CACHE ISSUES OF ALGEBRAIC MULTIGRID METHODS FOR LINEAR SYSTEMS WITH MULTIPLE RIGHT-HAND SIDES*

GUNDOLF HAASE† AND STEFAN REITZINGER‡

Abstract. This paper is concerned with the solution of a linear system with multiple right-hand sides. Such problems arise from nonlinear, time-dependent, inverse, or optimization problems. In order to solve these problems efficiently we use block variants of the conjugate gradient method and combine them with cache aware algorithms. Further, we describe the acceleration of algebraic multigrid (AMG) methods by using such cache aware algorithms. Finally, numerical studies are presented that show the high efficiency of the proposed methods.

Key words. algebraic multigrid, block conjugate gradient methods, cache algorithms, nonuniform memory access

1. Introduction.

The simulation of stationary processes is described by elliptic, (self-adjoint) partial differential equations (PDEs). Solving such a direct problem, e.g., determining the state variables from given source and boundary data, via a finite element (FE) discretization is standard in numerical software today. The situation changes for time-dependent, nonlinear, optimization, or inverse problems. Here, the numerical solution strategy yields a sequence of linear equations, and it is often necessary to solve a huge number of linear systems with different right-hand sides in order to solve the overall problem. In this paper we discuss related solution methods for multiple right-hand sides and the constant system matrix resulting from a self-adjoint elliptic PDE, i.e.,

$$K_h \underline{u}_h^i = \underline{f}_h^i, \qquad i = 1, \ldots, N_r, \tag{1.1}$$

where $K_h \in \mathbb{R}^{N_h \times N_h}$ denotes a symmetric positive definite (SPD) system matrix, $\underline{f}_h^i \in \mathbb{R}^{N_h}$ denotes a given ith right-hand side, $\underline{u}_h^i \in \mathbb{R}^{N_h}$ denotes the corresponding solution vector, and N_r expresses the overall number of right-hand sides. We are especially interested in the case where the system matrix stems from a second order self-adjoint elliptic PDE, e.g., the potential equation, Lamé equations, or Maxwell equations. In addition we distinguish two different settings of the given right-hand sides.

1. The right-hand sides can be computed in advance, e.g., inverse or optimization problems.
2. The right-hand sides are computed successively, e.g., time-dependent problems.

In many applications the right-hand sides $\{\underline{f}_h^i\}_{i=1}^{N_r}$ are not arbitrary, but the differences are small in a certain sense for $i = 1, \ldots, N_r$ or at least for a subsequence $i = s_1, \ldots, s_2$, $1 \leq s_1 < s_2 \leq N_r$. In [2, 20, 21, 26, 29] the properties of such a sequence of right-hand sides were exploited by using variants of the conjugate gradient (CG) (or, equivalently, the Lanczos) method. The first ideas concerning the CG method with multiple right-hand sides are due to [20, 21], and later an analysis of the method was given in [2, 26, 29]. An application for the sensitivity analysis in shape optimization can be found in [4]. These methods have to store all Krylov subspace vectors, which requires additional memory in comparison to simpler solution methods. Memory was very expensive at the time of the earlier papers and therefore the methods were not very popular. Additionally, the known preconditioners for the CG method were not optimal and therefore the Krylov subspace became very large. However, variants were suggested (see [26, 29]) that do not need to store the Krylov subspace if the right-hand sides can be calculated in advance.

At the present time there are optimal preconditioners (with respect to memory and arithmetic costs) such as multigrid (MG) methods [1, 28, 10] available for nontrivial practical problems so that the Krylov subspace can be kept small. For some theory on MG preconditioners, see [14]. Since geometric MG methods have several drawbacks when they are applied to engineering applications, we use algebraic multigrid (AMG) methods which essentially require the system matrix and the right-hand side of the original discretization; see [25, 23, 9, 28] for details.

The second part of the paper is concerned with cache aware techniques for MG methods and reduction of arithmetic costs in an implementation. In contrast to cache optimization techniques for tensor product grids [7, 15, 16], we focus our attention on cache aware programming techniques for unstructured finite element method (FEM) grids [12, 5, 6]. Although most of the techniques used in our paper have been well known for decades [11], whether it pays to use these techniques also depends on the specialties of the problem and the hardware. Furthermore, we apply such cache aware algorithms for simultaneous right-hand sides even if they do not correlate.

The remainder of the paper is organized as follows: Section 2 describes the algorithmic tuning of MG codes in general, which is especially applied to the AMG software package PEBBLES [22]. Section 3 is concerned with simultaneous right-hand sides and an appropriate memory management. Additionally, we describe the preconditioned CG version for multiple right-hand sides. Section 4 presents numerical studies with academic and real life applications, followed by conclusions and further remarks in section 5.

2. Algorithmic improvements of multigrid. We have to solve (1.1) N_r times (e.g., $N_r \approx 10000$) for different right-hand sides by using an MG preconditioned CG method. Therefore, even a minor saving of solution time for one solve accumulates to a substantially faster response to the overall problem.

All algorithms have the problem that their response time is much more determined by data access than by floating point operations. This is caused by the characteristics of recent processors where the floating point unit can operate much faster than the data can be transferred from main memory into its registers. The problem increases with systems of equations resulting from unstructured FE-meshes.

2.1. Improved data structures. All CPUs possess up to three levels of cache, and having all data available in the fastest cache would be the perfect data management for all sorts of algorithms. Unfortunately, our problems are much too big to fit in the caches and so the CPU has to load the data needed next into the faster caches (also taking into account the cache hierarchy). Each time the CPU does not

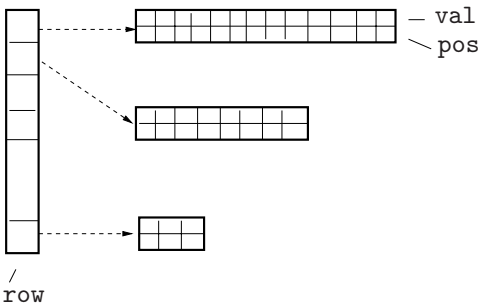

FIG. 2.1. *Principle structure of the original matrix memory management.*

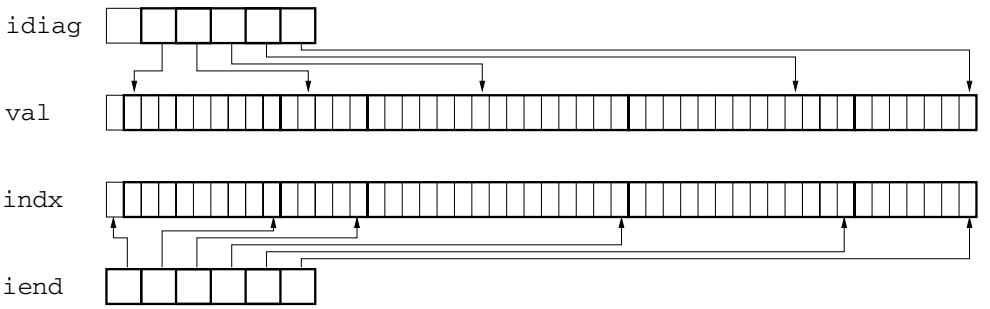

FIG. 2.2. *Matrix in CRS storage with additional diagonal pointer.*

find its data in the cache, i.e., a cache miss occurs, the processor has to stop until the data is transferred from main memory or lower level caches, and the whole execution of that algorithm is significantly delayed. Recent processor and compiler technology tries to decrease the number of cache misses by data prefetching; i.e., more data than is actually needed is loaded into the cache. This technique speculates that subsequent data in memory will be needed soon for calculations [5]. Data is always transferred as full cache line, e.g., 128 bytes long, from main memory into the caches instead of loading only a single real number. Therefore, our data structures should support the cache line technique by storing and accessing data linearly in the memory, and this data should be reused as often as possible without being removed from the cache. The prefetching of data can be additionally supported by a very careful use of pointers and other indirect addressing techniques. Figure 2.1 presents a closer look at the very flexible pointer-based storage scheme for the sparse stiffness matrix K_h resulting from an unstructured FE-mesh used in the original AMG-code PEBBLES [22] (written in C++). However, the memory access pattern of these data structures is not well suited for cache efficient implementations since data of adjacent matrix rows may be stored in nonadjacent memory areas. Consequently, we replaced that storage scheme by the classical compressed row storage (CRS) format for sparse matrices containing vectors `val`, `indx`, `iend` for storing matrix values, column indices, and indices of last row entry; see Figure 2.2. We added an additional vector storing the diagonal pointers `idiag` to accelerate smoothing procedures. The symmetry of the matrix is not exploited in the storage scheme; i.e., we store all nonzero entries, but this allows faster algorithms for symmetric matrices (see Algorithm 4). The interpolation weights should be stored in the original CRS format. These changes in the matrix and interpolation weight storage accelerated the code by 10–15%.

2.2. Avoiding data traffic. Another way to accelerate MG-codes consists of avoiding data traffic and arithmetic operations that are not necessary. Let us have a closer look at the classical MG algorithm (see, e.g., [10, 28, 1]), presented in Algorithm 1, where $q = 1$ denotes the finest level and $q = \ell$ the coarsest level. $\{K_j, P_j\}_{j=1}^{\ell}$ includes system and interpolation matrices for all levels. In the following we discuss the MG algorithm for one right-hand side only and denote two consecutive fine and coarse levels by q and $q+1$, respectively.

Algorithm 1 Multigrid $\underline{u}_q \longleftarrow \mathrm{MG}(\{K_j, P_j\}_{j=1}^{\ell}, \underline{u}_q, \underline{f}_q, q)$.

if $q == \ell$ **then**
  $\underline{u}_q \longleftarrow$ SOLVE$(\, K_q \cdot \underline{u}_q \;=\; \underline{f}_q \,)$
else
  $\widetilde{\underline{u}}_q \longleftarrow$ SMOOTHF$(K_q, \underline{u}_q, \underline{f}_q)$
  $\underline{d}_q \longleftarrow \underline{f}_q - K_q \cdot \widetilde{\underline{u}}_q$
  $\underline{d}_{q+1} \longleftarrow (P_q)^T \cdot \underline{d}_q$
  $\underline{w}_{q+1} \longleftarrow 0$
  $\underline{w}_{q+1} \longleftarrow \mathrm{MG}(\{K_j, P_j\}_{j=1}^{\ell}, \underline{w}_{q+1}, \underline{d}_{q+1}, q+1)$
  $\underline{w}_q \longleftarrow P_q \cdot \underline{w}_{q+1}$
  $\widetilde{\underline{u}}_q \longleftarrow \widetilde{\underline{u}}_q + \underline{w}_q$
  $\underline{u}_q \longleftarrow$ SMOOTHB$(K_q, \widehat{\underline{u}}_q, \underline{f}_q)$
end if

A modular concept of the original MG algorithm realizes the calculation of the defect $\underline{d}_q \longleftarrow \underline{f}_q - K_q \cdot \widetilde{\underline{u}}_q$ in a way that the result of matrix-vector multiplication is stored in a temporary vector which is subtracted from $\underline{f}_q$ afterwards. Both steps can be combined in a routine DEFECT which saves two accesses to the temporary vector.

The interpolation of the correction from the coarse grid and the correction of the existing solution vector with it, i.e.,

$$\underline{u}_q = \underline{u}_q + P_q \cdot \underline{w}_{q+1}, \tag{2.1}$$

is usually realized in three steps ($\underline{w}_q \longleftarrow 0$, $\underline{w}_q \longleftarrow \underline{w}_q + P_q \cdot \underline{w}_{q+1}$, $\underline{u}_q \longleftarrow \underline{u}_q + \underline{w}_q$). The direct implementation of (2.1) by loop fusion in a routine INTCORR requires only minor changes in the given interpolation routine but saves initialization and access to the auxiliary vector $\underline{w}_q$. Algorithm 2 presents the modified MG algorithm.

Algorithm 2 Modified multigrid $\underline{u}_q \longleftarrow \mathrm{MG}(\{K_j, P_j\}_{j=1}^{\ell}, \underline{u}_q, \underline{f}_q, q)$.

if $q == \ell$ **then**
  $\underline{u}_q \longleftarrow$ SOLVE$(\, K_q \cdot \underline{u}_q \;=\; \underline{f}_q \,)$
else
  $\widetilde{\underline{u}}_q \longleftarrow$ SMOOTHF$(K_q, \underline{u}_q, \underline{f}_q)$
  $\underline{d}_q \longleftarrow$ DEFECT$(K_q, \widetilde{\underline{u}}_q, \underline{f}_q)$
  $\underline{d}_{q+1} \longleftarrow (P_q)^T \cdot \underline{d}_q$
  $\underline{w}_{q+1} \longleftarrow 0$
  $\underline{w}_{q+1} \longleftarrow \mathrm{MG}(\{K_j, P_j\}_{j=1}^{\ell}, \underline{w}_{q+1}, \underline{d}_{q+1}, q+1)$
  $\widehat{\underline{u}}_q \longleftarrow$ INTCORR$(P_q, \widetilde{\underline{u}}_q, \underline{w}_{q+1})$
  $\underline{u}_q \longleftarrow$ SMOOTHB$(K_q, \widehat{\underline{u}}_q, \underline{f}_q)$
end if

2.3. Merging of defect calculation and smoother. A careful investigation of Algorithm 2 leads to the suspicion that some redundant calculations will be performed in SmoothF and Defect since the smoother as well as the defect calculation requires matrix-vector operations. And indeed, some results of the last Gauss–Seidel forward (analogously, backward) iteration (2.2) can be reused in the following defect calculation (2.3), $\forall i = 1, \ldots, n := N_q$ (= number of unknowns of level q):

$$\widetilde{u}_i = K_{ii}^{-1} \underbrace{\left(\underbrace{f_i - \sum_{j=1}^{i-1} K_{ij}\widetilde{u}_j}_{=:r} - \sum_{j=i+1}^{n} K_{ij}u_j \right)}_{=:v} = K_{ii}^{-1} v, \tag{2.2}$$

$$d_i = f_i - \sum_{j=1}^{n} K_{ij}\widetilde{u}_j = \underbrace{f_i - \sum_{j=1}^{i-1} K_{ij}\widetilde{u}_j}_{r} - \underbrace{K_{ii}\widetilde{u}_i}_{=v} - \sum_{j=i+1}^{n} K_{ij}\widetilde{u}_j$$

$$= r - v - \sum_{j=i+1}^{n} K_{ij}\widetilde{u}_j. \tag{2.3}$$

Note that we have access only to the nonzero elements of a matrix row although we write $j = 1, \ldots, n$ in order to simplify the notation. We combine the last smoothing sweep (2.2) and defect correction (2.3) for general matrices to Algorithm 3. The old vector $\underline{u}$ is overwritten by the new vector $\underline{\widetilde{u}}$, and thus no additional memory is required.

Algorithm 3 Merging of last smoothing sweep and defect calculation for general matrices in CRS.

for all $i = 1, \ldots, n$ **do**
  $r \longleftarrow f_i - \sum_{j=1}^{i-1} K_{ij}\widetilde{u}_j$
  $inv \longleftarrow 1.0/K_{ii}$
  $v \longleftarrow r - \sum_{j=i+1}^{n} K_{ij}u_j$
  $\widetilde{u}_i \longleftarrow v * inv$
  $d_i \longleftarrow r - v$
end for
for all $i = 1, \ldots, n$ **do**
  $d_i \longleftarrow d_i - \sum_{j=i+1}^{n} K_{ij}\widetilde{u}_j$
end for

The matrix is usually sparse and contains in sum NZE nonzero matrix elements in its n rows (NZE $= n^2$ in case of a fully occupied matrix). Algorithm 3 requires $\frac{3}{2} \cdot$ NZE arithmetic operations and accesses with matrix elements instead of $2 \cdot$ NZE when smoothing and defect calculation are separated. Unfortunately, we have to start again with the first row when accessing some matrix elements in the second loop; i.e., the upper triangular block of the matrix has to be transferred into the cache again. The two loops in the update of the defect, i.e., the last i-loop and the sum therein,

$$d_i \longleftarrow d_i - \sum_{j=i+1}^{n} K_{ij}\widetilde{u}_j \qquad \forall i = 1, \ldots, n,$$

can be interchanged and lead together with a swapping of indices i and j to

$$\{d_j \longleftarrow d_j - K_{ji}\widetilde{u}_i\}_{j=1}^{i-1} \qquad \forall i = 2, \ldots, n. \tag{2.4}$$

Now we could merge the two i-loops in Algorithm 3, but accessing the transposed matrix pattern would be much worse than before. In the case of a symmetric matrix, i.e., $K_{ij} = K_{ji}$, we can use K_{ij} instead of K_{ji} in (2.4) and suddenly we have to load each matrix row only once into cache. The combined routine SmoothFDefect for symmetric matrices is represented in Algorithm 4.

Algorithm 4 SmoothFDefect—Last smoothing sweep and defect calculation for symmetric matrices in CRS.

```
for all i = 1,...,n do
  r ⟵ f_i − Σ_{j=1}^{i−1} K_ij ũ_j
  inv ⟵ 1.0/K_ii
  v ⟵ r − Σ_{j=i+1}^{n} K_ij u_j
  ũ_i ⟵ v ∗ inv
  d_i ⟵ r − v
  for all j = 1,...,i − 1 do
    d_j ⟵ d_j − K_ij ũ_i
  end for
end for
```

2.4. Special initial solution for the first smoother sweep. The correction on the coarse grid $\underline{w}_{q+1}$ is set to zero before the MG-procedure for the next coarser level is called in Algorithm 2. This means that the recursive procedure $\mathrm{MG}(\{K_j, P_j\}_{j=1}^{\ell}, \underline{u}_q, \underline{f}_q, q)$ will get $\underline{u}_q = 0$ as a parameter and also as the initial solution for the first presmoothing sweep on that coarser level. This allows us to simplify iteration (2.2) to

$$\widetilde{u}_i \;=\; K_{ii}^{-1}\left(f_i - \sum_{j=1}^{i-1} K_{ij}\widetilde{u}_j\right), \tag{2.5}$$

which saves half of the arithmetic and memory operations and can be implemented in a routine SmoothF0.

Investigations on smoothers for two-dimensional (2D) tensor product grids with 5-point stencil discretization [31, 15] showed that merging three to five red-black Gauss–Seidel smoothing sweeps into one subroutine can accelerate the overall smoothing time by a factor of 2 to 3 on one of our target architectures (SGI OCTANE). But the latter requires combining five or more smoothing sweeps. Similar work on unstructured FE-meshes [6] achieved speedups in the range of 1.6 to 2. From our experiences with three-dimensional (3D) unstructured FE-meshes, it does not pay off to use more than two Gauss–Seidel iterations in the pre- as well as in the postsmoothing for simple potential problems. Therefore in our experiments we used a multigrid V-cycle with only one presmoothing and one postsmoothing sweep. This allows us to combine (2.5)

with (2.3) on coarser levels to obtain

$$\widetilde{u}_i = K_{ii}^{-1} \underbrace{\left(f_i - \sum_{j=1}^{i-1} K_{ij} \widetilde{u}_j \right)}_{=:v=:r},$$

$$d_i = - \sum_{j=i+1}^{n} K_{ij} \widetilde{u}_i,$$

resulting in NZE arithmetic operations and memory accesses when the only smoothing sweep is combined with the defect calculation in a routine SmoothF0Defect. The realization of SmoothF0 and SmoothF0Defect can be easily derived from Algorithm 4; the latter profits again from the matrix symmetry.

In order to replace SmoothF and Defect in Algorithm 2, the general routine SmoothDef$(K_q, \underline{u}_q, \underline{f}_q, \underline{d}_q, \nu, q)$ for merging smoothing and defect calculation on all levels has to take into account the implementation differences regarding the number ν of smoothing sweeps and the actual level q. The initial correction $\underline{u}_q$ on the coarser grids ($q > 1$) is always zero, but we have to assume an arbitrary nonzero initial guess for the solution $\underline{u}_1$ on the fine grid. Replacing SmoothF and Defect in Algorithm 2 with SmoothDef results in a fast MG-procedure.

Remark 2.1.

K_q NZE$_q$ q
NZE$_q$ N_q^2
$2 \cdot$ NZE$_q$ NZE$_q$

2.5. Coarse grid solver. Another important ingredient of AMG methods is the coarse grid solver. Since the average number of nonzero entries is growing on coarser levels in general, the application of a sparse solver becomes more and more expensive, and in addition the overall convergence rate of the AMG method worsens. Thus we like to construct a minimal number of levels ℓ. On the other side, the factorization of the coarse matrix using a sparse direct solver is relatively slow compared to the setup of AMG for many unknowns N_ℓ. Consequently, we have to find a compromise for when to stop the AMG coarsening process. In two dimensions we apply a sparse direct solver up to 50,000 unknowns, and the 3D limit is 10,000 unknowns. The package SuperLU [3] is used as a sparse direct solver in our applications.

3. Multiple right-hand sides. The second part of the paper concerns the efficient treatment of multiple right-hand sides. We discuss two different methods. The first is related to cache aware algorithms, and in principle a linear system with several right-hand sides is solved simultaneously. Therefore we need a special memory treatment of the right-hand sides. The other technique is related to the preconditioned CG method, where the previous technique is also applied.

3.1. Simultaneous right-hand sides. The idea behind this method simply consists of solving several equations at the same time independently of potential right-hand side correlations. Thus this method is well suited if the right-hand sides can be calculated in advance. The system matrix K_h remains the same, and so we change the code such that BLOCKSIZE systems of equations can be solved at the same time; see Algorithm 5.

Algorithm 5 Blocked loop for BLOCKSIZE right-hand sides.

```
for all s = 1, 1 + BLOCKSIZE, 1 + 2 * BLOCKSIZE, ..., N_r do
  ⋮
  for all k = s, ..., s + BLOCKSIZE − 1 do
    Solve K_h u_h^k = f_h^k
  end for
  ⋮
end for
```

The innermost loop in Algorithm 5 can be expressed as

$$\text{blockdiag}\{K_h\}\left(\underline{u}_h^k\right)_{k=s}^{s+\text{BLOCKSIZE}-1} \;=\; \left(\underline{f}_h^k\right)_{k=s}^{s+\text{BLOCKSIZE}-1} \quad ;$$

i.e., there is a chance to handle all BLOCKSIZE right-hand sides and solution vectors at the same time accessing the (unstructured) matrix K_h only once per matrix-vector operation inside the preconditioned CG (PCG) solution method used for solving the systems of equations. Let us have a look at two possible implementations of the matrix-vector operation where the matrix is stored in CRS format pointing to the end of the row; see Figure 2.2. First, we store BLOCKSIZE vectors separately as represented in Algorithm 6.

Algorithm 6 $\left(\underline{v}^k\right) \longleftarrow K \cdot \left(\underline{u}^k\right)$ with BLOCKSIZE separate vectors.

```
for all i = 1, 2, ..., size do                          {# rows in matrix}
  j1 = iend[i-1]+1 , j2 = iend[i]                       {begin, end of row}
  for all k = 1, 2, ..., BLOCKSIZE do
    v[i][k] = 0.0
  end for
  for all j = j1, j1 + 1, ..., j2 do
    jj = indx[j]                                        {column pointer}
    aij = val[j]                                        {matrix entry}
    for all k = 1, 2, ..., BLOCKSIZE do
      v[i][k] += aij * u[jj][k]
    end for
  end for
end for
```

Second, we store the first entries of all BLOCKSIZE vectors followed by the second entries; i.e., we merge the arrays. Together with a loop interchange, this should result in a better cache performance according to [11, section 5.5]. The implementation with block vectors is realized in Algorithm 7.

Both algorithms require the same number of memory accesses, and each matrix element is used BLOCKSIZE times in the innermost loop. But the block vector version in Algorithm 7 is much better suited for state-of-the-art processors since more useful data is found in one cache line; see also Figure 3.1 for illustration.

Algorithm 7 $\left(\underline{v}^k\right) \longleftarrow K \cdot \left(\underline{u}^k\right)$ with block vectors.

```
for all i = 1,2,...,size do                          {# rows in matrix}
  j1 = iend[i-1]+1 , j2 = iend[i]                    {begin, end of row}
  ii = (i-1)*BLOCKSIZE
  for all k = 1,2,...,BLOCKSIZE do
    v[ii+k] = 0.0
  end for
  for all j = j1, j1+1, ..., j2 do
    jj = (indx[j]-1)*BLOCKSIZE                       {column pointer}
    aij = val[j]                                     {matrix entry}
    for all k = 1,2,...,BLOCKSIZE do
      v[ii+k] += aij * u[jj+k]
    end for
  end for
end for
```

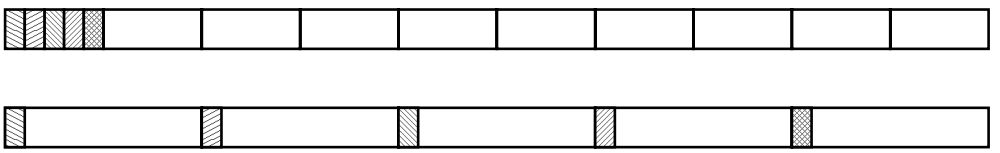

FIG. 3.1. *Storage scheme for separate vectors (bottom) and block vectors (top).*

The indirect addressing of vectors $\underline{u}_m$ via the column pointer causes misprefetching of data for the cache so that the cache lines have to be reloaded. In that case Algorithm 6 has to reload BLOCKSIZE-1 times more cache lines than Algorithm 7. Therefore, Algorithm 7 has a higher cache hit rate than Algorithm 6 and is faster at the end.

The changes in the CG algorithm are not dramatic. One should only be aware that the scalars of the CG algorithm will be represented by small vectors containing BLOCKSIZE scalars. The original stopping criterion for the CG tests the relative error with respect to the given tolerance. Now, we have to guarantee that each of the BLOCKSIZE errors is less than the tolerance. The simultaneous calculation of the inner product can be seen in Algorithm 8.

Algorithm 8 Inner products $(\alpha^k)_{k=1}^{\text{BLOCKSIZE}} \longleftarrow \left\langle \left(\underline{u}^k\right), \left(\underline{v}^k\right) \right\rangle$.

```
for all k = 1,2,...,BLOCKSIZE do
  α[k] = 0.0
end for
for all i = 0,1,...,size-1 do
  ii = i*BLOCKSIZE
  for all k = 1,2,...,BLOCKSIZE do
    α[k] += v[ii+k]*u[ii+k]
  end for
end for
```

Similar changes as in Algorithm 7 have to be made in the MG-components smoothing, defect calculation, interpolation, and prolongation.

3.2. Preconditioned Lanczos–Galerkin projection methods. While the multiple right-hand side method does not assume any information on the right-hand side properties, i.e., they are completely independent from each other, the second strategy profits from the speculation or the potential knowledge that sequencing right-hand sides are close to each other in a certain sense. Typically such problem setting arises from time-dependent equations where the right-hand sides most often vary slowly in time. We study the method of [26, 29], where a Lanczos method was used to derive a technique for the solution of a linear system with multiple right-hand sides. The condition number $\kappa(K_h) = \frac{\lambda_{\max}(K_h)}{\lambda_{\min}(K_h)}$ of the linear systems we are interested in behaves like $\mathcal{O}(h^{-2})$ as h tends to zero, where h denotes the typical mesh length of an FE-discretization. Thus the matrices are ill-conditioned, and therefore a CG method would require many iterations in order to solve the linear system up to a relative accuracy ϵ.

In order to circumvent this problem we use a preconditioner C_h which is optimal with respect to memory and arithmetic costs. Consequently, a constant number of iterations is required in order to solve a linear equation up to a fixed relative accuracy ϵ. Let us assume that the linear system (1.1) is preconditioned by C_h and we have $N_r = 2$, i.e.,

$$C_h^{-1/2} K_h C_h^{-1/2} \underline{v}_h^i = C_h^{-1/2} \underline{f}_h^i, \qquad \underline{u}_h^i = C_h^{-1/2} \underline{v}_h^i, \qquad i = 1, 2.$$

Using the abbreviations $B_h = C_h^{-1/2} K_h C_h^{-1/2}$ and $\underline{g}_h^i = C_h^{-1/2} \underline{f}_h^i$, we can apply the original technique of [26, 29] to the equations

$$B_h \underline{v}_h^i = \underline{g}_h^i, \qquad i = 1, 2\,. \tag{3.1}$$

The CG method applied to (3.1) and $i = 1$ produces after m steps a Krylov subspace

$$\mathcal{K}_m(B_h, \underline{z}_h^{1,0}) = \operatorname{span}\{B_h^0 \underline{z}_h^{1,0}, B_h \underline{z}_h^{1,0}, \ldots, B_h^{m-1} \underline{z}_h^{1,0}\}$$

with $\underline{z}_h^{1,0} = \underline{g}_h^1 - B_h \underline{v}_h^{1,0}$, $\underline{v}_h^{1,0} \equiv 0$. Furthermore, the quantities of the Lanczos method are written down for the original linear system (1.1). The approximative solution $\underline{u}_h^{1,m}$ of the original system (1.1) can be written in the form

$$\underline{u}_h^{1,m} = \sum_{i=0}^{m-1} \beta_i^1 \cdot C_h^{-1} \underline{r}_h^{1,i}$$

with $\underline{r}_h^{1,i} = K_h^i \underline{r}_h^{1,0}$, $\underline{r}_h^{1,0} = \underline{f}_h^1$. The coefficients β_i^j are calculated via the formula

$$\beta_i^j = (T_m^{-1} \alpha^j)_i, \qquad j = 1, 2\,, \tag{3.2}$$

where $T_m \in \mathbb{R}^{m \times m}$ is the tridiagonal matrix arising from the Lanczos process; see, e.g., [26, 29]. The vector $\alpha^j \in \mathbb{R}^m$ is calculated by

$$\alpha_i^j = \frac{\langle C_h^{-1} \underline{r}_h^{1,i}, \underline{f}_h^j \rangle}{\langle C_h^{-1} \underline{r}_h^{1,i}, \underline{r}_h^{1,i} \rangle}, \qquad j = 1, 2\,. \tag{3.3}$$

For further considerations let $\underline{f}_h^2$ be another right-hand side for (1.1). Since $\underline{f}_h^1$ and $\underline{f}_h^2$ are assumed to be close to each other, we perform the Galerkin projection onto $\mathcal{K}_m(B_h, \underline{z}_h^{1,0})$ of $\underline{f}_h^2$, i.e.,

$$\tilde{\underline{f}}_h^2 = \sum_{i=0}^{m-1} \alpha_i^2 \cdot \underline{r}_h^{1,i}\,,$$

with α_i^2 defined in (3.3). Consequently we get an approximate solution $\tilde{\underline{u}}_h^2$ for the solution of (1.1) in the form

$$\tilde{\underline{u}}_h^2 = \sum_{i=1}^{m-1} \beta_i^2 \cdot C_h^{-1} \underline{r}_h^{1,i}$$

with right-hand side $\underline{f}_h^2$ with β_i^2 defined in (3.2). From a heuristical point of view, $\tilde{\underline{u}}_h^2$ is a good approximation to $\underline{u}_h^2$ if the right-hand sides $\underline{f}_h^1$ and $\underline{f}_h^2$ are close. A rigorous analysis and algorithms are given in [26, 29, 2].

Without an optimal preconditioner C_h, the required basis might be very large, and therefore the memory requirements are unacceptable. But with an optimal preconditioner as, e.g., AMG, the required basis is very small. However we have to store $2 \cdot m$ vectors in $\mathbb{R}^{N_h}$, namely, $\{C_h^{-1} \underline{r}_h^{1,i}\}_{i=0}^{m-1}$ and $\{\underline{r}_h^{1,i}\}_{i=0}^{m-1}$. For the efficient calculation of the Galerkin projection we use the presented memory management for multiple vectors. In this way cache can be used efficiently. In order to perform a stable Galerkin projection we use the modified Gram–Schmidt algorithm (see [29]).

If the right-hand sides can be calculated in advance, then no storage of the Krylov basis is required [26, 29, 2].

4. Numerical studies. The presented methods are implemented in the AMG software package PEBBLES [22]. We always applied one symmetric V-cycle with one pre- and one postsmoothing step as preconditioner C_h. The CG iteration was stopped when a relative error reduction of ϵ had been achieved in the $\| \cdot \|_{KC^{-1}K}$-norm.

We used the C++ MIPSpro Compiler, Version 7.30, with the compiler options
`-64 -mips4 -r10000 -Ofast=ip27 -LNO:pf2=on:prefetch=2`
`-OPT:IEEE_arithmetic=3:roundoff=3:alias=RESTRICT -IPA`.
on OCTANE and ORIGIN running under IRIX 6.5. Adapting the options to the 400 MHz R14000 MIPS-processor on the SGI ORIGIN 3800 did not influence the run time too much. The processor possesses a 32 KB L1 data cache with 64 byte cache lines and a 4 MB L2 cache with 128 byte cache lines. Both caches are two-way set associative, and they use the least recently used (LRU) replacement policy. The SGI Octane-workstation (195MHz R10000) has a 1MB L2 cache with 128 byte cache lines and a 32 KB L1 data cache using 32 byte cache lines. The LINUX computer consisted of a 1.5 GHz AMD Athlon processor with a 256 kB L2 cache and a 64 kB L1 data cache both using 64 byte cache lines. We used the distribution by S.u.S.e. (version 7.1) as operating system and the g++ (gcc) compiler, Version 2.95, with the compiler options `-O3 -m486 -ffast-math`. Again, we tried several fancy options without any further gain in CPU-time.

The Lanczos–Galerkin approach from section 3.2 has been tested only on the LINUX system because its speedup is caused only by the reduction of the iteration numbers and not by hardware characteristics.

4.1. A 2D case study: Simultaneous right-hand sides. The first test example is concerned with the potential equation on the unit square and zero Dirichlet boundary conditions on one side of the square. On the remaining boundary we assume homogeneous Neumann boundary conditions. For an FE-discretization we use bilinear FE-functions on the equidistant grid. The right-hand sides are assumed to be of the form

$$(\underline{f}_h^i)_j = \sum_{k=0}^{n} \delta_{i,j+k} \cdot \zeta_k, \quad \zeta_k \neq 0\,, \qquad i = 1, \ldots, N_r, \quad j = 1, \ldots, N_h,$$

which are linear dependent if $n < N_r$. δ_{ij} denotes the Kronecker symbol.

First we study the method of simultaneous right-hand sides (see subsection 3.1) and fix the number of unknowns by $N_h = 90,000$. The memory required for storing all matrices and vectors is approximately 15MB + BLOCKSIZE*10MB. Since we do not need assumptions on the right-hand sides, we fix $n = N_r = \text{BLOCKSIZE}$ and $\zeta_k = 1$, $k = 0, \ldots, n$. The linear equation is solved up to a relative accuracy $\epsilon = 10^{-8}$. The performance gain with respect to simultaneous right-hand sides can be seen in Figure 4.1.

The first observation is that we get a rapid speedup for BLOCKSIZE = 5 and that the saturation effect starts at BLOCKSIZE = 20; i.e., it makes no sense to use more than 20 simultaneous right-hand sides. The gap between the graphs for OCTANE and ORIGIN is caused by the larger secondary cache on the SGI ORIGIN machine so that the cache hit rate was already better for the original code on it. The smaller caches on the LINUX computer moved the saturation point there to BLOCKSIZE = 5.

The speedups for the manually unrolled loops are significantly better than the normal speedups. Therefore, it is worthwhile to take some time implementing it for special applications. The large speedup difference for the LINUX computer may be caused by some weakness in the optimization strategy of the gcc compiler.

The speedup is only a measure of improving a code on a certain computer. The most interesting question is the CPU-time for solving a problem. Figure 4.2 presents the time for solving the systems of equations (1.1) resulting from our test example.

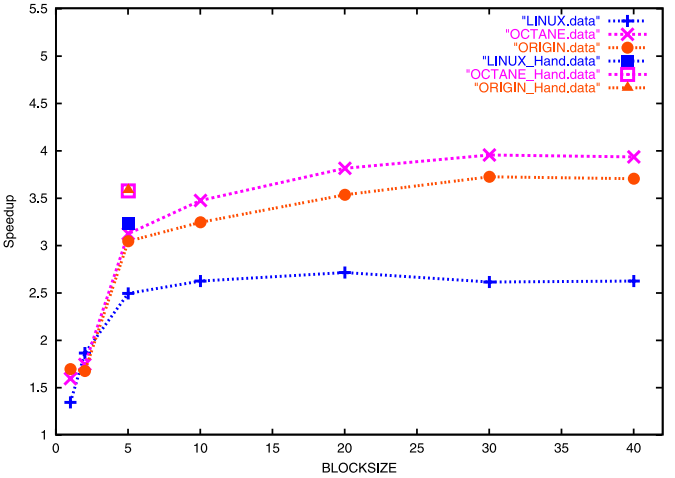

FIG. 4.1. *Overall performance gain with respect to simultaneous right-hand sides.*

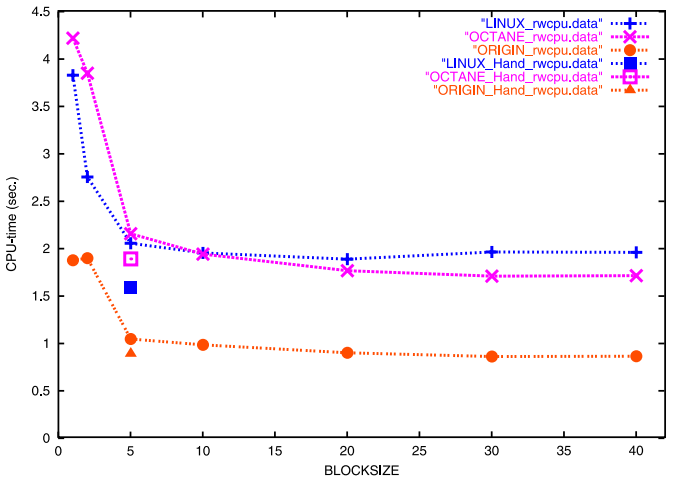

FIG. 4.2. *CPU-time per system of equations with respect to simultaneous right-hand sides.*

The performance gain due to the improved memory management and algorithmic improvements from section 2 can be also seen in Figure 4.1 as performance gain for one right-hand side. This sequential improvement is 1.7 on the ORIGIN, at little less than 1.6 on the OCTANE workstation, and it reduces to 1.4 on the LINUX computer. We did the tuning on the OCTANE computer for 90,000 unknowns, i.e., approximately 25 MB of data, due to the improved memory management and algorithmic improvements from section 2. These acceleration factors were mainly achieved by reducing the cache misses which improved the ratio of arithmetics to data transfer.

4.2. A 2D case study: Multiple right-hand sides. In contrast to the previous section we now consider a time-dependent problem but solve the sequence of arising equations with the technique of subsection 3.2. Let us assume the discretization of a parabolic equation on the unit square with implicit time-stepping and appropriate

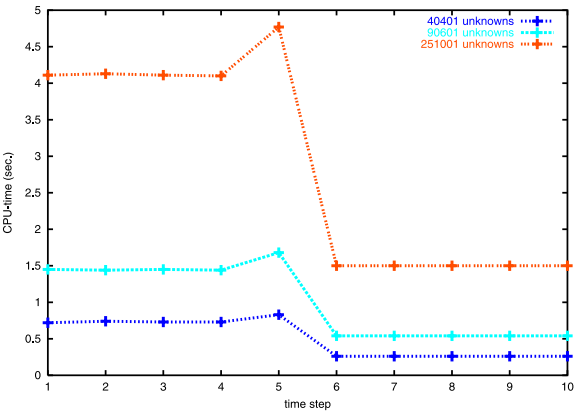

FIG. 4.3. *CPU-time for* 10 *time steps.*

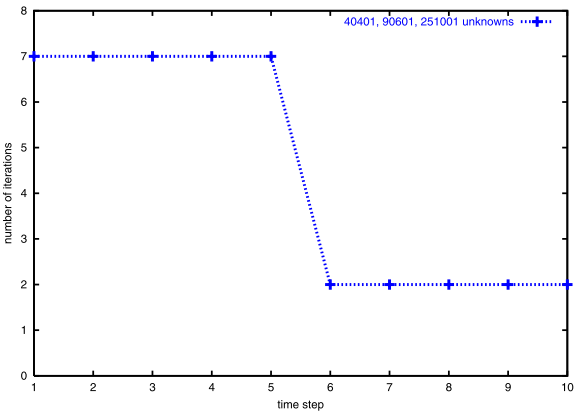

FIG. 4.4. *Number of iterations for* 10 *time steps.*

boundary and initial conditions. Thus we get

$$(\Delta t \cdot K_h + M_h)\underline{u}_h^{i+1} = \underline{f}_h^i$$

with K_h the stiffness matrix, M_h the mass matrix, and Δt the time increment. The right-hand sides have the form

$$(\underline{f}_h^i)_j = \Delta t / N_h - (M_h \underline{u}_h^i)_j,$$

where i denotes the time step. This problem is solved up to a relative accuracy $\epsilon = 10^{-6}$, and $\Delta t = 10^{-1}$.

The required CPU-time and the number of iterations for the time-dependent problem using the Lanczos–Galerkin technique are depicted in Figures 4.3 and 4.4. The overall CPU-time for the solution of the problem with 40,401, 90,601, and 251,001 unknowns is 5.05 seconds, 10.14 seconds, and 28.73 seconds on the LINUX system, respectively. The OCTANE system would result in a similar run time behavior. If we solved the problem without the projection technique, the required CPU-time would be significantly larger, especially for growing N_h. We observed acceleration factors up to 10–20 depending on the problem. Again the optimal AMG preconditioner is required to be h-independent.

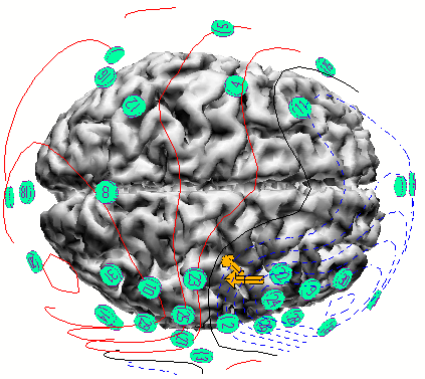

FIG. 4.5. *Dipole fit in the human brain.*

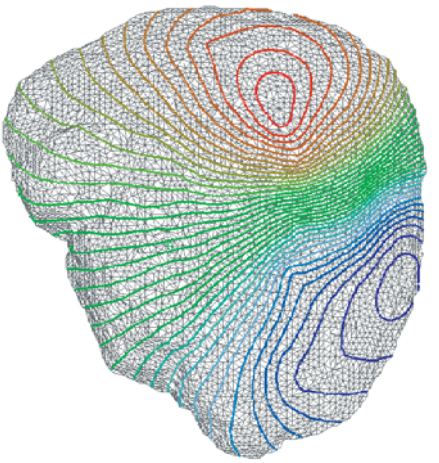

FIG. 4.6. *Solution of one dipole from an FE-discretization.*

4.3. Inverse source localization in the human brain. Finally we present a real life problem for which the technique of simultaneous right-hand sides (see subsection 3.1) is applied. The usage of the techniques is reported for the inverse source localization in the human brain[1] [36]. First, numerical studies of the behavior of our AMG solver applied to this problem are presented in [35, 34].

The problem setting is as follows. In order to determine sources in the human brain from given measurements, a system of linear equations has to be solved for approximately 10,000 right-hand sides within a certain inverse toolbox. The underlying anisotropic potential equation is discretized by the FE-method. The human head is discretized by tetrahedral finite elements, and its mesh contains 118,299 nodes. The resulting stiffness matrix has 1,815,991 nonzero elements. This sums to approximately 40MB + BLOCKSIZE*15MB for storing all matrices and vectors. The rather large number of right-hand sides that must be investigated in the inverse problem is caused by data measurements via magnetoencephalography (MEG) [36, 8, 32, 27, 34]. There exist very good techniques for data from electroencephalography (EEG) that significantly reduce the number of direct problems under consideration [18, 17, 13, 19, 30], and recent research shows that similar techniques can also be applied to MEG [33].

In Figure 4.5 the principle structure of the problem and the computational domain are presented. In Figure 4.6 a typical solution is given for one specific right-hand side. The system of equations with 118,299 unknowns with one right-hand side is solved in 10 seconds on the LINUX and the OCTANE systems, and in 5 seconds on the ORIGIN. The same system of equations with five right-hand sides and manual loop unrolling is solved in 22–23 seconds on LINUX/OCTANE and in 10.5 seconds on the ORIGIN.

Let us assume we could solve a bigger problem on a single processor computer in 50 seconds. From Figure 4.8 (and Figure 4.7) we see that we get a speedup of 2.3 for this real life problem. Equivalently, one right-hand side can be solved in about 21 seconds. Both figures concentrate on the performance gain by simultaneous right-hand sides without the additional acceleration by algorithmic improvements from section 2.

5. Conclusion and further remarks. In this paper we give an overview on cache aware techniques for the solution of linear systems with multiple right-hand sides. We have shown that a good AMG preconditioner for the PCG method improves the projection techniques in a straightforward way. Moreover, we can use cache effects from section 3.1 in the case of simultaneous right-hand sides if the vectors are known in advance. Here, the acceleration by these cache effects reaches a factor of 4. The multiple right-hand side approach from section 3.2 is much better suited for an a priori unknown sequence of right-hand sides as can be seen in the experiments in section 4.2.

A straightforward step is the parallelization of the proposed techniques in order to gain the required overall speedup for real life applications [24].

AUGMENTED IMPLICITLY RESTARTED LANCZOS BIDIAGONALIZATION METHODS*

JAMES BAGLAMA† AND LOTHAR REICHEL‡

Dedicated to Henk van der Vorst on the occasion of his 60th birthday

Abstract. New restarted Lanczos bidiagonalization methods for the computation of a few of the largest or smallest singular values of a large matrix are presented. Restarting is carried out by augmentation of Krylov subspaces that arise naturally in the standard Lanczos bidiagonalization method. The augmenting vectors are associated with certain Ritz or harmonic Ritz vectors. Computed examples show the new methods to be competitive with available schemes.

Key words. singular value computation, partial singular value decomposition, iterative method, large-scale computation

DOI. 10.1137/04060593X

1. Introduction.

Many problems in scientific computation require knowledge of a few of the largest or smallest singular values of a matrix and associated left and right singular vectors. These problems include the approximation of a large matrix by a matrix of low rank, the computation of the null space of a matrix, total least-squares problems (see, e.g., Björck [4, sections 4.6 and 7.6.5]), as well as the tracking of signals; see, e.g., Comon and Golub [8] for a discussion of the latter.

Let $A \in \mathbb{R}^{\ell\times n}$ be a large sparse matrix. We may assume that $\ell \geq n$, because otherwise we replace the matrix by its transpose. Let

$$\sigma_1^{(A)} \geq \sigma_2^{(A)} \geq \cdots \geq \sigma_n^{(A)} \geq 0 \tag{1.1}$$

denote the singular values of A, and let $u_j^{(A)} \in \mathbb{R}^\ell$ and $v_j^{(A)} \in \mathbb{R}^n$, $1 \leq j \leq n$, be associated left and right singular vectors, respectively. Hence,

$$Av_j^{(A)} = \sigma_j^{(A)} u_j^{(A)}, \qquad A^T u_j^{(A)} = \sigma_j^{(A)} v_j^{(A)}, \qquad 1 \leq j \leq n, \tag{1.2}$$

and

$$A = \sum_{j=1}^{n} \sigma_j^{(A)} u_j^{(A)} (v_j^{(A)})^T.$$

The matrices $U_n^{(A)} = [u_1^{(A)}, u_2^{(A)}, \ldots, u_n^{(A)}]$ and $V_n^{(A)} = [v_1^{(A)}, v_2^{(A)}, \ldots, v_n^{(A)}]$ have orthonormal columns. We refer to $\{\sigma_j^{(A)}, u_j^{(A)}, v_j^{(A)}\}$ as a singular triplet of A. Singular

triplets associated with large (small) singular values are referred to as large (small) singular triplets.

This paper presents new restarted Lanczos bidiagonalization methods for computing a few of the largest or smallest singular triplets. The methods compute sequences of projections of A onto judiciously chosen low-dimensional subspaces. Restarting is implemented by augmentation of Krylov subspaces that are determined similarly as in the standard Lanczos bidiagonalization method.

Application of m steps of partial Lanczos bidiagonalization to the matrix A with initial unit vector $p_1 \in \mathbb{R}^n$ yields the decompositions

$$AP_m = Q_m B_m, \tag{1.3}$$

$$A^T Q_m = P_m B_m^T + r_m e_m^T, \tag{1.4}$$

where $P_m \in \mathbb{R}^{n\times m}$, $Q_m \in \mathbb{R}^{\ell\times m}$, $P_m^T P_m = I_m$, $P_m e_1 = p_1$, $Q_m^T Q_m = I_m$, $r_m \in \mathbb{R}^n$, and

$$P_m^T r_m = 0. \tag{1.5}$$

Further, the matrix

$$B_m := \begin{bmatrix} \alpha_1 & \beta_1 & & & & 0 \\ & \alpha_2 & \beta_2 & & & \\ & & \alpha_3 & \beta_3 & & \\ & & & & \ddots & \\ & & & & \ddots & \beta_{m-1} \\ 0 & & & & & \alpha_m \end{bmatrix} \in \mathbb{R}^{m\times m} \tag{1.6}$$

is upper bidiagonal, $I_m \in \mathbb{R}^{m\times m}$ denotes the identity matrix, and e_j denotes the jth axis vector. We refer to the decompositions (1.3)–(1.4) as a partial Lanczos bidiagonalization of A and to the vector r_m in (1.4) as the residual vector; see Björck [4, section 7.6] for a recent discussion on partial Lanczos bidiagonalization. The number of bidiagonalization steps, m, is assumed to be small enough so that the decompositions (1.3)–(1.4) with the stated properties exist.

In applications of interest to us, m is not very large, and the singular triplets $\{\sigma_j^{(B_m)}, u_j^{(B_m)}, v_j^{(B_m)}\}_{j=1}^m$ of B_m can be computed inexpensively by the Golub–Kahan algorithm [10]. Approximate singular triplets of A, denoted by $\{\tilde\sigma_j^{(A)}, \tilde u_j^{(A)}, \tilde v_j^{(A)}\}$, can be determined from the singular triplets of B_m and the matrices P_m and Q_m in the decompositions (1.3)–(1.4); see section 2 for details.

When the matrix A is large, i.e., when ℓ and possibly n are large, the storage requirement of the partial Lanczos bidiagonalization (1.3)–(1.4) is large, unless the number of Lanczos bidiagonalization steps, m, is small. However, for a small value of m, the desired singular triplets of A may be approximated poorly by computed approximate singular triplets $\{\tilde\sigma_j^{(A)}, \tilde u_j^{(A)}, \tilde v_j^{(A)}\}$. In order to circumvent this difficulty, several methods have been proposed that are based on the computation of partial Lanczos bidiagonalizations (1.3)–(1.4) with m small for a sequence of initial vectors p_1; see, e.g., [5, 13, 14, 15, 16, 17, 28]. These methods are commonly referred to as restarted partial Lanczos bidiagonalization methods. We will comment on some of these methods below. They differ in their choice of initial vector p_1 used for the

restarts and in their implementation of the restarting procedure. Ideally, we would like p_1 to be a linear combination of the right singular vectors of A associated with the desired singular values.

Sorensen [29] proposed efficient approaches for restarting the Arnoldi and the Lanczos tridiagonalization procedures. These approaches can be thought of as curtailed QR-algorithms, and, similarly to the QR-algorithms, their performance depends critically on the selection of shifts; see also [1, 7, 21, 30] for discussions and extensions. Björck, Grimme, and Van Dooren [5] derived analogous recursion formulas for a restarted Lanczos bidiagonalization method and presented an application to the solution of ill-posed problems. Recently, Kokiopoulou, Bekas, and Gallopoulos [17] applied these recursion formulas to compute a few desired singular triplets of a large sparse matrix. The shifts are applied by "chasing the bulge" in a curtailed QR-algorithm. Other implementations of restarted Lanczos bidiagonalization are discussed in [13, 14, 15, 16, 28]. The present paper describes mathematically equivalent, but numerically more robust, implementations of the methods discussed by Kokiopoulou, Bekas, and Gallopoulos [17].

This paper is organized as follows. Section 2 reviews Lanczos bidiagonalization and introduces notation used in the remainder of the paper. Section 3 describes our implementations of restarted Lanczos bidiagonalization. Restarting is carried out by augmenting the Krylov subspaces that arise naturally in the standard Lanczos bidiagonalization method by Ritz vectors or harmonic Ritz vectors associated with desired singular triplets. A few computed examples, which compare the performance of several methods and implementations, are presented in section 4.

2. Lanczos bidiagonalization. The following algorithm determines the partial Lanczos bidiagonalization (1.3)–(1.4) of the large sparse matrix $A \in \mathbb{R}^{\ell\times n}$. The number of Lanczos bidiagonalization steps, m, is typically much smaller than either one of the matrix dimensions ℓ and n. Throughout this paper $\|\cdot\|$ denotes the Euclidean vector norm or the associated induced matrix norm. We remark that the methods described can easily be modified to apply to matrices A with complex-valued entries; the main modification required is that the matrices P_m, Q_m, and B_m in (1.3)–(1.4) may have complex-valued entries, and transposition has to be replaced by transposition and complex conjugation. The MATLAB code used for the computed examples of section 4 can be applied to matrices A with complex-valued entries.

ALGORITHM 2.1. LANCZOS BIDIAGONALIZATION.

$A \in \mathbb{R}^{\ell\times n}$
A A^T
$p_1 \in \mathbb{R}^n$:
m :

$P_m = [p_1, p_2, \ldots, p_m] \in \mathbb{R}^{n\times m}$:
$Q_m = [q_1, q_2, \ldots, q_m] \in \mathbb{R}^{\ell\times m}$:
$B_m \in \mathbb{R}^{m\times m}$: (1.6) α_j β_j
$r_m \in \mathbb{R}^n$:

1 $P_1 := p_1$. $q_1 := Ap_1$.
2 $\alpha_1 := \|q_1\|$. $q_1 := q_1/\alpha_1$. $Q_1 := q_1$.
3 $j = 1 : m$
4 $r_j := A^T q_j - \alpha_j p_j$.

5 [illegible] $r_j := r_j - P_j(P_j^T r_j)$.
6 [illegible] $j < m$ [illegible]
7 $\beta_j := \|r_j\|$. $p_{j+1} := r_j/\beta_j$. $P_{j+1} := [P_j, p_{j+1}]$.
8 $q_{j+1} := Ap_{j+1} - \beta_j q_j$.
9 [illegible] $q_{j+1} := q_{j+1} - Q_j(Q_j^T q_{j+1})$.
10 $\alpha_{j+1} := \|q_{j+1}\|$. $q_{j+1} := q_{j+1}/\alpha_{j+1}$. $Q_{j+1} := [Q_j, q_{j+1}]$.
11 [illegible]
12 [illegible]

When the computations with Algorithm 2.1 are carried out in finite precision arithmetic and the columns of P_m and Q_m are not reorthogonalized, the computed columns might be far from orthogonal. We therefore reorthogonalize the columns of these matrices in lines 5 and 9 of the algorithm.

Several reorthogonalization strategies for the columns of the matrices P_m and Q_m are discussed in the literature. Larsen [18] found that when m is fairly large and one is interested in computing a few of the largest singular triplets of A, partial reorthogonalization gives comparable accuracy and requires less computational work than full reorthogonalization, but when a few of the smallest singular triplets are desired, often (essentially) full reorthogonalization is required to achieve high accuracy. Wu and Simon [33] report that when m is not large, full reorthogonalization should be carried out, because due to the overhead associated with partial reorthogonalization, the latter is not competitive. Moreover, Simon and Zha [28] show that when the matrix A is not very ill-conditioned, only the columns of one of the matrices P_m or Q_m need to be reorthogonalized. Reorthogonalization of the columns of P_m only can reduce the computational effort required to compute the partial Lanczos bidiagonalization (1.3)–(1.4) considerably when $\ell \gg n$. Algorithm 2.1 can easily be modified to implement the latter approach.

The Lanczos bidiagonalization algorithm (Algorithm 2.1) requires the diagonal entries $\alpha_j > 0$, $1 \leq j \leq m$, as well as the superdiagonal entries β_j, $1 \leq j < m$, of B_m to be nonvanishing. Assume for the moment that $\alpha_j > 0$ for $1 \leq j < m$, and $\alpha_m = 0$. Then the vector q_m determined in line 8 of the algorithm vanishes, and the decompositions (1.3)–(1.4) can be expressed as

$$AP_m = Q_{m-1}B_{m-1,m}, \qquad A^T Q_{m-1} = P_m B_{m-1,m}^T,$$

where $B_{m-1,m}$ denotes the leading $(m-1) \times m$ submatrix of B_m. It follows that A is singular and that the singular values of $B_{m-1,m}$ are singular values of A. The associated singular triplets of A can be determined from P_m, Q_{m-1}, and the singular triplets of $B_{m-1,m}$. The singular values of $B_{m-1,m}$ are nonvanishing. Moreover, the right singular vector of A associated with the zero singular value can be expressed as a linear combination of the columns of P_m, e.g., by using the singular value decomposition of B_m. However, the corresponding left singular vector of A is not readily available. For simplicity, we will in the remainder of this paper assume that all α_j are positive.

It follows from Algorithm 2.1 that β_m, the last superdiagonal element of the upper bidiagonal matrix $B_{m+1} \in \mathbb{R}^{(m+1)\times(m+1)}$ obtained by $m+1$ steps of partial Lanczos bidiagonalization, is given by

$$\beta_m := \|r_m\| \tag{2.1}$$

and therefore can be computed when the decompositions (1.3)–(1.4) are available. We may assume that $\beta_m > 0$, because otherwise the singular values of B_m are singular

values of A, and the associated singular triplets of A can be determined from the singular value decomposition of B_m and the matrices P_m and Q_m. If $\beta_m = 0$ and the determined singular triplets of A include all the desired ones, then we are done; otherwise we proceed to compute additional singular triplets by the methods described in this paper.

When $\beta_m > 0$, the last column of $P_{m+1} := [P_m, p_{m+1}]$ is given by

$$p_{m+1} := r_m/\beta_m, \tag{2.2}$$

and the relation (1.4) can be expressed as

$$A^T Q_m = P_{m+1} B_{m,m+1}^T, \tag{2.3}$$

where the matrix $B_{m,m+1} \in \mathbb{R}^{m\times(m+1)}$ is obtained by appending the column $\beta_m e_m$ to B_m. In particular, the matrices in the decomposition (2.3) are available after m Lanczos bidiagonalization steps. We also note that $B_{m,m+1}$ is the leading $m \times (m+1)$ submatrix of the matrix B_{m+1} obtained after $m+1$ steps of Lanczos bidiagonalization.

We will use the connection between partial Lanczos bidiagonalization (1.3)–(1.4) of A and partial Lanczos tridiagonalization of the matrix $A^T A$. Multiplying (1.3) by A^T from the left-hand side yields

$$A^T A P_m = P_m B_m^T B_m + r_m e_m^T B_m = P_m B_m^T B_m + \alpha_m r_m e_m^T, \tag{2.4}$$

where the last equality follows from the fact that B_m is upper bidiagonal. The matrix

$$T_m := B_m^T B_m \in \mathbb{R}^{m\times m} \tag{2.5}$$

is symmetric and tridiagonal, and the expression (2.4) is a partial Lanczos tridiagonalization of $A^T A$ with initial vector $p_1 = P_m e_1$; see, e.g., [11, section 9.1.2] for a discussion on Lanczos tridiagonalization. Since T_m is tridiagonal, (2.4) shows that the columns of P_m satisfy a three-term recurrence relation; the columns form an orthonormal basis of the Krylov subspace

$$\mathbb{K}_m(A^T A, p_1) = \operatorname{span}\{p_1, A^T A p_1, (A^T A)^2 p_1, \ldots, (A^T A)^{m-1} p_1\}. \tag{2.6}$$

Similarly, multiplying (1.4) by A from the left-hand side yields

$$A A^T Q_m = Q_m B_m B_m^T + A r_m e_m^T. \tag{2.7}$$

The columns of Q_m form an orthonormal basis of the Krylov subspace

$$\mathbb{K}_m(A A^T, q_1) = \operatorname{span}\{q_1, A A^T q_1, (A A^T)^2 q_1, \ldots, (A A^T)^{m-1} q_1\} \tag{2.8}$$

with $q_1 := A p_1$. We remark that since the columns of Q_m are not, in general, orthogonal to $A r_m$, the decomposition (2.7) typically is not a Lanczos tridiagonalization of $A A^T$.

Let $\{\sigma_j^{(B_m)}, u_j^{(B_m)}, v_j^{(B_m)}\}$, $1 \le j \le m$, be the singular triplets of B_m enumerated so that

$$\sigma_1^{(B_m)} \ge \sigma_2^{(B_m)} \ge \cdots \ge \sigma_m^{(B_m)} \ge 0. \tag{2.9}$$

Then, analogously to (1.2),

$$B_m v_j^{(B_m)} = \sigma_j^{(B_m)} u_j^{(B_m)}, \qquad B_m^T u_j^{(B_m)} = \sigma_j^{(B_m)} v_j^{(B_m)}, \qquad 1 \le j \le m, \tag{2.10}$$

and the $m \times m$ matrices of left and right singular vectors

$$U_m^{(B_m)} := [u_1^{(B_m)}, u_2^{(B_m)}, \ldots, u_m^{(B_m)}], \qquad V_m^{(B_m)} := [v_1^{(B_m)}, v_2^{(B_m)}, \ldots, v_m^{(B_m)}]$$

are orthogonal.

We determine approximate singular triplets $\{\tilde{\sigma}_j^{(A)}, \tilde{u}_j^{(A)}, \tilde{v}_j^{(A)}\}$, $1 \le j \le m$, of A from the singular triplets of B_m by

$$\tilde{\sigma}_j^{(A)} := \sigma_j^{(B_m)}, \qquad \tilde{u}_j^{(A)} := Q_m u_j^{(B_m)}, \qquad \tilde{v}_j^{(A)} := P_m v_j^{(B_m)}. \tag{2.11}$$

Combining (2.10) with (1.3)–(1.4) shows that

$$A\tilde{v}_j^{(A)} = \tilde{\sigma}_j^{(A)} \tilde{u}_j^{(A)}, \quad A^T \tilde{u}_j^{(A)} = \tilde{\sigma}_j^{(A)} \tilde{v}_j^{(A)} + r_m e_m^T u_j^{(B_m)}, \quad 1 \le j \le m. \tag{2.12}$$

The equations (2.12) suggest that an approximate singular triplet $\{\tilde{\sigma}_j^{(A)}, \tilde{u}_j^{(A)}, \tilde{v}_j^{(A)}\}$ be accepted as a singular triplet of A if $r_m e_m^T u_j^{(B_m)}$ is sufficiently small. Specifically, our numerical method accepts $\{\tilde{\sigma}_j^{(A)}, \tilde{u}_j^{(A)}, \tilde{v}_j^{(A)}\}$ as a singular triplet of A if

$$\beta_m |e_m^T u_j^{(B_m)}| \le \delta \|A\| \tag{2.13}$$

for a user-specified value of δ, where we have used (2.1). The quantity $\|A\|$ in (2.13) is easily approximated by the singular value $\sigma_1^{(B_m)}$ of largest magnitude of the bidiagonal matrix B_m. The computation of $\sigma_1^{(B_m)}$ is inexpensive because the matrix B_m is small. During the computations of the desired singular triplets of A, typically, several matrices B_m and their singular value decompositions are computed. We approximate $\|A\|$ by the largest of the singular values of all the matrices B_m generated. This generally gives a good estimate of $\|A\|$.

3. Augmented Lanczos bidiagonalization methods. It is well known that the implicitly restarted Arnoldi and Lanczos tridiagonalization methods described by Sorensen [29] can suffer from numerical instability due to propagated round-off errors. The instability can delay or prevent convergence of desired eigenvalues and eigenvectors; see Lehoucq and Sorensen [21] for a discussion and remedies. Morgan [25] showed that the implicitly restarted Arnoldi method by Sorensen [29] can be implemented by augmenting the available Krylov subspace basis by certain Ritz vectors. Such an implementation can be less sensitive to propagated round-off errors than the implementation in [29]. Recently, Wu and Simon [33] described a so-called thick-restarted Lanczos tridiagonalization method for the symmetric eigenvalue problem. The method is based on augmenting Krylov subspaces by certain Ritz vectors; it is simple to implement and is mathematically equivalent to the implicitly restarted Lanczos tridiagonalization method of Sorensen [29]. This paper presents thick-restarted Lanczos bidiagonalization methods. We remark that thick-restarting techniques have also been used in the context of the Jacobi–Davidson and Arnoldi methods for eigenvalue computations; see Stathopoulos and Saad [31] and Stathopoulos, Saad, and Wu [32] for discussions and analyses.

3.1. Augmentation by Ritz vectors. Let the partial Lanczos bidiagonalization (1.3)–(1.4) be available, and assume that we are interested in determining the k largest singular triplets of A, where $k < m$. Note that the approximate right singular

vector $\tilde{v}_j^{(A)}$ of A, defined by (2.11), is a Ritz vector of A^TA associated with the Ritz value $(\tilde{\sigma}_j^{(A)})^2$. We have

$$A^TA\tilde{v}_j^{(A)} - (\tilde{\sigma}_j^{(A)})^2\tilde{v}_j^{(A)} = \alpha_m r_m e_m^T v_j^{(B_m)}, \qquad 1 \le j \le m. \tag{3.1}$$

The observation that the right-hand sides are parallel to r_m for all j forms the basis of the restarted Lanczos tridiagonalization method by Wu and Simon [33], as well as of the restarted Lanczos bidiagonalization method of this subsection.

We derive decompositions of the form (1.3)–(1.4) which allow us to choose the first k columns of the matrix P_m as Ritz vectors. The accuracy of these approximate left singular vectors and available approximate right singular vectors is then improved by restarting the computations. It follows from the orthonormality of the columns of the matrices P_m and $V_m^{(B_m)}$ that the Ritz vectors $\tilde{v}_j^{(A)}$ defined by (2.11) are orthonormal. Moreover, (1.5) shows that the $\tilde{v}_j^{(A)}$ are orthogonal to r_m.

Let the Ritz vectors $\tilde{v}_j^{(A)}$, $1 \le j \le k$, associated with the k largest Ritz values be available, assume that $r_m \neq 0$, and introduce the matrix

$$\tilde{P}_{k+1} := [\tilde{v}_1^{(A)}, \tilde{v}_2^{(A)}, \ldots, \tilde{v}_k^{(A)}, p_{m+1}]. \tag{3.2}$$

In view of (2.2), the last column of $\tilde{P}_{k+1}$ is parallel to the residual error (3.1). It follows from (2.11) that

$$A\tilde{P}_{k+1} = [\tilde{\sigma}_1^{(A)}\tilde{u}_1^{(A)}, \tilde{\sigma}_2^{(A)}\tilde{u}_2^{(A)}, \ldots, \tilde{\sigma}_k^{(A)}\tilde{u}_k^{(A)}, Ap_{m+1}]. \tag{3.3}$$

Orthogonalization of Ap_{m+1} against the vectors $\tilde{u}_j^{(A)}$ yields

$$Ap_{m+1} = \sum_{j=1}^{k} \tilde{\rho}_j \tilde{u}_j^{(A)} + \tilde{r}_k, \tag{3.4}$$

where the remainder $\tilde{r}_k$ is orthogonal to the vectors $\tilde{u}_j^{(A)}$, $1 \le j \le k$. The coefficients $\tilde{\rho}_j := (\tilde{u}_j^{(A)})^T Ap_{m+1}$ can be evaluated inexpensively by using the right-hand side of

$$(\tilde{u}_j^{(A)})^T Ap_{m+1} = p_{m+1}^T A^T \tilde{u}_j^{(A)} = p_{m+1}^T(\tilde{\sigma}_j^{(A)}\tilde{v}_j^{(A)} + r_m e_m^T u_j^{(B_m)}) = \beta_m e_m^T \tilde{u}_j^{(B_m)}.$$

We may assume that the vector $\tilde{r}_k$ is nonvanishing, because otherwise we can terminate the iterations; see below. Introduce the matrices

$$\tilde{Q}_{k+1} := \left[\tilde{u}_1^{(A)}, \tilde{u}_2^{(A)}, \ldots, \tilde{u}_k^{(A)}, \frac{\tilde{r}_k}{\|\tilde{r}_k\|}\right] \tag{3.5}$$

and

$$\tilde{B}_{k+1} := \begin{bmatrix} \tilde{\sigma}_1^{(A)} & & 0 & \tilde{\rho}_1 \\ & \ddots & & \vdots \\ & & \tilde{\sigma}_k^{(A)} & \tilde{\rho}_k \\ 0 & & & \tilde{\alpha}_{k+1} \end{bmatrix} \in \mathbb{R}^{(k+1)\times(k+1)}. \tag{3.6}$$

Thus, $\tilde{B}_{k+1}$ may have nonvanishing entries only on the diagonal and in the last column. Substituting (3.4) into (3.3) now yields the decomposition

$$A\tilde{P}_{k+1} = \tilde{Q}_{k+1}\tilde{B}_{k+1}, \tag{3.7}$$

which is analogous to (1.3).

We turn to the matrix

$$A^T\tilde{Q}_{k+1} = \left[A^T\tilde{u}_1^{(A)}, A^T\tilde{u}_1^{(A)}, \ldots, A^T\tilde{u}_k^{(A)}, A^T\frac{\tilde{r}_k}{\|\tilde{r}_k\|}\right], \tag{3.8}$$

which we would like to express in terms of $\tilde{P}_{k+1}$ and $\tilde{B}_{k+1}^T$. This will give an analogue of the decomposition (1.4). The first k columns of (3.8) are linear combinations of the vectors $\tilde{v}_j^{(A)}$ and p_{m+1}; specifically,

$$A^T\tilde{u}_j^{(A)} = \tilde{\sigma}_j^{(A)}\tilde{v}_j^{(A)} + r_m e_m^T u_j^{(B_m)} = \tilde{\sigma}_j^{(A)}\tilde{v}_j^{(A)} + p_{m+1}\tilde{\rho}_j, \qquad 1 \le j \le k, \tag{3.9}$$

where we have used (2.2). The last column of (3.8) is orthogonal to the Ritz vectors $\tilde{v}_j^{(A)}$,

$$(\tilde{v}_j^{(A)})^T A^T\frac{\tilde{r}_k}{\|\tilde{r}_k\|} = \tilde{\sigma}_j^{(A)}\frac{(\tilde{u}_j^{(A)})^T\tilde{r}_k}{\|\tilde{r}_k\|} = 0, \qquad 1 \le j \le k,$$

and therefore it can be expressed as

$$A^T\frac{\tilde{r}_k}{\|\tilde{r}_k\|} = \tilde{\gamma}_1 p_{m+1} + \tilde{f}_{k+1}, \tag{3.10}$$

where $\tilde{f}_{k+1} \in \mathbb{R}^n$ is orthogonal to the vectors $\tilde{v}_j^{(A)}$, $1 \le j \le k$, as well as to p_{m+1}. Since

$$p_{m+1}^T A^T\frac{\tilde{r}_k}{\|\tilde{r}_k\|} = \frac{\tilde{r}_k^T}{\|\tilde{r}_k\|}Ap_{m+1} = \frac{\tilde{r}_k^T}{\|\tilde{r}_k\|}\left(\sum_{j=1}^{k}\tilde{\rho}_j\tilde{u}_j^{(A)} + \tilde{r}_k\right) = \|\tilde{r}_k\|,$$

it follows from (3.10) that $\tilde{\gamma}_1 = \|\tilde{r}_k\|$. This observation, together with (3.9) and (3.10), gives the expression

$$A^T\tilde{Q}_{k+1} = \tilde{P}_{k+1}\tilde{B}_{k+1}^T + \tilde{f}_{k+1}e_{k+1}^T, \tag{3.11}$$

which is the desired analogue of the decomposition (1.4). We remark that $\tilde{f}_{k+1}$ can be computed from (3.10).

The similarity of the decompositions (3.7) and (3.11), and (1.3)–(1.4), suggests that it may be possible to append new columns to the matrices $\tilde{P}_{k+1}$ and $\tilde{Q}_{k+1}$ in a way similar to Lanczos bidiagonalization. We will show that this is indeed the case. For notational simplicity, denote the columns of $\tilde{P}_{k+1}$ and $\tilde{Q}_{k+1}$ by $\tilde{p}_j$ and $\tilde{q}_j$, respectively, i.e.,

$$\tilde{P}_{k+1} = [\tilde{p}_1, \tilde{p}_2, \ldots, \tilde{p}_{k+1}] \in \mathbb{R}^{n\times(k+1)}, \qquad \tilde{Q}_{k+1} = [\tilde{q}_1, \tilde{q}_2, \ldots, \tilde{q}_{k+1}] \in \mathbb{R}^{\ell\times(k+1)}.$$

We may assume that $\tilde{f}_{k+1} \neq 0$, because otherwise it follows from (3.7) and (3.11) that the singular values of $\tilde{B}_{k+1}$ are singular values of A, and we are done. Thus, let $\tilde{\beta}_{k+1} := \|\tilde{f}_{k+1}\|$ and $\tilde{p}_{k+2} := \tilde{f}_{k+1}/\tilde{\beta}_{k+1}$. Then the matrix $\tilde{P}_{k+2} := [\tilde{P}_{k+1}, \tilde{p}_{k+2}]$ has orthonormal columns.

Let

$$\tilde{\alpha}_{k+2}\tilde{q}_{k+2} := (I - \tilde{Q}_{k+1}\tilde{Q}_{k+1}^T)A\tilde{p}_{k+2}, \tag{3.12}$$

where $\tilde{\alpha}_{k+2} > 0$ is a scaling factor, such that $\tilde{q}_{k+2}$ is of unit length. We comment on the possibility of $\tilde{\alpha}_{k+2}$ vanishing below. Equation (3.11) yields

$$A^T \tilde{Q}_{k+1} = \tilde{P}_{k+1} \tilde{B}_{k+1}^T + \tilde{\beta}_{k+1} \tilde{p}_{k+2} e_{k+1}^T, \tag{3.13}$$

and substituting (3.13) into (3.12) shows that

$$\begin{aligned} \tilde{\alpha}_{k+2} \tilde{q}_{k+2} &= A\tilde{p}_{k+2} - \tilde{Q}_{k+1}(A^T \tilde{Q}_{k+1})^T \tilde{p}_{k+2} \\ &= A\tilde{p}_{k+2} - \tilde{Q}_{k+1}(\tilde{B}_{k+1} \tilde{P}_{k+1}^T + \tilde{\beta}_{k+1} e_{k+1} \tilde{p}_{k+2}^T)\tilde{p}_{k+2} \\ &= A\tilde{p}_{k+2} - \tilde{\beta}_{k+1} \tilde{Q}_{k+1} e_{k+1} = A\tilde{p}_{k+2} - \tilde{\beta}_{k+1} \tilde{q}_{k+1}. \end{aligned} \tag{3.14}$$

Let $\tilde{Q}_{k+2} := [\tilde{Q}_{k+1}, \tilde{q}_{k+2}] \in \mathbb{R}^{\ell \times (k+2)}$, and define $\tilde{B}_{k+2} \in \mathbb{R}^{(k+2)\times(k+2)}$ by first appending the column $\tilde{\beta}_{k+1} e_{k+1}$ and then the row $\tilde{\alpha}_{k+2} e_{k+2}^T$ to $\tilde{B}_{k+1}$, i.e.,

$$\tilde{B}_{k+2} := \begin{bmatrix} \tilde{\sigma}_1^{(A)} & & 0 & \tilde{\rho}_1 & 0 \\ & \ddots & & \vdots & \vdots \\ & & \tilde{\sigma}_k^{(A)} & \tilde{\rho}_k & 0 \\ & & & \tilde{\alpha}_{k+1} & \tilde{\beta}_{k+1} \\ 0 & & & & \tilde{\alpha}_{k+2} \end{bmatrix}.$$

It now follows from (3.7) and (3.14) that

$$A\tilde{P}_{k+2} = \tilde{Q}_{k+2} \tilde{B}_{k+2}. \tag{3.15}$$

We turn to the derivation of a decomposition of the form (3.13) with $k+1$ replaced by $k+2$. Let

$$\tilde{\beta}_{k+2} \tilde{p}_{k+3} := (I - \tilde{P}_{k+2} \tilde{P}_{k+2}^T) A^T \tilde{q}_{k+2}, \tag{3.16}$$

where $\tilde{\beta}_{k+2} > 0$ is a scaling factor, such that $\tilde{p}_{k+3}$ is of unit length. We may assume that a positive coefficient $\tilde{\beta}_{k+2}$ exists; otherwise we are done; see below. Substituting (3.15) into (3.16) yields

$$\tilde{\beta}_{k+2} \tilde{p}_{k+3} = A^T \tilde{q}_{k+2} - \tilde{P}_{k+2} \tilde{B}_{k+2}^T e_{k+2} = A^T \tilde{q}_{k+2} - \tilde{\alpha}_{k+2} \tilde{p}_{k+2},$$

which, together with (3.13), shows that

$$A^T \tilde{Q}_{k+2} = \tilde{P}_{k+2} \tilde{B}_{k+2}^T + \tilde{\beta}_{k+2} \tilde{p}_{k+3} e_{k+2}^T. \tag{3.17}$$

The decompositions (3.15) and (3.17) are analogous to (3.7) and (3.13). We therefore can continue in the same fashion by appending new columns to the matrices $\tilde{P}_j$ and $\tilde{Q}_j$, and new rows and columns to the matrices $\tilde{B}_j$, for $j = k+2, k+3, \ldots$. After a total of $m-k$ steps, we obtain the decompositions

$$A\tilde{P}_m = \tilde{Q}_m \tilde{B}_m, \qquad A^T \tilde{Q}_m = \tilde{P}_m \tilde{B}_m^T + \tilde{\beta}_m \tilde{p}_{m+1} e_m^T, \tag{3.18}$$

where the matrices $\tilde{P}_m$ and $\tilde{Q}_m$ have orthonormal columns and

$$\tilde{B}_m = \begin{bmatrix} \tilde{\sigma}_1^{(A)} & & 0 & \tilde{\rho}_1 & & 0 \\ & \ddots & & \vdots & & \\ & & \tilde{\sigma}_k^{(A)} & \tilde{\rho}_k & & \\ & & & \tilde{\alpha}_{k+1} & \tilde{\beta}_{k+1} & \\ & & & & \ddots & \\ & & & & \ddots & \tilde{\beta}_{m-1} \\ 0 & & & & & \tilde{\alpha}_m \end{bmatrix}.$$

The method now proceeds by first computing the singular value decomposition of $\tilde{B}_m$ and then determining the k largest approximate singular triplets of A from the k largest singular triplets of $\tilde{B}_m$; cf. (2.11). These triplets define new decompositions of the form (3.7) and (3.11), from which we compute new decompositions of the form (3.18). The computations proceed in this manner until sufficiently accurate approximations of the k largest singular triplets of A have been determined. An algorithm is presented in subsection 3.3 below.

We remark that the computations are analogous for determining the k smallest singular triplets of A. The vectors $\tilde{v}_j^{(A)}$, $1 \leq j \leq k$, in (3.2) should then be replaced by the right approximate singular vectors of the k smallest available approximate singular triplets of A. These approximate singular triplets are used to define decompositions (3.7) and (3.11), from which we compute decompositions (3.18) in the same manner as described above. We are interested in the k smallest singular triplets of the matrix $\tilde{B}_m$ in the decompositions (3.18). These triplets yield approximations of the k smallest triplets of A. The computations are continued until sufficiently accurate approximations of the k smallest singular triplets of A have been found. However, we note that when the k smallest singular triplets of A are desired, it can be advantageous to augment by harmonic Ritz vectors instead. This is discussed in subsection 3.2.

Finally, we comment on the cases when $\tilde{r}_k$ vanishes in (3.4) and when the left-hand sides of (3.12) and (3.16) vanish. In all these cases, one can show that the singular values of the matrix $\tilde{B}_j$ also are singular values of A and that the singular triplets of $\tilde{B}_j$ yield singular triplets of A.

3.2. Augmentation by harmonic Ritz vectors. Augmenting by Ritz vectors, as described in the previous subsection, or, equivalently, shifting by Ritz values, often gives good approximations to the largest singular triplets of A. However, Kokiopoulou, Bekas, and Gallopoulos [17] observed that when seeking to compute the smallest singular triplets of A, shifting by harmonic Ritz values can give faster convergence than shifting by Ritz values. This section describes how shifting by harmonic Ritz values can be implemented via augmentation by harmonic Ritz vectors. Harmonic Ritz vectors are approximate eigenvectors of A^TA associated with harmonic Ritz values of A^TA.

Let the partial Lanczos bidiagonalization (1.3)–(1.4) of A be available, and assume that all the diagonal and superdiagonal entries of B_m, as well as β_m given by (2.1), are nonvanishing. Then, in particular, B_m is nonsingular. The harmonic Ritz values $\hat{\theta}_j$ of A^TA associated with the partial Lanczos tridiagonalization (2.4) are the eigenvalues

of the generalized eigenvalue problem

$$((B_m^T B_m)^2 + \alpha_m^2 \beta_m^2 e_m e_m^T)\hat{w}_j = \hat{\theta}_j B_m^T B_m \hat{w}_j, \qquad 1 \le j \le m, \tag{3.19}$$

with $\hat{w}_j \in \mathbb{R}^m \backslash \{0\}$; see, e.g., Morgan [24] or Paige, Parlett, and van der Vorst [27] for properties of harmonic Ritz values.

