambda}_0 I)^{-1}$, $(\mathcal{W} + \lambda_0 I)^{-1}$, and $(\mathcal{W} + \bar{\lambda}_0 I)^{-1}$ into play.

3.1. Transformation to a skew-Hamiltonian operator. For finding the eigenvalues nearest the quadruplet $(\lambda_0, \bar{\lambda}_0, -\lambda_0, -\bar{\lambda}_0)$ the obvious rational transformation is

$$R_1(\lambda_0, \mathcal{W}) = (\mathcal{W} - \lambda_0 I)^{-1}(\mathcal{W} + \lambda_0 I)^{-1}(\mathcal{W} - \bar{\lambda}_0 I)^{-1}(\mathcal{W} + \bar{\lambda}_0 I)^{-1}. \tag{3.2}$$

If the target λ_0 is either real or purely imaginary, one may choose to use the simpler transformation

$$R_2(\lambda_0, \mathcal{W}) = (\mathcal{W} - \lambda_0 I)^{-1}(\mathcal{W} + \lambda_0 I)^{-1}. \tag{3.3}$$

Both R_1 and R_2 turn out to be skew-Hamiltonian. In what follows we will focus on the operator R_1. In every case we can make similar assertions about R_2.

The transformation $R_1(\lambda_0, \mathcal{W})$ maps all eigenvalues near to $\lambda_0, -\lambda_0, \bar{\lambda}_0, -\bar{\lambda}_0$ simultaneously to values of large modulus. Hence fast convergence of the eigenvalues near these points can be expected if we apply any of the standard iterative methods, [33, 39].

In order to apply an iterative method such as subspace iteration or the Arnoldi process, we need to be able to multiply the matrix R_1 by an arbitrary vector at reasonable cost, since this operation is performed repeatedly by these algorithms. Thus we need to be able to apply operators of the form $(\mathcal{W} - \sigma I)^{-1}$ inexpensively. We can either work with $\mathcal{W}$ directly or we can refer back to the original data $\mathcal{H}$ and $\mathcal{N}$. Substituting $\mathcal{Z}_1^{-1}\mathcal{H}\mathcal{Z}_2^{-1}$ for $\mathcal{W}$ in (3.2) and simplifying, we find that

$$\begin{aligned} R_1 &= R_1(\lambda_0, \mathcal{H}, \mathcal{N}, \mathcal{Z}_1, \mathcal{Z}_2) \\ &= \mathcal{Z}_2(\mathcal{H} - \lambda_0\mathcal{N})^{-1}\mathcal{N}(\mathcal{H} + \lambda_0\mathcal{N})^{-1}\mathcal{N}(\mathcal{H} - \bar{\lambda}_0\mathcal{N})^{-1}\mathcal{N}(\mathcal{H} + \bar{\lambda}_0\mathcal{N})^{-1}\mathcal{Z}_1. \end{aligned} \tag{3.4}$$

Since $\mathcal{Z}_1$, $\mathcal{Z}_2$, and $\mathcal{N}$ are sparse matrices, they can be applied easily. The only question, then, is how to apply operators of the form $(\mathcal{H}-\sigma\mathcal{N})^{-1}$ inexpensively. This question will be discussed in connection with specific applications in section 4.

We now consider the structural properties of $R_1(\lambda_0,\mathcal{W})$ and $R_2(\lambda_0,\mathcal{W})$, beginning with a well-known lemma.

LEMMA 3.1.

(i) *If $\mathcal{W}$ is Hamiltonian, then $\mathcal{W}^2$ is skew-Hamiltonian.*

(ii) *If $\mathcal{W}$ is skew-Hamiltonian, then $\mathcal{W}^2$ is skew-Hamiltonian.*

(iii) *If $\mathcal{W}$ is skew-Hamiltonian and invertible, then $\mathcal{W}^{-1}$ is skew-Hamiltonian.*

We omit the proof, which is straightforward, see, e.g., [1].

PROPOSITION 3.2. *If $\mathcal{W}\in\mathbf{R}^{2n\times 2n}$ is a Hamiltonian matrix, then $R_1(\lambda_0,\mathcal{W})$ in* (3.2) *is real and skew-Hamiltonian. If, in addition, λ_0 is either real or purely imaginary, then $R_2(\lambda_0,\mathcal{W})$ in* (3.3) *is also real and skew-Hamiltonian.*

Proof. Direct calculation shows that

$$R_1(\lambda_0,\mathcal{W}) = (|\lambda_0|^4 I + [2|\lambda_0|^2 - 4(\Re(\lambda_0))^2]\mathcal{W}^2 + \mathcal{W}^4)^{-1}.$$

Hence $R_1(\lambda_0,\mathcal{W})$ is a real matrix, and by Lemma 3.1 it is skew-Hamiltonian, since the skew-Hamiltonian matrices form a real vector space that contains the identity matrix.

A similar but simpler argument shows that $R_2(\lambda_0,\mathcal{W})$ is skew-Hamiltonian. ∎

Notice that the eigenvalues λ and $-\lambda$ of $\mathcal{W}$ both get mapped to $\mu=(\lambda^4+c_2\lambda^2+c_0)^{-1}$ of R_1 and to $\nu=(\lambda^2-\lambda_0^2)^{-1}$ of R_2, where $c_0=|\lambda_0|^4$ and $c_2=2|\lambda_0|^2-4(\Re(\lambda_0))^2$. Thus all eigenvalues of R_1 and R_2 have even multiplicity. This fact, which is true of skew-Hamiltonian matrices in general, must be taken into account by our numerical methods.

Recall that the *Krylov subspace* $\mathcal{K}_j(A,v)$ is defined by

$$\mathcal{K}_j(A,v) = \operatorname{span}\{v, Av, A^2v, \ldots, A^{j-1}v\}.$$

The Arnoldi method and other Krylov subspace methods generate Krylov subspaces, where v is the starting vector and A is the operator being applied, e.g., R_1 in our case; see [33]. Recall, furthermore, that a subspace $\mathcal{S}$ of $\mathbf{R}^{2n}$ is called *isotropic* if and only if $y^TJx=0$ for all $x,\ y\in\mathcal{S}$. In other words, $\mathcal{S}$ is isotropic if and only if $J\mathcal{S}$ is orthogonal to $\mathcal{S}$ with respect to the standard inner product on $\mathbf{R}^{2n}$; see [2]. The beauty of skew-Hamiltonian operators is that the Krylov subspaces that they generate are isotropic.

PROPOSITION 3.3. *Let $A\in\mathbf{R}^{2n\times 2n}$ be a skew-Hamiltonian matrix, let $v\in\mathbf{R}^{2n}$, and let j be a positive integer. Then the Krylov subspace $\mathcal{K}_j(A,v)$ is isotropic.*

Proof. Since A is real skew-Hamiltonian, one easily shows that all of its powers A^i, $i=0,1,2,3,\ldots$, are also skew-Hamiltonian. This means that JA^i is skew-symmetric. To establish isotropy of $\mathcal{K}_j(A,v)$, it suffices, by linearity, to prove that $(A^iv)^TJA^kv=0$ for all $i\ge 0$ and $k\ge 0$. Since $A^TJ=JA$, we have $(A^iv)^TJA^kv=v^TJA^{i+k}v$, which equals zero because JA^{i+k} is skew-symmetric. ∎

We now introduce an *isotropic* Arnoldi process, which will form the basis for our numerical method. At first we allow A to be an arbitrary $2n\times 2n$ real matrix. Recall that the Arnoldi process starts with an arbitrary unit vector q_1 and produces orthonormal vectors as follows. Given orthonormal vectors $q_1,\ldots,q_j$, the next vector q_{j+1} is generated by forming Aq_j and then orthogonalizing it against $q_1,\ldots,q_j$. Thus

$$q_{j+1}h_{j+1,j} = Aq_j - \sum_{i=1}^{j} q_ih_{ij},$$

where $h_{ij} = q_i^T A q_j$, $i = 1, \ldots, j$, and $h_{j+1,j}$ is a positive constant chosen so that $\|q_{j+1}\|_2 = 1$.

If we wish to build isotropic subspaces, we should orthogonalize against the vectors $Jq_1, \ldots, Jq_j$ as well. Thus the jth step of the *isotropic Arnoldi process* is

$$q_{j+1} h_{j+1,j} = A q_j - \sum_{i=1}^{j} q_i h_{ij} - \sum_{i=1}^{j} J q_i t_{ij}, \tag{3.5}$$

where

$$h_{ij} = q_i^T A q_j \quad \text{and} \quad t_{ij} = (Jq_i)^T A q_j, \tag{3.6}$$

and $h_{j+1,j}$ is a positive constant chosen so that $\|q_{j+1}\|_2 = 1$. This generates orthonormal vectors that span isotropic subspaces.

If A is real skew-Hamiltonian, then the coefficients t_{ij} in (3.5, 3.6) will all be zero, by Proposition 3.3. Thus the isotropic Arnoldi process reduces to the ordinary Arnoldi process in this case, at least in theory.

If the quantity on the right-hand side of (3.5) is zero, then the process breaks down. It can be continued by setting $h_{j+1,j} = 0$ and taking q_{j+1} to be any unit vector that is orthogonal to $q_1, \ldots, q_j$ and $Jq_1, \ldots, Jq_j$. Equation (3.5) holds in this case, too. In exact arithmetic, the process terminates after $n-1$ steps, as $q_1, \ldots, q_n$ together with $Jq_1, \ldots, Jq_n$ form an orthonormal basis of $\mathbf{R}^{2n}$.

Let $Q \in \mathbf{R}^{2n \times n}$ be the matrix whose columns are $q_1, \ldots, q_n$. Then (3.5) can be rewritten as

$$AQ = \begin{bmatrix} Q & -JQ \end{bmatrix} \begin{bmatrix} H \\ -T \end{bmatrix}, \tag{3.7}$$

where H is an upper Hessenberg matrix built from the coefficients h_{ij} and T is an upper triangular matrix built from the coefficients t_{ij}.

Recall that a matrix $S \in \mathbf{R}^{2n \times 2n}$ is *symplectic* if $S^T J S = J$. The next lemma recalls a few simple properties that we need; see [2].

LEMMA 3.4.

(i) *If the columns of $Q \in \mathbf{R}^{2n \times n}$ are orthonormal and span an isotropic subspace, then the matrix $\begin{bmatrix} Q & -JQ \end{bmatrix}$ is both orthogonal and symplectic.*

(ii) *If $\mathcal{N}$ is skew-Hamiltonian and S is symplectic, then $S^{-1}\mathcal{N}S$ is skew-Hamiltonian.*

Equation (3.7) implies that

$$A \begin{bmatrix} Q & -JQ \end{bmatrix} = \begin{bmatrix} Q & -JQ \end{bmatrix} \begin{bmatrix} H & N \\ -T & P \end{bmatrix} \tag{3.8}$$

for some N and P. The matrix $\mathcal{U} = \begin{bmatrix} Q & -JQ \end{bmatrix}$ is orthogonal and symplectic by Lemma 3.4, and we have

$$\mathcal{U}^{-1} A \mathcal{U} = \begin{bmatrix} H & N \\ -T & P \end{bmatrix}.$$

If A is skew-Hamiltonian, then, since the skew-Hamiltonian property is preserved under symplectic similarity by Lemma 3.4, we must have $P = H^T$, $T^T = -T$, and $N^T = -N$. Since T is upper triangular, the additional equation $T^T = -T$ implies

$T = 0$, which we had already noted. This gives the following result, which is not new [42].

PROPOSITION 3.5. *Let $\mathcal{N}$ be a real skew-Hamiltonian matrix. Then for every unit vector $q_1 \in \mathcal{R}^{2n}$ there exists an orthogonal symplectic matrix $\mathcal{U}$ that has q_1 as its first column such that*

$$\mathcal{U}^T \mathcal{N} \mathcal{U} = \begin{bmatrix} H & N \\ 0 & H^T \end{bmatrix}, \tag{3.9}$$

and H is in Hessenberg form.

The multiplicity of the eigenvalues of $\mathcal{N}$ is reflected in the structure of the matrix in (3.9). For each double eigenvalue of $\mathcal{N}$, one copy resides in H, and the other copy is in H^T.

When we apply the Arnoldi process to a large, sparse matrix in practice, we have neither the time nor the storage space to carry the process to completion. Instead we stop after k steps with $k \ll n$. The coefficients h_{ij} computed to this point form a $k \times k$ submatrix of H whose eigenvalues (*Ritz values*) we can compute and use as estimates of eigenvalues of H, and hence of $\mathcal{N}$. Since the eigenvalues do not appear in duplicate in H, we get each eigenvalue once, not twice. This is important to the success of the numerical method. If we make the effort to compute, say, six eigenvalues, we would like to get six distinct eigenvalues, not three eigenvalues in duplicate.

The developments outlined here are valid only for real matrices. However, it has been shown in [10] that for complex problems an embedding of the problem into a double sized real problem can be used to get a real skew-Hamiltonian problem from which all the spectral information can be obtained.

3.2. Transformation to symplectic form. Another natural rational transformation that is sometimes applied to Hamiltonian matrices is the generalized Cayley transform. See [27] for a detailed analysis. Given a target λ_0, the generalized Cayley transform of the Hamiltonian matrix $\mathcal{W}$ is

$$S_1(\lambda_0, \mathcal{W}) = (\mathcal{W} - \lambda_0 I)^{-1}(\mathcal{W} + \bar{\lambda}_0 I)(\mathcal{W} - \bar{\lambda}_0 I)^{-1}(\mathcal{W} + \lambda_0 I). \tag{3.10}$$

By using four factors we obtain a real matrix, even when the target λ_0 is complex. If λ_0 is real, we can use the simpler two-factor Cayley transform

$$S_2(\lambda_0, \mathcal{W}) = (\mathcal{W} - \lambda_0 I)^{-1}(\mathcal{W} + \lambda_0 I). \tag{3.11}$$

Notice that for $i = 1,\ 2$, $S_i^{-1}(\lambda) = S_i(-\lambda)$. Thus it is no more expensive to apply S_i^{-1} than S_i.

In terms of the original data we have

$$\begin{aligned} S_1 &= S_1(\lambda_0, \mathcal{H}, \mathcal{N}, \mathcal{Z}_1, \mathcal{Z}_2) \\ &= \mathcal{Z}_2(\mathcal{H} - \lambda_0 \mathcal{N})^{-1}(\mathcal{H} + \bar{\lambda}_0 \mathcal{N})(\mathcal{H} - \bar{\lambda}_0 \mathcal{N})^{-1}(\mathcal{H} + \lambda_0 \mathcal{N})\mathcal{Z}_2^{-1}. \end{aligned} \tag{3.12}$$

A similar expression holds for S_2.

We now discuss the structural properties of S_1 and S_2. The following proposition is well known [27].

PROPOSITION 3.6.

(i) *If $\mathcal{W} \in \mathbf{R}^{2n \times 2n}$ is Hamiltonian, then $S_1(\lambda_0, \mathcal{W})$ in* (3.10) *is real symplectic.*

(ii) *If $\mathcal{W} \in \mathbf{R}^{2n \times 2n}$ is Hamiltonian and λ_0 is real, then $S_2(\lambda_0, \mathcal{W})$ in* (3.11) *is real symplectic.*

The use of symplectic matrices has several advantages and disadvantages compared with skew-Hamiltonian matrices. First of all, in contrast to the skew-Hamiltonian case, not every symplectic matrix has a symplectic Schur form [22]. What is worse in the symplectic case is that in order to achieve a symplectic Hessenberg-like form with an orthogonal symplectic transformation matrix Q, we must choose a first column of Q that has a very special form [2]. Thus Arnoldi methods, with or without restarts, cannot be used with symplectic matrices, which is definitely a disadvantage of this rational transformation.

The transformation S_1 maps all eigenvalues near $\lambda_0, \bar{\lambda}_0$ simultaneously to values of large modulus. At the same time the eigenvalues near $-\lambda_0, -\bar{\lambda}_0$ are mapped close to 0. These correspond to large eigenvalues of the inverse transformation S_1^{-1}. The coexistence of extremely large and small eigenvalues is an inevitable consequence of the fact that eigenvalues of a symplectic matrix occur in quadruplets $\mu, \bar{\mu}, \mu^{-1}, \bar{\mu}^{-1}$. Any method that preserves the symplectic structure must extract quadruplets intact. This can be achieved by structure-preserving Lanczos-like methods that employ both S and S^{-1} in a symmetric manner. See [5, 6, 15] for structure-preserving implicitly restarted Lanczos-like methods applicable to symplectic problems. These are the sorts of methods we must apply to S_1 and S_2.

Another disadvantage of the Cayley transform is that it is effective only if the target λ_0 is not too close to the imaginary axis. Notice that if λ_0 is purely imaginary, then $S_1 = I$, which is not useful for extracting spectral information about $\mathcal{W}$.

An advantage of the Cayley transform approach is that, unlike the skew-Hamiltonian approach, it can be extended to complex matrices and matrix pencils in a straightforward way.

4. Applying the operators. In our two applications the matrices $\mathcal{N}$, $\mathcal{H}$, $\mathcal{Z}_1$, and $\mathcal{Z}_2$ have further structure that can be used to simplify the formulas.

4.1. Quadratic eigenproblems. Let us first study the quadratic eigenvalue problem in the linearization (2.8) with $\mathcal{N}$ in factored form (2.9). First,

$$\begin{aligned}\mathcal{H} - \sigma\mathcal{N} &= -\begin{bmatrix} \sigma M & \sigma G + K \\ -M & \sigma M \end{bmatrix} \\ &= \begin{bmatrix} I & -\sigma I \\ 0 & I \end{bmatrix} \begin{bmatrix} 0 & -Q(\sigma) \\ M & 0 \end{bmatrix} \begin{bmatrix} I & -\sigma I \\ 0 & I \end{bmatrix}, \end{aligned} \tag{4.1}$$

where

$$Q(\sigma) := \sigma^2 M + \sigma G + K. \tag{4.2}$$

Thus

$$\begin{aligned}(\mathcal{W} - \sigma I)^{-1} &= \mathcal{Z}_2(\mathcal{H} - \sigma\mathcal{N})^{-1}\mathcal{Z}_1 \\ &= \begin{bmatrix} M & \frac{1}{2}G \\ 0 & I \end{bmatrix} \begin{bmatrix} I & \sigma I \\ 0 & I \end{bmatrix} \begin{bmatrix} 0 & M^{-1} \\ -Q(\sigma)^{-1} & 0 \end{bmatrix} \begin{bmatrix} I & \sigma I \\ 0 & I \end{bmatrix} \begin{bmatrix} I & \frac{1}{2}G \\ 0 & M \end{bmatrix}. \end{aligned} \tag{4.3}$$

We can obtain an expression that does not involve M^{-1} by using one or the other of the factorizations

$$\begin{bmatrix} 0 & M^{-1} \\ -Q(\sigma)^{-1} & 0 \end{bmatrix} = \begin{bmatrix} 0 & I \\ -Q(\sigma)^{-1} & 0 \end{bmatrix} \begin{bmatrix} I & 0 \\ 0 & M^{-1} \end{bmatrix} \tag{4.4}$$

and

$$\begin{bmatrix} 0 & M^{-1} \\ -Q(\sigma)^{-1} & 0 \end{bmatrix} = \begin{bmatrix} M^{-1} & 0 \\ 0 & I \end{bmatrix} \begin{bmatrix} 0 & I \\ -Q(\sigma)^{-1} & 0 \end{bmatrix}. \tag{4.5}$$

Substituting (4.4) into (4.3) and combining the last three matrices, we obtain

$$(\mathcal{W} - \sigma I)^{-1} = \begin{bmatrix} M & \frac{1}{2}G \\ 0 & I \end{bmatrix} \begin{bmatrix} I & \sigma I \\ 0 & I \end{bmatrix} \begin{bmatrix} 0 & I \\ -Q(\sigma)^{-1} & 0 \end{bmatrix} \begin{bmatrix} I & \frac{1}{2}G + \sigma M \\ 0 & I \end{bmatrix}. \tag{4.6}$$

If we use (4.5) instead of (4.4), we obtain instead

$$(\mathcal{W} - \sigma I)^{-1} = \begin{bmatrix} I & \frac{1}{2}G + \sigma M \\ 0 & I \end{bmatrix} \begin{bmatrix} 0 & I \\ -Q(\sigma)^{-1} & 0 \end{bmatrix} \begin{bmatrix} I & \sigma I \\ 0 & I \end{bmatrix} \begin{bmatrix} I & \frac{1}{2}G \\ 0 & M \end{bmatrix}. \tag{4.7}$$

Both of these expressions are useful.

To apply this operator in either form (4.6) or (4.7) we will need a sparse LU decomposition of the sparse, nonsymmetric matrix $Q(\sigma)$ [17]. In $R_1(\lambda_0, \mathcal{W})$ there are four factors of the form $(\mathcal{W} - \sigma I)^{-1}$, corresponding to $\sigma = \pm\lambda_0$ and $\sigma = \pm\bar{\lambda}_0$. Thus it might appear that we need four sparse LU factorizations in order to apply R_1. However, one immediately observes that

$$\begin{aligned} Q(\bar{\sigma}) &= \bar{\sigma}^2 M + \bar{\sigma} G + K = \overline{Q(\sigma)}, \\ Q(-\sigma) &= \sigma^2 M - \sigma G + K = Q(\sigma)^T, \\ Q(-\bar{\sigma}) &= \bar{\sigma}^2 M - \bar{\sigma} G + K = \overline{Q(\sigma)}^T. \end{aligned} \tag{4.8}$$

An LU factorization of $Q(\sigma)$ immediately yields factorizations of $Q(\bar{\sigma})$, $Q(-\sigma)$, and $Q(-\bar{\sigma})$. Thus one sparse LU factorization is all we need.

There are several other ways to apply $(W - \sigma I)^{-1}$ efficiently to a real vector for real W and complex σ. One possibility is described in [30]. Another possibility is to embed the matrix in a double sized real matrix and then use a real factorization. Which of these different approaches is best will depend on the structure of the matrices G, K, amd M and also on the choice of shifts.

To derive the formulas for applying the operator R_1, we first discuss the application of R_2. If we combine expressions (4.6) and (4.7), replacing σ by λ_0 in (4.6) and by $-\lambda_0$ in (4.7), we obtain

$$\begin{aligned} R_2(\lambda_0, \mathcal{W}) &= (\mathcal{W} - \lambda_0 I)^{-1} (\mathcal{W} + \lambda_0 I)^{-1} \\ &= \begin{bmatrix} M & \frac{1}{2}G \\ 0 & I \end{bmatrix} \begin{bmatrix} I & \lambda_0 I \\ 0 & I \end{bmatrix} \begin{bmatrix} 0 & I \\ -Q(\lambda_0)^{-1} & 0 \end{bmatrix} \begin{bmatrix} I & G \\ 0 & I \end{bmatrix} \\ &\quad \times \begin{bmatrix} 0 & I \\ -Q(-\lambda_0)^{-1} & 0 \end{bmatrix} \begin{bmatrix} I & -\lambda_0 I \\ 0 & I \end{bmatrix} \begin{bmatrix} I & \frac{1}{2}G \\ 0 & M \end{bmatrix}, \end{aligned} \tag{4.9}$$

which can be readily translated into an algorithm for applying the operator R_2, i.e., for multiplying R_2 by a vector. For example, to multiply the factor $\left[\begin{smallmatrix} I & \frac{1}{2}G \\ 0 & M \end{smallmatrix}\right]$ by the vector $\left[\begin{smallmatrix} x \\ y \end{smallmatrix}\right]$, we only need to perform the operations $x \leftarrow x + \frac{1}{2}Gy$ and $y \leftarrow My$, which requires two sparse $n \times n$ matrix-vector products and one saxpy operation. To multiply $\left[\begin{smallmatrix} 0 & I \\ -Q(-\lambda_0)^{-1} & 0 \end{smallmatrix}\right]$ by $\left[\begin{smallmatrix} x \\ y \end{smallmatrix}\right]$, we perform the operations $\hat{x} \leftarrow -x$, $x \leftarrow y$, and $y \leftarrow Q(\lambda_0)^{-1}\hat{x}$. Given a sparse LU factorization of $Q(\lambda_0)$, we obtain $y \leftarrow Q(\lambda_0)^{-1}\hat{x}$ by

two sparse triangular solves. Applying these observations to (4.9), we easily determine the total work for multiplying $R_2(\lambda_0, \mathcal{W})$ by a vector.

The sparse LU factorization of $Q(\lambda_0)$ needs to be computed only once; then R_2 can be applied repeatedly. No further LU factorizations are needed unless the target λ_0 is changed. If λ_0 is real, then all operations are real and we may use R_2 instead of R_1.

Since $R_1(\lambda_0, \mathcal{W}) = R_2(\lambda_0, \mathcal{W})R_2(\bar{\lambda}_0, \mathcal{W})$, we obtain an expression for $R_1(\lambda_0, \mathcal{W})$ by combining two copies of (4.9), one with λ_0 replaced by $\bar{\lambda}_0$. Combining two matrices in the middle of the product, we eliminate one sparse matrix-vector product and one saxpy operation. Thus the cost of applying R_1 is just slightly less than twice that of applying R_2. We summarize the costs in Table 4.1.

TABLE 4.1
Operation count for applying the operator R_1, assuming a sparse LU factorization of $Q(\lambda_0)$ is available.

8	Sparse triangular solves
4	Symmetric sparse matrix-vector products Mz
5	Skew symmetric sparse matrix-vector products Gz
9	Saxpy operations

In general the arithmetic is complex; however, if λ_0 is real, then all operations are real.

If λ_0 is neither real nor purely imaginary, there is a trick that halves the cost of computing $R_1(\lambda_0, \mathcal{W})$ [30]. In this case one easily verifies that $R_1(\lambda_0, \mathcal{W})$ is proportional to the imaginary part of $R_2(\lambda_0, \mathcal{W})$, so we can obtain $R_1(\lambda_0, \mathcal{W})$ at the costs listed in Table 4.2 (with complex arithmetic) by simply computing $R_2(\lambda_0, \mathcal{W})$ and keeping the imaginary part.

TABLE 4.2
Operation count for applying the operator R_2, assuming a sparse LU factorization of $Q(\lambda_0)$ is available.

4	Sparse triangular solves
2	Symmetric sparse matrix-vector products Mz
3	Skew symmetric sparse matrix-vector products Gz
5	Saxpy operations

The symplectic operators S_1 and S_2 can be applied similarly. Inverting (4.7) and replacing σ by $-\sigma$, we obtain

$$(\mathcal{W} + \sigma I) = \begin{bmatrix} I & \frac{1}{2}G \\ 0 & M \end{bmatrix}^{-1} \begin{bmatrix} I & \sigma I \\ 0 & I \end{bmatrix} \begin{bmatrix} 0 & -Q(-\sigma) \\ I & 0 \end{bmatrix} \begin{bmatrix} I & \sigma M - \frac{1}{2}G \\ 0 & I \end{bmatrix}. \tag{4.10}$$

Now combining (4.7) with (4.10) and replacing σ by λ_0, we get the expression

$$\begin{aligned} S_2(\lambda_0, \mathcal{W}) &= (\mathcal{W} - \lambda_0 I)^{-1}(\mathcal{W} + \lambda_0 I) \\ &= \begin{bmatrix} I & \lambda_0 M + \frac{1}{2}G \\ 0 & I \end{bmatrix} \begin{bmatrix} 0 & I \\ -Q(\lambda_0)^{-1} & 0 \end{bmatrix} \begin{bmatrix} I & 2\lambda_0 I \\ 0 & I \end{bmatrix} \\ &\quad \times \begin{bmatrix} 0 & -Q(-\lambda_0) \\ I & 0 \end{bmatrix} \begin{bmatrix} I & \lambda_0 M - \frac{1}{2}G \\ 0 & I \end{bmatrix}, \end{aligned} \tag{4.11}$$

which can be readily translated into an algorithm for applying the operator S_2. The total work for multiplying $S_2(\lambda_0, \mathcal{W})$ by a vector is summarized in Table 4.3.

TABLE 4.3
Operation count for applying the operator S_2, assuming a sparse LU factorization of $Q(\lambda_0)$ is available.

2	Sparse triangular solves
3	Symmetric sparse matrix-vector products Mz
3	Skew symmetric sparse matrix-vector products Gz
1	Symmetric sparse matrix-vector product Kz
7	Saxpy operations

We have counted the operation $Q(-\lambda_0)v$ as three matrix-vector products, one each by M, G, and K, and two saxpy operations. The work can be decreased by computing $Q(-\lambda_0)$ in advance and storing it if there is sufficient storage space. If λ_0 is real, then all operations are real.

Juxtaposing two copies of (4.11), we obtain the following expression for $S_1(\lambda_0, \mathcal{W})$:

$$
\begin{aligned}
S_1(\lambda_0,\mathcal{W}) &= (\mathcal{W}-\lambda_0 I)^{-1}(\mathcal{W}+\lambda_0 I)(\mathcal{W}-\bar\lambda_0 I)^{-1}(\mathcal{W}+\bar\lambda_0 I)\\
&= \begin{bmatrix} I & \lambda_0 M+\frac{1}{2}G \\ 0 & I \end{bmatrix}\begin{bmatrix} 0 & I \\ -Q(\lambda_0)^{-1} & 0 \end{bmatrix}\begin{bmatrix} I & 2\lambda_0 I \\ 0 & I \end{bmatrix}\\
&\quad\times\begin{bmatrix} 0 & -Q(-\lambda_0) \\ I & 0 \end{bmatrix}\begin{bmatrix} I & 2\Re(\lambda_0)M \\ 0 & I \end{bmatrix}\begin{bmatrix} 0 & I \\ -Q(\bar\lambda_0)^{-1} & 0 \end{bmatrix}\\
&\quad\times\begin{bmatrix} I & 2\bar\lambda_0 I \\ 0 & I \end{bmatrix}\begin{bmatrix} 0 & -Q(-\bar\lambda_0) \\ I & 0 \end{bmatrix}\begin{bmatrix} I & \bar\lambda_0 M-\frac{1}{2}G \\ 0 & I \end{bmatrix},
\end{aligned}
\tag{4.12}
$$

which can be translated into an algorithm for applying the operator S_1. The total work for multiplying $S_1(\lambda_0, \mathcal{W})$ by a vector is summarized in Table 4.4.

TABLE 4.4
Operation count for applying the operator S_1, assuming a sparse LU factorization of $Q(\lambda_0)$ is available.

4	Sparse triangular solves
5	Symmetric sparse matrix-vector products Mz
4	Skew symmetric sparse matrix-vector products Gz
2	Symmetric sparse matrix-vector products Kz
11	Saxpy operations

In general the arithmetic is complex; however, if λ_0 is real, then all operations are real.

Typically, the triangular LU factors are sparse, but not nearly as sparse as the original matrices. Thus the most expensive operations listed in Tables 4.2–4.4 are the sparse triangular solves. The matrix-vector products are cheaper, but still significant. The saxpy operations are relatively insignificant. Bearing these facts in mind and comparing Tables 4.1 and 4.4, we conclude that the symplectic operator S_1 can be applied significantly less expensively than R_1 can.

4.2. Optimal control problems. Consider the SHH pencil

$$
\alpha\begin{bmatrix} E & 0 \\ 0 & E^T \end{bmatrix} - \beta\begin{bmatrix} A & -BB^T \\ C^TC & -A^T \end{bmatrix}
\tag{4.13}
$$

from the linear quadratic optimal control problems for descriptor systems, and consider the decomposition of $\mathcal{N}$ given by (2.2). We have

$$
\begin{aligned}
R_1 &= R_1(\lambda_0,\mathcal{H},\mathcal{N},\mathcal{Z}_1,\mathcal{Z}_2)\\
&= \mathcal{Z}_2(\mathcal{H}-\lambda_0\mathcal{N})^{-1}\mathcal{N}(\mathcal{H}+\lambda_0\mathcal{N})^{-1}\mathcal{N}(\mathcal{H}-\bar\lambda_0\mathcal{N})^{-1}\mathcal{N}(\mathcal{H}+\bar\lambda_0\mathcal{N})^{-1}\mathcal{Z}_1
\end{aligned}
$$

from (3.4). In this case each of the terms $(\mathcal{H}-\sigma\mathcal{N})^{-1}$ can be factored as

$$(\mathcal{H}-\sigma\mathcal{N})^{-1} = \begin{bmatrix} A-\sigma E & -BB^T \\ C^TC & -\left(A^T+\sigma E^T\right) \end{bmatrix}^{-1}$$

$$(4.14) = \begin{bmatrix} F^{-1} & 0 \\ 0 & I \end{bmatrix} \begin{bmatrix} I & BB^T \\ 0 & I \end{bmatrix} \begin{bmatrix} F & 0 \\ 0 & D^{-1} \end{bmatrix} \begin{bmatrix} I & 0 \\ -C^TC & I \end{bmatrix} \begin{bmatrix} F^{-1} & 0 \\ 0 & I \end{bmatrix},$$

where $F = A-\sigma E$ and $D = -\left(A^T+\sigma E^T\right)+C^TCF^{-1}BB^T$. To apply this operator we will certainly need an LU factorization of $A-\sigma E$. We will also need an LU factorization of $A^T+\sigma E^T$, which we will use together with the Sherman–Morrison–Woodbury formula [17] to evaluate D^{-1}.

We have to apply (4.14) with $\sigma = \lambda_0$, $\bar{\lambda}_0$, $-\lambda_0$, and $-\bar{\lambda}_0$. If we have sparse LU factorizations associated with one choice of σ, then we automatically get the other factorizations. For example, if we have LU factorizations $A-\lambda_0 E = L_1U_1$ and $A^T+\lambda_0E^T = L_2U_2$, then we also have

$$(4.15) \qquad \begin{array}{llll} A-\bar{\lambda}_0E &= \bar{L}_1\bar{U}_1, & A^T+\bar{\lambda}_0E^T &= \bar{L}_2\bar{U}_2, \\ A+\lambda_0E &= U_2^TL_2^T, & A^T-\lambda_0E^T &= U_1^TL_1^T, \\ A+\bar{\lambda}_0E &= \bar{U}_2^T\bar{L}_2^T, & A^T-\bar{\lambda}_0E^T &= \bar{U}_1^T\bar{L}_1^T. \end{array}$$

To apply D^{-1} efficiently, we exploit the fact that the term $C^TCF^{-1}BB^T$ has low rank. Recalling that m and p are the number of columns in B and C^T, respectively, let us assume that $p \le m$. (Otherwise, exchange the roles of B and C.) Then, with $A-\sigma E = T_1V_1$, $-\left(A^T+\sigma E^T\right) = T_2V_2$ being any of the factorizations listed above, we can apply the Sherman–Morrison–Woodbury formula [17] to obtain

$$\begin{aligned} D^{-1} &= (T_2V_2 + C^TCV_1^{-1}T_1^{-1}BB^T)^{-1} \\ &= V_2^{-1}(I - T_2^{-1}C^TN^{-1}CV_1^{-1}T_1^{-1}BB^TV_2^{-1})T_2^{-1}, \end{aligned} \qquad (4.16)$$

where $N = I + CV_1^{-1}T_1^{-1}BB^TV_2^{-1}T_2^{-1}C^T$ is by assumption a very small matrix $(p\times p)$ and typically full. The cost to compute N consists of $4p$ triangular solves plus $4nmp + 2mp^2$ flops (much less if B is sparse). An additional $2p^3$ flops are needed to invert this small matrix. This part of the computation must be done four times, once for each choice of σ.

With N^{-1} available we see from (4.16) that the cost of multiplying D^{-1} by a vector is essentially that of six sparse triangular solves. The other operations, such as multiplication of B by a vector, are relatively insignificant if B and C are sparse. Thus the cost of applying $(\mathcal{H}-\sigma\mathcal{N})^{-1}$ in (4.14) is 10 sparse triangular solves plus small change, and the cost of applying R_1 in (3.4) is 40 sparse triangular solves plus change. Similarly, the cost of applying S_1 (3.12) is a bit more than 20 sparse triangular solves.

4.3. Skew-Hamiltonian versus symplectic operators. We have already discussed some of the advantages and disadvantages of the two rational transformations that lead to skew-Hamiltonian and symplectic operators, respectively.

The advantage of the skew-Hamiltonian operator is that we can apply the IRA method, while for the symplectic operator we have to use special symplectic Lanczos methods with all their possible stability problems due to breakdowns or near-breakdowns. Due to the possible breakdowns, these latter methods are also more difficult to implement in practice; see [16]. Furthermore, as we have discussed, the

symplectic operator cannot be used when the target shift is close to or on the imaginary axis, which is a frequent situation in optimal control problems.

But the symplectic operators also have advantages, since the cost of applying the operator is roughly half of that for the skew-Hamiltonian operator, and the method is also applicable for complex pencils. It should be noted, though, that in the symplectic Lanczos method we need to apply both the operator and its inverse at each step.

Taking this comparison into account, we have implemented the IRA method based on the skew-Hamiltonian operator for its simplicity and numerical robustness, and since we can also use it with shifts near or on the imaginary axis.

5. Implementation of the skew-Hamiltonian Arnoldi method. We implemented a modified version of the IRA method [39] that applies the skew-Hamiltonian operator R_1 (3.4). Since our method is a skew-Hamiltonian, isotropic, IRA method, we call it SHIRA.

In order to preserve the structure, instead of a standard Arnoldi step we use the isotropic Arnoldi step (3.5), (3.6) with $A = R_1$. In exact arithmetic the coefficients t_{ij} should all be zero, but in practice roundoff errors cause them to be nonzero. By subtracting out the tiny components Jq_it_{ij}, we ensure that the spaces $\text{span}\{q_1, \ldots, q_j\}$ are isotropic to working precision. For accuracy we use the modified Gram–Schmidt method [17] to compute the coefficients h_{ij} and t_{ij}, rather than applying the formulas (3.5) literally. Finally, since modified Gram–Schmidt does not always generate vectors that are orthogonal to working precision [12], we perform two orthogonalization sweeps on $q_1, \ldots, q_j$. After j steps of the isotropic Arnoldi process we have vectors $q_1, \ldots, q_{j+1}$ satisfying

$$AQ_j = Q_jH_j + JQ_jT_j + q_{j+1}h_{j+1,j}e_j^T, \tag{5.1}$$

where $Q_j = [q_1 \cdots q_j]$, and H_j and T_j are matrices of coefficients. Our method ignores T_j and so depends on the fact that the elements of T_j are tiny. Our implementation of the IRA method is standard [39]; the shifts are chosen to select for the eigenvalues of A of largest magnitude. Each implicit restart, i.e., each iteration of the IRA method, produces a new configuration of the form (5.1) with a different starting vector q_1 and, typically, a smaller $h_{j+1,j}$. After several restarts, $h_{j+1,j}$ becomes negligible, and we have, up to roundoff errors,

$$AQ_j = Q_jH_j.$$

The eigenvalues of H_j are j of the eigenvalues of $A = R_1(\lambda_0, \mathcal{W})$, and they are typically the j largest in magnitude. If we actually want fewer than j eigenvalues, we can monitor $h_{k+1,k}$ for $k \le j$. If we stop when $h_{k+1,k}$ is negligible, we get k eigenvalues.

5.1. Eigenvalue computation. The Arnoldi process yields eigenvalues of the matrix $R_1(\lambda_0, \mathcal{W})$, but we actually want eigenvalues of the Hamiltonian matrix $\mathcal{W}$. Each eigenvalue μ of R_1 corresponds to two eigenvalues $\pm\lambda$ of $\mathcal{W}$ satisfying $(\lambda^2 - \lambda_0^2)(\lambda^2 - \bar{\lambda}_0^2) = 1/\mu$. A seemingly straightforward approach is to solve the quadratic equation

$$(\nu - \lambda_0^2)(\nu - \bar{\lambda}_0^2) = 1/\mu \tag{5.2}$$

for ν, and then compute $\pm\sqrt{\nu}$ to get the eigenvalues. Unfortunately, (5.2) has two solutions, only one of which corresponds to eigenvalues of $\mathcal{W}$. Thus one is faced with deciding which ν is the correct one.

We have adopted a different approach which dodges this decision and also allows us to make a final test of the backward stability of the result. Once $h_{k+1,k}$ is negligible, the space $\operatorname{span}\{q_1, \ldots, q_k\}$ is, up to roundoff errors, an invariant subspace under R_1. Normally it is also invariant under $\mathcal{W}^2$ (but not under $\mathcal{W}$) since R_1 is a function of $\mathcal{W}^2$. The space $\operatorname{span}\{q_1, \ldots, q_k\}$ can fail to be invariant under $\mathcal{W}^2$ only if two distinct eigenvalues of $\mathcal{W}^2$ are mapped to the same eigenvalue of R_1. We calculate the Ritz values of $\mathcal{W}^2$ with respect to the space $\operatorname{span}\{q_1, \ldots, q_k\}$; that is, we calculate the eigenvalues μ_i of $B = Q_k^T \mathcal{W}^2 Q_k$. Then $\pm\sqrt{\mu_i}$ are the eigenvalues of $\mathcal{W}$ that we seek.

As a byproduct of the computation of B, we obtain the vectors $\mathcal{W}^2 Q_k$, which we use to compute the residual

$$\left\| \mathcal{W}^2 Q_k - Q_k B \right\|_F \tag{5.3}$$

and thereby check whether or not $\operatorname{span}\{q_1, \ldots, q_k\}$ really is invariant under $\mathcal{W}^2$. This test is necessary because, as we have already mentioned, it can happen that a space that is invariant under R_1 fails to be invariant under $\mathcal{W}^2$. For example, if λ_0 is chosen so unfortunately that two distinct eigenvalues of $\mathcal{W}^2$ are mapped to the same eigenvalue of R_1, then R_1 will have a four-dimensional eigenspace spanned by two two-dimensional eigenspaces of $\mathcal{W}^2$. If the Arnoldi process picks up only one vector from this space, it will typically not be an eigenvector of $\mathcal{W}^2$, and the space $\operatorname{span}\{q_1, \ldots, q_k\}$ will not be invariant under $\mathcal{W}^2$.

It is interesting to note that the practical need for such a stability test is related to our insistence upon enforcing isotropy. In principle a Krylov subspace can contain at most a one-dimensional subspace of a multidimensional eigenspace, so the Arnoldi process will find at most one copy of a geometrically multiple eigenvalue. However, as is well known [40], roundoff errors will turn multiple eigenvalues into simple ones, and hence we will detect different approximations of the multiple eigenvalues. This is mostly a nuisance for us, because the eigenvalues of $\mathcal{W}^2$ are all geometrically multiple, and we would rather not pay to calculate two copies of each eigenvalue. Therefore, we use the isotropic Arnoldi method which enforces isotropy. It has the effect that each eigenvalue is picked up only once in practice. It has the unfortunate side effect that when a four-dimensional invariant subspace of R_1 consists of two two-dimensional invariant subspaces of $\mathcal{W}^2$, only one vector from that space is found, from which it is impossible to deduce eigenvectors of $\mathcal{W}^2$. Fortunately the merging of eigenspaces is a rare event.

Finally, we should note that this approach to eigenvalue calculation requires application of the operator $\mathcal{W}^2$. In our quadratic eigenvalue applications, linearized as in (2.5) or (2.8), we have

$$\mathcal{W} = \begin{bmatrix} I & -\frac{1}{2}G \\ 0 & I \end{bmatrix} \begin{bmatrix} 0 & -K \\ M^{-1} & 0 \end{bmatrix} \begin{bmatrix} I & -\frac{1}{2}G \\ 0 & I \end{bmatrix}.$$

To apply M^{-1}, we need to compute the Cholesky decomposition of M. Typically the Cholesky factor is quite sparse, and this step does not add substantially to the overall computing time. At this point in the computation we no longer need the LU factors of $Q(\lambda_0)$ (used for applying R_1), so we can use that storage space for the Cholesky factor of M.

5.2. Eigenvector computation. In the course of the eigenvalue computation we can easily obtain the corresponding Ritz vectors, which are eigenvectors of $\mathcal{W}^2$. Each of these is a particular member of a two-dimensional eigenspace of $\mathcal{W}^2$ but

in general not an eigenvector of $\mathcal{W}$. Thus, if we want eigenvectors to go with our eigenvalues, we need to do more work. This is a shortcoming of the skew-Hamiltonian approach.

Given eigenvalues, the quickest way to obtain corresponding eigenvectors is to perform inverse iteration. In the case of the quadratic eigenvalue problem, in view of [41], we refer back to the original form of the problem:

$$Q(\lambda)v = \lambda^2 Mv + \lambda Gv + Kv = 0.$$

For each eigenvalue λ we form a sparse LU decomposition of $Q(\lambda)$ and use the decomposition to perform one step of inverse iteration

$$v = Q(\lambda)^{-1}w.$$

Due to the form of linearization that we have used in (2.8), the bottom half of the eigenvector of $\mathcal{W}$ corresponds to an eigenvector of the quadratic eigenvalue problem. Therefore we use as starting vector w the bottom half of the $2n$-dimensional Ritz vector of $\mathcal{W}^2$ associated with λ^2. We have found that the choice of starting vectors is not crucial. Even random starting vectors produce good results. Note further that the residual $\|Q(\lambda)v\|_2 / \|v\|_2$ gives another measure of backward stability of the computation.

To compute the eigenvector associated with the eigenvalue $-\lambda$, we exploit the relationship $Q(-\lambda) = Q(\lambda)^T$. Thus, as in (4.8), the LU decomposition of $Q(\lambda)$ can also be used for the computation $v = Q(-\lambda)^{-1}w$.

If the complex eigenvalue λ has eigenvector v, then $\bar{\lambda}$ has eigenvector $\bar{v}$.

In summary, the cost of computing the eigenvectors associated with a pair $\{\lambda, -\lambda\}$ or a quadruple $\{\lambda, -\lambda, \bar{\lambda}, -\bar{\lambda}\}$ is one sparse LU decomposition plus four sparse triangular solves. If several sets of eigenvectors are wanted, they can be computed in parallel, given available processors and memory, or they can be computed sequentially, reusing the memory space for the LU decompositions.

6. Numerical results. We applied the skew-Hamiltonian Arnoldi method to solve numerous quadratic eigenvalue problems

$$\lambda^2 Mx + \lambda Gx + Kx = 0. \tag{6.1}$$

All computations were done in Matlab version 5.2 on a Linux machine.

In one class of problems that we considered, we built matrices of order $n = m^2$ by a tensor product construction. Let B denote the $m \times m$ nilpotent Jordan block

$$B = \begin{bmatrix} 0 & & & 0 \\ 1 & & & \\ & \ddots & & \\ & & 1 & 0 \end{bmatrix},$$

and define $\tilde{M} = \frac{1}{6}(4I_m + B + B^T)$, $\tilde{G} = B - B^T$, and $\tilde{K} = -(2I_m - B - B^T)$. Then we set

$$\begin{aligned} M &= c_{11} I_m \otimes \tilde{M} + c_{12} \tilde{M} \otimes I_m, \\ G &= c_{21} I_m \otimes \tilde{G} + c_{22} \tilde{G} \otimes I_m, \\ K &= c_{31} I_m \otimes \tilde{K} + c_{32} \tilde{K} \otimes I_m, \end{aligned} \tag{6.2}$$

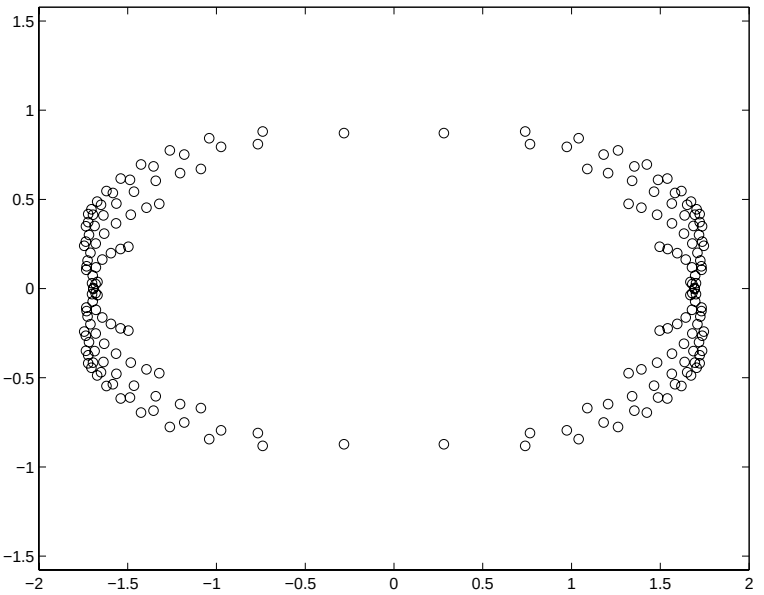

FIG. 6.1. *Eigenvalues of* 100×100 *quadratic pencil.*

where the coefficients c_{ij} are positive constants. We have $M = M^T > 0$, $G = -G^T$, and $K = K^T < 0$.

Example 6.1. If we take $m = 10$ and

$$\begin{array}{llllll} c_{11} & = & 1.00, & c_{12} & = & 1.30, \\ c_{21} & = & 1.35, & c_{22} & = & 1.10, \\ c_{31} & = & 1.00, & c_{32} & = & 1.20, \end{array} \tag{6.3}$$

then we obtain a 100×100 quadratic pencil, whose 200 eigenvalues are shown in Figure 6.1. These were computed by applying Matlab's `eig` command to the 200×200 matrix pencil (2.8), ignoring all structure, at a cost of 885×10^6 flops.

Suppose we want to use SHIRA to compute the 12 eigenvalues that are closest to the imaginary axis. Then, supposing that we know nothing about where the eigenvalues lie, our safest course of action is to choose a target shift λ_0 that lies on the imaginary axis. Table 6.1 shows the flop counts for computing these eigenvalues using three different choices of purely imaginary target. Results are given for our structured method SHIRA and a competing unstructured method, which applies the IRA method (in complex arithmetic) to the shifted inverted Hamiltonian operator $(\mathcal{W} - \lambda_0 I)^{-1}$; see (4.7). Because of the shift, this operator has no structure.

TABLE 6.1

Flop count for computing the 12 *smallest eigenvalues (and associated eigenvectors) of the pencil in Example* 6.1 *using structured and unstructured methods.*

	Flops (10^6)	
λ_0	SHIRA	Unstructured
$0.1i$	17.3	71.8
$1.0i$	11.4	26.3
$5.0i$	44.9	98.2

We see that both methods benefit from a good choice of shift, but regardless of shift, SHIRA outperforms the unstructured method by a factor of two or more. SHIRA applies IRA (in real arithmetic) to the skew-Hamiltonian operator R_1 (3.2) and finds the six largest eigenvalues (three complex-conjugate pairs), which correspond to three quadruplets of eigenvalues of (6.1). We used 10 Arnoldi steps per implicit restart. Using the shift $\lambda_0 = i$, for example, the competing method finds the six eigenvalues (in the upper half-plane) that are closest to the shift, not realizing that they constitute three pairs $(\lambda, -\bar{\lambda})$. We then deduce six other eigenvalues by taking complex conjugates. Again we used 10 Arnoldi steps per implicit restart. For both methods we used a deflation tolerance of 10^{-10}. In all cases the errors in the computed eigenvalues and eigenvectors were less than 10^{-9}.

Example 6.2. Consider another pencil built from matrices of the form (6.2), this time with $m = 5$. Use the same coefficients as in (6.3), except that $c_{21} = 0.1$. This results in a pencil whose smallest eigenvalues are real. The three smallest positive eigenvalues are

$$\begin{aligned} \lambda_1 &= 0.6726432397672, \\ \lambda_2 &= 0.9866442639296, \\ \lambda_3 &= 1.0689101679903. \end{aligned}$$

Using SHIRA with an appropriate tolerance and any reasonable shift (e.g., $\lambda_0 = 0$, i, or 0.5), we can compute these eigenvalues quickly, with any desired accuracy up to machine precision. The purpose of this example is to show that an unfortunate choice of shift can cause our eigenvalue computation scheme to fail. If we take $\lambda_0 = \hat{\lambda}_0 = \sqrt{(\lambda_1^2 + \lambda_2^2)/2}$, then the two eigenvalues λ_1^2 and λ_2^2 of $\mathcal{W}^2$ are mapped to the same eigenvalue of $R_1(\lambda_0, \mathcal{W})$, which then has a four-dimensional eigenspace associated with that eigenvalue. With this choice of λ_0, SHIRA is unable to calculate correct values for λ_1 and λ_2. Checking the residual (5.3), we find that $\left\|\mathcal{W}^2 Q_k - Q_k B\right\|_F \approx .37 \left\|\mathcal{W}^2 Q_k\right\|_F$, indicating that the space $\operatorname{span}\{q_1, \ldots, q_k\}$ is not invariant under $\mathcal{W}^2$. This is a red flag that tells us that our results cannot be trusted.

A simple remedy is to change λ_0. Even a tiny change suffices. For example, if we run SHIRA with $\lambda_0 = \hat{\lambda}_0 + 10^{-5}$ (and deflation tolerance 10^{-10}), we get the three smallest eigenvalues correct to twelve decimal places compared with the eigenvalues computed by the QZ-algorithm [17]. The residual (5.3) is $\left\|\mathcal{W}^2 Q_k - Q_k B\right\|_F \approx \left(4 \times 10^{-11}\right) \left\|\mathcal{W}^2 Q_k\right\|_F$, indicating that the subspace is invariant under $\mathcal{W}^2$ to within the desired tolerance.

Example 6.3. Finally, we consider a quadratic eigenvalue problem obtained by a finite element discretization of equations of elastic deformation of an anisotropic material [19, 21, 34]. The matrices have dimension 2223. Suppose we wish to find the twelve eigenvalues closest to the imaginary axis. It is known a priori that the eigenvalues lie near the real axis, so it makes sense to use a real target shift. In fact, the six smallest eigenvalues in the right half-plane are

$$\begin{aligned} \lambda_1 &= 0.96269644895, \\ \lambda_2 &= 0.98250961158 + 0.00066849814i, \\ \lambda_3 &= 0.98250961158 - 0.00066849814i, \\ \lambda_4 &= 1.35421843051, \\ \lambda_5 &= 1.39562564903, \\ \lambda_6 &= 1.49830518846. \end{aligned}$$

The flops needed to compute these eigenvalues by SHIRA using R_1, R_2, and the

TABLE 6.2
Flop count for computing smallest 12 *eigenvalues of the quadratic pencil in Example* 6.3 *using structured and unstructured methods.*

	Flops (10^7)		—
λ_0	SHIRA R_1	SHIRA R_2	Unstructured
0	32.6	28.4	140.1
0.3	32.6	28.5	79.6
0.6	28.4	25.7	69.8
0.9	28.4	23.0	50.7
1.2	19.8	17.5	31.5

unstructured method using various choices of real target shift are given in Table 6.2.

Again we used a deflation tolerance of 10^{-10}. We see that SHIRA can benefit from a good choice of λ_0 but also does well if a good shift is not known. In particular, it performs well even for the poor but safe choice $\lambda_0 = 0$. In each case SHIRA computes the six largest eigenvalues of $R_1(\lambda_0, \mathcal{W})$ or $R_2(\lambda_0, \mathcal{W})$, which turn out to be one complex pair and four real eigenvalues. These yield twelve eigenvalues of $\mathcal{W}$, one complex quadruplet, and four real $\{\lambda, -\lambda\}$ pairs. In all of these runs we used nine Arnoldi steps per implicit restart.

In contrast with SHIRA, the unstructured method is highly dependent on a good choice of shift. Given a good shift, such as $\lambda_0 = 1.2$, the unstructured method was nearly competitive with SHIRA. It computed the six positive eigenvalues closest to λ_0, which turned out to be the eigenvalues that we wanted. We then deduced the six negative eigenvalues $-\lambda_1, \ldots, -\lambda_6$ from the structure. We used nine Arnoldi steps per implicit restart.

The problem with the unstructured approach is that if we choose a target that is too large, we might miss the smallest eigenvalues. On the other hand, if we take a shift that is too close to the origin, then since an unstructured method does not reflect the relationship between the paired eigenvalues $\lambda, -\lambda, \bar{\lambda}, -\bar{\lambda}$, we end up computing some of the left half-plane eigenvalues explicitly. For example, in the case $\lambda_0 = 0.3$, λ_6 is not among the six smallest eigenvalues of the shifted operator. We had to compute nine eigenvalues in order to find $\lambda_1, \ldots, \lambda_6$; we also got $-\lambda_1$, $-\lambda_2$, and $-\lambda_3$. We took twelve Arnoldi steps per restart.

Using the shift $\lambda_0 = 0$, the safest choice, we have to compute all twelve eigenvalues explicitly. We used fifteen Arnoldi steps per restart. As Table 6.2 shows, many more flops were needed in this case than in all other cases.

Table 6.2 shows only the cost of the eigenvalue computation, which is SHIRA's strength. If one wants eigenvectors as well, the cost is an extra 15.7×10^7 flops for SHIRA and only 2.3×10^7 flops for the unstructured approach. If one adds these numbers to those in Table 6.2, one sees that SHIRA is still faster, indeed much faster in the cases where the best shift is not known in advance.

7. Conclusion. We have discussed structure preserving shift-and-invert Krylov subspace methods for the computation of a few eigenvalues and eigenvectors of large, sparse SHH pencils. We have demonstrated that a skew-Hamiltonian shift-and-invert IRA method can speed up the computation of desired eigenvalues in the interior of the spectrum significantly. Furthermore, by this approach it is guaranteed that the computed spectrum has the correct symmetry structure.

COMPARISON OF THE NODAL INTEGRAL METHOD AND NONSTANDARD FINITE-DIFFERENCE SCHEMES FOR THE FISHER EQUATION*

RIZWAN-UDDIN†

Abstract. The relationship between the so-called nonstandard finite-difference schemes and the nodal integral method (NIM) is investigated using the Fisher equation as a model problem. Exact and best finite-difference schemes are reviewed first. Next, the NIM for the Fisher equation is developed. It is shown that the NIM leads to a nonstandard evaluation of the derivatives. Moreover, the resulting scheme possesses the desirable characteristics of the nonstandard finite difference schemes, such as the nonlocal evaluation of the nonlinear terms. Thus, the NIM provides a systematic framework to obtain schemes *similar* to the *best finite-difference schemes*. Numerical results for a propagating front problem show that the NIM can capture the shape and speed of the front very accurately. Results also show that the *best finite-difference scheme* is stable for large grid sizes but only at the cost of inaccuracy in the front propagation speed. Additional results are obtained using the NIM for symmetric and asymmetric initial conditions. These describe the interaction of two fronts of advantageous genes that approach each other and merge. It is noted that the traveling fronts evolving from certain asymmetric initial conditions become indistinguishable from those that evolve from symmetric initial conditions.

Key words. nodal integral method, best finite-difference schemes, semianalytical numerical schemes, Fisher equation, wave propagation

1. Introduction.

Several nodal methods have been developed over the last two decades to solve partial differential equations (PDEs) [1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11]. A common feature among these is the analytical or semianalytical treatment of at least a part of the PDE(s). This is accomplished, for example, by introducing known solutions of one-dimensional, steady-state problems in multidimensional or time-dependent problems, or by reducing the PDEs to a set of ordinary differential equations (ODEs) via the transverse integration process, and then approximately solving the ODEs. Hence, a class of these methods is also known as *analytical nodal methods* [6, 8]. A major advantage of these methods is that they yield an accurate solution over large grid/step sizes. Consequently, these methods are especially suitable for problems with large spatial and/or time domains. The details of one particular kind of nodal method—the so-called *nodal integral* (*or integration*) *method* (NIM) [2, 5]—will be given in section 3 in the context of the Fisher equation (FE).

A different approach for the solution of PDEs (and ODEs) that also relies on analytical solutions or conservation laws leads to nonstandard finite-difference (NSFD) schemes such as the *exact finite-difference* (EFD) and/or the *best finite-difference* (BFD) schemes [12, 13, 14, 15, 16]. A finite-difference (FD) scheme is called an EFD scheme if the solution for all step sizes at all grid points is equal to the exact analytical solution of the differential equation at the corresponding grid points. It is intuitively expected that only those differential equations that have a closed form exact solution

will lead to EFD schemes. Not surprisingly, the interest in the EFD schemes—which are available for a limited number of ODEs and even fewer PDEs—is in their utility in gaining numerical insight for the development of improved FD schemes for problems that do not admit EFD schemes. For differential equations that do not admit EFD schemes, the corresponding notion of BFD schemes is developed—as the *next best thing* to an EFD scheme. While the idea of the EFD scheme is fairly well defined, the notion of the BFD scheme is a little vague. An FD scheme is called a BFD scheme if *the important properties of its solutions correspond exactly to the related properties of the solutions to the differential equation for all values of the step size* [15]. Specific important properties may include conservation laws, special cases of known exact solutions, and stability properties of fixed points, etc. BFD schemes for complex problems are developed by taking advantage of the known EFD schemes for simpler problems—imparting an analytical component to the BFD schemes.

A word on terminology: a *node* in the NIM (which roughly corresponds to the *grid point* in the FD methods) refers to a finite region in the space of independent variables. The discrete unknowns in the NIM are the phase variables *averaged* over $(n-1)$ dimensional surfaces of these nodes, where n is the number of independent variables in the problem.

Given the properties of the BFD schemes and the NIM, and their similar semi-analytical background, it is desirable to investigate the common features in these schemes with the goal of providing insight for the development of improved schemes. The fact that both schemes rely on specialized procedures specific to the problem at hand necessitates that this exercise be carried out in the context of a specific problem. The FE is chosen here to be the model problem for such a comparison.

The FE

$$\frac{\partial u(x,t)}{\partial t} = \frac{\partial^2 u(x,t)}{\partial x^2} + \lambda u(x,t)(1-u(x,t)) \tag{1}$$

describes the propagation of an advantageous gene in a one-dimensional infinite medium [17]. Kolmogoroff, Petrovsky, and Piscounov [18] studied this equation and showed, among other properties, that for all bounded initial conditions (ICs) in an infinite domain, the results remain bounded. Canosa [19] developed a second order perturbation solution for the FE for large characteristic speeds. Later, Gazdag and Canosa [20] used the *accurate space derivative* (ASD) technique [21] to numerically solve the FE and showed the evolution of various ICs into the traveling wave of minimal speed. Convergence of the ASD method required cutting off the right-hand tail of the wave moving toward the right. Moreover, the speed with which an IC evolved to the time-asymptotic minimum speed wave also depended upon the point at which the right-hand tail was cut off. As is shown below, the NIM does not have such restrictions. An excellent review of the FE (and other nonlinear diffusion problems), its properties, and its numerical solutions is given by Sachdev [22].

The rest of this paper is divided into five sections. The EFD and BFD schemes are briefly reviewed in section 2. The NIM is developed for the FE in section 3. The NIM scheme is compared in section 4 with the BFD scheme of Mickens [15], and similarities and differences between the two schemes are identified. Numerical results and discussion are in section 5. Section 6 summarizes the paper.

2. Review of EFDs and BFDs. This section is based on the material in [12, 15, 16]. Consider the following first and second order ODEs:

$$\frac{dy(t)}{dt} = \mu y(t), \tag{2}$$

$$\frac{d^2y(x)}{dx^2} + \nu y(x) = 0. \tag{3}$$

Various discrete approximations for the derivative in these equations lead to the standard FD schemes for the two equations. By standard FD schemes (SFD), we mean ones in which the derivatives are approximated by, for example, the backward, forward, or central difference formulas. With forward differences for the first derivative and central differences for the second derivative, the discrete forms of (2) and (3) are

$$\frac{y_j - y_{j-1}}{\Delta t} = \mu y_{j-1} \tag{4}$$

and

$$\frac{y_{i+1} - 2y_i + y_{i-1}}{(\Delta x)^2} + \nu y_i = 0, \tag{5}$$

where the subscript i indicates the spatial grid points and the subscript j indicates the time level. Later, for space- *and* time-dependent problems, the same subscripts, separated by a comma, will be used. Equations (4) and (5) will be referred to as the SFD schemes for (2) and (3), respectively. But, given the fact that the exact solution of (2) and (3) is known to any sophomore, one can easily construct the *exact* FD schemes for them by first (exactly) solving the differential equations with the corresponding initial and boundary conditions, and then by rewriting the solution in the same format as (4) and (5) [12]. This leads to

$$\frac{y_j - y_{j-1}}{\left(\dfrac{e^{\mu \Delta t} - 1}{\mu}\right)} = \mu y_{j-1} \tag{6}$$

and

$$\frac{y_{i+1} - 2y_i + y_{i-1}}{\dfrac{4}{\nu}\left[\sin\left(\dfrac{\sqrt{\nu}\,\Delta x}{2}\right)\right]^2} + \nu y_i = 0. \tag{7}$$

The SFD schemes—(4) and (5)—and the EFD schemes—(6) and (7)—differ from each other only by the denominators in the approximations of the derivatives. However, the latter schemes have no restrictions on the size of the time step or grid size—the results will always be exact (to machine accuracy). On the other hand, restrictions on the size of these parameters for the SFD schemes are well known. Note that the approximations for the derivatives in the SFD schemes are functions of the discrete variables and the grid size (Δt or Δx), whereas the "approximations" for the derivatives in the EFD schemes depend also on the system parameters (μ, ν).

This observation that the EFD schemes differ from the SFD schemes by so little (at least in these very simple cases), motivated a similar approach for *real* problems with no exact solution. As a generalization of the approximation for the first and second order derivatives, a general FD scheme has been suggested [15] in which the denominator in the FD approximations of the derivatives is generalized to functions of the grid size *and* problem parameters

$$\frac{y_j - y_{j-1}}{\Psi(\Delta t, \mu)} = \mu y_{j-1} \tag{8}$$

and

$$\frac{y_{i+1} - 2y_i + y_{i-1}}{\phi(\Delta x, \nu)} + \nu y_i = 0, \tag{9}$$

where $\Psi(\Delta t, \mu)$ and $\Phi(\Delta x, \nu)$ behave like

$$\Psi(\Delta t, \mu) = (\Delta t) + O((\Delta t)^2), \tag{10}$$

$$\Phi(\Delta x, \nu) = (\Delta x)^2) + O((\Delta x)^3). \tag{11}$$

The fact that (2) and (3) have known exact solutions made it easy, in fact possible, to find EFD schemes for them. For *nonlinear* ODEs that do not admit exact solutions, other conditions—some generic and some specific to each equation—are imposed to arrive at a *BFD* scheme. Consider the following equation:

$$\frac{d^2y}{dx^2} + \nu y(1 - y) = 0. \tag{12}$$

There is no EFD scheme for (12). Hence, a BFD scheme is developed by preserving the constant of motion of the above ODE (the energy, E, of the nonlinear conservative oscillator) [13]. In arriving at the BFD scheme for (12), it is also required that the BFD scheme for the nonlinear problem must reduce to the EFD for the linear problem when the nonlinear term is absent. The details are given in [13, 16].

While the development of the EFD and BFD schemes for ODEs is seemingly straightforward, extensions to PDEs have relied on somewhat ad hoc methods. One approach is to first develop the EFD/BFD schemes for the *subproblems* of the PDE in question. Subproblems are simply obtained from the original PDE by considering, for example, the steady-state case, the space-independent case, the linear version of the PDE, etc. These schemes are then combined in such a way that the discrete representation of the PDE reduces to the discrete version of the appropriate continuous subproblem in the corresponding limit [15]. For example, the BFD scheme for the FE is obtained by combining the EFD scheme for the space-independent case ($d^2u/dx^2 = 0$), the SFD scheme for the $\lambda = 0$ case, and the BFD scheme for the time-independent case ($du/dt = 0$, (12)). The BFD scheme for the FE is constructed such that *in the appropriate limit the scheme reduces to the proper discrete model of the relevant subequation* [16]. This leads to the following discretization for the FE:

$$\begin{aligned}\frac{u_{i,j} - u_{i,j-1}}{\left(\dfrac{e^{\lambda \Delta t} - 1}{\lambda}\right)} &= \frac{u_{i+1,j} - 2u_{i,j} + u_{i-1,j}}{\dfrac{4}{\lambda}\left[\sin\left(\dfrac{\sqrt{\lambda}\,\Delta x}{2}\right)\right]^2} \\ &\quad + \lambda u_{i,j-1} - \lambda\left(\frac{u_{i+1,j} + u_{i,j} + u_{i-1,j}}{3}\right) u_{i,j-1},\end{aligned} \tag{13}$$

where i indicates the spatial grid point and j is the time step counter. Here, the first order time- and the second order space derivatives are approximated by nonstandard approximations similar to those in (6) and (7) for the linear equations with EFD schemes. The nonlinear term in the discretized FE is represented *nonlocally*, i.e., it is evaluated not at one grid point but rather as the product of the *local* population density at the previous time step and a population density averaged over the three consecutive grid points at the current time step. This feature—nonlocal evaluation of

the nonlinear terms—appears repeatedly in such schemes. Despite the implicit nature of the other terms, the linear term is evaluated at the *previous* time step, and so is one of the u variables in the nonlinear (u^2) term. These features make this BFD scheme significantly different from SFD schemes.

In the next section, where the NIM is developed for the FE, it is shown that the discrete set of equations for the NIM—obtained through a much more systematic procedure than those used to obtain the BFD scheme—also has many of the same features.

3. NIM formulation for the FE. The space-time domain is divided into layers of n_x spatial *elements*, or *nodes*, each of width $2a$ in the horizontal (spatial) direction and of height Δt. Nonuniform nodes in space can easily be incorporated. A coordinate system local to each space-time node is defined with the origin at the bottom-center of the node. See Figure 1. Hence, $-a \le x' \le a$, $t_j \le t' \le t_j + \Delta t$. The space-averaged/time-dependent and time-averaged/space-dependent population densities over each node (i, j) are defined as

$$\bar{u}^x_{i,j}(t') \equiv \frac{1}{(2a)} \int_{-a}^{+a} u(x', t')\, dx', \tag{14}$$

$$\bar{u}^t_{i,j}(x') \equiv \frac{1}{\Delta t} \int_{t_j}^{t_j+\Delta t} u(x', t')\, dt'. \tag{15}$$

The discrete variables associated with the node (i, j) are $\bar{u}^x_{i,j}(\equiv \bar{u}^x_{i,j}(t' = t_j + \Delta t))$ and $\bar{u}^t_{i,j}(\equiv \bar{u}^t_{i,j}(x' = +a))$. Having defined the transverse-averaged, local phase variables, the next step in the development of the NIM is to reduce the PDE to a set of ODEs—one for each independent variable, obtained by averaging over all independent variables except one. As explained in detail below, the ODEs are then solved, and the constant(s) are eliminated in favor of the discrete variables at node interfaces. A set of coupled algebraic equations for the discrete variables is then obtained by imposing appropriate interface conditions (C^0, C^1, etc.) at node interfaces.

In general, the ODEs for transverse-averaged variables cannot be solved exactly. Hence, all the terms that can lead to an exact homogeneous solution are retained on the left-hand side, while the other terms are lumped into what is often called the *pseudosource term* on the right-hand side of the transverse-integrated equations. Complete solutions of the ODEs are written as the sum of the homogeneous and particular solutions. The pseudosource terms, being a function of the dependent variables, must be approximated before the particular solutions for the ODEs can be explicitly written. The pseudosource terms are hence projected onto a complete set of basis functions and truncated at a desired order. The number of terms kept in the expansion determine the order of the numerical scheme [5]. Since the pseudosource terms are unknown, this projection is only formal, and a scheme must be identified to determine the coefficients. Nodal schemes vary based on how these coefficients are determined. One approach is to approximate the pseudosource terms using the discrete variables from the previous iteration [2]. A second approach involves the imposition of certain constraint conditions to arrive at additional algebraic equations to eliminate the coefficients [5]. This is the procedure used below in the development of the NIM for the FE.

The FE allows us the freedom to incorporate the linear term in either the solution of the time-averaged equation, or in the solution of the space-averaged equation, or in both. A priori it is difficult to decide exactly how the linear term must be "divided"

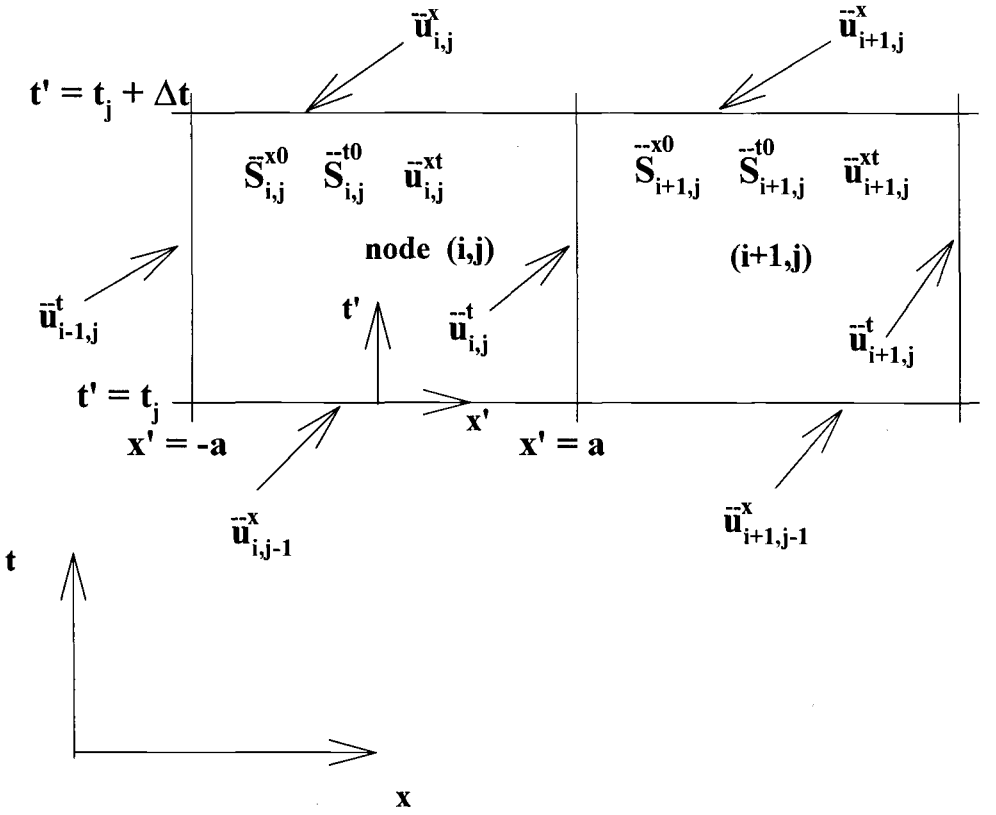

FIG. 1. *Schematic diagram of the space-time nodes and discrete variables in the nodal integral method.*

between the two ODEs for best results. Hence, we proceed with a general approach which allows us to numerically investigate the role of the linear term in each of the ODEs. The linear term in the FE is hence written as

$$\lambda u(x,t) \equiv \lambda(\alpha+\beta)u(x,t), \tag{16}$$

where $(\alpha+\beta)=1$.

Operating on the FE by $\frac{1}{\Delta t}\int_{t_j}^{t_j+\Delta t} dt'$, the equation for the time-step averaged, space-dependent, local population density becomes

$$\begin{aligned}\frac{d^2\bar{u}^t(x')}{dx'^2} + \lambda\alpha\bar{u}^t(x') &= \bar{S}^t(x') \\ &\equiv \frac{1}{\Delta t}\int_{t_j}^{t_j+\Delta t}\left(\frac{\partial u(x',t')}{\partial t'} - \lambda\beta u(x',t') + \lambda u^2(x',t')\right) dt',\end{aligned} \tag{17}$$

and the nodal space-averaged, time-dependent equation—obtained by operating on the FE by $\frac{1}{2a}\int_{-a}^{+a} dx'$—is

$$\frac{d\bar{u}^x(t')}{dt'} - \lambda\beta\bar{u}^x(t') = \bar{S}^x(t')$$

$$\equiv \frac{1}{2a}\int_{-a}^{+a}\left(\frac{\partial^2 u(x',t')}{\partial x'^2} + \lambda\alpha u(x',t') - \lambda u^2(x',t')\right)dx', \tag{18}$$

where the subscript (i,j) has been omitted for convenience. The two ODEs are now solved. Note that different combinations of α and β will yield different functional forms for node interior variation of the space-averaged/time-dependent and time-averaged/space-dependent population densities. Specifically, assuming λ is always positive, a positive, zero, or negative α will yield (for zeroth order approximation for the pseudosource term), respectively, a trigonometric, quadratic, or exponential variation over the space dimension. Similarly, a positive/negative or zero β will yield, respectively, an exponential or linear variation for the space-averaged population density over time. In the development below, α may be negative, and hence the trigonometric functions with complex arguments in those cases will actually be exponential (or hyperbolic) functions.

À la nodal integral scheme [5], the pseudosource terms $\bar{S}^t(x')$ and $\bar{S}^x(t')$ in (17) and (18) are expanded in, say, Legendre polynomials, and truncated at the zeroth order—which is known to lead to a second order scheme. Hence, $\bar{S}^t(x') \cong \bar{S}^{t0}$ and $\bar{S}^x(t') \cong \bar{S}^{x0}$. Equations (17) and (18) are now solved over the node (i,j) with initial and boundary conditions (Figure 1)

$$\begin{aligned} \bar{u}^x(t'=t_j) &= \bar{u}^x_{i,j-1}, \\ \bar{u}^t(x'=-a) = \bar{u}^t_{i-1,j}, &\qquad \bar{u}^t(x'=a) = \bar{u}^t_{i,j}. \end{aligned} \tag{19}$$

The results are

$$\bar{u}^t(x') = \left[\frac{\bar{S}^{t0}_{i,j}}{\lambda\alpha}\right] - \left[\frac{2\bar{S}^{t0}_{i,j} - (\lambda\alpha)(\bar{u}^t_{i,j} + \bar{u}^t_{i-1,j})}{2(\lambda\alpha)\cos(\sqrt{\lambda\alpha}\,a)}\right]\cos(\sqrt{\lambda\alpha}\,x')$$

$$+ \left[\frac{(\bar{u}^t_{i,j} - \bar{u}^t_{i-1,j})}{2\sin(\sqrt{\lambda\alpha}\,a)}\right]\sin(\sqrt{\lambda\alpha}\,x') \tag{20}$$

and

$$\bar{u}^x(t') = -\frac{\bar{S}^{x0}_{i,j}}{(\lambda\beta)} + \left[\frac{\bar{S}^{x0}_{i,j}}{(\lambda\beta)} + \bar{u}^x_{i,j-1}\right]e^{\lambda\beta(t'-t_j)}, \tag{21}$$

where, again, it is understood that these are *local* solutions within the space-time node (i,j).

The discrete equation for the time-step-averaged population density, $\bar{u}^t_{i,j}$, is obtained by requiring the first derivative of the time-step-averaged u to be continuous at the node interface (continuity of flux condition). Hence, two expressions are evaluated and equated for the derivative $d\bar{u}^t(x')/dx'$ at the common interface between nodes i and $(i+1)$, i.e., (20)—which is for node (i,j)—is differentiated and evaluated at $x' = a$, and the result is equated to the derivative of the corresponding equation for the node $(i+1,j)$ evaluated at $x' = -a$. This yields the three point scheme that relates $\bar{u}^t_{i-1,j}$, $\bar{u}^t_{i,j}$, and $\bar{u}^t_{i+1,j}$:

$$\frac{\bar{u}^t_{i+1,j} - 2\bar{u}^t_{i,j} + \bar{u}^t_{i-1,j}}{\dfrac{4}{\lambda\alpha}\left[\sin\left(\dfrac{\sqrt{\lambda\alpha}\,\Delta x}{2}\right)\right]^2} + \lambda\alpha\bar{u}^t_{i,j} = \frac{(\bar{S}^{t0}_{i,j} + \bar{S}^{t0}_{i+1,j})}{2}. \tag{22}$$

The discrete equation for the space-averaged population density for the node, $\bar{u}^x_{i,j}$, is obtained by simply evaluating (21) at $t' = (t_j + \Delta t)$:

$$\frac{\bar{u}^x_{i,j} - \bar{u}^x_{i,j-1}}{\left[\dfrac{e^{\lambda\beta\Delta t} - 1}{\lambda\beta}\right]} - \lambda\beta\bar{u}^x_{i,j-1} = \bar{S}^{x0}_{i,j}. \tag{23}$$

To eliminate the pseudosource terms $\bar{S}^{t0}_{i,j}$ and $\bar{S}^{x0}_{i,j}$, two conditions are imposed [5]. First the FE (1) is integrated over the space-time node

$$\frac{1}{2a\Delta t}\int_{-a}^{+a}\int_{t_j}^{t_j+\Delta t}\left(\frac{\partial u(x',t')}{\partial t'} - \frac{\partial^2 u(x',t')}{\partial x'^2}\right.$$

$$\left. - \lambda\alpha u(x',t') - \lambda\beta u(x',t') + \lambda u^2(x',t')\right) dx'\,dt' = 0, \tag{24}$$

which, using the definitions of the pseudosource terms $\bar{S}^{t0}_{i,j}$ and $\bar{S}^{x0}_{i,j}$ from (17) and (18), becomes

$$\bar{S}^{t0}_{i,j} = \bar{S}^{x0}_{i,j} + \lambda(\bar{u}^{xt}_{i,j})^2, \tag{25}$$

where the average of the product has been approximated by the product of the averages, which is known to lead to a second order error [5], and the space-time-node-averaged velocity $\bar{u}^{xt}_{i,j}$ is defined in (26). The second condition is obtained by requiring that the space-time-node-averaged population density obtained by first averaging in time and then in space should be equal to the average population density obtained by first averaging in space and then in time, i.e.,

$$\bar{u}^{tx} \equiv \frac{1}{2a}\int_{-a}^{+a}\bar{u}^t(x')\,dx' = \frac{1}{\Delta t}\int_{t_j}^{t_j+\Delta t}\bar{u}^x(t')\,dt' \equiv \bar{u}^{xt}. \tag{26}$$

Equation (26) is evaluated by substituting the expressions for $\bar{u}^t(x')$ and $\bar{u}^x(t')$ from (20) and (21), respectively.

The node-averaged population density and the pseudosource terms are eliminated using (25) and (26) from the set of discrete equations (22) and (23). Expressions for $\bar{u}^x_{i,j}$ and $\bar{u}^t_{i,j}$ obtained after eliminating the pseudosource terms, $\bar{S}^{t0}_{i,j}$ and $\bar{S}^{x0}_{i,j}$, are given in the appendix. Equations (22), (23), and (25)—*with* pseudo source terms—are, however, much more instructive in analyzing the discrete form of the FE for the NIM than those given in the appendix (with pseudosource terms eliminated). Here, to explicitly bring out the nonlinear terms in the discrete equations, (23) and (22) are combined with (25) and rewritten below.

$$\frac{\bar{u}^x_{i,j} - \bar{u}^x_{i,j-1}}{\left[\dfrac{e^{\lambda\beta\Delta t} - 1}{\lambda\beta}\right]} - \lambda\beta\bar{u}^x_{i,j-1} + \lambda(\bar{u}^{xt}_{i,j})^2 = \bar{S}^{t0}_{i,j}, \tag{27}$$

$$\frac{\bar{u}^t_{i+1,j} - 2\bar{u}^t_{i,j} + \bar{u}^t_{i-1,j}}{\dfrac{4}{\lambda\alpha}\left[\sin\left(\dfrac{\sqrt{\lambda\alpha}\,\Delta x}{2}\right)\right]^2} + \lambda\alpha\bar{u}^t_{i,j} - \lambda\left[\frac{(\bar{u}^{xt}_{i,j})^2 + (\bar{u}^{xt}_{i+1,j})^2}{2}\right] = \frac{(\bar{S}^{x0}_{i,j} + \bar{S}^{x0}_{i+1,j})}{2}. \tag{28}$$

The structure of the discrete equations and their relationship to each other can now clearly be seen. Both (27) and (28) represent a discrete version of the FE. Hence, when compared with the FE, these equations' RHSs must represent the terms missing on their LHSs. Equation (27) is missing the diffusion term and the α-fraction of the linear term. The zeroth order approximation of the time-step-averaged pseudosource term, RHS of (27), indeed represents these terms missing from the LHS of (27); see (17). Equation (28), on the other hand, is missing the time derivative and the β-fraction of the linear term. Equation (18) shows that the RHS of (28) indeed represents the terms missing on the LHS, calculated in an average sense over the nodes on both sides of the surface on which the continuity of the derivative condition (C^1) is being imposed. Additional comments on the structure of these discrete equations are made in the next section.

4. Comparison of the BFD scheme and the NIM. The most obvious difference between the NIM and the BFD scheme (or the FD schemes in general) is that unlike point values in the FD schemes, the discrete variables in the NIM are the transverse-averaged variables at node surfaces. The number of discrete unknowns per node in the NIM is equal to the number of independent variables. Consequently for the FE, while there is only one unknown, the population density $u_{i,j}$, per grid point in the FD schemes, there are two unknowns (and hence two equations) for each of the space-time node, (i, j), in the NIM: the space-averaged population density at the top surface $\bar{u}^x_{i,j}$ and the time-averaged population density at the right surface $\bar{u}^t_{i,j}$. Hence, care should be exercised when comparing the two schemes.

The implicit BFD scheme for the FE is given by (13). Corresponding discrete equations for the NIM are (27) and (28), which clearly show the similarities with the BFD scheme. In the discrete equation for $\bar{u}^x_{i,j}$, (27), the time-derivative for the space-averaged population density is represented by the nonstandard form, as is the second derivative with respect to x in the discrete equation for the time-averaged population density $\bar{u}^t_{i,j}$, (28). The linear term in the discrete equation for $\bar{u}^x_{i,j}$ (27) is, as in the BFD scheme, evaluated at the *previous* time step. On the other hand, the linear term in (28) (second term on the LHS) is, in terms of the only appropriate discrete variable, the time-averaged population density at the point where the derivative is being evaluated. For comparison, the (entire) linear term in the BFD scheme is evaluated at the previous time step.

As stated previously, one of the characteristics of the BFD schemes is that the nonlinear terms in the discrete schemes are evaluated *nonlocally*. In fact, nonlocal evaluation of the nonlinear terms is considered to be essential in a BFD scheme [15]. Precisely how the nonlinear term must be evaluated is not known a priori and varies from one problem to another. For the FE, the u^2 term is represented by the product of the *local* u variable at the *previous* time step and the average of the population density at three grid points at the *current* time step. As in the BFD scheme, the NIM also leads to a discrete set of equations that requires nonlocal evaluation of the nonlinear terms. Moreover, the form of the nonlinear terms in the NIM has a precise physical meaning—each of the u variables is simply the average u over the immediate space-time domain that influences the discrete variable being evaluated. Marching in time—given $\bar{u}^x_{i,j-1}$, find $\bar{u}^x_{i,j}$—involves only a single node, and hence the nonlinear term in (27) is simply the square of the average population density in that node, (i, j). See Figure 1. On the other hand, evaluation of the time-step-averaged population density, $\bar{u}^t_{i,j}$ (28), depends upon two nodes, (i, j) and $(i+1, j)$, the unknown being at the interface of these two nodes. The nonlinear term is hence approximated nonlocally

as the arithmetic *average* of the square of the space-time-averaged population density in the neighboring nodes on each side.

Both schemes preserve some of the constants of motion. While only the time-independent subproblem of the BFD scheme conserves energy, the general space- and time-dependent NIM does satisfy the original PDE over each space-time node in an integral sense—a direct consequence of one of the conditions imposed to evaluate expressions for the pseudosource terms.

The systematic approach of the NIM for PDEs clearly shows that FD-type schemes that have the properties of the BFD schemes can be developed via a transverse integration process. This systematic approach of the NIM is in contrast with the *combining* process of the BFD schemes that requires the *assembly* of the FD schemes for subproblems such that the full model reduces to the BFD or EFD model of the subproblems in the appropriate limits [16].

5. Results and discussion. Four numerical examples are presented. The first example is used to compare the BFD scheme and the NIM. This example is also used to carry out parametric studies on time step size, grid/node size, optimum values of α and β, etc. The other three problems are chosen to investigate the evolution from different ICs, representing symmetric and asymmetric initial distributions of the population density, leading to the asymptotic solution. Neither the BFD scheme nor the NIM required cutting off the tails of the moving fronts for convergence as required by the ASD method [20, 21].

Example 1. The initial population density is 1 for $x < 0$ and zero for $x > 0$. Boundary conditions are set at 0 for $x \to \infty$, and 1 for $x \to -\infty$. The initial step-profile in this case evolves to a front with (minimum) wave speed of $c = 2$ and propagates to the right [19]. Boundary conditions for the numerical calculations are specified at $x = -20$ and $x = 80$. The calculations were repeated with boundary conditions specified at $x = -10$ and $x = 30$, and no noticeable differences were found in the results. Results of the BFD scheme at $t = 10$ for $\Delta t = 0.01$ and for various spatial grid sizes are shown in Figure 2a. At a grid size of about 0.333, the solution reaches its asymptotic behavior, and there is no noticeable change in the solution for $\Delta x = 0.25$. The profile compares very well with the second order asymptotic solution given by Canosa [19]. There are no wiggles in the solution even at very coarse grid sizes. However, the wave speed is clearly much higher than the minimum speed of 2 for simulations with large Δx. The original motivation for the BFD schemes was to take advantage of the EFD schemes of similar equations and develop FD schemes that will be free of elementary instabilities [16]. That goal for simulations with large Δx is achieved for the FE, so it seems, only by sacrificing the correct propagation speed. The effect of the time step size on accuracy is reported in Figure 2b. The BFD scheme yields fairly good results even with $\Delta t = 0.05$, and the profile obtained using $\Delta t = 0.01$ is essentially indistinguishable from that obtained with $\Delta t = 0.005$. The population density profiles at different times, obtained with $\Delta x = 0.5$ and $\Delta t = 0.01$, are presented in Figure 2c. As expected, after the initial transient, the front moves with the minimum speed of 2 to the right.

Corresponding results for the NIM are shown in Figures 3 and 4. For all NIM results in this paper, values of the time-step-averaged u variable $\bar{u}^t_{i,j}$ are plotted at discrete values of the x coordinate. Recall that these are u values at discrete x coordinates but are averaged over the jth time step. For the NIM, the role of α and β on the accuracy of the results is first investigated with $\Delta t = 0.01$ and a relatively coarse spatial grid size of $\Delta x = 1$ (All combinations of α and β studied resulted in

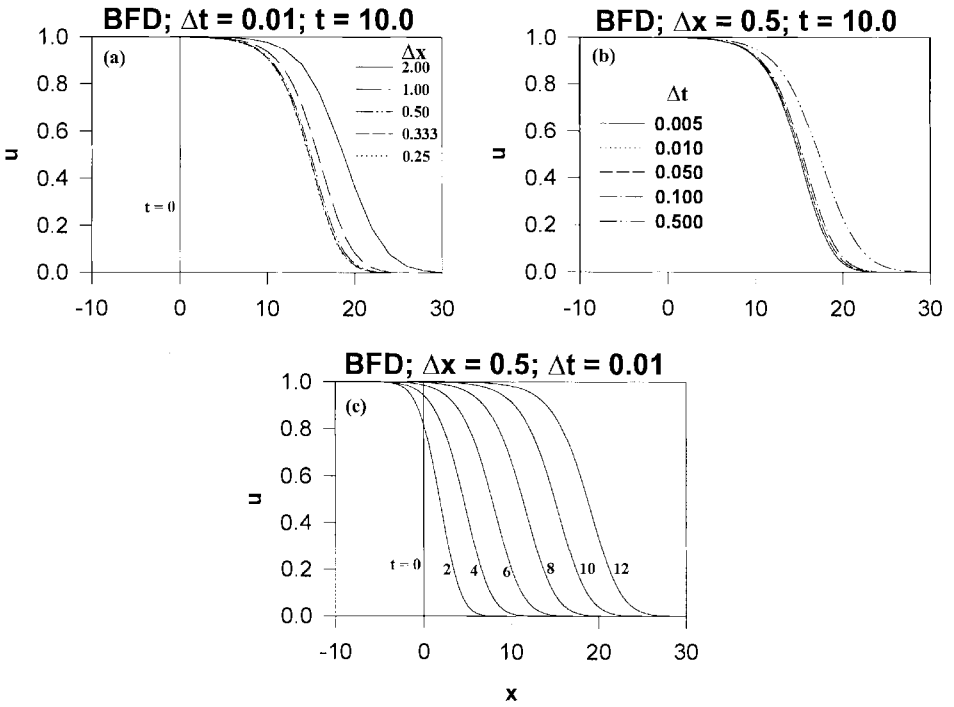

FIG. 2. *Parametric studies for the best finite difference scheme:* (a) *Grid effect,* (b) *time step size effect,* (c) *propagating front starting from a step function.*

very accurate results at fine mesh sizes.) Results in Figure 3, when compared with the fine grid solution of the BFD scheme (as well as the fine grid NIM solutions), show that the combination $(\alpha, \beta) = (-1, 2)$ yields the most accurate solution. Notice that this means that the node interior spatial solution for the time-step-averaged population density is being represented by hyperbolic functions. It is believed that this choice is dictated by the fact that local spatial segments of the propagating front are better represented (modeled) by hyperbolic functions than by trigonometric functions. Hence, for $\alpha = -1$, the (local) solution for $\bar{u}^t(x')$ is of the form

$$\bar{u}^t(x') = -\frac{\bar{S}^{t0}}{\lambda} + C_1 \sinh(\sqrt{\lambda}\, x') + C_2 \cosh(\sqrt{\lambda}\, x').$$

For problems with a more *wavy* (oscillatory) spatial solution, a positive value of α is expected to be optimal. For the rest of the calculations reported in this paper we used $(\alpha, \beta) = (-1, 2)$.

The effect of node size on the results of the NIM is shown in Figure 4a. Comparison of results in Figures 2a and 4a clearly shows that the NIM—though very slightly contaminated by an undershoot for the very large node size of 2.0—yields the same level of accuracy with $\Delta x = 1$ as the BFD scheme yields with $\Delta x = 0.25$. Recalling that there are two unknowns in the NIM for each node, compared to the single unknown per grid point for the BFD scheme, the above comparison shows that for the same number of unknowns, the results obtained using the NIM with $n_x/2$ nodes are comparable in accuracy to the results from the BFD scheme with n_x grid points.

The time step can similarly be rather large in the NIM. As shown in Figure 4b, for Δt as large as 0.2, the NIM yields very good accuracy. The "error" in the simulation

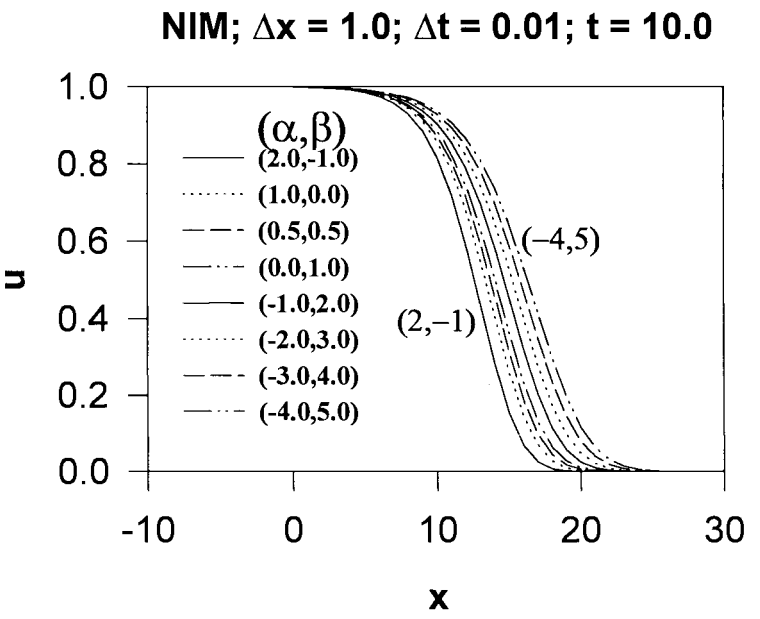

FIG. 3. *Parametric study to determine the effects of the parameters α and β on the accuracy of the numerical result for the nodal integral method. $\bar{u}^t_{i,j}$ is plotted at $t = 10$ for different combinations of α and β.*

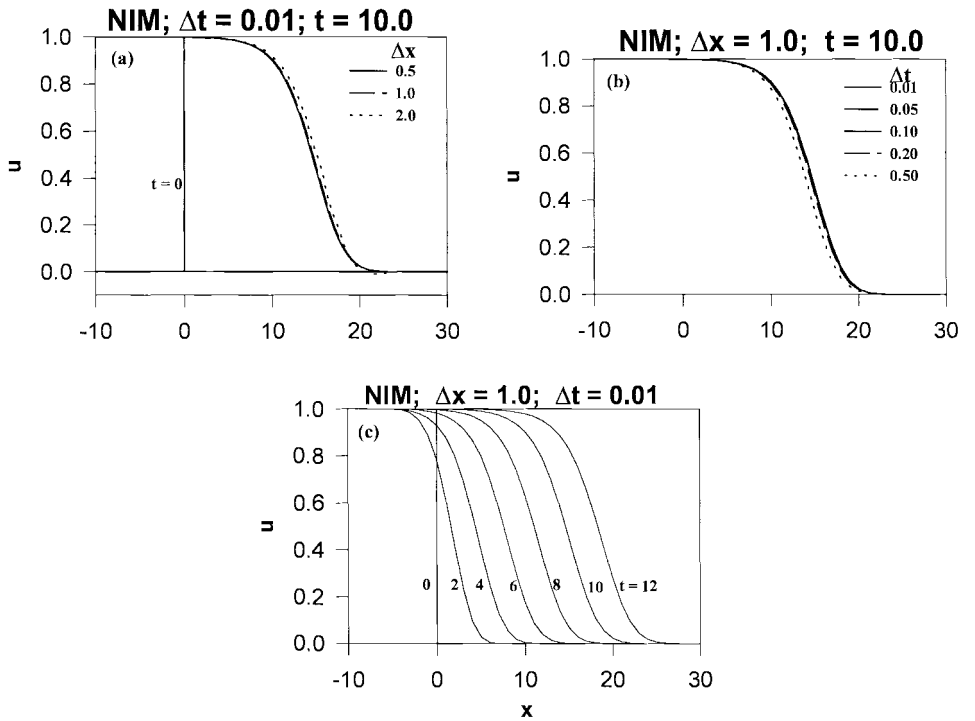

FIG. 4. *Parametric studies for the nodal integral method. Shown are values of $\bar{u}^t_{i,j}$ at discrete values of the x coordinate:* (a) *Grid effect,* (b) *time step size effect,* (c) *propagating front starting from a step function.*

with an even larger time-step of $\Delta t = 0.5$ is not as big as it might appear from Figure 4b. Recall that for the NIM, the discrete variable being plotted here is the u variable *averaged* over the last time-step. Hence, $\bar{u}^t_{i,j}$ for different Δt cases are averaged over different time segments: over $9.99 < t < 10.0$ for the $\Delta t = 0.01$ case, and over $9.5 < t < 10$ for the $\Delta t = 0.5$ case. Consequently, with a propagating speed of 2, the front for the latter case is *expected* to be about 0.5 units behind the former. Figure 4c shows the traveling front profile at different times obtained using the NIM. As in the BFD case, the front moves with a velocity of 2 to the right after the initial transient.

Results obtained using the BFD scheme and the NIM are compared with their corresponding reference results in Figure 5. For the BFD scheme, the population density u obtained using $\Delta t = 0.1$ and $\Delta x = 0.5$ is plotted at $t = 10$. The corresponding reference solution was obtained using the BFD scheme with $(\Delta x, \Delta t) = (0.25, 0.01)$. For the NIM, the time-step averaged population density is calculated with $\Delta t = 0.1$ and $\Delta x = 1.0$, leading to the same number of discrete unknowns as those in the BFD calculation. The reference result for the NIM was calculated with $(\Delta x, \Delta t) = (0.5, 0.01)$. (See the comment made above in reference to Figure 4b when comparing the results obtained using the NIM with two different time steps.) The propagating front calculated using the BFD scheme is moving faster than the reference solution. The NIM results, however, match very well with the corresponding reference results.

Examples 2–4. Evolution of three different ICs is studied in these problems using the NIM. All problems were solved with $\Delta x = 1.0$, $(\alpha, \beta) = (-1, 2)$, and with zero boundary conditions specified at $x = -40$ and $x = 40$.

The evolution of the initially concentrated population density of the advantageous gene, $u(x,0) = 1$ for $-1 \leq x \leq 1$ and zero elsewhere, is shown in Figure 6a. As expected, strong diffusion initially causes the population density to drop at the site of its initial concentration, but it recovers with time as a result of the (nonlinear) generation term. As time increases, two fronts of the advantageous gene, symmetric about the origin, travel to the left and right with the minimum speed.

To study the interaction of two wave fronts approaching each other, the FE is solved with ICs that are symmetric or asymmetric about the origin. The interaction of two symmetric concentrations of the population density is studied with the IC $u(x,0) = 1$ for $-5 \leq x \leq -4$ and $4 \leq x \leq 5$, and zero elsewhere. The symmetric evolution of the initial profile is shown in Figure 6b. To study the asymmetric IC and its effect on front propagation, the FE was solved with $u(x,0) = 1.0$ for $4 \leq x \leq 5$ and $u(x,0) = 0.5$ for $-5 \leq x \leq -4$, and $u(x,0) = 0$ elsewhere. The resulting population density profiles at different times are shown in Figure 6c. An interesting feature in the asymmetric IC problem is that at large times ($t > 10$), the effect of the initial asymmetry disappears and the left moving front and the right moving front have shapes and positions that are almost mirror images of each other (Figure 6c) and, more importantly, are almost the same as those at the corresponding time for the symmetric IC problem; see Figure 6b. For the asymmetric problem, the right moving front—while maintaining the evolution of its own shape and speed that matches with the right moving front in the symmetric problem—*helps* the left moving front, which is initially smaller, to gain its amplitude. This is accomplished by the asymmetry at the origin which causes diffusion from the right to the left. Being a nonzero-sum game—due to the generation term—the shape and speed of the right moving front is little affected by this *generosity*.

6. Summary and conclusions. An NIM has been developed for the FE and compared with the corresponding NSFD scheme. It was shown that the nodal integral approach is relatively more systematic than the rather ad hoc development of the NSFD scheme. The discrete variables in the two schemes are different: there are point values in the NSFD scheme and locally averaged variables in the case of the NIM. This, for the FE, leads to twice as many discrete unknowns in the NIM for the same number of grid points as in the NSFD scheme. A higher number of discrete unknowns per node, however, does not pose a limitation on the NIM due to its high accuracy even on coarse meshes.

There are many similarities in the final sets of discrete equations obtained via the two significantly different approaches. Specifically, a rearrangement of the set of discrete equations for the NIM—which is developed without explicitly approximating the derivatives as is common in the FD-type schemes—showed that the first order time- and second order space-derivatives in this approach are indeed approximated by nonstandard representations similar to those used in the NSFD scheme. Moreover, it was shown that the nodal integral scheme has some of the desirable features of the NSFD schemes such as the nonlocal evaluation of the nonlinear terms.

In reference to other possible applications, it must be pointed out that extension of the NIM to higher dimensions is fairly straightforward. Moreover, it has already been applied to sets of PDEs [2, 5, 7]. The major drawback of the (standard) NIM is that the scheme is limited to geometric domains that can be formed by a union of rectangles. This limitation results from the transverse-integration step that is used to reduce a PDE in N independent variables to a set of N ODEs. Recently developed hybrid nodal schemes for the heat conduction equation [23] and for the

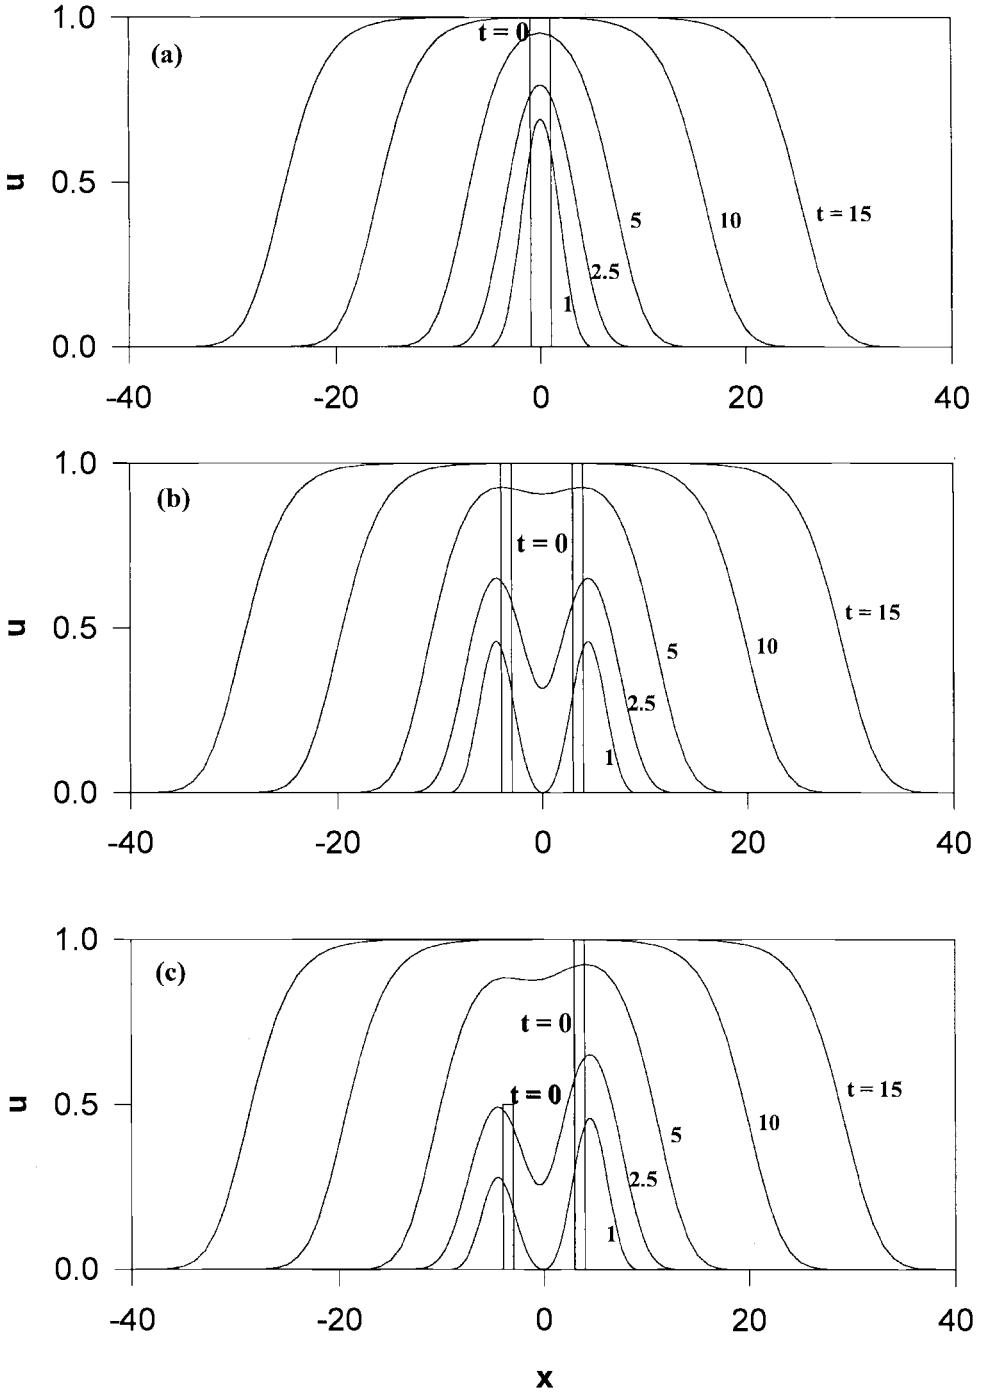

FIG. 6. *Evolution from different initial conditions (NIM results):* (a) *A single lump of concentrated gene at and around the center,* (b) *two symmetric lumps of concentrated gene,* (c) *two asymmetric lumps of concentrated gene.*

multidimensional, convection-diffusion equation [24] have, however, relaxed this restriction. Hybrid schemes applicable in irregular geometries for other sets of PDEs are under development.

Numerical results presented for the FE for various symmetric and asymmetric ICs showed that both schemes are very accurate on fine mesh sizes. The NIM, however, yields very accurate results even for a relatively coarse mesh size. In fact, results obtained using the NIM with half as many grid points (nodes) as those used in the NSFD scheme—leading to the same number of discrete unknowns in both schemes—were better than the corresponding results obtained using the NSFD scheme.

Appendix. The expressions for $\bar{u}^x_{i,j}$ and $\bar{u}^t_{i,j}$ are given by

$$\bar{u}^x_{i,j} = \bar{u}^x_{i,j-1} f_2 + f_5 f_3 \bar{S}^{x0},$$

$$\bar{u}^t_{i,j} = \frac{f_1 \left(\bar{u}^t_{i-1,j} + \bar{u}^t_{i+1,j}\right)/2 - f_{10}\bar{u}^t_{i+1,j} - \lambda\left(u^{avg\,2}_{i,j} + u^{avg\,2}_{i+1,j}\right) - (g_i + g_{i+1})}{f_{12}}$$

where

$$f_1 = \frac{\lambda\alpha}{\sin^2(\sqrt{\lambda\alpha}\,a)}, \qquad f_2 = e^{2\lambda\beta\tau}, \qquad f_3 = \frac{f_2 - 1}{2\lambda\beta\tau},$$

$$f_4 = \frac{\tan(\sqrt{\lambda\alpha}\,a)}{\sqrt{\lambda\alpha}\,a}, \qquad f_5 = 2\tau, \qquad f_6 = f_1 - 2\lambda\alpha,$$

$$f_7 = \frac{f_3 - 1}{\lambda\beta}, \qquad f_8 = \frac{f_4 - 1}{\lambda\alpha}, \qquad f_9 = f_7 + f_8,$$

$$f_{10} = \frac{f_4}{2f_9}, \qquad f_{11} = -\lambda f_8, \qquad f_{12} = f_1 - 2\lambda\alpha + f_{10},$$

$$g_i = \frac{f_4\bar{u}^t_{i-1,j}/2 + f_{11}u^{avg\,2}_{i,j} - f_3\bar{u}^x_{i,j-1}}{f_9}, \qquad \bar{S}^{x0}_{i,j} = f_{10}\bar{u}^t_{i,j} + g_i,$$

$$u^{avg}_{i,j} = \frac{f_3\bar{u}^x_{i,j-1} + f_7\left(f_{10}\bar{u}^t_{i,j} + \dfrac{f_4\bar{u}^t_{i-1,j} - f_3\bar{u}^x_{i,j-1}}{f_9}\right)}{1 - (f_7 f_{11}/f_9)\,u^{avg}_{i,j}}.$$

FAST FINITE VOLUME SIMULATION OF 3D ELECTROMAGNETIC PROBLEMS WITH HIGHLY DISCONTINUOUS COEFFICIENTS*

E. HABER† AND U. M. ASCHER‡

Abstract. We consider solving three-dimensional electromagnetic problems in parameter regimes where the quasi-static approximation applies and the permeability, permittivity, and conductivity may vary significantly. The difficulties encountered include handling solution discontinuities across interfaces and accelerating convergence of traditional iterative methods for the solution of the linear systems of algebraic equations that arise when discretizing Maxwell's equations in the frequency domain.

The present article extends methods we proposed earlier for constant permeability [E. Haber, U. Ascher, D. Aruliah, and D. Oldenburg, *J. Comput. Phys.,* 163 (2000), pp. 150–171; D. Aruliah, U. Ascher, E. Haber, and D. Oldenburg, *Math. Models Methods Appl. Sci.*, to appear.] to handle also problems in which the permeability is variable and may contain significant jump discontinuities. In order to address the problem of slow convergence we reformulate Maxwell's equations in terms of potentials, applying a Helmholtz decomposition to either the electric field or the magnetic field. The null space of the **curl** operators can then be annihilated by adding a stabilizing term, using a gauge condition, and thus obtaining a strongly elliptic differential operator. A staggered grid finite volume discretization is subsequently applied to the reformulated PDE system. This scheme works well for sources of various types, even in the presence of strong material discontinuities in both conductivity and permeability. The resulting discrete system is amenable to fast convergence of ILU-preconditioned Krylov methods.

We test our method using several numerical examples and demonstrate its robust efficiency. We also compare it to the classical Yee method using similar iterative techniques for the resulting algebraic system, and we show that our method is significantly faster, especially for electric sources.

Key words. Maxwell's equations, solution discontinuities, Helmholtz decomposition, Coulomb gauge, finite volume, Krylov methods, mixed methods, preconditioning

1. Introduction.

The need for calculating fast, accurate solutions of three-dimensional electromagnetic equations arises in many important application areas including, among others, geophysical surveys and medical imaging [34, 40, 3]. Consequently, a lot of effort has recently been invested in finding appropriate numerical algorithms. However, while it is widely agreed that electromagnetic phenomena are generally governed by Maxwell's equations, the choice of numerical techniques to solve these equations depends on parameter ranges and various other restrictive assumptions, and as such is to a significant degree application-dependent [24, 40, 3].

The present article is motivated by remote sensing inverse problems, e.g., in geophysics, where one seeks to recover material properties—especially conductivity—in an isotropic but heterogeneous body, based on measurements of electric and magnetic fields on or near the earth's surface. The forward model, on which we concentrate here, consists of Maxwell's equations in the frequency domain over a frequency range which excludes high frequencies. Assuming a time-dependence $e^{-\imath\omega t}$, these equations

are written as

$$\boldsymbol{\nabla} \times \boldsymbol{E} - \imath\omega\mu\boldsymbol{H} = \boldsymbol{0}, \tag{1.1a}$$

$$\boldsymbol{\nabla} \times \boldsymbol{H} - \widehat{\sigma}\boldsymbol{E} = \boldsymbol{J}^s, \tag{1.1b}$$

$$\nabla \cdot (\epsilon \boldsymbol{E}) - \rho = 0, \tag{1.1c}$$

$$\nabla \cdot (\mu \boldsymbol{H}) = 0, \tag{1.1d}$$

where μ is the magnetic permeability, σ is the conductivity, ϵ is the electrical permittivity,

$$\widehat{\sigma} = \sigma - \imath\omega\epsilon, \tag{1.2}$$

$\boldsymbol{J}^s$ is a known source current density, and ρ is the (unknown) volume density of free charges. In our work we assume that the physical properties $\mu > 0$, $\epsilon > 0$, and $\sigma \geq 0$ can vary with position, and $\mu\epsilon\omega^2 L^2 \ll 1$, where L is a typical length scale (cf. [43]). The electric field $\boldsymbol{E}$ and the magnetic field $\boldsymbol{H}$ are the unknowns, with the charge density defined by (1.1c). Note that as long as $\omega \neq 0$, (1.1d) is redundant and can be viewed as an invariant of the system, obtained by taking the $\nabla\cdot$ of (1.1a). The system (1.1) is defined over a three-dimensional spatial domain Ω. In principle, the domain Ω is unbounded (i.e., $\Omega = \mathbb{R}^3$), but, in practice, a bounded subdomain of $\mathbb{R}^3$ is used for numerical approximations. In this paper we have used the boundary conditions (BCs)

$$\boldsymbol{H} \times \boldsymbol{n}\Big|_{\partial\Omega} = 0, \tag{1.3}$$

although other BCs are possible.

A number of difficulties arises when attempting to find numerical solutions for this three-dimensional PDE system. These difficulties include handling regions of (almost) vanishing conductivity, handling different resolutions in different parts of the spatial domain, handling the multiple scale lengths over which the physical properties can vary, and handling regions of highly varying conductivity, magnetic permeability, or electrical permittivity, where jumps in solution properties across interfaces may occur.

On the other hand, the nature of the data (e.g., measurements of the electric and/or magnetic fields at the surface of the earth) is such that one cannot hope to recover to a very fine detail the structure of the conductivity σ or the permeability μ. We therefore envision, in accordance with the inverse problem of interest, a possibly nonuniform tensor product grid covering the domain Ω, where $\widehat{\sigma}$ and μ are assumed to be smooth or even constant inside each grid cell, but they may have significant jump discontinuities that can occur anywhere in Ω across cell interfaces. The source $\boldsymbol{J}^s$ is, however, assumed not to have jumps across interfaces. The relative geometric simplicity resulting from this modeling assumption is key in obtaining highly efficient solvers for the forward problem.

Denoting quantities on different sides of an interface by subscripts 1 and 2, it can be easily shown [41] that across an interface

$$\boldsymbol{n} \cdot (\widehat{\sigma}_1 \boldsymbol{E}_1 - \widehat{\sigma}_2 \boldsymbol{E}_2) = 0, \tag{1.4a}$$

$$\boldsymbol{n} \times (\boldsymbol{E}_1 - \boldsymbol{E}_2) = 0, \tag{1.4b}$$

$$\boldsymbol{n} \cdot (\mu_1 \boldsymbol{H}_1 - \mu_2 \boldsymbol{H}_2) = 0, \tag{1.4c}$$

$$\boldsymbol{n} \times (\boldsymbol{H}_1 - \boldsymbol{H}_2) = 0. \tag{1.4d}$$

These conditions imply that neither $\boldsymbol{E}$ nor $\boldsymbol{H}$ are continuous in the normal direction when $\widehat{\sigma}$ and μ have a jump discontinuity across a cell face, and likewise, $\widehat{\sigma}\boldsymbol{E}$ and $\mu\boldsymbol{H}$ are not necessarily continuous in tangential directions. Care must therefore be exercised when numerical methods are employed which utilize these variables if they are to be defined where they are double-valued.

By far the most popular discretization for Maxwell's equations is Yee's method [46] (see discussions and extensions in [40, 30, 21]). This method employs a staggered grid, necessitating only short, centered first differences to discretize (1.1a) and (1.1b). In the more usual application of this method, the electric field components are envisioned on the cell's edges and the magnetic field components are on the cell's faces—see Figure 1. It is further possible to eliminate the components of the magnetic field from the

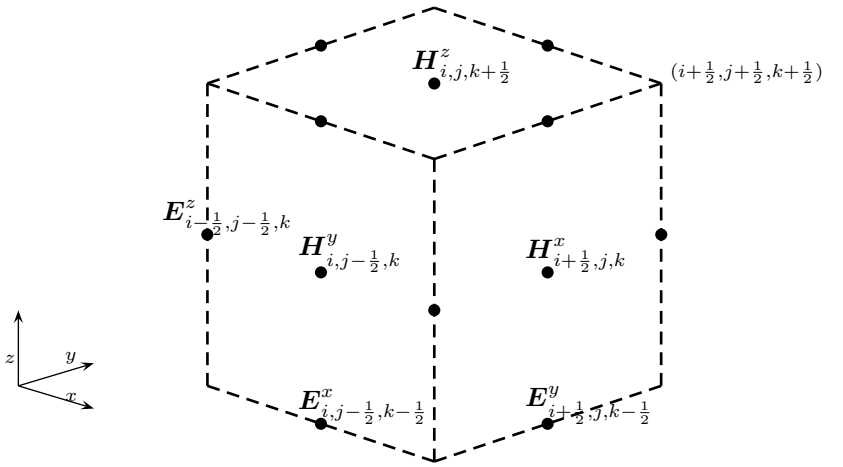

FIG. 1. *A staggered discretization of* $\boldsymbol{E}$ *and* $\boldsymbol{H}$ *in three dimensions:* $\boldsymbol{E}$*-components are on the edges, and* $\boldsymbol{H}$*-components are on the faces.*

discrete equations, obtaining a staggered discretization for the second order PDE in $\boldsymbol{E}$,

$$\boldsymbol{\nabla} \times (\mu^{-1}\boldsymbol{\nabla} \times \boldsymbol{E}) - \imath\omega\widehat{\sigma}\boldsymbol{E} = \imath\omega\boldsymbol{J}^{\boldsymbol{s}}. \tag{1.5}$$

Related methods include the finite integration technique and certain mixed finite element methods [44, 6, 29, 16]. Although these methods are often presented in the context of time-domain Maxwell's equations, the issues arising when applying an implicit time-discretization (a suitable technique under our model assumptions) are somewhat similar to the ones we are faced with here.

The popularity of Yee's method is due in part to its conservation properties and other ways in which the discrete system mimics the continuous system [21, 17, 6, 5]. However, iterative methods to solve the discrete system may converge slowly in low frequencies, due to the presence of the nontrivial null space of the **curl** operator, and additional difficulties arise when highly discontinuous coefficients are present [34, 28, 38, 19]. There are two major reasons for these difficulties. First, the conductivity can essentially vanish (for example, in the air, which forms part of Ω); from an analytic perspective, the specific subset of Maxwell's equations used typically forms an almost-singular system in regions of almost-vanishing $\widehat{\sigma}$. Even in regions where the conductivity is not close to vanishing, the resulting differential operator is strongly

coupled and not strongly elliptic [7, 2]. Second, in cases of large jump discontinuities, care must be taken to handle $\boldsymbol{H}$ and $\widehat{\boldsymbol{J}} = \widehat{\sigma}\boldsymbol{E}$ carefully, since these are located, as in Figure 1, where they are potentially discontinuous.

In [2], we addressed the often slow convergence of iterative methods when used for the equations resulting from the discretization of (1.5) by applying a Helmholtz decomposition first, obtaining a potential formulation with a Coulomb gauge condition. This change of variables (used also in [4, 13, 26, 32], among many others) splits the electric field into components in the active and the null spaces of the **curl** operator. A further reformulation, reminiscent of the pressure-Poisson equation for the incompressible Navier–Stokes equations [15, 37], yields a system of strongly elliptic, weakly coupled PDEs for which more standard preconditioned Krylov space methods are directly applicable.

In [17], we further addressed possible significant jumps in the conductivity while μ is assumed constant by employing a finite volume discretization on a staggered grid, akin to Yee's method with the locations of $\boldsymbol{E}$- and $\boldsymbol{H}$-components exchanged, as in Figure 2. The normal components of $\boldsymbol{E}$ are now double-valued, but this is taken care

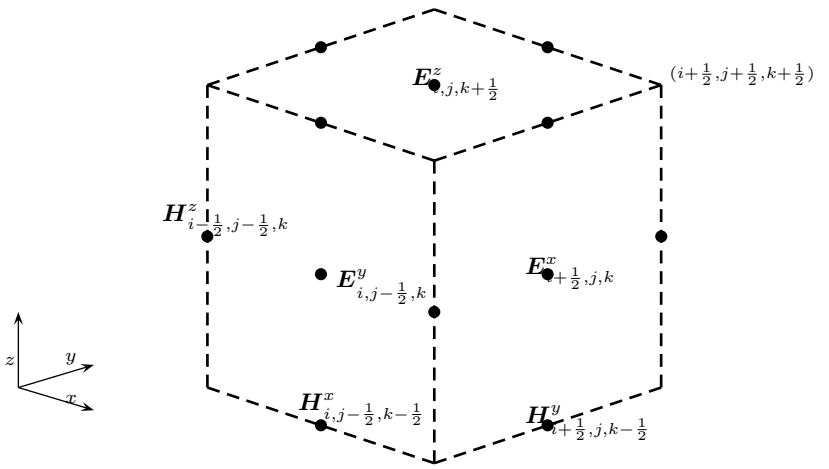

FIG. 2. *A staggered discretization of* $\boldsymbol{E}$ *and* $\boldsymbol{H}$ *in three dimensions:* $\boldsymbol{E}$*-components are on the faces, and* $\boldsymbol{H}$*-components are on the edges.*

of in an elegant way by the Helmholtz decomposition of $\boldsymbol{E}$ and by introducing the (generalized) current

$$\widehat{\boldsymbol{J}} = \widehat{\sigma}\boldsymbol{E} = (\sigma - \imath\omega\epsilon)\boldsymbol{E} \tag{1.6}$$

into the equations. The **curl** operators in (1.5) are replaced by the vector Laplacian according to the vector identity

$$\boldsymbol{\nabla} \times \boldsymbol{\nabla} \times = -\nabla^2 I + \operatorname{grad} \nabla \cdot \tag{1.7}$$

for sufficiently smooth vector functions (not $\boldsymbol{E}$).

In this paper we generalize our approach from [2, 17] to the case where the magnetic permeability μ may be highly discontinuous as well. This is a realistic case of interest in geophysical applications, although usually the jump in conductivity dominates the jump in permeability. Now the roles of $\boldsymbol{E}$ and $\boldsymbol{H}$ are essentially dual, and it is possible to apply a Helmholtz decomposition to either $\boldsymbol{E}$ or $\boldsymbol{H}$, keeping the other

unknown vector function intact. We choose to decompose the electric field $\boldsymbol{E}$, referring to Figure 2 for the locations of the $\boldsymbol{H}$-unknowns in the ensuing discretization. The major departure from our previous work is in the fact that the identity (1.7) does not directly extend for the operator $\boldsymbol{\nabla}\times(\mu^{-1}\boldsymbol{\nabla}\times)$ appearing in (1.5). We can, however, stabilize this operator by subtracting $\mathrm{grad}(\mu^{-1}\nabla\cdot)$ (see, e.g., [24]), and this forms the basis for our proposed method. In cases of constant magnetic permeability or electric conductivity the formulation can be reduced to our previous formulation in [17] or a variant thereof.

Our approach to dealing with possible discontinuities can be viewed as using a set of variables which are continuous across cell faces and another set which are continuous along cell edges. The introduction of such unknowns is strongly connected to mixed finite elements which are used for highly discontinuous problems [8, 9, 19].

The paper is laid out as follows. In section 2, we reformulate Maxwell's equations in a way which enables us to extend our methods. The resulting system is amenable to discretization using a finite volume technique described in section 3.

The extension and generalization of our approach from [2] through [17] to the present article is not without a price. This price is an added complication in the sparsity structure of the resulting discrete system and a corresponding added cost in the iterative solution of such systems. We briefly describe the application of Krylov space methods to solve the system of algebraic equations in section 4. We use BICGSTAB (see, e.g., [35]) together with one of two preconditioners: an incomplete block LU decomposition (which is a powerful preconditioner in the case of diagonally dominant linear systems) and SSOR. The system's diagonal dominance is a direct consequence of our analytic formulation.

We present the results of numerical experiments in section 5 and compare results obtained using our method with those obtained using a more traditional Yee discretization. If the source is not divergence-free, as is the case for electric (but not magnetic) sources, then our method is better by more than two orders of magnitude. The method works well also for a case where the problem coefficients vary rapidly. We conclude with a short summary and further remarks.

2. Reformulation of Maxwell's equations. Maxwell's equations (1.1a) and (1.1b) can be viewed as flux balance equations, i.e., each term describes the flux which arises from a different physical consideration, and the equations are driven by the conservation of fluxes. (In fact, this was how they were originally developed [27].) Therefore, in both (1.1a) and (1.1b) we have a flux term which should be balanced. In (1.1b) the *generalized current density* $\widehat{\boldsymbol{J}}$ defined in (1.6) is balanced with the source and the flux which arise from magnetic fields, and in (1.1a) the *magnetic flux*

$$\boldsymbol{B} = \mu\boldsymbol{H} \tag{2.1}$$

is balanced with the flux which arises from electric fields. In our context these fluxes are well defined on cell faces, but they may be multivalued at cell edges.[1]

Furthermore, the leading differential operator in (1.5), say, has a nontrivial null space. Rather than devising iterative methods which directly take this into account (as, e.g., in [3, 19, 39, 33]), we transform the equations before discretization.

We decompose $\boldsymbol{E}$ into its components in the active space and in the null space of

[1] Under appropriate conditions, $\boldsymbol{B}, \widehat{\boldsymbol{J}} \in H(div;\Omega)$, whereas $\boldsymbol{E}, \boldsymbol{H} \in H(\mathbf{curl};\Omega)$; see, e.g., [14].

the **curl** operator:

$$\boldsymbol{E} = \boldsymbol{A} + \operatorname{grad}\phi, \tag{2.2a}$$

$$\nabla \cdot \boldsymbol{A} = 0. \tag{2.2b}$$

We could decompose $\boldsymbol{H}$ instead in a similar way, but we would not decompose both. Here we have chosen to concentrate on the decomposition of $\boldsymbol{E}$. Substituting (2.2) into Maxwell's equations, we obtain

$$\boldsymbol{\nabla} \times \boldsymbol{A} - \imath\omega\mu\boldsymbol{H} = \boldsymbol{0}, \tag{2.3a}$$

$$\boldsymbol{\nabla} \times \boldsymbol{H} - \widehat{\sigma}(\boldsymbol{A} + \operatorname{grad}\phi) = \boldsymbol{J^s}, \tag{2.3b}$$

$$\nabla \cdot \boldsymbol{A} = 0. \tag{2.3c}$$

Furthermore, (1.5) becomes

$$\boldsymbol{\nabla} \times (\mu^{-1}\boldsymbol{\nabla} \times \boldsymbol{A}) - \imath\omega\widehat{\sigma}(\boldsymbol{A} + \operatorname{grad}\phi) = \imath\omega\boldsymbol{J^s}, \tag{2.4a}$$

$$\nabla \cdot \boldsymbol{A} = 0. \tag{2.4b}$$

Note that across an interface between distinct conducting media we have, in addition to (1.4),

$$\boldsymbol{n} \times (\boldsymbol{A}_1 - \boldsymbol{A}_2) = 0, \tag{2.5a}$$

$$\boldsymbol{n} \cdot (\boldsymbol{A}_1 - \boldsymbol{A}_2) = 0, \tag{2.5b}$$

$$\boldsymbol{n} \cdot (\epsilon_1 \operatorname{grad}\phi_1 - \epsilon_2 \operatorname{grad}\phi_2) = \rho_s, \tag{2.5c}$$

$$\boldsymbol{n} \cdot (\widehat{\boldsymbol{J}}_1 - \widehat{\boldsymbol{J}}_2) = 0, \tag{2.5d}$$

where ρ_s in (2.5c) is an electric surface charge density. These conditions and the differential equations (1.1) imply that while $\widehat{\boldsymbol{J}} \cdot \boldsymbol{n}$ is continuous, $\boldsymbol{E} \cdot \boldsymbol{n}$ is not. Moreover, $\operatorname{grad}\phi$ inherits the discontinuity of $\boldsymbol{E} \cdot \boldsymbol{n}$, while $\boldsymbol{A}$ is continuous, and both $\nabla \cdot \boldsymbol{A}$ and $\boldsymbol{\nabla} \times \boldsymbol{A}$ are bounded (cf. [14]).

In [17] we had the relation $\boldsymbol{\nabla} \times \boldsymbol{\nabla} \times \boldsymbol{A} = -\nabla^2\boldsymbol{A}$ holding. However, when μ varies, the identity (1.7) does not extend directly, and we must deal with the null space of $\boldsymbol{\nabla} \times \boldsymbol{A}$ in a different way.

Let us define the Sobolev spaces

$$\boldsymbol{W}(\Omega) = \{\boldsymbol{v} \in [L^2(\Omega)]^3;\ \boldsymbol{\nabla} \times \boldsymbol{v} \in [L^2(\Omega)]^3, \nabla \cdot \boldsymbol{v} \in L^2(\Omega)\} \tag{2.6a}$$

equipped with the usual norm (see, e.g., [14])

$$\|\boldsymbol{v}\|_{\boldsymbol{W}(\Omega)} = \{\|\boldsymbol{v}\|^2 + \|\boldsymbol{\nabla} \times \boldsymbol{v}\|^2 + \|\nabla \cdot \boldsymbol{v}\|^2\}^{1/2} \tag{2.6b}$$

(the $L^2(\Omega)$- and $[L^2(\Omega)]^3$- norms are used on the right-hand side of (2.6b)), and

$$\boldsymbol{W}_0(\Omega) = \left\{\boldsymbol{v} \in \boldsymbol{W}(\Omega);\ \nabla \cdot \boldsymbol{v}\Big|_{\partial\Omega} = 0,\ \boldsymbol{\nabla} \times \boldsymbol{v} \times \boldsymbol{n}\Big|_{\partial\Omega} = \boldsymbol{0}\right\}. \tag{2.6c}$$

Green's formula yields, for any $\boldsymbol{u} \in \boldsymbol{W}(\Omega)$, $\boldsymbol{v} \in \boldsymbol{W}_0(\Omega)$,

$$\begin{aligned}&(\boldsymbol{\nabla} \times (\mu^{-1}\boldsymbol{\nabla} \times \boldsymbol{u}), \boldsymbol{v}) - (\operatorname{grad}(\mu^{-1}\nabla \cdot \boldsymbol{u}), \boldsymbol{v})\\ &= \mu^{-1}[(\boldsymbol{\nabla} \times \boldsymbol{u}, \boldsymbol{\nabla} \times \boldsymbol{v}) + (\nabla \cdot \boldsymbol{u}, \nabla \cdot \boldsymbol{v})]\end{aligned}$$

(see, e.g., [24]), where the usual notation for inner product in $L^2(\Omega)$ and $[L^2(\Omega)]^3$ is used. Thus, for any $\boldsymbol{u} \in \boldsymbol{W}_0(\Omega)$, if $\boldsymbol{u} \neq \boldsymbol{0}$, then

$$(\boldsymbol{\nabla} \times (\mu^{-1}\boldsymbol{\nabla} \times \boldsymbol{u}), \boldsymbol{u}) - (\operatorname{grad}(\mu^{-1}\nabla \cdot \boldsymbol{u}), \boldsymbol{u}) > 0.$$

We may therefore stabilize (2.4a) by subtracting a term which by (2.4b) vanishes:

$$\boldsymbol{\nabla} \times (\mu^{-1}\boldsymbol{\nabla} \times \boldsymbol{A}) - \operatorname{grad}(\mu^{-1}\nabla \cdot \boldsymbol{A}) - \imath\omega\widehat{\sigma}(\boldsymbol{A} + \operatorname{grad}\phi) = \imath\omega\boldsymbol{J}^{\boldsymbol{s}}, \tag{2.7}$$

obtaining a strongly elliptic operator for $\boldsymbol{A}$, provided $\boldsymbol{A} \in \boldsymbol{W}_0(\Omega)$. The latter condition is guaranteed by the choice (2.10b) together with (2.10a), as elaborated below.

A similar stabilization (or penalty) approach was studied with mixed success in [11, 24]. However, our experience and thus our recommendation are more positive because of the discretization we utilize. We elaborate further upon this point in the next section.

Using (2.3c), we can write (2.3b) as

$$\boldsymbol{\nabla} \times \boldsymbol{H} - \operatorname{grad}\psi - \widehat{\boldsymbol{J}} = \boldsymbol{J}^{\boldsymbol{s}}, \tag{2.8a}$$

$$\psi - \mu^{-1}\nabla \cdot \boldsymbol{A} = 0. \tag{2.8b}$$

This may be advantageous in the case of discontinuous μ, similarly to the mixed formulation used for the simple *div-grad* system

$$\nabla \cdot (\sigma \operatorname{grad}\phi) = q$$

in [8, 31, 9, 12] and elsewhere.

Our final step in the reformulation is to replace, as in [17], the gauge condition (2.3c) on $\boldsymbol{A}$ by an indirect one, obtained upon taking $\nabla\cdot$ of (2.8a) and simplifying using (2.8b) and (2.3c). This achieves only a weak coupling in the resulting PDE system. We note that the replacing of the gauge condition (2.3c) is similar to the pressure-Poisson equation in computational fluid dynamics [37, 15]. The complete system, to be discretized in the next section, can now be written as

$$\boldsymbol{\nabla} \times \boldsymbol{H} - \operatorname{grad}\psi - \widehat{\boldsymbol{J}} = \boldsymbol{J}^{\boldsymbol{s}}, \tag{2.9a}$$

$$\imath\omega\mu\boldsymbol{H} - \boldsymbol{\nabla} \times \boldsymbol{A} = \boldsymbol{0}, \tag{2.9b}$$

$$\mu\psi - \nabla \cdot \boldsymbol{A} = 0, \tag{2.9c}$$

$$-\nabla \cdot \widehat{\boldsymbol{J}} = \nabla \cdot \boldsymbol{J}^{\boldsymbol{s}}, \tag{2.9d}$$

$$\widehat{\boldsymbol{J}} - \widehat{\sigma}(\boldsymbol{A} + \operatorname{grad}\phi) = \boldsymbol{0}. \tag{2.9e}$$

In order to complete the specification of this system, we must add appropriate BCs. First, we note that the original BC (1.3) can be written as

$$(\boldsymbol{\nabla} \times \boldsymbol{A}) \times \boldsymbol{n}\Big|_{\partial\Omega} = \boldsymbol{0}. \tag{2.10a}$$

An additional BC on the normal components of $\boldsymbol{A}$ is required for the Helmholtz decomposition (2.2) to be unique. Here we choose (corresponding to (2.6c))

$$\boldsymbol{A} \cdot \boldsymbol{n}\Big|_{\partial\Omega} = 0. \tag{2.10b}$$

This, together with (2.2), determines $\boldsymbol{A}$ for a given $\boldsymbol{E}$.

Moreover, since (2.9d) was obtained by taking the $\nabla\cdot$ of (2.9a), additional BCs are required on either $\partial\phi/\partial n$ or ϕ. For this we note that the original BC (1.3) together with the PDE (1.1b) imply also

$$\widehat{\boldsymbol{J}}\cdot\boldsymbol{n}\Big|_{\partial\Omega} = -\boldsymbol{J^s}\cdot\boldsymbol{n}\Big|_{\partial\Omega}. \tag{2.10c}$$

The latter relation (2.10c), together with (2.10b), implies $\frac{\partial\phi}{\partial n}=0$ at the boundary.[2,3]

The above conditions determine ϕ up to a constant. We pin this constant down arbitrarily, e.g., by requiring

$$\int_\Omega \phi\, dV = 0. \tag{2.10d}$$

Finally, we note that (2.10c), together with (2.9a) and (1.3), imply, in turn, that $\frac{\partial\psi}{\partial n}=0$ at the boundary. Since (2.9a) and (2.9d) imply that

$$\nabla^2\psi = 0,$$

we obtain $\psi\equiv 0$, and thus we retrieve (2.3c) by pinning ψ down to 0 at one additional point. From this and (2.10a) it then follows that $\boldsymbol{A}\in\boldsymbol{W}_0(\Omega)$ (see (2.6c)).

The system (2.9) subject to the BCs (2.10) and ψ pinned at one point is now well-posed.