The eigenpairs $\{\hat{\theta}_j, \hat{w}_j\}$ of (3.19) can be computed without forming the matrix $B_m^T B_m$ as follows. Let

$$w_j := B_m \hat{w}_j. \tag{3.20}$$

Then (3.19) can be expressed as

$$(B_m B_m^T + \beta_m^2 e_m e_m^T) w_j = \hat{\theta}_j w_j, \tag{3.21}$$

where we may choose the eigenvectors w_j to be orthonormal. Let $B_{m,m+1}$ be the matrix in (2.3), and note that

$$B_{m,m+1} B_{m,m+1}^T = B_m B_m^T + \beta_m^2 e_m e_m^T. \tag{3.22}$$

Introduce the singular triplets $\{\sigma_j^{(B_{m,m+1})}, u_j^{(B_{m,m+1})}, v_j^{(B_{m,m+1})}\}$, $1 \le j \le m$, of the matrix $B_{m,m+1}$, and let them be enumerated so that

$$0 < \sigma_1^{(B_{m,m+1})} \le \sigma_2^{(B_{m,m+1})} \le \cdots \le \sigma_m^{(B_{m,m+1})}. \tag{3.23}$$

This enumeration differs from the one for the singular values of B_m (cf. (2.9)), because in the present subsection we are concerned with the computation of the $k < m$ smallest singular triplets of A. Throughout this subsection, we use the following simplified notation:

$$\sigma_j' = \sigma_j^{(B_{m,m+1})}, \qquad u_j' = u_j^{(B_{m,m+1})}, \qquad v_j' = v_j^{(B_{m,m+1})}.$$

The k smallest singular triplets of $B_{m,m+1}$ determine the matrices

$$\begin{aligned} U_k' &:= [u_1', u_2', \ldots, u_k'] \in \mathbb{R}^{m \times k}, \\ V_k' &:= [v_1', v_2', \ldots, v_k'] \in \mathbb{R}^{(m+1) \times k}, \\ \Sigma_k' &:= \mathrm{diag}[\sigma_1', \sigma_2', \ldots, \sigma_k'] \in \mathbb{R}^{k \times k}, \end{aligned} \tag{3.24}$$

where U_k' and V_k' have orthonormal columns, and

$$B_{m,m+1} V_k' = U_k' \Sigma_k', \qquad B_{m,m+1}^T U_k' = V_k' \Sigma_k'. \tag{3.25}$$

We refer to (3.25) as a partial singular value decomposition of $B_{m,m+1}$. It follows from (3.22) and (3.25) that $\{(\sigma_j')^2, u_j'\}$ is an eigenpair of (3.21), and (3.20) shows that $\{(\sigma_j')^2, B_m^{-1} u_j'\}$ is an eigenpair of (3.19). Thus, the eigenpairs of (3.19) and (3.21) associated with the k smallest eigenvalues can be determined from the partial singular value decomposition (3.25). Gu and Eisenstat [12] describe how the singular value decomposition of $B_{m,m+1}$ can be computed by updating the singular value decomposition of B_m; see also Bunch and Nielsen [6]. However, when A is large and m is small, the computational effort required for determining the singular value decompositions of B_m and $B_{m,m+1}$ is negligible. We will therefore not dwell on the computation of (3.25).

The harmonic Ritz vector of A^TA associated with the harmonic Ritz value $\hat{\theta}_j$ is given by

$$\hat{v}_j := P_m \hat{w}_j; \tag{3.26}$$

see, e.g., [24, 27]. Morgan and Zeng [26] recently pointed out that the residual errors associated with different harmonic Ritz pairs $\{\hat{\theta}_j, \hat{v}_j\}$ are parallel. We show this result for the problem at hand, because this property is central for our augmentation method. Thus, using (2.4), (3.20), (3.21), and (3.26), we obtain

$$\begin{aligned} A^TA\hat{v}_j - \hat{\theta}_j\hat{v}_j &= A^TAP_m\hat{w}_j - \hat{\theta}_jP_m\hat{w}_j \\ &= (P_mB_m^TB_m + \alpha_m r_m e_m^T)\hat{w}_j - \hat{\theta}_jP_m\hat{w}_j \\ &= P_m(B_m^TB_m - \hat{\theta}_jI_m)\hat{w}_j + \alpha_m r_m e_m^T\hat{w}_j \\ &= P_mB_m^{-1}(B_mB_m^T - \hat{\theta}_jI_m)w_j + r_m e_m^Tw_j \\ &= P_mB_m^{-1}(-\beta_m^2 e_m e_m^Tw_j) + r_m e_m^Tw_j \\ &= e_m^Tw_j(r_m - \beta_m^2 P_mB_m^{-1}e_m). \end{aligned}$$

It is convenient to define the scaled residual vector

$$\hat{r}_m := p_{m+1} - \beta_m P_m B_m^{-1} e_m, \tag{3.27}$$

where we have used (2.2).

We are in a position to derive relations analogous to (3.7) and (3.11) for harmonic Ritz vectors. Equations (3.20), (3.26), and (3.27) yield

$$[\hat{v}_1\sigma_1', \hat{v}_2\sigma_2', \ldots, \hat{v}_k\sigma_k', \hat{r}_m] = P_{m+1}\begin{bmatrix} B_m^{-1}U_k'\Sigma_k' & -\beta_m B_m^{-1}e_m \\ 0 & 1 \end{bmatrix},$$

where the matrix P_{m+1} is the same as in (2.3). Introduce the QR-factorization

$$\begin{bmatrix} B_m^{-1}U_k'\Sigma_k' & -\beta_m B_m^{-1}e_m \\ 0 & 1 \end{bmatrix} = Q_{k+1}'R_{k+1}', \tag{3.28}$$

where $Q_{k+1}' \in \mathbb{R}^{(m+1)\times(k+1)}$ has orthonormal columns and $R_{k+1}' \in \mathbb{R}^{(k+1)\times(k+1)}$ is upper triangular.

Consider the matrix

$$\hat{P}_{k+1} = [\hat{p}_1, \hat{p}_2, \ldots, \hat{p}_{k+1}] := P_{m+1}Q_{k+1}'. \tag{3.29}$$

Its columns $\hat{p}_j$ are orthonormal since both P_{m+1} and Q_{k+1}' have orthonormal columns. Equations (1.3) and (3.28) yield

$$\begin{aligned} A\hat{P}_{k+1} &= [AP_m, Ap_{m+1}]Q_{k+1}' \\ &= [Q_mB_m, Ap_{m+1}]\begin{bmatrix} B_m^{-1}U_k'\Sigma_k' & -\beta_m B_m^{-1}e_m \\ 0 & 1 \end{bmatrix}(R_{k+1}')^{-1} \\ &= [Q_mU_k'\Sigma_k', -\beta_m q_m + Ap_{m+1}](R_{k+1}')^{-1}. \end{aligned}$$

In the derivation of our method, we assume only that the matrix B_m is upper triangular, because B_m has this property after restarts. Below we comment on possible simplifications when B_m is upper bidiagonal.

Let

$$\hat{Q}_k := Q_mU_k'. \tag{3.30}$$

The columns of this matrix are orthonormal, and we define the Fourier coefficients

$$\hat{c}_k = [\hat{\gamma}_1, \hat{\gamma}_2, \ldots, \hat{\gamma}_k]^T := \hat{Q}_k^T(-\beta_m q_m + A p_{m+1}).$$

The vector

$$\hat{\alpha}_{k+1}\hat{q}_{k+1} := -\beta_m q_m + A p_{m+1} - \hat{Q}_k \hat{c}_k$$

is orthogonal to the columns of $\hat{Q}_k$, and the scaling factor $\hat{\alpha}_{k+1} > 0$ is chosen so that $\hat{q}_{k+1}$ is of unit length. It follows that

$$A\hat{P}_{k+1} = \hat{Q}_{k+1}\hat{B}_{k+1}, \tag{3.31}$$

where

$$\hat{Q}_{k+1} := [\hat{Q}_k, \hat{q}_{k+1}] \in \mathbb{R}^{\ell\times(k+1)}, \tag{3.32}$$

$$\hat{B}_{k+1} := \begin{bmatrix} \sigma_1' & & & 0 & \hat{\gamma}_1 \\ & \sigma_2' & & & \hat{\gamma}_2 \\ & & \ddots & & \vdots \\ & & & \sigma_k' & \hat{\gamma}_k \\ 0 & & & & \hat{\alpha}_{k+1} \end{bmatrix} (R_{k+1}')^{-1} \in \mathbb{R}^{(k+1)\times(k+1)}. \tag{3.33}$$

Thus, $\hat{Q}_{k+1}$ has orthonormal columns, and $\hat{B}_{k+1}$ is the product of two upper triangular matrices, one of which has nonzero entries only on the diagonal and in the last column. In particular, $\hat{B}_{k+1}$ is upper triangular. The decomposition (3.31) is the desired analogue of (3.7). When B_m is given by (1.6), one can show that $\hat{\alpha}_{k+1} = \alpha_{m+1}$, $\hat{q}_{k+1} = q_{m+1}$, and $\hat{c}_k = 0$.

We now derive an analogue of the decomposition (3.11). Let $\hat{Q}_k$ be given by (3.30). Then (3.25) yields

$$A^T\hat{Q}_k = A^T Q_m U_k' = P_{m+1}B_{m,m+1}^T U_k' = P_{m+1}V_k'\Sigma_k'. \tag{3.34}$$

It follows from the decomposition on the left-hand side of (3.25) that

$$[I_m, \beta_m B_m^{-1} e_m]V_k' = B_m^{-1}U_k'\Sigma_k',$$

and therefore

$$V_k' = \begin{bmatrix} B_m^{-1}U_k'\Sigma_k' & -\beta_m B_m^{-1}e_m \\ 0 & 1 \end{bmatrix} \begin{bmatrix} I_k \\ e_{m+1}^T V_k' \end{bmatrix}. \tag{3.35}$$

Substituting (3.35) into (3.34), using (3.28) and (3.29), gives

$$A^T\hat{Q}_k = P_{m+1}Q_{k+1}'R_{k+1}' \begin{bmatrix} I_k \\ e_{m+1}^T V_k' \end{bmatrix} \Sigma_k' = \hat{P}_{k+1}R_{k+1}' \begin{bmatrix} I_k \\ e_{m+1}^T V_k' \end{bmatrix} \Sigma_k'. \tag{3.36}$$

Let $\hat{B}_{k,k+1}$ be the leading $k \times (k+1)$ submatrix of the upper triangular matrix $\hat{B}_{k+1}$ in (3.31). Then (3.31) yields

$$\hat{Q}_k^T A\hat{P}_{k+1} = \hat{B}_{k,k+1}. \tag{3.37}$$

It follows from (3.36) that

$$\hat{P}_{k+1}^T A^T \hat{Q}_k = R'_{k+1} \begin{bmatrix} I_k \\ e_{m+1}^T V'_k \end{bmatrix} \Sigma'_k,$$

and comparison with (3.37) shows that

$$R'_{k+1} \begin{bmatrix} I_k \\ e_{m+1}^T V'_k \end{bmatrix} \Sigma'_k = \hat{B}_{k,k+1}^T.$$

Hence, (3.36) can be expressed as

$$A^T \hat{Q}_k = \hat{P}_{k+1} \hat{B}_{k,k+1}^T. \tag{3.38}$$

We turn to the last column, $A^T \hat{q}_{k+1}$, of $A^T \hat{Q}_{k+1}$. Equation (3.31) yields

$$\hat{P}_{k+1}^T A^T \hat{q}_{k+1} = \hat{B}_{k+1}^T \hat{Q}_{k+1}^T \hat{q}_{k+1} = \hat{B}_{k+1}^T e_{k+1} = \hat{\alpha}_{k+1} e_{k+1},$$

where $\hat{\alpha}_{k+1}$ denotes the last diagonal entry of $\hat{B}_{k+1}$. Thus,

$$A^T \hat{q}_{k+1} = \hat{\alpha}_{k+1} \hat{p}_{k+1} + \breve{r}_{k+1}, \tag{3.39}$$

where $\hat{P}_{k+1}^T \breve{r}_{k+1} = 0$. Combining (3.38) and (3.39) yields

$$A^T \hat{Q}_{k+1} = \hat{P}_{k+1} \hat{B}_{k+1}^T + \breve{r}_{k+1} e_{k+1}^T, \tag{3.40}$$

which is the desired analogue of (3.11). Note that the residual vector $\breve{r}_{k+1}$ can be computed from (3.39), because the other terms are explicitly known.

Let $\hat{\beta}_{k+1} := \|\breve{r}_{k+1}\|$ and $\hat{p}_{k+2} := \breve{r}_{k+1}/\hat{\beta}_{k+1}$, and define

$$\hat{P}_{k+2} := [\hat{P}_{k+1}, \hat{p}_{k+2}], \qquad \breve{B}_{k+1,k+2} := [\hat{B}_{k+1}, \hat{\beta}_{k+1} e_{k+1}].$$

Then (3.40) can be written in the form

$$A^T \hat{Q}_{k+1} = \hat{P}_{k+2} \breve{B}_{k+1,k+2}^T,$$

which is an analogue of (2.3).

Given the decompositions (3.31) and (3.40), we can proceed analogously as in subsection 3.1 to compute the decompositions

$$A\hat{P}_m = \hat{Q}_m \hat{B}_m, \qquad A^T \hat{Q}_m = \hat{P}_m \hat{B}_m^T + \breve{r}_m e_m^T, \tag{3.41}$$

where $\hat{P}_m \in \mathbb{R}^{n\times m}$ has orthonormal columns with leading $n \times (k+2)$ submatrix $\hat{P}_{k+2}$, $\hat{Q}_m \in \mathbb{R}^{\ell\times m}$ has orthonormal columns with leading $\ell \times (k+1)$ submatrix $\hat{Q}_{k+1}$, and

$$\hat{B}_m = \begin{bmatrix} \hat{B}_{k+1} & \hat{\beta}_{k+1} & & & & 0 \\ & \hat{\alpha}_{k+2} & \hat{\beta}_{k+2} & & & \\ & & \hat{\alpha}_{k+3} & \hat{\beta}_{k+3} & & \\ & & & & \ddots & \\ & & & & \ddots & \hat{\beta}_{m-1} \\ 0 & & & & & \hat{\alpha}_m \end{bmatrix} \in \mathbb{R}^{m\times m}$$

has the $(k+1)\times(k+1)$ leading principal submatrix $\hat{B}_{k+1}$ and an $(m-k-1)\times(m-k-1)$ upper bidiagonal trailing principal submatrix. The residual vector $\breve{r}_m$ is orthogonal to the columns of $\hat{P}_m$. The method of this subsection can be restarted by letting $B_m := \hat{B}_m$, $P_m := \hat{P}_m$, $Q_m := \hat{Q}_m$, $r_m := \breve{r}_m$, and $\beta_m := \|\breve{r}_m\|$.

We remark that the accurate computation of the vector $B_m^{-1}e_m$, used in (3.28), can be difficult when the matrix B_m has a large condition number $\kappa(B_m) := \sigma_m^{(B_m)}/\sigma_1^{(B_m)}$, where the singular values are enumerated as in (3.23). In this case, we switch from augmentation by harmonic Ritz vectors to augmentation by Ritz vectors. Details are provided in the following subsection.

3.3. An augmented Lanczos bidiagonalization algorithm. We describe an algorithm for the computation of a few of the largest or smallest singular triplets of a large matrix A. The algorithm is based on augmentation by Ritz vectors or harmonic Ritz vectors as described in the previous subsections. The Boolean variable *harmonic* suggests the type of augmentation used. If *harmonic* is true and B_m is not too ill-conditioned, then the augmentation scheme of subsection 3.2 is applied; otherwise augmentation is carried out according to subsection 3.1.

ALGORITHM 3.1. AUGMENTED LANCZOS BIDIAGONALIZATION.

The above algorithm is a simplification of the actual computations carried out. For instance, the algorithm exits when a matrix B_m that is numerically singular has been detected, but the available decompositions of A can be used to determine singular triplets of A; see the discussion in section 1. Moreover, the number of augmented vectors used at each restart is typically larger than the number of desired singular triplets. Assume that k' of the desired k singular triplets have been found. We then augment by $k + k''$ (instead of k) singular triplets, where k'' is chosen as large as possible, such that $k'' \leq k'$ and $k + k'' \leq m - 3$. The term -3 secures that at least three orthogonalization steps can be carried out between restarts. This approach has been advocated by Lehoucq [20] in the context of the implicitly restarted Arnoldi method. It often yields faster convergence without increasing the memory requirement. Finally, our implementation enforces two-sided reorthogonalization when $\kappa(B_m) > \epsilon^{-1/2}$. MATLAB code is available at the authors' home pages.

4. Numerical examples. All computations were carried out using MATLAB version 6.5 R13 on a Dell 530 workstation with two 2.4 GHz (512k cache) Xeon processors and 2 GB (400 MHz) of memory running under the Windows XP operating system. Machine epsilon is $\epsilon = 2.2 \cdot 10^{-16}$.

We compare our methods, outlined by Algorithm 3.1, with methods recently proposed by Hochstenbach [14, 13] and Kokiopoulou, Bekas, and Gallopoulos [17], as well as with the MATLAB internal function `svds` and the scheme proposed in [2]. Hochstenbach [14, 13] presents a Jacobi–Davidson method. This is a powerful scheme when a good preconditioner for the linear system of equations that has to be solved is available. In our computed examples, we assume that no good preconditioner is known, and we apply the method without preconditioner. The linear system of equations is solved by the GMRES iterative method. The MATLAB implementation[1] `jdsvd` offers several extraction choices, such as standard, u-harmonic, v-harmonic, double-harmonic, and refined. In our numerical examples, refined extraction often gave best accuracy. This is consistent with results reported by Hochstenbach [14]. We refer to the Jacobi–Davidson method with refined extraction as `jdsvd(Ref)`. The code `jdsvd` is still under development, and we used the version available to us at the time of the numerical experiments.

Our methods are mathematically, but not numerically, equivalent to the methods proposed by Kokiopoulou, Bekas, and Gallopoulos [17]. We used the MATLAB implementation `irlanb` by Kokiopoulou, Bekas, and Gallopoulos [17] in our comparison. The code `irlanb` calls Larsen's MATLAB code `lanbpro` [18] to compute partial Lanczos bidiagonalizations with partial reorthogonalization. `irlanb` is designed for computing a few of the smallest singular triplets but not for computing a few of the largest ones. The code therefore is not used in Examples 4 and 5 below. Ritz values and harmonic Ritz values can be used as shifts. We refer to `irlanb` with these shift selections as `irlanb(R)` and `irlanb(H)`, respectively. The code `irlanb` is still under development, and we report results for the version available to us at the time of the numerical experiments.

The internal MATLAB function `svds` uses FORTRAN codes of ARPACK [22]. It calls an eigenvalue routine to compute eigenvalue-eigenvector pairs associated with positive eigenvalues of the symmetric matrix

$$Z := \begin{bmatrix} 0 & A \\ A^T & 0 \end{bmatrix} \in \mathbb{R}^{(\ell+n)\times(\ell+n)}. \tag{4.1}$$

[1] Code is available at http://www.case.edu/artsci/math/hochstenbach/software/jdsvd.html

The matrix Z has the eigenvalues

$$\pm\sigma_1^{(A)}, \pm\sigma_2^{(A)}, \ldots, \pm\sigma_n^{(A)},$$

as well as $\ell - n$ zero eigenvalues, where we as usual assume that $\ell \geq n$. The eigenvectors of Z yield both the right and left singular vectors of A. The method requires the computation of eigenpairs associated with eigenvalues near zero when determining the smallest singular triplets of A. This can be difficult when Z has many positive and negative eigenvalues of large magnitude. For this reason, the `svds` function uses a shift-and-invert approach for computing the smallest singular triplets. This requires factorization of the matrix Z, and therefore the function `svds` typically demands much more storage than the other methods in our comparison. Since `svds` does not yield the number of linear systems of equations that have to be solved, we report only the CPU time required.

The MATLAB code `irblsvds` implements an implicitly restarted block-Lanczos method applied to the matrix (4.1) for the computation of a few singular triplets of A. The method and code are described in [2, 3].[2] The matrix Z is used only for evaluation of matrix-vector products; in particular, the matrix Z is not factored. The code `irblsvds` is not, in general, well suited for computing the smallest singular triplets of A when $\ell - n$ is large, because then Z has $\ell - n$ zero eigenvalues, and the code may determine these eigenvalues and associated eigenvectors instead of eigenpairs associated with tiny singular triplets of A. Unless indicated otherwise, we use the default value 3 for the block-size in our experiments with `irblsvds`. The largest number of consecutive block-Lanczos steps is chosen so that `irblsvds` has about the same storage requirement as the other codes. We note that of the methods used in the examples of this section, only the ones of the present paper are based on augmented matrix formulations.

The schemes of subsections 3.1 and 3.2 are implemented by the MATLAB code `irlba`.[2] The execution of `irlba` is determined by certain user-specified parameters; see Table 4.1. We refer to the augmentation method of subsection 3.1, based on Ritz vectors, as `irlba(R)` and to the augmentation method of subsection 3.2, based on harmonic Ritz vectors, as `irlba(H)`. The scheme `irlba(R)` with one- and two-sided full reorthogonalization is referred to as `irlba(R1)` and `irlba(R2)`, respectively. The analogous implementations of `irlba(H)` are denoted by `irlba(H1)` and `irlba(H2)`. One-sided full reorthogonalization reorthogonalizes the columns of the smaller of the matrices P_m and Q_m. Thus, when $\ell \geq n$, the columns of P_m are reorthogonalized.

The codes `irblsvds`, `irlanb`, `jdsvd`, and `svds` allow a user to choose numerous parameters that affect their performance. Unless stated otherwise, we use the default values for the parameters. Except for the function `svds`, we choose the parameters that affect storage so that all codes require about the same maximum computer storage.

It is impossible to use the same starting vector for all the methods, since some routines work with A and A^T and others with the matrix Z. To make our comparison less dependent on the choice of starting vector, we record the best results for each method over five runs using default random starting vector(s) generated by each code. We use the same starting vector when the same method is applied with different parameter values. The reported number of matrix-vector products is the total number of matrix-vector product evaluations with A and A^T for `irlba`, `irlanb`, and `jdsvd` and with Z for `irblsvds`.

[2] Code is available at the authors' home pages.

TABLE 4.1
Parameters for `irlba`.

adjust	Initial number of vectors added to the k restart vectors to speed up convergence. Default value: $adjust = 3$.
aug	A 4-letter string. The value RITZ yields the augmentation described in subsection 3.1; the value HARM gives augmentation according to subsection 3.2. Default value: aug = HARM if $sigma$ = SS, and aug = RITZ if $sigma$ = LS.
disps	When $disps > 0$, available approximations of the k desired singular values and norms of associated residual errors are displayed each iteration; $disps = 0$ inhibits display of these quantities. Default value: $disps = 0$.
k	Number of desired singular triplets. Default value: $k = 6$.
maxit	Maximum number of restarts. Default value: $maxit = 100$.
steps	Maximum number of Lanczos bidiagonalization steps. The parameter specifies the largest value of steps m in (1.3)–(1.4) and determines the storage requirement of the method. Default value: $steps = 20$.
reorth	A 3-letter string. The value ONE yields one-sided full reorthogonalization of the "shorter" vectors; the value TWO gives two-sided full reorthogonalization. When our available estimate of $\kappa(A)$ (see the discussion following (2.13)) is larger than $\epsilon^{-1/2}$, two-sided full reorthogonalization is used. Default value: $reorth$ = ONE.
sigma	A 2-letter string (SS for smallest and LS for largest) which specifies which extreme singular triplets are to be computed. Default value: $sigma$ = LS.
δ	Tolerance used for convergence check; see (2.13). Default value: $\delta = 10^{-6}$.
v_0	Initial vector for Lanczos bidiagonalization. When $\ell \geq n$, $p_1 := v_0$; cf. Algorithm 2.1. Default value: v_0 is a random vector with normally distributed entries.

' . ,' 1 (smallest singular value). We would like to compute the smallest singular triplet of the diagonal matrices

$$A := \mathrm{diag}[1, 2, \ldots, n], \qquad n = 100, 200, 300, 400.$$

Each code was instructed to determine only one singular triplet, the smallest one. This corresponds to the parameter values $sigma$ = SS and $k = 1$ for `irlba`. We allowed each of the codes `irlba`, `irlanb`, `jdsvd`, and `irblsvds` about the same amount of storage as required for carrying out 20 Lanczos bidiagonalization steps. In particular, the largest number of consecutive block-Lanczos steps allowed by `irblsvds` was limited to 7 (with block-size 3). This corresponds to about the same storage requirement as 21 Lanczos bidiagonalization steps. We let $adjust := 4$ for `irbla`; see Table 4.1. This forces both the `irlba` and `irlanb` codes to apply the same number of bidiagonalization steps in the first restart. We chose the tolerance 10^{-6} for all codes, i.e., $\delta := 10^{-6}$ in (2.13). For the `jdsvd` code we report only refined extraction, because this extraction method was the fastest. Figure 4.1 displays the CPU times required for the different methods. The MATLAB `svds` function is seen to be fastest. This may depend on the fact that `svds` is not coded in MATLAB and that it is based on a shift-and-invert approach. For large problems shift-and-invert may require unacceptable amounts of memory and execution time; however, when computation and storage of factors of matrices of the form $Z - \tau I$, where τ is a scalar, is feasible, then this approach is attractive. Among the methods that use only the matrices A and A^T for evaluating matrix-vector products, `irlba` is seen to be competitive.

' . ,' 2 (smallest singular values). We are interested in determining the smallest singular triplet of four matrices generated in MATLAB with the commands

$$A = randn(n), \qquad A(:, 1) = A(:, 10),$$

for $n = 200, 400, 600, 800$. Here $A = randn(n)$ determines an $n \times n$ matrix with

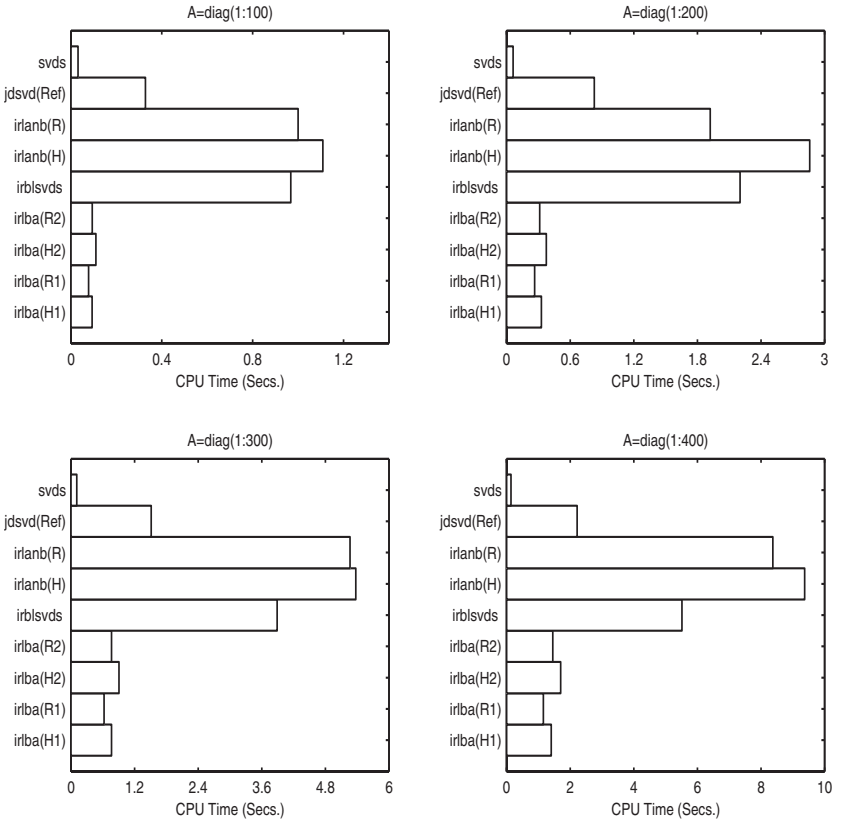

FIG. 4.1. *Example* 1: *CPU times for computing the smallest singular triplet.*

normally distributed entries with mean zero and variance one. The command $A(:,1) = A(:,10)$ overwrites column 1 by column 10 and secures that the matrix obtained has a zero singular value. This example illustrates that augmentation by harmonic Ritz vectors can give substantially faster convergence than augmentation by Ritz vectors.

The code `irlba` was used with $k = 1$, $\delta = 10^{-16}$, $reorth = \text{TWO}$, and $steps = 30$. Figure 4.2 shows the convergence to zero of the smallest computed singular value. The vertical axis displays the absolute error in the smallest computed singular value, i.e., the smallest computed singular value, and the horizontal axis shows the number of restarts. The cross-over label indicates when `irlba` switched from augmenting with harmonic Ritz vectors to augmenting with Ritz vectors. As mentioned in subsection 3.2, augmentation by harmonic Ritz vectors requires the solution of a linear system of equations with the matrix B_m (while augmentation by Ritz vectors does not). We switch from augmentation by harmonic Ritz vectors to augmentation by Ritz vectors when the condition number of the matrix B_m is larger than the square root of the reciprocal of machine epsilon; cf. Algorithm 3.1.

We remark that computing a singular triplet with a numerically vanishing singular value is not always possible since the approximated left singular vector $\tilde{u}_j^{(A)}$ lives in the Krylov subspace (2.8), which is restricted to the range of A. However, in the presence of round-off errors, `irlba` is often able to successfully compute singular triplets associated with zero singular values.

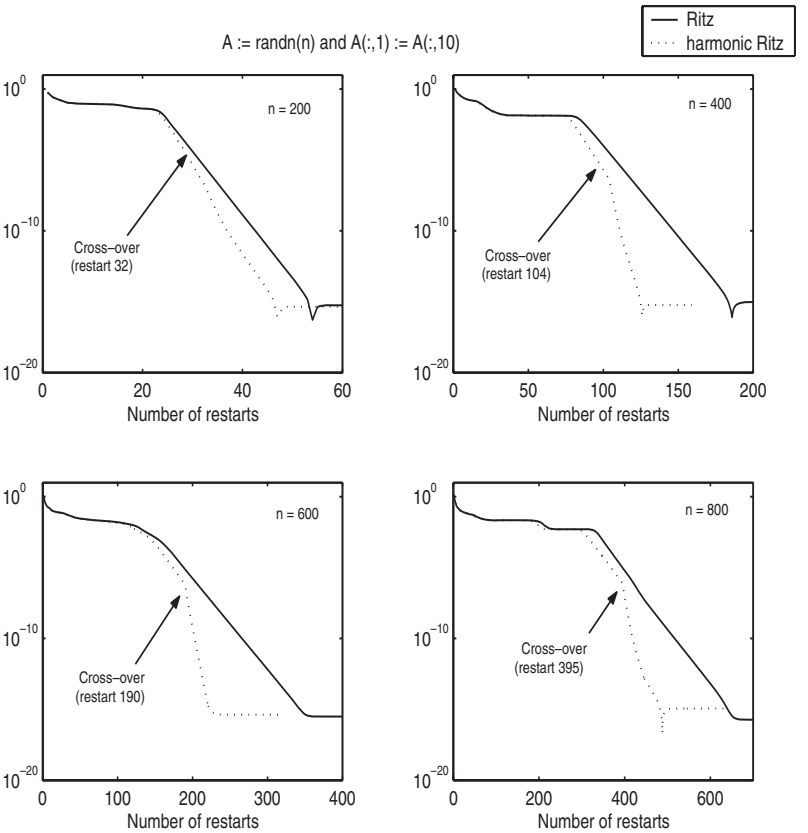

FIG. 4.2. *Example* 2: *Absolute error in the smallest singular value computed by* `irlba` *versus number of restarts using augmentation with Ritz vectors (solid curve) and augmentation with harmonic Ritz vectors (dotted curve). After the cross-over point augmentation is with Ritz vectors.*

3 (smallest singular values). We consider the 1033×320 matrix WELL1033 and the 1850×712 matrix WELL1850 from the set LSQ in the Harwell–Boeing sparse matrix collection [9]. These matrices arise from surveying problems. We would like to determine the six smallest singular triplets of these matrices and select the parameters for the different codes accordingly. For instance, for `irlba` we let *sigma* := SS and $k := 6$. All codes are allowed the amount of storage required for 40 Lanczos bidiagonalization steps. The number of implicit QR-steps in `irlanb` is chosen to be 31; this choice is consistent with the default value of the parameter *adjust* of `irlba`. It forces `irbla` and `irlanb` to apply the same number of Lanczos bidiagonalization steps in the first restart. The tolerance for all methods is set to $\delta = 10^{-6}$. `irlanb` with shifts chosen to be harmonic Ritz values gave better results than when Ritz values were used as shifts. We therefore report only results for the former. The restarted block-Lanczos method `irblsvds` used block-size 4 and was allowed to carry out at most 10 consecutive block-Lanczos steps between restarts. `jdsvd` gave the best results for refined extraction. Therefore we do not report results for other extraction methods. The MATLAB `svds` function was unable to find any of the desired singular triplets to requested accuracy for either of the matrices. Table 4.2 summarizes the computed results. The table shows that `irlba` was able to compute

all six singular values with the fewest matrix-vector product evaluations and the least CPU time for both matrices.

4 (largest singular values). The matrices MEDLINE, CRANFIELD, and CISI are standard term-by-document test matrices and can be obtained from the Cornell SMART FTP server[3] or the TMG web page.[4] They are of size 5735×1033, 4563×1398, and 5544×1460, respectively. We also consider the term-by-document matrix HYPATIA[5] of size 11390×1265 with 109056 nonzero terms from the web server at the Department of Mathematics, University of Rhode Island. HYPATIA was created in the same manner as standard term-by-document test matrices. All test matrices use the local term frequency (i.e., number of times a word occurs on a website) and have no global weighting or normalization. The parameter values chosen for the different methods are consistent with our desire to determine the 10 largest

singular triplets for each of these matrices; for `irlba` we let *sigma* :=LS and $k := 10$. The available storage is assumed to be large enough to simultaneously store all vectors generated during 20 consecutive steps of Lanczos bidiagonalization. The tolerance δ in the stopping criterion is 10^{-6}. Since we seek to determine the largest singular triplets, `irbla` uses the augmentation method of section 3.1. We report the results for one-sided and two-sided full reorthogonalization. The code `irblsvds` was used with block-size 4 and was allowed to carry out at most five consecutive block-Lanczos steps between restarts. The fastest extraction method for `jdsvd` was refined. Table 4.3 displays the performance of the methods and illustrates the competitiveness of

`irlba`. The code `irlanb` is not part of our comparison, since it is designed for the computation of only a few of the smallest singular triplets.

5 (condition number). We would like to determine the condition number $\kappa(A) := \sigma_1^{(A)}/\sigma_n^{(A)}$, where the singular values are enumerated according to (1.1), of the Läuchli matrix $A := L(n, \mu) \in \mathbb{R}^{(n+1)\times n}$ for $n = 20000$ and the default value of μ.[6] Thus, A has ones across the top row and μ on the subdiagonal; the remaining matrix entries are zero. This matrix often is used to illustrate the drawback of forming A^TA in least-squares computations; see [19]. The Läuchli matrix A is nonsingular; it has the simple singular value $\sqrt{n+\mu^2}$ and the singular value μ of multiplicity $n-1$ giving the condition number $\kappa(A) = 9.490724975767860 \cdot 10^9$, and therefore A^TA is numerically singular. `irlba` only implicitly works with the matrix A^TA and is able to compute $\kappa(A)$. Specifically, we let *sigma* :=LS and SS, $k := 1$, and we allow the storage required for all vectors generated by 20 consecutive steps of Lanczos bidiagonalization. The tolerance δ in the stopping criterion is set to machine epsilon ϵ. Two-sided full reorthogonalization was employed. We augmented by Ritz vectors when computing the largest singular value and, until the matrices B_m became ill-conditioned, by harmonic Ritz vectors when determining the smallest singular value. `irlba` required 0.703 and 0.796 seconds of CPU time to compute the largest and smallest singular values of A, respectively, and gave the condition number $9.490724975767925 \cdot 10^9$ with a relative error of $6.83 \cdot 10^{-15}$. Thus, the fact that A^TA is numerically singular does not cause `irlba` problems.

Acknowledgments. We would like thank Stratis Gallopoulos for a copy of the paper [17], Michiel Hochstenbach and Efi Kokiopoulou for providing copies of their codes, and Costas Bekas, Michiel Hochstenbach, and Efi Kokiopoulou for valuable comments and discussions.

A PARALLEL EIGENSOLVER FOR DENSE SYMMETRIC MATRICES BASED ON MULTIPLE RELATIVELY ROBUST REPRESENTATIONS*

PAOLO BIENTINESI†, INDERJIT S. DHILLON†, AND ROBERT A. VAN DE GEIJN†

Abstract. We present a new parallel algorithm for the dense symmetric eigenvalue/eigenvector problem that is based upon the tridiagonal eigensolver, Algorithm MR^3, recently developed by Dhillon and Parlett. Algorithm MR^3 has a complexity of $O(n^2)$ operations for computing all eigenvalues and eigenvectors of a symmetric tridiagonal problem. Moreover the algorithm requires only $O(n)$ extra workspace and can be adapted to compute any subset of k eigenpairs in $O(nk)$ time. In contrast, all earlier stable parallel algorithms for the tridiagonal eigenproblem require $O(n^3)$ operations in the worst case, while some implementations, such as divide and conquer, have an extra $O(n^2)$ memory requirement. The proposed parallel algorithm balances the workload equally among the processors by traversing a matrix-dependent *representation tree* which captures the sequence of computations performed by Algorithm MR^3. The resulting implementation allows problems of very large size to be solved efficiently—the largest dense eigenproblem solved in-core on a 256 processor machine with 2 GBytes of memory per processor is for a matrix of size 128,000 × 128,000, which required about 8 hours of CPU time. We present comparisons with other eigensolvers and results on matrices that arise in the applications of computational quantum chemistry and finite element modeling of automobile bodies.

1. Introduction.

The symmetric eigenvalue problem is ubiquitous in computational sciences; problems of ever-growing size arise in applications as varied as computational quantum chemistry, finite element modeling, and pattern recognition. In many of these applications, both time and space are limiting factors for solving the problem, and hence efficient parallel algorithms and implementations are needed. The best approach for computing all the eigenpairs (eigenvalues and eigenvectors) of a dense symmetric matrix involves three phases: (1) [illegible]—reduce the given symmetric matrix A to tridiagonal form T; (2) [illegible]—compute all the eigenpairs of T; (3) [illegible]—map T's eigenvectors into those of A. For an $n \times n$ matrix, the reduction and backtransformation phases require $O(n^3)$ arithmetic operations each. Until recently, all algorithms for the tridiagonal eigenproblem too had cubic complexity in the worst case; these include the remarkable QR algorithm [26, 27, 36], inverse iteration [42], and the divide and conquer method [10].

In fact, the tridiagonal problem can be the computational bottleneck for large problems taking nearly 70–80% of the total time to solve the entire dense problem. For example, on a 2.4 GHz Intel Pentium 4 processor the tridiagonal reduction and backtransformation of a 2000 × 2000 dense matrix takes about 32 seconds, while

†Department of Computer Sciences, The University of Texas at Austin, Austin, TX 78712 (pauldj@cs.utexas.edu, inderjit@cs.utexas.edu, rvdg@cs.utexas.edu).

LAPACK's bisection and inverse iteration software takes 106 seconds to compute all the eigenpairs of the tridiagonal. The timings for a 4000×4000 matrix clearly show the $O(n^3)$ behavior: 290 seconds for tridiagonal reduction and backtransformation, and 821 seconds for bisection and inverse iteration to solve the tridiagonal eigenproblem. Timings for the tridiagonal QR algorithm are 86 seconds for $n = 2000$ and 1099 seconds for $n = 4000$. More detailed timing results are given in section 4.

Recently, Dhillon and Parlett proposed Algorithm MRRR or MR^3 (multiple relatively robust representations) [13, 18, 17], which gives the first stable $O(nk)$ algorithm to compute k eigenvalues and eigenvectors of a symmetric tridiagonal matrix. In this paper we present a parallel algorithm based on Algorithm MR^3 for computing any subset of eigenpairs of a dense symmetric matrix; this yields the first parallel implementation of Algorithm MR^3. We refer to the parallel algorithm as PMR^3 (parallel MR^3). As a consequence, the time spent by the proposed algorithm on the tridiagonal eigenproblem is negligible compared to the time spent on reduction and backtransformation. For example, to compute all the eigenpairs of a 15,000 × 15,000 matrix on 16 processors the new algorithm requires 546 seconds for reduction, 22.2 seconds for the tridiagonal solution, and 160 seconds for backtransformation. In comparison, the corresponding timings for existing implementations for the tridiagonal eigensolution are 2054 seconds for the QR algorithm and 92.4 seconds for the divide and conquer method. For a 32,000 × 32,000 matrix the timings for PMR^3 on 16 processors are 4876 seconds for the reduction, 118 seconds for the tridiagonal solution, and 1388 seconds for backtransformation. These timings clearly contrast the $O(n^2)$ complexity of Algorithm MR^3 as opposed to the $O(n^3)$ reduction and backtransformation phases.

Moreover, some of the earlier algorithms have extra memory requirements: the ScaLAPACK divide and conquer code (PDSTEVD) requires extra $O(n^2)$ storage, while the inverse iteration code (PDSTEIN) can lead to a memory imbalance on the processors depending upon the eigenvalue distribution. Thus neither PDSTEVD nor PDSTEIN can be used to solve the above-mentioned 32,000 × 32,000 eigenproblem on 16 processors. In contrast, our parallel algorithm requires only workspace that is linear in n and the memory needed to store the eigenvectors of the tridiagonal problem is evenly divided among processors, thus allowing us to efficiently solve problems of very large size. The largest dense problem we have solved "in-core" on a 256 processor machine with 2 GBytes of memory per processor is a matrix of size 128,000 × 128,000, which required about 8 hours of computation time. Section 4 contains further timing results for the parallel implementations.

The rest of the paper is organized as follows. Section 2 reviews previous work on algorithms for the dense symmetric eigenvalue problem. In section 3, we present the proposed parallel Algorithm PMR^3, which uses multiple relatively robust representations for the tridiagonal problem. Section 4 presents detailed timing results comparing Algorithm PMR^3 with existing software. These include results on matrices that arise in the real-life applications of computational quantum chemistry and finite element modeling of automobile bodies.

A word on the notation used throughout the paper. T indicates a symmetric tridiagonal matrix, n represents the size of a matrix, eigenvalues are denoted by λ, and eigenvectors are denoted by $\boldsymbol{v}$. Computed quantities will often be denoted by "hatted" symbols, for example, $\hat{\lambda}$ and $\hat{\boldsymbol{v}}$. The number of processors in a parallel computation is p, while the ith processor is denoted by p_i.

2. Related work. As mentioned earlier, most algorithms for the dense symmetric eigenvalue problem proceed in three phases. The first and third phases, House-

holder reduction and backtransformation, are fairly standard and described in section 3.2. The second stage, tridiagonal eigensolution, has led to a variety of interesting algorithms; we now give a quick overview of existing methods, emphasizing their parallel versions.

The QR algorithm, independently invented by Francis [26, 27] and Kublanovskaya [36], is an iteration that produces a sequence of similar matrices that converges to diagonal form. When the starting matrix is symmetric and tridiagonal, each iterate produced by the QR algorithm is also symmetric and tridiagonal. Convergence to diagonal form is rapid (ultimately cubic) with a suitable choice of shifts [38]. A fast square-root-free version of QR developed by Pal, Walker, and Kahan (PWK) is useful if only eigenvalues are desired [38]. Another attractive alternative, in the latter case, is to use the differential quotient-difference algorithm (dqds) that is based on the related LR iteration [24]. In practice 2–3 iterations, on average, are needed per eigenvalue in the QR algorithm where each iteration is composed of at most $n-1$ Givens rotations. Thus all eigenvalues can be computed at a cost of $O(n^2)$ operations, while the accumulation of Givens rotations required for computing orthogonal eigenvectors results in $O(n^3)$ operations (in practice, $6n^3$ to $9n^3$ operations are observed).

The inherent sequential nature of the QR algorithm makes the eigenvalue computation hard to parallelize. However, when eigenvectors are needed, an effective parallel algorithm that yields good speedups can be obtained as follows. First, the Householder reflections computed during the reduction are accumulated in approximately $\frac{4}{3}n^3$ operations to form a matrix Z, which is then evenly partitioned among the p processors so that each processor owns approximately n/p rows of Z. The tridiagonal matrix is duplicated on all processors and the $O(n^2)$ eigenvalue computation is redundantly performed on all processors, while the Givens rotations are directly applied on each processor to its part of Z. This accumulation achieves perfect speedup since all processors can simultaneously update their portion of Z without requiring any communication, thus leading to an overall parallel complexity of $O(n^3/p)$ operations. A faster algorithm (up to a factor of 2) can be obtained by using perfect shifts and inner deflations [16].

A major drawback of the QR algorithm is that it is hard to adapt to the case when only a subset of eigenvalues and eigenvectors is desired at a proportionately reduced operation count. Thus a commonly used parallel solution is to invoke the bisection algorithm followed by inverse iteration [32]. The bisection algorithm was first proposed by Givens in 1954 and allows the computation of k eigenvalues of a symmetric tridiagonal T in $O(kn)$ operations [28]. Once accurate eigenvalues are known, the method of inverse iteration may be used to compute the corresponding eigenvectors [42]. However, inverse iteration can guarantee only small residual norms. It cannot ensure orthogonality of the computed vectors when eigenvalues are close. A commonly used "remedy" is to orthogonalize each approximate eigenvector, using the modified Gram–Schmidt method, against previously computed eigenvectors of "nearby" eigenvalues—the LAPACK and EISPACK implementations orthogonalize when eigenvalues are closer than $10^{-3}\|T\|$. Unfortunately even this conservative strategy can fail to give accurate answers in certain situations [14]. The amount of work required by inverse iteration to compute all the eigenvectors of a symmetric tridiagonal matrix depends strongly upon the distribution of eigenvalues (unlike the QR algorithm, which always requires $O(n^3)$ operations). If eigenvalues are well separated (gaps greater than $10^{-3}\|T\|$), then $O(n^2)$ operations are sufficient. However, when eigenvalues are clustered, current implementations of inverse iteration can take up to $10n^3$ operations due to orthogonalization [34]. Unfortunately the latter sit-

uation is the norm rather than the exception for large matrices since even uniform eigenvalue spacings when n exceeds 1000 can lead to eigenvalue gaps smaller than $10^{-3}\|T\|$.

When eigenvalues are well separated, both bisection and inverse iteration can be effectively parallelized leading to a complexity of $O(n^2/p)$ operations. However, as remarked above, the common situation for large matrices is that inverse iteration requires $O(n^3)$ operations; see section 4.3 for some timings. Thus, parallel inverse iteration requires $O(n^3/p)$ operations in these situations. Moreover, considerable communication is required when Gram–Schmidt orthogonalization is done across processor boundaries. Indeed, to avoid communication, the current inverse iteration implementation in ScaLAPACK (PDSTEIN) computes all the eigenvectors corresponding to a cluster of eigenvalues on a single processor, thus leading to a parallel complexity of $O(n^3)$ in the worst case and also an imbalance in the memory required on each processor [8, p. 48].

The bisection algorithm to find eigenvalues has linear convergence and can be quite slow. To speed up bisection, there have been many attempts to employ faster zero-finders such as the Rayleigh quotient iteration [38], Laguerre's method [37, 39], and the zeroin scheme [11, 9]. These zero-finders can speed up the computation of isolated eigenvalues by a considerable amount, but they seem to stumble when eigenvalues cluster. In all these cases, the corresponding eigenvectors still need to be computed by inverse iteration.

The divide and conquer method proposed by Cuppen in 1981 is a method specially suited for parallel computation [10, 20]; remarkably this algorithm also yields a faster sequential implementation than QR. The basic strategy of the divide and conquer algorithm is to express the tridiagonal matrix as a low-rank modification of a direct sum of two smaller tridiagonal matrices. This modification may be a rank-one update or may be obtained by crossing out a row and column of the tridiagonal. The entire eigenproblem can then be solved in terms of the eigenproblems of the smaller tridiagonal matrices, and this process can be repeated recursively. For several years after its inception, it was not known how to guarantee numerically orthogonality of the eigenvector approximations obtained by this approach. However, Gu and Eisenstat found a solution to this problem, leading to robust software based on their strategy [30].

The main reason for the unexpected success of divide and conquer methods on serial machines is [illegible], which occurs when an eigenpair of a submatrix of T is an acceptable eigenpair of a larger submatrix. The greater the amount of deflation, which depends on the eigenvalue distribution and on the structure of the eigenvectors, the lesser the work required in these methods. For matrices with clustered eigenvalues, deflation can be extensive; however, in general, $O(n^3)$ operations are needed. The divide and conquer method is suited for parallelization since smaller subproblems can be solved independently on various processors. However, communication costs for combining subproblems are substantial, especially when combining the larger subproblems to get the solution to the full problem [43]. A major drawback of the divide and conquer algorithm is its extra $O(n^2)$ memory requirement—as we shall see later, this limits the largest problem that can be solved using this approach.

2.1. Other solution methods. The oldest method for solving the symmetric eigenproblem dates back to Jacobi [33]. Jacobi's method does not reduce the dense symmetric matrix to tridiagonal form, as most other methods do, but works on the dense matrix at all stages. It performs a sequence of plane rotations, each of which annihilates an off-diagonal element (which is filled in during later steps). There are

a variety of Jacobi methods that differ solely in their strategies for choosing the next element to be annihilated. All good strategies tend to diminish the off-diagonal elements, and the resulting sequence of matrices converges to the diagonal matrix of eigenvalues.

Jacobi's method fell out of favor with the discovery of the QR algorithm. The primary reason is that, in practice, the cost of even the most efficient variants of the Jacobi iteration is an order of magnitude greater than that of the QR algorithm. Nonetheless, it has periodically enjoyed a resurrection since it can be efficiently parallelized, and theoretical results show it to be more accurate than the QR algorithm [12].

The symmetric invariant subspace decomposition algorithm (SYISDA) formulates the problem in a dramatically different way [5]. The idea is to scale and shift the spectrum of the given matrix so that its eigenvalues are mapped to the interval $[0, 1]$, with the mean eigenvalue being mapped to $\frac{1}{2}$. Letting B equal the transformed matrix, a polynomial p is applied to B with the property that $\lim_{i\to\infty} p^i([0, 1]) = \{0, 1\}$. By applying this polynomial to B in the iteration $C_0 = B$, $C_{i+1} = p(C_i)$ until convergence, all eigenvalues of C_{i+1} eventually become arbitrarily close to 0 or 1. The eigenvectors of C_{i+1} and A are related in such a way that allows the computation of two subspaces that can then be used to decouple matrix A into two subproblems, each of size roughly half that of A. The process then continues with each of the subproblems. The benefit of the SYISDA approach is that the computation can be cast in terms of matrix-matrix multiplication, which can attain near-peak performance on modern microprocessors and parallelizes easily [19, 31]. Unfortunately, this benefit is accompanied by an increase in the operation count, to the point where SYISDA is not considered to be competitive.

2.2. Parallel libraries. A great deal of effort has been spent in building efficient parallel symmetric eigensolvers for distributed systems. Specially designed software for this problem has been developed as part of a number of numerical libraries. Among these the best known are the Scalable Linear Algebra Package (ScaLAPACK) [21, 8], Parallel Eigensolver (PeIGS) [23], the Parallel Research on Invariant Subspace Methods (PRISM) project [5], and the Parallel Linear Algebra Package (PLAPACK) [44]. All of these packages attempt to achieve portability by embracing the Message-Passing Interface (MPI) and the Basic Linear Algebra Subprograms (BLAS) [19].

The ScaLAPACK project is an effort to parallelize the Linear Algebra Package (LAPACK) [1] to distributed memory architectures. It supports a number of different algorithms, as further discussed in the experimental section. PeIGS supports a large number of chemistry applications that give rise to large dense eigenvalue problems. It includes a parallel tridiagonal eigensolver that is based on a very early version of Algorithm MR^3; this preliminary version does limited Gram–Schmidt orthogonalization; see [15]. The PRISM project implements the SYISDA approach outlined in section 2.1. PLAPACK currently supports a parallel implementation of the QR algorithm as well as the algorithm that is the topic of this paper.

3. The proposed algorithm. We now present the proposed parallel algorithm. Section 3.1 describes how the tridiagonal eigenproblem can be solved using the method of multiple relatively robust representations (MR^3), while section 3.2 briefly describes the phases of Householder reduction and backtransformation.

3.1. Tridiagonal eigensolver using multiple relatively robust representations. Algorithm MR^3 was recently introduced by Dhillon and Parlett [13, 18, 17] for the task of computing k eigenvectors of a symmetric tridiagonal matrix T, and

has a complexity of $O(nk)$ operations. The superior time complexity of the algorithm is achieved by avoiding Gram–Schmidt orthogonalization, which in turn is the result of high relative accuracy in intermediate computations.

3.1.1. The sequential algorithm. We provide the main ideas behind Algorithm MR^3; an in-depth technical description and justification of the algorithm can be found in [13, 18, 17]. There are three key ingredients that form the backbone of Algorithm MR^3:

1. A relatively robust representation (RRR) is a representation that determines its eigenvalues and eigenvectors to high relative accuracy; i.e., small componentwise changes to individual entries of the representation lead to small relative changes in the eigenvalues and small changes in the eigenvectors (modulo relative gaps between eigenvalues; see (2) below). Unfortunately, the traditional representation of a tridiagonal by its diagonal and off-diagonal elements does not form an RRR; see [18, sect. 3] for an example. However, the bidiagonal factorization $T = LDL^t$ of a positive definite tridiagonal is an RRR, and in many cases an indefinite LDL^t also forms an RRR [18]. We now make precise the conditions needed for LDL^t to be an RRR: Write l_i for $L(i+1,i)$ and d_i for $D(i,i)$. Define the relative gap of $\hat{\lambda}$, where $\hat{\lambda}$ is closer to λ than to any other eigenvalue of LDL^t, to be

$$\text{relgap}(\hat{\lambda}) := \text{gap}(\hat{\lambda})/|\hat{\lambda}|,$$

where $\text{gap}(\hat{\lambda}) = \min\{|\nu - \hat{\lambda}| : \ \nu \neq \lambda, \ \nu \in \text{spectrum}(LDL^t)\}$. We say that $(\lambda, \boldsymbol{v})$ is determined to high relative accuracy by L and D if small relative changes, $l_i \to l_i(1+\eta_i)$, $d_i \to d_i(1+\delta_i)$, $|\eta_i| < \xi$, $|\delta_i| < \xi$, $\xi \ll 1$, cause changes $\delta\lambda$ and $\delta\boldsymbol{v}$ that satisfy

$$\frac{|\delta\lambda|}{|\lambda|} \leq K_1 n\xi, \quad \lambda \neq 0, \tag{1}$$

$$|\sin\angle(\boldsymbol{v}, \boldsymbol{v}+\delta\boldsymbol{v})| \leq \frac{K_2 n\xi}{\text{relgap}(\lambda)} \tag{2}$$

for modest constants K_1 and K_2, say, smaller than 100. We call such an LDL^t factorization an RRR for $(\lambda, \boldsymbol{v})$. The advantage of an RRR is that the eigenvalues and eigenvectors can be computed to high relative accuracy as governed by (1) and (2). For more details see [18].

2. Once an accurate eigenvalue $\hat{\lambda}$ is known, its eigenvector may be computed by solving the equation $(LDL^t - \hat{\lambda}I)\boldsymbol{z} \approx 0$. However, it is not straightforward to solve this equation: the trick is to figure out what equation to ignore in this nearly singular system. Unable to find a solution to this problem, current implementations of inverse iteration in LAPACK and EISPACK solve $(LDL^t - \hat{\lambda}I)\boldsymbol{z}_{i+1} = \boldsymbol{z}_i$ and take $\boldsymbol{z}_0$ to be a random starting vector (this difficulty was known to Wilkinson [45, p. 318]). This problem was solved recently by using twisted factorizations that are obtained by gluing a top-down (LDL^t) and a bottom-up (UDU^t) factorization. The solution is presented in Algorithm Getvec below; see [18, 40, 25] for more details.

3. By using an RRR and Algorithm Getvec for computing eigenvectors, it can be shown that the computed eigenvectors are numerically orthogonal when the eigenvalues have large relative gaps [18]. However, when eigenvalues have small relative gaps, the above approach is not adequate. For the case of small relative gaps, Algorithm MR^3 uses

ALGORITHM Getvec(L,D, $\hat{\lambda}$).

Input: L is unit lower bidiagonal (l_i denotes $L(i+1,i)$, $1 \le i \le n-1$), and D is diagonal (d_i denotes $D(i,i)$, $1 \le i \le n$); LDL^t is the input tridiagonal matrix assumed to be irreducible. $\hat{\lambda}$ is an approximate eigenvalue.

Output: $\boldsymbol{z}$ is the computed eigenvector.

I. Factor $LDL^t - \hat{\lambda}I = L_+D_+L_+^t$ by the dstqds (differential stationary quotient-difference with shift) transform.

II. Factor $LDL^t - \hat{\lambda}I = U_-D_-U_-^t$ by the dqds (differential progressive quotient-difference with shift) transform.

III. Compute γ_k for $k = 1, \ldots, n$ by the formula $\gamma_k = s_k + \frac{d_k}{D_-(k+1)}p_{k+1}$ that involves the intermediate quantities s_k and p_{k+1} computed in the dstqds and dqds transforms (for details see [18, sect. 4.1]). Pick an r such that $|\gamma_r| = \min_k |\gamma_k|$. Form the twisted factors with twist index r, N_r and Δ_r, which satisfy $N_r\Delta_rN_r^t = LDL^t - \hat{\lambda}I$.

IV. Form the approximate eigenvector $\boldsymbol{z}$ by solving $N_r^t\boldsymbol{z} = \boldsymbol{e}_r$ ($\boldsymbol{e}_r$ is the rth column of the identity matrix I), which is equivalent to solving $(LDL^t - \hat{\lambda}I)\boldsymbol{z} = N_r\Delta_rN_r^t\boldsymbol{z} = \boldsymbol{e}_r\gamma_r$ since $N_r\boldsymbol{e}_r = \boldsymbol{e}_r$ and $\Delta_r\boldsymbol{e}_r = \gamma_r\boldsymbol{e}_r$:

$$z(r) = 1.$$

$$\text{For } i = r-1, \ldots, 1, \quad z(i) = \begin{cases} -L_+(i)z(i+1), & z(i+1) \neq 0, \\ -(d_{i+1}l_{i+1}/d_il_i)z(i+2), & \text{otherwise.} \end{cases}$$

$$\text{For } j = r, \ldots, n-1, \quad z(j+1) = \begin{cases} -U_-(j)z(j), & z(j) \neq 0, \\ -(d_{j-1}l_{j-1}/d_jl_j)z(j-1), & \text{otherwise.} \end{cases}$$

Note that d_il_i is the $(i, i+1)$ element of LDL^t.

V. Set $\boldsymbol{z} \leftarrow \boldsymbol{z}/\|\boldsymbol{z}\|$.

FIG. 1. *Algorithm* Getvec *for computing the eigenvector of an isolated eigenvalue.*

multiple RRRs, i.e., multiple factorizations $L_cD_cL_c^t = LDL^t - \tau_cI$, where τ_c is close to a cluster. The shifts τ_c are chosen to "break" clusters, i.e., to make relative gaps bigger (note that relative gaps change upon shifting by τ_c). After forming the new representation $L_cD_cL_c^t$, the eigenvalues in the cluster are "refined" so that they have high relative accuracy with respect to $L_cD_cL_c^t$. Finally the eigenvectors of eigenvalues that become relatively well separated after shifting are computed by Algorithm Getvec using $L_cD_cL_c^t$; the process is iterated for eigenvalues that still have small relative gaps. Details are given in Algorithm MR^3 below. The tricky theoretical aspects that address the relative robustness of intermediate representations and whether the eigenvectors computed using different RRRs are numerically orthogonal may be found in [41] and [17]. It is important to note that orthogonality of the computed eigenvectors is achieved without Gram–Schmidt being used in any of the procedures.

We first present Algorithm Getvec in Figure 1. Getvec takes an LDL^t factorization and an approximate eigenvalue $\hat{\lambda}$ as input and computes the corresponding eigenvector by forming the appropriate twisted factorization $N_r\Delta_rN_r^t = LDL^t - \hat{\lambda}I$. The twist index r in step III of Figure 1 is chosen so that $|\gamma_r| = \min_k |\gamma_k|$ and is followed by solving $(LDL^t - \hat{\lambda}I)\boldsymbol{z} = \gamma_r\boldsymbol{e}_r$; thus r is the index of the equation that is ignored and provides a solution to Wilkinson's problem mentioned above [40]. The result-

ing eigenvector is accurate since differential transformations are used to compute the twisted factorization, and the eigenvector is computed solely by multiplications (no additions or subtractions) in step IV of the algorithm. We assume that LDL^t is an irreducible tridiagonal, i.e., all off-diagonals are nonzero. Details on twisted factorizations, differential quotient-difference transforms, and Algorithm Getvec may be found in [18].

Algorithm Getvec computes a single eigenvector of an RRR; it was shown in [18] that the computed eigenvector is highly accurate and so is numerically orthogonal to all other eigenvectors if the corresponding eigenvalue has a large relative gap. However, if Getvec is invoked when the corresponding eigenvalue is part of a cluster, the computed vector will, in general, not be orthogonal to other eigenvectors in the cluster. The difficulty is that, as seen by (2), the eigenvectors of eigenvalues with small relative gaps are highly sensitive to tiny changes in L and D.

To overcome this problem, Algorithm MR^3, given in Figure 2, uses multiple LDL^t factorizations—the basic idea is that there will be an LDL^t factorization for each cluster of eigenvalues. A new LDL^t factorization is formed per cluster in order to increase relative gaps within the cluster. Once an eigenvalue has a large relative gap, Algorithm Getvec is invoked to compute the corresponding eigenvector, as seen in step II of Figure 2. Otherwise we are in the presence of a cluster Γ_c of eigenvalues and a new representation $L_cD_cL_c^t = LDL^t - \tau_c I$ needs to be computed. The shift τ_c is chosen in such a way such that (a) the new representation is relatively robust for the eigenvalues in Γ_c and (b) at least one of the shifted eigenvalues in Γ_c is relatively well separated from the others. The process is iterated if other clusters are encountered. The inputs to MR^3 are an index set Γ_0 that specifies the desired eigenpairs, the symmetric tridiagonal matrix T given by its traditional representation of diagonal and off-diagonal elements, and a tolerance *tol* for relative gaps. Note that the computational path taken by MR^3 depends on the relative gaps between eigenvalues. We again emphasize that MR^3 does not need any Gram–Schmidt orthogonalization of the eigenvectors.

3.1.2. Representation trees. The sequence of computations in Algorithm MR^3 can be pictorially expressed by a [illegible]. Such a tree contains information about how the eigenvalues are clustered (nodes of the tree) and what shifts are used to "break" a cluster (edges of the tree). A precise description of a representation tree can be found in [17]. Here we present a slightly simplified version of the tree, without specifying edge labels, which will facilitate the description of the parallel algorithm.

The root node of the representation tree is denoted by (L_0, D_0, Γ_0), where $L_0D_0L_0^t$ is the base representation obtained in step 1A of Algorithm MR^3; see Figure 2. An example representation tree is shown in Figure 3. Let Π_c be an internal node of the tree and let Π_p be its parent node. If Π_c is a nonleaf node, it will be denoted by (L_c, D_c, Γ_c), where the index set Γ_c is a proper subset of Γ_p, the index set of the parent node $\Pi_p = (L_p, D_p, \Gamma_p)$. Node Π_c indicates that $L_cD_cL_c^t$ is a representation that is computed by shifting, $L_pD_pL_p^t - \tau_c = L_cD_cL_c^t$, and will be used for computing the eigenvectors indexed by Γ_c. If Π_c is a leaf node instead, it will be denoted only by the singleton $\{c\}$, where $c \in \Gamma_p$. The singleton node $\{c\}$ signifies that the eigenvalue λ_c has a large relative gap with respect to the parent representation $L_pD_pL_p^t$, and its eigenvector will be computed by Algorithm Getvec.

Figure 3 gives an example of a representation tree for a matrix of size 11 for which all the eigenvectors are desired: the root contains the representation L_0, D_0 and the index set $\Gamma_0 = \{1, 2, \ldots, 11\}$. The algorithm begins by classifying the eigenvalues: in this example λ_1, λ_4, and λ_{11} are well separated, so in the tree they appear as singleton

ALGORITHM $\mathsf{MR}^3(T,\Gamma_0,tol)$.
Input: T is the given symmetric tridiagonal;
Γ_0 is the index set of desired eigenpairs;
tol is the input tolerance for relative gaps, usually set to 10^{-3}.
Output: $(\hat\lambda_j, \hat{\boldsymbol{v}}_j), j \in \Gamma_0$, are the computed eigenpairs.
1. Split T into irreducible subblocks $T_1, T_2, \ldots, T_\ell$.
For each subblock T_i, $i = 1, \ldots, \ell$, do:
A. Choose μ_i, and compute L_0 and D_0 such that $L_0 D_0 L_0^t = T_i + \mu_i I$ is a factorization that determines the desired eigenvalues and eigenvectors, λ_j and $\boldsymbol{v}_j$, $j \in \Gamma_0$, to high relative accuracy. In general, the shift μ_i can be in the interior of T_i's spectrum, but a safe choice is to make $T_i + \mu_i I$ positive or negative definite.
B. Compute the desired eigenvalues of $L_0 D_0 L_0^t$ to high relative accuracy by the dqds algorithm [24] or by bisection using a differential quotient-difference transform.
C. Form a work queue Q, and initialize $Q = \{(L_0, D_0, \Gamma_0)\}$. Call $\mathsf{MR}^3_\mathsf{Vec}(Q,tol)$.
end for
Subroutine $\mathsf{MR}^3_\mathsf{Vec}(Q,tol)$

While queue Q is not empty:
I. Remove an element (L, D, Γ) from the queue Q. Partition the computed eigenvalues $\hat\lambda_j, j \in \Gamma$, into clusters $\Gamma_1, \ldots, \Gamma_h$ according to their relative gaps and the input tolerance tol. The eigenvalues are thus designated as [illegible] (cluster size equals 1) or [illegible]. More precisely, if $\mathsf{rgap}(\hat\lambda_j) := \min_{i \neq j} |\hat\lambda_j - \hat\lambda_i|/|\hat\lambda_j| \geq tol$, then $\hat\lambda_j$ is isolated. On the other hand, all consecutive eigenvalues $\hat\lambda_{j-1}, \hat\lambda_j$ in a nontrivial cluster Γ_c ($|\Gamma_c| > 1$) satisfy $|\hat\lambda_j - \hat\lambda_{j-1}|/|\hat\lambda_j| < tol$.
II. For each cluster Γ_c, $c = 1, \ldots, h$, perform the following steps.
If $|\Gamma_c| = 1$ with eigenvalue $\hat\lambda_j$, i.e., $\Gamma_c = \{j\}$, **then** invoke Algorithm $\mathsf{Getvec}(L,D,\hat\lambda_j)$ to obtain the computed eigenvector $\hat{\boldsymbol{v}}_j$.
else
a. Pick τ_c near the cluster and compute $LDL^t - \tau_c I = L_c D_c L_c^t$ using the dstqds (differential form of stationary quotient-difference) transform; see [18, sect. 4.1] for details.
b. "Refine" the eigenvalues $\hat\lambda - \tau_c$ in the cluster so that they have high relative accuracy with respect to the computed $L_c D_c L_c^t$. Set $\hat\lambda \leftarrow (\hat\lambda - \tau_c)_{refined}$ for all eigenvalues in the cluster.
c. Add (L_c, D_c, Γ_c) to the queue Q.
end if
end for
end while

FIG. 2. *Algorithm* MR^3 *for computing orthogonal eigenvectors without using Gram–Schmidt orthogonalization.*

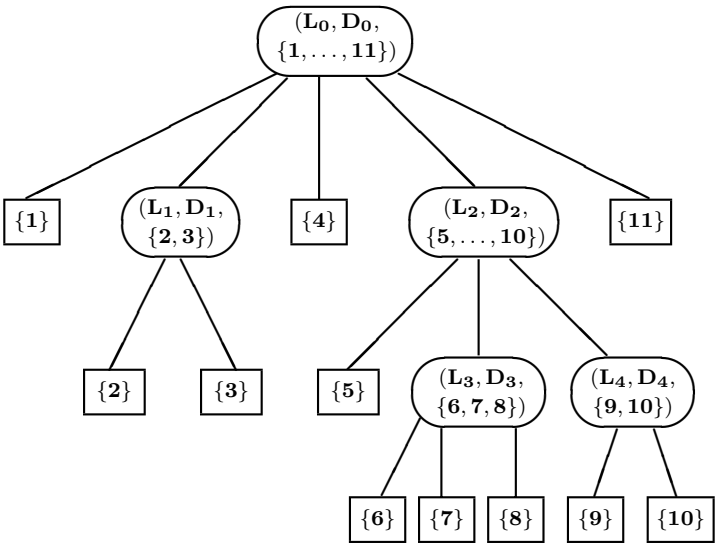

FIG. 3. *An example representation tree for a matrix of size* 11.

leaves (their eigenvectors can be directly computed by the calls $\mathsf{Getvec}(L_0, D_0, \hat{\lambda}_i)$, $i = 1, 4$, and 11). The second and third eigenvalues violate the condition $|(\hat{\lambda}_3 - \hat{\lambda}_2)/\hat{\lambda}_3| \geq tol$, and therefore they form a cluster; a new representation $L_1 D_1 L_1^t = L_0 D_0 L_0^t - \tau_1 I$ has to be computed and the two eigenvalues have to be refined to have high relative accuracy with respect to L_1 and D_1. This is represented by the node $(L_1, D_1, \{2, 3\})$. Similarly the eigenvalues $\{\lambda_5, \ldots, \lambda_{10}\}$ are clustered: a new representation $L_2 D_2 L_2^t = L_0 D_0 L_0^t - \tau_2 I$ is computed as shown by the node $(L_2, D_2, \{5, \ldots, 10\})$. This illustrates the working of Algorithm MR^3 for all the nodes at depth 1 in the representation tree of Figure 3.

The computation proceeds by classifying the eigenvalues of the two internal nodes $(L_1, D_1, \{2, 3\})$ and $(L_2, D_2, \{5, \ldots, 10\})$. From the tree it can be deduced that the two eigenvalues λ_2 and λ_3 in the first internal node are now relatively well separated, while the second node is further fragmented into a relatively well separated eigenvalue λ_5 and two nodes with clusters: nodes $(L_3, D_3, \{6, 7, 8\})$ and $(L_4, D_4, \{9, 10\})$. Finally these two clusters are further fragmented to yield singletons, and these eigenvectors are computed by Algorithm Getvec. Note that, as seen by the description of Algorithm MR^3 in Figure 2, the representation tree is processed in a breadth-first fashion.

For most matrices, the depth of the representation tree is quite small; we give here a sketch of the representation tree for two matrices that arise in the finite element modeling of automobile bodies (see section 4.1 for more details). The tree for the matrix auto.13786 (n = 13,786) has maximum depth 2; at depth 1 there are 12,937 singleton nodes, 403 clusters of size 2, 10 clusters of size 3, and 1 cluster of size 13. The tree for the matrix auto.12387 (n = 12,387) also has maximum depth 2 even though it has many more internal nodes: it has 5776 singletons and 1991 nodes corresponding to clusters with sizes ranging from 2 to 31.

A further note about reducible matrices: the solution is computed by iterating over the subblocks, and thus the sequence of computations can be captured by a forest of trees (one for each subblock) rather than by a single tree.

3.1.3. The parallel algorithm. We now describe Algorithm PMR^3. The input to the algorithm is a tridiagonal matrix T, an index set Γ_0 of desired eigenpairs, a tolerance parameter $_{,\prime}$, and the number of processors p that execute the algorithm. We target our algorithm to a distributed memory system, in which each processor has its own local main memory and communication is done by message-passing. We assume that the tridiagonal matrix is available on every processor before the algorithm is invoked.

We first discuss the parallelization strategy before describing the algorithm in detail. Let the size of the input index set Γ_0 be k; i.e., k eigenvalues and eigenvectors are to be computed. The total $O(kn)$ complexity of Algorithm MR^3 can be broken down into the work required at each node of the representation tree:

1. Each leaf node requires the computation of an eigenvector by Algorithm Getvec, which requires $O(n)$ operations (at most $2n$ divisions and $10n$ multiplications and additions).
2. Each internal node (L_c, D_c, Γ_c) requires (a) computation of the representation $L_c D_c L_c^t = L_i D_i L_i^t - \tau_c I$, and (b) refinement of the eigenvalues corresponding to the index set Γ_c so that they have high relative accuracy with respect to $L_c D_c L_c^t$. Computing the representation by the differential stationary quotient-difference transform requires $O(n)$ operations (n divisions, $4n$ multiplications and additions), while refinement of the eigenvalues can be done in $O(n|\Gamma_c|)$ operations using a combination of bisection and Rayleigh quotient iteration.

We aim for a parallel complexity of $O(\frac{nk}{p} + n)$ operations. Due to communication overheads, we will not attempt to parallelize $O(n)$ procedures, such as computing a single eigenvector or computing a new representation. Our strategy for the parallel algorithm will be to divide the leaf nodes equally among the processors, i.e., each processor will make approximately k/p calls to Algorithm Getvec. Thus each processor is assigned a set of eigenvectors that are to be computed locally.

However, before the leaf nodes can be processed the computation at the internal nodes needs to be performed. Each internal node (L_c, D_c, Γ_c) is associated with a subset of q processors, $q \leq p$, that are responsible for computing the eigenvectors in Γ_c. Since k eigenvectors are to be computed by a total of p processors, q approximately equals $\lceil p|\Gamma_c|/k \rceil$. Note that since $|\Gamma_c|$ is small in most practical applications (see comments towards the end of section 3.1.2), q is mostly small; in our examples, q is usually 1, sometimes 2, but rarely greater than 2. If q equals 1, the computation at each internal node is just done serially. If q is greater than 1, the parallel algorithm will process an internal node as follows: the representation $L_c D_c L_c^t$ is computed (redundantly) by each of the q processors. The eigenvalue refinement using bisection or Rayleigh quotient iteration ($O(n)$ per eigenvalue) is then parallelized over the q processors, resulting in a parallel complexity $(n|\Gamma_c|/q) = O(nk/p)$. Since many subsets of processors may be handling internal nodes at the same time, the overall parallel complexity is $O(\frac{nk}{p} + n)$. Note that due to communication overheads in a practical implementation, we impose a threshold on $|\Gamma_c|$ before the refinement is performed in parallel; if $|\Gamma_c|$ is below this threshold, the computation is carried out redundantly on all the q processors. On heterogeneous parallel machines, the redundant computation on every processor will need to be replaced by computation on a designated processor followed by a broadcast of the computed results to the other participating processors [7].

Figure 4 gives a description of Algorithm PMR^3 according to the strategy outlined

ALGORITHM $\mathsf{PMR}^3(T, \Gamma_0, tol, p)$. {executed by processor p_s}

Input: T is the given symmetric tridiagonal;
Γ_0 is the index set of desired eigenpairs;
tol is the input tolerance for relative gaps, usually set to 10^{-3};
p is the number of processors that execute the algorithm.

Output: $(\hat{\lambda}_j, \hat{\boldsymbol{v}}_j), j \in \Gamma_0$ are the computed eigenpairs.

1. Split T into irreducible subblocks $T_1, T_2, \ldots, T_\ell$.
For each subblock T_i, $i = 1, \ldots, \ell$, do:
A. Choose μ_i such that $L_0 D_0 L_0^t = T_i + \mu_i I$ is a factorization that determines the desired eigenvalues and eigenvectors, λ_j and $\boldsymbol{v}_j$, $j \in \Gamma_0$, to high relative accuracy.
B. Compute the desired eigenvalues Λ_i of $L_0 D_0 L_0^t$ to high relative accuracy by the dqds algorithm [24] or by parallel bisection using a differential quotient-difference transform. Let $\Gamma_i \subseteq \Gamma_0$ be the index set corresponding to Λ_i that contains the desired eigenvalues.
end for

2. Determine the subset $\Gamma_0^s \subseteq \Gamma_0$ of eigenvectors to be computed locally. Form a work queue $\bar{Q}$, and initialize it with all the subblocks (L_i, D_i, Γ_i) containing eigenvectors to be computed locally, i.e., the subblocks for which $\Gamma_i \cap \Gamma_0^s \neq \emptyset$, with $i = 1, \ldots, \ell$.

3. While queue $\bar{Q}$ is not empty:
I. Remove an element (L, D, Γ) from the queue $\bar{Q}$. Partition the computed eigenvalues $\hat{\lambda}_j, j \in \Gamma$, into clusters $\Gamma_1, \ldots, \Gamma_h$ according to their relative gaps and the input tolerance tol.
II. For each cluster Γ_c, $c = 1, \ldots, h$, perform the following steps:

If $\Gamma_c \subseteq \Gamma_0^{p_s}$ **then** all eigenvectors in Γ_c have to be computed locally. The eigenvectors are computed by invoking $\mathsf{MR}^3_\mathsf{Vec}((L, D, \Gamma_c), tol)$.

elseif $\Gamma_c \cap \Gamma_0^s = \emptyset$ **then** the cluster Γ_c does not contain any eigenvector that needs to be computed locally. Discard the cluster Γ_c.

elseif $\Gamma_c \cap \Gamma_0^s \neq \emptyset$ **then** the cluster Γ_c contains some eigenvectors to be computed locally, and needs to be further fragmented by the following steps.

- Pick τ_c near the cluster and compute $LDL^t - \tau_c I = L_c D_c L_c^t$ using the dstqds transform; see [18, sect. 4.1] for details.
- "Refine" the eigenvalues $\hat{\lambda} - \tau_c$ in the cluster so that they have high relative accuracy with respect to the computed $L_c D_c L_c^t$. Set $\hat{\lambda} \leftarrow (\hat{\lambda} - \tau_c)_{refined}$ for all eigenvalues in the cluster.
- Add (L_c, D_c, Γ_c) to the queue $\bar{Q}$.

end if

FIG. 4. *Algorithm* PMR^3 *for parallel computation of a subset* Γ_0 *of eigenvalues and eigenvectors.*

above. In order to show how subblocks of T are handled by the parallel algorithm, we do not assume that T is irreducible. Each processor will compute k/p eigenvectors, assuming k is divisible by p. Once the eigenvalues are grouped according to the subblocks and sorted (per subblock), work is assigned to the processors in a block cyclic manner; i.e., processor p_0 is assigned eigenvectors $1, 2, \ldots, k/p$, processor p_1 is assigned eigenvectors $k/p + 1, \ldots, 2k/p$, and so on. Thus the memory requirement to store the eigenvectors is exactly $(n \cdot k/p)$ floating point numbers per processor. The extra workspace required is linear in n, so problems of large size can be tackled. To give an idea of the limits of the sequential implementation, the size n of the largest problem that can be solved (with $k = n$) on a computer equipped with 1.5 GBytes of memory is about 14,000 when all the eigenvectors are required, while to solve a problem of size 30,000 a computer should be equipped with about 7 GBytes of main memory.

As seen in Figure 4, the eigenvectors are computed by invoking the sequential algorithms Getvec or MR^3_Vec (which in turn invokes Getvec). In terms of the representation tree, each processor maintains a local work queue $\bar{Q}$ of nodes (possibly leaves) which collectively index a superset of the eigenvectors to be computed locally. Initially all the processors have a single node in the queue corresponding to the desired index set Γ_0. The representation tree is traversed in a breadth-first fashion to fragment the clusters until all the eigenvectors of a node are local. Fragmenting a cluster is equivalent to descending one level in the representation tree. Nodes that contain eigenvectors all of which are associated with other processors are removed from the local queue of the processor. Once a node contains only eigenvectors to be computed locally, the sequential algorithms Getvec or MR^3_Vec are invoked depending on the size of the cluster. Recall that there is a tree for each subblock.

A word about the initial eigenvalue computation. The dqds algorithm for computing the eigenvalues is very fast but, like the QR algorithm, is inherently sequential. Moreover, the dqds algorithm cannot be adapted to compute k eigenvalues in $O(nk)$ time, instead always requiring $O(n^2)$ computations. On the other hand the bisection algorithm is easily parallelized [3]; however, bisection is rather slow. Thus in a parallel implementation, it is often preferable to redundantly compute the eigenvalues on each processor unless p is large or unless only a small subset of the n eigenvalues is desired. A quick calculation reveals the decision procedure to decide whether to use bisection or dqds. Bisection is linearly convergent, and finds one additional bit of an eigenvalue at every iteration. Thus, computing the desired eigenvalues by parallel bisection on p processors requires approximately $52n|\Gamma_0|/p$ operations in IEEE double precision arithmetic. On the other hand, dqds requires about 3 iterations, on average, to compute each eigenvalue to full relative accuracy. But dqds cannot be parallelized, so it requires approximately $3n^2$ operations irrespective of Γ_0. As a result, in our implementation, we use the dqds algorithm to redundantly compute all eigenvalues on the p processors when $3n^2 \leq 52n|\Gamma_0|/p$, i.e., $p \leq 17|\Gamma_0|/n$; otherwise we use parallel bisection.

We now illustrate the parallel execution of the algorithm on the matrix of Figure 3, assuming we want to compute all 11 eigenvectors on 3 processors. In Figure 5 we have annotated the representation tree of Figure 3 to show how the tree is processed by the 3 processors. Initially the eigenvalues $\Lambda_0 = \{\lambda_1, \ldots, \lambda_{11}\}$ are computed. Then based on the relative gaps between eigenvalues each processor determines whether a cluster is to be computed locally, has to be fragmented, or has to be discarded. The labels p_0, p_1, p_2 on the root node denote that each of the 3 processors is involved in the computation.

Processor p_0 classifies the eigenvalues λ_1 through λ_4, but discards all the clusters (possibly singletons) from λ_5 to the end of the spectrum as they do not contain

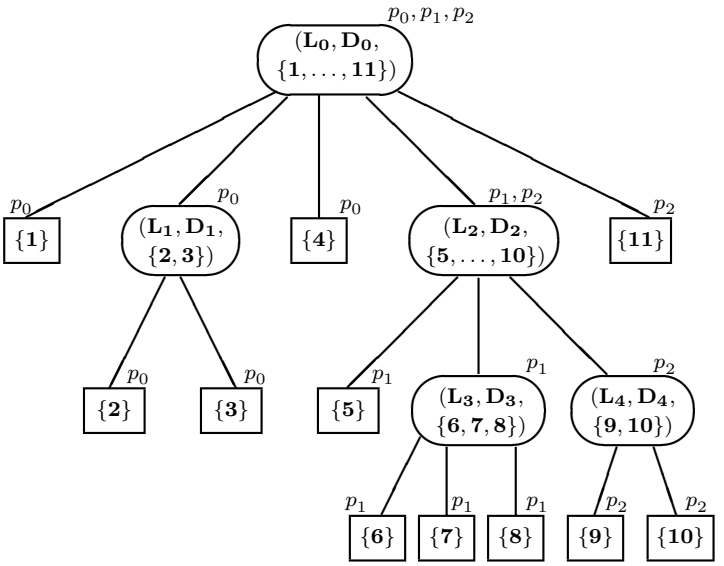

FIG. 5. *Representation tree annotated to describe the execution of the parallel algorithm. The matrix size is* 11*; the algorithm is run on* 3 *processors.*

eigenvectors to be computed locally. The clusters $\{\lambda_1\}$, $\{\lambda_2, \lambda_3\}$, $\{\lambda_4\}$ contain eigenvalues local to p_0, so the corresponding nodes in the tree are labeled p_0. In classifying the eigenvalues, both processors p_1 and p_2 find that the cluster $\{\lambda_5, \ldots, \lambda_{10}\}$ contains eigenvalues whose eigenvectors are to be computed locally: λ_5 through λ_8 for p_1 and λ_9, λ_{10} for p_2. The new representation is computed redundantly by both p_1 and p_2, and the refinement of eigenvalues λ_5 through λ_{10} is parallelized over p_1 and p_2. Thus the node is labeled p_1 as well as p_2 in Figure 5. The singleton λ_{11} is recognized as local by p_2 and therefore labeled p_2. The eigenvalue classification for node $(L_2, D_2, \{5, \ldots, 10\})$ is independently performed by processors p_1 and p_2: p_1 recognizes the clusters $\{\lambda_5\}$, $\{\lambda_6, \lambda_7, \lambda_8\}$ to contain local eigenvalues and discards the cluster $\{\lambda_9, \lambda_{10}\}$; vice versa for processor p_2. Nodes $\{5\}$ and $(L_3, D_3, \{6, 7, 8\})$ are therefore labeled p_1 while node $(L_4, D_4, \{9, 10\})$ is labeled p_2.

It is important to realize that the parallel algorithm traverses the sequential representation tree in parallel. Assuming identical arithmetic on all processors, this implies that the computed eigenvectors match exactly the ones computed by the sequential algorithm and therefore satisfy the same accuracy properties.

3.2. Householder reduction and backtransformation. To solve the dense, symmetric eigenproblem the solution to the tridiagonal eigenproblem is preceded by reduction to tridiagonal form and followed by a backtransformation stage to obtain the eigenvectors of the dense matrix. We will see in the performance section that Algorithm PMR^3 discussed in the previous section reduces the cost of the tridiagonal eigenproblem sufficiently so that it is the reduction and backtransformation stages that dominate the computation time. In this section, we give a brief overview of the major issues behind the parallel implementation of these stages. A more detailed discussion can be found in [4].

Reduction to tridiagonal form is accomplished through the application of a se-

quence of orthogonal similarity transformations; usually Householder transformations are preferred to Givens rotations. At the ith step in the reduction, a Householder transformation is computed that annihilates the elements in the ith column that lie below the first subdiagonal. This transformation is then applied to the matrix from the left and the right, after which the computation moves on to the next column of the updated matrix. Unfortunately, this simple "unblocked" algorithm is rich in matrix-vector operations (matrix-vector multiplications and symmetric rank-one updates, to be exact) which do not achieve high performance on modern microprocessors. Thus, a blocked version of the algorithm is derived from the unblocked algorithm by delaying updates to the matrix, accumulating those updates into a so-called symmetric rank-k update [22]. This casts the computation in terms of matrix-matrix multiplication, which can achieve much better performance. However, it is important to note that even for the blocked algorithm, approximately half the computation is in symmetric matrix-vector multiplication. This means that the best one can hope for is that implementations based on the blocked algorithm improve performance by a factor of 2 over implementations based on the unblocked algorithm.

The backtransformation stage applies the Householder transforms encountered during the reduction to tridiagonal form to the eigenvectors computed for the tridiagonal matrix. It is well known how to accumulate such Householder transforms into block Householder transforms so that the computation is again cast in terms of matrix-matrix multiplication [6]. This time essentially all computation involves matrix-matrix multiplication, allowing very high performance to be achieved.

Parallel implementation of both these stages now hinges on the fact that the parallel implementation of the symmetric matrix-vector multiplication, the symmetric rank-k update, and matrix-matrix multiplication is scalable, and can achieve high performance. Since these issues are well understood, we omit presenting them here and refer the reader to [32, 31]. Some subtle differences in the parallel implementations of these stages as supported by ScaLAPACK and PLAPACK are given in the appendix of [4]. Essentially, the ScaLAPACK and PLAPACK implementations are tuned for smaller and larger matrices, respectively.

4. Experimental results. This section presents timing results for the proposed algorithm. First we report results on the dense problem in section 4.2: it will be apparent that very large problems can now be tackled and that the tridiagonal eigenproblem is an order of magnitude faster than the reduction and backtransformation stages. In section 4.3 we focus on the tridiagonal eigensolvers and show that Algorithm PMR^3 achieves the best performance compared to previous algorithms.

4.1. Implementation details and test matrices. All experiments were conducted on a cluster of Linux workstations. Each node in the cluster consisted of a dual Intel Pentium 4 processor (2.4 GHz) with 2 GBytes of main memory. The nodes were connected via a high-performance network (2 Gigabit/s) from Myricom. In our experiments, only one processor per node was enabled. The reason for using one processor was primarily related to the fact that during early experiments it was observed that reliable timings were difficult to obtain when both processors were enabled. Notice that the qualitative behavior of the different algorithms and implementations is not affected by this decision, even if the quantitative results are.

We will often refer to our proposed parallel dense eigensolver as Dense PMR^3, and use PMR^3 to denote the tridiagonal eigensolver outlined in Figure 4; however, sometimes we just use PMR^3 when it is clear whether we are referring to the dense or tridiagonal eigensolver. Dense PMR^3 has been implemented using the PLAPACK

library for Householder reduction and backtransformation, while PMR^3 has been implemented in C and Fortran using the MPI library for communications and LAPACK for numerical routines.

We compare dense PMR^3 with the ScaLAPACK implementations of (a) bisection and inverse iteration (routine PDSYEVX) and (b) divide and conquer (routine PDSYEVD), and the PLAPACK implementation of (c) the QR algorithm (routine PLA_VDVt). All the routines have been compiled with the same optimization flags enabled and linked to the same high-performance BLAS library (the so-called GOTO BLAS, which in our experience achieve the highest performance on this machine [29]).

All dense eigensolvers have been tested on symmetric matrices of sizes ranging from 8000 to 128,000 with given eigenvalue distributions. We considered 4 types of diverse eigenvalue distributions:

1. UNIFORM (ε to 1):
$$\lambda_i = \varepsilon + (i-1) * \tau, \quad i = 1, 2, \ldots, n,$$
where $\tau = (1-\epsilon)/(n-1)$.
2. GEOMETRIC (ε to 1):
$$\lambda_i = \varepsilon^{(n-i)/(n-1)}, \quad i = 1, 2, \ldots, n.$$
3. RANDOM (ε to 1): the eigenvalues are drawn from a uniform distribution on the interval $[0, 1]$.
4. CLUSTERED at ε:
$$\lambda_1 \approx \lambda_2 \approx \cdots \approx \lambda_{n-1} \approx \varepsilon \text{ and } \lambda_n = 1.$$

In addition to the above "constructed" matrices, we also report timings for matrices arising in applications. We considered three matrices from computational quantum chemistry of sizes 966, 1687, and 2053, occurring, respectively, in modeling of the biphenyl molecule, study of bulk properties for the $SiOSi_6$ molecule, and solution of a nonlinear Schrödinger problem using the self-consistent Hartree–Fock method for the zeolite ZSM-5. More details on these matrices can be found in [2, 13].

We also considered three matrices (sizes 7923, 12387, 13786) that arise in frequency response analyses of automobile bodies. These matrices come from a symmetric matrix pencil arising from a finite element model of order 1 million or so, going through a process of dividing the entire structure into several thousand "substructures" using nested dissection and finding the "lowest" eigenvectors for each substructure. Projecting the matrix pencil onto the substructure eigenvector subspace and then converting to standard form followed by Householder reduction yields the test tridiagonal matrices. Details on producing these matrices can be found in [35].

Notice that the matrices for which we report results are at least one order of magnitude larger than the results reported in [43, 32].

4.2. Results for the dense problem. We now present performance results for computing all eigenpairs of a dense symmetric matrix highlighting the difference between the $O(n^3)$ reduction and backtransformation stages and the $O(n^2)$ tridiagonal computation of PMR^3.

When possible we compare the proposed algorithm against the ScaLAPACK implementation of divide and conquer (PDSYEVD) [43] since the latter routine is the fastest among the tridiagonal eigensolvers currently available in ScaLAPACK. All matrices considered in the following results have random distribution of eigenvalues, i.e.,

TABLE 1

matrices designated RANDOM in section 4.1. Note that neither the reduction nor the backtransformation stage is affected by the distribution of eigenvalues in the input matrix. Comparisons with other tridiagonal eigensolvers (QR algorithm, bisection, and inverse iteration) on matrices with varying eigenvalue distributions are given in section 4.3.

In Tables 1 and 2 we report timings for matrices of sizes 8000 and 15,000, respectively. The stages of dense PMR^3 are labeled PLAPACK (for reduction and backtransformation) and PMR^3 (for the tridiagonal solution), while the stages for the routine PDSYEVD are similarly labeled ScaLAPACK and PDSTEDC (the tridiagonal divide and conquer routine). As mentioned in section 2, a major drawback of the divide and conquer algorithm is its extra $O(n^2)$ memory requirement. As a result, there are several instances where PMR^3 can be run on a particular matrix, but PDSTEDC cannot be run; the symbol "_" in the tables indicates that the experiment could not be run because of memory constraints.

Figure 6 gives a pictorial view of the dense PMR^3 timings in Table 2. It is easy to see from the figure that the tridiagonal stage is an order of magnitude faster than the reduction and backtransformation stages. As justified by the calculations in section 3.1.3, Algorithm PMR^3 uses dqds for the initial eigenvalue computation when $p \leq 17|\Gamma_0|/n$; here $|\Gamma_0| = n$, so dqds is used when $p \leq 17$; otherwise parallel bisection with a differential quotient-difference transform is used.

Next we present timings for an incremental test of dense PMR^3, keeping the memory allocation per processor constant while increasing the matrix size and the number of processors accordingly. To compute all eigenvectors, the memory requirement is quadratic in n; hence for fixed memory per processor when the matrix size is doubled, four times as many processors are needed. So we give results for dense PMR^3

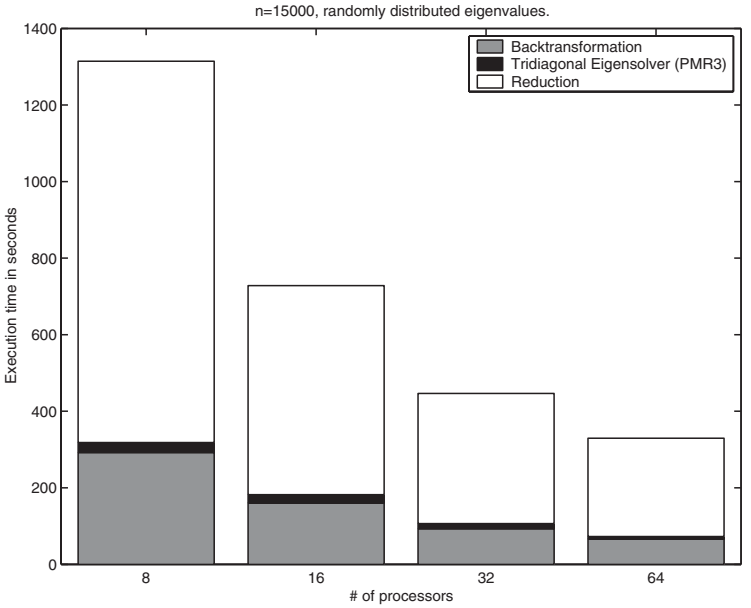

FIG. 6. *Timing breakdown for the dense* PMR^3 *algorithm,* $n = 15{,}000$.

on matrices of sizes 8000, 16,000, 32,000, 64,000, and 128,000 using 1, 4, 16, 64, and 256 processors, respectively. Table 3 includes these timings in addition to extrapolated timings for the PLAPACK QR implementation.[1] We are unable to run divide and conquer (PDSYEVD) for this test, as it runs out of memory. The difference in complexity between the $O(n^2)$ tridiagonal eigensolver versus the $O(n^3)$ reduction and backtransformation is again obvious.

Indicating by $T_p(n)$ the total time from Table 3 to solve a problem of size n with p processors, we plot in Figure 7 the [illegible]: the ratio $T_p(n\sqrt{p})/T_1(n)$ with $p = 1, 4, 16, 64, 256$. Since the dense eigensolver has $O(n^3)$ complexity, doubling the matrix size and deploying four times as many processors, assuming constant

[1]The performance of the QR algorithm applied to tridiagonal matrices is very predictable; the extrapolated timings have been obtained by running the tridiagonal problem with a larger number of processors (thereby avoiding memory problems) and adjusting the times for reduction and backtransformation, assuming perfect parallelization.

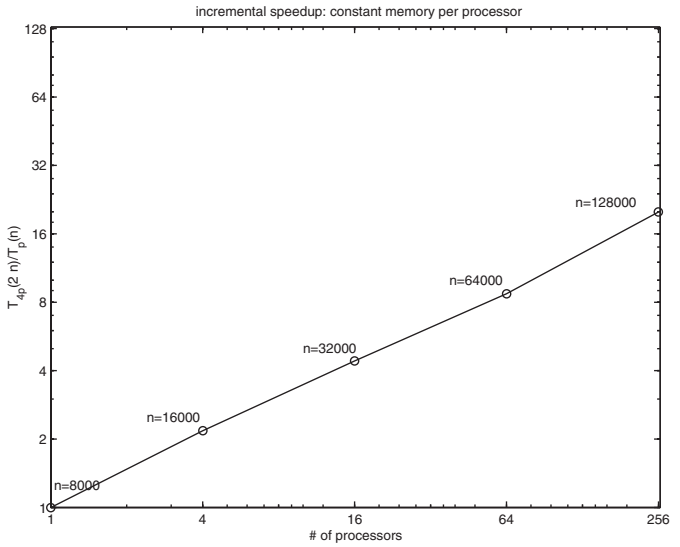

FIG. 7. *Incremental speedup.*

TABLE 4

Orthogonality and residual results for dense PMR^3. *Given the dense matrix A, the computed eigenvalues $\hat{\Lambda}$, and the computed eigenvectors $\hat{V}$, we display here* $\max_{i,j} |\hat{V}^T\hat{V} - I|_{ij}$ *(orthogonality) and* $\max_{i,j} |A\hat{V} - \hat{V}\hat{\Lambda}|_{ij}$ *(residual).*

Size		RANDOM	UNIFORM	GEOMETRIC	CLUSTERED
8000	Orthogonality	7.7e-11	2.0e-11	7.7e-12	2.5e-15
	Residual	3.7e-11	1.1e-11	1.5e-13	8.4e-16
15,000	Orthogonality	1.2e-10	1.0e-11	1.5e-11	1.7e-15
	Residual	1.9e-10	5.2e-12	6.8e-14	2.3e-16

performance per processor, the ratio $T_{4p}(2n)/T_p(n)$ equals

$$\frac{T_{4p}(2n)}{T_p(n)} = \frac{2^3 \ \frac{T_p(n)}{4}}{T_p(n)} = \frac{8}{4} = 2.$$

The log-log graph in Figure 7 testifies that the theoretical prediction is almost perfectly matched in practice. This demonstrates that dense PMR^3 scales up well in performance and larger problems can be tackled effectively when more processors are available.

Finally, in Table 4 we report on the accuracy of Algorithm PMR^3. Note that the eigenvalues and eigenvectors returned by PMR^3 are exactly the same as those computed by the sequential algorithm; therefore they satisfy the properties for residual and orthogonality described in [17].

4.3. Results for the tridiagonal problem. We now focus on the tridiagonal stage, comparing the performance of three different algorithms on matrices with differing eigenvalue distributions. With earlier QR or inverse iteration–based algorithms, the tridiagonal eigenproblem is often the bottleneck in the solution of the dense eigenproblem. For example, running sequential code for a matrix of size 2000 with uniformly distributed eigenvalues, the reduction and backtransformation stages take a total of about 32 seconds, while the tridiagonal eigenproblem takes 86 seconds

TABLE 5

for the QR algorithm, 106 seconds for bisection and inverse iteration, 4 seconds for the divide and conquer algorithm, but only .8 seconds for MR^3. The timings for a matrix of size 4000 are 290 seconds for reduction and backtransformation, 1099 seconds for QR, 821 for bisection and inverse iteration, 24 seconds for divide and conquer, and 3.1 seconds for MR^3. Note the $O(n^2)$ behavior of MR^3 as compared to the other tridiagonal methods. The above timings use the optimized GOTO BLAS; however, it may not always be possible to obtain optimized BLAS, especially for newer CPUs. The timings for $n = 4000$ using Fortran BLAS are 1125 seconds for QR, 830 for bisection and inverse iteration, 176 seconds for divide and conquer, and 3.4 seconds for MR^3. Thus, divide and conquer suffers the most when using Fortran BLAS.

In the following we illustrate the parallel performance of Algorithm PMR^3. Tables 5 and 7 include the timings for PMR^3 when the number of processors and eigenvalue distributions are varied. We compare our results with ScaLAPACK's divide and conquer routine (PDSYEVD) whenever possible; again the symbol "_" in the table indicates that the experiment could not be run because of memory constraints. We also present timings for a PLAPACK implementation of QR (PLA_VDVt); we found the ScaLAPACK QR implementation (PDSYEV) to be slower than the equivalent algorithm implemented with PLAPACK, probably due to synchronization issues; for this reason we omit PDSYEV timings. Finally for the experiment on matrices of size 8000 we also show timings for the ScaLAPACK implementation of bisection and inverse iteration (PDSTEBZ+PDSTEIN). An asterisk indicates that the experiment has not been run because of excessive time needed.

Table 5 shows that for matrices of order 8000 the PMR^3 algorithm is faster than all the other algorithms. In particular it is several orders of magnitude faster than bisection and inverse iteration; notice that the performance of the latter does not improve when increasing the number of processors. This is due to the presence of a large cluster of eigenvalues as judged by PDSTEIN. Since PDSTEIN does not split clusters across processors, all eigenvectors of the large cluster end up being computed

on a single processor. Since PDSTE(BZ+IN) is not competitive, we do not present its results in Table 7. Routine PLA_VDVt is also several orders of magnitude slower than PMR^3, but it achieves perfect speedup and does not suffer from the memory problems of PDSTEDC.

Algorithm PMR^3 attains good performance, but for $p \leq 16$ it does not exhibit particularly good speedups due to the redundant serial eigenvalue computation. It is interesting to analyze the timings for just the eigenvector computations; we display these values in Table 6. Notice that the eigenvector computations attain very good speedups (the timings given for $p = 1$ are for the serial code, not the parallel code with $p = 1$). The exception is the case of clustered eigenvalues, for which the entire computation is extremely fast independent of the number of processors.

Results for matrices of size 15,000 are displayed in Table 7. The proposed algorithm is again the fastest in all the experiments. Finally, we consider six tridiagonal matrices coming from applications. Timings for PMR^3 are shown in Table 8; the parallel algorithm is again seen to be very fast; for example, it takes only $5 + 0.7$ seconds for a matrix of size 13,786 on 64 processors. Algorithm PMR^{3}achieves good speedups for the eigenvector computation in all cases, and the speedups for the eigenvalue computation are almost perfect when $p \geq 16$, i.e., when parallel bisection is used.

5. Conclusions. In this paper, we have presented a new parallel eigensolver for computing all or a subset of the eigenvectors of a dense symmetric matrix. The tridiagonal kernel is not only faster than previous algorithms, but also scales up well in memory requirements ($O(n)$ work space), allowing for very large eigenproblems to be solved. As a result, the time now spent in the tridiagonal eigenproblem is negligible

compared to the stages of Householder reduction and backtransformation. Thus, the onus is now squarely on speeding up the latter two stages if the dense symmetric eigensolver is to be sped up further.

Acknowledgments. We are indebted to the Center for Computational Research at the University at Buffalo, SUNY, for the use of their 300 compute node Dell Linux Cluster. We also acknowledge the Texas Advanced Computing Center (TACC) for use of their 32 compute node IBM Pentium III Linux Cluster. We thank George Fann for providing the matrices from computational quantum chemistry, and Jeff Bennighof and Mintae Kim for the matrices arising from frequency analyses of automobile bodies.

MULTIGRID METHODS FOR IMPLICIT RUNGE–KUTTA AND BOUNDARY VALUE METHOD DISCRETIZATIONS OF PARABOLIC PDEs*

JAN VAN LENT† AND STEFAN VANDEWALLE†

Abstract. Advanced time discretization schemes for stiff systems of ordinary differential equations (ODEs), such as implicit Runge–Kutta and boundary value methods, have many appealing properties. However, the resulting systems of equations can be quite large and expensive to solve. Many techniques, exploiting the structure of these systems, have been developed for general ODEs. For spatial discretizations of time-dependent partial differential equations (PDEs) these techniques are in general not sufficient and also the structure arising from spatial discretization has to be taken into consideration. We show here that for time-dependent parabolic problems, this can be done by multigrid methods, as in the stationary elliptic case. The key to this approach is the use of a smoother that updates several unknowns at a spatial grid point simultaneously. The overall cost is essentially proportional to the cost of integrating a scalar ODE for each grid point. Combination of the multigrid principle with both time stepping and waveform relaxation techniques is described, together with a convergence analysis. Numerical results are presented for the isotropic heat equation and a general diffusion equation with variable coefficients.

Key words. parabolic partial differential equations, implicit Runge–Kutta methods, boundary value methods, multigrid, time stepping, waveform relaxation

DOI. 10.1137/030601144

1. Introduction.

Large, stiff systems of ordinary differential equations (ODEs) are often solved using low order methods such as the implicit Euler scheme. This choice is usually dictated by implementation and computational complexity issues. Several more advanced time discretization schemes such as implicit Runge–Kutta (IRK) methods [9] and, more recently, boundary value methods (BVMs), block boundary value methods (BBVMs) [4, 11, 12], and general linear methods (GLMs) [6] have been developed. These methods offer high orders of accuracy together with favorable stability properties, error estimators, and other interesting features. Unfortunately, the linear algebra cost per time step is in general very large for these methods. When a general IRK method with three stages or a BVM with three steps is applied, for example, the dimension of the linear systems is three times that of the implicit Euler case. The cost of solving these systems with standard methods is prohibitively large.

For general ODEs many specialized linear algebra methods have been developed and implemented in ODE software. These methods exploit the structure arising from carefully chosen time discretization formulae, such as diagonally or singly implicit Runge–Kutta methods [5, 6, 9]. Since the systems arising from spatial discretization of a time-dependent partial differential equation (PDE) can be extremely large, it becomes important to use specialized methods that also exploit the structure arising from discretization in space. We will show here that for parabolic PDEs this can be

†Katholieke Universiteit Leuven, Department of Computer Science, Celestijnenlaan 200A, B-3001 Leuven, Belgium (Jan.Vanlent@cs.kuleuven.ac.be, Stefan.Vandewalle@cs.kuleuven.ac.be). The first author is Research Assistant of the Fund for Scientific Research–Flanders (Belgium) (F.W.O.-Vlaanderen).

done very effectively by using multigrid methods. The methods exploiting structure arising from the time discretization formula can still be used as well, but with a good multigrid solver, this may no longer be absolutely necessary.

Some of the results in this paper, especially with respect to multigrid for IRK methods, have already been reported by other authors; see, e.g., [5, 19]. Their results are considerably extended here and cast into the more general framework of time stepping and block time stepping with GLMs. The use of multigrid for BVM and BBVM discretizations is new. This approach enables efficient solution of the BVM and BBVM linear systems, even for very large-scale semidiscrete PDE problems.

In section 2 we describe several high order time discretization schemes as well as the finite difference discretization used for the spatial domain. The multigrid iterative method is introduced in section 3, and we explain how it can be applied successfully for the systems arising from time stepping and block time stepping schemes. Section 4 shows how the convergence of the iterative methods for time stepping can be analyzed. The main theoretical results are presented in section 5 where waveform relaxation methods for block time stepping using GLMs and BBVMs are analyzed. Numerical results for two model problems, an isotropic and an anisotropic diffusion equation, are presented in section 6. A number of different IRK and BVM schemes are considered. The corresponding theoretical multigrid convergence rates are evaluated by means of a two-grid Fourier mode analysis and verified by extensive numerical experiments. One of the experiments involves the solution of an implicit linear system with more than 23 million unknowns, corresponding to a BVM discretization of the two-dimensional diffusion equation on a 256×256 spatial mesh, with 360 time steps computed simultaneously. One multigrid iteration step, gaining approximately one extra digit of solution accuracy, takes about 5 minutes on a 1.7 GHz Intel® Pentium® 4 system with 1 GB internal memory. Hence, the results clearly illustrate the effectiveness of the multigrid algorithm for use with implicit time integration methods, even for extremely large systems.

2. Time and space discretization schemes. In this article we consider parabolic equations of the form

$$\frac{\partial u}{\partial t} = \mathcal{L}u + f, \tag{2.1}$$

where $\mathcal{L}$ is an elliptic operator. To allow theoretical analysis and to keep the notation concise we assume that $\mathcal{L}$ is time-independent. All algorithms presented here are, however, applicable to the more general case where $\mathcal{L}$ is time-dependent. We also consider only discretization in time with a constant time step and finite difference discretizations in space on equidistant, rectangular grids with Dirichlet boundary conditions. The methods presented here can, however, be extended to three-dimensional problems and finite element discretizations on regular or irregular grids with more general boundary conditions.

2.1. Time discretization. We consider methods for stiff initial value problems of the form

$$\dot{y}(t) = f(t, y(t)), \tag{2.2}$$

where $t \in \Omega_t$, $y(t) \in V$, and $y(0) = y_0 \in V$ is given. The time domain can be bounded ($\Omega_t = [0, T]$) or unbounded ($\Omega_t = \mathbb{R}^+$). The space V can be, for example, $\mathbb{R}$ in the case of a scalar ODE, or $\mathbb{R}^m$ for a system of ODEs. Time-dependent PDEs also fit this setting with V a space of functions on some spatial domain Ω.

A brief description is given of linear multistep formulae, IRK methods, GLMs, and BVMs. For detailed information, we refer to the books [4, 5, 6, 8, 9]. The stability domains of the methods are described in section 5.1. The parameters of the schemes used in the numerical experiments can be found in Appendix A.

(LMFe) use solutions at several previous time steps in a formula of the form

$$\sum_{j=-k}^{0} \alpha_{k+j} y_{i+j} = \Delta t \sum_{j=-k}^{0} \beta_{k+j} f(t_{i+j}, y_{i+j}), \tag{2.3}$$

where $y_i \approx y(t_i) \in V$, $t_i = i\Delta t$, and α_j, β_j, $j = 0, \ldots, k$ are the parameters of the method. There is an equation for every $i = k, \ldots, n$. Since only y_0 is given, the values $y_1, \ldots, y_{k-1}$ have to be obtained by other methods. The index j ranges from $-k$ to 0 to indicate the similarity with the BVMs formulated below and to emphasize that the set of equations (2.3) for $i = k, \ldots, n$ can be described by a banded lower triangular matrix. For stiff initial value problems, implicit LMFe ($\beta_k \neq 0$) will be used. A well-known class of implicit LMFe are the so-called backward difference formulae (BDFe) [9, 16]. Note, however, that it is impossible to construct A-stable LMFe of order higher than 2. If $y(t) \in \mathbb{R}^m$, then in each step a system of m equations has to be solved. For the methods discussed below the systems can be much larger. Unlike the LMFe, the methods below can exhibit very good stability properties, even for high order discretizations.

(IRK) methods [5, 6, 9] use a number of intermediate quantities to advance one time step. These stage values $\tilde{y}_i \in V^s$ are calculated from

$$\tilde{y}_i = \mathbf{1}_s y_{i-1} + \Delta t A \tilde{f}(\tilde{t}_i, \tilde{y}_i), \tag{2.4}$$

where $\tilde{t}_i = \mathbf{1}_s t_{i-1} + c\Delta t$, $\mathbf{1}_s = [1 \cdots 1]^T \in \mathbb{R}^s$, and $\tilde{f}$ indicates componentwise application of f. The stage values $\tilde{y}_i$ are then used to calculate $y_i \in V$ using

$$y_i = y_{i-1} + \Delta t b^T \tilde{f}(\tilde{t}_i, \tilde{y}_i). \tag{2.5}$$

The parameters of the methods are contained in the matrix $A \in \mathbb{R}^{s \times s}$ and the vectors $b, c \in \mathbb{R}^s$, where s denotes the number of stage values. Some well-known methods are the Gauss, Radau, and Lobatto methods [5, 6, 9].

Both LMFe and IRK methods belong to the class of so-called (GLMs) [6, 9]. There are several ways to formulate this more general class of methods (see [6]). We choose to use the equations

$$\tilde{y}_i = C y_{i-1} + \Delta t A \tilde{f}(\tilde{t}_i, \tilde{y}_i), \tag{2.6}$$

$$y_i = D y_{i-1} + \Delta t B \tilde{f}(\tilde{t}_i, \tilde{y}_i), \tag{2.7}$$

where $A \in \mathbb{R}^{s \times s}$, $B \in \mathbb{R}^{r \times s}$, $C \in \mathbb{R}^{s \times r}$, and $D \in \mathbb{R}^{r \times r}$. Both $\tilde{y}_i \in V^s$ and $y_i \in V^r$ are vectors. This formulation highlights the analogy with IRK methods. The stage values $\tilde{y}_i$ are typically approximations of $y(t)$ for some t in the current time step. The vectors y_i can contain, for example, approximations of $y(t)$, brought forward from previous time steps or scaled approximations of derivatives of $y(t)$. In order to have a stable method, D has to be power bounded. Further conditions are needed to ensure that the method is consistent. The matrices C and D are typically chosen such that D is of rank one and also $D\mathbf{1}_r = \mathbf{1}_r$ and $C\mathbf{1}_r = \mathbf{1}_s$.

Within the family of GLMs many special methods have been developed that try to combine the efficiency of LMFe and the good stability properties of IRK methods. The computational complexity of IRK methods and GLMs depends mainly on the structure of A. In a Newton iteration for (2.6), the Jacobian is usually taken constant for all stages. An eigenvalue decomposition of A then reduces the system of order sm to s systems of order m. For general matrices A this will, however, involve using complex arithmetic. This can be avoided when A is lower triangular or diagonal. In some cases the cost can be further reduced if in addition the diagonal elements of A all have the same value. If A is diagonal, all stages can be solved in parallel. Increased efficiency can also be attained if A has only a single eigenvalue. For information and references about IRK and GLMs with special structures, see [5, 6, 9]. In the rest of the article, we will derive results for GLMs. The results for the subclass of IRK methods can be retrieved by taking $r = 1$, $B = b^T$, $C = \mathbf{1}_s$, and $D = 1$.

Another, more recent, type of method are the [illegible] (BVMs) [4, 11, 12], which can be interpreted as a generalization of the LMFe. The discretization is obtained by first assuming that the ODE is a boundary value problem and then imposing extra initial and final conditions on the values at the boundaries that are in fact unknown. A k-step BVM has for each $i = k_1, \ldots, n - k_2$ an equation of the form

$$\sum_{j=-k_1}^{k_2} \alpha_{k_1+j} y_{i+j} = \Delta t \sum_{j=-k_1}^{k_2} \beta_{k_1+j} f(t_{i+j}, y_{i+j}). \tag{2.8}$$

The main difference with the traditional LMF is that j ranges from $-k_1$ to k_2 ($k = k_1 + k_2$). The extra $k_1 - 1$ initial and k_2 final equations are of the form

$$\sum_{j=0}^{k} \alpha_j^{(i)} u_j = \Delta t \sum_{i=0}^{k} \beta_j^{(i)} f(t_j, u_j), \qquad i = 1, \ldots, k_1 - 1, \tag{2.9}$$

$$\sum_{j=0}^{k} \alpha_j^{(i)} u_{n-k+j} = \Delta t \sum_{j=0}^{k} \beta_j^{(i)} f(t_{n-k+j}, u_{n-k+j}), \qquad i = n - k_2 + 1, \ldots, n, \tag{2.10}$$

where the coefficients $\alpha_j^{(i)}$ and $\beta_j^{(i)}$ are chosen such that the truncation errors for the initial and final conditions are of the same order as for the basic method (2.8). The matrices describing the systems involved are banded, as for LMFe, but no longer lower triangular. The n equations (2.8)–(2.10) can be written as

$$A_e y_e = \Delta t B_e f(t_e, y_e),$$

with $t_e \in \mathbb{R}^{n+1}$, $y_e \in V^{n+1}$, and A_e, $B_e \in \mathbb{R}^{n\times(n+1)}$. The e subscript indicates that the known initial value is included. The matrix A_e has the following structure:

$$A_e = \begin{bmatrix} \alpha_0^1 & \alpha_1^1 & \cdots & \alpha_k^1 & & & \\ \vdots & \vdots & \cdots & \vdots & & & \\ \alpha_0^{k_1-1} & \alpha_1^{k_1-1} & \cdots & \alpha_k^{k_1-1} & & & \\ & \alpha_0 & & \cdots & \alpha_k & & \\ & & \ddots & & \cdots & \ddots & \\ & & & \alpha_0 & & \cdots & \alpha_k \\ & & & \alpha_0^{n-k_2+1} & & \cdots & \alpha_k^{n-k_2+1} \\ & & & \vdots & & \cdots & \vdots \\ & & & \alpha_0^n & & \cdots & \alpha_k^n \end{bmatrix}. \tag{2.11}$$

Replacing α by β yields the structure for B_e. Using the partitions $A_e = [a_0|A]$ and $B_e = [b_0|B]$, where we split off the first columns, we can rewrite this as a system for the unknowns $y \in V^n$. We get

$$Ay = \Delta t B f(t, y) + g_0, \tag{2.12}$$

where $g_0 = -a_0 y_0 + \Delta t b_0 f(t_0, y_0)$ contains the initial condition.

We conclude this part on time discretization schemes with a method that can form an extra step in the process of transforming the continuous problem (2.2) to a discrete problem. Dividing the time interval into n subintervals leads to the sequence of subproblems

$$\begin{aligned} &\dot{y}_i(t) = f(t, y_i), \quad y_i : [t_{i-1}, t_i] \to V, \quad i = 1, \ldots, n, \\ &y_1(t_0) = y_0, \quad y_i(t_{i-1}) = y_{i-1}(t_{i-1}), \quad i = 2, \ldots, n, \end{aligned}$$

where the final value of one subinterval is used as the initial condition on the next. This procedure is called time windowing or block time stepping.

Applying time windowing and a k-step BVM using s time steps on each of the subintervals yields a [illegible] (BBVM) [4, 11, 12]:

$$Ay_i + A_0 y_{i-1} = \Delta t B f(t_i, y_i) + \Delta t B_0 f(t_{i-1}, y_{i-1}), \tag{2.13}$$

where $t_i \in \mathbb{R}^s$, $y_i \in V^s$, $A_0 = a_0 e_s^T$, $B_0 = b_0 e_s^T \in \mathbb{R}^{s \times s}$, and $e_s = [0 \cdots 0\, 1]^T \in \mathbb{R}^s$. This approach allows matrices A and $B \in \mathbb{R}^{s \times s}$ of much lower dimension. When $s \approx k$ these matrices can no longer be considered banded and the Toeplitz character is lost.

[illegible] 2.1 It is straightforward to formulate IRK methods as BBVMs and GLMs as so-called BBVMs with memory. The main difference in the latter case is that the matrices A_0 and B_0 are general. If y_i and $\tilde{y}_i$ are the values and stage values calculated by a GLM defined by A, B, C, and D, then using, for example,

$$\hat{y}_i = \begin{bmatrix} \tilde{y}_i \\ y_i \end{bmatrix},$$

we get a BBVM for $\hat{y}_i$ defined by the matrices

$$\hat{A} = \begin{bmatrix} I & 0 \\ 0 & I \end{bmatrix}, \quad \hat{A}_0 = \begin{bmatrix} 0 & -C \\ 0 & -D \end{bmatrix}, \quad \hat{B} = \begin{bmatrix} A & 0 \\ B & 0 \end{bmatrix}, \quad \hat{B}_0 = \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix}.$$

[illegible] 2.2 It is also possible to formulate BBVMs as GLMs. Using, for example,

$$\tilde{y}_i = y_i = \begin{bmatrix} \hat{y}_i \\ \hat{y}_{i-1} \end{bmatrix},$$

and assuming that $\hat{A}^{-1}$ exists, we get

$$A = B = \begin{bmatrix} \hat{A}^{-1}\hat{B} & \hat{A}^{-1}\hat{B}_0 \\ 0 & 0 \end{bmatrix}, \quad C = D = \begin{bmatrix} -\hat{A}^{-1}\hat{A}_0 & 0 \\ I & 0 \end{bmatrix}.$$

[illegible] 2.3 It is important to note that Δt has a different interpretation in GLMs and BBVMs. For BBVMs it is the distance between stage values; for GLMs it is the length of one time step, which contains s stage values.

For more information on BBVMs and GLMs we refer to [4, 6, 11, 12].

2.2. Space discretization. We consider equations of the form

$$\mathcal{L}u = (au_x)_x + (bu_y)_y + cu = f, \tag{2.14}$$

where u, a, b, c, and f are functions defined on a spatial domain. More specifically, we consider only the unit square $\Omega = [0,1]^2$ and define the equidistant rectangular grid

$$\begin{aligned} x_i &= i\Delta x, \qquad i = 0, \ldots, n_x, \qquad \Delta x = n_x^{-1}, \\ y_j &= j\Delta y, \qquad j = 0, \ldots, n_y, \qquad \Delta y = n_y^{-1}. \end{aligned}$$

Using central differences we can approximate (2.14) by

$$c_{i,j}^{0,0}u_{i,j} + c_{i,j}^{-1,0}u_{i-1,j} + c_{i,j}^{1,0}u_{i+1,j} + c_{i,j}^{0,-1}u_{i,j-1} + c_{i,j}^{0,1}u_{i,j+1} = f_{i,j},$$

where $i = 1, \ldots, n_x - 1$, $j = 1, \ldots, n_y - 1$, $u_{i,j} \approx u(x_i, y_j)$, and

$$\begin{aligned} c_{i,j}^{\pm 1,0} &= \Delta x^{-2} a(x_i \pm \Delta x/2, y_j), \qquad c_{i,j}^{0,\pm 1} = \Delta y^{-2} b(x_i, y_j \pm \Delta y/2), \\ c_{i,j}^{0,0} &= c(x_i, y_j) - c_{i,j}^{-1,0} - c_{i,j}^{1,0} - c_{i,j}^{0,-1} - c_{i,j}^{0,1}. \end{aligned}$$

Packing the unknowns at the interior points of the grid into a vector of dimension $m = (n_x - 1)(n_y - 1)$ using, for example, the ordering

$$u_k = u_{i,j}, \qquad k = (i-1)(n_y - 1) + j,$$

the discrete system can be represented in the matrix form

$$Lu = f, \tag{2.15}$$

with $u, f \in \mathbb{R}^m$ and $L \in \mathbb{R}^{m \times m}$. The boundary conditions are incorporated in f. The matrix L is sparse and has a block tridiagonal structure with tridiagonal subblocks.

3. Time integration: Time stepping and waveform relaxation.

3.1. Introduction: Classical iterative methods and multigrid. It is well known that for systems of equations involving large sparse matrices, such as the ones derived from discretizing PDEs, direct methods are often inefficient. Many iterative methods, on the other hand, deal very well with these kinds of problems. Two very simple iterative schemes are the Jacobi and the Gauss–Seidel methods. Both can be described using a splitting of the system matrix. Using $L = L^+ + L^-$ and (2.15) the iteration scheme becomes

$$L^+ u^{(\nu)} + L^- u^{(\nu-1)} = f.$$

The matrix L^+ is chosen such that this system can be easily solved. For the Jacobi method it contains only the diagonal of L. For the Gauss–Seidel method it is the lower triangular part of L. Unlike for the Jacobi method, the ordering of the unknowns is relevant for the Gauss–Seidel method. Common orderings on two-dimensional grids are lexicographical and red-black. For more variations and other iterative methods of this kind we refer to [26]. A description of methods appropriate for time-dependent parabolic equations with spatial anisotropy can be found in [27].

A Jacobi or Gauss–Seidel iteration step can be implemented very efficiently in the case of sparse matrices. The implementation is even simpler when uniform grids are

$\text{mg}(\mathbf{x}^{(0)}, \mathbf{A}, \mathbf{b}) \to \mathbf{x}^{(3)}$
- $\mathbf{x}^{(1)} \leftarrow \text{smooth}(\mathbf{x}^{(0)}, \mathbf{A}, \mathbf{b}, \mu_1)$
- $\bar{\mathbf{b}} \leftarrow \mathbf{R}(\mathbf{b} - \mathbf{A}\mathbf{x}^{(1)})$
- $\bar{\mathbf{x}} \leftarrow \text{cgc}(\bar{\mathbf{A}}, \bar{\mathbf{b}})$
- $\mathbf{x}^{(2)} \leftarrow \mathbf{x}^{(1)} + \mathbf{P}\bar{\mathbf{x}}$
- $\mathbf{x}^{(3)} \leftarrow \text{smooth}(\mathbf{x}^{(2)}, \mathbf{A}, \mathbf{b}, \mu_2)$

$\text{cgc}(\bar{\mathbf{A}}, \bar{\mathbf{b}}) \to \bar{\mathbf{x}}$
- $\bar{\mathbf{x}} \leftarrow \bar{\mathbf{A}}^{-1}\bar{\mathbf{b}}$

$\text{smooth}(\mathbf{x}^{(0)}, \mathbf{A}, \mathbf{b}, \mu) \to \mathbf{x}^{(\mu)}$
- for $\nu = 1, \ldots, \mu$
  solve $\mathbf{A}^{+}\mathbf{x}^{(\nu)} = \mathbf{b} - \mathbf{A}^{-}\mathbf{x}^{(\nu-1)}$

ALGORITHM 3.1: Two-grid iteration for $\mathbf{A}\mathbf{x} = \mathbf{b}$, using the splitting $\mathbf{A} = \mathbf{A}^{+} + \mathbf{A}^{-}$.

$\text{cgc}(\bar{\mathbf{A}}, \bar{\mathbf{b}}) \to \bar{\mathbf{x}}$
- $\bar{\mathbf{x}} \leftarrow 0$
- γ times
  $\bar{\mathbf{x}} \leftarrow \text{mg}(\bar{\mathbf{x}}, \bar{\mathbf{A}}, \bar{\mathbf{b}})$

ALGORITHM 3.2: Coarse grid correction for multigrid iteration. V-cycle: $\gamma = 1$, W-cycle: $\gamma = 2$.

used. Unfortunately these simple splitting methods may converge very slowly. They do, however, form the basis of the very efficient multigrid methods discussed next.

Algorithm 3.1 gives a schematic overview of a two-grid iteration for a linear system of the form $\mathbf{A}\mathbf{x} = \mathbf{b}$. The quantities $\mathbf{x}$ and $\mathbf{b}$ are elements of a vector space approximating functions on a spatial domain. The operator $\mathbf{A}$ is a discrete approximation to an elliptic operator. The barred symbols indicate quantities and operators on a coarse grid. Restriction $\mathbf{R}$ and prolongation $\mathbf{P}$ are the intergrid operators, transferring quantities from the fine to the coarse level and vice versa. The whole iteration can be written as $\mathbf{x}^{(3)} = \mathbf{M}\mathbf{x}^{(0)} + \mathbf{q}$ or, equivalently, $\mathbf{e}^{(3)} = \mathbf{M}\mathbf{e}^{(0)}$ for the errors $\mathbf{e}^{(\cdot)} = \mathbf{x}^{(\cdot)} - \mathbf{x}$. It is straightforward to derive the following form for the two-grid iteration operator

$$\mathbf{M} = \mathbf{K}^{\mu_2}(\mathbf{I} - \mathbf{P}\bar{\mathbf{A}}^{-1}\mathbf{R}\mathbf{A})\mathbf{K}^{\mu_1},$$
$$\mathbf{K} = -\mathbf{A}^{+-1}\mathbf{A}^{-}.$$

In the two-grid iteration the equation $\bar{\mathbf{A}}\bar{\mathbf{x}} = \bar{\mathbf{b}}$ on the coarse grid is solved exactly. We can, however, solve this equation using the same iterative algorithm. Algorithm 3.2 shows how the two-grid iteration can be extended to a general multigrid iteration by applying this idea recursively. Discretizations on a hierarchy of increasingly coarser grids are used. The problem on the coarsest level can be solved exactly or approximately by applying a few smoothing steps.

For clarity we consider only linear problems. Nonlinear problems can be solved by embedding the multigrid algorithm as a linear solver in a Newton iteration or by using a nonlinear multigrid scheme [26]. Here, we use the multigrid method as a solver, not as a preconditioner for a Krylov subspace method [34]. Finally, we will consider only the standard geometric multigrid procedure for discretizations on regular, rectangular grids. For irregular grids and other multigrid techniques, such as the algebraic multigrid (AMG) method, we refer to [26].

The standard geometric multigrid method for discretization (2.15) of the elliptic equation (2.14) fits the framework described here with

$$\mathbf{x} = u, \quad \mathbf{b} = f,$$

$$\mathbf{A} = L, \quad \mathbf{A}^+ = L^+, \quad \mathbf{A}^- = L^-,$$

where $\mathbf{x}, \mathbf{b} \in \mathbb{R}^m$. For a given coarsest grid, the hierarchy of grids is built up by successively doubling the number of intervals in both the x- and the y-direction. $\mathbf{R} = R$ and $\mathbf{P} = P$ are the standard full weighting restriction and bilinear interpolation operators. For details we refer to [26].

By changing the order in which the discretization and solution methods are applied, a whole variety of multigrid based solution methods for time-dependent problems can be derived. We now formulate the two families of methods we will focus on in the remainder of this article.

3.2. Iterative methods for time stepping schemes. If we apply any of the time discretization schemes discussed in section 2 to a time-dependent PDE, we get a so-called time stepping method. In the case of a parabolic initial value problem, the elliptic subproblems can be solved using a multigrid algorithm. One smoothing step consists of a loop over all spatial grid points, updating all unknowns for the considered time step simultaneously. For LMF methods there is only one unknown per grid point and only scalar computations are required. An s-dimensional system has to be solved at each grid point in the IRK, GLM, and BBVM cases. Since s is usually small, this can be done using a standard dense solver. It is still possible to use eigenvalue decompositions or methods with a special structure, as described in section 2, but this will generally not be necessary. The BVM case cannot be considered a time stepping method since the values at all time steps have to be obtained from a system of equations that is banded but not triangular or block triangular.

Applying to (2.1) first a time discretization from section 2.1 and then the space discretization and the splitting of the discretized elliptic operator introduced in sections 2.2 and 3.1, we get the following iterative methods, which can all be used as the smoother in a multigrid scheme.

Using an LMF (2.3) results in

$$\begin{aligned}\sum_{j=-k}^{0} \alpha_{k+j} u_{i+j}^{(\nu)} = \Delta t \sum_{j=-k}^{0} \beta_{k+j} L^+ u_{i+j}^{(\nu)} \\ + \Delta t \sum_{j=-k}^{0} \beta_{k+j} L^- u_{i+j}^{(\nu-1)} + \Delta t \sum_{j=-k}^{0} \beta_{k+j} f_{i+j}.\end{aligned} \tag{3.1}$$

Note that additional methods have to be provided to approximate the initial values $u_i \in \mathbb{R}^m, i = 1, \ldots, k-1$, to turn this into a practical method.

When we apply a BVM (2.8), we get

$$\begin{aligned}\sum_{j=-k_1}^{k_2} \alpha_{k_1+j} u_{i+j}^{(\nu)} = \Delta t \sum_{j=-k_1}^{k_2} \beta_{k_1+j} L^+ u_{i+j}^{(\nu)} \\ + \Delta t \sum_{j=-k_1}^{k_2} \beta_{k_1+j} L^- u_{i+j}^{(\nu-1)} + \Delta t \sum_{j=-k_1}^{k_2} \beta_{k_1+j} f_{i+j}.\end{aligned} \tag{3.2}$$

The initial and final conditions can be derived in the same way from (2.9) and (2.10).

For a GLM described by (2.6) and (2.7), the smoother becomes

$$\begin{aligned}\tilde{u}_i^{(\nu)} = (C \otimes I_m) u_{i-1}^{(\nu)} + \Delta t (A \otimes L^+) \tilde{u}_i^{(\nu)} \\ + \Delta t (A \otimes L^-) \tilde{u}_i^{(\nu-1)} + \Delta t (A \otimes I_m) \tilde{f}_i,\end{aligned} \tag{3.3}$$

$$u_i^{(\nu)} = (D \otimes I_m)u_{i-1}^{(\nu)} + \Delta t(B \otimes L^+)\tilde{u}_i^{(\nu)} + \Delta t(B \otimes L^-)\tilde{u}_i^{(\nu-1)} + \Delta t(B \otimes I_m)\tilde{f}_i, \tag{3.4}$$

where "$\otimes$" denotes the matrix Kronecker product.

Discretizing time using a BBVM (2.13) results in the iterative method

$$\begin{aligned}(A\otimes I_m)u_i^{(\nu)} &+ (A_0 \otimes I_m)u_{i-1}^{(\nu)} \\ &= \Delta t(B \otimes L^+)u_i^{(\nu)} + \Delta t(B \otimes L^-)u_i^{(\nu-1)} + \Delta t(B \otimes I_m)f_i \\ &\quad + \Delta t(B_0 \otimes L^+)u_{i-1}^{(\nu)} + \Delta t(B_0 \otimes L^-)u_{i-1}^{(\nu-1)} + \Delta t(B_0 \otimes I_m)f_{i-1}.\end{aligned} \tag{3.5}$$

The BVM discretization corresponds to taking the number of subintervals $n = 1$.

3.3. Waveform relaxation methods for block time stepping schemes. An interesting modification of the time stepping schemes is to collect the equations associated with a consecutive set of time steps together into one big system of equations [10, 25, 35]. Combining four BDF1 time steps, for example, results in a system of equations of the form

$$(A \otimes I_m)u = \Delta t(B \otimes L)u + \Delta t(B \otimes I_m)f + g_0,$$

where $u, f, g_0 \in \mathbb{R}^{4m}$, $B = I_4$, and

$$A = \begin{bmatrix} 1 & & & \\ -1 & 1 & & \\ & -1 & 1 & \\ & & -1 & 1 \end{bmatrix}.$$

Information about the previous time step is incorporated in g_0 as in (2.12). The splitting $L = L^+ + L^-$ leads to an iteration of the form

$$(A \otimes I_m)u^{(\nu)} = \Delta t(B \otimes L^+)u^{(\nu)} + \Delta t(B \otimes L^-)u^{(\nu-1)} + \Delta t(B \otimes I_m)f + g_0.$$

This can be seen as a collective update for all the unknowns on the set of time levels considered and can be executed by solving a series of small systems of equations, one 4 x 4 system at each grid point in this particular example. We call this type of method a block time stepping scheme and the associated iteration a discrete waveform relaxation method. As mentioned in the previous section, "block time stepping" is the only option for BVMs. Similar extensions are possible for any other LMFe as well as for GLMs and BBVMs. For LMFe the subsystems are lower triangular and characterized by matrices A and B of the form

$$A = \begin{bmatrix} \alpha_k & & & & \\ \vdots & \ddots & & & \\ \alpha_0 & \dots & \alpha_k & & \\ & \ddots & \ddots & \ddots & \\ & & \alpha_0 & \dots & \alpha_k \end{bmatrix}.$$

For BVMs they are banded of the form (2.11), and in the case of GLMs or BBVMs they are block lower triangular. For all these cases, the systems that arise when using a discrete waveform relaxation method can be easily solved by direct methods.

. . . . 3 1 Another way of deriving the methods in this section is to first transform (2.1) into the system of ODEs

$$\dot{u} = Lu + f \tag{3.6}$$

by discretizing only the spatial domain. This fits the framework outlined in section 3.1 with $u, f : \Omega_t \to R^m$ and the operator $\mathbf{A} = \frac{d}{dt} - L$. The splitting $\mathbf{A}^+ = \frac{d}{dt} - L^+$, $\mathbf{A}^- = -L^-$ gives us the smoother

$$\dot{u}^{(\nu)} = L^+ u^{(\nu)} + L^- u^{(\nu-1)} + f \tag{3.7}$$

and thus a multigrid algorithm. This algorithm can be defined on a time interval that is finite, $\Omega_t = [0, T]$, or infinite, $\Omega_t = [0, \infty)$. In this continuous waveform relaxation method, one smoothing step consists of the solution of m scalar ODEs, one for each grid point. Applying any of the time discretization schemes to solve these brings us back to the discrete waveform relaxation methods discussed before.

3.4. Remarks. The equations to be solved for the time stepping and block time stepping schemes are exactly the same. The corresponding multigrid methods differ only in the order in which the unknowns are updated. In the time stepping case the ODE solver forms the outer loop and a multigrid solver is used within each time step. In the waveform relaxation case, the multigrid solver forms the outer loop and the ODE solver is used within its smoother. Summarizing, we can say that a time stepping method loops over time steps, then multigrid iterations, then multigrid levels, then smoothing steps, and finally grid points. A waveform relaxation method loops over multigrid iterations, then multigrid levels, then smoothing steps, then grid points, and finally time steps. In both cases the cost of one multigrid iteration is equivalent to the cost of solving a scalar ODE at each grid point.

The approach discussed here has to be contrasted with other approaches for the solution of systems arising from the discretization of general ODEs. One approach to solving systems with matrices of the form $A \otimes I_m - \Delta t B \otimes L$, obtained by using BVMs, is to use circulant approximations for the matrices A and B to precondition a Krylov subspace iteration (see, for example, [2, 3, 7, 13]). This essentially comes down to splitting the matrices A and B, whereas we split the matrix L. The approaches are, of course, not mutually exclusive, but for the small subsystems that have to be solved at each grid point in our multigrid smoothers, direct methods are hard to beat. Finally, we note that smoothers derived by directly applying the Jacobi or Gauss–Seidel methods to the system matrix give very unsatisfactory results.

4. Convergence analysis for the time stepping case. In this section we present a convergence analysis of the iterative methods for time stepping schemes discussed in the previous sections. We use the asymptotic convergence factor, i.e., the spectral radius of the iteration operator, as a measure for convergence. In the time stepping case the iterates are vectors and the iteration operator is a matrix. The convergence factors can therefore be derived using only linear algebra manipulations.

4.1. Classical iterative methods. For the LMF case, we obtain from (4.1) the error iteration

$$\alpha_k I_m e_i^{(\nu)} = \Delta t \beta_k L^+ e_i^{(\nu)} + \Delta t \beta_k L^- e_i^{(\nu-1)}, \tag{4.1}$$

where the iteration errors are $e_i^{(\nu)} = u_i^{(\nu)} - u_i \in \mathbb{R}^m$. Let $\mathcal{K}_{\Delta t}$ be the corresponding iteration operator. The convergence factor we are looking for is

$$\begin{aligned}\rho\left(\mathcal{K}_{\Delta t}\right) &= \rho\left((\alpha_k I_m - \Delta t \beta_k L^+)^{-1} \Delta t \beta_k L^-\right) \\ &= \rho\left(\left(\frac{1}{\Delta t}\frac{\alpha_k}{\beta_k} I_m - L^+\right)^{-1} L^-\right),\end{aligned}$$

where we assumed that $\beta_k \neq 0$ and $\frac{1}{\Delta t}\frac{\alpha_k}{\beta_k} \notin \sigma(L^+)$. Introducing the operator

$$K(z) = (z I_m - L^+)^{-1} L^-, \tag{4.2}$$

we can write this as

$$\rho\left(\mathcal{K}_{\Delta t}\right) = \rho\left(K\left(\frac{1}{\Delta t}\frac{\alpha_k}{\beta_k}\right)\right).$$

We can now state the following theorem.

THEOREM 4.1. $\mathcal{K}_{\Delta t}$ [illegible] (3.1) [illegible] $\Sigma = \left\{\frac{\alpha_k}{\beta_k}\right\}$ [illegible] $\frac{1}{\Delta t}\Sigma \cap \sigma(L^+) = \phi$ [illegible]

$$\rho(\mathcal{K}_{\Delta t}) = \left[\rho\big(K(z)\big)\right]_{z \in \frac{1}{\Delta t}\Sigma}. \tag{4.3}$$

Note that for the Gauss–Seidel and Jacobi methods, the operator $K(z)$ is the iteration matrix for the equivalent splitting method applied to

$$zu = Lu + f, \tag{4.4}$$

which is the Laplace transform of the system of ODEs (3.6).

For block BVMs (with standard BVMs and LMFe as special cases), we get

$$(A \otimes I_m) e_i^{(\nu)} = \Delta t (B \otimes L^+) e_i^{(\nu)} + \Delta t (B \otimes L^-) e_i^{(\nu-1)}, \tag{4.5}$$

where $e_i^{(\nu)} = u_i^{(\nu)} - u_i \in \mathbb{R}^{sm}$. Let $\mathcal{K}_{\Delta t}$ be the corresponding iteration operator. Assuming that B^{-1} exists and that $\frac{1}{\Delta t}\sigma(B^{-1}A) \cap \sigma(L^+) = \phi$, we get

$$\begin{aligned}\rho\left(\mathcal{K}_{\Delta t}\right) &= \rho\left((A \otimes I_m - \Delta t B \otimes L^+)^{-1} \Delta t (B \otimes L^-)\right) \\ &= \rho\left(\left(\frac{1}{\Delta t} B^{-1}A \otimes I_m - I_s \otimes L^+\right)^{-1} (I_s \otimes L^-)\right),\end{aligned}$$

which we can write as

$$\rho\left(\mathcal{K}_{\Delta t}\right) = \rho\left(K\left(\frac{1}{\Delta t} B^{-1} A\right)\right).$$

This leads us to the following theorem.

THEOREM 4.2. $\mathcal{K}_{\Delta t}$ [illegible] (3.5) [illegible] $\Sigma = \sigma(B^{-1}A)$ [illegible] $\frac{1}{\Delta t}\Sigma \cap \sigma(L^+) = \phi$ [illegible]

$$\rho(\mathcal{K}_{\Delta t}) = \max_{z \in \frac{1}{\Delta t}\Sigma} \rho(K(z)). \tag{4.6}$$

By choosing Σ an appropriate subset of $\mathbb{C}$, (4.6) will apply to all other time discretization methods considered here (max is replaced by sup when Σ is an infinite set).

In the IRK/GLM time stepping case, the iterative method is used to find the solutions of the equations for the stage values. The values u_i are calculated directly from $\tilde{u}_i$ and do not take part in the iteration. The iteration for the errors $\tilde{e}_i^{(\nu)} = \tilde{u}_i^{(\nu)} - \tilde{u}_i \in \mathbb{R}^{sm}$ becomes

$$\tilde{e}_i^{(\nu)} = \Delta t(A \otimes L^+)\tilde{e}_i^{(\nu)} + \Delta t(A \otimes L^-)\tilde{e}_i^{(\nu-1)}. \tag{4.7}$$

The convergence factor of the corresponding iteration operator $\mathcal{K}_{\Delta t}$ can be written as

$$\begin{aligned}\rho\left(\mathcal{K}_{\Delta t}\right) &= \rho\left(\left(I_s \otimes I_m - \Delta t A \otimes L^+\right)^{-1}(\Delta t A \otimes L^-)\right) \\ &= \rho\left(K\left(\frac{1}{\Delta t}A^{-1}\right)\right),\end{aligned}$$

where we assume that A^{-1} exists and $\frac{1}{\Delta t}\sigma(A^{-1}) \cap \sigma(L^+) = \phi$.

THEOREM 4.3. [illegible] $\mathcal{K}_{\Delta t}$ [illegible] (3.3) [illegible] $\Sigma = \sigma(A^{-1})$ [illegible] $\frac{1}{\Delta t}\Sigma \cap \sigma(L^+) = \phi$ [illegible]

$$\rho(\mathcal{K}_{\Delta t}) = \max_{z \in \frac{1}{\Delta t}\Sigma} \rho(K(z)). \tag{4.8}$$

4.2. Multigrid. A standard approach for the convergence analysis of geometric multigrid methods is to consider a two-grid method applied to an equation with constant coefficients and periodic boundary conditions for the spatial domain. These simplifications make it possible to do a Fourier mode analysis. This so-called two-grid local Fourier mode analysis provides an indication of what convergence to expect for the multigrid iteration. For more information on convergence analysis of multigrid methods we refer to [26, 30, 34]. A three-grid analysis can be found in [33]. As an example we show how the analysis for classical iterative methods can be extended to a two-grid time stepping method using a BBVM time discretization. The results for the other time stepping schemes are analogous.

We first derive the equivalent to the operator $K(z)$ by applying the framework in section 3.1 to (4.4). Using $\mathbf{A} = zI_m - L$, $\mathbf{A}^+ = zI_m - L^+$, $\mathbf{A}^- = -L^-$, $\mathbf{R} = R$, $\mathbf{P} = P$, and $\bar{\mathbf{A}} = zI_{\bar{m}} - \bar{L}$, we obtain the two-grid iteration matrix

$$M(z) = K(z)^{\mu_2}(I - P(zI_{\bar{m}} - \bar{L})^{-1}R(zI_m - L))K(z)^{\mu_1}, \tag{4.9}$$

where $K(z)$ is defined as before.

Doing the same for $\mathbf{A} = A \otimes I_m - \Delta t B \otimes L$, $\mathbf{A}^+ = A \otimes I_m - \Delta t B \otimes L^+$, $\mathbf{A}^- = -\Delta t B \otimes L^-$, $\mathbf{R} = I_s \otimes R$, $\mathbf{P} = I_s \otimes P$, and $\bar{\mathbf{A}} = A \otimes I_{\bar{m}} - \Delta t B \otimes \bar{L}$, we derive that the iteration operator for the two-grid method using (3.5) as smoother can be written as

$$\mathcal{M}_{\Delta t} = M\left(\frac{1}{\Delta t}B^{-1}A\right).$$

The results from the previous section therefore hold for the two-grid iteration if we replace $K(z)$ by $M(z)$ and extend the condition on the set Σ to

$$\frac{1}{\Delta t}\Sigma \cap (\sigma(L^+) \cup \sigma(\bar{L})) = \phi.$$

5. Convergence analysis for the block time stepping case. Waveform relaxation schemes were first introduced and analyzed in a qualitative way in the electrical engineering literature [17, 31, 32]. Here we follow the more quantitative convergence analysis introduced in [21, 22]. This analysis was extended to multigrid waveform relaxation [19, 28], IRK time discretizations [5, 19], time periodic problems [28], and space discretizations using finite elements [14, 15]. In this section we present an analysis for GLMs and BBVMs. Notation and presentation are mainly taken from the last two references, except that for clarity we will not consider finite element discretizations here. As usual, we consider methods defined on infinite time intervals since this provides results that correspond better to numerically observed behavior. For further motivation of this approach we refer to [14, 21, 28]. Weighted norms or pseudospectra can also be used to obtain meaningful information about convergence. In [20] the convergence analysis on infinite time intervals is shown to be a limiting case of the pseudospectral analysis.

5.1. Preliminaries: The stability domain and its complement. Stability domains of time discretization schemes play an important part in the convergence analysis of discrete waveform relaxation methods. We recall the definitions of the stability domains of the methods considered here. For each method we also introduce a set $\Sigma \subset \mathbb{C}$ that we will later encounter in the convergence analysis. For the case of LMFe a close relation exists between Σ and the stability domain. We show that the same relation holds for GLMs (and therefore also for IRK methods), BVMs, and BBVMs. As a bonus, this relation provides us with a convenient way to calculate points on a curve containing the boundary of the stability domain.

The linear stability of a time discretization scheme is studied using the Dahlquist test equation [9]

$$y' = \lambda y, \quad y(0) = y_0. \tag{5.1}$$

The stability domain consists of all $z = \Delta t\lambda \in \mathbb{C}$ for which the discrete solution is bounded. The interior of the stability domain, also called the open stability domain, consists of all z for which the discrete solution converges to 0. Only the definitions for open stability domains are given since they are simpler and sufficient for the rest of the discussion.

For an LMF (2.3) we define the polynomials

$$a(w) = \sum_{j=0}^{k} \alpha_j w^j \quad \text{and} \quad b(w) = \sum_{j=0}^{k} \beta_j w^j \tag{5.2}$$

and make the common assumptions of irreducibility, consistency, and zero stability [6, 8]. Furthermore, we consider only implicit methods ($\beta_k \neq 0$). We can use the same definitions for BVMs [4]. Again, the methods are assumed to be irreducible, consistent, and zero stable. BVMs are implicit by nature.

DEFINITION 5.1. [illegible] (k_1, k_2, k_2) [illegible] k_1 [illegible] k_2 [illegible] k_3 [illegible]

By applying each of the schemes in section 2.1 to the test equation (5.1), we obtain the following definitions.

DEFINITION 5.2. [illegible] S [illegible] k [illegible] $z \in \mathbb{C}$ [illegible] $a(w) - zb(w)$ [illegible] $(k, 0, 0)$

A generalization of the stability concept to BVMs can be found in [1, 4].

DEFINITION 5.3. (k_1, k_2) S $z \in \mathbb{C}$ $a(w) - zb(w)$ $(k_1, 0, k_2)$

DEFINITION 5.4. S $z \in \mathbb{C}$ $D + B(z^{-1}I_s - A)^{-1}C$ $(s, 0, 0)$ [6, 9]

DEFINITION 5.5. S $z \in \mathbb{C}$ $-(A - zB)^{-1}(A_0 - zB_0)$ $(s, 0, 0)$ [4, 12]

An LMF, GLM, or BBVM is called A-stable if the left half-plane is contained in its stability domain. A BVM is called A_{k_1,k_2}-stable if the left half-plane is contained in its (k_1, k_2)-stability domain. These are desirable, if not essential, properties when solving stiff systems of ODEs. An A-stable LMF cannot have order higher than 2. Many families of IRK methods exist that are A-stable for any order. Generalized Adams methods (GAMs) and generalized backward difference formulae (GBDFe) are A_{k_1,k_2}-stable BVMs. When used as BBVMs, GAMs are A-stable up to order 8 and GBDFe up to order 4. By adding a few points near the edges of the equidistant grid in a time step, A-stable methods of any order can be constructed.

In the convergence analysis of LMFe we encounter the set

$$\Sigma = \left\{ z \in \mathbb{C} : z = \frac{a}{b}(w), |w| \geq 1 \right\}. \tag{5.3}$$

In the BVM case we have

$$\Sigma = \{ z \in \mathbb{C} : a(w) - zb(w) \text{ is not of type } (k_1, 0, k_2) \}. \tag{5.4}$$

It is clear that in each case Σ is the complement in $\mathbb{C}$ of the open stability domain S, i.e.,

$$\Sigma = \mathbb{C} \setminus S. \tag{5.5}$$

We now introduce the sets Σ that we encounter in the convergence analysis of GLMs and BBVMs and show that (5.5) still holds.

LEMMA 5.6. S 5.4 Σ

$$\Sigma = \{ z \in \mathbb{C} : z^{-1} \in \sigma(A + C(wI_r - D)^{-1}B), |w| \geq 1 \}; \tag{5.6}$$

(5.5)

. We first prove the following lemma.

LEMMA 5.7. $A \in \mathbb{C}^{s \times s}$ $B \in \mathbb{C}^{r \times s}$ $C \in \mathbb{C}^{s \times r}$ $D \in \mathbb{C}^{r \times r}$ $p, q \in \mathbb{C}$

1. $q \in \sigma(A + C(pI_r - D)^{-1}B)$,
2. $p \in \sigma(D + B(qI_s - A)^{-1}C)$,

$(p \notin \sigma(D),\ q \notin \sigma(A))$

. Because of symmetry, it is enough to prove that the first statement implies the second. Using the definition of an eigenvalue, the first statement results in the following sequence of implications:

$$\begin{aligned}
&\exists x \neq 0 : C(pI_r - D)^{-1}Bx + Ax = qx && \wedge \quad Bx \neq 0, \\
&\exists x \neq 0 : C(pI_r - D)^{-1}Bx = (qI_s - A)x && \wedge \quad Bx \neq 0, \\
&\exists x \neq 0 : (qI_s - A)^{-1}C(pI_r - D)^{-1}Bx = x && \wedge \quad Bx \neq 0,
\end{aligned}$$

$$\begin{aligned}
&\exists x \neq 0 : B(qI_s - A)^{-1}C(pI_r - D)^{-1}Bx = Bx \quad \wedge \quad Bx \neq 0,\\
&\exists y \neq 0 : B(qI_s - A)^{-1}Cy = (pI_r - D)y \quad \wedge \quad Cy \neq 0,\\
&\exists y \neq 0 : B(qI_s - A)^{-1}Cy + Dy = py \quad \wedge \quad Cy \neq 0.
\end{aligned}$$

By the definition of an eigenvalue, this yields the second statement. □

Using Lemma 5.7 we see that $z \in \Sigma$ if and only if there exists a w such that

$$w \in \sigma(D + B(z^{-1}I_s - A)^{-1}C) \quad \text{and} \quad |w| \geq 1$$

or, equivalently, $z \notin S$. □

5 8 Lemma 5.7 can also be proved by applying the identity

$$\begin{aligned}
\det\left(\begin{bmatrix} M_{11} & M_{12} \\ M_{21} & M_{22} \end{bmatrix}\right) &= \det(M_{11})\det(M_{22} - M_{21}M_{11}^{-1}M_{12})\\
&= \det(M_{11} - M_{12}M_{22}^{-1}M_{21})\det(M_{22})
\end{aligned}$$

to the matrix

$$\begin{bmatrix} qI_s - A & -C \\ -B & pI_r - D \end{bmatrix}.$$

LEMMA 5.9. S

5.5 Σ

$$\Sigma = \{z \in \mathbb{C} : z \in \sigma\big((B + w^{-1}B_0)^{-1}(A + w^{-1}A_0)\big); |w| \geq 1\}; \tag{5.7}$$

(5.5)

. We first prove the following lemma.

LEMMA 5.10. $A, B, A_0, B_0 \in \mathbb{C}^{s\times s}$ $p, q \in \mathbb{C}$

1. $q \in \sigma((B_0 + pB)^{-1}(A_0 + pA))$
2. $p \in \sigma(-(A - qB)^{-1}(A_0 - qB_0))$

. Because of symmetry, it is enough to prove that the first statement implies the second. Using the definition of an eigenvalue, the first statement results in the following sequence of implications:

$$\begin{aligned}
&\exists x \neq 0 : (B_0 + pB)^{-1}(A_0 + pA)x = qx,\\
&\exists x \neq 0 : (A_0 + pA)x = q(B_0 + pB)x,\\
&\exists x \neq 0 : (A_0 - qB_0)x = -p(A - qB)x,\\
&\exists x \neq 0 : -(A - qB)^{-1}(A_0 - qB_0)x = px.
\end{aligned}$$

By the definition of an eigenvalue, this yields the second statement. □

Using Lemma 5.10 we see that $z \in \Sigma$ if and only if there exists a w such that

$$w \in \sigma\big(-(A - zB)^{-1}(A_0 - zB_0)\big) \quad \text{and} \quad |w| \geq 1$$

or, equivalently, $z \notin S$. □

5 11 Taking $w = e^{\epsilon + i\theta}$ with $\epsilon > 0$ in the definition of Σ provides a convenient way to calculate points outside the stability domain. If Σ is used in a formula of the form (4.6) and if all poles of $K(z)$ lie in S, then the maximum (supremum) can be taken over the curve defined by $\epsilon = 0$ instead of over the whole set Σ.

5.2. Convergence analysis of discrete waveform relaxation. We first state without proof two lemmas regarding the convergence of convolution operators. In what follows $\mathcal{H}_{\Delta t}$ is a discrete linear convolution operator with a matrix-valued kernel $h_{\Delta t}$, i.e.,

$$(\mathcal{H}_{\Delta t}e)_i = \sum_{j=0}^{i} h_{i-j}e_j,$$

where $e_i \in \mathbb{C}^d$ and $h_i \in \mathbb{C}^{d\times d}$.

The first lemma relates the convergence factor of a discrete convolution operator acting on finite sequences to the convergence factor of the first term of the discrete Laplace transform of its kernel (see [15, 22]).

LEMMA 5.12. [illegible] $\mathcal{H}_{\Delta t}$ [illegible] $l_p(n+1;\mathbb{C}^d)$ [illegible] $1 \le p \le \infty$ [illegible] n [illegible] $\mathcal{H}_{\Delta t}$ [illegible]

$$\rho(\mathcal{H}_{\Delta t}) = \rho(h_0) = \rho(H_{\Delta t}(\infty)), \tag{5.8}$$

[illegible] $H_{\Delta t}(w) = \sum_{i=0}^{n} h_i w^{-i}$ [illegible] $h_{\Delta t}$

For discrete convolution operators acting on infinite sequences we get the following lemma (see [22, 15]).

LEMMA 5.13. [illegible] $\mathcal{H}_{\Delta t}$ [illegible] $l_p(\infty;\mathbb{C}^d)$ [illegible] $1 \le p \le \infty$ [illegible] $h_{\Delta t} \in l_1(\infty;\mathbb{C}^{d\times d})$ [illegible] $\mathcal{H}_{\Delta t}$ [illegible]

$$\rho(\mathcal{H}_{\Delta t}) = \sup_{|w|\ge 1} \rho(H_{\Delta t}(w)) = \sup_{|w|=1} \rho(H_{\Delta t}(w)), \tag{5.9}$$

[illegible] $H_{\Delta t}(w) = \sum_{i=0}^{\infty} h_i w^{-i}$ [illegible] $h_{\Delta t}$

We now use Lemma 5.13 to derive convergence factors for the discrete waveform relaxation method on infinite time intervals using the LMF, BVM, GLM, and BBVM time discretization schemes. By taking $|w| \to \infty$, we can then see that the results for finite time intervals are the same as for time stepping.

To apply Lemma 5.13 we will have to prove the boundedness of the convolution kernels involved. To this end we will use a matrix version of Wiener's inversion theorem.

THEOREM 5.14 (Wiener's inversion theorem). [illegible] $A_{\Delta t}$ [illegible] $A_{\Delta t} \in l_1(\infty;\mathbb{C}^{d\times d})$ [illegible]

$$\det \sum_{i=0}^{\infty} A_i w^{-i} \neq 0$$

[illegible] $|w| \ge 1$ [illegible] $\sum_{i=0}^{\infty} B_i w^{-i} = (\sum_{i=0}^{\infty} A_i w^{-i})^{-1}$ [illegible] $B_{\Delta t} \in l_1(\infty;\mathbb{C}^{d\times d})$

For a proof we refer to [18] or [22].

5.2.1. LMF. From (3.1) we find the error iteration

$$\sum_{j=-k}^{0} \alpha_{k+j} e_{i+j}^{(\nu)} = \Delta t \sum_{j=-k}^{0} \beta_{k+j} L^{+} e_{i+j}^{(\nu)} + \Delta t \sum_{j=-k}^{0} \beta_{k+j} L^{-} e_{i+j}^{(\nu-1)}.$$

By taking the discrete Laplace transform of these equations and assuming that $e_0 = \cdots = e_{k-1} = 0$, we get

$$\big(a(w)I_m - \Delta t b(w) L^{+}\big) e^{(\nu)}(w) = \Delta t b(w) L^{-} e^{(\nu-1)}(w),$$

where $e^{(\nu)}(w) = \sum_{i=k}^{\infty} e_i^{(\nu)} w^{-i}$ and a and b are the stability polynomials as defined by (5.2). The discrete Laplace transform of the operator $\mathcal{K}_{\Delta t}$, described by (3.1), is therefore

$$\begin{aligned} K_{\Delta t}(w) &= \left(a(w)I_m - \Delta t b(w) L^+\right)^{-1} \Delta t b(w) L^- \\ &= K\left(\frac{1}{\Delta t}\frac{a}{b}(w)\right). \end{aligned} \tag{5.10}$$

The following lemma is proved in [15, 22]. We omit the proof since it is very similar to the ones given below for GLMs and BBVMs. The open stability domain S is the one defined by Definition 5.2.

LEMMA 5.15. $\sigma(\Delta t L^+) \subset S$ $\mathcal{K}_{\Delta t}$ $l_p(\infty; \mathbb{C}^m)$

Combining Lemmas 5.13 and 5.15 with (5.10) and (5.3) results in the following theorem.

THEOREM 5.16. $\mathcal{K}_{\Delta t}$ $l_p(\infty; \mathbb{C}^m)$ $1 \le p \le \infty$ $\sigma(\Delta t L^+) \subset S$

$$\rho(\mathcal{K}_{\Delta t}) = \sup_{z \in \frac{1}{\Delta t}\Sigma} \rho(K(z)) = \sup_{z \in \frac{1}{\Delta t}\partial\Sigma} \rho(K(z)). \tag{5.11}$$

We can take $|w| \to \infty$ and retrieve the results for time stepping and discrete waveform relaxation on finite intervals.

5.2.2. BVM. The convergence analysis for BVM waveform relaxation on infinite sequences can formally proceed as in the finite case (see (4.5)). As in the LMF case, we assume $e_0, \ldots, e_{k_1-1} = 0$. The error equation becomes

$$(A \otimes I_m) e^{(\nu)} = \Delta t (B \otimes L^+) e^{(\nu)} + \Delta t (B \otimes L^-) e^{(\nu-1)}, \tag{5.12}$$

where A and B are no longer matrices but infinite banded Toeplitz operators of the form

$$A = \begin{bmatrix} \alpha_{k_1} & \cdots & \alpha_k & & \\ \vdots & \ddots & & \ddots & \\ \alpha_0 & & & & \\ & \ddots & & & \end{bmatrix}, \qquad B = \begin{bmatrix} \beta_{k_1} & \cdots & \beta_k & & \\ \vdots & \ddots & & \ddots & \\ \beta_0 & & & & \\ & \ddots & & & \end{bmatrix}. \tag{5.13}$$

A relation of the form (4.6) can again be derived where the set Σ is now the spectrum of the operator $B^{-1}A$. It can be seen that this corresponds to Σ as defined in 5.4 (for more information we refer to [4]). The BVM case, of course, reduces to the LMF case for $k_2 = 0$.