3. Deriving a discretization. As in [17], we employ a finite volume technique on a staggered grid, where $\widehat{\boldsymbol{J}}$ and $\boldsymbol{A}$ are located at the cell's faces, $\boldsymbol{H}$ is at the cell's edges, and ϕ and ψ are located at the cell's center. Correspondingly, the discretizations of (2.9d) and (2.9c) are centered at cell centers, those of (2.9e) and (2.9a) are centered at cell faces, and that of (2.9b) is centered at cell edges. The variables distribution over the grid cell is summarized in Table 1.

TABLE 1

Summary of the discrete grid functions. Each scalar field is approximated by the grid functions at points slightly staggered in each cell $e_{i,j,k}$ of the grid.

$$\begin{array}{cc}
A^x{}_{i+\frac12,j,k} \approx A^x(x_{i+\frac12},y_j,z_k) & \hat{J}^x_{i+\frac12,j,k} \approx \hat{J}^x(x_{i+\frac12},y_j,z_k)\\
A^y{}_{i,j+\frac12,k} \approx A^y(x_i,y_{j+\frac12},z_k) & \hat{J}^y_{i,j+\frac12,k} \approx \hat{J}^y(x_i,y_{j+\frac12},z_k)\\
A^z{}_{i,j,k+\frac12} \approx A^z(x_i,y_j,z_{k+\frac12}) & \hat{J}^z_{i,j,k+\frac12} \approx \hat{J}^z(x_i,y_j,z_{k+\frac12})\\
H^x_{i,j+\frac12,k+\frac12} \approx H^x(x_i,y_{j+\frac12},z_{k+\frac12}) & \\
H^y_{i+\frac12,j,k+\frac12} \approx H^y(x_{i+\frac12},y_j,z_{k+\frac12}) & \\
H^z_{i+\frac12,j+\frac12,k} \approx H^z(x_{i+\frac12},y_{j+\frac12},z_k) & \\
\psi_{i,j,k} \approx \psi(x_i,y_j,z_k) & \\
\phi_{i,j,k} \approx \phi(x_i,y_j,z_k) &
\end{array}$$

To approximate $\nabla\cdot\boldsymbol{u}$ for $\boldsymbol{u}=(u^x,u^y,u^z)^T$ over a grid cell $e_{i,j,k}$, we integrate at first over the cell using the Gauss divergence theorem

$$\frac{1}{|e_{i,j,k}|}\int_{e_{i,j,k}} \nabla\cdot\boldsymbol{u}\, dV = \frac{1}{|e_{i,j,k}|}\int_{\partial e_{i,j,k}} \boldsymbol{u}\cdot\boldsymbol{n}\, dS,$$

[2] In cases where the original BC is different from (1.3) we still use the BC $\partial\phi/\partial n=0$ as an asymptotic value for an infinite domain. Alternatively, note the possibility of applying the Helmholtz decomposition to $\boldsymbol{H}$, although generally there are good practical reasons to prefer the decomposition (2.2) of $\boldsymbol{E}$ (for one, because the jumps in σ are typically much larger than in μ—see section 5).

[3] In our geophysical applications, $\boldsymbol{J^s}\cdot\boldsymbol{n}$ vanishes at the boundary.

and then we use midpoint quadrature on each face to evaluate each component of the surface integrals appearing on the right-hand side above. Thus, define

$$\nabla_{i,j,k} \cdot \boldsymbol{u} = \frac{u^x_{i+\frac{1}{2},j,k} - u^x_{i-\frac{1}{2},j,k}}{h^x_i} + \frac{u^y_{i,j+\frac{1}{2},k} - u^y_{i,j-\frac{1}{2},k}}{h^y_j} + \frac{u^z_{i,j,k+\frac{1}{2}} - u^z_{i,j,k-\frac{1}{2}}}{h^z_k} \tag{3.1}$$

and express the discretization of (2.9d) and (2.9c) on each grid cell as

$$\nabla_{i,j,k} \cdot \widehat{\boldsymbol{J}} + \nabla_{i,j,k} \cdot \boldsymbol{J^s} = 0, \tag{3.2a}$$

$$\psi_{i,j,k} = \mu^{-1}_{i,j,k} \nabla_{i,j,k} \cdot \boldsymbol{A}, \tag{3.2b}$$

where $\mu_{i,j,k} = \mu(x_i, y_j, z_k)$. Note that we are not assuming a uniform grid: each cell may have different widths in each direction. The BCs (2.10) are used at the end points of (3.2).

Next, consider the discretization at cell faces. Following [17], we define the *harmonic average* of $\widehat{\sigma}$ between neighboring cells in the x-direction by

$$\widehat{\sigma}_{i+\frac{1}{2},j,k} = h^x_{i+\frac{1}{2}} \left(\int_{x_i}^{x_{i+1}} \widehat{\sigma}^{-1}(x, y, z) dx \right)^{-1}, \tag{3.3a}$$

where $h^x_{i+\frac{1}{2}} = x_{i+1} - x_i = (h^x_{i+1} + h^x_i)/2$. If $\widehat{\sigma}$ is assumed constant over each cell, this integral evaluates to

$$\widehat{\sigma}_{i+\frac{1}{2},j,k} = h^x_{i+\frac{1}{2}} \left(\frac{h^x_i}{2\widehat{\sigma}_{i,j,k}} + \frac{h^x_{i+1}}{2\widehat{\sigma}_{i+1,j,k}} \right)^{-1}. \tag{3.3b}$$

Then, the resulting approximation for the x-component of (2.9e) is (see [17])

$$\hat{J}^x_{i+\frac{1}{2},j,k} = \widehat{\sigma}_{i+\frac{1}{2},j,k} \left(A^x{}_{i+\frac{1}{2},j,k} + \frac{\phi_{i+1,j,k} - \phi_{i,j,k}}{h^x_{i+\frac{1}{2}}} \right). \tag{3.3c}$$

Next, we discretize (2.9a) as in [46]. Writing the x-component of these equations,

$$(\partial_z H^y - \partial_y H^z) - \partial_x \psi - \hat{J}^x = s^x,$$

where we denote $\boldsymbol{J^s} = (s^x, s^y, s^z)^T$, a discretization centered at the center of the cell's x-face results in

$$\begin{aligned} &\frac{H^y_{i+\frac{1}{2},j,k+\frac{1}{2}} - H^y_{i+\frac{1}{2},j,k-\frac{1}{2}}}{h^z_k} - \frac{H^z_{i+\frac{1}{2},j+\frac{1}{2},k} - H^z_{i+\frac{1}{2},j-\frac{1}{2},k}}{h^y_j} \\ &- \frac{\psi_{i+1,j,k} - \psi_{i,j,k}}{h^x_{i+\frac{1}{2}}} - \hat{J}^x_{i-\frac{1}{2},j,k} = s^x_{i+\frac{1}{2},j,k}. \end{aligned} \tag{3.4}$$

Similar expressions to those in (3.3c) and (3.4) can be derived in the y- and z-directions. The BCs (1.3) are used to close (3.4). Using (3.3c), we can eliminate $\widehat{\boldsymbol{J}}$ from (3.2a) and obtain a discrete equation in which the dominant terms all involve ϕ. The resulting stencil for ϕ has seven points. We also apply the obvious quadrature for the single condition (2.10d).

Finally, we discretize the edge-centered (2.9b). Consider, say, the x-component of (2.9b), written as

$$\partial_z A^y - \partial_y A^z = \imath\omega\mu H^x.$$

Integrating this equation over the surface of a rectangle with corners

$$(x_i, y_j, z_k),\ (x_i, y_{j+1}, z_k),\ (x_i, y_{j+1}, z_{k+1}),\ (x_i, y_j, z_{k+1}),$$

the expression on the left-hand side is integrated using the Gauss **curl** theorem, and μ on the right-hand side is averaged over the rectangular area to obtain a value on the edge. We do not divide through by μ before this integration because we wish to integrate the magnetic flux, which is potentially less smooth around an edge than the magnetic field. This yields

$$\mu_{i,j+\frac{1}{2},k+\frac{1}{2}} = [h^y_{j+\frac{1}{2}} h^z_{k+\frac{1}{2}}]^{-1} \left(\int_{y_j}^{y_{j+1}} \int_{z_k}^{z_{k+1}} \mu(x_i, y, z) dy dz \right). \tag{3.5a}$$

If μ is assumed to be constant over each cell, this integral evaluates to

$$\begin{aligned} &\mu_{i,j+\frac{1}{2},k+\frac{1}{2}} \\ &= [h^y_{j+\frac{1}{2}} h^z_{k+\frac{1}{2}}]^{-1} \left(\frac{\mu_{i,j,k} h^y_j h^z_k + \mu_{i,j+1,k} h^y_{j+1} h^z_k + \mu_{i,j+1,k+1} h^y_{j+1} h^z_{k+1} + \mu_{i,j,k+1} h^y_j h^z_{k+1}}{4} \right). \end{aligned} \tag{3.5b}$$

Then, the resulting approximation for the x-component of (2.9b) is

$$\begin{aligned} H^x_{i,j+\frac{1}{2},k+\frac{1}{2}} = (\imath\omega\mu_{i,j+\frac{1}{2},k+\frac{1}{2}})^{-1} \Bigg(&\frac{A^y_{i,j+\frac{1}{2},k+1} - A^y_{i,j+\frac{1}{2},k}}{h^z_{k+\frac{1}{2}}} \\ &- \frac{A^z_{i,j+1,k+\frac{1}{2}} - A^z_{i,j,k+\frac{1}{2}}}{h^y_{j+\frac{1}{2}}} \Bigg). \end{aligned} \tag{3.5c}$$

Using (3.2b) as well as (3.5c) and similar expressions derived in the y- and z-directions, we substitute for $\boldsymbol{H}$ and ψ in (3.4) and obtain a discrete system of equations for $\boldsymbol{A}$. The resulting stencil for $\boldsymbol{A}$ has 19 points and the same structure as for the discretization of the operator

$$\boldsymbol{\nabla} \times (\mu^{-1} \boldsymbol{\nabla} \times) - \operatorname{grad}(\mu^{-1} \nabla \cdot).$$

The difference between this discretization and a direct discretization of the latter is that μ at the interface is naturally defined as an arithmetic average and not a harmonic average.

The discretization described above can be viewed as a careful extension of Yee's method, suitable for discontinuous coefficients and amenable to fast iterative solution methods. It is centered, conservative, and second order accurate. Note that throughout we have used a consistent, compact discretization of the operators $\nabla \cdot$, $\boldsymbol{\nabla} \times$, and grad. We can denote the corresponding discrete operators by $\nabla_h \cdot$, $\boldsymbol{\nabla}_h \times$, and grad_h and immediately obtain the following identities (cf. [38, 23, 22, 20]):

$$(\boldsymbol{\nabla}_h \times) \operatorname{grad}_h = \boldsymbol{0}, \tag{3.6a}$$

$$(\nabla_h \cdot)(\boldsymbol{\nabla}_h \times) = 0, \tag{3.6b}$$

$$\operatorname{grad}_h(\nabla_h \cdot) - (\boldsymbol{\nabla}_h \times)(\boldsymbol{\nabla}_h \times) = (\nabla_h \cdot) \operatorname{grad}_h. \tag{3.6c}$$

These are, of course, analogues of vector calculus identities which hold for sufficiently differentiable vector functions. The BCs (2.10) are discretized using these discrete operators as well.

Next, note that upon applying $\nabla_h \cdot$ to (3.4) and using (3.6b) and (3.2a), we obtain

$$\nabla_h \cdot \operatorname{grad}_h \psi = 0.$$

Moreover, from (3.4) and (2.10c), the discrete normal derivative of ψ vanishes at the boundaries as well. Setting ψ to 0 arbitrarily at one point,

$$\psi_{1,1,1} = 0$$

then determines that $\psi \equiv 0$ throughout the domain (as a grid function). We obtain another conservation property of our scheme, namely, a discrete divergence-free $\boldsymbol{A}$:

$$\nabla_h \cdot \boldsymbol{A} = 0. \tag{3.7}$$

Recall the stabilizing term added in (2.7). For the exact solution this term obviously vanishes. Now, (3.7) assures us that the corresponding discretized term vanishes as well (justifying use of the term "stabilization," rather than "penalty"). This is not the case for the nodal finite element method which was considered in [24, 11]. For an approximate solution that does not satisfy (3.7), the stabilization term may grow in size when μ varies over a few orders of magnitude, or else $\nabla_h \cdot \boldsymbol{A}$ grows undesirably in an attempt to keep $\mu^{-1}\nabla_h \cdot \boldsymbol{A}$ approximately constant across an interface [24].

The particular way we average across discontinuities, namely, arithmetic averaging of μ at cell edges and harmonic averaging of $\widehat{\sigma}$ at cell faces, can be important. The averaging can be viewed as a careful approximation of the constitutive relationship for discontinuous coefficients (see, e.g., [36, 38, 1] and many others). To show that, we look first at the relation

$$\hat{J}^x = \widehat{\sigma} E^x$$

across a face whose normal direction is x. This flux flows in series, and therefore an approximate $\widehat{\sigma}$ that represents the bulk property of the flow through the volume is given by the harmonic average (corresponding to an arithmetic average of the resistivities). Next, we look at the relation

$$B^x = \mu H^x,$$

where μ is an edge variable and B^x is the flux through four cells which share that edge. Here the flow is in parallel, which implies that we need to approximate μ on the edge by an arithmetic average.

Note also that if we use the more common implementation of Yee's method (i.e., $\boldsymbol{H}$ on the cell's faces and $\boldsymbol{E}$ on the cell's edges), then the roles of $\widehat{\sigma}$ and μ interchange and we need to average μ harmonically and $\widehat{\sigma}$ arithmetically (see also [1]).

4. Solution of the discrete system. After the elimination of $\boldsymbol{H}$, ψ, and $\widehat{\boldsymbol{J}}$ from the discrete equations, we obtain a large, sparse system for the grid functions corresponding to $\boldsymbol{A}$ and ϕ:

$$K\ u\ = \begin{pmatrix} H_1 - \imath\omega S & \imath\omega S D^T \\ -DS & H_2 \end{pmatrix} \begin{pmatrix} \boldsymbol{A} \\ \phi \end{pmatrix} = \begin{pmatrix} b_A \\ b_\phi \end{pmatrix} = b. \tag{4.1}$$

Here

$$H_1 = C^T M C + D^T M_c D$$

is the result of the discretization of the operator $\boldsymbol{\nabla} \times \mu^{-1} \boldsymbol{\nabla} \times \; - \operatorname{grad} \mu^{-1} \nabla \cdot$, C corresponds to the discretization of the operator $\boldsymbol{\nabla} \times$, D likewise corresponds to the discretization of the operator $\nabla \cdot$, the diagonal matrix S results from the discretization of the operator $\widehat{\sigma}(\cdot)$, M and M_c similarly arise from the operator $\mu^{-1}(\cdot)$ at cell edges and at cell centers, respectively, and $H_2 = DSD^T$ represents the discretization of $\nabla \cdot (\widehat{\sigma} \operatorname{grad}(\cdot))$. In regions of constant μ the matrix H_1 simplifies into a discretization of the vector Laplacian. The blocks are weakly coupled through interfaces in μ. A typical sparsity structure of H_1 for variable μ, as contrasted with constant μ, is displayed in Figure 3. The structure of the obtained system is similar to that in [17],

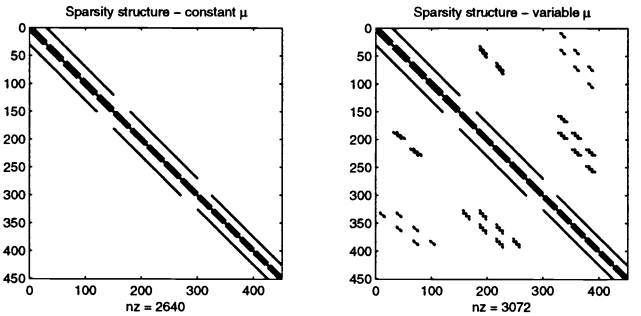

FIG. 3. *Sparsity structure of the matrix H_1 corresponding to variable μ (right) and to constant μ (left).*

although the main block diagonal is somewhat less pleasant.

Note that as long as the frequency is low enough that the diffusion number satisfies

$$d = \omega \mu \sigma h \ll 1$$

(where h is the maximum grid spacing), the matrix is dominated by the diagonal blocks. This allows us to develop a block preconditioner good for low frequencies ω based on the truncated ILU (ILU(t)) decomposition of the major blocks [35]. Thus, we approximate K by the block diagonal matrix

$$\hat{K} = \begin{pmatrix} H_1 & 0 \\ 0 & H_2 \end{pmatrix} \tag{4.2}$$

and then use ILU(t) to obtain a sparse approximate decomposition of the matrix $\hat{K}$. This decomposition is used as a preconditioner for the Krylov solver. Note that, although K is complex, the approximation $\hat{K}$ is real, and therefore we need to apply the ILU decomposition only to two real matrices, which saves memory.

The block approximation (4.2) makes sense for our discretization but not for the direct staggered grid discretization of (1.1). Thus, the reformulation and subsequent discretization of Maxwell's equations allow us to easily obtain a good block preconditioner in a modular manner, while the discretization of (1.1) does not.

5. Numerical examples. In this section we present numerical results using our method with standard Krylov-type methods and preconditioners for solving the

resulting discrete systems. We vary the type of source used, the size of jumps in the coefficients σ and μ, the preconditioner, and the grid size.

We have verified second order convergence of the method and compared our results to those from another code in [17, 18]. Here our goal is to demonstrate the efficacy of our proposed method for variable μ.

In the tables below, "iterations" denotes the number of BICGSTAB iterations needed for achieving a relative accuracy of 10^{-7}, "operations" denotes the number of giga-flops required, the SSOR parameter (when used) equals 1, and the ILU threshold (when used) equals 10^{-2}. The latter threshold is such that in our current MATLAB implementation iterations involving these two preconditioners cost roughly the same.

5.1. Example set 1. We derive the following set of experiments. Let the air's permeability be $\mu_0 = 4\pi \cdot 10^{-7}$ H/m and its permittivity be $\epsilon_0 = 8.85 \cdot 10^{-12}$ F/m. We assume a cube of constant conductivity σ_c and permeability μ_c embedded in an otherwise homogeneous earth with conductivity $\sigma_e = 10^{-3}$ S/m and permeability $\mu_e = \mu_0$; see Figure 4. In a typical geophysical application, the conductivity may range over four orders of magnitude and more, whereas the permeability rarely changes over more than one order of magnitude. Therefore, we experiment with conductivity σ_c ranging from 10^{-2} S/m to 10^3 S/m and permeability μ_c ranging from μ_0 to $1000\mu_0$.

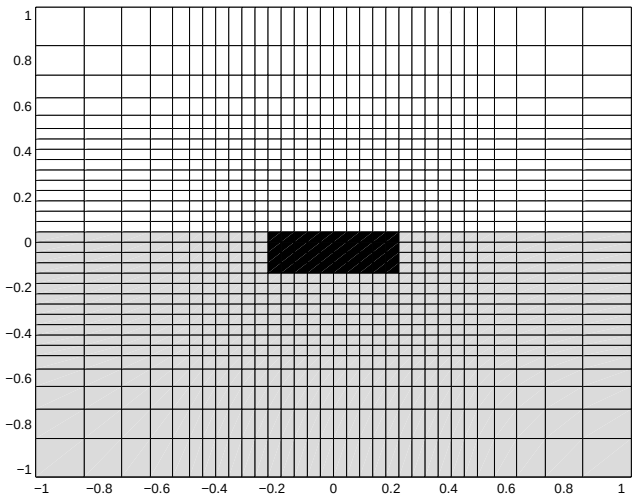

FIG. 4. *The setting of our first numerical experiment. A cube of conductivity σ_c and permeability μ_c is embedded inside a homogeneous earth with conductivity σ_e and permeability μ_e. Also, in the air $\widehat{\sigma} = -\imath\omega\epsilon_0$ and $\mu = \mu_0$.*

We experiment with two different sources: (i) a magnetic source (a plane wave), and (ii) an electric dipole source in the x direction centered at $(0, 0, 0)$. The fact that the first source is magnetic implies that it is divergence-free. This source lies entirely in the active space of the **curl** operator. In contrast, the electric source is not divergence-free.

Both sources are assumed to oscillate with different frequencies ranging from 1 to 10^6 Hz. The solution is obtained, unless otherwise noted, on a nonuniform tensor grid (see Figure 4) consisting of 32^3 cells. There are 95232 (complex) $\boldsymbol{E}$ unknowns corresponding to this grid and 128000 (complex) $\boldsymbol{A}, \phi$ unknowns. We then solve the system using the method described in the previous section.

5.1.1. Example 1a. In order to be able to compare the resulting linear algebra solver with that corresponding to Yee's method, we discretize the system

$$\boldsymbol{\nabla} \times [\mu^{-1} \boldsymbol{\nabla} \times (\widehat{\boldsymbol{J}}/\widehat{\sigma})] - \imath\omega \widehat{\boldsymbol{J}} = \imath\omega \boldsymbol{J}^s \tag{5.1}$$

using the staggered grid depicted in Figure 2, i.e., where $\widehat{\boldsymbol{J}}$ is on the cell's faces, which is similar to the discretization in [28]. This yields the discrete system

$$(C^T M C - \imath\omega S)e = \hat{b}$$

for the unknown vector e corresponding to grid values of $\widehat{\boldsymbol{J}}/\widehat{\sigma}$, where the matrices C, M, and S are defined in section 4 and $\hat{b}$ depends on the source. In order to solve this system as well as ours, we use BICGSTAB and an SSOR preconditioner. The comparison between the methods for the case $\sigma_c = 10^3\sigma_e$, $\mu_c = 100\mu_0$, and different frequencies is summarized in Table 2.

TABLE 2

Iteration counts and computational effort for our method $(\boldsymbol{A}, \phi)$ and the traditional implementation of Yee's method (applied to $\boldsymbol{E}$, or $\widehat{\boldsymbol{J}}$) for example set 1 using both an electric source and a magnetic source.

	Electric source				Magnetic source			
ω	Iterations		Operations		Iterations		Operations	
	$\boldsymbol{A}, \phi$	$\boldsymbol{E}$	$\boldsymbol{A}, \phi$	$\boldsymbol{E}$	$\boldsymbol{A}, \phi$	$\boldsymbol{E}$	$\boldsymbol{A}, \phi$	$\boldsymbol{E}$
10^0	46	9856	3.8	640	77	86	5.0	5.6
10^2	66	10323	4.3	670	82	91	5.3	5.9
10^4	77	10878	5.0	706	89	103	5.8	6.7
10^6	97	11212	6.3	728	99	113	6.4	7.3

Table 2 shows that our method converges in a moderate number of iterations for both sources, despite the presence of significant jumps in μ and σ. On the other hand, the more traditional discretization performs poorly for the electric source and comparably to our method for the magnetic source. Slow convergence of the direct staggered discretization of Maxwell's equations in the case of an electric source will happen also when $\boldsymbol{E}$ is defined on the grid's edges.

These results clearly show an advantage of our formulation over the original Yee formulation, even for a simple preconditioning, especially for electric sources and in low frequencies. In such circumstances, the discretized first term on the left-hand side of (5.1) strongly dominates the other term, and the residual in the course of the BICGSTAB iteration has a nontrivial component in the null space of that operator; hence its reduction is very slow. The magnetic source, on the other hand, yields a special situation where, so long as the discrete divergence and the roundoff error are relatively small, the residual component in the null space of the leading term operator is also small; hence the number of iterations using the traditional method is not much larger than when using our method.

5.1.2. Example 1b. Next, we test the effect of discontinuities on our method. We use the electric source and record the number of BICGSTAB iterations needed for our method to converge for various values of $\tilde{\mu} = \mu_c/\mu_e$ and $\tilde{\sigma} = \sigma_c/\sigma_e$, when using block ILU(t) preconditioning as described in the previous section. The results are summarized in Table 3.

Note that large jump discontinuities in σ do not significantly affect the rate of convergence of the iterative linear system solver for our method, but large jump discontinuities in μ have a decisive effect. Results in a similar spirit were reported in [19]

TABLE 3
Iteration counts for different frequencies, conductivities, and permeabilities in example set 1. *The conductivity/permeability structure is a cube in a half-space.*

		$\tilde{\sigma}$

10^6	10^1	62	56	50	52	57	53
	10^2	105	95	89	89	91	80
	10^3	365	290	301	270	286	287

regarding the effect of discontinuities in μ on a specialized multigrid method for an edge-element discretization. However, even for large discontinuities in μ the number of iterations reported in Table 3 remains relatively small compared with similar experiments reported in [34] (for constant μ) and [10]. We attribute the increase in the number of iterations as the jump in μ increases in size to a corresponding degradation in the condition number of K in (4.1). This degradation, however, does not depend strongly on grid size, as we verify next.

5.1.3. Example 1c. In the next experiment, we use the cube model with the electric source to evaluate the influence of the grid on the number of iterations. We fix $\omega = 10^2$ and test our method on a case with a modest coefficient jump $\tilde{\mu} = 10$ and on a case with a large jump $\tilde{\mu} = 10^3$. A set of uniform grids in the interval $[-1, 1]^3$ is considered. For each grid we record the resulting number of iterations using both the SSOR and the block ILU preconditioners. The results of this experiment are gathered in Table 4.

TABLE 4
Iteration counts for different grids, for two sets of problem coefficients and using two preconditioners.

	$\tilde{\mu} = \tilde{\sigma} = 10$		$\tilde{\mu} = \tilde{\sigma} = 1000$	
Grid size	ILU	SSOR	ILU	SSOR
8^3	6	20	58	268
16^3	10	32	108	453
32^3	23	52	213	789
64^3	31	76	396	1302

We observe that the number of iterations increases as the number of unknowns increases. The increase appears to be roughly proportional to the number of unknowns to the power 1/3. The growth in number of iterations as a function of grid size is also roughly similar for both preconditioners, although the block ILU requires fewer iterations (about 1/4 for $\tilde{\mu} = 1000$) for each grid. However, ILU requires more memory than SSOR, which may prohibit its use for very large problems. The increase rate is also similar, as expected, for both values of $\tilde{\mu}$. The rate of increase in number of iterations as $\tilde{\mu}$ increases appears essentially independent of the grid size. Practically, however, this increase is substantial and may be hard to cope with for (perhaps unrealistically) large values of $\tilde{\mu}$ using the present techniques.

5.2. Example 2. In our next experiment we consider a more complicated earth structure. We employ a random model, which is used by practitioners in order to simulate stochastic earth models [25]. Two distinct value sets (σ_1, μ_1), (σ_2, μ_2) and a probability P are assumed for the conductivities and permeabilities: for each cell, the probability of having values $\sigma_1,\ \mu_1$ is P, and the probability of having values $\sigma_2,\ \mu_2$ is $1 - P$. This can be a particularly difficult model to work with, as the conductivity and permeability may jump anywhere from one cell to the next, not necessarily just across a well-defined manifold. A cross-section of such a model is plotted in Figure 5. We then carry out experiments as before for frequencies ranging from 0 to 10^6 Hz.

FIG. 5. *The setting of example set* 2.

We use the random model with different conductivities, permeabilities, and frequencies and the electric source, with $P = 0.5$ on the domain $[-1, 1]^3$ (in km). We employ a uniform grid of size 44^3 and use both the block ILU and the SSOR preconditioners. The results of this experiment in terms of iteration counts are summarized in Table 5. The results show that our solution method is effective even for highly varying conductivity. As before, the method deteriorates when very large variations in μ are present.

We can also see from Table 5 that the block ILU preconditioner works very well for low frequencies, but it is not very effective for high frequencies. It is easy to check that in all cases where the block ILU preconditioner fails to achieve convergence (denoted "nc," meaning failure to achieve a residual of 10^{-7} in 800 iterations) the maximum grid spacing h satisfies $\omega\mu\sigma\ h \gg 1$. In such a case the discretization of the leading terms of the differential operator no longer yields the dominant blocks in the matrix equations (4.1), and therefore our block ILU preconditioner fails. Thus, for high frequency and high conductivity we require more grid points in order for this preconditioner to be effective. This is also consistent with the physics, as the skin

depth [45] decreases and the attenuated wave can be simulated with fidelity only on a finer grid.

6. Summary and further remarks. In this paper we have developed a fast finite volume algorithm for the solution of Maxwell's equations with discontinuous conductivity and permeability. The major components of our approach are as follows.

- Reformulation of Maxwell's equations. The Helmholtz decomposition is applied to $\boldsymbol{E}$; then a stabilizing term is added, resulting in a strongly elliptic system; the system is written in first order form to allow flexibility in the ensuing discretization; and finally, the divergence-free Coulomb gauge condition is eliminated using differentiation and substitution, which yields a weakly coupled PDE system enabling an efficient preconditioner for the large, sparse algebraic system which results from the discretization.
- Discretization using staggered grids, respecting continuity conditions, and carefully averaging material properties across discontinuities. For this discretization, the stabilizing term vanishes at the exact solution of the discrete equations, which is important for cases with large contrasts in μ.
- Solution of the resulting linear system using fast preconditioned Krylov methods.

The resulting algorithm was tested on a variety of problems. We have shown dramatic improvement over the more standard algorithm when the source is electric. Good performance was obtained even when the coefficients μ and σ were allowed to vary rapidly on the grid scale—a case which should prove challenging for multigrid methods.

The project that has motivated us is electromagnetic inverse problems in geophysical prospecting [42]. Solving the forward problem, i.e., Maxwell's equations as in the present article, is a major bottleneck for the data inversion methods—indeed, it may have to be carried out dozens, if not hundreds, of times for each data inversion. Thus, extremely fast solvers of the problem discussed in our paper are needed. Based on the algorithm described here an implementation has been carried out which solves realistic instances of this forward problem in less than two minutes on a single-processor PC, enabling derivation of realistic algorithms at low cost for the inverse problem.

Acknowledgments. We wish to thank Drs. Doug Oldenburg and Dave Moulton for fruitful discussions and an anonymous referee for valuable comments on the first two sections of our exposition.

EXACT PREDICTION OF QR FILL-IN BY ROW-MERGE TREES*

SUELY OLIVEIRA†

Abstract. Row-merge trees for forming the QR factorization of a sparse matrix A are closely related to elimination trees for the Cholesky factorization of A^TA. Row-merge trees predict the exact fill-in (assuming no numerical cancellation) provided A satisfies the strong Hall property, but overestimate the fill-in in general. However, here a fast and simple postprocessing step for row-merge trees is presented that predicts the exact fill-in for sparse QR factorization using Householder reflectors for general matrices.

Key words. row-merge trees, elimination trees, QR factorization

1. Introduction.

Matrix factorizations of sparse matrices typically result in creating further nonzero entries, or *fill-in*. If this fill-in can be accurately predicted in advance, then the factorization can be performed in less time, as the additional memory needed can be allocated once in advance. Notice that fill-in can be reduced with some matrix reordering algorithms. After that, the algorithms presented in this paper can be used. The algorithms discussed here do not affect the amount of fill-in but predict the fill-in before the factorization [17]. Performance comparisons between our algorithms and the Dulmage–Mendelsohn decomposition [20, 19] will be presented at the end of the paper, but notice that even though our new algorithms perform well in these comparisons, the Dulmage–Mendelsohn decomposition can be used to predict fill-in and to achieve other goals as well (such as re-ordering rows and columns to give a block-triangular form); see, for example, [15, 20, 19]. Also notice that the algorithms in [19] can compute the fill-in in time $O(n\,nz(A))$ if no column permutation is allowed, where $nz(A)$ is the number of nonzeros in A. The elimination tree algorithms presented in this paper appear to be significantly faster than this. Perhaps what is most significant about the algorithms presented here is that they are developed by modifying the construction of elimination trees or row-merge trees and may give new insight into the graphical prediction of fill-in. Furthermore, elimination trees [13] can be used to compute symbolic factorizations, to direct the factorization of matrices in multifrontal methods [13, 14], and also to assist in parallelizing sparse systems solvers. The QR fill-in problem considered in this paper is similar to the sparse Gaussian elimination with partial pivoting considered in [7] in the sense that the fill-in for QR factorization is the union of the fill-in for Gaussian elimination with partial pivoting, over all pivot sequences.

The elimination tree of a symmetric positive definite matrix B is readily defined in terms of its Cholesky factors: if $B = R^TR$ with R upper triangular, then $ET(B)$ is the forest with nodes $\{1, 2, \ldots, n\}$, where node p is the parent of node j if $p = \min\{\, i \mid i > j,\ r_{ji} \neq 0 \,\}$. That is, p is the first row/column to be updated at the jth stage of the Cholesky factorization of B. The elimination tree for Cholesky factorizations can

†Department of Computer Science and Department of Mathematics, The University of Iowa, Iowa City, IA 52242-1419 (oliveira@cs.uiowa.edu).

be efficiently computed from the original matrix B; indeed, it can be computed in $O(nz(B)\,\alpha(nz(B)))$ time, where $nz(B)$ is the number of nonzeros of the $n \times n$ matrix B, and $\alpha(\cdot)$ is the inverse Ackermann function of Tarjan [22]. Whenever $j \geq i$, if $b_{jk} \neq 0$ and i is an ancestor of k in the elimination tree, then $r_{ij} \neq 0$ [13]. Furthermore, there are no other nonzeros in R. Note that each node is regarded as an ancestor of itself. Unless there is numerical cancellation, $ET(B)$ does not depend on the numerical values in B. The elimination tree is sometimes called the *elimination forest* since it is not necessarily connected.

The graph of an $n \times n$ symmetric matrix B (denoted $G(B)$) is the graph on n nodes $\{1, 2, \ldots, n\}$ with an edge connecting nodes i and j (denoted $i \sim j$) if and only if $b_{ij} \neq 0$ and $i \neq j$; nodes are labeled by the row or column number. Unsymmetric and rectangular matrices are represented by bipartite graphs. For a symmetric positive definite matrix B, unless there is numerical cancellation in the Cholesky factorization $B = R^T R$, the symbolic factorization is the graph $G(R + R^T)$ and is denoted $G^+(B)$. Forming $G^+(B)$ can be defined in graph theoretic terms: $i \sim j$ in $G^+(B)$ if and only if there is a path from i to j in $G(B)$ whose nodes are all less than $\min(i, j)$.

For the QR factorization of an $m \times n$ matrix A it is more appropriate to consider the *bipartite graph* of A ($BG(A)$) whose nodes consist of the rows $\mathcal{R} = \{ r_1, r_2, \ldots, r_m \}$ and columns $\mathcal{C} = \{ c_1, c_2, \ldots, c_n \}$ (which are disjoint sets), and $r_i \sim c_j$ if and only if $a_{ij} \neq 0$. The symbolic QR factorization of A can be computed similarly to the way the Cholesky factorization of a symmetric positive definite matrix is computed and is based on the *row-merge tree of* A, which we define in section 1.2. We consider QR factorizations obtained by Householder orthogonalization. Each jth step of a Householder orthogonalization of A is achieved by multiplying matrix $A^{(j)}$ by a Householder reflector $H_j = I - \beta_j w_j w_j^T$ [10]. The matrices H_j are constructed to zero all the column entries below the jth diagonal of matrix $A^{(j)}$. We then set $A^{(j+1)} = H_j A^{(j)}$. At the nth step we are finally left with an upper triangular matrix $R = A^{(n)}$. The $Q = H_1 H_2 \ldots H_n$ factor is usually represented by the matrix W of Householder vectors (column j of W is the w_j vector used to construct the Householder reflector H_j) and the vector β. Thus, the main problem is to determine the sparsity structures of W and R. In this paper, the fill-in for the QR factorization will be determined from the graphs and related row-merge trees mentioned above, for any full-rank matrix.

1.1. Hall matrices and graphs. A bipartite graph $G = (V_1, V_2, E)$ is a *Hall graph* if for every set $N \subset V_2$, there are no fewer nodes (in V_1) adjacent to N than are in N. For example, if $N = V_2$, then the set of nodes adjacent to N must be no smaller than N; thus $|V_1| \geq |V_2|$. The bipartite graph G is *strong Hall* if for all $N \subset V_2$ such that $N \neq V_2$, the set of nodes adjacent to N has size at least $|N| + 1$.

A matrix A is said to be a Hall matrix (resp., a strong Hall matrix) if $BG(A)$ is a Hall graph (resp., strong Hall graph). Consider V_1 to be $\mathcal{R}$ and V_2 to be $\mathcal{C}$. If A is a full-rank matrix with $m \geq n$, then it is a Hall matrix [8, Cor. 2.4]. In addition, if A is a strong Hall matrix, then the fill pattern of the Cholesky factor R of the symbolic product $A^T A$ is equal to the fill pattern for the symbolic R factor in the QR factorization of A [1]. Problems arise for matrices A that are not strong Hall matrices. Consider, for example,

$$A = \begin{bmatrix} \times & \times & \times & \cdots & \times \\ & \times & & & \\ & & \times & & \\ & & & \ddots & \\ & & & & \times \end{bmatrix}, \tag{1.1}$$

for $i = 1, \ldots, m$: $S(u_i) \leftarrow \{ c_j \mid a_{ij} \neq 0 \} \cup \{c_i\}$
for $j = 1, \ldots, n$: $S(p_j) \leftarrow S(u_j)$
for $j = 1, \ldots, n$: $S(p_j) \leftarrow \bigcup_{x \in \mathcal{U} \cup \mathcal{P} : c_j \in S(x)} S(x) \bigcap \{c_{j+1}, \ldots, c_n\}$

FIG. 1.1. *Symbolic QR factorization.*

which is a matrix with nonzeros in the first row and diagonal only. This matrix is a Hall matrix but not a strong Hall matrix. The QR factorization of A is trivial. However, forming $A^T A$ symbolically gives a dense matrix (due to the dense row in A). Thus from the nonzero structure of $A^T A$, it appears that the R in the QR factorization is dense, although it clearly is not. On the other hand,

$$A' = \begin{bmatrix} \times & \times & \times & \ldots & \times \\ \times & \times & \times & \ldots & \times \\ & \times & & & \\ & & \times & & \\ & & & \ddots & \\ & & & & \times \end{bmatrix} \tag{1.2}$$

is a strong Hall matrix, and the R in the QR factorization *is* dense. As we will show in this paper, distinguishing these cases can be done by postprocessing the row-merge tree. A paper which finds the fill-in structure of Q and R is [11]. Their methods are based on matchings and Hall matrices properties, which differ from the methods used here. In this paper, the fill-in for the QR factorization for nonstrong Hall matrices will be determined from the graphs and related row-merge trees.

1.2. QR factorizations and row-merge trees. Hereafter, we assume that A is an $m \times n$ Hall matrix with $m \geq n$, and the rows and columns have been matched so that $a_{ii} \neq 0$ for all i. As mentioned before, if A is not a Hall matrix, it cannot be full rank.

The appropriate generalization of elimination trees to QR factorizations is the *row-merge tree* [12, 18] of a nonsymmetric matrix A. This can be derived from the crude symbolic QR factorization of A. Let A be $m \times n$, with $m \geq n$. Let $\mathcal{U} = \{u_1, u_2, \ldots, u_m\}$ denote the *unprocessed* rows of A, and let $\mathcal{P} = \{p_1, p_2, \ldots, p_n\}$ denote the processed rows of A (existing rows of R, after the QR factorization has been performed). Define $index(u_l) = l$ and $index(p_k) = k$. Define $S(x)$ to be the set of nonzero entries in x, and specifically consider $S(u_i)$ to be the set of nonzero entries columns in the ith row *before* the factorization algorithm is started, plus the diagonal column (vertex number for the diagonal column). The set $S(p_j)$ is built through the last loop in Figure 1.1 pseudocode. It gives an upper bound on the set of nonzero entries in row j ($j \leq m$) after the jth step of Householder QR factorization, less the entries before the $(j+1)$th column. We define the set $\mathcal{R}_j \subset \mathcal{R}$ to be the set of rows x which have a nonzero in the jth column ($c_j \in S(x)$) at the jth step of the Householder QR with $index(x) \geq j$. At the jth step of this loop, the union is over all rows in $\mathcal{U}$ or in $\mathcal{P}$ such that the row x is in $\mathcal{R}_j$. The set of nonzero entries of row p_j ($S(p_j)$) is then defined as this union intersected with the set of posterior columns (i.e., $c_{j+1}, \ldots, c_n$). Unless there is numerical cancellation, if any row in $\mathcal{R}_j$ has a nonzero in column $k > j$, after performing the jth step, all rows in this set will have a nonzero entry in column k.

The symbolic QR factorization described in Figure 1.1 gives an upper bound on the sparsity patterns of the matrix R: $r_{ij} \neq 0$ only if $i = j$ or $c_j \in S(p_i)$. It is not

```
for k = 1, 2, ..., n
    for each i such that a_ik ≠ 0
        j ← max{ r < k | a_ir ≠ 0 }
        s ← top of tree containing j
        if s ≠ k
            parent(s) ← k
```

FIG. 1.2. *Algorithm for constructing* ET(CIG(A)).

exact in general, since it assumes $|\mathcal{R}_j| > 1$ for all j; in other words, a row with a nonzero in column j (sparsity pattern $S(p_j)$) is assumed to participate in succeeding stages of the QR factorization, even if it is the only row with a nonzero in column j. The algorithm of Figure 1.1 is exact if A is a strong Hall matrix (since $|\mathcal{R}_j| > 1$ for all j, in this case); however, if A is a Hall matrix but not a strong Hall matrix, then the fill-in predicted by Figure 1.1 can greatly overestimate the true fill-in. In addition, the cost of this algorithm is similar to the cost of actually performing the QR factorization, so row-merge trees have been developed [12].

Note that if A has nonzeros on the diagonal, then the first line of Figure 1.1 can be replaced by: **for** $i = 1, \ldots, m$: $S(u_i) \leftarrow \{\, c_j \mid a_{ij} \neq 0 \,\}$. Nonzeros on the diagonal can usually be achieved by computing a maximal matching of columns to rows; in fact, for Hall matrices the maximal matching will also be a complete matching (that is, every column will be matched to a row). Consequently, for Hall matrices, swapping the row matched to column j with row j for all j will put nonzeros in all of the diagonal entries without creating additional fill-in.

The *row-merge tree* on nodes $\mathcal{R} \cup \mathcal{C}$ can then be defined by the condition that c_j is the parent node of r_i if $j = \min\{\, k \mid c_k \in S(u_i) \,\}$, and the parent of node c_k is c_j where $j = \min\{\, l \mid c_l \in S(p_k) \,\}$. Hereafter, we denote the *row-merge tree* of A as $RM(A)$.

Related to these graphs is the *column intersection graph* of A [8]. Providing there is no numerical cancellation in forming A^TA, the column intersection graph $CIG(A)$ is just $G(A^TA)$. More formally, the column intersection graph of A is defined as the graph on the nodes $\{c_1, \ldots, c_n\}$, where $c_k \sim c_l$ (c_k is connected to c_l) if there is a j where both a_{jk} and a_{jl} are nonzero. Liu [12] showed that the elimination tree of $CIG(A)$ ($ET(CIG(A))$) is equal to $RM(A)$ minus all nodes in $\mathcal{R}$ and edges incident to $\mathcal{R}$. Computationally, $ET(CIG(A))$ is a useful tool because it can be computed directly from A without needing to construct $CIG(A)$ or A^TA, by using the algorithm in Figure 1.2. We also refer the reader to the algorithm of [9, Fig. 2], which achieves the same task and is similar in nature. Other papers where this task is achieved are [3, 4], which use an unrelated algorithm.

The algorithm in Figure 1.2 is a modification of Liu's algorithm for the symmetric case [13], which is shown in Figure 1.3. Note that the line "$s \leftarrow$ top of tree containing j" can be computed using a union-find data structure with path compression in amortized time $O(\log(n))$ time [2, p. 449], or in amortized time $O(\alpha(nz(A), n))$, where α is an inverse of the Ackermann function if the method also uses the union-by-rank heuristic [2, pp. 450–457]. However, the union-by-rank heuristic requires additional work since the representative of a subset is determined by the algorithm, and is not necessarily the root of a component of the currently constructed elimination tree or forest.

Notice that the elimination tree $T = ET(CIG(A))$ is the smallest tree or forest T

```

FIG. 2.1. *Postprocessing step.*

that satisfies the relations "l is an ancestor of k" whenever $l > k$ and $a_{jk}, a_{jl} \neq 0$ for some j. The row-merge tree $RM(A)$ can be formed from T by adding $\mathcal{R}$ to the set of nodes and adding edges from r_i to c_k if $k = \min\{\, s \mid a_{is} \neq 0 \,\}$. For an arbitrary tree or forest T, let $RM(T)$ denote the tree or forest formed by adding $\mathcal{R}$ to the set of nodes and by adding edges from r_i to c_k, where $k = \min\{\, s \mid a_{is} \neq 0 \,\}$.

Given the elimination tree $T = ET(CIG(A))$, the fill-in can be estimated as follows [13]: Column j of R has nonzeros in rows r_k, where c_k is an ancestor of some row r_i in $RM(T)$, where $a_{ij} \neq 0$ and $k \leq j$. Row i of W has nonzeros in columns c_k, where c_k is an ancestor of r_i in $RM(T)$ and $k \leq i$. The estimated fill-in based on the $ET(CIG(A))$ is the same as the fill-in predicted by the crude symbolic QR factorization algorithm in Figure 1.1.

The fill-in for the QR factorization can be computed from $ET(CIG(A))$ and A with just $O(n)$ storage overhead and $O(nz(R) + nz(W) + n)$ time; just to count the number of nonzeros requires just $O(1)$ additional storage and $O(nz(R) + nz(W) + n)$ time.

2. Postprocessing the row-merge tree. If $|\mathcal{R}_k| > 1$ for all k, then the assumptions underlying the algorithm in Figure 1.1 are correct, and the methods of the previous paragraph for computing the sparsity patterns of R and W give the correct fill-in. However, if $|\mathcal{R}_k| = 1$ for some k, then we must have $\mathcal{R}_k = \{r_k\}$. In this case, the elimination tree T must be postprocessed to give the correct fill-in.

In this section we introduce a postprocessing algorithm which should be applied when $|\mathcal{R}_k| = 1$ for some k. This algorithm should be performed after constructing $ET(CIG(A))$ and adding the row nodes to construct the row-merge tree of A as described in the previous section. This postprocessed row-merge tree predicts fill-in at least as well as the original row-merge tree does. How to predict fill-in given a row-merge tree was described near the end of the last section. We have to thread the tree so that the children of a given node can be found in $O(1)$ time per child node. Threading a tree of n nodes (defined by a *parent* array) requires just $O(n)$ operations and $O(n)$ storage. The postprocessing step for an $m \times n$ matrix A takes just $O(m+n)$ operations, including the tree threading step.

The postprocessing algorithm is shown in Figure 2.1. Note that the final computed value of $count(j)$ is the number of rows that participate in the jth stage of the QR

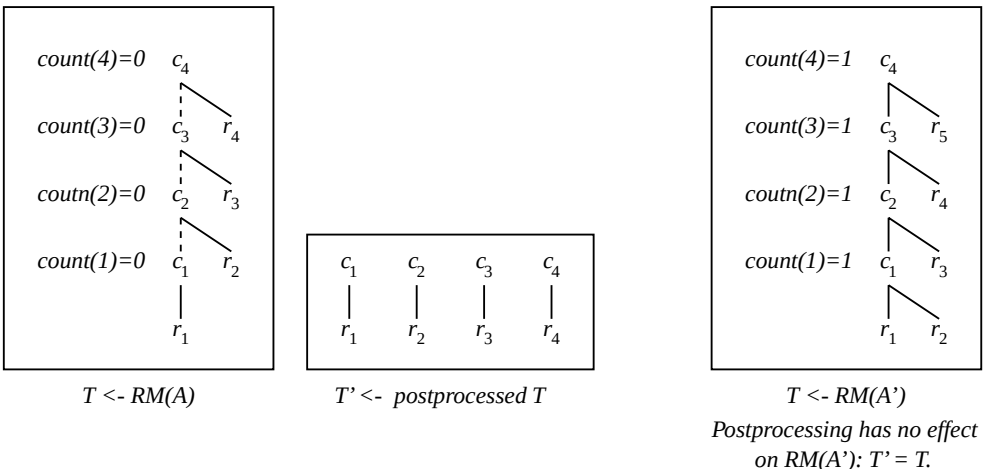

FIG. 2.2. *Row-merge trees and the effects of postprocessing on example matrices A and A′.*

factorization minus one. It is also the number of row nodes in the row-merge tree rooted at c_j minus the number of column nodes in this tree. The first loop in Figure 2.1 initializes the array $count(j)$ for all n columns. The second loop finds out for each row i what is the column number of the first nonzero appearance in that row and adds 1 to the count for that column. In other words, $count(k)$ states how many rows have the first nonzero in column k (the number of row children of k). In example (1.1) in section 1 we have $count(1) = count(2) = count(3) = count(4) = 1$ after the second loop. The third loop finds the number of row descendents of node j minus the number of its column descendents (including itself). The final values of $count(j)$ are shown for examples (1.1) and (1.2) in Figure 2.2. If the value of $count(j)$ is equal to zero, then that node is disconnected from the tree above. For the example matrices A and A' in ((1.1) and (1.2)), the row-merge trees and the effect of postprocessing are shown in Figure 2.2.

The basis for this postprocessing algorithm is a more refined understanding of the symbolic Householder QR factorization shown in Figure 1.1. As mentioned earlier, that algorithm is expensive and previous approaches based on row-merge trees exist. Our new algorithms show that we can do better by postprocessing the row merge trees. The set $S(p_j)$ is the set of nonzero entries in row j after the jth step of the QR algorithm, minus the c_j entry. Note that the jth row no longer participates in the succeeding steps of the QR factorization after the jth step. If only row j has a nonzero in column j at the jth stage of the QR factorization, then no Householder operation needs to be performed, and thus $S(p_j)$ is irrelevant to the calculation of $S(p_l)$ for $l > j$. This fact is ignored by the symbolic QR factorization in Figure 1.1.

If we reconsider the algorithm in Figure 1.1 with this in mind, then for $j = 1, 2, \ldots, n$ there should be a count of the number of rows in $\mathcal{R}_j$ (which is $count(j)+1$). If $|\mathcal{R}_j| \leq 1$, then the jth step of the QR factorization is trivial, and $S(p_j)$ is irrelevant for future steps in the factorization. If we add one to $count(j)$ at the end of the algorithm in Figure 2.1, we obtain the number of rows participating in the jth stage of the factorization. This explains why we should disconnect the tree when $count(j) = 0$, creating the postprocessed tree T'. Now we have new row-merge trees from which we can obtain improved estimates of the fill-in.