5.2.3. IRK and GLM. From (3.3) and (3.4) we derive that the error iteration for the discrete waveform relaxation method using a GLM can be described by

$$\tilde{e}_i^{(\nu)} = (C \otimes I_m) e_{i-1}^{(\nu)} + \Delta t (A \otimes L^+) \tilde{e}_i^{(\nu)} + \Delta t (A \otimes L^-) \tilde{e}_i^{(\nu-1)}, \tag{5.14}$$

$$e_i^{(\nu)} = (D \otimes I_m) e_{i-1}^{(\nu)} + \Delta t (B \otimes L^+) \tilde{e}_i^{(\nu)} + \Delta t (B \otimes L^-) \tilde{e}_i^{(\nu-1)}. \tag{5.15}$$

Applying the discrete Laplace transform to these equations results in

$$P(w) \hat{e}^{(\nu)}(w) = Q(w) \hat{e}^{(\nu-1)}(w), \tag{5.16}$$

with

$$\hat{e}^{(\nu)}(w) = \begin{bmatrix} \tilde{e}^{(\nu)}(w) & e^{(\nu)}(w) \end{bmatrix}^T,$$
$$P(w) = \begin{bmatrix} I_s \otimes I_m - \Delta t A \otimes L^+ & -w^{-1}C \otimes I_m \\ -\Delta t B \otimes L^+ & I_r \otimes I_m - w^{-1}D \otimes I_m \end{bmatrix},$$
$$Q(w) = \begin{bmatrix} \Delta t A \otimes L^- & 0 \\ \Delta t B \otimes L^- & 0 \end{bmatrix}.$$

By eliminating $e^{(\nu)}(w)$ from (5.16) we get the following iteration for $\tilde{e}^{(\nu)}(w)$:

$$\begin{aligned} \big[I_s \otimes I_m - (\Delta t A + w^{-1}C(I_r - w^{-1}D)^{-1}\Delta t B) \otimes L^+\big]\tilde{e}^{(\nu)}(w) \\ = \big[(\Delta t A + w^{-1}C(I_r - w^{-1}D)^{-1}\Delta t B) \otimes L^-\big]\tilde{e}^{(\nu-1)}(w). \end{aligned}$$

If we denote by $\mathcal{K}_{\Delta t}$ the operator mapping $\tilde{e}^{(\nu-1)}$ to $\tilde{e}^{(\nu)}$, then its discrete Laplace transform is

$$K_{\Delta t}(w) = K\left(\frac{1}{\Delta t}\big(A + w^{-1}C(I_r - w^{-1}D)^{-1}B\big)^{-1}\right). \tag{5.17}$$

The following lemma provides a sufficient condition for $\mathcal{K}_{\Delta t}$ to be bounded. The open stability domain S is the one defined by Definition 5.4.

LEMMA 5.17. [illegible] $\sigma(\Delta t L^+) \subset S$ [illegible] $\mathcal{K}_{\Delta t}$ [illegible] $l_p(\infty; \mathbb{C}^{sm})$ [illegible]. It is sufficient to prove that $P(w)^{-1}Q(w)$ is the discrete Laplace transform of an l_1-sequence. It is clear that both $P(w)$ and $Q(w)$ are discrete Laplace transforms of l_1-sequences. By Wiener's theorem we have that $P(w)^{-1}$ is the Laplace transform of an l_1-sequence if

$$\det(P(w)) \neq 0 \quad \text{for } |w| \geq 1. \tag{5.18}$$

If this is true, then $P(w)^{-1}Q(w)$ is the discrete Laplace transform of the convolution of two l_1-sequences and therefore the operator corresponding to (5.14) and (5.15) is bounded. Condition (5.18) can hold only if the condition

$$\det\left(\begin{bmatrix} I_s - zA & -w^{-1}C \\ -zB & I_r - w^{-1}D \end{bmatrix}\right) \neq 0 \tag{5.19}$$

holds for all $z \in \sigma(\Delta t L^+)$ and all $|w| \geq 1$. By considering the LU factorization of the matrix, we see that condition (5.19) is equivalent to the conditions

$$\det(I_s - zA) \neq 0, \tag{5.20}$$
$$\det(I_r - w^{-1}D - zB(I_s - zA)^{-1}w^{-1}C) \neq 0. \tag{5.21}$$

For z to be in S, the matrix $D + B(z^{-1}I_s - A)^{-1}C$ has to be well defined and therefore condition (5.20) is satisfied. Suppose equality holds for some $z \in \sigma(\Delta t L^+)$ in (5.21). This would mean that

$$w \in \sigma(D + zB(I_s - zA)^{-1}C)$$

with $|w| \geq 1$ and therefore $z \notin S$. This contradicts the assumption of the lemma. Hence, (5.21) is satisfied. ∎

Combining Lemmas 5.13 and 5.17 with equations (5.17) and (5.6) results in the following theorem.

THEOREM 5.18. [illegible] $\mathcal{K}_{\Delta t}$ [illegible] $l_p(\infty; \mathbb{C}^{sm})$ [illegible] $1 \leq p \leq \infty$ [illegible] $\sigma(\Delta t L^+) \subset S$ [illegible]

$$\rho(\mathcal{K}_{\Delta t}) = \sup_{z \in \frac{1}{\Delta t}\Sigma} \rho(K(z)) = \sup_{z \in \frac{1}{\Delta t}\partial\Sigma} \rho(K(z)). \tag{5.22}$$

5.2.4. BBVM. Using (3.5) and $e_i^{(\nu)} = u_i^{(\nu)} - u_i \in \mathbb{C}^{sm}$, we find the error iteration

$$\begin{aligned}(A\otimes I_m)e_i^{(\nu)} + (A_0 \otimes I_m)e_{i-1}^{(\nu)} \\ = \Delta t(B \otimes L^+)e_i^{(\nu)} + \Delta t(B \otimes L^-)e_i^{(\nu-1)} \\ + \Delta t(B_0 \otimes L^+)e_{i-1}^{(\nu)} + \Delta t(B_0 \otimes L^-)e_{i-1}^{(\nu-1)}.\end{aligned}$$

Applying the discrete Laplace transform to these equations results in

$$\begin{aligned}\left[(A + w^{-1}A_0) \otimes I_m\right] e^{(\nu)}(w) = \left[\Delta t(B + w^{-1}B_0) \otimes L^+\right] e^{(\nu)}(w) \\ + \left[\Delta t(B + w^{-1}B_0) \otimes L^-\right] e^{(\nu-1)}(w).\end{aligned} \tag{5.23}$$

The discrete Laplace transform of the operator $\mathcal{K}_{\Delta t}$ described by (3.5) is therefore

$$K_{\Delta t}(w) = K\left(\frac{1}{\Delta t}(B + w^{-1}B_0)^{-1}(A + w^{-1}A_0)\right).$$

In order to apply Lemma 5.13, the operator $\mathcal{K}_{\Delta t}$ must be bounded. A sufficient condition is provided by the following lemma. The open stability domain S is the one defined by Definition 5.5.

LEMMA 5.19. [illegible] $\sigma(\Delta t L^+) \subset S$ [illegible] $\mathcal{K}_{\Delta t}$ [illegible] $l_p(\infty;\mathbb{C}^{sm})$ [illegible]. It is sufficient to prove that $K_{\Delta t}(w)$ is the discrete Laplace transform of an l_1-sequence. Following the same reasoning as for Lemma 5.17, we arrive at the condition

$$\det\left((A + w^{-1}A_0) \otimes I_m - \Delta t(B + w^{-1}B_0) \otimes L^+\right) \neq 0 \tag{5.24}$$

for $|w| \geq 1$. This condition can hold only if

$$\det\left((A + w^{-1}A_0) - z(B + w^{-1}B_0)\right) \neq 0 \tag{5.25}$$

for $z \in \sigma(\Delta t L^+)$. If we assume that equality holds, then using Lemma 5.10 we get

$$w \in \sigma(-(A - zB)^{-1}(A_0 - zB_0)).$$

Because $|w| \geq 1$ this would mean that $z \notin S$, which contradicts the assumption of the lemma and therefore (5.25) is true. □

Combining Lemmas 5.13 and 5.19 with equations (5.23) and (5.7) results in the following theorem.

THEOREM 5.20. [illegible] $\mathcal{K}_{\Delta t}$ [illegible] $l_p(\infty;\mathbb{C}^{sm})$ [illegible] $1 \leq p \leq \infty$ [illegible] $\sigma(\Delta t L^+) \subset S$ [illegible]

$$\rho(\mathcal{K}_{\Delta t}) = \sup_{z\in\frac{1}{\Delta t}\Sigma} \rho(K(z)) = \sup_{z\in\frac{1}{\Delta t}\partial\Sigma} \rho(K(z)). \tag{5.26}$$

5.3. Multigrid convergence analysis. As in the time stepping case the results for the two-grid iteration can be found by substituting $M(z)$ for $K(z)$. The condition on the set Σ becomes $(\sigma(\Delta t L^+) \cup \sigma(\bar{L})) \subset S$. For proofs we refer to [14, 15, 19, 28].

TABLE 5.1
The sets Σ to be maximized over in (4.6).

LMF	GLM	BVM	BBVM
$\frac{\alpha_k}{\beta_k}$	$\sigma(A^{-1})$	$\sigma(B^{-1}A)$	$\sigma(B^{-1}A)$
$\frac{a(w)}{b(w)}$	$\sigma\left((A+C(wI_r-D)^{-1}B)^{-1}\right)$	$\frac{a(w)}{b(w)}$	$\sigma\left((B_0+wB)^{-1}(A_0+wA)\right)$

5.4. Relation to a continuous in time method. The asymptotic convergence factor for the continuous multigrid waveform relaxation method on infinite intervals using (3.7) as smoother is given by

$$\rho = \sup_{z\in\mathbb{C}^+} \rho(M(z)) = \sup_{z\in i\mathbb{R}} \rho(M(z)),$$

assuming that $(\sigma(L^+) \cup \sigma(\bar{L})) \subset \mathbb{C}^-$ [14, 19, 28]. Therefore, when $\Sigma \subset \mathbb{C}^+$, the convergence factor of discrete waveform relaxation is bounded by that of continuous waveform relaxation. This is the case for LMFe, GLMs, and BBVMs that are A-stable and for A_{k_1,k_2}-stable BVMs.

5.5. Summary. The asymptotic convergence factor of the multigrid methods for time-dependent problems described above can be found from

$$\rho = \sup_{z\in\frac{1}{\Delta t}\partial\Sigma} \rho(M(z)). \tag{5.27}$$

The appropriate sets Σ for different time discretization schemes are listed in Table 5.1. The first row refers to time stepping and discrete waveform relation on finite intervals; the second row refers to discrete waveform relation on infinite intervals. Note that except for the BVM case the first row can be derived by taking $|w| \to \infty$. The function $\rho(M(z))$ can be estimated by a local mode Fourier analysis of the two-grid iteration applied to the elliptic equation

$$zu = \mathcal{L}u + f.$$

6. Numerical results. The time discretization schemes used for the numerical experiments are implicit Euler (=BDF1=GBDF1=RadauIIA1), the backward difference formula with 5 steps (BDF5), the Radau IIA implicit Runge–Kutta method with 3 stages (RAD3), the generalized Adams methods with 4 steps (GAM4), and the generalized backward difference formula with 5 steps (GBDF5). All but the implicit Euler method are fifth order methods. The GAM4 and GBDF5 boundary value methods were also used as block BVMs (BGAM4, BGBDF5). The coefficients for the discretization schemes used can be found in Appendix A.

We prefer to report convergence rates instead of convergence factors. The convergence rate R is defined by

$$R = -\log_{10}(\rho)$$

and can be interpreted as the average number of additional correct digits obtained per iteration. The asymptotic convergence rate can be estimated using

$$\rho_n^m = \frac{\|e_n\|_\infty}{\|e_{n-m}\|_\infty}, \qquad R_n^m = -\frac{\log_{10}(\rho_n^m)}{m}, \tag{6.1}$$

where e_i is the error after the ith iteration. We used the average of R_i^1 for $i = 10, \ldots, 20$ for all numerical experiments reported here. This corresponds to taking the geometric mean of ρ_i^1 or taking $n = 20$, $m = 10$ in (6.1).

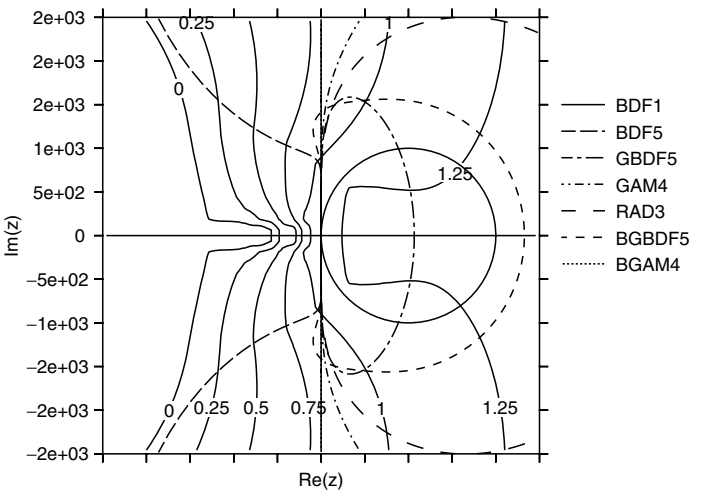

FIG. 6.1. *Contour lines of the convergence rate* $R(z) = -\log_{10}\rho(M(z))$ *and boundaries of the sets* Σ *for discrete waveform relaxation on infinite time domains. The boundary for the BGAM4 discretization coincides with the imaginary axis.*

6.1. Heat equation. As a first example we consider the heat equation

$$u_t = u_{xx} + u_{yy} + f \tag{6.2}$$

on the unit square. The problem is discretized on a grid with $\Delta x = \Delta y = 2^{-5}$. The two-grid analysis was conducted for full weighting restriction, bilinear interpolation, and 1 pre- and 1 postsmoothing red-black Gauss–Seidel step. Time integration is over $\Omega_t = [0, 1]$; i.e., $\Delta t = 3 \cdot 10^{-3}$ for the RAD3 discretization and $\Delta t = 10^{-3}$ for all others. Figure 6.1 shows contour lines of the predicted convergence rate $R(z)$ together with the boundaries of the regions Σ of the discretization schemes used in waveform relaxation on infinite time domains. We expect convergence for the BDF5 discretization to be slow since the boundary of the corresponding set Σ nearly touches the line $R = 0$. If these lines were to touch or intersect, convergence would no longer be guaranteed. Note that all but the BDF5 and BGBDF5 method are A-stable. The BGBDF5 method is, however, very close to being A-stable and we expect very good convergence. The results are presented in Table 6.1. The first row contains the results for time stepping or discrete waveform relaxation on a finite domain. These results are obtained by maximizing $R(z)$ over Σ, which, in this case, is a discrete set of points. The BVMs (GAM4 and GBDF5) cannot be used in a time stepping sense. The second row of Table 6.1 contains the results for discrete waveform relaxation on infinite time domains. The results were obtained by maximizing over a number of points on the curves depicted in Figure 6.1. The points were found by taking $w = \exp(\frac{2\pi ik}{n})$, $k = 0, \ldots, n-1$, $n = 200$ in the definitions of the sets Σ. Since $\Sigma = \mathbb{C}^+$ for the

BGAM4 discretization, the last result in the table provides a good approximation to the convergence rate for continuous waveform relaxation. From these results we expect good convergence for all methods except waveform relaxation with BDF5 time discretization.

Decreasing Δt corresponds to a proportional increase in the size of the sets Σ in Figure 6.1. Similarly, when Δx and Δy are decreased simultaneously, the contour lines of $\rho(M(z))$ have approximately the same shape but on a larger scale (the dependency is quadratic in this case). This can be explained by observing that scaling L, L^+, and L^- in the formulae for $K(z)$ and $M(z)$ is equivalent to the inverse scaling of z. Decreasing Δx and Δy will, of course, also increase the size of all the matrices involved, but this can be neglected for fine discretizations (large matrices). Figure 6.1 can thus be used to estimate the convergence for other discretization resolutions by changing the relative size of the curves depicted.

For the numerical experiments the initial conditions, the Dirichlet boundary conditions, and the source term f are chosen such that the exact solution is $u = 0$. We use a standard W-cycle geometric multigrid algorithm with 5 levels, full weighting restriction, bilinear interpolation and 1 pre- and 1 postsmoothing red-black Gauss–Seidel step. The spatial domain is discretized using finite differences. The grid sizes are $\Delta x = \Delta y = 2^{-1}$ on the coarsest grid and $\Delta x = \Delta y = 2^{-5}$ on the finest grid. As in the analysis the time steps are $\Delta t = 3 \cdot 10^{-3}$ for RAD3 and $\Delta t = 10^{-3}$ otherwise. The number of time steps for each method was chosen such that the number of unknowns per spatial grid point was minimal in the time stepping case and the same for all methods in the waveform relaxation case. Table 6.2 shows the number of time steps and the number of unknowns per time step for each method. All unknowns were set to 1 for the initial approximation.

The results are presented in Table 6.3. It is clear that they correspond very well to the results obtained from the theoretical analysis. The theoretical convergence rates are not strictly lower bounds (upper bounds on the convergence factors), since they are asymptotic convergence rates obtained using a local Fourier mode two-grid approximation. Similar results with poor convergence for the BDF5 method and convergence rates close to 1 for the other methods were obtained for waveform relaxation on grids of dimensions $2^5 \times 2^5 \times 10^4$, $2^8 \times 2^8 \times 360$, and $2^9 \times 2^9 \times 60$. We can conclude that, for this problem, multigrid methods are very efficient even when using high order time discretization schemes.

TABLE 6.4
Convergence rates for the MGS iteration (diffusion equation with variable coefficients).

	BDF1	BDF5	GBDF5	GAM4	RAD3	BGBDF5	BGAM4
TS	1.50	1.34	-	-	1.91	1.34	1.47

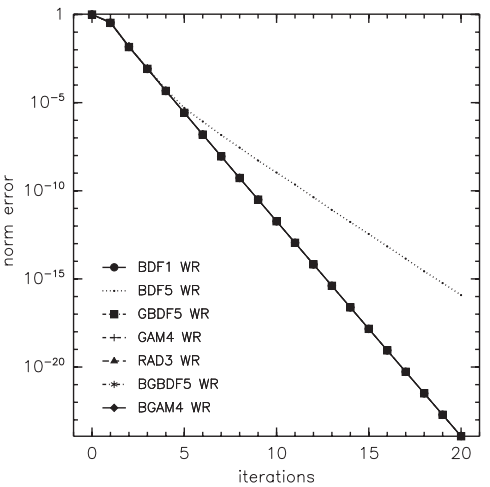

FIG. 6.2. *Convergence of MGS method (diffusion equation with variable coefficients).*

6.2. Diffusion equation with variable coefficients. The next example is a more general diffusion equation of the form

$$u_t = (au_x)_x + (bu_y)_y + f,$$
$$a(x, y, t) = \exp(10(x - y)),$$
$$b(x, y, t) = \exp(-10(x - y)).$$

This is a so-called anisotropic problem since the diffusion coefficients in a certain point can be very different depending on the direction of diffusion. Standard multigrid methods do not handle this type of problem well and yield very slow convergence (e.g., $R = 0.1$). However, just as we did with the original multigrid algorithm, we can extend multigrid methods developed for time-independent anisotropic problems to time-dependent ones. Here we used the "multigrid as smoother" (MGS) method which uses the same simple smoothers as before, together with an extended hierarchy of coarse grids. For more information on multigrid for anisotropic problems, we refer to [23, 24, 26, 27, 29].

The same discretizations, initial and boundary conditions, and initial approximation were used as for the previous example. The multigrid algorithm uses full weighting restriction, bilinear and linear interpolation, and 1 pre- and 1 postsmoothing step. The smoothing consists of a multigrid semicoarsening step in the x-direction followed by one in the y-direction, both using only 1 presmoothing red-black Gauss–Seidel step. A hierarchy of 5×5 grids is used. The results are presented in Table 6.4. The convergence history of the MGS waveform relaxation method is visualized in Figure 6.2 for different time discretization schemes. Except for the BDF5 method,

the convergence histories are indistinguishable. We see once more that it is possible to obtain very efficient multigrid methods even when high order time discretization schemes are used.

7. Concluding remarks. We have shown by theoretical analysis and numerical experiments that it is possible to develop efficient multigrid methods for high order time discretizations of parabolic equations. The analysis shows that the stability of the time discretization scheme is important for the convergence of multigrid methods. Among schemes with good stability properties (such as A-stability), the convergence is comparable. Depending on the problem at hand, a suitable scheme can be chosen taking into account other properties such as implementation cost, efficiency, and availability of error estimators. Since the cost of a multigrid iteration in a time stepping or block time stepping scheme is proportional to the cost of solving a sequence of scalar ODEs over a time step or over a block of time steps, it suffices to consider the properties of the time discretization scheme when applied to scalar equations. Furthermore, the convergence for parabolic problems is roughly equivalent to the convergence of the corresponding multigrid methods for elliptic equations. This means that both theoretical analysis and experience with elliptic equations can be used as guidelines to determine whether it is worthwhile to invest in the implementation of a multigrid method. Experience with the elliptic case also gives an indication of how the multigrid method will compare to other iterative methods such as GMRES or BiCGstab. It is also possible to use multigrid as a preconditioner for these methods [34]. Considering the success of multigrid methods for stationary equations it is clear that multigrid methods for time-dependent equations show great promise.

Appendix A. Coefficient matrices.

A.1. Implicit Runge–Kutta methods. We considered only the Radau IIA method with 3 stages.

RAD3:

$$A = \begin{bmatrix} \frac{88-7\sqrt{6}}{360} & \frac{296-169\sqrt{6}}{1800} & \frac{-2+3\sqrt{6}}{225} \\ \frac{296+169\sqrt{6}}{1800} & \frac{88+7\sqrt{6}}{360} & \frac{-2-3\sqrt{6}}{225} \\ \frac{16-\sqrt{6}}{36} & \frac{16+\sqrt{6}}{36} & \frac{1}{9} \end{bmatrix}, \quad b = \begin{bmatrix} \frac{16-\sqrt{6}}{36} \\ \frac{16+\sqrt{6}}{36} \\ \frac{1}{9} \end{bmatrix}, \quad c = \begin{bmatrix} \frac{4-\sqrt{6}}{10} \\ \frac{4+\sqrt{6}}{10} \\ 1 \end{bmatrix}.$$

A.2. Boundary value methods. The coefficient matrices A_e and B_e for the LMFe and BBVMs we used are given below. The boldface rows correspond to the coefficients α_j and β_j of the basic method (2.8). The rows above correspond to the initial conditions and the rows below to the final conditions. The coefficient matrices for $s > k$ are obtained by repeating the boldface rows as in (2.11).

BDF1:

$$A_e = \left[\begin{array}{c|c} \mathbf{-1} & \mathbf{1} \end{array}\right], \quad B_e = \left[\begin{array}{c|c} \mathbf{0} & \mathbf{1} \end{array}\right].$$

GAM4:

$$A_e = \left[\begin{array}{c|ccc} -1 & 1 & & \\ \mathbf{-1} & \mathbf{1} & & \\ & -1 & 1 & \\ & & -1 & 1 \end{array}\right], \quad B_e = \frac{1}{720}\left[\begin{array}{c|cccc} 251 & 646 & -264 & 106 & -19 \\ \mathbf{-19} & \mathbf{346} & \mathbf{456} & \mathbf{-74} & \mathbf{11} \\ 11 & -74 & 456 & 346 & -19 \\ -19 & 106 & -264 & 646 & 251 \end{array}\right].$$

GBDF5:

$$A_e = \frac{1}{60}\left[\begin{array}{c|ccccc} -12 & -65 & 120 & -60 & 20 & -3 \\ 3 & -30 & -20 & 60 & -15 & 2 \\ \mathbf{-2} & \mathbf{15} & \mathbf{-60} & \mathbf{20} & \mathbf{30} & \mathbf{-3} \\ 3 & -20 & 60 & -120 & 65 & 12 \\ -12 & 75 & -200 & 300 & -300 & 137 \end{array}\right], \quad B_e = \left[\begin{array}{c|ccccc} 0 & 1 & & & & \\ 0 & & 1 & & & \\ \mathbf{0} & & & \mathbf{1} & & \\ 0 & & & & 1 & \\ 0 & & & & & 1 \end{array}\right].$$

BDF5. The last rows of the previous matrices contain the coefficients of the BDF5 method.

RAD3. The Radau IIA methods can be easily formulated as a BBVM. It is important to note that the points within a time step are not equidistant as in the previous BVMs and that the time step Δt has a different interpretation:

$$A_e = \left[\begin{array}{c|ccc} -1 & 1 & & \\ -1 & & 1 & \\ -1 & & & 1 \end{array}\right], \quad B_e = \left[\begin{array}{c|ccc} 0 & \frac{88-7\sqrt{6}}{360} & \frac{296-169\sqrt{6}}{1800} & \frac{-2+3\sqrt{6}}{225} \\ 0 & \frac{296+169\sqrt{6}}{1800} & \frac{88+7\sqrt{6}}{360} & \frac{-2-3\sqrt{6}}{225} \\ 0 & \frac{16-\sqrt{6}}{36} & \frac{16+\sqrt{6}}{36} & \frac{1}{9} \end{array}\right].$$

Acknowledgments. Some of the results were verified using a version of the Fourier analysis code `LFA00_2D_scalar` [33] extended to complex numbers in collaboration with its author. We would like to thank the anonymous referees for their helpful comments.

EFFICIENTLY COMPUTING MANY ROOTS OF A FUNCTION*

D. J. KAVVADIAS†, F. S. MAKRI†, AND M. N. VRAHATIS†

Dedicated to the memory of Árpád Elbert (1939–2001)

Abstract. We present a new bisection based method for counting and computing roots of a function in a given interval. Our method is focused on very large problems, i.e., instances with the number of roots of the order of hundreds. The method draws its power from the fact that the roots are expected to be many, and is able to discover a large percentage of them very efficiently. Its main advantage, apart from its efficiency, is the fact that it requires only the sign of the function at a certain point and not its actual value. Also, its simplicity makes it a suitable preprocessing step for reducing the size of the problem, prior to more robust but also more demanding methods. The algorithm is accompanied by a probabilistic analysis of its behavior, which shows that a simple existence criterion like Bolzano's rule can be a powerful tool in the zerofinding process.

Key words. zerofinding, expected behavior, bisection based methods, counting and computing the roots of a function, very large problems, Riemann's hypothesis, zeta-function, special functions, Elbert's conjecture

AMS subject classifications. 65H05, 65Y20

DOI. 10.1137/S1064827502406531

1. Introduction.

In this paper we present a bisection based method for the problem of counting and computing the simple roots of a single equation:

$$f(x) = 0 \tag{1.1}$$

in a given interval (a, b) where $f: [a, b] \subset \mathbb{R} \to \mathbb{R}$ is continuous. The only computable information required by the proposed method is the algebraic signs of the function values. The method is focused on very large instances of the problem (with roots in the order of hundreds or more).

Pieces of information concerning all of the roots (or a large fraction of them), as well as all the extrema of a function $f: [a, b] \subset \mathbb{R} \to \mathbb{R}$, are of major importance in many different fields in science and technology such as mechanics, physical sciences, statistics, and operations research. For instance, the problem of locating local maxima and minima of a function (or zeros of the derivative of a function) from approximate measurement results is vital for many physical applications. In spectral analysis, chemical species are identified by locating local maxima of the spectra. In radioastronomy, sources of celestial radio emission and their subcomponents are identified by locating local maxima of the measured brightness of the radio sky. Elementary particles are identified by locating local maxima of the experimental curves (for a discussion of the importance of the above mentioned problems for applications, see [28]). The importance of the problem has attracted the attention of many research efforts, and as a result many different approaches to the problem exist. Regarding special functions, for example, Lozier [17] and Lozier and Olver [18] have provided a survey of algorithms and software for the numerical evaluation of special functions.

*Received by the editors April 30, 2002; accepted for publication (in revised form) November 4, 2004; published electronically August 17, 2005.

†Department of Mathematics, University of Patras, GR–26110 Patras, Greece, and University of Patras Artificial Intelligence Research Center, University of Patras, GR–26110 Patras, Greece (djk@math.upatras.gr, makri@math.upatras.gr, vrahatis@math.upatras.gr).

They have pointed out that the available software for special functions (including the zerofinding approach) exhibits gaps and defects with respect to the needs of modern high-performance computing. In particular, the software regarding the zeros of Bessel functions has a low cumulative score as reported in [17, p. 351], and thus the computation of the zeros of special functions is an area of particular need.

Apart from its practical significance, the problem of computing zeros of a function poses theoretical challenges that have attracted the attention of the scientific community for many years. A characteristic paradigm is the famous [illegible], which is one of the main open problems of mathematics (and was included by Hilbert as Problem No. 8 in his famous 1900 list of 23 problems). According to this hypothesis, all complex roots $s_1 = \Re(s_1) + i\,\Im(s_1), s_2 = \Re(s_2) + i\,\Im(s_2), \ldots$, of Riemann's ζ-function (zeta-function)

$$\zeta(s) = \sum_{n=1}^{\infty} \frac{1}{n^s}$$

(i.e., the values for which $\zeta(s_k) = 0$) are located on the straight line $\Re(s_k) = 1/2$ in the complex plane (except for the known zeros which are negative integers). It is known that the imaginary parts of the roots of Riemann's ζ-function are uniformly distributed. Riemann's ζ-function has proved to be of fundamental importance not only in the theory of prime numbers, but also in the higher theory of the Gamma-function and allied functions. Numerical computation of the roots of the ζ-function in a specific interval may gather evidence that hopefully will help in resolving the problem.

In addition, the task of massive calculation of zeros of functions in one variable also emerges naturally in recently posed problems. Such a problem is [illegible]. More specifically, in [3, p. 75] Elbert pointed out that the density property of the zeros of Bessel functions plays an important role, and better insight into the distribution of these zeros is required (see also [11, 12], where Joó dealt with oscillation of circular membranes). Elbert considered the set

$$\mathcal{S} = \bigcup_{n,k=1}^{\infty} \{j_{nk}\} = \bigcup_{j=1}^{\infty} \{x_j\},$$

where j_{nk} is the kth positive zero of the Bessel function of first kind, $J_n(x)$, and $x_1 < x_2 < \cdots$, and he conjectured that [3]

$$\limsup_{j\to\infty} x_j(x_{j+1} - x_j) < \infty.$$

For results on the massive calculation and more information on the values $x_j(x_{j+1} - x_j)$, see [23].

The proposed method takes advantage of the abundance of roots, in an attempt to very inexpensively (in terms of computing resources) locate a large number of roots, thus reducing the size of the problem. The algorithm almost "blindly" searches for roots by employing only Bolzano's existence criterion (see next section). It turns out, however, that even this simple rule is sufficient to guide the algorithm in discovering a large proportion of the total set of roots. Thus with very few sign determinations, the problem can be considerably reduced. But this is already more than could be expected from such a simple method: While new roots are being discovered, the cost

gets increasingly high to a point where it becomes unprofitable to continue. The algorithm stops when a predetermined fraction of the roots has been discovered. This requires a method of estimating the number of roots as the algorithm proceeds. After the termination of the algorithm the unsearched parts of the interval must be searched by a different, more demanding, method. The main advantage of the proposed method is its simplicity, which follows precisely from the expectation that with high probability even a simple search for a root will prove successful due to the abundance of roots.

In this paper we also study analytically the expected behavior of the method and give theoretical justification of its good performance.

We mention that there has been a surge of interest concerning the expected behavior of numerical algorithms [6, 7, 8, 20, 24, 27] and [13, 14]. The traditional approach in evaluating a numerical method usually involves a number of experiments on a number of inputs, either of individual interest or randomly constructed by altering certain parameters of the problem. Very few numerical methods exist that are accompanied by a robust analysis of their expected behavior.

A by-product of the algorithm is an estimation of the number of roots in an interval. This problem is interesting on its own, either to a priori evaluate the size of a problem or, as in this case, to establish a stopping criterion for the method.

Other approaches that have been used, aiming to find all solutions of systems of equations as well as the global optimum of a function, are based on interval analysis (see, e.g., [1, 9, 15, 19]). The corresponding existence tool of these methods is the availability of the range of the function in a given interval, which can be implemented using interval arithmetic, although range overestimation may occur, and hence efficiency problems must be resolved. This tool will, with mathematical rigor, give either a "no" or an "unknown" answer. The former case proceeds by subdividing the interval into two halves and employing additional criteria. The way the evaluation of functions is encoded influences the answer, which is usually pessimistic (i.e., "unknown"). In the vicinity of a root, interval Newton methods (see, e.g., [15, 19]) may, however, with slightly more computational effort, give an unambiguous "yes" answer.

In the next section we give some background material on the bisection method, as was modified in [29, 30]. In section 3 we briefly discuss the main steps of the algorithm to present a (central to our analysis) probabilistic result which follows in section 4. Then in section 5 we give a method for estimating the total number of roots. A more detailed description of the method, which also refers to the theoretical analysis, is presented in section 6. We end in section 7 by presenting some conclusions and future work.

2. Background material. A simple oracle on the existence of a solution of $f(x) = 0$ in some interval (a, b) where the function f is continuous in $[a, b]$ is the following criterion:

$$f(a)\, f(b) < 0 \quad \text{or} \quad \operatorname{sgn} f(a) \operatorname{sgn} f(b) = -1,$$

where sgn is the well-known three-valued sign function. This criterion is known as Bolzano's existence criterion. (For a generalization of this criterion to higher dimensions, see [31].) Note that this oracle may introduce a one-sided error; i.e., a positive response means that at least one root exists, but a negative response may correspond to the existence of an even number of simple roots.

The simplicity of this criterion is what makes it attractive even though it has the above disadvantage. Thus it will be our main tool in what follows. More elaborate relations can give more information on the existence of roots. For example, interval

analysis uses the range of the function to decide whether a root exists (see, e.g., [15, 19]). Another approach is given in [16]. An even more complicated oracle which gives the exact number of roots $\mathcal{N}^r$ is based on topological degree theory using Kronecker's integral on a Picard's extension [10, 21]. This oracle was used in [14] as part of the first phase of an algorithm for the isolation of all of the simple roots of a function $f(x)$ in an interval (a, b) and returns the number of roots $\mathcal{N}^r$ using the formula

$$\mathcal{N}^r = -\frac{\gamma}{\pi}\int_a^b \frac{f(x)f''(x) - f'^2(x)}{f^2(x) + \gamma^2 f'^2(x)}\,dx + \frac{1}{\pi}\arctan\left(\frac{\gamma\,[f(a)f'(b) - f(b)f'(a)]}{f(a)f(b) + \gamma^2 f'(a)f'(b)}\right), \tag{2.1}$$

where γ is an arbitrary small real positive constant, i.e., $\gamma \simeq 1$. (For a variation of the CPU time for the computation of $\mathcal{N}^r$ versus γ, see [36].) It was explicitly shown by Picard [21, 22] that relation (2.1) is independent of the value of γ.

The algorithm of [14] uses bisection in its second phase to compute the roots. Specifically, it uses the following simplified version described in [29]:

$$x_{i+1} = x_i + c\,\mathrm{sgn}f(x_i)/2^{i+1}, \quad i = 0, 1, \ldots, \tag{2.2}$$

where $c = \mathrm{sgn}f(a)\,(b - a)$. The sequence (2.2) converges to a root $r \in (a, b)$ if for some x_i,

$$\mathrm{sgn}f(x_0)\,\mathrm{sgn}f(x_i) = -1, \quad \text{for} \quad i = 1, 2, \ldots.$$

Furthermore, the number of iterations ν which are required to obtain an approximate root r^* such that $|r - r^*| \leqslant \varepsilon$ for some $\varepsilon \in (0, 1)$ is given by

$$\nu = \left\lceil \log(b - a)\,\varepsilon^{-1} \right\rceil, \tag{2.3}$$

where the logarithm in the above relation and also in the rest of the paper is taken with base two. Instead of the iterative formula (2.2) we can also use the following one:

$$x_{i+1} = x_i - c\,\mathrm{sgn}f(x_i)/2^{i+1}, \quad i = 0, 1, \ldots, \tag{2.4}$$

where $c = \mathrm{sgn}f(b)\,(b - a)$.

The reason for choosing the bisection method is that it always converges within the given interval (a, b) and is a globally convergent method. Moreover it has a great advantage since it is worst-case optimal; i.e., it possesses asymptotically the best possible rate of convergence in the worst case [25, 26]. This means that it is guaranteed to converge within the predefined number of iterations, and, moreover, no other method has this property. Therefore, using relation (2.3) it is easy to have beforehand the number of iterations that are required for the attainment of an approximate root to a predetermined accuracy. Finally, the bisection method requires only the algebraic signs of the function values to be computed, as is evident from (2.2) or (2.4); thus it can be applied to problems with imprecise function values. As a consequence for problems where the function value follows as a result of an infinite series (e.g., Bessel or Airy functions), it can be shown [35, 37] that the sign stabilizes after a relatively small number of terms of the series and the calculations can be sped up considerably.

3. A high level description of the method. Here is an informal description of the algorithm. For the detailed algorithm, see subsection 6.1. The algorithm gets as input the fraction of the roots that are required to be computed and begins by

subdividing the interval into two equal subintervals. Alternatively, it may get as input a predetermined "budget" of function evaluations. The main body of the algorithm consists of three steps.

1. A number of subintervals stored from previous steps, enter Step 1. These subintervals resulted from dividing the original interval, and at the first iteration these are just the two halves mentioned above. We determine the sign of the function at the endpoints of these subintervals. Depending on the number of simple roots in each subinterval, its endpoints will have the same signs (in the case of even roots) or opposite signs (in the case of odd roots). We therefore have certainty on the existence of at least one simple root in an interval with opposite signs, so we proceed in discovering a root in those intervals using the bisection method.

2. Note that at this point our interval has been divided into subintervals whose endpoints are of the same sign. These subintervals are kept for further examination if our stopping criterion has not been fulfilled yet. We propose two variants of a stopping criterion. The first (which we consider to be more interesting and suggest as the main variant of the algorithm) requires that a fraction of the total number of roots must be discovered before terminating the algorithm. The second terminates the algorithm if a predefined budget of function evaluations has expired.

3. If the stopping criterion has not been fulfilled, we subdivide the set of subintervals with maximum length (among all subintervals that have been stored) into two halves and go back to Step 1. Otherwise we output the discovered roots and halt.

Observe that the algorithm uses the function only to compute its sign at specific points during its execution. Thus, if the sign is available by other means, apart from a direct calculation (and this mainly refers to an inexact calculation using some kind of approximation of the function value), the algorithm can still run without any problem [4, 5, 35, 37]. As a result, the actual problem that the algorithm solves is that of discovering N hidden points in the interval, using only an that answers queries of the following form: "Is the number of points in a specific subinterval (a, b) odd or even?"

4. The distribution of odd subintervals. In this section we find the probability of having k specific subintervals containing an odd number of roots. The probability space on which we make our calculations and the whole framework can be found in [14]. We briefly mention here that we view each root as a random point in the interval $(0, 1)$. That is, we assume without loss of generality that the given interval is normalized, i.e., its length is 1. This assumption is followed throughout this paper. We also make the assumption that the roots are and distributed; i.e., intervals of equal length have equal probability of containing a root. Consequently, the length ℓ of a subinterval also gives the probability of a randomly chosen point to lie within this subinterval.

Consider the following situation: N points are chosen randomly and uniformly in the interval $(0, 1)$. Assume that we have chosen m nonoverlapping subintervals all of the same length ℓ. We view the remaining part of the interval (which may not be connected) as the $(m + 1)$-st subinterval.

Let us denote by E the event that each one of k specific subintervals contains an odd number of roots and the remaining $m - k$ contain an even number of roots. The following theorem gives the exact probability of the event E.

THEOREM 4.1. $(0,1)$ N m

ℓ [illegible] k [illegible] m [illegible]

$$\mathrm{P}(E) = \frac{1}{2^m} \sum_{S} \binom{N}{S} \ell^S (1 - m\ell)^{N-S} \sum_{j=0}^{m} (m - 2j)^S \sum_{i=0}^{j} (-1)^i \binom{k}{i} \binom{m-k}{j-i}. \tag{4.1}$$

[illegible]. We associate with the ith subinterval, $i = 1, 2, \ldots, m$, a random variable X_i, $i = 1, 2, \ldots, m$, that takes the value 1 if the number of points in the subinterval is odd and 0 if it is even. These variables are identically distributed since we have assumed that the roots are uniformly distributed and the subintervals have equal length. The probability of the event E is given by

$$\mathrm{P}(E) = \mathrm{P}(X_{i_1} = 1, \ldots, X_{i_k} = 1, X_{i_{k+1}} = 0, \ldots, X_{i_m} = 0),$$

where $i_1, i_2, \ldots, i_m$ is a permutation of the set $\{1, 2, \ldots, m\}$. Notice that $\mathrm{P}(E)$ is independent of the specific permutation $i_1, i_2, \ldots, i_m$ since a point has the same probability equal to ℓ of being in each of the m subintervals.

The arrangement of the N points in the $m + 1$ subintervals can therefore be seen as a repetition N times of an experiment with $m + 1$ possible outcomes, the first m of which each have probability ℓ, and the last $(1 - m\ell)$. Let S, $0 \leqslant S \leqslant N$ be the total number of points in the m subintervals. The number of ways the subintervals $i_1, i_2, \ldots, i_m$ will contain, respectively, $\nu_{i_1}, \nu_{i_2}, \ldots, \nu_{i_m}$ points is given by the multinomial coefficient $\binom{S}{\nu_{i_1}, \ldots, \nu_{i_m}}$. Hence we get for $\mathrm{P}(E)$

$$\mathrm{P}(E) = \sum_{S} \binom{N}{S} \sum \binom{S}{\nu_{i_1}, \ldots, \nu_{i_m}} \ell^{\nu_{i_1} + \cdots + \nu_{i_m}} (1 - m\ell)^{N - (\nu_{i_1} + \cdots + \nu_{i_m})}, \tag{4.2}$$

where the inner summation is over all nonnegative integers $\nu_{i_1}, \nu_{i_2}, \ldots, \nu_{i_m}$ satisfying the conditions $\nu_{i_1} + \nu_{i_2} + \cdots + \nu_{i_m} = S$ with $\nu_{i_1}, \nu_{i_2}, \ldots, \nu_{i_k}$ being odd numbers and $\nu_{i_{k+1}}, \nu_{i_{k+2}}, \ldots, \nu_{i_m}$ being even. The above equation therefore becomes

$$\mathrm{P}(E) = \sum_{S} \binom{N}{S} \ell^S (1 - m\ell)^{N-S} \sum \binom{S}{\nu_{i_1}, \ldots, \nu_{i_m}}. \tag{4.3}$$

The proof now rests in finding a more easily computable form for the sum of multinomial coefficients, since the number of different tuples of $\nu_{i_1}, \nu_{i_2}, \ldots, \nu_{i_m}$ that fulfill the requirements is very large for any reasonable problem size, not to mention for computing large factorials.

Notice that the sum of multinomial coefficients (which we denote by $C(S, m, k)$) gives the number of permutations of S out of m distinct objects with repetitions such that k specific objects are each selected an odd number of times and the remaining $m - k$ are selected an even number of times.

Let us denote by $B(u, v)$ the number of v-permutations of u objects with repetition where each object is selected an odd number of times. In [2, p. 227] $B(u, v)$ is given

by

$$B(u,v) = \begin{cases} 2^{v-u+1} \displaystyle\sum_{j=0}^{\frac{u}{2}-1} (-1)^j \binom{u}{j} \left(\frac{u}{2}-j\right)^v, & u \text{ even, } v \text{ even,} \\ 0, & u \text{ even, } v \text{ odd,} \\ 2^{v-u+1} \displaystyle\sum_{j=0}^{\frac{u-1}{2}} (-1)^j \binom{u}{j} \left(\frac{u}{2}-j\right)^v, & u \text{ odd, } v \text{ odd,} \\ 0, & u \text{ odd, } v \text{ even.} \end{cases} \tag{4.4}$$

Let us also denote by $A(u,v)$ the number of v-permutations of u objects with repetition where each object is selected an even number of times. In the same reference, $A(u,v)$ is given by

$$A(u,v) = \begin{cases} 2^{-u} \displaystyle\sum_{j=0}^{u} \binom{u}{j} (u-2j)^v, & v \text{ even,} \\ 0, & v \text{ odd.} \end{cases} \tag{4.5}$$

So if we assume that ν points in total lie in the k subintervals which are expected to have an odd number of points, the remaining $S-\nu$ lie in the remaining $m-k$ subintervals. We may therefore express $C(S,m,k)$ in terms of $A(u,v)$ and $B(u,v)$ as follows:

$$C(S,m,k) = \sum_{\nu=k}^{S} \binom{S}{\nu} B(k,\nu) A(m-k, S-\nu). \tag{4.6}$$

This sum can now be transformed using (4.4) and (4.5), resulting in

$$C(S,m,k) = \frac{1}{2^m} \sum_{j=0}^{m} (m-2j)^S \sum_{i=0}^{j} (-1)^i \binom{k}{i} \binom{m-k}{j-i}. \tag{4.7}$$

Substituting the above in (4.3) we get (4.1). □

When the initial interval is partitioned into m equal subintervals, i.e., when $m\ell = 1$, then all N roots must necessarily lie in the m subintervals. Let us denote E' the event that k specific subintervals have an odd number of roots under this assumption. We have the following corollary.

COROLLARY 4.1. [illegible] E' [illegible]

$$\mathrm{P}(E') = \frac{1}{2^m m^N} \sum_{j=0}^{m} (m-2j)^N \sum_{i=0}^{j} (-1)^i \binom{k}{i} \binom{m-k}{j-i}. \tag{4.8}$$

[illegible]. In this situation there are only m possible outcomes of the experiment, all of the same probability ℓ. The analysis above that resulted in (4.1) now gives the above formula. □

5. Estimating the total number of roots. Our stopping criterion in the main variant of the algorithm requires the knowledge of the total number of roots in the interval. For this purpose, the algorithm, in parallel with its main task of computing roots, also estimates the total number of roots. The estimation of the total number of

roots is revised after each iteration, when new roots have been discovered. Hence, at the beginning of the algorithm there is only a rough estimation of the number of roots, but as we proceed the additional information allows us to be more accurate in our prediction. For our estimation method we shall need the following two propositions.

PROPOSITION 5.1. [illegible] N [illegible] p_{odd} [illegible] ℓ [illegible]

$$p_{\text{odd}} = \frac{1-(1-2\ell)^N}{2}. \tag{5.1}$$

[illegible]. Let p_{even} be the probability that a subinterval of length ℓ contains an even number of roots. Then clearly $p_{\text{odd}} = 1 - p_{\text{even}}$. Recall that ℓ is the probability of having a specific root in an interval of length ℓ. Now

$$p_{\text{even}} = (1-\ell)^N + \binom{N}{2}\ell^2(1-\ell)^{N-2} + \binom{N}{4}\ell^4(1-\ell)^{N-4} + \cdots.$$

Observe that the right-hand side equals $\frac{1}{2}\left[(x+y)^N + (x-y)^N\right] = \frac{1}{2}\left[1+(1-2\ell)^N\right]$ for $x = 1-\ell$ and $y = \ell$. □

Notice that for a number of roots N on the order of 20 or so, p_{odd} is very close to $1/2$ for large enough ℓ. Therefore, roughly half of the intervals have at least one root. This is natural, since when the number of roots is large, the intervals with odd roots and the intervals with even roots are expected to be about the same. In such a case, after computing the roots, it is worthwhile continuing by subdividing the largest intervals. When, however, we have discovered a number of roots close to the total (and thus the remaining roots are few), the number of intervals with no roots begins to increase, and thus the required sign evaluations per root also increase.

To quantify the above, consider the random variables X_i, $i = 1, \ldots, m$, introduced in the previous section. These variables are not independent since, for example, if $m = N+1$ and we know that $X_i = 1$ for $i = 1, 2, \ldots, m-1$, the event $X_m = 0$ has probability 1; i.e., the probability of an X_i taking a certain value is influenced by the values of the other variables. This dependency is, however, very weak for large values of N in the sense that the joint probability distribution function of the X_i's is very close, yet not equal, to the product of the marginal distribution functions.

If the number of roots in any of the subintervals were independent from the number of roots in the other subintervals, then the probability of the event E (see the previous section) would be given by the formula $p_2 = (p_{\text{odd}})^k(1-p_{\text{odd}})^{m-k}$. This follows from the observation that the probability of having odd roots is p_{odd} for all subintervals of length ℓ, which along with the assumption of independence gives the above. What we show next is that the exact probability p_1 of E as given by (4.1) is actually very close to p_2. We demonstrate this by comparing p_1 and p_2 numerically.

In Table 5.1 we have included a small fraction of extensive numerical comparisons of p_1 and p_2 for several values of the parameters N, m, k, and ℓ. To reduce the size of the table, we present here results for ℓ fixed to a typical value of $m/0.8$. The results show that p_1 and p_2 are close enough to be considered equal for the purpose of estimating the number of roots N.

It is therefore a satisfactory approximation to consider the X_i's as independent Bernoulli random variables with probability given by (5.1). The following is a straightforward estimation of this probability.

TABLE 5.1
Numerical comparison of p_1 and p_2 for several values of the parameters N, m, and k.

N	m	k	p_1	p_2
100	20	2	0.952×10^{-6}	0.953×10^{-6}
100	20	15	0.959×10^{-6}	0.959×10^{-6}
100	50	5	0.367×10^{-14}	0.404×10^{-14}
100	50	40	0.246×10^{-15}	0.268×10^{-15}
100	120	12	0.101×10^{-27}	0.153×10^{-26}
100	120	70	0.333×10^{-41}	0.514×10^{-40}
500	100	10	0.808×10^{-30}	0.808×10^{-30}
500	600	60	0.816×10^{-134}	0.161×10^{-133}
1000	200	40	0.152×10^{-64}	0.454×10^{-64}
1000	200	160	0.596×10^{-60}	0.596×10^{-60}
1000	500	100	0.213×10^{-145}	0.390×10^{-145}
1000	500	400	0.393×10^{-156}	0.104×10^{-155}

PROPOSITION 5.2. [illegible] m [illegible] ℓ k [illegible] $(1-\alpha)$ [illegible] α [illegible] 0 [illegible] 1 [illegible] p_{odd} [illegible] ℓ [illegible]

$$p_{\text{lower}} \leqslant p_{\text{odd}} \leqslant p_{\text{upper}},$$

[illegible]

$$p_{\text{lower}} = \frac{k - z_{\alpha/2}\sqrt{\frac{k(m-k)}{m}}}{m},$$

$$p_{\text{upper}} = \frac{k + z_{\alpha/2}\sqrt{\frac{k(m-k)}{m}}}{m},$$

[illegible] $z_{\alpha/2}$ [illegible]

$$\text{Prob}(-z_{\alpha/2} \leqslant Z \leqslant z_{\alpha/2}) = 1 - \alpha,$$

[illegible] Z [illegible]. Consider the m subintervals. Let X_i be a random variable assuming value 1 if the ith subinterval has opposite signs and 0 otherwise, $i = 1, \ldots, m$. By the discussion above, the $X_i, i = 1, \ldots, m$, are considered to be independent Bernoulli random variables $B(1, p_{\text{odd}})$. A confidence interval for p_{odd} with approximate confidence coefficient $(1-\alpha)$ is given by

$$\frac{k}{m} - z_{\alpha/2}\sqrt{\frac{\frac{k}{m}\left(1-\frac{k}{m}\right)}{m}} \leqslant p_{\text{odd}} \leqslant \frac{k}{m} + z_{\alpha/2}\sqrt{\frac{\frac{k}{m}\left(1-\frac{k}{m}\right)}{m}},$$

which proves the proposition. □

For example, when $\alpha = 0.05$, then $z_{\alpha/2} = 1.96$. We use the above confidence interval to estimate p_{odd} and then use (5.1) to estimate N. This is done by computing

two values for N, calling them N_{lower} and N_{upper}. The first is computed by solving the equation (with respect to N)

$$p_{\text{lower}} = \frac{1-(1-2\ell)^N}{2}, \tag{5.2}$$

and the second is computed by solving the equation

$$p_{\text{upper}} = \frac{1-(1-2\ell)^N}{2}. \tag{5.3}$$

Notice that in some cases N_{upper} and even N_{lower} can be infinite. This will happen when insufficient data are available for determining exact values for the confidence interval. But for our purposes this is immaterial: in either of these cases we continue subdividing the intervals.

When after some iterations, both ends of the confidence interval are well defined, we choose some preferable value for N. A good choice seems to be $(N_{\text{lower}}+N_{\text{upper}})/2$. Or, we may decide to be on the safe side and choose N to be N_{upper}. Whichever we choose, we use it to decide whether it is time to terminate.

6. The method and its theoretical analysis. In this section we study the expected behavior of the algorithm as a function of the problem size N and the required fraction of roots λ. Our assumption is that, using the method described in the previous section, we know the total number of roots N, even though this can only be determined approximately within the confidence interval. Knowing N, the algorithm will run until a fraction λ of the roots has been discovered, i.e., λN roots. Clearly λ can vary from values close to 0, resulting in a quick termination of the algorithm, to values close to 1, which increase the cost of discovering new roots to forbiddingly high levels, after a large percentage has been discovered. Such values of λ will render the algorithm very costly and should not be used. We next give the expected cost of the algorithm for specific λ. To this end, we first give a technical definition that facilitates our analysis.

DEFINITION 6.1. [illegible] iteration number [illegible] i [illegible] ℓ [illegible] $\ell = 2^{-i}$

The reason for this definition is that at Step 1 of the algorithm, after dividing the intervals, we would typically expect some subintervals to have an even number and some to have an odd number of roots. If at some stage of execution of the algorithm all previous executions of Step 1 gave subintervals of both types or only even ones, then the iteration number i would coincide with what one would normally expect as iteration, since one execution of the three steps results in dividing the length of the largest subintervals by 2. But there is also the possibility that the intervals entering Step 1 are all of odd roots. In this case all subintervals would be further divided by bisection in Step 1 in the same "ordinary" iteration. We therefore give the above definition to relate the length of the largest even subintervals with the iteration number. Notice that the event of having all subintervals with an odd number of roots has small probability (actually it could only happen with some meaningful probability in the first few iterations). Therefore the iteration i as described above is an integer very close to the "ordinary" iteration. Note also that if the algorithm is in iteration i, then the effect on the original interval is the same as directly dividing it into 2^i equal subintervals and executing bisection in those subintervals that have an odd number of roots.

The next theorem gives the expected number of odd subintervals and hence the expected number of discovered roots in iteration i.

THEOREM 6.1. [illegible] $(0,1)$ [illegible] m [illegible]

$$\mathrm{E}_d = \frac{m^N - (m-2)^N}{2m^{N-1}}. \tag{6.1}$$

[illegible]. The probability of getting, after the division into m subintervals, k odd subintervals is given by $\binom{m}{k}\mathrm{P}(E')$. E' is the event where, after the division into m subintervals, k [illegible] intervals have an odd number of roots and the remaining $m-k$ have an even number. This event was formally defined in section 4 where its probability also was derived and is given by (4.8). Hence we have

$$\begin{aligned}
\mathrm{E}_d &= \sum_{k=0}^{m} k\binom{m}{k}\mathrm{P}(E') \\
&= \frac{1}{2^m m^N}\sum_{k=0}^{m} k\binom{m}{k}\sum_{j=0}^{m}(m-2j)^N\sum_{i=0}^{j}(-1)^i\binom{k}{i}\binom{m-k}{j-i} \\
&= \frac{1}{2^m m^N}\sum_{j=0}^{m}(m-2j)^N\binom{m}{j}\sum_{i=0}^{j}(-1)^i\binom{j}{i}\sum_{k=0}^{m} k\binom{m-j}{k-i}.
\end{aligned}$$

Now the rightmost sum is easily seen to be $(m-j)2^{m-j-1} + i2^{m-j}$. By substituting and after some algebraic manipulations, the theorem follows. □

Assume now that a fraction λ of the roots is required. In the ith iteration we have $m = 2^i$ and by substituting we get that the iteration where this is achieved, on average, is the solution rounded above, for i, of the equation

$$\lambda N = \frac{2^{iN} - (2^i - 2)^N}{2^{i(N-1)+1}}. \tag{6.2}$$

Table 6.1 gives the solution of (6.2) for various values of N and λ.

TABLE 6.1
Iteration and expected work for achieving a fraction of roots λ.

		N = 100		500		1000		5000	
		i	w	i	w	i	w	i	w
λ	0.5	7	776	10	3508	11	6515	13	25522
	0.7	8	1093	11	5175	12	9650	14	37146
	0.9	10	1919	13	11313	14	21724	16	83230
	0.95	11	2898	14	19203	15	37454	17	144998

As for the expected work for achieving the fraction λ, notice that at iteration i, where d odd subintervals have been discovered, $(2^i + 1)$ sign determinations are required to split the interval into 2^i subintervals, and if d of those are odd, then bisection will be applied to each of them, requiring $\log(\ell/\varepsilon)$ additional sign determinations where ℓ is the length of the subinterval. But $\ell = 2^{-i}$, and i is the solution of (6.2). Hence, we have the following corollary.

COROLLARY 6.1.

$$w = 2^i + \lambda N \log \frac{\ell}{\varepsilon} + 1 \equiv 2^i - \lambda N(i + \log \varepsilon) + 1, \tag{6.3}$$

(6.2)

Table 6.1 also gives the value of the expected work for various values of N and λ.

Another interesting aspect of the behavior of the algorithm is the increase of as a function of the iteration. Since an exact calculation of this seems to be hard, we approximate it as follows.

Let E_{d_i} be the expected number of discovered roots by the end of iteration i. Then, the expected number of discovered roots in iteration $i+1$ is $\mathrm{E}_{d_{i+1}} - \mathrm{E}_{d_i}$. Also, using Corollary 6.1, the expected work in iteration $i+1$ is $2^i - (i + \log \varepsilon)(\mathrm{E}_{d_{i+1}} - \mathrm{E}_{d_i}) - \mathrm{E}_{d_{i+1}}$. We approximate the expected work per root in iteration $i+1$ by the fraction of the expected work in iteration $i+1$ divided by the expected number of discovered roots in the same iteration. We call this fraction E^*_{i+1}. By the above discussion this is given by

$$E^*_{i+1} = \frac{2^i - \mathrm{E}_{d_{i+1}}}{\mathrm{E}_{d_{i+1}} - \mathrm{E}_{d_i}} - i - \log \varepsilon. \tag{6.4}$$

In Figure 6.1 we plot E^*_i for $N = 1000$ and $\varepsilon = 10^{-6}$ as a function of i. We have chosen to present the plot as a continuous curve, even though i is an integer, to better demonstrate its shape. It is interesting to note that the expected cost per root (as approximated by E^*) first decreases slightly and, after reaching a minimum, subsequently increases rapidly. The first part of the plot is explained since in the first iterations, discovering odd intervals is easy (about half of the intervals are odd), but computing the roots in those intervals costs more to the bisection (computing a root in an interval requires one more sign determination than in an interval of half the length). The subsequent rapid increment is caused by the fact that after some iteration, the odd intervals are becoming rare and increasingly more function evaluations are spent dividing an even interval and getting two even subintervals. After that point the behavior of the algorithm deteriorates rapidly and it soon becomes inefficient. This is the point to stop execution.

6.1. A detailed description of the proposed algorithm. In this section we give a detailed description of the proposed algorithm based on the previous results and analysis. The algorithm takes as input the desired fraction of the roots, λ.

1. Divide the interval into two equal subintervals. Set $i = 1$ and $m = 2$.
2. Let A be the set of subintervals with opposite signs at their endpoints and let k be its cardinality, i.e., $k = |A|$. Let B be the set of subintervals with the same signs at their endpoints.
3. Find one root in each interval in A using bisection (2.2) or (2.4). As bisection proceeds, it leaves out intervals with an even number of roots. Add those into set B.
4. Estimate the total number of roots using relations (5.2) and (5.3), where p_{lower} and p_{upper} are given in Proposition 5.2. In these equations take $\ell = 2^{-i}$, where i is the number of the current iteration, and use the parameters $m = 2^i$ and k defined above.
5. If both N_{lower} and N_{upper} are finite, check whether $d \geqslant \lambda N$. $N = (N_{\text{lower}} + N_{\text{upper}})/2$, and d is the number of discovered roots up to this point.

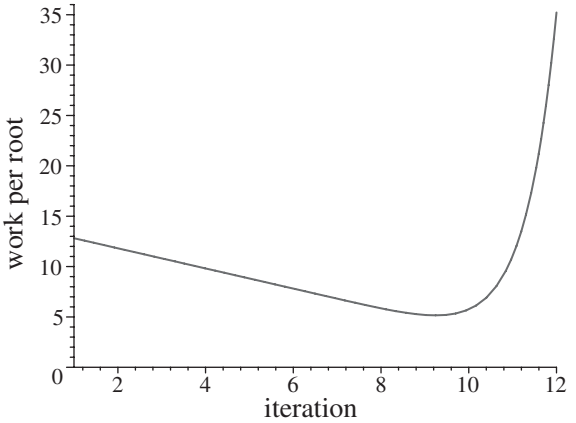

FIG. 6.1. *Expected work per root vs. iteration ($N = 1000$).*

6. If the criterion is not fulfilled or at least one of the N is infinite, then replace in B each subinterval [illegible] by its two halves. Set $i = i + 1$ and $m = 2^i$ and go to step 2.
7. If the stopping criterion of step 5 is fulfilled, then output the roots and terminate.

A useful observation that helps in improving the efficiency of the code (though it is not our goal to give implementation details here) is that set B is best implemented as a [illegible], i.e., a data structure that allows easy insertions and removals of its items and, what is most important, easy location of the largest element (in constant time). This is needed in steps 3 (insertion) and 6 (find max and removal). Actually, B is best viewed as a set consisting of subsets, where each subset contains subintervals of the same size. These sets are kept sorted by the heap structure, to minimize access time to the largest ones, as required in step 6.

The subdivision into intervals which are fractions that are a power of two is justified as follows: Recall that after we identify an interval with opposite signs at its endpoints, we proceed in discovering a root using bisection (this is step 3 above). But this has the side effect that these intervals will be subdivided further in the process of discovering the root. Now if we choose the initial subintervals to be a power of two, all of these subdivisions that emerge from bisection can be used in the future should the algorithm proceed to subsequent iterations, and thus some sign determinations can be saved. Moreover, this simplifies our arithmetic since each subinterval may be represented not by two real numbers but by its left endpoint and its size, which, in turn, may be represented by two integers, the exponents of actual numbers.

7. Conclusion and further research. As a conclusion, we have addressed the problem of computing the roots of a function when the number of roots is very large. This is a formidable problem with many applications in various fields of science. It seems possible, however, to attack the problem precisely by taking advantage of its size. To this end we have presented an algorithm that effectively discovers roots using an almost "blind" search up to a point where the original size of the problem has been greatly reduced. Then, more robust and expensive methods can be used to completely solve the problem. We have also given theoretical justification of its good performance, based on a probabilistic framework. The main advantages of the

proposed methodology are its simplicity, which results in fairly simple programming, and its efficiency, which increases with the problem size.

There are several possible directions to which this work may be extended. One very natural one is to consider an arbitrary distribution of roots, along the lines of [13]. An interesting problem in this case is to transform the method of estimating the number of roots that we presented here, in a way that takes into account the given distribution.

Moreover, there is no reason to limit the search space to a single dimension. With appropriate assumptions and, most of all, an appropriate existence criterion similar to Bolzano's, for instance, the Poincaré–Miranda hypercubes, Sperner simplices, or the characteristic polyhedra [16, 29, 30, 31, 32, 33, 34], it might be possible to extend the method to higher dimensions.

Finally, the most interesting extension is, of course, to apply the algorithm on a natural, real problem like the ones mentioned in the introduction.

Acknowledgment. The authors wish to thank the anonymous referees for their constructive comments, suggestions, and valuable criticisms, which helped us to improve the paper.

ON QUANTITATIVE ANALYSIS METHODS FOR MULTIGRID SOLUTIONS*

BORIS DISKIN†, JAMES L. THOMAS‡, AND RAYMOND E. MINECK‡

Abstract. Limitations of the classical local-mode Fourier (LMF) analysis in application to multigrid solutions of variable-coefficient problems are well known. This paper introduces alternative, very general, quantitative analysis methods for multigrid solutions of partial differential equations. The methods are applied to available, nonperfect multigrid solvers that deal with practical problems. The analysis methods considered in this paper focus on the main complementary parts of a multigrid cycle: relaxation and coarse-grid correction. Tasks for these parts, e.g., error smoothing for relaxation and reduction of smooth errors for coarse-grid correction, are assumed to be assigned in advance. Idealized relaxation (IR) and idealized coarse-grid (ICG) iterations are introduced. In these iterations, one part of the cycle (relaxation for IR iterations and coarse-grid correction for ICG iterations) is replaced with an idealized imitation known to be efficient for the assigned task; its complementary part is the actual part of a two-grid cycle. The analysis compares performances of the actual cycle and idealized iterations.

The IR and ICG iterations are very general and can be directly applied in the most complicated simulations including highly variable (or nonlinear) coefficients, complex geometries, and unstructured grids. The results of this analysis are not single-number estimates; they are rather convergence patterns of the iterations that may either confirm or refute expectations indicating what part of the actual solver is inefficient in carrying out the assigned task. The generality of the analysis makes it a valuable tool for analyzing complicated large-scale computational problems, where no other analysis methods are currently available.

In this paper, the IR and ICG iterations are applied to model problems of progressive complexity. The analysis proved sensitive to very delicate details of the actual multigrid cycle, pointing clearly to each instance when a part of the algorithm was inefficient.

Key words. multigrid methods, quantitative analysis, partial differential equations

1. Introduction.

The subject of this paper is new, very general quantitative analysis methods for multigrid solutions of partial differential equation (PDE) problems. Multigrid solvers have proven to be the most efficient iterative methods for discretized PDE systems. Brandt [3, 7] defines a multigrid solver as having textbook multigrid efficiency (TME) if the solutions to the governing system of equations are attained in a total computational work that does not exceed a few (less than 10) minimal work units; a work unit is defined as the computational work required for one residual evaluation. The TME descriptor stems from the efficient multigrid solutions that have been demonstrated for elliptic problems and are available in multigrid textbooks [12, 27, 28]. Recently, TME methods have been developed for several nonelliptic problems in computational fluid dynamics (CFD) [26].

The development of quantitative analysis methodologies for iterative solutions of large-scale computational problems has lagged behind the multigrid practices. Some

methods, such as direct analyses of matrices corresponding to iterative solutions of discretized differential equations, may be useful for small model problems (see, e.g., [13] for the matrix analysis of one-dimensional defect-correction iterations), but are prohibitively expensive for multidimensional large-scale problems. Other methods, such as [18, 29], are qualitative and cannot provide sharp convergence estimates for practical algorithms. For many years, the local-mode Fourier (LMF) analysis has been the major practical tool for quantitative evaluation of multigrid convergence. The details of the analysis can be found in the literature [3, 6, 25, 27, 28]. Certain limitations of the LMF analysis, such as inability to account for boundary conditions and irregular coefficients, have also been known for a long time. These limitations make the LMF analysis inapplicable to many important computational problems, such as problems with highly variable coefficients, complex geometries, and unstructured grids, where other, more general, analysis techniques must be applied.

A typical approach to analyzing complex problems is based on the following steps: (1) identify contributors to different aspects of the problem, (2) formulate simplified models to isolate each identified contributor, (3) solve the simplified models, (4) extend the solutions to actual problems that cannot be directly analyzed. When applied to iterative methods, such an approach often leads to dramatic improvements of convergence properties of iterations. However, if the actual difficulty is represented not by a single object or phenomenon, but rather by interactions between several (or many) objects and phenomena, analytically solvable models of such interactions are scarce.

An alternative, more generally applicable approach is to employ an available, nonperfect solver to deal with a practical problem in its entirety, and then to isolate, identify, and improve the parts of the solver responsible for the less-than-optimal performance. This approach closely relates to the [illegible] concept introduced in [8] to evaluate multigrid efficiency of a given combination of a relaxation scheme with a set of coarse-grid variables.

The analysis methods introduced in this paper focus on the main complementary parts of a multigrid cycle: relaxation and coarse-grid correction. The full-weighting restriction and bilinear prolongation operators are fixed and assumed suitable for efficient multigrid solution. The novel analysis techniques, idealized relaxation (IR) and idealized coarse-grid (ICG) iterations, are applied to two-grid cycles solving PDE problems. Each part of the cycle is assigned with a task known in advance, e.g., relaxation may be assigned to smooth errors, coarse-grid correction may be assigned to reduce smooth error components.

To apply the new analysis, we first choose a desired sample fine-grid solution (zero is a natural choice for linear problems) and substitute it into the equations to generate the corresponding right-hand side and boundary data. Then we form an initial guess (for example, a random perturbation of the solution); thus, the fine-grid algebraic error is known. In the proposed analysis, idealized iterations probe the actual two-grid cycle to identify parts limiting the overall efficiency. In these iterations, one part of the cycle is actual, and its complementary part is replaced with an idealized imitation. The idealized imitations do not depend on the operators to be solved. They are numerical procedures acting directly on the known algebraic error to efficiently fulfill the task assigned to the corresponding part of the two-grid cycle. The results of the analysis are not single-number estimates; they are rather convergence patterns of the iterations that may either confirm or refute our expectations indicating what part of the actual cycle is not efficient in carrying out the assigned task. The possible implications from this analysis are at least twofold: one can seek a better

implementation of the identified part of the solver leaving other parts unchanged or one can adjust the algorithmic design by changing assignments to some (or all) parts of the solver. As an illustration of design adjustments, in some multigrid solvers for nonelliptic PDE problems, the relaxation assignment is extended beyond smoothing to reduce some smooth error components as well.

The new analysis methods can be regarded as a numerical extension of the LMF analysis to the problems where the classical LMF analysis is inapplicable. The idealized iterations are very general and can be directly applied in the most complicated situations including highly variable (or nonlinear) coefficients, global solvers, complex geometries, and unstructured grids. Similar to the LMF analysis, the idealized iterations are not constructive; they indicate algorithmic inefficiency but do not suggest a remedy. On the other hand, easily available additional information, such as the frequency content (in the LMF analysis) or shape and patterns (in the IR and ICG analysis) of slowly converging error, may hint at possible improvements to the algorithm. As shown by examples in section 5, the new analysis methods are sensitive to very delicate details of the tested two-grid cycle, clearly indicating what part of the algorithm is inefficient.

The material in this paper is organized as follows. Section 2 introduces the IR and ICG iterations as analysis methods for a two-grid cycle. In section 3, a motivating stagnation-flow problem, which is very difficult for standard analytical methods, is formulated. Section 4 discusses the limitations of LMF analysis in application to variable-coefficient problems. Section 5 presents examples of IR and ICG analysis applications; the limits of applicability of the LMF analysis are also demonstrated. An efficient multigrid solver for the motivating stagnation-flow problem that capitalizes on the findings of the new analysis is reported in section 6. The paper is concluded with some discussions in section 7.

2. IR and ICG iterations. IR and ICG iterations are analysis methods that test computational efficiency of a two-grid cycle. The two-grid cycle amplification matrix, $\mathbf{M}_h$, transforms the initial fine-grid algebraic error, $\mathbf{e}_h^{\text{old}}$, into the after-cycle error, $\mathbf{e}_h^{\text{new}}$,

$$\mathbf{e}_h^{\text{new}} = \mathbf{M}_h \mathbf{e}_h^{\text{old}}. \tag{2.1}$$

The amplification matrix can be defined as

$$\mathbf{M}_h = \mathbf{S}_h^{\nu_2} \mathbf{C}_h \mathbf{S}_h^{\nu_1}. \tag{2.2}$$

Here, ν_1 and ν_2 are small nonnegative integers representing the number of pre- and postrelaxation sweeps, $\mathbf{S}_h$ is the relaxation amplification matrix, and $\mathbf{C}_h$ is the amplification matrix of the coarse-grid correction:

$$\mathbf{C}_h = \mathbf{E}_h - \mathbf{P}_H^h \mathbf{L}_H^{-1} \mathbf{R}_h^H \mathbf{L}_h, \tag{2.3}$$

where $\mathbf{L}_h$ and $\mathbf{L}_H$ are the fine- and coarse-grid operator matrices, $\mathbf{P}_H^h$ and $\mathbf{R}_h^H$ are the prolongation and restriction matrices, and $\mathbf{E}_h$ is the fine-grid identity matrix.

For IR iterations, the coarse-grid correction part is actual and the relaxation is idealized. Assuming that the relaxation assignment is smoothing only, the idealized relaxation may be defined as an explicit error-averaging procedure. Some efficient averaging procedures can be derived from relaxation matrices, e.g., Gauss–Seidel or Jacobi, for a discretized Laplace operator. In this paper, we employ two IR procedures.

The first error-averaging procedure,

$$e_{i_1,i_2} \longleftarrow \frac{1}{4}\begin{bmatrix} 0 & 1 & 0 \\ 1 & 0 & 1 \\ 0 & 1 & 0 \end{bmatrix} e_{i_1,i_2}, \tag{2.4}$$

is performed in a lexicographic order and corresponds to the Gauss–Seidel relaxation for the five-point Laplacian. The second IR procedure corresponds to standard full-weighting averaging with stencil

$$e_{i_1,i_2} \longleftarrow \frac{1}{16}\begin{bmatrix} 1 & 2 & 1 \\ 2 & 4 & 2 \\ 1 & 2 & 1 \end{bmatrix} e_{i_1,i_2}. \tag{2.5}$$

The averaging (2.5) is simultaneously performed at all interior points. This procedure can be considered as a damped Jacobi relaxation for a nine-point Laplacian.

In IR analysis of a two-grid cycle, at each relaxation step, the known exact solution, if not zero, is subtracted from the current approximation to obtain the algebraic error function. The explicit averaging procedure is applied directly to the error function. The exact solution is then added back. The coarse-grid correction remains unchanged. If the convergence of IR iterations is much better than the convergence of the actual cycle, we conclude that the actual relaxation is not a sufficiently good smoother. Slow convergence of IR iterations indicates insufficient coarse-grid correction.

In ICG iterations, the relaxation scheme is actual and coarse-grid correction is idealized. Assuming that the actual restriction and prolongation operators are suitable for efficient multigrid solution, the ICG correction involves ideal operators $\mathbf{L}_H$ and $\mathbf{L}_h$, such that $\mathbf{L}_H^{-1}$ is an accurate approximation to $\mathbf{L}_h^{-1}$ for smooth components. The best ideal operators are the corresponding identity matrices. With this choice, the ICG correction becomes

$$\mathbf{C}_h^{\text{ideal}} = \mathbf{E}_h - \mathbf{P}_H^h \mathbf{R}_h^H. \tag{2.6}$$

In ICG analysis of a two-grid cycle, the ideal coarse-grid correction replaces the actual one. The idealized $\mathbf{C}_h^{\text{ideal}}$ is applied directly to the known algebraic errors obtained after pre-relaxation sweep(s) of the actual relaxation. If the performance of the ICG iterations is much better than the performance of actual two-grid cycle, we can conclude that the actual coarse-grid correction is lacking. Slow convergence observed in the ICG iterations is a sign of poor smoothing in relaxation.

The intended application of the IR and ICG iterations is to identify inefficient parts of an unacceptably slow actual cycle. It is assumed that the efficiency goal is defined in advance together with the assignments for each part of the cycle. The overall efficiency considerations set some additional requirements for the idealized imitations: in particular, the "reference cycle," which uses both IR and ICG iterations, has to meet the efficiency goal. In general, the convergence rate of the reference cycle represents a sensitivity threshold, i.e., the IR and ICG iterations, with given idealized imitations, may suggest some meaningful improvements only for actual cycles with convergence rates significantly slower than this threshold. The numerical tests where actual cycle converges with the rates superior (or comparable) to the threshold should be regarded as indications of sufficient efficiency of the actual cycle.

Note that the idealized iterations are not restricted to structured-grid applications. All multigrid algorithms, including unstructured-grid solvers, have inherently

available averaging procedures as well as restriction and prolongation operators that can be used for the idealized iterations.

3. Motivating problem. The set of two-dimensional nonconservative incompressible Euler equations is defined as

$$\begin{aligned} uu_x + vu_y + p_x &= f_u, \\ uv_x + vv_y + p_y &= f_v, \\ u_x + v_y &= f_c, \end{aligned} \tag{3.1}$$

where variables u, v, and p represent the x-directional velocity, the y-directional velocity, and the pressure, respectively. The first and second equations are referred as the u- and v-momentum equations, respectively; the third equation is the continuity equation. Standard boundary conditions for this formulation are the velocity components specified at the inflow boundary, the pressure specified at the outflow boundary, and the tangency condition (where the normal velocity component is set to zero) defined at the body surface.

The [illegible] is defined as a flow against a solid plane located at $x = 0$. The exact solutions have the form

$$\begin{aligned} u &= -ax, \\ v &= ay, \\ p &= -a^2 \tfrac{x^2+y^2}{2}, \end{aligned} \tag{3.2}$$

where a is an arbitrary constant.

A typical computational domain for the plane stagnation flow is a square $(x, y) \in [-D, 0] \times [-D/2, D/2]$. The inflow boundary is defined at the left vertical edge, $x = -D$, the outflow boundaries are at the horizontal edges, $y = \pm D/2$, and the tangency condition is defined at the plane surface, $x = 0$. If the boundary conditions are symmetric with respect to the axis $y = 0$, the stagnation point is located at $(x, y) = (0, 0)$.

The pressure-equation formulation [22, 23] is obtained from (3.1) by replacing the continuity equation with an equation for the pressure

$$\begin{aligned} uu_x + vu_y + p_x &= f_u, \\ uv_x + vv_y + p_y &= f_v, \\ (u_x)^2 + 2u_y v_x + (v_y)^2 + \Delta p &= f_p. \end{aligned} \tag{3.3}$$

The major advantage of this formulation is an easily available h-elliptic collocated-grid discretization. (See definition and discussions related to h-ellipticity in [2, 3, 27].) Besides the standard set of boundary conditions (given above), the pressure-equation formulation (3.3) requires an additional boundary condition at the inflow boundary. To ensure the same solution for the problems (3.1) and (3.3), this additional boundary condition is taken as the continuity equation enforced at the inflow boundary. This boundary condition can be implemented in a number of ways; a convenient choice is through the Neumann condition for the pressure derivative obtained by manipulating the normal (to the boundary) momentum equation and the continuity equation at the inflow boundary. That is,

$$\partial_x p = f_u - u\partial_x u - v\partial_y u = f_u + u(\partial_y v - f_c) - v\partial_y u, \tag{3.4}$$

where $f_u + u(\partial_y v - f_c) - v\partial_y u$ is a known quantity at the inflow boundary.

The second-order accurate interior discretization, $\mathbf{R}(\mathbf{q})$, of (3.3) is defined as upwind differencing for the convection operators of the momentum equations and central difference approximations for the pressure gradient; in the pressure equation, the standard h-elliptic five-point discretization, Δ^h, is applied for the Laplacian of the pressure, and central differencing is applied for the velocity derivatives. That is,

$$\mathbf{R}(\mathbf{q}) \equiv \begin{pmatrix} u\partial_x^u u + v\partial_y^u u + \partial_x^c p \\ u\partial_x^u v + v\partial_y^u v + \partial_y^c p \\ (\partial_x^c u)^2 + 2(\partial_y^c u)(\partial_x^c v) + (\partial_y^c v)^2 + \Delta^h p \end{pmatrix} = \begin{pmatrix} f_u \\ f_v \\ f_p \end{pmatrix}, \tag{3.5}$$

where $\mathbf{q} = (u, v, p)^T$, and superscripts u and c denote second-order accurate upwind and central differences for the first derivatives, respectively. Discretization of the Dirichlet conditions of given velocity components at the inflow boundary and given pressure at the outflow is straightforward. The Neumann conditions for the pressure can be implemented explicitly by employing a one-sided difference approximation for the normal derivative. With this implementation, the discrete pressure equation is not defined at the boundary. An alternative implementation uses two discrete equations for pressure defined at the same boundary point: a central approximation for the normal pressure derivative and a modified pressure equation. The pressure value located in the exterior of the computational domain is eliminated from these two equations. In the modified pressure equation, some velocity derivatives, $u_y, v_y, u_x = f_c - v_y$, are computed analytically from the Dirichlet conditions for the velocities; the derivative v_x is discretized with a one-sided stencil. An advantage of the latter implementation is a more compact stencil obtained for differencing the pressure at the boundary. For the discrete formulation (3.5), two numerical closure equations are required at the inflow boundary; one numerical closure equation is required at each outflow boundary and at the plane surface. The closure equations are usually modified discrete approximations to the target differential equations different from the discretizations in the interior. Detailed discussions and numerical tests for different boundary conditions can be found in [17].

The Newton linearization, $\frac{\partial \mathbf{R}}{\partial \mathbf{q}}$, of the operator (3.5) around the solution $\mathbf{q}$ is defined as

$$\frac{\partial \mathbf{R}}{\partial \mathbf{q}} \equiv \begin{pmatrix} Q^u + (\partial_x^u u) & (\partial_y^u u) & \partial_x^c \\ (\partial_x^u v) & Q^u + (\partial_y^u v) & \partial_y^c \\ 2(\partial_x^c u)\partial_x^c + 2(\partial_x^c v)\partial_y^c & 2(\partial_y^c v)\partial_y^c + 2(\partial_y^c u)\partial_x^c & \Delta^h \end{pmatrix}, \tag{3.6}$$

where $Q^u = u\partial_x^u + v\partial_y^u$ is a second-order accurate upwind discretization of the linear convection operator.

4. Limitations of LMF analysis. In this section, we discuss some limitations of the LMF analysis in applications to variable-coefficient problems. A rigorous LMF analysis for uniformly elliptic variable-coefficient problems has been considered in [5].

The classical LMF analysis applied to a variable-coefficient problem is defined in the following three steps.

1. Form a set of constant-coefficient approximations by freezing the variable coefficients at some locations, e.g., grid nodes.
2. Analyze each constant-coefficient problem on the infinite (or periodic) domain.
3. Take the final estimate of the analysis as the worst estimate among all the constant-coefficient problems.

The infinite grid assumption makes the LMF analysis intrinsically incapable of predicting the effects of boundary conditions. On finite computational domains, the choice of discrete boundary conditions and the way these conditions are treated in iterations can dramatically affect the convergence properties of iterations. A poor choice of boundary conditions may lead to an ill-posed discrete problem, even if the corresponding differential problem is well posed. Significant convergence deterioration may occur in the simplest well-known problems, e.g., the Laplace equation, as a result of improper handling of the boundary conditions. Some modifications of the LMF analysis, such as a half-space analysis of the first differential approximation (FDA analysis) [1, 11] and a discrete half-space analysis [16], have been developed to take the boundary conditions into account.

For the same reason, the LMF analysis cannot account for the downstream accuracy propagation that is an important convergence mechanism for some nonelliptic problems. In the presence of this mechanism, the accuracy is first achieved near the inflow boundary and then propagates downstream into the interior of the domain. (For illustration, see Figure 5.3 in section 5.2.) The computational domain affected by the downstream accuracy propagation may become very large, growing with each iteration. In the case of a downstream marching, it may expand to the entire domain in just one iteration. The estimates of the LMF analysis for nonelliptic flow problems can, however, be accurate in the areas that have yet to be affected by the downstream accuracy propagation from the inflow boundary. For iterative solvers of hyperbolic problems, e.g., nonmarching multigrid methods for the convection equation, LMF analysis estimates are usually accurate for the initial convergence; eventually, the accuracy propagated downstream from the inflow boundary extends over the entire computational domain.

Another serious limitation of the LMF analysis is the constant-coefficient framework itself. Accuracy of the LMF analysis extension to general variable-coefficient (or nonlinear) problems is limited by the accuracy of constant-coefficient approximations to the target problem. In this context, approximation means that the values of actual (variable) coefficients do not deviate significantly from a constant state.

There are many ways to measure how well a constant-coefficient formulation approximates a variable-coefficient one in a certain region. Here, we adopt a strong requirement that limits variation in each variable coefficient separately. Let $C_k(\mathbf{x})$, $k = 1, 2, \ldots$, be variable coefficients of the operator $\mathbf{L}_v$, and let

$$C_k^0 = C_k(\mathbf{x}_0) \tag{4.1}$$

be values of $C_k(\mathbf{x})$ frozen at the point $\mathbf{x}_0 = (x_0, y_0)$. We regard the constant-coefficient operator $\mathbf{L}_c$ obtained by freezing coefficients of $\mathbf{L}_v$ as approximating $\mathbf{L}_v$ in the vicinity of the point $\mathbf{x}_0$ with a relative accuracy ϵ, if there is a nonvanishing neighborhood $\Omega_{\mathbf{x}_0}^{s_1,s_2} = \{\mathbf{x} = (x, y), |x - x_0| < s_1, |y - y_0| < s_2\}$ such that, within this neighborhood,

$$|C_k^0 - C_k(\mathbf{x})| < \epsilon |C_k^0| \tag{4.2}$$

for any coefficient $C_k(\mathbf{x})$ of $\mathbf{L}_v$. The rectangular domain $\Omega_{\mathbf{x}_0}^{s_1,s_2}$ is called the ϵ-neighborhood of the point $\mathbf{x}_0$.

For any chosen ϵ, the values of s_1 and s_2 provide the scales at which the constant-coefficient problem approximates the variable-coefficient one with relative ϵ-accuracy. Reasonable values for ϵ are between zero and one, with $\epsilon = 0.5$ intuitively considered as a practical value. See Figure 4.1 for illustration of typical ϵ-neighborhoods for a

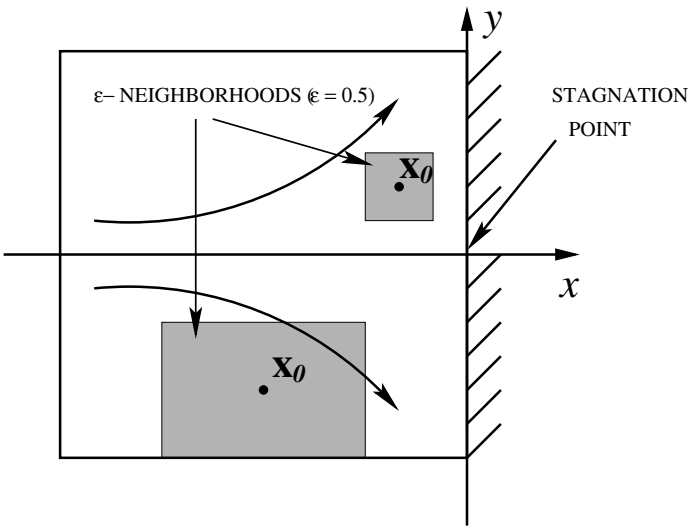

FIG. 4.1. *Model variable coefficient operator* (4.3)*: ϵ-neighborhoods corresponding to $\epsilon = 0.5$.*

variable-coefficient convection equation

$$-xu_x + yu_y = 0. \tag{4.3}$$

For the variable coefficients frozen at the point $\mathbf{x}_0 = (x_0, y_0)$, one should confine the LMF analysis to a computational subdomain that is located entirely within the ϵ-neighborhood of the point $\mathbf{x}_0$. If an ϵ-neighborhood is smaller than several mesh sizes in each dimension, the ϵ-neighborhood is considered vanishing; the LMF analysis should not be applied at this neighborhood. Implementation of the ϵ-neighborhood concept together with an assumption on the minimal number of mesh intervals sets some lower bounds on the ratios of coefficient to mesh size, e.g., the bound $\frac{y_0}{h} > 4$ occurs for (4.3) with $\epsilon = 0.5$ and a minimum of four mesh intervals in the y-direction per ϵ-neighborhood. Within this ϵ-neighborhood concept, some regions, such as the stagnation stream line, are inaccessible to the LMF analysis.

5. Examples of idealized iteration analysis.

5.1. Example 1: Skew discretization of Laplace equation. The first model problem is a two-grid cycle for a skew discretization of the Laplace operator. The computational domain is a unit square with the 17×17 uniform isotropic Cartesian grid. The discretization

$$\mathbf{L}u_{i_1,i_2} \equiv \frac{1}{2h^2}\left(u_{i_1+1,i_2+1} + u_{i_1-1,i_2+1} + u_{i_1+1,i_2-1} + u_{i_1-1,i_2-1} - 4u_{i_1,i_2}\right) = 0 \tag{5.1}$$

is subject to the Dirichlet boundary conditions. This formulation lacks h-ellipticity; therefore, a typical local relaxation exhibits poor smoothing properties. The tested solver is a two-grid (1, 2)-cycle with lexicographic point Gauss–Seidel relaxation, full coarsening, bilinear prolongation, and full-weighting residual restriction.

Classical LMF analysis can easily identify the problem. The smoothing factor, μ, of the Gauss–Seidel relaxation is computed as

$$\mu = \max_{\theta^{\mathrm{hf}}} \left| \frac{e^{i(\theta_y+\theta_x)} + e^{i(\theta_y-\theta_x)}}{4 - e^{-i(\theta_y+\theta_x)} - e^{-i(\theta_y-\theta_x)}} \right|, \tag{5.2}$$

where the maximum is taken over high-frequency modes

$$\theta^{\mathrm{hf}} = \left\{ (\theta_x, \theta_y), |\theta_x| \le \pi, |\theta_y| \le \pi, \max(|\theta_x|, |\theta_y|) \ge \frac{\pi}{2} \right\}. \tag{5.3}$$

The smoothing factor approaches unity for $|\theta_x| = |\theta_y| = \pi$.

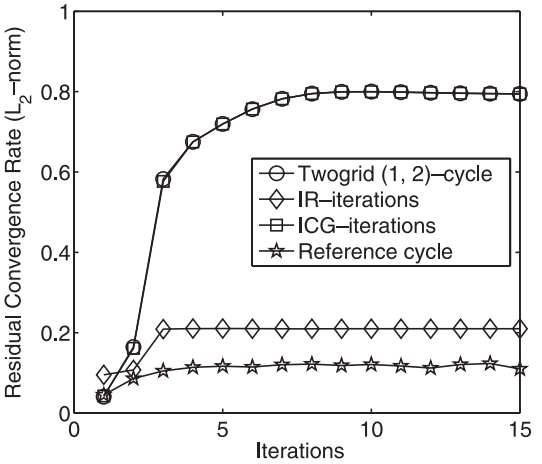

FIG. 5.1. *Convergence rates for skew Laplacian.*

The idealized iterations are effective indicators as well. The averaging procedure used in the IR iterations is given by (2.4). The convergence rates per iteration for actual cycle, reference cycle, IR, and ICG iterations are shown in Figure 5.1. The convergence rate of the two-grid cycle is well above the sensitivity threshold defined by the reference cycle. Recall that reference cycle employs both IR and ICG correction. Both IR and ICG iterations clearly point to poor smoothing in the actual cycle.

Regarding possible convergence improvements, the best advice is to avoid using non-h-elliptic discretization schemes. If one must solve the skew-Laplacian formulation, a good strategy is to consider this formulations as two uncoupled problems. Using a checkerboard analogy, the solver for the equations defined at black nodes should be independent of the solver for the formulation at white nodes. Considered at nodes of the same color, the discretization (5.1) is h-elliptic.

5.2. Example 2: Convection equation. In this section, we analyze a two-grid solver for the standard first-order accurate upwind discretization of the constant-coefficient convection equation

$$\partial_x^h u + \partial_y^h u = 0, \tag{5.4}$$

where ∂_x^h and ∂_y^h are two-point upwind differences for the x- and y-derivatives, respectively. A rectangular computational domain is covered by a uniform Cartesian

grid with the characteristics aligning with the diagonal direction. This is a nonelliptic problem known to represent difficulties for standard multigrid solvers. The solver to be tested is a standard full-coarsening two-grid $(1, 2)$-cycle including a red-black relaxation scheme with an underrelaxation parameter $w = 0.8$, full-weighting residual restriction, and bilinear prolongation. The coarse-grid discretization is identical to the discretization on the fine-grid. The LMF analysis for this problem is available in [27]. The relaxation smoothing factor is predicted as 0.52; the convergence of the two-grid cycle is limited by coarse-grid correction and is estimated as 0.5 per cycle. The slowly converging error components are smooth components that are much smoother in the characteristic direction than in other directions. These components are called characteristic components.

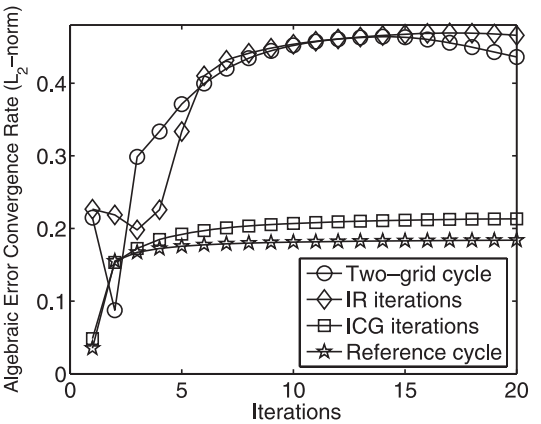

FIG. 5.2. *Convergence rates for a first-order discretization of the convection equation with periodic boundary conditions in the y-direction. Standard coarse-grid discretization.*

The numerical tests including the two-grid $(1, 2)$-cycle, IR and ICG iterations, and reference cycle have been performed on uniform grid, 1025×65 (domain 16×1), with the zero inflow boundary condition at $x = 0$ and periodic boundary conditions in the y-direction. The x-size of the domain has been chosen to be long enough for observing convergence slowdown caused by characteristic error components. The initial approximation is random. The results are shown in Figure 5.2. The averaging procedure used in IR iterations is given by (2.5).

Convergence rates of the two-grid $(1, 2)$-cycle are much slower than the rates of the reference cycle and close to the predictions of the LMF analysis. Convergence rates of IR and ICG iterations identify the coarse-grid correction as a part of the cycle limiting the overall efficiency. Similar to the frequency content in the LMF analysis, the profile of the algebraic errors after many iterations (see Figure 5.3 for errors after 20 and 40 iterations) clearly indicates the type of error that is slow to converge, namely smooth characteristic error. Moreover, the error profile demonstrates the effect of accuracy propagation from the inflow boundary. This important convergence mechanism for nonelliptic problems eludes the LMF analysis.

To improve convergence rates of multigrid solvers for convection-dominated (and other nonelliptic) problems, one can facilitate the accuracy propagation from the inflow boundary by employing a "global" relaxation scheme, e.g., downstream marching [11, 16] or implicit line relaxation [20]. In this context, "global" relaxation means that the relaxation scheme strongly affects at least some smooth errors, as opposed

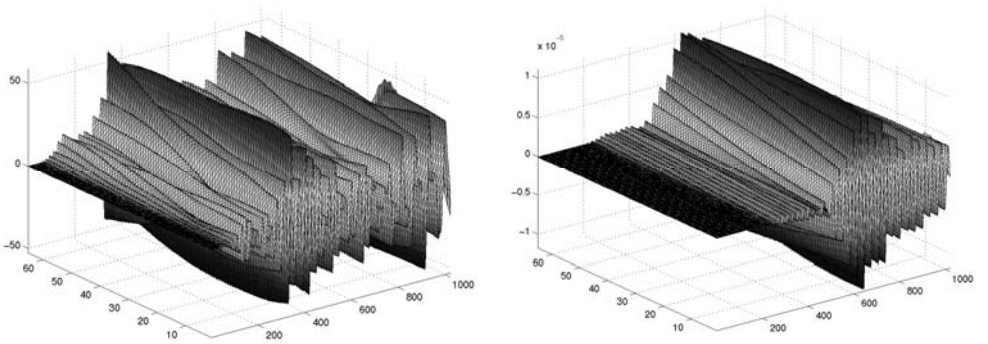

FIG. 5.3. *Error surface after* 20 *(left) and* 40 *(right) two-grid* $(1,2)$*-cycles for a first-order discretization of the convection equation with periodic boundary conditions in the* y*-direction. Grid* 1025×65.

to "local" relaxation that mostly affects high-frequency errors. Within such an approach, the relaxation assignment is extended to reduce both oscillatory and characteristic errors. The approach requiring characteristic error reduction in relaxation can be efficient as long as the characteristics of the nonelliptic operator are not closed. For problems with closed characteristics, the characteristic errors should be reduced in coarse-grid correction.

For efficient coarse-grid correction, the coarse-grid discretization should be adjusted to better approximate the fine-grid operator. One way to adjust the discretization is to employ a Galerkin coarse-grid operator with intergrid transfers satisfying certain accuracy conditions [30]. Another way is to explicitly add some adjustment terms to the coarse-grid operator to match the fine-grid (characteristic-component) first differential approximation [9, 14, 15, 19]. For the fine-grid discretization (5.4), the coarse-grid operator can be modified as

$$\bar{\partial}_x^h = \partial_x^h + \frac{h}{4}\partial_{xx}^u, \tag{5.5}$$

where $\bar{\partial}_x^h$ is a modified discretization of the x-derivative, ∂_x^h is the first-order upwind discretization, and ∂_{xx}^u is the first-order accurate three-point upwind discretization of the second derivative. The discretization of the y-derivative has been modified accordingly. With this modified coarse-grid operator, convergence rates of the two-grid $(1,2)$-cycle are improved significantly to 0.27 per cycle, as shown in Figure 5.4; the rates of IR iterations also improved. ICG iterations and reference cycle are unaffected, as expected.

5.3. Example 3: Laplace equation with Neumann boundary condition. In this section, the IR and ICG analyses are applied to the Laplace equation defined on a square domain $(x, y) \in [0,1] \times [0,1]$ with one Neumann boundary condition at $x = 1$ and the Dirichlet conditions at other boundaries. The Laplacian is discretized on a uniform 65×65 grid with the standard five-point stencil. The Neumann boundary condition is discretized with a three-point, one-sided differencing. The solution method is a full-coarsening two-grid $(1,2)$-cycle with lexicographic point Gauss–Seidel relaxation, full-weighting residual restriction, and bilinear prolongation. At the end of the relaxation sweep, the residuals of the Neumann equations at the boundary are zeros.

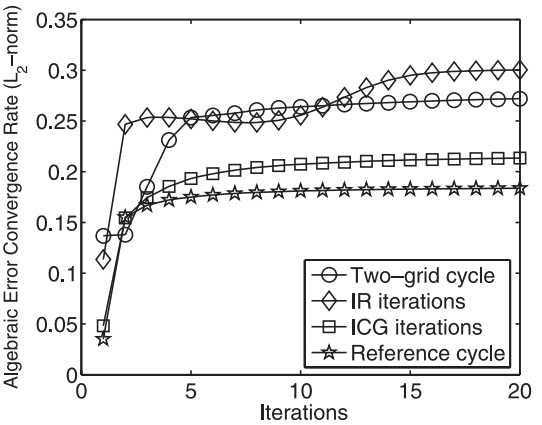

FIG. 5.4. *Convergence rates for a first-order discretization of the convection equation with periodic boundary conditions in the y-direction. Grid* 1025×65. *Modified coarse-grid discretization.*

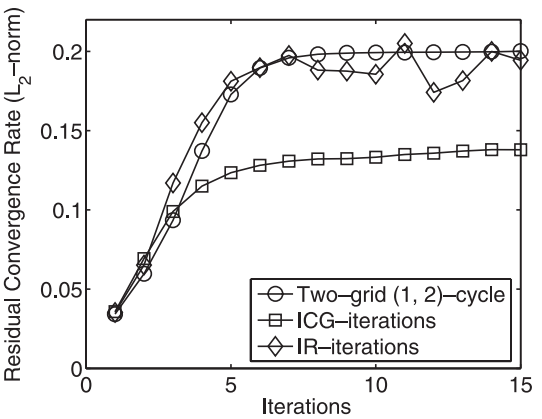

FIG. 5.5. *Convergence rates for the Laplace equation with Neumann boundary conditions. No boundary relaxation.*

For the two-grid $(1,2)$-cycle, the LMF analysis predicts the convergence rate of 0.12 per cycle. Figure 5.5 shows the residual convergence rates for the two-grid $(1,2)$-cycle and for the corresponding IR and ICG iterations. IR iterations employ the averaging procedure (2.4) in the interior performed in the lexicographic order. At the Neumann boundary, the error is averaged as

$$e_{i_1,i_2} \longleftarrow \frac{1}{2}\left(e_{i_1,i_2+1} + e_{i_1,i_2-1}\right). \tag{5.6}$$

In this test, convergence rates of reference cycle and ICG iterations are identical. The asymptotic convergence rate of the actual two-grid cycle is 0.20, noticeably worse than the rate predicted by the LMF analysis and observed in computations with all-Dirichlet boundary conditions.

The difficulty associated with the Neumann boundary relates to large interior residuals created after relaxing boundary conditions. The standard full-weighting

residual restriction near the Neumann boundary is inaccurate and degrades the quality of the coarse-grid correction. The LMF analysis cannot account for this effect. The ICG and IR iterations clearly indicate that the coarse-grid correction should be improved to accelerate convergence of the two-grid cycle.

There are several approaches to overcome this convergence slowdown; e.g., one can design a more accurate restriction operator near the Neumann boundary [27] or a local relaxation scheme that does not create large interior residuals. A more general approach, directly extendible to more complicated computational problems, is to apply a block relaxation near the boundary relaxing simultaneously all the equations defined at a certain number (, .) of grid lines adjacent to the Neumann boundary. With (almost) zero residuals in a boundary vicinity, an accurate residual restriction is no longer important. We refer to this special block relaxation as . The boundary relaxation procedure, performed once per cycle before transferring residuals to the coarse grid, can be considered a part of an improved coarse-grid correction scheme. Figure 5.6 illustrates the sensitivity of the two-grid $(1, 2)$-cycle and the IR iterations to the depth of the boundary relaxation region. The ICG iterations are not sensitive to the presence of boundary relaxation.

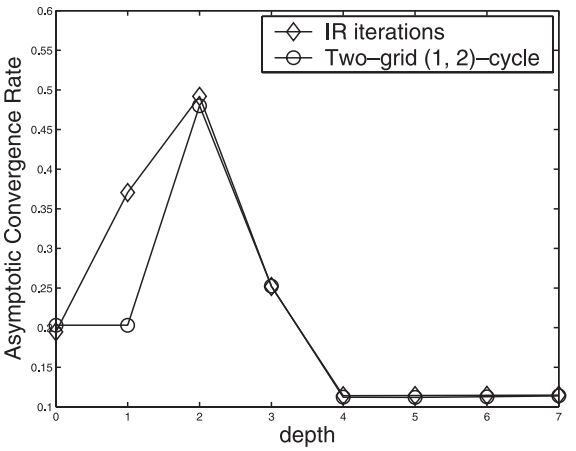

FIG. 5.6. *Convergence rates for the Laplace equation with Neumann boundary conditions. Boundary relaxation is applied once before residual restriction.*

The test results can be summarized as follows: For small depths of the boundary relaxation region, $0 \leq depth \leq 3$, the convergence rates of both iterations are not satisfactory. For $depth \geq 4$ the desired convergence rates of 0.12 per cycle are achieved. The performance of iterations is not sensitive to further expansions of the boundary relaxation region. Thus, the value $depth = 4$ is considered optimal. The optimal depth depends on the discretization stencils for boundary and interior equations, but does not depend on the grid size. A smaller optimal boundary relaxation depth can be achieved with a more compact discretization of boundary conditions. For example, a two-point wide discretization of the Neumann condition, derived from joint formulation of the interior five-point Laplacian and the central approximation for the normal derivative at the boundary, leads to the optimal $depth = 3$. The optimal $depth = 3$ can also be achieved for noncompact discretization of the Neumann boundary condition if the boundary relaxation procedure is performed at the end of each relaxation sweep rather than once per cycle. Such an arrangement softens

the residual jump at the interface between the boundary relaxation region and the interior. The latter relaxation-based implementation should not obscure the major role of boundary relaxation as facilitating coarse-grid correction. In practice, we are following an empirical rule to relax simultaneously all the discrete (physical and numerical) boundary conditions as well as all the interior equations that share data with the boundary condition equations.

5.4. Example 4: System of constant-coefficient PDEs. In this section we analyze a two-grid solver for a system of constant-coefficient equations related to the full Newton linearization (3.6) for the plane-flow solution (3.2) with $a = 1$. The system of constant-coefficient differential equations is formulated as

$$\mathbf{L}(\mathbf{q}) \equiv \begin{pmatrix} \bar{Q}^u - 1 & 0 & \partial_x^c \\ 0 & \bar{Q}^u + 1 & \partial_y^c \\ -2\partial_x^c & 2\partial_y^c & \Delta^h \end{pmatrix} \mathbf{q} = 0, \tag{5.7}$$

where $\mathbf{q} = (u, v, p)^T$, $\bar{Q}^u = \bar{u}\partial_x^u + \bar{v}\partial_y^u$, and $\bar{u}$ and $\bar{v}$ are positive constants. The computational domain is a rectangle $(x, y) \in [-\bar{u} - X, -\bar{u} + X] \times [\bar{v} - Y, \bar{v} + Y]$ with

$$0 < X \le \frac{\bar{u}}{2}, \qquad 0 < Y \le \frac{\bar{v}}{2}. \tag{5.8}$$

The latter conditions, referred as [illegible], are introduced to ensure that the constant-coefficient problem provides a good relative ϵ-accuracy ($\epsilon = 0.5$) in approximating the full-Newton linearization of the plane flow in the vicinity of $\mathbf{x}_0 = (-\bar{u}, \bar{v})$. A uniform Cartesian grid with a minimum of four mesh intervals in each spatial direction is applied. The physical boundary conditions are the following: u, v, and $\partial_x p$ are given at the inflow $x = -\bar{u} - X$; p is given at the outflow $x = -\bar{u} + X$; and periodicity is assumed in the y-direction ($\mathbf{q}(x, \bar{v} - Y) = \mathbf{q}(x, \bar{v} + Y)$). The normal derivative of the pressure, $\partial_x p$, at the inflow boundary is discretized with the second-order accurate, three-point, one-sided stencil. The numerical closure equations include central differencing for the x-derivative in the operator $\bar{Q}^u$ at the interior grid points adjacent to the inflow boundary; at the outflow, the x-derivative of the pressure in the first momentum equation is discretized with the three-point upwind stencil. The exact solution of the problem is $\mathbf{q} \equiv 0$.

The relaxation scheme consists of three steps.

(i) Line-implicit Gauss–Seidel relaxation is performed for the Laplace operator in the pressure equation with frozen u and v. In this relaxation, all the pressure equations defined at a vertical grid line with the same y-coordinate are relaxed simultaneously; this y-implicit relaxation scheme proceeds in the [illegible] direction, from the outflow to the inflow.

(ii) The boundary relaxation ($depth = 5$) is performed near the inflow boundary. All the equations defined at the five-grid lines adjacent to the inflow boundary (the boundary included) are solved simultaneously. Values of u, v, and p in the interior beyond the boundary relaxation region remain unchanged.

(iii) The momentum equations are [illegible] marched for u and v with p being fixed.

At the end of the relaxation sweep, the residuals of the momentum equations are zero.

The LMF analysis for this solver provides the following estimates. The Fourier symbol of the relaxation scheme is computed as

(5.9)
$$\hat{\mathbf{S}} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} - \begin{pmatrix} \hat{Q}-1 & 0 & \hat{\partial}_x^c \\ 0 & \hat{Q}+1 & \hat{\partial}_y^c \\ 0 & 0 & G\hat{S}^h \end{pmatrix}^{-1} \begin{pmatrix} \hat{Q}-1 & 0 & \hat{\partial}_x^c \\ 0 & \hat{Q}+1 & \hat{\partial}_y^c \\ -2\hat{\partial}_x^c & 2\hat{\partial}_y^c & \hat{\Delta}^h \end{pmatrix},$$

where

(5.10)
$$\begin{aligned} &\hat{Q} = \tfrac{\bar{u}}{h}\left(\tfrac{3}{2} - 2e^{-i\theta_x} + \tfrac{1}{2}e^{-i2\theta_x}\right) + \tfrac{\bar{v}}{h}\left(\tfrac{3}{2} - 2e^{-i\theta_y} + \tfrac{1}{2}e^{-i2\theta_y}\right), \\ &\hat{\partial}_x^c = \tfrac{i}{h}\sin(\theta_x), \\ &\hat{\partial}_y^c = \tfrac{i}{h}\sin(\theta_y), \\ &\hat{\Delta}^h = \tfrac{1}{h^2}\left(2\cos(\theta_x) + 2\cos(\theta_y) - 4\right), \\ &G\hat{S}^h = \tfrac{1}{h^2}\left(e^{i\theta_x} + 2\cos(\theta_y) - 4\right), \end{aligned}$$

θ_x and θ_y are normalized Fourier frequencies, $|\theta_x| \le \pi$, $|\theta_y| \le \pi$. The smoothing factor, μ, is

(5.11)
$$\mu = \max_{\theta^{\mathrm{hf}}} \rho(\hat{\mathbf{S}}),$$

where $\rho(\hat{\mathbf{S}})$ is the spectral radius of the matrix $\hat{\mathbf{S}}$, and the maximum is taken over the set of high-frequency Fourier modes θ^{hf} defined in (5.3).

The unrestricted LMF analysis considers the infinite domain with no compatible-coefficient restrictions (5.8) applied. This analysis predicts divergence of the relaxation scheme for high-frequency error components. For $\theta_x = \pi/2$, $\theta_y = -\pi/2$, and $\frac{\bar{u}}{h} = \frac{\bar{v}}{h} = \frac{1}{2}$, the convection symbol $\hat{Q} = 1$ and the smoothing factor $\rho(\mathbf{S}_h) = \infty$. Imposing the compatible-coefficient restrictions (5.8) together with the assumption that there are at least four mesh intervals in each dimension effectively implies $\frac{\bar{u}}{h} \ge 4$, $\frac{\bar{v}}{h} \ge 4$. With these restrictions, the LMF analysis predicts the smoothing factor of 0.53 on the 4×4 grid and factors better than 0.5 at finer grids converging to $\frac{1}{\sqrt{5}}$; this latter value is the smoothing factor of line relaxation for the scalar Laplace equation.

TABLE 5.1
Smoothing and amplification factors for the ϵ-neighborhood corresponding to $\bar{u} = \bar{v} = 1$, $\epsilon = 0.5$.

	Relaxation		Two-grid
N	Smoothing	Amplification	Amplification
8	0.51	1.00	0.14
16	0.51	1.14	1.71
32	0.50	1.17	2.60
58	0.50	18.66	31703.
64	0.50	1.46	8.15
128	0.50	1.80	24.23

For $\bar{u} = \bar{v} = 1$, the relaxation amplification factors are bounded by 1 everywhere except for the characteristic errors. As an example, Table 5.1 collects the relaxation smoothing and amplification factors (the pressure equation is relaxed with lexicographic pointwise Gauss–Seidel relaxation), as well as the amplifications factors of the corresponding two-grid (1, 2)-cycle. As noted previously, the smoothing factors are good. The amplification factors are erratic. On finer grids, the amplification factor

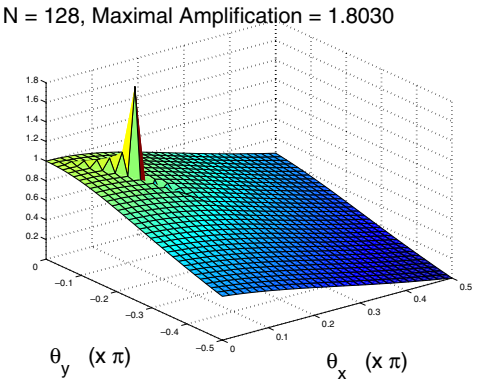

FIG. 5.7. *Relaxation amplification factor.*

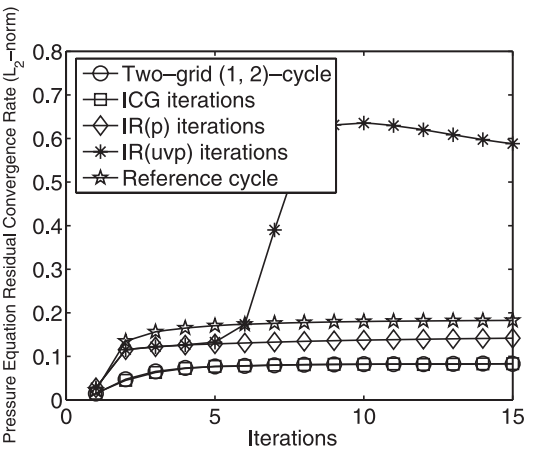

FIG. 5.8. *Convergence rates of the pressure equation residuals in solutions of the constant-coefficient problem* (5.7). *Grid* 257×33.

tends to infinity for certain smooth (but not the smoothest) characteristic frequencies of the convection operator ($\theta_x = -\theta_y$), for which the symbol $\hat{Q}$ approaches 1. On coarse grids, the smallest possible value of $|\hat{Q} - 1|$ is determined by the mesh size h and the frequency increment $\delta\theta$ and may vary nonmonotonically; that explains the irregular behavior of the amplification factors. For illustration purposes, the results for a nonstandard 59×59 grid are added to the table. At this grid, $h = 1/58$, and, for $\theta_x = -\theta_y = \frac{8}{58}\pi$, $\hat{Q} = 0.9909$. Figure 5.7 illustrates the relaxation amplification factor over a part of the frequency domain. More details of the analysis can be found in [17]. The LMF analysis does not account for the accuracy propagation from the inflow boundary, that is a major convergence mechanism for this two-grid cycle. Employment of a downstream marching in the relaxation scheme on a domain restricted as (5.8) ensures that the smooth characteristic errors, for which the LMF analysis predicts divergence, are strongly affected by the inflow boundary.

Figure 5.8 shows the convergence rates of the L_2-norm of the pressure-equation residuals for the four iterative methods solving problem (5.7) with $\bar{u} = \bar{v} = 1$ on the computational domain $(x, y) \in [-\frac{3}{2}, -\frac{1}{2}] \times [\frac{15}{16}, \frac{17}{16}]$ covered by the uniform isotropic

257×33 Cartesian grid. The size and shape of the domain have been chosen to satisfy compatible-coefficient restriction (5.8) and to have an isotropic grid with a large number of grid nodes between the inflow and outflow boundaries. The plot marked "Two-grid (1, 2)-cycle" shows the convergence rates of a two-grid cycle solving (5.7). The cycle includes the three-step relaxation scheme described above, full coarsening, full-weighting residual restriction, and bilinear prolongation. We use the coarse-grid discretization identical to (5.7), therefore, the assignment for relaxation is extended. That is, we suggest that downstream marching of the momentum equations efficiently reduces the smooth characteristic errors that cannot be approximated on the coarse grid. To illustrate the importance of this extended assignment for relaxation, we include two different IR iterations: IR iteration of the first type, IR(p) iteration, replaces step (i) in the relaxation scheme with the averaging procedure (2.5) for the pressure only. Boundary relaxation and downstream marching at steps (ii) and (iii) are performed as in actual relaxation. The second type of IR iterations is IR(uvp) iterations, where steps (i), (ii), and (iii) are replaced by averaging (2.5) for u, v, and p, and no downstream marching is performed.

Convergence rates of the actual cycle are better than convergence rate of the reference cycle with IR(uvp) iterations, indicating the efficiency goal is achieved. ICG iterations and IR(p) iterations provide an accurate estimate for the convergence of the actual cycle. The convergence rates of the ICG iterations and the two-grid cycle are virtually indistinguishable; the IR(p) convergence rates are predictably somewhat worse because line relaxation damps certain intermediate (neither high-frequency nor very smooth) error components significantly better than the ideal averaging procedure (2.5). With progressive grid refinement, the (not shown) convergence rates of the IR(uvp) iterations tend to the value 0.75; this is in agreement with the LMF analysis predictions for convergence rates of full-coarsening multigrid methods applied to a second-order discretization of the convection equation.

Although not shown in the figure, on larger domains (e.g., $[-5, 3] \times [\frac{1}{2}, \frac{3}{2}]$), accuracy propagation from the inflow boundary does not dominate the entire computational domain; divergence of the two-grid cycle is indeed observed in numerical tests, as predicted by the LMF analysis. However, on such domains, the compatible-coefficient restrictions (5.8) are violated; therefore, the formulation (5.7) does not provide a relevant constant-coefficient approximation to the variable-coefficient problem (3.6).

6. Multigrid solver for plane stagnation flow. The basic cycle employed in the multigrid algorithm for solution of the discrete equations (3.5) is an FV(ν_1, ν_2) cycle sketched in Figure 6.1. The FV cycle represents a modification of the well-known multigrid F cycle (see, e.g., [27]). The multigrid solutions have been obtained as follows: Random initial approximation has been assigned at each grid, and a full approximation scheme (FAS) version of FV(1,2) multigrid cycle has been used. The nonlinear equations at the fixed coarsest grid have been solved exactly; thus, finer grids used progressively more levels of multigrid. Compact formulations for discrete boundary conditions at the inflow and tangency boundaries have been implemented (see section 3 and [17]). The relaxation scheme included four steps: (1) point Gauss–Seidel relaxation of the pressure equation performed in a downstream order, (2) downstream relaxation of momentum equations, (3) boundary relaxation ($depth = 3$) at the inflow boundary, and (4) boundary relaxation ($depth = 3$) at the tangency boundary. Within the FAS cycle, the four-step relaxation scheme, full coarsening, full-weighting restriction of residuals, and bilinear prolongation of corrections have been used with direct injection of the nonlinear solution to the coarser level.

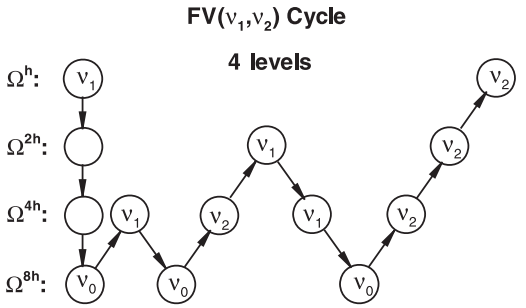

FIG. 6.1. *Schematic of the FV cycle for 4-level multigrid where ν_0 denotes the number of relaxations on the coarsest mesh (Ω^{8h}).*

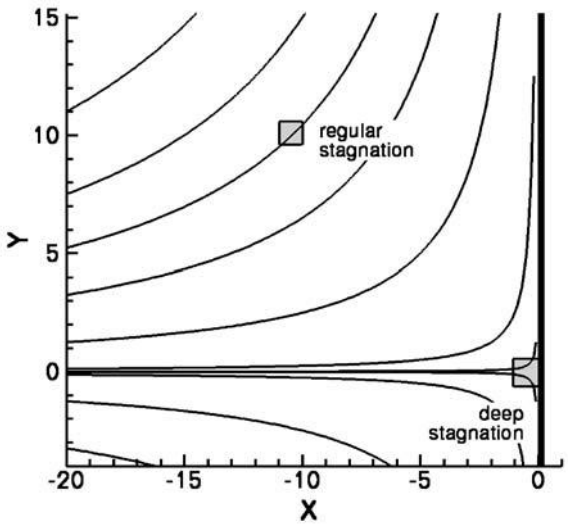

FIG. 6.2. *Plane stagnation flow streamlines and locations of the computational domains.*

Multigrid convergence has been studied for two plane stagnation flow regimes illustrated in Figure 6.2: (1) deep stagnation regime, where stagnation point is a part of the computational boundary; and (2) the regular stagnation flow, where the computational domain is shifted away from stagnation. For efficient solutions of stagnation flows in general curvilinear geometries, we refer readers to [17].

The convergence of the L_2-norm of residuals for the regular stagnation regime is shown in the left plot of Figure 6.3. Diamonds correspond to the residuals of the pressure equation; circles and squares denote residuals of the u- and v-momentum equations, respectively. The largest residuals at each cycle are those of the pressure equation with the momentum residuals generally 1-2 orders of magnitude smaller. The computational results are obtained on the unit-square domain centered at $(x, y) = (-10.5, 10)$. The finest isotropic grid is 65×65 and the coarsest grid level was 5×5. Because there is no discretization error for the plane-flow equations, the initial approximations on all grids is taken as random perturbations of the exact solutions for all variables. The convergence rates are grid-independent and very fast, more than an order of magnitude per cycle.

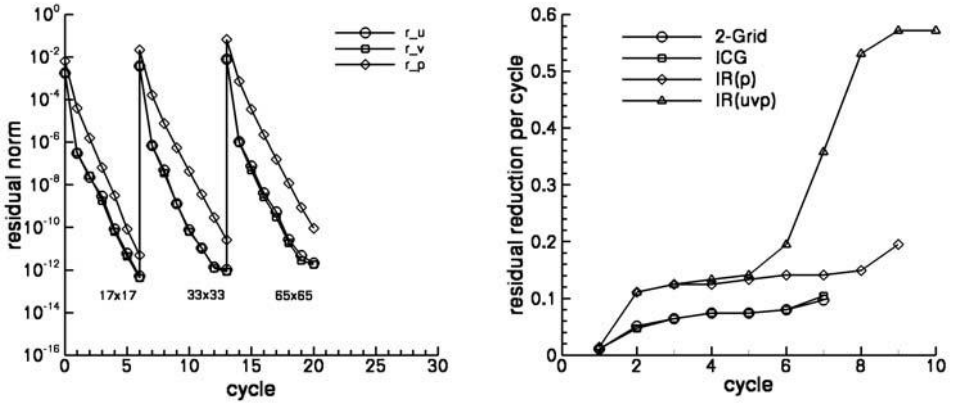

FIG. 6.3. *Residual convergence history and idealized analysis for regular stagnation regime.*

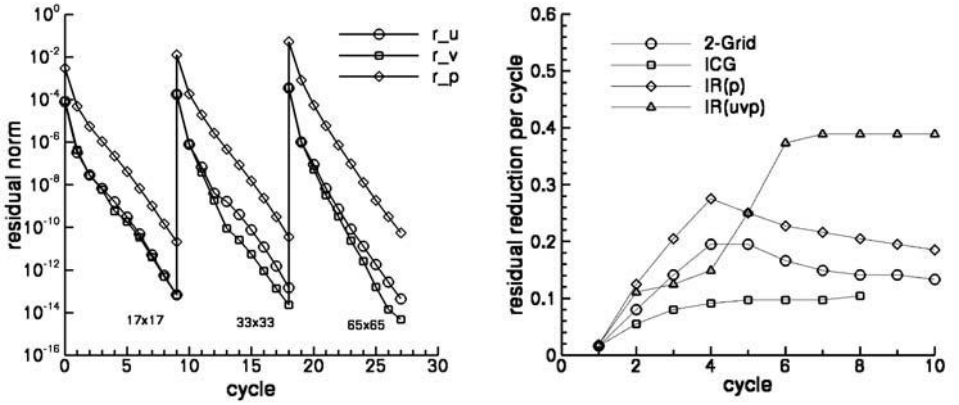

FIG. 6.4. *Residual convergence history and idealized analysis for deep stagnation regime.*

The right plot of Figure 6.3 illustrates the results of the IR and ICG iteration analysis in application to the nonlinear regular stagnation flow equations. Convergence rates of four iterations are compared on the 65×65 grid: (1) the actual two-grid cycle, (2) the ICG iterations, (3) IR(p) iterations, where explicit full-weighting averaging of algebraic error in the pressure replaces the relaxation of the pressure equation, and (4) IR(uvp) iterations where the entire relaxation sweep is replaced with full-weighting averaging of algebraic errors in u, v, and p. The convergence rates of the IR(uvp) iterations, which are significantly worse than the convergence rates of other iterations, point to some smooth (characteristic) error components that cannot be reduced in the coarse-grid correction. Fast convergence rates in IR(p) iterations confirm that the slow components are efficiently reduced in the downstream marching of the momentum equations. The reference cycle for these nonlinear computations is the same as for constant-coefficient equations in section 5.4, providing the reference convergence rates of 0.18 per cycle. The actual cycle, IR(p) and ICG iterations converge with better asymptotic rates. Close similarity between convergence rates of the actual two-grid cycle, ICG iterations, and IR(p) iterations indicate the optimal efficiency of the actual cycle.

Figure 6.4 presents convergence results for the deep stagnation flow regime. The

convergence rates are grid-independent but show a slight deterioration to approximately 0.14 per cycle asymptotically and a maximal (worst) convergence rate of approximately 0.21. The same four iterations described above have been performed for analysis of convergence in the deep stagnation regime. IR(uvp) iterations again converge slowly; convergence rates of other iterations are faster than rates of the reference cycle and very close to each other, confirming that the developed multigrid algorithm is optimally efficient.

7. Discussion. Some limitations of the classical LMF analysis that make the LMF analysis inapplicable to stagnation-flow problems have been discussed. A concept of ϵ-neighborhood has been introduced to restrict the computational domain to subdomains where there are accurate constant-coefficient approximations to the target variable-coefficient (or nonlinear) problem. With this restriction, some areas of the stagnation flow are inaccessible to the LMF analysis.

A new general approach to quantitative analysis of sophisticated multigrid solvers has been presented. The approach emphasizes the design stage of the process of developing efficient multigrid solutions. Each part of a multigrid solver is assumed to perform a certain task that is well understood and clearly formulated. The new analysis introduces IR and ICG iterations as tools to probe the complementary parts of a multigrid cycle, relaxation and coarse-grid correction. In a practical multigrid solver, one of these parts is replaced with an idealized imitation. The idealized imitation is not an optimally efficient procedure; it is rather a procedure that assuredly fulfills the task assigned to the corresponding part of the multigrid solver. The tests presented in this paper show that comparisons of the convergence rates of IR and ICG iterations with the actual two-grid cycle clearly detect deficiencies of the cycle. The convergence of the actual cycle can be improved either by adjusting parts of the cycle to better perform the assigned tasks or by redesigning the algorithm (redefining some tasks to parts of the cycle) to efficiently reduce slowly converging errors.

The IR and ICG iterations can be viewed as a numerical extension of the LMF analysis to problems where direct analytical methods are unavailable. The concept of isolating and probing parts of an algorithm by implementing idealized imitations for other parts is very general. The major disadvantage of this new analysis (shared by the LMF analysis as well) is that the analysis is not constructive; it detects problems but does not suggest remedies. However, problem detection is a big step forward for complicated applications where no other quantitative analysis methods are available. ICG and IR iterations have already been applied to some complicated nonlinear CFD problems with complex geometries on unstructured grids. The results of these applications have been encouraging in identifying the reasons for relatively slow convergence of practical solvers. In some cases, we have been able to cure the problems, e.g., IR and ICG analysis helped to develop TME solvers for stagnation-flow problems in general geometries [17]; in other cases (unstructured grid applications), we are still in search for adequate remedies.

There are many possible directions to extend the IR and ICG analysis. One can use the spectral radius of the idealized iterations as an estimate for the asymptotic convergence of the actual cycle. Such an extension may add rigorousness to the analysis, but probably limits its scope to problems of relatively low complexity, where computing the spectral radius is viable. Another possible extension is toward algebraic multigrid (AMG) [4, 10, 21, 24]. A usual assignment for an AMG relaxation is to reduce errors producing large residuals, i.e., the errors corresponding to large eigenvalues of the corresponding matrix; an AMG "coarse-grid" correction is typically

assigned to reduce algebraically smooth errors that are not necessarily geometrically smooth. The assignments extensively rely on the specific matrix; it is hardly possible to design general idealized iterations that would work for any AMG solver. However, assuming restriction, $\mathbf{R}_h^H$, and prolongation, $\mathbf{P}_h^H$, that preserve algebraically smooth functions, the ICG correction (2.6) is a good choice for general AMG applications. This choice emphasizes that errors that do not change much when transferred to the coarse grid, and then back to the fine grid, are designated as "smooth" to be handled by the coarse-grid operator. It follows that errors that do change much by the intergrid transfers are "nonsmooth" and need to be handled well by the smoother. A good idealized smoother must provide fast convergence of the reference cycle; a possible choice for IR is the composition of restriction and prolongation operators, $\mathbf{P}_H^h\mathbf{R}_h^H$. With this choice, the eigenvalues, λ_{ref}, of the iteration matrix of the reference cycle,

$$\left(\mathbf{P}_H^h\mathbf{R}_h^H\right)^{\nu_1}\left(\mathbf{E}_h - \mathbf{P}_H^h\mathbf{R}_h^H\right)\left(\mathbf{P}_H^h\mathbf{R}_h^H\right)^{\nu_2}, \tag{7.1}$$

are all in the form

$$\lambda_{\text{ref}} = \lambda^\nu(1-\lambda), \tag{7.2}$$

where λ denotes any eigenvalue of the matrix $\mathbf{P}_H^h\mathbf{R}_h^H$, and $\nu = \nu_1 + \nu_2$ is the total number of relaxations performed per one coarse-grid correction. The expression (7.2) achieves its local maximum when $\lambda = \nu/(\nu+1)$, yielding

$$\left|\lambda_{\text{ref}}\right| = \frac{\nu^\nu}{(\nu+1)^{(\nu+1)}}, \tag{7.3}$$

e.g., $\frac{1}{4}$, $\frac{4}{27}$, and $\frac{27}{256}$ for $\nu = 1$, 2, and 3, respectively, which seems very satisfactory.

Of course, $|\lambda_{\text{ref}}|$ might attain its global maximum on the "boundary," i.e., on the convex hull of the eigenvalues of $\mathbf{P}_H^h\mathbf{R}_h^H$ in the complex plane. If all eigenvalues of $\mathbf{P}_H^h\mathbf{R}_h^H$ are real (e.g., when $\mathbf{P}_H^h\mathbf{R}_h^H$ is symmetric), to find the global maximum, one only needs to consider the largest and smallest values of λ. In the particular common case where $\mathbf{R}_h^H$ is the (suitably scaled) transpose of $\mathbf{P}_H^h$, $\mathbf{P}_H^h\mathbf{R}_h^H$ is symmetric, positive semidefinite, so all of its eigenvalues are real and nonnegative. Furthermore, if $\mathbf{P}_H^h$ and $\mathbf{R}_h^H$ are properly scaled, the largest value of λ does not exceed 1, i.e., no eigenfunction is amplified by restriction followed by prolongation. Therefore, the spectral radius of the reference cycle is indeed given by (7.3). This will generally be the case, when the eigenvalues of $\mathbf{P}_H^h\mathbf{R}_h^H$ are real, except in unrealistic cases where $\mathbf{P}_H^h\mathbf{R}_h^H$ amplifies some eigenfunction significantly or changes signs of its elements. If $\mathbf{P}_H^h\mathbf{R}_h^H$ has complex eigenvalues, there may be some (often slight) deterioration of convergence of the reference cycle (which can be analyzed in a similar way). In this case, performing IR iterations which alternate between $(\mathbf{P}_H^h\mathbf{R}_h^H)^T$ and $\mathbf{P}_H^h\mathbf{R}_h^H$ may yield improved results.

TWO NUMERICAL METHODS FOR RECOVERING SMALL INCLUSIONS FROM THE SCATTERING AMPLITUDE AT A FIXED FREQUENCY*

HABIB AMMARI†, EKATERINA IAKOVLEVA†, AND DOMINIQUE LESSELIER‡

Abstract. In this paper two noniterative algorithms for locating small electromagnetic inclusions from the scattering amplitude at a fixed frequency are developed. In particular, a variety of numerical results is presented to highlight their potential and their limitations.

Key words. inverse scattering problem, scattering amplitude, Helmholtz equation, electromagnetic inclusions, reconstruction, MUSIC algorithm, analytic continuation, FFT

1. Introduction.

In this paper, we consider two-dimensional electromagnetic scattering from a collection of small electromagnetic inclusions. We suppose that there is a finite number of electromagnetic inclusions in $\mathbb{R}^2$, each of the form $z_j+\alpha B_j$, where $B_j \subset \mathbb{R}^2$ is a bounded, smooth ($\mathcal{C}^\infty$) domain containing the origin. The total collection of inclusions thus takes the form $\mathcal{I}_\alpha = \bigcup_{j=1}^m z_j + \alpha B_j$. The points $z_j \in \mathbb{R}^2$, $j = 1, \ldots, m$, which determine the location of the inclusions, are assumed to satisfy the following: $|z_j - z_l| \geq d_0 > 0$ for all $j \neq l$. The value of α, the common order of magnitude of the diameters of the inclusions, is taken as a small fraction of the wavelength of the wavefield at the operation frequency, which enables us to speak of small inclusions.

Let μ_0 and ε_0 denote the magnetic permeability and the electric permittivity of the free space; we shall assume that these are positive constants. Let μ^j and ε^j denote the permeability and the permittivity of the jth inclusion, $z_j + \alpha B_j$; these are also assumed to be positive constants. Using this notation, we introduce the piecewise constant magnetic permeability

$$\mu_\alpha(x) := \begin{cases} \mu^j & \text{in } z_j + \alpha B_j,\ j = 1, \ldots, m, \\ \mu_0 & \text{in } \mathbb{R}^2 \backslash \overline{\mathcal{I}_\alpha}. \end{cases}$$

The piecewise constant electric permittivity $\varepsilon_\alpha(x)$ is defined analogously by

$$\varepsilon_\alpha(x) := \begin{cases} \varepsilon^j & \text{in } z_j + \alpha B_j,\ j = 1, \ldots, m, \\ \varepsilon_0 & \text{in } \mathbb{R}^2 \backslash \overline{\mathcal{I}_\alpha}. \end{cases}$$

Contrasts, to be used later in these specific forms, between the electromagnetic parameters of the inclusions and those of the free space thereupon follow as

$$\gamma_\mu^j = \frac{\mu^j}{\mu_0} - 1, \quad \gamma_\varepsilon^j = \frac{\varepsilon^j}{\varepsilon_0} - 1.$$

‡Département de Recherche en Électromagnétisme, Laboratoire des Signaux et Systèmes (CNRS-SUPÉLEC-UPS), Plateau de Moulon, 91192 GIF-sur-Yvette, France (lesselier@lss.supelec.fr).

Let $k = \omega\sqrt{\varepsilon_0\mu_0} > 0$ be the wavenumber, where $\omega > 0$ is a given frequency of operation, and let $u_0(x,\hat{\xi}) = e^{ik\hat{\xi}\cdot x}$, for $x \in \mathbb{R}^2$, denote a plane wave in $\mathbb{R}^2$ of direction $\hat{\xi} \in$ ¸ ^{1}, where ¸ ^{1} is the unit sphere in $\mathbb{R}^2$.

Let the electric field u_α be defined as the solution to the Helmholtz equation

$$\left(\nabla \cdot \frac{1}{\mu_\alpha}\nabla + \omega^2\varepsilon_\alpha\right) u_\alpha = 0 \quad \text{in } \mathbb{R}^2,$$

with the Rellich–Sommerfeld radiation condition, as $r = |x| \to +\infty$,

$$\lim_{r\to\infty} \sqrt{r}\left(\partial_r(u_\alpha - u_0) - ik(u_\alpha - u_0)\right) = 0.$$

Define the scattering amplitude at the fixed frequency ω, $A_\alpha(x/|x|,\hat{\xi})$, to be the function which satisfies

$$u_\alpha(x) = u_0(x) + A_\alpha\left(\frac{x}{|x|},\hat{\xi}\right)\frac{e^{ik|x|}}{\sqrt{|x|}} + o\left(\frac{1}{\sqrt{|x|}}\right)$$

as $|x| \to \infty$, uniformly with respect to $\hat{x} = x/|x|$ and $\hat{\xi}$ on S^1. From [3], the following asymptotic formula for the scattering amplitude A_α holds uniformly:

$$A_\alpha(\hat{x},\hat{\xi}) = \alpha^2\frac{k^2(1+i)}{4\sqrt{\pi k}}\sum_{j=1}^{m} e^{-ik(\hat{x}-\hat{\xi})\cdot z_j}\left(\gamma_\mu^j\,\hat{x}\,M^j\,\hat{\xi} + \gamma_\varepsilon^j|B_j|\right) + o(\alpha^2) \tag{1.1}$$

for any $\hat{\xi}$ and $\hat{x}$ on ¸ ^{1}, where the remainder $o(\alpha^2)$ is independent of the set of points $\{z_j\}_{j=1}^m$. The matrix $M^j, j = 1,\ldots,m$, is the polarization tensor associated with the domain B_j and the magnetic permeability μ^j; see [7]. The matrix M^j is given by

$$(M^j)_{kl} = \frac{\mu_0}{\mu^j}\int_{B_j} \partial_{y_k}\phi_l\,dy, \tag{1.2}$$

where ϕ_l is defined as the unique solution to

$$\begin{cases} \Delta\phi_l = 0 \quad \text{in } B_j \text{ and in } \mathbb{R}^2 \setminus \overline{B_j}, \\ \phi_l \text{ is continuous across } \partial B_j, \\ \dfrac{\mu^j}{\mu_0}(\partial_\nu\phi_l)^+ - (\partial_\nu\phi_l)^- = 0 \quad \text{on } \partial B_j, \\ \phi_l(y) - y_l \to 0 \quad \text{as } |y| \to \infty. \end{cases}$$

Here ν denotes the outward unit normal to ∂B_j; superscripts + and − indicate the limiting values as we approach ∂B_j from outside B_j and from inside B_j. Note that if the inclusion B_j is a disk, then its polarization tensor M^j has the following explicit form:

$$M^j = \frac{2\mu_0}{\mu_0 + \mu^j}|B_j|\,I_2 = m^j I_2, \tag{1.3}$$

where I_2 is the 2×2 identity matrix .

For convenience, we drop the constant $k^2(1+i)/(4\sqrt{\pi k})$ from the above expansion of A_α and denote by $A_\alpha^{(1)}$ the leading-order term in (1.1), that is,

$$A_\alpha^{(1)}(\hat{x},\hat{\xi}) = \alpha^2 \sum_{j=1}^{m} e^{-ik(\hat{x}-\hat{\xi})\cdot z_j} \left(\gamma_\mu^j\, \hat{x}\, M^j\, \hat{\xi} + \gamma_\varepsilon^j |B_j|\right). \tag{1.4}$$

Let $\{\hat{\xi}_p\}_{p=1}^n \subset\, ^1$ be a finite subset of incidence directions and let $\{\hat{x}_l\}_{l=1}^n \subset\, ^1$ be a finite subset of observation directions. Our aim in this paper is to develop two noniterative algorithms to determine the locations $z_j, j = 1,\dots,m$, and some geometric features of the inclusions from $A_\alpha^{(1)}(\hat{x}_p,\hat{\xi}_l)\big|_{\hat{x}_p=-\hat{\xi}_p}$ for $l,p = 1,\dots,n$. We first develop a robust numerical method of MUSIC (short for multiple-signal classification) type for identifying $\mathcal{I}_\alpha$. We briefly sketch the theoretical foundation of this method for solving our inverse scattering problem and provide a mathematical study of the focusing properties of the eigenvectors of the so-called multistatic response (MSR) matrix $(A_\alpha^{(1)}(\hat{x}_p,\hat{\xi}_l)\big|_{\hat{x}_p=-\hat{\xi}_p})_{l,p=1,\dots,n}$. Then we discuss the second method, which is based on analytic continuation and a fast Fourier transform (FFT) algorithm. This method has been introduced in [3] for three-dimensional scattering problems. Its adaptation to the two-dimensional case and key steps of its numerical implementation are described here. Finally we present a variety of numerical results to highlight the potential and the limitations of these two algorithms.

In concluding this introduction, we would like to refer to the survey paper by Colton, Coyle, and Monk [10] for a presentation of a number of other reconstruction algorithms in inverse scattering for the Helmholtz equation, emphasizing the linear-sampling method. This approach has some similarities to the MUSIC-type algorithm developed here. It is also worth mentioning that in the case where the data are discrete versions of the Neumann-to-Dirichlet boundary map, Brühl, Hanke, and Vogelius [6] used a corresponding asymptotic perturbation formula for small conductivity inclusions in combination with MUSIC (and linear-sampling) ideas to design a very effective algorithm for determining the locations of the inclusions. We also refer to the closely related nice works by Vogelius and Volkov [24] and Volkov [25] and to the monograph [1] for a systematic exposition of recent developments on the reconstruction of small inclusions.

2. MUSIC algorithm. MUSIC (multiple-signal classification) is generally used in signal processing problems as a method for estimating the individual frequencies of multiple-harmonic signals [23]. The MUSIC algorithm makes use of the eigenvalue structure of the so-called multistatic response (MSR) matrix. A more detailed description of this algorithm can be found in [11] and [8]. See also [21, 16, 22, 19].

Following [2] we first briefly recall how the MUSIC algorithm can be applied to the problem of locating m small inclusions with different electromagnetic parameters from those of the free space from the MSR matrix $(A_\alpha^{(1)}(\hat{x}_p,\hat{\xi}_l)\big|_{\hat{x}_p=-\hat{\xi}_p})_{l,p=1,\dots,n}$. Then we present a complete mathematical study of the focusing properties of the eigenvectors of this matrix. To the best of our knowledge, these qualitative results are new. The eigenvectors corresponding to significant eigenvalues span some kind of signal subspace in the sense that they contain nearly all the information about the inclusions which can be extracted from the MSR matrix. The others span some kind of noise subspace. The aim of the MUSIC type of algorithm is to use the eigensystem analysis of the MSR matrix to determinine the location and recover some geometric features (namely, the polarization tensors defined by (1.2)) of the small inclusions from the signal space.

We consider separately the following three cases, which we believe to be representative of the pros and cons of our MUSIC-type reconstruction:

(1) $\gamma_\mu^j = 0$ for all $j = 1, \dots, m$.
(2) $\gamma_\varepsilon^j = 0$ for all $j = 1, \dots, m$.
(3) $\gamma_\mu^j \neq 0$ and $\gamma_\varepsilon^j \neq 0$ for all $j = 1, \dots, m$.

2.1. The first case: Dielectric inclusions. We suppose $n \geq m$ and define the MSR matrix $\mathrm{A} = (\mathrm{A}_{pl})_{p,l=1}^n \in \mathbb{C}^{n\times n}$ by

$$\mathrm{A}_{pl} = A_\alpha^{(1)}(\hat{x}_p, \hat{\xi}_l)\big|_{\hat{x}_p = -\hat{\xi}_p} = \sum_{j=1}^m \tau_j e^{ik(\hat{\xi}_p + \hat{\xi}_l)\cdot z_j}$$

for $p, l = 1, \dots, n$, where $\tau_j = \alpha^2 \gamma_\varepsilon^j |B_j|$. Defining the matrices $\mathrm{T} \in \mathbb{R}^{m\times m}$ and $\mathrm{S} = [\mathrm{s}_1 \dots \mathrm{s}_m] \in \mathbb{C}^{n\times m}$ by

$$\mathrm{T} = \mathrm{diag}(\tau_j) \quad \text{and} \qquad \mathrm{s}_j = (e^{ik\hat{\xi}_1\cdot z_j}, \dots, e^{ik\hat{\xi}_n\cdot z_j})^T \text{ for } j = 1, \dots, m,$$

we then observe that A admits the decomposition

$$\mathrm{A} = \mathrm{STS}^T, \tag{2.1}$$

where $\mathrm{S}^T \in \mathbb{C}^{m\times n}$ denotes the transpose of S. Using (2.1), we immediately see that A is symmetric and $\bar{\mathrm{A}}^T = \bar{\mathrm{A}}$, where $\bar{\mathrm{A}}$ is the complex conjugate of A.

Throughout this section, we consider $\{\hat{\xi}_p\}_{p\in\mathbb{N}} \subset S^1$ to be a countable set of directions with the property that any analytic function which vanishes in $\hat{\xi}_p$ for all $p \in \mathbb{N}$ vanishes identically on S^1. This technical assumption is necessary to rigorously prove Propositions 2.1, 2.2, and 2.3. See, for example, [16].

Now a standard argument from linear algebra yields that if $n \geq m$ and if the matrix S has maximal rank m, then the ranges $\mathcal{R}(\mathrm{S})$ and $\mathcal{R}(\mathrm{A}\bar{\mathrm{A}})$ coincide. Thus

$$\mathcal{R}(\mathrm{A}\bar{\mathrm{A}}) = \mathcal{R}(\mathrm{S}) = \mathrm{span}\{\mathrm{s}_1, \dots, \mathrm{s}_m\}.$$

But since the locations z_j are well separated, then using the property that any analytic function which vanishes in $\hat{\xi}_p$ for all $p \in \mathbb{N}$ vanishes identically, it can be immediately seen that there exists $n_0 \geq m$ such that for any $n \geq n_0$ the matrix S has maximal rank m.

Let $a \in \mathbb{R}\backslash\{0\}$; for any point $z \in \mathbb{R}^2$ we define the vector $g_{z,a} \in \mathbb{C}^n$ by

$$g_{z,a} = (ae^{ik\hat{\xi}_1\cdot z}, \dots, ae^{ik\hat{\xi}_n\cdot z})^T. \tag{2.2}$$

We note that $g_{z_1,a}, \dots, g_{z_m,a}$ are the columns of the matrix aS.

The main tool for the identification of the locations $z_j, j = 1, \dots, m$, is the following [16].

PROPOSITION 2.1. [illegible] $n_0 \in \mathbb{N}$ [illegible] $n \geq n_0$ [illegible] $g_{z,a}$ [illegible] (2.2), [illegible] $\mathcal{R}(\mathrm{S})$ [illegible] $z \in \{z_1, \dots, z_m\}$

Next let the singular value decomposition (SVD) of the matrix A be defined by $\mathrm{A} = \mathrm{V}\Sigma\overline{\mathrm{W}}^T$, where $\mathrm{V}, \mathrm{W} \in \mathbb{C}^{n\times n}$ are unitary and $\Sigma = \mathrm{diag}\{\sigma_1, \sigma_2, \dots, \sigma_n\}$ is a real nonnegative diagonal matrix, where $\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_m > 0$ and σ_i, $i = m+1, \dots, n$,

are all zero (or [illegible]).[1] The numbers $\{\sigma_i\}$ are the nonnegative square roots of the eigenvalues of $\mathrm{A}\bar{\mathrm{A}}^T = \mathrm{A}\bar{\mathrm{A}}$. The columns of V are the eigenvectors of $\mathrm{A}\bar{\mathrm{A}}$ and the columns of W are the eigenvectors of $\bar{\mathrm{A}}\mathrm{A}$ (arranged in the same order as the corresponding eigenvalues σ_i^2). We note that the SVD of A can be written in the form $\mathrm{A} = \mathrm{V}\Sigma\mathrm{V}^{\mathrm{T}}$ (which is Takagi's factorization or an SVD for symmetric matrices in which $\mathrm{V} = \overline{\mathrm{W}}$). The first m columns of V, $\{v_1, v_2, \ldots, v_m\}$, provide an orthonormal basis for the space of A which is denoted by V_S, and the rest of the matrix V, $\{v_{m+1}, v_{m+2}, \ldots, v_n\}$, provides a basis for the left null (or the [illegible]) space of A, denoted by V_N. Then the best rank approximation for A is $(\mathrm{V}_S\overline{\mathrm{V}}_S^T)\mathrm{A}$ with error $E = \mathrm{A} - (\mathrm{V}_S\overline{\mathrm{V}}_S^T)\mathrm{A}$.

From Proposition 2.1 we have that a test point z coincides with one of the positions z_j if and only if $g_{z,a} \in \mathcal{R}(\mathrm{A}\bar{\mathrm{A}})$ or, equivalently, if $\mathrm{P}g_z = 0$, where $\mathrm{P} = \mathrm{I} - (\mathrm{V}_S\overline{\mathrm{V}}_S^T)$ is the orthogonal projection onto the null (or the [illegible]) space of A. Thus we can form an image of z_j, $j = 1, \ldots, m$, by plotting, at each point z, the quantity

$$W_a(z) = \frac{1}{||\mathrm{P}g_{z,a}||}.$$

The resulting plot will have large peaks at the positions z_j, $j = 1, \ldots, m$.

2.1.1. SVD of the MSR matrix. By virtue of (2.1), the MSR matrix A can be written as

$$\mathrm{A} = \mathrm{STS}^T = \sum_{j=1}^{m} \tau_j \mathrm{s}_j \mathrm{s}_j^T. \tag{2.3}$$

We first consider m uncorrelated inclusions and introduce

$$\mathrm{A}_j = \tau_j \mathrm{s}_j \mathrm{s}_j^T, \quad j = 1, \ldots, m. \tag{2.4}$$

The matrix A_j therefore satisfies

$$\mathrm{A}_j\bar{\mathrm{A}}_j = \tau_j^2 ||\bar{\mathrm{s}}_j||^2 \mathrm{s}_j\bar{\mathrm{s}}_j^T, \quad \bar{\mathrm{A}}_j\mathrm{A}_j = \tau_j^2 ||\mathrm{s}_j||^2 \bar{\mathrm{s}}_j\mathrm{s}_j^T$$

for $j = 1, \ldots, m$, where $||\mathrm{s}_j||^2 = \bar{\mathrm{s}}_j^T\mathrm{s}_j = n$. The eigenvectors v_j and w_j of the matrices $\mathrm{A}_j\bar{\mathrm{A}}_j$ and $\bar{\mathrm{A}}_j\mathrm{A}_j$, having nonzero singular values σ_j, are given by

$$v_j = \frac{\mathrm{s}_j}{||\mathrm{s}_j||} = \frac{\mathrm{s}_j}{\sqrt{n}}, \quad w_j = \frac{\bar{\mathrm{s}}_j}{||\bar{\mathrm{s}}_j||} = \frac{\bar{\mathrm{s}}_j}{\sqrt{n}}, \tag{2.5}$$

and

$$\sigma_j = n|\tau_j|. \tag{2.6}$$

Now, let us turn to the matrix A, defined by (2.3), and consider the equations

$$\mathrm{A}\bar{\mathrm{A}}\hat{v}_j = \hat{\sigma}_j^2\hat{v}_j, \quad \bar{\mathrm{A}}\mathrm{A}\hat{w}_j = \hat{\sigma}_j^2\hat{w}_j. \tag{2.7}$$

Since $\mathcal{R}(\mathrm{A}\bar{\mathrm{A}}) = \mathrm{span}\{\mathrm{s}_1, \ldots, \mathrm{s}_m\} = \mathrm{span}\{v_1, \ldots, v_m\}$, then the singular vector $\hat{v}_j$ are linear combinations of the array vectors v_j, while $\hat{w}_j$ are linear combinations of the array vectors $w_j = \bar{v}_j$, i.e.,

$$\hat{v}_j = \sum_{l=1}^{m} a_{jl} v_l, \quad \hat{w}_j = \sum_{l=1}^{m} \bar{a}_{jl} \bar{v}_l, \tag{2.8}$$

[1] That is, if A is the noisy MSR matrix.

where $a_j = (a_{j1}, \ldots, a_{jm})^T \in \mathbb{C}^m$, with $||a_j|| = 1$ as a normalization.

Introduce

$$H_{jl} = \bar{v}_j^T v_l, \quad j, l = 1, \ldots, m. \tag{2.9}$$

If we substitute (2.3) and (2.8) into (2.7), we obtain that

$$\mathrm{L}\bar{\mathrm{L}}a_j = \hat{\sigma}_j^2 a_j, \quad \bar{\mathrm{L}}\mathrm{L}\bar{a}_j = \hat{\sigma}_j^2 \bar{a}_j, \tag{2.10}$$

where matrix $\mathrm{L} \in \mathbb{C}^{m\times m}$ is given by $\mathrm{L}_{pq} = n\tau_p \bar{H}_{pq}$, $p, q = 1, \ldots, m$.

Following [11, 12], we first consider the case where the quantity H_{jl} is approximately $\delta_{jl}, j, l = 1, \ldots, m$. Here δ_{jl} is the Kronecker delta function. From (2.10) we get $\hat{\sigma}_j \approx n|\tau_j|$ and $a_{jl} \approx \delta_{jl}$. It then follows that the singular vectors, having nonzero singular values, are approximately given by $\hat{v}_j \approx v_j$, $\hat{w}_j \approx w_j$ for $j = 1, \ldots, m$. From the discussion above, we conclude that A has m nonzero singular values, each corresponds to the nonzero singular value of one of the matrices A_j. Moreover, the signal space of A is the space spanned by the eigenvectors of $\mathrm{A}_j, j = 1, \ldots, m$.

In the general case $(H_{pq})_{p,q=1}^n$ will not be a diagonal matrix and the spectral analysis of A does not simplify from its general form given in (2.3). In this case, from (2.9) we have

$$H_{jl} = \bar{v}_j^T v_l = \frac{1}{n}\sum_{p=1}^{n} e^{ik(z_l - z_j)\cdot\hat{\xi}_p} \approx J_0(k|z_j - z_l|), \tag{2.11}$$

$j, l = 1, \ldots, m$, for sufficiently large n. Here, J_0 is the Bessel function of the first kind and order zero. It is easy to see from the above approximation that H_{jl} is always nonzero. However, if $k|z_l - z_j|$ is large enough, then H_{jl} is small.

Using (2.11) the matrix L is approximated by a real matrix and (2.10) can be reduced to

$$\mathrm{L}a_j = \lambda_j a_j, \quad j = 1, \ldots, m, \tag{2.12}$$

where λ_j is the eigenvalue of the matrix L associated with the eigenvector $a_j \in \mathbb{R}^m$, and $|\lambda_j| = \hat{\sigma}_j$.

Let $\tau_j = |\tau_j|e^{2i\phi_j}$, $j = 1, \ldots, m$. Since in our case the constants $\tau_j \in \mathbb{R}$, then $\phi_j = 0$ if τ_j is positive and $\phi_j = \pi/2$ if τ_j is negative. The matrix L admits the decomposition $\mathrm{L} = \mathrm{D}\tilde{\mathrm{L}}\mathrm{D}^{-1}$, where $\mathrm{D} = \mathrm{diag}(\sqrt{|\tau_1|}e^{i\phi_1}, \ldots, \sqrt{|\tau_m|}e^{i\phi_m})$ and $\tilde{\mathrm{L}} \in \mathbb{C}^{m\times m}$ is given by

$$\tilde{\mathrm{L}}_{pq} = n\sqrt{|\tau_p||\tau_q|}e^{i(\phi_p+\phi_q)}H_{pq}, \quad p, q = 1, \ldots, m.$$

Therefore, the matrices L and $\tilde{\mathrm{L}}$ are similar, and thus they have the same eigenvalues, counted with their multiplicity.

We are now ready to investigate the singular values and eigenvectors of the matrix L, which is similar to $\tilde{\mathrm{L}}$ written as $\tilde{\mathrm{L}} = \Lambda + \mathrm{E}$, where $\Lambda = \mathrm{diag}(n\tau_1, \ldots, n\tau_m)$ and E is some (symmetric) perturbation matrix.

Let us assume that the values $|\tau_j|$ are arranged in decreasing order $|\tau_1| \geq \cdots \geq |\tau_m|$. Let

$$R_p(\tilde{\mathrm{L}}) = \sum_{\substack{q=1\\ q\neq p}}^{m} \frac{\sqrt{|\tau_p||\tau_q|}}{|\tau_1|}|H_{pq}|, \quad p, q = 1, \ldots, m. \tag{2.13}$$

Then by Geršgorin's theorem [15] all eigenvalues of $\tilde{\mathrm{L}}$ (which are in our case real) are located in the union of m intervals

$$\bigcup_{p=1}^{m}\left\{x'=\frac{x}{n}\in\mathbb{R}:\left|\frac{x'}{|\tau_1|}-\frac{\tau_p}{|\tau_1|}\right|\le R_p(\tilde{\mathrm{L}})\right\}\equiv G(\tilde{\mathrm{L}}). \tag{2.14}$$

Furthermore, if a union of p of the m intervals forms a connected region that is disjoint from all the remaining $m-p$ intervals, then there are precisely p eigenvalues of $\tilde{\mathrm{L}}$ in this region. Now, from (2.13) we conclude that if

$$|\tau_1|\gg\cdots\gg|\tau_m|, \tag{2.15}$$

then all Geršgorin's intervals are disjoint, $\lambda_p\to n\tau_p$, or, equivalently, $\hat{\sigma}_p\to\sigma_p=n|\tau_p|$, and the eigenvector $\hat{v}_p$ is approximately v_p for $p=1,\dots,m$. The eigenvectors of the MSR matrix then produce selective focusing onto the dielectric inclusions.

On the other hand, if $\tau_1=\cdots=\tau_m=\tau$, then all eigenvalues are located in the interval

$$\left\{x'=\frac{x}{n}\in\mathbb{R}:|x'-\tau|\le|\tau|\sum_{\substack{q=1\\q\neq p}}^{m}|H_{pq}|\right\},\quad p=1,\dots,m.$$

Let $\lambda_1(\mathrm{E})\ge\cdots\ge\lambda_m(\mathrm{E})$ are the ordered eigenvalues of E; then $\lambda_p=n\tau+n\tau\lambda_p(\mathrm{E})$ for all $p=1,\dots,m$. The maximal error is $n|\tau|\rho(\mathrm{E})$, where $\rho(\mathrm{E})$ is the spectral radius of E, which is the radius of the smallest disk centered at the origin in the complex plane that includes all the eigenvalues of E; see [15].

The MSR matrix may admit in this situation nonsimple eigenvalues. The diagonalization of the latter cannot choose the selective focusing densities among all their linear combinations which compose the corresponding eigenspace. The nice focusing properties will disappear, at least for some groups of eigenvalues. See [18, 14].

2.2. The second case: Permeable inclusions. In this case the MSR matrix $\mathrm{A}=(\mathrm{A}_{pl})_{p,l=1}^{n}\in\mathbb{C}^{n\times n}$ is defined by

$$\mathrm{A}_{pl}=A_{\alpha}^{(1)}(\hat{x}_p,\hat{\xi}_l)\big|_{\hat{x}_p=-\hat{\xi}_p}=-\sum_{j=1}^{m}e^{ik(\hat{\xi}_p+\hat{\xi}_l)\cdot z_j}\hat{\xi}_p\cdot\beta_j\hat{\xi}_l$$

for $p,l=1,\dots,n$, where $\beta_j=\alpha^2\gamma_\mu^j\mathrm{M}^j\in\mathbb{R}^{2\times2}$.

We define the matrix $\mathrm{D}=[\mathrm{d}_1\dots\mathrm{d}_{2m}]\in\mathbb{C}^{n\times2m}$ by

$$\mathrm{d}_{2(j-1)+p}=(\mathrm{e}_p\cdot\hat{\xi}_1e^{ik\hat{\xi}_1\cdot z_j},\dots,\mathrm{e}_p\cdot\hat{\xi}_ne^{ik\hat{\xi}_n\cdot z_j})^T,\quad j=1,\dots,m,p=1,2,$$

where $\{\mathrm{e}_p\}_{p=1,2}$ denotes an orthonormal basis in $\mathbb{R}^2$.

We observe that A admits the decomposition

$$\mathrm{A}=\mathrm{DBD}^T, \tag{2.16}$$

where $\mathrm{B}=\mathrm{diag}(-\beta_j)\in\mathbb{R}^{2m\times2m}$. It then follows immediately that A is symmetric.

Analogously to case 1, if $n\ge2m$ and if the locations z_j are well separated, then the matrix D has maximal rank $2m$, and the ranges $\mathcal{R}(\mathrm{D})$ and $\mathcal{R}(\mathrm{A}\bar{\mathrm{A}})$ coincide. Thus

$$\mathcal{R}(\mathrm{A}\bar{\mathrm{A}})=\mathcal{R}(\mathrm{D})=\mathrm{span}\{\mathrm{d}_1,\dots,\mathrm{d}_{2m}\}.$$

Let $b \in \mathbb{R}^2 \backslash \{0\}$; for any point $z \in \mathbb{R}^2$ we define the vector $g_{z,b} \in \mathbb{C}^n$ by

$$g_{z,b} = \left(b \cdot \hat{\xi}_1 e^{ik\hat{\xi}_1 \cdot z}, \ldots, b \cdot \hat{\xi}_n e^{ik\hat{\xi}_n \cdot z} \right)^T. \tag{2.17}$$

We note that $g_{z_j,b}$ is the linear combination of the vector columns d_{2j-1} and d_{2j}, $j = 1, \ldots, m$, of the matrix D. The following proposition holds (see [2]).

PROPOSITION 2.2. [illegible] $b \in \mathbb{R}^2 \backslash \{0\}$ [illegible] $g_{z,b} \in \mathbb{C}^n$ [illegible] (2.17) [illegible] [illegible] $n_0 \in \mathbb{N}$ [illegible] $n \geq n_0$ [illegible] $g_{z,b} \in \mathcal{R}(\mathrm{D})$ [illegible] $z \in \{z_1, \ldots, z_m\}$

Once again let the SVD of the matrix A be defined by $\mathrm{A} = \mathrm{V}\Sigma\overline{\mathrm{W}}^T$. Since the rank of A is $2m$, then the first $2m$ columns of V, $\{v_1, v_2, \ldots, v_{2m}\}$, provide an orthonormal basis for the space of A which is denoted by V_S, and the rest of the matrix V, $\{v_{2m+1}, v_{2m+2}, \ldots, v_n\}$, provides a basis for left null space of A, denoted by V_N. Then the best rank approximation for A is $(\mathrm{V}_S\overline{\mathrm{V}}_S^T)\mathrm{A}$ with error $E = \mathrm{A} - (\mathrm{V}_S\overline{\mathrm{V}}_S^T)\mathrm{A}$.

From Proposition 2.2 we have that a test point z coincides with one of the positions z_j if and only if $g_{z,b} \in \mathcal{R}(\mathrm{A}\bar{\mathrm{A}})$ or, equivalently, if $\mathrm{P}g_{z,b} = 0$, where $\mathrm{P} = \mathrm{I} - (\mathrm{V}_S\overline{\mathrm{V}}_S^T)$ is the orthogonal projection onto the null space of A.

Thus we can form an image of $z_j, j = 1, \ldots, m$, by plotting, at each point z, the quantity

$$W_b(z) = \frac{1}{||\mathrm{P}g_{z,b}||}.$$

The resulting plot will have large peaks at the positions z_j, $j = 1, \ldots, m$.