```
for k = 1, 2, ..., n:   parent(j) ← NULL
for k = 1, 2, ..., n
    for each i such that a_ik ≠ 0
        p ← min{ q | a_iq ≠ 0 }
        j ← max{ r < k | a_ir ≠ 0 }
        s ← top of tree containing j
        if k, s, and p all belong to the same component of T' and s ≠ k
            parent(s) ← k
```

FIG. 2.3. *Reprocessing step which constructs T'' based on T'.*

After postprocessing, $nz(W)$ can be computed from $ET(CIG(A))$ and A in $O(n)$ time by the formula

$$nz(W) = \sum_{j=1}^{n} (count(j) + 1). \tag{2.1}$$

If we postprocess the elimination tree T' again, we do not change the value of the *count* array and have no affect on $nz(W)$. However, this postprocessed elimination tree T' can be used to compute a new elimination tree T'' which will give more information about $nz(W)$. This reprocessing creates a new elimination tree or forest T''. To illustrate the necessity of reprocessing the postprocessed elimination tree, consider the matrix

$$A'' = \begin{bmatrix} \times & \times & \times & \times \\ & \times & & \\ & & \times & \\ & \times & & \times \end{bmatrix}. \tag{2.2}$$

The steps of the reprocessing algorithm are shown in Figure 2.3. The algorithm mirrors the earlier algorithm in Figure 1.2 for computing $ET(CIG(A))$, except that T' is used to filter the construction of the elimination tree. This means that if two nodes are connected in T'', they must be connected in T'. The elimination tree $ET(CIG(A''))$ and the results of postprocessing and reprocessing the elimination tree using the algorithm of Figure 2.3 are shown in Figure 2.4.

To explain how the algorithm proceeds for the this example, start by looking at T' (the tree obtained after the postprocessing scheme is applied). The generated tree T'' by the reprocessing algorithm is similar to the original tree T' until the second loop reaches the value $k = 3$. When $k = 3$ ($p = 1$, $j = 2$, and $s = 2$), the statement $parent(s) \leftarrow k$ of algorithm 2.3 is not executed, since k, s, and p do not belong to the same component of T'. Nevertheless, during the next iteration of this loop, when $k = 4$, that same statement will connect node 2 to its new parent, node 4.

The postprocessing and subsequent reprocessing steps can be applied recursively until postprocessing does not alter the elimination tree or forest (that is, $count(j) > 0$ for all j). Define $T'' = ET^*(A, T)$ to be the elimination forest that results from the following two-step process: (1) applying postprocessing to the elimination tree T and then (2) reprocessing the resulting forest T' to produce T'', using algorithms in Figures 2.1 and 2.3, respectively.

Since $ET^*(A, T)$ is either unchanged ($T'' = T$) or more disconnected than T, recursive applications of $T^{(k+1)} \leftarrow ET^*(A, T^{(k)})$ will terminate after at most n iterations. In practice, the number of iterations needed to obtain $T^{(k+1)} = T^{(k)}$ is very

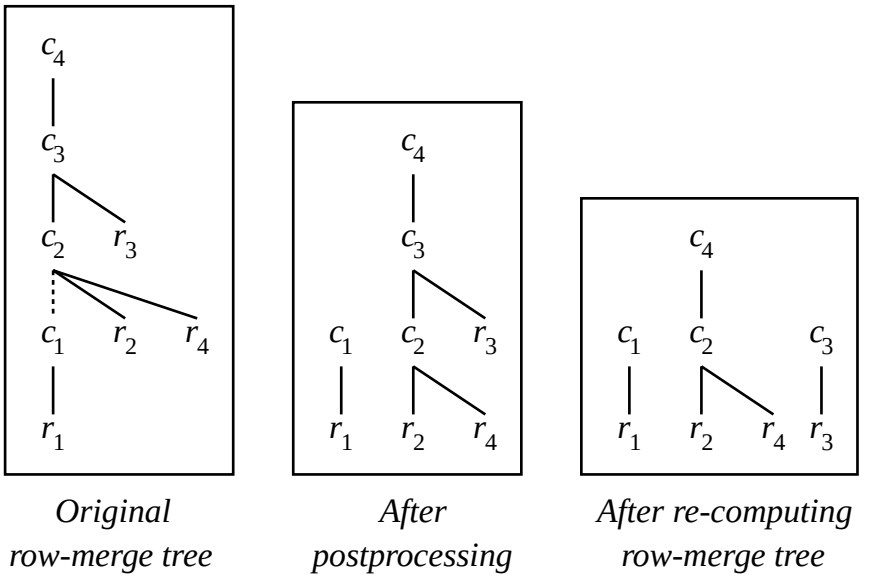

FIG. 2.4. *Original, postprocessed, and recomputed elimination trees for* A''.

small. Let T^* be this final elimination forest where $T^* = ET^*(A, T^*)$. Then, for this forest, $count(j) > 0$ for all nodes j that are not root nodes. Thus, the predicted sparsity structure of the rows in each tree of T^* is correct, and the sparsity structure predicted by T^* is the exact fill-in pattern for the Householder QR factorization.

Determining if two nodes are in a common connected component of a tree or forest T (as done in the core of loop k) can be performed in $O(1)$ time after an *ancestor* array is constructed containing the top-most ancestor of each node in T, which can be done in $O(n \log n)$ time, where n is the number of nodes of T.

3. Computational results. The following operations were implemented: computing the elimination tree of the column intersection graph $ET(CIG(A))$ (including threading the trees), the postprocessing algorithms of Figures 2.1 and 2.3, a maximal matching algorithm [6] for bipartite graphs, and the Dulmage–Mendelsohn decomposition [20]. Note that only path compression was used for the union-find data structures in the construction of the elimination trees [2, p. 447], and not union-by-rank. This is the approach used for constructing $ET(CIG(A))$ in the recent SuperLU code under development by Demmel et al., which is referred to in [5]. The implementation of the maximal matching algorithm follows the recommendations of [6]. These algorithms were implemented in terms of the Meschach matrix library in C [21]. Our algorithms predicted the exact fill-in for all test matrices, as expected. Our test matrices included all rectangular matrices plus some square matrices from the Harwell–Boeing collection. Matrices which had more columns than rows were transposed before performing any calculations. No column or row reordering was performed on these matrices, since we aim solely to analyze the performance of our fill-in prediction algorithms.

Other test problems were 10×10 matrices with nonzeros only in the first row and the diagonal. Our new routines correctly deduced the number of nonzero entries for R, which for this matrix has just 19 nonzeros, using the postprocessed $ET(CIG(A))$ tree (i.e., no fill-in), while the unprocessed tree predicted 55 nonzeros

(i.e., complete fill-in, as was expected from $A^T A$). Also, matrix A'' of (2.2) was used as a test matrix, and the results confirmed expectations. Our routines were compiled and run on a Hewlett–Packard Visualize C3000 with standard optimization switches set on.

The basic data for the matrices are listed in Table 3.1, and the timings for the operations are listed in Table 3.2. In Table 3.1, $\#nz$ is the number of nonzeros of the original matrix, $nz(R)$ is the number of nonzeros of R in the QR factorization, and $nz(W)$ is the number of nonzeros in the matrix of Householder vectors that represents Q. In Table 3.2, $ETCIG1$ refers to the time to compute the elimination

tree of the column intersection graph of the matrix, and $ETCIG2$ is the amount of additional time needed for all subsequent computations of $ET^*(A,T)$ in order to compute the final elimination tree, T^*. The columns "Thread" and "Postproc" give the time needed to thread the elimination tree and to perform the postprocessing of the algorithm in Figure 2.1, respectively.

The Dulmage–Mendelsohn decomposition gives an alternative way of predicting the exact fill-in of QR factorization. The decomposition itself is a reordering of the rows and columns of the matrix so that the matrix is put into block-upper-triangular form with strong Hall diagonal blocks. The columns "Coarse" and "Fine" of Table 3.2

give the times needed for the coarse and fine phases of the Dulmage–Mendelsohn decomposition [20] after the computation of a maximal matching. Finally, the column "MM" gives the time needed to compute a maximal matching, which is an essential step in the Dulmage–Mendelsohn algorithm. Note that the times given do not include the times for computing the fill-in for the QR factorization using either approach.

When we add the times $ETCIG1$ and $ETCIG2$ and compare with the sum of the times for the coarse and fine phases of the Dulmage–Mendelsohn method, we always get smaller times for the sum of elimination tree times ($ETCIG1$ plus $ETCIG2$). Notice that after the Dulmage–Mendelsohn decomposition, there are still other steps for the prediction of the QR fill-in which are not taken into account. Our results show that our new algorithms based on postprocessed row-merge trees are usually faster than methods based on Dulmage–Mendelsohn approaches.

Acknowledgments. I would like to thank David Stewart for proofreading the paper, Alex Pothen and Esmond Ng for interesting conversations, and, finally, the referees for comments which improved the paper.

ON SCHWARZ ALTERNATING METHODS FOR THE INCOMPRESSIBLE NAVIER–STOKES EQUATIONS*

S. H. LUI†

Abstract. The Schwarz alternating method can be used to solve linear elliptic boundary value problems on domains which consist of two or more overlapping subdomains. The solution is approximated by an infinite sequence of functions which result from solving a sequence of elliptic boundary value problems in each of the subdomains.

This paper considers four Schwarz alternating methods for the N-dimensional, steady, viscous, incompressible Navier–Stokes equations, $N \leq 4$. It is shown that the Schwarz sequences converge to the true solution provided that the Reynolds number is sufficiently small.

1. Introduction.

The Schwarz alternating method was devised by H. A. Schwarz more than one hundred years ago to solve linear boundary value problems. It has garnered interest recently because of its potential as a very efficient algorithm for parallel computers. In Tai and Espedal [11] and Dryja and Hackbusch [4], the authors show convergence of Schwarz methods for some nonlinear problems. In Lui [10], proofs of convergence of Schwarz alternating methods for some 2nd-order nonlinear elliptic PDEs were attained. In this sequel, we prove convergence of four Schwarz methods for the N-dimensional, steady, incompressible, viscous Navier–Stokes equations, $N \leq 4$, provided that the Reynolds number is sufficiently small.

Many authors have demonstrated numerically the effectiveness of Schwarz methods in solving fluid problems at moderate Reynolds numbers. See, for example, the proceedings of the annual domain decomposition conferences, beginning with [7], [3], [2], [8], [6], and references therein. This list is of course far from complete.

This paper appears to be the first attempt to prove convergence of Schwarz methods for the Navier–Stokes equations, though only for small Reynolds numbers. It follows closely the framework developed in the fundamental paper of Lions [9], where the convergence of the Schwarz method for the Stokes equations is proved. We treat the Navier–Stokes equations as a nonlinear perturbation of the Stokes equations. Although we concentrate mostly on the two-subdomain case, we shall derive an additive version which converges for multiple subdomains.

Let Ω be a bounded connected domain in $\mathbb{R}^N$ with a smooth boundary. Suppose $\Omega = \Omega_1 \cup \Omega_2$, where the subdomains Ω_i have smooth boundaries and are overlapping. Let $H_0^1(\Omega)^N$ denote the Cartesian product of N Sobolev spaces $H_0^1(\Omega)$ (consisting of all functions whose first derivatives are in $L^2(\Omega)$ and whose value vanishes on $\partial\Omega$ in the trace sense), and define $L^2(\Omega)^N$ as the Cartesian product of N copies of $L^2(\Omega)$. The space $H^{1/2}(\partial\Omega)^N$ is defined similarly. Let

$$V = \{u \in H_0^1(\Omega)^N,\ \text{div } u = 0\}$$

and

$$V_i = \{u \in H_0^1(\Omega_i)^N,\ \text{div } u = 0\}, \qquad i = 1, 2.$$

Let u_i denote the ith component of the vector u. Denote the inner product in the Sobolev space $H_0^1(\Omega)^N$ by

$$[u, v] = \sum_{i=1}^{N} \int_\Omega \nabla u_i \cdot \nabla v_i,$$

and let $\|u\|_1 = [u, u]^{1/2}$. In this paper, a function in $H_0^1(\Omega_i)^N$ is considered as a function defined on the whole domain by extension by zero.

Given f from the dual space $H^{-1}(\Omega)^N$ with norm $\|\cdot\|_{-1}$, the Stokes problem for $u \in H_0^1(\Omega)^N$ and $p \in L_0^2(\Omega) \equiv \{q \in L^2(\Omega),\ \int_\Omega q = 0\}$ is

$$-\triangle u + \nabla p = f \ \text{ and } \ \text{div } u = 0 \text{ on } \Omega.$$

It is well known ([12], for instance) that there is a unique solution $(u, p) \in H_0^1(\Omega)^N \times L_0^2(\Omega)$. Write $u = S^{-1}f$, where $S^{-1} : H^{-1}(\Omega)^N \to V$ is the solution operator for the velocity u. It is again well known that $(\|u\|_1 + \|p\|_{L^2(\Omega)}) \le C\,\|f\|_{-1}$ for some constant C. In particular, $\|S^{-1}\|_1 \le C$. Similarly, define S_i^{-1} as the solution operator for the velocity for the Stokes problem on Ω_i.

The subdomains Ω_i are said to overlap if $H_0^1(\Omega)^N = H_0^1(\Omega_1)^N + H_0^1(\Omega_2)^N$. In this case, the work of Lions [9] shows that $V = V_1 + V_2$. Let P_i denote the orthogonal (with respect to the inner product $[\cdot, \cdot]$) projection from V onto V_i, $i = 1, 2$. It is well known that

$$d \equiv \max\left(\|(I - P_2)(I - P_1)\|_1,\ \|(I - P_1)(I - P_2)\|_1\right) < 1. \tag{1.1}$$

See Lions [9] and Bramble et al. [1]. Throughout this paper, C will denote a positive constant which may not be the same at different occurrences.

In the next section, we give a statement of the problem including an estimate for the nonlinear term. Following that, we prove convergence for a nonlinear Schwarz sequence where each subdomain problem is a nonlinear one. In the next three sections, we develop three variations of the nonlinear Schwarz sequence and prove convergence. These sequences are more practical in that only linear subdomain problems are encountered and that in two of these, the subdomain problems are independent so that they can be solved concurrently. In the final section, we discuss the case of many subdomains and nonhomogeneous boundary conditions. This paper concludes with some suggestions for future work.

2. Navier–Stokes equations. The N-dimensional, steady, viscous, incompressible Navier–Stokes equations in nondimensional form are

$$\begin{aligned} (u \cdot \nabla)u &= -\nabla p + \frac{1}{R}\triangle u + f \text{ on } \Omega, \\ \text{div } u &= 0 \text{ on } \Omega, \end{aligned}$$

with the boundary conditions

$$u = g \text{ on } \partial\Omega,$$

where $u \in H^1(\Omega)^N$, g is the given velocity on the boundary with $\|g\|_{H^{1/2}(\partial\Omega)^N} \leq 1$, f is the forcing term in $L^2(\Omega)^N$, p is the pressure, and R is the Reynolds number. We assume that g satisfies the compatibility condition $\int_{\partial\Omega} g \cdot \nu = 0$, where ν denotes the (outward) unit normal. We use u to denote the unique solution to this equation.

We shall need the following lemma. A similar version states the continuity of a certain trilinear form containing the convective term of the Navier–Stokes equations. See, for instance, Temam [12].

LEMMA 1. *Let $U = \{u \in H^1(\Omega)^N,\ div\ u = 0\}$. For $N \leq 4$, define the function $F : U \times U \to V$ by $F(u,v) = S^{-1}(u \cdot \nabla)v$. Then $\|F(u,v)\|_1 \leq C\|u\|_1\ \|v\|_1$.*

Proof. Let $z = F(u,v) \in V$. Then $Sz = (u \cdot \nabla)v$, which implies

$$[z,z] = \int_\Omega z \cdot (u \cdot \nabla)v = -\int_\Omega v \cdot (u \cdot \nabla)z.$$

By Holder's inequality, we have for any $0 < \epsilon \leq 1/2$

$$\left| \int_\Omega v_j u_i \frac{\partial z_j}{\partial x_i} \right| \leq \|v_j\|_{L^{2/\epsilon}(\Omega)} \|u_i\|_{L^{2/\epsilon}(\Omega)} \|z_j\|_{H_0^1(\Omega)}.$$

By the Sobolev embedding theory, we have a continuous embedding $H^s(\Omega) \to L^{2/\epsilon}(\Omega)$ for $s = N(1-\epsilon)/2$. When $N \leq 4$, we can arrange $s = 1$ by choosing an appropriate ϵ. (For $N = 2$, let $\epsilon \to 0$; for $N = 3$ or 4, pick $\epsilon = 1 - 2/N$.) Thus

$$\|z\|_1^2 \leq C\|z\|_1\ \|u\|_1\ \|v\|_1,$$

and the conclusion of the lemma follows. ∎

In light of this lemma, we restrict our work to the case $N \leq 4$ in the remainder of this paper. Initially, *we only discuss the case $g \equiv 0$*, which has a clearer exposition. The general case will be addressed in the last section. In the next section, we define a Schwarz sequence and prove its convergence.

3. Nonlinear Schwarz sequence. Let $u^{(0)} \in V$. For $n = 0, 1, 2, \ldots$, define the nonlinear Schwarz sequence as

$$\begin{aligned} (u^{(n+\frac{1}{2})} \cdot \nabla)u^{(n+\frac{1}{2})} &= -\nabla p^{(n+\frac{1}{2})} + \frac{1}{R}\triangle u^{(n+\frac{1}{2})} + f \text{ on } \Omega_1, \\ \text{div } u^{(n+\frac{1}{2})} &= 0 \text{ on } \Omega_1, \\ u^{(n+\frac{1}{2})} &= u^{(n)} \text{ on } \partial\Omega_1 \end{aligned}$$

and

$$\begin{aligned} (u^{(n+1)} \cdot \nabla)u^{(n+1)} &= -\nabla p^{(n+1)} + \frac{1}{R}\triangle u^{(n+1)} + f \text{ on } \Omega_2, \\ \text{div } u^{(n+1)} &= 0 \text{ on } \Omega_2, \\ u^{(n+1)} &= u^{(n+\frac{1}{2})} \text{ on } \partial\Omega_2. \end{aligned}$$

Here, $u^{(n+\frac{1}{2})}$ is considered as a function in V by defining it to be $u^{(n)}$ on $\overline{\Omega} \setminus \overline{\Omega}_1$, and $u^{(n+1)}$ is defined as $u^{(n+\frac{1}{2})}$ on $\overline{\Omega} \setminus \overline{\Omega}_2$. The first thing to check is that the compatibility conditions

$$\int_{\partial\Omega_1} u^{(n)} \cdot \nu = 0 = \int_{\partial\Omega_2} u^{(n+\frac{1}{2})} \cdot \nu$$

are satisfied. We claim that they are satisfied for all n provided that

$$\int_{\Gamma_1} u^{(0)} \cdot \nu = 0 \tag{3.1}$$

holds, where $\Gamma_1 = \partial\Omega_1 \cap \Omega_2$.

The claim is proved by induction. For $n = 0$,

$$\int_{\partial\Omega_1} u^{(0)} \cdot \nu = \int_{\Gamma_1} u^{(0)} \cdot \nu = 0$$

by (3.1). Since div $u^{(\frac{1}{2})} = 0$ on $\Omega_1 \cap \Omega_2$,

$$0 = \int_{\Gamma_1} u^{(\frac{1}{2})} \cdot \nu + \int_{\Gamma_2} u^{(\frac{1}{2})} \cdot \nu = \int_{\Gamma_1} u^{(0)} \cdot \nu + \int_{\Gamma_2} u^{(\frac{1}{2})} \cdot \nu = \int_{\Gamma_2} u^{(\frac{1}{2})} \cdot \nu.$$

Here $\Gamma_2 = \partial\Omega_2 \cap \Omega_1$. The induction step is proved by a similar calculation.

The main result is that this Schwarz sequence converges to the true solution provided that the Reynolds number is sufficiently small.

THEOREM 1. *Assuming that $u^{(0)} \in V$ satisfies* (3.1) *and that R is sufficiently small (see* (3.9 *and* 3.10)*, the nonlinear Schwarz sequence converges geometrically to the true solution u in the norm $\|\cdot\|_1$.*

Proof. Let $v_1 \in V_1$. Multiply the PDE in Ω_1 by v_1, and then integrate by parts to obtain the weak form

$$\int_{\Omega_1} v_1 \cdot (u^{(n+\frac{1}{2})} \cdot \nabla) u^{(n+\frac{1}{2})} = -\frac{1}{R}[u^{(n+\frac{1}{2})}, v_1] + \int_{\Omega_1} f \cdot v_1.$$

Note that v_1 is divergence-free and hence the pressure term drops out. Now

$$[u^{(n+\frac{1}{2})} - u^{(n)}, v_1] = [-P_1 u^{(n)}, v_1] - R \int_{\Omega_1} v_1 \cdot (u^{(n+\frac{1}{2})} \cdot \nabla) u^{(n+\frac{1}{2})} + R \int_{\Omega_1} f \cdot v_1.$$

Since $u^{(n+\frac{1}{2})} - u^{(n)} \in V_1$, we have

$$u^{(n+\frac{1}{2})} - u^{(n)} = -P_1 u^{(n)} - R S_1^{-1} (u^{(n+\frac{1}{2})} \cdot \nabla) u^{(n+\frac{1}{2})} + R S_1^{-1} f.$$

Define $e^{(n)} = u^{(n)} - u$ and $e^{(n+\frac{1}{2})} = u^{(n+\frac{1}{2})} - u$. Since $P_1 u = -R S_1^{-1}(u \cdot \nabla) u + R S_1^{-1} f$, we obtain

$$e^{(n+\frac{1}{2})} - e^{(n)} = P_1 u + R S_1^{-1}(u \cdot \nabla) u - R S_1^{-1}(u^{(n+\frac{1}{2})} \cdot \nabla) u^{(n+\frac{1}{2})} - P_1 u^{(n)}$$

or

$$e^{(n+\frac{1}{2})} = (I - P_1) e^{(n)} + R F_1(e^{(n+\frac{1}{2})}), \tag{3.2}$$

where

$$\begin{aligned} F_1(e^{(n+\frac{1}{2})}) &= -S_1^{-1}((u^{(n+\frac{1}{2})} \cdot \nabla) u^{(n+\frac{1}{2})} - (u \cdot \nabla) u), \\ &= -S_1^{-1}((e^{(n+\frac{1}{2})} \cdot \nabla) e^{(n+\frac{1}{2})} + (u \cdot \nabla) e^{(n+\frac{1}{2})} + (e^{(n+\frac{1}{2})} \cdot \nabla) u). \end{aligned} \tag{3.3}$$

Similarly,

$$e^{(n+1)} = (I - P_2) e^{(n+\frac{1}{2})} + R F_2(e^{(n+1)}), \tag{3.4}$$

where

$$F_2(e^{(n+1)}) = -S_2^{-1}\left((e^{(n+1)}\cdot\nabla)e^{(n+1)} + (u\cdot\nabla)e^{(n+1)} + (e^{(n+1)}\cdot\nabla)u\right). \tag{3.5}$$

Combining these equations, we obtain

$$e^{(n+\frac{1}{2})} = (I-P_1)(I-P_2)e^{(n-\frac{1}{2})} + R(I-P_1)F_2(e^{(n)}) + RF_1(e^{(n+\frac{1}{2})}) \tag{3.6}$$

and

$$e^{(n+1)} = (I-P_2)(I-P_1)e^{(n)} + R(I-P_2)F_1(e^{(n+\frac{1}{2})}) + RF_2(e^{(n+1)}). \tag{3.7}$$

Having developed the error equations, the rest of the proof can be divided into three steps. The first is to derive an estimate for $\|F_i\|_1$, and then show that $\{\|e^{(n)}\|_1\}$ is bounded and, finally, that it is convergent to zero.

In the first step, we give a bound on $\|F_1(e^{(n+\frac{1}{2})})\|_1$. This is accomplished by directly applying the lemma (on Ω_1):

$$\|F_1(e^{(n+\frac{1}{2})})\|_1 \le C\|e^{(n+\frac{1}{2})}\|_1(2\|u\|_1 + \|e^{(n+\frac{1}{2})}\|_1).$$

A similar bound holds for $\|F_2(e^{(n)})\|_1$.

In the second step of the program, we show by induction that, provided R is sufficiently small, $\|e^{(n+\frac{1}{2})}\|_1, \|e^{(n)}\|_1 \le M$ for every n, where

$$M = \max(\|e^{(0)}\|_1, \|e^{(\frac{1}{2})}\|_1).$$

Suppose $\|e^{(n-\frac{1}{2})}\|_1, \|e^{(n)}\|_1 \le M$. From (1.1) and (3.6),

$$\begin{aligned}\|e^{(n+\frac{1}{2})}\|_1 \le{}& d\|e^{(n-\frac{1}{2})}\|_1 + RC\|e^{(n)}\|_1(2\|u\|_1 + \|e^{(n)}\|_1)\\ &+RC\|e^{(n+\frac{1}{2})}\|_1(2\|u\|_1 + \|e^{(n+\frac{1}{2})}\|_1)\end{aligned} \tag{3.8}$$

or

$$0 \le \epsilon a^2 - (1-2\epsilon\|u\|_1)a + \alpha,$$

where $\epsilon = RC$, $a = \|e^{(n+\frac{1}{2})}\|_1$, and $\alpha = dM + \epsilon M(M+2\|u\|_1)$. The roots of the associated quadratic equation are

$$\begin{aligned} r_\pm &= \frac{1-2\|u\|_1\epsilon \pm \sqrt{(1-2\|u\|_1\epsilon)^2 - 4\epsilon\alpha}}{2\epsilon}\\ &= \frac{1}{\epsilon} - (dM + 2\|u\|_1) + O(\epsilon), \qquad dM + O(\epsilon).\end{aligned}$$

Hence the inequality is equivalent to $a \ge r_+$ or $a \le r_-$. The first root, r_+, is extraneous because in this case, as $\epsilon \to 0$, $a = \|e^{(n+\frac{1}{2})}\|_1 \to \infty$, which is absurd. Hence we have $\|e^{(n+\frac{1}{2})}\|_1 \le r_- \le M$ for ϵ sufficiently small. Here, sufficiently small means $\epsilon \le (1-d)/2(M+2\|u\|_1)$ or

$$R \le \frac{1-d}{2C(M+2\|u(R)\|_1)}. \tag{3.9}$$

Here, we emphasize the dependence of u on R by writing $u(R)$. From (3.7), with the same bound on R, we also have $\|e^{(n+1)}\|_1 \le M$. Hence by induction, $\|e^{(n)}\|_1, \|e^{(n+\frac{1}{2})}\|_1 \le M$ for every n.

Finally, we are ready to show the convergence of the Schwarz sequence. As a consequence of the above, we have

$$\|F_1(e^{(n+\frac{1}{2})})\|_1 \le C(M + 2\|u\|_1)\|e^{(n+\frac{1}{2})}\|_1$$

and similarly for $\|F_2(e^{(n)})\|_1$. By applying $(I - P_2)$ to (3.4) with n replaced by $n-1$, we obtain $(I - P_2)e^{(n)} = (I - P_2)e^{(n-\frac{1}{2})}$. From (3.6)

$$\begin{aligned}\|e^{(n+\frac{1}{2})}\|_1^2 &= \|P_1 e^{(n+\frac{1}{2})}\|_1^2 + \|(I - P_1)e^{(n+\frac{1}{2})}\|_1^2 \\ &\le \epsilon^2\|e^{(n+\frac{1}{2})}\|_1^2 + (d + \epsilon)^2\|e^{(n)}\|_1^2,\end{aligned}$$

where $\epsilon = RC(2\|u\|_1 + M) < 1$ by (3.9). From this, we obtain

$$\|e^{(n+\frac{1}{2})}\|_1 \le \frac{d + \epsilon}{\sqrt{1 - \epsilon^2}}\|e^{(n)}\|_1.$$

Similarly,

$$\|e^{(n+1)}\|_1 \le \frac{d + \epsilon}{\sqrt{1 - \epsilon^2}}\|e^{(n+\frac{1}{2})}\|_1.$$

Hence a sufficient condition for convergence is that $d + \epsilon < \sqrt{1 - \epsilon^2}$ or

$$R < \frac{\sqrt{2 - d^2} - d}{2C(2\|u(R)\|_1 + M)}.$$

This condition is weaker than (3.9).

We now strengthen (3.9) slightly to ensure that the resulting condition does not lead to a vacuous set of problems. It is known ([12], for instance) that if

$$R^2\|f\|_{-1} < C_1,$$

where C_1 is a known constant, then the Navier–Stokes equations have a unique solution u with the bound $\|u\|_1 \le R\|f\|_{-1} < \sqrt{C_1\,\|f\|_{-1}}$. Hence (3.9) can be replaced by the stronger condition

$$R \le \min\left(\frac{1 - d}{2C(M + 2\sqrt{C_1\,\|f\|_{-1}})},\ \sqrt{\frac{C_1}{\|f\|_{-1}}}\right), \tag{3.10}$$

where the right-hand side consists of known quantities. Thus we conclude that if (3.10) is satisfied, the nonlinear Schwarz sequence converges geometrically. □

Strictly speaking, $e^{(\frac{1}{2})}$ is not part of the data of the problem. Instead of the definition of M above, we can define $M = 2\|e^{(0)}\|_1$. Using (3.2), $\|e^{(\frac{1}{2})}\|_1 \le M$ provided that $R^{-1} \ge 4C(u + \|e^{(0)}\|_1)$. An inequality corresponding to (3.9) is

$$R \le \frac{1 - d}{4C(\|e^{(0)}\|_1 + \|u(R)\|_1)}.$$

4. Linear Schwarz sequence. In the previous section, each Schwarz iteration requires the solution of a nonlinear PDE in each subdomain. From a practical point of view, we of course prefer to solve linear problems whenever possible. Now, we demonstrate a version of the Schwarz method where only linear PDEs need to be solved.

Let $u^{(0)} \in V$, and assume it satisfies (3.1). For $n = 0, 1, 2, \ldots$, define the linear Schwarz sequence as

$$\begin{aligned}(u^{(n)} \cdot \nabla)u^{(n+\frac{1}{2})} &= -\nabla p^{(n+\frac{1}{2})} + \frac{1}{R}\triangle u^{(n+\frac{1}{2})} + f \text{ on } \Omega_1,\\ \text{div } u^{(n+\frac{1}{2})} &= 0 \text{ on } \Omega_1,\\ u^{(n+\frac{1}{2})} &= u^{(n)} \text{ on } \partial\Omega_1\end{aligned}$$

and

$$\begin{aligned}(u^{(n+\frac{1}{2})} \cdot \nabla)u^{(n+1)} &= -\nabla p^{(n+1)} + \frac{1}{R}\triangle u^{(n+1)} + f \text{ on } \Omega_2,\\ \text{div } u^{(n+1)} &= 0 \text{ on } \Omega_2,\\ u^{(n+1)} &= u^{(n+\frac{1}{2})} \text{ on } \partial\Omega_2.\end{aligned}$$

Notice that the above equations are linear and that the compatibility conditions are satisfied.

The main result is that this Schwarz sequence converges to the true solution provided that the Reynolds number is sufficiently small.

THEOREM 2. *Assuming that $u^{(0)} \in V$ satisfies* (3.1) *and that R is sufficiently small, the linear Schwarz sequence converges to the true solution u in the norm $\|\cdot\|_1$.*

Proof. The proof is similar to before, and we only give the key steps. We have expressions for the error sequence that are similar to those used before:

$$\begin{aligned}e^{(n+\frac{1}{2})} &= (I - P_1)e^{(n)} + RF_1(e^{(n+\frac{1}{2})}, e^{(n)}),\\ e^{(n+1)} &= (I - P_2)e^{(n+\frac{1}{2})} + RF_2(e^{(n+1)}, e^{(n+\frac{1}{2})}),\end{aligned}$$

where

$$\begin{aligned}F_1(e^{(n+\frac{1}{2})}, e^{(n)}) &= -S_1^{-1}((e^{(n)} \cdot \nabla)e^{(n+\frac{1}{2})} + (u \cdot \nabla)e^{(n+\frac{1}{2})} + (e^{(n)} \cdot \nabla)u),\\ F_2(e^{(n+1)}, e^{(n+\frac{1}{2})}) &= -S_2^{-1}((e^{(n+\frac{1}{2})} \cdot \nabla)e^{(n+1)} + (u \cdot \nabla)e^{(n+1)} + (e^{(n+\frac{1}{2})} \cdot \nabla)u).\end{aligned}$$

Note that we have the estimates

$$\begin{aligned}\|F_1(e^{(n+\frac{1}{2})}, e^{(n)})\|_1 &\le C(\|e^{(n+\frac{1}{2})}\|_1\|e^{(n)}\|_1 + \|u\|_1\|e^{(n+\frac{1}{2})}\|_1 + \|e^{(n)}\|_1),\\ \|F_2(e^{(n+1)}, e^{(n+\frac{1}{2})})\|_1 &\le C(\|e^{(n+1)}\|_1\|e^{(n+\frac{1}{2})}\|_1 + \|u\|_1\|e^{(n+1)}\|_1 + \|e^{(n+\frac{1}{2})}\|_1).\end{aligned}$$

Combining the error sequences, we obtain the error equations

$$\begin{aligned}e^{(n+\frac{1}{2})} &= (I - P_1)(I - P_2)e^{(n-\frac{1}{2})} + R(I - P_1)F_2(e^{(n)}, e^{(n-\frac{1}{2})}) + RF_1(e^{(n+\frac{1}{2})}, e^{(n)}),\\ e^{(n+1)} &= (I - P_2)(I - P_1)e^{(n)} + R(I - P_2)F_1(e^{(n+\frac{1}{2})}, e^{(n)}) + RF_2(e^{(n+1)}, e^{(n+\frac{1}{2})}).\end{aligned}$$

As before, we show that, provided R is sufficiently small, ($R \le (1 - d)/2C(M + \|u\|_1 + 1)$) for every n, $\|e^{(n)}\|_1, \|e^{(n+\frac{1}{2})}\|_1 \le M$, where $M = \max(\|e^{(0)}\|_1, \|e^{(\frac{1}{2})}\|_1)$. From this we obtain

$$\begin{aligned}\|F_1(e^{(n+\frac{1}{2})}, e^{(n)})\|_1 &\le C(M + \|u\|_1)\|e^{(n+\frac{1}{2})}\|_1 + C\|e^{(n)}\|_1,\\ \|F_2(e^{(n+1)}, e^{(n+\frac{1}{2})})\|_1 &\le C(M + \|u\|_1)\|e^{(n+1)}\|_1 + C\|e^{(n+\frac{1}{2})}\|_1.\end{aligned}$$

Applying these inequalities to the error equations, we have

$$\begin{bmatrix} \|e^{(n+1)}\|_1 \\ \|e^{(n+\frac{1}{2})}\|_1 \end{bmatrix} \le A \begin{bmatrix} \|e^{(n+\frac{1}{2})}\|_1 \\ \|e^{(n)}\|_1 \end{bmatrix} \quad \text{and} \quad \begin{bmatrix} \|e^{(n+\frac{1}{2})}\|_1 \\ \|e^{(n)}\|_1 \end{bmatrix} \le A \begin{bmatrix} \|e^{(n)}\|_1 \\ \|e^{(n-\frac{1}{2})}\|_1 \end{bmatrix},$$

where

$$A = \begin{bmatrix} \frac{\epsilon(M+\|u\|_1+1)}{1-\epsilon(M+\|u\|_1)} & \frac{d+\epsilon}{1-\epsilon(M+\|u\|_1)} \\ 1 & 0 \end{bmatrix},$$

where $\epsilon = RC$. For convergence, it is sufficient that the spectral radius of A is less than one:

$$\frac{\epsilon(M+\|u\|_1+1) \pm \sqrt{\epsilon^2(M+\|u\|_1+1)^2 + 4(d+\epsilon)(1-\epsilon(M+\|u\|_1))}}{2(1-\epsilon(M+\|u\|_1))} < 1.$$

This is equivalent to

$$R < \frac{1-d}{2C(M+\|u\|_1+1)}. \tag{4.1}$$

Of course, a variation of (3.10) can be used as an upper bound. ∎

5. Parallel Schwarz sequence. For the two previous Schwarz methods, the iterates must be computed sequentially. In this section, we suggest a Schwarz sequence where the two subdomain problems are independent, and thus they can be solved simultaneously. This sequence also converges provided that the Reynolds number is sufficiently small.

Let $u^{(0)} \in V$, and assume that it satisfies

$$\int_{\Gamma_i} u^{(0)} \cdot \nu = 0, \qquad i = 1, 2. \tag{5.1}$$

Define $u^{(-\frac{1}{2})} = u^{(0)}$. For $n = 0, 1, 2, \ldots$, define the parallel Schwarz sequence as

$$\begin{aligned} (u^{(n)} \cdot \nabla) u^{(n+\frac{1}{2})} &= -\nabla p^{(n+\frac{1}{2})} + \frac{1}{R} \triangle u^{(n+\frac{1}{2})} + f \text{ on } \Omega_1, \\ \text{div } u^{(n+\frac{1}{2})} &= 0 \text{ on } \Omega_1, \\ u^{(n+\frac{1}{2})} &= u^{(n)} \text{ on } \partial\Omega_1 \end{aligned}$$

and

$$\begin{aligned} (u^{(n-\frac{1}{2})} \cdot \nabla) u^{(n+1)} &= -\nabla p^{(n+1)} + \frac{1}{R} \triangle u^{(n+1)} + f \text{ on } \Omega_2, \\ \text{div } u^{(n+1)} &= 0 \text{ on } \Omega_2, \\ u^{(n+1)} &= u^{(n-\frac{1}{2})} \text{ on } \partial\Omega_2. \end{aligned}$$

We define $u^{(n+1)}$ as $u^{(n-\frac{1}{2})}$ on $\overline{\Omega} \setminus \overline{\Omega}_2$. Notice that the above equations are linear and can be solved independently. We again can check that the compatibility conditions are satisfied.

THEOREM 3. *Assuming that $u^{(0)} \in V$ satisfies* (5.1) *and that R is sufficiently small, the parallel Schwarz sequence converges to the true solution u in the norm $\|\cdot\|_1$.*

Proof. The proof is similar to before, and we only give the key steps. We have expressions for the error sequence that are similar to those used before:

$$e^{(n+\frac{1}{2})} = (I - P_1)e^{(n)} + RF_1(e^{(n+\frac{1}{2})}, e^{(n)}),$$
$$e^{(n+1)} = (I - P_2)e^{(n-\frac{1}{2})} + RF_2(e^{(n+1)}, e^{(n-\frac{1}{2})}).$$

Combining the error sequences, we obtain the error equations

$$e^{(n+\frac{1}{2})} = (I - P_1)(I - P_2)e^{(n-\frac{3}{2})} + R(I - P_1)F_2(e^{(n)}, e^{(n-\frac{3}{2})}) + RF_1(e^{(n+\frac{1}{2})}, e^{(n)}),$$
$$e^{(n+1)} = (I - P_2)(I - P_1)e^{(n-1)} + R(I - P_2)F_1(e^{(n-\frac{1}{2})}, e^{(n-1)}) + RF_2(e^{(n+1)}, e^{(n-\frac{1}{2})}),$$

where $e^{(-\frac{3}{2})} \equiv e^{(0)}$.

As before, we show that, provided R is sufficiently small, ($R \le (1-d)/2C(M + \|u\|_1 + 1)$) for every n, $\|e^{(n)}\|_1, \|e^{(n+\frac{1}{2})}\|_1 \le M$, where $M = \max(\|e^{(0)}\|_1, \|e^{(\frac{1}{2})}\|_1)$. Hence we have the estimates

$$\|F_1(e^{(n+\frac{1}{2})}, e^{(n)})\|_1 \le C(M + \|u\|_1)\|e^{(n+\frac{1}{2})}\|_1 + C\|e^{(n)}\|_1,$$
$$\|F_2(e^{(n+1)}, e^{(n-\frac{1}{2})})\|_1 \le C(M + \|u\|_1)\|e^{(n+1)}\|_1 + C\|e^{(n-\frac{1}{2})}\|_1.$$

Applying these inequalities to the error equations, we have

$$\begin{bmatrix} \|e^{(n+1)}\|_1 \\ \|e^{(n+\frac{1}{2})}\|_1 \\ \|e^{(n)}\|_1 \\ \|e^{(n-\frac{1}{2})}\|_1 \end{bmatrix} \le A \begin{bmatrix} \|e^{(n)}\|_1 \\ \|e^{(n-\frac{1}{2})}\|_1 \\ \|e^{(n-1)}\|_1 \\ \|e^{(n-\frac{3}{2})}\|_1 \end{bmatrix},$$

where

$$A = \begin{bmatrix} 0 & \frac{\epsilon(M+\|u\|_1+1)}{1-\epsilon(M+\|u\|_1)} & \frac{d+\epsilon}{1-\epsilon(M+\|u\|_1)} & 0 \\ \frac{\epsilon(M+\|u\|_1+1)}{1-\epsilon(M+\|u\|_1)} & 0 & 0 & \frac{d+\epsilon}{1-\epsilon(M+\|u\|_1)} \\ 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \end{bmatrix},$$

and $\epsilon = RC$. For convergence, it is sufficient that the spectral radius of A is less than one. This is equivalent to

$$R < \frac{1-d}{2C(M + \|u\|_1 + 1)}, \tag{5.2}$$

which is the same estimate as that of the linear Schwarz method. □

6. Additive Schwarz sequence. In this section, we demonstrate the convergence of the additive Schwarz sequence, which was originally introduced in [5] for linear elliptic equations and has been used successfully in practice.

Let $u^{(0)} \in V$. For $n = 0, 1, 2, \ldots$, define $d^{(n+\frac{1}{2})} \in V_1$ and $d^{(n+1)} \in V_2$ as the solutions of

$$[d^{(n+\frac{1}{2})}, v_1] = R\int_{\Omega_1} f \cdot v_1 - R\int_{\Omega_1} v_1 \cdot (u^{(n)} \cdot \nabla)u^{(n)} - [u^{(n)}, v_1], \qquad v_1 \in V_1,$$

and of

$$[d^{(n+1)}, v_2] = R\int_{\Omega_2} f \cdot v_2 - R\int_{\Omega_2} v_2 \cdot (u^{(n)} \cdot \nabla)u^{(n)} - [u^{(n)}, v_2], \qquad v_2 \in V_2.$$

The additive Schwarz sequence is defined as

$$u^{(n+1)} = u^{(n)} + \omega(d^{(n+\frac{1}{2})} + d^{(n+1)}),$$

where ω is a relaxation parameter. Roughly speaking, $d^{(n+\frac{1}{2})}$ and $d^{(n+1)}$ are corrections to the iterate $u^{(n)}$ in the subdomains Ω_1 and Ω_2, respectively, and the right-hand sides of the above equations defining the corrections are the residuals of $u^{(n)}$ in the subdomains. Ignoring the nonlinear terms, the above sequence is precisely the additive Schwarz sequence for the Stokes problem. Notice that the above Stokes equations can be solved independently and no additional assumption on $u^{(0)}$ is required.

THEOREM 4. *Suppose $u^{(0)} \in V$. Assuming that $0 < \omega < 1/2$ and that R is sufficiently small, the additive Schwarz sequence converges geometrically to the true solution u in the norm $\|\cdot\|_1$.*

Proof. We sketch only the proof, recording the key equations. From the defining equations, we have

$$d^{(n+\frac{1}{2})} = -P_1 e^{(n)} + RF_1(e^{(n)}),$$
$$d^{(n+1)} = -P_2 e^{(n)} + RF_2(e^{(n)}),$$

from which we obtain

$$e^{(n+1)} = (I - \omega\,(P_1 + P_2))e^{(n)} + \omega R(F_1(e^{(n)}) + F_2(e^{(n)})),$$

where F_1 and F_2 were defined in (3.3) and (3.5). When $0 < \omega < 1/2$, $\|I - \omega\,(P_1 + P_2)\|_1 < 1$. Applying the estimates for F_i and the condition

$$R < \frac{1 - \|I - \omega\,(P_1 + P_2)\|_1}{2\omega C(\|u^{(0)} - u\|_1 + 2\|u\|_1)}, \tag{6.1}$$

we can show that $\|e^{(n)}\|_1 \leq \|e^{(0)}\|_1$ for all n. This condition (or a variation of (3.10)) is also sufficient to guarantee geometric convergence of the additive Schwarz sequence. ∎

7. Discussion and conclusion. In this paper, we show the convergence of four Schwarz alternating methods for the N-dimensional, steady, incompressible Navier–Stokes equations provided that the Reynolds number is sufficiently small and $N \leq 4$. Our results are valid only for the two-subdomain case. It is interesting to see that the bounds (3.9, 4.1, 5.2, 6.1) on the Reynolds number for the four methods are approximately the same. (The constant C appearing in these four estimates can be taken to be the same number.)

The result for finitely many subdomains is again that the Schwarz sequence converges provided that R is sufficiently small. Except for the additive Schwarz scheme, we cannot give an explicit bound for R. The difficulty is in obtaining an explicit expression for the spectral radius of a certain matrix. We elaborate on this point below. To simplify the analysis, assume that any three distinct subdomains have an empty intersection.

First, we need the following lemma which was shown by Lions [9] for the two-subdomain case. The general case is true by induction. We include a proof for completeness.

LEMMA 2. *Suppose $H_0^1(\Omega)^N = H_0^1(\Omega_1)^N + \cdots + H_0^1(\Omega_m)^N$. Let V and V_i be subspaces of $H_0^1(\Omega)^N$ and $H_0^1(\Omega_i)^N$, respectively, consisting of divergence-free functions. Then $V = V_1 + \cdots + V_m$.*

Proof. First consider the case when $m = 2$. Let $u \in V$. We need to show that $u = v_1 + v_2$ for some $v_i \in V_i$, $i = 1, 2$. Since the domains are overlapping, we have $u = u_1 + u_2$ for some $u_i \in H_0^1(\Omega_i)^N$. Let $h = \text{div } u_1$. Let $\Omega_{12} = \Omega_1 \cap \Omega_2$ and $\Omega_{11} = \Omega_1 \cap \overline{\Omega_2}^c$. We claim that $\int_{\Omega_{12}} h = 0$, and so the PDE

$$\text{div } w = h \text{ on } \Omega_{12}$$

has a solution $w \in H_0^1(\Omega_{12})^N$. By extending w by 0 to Ω, we can define $v_1 = u_1 - w$ and $v_2 = u_2 + w$. By construction, div $v_1 = 0$ and div $v_2 = -$ div $u_1 +$ div $w = 0$.

The claim can be shown by the following calculation. Let ν be the unit outward normal to $\partial\Omega_{12}$, and let ν_1 be the unit outward normal to $\partial\Omega_{11}$. Then

$$\int_{\Omega_{12}} h = \int_{\partial\Omega_{12}} u_1 \cdot \nu = \int_{\Gamma_2} u \cdot \nu = -\int_{\partial\Omega_{11}} u \cdot \nu_1 = -\int_{\Omega_{11}} \text{div } u = 0.$$

Now consider the m subdomain case. By induction hypothesis and the fact that the subdomains are overlapping,

$$U \equiv V_1 + \cdots + V_{m-1} = \{v \in H_0^1(\Omega_1 \cup \cdots \cup \Omega_{m-1}), \quad \text{div } v = 0\}.$$

Since $H_0^1(\Omega)^N = H_0^1(\Omega_1 \cup \cdots \cup \Omega_{m-1})^N + H_0^1(\Omega_m)^N$, the result of the two-subdomain case yields the desired conclusion $V = U + V_m$. ∎

For m subdomains, we can obtain an error equation analogous to (3.6). For instance,

$$e^{(n+1)} = (I - P_m) \cdots (I - P_1) e^{(n)} + \cdots,$$

where P_i is the orthogonal projection (with respect to $[\cdot, \cdot]$) of V onto V_i and $[+ \cdots]$ is a sum of m quadratic terms. Armed with Lemma 2, it is well known [9], [1] that

$$d = \|(I - P_m) \cdots (I - P_1)\|_1 < 1$$

for overlapping subdomains. In a similar way as before, we can show that the nonlinear Schwarz sequence is bounded and that

$$\begin{bmatrix} \|e^{(n+\frac{m-1}{m})}\|_1 \\ \|e^{(n+\frac{m-2}{m})}\|_1 \\ \vdots \\ \|e^{(n+\frac{1}{m})}\|_1 \\ \|e^{(n)}\|_1 \end{bmatrix} \le A^{mn} \begin{bmatrix} \|e^{(\frac{m-1}{m})}\|_1 \\ \|e^{(\frac{m-2}{m})}\|_1 \\ \vdots \\ \|e^{(\frac{1}{m})}\|_1 \\ \|e^{(0)}\|_1 \end{bmatrix}, \qquad A = \begin{bmatrix} \frac{\epsilon}{1-\epsilon} & \frac{\epsilon}{1-\epsilon} & \cdots & \frac{\epsilon}{1-\epsilon} & \frac{d}{1-\epsilon} \\ 1 & 0 & \cdots & \cdots & 0 \\ 0 & 1 & \ddots & & \vdots \\ \vdots & \ddots & \ddots & \ddots & \vdots \\ 0 & \cdots & 0 & 1 & 0 \end{bmatrix},$$

where $\epsilon = RC(M + 2\|u\|_1)$ and $e^{(n+\frac{i}{m})}$ is the error of the iterate defined on the ith subdomain. Hence a sufficient condition for convergence is that the spectral radius of A is less than one. The spectral radius is $d^{1/m} + o(\epsilon)$, and thus for all ϵ sufficiently small, the Schwarz sequence converges. Because it does not seem possible to write down an explicit expression for the spectral radius, we cannot give an explicit bound on R.

The additive Schwarz method generalizes directly to the m-subdomain case. It converges if

$$R < \frac{1 - \|I - \omega\,(P_1 + \cdots + P_m)\|_1}{m\omega C(\|u^{(0)} - u\|_1 + 2\|u\|_1)},$$

where $0 < \omega < 1/K$, where K is the minimum number of colors needed to color the subdomains in such a way that overlapping subdomains are assigned different colors.

Nonhomogeneous boundary conditions can also be treated by making a change of variable. Define $w = u - g$, where g is the Dirichlet data on $\partial\Omega$ which is extended to be a divergence-free function in $H^1(\Omega)^N$. Then the Navier–Stokes equations become

$$(w \cdot \nabla)w + (g \cdot \nabla)w + (w \cdot \nabla)g = -\nabla p + \frac{1}{R}\triangle w + G$$

for $w \in V$ and

$$G = \frac{1}{R}\triangle g + f - (g \cdot \nabla)g.$$

The analysis goes through as before. For instance, the nonlinear Schwarz sequence for $w^{(n+\frac{1}{2})}$ is defined by

$$\begin{aligned}(w^{(n+\frac{1}{2})} \cdot \nabla)w^{(n+\frac{1}{2})} + (g \cdot \nabla)w^{(n+\frac{1}{2})} + (w^{(n+\frac{1}{2})} \cdot \nabla)g \\ = -\nabla p^{(n+\frac{1}{2})} + \frac{1}{R}\triangle w^{(n+\frac{1}{2})} + G \text{ on } \Omega_1, \\ \text{div } w^{(n+\frac{1}{2})} = 0 \text{ on } \Omega_1, \\ w^{(n+\frac{1}{2})} = w^{(n)} \text{ on } \partial\Omega_1,\end{aligned}$$

the existence of which is guaranteed provided that the compatibility condition

$$\int_{\Gamma_1} w^{(0)} \cdot \nu = 0$$

is satisfied. In a similar manner as before, we obtain $e^{(n+\frac{1}{2})} = (I - P_1)e^{(n)} + RG_1(e^{(n+\frac{1}{2})})$, where

$$G_1(e^{(n+\frac{1}{2})}) = -S_1^{-1}((g \cdot \nabla)e^{(n+\frac{1}{2})} + (e^{(n+\frac{1}{2})} \cdot \nabla)g) + F_1(e^{(n+\frac{1}{2})})$$

and $e^{(n+\frac{1}{2})} = w^{(n+\frac{1}{2})} - (u - g)$. Hence we have the estimate

$$\|G_1(e^{(n+\frac{1}{2})})\|_1 \le C\,\|e^{(n+\frac{1}{2})}\|_1(2(\|u\|_1 + \|g\|_1) + \|e^{(n+\frac{1}{2})}\|_1).$$

Following the analysis as before, we obtain convergence provided that

$$R < \frac{1 - d}{2C(M + 2(\|u\|_1 + \|g\|_1))}.$$

To prove convergence for a Reynolds number which is not small, we need to get a sharper norm estimate for (3.6) than the simple one given by (3.8) (or a completely different approach than the perturbational one taken here). For example, for the nonlinear Schwarz method, if we estimate (3.6) by (3.8), then, even if we assume a stronger inequality than (3.8) by dropping the quadratic terms

$$\|e^{(n+\frac{1}{2})}\|_1 \le d\|e^{(n-\frac{1}{2})}\|_1 + 2RC\|u\|_1\|e^{(n)}\|_1 + 2RC\|u\|_1\|e^{(n+\frac{1}{2})}\|_1,$$

convergence still requires $R < (1 - d)/4C\|u\|_1$.

Other future work includes extending our results to the time dependent case and the consideration of Schwarz methods on nonoverlapping subdomains.

Acknowledgments. I thank Professor Alfio Quarteroni for an extremely beneficial discussion. I am also grateful to the referees for making many excellent suggestions.

ALGEBRAIC TWO-LEVEL PRECONDITIONERS FOR THE SCHUR COMPLEMENT METHOD*

L. M. CARVALHO†, L. GIRAUD‡, AND P. LE TALLEC§

Abstract. The solution of elliptic problems is challenging on parallel distributed memory computers since their Green's functions are global. To address this issue, we present a set of preconditioners for the Schur complement domain decomposition method. They implement a global coupling mechanism, through coarse-space components, similar to the one proposed in [Bramble, Pasciak, and Shatz, *Math. Comp.*, 47 (1986), pp. 103–134]. The definition of the coarse-space components is algebraic; they are defined using the mesh partitioning information and simple interpolation operators. These preconditioners are implemented on distributed memory computers without introducing any new global synchronization in the preconditioned conjugate gradient iteration. The numerical and parallel scalability of those preconditioners are illustrated on two-dimensional model examples that have anisotropy and/or discontinuity phenomena.

1. Introduction.

In the recent years, there has been an important development of domain decomposition algorithms for solving numerically partial differential equations. Elliptic problems are challenging since their Green's functions are global: the solution at each point depends upon the data at all other points. Nowadays some methods possess optimal convergence rates for given classes of elliptic problems. It can be shown that the condition number of the associated preconditioned systems is independent of the number of subdomains and is either independent of or logarithmically dependent on the size of the subdomains. That optimality and these quasi-optimality properties are often achieved thanks to the solution of a coarse problem defined on the whole physical domain. Through the use of coarse spaces, this approach captures the global behavior of the elliptic equations.

Various domain decomposition techniques, from the eighties and nineties, have suggested different global coupling mechanisms and various combinations between them and the local preconditioners. In the framework of nonoverlapping domain decomposition techniques, we refer, for instance, to BPS (Bramble, Pasciak, and Schatz) [2], vertex space [6, 19], and some extended balancing Neumann–Neumann [13, 14, 15], as well as FETI (finite element tearing and interconnection) [8, 16], for the presentation of major two-level preconditioners.

Even though the theory for domain decomposition techniques is well developed (see [4, 18, 20] and the references therein) for regular enough elliptic two-dimensional and three-dimensional equations, there are situations, even in two dimensions, that either are not covered by the theory or have constants appearing in the theoretical

bounds for the condition numbers which can be very large. Such situations might occur, for instance, in the solution of scalar heterogeneous, anisotropic elliptic problems. In that respect we consider in this paper two-level domain decomposition methods based on algebraic constructions of the coarse space for the solution of heterogeneous, anisotropic two-dimensional elliptic problems defined on structured or unstructured discretizations. Such numerical difficulties arise in the equations involved in semiconductor device simulation that was actually one of the main motivations for this work, as illustrated in one of our numerical examples. Through an experimental study of the numerical and parallel scalability of the preconditioned Schur complement method, we investigate some new coarse-space preconditioners. They are closely related to BPS [2], although we propose different coarse spaces to construct their coarse components. Furthermore, we propose a parallel implementation of the preconditioned Schur complement method that does not require any new global synchronization in the iteration loop of the preconditioned conjugate gradient solver.

The paper is organized as follows. In section 2, we formulate the problem and introduce the notation. In section 3, we describe the various coarse spaces we have considered when defining the preconditioners' coarse-space components. Section 4 provides some details on the parallel distributed implementation of the resulting domain decomposition algorithm. Computational results illustrating the numerical and parallel scalability of the preconditioners are given in section 5.

2. Preliminaries and notation. The purpose of this section is two-fold. First, we formulate a two-dimensional elliptic model problem. Then we introduce the notation that will allow us to define the coarse spaces we have considered in our preconditioners.

We consider the following 2nd order self-adjoint elliptic problem on an open polygonal domain Ω included in $\mathbb{R}^2$:

$$\left\{ \begin{array}{rcll} -\frac{\partial}{\partial x}(a(x,y)\frac{\partial v}{\partial x}) - \frac{\partial}{\partial y}(b(x,y)\frac{\partial v}{\partial y}) & = & F(x,y) & \text{in} \quad \Omega, \\ v & = & 0 & \text{on} \quad \partial\Omega, \end{array} \right. \tag{1}$$

where $a(x,y)$, $b(x,y) \in \mathbb{R}^2$ are bounded positive functions on Ω. We assume that the domain Ω is partitioned into N nonoverlapping subdomains $\Omega_1, \ldots, \Omega_N$ with boundaries $\partial\Omega_1, \ldots, \partial\Omega_N$. We discretize (1) either by finite differences or finite elements resulting in a symmetric and positive definite linear system with sparse possibly unstructured matrix

$$Au = f.$$

Let B be the set of all the indices of the discretized points which belong to the interfaces between the subdomains. Grouping the points corresponding to B in the vector u_B and the ones corresponding to the interior I of the subdomains in u_I, we get the reordered problem

$$\begin{pmatrix} A_{II} & A_{IB} \\ A_{IB}^T & A_{BB} \end{pmatrix} \begin{pmatrix} u_I \\ u_B \end{pmatrix} = \begin{pmatrix} f_I \\ f_B \end{pmatrix}. \tag{2}$$

Eliminating u_I from the second block row of (2) leads to the following reduced equation for u_B:

$$Su_B = f_B - A_{IB}^T A_{II}^{-1} f_I, \quad \text{where } S = A_{BB} - A_{IB}^T A_{II}^{-1} A_{IB} \tag{3}$$

is the Schur complement of the matrix A_{II} in A and is usually referred to as the Schur complement matrix.

To describe the preconditioners, we need to define a partition of B. Let V_j be the singleton sets that contain one index related to one cross point and let $V = \cup_j V_j$ be the set with all those indices; each cross point is represented by $\times$ in Figure 1.

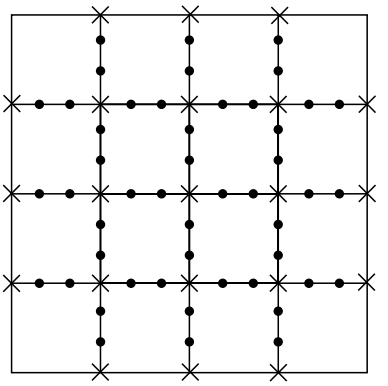

FIG. 1. *A* 4×4 *box decomposition with edge* ($\bullet$) *and vertex* ($\times$) *points.*

If $j \neq l$, $(j,l) \in \{1,2,\ldots,N\}^2$ and j and l are such that Ω_j and Ω_l are neighboring subdomains (i.e., $\partial\Omega_j$ and $\partial\Omega_l$ share at least one edge of the mesh), then we can define each edge E_i by

$$E_i = (\partial\Omega_j \cap \partial\Omega_l) - V.$$

In Figure 1, the points belonging to the m edges $(E_i)_{i=1,m}$ are represented by $\bullet$.

We can thus describe the set B as

$$B = \left(\bigcup_{i=1}^{m} E_i \right) \cup V, \tag{4}$$

which is a partition of the interface B into m edges E_i and the set V.

Here, we remark that we mix continuous curves, $\partial\Omega_i$, with sets of indices. This ambiguity can be disregarded if we consider that, in order to minimize notation, the symbols Ω_i and $\partial\Omega_i$ represent either continuous sets or discrete sets of indices associated with the grid points. In addition we will refer to as the support of a sparse vector the set of indices of its nonzero entries.

3. The preconditioners. The classical BPS preconditioner [2] can be briefly described as follows. We first define a series of projection and interpolation operators. Specifically, for each E_i we define $R_i = R_{E_i}$ as the standard pointwise restriction of nodal values on E_i. Its transpose extends grid functions in E_i by zero on the rest of the interface B. Similarly we define R_V the canonical restriction on V. Thus, we set $S_{ij} \equiv R_i S R_j^T$ and $S_V \equiv R_V S R_V^T$. Additionally, let's assume that $\Omega_1, \ldots, \Omega_N$ form the elements of a coarse grid mesh, τ^H, with mesh size H. We then define grid transfer operators between the interface and the coarse grid. R^T is an interpolation operator which corresponds to using linear interpolation between two adjacent cross points V_j, V_k (i.e., adjacent points in τ^H connected by an edge E_i) to define values on

the edge E_i. Finally, A_H is the Galerkin coarse grid operator $A_H = RAR^T$ defined on τ^H.

With these notations a very close variant of the BPS preconditioner is defined by

$$M_{BPS} = \sum_{E_i} R_i^T S_{ii}^{-1} R_i + R^T A_H^{-1} R, \tag{5}$$

as described, for instance, in this algebraic form in [4]. It can be interpreted as a generalized block Jacobi preconditioner for the Schur complement system (3) where the block diagonal preconditioning for S_V is omitted and a residual correction is used on a coarse grid. The coarse grid term $R^T A_H^{-1} R$ allows us to incorporate a global coupling between the interfaces.

This global coupling is critical for scalability. In particular, it has been shown in [2] that, when applying the original BPS technique to a uniformly elliptic operator, the preconditioned system has a condition number

$$\kappa(M_{BPS} S) = \mathcal{O}(1 + \log^2(H/h)),$$

where h is the mesh size. This implies that the condition number depends only weakly on the mesh spacing and on the number of processors. Therefore, such a preconditioner is appropriate for large systems of equations on large processor systems.

Similarly to BPS, we consider a class of preconditioners described in a generic way as

$$M = M_{local} + M_{global},$$

where

- M_{local} is a block diagonal preconditioner with one block for each edge E_i;
- M_{global} is also computed using a Galerkin formula, but involving S instead of A and using different coarse spaces and restriction operators.

In the rest of this paper, we will define various preconditioners that differ only in the definition of M_{global}. Our goal is to obtain performance similar to those of the original BPS preconditioner even in the presence of anisotropy or heterogeneity, with a simple algebraic structure and a parallel implementation strategy. In particular, for practical implementation purposes within a general purpose computer code, we do not want to refer explicitly to an underlying coarse grid, or to underlying basis functions, since these notions are always hard to identify in practice when using general grids, finite elements, or mixed finite elements.

Let U be the algebraic space of nodal vectors where the Schur complement matrix is defined, and let U_0 be a q-dimensional subspace of U. Elements of U_0 are characterized by the set of nodal values that they can achieve. This subspace will be called coarse space.

Let $R_0 : U \to U_0$ be a restriction operator which maps full vectors of U into vectors in U_0, and let $R_0^T : U_0 \to U$ be the transpose of R_0, an extension operator which extends vectors from the coarse space U_0 to full vectors in the fine space U.

The Galerkin coarse-space operator

$$A_0 = R_0 S R_0^T, \tag{6}$$

in some way, represents the Schur complement on the coarse space U_0.

The global coupling mechanism is introduced by the coarse component of the preconditioner which can thus be defined as $M_{global} = R_0^T A_0^{-1} R_0$.

The following lemma ensures the correctness of the operators with which we work.

LEMMA 1. *If the operator R_0^T is of full rank and if S is nonsingular, symmetric, and positive definite, then the matrix A_0, defined in* (6)*, is nonsingular, symmetric, and positive definite.*

The coarse-space preconditioners will differ only in the choice of the coarse space U_0 and the interpolation operator R_0^T. For convergence reasons, and similarly to the Neumann–Neumann and balancing Neumann–Neumann preconditioner [13, 14], R_0^T must be a partition of the unity in U in the sense that

$$R_0^T \mathbf{1} = \mathbf{1}, \tag{7}$$

where the symbol $\mathbf{1}$ denotes the vectors of all 1's that have different size in the right- and left-hand sides of (7).

With these notations and definitions, all the preconditioners presented in what follows can be written as

$$M = \sum_{E_i} R_i^T \tilde{S}_{ii}^{-1} R_i + R_0^T A_0^{-1} R_0, \tag{8}$$

where we usually replace S_{ii} in (5) by an approximation $\tilde{S}_{ii}$ computed using a probing technique [5, 11].

In the next section, we define various coarse spaces and restriction operators which can be used in a very general framework. The support of the basis vectors Z_k has inspired the name of the coarse spaces. Although a large number of different preconditioners can then be proposed, we restrict our study to five combinations of coarse spaces and restriction operators.

3.1. Vertex-based coarse space. The first coarse space we consider is similar to the BPS one. Each degree of freedom of U_0 is associated with one vertex V_j, and the basis vectors generating the nodal values of the elements of U_0 can be defined as follows. Let $V_k \subset V$ be a singleton set that contains the index associated with a cross point and $(E_j)_{(j \in J_k)}$ be the adjacent edges to V_k. Let m_c denote the number of vertex points; then

$$\widetilde{\mathcal{I}}_k = \bigcup_{(j \in J_k)} E_j \cup V_k$$

is the set of indices we associate with the cross point V_k to define the support of the basis vectors.

Let Z_k be a vector defined on B and $Z_k(i)$ its ith component. Then the vertex-based coarse space U_0 can be defined as

$$U_0 = \text{span}[Z_k : k = 1, \ldots, m_c], \text{ where } \quad Z_k(i) = \begin{cases} 1 & \text{if } i \in \widetilde{\mathcal{I}}_k, \\ 0 & \text{elsewhere.} \end{cases}$$

The set $\widetilde{\mathcal{I}}_k$ associated with a cross point V_k is depicted in Figure 2. The set of vectors $\mathcal{B} = \{Z_1, Z_2, \ldots, Z_{m_c}\}$ forms a basis for the subspace U_0, as these vectors span U_0 by construction and they are linearly independent.

For this coarse space, we consider three different restriction operators R_0 and their associated prolongation operator R_0^T.

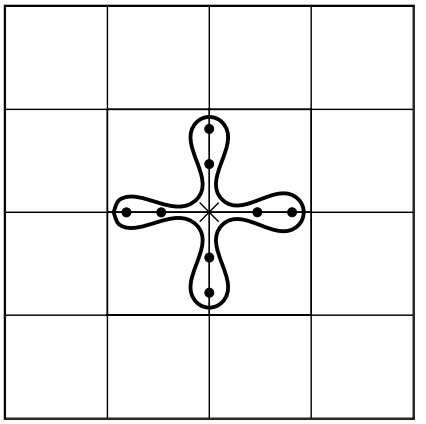

FIG. 2. *Support of one basis vector of the "vertex" coarse space.*

3.1.1. Flat restriction operator. This operator returns for each set $\widetilde{\mathcal{I}}_k$ the weighted sum of values of all the nodes in $\widetilde{\mathcal{I}}_k$. The weights are determined by the inverse of the number of sets $\widetilde{\mathcal{I}}_k,\ k \in \{1, 2, \ldots, m_c\}$, that a given node belongs to. For two-dimensional problems, the weight for the cross points is 1 and for an edge point is 1/2.

3.1.2. Linear interpolation operator. The interpolation operators in this section and the next are basically one-dimensional interpolations on the edges E_i of values defined at the cross points that are its endpoints. In this respect, let us describe them in the one-dimensional framework obtained by mapping the edge E_i on the interval (0,1) through the map $\phi(M_j) = \dfrac{\sum k \leq j |M_{k-1}M_k|}{\sum k \in E_i |M_{k-1}M_k|}$. We consider the following one-dimensional model problem:

$$\left\{ \begin{array}{rcll} -\dfrac{d}{dx}\left(a(x)\dfrac{d}{dx}u(x)\right) & = & f & \text{in (0.1)}, \\ u(x) & = & 0 & \text{at } x = 0 \text{ and } 1. \end{array} \right. \tag{9}$$

Let $H^1(0,1)$ be the standard Sobolev space on the interval (0,1) and $H_0^1(0,1)$ its subspace whose functions vanish at $x = 0$ and $x = 1$. Given a grid $x_j^h = jh, j = 0, \ldots, n$, on $(0,1)$ as the image of the original discretization of E_i, define the fine grid linear finite element space to be

$$V^h = \{v^h \in H_0^1(0,1) : v^h \text{ is linear on } [x_j^h, x_{j+1}^h], j = 0, \ldots, n-1\}$$

and denote the set of nodal basis by $\{\phi_j^h\}_{j=0}^n$.

Let $(x_i^H)_{i=1,m}$ be the set of coarse grid points defined by the vertices of the partitioning of $(0,1)$ into nonoverlapping subdomains. Now, we define the coarse subspace $V^H = span\{\phi_i^H : i = 1, \ldots, m\}$, where ϕ_i^H are the coarse grid nodal basis functions.

Since $\{\phi_i^H\}$ is a basis of V^H, which is a subspace of V^h, there exists a unique matrix R_0^T of size $n-1 \times m$ such that

$$[\phi_1^H \cdots \phi_m^H] = [\phi_1^h \cdots \phi_{n-1}^h] R_0^T,$$

which is usually referred to as the local interpolation matrix. We depict in Figure 3 an example of a coarse grid basis function that defines the linear interpolation.

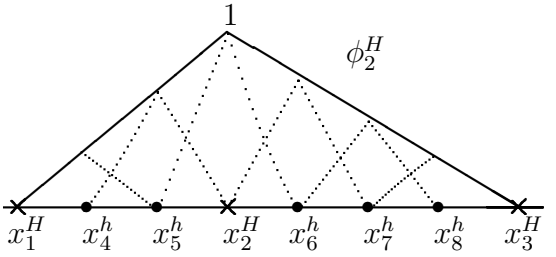

FIG. 3. *Coarse grid basis function ϕ_2^H associated with the linear interpolation.*

When we use block Jacobi as the local preconditioner combined with the vertex coarse space using this linear prolongation operator, the resulting preconditioner is equivalent to the one proposed in [2].

Let A be the matrix defined in (2). Let A_V be the Galerkin coarse grid operator associated with A defined by

$$A_V = \widetilde{R}_0 A \widetilde{R}_0^T, \tag{10}$$

where $\widetilde{R}_0$ is a restriction operator from Ω to the coarse space U_0. It has been shown [2, 20] that, in general, for elliptic problems the operator A_V is spectrally equivalent to

$$R_0 S R_0^T, \tag{11}$$

and for a few cases these coarse operators are even equal.

If we have used the approach defined by (10), the construction of the coarse space would have been reduced to some matrix-vector multiplications with A and the factorization of A_V. Nevertheless, we deal with problems for which only the spectral equivalence between (10) and (11) is ensured. For this reason, we have preferred to use the Galerkin coarse grid correction with the Schur complement matrix as described in (11) rather than the one proposed in a similar matrix form in [4] that used A_V defined by (10).

3.1.3. Operator-dependent restriction operator. The origin of the operator-dependent restriction is the operator-dependent transfer operator proposed in the framework of multigrid methods; see [23] and references therein. In [10], the authors proposed an extension of these operators for two-dimensional nonoverlapping domain decomposition methods. The general purpose of these operators is to construct from u defined on V an interpolation $\tilde{u}$ defined on B that is piecewise linear so that $a\frac{\partial \tilde{u}}{\partial x}$ and $b\frac{\partial \tilde{u}}{\partial y}$ are continuous even when either a or b in (1) are discontinuous along an edge E_i.

Similarly to the linear interpolation, we can define the operator-dependent interpolation in one-dimension through the definition of the coarse grid basis functions ϕ_i^H. In that case those basis functions are constructed by solving the following local problem in $[x_{i-1}^H, x_i^H]$:

$$\begin{cases} -\dfrac{d}{dx}(a(x)\dfrac{d}{dx}\phi_i^H) = 0 \quad \text{in } [x_{i-1}^H, x_i^H], \\ \phi_i^H(x_{i-1}^H) = 0, \phi_i^H(x_i^H) = 1. \end{cases} \tag{12}$$

In Figure 4, we depict the basis function ϕ_2^H when the function $a(x)$ is piecewise constant with some discontinuities at x_5^h and x_7^h.

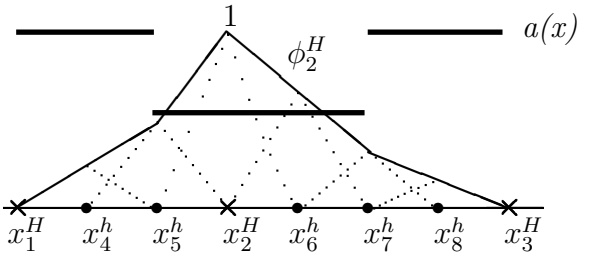

FIG. 4. *Coarse grid basis function ϕ_2^H associated with the operator-dependent interpolation.*

We omit the computational details and notice only that such operators

- can be constructed by solving one tridiagonal linear system for each E_i, which corresponds to the solution of (12). The size of the tridiagonal matrices is the number of nodes on E_i;
- reduce to a linear interpolation when $a \equiv 1$ and $b \equiv 1$;
- in one dimension reduce to the multigrid energy minimization approach [21, 22] or to the multigrid operator-dependent interpolation with harmonic averaging [10], when every other point is a coarse point (i.e., each subdomain contains only one point).

3.2. Subdomain-based coarse space. With this coarse space, we associate one degree of freedom with each subdomain. Let B be as defined in (4). Let Ω_k be a subdomain and $\partial\Omega_k$ its boundary. Then

$$\overline{\mathcal{I}}_k = \partial\Omega_k \cap B$$

is the set of indices we associate with the domain Ω_k. Figure 5 shows the elements of a certain set $\overline{\mathcal{I}}_k$.

Let Z_k be a vector defined on B and let $Z_k(i)$ be its ith component. Then the subdomain-based coarse space U_0 can be defined as

$$U_0 = \text{span}[Z_k : k = 1, \ldots, N], \text{ where } \quad Z_k(i) = \begin{cases} 1 & \text{if } i \in \overline{\mathcal{I}}_k, \\ 0 & \text{otherwise.} \end{cases}$$

Notice that for the example depicted in Figure 5, $[Z_k]$ is rank deficient. Indeed, if we consider $\tilde{v} = \sum_{i=1}^{N} \alpha_i Z_i$, where the α_i are in a checkerboard pattern, equal to -1 and $+1$, it is easy to see that $\tilde{v} = 0$.

Nevertheless, this rank deficiency can be easily removed by discarding one of the vectors of $[Z_k]$. In this particular situation, the set of vectors $\mathcal{B} = \{Z_1, Z_2, \ldots, Z_{N-1}\}$ forms a basis for the subspace U_0.

The considered restriction operator R_0 returns for each subdomain $(\Omega_i)_{i=1,N-1}$ the weighted sum of the values at all the nodes on the boundary of that subdomain. The weights are determined by the inverse of the number of subdomains in $(\Omega_i)_{i=1,N-1}$ each node belongs to. For all the nodes but the ones on $\partial\Omega_N$ (in our particular example) this weight is $1/2$ for the points on an edge and $1/4$ for the cross points. These weights can be replaced as in [13] by operator dependent weights $R_0(i,k) = a_i/(a_i + a_j)$ on the edge separating Ω_i from Ω_j, but this choice has not been tested numerically in the present work.

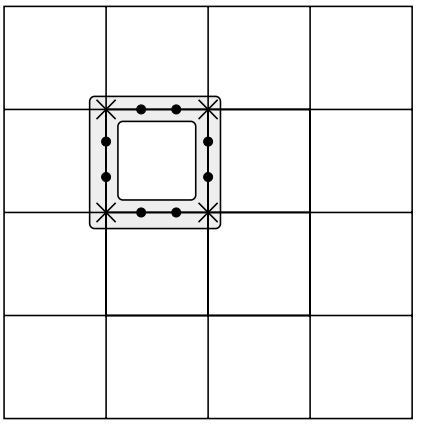

FIG. 5. *Support of one basis vector of the "subdomain" coarse space.*

Remark 1. Although used in a completely different context, this coarse space is similar to the one used in the balancing Neumann–Neumann preconditioner for Poisson-type problems [14]. We use one basis vector for each subdomain, whereas in balancing Neumann–Neumann the basis vectors are defined only for interior subdomains for solving the Dirichlet problem (1), which are the subdomains where the local Neumann problems are singular.

3.3. Edge-based coarse space. We refine the coarse space based on the subdomains, and we introduce one degree of freedom per interface between two neighboring subdomains, that is, when $\partial\Omega_i$ and $\partial\Omega_j$ share at least one edge of the mesh.

Let E_k be an edge and V_j and V_l its adjacent cross points; then

$$\hat{\mathcal{I}}_k = E_k \cup V_j \cup V_l$$

is the set of indices we associate with the edge E_k.

Let Z_k be defined on B, and let $Z_k(i)$ be its ith component. Let m_e denote the number of edges $E_i \subset B$; then the edge-based coarse space U_0 can be defined as

$$U_0 = \text{span}[Z_k : k = 1, \ldots, m_e], \qquad \text{where} \quad Z_k(i) = \begin{cases} 1 & i \in \hat{\mathcal{I}}_k, \\ 0 & \text{otherwise.} \end{cases}$$

The set $\hat{\mathcal{I}}_k$ associated with an element of the coarse space U_0 is depicted in Figure 6. The set of vectors $\mathcal{B} = \{Z_1, Z_2, \ldots, Z_{m_e}\}$ forms a basis for the subspace U_0; as before, these vectors span U_0 by construction and are linearly independent.

The considered restriction operator R_0 returns for each edge the weighted sum of the values at all the nodes on that edge. The weights are determined by the inverse of the number of edges each node belongs to. For the decomposition depicted in Figure 1, the weights for the restriction operator are 1 for points belonging to E_k and 1/4 for those belonging to V_l and V_j.

4. Parallel implementation. The independent solutions of local PDE problems expressed by the domain decomposition techniques are particularly suitable for parallel distributed computation. In a parallel distributed memory environment each

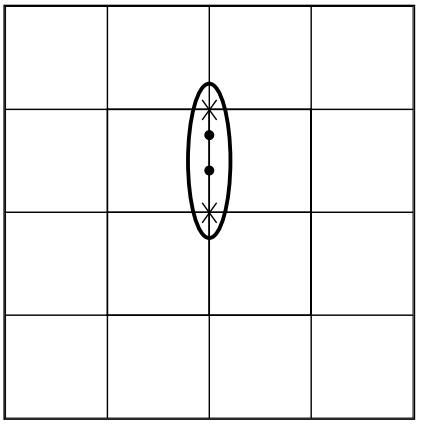

FIG. 6. *Support of one basis vector of the "edge" coarse space.*

subdomain can be assigned to a different processor. With this mapping, all but two of the basic linear algebra operations in the preconditioned conjugate gradient can be implemented either without communication or with neighbor-to-neighbor communication only. The only two steps that require global communication are the dot product computation and the solution of the coarse problem performed at each iteration. In what follows, we will describe how the construction of the coarse components of our preconditioners can be performed in parallel with only one reduction. We will also show how the coarse problem solution can be implemented without any extra global communication within the iteration loop.

4.1. Construction of the preconditioner. The linear systems associated with the coarse spaces described above are much smaller than the linear systems associated with the local Dirichlet problems, which have to be solved when computing the matrix-vector product by S. In this respect, we construct the coarse matrix A_0 once and assemble it on all the processors so that we can redundantly perform in parallel its solution at each preconditioned conjugate gradient iteration. Furthermore, we can take advantage of the structure of S and R_0 to construct A_0 in parallel. Without any communication each processor can compute the contribution of its subdomain to the entries of A_0 via matrix-vector and scalar products that involve only its local Schur complement and the vectors whose support intercepts the boundary of its subdomain. At this stage, all the processors have some nonassembled entries of A_0, and a global sum reduction (MPI_Allreduce) enables them to assemble A_0 on all the processors that can then factorize it. As the Schur complement matrix is not assembled, the most expensive part of the construction is the matrix-vector product with the local Schur complement that requires the solution of the Dirichlet problems. For each processor, the number of solutions is equal to the number of basis vector supports that intercept the boundary of the subdomain the processor is in charge of. For a box decomposition of a uniform finite elements or finite differences mesh, the number of Dirichlet problem solutions to be performed by an internal subdomain is

- four for the vertex-based coarse component,
- eight for the subdomain based coarse component (that can reduce to four for a five-point finite difference scheme as the row in A associated to the cross

points is unchanged in S),
- four for the edge-based coarse component.

4.2. Application of the preconditioner. Having made the choice of a redundant solution of the coarse component on each processor, we can further exploit this formulation to avoid introducing any new global synchronization in the preconditioned conjugate gradient iterations described below.

$$
\begin{aligned}
&x^{(0)} = 0,\ r^{(0)} = b\\
&\textbf{repeat}\\
&\quad z^{(k-1)} = Mr^{(k-1)} \qquad (13)\\
&\quad \textbf{if } k = 1 \textbf{ then}\\
&\quad\quad p^{(1)} = z^{(0)}\\
&\quad \textbf{else}\\
&\quad\quad \beta^{(k-1)} = \boxed{z^{(k-1)^T} r^{(k-1)}} / z^{(k-2)^T} r^{(k-2)}, \qquad (14)\\
&\quad\quad p^{(k)} = z^{(k-1)} + \beta^{(k-1)} p^{(k-1)} \qquad (15)\\
&\quad \textbf{endif}\\
&\quad q^{(k)} = Sp^{(k)},\\
&\quad \alpha^{(k)} = z^{(k-1)^T} r^{(k-1)} / \boxed{p^{(k)^T} q^{(k)}},\\
&\quad x^{(k)} = x^{(k-1)} + \alpha^{(k)} p^{(k)},\\
&\quad r^{(k)} = r^{(k-1)} - \alpha^{(k)} q^{(k)}\\
&\textbf{until convergence}
\end{aligned}
$$

The steps involving a potential global synchronization are boxed, while the calculation of Mr and Sp involve only neighbor-to-neighbor communication.

If we now unroll (13) in the preconditioned conjugate gradient algorithm using the general definition of the preconditioner, we have

$$
\begin{aligned}
z_k &= \left(\sum_{E_i} R_i^T \tilde{S}_{ii}^{-1} R_i + R_0^T A_0^{-1} R_0 \right) r_k\\
&= \sum_{E_i} (R_i^T \tilde{S}_{ii}^{-1} R_i r_k) + R_0^T A_0^{-1} R_0 r_k. \qquad (16)
\end{aligned}
$$

Each term of the summation in (16) is computed by one processor with possible one neighbor-to-neighbor communication. Furthermore, the numerator of (14) can also be rewritten as

$$
\begin{aligned}
(r_k, z_k) &= (r_k, Mr_k)\\
&= \left(r_k, \left(\sum_{E_i} R_i^T \tilde{S}_{ii}^{-1} R_i + R_0^T A_0^{-1} R_0 \right) r_k \right)\\
&= \sum_{E_i} (R_i r_k, \tilde{S}_{ii}^{-1} R_i r_k) + (R_0 r_k, A_0^{-1} R_0 r_k). \qquad (17)
\end{aligned}
$$

The right-hand side of (17) has two parts. The first is naturally local because it is related to the diagonal block preconditioner. The second, with the presented formulation, is global but does not require any new global reduction. $R_0 r_k$ is actually

composed of entries that are calculated in each subdomain ("interface" coarse space) or group of neighboring subdomains ("vertex" and "domain" coarse spaces). After being locally computed, the $R_0 r_k$ entries are gathered on all the processors thanks to the reduction used to assemble each local partial dot product $(R_i r_k, \tilde{S}_{ii}^{-1} R_i r_k)$. At this stage the solution $A_0^{-1} R_0 r_k$ can be performed redundantly on each processor, and β in (14) can be computed by each processor. Rewriting these steps in the iteration loop allows us to introduce the coarse component without any extra global synchronization. With this approach, we avoid a well-known bottleneck when using Krylov methods on parallel distributed memory computers.

5. Numerical experiments. We consider the solution of (1) discretized by a five-point central difference scheme on a uniform mesh using a preconditioned Schur complement method. We illustrate the numerical scalability of the proposed preconditioners on academic two-dimensional model test cases that have both anisotropy and discontinuity.

For all the experiments, the convergence is attained when the 2-norm of the residual normalized by the 2-norm of the right-hand side is less than 10^{-5}. All the computations are performed using 64-bit arithmetic. The $\tilde{S}_{ii}$ approximations in (8) are tridiagonal matrices.

5.1. Model problems. For the numerical experiments, we consider model problems that have both discontinuous and anisotropic phenomena. These difficulties arise in the equations involved in semiconductor device simulation, which was actually one of the main motivations for this study.

Figure 7 represents a unit square divided into six regions with piecewise constant functions g_j, $j = 1$ or 3. We consider the problems as having low intensity if $j = 1$ and high intensity if $j = 3$. Let a and b be the functions of the elliptic problem as described in (1). Using this notation, we can define different problems with different degrees of difficulty. In the following description, the acronyms in capital letters are used to refer to the problems in Tables 2 and 3:

- high discontinuity (HD): $a = b = g_3$,
- low discontinuity (LD): $a = b = g_1$,
- high anisotropy (HA): $a = 10^3$ and $b = 1$,
- low anisotropy (LA): $a = 10$ and $b = 1$,
- high discontinuity and high anisotropy (HDA): $a = g_3$ and $b = 1$,
- low discontinuity and low anisotropy (LDA): $a = g_1$ and $b = 1$.

The preconditioners with the coarse components are denoted in the tables:

sd: subdomain defined in section 3.2,
vl: vertex-linear defined in section 3.1 with the linear interpolation,
vo: vertex-operator-dependent defined in section 3.1.3 with the operator-dependent interpolation,
vf: vertex-flat defined in section 3.1 with the flat interpolation,
ed: edge defined in section 3.3,
no: without coarse space in this case we only use the local preconditioner (block diagonal).

5.2. Numerical behavior. We study the numerical scalability of the preconditioners by investigating the dependence of the convergence on the number and on the size of the subdomains. First, in Table 1, we give the figures for the five coarse spaces when solving the Poisson's problem. As we could expect, the behavior of all coarse-space options does not depend on the number of subdomains. There is only a

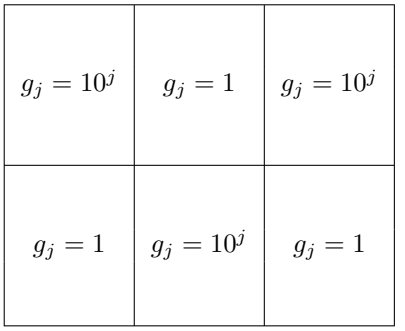

FIG. 7. *Definition of two discontinuous functions on* Ω*, the unit square of* $\mathbb{R}^2$.

small growth in the number of iterations for subdomain, vertex-flat and edge, when the number of subdomains goes from 16 to 64.

5.2.1. Dependency of the coarse preconditioners on H. In Table 2, we report the number of preconditioned conjugate gradient iterations for each model problem. For these tests, we vary the number of subdomains while keeping constant their sizes (i.e., H variable with $\frac{H}{h}$ constant). In this table each subdomain is a 16×16 grid and the number of subdomains goes from 16 up to 1024 using a box decomposition; that is 4×4 decomposition up to 32×32 decomposition.

In the first row, we see the growth of the number of iterations of a block Jacobi preconditioner without using any coarse grid correction. Its numerical behavior is well known and is governed by the following theoretical bound for its condition number (see, for instance, [4]):

$$\text{cond}(M_{\text{bJ}} S) \leq C H^{-2}(1 + \log^2(H/h)), \tag{18}$$

where M_{bJ} denotes the block Jacobi preconditioner and C is a constant independent of H and h. The number of iterations of the block Jacobi preconditioner, reported in the first row of the tables, doubles successively, which is consistent with the theoretical upper bound in (18).

For HD and LD the behavior of all coarse alternatives is similar to the one observed for Poisson's problem in Table 1, that is, the number of iterations is independent of the number of subdomains. For LA and LDA, this similarity is still true for vertex-linear and vertex-operator-dependent; the three others exhibit a slight insignificant increase in the number of iterations.

For HA, the coarse spaces subdomain-based and vertex-flat do not improve the convergence for a number of subdomains less than 1024. For vertex-linear and vertex-

operator the improvement is modest for 256 processors. It seems that on this example the condition numbers of the preconditioned linear systems with and without the coarse components are comparable, for instance, 2×10^2 with and 6×10^2 without the vertex-linear coarse component using 256 subdomains. More precisely, the smallest eigenvalue is not as affected by the use of the coarse component as it is for the other model problems. In the presence of high anisotropy (HA and HDA), the convergence rate of all the alternatives is comparable and depends on the number of subdomains, while an asymptotic behavior tends to appear when the number of subdomains increases.

5.2.2. Dependency of the coarse preconditioners on $\frac{H}{h}$. To study the sensitivity of the preconditioners to the size of the subdomains (i.e., $\frac{H}{h}$ variable with H constant), we report in Table 3 the experiments observed with 256 subdomains (16×16 box decomposition) when the size of the subdomains varies from 8×8 up to 32×32.

We observe that the convergence of all the preconditioners depends slightly on the size of the subdomains. Furthermore, in the anisotropic experiments (HA and HDA), this dependence is surprisingly negligible for the vertex-linear and vertex-operator-dependent alternatives. The number of iterations of those two preconditioners tends to be stable around 64 and 80 for the problems HA and HDA, respectively.

5.2.3. General comments. Summarizing the 48 experiments reported in Tables 2 and 3, operator-dependent had the best behavior on 19 experiments, edge on 11, and vertex-linear on one. Operator-dependent and vertex-linear had the same behavior on 15 tests, operator-dependent and edge on one, and vertex-linear, edge, and operator-dependent presented the same number of iteration in only one experiment. Although the closest variant to genuine BPS, that is, vertex-linear, appears to be quite robust on the examples considered in this paper, it is outperformed by operator-dependent for discontinuous problems and by edge on anisotropic problems. In addition, as the other vertex-based coarse components, BPS and its variants are no longer applicable when the domain partitioning does not exhibit a coarse mesh, as might be the case on unstructured meshes, while both domain- and edge-based coarse

components are still well defined.

On problems that are not highly anisotropic, all the coarse components give rise to preconditioners that are independent of or weakly dependent on the number of subdomains and that have a mild dependence on the size of the subdomains.

If we compare the LD and HD columns, we see that all the preconditioners are quite insensitive to discontinuity. Further, the vertex-operator-dependent alternative, specifically designed to handle interfaces that cross a discontinuity, has the best performance.

The numerical experiments tend to show that the most dominating component is not the granularity of the coarse space (the finest is not necessarily the best) but the restriction/interpolation operator R_0, as shown in the experiments with vertex. The restriction operator governs, in most cases, the quality of the coarse representation of the complete equation. The flat interpolation operator is always the worst and operator-dependent behaves the best on problems with discontinuities for which it was designed.

For discontinuous problems, LD and HD, vertex-operator-dependent is the most efficient, while for highly anisotropic problems, HA and HDA, edge is the most efficient for all cases but one. For LA and LDA operator-dependent and vertex-linear had the same behavior. The good performance of edge on anisotropic problems can be explained by the fact that we consider anisotropies aligned with the discretization, and because we use regular box decompositions, two opposite edges E_i of a subdomain are strongly coupled. The edge coarse space captures the strong coupling, while the other alternatives mix, and therefore miss, this information. This latter behavior is related to the fact that the supports of the basis vectors of all coarse spaces, excluding edge, contain at least two weakly coupled edges. So the transfer operators are not able, in this specific case, to retrieve and to spread the most appropriate information.

To conclude with the numerical experiments we consider results observed with a semiconductor simulation code, similar to the one described in [17], that solves the drift-diffusion equations using finite difference discretization. We omit the details of the drift-diffusion equation solution and mention only that it involves two nested iterations: the outer is a continuation loop, the inner a nonlinear Gauss–Seidel itera-

tion (Gummel's algorithm) that requires the solution of three linear systems at each step; we refer the reader to [3] and the references therein for further details on those equations and the numerical solution techniques, as well as for the description of the MOSFET semiconductor device considered for these experiments. The numbers of iterations displayed in Table 4 correspond to the average number of iterations for the linear system solutions involved in the Gummel's iterations for the last continuation step. The equations are discretized on a 257×257 nonuniform grid. This table shows that the use of one of the coarse-space preconditioners proposed in this paper enables us to significantly prevent the increase of the number of iterations when the number of subdomains is increased for the solution of a real life application.

5.3. Parallel behavior. We investigate the parallel scalability of the proposed implementation of the preconditioners. For each experiment, we map one subdomain on each processor of the parallel computer. In what follows, the number of subdomains and the number of processors will be always the same. The target computer is a 128-node T3D located at CERFACS, using MPI as message passing library. The solution of the local Dirichlet problem is performed using either the sparse direct solver MA27 [7] from the Harwell Subroutine Library or a skyline [9] solver. The factorization of the tridiagonal probed matrices, used in the local part of the preconditioners (see (8)) is performed using a LAPACK [1] band solver.

To study the parallel behavior of the code, we report the maximum elapsed time (in seconds) spent by one of the processors in each of the main steps of the domain decomposition method when the number of processors is varied for solving the standard Poisson's equation. In the following tables, the rows titled "init." correspond mainly to the time for factorizing the matrix associated with the local Dirichlet problems; "setup local" is the time to construct and factorize the probing approximations $\tilde{S}_{ii}$; "setup coarse" is the time required to construct and factorize the matrix associated with the coarse problem; "iter." is the time spent in the iteration loop of the preconditioned conjugate gradient. Finally, the row "total" permits us to evaluate the parallel scalability of the complete methods (i.e., numerical behavior and parallel implementation), while "time per iter." illustrates only the scalability of the parallel implementation of the preconditioned conjugate gradient iterations. The elapsed time corresponds to a maximum, and there is some unbalance among the processors in different kernels. Therefore the reported total time differs from the sum of the time for each individual kernel.

To illustrate the extra cost introduced by the construction and the solution of the coarse problem at each iteration, we give in Tables 5, 6, and 7 the time spent in each step of the algorithm with (left column) and without (right column) the considered coarse component of the preconditioner.

We report experiments with the domain-based coarse space in Table 5. Results with the vertex-based coarse space are displayed in Table 6. For those experiments, we use MA27 to solve the local Dirichlet problems defined on 100×100 grids. That subdomain size was the largest we could use according to the 128 MB memory available

on each node of the target computer.

We can first observe that the numerical behavior of those preconditioners is again independent of the number of subdomains. It can be seen that the parallel implementation of the Schur complement method with only a local preconditioner scales perfectly as the time per iteration is constant and does not depend on the number of processors (i.e., 0.115 seconds on 4 processors and 0.118 on 128 nodes; both figures were rounded to 0.12 seconds when reported in Table 5 and 6).

The above scalable behavior is also observed when the coarse components, vertex or subdomain, are introduced. For instance, with the vertex-based preconditioner, the time per iteration grows from 0.116 seconds on 4 processors up to 0.122 seconds on 128 processors (again rounded to 0.12 seconds in Table 6). There are two main reasons for this scalable behavior. First, the solution of the coarse problems is negligible compared to the solution of the local Dirichlet problems. Second, the parallel implementation of the coarse components does not introduce any extra global communication.

In any case the methods scale fairly well, when the number of processors grows from 8 (to solve a problem with 80,000 unknowns) up to 128 (to solve a problem with 1.28 million unknowns). The ratios between the total elapsed time expended for running on 128 and on 8 processors are 1.18, with the vertex-based coarse preconditioner, and 1.47, with the domain-based one. That latter larger value is only due to an increase of the number of iterations.

One of the most expensive kernels of this method is the factorization of the local Dirichlet problems. Therefore, the tremendous reduction in the number of iterations induced by the use of the coarse alternatives—five times fewer iterations for the vertex-based preconditioner—is not reflected directly on a reduction of the total time. The total time is an affine function of the number of iterations with an incompressible overhead due to the Cholesky factorization at the very beginning of the domain decomposition method.

Nevertheless, if we use a less efficient local solver, which will slow down the iteration time, the gap between the solution time with and without the coarse component would increase. To illustrate this behavior, we display in Table 7 the parallel performance of the vertex-based coarse preconditioner, where we replace MA27 by a skyline solver. The size of the subdomains is smaller than the size used for testing with MA27 because the skyline solver is more memory-consuming than MA27, and 80×80 is the biggest size that fits in the memory of the computer.

6. Concluding remarks. We have presented two-level preconditioners for Schur complement domain decomposition methods in two dimensions built by combining a block diagonal preconditioner, a variant of the local component of the BPS preconditioner, with a set of new algebraic coarse-space components. They are defined using the mesh partitioning information and simple interpolation operators that follow a partition of unity principle. We have illustrated their numerical behavior on a set of two-dimensional model problems that have both anisotropy and discontinuity. Those experiments tend to show that the most dominating component is not the granularity of the coarse space (the finest is not necessarily the best) but the restriction/interpolation operator R_0. This operator governs, in most cases, the quality of the coarse representation of the complete equation. Two of the new coarse alternatives present a number of iterations equal to or less than the traditional BPS on problems which have anisotropy and/or discontinuity. One of these alternatives, edge-based, is a little more expensive. Nevertheless, as the coarse part of the preconditioner impacts neither the overall construction of the two-level preconditioner nor the cost of each iteration, these alternatives are a valid contribution on the development of this area.

The experiments have been performed on regular meshes, but there is no limitation for the implementation of the proposed two-level preconditioners on unstructured grids, whereas the possible rank deficiency, which appears in the domain-coarse alternative, may be more tricky to discard.

Those numerical methods are targeted for parallel distributed memory computers. In this respect, we have proposed a message-passing implementation that does not require any new global synchronization in the preconditioned conjugate gradient iterations, which is a well-known bottleneck for Krylov methods in distributed memory environments. We illustrated that the numerical scalability of the preconditioners combined with the parallel scalability of the implementation result in a set of parallel scalable numerical methods.

Finally, we point out that two-dimensional problems with anisotropy and discontinuity arise in device modeling. In an ongoing work, some of our new coarse pre-

conditioners have been successfully implemented in a two-dimensional unstructured mixed finite element code for the simulation of semiconductor devices [12].

ASYMPTOTIC ANALYSIS OF THE LAMINAR VISCOUS FLOW OVER A POROUS BED*

WILLI JÄGER†, ANDRO MIKELIĆ‡, AND NICOLAS NEUSS†

Abstract. We consider the laminar viscous channel flow over a porous surface. The size of the pores is much smaller than the size of the channel, and it is important to determine the effective boundary conditions at the porous surface. We study the corresponding boundary layers, and, by a rigorous asymptotic expansion, we obtain Saffman's modification of the interface condition observed by Beavers and Joseph. The effective coefficient in the law is determined through an auxiliary boundary-layer type problem, whose computational and modeling aspects are discussed in detail. Furthermore, the approximation errors for the velocity and for the effective mass flow are given as powers of the characteristic pore size ε. Finally, we give the interface condition linking the effective pressure fields in the porous medium and in the channel, and we determine the jump of the effective pressures explicitly.

Key words. homogenization, periodic structures, Navier–Stokes, Beavers–Joseph, interface law, boundary layer, unbounded domain, finite elements, multigrid

1. Introduction.

Finding effective boundary conditions at the surface which separates a channel flow and a porous medium is a classical problem.

Supposing a laminar incompressible and viscous flow, we find out immediately that the effective flow in a porous solid is described by Darcy's law. In the free fluid we obviously keep the Navier–Stokes system. Hence we have two completely different systems of partial differential equations. First, Darcy's law combined with the incompressibility gives a second order equation for the pressure and a first order system for the velocity. In the Navier–Stokes system, the orders of the corresponding differential operators are different, and it is not clear what kind of conditions one should impose at the interface between the free fluid and the porous part. Clearly, due to the incompressibility, the normal mass flux should be continuous. Other classically used conditions are the continuity of the pressure and, for a free fluid, the vanishing of the tangential velocity at the interface.

Let us discuss the mathematical background of the interface conditions. It is well known that Darcy's law is a statistical result giving the average of the momentum equation (the Navier–Stokes equations) over the pore structure. Its rigorous derivation involves the weak convergence in $H(\Omega, \mathrm{div})$ (respectively, the two-scale convergence) of velocities, and only the continuity of the normal velocities is preserved. Other continuity conditions at the interface are generally lost, such that further analysis is required.

Concerning other interface conditions used in engineering literature, the vanishing

of the tangential velocity is found to be an unsatisfactory approximation, and in [2] a new condition is proposed. The condition reads

$$\nabla \vec{u}^{eff} \cdot \vec{\nu} \cdot \vec{\tau} = \alpha K^{-1/2} (\vec{u}^{eff} - \vec{v}^{f}) \cdot \vec{\tau}, \tag{1.1}$$

where $\vec{u}^{eff}$ is the effective velocity in the channel, $\vec{v}^{f}$ is the mean filtration velocity given by Darcy's law, $\vec{\tau}$ is a tangent vector to the interface, $\vec{\nu}$ is the normal into the fluid, K is the permeability of the porous medium, and the scalar α is a function of the geometry of the porous medium.

In [2], this law is derived by heuristic arguments and is justified experimentally. A theoretical attempt to derive (1.1) is undertaken in [17], and, using a statistical approach, a Brinkman type approximation in the transition layer is derived. A matching argument then allows us to obtain the formula

$$\vec{u}^{eff} \cdot \vec{\tau} = \frac{1}{\alpha} K^{1/2} \nabla \vec{u}^{eff} \cdot \vec{\nu} \cdot \vec{\tau} + \mathcal{O}(K). \tag{1.2}$$

The interested reader can also consult the lecture notes [4].

Different considerations can be found in [5] and [12]. They distinguish two cases.

(a) The pressure gradient on the side of the porous solid of the interface is normal to the interface. Consequently, we have a balanced flow on both sides of the interface. Then, using an asymptotic point of view, the following laws are obtained in [12]:

$$\vec{u}^{eff} \cdot \vec{\nu} = \vec{v}^{f} \cdot \vec{\nu}, \quad p = \text{ const.} \tag{1.3}$$

on the interface. This case describes the flows in cavities. The mathematical justification is in [9]. We shall not consider it in this paper.

(b) The pressure gradient on the side of the porous solid at the interface is not normal. This case is considered in the fundamental paper [5]. After discussing the orders of magnitude of the unknowns, it is found that on the interface the velocity of the free fluid is zero, and the pressure is continuous.

All results cited above are not mathematically rigorous. Furthermore, different approaches give different results, and two natural questions arise immediately.

(Q1) What are the correct matching conditions (i.e., conditions at the interface) between those two flow equations?

(Q2) What are the effective constants entering the matching conditions?

We are going to answer those questions in the following. In section 2, we define our problem and discuss some simple approximations. In section 3, we introduce an important auxiliary problem of boundary-layer type which we need to construct a better approximation, and section 4 gives additional results for an analogous problem on a finite strip. Then, in section 6, we show how the computation of the constants involved in the interface conditions works in practice. Finally, in section 7, the effective equations with the Beavers–Joseph type boundary condition are presented together with improved error estimates. It turns out that the difference between Darcy's pressure in the porous part and the effective channel pressure is equal to a constant multiple of the effective channel shear stress, thus contradicting [12].

2. Setting of the problem. This section deals with the equations describing fluid motion over a porous bed, under a uniform pressure gradient. We assume the condition of the experiment by Beavers and Joseph [2], i.e., a stationary laminar incompressible viscous flow.

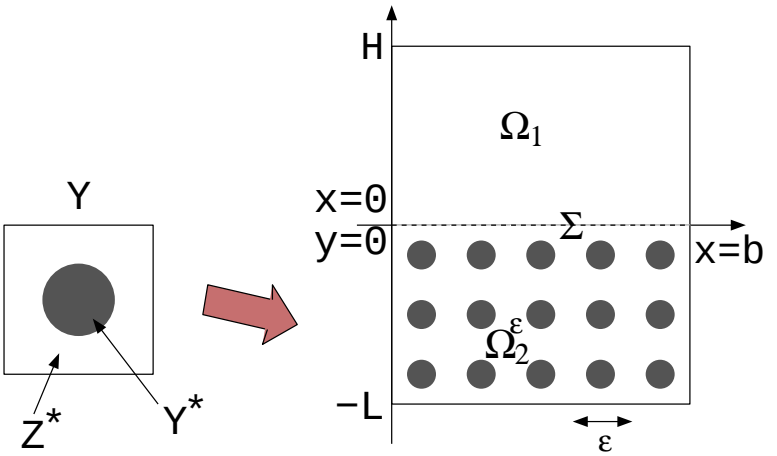

FIG. 2.1. *The flow region* Ω^ε.

For simplicity reasons, we consider a flow over a periodic porous medium with a characteristic pore size ε. The flow region $\Omega^\varepsilon \subset \Omega = (0,b) \times (-L,H)$ consists of two parts; see Figure 2.1. The upper part $\Omega_1 = (0,b) \times (0,H)$ is the channel, and the lower part Ω_2^ε is the porous medium which is obtained by putting solid obstacles of size $\varepsilon \ll b$ into the domain $\Omega_2 = (0,b) \times (-L,0)$. With Σ we denote the (permeable) interface between Ω_1 and Ω_2. More precisely, let $Y = (0,1)^2$ be made of two complementary parts, the solid part Z^* and the fluid part Y^*. It is assumed that Z^* is a smooth closed subset of Y, strictly included in Y, $Y^* \cap Z^* = \emptyset$, and $Y^* \cup Z^* = Y$. Now assume that both b and L are integer multiples of ε. Then the domain $\Omega_2 = (0,b) \times (-L,0)$ can be covered by a regular mesh of $N(\varepsilon)$ cells of size ε. Each cell $Y_k^\varepsilon = \varepsilon(Y+k)$ is divided into a fluid part $\varepsilon(Y^*+k)$ and a solid part $\varepsilon(Z^*+k)$. The fluid part Ω_2^ε of the porous medium is therefore

$$\Omega_2^\varepsilon = \Omega_2 \setminus \bigcup_{k=1}^{N(\varepsilon)} \varepsilon(Z^*+k) = \Omega_2 \cap \bigcup_{k=1}^{N(\varepsilon)} \varepsilon(Y^*+k)\,, \tag{2.1}$$

and the whole flow region is

$$\Omega^\varepsilon = \Omega_1 \cup \Sigma \cup \Omega_2^\varepsilon\,. \tag{2.2}$$

After specifying the geometry, we consider the equations determining the velocity field u^ε and the pressure field p^ε in the Beavers–Joseph experiment:

$$-\mu \triangle \vec{u}^\varepsilon + (\vec{u}^\varepsilon \nabla)\vec{u}^\varepsilon + \nabla p^\varepsilon = 0 \quad \text{in } \Omega^\varepsilon\,, \tag{2.3}$$

$$\operatorname{div} \vec{u}^\varepsilon = 0 \quad \text{in } \Omega^\varepsilon\,, \tag{2.4}$$

$$\vec{u}^\varepsilon = 0 \quad \text{on } (\partial\Omega^\varepsilon \setminus \partial\Omega) \cup (0,b) \times (\{-L\} \cup \{H\})\,, \tag{2.5}$$

$$u_2^\varepsilon = 0 \quad \text{on } (\{0\} \cup \{b\}) \times (-L,H)\,, \tag{2.6}$$

$$p^\varepsilon = p_0 \quad \text{on } \{0\} \times (-L,H)\,, \tag{2.7}$$

$$p^\varepsilon = p_b \quad \text{on } \{b\} \times (-L,H)\,. \tag{2.8}$$

For small ε, this problem is extremely difficult to solve, so one has to look for approximations. Classically, the system (2.3)–(2.8) used to be approximated by a

Poiseuille flow in Ω_1, i.e., by

$$\begin{array}{rcll} \vec{v}^0 & = & \left(\dfrac{p_b - p_0}{2b\mu} x_2(x_2 - H), 0\right) & \text{for} \quad 0 \le x_2 \le H, \\ \vec{v}^0 & = & 0 & \text{for} \quad -L \le x_2 < 0, \\ p^0 & = & \dfrac{p_b - p_0}{b} x_1 + p_0 & \text{for} \quad 0 \le x_1 \le b, \end{array} \tag{2.9}$$

and, indeed, it could be shown in [10] that (2.9) is an approximation in the following sense:

$$\int_{\Omega_p^\varepsilon} |\vec{u}^\varepsilon(x)|^2 \, dx \le C\varepsilon^3 \,, \tag{2.10}$$

$$\int_{\Omega_1} |\vec{u}^\varepsilon(x) - \vec{v}^0(x)|^2 \, dx + \int_\Sigma |\vec{u}^\varepsilon(x_1, 0)|^2 \, dx_1 \le C\varepsilon^2 \,, \tag{2.11}$$

$$\int_{\Omega_1} |p^\varepsilon(x) - p^0(x)|^2 \, dx + \int_{\Omega^\varepsilon} |\nabla \vec{u}^\varepsilon(x) - \nabla \vec{v}^0(x)|^2 \, dx \le C\varepsilon \,, \tag{2.12}$$

$$\forall \gamma > 0 : \quad b \int_0^H |u_1^\varepsilon(0, x_2) - v_1^0(x_2)| \, dx_2 \le C\varepsilon^{3/4 - \gamma} \,. \tag{2.13}$$

The above estimates indicate that in the L^2-sense $\vec{u}^\varepsilon = \vec{v}^0 + O(\varepsilon)$ in Ω_1, $\vec{u}^\varepsilon = O(\varepsilon^{3/2})$ in Ω_2, $\nabla \vec{u}^\varepsilon = \nabla \vec{v}^0 + O(\sqrt{\varepsilon})$ in Ω^ε, $p^\varepsilon = p^0 + O(\sqrt{\varepsilon})$ in Ω_1, $p^\varepsilon = O(1)$ in Ω_2^ε, $\vec{u}^\varepsilon = O(\varepsilon)$ on Σ, and the effective mass flow behaves as $-H^3 \frac{p_b - p_0}{12\mu} + O(\varepsilon^{3/4-\gamma})$.

As shown in [2] and [17], this $O(\varepsilon)$ approximation often is not good enough. Therefore, we would like to continue with the asymptotic expansion for $\vec{u}^\varepsilon$ and p^ε. Energy estimates from [10] imply that $\nabla \vec{u}^\varepsilon = \nabla \vec{v}^0 + O(\varepsilon)$ in the interior of Ω_1 but that $\nabla \vec{u}^\varepsilon = \nabla \vec{v}^0 + O(\sqrt{\varepsilon})$ globally in Ω. Further, they show that there is an oscillatory boundary layer confined to the neighborhood of Σ which can be represented in the form

$$\vec{\beta}^{bl,\varepsilon}(x) = \varepsilon \vec{\beta}^{bl}\left(\frac{x}{\varepsilon}\right) \qquad \text{and} \qquad \omega^{bl,\varepsilon}(x) = \omega^{bl}\left(\frac{x}{\varepsilon}\right), \quad x \in \Omega^\varepsilon, \tag{2.14}$$

where $\vec{\beta}^{bl}, \omega^{bl}$ are solutions to a Stokes problem on an infinite strip Z^{bl}, which we discuss in section 3.

3. The auxiliary boundary layer problem. Let $Z^{bl} = Z^+ \cup S \cup Z^-$ with $Z^+ = (0,1) \times (0, +\infty)$, $S = (0,1) \times \{0\}$, and $Z^- = (0,1) \times (-\infty, 0) \setminus \cup_{k=1}^\infty (Z^* - \{0, k\})$; see Figure 3.1. For later use, we also introduce the following notation ($k \in \mathbb{Z}$):

$$\begin{array}{c} Z_k = Z^{bl} \cap (0,1) \times (k, k+1) \,, Z_l^k = Z^{bl} \cap (0,1) \times (l, k) \,, \\ Z_{<k} = Z_{-\infty}^0 \,, Z_{>k} = Z_0^{+\infty}. \end{array} \tag{3.1}$$

Now $\{\vec{\beta}^{bl}, \omega^{bl}\}$ are the solutions to the problem

$$-\triangle_y \vec{\beta}^{bl} + \nabla_y \omega^{bl} = 0 \qquad \text{in } Z^+ \cup Z^- \,, \tag{3.2}$$

$$\operatorname{div}_y \vec{\beta}^{bl} = 0 \qquad \text{in } Z^+ \cup Z^- \,, \tag{3.3}$$

$$\left[\vec{\beta}^{bl}\right]_S (\cdot, 0) = 0 \quad \text{on } S \,, \tag{3.4}$$

$$\left[(\nabla_y \vec{\beta}^{bl} - \omega^{bl} I) e_2\right]_S (\cdot, 0) = e_1 \quad \text{on } S \,, \tag{3.5}$$

$$\vec{\beta}^{bl} = 0 \quad \text{on } \bigcup_{k=1}^\infty \{\partial Z^* - (0,k)\}, \quad \{\vec{\beta}^{bl}, \omega^{bl}\} \text{ is } y_1 - \text{periodic.} \tag{3.6}$$

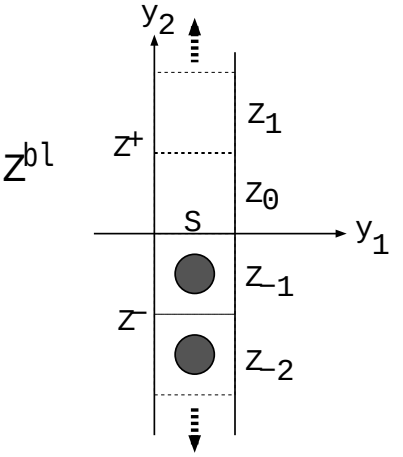

FIG. 3.1. *The boundary layer cell* Z^{bl}.

Further, in order to define ω^{bl} uniquely, we require

$$\omega^{bl}(y_1, y_2) \to 0 \quad (y_2 \to -\infty)\,. \tag{3.7}$$

A variational formulation of this problem is as follows. Find a locally square integrable vector field $\vec{\beta}^{bl} \in W$ satisfying

$$\int_{Z^{bl}} \nabla\vec{\beta}^{bl}\nabla\vec{\varphi} = -\int_S \vec{e}_1\vec{\varphi} \quad \forall\vec{\varphi} \in W, \tag{3.8}$$

where W is the function space which contains all y_1-periodic, divergence-free, locally square integrable vector fields $\vec{z}$ defined on Z^{bl}, having finite viscous energy $\int_{Z^{bl}} |\nabla\vec{z}(y_1, y_2)|^2\, dy$, and satisfying the no-slip boundary condition at the solid boundaries $\cup_{k=1}^{\infty}(\partial Z^* - \{0, k\})$.

In [9, Proposition 3.22, pp. 462–463] the following result is proved.

THEOREM 3.1. *The problem* (3.8) *has a unique solution* $\vec{\beta}^{bl} \in W$. *It is locally infinitely differentiable outside of the interface* S. *Furthermore, a pressure field* ω^{bl} *exists, which is unique up to an additive constant and locally infinitely differentiable outside of the interface* S, *such that* (3.2) *holds. In a neighborhood of* S, $\vec{\beta}^{bl} - ((y_2 - y_2^2/2)e^{-y_2}H(y_2), 0) \in W^{2,q}$ *and* $\omega^{bl} \in W^{1,q}$ *for all* $q \in [1, +\infty)$.

The following lemma states some simple properties of $\{\vec{\beta}^{bl}, \omega^{bl}\}$:

LEMMA 3.2. *Extend* $\vec{\beta}^{bl}$ *with* $\vec{\beta}^{bl} = 0$ *on* $\cup_{k=1}^{l}(Z^* - (0, k))$. *Then* $\{\vec{\beta}^{bl}, \omega^{bl}\}$ *satisfies*

$$\int_0^1 \beta_2^{bl}(y_1, a)\, dy_1 = 0 \quad \forall a \in \mathbb{R}, \tag{3.9}$$

$$\int_0^1 \omega^{bl}(y_1, a)\, dy_1 = \int_0^1 \omega^{bl}(y_1, b)\, dy_1 \quad \forall a, b \geq 0, \tag{3.10}$$

$$\int_0^1 \beta_1^{bl}(y_1, a)\, dy_1 = \int_0^1 \beta_1^{bl}(y_1, b)\, dy_1 \quad \forall a, b \geq 0, \tag{3.11}$$

$$\int_0^1 \beta_1^{bl}(y_1, 0)\, dy_1 = -\int_{Z^{bl}} |\nabla\vec{\beta}^{bl}(y)|^2\, dy\,. \tag{3.12}$$

Proof. See [11]. □

We expect that the problem (3.2)–(3.7) represents a boundary layer. This means that changes of the velocity and the pressure fields are concentrated around the interface S and vanish very rapidly with increasing distance from S. In linear elasticity, results of this type are called Saint-Venant's principle. Saint-Venant's principle is also valid in our case, and we want to discuss this in more detail.

We start our considerations with Z^+ (the part of Z^{bl} filled by the fluid). Here, one can obtain sharp decay estimates by using results for the decay of solutions of general elliptic equations (see Theorem 10.1 from [13], which is an application of Tartar's lemma).

THEOREM 3.3. *Let*

$$\xi^{bl} = \operatorname{curl} \vec{\beta}^{bl} = \frac{\partial \beta_1^{bl}}{\partial y_2} - \frac{\partial \beta_2^{bl}}{\partial y_1}\,. \tag{3.13}$$

Then, for every $a > 0$ and $\alpha \in \mathbb{N}^2$, we have

$$\left|D^\alpha \xi^{bl}(y_1, y_2)\right| \le C(\alpha, a) e^{-2\pi y_2} \quad \forall y_1 \in (0,1), y_2 > a\,. \tag{3.14}$$

Proof. See [11]. □

With the help of this estimate for $\xi^{bl} = \operatorname{curl} \vec{\beta}^{bl}$, we can prove exponentially fast stabilization of $\vec{\beta}^{bl}$.

COROLLARY 3.4. *Let*

$$C_1^{bl} := \int_0^1 \beta_1^{bl}(y_1, 0)\, dy_1\,. \tag{3.15}$$

Then for every $\alpha \in \mathbb{N}^2$, $a > 0$, and $\delta < 2\pi$ we have

$$\left|\vec{\beta}^{bl}(y_1, y_2) - (C_1^{bl}, 0)\right| + \left|D^\alpha \vec{\beta}^{bl}(y_1, y_2)\right| \le C(a, \delta, \alpha) e^{-\delta y_2} \quad \forall y_2 > a\,. \tag{3.16}$$

Proof. See [11]. □

For the pressure field ω^{bl}, we have the following.

COROLLARY 3.5. *For*

$$C_\omega^{bl} := \int_0^1 \omega^{bl}(y_1, 0)\, dy_1 \tag{3.17}$$

we have

$$\left|\omega^{bl}(y_1, y_2) - C_\omega^{bl}\right| \le C e^{-2\pi y_2} \quad \forall y_2 > 0\,. \tag{3.18}$$

Proof. See [11]. □

Now we turn our attention to the porous part Z^-. Due to the presence of the solid obstacles, our estimates are much less precise in this case.

LEMMA 3.6. *Let the distance between the solid obstacles and the boundary of the unit cell Y be bigger than or equal to $2d_*$. Let $\vec{\beta}^{bl}$ be the solution of* (3.2)–(3.7)*, and let $l \in \mathbb{Z}, l < -1$. We introduce a function $\vec{\beta}^{lower}$ by*

$$\vec{\beta}^{lower}(y) = \vec{\beta}^{bl} \quad for \quad y_2 \ge l, \tag{3.19}$$

$$\vec{\beta}^{lower}(y) = 0 \quad for \quad y_2 \le l - d_*, \tag{3.20}$$

$$\beta_1^{lower}(y) = \frac{-y_2+l-d_*}{d_*^2}\Bigg[(-y_2+l-d_*)\left(\beta_1^{bl}(y_1,y_2)+\frac{2}{d_*}\int_0^{y_1}\beta_2^{bl}(\xi,2l-y_2)\,d\xi\right)$$

$$+2\int_{y_2}^{l}\beta_1^{bl}(y,\eta)\,d\eta+2\int_0^{y_1}\beta_2^{bl}(\xi,l)d\xi+\frac{4}{d_*}\int_l^{2l-y_2}\int_0^{y_1}\beta_2^{bl}(\xi,\eta)\,d\xi\,d\eta\Bigg], \tag{3.21}$$

$$\beta_2^{lower}(y) = \frac{(y_2-l-d_*)^2}{d_*^2}\left(\beta_2^{bl}(y_1,y_2)+\frac{2}{d_*}\int_l^{2l-y_2}\beta_2^{bl}(y_1,\eta)\,d\eta\right) \tag{3.22}$$

$$for\quad y\in[0,1]\times(l-d_*,l)\,.$$

Then $\vec{\beta}^{lower}\in W\cap H^1(Z^{bl})^2$, *and with* $Z_{l,l-1}:=Z_l\cup(0,1)\times\{l\}\cup Z_{l-1}$, *we have*

$$\|\nabla\vec{\beta}^{lower}\|^2_{L^2(Z_l)^4}\le C^{lower}\|\nabla\vec{\beta}^{bl}\|^2_{L^2(Z_{l,l-1})^4}\,, \tag{3.23}$$

where the constant C^{lower} *satisfies*

$$C^{lower}\le\frac{28}{d_*^3}+C_P\frac{392}{d_*^4} \tag{3.24}$$

with C_P *denoting the Poincaré constant appearing in*

$$\left\|\beta_j^{bl}\right\|^2_{L^2(Z_{l,l-1})}\le C_P\left\|\nabla\beta_j^{bl}\right\|^2_{L^2(Z_{l,l-1})^2}. \tag{3.25}$$

If we further assume that the ball $B_\rho(1/2,1/2)$ *with radius* ρ *and center* $(1/2,1/2)$ *is contained in* Z^*, *an easy calculation in polar coordinates yields the estimate*

$$C_P\le\frac{1}{4}\ln\frac{1}{\rho\sqrt{2}}, \tag{3.26}$$

which (together with $d_*\le 1$*) results in the estimate*

$$\|\nabla\vec{\beta}^{lower}\|^2_{L^2(Z_l)^4}\le\frac{14}{\rho d_*^4}\left(2d_*+7\ln\frac{1}{\rho\sqrt{2}}\right)\|\nabla\vec{\beta}^{bl}\|^2_{L^2(Z_l\cup Z_{l-1})^4}\,. \tag{3.27}$$

Proof. This is a tedious but straightforward calculation; for details see [11]. ∎

With the help of Lemma 3.6, we are able to deduce the exponential decay of $\nabla\vec{\beta}^{bl}$.

PROPOSITION 3.7. *Assume that* $l\in\mathbb{Z}$ *with* $l<0$. *Define* $Z_{<l}$ *as in* (3.1). *Then the solution* $\vec{\beta}^{bl}$ *of problem* (3.8) *fulfills*

$$\|\nabla\vec{\beta}^{bl}\|_{L^2(Z_{<l})}\le\|\nabla\vec{\beta}^{bl}\|_{L^2(Z^-)^4}e^{-\gamma^{lower}|l|}\,, \tag{3.28}$$

where

$$\gamma^{lower}=\frac{1}{2}\ln\left(\frac{C^{lower}+1}{C^{lower}}\right). \tag{3.29}$$

Proof. If we test (3.8) with some function $\vec{\beta}^{bl}-\vec{\beta}^{lower}$, where $\vec{\beta}^{lower}$ is the function constructed in the previous lemma, this results in the estimate

$$\|\nabla\vec{\beta}^{bl}\|^2_{L^2(Z_{<l})^4}\le C^{lower}\|\nabla\vec{\beta}^{bl}\|^2_{L^2(Z_{l,l-1})^4}\,. \tag{3.30}$$

Using the hole-filling technique as in [9, Lemma 2.4] (we add $C_{lower}\|\nabla\vec{\beta}^{bl}\|^2_{L^2(Z_{<l-2})}$ to both sides of (3.30) and evaluate the resulting recursion), we obtain exponential decay with rate γ^{lower} given by (3.29). □

Applying local regularity results, one immediately obtains the following corollary.

COROLLARY 3.8. *For any $a < 0$, $\alpha \in \mathbb{N}$, the solution $\{\vec{\beta}^{bl}, \omega^{bl}\}$ decays exponentially for $y_2 \to -\infty$, i.e.,*

$$|D^\alpha \vec{\beta}^{bl}(y_1, y_2)| + |D^\alpha \omega^{bl}(y_1, y_2)| \le C(a, \alpha) e^{-\gamma^{lower}|y_2|} \tag{3.31}$$

for all $y_2 < a < 0$.

The above results imply that $\vec{\beta}^{bl}$ is a boundary-layer type velocity field and ω^{bl} is a boundary-layer type pressure. Only the constants C_1^{bl} and C_ω^{bl} from (3.15) and (3.17) will enter the effective flow equations in the channel. They contain the information about the geometry of the porous bed.

REMARK 3.9. *As we shall see from the numerical examples, in general $C_\omega^{bl} \neq 0$. However, if the geometry of Z^- is axisymmetric with respect to reflections around the axis $y_1 = 1/2$, i.e., $\partial Z^*(y_1, y_2) = \partial Z^*(1 - y_1, y_2)$, then $C_\omega^{bl} = 0$. This result is obtained by the following simple argument.*

Let Z^- be axisymmetric around the axis $y_1 = 1/2$. Let $\vec{\beta}^{bl}$ be a solution for (3.2)–(3.7). *Then $(\beta_1^{bl}(1-y_1, y_2),\ -\beta_2^{bl}(1-y_1, y_2),\ -\omega^{bl}(1-y_1, y_2))$ is also a solution. By uniqueness, it must be equal to $(\vec{\beta}^{bl}, \omega^{bl})$ and we conclude that $\omega^{bl}(1 - y_1, y_2) = -\omega^{bl}(y_1, y_2)$. Therefore,* (3.10) *implies $C_\omega^{bl} = 0$.*

4. Approximation of the boundary layer problem on a finite domain. In this section we propose a scheme for computing the actual values of C_1^{bl} and C_ω^{bl} for cases where the geometry of the porous medium is known. Since problem (3.2)–(3.7), respectively, (3.8) is defined on an infinite domain Z^{bl}, the first step is to approximate its solution with solutions of problems defined on finite domains of the form $Z_l^k := Z^{bl} \cap (0, 1) \times (l, k)$, where $l < 0 < k$. Let, therefore, $\{\vec{\beta}_{k,l}^{bl}, \omega_{k,l}^{bl}\}$ be the solution of

$$-\triangle_y \vec{\beta}_{k,l}^{bl} + \nabla_y \omega_{k,l}^{bl} = 0 \quad \text{in } Z_l^0 \cup Z_0^k\,, \tag{4.1}$$

$$\operatorname{div}_y \vec{\beta}_{k,l}^{bl} = 0 \quad \text{in } Z_l^0 \cup Z_0^k\,, \tag{4.2}$$

$$\left[\vec{\beta}_{k,l}^{bl}\right]_S(\cdot, 0) = 0 \quad \text{on } S\,, \tag{4.3}$$

$$\left[\{\nabla_y \vec{\beta}_{k,l}^{bl} - \omega_{k,l}^{bl} I\} e_2\right]_S(\cdot, 0) = e_1 \quad \text{on } S\,, \tag{4.4}$$

$$\vec{\beta}_{k,l}^{bl} = 0 \quad \text{on } \bigcup_{n=1}^{\infty} \{\partial Z^* - (0, n)\}, \quad \{\vec{\beta}_{k,l}^{bl}, \omega_{k,l}^{bl}\} \text{ is } y_1 - \text{periodic}\,, \tag{4.5}$$

with the following additional boundary conditions motivated by Corollary 3.4 and Proposition 3.7:

$$\vec{\beta}_{k,l}^{bl}(y_1, l) = (0, 0)\,, \quad (\beta_{k,l}^{bl})_2(y_1, k) = \frac{\partial (\beta_{k,l}^{bl})_1}{\partial y_2}(y_1, k) = 0 \quad \forall y_1 \in [0, 1]\,. \tag{4.6}$$

Further, to define the pressure field $\omega_{k,l}^{bl}$ uniquely, we require

$$\int_{y_2 = l} \omega_{k,l}^{bl}\, dy = 0\,. \tag{4.7}$$

Let us define

$$C^{bl}_{1,k,l} := \int_0^1 (\beta^{bl}_{k,l})_1(y_1, 0)\, dy_1 \tag{4.8}$$

and

$$C^{bl}_{\omega,k,l} := \int_0^1 \omega^{bl}_{k,l}(y_1, 0)\, dy_1 = \int_0^1 \omega^{bl}_{k,l}(y_1, a)\, dy_1 \quad \forall\, 0 < a \le k\,. \tag{4.9}$$

Then, analogous to the estimates on $(\vec{\beta}^{bl}, \omega^{bl})$ of the previous section, one can prove the following properties for the solution $(\vec{\beta}^{bl}_{k,l}, \omega^{bl}_{k,l})$ of (4.1)–(4.7).

LEMMA 4.1. *For every $0 < a < k$, $0 < \delta < 2\pi$, and $\alpha \in \mathbb{N}^2$, there are constants $C(a, \delta, \alpha)$ such that for all $y \in Z^k_a$ we have*

$$|\vec{\beta}^{bl}_{k,l}(y_1, y_2) - (C^{bl}_{1,k,l}, 0)| + |D^\alpha \vec{\beta}^{bl}_{k,l}(y_1, y_2)| \le C(a, \alpha, \delta) e^{-\delta y_2}\,, \tag{4.10}$$

and

$$\left|\omega^{bl}_{k,l}(y_1, y_2) - C^{bl}_{\omega,k,l}\right| \le C e^{-2\pi y_2}\,. \tag{4.11}$$

For $m \in \mathbb{Z}, l < m < -1$, we have

$$\|\vec{\beta}^{bl}_{k,l}\|_{L^2(Z^0_l \setminus \overline{Z^0_m})^4} \le C e^{-\gamma^{lower}|m|} \tag{4.12}$$

with γ^{lower} from (3.29). *Furthermore, for $y \in Z^0_l$*

$$|\vec{\beta}^{bl}_{k,l}(y)| + |\nabla \vec{\beta}^{bl}_{k,l}(y)| + |\omega^{bl}_{k,l}(y_1, y_2)| \le C e^{-\gamma^{lower}|y_2|}\,. \tag{4.13}$$

From these estimates we obtain the following proposition.

PROPOSITION 4.2. *Let $\{\vec{\beta}^{bl}_{k,l}, \omega^{bl}_{k,l}\}$ be the solution of problem* (4.1)–(4.7). *Then, for every $\delta < 2\pi$, a constant C exists such that*

$$\|\nabla \vec{\beta}^{bl}_{k,l} - \nabla \vec{\beta}^{bl}\|_{L^2(Z^k_l)} \le C(e^{-\delta k} + e^{-\gamma^{lower}|l|})\,. \tag{4.14}$$

Proof. Let $\xi := \vec{\beta}^{bl} - \vec{\beta}^{bl}_{k,l}$ and $\omega := \omega^{bl} - \omega^{bl}_{k,l}$. Then (ξ, ω) is y_1-periodic, vanishes on $\cup_{k=1}^{l}(\partial Z^* - (0, k))$, and solves the Stokes equation in Z^k_l. Set

$$\hat{\xi} := \begin{cases} \xi\,, & l + 1 \le y_2, \\ \xi^{lower}\,, & l + 1 - d_* \le y_2 < l + 1, \\ 0\,, & l < y_2 < l + 1 - d_*, \end{cases} \tag{4.15}$$

where ξ^{lower} is derived from ξ in the same way as $\vec{\beta}^{lower}$ was derived from $\vec{\beta}^{bl}$ in Lemma 3.6. Testing the momentum equation with $\hat{\xi}$, we obtain

$$\int_{Z^k_{l+1}} |\nabla \xi|^2 + \int_{l+1-d_*}^{l+1} \int_0^1 \nabla \xi \nabla \xi^{lower} = \int_0^1 (\nabla \xi - \omega I)\vec{e}_2 \xi\, dy_1\, |_{y_2 = k}\,. \tag{4.16}$$

Now note that ω may be replaced by $\omega - c$ for an arbitrary $c \in \mathbb{R}$ due to $\int_{y_2 = \text{const}} \xi_2 = 0$. Then we can apply the exponential stabilization results for $\{\vec{\beta}^{bl}, \omega^{bl}\}$ and $\{\vec{\beta}^{bl}_{k,l}, \omega^{bl}_{k,l}\}$ from (3.16), (3.18), (4.10), and (4.11) to obtain (4.14). ∎

The approximation error between C_1^{bl} and $C_{1,k,l}^{bl}$ can then be estimated as follows.

COROLLARY 4.3. *For every $\delta < 2\pi$, there is a constant C such that*

$$\left|C_1^{bl} - C_{1,k,l}^{bl}\right| \le C(e^{-2\pi k} + e^{-\gamma^{lower}|l|})\,. \tag{4.17}$$

Proof. Note that

$$\left|C_1^{bl} - C_{1,k,l}^{bl}\right| = \left|\int_{Z_0} \beta_1^{bl} - (\beta_{k,l}^{bl})_1\right| \le \left\|\beta_1^{bl} - (\beta_{k,l}^{bl})_1\right\|_{L^2(Z_0)}, \tag{4.18}$$

which can be estimated as desired by using Poincaré's inequality on $Z_0 \cup Z_{-1}$ together with (4.14). □

In order to obtain estimates for the pressure difference $\omega_{k,l}^{bl} - \omega^{bl}$, we need the following result.

LEMMA 4.4. *For each $F \in L^2(Z_l^k)$ satisfying $\int_{Z_l^k} F = 0$, there is a function $\vec{\varphi} \in H^1(Z_l^k)$ vanishing on the boundaries $y_2 = k$, $y_2 = l$, and $\cup_{k=1}^{l}(\partial Z^* - (0,k))$ and satisfying* $\operatorname{div}\vec{\varphi} = F$ *together with the stability estimate*

$$\|\nabla\vec{\varphi}\|_{L^2(Z_l^k)} \le C(k+|l|)\|F\|_{L^2(Z_l^k)}\,. \tag{4.19}$$

More generally, if $F \in H^r(Z_l^k)$ for some integer $r \ge 0$, then $\vec{\varphi}$ can be chosen such that

$$\|\vec{\varphi}\|_{H^r(Z_l^k)} \le C(k+|l|)\|F\|_{H^{r-1}(Z_l^k)}\,. \tag{4.20}$$

Proof. The proof is similar to the proof of Lemma 3.4 in [9] and can be found in [11]. □

With the help of this lemma we obtain the following proposition.

PROPOSITION 4.5. *Let ω^{bl} and $\omega_{k,l}^{bl}$ be the pressure fields determined by* (3.2)–(3.7)*, respectively,* (4.1)–(4.7)*. Then, for every $\delta < 2\pi$, there is a constant C such that*

$$\left\|\omega^{bl} - \omega_{k,l}^{bl}\right\|_{L^2(Z_l^k)} \le C(k+|l|)(e^{-\delta k} + e^{-\gamma^{lower}|l|})\,. \tag{4.21}$$

For the difference $C_\omega^{bl} - C_{\omega,k,l}^{bl}$ we have the better estimate

$$\left|C_\omega^{bl} - C_{\omega,k,l}^{bl}\right| \le C\sqrt{|l|}(e^{-\delta k} + e^{-\gamma^{lower}|l|})\,. \tag{4.22}$$

Proof. Set $\bar{\omega} := \frac{1}{|Z_l^k|}\int_{Z_l^k}(\omega^{bl} - \omega_{k,l}^{bl})$, and let $F := \omega^{bl} - \omega_{k,l}^{bl} - \bar{\omega}$. Since $\int_{Z_l^k} F = 0$, Lemma 4.4 yields a function $\vec{\varphi}$ which we can use as a test function in the difference of momentum equations

$$-\triangle(\vec{\beta}^{bl} - \vec{\beta}_{k,l}^{bl}) + \nabla(\omega^{bl} - \omega_{k,l}^{bl}) = 0\,. \tag{4.23}$$

Inserting $\bar{\omega}$ in the pressure term, testing with $\vec{\varphi}$, and doing a partial integration, we obtain

$$\int_{Z_l^k} \nabla(\vec{\beta}^{bl} - \vec{\beta}_{k,l}^{bl})\nabla\vec{\varphi}\,dx = \int_{Z_l^k} F^2\,dx\,. \tag{4.24}$$

If we now use the stability estimate (4.19) together with (4.14), this yields

$$\left\|\omega_{k,l}^{bl} - \omega^{bl} - \bar{\omega}\right\|_{L^2(Z_l^k)} \le C(k+|l|)(e^{-2\pi k} + e^{-\gamma^{lower}|l|})\,. \tag{4.25}$$

Finally, to estimate $\bar{\omega}$, let $r_j := \int_{Z_j} \omega(y)$. Then we have $|\bar{\omega}| \le |r_l| + \sum_{j=l}^{-1} |r_{j+1} - r_j|$. By Theorem 3.7 of [9], we also have

$$|r_{j+1} - r_j| \le C \|\nabla(\vec{\beta}^{bl} - \vec{\beta}^{bl}_{k,l})\|_{L^2(Z_j^{j+2})}\,, \tag{4.26}$$

which can be used together with (4.13) to estimate

$$|\bar{\omega}| \le C e^{-\gamma^{lower}|l|} + C\sqrt{|l|}\|\nabla(\vec{\beta}^{bl} - \vec{\beta}^{bl}_{k,l})\|_{L^2(Z_l^1)}\,. \tag{4.27}$$

Using the triangle inequality in (4.25) together with (4.27) and (4.14), we obtain (4.21).

In order to get (4.22), we note that

$$\left|C^{bl}_{\omega} - C^{bl}_{\omega,k,l}\right| = |r_0| \le |r_l| + \sum_{j=l}^{-1} |r_{j+1} - r_j|\,, \tag{4.28}$$

such that the estimate follows directly from (4.27) and (4.14). ∎

We complete this section with a regularity result, which we will need in the following.

PROPOSITION 4.6. *Let $f \in L^2(Z_l^k)^2$, and let $\{\xi, \pi\}$ be the y_1-periodic solution of the nonhomogeneous Stokes system with right-hand side f in Z_l^k, boundary conditions*

$$\xi = 0 \quad \text{on } \{y_2 = l\} \cup \bigcup_{k=1}^{l} (\partial Z^* - (0,k))\,, \quad \xi_2 = \frac{\partial \xi_1}{\partial y_2} = 0 \quad \text{on } \{y_2 = k\}\,, \tag{4.29}$$

and pressure normalization $\int_{y_2=l} \pi \, dy = 0$. Then we have the estimate

$$\begin{aligned} \|\nabla\xi\|_{L^2(Z_l^k)} + \|\xi_2\|_{L^2(Z_l^k)} + \left\| \frac{\xi_1}{1 + \max\{y_2, 0\}} \right\|_{L^2(Z_l^k)} + \left\|D^2\xi\right\|_{L^2(Z_l^k)} + \|\nabla\pi\|_{L^2(Z_l^k)} \\ \le C(\|f_2\|_{L^2(Z_l^k)} + \|f_1(1 + \max\{y_2, 0\})\|_{L^2(Z_l^k)}) \end{aligned} \tag{4.30}$$

with a constant C independent of k and l.

Proof. The proof is rather technical but standard. For details, see [11]. ∎

COROLLARY 4.7. *Let $\{\vec{\beta}^{bl}_{k,l}, \omega^{bl}_{k,l}\}$ be the solution to* (4.1)–(4.7), *and let*

$$\tilde{\beta} := \vec{\beta}^{bl}_{k,l} - \vec{e_1} \max\left\{ y_2 - \frac{y_2^2}{2}, 0 \right\} \frac{(k-1)e^{-y_2} + e^{-k}(1 - 2k + \frac{k^2}{2})}{k - 1 + e^{-k}(1 - 2k + \frac{k^2}{2})}\,. \tag{4.31}$$

Then

$$\|D^2\tilde{\beta}\|_{L^2(Z_l^k)} + \left\|\nabla\omega^{bl}_{k,l}\right\|_{L^2(Z_l^k)} \le C\,, \tag{4.32}$$

where C can be chosen independent from k and l.

5. Discretization. Now we turn our attention to the discretization of problem (4.1)–(4.7). Essentially, we use a stabilized finite element discretization in the sense of [8], [3]. Unfortunately, in both of these papers only polygonal domains were considered, so the direct application of these results to our domain Z_l^k is unsatisfying because of the curved boundaries $\cup_{k=1}^{l}(\partial Z^* - (0,k))$. We resolve this difficulty by using generalized domain partitions given by nonlinear mappings of the elements while

essentially keeping the approximation results known for usual domain partitions with linear mappings; see [19], [20], [1], [15]. While this is very convenient theoretically, the practical implementation will usually be too complicated. Therefore, it is important that the use of a simpler polygonal approximation of the domain can be interpreted as a perturbation of this approach; see the discussion at the end of this section.