2.2.1. SVD of the MSR matrix. Through this subsection we assume for simplicity that all the matrices M^j are diagonal. This holds when all the B_j are disks or ellipses with the same axes. Then let the matrix $\beta_j = \alpha^2\gamma_\mu^j\mathrm{M}^j \in \mathbb{R}^{2\times 2}$ be represented as $\beta_j = \mathrm{diag}(\beta_{1,j}, \beta_{2,j})$. By virtue of (2.16) the MSR matrix A can be written as

$$\mathrm{A} = \mathrm{DBD}^T = \sum_{j=1}^{m} \beta_{1,j}\mathrm{d}_{2j-1}\mathrm{d}_{2j-1}^T + \beta_{2,j}\mathrm{d}_{2j}\mathrm{d}_{2j}^T. \tag{2.18}$$

Analogously to the first case, we first consider m independent problems, each corresponding to one inclusion, and introduce

$$\mathrm{A}_j = \beta_{1,j}\mathrm{d}_{2j-1}\mathrm{d}_{2j-1}^T + \beta_{2,j}\mathrm{d}_{2j}\mathrm{d}_{2j}^T, \quad j = 1, \ldots, m. \tag{2.19}$$

Let $\hat{\xi}_t = (\hat{\xi}_{1,t}, \hat{\xi}_{2,t}) = (\cos\theta_t, \sin\theta_t)$, where $\theta_t = \frac{2\pi(t-1)}{n}$ is the angle of observation, $t = 1, \ldots, n$. From the definition of the vector columns d of the matrix D we have

$$\bar{\mathrm{d}}_{2j-1}^T\mathrm{d}_{2j-1} = \sum_{t=1}^{n} \hat{\xi}_{1,t}^2 = \sum_{t=1}^{n} \cos^2\theta_t = \frac{n}{2}, \tag{2.20}$$

$$\bar{\mathrm{d}}_{2j}^T\mathrm{d}_{2j} = \sum_{t=1}^{n} \hat{\xi}_{2,t}^2 = \sum_{t=1}^{n} \sin^2\theta_t = \frac{n}{2}, \tag{2.21}$$

$$\bar{\mathrm{d}}_{2j-1}^T\mathrm{d}_{2j} = \sum_{t=1}^{n} \hat{\xi}_{1,t}\hat{\xi}_{2,t} = \sum_{t=1}^{n} \cos\theta_t \sin\theta_t = 0. \tag{2.22}$$

Then from (2.19), (2.20), (2.21), and (2.22) we obtain that

$$\begin{aligned}\mathrm{A}_j\bar{\mathrm{A}}_j &= \beta_{1,j}^2||\bar{\mathrm{d}}_{2j-1}||^2\mathrm{d}_{2j-1}\bar{\mathrm{d}}_{2j-1}^T + \beta_{2,j}^2||\bar{\mathrm{d}}_{2j}||^2\mathrm{d}_{2j}\bar{\mathrm{d}}_{2j}^T,\\ \bar{\mathrm{A}}_j\mathrm{A}_j &= \beta_{1,j}^2||\mathrm{d}_{2j-1}||^2\bar{\mathrm{d}}_{2j-1}\mathrm{d}_{2j-1}^T + \beta_{2,j}^2||\mathrm{d}_{2j}||^2\bar{\mathrm{d}}_{2j}\mathrm{d}_{2j}^T\end{aligned}$$

for $j = 1, \dots, m$. It then follows that the eigenvectors v_{2j-1}, v_{2j} and w_{2j-1}, w_{2j} of the matrices $\mathrm{A}_j\bar{\mathrm{A}}_j$ and $\bar{\mathrm{A}}_j\mathrm{A}_j$, having nonzero singular values σ_j, are given by

$$\begin{aligned} v_{2(j-1)+p} &= \frac{\mathrm{d}_{2(j-1)+p}}{||\mathrm{d}_{2(j-1)+p}||} = \sqrt{\frac{2}{n}}\,\mathrm{d}_{2(j-1)+p},\\ w_{2(j-1)+p} &= \frac{\bar{\mathrm{d}}_{2(j-1)+p}}{||\bar{\mathrm{d}}_{2(j-1)+p}||} = \sqrt{\frac{2}{n}}\,\bar{\mathrm{d}}_{2(j-1)+p},\\ \sigma_{2(j-1)+p} &= \frac{n}{2}|\beta_{p,j}| \quad \text{for } p = 1,2 \text{ and } j = 1, \dots, m.\end{aligned} \tag{2.23}$$

Now, let us turn to matrix A, defined by (2.18), and consider the equations

$$\mathrm{A}\bar{\mathrm{A}}\hat{v}_{l'} = \hat{\sigma}_{l'}^2\hat{v}_{l'}, \quad \bar{\mathrm{A}}\mathrm{A}\hat{w}_{l'} = \hat{\sigma}_{l'}^2\hat{w}_{l'}. \tag{2.24}$$

Since $\mathcal{R}(\mathrm{A}\bar{\mathrm{A}}) = \mathrm{span}\{\mathrm{d}_1, \dots, \mathrm{d}_{2m}\} = \mathrm{span}\{v_1, \dots, v_{2m}\}$, then the singular vectors $\hat{v}_{l'}$ are linear combinations of the array vectors $v_{l'}$, while the vectors $\hat{w}_{l'}$ are linear combinations of the array vectors $w_{l'} = \bar{v}_{l'}$ for $l' = 1, \dots, 2m$. Let

$$H_{l',q'} = \bar{v}_{l'}^T v_{q'}, \quad l', q' = 1, \dots, 2m. \tag{2.25}$$

Define

$$\begin{aligned} l' &= 2(l-1) + p,\\ q' &= 2(q-1) + p', l, q = 1, \dots, m, \;\; p, p' = 1, 2.\end{aligned}$$

Using the polar coordinates $z_q - z_l = |z_l - z_q|(\cos\alpha_{lq}, \sin\alpha_{lq})$, we compute

$$H_{l',q'} = \frac{\sum_{t=1}^n \hat{\xi}_{p,t}\,\hat{\xi}_{p',t}\,e^{ik|z_l - z_q|\cos(\theta_t - \alpha_{lq})}}{\sqrt{\sum_{t=1}^n \hat{\xi}_{p,t}^2}\sqrt{\sum_{t=1}^n \hat{\xi}_{p',t}^2}}.$$

For $l = q$ we compute $H_{l',q'}$ from (2.20), (2.21), and (2.22), while for $l \neq q$ we have

$$\begin{aligned} &H_{l',q'} \approx J_0(k|z_l - z_q|) - \cos(2\alpha_{lq})J_2(k|z_l - z_q|) && \text{if } p = p' = 1,\\ &H_{l',q'} \approx J_0(k|z_l - z_q|) + \cos(2\alpha_{lq})J_2(k|z_l - z_q|) && \text{if } p = p' = 2,\\ &H_{l',q'} \approx \sin(2\alpha_{lq})J_2(k|z_l - z_q|) && \text{if } p \neq p'.\end{aligned} \tag{2.26}$$

Here, J_0 and J_2 are the Bessel functions of the first kind and of orders 0 and 2, respectively.

Analogously to the first case, we first consider the case where $H_{l',q'} \approx \delta_{l',q'}$, $l', q' = 1, \dots, 2m$. In this situation, we obtain $\hat{\sigma}_{l'} = \hat{\sigma}_{2(j-1)+p} \approx \frac{n}{2}|\beta_{p,j}|$. Moreover, the singular vectors, having nonzero singular values, are given by $\hat{v}_{l'} \approx v_{l'}$, $\hat{w}_{l'} \approx w_{l'}$ for $l' = 1, \dots, 2m$.

We also obtain that the $2m$ nonzero singular values of A are those of m uncorrelated matrices A_j. Similarly, the signal space of A is spanned by the eigenvalues of

$A_j, j = 1, \ldots, m$. Note that for each inclusion two singular values correspond. A natural question would be whether one could localize the inclusions independently of each other. In the general case the answer is no. However, if all the inclusions are disks, then, because $\beta_{1,j} = \beta_{2,j}, j = 1, \ldots, m$, the two singular values corresponding to the same inclusion coincide, and thus it would be possible to localize them independently.

Finally, the following conclusion can be made if all the quantities $\gamma_\mu^j M^j$ are different enough. If $|\beta_{1,1}| \geq |\beta_{2,1}| \gg |\beta_{1,2}| \geq |\beta_{2,2}| \gg \cdots \gg |\beta_{1,m}| \geq |\beta_{2,m}|$, then $\hat{\sigma}_{2(j-1)+p}$ is close to $\sigma_{2(j-1)+p}$, $j = 1, \ldots, m$, $p = 1, 2$, and the two first singular values correspond to the inclusion with the highest $\gamma_\mu^j M^j$. Following [6], the quantities $\gamma_\mu^j M^j$ can be recovered from the singular values of the MSR matrix once the positions of the inclusions have been determined.

2.3. The third case: Dielectric and permeable inclusions. In this case the MSR matrix $\mathrm{A} = (\mathrm{A}_{pl})_{p,l=1}^n \in \mathbb{C}^{n\times n}$ is defined by

$$\begin{aligned}\mathrm{A}_{pl} &= A_\alpha^{(1)}(\hat{x}_p, \hat{\xi}_l)\big|_{\hat{x}_p = -\hat{\xi}_p} \\ &= -\sum_{j=1}^m e^{ik(\hat{\xi}_p+\hat{\xi}_l)z_j}\hat{\xi}_p\beta_j\hat{\xi}_l + \sum_{j=1}^m \tau_j e^{ik(\hat{\xi}_p+\hat{\xi}_l)\cdot z_j}\end{aligned}$$

for $p, l = 1, \ldots, n$, where $\beta_j = \alpha^2\gamma_\mu^j \mathrm{M}^j \neq 0$ and $\tau_j = \alpha^2\gamma_\varepsilon^j |B_j| \neq 0$ for $j = 1, \ldots, m$.

By virtue of (2.1) and (2.16) we have

$$\mathrm{A} = \mathrm{DBD}^T + \mathrm{STS}^T = \mathrm{HEH}^T,$$

where $\mathrm{H} = [\mathrm{d}_1 \ldots \mathrm{d}_{2m} | \mathrm{s}_1 \ldots \mathrm{s}_m] \in \mathbb{C}^{n\times 3m}$ and $\mathrm{E} = \mathrm{diag}\{\mathrm{B}, \mathrm{T}\} \in \mathbb{C}^{3m\times 3m}$.

We assume that for any set of m distinct points $z_1, \ldots, z_m$, the $3m$ vectors $\{\mathrm{d}_{2j-1}, \mathrm{d}_{2j}, \mathrm{s}_j,\ j = 1, \ldots, m\}$ are linearly independent.

As previously, observe that if $n \geq 3m$ and if the locations z_j are well separated, then the matrix H has maximal rank $3m$, and the ranges of $\mathcal{R}(\mathrm{H})$ and $\mathcal{R}(\mathrm{A}\bar{\mathrm{A}})$ coincide. Thus

$$\mathcal{R}(\mathrm{A}\bar{\mathrm{A}}) = \mathrm{span}\{\mathrm{d}_{2j-1}, \mathrm{d}_{2j}, \mathrm{s}_j,\ j = 1, \ldots, m\}.$$

Let $c \in \mathbb{R}^3\backslash\{0\}$; for any point $z \in \mathbb{R}^2$ we define the vector $g_{z,c} \in \mathbb{C}^n$ by

$$g_{z,c} = \left(c \cdot h_{\hat{\xi}_1} e^{ik\hat{\xi}_1\cdot z}, \ldots, c \cdot h_{\hat{\xi}_n} e^{ik\hat{\xi}_n\cdot z}\right)^T, \tag{2.27}$$

where $h_{\hat{\xi}_p} = (\mathrm{e}_1 \cdot \hat{\xi}_p, \mathrm{e}_2 \cdot \hat{\xi}_p, 1)^T \in \mathbb{R}^3$, $p = 1, \ldots, n$. We note that $g_{z_j,c}$ is a linear combination of the vector columns d_{2j-1}, d_{2j}, and s_j, $j = 1, \ldots, m$, of the matrix H.

Following arguments similar to those for cases 1 and 2, we can show the following result [2].

PROPOSITION 2.3. [illegible] $c \in \mathbb{R}^3\backslash\{0\}$ [illegible] $g_{z,c} \in \mathbb{C}^n$ [illegible] (2.27) [illegible] [illegible] $n_0 \in \mathbb{N}$ [illegible] $n \geq n_0$ [illegible] $g_{z,c} \in \mathcal{R}(\mathrm{H})$ [illegible] $z \in \{z_1, \ldots, z_m\}$

Analogously to cases 1 and 2, let the SVD of matrix A be defined by $\mathrm{A} = \mathrm{V}\Sigma\overline{\mathrm{W}}^T$. Since the rank of A is $3m$, then the first $3m$ columns of V, $\{v_1, \ldots, v_{3m}\}$, provide an orthonormal basis for the space of A which is denoted by V_S, and the rest of the matrix V, $\{v_{3m+1}, v_{3m+2}, \ldots, v_n\}$, provides the basis for left null space of A, denoted by V_N. Then the best rank approximation for A is $(\mathrm{V}_S\overline{\mathrm{V}}_S^T)\mathrm{A}$ with error $E = \mathrm{A} - (\mathrm{V}_S\overline{\mathrm{V}}_S^T)\mathrm{A}$.

From Proposition 2.3 we have that a test point z coincides with one of the positions z_j if and only if $\mathrm{P}g_{z,c} = 0$, where $\mathrm{P} = \mathrm{I} - (\mathrm{V}_S\overline{\mathrm{V}}_S^T)$ is the orthogonal projection onto the null space of A.

Thus we can form an image of $z_j, j = 1, \ldots, m$, by plotting, at each point z, the quantity

$$W_c(z) = \frac{1}{||\mathrm{P}g_{z,c}||}.$$

The resulting plot will have large peaks at the locations of $z_j, j = 1, \ldots, m$.

2.3.1. The SVD of the MSR matrix. This case is the superposition of the first and second cases. As in the previous case, we assume for simplicity that all the matrices M^j are diagonal. The MSR matrix A can be written as

$$\mathrm{A} = \sum_{j=1}^{m} \beta_{1,j}\mathrm{d}_{2j-1}\mathrm{d}_{2j-1}^T + \beta_{2,j}\mathrm{d}_{2j}\mathrm{d}_{2j}^T + \tau_j \mathrm{s}_j \mathrm{s}_j^T. \tag{2.28}$$

Introduce

$$\mathrm{A}_j = \beta_{1,j}\mathrm{d}_{2j-1}\mathrm{d}_{2j-1}^T + \beta_{2,j}\mathrm{d}_{2j}\mathrm{d}_{2j}^T + \tau_j \mathrm{s}_j \mathrm{s}_j^T, \quad j = 1, \ldots, m. \tag{2.29}$$

Set again $\hat{\xi}_t = (\hat{\xi}_{1,t}, \hat{\xi}_{2,t}) = (\cos\theta_t, \sin\theta_t)$, where $\theta_t = \frac{2\pi(t-1)}{n}$ is the angle of observation, $t = 1, \ldots, n$; then

$$\bar{\mathrm{d}}_{2j-1}^T \mathrm{s}_j = \sum_{t=1}^{n} \hat{\xi}_{1,t} = \sum_{t=1}^{n} \cos\theta_t = 0, \tag{2.30}$$

$$\bar{\mathrm{d}}_{2j}^T \mathrm{s}_j = \sum_{t=1}^{n} \hat{\xi}_{2,t} = \sum_{t=1}^{n} \sin\theta_t = 0. \tag{2.31}$$

From (2.29), (2.20), (2.21), (2.22), (2.30), and (2.31) it then follows that

$$\mathrm{A}_j\bar{\mathrm{A}}_j = \beta_{1,j}^2||\bar{\mathrm{d}}_{2j-1}||^2\mathrm{d}_{2j-1}\bar{\mathrm{d}}_{2j-1}^T + \beta_{2,j}^2||\bar{\mathrm{d}}_{2j}||^2\mathrm{d}_{2j}\bar{\mathrm{d}}_{2j}^T + \tau_j^2||\bar{\mathrm{s}}_j||^2\mathrm{s}_j\bar{\mathrm{s}}_j^T,$$
$$\bar{\mathrm{A}}_j\mathrm{A}_j = \beta_{1,j}^2||\mathrm{d}_{2j-1}||^2\bar{\mathrm{d}}_{2j-1}\mathrm{d}_{2j-1}^T + \beta_{2,j}^2||\mathrm{d}_{2j}||^2\bar{\mathrm{d}}_{2j}\mathrm{d}_{2j}^T + \tau_j^2||\mathrm{s}_j||^2\bar{\mathrm{s}}_j\mathrm{s}_j^T$$

for $j = 1, \ldots, m$. Therefore, the eigenvectors $v_{3j-2}, v_{3j-1}, v_{3j}$ and $w_{3j-2}, w_{3j-1}, w_{3j}$ of the matrices $\mathrm{A}_j\bar{\mathrm{A}}_j$ and $\bar{\mathrm{A}}_j\mathrm{A}_j$, having nonzero singular values σ_j, are given by

$$\{v_{3j-2}, v_{3j-1}, v_{3j}\} = \left\{\frac{\mathrm{d}_{2j-1}}{||\mathrm{d}_{2j-1}||}, \frac{\mathrm{d}_{2j}}{||\mathrm{d}_{2j}||}, \frac{\mathrm{s}_j}{||\mathrm{s}_j||}\right\}, \tag{2.32}$$

$$\{w_{3j-2}, w_{3j-1}, w_{3j}\} = \left\{\frac{\bar{\mathrm{d}}_{2j-1}}{||\bar{\mathrm{d}}_{2j-1}||}, \frac{\bar{\mathrm{d}}_{2j}}{||\bar{\mathrm{d}}_{2j}||}, \frac{\bar{\mathrm{s}}_j}{||\bar{\mathrm{s}}_j||}\right\}, \tag{2.33}$$

and

$$\{\sigma_{3j-2}, \sigma_{3j-1}, \sigma_{3j}\} = \left\{\frac{n}{2}|\beta_{1,j}|, \frac{n}{2}|\beta_{2,j}|, n|\tau_j|\right\}. \tag{2.34}$$

Since $\mathcal{R}(\mathrm{A}\bar{\mathrm{A}}) = \mathrm{span}\{\mathrm{d}_1, \ldots, \mathrm{d}_{2m}, \mathrm{s}_1, \ldots, \mathrm{s}_m\} = \mathrm{span}\{v_1, \ldots, v_{3m}\}$, then the singular vectors $\hat{v}_{l'}$ are linear combinations of the array vectors $v_{l'}$, while $\hat{w}_{l'}$ are linear combinations of the array vectors $w_{l'} = \bar{v}_{l'}$ for $l' = 1, \ldots, 3m$.

Let

$$H_{l',q'} = \bar{v}_{l'}^T v_{q'}, \quad l', q' = 1, \dots, 3m. \tag{2.35}$$

Define

$$\begin{aligned} l' &= 3(l-1)+p, \\ q' &= 3(q-1)+p', l, q = 1, \dots, m, \;\; p, p' = 1, 2, 3. \end{aligned}$$

Using the polar coordinates $z_q - z_l = |z_l - z_q|(\cos\alpha_{lq}, \sin\alpha_{lq})$, we compute

$$H_{l',q'} = \frac{\sum_{t=1}^n \hat{\xi}_{p,t}\, e^{ik|z_l - z_q|\cos(\theta_t - \alpha_{lq})}}{\sqrt{n}\sqrt{\sum_{t=1}^n \hat{\xi}_{p,t}^2}}, \;\; p = 1, 2, \; p' = 3, \; l \neq q. \tag{2.36}$$

For $l = q$ we compute $H_{l',q'}$ from (2.20), (2.21), (2.22), (2.30), and (2.31). Suppose $l \neq q$. For $p, p' = 1, 2$ we refer to section 2.2.1. Otherwise, the following holds:

$$\begin{aligned} &H_{l',q'} \approx i\sqrt{2}\,\cos(\alpha_{lq}) J_1(k|z_l - z_q|) && \text{if } p = 1, p' = 3, \\ &H_{l',q'} \approx i\sqrt{2}\,\sin(\alpha_{lq}) J_1(k|z_l - z_q|) && \text{if } p = 2, p' = 3, \\ &H_{l',q'} \approx J_0(k|z_l - z_q|) && \text{if } p = p' = 3, \end{aligned} \tag{2.37}$$

where J_1 is the Bessel function of the first kind and order one.

To conclude this subsection, we note that in the case where $H_{l',q'} \approx \delta_{l',q'}$ for $l', q' = 1, \dots, 3m$, we get $\hat{\sigma}_{3(j-1)+p} \approx \frac{n}{2}|\beta_{p,j}|$, $p = 1, 2$; $\hat{\sigma}_{3j} \approx n|\tau_j|$. Moreover, the singular vectors, having nonzero singular values, are given by $\hat{v}_{3(j-1)+p} \approx v_{3(j-1)+p}$, $\hat{w}_{3(j-1)+p} \approx w_{3(j-1)+p}$ for $j = 1, \dots, m$ and $p = 1, 2, 3$.

Suppose that $\gamma_\mu^j M^j$ and $\gamma_\varepsilon^j |B_j|$ are all different enough and α_{lq} are such that the right-hand sides of the two first equations in (2.37) take small values. Then we may claim that if $|\beta_{1,1}| \geq |\beta_{2,1}| \gg |\beta_{1,2}| \geq |\beta_{2,2}| \gg \cdots \gg |\beta_{1,m}| \geq |\beta_{2,m}|$ and $|\tau_1| \gg \cdots \gg |\tau_m|$, then $\hat{\sigma}_{2(j-1)+p}$ is close to $\sigma_{2(j-1)+p}$ and the two first singular values correspond to the inclusion with the highest $\gamma_\mu^j M^j$.

3. Fourier algorithm. In this section we present a second linear (noniterative) method to determine the location of the small inclusions from scattering amplitude measurements for a fixed frequency. This method, like the variational algorithm introduced in [4], reduces the reconstruction problem of the small inclusions to the calculation of an inverse Fourier transform. Using (1.4) we will see that the points z_j, which determine the location of the inclusions, can be recovered by performing an appropriate Fourier inversion.

The general lines of our method were first introduced in [3] for the three-dimensional scattering problem and used by Volkov [25] together with a projection technique on two-dimensional planes for recovering the positions of the inclusions. Here we consider the two-dimensional case and explain in detail how this algorithm applies by using explicit Fourier series representation of the scattering amplitude. The key steps of its numerical implementation are also described.

We assume that we are in possession of $A_\alpha^{(1)}(\hat{x}_l, \hat{\xi}_{l'})$ for a collection of pairs $(\hat{x}_l, \hat{\xi}_{l'})$, where $l = 1, \dots, L$ and $l' = 1, \dots, L'$. For simplicity we suppose that all the inclusions are disks. We then rewrite (1.4) as follows:

$$A_\alpha^{(1)}(\hat{x}, \hat{\xi}) = \alpha^2 \sum_{j=1}^m e^{-ik(\hat{x}-\hat{\xi})\cdot z_j} \left(\gamma_\mu^j\, m^j \hat{x}\cdot\hat{\xi} + \gamma_\varepsilon^j |B_j| \right), \quad \hat{x}, \; \hat{\xi} \in \text{¸}^{\,1}, \tag{3.1}$$

where m^j is defined by (1.3). We first observe that

$$A_\alpha^{(1)}(\hat{x},\hat{\xi}) = A_\alpha^{(1)}(-\hat{\xi},-\hat{x}), \quad A_\alpha^{(1)}(\hat{x},\hat{\xi}) = \overline{A}_\alpha^{(1)}(-\hat{x},-\hat{\xi}) \quad \forall \hat{x},\hat{\xi} \in \ ^1,$$

where $\overline{A}_\alpha^{(1)}$ denotes the complex conjugate of $A_\alpha^{(1)}$.

Define, for $l = 1,\dots,L$ and $l' = 1,\dots,L'$, the coefficients $a_{l,l'}$ by $a_{l,l'} = A_\alpha^{(1)}(\hat{x}_l,\hat{\xi}_{l'})$. Our reconstruction procedure is divided into three steps.

1. Given that $a_{l,l'}$, we can compute using the FFT as an accurate approximation of $A_\alpha^{(1)}(\hat{x},\hat{\xi})$ on $^1 \times \ ^1$.

2. Let $\mathcal{M}$ denote the following complex variety: $\mathcal{M} = \{\xi \in \mathbb{C}^2,\ \xi\cdot\xi = 1\}$. It is easy to see that $A_\alpha^{(1)}(\hat{x},\hat{\xi})$ has an analytic continuation to $\mathcal{M}\times\mathcal{M}$. Let $(Y_p)_{p=0,1,\dots,}$ denote the normalized (in $L^2(\ ^1)$) spherical harmonics. Denote by A_p the Fourier coefficients of $A_\alpha^{(1)}$:

$$A_\alpha^{(1)}(\hat{x},\hat{\xi}) = \sum_p A_p(\hat{x})Y_p(\hat{\xi}) \quad \forall \hat{x},\hat{\xi} \in \ ^1. \tag{3.2}$$

Recall from Step 1 that we are in fact in possession of an accurate approximation on ^{1} of $A_p(\hat{x})$, $p \le P$ for some P. In view of (3.2), the analytic continuation of the truncated Fourier series

$$\sum_{p;\, p\le P} A_p(\hat{x})Y_p(\hat{\xi})$$

of $A_\alpha^{(1)}(\hat{x},\hat{\xi})$ on $\mathcal{M}\times\mathcal{M}$ can be obtained by using the standard analytic continuation of the spherical harmonics $(Y_p(\hat{\xi}))_p$ on the complex variety $\mathcal{M}$ followed by another analytic continuation of the Fourier expansion in $\hat{x}$. We know that the analytic continuation of $A_\alpha^{(1)}$ from $^1\times\ ^1$ to $\mathcal{M}\times\mathcal{M}$ is unique. In fact, $\mathcal{M}$ is a one-dimensional complex variety and S^1 is a totally real one-dimensional real submanifold of $\mathcal{M}$. Thus an analytic function which vanishes on S^1 must be 0; see, for example, [5].

3. Recall that, given $a_{l,l'}$ for $l = 1,\dots,L$ and $l' = 1,\dots,L'$, we have constructed through Steps 1 and 2 an accurate approximation of the function $A_\alpha^{(1)}(\hat{x},\hat{\xi})$ that is analytic on $\mathcal{M}\times\mathcal{M}$ and is such that $A_\alpha^{(1)}(\hat{x}_l,\hat{\xi}_{l'}) = a_{l,l'}$ for all $l = 1,\dots,L$ and $l' = 1,\dots,L'$. However, for any $\xi \in \mathbb{R}^2$, we know that there exist ξ_1 and ξ_2 in $\mathcal{M}$ such that $\xi = k(\xi_1 - \xi_2)$; for example, if $|\xi| > 2k$, then

$$\xi_1 = \frac{\xi}{2k} + i\eta, \quad \xi_2 = -\frac{\xi}{2k} + i\eta, \tag{3.3}$$

where $\eta \in \mathbb{R}^2$ such that $\xi\cdot\eta = 0$, and

$$|\eta|^2 = \begin{cases} 0 & \text{for } |\xi| \le 2k, \\ \dfrac{|\xi|^2}{4k^2} - 1 & \text{for } |\xi| > 2k. \end{cases}$$

In particular, if $\xi = 0$, we may choose $\xi_1 = \xi_2 = 1/\sqrt{2}$. Let us now view $(a_{l,l'})$ as a function of $\xi \in \mathbb{R}^2$. Since $\xi_1\cdot\xi_2 = 1 - |\xi|^2/(2k^2)$, we can rewrite $A_\alpha^{(1)}(\xi_1,\xi_2)$ as

$$A_\alpha^{(1)}(\xi) := A_\alpha^{(1)}(\xi_1,\xi_2) = \alpha^2 \sum_{j=1}^m e^{-i\xi\cdot z_j}\left(\gamma_\mu^j m^j\left(1 - \frac{|\xi|^2}{2k^2}\right) + \gamma_\varepsilon^j |B_j|\right), \tag{3.4}$$

and therefore we are now in possession of an approximation to $A_\alpha^{(1)}(\xi)$ for any $\xi \in \mathbb{R}^2$. Here we rely on the fact that the analytic continuation is unique.

Recall that $e^{-i\xi\cdot z_j}$ (up to a multiplicative constant) is exactly the Fourier transform of the Dirac function δ_{z_j} (a point mass located at z_j). Multiplication by powers of ξ in Fourier space corresponds to differentiation of the Dirac function. Therefore, using the inverse Fourier transform, $\mathcal{F}^{-1}$, we obtain

$$\mathcal{F}^{-1}(A_\alpha^{(1)}) = \sum_{j=1}^{m} L_j(\delta_{z_j}),$$

where L_j are, in view of (3.2), second-order constant coefficient differential operators. Hence $A_\alpha^{(1)}(\xi)$ is the inverse Fourier transform of a distribution with its support at the locations of the centers of inclusions z_j.

We now give an explicit and useful Fourier representation of $A_\alpha^{(1)}$. In the polar system of coordinates, let $\hat{x} = (\cos\phi, \sin\phi), \hat{\xi} = (\cos\theta, \sin\theta)$, and $z_j = |z_j|(\cos\zeta_j, \sin\zeta_j)$. We write

$$A_\alpha^{(1)}(\theta,\phi) = \alpha^2 \sum_{j=1}^{m} e^{-ik|z_j|(\cos(\phi-\zeta_j)-\cos(\theta-\zeta_j))} \left(\gamma_\mu^j\, m^j \cos(\phi-\theta) + \gamma_\varepsilon^j |B_j|\right). \tag{3.5}$$

Let $k|z_j| = x_j$. Since $e^{iz\sin\alpha} = \sum_{n=-\infty}^{+\infty} J_n(z)e^{in\alpha}$, we can write

$$e^{-ix_j\cos(\phi-\zeta_j)} = e^{ix_j\sin(\phi-\zeta_j-\frac{\pi}{2})} = \sum_{p=-\infty}^{+\infty} J_p(x_j)e^{ip\phi}e^{-ip(\zeta_j+\frac{\pi}{2})}, \tag{3.6}$$

where $J_q(z)$ denotes the Bessel function of the first kind and order q. Similarly, we have

$$e^{ix_j\cos(\theta-\zeta_j)} = e^{ix_j\sin(\theta-\zeta_j+\frac{\pi}{2})} = \sum_{l=-\infty}^{+\infty} J_l(x_j)e^{il\theta}e^{-il(\zeta_j-\frac{\pi}{2})}. \tag{3.7}$$

By multiplying (3.6) by (3.7) we get

$$e^{-ix_j(\cos(\phi-\zeta_j)-\cos(\theta-\zeta_j))} = \sum_{p=-\infty}^{+\infty}\sum_{l=-\infty}^{+\infty} \tilde{c}_{pl}J_p(x_j)J_l(x_j)e^{ip\phi}e^{il\theta}, \tag{3.8}$$

where

$$\tilde{c}_{pl} = e^{-ip(\zeta_j+\frac{\pi}{2})}e^{-il(\zeta_j-\frac{\pi}{2})}. \tag{3.9}$$

Making use of the trigonometric formula $\cos(\phi-\theta) = \frac{1}{2}(e^{i\phi}e^{-i\theta} + e^{-i\phi}e^{i\theta})$ we get

$$\begin{aligned}&\sum_{p=-\infty}^{+\infty}\sum_{l=-\infty}^{+\infty} \tilde{c}_{pl}J_p(x_j)J_l(x_j)e^{ip\phi}e^{il\theta}\cos(\phi-\theta)\\ &\quad= \frac{1}{2}\sum_{p=-\infty}^{+\infty}\sum_{l=-\infty}^{+\infty} \left(\tilde{c}_{p-1,l+1}J_{p-1}(x_j)J_{l+1}(x_j) + \tilde{c}_{p+1,l-1}J_{p+1}(x_j)J_{l-1}(x_j)\right)e^{ip\phi}e^{il\theta}.\end{aligned}$$

From the recurrence formulae

$$J_{q-1}(z) + J_{q+1}(z) = \frac{2q}{z}J_q(z), \quad J_{q-1}(z) - J_{q+1}(z) = 2J_q'(z), \quad q \in \mathbb{Z},$$

together with the fact that $\tilde{c}_{p-1,l+1} = \tilde{c}_{pl}e^{i\pi}$, $\tilde{c}_{p+1,l-1} = \tilde{c}_{pl}e^{-i\pi}$, it immediately follows that

$$\begin{aligned}(3.10)\qquad &\sum_{p=-\infty}^{+\infty}\sum_{l=-\infty}^{+\infty}\tilde{c}_{pl}J_p(x_j)J_l(x_j)e^{ip\phi}e^{il\theta}\cos(\phi-\theta)\\ &\quad=\sum_{p=-\infty}^{+\infty}\sum_{l=-\infty}^{+\infty}\tilde{c}_{pl}\left(-J_p'(x_j)J_l'(x_j)+\frac{pl}{{x_j}^2}J_p(x_j)J_l(x_j)\right)e^{ip\phi}e^{il\theta}.\end{aligned}$$

Finally, using (3.5) and (3.10), we obtain that for θ and ϕ on the real axis, $A_\alpha^{(1)}(\theta,\phi)$ is given by its Fourier series,

$$(3.11)\qquad A_\alpha^{(1)}(\theta,\phi)=\sum_{p=-\infty}^{+\infty}\sum_{l=-\infty}^{+\infty}C_{pl}e^{ip\phi}e^{il\theta},$$

where the Fourier coefficients C_{pl} are given by

$$(3.12)\qquad C_{pl}=\alpha^2\tilde{c}_{pl}\sum_{j=1}^{m}c_{pl}^j,$$

and

$$c_{pl}^j=\left(-J_p'(x_j)J_l'(x_j)+J_p(x_j)J_l(x_j)\frac{pl}{x_j^2}\right)\gamma_\mu^j\,m^j+J_p(x_j)J_l(x_j)\gamma_\varepsilon^j|B_j|.$$

The reconstruction procedure described below can be reformulated as follows. Recall that for θ and ϕ on the real axis, $A_\alpha^{(1)}(\phi,\theta)$ is given by its Fourier series (3.11). Then, for any $\xi\in\mathbb{R}^2$, one determines the values for $\tilde{\phi}$ and $\tilde{\theta}$ (via the vectors ξ_2 and ξ_1) in order to satisfy (3.3); plugging these values into the truncated Fourier series for $A_\alpha^{(1)}$ yields C_{pl} the plth Fourier coefficient of $A_\alpha^{(1)}$ as

$$(3.13)\qquad A_\alpha^{(1)}(\tilde{\phi},\tilde{\theta})=\sum_{p,l=0}^{n-1}C_{pl}e^{ip\tilde{\phi}}e^{il\tilde{\theta}}.$$

Then, letting $\tilde{\phi}_I=\max|\mathrm{imag}\,(\tilde{\phi})|$ and $\tilde{\theta}_I=\max|\mathrm{imag}\,(\tilde{\theta})|$ for the complex values of $\tilde{\phi}$ and $\tilde{\theta}$, the sufficient condition for convergence of (3.13) is

$$(3.14)\qquad \left|C_{n/2-1,n/2-1}\right|e^{(n/2-1)\tilde{\phi}_I}e^{(n/2-1)\tilde{\theta}_I}\to 0\quad\text{as } n\to\infty.$$

It follows that one can estimate $A_\alpha^{(1)}$ for those complex values $\tilde{\phi}$ and $\tilde{\theta}$ that are close to the real axis if n is large enough, emphasizing the fact that the choice of the number n depends upon the value of k, and upon the locations of the inclusions themselves (i.e., $|z_j|, j=1,\ldots,m$). Note that to (numerically) compute (3.13), the regularization technique developed by Franklin in [13] can be used.

Let R be such that $2R$ is the radius of the disk where (3.14) holds. The function $A_\alpha^{(1)}$ is then estimated within the square $\Omega(R)=[-\sqrt{2}R,\sqrt{2}R]^2$, letting the spectral radius R be larger than k. In view of the above, we have two cases of interest:

- there exist $\tilde{\phi}$ and $\tilde{\theta}$ which are complex-valued, and one is zero-padding the Fourier domain by $A_\alpha^{(1)}(\tilde{\phi},\tilde{\theta}):=0$ for all complex values of $\tilde{\phi}$ and $\tilde{\theta}$;

- there exist $\tilde{\phi}$ and $\tilde{\theta}$ which are complex-valued, and one applies the method of analytic continuation by FFT in order to estimate $A_\alpha^{(1)}$.

As will be shown by the numerical results, if $k|z_j|$ is small, then n is not sufficiently large, which implies that $R \gg k$, while if $k|z_j|$ is large, then R tends to k and thus would be more appropriate to apply the zero-padding algorithm.

The number of data (sampling) points N^2 needed for an accurate discrete Fourier inversion of $A_\alpha^{(1)}$ follows from the so-called Shannon theorem [11]. We need (conservatively), of order $(2L/\delta)^2$, sampled values to reconstruct a collection of inclusions that lies inside a square of side $2L$, where the (spatial) resolution $\delta = \pi/2k$ for the zero-padding algorithm, while it is given by $\delta = \pi/\sqrt{2}R$ for the method of analytic continuation.

4. Numerical experimentation. The configuration of interest is schematized in Figure 4.1. One is considering an array $\{A_j\}$ of n ideal antennas that are hypothetically radiating from and receiving at infinity in $\mathbb{R}^2$. That is, one assumes that, at one (and only one, which is a rather adverse situation) circular frequency ω one knows the values a_{lp}—those may be affected by noise, as seen in one subsection later on—of the far field pattern $A_\alpha^{(1)}(-\hat{\xi}_l, \hat{\xi}_p)$, $l, p = 1, \ldots, n$, for a small finite number (it will be set to 20 in all examples) of equidistantly distributed directions of illumination $\hat{\xi}_p = -(\cos\theta_p, \sin\theta_p)$, and for the opposite set of directions of observation, letting $\theta_p = 2\pi(p-1)/n$, $p = 1, \ldots, n$.

These directions are taken all around (i.e., one is speaking of a full-view inverse problem) an unknown finite number of homogeneous inclusions located at unknown positions within some prescribed domain of free space (air). As considered before these inclusions may have their dielectric permittivity (first case) or magnetic permeability (second case) or both (third case) that are differing (then, always with superior real-positive values) from those, $\mu_0 = 1$ and $\varepsilon_0 = 1$, of the embedding medium.

As is evident from the previous theoretical material, what matter are the real-positive valued contrasts γ_ε^j, and/or the real-positive valued contrasts γ_μ^j (then, mul-

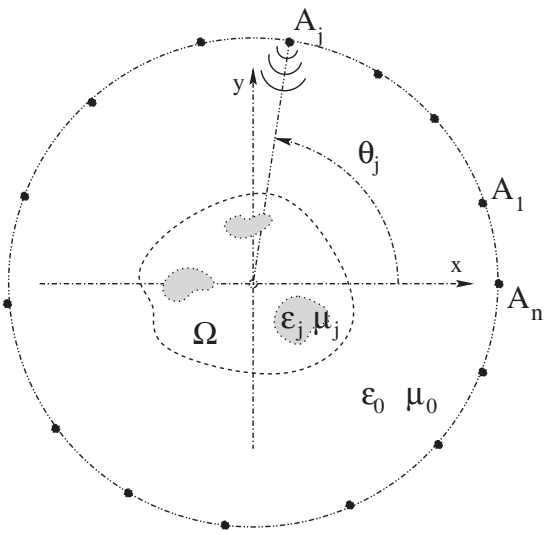

FIG. 4.1. *The full-view measurement setup.*

tiplied by the amplitude of the polarization tensor for a disk), noting that the higher the relative permittivity or permeability, the larger the magnitude of the resulting weight factor.

As for the single circular frequency of operation, it is set between the low-frequency value $\omega = 1$ and the high one $\omega = 10$, associated to wavenumbers k between 1 and 10 and to wavelengths in air between 2π and 0.2π, these figures being recalled when weighting in the usually expected half-a-wavelength far field resolutions with respect to those reached thereafter via the MUSIC algorithm (section 4.1) and Fourier reconstruction (section 4.2).

4.1. Examples of MUSIC reconstructions. As discussed in the theoretical examination, the nature (dielectric and/or magnetic) of the inclusions with respect to that of the embedding medium (here a purely dielectric and non magnetic medium) is essential to the results expected. Next, one is displaying and briefly analyzing a small number of numerical results from synthetically generated data in the three generic scattering cases previously studied.

The configuration involves two small homogeneous circular disks of diameter $\alpha = 0.1$ denoted B_1 and B_2 and, respectively, centered at $z_1 = (-0.45, 0.43)$ and $z_2 = (0.52, -0.44)$, to be retrieved using 20 illuminations and the corresponding observations within a prescribed search box, being the square one $\Omega = [-2, 2]\times[-2, 2] \subset \mathbb{R}^2$.

Corresponding dielectric permittivities ε^j, $j = 1, 2$, are equated to 5 and 2, and magnetic permeabilities μ^j, $j = 1, 2$, are equated to 5 and 2. Specific examples tailored to the analysis of the singular values assume identical values $\varepsilon^j = 3$ and/or $\mu^j = 3$, $j = 1, 2$. Unless stated otherwise for the study of the behavior of the approach versus frequency, the circular frequency of operation is fixed at $\omega = 4$.

Within the above setting, the retrieval of the inclusions involves the calculation of the SVD $\mathrm{A} = \mathrm{U}\Sigma\bar{\mathrm{V}}^T$ of the matrix $\mathrm{A} = (a_{l,p}) \in \mathbb{C}^{n\times n}$. Then, for each discrete location $z \in \Omega$ (the sampling step henceforth is $h = 0.05$), the identifiers of interest are

- in the first case: $W_a(z)$, $a = 1$;
- in the second case: $W_b(z)$, $b = \{(1, 0), (0, 1), (1, 1)\}$;
- in the third case: $W_c(z)$, $c = \{(1, 1, 0), (0, 0, 1), (1, 1, 1)\}$,

calculated within Ω, the specific values of b and c here having being inferred from the numerical experimentation. Plots of $z \to W_\cdot(z)$ illustrate the result achieved, sharp peaks being expected to occur at the locations of the inclusions, z_j, $j = 1, 2$. Other accompanying results displayed consist of the singular values of A, using a standard log scale, and also of grayscale maps of appropriate norms of "back-propagated" singular vectors or combinations.

4.1.1. The first case: Dielectric inclusions. In this purely dielectric case, the singular values are displayed in Figure 4.2; the identifier $W_a(z)$, where one has, for simplicity, let $a = 1$, is displayed in Figure 4.3; and the amplitudes of the scalar products of the singular vectors V_j with $g_{z,a}$ are displayed in Figure 4.4. The distribution of the nonzero singular values of A as a function of frequency $\omega = 1 : 10$ is shown in Figure 4.5 either for different inclusions ($\varepsilon^1 = 5$, $\varepsilon^2 = 2$) or for identical ones ($\varepsilon^1 = 3$, $\varepsilon^2 = 3$).

Results obtained as such are easy to interpret. Two singular values emerge from the 18 others in the noise subspace, and they range in accordance with the contrast of the corresponding inclusions. The two said inclusions are sharply retrieved, with a resolution no more than a small fraction of the wavelength (and isotropic, in tune with the fact that the search space is illuminated and seen from all around). As for the

singular vectors, once operated upon by $g_{z,a}$, they focus on the inclusions, as expected in the configuration under study. Finally, the evolution as a function of frequency of the singular values confirms that permittivity contrasts that are different enough lead to singular values that are very close to the $n\tau_j$ values on the whole frequency band. This is no longer true, however, with identical contrasts for which the singular values appear to oscillate in opposite phase above or below the common value of $n\tau_j$.

4.1.2. The second case: Permeable inclusions. In this purely magnetic case (in terms of the inclusions), the singular values are displayed in Figure 4.6; the identifier $W_b(z)$ is displayed in Figure 4.7 for $b = (1, 0)$, in Figure 4.8 for $b = (0, 1)$, and in Figure 4.9 for $b = (1, 1)$; and the 2-norm of the matrix

$$\tilde{\mathrm{V}}_j(z) = \begin{bmatrix} \mathrm{V}_{2j-1} \cdot g_{z,(1,0)} & \mathrm{V}_{2j} \cdot g_{z,(1,0)} \\ \mathrm{V}_{2j-1} \cdot g_{z,(0,1)} & \mathrm{V}_{2j} \cdot g_{z,(0,1)} \end{bmatrix}, \quad j = 1, 2, \tag{4.1}$$

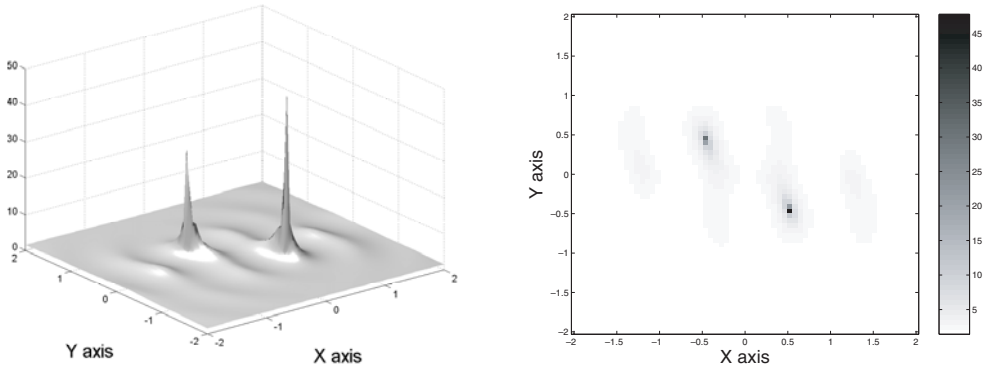

FIG. 4.7. *Case* 2 *(permeability contrasts only):* 3*D plot and grayscale map of* $W_b(z)$, $b = (1, 0)$, *for all points* z *in* Ω *(refer to Figure* 4.6*).*

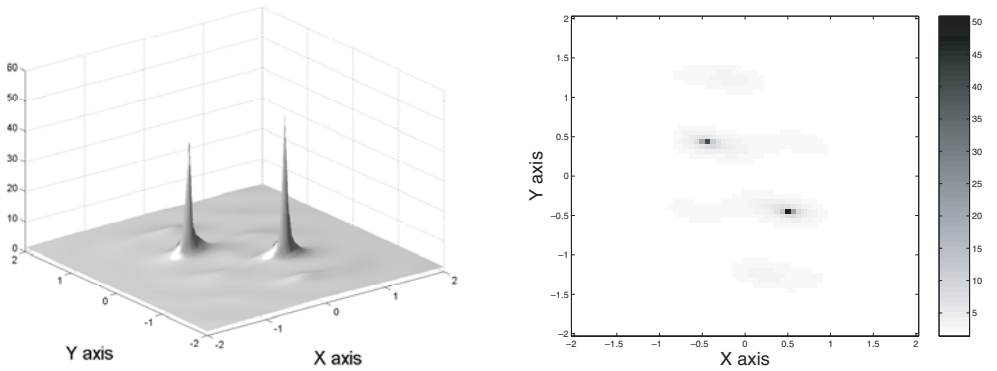

FIG. 4.8. *Case* 2 *(permeability contrasts only):* 3*D plot and grayscale map of* $W_b(z)$, $b = (0, 1)$, *for all points* z *in* Ω *(refer to Figure* 4.6*).*

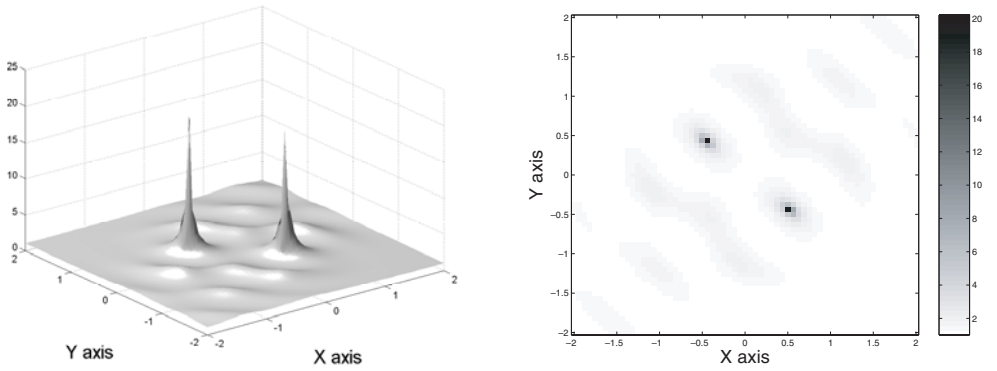

FIG. 4.9. *Case* 2 *(permeability contrasts only):* 3*D plot and grayscale map of* $W_b(z)$, $b = (1, 1)$, *for all points* z *in* Ω *(refer to Figure* 4.6*).*

is displayed in Figure 4.10, each subplot ($j = 1, 2$) being calculated from the combination of two singular vectors associated with the same inclusion. The distribution of the nonzero singular values of A as a function of frequency, $\omega = 1 : 10$, is shown

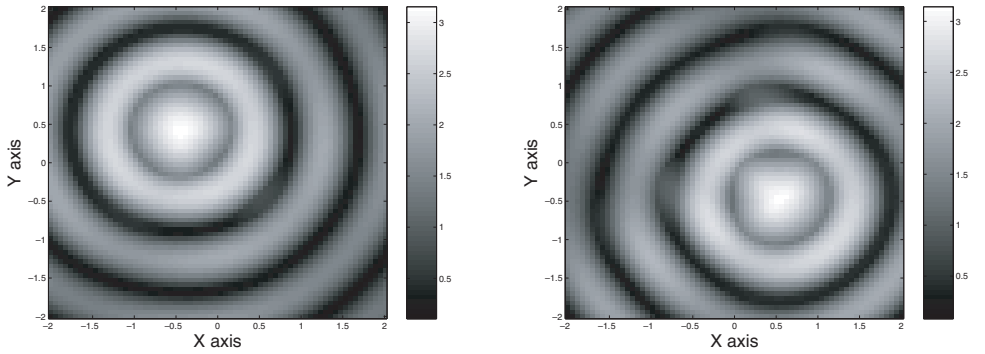

FIG. 4.10. *Case* 2 *(permeability contrasts only): grayscale maps of the* 2*-norm of the matrix* $\tilde{\mathrm{V}}_j(z)$, $j = 1, 2$, *defined by* (4.1), *for all points* z *in* Ω *(refer to Figures* 4.6 *to* 4.9*).*

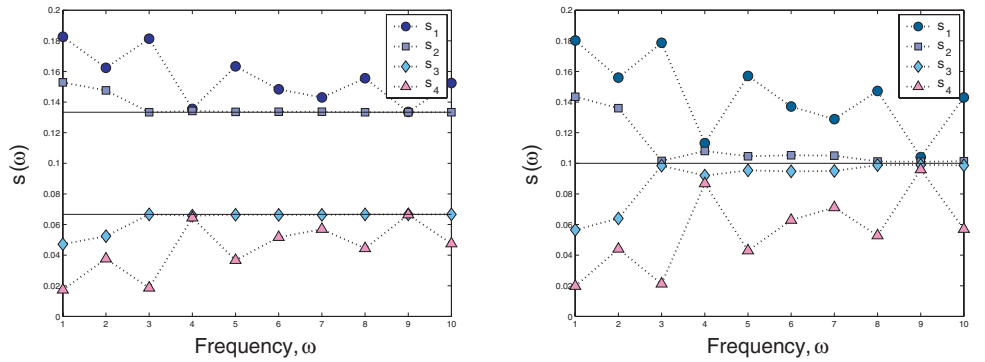

FIG. 4.11. *Case* 2 *(permeability contrasts only): distribution of the nonzero singular values of* A *as a function of frequency,* $\omega = 1 : 10$, *for different or identical inclusions.* (a) *depicts the four nonzero singular values of* A *for* $\mu^1 = 5$, $\mu^2 = 2$*;* (b) *depicts the four nonzero singular values of* A *for* $\mu^1 = 3$, $\mu^2 = 3$. *In both cases the solid line denotes the values taken by* $n\beta_j/2$, $j = 1, 2$.

in Figure 4.11 either for different inclusions ($\mu^1 = 5$, $\mu^2 = 2$) or for identical ones ($\mu^1 = 3$, $\mu^2 = 3$).

As previously, the results obtained are easy to interpret. Only four singular values emerge from noise, each couple (with almost identical value) being associated to one specific inclusion, and those couples range according to the permeability contrast. The inclusions, observed via different $W_b(z)$, are clearly discriminated from the background, the visual aspect depending upon the choice of b. The focusing of the singular vectors as seen from displays of the 2-norm of the vector couples defined in the above, is rather good, noticing that V_1 and V_2 are associated to B_1, and V_3 and V_4 are associated to B_2, i.e., from the most permeable inclusion to the least one. Finally, the evolution as a function of frequency of the singular values—as previously observed in the dielectric case, yet in less obvious a fashion due to the doubling of the number of singular values—exemplifies that permeability contrasts that are different enough lead to singular values that are very close to (here, often almost identical with) the $n\beta_j/2$ values on the whole frequency band. This is no longer true, however, with identical contrasts for which the singular values appear to oscillate in opposite phase

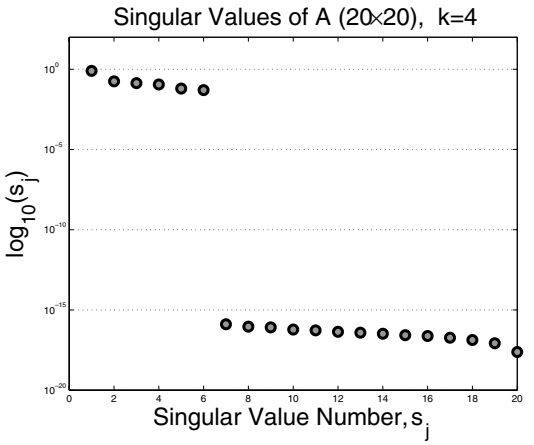

FIG. 4.12. *Case 3 (permittivity and permeability contrasts): distribution of the singular values of* A *for* $n = 20$ *illuminations.*

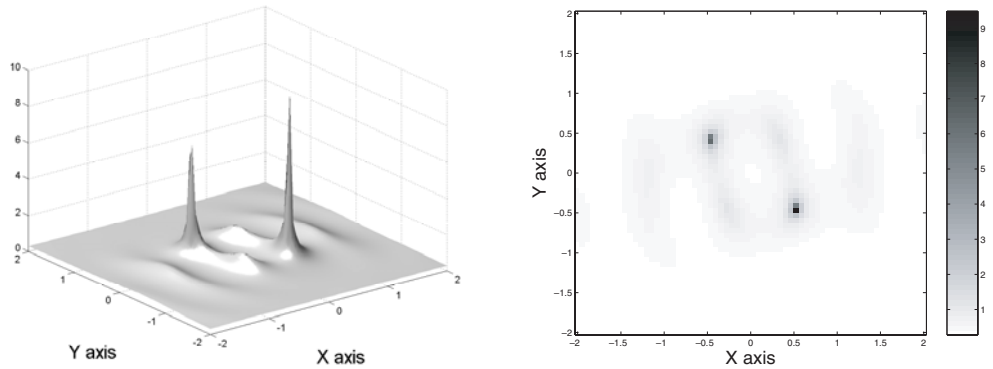

FIG. 4.13. *Case 3 (permittivity and permeability contrasts): 3D plot and grayscale map of* $W_c(z)$, $c = (1, 1, 0)$, *for all points* z *in* Ω *(refer to Figure* 4.12*).*

above or below the common value of $n\beta/2$.

4.1.3. The third case: Dielectric and permeable inclusions. In this full case, the singular values are displayed in Figure 4.12, and the identifier $W_c(z)$ is displayed in Figure 4.13 for $c = (1, 1, 0)$, in Figure 4.14 for $c = (0, 0, 1)$, and in Figure 4.15 for $c = (1, 1, 1)$. The 2-norm of the matrix

$$\tilde{\mathrm{V}}_j(z) = \begin{cases} V_j \cdot g_{z,a=1}, & j = 1, 2, \\ \begin{bmatrix} \mathrm{V}_{2j-3} \cdot g_{z,(1,0)} & \mathrm{V}_{2j-2} \cdot g_{z,(1,0)} \\ \mathrm{V}_{2j-3} \cdot g_{z,(0,1)} & \mathrm{V}_{2j-2} \cdot g_{z,(0,1)} \end{bmatrix}, & j = 3, 4, \end{cases} \tag{4.2}$$

is shown in Figure 4.16 for $j = 1, 2$ and Figure 4.17 for $j = 3, 4$. Each subplot is calculated from the singular vectors (or a combination thereof) associated with the same inclusion and the same property of this inclusion (dielectric or magnetic). As for the distribution of the nonzero singular values of A as a function of frequency considered before, it is left out for simplicity in view of the large number of singular values.

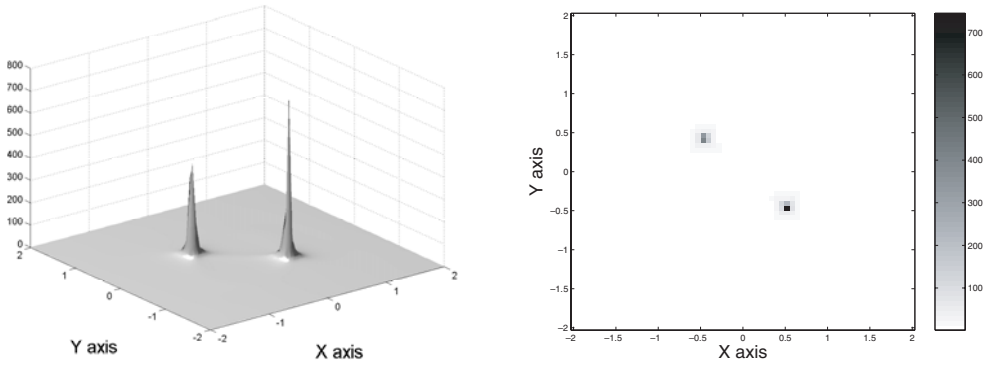

FIG. 4.14. *Case* 3 *(permittivity and permeability contrasts):* 3*D plot and grayscale map of* $W_c(z)$, $c = (0, 0, 1)$, *for all points* z *in* Ω *(refer to Figure* 4.12*).*

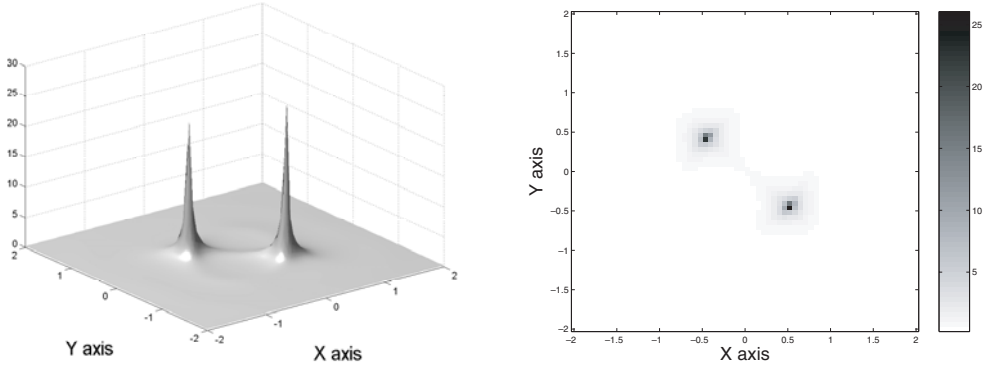

FIG. 4.15. *Case* 3 *(permittivity and permeability contrasts):* 3*D plot and grayscale map of* $W_c(z)$, $c = (1, 1, 1)$, *for all points* z *in* Ω *(refer to Figure* 4.12*).*

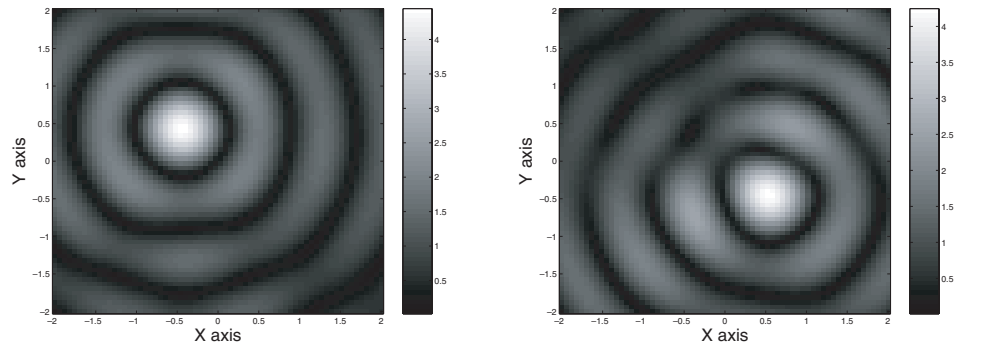

FIG. 4.16. *Case* 3 *(permittivity and permeability contrasts): grayscale maps of the* 2*-norm of the matrix* $\tilde{\mathrm{V}}_j(z)$, $j = 1, 2$, *defined by* (4.2), *for all points* z *in* Ω *(refer to Figures* 4.12 *to* 4.15*).*

The results obtained are evidently not as easy to interpret as before due to the more complicated character of the inclusions. Still, the singular values of the signal subspace emerge from noise—six of them—each triplet being associated to one specific inclusion, but with no obvious ranging observed. The inclusions, again, observed via

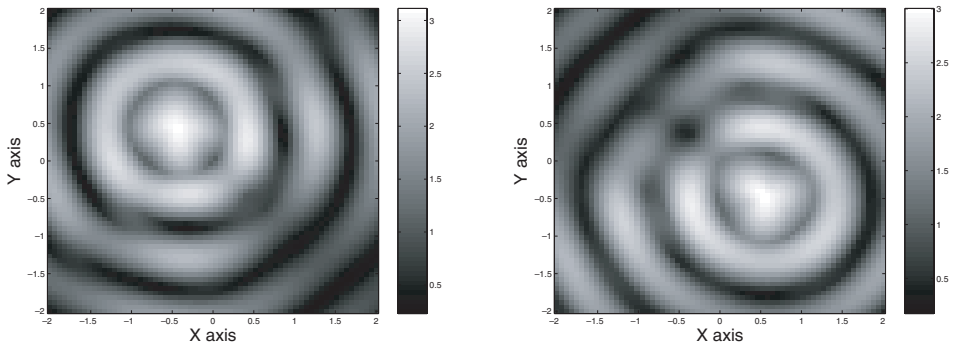

FIG. 4.17. *Case 3 (permittivity and permeability contrasts): grayscale maps of the 2-norm of the matrix* $\tilde{\mathrm{V}}_j(z)$, $j = 3, 4$, *defined by* (4.2), *for all points* z *in* Ω *(refer to Figures* 4.12, 4.13, 4.14, *and* 4.15*).*

different $W_c(z)$, are clearly discriminated from the background, the visual aspect depending upon the choice of c. As for the focusing of the singular vectors as seen from displays of the 2-norms defined in the above, it works for the most contrasted inclusion, B_1, both for the vectors V_3 and V_4 involved with the permeability and those, V_1, involved with the permittivity, but it does less with the least contrasted one, B_2, for which the maps would be difficult to interpret in the absence of any prior knowledge on the inclusions.

4.2. Examples of Fourier reconstructions. In this subsection a number of numerical examples illustrate the reconstruction by the Fourier method. In all such examples, the function $A_\alpha^{(1)}$ is estimated within the square $\Omega(R) = [-\sqrt{2}R, \sqrt{2}R]^2$, letting the spectral radius R be larger than k.

The configuration is the same as it is for the MUSIC algorithm (section 4.1), involving two small homogeneous circular disks of diameter $\alpha = 0.1$ still denoted as B_1 and B_2 and, respectively, centered at $z_1 = (-0.45, 0.43)$ and $z_2 = (0.52, -0.44)$, with $\varepsilon^1 = 3$ and $\varepsilon^2 = 2.5$, and/or $\mu^1 = 3$ and $\mu^2 = 2.5$. The assumption is made that, for the inversion carried out at frequency $\omega = 1$ ($k = 1$), such inclusions lie inside the square $[-6, 6]^2$, for which three-dimensional plots of $|\mathcal{F}^{-1}(A_\alpha^{(1)})|$ calculated by an inverse discrete Fourier transform (DFT) will thus be given, the pertinent contour plots being drawn for visibility only within the smaller square $[-3, 3]^2$. Note that one is using 16 angles θ and ϕ in $[0, 2\pi]$ in order to compute the Fourier coefficients.

The retrieval of purely dielectric inclusions is illustrated in Figures 4.18 and 4.19 via three-dimensional plots and contour plots of $|\mathcal{F}^{-1}(A_\alpha^{(1)})|$ which are obtained by carrying out either zero-padding (Figure 4.18) or analytic continuation (Figure 4.19); note that the number of data (sampling) points N^2 that are needed for an accurate discrete Fourier inversion of $A_\alpha^{(1)}$ in the square $\Omega(R = 5)$ is equal to 28^2.

The results show that the zero-padding approach does not enable us to discriminate between the two inclusions, and the corresponding resolution δ is appraised to be of the order of half a wavelength (1.57). On the contrary, the analytic continuation succeeds in providing this discrimination, associated to a much sharper resolution, of the order of one-seventh of a wavelength and even less (about 0.43 as confirmed by the figure).

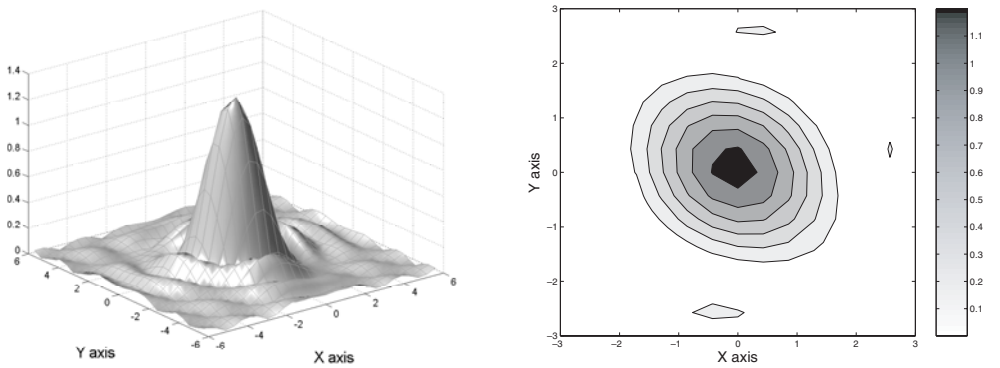

FIG. 4.18. *Retrieval of two purely dielectric inclusions with different contrasts by zero-padding at* $k = 1$ *(the resolution* δ *achieved is* ≈ 1.57*).*

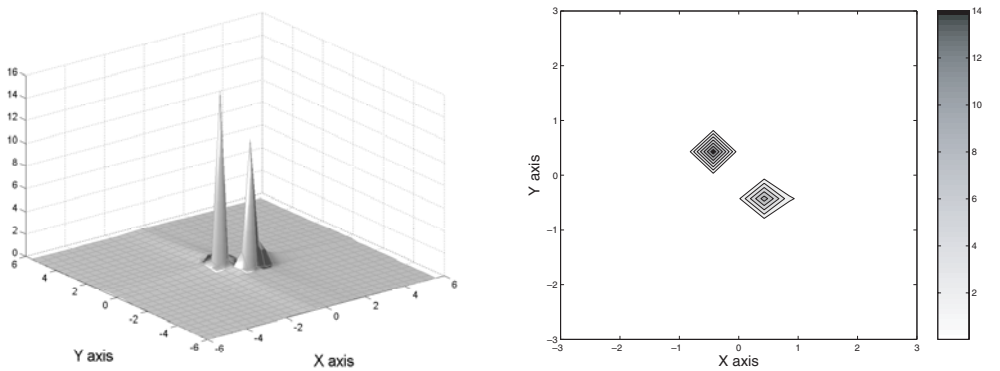

FIG. 4.19. *Retrieval of two purely dielectric inclusions with different contrasts by analytic continuation at* $k = 1$ *(the resolution* δ *achieved is* ≈ 0.43*).*

Correspondingly, the retrieval of purely magnetic inclusions is illustrated in Figures 4.20 and 4.21 via three-dimensional plots and contour plots of $|\mathcal{F}^{-1}(A_\alpha^{(1)})|$ obtained by carrying out either zero-padding (Figure 4.20) or analytic continuation (Figure 4.21) (with a slightly smaller Ω than before, $R = 4.5$); note that the number of data (sampling) points N^2 that are needed for an accurate discrete Fourier inversion of $A_\alpha^{(1)}$ in the square $\Omega(R = 4.5)$ is equal to 24^2.

The same conclusion as with the dielectric inclusions holds: failure of the zero-padding approach (which is yielding a complicated image from which one cannot infer much, except the fact that some object is in the search domain) and efficiency of the analytic continuation, though with a slightly lower resolution (of the order of 0.5), as is easily seen by comparing Figure 4.21 with Figure 4.19, both being computed in close conditions.

Finally, dielectric and permeable inclusions are tackled simultaneously, values of permittivity and permeability being those previously chosen. This is illustrated in Figures 4.22 and 4.23 via three-dimensional plots and contour plots of $|\mathcal{F}^{-1}(A_\alpha^{(1)})|$ obtained by carrying out either zero-padding (Figure 4.22) or analytic continuation (Figure 4.23); note that the number of data (sampling) points N^2 that are needed

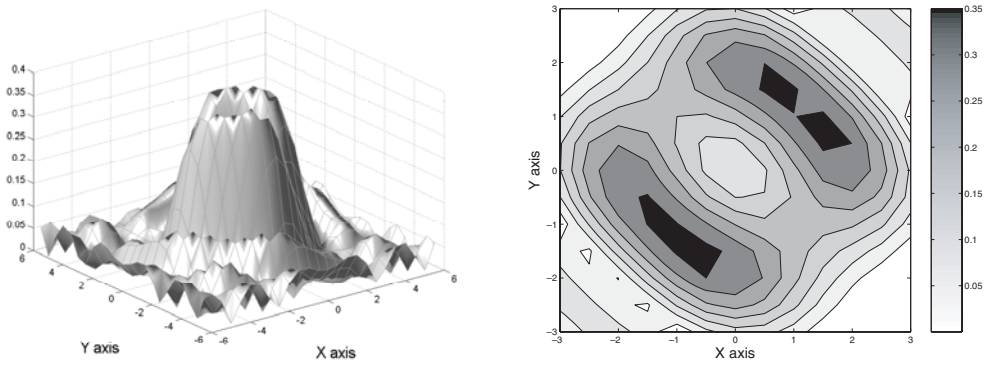

FIG. 4.20. *Retrieval of two purely magnetic inclusions with different contrasts by zero-padding at* $k = 1$ *(the resolution* δ *achieved is* ≈ 1.57*).*

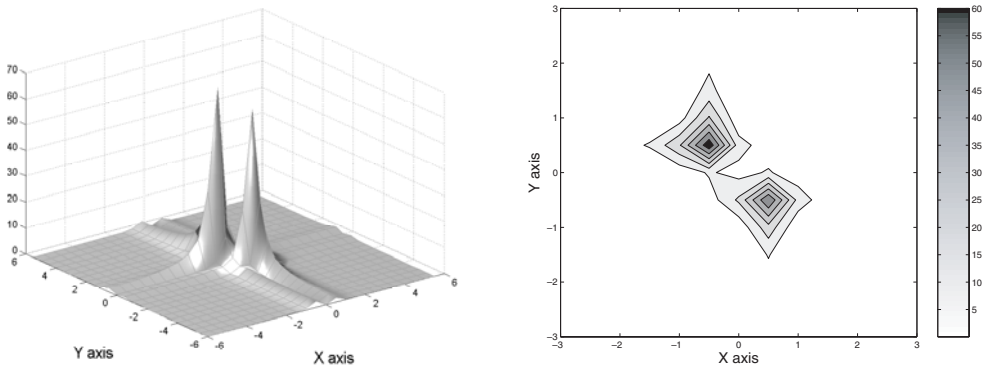

FIG. 4.21. *Retrieval of two purely magnetic inclusions with different contrasts by analytic continuation at* $k = 1$ *(the resolution* δ *achieved is* ≈ 0.5*).*

for an accurate discrete Fourier inversion of $A_\alpha^{(1)}$ in the square $\Omega(R = 4.5)$ is equal to 24^2. Again the analytic continuation is the only successful method retrieving the two inclusions, the resolution (and the visual aspect of the three-dimensional and contour plots) being like the one observed with the purely magnetic inclusions (the poorer result, in effect).

In the second set of numerical examples (for brevity, only purely dielectric inclusions are considered) one still keeps the number of inclusions equal to two, yet one of them is located much farther away from the center of the search domain than before, at $z_1 = (-4.0, 0.43)$, the other being located about as before, at $z_2 = (0.42, -0.44)$. Also, the inclusions are now identical, with $\varepsilon^1 = 3$ and $\varepsilon^2 = 3$. The assumption of the inversion is that they lie within the square $[-12, 12]^2$, contour plots being displayed in the smaller square $[-5.5, 5.5]^2$. The frequency of operation is the same as previously chosen, at $\omega = 1$ $(k = 1)$.

Figures 4.24 and 4.25 show three-dimensional plots and contour plots of $|\mathcal{F}^{-1}(A_\alpha^{(1)})|$ obtained by carrying out either zero-padding (Figure 4.24) or analytic continuation (Figure 4.25); note that the number of data (sampling) points N^2 that are needed for an accurate discrete Fourier inversion of $A_\alpha^{(1)}$ in the square $\Omega(R = 1.8)$ is equal to 20^2.

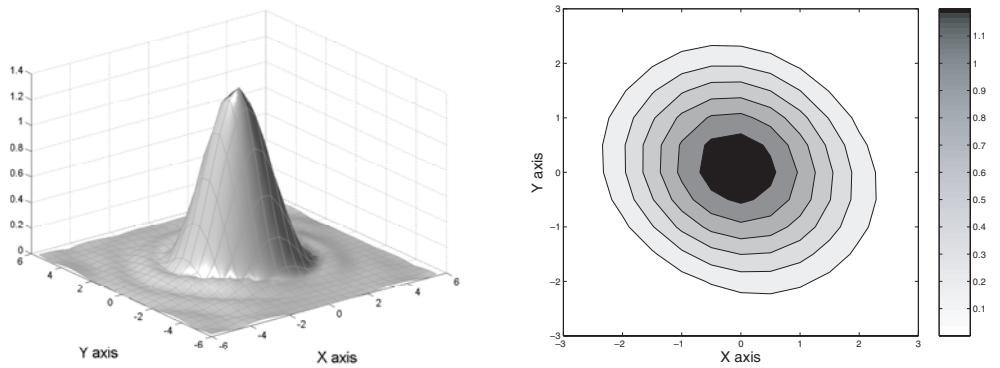

FIG. 4.22. *Retrieval of both dielectric and magnetic inclusions with different contrasts by analytic continuation at* $k = 1$ *(the resolution* δ *achieved is* ≈ 1.57*).*

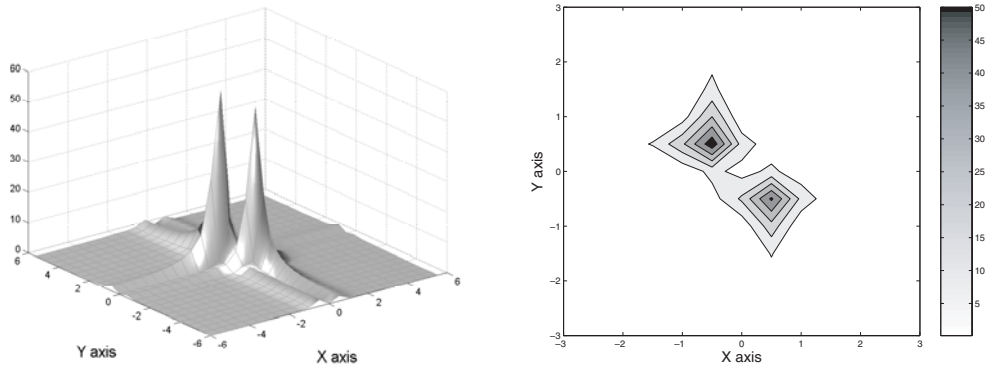

FIG. 4.23. *Retrieval of both dielectric and magnetic inclusions at* $k = 1$ *by analytic continuation (the resolution* δ *achieved is* ≈ 0.5*).*

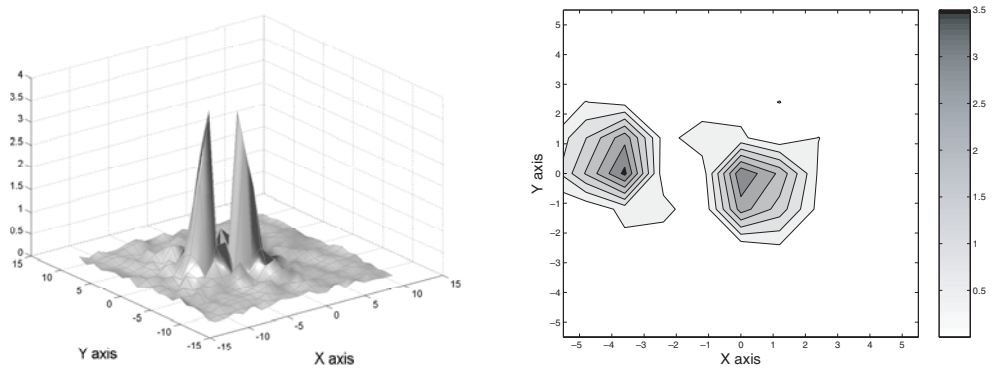

FIG. 4.24. *Retrieval of identical dielectric inclusions, one remote from the center of the search domain, at* $k = 1$ *by zero-padding (the resolution* δ *achieved is* ≈ 1.57*).*

Let us emphasize here that one has been using 32 angles θ and ϕ in $[0, 2\pi]$, because of the eccentricity of the first inclusion, for the angles θ and ϕ in order to suitably calculate the Fourier coefficients, and, as a matter of fact, one is able

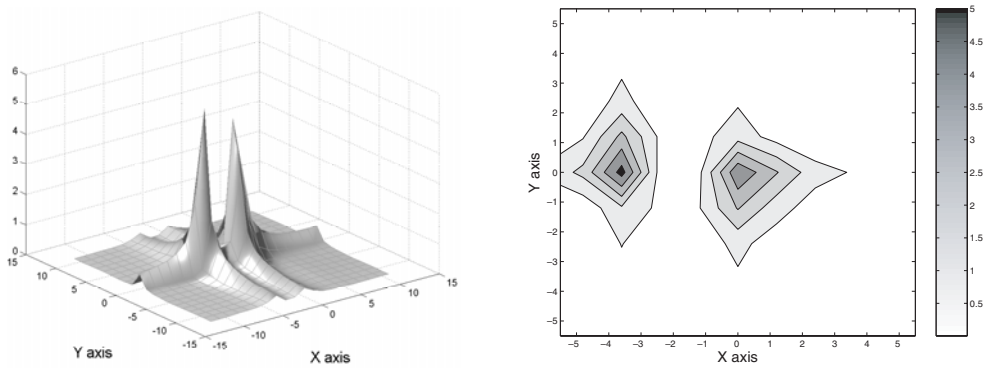

FIG. 4.25. *Retrieval of identical dielectric inclusions, one remote from the center of the search domain, by analytic continuation at* $k = 1$ *(the resolution* δ *achieved is* ≈ 1.2*).*

to extend the function $A_\alpha^{(1)}$ on the square $\Omega(R = 1.8)$—choosing a higher R yields divergent results.

Now, contrary to what was observed before, both approaches (zero-padding and analytic continuation) tend to behave likewise, as evidenced by the similarity of Figures 4.24 and 4.25. That is, there seems no interest in performing the analytic continuation as exemplified by the low maximal value of R, since it is not able to perform this continuation far enough in the spectral plane to improve upon the zero-padding results.

WHY ARE HIGH-DIMENSIONAL FINANCE PROBLEMS OFTEN OF LOW EFFECTIVE DIMENSION?*

XIAOQUN WANG† AND IAN H. SLOAN‡

Abstract. Many problems in mathematical finance can be formulated as high-dimensional integrals, where the large number of dimensions arises from small time steps in time discretization and/or a large number of state variables. Quasi–Monte Carlo (QMC) methods have been successfully used for approximating such integrals. To understand this success, this paper focuses on investigating the special features of some typical high-dimensional finance problems, namely, option pricing and bond valuation. We provide new insight into the connection between the effective dimension and the efficiency of QMC, and we present methods to analyze the dimension structure of a function. We confirm the observation of Caflisch, Morokoff, and Owen that functions from finance are often of low effective dimension, in the sense that they can be well approximated by their low-order ANOVA (analysis of variance) terms, usually just the order-1 and order-2 terms. We explore *why* the effective dimension is small for many integrals from finance. By deriving explicit forms of the ANOVA terms in simple cases, we find that the importance of each dimension is naturally weighted by certain hidden weights. These weights characterize the relative importance of different variables or groups of variables and limit the importance of the higher-order ANOVA terms. We study the variance ratios captured by low-order ANOVA terms and their asymptotic properties as the dimension tends to infinity, and we show that with the increase of dimension the lower-order terms continue to play a significant role and the higher-order terms tend to be negligible. This provides some insight into high-dimensional problems from finance and explains why QMC algorithms are efficient for problems of this kind.

Key words. quasi–Monte Carlo, effective dimension, option pricing, bond valuation

DOI. 10.1137/S1064827503429429

1. Introduction.

Many problems in mathematical finance can be formulated as high-dimensional integrals, or, after appropriate transformations as integrals over the d-dimensional unit cube,

$$I_d(f) = \int_{[0,1]^d} f(\mathbf{x}) d\mathbf{x}.$$

For large d it is well known that classical methods are not feasible because of the curse of dimension, but it is by now also well known that Monte Carlo (MC) methods (see Boyle, Broadie, and Glasserman [2]) and quasi–Monte Carlo (QMC) methods (see Paskov and Traub [19]) can provide powerful tools for approximating such integrals. The MC estimate in its simplest form is

$$Q_{n,d}(f) = \frac{1}{n} \sum_{i=1}^{n} f(\mathbf{x}_i), \qquad \mathbf{x}_i \in [0,1]^d,$$

where the points $\mathbf{x}_1, \ldots, \mathbf{x}_n$ are independent and identically distributed (i.i.d.) random samples from the uniform distribution on $[0,1]^d$. The QMC methods take the same form, but now with $\mathbf{x}_1, \ldots, \mathbf{x}_n$ chosen deterministically, so as to yield better uniformity than the random samples.

The apparent success in the 1990s of QMC methods for some high-dimensional problems in finance (Paskov and Traub [19]) was a cause for surprise, given that the error bound given by the Koksma–Hlawka inequality (Niederreiter [14]) is of order $O(n^{-1}(\log n)^d)$ as n increases, which for large d increases with increasing n until we reach astronomically large values of n. Some other research also showed the high efficiency of QMC methods for high-dimensional integrals in finance (see Acworth, Broadie, and Glasserman [1], Joy, Boyle, and Tan [10], and Ninomiya and Tezuka [15]). Sparse grids may also have good performance for finance applications (see Gerstner and Griebel [4]). It is by now well accepted, following the work of Caflisch, Morokoff, and Owen [3], Imai and Tan [9], Owen [17], Paskov [18], and Wang and Fang [28], that the qualitative explanation lies in the fact that the [illegible] is small, even though the nominal dimension is very large. (Two notions of effective dimension, namely, the truncation and superposition dimensions, are defined precisely in section 2.)

The main purpose of this paper is to explore [illegible] the effective dimension is small for many integrals from finance. We do this by studying some simple model problems in finance and exploring what happens (as far as possible by analytic means) as the nominal dimension d approaches ∞. There are two main sources of the high dimensionality of d: one is time discretization (for example, a path-dependent option pricing model can be thought of as arising from discretization of an underlying continuous process), and the other is the existence of a large number of different assets or securities.

In the case of time discretization, the number of time steps (and hence the dimension) increases as the time step shortens, but the problem as it relates to a single time step becomes in a certain sense simpler. For a simplified option pricing situation (geometric Asian call option with zero strike price) we show that the superposition dimension actually has a limit as $d \to \infty$ (see Theorem 5.1). In this situation the high value of d becomes in a sense irrelevant. For nonzero but small strike prices the situation is little changed. For multiasset options the situation can be even more favorable, with the superposition dimension approaching 1 as $d \to \infty$ in the case of zero strike price. It is natural to ask whether the property of low superposition dimension is common for finance problems. We thus study one more problem, namely, the bond valuation (see Theorem 5.2). Since the main focus of this paper is directed towards the possible special properties of finance problems and the reasons for such properties, we limit ourselves to simple models where closed solutions may also exist.

Explaining the surprisingly good performance of QMC methods for some high-dimensional integrals is a challenging problem. A possible theoretical explanation is given in Sloan and Woźniakowski [22] by introducing [illegible] function classes, where the variables are given weights depending on their importance. A number of works have been devoted to studying the (strong) tractability of multivariate integration, as well as constructing algorithms that achieve the corresponding (strong) tractability error bounds (see Hickernell and Wang [7], Wang [27], and Sloan, Kuo, and Joe [20]).

This paper is organized as follows. After introducing the analysis of variance (ANOVA) decomposition and effective dimensions in section 2, we discuss the relationship of effective dimension to the integration error and perform a numerical experiment that illustrates the relationship. In section 3 we discuss methods to ana-

lyze the effective dimensions and variance ratios. In section 4, we consider the pricing of path-dependent and multiasset options and show numerically that these nominally high-dimensional problems are often low-dimensional in the sense that the functions are dominated by their lower-order ANOVA terms (usually just the order-1 and order-2 terms). In section 5 we come to the main results of the paper, where we investigate high-dimensional option pricing and bond valuation problems are often of low superposition dimension: we do this by identifying the inherent in the problems that control the relative importance of different (groups of) variables and by studying the variance ratios and their asymptotic properties (as $d \to \infty$). These weights often become smaller as the nominal dimension d increases, offsetting the increased inherent difficulty caused by the high dimensionality. The problems of nonsmoothness involved in the integrands are also discussed. Concluding remarks are presented in the last section.

2. The effective dimensions of functions.

2.1. The definitions of effective dimensions and variance ratios. Let $\mathcal{A} = \mathcal{A}_d = \{1, 2, \ldots, d\}$. For any subset $u \subseteq \mathcal{A}$, let $|u|$ denote its cardinality and let $\mathcal{A} - u$ denote its complementary set in $\mathcal{A}$. Consider a square-integrable function f defined on $[0,1]^d$. We say that the expansion

$$f(\mathbf{x}) = \sum_{u \subseteq \mathcal{A}} f_u(\mathbf{x}) \tag{1}$$

is an ANOVA decomposition of f if for each f_u with $\emptyset \neq u \subseteq \mathcal{A}$ the following is satisfied:

$$\int_0^1 f_u(\mathbf{x}) dx_j = 0 \ \text{ if } \ j \in u. \tag{2}$$

It is easy to show that $f_\emptyset = I_d(f)$ and that $f_u(\mathbf{x})$ can be determined recursively by

$$f_u(\mathbf{x}) = \int_{[0,1]^{d-|u|}} f(\mathbf{x}) d\mathbf{x}_{\mathcal{A}-u} - \sum_{v \subset u} f_v(\mathbf{x}) \quad \text{for} \quad \emptyset \neq u \subseteq \mathcal{A},$$

where the last sum is over strict subsets v of u. Each term f_u expresses the cooperative contribution of a distinct group of variables to f. It follows from (2) that the ANOVA decomposition (1) is orthogonal: $\int_{[0,1]^d} f_u(\mathbf{x}) f_v(\mathbf{x}) d\mathbf{x} = 0$ whenever $u \neq v$. Therefore,

$$\sigma^2(f) = \sum_{\emptyset \neq u \subseteq \mathcal{A}} \sigma_u^2(f),$$

where $\sigma^2(f) = I_d(f^2) - [I_d(f)]^2$ is the variance of f and $\sigma_u^2(f) = \int_{[0,1]^d} [f_u(\mathbf{x})]^2 d\mathbf{x}$ is the variance of f_u (for $|u| > 0$). The of the ANOVA term f_u is $|u|$, the cardinality of u.

Let u be a nonempty subset of $\mathcal{A}$. The variance corresponding to u and all its subsets is defined as

$$T_u(f) := \sum_{\emptyset \neq v \subseteq u} \sigma_v^2(f). \tag{3}$$

The function f has d_t (called the , or "TD" for short) if

$$T_{\{1,\ldots,d_t\}}(f) \geq p\, \sigma^2(f);$$

it has [illegible] d_s [illegible] (called the [illegible] , or "SD") if

$$\sum_{0<|u|\le d_s} \sigma_u^2(f) \ge p\,\sigma^2(f),$$

where p is a parameter close to 1. In this paper, we choose $p = 0.99$. The notion of effective dimension was introduced by Caflisch, Morokoff, and Owen [3]. The TD is roughly the number of important variables, if the variables are ordered by their importance. The SD does not depend on the order in which the variables are indexed and is the more useful concept when all variables are equally important (e.g., isotropic functions).

The effective dimension depends on p. To avoid this, we introduce two related notions that are independent of p. The [illegible] are defined as the ratios

$$S_u(f) = \sigma_u^2(f)/\sigma^2(f) \quad \text{for} \quad \emptyset \ne u \subseteq \mathcal{A},$$

which measure the relative importance of f_u (see Sobol [24]). The [illegible] captured by all order-ℓ ANOVA terms are defined as

$$R_{(\ell)}(f) = \sum_{|u|=\ell} \sigma_u^2(f)/\sigma^2(f) = \sum_{|u|=\ell} S_u(f),$$

which indicate the relative importance of all order-ℓ ANOVA terms taken together.

2.2. How does QMC error depend on effective dimension? The relation between QMC error and effective dimension can be understood in terms of variants of the Koksma–Hlawka inequality. The classical Koksma–Hlawka inequality (see Niederreiter [14]) is

$$|I_d(f) - Q_{n,d}(f)| < D^*_{n,d}(P_n)V(f),$$

where $P_n := \{\mathbf{x}_1, \ldots, \mathbf{x}_n\}$ is the set of QMC points, $V(f)$ is the variation of f in the sense of Hardy and Krause, and $D^*_{n,d}(P_n)$ is the [illegible] of P_n, which is a geometric measure of the departure from uniformity of P_n. It is the growth of the star discrepancy with n that is the source of the poor behavior when d is large, as mentioned in the introduction.

If f can be well approximated by just a few ANOVA terms, for example,

$$f \approx \sum_{|u|\le d_0,\, u\subseteq\mathcal{A}_d} f_u,$$

where $d_0 = 2$ or 3, then it would seem better to use an error bound of the form

$$|I_d(f) - Q_{n,d}(f)| \le \sum_{\phi\ne u\subseteq\mathcal{A}_d} D_u(P_n)\|f_u\|. \tag{4}$$

A bound of this form was developed by Hickernell [5, 6], with $\|f_u\|$, the norm of f_u in a certain $|u|$-dimensional Hilbert space, given there by

$$\|f_u\|^2 = \int_{[0,1]^{|u|}} \left|\frac{\partial^{|u|} f_u}{\partial x_u}(\mathbf{x}_u)\right|^2 d\mathbf{x}_u,$$

and $D_u(P_n)$ a positive number that depends only on the projection $P_{n,u}$ of P_n obtained by neglecting the components x_{ji} of each point $\mathbf{x}_i \in P_n$ for which $j \notin u$.

To see how QMC error depends on the effective dimension, consider two extreme cases. The first case is that f is a function of the form $f(\mathbf{x}) = \sum_{u \subseteq \{1,\dots,d_0\}} f_u(\mathbf{x})$ for some $d_0 < d$. From (4), the error $I_d(f) - Q_{n,d}(f)$ depends only on $D_u(P)$ with $u \subseteq \{1,\dots,d_0\}$. The second case is that f is a function such that $f(\mathbf{x}) = \sum_{|u| \le d_0} f_u(\mathbf{x})$ for some d_0. Based on (4), the error depends only on $D_u(P)$ with $|u| \le d_0$. For these extreme cases, if d_0 is small, good results can be expected by using QMC.

Of course, it will not usually happen that f is exactly low-dimensional as in the extreme cases, but it is often the case that f can be "close" to low-dimensional. Let

$$h(\mathbf{x}) := \sum_{u \subseteq \{1,\dots,d_0\}} f_u(\mathbf{x}) \quad \text{or} \quad h(\mathbf{x}) := \sum_{|u| \le d_0} f_u(\mathbf{x}),$$

where f_u are the ANOVA terms of f, and d_0 is small. Let $\rho := \sigma^2(h)/\sigma^2(f)$ be the variance ratio captured by h. Then, since $I_d(f-h) = 0$ and $f - h$ is orthogonal to h,

$$||f-h||_2^2 = \int_{[0,1]^d} [f(\mathbf{x}) - h(\mathbf{x})]^2 d\mathbf{x} = \sigma^2(f-h) = (1-\rho)\,\sigma^2(f).$$

If ρ is close to 1, then f can be well approximated in the L_2-norm by h. By splitting f into the sum of two parts, $f = h + (f-h)$, we have

$$|I_d(f) - Q_{n,d}(f)| \le |I_d(h) - Q_{n,d}(h)| + |I_d(f-h) - Q_{n,d}(f-h)|. \tag{5}$$

The analysis for the first term is the same as above. It is reasonable to assume that

$$|I_d(h) - Q_{n,d}(h)| \le a\,\sigma(h)/\sqrt{n} \quad \text{for some } a > 0.$$

The parameter a measures how large the QMC error for h is in comparison to the MC error for h. In general, a is small. In our experience, for common low discrepancy point sets and for n in the thousands, it is common that $a < 1/10$ or even $a < 1/100$.

Now consider the second term on the right-hand side of (5). Since

$$\mathbb{E}[|I_d(f-h) - Q_{n,d}^{\mathrm{MC}}(f-h)|^2] = \sigma^2(f-h)/n,$$

where $Q_{n,d}^{\mathrm{MC}}$ denotes a quadrature with random nodes $\mathbf{x}_1,\dots,\mathbf{x}_n$, Chebyshev's inequality yields

$$\lambda\left(\left\{(\mathbf{x}_1,\dots,\mathbf{x}_n) : |I_d(f-h) - Q_{n,d}^{\mathrm{MC}}(f-h)| \le b\,\sigma(f-h)/\sqrt{n}\right\}\right) \ge 1 - b^{-2}.$$

Here λ is the Lebesgue measure and b is an arbitrary positive number. For instance, with $b = 5$, the probability of the quadratures achieving

$$|I_d(f-h) - Q_{n,d}^{\mathrm{MC}}(f-h)| \le 5\,\sigma(f-h)/\sqrt{n}$$

is at least 0.96. Thus the error of an arbitrary realization of random quadratures would not be much worse than $\sigma(f-h)/\sqrt{n}$. Experience suggests that a QMC rule rarely gives a much worse result than MC. Suppose that for some $b > 0$,

$$|I_d(f-h) - Q_{n,d}(f-h)| \le b\,\sigma(f-h)/\sqrt{n}.$$

From the analysis above, we have

$$|I_d(f) - Q_{n,d}(f)| \le a\sigma(h)/\sqrt{n} + b\sigma(f-h)/\sqrt{n} = \left(a\sqrt{\rho} + b\sqrt{1-\rho}\right)\,\sigma(f)/\sqrt{n}.$$

As a benchmark, we recall that the root mean square of the MC error is $\sigma(f)/\sqrt{n}$. Thus the relative QMC error with respect to MC error depends on the following:

- How well does QMC work for h or $f-h$ with respect to MC? This is characterized by a or b, respectively.
- How well can f be approximated in the L_2-norm by h (or how small is the variance of $f-h$ with respect to that of f)? This is measured by ρ.

To get a feeling of the QMC error with comparing to MC error, consider two cases:

- Normal case: $a=1/100$, $b=1$, $\rho=0.99$; then $|I_d(f)-Q_{n,d}(f)|\le 0.110\,\sigma(f)/\sqrt{n}$.
- Optimistic case: $a=1/1000$, $b=1$, $\rho=0.999$; then $|I_d(f)-Q_{n,d}(f)|\le 0.003\sigma(f)/\sqrt{n}$.

Effective dimensions can be viewed as measures of how well f can be approximated by a sum of lower-dimensional functions. For example, let $h(\mathbf{x}) := \sum_{|u|\le d_s} f_u(\mathbf{x})$, where d_s is the SD; then by definition

$$||f-h||_2^2 \le (1-p)\sigma^2(f) = 0.01\sigma^2(f).$$

If d_s is small (say, $d_s \le 2$), then even if the TD d_t is large, we have good reason to expect superiority of QMC over MC.

It is useful to perform an experiment to see how the QMC error depends on effective dimensions. Consider the functions

$$f(\mathbf{x}) = \prod_{j=1}^{d} \left(1 + a\tau^j\,(x_j - 1/2)\right), \tag{6}$$

where a and τ are parameters which control the effective dimension (a mainly controls the SD, while τ mainly controls the TD). Obviously, $I_d(f)=1$ for all a,τ, and d. The effective dimensions can be easily determined by the method of Wang and Fang [28]. Table 1 presents the effective dimensions and the root mean square errors (RMSEs) of MC and QMC in dimension $d=50$. In MC, the RMSE is computed as $\sigma(f)/\sqrt{n}$. In QMC, the sequence of Sobol [23] is used and the RMSE is computed based on 30 random shifts. The ratios of the RMSE of QMC with respect to that of MC are also given. The dependence of the QMC error on the effective dimensions is clear from the comparisons. In summary, the superiority of QMC is observed for two classes of functions:

- The class of functions with small TD (see the columns with $\tau=0.1$ and $\tau=0.5$ in Table 1). The efficiency of QMC for this class of functions is especially high.
- The class of functions with small SD (especially if the order-1 part plays the major role). In this case the TD can be large (see the row with $a=0.1$ in Table 1). Note that when $\tau=1$, the function f depends equally on the variables, but different orders of ANOVA terms may have quite different contribution to f.

We do not observe the superiority of QMC if both the TD and SD are large (say, $d_t>30$ and $d_s>5$). In fact, in such cases (see the case of $a=10$ and $\tau=1$), both MC and QMC may give unreasonable results (this can be explained by the large variance: $\sigma^2(f)\approx 3.18\times 10^{48}$ for $a=10,\tau=1$, and $d=50$). There is no sense in comparing their RMSEs in this case. Note that it is shown in Owen [16] that low SD is necessary for QMC to be much better than MC with practical sample size n.

3. Computing the effective dimensions.

3.1. Estimating the effective dimensions and variance ratios. In some specific cases, simple formulas are available for computing the effective dimensions

TABLE 1

The TD and SD (d_t, d_s), the RMSE for function (6) in dimension $d = 50, n = 2^{14}$. The ratios of the RMSE of QMC with respect to the RMSE of MC are in the parentheses.

		$\tau = 0.1$	$\tau = 0.5$	$\tau = 0.8$	$\tau = 0.9$	$\tau = 1$

		(0.009)	(0.073)	(0.891)	(0.769)	− − −

and variance ratios, but in the general case numerical algorithms have to be used. A numerical algorithm to determine the TD of an arbitrary function is given in Wang and Fang [28]. For any fixed set $u \subseteq \mathcal{A}$, write $\mathbf{x} = (\mathbf{x}_u, \mathbf{x}_{\mathcal{A}-u})$ and $\mathbf{y} = (\mathbf{y}_u, \mathbf{y}_{\mathcal{A}-u})$. The variance corresponding to u and all its subsets defined in (3) can be expressed as (see Sobol [24])

$$T_u(f) = \int_{[0,1]^{2d-|u|}} f(\mathbf{x}) f(\mathbf{x}_u, \mathbf{y}_{\mathcal{A}-u}) d\mathbf{x} d\mathbf{y}_{\mathcal{A}-u} - [I_d(f)]^2. \tag{7}$$

The TD can be determined by computing $T_u(f)$ with $u = \{1, \dots, \ell\}$ for $\ell = 1, 2, \dots$.

Determining the SD of an arbitrary function is much more difficult, since we have to compute all the variances $\sigma_u^2(f)$ for subsets u up to some order. In principle, this can be done as follows. For $|u| = 1$, $\sigma_u^2(f) = T_u(f)$, so it can be computed directly by (7). For $|u| = 2$ and, say, $u = \{i, j\}$, $\sigma_{\{i,j\}}^2(f)$ can be estimated from

$$T_{\{i,j\}}(f) = \sigma_{\{i\}}^2(f) + \sigma_{\{j\}}^2(f) + \sigma_{\{i,j\}}^2(f),$$

where $T_{\{i,j\}}(f)$ can be computed by (7). Continuing this process, all the variances $\sigma_u^2(f)$ for subsets u up to some order can be computed. For large d, such an approach is computationally expensive. Moreover, for large $|u|$ (say, $|u| \geq 3$) there is often a loss of accuracy. If f is a symmetric function, the computation can be simplified, since now $\sigma_u^2(f)$ depends on u only through $|u|$.

For large d, one strategy to verify whether a function has low SD is to compute the variance ratios of low-order ANOVA terms, such as the order-1 and order-2 terms. An alternative is to compute the mean dimension in the superposition sense (see Owen [17] and Liu and Owen [11]).

3.2. A special class of functions. Computing $T_u(f)$ is an important step in determining both the TD and SD. The dimension of the resulting integrals for $T_u(f)$ can be very large. We show that such integrals can be reduced to three-dimensional integrals in some cases. In fact, some finance problems are related to the computations of integrals of the form (see the next section for examples)

$$J := \int_{\mathbb{R}^d} \max(0,\ e^{F(\mathbf{z})} - K) p_d(\mathbf{z}) d\mathbf{z} \quad \text{with} \quad F(\mathbf{z}) = \sum_{j=1}^{d} a_j z_j, \tag{8}$$

where a_j, K are constants and

$$p_d(\mathbf{z}) = (2\pi)^{-d/2} \exp\left(-\frac{1}{2}\sum_{j=1}^{d} z_j^2\right) \tag{9}$$

is the density of the standard normal distribution. The integral (8) can be written as a d-dimensional integral over the unit cube $[0,1]^d$:

$$J = \int_{[0,1]^d} f(\mathbf{x})d\mathbf{x} \text{ with } f(\mathbf{x}) = \max(0,\ \exp(F(\Phi^{-1}(x_1), \ldots, \Phi^{-1}(x_d))) - K),$$

where $\Phi(x) := \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{x} e^{-t^2/2} dt$ is the normal probability integral and Φ^{-1} is its inverse.

The integral (8) can be reduced to a one-dimensional integral, thereby allowing a useful test of the efficiency of d-dimensional QMC algorithms for such integrals. For the vector $\mathbf{z} = (z_1, \ldots, z_d)^T$ with the density function $p_d(\mathbf{z})$, the variable $\sum_{j=1}^{d} a_j z_j$ is a normal random variable with mean zero and variance $b^2 := \sum_{j=1}^{d} a_j^2$. Put $w := b^{-1} \sum_{j=1}^{d} a_j z_j$, so that w is a standard normal random variable. Then we can write

$$J = \int_{-\infty}^{\infty} \max(0,\ e^{bw} - K) p_1(w) dw = \int_0^1 \max(0, e^{b\Phi^{-1}(x)} - K) dx.$$

A similar method can be used to transform the integral involved in $T_u(f)$ (see (7)). Indeed, for any given nonempty set $u \subseteq \mathcal{A}$, put $b_u^2 := \sum_{j \in u} a_j^2$. According to Sobol's formula (7), we have

$$T_u(f) + [I_d(f)]^2 = \int_0^1 \int_0^1 \int_0^1 F^u(x,y) F^u(x,z) dx dy dz,$$

where

$$F^u(x,y) = \max(0,\ \exp[b_u \Phi^{-1}(x) + b_{\mathcal{A}-u} \Phi^{-1}(y)] - K).$$

Thus the integrals involved in $T_u(f)$ can be reduced to three-dimensional integrals. This reduces the computational cost significantly. This method will be used in the next section.

4. High-dimensional finance problems are often of low effective dimension. In this section we investigate empirically the nature of option pricing problems by estimating the SD. The TD for these problems has been computed in Wang and Fang [28]. It turned out that the TD is almost as large as the nominal dimension d (if the Brownian motion is generated by the standard method), and thus the success of QMC in this case cannot be explained by a small TD.

4.1. Path-dependent options. Consider the pricing of a path-dependent option with payoff $g(S_{t_1}, \ldots, S_{t_d})$, where $S_{t_1}, \ldots, S_{t_d}$ are the prices of the underlying asset at times $t_1, \ldots, t_d$. Suppose the prices are sampled at equally spaced times $t_0 = 0, t_j = t_{j-1} + \Delta t, j = 1, \ldots, d, \Delta t = T/d$, where T is the expiration date. For simplicity of presentation, assume that under [illegible] (i.e., [illegible]) the underlying asset follows geometric Brownian motion:

$$dS_t = rS_t dt + \sigma S_t dB_t, \tag{10}$$

where r is the risk-free interest rate, σ is the volatility, and B_t is the standard Brownian motion. The analytical solution to (10) is

$$S_t = S_0 \exp((r - \sigma^2/2)t + \sigma B_t). \tag{11}$$

Based on the risk-neutral valuation (see Hull [8]), the value of the option at $t = 0$ is

$$\mathbb{E}[e^{-rT} g(S_{t_1}, \ldots, S_{t_d})],$$

where $\mathbb{E}[\cdot]$ is the expectation under the risk-neutral measure.

Let $(y_1, \ldots, y_d)^T := (B_{t_1}, \ldots, B_{t_d})^T$. It is normally distributed with mean zero and covariance matrix $V = (\min(t_i, t_j))_{i,j=1}^d$. Defining $\mu_j = \log S_0 + (r - \sigma^2/2)t_j$, from (11) we have $S_{t_j} = \exp(\mu_j + \sigma y_j)$. The payoff can be written as

$$g(S_{t_1}, \ldots, S_{t_d}) = g(e^{\mu_1 + \sigma y_1}, \ldots, e^{\mu_d + \sigma y_d}) =: H(\mathbf{y}).$$

The value of the option at time $t = 0$ can then be written as

$$\begin{aligned} \mathbb{E}[e^{-rT} g(S_{t_1}, \ldots, S_{t_d})] &= \frac{e^{-rT}}{(2\pi)^{d/2}\sqrt{\det V}} \int_{\mathbb{R}^d} H(\mathbf{y}) e^{-\frac{1}{2}\mathbf{y}^T V^{-1}\mathbf{y}} d\mathbf{y} \\ &= e^{-rT} \int_{\mathbb{R}^d} H(A\mathbf{z}) p_d(\mathbf{z}) d\mathbf{z}, \end{aligned}$$

where a linear transformation $(y_1, \ldots, y_d)^T = A(z_1, \ldots, z_d)^T$ is introduced using an arbitrary $d \times d$ matrix A satisfying $AA^T = V$. This change of variables can be interpreted as a covariance matrix decomposition $V = AA^T$ or as a generation of the Brownian motion:

$$(B_{t_1}, \ldots, B_{t_d})^T = A(z_1, \ldots, z_d)^T, \tag{12}$$

where $z_j \sim N(0,1), j = 1, \ldots, d$, are i.i.d. standard normal variables. The [illegible] (or [illegible]) generates the Brownian motion sequentially in time:

$$B_0 = 0, \;\; B_{t_j} = B_{t_{j-1}} + \sqrt{\Delta t}\, z_j, \;\; z_j \sim N(0,1), \quad j = 1, \ldots, d. \tag{13}$$

Consider Asian call options based on the geometric or arithmetic average of the underlying asset. Their terminal payoffs are, respectively, $\max(0, \prod_{j=1}^d S_{t_j}^{1/d} - K)$ or $\max(0, \frac{1}{d}\sum_{j=1}^d S_{t_j} - K)$, where K is the strike price at T. For the geometric average, we have

$$\prod_{j=1}^d S_{t_j}^{1/d} = \exp\left(m + \frac{\sigma}{d}\sum_{j=1}^d y_j\right) = \exp\left(m + \frac{\sigma}{d}\sum_{k=1}^d A_k z_k\right),$$

where $A_k = \sum_{j=1}^d a_{jk}$, with a_{jk} the elements of A, and

$$m := m_d = \frac{1}{d}\sum_{j=1}^d \mu_j = \log S_0 + \frac{1}{2}\left(r - \frac{\sigma^2}{2}\right)(T + \Delta t). \tag{14}$$

Thus for the geometric average case the resulting integral $\mathbb{E}[e^{-rT} g(S_{t_1}, \ldots, S_{t_d})]$ has the special form (8), excluding a constant factor. The computation of the variance ratios can be significantly simplified, as shown in section 3.2.

TABLE 2

The variance ratios (in percentage) captured by order-1 and order-2 ANOVA terms for geometric Asian options: $S_0 = 100$, $\sigma = 0.2$, $r = 0.1$, $T = 1$ year.

Dimension	$K = 90$		$K = 100$		$K = 110$	
	order-1	order-2	order-1	order-2	order-1	order-2
8	95.58	4.00	85.00	13.74	65.79	29.93
16	95.38	4.40	83.20	15.60	60.76	33.99
32	95.26	4.78	82.22	17.81	57.99	37.71
64	95.12	5.05	81.63	19.40	56.46	40.38

TABLE 3

The same as Table 2, but for arithmetic Asian options, look-back options, and barrier options ($B_a = K - 10$). Look-back options do not depend on the strike price.

Options	Dimension	$K = 90$		$K = 100$		$K = 110$	
		order-1	order-2	order-1	order-2	order-1	order-2
Arithmetic Asian option	4	96.16	3.56	88.52	10.67	74.89	22.90
	8	95.12	4.99	84.53	16.12	65.02	35.17
	16	94.71	5.10	82.22	17.30	60.10	38.42
Look-back option	4	92.68	6.12	92.68	6.12	92.68	6.12
	8	89.49	6.59	89.49	6.59	89.49	6.59
	16	88.56	7.21	88.56	7.21	88.56	7.21
Barrier option	4	92.70	6.17	81.09	16.49	60.94	32.97
	8	91.90	4.87	76.61	19.38	47.94	41.49
	16	90.75	4.04	74.31	21.56	46.37	43.72

We will also consider other path-dependent options look-back and barrier options. For a European look-back call option, the payoff is $g(S_{t_1}, \ldots, S_{t_d}) = S_T - \min\{S_{t_1}, \ldots, S_{t_d}\}$. For a European down-and-out call option, the payoff is (with barrier B_a)

$$g(S_{t_1}, \ldots, S_{t_d}) = \begin{cases} \max(0,\ S_T - K) & \text{if, for all } j = 1, \ldots, d, S_{t_j} > B_a, \\ 0 & \text{if, for some } j = 1, \ldots, d, S_{t_j} \le B_a. \end{cases}$$

In our investigations the Brownian motion is generated by the standard construction (13). All integrals involved in the computations of the variance ratios are approximated by QMC based on Sobol points with $n = 2^{18}$. In Tables 2 and 3 we present the computational results for the variance ratios captured by order-1 and order-2 ANOVA terms. (Due to integration and rounding errors, in some cases $100R_{(1)}(f) + 100R_{(2)}(f) > 100$.) For geometric Asian options (Table 2), we observe that for $K = 90$ and $K = 100$ the order-1 and order-2 terms capture more than 99% of the total variance; for $K = 110$, the percentage is more than 94%. The strike price K has some effects on the variance ratios: when K increases, $R_{(1)}(f)$ decreases, while $R_{(2)}(f)$ increases; however, their sum is always close to 1.

The computations of the variance ratios for the other options are more difficult, since the method in section 3.2 cannot be used. We have to use the method in section 3.1 and must restrict the value of d. We observe a similar phenomenon for these options (Table 3).

4.2. Multiasset options. Consider a European multiasset derivative with terminal payoff $\phi(S_T^1, \ldots, S_T^d)$, where $S_T^1, \ldots, S_T^d$ are the prices of d risky assets at time T. Assume that in a risk-neutral measure the prices $(S_t^1, \ldots, S_t^d)$ of the assets satisfy

$$dS_t^j = rS_t^j dt + \sigma_j S_t^j dB_t^j, \quad j = 1, \ldots, d,$$

where σ_j are volatilities and $B_t^1, \ldots, B_t^d$ are correlated Brownian motions with correlations ρ_{ij}. The solutions to the stochastic differential equations are given by

$$S_t^j = S_0^j \exp((r - \sigma_j^2/2)t + \sigma_j B_t^j), \quad j = 1, \ldots, d. \tag{15}$$

Note that the random vector $(B_T^1, \ldots, B_T^d)^T =: (y_1, \ldots, y_d)^T$ is normally distributed with mean zero and covariance matrix

$$\Sigma = (\rho_{ij} T)_{i,j=1}^d. \tag{16}$$

Put $\nu_j := \log S_0^j + (r - \frac{1}{2}\sigma_j^2)T$. Since $S_T^j = e^{\nu_j + \sigma_j y_j}$, the payoff can be written as $\phi(S_T^1, \ldots, S_T^d) = \phi(e^{\nu_1 + \sigma_1 y_1}, \ldots, e^{\nu_d + \sigma_d y_d}) =: G(\mathbf{y})$. Therefore, the current price of the derivative security can be expressed as

$$\mathbb{E}[e^{-rT}\phi(S_T^1, \ldots, S_T^d)] = e^{-rT} \int_{\mathbb{R}^d} G(A\mathbf{z}) p_d(\mathbf{z}) d\mathbf{z},$$

where A is any real $d \times d$ matrix satisfying $AA^T = \Sigma$. This matrix A corresponds to a method of generating the correlated Brownian motions:

$$(B_T^1, \ldots, B_T^d)^T = A\,(z_1, \ldots, z_d)^T.$$

The standard method corresponds to the Cholesky decomposition of the matrix $\Sigma = AA^T$. This is the choice we use for our analysis and numerical computations.

For a European call option on the geometric average over the d assets, we have

$$\phi(S_T^1, \ldots, S_T^d) = \max\left(0,\ \exp\left(\frac{1}{d}\sum_{j=1}^d (\nu_j + \sigma_j y_j)\right) - K\right). \tag{17}$$

Just the same as for the geometric Asian option, the corresponding integral also has the special form (8), allowing a faster computation of the variance ratios. For a call option on the arithmetic average over the d assets, the payoff is $\phi(S_T^1, \ldots, S_T^d) = \max(0,\ \frac{1}{d}\sum_{j=1}^d S_T^j - K)$.

In Tables 4 and 5 we present the computational results. The conclusion is similar to the cases of path-dependent options. For $K = 90$ and $K = 100$, the order-1 and order-2 terms capture over 99% of the total variance; for $K = 110$, the percentage is larger than 97%. A new feature is that as the nominal dimension increases, the sum of the variance ratios of the order-1 and order-2 terms may increase (for example, for the cases of $K = 90$ and 100). We also observe that regarding the variance ratios, there is not much difference between the geometric and arithmetic Asian options (though their analytical tractability is different).

5. Why are high-dimensional finance problems often of low effective dimension? Very high-dimensional problems often occur in finance because of small time increments and/or a large number of assets or other state variables. In the previous section we found numerically that these nominally high-dimensional problems are often of low SD (even if dimension reduction techniques are not used). Here we try to investigate theoretically the reason for this phenomenon, i.e., why the effective dimension is small. It is important to know what controls the complexity of the problems, and how the quantities relating to dimension (e.g., variance ratios and effective dimensions) change as the number of time steps and/or the number of risky

TABLE 4
The variance ratios (in percentage) captured by the order-1 and order-2 ANOVA terms for geometric multiasset options: $S_0^j = 100, \sigma_j = 0.2, \rho_{ij} = 0.3 (i \neq j), r = 0.1, T = 1$.

Dimension	$K = 90$		$K = 100$		$K = 110$	
	order-1	order-2	order-1	order-2	order-1	order-2
8	97.34	2.45	90.03	9.11	74.38	23.07
16	97.63	2.51	90.13	9.23	72.84	24.68
32	97.74	2.80	90.22	9.43	72.04	26.82
64	97.72	2.22	90.22	9.71	71.56	28.60

TABLE 5
The same as Table 4, but for arithmetic multiasset options.

Dimension	$K = 90$		$K = 100$		$K = 110$	
	order-1	order-2	order-1	order-2	order-1	order-2
4	98.19	1.36	92.96	5.95	81.94	16.11
8	97.52	3.36	91.91	7.99	77.62	22.19
16	97.23	3.64	91.12	8.63	75.57	23.38

assets increases (or even tends to infinity). We also explore how the model parameters affect the dimension structure of the integrands. We consider not only option pricing problems but also bond valuation problems. Note that our purpose is not to solve the pricing or valuation problems themselves under complicated models. We are trying to understand the reason for the special property (e.g., low SD) under simplified models or situations where closed solutions may also exist.

5.1. Option pricing. Consider first the case of a geometric Asian option. In the standard construction of Brownian motion (13), the generating matrix A in (12) is just the [illegible] of the covariance matrix $V = (\min(t_i, t_j))_{i,j=1}^d$:

$$A = \sqrt{\Delta t} \begin{pmatrix} 1 & 0 & \cdots & 0 \\ 1 & 1 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 1 & 1 & \cdots & 1 \end{pmatrix}.$$

Let A_j be the sum of the jth column of A. From the discussion in section 4.1 the price of the geometric Asian call option can be written as

$$e^{-rT} \int_{[0,1]^d} \max \left(0,\ \exp \left(m + \sum_{j=1}^{d} a_j \Phi^{-1}(x_j) \right) - K \right) d\mathbf{x}, \tag{18}$$

where

$$a_j = \frac{\sigma}{d} A_j = \frac{d-j+1}{d}\, \sigma \sqrt{\Delta t} = \frac{d-j+1}{d\sqrt{d}}\, \sigma \sqrt{T}, \quad j = 1, \ldots, d. \tag{19}$$

For a given T, the nominal dimension d is inversely proportional to the time step Δt (since $d = T/\Delta t$): the smaller the time step Δt, the larger the dimension d. The integrand in (18) depends on the parameters a_j (the "weights"), which in turn depend on the time step Δt: as Δt becomes smaller, the weights a_j decrease (the weights also depend on the model parameters σ and T). We shall show that these weights control the relative importance of different (groups of) variables and play an essential role

in characterizing the complexity of the problem. These weights are not introduced artificially, but are determined by the nature of the problem and by the generation of the Brownian motion. The weights are small when the step length Δt is small, i.e., when the dimension d is large.

To see the potential influence of the parameters a_j, it is convenient to consider first the extreme case $K = 0$. The general case $K \neq 0$ will be studied in the next subsection. For $K = 0$, the integrand in (18) can be written as (excluding a constant factor)

$$f(\mathbf{x}) := \prod_{j=1}^{d} g_j(x_j) \quad \text{with} \quad g_j(x_j) = \exp\left(a_j \Phi^{-1}(x_j)\right). \tag{20}$$

(An arbitrary construction of Brownian motion (12) leads to the same form of function, but with different parameters a_j.) By direct calculation we then have

$$m_j := \int_0^1 g_j(x)dx = e^{\frac{1}{2}a_j^2} \quad \text{and} \quad \lambda_j^2 := \int_0^1 (g_j(x) - m_j)^2 dx = e^{a_j^2}(e^{a_j^2} - 1).$$

It follows that $I_d(f) = \prod_{j=1}^d m_j$ and

$$\sigma^2(f) = \prod_{j=1}^{d} \left(m_j^2 + \lambda_j^2\right) - \prod_{j=1}^{d} m_j^2 = [I_d(f)]^2 \left(e^{\sum_{j=1}^d a_j^2} - 1\right). \tag{21}$$

The ANOVA terms of f and the corresponding variances (for $u \neq \emptyset$) are

$$f_u = \prod_{j \in u} (g_j(x_j) - m_j) \cdot \prod_{j \notin u} m_j,$$

and

$$\sigma_u^2(f) = \prod_{j \in u} \lambda_j^2 \prod_{j \notin u} m_j^2 = [I_d(f)]^2 \prod_{j \in u} \left(e^{a_j^2} - 1\right). \tag{22}$$

The relative importance of the term f_u to f can be measured by the sensitivity index,

$$S_u(f) = \frac{\sigma_u^2(f)}{\sigma^2(f)} = \frac{\prod_{j \in u} \left(e^{a_j^2} - 1\right)}{e^{\sum_{j=1}^d a_j^2} - 1},$$

indicating how the parameters a_j control the relative importance of different variables. The relative importance of all order-ℓ ANOVA terms can be measured by the variance ratio (see section 2.1):

$$R_{(\ell)}(f) = \frac{\sum_{|u|=\ell} \sigma_u^2(f)}{\sigma^2(f)} = \frac{\sum_{|u|=\ell} \prod_{j \in u} \left(e^{a_j^2} - 1\right)}{e^{\sum_{j=1}^d a_j^2} - 1}. \tag{23}$$

Before studying the relative size of $R_{(\ell)}(f)$ and their asymptotic properties as $d \to \infty$, we mention several important features of the parameters a_j given in (19). First, from (19) we have, for fixed T,

$$a_j = O(\sqrt{\Delta t}) = O(d^{-1/2}) \ \text{ as } \ \Delta t \to 0, \ \ j = 1, 2, \ldots. \tag{24}$$

It follows that

$$e^{a_j^2} - 1 = a_j^2 + a_j^4/2 + \cdots = a_j^2 + O(d^{-2}). \tag{25}$$

Second, according to (19),

$$\sum_{j=1}^{d} a_j^2 = \frac{\sigma^2 \Delta t}{d^2} \sum_{j=1}^{d} j^2 = \frac{\sigma^2 T}{3} + O(\Delta t). \tag{26}$$

Therefore, $\Gamma := \lim_{d\to\infty} \sum_{j=1}^{d} a_j^2 = \frac{\sigma^2 T}{3}$. Based on these properties, we see from (21) that the variance of f is stable with respect to d, $\lim_{d\to\infty} \sigma^2(f) = e^{\Gamma}(e^{\Gamma} - 1)$, implying that the nominal dimension becomes in a sense irrelevant at least for MC. Moreover, from (25) we have $e^{a_j^2} - 1 = O(\Delta t)$. Therefore, from (22) we have, for $\ell = 1, 2, \ldots,$

$$\sigma_u^2(f) = O((\Delta t)^{\ell}) = O(d^{-\ell}) \ \text{ for } \ |u| = \ell.$$

This means that a small time step Δt leads to effects that are increasingly dominated by the lower-order terms.

We are particularly interested in the variance ratios captured by low-order ANOVA terms and their asymptotic properties. The variance ratio captured by order-1 terms is

$$\begin{aligned} R_{(1)}(f) = \frac{\sum_{j=1}^{d} \sigma_{\{j\}}^2(f)}{\sigma^2(f)} &= \frac{\sum_{j=1}^{d} (e^{a_j^2} - 1)}{e^{\sum_{j=1}^{d} a_j^2} - 1} \\ &= \frac{\sum_{j=1}^{d} a_j^2 + O(\Delta t)}{e^{\sum_{j=1}^{d} a_j^2} - 1} = \frac{\Gamma}{e^{\Gamma} - 1} + O(\Delta t), \end{aligned} \tag{27}$$

where we have used the relations (25) and (26). The leading term is close to 1 for usual values of the volatility σ and T (see Table 6). Similarly, the variance ratio captured by order-2 ANOVA terms is

$$\begin{aligned} R_{(2)}(f) = \frac{\sum_{i<j} \sigma_{\{i,j\}}^2(f)}{\sigma^2(f)} &= \frac{\sum_{i<j} (e^{a_i^2} - 1)(e^{a_j^2} - 1)}{e^{\sum_{j=1}^{d} a_j^2} - 1} \\ &= \frac{\sum_{i<j} (a_i^2 + O(d^{-2}))\ (a_j^2 + O(d^{-2}))}{e^{\sum_{j=1}^{d} a_j^2} - 1} \\ &= \frac{\frac{1}{2} \sum_{i=1}^{d} a_i^2 \ \sum_{j=1}^{d} a_j^2 - \frac{1}{2} \sum_{j=1}^{d} a_j^4 + O(\Delta t)}{e^{\sum_{j=1}^{d} a_j^2} - 1} \\ &= \frac{\Gamma^2/2}{e^{\Gamma} - 1} + O(\Delta t). \end{aligned}$$

The leading term is smaller than that for $R_{(1)}(f)$ for usual values of σ and T. In general, for any fixed $\ell = 1, 2, \ldots,$ a simple formula exists for $\lim_{d\to\infty} R_{(\ell)}(f)$.

THEOREM 5.1. [illegible] $f_d(\mathbf{x}) := f(\mathbf{x})$ [illegible] (20) [illegible] a_j [illegible] (19) [illegible]

$$\Gamma := \lim_{d\to\infty} \sum_{j=1}^{d} a_j^2 = \sigma^2 T/3.$$

$\ell = 1, 2, \ldots,$

$$\lim_{d\to\infty} R_{(\ell)}(f_d) = \lim_{d\to\infty} \frac{\sum_{i_1<i_2<\cdots<i_\ell} \prod_{k=1}^{\ell} \left(e^{a_{i_k}^2} - 1\right)}{e^{\sum_{j=1}^{d} a_j^2} - 1} = \frac{\Gamma^\ell/\ell!}{(e^\Gamma - 1)}.$$

The easy proof is analogous to that for $R_{(2)}(f)$ above and is based on the special properties (24)–(26) of the parameters a_j. Note that the numerator in the formula for $\lim_{d\to\infty} R_{(\ell)}(f_d)$ is just the ℓth term of the Taylor expansion of $e^\Gamma - 1$:

$$e^\Gamma - 1 = \sum_{\ell=1}^{\infty} \frac{\Gamma^\ell}{\ell!}.$$

The asymptotics above also show how the model parameters affect the variance ratios: the variance ratios depend on σ and T through $\sigma^2 T$. The quantity $\sigma^2 T$ is typically small for real option pricing problems (in the range, say, $0.01 \sim 0.2$), so $R_{(1)}(f)$ is close to 1, $R_{(2)}(f)$ is small, and all higher-order variance ratios $R_{(\ell)}(f)$ for $\ell > 2$ are very small. Therefore, the functions are dominated by order-1 and order-2 terms (especially the order-1 terms). As the volatility increases and/or as the time to expiration lengthens, $R_{(1)}(f)$ decreases slightly, while others increase. Numerical comparisons of the limiting variance ratios make their relative size clear. For example, for $\sigma = 0.2, T = 1$, the values of $\lim_{d\to\infty} R_{(\ell)}(f)$ are $9.933\times10^{-1}, 6.622\times10^{-3}, 2.943\times10^{-5}$, and 9.811×10^{-8} for $\ell = 1, \ldots, 4$, respectively.

1. If we change the value of the volatility to $\sigma = 10$, which is unrealistic but of academic interest, then Theorem 5.1 is still true. However, the order-1 and order-2 terms no longer dominate the functions. In fact, for $\sigma = 10$ and $T = 1$, $\lim_{d\to\infty} R_{(1)}(f_d) = 1.113\times10^{-13}$ and $\lim_{d\to\infty} R_{(2)}(f_d) = 1.855\times10^{-12}$. Fortunately, for finance problems, σ is often between 0.1 and 0.5. This is one reason for the low SD of real finance problems.

2. Consider an arbitrary construction of Brownian motion (12), i.e., a decomposition for the covariance matrix V. Let A_j be the sum of the jth column of the associated matrix A and let $a_j = \frac{\sigma}{d} A_j$. The quantity $\sum_{j=1}^{d} a_j^2$ is independent of the construction, since it is the variance of $\log(\prod_{j=1}^{d} S_{t_j}^{1/d})$ and must be the same for all constructions, and so is the limit $\Gamma := \lim_{d\to\infty} \sum_{j=1}^{d} a_j^2 = \sigma^2 T/3$. Under any construction the variance ratio captured by order-1 terms for the corresponding function f as in (20) becomes

$$R_{(1)}(f) = \frac{\sum_{j=1}^{d}(e^{a_j^2} - 1)}{e^{\sum_{j=1}^{d} a_j^2} - 1} = \frac{\sum_{j=1}^{d} a_j^2 + \frac{1}{2}\sum_{j=1}^{d} a_j^4 + \cdots}{e^{\sum_{j=1}^{d} a_j^2} - 1} \ge \frac{\Gamma}{e^\Gamma - 1} + O(\Delta t). \tag{28}$$

Thus any construction leads asymptotically to no smaller variance ratio $R_{(1)}(f)$ (or no weaker property of the function f) than the standard construction does; see (27).

Now consider the arithmetic Asian option. With $K = 0$, the payoff function is

$$g_A(S_{t_1}, \ldots, S_{t_d}) = \frac{1}{d}\sum_{j=1}^{d} S_{t_j}.$$

Under the standard construction of the Brownian motion (13), from (11) we have

$$S_{t_j} = \exp\left(\mu_j + \sigma\sqrt{\Delta t}(\Phi^{-1}(x_1) + \cdots + \Phi^{-1}(x_j))\right) =: e^{\mu_j} F_j(\mathbf{x}),$$

with $x_1, \ldots, x_d$ being i.i.d. uniformly distributed random variables on $[0,1]$. Thus the function g_A is the arithmetic mean of some functions of the form (20), excluding constant factors:

$$g_A(S_{t_1}, \ldots, S_{t_d}) = \frac{1}{d} \sum_{j=1}^{d} e^{\mu_j} F_j(\mathbf{x}).$$

Take the function $F_d(\mathbf{x})$ as an example:

$$F_d(\mathbf{x}) = \exp\left(\sigma\sqrt{\Delta t}(\Phi^{-1}(x_1) + \cdots + \Phi^{-1}(x_d))\right).$$

Such a function has exactly the same form as (20), but with different weights:

$$a_j = \sigma\sqrt{\Delta t} = O(\sqrt{\Delta t}) \ \text{ as } \ \Delta t \to 0, \ \ j = 1, \ldots, d. \tag{29}$$

The time step Δt enters to the parameters a_j in a similar way to that seen earlier. Moreover, in this case $\Gamma := \lim_{d\to\infty} \sum_{j=1}^{d} a_j^2 = \sigma^2 T$. With this Γ, Theorem 5.1 is still valid, and thus we have similar conclusions to those above: the variance ratio captured by order-ℓ ANOVA terms satisfies

$$\lim_{d\to\infty} R_{(\ell)}(F_d) = \frac{\Gamma^\ell/\ell!}{(e^\Gamma - 1)}.$$

Again, the lower-order terms capture most of the variance. The comparisons are given in Table 6.

For the multiasset options studied in subsection 4.2 the source of the high dimensionality is different: now the dimensionality comes from the number of risky assets rather than from time discretization. Since our main purpose is to see how the number of risky assets affects the integrand, we restrict ourselves to the case that $\rho_{ij} = 0$ for $i \neq j$ (choosing a high degree of correlation would be similar to reducing the dimension of the problem). Consider the geometric multiasset option. The Cholesky matrix of the covariance matrix in (16) is $A = \sqrt{T}\ \mathbf{I}$, where $\mathbf{I}$ is the $d \times d$ identity matrix; thus $B_T^j = \sqrt{T}\ \Phi^{-1}(x_j)$. From (15) we have

$$S_T^j = S_0^j \exp\left(\left(r - \frac{1}{2}\sigma_j^2\right) T + \sigma_j B_T^j\right) = S_0^j \exp\left(\left(r - \frac{1}{2}\sigma_j^2\right) T + \sigma_j\sqrt{T}\Phi^{-1}(x_j)\right),$$

which depends only on one variable x_j. With $K = 0$, from (17) the corresponding integrand is of the form (excluding a constant factor)

$$f(\mathbf{x}) := \exp\left(\sum_{j=1}^{d} \frac{\sigma_j\sqrt{T}}{d}\Phi^{-1}(x_j)\right).$$

Once more, such a function is of the same form as (20), now with the weights

$$a_j = \sigma_j\sqrt{T}/d = O(d^{-1}) \ \text{ as } \ d \to \infty, \ \ j = 1, \ldots, d. \tag{30}$$

With the number of risky assets increasing, the parameters a_j decrease (they decrease even faster than for the cases of Asian options). For the parameters in (30), assume that $\sigma_j = \sigma$ for all j. We have

$$\sum_{j=1}^{d} a_j^2 = \sigma^2 T/d.$$

TABLE 6

The variance (in percentage) captured by the order-1 and order-2 ANOVA terms for the functions (20) *with three choices of a_j, which corresponds to several kinds of option pricing problems ($\sigma = 0.2, T = 1, K = 0$). The last row gives the limiting values.*

Dimension	$a_j = \frac{d-j+1}{d}\,\sigma\sqrt{T/d}$		$a_j = \sigma\sqrt{T/d}$		$a_j = \sigma\sqrt{T}/d$	
	order-1	order-2	order-1	order-2	order-1	order-2
8	99.372	0.626	98.259	1.724	99.781	0.218
16	99.350	0.647	98.136	1.842	99.883	0.117
64	99.338	0.659	98.044	1.931	99.969	0.031
256	99.336	0.661	98.021	1.953	99.992	0.008
1024	99.335	0.662	98.015	1.958	99.998	0.002
4096	99.335	0.662	98.014	1.960	99.9999	0.00001
∞	99.335	0.662	98.013	1.960	100.00	0.0

Thus the variance ratio captured by order-1 ANOVA terms is

$$R_{(1)}(f) = \frac{\sum_{j=1}^d \sigma^2_{\{j\}}(f)}{\sigma^2(f)} = \frac{\sum_{j=1}^d a_j^2 + O(d^{-3})}{e^{\sum_{j=1}^d a_j^2} - 1} = \frac{\sigma^2/d + O(d^{-3})}{\sigma^2/d + O(d^{-2})} = 1 + O(d^{-1}).$$

Similarly, the variance ratio captured by order-2 ANOVA terms is

$$R_{(2)}(f) = \frac{\sum_{i<j} \sigma^2_{\{i,j\}}(f)}{\sigma^2(f)} = \frac{\sum_{i<j}(e^{a_i^2} - 1)(e^{a_j^2} - 1)}{\sigma^2(f)} = \frac{O(d^{-2})}{O(d^{-1})} = O(d^{-1}).$$

The variance ratios captured by higher-order ANOVA terms are of order $o(d^{-1})$. So even the order-1 part of the integrand captures almost all of the variance. As the number of assets increases, the integrand becomes even closer (in the L_2-norm) to the sum of its order-1 terms (this is confirmed by the computational results in Table 6).

For the arithmetic multiasset options, the corresponding integrands are even simpler. Indeed, under the assumption of $\rho_{ij} = 0$ for $i \neq j$, as shown above we have

$$S_T^j = S_0^j \exp\left(\left(r - \frac{1}{2}\sigma_j^2\right)T + \sigma_j\sqrt{T}\Phi^{-1}(x_j)\right), \quad j = 1, \ldots, d.$$

Thus with $K = 0$ the payoff function, $\phi(S_T^1, \ldots, S_T^d) = \frac{1}{d}\sum_{j=1}^d S_T^j$, is completely a sum of one-dimensional functions.

Table 6 presents the variance ratios of order-1 and order-2 terms for functions of the form (20) with the parameters a_j given by (19), or (29) or (30), respectively, which correspond to several kinds of option pricing problems (geometric Asian option, arithmetic Asian option, and geometric multiasset option). These ratios are computed by (23) for each given d. We see that in all cases for dimensions up to thousands the variance percentages of order-1 and order-2 terms are close to 100%, and they do not change much when the nominal dimension increases. The limiting values of $R_{(1)}(f)$ and $R_{(2)}(f)$ give us confidence to conclude that no matter how large the nominal dimension is, the functions remain low-dimensional in the superposition sense.

For a multiasset path-dependent option (Asian basket option), the dimension is the number of time steps times the number of assets. Similar method can be used to analyze the dimension structure in this case. We omit the details.

5.2. The impact of the strike price and the nonsmoothness. The whole section 4 has been devoted to the empirical investigation for strike prices $K \neq 0$. By

comparing the empirical results there with the results in section 5.1 for $K = 0$, we find that their associated functions have similar dimension structure if K/S_0 is relatively small: the low-order terms dominate the functions. For relatively large K/S_0, the difference can be significant. For $K \neq 0$, the theoretical ANOVA analysis is more difficult and is more involved (in general, the theoretical ANOVA analysis is much more difficult than the pricing problem itself). As a partial solution, we make some attempts to understand (a) the impact of the strike price on the total variance; (b) the impact of the nonsmoothness involved in the integrands.

We concentrate on the geometric Asian call option. The underlying integral is shown in (18). Define

$$F(\mathbf{x}) := e^{-rT}\left[e^m f(\mathbf{x}) - K\right] \quad \text{with} \quad f(\mathbf{x}) = \prod_{j=1}^{d} \exp\left(a_j \Phi^{-1}(x_j)\right), \tag{31}$$

where m is defined in (14). The underlying function in (18) is just the function

$$F^+(\mathbf{x}) := \mathbf{1}_{\{F(\mathbf{x})\geq 0\}}\, F(\mathbf{x}),$$

where $\mathbf{1}_{\{.\}}$ is the indicator function. The function $f(\mathbf{x})$ in (31) is the one we studied earlier for $K = 0$, and its dimension structure is clear. Obviously, the functions $F(\mathbf{x})$ and $f(\mathbf{x})$ have the same variance ratios and the same effective dimensions (since a constant factor and a constant term do not affect these), and thus $F(\mathbf{x})$ also has the same low SD as $f(\mathbf{x})$ does.

(a) The impact of the strike price on the total variance. The strike price K determines how large a part of the function $F(\mathbf{x})$ is cut away by the indicator function $\mathbf{1}_{\{F(\mathbf{x})\geq 0\}}$. The impact of K on the total variance is an indicator of its importance. Analytical formulas are available for the variances $\sigma^2(F)$ and $\sigma^2(F^+)$. First,

$$\sigma^2(F) = \exp(-2rT + 2m)\, \sigma^2(f),$$

where $\sigma^2(f)$ is given by (21). Second, for the function $F^+(\mathbf{x})$, a change of variables (similar to the one used in subsection 3.2) leads to

$$I_d(F^+) = \int_{[0,1]^d} F^+(\mathbf{x}) d\mathbf{x} = e^{-rT}\left[e^{m+s_d^2/2}\Phi(d_1) - K\Phi(d_2)\right]$$

(this is the analytical formula for the geometric Asian call option) and

$$I_d((F^+)^2) = e^{-2rT}\left[e^{2m+2s_d^2}\Phi(d_0) - 2Ke^{m+s_d^2/2}\Phi(d_1) + K^2\Phi(d_2)\right],$$

where

$$s_d^2 = \sum_{j=1}^{d} a_j^2, \quad d_1 = \frac{m - \log K + s_d^2}{s_d}, \quad d_2 = d_1 - s_d, \quad d_0 = d_1 + s_d.$$

The variance of F^+ is $\sigma^2(F^+) = I_d((F^+)^2) - [I_d(F^+)]^2$. Note that when $d \to \infty$, all the parameters m, s_d, d_0, d_1, d_2 have limits; thus $\lim_{d\to\infty} \sigma^2(F)$ and $\lim_{d\to\infty} \sigma^2(F^+)$ exist (this implies that the increase of d has no essential influence on the variance and thus on the MC error). The values of the ratios $\sigma^2(F)/\sigma^2(F^+)$ and their limit are

TABLE 7

The values of the ratio $\sigma^2(F)/\sigma^2(F^+)$ for $\sigma = 0.2$, $r = 0.1$, $T = 1$. The last row gives the limit as $d \to \infty$. The function $F(\mathbf{x})$ is defined in (31).

Dimension	$K/S_0 = 0.8$	$K/S_0 = 0.9$	$K/S_0 = 1.0$	$K/S_0 = 1.1$	$K/S_0 = 1.2$
16	1.016	1.154	1.765	4.050	13.587
64	1.013	1.148	1.778	4.266	15.419
256	1.013	1.146	1.782	4.325	15.944
1024	1.013	1.146	1.782	4.340	16.080
4096	1.013	1.146	1.783	4.344	16.114
∞	1.013	1.146	1.783	4.345	16.126

given in Table 7. We observe that for relatively small K/S_0 (say, $K/S_0 \le 0.9$), the variance of F^+ is close to that of F, i.e., the influence of K on the total variance is not significant; thus we have good reason to expect that the function F^+ has dimension structure similar to F. This is confirmed by the empirical investigation in section 4 (see Table 2). If K/S_0 is relatively large (say $K/S_0 \ge 1.1$), the difference between F and F^+ can be significant. However, the total variance of F^+ is small, implying the problem is relatively easy for MC.

(b) Nonsmoothness or discontinuity. Note that for $\mathbf{x}$ satisfying $F(\mathbf{x}) \neq K$,

$$\frac{\partial F^+(\mathbf{x})}{\partial x_j} = \mathbf{1}_{\{F(\mathbf{x})\ge 0\}} \frac{\partial F(\mathbf{x})}{\partial x_j}.$$

Due to the characteristic function $\mathbf{1}_{\{F(\mathbf{x})\ge 0\}}$, the function $F^+(\mathbf{x})$ has no partial derivatives at $\mathbf{x}$ satisfying $F(\mathbf{x}) = K$ unless $\frac{\partial F(\mathbf{x})}{\partial x_j} = 0$ when $F(\mathbf{x}) = K$. Nevertheless, most ANOVA terms are smooth: using a method similar to that of Liu and Owen [11], we conclude that for the integrand $F^+(\mathbf{x})$, the only nonsmooth ANOVA term is the highest-order one $F^+_{\mathcal{A}}(\mathbf{x})$, which is the difference of F^+ and all its lower-order terms. In fact, letting $h(x_2, \dots, x_d) = m + \sum_{j=2}^d a_j \Phi^{-1}(x_j)$, we have

$$\begin{aligned} H(x_2, \dots, x_d) &:= \int_0^1 F^+(\mathbf{x}) dx_1 \\ &= e^{-rT} \left[e^{h + a_1^2/2} \Phi\left(\frac{h - \log K + a_1^2}{a_1} \right) - K \Phi\left(\frac{h - \log K}{a_1} \right) \right]. \end{aligned}$$

Thus integrating $F^+(\mathbf{x})$ with respect to one variable results in a function that is differentiable with respect to all the others. Further integration with respect to other variables gives still smoother functions. The smaller $|u|$ is, the smoother F^+_u is.

The importance of the term $F^+_{\mathcal{A}}$ is measured by the sensitivity index $S(F^+_{\mathcal{A}})$, i.e., the ratio $\sigma^2(F^+_{\mathcal{A}})/\sigma^2(F^+)$. A conservative estimate of the variance of $F^+_{\mathcal{A}}$ can be obtained by

$$\sigma^2(F^+_{\mathcal{A}}) \le \sigma^2(F^+) - T_{\{d\}}(F^+) - T_{\{1,\dots,d-1\}}(F^+),$$

where $T_{\{d\}}(F^+)$ and $T_{\{1,\dots,d-1\}}(F^+)$ can be easily computed by the method in subsection 3.2. We find, for the geometric Asian option with the model parameters in Table 2 and for $d = 64$, that the ratio $\sigma^2(F^+_{\mathcal{A}})/\sigma^2(F^+)$ is bounded by 0.00016, 0.00019, or 0.00035 for $K = 90, 100, 110$, respectively. Therefore, the nonsmooth part of the function F^+ is negligible, and the smooth part dominates. Some other options also have nonsmooth or discontinuous payoff, allowing similar methods to be used.

An alternative approach to dealing with the nonsmoothness is to use smoothing techniques. Smoothing techniques may lead to improved QMC results, since the accuracy of QMC relates to the smoothness of the integrands (see Moskowitz and Caflisch [12] and Wang [26]). Here we use conditional MC. Since $\mathbb{E}(F^+|x_2,\dots,x_d) = H(x_2,\dots,x_d)$, we have

$$\mathbb{E}(F^+) = \mathbb{E}(\mathbb{E}(F^+|x_2,\dots,x_d)) = \mathbb{E}(H(x_2,\dots,x_d)).$$

Here we treat $x_1,\dots,x_d$ as being the i.i.d. uniformly distributed random variables on $[0,1]$. We believe that smoothing techniques may also change the ANOVA structure of the underlying function and make the problem more suited to QMC. The efficiency of smoothing techniques for QMC in finance deserves extensive study.

5.3. Bond valuation for a stochastic interest rate. Is the inherent feature (e.g., small SD) of option pricing common in finance problems? Consider now a different kind of problem: finding the fair price of a T-year zero-coupon bond with a face price of 1 (see Ninomiya and Tezuka [15] and Morokoff [13]). We assume that the interest rate follows a mean reverting process (Vasicek [25]):

$$dr = a(b-r)dt + \sigma dB_t, \quad r(0) = r_0, \tag{32}$$

where a, b are constants (the reversion speed and reversion level, respectively), σ is the volatility, and B_t is the standard Brownian motion. According to the arbitrage pricing theory (Hull [8]), the price of a discount bond at time 0 with maturity T is given by

$$P(T) = \mathbb{E}\left(\exp\left(-\int_0^T r(s)ds\right)\right) \tag{33}$$

under the risk-neutral measure. It can be solved analytically (Vasicek [25]). Still, it is a good example to study the dimension structure of the underlying function. A simulation-based procedure is to discretize the time and approximate the model by Euler approximation:

$$r_j - r_{j-1} = a(b-r_{j-1})\Delta t + \sigma\sqrt{\Delta t}\, z_j, \quad z_j \sim N(0,1), \quad j = 1,\dots,d-1, \tag{34}$$

where $\Delta t = T/d$ and r_j is the interest rate at $t_j = j\Delta t$. The discrete-time version of (33) is

$$P_d(T) = \mathbb{E}\left(\exp\left(-\Delta t\sum_{j=0}^{d-1} r_j\right)\right). \tag{35}$$

The resulting integral is $(d-1)$-dimensional. To reduce the time discretization error to an acceptable level, one should make the discretization fine enough. As a result, the dimension can be thousands (Ninomiya and Tezuka [15]). Now we analyze the integrand in (35). Let $\beta = 1 - a\Delta t$; then (34) can be written as

$$r_j - b = (r_{j-1} - b)\beta + \sigma\sqrt{\Delta t}\, z_j, \quad j = 1,\dots,d-1.$$

This leads in matrix notation to

$$\begin{pmatrix} r_1 \\ r_2 \\ r_3 \\ \vdots \\ r_{d-1} \end{pmatrix} = \sigma\sqrt{\Delta t} \begin{pmatrix} 1 & 0 & 0 & \cdots & 0 \\ \beta & 1 & 0 & \cdots & 0 \\ \beta^2 & \beta & 1 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \beta^{d-2} & \beta^{d-3} & \beta^{d-4} & \cdots & 1 \end{pmatrix} \begin{pmatrix} z_1 \\ z_2 \\ z_3 \\ \vdots \\ z_{d-1} \end{pmatrix} + \mathbf{H}, \tag{36}$$

where $\mathbf{H}$ is a vector with the jth entry $H_j = b + (r_0 - b)\beta^j$. It follows that

$$r_j = \sigma\sqrt{\Delta t}\,\left(\beta^{j-1}z_1 + \beta^{j-2}z_2 + \cdots + z_j\right) + H_j, \quad j = 1, \ldots, d-1.$$

Thus

$$\exp\left(-\Delta t \sum_{j=0}^{d-1} r_j\right) = \exp\left(\gamma_1 z_1 + \cdots + \gamma_{d-1} z_{d-1} - G\right), \tag{37}$$

where $G = \Delta t(r_0 + \sum_{j=1}^{d-1} H_j)$, and the parameters γ_j are given by

$$\gamma_j = -\sigma\Delta t^{3/2}(1 + \beta + \cdots + \beta^{d-j-1}), \quad j = 1, \ldots, d-1.$$

We are interested in the case $a \neq 0$ (if $a = 0$, then the Vasicek model reduces to Brownian motion, which is unsuitable for interest rate processes). For $a \neq 0$, we have $\beta \neq 1$, and

$$\gamma_j = -\sigma\Delta t^{3/2}\frac{1-\beta^{d-j}}{1-\beta} = -\frac{\sigma\sqrt{\Delta t}}{a}(1-\beta^{d-j}). \tag{38}$$

From (37) the integral (35) can then be written as

$$P_d(T) = \int_{\mathbb{R}^{d-1}} \exp\left(\sum_{j=1}^{d-1}\gamma_j z_j - G\right) p_{d-1}(z_1, \ldots, z_{d-1}) dz_1 \cdots dz_{d-1},$$

where p_{d-1} is given in (9). Using a change of variables $z_j = \Phi^{-1}(x_j), j = 1, \ldots, d-1$, we obtain an integral over $[0,1]^{d-1}$, with the integrand in the form (excluding a constant factor)

$$f(\mathbf{x}) := \prod_{j=1}^{d-1} g_j(x_j) \quad \text{with} \quad g_j(x_j) = \exp\left(\gamma_j \Phi^{-1}(x_j)\right), \tag{39}$$

This is of exactly the same form as the one in (20); only the parameters γ_j are different. The parameters in (38) have a property similar to the ones in (19). For example, we have $\gamma_j = O(\sqrt{\Delta t})$ as $\Delta t \to 0$ for each j. By direct calculation, we obtain

$$\Gamma := \lim_{d\to\infty}\sum_{j=1}^{d-1}\gamma_j^2 = \frac{\sigma^2}{2a^3}(4e^{-aT} - e^{-2aT} + 2aT - 3) = \sigma^2 T^3\left(\frac{1}{3} - \frac{a}{4}T + \frac{7a^2}{60}T^2 + \cdots\right). \tag{40}$$

Analogous to Theorem 5.1 for the case of Asian options, we have the following.

THEOREM 5.2. (32)

(i) (39) γ_j (38) $R_{(\ell)}(f)$ (23) a_j γ_j

(ii) ℓ

TABLE 8

The variance ratios (in percentage) captured by low-order ANOVA terms for bond valuation with $a = 0.1817303, \sigma = 0.02$. The last row gives the limiting values. The effective dimensions (d_t and d_s) are in the parentheses. The paths are constructed by the standard method (36)*. Note that the results are independent of the parameter b in the Vasicek model.*

$$\lim_{d\to\infty} R_{(\ell)}(f) = \frac{\Gamma^\ell/\ell!}{(e^\Gamma - 1)}, \quad \ell = 1, 2, \ldots,$$

[illegible] Γ [illegible] (40)

The variance ratios and their limits for bond valuation are similar to those for option pricing. From Theorem 5.2 and from the formula (40) for Γ, it can be seen that the variance ratios are mainly determined by the quantity $\sigma^2 T^3$. A difference from option pricing is that now the time length T may be quite long, say, $T > 10$ years. Thus the bond valuation problems have a more sensitive dependence on σ. If σ is relatively small, then the conclusions are similar to those for option pricing (even if T is large). Table 8 presents the variance ratios for $\sigma = 0.02$. The last row presents the limiting values. We also compute the effective dimensions using the method in Wang and Fang [28]. We observe that the SD is small and is insensitive to the nominal dimension ($d_s \le 2$ for $T = 20$ and $d_s \le 3$ for $T = 30$), but the TD is almost as large as the nominal dimension.

For larger σ (say, $\sigma = 0.1$), the situation can be quite different. If T is also large (say, $T \ge 20$), the variance ratios of low-order terms are very small. The effective dimension (not only the TD, but also the SD) can be large (see Table 9). The associated problem can be hard for QMC, since now the high-order ANOVA terms are important, and it is difficult to make the high-order projections of a QMC point set more uniform than those of a random point set for practical sample size (see Wang and Sloan [30]).

However, the situation changes completely if the interest rate paths are generated by [illegible] (PCA). The idea of PCA remains the same as in Acworth, Broadie, and Glassman [1]. The comparisons are given in Table 9. We observe that "low-dimensional" integrands are regained by using PCA: the integrands are low-dimensional, [illegible]. For example, for $T = 30$ the TD and SD in PCA are no larger than 6 and 3, respectively (for nominal dimension up to thousands)! Both the TD and SD are reduced significantly; especially, the variance ratios of the order-1 terms are increased dramatically. Moreover, in PCA construction both the TD and SD are very [illegible] to the nominal dimension, indicating the possibility of breaking the curse of dimension-

TABLE 9

The same as Table 8*, but with* $a = 0.1817303$, $\sigma = 0.1$ *(the volatility is much larger than the one used in Table* 8*). Two methods of path constructions are considered: the standard construction* (36) *and the construction based on PCA.*

$d-1$	$T=20$ (Standard)		$T=20$ (PCA)		$T=30$ (Standard)		$T=30$ (PCA)	
	order-1 (d_t)	order-2 (d_s)	order-1 (d_t)	order-2 (d_s)	order-1 (d_t)	order-2 (d_s)	order-1 (d_t)	order-2 (d_s)
16-1	10.790 (15)	21.465 (7)	90.835 (4)	8.932 (2)	1.021 (15)	4.147 (10)	75.994 (6)	22.781 (3)
64-1	10.029 (59)	18.653 (8)	91.170 (4)	8.599 (2)	0.930 (61)	3.221 (12)	78.472 (6)	20.407 (3)

ality. More research is needed to understand theoretically how dimension reduction techniques could change the dimension structure and change the (strong) tractability properties of the underlying problems. Moreover, dimension reduction techniques which can take into account the characteristics of a given problem are desirable.

6. Concluding remarks. The potential sources of dimensionality of finance problems are the small time increments and/or the large number of the state variables. Is there really a curse of dimensionality for such problems? It is found that these problems are often of low effective dimension in the superposition sense. In other words, an ANOVA expansion up to the second order can often provide a quite satisfactory approximation to the function. This property does not seem to change as the nominal dimension increases. We believe that these properties are closely related to the concentration of measure.

The observations are justified by theoretical analysis. By carefully analyzing simplified models of some typical finance problems, we found that the underlying functions are controlled by some weights, which are determined by the nature of the problems. These weights limit the importance of the higher-dimensional structures and offset the effect of high dimensionality. By studying the variance ratios and their asymptotic behavior as $d \to \infty$, we found that these quantities depend critically on the weights. For option pricing problems the low-order ANOVA terms (usually the order-1 and order-2 terms) always play the major role, while the higher-order terms tend to be negligible. It can even happen that as the dimension increases the problem becomes easier (in the sense of smaller SD)! For bond valuation problems with small value of σ or T, the conclusions are similar. However, large values of σ and T may lead to quite different situation: the SD can be not so small and the problems can be truly hard for QMC. However, "low-dimensional" integrands, not only in the superposition sense, but also in the truncation sense, are regained by using PCA. This demonstrates the power of PCA. Further study of the effect of dimension reduction techniques is needed. We observed that in all examples the SD (in standard or PCA construction) is very insensitive to the nominal dimension. This justifies the use of "finite-order" weights in Sloan, Wang, and Woźniakowski [21] (where it was shown that the computational complexity depends exponentially on the highest order of the ANOVA terms that need to be taken into account).

We have analyzed some finance problems under relatively basic models and using

basic discretization schemes. More complex models, problems, and more accuracy discretization schemes are worth investigating (however, theoretical ANOVA analysis under more complicated models can be much more difficult). Stochastic differential equations have been widely used to describe the dynamics of the financial assets. In numerical practice it is common to approximate a continuous process with a time-discretized one with a large number of time steps. We believe that "low SD" property (in ANOVA decomposition) could be a common feature for the integrals arising from time discretization. For approximating such integrals the uniformity of the low-order projections of the point set is crucial. Fortunately, as shown in Wang and Sloan [30], common low discrepancy point sets have smaller superposition discrepancy of lower order (such as order-1) than random point sets do, even for large d and small n. The inherent features of low discrepancy point sets, in combination with the special properties of the finance problems (low effective dimension in superposition or even in truncation sense) result in the effectiveness of QMC methods for nominally high-dimensional finance problems.

The investigations enable us to better understand the special features of finance problems and indicate ways to construct more efficient QMC algorithms and ways to design powerful efficiency improvement techniques. For example, based on such information, we were able in [29] to find suitable weights for use in the algorithmic construction of efficient lattice rules (in that paper we also explained why classical lattice rules are not suitable for high-dimensional finance problems). Moreover, the special properties of finance problems indicate that in order to construct more efficient QMC point sets for such problems, we need mainly to concentrate on the uniformity of low-order projections, especially the order-1 and order-2 projections. The lattice rules constructed based on such an idea are potentially useful. For the construction of digital nets (see Niederreiter [14]), it would be also desirable to use new quality parameters (instead of the traditional t-value) to reflect those characteristics. Such quality parameters would describe the quality of the distribution in the low-order projections of the point sets. The common property of low SD or even nearly additive feature for finance problems may enable us to develop general techniques to improve the efficiency for such problems.

Acknowledgment. The authors would like to thank the editor and the referees for their valuable comments.

COMPUTATION OF MEAN DRAG FOR BLUFF BODY PROBLEMS USING ADAPTIVE DNS/LES*

JOHAN HOFFMAN†

Abstract. We compute the time average of the drag in two benchmark bluff body problems: a surface mounted cube at Reynolds number 40000, and a square cylinder at Reynolds number 22000, using adaptive DNS/LES. In adaptive DNS/LES the Galerkin least-squares finite element method is used, with adaptive mesh refinement until a given stopping criterion is satisfied. Both the mesh refinement criterion and the stopping criterion are based on a posteriori error estimates of a given output of interest, in the form of a space-time integral of a computable residual multiplied by a dual weight, where the dual weight is obtained from solving an associated dual problem computationally, with the data of the dual problem coupling to the output of interest. No filtering is used, and in particular no Reynolds stresses are introduced. We thus circumvent the problem of closure, and instead we estimate the error contribution from subgrid modeling a posteriori, which we find to be small. We are able to predict the mean drag with an estimated tolerance of a few percent using about 10^5 mesh points in space, with the computational power of a PC.

Key words. adaptive DNS/LES, adaptive finite element method, duality, a posteriori error estimate, turbulence, large eddy simulation, direct numerical simulation, bluff body problem, surface mounted cube, square cylinder

1. Introduction.

The Navier–Stokes equations form the basic mathematical model in fluid mechanics and describe a large variety of phenomena of fluid flow occurring in hydro- and aerodynamics, the processing industry, biology, oceanography, meteorology, geophysics, and astrophysics. The [illegible] $Re = \frac{UL}{\nu}$, where U is a characteristic flow velocity, L a characteristic length scale, and ν the viscosity of the fluid, is used to characterize different flow regimes. If Re is relatively small ($Re \leq 10-100$), then the flow is viscous and the flow field is ordered and smooth or [illegible], while for larger Re, the flow will at least partly be [illegible] with time-dependent nonordered features on a range of length scales down to a smallest scale of size $Re^{-3/4}$, assuming $L = 1$. In many applications of scientific and industrial importance Re is very large, of the order 10^6 or larger, and the flow shows a combination of laminar and turbulent features. To resolve all the features of a turbulent flow at $Re = 10^6$ in a [illegible] would require of the order $Re^3 = 10^{18}$ mesh points in space time, and thus would be impossible on any foreseeable computer.

To overcome the impossibility of DNS for higher Reynolds numbers one seeks to reduce the problem by some sort of [illegible]. In a traditional approach to CTM, such as large eddy simulation (LES), one seeks to computationally approximate an averaged solution of the Navier–Stokes equations. This is typically done by averaging (or filtering) the Navier–Stokes equations to derive a new set of modified equations, for the averaged variables, to solve. By averaging the nonlinear term in the Navier–Stokes equations one is left with the problem of [illegible] — to model the so-called [illegible] in a [illegible], which is the major open

problem of today. There is an extensive amount of work on LES, in particular regarding the closure problem and the construction of various subgrid models, and we refer the reader to [23] and the references therein for details.

Another important aspect of turbulence simulation is in what sense a solution is accurate, that is, what output from a solution can be considered to be well determined. The computational version of this question is, This connects to questions of weak uniqueness for the Navier–Stokes equations, investigated in [14, 17, 18]. In particular, full resolution does not automatically give pointwise accuracy, and thus also in the case of DNS, questions of computability and predictability are crucial. For example, mean value output is typically less expensive to compute than more pointwise output; see [12, 13, 14, 17, 18].

In this paper we compute the mean drag of two bluff bodies in turbulent flow, using , a new approach to CTM. In adaptive DNS/LES we do not use any filtering, instead we use the Galerkin/least-squares space-time finite element method, here referred to as the G2, to compute approximate weak solutions to the exact Navier–Stokes equations directly, adaptively refining the computational mesh until a given tolerance is reached with respect to the error in a certain output of interest. Parts of the computational domain are resolved in a DNS, and other parts are left unresolved in an LES with the least-squares stabilization in G2 acting as a dissipative subgrid model. In particular, the adaptive algorithm in itself determines the degree of resolution needed in different parts of the domain to satisfy the stopping criterion. For the computational examples in this paper, the flow is typically fully resolved in a DNS in laminar parts of the domain, whereas the smallest mesh size in the turbulent wake is much larger than the theoretically estimated smallest scale of the turbulent flow, and thus we regard the wake as being left unresolved in an LES. The adaptive mesh refinement is based on in the form of a space-time integral of a residual times a dual weight, where the dual weight is obtained by solving an associated linear dual problem with data connecting to the output of interest. The stability of the dual weight under the mesh refinement is crucial, and is controlled computationally through the adaptive algorithm, assuring reliability of the a posteriori error estimates.

Adaptive DNS/LES thus provides an adaptive method for the computation of chosen output, based on quantitative error control, with a key ingredient being the output sensitivity information obtained from the dual problem. No Reynolds stresses are introduced, and we thus circumvent the problem of closure.

The idea of using duality arguments in a posteriori error estimation goes back to Babuška and Miller [2] in the context of postprocessing "quantities of physical interest" in elliptic model problems. A framework for more general situations has since then been systematically developed. For a more detailed account of the development of this framework, including references, we refer the reader to the review papers [6, 4, 15, 9]. For incompressible flow, applications of adaptive finite element methods based on this framework have been increasingly advanced with computation of functionals such as the drag force for two-dimensional (2d) stationary benchmark problems in [3, 8], drag and lift forces and pressure differences for three-dimensional (3d) stationary benchmark problems in [11], and time-dependent problems in 3d in [13]. In [12], this framework is extended to turbulent flow using LES, with a posteriori error estimates with respect to the averaged solution, in terms of the Reynolds stresses that need to be modelled. These a posteriori error estimates are then used in an adaptive algorithm

to compute the drag coefficient for a surface mounted cube in [10].

In [16], the generalization to adaptive DNS/LES is presented as a general methodology to handle laminar and turbulent flows. Adaptive DNS/LES may be thought of as a straightforward application of the framework for adaptive error control in [6] to the Navier–Stokes equations, based on a posteriori error estimates, with an error contribution from discretization of the exact Navier–Stokes equations, and a modeling error contribution from the stabilization in G2.

To study the efficiency of adaptive DNS/LES, we here present results for two benchmark bluff body problems, described, e.g., in [22]: (i) a surface mounted cube at Reynolds number 40000, for which some results using adaptive DNS/LES are included also in [16], and (ii) a square cylinder at Reynolds number 22000. The results in this paper indicate that we are able to predict the drag coefficient in (i)–(ii) with an estimated tolerance of a few percent, using about 10^5 mesh points in space, with the computational power of a PC.

An outline of this paper is as follows. In section 2 we recall the Navier–Stokes equations as a model for viscous incompressible flow, and we state the corresponding discretization using cG(1)cG(1), a variant of G2. In section 3 we present adaptive DNS/LES cG(1)cG(1), including a posteriori error estimates for drag, and in section 4 we present computational results for the problems (i)–(ii) using adaptive DNS/LES cG(1)cG(1).

2. The Navier–Stokes equations. The incompressible Navier–Stokes equations expressing conservation of momentum and incompressibility of a unit density Newtonian fluid, with constant kinematic viscosity $\nu > 0$ enclosed in a volume Ω in $\mathbb{R}^3$ (where we assume that Ω is a polygonal domain) with homogeneous Dirichlet boundary conditions, take the form: Find (u, p) such that

$$\begin{aligned} \dot{u} + (u \cdot \nabla)u - \nu\Delta u + \nabla p &= f \quad \text{in } \Omega \times I, \\ \nabla \cdot u &= 0 \quad \text{in } \Omega \times I, \\ u &= 0 \quad \text{on } \partial\Omega \times I, \\ u(\cdot, 0) &= u_0 \quad \text{in } \Omega, \end{aligned} \tag{2.1}$$

where $u(x,t) = (u_i(x,t))$ is the [illegible] vector and $p(x,t)$ is the [illegible] of the fluid at (x,t), and f, u_0, $I = (0,T)$ are a given driving force, initial data, and time interval, respectively. The quantity $\nu\Delta u - \nabla p$ represents the total fluid force, and may alternatively be expressed as

$$\nu\Delta u - \nabla p = \operatorname{div}\sigma(u,p), \tag{2.2}$$

where $\sigma(u,p) = (\sigma_{ij}(u,p))$ is the [illegible], with components $\sigma_{ij}(u,p) = 2\nu\epsilon_{ij}(u) - p\delta_{ij}$, composed of the [illegible] $2\nu\epsilon_{ij}(u)$ with zero trace and an isotropic pressure: here $\epsilon_{ij}(u) = (u_{i,j} + u_{j,i})/2$ is the [illegible], with $u_{i,j} = \partial u_i/\partial x_j$, and δ_{ij} is the usual Kronecker delta, the indices i and j ranging from 1 to 3. We assume that (2.1) is normalized so that the reference velocity and typical length scale are both equal to one. The Reynolds number Re is then equal to ν^{-1}.