Let Ω be a Lipschitz domain, and let $\mathcal{T}_h$ be a partition of Ω in subsets e, called elements, where each element e is the image of a reference element $\hat{e}$ under a mapping $\Phi_e : \hat{e} \to e$, where $\hat{e}$ is either the reference triangle $\hat{T} := \{(x_1, x_2) \mid x_1 \geq 0, x_2 \geq 0, x_1 + x_2 \leq 1\}$ or the reference quadrangle $\hat{Q} := [0,1]^2$.

We require the following properties of the partition $\mathcal{T}_h$.

1. $\cup_{e \in \mathcal{T}_h} e = \bar{\Omega}$.
2. For two elements $e \neq e'$ we have $\mathrm{int}(e) \cap e' = \emptyset$.
3. A side of an element e (which is defined as the image of a side of $\hat{e}$) is either a subset of $\partial\Omega$ or the side of exactly one other element $e' \neq e$. In the second case, we require that the mapping $\Phi_{e'}^{-1} \circ \Phi_e$ restricted to the corresponding side of $\hat{e}$ is linear.
4. The $\Phi_e : \hat{e} \to e$ are bi-Lipschitzian mappings with
$$\|\nabla \Phi_e\|_\infty \leq C_1 \operatorname{diam}(e)\,, \quad \left\|\nabla \Phi_e^{-1}\right\|_\infty \leq C_1 \operatorname{diam}(e)^{-1} \tag{5.1}$$
for some constant $C_1 > 0$.
5. $\Phi_e \in W^{2,\infty}$, with $\|D^2 \Phi_e\|_\infty \leq C_2 \operatorname{diam}(e)^2$.
6. For simplicity reasons, we consider only quasi-uniform partitions, i.e., a constant $C_3 > 0$ exists such that for $h := \max_{e \in \mathcal{T}_h} \operatorname{diam}(e)$ we have $\operatorname{diam}(e) \geq C_3 h$ for all $e \in \mathcal{T}_h$.

Arbitrarily fine triangulations of this kind exist, which can be shown by modifying triangulations of polygonal approximations of the domain Ω; see [19]. The quality of the domain partition $\mathcal{T}_h$ is determined by the constants C_1, C_2, C_3. Uniform refinement of such a partition results in a new partition which still has the above properties (especially property 5).

Next let
$$\mathcal{FE}(\hat{e}) = \begin{cases} P_1 & \text{if} \quad e = \hat{T}, \\ Q_1 & \text{if} \quad e = \hat{Q}, \end{cases} \tag{5.2}$$
where P_1 is the space of linear polynomials, and Q_1 is the span of P_1 and the polynomial $x_1 x_2$. With these finite elements, we can define the space
$$\mathcal{S}_h := \{\psi \in H^1(\Omega) \mid \ \forall e : \psi \circ \Phi_e \in \mathcal{FE}(\hat{e})\}\,. \tag{5.3}$$

The following approximation result is then the substitute for approximation results on triangulations with linear element mappings.

THEOREM 5.1. *Let Ω, $\mathcal{T}_h$, and $\mathcal{S}_h$ be as above. Then, for $u \in H^1(\Omega)$, a $u_h \in \mathcal{S}_h$ exists such that*
$$\|u - u_h\|_{L^2(\Omega)} + h\|\nabla u_h\|_{L^2(\Omega)} \leq Ch\|\nabla u\|_{L^2(\Omega)}\,. \tag{5.4}$$
Second, for $u \in H^2(\Omega)$, a $u_h \in \mathcal{S}_h$ exists such that
$$\|u - u_h\|_{L^2(\Omega)} + h\|\nabla(u - u_h)\|_{L^2(\Omega)} \leq Ch^2(\|\nabla u\|_{L^2(\Omega)} + \left\|D^2 u\right\|_{L^2(\Omega)})\,. \tag{5.5}$$
Additionally, if u has zero boundary values on some component of $\partial\Omega$, then u_h can also be chosen such that it has zero boundary values on that boundary component.

In all cases, the constants depend only on the smoothness of the domain and the quality of the domain partition $\mathcal{T}_h$.

Proof. See [19], [20] for the case of (deformed) triangular elements, and see [15], where the case of (deformed) quadrilaterals is also handled by using a generalized interpolation operator of Clément type. ∎

REMARK 5.2. *In contrast to standard interpolation results for triangulations with linear element mappings, the term $\|\nabla u\|_{L^2(\Omega)}$ appears on the right-hand side of* (5.5). *This is due to the fact that linear functions are no more interpolated exactly (in contrast to constant functions). Note that this estimate is possible only because of the Φ_e approximating linear mappings in the limit* $\operatorname{diam}(e) \to 0$ *(see property* 5 *required for the partition $\mathcal{T}_h$).*

Now, let $\Omega = Z_l^k$, and let $\mathcal{T}_h$ be a domain partition of Z_l^k (fitting across the lateral boundaries, where periodic boundary conditions are prescribed for problem (3.2)–(3.7)). Then define $\mathcal{S}_h$ analogously to (5.3) as

$$\mathcal{S}_h := \{\psi \in H^1(Z_l^k) \mid \psi \text{ is } y_1 - \text{periodic } \wedge\ \forall e : \psi \circ \Phi_e \in \mathcal{FE}(\hat{e})\}\,, \tag{5.6}$$

and ansatz spaces for velocity and pressure

$$\vec{H}_h := \Bigg\{ \vec{\varphi}_h \in \mathcal{S}_h^2 \mid \vec{\varphi}_h = 0 \text{ on } \{y_2 = l\} \cup \bigcup_{k=1}^{l} (\partial Z^* - (0,k)),$$

$$(\vec{\varphi}_h)_2 = 0 \text{ on } \{y_2 = k\} \Bigg\}, \tag{5.7}$$

$$L_h := \left\{ \psi_h \in \mathcal{S}_h \mid \int_{y_2=l} \psi_h \, dy = 0 \right\}. \tag{5.8}$$

We now search for $(\vec{\beta}_{k,l,h}^{bl}, \omega_{k,l,h}^{bl}) \in \vec{H}_h \times L_h$, which is the solution to

$$\int_{Z_l^k} \nabla \vec{\beta}_{k,l,h}^{bl} \nabla \vec{\varphi}_{k,l,h} \, dy + \int_{Z_l^k} \nabla \omega_{k,l,h}^{bl} \vec{\varphi}_{k,l,h} \, dy = -\int_S \vec{\varphi}_{k,l,h} \cdot \vec{e}_1\,, \tag{5.9}$$

$$\int_{Z_l^k} \operatorname{div} \vec{\beta}_{k,l,h}^{bl} \chi_{k,l,h} + \alpha \sum_{Q \in \mathcal{T}_h} h_Q^2 \int_Q \nabla \omega_{k,l,h}^{bl} \nabla \chi_{k,l,h} \, dy = 0 \tag{5.10}$$

for all $(\vec{\varphi}_{k,l,h}, \chi_{k,l,h}) \in \vec{H}_h \times L_h$. The second term in (5.10) must be included for the above pair of ansatz spaces to stabilize the discretization; see [8], [3]. The constant α can be any positive number. The following error estimates then hold.

PROPOSITION 5.3. *Let $\mathcal{T}_h, \vec{H}_h, L_h$ be defined as above. Assume that the interior boundary $S = \{y_2 = 0\}$ is aligned with the sides of the elements of $\mathcal{T}_h$, let $(\vec{\beta}_{k,l}^{bl}, \omega_{k,l}^{bl})$ be the solution of problem* (4.1)–(4.7)*, and let $(\vec{\beta}_{k,l,h}^{bl}, \omega_{k,l,h}^{bl}) \in \vec{H}_h \times L_h$ be the solution of* (5.9)–(5.10). *Furthermore, let*

$$R(\vec{\beta}_{k,l}^{bl}, \omega_{k,l}^{bl}) = \|\nabla \vec{\beta}_{k,l}^{bl}\|_{L^2(Z_l^k)} + \|D^2 \vec{\beta}_{k,l}^{bl}\|_{L^2(Z_0^k)} + \|D^2 \vec{\beta}_{k,l}^{bl}\|_{L^2(Z_l^0)} + \|\nabla \omega_{k,l}^{bl}\|_{L^2(Z_l^k)}\,.$$

Then we have an error estimate in the viscous energy norm of the form

$$\|\nabla(\vec{\beta}_{k,l,h}^{bl} - \vec{\beta}_{k,l}^{bl})\|_{L^2(Z_l^k)} \le ChR(\vec{\beta}_{k,l}^{bl}, \omega_{k,l}^{bl})\,, \tag{5.11}$$

together with a stability estimate for the pressure gradient of the form

$$\left(\sum_Q h_Q^2 \big\|\nabla(\omega_{k,l,h}^{bl} - \omega_{k,l}^{bl})\big\|_{L^2(Q)}^2 \right)^{\frac{1}{2}} \le ChR(\vec{\beta}_{k,l}^{bl}, \omega_{k,l}^{bl})\,. \tag{5.12}$$

We further have the L^2-error estimate for the pressure

$$\left\| \omega^{bl}_{k,l,h} - \left(\omega^{bl}_{k,l} - \frac{1}{\left|Z^k_l\right|} \int_{Z^k_l} \omega^{bl}_{k,l}\, dy \right) \right\|_{L^2(Z^k_l)} \leq C(k+|l|)hR(\vec{\beta}^{bl}_{k,l}, \omega^{bl}_{k,l}) \tag{5.13}$$

and the velocity

$$\|\vec{\beta}^{bl}_{k,l,h} - \vec{\beta}^{bl}_{k,l}\|_{L^2(Z^k_l)} \leq C(k+1)h^2 R(\vec{\beta}^{bl}_{k,l}, \omega^{bl}_{k,l}) \tag{5.14}$$

with a constant C which is independent of k and l.

Proof. The proof can be done as in [8], [3], or [7] with the following modifications. First, on our more general domain partitions, the approximation results from Theorem 5.1 replacing the standard ones. Second, [8], [3], [7] handle only the Dirichlet case. However, one can easily check that their proofs can be transferred with almost no changes because the slip boundary condition still allows for partial integration with vanishing boundary terms. For (5.13), the proof uses the assertion of Lemma 4.4 such that the factor $k+|l|$ needs to be included in the estimate. For (5.14), one needs the H^2-regularity estimate from Proposition 4.6 which introduces the factor $k+1$. ∎

We now describe the definition of the discrete approximations to $C^{bl}_{1,k,l}$ and $C^{bl}_{\omega,k,l}$. First, we set

$$C^{bl}_{1,k,l,h} := \int_S (\beta^{bl}_{k,l,h})_1 \,. \tag{5.15}$$

Second, in order to obtain good error estimates for the numerical approximation of $C^{bl}_{\omega,k,l}$, we define $C^{bl}_{\omega,k,l,h}$ as a smoothly weighted average of the pressure field in the following way. Let $\tilde{\lambda} : [0,1] \to [0,1]$ be a Lipschitz-continuous function satisfying $\lambda(0) = 0$, $\lambda(1) = 1$, and $\int_0^1 \lambda(x)\, dx = 1$. Then define $\tilde{\lambda} : Z^k_l \to \mathbb{R}$ as

$$\tilde{\lambda}(y_1, y_2) = \begin{cases} \lambda(y_2 - (k-1)) & \text{for} \quad y_2 \geq k-1, \\ -\left(\int_{Z_{-1}} \lambda(-y_2)\, dy \right)^{-1} \lambda(l+1-y_2) & \text{for} \quad y_2 \leq l+1, \\ 0 & \text{elsewhere.} \end{cases} \tag{5.16}$$

It is obvious that $\int_{Z_k} \tilde{\lambda}(y)\, dy = -\int_{Z_l} \tilde{\lambda}(y)\, dy = 1$, such that we may approximate $C^{bl}_{\omega,k,l}$ by

$$C^{bl}_{\omega,k,l,h} := \int_{Z^k_l} \tilde{\lambda}(y)\, \omega^{bl}_{k,l,h}(y)\, dy \,. \tag{5.17}$$

Then we can prove the following proposition.

PROPOSITION 5.4. *For $C^{bl}_{1,k,l,h}, C^{bl}_{\omega,k,l,h}$ given by* (5.15), (5.17) *we have the estimates*

$$\left| C^{bl}_{1,k,l,h} - C^{bl}_{1,k,l} \right| \leq C(k+1)h^2 \,, \tag{5.18}$$

$$\left| C^{bl}_{\omega,k,l,h} - C^{bl}_{\omega,k,l} \right| \leq C(k+1)(k+|l|)h^2 + Ce^{-\gamma^{lower}|l|} \,. \tag{5.19}$$

Proof. In order to show (5.18), we use the definitions (4.8) and (5.15) in the momentum equations (4.1) and (5.9) to obtain

$$C^{bl}_{1,k,l,h} - C^{bl}_{1,k,l} = \int_S (\vec{\beta}^{bl}_{k,l,h} - \vec{\beta}^{bl}_{k,l}) \vec{e_1}\, ds$$
$$= \int_{Z^k_l} \nabla \vec{\beta}^{bl}_{k,l} \nabla (\vec{\beta}^{bl}_{k,l} - \vec{\beta}^{bl}_{k,l,h})\, dx + \int_{Z^k_l} \nabla \omega^{bl}_{k,l} (\vec{\beta}^{bl}_{k,l} - \vec{\beta}^{bl}_{k,l,h})\, dx$$
$$= \int_{Z^k_l} |\nabla (\vec{\beta}^{bl}_{k,l} - \vec{\beta}^{bl}_{k,l,h})|^2\, dx - \int_{Z^k_l} \nabla (\omega^{bl}_{k,l} - \omega^{bl}_{k,l,h}) \vec{\beta}^{bl}_{k,l,h}\, dx + \int_{Z^k_l} \nabla \omega^{bl}_{k,l} (\vec{\beta}^{bl}_{k,l} - \vec{\beta}^{bl}_{k,l,h})\, dx\,.$$

Here, the first term is of order $O(h^2)$ by (5.11), the second term can be estimated as

$$\int_{Z^k_l} \nabla (\omega^{bl}_{k,l} - \omega^{bl}_{k,l,h}) \vec{\beta}^{bl}_{k,l,h}\, dx = \int_{Z^k_l} \nabla (\omega^{bl}_{k,l} - \omega^{bl}_{k,l,h}) (\vec{\beta}^{bl}_{k,l,h} - \vec{\beta}^{bl}_{k,l})\, dx = O((k+1)h^2)$$

by (5.14), and, if one applies (5.10), the third term can be estimated as

$$\int_{Z^k_l} \nabla \omega^{bl}_{k,l} (\vec{\beta}^{bl}_{k,l} - \vec{\beta}^{bl}_{k,l,h})\, dx = \int_{Z^k_l} \nabla (\omega^{bl}_{k,l} - \omega^{bl}_{k,l,h}) (\vec{\beta}^{bl}_{k,l} - \vec{\beta}^{bl}_{k,l,h}) + \alpha \sum_{Q \in \mathcal{T}_h} h_Q^2 \int_Q \left| \nabla \omega^{bl}_{k,l,h} \right|^2.$$

Next, if we use (5.14) and (5.12), we can see that the resulting terms are of order $O((k+1)h^2)$ and $O(h^2)$, respectively. Thus we have shown (5.18).

In order to show the estimate (5.19), we first note that

$$C^{bl}_{\omega,k,l} - C^{bl}_{\omega,k,l,h} = \int_{Z^k_l} (\omega^{bl}_{k,l}(y) - \omega^{bl}_{k,l,h}(y)) \tilde{\lambda}(y)\, dy + O(e^{-\gamma^{lower}|l|}) \tag{5.20}$$

by (4.13), (4.9), and (5.17). Next let $\vec{\varphi} \in H^2(Z^k_l)$ be the vector field given by Lemma 4.4, which satisfies $\operatorname{div} \vec{\varphi} = \tilde{\lambda}$, $\vec{\varphi} = 0$ on ∂Z^k_l, and

$$\left\| D^2 \vec{\varphi} \right\|_{L^2(Z^k_l)} \leq C(k + |l|)\,. \tag{5.21}$$

Furthermore, Theorem 5.1 yields the existence of an interpolating vector field $\vec{\varphi}_h \in \vec{H}_h$ which fulfills

$$\|\vec{\varphi} - \vec{\varphi}_h\|_{L^2(Z^k_l)} + h \|\nabla (\vec{\varphi} - \vec{\varphi}_h)\|_{L^2(Z^k_l)} \leq C h^2 \left\| D^2 \vec{\varphi} \right\|_{L^2(Z^k_l)}. \tag{5.22}$$

By using this, we can estimate the first term from the right-hand side of (5.20) as follows:

$$\int_{Z^k_l} (\omega^{bl}_{k,l} - \omega^{bl}_{k,l,h})\, \tilde{\lambda}\, dy = \int_{Z^k_l} (\omega^{bl}_{k,l} - \omega^{bl}_{k,l,h}) \operatorname{div} \vec{\varphi}\, dy = \int_{Z^k_l} \nabla (\omega^{bl}_{k,l} - \omega^{bl}_{k,l,h})\, \vec{\varphi}\, dy$$
$$= \int_{Z^k_l} \nabla (\omega^{bl}_{k,l} - \omega^{bl}_{k,l,h})\, (\vec{\varphi} - \vec{\varphi}_h)\, dy - \int_{Z^k_l} \nabla (\vec{\beta}^{bl}_{k,l} - \vec{\beta}^{bl}_{k,l,h})\, \nabla \vec{\varphi}_h\, dy\,.$$

Here, the first term is of order $C(k+|l|)h^2$ by (5.12), (5.22), and (5.21). The second term can be estimated by replacing first $\vec{\varphi}_h$ by $\vec{\varphi}$, which can be done up to an error of order $C(k+|l|)h^2$ due to (5.11), (5.22), and (5.21). For the rest, a partial integration yields

$$\int_{Z^k_l} \nabla (\vec{\beta}^{bl}_{k,l} - \vec{\beta}^{bl}_{k,l,h}) \nabla \vec{\varphi}\, dy = \int_{Z^k_l} (\vec{\beta}^{bl}_{k,l} - \vec{\beta}^{bl}_{k,l,h}) \Delta \vec{\varphi}\, dy \leq C(k+1)(k+|l|)h^2 \tag{5.23}$$

if one uses (5.14) and (5.21). Thus, (5.19) is also proved. ∎

As mentioned at the beginning of this section, the practical implementation of domain partitions with nonlinear element mappings is rather complicated. It is usually easier to approximate a domain Ω with curved boundaries by polygonal domains Ω_h, which then can be partitioned in triangles and/or quadrangles (see, for example, [18]). However, it can be shown that, on a discrete level, this simpler approach is equivalent to our theoretically more convenient formulation up to a quadrature error of optimal order; see [16].

6. Numerical results. We are now ready to demonstrate our method for computing the constants C^{bl}_1 and C^{bl}_ω on specific examples. First, we consider the symmetric geometry shown on the left part of Figure 6.1. The boundary ∂Z^* is a circle with radius 0.25 and center at $(0.5, 0.5)$. On the right-hand side of Figure 6.1, the initial polygonal approximation and the initial grid $\mathcal{T}_{h_0}$ with quadrangle elements (see section 5) is depicted. $\mathcal{T}_{h_0}$ is then uniformly refined, yielding further grids $\mathcal{T}_{h_1}, \ldots, \mathcal{T}_{h_J}$. By using the discretization described in the previous section, we obtain for every $\mathcal{T}_{h_i}, i = 1, \ldots, J$, a system of linear equations which must be solved to obtain the discrete solution $\{\vec{\beta}^{bl}_{k,l,h}, \omega^{bl}_{k,l,h}\}$.

Since the arising linear systems are very large, we have applied the multigrid method, which is known to be of optimal complexity for a large range of problems; see [6]. However, due to the pressure stabilization and the polygonal approximation of the smooth boundary $\cup^l_{k=1}(\partial Z^* - (0, k))$, we are not in a Galerkin setting. In this case, it is known that the simple multigrid V-cycle (one coarse-grid correction between pre- and postsmoothing) does not have to converge independently of the number of levels. We therefore used the W-cycle (two coarse-grid corrections between smoothing). Both pre- and postsmoothing are done by two steps of a block incomplete decomposition, where each block contains the unknowns of one grid node (the corners of the elements). And, indeed, our numerical observations confirm that this method is robust with respect to the number of levels and variations of the parameters k, l; see also Table 6.5 below.

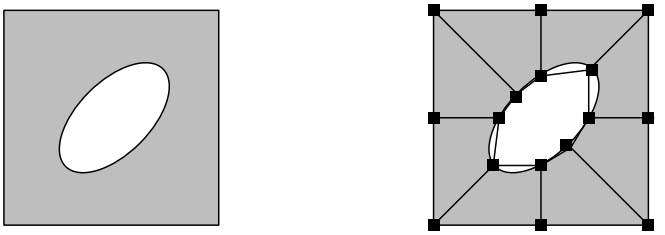

FIG. 6.2. *Unsymmetric cell and coarsest grid.*

TABLE 6.2
Results for the unsymmetric cell ($k = l = 2$).

5	-0.524602	$2.584 \cdot 10^{-4}$	-0.446836	$5.798 \cdot 10^{-4}$
∞	$-0.524501 \pm 4.9 \cdot 10^{-6}$		$-0.4464 \pm 1.4 \cdot 10^{-4}$	

In Table 6.1, the results for a computation with $k = l = 2$ are shown. Starting from the coarsest level, which contains 20 elements, we refine five times, which yields a grid with 20480 elements (61440 unknowns). On each level $j = 0, \dots, 5$, we solve the discretized equation and compute the approximations $C^{bl}_{1,k,l,h}$ and $C^{bl}_{\omega,k,l,h}$, given by (5.15) and (5.17) (with the choice $\lambda(x) = x$ in (5.16)). The value given for $j = \infty$ is computed by polynomial extrapolation. We see that both $C^{bl}_{1,k,l,h}$ and $C^{bl}_{\omega,k,l,h}$ converge to limit values with rate $O(h^2)$, which we expected from Proposition 5.3. As shown in Remark 3.9, C^{bl}_{ω} must be zero. Since our grid is symmetric, the solution of the discrete problem also has the same symmetry property, such that the approximations $C^{bl}_{\omega,k,l,h}$ are zero up to machine accuracy.

TABLE 6.3
$C^{bl}_{1,k,l}$ (extrapolated) for varying k, l.

$l \setminus k$	1	2	3
1	-0.524500	-0.524500	-0.524500
2	-0.524500	-0.524501	-0.524501
3	-0.524500	-0.524501	-0.524501

Let us now assume that the porous part is generated by the unsymmetric cell from Figure 6.2, where the boundary curve is given by the ellipse

$$[0, 2\pi] \ni \phi \mapsto (0.5, 0.5) + \frac{0.25}{1.0 + 0.3\cos(2\phi + 1.5708)}(\cos\phi, \sin\phi)\,. \tag{6.1}$$

For this domain we obtain the results shown in Table 6.2. Both $C^{bl}_{1,k,l,h}$ and $C^{bl}_{\omega,k,l,h}$ converge again with order $O(h^2)$, which is in accordance with Proposition 5.3. The error arising from the cutting of the domain is not noticeable any more already for $k = l = 2$. This is shown in Tables 6.3 and 6.4, where the results for varying k and l are given. Note that even the values for $k = l = 1$ are accurate up to the extrapolation error.

TABLE 6.4

1	-0.3750	-0.3750	-0.3750
2	-0.4464	-0.4464	-0.4464
3	-0.4464	-0.4464	-0.4464

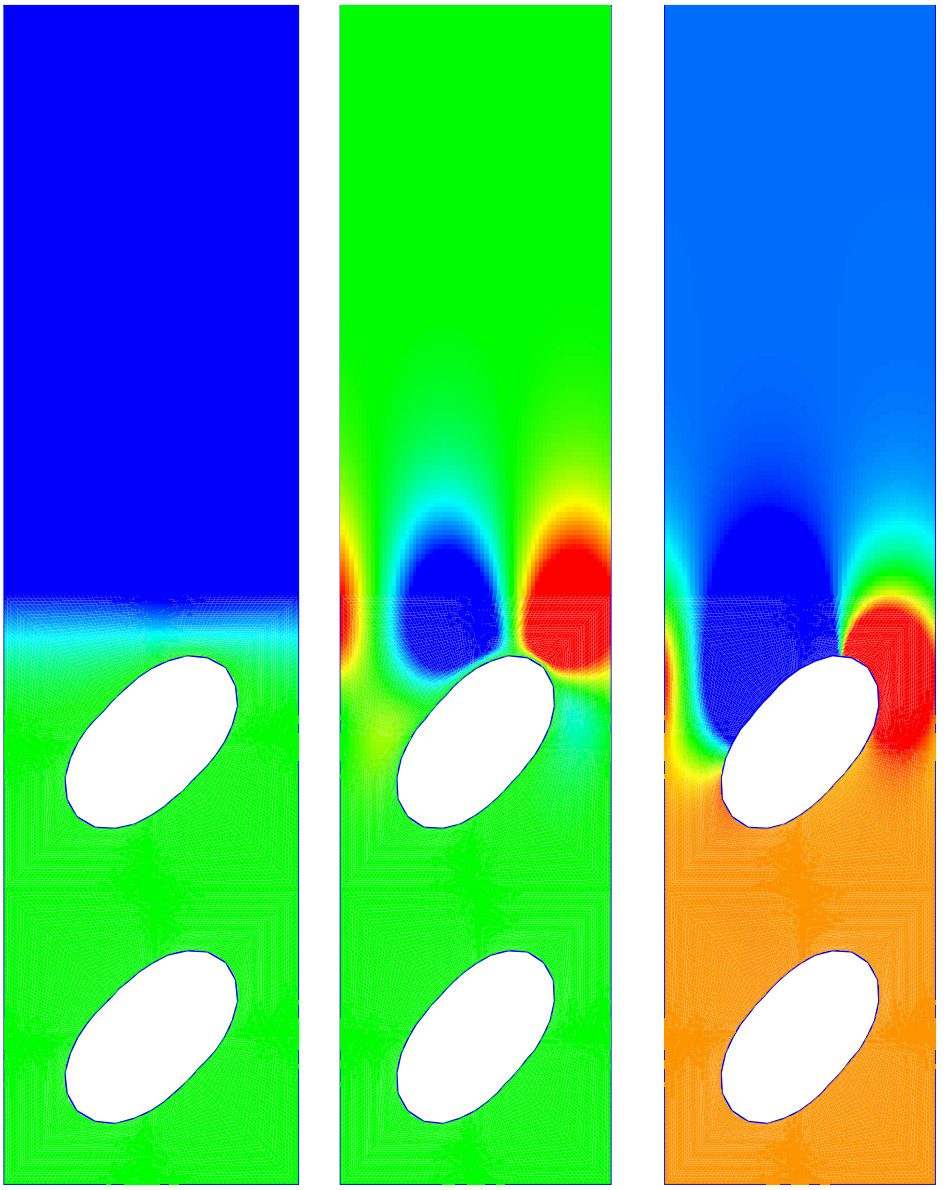

FIG. 6.3. *Detail from a picture showing* β_1^{bl}, β_2^{bl}, *and* ω^{bl}.

TABLE 6.5
Multigrid convergence rates.

$k,l \setminus j$	1	2	3	4	5
$k,l=1$	0.093	0.144	0.193	0.168	0.176
$k,l=2$	0.209	0.152	0.194	0.168	0.176
$k,l=3$	0.247	0.168	0.194	0.168	0.176

Figure 6.3 shows the three solution components β_1^{bl}, β_2^{bl}, and ω^{bl}. From here and from the values of C_ω^{bl} in Table 6.2, it is obvious that a pressure jump occurs inside the boundary layer.

Finally, Table 6.5 shows the convergence rates of our multigrid iteration. As we expected from the discussion above, it is perfectly robust with respect to the number of levels. So far, we did not observe a significant dependency on k or l, even if one might expect some deterioration, since the error estimates from Proposition 5.3 are needed in the usual W-cycle convergence theory. The reason might be that sharper error estimates are possible in suitably weighted norms.

7. The effective equations. It turned out that $\vec{\beta}^{bl}$ stabilizes exponentially fast to a constant vector $(C_1^{bl},0)$ for $y_2 \to +\infty$ (and to 0 for $y_2 \to -\infty$), which translates into $\vec{\beta}^{bl,\varepsilon}$ tending to $\varepsilon(C_1^{bl},0)$ for $x_2 \to +\infty$. This forces us to consider the corresponding counter-flow in the channel, which is described by the following two-dimensional (2D) Oseen–Couette system in Ω_1:

$$-\mu\triangle\vec{d} + \nabla g + v_1^0 \frac{\partial \vec{d}}{\partial x_1} + d_2 \frac{\partial v_1^0}{\partial x_2}\vec{e}_1 = 0 \quad \text{in } \Omega_1\,, \tag{7.1}$$

$$\operatorname{div} \vec{d} = 0 \quad \text{in } \Omega_1\,, \tag{7.2}$$

$$\vec{d} = \vec{e}_1 \text{ on } \Sigma, \qquad \vec{d} = 0 \text{ on } (0,b)\times\{H\}, \tag{7.3}$$

$$d_2 = 0\,,\ g = 0 \text{ on } (\{0\}\cup\{b\})\times(0,H)\,. \tag{7.4}$$

If we assume that $\mathrm{Re} := \frac{1}{8\mu^2}|p_b - p_0|H^2$ is not too big, the problem (7.1)–(7.4) has a unique solution in the form of 2D Couette flow $\vec{d} = (1-\frac{x_2}{H})\vec{e}_1$ and $g = 0$.

Following the ideas from [9], we write down the correction of order ε for the velocity. Essentially, it corresponds to the elimination of the tangential component of the normal stress at Σ, caused by the approximation by Poiseuille's flow and its contribution to the energy estimate. The correction reads

$$\vec{u}^\varepsilon = \vec{v}^0 H(x_2) - \varepsilon\vec{\beta}^{bl}\left(\frac{x}{\varepsilon}\right)\frac{\partial v_1^0}{\partial x_2} + \varepsilon C_1^{bl}\left(\frac{\partial v_1^0}{\partial x_2}\vec{e}_1 + \vec{d}\right)H(x_2) + O(\varepsilon^2). \tag{7.5}$$

The correction of the velocity field by the oscillatory boundary layer velocity $\vec{\beta}^{bl,\varepsilon}$ involves the introduction of the boundary layer pressure field $\omega^{bl,\varepsilon}$. Hence, as usual for flow problems, it is necessary to correct the pressure field simultaneously. The corresponding pressure correction reads

$$p^\varepsilon = p^0 H(x_2) + p^{1,\varepsilon} H(-x_2) - \big(\omega^{bl,\varepsilon} - H(x_2)C_\omega^{bl}\big)\mu\frac{\partial v_1^0}{\partial x_2}(0) + o(1). \tag{7.6}$$

Here, $p^{1,\varepsilon}$ is an appropriate regularization of the effective pressure p in the porous bed, defined by

$$\operatorname{div}\big(K\nabla p\big) \quad = \quad 0 \qquad \text{in } \Omega_2, \tag{7.7}$$

$$p(x_1,-0) = p^0(x_1) + \mu C_\omega^{bl}\frac{\partial v_1^0}{\partial x_2}(0) \quad \text{on } \Sigma, \tag{7.8}$$

$$(K\nabla p)\cdot e_2 = 0 \quad \text{on } (0,b)\times\{-L\}, \tag{7.9}$$

$$p = p_0 \quad \text{on } \{0\}\times(-L,0), \quad \text{and} \quad p = p_b \quad \text{on } \{b\}\times(-L,0), \tag{7.10}$$

where the permeability tensor K is defined as $K_{ij} = \int_{Y^*} w_i^j(y)\,dy$. Here, the w_i^j are solutions of the auxiliary problems

$$-\triangle_y \vec{w}^j + \nabla_y \pi^j = \vec{e}_j \quad \text{in } Y^*, \tag{7.11}$$

$$\operatorname{div}_y \vec{w}^j = 0 \quad \text{in } Y^*, \tag{7.12}$$

$$\vec{w}^j = 0 \quad \text{on } \partial Z^*, \quad \{\vec{w}^j, \pi^j\} \text{ is } Z\text{-periodic}, \quad \int_{Y^*}\pi^j = 0\,. \tag{7.13}$$

The pressure field p is a C^∞-function outside the corners. However, due to the discontinuities of the traces at $(0,0)$ and at $(b,0)$, its gradient is not square integrable in Ω_2. We must regularize the values at the upper corners, and $p^{1,\varepsilon}$ is such a regularization, satisfying $p = p^{1,\varepsilon} + O(\sqrt{\varepsilon})$.

Let us now introduce the difference $\mathcal{U}_0^\varepsilon$ between the velocity field $\vec{u}^\varepsilon$ and its expansion up to order $O(\varepsilon)$, i.e., we set

$$\vec{\mathcal{U}}_0^\varepsilon(x) = \vec{u}^\varepsilon - \vec{v}^0 + \vec{\beta}^{bl,\varepsilon}\frac{\partial v_1^0}{\partial x_2}(0) - \varepsilon C_1^{bl}\frac{\partial v_1^0}{\partial x_2}(0)H(x_2)\frac{x_2}{H}\vec{e}_1. \tag{7.14}$$

Then, after constructing the corresponding outer boundary layer, it was proved in [10] that

$$\int_0^b\int_{-L}^0 |\vec{\mathcal{U}}_0^\varepsilon(x)|^2\,dx + \varepsilon^2\int_0^b\int_{-L}^H |\nabla\vec{\mathcal{U}}_0^\varepsilon(x)|^2\,dx \le C\varepsilon^4|\log\varepsilon|^2\,, \tag{7.15}$$

$$\int_0^b |\vec{\mathcal{U}}_0^\varepsilon(x_1,0)|^2\,dx_1 + \int_0^b\int_0^H |\vec{\mathcal{U}}_0^\varepsilon(x)|^2\,dx \le C\varepsilon^3|\log\varepsilon|^2\,. \tag{7.16}$$

It should be noted that the presence of the logarithmic term is a consequence of the corner singularities in the effective pressure. It was proved in [9] that in the absence of the boundary singularities, the above estimates hold without the $\log\varepsilon$ term. Therefore, in the interior of the domain Ω, the expansion (7.5) is of order $O(\varepsilon^{3/2})$. Globally, it is of order $O(\varepsilon^{3/2}|\log\varepsilon|)$.

The estimates (7.15)–(7.16) are sufficient for calculating the next order correction at the interface Σ. The estimate (7.16) gives us a possibility of approximating the velocity values at Σ by an oscillatory velocity field. Computationally, it is not very useful.

In view of the problem setting in [9], the Beavers–Joseph law corresponds to taking into the account the next order corrections for the velocity. In fact, we formally get on the interface Σ

$$\frac{\partial u_1^\varepsilon}{\partial x_2} = \frac{\partial v_1^0}{\partial x_2}(0)\left(1 - \frac{\partial\beta_1^{bl}}{\partial y_2}\left(\frac{x}{\varepsilon}\right)\right) + \frac{\partial\mathcal{U}_{01}^\varepsilon}{\partial x_2} + O(\varepsilon)\,, \tag{7.17}$$

$$\frac{1}{\varepsilon}u_1^\varepsilon = -\beta_1^{bl}\left(\frac{x}{\varepsilon}\right)\frac{\partial v_1^0}{\partial x_2}(0) + O(\sqrt{\varepsilon}|\log\varepsilon|)\,, \tag{7.18}$$

$$\begin{aligned} u_1^\varepsilon + \varepsilon C_1^{bl}\frac{\partial u_1^\varepsilon}{\partial x_2} = \mathcal{U}_{01}^\varepsilon + \varepsilon C_1^{bl}\frac{\partial\mathcal{U}_{01}^\varepsilon}{\partial x_2} + \frac{\partial v_1^0}{\partial x_2}(0)\left(\varepsilon C_1^{bl} - \beta_1^{bl}\left(\frac{x}{\varepsilon}\right)\right) \\ -\varepsilon C_1^{bl}\frac{\partial v_1^0}{\partial x_2}(0)\frac{\partial\beta_1^{bl}}{\partial y_2}\left(\frac{x}{\varepsilon}\right) + O(\varepsilon^2)\,. \end{aligned} \tag{7.19}$$

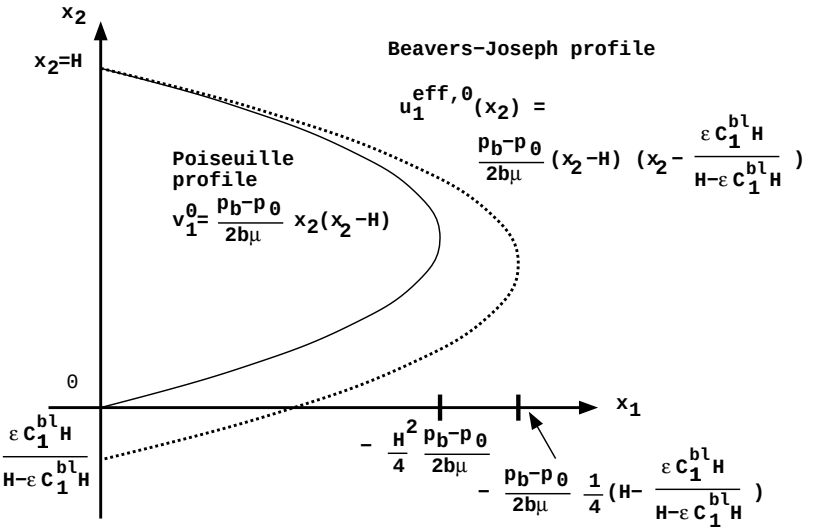

FIG. 7.1. *Beavers–Joseph versus Poiseuille profile.*

Integrals of the absolute value of the right-hand side are not small, since our estimates do not give any pointwise control of ∇u on Σ. Nevertheless, the right-hand side of (7.19) is small in the appropriate Sobolev norm of a negative order. The precise estimates are in [10]. Hence we get the effective law

$$u_1^\varepsilon + \varepsilon C_1^{bl} \frac{\partial u_1^\varepsilon}{\partial x_2} = 0 \quad \text{on } \Sigma, \tag{7.20}$$

which is exactly Saffman's modification of the Beavers–Joseph law from (1.2) with $\frac{1}{\alpha} K^{1/2} = -\varepsilon C_1^{bl}$.

Let us introduce the effective flow equations in Ω_1 through the following boundary value problem. Find a velocity field $\vec{u}^{\,eff}$ and a pressure field p^{eff} such that

$$-\mu \triangle \vec{u}^{\,eff} + (\vec{u}^{\,eff} \nabla)\vec{u}^{\,eff} + \nabla p^{eff} = 0 \quad \text{in } \Omega_1, \tag{7.21}$$

$$\operatorname{div} \vec{u}^{\,eff} = 0 \quad \text{in } \Omega_1, \tag{7.22}$$

$$\vec{u}^{\,eff} = 0 \quad \text{on } (0,b) \times \{H\}, \tag{7.23}$$

$$u_2^{eff} = 0 \quad \text{on } (\{0\} \cup \{b\}) \times (0,H), \tag{7.24}$$

$$p^{eff} = p_0 \quad \text{on } \{0\} \times (0,H) \text{ and } p^{eff} = p_b \quad \text{on } \{b\} \times (0,H), \tag{7.25}$$

$$u_2^{eff} = 0 \text{ and } u_1^{eff} + \varepsilon C_1^{bl} \frac{\partial u_1^{eff}}{\partial x_2} = 0 \text{ on } \Sigma. \tag{7.26}$$

Under the same assumption of laminarity as for problem (7.1)–(7.4), the problem (7.21)–(7.26) has a unique solution $\{\vec{u}^{\,eff}, p^{eff}\}$ with $p^{eff} = p^0$ and

$$\vec{u}^{\,eff} = \left(\frac{p_b - p_0}{2b\mu} \left(x_2 - \frac{\varepsilon C_1^{bl} H}{H - \varepsilon C_1^{bl}} \right) (x_2 - H), 0 \right) \quad \text{for } 0 \le x_2 \le H \tag{7.27}$$

(see Figure 7.1). The effective mass flow rate through the channel is

$$M^{eff} = b \int_0^H u_1^{eff}(x_2)\, dx_2 = -\frac{p_b - p_0}{12\mu} H^3 \frac{H - 4\varepsilon C_1^{bl}}{H - \varepsilon C_1^{bl}}\,. \tag{7.28}$$

By using the theory of very weak solutions for the Stokes system, the following approximation properties of $\{\vec{u}^{eff}, p^{eff}, M^{eff}\}$ are proved in [10]:

$$\int_0^H \int_0^b \left|p^\varepsilon - p^{eff}\right|^2 dx + \varepsilon \int_0^H \int_0^b \left|\nabla(\vec{u}^\varepsilon - \vec{u}^{eff})\right| dx \le C\varepsilon^2 |\log \varepsilon|^2, \tag{7.29}$$

$$\int_0^H \int_0^b \left|\vec{u}^\varepsilon - \vec{u}^{eff}\right|^2 dx + \int_0^H \int_0^b \left|M^\varepsilon - M^{eff}\right|^2 dx \le C\varepsilon^3 |\log \varepsilon|^2. \tag{7.30}$$

The estimates (7.29)–(7.30) justify Saffman's modification of the law by Beavers and Joseph. Furthermore, we are able to calculate their proportionality factor; it is equal to $-K^{1/2}/C_1^{bl}$. We note that (7.26) is not the only possible interface law. If one replaces the Beavers–Joseph law by $u_1^{eff} = \varepsilon C_1^{bl} \frac{\partial v_1^0}{\partial x_2}(0)$, the estimates (7.29)–(7.30) remain valid. However, such a condition involves the knowledge of the zeroth order approximation v_1^0 and is not really an interface condition.

At this stage, we can consider the approximation to the channel flow as satisfactory, but we still must determine the filtration velocity and the pressure in the porous medium. We have already mentioned the influence of corner singularities on the solution of the problem (7.8)–(7.10). In order to avoid the discussion of such effects, we limit ourselves to the behavior in the interior of the porous medium. The inertia effects are negligible, and we can use the theory from [9, Theorem 3]. In the interior, all boundary layer effects are exponentially small, and we have

$$\vec{u}^\varepsilon = -\varepsilon^2 \sum_{j=1}^{2} \vec{w}^j \left(\frac{x}{\varepsilon}\right) \frac{\partial p(x)}{\partial x_j} + O(\varepsilon^3), \tag{7.31}$$

where $\vec{w}^j$, $j = 1, 2$, are defined by (7.11). Hence the filtration velocity is given through the Darcy law $\vec{v}^f(x) = -K\nabla p(x)$ in Ω_2.

Far away from the corners, the pressure field p approximates p^ε at order $O(\sqrt{\varepsilon})$. It can be determined only after we have found the effective pressure field in the channel and the stabilization constant C_ω^{bl} giving the pressure difference at infinities for the auxiliary problem. As shown in section 6, this stabilization constant is generally different from zero, and we must use the interface law

$$p^{eff}(x_1, -0) = p^{eff}(x_1, +0) + \mu C_\omega^{bl} \frac{\partial v_1^0}{\partial x_2}(0) \qquad \text{on } \Sigma. \tag{7.32}$$

This shows that, contrary to intuition, *the effective pressure in the system channel flow/porous medium is not always continuous*. Thus the continuity assumption for the effective pressure from [12] is not correct in general.

Finally, let us note that we have some freedom in choosing the position of the interface. It could be set at any distance of order $O(\varepsilon)$ from the solid obstacles. Intuitively, the law of Beavers and Joseph should be independent of such a choice. This invariance result can be established rigorously, and we refer for details to [14], where it was proved that a perturbation of order $O(\varepsilon)$ in the position of the interface leads to a change of the constant C_1^{bl}, but $\vec{u}^{eff}$ changes only at order $O(\varepsilon^2)$.

SPECIAL BILINEAR QUADRILATERAL ELEMENTS FOR LOCALLY REFINED FINITE ELEMENT GRIDS*

WEIGANG WANG†

Abstract. A set of special bilinear quadrilateral elements are developed to handle irregular nodes on the interface between different refinement levels in 1-irregular meshes for the adaptive finite element method. With this alternative approach, irregular nodes are eliminated, and at the same time the C^0 continuity at interelements is strictly ensured. The new elements simplify the refinement procedure and circumvent many inconveniences in local refinement with linear quadrilateral elements. Solutions to problems of a heat conduction, a reaction-diffusion, and incompressible and viscous flows past a circular cylinder are respectively presented to test the effectiveness of special elements. They demonstrate good accuracy and a potential applicability to more complex problems.

1. Introduction.

Adaptive finite element methods (AFEM) with quadrilateral elements pose certain special difficulties in handling the elements close to the interface between different refinement levels. Specifically, the local refinement procedure results in irregular nodes ("hanging nodes," "virtual nodes," or "slave nodes" in some literature) at the interface. Improper handling of these irregular nodes causes a discontinuous solution at the interface, thereby degrading the accuracy of the whole discretized system.

Different approaches have been proposed to handle these irregular nodes. A short review of those methods can be found in [20]. There exist three different approaches, i.e., converting irregular nodes to regular ones by dividing some additional elements [13, 15, 17], constructing additional constraint equations [6], and reconstructing interpolation functions [1, 9, 16]. The approach of dividing additional elements often results in a discretized system with quadrilateral elements or a combination of quadrilateral and triangular elements. In both situations, the resulting systems are full of elements with undesirable aspect ratios which often decrease the accuracy locally or globally. The additionally divided elements often cause inconvenience (from a programming point of view) in the further refinement process. The method with additional constraint equations is often a complicated procedure and is difficult to use directly in existing FEM codes. The approach of reconstructing interpolation functions is often carried out under certain restrictive conditions which are not directly extended to complex cases.

However, the different approaches share a common goal, namely, to ensure the continuity of unknowns (represented by interpolation functions) across the interelements, whatever elements are used. In addition to this so-called C^0 continuity, another important requirement is that the methods should be easy to use and should be able to handle complex cases.

In the following context, we use the notions "interelements" and "interface between elements" interchangeably unless stated otherwise. In fact, both indicate the interior border between elements.

The interpolation functions for the FEM are mostly constructed in a piecewise manner, the C^0 continuity at interelements being inevitably determined (not entirely, though) by the behavior of the interpolation functions applied there. In the present paper, we propose an alternative concept for the local refinement with bilinear quadrilateral elements in 1-irregular meshes. Specifically, a set of special elements and their interpolation functions are constructed in order to keep the C^0 continuity at the interelements and to simplify the refinement process.

These specially designed elements possess some unique features. They *geometrically* do not satisfy one of the basic requirements for a finite element, i.e., $\cap\Omega^e = \emptyset$, where Ω^e, $e = 1, 2, \ldots, n$ are the finite elements in a bounded region. They, in fact, have geometric overlaps if we consider the geometric border of an element as defined by the element's own nodes. However, considering the contribution of every element to the weighted residual equations, the classic definition is strictly satisfied. This *forward* (*delayed* might be more precise) enforcement of the basic requirement simplifies the local refinement procedure with linear quadrilateral elements. In fact, these special elements with their corresponding special interpolation functions make the C^0 continuity at the interelements a relatively easier task and circumvent many inconveniences in the local refinement process.

Similar to normal bilinear elements, these special elements are self-contained. The special elements simply ignore the existing irregular nodes and internally build up on their own (by the interpolation functions). Both the aforementioned features allow the existing FEM software to easily adopt the concept with minimum effort involved. The special elements also can be used in the cases with distorted elements without losing the C^0 continuity at the interelement with irregular nodes. Furthermore, it is possible to extend the concept to the discretization for triangular elements and for 3-dimensional cases.

The concept of constructing special bilinear quadrilateral elements is, in fact, a generalization of a similar idea proposed in a companion paper about special *quadratic* quadrilateral elements [20]. Interested readers are referred to that paper for additional details. The *forward* enforcement of the basic requirement for a finite element is used in both situations. However, the interface location, the geometric parameters, and the corresponding C^0 continuity condition for bilinear quadrilateral elements are more complex and need more rigorous verifications, which the emphasis of the present paper is focused on.

2. Local refinement with special elements. Shown in Figure 2.1 (a) is a typical situation where the elements at two different levels of refinement meet at interface *amb*. A big element 1 and two small elements 2 and 3 are drawn separately for clarity in Figure 2.1 (b). Element 1 has four regular corner nodes and has no more nodes on side *ab*, while elements 2 and 3 both have three regular corner nodes and another corner node m somewhere on interface *ab*. From a discretization point of view, node m is an unusual node because it only depends on elements 2 and 3 but never directly on element 1 even though node m falls geometrically into element 1's domain. Node m is the so-called irregular node. A similar situation also appears in the unstructured meshes for finite difference or finite volume methods.

In the following, we introduce a new concept to handle the problem caused by the irregular nodes in local refinement with bilinear quadrilateral elements. The

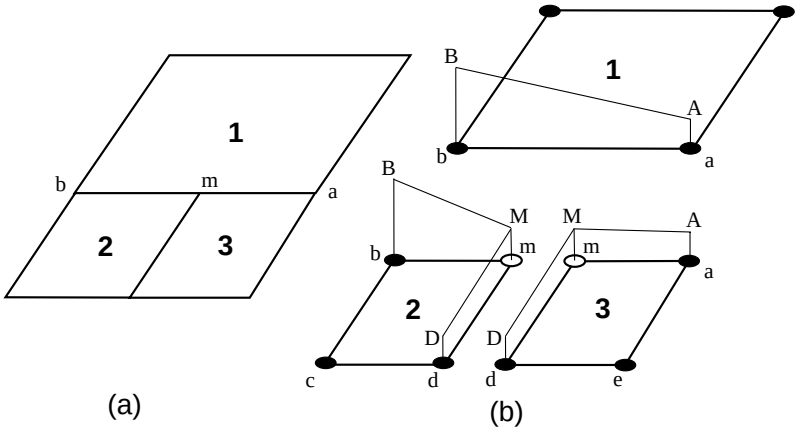

FIG. 2.1. *Bilinear quadrilateral elements in transient region of a* 1*-irregular mesh. The numbers indicate elements, the lower-case letters denote the nodes, and the upper-case letters denote the nodal values, while thick lines mark the element borders and thin lines show unknown's value represented by interpolation functions; the regular nodes are marked by solid circles and the irregular nodes by void circles.*

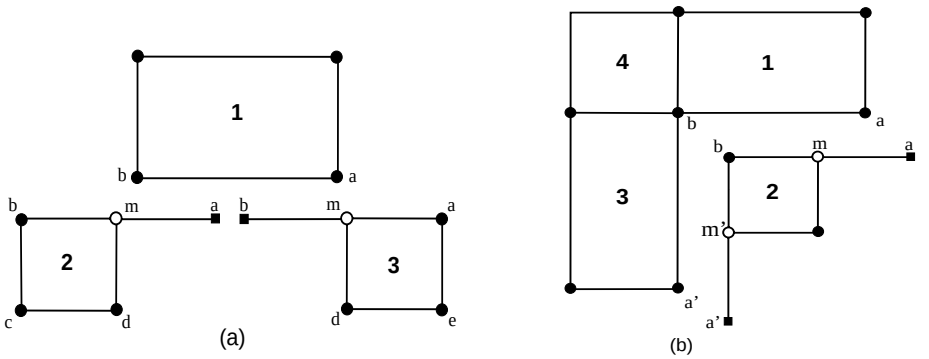

FIG. 2.2. *Special bilinear quadrilateral elements of the first* (2) *and the second* (3) *kind in* (a)*, and the third kind* (2) *in* (b)*. A solid square indicates an irregular node's replacement node.*

basic idea is to maintain the C^0 continuity at interfaces by eliminating the irregular nodes completely. For the small element with an irregular node on the interface, e.g., element 2 in Figure 2.2 (a), this can be readily achieved by *creating a new interpolation function without the irregular node but with a corresponding extra regular node*. Specifically, we construct special bilinear interpolation functions for element 2 based on nodes b, c, d, and a. Node a is a replacement for irregular node m and is taken from the big element at the other side of the interface ab (this replacement node can also be considered as taken from neighboring small element 3); see Figure 2.2 (a). Similarly, the special bilinear interpolation functions for element 3 can be constructed based on nodes d, e, a, and b. Subsequently, elements 2 and 3 are called special elements of the first and the second kind, respectively.

In reality, there may appear another kind of special element. This element appears normally at corner-like interfaces between different refinement levels. Element 2, shown in Figure 2.2 (b), is the special element of this third kind. Comparing special element 2 of the third kind in Figure 2.2 (b) with those of the first and second kind in Figure 2.2 (a), we can clearly recognize that the special element of the third kind is, in fact, a geometrical combination of the first and the second kind.

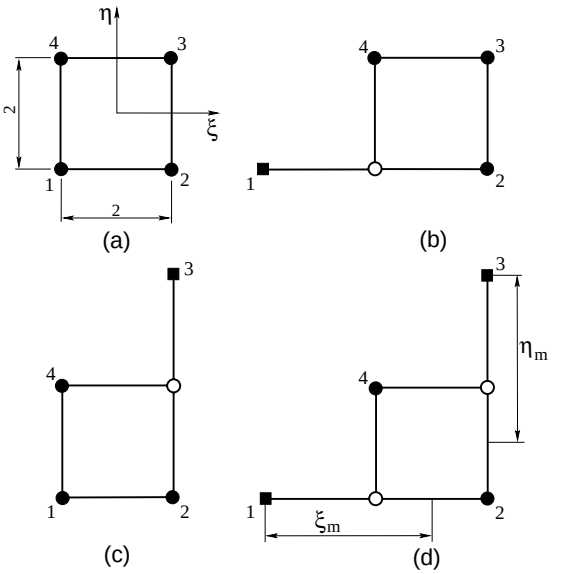

FIG. 2.3. *Normal* (a) *and special bilinear quadrilateral elements of the first* (b)*, the second* (c)*, and the third* (d) *kind in natural coordinates. The numbers beside solid circles and squares denote the node numbers.*

Analyzing special elements 2 and 3 in Figure 2.2 (a), we can see that each has four nodes, and thus the bilinear interpolation functions can be constructed in quite a normal way. Geometrically, elements 2 and 3 are mirror images of each other. Based on the concept explained above, irregular node m does not appear in either element 2 or element 3, and therefore the geometrical border for a special element is not directly defined by its four nodes. If we would define the border of the special elements only by their nodes, an overlapping area ($\triangle abd$) would appear between special elements 2 and 3.

Next we define an interface in this overlapping triangle, so that the overlapping area will be counted once and only once into the finite element equations, and at the same time the condition of the C^0 continuity is strictly held at such an interface. This can be achieved by *forwarding* the enforcement of the basic requirement for subdivision with finite elements to a later stage, i.e., at the stage of constructing interpolation functions. In this way, the C^0 continuity and the basic requirement for the finite elements will both be strictly satisfied. This *forward* enforcement of the basic requirement for an element forms the very base of the interpolation functions constructed below.

Collecting the normal as well as the special elements for bilinear quadrilateral elements, the four different elements are shown in Figure 2.3. In the following, we first list the interpolation functions for the special elements. A more rigorous analysis and an explanation about the C^0 continuity will be given in the next section.

The special interpolation functions for the special elements and the normal elements can be constructed in a systematic way, and the following general form can be obtained:

$$
\begin{aligned}
\Phi_1 &= \frac{(1-\xi)(1-\eta)}{2(1-\xi_m)},\\
\Phi_2 &= -\frac{1+\xi_m-\eta_m+3\xi_m\eta_m-(1+\xi_m+3\eta_m-\xi_m\eta_m)\xi}{4(1-\xi_m)(1+\eta_m)}\\
&\quad -\frac{(1-3\xi_m-\eta_m-\xi_m\eta_m)\eta+(3-\xi_m+\eta_m+\xi_m\eta_m)\xi\eta}{4(1-\xi_m)(1+\eta_m)},\\
\Phi_3 &= \frac{(1+\xi)(1+\eta)}{2(1+\eta_m)},\\
\Phi_4 &= \frac{(1-\xi)(1+\eta)}{4},
\end{aligned}
\tag{2.1}
$$

where parameters ξ_m and η_m indicate the different kinds of bilinear elements used and their values also depend on the degree of irregularity of the elements. Parameters ξ_m and η_m are, respectively, the two coordinates of irregular nodes' replacement nodes; see Figures 2.3 (a) and (d).

As an example, we take a case with rectangular elements. The normal and special rectangular elements are generated only by dividing another rectangular element equally into four small elements and vice versa. In the case of $\xi_m = -1$ and $\eta_m = 1$, the interpolation functions of a normal 4-node element (see Figure 2.3 (a)) can be obtained. If we set $\xi_m = -3$ and $\eta_m = 1$, a special element of the first kind results; see Figure 2.3 (b). The interpolation functions for the elements of the second and the third kind can be derived in a similar way by choosing different values of ξ_m and η_m. Some possible values of ξ_m and η_m for simple cases are listed in Table 2.1 for the normal and the three special elements.

TABLE 2.1
Parameters ξ_m and η_m for normal and special bilinear quadrilateral elements in simple cases.

Element type	In Figure 2.3	ξ_m	η_m
Normal	(a)	-1	1
1st	(b)	-3	1
2nd	(c)	-1	3
3rd	(d)	-3	3

By a simple analysis based on the property of bilinear functions, the C^0 continuity at the interface between one big and two small elements (e.g., *ab* in Figure 2.1) is strictly ensured. However, the C^0 continuity at the interface between the first and the second special elements is not so obvious. In fact, where the interface should be located depends on parameters ξ_m and η_m. More geometrical implications of the two parameters will be explained in the next section. Here we only state that, for the cases with rectangular elements where we generate the new elements for the next refinement level by bisecting equally the big element's sides, the parameters in Table 2.1 will always result in the right interfaces between elements as well as the corresponding C^0 continuity. Furthermore, the interpolation functions in (2.1) with the parameters in Table 2.1 can accommodate also slightly distorted quadrilateral elements without deteriorating the accuracy of the system significantly.

In some situations, the elements at a finer refinement level might not be created by halving the elements at the coarse refinement level, for instance, in the case of a nonrectangular domain, at places close to a moving interface in multiphase flows, in a moving boundary, or some other cases where general quadrilateral elements are desired. The C^0 continuity condition at the interface between two corresponding spe-

cial elements might not be satisfied for such general cases by choosing parameters ξ_m and η_m from Table 2.1.

In the next section, we demonstrate, in a more rigorous manner, the C^0 continuity at the interface between the two related special elements and the corresponding conditions. The proper values for parameters ξ_m and η_m will be derived thereafter for more general cases.

3. C^0 continuity of special elements. Since the special elements of the third kind can be obtained virtually by combining the first and the second kind, for the most part of the present section, we describe in detail the C^0 continuity analysis of the special elements of the first and the second kind because they possess the essential feature; later in this section the special element of the third kind will be used to derive the parameters ξ_m and η_m since other special elements can be derived from the third kind.

Shown in Figure 3.1 (a) are the two special elements in their surrounding area, while the enlarged version of elements 2 and 3 is illustrated in Figure 3.1 (b). The interface between the bigger element 1 and the two smaller elements 2 and 3 connects a coarse and a fine refinement level in this part of the 1-irregular mesh. As can

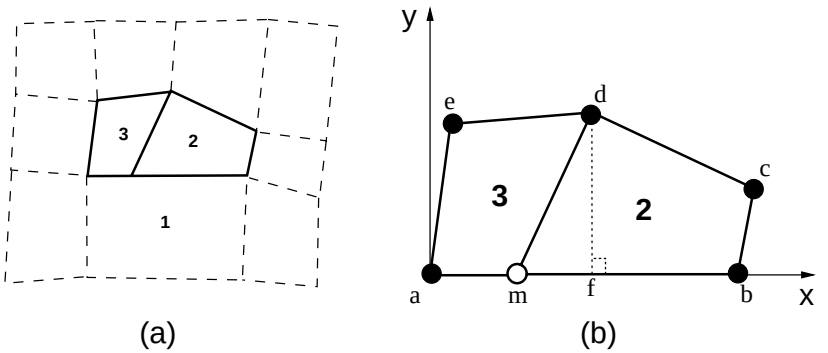

FIG. 3.1. *Special bilinear quadrilateral elements of the first and the second kind. The numbers indicate the elements, and the letters indicate the nodes; solid lines indicate the elements of the first and the second kind, and dashed lines indicate the surrounding elements; the dotted line represents the projecting path for node d to its projecting point f on interface ab.*

be seen, both elements 2 and 3 are quite arbitrary in shape in order to cover general cases. Without losing generality, we have moved the two elements to a new coordinate system by rotating and shifting only. Specifically, node a is moved to the origin, and interface ab is rotated to coincide with x-axis; see Figure 3.1 (b).

Let the nodal values for elements 2 and 3 be u_a, u_b, u_c, u_d, and u_e. We construct two bilinear interpolation functions using nodal coordinates and nodal values for elements 2 and 3, respectively. These interpolation functions form two bilinear surfaces over the two elements in 2-dimensional space. The behaviors of the two interpolation functions over the triangular area $\triangle abd$ (where all potential interfaces between elements 2 and 3 could be located) will be the focus of the following analysis.

The bilinear interpolation function ψ_{ij} for each node j in element i can be constructed in the general form

$$\psi_{ij} = \alpha_{ij} + \beta_{ij}x + \gamma_{ij}y + \delta_{ij}xy, \tag{3.1}$$

where x and y are the coordinates, and α_{ij}, β_{ij}, γ_{ij}, and δ_{ij} represent the polynomial coefficients determined by corresponding nodal coordinates. As explained in section 2,

we construct the special elements and the special interpolation functions by choosing nodes $a, b, c,$ and d for element 2 and nodes $a, b, d,$ and e for element 3. The expressions for the interpolation functions are quite lengthy. In the following, only the interpolation functions for element 3 are listed:

$$\psi_{3a} = 1 - \frac{x}{x_b} - \frac{x\,y(-x_b y_d + x_e y_d + x_b y_e - x_d y_e)}{x_b(x_d - x_e)y_d y_e} - \frac{y(x_b x_d y_d - x_d x_e y_d - x_b x_e y_e + x_d x_e y_e)}{x_b(x_d - x_e)y_d y_e}, \tag{3.2}$$

$$\psi_{3b} = \frac{x\,x_e y\,y_d - x_d x_e y\,y_d - x\,x_d y y_e + x_d x_e y\,y_e + x\,x_d y_d y_e - x\,x_e y_d y_e}{x_b(x_d - x_e)y_d y_e}, \tag{3.3}$$

$$\psi_{3d} = \frac{(x - x_e)y}{(x_d - x_e)y_d}, \tag{3.4}$$

$$\psi_{3e} = \frac{(x - x_d)y}{(x_e - x_d)y_e}. \tag{3.5}$$

The element-wise interpolation functions for these two elements therefore can be expressed in the following form:

$$\Psi_2 = \sum_{j=a,b,c,d} \psi_{2j} u_j, \tag{3.6}$$

$$\Psi_3 = \sum_{j=a,b,d,e} \psi_{3j} u_j, \tag{3.7}$$

where u_j denotes the nodal value at node j, and Ψ_2 and Ψ_3 indicate the interpolation functions for elements 2 and 3, respectively.

To prove the C^0 continuity, we analyze the behaviors of Ψ_2 and Ψ_3 at interface dm, a segment of straight line starting from node d and ending at irregular node m which can be anywhere on interface ab. Interface dm can be generally expressed as

$$x = x_m + \frac{x_d - x_m}{y_d} y. \tag{3.8}$$

If we substitute (3.6) and (3.7) with (3.8) and extract the essential terms, the difference between the two interpolation functions at interface dm can be written as

$$\Psi_3 - \Psi_2 = \frac{(x_d - x_m)y(y - y_d)}{x_b(x_c - x_d)(x_d - x_e)y_c y_d^2 y_e} F(u_j, x_j), \tag{3.9}$$

where $F(u_j, x_j)$ is a lengthy sum of many terms like $u_b x_b x_c y_c y_d, u_e x_b x_c y_c y_d$, and so on.

From (3.9), we can now make several important conclusions and obtain the answers to all uncertain aspects raised earlier:

1. At interface dm, the difference expressed by the two interpolation functions from special elements 2 and 3 is not always zero; in other words, the C^0 continuity does not always hold at any interface lying inside the overlapping area ($\triangle abd$); the discontinuity, however, never takes place at the interface's two ends of $y = y_a (= 0)$ and $y = y_d$; furthermore, a gap or an overlap between the two elements also occurs in case of the discontinuity if elements 2 and 3 are isoparametric ones.

2. The C^0 continuity is strictly satisfied (that is, $\Psi_3 - \Psi_2 = 0$) if interface dm is perpendicular to the interface between the normal element and the two special elements, specifically, $x_m = x_d (= x_f)$, for the case in Figure 3.1 (b).

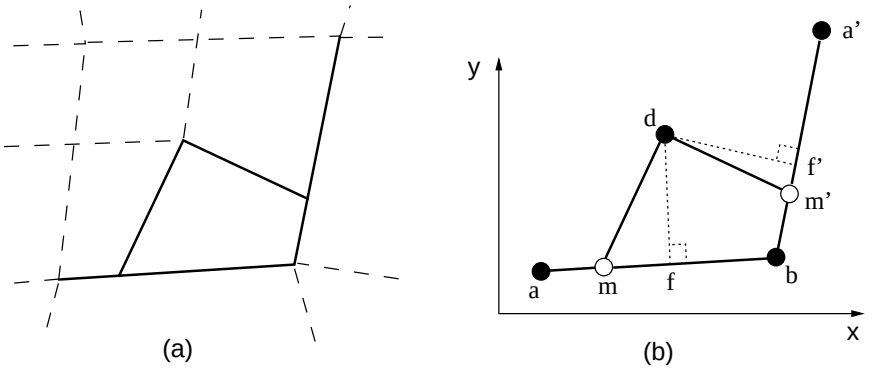

FIG. 3.2. *Special bilinear element of the third kind in the transient region. The solid lines indicate the element of the third kind, and the dashed lines indicate the surrounding elements; the dotted lines represent the projecting path for node d.*

3. Under some extreme circumstances, for instance, $x_b = x_a$, $x_c = x_d$, $x_d = x_e$, $y_c = y_b$, $y_d = y_m$ or $y_e = y_a$, (3.9) might become singular (it also depends on $F(u_j, x_j)$, see (3.9); in fact, one or more quadrilateral elements would degrade into a triangle, a line, or even a single point if such unusual element distortions occur; furthermore, another case with distorted elements might occur when node d's projecting point f falls outside interface ab; for these highly distorted elements, the C^0 continuity cannot be ensured.

The essential task in applying the special elements now reduces to that of keeping the interface between the two special elements (always in pairs for 1-irregular meshes) at the finer refinement level perpendicular to the corresponding interface connecting the finer and the coarser refinement levels. The implicit prerequisite is naturally that the projecting point m must fall in between on the related interface. If not, the elements involved must have been severely distorted.

Since the information at the irregular node is replaced by some linear relations through the corresponding regular nodes, the irregular node will not appear in the finite element equations at all. Therefore, the *right* interface between the corresponding special elements will be implicitly merged into the special interpolation functions. Only after achieving that, the special elements can satisfy the basic requirement for the finite elements:

$$\cup\overline{\Omega^e} = \Omega \text{ and } \Omega^e = \emptyset,$$

where Ω^e, $e = 1, 2, \ldots, n$ are element subdomains of a discretization of a bounded region Ω in $\mathbb{R}^d$ where n is the number of elements and d is the number of space dimensions.

In the following, we use the condition for the *right* interface to derive parameters ξ_m and η_m for (2.1). Shown in Figure 3.2 are a bilinear element of the third kind and its nearby region in a part of the 1-irregular mesh close to an interface where two different refinement levels meet. Based on the aforementioned perpendicularity condition for the corresponding two interfaces, the projecting point of node d to interface ab can be derived as

$$x_f = -\frac{((x_a - x_b)(x_a - x_b) + (y_a - y_b)^2)(-x_b y_a + x_a y_b)}{((x_a - x_b)(x_a - x_b) + (y_a - y_b)^2)(y_a - y_b)} + \frac{(-x_a + x_b)(x_a - x_b)(x_b y_a - x_a y_b)}{((x_a - x_b)(x_a - x_b) + (y_a - y_b)^2)(y_a - y_b)} \tag{3.10}$$

$$
\begin{aligned}
y_f = &-\frac{(-x_a+x_b)(y_a-y_b)(-x_ax_d+x_bx_d-y_ay_d+y_by_d)}{((x_a-x_b)(x_a-x_b)+(y_a-y_b)^2)(y_a-y_b)},\\
&-\frac{(x_a-x_b)(x_by_a-x_ay_b)}{(x_a-x_b)(x_a-x_b)+(y_a-y_b)^2}\\
&-\frac{(y_a-y_b)(-x_ax_d+x_bx_d-y_ay_d+y_by_d)}{(x_a-x_b)(x_a-x_b)+(y_a-y_b)^2}.
\end{aligned}
\tag{3.11}
$$

According to the coordinates of projecting point f and nodes a and b, the ratio of af to fb can be obtained as

$$
\frac{af}{fb}=\frac{(x_a-x_b)(x_a-x_d)+(y_a-y_b)(y_a-y_d)}{(x_a-x_b)(-x_b+x_d)+(y_a-y_b)(-y_b+y_d)}.
\tag{3.12}
$$

Considering the natural coordinate system and node numbers used in Figure 2.3, parameter ξ_m therefore can be written as

$$
\begin{aligned}
\xi_m &= -1-2\left|\frac{af}{fb}\right|\\
&= -1-2\left|\frac{(x_1-x_2)(x_1-x_4)+(y_1-y_2)(y_1-y_4)}{(x_1-x_2)(x_2-x_4)+(y_1-y_2)(y_2-y_4)}\right|,
\end{aligned}
\tag{3.13}
$$

where x_j and y_j denote the physical coordinates and j is the corresponding node number used in interpolation functions in natural coordinates (see Figure 2.3 as well as (2.1)). The similar procedure can be adopted to obtain parameter η_m, which can be subsequently written as

$$
\begin{aligned}
\eta_m &= 1+2\left|\frac{a'f'}{f'b}\right|\\
&= 1+2\left|\frac{(x_3-x_2)(x_3-x_4)+(y_3-y_2)(y_3-y_4)}{(x_3-x_2)(x_2-x_4)+(y_3-y_2)(y_2-y_4)}\right|.
\end{aligned}
\tag{3.14}
$$

It can be seen from (3.13) and (3.14) that parameters ξ_m and η_m depend only on the geometrical information of the elements. Furthermore, special elements appear always in pairs in the 1-irregular mesh, for instance, one first kind with one second kind, one first kind with one third kind, and so on. Therefore, parameter ξ_m of a special element of the first kind and parameter η_m of its counterpart (e.g., the second kind) are not independent but are related to each other by the relation of $\eta_m = 1 - 4/(\xi_m + 1)$. Note that this relation is correct only for special elements of the first and second kind (or the first and third kind), where $\xi_m \neq -1$. There exist similar relations between other special elements as well.

Though the C^0 continuity exists at the interface, the first-order derivative across the interface is normally discontinuous, which is a general feature of non-Hermite elements. However, the magnitude of this discontinuity indicates, indirectly at least, part of the discretization error in the system [20]. The error indicator based on this discontinuity will be used to perform the local refinement for the test cases in section 4.

The special elements can be quite systematically incorporated into AFEM. Element dividing in 1-irregular meshes can start in general from normal elements since special elements appear only at the finer-element side of the interface between different refinement levels. Element merging, on the other hand, can start from special as well as normal elements. However, the merging process often alters some neighboring

elements into special elements, and therefore some additional operation is needed to make some new special elements in the surrounding area. The remaining part of the refinement procedure, for instance, the interpolation for the new nodes, the update of data structure, and so on, is more or less the same as any other refinement procedure in AFEM.

Since special elements are self-contained as any normal bilinear quadrilateral element and do not require any information about their irregular nodes, they can be used conveniently and flexibly in a wide range of implementations. For instance, they can be adopted into other currently available FEM codes with minimal modification.

If we only consider the actual domain of a special element on which the local weighted residual equations later actually depend, the special element has kept approximately the original geometric aspect ratio. Though it does not indicate a perfect subdivision with exactly the same aspect ratio because the replacement node to an irregular one is often away from the actual domain, the special elements do keep, to certain extent, this ratio in an aforementioned way. This feature is always desirable, and it potentially improves the accuracy in the region close to the interface between different refinement levels.

Compared to the normal linear quadrilateral elements, only a small amount of extra computing effort is required to calculate parameters ξ_m and η_m from (3.13) and (3.14) for the interpolation functions in (2.1). Other possible extra resources might include a small amount of memory to store the element type, or this information can be determined based on the neighbors of an element, which in any case is needed for an unstructured mesh in AFEM.

4. Numerical test cases. In this section, the numerical test cases are presented. Specifically, the three cases are a heat transfer problem with a Laplace equation, a model combustion problem, and a viscous flow past a circular cylinder with incompressible Navier–Stokes equations. All test cases have been calculated with a research code FESTAL v.2.1 (Finite Element System for Turbulent and Laminar Combustion) which is still in development by the author. Standard Galerkin (SG) and streamline upwind/Petrov–Galerkin (SUPG) approaches have been implemented. In the following, only the SG approach is used. We skip the formulation of the FEM, and the interested readers should refer to FEM literature for details (for example, [5, 18]).

For Navier–Stokes equations, the method of successive substitution [18] or the SIMPLE algorithm [14] is used to solve the nonlinear system. The AFEM with the special elements introduced in section 2 is used for the local refinement of all test cases. Furthermore, use is made of the error indicator [20] based on the discontinuity of the first-order derivative at interelements. Later in this section we introduce another indicator based on the flow acceleration to capture the localized phenomena such as those in the vortex region.

First, we solve a 2-dimensional heat conduction problem [10] which can be stated as

$$\frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2} = 0, \tag{4.1}$$

subject to the boundary conditions

$$\begin{aligned} T &= T_1 && \text{at } x = \pm W/2 \quad \text{or} \quad y = 0, \\ T &= T_m \cos\frac{\pi x}{W} + T_1 && \text{at } y = H, \end{aligned}$$

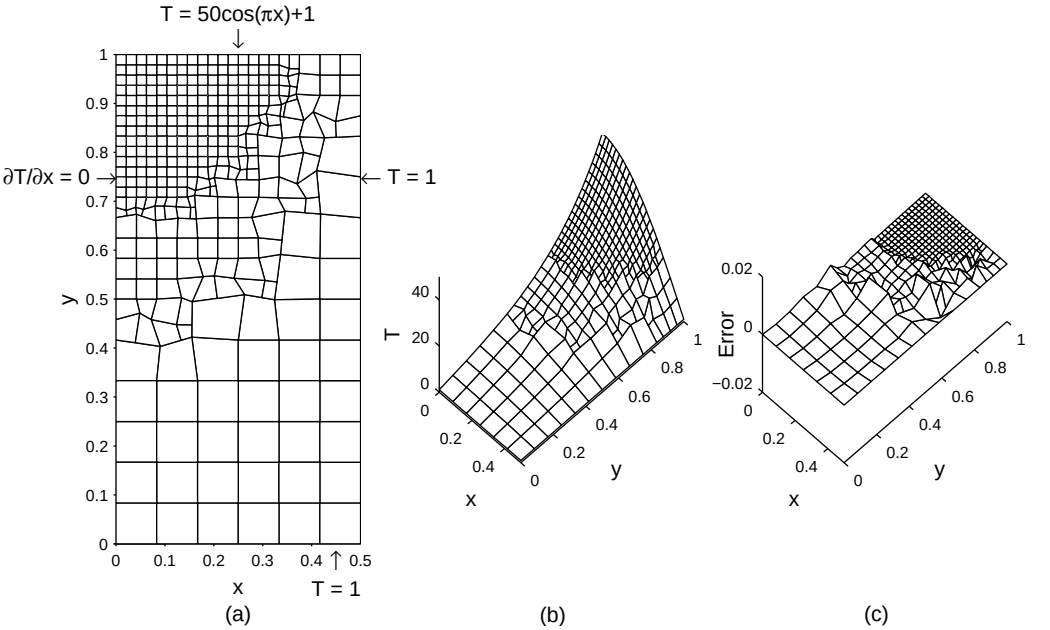

FIG. 4.1. *Mesh and boundary conditions* (a)*, solution* (b) *and its estimated numerical error* (c) *are calculated with special and normal elements for a heat conduction problem. The distortion of the elements close to the interface of different refinement levels are arbitrarily introduced. The* 1*-irregular mesh consists of* 363 *nodes in* 342 *elements.*

where T denotes the nondimensional temperature, T_1 and T_m represent some constant temperature, and W and H are the width and height of the rectangular domain, respectively. The analytical solution is

$$T = T_m \frac{\sinh(\pi y/W)}{\sinh(\pi H/W)} \cos\frac{\pi x}{W} + T_1, \tag{4.2}$$

which makes the direct calculation of numerical error possible. It can be seen that the solution of the problem is highly nonlinear. Therefore, it is a suitable test problem to discretize and to solve with special bilinear elements. We choose $T_1 = 1$ and $T_m = 50$ in a unit square ($W = H = 1$) first and make use of its symmetry feature. The discretization is carried out in a domain of 0.5×1 with a homogeneous Neumann boundary condition applied at $x = 0$; see Figure 4.1 (a). In this case, all three kinds of special elements are deployed in the area where the discontinuity of the first-order derivative at the interelements is large. Shown in Figure 4.1 are the mesh with special and normal elements (a), the numerical solution (b), and the numerical error (c). The arbitrarily distorted elements close to the interface separating different refinement levels are introduced to test the robustness and the reliability of the special elements.

The numerical error is calculated as the difference between the numerical result and the analytical solution from (4.2). Obviously, the error in the region full of normal elements is small, which indicates also that the discontinuity of the first-order derivative at the interelements is not big enough to allow further refinement. Close to the interface between different refinement levels, a bigger error appears. The error largely results from the changing aspect ratio of distorted elements, the discretization error inherited by using bilinear elements, the error caused by discontinuity of the first-order (or higher-order) derivative of the global interpolation functions, and the truncation error from the computer.

However, after considering all of these factors, we find that the maximum value for relative error in the whole domain is 0.67%, while the average error norm is 4.8×10^{-5}. Quite an accurate numerical solution has been obtained from the mesh with such distorted elements. The seemingly rough mesh surface shown in Figure 4.1 (b) is actually the visual effect of the interior borders of distorted elements, and the surface is, in fact, quite smooth.

The next test case is a model combustion problem [1] with a one-step reaction ($A \to B$):

$$\frac{\partial T}{\partial t} = \frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2} + D(1+\alpha - T)\exp\left(-\frac{\delta}{T}\right), \tag{4.3}$$

where α denotes the heat release rate, D denotes the Damköhler number, δ denotes the activation energy, and R denotes the reaction rate. Following [1], we choose $\alpha = 1$, $\delta = 20$, and $R = 5$. The initial condition for this case can be written as

$$T = 2, \quad x = 0 \text{ and } y = 0, \tag{4.4}$$

$$T = 1, \quad \text{otherwise.} \tag{4.5}$$

The initial condition at the origin, in fact, produces a constant "hot spot" and serves as an ignition source. The following boundary conditions are employed:

$$T = 2, \quad x = 0, \text{ and } y = 0, \tag{4.6}$$

$$\frac{\partial T}{\partial x} = 0, \quad x = 0, \ y \neq 0, \text{ and } y \neq 1, \tag{4.7}$$

$$\frac{\partial T}{\partial y} = 0, \quad y = 0, \ x \neq 0, \text{ and } x \neq 1, \tag{4.8}$$

$$T = 1, \quad x = 1, \text{ or } y = 0. \tag{4.9}$$

Physically, (4.3)–(4.9) describe an ignition process and a flame propagation after the ignition. Reactant A is converted into product B of high temperature during the combustion process. This problem has a nonlinear source term, which also makes a good test case. Though the analytical solution is not available, it is however a suitable case to test how the refinement strategy effectively works. Specifically, it tests how the local refinement with special elements closely follows the moving flame front in an unsteady phenomenon.

For this case, the element refinement is carried out by bisecting equally the big element's sides and the element merging by combining four small neighboring elements together if the error indicators (the discontinuities of first-order derivatives at inter-elements) fall outside the specified limits (or criteria).

The initial mesh is constructed with all three kinds of special bilinear elements introduced in section 2 as well as normal elements. The finest mesh around the origin is used to simulate better the ignition source at $t = 0$; see Figure 4.2 (a). There are 97 elements with 106 nodes in the mesh. The biggest element is 0.25×0.25, the smallest element is only 0.00098×0.00098 in size, and there are many special elements with different sizes in between. The use of special elements makes it practically possible to concentrate very few but extremely fine elements around the ignition source and to use coarse elements elsewhere.

Shown in Figure 4.2 is a sequence of numerical results from the initial condition until the flame reaches the boundaries opposite the hot spot. The 3-dimensional mesh

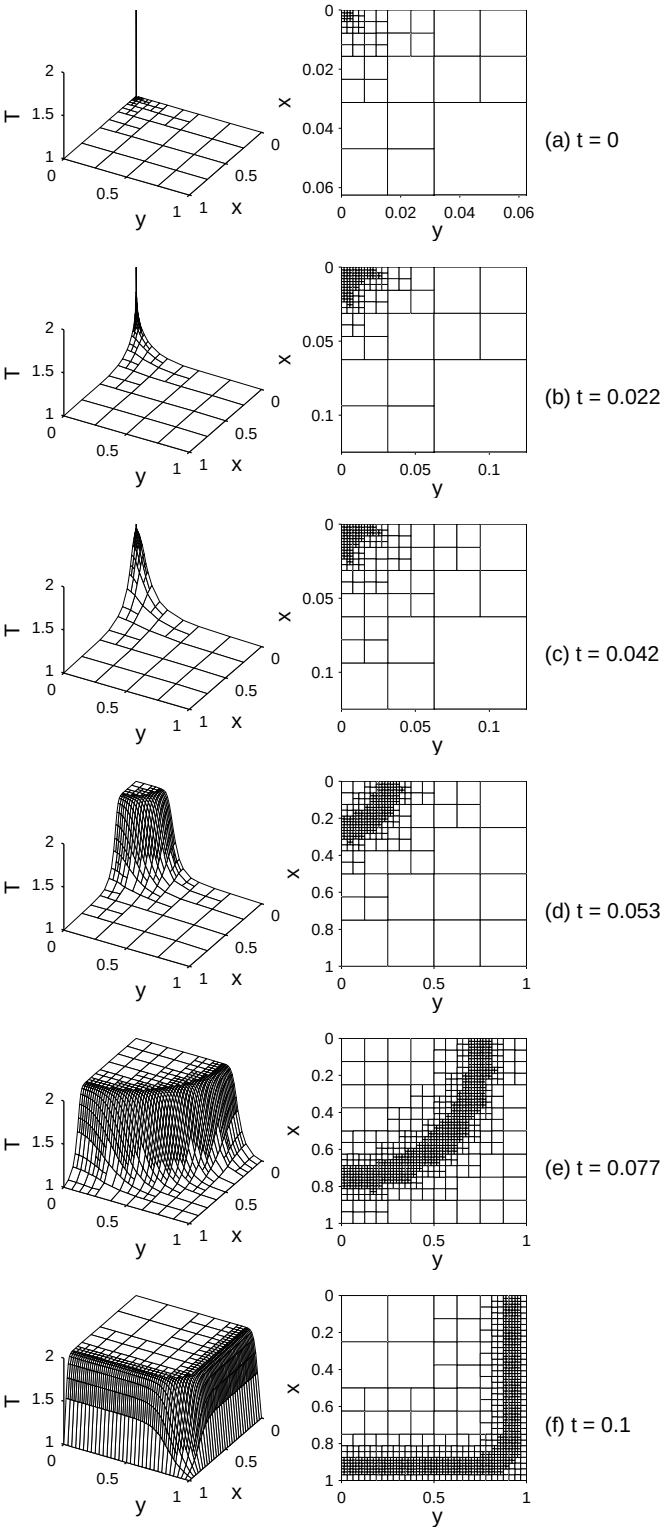

FIG. 4.2. *Numerical results with special linear elements on a sequence of adapted meshes for a model combustion problem. Mesh properties (number of nodes/number of elements):* (a) 106/97, (b) 188/181, (c) 203/196, (d) 304/313, (e) 900/949, *and* (f) 904/937.

surfaces at the left show numerical solutions at different times, and the 2-dimensional meshes at the right illustrate the element distribution close to the reaction zone.

The reactant is truly ignited at about $t = 0.042$; see Figure 4.2 (c). Before the ignition and during this ignition delay period, the reactant is actually undergoing a heat accumulating process around the hot spot (Figures 4.2 (a) and (b)). During this period, the ignition source induces a highly nonlinear feature around it, and correspondingly the elements are deployed at seven to eight different refinement levels in the whole domain with the finest close to the ignition source. After the ignition, the flame front begins to propagate outwards, and the finer elements start to be taken out from the region close to the ignition source until the flame front arrives at the boundaries, as shown in Figure 4.2 (c)–(f).

The fine elements generated from the local refinement process follow quite well with the flame front and leave the hot product behind with coarse elements. The finest elements are deployed exactly near the flame front where they are needed, and the special elements in the transient region give a smooth transition from the slowly to rapidly changing dynamic and chemical phenomena, or vice versa. As mentioned earlier, the error indicator based on the discontinuity of the first-order derivatives at the interelements have been used quite effectively throughout the self-adaptive refinement procedure. Before and after the ignition, the criteria for the error indicator were adjusted during the run time. Specifically, a higher upper limit was used before the ignition, and a lower upper limit was used after the ignition because the physical process shows a much stronger nonlinear feature before and during the ignition process than during the flame propagating process.

The last test case is a viscous flow past a circular cylinder (with a diameter of unity) described with incompressible Navier–Stokes equations of primitive variables. The dimensionless form of the governing equation can be written as

$$\begin{aligned} &\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0, \\ &u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y} = -\frac{\partial p}{\partial x} + \frac{1}{Re}\left(\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2}\right), \\ &u\frac{\partial v}{\partial x} + v\frac{\partial v}{\partial y} = -\frac{\partial p}{\partial y} + \frac{1}{Re}\left(\frac{\partial^2 v}{\partial x^2} + \frac{\partial^2 v}{\partial y^2}\right), \end{aligned} \tag{4.10}$$

where u and v denote the components of the velocity vector, p is the pressure, and Re is the Reynolds number. To discretize these equations, we take quadratic elements [20] for velocities and bilinear elements for pressure to satisfy the Babuska–Brezzi condition [2, 3]. To treat the convection terms, the method of successive substitution is used, which is quite suitable for such cases with moderate Reynolds numbers. For convection-dominated flows with higher Reynolds numbers, some upwind schemes [4, 12, 11] have to be considered.

Stable numerical solutions can be obtained for relatively higher Reynolds numbers, though experiments show that the vortex in the wake of a circular cylinder becomes oscillating at about $\mathrm{Re} \geq 40$ and the so-called Kármán vortex street develops. In the experiment, the influences of the possibly asymmetric cylinder, the improper alignment of the flow field, the potential 3-dimensional nature, and the disturbance in the laboratory all contribute to the earlier onset of the flow transition from steady to unsteady. In 2-dimensional numerical simulation, however, the absence of these influences delays the flow transition to unstable vortex shedding.

The incompressible viscous flows with Reynolds numbers of 10, 20, 40, and 100 have been calculated with special elements. In the following, the results of pressure are the focus for the analysis because only pressure is discretized on bilinear quadrilateral elements.

The calculation is started initially from an unstructured mesh with 553 nodes in 168 elements that covers half of the symmetric physical domain. Shown in Figure 4.3 (a) is the initial mesh with the boundary conditions. The initial mesh is constructed based on some knowledge of the flow; of 168 general quadrilateral elements, finer elements are distributed near the cylinder and aligned with the flow; a constant velocity is specified for the incoming flow, nonslip condition is used for the velocity on the surface of the cylinder, and the boundary condition for pressure is simply specified on a single boundary node at the top-right corner.

The local refinement is carried out at every few iteration steps. Though the elements are general quadrilaterals, the element refinement is still performed by halving the big element's sides, and the element merging is performed by combining four small neighboring elements.

In addition to the discontinuity of the first-order derivative, the error indicator also takes into account the contribution from the velocity direction changes within the element, in order to capture the vortex in the wake. Specifically, the element refinement also takes place in the region where the velocity vectors have a tendency to turn rapidly. We construct the following indicator, $e_{a,i}$, to measure such a tendency:

$$e_{a,i} = \frac{1}{\pi} \max \left\{ [\arctan(A_j) - \arctan(A_k)] : \ j,k \in \{\text{nodes in element } i\} \right\}, \tag{4.11}$$

$$A_l = \left(\frac{\partial v}{\partial x} u_l + \frac{\partial v}{\partial y} v_l \right) \Bigg/ \left(\frac{\partial u}{\partial x} u_l + \frac{\partial u}{\partial y} v_l \right), \qquad l = j,k. \tag{4.12}$$

For a steady state case, A_l equals $\frac{dv}{dt} / \frac{du}{dt}$, and therefore $\arctan(A_l)$ represents the acceleration direction of the flow at the location of node l. Indicator $e_{a,i}$ is a sensitive parameter to detect the possible direction change of the flow, for instance, in the vortex or the recirculation zone. The quantity $[\arctan(A_j) - \arctan(A_k)]$ is defined as the difference of flow acceleration directions at nodes j and k, which should be positive and less than π. Obviously, $e_{a,i}$ vanishes in the region where the flow goes straight.

The indicator for every individual dependent variable (unknown) is summed up without weighting (or with weighting to emphasize the influence of certain variables), and a single indicator is formed on element basis. By specifying a lower and an upper limit (criterion), refining or coarsening of elements is performed if the error indicators for the elements fall outside the specified range. In the self-adaptive procedure, special and normal elements are removed or added accordingly. Moreover, for different Reynolds numbers, the computational domain is extended in the y-direction until the pressure on the cylinder surface no longer depends on the domain size.

Shown in Figure 4.3 (b) and (c) is the final mesh for the converged solution with a Reynolds number of 20. In the adaptive process 375 elements with 1176 nodes are reasonably well distributed across the whole domain; see Figure 4.3 (b). Very fine elements are deployed in the region close to the front stagnation point and near the cylinder, less finer elements are deployed in the area further away from the cylinder and in the wake of the cylinder, and very coarse elements are distributed in the upper and down streams and in the far field. In the whole domain the smallest element is

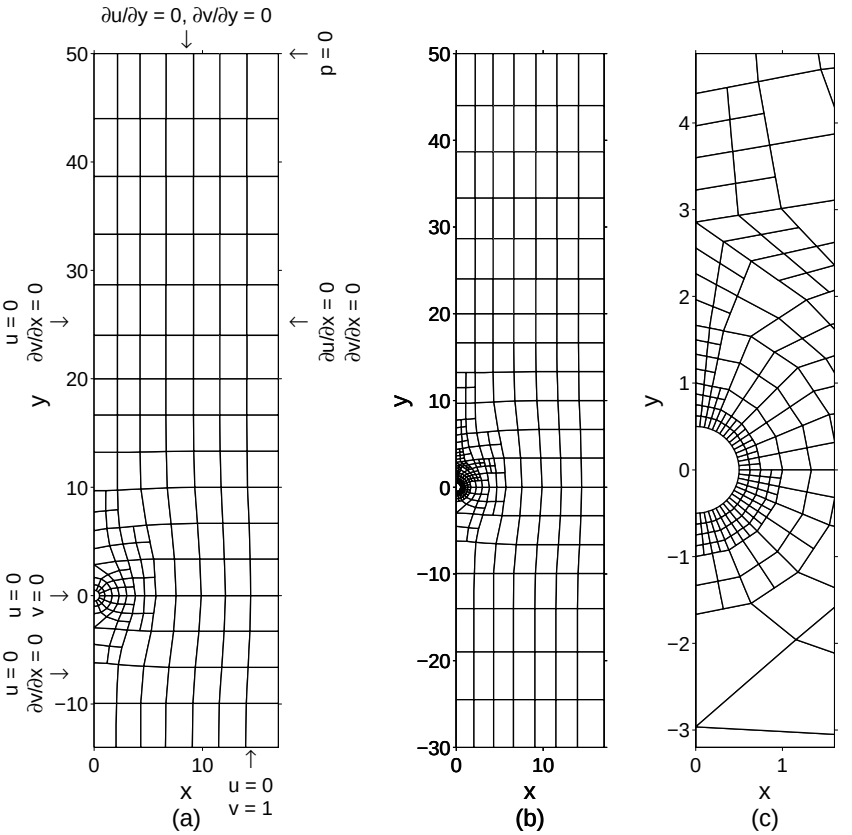

FIG. 4.3. *Initial mesh (*553 *nodes in* 168 *elements) and boundary conditions* (a) *for the flows past a circular cylinder, the final mesh* (b) *with* 1176 *nodes in* 375 *elements, and the closeup* (c) *of the mesh in the region around the cylinder for a case with a Reynolds number of* 20.

TABLE 4.1
Mesh properties and flow characteristics for the viscous flows past a circular cylinder with various Reynolds numbers.

Re	Domain	Element number	Node number	Separation point[°]	Vortex center location	Reattachment point
10	17×74	344	1085	163	0.108, 0.617	0.744
20	17×80	375	1176	143	0.209, 0.849	1.419
40	17×92	395	1238	133	0.289, 1.193	2.758
100	17×112	428	1341	123	0.402, 2.585	6.339

about 0.049×0.049, and the biggest one is 3×6 in size. Meshes for the other three cases have similar features. Table 4.1 shows some properties of the final meshes for the four cases. Since the elements are "economically" distributed, a relatively small number of discretized points (nodes) are required to accurately predict the detailed feature of each flow. For a typical case with a Reynolds number of 100, the mesh with special elements consists of 1341 nodes, while the numerical solutions were based on meshes of 3721 and 7410 discretized points in [7] and [8], respectively.

The pressure distribution on the surface of a body in a flow field is important for the prediction of the drag and the lift coefficients. Illustrated in Figure 4.4 are the pressure distributions obtained by the semianalytical method of series truncation [19],

by the finite difference discretization of streamfunction-vorticity formulation [7, 8], and by the discretization of primitive variables with special quadratic elements [20] and special bilinear elements introduced in section 2. The pressures at the front and rear stagnation points, p_f and p_r, respectively, are also listed in Table 4.2. It can be seen that quite good agreements have been achieved.

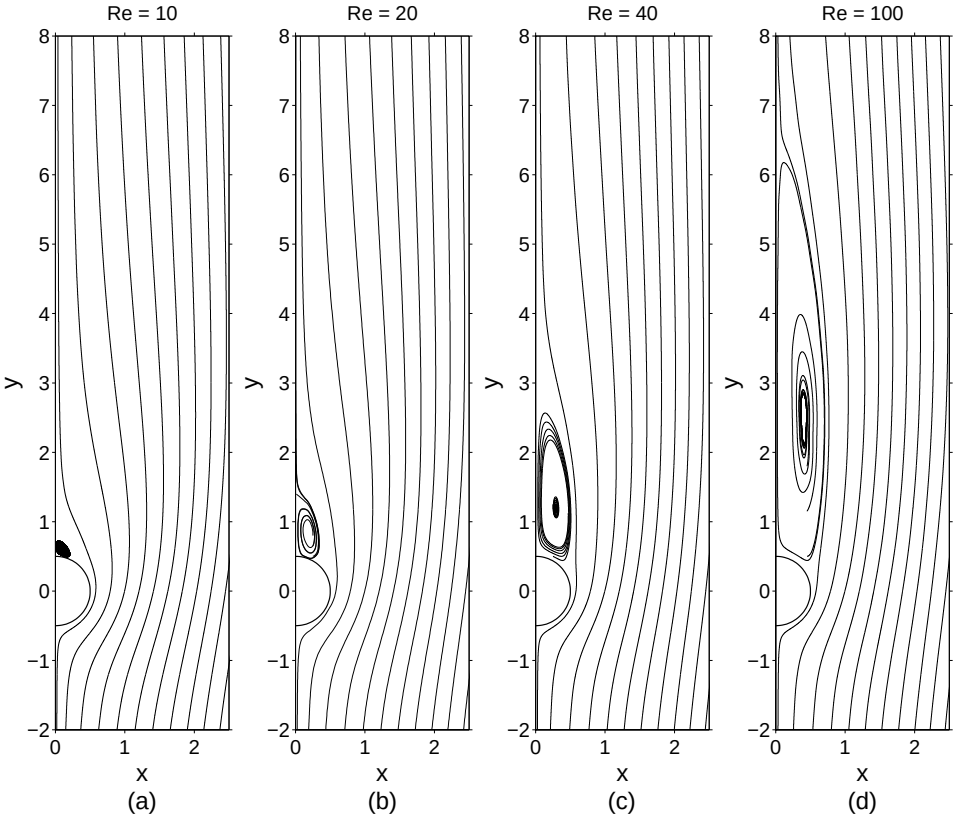

FIG. 4.5. *Streamlines for flows past a circular cylinder with Reynolds numbers of* 10 (a), 20 (b), 40 (c), *and* 100 (d). *The streamlines in the vortex regions are truncated for clarity.*

In the following, velocity-related results are presented only for completeness because the velocity is discretized on special quadratic elements. Shown in Figures 4.5 and 4.6 are the streamline plots and velocity fields in the vicinity of the cylinder for four different Reynolds numbers, respectively. The streamlines have been obtained from the postprocessing of velocity.

The separation points, the vortex centers, and the reattachment points for these four cases are listed in Table 4.1. The separation point is measured anticlockwise from the front stagnation point and is given in degree; the location of vortex center is described as a coordinate pair, while the reattachment point is indicated by its y-coordinate.

The vortex behind the cylinder starts to develop at $\mathrm{Re} = 7.334$, which is estimated as the reattachment point reaches the second node at the symmetric axis $(x = 0, y = 0.5625)$ above the cylinder. With an increasing Reynolds number, the streamline indicates clearly that the vortex grows with the reattachment point moving downstream, and the separation point moves back toward the front stagnation point; see Table 4.1 and Figure 4.5.

Velocity fields show that the flow decelerates toward the front stagnation point and accelerates over the cylinder, and the vortex develops in the wake for a Reynolds number ranging from 10 to 100. The velocity magnitude in the vortex zone is rather small even though the vectors are scaled up three times to make the vortex structure

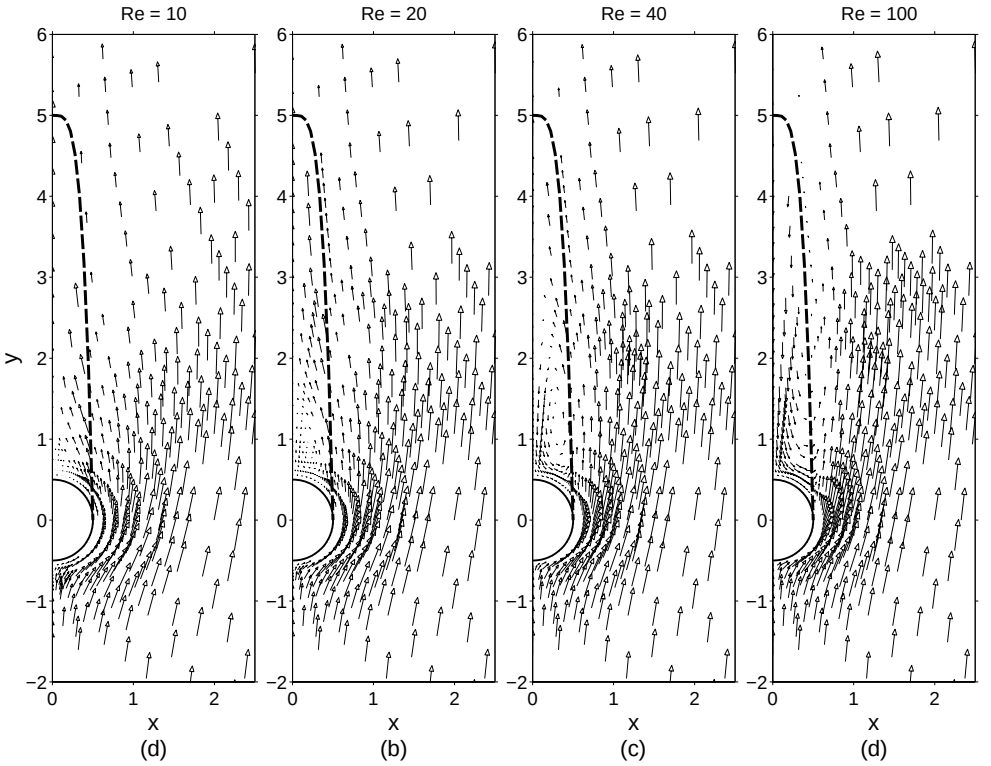

FIG. 4.6. *Velocity fields for viscous flows past a circular cylinder with Reynolds numbers of* 10 (a), 20 (b), 40 (c), *and* 100 (d). *For clarity, some velocity vectors have been taken out in regions with fine elements, and the vectors confined in the region marked with thick dashed lines are scaled up with a factor of* 3.

visible; see Figure 4.6. The error indicator based on the direction change of flow acceleration plays an important role in capturing the vortex structure in the flow field with such small velocities.

5. Final remarks. Special linear quadrilateral elements possess many useful features for the AFEM. These elements are C^0 continuous at interfaces, self-contained, accurate, capable of handling distortion, and easy to implement. The test cases have shown that they can be used effectively in solving such problems as heat transfer, diffusion, diffusion-reaction, pure fluid dynamic, and simple combustion cases.

With the error indicators based on the discontinuity of the first-order derivatives at interelements and the acceleration direction of the flow in an element, the AFEM with special linear quadrilateral elements captures well the localized physical phenomena in the domain of interest.

The implementation of special elements is quite a straightforward procedure. Only a small amount of additional computer storage and computing time is required in terms of the bookkeeping list or the discretization.

Appendix. Special triangular elements.

The concept of special elements can be extended to triangular elements. Shown in Figure A.1 is a typical situation where different triangular elements at different refinement levels meet.

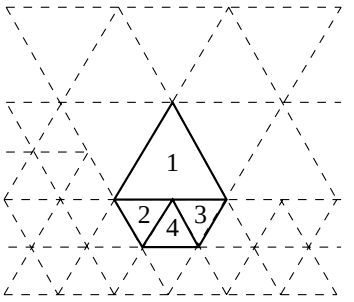

FIG. A.1. *Triangular elements in a transient region.*

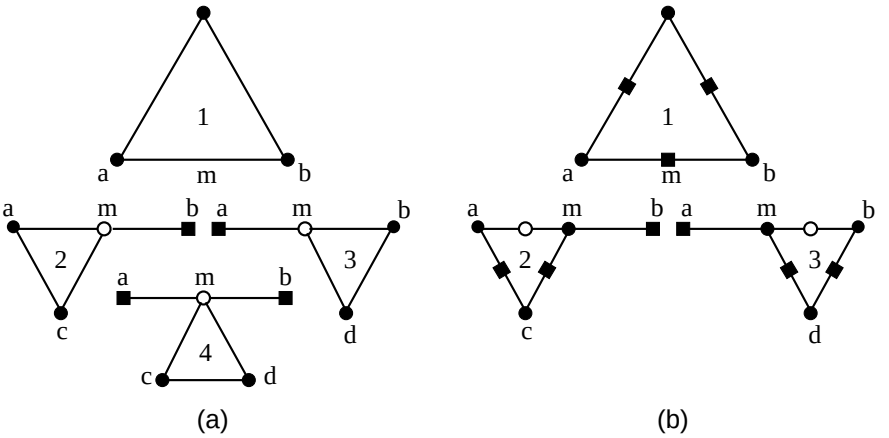

FIG. A.2. *Special linear* (a) *and quadratic* (b) *triangular elements. The numbers indicate elements, and the lower-case letters represent nodes; the solid circles indicate regular corner nodes, the void circles indicate irregular nodes, and the solid squares indicate middle nodes or irregular nodes' replacement nodes.*

In the following, we consider a case of dividing a triangular element into four smaller triangles and generating one irregular node only at one side of a small triangle. The triangular element with more than one side at the interface between different refinement levels can always be transformed or reconstructed so that only one side faces at such an interface.

For the case with linear triangular elements, three different special triangular elements can be constructed to satisfy the C^0 continuity conditions at interelements; see Figure A.2 (a). Special element 2 with nodes a, b, and c and special element 3 with nodes d, b, and a can be created. Because element 4 has only *one* apex (irregular node m) on interface ab, special element 4 has to be constructed uniquely and consistently by taking the information from four regular nodes (a, b, d, and c) instead of three. Elements 2, 3, and 4 are the special linear triangular elements of the first, second, and third kind, respectively.

Since the nodal values of a linear triangular element are always on a plane with straight sides, irregular node m can be placed anywhere on interface ab, and the C^0 continuity between elements 1, 2, 3, and 4 is always kept. However, to place this irregular node at the middle of interface ab can better maintain the aspect ratio during the refinement process and is most desired because of the accuracy consideration.

It can be seen that each of the special elements 2 and 3 has three nodes, and

their linear interpolation functions can be therefore constructed. The interpolation functions for element 4 require information of four nodes (see Figure A.2 (a)), and therefore the interpolation function cannot be constructed in a self-contained manner. This might not be convenient from a programming point of view, but it avoids dividing element 1, as in the procedure with a red-green refinement approach.

Similar to the case for quadrilateral elements, the information about node m will be merged consistently into the interpolation functions of the three special elements, which results in the C^0 continuity between elements 1, 2, 3, and 4.

For the case with quadratic triangular elements, only two special elements are required, that is, element 2 of the first kind, and element 3 of the second kind; see Figure A.2 (b). Element 1 is a normal six-node triangular element with a single middle node, node m, on interface ab. Element 2 has three corner nodes, two middle nodes, and an irregular node on interface am, and so does element 3.

In order to keep the C^0 continuity across interface am, we choose node b to replace the irregular node and to form special element 2. The property of the interpolation functions guarantees the C^0 continuity at interface am. A similar procedure can be applied to element 3, and the C^0 continuity will be satisfied at interface mb. It can be seen that the two special elements are self-contained for the case with quadratic triangular elements, which is not the case for special linear triangular elements.

Acknowledgments. The author wishes to thank Professor B. Rogg for the helpful discussion and Dipl.-Ing. B. Michaelis for the valuable suggestions and for the assistance in verifying some important details. The author is grateful to Dr. K. N. Lakshmisha for carefully reading the manuscript and making many useful suggestions. The author is also greatly indebted to emeritus Professor K. Gersten for his inspiring advice. Furthermore, the constructive suggestions and comments of the anonymous referees are greatly acknowledged.

CONSTRAINT PARTITIONING FOR STABILITY IN PATH-CONSTRAINED DYNAMIC OPTIMIZATION PROBLEMS*

SOUMYENDU RAHA† AND LINDA R. PETZOLD‡

Abstract. In this paper an algorithm for extracting a stable differential-algebraic subsystem from a path-constrained dynamical system is proposed. The subsystem may be integrated directly by a differential-algebraic system integrator to evaluate constraints in shooting- or multiple shooting-type direct methods for solving path-constrained dynamic optimization problems. The algorithm appends algebraic constraints to the unconstrained ordinary differential equation subsystem based on a stability estimate for the resulting differential-algebraic system. The logarithmic norm is used to compute a stability estimate for index 1 and index 2 subsystems. The working of the algorithm is illustrated with examples.

Key words. dynamic optimization, stability, path constraints, constraint partitioning

1. Introduction.

Dynamic optimization problems where some of the state variables of the dynamic system are required to follow prescribed functions in time (path constraints) are referred to as path-constrained dynamic optimization problems. This kind of preprogramming gives rise to constraints which, along with the ordinary differential equations (ODEs) or differential-algebraic equations (DAEs) describing the dynamic system, may increase the index [1], [5] and/or alter the stability of the resulting DAE problem. Since available algorithms can integrate DAEs up to differential index 2, the dynamic optimization problem is often solved [19], [18], [16] by an optimization scheme that incorporates integrating a lower-index (1 or 2) DAE system originating from the dynamical system. This paper addresses the problems of finding an optimal set of criteria based on stability of the DAE for identifying constraints which are best included in the DAE, rather than enforced by the optimizer.

A general path-constrained dynamics system can be written as

$$\text{(1a)} \qquad \text{Minimize} \qquad J = \int_0^{t_{\text{final}}} \chi(x,u,t)\,dt$$

$$\text{subject to}$$

$$\text{(1b)} \qquad F(\dot{x},x,u,t) = 0,$$

$$\text{(1c)} \qquad g(x,u,t) \le 0,$$

$$\text{(1d)} \qquad b_u \ge \begin{pmatrix} x^T & u^T \end{pmatrix}^T \ge b_l.$$

These problems may be solved by shooting- or multiple shooting-type methods [2], [16], [18], [19]. In a multiple shooting-type scheme, the original time interval of the problem is subdivided into subintervals $[t_k, t_{k+1}] \in [t_0, t_{\text{final}}]$. The DAEs (1b)–(1c) or subsystems thereof are integrated over the subintervals. Enforcement of continuity of the variables across the subintervals leads to constraints for the overall nonlinear optimization problem (1). Variables not included in the DAE are modeled as polynomial functions in time, and their coefficients are optimization variables. Smoothness and continuity of the polynomial approximations across the subinterval boundaries are expressed as constraints in the nonlinear optimization problem (1). All remaining constraints and bounds that have not been included in the DAE (1b)–(1c) or its subsystem for integration are handled from the overall optimization problem (1). Typically, the algebraic constraints excluded from the DAE system are entered in the optimizer as some positive function representing the constraint violation integrated over a shooting subinterval, which is required not to exceed a small positive quantity.

For this algorithm to work we must be able to integrate the DAE subsystem efficiently to the end of each subinterval. Thus we must choose the subsystem so that it is lower index (index 1 or 2) and stable. For nonlinear problems it may also be important that the subsystem is physically reasonable.

The choice of variables and constraints to include in the partitioned DAE (pDAE), can influence the stability of the pDAE, as illustrated by the following example. Consider the system

$$\begin{aligned} \dot{x} &= 1000.0x + u, \\ bx + u &= 0. \end{aligned}$$

The system is unstable when the constraint is included in the optimizer and the ODE is integrated (u being handled by the optimizer). But the system is stable for $b = 10000$ when integrated as an index 1 DAE. Additional constraints can also destabilize a pDAE, as we will see later.

Several algorithms have been proposed in the literature for partitioning DAE systems based on *structure*. In [9], a graph-based partitioning algorithm is proposed to yield a system with index 1 structure, and in [19] and [10] partitioning algorithms based on nonsingularity of the index 1 Jacobian are described. Noting that recent DAE software, e.g., RADAU5 [12] and DASPK3.0 [15], can handle index 1 and certain kinds of index 2 systems, in a forthcoming paper [17] we outline an algorithm for partitioning to obtain index 1 and index 2 structure.

The focus of the present paper is on partitioning for *stability*. Thus we assume that, if necessary, the problem has already been partitioned for index 1 or index 2 structure (i.e., that index 1 and index 2 constraints and corresponding variables have been identified) and can be written in the form

$$\text{Minimize} \qquad J = \int_{t_0}^{t_{\text{final}}} \chi(x, u, t)\, dt, \tag{2a}$$

subject to pDAE

$$\dot{x} = f(x, v, w, u_2(t), t), \tag{2b}$$

index 1 constraints

$$\Psi_1(x, v, t) = 0, \tag{2c}$$

index 2 constraints

$$\Psi_2(x, t) = 0, \tag{2d}$$

path constraints

$$p(x,t) = 0, \tag{2e}$$

and inequality constraints

$$c(x,t) \le 0, \tag{2f}$$

$$b_u \ge \begin{pmatrix} x^T & v^T & w^T & u_2(t)^T \end{pmatrix}^T \ge b_l, \tag{2g}$$

where $\frac{\partial \Psi_1}{\partial v}$ is nonsingular for index 1 and $\frac{\partial \Psi_2}{\partial x}\frac{\partial f}{\partial w}$ is nonsingular for index 2. Here the control vector u has been partitioned as $(v,w)^T$ and $u_2(t)$.

We note that partitioning is an issue for shooting and multiple shooting methods. An alternative to these methods is to apply a boundary value approach with a full discretization of the DAE system [4], [7]. For that approach, the stability concerns addressed here are no longer relevant and partitioning would not be needed.

In the next sections, stability criteria and computable estimates for building the pDAEs are developed. The criteria are based on logarithmic norms of quantities associated with the stability of the pDAE and physical information available about the dynamical system. An algorithm based on these criteria is given, and its working is illustrated with examples.

2. Measures of stability. To assess the stability we will consider the DAE system linearized at $t = t_k$

$$F_d := \dot{x} - f(x,v,w,u_2(t),t) := \dot{x} - (Hx + Qv + Tw + r(t)) = 0, \tag{3a}$$

$$\Psi_1 := C_v v + C_1 x + r_1(t) = 0, \tag{3b}$$

$$\Psi_2 := C_2 x + r_2(t) = 0, \tag{3c}$$

where $H \in \mathcal{R}^{n_x \times n_x}$, $Q \in \mathcal{R}^{n_x \times n_v}$, $T \in \mathcal{R}^{n_x \times n_w}$, $C_v \in \mathcal{R}^{n_v \times n_v}$, $C_1 \in \mathcal{R}^{n_v \times n_x}$, and $C_2 \in \mathcal{R}^{n_w \times n_x}$. The vectors $x \in \mathcal{R}^{n_x}$, $v \in \mathcal{R}^{n_v}$, $w \in \mathcal{R}^{n_w}$, $r(t) : \mathcal{R} \to \mathcal{R}^{n_x}$, $r_1(t) : \mathcal{R} \to \mathcal{R}^{n_v}$, and $r_2(t) : \mathcal{R} \to \mathcal{R}^{n_w}$. The local stability of an ODE of the form $\dot{x} = f(x,t)$ at $t = t_k$ is measured in terms of the largest real part in the set of eigenvalues of $\frac{\partial f}{\partial x}$ evaluated at $t = t_k$. Thus, $\max_\lambda \Re(\lambda(\frac{\partial f}{\partial x})) \le 0$ for a locally stable ODE. For nonlinear ODEs the logarithmic norm has often been used as a measure of stability [11]. In this section we outline and derive some basic properties of the logarithmic norm that will be needed in the derivation of the stability estimates of section 3.

For estimating bounds we shall use of the following well-known property.

LEMMA 2.1. *For any square symmetric real matrix H and any unit vector e, the expression $e^H H e$ subject to the condition $e^H e - 1 = 0$ is a maximum when e is an eigenvector corresponding to the maximum eigenvalue of H, and then* $\max_e e^H H e = \lambda_{\max}(H)$. *Also, it is known that* $\min_e e^H H e = \lambda_{\min}(H)$. *Hence for any unit vector* $e \in \mathcal{C}^{n_H}$, $\lambda_{\min}(H) \le e^H H e \le \lambda_{\max}(H)$.

The logarithmic norm provides an upper bound of the real part of the eigenvalue of the stability matrix.

DEFINITION 2.2 (logarithmic norm). *The logarithmic norm for a square matrix H in real or complex space is defined as*

$$\mu(H) := \lim_{\epsilon \to 0, \epsilon > 0} \frac{||I + \epsilon H|| - 1}{\epsilon}. \tag{4}$$

The logarithmic norm depends on the choice of matrix norm. In this paper we use the matrix norm induced by the 2-norm. Then the logarithmic norm for a square matrix $H \in \mathcal{R}^{n\times n}$ is given by (following Theorem 10.5 in Chapter I10 in [11])

$$\mu(H) = \max_{\lambda} \lambda(0.5(H^T + H)) \quad \text{when} \quad ||.|| = ||.||_2, \tag{5}$$

where λ denotes the eigenvalues. Also, the logarithmic norm satisfies a triangle inequality property along with some other useful ones. For a square matrix $H, H_1, H_2 \in \mathcal{R}^{n\times n}$,

$$\mu(H_1 + H_2) \leq \mu(H_1) + \mu(H_2) \tag{6a}$$

$$-||H|| \leq \mu(H) \leq ||H||, \tag{6b}$$

$$\mu(\alpha H) = \alpha\mu(H) \quad \text{for} \quad \alpha \geq 0, \tag{6c}$$

$$\mu\left(\int H(t)dt\right) \leq \int \mu(H(t))dt. \tag{6d}$$

All the above properties can be proved from the basic definition (4) of the logarithmic norm and by using the triangle inequality and other properties of the 2-norm ($||.||$).

Besides the above properties, the logarithmic norm is preserved under a unitary transformation.

LEMMA 2.3. *If H is a square matrix and Q is a unitary square matrix of the same dimension, then*

$$\mu(QHQ^T) = \mu(H). \tag{7}$$

Proof. Using the property (5), we obtain

$$\mu(QHQ^T) = \max_{\lambda} \lambda(0.5(QHQ^T + QH^TQ^T)) = \max_{\lambda} \lambda(0.5Q(H + H^T)Q^T).$$

Since a unitary transformation leaves the eigenvalues of a matrix unchanged, we have

$$\max_{\lambda} \lambda(0.5Q(H + H^T)Q^T) = \max_{\lambda} \lambda(0.5(H + H^T)). \qquad \square$$

Next, we establish the connection between the logarithmic norm and the maximum real part in the set of eigenvalues of a real square matrix.

LEMMA 2.4. *The following estimate holds for a square matrix $H \in \mathcal{R}^{n_H\times n_H}$:*

$$\max_{\lambda} \quad \Re(\lambda(H)) \leq \mu(H).$$

Proof. The above relation follows from the property of the logarithmic norm (5) so that $\mu(H) = \max_\lambda \lambda(\frac{(H+H^T)}{2})$. Since the eigenvector $e_\mu^{\max}$ corresponding to the maximum eigenvalue $\lambda_\mu^{\max}$ of $\frac{(H+H^T)}{2}$ maximizes the function $e_\mu^T \frac{(H+H^T)}{2} e_\mu$ subject to $e_\mu^T e_\mu - 1 = 0$, the choice of any other unit vector such as the eigenvector $e_H^{\max}$ (i.e., the eigenvector corresponding to the eigenvalue of H having the maximum real part) of H leads to a lesser value of the function. Also $\lambda_\mu^{\max}$ (where the subscript denotes the eigenvalue of $H^T + H$ and the superscript denotes the maximum value of an eigenvalue) and e are always real for real H since $H + H^T$ is a real symmetric matrix. Thus, using Lemma 2.1, we get

$$\mu(H) = \lambda_\mu^{\max} = e_\mu^{\max T} \frac{(H + H^T)}{2} e_\mu^{\max} \geq 0.5(e_H^{\max H} H e_H^{\max} + e_H^{\max H} H^T e_H^{\max})$$
$$= \max_{\lambda} \Re(\lambda(H)). \qquad \square$$

The logarithmic norm of a rank 1 system can be used to get estimates for the change in stability of a pDAE system by appending a single algebraic constraint.

LEMMA 2.5 (logarithmic norm of a rank 1 update). *Let u_1 and u_2 be unit vectors of dimension n. The logarithmic norm of the rank 1 matrix $u_1 u_2^T$ is given by*

$$\mu(u_1 u_2^T) = \max(0.5(u_1^T u_2 \pm 1), 0) \quad for \quad n > 2, \tag{8a}$$

$$\mu(u_1 u_2^T) = \max(0.5(u_1^T u_2 \pm 1)) \quad for \quad n = 2. \tag{8b}$$

Proof. Using property (5) the eigenvalues of the rank 2 system $0.5(u_1 u_2^T + u_2 u_1^T)$ are $0.5(u_1^T u_2 \pm 1)$ with the corresponding eigenvectors being $\frac{u_1 \pm u_2}{2}$. If $n > 2$, the system being rank 2, the other eigenvalues are zero. ∎

3. Stability of the pDAE. In this section we study the stability of index 1 and index 2 DAEs. We present conditions based on the logarithmic norm for assessing the effect of stability of appending or deleting a single algebraic constraint from the pDAE.

3.1. Index 1 stability. The underlying ODE (UODE) for an index 1 subsystem is locally stable if the largest real part of the eigenvalues of $H - QC_v^{-1}C_1$ is less than or equal to zero. For practical computations we require it to be less than a positive real number (TOL) of suitable size. This condition can be written in terms of the logarithmic norm.

THEOREM 3.1 (index 1 stability). *The index 1 pDAE subsystem is stable if*

$$\mu(H - QC_v^{-1}C_1) \leq 0. \tag{9}$$

Proof. The proof follows from Lemma 2.4. ∎

COROLLARY 3.2. *An unstable ODE ($\mu(H) > 0$) or a pDAE already in place can be stabilized by appending index 1 constraints if for the resulting system*

$$\mu(H - QC_v^{-1}C_1) \leq \mu(H) + \mu(-QC_v^{-1}C_1) \leq 0,$$

or

$$\mu(-QC_v^{-1}C_1) \leq -\mu(H). \tag{10}$$

The condition for checking the stability of an index 1 subsystem upon appending a single algebraic constraint can be deduced using the analytical result in Lemma 2.5. For a single algebraic constraint, Q is a column vector (say, $\tilde{Q}$), C_1 is a row vector (say, $\tilde{C_1}$), and C_v is a scalar represented by c_v. Let $u_Q = \frac{-\tilde{Q}}{||\tilde{Q}||_2}$, $u_{C_1}^T = \frac{\text{sign}(c_v)\tilde{C_1}}{||\tilde{C_1}||_2}$, and $\gamma = \frac{||\tilde{Q}||_2 . ||\tilde{C_1}||_2}{|c_v|} \geq 0$. Then $\mu(H - \tilde{Q}c_v^{-1}\tilde{C_1}) = \mu(H + \gamma u_Q u_{C_1}^T)$. Computationally, the condition for stability is

$$\mu(H + \gamma u_Q u_{C_1}^T) \leq \mu(H) + \mu(\gamma u_Q u_{C_1}^T) = \mu(H) + \tilde{\gamma} \leq TOL, \tag{11}$$

where $\tilde{\gamma}$ is defined using Lemma 2.5 as

$$\mu(\gamma u_Q u_{C_1}^T) = \tilde{\gamma} = \gamma \max\left(0, \frac{(u_{C_1}^T u_Q \pm 1)}{2}\right) \tag{12}$$

for $n_x > 2$ (where n_x is the dimension of x). For $n_x = 2$, the maximum is taken over $\frac{(u_{C_1}^T u_Q \pm 1)}{2}$ only. ∎

Next we compute (12) for each index 1 constraint being appended to a group of already existing index 1 constraints. Thus let

$$\Psi_1 \equiv C_1 x + C_v v + c_c v_1 + r_1(t) = 0$$

be the existing group of constraints to which a constraint of the form

$$\tilde{C}_1 x + c_v v_1 + c_r v + r_{11}(t) = 0$$

is considered for being appended. This is equivalent to appending the constraint

$$\bar{\Psi}_1 \equiv \bar{C}_1 x + \bar{C}_v v_1 + \bar{r}_1(t) = 0$$

to the UODE

$$\dot{x} = (H - QC_v^{-1}C_1)x + Tw(t) + r(t),$$

where

$$\bar{C}_1 = \tilde{C}_1 - c_r C_v^{-1} C_1, \tag{13a}$$

$$\bar{C}_v = c_v - c_r C_v^{-1} c_c, \tag{13b}$$

and $\bar{r}_1(t)$ represents the terms that are functions of time only. While evaluating (12), u_{C_1} is computed as $u_{\bar{C}_1} = \frac{\text{sign}(\bar{C}_v)C_1}{||\bar{C}_1||_2}$. Then $\tilde{\gamma}$ for second or later index 1 constraints is computed as

$$\tilde{\gamma}_{\text{append}} = \frac{||\tilde{Q}||_2 ||\bar{C}_1||_2}{|\bar{C}_v|} \max\left(0, \frac{(u_{\bar{C}_1}^T u_Q \pm 1)}{2}\right) \tag{14}$$

(for $n_x > 2$), where $\tilde{Q}$ is the column vector in the differential equations corresponding to the algebraic variable chosen for the index 1 equation under consideration. Summarizing, we have the following theorem.

THEOREM 3.3 (stability of index 1 constraints). *Checking* (11)*, with* $\tilde{\gamma}$ *given by* (12) *or* (14) *as appropriate, is sufficient for determining the stability when including a single index* 1 *algebraic constraint in the pDAE.*

Proof. The proof follows from the discussion above. ∎

3.2. Index 2 stability. The stability analysis for an index 2 pDAE is done by reducing the system to an essential underlying ODE (EUODE) [3]. The index 2 system ((3a)–(3c)) can be reduced to a UODE by differentiating the index 2 constraint once with respect to t and eliminating the index 1 variables to obtain an expression for w. Thus

$$w = -(C_2T)^{-1}(C_2Hx - C_2QC_v^{-1}C_1x - C_2QC_v^{-1}r_1(t) + C_2r(t) + \dot{C}_2x + \dot{r}_2(t)).$$

Also define

$$R := (I_{n_x} - T(C_2T)^{-1}C_2). \tag{15}$$

Then the UODE can be written as

$$\begin{aligned}\dot{x} = &(R(H - QC_v^{-1}C_1) - T(C_2T)^{-1}\dot{C}_2)x \\ &+R(r(t) - QC_v^{-1}r_1(t)) - T(C_2T)^{-1}\dot{r}_2(t).\end{aligned} \tag{16}$$

The idempotent projection R has certain properties in connection with its decomposition. A decomposition of R (e.g., QR, SVD, or Schur) can be used to obtain an EUODE from (16). In this paper, for simplicity we use the QR-decomposition of R to construct an EUODE for the index 2 subsystem.

LEMMA 3.4. *The projection $R \in \mathcal{R}^{n_x \times n_x}$ is idempotent and has a rank of $n_x - n_w$ with exactly n_w eigenvalues of zero and n_x eigenvalues of* 1.

Proof. R is idempotent by construction: $RR = (I_{n_x} - T(C_2T)^{-1}C_2) = R$.

From the definition of R (15) it is obvious that $C_2R = 0$. If λ_R denotes an eigenvalue and e_R denotes an eigenvector of R, the eigenvalue equation for R is obtained as $Re_R - \lambda_R e_R = 0$, which after premultiplication by C_2 yields $\lambda_R C_2 e_R = 0$. Then either $\lambda_R = 0$ or $C_2 e_R = 0$. If $C_2 e_R = 0$, then $Re_R - \lambda_R e_R = 0$ gives $e_R - \lambda_R e_R = 0$, i.e., $\lambda_R = 1$ (e_R being a unit vector). Again, if $\lambda_R \neq 1$, then $Re_R = 0$, in which case the eigenvector corresponds to $\lambda_R = 0$. When $\lambda_R = 0$, $C_2 e_R \neq 0$. Since C_2 is of rank n_w, row vectors of C_2 have a basis of n_w independent vectors of dimension n_x. Thus it is possible to find a set of n_w unit vectors of dimension n_x such that $C_2 e_R \neq 0$ and such that they are the eigenvectors corresponding to $\lambda_R = 0$. Corresponding to $\lambda_R = 1$, it is then possible to find $n_x - n_w$ other unit eigenvectors orthogonal to row vectors of C_2. Thus R has n_w zero eigenvalues, and its other $n_x - n_w$ eigenvalues are 1. Thus the upper triangular matrix from the Schur decomposition of R has n_w zeroes and $n_x - n_w$ 1's on the diagonal and can be written in the form $\begin{pmatrix} I_{n_x \times n_w} & \Xi \\ 0 & 0 \end{pmatrix}$. Then R has $n_x - n_w$ nonzero singular values and hence a rank equal to $n_x - n_w$. ∎

LEMMA 3.5. *If $\bar{W} \in \mathcal{R}^{n_x \times n_x}$ and $\bar{S} \in \mathcal{R}^{n_x \times n_x}$ are the unitary matrix and the upper triangular matrices, respectively, obtained from the QR-decomposition of R, then $\bar{W}$ can be partitioned as $(W \quad \tilde{W})$ and $\bar{S}$ can be partitioned as $\binom{S}{0}$, where W is an $n_x \times n_x - n_w$ real matrix, S is an $n_x - n_w \times n_x$ real matrix, and $\tilde{W}$ is an $n_x \times n_w$ real matrix. Then $W^TW = I_{n_x - n_w}$, $W^T\tilde{W} = 0$, $SW = I_{n_x - n_w}$, $ST = 0$, and $C_2W = 0$.*

Proof. The matrix $\bar{S}$ is upper triangular and of the same rank as R, i.e., $n_x - n_w$, and n_w of its diagonal elements are zero. The rows corresponding to these diagonal elements must be zero; otherwise, the rank of $\bar{S}$ will be higher than that of R. These empty rows can be partitioned away as the lower n_w rows of $\bar{S}$. Thus $R = (W \quad \tilde{W})\binom{S}{0} = WS$.

Since $\bar{W}$ is a unitary matrix, the columns of $\bar{W}$ are orthonormal. Hence $W^TW = I_{n_x - n_w}$. Since the columns of $\tilde{W}$ are orthogonal to those of W, $\tilde{W}^TW = 0$.

Since $RT = 0$ by construction and $S = W^TR$, we have $ST = 0$. Since $ST = 0$, we have $SR = S$, i.e., $SWS = S$, i.e., $SW = (SS^T)^{-1}(SS^T) = I_{n_x - n_w}$. The matrix SS^T is invertible because S is of full row $(n_x - n_w)$ rank. Since $W = RW$ and $C_2R = 0$ by construction, we have $C_2W = 0$. ∎

Next the effect of transformation with S and W on eigenvalues of a square matrix is examined.

LEMMA 3.6. *If $A \in \mathcal{R}^{n_x \times n_x}$ and S and W have been defined as above, then*

$$\lambda_{\max}(SAW) = \lambda_{\max}(A)k, \qquad 0 \leq |k| \leq 1, \tag{17}$$

or

$$\max_{\lambda} |\lambda(SAW)| \leq \max_{\lambda} |\lambda(A)|, \tag{18}$$

where $\lambda_{\max}$ is the eigenvalue having the maximum absolute value.

Proof. The eigenvalue equation for SAW is $SAWe - \lambda_0 e = 0$, where λ_0 is an eigenvalue of SAW and $e \in \mathcal{C}^{n_x - n_w}$ is an eigenvector for SAW. Let $e = W^T p$, where p is a unit vector of dimension n_x. The eigenvalue problem is rewritten as $SAWW^T p - \lambda_0 W^T p = 0$. This is equivalent to solving $RAWW^T p - \lambda_0 WW^T p = 0$. Since WW^T is an idempotent matrix and $W^T W = I_{n_x - n_w}$, WW^T can be decomposed as $Q_1 \begin{pmatrix} I_{n_x - n_w} & 0 \\ 0 & 0 \end{pmatrix} Q_1^T$, Q_1 being a $n_x \times n_x$ unitary matrix. Also, R is decomposed as $Q \begin{pmatrix} I_{n_x \times n_w} & \Xi \\ 0 & 0 \end{pmatrix} Q^T$. Substituting the decompositions, we obtain

$$Q_1^T Q \begin{pmatrix} I_{n_x \times n_w} & \Xi \\ 0 & 0 \end{pmatrix} Q^T A Q_1 \begin{pmatrix} I_{n_x - n_w} & 0 \\ 0 & 0 \end{pmatrix} Q_1^T p = \lambda_0 \begin{pmatrix} I_{n_x - n_w} & 0 \\ 0 & 0 \end{pmatrix} Q_1^T p,$$

$$Q_1^T Q \begin{pmatrix} I_{n_x \times n_w} & \Xi \\ 0 & 0 \end{pmatrix} Q^T A Q_1 \begin{pmatrix} v \\ 0 \end{pmatrix} = \lambda_0 \begin{pmatrix} v \\ 0 \end{pmatrix},$$

where v is a vector of dimension $n_x - n_w$ and $||v||_2 \leq 1$. A is decomposed as $Q_A N Q_A^T$, where Q_A is a unitary matrix and N is an upper triangular matrix. The eigenvalues λ_0 are then based on upper $n_x - n_w$ rows and columns of N. Thus $k \max(\lambda_0) = \max(\lambda(A))$ and $|\max(\lambda_0)| \leq \max(\lambda(A))$. ∎

COROLLARY 3.7. *In Lemma* 3.6, *if the transformation is* $W^T AW$ *instead of* SAW, *the results in* (18) *also hold true.*

The proof can be completed by substituting W^T for S. Since WW^T is idempotent, the eigenvalue equation for WW^T is $WW^T e - \lambda_{WW^T} e = 0$, i.e., $WW^T(1 - \lambda_{WW^T})e = 0$, where e is a unit vector of dimension n_x. Then $\lambda_{WW^T} = 1$ or $WW^T e = 0$. If $WW^T e = 0$, $\lambda_{WW^T} = 0$. If $\lambda_{WW^T} = 1$, then $WW^T e = e$ and $C_2 e = 0$. Since $\text{rank}(C_2) = n_w$, there will be exactly $n_x - n_w$ eigenvalues equal to 1. The other n_w eigenvalues are 0. Hence $0 \leq |p_{\max}^T WW^T p_{\max}| \leq 1$ (Lemma 2.1). Hence the results in (17) hold for a $W^T AW$ type transformation.

An EUODE can be deduced by substituting $x \in \mathcal{R}^{n_x}$ by a variable $\xi \in \mathcal{R}^{n_x - n_w}$. Let $\xi = Sx$. Then it follows from (3c) that $x = W\xi - T(C_2 T)^{-1} r_2$. It is assumed that R is at least once-differentiable (with respect to t) almost everywhere over the interval of integration ($t_0 \leq t \leq t_{\text{final}}$) and that R is of constant rank everywhere over the interval. Then W is differentiable at least once over the interval of integration. [8].

LEMMA 3.8. *If* $R \in \mathrm{C}^1(t)$, *then* $W \in \mathrm{C}^1(t)$ *and* $S \in \mathrm{C}^1(t)$.

Proof. Since R has constant rank all over the interval $t_0 \leq t \leq t_{\text{final}}$, Corollary 2.5 in [8] can be applied to R to get a QR-decomposition differentiable at least once with respect to t over the interval of integration. ∎

The UODE can be written in terms of ξ and premultiplied by S to obtain an EUODE

$$\dot{\xi} = -S\dot{W}\xi + S(H - QC_v^{-1}C_1)W\xi + \{\text{terms in } t\}. \tag{19}$$

The stability of the EUODE is then determined by the largest real part of the eigenvalues of

$$M := S(H - QC_v^{-1}C_1)W - S\dot{W}. \tag{20}$$

Let $\bar{H} := H - QC_v^{-1}C_1$. Then

$$M := W^T R\bar{H}W - W^T R\dot{W} = W^T \bar{H}W - W^T T(C_2 T)^{-1} C_2 \bar{H}W \\ -W^T \dot{W} + W^T T(C_2 T)^{-1} C_2 \dot{W}.$$

The logarithmic norm can be expressed as

$$\mu(M) = \mu(W^T\bar{H}W - W^TT(C_2T)^{-1}C_2\bar{H}W - W^T\dot{W} + W^TT(C_2T)^{-1}C_2\dot{W}).$$

Since $W^TW =$ a constant (identity) matrix and $\dot{W}^TW + W^T\dot{W} = \dot{I} = 0$, using (5), we have

$$\mu(M) = \mu(W^T\bar{H}W - W^TT(C_2T)^{-1}C_2\bar{H}W + W^TT(C_2T)^{-1}C_2\dot{W}). \tag{21}$$

Using the corollary to Lemma (3.6), the definition (5), and that $C_2W = 0$, we get

$$\begin{aligned}\mu(M) &= \mu(W^T\bar{H}W - W^TT(C_2T)^{-1}C_2\bar{H}W - W^TT(C_2T)^{-1}\dot{C}_2W)\\ &\le \mu(R\bar{H} - T(C_2T)^{-1}\dot{C}_2).\end{aligned} \tag{22}$$

The last expression on the right is the logarithmic norm for the stability matrix of the UODE (16). Thus checking $\mu(R\bar{H} - T(C_2T)^{-1}\dot{C}_2) \le 0$ is sufficient for the stability of the index 2 pDAE. This implies that if the index 1 differentiated form of the constraint yields a stable pDAE in terms of the logarithmic norm measure, the index 2 system is then stable too. In (21), $\mu(M) \le \mu(W^T\bar{H}W) \le \mu(\bar{H})$ when $T = C_2^T$, i.e., when $W^TT = 0$. Thus index 2 constraints with $T = C_2^T$ can be appended to the pDAE without destabilizing it. Also, when $(C_2\bar{H} + \dot{C}_2)R = 0$, the index 2 constraint does not change the stability of the existing pDAE.

Using (20) and Lemma 3.6, we obtain

$$\max(\Re(\lambda(S\bar{H}W - S\dot{W}))) = \max(\Re(\lambda(S\bar{H}W + SW\dot{S}W))),$$

leading to

$$\begin{aligned}&\max(\Re(\lambda(S(\bar{H} + W\dot{S})W)))\\ &= \max(\Re(\lambda(S(\bar{H} + W\dot{W}^T - WW^TT(C_2T)^{-1}\dot{C}_2)W)))\end{aligned} \tag{23}$$

and

$$\max(\Re(\lambda(S\bar{H}W + \dot{S}W))) \le \max(\Re(\lambda(\bar{H} + W\dot{W}^T - WW^TT(C_2T)^{-1}\dot{C}_2))).$$

For $T \ne C_2^T$ a computable criterion for the stability of the index 2 pDAE can be derived. Using (8), we can write

$$\begin{aligned}&\max(\Re(\lambda(\bar{H} + W\dot{W}^T - WW^TT(C_2T)^{-1}\dot{C}_2)))\\ &\le \mu(\bar{H} + W\dot{W}^T - WW^TT(C_2T)^{-1}\dot{C}_2).\end{aligned} \tag{24}$$

The use of the triangle inequality (6a) on (24) separates the index 2 logarithmic norm terms from the index 1 subsystem of the pDAE yielding

$$\mu(\bar{H} + W\dot{W}^T - WW^TT(C_2T)^{-1}\dot{C}_2) \le \mu(\bar{H}) + \mu(W\dot{W}^T) + \mu(-WW^TT(C_2T)^{-1}\dot{C}_2).$$

The term $\mu(W\dot{W}^T)$ can be bounded as follows.

LEMMA 3.9. *With W defined as above, $\mu(-T(C_2T)^{-1}\dot{C}_2) \ge \mu(W\dot{W}^T) \ge 0$.*

Proof. The following relationship can be derived.

$$\begin{aligned}\mu(W\dot{W}^T) &= 0.5\max_{\lambda}\lambda(W\dot{W}^T + \dot{W}W^T) = 0.5\mu(\overline{\dot{WW^T}})\\ &= 0.5\mu(-\overline{\dot{\tilde{W}}\tilde{W}^T}) = \max_{\lambda}\lambda\left(-\frac{\dot{\tilde{W}}\tilde{W}^T + \tilde{W}\dot{\tilde{W}}^T}{2}\right),\end{aligned}$$

where $\tilde{W}$ is a part of the partitioned matrix $\bar{W}$ as described in Lemma (3.5) and $\dot{\tilde{W}\tilde{W}^T} = \frac{d}{dt}(\tilde{W}\tilde{W}^T)$. Thus

$$
\begin{aligned}
&\mu(W\dot{W}^T)\\
&= \max_{\lambda} \lambda \left(-0.5 \begin{pmatrix} W^T \\ \tilde{W}^T \end{pmatrix} (\dot{\tilde{W}}\tilde{W}^T + \tilde{W}\dot{\tilde{W}}^T) \begin{pmatrix} W & \tilde{W} \end{pmatrix} \right)\\
&= \max_{\lambda} \lambda \left(-0.5 \begin{pmatrix} 0 & W^T\dot{\tilde{W}} \\ (W^T\dot{\tilde{W}})^T & \tilde{W}^T\dot{\tilde{W}} + \dot{\tilde{W}}^T\tilde{W} \end{pmatrix} \right)\\
&= \max_{\lambda} \lambda \left(-0.5 \begin{pmatrix} 0 & W^T\dot{\tilde{W}} \\ (W^T\dot{\tilde{W}})^T & 0 \end{pmatrix} \right)\\
&= \max_{\lambda} \lambda \left(-0.5 \begin{pmatrix} 0 & W^T(T(C_2T)^{-1}\dot{C}_2)^T\tilde{W} \\ \tilde{W}^T(T(C_2T)^{-1}\dot{C}_2)W & 0 \end{pmatrix} \right)\\
&= \max_{\lambda} \lambda \left(-0.5 \begin{pmatrix} W & \tilde{W} \end{pmatrix} \begin{pmatrix} 0 & W^T(T(C_2T)^{-1}\dot{C}_2)^T\tilde{W} \\ \tilde{W}^T(T(C_2T)^{-1}\dot{C}_2)W & 0 \end{pmatrix} \begin{pmatrix} W^T \\ \tilde{W}^T \end{pmatrix} \right)\\
&= \max_{\lambda} \lambda \left(-0.5(\tilde{W}\tilde{W}^T(T(C_2T)^{-1}\dot{C}_2)^TWW^T + (\tilde{W}\tilde{W}^T(T(C_2T)^{-1}\dot{C}_2)^TWW^T)^T) \right)\\
&= \mu(-\tilde{W}\tilde{W}^T(T(C_2T)^{-1}\dot{C}_2)WW^T)\\
&= \mu(-(T(C_2T)^{-1}\dot{C}_2)WW^T + WW^T(T(C_2T)^{-1}\dot{C}_2)WW^T).
\end{aligned}
$$

The above derivation uses the preservation property of eigenvalues under a unitary transformation (Lemma 2.3) and the following relationships from the definition of W, $\tilde{W}$, and R as given in the last section.

$$
\begin{aligned}
\tilde{W}^T R = \tilde{W}^T - \tilde{W}^T(T(C_2T)^{-1}C_2) = 0,\\
\dot{\tilde{W}}^T = \dot{\tilde{W}}^T(T(C_2T)^{-1}C_2) + \tilde{W}^T\frac{d(T(C_2T)^{-1})}{dt}C_2 + \tilde{W}^TT(C_2T)^{-1}\dot{C}_2,\\
\dot{\tilde{W}}^TW = \tilde{W}^TT(C_2T)^{-1}\dot{C}_2W.
\end{aligned}
$$

Using (5) the logarithmic norm can be evaluated through the eigenvalue equation for

$$-\tilde{W}\tilde{W}^T(T(C_2T)^{-1}\dot{C}_2)WW^Te - WW^T(T(C_2T)^{-1}\dot{C}_2)^T\tilde{W}\tilde{W}^Te - 2\lambda e = 0,$$

where λ is the eigenvalue and the unit vector e is the corresponding eigenvector. Also, C_2 and $\tilde{W}$ being at least of rank n_w, $C_2\tilde{W} \in \mathcal{R}_{n_w \times n_w}$ is invertible so that

$$\tilde{W}^T\tilde{W} = \tilde{W}^TT(C_2T)^{-1}C_2\tilde{W} = I_{n_w},$$

whence

$$(C_2\tilde{W})^{-1} = \tilde{W}^TT(C_2T)^{-1}.$$

Since $C_2W = 0$, after premultiplying the above by C_2, we have $2\lambda C_2e = -\dot{C}_2WW^Te$. We can substitute this in the eigenvalue equation, and, by using $\tilde{W}^T = \tilde{W}^TT(C_2T)^{-1}C_2$, we get

$$\lambda e^T\tilde{W}\tilde{W}^TT(C_2T)^{-1}C_2e = 0.5\lambda,$$

leading to

$$\lambda e^T\tilde{W}\tilde{W}^Te = 0.5\lambda,$$

whence either $\lambda = 0$ or $e^T\tilde{W}\tilde{W}^T e = 0.5$ (or $e^T WW^T e = 0.5$). Corresponding to the latter relationships, $\mu(W\dot{W}^T)$ is the logarithmic norm of a partial matrix obtained from orthogonal transformation of the matrix $(-T(C_2T)^{-1}\dot{C}_2)$, padded with zeros. Both WW^T and $\tilde{W}\tilde{W}^T$ are matrices with eigenvalues at 0 and 1 only. Hence their Schur decompositions can be written as $WW^T = Q_0\begin{pmatrix} I_{n_w \times n_x} & 0 \\ 0 & 0 \end{pmatrix} Q_0^T$ and $\tilde{W}\tilde{W}^T = Q_0\begin{pmatrix} 0 & 0 \\ 0 & I_{n_w} \end{pmatrix} Q_0^T$, respectively. Then

$$\mu(-\tilde{W}\tilde{W}^T(T(C_2T)^{-1}\dot{C}_2)WW^T)$$
$$= \mu\left(-\begin{pmatrix} 0 & 0 \\ 0 & I_{n_w} \end{pmatrix} Q_0(T(C_2T)^{-1}\dot{C}_2)Q_0^T \begin{pmatrix} I_{n_w \times n_x} & 0 \\ 0 & 0 \end{pmatrix}\right) \leq \mu(-T(C_2T)^{-1}\dot{C}_2).$$

Hence $\mu(W\dot{W}^T) \leq \mu(-T(C_2T)^{-1}\dot{C}_2)$.

Differentiating both sides in (6d), we get the property by which

$$\mu(W\dot{W}^T) = 0.5\mu(\dot{\overline{WW^T}}) \geq \dot{\mu}(WW^T) = 0. \qquad \square$$

Since $W^TW = I_{n_w \times n_x}$ and WW^T is an idempotent matrix with eigenvalues of 0 and 1 only, the matrix WW^T has a Schur decomposition of the form $Q_0\begin{pmatrix} I_{n_w \times n_x} & 0 \\ 0 & 0 \end{pmatrix} Q_0^T$. Using the corollary to Lemma 3.6, we can estimate $\mu(-WW^TT(C_2T)^{-1}\dot{C}_2) \leq \mu(-T(C_2T)^{-1}\dot{C}_2)$. Hence we get

$$\mu(\bar{H}) + \mu(W\dot{W}^T) + \mu(-WW^TT(C_2T)^{-1}\dot{C}_2) \leq \mu(H) + 2\mu(-T(C_2T)^{-1}\dot{C}_2). \tag{25}$$

If C_2 is constant, the index 2 constraint does not destabilize the existing pDAE significantly.

Applying the triangle inequality of the logarithmic norm to (25), we have obtained the stability estimate for index 2 pDAE as $\mu(\bar{H})+\mu(W\dot{W}^T)+\mu(-WW^TT(C_2T)^{-1}\dot{C}_2)$, which has been shown to be less than or equal to $\mu(\bar{H}) + 2\mu(-T(C_2T)^{-1}\dot{C}_2)$. Using (17), $\max(\Re(\lambda(S\bar{H}W + \dot{S}W)))$ can be estimated as follows. Since for all practical purposes H is the dominant matrix term in $\bar{H}$, k as described in (17) is estimated as $p_{H,\max}^T R p_{H,\max}$, where $p_{H,\max}$ is the normalized eigenvector corresponding to the largest eigenvalue of H. Then, applying Lemma 2.4, we obtain

$$\begin{aligned}
&\max(\Re(\lambda(S(\bar{H} + W\dot{S})W))) \leq \max(|\lambda(S(\bar{H} + W\dot{S})W)|) \\
&= |k\lambda_{\max}(\bar{H} + W\dot{S})| = |k||\lambda_{\max}(\bar{H} + W\dot{S})| \leq |k|\mu(\bar{H} + W\dot{S}) \\
&= |k|(\mu(\bar{H}) + 2\mu(-T(C_2T)^{-1}\dot{C}_2)).
\end{aligned}$$

Thus we have shown the following theorem.

THEOREM 3.10 (index 2 stability). *The index* 2 *pDAE is stable if*

$$\mu(\bar{H}) + 2\mu(-T(C_2T)^{-1}\dot{C}_2) \leq 0.$$

For practical computations we take $|k| \approx 1$ (when $0 < |k| \leq 1$) and require

$$\mu(\bar{H}) + 2\mu(-T(C_2T)^{-1}\dot{C}_2) \leq \frac{TOL}{|k|} = TOL \tag{26}$$

for the index 2 subsystem to be stable.

Any index 2 algebraic constraint which is a candidate for being appended to the already constituted pDAE system is thus checked for $T = C_2^T$, C_2 constant, and for $(C_2\bar{H} + \dot{C}_2)R = 0$, failing which the check (26) is done.

In the case of a single index 2 constraint being checked for stability, an analytical expression for $\mu(-T(C_2T)^{-1}\dot{C}_2)$ is obtained using the result in Lemma 2.5. In this case, C_2 is a row vector (denoted by $\tilde{C}_2$), T is a column vector (denoted by $\tilde{T}$), and $R = I - \frac{u_T u_{C_2}^T}{u_{C_2}^T u_T}$, where $u_{C_2} = \tilde{C}_2^T/||\tilde{C}_2||_2$ and $u_T = \tilde{T}/||\tilde{T}||_2$. Then $||S|| = ||R|| = \frac{1}{u_{C_2}^T u_T}$. The change in the stability measure by appending a single index 2 constraint can be estimated via

$$\mu\left(-\frac{u_T\dot{\tilde{C}}_2}{\tilde{C}_2 u_T}\right) = \max\left(\frac{-\text{sign}(\tilde{C}_2\tilde{T})\dot{\tilde{C}}_2\tilde{T} \pm ||\dot{\tilde{C}}_2||_2||\tilde{T}||_2}{2|\tilde{C}_2\tilde{T}|}, 0\right) \tag{27}$$

for $n_x > 2$. For $n_x = 2$, the maximum is taken over $\frac{-\text{sign}(\tilde{C}_2\tilde{T})\dot{\tilde{C}}_2\tilde{T} \pm ||\dot{\tilde{C}}_2||_2||\tilde{T}||_2}{2|\tilde{C}_2\tilde{T}|}$ only. The term $\dot{C}_2$ is obtained through automatic differentiation of the coefficient matrix C_2 in the linearized constraint equations. Further, the term $\mu(W\dot{W}^T)$, i.e., $0.5\mu(-\dot{\overline{\tilde{W}\tilde{W}^T}})$, can be analytically evaluated for a single index 2 constraint. From the property of $\tilde{W}$ (refer to Lemma 3.9), for a single constraint it can be constructed as a unit column vector: $\tilde{W} = \frac{\tilde{C}_2^T}{||\tilde{C}_2||_2} = u_{C_2}$. Let $\dot{u}_{C_2} = \gamma_2\bar{u}_{C_2}$ (recall that the rate of change of a unit vector is orthogonal to it), where $\bar{u}_{C_2}^T u_{C_2} = 0$ and $\gamma_2 = ||\dot{u}_{C_2}||_2$. Hence, using the result in Lemma 2.5,

$$\mu(W\dot{W}^T) = 0.5\mu(-\dot{\overline{\tilde{W}\tilde{W}^T}}) = 0.5\mu(-\dot{\overline{u_{C_2}u_{C_2}^T}}) = \gamma_2/2 = 0.5||\dot{u}_{C_2}||_2. \tag{28}$$

Putting (28) and (27) together, (26) can be revised for a single index 2 constraint. Thus we have shown that the following holds.

THEOREM 3.11 (stability for index 2 constraints). *Checking*

$$\mu(\bar{H}) + 0.5||\dot{u}_{C_2}||_2 + \max\left(\frac{-\text{sign}(\tilde{C}_2\tilde{T})\dot{\tilde{C}}_2\tilde{T} \pm ||\dot{\tilde{C}}_2||_2||\tilde{T}||_2}{2|\tilde{C}_2\tilde{T}|}, 0\right) \le \frac{TOL}{|k|} \tag{29}$$

(for $n_x > 2$) is sufficient for determining the stability when including a single index 2 algebraic constraint in the pDAE.

3.3. A practical criterion for constraint inclusion. For some types of systems, in particular, nonlinear highly oscillatory systems such as the stiff spring pendulum and wheelset on rails examples described later, the logarithmic norm of the original system may already be large. Thus the criteria (14) and (29) would partition all constraints out of the DAE, even if they do not further increase the logarithmic norm. Hence in practice we relax the criteria to require only that the constraints do not increase the logarithmic norm by much. Thus, instead of checking simply if $\mu \le TOL$, the stability check for accepting a constraint is modified as

$$\mu \le \max\left(\frac{TOL}{|t_{\text{final}} - t_0|}, 3\ TOL_0\right), \tag{30}$$

where TOL_0 is the logarithmic norm of the unconstrained dynamic system.

3.4. Stability of the nonlinear pDAE system. For nonlinear systems, the stability can be examined only in the neighborhood of $t = t_k$, i.e., at the beginning of a shooting (integration) subinterval. The logarithmic norm can be used to get an estimate of the stability of the nonlinear system. Consider an index 2 pDAE:

$$\dot{x} = f(x, w, u_2(t), t),$$

$$\text{where} \quad f := h(x,t) + \varphi(t, x, w, u_2(t)), \tag{31a}$$

$$\Psi_2(t, x) = 0. \tag{31b}$$

Let the UODE (16) be rewritten in the form

$$\dot{x} = h(x,t) + \varphi(t, x, w(x,t), u_2(t)), \tag{32}$$

where $w(x,t) = -(C_2T)^{-1}(C_2Hx - C_2QC_v^{-1}C_1x - C_2QC_v^{-1}r_1(t) + C_2r(t) + \dot{C}_2x + \dot{r}_2(t))$. Then the largest real part in the eigenvalues of the matrix

$$M_0 := \frac{\partial h}{\partial x} + \frac{\partial \varphi}{\partial x} - \varphi_{,w}\left(\Psi_{2,x}\varphi_{,w}\right)^{-1}\left(\frac{\partial\left(\Psi_{2,x}h + \Psi_{2,t}\right)}{\partial x} + \Psi_{2,x}\varphi_{,x}\right)$$

gives an estimate of the stability of the UODE (32). Using the properties of the logarithmic norm [11], we get

$$\max_{\lambda} \quad \Re(\lambda(M_0)) \le \mu\left(\frac{\partial h}{\partial x}\right) + \mu\left(\frac{\partial \varphi}{\partial x} - \varphi_{,w}\left(\Psi_{2,x}\varphi_{,w}\right)^{-1}\left(\frac{\partial\left(\Psi_{2,x}h + \Psi_{2,t}\right)}{\partial x} + \Psi_{2,x}\varphi_{,x}\right)\right).$$

Let D be defined as

$$D := -\varphi_{,w}\left(\left(\Psi_{2,x}\varphi_{,w}\right)^{-1}\left(\frac{\partial\left(\Psi_{2,x}h + \Psi_{2,t}\right)}{\partial x} + \Psi_{2,x}\varphi_{,x}\right)\right).$$

Then the above relationship gives $\max_\lambda \Re(\lambda(M_0)) \le 0$ when $\mu(\frac{\partial h}{\partial x}) \le -\mu(\frac{\partial \varphi}{\partial x} + D)$. If at $t = t_k$, $\mu(\frac{\partial h}{\partial x}) + \mu(\frac{\partial \varphi}{\partial x} + D) \le 0$, then the index 2 pDAE is stable at the beginning of the shooting subinterval.

If $\tilde{x}$ is an approximate solution to the UDOE (32), then by Theorem I10.6 in [11], given

$$\mu\left(\frac{\partial h}{\partial x}(t,\varsigma) + \frac{\partial \varphi}{\partial x}(t,\varsigma)\right) \le -\mu(D), \qquad \varsigma \in [x, \tilde{x}],$$

$$||\dot{\tilde{x}} - f||_2 \le \delta(t),$$

$$||x(t_k) - \tilde{x}(t_k)||_2 \le \rho,$$

it can be stated that for $t \ge t_k$,

$$||x(t) - \tilde{x}(t)||_2 \le e^{L(t)}\left(\rho + \int_{t_k}^{t} e^{-L(\tau)}\delta(\tau)d\tau\right), \qquad t_k \le t \le t_{k+1}.$$

For the UODE (32) to be stable, it is sufficient that $L(t) \le 0$. This is satisfied if

$$L(t) = -\int_{t_k}^{t} \mu(D)(\tau)d\tau \le 0, \qquad t_k \le t \le t_{k+1}. \tag{33}$$

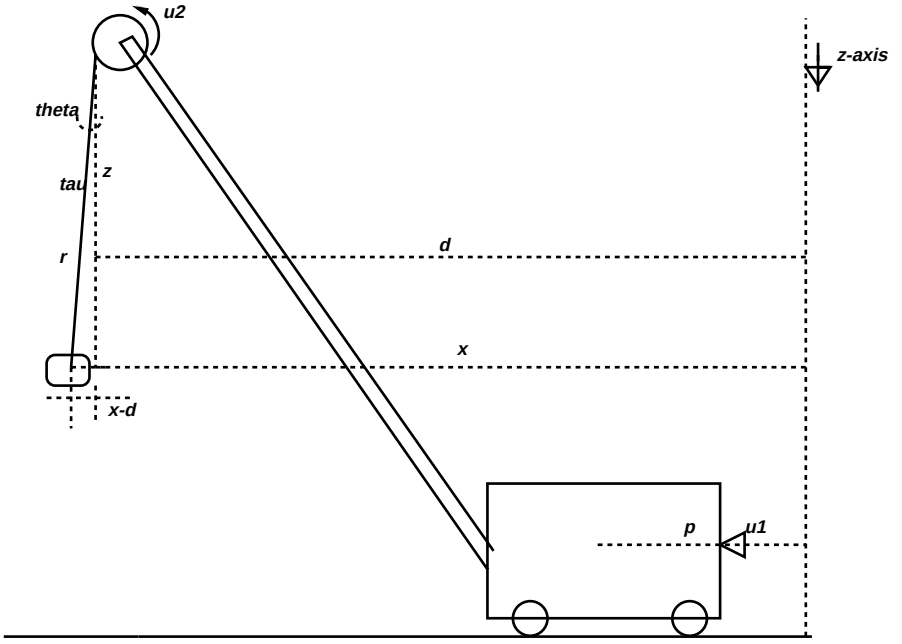

FIG. 4.1. *Planar crane model.*

This condition can be used to get an estimate over the entire interval of integration of the nonlinear pDAE as compared to a local estimate at a particular t via the logarithmic norm of the linearized system, although we do not pursue this further here.

4. Physically important scleronomic constraints. Scleronomic constraints describe additional physical or geometrical features of the dynamics system. In mechanics, these constraints are defined as algebraic kinematic equations of the form $\Psi_3(x) = 0$, in which time does not appear explicitly. Beyond the stability of the pDAE, constraints describing physical or geometrical relationships among the state variables play an important role in the general well-conditioning of the dynamic optimization problem. The preservation of these constraints is important in order to obtain physically meaningful results. Since many modern optimization methods are infeasible methods (i.e., the constraints handled by the optimization method are satisfied only upon convergence of the optimizer), the integration of the pDAE without these constraints may produce unphysical results.

4.1. Example: Planar model of a crane. This example is a planar rigid body model of a crane manipulating a payload, which must be lifted along a specified trajectory [6]. The problem is illustrated schematically in Figure 4.1. The crane is a mechanical system in planar Cartesian coordinates, x and z, denoting the horizontal and vertical positions of the payload. The other state variables are d, the horizontal distance traveled by the crane trolley from the origin, and r, the paid out cable length. The equations are

$$M_2\ddot{x} = -\tau \sin(\theta), \tag{34a}$$

$$M_2\ddot{z} = -\tau \cos(\theta) + mg, \tag{34b}$$

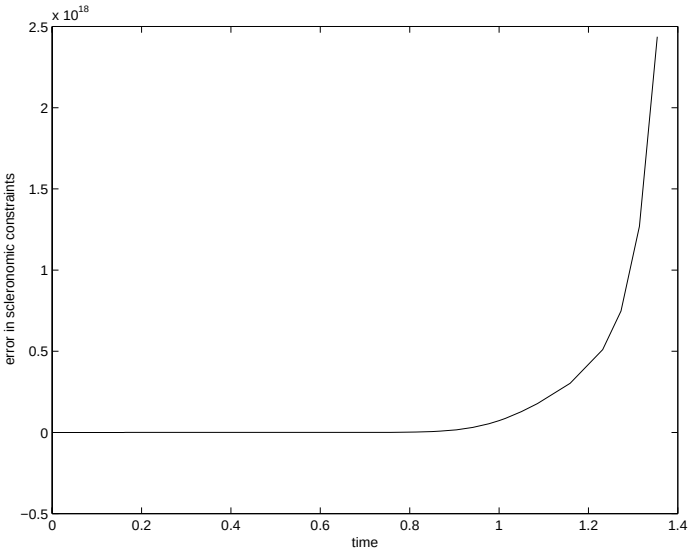

FIG. 4.2. *Partial plot of errors neglecting scleronomic constraint.*

$$M_1\ddot{d} = -C_1\dot{d} + u_1 + \tau\sin(\theta), \tag{34c}$$

$$J\ddot{r} = -C_2\dot{r} - C_3u_2 + C_3^2\tau, \tag{34d}$$

$$0 = \theta - \tan^{-1}((x-d)/z), \tag{34e}$$

$$0 = r^2 - (x-d)^2 - z^2, \tag{34f}$$

$$x = \phi_1(t), \tag{34g}$$

$$z = \phi_2(t), \tag{34h}$$

where M_1, M_2, and m are the masses of the trolley, cable, and payload system and the payload alone, respectively. C_1, C_2, and C_3 are constants, and J is the mass moment of inertia for the pulley paying out the cable. The algebraic variables are τ, the tension in the cable, and θ, the cable angle with vertical. The horizontal force driving the trolley (u_1) and torque driving the pulley in the winch (u_2) are the two control variables. Equations (34g) and (34h) describe the specified path of the payload.

Figure 4.2 illustrates the error ($\int_{t0}^{t_{\text{final}}} ||r^2 - (x-d)^2 - z^2)||_2 dt$) in simulating the planar crane problem with an index 1 pDAE consisting of (34a)–(34e) only and excluding equation (34f). The exclusion of (34f) physically means violation of the condition that the load is tied to the pulley by a cable of finite length measured as the square root of the sum of the vertical and horizontal deflections squared.

While the physical constraints inherently should be included with the pDAE, they can raise the index of the pDAE to higher than 2. As an example, (34f) in the crane example when included in the pDAE (34a)–(34e) raises the index of the system to 3. In cases where the constraints raise the index of the pDAE to higher than 2, a suitable index reduction method can be adopted. If the kinematic degrees of freedom of the physical system is known, then the number of differential equations *minus* the number of kinematic degrees of freedom gives the number of physical constraints which must be included in the pDAE.

A measure for identifying a scleronomic constraint for possible inclusion in the pDAE may be introduced. If a scleronomic constraint Ψ_3 which raises the index of the

pDAE to $q+2$ is being introduced into an index 2 pDAE via differentiating q times (written as $\Psi_3^{(q)}$), then the following estimate for the possible shift in eigenvalues at $t = t_k$ can be used:

$$\mu(\bar{H}) + 2\mu(-T(\Psi_{3,x}^{(q)}T)^{-1}\dot{\Psi}_{3,x}^{(q)}) \leq \frac{TOL_n}{|k|}. \tag{35}$$

The above relationship can be obtained by substituting $\Psi_{3,x}^{(q)}$ for C_2 in (26). The tolerance TOL_n is chosen as per the practical criterion for constraint inclusion given in section 3.3.

5. The partitioning algorithm. Based on considering one algebraic constraint at a time, a partitioning algorithm that returns a locally (at the point of linearization) index 2 or lower pDAE is designed. Constraints are examined for their impact on stability. In this section we discuss the essential components.

5.1. Design of the algorithm. Our strategy for partitioning for stability is to examine one constraint at a time for its effect on stability via criterion (14) and (29). First we examine index 1 constraints and then index 2 constraints. Finally, a check-back of blocks of constraints is done to ensure full system stability.

5.1.1. Partitioning of index 1 and index 2 subsystems. When the constraint under consideration has the option of choosing from more than one algebraic variable to which it can be linked, the search for the dominant algebraic variable corresponding to the constraint must be done in an economical way. The direct way of associating the possible variables is to mark all the possible variables and then go on to the next equation and so on. After the algebraic variables have been identified, all possible combinations of the variables are explored, and the one that gives the pDAE with the lowest logarithmic norm is associated with the index 1 subsystem. For large systems this method will be computationally very expensive. Hence a trade-off policy is adopted. The following explains the policy for both index 1 and index 2 systems.

Policy 1. For small systems, all possible algebraic variables corresponding to the current algebraic equation under consideration for entry into the index 1 or index 2 subsystem are tried out. Thus for all algebraic variables the logarithmic norm for the index 1 or index 2 subsystem (up to and including the current algebraic equation) is evaluated. The one that gives the lowest logarithmic norm is associated with the index 1 or index 2 constraint under consideration. This is feasible only for very small systems since a complete search involves exponential computational complexity.

Policy 2. For a very large system with many coupled terms across the algebraic variables, the above policy may prove to be too expensive. In those cases, the policy is to look for a variable "moderately connected" with the differential variables in the current equation. This can be done by directly starting the search for a nonzero scalar $\frac{||\tilde{C}_1||_2}{c_v} \leq 0.5(\min_v(\frac{||\tilde{C}_1||_2}{c_v}) + \max_v(\frac{||\tilde{C}_1||_2}{c_v}))$ (for index 2, substitute $\tilde{C}_2\tilde{T}$ in place of c_v), where the minimum and the maximum are taken over the possible algebraic variables in the equation being considered. If this choice yields an unacceptable logarithmic norm, the next higher c_v ($\tilde{C}_2\tilde{T}$) is considered and so on. Since the logarithmic norm is inversely proportional to c_v ($\tilde{C}_2\tilde{T}$ for index 2), the larger ratios need not be explored. The scalars c_v or $\tilde{C}_2\tilde{T}$ may be suitably scaled over the range of their values. This policy was implemented in the test program that produced the results in section 6.

5.1.2. Rejecting constraints during check back for stability. The algorithm has the limitation that during stability analysis the effect of the terms (corresponding to the new algebraic variable being included in the pDAE) coupling existing

constraints and the constraint under consideration are ignored. Hence, after accepting a few constraints, a check back for the overall stability of the pDAE is needed. While performing the local stability check for a single algebraic equation, the new algebraic variable corresponding to this equation must be picked in such a way that the local stability check is a fair estimate of the stability of the pDAE and that the global check pointing will not change the built-up pDAE unless absolutely necessary.

If it is found during checking back that the global logarithmic norm of the pDAE violates the practical criterion (30), then some of the constraints must be rejected to keep the system stable. In keeping with Policy 2, for index 1 constraints we leave out the last appended constraint and the algebraic variable having the maximum $\frac{||\tilde{C}_1||_2}{|c_v|}$ (scaled over the range of values c_v takes in the problem), and we check for overall stability in terms of the recomputed overall logarithmic norm. If the system is still unstable, the procedure is repeated on the next constraint on the block of constraints being checked. This is done until a stable index 1 pDAE is found. For an index 2 system, the same thing is done on the constraint having the largest $||\dot{\tilde{C}}_2||_2/|\tilde{C}_2\tilde{T}|$ in the block of constraints being checked, and variables with maximum $||\dot{\tilde{C}}_2||_2/|\tilde{C}_2\tilde{T}|$ are rejected.

6. Examples of partitioning. In this section we illustrate the partitioning strategy with several examples. The results are shown only at a representative multiple shooting node. For a DAE that changes its type interval to interval, the application of the partition algorithm at the beginning of the interval automatically decides the subsystem that can be integrated directly and the constraints and variables to be handled from the optimizer.

6.1. Partitioning the crane model. For the crane model described earlier, constraints (34e) and (34f) are both scleronomic constraints, i.e., they describe some geometric structure of the physical problem. Constraint (34e) introduces the measurement of θ, the angle by which the payload deviates from the vertical. Constraint (34f) connects the payload to the pulley by relating its horizontal and vertical positions to the length of the cable paid out. Violation of constraint (34f) in the pDAE would produce an unphysical simulation since the payload is now modeled as detached from the cable. This is evident from the plot of x, z, d, and r in Figure 6.1.

Applying the algorithm to this model, constraint (34e) is included in the pDAE since it satisfies the index 1 structure and stability criterion. The resulting UODE in x does not have large eigenvalues in $\mathcal{C}^+$ at $t = t_0$. For a practical physical application, the eigenvalues of the pDAE system can be expected to be of moderate size, and the system can be expected to be stable. The constraint equation (34f) is an index 3 scleronomic constraint (known from the physics of the problem) and is reduced to its index 2 form via one differentiation of constraint (34f) with respect to t,

$$r\dot{r} - (x - d)(\dot{x} - \dot{d}) - z\dot{z} = 0, \tag{36}$$

or to index 1 via two differentiations of constraint (34f) with respect to t (if the available DAE integration software can integrate index 1 or 0 systems only). The other constraints (the preprogrammed trajectory of the payload, (34g), and (34h)) are handled from the SQP method.

In the crane model the partition algorithm detects and accepts the index 1 constraint (34e) at $t = 0$. The value of TOL was set at 20.0. The interval of integration is from $t_0 = 0$ to $t_{\text{final}} = 8$. The value of TOL_0 in (30) was set at 0. The initial values

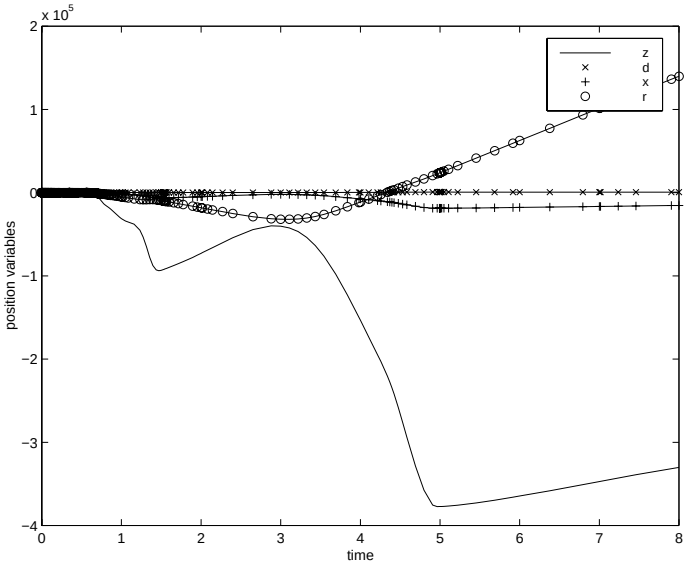

FIG. 6.1. *Crane problem using equations* (34a)–(34e) *in the pDAE.*

are $x = 3.0$, $\dot{x} = 2.7$, $z = 21.0$, $\dot{z} = -2.0$, $d = 1.0$, $\dot{d} = 2.7$, $r = ((x-d)^2 + z^2)^{0.5}$, $\dot{r} = -2.0$, $\tau = 980.0$, $u_1 = 0$, $u_2 = 0$, and $\theta = \tan^{-1}(\frac{(x-d)}{z})$. The logarithmic norm of the stability matrix H for the crane model at $t = 0$ is 0.5, and with the addition of the index 1 constraint (34e) it goes up to 0.82794. This is less than $\max(TOL/8, 3TOL_0)$ (see (30)), and the constraint (34e) is accepted. The angle θ of deflection from the vertical is chosen as the index 1 variable.

The search for index 2 constraints returns the empty set. In order to search for index 3 scleronomic constraints, the remaining algebraic equations are differentiated using automatic differentiation once with respect to time. The index 2 search algorithm is reapplied, and the algorithm returns the differentiated form of constraint (34f), i.e., (36), as an index 2 constraint suitable for inclusion in the pDAE system. Here $|k| = 0.9999$. The logarithmic norm of the index 2 pDAE stability matrix (using (29)) is 1.61502, and the tension in the cable τ is returned as the corresponding index 2 variable. The matrix S from the stability analysis changes very slowly in the neighborhood of $t = 0$ since $T = (0, 0, 0, 0, -\sin(\theta), -\cos(\theta), \sin(\theta), C_3^2)^T$ remains almost unchanged due to very small changes in $\theta \approx 0$ (i.e., an almost vertical cable undergoing only small swings). Hence the logarithmic norm changes only slightly even after the constraint (36) has been appended to the pDAE in its differentiated form. During check back, the overall logarithmic norm of the accepted pDAE system is computed as 1.09717, which is smaller than $\max(TOL/8, 3TOL_0)$ and is acceptable. Building the whole system takes 9.82×10^{-2} CPU seconds on a 180 MHZ IP32 processor SGI O2 computer.

The crane model yields the same partitioning result when the algorithm is applied at $t = 2, 4$, and 6 seconds.

Even though the constraint (36) slightly raises the logarithmic norm estimate for the index 2 pDAE system thus constructed, this partition leads to a more physical and well-conditioned problem. The plots in Figures 6.2 and 6.3 are the results obtained from a multiple shooting-type scheme using DASPK3.0 [15] as the DAE integrator

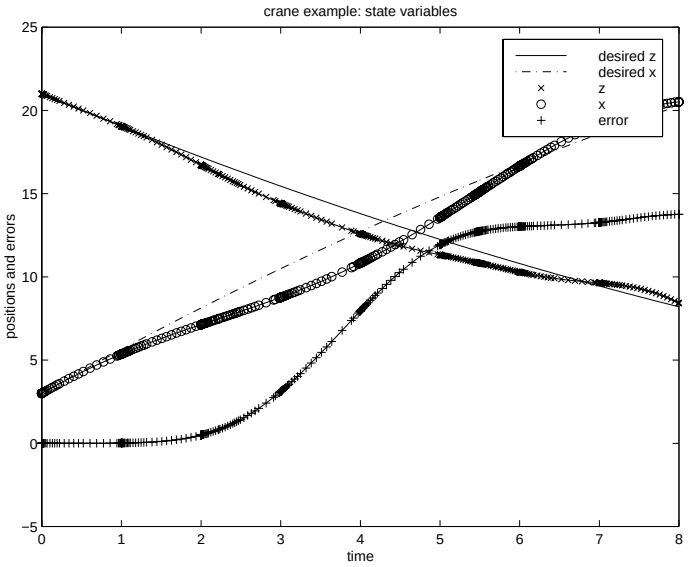

FIG. 6.2. *Crane problem using equations* (34a)–(34e) *and* (36) *in the pDAE.*

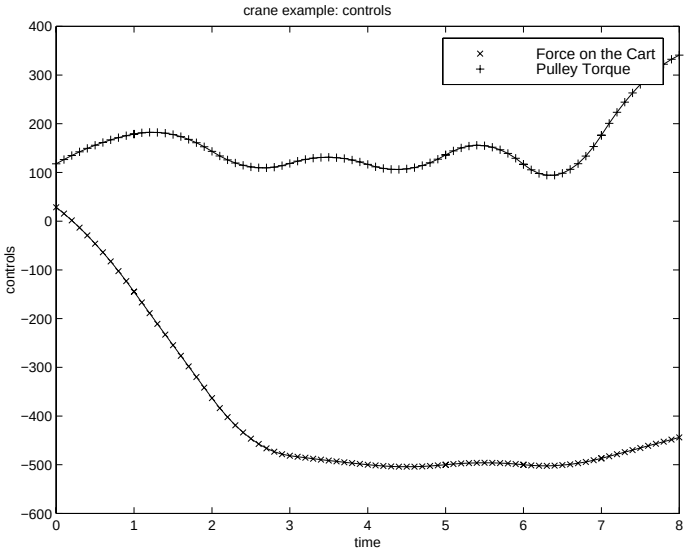

FIG. 6.3. *Crane controls using equations* (34a)–(34e) *and* (36) *in the pDAE.*

and SNOPT as the NLP method [16]. In this case, the path constraints are chosen as $p_1 \equiv x - (-0.0675t^2 + 2.7t + 3.0) = 0$ and $p_2 \equiv z - (-21.0 - 0.05t^2 + 2.0t) = 0$. The optimizer SNOPT stops at an acceptable point which cannot be improved further after three major iterations (with 188, 182, 112, and 1 minor iterations). The objective function is given by the error integral $\int_{t_0}^{t_{\text{final}}} (p_1^2 + p_2^2)^{0.5} dt$. The error integral has been reduced to 13.76067. This corresponds to a reduction in the SNOPT merit function from $1.79271101E + 10$ to $1.25966891E + 07$. The time interval was $0 \leq t \leq 8$. The controls (u_1 and u_2) have been modeled as quadratic polynomials over each of the

eight shooting intervals used for the problem. The tolerances for DASPK3.0 were $rtol = 10^{-7}$ and $atol = 10^{-7}$, and all tolerances for SNOPT were 10^{-5}. The control and state continuity constraints across the shooting intervals have been satisfied to less than or equal to 0.1 when the optimizer has stopped. The time taken for solving this problem is 1421.91 seconds.

With the same parameter settings for the numerical methods, a pDAE formulation leaving (34f) with the optimizer as a path constraint and treating τ as an additional control variable has been attempted. The plot in Figure 6.1 is obtained from the results. The solution is incorrect. After six major iterations in SNOPT (162, 50, 72, 8, 1, 9, and 22 minor iterations) the merit function is reduced from $3.28975960E+21$ to $5.63316979E+12$. But in the process the error integral $\int_{t_0}^{t_{\text{final}}}(p_1^2+p_2^2+((x-d)^2+z^2-r^2)^2)^{0.5}dt$ is minimized to 2446227.48766, beyond which the optimizer fails to find descent directions. Clearly the stopping point is an unacceptable solution to the physical problem. Many of the continuity constraints in the multiple shooting method are unacceptably violated.

6.2. Analytical example. Consider the system

$$\dot{x}_1 = (2-t)\nu y + q_1(t), \tag{37a}$$

$$\dot{x}_2 = (\nu-1)y + q_2(t), \tag{37b}$$

$$0 = (t+2)x_1 + (t^2-4)x_2 + r(t) \tag{37c}$$

for $0 \le t \le 1$ and $\nu \ge 1$. This is an index 2 system since $\begin{pmatrix}(t+2) & (t^2-4)\end{pmatrix}\begin{pmatrix}(2-t)\nu \\ (\nu-1)\end{pmatrix}$ is nonzero for the given interval of t and ν. The idempotent projection $R(t,\nu) = \begin{pmatrix}1-\nu & \nu(2-t) \\ \frac{\nu-1}{t-2} & \nu\end{pmatrix}$. The EUODE (the homogeneous part only) is

$$\dot{\xi} = -\frac{\nu}{2-t}\xi.$$

Then

$$W = \begin{pmatrix}\frac{2-t}{(5-4t+t^2)^{0.5}} \\ \frac{1}{(5-4t+t^2)^{0.5}}\end{pmatrix}, \qquad \dot{W} = \begin{pmatrix}\frac{-1}{((5-4t+t^2))^{1.5}} \\ \frac{-(t-2)}{(5-4t+t^2)^{1.5}}\end{pmatrix},$$

and

$$\mu(-T(C_2T)^{-1}\dot{C}_2) = \frac{(1+0.5t)\nu - t + (0.25+t^2+(-0.5-2t^2)\nu+\nu^2(0.25+t^2)(5-4t+t^2))^{0.5}}{t^2-4}.$$

The term $\mu(H) = 0$ here, and y is the index 2 variable. In this case the stability criterion reduces to $\mu(W\dot{W}^T) + \mu(-T(C_2T)^{-1}\dot{C}_2) \le TOL$. Here $\mu(W\dot{W}^T)$ takes values between 0 and 0.25 for the same values of ν. The index 2 stability is determined by $\mu(-T(C_2T)^{-1}\dot{C}_2)$, which varies between 0 and 30 for $0 \le t \le 1$ and $1 \le \nu \le 1000$. The value of TOL was chosen as 20.0. In this example the practical tolerance from (30) is same as the original TOL value, since the time interval is unity and the logarithmic norm of the unconstrained dynamics is zero. For $\nu < 1$ the value of $Y(\nu,t) := \mu(-T(C_2T)^{-1}\dot{C}_2)$ goes up with decreasing ν and increasing t. For $\nu < 0$ the constraint is rejected. Table 6.1 illustrates the decision making of the partitioning algorithm. The plot in Figure 6.4 shows that the index 2 constraint is acceptable for

TABLE 6.1
Output from PARTITION algorithm, $t = 0$, $|k| = 1$, $H = 0$, $TOL = 20$.

Eqn.	ν	$\mu(-2T(C_2T)^{-1}\dot{C}_2)$	Decision
37	1	0.4828	constraint accepted
37	10	5.7903	constraint accepted
37	100	58.9052	constraint rejected

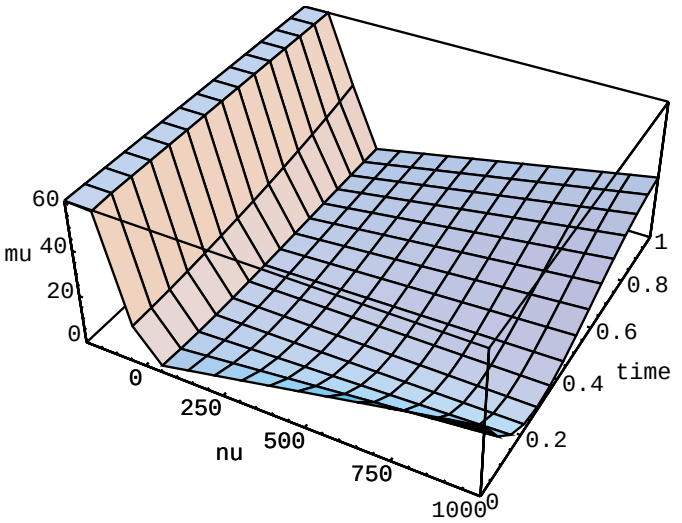

FIG. 6.4. *$\mu(-T(C_2T)^{-1}\dot{C}_2)$ for the analytical example.*

$1 \leq \nu \leq 30$ when the value of TOL is chosen as 20.0 and the value of TOL_0 in (30) is chosen as 0. But for $\nu \leq 0$ the constraint destabilizes the system, and for $\nu >> 0$ the constraint becomes unacceptable for inclusion in the DAE.

The logarithmic norm based stability estimate for the analytical example are overestimates from the eigenvalue point of view. But eigenvalues do not give the complete picture of stability for the numerical integration method [14]. This is especially true when the stability matrix is nonnormal or has a high norm compared to the maximum real part of its eigenvalues. In such cases, the maximum real part of the pseudoeigenvalues of the stability matrix often gives a more realistic estimate of stability with respect to a numerical integration method. From the definition of pseudoeigenvalue a relationship between the maximum real part of the pseudoeigenvalues and the logarithmic norm is obtained. The pseudoeigenvalue (λ_ϵ) of a matrix $A \in \mathcal{R}^{n\times n}$ is defined [14] as

$$\lambda_\epsilon(A) = \lambda(A + E), \quad \text{where} \quad \epsilon \geq ||\mathrm{E}||_2 \geq 0. \tag{38}$$

For stability it is required that $\max(\Re(\lambda_\epsilon)) \leq TOL_1$, where TOL_1 is a small positive number. In our experiments we set TOL_1 to 2.0. The number ϵ is usually small and is chosen as $10^{-6}, 10^{-3}, 10^{-1}, 1$ for plotting the contour lines (or a surface) on the complex plane. Using the triangle inequality property of the logarithmic norm, the bound $-||A||_2 \leq \mu(A) \leq ||A||_2$, and Lemma 2.4, we get

$$\max_{\lambda_\epsilon} \Re(\lambda_\epsilon(A)) = \max_{\lambda} \Re(\lambda(A + E)) \leq \mu(A + E) \leq \mu(A) + \mu(E) \leq \mu(A) + \epsilon. \tag{39}$$

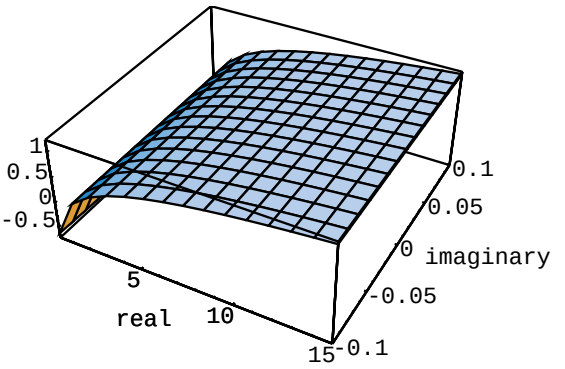

FIG. 6.5. $\lambda_\epsilon(-T(C_2T)^{-1}\dot{C}_2)$ *at* $t = 0$ *and* $\nu = 1000.0$ *for the analytical example* (37). *The vertical axis is* $\log_{10}\epsilon$.

In the analytical example, one would expect to obtain a highly stable EUODE (eigenvalue $= -1000$ for $\nu = 1000$ and $t = 1$) from the index 2 system for $\nu >> 1$. But the pseudoeigenvalues (Figure 6.5) indicate that numerical perturbation of the order of 0.1 can destabilize the system for $\nu >> 1$. The behavior of the system predicted by the logarithmic norm is confirmed by results from numerical simulations in [3].

6.3. Nonlinear oscillatory problems. The logarithmic norm can be very large for some nonlinear oscillatory systems, without the systems being unstable. Here we consider two such systems and discuss the implications for logarithmic norm-based stability criteria.

Stiff spring pendulum. Consider the ODE for a pendulum suspended at one end by a massless spring

$$\begin{aligned} \dot{p} - u &= 0, \\ \dot{q} - v &= 0, \\ \dot{u} + \frac{p((p^2+q^2)^{0.5} - 1)}{\epsilon^2(p^2+q^2)^{0.5}} &= 0, \\ \dot{v} + \frac{q((p^2+q^2)^{0.5} - 1)}{\epsilon^2(p^2+q^2)^{0.5}} - 1 &= 0, \end{aligned}$$

where p and q are the generalized position coordinates, u and v are the corresponding speeds, and $\epsilon \to 0$ is a nonzero small number. The system is an ODE for which the logarithmic norm (with $\epsilon = 10^{-3.0}$, $p = 0.6$, $q = 0.8$) is $O(\frac{1}{\epsilon^2})$ (499999.5), but the largest real part of the eigenvalues is zero, and the largest imaginary part of the eigenvalues is $O(\frac{1}{\epsilon})$ (1000). Thus the logarithmic norm captures the local (transient) high frequency oscillations.

The stiff spring pendulum is highly oscillatory. For a more complete description of this system, see [13]. For any numerical method to be able to follow the oscillations, it must take steps of size $O(\frac{1}{\epsilon})$. The large value of $O(\frac{1}{\epsilon^2})$ for the logarithmic norm gives an indication that a large number of time steps may be needed to accurately integrate this system over a time interval of length $O(1)$. Although a linear oscillatory system has a logarithmic norm of zero, this mechanical system has a high logarithmic norm due to the highly oscillatory transformation of variables which would be needed to

transform from Cartesian coordinates to a set of coordinates where the system would be nearly linear. In general, one might expect that for highly oscillatory mechanical systems of this type, the number of time steps which would be needed to accurately solve the problem will be proportional to the square root of the logarithmic norm times the length of the time interval for integration. Although this may be a large number of time steps, users who want to solve this problem will have to go ahead and do this work. Thus a large value of the logarithmic norm, especially as in this case for the ODE, is not necessarily an indicator that the problem should not be solved but rather a warning that this may require many time steps.

Wheelset on rails. This problem is a nonlinear highly oscillatory DAE and illustrates that with the practical stability criterion (30) our estimates make a reasonable decision regarding partitioning of the constraints. This DAE system was obtained from a standard test set at CWI, the Netherlands, at http://www.cwi.nl/cwi/projects/IVPtestset/descrip.htm. The system consists of equations describing oscillatory and rotational dynamics of two wheels joined by an axle through a spring-damper (damped suspension). The constraints describe the geometrical integrity of the system and the requirement that the wheels travel on a set of rails. The first 11 equations and variables 1 through 11 are differential equations and variables. The logarithmic norm for the differential system is computed as 8648. The time interval of integration is 20 seconds. The value of TOL was set to 20.0, and TOL_0 was set to 9000, since we expect the logarithmic norm to reflect the high frequency oscillations rather than the stability of the system. The output verifies the correct working of the present algorithm. The constraint equations 14 through 17 are index 1. The corresponding index 1 variables are 15, 14, 13, and 12. The estimated logarithmic norm increases cumulatively to 13166 (ODE + constraint 14), 13170 (ODE + constraints 14 and 15), 16647 (ODE + constraints 14, 15, 16), and then to 16649 (ODE + constraints 14, 15, 16 and 17) as the index 1 constraints are appended one after another. The remaining system (equations 12 and 13) includes index 2 equations and variables. Appending constraint 12 changes the estimated logarithmic norm (29) to 16483, and after appending 13, the logarithmic norm of the complete (ODE + constraints 12–17) system (using (29)) is estimated as 16403. The parameter $|k|$ was computed as 0.998. The CPU time taken to build the complete system was 0.1343s. All the constraints were accepted in the pDAE (ODE + constraints 12–17). During check back, the eigenvalue of the UODE for the pDAE system (ODE + constraints 12–17) was computed as 5.46020. Considering the relatively small interval of simulation, we decided to integrate the pDAE with all the constraints.

The wheel-axle problem was integrated using DASPK3.0 from 0 to 10 seconds with all the relative and absolute tolerances set to 0.0001. The integration was successfully completed in 5951 steps of which 5094 steps were accepted. For the tolerances set to 0.000001, the integration process took 15893 steps (of which 14204 steps were accepted) to complete. This confirms our rough estimates.

TWO ELEMENT-BY-ELEMENT ITERATIVE SOLUTIONS FOR SHALLOW WATER EQUATIONS*

C. C. FANG† AND TONY W. H. SHEU†

Abstract. In this paper we apply the generalized Taylor–Galerkin finite element model to simulate bore wave propagation in a domain of two dimensions. For stability and accuracy reasons, we generalize the model through the introduction of four free parameters. One set of parameters is rigorously determined to obtain the high-order finite element solution. The other set of free parameters is determined from the underlying discrete maximum principle to obtain the monotonic solutions. The resulting two models are used in combination through the flux correct transport technique of Zalesak, thereby constructing a finite element model which has the ability to capture hydraulic discontinuities. In addition, this paper highlights the implementation of two Krylov subspace iterative solvers, namely, the bi-conjugate gradient stabilized (Bi-CGSTAB) and the generalized minimum residual (GMRES) methods. For the sake of comparison, the multifrontal direct solver is also considered. The performance characteristics of the investigated solvers are assessed using results of a standard test widely used as a benchmark in hydraulic modeling. Based on numerical results, it is shown that the present finite element method can render the technique suitable for solving shallow water equations with sharply varying solution profiles. Also, the GMRES solver is shown to have a much better convergence rate than the Bi-CGSTAB solver, thereby saving much computing time compared to the multifrontal solver.

Key words. Taylor–Galerkin finite element model, discrete maximum principle, flux correct transport technique, Bi-CGSTAB, GMRES, multifrontal direct solver, sharply varying

1. Introduction.

Many environmental problems, such as tides in oceans, breaking waves on shallow beaches, flood waves in rivers, mountain torrents, and estuary flows [1] are closely related to the motion of unsteady free-surface flow. Predicting the height and speed of the bore wave is the first step in providing useful information for flood control and for the design of channel walls. It is the practical importance of simulating shallow water equations that motivated the present study.

The shallow water height is analogous to gas density in gas dynamic equations. Since gas dynamic equations admit discontinuous solutions, called shocks and contact discontinuities, this analogy between two fields of equations implies that it is possible to observe hydraulic jumps and bores in water and in the atmosphere. Numerically capturing these discontinuous phenomena in hydraulics has become a major area of theoretical and computational study. For suppressing dispersive oscillations exhibited near the shock front, significant effort has been directed toward the development of high-resolution hydraulic methods. Shock-capturing methods were first developed by Godunov [2] and Van Leer [3]. Development of high-resolution schemes was followed by adoption of the total variation diminishing (TVD) scheme of Harten [4], the parabolic method (PPM) of Colella and Woodward [5], and the essentially nonoscillatory (ENO) schemes of Harten and Osher [6] to obtain numerically very accurate but computationally absolute stable solutions. Most of these high-resolution schemes

were, unfortunately, developed within the one-dimensional framework. The desire to avoid this limitation has prompted many researchers to capture bore waves in an open-channel flow and hydraulic jumps in a genuinely multidimensional dam-break problem [7, 8, 9, 10, 11, 12, 13, 14, 15]. Since the flux corrected transport (FCT) algorithm was originally developed without resorting to a single spatial dimension [16, 17], we consider the FCT algorithm to be one of the most suitable choices for multidimensional hydraulic calculations.

As is typical with other finite element flow simulations, we work with a large matrix equation. Thus, we must minimize this disadvantage if we are to compete with other structured-type discretization methods. To this end, we consider in the present work two iterative solvers and one very effective direct solver. Both iterative solvers, namely, the bi-conjugate gradient stabilized (Bi-CGSTAB) of Van der Vorst [18] and the generalized minimum residual (GMRES) of Saad and Schultz [19], are the ensemble of conjugate gradient method for solving the non-Hermitian linear system of algebraic equations. These two Krylov subspace methods differ in the vectors used to iterate the approximation solution. GMRES iterates the approximate solution in terms of Arnoldi vectors while Bi-CGSTAB accomplishes the same task through the use of unsymmetric Lanczos vectors. These vectors are chosen to overcome the difficulty regarding the nonexistence of the orthogonal tridiagonalization of the finite element stiffness matrix for shallow water equations. Since we wish to address the performance of solution solvers, we also consider the direct solver for completeness. In order to compete with the above state-of-the-art iterative solvers, we consider in this assessment study the multifrontal direct solver of Duff and Reid [20]. This solver is regarded as a refinement of the frontal solver of Irons [21].

The remainder of this paper is organized in six sections. Section 2 presents assumptions that lead to the St. Venant shallow water equations. In section 3, we present the Taylor–Galerkin finite element model, which can faithfully preserve the inherent hyperbolic conservation law [22]. Specific to the present finite element model is that four free parameters and one damping parameter are used to obtain higher prediction accuracy in the high-order scheme while accommodating the monotonicity property in the low-order scheme [23]. Section 3.3 explains how the high-order and low-order Taylor–Galerkin formulations can be used in combination to obtain a nonoscillatory solution. This is followed by presentation of two iterative solution solvers and one direct solver that can be used to solve the nonsymmetric finite element equations. The objective is to assess the efficiency of the solution solvers used to obtain finite element solutions from indefinite and unsymmetric matrix equations. In section 5, we provide analytical evidence by showing that the numerical model and solution solvers can render techniques suitable for hydraulic problems with sharp gradients. All results of model tests are well in agreement with the analytic data. With this success in analytical validation, we proceed to study the dam-break problem. Finally, a brief discussion together with some conclusions is presented in section 6.

2. Mathematical formulation. Shallow water equations are derived under zero fluid viscosity and surface tension assumptions. Wind shear and Coriolis forces are not taken into account. Working equations for incompressible free-surface fluid flows are derived under the small bottom slope condition. Another key assumption in the derivation is that the vertical component of the flow acceleration has negligible influence on the pressure. A hydrostatic pressure distribution is thus assumed. Given the above assumptions, the St. Venant shallow water equations, which govern mass and momentum conservation, are derived in terms of a solution vector $\mathbf{U}$ of the

conservative type [24]

$$\mathbf{U}_t + \mathbf{F}_x + \mathbf{G}_y = \mathbf{S}, \tag{2.1}$$

where $\mathbf{U} = (h, hu, hv)^{\mathrm{T}}$. In the above, h is the water depth, and u and v are the depth-averaged velocity components in the x- and y-directions, respectively. Denote g as the gravitational acceleration; the physical fluxes are derived as $\mathbf{F} = (h\,u, h\,u^2 + \frac{1}{2}g\,h^2, h\,u\,v)^{\mathrm{T}}$ and $\mathbf{G} = (h\,v, h\,u\,v, h\,v^2 + \frac{1}{2}g\,h^2)^{\mathrm{T}}$. Without loss of generality, both friction losses and bed slopes are neglected to simplify the analysis.

Given initially smooth data for the present homogeneous case ($\mathbf{S} = \mathbf{0}$), the quasi-linear hyperbolic system of partial differential equations may admit discontinuities, such as bore waves that are often observed in practice, owing to nonlinear advective terms in the equations [25]. In time-accurate simulation of St. Venant equations, it is customary to rewrite working equations in their nonconservative equivalent forms to better show the characteristic nature of the hyperbolic system. Transformation of the conservative form into its nonconservative counterpart involves using the gravity wave velocity $c = (g\,h)^{1/2}$. The resulting eigenvectors and eigenvalues are critical in hydraulic simulation since they represent the characteristic speed and direction of signal transmission.

3. Finite element model. Within the weighted residual context, (2.1) can be approximated in its weak form through the use of a test function $\mathbf{W}$. This leads to

$$\sum_{el=1}^{n_{el}} \int_{\Omega^{el}} \int_{t_n}^{t_{n+1}} \mathbf{W} \left[\frac{\partial \mathbf{U}}{\partial t} + \frac{\partial \mathbf{F}}{\partial x} + \frac{\partial \mathbf{G}}{\partial y} \right] d\,t\,d\,\Omega^{el} = 0. \tag{3.1}$$

Define $\delta\mathbf{U}^n = \mathbf{U}^{n+1} - \mathbf{U}^n$ and $\mathbf{I} = \frac{\partial}{\partial x}\int_{t_n}^{t_{n+1}} \mathbf{F}\,dt + \frac{\partial}{\partial y}\int_{t_n}^{t_{n+1}} \mathbf{G}\,dt$; (3.1) can be expressed as follows through time integration:

$$\sum_{el=1}^{n_{el}} \int_{\Omega^{el}} (\mathbf{W}\delta\mathbf{U}^n - \mathbf{W}\,\mathbf{I})\,d\Omega^{el} = 0. \tag{3.2}$$

Analysis is carried out by performing Taylor series expansion of $\mathbf{F}$ and $\mathbf{G}$ with respect to t_n. Take $\mathbf{F}$ as an example; we can represent this vector in terms of Taylor series expansion terms terminated at the time increment $(t - t_n)^3$:

$$\mathbf{F} = \mathbf{F}^n + \left.\frac{\partial \mathbf{F}}{\partial t}\right|^n (t - t_n) + \frac{1}{2}\left.\frac{\partial^2 \mathbf{F}}{\partial t^2}\right|^n (t - t_n)^2 + \mathcal{O}(t - t_n)^3. \tag{3.3}$$

Recall that $\frac{\partial \mathbf{U}}{\partial t} = -\mathbf{F}_x - \mathbf{G}_y$ and $\frac{\partial \mathbf{F}}{\partial t} = \frac{\partial \mathbf{F}}{\partial \mathbf{U}}\frac{\partial \mathbf{U}}{\partial t} = \mathbf{A}\frac{\partial \mathbf{U}}{\partial t}$; we introduce two free parameters α and β and rewrite $\partial\mathbf{F}/\partial t$ exactly as $\frac{\partial \mathbf{F}}{\partial t} = \alpha\mathbf{A}\frac{\partial \mathbf{U}}{\partial t} + \beta\mathbf{A}[-\frac{\partial \mathbf{F}}{\partial x} - \frac{\partial \mathbf{G}}{\partial y}]$, provided that α and β are constrained by $\alpha + \beta = 1$. Moreover, we can approximate the time derivative term $\partial\mathbf{F}/\partial t$ to obtain

$$\begin{aligned} \frac{\partial^2 \mathbf{F}}{\partial t^2} = &-\gamma \left(\mathbf{A}^2 \frac{\partial^2 \mathbf{U}}{\partial t \partial x} + \mathbf{A}\,\mathbf{B} \frac{\partial^2 \mathbf{U}}{\partial t \partial y} \right)\Bigg|^n \\ &+ \mu \left[\mathbf{A}^2 \left(\frac{\partial^2 \mathbf{F}}{\partial x^2} + \frac{\partial^2 \mathbf{G}}{\partial x \partial y} \right) + \mathbf{A}\,\mathbf{B} \left(\frac{\partial^2 \mathbf{F}}{\partial x \partial y} + \frac{\partial^2 \mathbf{G}}{\partial y^2} \right) \right]\Bigg|^n . \end{aligned} \tag{3.4}$$

As in the above, the free parameters γ and μ, which are constrained by $\gamma + \mu = 1$, are also introduced. Substitution of $\frac{\partial \mathbf{F}}{\partial t}$ and $\frac{\partial^2 \mathbf{F}}{\partial t^2}$ into (3.3) leads to

$$\begin{aligned}\mathbf{F} = \mathbf{F}^n &+ \left[\alpha \mathbf{A} \frac{\partial \mathbf{U}}{\partial t} - \beta \mathbf{A} \left(\frac{\partial \mathbf{F}}{\partial x} + \frac{\partial \mathbf{G}}{\partial y} \right) \right] \Bigg|^n (t - t_n) \\ &- \frac{1}{2} \left\{ \gamma \left(\mathbf{A}^2 \frac{\partial^2 \mathbf{U}}{\partial t \partial x} + \mathbf{AB} \frac{\partial^2 \mathbf{U}}{\partial t \partial y} \right) - \mu \left[\mathbf{A}^2 \left(\frac{\partial^2 \mathbf{F}}{\partial x^2} + \frac{\partial^2 \mathbf{G}}{\partial x \partial y} \right) \right. \right. \\ &\left. \left. + \mathbf{AB} \left(\frac{\partial^2 \mathbf{F}}{\partial x \partial y} + \frac{\partial^2 \mathbf{G}}{\partial y^2} \right) \right] \right\} \Bigg|^n (t - t_n)^2 + \mathcal{O}((t - t_n)^3). \end{aligned} \tag{3.5}$$

Similarly, we can expand $\mathbf{G}$ with respect to quantities evaluated at time t_n:

$$\begin{aligned}\mathbf{G} = \mathbf{G}^n &+ \left[\alpha \mathbf{B} \frac{\partial \mathbf{U}}{\partial t} - \beta \mathbf{B} \left(\frac{\partial \mathbf{F}}{\partial x} + \frac{\partial \mathbf{G}}{\partial y} \right) \right] \Bigg|^n (t - t_n) \\ &- \frac{1}{2} \left\{ \gamma \left(\mathbf{BA} \frac{\partial^2 \mathbf{U}}{\partial t \partial x} + \mathbf{B}^2 \frac{\partial^2 \mathbf{U}}{\partial t \partial y} \right) - \mu \left[\mathbf{BA} \left(\frac{\partial^2 \mathbf{F}}{\partial x^2} + \frac{\partial^2 \mathbf{G}}{\partial x \partial y} \right) \right. \right. \\ &\left. \left. + \mathbf{B}^2 \left(\frac{\partial^2 \mathbf{F}}{\partial x \partial y} + \frac{\partial^2 \mathbf{G}}{\partial y^2} \right) \right] \right\} \Bigg|^n (t - t_n)^2 + \mathcal{O}((t - t_n)^3). \end{aligned} \tag{3.6}$$

By substituting (3.5)–(3.6) into (3.2) and choosing bilinear polynomials as test and basis functions, we can derive the finite element equation in the δ-form as follows:

$$\mathbf{M}_c \, \delta \mathbf{U}^n = \mathbf{R}. \tag{3.7}$$

In the above, $\mathbf{M}_c$ denotes the consistent mass matrix:

$$\begin{aligned}\mathbf{M}_{ij}^{el} = &\int_{\mathbf{\Omega}^{el}} \left\{ \mathbf{N}_i \mathbf{N}_j - \frac{1}{2} \alpha \Delta t \left(\frac{\partial \mathbf{N}_i}{\partial x} A + \frac{\partial \mathbf{N}_i}{\partial y} B \right) \mathbf{N}_j \right. \\ &+ \frac{1}{6} \gamma \Delta t^2 \left[\frac{\partial \mathbf{N}_i}{\partial x} \left(A^2 \frac{\partial \mathbf{N}_j}{\partial x} + AB \frac{\partial \mathbf{N}_j}{\partial y} \right) + \frac{\partial \mathbf{N}_i}{\partial y} \left(BA \frac{\partial \mathbf{N}_j}{\partial x} + B^2 \frac{\partial \mathbf{N}_j}{\partial y} \right) \right] \Bigg\} d\mathbf{\Omega}^{el} \\ &- \int_{\mathbf{\Gamma}} \left\{ -\frac{1}{2} \alpha \Delta t \mathbf{N}_i \left(n_x A + n_y B \right) \mathbf{N}_j + \frac{1}{6} \gamma \Delta t^2 \mathbf{N}_i \left[n_x \left(A^2 \frac{\partial \mathbf{N}_j}{\partial x} + AB \frac{\partial \mathbf{N}_j}{\partial y} \right) \right. \right. \\ &\left. \left. + n_y \left(BA \frac{\partial \mathbf{N}_j}{\partial x} + B^2 \frac{\partial \mathbf{N}_j}{\partial y} \right) \right] \right\} d\mathbf{\Gamma}. \end{aligned} \tag{3.8}$$

In (3.7), $\delta \mathbf{U}^n (\equiv \mathbf{U}^{n+1} - \mathbf{U}^n)$ is the vector of nodal increment and $\mathbf{R}$ $(\equiv \mathbf{C}\mathbf{F}^n + \tilde{\mathbf{C}}\mathbf{G}^n)$ is the vector of element contributions added to the finite element nodes. For detailed expressions of $\mathbf{C}$ and $\tilde{\mathbf{C}}$, refer to [23].

3.1. High-order Taylor–Galerkin finite element model. To resolve discontinuous solutions, we employ the FCT technique of Zalesak [17]. The idea behind this algorithm is to combine an accurate high-order scheme with a monotonic low-order scheme. To make this scheme effective, we require that the former scheme be used in the smooth regime and the low-order scheme only in regions near discontinuities.

The key to constructing an efficient FCT finite element model is to develop a model that can provide a high level of accuracy. To this end, we exploit the modified equation analysis for the determination of the free parameters α, β, γ, and μ a priori to obtain higher-order accuracy. The strategy we adopt to achieve this goal is to take into consideration the scalar transport equation, $\phi_t + a\,\phi_x + b\,\phi_y = 0$, in the flow

with the constant velocity vector $\vec{u} = (a, b)$. The modified equation analysis reveals the rational use of $(\alpha^h, \beta^h, \gamma^h, \mu^h) = (0, 1, 1, 0)$ [23]. With these parameters, the resulting modified equation reads as

$$\begin{aligned} &\phi_t + a\,\phi_x + b\,\phi_y \\ &= T_1\,\phi_{xxxx} + T_2\,\phi_{xxxy} + T_3\,\phi_{xxyy} + T_4\,\phi_{xyyy} + T_5\,\phi_{yyyy} + \cdots, \end{aligned} \tag{3.9}$$

where $T_1 = \frac{1}{24}\,a\,\Delta x^3\,\nu_x\,({\nu_x}^2 - 1)$, $T_2 = \frac{1}{6}\,b\,\Delta x^3\,{\nu_x}^3$, $T_3 = -\frac{1}{12}\,b^2\,\Delta x^2\,\Delta t\,{\nu_x}^2$, $T_4 = \frac{1}{6}\,a\,\Delta y^3\,{\nu_y}^3$, $T_5 = \frac{1}{24}\,b\,\Delta y^3\,\nu_y\,({\nu_y}^2 - 1)$. In light of the spatial third-order accuracy, and the first-order temporal accuracy, the above Taylor–Galerkin finite element model shows promise as a means of predicting a smoothly distributed water height in shallow water equations.

3.2. Low-order Taylor–Galerkin finite element model. The next step in the development of the Taylor–Galerkin FCT (TG-FCT) finite element model is to derive the low-order model from the generalized Taylor–Galerkin finite element model. To achieve this goal, the model is not allowed to produce any nonphysical or numerical wiggles. This monotonicity and strictly positive field variable requirement is a key to success in any FCT method. The better the low-order scheme, the easier the task of limiting fluxes.

The development of a low-order finite element model proceeds as follows. We first rewrite (3.7) as

$$\mathbf{M}_c\,\mathbf{U}^{n+1} = \mathbf{R}^n + \mathbf{M}_c\mathbf{U}^n. \tag{3.10}$$

The derivation is followed by lumping the above equation to get

$$\mathbf{M}_l\,\mathbf{U}^{n+1} = \mathbf{R}^n + \mathbf{M}_c\mathbf{U}^n. \tag{3.11}$$

The above lumping-mass approximation helps to stabilize the discretized equation. Subtracting $\mathbf{M}_l\,\mathbf{U}^n$ from both sides of (3.11), we obtain

$$\mathbf{M}_l\,\delta\mathbf{U}^n = \mathbf{R}^n + (\mathbf{M}_c - \mathbf{M}_l)\,\mathbf{U}^n. \tag{3.12}$$

Further refinement of (3.12) can be made by multiplying c_d $(0 \le c_d \le 1)$ by the added mass diffusion term to better control the predicted solution. This helps us avoid the introduction of unnecessarily large diffusion errors. The resulting model for obtaining the lower-order Taylor–Galerkin finite element solution $\mathbf{U}^n$ reads as

$$\mathbf{M}_l\,\delta\mathbf{U}^n = \mathbf{R}^n + c_d\,(\mathbf{M}_c - \mathbf{M}_l)\,\mathbf{U}^n, \tag{3.13}$$

where $\mathbf{M}_l = \mathcal{A}_{el=1}^{n_{el}}(\mathrm{diag}(\sum_{j=1}^{n_{\max}} \mathbf{M}_{cij}^{el}))$. In order to satisfy the requirement placed on the low-order scheme in any FCT method, we employ the discrete maximum theory [26, 27, 28]. Based on this underlying theory, the matrices involved in (3.13) are of the M-matrix type provided that the five free parameters introduced into the scalar formulation are prescribed as $(\alpha^l, \beta^l, \gamma^l, \mu^l, c_d) = (0, 0, 0, 0, 0.425)$.

When simulating nonlinear shallow water equations, we may encounter a sonic flow situation. In this case, entropy fix must be invoked in order to avoid nonphysical rarefaction shocks at the sonic point. To satisfy the entropy satisfaction property when the sonic condition is detected, we should add an entropy flux term, $\frac{\partial}{\partial x}(b(\nu_x)\frac{\partial \mathbf{U}}{\partial x}) + \frac{\partial}{\partial y}(b(\nu_y)\frac{\partial \mathbf{U}}{\partial y})$, to the region where it is needed. The damping coefficients used in the entropy flux are as follows [29]:

$$b(\nu_i) = c_e\,\frac{\Delta t}{2\lambda^2}\,q(\nu_i), \tag{3.14}$$

where $\lambda = \Delta t/\Delta x$ (or $\Delta t/\Delta y$), $\nu_i = \frac{\Delta t}{\Delta x}(u-c)$ (or $\nu_i = \frac{\Delta t}{\Delta y}(v-c)$), and

$$q(\nu_i) = \begin{cases} 0, & |\nu_i| \geq \epsilon, \\ \epsilon^2 - \nu_i^2, & |\nu_i| < \epsilon. \end{cases} \tag{3.15}$$

In what follows, we set $\epsilon = 0.2$ and $c_e = 2.0$.

3.3. FCT filtering algorithm. Having determined the values $(\alpha, \beta, \gamma, \mu, c_d)$ needed to obtain high- and low-order finite element solutions, we can use two Taylor–Galerkin models in combination to obtain positive and accurate results which are free of nonphysical fluctuations. Use of the two schemes in combination was proposed by Zalesak [17]. We follow closely the FCT scheme of Zalesak by calculating $\delta\mathbf{U}^h$ from the high-order model using either the iterative solvers or the multifrontal direct solver [30] discussed below.

Upon obtaining the solution $\delta\mathbf{U}^h$, we can compute the antidiffusive flux array $\mathbf{F}^{el^h}$ in each element:

$$\mathbf{F}^{el^h} = [F_i^{el^h}] = \mathbf{M}_{l_h}^{-1}\,[\mathbf{R}^{el^h} - (\mathbf{M}_c{}^{el^h} - \mathbf{M}_l{}^{el^h})\,\delta\mathbf{U}^h]. \tag{3.16}$$

The calculation is followed by computing the antidiffusive flux array $\mathbf{F}^{el^l}$ from the low-order Taylor–Galerkin solution $\delta\mathbf{U}^l$. The resulting antidiffusive flux array, $\mathbf{F}^{el^l}$, in each element is computed according to $\mathbf{F}^{el^l} = [\mathbf{M}_l{}^{-1}\mathbf{R}^{el^l}]$. When antidiffusive fluxes $\mathbf{F}^{el^h}$ and $\mathbf{F}^{el^l}$ become available, we can calculate the corrected antidiffusive flux array $\mathbf{F}^{el^c}$ [17]. The filtering processes finish with the calculation of $\mathbf{U}^{n+1}$ by means of $\mathbf{U}^{n+1} = \mathbf{U}^l + \mathcal{A}_{el=1}^{n_{el}}(\mathbf{F}^{el^c})$.

4. Solution solvers. The iterative solution solver is a strong rival to its direct counterpart because it is less prone to fill-in problems. However, though the storage problem can be considerably resolved, iterative methods have shortcomings of their own. Chief among these shortcomings is the poor control of convergence behavior. Due to space limitations, we will confine our review to iterative solvers based on the minimization concept. The conjugate gradient method of Hestenes and Stiefel [31], considered to be the pioneering work of this class of solvers, works effectively only for a matrix equation having clustered eigenvalues and suffers from pivoting breakdown when matrix symmetry is lost. Refinement of this Krylov subspace method in order to overcome the matrix asymmetry difficulty has been the primary focus of research during the last two decades.

In the literature, nonstationary iterative methods, which have the ability to resolve matrix asymmetry, are frequently referred to [32]. The Chebyshev methods are applicable only to positive definite equations [33]. Also, use of this class of methods requires knowledge of the eigenvalue spectrum a priori. To circumvent deficiencies in irregular convergence behavior and the indispensable transpose operation of the coefficient matrix inherent in the bi-conjugate gradient (Bi-CG) method [34], the Arnoldi or Lanczos algorithms were proposed. Like the Arnoldi algorithm, the GMRES method [19] iterates the approximation solution through use of a self-orthogonal sequence. Due to the prohibitive storage demand, the residual can be minimized optimally by adding a restart capability. In the iteration, no more than n steps are needed for an n by n matrix to reach convergence.

Within the Lanczos framework, product methods, such as conjugate gradient squares (CGS) [35], quasi-minimal residual (QMR) [36], and Bi-CGSTAB [18], are

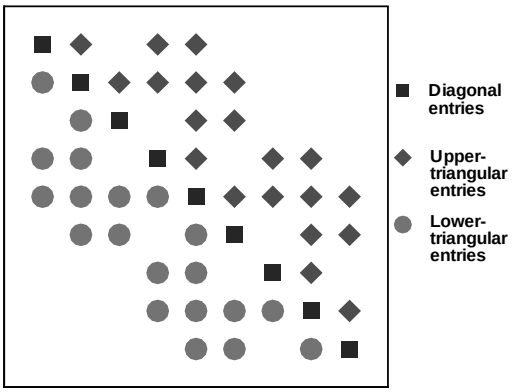

FIG. 4.1. *An illustration of the sparse matrix assembled from* 2×2 *elements.*

preferable for tackling equation asymmetry. The exploration of a set of dual orthogonal vectors is the building block of this class of methods. The QMR method of Freund and Nachtigal [36] was designed to avoid irregular convergence behavior. This method, unfortunately, suffers from the need to transpose the stiffness matrix. CGS, on the other hand, avoids the need for matrix transpose but inhibits irregular convergence behavior because it accommodates the same contraction polynomial as does Bi-CG. Besides the transpose-free version of QMR [37], the Bi-CGSTAB method of Van der Vorst [18] is a rational alternative. Bi-CGSTAB iterates the approximation solution in terms of unsymmetric Lanczos vectors, in conjunction with the local minimization method GMRES(1). Through manipulation of equal-order contraction polynomials of different kinds, one can dispense with transpose matrix procedures and suppress irregular convergence behavior. Nevertheless, much work still needs to be done so that pivoting breakdown and Lanczos breakdown can be avoided.

The choice of an appropriate solver for obtaining finite element solutions depends on the type of matrix equations employed. Take matrix equations constructed from 2×2 elements as an example; the sparse matrix, as shown in Figure 4.1, is found to be unsymmetric. Further eigenvalue analysis reveals that the matrix equations are indefinite, thus limiting application of conventional iterative solvers. In this study, we will consider two state-of-the-art iterative solvers and attempt to make a definite assessment of the multifrontal direct solver [30]. Two iterative solvers are the GMRES solver of Saad and Schultz [19] and the Bi-CGSTAB iterative solver of Van der Vorst [18]. These iterative solvers are variants of conjugate gradient methods.

4.1. The GMRES iterative solver. We will consider first the GMRES method of Saad and Schultz [19]. This nonstationary iterative solution solver is considered to be an extension of minimal residual (MINRES) which can be used to solve unsymmetric matrix equations. A sequence of tridiagonal matrices is used to obtain a progressively improved distribution of the eigenvalues of the original non-Hermitian linear stiffness matrix system. GMRES iterates the solution with the aid of Arnoldi vectors to overcome the difficulty of the nonsymmetry of the matrix equations. The employed Arnoldi algorithm involves partial tridiagonalization of the original matrix equations using one set of orthogonal vectors $\underline{\mathbf{Q}}$ to yield $\underline{\mathbf{Q}}^T \underline{\underline{\mathbf{A}}}\, \underline{\mathbf{Q}} = \underline{\mathbf{H}}$, where $\underline{\mathbf{H}}$ is

the Hessenberg reduction. The column-by-column generation of $\underline{\mathbf{Q}}$ has the property of $\underline{\mathbf{Q}}^T\,\underline{\mathbf{Q}} = \underline{\mathbf{I}}$ (i.e., identity matrix).

GMRES follows the modified Gram–Schmidt orthogonalization procedure. It invokes a restart capability to control the storage requirement. In GMRES, the main steps are as follows:

Set $\underline{\mathbf{x}}_0$ as an initial guess
For $j = 1, 2, \ldots$
  Solve $\underline{\mathbf{r}}$ from $\underline{\mathbf{r}} = \underline{\mathbf{b}} - \underline{\underline{\mathbf{A}}}\,\underline{\mathbf{x}}_0$ ⟵ element-by-element procedure
  $\underline{\mathbf{v}}_1 = \underline{\mathbf{r}}/\|\underline{\mathbf{r}}\|_2$
  $s := \|\underline{\mathbf{r}}\|_2$
  for $i = 1, 2, 3, \ldots, m$
    Solve $\underline{\mathbf{w}}$ from $\underline{\mathbf{w}} = \underline{\underline{\mathbf{A}}}\,\underline{\mathbf{v}}_i$ ⟵ element-by-element procedure
    for $k = 1, \ldots, i$
      $h_{k,i} = (\underline{\mathbf{w}}, \underline{\mathbf{v}}_k)$
      $\underline{\mathbf{w}} = \underline{\mathbf{w}} - h_{k,i}\,\underline{\mathbf{v}}_k$
    end
    $h_{i+1,i} = \|\underline{\mathbf{w}}\|_2$
    $\underline{\mathbf{v}}_{i+1} = \underline{\mathbf{w}}/h_{i+1,i}$
    apply $J_1, \ldots, J_{i-1}$ on $(h_{1,i}), \ldots, h(i+1, i))$
    construct J_i, acting on the ith and $(i+1)$st components of $h_{\cdot,i}$,
      such that the $(i+1)$st component of $J_i\,h_{\cdot,i}$ is with the value of 0
    $s := J_i\,s$
    if $s(i+1)$ is small enough, then (**UPDATE** $(\tilde{\underline{\mathbf{x}}}, i)$ and quit)
  end
  UPDATE $(\tilde{\underline{\mathbf{x}}}, m)$
End

The **UPDATE** $(\tilde{\underline{\mathbf{x}}}, i)$ procedure is as follows:

Compute $\underline{\mathbf{y}}$ from $\underline{\underline{\mathbf{H}}}\,\underline{\mathbf{y}} = \underline{\mathbf{s}}$,
  in which the upper $i \times i$ triangular part of $\underline{\underline{\mathbf{H}}}$ has $h_{i,j}$ as its elements,
  $\underline{\mathbf{s}}$ is the first i components of s
$\tilde{\underline{\mathbf{x}}} = \underline{\mathbf{x}}_0 + \underline{\mathbf{y}}_1\underline{\mathbf{v}}_1 + \underline{\mathbf{y}}_2\underline{\mathbf{v}}_2 + \cdots + \underline{\mathbf{y}}_i\underline{\mathbf{v}}_i$
$s_{i+1} = \|\underline{\mathbf{b}} - \underline{\underline{\mathbf{A}}}\,\tilde{\underline{\mathbf{x}}}\|_2$ ⟵ element-by-element procedure
if $\tilde{\underline{\mathbf{x}}}$ is accurate enough, then quit
else $\underline{\mathbf{x}}_0 = \tilde{\underline{\mathbf{x}}}$.

In the above, the inner product coefficients $\|w^i\|$ and (w^i, v^k) are stored in a Hessenberg matrix. Upon obtaining the values of y_k, which are designed to minimize the residual norm $\|\underline{\mathbf{b}} - \underline{\underline{\mathbf{A}}}\,\underline{\mathbf{x}}^{(j)}\|$, the GMRES iterations are constructed as $x^j = x^0 + \sum_{i=1} y_i v^i$. GMRES will converge in no more than n iterations when an n by n matrix equation is solved. This is practically infeasible since the storage and computational requirements are prohibitive if n is large. In fact, the crucial factor for successful application of GMRES lies in the restart coded in the program. For this reason, the restarting capability is a built-in feature that can yield the above restarted GMRES(m), where m denotes the termination number of iteration. The choice of m, however, has no theoretical foundation and thus is very difficult to determine. Since there is no definitive rule for the choice of m, we determine it through numerical experiments. After conducting extensive investigations, we consider $m = 5$ in all the calculations. For additional details of GMRES(m), see Van der Vorst [18].

4.2. The Bi-CGSTAB iterative solver. The Bi-CG method of Fletcher [34] suffers from instability problem arising from the unsymmetric Lanczos process when

it is used to solve the non-Hermitian system of equations. As a result, considerable effort has been directed toward developing a more stable algorithm. The CGS method is considered as a variant of Bi-CG, known as Bi-CGSTAB. Since the Bi-CGSTAB method is known for its smooth approach to convergence, we will consider this method in our assessment study.

Like the Bi-CG method, Bi-CGSTAB iterates the approximate solution by means of unsymmetric Lanczos vectors. The difficulty arises from the nonsymmetry property of the finite element stiffness matrix $\underline{\underline{\mathbf{A}}}$, which results in the nonexistence of the orthogonal tridiagonalization $\underline{\mathbf{Q}}^T \underline{\underline{\mathbf{A}}}\, \underline{\mathbf{Q}} = \underline{\mathbf{T}}$, where $\underline{\mathbf{T}}$ is a tridiagonal matrix. As a result, partial tridiagonalization of $\underline{\underline{\mathbf{A}}}$ is needed to implement the algorithm. The unsymmetric Lanczos algorithm allows partial tridiagonalization of $\underline{\underline{\mathbf{A}}}$ by making use of two sets of biorthogonal vectors. This approach involves computing columns of $\underline{\mathbf{Q}}$ and $\underline{\mathbf{P}}$, which are subject to $\underline{\mathbf{P}}^T \underline{\mathbf{Q}} = \underline{\mathbf{I}}$, so that $\underline{\mathbf{P}}^T \underline{\underline{\mathbf{A}}}\, \underline{\mathbf{Q}} = \underline{\mathbf{T}}$ is tridiagonal.

It has been known for quite some time that effective use of iterative methods depends highly upon the nonzero profile of the coefficient matrix. The strategies of ordering nodal points and allocating working variables are essential because they have a direct effect on the matrix bandwidth and, thus, matrix sparsity. A means of storing the matrix in the core memory is needed in the finite element analysis, where sparse matrix equations are encountered. Like the compressed matrix used in the finite difference setting, we can store a matrix at the element level so as to dispense with unnecessary storage of voids. This motivates us to conduct finite element analysis on an element-by-element basis. In this paper, we incorporate the element-by-element capability into the Bi-CGSTAB of Van der Vorst [18]:

Compute $\underline{\mathbf{r}}_0 = \underline{\mathbf{b}} - \underline{\underline{\mathbf{A}}}\, \underline{\mathbf{x}}_0$ for an initial guess vector $\underline{\mathbf{x}}_0$
Choose $\overline{\underline{\mathbf{r}}}$, such that $(\overline{\underline{\mathbf{r}}}, \underline{\mathbf{r}}_0) \neq 0$
For $i = 1, 2, \ldots$
  $\rho_{i-1} = (\overline{\underline{\mathbf{r}}}, \underline{\mathbf{r}}_{i-1})$
  if $\rho_{i-1} < \epsilon_1$ [**near break down**]
  if $i = 1$
    $\underline{\mathbf{p}}_i = \underline{\mathbf{r}}_{i-1}$
  else
    $\beta_{i-1} = (\rho_{i-1}/\rho_{i-2})(\alpha_{i-1}/\omega_{i-1})$
    $\underline{\mathbf{p}}_i = \underline{\mathbf{r}}_{i-1} + \beta_{i-1}\,(\underline{\mathbf{p}}_{i-1} - \omega_{i-1}\,\underline{\mathbf{v}}_{i-1})$
  endif
  $\underline{\mathbf{v}}_i = \sum_{elem} (\underline{\underline{\mathbf{A}}}_{elem}\, \underline{\mathbf{p}}_i)$ ⟵ element-by-element procedure
  $\alpha_i = \rho_{i-1}/(\overline{\underline{\mathbf{r}}}, \underline{\mathbf{v}}_i)$
  if $(\overline{\underline{\mathbf{r}}}, \underline{\mathbf{v}}_i) < \epsilon_2$ [**near break down**]
  $\underline{\mathbf{s}} = \underline{\mathbf{r}}_{i-1} - \alpha_i\, \underline{\mathbf{v}}_i$
  $\underline{\mathbf{t}} = \sum_{elem} (\underline{\underline{\mathbf{A}}}_{elem}\, \underline{\mathbf{s}})$ ⟵ element-by-element procedure
  if $\|\underline{\mathbf{s}}\|_2 < \epsilon$
    $\omega_i = 0$
  else
    $\omega_i = (\underline{\mathbf{t}}, \underline{\mathbf{s}})/(\underline{\mathbf{t}}, \underline{\mathbf{t}})$
  endif
  $\underline{\mathbf{x}}_i = \underline{\mathbf{x}}_{i-1} + \alpha_i\, \overline{\underline{\mathbf{p}}}_i + \omega_i\, \overline{\underline{\mathbf{s}}}$
  $\underline{\mathbf{r}}_i = \underline{\mathbf{b}} - \underline{\underline{\mathbf{A}}}\, \underline{\mathbf{x}}_i$
  check convergence; continue if necessary $(\omega_i \neq 0)$
End

For the two iterative methods considered here, the calculation is terminated when the

residual-norm criterion $\|\underline{\mathbf{r}}\|_2 < 10^{-10}$ is satisfied.

4.3. Multifrontal direct solver. One of the significant advances in finite element computations was the frontal direct solver developed in 1970 [21]. The frontal solver begins by assembling the matrix for each element. This is followed by incorporating element matrices into the global system of matrices. The elimination of equations is allowed whenever possible, rather than assembling the whole system of elementary finite element matrices. Instead, we examine whether there exists any row which corresponds to the fully contributed nodes; if there is, we store the row, the variables associated with it, and the right-hand side, and then eliminate this row. This process continues until all the elements have been assembled and the elimination procedure is completed. The calculation of solutions is followed by performing backward-substitution.

The multifrontal direct solver can be refined in different ways. The most important solver of this kind is the one developed in 1983 [20]. As the name indicates, many frontal matrices are involved in the course of applying multifrontal solver. The matrix is divided into several balanced substructures. A tree structure is needed to define the order of assembly of element matrices. After the finite element mesh is partitioned, a frontal method is applied to each user's defined substructure to eliminate the interior nodes. A set of substructure matrices is thus generated to complete the elimination process. This is followed by backward-substitution to obtain finite element solutions.

5. Numerical results. We will first consider test problems which are amenable to analytical solutions in order to demonstrate the validity and usefulness of the TG-FCT finite element model. The first problem is shown schematically in Figure 5.1. In the square of unit length, a sharp scalar profile was set as the initial condition. The centroid of the square profile was located at (0.25, 0.25). This initially discontinuous scalar profile was transported in the flow specified by $u = \sqrt{2}/2$, $v = \sqrt{2}/2$. Rectangular Cartesian grids were uniformly overlaid on the region of interest. The grid spacings were set as $\Delta x = \Delta y = 0.01$, and the time increment for this study was chosen to be $\Delta t = 0.001$. The calculation for this study was terminated at $t = 0.5$. The numerical models were run using iterative and direct solvers with a tolerance equal to 10^{-10}. The result shown in Figure 5.2 clearly indicates that the passive scalar was well predicted without observable oscillations. This validation test shows that the scheme adopted here has the ability to resolve discontinuities.

We now turn to making a comparison of the employed frontal, GMRES(5), and Bi-CGSTAB solution solvers. The user, system, and CPU times shown in Table 5.1 are obtained for the codes run on an Intel Celeron/466 MHz processor. As this table shows, GMRES(5) consumes only 1/9 CPU time as that computed by the frontal solver. As for the Bi-CGSTAB solver, it is slower than the GMRES(5) by a factor of 7/9. One plausible reason for explaining the savings in CPU time of the GMRES solver is due to its relatively regular convergence. Taking $t = \Delta t$ as an example, the convergent histories, shown in Figure 5.3, clearly show that the specified tolerance is reached much more quickly when GMRES is employed. As for the CPU time spent in this arbitrarily chosen time step, the ratio of $\text{CPU}|_{\text{GMRES(5)}}$ / $\text{CPU}|_{\text{Bi-CGSTAB}}$ is equal to 4/5.

The next problem was intended to test the ability of the scheme to resolve discontinuous field variables in shallow water equations. In this validation, we solve for a one-dimensional dam-break problem using the proposed two-dimensional finite element code. The problem, shown in Figure 5.4, involved a dam 100 m in length.

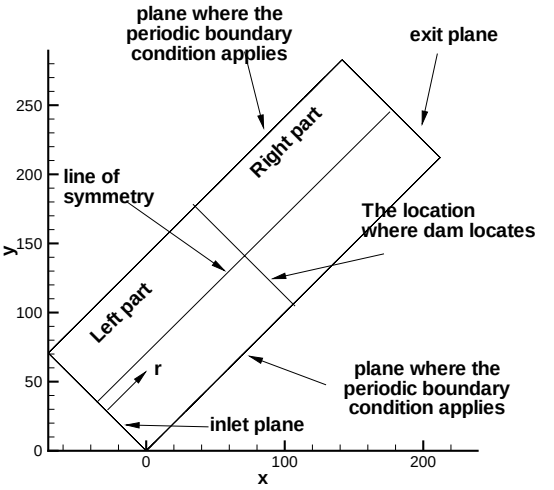

FIG. 5.4. *The configuration of the one-dimensional dam-break problem.*

For the present study, a channel 300 m long and 100 m wide was used and was discretized into 301×7 grids for numerical calculation. The case under investigation was a subcritical flow with a water-height ratio of 2. Both the upstream and downstream boundary conditions remained unchanged during the calculation. For this purpose, the test was run at $t = 10$ s.

Figure 5.5 shows the water height, which compares very favorably with the following analytic data of Stoker [38]:

$$h(\tilde{x},t) = \begin{cases} h_1 & \text{if } \frac{\tilde{x}}{t} \le -\sqrt{gh_1}, \\ \left(\frac{1}{9g}\right)\left[2\sqrt{gh_1} - \frac{\tilde{x}}{t}\right]^2 & \text{if } -\sqrt{gh_1} \le \frac{\tilde{x}}{t} \le \left[u_m - \sqrt{gh_m}\right], \\ h_m & \text{if } \left[u_m - \sqrt{gh_m}\right] \le \frac{\tilde{x}}{t} \le s, \\ h_2 & \text{if } s \le \frac{\tilde{x}}{t} \le \infty. \end{cases} \tag{5.1}$$

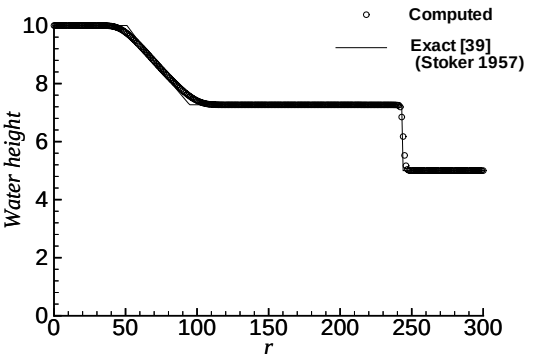

FIG. 5.5. *The comparison of the solution of the one-dimensional dam-break problem with the Stoker's analytic solution. The grid size for this problem is* $\Delta r = 1$.

We denote here $\tilde{x} = x - x_0$, where x_0 is the location of the discontinuity. In the above, h_m and u_m are the water height and velocity in the middle of this channel, and their values are related to the shock propagation speed s:

$$h_m = \frac{1}{2}\left[\sqrt{1 + \frac{8s^2}{gh_2}} - 1\right] h_2, \tag{5.2}$$

$$u_m = s - \frac{gh_2}{4s}\left[1 + \sqrt{1 + \frac{8s^2}{gh_2}}\right]. \tag{5.3}$$

The shock speed s is the positive real root of the following equation:

$$u_m + 2\sqrt{gh_m} - 2\sqrt{gh_1} = 0. \tag{5.4}$$

It is seen from the computed solutions that the shock wave can be resolved within 4 mesh points. No postshock oscillations are observed in the solution. Also, the improved accuracy is attributable to the high-order Taylor–Galerkin scheme, which is applied in regions away from the discontinuity.

We will now consider wave propagation in a basin of simple geometry. Figure 5.6 shows a typical configuration extensively used to study shallow water where bore waves may develop. At the midpoint of the square basin, a dam with a width of 10 m equally divides the water into two parts. On both sides of this idealized dam, the water elevations have a height ratio other than 1. At time $t = 0^+$, the dam is partially broken, leading to a breach with a width of 75 m. The resulting flow pattern in this partially breached dam depends on whether it is classified as being subcritical or supercritical. The case examined here is a subcritical flow with $h_L/h_R = 2$, where $h_L\,(\equiv 10$ m) denotes the initial water elevation on the left side of the basin while $h_R\,(\equiv 5$ m) represents the water height on the right side. Given that the ratio h_L/h_R has a value other than 1, water proceeds toward the downstream side through the breach, which is located in the region $y = 95$ m to $y = 170$ m. When the dam breaks, a bore wave starts to propagate forward and spread laterally. At the same time, a negative depression wave spreads upstream. In addition, a standing wave will appear

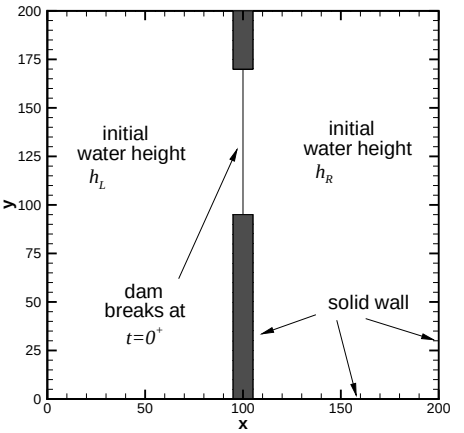

FIG. 5.6. *The configuration of the two-dimensional dam-break problem.*

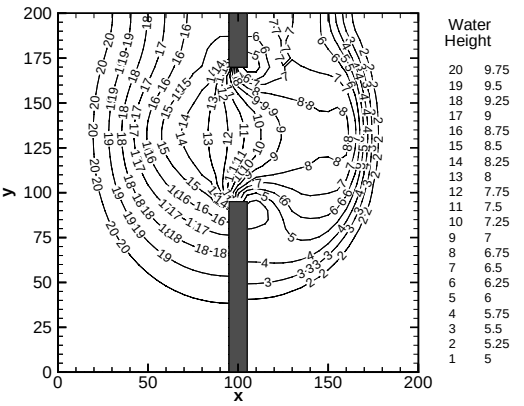

FIG. 5.7. *The contours of water height of the two-dimensional dam-break problem.*

due to the reduction of velocity at the two side walls. Our goal is to numerically predict the time-evolving propagation and spreading of the wave into the reservoir.

With the Courant number set as 0.1, the numerical code was run on a domain of uniform spacing, $\Delta x = \Delta y = 5$. Figure 5.7 plots the contour values of the water elevation obtained using the proposed TG-FCT method at $t = 7.2$ s. These values show that the right traveling bore wave and left traveling depression wave have both been predicted. The results also reveal the ability of the FCT scheme to capture sharp solutions, as seen from the abrupt depression of the water surface elevation in the vicinity of the breach edge. The appearance of this sharp depression wave is theoretically justified since strong rarefactions are established in the inviscid flow regime where large velocity gradients appear. In light of this fact, we plot in Figure 5.8 the velocity vector to show the sharp depression in the water surface elevation around the breach edge. From this velocity vector plot, we are led to conclude that the regions with large velocity gradients observed near the edge of the breach appear to be those which are most subject to abrupt depression in the water surface elevation.

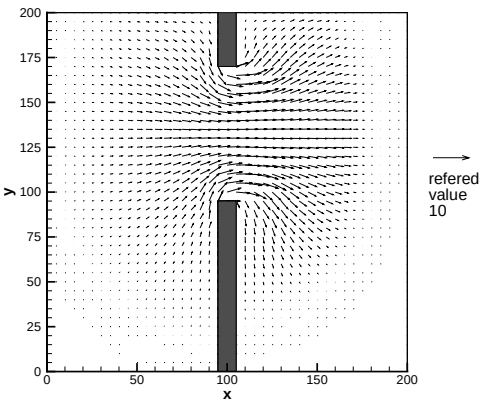

FIG. 5.8. *The velocity vector of the two-dimensional dam-break problem.*

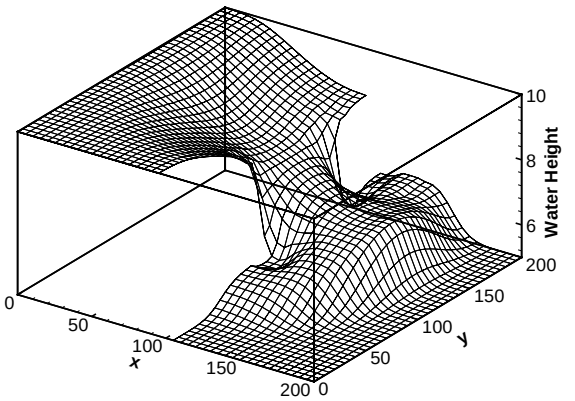

FIG. 5.9. *The three-dimensional view of the water height of the two-dimensional dam-break problem.*

To present the solution clearly, we plot in Figure 5.9 a three-dimensional water surface at $t = 7.2$ s after the dam breaks.

Having demonstrated the advantage of using the GMRES(5) solver over the Bi-CGSTAB solver, we simply consider the GMRES solver in the shallow water calculation and make a computational assessment with the two employed direct solvers. Table 5.2 shows that GMRES(5) is ten times faster than the frontal solver. As for the multifrontal direct solver, it takes only 1/3 of the CPU time needed for the direct solver. Note that the times summarized in Table 5.2 are obtained on an SGI Origin 2000 computer. This performance test demonstrates the effective utility of the multifrontal solver and, more importantly, ensures the advantage of applying the GMRES iterative solver to shallow water analyses.

To show that this method is applicable to predicting a more severely changing solution profile, we considered a supercritical flow. The initial water height ratio was prescribed as $h_R/h_L = 0.05$. As Figure 5.10 shows, water heights were captured in a sharp and nonoscillatory way. This test also sheds light on the effectiveness of adding entropy flux to the region where needed (near the sonic point) since no expansion

TABLE 5.2

The comparison of CPU times (in seconds) for solving the dam-break problem using the frontal, multifrontal, and GMRES solvers.

Method	User time	System time	CPU time
frontal [21]	28961	199	29160
multifrontal [20]	9657	142	9799

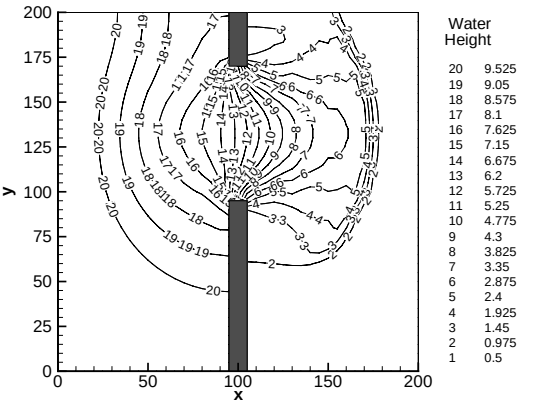

FIG. 5.10. *The contours of water height of the two-dimensional dam-break problem with* $h_R/h_L = 0.05$.

shock is observed. It is thus concluded that the FCT technique incorporated into the Taylor–Galerkin formulation has the ability to suppress dispersive errors near a discontinuity without adding dissipation error which could deteriorate the solution.

6. Concluding remarks. We have applied in this paper a generalized Taylor–Galerkin finite element model to simulate shallow water equations in two dimensions. By prescribing different sets of free parameters a priori, we can render the technique suitable for hydraulic problems having sharply or smoothly varying solution profiles. We have applied the FCT filtering scheme to obtain high-resolution solutions. The main idea of developing the high-order TG-FEM model is the adoption of modified equation analysis. As for the free parameters used in the low-order Taylor–Galerkin model, we employ the discrete maximum principle to construct a stiffness matrix of the M-matrix type. The avoidance of numerical oscillations near the discontinuity and the higher level of prediction accuracy in the smooth region make this scheme a robust tool for solving differential equations governing shallow water height. The code was run on several test problems to study the method's performance and the solver's efficiency, with particular attention paid to the shock-capturing ability and the computational advantage. For the purpose of validation, we have chosen ones for which exact solutions are available. These include the scalar equation and the shallow water equations. Numerical results show that field variables were captured in a sharp and nonoscillatory way in both subcritical and supercritical situations. Through computational exercises, we advocate the use of iterative solution solvers. Of two investigated iterative solvers, the GMRES outperforms the Bi-CGSTAB solver. The present study also shows the advantage of applying the multifrontal direct solver over the frontal direct solver as far as the present shallow water analysis is considered.

COULOMB INTERACTIONS ON PLANAR STRUCTURES: INVERTING THE SQUARE ROOT OF THE LAPLACIAN*

ZYDRUNAS GIMBUTAS†, LESLIE GREENGARD‡, AND MICHAEL MINION§

Abstract. We present an adaptive fast multipole method for inverting the square root of the Laplacian in two dimensions. Solving this problem is the dominant computational cost in many applications arising in electrical engineering, geophysical fluid dynamics, and the study of thin films. It corresponds to the evaluation of the field induced by a planar distribution of charge or vorticity. Our algorithm is direct and assumes only that the source distribution is discretized using an adaptive quad-tree. The amount of work grows linearly with the number of mesh points.

Key words. quasi-geostrophic fluid dynamics, integral equation methods, thin films, planar circuits

1. Introduction.

In this paper, we present a fast, adaptive, numerical method for solving the pseudodifferential equation

$$(-\Delta)^{1/2}\psi = \omega \tag{1.1}$$

in the plane, where Δ denotes the Laplacian operator. This equation appears in a variety of different mathematical models for problems in surface physics, some of which are described below. We assume that $\omega(x) \in L^2(\mathbf{R}^2)$, with Fourier transform

$$\hat{\omega}(\mathbf{k}) = \int_{\mathbf{R}^2} \omega(\mathbf{x}) e^{-2\pi i\, \mathbf{k}\cdot\mathbf{x}} d\mathbf{x}.$$

The symbol of $-\Delta$ is $1/(2\pi|\mathbf{k}|)^2$, so that the solution to (1.1) can be written as

$$\psi(\mathbf{x}) = \int_{\mathbf{R}^2} \frac{\hat{\omega(\mathbf{k})}}{2\pi|\mathbf{k}|}\, e^{2\pi i\, \mathbf{k}\cdot\mathbf{x}} d\mathbf{k}. \tag{1.2}$$

Alternatively, we can seek a Green's function for this operator by solving the equation

$$(-\Delta)^{1/2} G(\mathbf{x}) = \delta(\mathbf{x}).$$

A straightforward calculation yields

$$G(\mathbf{x}) = \int_{\mathbf{R}^2} \frac{1}{2\pi|\mathbf{k}|} e^{2\pi i \mathbf{k}\cdot\mathbf{x}} d\mathbf{k} = \frac{1}{2\pi|\mathbf{x}|}, \tag{1.3}$$

from which the inversion formula

$$\psi(\mathbf{x}) = \int_{\mathbf{R}^2} \frac{\omega(\mathbf{y})}{2\pi|\mathbf{x}-\mathbf{y}|}\, d\mathbf{y} \tag{1.4}$$

follows.

Since the function $G(\mathbf{x})$ obtained in (1.3) is the Green's function for the three-dimensional Laplacian, we can think of (1.1) and (1.4) as describing a three-dimensional Poisson equation for which $\omega(\mathbf{x})$ is a singular density lying entirely on the plane $z = 0$. Applications involving such surface interactions include the study of planar circuits in electrical engineering, a variety of problems in thin films [5, 19, 20], and certain problems in tomography [7]. In quasi-geostrophic fluid dynamic models [17], one encounters an equation analogous to the incompressible Navier–Stokes equations which take the form

$$\begin{aligned} \omega_t + (U \cdot \nabla)\omega &= \nu \Delta \omega, \\ U &= \nabla^{\perp}\psi, \\ (-\Delta^{1/2})(-\psi) &= \omega, \end{aligned} \tag{1.5}$$

where U is a velocity field, ω is a vorticity-like variable, and ψ is a stream function. In the past three years, these equations have seen a new wave of interest stemming, in part, from observations made in [6] which draw interesting analogies between the quasi-geostrophic equations and the three-dimensional incompressible Euler equations. Another interesting application is a two-fluid model system which supports internal waves and which can be applied to a variety of geophysical model systems [3]. One specific example is a vertically stratified fluid in which one layer is much thinner than the other, and in which the square root of the Laplacian plays a fundamental role.

All of the preceding application areas would benefit from adaptive numerical simulation tools in order to resolve complex solution features. Most existing numerical methods for solving (1.1), however, rely on the spectral form of the solution given in (1.2) and are implemented via the fast Fourier transform. This approach precludes the use of adaptivity and constrains the computational domain to be periodic.

Direct evaluation of the convolution integral (1.4) involves interactions between all pairs of grid points. Hence, with N points in the discretization, the work involved would require $O(N^2)$ operations. In this paper, we describe two special purpose fast multipole methods (FMMs) for the computation of the integral transform (1.4) for which the work required grows linearly with the number of grids points. This approach allows for adaptive mesh refinement and the imposition of either free-space or periodic boundary conditions. Related methods have been developed in [2, 14, 16].

2. Data structures and the FMM. We assume that the source distribution ω in (1.1) is supported inside the unit square D, centered at the origin, on which is superimposed a hierarchy of refinements (a quad-tree). Grid level 0 is defined to be D itself, and grid level $l+1$ is obtained recursively by subdividing each square at level l into four equal parts. Using standard terminology, if d is a fixed square at level l, the four squares at level $l+1$ obtained by its subdivision will be referred to as its children. In order to allow for adaptivity, we do not use the same number of levels in all regions of D. We do, however, assume that the quad-tree satisfies one fairly standard restriction, namely, that two leaf nodes which share a boundary point must be no more than one refinement level apart (Figure 1).

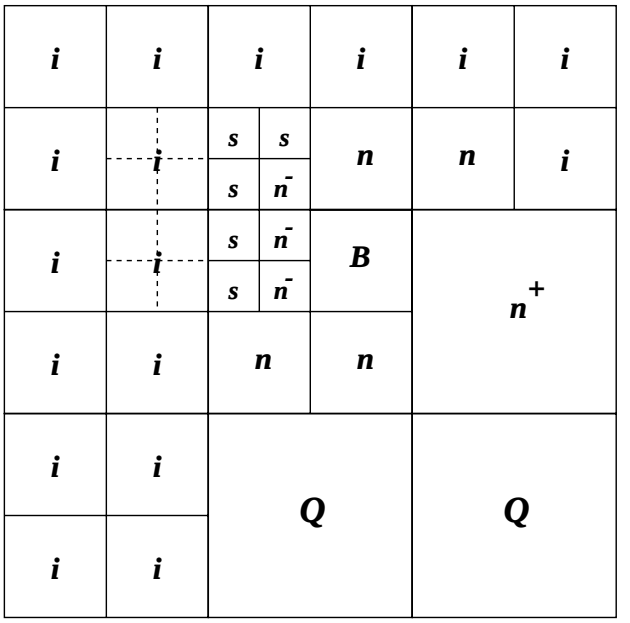

FIG. 1. *For the childless node* $\boldsymbol{B}$*, colleagues are labeled by* $\boldsymbol{n}$*, coarse neighbors are labeled* $\boldsymbol{n}^+$*, and fine neighbors are labeled* $\boldsymbol{n}^-$*. The interaction list for* B *consists of the boxes marked by* $\boldsymbol{i}$ *as well as those marked by* $\boldsymbol{Q}$*. The boxes marked by* $\boldsymbol{s}$ *are children of* B*'s colleagues which are separated from* B*, so they are not fine neighbors. They constitute the* s-list *for* B *(see Definition* 2.1*).*

The leaf nodes on which the source distribution is given will be denoted by D_i. Thus, $D = \cup_{i=1}^{M} D_i$ and we rewrite (1.4) in the form

$$\psi(\mathbf{x}) = -\sum_{i=1}^{M} \int_{D_i} \frac{\omega(\mathbf{y})}{2\pi|\mathbf{x}-\mathbf{y}|}\, d\mathbf{y}. \tag{2.1}$$

DEFINITION 2.1. *The* colleagues *of a square* B *are squares at the same refinement level which share a boundary point with* B*. (*B *is considered to be a colleague of itself.) The* coarse neighbors *of* B *are leaf nodes at the level of* B*'s parent which share a boundary point with* B*. The* fine neighbors *of* B *are leaf nodes one level finer than* B *which share a boundary point with* B*. Together, the union of the colleagues and coarse and fine neighbors of* B *will be referred to as* B*'s* neighbors*. The* s-list *of a box* B *consists of those children of* B*'s colleagues which are not fine neighbors of* B*.*

The interaction region *for* B *consists of the area covered by the neighbors of* B*'s parent, excluding the area covered by* B*'s colleagues and coarse neighbors. The* interaction list *for* B *consists of those squares in the interaction region which are at the same refinement level, as well as leaf nodes in the interaction region which are at coarser levels. When the distinction is important, the squares at the same refinement level will be referred to as the* standard interaction list*, while the squares at coarser levels will be referred to as the* coarse interaction list*.*

In our FMM, following [4, 11, 12], terms in the convolution integral (2.1) from neighbor leaf nodes are computed directly. More distant interactions are accounted for on coarser levels through the use of a hierarchy of far-field and local multipole expansions. We consider the local interactions first.

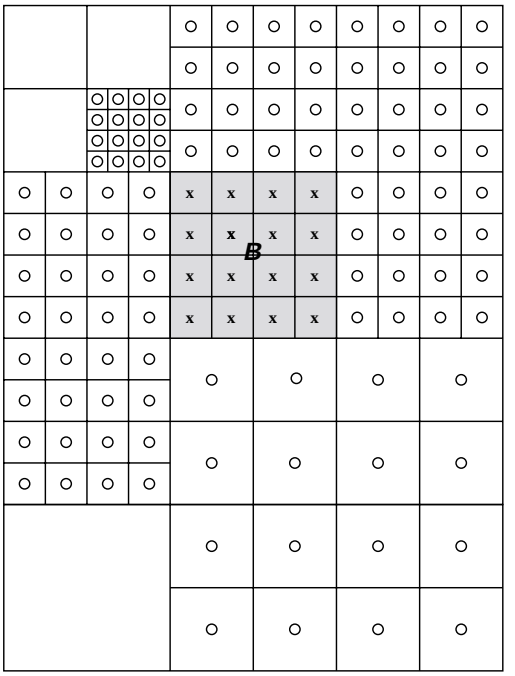

FIG. 2. *The source distribution ω is given on a cell-centered 4×4 grid in the central square B. The field induced by the distribution on B's neighbors can be tabulated and stored. In the adaptive grid, neighbors can be at the same refinement level as B, one coarser or one finer.*

2.1. Local interactions. We assume that we are given ω on a cell-centered 4×4 grid for each leaf node B. We can, therefore, take these 16 data points and construct a fourth-order polynomial approximation to ω of the form

$$\omega_B(x,y) \approx \sum_{j=1}^{10} c_B(j)\, b_j(x - x_B, y - y_B),$$

where (x_B, y_B) denotes the center of B. The basis functions $b_j(x,y)$ are given by

$$1,\ x,\ y,\ x^2,\ xy,\ y^2,\ x^3,\ x^2y,\ xy^2,\ y^3$$

for $j = 1,\ldots,10$, respectively. If we let $\vec{\omega_B} \in \mathbf{R}^{16}$ denote the discrete function values in standard ordering, then the calculation of the coefficient vector $\vec{c}_B$ is clearly overdetermined. We obtain it through a least squares fit based on the singular value decomposition. The pseudoinverse matrix $\mathcal{P} \in \mathbf{R}^{10\times16}$, such that

$$\vec{c}_B = \mathcal{P}\,\vec{\omega_B}$$

can be precomputed and stored.

Consider now a target point Q, which lies in a neighbor of B (Figure 2). Then, the field induced by ω_B is approximated by

$$\psi_B(Q) = \sum_{j=0}^{10} c_B(j) w(Q,j), \tag{2.2}$$

where

$$w(Q,j) = \int_B \frac{b_j(x - x_B, y - y_B)}{2\pi|Q - (x,y)|}\, dxdy. \tag{2.3}$$

Since the target points Q are regularly spaced in each neighboring square, we can precompute the weights (2.3) for each of the sixteen possible locations at each of 9 possible colleagues, 12 possible fine neighbors, and 8 possible coarse neighbors. To be more precise, we can precompute the weights assuming that B is the unit square $[-0.5, 0.5]^2$, because of the following straightforward lemma.

LEMMA 2.2. *Let B be a leaf node at level l and let Q denote a target point in one of B's neighbors. Let Q^* denote the scaled target point for the unit cell centered at the origin*

$$Q^* = 2^l \cdot (Q - (x_B, y_B)),$$

and let

$$w^*(Q^*, j) = \int_{-1/2}^{1/2} \int_{-1/2}^{1/2} \frac{b_j(x,y)}{2\pi|Q^* - (x,y)|}\, dxdy. \tag{2.4}$$

Then the integral $w(Q,j)$ defined in (2.3) *is given by*

$$w(Q,j) = w^*(Q^*, j) \cdot 2^{-[d+1]l},$$

where d is the degree of the polynomial basis function b_j.

Thus, we need only obtain weights for a box of unit area. Elementary counting arguments show that the storage required for this precomputation is

$$\begin{aligned} 16 \cdot 10 \cdot 9 &\text{ real numbers} \quad \text{for colleagues,} \\ 16 \cdot 10 \cdot 12 &\text{ real numbers} \quad \text{for fine neighbors,} \\ 16 \cdot 10 \cdot 8 &\text{ real numbers} \quad \text{for coarse neighbors,} \end{aligned}$$

for a total of 4640 real numbers.

2.2. Far-field interactions. We turn now to the calculation of far-field interactions, which are computed by means of multipole expansions. We refer the reader to [9, 15, 18] for more detailed discussions of potential theory. Our starting point is the usual multipole expansion for a charge distribution, which we state formally as a theorem.

THEOREM 2.3 (multipole expansion). *Let $\sigma(T)$ be a charge distribution contained within S, a sphere of radius a centered at the origin, and let $Q = (r, \theta, \phi) \in \mathbb{R}^3$ with $r > a$. Then the field at Q induced by the charge distribution*

$$\Phi(Q) = \int_S \frac{\sigma(T)}{2\pi|T - Q|}\, dT$$

can be described by the multipole expansion

$$\Phi(Q) = \sum_{n=0}^{\infty} \sum_{m=-n}^{n} \frac{M_n^m}{r^{n+1}} \cdot P_n^m(\cos\theta) e^{im\phi}\ , \tag{2.5}$$

where P_n^m denotes the standard associated Legendre function and

$$M_n^m = \frac{(n-|m|)!}{(n+|m|)!}\int_S \frac{1}{2\pi}\sigma(T)\cdot\rho^n\cdot P_n^{|m|}(\cos\alpha)e^{im\beta}dT. \tag{2.6}$$

In the preceding expression, (ρ,α,β) are the spherical coordinates of T. Furthermore, for any $p\geq 1$,

$$\left|\Phi(Q)-\sum_{n=0}^{p}\sum_{m=-n}^{n}\frac{M_n^m}{r^{n+1}}\cdot P_n^m(\cos\theta)e^{im\phi}\right| \leq \frac{1}{2\pi}\left(\frac{\int_S|\sigma(T)|\,dT}{r-a}\right)\left(\frac{a}{r}\right)^{p+1}. \tag{2.7}$$

In the setting of the present paper, the sources and targets are restricted to the plane $z=0$, so that in the preceding formulas, $Q=(r,\pi/2,\phi)$ and $T=(\rho,\pi/2,\beta)$ when expressed in spherical coordinates. Thus, for a charge distribution σ supported in a square D centered at the origin and a target point Q lying in the interaction list for B, $\Phi(Q)$ can be expressed as a multipole expansion of the form

$$\Phi(Q)=\sum_{n=0}^{\infty}\sum_{m=-n}^{n}M_n^m\cdot\frac{e^{im\phi}}{r^{n+1}}, \tag{2.8}$$

with

$$M_n^m=\frac{(n-|m|)!}{(n+|m|)!}[P_n^m(0)]^2\int_B\frac{1}{2\pi}\sigma(T)\rho^n e^{im\beta}\,dT, \tag{2.9}$$

where (ρ,β) are the polar coordinates of T (Figure 3). The error estimate (2.7) takes the special form

$$\left|\Phi(Q)-\sum_{n=0}^{p}\sum_{m=-n}^{n}M_n^m\cdot\frac{e^{im\phi}}{r^{n+1}}\right|\leq\frac{1}{2\pi}\left(\frac{\int_D|\sigma(T)|\,dT}{2a}\right)\left(\frac{\sqrt{2}}{3}\right)^{p+1}, \tag{2.10}$$

where a^2 is the area of D.

Within the FMM, it is convenient to be able to describe the field within a region due to sources which are far away. For this, suppose that Q lies in D and that

$$\Psi(Q)=\int_S\frac{\sigma(P)}{2\pi|P-Q|}\,dP,$$

where the region S lies outside the nine colleagues of D (Figure 3). Then

$$\Psi(Q)=\sum_{n=0}^{\infty}\sum_{m=-n}^{n}L_n^m\cdot r^n\,e^{im\phi}, \tag{2.11}$$

with

$$L_n^m=\frac{(n-|m|)!}{(n+|m|)!}[P_n^m(0)]^2\int_S\frac{1}{2\pi}\sigma(P)\frac{e^{im\theta}}{\rho^{n+1}}\,dP, \tag{2.12}$$

where (ρ,θ) are the polar coordinates of P. Furthermore,

$$\left|\Psi(Q)-\sum_{n=0}^{p}\sum_{m=-n}^{n}L_n^m\cdot r^n\,e^{im\phi}\right|\leq\frac{1}{2\pi}\left(\frac{\|\sigma(P)\|_{L_1}}{a}\right)\left(\frac{\sqrt{2}}{3}\right)^{p+1}. \tag{2.13}$$

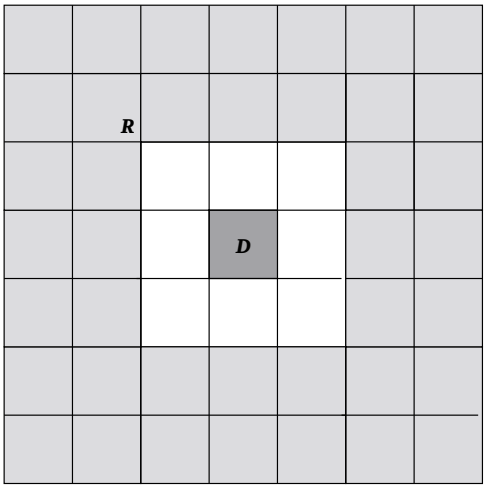

FIG. 3. *For the box D, the interaction region is contained within the outer shaded region.*

The FMM relies on the ability to manipulate multipole and local expansions for every box in the tree hierarchy. We omit the technical details and refer the reader to the original papers [4, 9, 11, 12].

DEFINITION 2.4. *We denote by $S_{l,k}$ the kth square at refinement level l.*

We denote by $\Phi_{l,k}$ the multipole expansion describing the far field due to the source distribution supported inside $S_{l,k}$.

We denote by $\Psi_{l,k}$ the local expansion describing the field due to the source distribution outside the neighbors of $S_{l,k}$.

We denote by $\tilde{\Psi}_{l,k}$ the local expansion describing the field due to the source distribution outside the neighbors of the parent *of $S_{l,k}$.*

REMARK 2.1. *Let $S_{l,k}$ be a square in the quad-tree hierarchy and let $S_{l',k'}$ be a square in its interaction list. Then there is a linear operator $\mathcal{T}_{MM}$ for which*

$$\Phi_{l,k} = \mathcal{T}_{MM}[\Phi(C_1), \Phi(C_2), \Phi(C_3), \Phi(C_4)], \tag{2.14}$$

where $\Phi(C_j)$ denotes the multipole expansion for the jth child of $S_{l,k}$. In other words, we can merge the expansions for four children into a single expansion for the parent. Similarly, there is a linear operator $\mathcal{T}_{LL}$ for which

$$[\tilde{\Psi}(C_1), \tilde{\Psi}(C_2), \tilde{\Psi}(C_3), \tilde{\Psi}(C_4)] = \mathcal{T}_{LL}\, \Psi_{l,k}, \tag{2.15}$$

where C_j denotes the jth child of $S_{l,k}$. In other words, we can shift the local expansion Ψ for a box to the corresponding expansion $\tilde{\Psi}$ for each of its children. Finally, there is a linear operator $\mathcal{T}_{ML}$ for which the field in $S_{l,k}$ due to the source distribution in $S_{l',k'}$ is described by $\Psi = T_{ML}\Phi_{l',k'}$. It is easy to verify that

$$\Psi_{l,k} = \tilde{\Psi}_{l,k} + \sum_{i \in \mathcal{IL}} T_{ML}\Phi_i, \tag{2.16}$$

where $\mathcal{IL}$ denotes the interaction list for square $S_{l,k}$.

REMARK 2.2. *One slight complication in the adaptive algorithm concerns the interaction between boxes of different sizes. Referring to Figure* 1*, we need to account for the influence of a childless square B on each box marked s and vice versa.*

(This interaction clearly doesn't arise if B undergoes further refinement.) For the box marked s, its multipole expansion is rapidly convergent at each of the sixteen target points in B. Thus, its influence can be computed by direct evaluation of the truncated series. For the reverse, however, note that B's multipole expansion is not so rapidly convergent. In this case, we directly compute the coefficients of the local expansion in s from the formula (2.12). *A more precise statement than* (2.16) *is*

$$\Psi_{l,k} = \tilde{\Psi}_{l,k} + \sum_{i \in SIL} T_{ML}\Phi_i, + \sum_{i \in CIL} L_{direct}(\vec{\omega}_i), \tag{2.17}$$

where SIL denotes the standard interaction list and CIL denotes the coarse interaction list. The operator L_{direct}, which maps the coefficients of the polynomial approximation of the density in the coarse box onto the p^2 coefficients of the local expansion can be precomputed and stored.

The bulk of the work in the FMM involves the application of the operators $\mathcal{T}_{MM}, \mathcal{T}_{ML}, \mathcal{T}_{LL}$ in a systematic fashion. Unfortunately, these operators are dense. Using multipole and local expansions truncated after p^2 terms, the naive cost of application is proportional to p^4. Modern versions of the FMM have reduced this cost to $O(p^3)$ or $O(p^2)$ [12].

ALGORITHM.

Initialization

Comment [We assume we are given a square domain $D = S_{0,0}$, on which is superimposed an adaptive hierarchical quad-tree structure. We let M be the number of leaf nodes and denote them by $D_i,\ i = 1, \ldots, M$. The number of grid points is, therefore, $N = 16M$. We let p denote the order of the multipole expansion ($p \approx \log_2 \epsilon$, where ϵ is the desired accuracy). We let l_{max} denote the maximum refinement level.]

Step I: Multipole sweep

Upward pass

for $l = levmax, \ldots, 0$
  for all boxes j on level l
    if j is childless **then**
      form the multipole expansion $\Phi_{l,j}$ from (2.9)
    else
      form the multipole expansion $\Phi_{l,j}$ by merging the expansions of its children using the operator $\mathcal{T}_{MM}$ (see (2.14))
  end
end

Downward pass

Initialize the local expansion $\Psi_{0,0} = 0$.
for $l = 1, \ldots, levmax$
  for all squares j on level l
    Compute $\tilde{\Psi}_{l,j}$ by shifting its parent's Ψ expansion using the operator $\mathcal{T}_{LL}$
    Compute $\Psi_{l,j}$ by adding in the contributions from all squares in j's interaction list according to (2.17).
    if j is childless **then**
      for all boxes k in the *s-list* of j:
        evaluate the multipole expansion Φ_k at each target in square j.
      end
      Evaluate the local expansion $\Psi_{l,j}$ at each

target in square j.
endif
end
end

Cost [The upward pass requires approximately Mp^2 work, where M is the number of leaf nodes. The downward pass requires approximately $12Mp^2 + 4Mp^3$ work (see Remark 2.3 below).]

Step II: Local interactions

Comment [At this point, for each leaf node D_i, we have computed the influence of the source distribution ω over all leaf nodes D_j outside the neighbors of D_i.]

do $i = 1, \ldots, M$
For each target point in D_i, evaluate the influence of each neighbor according to (2.2) using the precomputed tables of coefficients (2.4).
end

Cost [The maximum number of neighbors a square can have is thirteen (twelve fine neighbors and itself). Thus the local work is bounded by $12 \cdot 10 \cdot N$ operations.]

REMARK 2.3. *It is somewhat difficult to determine the cost of Step* I *precisely, since it depends on the actual structure of the adaptive quad-tree. A reasonable estimate for the total work is*

$$N\left(120 + \frac{12}{16}p^2 + \frac{4}{16}p^3\right).$$

2.3. The generalized FMM. One drawback of the preceding scheme is that it relies on spherical harmonic expansions. These are particularly efficient tools for fully three-dimensional calculations, but they make no use of the fact that we are restricted to a two-dimensional domain. In fact, a two-dimensional Taylor series would have served equally well. In the last few years, methods related to the FMM have been developed which are based only on the fact that the far field is smooth [1, 2, 8, 14]. The paper [8] presents a generalized FMM based on "compressing" operators with the singular value decomposition (SVD). To understand this approach, let us reconsider the situation depicted in Figure 3.

DEFINITION 2.5. *Let $\mathcal{C}$ denote the space of real analytic charge distributions defined on a square D and let $\mathcal{P}$ denote the space of real analytic functions defined on the outer shaded region R depicted in Figure* 3. *We define the operator $\mathcal{O} : \mathcal{C} \to \mathcal{P}$ according to $\mathcal{O}(\sigma) = \Phi_\sigma$, where*

$$\Phi_\sigma(Q) = \int_D \frac{\sigma(P)}{2\pi|P - Q|}\, dP.$$

We also define the dual operator $\mathcal{S} : \mathcal{P} \to \mathcal{C}$ according to $\mathcal{S}(\sigma) = \Psi_\sigma$, where σ is a charge distribution defined on R, $P \in D$, and

$$\Psi_\sigma(P) = \frac{1}{2\pi} \int_R \frac{\sigma(Q)}{2\pi|P - Q|}\, dQ.$$

REMARK 2.4. *The spaces $\mathcal{C}$ and $\mathcal{P}$ are infinite-dimensional, but both $\sigma \in \mathcal{C}$ and $\Phi_\sigma \in \mathcal{P}$ can be approximated arbitrarily well by a finite tensor-product Legendre series*

$$\sigma(x, y) \approx \sum_{n=0}^{\mathcal{N}} \sum_{m=0}^{\mathcal{N}} \alpha_n^m P_n(x) P_m(y), \tag{2.18}$$

$$\Phi_\sigma(\xi,\eta) \approx \sum_{n=0}^{\mathcal{N}} \sum_{m=0}^{\mathcal{N}} \beta_n^m P_n(\xi) P_m(\eta), \tag{2.19}$$

where P_n is the Legendre polynomial of degree n scaled to the dimensions of D. More precisely, we suppose that there is an expansion of the form (2.19) *for each of the* 40 *squares comprising the region R.*

For $\mathcal{N}$ sufficiently large, we can approximate the operator $\mathcal{O}$ by the finite-dimensional matrix

$$\mathcal{O}_{\mathcal{N}} : \mathbb{R}^{\mathcal{N}^2} \rightarrow \mathbb{R}^{40\mathcal{N}^2},$$

mapping the coefficients $\{\alpha_n^m\}$ in the expansion of the charge density σ to the 40 sets of coefficients $\{\beta_n^m\}$ in the expansions of Φ_σ. If we let the SVD of $\mathcal{O}_{\mathcal{N}}$ be given by

$$\mathcal{O}_{\mathcal{N}} = U_{\mathcal{N}} \Sigma_{\mathcal{N}} V_{\mathcal{N}}^T,$$

then $\mathcal{O}_{\mathcal{N}}$ can be *compressed* by retaining only the first k terms in the decomposition:

$$\mathcal{O}_{\mathcal{N}} \approx \; U_{\mathcal{N}}(k)\, \Sigma_{\mathcal{N}}(k)\, V_{\mathcal{N}}(k)^T, \tag{2.20}$$

where $V_{\mathcal{N}}(k) \in \mathbb{R}^{\mathcal{N}^2 \times k}$, where $U_{\mathcal{N}}(k) \in \mathbb{R}^{40\mathcal{N}^2 \times k}$, and $\Sigma_{\mathcal{N}}(k) \in \mathbb{R}^{k \times k}$. This leaves one open question: for a given precision ϵ, how large must $\mathcal{N}$ and k be so that

$$\|\mathcal{O}(\sigma) - \; U_{\mathcal{N}}(k)\, \Sigma_{\mathcal{N}}(k)\, V_{\mathcal{N}}(k)^T\, P_{\mathcal{N}}\sigma\| < \epsilon, \tag{2.21}$$

where $P_{\mathcal{N}}$ is the operator projecting σ onto its truncated Legendre series? Similarly, $\mathcal{S}$ has an approximate SVD

$$\mathcal{S}_{\mathcal{N}} = W_{\mathcal{N}}(k) \Omega_{\mathcal{N}}(k) Y_{\mathcal{N}}(k)^T,$$

where $Y_{\mathcal{N}}(k) \in \mathbb{R}^{40\mathcal{N}^2 \times k}$, where $W_{\mathcal{N}}(k) \in \mathbb{R}^{\mathcal{N}^2 \times k}$, and $\Omega_{\mathcal{N}}(k) \in \mathbb{R}^{k \times k}$. It remains also to determine $\mathcal{N}$ and k so that

$$\|\mathcal{S}(\sigma) - \; W_{\mathcal{N}}(k)\, \Omega_{\mathcal{N}}(k)\, Y_{\mathcal{N}}(k)^T\, P_{\mathcal{N}}\sigma\| < \epsilon. \tag{2.22}$$

This is a rather complicated matter to handle analytically [8, 13] but straightforward to determine computationally. One can simply increase $\mathcal{N}$ and k until the desired level of accuracy is achieved, and we summarize the results in Table 1. The generalized FMM then proceeds as above with the following changes.

1. $\Phi_{l,j}$ is used to denote the projection of the charge density in box j at level l onto the first k right-singular vectors $V_{\mathcal{N}}(k)$ of $\mathcal{O}$ scaled to that level. $\Phi_{l,j}$ is stored as a k-vector, which we refer to as the "outgoing" coefficients. The right-singular vectors correspond, in some sense, to the multipole terms $e^{im\phi}/r^{n+1}$.
2. $\Psi_{l,j}$ and $\tilde{\Psi}_{l,j}$ are defined as before, except that we describe the field due to distant sources in terms of its projections onto the left singular vectors $W_{\mathcal{N}}(k)$ of $\mathcal{S}$. These fields are stored as k-vectors of "incoming" coefficients.
3. In Step I: *Upward pass*, if box j is childless, we compute $\Phi_{l,j} = V_{\mathcal{N}}(k)^T\sigma$. Since σ is described by ten polynomial coefficients, this requires $10k$ operations; the inner product of each of the k singular vectors with each of the ten basis functions can be precomputed and stored.

TABLE 1
Degree of Legendre expansions $\mathcal{N}$ and number of terms in the SVD k required to approximate the operators $\mathcal{O}$ and $\mathcal{S}$ to the indicated precision.

ϵ	$k(\mathcal{O})$	$\mathcal{N}(\mathcal{O})$	$k(\mathcal{S})$	$\mathcal{N}(\mathcal{S})$
10^{-3}	9	4	9	4
10^{-6}	36	8	36	8
10^{-8}	49	10	49	10
10^{-11}	144	14	144	14

4. In Step I: *Upward pass*, if box j has children, we project the "outgoing coefficients" of the four children onto the first k right singular vectors at j's level. This merging operator requires k^2 operations per square, since each matrix entry in the transformation can be precomputed and stored.
5. In Step I: *Downward pass*, where we had made use of the operator $\mathcal{T}_{LL}$, we now project the "incoming" field of the parent's Ψ expansion to form $\tilde{\Psi}_{l,j}$ using left singular vectors.
   This requires k^2 operations, since each matrix entry in the transformation can be precomputed and stored.
6. In Step I: *Downward pass*, we compute $\Psi_{l,j}$ by analogy with (2.17). We need to convert the "outgoing" coefficients for a box in the interaction list of square j to the corresponding "incoming" coefficients. Each entry in the conversion matrix is rather complicated, coupling the right-singular vectors of $\mathcal{O}$ to the left-singular vectors of $\mathcal{S}$. This matrix, however, can be precomputed and stored, so that the total cost is at most $27k^2$ operations per square.
7. In Step I: *Downward pass*, we also need to evaluate the "local expansion." This information is now encoded in the left singular vector coefficients and a naive method would require access of each left singular vector (of dimension $\mathcal{N}^2$).
   Fortunately, we can precompute the influence of each singular vector at each of the sixteen target points, so that only $16k$ operations are required at this stage.

REMARK 2.5. *A reasonable estimate for the total work of the generalized FMM is*

$$N\left(120 + \frac{27}{16}k^2 + 2k\right).$$

The first term corresponds to the local work, the second term to the expansion shifting work, and the third term to the work involved in forming and evaluating expansions at leaf nodes.

2.4. Periodic boundary conditions. The inversion formula (1.4) and the fast algorithm described above assume that the right-hand side ω is supported within a unit square. In certain applications, however, one would like to consider ω to be periodically extended to cover the entire $x - y$ plane. This requires a modest modification of the FMM, following the ideas presented in [11]. At the end of the upward pass of the algorithm, we have a net multipole expansion

$$\Phi(Q) = \sum_{n=0}^{\infty} \sum_{m=-n}^{n} M_n^m \cdot \frac{e^{im\phi}}{r^{n+1}} \tag{2.23}$$

TABLE 2

Timing results for the two FMMs for 3-digit accuracy. The time for the generalized FMM using 9 singular functions is denoted by T_{alg}, while the L_2 error of the result is denoted by E_{alg}. The time and L_2 error for the classical FMM using 8th-order spherical harmonics are denoted by T_{sh} and E_{sh}, respectively. The time for direct calculation is denoted by T_{dir}.

N	T_{alg}	T_{sh}	T_{dir}	$E_2(alg)$	$E_2(sh)$
200	0.01	–	0.02	$.11 \cdot 10^{-3}$	$.10 \cdot 10^{-3}$
400	0.02	0.10	0.08	$.14 \cdot 10^{-3}$	$.93 \cdot 10^{-4}$
800	0.08	0.22	0.34	$.19 \cdot 10^{-3}$	$.11 \cdot 10^{-3}$
1600	0.12	0.47	1.40	$.20 \cdot 10^{-3}$	$.19 \cdot 10^{-3}$
3200	0.28	1.13	5.77	$.26 \cdot 10^{-3}$	$.21 \cdot 10^{-3}$
6400	0.51	2.14	22.98	$.28 \cdot 10^{-3}$	$.26 \cdot 10^{-3}$

for the whole unit square. This is also the expansion for each periodic image of the square (with respect to its own center). If we imagine that D represents the unit square in Figure 3, then all such images except for the nearest (unshaded) neighbors are separated from D. Thus, the totality of the field they induce inside D is accurately representable as a single local expansion of the form

$$\Psi(Q) = \sum_{n=0}^{\infty} \sum_{m=-n}^{n} L_n^m \cdot r^n \, e^{im\phi}. \tag{2.24}$$

It remains only to obtain the operator mapping the coefficients $\{M_n^m\}$ to the coefficients $\{L_n^m\}$. We refer the reader to [10] for a discussion of this operator, which is based on the precomputation of certain lattice sums. The local expansion which describes the field due to all squares outside the neighbors of D can be denoted by $\Psi_{0,0}$ within the context of the FMM described above. In the rest of the algorithm, only two slight modifications are required; the interaction list and the local computations must be adjusted for boxes near the boundary to account for periodic images. This involves no significant increase in the amount of work.

3. Numerical results. The two algorithms described above have been implemented using a combination of Fortran 77 and C. All of the timings listed below correspond to calculations performed on an UltraSparc-I/167 with 128Mb RAM.

Example 1. In our first experiment, we consider the discrete N-body problem

$$\phi(\mathbf{x}_j) = \sum_{\substack{i=1 \\ i \neq j}}^{N} \frac{q_i}{2\pi \|\mathbf{x}_i - \mathbf{x}_j\|}$$

with source locations $\{\mathbf{x}_i\}$ randomly but uniformly distributed in the unit square and source strengths randomly distributed in $[-1, 1]$. We compare the performance of the two FMMs at 3-, 6-, and 12-digit accuracy (Tables 2, 3, and 4).

REMARK 3.1. *Subsequent calculations will rely on the generalized FMM, since our numerical experiments show it to be three to four times faster than the spherical harmonic-based code.*

Example 2. We consider a smooth distribution of charge:

$$f(x, y) = x \, \exp(-500x^2).$$

In Table 5, we show the results of inverting the square root of the Laplacian on a uniform $N_1 \times N_1$ grid using the generalized FMM with 24 singular functions, the

generalized FMM with 36 singular functions, and the FFT. To compare the performance of the FMM with the FFT, we also compute the number of points processed per second by both schemes and a ratio of their timings (Table 6).

The following observations can be made from the data:

1. The generalized FMMs converge (more or less) as expected for a fourth-order accurate method. The 24 singular function and 36 singular function versions yield the same accuracy until $N_1 = 512$, at which point the 24 singular function FMM is dominated by the FMM precision rather than the error in polynomial approximation. The FFT is, of course, rapidly convergent for this right-hand side, since it is effectively smooth and periodic.

TABLE 7

Performance of the adaptive FMM using 24 singular functions for Example 3. The first column shows the tolerance in discretizing the right-hand side. The second, third, and fourth columns show the maximum number of levels, the total number of boxes, and the total number of discretization points used in the FMM at that tolerance. The fifth column shows the number of points that would be required by a uniform grid at the finest level using an FFT-based scheme. The sixth column shows the time required (secs.), and the last column shows the number of points processed per second.

Tol	$Level$	N_{boxes}	N_{pts}	N_{uni}	T_{alg}	P_{24}
10^{-3}	7	889	10672	(262144)	0.328	32537
10^{-4}	7	1489	17872	(262144)	0.523	34172
10^{-5}	8	3265	39184	(1048576)	1.128	34736
10^{-6}	9	5369	64432	(4194304)	1.868	34493
10^{-7}	9	12977	155728	(4194304)	4.414	35280

2. The timings for the FMMs grow linearly with the number of unknowns, while the timings for the FFT grow like $N_1^2 \log N_1$. By the time there are 250,000 unknowns, the 5-digit FMM (24 singular functions) is about 10 times as costly as the FFT. The 7-digit FMM (36 singular functions) is about 20 times as costly.

Example 3. We next consider a more complex distribution of charge

$$f(x,y) = g(x-0.25, y-0.25) + g(x+.15, y-.15) + g(x-.05, y+.25),$$

where

$$g(x,y) = xy\,\exp(-2000x^2)\,\exp(-2000y^2).$$

There are three sharply peaked contributions to the total charge, and the right-hand side is discretized adaptively. Our refinement strategy is straightforward. Let B be a leaf node with 16 grid points, as discussed in section 2.1, and let $f_B(x,y)$ denote the fourth-order polynomial used to approximate the right-hand side on B. We then evaluate $f_B(x,y)$ on an 8×8 grid covering B and compute the discrete L_2 error $E_2 = \|f(x,y) - f_B(x,y)\|_2$ over these target points. If $E_2 > tol$, the leaf node B is subdivided. Our results are summarized in Table 7.

Example 4. In our last example, we consider a discontinuous right-hand side

$$f(x,y) = \begin{cases} 3 & |x+y| > 1/2, \\ -1 & \text{otherwise.} \end{cases}$$

Figure 4 shows the function $f(x,y)$ and the adaptive mesh generated by the discretization technique outlined in Example 3. Figure 5 shows the computed solution. Timing results are summarized in Table 8.

4. Conclusions. We have developed an adaptive direct solver for inverting the square root of the Laplacian in two dimensions. While our first implementation relied on a classical spherical-harmonic-based FMM, a faster scheme uses a generalized FMM [8], which constructs optimal representations for the far field using an SVD. The method can be used in free space or with periodic boundary conditions, and the amount of work scales linearly with the number of grid points in the computational domain. The method is an order of magnitude slower than an FFT-based scheme on uniform grids, but quickly surpasses such schemes once adaptive refinement is required. Applications of the method to some problems in fluid dynamics will be reported at a later date.

CGNR IS AN ERROR REDUCING ALGORITHM*

CHUNGUANG LI†

Abstract. The CGNR algorithm is a robust algorithm solving large nonsymmetric linear systems. In this short note, we show that the norm of the error vector of CGNR approximation decreases monotonically during its iteration. Few iterative algorithms have this error reducing property. The result indicates that the simple CGNR algorithm is still a potential one in practical use.

Key words. linear systems, CGNR algorithm, norm, residual vector, error vector

AMS subject classification. 65F10

PII. S1064827500375990

1. Introduction.

Consider large linear system

$$Ax = b, \tag{1.1}$$

where A and b are given, A is a nonsingular $n \times n$ real matrix, and b is an n-vector. The CGNR algorithm is the conjugate gradients (CG) method applied to the equivalent system–normal equations–

$$A^T Ax = A^T b, \tag{1.2}$$

which is an s.p.d. system. The CGNR algorithm can be described as follows [6].

ALGORITHM 1.1 (CGNR algorithm).

1. *Compute* $r_0 = b - Ax_0, z_0 = A^T r_0, p_0 = z_0$;
2. *For* $i = 0, 1, \ldots,$ *until convergence Do*
3. $w_i = Ap_i$;
4. $\alpha_i = \|z_i\|_2^2 / \|w_i\|_2^2$;
5. $x_{i+1} = x_i + \alpha_i p_i$;
6. $r_{i+1} = r_i - \alpha_i w_i$;
7. $z_{i+1} = A^T r_{i+1}$;
8. $\beta_i = \|z_{i+1}\|_2^2 / \|z_i\|_2^2$;
9. $p_{i+1} = z_{i+1} + \beta_i p_i$;
10. *EndDo*

This algorithm is quite robust since the CG algorithm is robust for an s.p.d. linear system. The main difficulty in using the CGNR algorithm is that the condition number is squared, i.e., $\kappa(A^T A) = \kappa^2(A)$.

For a long time, the CGNR algorithm has had a bad reputation because of the squaring of the condition number. However, in our numerical tests we often see that the CGNR algorithm is a successful method in many difficult situations. The fact was also observed by other authors; see Saad [5], Saylor [7], and Nachtigal [4]. By a careful analysis, we can find that the CGNR algorithm is not only a residual minimizing method but also an error reducing method. Few algorithms among the Krylov subspace iterative methods have this useful property.

†Department of Mathematics, Zhengzhou University, Daxue Road No. 75, Zhengzhou, Henan, 450052, People's Republic of China (cglizd@public2.zz.ha.cn).

The error reducing property of the CGNR algorithm seems to be not generally known. Our major aim here is to prove this property strictly.

2. Main results. The CGNR algorithm is mathematically equivalent to the CG method applied to the s.p.d. linear system (1.2). It has the following optimal property concerning the residuals.

PROPOSITION 2.1. *Let x_k be the approximation produced at the k*th *step by the CGNR algorithm (k*th *iterate). Then x_k minimizes function $\|b-Ax\|_2^2$ over all vectors in the affine Krylov subspace*

$$x_0 + \mathcal{K}_k(A^TA, A^Tr_0) = x_0 + \ span\ \left\{A^Tr_0, A^TAA^Tr_0, \ldots, (A^TA)^{k-1}A^Tr_0\right\}, \tag{2.1}$$

in which $r_0 = b-Ax_0$ is the initial residual with respect to the original system $Ax = b$.

This property is a direct consequence of the optimal property of the CG method. Its proof can be found in Saad [6, p. 238].

PROPOSITION 2.2. *Let x^* be the exact solution of the system $Ax = b$, and let $e_k = x^* - x_k$ be the error vector of the CGNR iterate x_k. Then the 2-norm of e_k decreases monotonically, i.e.,*

$$\|e_{k+1}\|_2 \le \|e_k\|_2, k = 0, 1, \ldots. \tag{2.2}$$

This proposition exhibits that the CGNR algorithm has an error reducing property. We give its proof here. At first, we establish two lemmas.

LEMMA 2.3. *The residuals with respect to* (1.2), $z_0, z_1, \ldots, z_k, \ldots$, *are orthogonal to each other, i.e.,*

$$z_i^H z_j = \begin{cases} 0, & i \ne j, \\ \|z_i\|_2^2, & i = j, \end{cases} \tag{2.3}$$

in which $z_i = A^Tb - A^TAx_i$ is the residual vector with respect to the linear system (1.2).

This is a generally known result of the CG method for the s.p.d. linear system. Its proof can be found in any text book concerning the CG method; see for example, Saad [6, p. 178].

LEMMA 2.4. *The direction vector p_k in the CGNR algorithm is a linear combination of the residuals $z_0, z_1, \ldots, z_k$,*

$$p_k = \xi_k \left(\frac{z_0}{\xi_0} + \frac{z_1}{\xi_1} + \cdots + \frac{z_k}{\xi_k}\right), k = 0, 1 \ldots, \tag{2.4}$$

where

$$\xi_j = \|z_j\|_2^2,\ z_j = A^Tb - A^TAx_j,\ j = 0, 1, \ldots, k.$$

Proof. From lines 9 and 8 of the CGNR algorithm, we have

$$p_{i+1} = z_{i+1} + \beta_i p_i, \quad \beta_i = \|z_{i+1}\|_2^2/\|z_i\|_2^2.$$

So, we get

$$\begin{aligned} p_{i+1} = &\ z_{i+1} + \beta_i p_i \\ = &\ \xi_{i+1}\left(\frac{p_i}{\xi_i} + \frac{z_{i+1}}{\xi_{i+1}}\right). \end{aligned}$$

We see that

$$\begin{aligned} p_0 &= z_0, \\ p_1 &= \xi_1 \left(\frac{p_0}{\xi_0} + \frac{z_1}{\xi_1} \right) = \xi_1 \left(\frac{z_0}{\xi_0} + \frac{z_1}{\xi_1} \right), \\ p_2 &= \xi_2 \left(\frac{p_1}{\xi_1} + \frac{z_2}{\xi_2} \right) = \xi_2 \left(\frac{z_0}{\xi_0} + \frac{z_1}{\xi_1} + \frac{z_2}{\xi_2} \right). \end{aligned}$$

In general, we have

$$p_k = \xi_k \left(\frac{p_{k-1}}{\xi_{k-1}} + \frac{z_k}{\xi_k} \right) = \xi_k \left(\frac{z_0}{\xi_0} + \frac{z_1}{\xi_1} + \cdots + \frac{z_{k-1}}{\xi_{k-1}} + \frac{z_k}{\xi_k} \right), k = 0, 1 \ldots .$$

This is just (2.4). □

Now, we turn to prove Proposition 2.2.

Proof of Proposition 2.2. From the CGNR algorithm, line 5 of Algorithm 1.1, we have

$$\begin{aligned} \|e_k\|_2^2 &= \|x^* - x_k\|_2^2 \\ &= \|x^* - x_{k+1} + \alpha_k p_k\|_2^2 \\ &= \|x^* - x_{k+1}\|_2^2 + 2\alpha_k p_k^H (x^* - x_{k+1}) + \|\alpha_k p_k\|_2^2 \\ &= \|e_{k+1}\|_2^2 + 2\alpha_k p_k^H (x^* - x_{k+1}) + \|\alpha_k p_k\|_2^2. \end{aligned}$$

Inequality (2.2) holds if we show that

$$p_k^H (x^* - x_{k+1}) \geq 0, \quad k = 0, 1, \ldots . \tag{2.5}$$

It is well known that the CGNR algorithm will be terminated at most n steps for the s.p.d. linear system (1.2) in exact arithmetic (in the absence of round-off errors), where n is the dimension of the linear system. So, we have $x^* = x_n$. The inequality (2.5) holds when $k = n - 1$. If $k < n - 1$, from the update of x_k in the CGNR algorithm, we have

$$x^* = x_n = x_{k+1} + \alpha_{k+1} p_{k+1} + \alpha_{k+2} p_{k+2} + \cdots + \alpha_{n-1} p_{n-1}.$$

Consequently,

$$p_k^H (x^* - x_{k+1}) = \alpha_{k+1} p_k^H p_{k+1} + \cdots + \alpha_{n-1} p_k^H p_{n-1}. \tag{2.6}$$

By virtue of Lemmas 2.3 and 2.4, for $j = k+1, k+2, \ldots, n-1$, we have

$$\begin{aligned} p_k^H p_j = \;& \xi_k \xi_j \left(\frac{z_0}{\xi_0} + \cdots + \frac{z_k}{\xi_k} \right)^H \left(\frac{z_0}{\xi_0} + \cdots + \frac{z_j}{\xi_j} \right) \\ = \;& \xi_k \xi_j \left(\frac{1}{\xi_0} + \cdots + \frac{1}{\xi_k} \right) \geq 0. \end{aligned}$$

In (2.6), $\alpha_j, j = k+1, k+2, \ldots, n-1$ are nonnegative real numbers. Now, we get to know that the right-hand side of (2.6) is nonnegative. This establishes inequality (2.5) and hence inequality (2.2). □

Note. Proposition 2.2 had been pointed out by Ehrig and Deuflhard in an unpublished report [2]. However, their proof given in [2] is too technical to be understood. The new proof here is likely more clear and direct.

Combining the above two propositions, we get the following important theorem.

THEOREM 2.5. *CGNR is both residual minimizing and error reducing.*

3. Further remarks. In the Krylov subspace iterative methods, the relationships between the norm of the residual vector and the norm of the error vector are

$$\|r_k\| = \|Ae_k\| \leq \|A\| \cdot \|e_k\|,$$

and

$$\|e_k\| = \|A^{-1}r_k\| \leq \|A^{-1}\| \cdot \|r_k\|.$$

However, curves of the error norm and the residual norm are not always in the same tendency. Examples were found when the norm of residual was still decreasing but the norm of error was stagnating. See Bruaset [1, p. 63, Example 3.2] and Weiss [8, Example 1]. The generalized minimal error (GMERR) algorithm was introduced by Weiss [8] in order to find the "optimal" approximation with the minimal norm of the error in the corresponding affine Krylov subspace. However, the implementation of GMERR is quite complicated in computing. So, at this point, Theorem 2.5 indicates that the simple CGNR algorithm is a potential method in practical use.

We would like to mention that even if the CGNR algorithm has the error reducing property, the residual norm should be still used for monitoring the convergence in practical computing since we cannot estimate the error norm during its iteration process.

At last, we mention that the condition number of the normal equations (1.2) could be reduced by using preconditioning techniques. Limited numerical test results using the polynomial preconditioning techniques were reported in Li [3]. Further numerical tests using the other preconditioners, which might have better performance, are being undertaken.

Acknowledgments. The author is grateful to Professors Chengxian Xu and Wenyu Sun for their kindly instructions and useful discussions.

FAST BIT-REVERSALS ON UNIPROCESSORS AND SHARED-MEMORY MULTIPROCESSORS*

ZHAO ZHANG† AND XIAODONG ZHANG†

Abstract. In this paper, we examine different methods using techniques of blocking, buffering, and padding for efficient implementations of bit-reversals. We evaluate the merits and limits of each technique and its application and architecture-dependent conditions for developing cache-optimal methods. Besides testing the methods on different uniprocessors, we conducted both simulation and measurements on two commercial symmetric multiprocessors (SMP) to provide architectural insights into the methods and their implementations. We present two contributions in this paper: (1) Our integrated blocking methods, which match cache associativity and translation-lookaside buffer (TLB) cache size and which fully use the available registers, are cache-optimal and fast. (2) We show that our padding methods outperform other software-oriented methods, and we believe they are the fastest in terms of minimizing both CPU and memory access cycles. Since the padding methods are almost independent of hardware, they could be widely used on many uniprocessor workstations and multiprocessors.

Key words. cache optimizations, memory hierarchy, bit-reversals, shared-memory multiprocessors, parallel computing

1. Introduction.

Many FFT algorithms require data reordering operations of *bit-reversal*. If the bit-reversal operations are not implemented properly, those FFT operations can slow down significantly. On the other hand, it is easy to improperly implement bit-reversals on uniprocessors and multiprocessors. This is because the performance of bit-reversals is highly sensitive to how caches and memory hierarchies are used in the implementations. In other words, a fast bit-reversal implementation must be cache effective. Several papers have well addressed the significance and effects of considering memory hierarchy to bit-reversals (e.g., [2], [11], and [15]). Besides the important usage for FFT, different versions of bit-reversal implementations can also be used as benchmark programs to evaluate the memory hierarchy of various computer systems.

With the rapid development of RISC and VLSI technology, the speed of processors has increased dramatically in the past decade. Processor clock rates have doubled every 1–2 years. Nevertheless, the memory speed has increased at a much slower pace. Therefore we have seen and will continue to see an increasing gap in speed between processor and memory, and this gap makes performance of application programs on both uniprocessor and multiprocessor systems rely more and more on effective usage of caches. Performance degradation of bit-reversals is mainly caused by cache conflict misses. Bit-reversals are often repeatedly used as fundamental subroutines for scientific programs, such as FFT. Thus, in order to gain the best performance, cache-

http://www.siam.org/journals/sisc/22-6/35970.html

†Department of Computer Science, College of William and Mary, Williamsburg, VA 23187-8795 (zzhang@cs.wm.edu, zhang@cs.wm.edu).

optimal methods and their implementations should be carefully and precisely done at the programming level. This type of performance programming for some special programs, such as bit-reversals, may significantly outperform an optimization from an automatic tool, such as a compiler.

A standard bit-reversal program is described as follows:

```
for i = 1, N
    Y[i'] = X[i]
```

The values of array X in their sequential positions i are copied to array Y in their bit-reversal positions, i' for $i = 1, \ldots, N$, where $N = 2^n$. The above program says that X is a bit-reversal reordering of Y. The indices of i and i' of X and Y are represented by a sequence of n binary digits. Positions i and its bit-reversal i' are defined in [11] as

$$i = \sum_{j=0}^{n-1} a_j 2^j \quad \text{and} \quad i' = \sum_{j=0}^{n-1} a_j 2^{n-1-j},$$

where a_j is either 0 or 1. For example, a 5-bit reversal of $i = 10010$ is $i' = 01001$.

The bit-reversal operations have following unique characteristics: First, in many implementations, each element in an array is used (read or written) only once for its copy operation. Thus, the reorderings have only spatial locality but no temporal locality for elements. Second, the loops follow certain sequences with high spatial locality. Bit-reversals are highly sensitive to problem sizes, cache sizes, and cache line sizes. Since the data array sizes are a power of 2, multiple elements stored in different memory locations could map to the same cache line, causing severe cache conflict misses and cache thrashing. The reason is simple. Most commercial computers use direct-mapped or n-way associative caches where the mapping functions of cache sizes are also related to powers of 2.

We use an identical unit, called an "element," to represent the sizes of data arrays, caches, and others such as buffers and blocking. One element may represent a 4-byte integer, a 4-byte floating point number, or an 8-byte double floating point number. Because the sizes of caches and cache lines are always a multiple of an element in practice, this identical unit for all sizes is practically meaningful for both architects and application programmers and makes the discussions straightforward. Here are the algorithmic and architectural parameters we will use to describe cache-optimal methods of bit-reversals.

- C: data cache size, which could be further defined as C_{L1} and C_{L2} for data cache sizes of L1 and L2, respectively.
- L: the size of a cache line, which could be further defined as L_{L1} and L_{L2} for cache lines of L1 and L2, respectively.
- K: cache associativity, which could be further defined as K_{L1} and K_{L2} for cache associativity of L1 and L2, respectively.
- K_{TLB}: translation-lookaside buffer (TLB) cache associativity. (A TLB cache is a small buffer that holds most recent memory page mappings. The concept will be discussed in detail later in the paper.)
- T_s: number of entries in the TLB cache.
- N: the data size for the bit-reversal vector of size $N = 2^n$, where n is the number bits used in the vector index.
- B_{cache}: blocking size of a $B \times B$ submatrix for cache.
- B_{TLB}: blocking size for TLB.
- P_s: a memory page size.

In this paper, we examine different methods using techniques of blocking, buffering, and padding for efficient implementations. We evaluate the merits and limits of each technique and its application and architecture-dependent conditions for developing cache-optimal methods. Although our methods are developed for out-of-place bit-reversals, they are also applicable to in-place bit-reversals where X and Y are the same array.

Symmetric multiprocessor (SMP) systems have become practical and cost-effective servers for scientific computing and other applications. Although parallel efficiency and communication latency reduction are major performance concerns, computations on an SMP share many common considerations with uniprocessors. The most important one is the effective usage of memory hierarchies. When the cache locality of each processor is effectively exploited, the memory accesses to the shared-memory will be reduced, and so will be the memory access contention. People have studied parallel data reordering algorithms on distributed-memory systems with special networks, such as hypercubes (see, e.g., [6] and [9]). In this study, we target parallel bit-reversals on SMPs and show the significant impact of the cache and TLB considerations for efficient method development and implementations. We also evaluate the performance impact of SMP interconnection networks.

Our algorithm designs and implementations are optimized by considering several nontraditional but practical and performance-effective factors, namely, the programming complexity, memory space requirement, instruction count, cross interference among the data arrays, and program portability. We will summarize the limits and merits of different bit-reversal methods based on these considerations after we have discussed the designs and presented the performance results, aiming at providing a guideline for performance programming and memory performance optimization for other scientific computing applications.

We present two contributions in this paper: (1) Our integrated blocking methods, which match cache associativity and TLB cache size and which fully use the available registers, are cache-optimal and fast. (2) We show that our padding methods outperform other software-oriented methods and believe they are the fastest in terms of minimizing both CPU and memory access cycles. Since the padding methods are almost independent of hardware, they could be widely used on many uniprocessor workstations and SMP multiprocessors.

The rest of the paper is organized as follows. We discuss the inherently blocking nature of bit-reverse operations and the effectiveness and limits of blocking techniques for solving the problems in section 2. In section 3, we evaluate a software buffering technique and our methods using existing hardware components for implementing the data reordering. Our new method integrating blocking and padding will be presented in section 4. We discuss blocking and padding techniques for TLB in section 5. The experimental measurements and analyses for evaluating different methods on uniprocessor workstations and SMP multiprocessors will be reported in sections 6 and 7. We summarize the work in section 8.

2. Blocking for bit-reversals. The blocked memory access patterns of bit-reversals can be easily viewed when we convert the one-dimensional vector to a two-dimensional equivalent array in Figure 1. All the reordering elements and elements in other groups will be allocated along the column in the two-dimensional equivalent array forming a block.

In this blocking method, the bit-reversal reordering is performed block by block, where the operations for each block are implemented similarly to the Evans method

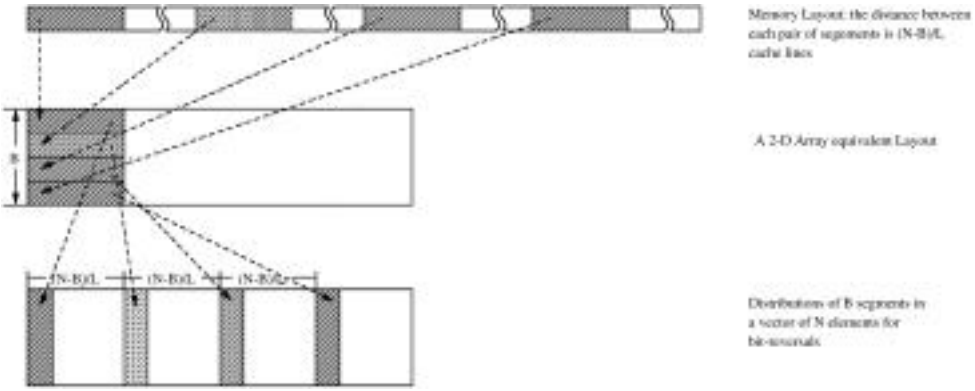

FIG. 1. *Memory layout of a blocked bit-reversals, where* $B = B_{cache}$.

[7]. (The Evans method is used to construct a hybrid method in [11].) The program in the appendix presents such an implementation along with padding technique. (The padding technique will be discussed in section 4.) The blocking algorithm we have used can be classified as a hybrid method.

In general, for a bit-reversal vector of $N = 2^n$ elements, the block size B_{cache} is a power of 2, denoted by $B_{cache} = 2^b$. Each of the B_{cache} elements in X has the address format of fg, where g is B_{cache} bits and f has $n - b$ bits. Each of the corresponding B_{cache} elements in Y has the address format of $g'f'$. Therefore, the distance between two nearest elements in the same group in Y is $2^{n-b} = N/B_{cache}$.

Choosing the cache line size as the minimum blocking size ($B_{cache} = L$), we can easily calculate the maximum N's for the bit-reversal vector based on different data cache sizes. For example, for a large cache of 2 MB, the blocking technique is effective up to an 18-bit-reversal reordering which represents 268,144 data elements, where each element is an 8-byte double type, and the cache line is 32 bytes. In practice, the data size of bit-reversals could easily be larger than $n = 20$ [11].

3. Blocking with buffers. As we have shown, the effectiveness of blocking is limited by the size of the data arrays. In theory, the smallest blocking size could be 2×2. A cache line in a modern processor usually holds more than 2 elements, i.e., is larger than 16 bytes. If we choose a 2×2 block, the data in a cache line will not be fully used before their replacement, causing more cache misses in the reorderings. The bit-reversal reordering demands large cache space to make blocking effective. In order to effectively use limited cache space, Gatlin and Carter [8] present an effective method using an additional buffer to first hold the conflict-missed elements of a block in one array temporarily and then copy the block to their reordered positions in the other array. In this section, we discuss implementations of blocking methods supported by both software and hardware buffers.

3.1. Blocking with a software buffer and its limits. Because this buffer is defined in a reordering program, we call it "software buffer." This buffer shares the allocation space with the data arrays X and Y in the cache.

There are two major limits in this approach. First, the buffer itself may interfere with arrays of X and Y, causing additional access conflicts. This interference is certain when the sizes of X and Y are larger than the size of the cache, C. Each cache block or set is mapped from arrays X and Y more than once. No matter where the buffer is

located in the cache, it will interfere with them. The larger the buffer size, the more interference will occur.

The second limit is the additional copy overhead time involved in moving data from the array X to the buffer and then in moving them to the target array in their reordered positions. This overhead exactly doubles the instruction cycles for data copying. The data copy through a buffer is a worthy investment if the number of cycles lost from cache misses is much higher than the additional CPU cycles for the data copy.

To overcome the two limits, we propose several alternatives to eliminate cache interference caused by the software and to reduce or eliminate the data copy time.

3.2. Cache structure dependent blocking. We will present several blocking methods which depend on the cache organization of the running machine. These methods can be implemented at the user programming level.

Blocking based on set associativity. The cache associativity, K, is an important factor to consider for blocking. If $K \geq L$, an $L \times L$ or a $K \times K$ blocking method for bit-reversals would effectively avoid conflict misses. Because the hit time is a less sensitive performance factor than the cache misses in the L2 cache, a higher associativity of the L2 cache is more effective than that of L1. If a cache line holds 4 double floating point elements ($L = 4$ elements of 32 bytes in Pentium processors), a 4×4 blocking method without any data buffer is able to fully use the cache associativity. The blocking method would gain more benefit from caches of associativity higher than 4, such as a design in [20].

What would we do if the associativity is not sufficiently high for the blocking, or $K < L$? One solution is to make a $K \times L$ rectangular blocking. Unfortunately bit-reversals require an $L \times L$ blocking.

Supplement with registers. We may also consider using the available registers to supplement a low associativity cache. The number of registers available to a user program is limited. Normally, a uniprocessor provides up to 16 registers to users. For example, for a 2-way associative cache, we need 8 registers to buffer 2 additional cache lines so that we could effectively make a 4×4 blocking as if we ran the program on a 4-way associative cache.

We develop a more efficient blocking method for bit-reversals, which requires only $(L-K) \times (L-K)$ registers. The operation sequence of this method is in three steps: (1) The $L - K$ cache lines of X are stored in K cache lines of Y and accessed by copying its $(L - K) \times K$ elements to Y in the reordered positions and copying the rest of $(L-K) \times (L-K)$ elements to a buffer consisting $(L-K) \times (L-K)$ registers. (2) The rest of K lines of X are brought to the cache set, and its $K \times K$ elements are copied to Y in the reordered positions. (3) Finally, the $(L - K) \times (L - K)$ elements in the register buffer and the rest of the $(L - K) \times K$ elements are copied to Y in their reordered positions. A cache set will be used more than twice if $K < L/2$.

Besides the advantage of no access conflicts between the register buffer and the arrays of X and Y, there is another advantage of using registers to buffer the data in a load/store processor. A data copy through the registers from X to Y is equivalent to the two-step process of load and store, and thus there will be no additional overhead. We will show our experimental performance in section 5.

Using registers as the buffer. If the cache is direct-mapped, we have to fully rely on a buffer for blocking. Here we discuss some ways to use registers to serve the buffer in order to eliminate the potential cache conflicts and eliminate extra data

copying by taking advantage of the load/store operations. The number of registers for a buffer of $L \times L$ elements is determined by the number of elements a cache line can hold. The length of a cache line of the L1 cache in some processors, such as Sun SPARC Micro I and II, is $L = 2$ of 16 bytes, which holds only two floating point elements. The blocking size could be as small as 2×2 using a buffer of 4 registers.

The cache line length of the L1 cache in many advanced workstations is 32 bytes, such as the Sun Ultra and Intel Pentium processors, each of which holds 4 double floating point elements. In this case, we need a buffer of $4 \times 4 = 16$ registers for a blocking. This would be difficult due to the limited number of available registers. We have two solutions for this. First, we use only the number of registers available to form a smaller buffer than it should be, which will not make each cache line fully used and will cause additional cache misses. Our experiments show that this blocking method of using a buffer of insufficient number of registers still achieves a reasonable performance improvement and outperforms the implementation using a software buffer.

The second method is to further reduce the size of the buffer, which reduces the required number of registers by using our $(L - K) \times (L - K)$ blocking method.

L1 cache versus L2 cache. The main objective of building two-level caches is to make the L1 cache small enough to catch up to the cycle time of the fast CPU and to make the L2 cache large enough to capture as many accesses as possible [12]. In practice, the data size of a bit-reversal is larger than the size of the L2 cache. L1 and L2 caches offer different sizes of the cache line, L, and the associativity, K. Both of the following alternatives are effective for blocking. (1) Taking advantage of a short cache line and fast hit time of the L1 cache, we could effectively use limited registers as the buffer and make a small $L \times L$ blocking effective. (2) Taking advantage of high associativity of the L2 cache, we could effectively use both associativity and supplemental registers as the buffer and make a large $L \times L$ blocking effective.

3.3. Victim-cache-aided blocking. Victim cache [13] is a small fully associative cache serving as the buffer containing only cache blocks due to conflict misses from L1 cache. This is an on-chip cache connected between L1 and the next level cache or memory. On a miss in L1, the victim cache is first checked before going to the next level. If the missed block is found there, the victim cache block and the L1 cache block are swapped and then the block is delivered to CPU from the L1 cache. Victim cache has been available in some commercial workstations, such as HP7200.

The minimum number of victim cache lines required for $L \times L$ blockings of transpose and bit-reversal reorderings is $L - K$. In the execution, $L \times L$ elements of each blocking are allocated in a set of K lines in L1 cache, and the rest of the elements are allocated in the $L - K$ lines of the victim cache. The victim cache is able to hold all the conflict misses in the reorderings by an $L \times L$ blocking. In addition, a conflict miss in the L1 cache that hits in the victim cache has only one additional cycle miss penalty. Thus, a simple $L \times L$ blocking method would be effective if such a victim cache is available.

However, the victim cache does not have a direct connection with the CPU. When a data hit happens in the victim cache, it has to be first swapped to the L1 cache and then delivered to CPU. This swapping operation is unnecessary for our reordering algorithms. Without counting the cold misses of bringing the elements in the first column for an $L \times L$ blocking and considering the LRU replacement policy, the entire blocking will have $L \times (L - 1)$ conflict misses in the L1 cache, which are then found in the victim cache. This also means that each of such a blocking needs $L \times (L - 1)$ additional swapping cycles between the L1 cache and the victim

cache, which is independent of the associativity, K. In contrast with the blocking method based on the associativity supplemented by registers, the swapping cycles in the victim cache are additional overhead. Despite this, a victim-cache-aided blocking is more efficient than a blocking method with a software buffer because there are no cross interference conflicts between the victim buffer and arrays of X and Y.

4. Blocking with padding. Padding is a technique that modifies the data layout of a program so that the conflict misses are reduced or eliminated. The data layout modification can be done at run-time by system software [3, 19] or at compile-time by complier optimization [16]. Sharing the same objective of compiler optimization to change the base addresses of potentially conflicting cache blocks in the reorderings, we insert padding variables inside the data array. For example, the padding can be done as part of the last butterfly for the decimation in an FFT computation without additional cost, and the output is not padded.

However, we notice that this free padding opportunity may not be easily found, and the bit-reversal result may be padded in some cases. For example, the padding of a recursive implementation of the Cooley–Tukey FFT algorithm [5] is more complex than the padding in our implementations. The padding method produces padded results in a vector if the bit-reversals are done in an inplaced fashion. The accesses to the padded results need to go through a simple address converting process with additional CPU cycles. In addition, our methods target bit-reversals based on the data size of powers of 2. However, FFT algorithms are not limited to this data size. If the data size is not a power of 2, the padding method will be more complex to implement. Poor memory performance of bit-reversals has been reported even for nonpower of 2 data sizes (see, e.g., [2]).

Since the data arrays of bit-reversals form a vector whose size is power of 2, the padding is highly regular, inserting L elements or a cache line space starting at the vector positions of N/L, $2 \times N/L$, ..., and $(L-1) \times N/L$. Using L elements or a section data of a cache line to separate the vector at these L points can completely eliminate the cache conflicts caused by the address mapping based on powers of 2. Again during execution, the reordering data copies are directly conducted between the arrays X and Y without going through a data buffer. Another advantage is that the number of padding elements needed is only $L \times L$ or L cache lines and is independent of the data array size, N. Compared with the data size of bit-reversals, the number of padding elements is insignificant. Figure 2 shows how the data layout of a bit-reversal vector is modified by padding so that conflict misses are eliminated.

Compiler optimization targets a large range of application programs and automatically inserts padding variables in the programs for users. An optimal padding is application program dependent. For example, padding positions are different from different applications in order to effectively change base addresses of conflicting cache blocks [18]. Based on the unique nature of the data reordering, the optimal padding unit used by our methods for bit-reversals is a cache line with L elements. In contrast, a compiler optimization normally uses an element as the basic padding unit. How many padding units to use and where to pad in the data arrays are determined by some approximation models which may not precisely fit the unique memory access patterns of each case. In addition, applying the padding technique to bit-reversals embedded in applications would not increase complexity in the entire computation. For example, when a padded bit-reversal is performed in an FFT computation, it has little effect on the neighboring butterfly operations.

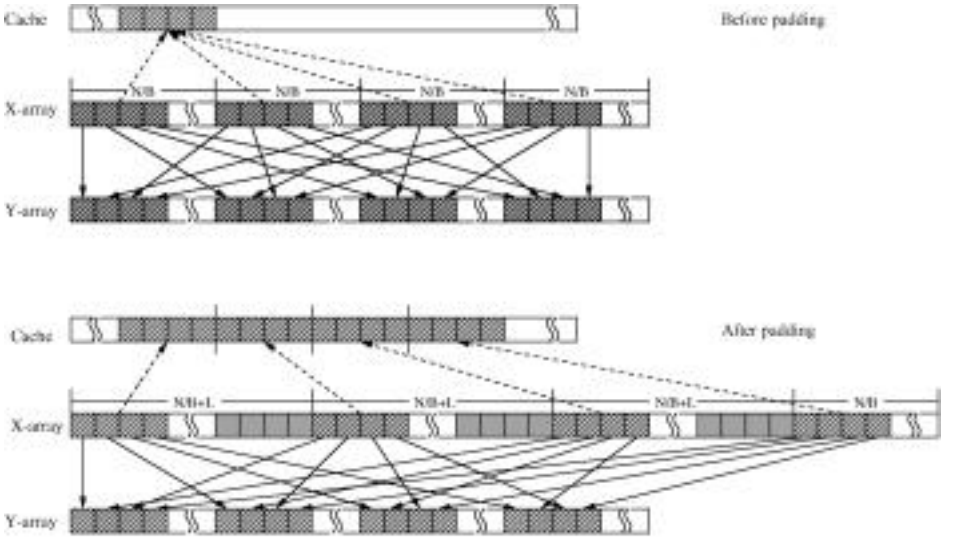

FIG. 2. *Data layout of a bit-reversal is modified by padding, where* $B = B_{cache} = L$.

5. Blocking and padding for TLB. The TLB is a special cache that stores the most recently used virtual-physical page translations for memory accesses. The TLB is a small and usually fully associative cache. Each entry points to a memory page of 4 KB to 64 KB. The page size is normally fixed at the level of operating systems and cannot be changed by user programs. A TLB cache miss will make the system retrieve the missing translation from the page table in memory and then select a TLB entry to replace. When the data to be accessed in our blocking method is larger than the amount of data of all the memory pages that the TLB can hold, we will have TLB thrashing. In this section, we will discuss and present blocking and padding methods for TLB cache optimizations.

5.1. Blocking for a fully associative TLB. Before giving a general model to show how the blocking size is affected by the TLB size, let's go through an example to show that a moderate N for bit-reversals would easily lead to TLB cache thrashing. The 64 pages in the TLB of the Sun UltraSparc-II processor hold $64 \times 1024 = 65536$ elements, which represents a 16-bit-reversal of $N = 2^{16}$. Since we have two vectors X and Y, the TLB can hold a 15-bit-reversal of $N = 2^{15}$ elements. This is also consistent with our experiments on this machine, where execution time per element was a constant until $n = 15$, but sharply increased at $n = 16$ bit-reversals caused by the TLB misses.

In our cache-optimal methods, we include an outer loop to form a blocking for TLB, whose size is denoted as B_{TLB}. The blocking size of B_{TLB} for bit-reversals when $N \geq T_s \times P_s$ is

$$B_{TLB} \leq T_s,$$

where P_s is the page size in elements, and T_s is the number of entries of the TLB. On the other hand, the B_{TLB} should be chosen as large as possible to make effective use of the page space. When $N < T_s \times P_s$, the data size of a bit-reversal will be less than the data size covered by the TLB. Thus there is no need for TLB optimizations.

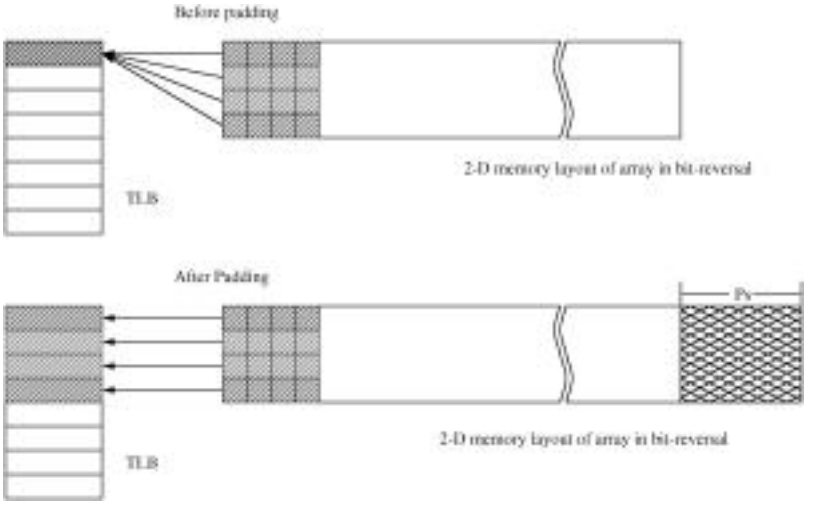

FIG. 3. *Padding for TLB: the data layout is modified by inserting a page space at multiple locations, where* $B_{TLB} = 4$, $K_{TLB} = 1$, $T_s = 8$.

5.2. Padding for a set-associative TLB. Some processors' TLBs are not fully associative, but set-associative. For example, the TLB in the Pentium-II 400 processor is 4-way associative ($K_{TLB} = 4$). A simple blocking based on the number of TLB entries is not cache-optimal, because multiple pages within a TLB-size-based blocking may map to the same TLB cache set and cause TLB cache conflict misses.

If the size N of a bit-reversal vector is a multiple of $T_s \times P_s$, where T_s is the number of TLB entries and P_s is the page size in elements, and if $K_{TLB} < B_{TLB}$, then TLB cache conflict misses will occur. This could easily happen in practice. For example, on the Pentium-II 400, N is equal to $128K$ elements (one element = 8 bytes) for a 17-bit-reversal, and this N is two times the value $T_s \times P_s$ of the machine, where $T_s = 64$, and $P_s = 1024$ elements.

In a way similar to the technique of padding for the data cache, we insert a page of elements or a page of space starting at the vector positions of N/L, $2 \times N/L, \ldots$ and $(L-1) \times N/L$ to eliminate the conflict of TLB cache misses. Figure 3 gives an example of the padding for TLB, where the TLB is a direct-mapped cache of 8 entries, blocking size is $B_{TLB} = 4$, and the number of elements of a row is a multiple of 8 page elements. Before padding, each of blocking row is mapped to the same cache line of the TLB. After padding, these rows are mapped to different cache lines of the TLB.

Combining padding for data cache and padding for TLB cache, we are inserting $L+P_s$ elements or a page plus a cache line space in L locations separated by a distance of N/L elements.

In practice, we selected more than N/L points to insert the padding variables to eliminate both data cache and TLB conflict misses. This approach could effectively merge two nested paddings (one for data cache and the other one for TLB) into a single one. An optimal number of inserting points can be easily determined experimentally based on the size of the TLB cache. The padding optimizations are all based on L2 cache in our experiments.

Partial index mapping addresses of bit-reversals are precalculated and stored in a small table as shown in the program in the appendix. This approach further improves

TABLE 1
Architectural parameters of the 5 workstations we have used for the experiments. All specifications on L1 cache refer to the L1 data cache, and all L2s are uniform. Each L2 cache block on UltraSPARC-IIi consists of 2 16-byte subblocks. The hit times of L1, L2 and the main memory are measured by lmbench [14], and their units are converted from nanosecond (ns) to their CPU cycles.

Workstations	SGI O2	Sun Ultra 5	Sun E-450	Pentium	XP1000
Processor type	R10000	UltraSparc-IIi	UltraSparc II	P-II 400	Alpha 21264
Clock rate (MHz)	150	270	300	400	500
L1 cache (KBytes)	32	16	16	16	64
L1 block size (Bytes)	32	32	32	32	64
L1 associativity	2	1	1	4	2
L1 hit time (cycles)	2	2	2	2	3
L2 cache (KBytes)	64	256	2048	256	4096
L2 block size (Bytes)	64	64	64	32	64
L2 associativity	2	2	2	4	1
L2 hit time (cycles)	13	14	10	21	15
TLB size (entries)	64	64	64	64	128
TLB associativity	64	64	64	4	128
Memory latency (cycles)	208	76	73	68	92

the performance because the table will be accessed in the cache during the computation, and the precalculation overhead is trivial. The time for the precalculation is included in the total execution time.

6. Experimental results and performance evaluation. We have implemented and tested all the bit-reversal methods discussed in the previous sections on an SGI O2 workstation, a Sun Ultra-5 workstation, a Sun SMP server E-450, a Pentium PC, and a Compaq XP1000 workstation. We will present and evaluate the performance of different methods on different machines.

6.1. Experimental environment and evaluation methodology. We used "lmbench" [14] to measure the latencies of memory hierarchies at different levels on each machine. The architectural parameters of the 5 machines are listed in Table 1.

We focus the performance evaluation on methods and implementations of bit-reversals in this paper. We compared all our methods with the method of blocking with a software buffer which was recently published in [8]. We denote this method as "bbuf-br"—blocking with buffer for bit-reversals. Two of our methods are experimentally compared: "breg-br"—blocking with associativity and registers for bit-reversals, and "bpad-br"—blocking with padding for bit-reversals. We have also applied blocking or padding technique for the TLB in these two methods based on the TLB associativity.

All the programs use a standard subroutine to calculate the bit-reversal value for a given address. The execution times were collected by "gettimeofday()," a standard Unix timing function. The resolution of this function is 1 μs on the machines being measured, which is significantly smaller than the execution times of any programs we have measured. A small bit-reversal table is precalculated, and we exclude this calculation time. The reported time unit is cycles per element (CPE):

$$CPE = \frac{execution\ time \times clock\ rate}{N},$$

where *execution time* is the measured time in seconds, *clock rate* is the CPU speed (cycles/second) of the machine where the program is run, and N is the number of elements of the bit-reversal program. Besides the different methods of bit-reversals, we also measured the execution time of a program copying elements between X and Y. This program has the same number of data copying operations with a continuous memory access pattern. We use the execution time of this program to provide a base line reference for bit-reversal programs and show how close a bit-reversal execution is to its ideal time. We denote this reference program as "base." Each method is further divided into "float" data type using 4 bytes to represent an element, and "double" type using 8 bytes to represent an element. The data type divisions will show the performance impact of the cache line length.

For all experiments on different machines, the bit-reversal programs first call a routine to flush the cache to make sure that all the data are allocated only in the memory. All experiments were repeated multiple times.

6.2. Effects of TLB and virtual memory. Before measuring and comparing the performance of different bit-reversal methods, we experimentally evaluated the effects of TLB and virtual memory to confirm our assumptions and analyses.

Selection of TLB blocking size. The TLB blocking size is a sensitive performance parameter to be selected, which is determined by the size of the TLB if it is fully associative. We executed program "bpad-br" (blocking with padding for bit-reversals) with $n = 20$ on a single node of Sun E-450 by changing the blocking sizes for TLB from 8 to 128. The TLB of the E-450 is a fully associative cache with 64 entries. Figure 4 shows the measured cycles per element of the program of different blocking sizes on the node. Our experimental results are consistent with our analyses in the previous section. When the blocking size for TLB was 64, the execution time curve increased sharply. This is because arrays X and Y together demanded more than 64 pages and caused TLB thrashing.

Virtual memory versus physical memory addresses. All our analyses are based on cache mappings between memory pages in the virtual address space and cache blocks in the physical memory address space. This assumes that contiguous memory pages will be contiguously mapped to the cache. This assumption is guaranteed for the virtual-address caches [4]. However, all our experiments have been performed on machines with physical address L2 caches. Since the virtual-physical translations for L2 caches are handled by operating systems, our assumptions may sometimes be inaccurate. In order to show that many operating systems attempt to map contiguous virtual pages to cache blocks contiguously so that our virtual-address-based study is practically meaningful and effective, we conducted a simulation by using the SimOS [17] and measurements on different workstations to observe how an operating system makes translations from virtual memory addresses to their physical addresses.

The SimOS simulates a complete hardware of SGI machines and runs the IRIX 5.3 operating system in the simulation. We executed a blocking-only program of bit-reversals using the cache line L as the blocking size. The bit-reversal vector size was changed from $n = 15$ to $n = 22$. We measured the miss rates on array X. The cache size was set to 2 MB holding two double type arrays up to $n = 18$ in the virtual memory space. Figure 5 gives consistent results from the SimOS simulation: when $n > 18$, the miss rate on array X was sharply increased to 100% from 12.5%.

From this experiment, we have observed that virtual-physical translations from

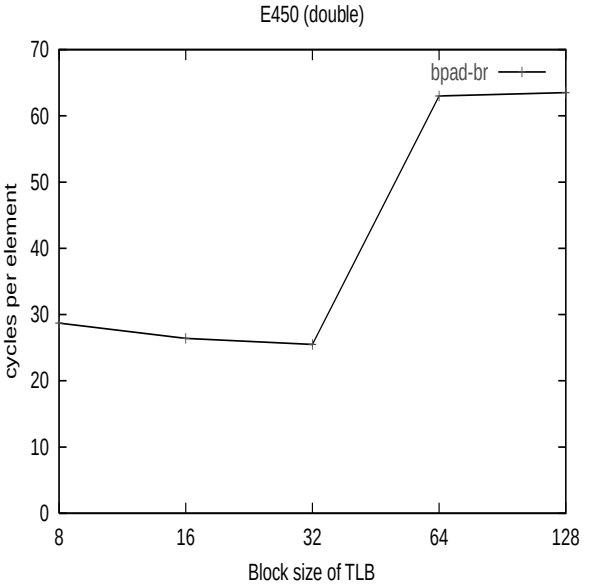

FIG. 4. *Changing the TLB blocking sizes on a single node of the Sun E-450: when the blocking size for TLB was larger than* 32*, the execution time curve was sharply increased.*

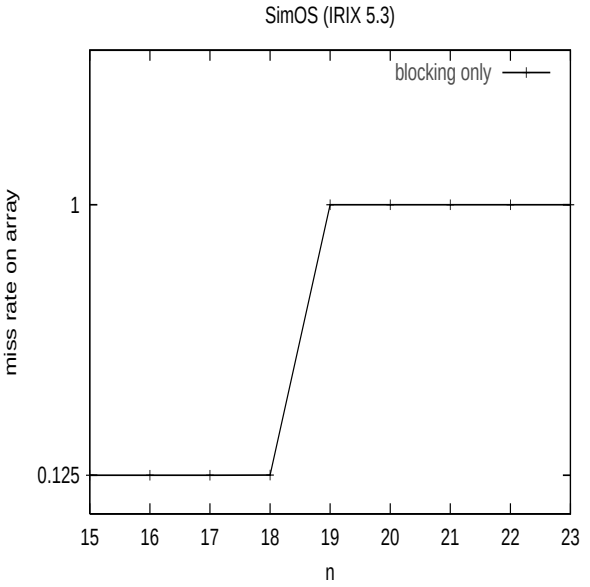

FIG. 5. *Using the SimOS to observe the miss rates by changing the size of the bit-reversal arrays of a blocking-only program: when* $n > 18$*, the miss rate was sharply increased to* 100%.

the IRIX 5.3 operating system are quite consistent with our assumption of "contiguous allocations."

We have also run the similar experiments on different targeted workstations with different operating systems, such as Linux and Solaris, to measure the changes of execution times when the data size is changed. Our measurements are also consistent

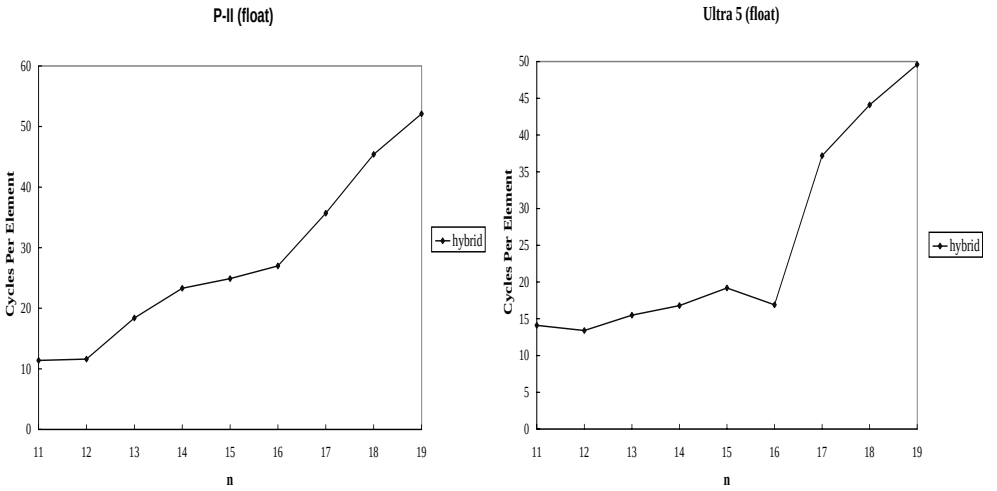

FIG. 6. *Execution times of the hybrid method on the Pentium*-II *(left figure) and on the Ultra*-5 *machine (right figure).*

to the SimOS results and indicate that the larger the data arrays to be used, the more likely an operating system will allocate the pages contiguously. Because our study targets large data sets, our analyses based on the virtual memory space is reasonably accurate. In addition, our methods assume that the operating system uses a uniform page size for page allocation, which is consistent with most commercial and commonly used operating systems.

6.3. Performance of the hybrid method for bit-reversals. In order to show the effectiveness of our cache optimizations, we first plot the measured execution times of the hybrid method[1] in "float" data types on the Pentium-II and the Ultra-5 machines in Figure 6. Although the hybrid method did reasonably well for $n \leq 16$ on Pentium-II and $n \leq 12$ on Ultra-5, the execution times significantly increased due to limited cache performance after the data size was further increased.

6.4. Performance comparisons on the SGI O2. The SGI O2 is a 1995 product using an R10000 processor of 150 MHz, 32 KB 2-way associative L1 cache, and 64 KB 2-way associative L2 cache. The cache line of L2 is 64 bytes. Since the associativity of L2 is low, and the cache line of L2 is relatively long, it is difficult to do blocking with associativity and available registers. We implemented only the blocking with padding method to compare with blocking with software buffer and the base reference.

We scaled bit-reversal methods from $n = 16$ to $n = 21$. Figure 7 shows the comparisons of CPE among the three programs of both "float" type and "double" type on the SGI O2 machine. The measurements show that the padding method slightly reduced the execution time compared with the method of blocking with software buffer. The time reduction was up to 6%. The reason for the small performance improvement comes from the extremely long memory latency (208 cycles) of the O2 machine. The reduction and saving of instruction cycles for data copies from padding became less significant because memory latencies caused by the required cold misses in both methods were dominant in execution.

[1]The program was written in Fortran by Alan Karp.

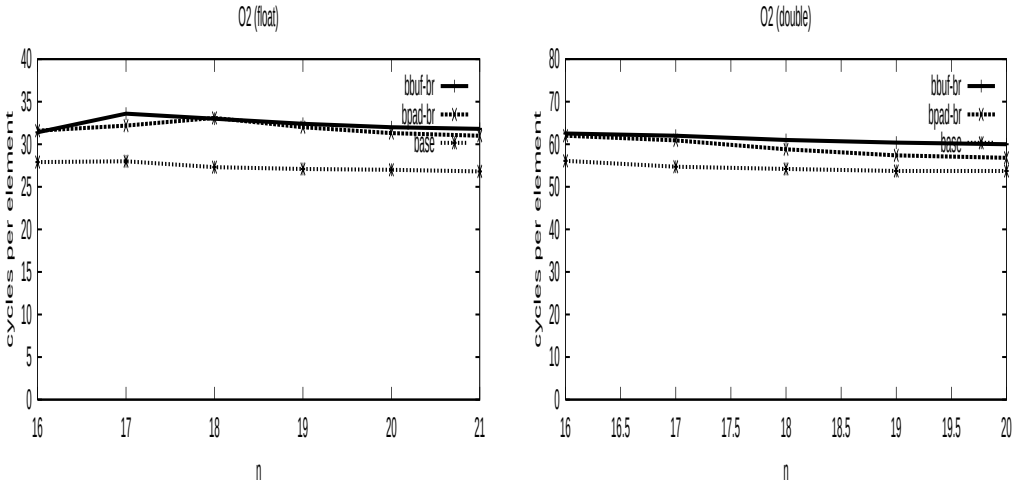

FIG. 7. *Execution comparisons on the SGI O2 workstation: "bbuf-br" represents the method of blocking with software buffer; "bpad-br" represents the method of blocking with padding; and "base" represents the ideal base line reference.*

6.5. Performance comparisons on the Sun Ultra-5. The Sun Ultra-5 is a 1998 product using an UltraSparc-IIi processor of 275 MHz, 16 KB direct-mapped L1 cache, and 256 KB 2-way associative L2 cache. The cache line of L1 is 32 bytes consisting of two 16-byte subblocks, and L2 is 64 bytes long. Similar to the SGI O2, the associativity of L2 on the Ultra-5 is low, and the cache line of L2 is relatively long, so it is difficult to do blocking with associativity and available registers. We implemented only the blocking with padding method to compare with blocking with software buffer and the base reference.

We scaled the bit-reversal methods from $n = 16$ to $n = 23$. Figure 8 shows the comparisons of cycles per element among the three programs of both "float" type and "double" type on the Ultra-5. The memory latency of the Ultra-5 (76 cycles) is significantly lower than that of the O2. We observed a more significant performance improvement from the method of blocking with padding over that of blocking with software buffer. For example, using "float" type, the padding program is 14% faster than that of blocking with buffer for $n = 20$ or larger. A L2 cache line of the Ultra-5 holds 16 "float" type elements ($L = 16$), and 8 "double" type elements ($L = 8$). The larger the L, the higher overhead the blocking with software buffer will have. This has been confirmed by our comparative experiments between the "float" and "double" types on the Ultra-5 shown in Figure 8.

6.6. Performance comparisons on the Sun E-450. The Sun E-450 is a 1998 4-processor SMP product. Each of the 4 nodes is an UltraSparc-2 processor of 300 MHz, 16 KB direct-mapped L1 cache, and 2 MB 2-way associative L2 cache. The cache line of L1 is 32 bytes consisting of two 16-byte subblocks, and L2 is 64 bytes long. Due to the limited associativity and a relatively long L2 cache line, we implemented only the blocking with padding method to compare with blocking with software buffer and the base reference.

We scaled the bit-reversal methods from $n = 16$ to $n = 25$. Figure 9 shows the comparisons of CPE among blocking with software buffer, blocking with padding, and the base program on a single node of E-450, each of which has both "float" type and

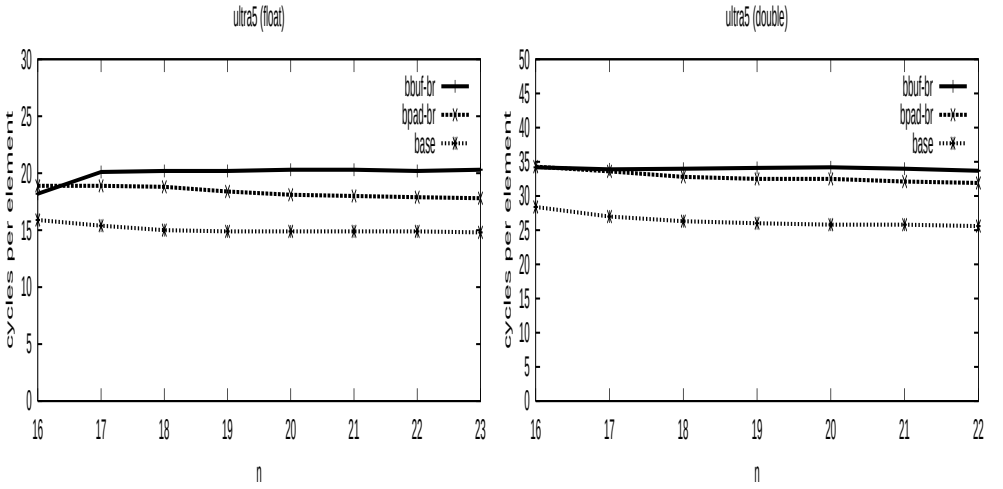

FIG. 8. *Execution comparisons on the Sun Ultra-5 workstation: "bbuf-br" represents the method of blocking with software buffer; "bpad-br" represents the method of blocking with padding; and "base" represents the ideal base line reference.*

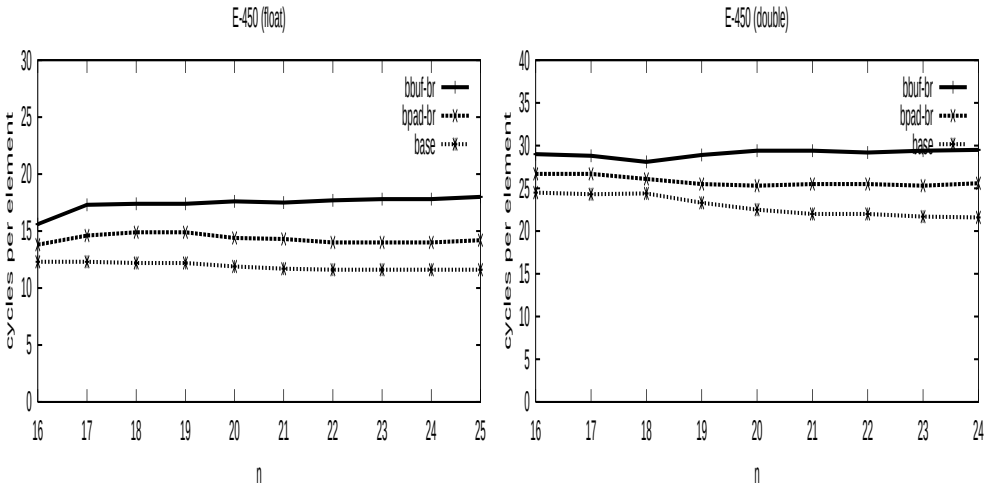

FIG. 9. *Execution comparisons on the Sun E-450 SMP: "bbuf-br" represents the method of blocking with software buffer; "bpad-br" represents the method of blocking with padding; and "base" represents the ideal base line reference.*

"double" type. The memory latency of the Ultra-5 (73 cycles) is slightly lower than that of Ultra-5. On this machine, we observed higher performance improvement from the method of blocking with padding over that of blocking with software buffer. For example, using "float" type, the padding program is 22% faster than that of blocking with buffer for $n = 20$ or larger. Our comparative experiments between the "float" and "double" types on E-450 in Figure 9 also confirms that the larger the L, the higher performance the padding method would achieve.

6.7. Performance comparisons on the Pentium-II 400. The Pentium PC we used is a 1998 product using a Pentium-II 400 processor of 400 MHz, 8 KB direct-mapped L1 cache, and 256 KB 4-way associative L2 cache. The cache lines of both

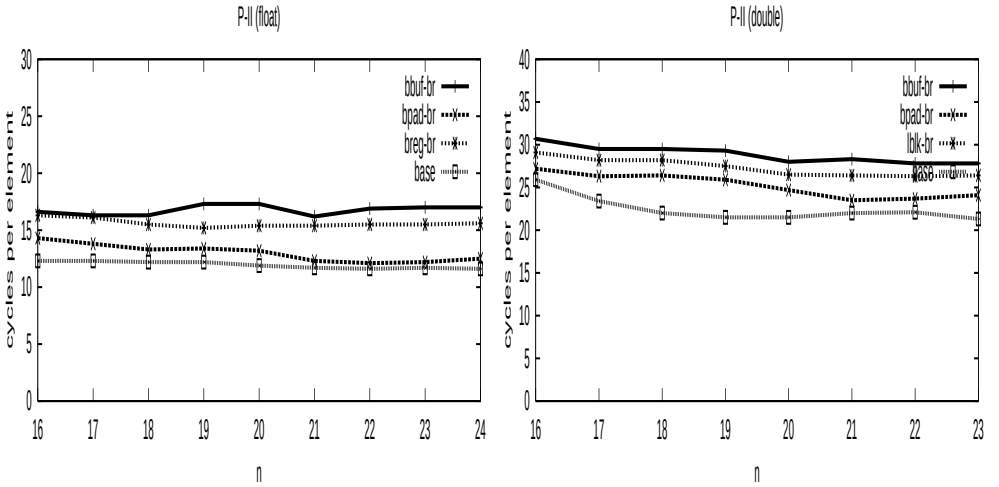

FIG. 10. *Execution comparisons on the Pentium*-II 4000 *PC: "bbuf-br" represents the method of blocking with software buffer; "bpad-br" represents the method of blocking with padding; "breg-br" represents the method of blocking with associativity and registers; and "base" represents the ideal base line reference.*

L1 and L2 are 32 bytes. Since the L2 associativity is high, we are able to implement the method of blocking with associativity and available registers, L2 cache line $L = 8$ elements for a "float" type, and we need $(L-K)(L-K) = 16$ registers to supplement the 4-way associative cache. An L2 cache line holds 4 "double" type elements ($L = 4$). Thus, we do not need any registers to supplement but simply make a 4×4 blocking. The TLB of the Pentium processor is a 4-way associative cache of 64 entries. We used our padding for the TLB technique to avoid TLB misses. We implemented the blocking with padding method and the blocking with associativity and registers to compare with blocking with software buffer and the base reference.

We scaled the bit-reversal methods from $n = 16$ to $n = 24$. Figure 10 shows the comparisons of cycles per element among the four programs. As we expected, the paddings for both cache and TLB were highly effective, and the padding program performed the best. For example, using "float" type, the padding program is about 40% faster than that of blocking with buffer for $n = 22$ or larger. We also show that the method using available registers to supplement associativity is effective. Although it is not as good as the padding program due to the increase of the instruction counts for additional data copies, it still achieved up to 12% execution reduction over the blocking with software buffer program. As we expected, the execution time of the method using the 4-way associative L2 cache without the supplement of registers to form a 4×4 blocking was delayed mainly by the longer L2 cache hit time. The performance of this method still outperformed the method of blocking with a software buffer.

6.8. Performance comparisons on the Compaq XP-1000. The Compaq XP-1000 is a 1999 product using an Alpha 21264 processor of 500 MHz, 64 KB 2-way associative L1 cache, and 4 MB 2-way associative L2 cache. The cache lines of both L1 and L2 are 64 bytes long. Similar to the SGI and Sun machines, the associativity of L2 on the XP 1000 is low, and the cache line of L2 is relatively long, so it is difficult to do blocking with associativity and available registers. We implemented only the

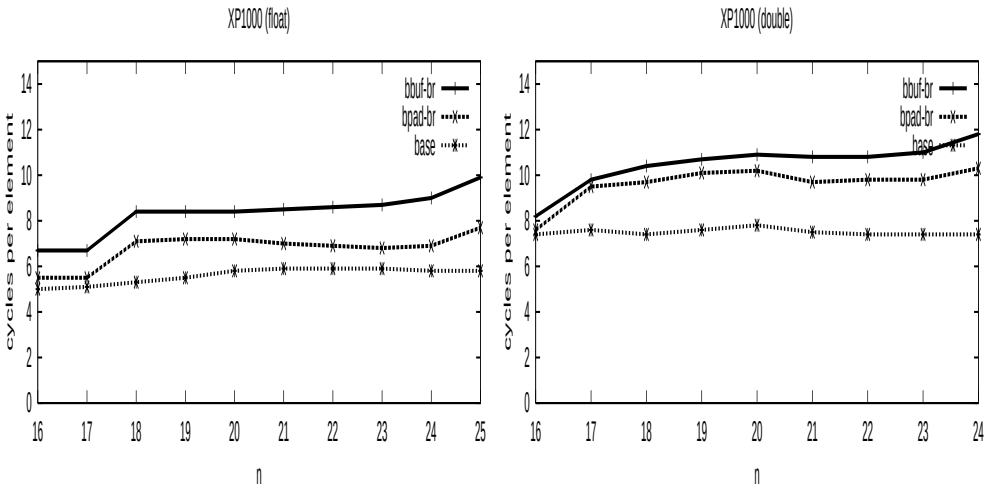

FIG. 11. *Execution comparisons on the Compaq XP-*1000 *workstation: "bbuf-br" represents the method of blocking with software buffer; "bpad-br" represents the method of blocking with padding; and "base" represents the ideal base line reference.*

blocking with padding method to compare with blocking with software buffer and the base reference.

We scaled the bit-reversal methods from $n = 16$ to $n = 25$. Figure 11 shows the comparisons of CPE among the three programs of both "float" type and "double" type on the XP-1000 machine. As we expected, we achieved better or comparable performance to the ones on the Sun machines. For example, using "float" type, for $n = 24$ or larger, the padding program is 30% faster than that of blocking with buffer, and 15% faster for "double" type.

7. Performance evaluation on SMP multiprocessors. We implemented the bit-reversal methods on two SMP multiprocessors: the Sun E-450 and the HP 9000 V2200. The parallel bit-reversal program on an SMP with M processors is described using POSIX thread primitives [10] as follows:

```
bit_reversal(id)
  my_start = id*(N/M);
  my_end = (id-1)*(N/M);
  for i = 1, N
    Y[i'] = X[i];
```

The bit-reversal operations are evenly distributed among M processors.

7.1. Performance comparisons on the Sun E-450. The Sun E-450 is a 1998 4-processor SMP product. Each of the 4 nodes is an UltraSparc-2 processor of 300 MHz, 16 KB direct-mapped L1 cache, and 2 MB 2-way associative L2 cache. The cache line of L1 is 32 bytes consisting of two 16-byte subblocks, and L2 cache line is 64 bytes. Due to the limited associativity and a relatively long L2 cache line, we implemented only the blocking with padding algorithm to compare with blocking with software buffer and the base reference.

We scaled the bit-reversal algorithms from $n = 16$ to $n = 24$. Figure 12 shows the comparisons of CPE among blocking with software buffer, blocking with padding, and the base program on the E-450 of 4 nodes, each of which has both "float" type and "double" type. On this machine, we observed some performance improvement

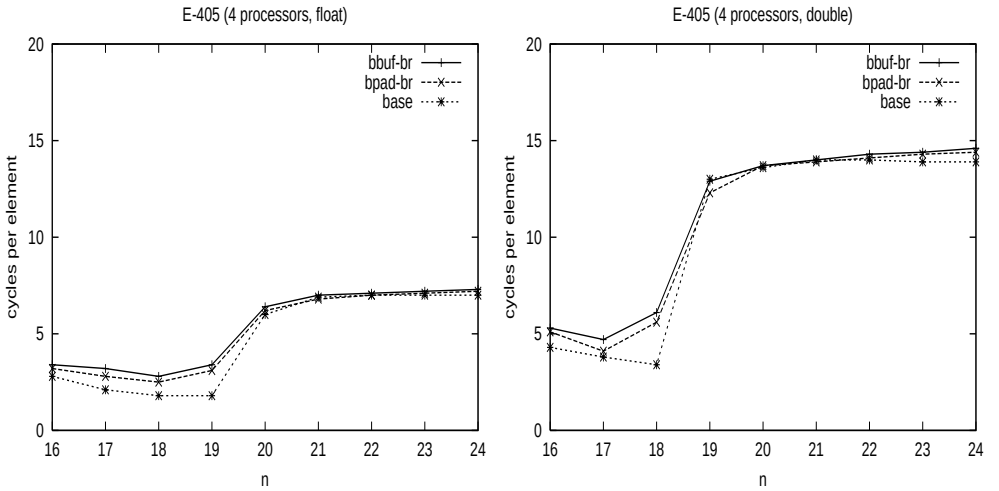

FIG. 12. *Execution comparisons on Sun E-450 SMP of 4 processors: "bbuf-br" represents the algorithm of blocking with software buffer; "bpad-br" represents the algorithm of blocking with padding; and "base" represents the ideal base line reference.*

when $n \leq 18$ from the algorithm of blocking with padding over that of blocking with software buffer.

However, when $n > 18$ of double type or $n > 19$ of float type, each processor has to process a data set larger than its cache capacity. Multiple processors simultaneously access the memory through a shared data link would cause the contention to degrade the performance. Since the data to be accessed from different processors are distributed in different locations, a crossbar interconnection network to link each processor to all the memory modules would significantly reduce the contention. The E-450 does have a 5×5 crossbar to connect 2 pairs of processors, 2 I/O ports, and the memory. The communications between the 4 processors the memory modules are connected through the single memory data link. Figure 13 shows the crossbar interconnections of the E-450 among the processors, the shared-memory modules, and the 2 I/O ports. The contention occurs in the memory data link when the multiple processors request memory accesses simultaneously.

We have observed severe performance degradation caused by the memory access contention. Figure 12 shows that this contention makes the execution time curves of the three programs jump sharply and merge together when $n > 18$ of double type and $n > 19$ of float type. In contrast, on a single processor of E-450, accesses to the memory through the memory bus have no contention so that the algorithms were scaled well.

7.2. Performance comparisons on the HP 9000 V2200. HP 9000 V2200 is a 1997 SMP product with up to 16 processors. We used 4 processors for performance comparisons. Each node is a HP PA-8200 processor of 200 MHz with a 2 MB direct-mapped L1 data cache. The cache line is 32 bytes. Due to limited associativity, we implemented only the blocking with padding algorithm to compare with blocking with software buffer and the base reference.

The HP SMP has a crossbar interconnection network, the HyperPlane crossbar, to connect up to 8 pairs of processors to 8 memory modules. Multiple pairs of processors can access different memory modules simultaneously. Each pair of the processors is

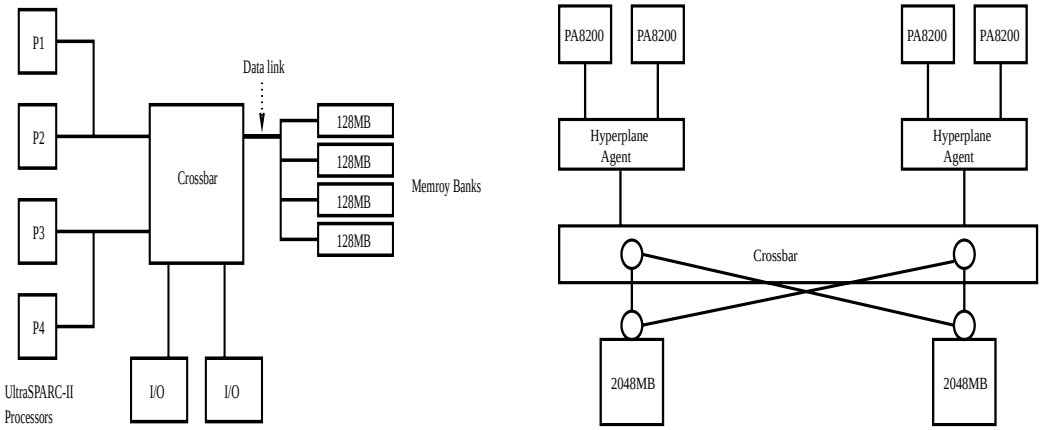

FIG. 13. *Architecture comparisons between Sun E-*450 *SMP (left) and HP* 9000 *V*2200 *SMP (right): the memory data link of the E-*450 *may become a bottleneck when simultaneous memory access requests from multiple processors; the HyperPlane crossbar connected between the memory modules and the processors on the HP* 9000 *V*2200 *can effectively reduce the contention.*

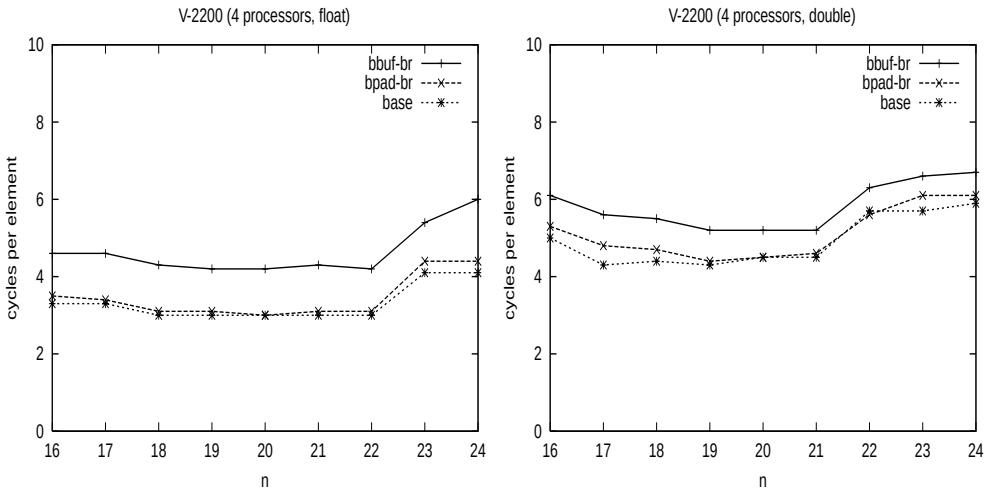

FIG. 14. *Execution comparisons on HP* 9000 *V*2200*: "bbuf-br" represents the algorithm of blocking with software buffer; "bpad-br" represents the algorithm of blocking with padding; and "base" represents the ideal base line reference.*

connected to the crossbar through an adaptor called HyperPlane Runway Agent. Figure 13 gives the interconnection structure of the HP 9000 V2200 of 4 processors.

In our experiments, the 4 processors are divided into 2 pairs which are connected to 2 memory modules by a 2×2 hyperplane crossbar. Each pair of processors may have contention to compete the adaptor, but the crossbar is able to allow simultaneous data accesses among the memory modules. The negative performance effect due to the data link contention observed on Sun E-450 was significantly reduced on the HP SMP, which shows the effectiveness of the crossbar. Figure 14 shows comparative execution time curves between the "float" and "double" types on E-450 in Figure 14. The execution times of the 3 programs are quite stable and independent of the size of n. Both the padding programs of the float type and of the double type outperformed

TABLE 2

Summary of the blocking methods and their impact on the three aspects of performance (cross interference, instruction count, and memory space) and on the program complexity. The performance of "blocking only" method is the base line for comparisons. Note: + means that the method quantitatively increases the factor and hurts the performance, and blank means it has no impact. The program complicity is subjective and compared with the "block only" method, with 1 *being a slightly more complex, and* 2 *a moderately more complex.*

Methods	Cross interference	Instruction count	Memory space	Program complexity	Comments
Blocking only				0	limited by data sizes.
Blocking with software buffer	+	+	+	1	system independent.
Blocking with register buffer				1	limited by the number of available registers.
Blocking with associativity and registers				2	works well on high associativity caches.
Blocking with padding			+	1	works well on all systems.
TLB blocking				0	a TLB size dependent outer loop, effective for fully associative TLBs.
TLB padding			+	1	paddings by using L pages, effective for set associative TLBs.

the blocking methods with buffer up to 40% and 18%, respectively. Their execution curves almost merge together with the base reference curve.

8. Conclusion. We have examined and developed cache-optimal methods for bit-reversal data reorderings. These methods have been tested on 5 representative uniprocessor workstations of 1995 to 1999 products to show their effectiveness. Different methods have their own merits and limits. The blocking-only method is limited by data sizes. Although the blocking-with-software-buffer method is architecture independent, it increases cross interference and instruction count and needs additional memory space. The blocking-with-a-register-buffer method is fast but is limited by the number of available registers. Blocking with associativity and with registers work well on high associativity caches. We have shown that the methods of blocking with padding, blocking for TLB, and padding for TLB can effectively exploit cache locality and are almost independent on hardware. Thus, they could be widely used on many uniprocessors workstations and SMP multiprocessors. We summarize different techniques and their merits and limits in Table 2, which gives a guideline for application users to choose a technique based on the size of the problem and the machines available.

The methods have also tested on two commercial SMP multiprocessors. By exploiting cache locality of each processor, we have effectively eliminated the conflict misses so that accesses to the shared memory and contention are minimized. However, another potential bottleneck on SMPs is the data access contention to the shared-memory. We show that crossbar interconnections between processors and memory modules play an important role to parallel bit-reversal data reorderings.

CHECKPOINTING SCHEMES FOR ADJOINT CODES: APPLICATION TO THE METEOROLOGICAL MODEL MESO-NH*

I. CHARPENTIER†

Abstract. The adjoint code of a nonlinear computer model calculates gradients along a trajectory that has to be known at integration time. When the storage of the whole trajectory requires too large an amount of memory, the calculation of the adjoint code is split and is done part by part from restart points called checkpoints. Griewank proposed a checkpointing method named *Revolve*, which provides an optimal logarithmic behavior with respect to time and memory requirement. In this work, some checkpointing schedules are proposed. Some of them correspond to special cases of *Revolve*.

The user's preference is essential to choose between time and memory requirements. This is a key point for adjoint codes of temporal models such as the meteorological model Meso-NH that may be used for weather forecasts. When the computational time is the top priority, a particular checkpointing scheme allows computation of the adjoint code with at most one extra integration of the model. The memory requirement behaves then as the square root of the number of iterations of the model. Checkpointing schemes are tested on adjoint simulations of Meso-NH.

Key words. checkpointing algorithms, adjoint codes, inverse problems, nonlinear least squares, three-dimensional (3D) meteorological simulations, leap-frog schemes

1. Introduction.

Computational methods using derivatives are now classical for solving inverse problems through optimal control theory [14]. From a scientific computing point of view, the latter are nonlinear least square calculations on a vector function that is defined as a solution of a partial differential equation problem. Such optimization problems may be solved using gradients that are calculated via the differentiation of the numerical code representing the original model.

According to theoretical bounds (see, for example, [17] and [6]), the reverse mode of differentiation allows the generation of an adjoint code involving at most five times the number of operations of the original model. However, this surprisingly low operation count requires the storage of the full trajectory. The *trajectory* is formed by the values of the variables of the original model that may be used for the evaluation of linearized statements. The calculation of the trajectory has to be performed before (or during) the backward integration of the adjoint code. When the differentiated codes require too large an amount of memory, a possible solution is to implement algorithms such as Griewank's *Revolve* checkpointing method (named *Treeverse* in [7]), which provides an optimal logarithmic behavior in terms of time and memory requirement.

More generally, the strategy to solve the trajectory problem arising in adjoint computations is based on the classical idea of "divide and conquer." Since the whole trajectory cannot be stored, the calculation of the adjoint code is split and done part by part from restart points called *checkpoints*. Extra forward iterations of the original

†Projet IDOPT, LMC-IMAG, 51 Rue des Mathématiques, BP 53, F-38041 Grenoble Cedex 9, France (Isabelle.Charpentier@imag.fr).

model are then necessary to progress between checkpoints. The main problem is to find a partition of the computations that minimizes the number of extra forward iterations. The paper describes and analyzes several algorithms in order to facilitate the user's preference between computational time and memory requirement. Some of them correspond to particular parameter choices in *Revolve*. Particular attention is devoted to evolutionary problems solved using leap-frog schemes [1]. Numerical tests are performed on the meteorological model Meso-NH [12] that may be used for operational (real time) weather forecasts. The differentiation work that generates the adjoint of Meso-NH was published in [2] and [1].

The layout of the paper is as follows. Section 2 introduces optimal control methods suitable for the meteorological model Meso-NH and points out the problem of the size of the trajectory. Section 3 presents checkpointing algorithms that allow the solution of the trajectory problem, whereas the case of leap-frog schemes is discussed in section 4. Section 5 reports numerical results, and section 6 concludes on some discussion about the efficiency of checkpointing schemes.

2. Computation of gradients. Derivatives are very helpful for a large number of numerical methods in very different fields. For example, derivatives are usable for performing sensitivity analysis of a numerical model with respect to perturbations of its initial conditions, or for the validation of a model with respect to some of its parameters. Likewise, inverse problems may be solved through gradient methods. These are nowadays in use for weather forecasts [18].

2.1. Variational data assimilation process. Variational data assimilation techniques [3], [13] are used in most of the operational meteorological models. Let Ω be an open bounded domain of the atmosphere, let $[0,T]$ be the time interval, and let X be the *state variable* belonging to the set $\mathcal{X}$ of admissible states of the atmosphere. For the sake of simplicity, the governing equations that define the *original model* are written in the following form:

$$\begin{cases} \dfrac{dX}{dt} = F(X) \quad \text{in } \Omega \times (0,T), \\ \\ X(0) = X_0 \quad \text{in } \Omega, \\ + \text{ boundary conditions.} \end{cases} \tag{2.1}$$

In the previous system, F is a nonlinear differentiable operator from $\mathcal{X}$ to $\mathcal{X}$ that describes the dynamic behavior of the model, and X_0 is the initial state. System (2.1) is supposed to have a unique solution in $\mathcal{X}$ for all $t \in [0,T]$.

When studying the atmospheric circulation, the main goal to achieve has always been weather forecasting, i.e., one wants to predict the state of the atmosphere after time T. This requires a good numerical model and the knowledge of a "good" approximation of the state of the atmosphere at time T.

The aim of the data assimilation process is to find this good approximation by including observed data in the model. Observed data $X_{obs} \in \mathcal{X}_{obs}$ that are acquired during the interval [0,T], for example, by surface stations and/or pilot balloons are introduced into the numerical model by means of a cost function $J : \mathcal{X} \longrightarrow \mathbb{R}$ such that

$$J(X_0) = \frac{1}{2} \int_0^T ||H(X) - X_{obs}||^2 dt. \tag{2.2}$$

The observation operator H maps $\mathcal{X}$ to $\mathcal{X}_{obs}$. Let X_0^{opt} be the solution of the nonlinear least square problem

$$\textit{Find } X_0 \textit{ such that } J(X_0) \textit{ is minimal.} \tag{2.3}$$

A well-known necessary condition for the local optimality is then the stationarity equation

$$\nabla J(X_0) = 0.$$

As a consequence, the optimal state X_0^{opt} is the initial state such that the solution X of (2.1) fits at best the observed data. Meteorologists use the resulting solution $X(T)$ as a fair initial condition for forecasting experiments.

Algorithmic differentiation [8] proposes two methods for the calculation of the gradient of J: the direct mode that generates tangent linear codes and the reverse mode that generates adjoint codes. This paper is only concerned with the second one. The reader is referred to [8] for more information on algorithmic differentiation.

2.2. Reverse mode of differentiation. Let the *adjoint variable* P be the solution of the *adjoint system*

$$\begin{cases} \dfrac{dP}{dt} + \left[\dfrac{\partial F}{\partial X}(X)\right]^* P = H^*(H(X) - X_{obs}) \quad \text{in } \Omega \times (0,T), \\ P(T) = 0 \quad \text{in } \Omega, \\ + \text{ boundary conditions}, \end{cases} \tag{2.4}$$

where $[\frac{\partial F}{\partial X}(X_0)]^*$ denotes the transposed Jacobian of F. One may prove [13] that the gradient of J is given by

$$\nabla J = -P(0). \tag{2.5}$$

According to (2.5), the computation of all the components of ∇J requires only a single evaluation of the adjoint system. Moreover, theoretical results indicate that the ratio between the number of operations of the adjoint statement and the number of operations of the original statement is lower than 5 for any statement.

In the case of nonlinear equations, it is necessary to solve the original system (2.1) to compute and to record the trajectory before the evaluation of the adjoint system (2.4). This constitutes what one calls the *forward sweep*. The trajectory is then restored to evaluate adjoint statements during the *reverse sweep*.

The management of the trajectory is often the key point of the adjoint code. There exist essentially two manners for saving trajectory information in an adjoint code. In the first one, parts of the trajectory are locally recomputed and stored using local variables, while in the second one, the trajectory is stored on a last-in-first-out stack. These options are discussed in [4]. Nevertheless, the size of the trajectory of a model sometimes exceeds the memory capacities of a given computer.

2.3. The meteorological model Meso-NH. As an example, we study the trajectory problem on the nonhydrostatic meso-scale meteorological model Meso-NH (30,000 lines) developed by the Centre National de Recherches en Météorologie and the Laboratoire d'Aérologie of Toulouse (France). In a summary, the governing equations of the atmosphere are discretized using explicit finite difference methods in both

time and space. The time-stepping is coded using a leap-frog scheme. An extensive description of the Meso-NH package is given in [15] and [16].

Meso-NH has been differentiated [2] with respect to the state variables. Defined on a large spatial grid, these are wind velocity components, dry potential temperature, turbulent kinetic energy, six mixing ratios of water, N passive source terms (chemical pollutants, for example), and pressure.

The differentiation work is carried out using the automatic differentiation tool Odyssée [5] and appropriate posttreatments [2]. The resulting codes are gathered in the MesODiF package [1]. The management of the trajectory is realized according to the following two principles.

- Only state variables are stored at the beginning of each time-step (in the main routine).
- A few local variables are recomputed at each iteration.

The original adjoint code, called *OAC-MesODiF*, performs a full forward sweep before the full reverse one. The storage is realized on a fast disk of 1.2 giga-word space.

A first example is chosen in order to evaluate the performances of *OAC-MesODiF*. The two-dimensional (2D) simulation trial takes place on a computational domain (180 km$\times$ 15 km) containing a bell shaped mountain with an altitude of 500 m and a base of 10 km. The domain is discretized by 90 points in the horizontal plane (x-axis) that are duplicated 63 times in the vertical grid (z-axis). One notices that the same code Meso-NH is used to perform 2D and three-dimensional (3D) simulations. This is why three grid points are used in the y-direction even though one deals with a 2D simulation. One calculates wind components and temperature only. The physical duration T of the simulation is 2,000 seconds with a time-step of 20 seconds. Finally, the state vector is represented using 62,000 reals in that simulation.

Table 2.1 shows measurements of the execution time for an evaluation of *OAC-MesODiF*.

TABLE 2.1
Runtime measurements and ratios of both Meso-NH and OAC-MesODiF.

	Original code Meso-NH	Adjoint code *OAC-MesODiF*
CPU time	12.97	39.53
Ratio	1	3.05
Theoretical bound for the ratio	1	5

As far as computational time is concerned, *OAC-MesODiF* is efficient since the ratio between the CPU time of *OAC-MesODiF* and the CPU time of the original model, rather equal to 3, is lower than the theoretical bound. Such performances result from the trajectory management we have implemented. The other side of the coin is that this management induces the construction of a trajectory that takes up 20% of the 1.2 giga-words of memory allowed by the computer we use.

2.4. Current meteorological simulations and trajectory problems. Usually the size of the trajectory is small when the original code is such that the number of statements (written as a straight-line program) and the number of iterations are small quantities. Iterative schemes do not always satisfy these constraints since the size of the trajectory strongly depends on the number of iterations. One may distinguish evolutionary problems that have predicted costs, since the number of iterations

is known, from fixed point algorithms like conjugate gradient or quasi-Newton methods. For that second class the number of iterations, related to the verification of a stopping criterion, is unknown. This paper is devoted only to evolutionary problems. The number of iterations is denoted by P.

A set of trial simulations with a physical meaning [12] is given in Table 2.2.

TABLE 2.2
Trial simulations for a meso-scale model.

Simulation	Discretization		Memory	CPU
	# grid points	# time-steps	mega-words	seconds
Mountain waves (2D)	$90 \times 3 \times 63$	3000	2.4	167
Mountain waves	$180 \times 3 \times 63$	100	3.3	200
Mountain waves (3D)	$128 \times 96 \times 180$	889	110	7400
Baroclinic waves	$96 \times 48 \times 33$	4320	8.5	1886

Memory information (given in the 4th column) takes into account both state variables and local variables required to perform one time-step. For the sake of simplicity, one assumes that this amount of memory is used at each iteration even though local variables could be counted once.

Multiplying the amount of memory by the number of time-steps indicates that trajectories are sometimes larger than the upper limit of 1.2 giga-words. Thus *OAC-MesODiF* cannot be run.

3. Checkpointing algorithms. Many problems in computer sciences or numerical analysis may be tackled by the so-called basic idea of "divide and conquer." This applies to the evaluation of adjoint codes: one divides the computations (i.e., the trajectory), and one performs recalculations into adjoint codes.

Griewank [7] proposed to save the state of the system from time to time during runs of the original code. These are called *checkpoints*, and they allow for the computation of parts of the trajectory without systematically coming back to the initial point. In the following, the word "checkpoint" refers to the moment it is set, the recorded data, and the number of the checkpoint. Checkpoints are stored on a stack in a last-in-first-out manner. Forward sweeps and reverse sweeps are then done, part by part, from checkpoints. A simple checkpointing algorithm reads as follows.

run the original code and **store** some checkpoints
(as described in sections 3.3.2 (*Periodis* scheme) and 3.4 (*Twice* scheme))
for all the checkpoints (taken in the reverse order)
restore the checkpoint
perform a forward sweep from the checkpoint to the previously removed one (or to the Pth iteration)
perform a reverse sweep down to the checkpoint
remove the checkpoint from the stack.

Checkpoints can be set at any point in a computational graph, but the remaining problem is to know the active variables to be taped. Checkpointing is easy to implement for time-stepping problems, where a natural point is the beginning of a time-step. It is even easier for the adjoint of Meso-NH because the trajectory management already defines points (section 2.3) where state variables values are stored.

Using checkpointing algorithms introduces *extra forward steps* of the original code. Regarding the computational time, this number of iterations N_{it} is chosen as a mea-

sure for the performances of the algorithms. Forward sweeps that integrate the model and store the trajectory are not counted in N_{it} since they are always performed once during the adjoint code evaluation. One notices that checkpoints are not set during a forward sweep; they are only set during evaluations of the original code. A second measure is concerned with the maximal number K of checkpoints that need to be kept in memory at any time.

From the user's point of view, the choice of a checkpointing scheme essentially depends on the particular code and the particular computer he deals with. An interesting problem is then to find a partition for the calculations that minimizes the number of extra iterations and/or the number of checkpoints. A large variety of schedules is discussed in the following; some of them are derived from Griewank's *Revolve* [7].

3.1. Notations. The main iterative loop of the original model one deals with solves an explicit finite difference scheme. For the sake of simplicity, one assumes that the P steps of the loop have the same execution time and generate a trajectory of the same size S.

A trajectory decomposes into two parts: on one hand state variables, and on the other hand, local variables. The variables of the second part are local to an iteration, i.e., the amount of memory needed for their storage is independent of the number of iterations. For the sake of simplicity, in complexity estimates, trajectories are nevertheless assumed to be of size S.

One denotes by

- R_O the execution time used to perform one time-step of the original model,
- R_T the execution time used to perform one time-step during a forward sweep,
- R_A the execution time used to perform one time-step during a reverse sweep, and
- R_C the execution time and S_C the amount of memory required to store a checkpoint.

One observes that the storage of a checkpoint is generally far less time-consuming than the execution of one time-step of a reverse sweep ($R_C << R_A$). Furthermore, S_C is usually much smaller than S because the trajectory generated during one iteration includes many intermediate values that are saved for the reverse sweep.

The adjoint code of Meso-NH behaves differently since one may assume that $S = S_C$. This is due to the fact that state variables are read at the beginning of each time-step of the reverse sweep, a few local recomputations depending on these variables (section 2.3) being added to perform the backward integration.

In order to describe the schemes, one introduces the following three integer parameters:

- the maximal number K of checkpoints in memory,
- the maximal number times τ any particular time-step is repeated, and
- the maximal length ν of a forward sweep during which no checkpoints are set.

3.2. Griewank's *Revolve* routine. Griewank [7] proposes to split the evaluation of the adjoint code with respect to a binomial law β that depends on parameters

K and τ:

$$\begin{aligned}\beta(K,\tau) &= \frac{(K+\tau)!}{K!\tau!} \\ &= \frac{(K-1+\tau)!}{(K-1)!\tau!} + \frac{(K+\tau-1)!}{K!(\tau-1)!} = \beta(K-1,\tau) + \beta(K,\tau-1).\end{aligned} \tag{3.1}$$

The checkpointing schedule *Revolve* may be written as follows:

compute or choose adequate parameters $K \geq 0$ and $\tau \geq 0$
CALL *Revolve* $(1, P, K, \tau)$

RECURSIVE ROUTINE *Revolve* (B, E, k, t)
IF ($(E - B > t)$ and $(k > 0)$) **THEN**
    store the checkpoint at time B (if it differs from the current checkpoint)
    run the original model from B to $I = B + \beta(k, t-1)$
    CALL *Revolve* $(I, E, k-1, t)$
    restore the checkpoint (time B)
    CALL *Revolve* $(B, I, k, t-1)$
ELSE
    restore the checkpoint (time B)
    compute trajectories and **evaluate** the adjoint from E down to B
    remove the checkpoint (time B) from the stack
END IF

The last-in-first-out process is well adapted to this recursive scheme:

- one stores a checkpoint if it differs from the current one,
- one always reads the last checkpoint of the stack, and
- one removes the last checkpoint after the adjoint evaluation.

One notices that the checkpoint at time B is stored once and restored twice at least. In fact, the evaluation of the adjoint code may require several readings of the same checkpoint, especially when trajectories are locally recomputed.

Assuming that the underlying iteration is a single step recurrence ($\nu = 1$), one proves the following results.

THEOREM 3.1. *Let P be the number of forward iterations.*

1. *The adjoint code is calculable by Revolve if and only if parameters $K \in \mathbb{N}^*$ and $\tau \in \mathbb{N}^*$ are such that*

$$P \;\leq\; \beta(K,\tau).$$

2. *The minimal number of forward steps that are required to revert a sequence of P time-steps storing up to K checkpoints at any time satisfies*

$$N_{it} = \tau P - \beta(K+1, \tau-1), \tag{3.2}$$

where τ is chosen such that

$$\beta(K, \tau-1) < P \leq \beta(K,\tau). \tag{3.3}$$

3. *From among the checkpointing schedules satisfying the first two assertions, there exists a scheme that minimizes the number of checkpoints settings.*

Proof. Assertions of Theorem 3.1 are proved in [7], [11], and [9]. ∎

One notices that the scheme described in [11] is similar to *Revolve*. It has been incorporated into the automatic differentiation tool Odyssée [5] for generating adjoint codes.

The following temporal and spatial costs, $R_{Revolve}$ and $S_{Revolve}$, for the evaluation of the adjoint code incurred

$$\left\{ \begin{array}{l} R_{Revolve} \simeq N_{it} R_O + P R_T + P R_A, \\ S_{Revolve} = \nu S + K S_C. \end{array} \right. \tag{3.4}$$

For the choice $K \simeq \tau$ one deduces from Stirling's formula (see [7]) that the temporal complexity, which is related to N_{it}, is of the order of $P \log(P)$. The corresponding spatial complexity is of the order of $\log(P)$.

Leap-frog schemes are not single step recurrences. Hence *Revolve* as described in [7] cannot be fairly compared to other schemes [1]. Fortunately, the assumption "$\nu = 1$" has been recently relaxed in [19] and [10]. To prove the optimality of *Revolve* in such a case, A. Walther [19] introduces "mega-steps" that treat a few successive iterates as a unique one.

3.3. Other checkpointing algorithms. The iterative problem with P iterations is split into $K \geq 1$ subproblems $[t_{k-1}, t_k]_{k=1,\ldots,K}$ of $\nu_k \in \mathbb{N}$ time-steps that are supposed to be performed in one sweep. The partition is assumed to satisfy

$$\left\{ \begin{array}{ll} 0 = t_0 < t_1 < \cdots < t_{K-1} < t_K = P, & \\ t_k - t_{k-1} = \nu_k & \forall k \in \{1, \ldots, K\}, \\ \nu_k \geq \nu_{k+1} & \forall k \in \{1, \ldots, K-1\}, \\ \displaystyle\sum_{k=1}^{K} \nu_k = P. & \end{array} \right. \tag{3.5}$$

3.3.1. Computation from the initial state (*FISC*). For the sake of simplicity, intervals are supposed to be of the same length ν, i.e.,

$$t_k = k\nu \quad \forall\ k \in \{0, \ldots, K\}.$$

The parameter K must obviously be chosen such that $P/\nu \leq K < P/\nu + 1$. A unique checkpoint, the initial state, is saved once. The original code reads the checkpoint and runs without recording intermediate variables until the kth interval. A forward sweep is then executed so as to generate the trajectory from iteration t_k to iteration t_{k+1}; this trajectory is immediately used for the corresponding reverse sweep. The process loops until the adjoint system is completely evaluated. When ν is equal to 1, this schedule corresponds to *Revolve* $(1, P, 1, P)$: *FISC* is the upper bound of *Revolve* in terms of time requirement and its lower bound in terms of memory requirement.

In Figure 3.1, the number of extra forward steps is clearly equal to the area (computed using a rectangle method) of the triangle limited by forward and reverse sweeps. This algorithm then induces $N_{it} = K(K-1)\nu/2$ extra forward iterations: the temporal complexity is of the order of P^2. As a consequence, the expensive FISC scheme must be avoided when the number of intervals is large. However, this simple scheme could be used for a partition containing a few intervals (typically, 2 or 3).

3.3.2. Periodic distribution of checkpoints (*Periodis*). As in section 3.3.1, the iterative problem is divided into K subproblems of length ν. A first forward integration of the P iterations sets regularly the checkpoints that are used in reverse

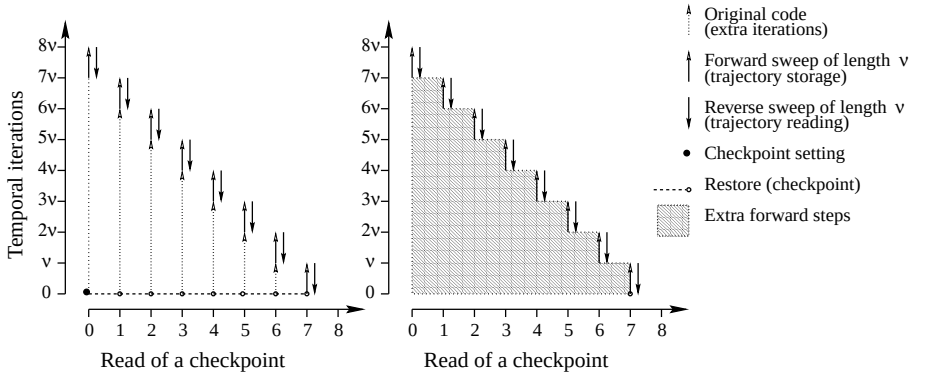

FIG. 3.1. *Computation from the initial state (FISC).*

order to evaluate, part by part, the adjoint code. This process is drawn in Figure 3.2. If the amount of memory is sufficiently large, the original problem is solved twice:

- once to set the checkpoints (original code),
- once for the construction of each of the K parts of the trajectory (forward sweeps).

This two levels scheme, which is called *Periodis*, induces $N_{it} = (K-1)\nu \simeq P$ extra forward steps. Such a partition is well adapted to simulations in which computational time is the main concern. On the other hand, *Periodis* requires a potentially large amount of memory which varies linearly with respect to the number of iterations P. This constraint is relaxed in section 3.4.

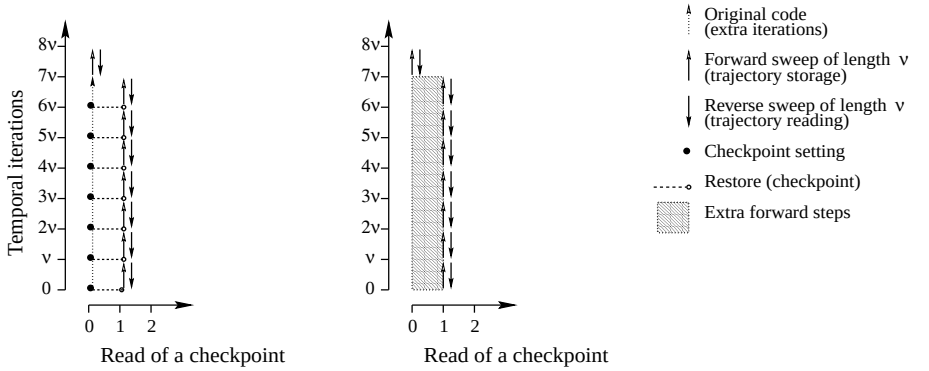

FIG. 3.2. *Periodic distribution of checkpoints (Periodis).*

When $\nu = 1$, this schedule is equivalent to *Revolve* $(1, P, P, 1)$. In that case, checkpoints are stored and restored once at every time-step. Afterward small computations are performed to supply the remaining part of the trajectory (local variables). This user-friendly strategy is used at the European Centre for Medium-Range Weather Forecast (ECMWF, Reading, UK) for the evaluation of the adjoint code of the operational meteorological model IFS (global circulation model). Although it uses a large amount of memory, the top priority at the European Center is given to the CPU time because the purpose of any operational model is to provide a forecast in time.

3.4. Distribution through arithmetic regression (*Twice*). The size of the checkpoint stack and the size of the trajectory one can store between two successive checkpoints may be managed with respect to the fixed amount of memory Q of a computer.

As a consequence, one chooses parameters K and ν such that KS_C and νS are both smaller than Q. This is not always possible. A solution is then to partition the calculations such that ν_k varies with respect to the number of checkpoints that are already stored at time t_k. Checkpoints are no longer assumed to be equidistant.

One searches couples $(k, \nu_k)_{k=1,\dots,K}$ such that

$$\begin{cases} \nu_k \geq 1 \quad \forall\ k \in \{1, \dots, K\}, \\ \nu_k S + k S_C \leq Q. \end{cases} \tag{3.6}$$

Once the partition is determined, *Twice* runs as *Periodis*: the original model is integrated twice. An integration of the original model is done to store the checkpoints that are then used in reverse order to evaluate, part by part, the adjoint code. Drawn in Figure 3.3, the *Twice* process is easy to implement. It may be viewed as *Revolve* $(1, P, K, 2)$, which first sets the K checkpoints and then performs forward sweeps. The amount of memory released when removing a checkpoint is reused for trajectories computations, i.e.,

$$\nu_k \geq \nu_{k+1} \quad \forall\ k \in \{1, \dots, K-1\}.$$

In some sense *Twice* is the lower bound of *Revolve* in terms of computational time and its upper bound in terms of memory requirement.

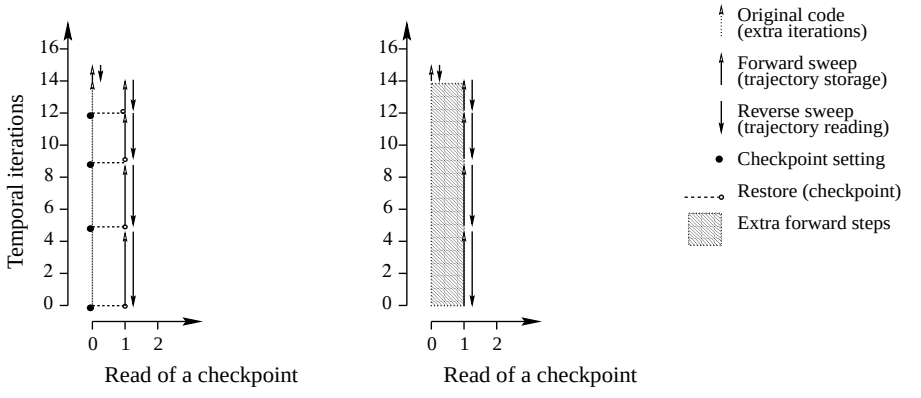

FIG. 3.3. *Reverse integration in a constant space (Twice)* $\{P = 15,\ K = 4,\ and\ \tau = 1\}$.

When $S_C = S$, which is true for Meso-NH (section 3.1), one proves the following.

THEOREM 3.2. *Let P be the number of forward iterations, and let Q be the quantity of available memory.*

1. *The adjoint code is calculable by Twice if and only if integers ν and K are positive and such that*

$$\begin{cases} P \leq \dfrac{\nu(\nu-1)}{2}, \\ \nu S < Q, \\ \dfrac{2\nu - 1 - \sqrt{(2\nu-1)^2 - 8P}}{2} \leq K \leq \nu - 1. \end{cases} \tag{3.7}$$

2. *The computational costs are equal to*

$$\text{(3.8)} \qquad \begin{cases} N_{it} = \displaystyle\sum_{k=1}^{K-1} \nu_k \simeq P, \\ R_{Twice} = N_{it} R_O + P(R_T + R_A) + K R_C, \\ S_{Twice} = \nu S \simeq Q. \end{cases}$$

Proof. Assume that $S = S_C$. Let ν be the largest positive integer such that

$$\nu < \frac{Q}{S}.$$

If $\nu \geq P$, then the adjoint code is computable without the use of a checkpointing algorithm. Otherwise, the construction of ν_k and t_k according to (3.6) obviously implies that

$$\nu_k = \nu - k \quad \forall\ k,\ 0 \leq k < \nu.$$

This means that intervals $[t_{k-1}, t_k]$ (for all $k,\ 0 \leq k < \nu$) are such that

$$\text{(3.9)} \qquad \begin{cases} t_0 = 0, \\ t_k = t_{k-1} + \nu - k = \displaystyle\sum_{l=1}^{k-1} \nu_l + \nu_k = \sum_{l=1}^{k} \nu_l \qquad \forall\ k,\ 0 \leq k < \nu. \end{cases}$$

One observes that *Twice* can perform the backward iterations if and only if there always exists a sufficient amount of memory for the storage of a trajectory of length ν_k, i.e., ν_k needs to be a positive integer for all $k \in \{0, \ldots, \nu - 1\}$. Thus a sequence of P time-steps can be reverted if and only if ν satisfies

$$\text{(3.10)} \qquad P \leq \sum_{l=1}^{\nu-1} (\nu - l) = \sum_{l=1}^{\nu-1} l = \frac{\nu(\nu-1)}{2}.$$

According to ν, the minimum number of checkpoints $K < \nu$ has to satisfy

$$\text{(3.11)} \qquad P \leq \sum_{l=1}^{K} \nu_l = \sum_{l=1}^{K} \nu - l = K\nu - \frac{K(K+1)}{2},$$

i.e.,

$$\text{(3.12)} \qquad \frac{2\nu - 1 - \sqrt{(2\nu-1)^2 - 8P}}{2} \leq K \leq \nu - 1.$$

One derives assertion 2 from the previous results. ∎

It follows that the temporal complexity is independent of P as for *Periodis*, whereas the spatial complexity decreases to $O(\sqrt{P})$.

3.4.1. Bisection method (*Bisection*). For many numerical purposes such as a search in an ordered table, a root finding, or the "all-to-all" parallel communication scheme, it is hard to do better than bisection. For example, it will find the place of any element, in a table of size P, in about $\log_2 P$ tries. One may use a bisection scheme (Figure 3.4) for adjoint calculations, too.

In this section, checkpoints are at least lagged by ν iterations. The number K of checkpoints which are required to revert the sequence of P iterations, and the number of extra forward iterations, are such that

$$\left\{ \begin{array}{l} \log_2\left(\dfrac{P}{\nu}\right) \leq K < \log_2\left(\dfrac{P}{\nu}\right) + 1, \\ N_{it} = \dfrac{KP}{2}. \end{array} \right. \tag{3.13}$$

It follows that the temporal complexity of the *Bisection* schedule is of the order of $P\log(P)$ for a spatial complexity of the order of $\log(P)$. The complexities are equivalent to those of *Revolve*. Nevertheless, due to constants, *Revolve* is better than *Bisection* as far as actual extra forward steps are considered.

A bisection routine may be written as follows.

RECURSIVE ROUTINE *Bisection*(B, E, ν)
IF $(E - B > \nu)$ **THEN**
  $M = (E - B)/2$
  store the checkpoint at time B (if it differs from the current checkpoint)
  run the original model from B to M
  CALL *Bisection*(M, E, ν)
  restore the checkpoint (time B)
  CALL *Bisection*(B, M, ν)
ELSE
  restore the checkpoint (time B)
  compute trajectories and **evaluate** the adjoint from E down to B
  remove the checkpoint (time B) from the stack.
ENDIF

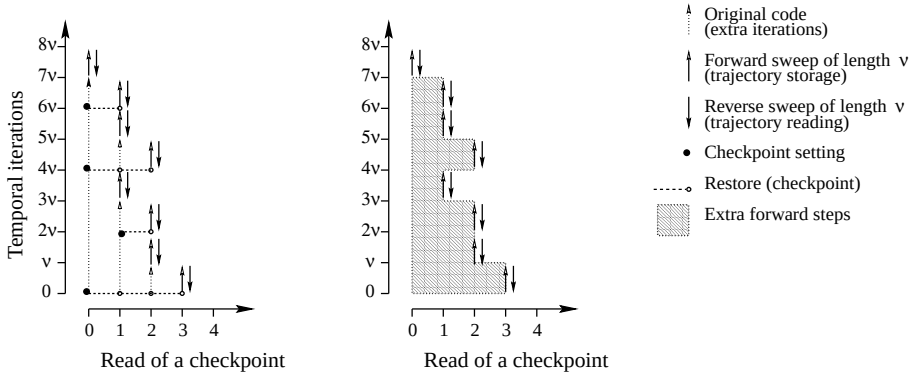

FIG. 3.4. *Bisection scheme.*

4. Leap-frog schemes and differentiation. Let F be a nonlinear differentiable function. The staggered leap-frog method, which allows for solving the equation

$$\frac{\partial X}{\partial t} = F(X) \text{ in } \Omega \times (0, T),$$

is defined as follows. Use the values of X^p at iteration p to compute $(F_j^p)_j = F(X^p)$ on the spatial grid that discretizes Ω. Then compute new values X^{p+1} using the time

centered values of the function F:

$$\left\{\begin{array}{l} X^0 \text{ is given,} \\ X_j^1 - X_j^0 = \Delta t F_j^0, \\ X_j^{p+1} - X_j^{p-1} = 2\Delta t F_j^p \qquad \forall p \in \{1, \ldots, P-1\}. \end{array}\right. \tag{4.1}$$

In the former equations Δt denotes the length of the time-step.

A convenient way to code a leap-frog scheme is to use three variables that, respectively, contain the values of the solution at iterations $p-1$, p, and $p+1$. These variables are denoted, respectively, by X_M, X_T, and X_R. When $p \in \{1, \ldots, P-1\}$, (4.1) may be solved using the following sequence of statements:

$$\left\{\begin{array}{ll} X_R = 2\Delta t F(X_T) + X_M, & \text{computation of the model,} \\ X_M = X_T, & \text{temporal advances,} \\ X_T = X_R. & \end{array}\right. \tag{4.2}$$

The computation of X_R requires the knowledge of X_M and X_T. In particular, a correct restart of a simulation from a checkpoint implies that one has saved the state variables at the previous two iterations.

4.1. Differentiation of a leap-frog scheme. The adjoint model that corresponds to the sequence of statements (4.2) is written as follows:

$$\left\{\begin{array}{l} \widehat{X_R} = \widehat{X_R} + \widehat{X_T}, \\ \widehat{X_T} = 0, \\ \widehat{X_T} = \widehat{X_T} + \widehat{X_M}, \\ \widehat{X_M} = 0, \\ \widehat{X_M} = \widehat{X_M} + \widehat{X_R}, \\ \widehat{X_T} = \widehat{X_T} + 2\Delta t \left[\dfrac{\partial F}{\partial X_T}(X_T)\right]^* \widehat{X_R}, \\ \widehat{X_R} = 0. \end{array}\right. \tag{4.3}$$

Let us assume that the nonlinear term $F(X)$ at iteration p depends only on values of X^p, which is locally equal to X_T in (4.2). Variable X_M enters linearly in the right-hand side of the first equation of (4.2). Therefore, the useful trajectory is limited to X_T. As a consequence, the memory required for the storage of the trajectory (X_T) is twice smaller than the memory required for the storage of the state solution (X_T, X_M) at a checkpoint.

Remark. Systems (4.2) and (4.3) were introduced in order to explain the underlying property of the adjoint of some leap-frog schemes. However, the useful trajectory is limited to X_T even if function F is nonlinear in both X_M and X_T. This is due to the fact that temporal advances assign X_M to X_T, and one can read the trajectory in advance to get X_M: storing X_M and X_T is a redundant task.

4.2. Leap-frog scheme of Meso-NH. In meteorological and oceanic models, time-stepping is achieved by a basic leap-frog scheme associated with an Asselin filter applied at each time-step in order to avoid time splitting. Variables X_M and X_T are filtered using linear combinations of values of X_M, X_T, and X_R:

$$\left\{\begin{array}{ll} X_R = 2\Delta t F(X_T) + X_M, & \text{computation of the model,} \\ X_M = \eta X_M + (1-2\eta) X_T + \eta X_R, & \text{temporal advance with a filter,} \\ X_T = X_R. & \end{array}\right. \tag{4.4}$$

The coefficient η is positive real and $\eta < 0.5$. Checkpoints are again formed by values of X_M and X_T. On the other hand, trajectories require

- X_T if function F is nonlinear in X_T only, and
- (X_M, X_T) if function F is nonlinear in the two variables. This occurs when a numerical horizontal diffusion is applied on the fluctuations of state variables.

The trial simulation presented in section 2.3 satisfies $F = F(X_T)$. Let U, W, Θ, and Φ denote the variables used for the wind fields, the temperature, and the pressure, respectively. These are 3D arrays. Indexes $_M$, $_T$, and $_R$ are used to distinguish iterates. Since the model equations are nonlinear in $X_T = \{U_T,\ W_T,\ \Theta_T\}$ only, the knowledge of X_T is sufficient to evaluate one time-step of the adjoint integration. On the other hand, a restart of the Meso-NH model from a given checkpoint requires the knowledge of the two sets of variables $X_M = \{U_M,\ W_M,\ \Theta_M,\ \Phi_M\}$ and X_T. As a consequence, one has the following ratio:

$$\frac{S_C}{S} = \frac{\text{memory for one checkpoint}}{\text{memory for a trajectory of one step}} = \frac{\#X_M + \#X_T}{\#X_T} = \frac{7}{3},$$

where $\#X_M$ is the cardinal number of the set X_M.

Remark. The variable Φ_T does not belong to X_T because of the anelastic approximation used to solve the pressure equation.

When the code is governed by a leap-frog scheme such as defined before, the size of the useful trajectory may be reduced up to a factor 2. Larger simulations may be tackled without a checkpointing scheme. Otherwise, *Periodis* and *Twice* can easily take into account this property. This allows us to store more time-steps between two successive checkpoints and to run larger simulations. *Revolve* also takes into account the gain in memory related to leap-frog schemes as soon as one implements the original model with mega-steps of length $\nu = 2$ (see [19] for details).

Whatever the chosen scheme is, the gain in memory can be changed into a gain in CPU time since one may run simulations twice longer in terms of iterations.

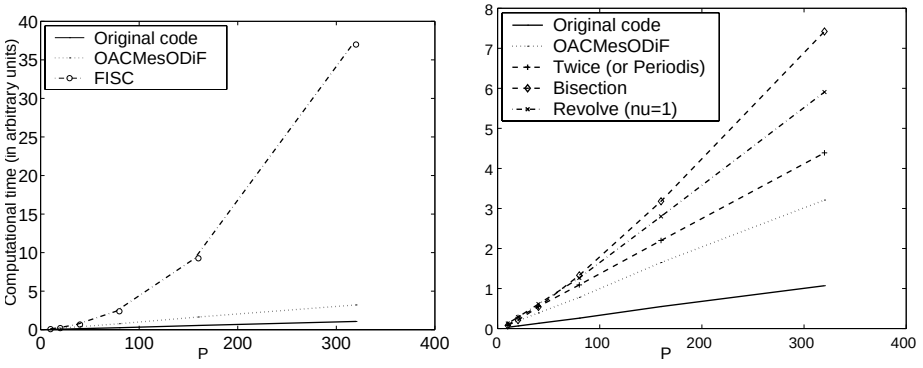
5. Numerical results. The Meso-NH model is used to compare the schemes. The results indicate only the general behavior in CPU time of adjoint computations performed with checkpointing schemes. This choice is relevant when one deals with an optimization process that integrates the adjoint code several times. The reader is referred to [9] for details on the memory requirement of *Revolve*.

5.1. Temporal cost of checkpointing schemes. The following two graphs indicate the computational time in an arbitrary unit spent to evaluate the adjoint code of Meso-NH with respect to the number of iterations $P \in \{10, 20, 40, 80, 160, 320\}$. Checkpoints are set every ν =10 steps for *FISC*, *Periodis*, and *Bisection*.

In order to allow fair comparisons, the same quantity of memory is used for *Bisection* ($\nu_B = 10$, $K_B = \log_2(P/\nu)$) and *Revolve* ($\nu_R = 1$, $K_R = \nu_B + K_B$). *Twice* uses the same amount of memory as *Bisection* as far as $P \leq 160$, whereas $K_T = 18$ checkpoints and a maximal length $\nu_T = 36$ are required to reverse 320 iterations.

The quadratic behavior of *FISC*, computations from the initial state, appears clearly in Figure 5.1. In Figure 5.1 one observes the affine behavior of the two levels scheme *Twice*. The numbers of iterations of *Periodis* and *Twice* differ only by a few units. They almost lead to the same curve because computations were done using a fast access disc. As expected, one obtains the CPU time of these schemes when one adds the CPU time of *OAC-MesODiF* to the CPU time of the original model.

Revolve results are almost similar to those obtained with *Periodis* when using mega-steps of length $\nu = 2$ that are adapted to the leap-frog process. One notices



(a) Quadratic behavior of FISC.

(b) Schemes with a linear or logarithmic behavior.

FIG. 5.1. *Computational time of checkpointing algorithms.*

that the improvement proposed in [19] is important since the results are really better than those obtained using *Revolve* with $\nu = 1$. From a theoretical point of view, the logarithmic growth applies only when parameters K and τ of *Revolve* are chosen according to formula (3.3). One notices that choosing a larger parameter K allows one to reduce the number of extra iterations.

The numerical logarithmic behavior of the bisection scheme is in good agreement with the theory. One observes that *Revolve* ($\nu = 1$) reaches a better compromise between time and memory requirements than *Bisection* ($\nu = 10$). This is a general result (depending on constants) when comparing the two schemes.

5.2. Trial meteorological simulations. Each of the trial meteorological simulations described in section 2.3 can be run with a suitable algorithm. The priority is again given to the CPU time at the expense of the use of a large amount of memory (1.2 giga-words). In Table 5.1 the performances are measured with respect to the number of extra forward steps N_{it}.

TABLE 5.1
Checkpointing scheme for large meteorological simulations.

Simulation	P	Memory (S_C) mega-words	Scheme	(ν, K)	N_{it}
Mount. waves (2D)	3000	2.4	*Twice*	(200,111)	2889
Mount. waves	100	3.3	not necessary		0
Mount. waves (3D)	889	110	*Revolve* ($\nu = 1$)	(4,10)	3192
Baroclin. waves	4320	8.5	*Twice*	(140,140)	4180

6. Conclusions. *Periodis* and *Twice* schemes are easy to implement and are good in terms of computational time since the evaluation of the adjoint code requires only two integrations of the original code: one for setting the checkpoints and another one for the construction of each of the K parts of the trajectory.

It appears that the evaluation of the adjoint code of the meteorological model Meso-NH can usually be realized with the *Twice* scheme. This is especially true when the iterative scheme of the model is governed by a leap-frog method as described in section 4. However, one notices that *Revolve* [19] always offers an optimal solution.

In the examples it appears that the ratio between the CPU time of the calculation of one gradient with the adjoint code of Meso-NH and the CPU time of the evaluation of the original model is equal to

- 3 when *OAC-MesODiF* applies (the amount of memory is sufficient to store all the trajectory),
- 4 when one has enough memory to run *Twice* or *Revolve* $(1, P, K, 2)$ $(\nu = 2)$,
- 5.6 for the 3D mountain waves simulation described in Tables 2.2 and 5.1 when using Griewank's *Revolve* subroutine $(\nu = 1)$.

In conclusion, checkpointing algorithms allow for gradient computations of applications that require the storage of large trajectories.

A SEMI-LAGRANGIAN FINITE VOLUME METHOD FOR NEWTONIAN CONTRACTION FLOWS *

T. N. PHILLIPS† AND A. J. WILLIAMS‡

Abstract. A new finite volume method for solving the incompressible Navier–Stokes equations is presented. The main features of this method are the location of the velocity components and pressure on different staggered grids and a semi-Lagrangian method for the treatment of convection. An interpolation procedure based on area-weighting is used for the convection part of the computation. The method is applied to flow through a constricted channel, and results are obtained for Reynolds numbers, based on half the flow rate, up to 1000. The behavior of the vortex in the salient corner is investigated qualitatively and quantitatively, and excellent agreement is found with the numerical results of Dennis and Smith [*Proc. Roy. Soc. London A*, 372 (1980), pp. 393–414] and the asymptotic theory of Smith [*J. Fluid Mech.*, 90 (1979), pp. 725–754].

Key words. semi-Lagrangian approach, Navier–Stokes, finite volume method, contraction geometry, staggered mesh, SIMPLER algorithm

1. Introduction.

In this paper a semi-Lagrangian finite volume method is presented for solving incompressible flows of Newtonian fluids. This approach is shown to be particularly well suited to solving the Navier–Stokes equations for which the discretization of the governing equations is well known to be crucial when the flow is convection dominated. Numerical difficulties can occur for large values of the Reynolds number, a nondimensional quantity which measures the relative importance of convection compared to diffusion. Central difference schemes, which perform well for low Reynolds number flows, are prone to numerical difficulties for higher Reynolds numbers. For low Reynolds numbers central difference schemes produce a diagonally dominant system of equations which can be solved without any difficulty using standard relaxation techniques. At higher Reynolds numbers diagonal dominance is lost with the result that one can encounter problems using the same schemes. These difficulties can manifest themselves in several ways. For example, relaxation techniques may fail to converge, and if a solution is obtained for the steady problem, it may exhibit physically unrealistic oscillations.

A popular finite volume approach for overcoming the difficulties associated with the treatment of convection uses interpolation biased towards the upwind direction when the flow is convection dominated. Low-order interpolation invariably results in artificial or false diffusion being added to the scheme. The effect of this is a degradation in accuracy. Higher-order interpolation schemes such as quadratic upwind interpolation for convection kinematics (QUICK) [6] and SMART [9] increase the complexity of the scheme and create difficulties near boundaries. In the presence of high gradients, they may additionally produce overshoot or undershoot values. Nonlinear flux limiting functions may be used in conjunction with high-order upwinding

techniques to prevent the appearance of over- or undershoots. The underlying idea behind these techniques is to control the gradients of the computed solution through the use of total variation diminishing schemes (TVD) schemes (see Hirsch [1] for a comprehensive review of this subject). It is the treatment of convection together with the positioning of the mesh points that distinguish one finite volume method from another.

In time-dependent calculations standard finite volume schemes possess time-step restrictions due to stability. These may be more severe than the conditions imposed by accuracy considerations alone. When particle following techniques are used the stability conditions are much less restrictive. However, the unrestricted movement of the points used in Lagrangian methods, which involves following a fixed set of particles throughout the flow, introduces other difficulties. For example, a set of fluid particles which is initially regularly distributed soon becomes greatly deformed, in general, and is thus rendered unsuitable for numerical integration. Semi-Lagrangian methods avoid this difficulty while still following particles. A semi-Lagrangian method for treating the convection term, in which particles on a regular grid of points are traced backwards over a single time-step to their departure points, provides the focus of this paper. Although semi-Lagrangian finite volume methods have been developed for advection problems [22, 24, 25], this paper describes their application to problems in Newtonian computational fluid dynamics. This scheme circumvents the problems associated with upwind biased interpolation schemes, possesses less restrictive stability requirements, and combines the advantages of fixed grids inherent in Eulerian methods with modifications to the location of grid points at previous time-steps based on the Lagrangian approach.

The remaining terms in the governing equations are treated implicitly and are discretized by integrating over an appropriate control volume. The discrete equations are solved using the semi-implicit method for pressure linked equations revised (SIMPLER) [19] algorithm. Therefore, this approach may be viewed as a time-splitting scheme in which the different operators in the governing equations are discretized by appropriate techniques.

The emphasis in this paper is on the semi-Lagrangian treatment of convection. This can only be accomplished within the framework of time-splitting schemes for time-dependent problems. Therefore, the proposed semi-Lagrangian finite volume method is described for time-dependent problems even though, in this paper, it is only used as a means of reaching the steady state solution. The temporal accuracy of the scheme depends on the discretization of the characteristic paths as well as the temporal discretization of the governing equations. Since a first-order scheme is used for the latter, there is no advantage in using a higher-order scheme for the characteristic calculation. The development of high-order discretizations for all the component parts of the proposed scheme is an area of ongoing activity.

The important features of the method are illustrated on a pure convection problem before it is applied to the flow through an abruptly contracting channel in which the ratio of the channel widths before and after the contraction is 2:1. Numerical results are presented for Reynolds numbers in the range [0,1000]. The behavior of the vortex in the salient corner is investigated, and comparisons are made with other results in the literature. Smith [12] developed an asymptotic theory for the flow upstream of the contraction. Good agreement is shown with this theory for the location of the upstream separation point for Reynolds numbers greater than about 100. The size of the salient corner vortex decreases as the Reynolds number increases from 0 to around

50. As the Reynolds number is increased further, the vortex grows slowly.

This paper is organized as follows. In section 2 the governing equations and flow geometry are described. The location of the dependent variables on a staggered grid and the conventional finite volume discretization of the governing equations are described in section 3. In section 4 we describe the semi-Lagrangian treatment of the convection terms. In section 5 we show how this is incorporated into a solution procedure for solving the Navier–Stokes equations based on the SIMPLER algorithm. Numerical results and comparisons with other work are presented in section 6. Finally, concluding remarks are made in section 7.

2. Governing equations. We consider the laminar flow of an incompressible fluid of viscosity η through an abruptly contracting channel with walls at $y = \pm 1$ for $x < 0$, $y = \pm\frac{1}{2}$ for $x > 0$, and $\frac{1}{2} \leq |y| \leq 1$ for $x = 0$. A schematic diagram of the lower half of this geometry is shown in Figure 1. Upstream of the contraction we impose parabolic Poiseuille flow, and we suppose that the flow is parabolic again far enough downstream. Since the flow is symmetric about $y = 0$, it is only necessary to seek a solution for $y \leq 0$.

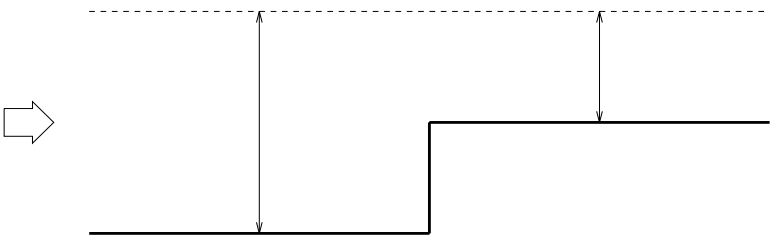

FIG. 1. *Geometry for the* 2:1 *planar contraction.*

The time-dependent Navier–Stokes equations are

$$\rho\left[\frac{\partial \boldsymbol{u}}{\partial t} + \boldsymbol{u}.\nabla\boldsymbol{u}\right] = \eta\nabla^2\boldsymbol{u} - \nabla p, \tag{2.1}$$

$$\nabla.\boldsymbol{u} = 0, \tag{2.2}$$

where $\boldsymbol{u} = (u, v)$ is the velocity vector, p is the pressure, and ρ is the density. Nondimensional quantities are defined as

$$\boldsymbol{x}^* = \frac{\boldsymbol{x}}{L}, \quad t^* = \frac{Ut}{L}, \quad \boldsymbol{u}^* = \frac{\boldsymbol{u}}{U}, \quad p^* = \frac{p}{\rho U^2},$$

where U is a characteristic flow speed and L is a characteristic length scale of the flow. With the Reynolds number, Re, defined by

$$Re = \frac{\rho U L}{\eta},$$

we may write the Navier–Stokes equations in dimensionless form. In two-dimensional

component form they are

$$\frac{\partial u}{\partial t} + u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y} = \frac{1}{Re}\left[\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2}\right] - \frac{\partial p}{\partial x}, \tag{2.3}$$

$$\frac{\partial v}{\partial t} + u\frac{\partial v}{\partial x} + v\frac{\partial v}{\partial y} = \frac{1}{Re}\left[\frac{\partial^2 v}{\partial x^2} + \frac{\partial^2 v}{\partial y^2}\right] - \frac{\partial p}{\partial y}, \tag{2.4}$$

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0, \tag{2.5}$$

where we have dropped the $*$ notation for ease of notation.

For the contraction problem the characteristic length scale (L) is chosen to be the downstream half-channel width, and the characteristic flow speed (U) is chosen to be the mean velocity across half of the downstream channel. Therefore, the boundary conditions are given by

$$\boldsymbol{u} = 0 \quad \text{on} \quad y = \begin{cases} -1 & \text{for } x \le 0, \\ -\frac{1}{2} & \text{for } x \ge 0, \end{cases}$$

$$\boldsymbol{u} = 0 \quad \text{on} \quad x = 0 \text{ for } -1 \le y \le -\frac{1}{2},$$

$$v = 0, \frac{\partial u}{\partial y} = 0 \quad \text{on} \quad y = 0,$$

$$u \to \frac{3}{2}(1 - y^2),\ v \to 0 \quad \text{as} \quad x \to -\infty,$$

$$u \to 3(1 - 4y^2),\ v \to 0 \quad \text{as} \quad x \to \infty.$$

3. Finite volume discretization. The finite volume method is generally applied to a system of differential equations written in conservation form, e.g.,

$$\frac{\partial \boldsymbol{w}}{\partial t} + \frac{\partial \boldsymbol{f}}{\partial x} + \frac{\partial \boldsymbol{g}}{\partial y} = \boldsymbol{S}, \tag{3.1}$$

where $\boldsymbol{w}$ is the vector of unknowns, $\boldsymbol{f}$ and $\boldsymbol{g}$ are vector functions of $\boldsymbol{x} = (x, y)$, $\boldsymbol{w}$, and $\nabla \boldsymbol{w}$, and $\boldsymbol{S}$ is the source term. In this paper we consider cell center finite volume methods. These methods are closely related to finite difference methods.

A grid is placed on the computational domain, and a control or finite volume is associated with each unknown on the grid. Each component equation of (3.1) is integrated over the appropriate control volume. Finite difference type approximations are then used to approximate line integrals over each side of the control volume. There is a number of ways of doing this, each leading to a numerical scheme satisfying certain properties. In the finite volume formulation mass and momentum are conserved over every control volume and therefore over the whole computational domain. The property of conservation of physical quantities, which is preserved by the discrete system, is one of the attractions and advantages of the finite volume method.

A staggered grid is used in which the different dependent variables are approximated at different mesh points (see Figure 2). This type of mesh arrangement ensures that the solution is not polluted by spurious pressure modes. On a nonstaggered mesh the familiar checkerboard mode is present.

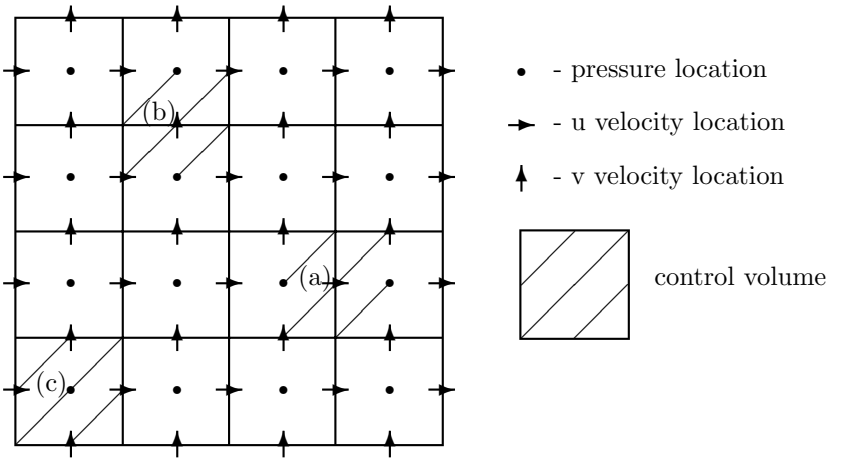

FIG. 2. *A staggered grid depicting the control volumes for* (a) *u-momentum equation,* (b) *v-momentum equation, and* (c) *continuity equation.*

TABLE 1
Definition of the symbols in the general equation (3.2).

Equation	ϕ	δ	Γ	S_ϕ
u-momentum	u	1	$(Re)^{-1}$	$-\frac{\partial p}{\partial x}$
v-momentum	v	1	$(Re)^{-1}$	$-\frac{\partial p}{\partial y}$
continuity	1	0	0	0

Each of the governing equations (2.3)–(2.5) can be cast into the general conservative form

$$\delta\frac{\partial\phi}{\partial t}+\frac{\partial}{\partial x}\left(u\phi-\Gamma\frac{\partial\phi}{\partial x}\right)+\frac{\partial}{\partial y}\left(v\phi-\Gamma\frac{\partial\phi}{\partial y}\right)=S_\phi, \tag{3.2}$$

where δ and Γ are constants and ϕ and S_ϕ are functions that are defined depending on the particular equation under consideration (see Table 1).

Equation (3.2) is discretized in time using the backward Euler method with time-step Δt to give

$$\frac{\partial}{\partial x}\left(u\phi^{n+1}-\Gamma\frac{\partial\phi^{n+1}}{\partial x}\right)+\frac{\partial}{\partial y}\left(u\phi^{n+1}-\Gamma\frac{\partial\phi^{n+1}}{\partial y}\right)=S_\phi^{n+1}-\frac{\delta}{\Delta t}(\phi^{n+1}-\phi^n), \tag{3.3}$$

where ϕ^{n+1} denotes the approximation to the variable ϕ at the $(n+1)$th time-step. Note that this semidiscrete scheme can be used as the basis for determining solutions to transient or steady problems.

The finite volume methodology proceeds by integrating (3.3) over a control volume

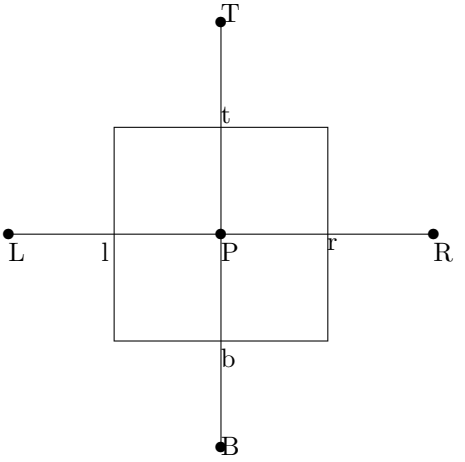

FIG. 3. *A general control volume.*

(see Figure 3, for example) and using the divergence theorem. This yields the equation

$$\begin{aligned}\int_b^t \left[\left(u\phi^{n+1} - \Gamma\frac{\partial\phi^{n+1}}{\partial x}\right)_r - \left(u\phi^{n+1} - \Gamma\frac{\partial\phi^{n+1}}{\partial x}\right)_l\right] dy \\ + \int_l^r \left[\left(v\phi^{n+1} - \Gamma\frac{\partial\phi^{n+1}}{\partial y}\right)_t - \left(v\phi^{n+1} - \Gamma\frac{\partial\phi^{n+1}}{\partial y}\right)_b\right] dx \\ = \int_b^t\int_l^r \left[S_\phi^{n+1} - \frac{\delta}{\Delta t}(\phi^{n+1} - \phi^n)\right] dxdy. \end{aligned} \tag{3.4}$$

Each of the integral terms on the left-hand side of (3.4) represents a transport by convection and diffusion through the relevant control-volume face. All schemes use central differences to approximate the diffusive flux across each face. For example, across the vertical face passing through the point r we have

$$\left(\frac{\partial\phi}{\partial x}\right)_r \simeq \frac{\phi_R - \phi_P}{\Delta x}. \tag{3.5}$$

It is the approximation of the convective flux which differentiates one finite volume scheme from another. We shall review briefly some of the common approaches, many of which are based on some form of upwinding to retain accuracy and stability when convection dominates diffusion.

A central difference approximation to the convective flux would take the form

$$(u\phi^{n+1})_r \simeq u_r^n \frac{(\phi_R^{n+1} + \phi_P^{n+1})}{2}, \tag{3.6}$$

for example. Note that the velocity component u is frozen at its value from the previous time-step. In steady calculations it would be frozen at its value from the previous iteration since iterative methods are generally used to solve the algebraic equation resulting from a finite volume discretization. Therefore, in the case of the u-momentum equation, we arrive at the discretization

$$\begin{aligned} A_P u_P^{n+1} = A_R u_R^{n+1} + A_L u_L^{n+1} + A_T u_T^{n+1} + A_B u_B^{n+1} \\ + \frac{u_P^n \Delta x \Delta y}{\Delta t} + (p_l^{n+1} - p_r^{n+1})\Delta y, \end{aligned} \tag{3.7}$$

where

$$A_R = -\frac{F_r}{2} + D_r,$$
$$A_L = \frac{F_l}{2} + D_l,$$
$$A_T = -\frac{F_t}{2} + D_t,$$
$$A_B = \frac{F_b}{2} + D_b,$$
$$A_P = A_R + A_L + A_T + A_B + F_r - F_l + F_t - F_b + \frac{\Delta x \Delta y}{\Delta t}, \tag{3.8}$$

and $F_r = u_r^n \Delta y$, $D_r = \frac{1}{Re}\frac{\Delta y}{\Delta x}$, etc.

The local truncation error for the central-difference approximation is second-order. An essential requirement for a bounded solution is that all the coefficients A_{nb}, where the subscript nb refers to the neighbors of P, should be of the same sign, usually all positive. If the resulting system of equations is diagonally dominant, then many of the standard iterative methods can be used, and convergence is guaranteed. This property is assured, and oscillatory solutions arising from negative roots to the characteristic equation are prevented, if the following conditions are satisfied:

$$A_{nb} > 0 \quad \text{and} \quad A_P \geq -(A_R + A_L + A_T + A_B). \tag{3.9}$$

However, looking at the coefficients given in (3.8), we see that in some circumstances some coefficients A_{nb} may become negative. Thus for convergence to be guaranteed we require the mesh Peclet number given by

$$Pe = \frac{F}{D},$$

where $F = u\Delta y$ and $D = \frac{1}{Re}\frac{\Delta y}{\Delta x}$, to be less than 2 in order to satisfy this boundedness criterion, i.e.,

$$u\, Re \Delta x < 2,$$

or

$$\Delta x < \frac{2}{u\, Re}. \tag{3.10}$$

Similarly, we also require

$$\Delta y < \frac{2}{v\, Re}. \tag{3.11}$$

For $Pe > 2$ the scheme may converge but to physically unrealistic solutions. This means that the central-difference method is limited to low values of Re unless the mesh is suitably refined so that conditions (3.10) and (3.11) are satisfied. Since this would be computationally expensive, the central-difference technique is not suitable for convection-dominated flow problems.

From a physical point of view central difference schemes are not suitable for convection dominated problems because the direction of the flow is not used in the derivation of the approximation. The upwind scheme takes this into account and

proposes that the value of u at the interface is equal to the value of u at the grid point on the upwind side of the face, i.e.,

$$u_r^{n+1} = \begin{cases} u_P^{n+1} & \text{if } u_r^n > 0, \\ u_R^{n+1} & \text{if } u_r^n < 0. \end{cases} \tag{3.12}$$

This approximation again leads to an equation of the form (3.7), but now the coefficients satisfy the boundedness criterion (3.9) for all Reynolds numbers. The local truncation error for the upwind scheme is first order. Since the upwind scheme is simple to use, it has been widely applied in applications in computational fluid dynamics. It is easily extended to three-dimensional problems. However, a major drawback with the scheme is that it causes the distribution of the transported properties to become smeared, particularly when the flow is not aligned with the grid lines. The error has a diffusion-like appearance and is referred to as artificial diffusion. Refinement of the grid can overcome this problem, but it is expensive. At high Reynolds numbers the error due to artificial diffusion can be large enough to give physically incorrect results.

In an attempt to reduce the amount of false diffusion present in the simple upwind scheme and to improve the overall accuracy of the finite volume scheme Leonard [6] introduced the QUICK scheme to approximate the convective fluxes. This scheme is based on the use of a second degree polynomial biased toward the upstream direction to interpolate the value of the dependent variable, u_r, at each face of the control volume.

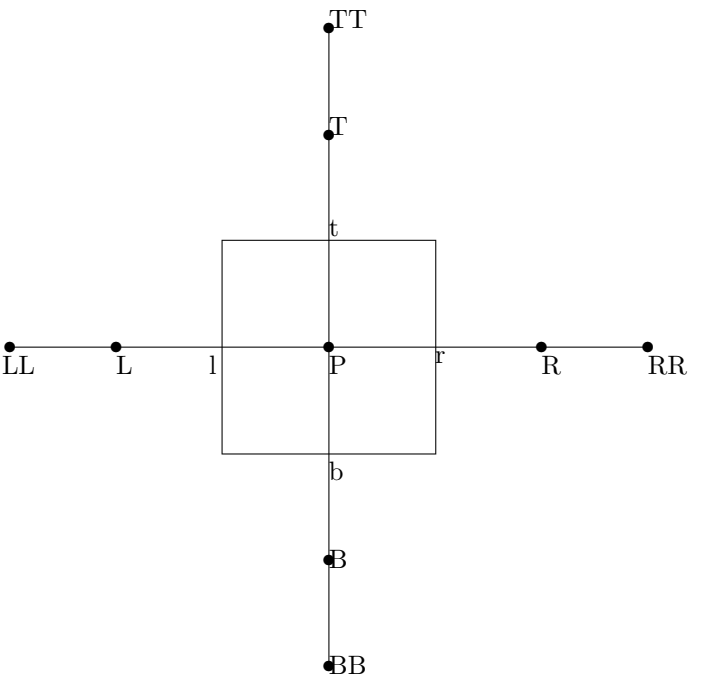

FIG. 4. *A control volume for use with the QUICK scheme.*

This leads to a third order approximation possessing a larger stencil as shown in Figure 4. A drawback of the scheme is that the coefficients corresponding to points R, L, T, and B are not guaranteed to be positive and the coefficients corresponding to points RR, LL, TT, and BB are negative. Thus the QUICK scheme is only

conditionally stable, and there is a tendency for QUICK to give oscillatory results. Furthermore, the conversion of this method to a three-dimensional scheme is likely to cause more difficulties than the upwind method due to the extra terms in the momentum equations.

In this paper we have pursued an entirely different approach to the treatment of convection. Instead of using upwinding to stabilize the scheme at moderate values of the Reynolds number, we have chosen to treat convection in a semi-Lagrangian manner. This is described in the next section.

4. A semi-Lagrangian approach. The underlying problem with the traditional finite volume treatment of convection diffusion problems is that the convection term is discretized using what is essentially a technique that has been constructed and tested for diffusion problems. Upwinding attempts to redress the situation as far as convection is concerned by giving some weighting to the convection part of the problem. The approach adopted in this paper is a time-splitting technique in which we decouple the treatment of convection and diffusion and use appropriate methods of discretization for each subproblem. Over each time interval $[t_n, t_{n+1}]$ we solve a convection equation of the form

$$\frac{\partial \boldsymbol{u}}{\partial t} + \boldsymbol{u}^n.\nabla \boldsymbol{u} = 0, \tag{4.1}$$

followed by the solution of an unsteady generalized Stokes problem

$$\frac{\partial \boldsymbol{u}}{\partial t} - \frac{1}{Re}\nabla^2 \boldsymbol{u} + \nabla p = 0, \tag{4.2}$$

$$\nabla.\boldsymbol{u} = 0. \tag{4.3}$$

The natural frame of reference in which to solve (4.1) is defined by the particle following transformation

$$\begin{aligned} \frac{d\xi(t)}{dt} &= u^n(\xi(t), \eta(t), \tau), \\ \frac{d\eta(t)}{dt} &= v^n(\xi(t), \eta(t), \tau), \\ \frac{d\tau(t)}{dt} &= 1, \end{aligned} \tag{4.4}$$

where ξ and η are the spatial variables and τ is the temporal variable. For $\mathbf{x} = (x, y) \in \mathrm{R}^2$ the solution of the system of ordinary differential equations (4.4) for $t \in [t_n, t_{n+1}]$ subject to

$$\xi(t_{n+1}) = x, \quad \eta(t_{n+1}) = y, \quad \tau(t_{n+1}) = t_{n+1}, \tag{4.5}$$

is a continuous curve, known as the trajectory, in space-time passing through the point (x, y, t_{n+1}). After applying a transformation which satisfies (4.4), the governing equation for $\mathbf{u}$ becomes

$$\frac{d\mathbf{u}}{d\tau}(\xi, \eta, \tau) = 0. \tag{4.6}$$

Thus smooth solutions of (4.1) are constant along the characteristic paths [18].

In this section we concentrate on the novel features of our finite volume scheme which is the discretization of (4.1) using a semi-Lagrangian approach. This approach

differs from that proposed by Manson and Wallis [25]. The scheme of Manson and Wallis [25] was developed for pure advection problems in one dimension and is based on a fractional-staged strategy that combines a conventional control volume discretization over a partial time-step $\tau\Delta t$ $(0 < \tau < 1)$ with a semi-Lagrangian treatment over the partial time-step $(1-\tau)\Delta t$. The value of τ is chosen to avoid the need for interpolation in the semi-Lagrangian part of the calculation. The solution of (4.2) and (4.3) follows standard finite volume methodology. The discrete formulation of this problem can be solved using the SIMPLER approach, for example.

The computational domain is partitioned into a number of nonoverlapping control volumes or cells, $C_{i,j}$. This grid, known as the reference grid, remains fixed in space for all time. Consider the mesh associated with one of the dependent variables, ϕ, say, where $\phi = u$ or v. Let $C_{i,j}$ be one such control volume. Let the positions of the corners of cell $C_{i,j}$ be located at the points $\mathbf{X}_{i\pm1/2,j\pm1/2} = (x_{i\pm1/2}, y_{j\pm1/2})$. Particles which arrive at these four corner points at time $t = t_{n+1}$ were located at the vertices of some cell, which is to be determined as part of the solution process, at time $t = t_n$. In general, this will be a deformed control volume which may lie anywhere on the underlying grid or indeed outside the domain if the time-step is sufficiently large. We approximate this cell by a quadrilateral $C^{*n}_{i,j}$, formed by joining the departure points by straight line segments.

Associated with each cell $C_{i,j}$ at each time $t_n = n\Delta t$ an approximation is introduced, denoted by $\bar{\phi}^n_{i,j}$, to the cell average of $\phi(x, y, t_n)$, i.e.,

$$\phi^n_{i,j} \approx \frac{1}{\Delta x_i \Delta y_j} \iint_{C_{i,j}} \phi(x, y, t_n)\, dxdy, \tag{4.7}$$

where

$$\Delta x_i = x_{i+1/2} - x_{i-1/2}, \quad \Delta y_j = y_{j+1/2} - y_{j-1/2}.$$

Note that $\phi^n_{i,j}$ will, in general, be distinct from the pointwise approximation to $\phi(x_i, y_j, t_n)$.

An approximation to the solution of (4.1) is given by

$$\bar{\phi}^{n+1}_{i,j} = \bar{\phi}^{*n}_{i,j}, \tag{4.8}$$

where

$$\bar{\phi}^{*n}_{i,j} \approx \frac{1}{\Delta x_i \Delta y_j} \iint_{C^{*n}_{i,j}} \phi(x, y, t_n)\, dxdy. \tag{4.9}$$

Thus there are two stages to the numerical calculation at each time-step. In the first stage the departure points are determined. These are the vertices of the cells $C^{*n}_{i,j}$. In the second stage the cell average values of ϕ^{*n} are determined from a knowledge of the cell average values of ϕ at time $t = t_n$ on the reference grid. These values are then inserted into the discretized versions of equations (4.2) and (4.3) in order to determine the values of velocity and pressure at the new time-step.

4.1. Calculation of departure points. The departure points at time t_n of each point on the reference grid are determined by solving the particle following transformation (4.4) for $t \in [t_n, t_{n+1}]$, subject to

$$\xi(t_{n+1}) = x_{i+\frac{1}{2},j+\frac{1}{2}}, \quad \eta(t_{n+1}) = y_{i+\frac{1}{2},j+\frac{1}{2}}, \quad \tau(t_{n+1}) = t_{n+1}. \tag{4.10}$$

This computation is performed for each grid point, i.e., for a suitable range of values of i and j in (4.10). The solution of this problem describes the path of the particle that passes through the grid point

$$\mathbf{X}_{i+\frac{1}{2},j+\frac{1}{2}} = (x_{i+\frac{1}{2},j+\frac{1}{2}}, y_{i+\frac{1}{2},j+\frac{1}{2}})$$

at time $t = t_{n+1}$. Each of these paths is traced backwards in time over one time-step. For example, if $C_{i,j}$ represents a control volume for the u component of velocity, then the following one-step method may be used to determine the positions of the corners of $C^{*n}_{i,j}$:

$$\begin{aligned} x^{*n}_{i+\frac{1}{2},j+\frac{1}{2}} &= x^{n+1}_{i+\frac{1}{2},j+\frac{1}{2}} - \frac{\Delta t}{4}(u^n_{i,j} + u^n_{i+1,j} + u^n_{i,j+1} + u^n_{i+1,j+1}), \\ y^{*n}_{i+\frac{1}{2},j+\frac{1}{2}} &= y^{n+1}_{i+\frac{1}{2},j+\frac{1}{2}} - \Delta t v^n_{i+\frac{1}{2},j+\frac{1}{2}}, \end{aligned} \tag{4.11}$$

where subscripts indicate grid locations and superscripts indicate the time-step. The above scheme is first-order in time. Higher-order schemes in time may also be used.

4.2. Calculation of area-weighting coefficients. At the beginning of each time-step the values of $\phi^n_{i,j}$ are known in all control volumes. Given the location of the departure points of the reference grid at time t_n, the values $\phi^{*n}_{i,j}$ must be determined. This approximation is generated by means of an area-weighting technique which uses a weighted sum of the values of ϕ^n over the control volumes on the reference grid which overlap with cell $C^{*n}_{i,j}$. Area-weighting techniques are not new, and they have been demonstrated to possess attractive stability properties. They were originally developed by users of particle-in-cell methods [21, 20]. In the Lagrange–Galerkin finite element method the evaluation of inner products using nonexact integration must be performed with great care [3]. Large classes of well-known quadrature rules lead to conditionally unstable schemes. However, the use of area-weighting can restore the stability properties of the exactly integrated schemes, albeit with a slight degradation in accuracy. In the application of this technique the centroid of each element is tracked, and the whole element is deemed to move without distortion and rotation. However, in the present application of the technique the control volumes are allowed to move with distortion and rotation.

The first-order area-weighting scheme of Scroggs and Semazzi [4] for determining the value of $\phi^{*n}_{i,j}$ is

$$\phi^{*n}_{i,j} = \frac{1}{\Delta x_i \Delta y_j} \sum_{I,J \in Z} \omega^{I,J}_{i,j} \bar{\phi}^n_{I,J}, \tag{4.12}$$

where $\omega^{I,J}_{i,j}$ is the common area between $C^{*n}_{i,j}$ and $C_{I,J}$, i.e., the area of $C_{I,J} \cap C^{*n}_{i,j}$, and Z is the set of indices of all the points in the computational domain. This involves determining how the cell $C^{*n}_{i,j}$ intersects with the control volumes in the fixed grid at time t_n and then to perform an area weighting based on the amount of overlap. Although this procedure is a straightforward exercise in coordinate geometry, it requires careful programming. Details can be found in Williams [17]. This scheme possesses the important property that when it is applied to systems of conservation laws the numerical approximation preserves the discrete conservation property identically, i.e.,

$$\sum_{i,j \in Z} u^{*n}_{i,j} = \sum_{i,j \in Z} u^{n+1}, \tag{4.13}$$

if the boundaries of each control volume $C_{I,J}$ remain inside the computational domain from time t_n to t_{n+1} since

$$\sum_{i,j\in Z} \omega_{i,j}^{I,J} = \text{area of } C_{I,J}. \tag{4.14}$$

Higher-order extensions of this scheme have been derived by Phillips and Williams [16] and have been applied to conservation laws. In particular, Phillips and Williams [16] apply the first-order and higher-order schemes to a rotating disk test problem. The results which have been obtained fully demonstrate the conservation properties of all the schemes.

5. Stability and accuracy. In this section we investigate the stability and convergence properties of the semi-Lagrangian scheme on a pure convection problem in one space dimension. Consider the scalar conservation law

$$\frac{\partial \phi}{\partial t} + a\frac{\partial \phi}{\partial x} = 0, \quad x \in \mathrm{R},\ 0 < t < T, \tag{5.1}$$

where a is a function of x and t, and T is some finite time, with the initial condition

$$\phi(x,0) = \phi_0(x), \quad x \in \mathrm{R}. \tag{5.2}$$

Assume a uniform distribution of grid points $\{x_j : j \in \mathrm{Z}\}$ in the x direction with $x_j = jh$. The discretization of this equation using the semi-Lagrangian scheme (4.8) and (4.12) is

$$\bar{\phi}_j^{n+1} = \bar{\phi}_j^{*n}, \tag{5.3}$$

where

$$\bar{\phi}_j^{*n} = \hat{\alpha}\bar{\phi}_{j-m-1}^{n} + (1-\hat{\alpha})\bar{\phi}_{j-m}^{n}, \tag{5.4}$$

where

$$\hat{\alpha} = \alpha - m,\ \alpha = \frac{a_j^{n+1}\Delta t}{h}.$$

Here we have assumed, without loss of generality, that the departure point at time $t = t_n$ of the particle which is at the point x_j at time $t = t_{n+1}$ lies in the interval $[x_{j-m-1}, x_{j-m}]$. Note that area-weighting in one dimension involves no more than linear interpolation using the information at the two nearest grid points.

Note. If $a(x,t)$ is not constant, then the characteristic path is not a straight line. In this case an error is incurred in locating the departure point. This contributes to the overall global error of the approximation. Furthermore, if $a(x,t)$ varies rapidly in the domain $x \in \mathrm{R}$, $0 < t < T$, then it is necessary to choose Δt sufficiently small so that the computed and the actual departure points of the characteristic passing through the point x_i at time t_{n+1} lie in the same reference cell.

5.1. Stability. The stability analysis is performed in the case when a is a positive constant. If we assume that (5.3)–(5.4) has a solution of the form

$$\bar{\phi}_j^n = \bar{\phi}^0 \lambda^n \exp(ikjh), \tag{5.5}$$

then we can show that λ is given by

$$\lambda = [1 - \hat{\alpha}(1 - \exp(-ikh))] \exp(-ikmh). \tag{5.6}$$

One can show the sufficient condition for stability, i.e., $|\lambda|^2 \leq 1$, is satisfied when

$$0 \leq \hat{\alpha} \leq 1.$$

This condition is satisfied since we have chosen the interval $[x_{j-m-1}, x_{j-m}]$ so that the departure point lies in it. So the scheme is unconditionally stable.

5.2. Convergence. We define the Sobolev space $W^{2,\infty}(\mathrm{R})$ by

$$W^{2,\infty}(\mathrm{R}) = \left\{ \psi : \sup_{x \in \mathrm{R}} \left| \frac{\partial^2 \psi}{\partial x^2} \right| < \infty \right\}$$

with corresponding seminorm

$$\|\psi\|_{2,\infty} \;=\; \sup_{x \in \mathrm{R}} \left| \frac{\partial^2 \psi}{\partial x^2} \right|.$$

Similarly, we define $W^{2,\infty}(\mathrm{R} \times [0,T])$ to be the space of functions with bounded second derivatives in $\mathrm{R} \times [0,T]$. We denote by $L^\infty(0,T;W^{2,\infty}(\mathrm{R}))$ the space of functions $\psi(x,t)$ defined in $\mathrm{R} \times [0,T]$ that belong to $W^{2,\infty}(\mathrm{R})$ for any $t \in [0,T]$ and that satisfy

$$\operatorname{ess} \sup_{t \in [0,T]} \|\psi(\cdot,t)\|_{2,\infty} < \infty.$$

This space is equipped with the norm

$$\|\psi\|_{L^\infty(0,T;W^{2,\infty}(\mathrm{R}))} = \operatorname{ess} \sup_{t \in [0,T]} \|\psi(\cdot,t)\|_{2,\infty}.$$

The following convergence result is proved in Phillips and Williams [16].

THEOREM 5.1. *Let the solution of* (5.1) *belong to*

$$W^{2,\infty}(\mathrm{R} \times [0,T]) \;\cap\; L^\infty(0,T;W^{2,\infty}(\mathrm{R})),$$

and let the numerical approximation be generated by (5.3)– (5.4). *Then the error* $e_j^n = \phi(x_j,t_n) - \bar{\phi}_j^n$ *satisfies the bound*

$$\|e^n\|_\infty = O(\Delta t) + O(\min(h, h^2/\Delta t)). \tag{5.7}$$

One can deduce from this result that for some values of the discretization parameters h and Δt the error will increase as Δt is reduced up to a maximum error which is $O(\Delta t)+O(h)$. This behavior of the error as a function of the time-step Δt is in general agreement with a result of Süli and Ware [7] for the spectral method of characteristics for a similar class of problems.

6. Method of solution. The generalized Stokes problem

$$\frac{\boldsymbol{u}^{n+1} - \boldsymbol{u}^{*n}}{\Delta t} = \frac{1}{Re} \nabla^2 \boldsymbol{u}^{n+1} - \nabla p^{n+1}, \tag{6.1}$$

$$\nabla . \boldsymbol{u}^{n+1} = 0, \tag{6.2}$$

with given boundary conditions on $\boldsymbol{u}^{n+1}$ is discretized using the traditional central difference approach described earlier. Note, however, that now there will be no contribution due to convection. After the governing equations have been discretized in time and space, a suitable solution strategy must be devised to solve the resulting system of algebraic equations. One option is to solve the full problem for velocity and pressure directly at each time-step. For a large number of degrees of freedom this is a very inefficient approach. Instead we have chosen to follow the semi-implicit method for pressure linked equations (SIMPLE) methodology first advocated by Patankar and Spalding [5], which involves decoupling the velocity and pressure computations and iterating between them until convergence is reached at each time-step.

Within the SIMPLE procedure the pressure correction equation is prone to divergence unless some underrelaxation is used. The method recommended by Patankar [19] underrelaxes the velocity components in the momentum equations, with a relaxation factor α approximately equal to 0.5, and to only add a fraction of the pressure correction to the pressure, i.e.,

$$p = p^* + \alpha_p p',$$

where α_p is approximately equal to 0.8. These values for α and α_p are suggested since they have been shown to be satisfactory for a large number of flow problems. They are not necessarily the optimum values and for some problems will not produce a converged solution. It is clear that α and α_p will vary for different flow situations and may also vary for different mesh sizes within the same computational domain. Other relaxation techniques may be applied, and some of these are discussed in [23]. Clearly this algorithm is not robust. In an effort to overcome this problem Patankar [8] devised SIMPLER—SIMPLE Revised.

The argument used in the derivation of SIMPLE is that since the neighbor-point velocity corrections are removed from the velocity correction formula, the pressure correction has the sole responsibility of correcting the velocities. This leads to severe changes in the pressure correction field. Patankar [19] supposes that the pressure correction equation does a reasonable job of correcting the velocities but a poor job of correcting the pressures. The SIMPLER methodology was developed to overcome this deficiency.

To derive a pressure field equation the momentum equation is first written as

$$u_r = \frac{\sum A_{nb} u_{nb} + b_r}{A_r} + d_r(p_P - p_R). \tag{6.3}$$

We define a pseudovelocity of the form

$$\hat{u}_r = \frac{\sum A_{nb} u_{nb} + b_r}{A_r}. \tag{6.4}$$

Substitution of (6.4) into (6.3) gives

$$u_r = \hat{u}_r + d_r(p_P - p_R). \tag{6.5}$$

Similarly, we have

$$v_t = \hat{v}_t + d_t(p_P - p_T). \tag{6.6}$$

The pressure equation is derived in a similar manner to the pressure correction equation. We again integrate the continuity equation over the control volume. If

we substitute (6.5) and (6.6) into the discrete continuity equation and rearrange the terms, we obtain

$$a_P p_P = a_R p_R + a_L p_L + a_T p_T + a_B p_B + b_1 \tag{6.7}$$

with

$$a_R = d_r \Delta y, \tag{6.8}$$

$$a_L = d_l \Delta y, \tag{6.9}$$

$$a_T = d_t \Delta x, \tag{6.10}$$

$$a_B = d_b \Delta x, \tag{6.11}$$

$$a_P = a_R + a_L + a_T + a_B, \tag{6.12}$$

$$b_1 = [\hat{u}_l - \hat{u}_r]\Delta y + [\hat{v}_b - \hat{v}_t]\Delta x. \tag{6.13}$$

No approximations have been used in the derivation of the pressure equation, so if a correct velocity field is used to calculate the pseudovelocities, the pressure equation will give the correct pressure at once.

The algorithm used is based on the SIMPLER algorithm suitably ammended to incorporate the semi-Lagrangian treatment of the convection term and is described below.

The algorithm.

1. Set $n \leftarrow 0$ and define an initial velocity field $\boldsymbol{u}^{(n)}$. Put $\boldsymbol{u} \leftarrow \boldsymbol{u}^{(n)}$.
2. Calculate $u^{*(n)}$ and $v^{*(n)}$ using the semi-Lagrangian approach described in section 4.
3. Calculate pseudovelocities $\hat{u}$, $\hat{v}$ from

$$\begin{aligned} \hat{u}_r &= \tfrac{\sum A_{nb} u_{nb} + b_r}{A_r}, \\ \hat{v}_t &= \tfrac{\sum A_{nb} v_{nb} + b_t}{A_t}, \end{aligned}$$

where

$$\begin{aligned} A_r &= \textstyle\sum_{nb} A_{nb} + \frac{\Delta x \Delta y}{\Delta t}, & A_t &= \textstyle\sum_{nb} A_{nb} + \frac{\Delta x \Delta y}{\Delta t}, \\ b_r &= u_r^{*(n)} \tfrac{\Delta x \Delta y}{\Delta t}, & b_t &= v_t^{*(n)} \tfrac{\Delta x \Delta y}{\Delta t}. \end{aligned}$$

4. Solve the pressure equation for p^*

$$a_P p_P^* = a_R p_R^* + a_L p_L^* + a_T p_T^* + a_B p_B^* + b,$$

where

$$\begin{aligned} a_R &= \tfrac{(\Delta y)^2}{A_r}, & a_L &= \tfrac{(\Delta y)^2}{A_l}, \\ a_T &= \tfrac{(\Delta x)^2}{A_t}, & a_B &= \tfrac{(\Delta x)^2}{A_b}, \\ a_P &= \textstyle\sum_{nb} a_{nb}, \end{aligned}$$

and

$$b = (\hat{u}_l - \hat{u}_r)\Delta y + (\hat{v}_b - \hat{v}_t)\Delta x.$$

5. Solve the momentum equations for u', v'.

$$\begin{aligned} A_r u_r' &= \textstyle\sum_{nb} A_{nb} u_{nb}' + b_r + \Delta y (p_P^* - p_R^*), \\ A_t v_t' &= \textstyle\sum_{nb} A_{nb} v_{nb}' + b_t + \Delta x (p_P^* - p_T^*). \end{aligned}$$

6. Solve a pressure correction equation for p'

$$a_P p'_P = a_R p'_R + a_L p'_L + a_T p'_T + a_B p'_B + b,$$

where

$$b = (u'_l - u'_r)\Delta y + (v'_b - v'_t)\Delta x.$$

7. Correct the velocity field using

$$\begin{aligned} u_r &= u'_r + \tfrac{\Delta y}{A_r}(p'_P - p'_R), \\ v_t &= v'_t + \tfrac{\Delta x}{A_t}(p'_P - p'_T). \end{aligned}$$

8. Return to step 3 and repeat until convergence is obtained.
9. Set $\boldsymbol{u}^{(n+1)} \leftarrow \boldsymbol{u}$ and $n \leftarrow n+1$.
10. Return to step 2, let $\boldsymbol{u} \leftarrow \boldsymbol{u}^{(n)}$, and repeat until a steady state solution is obtained.

Note that step 2 is performed once at the beginning of each time-step and steps 3–8 take place within each time-step. Only when we have a convergent velocity solution within a time-step do we proceed to the next time-step.

7. Numerical results: Conservation law. In this section we perform a numerical experiment to illustrate the important features of the finite volume scheme developed in this paper. In this experiment we demonstrate the accuracy of this scheme by solving a problem possessing an exact solution. We consider uniform meshes only with $h = \Delta x = \Delta y$. Consider the model problem

$$\frac{\partial \phi}{\partial t} + x\frac{\partial \phi}{\partial x} - y\frac{\partial \phi}{\partial y} = 0,\ \mathbf{x} \in [1,2] \times [1,2],\ t \geq 0, \tag{7.1}$$

in which the velocity field, $\boldsymbol{u} = (x, -y)$, is divergence-free. On the two inflow boundaries we prescribe

$$\begin{aligned} \phi(1,y,t) &= 1 + y^2, \quad y \in [1,2],\ t \geq 0, \\ \phi(x,2,t) &= 1 + 4x^2, \quad x \in [1,2],\ t \geq 0. \end{aligned} \tag{7.2}$$

The initial condition is

$$\phi(x,y,0) = 0,\ x \in (1,2],\ y \in [1,2). \tag{7.3}$$

The steady state solution of this problem is

$$\phi(x,y) = 1 + (xy)^2. \tag{7.4}$$

The semi-Lagrangian algorithm is terminated when

$$\frac{\|\phi^{n+1} - \phi^n\|_\infty}{\Delta t} \leq 10^{-5}. \tag{7.5}$$

If $\tilde{\phi}_h$ denotes the converged numerical approximation to the steady state solution of the problem given by (7.4) on a grid with mesh size h, the accuracy of the discrete approximation is measured using

$$E(h) = \frac{\|\phi - \tilde{\phi}_h\|_\infty}{\|\tilde{\phi}_h\|_\infty}. \tag{7.6}$$

TABLE 2
Dependence of the error and number of iterations on mesh size with $\Delta t = 0.01$. Estimates of the order of spatial convergence are also given.

h	$\|e\|_\infty$	Iterations	p
0.25	1.013×10^{-1}	246	-
0.125	4.633×10^{-2}	182	1.13
0.0625	1.846×10^{-2}	140	1.33
0.03125	4.625×10^{-3}	111	1.36

TABLE 3
Dependence of the error on mesh size with $\Delta t = 0.001$.

h	$\|e\|_\infty$
0.25	1.088×10^{-1}
0.125	5.473×10^{-2}
0.0625	2.715×10^{-2}
0.03125	1.324×10^{-2}

In Table 2 we show how the error decays as a function of mesh size when $\Delta t = 10^{-2}$ for the scheme described in this paper. If it is assumed that the error behaves like $O(h^p)$, then the error information on two successive meshes given in Table 2 can be used to estimate the order, p, using

$$p = \frac{\ln(E(h)/E(h/2))}{\ln 2}.$$

These values are also provided in Table 2. We see that in the limit of small h the scheme is more than first-order accurate. The number of iterations required to attain the tolerance (7.5) is also given. An interesting feature is that for a given method the semi-Lagrangian algorithm converges in a fewer number of iterations as the mesh is refined. In Table 3 we show how the errors decay for a smaller time-step $\Delta t = 10^{-3}$. In all cases the errors are higher than the corresponding ones in Table 2 as predicted by the error estimate derived in Theorem 1, and the orders of spatial convergence are slightly lower. A second-order variant of the scheme has been developed for conservation laws [16]. This is based on a second-order Runge–Kutta method for determining the departure points and a second-order area-weighting scheme to ensure that the discrete conservation principle is satisfied identically.

8. Numerical results: Newtonian flow. In this section numerical calculations of laminar flow through a 2:1 contraction are presented for a range of Reynolds numbers. These calculations are compared with those generated by other authors [11], [10], [2] using different techniques. In particular, the behavior of the salient corner vortex is investigated qualitatively and quantitatively.

The work of Dennis and Smith [11] on the 2:1 contraction problem is a benchmark against which to test new and emerging numerical techniques for the Navier–Stokes equations. Their method is based on a finite difference approximation of the stream function-vorticity formulation of the governing equations. An upwind differencing scheme of Dennis and Hudson [13] is used to approximate the vorticity transport equation by adding an extra "viscous-like" term proportional to h^2. As we mentioned earlier, the standard upwind approximation is only first-order accurate. The addition of this term, known as artificial viscosity, is essential in order to obtain converged solutions for reasonably large values of Re. Without it the system of algebraic equations loses its diagonal dominance which presents convergence difficulties when solved by

iterative methods unless the mesh size is sufficiently decreased. The advantage of this upwinding scheme is that the second-order accuracy of the finite difference equations is maintained and that the artificial viscosity is applied sparingly at each grid point only if it is required. The local truncation error of the scheme is $O(h^2)$, and, therefore, it is strictly second order if $hRe << 1$. Therefore, for large values of Re small grid sizes are required for meaningful results.

Hunt [2] also uses a finite difference discretization of the stream function-vorticity formulation but on a nonuniform grid. The vorticity unknowns are eliminated to give a system solely in terms of unknown values of the stream function. There are some puzzling features of the scheme. First, when upwinding is used, the scheme fails to converge for $Re > 500$, even though one would expect the addition of a "viscous-like" term to have a stabilizing effect. Second, for a given value of Re, convergence becomes more difficult with mesh refinement.

Karageorghis and Phillips [10] use a spectral domain decomposition method to discretize the stream function formulation of the Navier–Stokes equations. The flow region is decomposed into a number of rectangular subdomains, on each of which the stream function is approximated by a truncated double Chebyshev expansion. The approximations are C^1 continuous across subregion interfaces. The nonlinear fourth-order partial differential equation for the stream function is linearized using Newton's method.

Mesh refinement is studied with reference to the size of the salient or corner vortex. This flow feature is also used as the basis of comparisons with other methods. The length of the corner vortex, L_1, is defined to be the distance between the point where the separation line meets the bottom of the channel and the salient corner. The width, L_2, of the corner vortex is defined to be the distance between the point where the separation line meets the wall parallel to the y-axis at $x = 0$ and the salient corner.

Numerical computations are performed on a series of meshes in order to ensure that the solutions obtained are independent of the mesh parameters. Both uniform and nonuniform meshes are used. The mesh parameters for the four uniform meshes (A–D) are given in Table 4. The main characteristics of the nonuniform meshes (E–G*) are given in Table 5. Meshes E–G* have mesh spacings which vary geometrically from the reentrant corner. In this way we can ensure a greater density of mesh points in the region where the solution changes most rapidly. Note that although meshes F and G contain approximately the same number of control volumes, they differ in the way the nonuniform mesh spacing varies. Mesh G is more refined around the reentrant corner than mesh F. Mesh G* corresponds to a computational domain in which the exit length is doubled from four to eight units. This extended domain allows for the examination of domain truncation effects on the numerical solution for $Re = 500$ and $Re = 1000$.

Tables 6 and 7 show the dependence of the length L_1 and the width L_2 of the salient corner vortex on the mesh. These flow characteristics are sensitive to the computational mesh. The results demonstrate that convergence with mesh refinement has been obtained over the whole range of values of the Reynolds number. The results on all the meshes were calculated with $\Delta t = 10^{-3}$. Tables 6 and 7 also show that the use of the extended domain has no appreciable effect on the values of L_1 and L_2, thus confirming that the length of the downstream channel is adequate for these computations.

Allowing $x \to \infty$ along $y = -\frac{1}{2}$, we would expect $\xi \to -12$ for a fully developed

TABLE 4
The mesh spacings and degrees of freedom for the uniform meshes A–D.

Mesh	Δx	Δy	degrees of freedom
Mesh A	$\Delta x = 0.05$	$\Delta y = 0.05$	6840
Mesh B	$\Delta x = 0.025$	$\Delta y = 0.05$	13720
Mesh C	$\Delta x = 0.05$	$\Delta y = 0.033$	10420
Mesh D	$\Delta x = 0.05$	$\Delta y = 0.025$	14000

TABLE 5
Mesh characteristics and degrees of freedom for the nonuniform meshes E–G*.

Mesh	Δx_{min}	Δy_{min}	Degrees of freedom
Mesh E	1.131×10^{-2}	2.5×10^{-2}	10800
Mesh F	1.131×10^{-2}	1.852×10^{-2}	14580
Mesh G	4.118×10^{-3}	1.512×10^{-2}	14400
Mesh G*	4.118×10^{-3}	1.512×10^{-2}	16800

flow profile at the exit. We may apply this test to check that the downstream channel is long enough for the Re numbers that we solve for. In Figures 5–7 we have plotted vorticity against downstream channel length for $Re = 1$, $Re = 100$, and $Re = 500$, respectively. These figures suggest that the downstream channel length of 4 is suitable for this range of Reynolds numbers.

The sensitivity of the computation with respect to the choice of time-step is shown in Table 8. In this table the dependence of L_1 with respect to the time-step is presented for $Re = 100$. The choice of time-step does not significantly influence the value of this characteristic of the flow problem.

The asymptotic theory of Smith [12] predicts that a separation will occur asymptotically far ahead of the step at a position $x = -L_1$, given by

$$L_1 = 0.1289 ln\, Re + D \,\text{for} Re \gg 1. \tag{8.1}$$

The constant D is of order unity, and its value depends on the contraction ratio. It is determined here by looking at the asymptotic behavior of $L_1 - 0.1289 ln\, Re$. From this analysis we obtain $D = -0.547$. In Figure 8 we plot L_1 given by (8.1) as a function of Re. On this figure we also include the values of L_1 obtained by our numerical calculations. Excellent agreement is obtained with the theoretical prediction for $Re \geq 300$. Note that the theoretical prediction is only valid for large values of the Reynolds number, although in Figure 8 it is plotted on the whole domain.

In Figures 9–14 the streamline contours are presented for Re=1, 10, 50, 100, 200, and 500, respectively, in the domain $-2 \leq x \leq 2$, $-1 \leq y \leq 0$. The salient corner vortex diminishes in size as Re increases from $Re = 1$ to $Re = 50$ and then starts to grow slowly for $Re > 50$.

In Table 9 we compare the values of L_1 obtained for different values of Re on mesh G (G* for $Re = 500,\ 1000$) with other results in the literature (Dennis and Smith [11], Hunt [2], and Karageorghis and Phillips [10]). The results of Dennis and Smith [11] have been obtained using two successive h^2-extrapolations on grids with mesh spacings of $h = \frac{1}{10}, \frac{1}{20}$ and $h = \frac{1}{40}$. The results of Hunt [2] are obtained using a transformed grid with 48×128 points and are calculated with and without the artificial viscosity term. The results of Karageorghis and Phillips are given for the most refined grid that they use with 1537 degrees of freedom.

The results in columns (a), (b), and (c) of Table 9 differ by at most 5% from each other for $1 \leq Re \leq 150$. As Re increases from 150, the values for L_1 in the first three

columns of the table become closer to each other and agree to within 2%. This shows that the semi-Lagrangian scheme performs particularly well for convection dominated flows. Hunt's finite difference scheme with artificial viscosity gives results that are closer to those in the first three columns than the scheme without artificial viscosity.

In Table 10 the width, L_2, is presented for various values of Re and is compared with the values published by Dennis and Smith [11] and Hunt [2]. The values in columns (a) and (b) are within 11% of each other, although as Re increases from $Re = 50$ this percentage difference falls and for $Re = 500$ the results in columns (a) and (b) are around 1% of each other. As for the L_1 results, this would appear to show that the semi-Lagrangian scheme behaves well for high values of Re. For the schemes of Hunt [2] the values of L_2 generated are smaller than those in the first two columns for the scheme with artificial viscosity and, equivalently, larger for the scheme without artificial viscosity.

An interesting feature of the results in Tables 9 and 10 is that as Re grows from 1 to 50, both values drop so that for $Re = 50$ the value of L_1 is approximately half of its equivalent value for $Re = 1$, and the value of L_2 is approximately a third of its value for $Re = 1$. As Re increases from 50 to 1000, both the width and the length of the vortex grow but at different rates; L_1 grows more quickly than L_2. At $Re = 500$ the length L_1 is slightly larger than it was for $Re = 1$, while the value of L_2 at $Re = 500$ is still only 50% of its value at $Re = 1$. This shows that the vortex grows in size along the upstream channel more quickly than up the wall at $x = 0$ as Re increases.

The maximum values of the stream function ψ, ψ_{max}, are presented in Table 11. As we would predict from the results in Tables 9 and 10, the strength of the vortex diminishes in size between $Re = 1$ and $Re = 50$ and then grows for $50 < Re \leq 1000$.

There is no downstream recirculation region pictured in the streamline plots

shown in Figures 9–14. However, a close examination of the values of u and v in the region of the reentrant corner indicates that for $Re \geq 100$ some recirculation may exist. For this part of the flow to be accurately resolved more work needs to be done on refining the mesh.

9. Concluding remarks. A semi-Lagrangian finite volume method for solving the time-dependent incompressible Navier–Stokes equations is presented. A time-splitting scheme is used to decouple the treatment of convection from the solution of a generalized Stokes problem. The convection problem is solved using a semi-Lagrangian approach in which the vertices of a control volume at the new time level are traced back in time over a time-step using a particle following transformation. The values of the velocity components in the transformed control volumes at the previous time level are determined using an area-weighting technique which ensures

that the conservation property enjoyed by the pure convection problem is satisfied indentically by construction. This approach circumvents problems associated with upwind biased schemes. The generalized Stokes problem is solved using the standard SIMPLER method. The scheme is applied to the flow through a 2:1 contraction and is demonstrated to be robust and accurate. Comparisons are made with other published work on this problem and excellent agreement is found.

Future work will concentrate on developing higher-order methods in time for integrating along the particle paths. The extension of this technique to problems in computational rheology is currently in progress [14, 15].

AN $\mathcal{O}(N)$ LEVEL SET METHOD FOR EIKONAL EQUATIONS*

SEONGJAI KIM†

Abstract. A propagating interface can develop corners and discontinuities as it advances. Level set algorithms have been extensively applied for the problems in which the solution has advancing fronts. One of the most popular level set algorithms is the so-called fast marching method (FMM), which requires total $\mathcal{O}(N \log_2 N)$ operations, where N is the number of grid points. The article is concerned with the development of an $\mathcal{O}(N)$ level set algorithm called the *group marching method* (GMM). The new method is based on the narrow band approach as in the FMM. However, it is incorporating a correction-by-iteration strategy to advance a group of grid points at a time, rather than sorting the solution in the narrow band to march forward a single grid point. After selecting a group of grid points appropriately, the GMM advances the group in two iterations for the cost of slightly larger than one iteration. Numerical results are presented to show the efficiency of the method, applied to the eikonal equation in two and three dimensions.

Key words. level set method, narrow band approach, eikonal equation, first-arrival traveltime

1. Introduction.

A propagating interface can develop corners and discontinuities as it advances. It is the case for the solution of, e.g., the eikonal equation, a Hamilton–Jacobi differential equation, in heterogeneous media. Since we do not know which values to assign to the gradient components at the corners and even do not know which values to assign to the function at discontinuities, the solution does not satisfy the equation in the normal (classical) sense. An immediate consideration is to introduce a nonclassical weak solution: a continuous function having possibly discontinuous gradients that solves the equation in average.

Unfortunately, the class of weak solutions is too big; the initial data for these problems does not determine weak solutions uniquely. One way to enforce the uniqueness is to add viscosity described by a dissipative term, e.g., a multiple of the negative Laplace operator, to the equation. The solution for a given viscosity is smooth and therefore uniquely determined. Then one may take the limit of these smooth solutions by letting the coefficient of the Laplace operator approach zero. If the limit exists, its solution is uniquely determined for the appropriate initial data; it is called a *viscosity solution*.

Properties of viscosity solutions were first studied by Lax [14] in the context of hyperbolic conservation laws; good references to work on them are [3, 4, 15].

It has been conjectured that *the first-arrival traveltime (FATT) field is a viscosity solution of the eikonal equation* [30]. The conjecture is supported by some theoretical results and by a great deal of numerical evidence. Techniques for computing viscosity solutions were developed first for hyperbolic conservation laws. Numerical methods for these conservation laws have utilized *upwind* finite differences (FDs) and have adapted to produce viscosity solutions of the eikonal equation [6, 12, 19, 25, 30]. Upwind FD techniques and their applications to Hamilton–Jacobi equations can be found in [16, 17, 18].

The level set method is a numerical technique to compute advancing fronts and has been applied to a wide range of important physical problems; see, e.g., [26, 27] and references therein. Even though its solution shows first-order accuracy, the level set method has been widely used mostly due to its built-in stability. It has been adapted for the computation of the FATT and implemented with the narrow band technique, called the *fast marching method* (FMM), in which the narrow band points form a neighborhood of advancing wavefronts [16, 19, 25, 26, 27, 29]. The FMM was first developed by Tsitsiklis [29] and later rederived by Sethian [25]. The FMM requires sorting the solution at each step of the narrow band. For the binary tree sorting, the total cost of the method becomes $\mathcal{O}(N \log_2 N)$. The main object of the article is to develop an $\mathcal{O}(N)$ level set method for the FATT, called the *group marching method* (GMM).

An outline of the paper is as follows. In section 2, the eikonal equation is introduced as the model equation, along with its numerical techniques to solve. The first-order upwind FD scheme is presented, and the FMM is briefly reviewed. In section 3, we suggest the GMM; a pseudocode is presented. Section 4 is devoted to the introduction of the *average normal slowness* which can improve accuracy of the solution. An approximate average slowness which can be easily implemented is discussed in the same section. In section 5, an alternative update formula is considered to improve flexibility in incorporating the average slowness. In section 6, the GMM is tested for various velocity models, update formulae, and average slowness incorporation, in two and three dimensions, and is compared with the FMM. It is numerically verified that the new method performs with the computation cost $\mathcal{O}(N)$. Section 7 discusses some important aspects on accuracy, efficiency, and applicability for the level set methods. The last section includes conclusions.

2. Preliminaries.

2.1. The eikonal equation. The eikonal equation in an isotropic medium is given by

$$|\nabla \tau(\mathbf{x}_s, \mathbf{x})|^2 = \frac{1}{v^2(\mathbf{x})}, \tag{2.1}$$

where $\tau(\mathbf{x}_s, \mathbf{x})$ is the traveltime of the acoustic wave from the source $\mathbf{x}_s$ to the location $\mathbf{x}$ and $v(\mathbf{x})$ denotes the velocity of the propagating wavefront at $\mathbf{x}$. For down-going wavefronts (advancing in the $(z+)$-direction), for example, the equation can be rewritten in the evolutionary form

$$\tau_z = \sqrt{s^2 - \tau_x^2 - \tau_y^2}, \tag{2.2}$$

where $s(= 1/v)$ is called the slowness, the reciprocal of the velocity.

As mentioned earlier, the FATT is a (continuous) viscosity solution of the eikonal equation. There have been various numerical techniques for FATTs: ray-tracing methods, FD methods, and algorithms based on Fermat's principle [24].

The use of ray tracing followed by interpolation of traveltimes is a popular and robust method for computing diffraction trajectories for small or moderate velocity contrasts. For regions with high velocity contrasts, ray tracing methods can produce quite large shadow zones where the computed traveltime field should be interpolated. Such ray-tracing/interpolation processes are cumbersome and computationally expensive, especially in three dimensions. For a comprehensive treatment of ray theory, see [1, 2, 7].

An alternative to the method is to compute traveltimes by solving directly the eikonal equation on a regular grid by FD schemes; see [5, 6, 12, 30, 31, 32] for standard expanding-box methods and [19, 21] for the level set method. A drawback of the standard FD eikonal solvers is that it is not easy to control the propagation angle of rays as it is with ray tracing methods. The level set method incorporating the narrow band method overcomes the drawback of the standard FD schemes; however, it has first-order accuracy and is hardly extendable for a higher-order scheme in realistic media. Nonetheless the FD eikonal solvers have their advantages: they are more efficient computationally than ray tracers and rarely produce shadow zones. The author recently suggested a stable FD eikonal solver incorporating a postsweeping iteration [12], which is second-order and readily extendable to higher-order schemes.

The current level set methods require sorting the traveltimes in the narrow band, a neighborhood of the wavefront, at each stage of the computation. The FMM [25, 28], a narrow band level set method, has adopted the binary tree sorting algorithm; the method turns out to require a total of $\mathcal{O}(N \log_2 N)$ operations, where N is the number of grid points. Even though the level set methods have first-order accuracy, they are still attractive due to their built-in stability and a wide range of applications. It is worth developing an optimal cooperating technique with which the level set method costs $\mathcal{O}(N)$ operations in total.

2.2. The FD scheme. For a numerical scheme for (2.1), consider a cubic domain

$$(x_{\min}, x_{\max}) \times (y_{\min}, y_{\max}) \times (z_{\min}, z_{\max});$$

partition it into $N_x \times N_y \times N_z$ cells of the uniform size $\Delta x \times \Delta y \times \Delta z$ with their vertices

$$\mathbf{x}_{i,j}^k = (x_i, y_j, z_k) = (x_{\min} + i\Delta x, y_{\min} + j\Delta y, z_{\min} + k\Delta z).$$

Let $\tau_{i,j}^k = \tau(\mathbf{x}_s, \mathbf{x}_{i,j}^k)$, and define the forward $(+)$ and backward $(-)$ difference operators for τ_x at the point $\mathbf{x}_{i,j}^k$:

$$D_x^{\pm}\tau_{i,j}^k = \pm\frac{\tau_{i\pm1,j}^k - \tau_{i,j}^k}{\Delta x}. \tag{2.3}$$

Define the *upwind* FD scheme for τ_x incorporating the first-arrivals:

$$\widehat{D}_x\tau_{i,j}^k = \text{mod\_max}\Big(\max\big(D_x^-\tau_{i,j}^k, 0\big), \min\big(D_x^+\tau_{i,j}^k, 0\big)\Big), \tag{2.4}$$

where mod_max returns the larger value in modulus. Note that

$$|\widehat{D}_x\tau_{i,j}^k| = \max\big(D_x^-\tau_{i,j}^k, -D_x^+\tau_{i,j}^k, 0\big),$$

which can be utilized in implementation.

After introducing the analogues for τ_y and τ_z, i.e., $\widehat{D}_y\tau_{i,j}^k$ and $\widehat{D}_z\tau_{i,j}^k$, we can formulate the upwind FD scheme for (2.1):

$$\Big(\widehat{D}_x\tau_{i,j}^k\Big)^2 + \Big(\widehat{D}_y\tau_{i,j}^k\Big)^2 + \Big(\widehat{D}_z\tau_{i,j}^k\Big)^2 = \Big(s_{i,j}^k\Big)^2. \tag{2.5}$$

For down-going wavefronts as in (2.2), the scheme can be explicitly rewritten as

$$\tau_{i,j}^{k+1} = \tau_{i,j}^k + \Delta z \cdot H[\tau]_{i,j}^k, \tag{2.6}$$

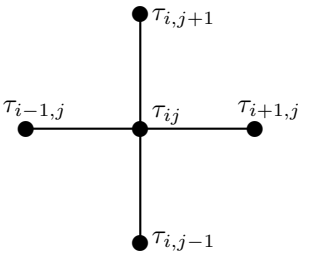

FIG. 1. *The update procedure of the FMM for* τ_{ij}.

where

$$H[\tau]_{i,j}^k = \sqrt{\left(s_{i,j}^k\right)^2 - \left(\widehat{D}_x \tau_{i,j}^k\right)^2 - \left(\widehat{D}_y \tau_{i,j}^k\right)^2}.$$

The quantity inside the radical can be negative in practical simulation. Then it can be either ignored or adjusted by a nonnegative value, depending on the algorithm adopted. In either case, it should be carefully designed not to violate causality or stability and not to deteriorate accuracy.

2.3. Review of the FMM. In this section we review the FMM, a narrow band level set algorithm, presented in [25, 27]. The FMM begins from the source and updates the traveltimes at neighboring grid points. The six neighboring points (four in two dimensions) form the first stage of the narrow band. Then, the FMM expands the narrow band by updating traveltimes at neighboring downwind points of a *Trial* point in the narrow band, and accepting the trial point as an *Alive* (completed) point. The trial point is selected such that its traveltime is smallest among all values available from the narrow band, for which the FD scheme easily satisfies causality.

We summarize the FMM as follows [27]. First, tag the source point as *Alive*, where the traveltime is zero. Then compute traveltimes at all points one grid point away from the source, and tag them as *Close*. Finally, tag *Far* all other grid points, and set the traveltimes for the *Far* points large. Then the FMM loop is carried out as follows.

(a) Let *Trial* be the point in *Close* having the smallest traveltime.
(b) Tag as *Close* all neighbors of *Trial* that are not *Alive*. (If the neighbor is in *Far*, remove it from the list and add it to the set *Close*.)
(c) Recompute the traveltimes at all *Close* neighbors of *Trial* using (2.5).
(d) Remove the point *Trial* from *Close* and add it to *Alive*.
(e) If *Close* is not empty, go to top of loop.

Note that in step (a) of the FMM loop, the point *Trial* is chosen to have the smallest traveltime among all values in *Close*. This implies that the traveltimes in *Close* should be sorted from the smallest to the largest, at each stage of the narrow band. When a binary tree sorting algorithm is applied, the cost is $\mathcal{O}(\log_2 N_B)$, where N_B is the number of grid points in *Close*. Due to the sorting algorithm, the total cost for the FMM becomes $\mathcal{O}(N \log_2 N)$, where N is the total number of grid points.

Now, we present the update procedure (c) of the FMM loop [27]. For a simple presentation, we illustrate it in two dimensions. Let $\mathbf{x}_{ij}$ be a *Close* neighbor of *Trial* to be updated from nearby values: $\tau_{i-1,j}$, $\tau_{i+1,j}$, $\tau_{i,j-1}$, and $\tau_{i,j+1}$. (See Figure 1.) The four nearby points connected by grid line segments form four quadrants; the FMM attempts to solve the quadratic equation given by each quadrant according to

$$\left(\widehat{D}_x \tau_{ij}\right)^2 + \left(\widehat{D}_y \tau_{ij}\right)^2 = \left(s_{ij}\right)^2. \tag{2.7}$$

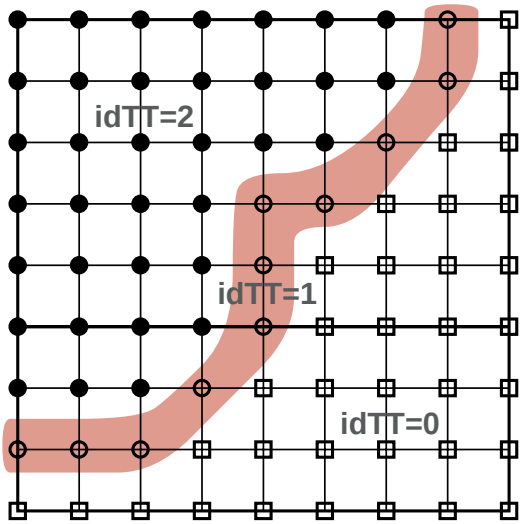

FIG. 2. *The GMM illustrated in two dimensions. The closed circles indicate the points already computed, the open circles form a neighborhood of a wavefront, and the open boxes correspond to the downwind points to be computed at the current stage or later.*

For example, we refer to possible contributors $\tau_{i+1,j}$ and $\tau_{i,j+1}$ (the first quadrant). Without loss of generality, there are two cases.

1. If only $\tau_{i+1,j}$ is known, then we find the larger solution τ of

$$\left(\frac{\tau - \tau_{i+1,j}}{\Delta x}\right)^2 = (s_{ij})^2. \tag{2.8}$$

2. If both $\tau_{i+1,j}$ and $\tau_{i,j+1}$ are known, then we find the larger real solution of

$$\left(\frac{\tau - \tau_{i+1,j}}{\Delta x}\right)^2 + \left(\frac{\tau - \tau_{i,j+1}}{\Delta y}\right)^2 = (s_{ij})^2. \tag{2.9}$$

For each of four quadrants, we construct all possible real solutions τ; we choose the smallest value for the traveltime τ_{ij}.

3. The GMM. A costly component of the narrow band methods is the sorting of the solution in each step of the narrow band of wavefronts, which costs $\mathcal{O}(\log_2 N)$ per grid point. Here we introduce a new narrow band level set algorithm, called the GMM, whose total computation cost is $\mathcal{O}(N)$.

Consider a neighborhood Γ of a wavefront; see the shaded area in Figure 2. (Γ corresponds to *Close* in the FMM.) In the current stage of the GMM, we will select a group of points G out of Γ, recompute the traveltimes at neighboring points of G that are not completed, register the neighboring points as members of Γ if they are not already registered, and finally tag "completed" for the points in G. The group of points should be carefully chosen in such a way that the computed solution does not violate causality, since in our algorithm the traveltimes are not sorted from the smallest to the largest. The main objective in this section is to develop a way to select such a group of points from the narrow band.

In the FMM, the traveltimes on the narrow band are sorted at each stage of the narrow band to find the smallest value, and the traveltime at a point is updated from

the real solutions of eight "quadratic equations" (in three dimensions), each of which associates with a west-east, south-north, and up-down combination of neighboring grid points. The main reason for the sorting and abundant computation is that we do not know where the wavefront is coming from and advancing to. If one wishes to advance the narrow band by a group of points, it is necessary to explicitly incorporate some aspects of wavefront directions into the computation algorithm. Also, it may require updating traveltimes more than once at neighboring downwind points of the group.

We begin with the two-dimensional (2D) case with $h = \Delta x = \Delta y$ for a simple presentation. Recall that in the FMM, the traveltime at a point $\mathbf{x}_{ij}$ is updated by choosing the minimum of the real solutions of four quadratic equations, each of which corresponds to one of four quadrants. So, given neighboring traveltimes, the minimum of the solutions of the quadratic equations must be associated with the quadrant where the raypath is passing before reaching at $\mathbf{x}_{ij}$. Let the first quadrant be in the upwind direction for $\mathbf{x}_{ij}$. (See Figure 1.) Then the updated traveltime at $\mathbf{x}_{ij}$, τ_{ij}, should satisfy

$$\left(\frac{\tau_{ij} - \tau_{i+1,j}}{h}\right)^2 + \left(\frac{\tau_{ij} - \tau_{i,j+1}}{h}\right)^2 = (s_{ij})^2. \tag{3.1}$$

Since τ_{ij} is the larger solution of the above equation,

$$\tau_{ij} \geq \frac{1}{2}(\tau_{i+1,j} + \tau_{i,j+1}). \tag{3.2}$$

Thus it follows from (3.1) and (3.2) that

$$\tau_{ij} \geq \min(\tau_{i+1,j}, \tau_{i,j+1}) + \delta\tau_{ij}, \quad \delta\tau_{ij} = \frac{1}{\sqrt{2}} \cdot h \cdot s_{ij}. \tag{3.3}$$

Defining $s_{\Gamma,\min} = \min\{s_{ij} : \mathbf{x}_{ij} \in \Gamma\}$, we can interpret (3.3) as follows. *Given two points* $\mathbf{x}_{i_1,j_1}$ *and* $\mathbf{x}_{i_2,j_2}$, *if their traveltime difference is less than*

$$\delta\tau \equiv \frac{1}{\sqrt{2}} \cdot h \cdot s_{\Gamma,\min},$$

the angle between the line segment $\overline{\mathbf{x}_{i_1,j_1}\mathbf{x}_{i_2,j_2}}$ *and the wavefront normal is larger than* 45 *degrees, i.e., rather perpendicular than parallel.*

Remark. In three dimensions, $\sqrt{2}$ in (3.3) and $\delta\tau$ should be replaced by $\sqrt{3}$. It can be shown with a physical insight as follows. We begin with the 2D problem. The equality in (3.3) holds only if $\tau_{i+1,j} = \tau_{i,j+1}$, i.e., $\mathbf{x}_{i+1,j}$ and $\mathbf{x}_{i,j+1}$ are on the same wavefront; the distance between the wavefront and $\mathbf{x}_{ij}$ is $h/\sqrt{2}$. When $\tau_{i+1,j} \neq \tau_{i,j+1}$, the traveltime increment at $\mathbf{x}_{ij}$, from $\min(\tau_{i+1,j}, \tau_{i,j+1})$, is clearly larger than $\delta\tau_{ij}$. Therefore, we can claim that $|\tau_{ij} - \min(\tau_{i+1,j}, \tau_{i,j+1})|$ is minimized when the wavefront including $\mathbf{x}_{i+1,j}$ and $\mathbf{x}_{i,j+1}$ (at the same time) reaches the target point $\mathbf{x}_{ij}$, which is the slowness multiplied by the distance between the wavefront and $\mathbf{x}_{ij}$. For the three-dimensional (3D) problem, there is no physical restriction to claim the same; here the distance between the target point and the wavefront including the adjacent three points becomes $h/\sqrt{3}$.

Now we are ready to choose the group G to be *completed* at a time. Define $\tau_{\Gamma,\min} = \min\{\tau_{ij} : \mathbf{x}_{ij} \in \Gamma\}$ and select G as follows:

$$G = \Big\{\mathbf{x}_{ij} \in \Gamma \,:\, \tau(\mathbf{x}_{ij}) \leq \tau_{\Gamma,\min} + \delta\tau\Big\}. \tag{3.4}$$

Let $\mathbf{x}_{i_1,j_1}$ and $\mathbf{x}_{i_2,j_2}$ be two points in G. When they are not adjacent, it is clear that their traveltimes do not affect each other in the update procedure. If they are adjacent, one can barely affect the other, since the wavefront normal is nearer to perpendicular, rather than parallel, to the line segment formed by the points. However, whether the two points are adjacent or not, their neighboring downwind points can be affected by both points. It can be the case, in particular, for intersecting wavefronts, i.e., at or near shocks. The neighboring points may have different traveltimes for a different order of updates, which implies that the group update may not be stable.

To fix instability, we update all the neighboring points of the group G twice—one in an order and the other in the opposite order. The double computation fixes instability. To see it, imagine that we try to update the neighboring points of G one more time. We can readily see that none of the neighboring points changes its traveltime during the extra updates. Of course, it also holds for the 3D problem with $\delta\tau = \frac{1}{\sqrt{3}} \cdot h \cdot s_{\Gamma,\min}$.

Now we summarize the above arguments as in the following algorithm (in three dimensions), called the GMM.

- *Initialization.*
  - (I1) Assign a large number to the traveltime array `TT`, e.g., $\texttt{TT}(\cdot,\cdot,\cdot) \equiv 1.0e5$;
  - (I2) Set zero for the traveltime index `idTT`, i.e., $\texttt{idTT}(\cdot,\cdot,\cdot) \equiv 0$;
  - (I3) Set $\texttt{delTAU} = \frac{1}{\sqrt{3}} \cdot \min(\Delta x, \Delta y, \Delta z) \cdot \min_{i,j,k} s^k_{i,j}$;
  - (I4) On the box of $(2 \times 2 \times 2)$ cells having the source at its center,
    - assign the analytic value of `TT` on the box;
    - set $\texttt{idTT}(\cdot,\cdot,\cdot) = 2$, at the source;
    - set $\texttt{idTT}(\cdot,\cdot,\cdot) \equiv 1$, on the surface of the box; save those point indices to the interface indicator array $\texttt{GAMMA}(\cdot,\cdot,\cdot)$;
    - set `TM` to be the minimum of `TT` on the surface of the box;
- *Marching Forward.*
  - (M1) Set $\texttt{TM} = \texttt{TM} + \texttt{delTAU}$;
  - (M2) For each (i,j,k) in `GAMMA`, in the reverse order, if $(\,\texttt{TT}(i,j,k) \le \texttt{TM}\,)$, recompute traveltimes of neighboring points (ℓ,m,n) where $\texttt{idTT} \le 1$;
  - (M3) For each (i,j,k) in `GAMMA`, in the forward order, if $(\,\texttt{TT}(i,j,k) \le \texttt{TM}\,)$,
    - (a) recompute traveltimes of neighboring points (ℓ,m,n) where $\texttt{idTT} \le 1$;
    - (b) if $\texttt{idTT} = 0$ at a neighboring point (ℓ,m,n), set $\texttt{idTT}(\ell,m,n) = 1$ and save (ℓ,m,n) into `GAMMA`;
    - (c) remove the index (i,j,k) out of `GAMMA`; set $\texttt{idTT}(i,j,k) = 2$;
  - (M4) If $\texttt{GAMMA} \neq \emptyset$, go to (M1);

Remark. Apparently, the reverse computation (M2) is cheaper to carry out than (M3); the double-computation (M2)–(M3) does not increase the computation cost twice. It can be made cheaper as follows. A step of the GMM advances a group of points including not only the global minimum (of the narrow band) but also all local minima that are less than or equal to `TM`. It is not difficult to see if a point in the group is a local minimum of the narrow band. Since it is not necessary to compute twice at local minima, one can modify the algorithm to skip the double-computation there. Let the point (i,j,k) in (M2) be recognized as a local minimum during the recomputation of neighboring downwind points. Then one can update `GAMMA` and `idTT` as in (b) and (c) of (M3); the point (i,j,k) would be skipped by (M3), since it is already out of `GAMMA`. More than half the points in a group seems a local minimum, in practice. The double-computation increases the computation cost, not twice, but

slightly.

Remark. The GMM is in fact an iterative update procedure, converging in two iterations. One may want to select G with a larger $\delta\tau$. In this case, the number of iterations must become larger. Rouy and Tourin [23] has chosen all the grid points as one group and carried out iterations up to convergence. The GMM can be viewed as an intermediate algorithm between the FMM [25, 27] ($\delta\tau = 0$) and the purely iterative algorithm of Rouy and Tourin [23] ($\delta\tau = \infty$).

Remark. When the slowness is constant, two group marchings advance the wavefront to a completely different outer surface. Such a feature can make the GMM more efficient than pointwise methods such as the FMM [27].

4. Average normal slowness. It is well known that the *exact* traveltime from the source $\mathbf{x}_s$ to a location $\mathbf{x}$ can be computed along the raypath

$$\tau(\mathbf{x}_s, \mathbf{x}) = \int_{\mathbf{x}_s}^{\mathbf{x}} \frac{1}{v(\mathbf{x}')} d\sigma = \int_{\mathbf{x}_s}^{\mathbf{x}} s(\mathbf{x}') d\sigma, \tag{4.1}$$

where σ is the length element along the raypath. This implies that accuracy of algorithm (2.5) can be improved by replacing $s_{i,j}^k$ by the *average normal slowness* $\widehat{s_{i,j}^k}$, which is obtained by integrating the slowness along the wavefront normal direction. The wavefront normal, by definition, is $v(\mathbf{x})\nabla\tau$ and is tangent to the raypath for isotropic media.

Velocities are often provided at grid points in practice; the velocity needs to be interpolated over the whole computation domain. For simplicity, we adopt the trilinear spline interpolation in three dimensions; i.e., the velocity is treated as a trilinear function in each cell.

As an example for the computation of the average normal slowness, consider a point $\mathbf{x}_{i,j}^k$ at which the wavefront normal is pointing the $(z+)$-direction. Let us compute $\tau_{i,j}^{k+1}$ out of $\tau_{i,j}^k$ and its adjacent traveltimes $\tau_{i\pm1,j}^k$ and $\tau_{i,j\pm1}^k$. Since $\widehat{D}_x\tau_{i,j}^k$ and $\widehat{D}_y\tau_{i,j}^k$ are likely zero at the point $\mathbf{x}_{i,j}^k$, we can see from (2.6), with $s_{i,j}^k$ replaced by $\widehat{s_{i,j}^k}$, that

$$\tau_{i,j}^{k+1} = \tau_{i,j}^k + \Delta z \cdot \widehat{s_{i,j}^k}, \tag{4.2}$$

where

$$\widehat{s_{i,j}^k} = \frac{1}{\Delta z} \cdot \int_{\mathbf{x}_{i,j}^k}^{\mathbf{x}_{i,j}^{k+1}} \frac{1}{v(\mathbf{x}')} d\sigma = \begin{cases} \dfrac{1}{v_{i,j}^k} = s_{i,j}^k & \text{if } v_{i,j}^{k+1} = v_{i,j}^k, \\ \dfrac{\log(v_{i,j}^{k+1}) - \log(v_{i,j}^k)}{v_{i,j}^{k+1} - v_{i,j}^k} & \text{else.} \end{cases}$$

In realistic media, it is difficult to compute the average normal slowness without raypath information. A reasonable approximation can be simply obtained as follows. For example, for the update from the first quadrant as in (2.8)–(2.9), we first check which one is smaller between $\tau_{i+1,j}$ and $\tau_{i,j+1}$. If $\tau_{i+1,j}$ is smaller, the wavefront normal would have a smaller angle to the line segment $\overline{\mathbf{x}_{i+1,j}\mathbf{x}_{i,j}}$ than to $\overline{\mathbf{x}_{i,j+1}\mathbf{x}_{i,j}}$. So it is reasonable to utilize

$$\widehat{s}_{i,j} \approx \begin{cases} s_{i,j} & \text{if } s_{i+1,j} = s_{i,j}, \\ \dfrac{\log(v_{i+1,j}) - \log(v_{i,j})}{v_{i+1,j} - v_{i,j}} & \text{else.} \end{cases} \tag{4.3}$$

When $\tau_{i,j+1}$ is smaller, the index $(i+1,j)$ in (4.3) should be replaced by $(i,j+1)$.

The practical accuracy of numerical algorithms for traveltimes seems strongly dependent on the ability of the numerical code to compute an *average slowness* close to the average normal slowness. No matter what the order of the numerical scheme is, the solution would turn out to have a first-order accuracy in general media if the point slowness is incorporated. (In principle, the energy does not propagate jumping over discrete points but advances their fronts through all the points in the medium.) Another degraded accuracy problem can appear at singularities such as the source points and caustics; it can be effectively treated by employing numerical techniques such as the locally uniform mesh refinement [12] and adaptive gridding approach [20].

5. An alternative update procedure in two dimensions. In this section, we consider an alternative update formula for the 2D problem which is slightly different from (2.8)–(2.9). We first define it as follows. To update $\tau_{i,j}$, choose the minimum from the four values

$$\begin{aligned} &\tau_{i\pm1,j} + \Delta x \cdot \max\Big(\alpha\widehat{s}_{ij},\ \sqrt{(\widehat{s}_{ij})^2 - (\widehat{D}_z\tau_{i\pm1,j})^2}\Big), \\ &\tau_{i,j\pm1} + \Delta z \cdot \max\Big(\beta\widehat{s}_{ij},\ \sqrt{(\widehat{s}_{ij})^2 - (\widehat{D}_x\tau_{i,j\pm1})^2}\Big), \end{aligned} \tag{5.1}$$

where

$$\alpha = \frac{\Delta x}{\sqrt{(\Delta x)^2+(\Delta z)^2}}, \quad \beta = \frac{\Delta z}{\sqrt{(\Delta x)^2+(\Delta z)^2}}.$$

Here the maximization with $\alpha\widehat{s}_{ij}$ or $\beta\widehat{s}_{ij}$ is incorporated so as not to violate stability.

The above update procedure utilizes delayed traveltime derivatives (purely forward), and therefore it is more efficient in implementation and performance than (2.8)–(2.9). However, it may be *unstable* without the maximization. For example, ignoring the factor $\alpha\widehat{s}_{ij}$, the updating value obtainable from the west (the direction of $\tau_{i-1,j}$) becomes

$$\tau_{i-1,j} + \Delta x \cdot \sqrt{(\widehat{s}_{ij})^2 - (\widehat{D}_z\tau_{i-1,j})^2}.$$

Consider the point $(i,j)=(1,2)$ in Figure 3. Since, apparently, $\widehat{D}_x\tau_{i-1,j-1}=0$ for a constant slowness, we see $(\widehat{s}_{ij})^2 = (\widehat{D}_z\tau_{i-1,j})^2$. So the updated final value of τ_{ij} would become at most $\tau_{i-1,j}$, which is wrong (an underestimation)!

The maximization is equivalent to imposing the *maximum angle condition* which takes care of only the rays coming to the point $\mathbf{x}_{ij}$ through the *numerical domain of dependence*. The maximum angle condition was first introduced in [8] and was adopted by Symes and his colleagues [13, 20]; see also [12]. When τ_{ij} is to be updated from the west, the numerical domain of dependence is the line segment $\overline{\mathbf{x}_{i-1,j-1}\mathbf{x}_{i-1,j+1}}$, and every ray approaching from the line segment to $\mathbf{x}_{ij}$ increases the traveltime τ_{ij} (from $\tau_{i-1,j}$) by $\alpha\widehat{s}_{ij}$ at minimum.

The purely forward update procedure (5.1) is as accurate as (2.8)–(2.9) in practical computation. We will see it here for a constant slowness and in section 6 for general media by numerical simulation. Let $h=\Delta x=\Delta z$ and $s(\mathbf{x})\equiv s_0$ in Figure 3. Let the traveltimes on the narrow band have been computed accurately. Let us try to compute $\tau_{1,2}$, whose analytic value is $\sqrt{5}hs_0 \approx 2.236\cdot hs_0$. First, we utilize the formula (2.8)–(2.9):

$$(\tau_{1,2}-\tau_{0,2})^2 + (\tau_{1,2}-\tau_{1,1})^2 = h^2 s_0^2. \tag{5.2}$$

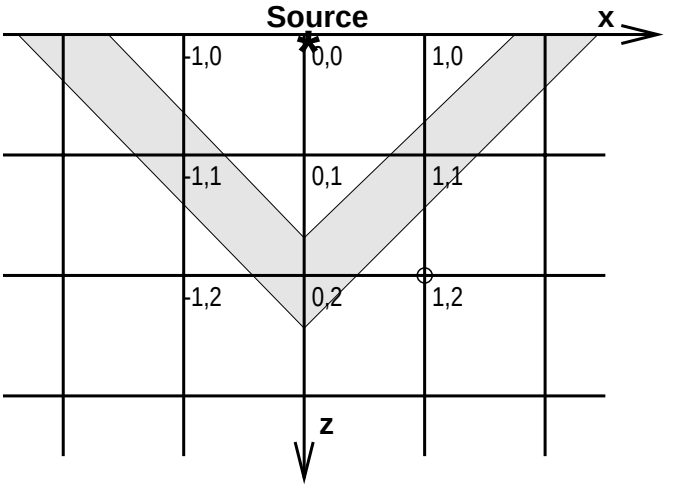

FIG. 3. *The narrow band method in two dimensions. The slowness is assumed to be constant. The shaded area denotes the narrow band at a certain moment. A point source is located at the origin marked by an asterisk.*

Replacing $\tau_{0,2}$ and $\tau_{1,1}$ by $2hs_0$ and $\sqrt{2}hs_0$, respectively, and solving the quadratic equation, we have

$$\tau_{1,2} \approx 2.351 \cdot hs_0,$$

which is the best value for $\tau_{1,2}$ from all former and other updates of (2.8)–(2.9). Now we apply (5.1):

$$\begin{aligned} \tau_{1,2} &= \tau_{1,1} + h \cdot \max\left(\tfrac{1}{\sqrt{2}}s_0,\ \sqrt{s_0^2 - (\widehat{D}_x\tau_{1,1})^2}\right), \\ \tau_{1,2} &= \tau_{0,2} + h \cdot \max\left(\tfrac{1}{\sqrt{2}}s_0,\ \sqrt{s_0^2 - (\widehat{D}_z\tau_{0,2})^2}\right). \end{aligned} \tag{5.3}$$

Again, substituting the analytic values, we have the minimum

$$\tau_{1,2} \approx 2.324 \cdot hs_0,$$

which slightly improves accuracy over (2.8)–(2.9). The above argument can be applied to every point.

The main reason for the introduction of (5.1) is not for such a slight improvement in accuracy, but for more efficient incorporation of the average normal slowness. Note that the formula (5.1) incorporates ray directions more explicitly than (2.8)–(2.9). Since chasing raypaths is expensive, an approximation can be utilized as follows. For example, for the update from the west, an approximate average slowness can be found as

$$\widehat{s}_{i,j} \approx \begin{cases} s_{ij} & \text{if } s_{i-1,j} = s_{i,j}, \\ \dfrac{\log(v_{i-1,j}) - \log(v_{i,j})}{v_{i-1,j} - v_{i,j}} & \text{else.} \end{cases} \tag{5.4}$$

The above is compared with (4.3) in the same line. In heterogeneous media, the above average slowness produces more accurate traveltimes with (5.1) than with (2.8)–(2.9); see numerical results in section 6.

TABLE 1
Accuracy and efficiency of the GMM in two dimensions. A point source is located at $(x, z) = (3000, 0)$.

		Point slowness				Average slowness			
		(2.8)–(2.9)		(5.1)		(2.8)–(2.9)		(5.1)	
v	M^2	CPU	$E(\tau^h)$	CPU	$E(\tau^h)$	CPU	$E(\tau^h)$	CPU	$E(\tau^h)$
v_1	100^2	0.13	4.6e-2	0.09	3.5e-2	0.15	3.4e-2	0.11	2.1e-2
	200^2	0.52	2.5e-2	0.37	1.8e-2	0.62	1.9e-2	0.44	8.2e-3
	400^2	2.14	1.3e-2	1.44	9.3e-3	2.43	1.0e-2	1.78	3.6e-3
v_2	100^2	0.14	3.6e-2	0.09	2.3e-2	0.17	3.5e-2	0.12	1.5e-2
	200^2	0.52	2.0e-2	0.35	1.1e-2	0.69	1.9e-2	0.51	7.2e-3
	400^2	2.10	1.1e-2	1.43	5.9e-3	2.71	1.0e-2	2.04	3.5e-3

Remark. In three dimensions, the numerical domain of dependence forms a solid quadrilateral whose edges have the same length. Since six of these surfaces cannot surround the point $\mathbf{x}_{ij}^k$ to be updated (so instability can happen), some auxiliary difference formulas should be introduced including the points diagonal from $\mathbf{x}_{ij}^k$ such that the union of numerical domains of dependence is all around in every direction to the target point. For the case $\Delta x = \Delta y = \Delta z$, it is not difficult to introduce such FDs. However, it would be very complicated for general cases. Alternatively, one may combine (2.8)–(2.9), the cell-oriented version, and (5.1), the line-oriented version.

6. Numerical experiments. The GMM in section 3 is implemented in two and three dimensions for the FATTs of (2.1). Set the domain $\Omega = (0, 6000\,\mathrm{m})^d$, $d = 2, 3$. We consider four different velocity models: for $\mathbf{x} \in \Omega$,

$$
\begin{aligned}
v_1(\mathbf{x}) &= 1000 + z \text{ m/s}, \\
v_2(\mathbf{x}) &= 1000 + 0.2x + 0.5z \text{ m/s}, \\
v_3(\mathbf{x}) &= 1000 + 0.3x + 0.2y + 0.4z \text{ m/s}, \\
v_4(\mathbf{x}) &= \begin{cases} 4500 \text{ m/s} & \text{if } \mathbf{x} \in [1500, 4500]^d, \\ 2000 \text{ m/s} & \text{else.} \end{cases}
\end{aligned} \tag{6.1}
$$

(For 2D cases, the y-components are dropped.) The domain is partitioned with $h = \Delta x = \Delta y = \Delta z = 6000/M$ for $M > 0$. Point sources are imposed inside or on the surface of the domain. The traveltimes in linear velocities can be computed analytically; the numerical error is measured as

$$E(\tau^h) = \|\tau^h - \tau_{\text{analytic}}\|_\infty,$$

where τ^h denotes the computed traveltime with a grid size h. The average normal slowness is approximated by (4.3) and (5.4).

The main/driver routines are written in C++, and the core computation routines are in F77. The computation is carried out on a Gateway Solo, a 266 MHz laptop having 128M memory and a Linux operating system. The elapsed time CPU is the user time measured in seconds.

Table 1 compares the accuracy and efficiency of the GMM in two dimensions between the point slowness and the average slowness, and between the quadratic formula (2.8)–(2.9) and the purely forward formula (5.1). Two different velocities (v_1 and v_2) are selected here, and a point source is located at $(x, z) = (3000, 0)$. As one can see from the table, incorporating the average slowness increases about 20–25% computation cost, while the formula (5.1) decreases about 30% the cost of (2.8)–(2.9). The velocity v_1 has a larger variance (in particular, in the vertical direction)

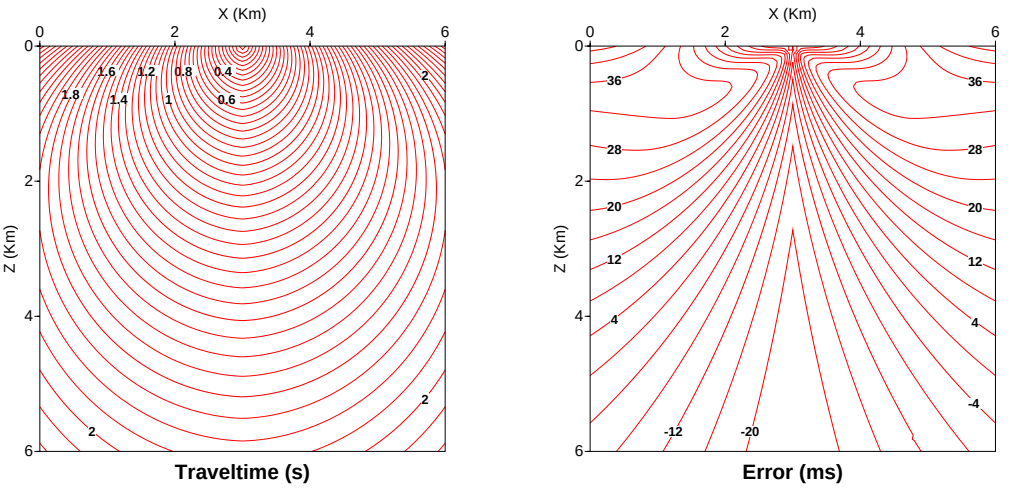

FIG. 4. *The computed traveltime (in seconds) and the error* $\tau^h - \tau_{\text{analytic}}$ *(in milliseconds). Set* $v = v_1$*, and the point source is located at* $(x, z) = (3000, 0)$*. The point slowness is incorporated with the updated formula* (2.8)–(2.9).

than v_2; the formula (5.1) incorporating the average slowness has improved accuracy more dramatically for v_1 than for v_2. We can see from the last panel of the table that its accuracy is slightly better than linear, even measured in the maximum norm. Such *superlinear convergence* has been observed for most linear velocity models. The following should also be noticed.

- The computation cost of the GMM is $\mathcal{O}(N)$ for any choice of slowness and update formula.
- The formula (5.1) is more efficient and accurate than (2.8)–(2.9), whether the slowness is averaged or not.
- The average slowness better improves accuracy when incorporated with the purely forward formula (5.1).

Here we have employed a roughly averaged slowness; however, the numerical error has decreased by a factor of two to three. When the velocity is highly oscillatory or when a higher-order FD scheme is employed, the average slowness is essential to incorporate. The point slowness will impose a first-order accuracy for heterogeneous media, no matter how accurate the FD scheme is.

Figure 4 depicts the computed traveltime (in seconds) and the error $\tau^h - \tau_{\text{analytic}}$ (in milliseconds) for the example discussed in Table 1 ($v = v_1$). The point slowness is incorporated with the update formula (2.8)–(2.9). The error (right side) indicates that the method is both over- and underestimating. Overestimation is not a danger but just an accuracy problem; it can be improved through the minimizing process using more available updating values. On the other hand, underestimation has no way to be fixed.

In Figure 5, we present the error $\tau^h - \tau_{\text{analytic}}$ (in milliseconds) for the point slowness (left) and the average slowness (right), both incorporated with the update formula (5.1). As in Figure 4, $v = v_1$, and the point source is located at $(x, z) = (3000, 0)$. No underestimation has been observed for the formula (5.1), as one can see from these pictures. The error for the average slowness is smaller and smoother than that of the

point slowness. Note that the ray direction is vertical on the line segment $\{x = 3000\}$, where the solution incorporating the average slowness is computed without error. (It also can be figured out mathematically.)

In Table 2, we show numerical results for the FMM and GMM in three dimensions. The velocity is chosen as $v = v_3$, and a point source is located at $(x, y, z) = (3000, 3000, 1000)$. The update formula (2.8)–(2.9) is applied. We observe in 3D simulation that the computation cost of the FMM increases more rapidly than the problem size, while GMM costs $\mathcal{O}(N)$. One can easily expect that the GMM is three to five times faster than the FMM for problems of reasonable sizes. It should be noticed that the average slowness improves accuracy better for the GMM.

In Figure 6, we depict the computed traveltime of the GMM in three dimensions superimposed on the cross section $\{y = 3000\}$ of the velocity model $v = v_4$. The number of grid points is 100^3 and the source is located at $(x, y, z) = (1000, 3000, 1000)$. The update formula (2.8)–(2.9) is utilized incorporating the average slowness; the GMM takes 39.89 seconds. There one can see the shocks developed during the advancement of the wavefronts, due to the headwave out from the high velocity region.

7. Discussion. The GMM is yet to be tested for realistic models, in particular, in three dimensions. Since the performance of the GMM is weakly dependent on the

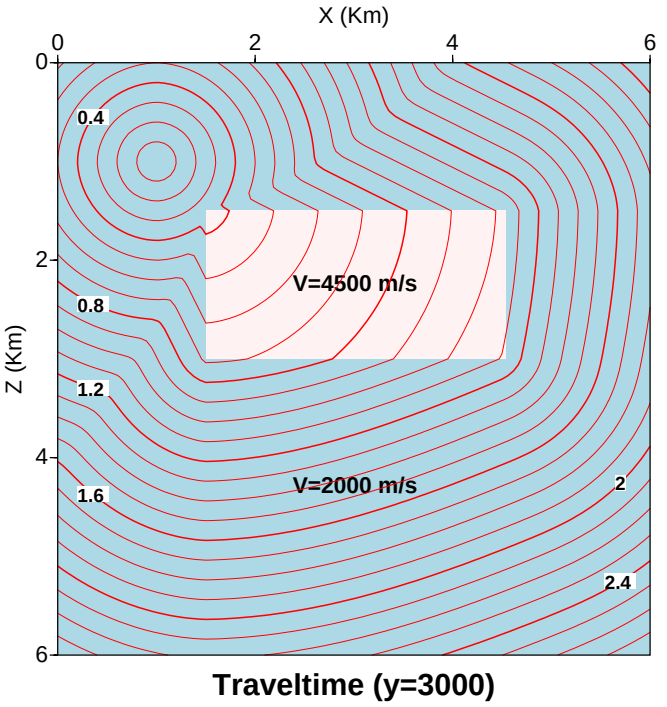

FIG. 6. *The computed traveltime of the GMM in three dimensions superimposed on the cross section* $\{y = 3000\}$ *of the velocity* $v = v_4$. *The number of grid points is* 100^3, *and the source is located at* $(x, y, z) = (1000, 3000, 1000)$.

velocity model, as one can see from Table 1, we can conclude that a 3D problem of a million unknowns can be solved in 40 seconds on a 266 MHz laptop. Nonetheless, I would like to discuss some important aspects on the accuracy, efficiency, and applicability of the level set methods, both the FMM [25, 27] and the GMM.

Higher-order extension. The level set methods are hard to incorporate high-order FD schemes. Sethian [27] suggested one-sided high-order schemes to be considered whenever the traveltimes at the corresponding points are available. Here one should notice that one-sided high-order FD schemes can produce a less accurate solution than the first-order scheme, in particular, in heterogeneous media. Even if the medium is constant, the one-sided second-order scheme easily produces underestimated solutions, as one can see from [27]. An interested reader can also check it for the computation of $\tau_{1,2}$ in Figure 3 using the second-order version of (5.2) presented in [27]. (Your result would be approximately $2.205 \cdot hs_0$; the exact value is $2.236 \cdot hs_0$.)

Computation cost. Now the level set method can be carried out for the computation cost of $\mathcal{O}(N)$ instead of $\mathcal{O}(N \log N)$. However, both the FMM and the GMM access the data (such as the solution, the narrow band points, and the binary tree (FMM)) in an almost random manner, rather than a systematic way along the loop indices. As a consequence, the algorithms can be more expensive than expected, depending on the computers adopted.

Applicability to the traveltime computation in seismology. Seismic image processing methods require an accurate computation of traveltimes of acoustic or elastic waves. When a set of seismic survey data is acquired utilizing the main frequency of 40Hz, for example, the period for the propagation of one wavelength is 25 milliseconds. For a reasonable image processing, the error should be much less than 25 milliseconds over the whole domain whose edge lengths are often 4,000 m to 9,000 m. For the example in Table 2, one has to choose approximately 300 points ($h = 20$ m) in each direction to keep the error below 10 milliseconds; the expected computation time is 16 to 19 minutes in the same machine (ignoring the memory problem), which is extremely expensive. Note that for a section of seismic image, the traveltimes are often computed for more than 10,000 shot-gathers. (If a machine of the same speed tested here is used, it will take at least four months for the traveltime computation.) See [8, 9, 10, 12, 13, 21, 22, 31] for numerical methods and related issues in the traveltime computation and seismic image processing.

Overall, the level set methods should be far more improved (particularly, in accuracy) for a wider range of applications. The update formula discussed at the end of section 5 for the 3D problem, a second-order FD scheme applicable to heterogeneous media, and applications to anisotropic media will be the subjects of a forthcoming paper [11].

8. Conclusions. An optimal level set method called the GMM has been suggested, based on a physical investigation for the solution on the narrow band of wavefronts. It has been applied to the computation of the FATTs of the eikonal equation in two and three dimensions. The GMM incorporates both the narrow band approach [25, 27] and the iterative scheme [23]; it converges in two iterations for a group of points in the narrow band. Strategies have been discussed to reduce the cost of the double-computation. We have introduced the average normal slowness to improve accuracy; its approximation is discussed for an efficient implementation. A new alternative update formula is suggested for the 2D problem, and it is numerically verified to be superior to that of the conventional level set methods in both efficiency and accuracy. For various velocities, grid sizes, and update formulae, the GMM has carried out its job for the cost $\mathcal{O}(N)$, where N is the total number of grid points. The GMM performs three to five times faster than the FMM for reasonable-size problems in three dimensions.

Acknowledgments. The author expresses his sincere thanks to Professor S. Osher, UCLA, for his interests and valuable comments. Constructive comments by two anonymous reviewers improved the paper and are much appreciated.

A SCALABLE PARALLEL ALGORITHM FOR INCOMPLETE FACTOR PRECONDITIONING*

DAVID HYSOM† AND ALEX POTHEN†

Abstract. We describe a parallel algorithm for computing incomplete factor (ILU) preconditioners. The algorithm attains a high degree of parallelism through graph partitioning and a two-level ordering strategy. Both the subdomains and the nodes within each subdomain are ordered to preserve concurrency. We show through an algorithmic analysis and through computational results that this algorithm is scalable. Experimental results include timings on three parallel platforms for problems with up to 20 million unknowns running on up to 216 processors. The resulting preconditioned Krylov solvers have the desirable property that the number of iterations required for convergence is insensitive to the number of processors.

Key words. incomplete factorization, ILU, preconditioning, parallel preconditioning

1. Introduction.

Incomplete factorization (ILU) preconditioning is currently among the most robust techniques employed to improve the convergence of Krylov space solvers for linear systems of equations. (ILU stands for incomplete LU factorization, where L and U are the lower and upper triangular (incomplete) factors of the coefficient matrix.) However, scalable parallel algorithms for computing ILU preconditioners have not been available despite the fact that they have been used for more than twenty years [12]. We report the design, analysis, implementation, and computational evaluation of a parallel algorithm for computing ILU preconditioners.

Our parallel algorithm assumes that three requirements are satisfied.

- The adjacency graph of the coefficient matrix (or the underlying finite element or finite difference mesh) must have good edge separators, i.e., it must be possible to remove a small set of edges to divide the problem into a collection of subproblems that have roughly equal computational work requirements.
- The size of the problem must be sufficiently large relative to the number of processors so that the work required by the subgraph on each processor is suitably large to dominate the work and communications needed for the boundary nodes.
- The subdomain intersection graph (to be defined later) should have a small chromatic number. This requirement will ensure that the dependencies in factoring the boundary rows do not result in undue losses in concurrency.

An outline of the paper is as follows. In section 2, we describe the steps in the parallel algorithm for computing the ILU preconditioner in detail and provide theoretical justification. The algorithm is based on an incomplete fill path theorem; the proof and discussion of the theorem are deferred to an appendix. We also discuss

the role that a subdomain graph constraint plays in the design of the algorithm, show that the preconditioners exist for special classes of matrices, and relate our work to earlier work on this problem. Section 3 contains an analysis that shows that the parallel algorithm is scalable for two-dimensional (2D-) and three-dimensional (3D-)model problems, when they are suitably ordered and partitioned. Section 4 contains computational results on Poisson and convection-diffusion problems. The first subsection shows that the parallel ILU algorithm is scalable on three parallel platforms; the second subsection reports convergence studies. We tabulate how the number of Krylov solver iterations and the number of entries in the preconditioner vary as a function of the preconditioner level for three variations of the algorithm. The results show that fill levels higher than one are effective in reducing the number of iterations; the number of iterations is insensitive to the number of subdomains; and the subdomain graph constraint does not affect the number of iterations while it makes possible the design of a simpler parallel algorithm.

The background needed for ILU preconditioning may be found in several books; see, e.g., [1, 15, 17, 33]. A preliminary version of this paper was presented at Supercomputing '99 and was published in the conference proceedings [18]. The algorithm has been revised, additional details have been included, and the proof of the theorem on which it is based has been added. The experimental results in section 4 are new, and most of them have been included in the technical reports [19, 20].

2. Algorithms. In this section we discuss the Parallel ILU (PILU) algorithm and its underlying theoretical foundations.

2.1. The PILU algorithm. Figure 2.1 describes the steps of the PILU algorithm at a high level; the algorithm is suited for implementation on both message-passing and shared-address space programming models.

The PILU algorithm consists of four major steps. In the first step, we create parallelism by dividing the problem into subproblems by means of graph partitioning. In the second step, we preserve the parallelism in the interior of the subproblems by locally scheduling the computations in each subgraph. In the third step, we preserve parallelism in the boundaries of the subproblems by globally ordering the subproblems through coloring a suitably defined graph. In the final step, we compute the preconditioner in parallel. Now we will describe the four steps in greater detail.

Step 1: Graph partitioning. In the first step of PILU, we partition the adjacency graph $G(A)$ of the coefficient matrix A into p subgraphs by removing a small set of edges that connects the subgraphs to each other. Each subgraph will be mapped to a distinct processor that will be responsible for the computations associated with the subgraph.

An example of a model five-point grid partitioned into four subgraphs is shown in Figure 2.2. For clarity, the edges corresponding to the coefficient matrix elements (within each subgraph or between subgraphs) are not shown. The edges drawn correspond to fill elements (elements that are zero in the coefficient matrix but are nonzero in the incomplete factors) that join the different subgraphs.

To state the objective function of the graph partitioning problem, we need to introduce some terminology. An edge is a *separator edge* if its endpoints belong to different subgraphs. A vertex in a subgraph is an *interior vertex* if all of its neighbors belong to that subgraph; it is a *boundary vertex* if it is adjacent to one or more vertices belonging to another subgraph. By definition, an interior vertex in a subgraph is not adjacent to a vertex (boundary or interior) in another subgraph. In Figure 2.2, the first 25 vertices are interior vertices of the subgraph S_0, and vertices numbered 26 through 36 are its

Input: A coefficient matrix, its adjacency graph, and the number of processors p.
Output: The incomplete factors of the coefficient matrix.

1. Partition the adjacency graph of the matrix into p subgraphs (subdomains), and map each subgraph to a processor. The objectives of the partitioning are that the subgraphs should have roughly equal work, and there should be few edges that join the different subgraphs.
2. On each subgraph, locally order interior nodes first, and then order boundary nodes.
3. Form the subdomain intersection graph corresponding to the partition, and compute an approximate minimum vertex coloring for it. Order subdomains according to color classes.
4. Compute the incomplete factors in parallel.
   a. Factor interior rows of each subdomain.
   b. Receive sparsity patterns and numerical values of the nonzeros of the boundary rows of lower-numbered subdomains adjacent to a subdomain (if any).
   c. Factor boundary rows in each subdomain and send the sparsity patterns and numerical values to higher-numbered neighboring subdomains (if any).

FIG. 2.1. *High level description of the PILU algorithm.*

boundary vertices. The goal of the partitioning is to keep the amount of work associated with the incomplete factorization of each subgraph roughly equal, while keeping the communication costs needed to factor the boundary rows as small as possible.

There is a difficulty with modeling the communication costs associated with the boundary rows. In order to describe this difficulty, we need to relate this cost more precisely to the separators in the graph. Define the *higher degree* of a vertex v as the number of vertices numbered higher than v in a given ordering. We assume that upward-looking, row-oriented factorization is used. At each boundary between two subgraphs, elements need to be communicated from the lower numbered subgraph to the higher numbered subgraph. The number of these elements is proportional to the sum of the higher degrees (in the filled graph $G(F)$) of the boundary vertices in the lower numbered subgraph. But unfortunately, we do not know the fill edges at this point since we have neither computed an ordering of $G(A)$ nor computed a symbolic factorization. We could approximate by considering higher degrees of the boundary vertices in the graph $G(A)$ instead of the filled graph $G(F)$, but even this requires us to order the subgraphs in the partition.

The union of the boundary vertices on all the subgraphs forms a *wide vertex separator*. This means that the shortest path from an interior vertex in any subgraph to an interior vertex in another subgraph consists of at least three edges; such a path has *length* at least three. The communication cost in the (forward and backward) triangular solution steps is proportional to the sum of the sizes of the wide vertex separators. None of the publicly available graph partitioning software has the minimization of wide separators as its objective function, but it is possible to modify existing software to optimize this objective.

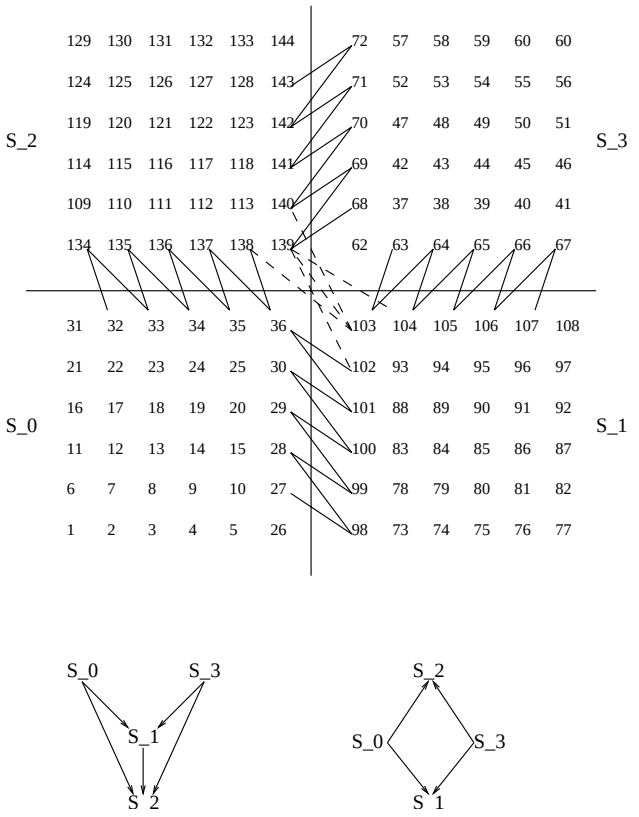

FIG. 2.2. *An example that shows the partitioning, mapping, and vertex ordering used in the PILU algorithm. The graph on the top is a regular* 12×12 *grid with a five-point stencil partitioned into four subdomains and then mapped on four processors. The subdomains are ordered by a coloring algorithm to reduce dependency path lengths. Only the level one and two fill edges that join the different subdomains are shown; all other edges are omitted for clarity. The figure on the bottom right shows the subdomain intersection graph when the subdomain graph constraint is enforced. (This prohibits fill between the boundary nodes of the subdomains* S_1 *and* S_2*, indicated by the broken edges in the top graph.) The graph on the bottom left shows the subdomain intersection graph when the subdomain graph constraint is not enforced.*

The goal of the partitioning step is to keep the amount of work associated with each subgraph roughly equal (for load balance) while making the communication costs due to the boundaries as small as possible. As the previous two paragraphs show, modeling the communication costs accurately in terms of edge and vertex separators in the initial graph $G(A)$ is difficult, but we could adopt the minimization of the wide separator sizes as a reasonable goal. This problem is NP-complete, but there exist efficient heuristic algorithms for partitioning the classes of graphs that occur in practical situations. (Among these graph classes are 2D-finite element meshes and 3D-meshes with good aspect ratios.)

Step 2: Local reordering. In the second step, in each subgraph we order the interior vertices before the boundary vertices. This ordering ensures that during the incomplete factorization, an interior vertex in one subgraph cannot be joined by a fill edge to a vertex in another subgraph, as will be shown later. Fill edges between two subgraphs can join only their boundary vertices together. Thus interior vertices corresponding to the initial graph $G(A)$ remain interior vertices in the graph of the

factor $G(F)$. The consequences of this are that the rows corresponding to the interior vertices in each subdomain of the initial problem $G(A)$ can be factored concurrently, and that communication is required only for factoring rows corresponding to the boundary rows. The reader can verify that in each subgraph in Figure 2.2 the interior nodes have been ordered before the boundary nodes.

The observation concerning fill edges in the preceding paragraph results from an application of the following *incomplete fill path theorem*. Given the adjacency graph $G(A)$ of a coefficient matrix A, the theorem provides a static characterization of where fill entries arise during an incomplete factorization $A = \hat{L}\hat{U} + E$, where $\hat{L}$ is the lower triangular incomplete factor, $\hat{U}$ is the upper triangular incomplete factor, and E is the remainder matrix. The characterization is static in that fill is completely described by the structure of the graph $G(A)$; no information from the factor is required.

We need a definition before we can state the theorem. A *fill path* is a path joining two vertices i and j, all of whose interior vertices are numbered lower than the end vertices i and j.[1]

Recall also the definition of the levels assigned to nonzeros in an incomplete factorization. To discuss the sparsity pattern of the incomplete factors, we consider the filled matrix $F = \hat{L} + \hat{U} - I$. The sparsity pattern of F is initialized to that of A. All nonzero entries in F corresponding to nonzeros in A have level zero, and zero entries have level infinity. New entries that arise during factorization are assigned a level based on the levels of the causative entries, according to the rule

$$\text{level}(f_{ij}) = \min_{1 \le h < \min\{i,j\}} \{\text{level}(f_{ih}) + \text{level}(f_{hj}) + 1\}.$$

The incomplete fill path theorem describes an intimate relationship between fill entries in ILU(k) factors and path lengths in graphs.

THEOREM 2.1. *Let $F = \hat{L} + \hat{U} - I$ be the filled matrix corresponding to an incomplete factorization of A, and let f_{ij} be a nonzero entry in F. Then f_{ij} is a level k entry if and only if there exists a shortest fill path of length $k+1$ that joins i and j in $G(A)$.*

A proof and a discussion of this theorem are included in the appendix.

Now consider the adjacency graph $G(A)$ and a partition $\Pi = \{S_0, \ldots, S_{p-1}\}$ of it into subgraphs (subdomains). Any path joining two interior nodes in distinct subdomains must include at least two boundary nodes, one from each of the subgraphs; since each boundary node is numbered higher than (at least one of) the path's end vertices (since these are interior nodes in the subgraph), this path cannot be a fill path. If two interior nodes belonging to separate subgraphs were connected by a fill path and the corresponding fill entry were permitted in F, the interior nodes would be transformed into boundary nodes in $G(F)$. This is undesirable for parallelism, since then there would be fewer interior nodes to be eliminated concurrently.

The local ordering step preserves interior and boundary nodes during the factorization and ensures that a subdomain's interior rows can be factored independently of row updates from any other subdomain. Therefore, when subdomains have relatively large interior/boundary node ratios, and contain approximately equal amounts of computational work, we expect PILU to exhibit a high degree of parallelism.

[1]The reader has doubtless noted that *interior* is used in a different sense here than previously. We trust it will be obvious from the context where *interior* is used to refer to nodes in paths and where it is used to refer to nodes in subgraphs.

Step 3: Global ordering. The global ordering phase is intended to preserve parallelism while factoring the rows corresponding to the boundary vertices. In order to explain the loss of concurrency that could occur during this phase of the algorithm, we need the concept of a subdomain intersection graph, which we shall call a subdomain graph for brevity.

The subdomain graph $S(G, \Pi) = (V_s, E_s)$ is computed from a graph G and its partition $\Pi = \{S_0, \ldots, S_{p-1}\}$ into subgraphs. The vertex set V_s contains a vertex corresponding to every subgraph in the partition; the edge set E_s contains edge $\{S_i, S_j\}$ if there is an edge in G with one endpoint in S_i and the other in S_j. We can compute a subdomain graph $S(A)$ corresponding to the initial graph $G(A)$ and its partition. (This graph should be denoted $S(G(A), \Pi)$, but we shall write $S(A)$ for simplicity.) We could also compute a subdomain graph $S(F)$ corresponding to the graph of the factor $G(F)$. The subdomain graph $S(A)$ corresponding to the partition of the initial graph $G(A)$ (the top graph) in Figure 2.2 is shown in the graph at the bottom right in that figure.

We impose a constraint on the fill, *the subdomain graph constraint.* The subdomain graph corresponding to $G(F)$ is restricted to be identical to the subdomain graph corresponding to $G(A)$. This prohibits some fill in the filled graph $G(F)$: if two subdomains are not joined by an edge in the original graph $G(A)$, any fill edge that joins those subdomains is not permitted in the graph of the incomplete factor $G(F)$. The description of the PILU algorithm in Figure 2.1 assumes that the subdomain graph constraint is satisfied. This constraint makes it possible to obtain scalability in the parallel ILU algorithm. Later, we discuss how the algorithm should be modified if this constraint is relaxed.

Each subdomain's nodes (in $G(A)$) are ordered contiguously. Consequently, saying "subdomain r is ordered before subdomain s" is equivalent to saying "all nodes in subdomain r are ordered, and then all nodes in subdomain s are ordered." This permits $S(A)$ to be considered as a directed graph, with edges oriented from lower to higher numbered vertices.

Edges in $S(F)$ indicate data dependencies in factoring the boundary rows of the subdomains. If an edge in $S(F)$ joins r and s and subdomain r is ordered before subdomain s, then updates from the boundary rows of r have to be applied to the boundary rows of s before the factorization of the latter rows can be completed. It follows that ordering $S(F)$ so as to reduce directed path lengths reduces serial bottlenecks in factoring the boundary rows. If we impose the subdomain graph constraint, these observations apply to the subdomain graph $S(A)$ as well since then $S(A)$ is identical with $S(F)$.

We reduce directed path lengths in $S(A)$ by coloring the vertices of the subdomain graph with few colors using a heuristic algorithm for graph coloring, and then by numbering the subdomains by color classes. The boundary rows of all subdomains corresponding to the first color can be factored concurrently without updates from any other subdomains. These subdomains update the boundary rows of higher numbered subdomains adjacent to them. After the updates, the subdomains that correspond to the second color can factor their boundary rows. This process continues by color classes until all subdomains have factored their boundary rows. The number of steps it takes to factor the boundary rows is equal to the number of colors it takes to color the subdomain graph.

In Figure 2.2, let p_i denote the processor that computes the subgraph S_i. Then p_0 computes the boundary rows of S_0 and sends them to processors p_1 and p_2. Similarly,

p_3 computes the boundary rows of subgraph S_3 and sends them to p_1 and p_2. The latter processors first apply these updates and then compute their boundary rows.

How much parallelism can be gained through subdomain graph reordering? We can gain some intuition through analysis of simplified model problems, although we cannot answer this question a priori for general problems and all possible partitions. Consider a matrix arising from a second order PDE that has been discretized on a regularly structured 2D grid using a standard five-point stencil. Assume that the grid is naturally ordered and that it has been partitioned into square subgrids and mapped into a square grid of p processors. In the worst case, the associated subdomain graph, which itself has the appearance of a regular 2D grid, can have a dependency path of length $2(\sqrt{p}-1)$. Similarly, a regularly structured 3D grid discretized with a seven-point stencil that is naturally ordered and then mapped on a cube containing p processors can have a dependency path length of $3(\sqrt[3]{p}-1)$. However, regular 2D grids with the five-point stencil and regular 3D grids with the seven-point stencil are bipartite graphs and can be colored with two colors. If all subdomains of the first color class are numbered first, and then all subdomains of the second color class are numbered, the longest dependency path in S will be reduced to one. This discussion shows that coloring the subdomain graph is an important step in obtaining a scalable parallel algorithm.

Step 4: Preconditioner computation. Now that the subdomains and the nodes in each subdomain have been ordered, the preconditioner can be computed. We employ an upward-looking, row oriented factorization algorithm. The interior of each subdomain can be computed concurrently by the processors, and the boundary nodes can be computed in increasing order of the color classes. Either a level-based ILU(k) or a numerical threshold based ILUT(τ, p) algorithm may be employed on each subdomain. Different incomplete factorization algorithms could be employed in different subdomains when appropriate, as in multiphysics problems. Different fill levels could be employed for the interior nodes in a subdomain and for the boundary nodes to reduce communication and synchronization costs.

2.2. Relaxing the subdomain graph constraint. Now we consider how the subdomain graph constraint might be relaxed. Given a graph $G(A)$ and a partition of it into subgraphs, we color the subdomain graph $S(A)$ and order its subdomains as before. Then we compute the graph $G(F)$ of an incomplete factor and its subdomain graph $S(F)$. To do this, we need to discover the dependencies in $S(F)$, but initially we have only the dependencies in $S(A)$ available. This has to be done in several rounds, because fill edges could create additional dependencies between the boundary rows of subdomains, which in turn might lead to further dependences. The number of rounds needed is the length of a longest dependency path in the subdomain graph $G(F)$, and this could be $\Omega(p)$. This discussion applies when an ILU(k) algorithm is employed, with symbolic factorization preceding numerical factorization. If ILUT were to be employed, then symbolic factorization and numerical factorization must be interleaved, as would be done in a sequential algorithm.

We can then color the vertices of $S(F)$ to compute a schedule for factoring the boundary rows of the subdomains. For achieving concurrency in this step the subdomain graph $S(F)$ should have a small chromatic number (independent of the number of vertices in $G(A)$). Note that the description of the PILU algorithm in Figure 2.1 needs to be modified to reflect this discussion when the subdomain graph constraint is relaxed.

The graph $G(F)$ in Figure 2.2 indicates the fill edges that join S_1 to S_2 as broken

lines. The corresponding subdomain intersection graph $S(F)$ is shown on the lower left. The edge between S_1 and S_2 necessitates three colors to color $S(F)$: the subdomains S_0 and S_3 form one color class; S_1 by itself constitutes the second color class; and S_2 by itself makes up the third color class. Thus three steps are needed for the computation of the boundary rows of the preconditioner when the subdomain graph constraint is relaxed. Note that the processor responsible for the subdomain S_2 can begin computing its boundary rows when it receives an update from either S_0 or S_3, but that it cannot complete its computation until it has received the update from the subdomain S_1.

Theorem 2.1 has an intuitively simple geometric interpretation. Given an initial node i in $G(A)$, construct a topological "sphere" containing all nodes that are at a distance less than or equal to $k+1$ edges. Then a fill entry f_{ij} is admissible in an $ILU(k)$ factor only if j is within the sphere. Note that all such nodes j do not cause fill edges since there needs to be a fill path joining i and j. By applying Theorem 2.1, we can gain an intuitive understanding of the fill entries that may be discarded on account of the subdomain graph constraint. Referring again to Figure 2.2, we see that prohibited edges arise when two nonadjacent subdomains in $G(A)$ have nodes that are joined by a fill path of length less than $k+1$. No level zero edge is discarded by the constraint.

2.3. Existence of PILU preconditioners. The existence of preconditioners computed from the PILU algorithm can be proven for some classes of problems.

Meijerink and van der Vorst [28] proved that if A is an M-matrix, then ILU factors exist for any predetermined sparsity pattern, and Manteuffel [27] extended this result to H-matrices with positive diagonal elements. These results immediately show that PILU preconditioners with sparsity patterns based on level values exist for these classes of matrices. This is true even when different level values are used for the various subdomains and boundaries.

Incomplete Cholesky (IC) preconditioners for symmetric problems could be computed with our parallel algorithmic framework using preconditioners proposed by Jones and Plassmann [21] and by Lin and Moré [23] on each subdomain and on the boundaries. The sparsity patterns of these preconditioners are determined by the numerical values in the matrix and by memory constraints. Lin and Moré have proved that these preconditioners exist for M- and H-matrices. Parallel IC preconditioners also can be shown to exist for M- and H-matrices. If the subdomain graph constraint is not enforced, then the preconditioner computed in parallel corresponds to a preconditioner computed by the serial algorithm from a reordered matrix. If the constraint is enforced, some specified fill elements are dropped from the Schur complement; it can be shown that the resulting Schur complement matrix is componentwise larger than the former and hence still an M-matrix.

2.4. Relation to earlier work. We now briefly discuss earlier parallel ILU algorithms that are related to the PILU algorithm proposed here. Earlier attempts at parallel algorithms for preconditioning (including approaches other than incomplete factorization) are surveyed in [6, 12, 34]; orderings suitable for parallel incomplete factorizations have been studied inter alios in [4, 11, 13]. The surveys also describe the alternate approximate inverse approach to preconditioning.

Saad [33, section 12.6.1] discusses a distributed ILU(0) algorithm that has the features of graph partitioning, elimination of interior nodes in a subdomain before boundary nodes, and coloring the subdomains to process the boundary nodes in parallel. Only level 0 preconditioners are discussed there, so that fill between subdomains, or

within each subdomain, do not need to be considered. No implementations or results were reported, although Saad has informed us recently of a technical report [24] that includes an implementation and results. Our work, done independently, shows how fill levels higher than zero can be accommodated within this algorithmic framework. We also analyze our algorithm for scalability and provide computational results on the performance of PILU preconditioners. Our results show that fill levels higher than zero are indeed necessary to obtain parallel codes with scalability and good performance.

Karypis and Kumar [22] have described a parallel ILUT implementation based on graph partitioning. Their algorithm does not include a symbolic factorization, and they discover the sparsity patterns and the values of the boundary rows after the numerical computation of the interior rows in each subdomain. The factorization of the boundary rows is done iteratively, as in the discussion given above, where we show how the subdomain graph constraint might be relaxed. The partially filled graph of the boundary rows after the interior rows are eliminated is formed, and this graph is colored to compute a schedule for computing the boundary rows. Since fill edges in the boundary rows are discovered as these rows are being factored, this approach could lead to long dependency paths that are $\Theta(p)$. The number of boundary rows is $\Omega(N^{1/2})$ for 2D meshes, and $\Omega(N^{2/3})$ for 3D meshes with good aspect ratios. If the cost of factoring and communicating a boundary row is proportional to the number of rows, then this phase of their algorithm could cost $\Omega(p\sqrt{N})$, severely limiting the scalability of the algorithm (cf. the discussion in section 3).

Recently Magolu monga Made and van der Vorst [25, 26] have reported variations of a parallel algorithm for computing ILU preconditioners. They partition the mesh, linearly order the subdomains, and then permit fill in the interior and the boundaries of the subdomains. The boundary nodes are classified with respect to the number of subdomains they are adjacent to, and are eliminated in increasing order of this number. Since the subdomains are linearly ordered, a "burn from both ends" ordering is employed to eliminate the subdomains. Our approaches are similar, except that we additionally order the subdomains by means of a coloring to reduce dependency path lengths to obtain a scalable algorithm. They have provided an analysis of the condition number of the preconditioned matrices for a class of 2D second order elliptic boundary value problems. They permit high levels of fill (four or greater) as we do, and show that the increased fill permitted across the boundaries enables the condition number of the preconditioned matrix to be insensitive to the number of subdomains (except when the latter gets too great). We have worked independently of each other.

A different approach, based on partitioning the mesh into rectangular strips and then computing the preconditioner in parallel steps in which a "wavefront" of the mesh is computed at each step by the processors, was proposed by Bastian and Horton [3] and was implemented for shared memory multiprocessors recently by Vuik, van Nooyen, and Wesseling [36]. This approach has less parallelism than the one considered here.

3. Performance analysis. In this section we present simplified theoretical analyses of algorithmic behavior for matrices arising from PDEs discretized on 2D grids with five-point stencils and 3D grids with seven-point stencils. Since our arguments are structural in nature, we assume ILU(k) is the factorization method used. After a word about nomenclature, we begin with the 2D case.

The word *grid* refers to the grid (mesh) of unknowns for regular 2D and 3D grids with five- and seven-point stencils, respectively; this is identical to the adjacency graph $G(A)$ of the coefficient matrix of these problems. We use the terms *eliminating*

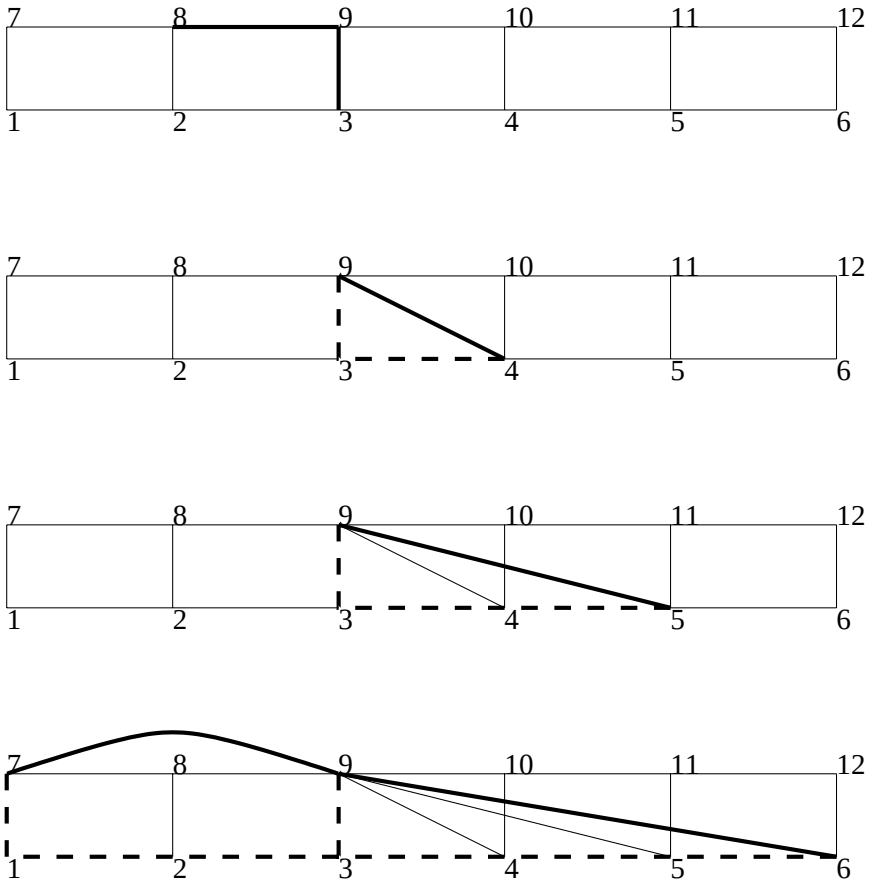

FIG. 3.1. *Counting lower triangular fill edges in a naturally ordered grid. We count the number of edges incident on vertex* 9. *Considering the graphs from top to bottom, we find that there are two level* 0 *edges; there is one level* 1 *edge, due to fill path* 9, 3, 4; *there is one level* 2 *edge due to fill path* 9, 3, 4, 5; *there are two level* 3 *edges, due to fill paths* 9, 3, 4, 5, 6 *and* 9, 3, 2, 1, 7. *We can generalize that two additional fill edges are created for every level greater than three, except near the boundaries. We conclude that asymptotically there are* $2k$ *lower triangular edges incident on a vertex in a level* k *factorization. Since the mesh corresponds to a structurally symmetric problem, there are* $2k$ *upper triangular edges incident on a vertex as well.*

a node and *factoring a row* synonymously.

We assume the grid has been block-partitioned, with each subdomain consisting of a square subgrid of dimension $c \times c$. We also assume the subdomain grid has dimensions $\sqrt{p} \times \sqrt{p}$, so there are p processors in total. There are thus $N = c^2 p$ nodes in the grid, and subdomains have at most $4c = 4\sqrt{\frac{N}{p}}$ boundary nodes.

If subdomain interior nodes are locally numbered in natural order and $k \ll c$, each row in the factor F asymptotically has $2k$ (strict) upper triangular and $2k$ (strict) lower triangular nonzero entries. The justification for this statement arises from a consideration of the incomplete fill path theorem; the intuition is illustrated in Figure 3.1.

Assuming that the classical ILU(k) algorithm is used for symbolic factorization, both symbolic and numeric factorization of row j entails $4k^2$ arithmetic operations. This is because for each lower triangular entry f_{ji} in matrix row j, factorization requires an arithmetic operation with each upper triangular entry in row i.

A red-black ordering of the subdomain graph gives an optimal bipartite division.

If red subdomains are numbered before black subdomains, our algorithm simplifies to the following three stages.

1. Red processors eliminate all nodes; black processors eliminate interior nodes.
2. Red processors send boundary-row structure and values to black processors.
3. Black processors eliminate boundary nodes.

If these stages are nonoverlapping, the cost of the first stage is bounded by the cost of eliminating all nodes in a subdomain. This cost is $4k^2c^2 = \frac{4k^2N}{p}$.

The cost for the second stage is the cost of sending structural and numerical values from the upper-triangular portions of the boundary rows to neighboring processors. If $k \ll c$, the incomplete fill path theorem can be used to show that, asymptotically, a processor only needs to forward values from c rows to each neighbor. We assume a standard, noncontentious communication model wherein α and β represent message startup and per-word-transfer times, respectively. We measure these times in nondimensional units of flops by dividing them by the time it takes to execute one flop. The time for an arithmetic operation is thus normalized to unity. Then the cost for the second step is $4(\alpha + 2k\beta c) = 4(\alpha + 2k\beta\sqrt{\frac{N}{p}})$.

Since the cost of factoring a boundary row can be shown to be asymptotically identical to that for factoring an interior row, the cost for eliminating the $4c$ boundary nodes is $(4k^2)(4c) = 16k^2\sqrt{\frac{N}{p}}$. Speedup can then be expressed as

$$\text{speedup} = \frac{4k^2N}{\frac{4k^2N}{p} + 4(\alpha + 2k\beta\sqrt{\frac{N}{p}}) + 16k^2\sqrt{\frac{N}{p}}}.$$

The numerator represents the cost for sequential execution, and the three terms in the denominator represent the costs for the three stages (arithmetic for interior nodes, communication costs, and arithmetic for the boundary nodes) of the parallel algorithm.

Three implications from this equation are in order. First, for a fixed problem size and number of processors, the parallel computational cost (the first and third terms in the denominator) is proportional to k^2, while the communication cost (the second term in the denominator) is proportional to k. This explains the increase in efficiency with level that we have observed. Second, if the ratio N/p is large enough, the first term in the denominator will become preeminent, and efficiency will approach 100%. Third, if we wish to increase the number of processors p by some factor while maintaining a constant efficiency, we need only increase the size of the problem N by the same factor. This shows that our algorithm is scalable. This observation is not true for a direct factorization of the coefficient matrix, where the dependencies created by the additional fill cause loss in concurrency.

For the 3D case we assume partitioning into cubic subgrids of dimension $c \times c \times c$ and a subdomain grid of dimension $p^{1/3} \times p^{1/3} \times p^{1/3}$, which gives $N = c^3p$. Subdomains have at most $6c^2$ boundary nodes. A development similar to that above shows that, asymptotically, matrix rows in the factor F have $2k^2$ (strict) upper and lower triangular entries, so the cost for factoring a row is $4k^4$. Speedup for this case can then be expressed as

$$\begin{aligned}\text{speedup} &= \frac{4k^4N}{\frac{4k^4N}{p} + 6(\alpha + 2k^2\beta(\frac{N}{p})^{1/3}) + 24k^4(\frac{N}{p})^{1/3}} \\ &= \frac{2k^4N}{\frac{2k^4N}{p} + 3(\alpha + 2k^2\beta(\frac{N}{p})^{1/3}) + 12k^4(\frac{N}{p})^{1/3}}.\end{aligned}$$

4. Results. Results in this section are based on the following model problems.
Problem 1. Poisson's equation in two or three dimensions:

$$\Delta u = g.$$

Problem 2. Convection-diffusion equation with convection in the xy plane:

$$-\varepsilon \triangle u + \frac{\partial}{\partial x} e^{xy} u + \frac{\partial}{\partial y} e^{-xy} u = g.$$

Homogeneous boundary conditions were used for both problems. Derivative terms were discretized on the unit square or cube, using 3-point central differencing on regularly spaced $n_x \times n_y \times n_z$ grids ($n_z = 1$ for 2D). The values for ε in Problem 2 were set to 1/500 and 1/1000. The problem becomes increasingly unsymmetric, and more difficult to solve accurately as ε decreases. The right-hand sides of the resulting systems, $Ax = b$, were artificially generated as $b = A\hat{e}$, where $\hat{e}$ is the all-ones vector.

ILU(k) preconditioning is amenable to performance analysis since the nonzero structures of ILU(k) preconditioners are identical for *any* PDE that has been discretized on a 2D or 3D grid with a given stencil. The structure depends on the grid and the stencil only and is not affected by numerical values if pivoting is not needed for numerical stability. Identical structures imply identical symbolic factorization costs, as well as identical flop counts during the numerical factorization and solve phases. In parallel contexts, communication patterns and costs are also identical. While preconditioner effectiveness—the number of iterations until the stopping criteria is reached—differs with the numerics of the particular problem being modeled, the parallelism available in the preconditioner does not.

The structure of ILUT preconditioners, on the other hand, is a function of the grid, the stencil, and the numerics. Changing the problem, particularly for non-diagonally dominant cases, can alter the preconditioner structure, even when the grid and stencil remain the same.

We report our performance evaluation for ILU(k) preconditioners, although the parallel algorithmic framework proposed here could just as easily work with ILUT(τ, p). We have compared the performance of ILU(k) with ILUT in an earlier report [18]. We report there that for Problem 2 with $\varepsilon = 1/500$, ILUT(0.001, 10) incurred more fill than ILU(5) on a 2D domain for grid sizes up to 400×400; for 3D domains and grid sizes up to $64 \times 64 \times 64$, the same ILUT preconditioner incurred fill between ILU(2) and ILU(3).

In addition to demonstrating that our algorithm can provide high degrees of parallelism, we address several other issues. We study the influence of the subdomain graph constraint on the fill permitted in the preconditioner and on the convergence of preconditioned Krylov space solvers. We also report convergence results as a function of the number of nonzeros in the preconditioner.

4.1. Parallel performance. We now report timing and scalability results for preconditioner factorization and application on three parallel platforms:

- an SGI Origin2000 at NASA Ames Research Center (AMES);
- the Coral PC Beowulf cluster at ICASE, NASA Langley Research Center;
- a Sun HPC 10000 Starfire server at Old Dominion University (ODU).

TABLE 4.1

Dashes (-) for Beowulf and HPC* 10000 *indicate that the machines have insufficient cpus to perform the runs.*

Procs	Origin2000 AMES	Beowulf (ICASE)	HPC 10000 (ODU)
1	2.04	2.27	2.13
8	2.44	3.11	2.43
27	2.96	4.06	2.97
64	3.11	4.64	-
125	3.18	-	-
216	3.32	-	-

Both problems were solved using Krylov subspace methods as implemented in the PETSc [2] software library. Problem 1 was solved using the conjugate gradient method, and Problem 2 was solved using Bi-CGSTAB [35]. PETSc's default convergence criterion was used, which is five orders of magnitude (10^5) reduction in the residual of the preconditioned system. We used our own codes for problem generation, partitioning, ordering, and symbolic factorization.

Table 4.1 shows incomplete factorization timings for a 3D memory-scaled problem with approximately 91,125 unknowns per processor. As the number of processors increases, so does the size of the problem. The coefficient matrix of the problem factored on 216 processors has about 19.7 million rows. ILU(2) was employed for the interior nodes, and ILU(1) was employed for the boundary nodes. Reading down any of the columns shows that performance is highly scalable, e.g., for the SGI Origin2000, factorization for 216 processors and 19.7 million unknowns required only 62% longer than the serial case. Scanning horizontally indicates that performance was similar across all platforms, e.g., execution time differed by less than a factor of two between the fastest (Origin2000) and slowest (Beowulf) platforms.

Table 4.2 shows similar data and trends for the triangular solves for the scaled problem. Scalability for the solves was not quite as good as for factorization; e.g., the solve with 216 processors took about 2.5 times longer than the serial case. This is expected due to the lower computation cost relative to communication and synchronization costs in triangular solution.

We observed that the timings for identical repeated runs on the HPC 10000 and SGI typically varied by 50% or more, while repeated runs on the Beowulf were remarkably consistent.

Table 4.3 shows speedup for a constant-sized problem of 1.7 million unknowns. There is a clear correlation between performance and subdomain interior/boundary node ratios; this ratio needs to be reasonably large for good performance.

The performances reported in these tables are applicable to any PDE that has been discretized with a seven-point central difference stencil since the sparsity pattern of the symbolic factor depends on the grid and the stencil only.

4.2. Convergence studies. Our approach for designing parallel ILU algorithms reorders the coefficient matrices whose incomplete factorization is being computed. This reordering could have a significant influence on the effectiveness of the ILU preconditioners. Accordingly, in this section we report the number of iterations of a preconditioned Krylov space solver needed to reduce the residual by a factor of 10^5.

We compare three different algorithms.

- Constrained PILU(k) is the parallel ILU(k) algorithm with the subdomain graph constraint enforced.
- In unconstrained PILU(k), the subdomain graph constraint is dropped, and all fill edges up to level k between the boundary nodes of different subdomains are permitted, even when such edges join two nonadjacent subdomains of the initial subdomain graph $S(A)$.
- In block Jacobi ILU(k) (BJILU(k)), all fill edges joining two different subdomains are excluded.

Intuitively, one expects, especially for diagonally dominant matrices, that larger amounts of fill in preconditioners will reduce the number of iterations required for convergence.

4.2.1. Fill count comparisons. For a given problem, the number of permitted fill edges is a function of three components: the factorization level, k; the subdomain size(s); and the discretization stencil. While the numerical values of the coefficients of a particular PDE influence convergence, they do not affect fill counts. Therefore, our first set of results consists of fill count comparisons for problems discretized on a $64 \times 64 \times 64$ grid using a standard, seven-point stencil.

Table 4.4 shows fill count comparisons between unconstrained PILU(k), constrained PILU(k), and block Jacobi ILU(k) for various partitionings and factorization levels. The data shows that more fill is discarded as the factorization level increases, and as subdomain size (the number of nodes in each subdomain) decreases. These two effects hold for both constrained PILU(k) and block Jacobi ILU(k) but are much more pronounced for the latter. For example, less than 5% of fill is discarded from unconstrained PILU(k) factors when subdomains contain at least 512 nodes (so that the

TABLE 4.4

Fill comparisons for the $64 \times 64 \times 64$ grid. U denotes unconstrained, C denotes constrained, and B denotes block Jacobi ILU(k) preconditioners. The columns headed "nzF/nzA" show the ratio of the number of nonzeros in the preconditioner to the number of nonzeros in the original problem and are indicative of storage requirements. The columns headed "constraint effects" present another view of the same data: here, the percentage of nonzeros in the constrained PILU(k) and block Jacobi ILU(k) factors are shown relative to that for the unconstrained PILU(k). These columns show the amount of fill dropped due to the subdomain graph constraint.

subgraphs on each processor are not too small), but up to 42% is discarded from block Jacobi factors. Thus, one might tentatively speculate that, for a given subdomain size and level, PILU(k) will provide more effective preconditioning than BJILU(k). We have observed similar behavior for 2D problems also. For both 2D and 3D problems, when there is a single subdomain the factors returned by the three algorithms are identical. For the single subdomain case, the ordering we have used corresponds to the natural ordering for these model problems.

An important observation to make in Table 4.4 is how the sizes (number of nonzeros) of the preconditioners depend on levels of fill. For the 3D problems considered here (cube with 64 points on each side, seven-point stencil), a level one preconditioner typically requires twice as much storage as the coefficient matrix A; when the level is two, this ratio is about three; when the level is three, it is about six; and when the level is four, it is about ten. For 2D problems (square grid with 256 points on a side,

TABLE 4.5

Iteration comparisons for the $64\times64\times64$ *grid. U denotes unconstrained, C denotes constrained, and B denotes block Jacobi ILU(k) preconditioners. The starred entries (*) indicate that, since there is a single subdomain, the factor is structurally and numerically identical to the unconstrained PILU(k). Dashed entries (-) indicate the solutions either diverged or failed to converge after* 200 *iterations. For Problem* 2*, when* $\varepsilon = 1/500$ *the level zero preconditioners did not reduce the relative error in the solution by a factor of* 10^5 *at termination; when* $\varepsilon = 1/1000$*, the level one preconditioners did not do so either.*

five-point stencil), the growth of fill with level is slower; the ratios are about 1.4 for level one, 1.8 for level two, 2.6 for level three, 3.5 for level four, 4.3 for level five, and 5.4 for level six.

In parallel computation fill levels higher than those employed in sequential computing are feasible since modern multiprocessors are either clusters or have virtual shared memory, and these have memory sizes that increase with the number of processors. Another point to note is that the added memory requirement for these level values is not as prohibitive as it is for a complete factorization. Hence it is practical to trade-off increased storage in preconditioners for reducing the number of iterations in the solver.

4.2.2. Convergence of preconditioned iterative solvers. The fill results in the previous subsection are not influenced by the actual numerical values of the

nonzero coefficients; however, the convergence of preconditioned Krylov space solvers is influenced by the numerical values. Accordingly, Table 4.5 shows iterations required for convergence for various partitionings and fill levels for the three variant algorithms that we consider. The data in these tables can be interpreted in various ways; we begin by discussing two ways that we think are primarily significant.

First, by scanning vertically one can see how changing the number of subdomains, and hence, matrix ordering, affects convergence. The basis for comparison is the iteration count when there is a single subdomain. The partitioning and ordering for these cases is identical to, and our data in close agreement with, that reported by Benzi, Joubert, and Mateescu [4] for natural ordering. (They report results for Problem 2 with $\varepsilon = 1/500$ but not for $\varepsilon = 1/1000$.)

A pleasing property of both the constrained and unconstrained PILU algorithms is that the number of iterations increases only mildly when we increase the number of subdomains from one to 512 for these problems. This insensitivity to the number of subdomains when the number of nodes per subdomain is not too small confirms that the PILU algorithms enjoy the property of parallel algorithmic scalability. For example, Poisson's equation (Problem 1) preconditioned with a level two factorization and a single subdomain required 24 iterations. Preconditioning with the same level, constrained PILU(k) on 512 subdomains needed only two more iterations. Similar results are observed for the convection-diffusion problems also. This property is a consequence of the fill between the subdomains that is included in the PILU algorithm. Similar results have been reported in [26, 36], and the first paper includes a condition number analysis supporting this observation.

Increasing the level of fill generally has the beneficial effect of reducing the number of iterations needed; this influence is largest for the worse-conditioned convection-diffusion problem with $\varepsilon = 1/1000$. For this problem, level zero preconditioners do not converge for reasonable subdomain sizes. Also, even though level one preconditioners require fewer iteration numbers than level two preconditioners in some cases, when the PETSc solvers terminate because the residual norms are reduced by 10^5, the relative errors are larger than 10^{-5} for the former preconditioners. The relative errors are also large for the convection-diffusion problem with $\varepsilon = 1/500$ when the level is set to zero.

Second, scanning the data in Table 4.5 horizontally permits evaluation of the subdomain graph constraint's effects. Again, unless subdomains are small and the factorization level is high; constrained and unconstrained PILU(k) show very similar behavior. Consider, for example, Poisson's equation (Problem 1) preconditioned with a level two factorization and 512 subdomains. The solution with unconstrained PILU(k) required 25 iterations while constrained PILU(k) required 26.

We also see that PILU(k) preconditioning is more effective than BJILU(k) for all 3D trials. (Recall that the single apparent exception, Problem 2, $\varepsilon = 1/500$, ILU(0) with $32,768$ nodes per subdomain, has large relative errors at termination.) Again, the extremes of convergence behavior are seen for Problem 2 with $\varepsilon = 1/1000$. Here, with level one preconditioners, BJILU(k) suffers large relative errors at termination while the other two algorithms do not, when the number of subdomains is 64 or fewer.

On 2D domains, while PILU(k) is more effective than BJILU(k) for Poisson's equation, BJILU(k) is sometimes more effective in the convection-diffusion problems.

We also examine iteration counts as a function of preconditioner size graphically. A plot of this data appears in Figure 4.1. In these figures the performance of the

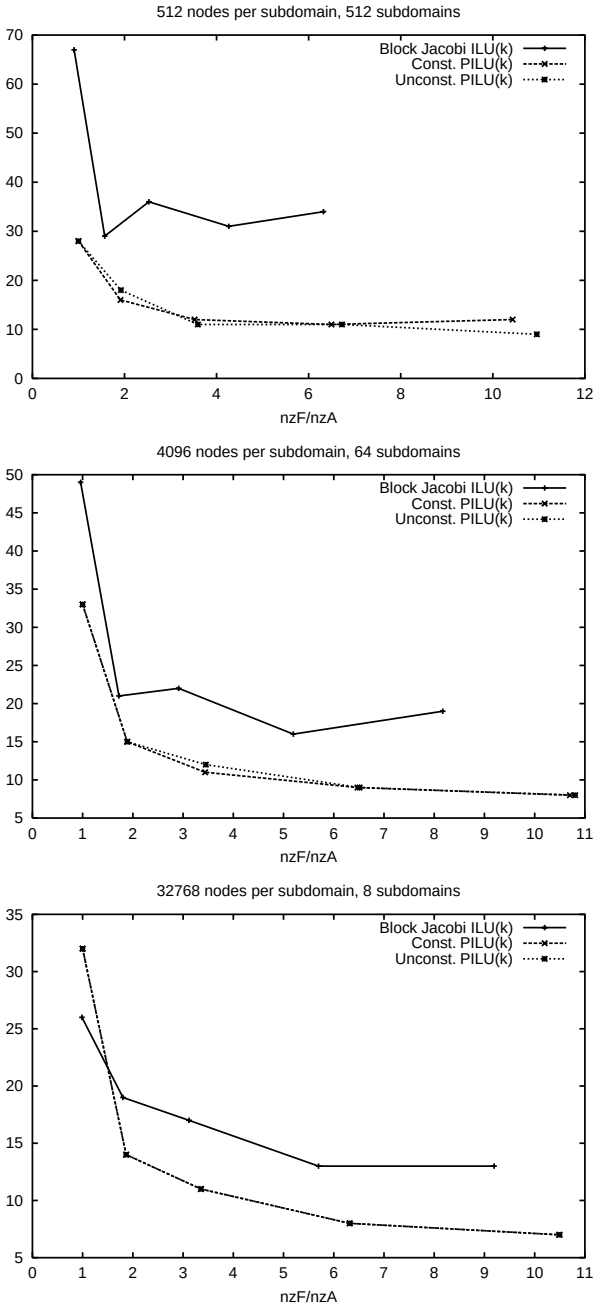

FIG. 4.1. *Convergence comparison as a function of preconditioner size for the convection-diffusion problem,* $\epsilon = 1/500$ *on the* $64 \times 64 \times 64$ *grid. Data points are for levels* 0 *through* 4. *Data points for constrained and unconstrained PILU(k) are indistinguishable in the third graph.*

constrained and unconstrained PILU algorithms is often indistinguishable. We find again that PILU(k) preconditioning is more effective than BJILU(k) for 3D problems for a given preconditioner size; however, this conclusion does not always hold for 2D

problems, especially for lower fill levels. As the number of vertices in the subdomains increases, higher fill levels become more effective in reducing the number of iterations needed for convergence. We find that fill levels as high as four to six can be the most effective when the subdomains are sufficiently large. Fill levels higher than these do not seem to be merited by these problems, even for the difficult convection-diffusion problems with $\varepsilon = 1/1000$, where a level four preconditioner reduces the number of iterations below ten.

5. Conclusions. We have designed and implemented a PILU algorithm, a scalable parallel algorithm for computing ILU preconditioners that creates concurrency by means of graph partitioning. The theoretical basis of the algorithm is the incomplete fill path theorem that statically characterizes fill elements in an incomplete factorization in terms of paths in the adjacency graph of the initial coefficient matrix. To obtain a scalable parallel algorithm, we employ a subdomain graph constraint that excludes fill between subgraphs that are not adjacent in the adjacency graph of the initial matrix. We show that the PILU algorithm is scalable by an analysis for 2D- and 3D-model problems and by computational results from parallel implementations on three parallel computing platforms.

We also study the convergence behavior of preconditioned Krylov solvers with preconditioners computed by the PILU algorithm. The results show that fill levels higher than one are effective in reducing the number of iterations, that the number of iterations is insensitive to the number of subdomains, and that the subdomain graph constraint does not affect the number of iterations needed for convergence while it makes possible the design of a scalable parallel algorithm.

Appendix. Proof of the incomplete fill path theorem.

THEOREM A.1. *Let $F = \hat{L} + \hat{U} - I$ be the filled matrix corresponding to an incomplete factorization of A, and let f_{ij} be a nonzero entry in F. Then f_{ij} is a level k entry if and only if there exists a shortest fill path of length $k+1$ that joins i and j in $G(A)$.*

Proof. If there is a shortest fill path of length $k+1$ joining i and j, we prove that the edge exists by induction on the length of the fill path.

Define a *chord* of a path to be an edge that joins two nonconsecutive vertices on the path. The fill path joining i and j is chordless, since a chord would lead to a shorter fill path.

The base case $k = 0$ is immediate, since a fill path of length one in the graph $G(A)$ is an edge $\{i, j\}$ in $G(A)$ that corresponds to an original nonzero in A.

Now assume that the result is true for all lengths less than $k+1$. Let h denote the highest numbered interior vertex on the fill path joining i and j.

We claim that the (i, h) section of this path is a shortest fill path in $G(A)$ joining i and h. This section is a fill path by the choice of h since all intermediate vertices on this section are numbered lower than h. If there were a fill path joining i and h that is shorter than the (i, h) section, then we would be able to concatenate it with the (h, j) section to form a shorter (i, j) fill path. Hence the (i, h) section is a shortest fill path joining i and h. Similarly, the (h, j) section of this path is the shortest fill path joining h and j.

Each of these sections has fewer than $k+1$ edges, and hence the inductive hypothesis applies. Denote the number of edges in the (i, h) ((h, j)) section of this path by k_1 (k_2), where $k_1 + k_2 = k + 1$. By the inductive hypothesis, the edge $\{i, h\}$ is a fill edge of level $k_1 - 1$, and the edge $\{h, j\}$ is a fill edge of level $k_2 - 1$. Now by the sum rule for updating fill levels, when the vertex h is eliminated, we have a fill edge

$\{i, j\}$ of level

$$(k_1 - 1) + (k_2 - 1) + 1 = (k_1 + k_2) - 1 = (k + 1) - 1 = k.$$

Now we prove the converse. Suppose that $\{i, j\}$ is a fill edge of level k; we show that there is a fill path in $G(A)$ of length $k + 1$ edges by induction on the level k.

The base case $k = 0$ is immediate, since the edge $\{i, j\}$ constitutes a trivial fill path of length one. Assume that the result is true for all fill levels less than k. Let h be a vertex whose elimination creates the fill edge $\{i, j\}$ of level k. Let the edge $\{i, h\}$ have level k_1, and let the edge $\{h, j\}$ have level k_2; by the sum rule for computing levels, we have that $k_1 + k_2 + 1 = k$. By the inductive hypothesis, there is a shortest fill path of length $k_1 + 1$ joining i and h, and such a path of length $k_2 + 1$ joining h and j. Concatenating these paths, we find a fill path joining i and j of length

$$(k_1 + 1) + (k_2 + 1) = k_1 + k_2 + 2 = k + 1.$$

We need to prove that the (i, j) fill path in the previous paragraph is a shortest fill path between i and j. Consider the elimination of any another vertex g that causes the fill edge $\{i, j\}$. By the choice of the vertex h, if the level of the edge $\{i, g\}$ is k'_1 and that of $\{g, j\}$ is k'_2, then $k'_1 + k'_2 + 1 \geq k$. The inductive hypothesis applies to the (i, g) and (g, j) sections, and hence the sum of their lengths is at least $k + 1$.

This completes the proof. □

This result is a generalization of the following theorem that characterizes fill in complete factorizations for direct methods, due to Rose and Tarjan [30].

THEOREM A.2. *Let $F = L + U - I$ be the filled matrix corresponding to the complete factorization of A. Then $f_{ij} \neq 0$ if and only if there exists a fill path joining i and j in the graph $G(A)$.*

Here we associate level values with each fill edge and relate it to the length of shortest fill paths. The incomplete fill path theorem enables new algorithms for incomplete symbolic factorization that are more efficient than the conventional algorithm that simulates numerical factorization. We have described these algorithms in an earlier work [29] and the report is in preparation.

D'Azevedo, Forsyth, and Tang [9] have defined the (sum) level of a fill edge $\{i, j\}$ using the length criterion employed here, and hence they were aware of this result. However, the theorem is neither stated nor proved in their paper. Definitions of level that compute levels of fill nonzeros by rules other than by summing the levels of the causative pairs of nonzeros have been used in the literature. The "maximum" rule defines the level of a fill nonzero to be the minimum over all causative pairs of the maximum value of the levels of the causative entries:

$$\text{level}(f_{ij}) = \min_{1 \leq h \leq \min\{i,j\}} \max\{\text{level}(f_{ih}), \text{level}(f_{hj})\} + 1.$$

A variant of the incomplete fill path theorem can be proved for this case, but it is not as simple or elegant as the one for the "sum" rule. Further discussion of these issues will be deferred to a future report.

Acknowledgments. We thank Dr. Edmond Chow of CASC, Lawrence Livermore National Laboratory, and Professor Michele Benzi of Emory University for helpful discussions.

ACCURATE COMPUTATIONS ON INERTIAL MANIFOLDS*

M. S. JOLLY†, R. ROSA‡, AND R. TEMAM§

Abstract. An algorithm is implemented for the computation of inertial manifolds to arbitrary accuracy. It is applied to the Kuramoto–Sivashinsky equation to recover the high wave number components of elements on the global attractor. The computational results demonstrate that this algorithm is significantly more accurate than previous methods, when compared after just a few iterations. An essential feature of the algorithm is that it does not require that the entire manifold be constructed. Hence the algorithm is particularly suited for computing trajectories on the manifold, and its computational complexity is independent of the dimension.

1. Introduction.

This paper demonstrates how to accurately compute inertial manifolds for evolutionary equations. These manifolds are finite-dimensional, exponentially attracting, positively invariant, and smooth. In terms of a Fourier series representation of the solution to a PDE, essentially the manifold provides a relation for the modes with high wave numbers in terms of those with low wave numbers. The existence of such a manifold typically hinges on whether there is a large enough gap in the spectrum of the linear part of the equation compared to the variation of the nonlinear part. A weaker gap condition appears in most constructive proofs of local (un)stable and center manifolds. Moreover, for local manifolds one may take a small enough neighborhood to reduce the strength of the nonlinear term and thereby achieve the gap condition. The accurate computation of such objects, however, even when the manifolds are two-dimensional, poses some special difficulties (see [24], [2], [31], and for related issues regarding invariant tori, see [12]).

We implement here an algorithm developed in [47] for the computation of inertial manifolds. It provides a sequence of approximate inertial manifolds (AIMs) which converges to the actual inertial manifold. This sequence is distinguished from all other sequences of AIMs, except that in [10], in that convergence may be achieved with the dimension of the manifold held fixed. The others typically need to increase the dimension in order to decrease the error from the inertial manifold. The sequence implemented here is distinguished from the earlier sequence in [10] in that the computational complexity of the algorithm is independent of the dimension of the manifold.

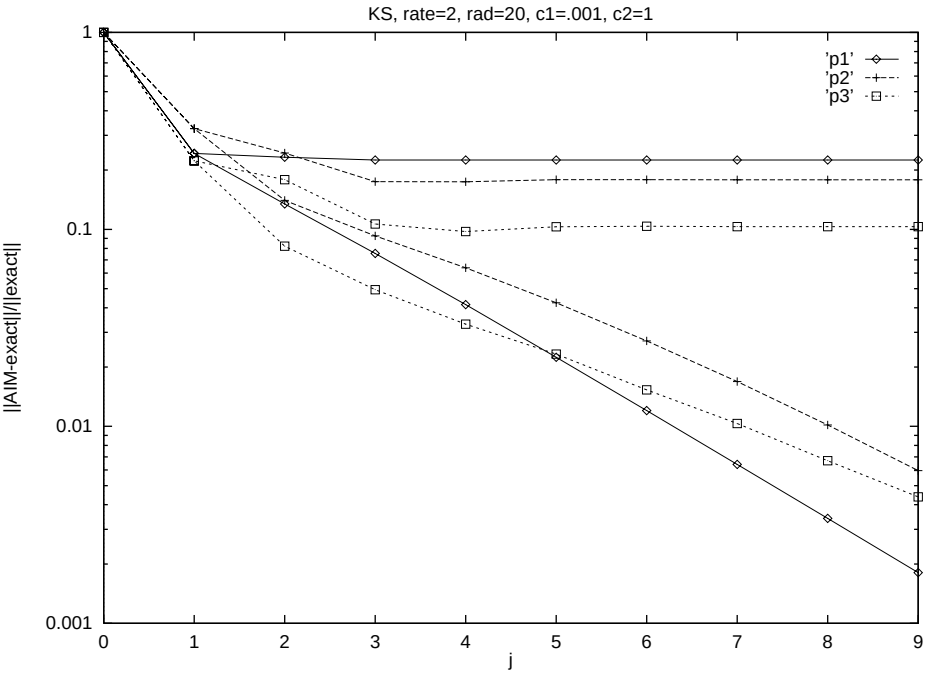

FIG. 1. *Relative error for Φ_j, Ψ_j at the points p_1,p_2, and p_3. The three upper plots are for Ψ_j, and the three lower plots are for Φ_j.*

If for a particular low-mode vector the corresponding high-mode vector is desired, then this algorithm can be applied without computing the high-mode vectors corresponding to other low-mode vectors. Its primary purpose, then, is not the construction of all or even a major portion of such a manifold. Rather, it is best suited for computing solutions *on* such manifolds, particularly, *backward in time*.

In the case of a PDE after spatial discretization, the dimension of a full stable manifold would increase with enhanced spatial accuracy. This is a situation where restricting the system to an inertial manifold can be quite useful. Doing so automatically picks out the relevant stable submanifold, which has low dimension and hence low complexity, so that it can be computed in a straightforward fashion, regardless of whether it consists of one or more connecting orbits. Precisely, this situation arises with the Kuramoto–Sivashinsky equation (KSE). The stability of connecting orbits for the KSE was demonstrated in [8] by means of a reduction to an approximate inertial form (given by Ψ_2 as defined in (3.8)). That work extends the parameter range for stability previously obtained in [1] by perturbative techniques. The stable and unstable manifolds which collide to form these connecting orbits were visualized in [32] and found to be intimately involved in the formation of a completely different set of Silnikov orbits. The computations in [32] were carried out for the same approximate inertial form (up to high order terms) as used in [8].

The point we wish to make is that we can now compute the inertial form for the KSE much more accurately than ever before. This is demonstrated by Figure 1, where the relative error in computing the manifold is measured at three locations on the global attractor, denoted p_1, p_2, and p_3 in Figure 2. The three upper plots are for the sequence of AIMs used in [8] and [32], and earlier in [33], [49]. As indicated by the leveling-off, there is rapid convergence in these instances, albeit to a manifold which is

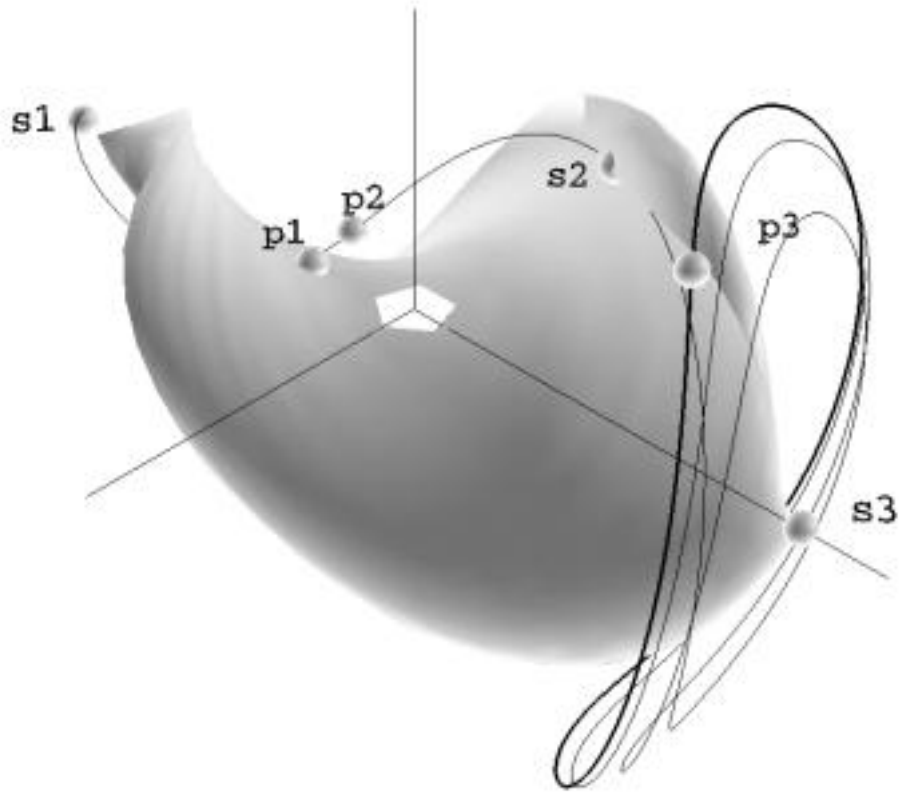

FIG. 2. *Elements of the global attractor for the KSE at* $L = L^*$.

not an inertial manifold, or even invariant. In contrast, the three lower plots indicate that the algorithm of interest here continues to converge, through nine iterations, to the attractor and hence the inertial manifold. These results are discussed in detail in section 4.

The general framework for the method is that of an evolutionary equation of the form

$$\frac{du}{dt} + Au = f(u), \quad u \in E, \quad u(0) = u_0, \tag{1.1}$$

where A is a linear operator and E is a Banach space. It is easiest to describe the approach in the particular case where A has a complete set of eigenvectors associated with a sequence of positive eigenvalues and E is a Hilbert space. An inertial manifold is often sought as the graph of a function $\Phi : PE \to QE$, where $P = P_n$ is the projector onto the span of the first n eigenfunctions of A and $Q = Q_n = I - P$. The

restriction of the flow to an inertial manifold yields the inertial form

$$\frac{dp}{dt} + Ap = Pf(p + \Phi(p)), \quad p(0) = p_0 \in PE, \tag{1.2}$$

which is a finite set of ODEs with the same long-time dynamics as the original evolutionary equation, which may very well be infinite-dimensional. This framework is similar to that for a more general class of invariant manifolds. The algorithm discussed here may be applied under less stringent conditions to local (un)stable manifolds. It has been adapted in [36] to compute inertial manifolds with delay and in [35] to compute center manifolds.

The existence of an inertial manifold is known for a number of physical systems including the KSE, the Cahn–Hilliard equation, and certain reaction diffusion equations in several space dimensions, just to name a few (see [7], [41], [51], and references therein). A great variety of numerical schemes based on AIMs have been developed, analyzed, and tested in the literature (see [13], [49], [20], and references therein). One issue is how much, if any, such methods can save in computing time. This article is not concerned with this question. Instead, we wish to demonstrate that one can accurately compute an inertial manifold so that the dimension of phase space can be kept quite small. Such a reduction can help in the geometric understanding of certain global bifurcations.

In the next section we provide the general assumptions for both the existence of an inertial manifold as well as the valid application of the algorithm. The algorithm itself is recalled in section 3, along with several rigorous estimates on its convergence from [47]. We then apply the method to the KSE in section 4. The computations in this case are compared to those of another sequence of AIMs. To carry out the computations, we are forced to truncate to a finite number of high modes. We provide error estimates for this effect in section 5.

2. General assumptions. The following assumptions guarantee both the existence of an inertial manifold and the convergence of the algorithm used here. While the framework is somewhat technical, we will need to refer to each element described below when we validate the rate of convergence in our implementation. The generality is motivated by the application to PDEs; the assumptions simplify considerably in the case of an ODE.

A1. The nonlinear term f in (1.1) is globally Lipschitz continuous from a Banach space E into another Banach space F,

$$|f(u) - f(v)|_F \le M_1 |u - v|_E \qquad \forall\, u, v \in E, \tag{2.1}$$

with

$$E \subset F \subset \mathcal{E};$$

the injections being continuous, each space is dense in the following one, and $\mathcal{E}$ is also a Banach space. It follows that

$$|f(u)|_F \le M_0 + M_1 |u|_E \qquad \forall\, u \in E,$$

for some $M_0 \ge 0$. (Actually, $M_0 = |f(0)|_F$ is optimal.)

A2. The linear operator $-A$ generates a strongly continuous semigroup $\{e^{-tA}\}_{t \ge 0}$ of bounded operators on $\mathcal{E}$ such that

$$e^{-tA} F \subset E \qquad \forall\, t > 0.$$

A3. There exist two sequences of numbers $\{\lambda_n\}_{n=n_0}^{n_1}$, $\{\Lambda_n\}_{n=n_0}^{n_1}$ for some $n_0 \in \mathbb{N}$, $n_1 \in \mathbb{N} \cup \infty$ with $0 < \lambda_n \leq \Lambda_n$ for $n_0 \leq n \leq n_1$, and a sequence $\{P_n\}_{n=n_0}^{n_1}$ of finite dimensional projectors, such that if $Q_n = I - P_n$, then the following exponential dichotomies hold.

$P_n\mathcal{E}$ is invariant under e^{-tA} for $t \geq 0$, and $\{e^{-tA}|_{P_n\mathcal{E}}\}_{t\geq 0}$ can be extended to a strongly continuous group $\{e^{-tA}P_n\}_{t\in\mathbb{R}}$ of bounded operators on $P_n\mathcal{E}$ with

$$\begin{aligned} &\|e^{-tA}P_n\|_{\mathcal{L}(E)} \leq K_1 e^{-\lambda_n t} \qquad \forall\ t \leq 0, \\ &\|e^{-tA}P_n\|_{\mathcal{L}(F,E)} \leq K_1 \lambda_n^{\alpha} e^{-\lambda_n t} \qquad \forall\ t \leq 0. \end{aligned} \tag{2.2}$$

$Q_n\mathcal{E}$ is positively invariant under e^{-tA} for $t \geq 0$ with

$$\begin{aligned} &\|e^{-tA}Q_n\|_{\mathcal{L}(E)} \leq K_2 e^{-\Lambda_n t} \qquad \forall\ t \geq 0, \\ &\|e^{-tA}Q_n\|_{\mathcal{L}(F,E)} \leq K_2 (t^{-\alpha} + \Lambda_n^{\alpha}) e^{-\Lambda_n t} \qquad \forall\ t > 0, \end{aligned} \tag{2.3}$$

where $K_1, K_2 \geq 1$, and $0 \leq \alpha < 1$. We will at times drop the subscripts on the projectors P and Q for simplicity.

A4. Equation (1.1) has a continuous semiflow $\{S(t)\}_{t\geq 0}$ in E, given by $S(t)u_0 = u(t)$, where $u = u(t)$ is the mild solution of (1.1) defined through the variation of constants formula

$$u(t) = e^{-tA}u_0 + \int_0^t e^{-(t-s)A} f(u(s))ds \qquad \forall\ t \geq 0.$$

A5. There exists $K_3 \geq 0$ independent of n such that

$$\|AP_n\|_{\mathcal{L}(E)} \leq K_3 \lambda_n.$$

A6. For simplicity we assume that A is invertible.

A7. The *spectral gap condition* (SGC)

$$\Lambda_n - \lambda_n > 3M_1K_1K_2[\lambda_n^{\alpha} + (1+\gamma_{\alpha})\Lambda_n^{\alpha}] \quad \text{holds for some } n \in \mathbb{N}, \tag{2.4}$$

where

$$\gamma_{\alpha} = \begin{cases} \int_0^{+\infty} e^{-r} r^{-\alpha} dr & \text{if } 0 < \alpha < 1, \\ 0 & \text{if } \alpha = 0. \end{cases}$$

In many PDE applications, the spectrum of A consists of positive semisimple eigenvalues

$$\mu_1 \leq \mu_2 \leq \cdots \text{ with } \mu_n \to +\infty, \tag{2.5}$$

associated with eigenvectors $w_1, w_2, \ldots$, so that we may set $\lambda_n = \mu_n$, $\Lambda_n = \mu_{n+1}$, and

$$P_n = \text{projector onto span } \{w_1, w_2, \ldots, w_n\}.$$

In most applications the phase space can be taken to be a Hilbert space. For some parabolic equations, however, depending on the relationship between the dimension of the space, the order of the linear term, and the strength of the nonlinear term, the appropriate phase space is merely a Banach space (see [40], for instance). Strictly

speaking, one needs only to have the exponential dichotomy in A3 to hold for the particular choice of n satisfying the SGC in A7, though typically one has many choices for the splitting in A3, and the SGC holds only for *some* large n. In some of the cases we will consider here, one or more of the first eigenvalues are negative, so we simply neglect those and start with Λ_{n_0} as the first positive eigenvalue and choose λ_{n_0} to be some positive number smaller than Λ_{n_0}. If the eigenvalues were semisimple but complex, one would take λ_n and Λ_n to be the real part of the eigenvalues. The assumption that the projector P_n is finite-dimensional excludes the cases in which A has a continuous spectrum, but that is only because we want a finite-dimensional inertial manifold in the end. The whole construction would go through if we allow P_n to be infinite-dimensional and hence A to have bands with continuous spectrum, and we would end up with an infinite-dimensional "inertial manifold."

In most applications the global Lipschitz condition in (2.1) does not hold for the evolutionary equation in its original form. This can be corrected by annihilating the nonlinearity outside a ball in phase space. To do so and to be assured that none of the long-time dynamics are altered, we require in this situation that the evolutionary system be dissipative. This means there is an absorbing ball $B_\rho \subset E$, i.e., there exists $\rho > 0$ such that

$$|S(t)u_0|_E \le \rho \quad \forall\ t \ge t_0(|u_0|_E) \ge 0.$$

The prepared evolutionary equation is to have the nonlinearity (and hence the dynamics) unchanged inside the ball and has the nonlinearity set to zero outside an even larger ball. We give a specific preparation procedure in section 4.

We briefly recall below the construction of the *exact* inertial manifold as done in [48]. The discretization of this approach is what leads to the algorithm tested here. There are a number of earlier alternative approaches to prove the existence of inertial manifolds which are mostly based on either the Lyapunov–Perron method (c.f. [17]) or the graph transform method of Hadamard (c.f. [7]), and which construct the *entire* manifold at once, as the graph of a function $\Phi : P_nE \to Q_nE$. This is in contrast to the approach here, a variation of the Lyapunov–Perron method in which for a given $p_0 \in P_nE$, the corresponding image $\Phi(p_0)$ is found in terms of a single trajectory on the manifold. Thus it is a one-dimensional object (the trajectory) which is discretized, rather than an n-dimensional object (the manifold). Earlier use of this approach can be found in [26], [27], [5], and [43].

The construction is described in two steps. First, we obtain an invariant manifold. Then the exponential attraction property is established, making the manifold in fact an inertial manifold. When (2.4) holds, we can find σ such that

$$\lambda_n + 2M_1K_1\lambda_n^\alpha < \sigma < \Lambda_n - 2M_1K_2(1+\gamma_\alpha)\Lambda_n^\alpha. \tag{2.6}$$

For σ in this range, a single trajectory on an invariant manifold can be found as the fixed point $\varphi = \varphi(p)$ of a mapping $\mathcal{T}(\cdot,p)$ given by

$$\begin{aligned}\mathcal{T}(\varphi,p)(t) = e^{-tA}p &- \int_t^0 e^{-(t-s)A}Pf(\varphi(s))ds \\ &+ \int_{-\infty}^t e^{-(t-s)A}Qf(\varphi(s))ds \quad \forall\ t \le 0, \quad \forall\ p \in PE,\end{aligned} \tag{2.7}$$

in the Banach space

$$\mathcal{F}_\sigma = \left\{ \varphi \in C\left((-\infty,0],E\right); \|\varphi\|_\sigma = \sup_{t\le 0}(e^{\sigma t}|\varphi(t)|_E) < +\infty \right\}.$$

The entire manifold $\mathcal{M}$ is the collection of such trajectories given by $\mathcal{M} = \text{graph}\Phi$, where $\Phi : PE \to QE$ is defined by the fixed point φ of (2.7),

$$\Phi(p) = Q\varphi(p)(0) \qquad \forall\ p \in PE.$$

The mapping $\mathcal{T}$ is a strict contraction in $\mathcal{F}_\sigma$, uniformly in PE, with

$$\|\mathcal{T}(\varphi_1, p) - \mathcal{T}(\varphi_2, p)\|_\sigma \leq \kappa_{n,\sigma}\|\varphi_1 - \varphi_2\|_\sigma \quad \forall\ \varphi_1, \varphi_2 \in \mathcal{F}_\sigma, \quad \forall\ p \in PE, \tag{2.8}$$

where

$$\kappa_{n,\sigma} \equiv \frac{M_1 K_1 \lambda_n^\alpha}{\sigma - \lambda_n} + \frac{M_1 K_2 (1+\gamma_\alpha)\Lambda_n^\alpha}{\Lambda_n - \sigma} < 1. \tag{2.9}$$

In order to show that the invariant manifold constructed as above is in fact an inertial manifold, all that remains is to establish the exponential attraction property. In fact, the SGC in A7 assures a stronger property sometimes referred to as *asymptotic completeness* or *exponential tracking* [18]. This means that corresponding to any initial condition $u_0 \in E$ there exists a particular solution *on* the manifold, to which the trajectory through u_0 is attracted at an exponential rate. The so-called relevance theorem asserts the same property for the center manifold of a fixed point provided the fixed point is stable [3].

The proof of the asymptotic completeness in [48] requires that σ be taken in a narrower range,

$$\lambda_n + 3M_1K_1K_2\lambda_n^\alpha < \sigma < \Lambda_n - 3M_1K_1K_2(1+\gamma_\alpha)\Lambda_n^\alpha. \tag{2.10}$$

In this case one has, in fact, that $\kappa_{n,\sigma} < 2/3$ so that the rate of contraction is guaranteed to be faster. Thus if we replace the gap condition in A7 with the weaker condition

$$\Lambda_n - \lambda_n > 2M_1K_1\lambda_n^\alpha + 2M_1K_2(1+\gamma_\alpha)\Lambda_n^\alpha, \tag{2.11}$$

we can satisfy (2.6) but not necessarily (2.10) and consequently have an invariant manifold $\mathcal{M} = \text{graph}\Phi$, which is not necessarily an inertial manifold. If (2.4) holds, then $\mathcal{M} = \text{graph}\Phi$ is indeed an inertial manifold.

We should mention that the same map in (2.7) is used in [43] in an alternate framework, where the contraction is obtained in a different space, leading to an SGC that is in fact weaker than (2.4) yet still gives both the invariance and exponential attraction. When applicable, the approach in [43] can provide a manifold of smaller dimension than that provided by A1–A7. Our error analysis for the discretization of the map in (2.7) will, however, use the assumptions in A1–A7.

A related object of study is the global attractor $\mathcal{A}$. Its existence is guaranteed provided the system is dissipative and the semiflow $S(t)$ is compact [25], [51]. In this case it can be defined by

$$\mathcal{A} = \bigcap_{t \geq 0} S(t)B_\rho.$$

This is the largest bounded invariant set for the system and contains all steady states, periodic solutions, and invariant tori, as well as the unstable manifolds associated with those objects. The global attractor must be contained in any inertial manifold and thus provides a lower bound on the minimal dimension for all inertial manifolds. Unlike inertial manifolds, the global attractor can be quite complicated geometrically and attract solutions at an algebraic rate.

3. The algorithm. To discretize the mapping $\mathcal{T}$, the function space $\mathcal{F}_\sigma$ is replaced by

$$\tilde{\mathcal{F}} = \{\psi : \ (-\infty, 0] \ \to E; \psi \text{ is piecewise constant with a finite number of discontinuities}\}.$$

Given a time step $\tau > 0$, a number of steps $N \in \mathbb{N}$, and a base point $p_0 \in PE$, we define $\mathcal{T}_\tau^N : \tilde{\mathcal{F}} \times PE \to \tilde{\mathcal{F}}$ by

$$\begin{aligned} \mathcal{T}_\tau^N(\psi, p_0)(t) = e^{k\tau A} P p_0 - \int_{-k\tau}^{0} e^{-(-k\tau - s)A} P f(\psi(s)) ds \\ + \int_{-\infty}^{-k\tau} e^{-(-k\tau - s)A} Q f(\psi(s)) ds, \qquad k = 0, 1, \dots, N, \end{aligned} \tag{3.1}$$

for $t \in (-(k+1)\tau, -k\tau]$ if $k < N$, or $t \in (-\infty, -N\tau]$ if $k = N$.

Note that $\mathcal{T}_\tau^N$ acts as a sort of "projection" of $\mathcal{T}$ on $\tilde{\mathcal{F}}$ in that

$$\mathcal{T}_\tau^N(\psi, p_0)(-k\tau) = \mathcal{T}(\psi, p_0)(-k\tau).$$

We now consider the particular sequence of AIMs in [47] by assigning as the initial guess

$$\varphi^0(p_0)(t) = p_0 \qquad \forall\ t \le 0, \qquad \forall\ p_0 \in PE, \tag{3.2}$$

and by choosing two sequences $\{\tau_j\}_{j\in\mathbb{N}}, \tau_j > 0$ and $\{N_j\}_{j\in\mathbb{N}}, N_j \in \mathbb{N}, N_j \ge 0$. Proceeding by Picard iteration, we have

$$\varphi^j(p_0) = \mathcal{T}_{\tau_j}^{N_j}(\varphi^{j-1}(p_0), p_0) \qquad \forall\ p_0 \in PE, \tag{3.3}$$

for $j = 1, 2, \dots$. Observe that τ_0 and N_0 are not relevant since $\varphi^0(p_0)$ is constant. The convergent sequence of AIMs is then given by

$$\mathcal{M}_j = \mathcal{M}_{j,n} = \text{ graph } \Phi_j = \{p + \Phi_j(p);\ p \in P_n E\},$$

where

$$\Phi_j(p_0) = Q_n \varphi^j(p_0)(0) \qquad \forall\ p_0 \in P_n E.$$

Again, since the approximating trajectories φ^j belong to $\tilde{\mathcal{F}}$, the integrals involved in the iteration process (3.3) can be explicitly calculated. For simplicity we denote

$$\varphi_k^j(p_0) = \varphi^j(p_0)(-k\tau_j), \qquad k = 0, 1, \dots, N_j,$$

for $p_0 \in PE$ and $j = 0, 1, \dots$, so that $\Phi_j = Q\varphi_0^j$. For the case where $k\tau_j < N_{j-1}\tau_{j-1}$, we have

$$\begin{aligned} \varphi_k^j(p_0) = e^{k\tau_j A} P p_0 - \int_{-k\tau_j}^{-\ell_k \tau_{j-1}} e^{-(-k\tau_j - s)A} P f(\varphi_{\ell_k}^{j-1}(p_0))\ ds \\ - \sum_{\ell=0}^{\ell_k - 1} \int_{-(\ell+1)\tau_{j-1}}^{-\ell\tau_{j-1}} e^{-(-k\tau_j - s)A} P f(\varphi_\ell^{j-1}(p_0))\ ds \\ + \int_{-\infty}^{-N_{j-1}\tau_{j-1}} e^{-(-k\tau_j - s)A} Q f(\varphi_{N_{j-1}}^{j-1}(p_0))\ ds \\ + \sum_{\ell=\ell_k+1}^{N_{j-1}-1} \int_{-(\ell+1)\tau_{j-1}}^{-\ell\tau_{j-1}} e^{-(-k\tau_j - s)A} Q f(\varphi_\ell^{j-1}(p_0))\ ds \\ + \int_{-(\ell_k+1)\tau_{j-1}}^{-k\tau_j} e^{-(-k\tau_j - s)A} Q f(\varphi_{\ell_k}^{j-1}(p_0))\ ds, \end{aligned} \tag{3.4}$$

where ℓ_k is a nonnegative integer defined by

$$\begin{cases} -(\ell_k+1)\tau_{j-1} < -k\tau_j \le -\ell_k\tau_{j-1} & \text{if } -(N_{j-1}+1)\tau_{j-1} < -k\tau_j, \\ \ell_k = N_{j-1} & \text{otherwise.} \end{cases} \tag{3.5}$$

The alternative case, where $k\tau_j \ge N_{j-1}\tau_{j-1}$, is actually simpler, as φ^{j-1} is constant over $(-\infty, k\tau_j]$. By a straightforward calculation of the integrals we have the following.

Case 1. $k\tau_j < N_{j-1}\tau_{j-1}$:

$$\begin{aligned} \varphi_k^j(p_0) &= e^{k\tau_j A}P_n p_0 - A^{-1}(e^{(k\tau_j-\ell_k\tau_{j-1})A}P_n - P_n)f(\varphi_{\ell_k}^{j-1}(p_0)) \\ &\quad - \sum_{\ell=0}^{\ell_k-1} A^{-1}(e^{(k\tau_j-\ell\tau_{j-1})A}P_n - e^{(k\tau_j-(\ell+1)\tau_{j-1})A}P_n)f(\varphi_\ell^{j-1}(p_0)) \\ &\quad + A^{-1}e^{-(N_{j-1}\tau_{j-1}-k\tau_j)A}Q_n f(\varphi_{N_{j-1}}^{j-1}(p_0)) \\ &\quad + \sum_{\ell=\ell_k+1}^{N_{j-1}-1} A^{-1}(e^{-(\ell\tau_{j-1}-k\tau_j)A} - e^{-((\ell+1)\tau_{j-1}-k\tau_j)A})Q_n f(\varphi_\ell^{j-1}(p_0)) \\ &\quad + A^{-1}(I - e^{-((\ell_k+1)\tau_{j-1}-k\tau_j)A})Q_n f(\varphi_{\ell_k}^{j-1}(p_0)). \end{aligned} \tag{3.6}$$

Case 2. $k\tau_j \ge N_{j-1}\tau_{j-1}$:

$$\begin{aligned} \varphi_k^j(p_0) &= e^{k\tau_j A}P_n p_0 - A^{-1}(e^{(k\tau_j-N_{j-1}\tau_{j-1})A}P_n - P_n)f(\varphi_{N_{j-1}}^{j-1}(p_0)) \\ &\quad - \sum_{\ell=0}^{N_{j-1}-1} A^{-1}(e^{(k\tau_j-\ell\tau_{j-1})A}P_n - e^{(k\tau_j-(\ell+1)\tau_{j-1})A}P_n)f(\varphi_\ell^{j-1}(p_0)) \\ &\quad + A^{-1}Q_n f(\varphi_{N_{j-1}}^{j-1}(p_0)). \end{aligned} \tag{3.7}$$

3.1. Comparison with other AIMs. Regardless of the choice of the sequences $\{\tau_j\}_{j\in\mathbb{N}}$ and $\{N_j\}_{j\in\mathbb{N}}$, the zeroth AIM is given by $\Phi_0 \equiv 0$ since $Q_n\varphi^0 \equiv 0$ for φ^0 given in (3.2). The first nontrivial approximation is given by $\Phi_1(p) = A^{-1}Qf(p)$. An alternative sequence of AIMs is defined implicitly (for large enough n, see [19], [16]) by the Q-component of the steady state equation

$$Ap = Qf(p+q).$$

This alternative sequence is found recursively by

$$\Psi_{j,n}(p) = \Psi_j(p) = A^{-1}Q_n f(p + \Psi_{j-1}(p)), \quad \Psi_0(p) \equiv 0, \quad p \in P_n\mathbb{H}. \tag{3.8}$$

Note that $\Phi_1 = \Psi_1$, which happens also to coincide with a manifold first introduced in [14] with a completely different derivation. For a number of PDE cases, in particular, for the KSE and two-dimensional Navier–Stokes equations, it has been shown that the $\mathcal{N}_{j,n} = \text{graph } \Psi_{j,n}$ converge to the global attractor $\mathcal{A}$ in the sense that

$$\text{dist}_E(\mathcal{A}, \mathcal{N}_{j,n}) \to 0 \quad \text{as } n \to \infty \tag{3.9}$$

for *any* fixed j, even for $j = 0$ (see [34], [53]). The convergence in (3.9) is valid even in the absence of the SGC, i.e., it is independent of the existence of an actual inertial manifold. Much of the motivation behind nonlinear Galerkin methods based

on such AIMs comes from an algebraic improvement in the estimates for the rate of convergence to the attractor for $j > 0$ compared to that for $j = 0$. In some cases, however, solutions to a PDE can be shown to be in the Gevrey class with respect to the spatial variable so that this improvement is on top of a decay rate in the wave number that is already exponential [23], [39]. A number of other AIMs have been introduced in an attempt to improve the approximation provided by $\mathcal{N}_{j,n}$ (see, for instance, [50], [11], [9]), but in each case one must increase the dimension of the manifold in order to converge to the attractor.

The distinction we wish to emphasize between the sequences $\{\mathcal{M}_{j,n}\}$ and $\{\mathcal{N}_{j,n}\}$ (and many like the latter) is that in the case of $\{\mathcal{M}_{j,n}\}$ we may instead fix n, hence the dimension of the manifolds, and achieve convergence as $j \to \infty$. We restate below, in slightly more generality, the main convergence result proved in [47].

THEOREM 3.1. *Assume that* A1–A6 *hold and that the sequences* $\{\tau_j\}_j$ *and* $\{N_j\}_j$ *are chosen so that*

$$0 < \tau_j \le c_1 \gamma^j \kappa_{n,\sigma}^j \qquad \forall\ j \in \mathbb{N}$$

with $\kappa_{n,\sigma}$ *as defined in* (2.9) *for* n *satisfying* (2.4) *(resp.,* (2.11)*), and*

$$N_j \tau_j \ge c_2 j \qquad \forall\ j \in \mathbb{N},$$

for some constants $c_1, c_2 > 0$*, some* $0 < \gamma < 1$*, and some* σ *satisfying* (2.10) *(resp.,* (2.6)*). Then*

$$d(\Phi, \Phi_j) \le c_3 e^{-c_4 j} \qquad \forall\ j \in \mathbb{N},$$

for suitable constants $c_3, c_4 > 0$*, and* $\mathcal{M} =$ *graph* Φ *is an inertial (resp., invariant) manifold.*

Thus if the SGC holds, then the convergence is to an inertial manifold. If one replaces the gap condition in A7 with the weaker condition (2.11), then the proof as in [47] for the convergence of the sequence $\{\mathcal{M}_{j,n}\}$ as $j \to \infty$ still goes through, but not the asymptotic completeness of, or even the exponential attraction to, the limiting manifold. The limiting manifold in that case is merely guaranteed to be invariant. Finally, in the absence of (2.11), the convergence to the global attractor is still guaranteed, provided $n \to \infty$ as well [47].

In the original method of proof for the existence of inertial manifolds [17], the manifold is the graph of the fixed point of the mapping described by

$$\Theta_{j+1}(p_0) = \int_{-\infty}^{0} e^{sA} Q f(\tilde{p} + \Theta_j(\tilde{p})) ds, \tag{3.10}$$

where $\tilde{p} = \tilde{p}(s; p_0, \Theta_j)$ solves

$$\frac{d\tilde{p}}{dt} + A\tilde{p} = Pf(\tilde{p} + \Theta_j(\tilde{p})), \quad \tilde{p}(0) = p_0. \tag{3.11}$$

In [10], a discretization of this mapping was presented and shown to provide a convergent algorithm for computing inertial manifolds. Such a discretization was actually implemented in [46] to compute the manifold for a reaction diffusion equation over a portion of $P_n\mathcal{E}$ in a case where $n = 2$. Note that to obtain Θ_{j+1} requires global knowledge of Θ_j as one cannot predict where the trajectory in $P\mathcal{E}$ of the solution to (3.11) will go, i.e., where one will need to evaluate Θ_j. Practically speaking, one

must interpolate the discrete representation of Θ_j to solve (3.11) backward in time. Thus the complexity of the computation grows dramatically with the dimension of the manifold n. Yet, if one is interested in computing the complete manifold (or at least a patch of it), the approach in [10] is probably more appropriate than the one used here.

If, however, one is primarily interested in computing particular solutions on the manifold, there is no need to compute the manifold in its entirety. In this case the objective is to solve the initial value problem for the inertial form (1.2) so that at each time step, one needs only to compute the functional relation $q = \Phi(p)$ at a particular $p \in P\mathcal{E}$ (or several such p locations, in a multistep scheme). To emphasize the difference with the approach in (3.10), note that to obtain φ_{j+1} via (2.7), one need only know φ_j, a one-dimensional object. Thus the complexity is essentially independent of the dimension of the manifold. Another application where one would prefer to apply (3.6), (3.7) is in postprocessing via an AIM [21]. Roughly speaking, in that approach one evolves the solution via an adequately accurate Galerkin (or nonlinear Galerkin) approximation to obtain final value $p(t_1)$, and then recovers values for the high modes *only at the final time* from $q(t_1) = \Phi_a(p(t_1))$, where Φ_a is some appropriately chosen AIM. In this instance the enslavement relation is needed only at a single base point.

While Theorem 3.1 gives the main motivation for implementing this algorithm, the validation of a code for this purpose requires more details from the analysis. Specifically, we need information about the convergence in $\tilde{\mathcal{F}}$. This is given in two lemmas below, which are proved in [47]. For both lemmas it is again assumed that A1–A7 hold. The first ingredient is an a priori estimate on the variation in time of the exact solution on the manifold.

LEMMA 3.2. *For $t < 0$ and τ such that $0 \le \tau \le -t$, we have that*

$$|\varphi(p_0)(t+\tau) - \varphi(p_0)(t)|_E \le \tau \beta_{n,\sigma} e^{-\sigma t}(1 + |p_0|_E)$$

for all $p_0 \in P_n E$, where

$$\beta_{n,\sigma} = 2M_0K_1\lambda_n^{\alpha} + \frac{2K_1(K_3\lambda_n + M_1\lambda_n^{\alpha})}{1-\kappa_{n,\sigma}}\left\{\frac{M_0K_1}{\lambda_n^{1-\alpha}} + \frac{(1+\gamma_\alpha)M_0K_2}{\Lambda_n^{1-\alpha}} + K_1\right\}. \tag{3.12}$$

It is not so much that we need to invoke the result of Lemma 3.2 as that we need the quantity $\beta_{n,\sigma}$, which plays a central role in the error estimate for the algorithm in (3.6), (3.7). The reason we restate Lemma 3.2 here is to recall the purpose of $\beta_{n,\sigma}$. While the expression in (3.12) is adequate under the general assumptions A1–A7, it is conceivable that for a particular PDE, one might know more about the variation of solutions, in which case a smaller expression for $\beta_{n,\sigma}$ might be found. The next lemma measures the actual error after applying the mapping $\tilde{\mathcal{T}}$. It states precisely how $\beta_{n,\sigma}$ enters into the estimate. We do not have a contraction in the strict sense. Rather, we have a contraction plus a residual which decreases provided the time step τ decreases and the product $N\tau$ increases.

LEMMA 3.3. *Let N be a nonnegative integer, let $\tau > 0$, and assume that σ and σ_0 satisfy* (2.10) *for a fixed $n \in \mathbb{N}$ with $\sigma_0 < \sigma$. Then for all $p_0 \in P_n E$ and all $\psi \in \tilde{\mathcal{F}}$,*

we have

$$\begin{aligned}\|\varphi(p_0) - \mathcal{T}_\tau^N(\psi, p_0)\|_\sigma &\le \kappa_{n,\sigma}\|\varphi(p_0) - \psi\|_\sigma \\ &+ \left(\tau\beta_{n,\sigma} + \frac{\beta_{n,\sigma_0}}{\sigma - \sigma_0}e^{-(\sigma-\sigma_0)N\tau}\right)(1 + |p_0|_E),\end{aligned} \tag{3.13}$$

where β is as in Lemma 3.2.

The expression for $\beta_{n,\sigma}$ serves as a guide to choosing a number of parameter settings for the algorithm. We will examine in section 5 the effects of particular terms in $\beta_{n,\sigma}$ on the error.

4. Application to the KSE. The KSE we consider is often written as

$$\frac{\partial u}{\partial t} + \frac{\partial^4 u}{\partial x^4} + \frac{\partial^2 u}{\partial x^2} + u\frac{\partial u}{\partial x} = 0, \quad (x,t) \in \mathbb{R} \times \mathbb{R}^+, \quad u(x,0) = u_0(x), \quad x \in \mathbb{R}, \tag{4.1}$$

subject to periodic boundary conditions $u(x,t) = u(x+L,t)$, $L > 0$. A considerable amount of theoretical and computational work on the KSE can be found in the literature (see [1], [4], [28], and [42] for a small sampling). The dissipativity for the KSE was first established only in the invariant subspace of odd functions in [44]. In fact, it was the KSE with periodic *and odd* boundary conditions that served as one of the first applications of the existence theory of inertial manifolds [15]. Dissipativity for the general periodic case has been established only somewhat recently, independently by Collet et al. [6] and Goodman [22] (see also the earlier work of Il'yashenko [29] and some simplifications in Pinto [45]). This paved the way for the existence of a global attractor and an inertial manifold in the general case. Nevertheless, in the computations which follow at the end of this section, *we restrict the flow to the odd subspace*, in part, to cut the dimension of the inertial manifold in half.

The dimension of the inertial manifold for the KSE was first estimated in [15] and later improved in [52] by using the estimate for the absorbing ball from [6]. These estimates, however, are of the form dim $\le cL^b$, where most of the effort is devoted to making the exponent b as small, yet the value of the constant c is not readily available. There is an arithmetic error in [52] which leads to a false estimate of dim $\le cL^{1.64}(\ln L)^{0.2}$ for the inertial manifold in the space L^2, when in fact that analysis should yield dim $\le cL^{2.7}(\ln L)^{0.2}$.

We wish to apply the algorithm at the moderate value of $L = L^* = 4\sqrt{2}\pi$ and thus must actually *evaluate* the dimension. This calculation has been carried out in [37] to arrive at rigorous values for the dimension for the KSE prepared at radii ranging from that of a ball which can be shown to be absorbing, down to a much smaller one which nevertheless seems to contain the global attractor. We sketch briefly here the main steps involved.

In the appendix to [37], A. Cheskidov calculates a rigorous radius of an absorbing ball in L^2 to be $\rho_0 = 972$ at $L = L^*$. (The same radius is valid for the general periodic case, even though the dimension of the inertial manifold will be larger.) Also in [37], we rework the analysis in [52] to obtain an explicit estimate for ρ_1, the radius of an absorbing ball in H^1, in terms of ρ_0.

The equation is prepared in a manner quite different from what is traditionally done, which is to replace f by f_ρ, where $f_\rho(u) = \chi_\rho(|u|_\diamond)f(u)$, with

$$\chi_\rho(r) = \chi\left(\frac{r^2}{\rho^2}\right) \tag{4.2}$$

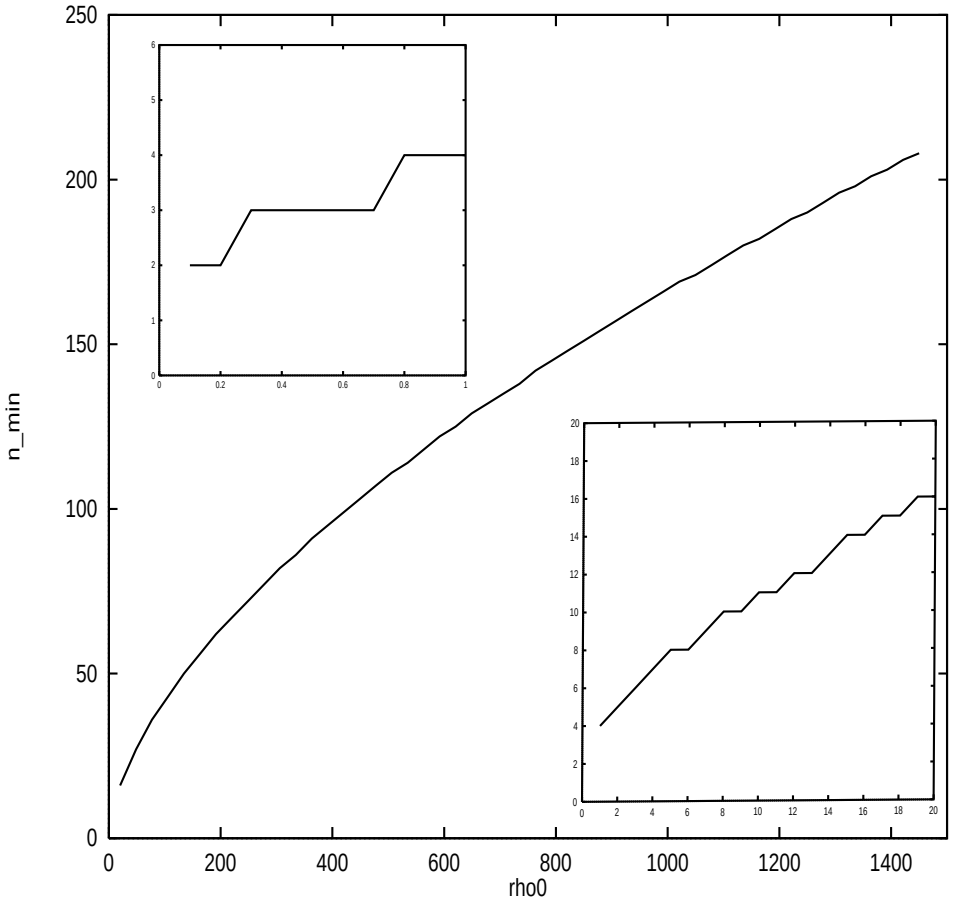

FIG. 3. *Minimal dimension of an inertial manifold for prepared KSE.*

for some norm $|\cdot|_\diamond$ and some function $\chi \in C^1(\mathbb{R}^+)$ satisfying

$$\chi|_{[0,1]} = 1, \quad \chi|_{[2,\infty)} = 0, \quad 0 \le \chi(s) \le 1 \quad \forall\, s \in [1,2], \quad \forall\, s \in \mathbb{R}^+. \tag{4.3}$$

Instead, we let $|\cdot|$, $|\cdot|_s$ denote the L^2 and H^s norms, respectively, and we show (in [37]) that

$$\left| u\frac{\partial u}{\partial x} - v\frac{\partial v}{\partial x} \right|_{-1} \le \sqrt{2}\rho_0^{1/2}\rho_1^{1/2}|u-v| \quad \text{provided } |u|, |v| \le \rho_0 \text{ and } |u|_1, |v|_1 \le \rho_1,$$

and thus the nonlinear term $f(u) = u\partial u/\partial x$ when restricted to the ball in H^1 is Lipschitz from the L^2-topology to the H^{-1}-topology. We then invoke the following theorem of Valentine (see [30]).

THEOREM 4.1. *Let E, F be Hilbert spaces, and let S be a subset of E. For any Lipschitz function $g : S \to F$ there exists a Lipschitz function $\tilde{g} : E \to F$ such that $\tilde{g}|_S = g$ and* $\mathrm{Lip}(\tilde{g}) = \mathrm{Lip}(g)$.

Thus we can extend the restriction of f to the ball in H^1 to a globally Lipschitz function from L^2 to H^{-1}, keeping the Lipschitz constant fixed at $M = \sqrt{2}\rho_0^{1/2}\rho_1^{1/2}$. Numerical evaluation of both sides of the sharp gap condition in [43] leads to a minimal

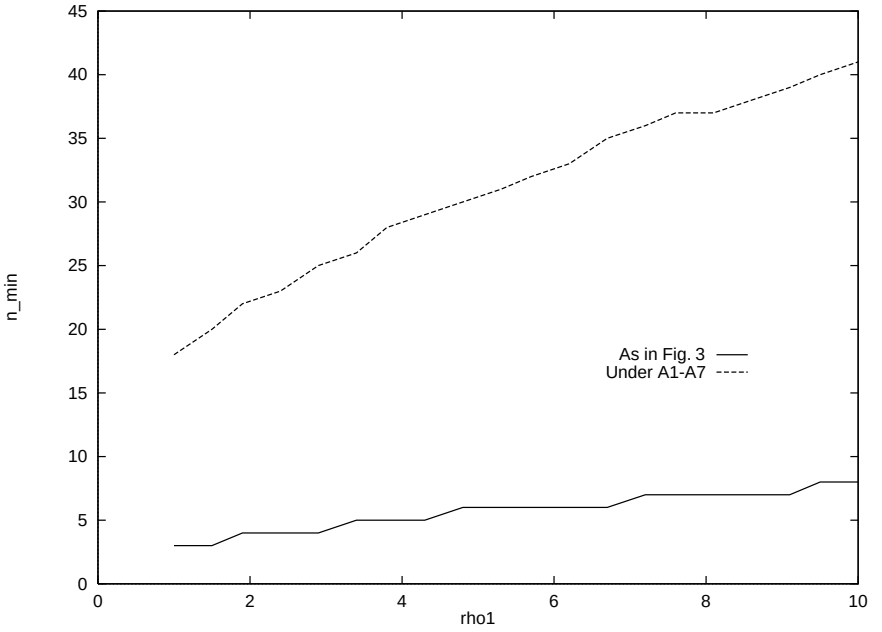

FIG. 4. *Minimal dimension under two different sets of assumptions.*

dimension of 164 (for $L = L^*$, in the odd case). If the estimate for the absorbing ball can be improved, so would be the estimate for the dimension of the manifold. This effect is displayed in Figure 3. One can also very well consider a possibly overly prepared equation, where the nonlinear term is modified outside a ball of *arbitrary* radius ρ_0, regardless of the rigorous estimate for the absorbing ball, much like in the case of a local invariant manifold. Any dynamics *entirely* within the ball of preparation are still preserved. On the other hand, we can expect trajectories of the KSE which are even just partially outside the ball to be altered in an indeterminable way.

The particular steps outlined above gave the best results of several explored in [37]. It is under the more general framework in A1–A7, however, that the error estimates in section 4 were derived. We express the KSE in the form of (1.1) by setting

$$Au = D^4u + D^2u + u, \qquad f(u) = -uDu + u, \tag{4.4}$$

so that the eigenvalues of the linear part are

$$\mu_k = \left(\frac{2\pi}{L}k\right)^4 - \left(\frac{2\pi}{L}k\right)^2 + 1, \quad k = 1, 2, \dots,$$

corresponding to a complete set of orthonormal eigenfunctions in L^2_{odd}

$$w_k(x) = \sqrt{\frac{2}{L}} \sin\left(\frac{2\pi}{L}kx\right).$$

Here we set $\lambda_n = \mu_n$ and $\Lambda_n = \mu_{n+1}$ for n to be determined by A7. (The treatment that produced Figure 3 used $Au = D^4u + D^2u$.)

We also select as spaces

$$E = H^1_{\text{odd}}, \quad F = \mathcal{E} = L^2_{\text{odd}}. \tag{4.5}$$

It is shown in [52] that the conditions A1–A6 hold for the spaces E,F, $\mathcal{E}$, as in (4.5) if $K_1 = K_2 = (\frac{4}{3})^{1/4}$, and $\alpha = 1/4$. Furthermore, it is shown in [37] that

$$|f(u) - f(v)| \le d_1(r)|u - v|_1, \quad \text{provided } |u|_1, |v|_1 < r,$$

where

$$d_1(r) = \sqrt{2}\tilde{L}^{1/2}r + \tilde{L}, \tag{4.6}$$

and $\tilde{L} = L/2\pi$.

We prepare the nonlinear term by applying Theorem 4.1 to obtain an extension of $f|_{B_r}$ to a globally Lipschitz function $f_r : H^1_{\text{odd}} \to L^2_{\text{odd}}$ such that $\text{Lip}(f_r) = d_1(r)$ and $f_r = f$ on B_r, the ball of radius r in H^1_{odd}. Thus we may take $M_0 = 0$ and $M_1 = d_1(r)$ in A1. In Figure 4 we plot the minimal dimension to satisfy the conditions A1–A7, along with the data from Figure 3, for comparison. In the latter case, we plot against the value of ρ_1 which is computed in terms of ρ_0, as in [52].

4.1. Computational results. Since we do not have an exact form for the inertial manifold we instead fix the length L and select several points on the global attractor, and hence on any inertial manifold. We then try to reproduce the Q-component of each point using only the P-component. We consider first the case where u is the solution to the eight-dimensional Galerkin approximation, and we proceed under the ansatz that there is a three-dimensional inertial manifold. Eight modes have been found to be the minimum needed for the Galerkin method to capture the correct dynamics; using more modes does not seem to change the qualitative features described below nor to introduce new elements to the global attractor [34], [38].

The computations are carried out on a renormalized version of the KSE

$$\frac{\partial v}{\partial \tau} + 4\frac{\partial^4 v}{\partial y^4} + \vartheta\left[\frac{\partial^2 v}{\partial y^2} + v\frac{\partial v}{\partial y}\right] = 0, \quad y \in [0, 2\pi], \tag{4.7}$$

where $\vartheta = L^2/\pi^2$ is taken to be the new parameter. The change of variables which relates (4.7) to (4.1) is given by

$$u(t,x) = lv\left(\frac{l^4}{4}t, lx\right) \quad \text{so that } |u|_1 = |u_x|_{L^2(0,L)} = l^{3/2}|v_y|_{L^2(0,2\pi)} = l^{3/2}|v|_1, \tag{4.8}$$

where $l = 2\pi/L$.

Several elements of the global attractor are shown in Figure 2 at $\vartheta = L^*/\pi^2 = 32$. Plotted here are most of the two-dimensional unstable manifold of the origin along with the one-dimensional unstable manifold of the "mixed-mode" steady state, labeled s_2, and a stable limit cycle (in bold). The axes are $\sin(x)$, $\sin(2x)$, and $\sin(3x)$, with the two-dimensional unstable manifold of the origin being tangent to the first two axes. The spheres labeled s_1 and s_3 represent bimodal (as they are along the $\sin(2x)$ axis) node and saddle steady states, respectively. There is a symmetric mixed-mode steady state which is hidden by the two-dimensional unstable manifold of the origin. We do not plot the one-dimensional unstable manifold of this second mixed-mode steady state, nor the two-dimensional unstable manifold of s_3, to avoid complicating

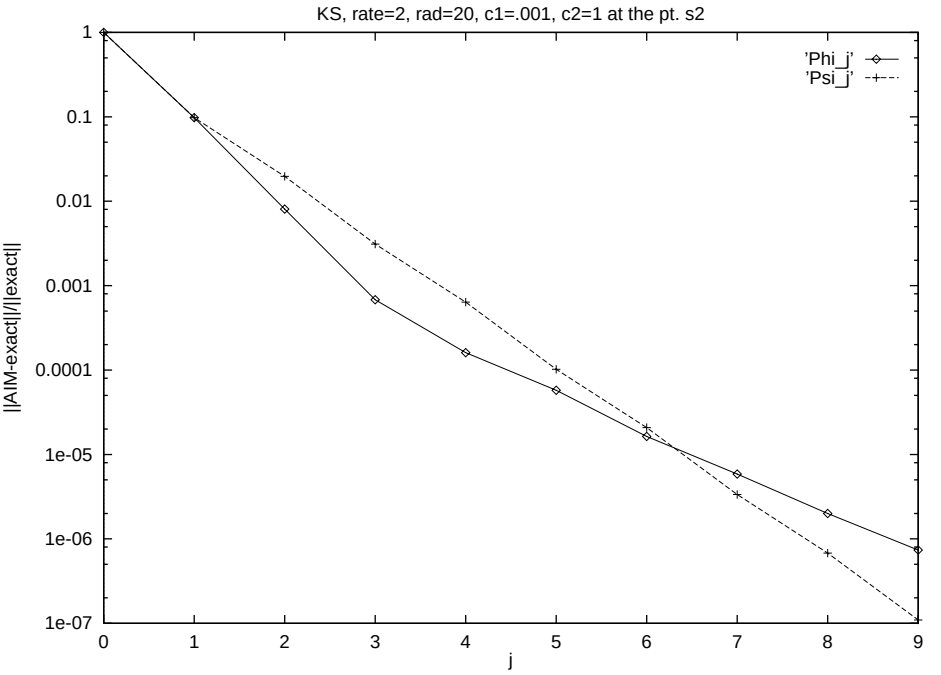

FIG. 5. *Relative error for Φ_j, Ψ_j at the steady state s_2.*

the picture. We can report, however, that the latter seems to have as its boundary s_3 and the limit cycle. Its shape is bowl-like, as indicated by the portion of the one-dimensional manifold of s_2 that approaches the limit cycle. Further extension of the two-dimensional unstable manifold of the origin suggests that it has as its boundary the unstable manifolds of mixed-mode steady states together with all of the steady states.

The convergence results for the sequences of AIMs given by Φ_j, Ψ_j, taken at the points p_1 (which is on the two-dimensional unstable manifold of the origin, not the one-dimensional manifold of s_2), p_2 (which is on the one-dimensional manifold of s_2), and p_3 (which is on the limit cycle) are shown in Figure 1. Note that the plots for Ψ_j all level off starting at small values of j. Indeed, it has been rigorously shown that in some sense the error in Ψ_2 is comparable to that of the limiting function $\Psi_\infty \equiv \lim_{j\to\infty} \Psi_j$. On the other hand the error for the sequence Φ_j continues to improve through $j = 9$ (and should do so beyond, until round-off errors produce diminished returns). At a steady state, however, one expects the two sequences to perform comparably, since graph Ψ_∞ contains all of the stationary solutions. This is confirmed by the results at s_2 shown in Figure 5.

To completely justify the computations we need to satisfy the gap condition and thus consider a manifold of higher dimension. All of the elements of the global attractor described above lie within a ball given by $|v|_1 \le 15$ in the phase space for (4.7), which by (4.8) corresponds to $|u|_1 \le 15 \cdot 2^{3/2} \cdot 32^{-3/4} \approx 3.2$. We see from Figure 4 that for the KSE prepared at $\rho_1 = 3.2$, rigorous analysis provides an inertial manifold of dimension five, and the convergence estimates in section 4 hold for a manifold of dimension 25.

With this in mind, we also consider a 64-mode Galerkin truncation of the KSE.

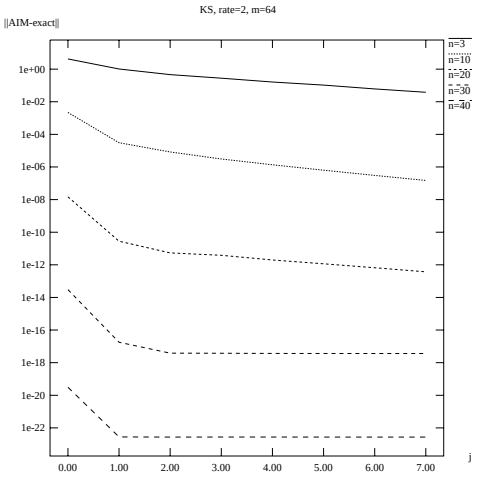

FIG. 6. *Gradient error from "exact" high-mode component of the point p3.*

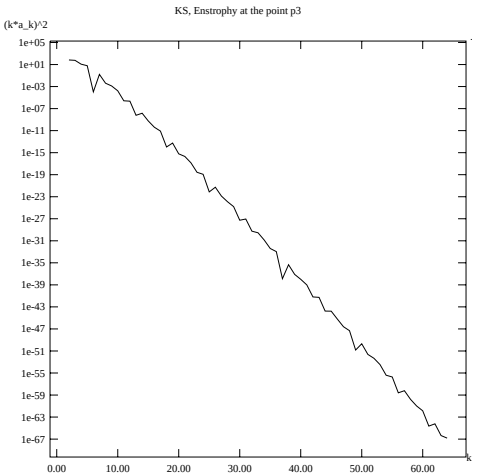

FIG. 7. *Spectrum of the H_1 norm of the point p3.*

We plot in Figure 6 the error of Φ_j from the "exact" Q_n-component at various values of n for the analogue of point p_3 for this finer discretization. The two observations to make are that the errors decrease dramatically as n increases, but that saturation sets in quickly as j increases in the cases where $n = 30$ and $n = 40$. One explanation for this is that the point p_3 is not exactly on the limit cycle. It was computed so that the image of the Poincaré return map (to the plane defined by the first mode being zero) differed from p_3 in the 12th decimal place in the $|\cdot|_1$ norm. The Q_n-component itself decays rapidly in this norm, as expected from the Gevrey regularity of the solution and as indicated in the plot of the spectrum of the H_1 norm in Figure 7. For these reasons we also plot the $|\cdot|_1$ norm of the residual between successive iterations in Figure 8. The fact that the residual continues to decay through seven iterations suggests that the saturation in Figure 6 was indeed due to the inaccuracy of the point p_3 rather than round-off error. The fact that the residual decays faster

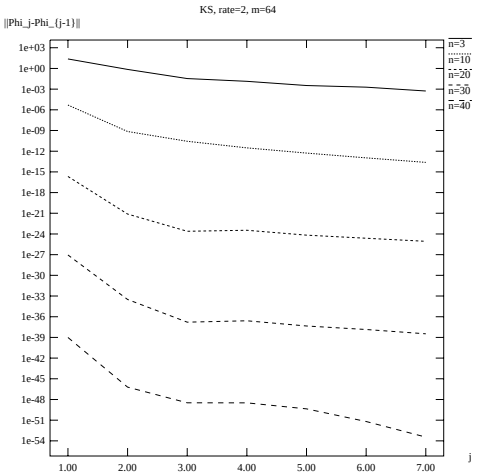

FIG. 8. *Gradient norm of residue.*

with increasing n is consistent with the convergence theory of the algorithm.

These computations have been carried out to compute invariant (perhaps inertial) manifolds for Galerkin approximations of the KSE. In the next section we analyze how these manifolds are connected to those for the PDE case.

5. Effect of truncating the high modes. In this section we examine the convergence of graph Φ_j to the exact inertial manifold as the wave number for truncation of the Q-modes is increased. Such a truncation is necessary for the PDE case considered here as the Q-mode is otherwise infinite-dimensional. It seems reasonable to expect that the convergence to the exact inertial manifold still takes place provided the threshold for this truncation tends to infinity along with either the dimension or the number of iterations. We outline how to show that this is indeed the case and quantify the error obtained with this further truncation even when the threshold for this truncation is kept bounded. The proofs for the estimates below are similar to those in [47] and can be found in [36].

5.1. Error estimates. For the analysis in this section, in addition to the assumptions made in section 2, we also require the following assumption.

A8. For $m > n$ we have $\Lambda_m > \Lambda_n$, $P_m P_n = P_n$, and, as a consequence, $Q_m Q_n = Q_m$.

The difference in the construction of the AIMs is that now we iterate the map $P_m \mathcal{T}_\tau^N$ instead of $\mathcal{T}_\tau^N$. The expression for the map $P_m \mathcal{T}_\tau^N$ is that for $\mathcal{T}_\tau^N$ in (3.1) with Q replaced by $P_m Q_n$, the other terms being unchanged. The same is true for the expressions (3.6) and (3.7) with respect to the "approximating trajectories" $\tilde{\varphi}_j$ obtained in this construction. More precisely, the AIMs are obtained in the following way. We first choose sequences $\{\tau_j\}_{j\in\mathbb{N}}$, $\tau_j > 0$, $\{N_j\}_{j\in\mathbb{N}}$, $N_j \in \mathbb{N}$, $N_j \geq 0$, and also $\{m_j\}_{j\in\mathbb{N}}$, $m_j > n$. Then we set

$$\tilde{\varphi}^0(p_0)(t) = p_0 \qquad \forall t \leq 0, \quad \forall p_0 \in P_n E,$$

and we proceed by Picard iteration:

$$\tilde{\varphi}^j(p_0) = P_{m_j} \mathcal{T}_{\tau_j}^{N_j}(\tilde{\varphi}^{j-1}(p_0), p_0) \qquad \forall p_0 \in P_n E.$$

Finally, we define the AIMs as the graphs

$$\tilde{\mathcal{M}}_j = \text{graph } \tilde{\Phi}_j = \{y + \tilde{\Phi}_j(y);\ y \in P_n E\}$$

of the maps $\tilde{\Phi}_j : P_n E \to P_{m_j} Q_n E$ defined by

$$\tilde{\Phi}_j(p_0) = P_{m_j} Q_n \tilde{\varphi}^j(p_0)(0) \qquad \forall p_0 \in P_n E.$$

Since the SGC (2.4) is satisfied, an inertial manifold $\mathcal{M} = \text{graph } \Phi$ of a function $\Phi : P_n E \to Q_n E$ exists as described in section 2, with $\Phi(p_0) = Q_n \varphi(p_0)$, where $\varphi(p_0)$ denotes the exact backward solution of (1.1) that passes through $p_0 + \Phi(p_0) \in \mathcal{M}$ at time $t = 0$, which is obtained as the fixed point of the map $\mathcal{T}(\cdot, p_0)$. For each $j \in \mathbb{N}$, one can show that the set $\tilde{\mathcal{M}}_j$ is a finite-dimensional topological submanifold of E.

For the convergence of the AIMs, one can proceed similarly to the proof in [47]. The first step concerns only the exact solution; hence we borrow it unmodified from [47]; it is Lemma 3.2 appearing in section 3 above. The second step is to estimate how the map $P_m \mathcal{T}_\tau^N$ brings elements in $\tilde{\mathcal{F}}$ closer to the exact orbits on the inertial manifold.

LEMMA 5.1. *Let N be a nonnegative integer, $m \in \mathbb{N}$ with $m > n$, and $\tau > 0$, and assume σ and σ_0 satisfy* (2.10) *with $\sigma_0 < \sigma$. Then for all $p_0 \in P_n E$ and all $\psi \in \tilde{\mathcal{F}}$, we have*

$$\begin{aligned} &\|\varphi(p_0) - P_m \mathcal{T}_\tau^N(\psi, p_0)\|_\sigma \le \kappa_{n,\sigma} \|\varphi(p_0) - \psi\|_\sigma \\ &+ \left(\tau \beta_{n,\sigma} + \frac{\beta_{n,\sigma_0}}{\sigma - \sigma_0} e^{-(\sigma - \sigma_0) N \tau} + \tilde{\beta}_{n,\sigma} \frac{\Lambda_m^\alpha}{\Lambda_m - \sigma} \right) (1 + |p_0|_E), \end{aligned} \tag{5.1}$$

where $\beta_{n,\sigma}$ and β_{n,σ_0} are as in Lemma 3.2*, and*

$$\tilde{\beta}_{n,\sigma} = K_2 (1 + \gamma_\alpha) \left\{ M_0 + \frac{M_1}{1 - \kappa_{n,\sigma}} \left[\frac{M_0 K_1}{\lambda_n^{1-\alpha}} + (1 + \gamma_\alpha) \frac{M_0 K_2}{\Lambda_n^{1-\alpha}} + K_1 \right] \right\}. \tag{5.2}$$

We may now estimate the distance from each "approximating trajectory" $\tilde{\varphi}^j(p_0)$ to the exact trajectory $\varphi(p_0)$ by iterating the estimate in Lemma 5.1.

LEMMA 5.2. *Let σ and σ_0 satisfy* (2.10) *with $\sigma_0 < \sigma$. Then*

$$\begin{aligned} &\sup_{p_0 \in P_n E} \frac{\|\varphi(p_0) - \tilde{\varphi}^j(p_0)\|_\sigma}{1 + |p_0|_E} \\ &\le \kappa_{n,\sigma}^j \left(K_1 + \frac{1}{1 - \kappa_{n,\sigma}} \left[\frac{M_0 K_1}{\lambda_n^{1-\alpha}} + (1 + \gamma_\alpha) \frac{M_0 K_2}{\Lambda_n^{1-\alpha}} + K_1 \right] \right) \\ &+ \sum_{\ell=0}^{j-1} \kappa_{n,\sigma}^\ell \left(\tau_{j-\ell} \beta_{n,\sigma} + \frac{\beta_{n,\sigma_0}}{\sigma - \sigma_0} e^{-(\sigma - \sigma_0) N_{j-\ell} \tau_{j-\ell}} + \tilde{\beta}_{n,\sigma} \frac{\Lambda_{m_{j-\ell}}^\alpha}{\Lambda_{m_{j-\ell}} - \sigma} \right), \end{aligned} \tag{5.3}$$

where $\beta_{n,\sigma}$ and β_{n,σ_0} are as in Lemma 3.2*, and $\tilde{\beta}_{n,\sigma}$ is as in Lemma* 5.1.

For the exponential convergence of the manifolds the sequences $\{\tau_j\}_j$, $\{N_j\}_j$, and $\{m_j\}_j$ have to be chosen appropriately.

THEOREM 5.3. *Assume* A1–A8 *hold. Assume also that it is possible to choose a sequence $\{m_j\}_j$ with $m_j > n$ and such that*

$$\Lambda_{m_j}^{1-\alpha} \ge \frac{c_0}{\delta^j} \qquad \forall j \in \mathbb{N}, \tag{5.4}$$

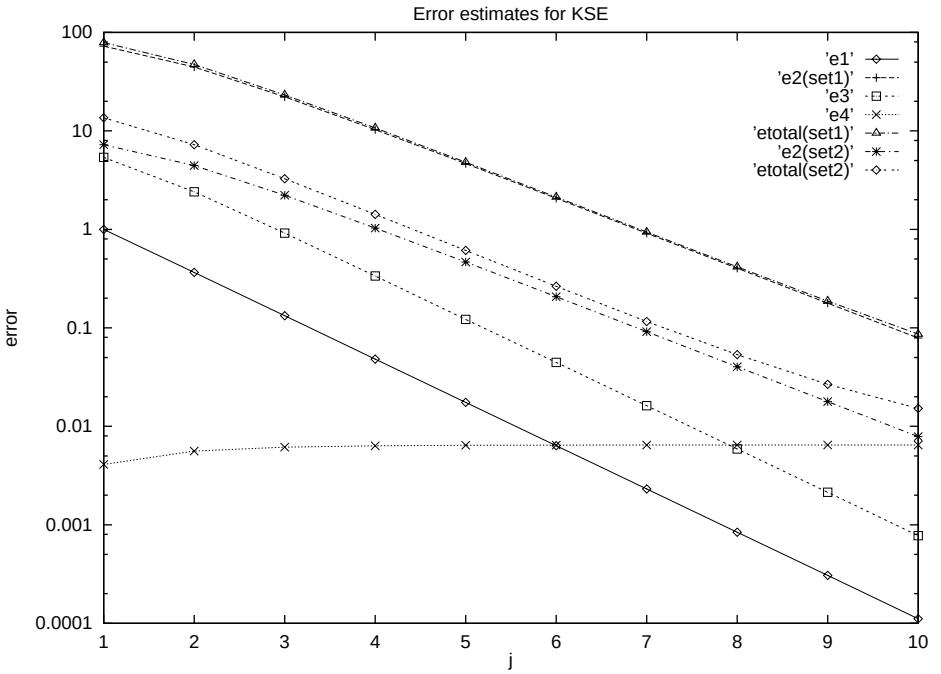

FIG. 9. *Total error estimate and individual terms in* (5.3) *for set*1*:* $c_1 = .001$*,* $c_2/c_1 = 1$*, and set*2*:*$c_1 = .0001$*,* $c_2/c_1 = 10$*.*

for some $c_1 > 0$ *and some* $0 < \delta < 1$*. Suppose that the sequences* $\{\tau_j\}_j$ *and* $\{N_j\}_j$ *are chosen so that*

$$0 < \tau_j \le c_1 \gamma^j \qquad \text{and} \qquad N_j \tau_j \ge c_2 j \quad \forall j \in \mathbb{N}, \tag{5.5}$$

for some $c_1, c_2 > 0$ *and some* $0 < \gamma < 1$*. Let now* σ *and* σ_0 *satisfy* (2.10) *with* $\sigma < \sigma_0$*. Let*

$$\epsilon = \min\{\kappa_{n,\sigma}, \max\{\gamma, e^{-c_2(\sigma-\sigma_0)}, \delta\}\},$$

which is less than 1*. Then, for any* η *with* $\epsilon < \eta < 1$*, there exists a* $c_\eta \ge 0$ *such that*

$$d(\Phi, \tilde{\Phi}_j) \le c_\eta \eta^j \qquad \forall j \in \mathbb{N}. \tag{5.6}$$

5.2. Application to the KSE. We saw in 4.1 that the KSE prepared at a radius $r = 3.2$ in $|\cdot|_1$; A1–A7 hold for $n \ge 25$. The condition A8 also holds, trivially. Here we fix $n = 40$ and observe that κ is a decreasing function of σ over the interval in (2.10). Thus we select σ and σ_0 to be the right and left endpoints (minus .001 and plus .001, respectively) in the calculation of $\beta_{n,\sigma}$, β_{n,σ_0} from (3.12), and $\tilde{\beta}_{n,\sigma}$ from (5.2). We consider a fixed truncation $m_j = m = 64$ and plot in Figure 9 the total error as estimated in (5.3) along with the individual terms denoted e1 through e4, consecutively from left to right (the last three are in the summation). The plots are for two algorithm settings, set1: $c_1 = .001$ $c_2/c_1 = 1$ (as in the previous runs for the KSE) and set2: $c_1 = .0001$ $c_2/c_1 = 10$. For the first setting, the term e2 dominates

by about a factor of ten suggesting that c_1 should be decreased by just this amount. By simultaneously increasing c_2/c_1 by the same factor in set2, we leave the terms e1, e3, and e4 unchanged and arrive at a total error which is fairly evenly balanced in all the terms. Note that e4 actually increases with the number of iterations since m_j is fixed in this case.

INITIAL VALUES FOR THE INVERSE TOEPLITZ EIGENVALUE PROBLEM*

DIRK LAURIE†

Abstract. We show how to find a symmetric Toeplitz matrix whose eigenvalues are close to a specified target set of n real numbers.

Key words. inverse eigenvalue problem, Toeplitz, initial values

AMS subject classifications. 65F18, 47B35

PII. S106482759935561X

1. Introduction.

A Toeplitz matrix is constant along all diagonals parallel to the main diagonal. A symmetric Toeplitz matrix

$$M_n(\mathbf{t}) = \begin{bmatrix} t_1 & t_2 & \dots & t_{n-1} & t_n \\ t_2 & t_1 & t_2 & \dots & t_{n-1} \\ \ddots & \ddots & \ddots & \ddots & \ddots \\ t_{n-1} & \dots & t_2 & t_1 & t_2 \\ t_n & t_{n-1} & \dots & t_2 & t_1 \end{bmatrix}$$

is therefore fully determined by its first row $\mathbf{t} = (t_1, t_2, \dots, t_n)$. In this paper "Toeplitz matrix" always means "real symmetric Toeplitz matrix."

The inverse Toeplitz eigenvalue problem is to find such a matrix whose eigenvalues are a given nondecreasing n-tuple

$$\boldsymbol{\lambda} = (\lambda_1, \lambda_2, \dots, \lambda_n), \quad \text{where} \quad \lambda_1 \le \lambda_2 \le \cdots \le \lambda_n,$$

of real numbers. The first proof of the existence of a solution to the inverse Toeplitz eigenvalue problem was given by Landau [8].

Since the proof is nonconstructive, the actual computation of such a solution still involves numerical methods. Several iterative methods have been suggested. In [9, 10, 3, 12], the iteration involves constructing a sequence of symmetric Toeplitz matrices whose eigenvalues are intended to approach the designated target. These methods start from an initial Toeplitz matrix.

In [4, 13], on the other hand, the iteration involves constructing a sequence of isospectral matrices (i.e., all having the same eigenvalues) which can only become stationary when a Toeplitz matrix is reached. These methods start from an initial matrix isospectral to the target. Such a matrix can be obtained from an initial Toeplitz matrix by finding its eigenvector matrix Q and calculating $Q\,\mathrm{diag}(\lambda_k)Q^{\mathsf{T}}$, provided that one can find a good way to associate eigenvectors with target eigenvalues. We shall say more about this question later.

The construction of good initial values, using some ideas from Landau's proof, is the topic of this paper. The method involves identifying n Toeplitz matrices

T_k, $k = 1, 2, \ldots, n$, with known eigenvalues, expressing the target eigenvalues as a linear combination of the eigenvalues of the matrices T_k and using as initial Toeplitz matrix the corresponding linear combination of the matrices T_k. It can therefore be viewed as linear interpolation in the space of Toeplitz matrices.

The structure of the paper is as follows: first we give an outline of Landau's proof in order to introduce the main ideas of the interpolation method; then we describe the method itself, its efficient implementation, and an interpretation of the method in terms of successive lower-dimensional interpolations; and finally we give the theoretical basis for the method in formal form. However, for those who are interested in results, not theory, here is a Matlab routine implementing the algorithm:

```
function [t,M,Q]=toepinit(lam)
% TOEPINIT  T=TOEPINIT(LAM) returns the first row of a symmetric Toeplitz
%           matrix T with eigenvalues close to the supplied eigenvalues LAM.
%           [T,M]=TOEPINIT(LAM) returns also a matrix M with the specified
%           eigenvalues, where M is close to Toeplitz.
%           [T,M,Q]=TOEPINIT(LAM) returns also the eigenvector matrix of M.

%  Dirk Laurie  1996-07-31

% Solve the equations
%   db(1)=lam(1), k=2:n, db(k-1)+db(k)=lam(k)
n=length(lam); lam=sort(lam(:))';
db=[0 filter(1,[1 1],lam)];

% C=toeplitz(c) is a circulant, S=toeplitz(s) is a skew-circulant
% T=toeplitz(t) is the required Toeplitz matrix
kc=[n+1:-2:1 rem(n+1,2)+2:2:n]; c=ifft(db(kc));
w=exp(pi*i*(0:n-1)/n);
ks=[n:-2:1 rem(n,2)+2:2:n]; s=w.*ifft(db(ks));
t=real(c+s); if nargout<2, return; end

[Q,D]=eig(toeplitz(t)); [d,k]=sort(diag(D));
Q=Q(:,k);
M=Q*diag(lam)*Q';
```

2. An outline of Landau's proof. The method suggested in this paper was inspired by ideas in Landau's proof. Although the proof itself is nonconstructive in the sense that it does not suggest an algorithm by which the inverse Toeplitz eigenproblem may be solved, it contains powerful and suggestive geometrical ideas which contribute much to the intuitive understanding of the problem. It is therefore not out of place, even in a numerical analysis journal, to devote some space to a qualitative summary of the method of proof.

We say that two Toeplitz matrices A and B are *equivalent* if each can be obtained from the other by an affine transformation with nonzero scale factor, i.e., $A = c_0 I + c_1 B$ with $c_1 \neq 0$. Similarly two nondecreasing n-tuples are equivalent if each can be obtained from the other by such an affine transformation. Equivalent matrices have all their eigenvectors in common, and their eigenvalues are equivalent under the same affine transformation under which the matrices are equivalent.

If a solution

$$M_n(t_1, t_2, \ldots, t_n)$$

to the inverse Toeplitz eigenproblem exists, then

$$M_n(t_1, -t_2, t_3, -t_4, \ldots, (-1)^{n-1}t_n)$$

is also a solution. There is therefore no loss of generality in looking only for solutions such that $t_2 \geq 0$.

A Toeplitz matrix is centrosymmetric, and therefore it is possible to assign parity (the property of being even or odd) to its eigenvalues as follows. For a vector $\mathbf{v} = (v_1, v_2, \ldots, v_k)$, the vector $\mathbf{v}_{\text{rev}}$ is obtained by writing the elements in reverse order, i.e., $\mathbf{v}_{\text{rev}} = (v_k, v_{k-1}, \ldots, v_1)$. A vector $\mathbf{v}$ is called *even* if $\mathbf{v} = \mathbf{v}_{\text{rev}}$ and odd if $\mathbf{v} = -\mathbf{v}_{\text{rev}}$. It is well known [2] that all eigenvectors of a symmetric centrosymmetric matrix with distinct eigenvalues are either even or odd: the parity of an eigenvalue is then that of its eigenvector. In the case of multiple eigenvalues, it is always possible to find a basis consisting only of even and odd eigenvectors.

Delsarte and Genin [6] showed that any solution to the inverse Toeplitz eigenvalue problem which is a continuous function of the eigenvalues must have the property that when the eigenvalues are in increasing order, adjacent eigenvalues are of opposite parity. This property is central to Landau's proof.

We now come to the proof itself.

- The Toeplitz matrices under consideration are restricted to *regular* matrices. A regular Toeplitz matrix has only simple eigenvalues, its largest eigenvalue is even, and adjacent eigenvalues λ_k, λ_{k+1}, $k = 1, 2, \ldots, n-1$, are of opposite parity; also, all leading submatrices of a regular matrix have these properties. Note that regular matrices must have $t_2 > 0$.
- Two degrees of freedom are eliminated by taking only one standard representative from each equivalence class of regular Toeplitz matrices, and from each equivalence class of eigenvalue n-tuples. This allows both sets of equivalence classes to be parametrized by $n-2$ real numbers.
  We denote by $\mathcal{T}_n$ the set of standard regular Toeplitz matrices, by $\mathcal{L}_n$ the set of standard eigenvalue n-tuples, and by $\widehat{\mathcal{T}}$ and $\widehat{\mathcal{L}}$, respectively, their representations in R^{n-2}. To avoid unnecessary circumlocution, we shall refer to a point in $\widehat{\mathcal{T}}$ as a "matrix" and impute properties of a matrix to it, when strictly speaking we mean the matrix associated with that point.
  The function Λ that maps a Toeplitz matrix to its sorted eigenvalues induces a map $\widehat{\Lambda}$ from $\widehat{\mathcal{T}}$ to $\widehat{\mathcal{L}}$ by mapping a standard matrix T to the standard eigenvalue vector equivalent to $\Lambda(T)$.
- The closure of $\widehat{\mathcal{T}}$ in R^{n-2} is compact, and its boundary is made up entirely of matrices with multiple eigenvalues—in other words, matrices that map to points on the boundary of $\widehat{\mathcal{L}}$. A consequence of this fact is that in order to check whether the matrices along a continuous path starting at a point in $\widehat{\mathcal{T}}$ are regular, it is not necessary to check the regularity of submatrices: it is sufficient to check that each matrix in the path has only simple eigenvalues.
- The topological degree of the map $\widehat{\Lambda}$ from $\widehat{\mathcal{T}}$ to the interior of $\widehat{\mathcal{L}}$ is constant. It is therefore sufficient to exhibit one point in the interior of $\widehat{\mathcal{L}}$ that is covered exactly once: then every point in $\widehat{\mathcal{L}}$ must be covered an odd number of times—therefore, at least once.
- An obvious parametrization of $\mathcal{L}_n$ is to use the "middle" eigenvalues ($\lambda_2 < \lambda_3 < \cdots < \lambda_{n-1}$), so that $\widehat{\mathcal{L}}$ is a simplex in R^{n-2}. $\widehat{\mathcal{T}}$ also has some properties reminiscent of those of a simplex. The boundary of $\widehat{\mathcal{T}}$ is described in terms of *vertices*, which have only two distinct eigenvalues each; *k-dimensional edges*

for $k = 1, 2, \ldots, n-4$, which have $k+2$ distinct eigenvalues at each point; and *faces*, which have $n-1$ distinct eigenvalues. Landau proves that each of the $n-1$ faces with $\lambda_k = \lambda_{k+1}$ has a nonempty intersection with the boundary of $\widehat{\mathcal{T}}$. In intuitive terms, the set $\widehat{\mathcal{T}}$ is rather like a simplex with curved faces. Figures 1 and 2 show a two-dimensional representation of $\mathcal{T}_4$ and a projection of a view of a three-dimensional representation of $\mathcal{T}_5$.

- There exists a path starting at the vertex where the largest eigenvalue is simple (this matrix has rank 1 and is easily seen to be unique) and moving along k-dimensional edges for increasing k, until finally a point in the interior of a face is reached, such that the map Λ is one-to-one and its Jacobian nonzero everywhere along the path. By continuity, there must then be some point in the interior of $\widehat{\mathcal{L}}$ at which these properties still hold. Its image is covered exactly once, which completes the proof.

Landau's paper concludes with the following conjecture, followed by the statement: "Of course, it would also be very interesting to find an algorithm for carrying it out."

CONJECTURE 1 (Landau). *The map from $\mathcal{L}_n$ to $\mathcal{T}_n$ is one-to-one.*

3. Initial values by linear interpolation.

3.1. The basic idea. The precise way of standardizing the eigenvalues and Toeplitz matrices is not crucial to Landau's proof. Landau uses $t_0 = 0,\ t_1 = 1$ for the matrices and $\lambda_1 = -1,\ \sum \lambda_i = 0$ for the eigenvalues. The map $\widehat{\Lambda}$ is in that case well defined but does not in general map a matrix to its eigenvalues.

For our purposes the most convenient standardization in both cases maps the smallest eigenvalue to 0 and the largest to 1. Let $T_k,\ k = 1, 2, \ldots, n-1$, be the Toeplitz matrices that correspond to the vertices of $\widehat{\mathcal{T}}$. Their eigenvalue n-tuples $L_k = \Lambda(T_k)$, given by

$$\begin{aligned} L_1 &= (0, 0, \ldots, 0, 1), \\ L_2 &= (0, \ldots, 0, 1, 1), \\ &\cdots\cdots \\ L_{n-1} &= (0, 1, 1, \ldots, 1), \end{aligned}$$

correspond to vertices of $\widehat{\mathcal{L}}$. In section 4 we give an explicit formula (5) for the matrices T_k.

Since the topological structure of $\widehat{\mathcal{T}}$ resembles that of $\widehat{\mathcal{L}}$, it is reasonable to suppose that simple linear interpolation might provide a good approximation to $\Lambda^{-1}(\boldsymbol{\lambda})$.

1. Express $\boldsymbol{\lambda}$ as a linear combination of the vertices of $\mathcal{L}_n$:

$$\boldsymbol{\lambda} = \sum_{k=1}^{n-1} a_k L_k.$$

From the eigenvalue n-tuples for L_k it is obvious that

$$a_{n-k} = \lambda_{k+1} - \lambda_k,\ k = 1, \ldots, n-1.$$

Since $\lambda_1 = 0$ and $\lambda_n = 1$, the coefficients a_k are nonnegative and sum to 1.

2. Approximate $\Lambda^{-1}(\boldsymbol{\lambda})$ by

$$\Gamma(\boldsymbol{\lambda}) = \sum_{k=1}^{n-1} a_k T_k.$$

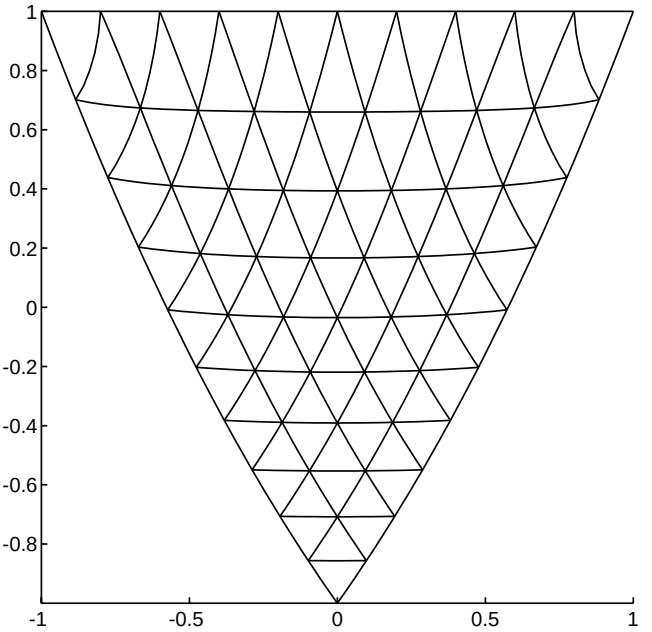

FIG. 1. *Toeplitz matrices with first row* $(0, 1, x, y)$ *are regular for* (x, y) *in the interior of the region shown. When the corresponding eigenvalues are affinely transformed to* $(0, \lambda, \mu, 1)$ *and displayed in the* (λ, μ) *plane, the lines form an equispaced triangular grid.*

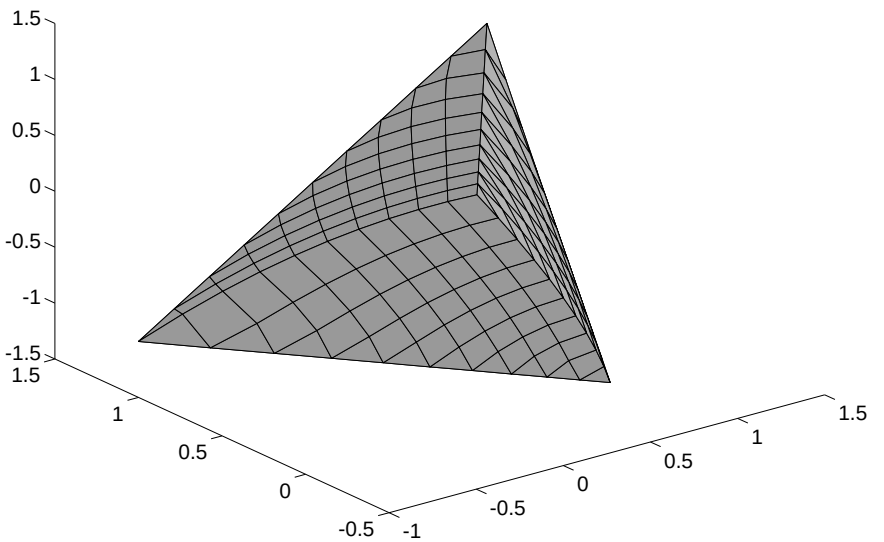

FIG. 2. *Toeplitz matrices with first row* $(0, 1, x, y, z)$ *are regular for* (x, y, z) *in the interior of the region shown. When the corresponding eigenvalues are affinely transformed to* $(0, \lambda, \mu, \nu, 1)$ *and displayed in the* (λ, μ, ν) *plane, the lines on each face form two of the three sets of lines that make up an equispaced triangular grid. The vertices* T_1, T_2, T_3, *and* T_4 *are, respectively, top, right, center, and left in the picture. The initial values are exact along the straight lines* T_1T_3 *and* T_2T4 *but not along the straight line* T_1T_4. *The lines* T_1T_2 *and* T_4T_3 *are actually congruent, although this view does not show the curvature of the former clearly.*

In general $\Gamma(\boldsymbol{\lambda})$ will not belong to $\mathcal{T}_n$ and may need to be standardized unless only the eigenvectors of the initial approximation are needed. (This is in fact true for most of the known iterative methods.)

This theoretical drawback could be avoided by using Landau's standardization ($t_1 = 0,\ t_2 = 1$) instead of ours: any convex combination of standardized matrices in that case is also standardized. This involves calculating

$$\sum_{k=1}^{n-1} \frac{a_k}{(T_k)_{1,2}} T_k$$

instead of $\Gamma(\boldsymbol{\lambda})$, which may not seem to be much less convenient. We shall see in the next section, however, that our standardization allows a fast way of calculating $\Gamma(\boldsymbol{\lambda})$ without explicitly finding the interpolation constants or even the matrices T_k; this expedient does not carry over to Landau's standardization.

The whole process of interpolation would be on shaky ground if it were possible to produce an initial matrix that is not regular. We therefore propose the following.

CONJECTURE 2. *Any linear combination with positive coefficients of regular Toeplitz matrices is itself a regular Toeplitz matrix.*

This conjecture is equivalent to saying that the set $\widehat{\mathcal{T}}$ with Landau's normalization $t_0 = 0, t_1 = 1$ is convex. The conjecture seems to be quite hard to prove but is certainly true for the Trench class of regular Toeplitz matrices [11]. These matrices have the integral representation

$$t_r = \frac{1}{\pi} \int_0^\pi f(\theta) \cos(r-1)\theta \, d\theta, \quad r = 1, \ldots, n, \tag{1}$$

where f is nonincreasing.

After transforming by an affine transformation the initial values thus found, one has in effect approximated the Toeplitz matrix having the original set of eigenvalues by a linear combination of $T_1, T_2, \ldots, T_n$, since $T_n = I$. All the coefficients in the linear combination except possibly the one involving T_n are of the same sign.

3.2. Implementation via circulant theory. A circulant is a Toeplitz matrix in which

$$t_{n-k+2} = t_k, \quad k = 2, 3, \ldots, n,$$

and a skew-circulant is a Toeplitz matrix in which

$$t_{n-k+2} = -t_k, \quad k = 2, 3, \ldots, n.$$

(Remember that we are dealing only with real symmetric Toeplitz matrices and therefore only with symmetric circulants and skew-circulants.) Any Toeplitz matrix $T = M_n(\mathbf{t})$ can be expressed as the sum of a circulant C and a skew-circulant S as follows:

$$C = M_n\left(t_1 - s_1, \tfrac{1}{2}(t_2 + t_n), \tfrac{1}{2}(t_3 + t_{n-1}), \ldots, \tfrac{1}{2}(t_n + t_2)\right),$$
$$S = M_n\left(s_1, \tfrac{1}{2}(t_2 - t_n), \tfrac{1}{2}(t_3 - t_{n-1}), \ldots, \tfrac{1}{2}(t_n - t_2)\right),$$

where s_1 is arbitrary.

It is a well-known fact [5] that any circulant is diagonalized by the Fourier matrix $F = [f_{jk}]$ with $f_{jk} = \omega^{(j-1)(k-1)}$, where $\omega = e^{-2\pi i/n}$: i.e., $F^{-1}CF = D = \operatorname{diag}(d_k)$.

We show in the proof of Lemma 2 that $d_k = d_{n-k+2}$ when k and $n-k+2$ are valid indices. In other words, all eigenvalues of C are double, except d_1 and (if $n = 2m$) d_{m+1}. The matrix C has at most $n_d = \lceil (n+1)/2 \rceil$ distinct eigenvalues. We say that a sequence $\mathbf{d} = (d_1, d_2, \ldots, d_n)$ such that $d_k = d_{n-k+2}$ is *circulant compatible.*

Similarly, any skew-circulant is diagonalized by the matrix WF with

$$W = \mathrm{diag}(1, \zeta, \zeta^2, \ldots, \zeta^{n-1}),$$

where $\zeta = e^{-\pi i/n}$: i.e., $(WF)^{-1} S W F = B = \mathrm{diag}(b_k)$. We show in the proof of Lemma 2 that $b_k = b_{n-k+1}$ when k and $n-k+1$ are valid indices. In other words, all eigenvalues of S are double, except (if $n = 2m-1$) b_m. The matrix S has at most $n_b = \lfloor (n+1)/2 \rfloor$ distinct eigenvalues. We say that a sequence $\mathbf{b} = (b_1, b_2, \ldots, b_n)$ such that $b_k = b_{n-k+1}$ is *skew-circulant compatible.*

Let $L = \mathrm{diag}(\boldsymbol{\lambda}_p)$, where $\boldsymbol{\lambda}_p$ is some permutation (to be specified later) of $\boldsymbol{\lambda}$. We wish to express L as $L = D + B$, where the diagonals of D and B are, respectively, circulant and skew-circulant compatible. The matrix equation $L = D + B$ amounts to a system of n linear equations for the $n+1$ unknowns $d_k,\ k = 1, 2, \ldots, n_d$, and $b_k,\ k = 1, 2, \ldots, n_b$. The extra degree of freedom could be used for making $\sum_{k=1}^{n} b_k = 0$, but in our Matlab code we found it simpler to make one of the unknowns zero.

Having found $C = FDF^{-1}$ and $S = WFB(WF)^{-1}$, we compute $C + S$ as an approximation to the regular Toeplitz matrix with eigenvalues $\boldsymbol{\lambda}$.

It remains to find the correct permutation of $\boldsymbol{\lambda}$. The vertices of L_n are all special cases of eigenvalue sequences that can be permuted to be circulant or skew-circulant compatible; certainly one would require that the corresponding vertices of $\mathcal{T}_n$ be found correctly. We show in Theorem 2 that this requirement is met when $d_k,\ k = 1, 2, \ldots, n_d$, and $b_k,\ k = 1, 2, \ldots, n_b$, are both arranged in nonincreasing order. We therefore have the equations

$$\begin{aligned} d_1 + b_1 &= \lambda_n, \\ d_2 + b_1 &= \lambda_{n-1}, \\ d_2 + b_2 &= \lambda_{n-2}, \\ &\cdots\cdots \end{aligned} \tag{2}$$

$$d_{n_d} + b_{n_b} = \lambda_1. \tag{3}$$

In the Matlab code, we put $d_{n_d} = 0$ if $n_d = n_b + 1$ (which happens when n is even) and $b_{n_b} = 0$ if $n_d = n_b$.

Since the procedure to find it is linear, and maps the vertices of $\mathcal{T}_n$ to those of L_n, the matrix $C + S$ is exactly the same $\Gamma(\boldsymbol{\lambda})$ that was in the previous section found by linear interpolation. The procedure via circulant theory is, however, computationally much easier because it can be carried out with the aid of the fast Fourier transform, as follows.

We need the first rows of C and S. Let $\mathbf{e}_1$ be the first row of the identity matrix, $\mathbf{1}$ a row vector of all ones, $\mathbf{b} = (b_1, b_2, \ldots, b_n)$, and $\mathbf{d} = (d_1, d_2, \ldots, d_n)$. We have

$$\mathbf{e}_1 C = \mathbf{e}_1 FDF^{-1} = \mathbf{1}DF^{-1} = \mathbf{d}F^{-1}$$

and

$$\mathbf{e}_1 S = \mathbf{e}_1 WFB(WF)^{-1} = \mathbf{1}B(WF)^{-1} = \mathbf{b}F^{-1}W^{-1}.$$

Since $1/\zeta = \overline{\zeta}$, the algorithm (implemented in the Matlab code of section 1) follows:

1. Solve (2)–(3).
2. Put $d_{n-k+2} = d_k,\ k = 2, 3, \ldots, n_b$, and calculate
$$(c_1, c_2, \ldots, c_n) = \texttt{ifft}(d_1, d_2, \ldots, d_n).$$
3. Put $b_{n-k+1} = b_k,\ k = 2, 3, \ldots, n_d$, and calculate
$$(s_1, s_2, \ldots, s_n) = \texttt{ifft}(b_1, b_2, \ldots, b_n).$$
4. The desired initial Toeplitz matrix has first row $(c_1 + s_1, c_2 + \overline{\zeta} s_2, \ldots, c_n + \overline{\zeta}^{n-1} s_n)$.

3.3. Composition of lower-dimensional interpolation. We now discuss yet another way to find $\Gamma(\boldsymbol{\lambda})$. The reason for so doing is not in order to find an alternative computational procedure but to gain extra understanding into exactly where the interpolation is exact and where it is only approximate.

We refer to the set of points on the boundary of $\mathcal{T}_n$ for which the Toeplitz matrix is circulant (resp., skew-circulant) as the *circulant* (resp., *skew-circulant*) *hyperedge.* By the exact formula for T_k, to be exhibited in section 4, we see that all odd-numbered vertices are on the circulant hyperedge, and all even-numbered vertices are on the skew-circulant hyperedge. In fact, the circulant hyperedge is simply the $(n_d - 1)$-dimensional convex hull of the odd-numbered vertices, and the skew-circulant hyperedge is simply the $(n_b - 1)$-dimensional convex hull of the even-numbered vertices.

These two hyperedges map linearly to hyperedges of $\mathcal{L}_n$ that are in their turn the convex hulls of the odd-numbered vertices L_{2k+1} and even-numbered vertices L_{2k}, respectively.

The linear interpolation procedure can therefore be factorized as follows:

1. Find points $\boldsymbol{\lambda}_C$ and $\boldsymbol{\lambda}_S$, respectively, on the circulant and skew-circulant hyperedges of $\mathcal{L}_n$, so that the straight line segment connecting them passes through $\boldsymbol{\lambda}$. This implies that for some constant a, $0 \le a \le 1$, we have $\boldsymbol{\lambda} = a\boldsymbol{\lambda}_C + (1 - a)\boldsymbol{\lambda}_S$, with equality if and only if $\boldsymbol{\lambda}$ itself is on either of these hyperedges.
2. Find points $A_C = \Lambda^{-1}(\boldsymbol{\lambda}_C) = \Gamma(\boldsymbol{\lambda}_C)$ and $A_S = \Lambda^{-1}(\boldsymbol{\lambda}_S) = \Gamma(\boldsymbol{\lambda}_S)$ by the above interpolation procedure, which is exact when restricted to a hyperedge.
3. Approximate $\Lambda^{-1}(\boldsymbol{\lambda})$ by $\mathbf{t}_2 = aA_C + (1 - a)A_S$.

To summarize, if we view the n-dimensional linear interpolation process as a composition of three lower-dimensional interpolations, one in the $(n_d - 1)$-dimensional circulant hyperedge, one in the $(n_b - 1)$-dimensional skew-circulant hyperedge, and one along the curve joining a point in one hyperedge to a point in the other, only this last one-dimensional interpolation is not exact.

4. Theorems and proofs. In this section we give the theoretical basis for the interpolation method described above. The derivation, and indeed our whole procedure, depends on the validity of Conjecture 2. We need to show that the association of eigenvalues with the eigenvectors of the circulants and skew-circulants is the proper one and to exhibit the explicit formula (5) for the vertex matrices T_k.

The first two lemmas allow us to find all Toeplitz matrices that could possibly be vertices of the set $\mathcal{T}_n$. In the cases with multiplicity of the nonzero eigenvalue from 2 to $n - 2$, there is more than one Toeplitz matrix with the desired eigenvalues and we need to determine which is regular.

LEMMA 1. *If A is symmetric Toeplitz, then A^2 is Toeplitz if and only if A is circulant or skew-circulant.*

Proof. It is convenient to write A as unsymmetric and use the symmetry later. Let $B = A^2$, where

$$A = \begin{bmatrix} a_0 & a_1 & \dots & a_{n-2} & a_{n-1} \\ a_{-1} & a_0 & a_1 & \dots & a_{n-2} \\ \ddots & \ddots & \ddots & \ddots & \ddots \\ a_{-n+2} & \dots & a_{-1} & a_0 & a_1 \\ a_{-n+1} & a_{-n+2} & \dots & a_{-1} & a_0 \end{bmatrix}.$$

Number the rows and columns of B from 0 to $n-1$. Then

$$b_{j,k} = a_{-j}a_k + a_{-j+1}a_{k-1} + \cdots + a_{n-j-1}a_{k-n+1}.$$

Since $b_{j,k} = b_{j+1,k+1}$ we obtain

$$a_{-j}a_k = a_{n-j}a_{k-n}, \quad j = 1, 2, \dots, n-1, \ k = 1, 2, \dots, n-1. \tag{4}$$

Put $k = j$ in (4) and recall that A is symmetric to obtain

$$a_j^2 = a_{n-j}^2 \implies a_j = \pm a_{n-j}, \quad j = 1, 2, \dots, n-1.$$

A is circulant (resp., skew-circulant) if the positive (resp., negative) sign applies for every j. If A is neither circulant nor skew-circulant, then both signs occur; i.e., there exist indices j, k such that $a_j = a_{n-j} \neq 0$ and $a_k = -a_{n-k} \neq 0$. This gives $a_j a_k = -a_{n-j}a_{n-k} \neq 0$, which contradicts (4). ∎

LEMMA 2. *Any symmetric Toeplitz matrix A with k eigenvalues equal to 1 and $n-k$ eigenvalues equal to 0 can be represented as $A = F^{-1}DF$ or as $A = WFB(WF)^{-1}$, where the diagonals of D and B are, respectively, circulant compatible and skew-circulant compatible sequences containing k ones and $n-k$ zeros, and F is the Fourier matrix $F = [f_{jk}]$ with $f_{jk} = \omega^{(j-1)(k-1)}$, where $\omega = e^{-2\pi i/n}$.*

Proof. Since A is symmetric and has all eigenvalues either 0 or 1, it is a projection matrix and satisfies $A^2 = A$. Since A is Toeplitz, by the previous lemma it must be either circulant or skew-circulant. In the circulant case ($A = C$), let $D = F^{-1}CF$. Since columns k and $n-k+2$ of F are conjugates, d_k and d_{n-k+2} are also conjugates. C is symmetric, and therefore all eigenvalues are real; so $d_k = d_{n-k+2}$, which is the required condition.

Similarly, in the skew-circulant case ($A = S$), columns k and $n-k+1$ of WF are conjugates. Let $B = (WF)^{-1}SWF$; then b_k and b_{n-k+1} are also conjugates, implying $b_k = b_{n-k+1}$. ∎

The following theorem separates out the even and odd parts of the two eigenvectors belonging to a double eigenvalue. This will allow us to work with real eigenvectors, which is more convenient for the theory, although less convenient in computation. As usual in eigenvalue work, "unique" is used in the sense that a nonzero multiple of an eigenvector is not considered different, and that ordering of eigenvectors does not matter.

THEOREM 1. *The unique real eigenvector matrix U with only even and odd*

columns such that $D = U^{\mathsf{T}}CU$ is diagonal for all symmetric circulants C is given by

$$\begin{aligned}
u_{j,1} &= \frac{1}{\sqrt{n}},\\
u_{j,2k} &= \sqrt{\frac{2}{n}}\sin\frac{(2j-1)k\pi}{n}, \qquad k = 1, 2, \ldots, \lfloor \tfrac{n-1}{2} \rfloor,\\
u_{j,2k+1} &= \sqrt{\frac{2}{n}}\cos\frac{(2j-1)k\pi}{n}, \qquad k = 1, \ldots, \lfloor \tfrac{n-1}{2} \rfloor,\\
u_{j,n} &= \frac{(-1)^{j-1}}{\sqrt{n}} \qquad \textit{if } n \textit{ is even.}
\end{aligned}$$

The unique real eigenvector matrix V with only even and odd columns such that $B = V^{\mathsf{T}}SV$ is diagonal for all symmetric skew-circulants S is given by

$$\begin{aligned}
v_{j,2k-1} &= \sqrt{\frac{2}{n}}\cos\frac{(2j-1)(k-\frac{1}{2})\pi}{n}, \qquad k = 1, 2, \ldots, \lfloor \tfrac{n}{2} \rfloor,\\
v_{j,2k} &= \sqrt{\frac{2}{n}}\sin\frac{(2j-1)(k-\frac{1}{2})\pi}{n}, \qquad k = 1, 2, \ldots, \lfloor \tfrac{n}{2} \rfloor,\\
v_{j,n} &= \frac{(-1)^{j-1}}{\sqrt{n}} \qquad \textit{if } n \textit{ is odd.}
\end{aligned}$$

Proof. Let $\mathbf{f}_k$ denote the kth column of F. $\mathbf{f}_k$ and $\mathbf{f}_{n-k+2}$ are orthogonal and conjugate and span a two-dimensional subspace belonging to a double eigenvalue. The real and imaginary parts of $\mathbf{f}_k$ form an orthogonal basis for this subspace but do not form an even-odd pair of vectors. To achieve this, we divide $\mathbf{f}_k$ by ζ^{k-1}, where $\zeta = e^{-\pi i/n}$. Note that $f_{jk} = \zeta^{2(j-1)(k-1)}$. The jth component of $\mathbf{z} = \zeta^{k-1}\mathbf{f}_k$ is $z_j = \zeta^{(2j-1)(k-1)}$. Then $z_j z_{n-j+1} = \zeta^{2n(k-1)} = 1$. Since z_j has modulus 1, this relation means that $z_{n-j+1} = \overline{z}_j$. Therefore $\Re(\mathbf{z})$ is even and $\Im(\mathbf{z})$ is odd, giving two columns that go into U.

The proof for V is similar but easier because the relevant columns of WF require no further scaling: we can immediately take real and imaginary parts. ∎

The way we have chosen the columns of U and V requires that the eigenvalues of the circulant (resp., skew-circulant) be ordered as $D = \mathrm{diag}(d_1, d_2, d_2, d_3, d_3, \ldots, d_{n_d})$ (resp., $B = \mathrm{diag}(b_1, b_1, b_2, b_2, \ldots, b_{n_b})$) instead of the previous ordering used when diagonalizing by F (resp., WF). We get all possibilities for the matrices T_k in this way, e.g., to find T_4 when $n = 8$ requires one of the following twelve cases:

Diagonal of D		Diagonal of B
$(1;1,1;0,0;0,0;1)$		$(1,1;1,1;0,0;0,0)$
$(1;0,0;1,1;0,0;1)$		$(1,1;0,0;1,1;0,0)$
$(1;0,0;0,0;1,1;1)$	or	$(1,1;0,0;0,0;1,1)$
$(0;1,1;1,1;0,0;0)$		$(0,0;1,1;1,1;0,0)$
$(0;1,1;0,0;1,1;0)$		$(0,0;1,1;0,0;1,1)$
$(0;0,0;1,1;1,1;0)$		$(0,0;0,0;1,1;1,1)$

These represent all solutions to the inverse Toeplitz eigenvalue problem with four ones and four zeros as target eigenvalues, but we are not yet able to identify which of these matrices could serve as the required vertex of a set of regular matrices. To do that, we need to assume the validity of Conjecture 2.

THEOREM 2. *If Conjecture* 2 *is true, then for points near the circulant hyperedge the eigenvector matrix is near* U, *and for points near the skew-circulant hyperedge the eigenvector matrix is near* V, *when the eigenvalues are arranged in decreasing order.*

Proof. Let $C = M_n(c_1, c_2, \ldots, c_n)$ be a point on the circulant hyperedge with double eigenvalues only, so that $d_1 > d_3 > d_5 > \cdots$ but $d_2 = d_3$, $d_4 = d_5$, etc. Select an even-odd pair of vectors as basis for the invariant subspace associated with each eigenvalue. The eigenvalue matrix M such that $M^{\mathsf{T}}CM = \operatorname{diag}(d_j)$ must then be some permutation U_P of U in which odd-even pairs of columns stay together, i.e.,

$$U_P = \begin{bmatrix} \mathbf{u}_{p_1} & \mathbf{u}_{p_2} & \mathbf{u}_{p_3} & \ldots & \mathbf{u}_{p_n} \end{bmatrix}$$

with $p_3 = p_2+1$, $p_5 = p_4+1$, etc. The odd-numbered columns of U_P are a permutation of the odd-numbered columns of U and are therefore even vectors. This observation remains true even when the eigenvalue gaps are arbitrarily small.

The matrix $H = M_n(0, 1, 0, 0, \ldots, 0)$ is easily seen to be a regular Toeplitz matrix: just take $f(\theta) = 2\cos\theta$ in (1). By Conjecture 2, the perturbed matrix

$$C_\delta = C + \delta H \text{ with } \delta > 0$$

should also be regular. For small values of δ, we can obtain excellent approximations to the eigenvalues of C_δ with the aid of Rayleigh quotients. Let λ be the eigenvalue of C having eigenvector $\mathbf{u}_k$. Then an approximation accurate to $\mathcal{O}(\delta^2)$ of the eigenvalue of C_δ whose eigenvector is close to $\mathbf{u}_k$ is

$$\begin{aligned} \mathbf{u}^{\mathsf{T}}(T + \delta H)\mathbf{u} &= \mathbf{u}^{\mathsf{T}}T\mathbf{u} + \delta\mathbf{u}^{\mathsf{T}}H\mathbf{u} \\ &= \lambda + 2\delta(u_{1,k}u_{2,k} + u_{2,k}u_{3,k} + \cdots + u_{n-1,k}u_{n,k}). \end{aligned}$$

We now look at the eigenvalues corresponding to odd-numbered columns of U_P. To an accuracy of $\mathcal{O}(\delta^2)$, these are

$$d_1 + 2\delta\mu_{p_1}, d_2 + 2\delta\mu_{p_3}, \ldots, d_k + 2\delta\mu_{p_{2k-1}},$$

where

$$\mu_k = u_{1,k}u_{2,k} + u_{2,k}u_{3,k} + \cdots + u_{n-1,k}u_{n,k}.$$

Since $d_k - d_{k+1}$ may be arbitrarily small, and the ordering of the eigenvalues needs to be preserved if the matrix is to remain regular, the columns of U_P need to be arranged so that the quantities $\mu_{p_1}, \mu_{p_3}, \mu_{p_5}, \ldots$ form a decreasing sequence. Straightforward if tedious trigonometric manipulation yields

$$\begin{aligned} \mu_1 &= \tfrac{n-1}{n}, \\ \mu_{2k+1} &= \tfrac{n-1}{n}\cos\tfrac{2k\pi}{n} - \tfrac{1}{n}, \quad k = 1, 2, \ldots, \lfloor \tfrac{n-1}{2} \rfloor. \end{aligned}$$

From the monotonicity of the cosine function over the interval $(0, \pi)$ it follows that $\mu_1 > \mu_3 > \mu_5 > \cdots$, which shows that the columns of U are already in the correct sequence.

A similar analysis showing that the columns of V are already in the correct sequence is left to the reader. ∎

With the sequence of eigenvalues determined, it is now a simple exercise to calculate the vertex matrices T_k.

THEOREM 3. *The vertex matrices T_k are given by*

$$T_k = \frac{1}{n} M_n \left(k, \frac{\sin k\theta}{\sin \theta}, \frac{\sin 2k\theta}{\sin 2\theta}, \ldots, \frac{\sin (n-1)k\theta}{\sin (n-1)\theta} \right), \tag{5}$$

where $\theta = \frac{\pi}{n}$.

Proof. The diagonal matrices D and B must start with k ones and end with $n-k$ zeros. When k is odd (resp., even), this pattern is compatible with the circulant (resp., skew-circulant) hyperedge. We obtain

$$T_m = \sum_{j=1}^{m} \mathbf{u}_j \mathbf{u}_j^{\mathsf{T}} \text{ when } m \text{ is odd;}$$
$$T_m = \sum_{j=1}^{m} \mathbf{v}_j \mathbf{v}_j^{\mathsf{T}} \text{ when } m \text{ is even.}$$

This gives

$$\begin{aligned} T_1 &= \tfrac{1}{n} M_n(1, 1, \ldots, 1), \\ T_{2k+1} &= T_{2k-1} + \tfrac{2}{n} M_n \left(\sin \frac{k\pi}{n} \sin \frac{(2j-1)k\pi}{n} + \cos \frac{k\pi}{n} \cos \frac{(2j-1)k\pi}{n},\ j = 1, 2, \ldots, n \right) \\ &= T_{2k-1} + \tfrac{2}{n} M_n \left(\cos \frac{2(j-1)k\pi}{n},\ j = 1, 2, \ldots, n \right). \end{aligned}$$

Similarly,

$$\begin{aligned} T_0 &= M_n(0, 0, \ldots, 0), \\ T_{2k} &= T_{2k-2} + \tfrac{2}{n} M_n \left(\cos \frac{(j-1)(2k-1)\pi}{n},\ j = 1, 2, \ldots, n \right). \end{aligned}$$

The recursions in both cases are seen to be special cases of

$$T_{k+1} = T_{k-1} + \tfrac{2}{n} M_n \left(\cos(j-1)k\theta,\ j = 1, 2, \ldots, n \right), \quad k = 1, 2, \ldots, n-2. \tag{6}$$

It is readily seen that the expression (5) satisfies this recursion. ∎

Remark. The entries of T_k are scaled values of Chebyshev polynomials of the second kind, and the recursion (6) is a well known relation ((22.5.8) in [1]) between Chebyshev polynomials.

The matrices U and V share a conspicuous property which is easy to verify: for all n, the kth columns of U and V show $k-1$ sign changes ($k = 1, 2, \ldots, n$). This leads us to the following.

CONJECTURE 3. *The sequence of elements of the eigenvector corresponding to the kth largest eigenvalue of a regular Toeplitz matrix shows $k-1$ sign changes, $k = 1, 2, \ldots, n$.*

Our final result exhibits a case where the initial values are not exact but show the correct qualitative behavior.

THEOREM 4. *If the sequence $\boldsymbol{\lambda}$ contains only three distinct eigenvalues $\alpha < \beta < \gamma$ of multiplicity m_α, m_β, and m_γ, respectively, then the matrix $\Gamma(\boldsymbol{\lambda})$ has the eigenvalue β with multiplicity m_β.*

Proof. Without loss of generality, assume $\boldsymbol{\lambda}$ is standardized so that $\alpha = 0$ and $\gamma = 1$. Let $\boldsymbol{\lambda}_1$ and $\boldsymbol{\lambda}_2$ be of the form $(0, 0, \ldots, 0, 1, 1, \ldots, 1)$ with m_α and $m_\alpha + m_\beta$ zeros, respectively. Then

$$\boldsymbol{\lambda} = \beta\boldsymbol{\lambda}_1 + (1-\beta)\boldsymbol{\lambda}_2.$$

Since $\boldsymbol{\lambda}_1$ and $\boldsymbol{\lambda}_2$ are vertices,

$$\Gamma(\boldsymbol{\lambda}) = \beta\Gamma(\boldsymbol{\lambda}_1) + (1-\beta)\Gamma(\boldsymbol{\lambda}_2).$$

Assume $\boldsymbol{\lambda}_1$ and $\boldsymbol{\lambda}_2$ belong to different hyperedges; otherwise the interpolation is exact and there is nothing to prove. Now consider

$$\Gamma(\boldsymbol{\lambda}) - \beta I = \beta(\Gamma(\boldsymbol{\lambda}_1) - I) + (1-\beta)\Gamma(\boldsymbol{\lambda}_2).$$

The interpolation is exact on hyperedges; therefore the matrices $\Gamma(\boldsymbol{\lambda}_1) - I$ and $\Gamma(\boldsymbol{\lambda}_2)$ have the eigenvalue 1 to the multiplicity m_α and m_γ, respectively. Since the two hyperedges are disjoint from each other and from the space of multiples of I, the rank of $\Gamma(\boldsymbol{\lambda}) - \beta I$ is $m_\alpha + m_\gamma$. This implies that the nullspace of $\Gamma(\boldsymbol{\lambda}) - \beta I$ has dimension m_β, which was to be proven. □

The theorem says nothing about the other two eigenvalues, and in fact in general they do not even stay multiple. It does imply, though, that the edge parametrized by $(0, \beta, \beta, \ldots, \beta, 1)$ corresponds to a straight line in the Landau standardization, even in the case of odd n when the interpolation is not exact.

5. Numerical examples. Following a suggestion of Higham [7], we tried finding extremely unfavorable examples by a method of direct search. The quantity to be maximized over standardized eigenvalue sequences $\boldsymbol{\lambda}$ was chosen as

$$f(\boldsymbol{\lambda}) = \|\boldsymbol{\lambda} - \Lambda(\Gamma(\boldsymbol{\lambda}))\|_1,$$

in other words, the sum of the absolute differences between the original sorted eigenvalues and those of the approximating Toeplitz matrix. The worst case was persistently found when there were two well-separated eigenvalues near 0.29 and 0.71, and all other eigenvalues very close to 0 and 1, with the two clusters of as equal size as possible. We model this behavior by

$$\lambda_k = \tfrac{1}{2}(1 + \tanh h(k - k_0)), \quad k = 1, 2, \ldots, n,$$

where $k_0 = \lfloor \frac{n}{2} \rfloor + \frac{1}{2}$ and $h = 2\tanh^{-1}(\sqrt{2} - 1)$. Eigenvalues distributed as above will be called "difficult" here. For example, for $n = 7$, the formula gives

$$\boldsymbol{\lambda} = (0.0120, 0.0664, 0.2929, 0.7071, 0.9336, 0.9880, 0.9979).$$

The eigenvalues of $\Gamma(\boldsymbol{\lambda})$ are

$$(0.0216, 0.1052, 0.3252, 0.6815, 0.8942, 0.9747, 0.9955).$$

From the point of view of iterative methods for the inverse Toeplitz eigenvalue problem, however, the interesting question is not so much how good the initial values are as how well they perform in an iterative setting. A typical relevant question is,

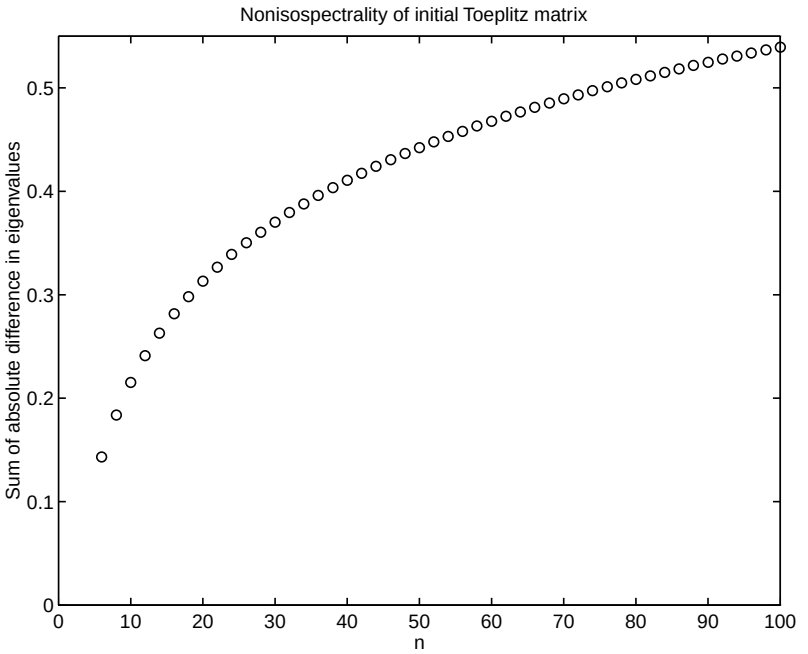

FIG. 3. *Sum of absolute deviation of eigenvalues of initial matrix* $\Gamma(\boldsymbol{\lambda})$ *for "difficult" target* $\boldsymbol{\lambda}$ *for even values of* n.

When Q are the eigenvectors of $\Gamma(\boldsymbol{\lambda})$ for "difficult" $\boldsymbol{\lambda}$, how close is $Q\,\mathrm{diag}(\lambda_k)Q^{\mathsf{T}}$ to a Toeplitz matrix? In the above case, we find

$$Q\,\mathrm{diag}(\lambda_k)Q^{\mathsf{T}} = \begin{bmatrix} 0.5743 & 0.3099 & -0.0613 & -0.0608 & 0.0358 & 0.0144 & -0.0278 \\ 0.3099 & 0.5677 & 0.2946 & -0.0563 & -0.0575 & 0.0351 & 0.0144 \\ -0.0613 & 0.2946 & 0.5711 & 0.2947 & -0.0556 & -0.0575 & 0.0358 \\ -0.0608 & -0.0563 & 0.2947 & 0.5718 & 0.2947 & -0.0563 & -0.0608 \\ 0.0358 & -0.0575 & -0.0556 & 0.2947 & 0.5711 & 0.2946 & -0.0613 \\ 0.0144 & 0.0351 & -0.0575 & -0.0563 & 0.2946 & 0.5677 & 0.3099 \\ -0.0278 & 0.0144 & 0.0358 & -0.0608 & -0.0613 & 0.3099 & 0.5743 \end{bmatrix}.$$

In Figures 3 and 4 we show $f(\boldsymbol{\lambda})$ and the deviation of $Q\,\mathrm{diag}(\lambda_k)Q^{\mathsf{T}}$ from Toeplitz form as a function of n.

One could also ask, When applied in practice in conjunction with some iterative method, how many iterations do the new starting values require in comparison to others that have been suggested? We applied Algorithm 1 from [10] with the difficult eigenvalues. The algorithm in question starts from an initial eigenvector matrix Q and proceeds as follows:

1. Calculate an approximate Toeplitz matrix T from the current Q, and form $A = Q^{\mathsf{T}}TQ$. This is obviously an $O(n^3)$ operation. The algorithm has two possible states: in the "normal" state the approximation is performed by Newton's method, and in the "emergency" state by projecting $Q\,\mathrm{diag}(\lambda_k)Q^{\mathsf{T}}$ to the closest Toeplitz matrix in the Frobenius norm.
2. Perform Jacobi rotations that successively annihilate the largest off-diagonal

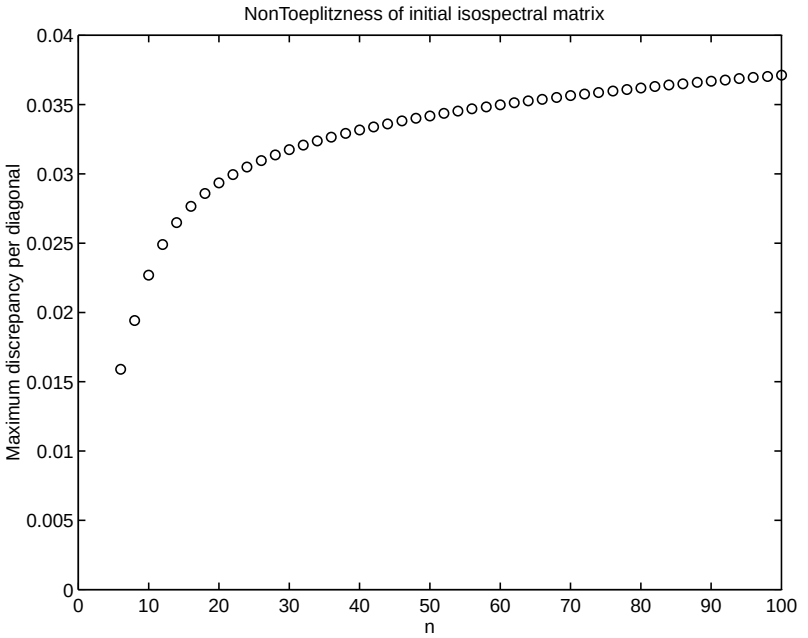

FIG. 4. *Largest difference between elements on the same diagonal in the initial isospectral matrix* $Q\,\mathrm{diag}(\lambda_k)Q^{\mathsf{T}}$ *with "difficult" eigenvalues* λ_k *for even values of* n.

elements of A, and apply the corresponding inverse rotations to Q. The process is not carried to completion (as Newton's method would require): instead, a rotation is made only as long as a certain criterion $\phi(Q)$ of closeness to the solution keeps on decreasing. Each rotation involves a search for the largest element and is followed by a rank 1 update of a certain $n \times n$ matrix, both of which are $O(n^2)$ operations.

3. If $\phi(Q)$ is small enough, exit with "success." If no rotations whatsoever were made in step 2, change to emergency state (if emergency state was already in effect, exit with "failure"); later the algorithm will revert to normal state when $\phi(Q)$ is small enough. Return to step 1.

In Table 1 we show the performance of the above algorithm from the initial values suggested here, compared to those in [9] and [12]. For small problems ($n \leq 10$) there is little difference between the three cases. For larger n, the use of the new initial values leads to fewer outer iterations and fewer rotations in total than the other two cases, and in no case leads to a situation where the emergency state of the algorithm is entered.

Also in a method based on isospectral flows, these initial values have been reported to be efficacious [13, pp. 115–117].

6. Conclusion. The motivation for much of the paper depends on the unproved Conjecture 2. It would be very interesting if this conjecture could be proved; in fact, the same can be said of progress on any of the conjectures cited or proposed in this paper. Nevertheless, as the numerical examples show, the initial values are practically useful when solving the inverse Toeplitz eigenvalue problem by iterative methods.

The present state of the art is that no constructive proof for the mere existence of a solution to the problem has been found yet: in particular, no iterative method

HIGH RESOLUTION SCHEMES FOR CONSERVATION LAWS WITH LOCALLY VARYING TIME STEPS*

CLINT DAWSON† AND ROBERT KIRBY†

Abstract. We develop upwind methods which use limited high resolution corrections in the spatial discretization and local time stepping for forward Euler and second order time discretizations. L^∞ stability is proven for both time stepping schemes for problems in one space dimension. These methods are restricted by a local CFL condition rather than the traditional global CFL condition, allowing local time refinement to be coupled with local spatial refinement. Numerical evidence demonstrates the stability and accuracy of the methods for problems in both one and two space dimensions.

Key words. spatially varying time steps, upwinding, conservation laws

1. Introduction.

Hyperbolic conservation laws model a wide range of physically interesting phenomena such as gas dynamics, shallow water flow, and advection of contaminants. Conservative high resolution methods with explicit time discretization have proven effective in capturing the sharp, moving fronts common in these applications. It is well known that such methods require the time step to satisfy a CFL condition in order to guarantee stability.

Local spatial refinement is often introduced in order to resolve these fronts more efficiently. However, this local refinement reduces the allowable time step for the explicit time discretizations typically employed. Rather than considering a fully implicit approach, in which the step size is often constrained by the nonlinear convergence anyway, we consider a method which allows the time step to vary spatially and satisfy a local CFL condition. In this way, we can increase the efficiency of the time stepping significantly in certain situations.

Another situation where local time stepping is useful is when modeling transport of some quantity by a highly varying velocity field. The advection of a species is described by an equation of the form

$$c_t + \nabla \cdot (\mathbf{u}c) = q, \tag{1}$$

where c is the concentration of the species, $\mathbf{u}$ is the velocity of the fluid transporting the species, and q represents source/sink terms. High resolution schemes have become popular for these problems, primarily because they are conservative and satisfy a maximum principle. The CFL constraint on the time step is determined by the ratio of the mesh spacing and the magnitude of the velocity. In certain cases, specifically in the presence of injection or production wells, the magnitude of $\mathbf{u}$ can vary substantially throughout the domain. In these situations, even if the mesh spacing is uniform, using a global CFL time step can be very restrictive, and local time stepping can result in substantial savings in computation time. It is important that the

local time stepping preserve the conservation and maximum principle properties of the underlying method. This situation was explored in some detail from a practical viewpoint in [3], and we will explore it from a more theoretical viewpoint here.

Local time stepping for one-dimensional scalar conservation laws was first proposed in Osher and Sanders [11]. They gave a thorough analysis of a first order spatial discretization with a local forward Euler time stepping scheme. This scheme allows each element to take either an entire time step or some fixed M smaller steps. In [3], the first author examined local time stepping for advection equations of the form (1), using high resolution schemes with slope limiters. Numerical results in two space dimensions were presented.

Another approach to local time stepping involves automatically taking smaller time steps where the mesh is refined. Berger and Oliger developed such an approach in [1], in which refined grids are laid over regions of the coarse mesh. These fine grids can have different orientation than the coarse one, and need not be nested. When the problem is integrated in time, small time steps are taken on the refined mesh and large time steps on the coarse mesh. Information is then passed between the grids by means of injection and interpolation. This approach allows higher order time integration, as the computation for each time step is done independently once the information is passed at the beginning of the time step.

In other work, Kallinderis and Baron [8] coupled the time refinement to the spatial refinement but used a single nonuniform mesh rather than multiple meshes. This work presented several methods (all first order) of handling the interface between regions with different time steps.

Flaherty et al. [5] have developed a parallel, adaptive discontinuous Galerkin method with a local forward Euler scheme which relies on interpolating values in time at interfaces between time steps of different sizes. This scheme, however, does not appear to conserve flux along these interfaces. Also, only first order in time methods are discussed.

In this paper, we seek to extend the work in [11] and [3] in two ways. First, we will show a maximum principle for a local forward Euler method when limited slopes are included. Second, we will show that the main ideas of local forward Euler discretizations may be extended to second order in time by way of the TVD Runge–Kutta methods of Gottlieb and Shu [6] and Shu [13]. A stability result for a constant coefficient case will be derived for this higher order method. We will also indicate how to extend this result to nonlinear problems. This analysis shows that we only need to satisfy a local CFL condition on each element.

The paper is outlined as follows. First, in section 2, we formulate a high resolution local forward Euler time discretization that employs some limited correction to the piecewise constant solution. In section 2.1, a maximum principle is derived for this approach. Then, a local time stepping procedure based on a second order time discretization is described in section 3, and a maximum principle for a simple case is given in section 3.1. Some extensions and implementation details are also discussed in this section. Finally, numerical results validating the theory are presented in section 4.

2. A high resolution method. We first consider the scalar conservation law

$$c_t + f(c)_x = 0, \tag{2}$$

together with the initial condition

$$c(x,0) = c_0(x). \tag{3}$$

We will partition the real line into intervals $I_j = \{x : x_{j-\frac{1}{2}} \le x < x_{j+\frac{1}{2}}\}$. We use the difference operator Δ_+ to denote a forward difference. That is, $\Delta_+ c_j \equiv c_{j+1} - c_j$ for some quantity c. A similar definition holds for Δ_- with $\Delta_- c_j \equiv c_j - c_{j-1}$. By integrating (2) over each I_j and using some consistent, Lipschitz numerical flux h at the cell edges, we obtain the semidiscrete scheme

$$\frac{dc_j}{dt} = -\frac{1}{\Delta x_j}\Delta_+ h(c_{j-1}, c_j), \tag{4}$$

where c_j is an approximation to the integral average of c over I_j. Examples of h include the Godunov flux and the Lax–Friedrichs flux. It is important that h is nondecreasing in the first variable and nonincreasing in the second variable. The initial condition is defined by simple projection. A standard forward Euler discretization can also be obtained in the obvious way.

In order to improve the accuracy of the above approach, we incorporate higher order "corrections" into the method. There are several ways of constructing these corrections. These include the piecewise linear reconstruction used in the monotone upwind scheme for conservation laws (MUSCL) of van Leer [14], the ENO reconstruction schemes of Harten and Osher [7], and the Runge–Kutta discontinuous Galerkin methods of Cockburn and Shu [2]. We shall not deal exclusively with any specific method but require certain properties of whichever is used. Since we are interested in second order accuracy, all of our examples assume linear approximations in space in each interval I_j.

After constructing the corrections and limiting them, we add them to the means to construct more accurate left and right states for the Riemann solutions. The corrections are denoted by tildes. Left states at an interface $x_{j+1/2}$ shall be denoted as $c_j + \tilde{c}_j \equiv c_{j+\frac{1}{2},L}$ and right states as $c_{j+1} - \tilde{\tilde{c}}_{j+1} \equiv c_{j+\frac{1}{2},R}$. In this way, the numerical flux at the edge is given by $h(c_{j+\frac{1}{2},L}, c_{j+\frac{1}{2},R})$.

Vital to the analysis is the assumption that the corrections introduce no new extrema into the solution. This allows corrections derived from the *minmod* slope limiter (described below) but rules out those derived from the modified *minmod* limiter of Shu [12] and the ENO schemes as introduced by Harten and Osher [7]. We can quantify this restriction as

$$-\theta \le \frac{\Delta_+ \tilde{\tilde{c}}_j}{\Delta_+ c_j} \le 1 \tag{5}$$

and

$$-\theta \le -\frac{\Delta_+ \tilde{c}_j}{\Delta_+ c_j} \le 1, \tag{6}$$

where $\theta \ge 0$.

The number θ is a chosen parameter which appears in the CFL condition. For example, see [2]. Geometrically, θ is related to the largest allowable ratio of differences between left and right states at consecutive edges relative to the means. This ratio can be allowed to be larger than 1, and we will see that such a situation will necessitate a restriction of the time step in order to guarantee a maximum principle. Consider the cells j and $j+1$ in Figure 1. The value $c_{j+\frac{1}{2},L} - c_{j-\frac{1}{2},L} \ge c_{j+1} - c_j$; however, the differences have the same sign. Thus

$$0 \le \frac{c_{j+\frac{1}{2},L} - c_{j-\frac{1}{2},L}}{c_{j+1} - c_j} = 1 + \frac{\Delta_+ \tilde{c}_j}{\Delta_+ c_j}, \tag{7}$$

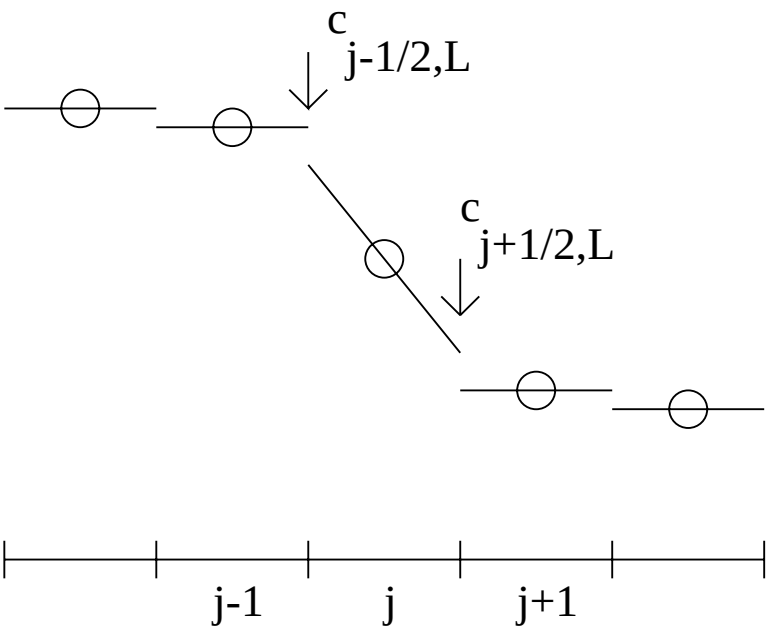

FIG. 1. *Slopes increase ratio of left states to means.*

and if θ satisfies (6), then

$$0 \le \frac{c_{j+\frac{1}{2},L} - c_{j-\frac{1}{2},L}}{c_{j+1} - c_j} \le 1 + \theta. \tag{8}$$

Specifically, suppose that we compute a slope, δc_j, using the *minmod* limiter. Thus,

$$\delta c_j = \begin{cases} \min\left(\frac{|\Delta_+ c_j|}{\Delta_+ x_j}, \frac{|\Delta_- c_j|}{\Delta_- x_j}\right) * \operatorname{sgn}(\Delta_+ c_j) & \text{if } \operatorname{sgn}(\Delta_+ c_j) = \operatorname{sgn}(\Delta_- c_j), \\ 0 & \text{otherwise.} \end{cases} \tag{9}$$

Set $\tilde{c}_j^u = \frac{\Delta x_j}{2} \delta c_j$. Then set

$$\tilde{c}_j = \begin{cases} \tilde{c}_j^u & \text{if } |\tilde{c}_j^u| \le |\Delta_\pm c_j|, \\ 0 & \text{otherwise.} \end{cases} \tag{10}$$

This last limiting step is necessary only in the case of nonuniform mesh. Finally, $\tilde{\tilde{c}}_j = \tilde{c}_j$. The corrections then have the property that

$$\operatorname{sgn}\left(\frac{\tilde{c}_j}{\Delta_\pm c_j}\right) \ge 0. \tag{11}$$

We can thus make the bound

$$1 + \frac{\Delta_+ \tilde{c}_j}{\Delta_+ c_j} \le 1 + \frac{\tilde{c}_{j+1}}{\Delta_+ c_j} \le 2. \tag{12}$$

We also have

$$1 + \frac{\Delta_+ \tilde{c}_j}{\Delta_+ c_j} \ge 1 - \frac{\tilde{c}_j}{\Delta_+ c_j} \ge 0 \tag{13}$$

and

$$1 - \frac{\Delta_+ \tilde{\tilde{c}}_j}{\Delta_+ c_j} \geq 1 - \frac{\tilde{c}_{j+1}}{\Delta_+ c_j} \geq 0. \tag{14}$$

Hence, (5) and (6) hold automatically with the choice $\theta = 1$.

More generally, suppose corrections $\tilde{c}_j^u$ and $\tilde{\tilde{c}}_j^u$ are computed by some means, and θ is chosen such that $0 \leq \theta \leq 1$. Define

$$\tilde{c}_j = \begin{cases} \tilde{c}_j^u & \text{if } 2|\tilde{c}_j^u| \leq \theta |\Delta_\pm c_j|, \\ 0 & \text{otherwise,} \end{cases} \tag{15}$$

with an analogous definition for $\tilde{\tilde{c}}_j$. Then

$$1 + \frac{\Delta_+ \tilde{c}_j}{\Delta_+ c_j} \geq 1 - \frac{|\tilde{c}_{j+1}|}{|\Delta_+ c_j|} - \frac{|\tilde{c}_j|}{|\Delta_+ c_j|} \geq 1 - \theta \geq 0 \tag{16}$$

and

$$1 + \frac{\Delta_+ \tilde{c}_j}{\Delta_+ c_j} \leq 1 + \theta. \tag{17}$$

We now present the first order local time discretization. It is a straightforward extension of the method in [11]. The only difference is that the flux terms are computed using the corrected quantities $c_{j+1/2,L}$, $c_{j+1/2,R}$ rather than piecewise constants. We allow each element to take either a whole time step or some fixed M substeps per main time step.

We begin by noting that the intervals I_j form a partition of the real line. In addition to the spatial partition, we also introduce the temporal partition of $[0, T)$ into time intervals $[t^n, t^{n+1}), n = 0, \ldots, N-1$, with $t^0 = 0$ and $t^N = T$. We denote $\Delta t^n \equiv t^{n+1} - t^n$ and define $\lambda_j^n \equiv \frac{\Delta t^n}{\Delta x_j}$. In order to describe the local time stepping scheme, we will need to further partition the time steps on certain elements. We denote by $\mathcal{C}^n$ the set of all indices j such that a single time step is taken from t^n to t^{n+1} on I_j. On the rest of the elements, we partition the time step $[t^n, t^{n+1})$ into the union of substeps $[t^{n+\eta_l}, t^{n+\eta_{l+1}})$, $l = 0, \ldots, M-1$. Further, $\{\sigma_k\}_{k=1}^M$ is a sequence of positive numbers summing to unity. The numbers η_l are given as the cumulative sum of the σ_k, that is, $\eta_l = \sum_{k=1}^l \sigma_k$, and $\eta_0 = 0$. Correspondingly, the substeps in the time interval are given by $t^{n+\eta_{l+1}} = t^{n+\eta_l} + \sigma_{l+1} \Delta t^n$. Notice that the elements on which the local steps are taken may change over time.

With this notation established, we can modify the predictor-corrector scheme of Osher and Sanders to a so-called high resolution scheme in space.

Following [11], for each $k = 1, \ldots, M-1$, the "predictor" is defined by

$$c_j^{n+\eta_k} = \begin{cases} c_j^n, & j \in \mathcal{C}^n, \\ c_j^n - \lambda_j^n \sum_{l=0}^{k-1} \sigma_{l+1} \Delta_+ h(c_{j-1/2,L}^{n+\eta_l}, c_{j-1/2,R}^{n+\eta_l}), & j \notin \mathcal{C}^n, \end{cases} \tag{18}$$

and the "corrector" is

$$c_j^{n+1} = c_j^n - \lambda_j^n \sum_{l=0}^{M-1} \sigma_{l+1} \Delta_+ h(c_{j-\frac{1}{2},L}^{n+\eta_l}, c_{j-\frac{1}{2},R}^{n+\eta_l}). \tag{19}$$

Notice that if $j-1, j, j+1 \in \mathcal{C}^n$, then the method on I_j reduces to forward Euler with a step size of Δt^n.

2.1. A maximum principle. In this section, we present a maximum principle for the method (18)–(19). The maximum principle will verify that L^∞ stability is attainable with only local assumptions regarding the mesh, time step, velocity, and corrections. It is vital to this analysis that we use a "strict" limiter (i.e., one that does not introduce new extrema).

We introduce some notation for the scheme as follows. We define terms involving the differences of the corrections relative to the means:

$$\kappa_{j,1} \equiv 1 - \frac{\Delta_- \tilde{\tilde{c}}_j}{\Delta_- c_j} \tag{20}$$

and

$$\kappa_{j,2} \equiv 1 + \frac{\Delta_- \tilde{c}_j}{\Delta_- c_j}, \tag{21}$$

where we may have a superscript of n,$n+\eta_l$, etc. Note that (5) and (6) give us the bounds $0 \le \kappa_{j,1}, \kappa_{j,2} \le 1+\theta$. We also define the coefficients $\gamma_{j,1}$ and $\gamma_{j,2}$ as the local Lipschitz coefficients of h. That is,

$$\gamma_{j,1}^{n+\eta_l} \equiv -\Lambda_j^{n+\eta_l} \left[\frac{h\left(c_{j+\frac{1}{2},L}^{n+\eta_l}, c_{j+\frac{1}{2},R}^{n+\eta_l}\right) - h\left(c_{j+\frac{1}{2},L}^{n+\eta_l}, c_{j-\frac{1}{2},R}^{n+\eta_l}\right)}{c_{j+\frac{1}{2},R}^{n+\eta_l} - c_{j-\frac{1}{2},R}^{n+\eta_l}} \right] \tag{22}$$

and

$$\gamma_{j,2}^{n+\eta_l} \equiv -\Lambda_j^{n+\eta_l} \left[\frac{h\left(c_{j+\frac{1}{2},L}^{n+\eta_l}, c_{j-\frac{1}{2},R}^{n+\eta_l}\right) - h\left(c_{j-\frac{1}{2},L}^{n+\eta_l}, c_{j-\frac{1}{2},R}^{n+\eta_l}\right)}{c_{j+\frac{1}{2},L}^{n+\eta_l} - c_{j-\frac{1}{2},L}^{n+\eta_l}} \right], \tag{23}$$

where

$$\Lambda_j^{n+\eta_l} = \begin{cases} \lambda_j^n & \text{if } j-1, j \text{ or } j+1 \in \mathcal{C}^n, \\ \sigma_{l+1}\lambda_j^n & \text{otherwise.} \end{cases} \tag{24}$$

If the flux f is smooth enough, then we can, as in [11], reduce the Lipschitz constants to a local supremum of $f'(c)$. Further, we define the terms

$$\alpha_{j,1} \equiv \gamma_{j,1}\kappa_{j,1} \tag{25}$$

and

$$\alpha_{j,2} \equiv \gamma_{j,2}\kappa_{j,2}. \tag{26}$$

By our assumptions (5) and (6) and the assumed monotonicity properties of h (h nondecreasing in its first argument, nonincreasing in its second), we have $\alpha_{j,1} \ge 0$, $\alpha_{j,2} \le 0$, and thus

$$\alpha_{j,1} - \alpha_{j,2} \ge 0. \tag{27}$$

For each j at each time $t^{n+\eta_l}$, we require the local CFL condition

$$1 - \alpha_{j,1}^{n+\eta_l} + \alpha_{j,2}^{n+\eta_l} \ge 0. \tag{28}$$

Here, we pause to discuss the relation between the terms (5)–(6) and the CFL condition (28). We require that

$$\alpha_{j,1}^{n+\eta_l} - \alpha_{j,2}^{n+\eta_l} \leq 1, \tag{29}$$

or

$$\gamma_{j,1}^{n+\eta_l} \kappa_{j,1}^{n+\eta_l} - \gamma_{j,2}^{n+\eta_l} \kappa_{j,2}^{n+\eta_l} \leq 1. \tag{30}$$

If the corrections are all zero, then each κ term is simply 1. However, as in Figure 1, our κ terms are only bounded by $1+\theta$. Consequently, in order to satisfy (28), we must possibly take a smaller time step than we would if we were not using the corrections. Equivalently, we could write our CFL condition as do Cockburn and Shu [2]:

$$\gamma_{j,1}^{n+\eta_l} - \gamma_{j,2}^{n+\eta_l} \leq \frac{1}{1+\theta}. \tag{31}$$

The L^∞ stability result of [11] depends upon showing that the operator which advances the solution forward is monotone. However, with the addition of the correction terms, the operator ceases to be monotone, and we must take a different approach. We begin by examining the basic global time stepping method (or $j \in \mathcal{C}^n \ \forall \ j$). The method is

$$c_j^{n+1} = c_j^n - \lambda_j^n \left[h\left(c_{j+\frac{1}{2},L}^n, c_{j+\frac{1}{2},R}^n \right) - h\left(c_{j-\frac{1}{2},L}^n, c_{j-\frac{1}{2},R}^n \right) \right]. \tag{32}$$

We can obtain L^∞ stability as follows. Add and subtract $h(c_{j+\frac{1}{2},L}^n, c_{j-\frac{1}{2},R}^n)$ in (32) and multiply and divide by the proper differences, and we have

$$c_j^{n+1} = c_j^n + \alpha_{j,1}^n \left(c_{j+1}^n - c_j^n \right) + \alpha_{j,2}^n \left(c_j^n - c_{j-1}^n \right), \tag{33}$$

or

$$c_j^{n+1} = \left(1 - \alpha_{j,1}^n + \alpha_{j,2}^n \right) c_j^n + \alpha_{j,1}^n c_{j+1}^n - \alpha_{j,2}^n c_{j-1}^n. \tag{34}$$

Then, by (27) and (28), we see that

$$\begin{aligned} |c_j^{n+1}| &\leq \left(1 - \alpha_{j,1}^n + \alpha_{j,2}^n \right) |c_j^n| + \alpha_{j,1}^n |c_{j+1}^n| - \alpha_{j,2}^n |c_{j-1}^n| \\ &\leq \sup_j |c_j^n|. \end{aligned} \tag{35}$$

By making similar arguments in the context of the local time stepping method, we have the following stability result.

PROPOSITION 2.1. *Assume* (5), (6), *and* (28) *hold, and the numerical flux* $h(u,v)$ *is nondecreasing in* u *and nonincreasing in* v*; then for* $n > 0$,

$$\sup_j |c_j^n| \leq \sup_j |c_j^0|,$$

where c_j^n *is defined by* (18)–(19).

Proof. The proof follows from looking separately at the cases in which $j \in \mathcal{C}^n$ and $j \notin \mathcal{C}^n$.

We begin with the case of $j \notin \mathcal{C}^n$. In this case, we may use the same technique as in the global time stepping case recursively to bound the solution at time $n+1$ in terms of the solution at time n.

$$
\begin{aligned}
|c_j^{n+\eta_l}| &= \left| c_j^{n+\eta_{l-1}} - \sigma_{l+1}\lambda_j^n \Delta_+ h\left(c_{j-\frac{1}{2},L}^{n+\eta_{l-1}}, c_{j-\frac{1}{2},R}^{n+\eta_{l-1}}\right)\right| \\
&= \left| c_j^{n+\eta_{l-1}} + \alpha_{j,1}^{n+\eta_{l-1}}\left(c_{j+1}^{n+\eta_{l-1}} - c_j^{n+\eta_{l-1}}\right)\right. \\
&\quad \left. + \alpha_{j,2}^{n+\eta_{l-1}}\left(c_j^{n+\eta_{l-1}} - c_{j-1}^{n+\eta_{l-1}}\right)\right| \\
&= |c_j^{n+\eta_{l-1}}|\left(1 - \alpha_{j,1}^{n+\eta_{l-1}} + \alpha_{j,2}^{n+\eta_{l-1}}\right) \\
&\quad + \alpha_{j,1}^{n+\eta_{l-1}}|c_{j+1}^{n+\eta_{l-1}}| - \alpha_{j,2}^{n+\eta_{l-1}}|c_{j-1}^{n+\eta_{l-1}}| \\
&\leq \max_{j-1\leq k\leq j+1} |c_k^{n+\eta_{l-1}}|.
\end{aligned} \tag{36}
$$

The α terms satisfy the same sign conditions as their global time stepping counterparts, so

$$
|c_j^{n+\eta_l}| \leq \max_{j-1\leq k\leq j+1} |c_k^{n+\eta_{l-1}}|. \tag{37}
$$

If $j^* \in [j-1, j+1]$ is the element on which the maximum occurs, and if $j^* \in \mathcal{C}^n$, then we are done for this element, as we have the solution bounded in terms of values at time n. If $j^* \notin \mathcal{C}^n$, then we apply this argument recursively.

Now, suppose that $j \in \mathcal{C}^n$. Using (18) in (19),

$$
\begin{aligned}
c_j^{n+1} &= c_j^n - \lambda_j^n \sum_{l=0}^{M-1} \sigma_{l+1}\Delta_+ h\left(c_{j-\frac{1}{2},L}^{n+\eta_l}, c_{j-\frac{1}{2},R}^{n+\eta_l}\right) \\
&= \sum_{l=0}^{M-1} \sigma_{l+1}\left(c_j^{n+\eta_{l-1}} - \lambda_j^n \Delta_+ h\left(c_{j-\frac{1}{2},L}^{n+\eta_l}, c_{j-\frac{1}{2},R}^{n+\eta_l}\right)\right) \\
&= \sum_{l=0}^{M-1} \sigma_{l+1}\left[c_j^{n+\eta_{l-1}} + \alpha_{j,1}^{n+\eta_{l-1}}\left(c_{j+1}^{n+\eta_{l-1}} - c_j^{n+\eta_{l-1}}\right)\right. \\
&\quad \left. + \alpha_{j,2}^{n+\eta_{l-1}}\left(c_j^{n+\eta_{l-1}} - c_{j-1}^{n+\eta_{l-1}}\right)\right] \\
&= \sum_{l=0}^{M-1} \sigma_{l+1}\left[c_j^{n+\eta_{l-1}}\left(1 - \alpha_{j,1}^{n+\eta_{l-1}} + \alpha_{j,2}^{n+\eta_{l-1}}\right)\right. \\
&\quad \left. + \alpha_{j,1}^{n+\eta_{l-1}} c_{j+1}^{n+\eta_{l-1}} - \alpha_{j,2}^{n+\eta_{l-1}} c_{j-1}^{n+\eta_{l-1}}\right].
\end{aligned} \tag{38}
$$

Again, using the monotonicity of h and (28), we have the sign conditions for the α terms, and

$$
\begin{aligned}
|c_j^{n+1}| &\leq \sum_{l=0}^{M-1} \sigma_{l+1}\left[|c_j^{n+\eta_{l-1}}|\left(1 - \alpha_{j,1}^{n+\eta_{l-1}} + \alpha_{j,2}^{n+\eta_{l-1}}\right)\right. \\
&\quad \left. + \alpha_{j,1}^{n+\eta_{l-1}}|c_{j+1}^{n+\eta_{l-1}}| - \alpha_{j,2}^{n+\eta_{l-1}}|c_{j-1}^{n+\eta_{l-1}}|\right] \\
&\leq \sum_{l=0}^{M-1} \sigma_{l+1} \max_{j-1\leq k\leq j+1} |c_k^{n+\eta_{l-1}}|.
\end{aligned} \tag{39}
$$

Now, each term $|c_k^{n+\eta_{l-1}}|$ may be bounded by prior information. If $k \in \mathcal{C}^n$, then $c_k^{n+\eta_{l-1}} = c_k^n$ and the bound is obvious. Otherwise, the above bound for $j \notin \mathcal{C}^n$ applies, and we are done. □

Note that while c_j^n remains constant in time on I_j, we might have to modify the correction terms on I_j at intermediate times if $j \in \mathcal{C}^n$ and $j-1 \notin \mathcal{C}^n$ or $j+1 \notin \mathcal{C}^n$ to avoid adding extrema to the solution.

Note also that for general problems, the CFL condition (28) for substeps after the first when $j \notin \mathcal{C}^n$ cannot be verified a priori without adjusting the time step at each substep. However, examining (25) and (26), we have uniform bounds on the κ terms by doing appropriate limiting. Moreover, with some knowledge of f, we can bound the γ terms locally depending on $f'(c)$ and the local mesh spacing. Thus we can estimate an upper bound on the α terms over regions of the domain, which can be used to set the local time steps over these regions. We have used this approach successfully in practice.

3. A second order time stepping scheme. We now turn to developing a local time stepping procedure based on a formally second order method. We are again interested in integrating the semidiscrete scheme

$$\frac{dc_j}{dt} = -\frac{1}{\Delta x_j}\Delta_+ h(c_{j-1/2,L}, c_{j-1/2,R}). \tag{40}$$

We first describe the basic method we are using, which is a second order Runge–Kutta scheme (in particular, Heun's method), shown to be TVD in [13, 6]. Then, we formulate the scheme for handling the interface between two regions with different time steps. We will assume the basic method holds for some distance away from the interfaces.

Heun's method for integrating (40) is given by

$$\overline{c}_j^{n+1} = c_j^n - \lambda_j^n \Delta_+ h(c_{j-1/2,L}^n, c_{j-1/2,R}^n), \tag{41}$$

$$w_j^{n+1} = \overline{c}_j^{n+1} - \lambda_j^n \Delta_+ h(\overline{c}_{j-1/2,L}^{n+1}, \overline{c}_{j-1/2,R}^{n+1}), \tag{42}$$

$$c_j^{n+1} = \frac{1}{2}\left(c_j^n + w_j^{n+1}\right). \tag{43}$$

Here $\overline{c}_{j+1/2,L}^{n+1} = \overline{c}_j^{n+1} + \tilde{\overline{c}}_j^{n+1}$, with an analogous definition for $\overline{c}_{j+1/2,R}^{n+1}$, where the corrections are computed as in (5)–(6). This method is nothing more than a convex combination of forward Euler steps and the initial value. Correspondingly, using the properties of the forward Euler method analyzed in the previous section, one easily obtains stability for this scheme.

PROPOSITION 3.1. *For the scheme* (41)–(43), *with corrections limited as in* (5)–(6) *and a CFL time-step constraint as in* (28), *we have*

$$\sup_j |c_j^n| \le \sup_j |c_j^0|.$$

For now, we are interested in computing at the interface on the space-time mesh shown in Figure 2. Thus, the time step in interval I_{j+1} is Δt and in I_j, $\Delta t/2$. For

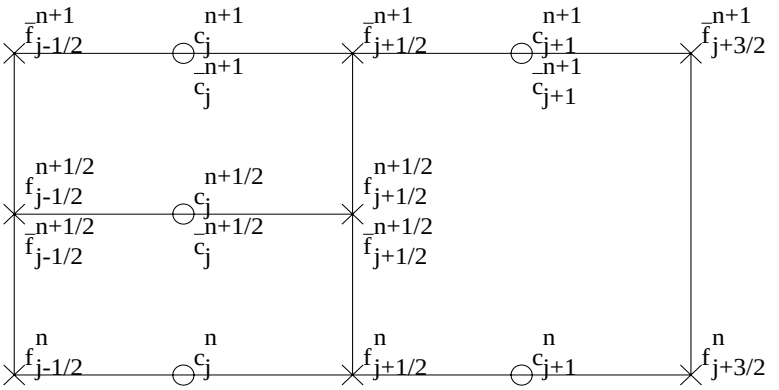

FIG. 2. *Local time stepping mesh.*

simplicity, we assume the time step is Δt for intervals to the right of $x_{j+1/2}$ and $\Delta t/2$ for intervals to the left of $x_{j+1/2}$. We will also assume for simplicity that $f(c) = uc$, where $u > 0$. We will describe the method and state conditions which the corrections $\tilde{c}$ should satisfy to ensure a maximum principle. We will then describe in more detail how the corrections may be constructed so as to satisfy these conditions. Finally, we will describe the method when the situation in Figure 2 holds and $u < 0$, and then discuss generalizations to a nonlinear flux function and to the case with M steps.

Thus, assuming $f(c) = uc$, where $u > 0$, to compute the solution in elements I_j and I_{j+1}, we use the following procedure.

Scheme I ($u > 0$).

(i) Compute corrections $\tilde{c}_{j-1}^n$, $\tilde{c}_j^n$, and $\tilde{c}_{j+1}^{n,1}$ by some means and limit them so that (44) is satisfied.

(ii) $\bar{c}_j^{n+\frac{1}{2}} = c_j^n - \frac{u\lambda_j^n}{2}\left[c_j^n + \tilde{c}_j^n - \left(c_{j-1}^n + \tilde{c}_{j-1}^n\right)\right]$.

(iii) Compute $\tilde{\bar{c}}_{j-1}^{n+1/2}$, $\tilde{\bar{c}}_j^{n+1/2}$, and $\tilde{c}_{j+1}^{n,2}$ so that (45) is satisfied.

(iv) $w_j^{n+\frac{1}{2}} = \bar{c}_j^{n+\frac{1}{2}} - \frac{u\lambda_j^n}{2}[\bar{c}_j^{n+\frac{1}{2}} + \tilde{\bar{c}}_j^{n+\frac{1}{2}} - (\bar{c}_{j-1}^{n+\frac{1}{2}} + \tilde{\bar{c}}_{j-1}^{n+\frac{1}{2}})]$.

(v) $c_j^{n+\frac{1}{2}} = \frac{1}{2}(c_j^n + w_j^{n+\frac{1}{2}})$.

(vi) Define $\tilde{c}_{j+1}^n \equiv \frac{1}{2}(\tilde{c}_{j+1}^{n,1} + \tilde{c}_{j+1}^{n,2})$.

(vii) $\bar{c}_{j+1}^{n+1} = c_{j+1}^{n+1/2} - u\lambda_{j+1}^n[c_{j+1}^n + \tilde{c}_{j+1}^n - \frac{1}{2}(c_j^n + \tilde{c}_j^n + \bar{c}_j^{n+\frac{1}{2}} + \tilde{\bar{c}}_j^{n+\frac{1}{2}})]$.

(viii) Compute $\tilde{c}_{j-1}^{n+\frac{1}{2}}$, $\tilde{c}_j^{n+\frac{1}{2}}$, and $\tilde{\bar{c}}_{j+1}^{n+1,1}$ so that (46) is satisfied.

(iv) $\bar{c}_j^{n+1} = c_j^n - \frac{u\lambda_j^n}{2}[c_j^{n+\frac{1}{2}} + \tilde{c}_j^{n+\frac{1}{2}} - (c_{j-1}^{n+\frac{1}{2}} + \tilde{c}_{j-1}^{n+\frac{1}{2}})]$.

(x) Compute $\tilde{\bar{c}}_{j-1}^{n+1}$, $\tilde{\bar{c}}_j^{n+1}$, and $\tilde{\bar{c}}_{j+1}^{n+1,2}$ so that (47) is satisfied.

(xi) $w_j^{n+1} = \bar{c}_j^{n+1} - \frac{u\lambda_j^n}{2}[\bar{c}_j^{n+1} + \tilde{\bar{c}}_j^{n+1} - (\bar{c}_{j-1}^{n+1} + \tilde{\bar{c}}_{j-1}^{n+1})]$.

(xii) $c_j^{n+1} = \frac{1}{2}(c_j^{n+\frac{1}{2}} + w_j^{n+1})$.

(xiii) Define $\tilde{\bar{c}}_{j+1}^{n+1} \equiv \frac{1}{2}(\tilde{\bar{c}}_{j+1}^{n,1} + \tilde{\bar{c}}_{j+1}^{n,2})$.

(xiv) $w_{j+1}^{n+1} = \bar{c}_{j+1}^n - u\lambda_{j+1}^n[\bar{c}_{j+1}^n + \tilde{\bar{c}}_{j+1}^n - \frac{1}{2}(c_j^{n+\frac{1}{2}} + \tilde{c}_j^{n+\frac{1}{2}} + \bar{c}_j^{n+1} + \tilde{\bar{c}}_j^{n+1})]$.

(xv) $c_{j+1}^{n+1} = \frac{1}{2}\left(c_{j+1}^n + w_{j+1}^{n+1}\right)$.

The corrections should satisfy the following conditions to guarantee a maximum principle:

$$-\theta \le -\frac{\tilde{c}_j^n - \tilde{c}_{j-1}^n}{c_j^n - c_{j-1}^n},\ -\frac{\tilde{c}_{j+1}^{n,1} - \tilde{c}_j^n}{c_{j+1}^n - c_j^n} \le 1, \tag{44}$$

$$-\theta \le -\frac{\tilde{\bar{c}}_j^{n+\frac{1}{2}} - \tilde{\bar{c}}_{j-1}^{n+\frac{1}{2}}}{\bar{c}_j^{n+\frac{1}{2}} - \bar{c}_{j-1}^{n+\frac{1}{2}}},\ -\frac{\tilde{c}_{j+1}^{n,2} - \tilde{\bar{c}}_j^{n+\frac{1}{2}}}{c_{j+1}^n - \bar{c}_j^{n+\frac{1}{2}}} \le 1, \tag{45}$$

$$-\theta \le -\frac{\tilde{c}_j^{n+\frac{1}{2}} - \tilde{c}_{j-1}^{n+\frac{1}{2}}}{c_j^{n+\frac{1}{2}} - c_{j-1}^{n+\frac{1}{2}}},\ -\frac{\tilde{\bar{c}}_{j+1}^{n+1,1} - \tilde{\bar{c}}_j^{n+\frac{1}{2}}}{\bar{c}_{j+1}^{n+1} - c_j^{n+1/2}} \le 1, \tag{46}$$

$$-\theta \le -\frac{\tilde{\bar{c}}_j^{n+1} - \tilde{\bar{c}}_{j-1}^{n+1}}{\bar{c}_j^{n+1} - \bar{c}_{j-1}^{n+1}},\ -\frac{\tilde{\bar{c}}_{j+1}^{n+1,2} - \tilde{\bar{c}}_j^{n+1}}{\bar{c}_{j+1}^{n+1} - \bar{c}_j^{n+1}} \le 1. \tag{47}$$

3.1. A maximum principle for the second order method. In this section, we derive a maximum principle for Scheme I above. The maximum principle argument allows for the method to have a time step on one cell that would violate the CFL condition on the adjacent cell. In particular, we assume

$$\frac{u\Delta t^n}{2\Delta x_j} \le \frac{1}{1+\theta} \tag{48}$$

and

$$\frac{u\Delta t^n}{\Delta x_{j+1}} \le \frac{1}{1+\theta}, \tag{49}$$

which is the usual CFL condition for grid blocks I_j and I_{j+1}.

Away from the interface, where the time step among adjacent cells is the same, the stability of the method is easily demonstrated. We summarize the result in the following proposition.

PROPOSITION 3.2. *Assume a time step of size Δt^n for all elements to the right of $x_{j+1/2}$ and size $\Delta t^n/2$ for all elements to the left of $x_{j+1/2}$, where Δt^n satisfies* (48) *and* (49). *Then, for Scheme* I *above with $f(c) = uc$ where $u > 0$, with corrections satisfying* (44)–(47) *on I_j and I_{j+1} and* (5)–(6) *elsewhere, we have*

$$\sup_j |c_j^n| \le \sup_j |c_j^0|. \tag{50}$$

Proof. For all blocks except I_j and I_{j+1}, the bound $|c_i^{n+1}| \le \sup_j |c_j^n|$ follows from the arguments used to prove Propositions 2.1 and 3.1. Furthermore, the only difference between the computation on I_j and the standard method is that there are somewhat different restrictions on the corrections, namely, they should satisfy (44)–(47). Thus, one can easily show that $|\bar{c}_j^{n+\frac{1}{2}}|$, $|w_j^{n+\frac{1}{2}}|$, $|c_j^{n+\frac{1}{2}}|$, $|\bar{c}_j^{n+1}|$, $|w_j^{n+1}|$ and hence $|c_j^{n+1}|$ are all bounded above by $\sup_j |c_j^n|$.

The solution on I_{j+1} must be more carefully analyzed. We will first show a maximum principle for $|\overline{c}_{j+1}^{n+1}|$. Then, this will be used to show maximum principles for $|w_{j+1}^{n+1}|$ and $|c_{j+1}^{n+1}|$.

Consider $\overline{c}_{j+1}^{n+1}$. The argument will proceed by the standard technique of choosing the CFL condition and using the restrictions on the corrections to guarantee that $\overline{c}_{j+1}^{n+1}$ is a convex combination of previous values. We define

$$\kappa_1 = 1 + \frac{\tilde{c}_{j+1}^{n,1} - \tilde{c}_j^n}{c_{j+1}^n - c_j^n} \tag{51}$$

and

$$\kappa_2 = 1 + \frac{\tilde{c}_{j+1}^{n,2} - \tilde{\overline{c}}_j^{n+\frac{1}{2}}}{c_{j+1}^n - \overline{c}_j^{n+\frac{1}{2}}}. \tag{52}$$

We can write the computation of $\overline{c}_{j+1}^n$ as

(53)

$$\begin{aligned}
\overline{c}_{j+1}^{n+1} &= c_{j+1}^n - \frac{u\Delta t^n}{\Delta x_{j+1}} \left[\left(c_{j+1}^n + \tilde{c}_{j+1}^n \right) - \frac{1}{2} \left(\left(c_j^n + \tilde{c}_j^n \right) - \left(\overline{c}_j^{n+\frac{1}{2}} + \tilde{\overline{c}}_j^{n+\frac{1}{2}} \right) \right) \right] \\
&= c_{j+1}^n - \frac{u\Delta t^n}{2\Delta x_{j+1}} \left[c_{j+1}^n + \tilde{c}_{j+1}^{n,1} - \left(c_j^n + \tilde{c}_j^n \right) + c_{j+1}^n + \tilde{c}_{j+1}^{n,2} - \left(\overline{c}_j^{n+\frac{1}{2}} + \tilde{\overline{c}}_j^{n+\frac{1}{2}} \right) \right] \\
&= c_{j+1}^n - \frac{u\Delta t^n}{2\Delta x_{j+1}} \left[\kappa_1 \left(c_{j+1}^n - c_j^n \right) + \kappa_2 \left(c_{j+1}^n - \overline{c}_j^{n+\frac{1}{2}} \right) \right] \\
&= c_{j+1}^n \left[1 - \frac{u\Delta t^n}{2\Delta x_{j+1}} \left(\kappa_1 + \kappa_2 \right) \right] + \frac{u\Delta t^n}{2\Delta x_{j+1}} \kappa_1 c_j^n + \frac{u\Delta t^n}{2\Delta x_{j+1}} \kappa_2 \overline{c}_j^{n+\frac{1}{2}}.
\end{aligned}$$

We note that the coefficients of the terms sum to 1. By (44) and (45), $\kappa_i \geq 0$, $i = 1, 2$, and

$$1 - \frac{u\Delta t^n}{2\Delta x_{j+1}} \left(\kappa_1 + \kappa_2 \right) \geq 0 \tag{54}$$

if the time step is chosen such that (49) is satisfied.

By the above-stated bound on $|\overline{c}_j^{n+\frac{1}{2}}|$, we can take the absolute value of each side of (53) and obtain

$$\begin{aligned}
|\overline{c}_{j+1}^{n+1}| &= |c_{j+1}^n| \left[1 - \frac{u\Delta t^n}{2\Delta x_{j+1}} \left(\kappa_1 + \kappa_2 \right) \right] + \frac{u\Delta t^n}{2\Delta x_{j+1}} \kappa_1 |c_j^n| + \frac{u\Delta t^n}{2\Delta x_{j+1}} \kappa_2 |\overline{c}_j^{n+\frac{1}{2}}| \\
&\leq \sup_j |c_j^n|.
\end{aligned} \tag{55}$$

Next, consider w_{j+1}^{n+1}. We define two new terms:

$$\kappa_3 = 1 + \frac{\tilde{\overline{c}}_{j+1}^{n+1,2} - \tilde{c}_j^{n+\frac{1}{2}}}{\overline{c}_{j+1}^{n+1} - c_j^{n+\frac{1}{2}}} \tag{56}$$

and

$$\kappa_4 = 1 + \frac{\tilde{\overline{c}}_{j+1}^{n+1,1} - \tilde{\overline{c}}_j^{n+1}}{\overline{c}_{j+1}^{n+1} - \overline{c}_j^{n+1}}. \tag{57}$$

The method can be written as

$$
\begin{aligned}
(58)\qquad w_{j+1}^{n+1} &= \bar{c}_{j+1}^{n+1} - \frac{u\Delta t^n}{\Delta x_{j+1}}\left[\bar{c}_{j+1}^{n+1} + \tilde{\bar{c}}_{j+1}^{n+1} - \frac{1}{2}\left(c_j^{n+\frac{1}{2}} + \tilde{c}_j^{n+\frac{1}{2}} + \bar{c}_j^{n+1} + \tilde{\bar{c}}_j^{n+1}\right)\right] \\
&= \bar{c}_{j+1}^{n+1} - \frac{u\Delta t^n}{2\Delta x_{j+1}}\left[\bar{c}_{j+1}^{n+1} + \tilde{\bar{c}}_{j+1}^{n+1,1}\right. \\
&\qquad \left. - \left(c_j^{n+\frac{1}{2}} + \tilde{c}_j^{n+\frac{1}{2}}\right) + \bar{c}_{j+1}^{n+1} + \tilde{\bar{c}}_{j+1}^{n+1,2} - \left(\bar{c}_j^{n+1} + \tilde{\bar{c}}_j^{n+1}\right)\right] \\
&= \bar{c}_{j+1}^{n+1} - \frac{u\Delta t}{2\Delta x_{j+1}}\left[\kappa_3\left(\bar{c}_{j+1}^{n+1} - c_j^{n+\frac{1}{2}}\right) + \kappa_4\left(\bar{c}_{j+1}^{n+1} - \bar{c}_j^{n+1}\right)\right] \\
&= \bar{c}_{j+1}^{n+1}\left[1 - \frac{u\Delta t^n}{2\Delta x_{j+1}}\left(\kappa_3 + \kappa_4\right)\right] + \frac{u\Delta t^n}{2\Delta x_{j+1}}\kappa_3 c_j^{n+\frac{1}{2}} + \frac{u\Delta t^n}{2\Delta x_{j+1}}\kappa_4 \bar{c}_j^{n+1}.
\end{aligned}
$$

As before, the coefficients sum to 1. By a similar argument, (46) and (47) give the nonnegativity of each κ term, and we have the same CFL restriction (49) as above. Taking the absolute value of each side of (58), we see that

$$
|w_{j+1}^{n+1}| \le \max\left(|\bar{c}_{j+1}^{n+1}|, |c_j^{n+\frac{1}{2}}|, |\bar{c}_j^{n+1}|\right),
$$

and each of these terms is bounded by the solution at time n. Finally

$$
\begin{aligned}
|c_{j+1}^{n+1}| &= \left|\frac{1}{2}\left(c_{j+1}^n + w_{j+1}^{n+1}\right)\right| \\
&\le \frac{1}{2}|c_{j+1}^n| + \frac{1}{2}|w_{j+1}^{n+1}| \\
&\le \sup_j |c_j^n|. \qquad \square
\end{aligned}
$$

To summarize, our method is conservative (the flux used at the right edge of element I_j is equal to that used at the left edge of I_{j+1}). We have demonstrated stability subject only to local CFL restrictions. Next we discuss the limiting of the corrections so that the conditions (44)–(47) are satisfied. Later, we will present numerical evidence demonstrating that local time stepping does not appear to degrade the accuracy of the method.

3.2. Computing and limiting the corrections. We discuss in slightly more detail the computation of the $\tilde{c}$ terms. We assume as before that θ is chosen so that $0 \le \theta \le 1$.

First, assume $\tilde{c}_j^n$, $\tilde{c}_{j-1}^n$, and $\tilde{c}_{j+1}^{n,1}$ are computed so that (44) is satisfied, say, using (15). We then set

$$
(59)\qquad \tilde{c}_{j+1}^{n,2} = \begin{cases} \tilde{c}_{j+1}^{n,1} & \text{if } 2|\tilde{c}_{j+1}^{n,1}| \le \theta|c_{j+1}^n - \bar{c}_j^{n+1/2}|, \\ 0 & \text{otherwise.} \end{cases}
$$

In a similar way, corrections $\tilde{\bar{c}}_j^{n+1/2}$ and $\tilde{\bar{c}}_{j-1}^{n+1/2}$ are computed so that the first inequality in (45) is satisfied, and $\tilde{\bar{c}}_j^{n+1/2}$ is limited so that

$$
(60)\qquad 2|\tilde{\bar{c}}_j^{n+1/2}| \le \theta|c_{j+1}^n - \bar{c}_j^{n+1/2}|.
$$

Hence, one can show

$$
(61)\qquad 0 \le \kappa_1, \kappa_2 \le 1 + \theta.
$$

Proceeding, $\tilde{c}_j^{n+1/2}$ and $\tilde{c}_{j-1}^{n+1/2}$ are computed so that the first inequality in (46) is satisfied, and so that

$$2|\tilde{c}_j^{n+1/2}| \le \theta|\overline{c}_{j+1}^{n+1} - c_j^{n+1/2}|; \tag{62}$$

$\tilde{\overline{c}}_{j+1}^{n+1,1}$ is computed so that it also satisfies

$$2|\tilde{c}_{j+1}^{n+1,1}| \le \theta|\overline{c}_{j+1}^{n+1} - c_j^{n+1/2}|. \tag{63}$$

Similarly, $\tilde{\overline{c}}_{j-1}^{n+1}$, $\tilde{\overline{c}}_j^{n+1}$, and $\tilde{\overline{c}}_{j+1}^{n+1,2}$ are computed so that (47) is satisfied. Thus

$$0 \le \kappa_3, \kappa_4 \le 1 + \theta. \tag{64}$$

3.3. The case $u < 0$. Consider Figure 2 again, now with $f(c) = uc$ and $u < 0$. This case is analogous to the situation in which $u > 0$ and the picture in Figure 2 is reversed, namely, the local time steps are to the right of the interface. In this case, to compute the solution in elements I_j and I_{j+1}, we use the following procedure.

Scheme II ($u < 0$).

(i) Compute corrections $\tilde{c}_j^n$, $\tilde{c}_{j+1}^{n,1}$, and $\tilde{c}_{j+2}^n$ so that (65) is satisfied.

(ii) $\overline{c}_j^{n+\frac{1}{2}} = c_j^n - \frac{u\lambda_j^n}{2}[c_{j+1}^n - \tilde{c}_{j+1}^{n,1} - (c_j^n - \tilde{c}_j^n)]$.

(iii) Compute $\tilde{\overline{c}}_j^{n+1/2}$ and $\tilde{c}_{j+1}^{n,2}$ so that (66) is satisfied.

(iv) $w_j^{n+\frac{1}{2}} = \overline{c}_j^{n+\frac{1}{2}} - \frac{u\lambda_j^n}{2}[c_{j+1}^n - \tilde{c}_{j+1}^{n,2} - (\overline{c}_j^{n+\frac{1}{2}} - \tilde{\overline{c}}_j^{n+\frac{1}{2}})]$.

(v) $c_j^{n+\frac{1}{2}} = \frac{1}{2}(c_j^n + w_j^{n+\frac{1}{2}})$.

(vi) Define $\tilde{c}_{j+1}^n \equiv \frac{1}{2}(\tilde{c}_{j+1}^{n,1} + \tilde{c}_{j+1}^{n,2})$.

(vii) $\overline{c}_{j+1}^{n+1} = c_{j+1}^n - u\lambda_{j+1}^n\left[c_{j+2}^n - \tilde{c}_{j+2}^n - \left(c_{j+1}^n - \tilde{c}_{j+1}^n\right)\right]$.

(viii) Compute $\tilde{c}_j^{n+\frac{1}{2}}$, $\tilde{\overline{c}}_{j+1}^{n+1,1}$, and $\tilde{\overline{c}}_{j+2}^{n+1}$ so that (67) is satisfied.

(ix) $\overline{c}_j^{n+1} = c_j^{n+1/2} - \frac{u\lambda_j^n}{2}[\overline{c}_{j+1}^{n+1} - \tilde{\overline{c}}_{j+1}^{n+1,1} - (c_j^{n+\frac{1}{2}} - \tilde{c}_j^{n+\frac{1}{2}})]$.

(x) Compute $\tilde{\overline{c}}_j^{n+1}$ and $\tilde{\overline{c}}_{j+1}^{n+1,2}$ to satisfy (68).

(xi) $w_j^{n+1} = \overline{c}_j^{n+1} - \frac{u\lambda_j^n}{2}[\overline{c}_{j+1}^{n+1} - \tilde{\overline{c}}_{j+1}^{n+1,2} - (\overline{c}_j^{n+1} - \tilde{\overline{c}}_j^{n+1})]$.

(xii) $c_j^{n+1} = \frac{1}{2}(c_j^{n+\frac{1}{2}} + w_j^{n+1})$.

(xiii) Define $\tilde{\overline{c}}_{j+1}^{n+1} \equiv \frac{1}{2}(\tilde{\overline{c}}_{j+1}^{n+1,1} + \tilde{\overline{c}}_{j+1}^{n+1,2})$.

(xiv) $w_{j+1}^{n+1} = \overline{c}_{j+1}^n - u\lambda_{j+1}^n[\overline{c}_{j+2}^{n+1} - \tilde{\overline{c}}_{j+2}^{n+1} - (\overline{c}_{j+1}^{n+1} - \tilde{\overline{c}}_j^{n+1})]$.

(xv) $c_{j+1}^{n+1} = \frac{1}{2}\left(c_{j+1}^n + w_{j+1}^{n+1}\right)$.

The conditions on the corrections in this case are

$$-\theta \le \frac{\tilde{c}_{j+1}^{n,1} - \tilde{c}_j^n}{c_{j+1}^n - c_j^n}, \frac{\tilde{c}_{j+2}^n - \tilde{c}_{j+1}^{n,1}}{c_{j+2}^n - c_{j+1}^n} \le 1, \tag{65}$$

$$-\theta \le \frac{\tilde{c}_{j+1}^{n,2} - \tilde{\overline{c}}_j^{n+1/2}}{c_{j+1}^n - \overline{c}_j^{n+1/2}}, \frac{\tilde{c}_{j+2}^n - \tilde{c}_{j+1}^{n,2}}{c_{j+2}^n - c_{j+1}^n} \le 1, \tag{66}$$

$$-\theta \le \frac{\tilde{\bar{c}}_{j+1}^{n+1,1} - \tilde{c}_j^{n+1/2}}{\bar{c}_{j+1}^{n+1} - c_j^{n+1/2}},\ \frac{\tilde{\bar{c}}_{j+2}^{n+1} - \tilde{\bar{c}}_{j+1}^{n+1,1}}{\bar{c}_{j+2}^{n+1} - \bar{c}_{j+1}^{n+1}} \le 1, \tag{67}$$

$$-\theta \le \frac{\tilde{\bar{c}}_{j+2}^{n+1} - \tilde{\bar{c}}_{j+1}^{n+1,2}}{\bar{c}_{j+2}^{n+1} - \bar{c}_{j+1}^{n+1}},\ \frac{\tilde{\bar{c}}_{j+1}^{n+1,2} - \tilde{\bar{c}}_j^{n+1}}{\bar{c}_{j+1}^{n+1} - \bar{c}_j^{n+1}} \le 1. \tag{68}$$

These conditions lead to the following result. The proof is left to the reader.

PROPOSITION 3.3. *Assume a time step of size Δt^n for all elements to the right of $x_{j+1/2}$ and size $\Delta t^n/2$ for all elements to the left of $x_{j+1/2}$, where Δt^n satisfies* (48) *and* (49) *(with u replaced by $-u$). Then, for Scheme* II *above with $f(c) = uc$ where $u < 0$, with corrections satisfying* (65)–(68) *on I_j and I_{j+1} and* (5)–(6) *elsewhere, we have*

$$\sup_j |c_j^n| \le \sup_j |c_j^0|. \tag{69}$$

3.4. Extension to a nonlinear flux function. The extension of the methods above to a more general numerical flux h essentially combines the ideas of Schemes I and II above. In particular, the method is as follows.

Scheme III (general flux function).

(i) Compute corrections $\tilde{c}_{j-1}^n$, $\tilde{c}_j^n$, $\tilde{c}_{j+1}^{n,1}$, and $\tilde{c}_{j+2}^n$ so that (44) and (65) are satisfied.

(ii) $\bar{c}_j^{n+\frac{1}{2}} = c_j^n - \frac{\lambda_j^n}{2}[h(c_j^n + \tilde{c}_j^n, c_{j+1} - \tilde{c}_{j+1}^{n,1}) - h(c_{j-1}^n + \tilde{c}_{j-1}^n, c_j^n - \tilde{c}_j^n)]$.

(iii) Compute $\tilde{\bar{c}}_{j-1}^{n+1/2}$, $\tilde{\bar{c}}_j^{n+1/2}$, and $\tilde{c}_{j+1}^{n,2}$ so that (45) and (66) are satisfied.

(iv) Compute $w_j^{n+\frac{1}{2}}$ by

$$w_j^{n+\frac{1}{2}} = \bar{c}_j^{n+\frac{1}{2}} - \frac{\lambda_j^n}{2}\left[h(\bar{c}_j^{n+\frac{1}{2}} + \tilde{\bar{c}}_j^{n+\frac{1}{2}}, c_{j+1}^n - \tilde{c}_{j+1}^{n,2}) - h(\bar{c}_{j-1}^{n+\frac{1}{2}} + \tilde{\bar{c}}_{j-1}^{n+\frac{1}{2}}, \bar{c}_j^{n+\frac{1}{2}} - \tilde{\bar{c}}_j^{n+\frac{1}{2}})\right].$$

(v) $c_j^{n+\frac{1}{2}} = \frac{1}{2}(c_j^n + w_j^{n+\frac{1}{2}})$.

(vi) Define $\tilde{c}_{j+1}^n \equiv \frac{1}{2}(\tilde{c}_{j+1}^{n,1} + \tilde{c}_{j+1}^{n,2})$.

(vii) Compute $\bar{c}_{j+1}^{n+1}$ by

$$\bar{c}_{j+1}^{n+1} = c_{j+1}^n - \lambda_{j+1}^n \Bigg[h(c_{j+1}^n + \tilde{c}_{j+1}^n, c_{j+2}^n - \tilde{c}_{j+2}^n) - \frac{1}{2}(h(c_j^n + \tilde{c}_j^n, c_{j+1}^n - \tilde{c}_{j+1}^{n,1}) + h(\bar{c}_j^{n+\frac{1}{2}} + \tilde{\bar{c}}_j^{n+\frac{1}{2}}, c_{j+1}^n - \tilde{c}_{j+1}^{n,2}))\Bigg].$$

(viii) Compute $\tilde{c}_{j-1}^{n+\frac{1}{2}}$, $\tilde{c}_j^{n+\frac{1}{2}}$, $\tilde{\bar{c}}_{j+1}^{n+1,1}$, and $\tilde{\bar{c}}_{j+2}^{n+1}$ so that (46) and (67) are satisfied.

(ix) Compute $\bar{c}_j^{n+1}$ by

$$\bar{c}_j^{n+1} = c_j^{n+\frac{1}{2}} - \frac{\lambda_j^n}{2}\left[h(c_j^{n+\frac{1}{2}} + \tilde{c}_j^{n+\frac{1}{2}}, \bar{c}_{j+1}^{n+1} - \tilde{\bar{c}}_{j+1}^{n+1,1}) - h(c_{j-1}^{n+\frac{1}{2}} + \tilde{c}_{j-1}^{n+\frac{1}{2}}, c_j^{n+\frac{1}{2}} - \tilde{c}_j^{n+\frac{1}{2}})\right].$$

(x) Compute $\tilde{\bar{c}}_{j-1}^{n+1}$, $\tilde{\bar{c}}_j^{n+1}$, and $\tilde{\bar{c}}_{j+1}^{n+1,2}$ so that (47) and (68) are satisfied.

(xi) Compute w_j^{n+1} by

$$w_j^{n+1} = \bar{c}_j^{n+1} - \frac{\lambda_j^n}{2}\left[h(\bar{c}_j^{n+1} + \tilde{\bar{c}}_j^{n+1}, \bar{c}_{j+1}^{n+1} - \tilde{\bar{c}}_{j+1}^{n+1,2}) - h(\bar{c}_{j-1}^{n+1} + \tilde{\bar{c}}_{j-1}^{n+1}, \bar{c}_j^{n+1} - \tilde{\bar{c}}_j^{n+1})\right].$$

(xii) $c_j^{n+1} = \frac{1}{2}(c_j^{n+\frac{1}{2}} + w_j^{n+1})$.

(xiii) Define $\tilde{\bar{c}}_{j+1}^{n+1} \equiv \frac{1}{2}(\tilde{\bar{c}}_{j+1}^{n,1} + \tilde{\bar{c}}_{j+1}^{n,2})$.
(xiv)

$$w_{j+1}^{n+1} = \bar{c}_{j+1}^{n+1} - \frac{\Delta t^n}{\Delta x_{j+1}} \left[h(\bar{c}_{j+1}^{n+1} + \tilde{\bar{c}}_{j+1}^{n+1}, \bar{c}_{j+2}^{n+1} - \tilde{\bar{c}}_{j+2}^{n+1}) \right.$$
$$\left. -\frac{1}{2}\left(h(c_j^{n+\frac{1}{2}} + \tilde{c}_j^{n+\frac{1}{2}}, \bar{c}_{j+1}^{n+1} - \tilde{\bar{c}}_{j+1}^{n+1,1}) + h(\bar{c}_j^{n+1} + \tilde{\bar{c}}_j^{n+1}, \bar{c}_{j+1}^{n+1} - \tilde{\bar{c}}_{j+1}^{n+1,2}) \right) \right].$$

(xv) $c_{j+1}^{n+1} = \frac{1}{2}\left(c_{j+1}^n + w_{j+1}^{n+1}\right)$.

3.5. Extension to M steps. Now suppose we take M steps in grid block I_j to one step in block I_{j+1}. The easier extension of the method described above is for the case where M is even, although an extension to M odd can also be made.

Assume M is even. When $M = 2$, note that to compute $\bar{c}_{j+1}^{n+1}$ we used the values c_j^n up through $\bar{c}_j^{n+1/2}$. The same is true in general. We compute $\bar{c}_j^{n+1/2}$ by taking $M/2$ steps in block I_j. The average of the fluxes along edge $j + 1/2$ over these steps is used to compute $\bar{c}_{j+1}^{n+1}$, just as above. The computation of w_{j+1}^{n+1} is analogous. We take $M/2$ steps to compute $\bar{c}_{j+1}^{n+1}$, starting with $c_j^{n+1/2}$, and the average of the fluxes along edge $j + 1/2$ is used to compute w_{j+1}^{n+1}.

The maximum principle argument can be carried through with appropriate limiting of the corrections. Similar to the case $M = 2$, at each substep i, $i = 1, \ldots, M/2$, we compute a correction $\tilde{c}_{j+1}^{n,i}$ in block I_{j+1} so that the analogues of (44), (45), (65), and (66) are satisfied. The final correction $\tilde{c}_{j+1}^n$ is the average of all of these substep corrections. Similarly, once $\bar{c}_{j+1}^{n+1}$ is computed, corrections $\tilde{\bar{c}}_{j+1}^{n+1,i}$ are computed at each substep so that the analogues of (46), (47), (67), and (68) are satisfied, and $\tilde{\bar{c}}_{j+1}^{n+1}$ is computed by averaging these corrections.

4. Numerical results. Here we present results examining the accuracy and stability of the method in section 3.

4.1. Linear example: Smooth problem. We will first show how local time stepping affects the errors and stability in the case of a smooth linear problem. Consider initial and boundary conditions such that the true solution is $\sin(\pi(x-t))$. The space-time domain is $[0,1]^2$. We have the following cases:

1. Uniform mesh of width Δx, global time step $\Delta t = \frac{2\Delta x}{3}$.
2. Region $[0, 0.5]$ refined to $\frac{\Delta x}{2}$, time step globally refined to $\Delta t = \frac{\Delta x}{3}$.
3. Region $[0, 0.5]$ refined to $\frac{\Delta x}{2}$, time step on $[0, 0.5]$ reduced (locally) by a factor of 2.

Examining Tables 1, 2, and 3, we see that the rate of convergence in L^2 in all three cases is around 1.5, which is to be expected for a *minmod*-limited method. Conceivably, the local time stepping could incur an $\mathcal{O}(h^{\frac{1}{2}})$ error which a constant time step would not incur. Thus, we turned off the limiter on the slopes and saw that the local stepping does not degenerate the order of accuracy, as we see second order convergence in Tables 4 and 5.

4.2. Linear example: Rough problem. Now that we have seen that the local time stepping scheme does not degenerate the accuracy of the approximation, we will show that the method is indeed stable with a local CFL condition. Consider the linear model case of $f(c) = c$ with $c(x, 0) = 1$ for $x < 0$ and $c(x, 0) = 0$ for $x > 0$. At $t = 0.5$, the true solution is a front at $x = 0.5$. Consider the following situations:

TABLE 1

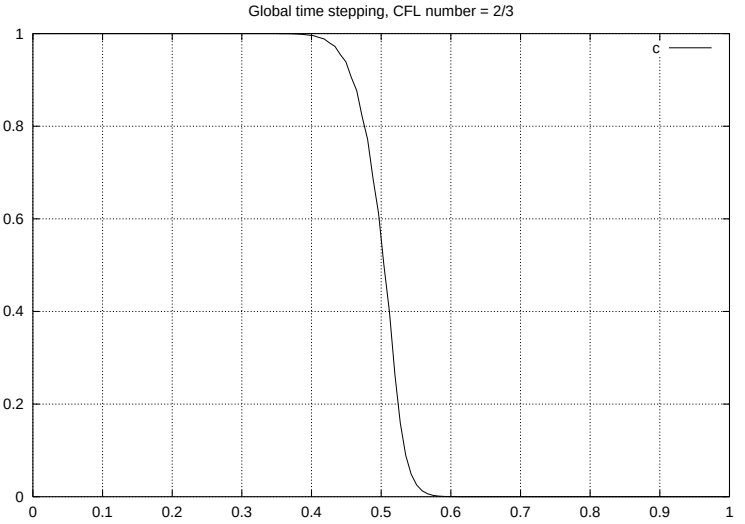

FIG. 3. *Global time stepping, model advective front.*

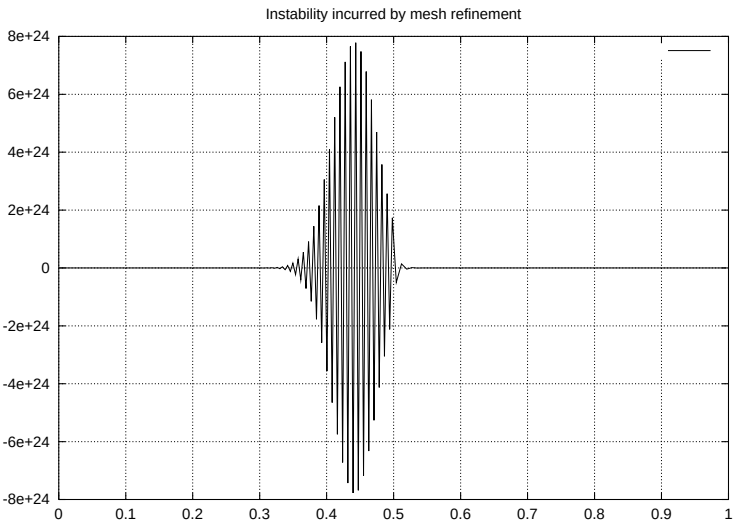

FIG. 4. *Local mesh refinement creates instability.*

1. Global uniform mesh, $\Delta x = \frac{1}{128}$, global CFL number of $\frac{2}{3}$.
2. Refine the mesh on $[0, 0.5]$ by a factor of 2, keep the same global time step. (CFL number in first half of the domain is $\frac{4}{3}$.)
3. Refine the time step on $[0, 0.5]$ by a factor of 2, giving a *local* CFL number of $\frac{2}{3}$ everywhere.

Observe that the front is propagated stably in the first case in Figure 3 but when the CFL condition is violated in the second case, we incur massive instability (Figure 4). However, the local time stepping method, with its local CFL condition, gives a stable and accurate approximation to the front in Figure 5.

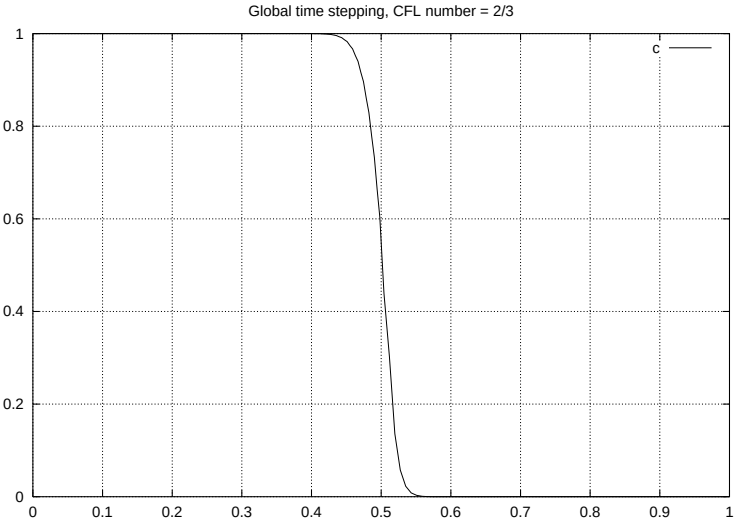

FIG. 5. *Local time stepping restores stability.*

4.3. Nonlinear example: Buckley–Leverett. Next, we examine a case where the flux is nonlinear. The Buckley–Leverett problem, given by

$$f(c) = \frac{c^2}{c^2 + a(1-c)^2}, \tag{70}$$

is a standard test problem arising in two-phase flow in porous media. This flux function is Lipschitz but nonconvex. In the case of $a = 0.25$, it is known from the Rankine–Hugoniot condition that the front is a rarefaction down to the point where $c = 0.44$, and then the solution jumps to $c = 0$. See, for example, [10] for a discussion. The Rankine–Hugoniot condition also gives that this front propagates at a velocity of 1.62. We performed a series of numerical experiments on a uniform mesh. First, we used global time stepping to verify that the code put the shock in the right location with the correct jump. Then, we refined the time step in the first half of the domain repeatedly in order to verify that the local time stepping did not alter the method's shock-capturing abilities. Each of these cases was run with a mesh spacing of $\Delta x = \frac{1}{128}$ and a main time step of $\Delta t = \frac{1}{160}$ to time $t = 0.5$. The true front should be at $x = 0.81$. These fronts were all near, though diffused, and further spatial refinements gave sharper fronts at the right spot. Figure 6 shows these results.

Further, we show that we have stability only subject to a local CFL constraint. Again, we consider three cases, with $\Delta x_{\max} = \frac{1}{128}$ and $\Delta t_{\max} = \frac{1}{160}$. In each case, the mesh width is $\frac{1}{2}\Delta x_{\max}$ on $[0, 0.5]$ and $\Delta x_{\max}$ elsewhere.

1. Global time step $\Delta t_{\max}$.
2. Global time step $\frac{1}{2}\Delta t_{\max}$.
3. Local time stepping.

As seen in Figure 7, the large time step in the presence of the local refinement has caused some mild instability with over- and undershoot. Due to the large velocity, this mild oscillation has propagated out of the first part of the domain and into the second. However, when the time step is refined either globally or locally in the presence of the mesh refinement, the front is well approximated.

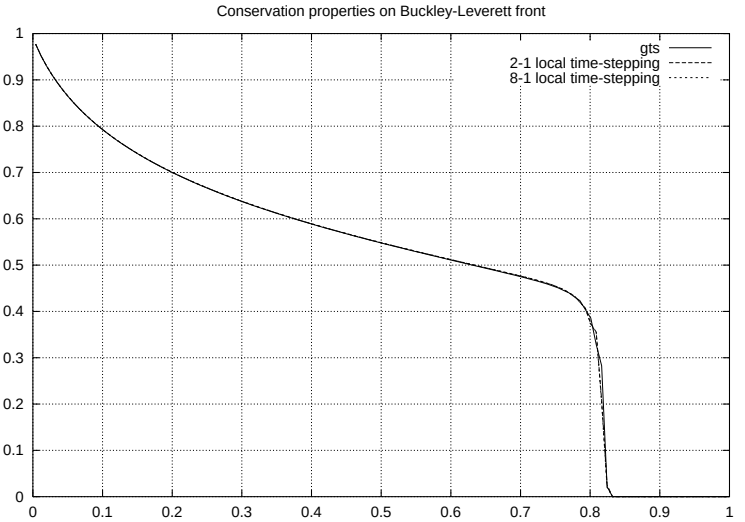

FIG. 6. *Local time stepping approximations to Buckley–Leverett front at* $x = 0.81$.

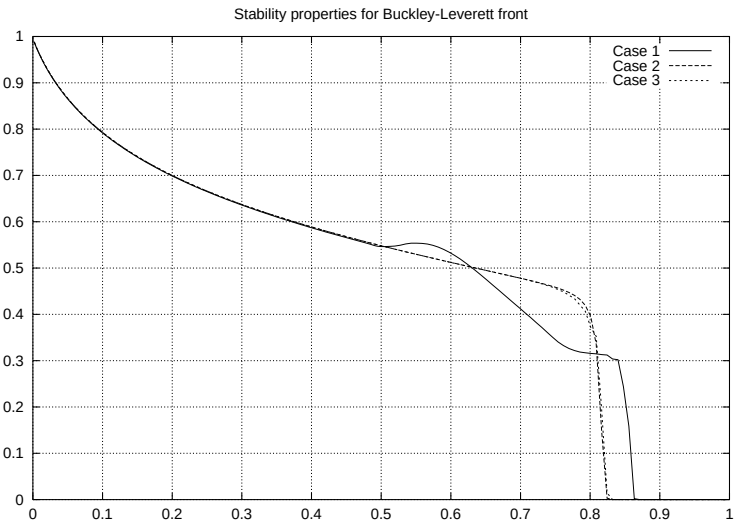

FIG. 7. *Local time stepping cures instability caused by local mesh refinement.*

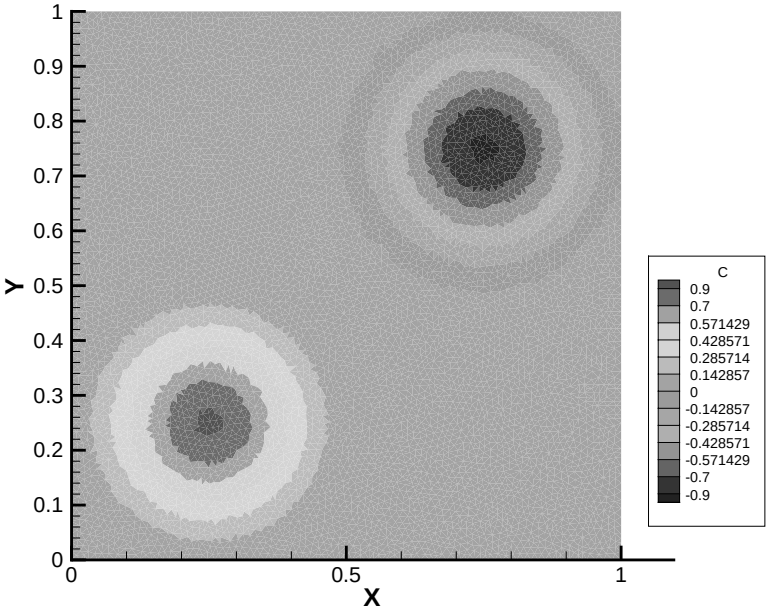

FIG. 8. *Initial condition for Burgers' equation, consisting of a cone of height* 1 *in the lower left corner, and a cone of height* -1 *in the upper right corner.*

5. Two-dimensional Burgers' equation. The local time stepping schemes described above have been extended to two space dimensions. The spatial discretization we have employed is based on a high resolution method developed by Durlofsky, Engquist, and Osher [4] for unstructured, triangular grids. The difference between what we have implemented and the method in [4] is in the slope-limiting step. Three different slopes are constructed using linear interpolation with the element and its neighbors. Then the steepest slope which does not introduce overshoot/undershoot at the edge boundaries is selected. The two methods differ in the case where no slopes satisfy this condition. In our implementation, the slope is set to zero in this case, whereas Durlofsky, Engquist, and Osher simply choose the interpolant with the smallest gradient.

Some results for local time stepping applied to the transport equation (1), with highly varying velocity fields, can be found in [9]. Here, we apply local time stepping to the two-dimensional inviscid Burgers' equation

$$c_t + f(c)_x + f(c)_y = 0, \tag{71}$$

where $f(c) = \frac{c^2}{2}$. We take as an initial condition a function consisting of two cone shapes, one with height 1 and the other with height -1. The initial condition is displayed in Figure 8.

In Burgers' equation, larger concentrations give rise to larger velocities. Consequently, the centers of the cones are advected along at a higher rate than the edges. Moreover, the positive cone has positive velocity and the negative cone negative velocity; thus, the cones approach each other and "collide" in the center of the domain. This general behavior is given in Figure 9, where we have shown the solution at time

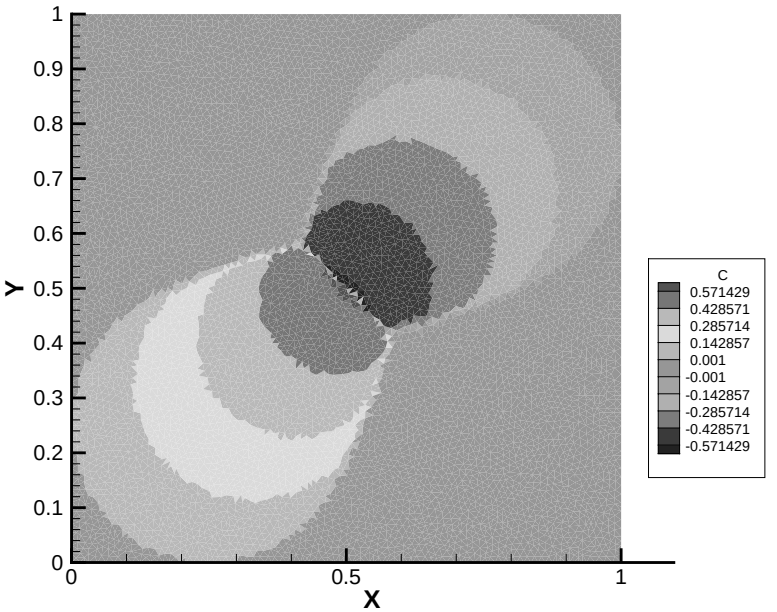

FIG. 9. *Global time stepping solution at* $T = 1.1$.

$T = 1.1$. This solution was obtained using the method in [4], modified as mentioned above, with Heun's method used for the temporal integration. The finite element mesh for this case, shown in Figure 10, consists of 15489 triangles and is unstructured.

An extension of the second order local time stepping scheme described previously was implemented for this problem. In our implementation, the elements take either the global CFL time step or a time step M times larger, assuming that this larger time step does not violate the local CFL constraint. The time steps are redistributed throughout the domain after each large time step. Numerical results for $M = 2$, 5, and 10 were generated. Relative L^1 and L^2 errors between the local and global time stepping solutions were computed at time $T = 1.1$. The relative L^1 error is

$$Error_{L^1} = \frac{\sum_E |c_{global}(x_E) - c_{local}(x_E)| m(E)}{\sum_E |c_{global}(x_E)| m(E)}, \tag{72}$$

where the sum on E is over all elements, x_E is the barycenter of element E, c_{global} is the global time stepping solution, c_{local} is the local time stepping solution, and $m(E)$ is the area of triangle E. A similar definition holds for the relative L^2 error. These errors are given in Table 6. Note that they are on the order of 1%.

Table 7 shows the CPU run times in seconds for each of these cases. Notice a speedup of about 1.7–2.4 for the M:1 time stepping scheme over the global time stepping scheme. For this problem, most elements near the peaks of the cones take the smaller (global CFL) time step, as these elements have larger velocity. As the simulation proceeds, the solution spreads and eventually more elements are forced to take the smaller time step. This phenomenon is seen in Figures 11 and 12, where the local time step distribution is plotted at times $T = .1$ and $T = 1.1$, respectively, for the case $M = 5$. For the $M = 10$ case, the small time step region is more extensive, because fewer elements meet the criterion necessary to take the larger time step. Thus, any gains in increasing M are offset somewhat, and consequently there

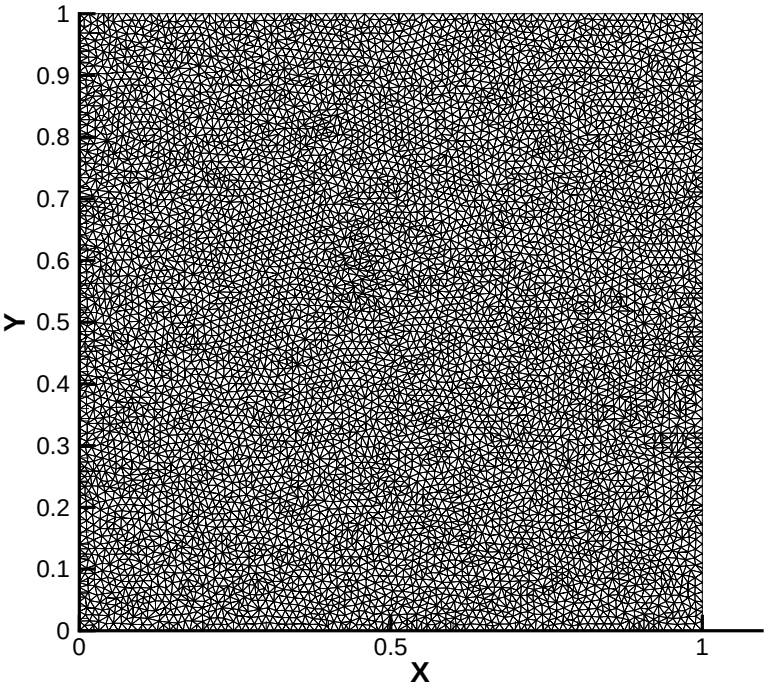

FIG. 10. *Finite element mesh for Burgers' equation test case.*

is not a dramatic decrease in run time as we increase M for this problem. In Figure 13, we have plotted the percentage of elements taking the global CFL time step vs. simulation time for $M = 2$, 5, and 10. Here we see that for $M = 2$, initially about 3.5% of the elements take the global CFL time step, and the percentage grows to about 7% by the final time, $T = 1.1$. For $M = 5$, the range is from about 20% to 27%, and for $M = 10$, the range is about 28% to 37%. For M too large, of course, all elements would be forced to take the global CFL time step.

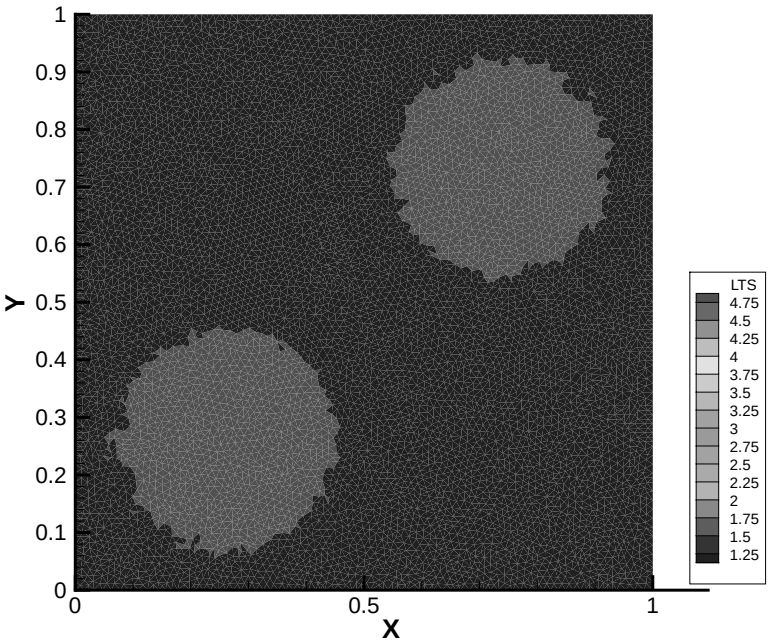

FIG. 11. *Distribution of local time steps for $M = 5$ and $T = .1$. Lighter region indicates where smaller time steps were taken.*

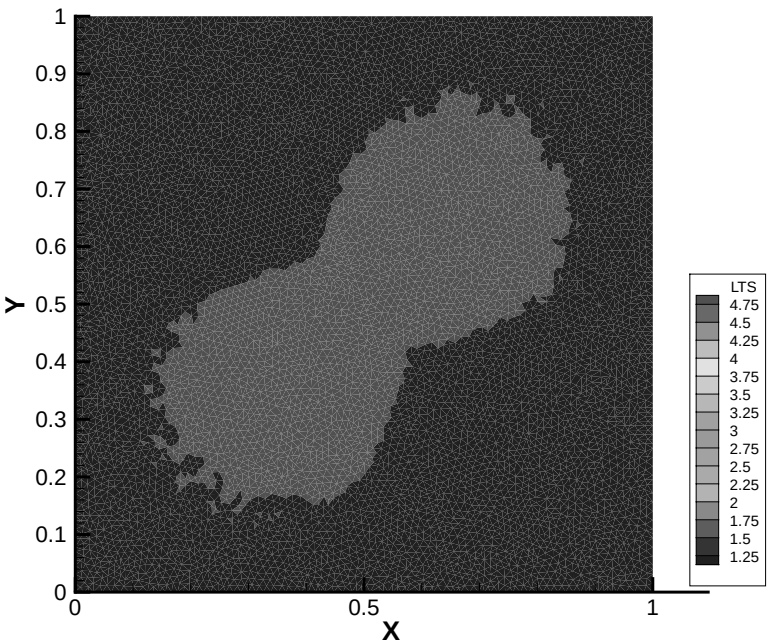

FIG. 12. *Distribution of local time steps for $M = 5$ and $T = 1.1$. Lighter region indicates where smaller time steps were taken.*

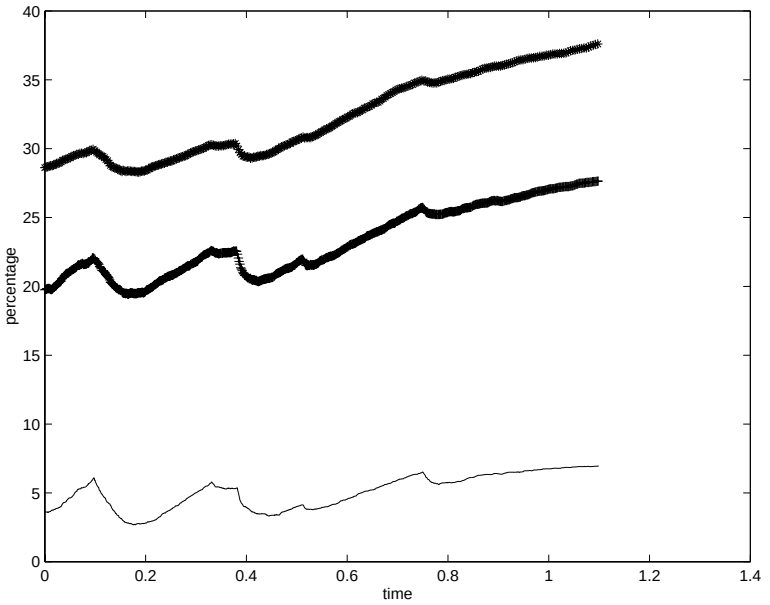

FIG. 13. *Percentage of elements taking the global CFL time step as a function of simulation time for $M = 2$ (solid line), $M = 5$ (+), and $M = 10$ (*).*

6. Conclusions. We have developed and proved maximum principles for local time stepping schemes based on first and second order time discretizations, and piecewise linear spatial discretizations. Numerical results given here and in [9] indicate that these local time stepping schemes exhibit similar accuracy and stability to the global time stepping schemes upon which they are based, at a fraction of the computational cost.

In this paper, we have not addressed the issue of whether our local time stepping schemes satisfy additional properties (TVB, etc.) from which we could conclude that the schemes converge to the entropy solution. However, all of our numerical results to date indicate that the local time stepping solutions are almost identical to those obtained by global time stepping. Thus, our experiences so far lead us to believe that our local time stepping schemes inherit the convergence properties of the related global scheme, though this has not been proven.