2.1. Discretization: cG(1)cG(1). The cG(1)cG(1) method is a variant of the G2 method [20, 13] using the continuous Galerkin method cG(1) in time instead of a discontinuous Galerkin method. With cG(1) in time the trial functions are continuous piecewise linear and the test functions are piecewise constant. cG(1) in space corresponds to both test functions and trial functions being continuous piecewise linear. Let $0 = t_0 < t_1 < \cdots < t_N = T$ be a sequence of discrete time steps with

associated time intervals $I_n = (t_{n-1}, t_n]$ of length $k_n = t_n - t_{n-1}$ and space-time slabs $S_n = \Omega \times I_n$, and let $W^n \subset H^1(\Omega)$ be a finite element space consisting of continuous piecewise linear functions on a mesh $\mathcal{T}_n = \{K\}$ of mesh size $h_n(x)$ with W_w^n the functions $v \in W^n$ satisfying the Dirichlet boundary condition $v|_{\Gamma_D} = w$.

We seek functions (U_h, P_h), continuous piecewise linear in space and time, and the cG(1)cG(1) method for the Navier–Stokes equations (2.1), with homogeneous Dirichlet boundary conditions, reads as follows:

For $n = 1, \ldots, N$, find $(U_h^n, P_h^n) \equiv (U_h(t_n), P_h(t_n))$ with $U_h^n \in V_0^n \equiv [W_0^n]^3$ and $P_h^n \in W^n$, such that

$$\begin{aligned}(2.3)\qquad &((U_h^n - U_h^{n-1})k_n^{-1} + \hat{U}_h^n \cdot \nabla \hat{U}_h^n, v) + (2\nu\epsilon(\hat{U}_h^n), \epsilon(v)) - (P_h^n, \nabla \cdot v)\\ &\qquad + (\nabla \cdot \hat{U}_h^n, q) + SD_\delta(\hat{U}_h^n, P_h^n; v, q) = (f, v) \quad \forall (v, q) \in V_0^n \times W^n,\end{aligned}$$

where $\hat{U}_h^n = \frac{1}{2}(U_h^n + U_h^{n-1})$, with the stabilizing term

$$SD_\delta(\hat{U}_h^n, P_h^n; v, q) \equiv (\delta_1(\hat{U}_h^n \cdot \nabla \hat{U}_h^n + \nabla P_h^n - f), \hat{U}_h^n \cdot \nabla v + \nabla q) + (\delta_2 \nabla \cdot \hat{U}_h^n, \nabla \cdot v),$$

and $\delta_1 = \frac{1}{2}(k_n^{-2} + |U|^2 h_n^{-2})^{-1/2}$ in the convection-dominated case $\nu < \hat{U}_h^n h_n$ and $\delta_1 = \kappa_1 h^2$ otherwise, $\delta_2 = \kappa_2 h$ if $\nu < \hat{U}_h^n h_n$ and $\delta_2 = \kappa_2 h^2$ otherwise, with κ_1 and κ_2 positive constants of unit size (in this paper we have $\kappa_1 = \kappa_2 = 1$), and

$$\begin{aligned}(v, w) &= \sum_{K \in \mathcal{T}_n} \int_K v \cdot w \, dx,\\ (\epsilon(v), \epsilon(w)) &= \sum_{i,j=1}^{3} (\epsilon_{ij}(v), \epsilon_{ij}(w)).\end{aligned}$$

We note that the viscous term $(2\nu\epsilon(U_h), \epsilon(v))$ may alternatively occur in the form $(\nu \nabla U_h, \nabla v) = \sum_{i=1}^3 (\nu \nabla (U_h)_i, \nabla v_i)$. In the case of Dirichlet boundary conditions the corresponding variational formulations are equivalent, but not so in the case of Neumann boundary conditions. If we have Neumann boundary conditions, we use the standard technique to apply these boundary conditions weakly.

3. Adaptive DNS/LES cG(1)cG1(1). In adaptive DNS/LES cG(1)cG(1) we do not apply any filter to the Navier–Stokes equations, and thus no Reynolds stresses are introduced. Instead we use cG(1)cG(1) to adaptively compute approximate solutions with the goal of satisfying a given tolerance with respect to the error in a specified output of interest.

Error indicators for mesh refinement and stopping criterions are both based on a posteriori error estimates, in the form of a space-time integral of a computable residual times a dual weight, where the dual weight is obtained from a computational approximation of the solution to an associated dual problem with data coupled to the output of interest.

3.1. Adaptive computation of the drag of a bluff body. We want to compute a mean value in time of the drag of a bluff body in a channel subject to a time-dependent turbulent flow:

$$(3.1)\qquad N(\sigma(u,p)) \equiv \frac{1}{|I|} \int_I \int_{\Gamma_0} \sum_{i,j=1}^{3} \sigma_{ij}(u,p) n_j \phi_i \, ds \, dt,$$

where (u,p) solves (2.1) in the fluid volume Ω surrounding the body (using suitable boundary conditions as specified below), Γ_0 is the surface of the body in contact with the fluid, and ϕ is a unit vector along the channel in the direction of the flow. We first use a standard technique to derive an alternative expression for the drag, which naturally fits with a Galerkin formulation, by extending ϕ to a function Φ defined in the fluid volume Ω and being zero on the remaining boundary Γ_1 of the fluid volume. Multiplying the momentum equation in (2.1) by Φ and integrating by parts, we get, using the zero boundary condition on Γ_1,

$$\begin{aligned} N(\sigma(u,p)) = \frac{1}{|I|}\int_I (\dot{u} + u\cdot\nabla u - f, \Phi) - (p, \nabla\cdot\Phi) \\ + (2\nu\epsilon(u), \epsilon(\Phi)) + (\nabla\cdot u, \Theta)\ dt, \end{aligned} \tag{3.2}$$

where we also added the integral of $\nabla\cdot u = 0$ multiplied by a function Θ. Obviously, the representation does not depend on the particular extension Φ of ϕ, or Θ.

We are thus led to compute an approximation of the drag $N(\sigma(u,p))$ from a computed (U_h, P_h) using the formula

$$\begin{aligned} N^h(\sigma(U_h,P_h)) = \frac{1}{|I|}\int_I (\dot{U}_h + U_h\cdot\nabla U_h - f, \Phi) - (P_h, \nabla\cdot\Phi) + (2\nu\epsilon(U_h), \epsilon(\Phi)) \\ + SD_\delta(U_h, P_h; \Phi, \Theta) + (\nabla\cdot U_h, \Theta)\ dt, \end{aligned} \tag{3.3}$$

where now Φ and Θ are finite element functions (with as before $\Phi = \phi$ on Γ_0 and $\Phi = 0$ on Γ_1), and where $\dot{U}_h = (U_h^n - U_h^{n-1})/k_n$ on I_n. We note the presence of the stabilizing term SD_δ in (3.3), compared to (3.2). This term is added in order to obtain the independence of $N^h(\sigma(U_h,P_h))$ from the choice of (Φ,Θ), which follows from (2.3).

3.2. The dual problem. We introduce the following dual problem: Find (φ,θ) with $\varphi = \phi$ on Γ_0 and $\varphi = 0$ on Γ_1, such that

$$\begin{aligned} -\dot{\varphi} - (u\cdot\nabla)\varphi + \nabla U_h\cdot\varphi - \nu\Delta\varphi + \nabla\theta = 0 \quad &\text{in } \Omega\times I, \\ \operatorname{div}\varphi = 0 \quad &\text{in } \Omega\times I, \\ \varphi(\cdot,T) = 0 \quad &\text{in } \Omega, \end{aligned} \tag{3.4}$$

where $(\nabla U_h\cdot\varphi)_j = (U_h)_{,j}\cdot\varphi$. The dual problem is a linear convection-diffusion-reaction problem where the convection acts backward in time and in the opposite direction of the exact flow velocity u. We note that the coefficient ∇U_h of the reaction term locally is large in turbulent regions, and thus potentially generating rapid exponential growth. However, ∇U_h is fluctuating and the net effect of the reaction term for the problems in this paper turns out to generate slower growth, as we learn from computing approximations of the dual solution.

3.3. An a posteriori error estimate. To derive a representation of the error $N(\sigma(u,p)) - N^h(\sigma(U_h,P_h))$, we subtract (3.3) from (3.2) with (Φ,Θ) finite element functions to get

$$\begin{aligned} N(\sigma(u,p)) - N^h(\sigma(U_h,P_h)) = \frac{1}{|I|}\int_I (\dot{u} + u\cdot\nabla u, \Phi) - (p, \nabla\cdot\Phi) \\ + (2\nu\epsilon(u), \epsilon(\Phi)) + (\nabla\cdot u, \Theta) - ((\dot{U}_h + U_h\cdot\nabla U_h, \Phi) - (P_h, \nabla\cdot\Phi) \\ + (2\nu\epsilon(U_h), \epsilon(\Phi)) + (\nabla\cdot U_h, \Theta) + SD_\delta(U_h, P_h; \Phi, \Theta))\ dt. \end{aligned} \tag{3.5}$$

With (φ,θ) the solution to the dual problem (3.4), we also have that

$$\begin{aligned}
&\frac{1}{|I|}\int_I (\dot u + u\cdot\nabla u,\varphi) - (p,\nabla\cdot\varphi) + (2\nu\epsilon(u),\epsilon(\varphi)) + (\nabla\cdot u,\theta)\\
&\quad - ((\dot U_h + U_h\cdot\nabla U_h,\varphi) - (P_h,\nabla\cdot\varphi) + (2\nu\epsilon(U_h),\epsilon(\varphi)) + (\nabla\cdot U_h,\theta))\ dt\\
&\quad = \frac{1}{|I|}\int_I -(\dot\varphi,e) + (u\cdot\nabla e + e\cdot\nabla U_h,\varphi) - (p-P_h,\nabla\cdot\varphi)\\
&\quad\quad + (2\nu\epsilon(e),\epsilon(\varphi)) + (\nabla\cdot e,\theta)\ dt = 0,
\end{aligned}\tag{3.6}$$

using partial integration with $\varphi(T) = e(0) = 0$, where $e = u - U_h$, and that $(u\cdot\nabla)u - (U_h\cdot\nabla)U_h = (u\cdot\nabla)e + (e\cdot\nabla)U_h$. By (3.5) and (3.6), we thus have that

$$\begin{aligned}
&N(\sigma(u,p)) - N^h(\sigma(U_h,P_h)) = \frac{1}{|I|}\int_I (\dot U_h + U_h\cdot\nabla U_h,\varphi-\Phi)\\
&- (P_h,\nabla\cdot(\varphi-\Phi)) + (\nabla\cdot U_h,\theta-\Theta) + (2\nu\epsilon(U_h),\nabla(\varphi-\Phi)) + SD_\delta(U_h,P_h;\Phi,\Theta)\\
&- ((\dot u + u\cdot\nabla u,\varphi-\Phi) - (p,\nabla\cdot(\varphi-\Phi)) + (\nabla\cdot u,\theta-\Theta) + (2\nu\epsilon(u),\nabla(\varphi-\Phi)))\ dt\\
&= \frac{1}{|I|}\int_I (\dot U_h + U_h\cdot\nabla U_h - f,\varphi-\Phi) - (P_h,\nabla\cdot(\varphi-\Phi))\\
&+ (\nabla\cdot U_h,\theta-\Theta) + (2\nu\epsilon(U_h),\nabla(\varphi-\Phi)) + SD_\delta(U_h,P_h;\Phi,\Theta)\ dt,
\end{aligned}$$

using partial integration with $\varphi = \Phi = \phi$ on Γ_0 and $\varphi = \Phi = 0$ on Γ_1. We have now proved the following error representation (Theorem 3.1), where we express the total error as a sum of error contributions from the different elements K in space (assuming here for simplicity that the space mesh is constant in time), and we use the subindex K to denote integration over element K so that $(\cdot,\cdot)_K$ denotes the appropriate $L_2(K)$ inner product.

THEOREM 3.1. [illegible] (u,p) [illegible] (U_h,P_h) [illegible] $cG(1)$ $cG(1)$ [illegible] (φ,θ) [illegible] (3.4) [illegible]

$$|N(\sigma(u,p)) - N^h(\sigma(U_h,P_h))| = \left|\sum_{K\in\mathcal{T}_n}\mathcal{E}_K\right|,$$

[illegible] $\mathcal{E}_K = e_D^K + e_M^K$ [illegible]

$$\begin{aligned}
e_D^K &= \frac{1}{|I|}\int_I \big((\dot U_h + U_h\cdot\nabla U_h - f,\varphi-\Phi)_K - (P_h,\nabla\cdot(\varphi-\Phi))_K\\
&\quad + (\nabla\cdot U_h,\theta-\Theta)_K + (2\nu\epsilon(U_h),\epsilon(\varphi-\Phi))_K\big)\ dt,\\
e_M^K &= \frac{1}{|I|}\int_I SD_\delta(U_h,P_h;\Phi,\Theta)_K\ dt.
\end{aligned}$$

We may view e_D^K as the error contribution from the discretization on element K, and e_M^K as the contribution from the subgrid model (stabilization) on element K.

From the error representation in Theorem 3.1 there are various possibilities to construct error indicators and stopping criterions in an adaptive algorithm. Using standard interpolation estimates, with (Φ,Θ) a finite element interpolant of (φ,θ), we may estimate the contribution e_D^K from discretization as follows (cf. [12]):

$$\begin{aligned}
e_D^K \le \frac{1}{|I|}\int_I \big((|R_1(U_h,P_h)|_K + |R_2(U_h,P_h)|_K)\cdot(C_h h^2|D^2\varphi|_K + C_k k|\dot\varphi|_K)\\
+ \|R_3(U_h)\|_K(C_h h^2\|D^2\theta\|_K + C_k k\|\dot\theta\|_K)\big)\ dt,
\end{aligned}$$

where the residuals R_i are defined by

$$\begin{aligned} R_1(U_h,P_h) &= |\dot{U}_h + U_h\cdot\nabla U_h + \nabla P_h - f - \nu\Delta U_h|,\\ R_2(U_h,P_h) &= \nu D_2(U_h),\\ R_3(U_h,P_h) &= |\operatorname{div} U_h|, \end{aligned} \tag{3.7}$$

with

$$D_2(U_h)(x,t) = \max_{y\in\partial K}(h_n(x))^{-1}\left|\left[\frac{\partial U_h}{\partial n}(y,t)\right]\right| \tag{3.8}$$

for $x\in K$, with $[\cdot]$ the jump across the element edge ∂K. D^2 denotes second-order spatial derivatives, and we write $|w|_K \equiv (\|w_1\|_K, \|w_2\|_K, \|w_3\|_K)$, with $\|w\|_K = (w,w)_K^{1/2}$, and let the dot denote the scalar product in $\mathbb{R}^3$.

Note that $R_1(U_h,P_h)$ is defined elementwise and that with piecewise linear basis functions in space the Laplacian ΔU_h is zero, and that $R_1(U_h,P_h)+R_2(U_h,P_h)$ bounds the residual of the momentum equation, with the Laplacian term bounded by the second-order difference quotient $D_2(U_h)$ arising from the jumps of normal derivatives across element boundaries.

Replacing the exact dual solution (φ,θ) by a computed approximation (φ_h,θ_h), we are led to the following a posteriori error estimate:

$$|N(\sigma(u,p)) - N^h(\sigma(U_h,P_h))| \approx \left|\sum_{K\in\mathcal{T}_n}\mathcal{E}_{K,h}\right|, \tag{3.9}$$

where $\mathcal{E}_{K,h} = e^K_{D,h} + e^K_{M,h}$ with

$$\begin{aligned} e^K_{D,h} &= \frac{1}{|I|}\int_I \big((|R_1(U_h,P_h)|_K + |R_2(U_h,P_h)|_K)\cdot(C_h h^2|D^2\varphi_h|_K + C_k k|\dot{\varphi}_h|_K)\\ &\quad + \|R_3(U_h)\|_K\cdot(C_h h^2\|D^2\theta_h\|_K + C_k k\|\dot{\theta}_h\|_K)\big)\,dt,\\ e^K_{M,h} &= \frac{1}{|I|}\int_I SD_\delta(U_h,P_h;\varphi_h,\theta_h)_K\,dt, \end{aligned}$$

where we have replaced the interpolant (Φ,Θ) by (φ_h,θ_h). Again we may view $e^K_{D,h}$ as the error contribution from the discretization on element K, and $e^K_{M,h}$ as the contribution from the subgrid model (stabilization) on element K.

Remark 3.2. Non-Dirichlet boundary conditions, such as slip conditions at lateral boundaries and transparant outflow conditions, introduce additional boundary terms in the error representation in Theorem 3.1. Since the dual solutions for the examples in this paper are small at such non-Dirichlet boundaries, we neglect the corresponding boundary terms in the computations.

Remark 3.3. In the computations we use $C_k = 1/2$ and $C_h = 1/8$ as constant approximations of the interpolation constants in Theorem 3.1. These values are motivated by simple analysis on reference elements.

Remark 3.4. Note that for Theorem 3.1 to be valid, we only need the solution (u,p) to satisfy a weak formulation of the Navier–Stokes equations, with sufficient regularity for (3.2) to make sense.

3.4. An adaptive algorithm. For simplicity, we have the space mesh and time step k being constant in time, with the time step being equal to the smallest element diameter in the space mesh. In the computations we use an algorithm for adaptive mesh refinement in space based on the a posteriori error estimate (3.9), of the form: [illegible] $\mathcal{T}^0$ [illegible] $k = 0$ [illegible]

(1) [illegible] $\mathcal{T}^k$
(2) [illegible] $\mathcal{T}^k$
(3) [illegible] $\left|\sum_{K\in\mathcal{T}_k}\mathcal{E}^k_{K,h}\right| <$ [illegible]
(4) [illegible] $\mathcal{T}^k$ [illegible] $\mathcal{E}^k_{K,h} \to \mathcal{T}^{k+1}$
(5) [illegible] $k = k + 1$ [illegible] (1)

By refining the mesh size h, also the time step k and the subgrid model from stabilization SD_δ are refined implicitly, since both k and δ depend on h. The subgrid model may thus be thought of as being implicitly modified as we refine the mesh. But the error estimate (3.9) also allows for a direct adaptive modification of both the time step k and the subgrid model SD_δ, by locally refining k and δ, respectively. In this paper, we have not investigated the potential gain in using direct local refinement of k and δ, or using a space mesh varying in time.

We note that the structure of the error estimate (3.9) allows for a general interpretation of the subgrid model SD_δ; we may think of SD_δ as being the part of the numerical method not being a standard Galerkin (here cG(1)cG(1)) discretization of the Navier–Stokes equations.

4. Numerical results. We now seek to compute the [illegible] c_D, a mean value in time of a normalized drag force. Due to computational cost we have to truncate the time interval over which we average, and thus we approximate c_D by $\bar{c}_D$, a normalized drag force averaged over a given time interval I, defined by

$$\bar{c}_D = \frac{2}{\bar{U}_h^2 A} \times N(\sigma(u,p)), \tag{4.1}$$

where $\bar{U}_h$ is a bulk inflow velocity, A is an area, and $N(\sigma(u,p))$ is defined by (3.1). In computations, we approximate $\bar{c}_D$ by $\bar{c}_D^h$, defined by

$$\bar{c}_D^h = \frac{2}{\bar{U}_h^2 A} \times N^h(\sigma(U_h,P_h)), \tag{4.2}$$

with $N^h(\sigma(U_h,P_h))$ defined by (3.3). Thus we may use a scaled version of the a posteriori error estimate (3.9) to estimate the error $|\bar{c}_D - \bar{c}_D^h|$.

Below we will show that in the case of two bluff body benchmark problems, it is possible to use adaptive DNS/LES to compute approximations $\bar{c}_D^h$, such that the error $|\bar{c}_D - \bar{c}_D^h|$ is less than a few percent, using the computational power of a PC.

4.1. Flow around a surface mounted cube. We first consider a basic benchmark problem of CFD of computing the drag of a surface mounted cube at Reynolds number 40000. The incoming flow is laminar time-independent with a laminar boundary layer on the front surface of the body, which separates and develops a turbulent time-dependent wake attaching to the rear of the body. The flow in this problem is thus very complex with a combination of laminar and turbulent features including boundary layers and a large turbulent wake; see Figure 4.1.

The cube side length is $H = 0.1$, and the cube is centrally mounted on the floor of a rectangular channel of length $15H$, height $2H$, and width $7H$, at a distance of $3.5H$ from the inlet. The cube is subject to a Newtonian flow (u,p) governed by the Navier–Stokes equations (2.1) with kinematic viscosity $\nu = 2.5\times10^{-6}$ and a unit inlet bulk velocity corresponding to a Reynolds number of 40000, using the dimension of the cube as characteristic dimension. The inlet velocity profile is interpolated from

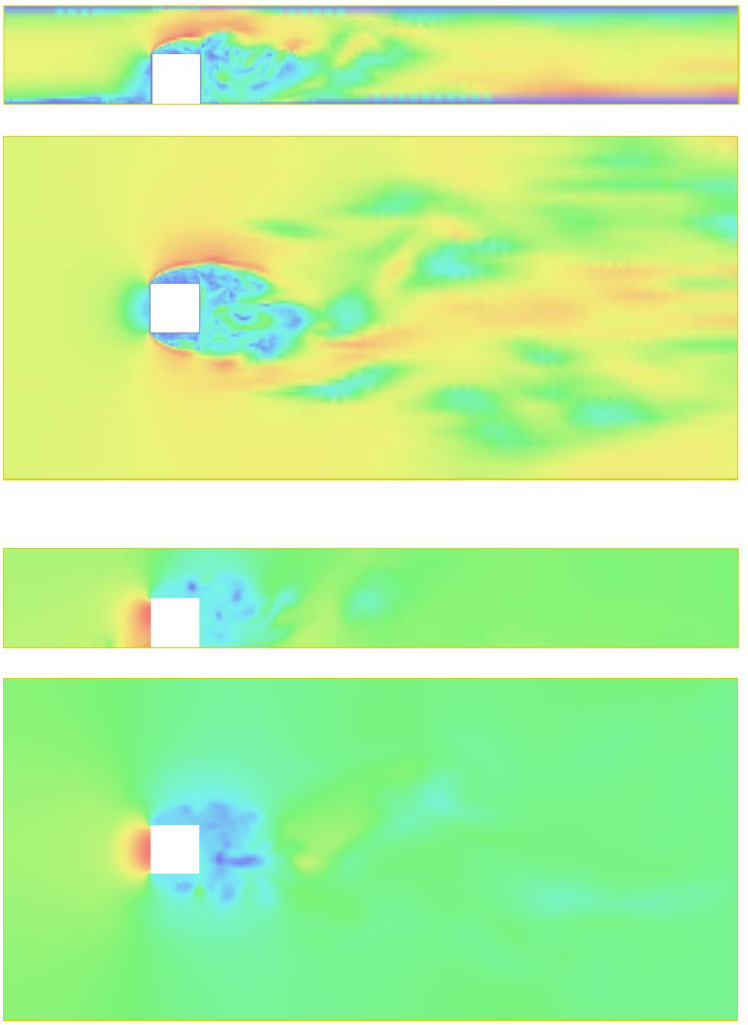

FIG. 4.1. *Surface mounted cube: Velocity* $|u|$ *(upper) and pressure* p *(lower), after* 16 *adaptive mesh refinements, in the* x_1x_2*-plane at* $x_3 = 3.5H$ *and in the* x_1x_3*-plane at* $x_2 = 0.5H$.

experiments, and we use no slip boundary conditions on the cube and the vertical channel boundaries, slip boundary conditions on the lateral channel boundaries, and a transparent outflow boundary condition.

We seek to approximate the drag coefficient $\bar{c}_D$, given by (4.1), averaged over a time interval $I = [0, 40H/\bar{U}_h]$ at fully developed flow. We set $\bar{U}_h = 1$ based on the bulk inflow velocity, and the area $A = H \times H = H^2$. This is a standard benchmark problem at the [illegible] [1], where also the inlet velocity profile is available for download.

In Figure 4.2 we plot the approximations $\bar{c}_D^h$ as we refine the mesh. We find that for the finer meshes $\bar{c}_D^h \approx 1.5$, a value that is well captured already using less than 10^5 mesh points. Without the contribution from the stabilizing terms in (3.3), we get a somewhat lower value for $\bar{c}_D^h$, where the difference is large on coarser meshes but

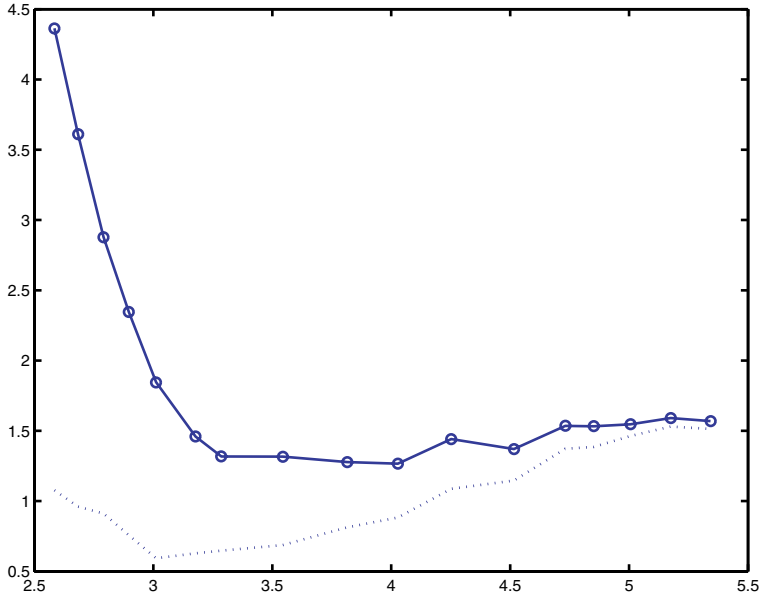

FIG. 4.2. *Surface mounted cube: Approximations of the drag coefficient* $\bar{c}_D^h$ *"∘" and the corresponding approximations without the contribution from the stabilizing term ":" in* (3.3)*, as functions of the* 10*-logarithm of the number of mesh points.*

small (less than 5%) on the finer meshes.

We know of no experimental reference values of $\bar{c}_D$, but in [5] a DNS is performed using about 70×10^6 degrees of freedom, with the same data as in this paper, giving $\bar{c}_D \approx 1.42$, where the stabilizing terms in (3.3) are not used for the evaluation of $\bar{c}_D$. The results in [5] should thus be compared to the somewhat lower values in Figure 4.2, resulting in a good agreement.

In [21], $\bar{c}_D$ is approximated using LES. The computational setup is similar to the one in this paper except for the numerical method, a different length of the time interval, and that in this paper we use a channel of length $15H$ compared to a channel of length $10H$ in [21]. Using LES with different meshes and subgrid models, approximations of $\bar{c}_D$ in the interval $[1.14, 1.24]$ are presented.

4.1.1. The dual solution. A snapshot of the dual solution is shown in Figure 4.3. We note that the dual solution, with boundary data on the cube, is of moderate size, and in particular is not exploding as pessimistic worst case analytical estimates may suggest, but rather seems to behave as if the net effect of the crucial reaction term (with large oscillating coefficient ∇U_h) is only a moderate growth. We also note that (φ_h, θ_h) is very concentrated in space, thus significantly influencing the adaptive mesh refinement. The resulting computational mesh after 15 adaptive mesh refinements is shown in Figure 4.3. The initial space mesh is uniform and very coarse, 384 mesh points, and without the dual weights in the a posteriori error estimate the mesh would come out quite differently. We notice in particular that the adaptive method automatically captures the turbulent wake, which seems to be essential for accurately computing drag.

4.1.2. A posteriori error estimates. In Figure 4.4 we plot the (normalized) a posteriori error estimates $e_{D,h}$ and $e_{M,h}$ from (3.9), as well as the true error based

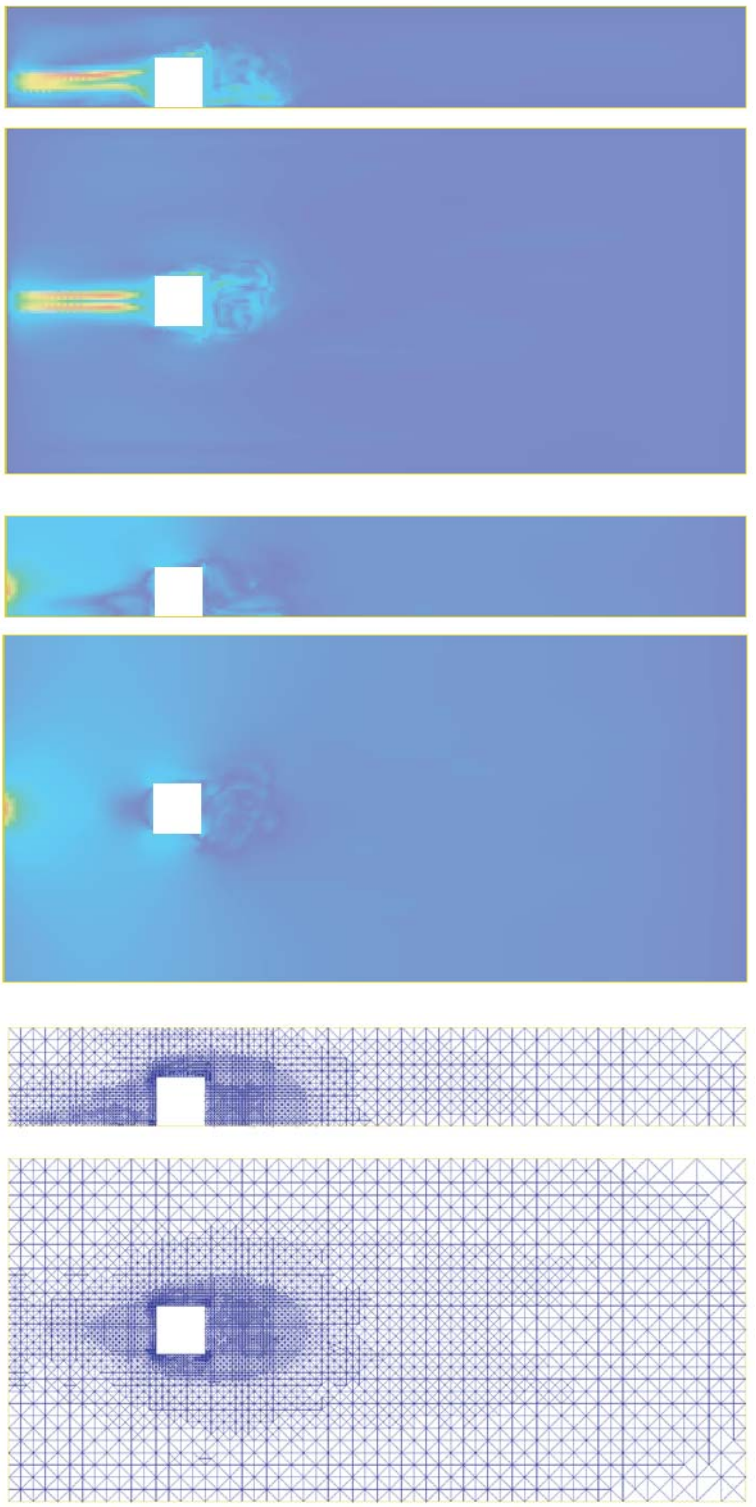

FIG. 4.3. *Surface mounted cube: Dual velocity* $|\varphi|$ *(upper), dual pressure* $|\theta|$ *(middle), and the resulting computational mesh (lower), in the* x_1x_2*-plane at* $x_3 = 3.5H$ *and in the* x_1x_3*-plane at* $x_2 = 0.5H$.

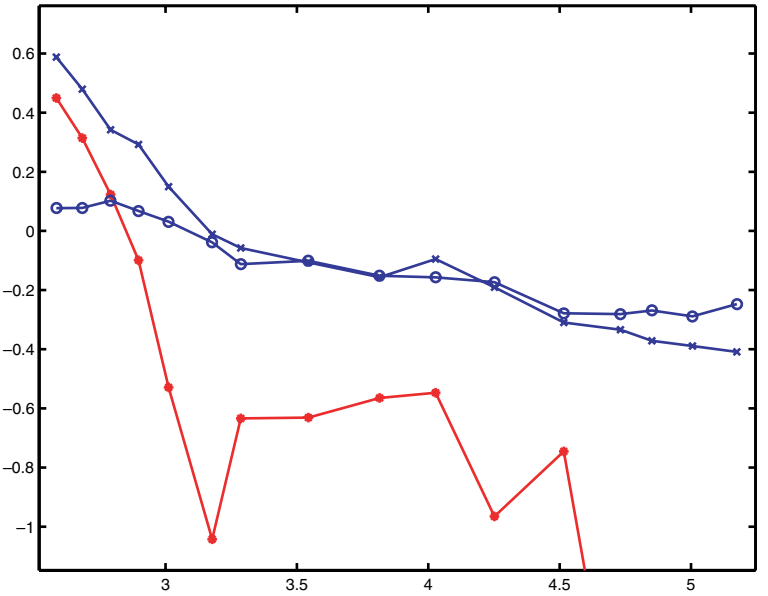

FIG. 4.4. *Surface mounted cube:* $\log_{10}$-$\log_{10}$ *plot of the (normalized) a posteriori error estimates* $e_{D,h}$ "$\circ$" *and* $e_{M,h}$ "$\times$" *and the true error* "$*$" *based on* $\bar{c}_D = 1.55$*, as functions of the number of mesh points in space.*

on the computational approximation on the finest mesh. The modeling error $e_{M,h}$ consists of sums in space and time of integrals over the space-time elements, and we may want to use a more conservative estimate of this term by taking the absolute values inside any or both of these sums. In the evaluation of $e_{M,h}$ in Figure 4.4, we have set the absolute values inside the sums in space and time.

We find that once the value for $\bar{c}_D^h$ has stabilized, the a posteriori error estimates indicate that it may be hard to further increase the precision.

4.2. Flow around a square cylinder. We now consider the benchmark problem of a square cylinder at Reynolds number 22000, based on the cylinder diameter $D = 0.1$ and the inflow velocity. The computational domain is a channel of size $21D \times 14D \times 4D$ in the x_1-direction with the cylinder directed in the x_3-direction and centered at $x_1 = 5D$ and $x_2 = 7D$. We have a unit inflow velocity, no slip boundary conditions on the cylinder, slip boundary conditions on the lateral boundaries, and a transparant outflow boundary condition.

As described, e.g., in [22, 7], characteristics of this flow are a turbulent wake of approximate diameter $1D$ attached to the trailing face of the cylinder, and two opposite shear layers periodically shedding vortices; see Figure 4.5. In addition, many authors have reported on a cycle-to-cycle variation, so-called [illegible], due to turbulence and 3d instabilities in the shear layers. In Figure 4.6, we show a time series of the vorticity for a computation on a fine mesh illustrating the transition in the shear layers.

The presence of phase jitter leads to complications when evaluating time averages, since the time averages are highly dependent of the length and location of the averaging interval, which has led to alternative ways to represent averages. One approach is to consider the so-called [illegible] [19], where a number of shedding cycles are chosen as "typical" for the flow, over which mean values are computed.

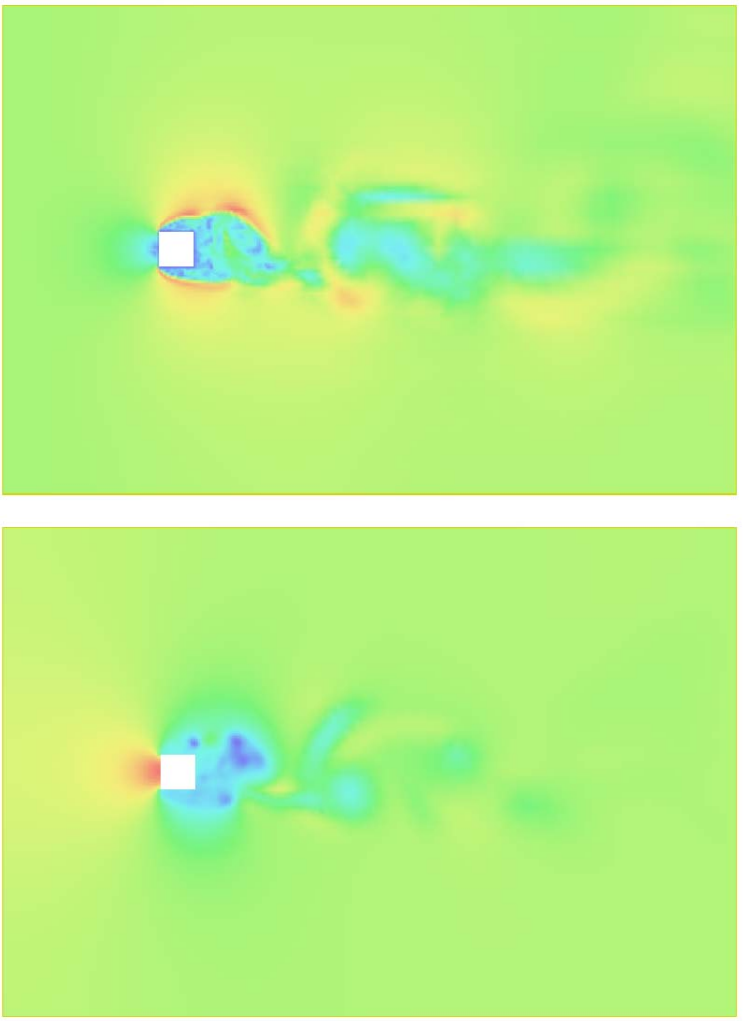

FIG. 4.5. *Square cylinder: Velocity* $|u|$ *(upper) and pressure* p *(lower), after nine adaptive mesh refinements, in the* x_1x_2*-plane at* $x_3 = 2D$.

We seek to approximate the drag coefficient $\bar{c}_D$, given by (4.1), averaged over a time interval $I = [0, 100D/\bar{U}_h]$ at fully developed flow, where we set $\bar{U}_h = 1$ based on the bulk inflow velocity, and the area $A = 4D \times D = 4D^2$.

In Figure 4.7 we plot the computed values of $\bar{c}_D^h$, as we refine the mesh. In Figure 4.7 we have also included the value for $\bar{c}_D^h$ without the stabilizing term in (3.3). For the finer meshes we get a $\bar{c}_D^h$ in the interval 2.0–2.4, and a value about 5% lower for the formulation without the stabilizing term. The variation in $\bar{c}_D^h$ could, to a certain degree, be explained by the effects of phase jitter, as noted above. In Figure 4.7 we plot the trajectory of the normalized drag force for the finest mesh, where we note variations in amplitude and local mean of the drag.

In [22], various reference values for this problem, including mean drag, are reported. Experimental reference values for $\bar{c}_D$ are reported to be in the interval 1.9–2.1, where the experiments are carried out with slightly different parameters, such as

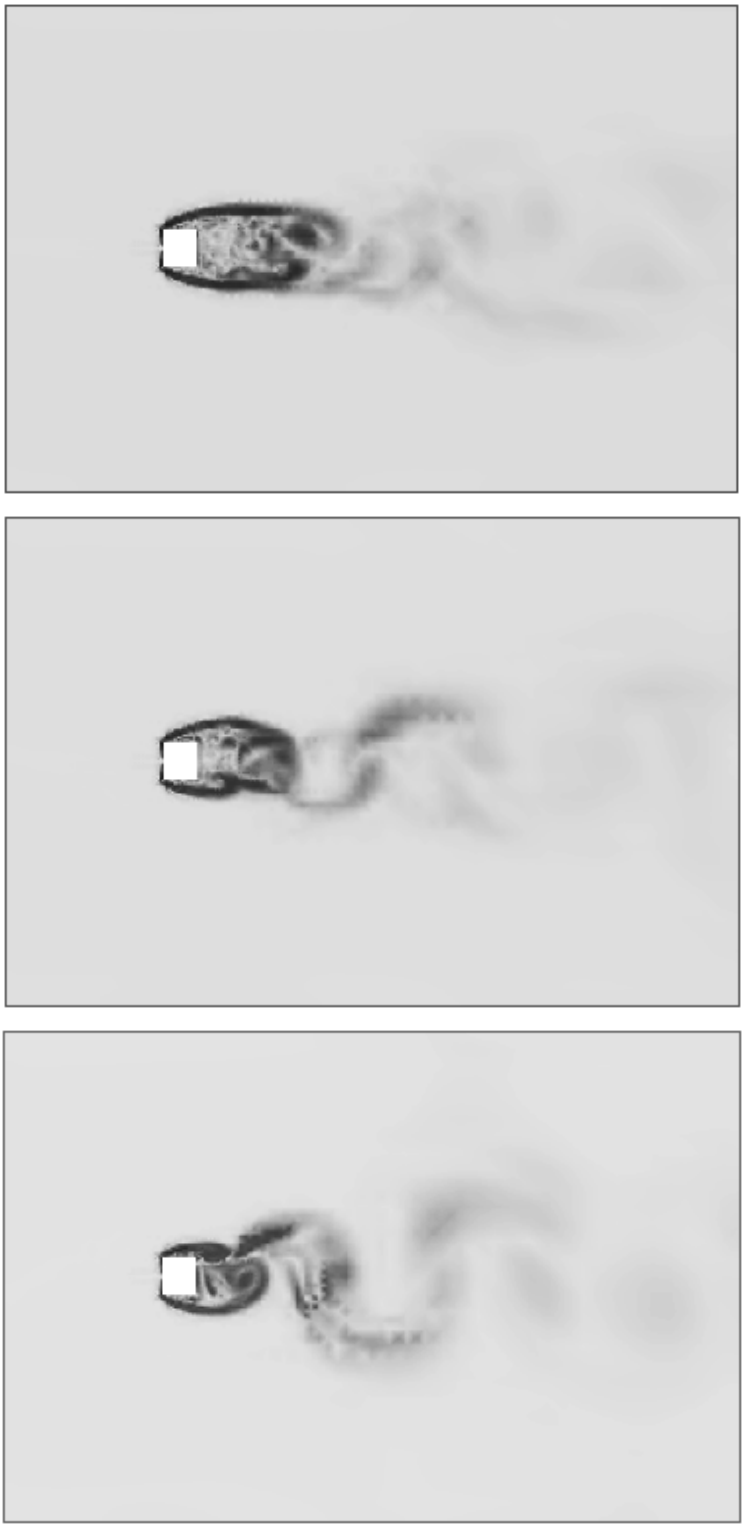

FIG. 4.6. *Square cylinder: Time evolution of the vorticity* $|\nabla \times u|$.

FIG. 4.7. *Square cylinder. Lower: normalized drag force as a function of time.*

a slightly lower Reynolds number, a longer cylinder, and a turbulent level of 2% in the inflow velocity. LES results are reported in the interval 1.66–2.77, and Reynolds averaged Naview–Stokes equations (RANS) results in the interval 1.6–2.0. To test the sensitivity in inflow data, we compare with a similar computation with 2% white noise added to the inflow velocity. The results are plotted in Figure 4.7, giving similar values for $\bar{c}_D^h$, although possibly somewhat lower, closer to the experimental results.

TABLE 4.1

Square cylinder. Reference values from [22]: Drag and lift ($\bar{c}_D$ and $\bar{c}_L$), and corresponding rms-values ($c_{D,rms}$ and $c_{L,rms}$), and Strouhal number St. The values in the parentheses correspond to evaluation of drag without contribution from the stabilizing term.

Output	Experiment	LES	RANS	Adaptive DNS/LES
$\bar{c}_D$	1.9–2.1	1.66–2.77	1.637–2.004	2.40 (2.31)
$c_{D,rms}$	0.1–0.2	0.10–0.27	—	0.17 (0.17)
$\bar{c}_L$	—	−0.3–0.007	—	−0.02
$c_{L,rms}$	0.1–1.4	0.38–1.79	—	0.84
St	0.132	0.066–0.15	0.134–0.143	0.14

As for the rest of the output data presented in [22], our results show a very good agreement, which we present in Table 4.1, where we give our results with adaptive DNS/LES for the finest mesh with about 1.2×10^5 mesh points in space, after nine adaptive mesh refinements.

Again we note the sensitivity in mean drag, where we, from Figure 4.7, can see that translating the averaging interval results in different $\bar{c}_D^h$. The computation of $\bar{c}_D^h$ in Table 4.1 corresponds to the interval $[10, 20]$ in Figure 4.7, and we see that translating this interval suitably would result in a lower $\bar{c}_D^h$, closer to the experimental reference values.

4.2.1. Dual solution. A snapshot of the dual solution is shown in Figure 4.8. We note that the dual solution, as in the case of the surface mounted cube, is of moderate size, and is concentrated in space. The resulting computational mesh after nine adaptive mesh refinements is shown in Figure 4.9. We notice that again the adaptive method automatically captures the turbulent wake, which is essential for accurately computing drag.

4.2.2. A posteriori error estimates. In Figure 4.10 we plot the (normalized) a posteriori error estimates $e_{D,h}$ and $e_{M,h}$ from (3.9), as well as an estimate of the true error based on the computational approximations on the finest meshes, suggesting that 2.2 may be a good candidate for a representative value of $\bar{c}_D$. In Figure 4.10, we set the absolute values inside the sums in space and time of $e_{D,h}$ and $e_{M,h}$. Thus error cancellation is not possible, leading to conservative error estimates.

4.3. Reliability and efficiency of the adaptive method. We now focus on two key points relating to the [illegible] and [illegible] of the adaptive method based on the a posteriori error estimate (3.9), which directly couples to whether this estimate indeed gives a reasonably sharp bound of the true error or not. The two key points are (i) replacement of u by a computed velocity U_h in the dual problem, and (ii) replacement of the dual solution (φ, θ) by a computed dual solution (φ_h, θ_h). We may view both these points to relate to a [illegible] of the dual solution under perturbations of (i) the convection coefficient and (ii) numerical computation.

We first consider the discretization error term $e_{D,h}$. We obtain a rough estimate of this term using Cauchy's inequality in space and time as follows (taking only space discretization coupled to φ into account and neglecting the small ν-term):

$$e_{D,h} \leq C_h \|hR_1(U_h, P_h)\| \|hD^2\varphi_h\|,$$

where $C_h \approx 0.1$, and by the least-squares stabilization in cG(1)cG(1) we have that $\|\sqrt{h}R_1(U_h, P_h)\|$ is bounded (recalling that $\delta_1 \sim h$, and neglecting the time derivative). Here $\|\cdot\| = \|\cdot\|_{L_2(I;L_2(\Omega))}$ denotes an L_2 norm in space time. Thus, very

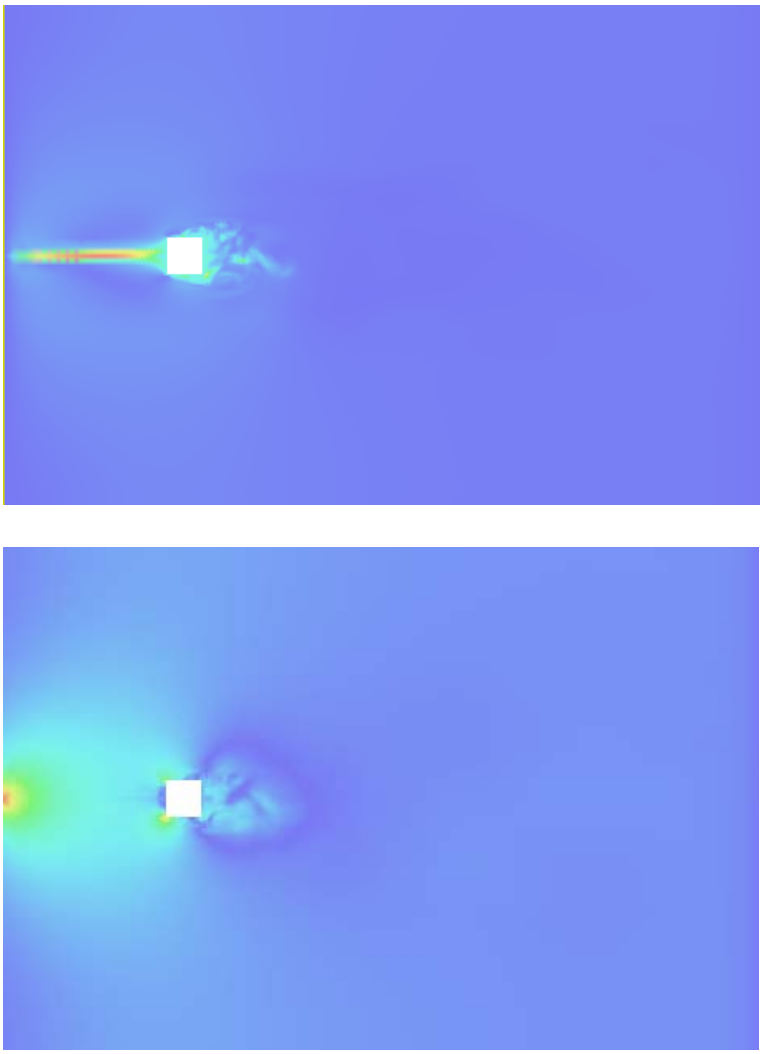

FIG. 4.8. *Square cylinder: Dual velocity* $|\varphi|$ *(upper) and dual pressure* $|\theta|$ *(lower), after nine adaptive mesh refinements with respect to mean drag, in the* x_1x_3*-plane at* $x_2 = 7D$ *and in the* x_1x_2*-plane at* $x_3 = 2D$*, with the darker color representing high values.*

roughly, we would expect to have

$$e_{D,h} \leq C_h\sqrt{h}\|hD^2\varphi_h\|.$$

In Figure 4.11 we display the variation of $\|hD^2\varphi_h\|$ as a function of the number of mesh points in space for the bluff body problems, and we find that after some initial refinements the dual solution shows a stability of $\|hD^2\varphi_h\|$ under the mesh refinement.

Next, the error contribution from subgrid modeling $e_{M,h} = SD_\delta(U_h, P_h; \varphi_h, \theta_h)$ may be estimated roughly as follows, using the basic energy estimate to bound $SD_\delta(U_h, P_h; U_h, P_h)$, Cauchy's inequality, and recalling that $\delta_1 \sim h$, to get

$$e_{M,h} \leq \sqrt{h}\|\nabla\varphi_h\|,$$

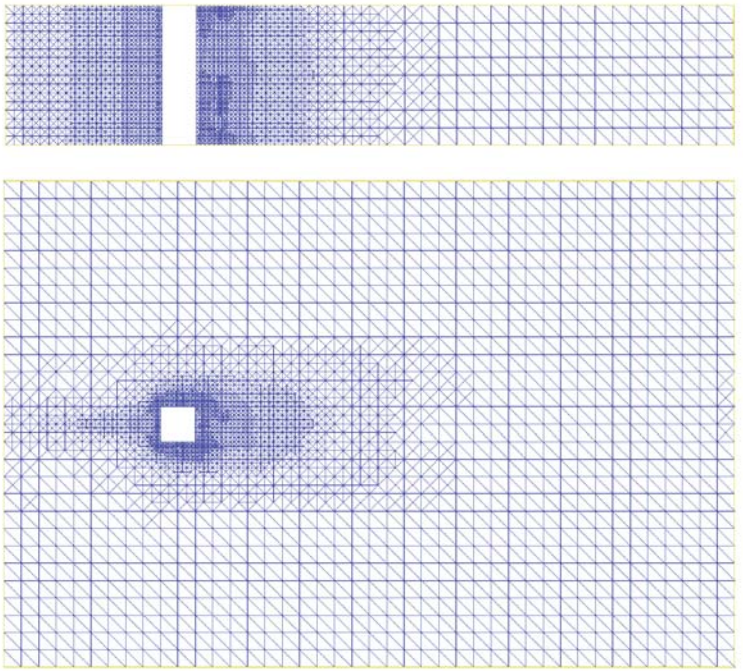

FIG. 4.9. *Square cylinder: Computational mesh after nine adaptive mesh refinements with respect to mean drag, in the x_1x_3-plane at $x_2 = 7D$ and in the x_1x_2-plane at $x_3 = 2D$.*

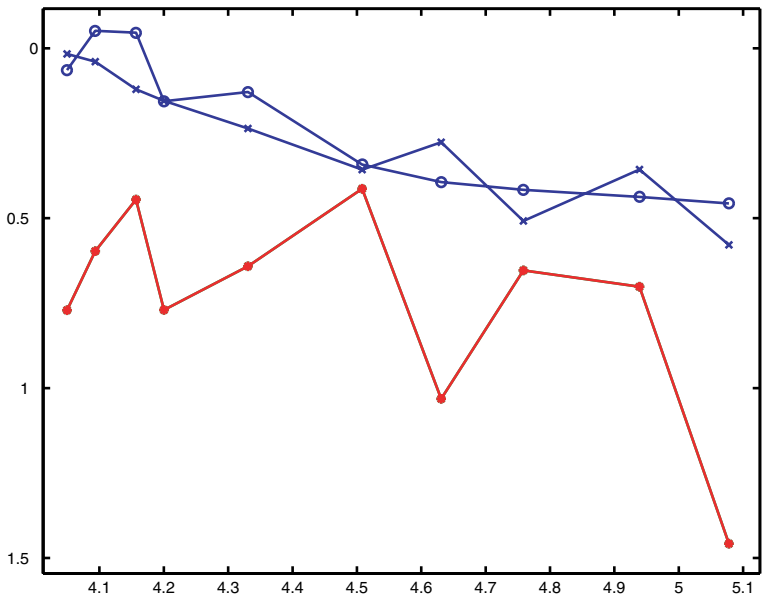

FIG. 4.10. *Square cylinder:* $\log_{10}$-$\log_{10}$ *plot of the (normalized) a posteriori error estimates* $e_{D,h}$ "$\circ$" *and* $e_{M,h}$ "$\times$" *and the true error "$*$" based on* $\bar{c}_D = 2.2$*, as functions of the number of mesh points in space.*

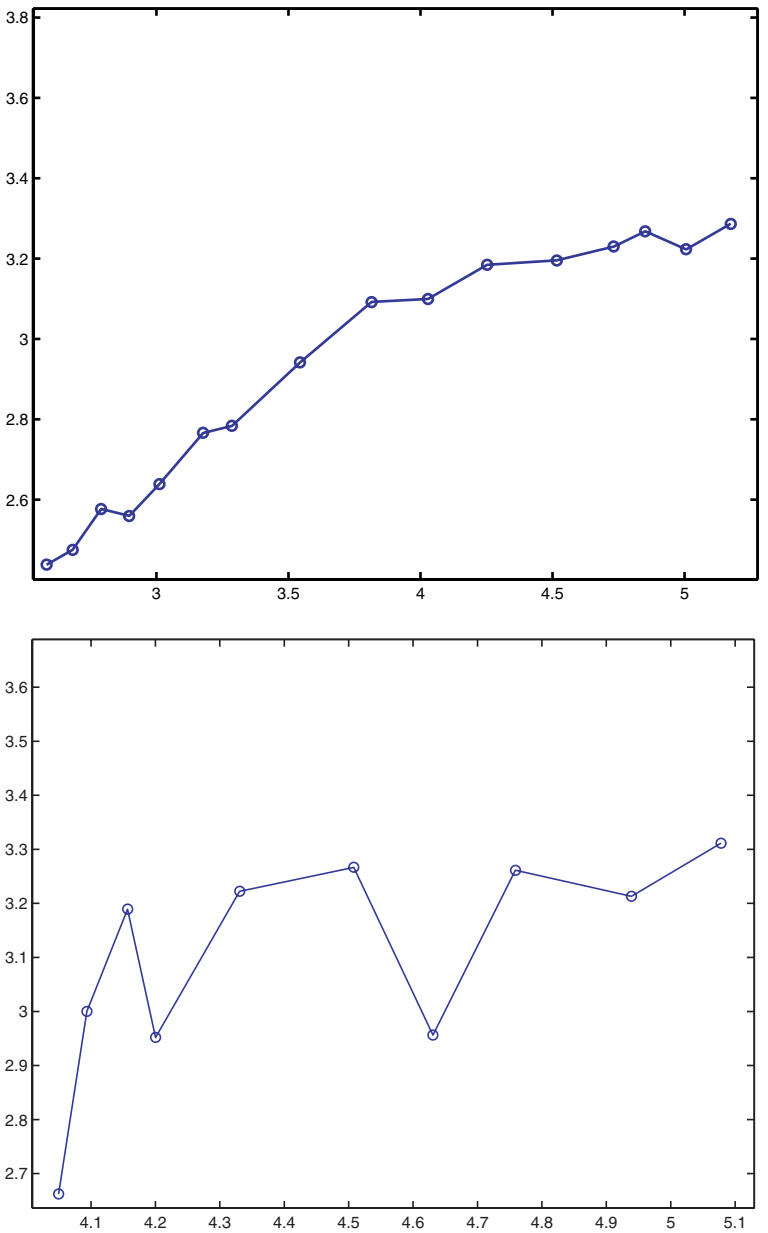

FIG. 4.11. Log_{10}-$\log_{10}$ *plot of the stability factor* $\|hD^2\varphi_h\|_{L_2(I;L_2(\Omega))}$ *for the surface mounted cube* (*upper*) *and the square cylinder* (*lower*), *versus number of mesh points in space.*

where we accounted only for the φ_h term. We notice in Figure 4.12 that $\|\nabla\varphi_h\|$ shows a stability under the mesh refinement suggesting that indeed $e_{M,h}$ may get below a moderate tolerance under refinement of the mesh without reaching a DNS.

Thus we conclude that the crucial computed dual weights show a stability under mesh refinement which indicates that the a posteriori error estimate (3.9) may be reliable and also reasonably efficient. In particular, we have given evidence that the net effect on the dual weights from replacing u by U_h in the dual problem may

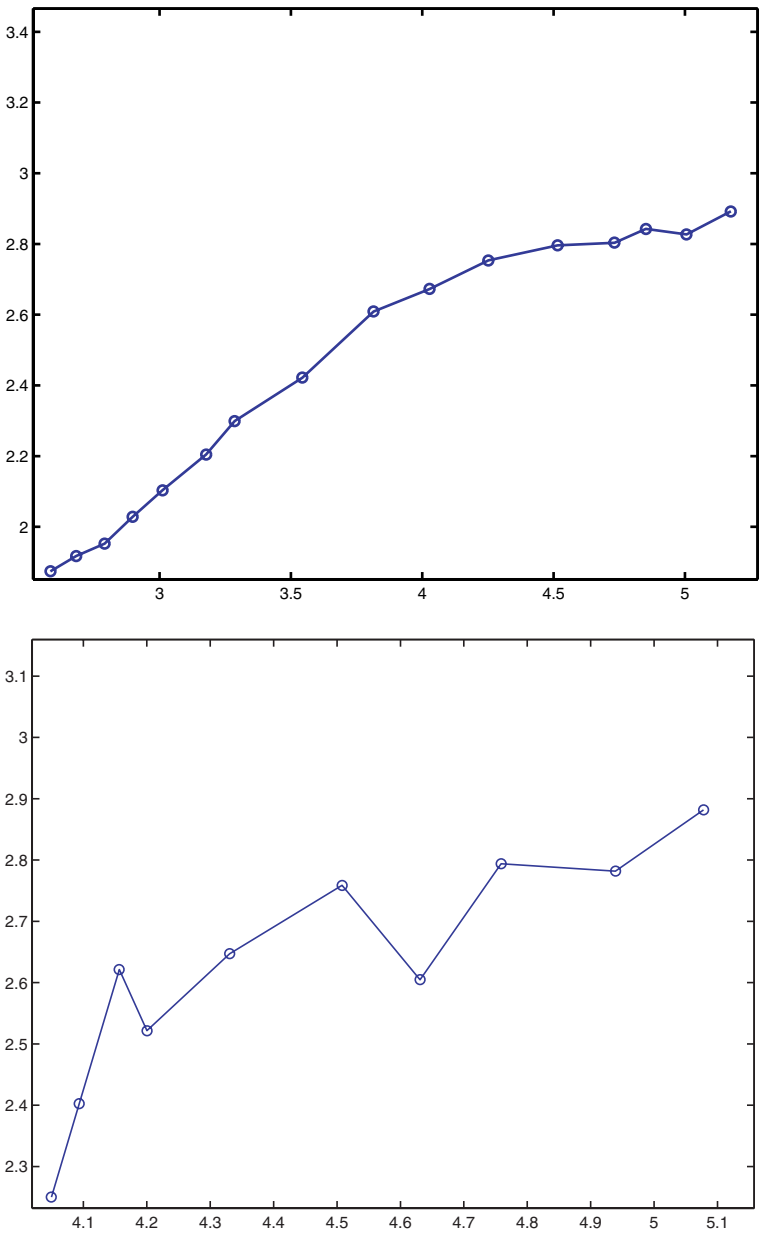

FIG. 4.12. Log_{10}-$\log_{10}$ *plot of the stability factor* $\|\nabla\varphi_h\|_{L_2(I;L_2(\Omega))}$ *for the surface mounted cube* (*upper*) *and the square cylinder* (*lower*), *versus number of mesh points in space.*

be small, even though this may correspond locally to a large perturbation since U_h cannot be expected to approximate u pointwise.

4.4. Turbulent dissipation. For accurate approximation of the drag in bluff body problems we need to capture the correct global dissipation, which follows from the basic global energy balances for the Navier–Stokes equations (2.1) and cG(1)cG(1) (2.3), obtained by multiplication by (u, p) and choosing $(v, q) = (U_h, P_h)$, respectively,

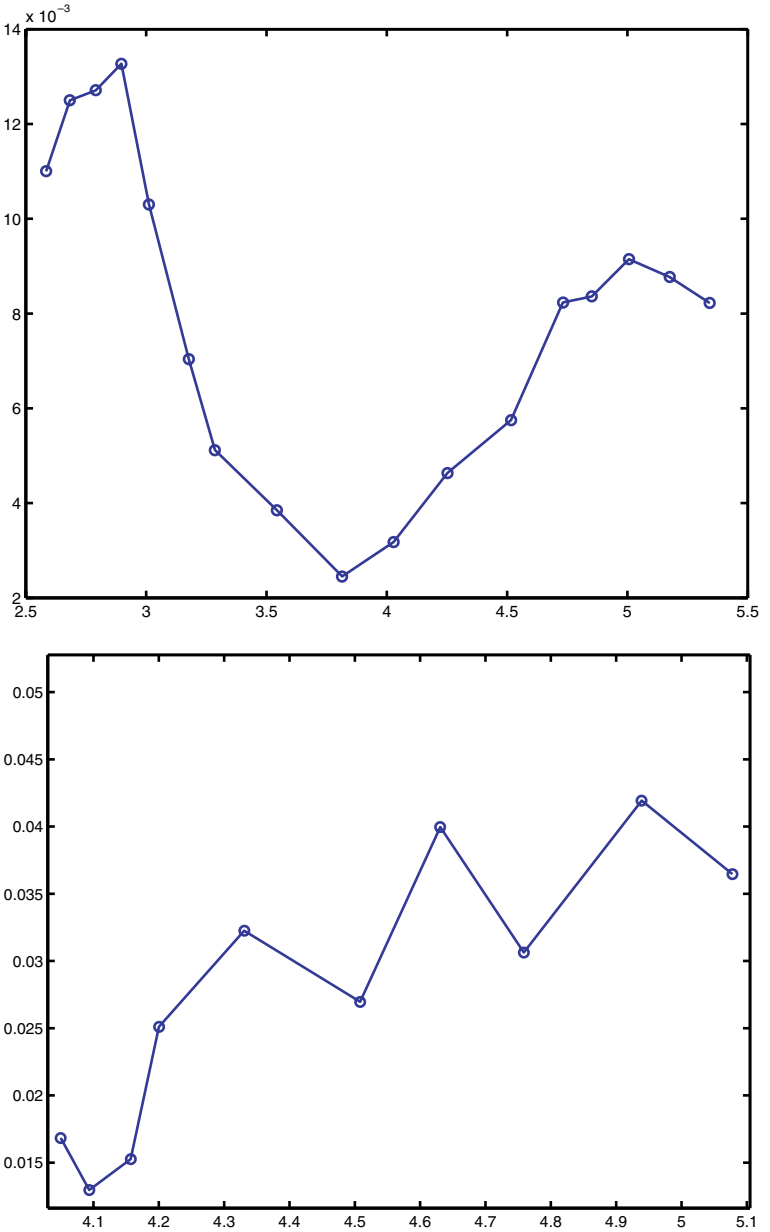

FIG. 4.13. *Volume of the turbulent wake, defined as the part of the domain with mean dissipation intensity of* $D(U_h, P_h) > 0.2$, *versus* $\log_{10}$ *of the number of mesh points, for the surface mounted cube* (*upper*) *and the square cylinder* (*lower*).

to get

$$\frac{d}{dt}\|u\|^2 \approx \int_{\Gamma_{\rm in}} pu \cdot n \; ds - \int_{\Gamma_{\rm out}} pu \cdot n \; ds - \nu\|\epsilon(u)\|^2,$$
$$\frac{d}{dt}\|U_h\|^2 \approx \int_{\Gamma_{\rm in}} P_h U_h \cdot n \; ds - \int_{\Gamma_{\rm out}} P_h U_h \cdot n \; ds - (\nu\|\epsilon(U_h)\|^2 + SD_\delta(U_h, P_h; U_h, P_h)),$$

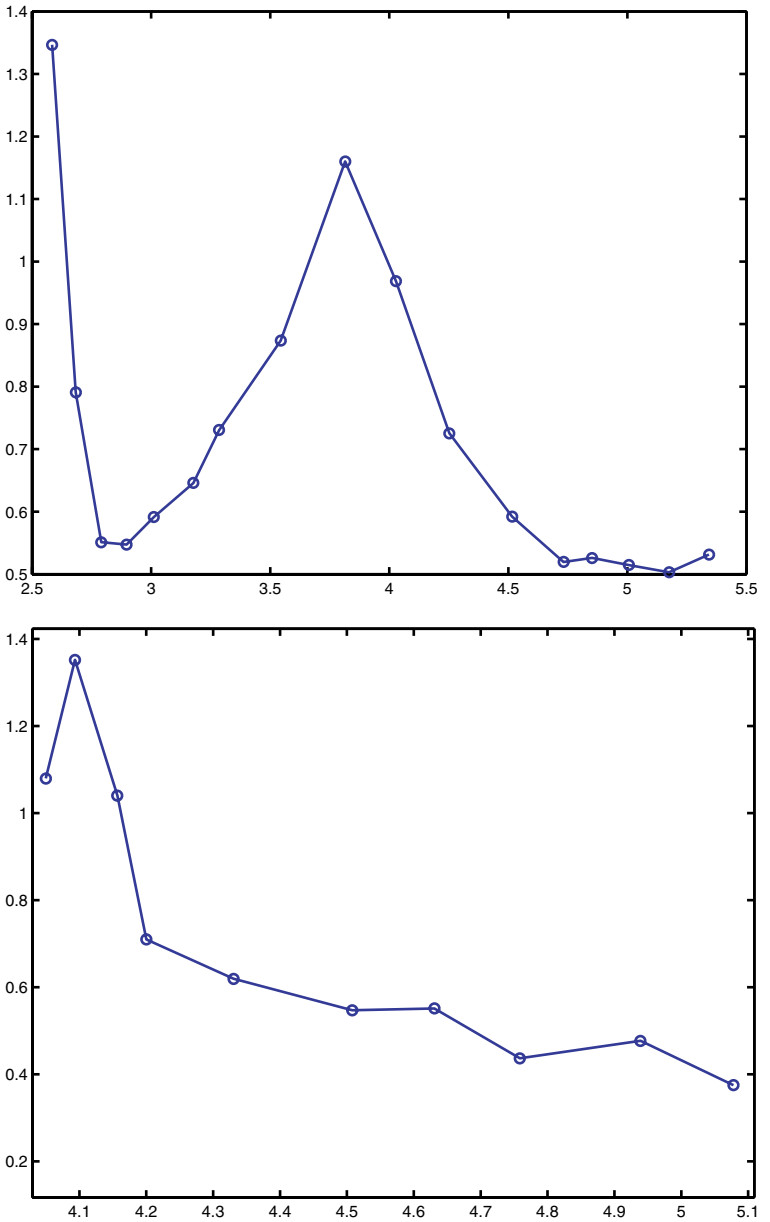

FIG. 4.14. *The mean value of the dissipation intensity of* $D(U_h, P_h)$ *as the sum of the intensity of* $D_\nu(U_h)$ *and the intensity of the stabilization term* $SD_\delta(U_h, P_h; U_h, P_h)$ *in the turbulent wake, versus* $\log_{10}$ *of the number of mesh points, for the surface mounted cube* (*upper*) *and the square cylinder* (*lower*).

using partial integration, dropping the small boundary terms containing ν, and denoting by Γ_{in} and Γ_{out} the inflow and outflow boundaries, respectively. Here $\|\cdot\|$ denotes the $L_2(\Omega)$ norm, and $D_\nu(u) = \nu\|\epsilon(u)\|^2$ represents the exact global dissipation (rate), and $D(U_h, P_h) = D_\nu(U_h) + SD_\delta(U_h, P_h; U_h, P_h)$ the corresponding cG(1)cG(1) approximate global dissipation (rate). We notice that the difference of the two boundary integrals represents the pressure drop from inflow to outflow, which

roughly should correspond to the drag. Since in the bluff body problems we have $\frac{d}{dt}\|u\|^2 \sim \frac{d}{dt}\|U_h\|^2 \sim 0$, we thus have that the pressure drop $\sim$ global dissipation, and thus we expect that the drag $\sim$ global dissipation.

In Figure 4.13 we show the development under the mesh refinement process of the volume of the turbulent wake. We note that the volume increases as the early refinement proceeds. The initial large values for the volume on the coarsest meshes are related to large numerical dissipation from the stabilization on these under resolved meshes. We may view the refinement as increasing the effective Reynolds number in the computation, and thus we may expect the expansion of the turbulent wake to parallel an expansion of the wake as the Reynolds number increases.

In Figure 4.14 we show (the mean value of) the computed intensity of the global dissipation $D(U_h, P_h)$ in the turbulent wake, being the sum of the intensity of $D_\nu(U_h)$, which is small, and the intensity of $SD_\delta(U_h, P_h; U_h, P_h)$ corresponding to the stabilization. We hope (the mean value of) $D(U_h, P_h)$ to be an approximation of (the mean value of) the dissipation rate $D_\nu(u)$, which we expect to be most significant in the turbulent wake. We observe that (the mean value of) the intensity of $D(U_h, P_h)$ is very nearly constant during the finer part of the refinement process, which we may take as evidence that indeed (the mean of) the intensity of the mesh dissipation $D(U_h, P_h)$ may approximate (the mean value of) the true fine scale dissipation intensity $D_\nu(u)$.

5. Summary and future directions. We have considered two bluff body benchmark problems, where we have shown that we are able to compute the drag coefficient to an estimated tolerance of a few percent, using about 10^5 mesh points in space, with the computational power of a PC.

The mesh refinement criterion and the stopping criterion of the adaptive algorithm are based on a posteriori error estimates of an output of interest, in the form of a space-time integral of a residual times a dual weight. The dual weight is obtained from the computational approximation of an associated dual problem with data coupled to the output of interest. We have presented computational evidence that crucial properties of the dual solution are stable under the adaptive mesh refinement.

In adaptive DNS/LES no filtering is used, but instead output from the exact Navier–Stokes equations is approximated directly, using cG(1)cG(1) with the least-squares stabilization acting as a dissipative subgrid model. In particular, we circumvent the problem of closure as no modeling of Reynolds stresses is necessary. Instead we estimate the error contribution from subgrid modeling a posteriori, which we find to be small.

Encouraged by the results in this paper, we plan to extend the study of adaptive DNS/LES to more benchmark problems of turbulent flow. In addition, there are many potential optimizations of the adaptive algorithm to investigate. For example, one would like to consider the possible gains of using dynamically changing meshes, adaptively refined time steps, and adaptive choice of different time steps in different parts of the domain. Also, one would like to adaptively choose δ in the stabilization SD_δ, or more generally, to adaptively choose the form of SD_δ.

THE EXPLICIT SIMPLIFIED INTERFACE METHOD FOR COMPRESSIBLE MULTICOMPONENT FLOWS*

BRUNO LOMBARD† AND ROSA DONAT‡

Abstract. This paper concerns the numerical approximation of the Euler equations for multicomponent flows. A numerical method is proposed to reduce spurious oscillations that classically occur around material interfaces. It is based on the explicit simplified interface method (ESIM), previously developed in the linear case of acoustics with stationary interfaces [J. Piraux and B. Lombard, *J. Comput. Phys.*, 168 (2001), pp. 227–248]. This technique amounts to a higher-order extension of the ghost fluid method introduced in Euler multicomponent flows [R. P. Fedkiw, T. Aslam, B. Merriman, and S. Osher, *J. Comput. Phys.*, 152 (1999), pp. 457–492]. The ESIM is coupled to sophisticated shock-capturing schemes for time-marching, and to level-sets for tracking material interfaces. Jump conditions satisfied by the exact solution and by its spatial derivative are incorporated in numerical schemes, ensuring a subcell resolution of material interfaces inside the meshing. Numerical experiments show the efficiency of the method for rich-structured flows.

Key words. Euler equations, multicomponent flows, jump conditions, interface methods, ghost fluid method, ENO-WENO, level-set

1. Introduction.

Let us consider multicomponent flows composed of pure inviscid fluids separated by material interfaces. These flows arise in a wide range of physical situations, from water-steam to bubbly flows, liquid suspensions, or even high-speed impacts on solids. They may be modeled by the Euler equations, augmented by additional equations describing the fluid composition. The numerical simulation of such configurations leads to major difficulties.

Indeed, even state-of-the-art numerical schemes for single-component flows cannot be applied directly in multicomponent flow simulations. These schemes give rise to oscillations and other computational inaccuracies near material interfaces. For example, any Godunov-type shock-capturing scheme which conserves the mass of individual species fails to maintain pressure equilibrium at a material interface [1]. The unphysical pressure oscillations stem from the fact that in a shock-capturing scheme, the transition across a material interface is governed by the numerical viscosity of the scheme. When two fluids are involved, intermediate states generated in the numerical transition layer (corresponding to the material interface) are not physically consistent with any component of the mixture: updating the pressure field via one particular equation of state (EOS) generates erroneous pressure fluctuations. Since material interfaces lack the compressive mechanisms associated to shocks, errors generated within the diffused interface escape and contaminate all flow variables.

Many numerical methods have been proposed to avoid these unphysical oscillations. See, e.g., [2] for a concise survey of up-to-date multicomponent methods. Remaining within the [illegible] (as opposed to [illegible]) computational framework, we distinguish two main approaches.

[illegible]. Material interfaces are approximated by diffused fronts. An artificial EOS (or mixture model) is defined, based on thermodynamical arguments [3, 17, 23], which is considered valid for the entire fluid mixture and is used to update the pressure from conserved variables. These models have been analyzed in [1, 2, 15, 16, 31]. The elimination of unphysical oscillations generally involves sacrificing strict conservation to some degree, except in [23] where a conservative algorithm maintains oscillations under a computationally acceptable level.

[illegible] (as in the present paper). A level-set function is used to track material interfaces in an Eulerian manner, i.e., without explicitly computing their location. Depending on the sign of the level-set, one applies the corresponding EOS. Thermodynamic properties of the fluid change discontinuously across material interfaces, which are preserved as sharp discontinuities. A simple approach was first used in [24], but it suffers from severe computational inaccuracies in multicomponent flow computations [16].

The [illegible] (GFM) [8] is the best-known method belonging to this second group. On each side of a material interface, two fluids are considered: the "real fluid" (i.e., the fluid that really exists on this side) and a "ghost fluid" (i.e., the fluid with the same pressure and velocity as the real fluid on that side, but the entropy of the real fluid on the other side). Near a material interface, classical single-component schemes are then simply applied both on "real fluid" values and on "ghost fluid" values. Extensions to multidimensional problems and to other physical situations have been tackled by the GFM [7, 9]. However, the GFM suffers from some inaccuracies which are not appreciated when material interfaces separate uniform states. These numerical artifacts are mainly due to the zeroth-order extrapolations used to define the ghost fluid. Simple minded first-order extrapolations do not work [8].

The goal of the present paper is to remove these drawbacks of the GFM by correctly increasing the precision of the computation across a material interface. We propose to implement a carefully designed first-order extrapolation procedure to obtain the "ghost fluid" values. To do so, we adapt the [illegible] (ESIM), previously developed for the linear hyperbolic systems of acoustics with stationary interfaces [21, 22, 27]. Note that another linear extrapolation in the context of the GFM has been proposed in [4] in order to couple Eulerian and Lagrangian computations. In the present paper, however, the goal is to enforce first-order jump conditions at material interfaces.

Interface methods have been widely used in the numerical treatment of boundaries and interfaces in PDEs; see, e.g., the [illegible] (IIM), applied to elliptic equations [18] and linear hyperbolic systems [34]. See [20, 27] for a concise survey of up-to-date interface methods. To our knowledge, the present paper is the first attempt to apply interface methods to the nonlinear hyperbolic system of the Euler equations. The computational complexity of the resulting algorithm is essentially the same as that of the GFM, and it can easily be coupled to a wide class of high-order shock-capturing schemes.

The paper is organized as follows. Section 2 recalls the level-set framework to model compressible multicomponent flows. Section 3 describes the numerical schemes. The interface method is detailed in section 4. Numerical tests are proposed in section

5. Conclusions and future works are drawn in section 6.

2. The level-set framework for multicomponent flows.

2.1. The Euler equations. We focus on multicomponent flows consisting of pure fluids separated by material interfaces. Assuming that all components can be described by a single velocity and pressure function, the flow can be modeled by the compressible Euler equations expressing conservation of mass, momentum, and energy of the fluid mixture. Let ρ be the density of the fluid mixture, u the velocity, p the pressure, and $e = \varepsilon + \frac{1}{2}u^2$ the specific total energy, with ε the specific internal energy. Then, we have

$$\frac{\partial}{\partial t}\boldsymbol{U} + \frac{\partial}{\partial x}\boldsymbol{f}(\boldsymbol{U}) = \boldsymbol{0}, \tag{2.1}$$

where the vector of conserved quantities $\boldsymbol{U}$ and the flux function $\boldsymbol{f}$ are

$$\boldsymbol{U} = \begin{pmatrix} \rho \\ \rho\, u \\ \rho\, e \end{pmatrix}, \qquad \boldsymbol{f}(\boldsymbol{U}) = \begin{pmatrix} \rho\, u \\ \rho\, u^2 + p \\ u\,(\rho\, e + p) \end{pmatrix}. \tag{2.2}$$

To close the system (2.1), we need to specify the EOS. In this paper, we consider the [illegible] EOS

$$p = (\gamma - 1)\,\rho\,\varepsilon - \gamma\, p_\infty, \tag{2.3}$$

where p_∞ is the stiffness parameter. The basic [illegible] case is recovered for $p_\infty = 0$; in this case, γ represents the ratio of specific heats. The EOS (2.3) is a reasonable approximation for gases, liquids, and even solids under huge pressure conditions [29]. The sound speed c is given by

$$c^2 = \frac{\gamma\,(p + p_\infty)}{\rho}. \tag{2.4}$$

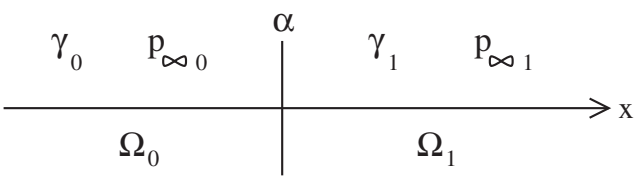

FIG. 2.1. *Two components Ω_0 and Ω_1 separated by a material interface.*

2.2. The level-set equation. The flow description is completed by an additional equation describing the fluid composition. In the level-set framework, a scalar function ϕ is used to track material interfaces. For the sake of simplicity, we consider only two components Ω_0 and Ω_1, separated by a material interface at $\alpha(t)$ (see Figure 2.1). We suppose that each fluid satisfies (2.3) and that physical parameters of (2.3) may be discontinuous at α:

$$(\gamma, p_\infty) = \begin{cases} (\gamma_0, p_{\infty\,0}) & \text{if } x \le \alpha, \\ (\gamma_1, p_{\infty\,1}) & \text{if } x > \alpha. \end{cases} \tag{2.5}$$

The marker variable ϕ is initialized as the signed distance function to $\alpha(0)$, which is known initially. Hence its zero level-set defines the material interface at $t = 0$, while its sign determines the region occupied by each fluid.

Since material interfaces propagate with the fluid velocity, the zero level-set of ϕ identifies the material interface for all $t > 0$ if $\phi(x, t)$ satisfies the advection initial value problem

$$\begin{cases} \dfrac{\partial \phi}{\partial t} + u \dfrac{\partial \phi}{\partial x} = 0, \\ \\ \phi(x, 0) = x - \alpha(0). \end{cases} \tag{2.6}$$

The evolution equation in (2.6) can be recast in conservation form by combining it with the conservation of mass,

$$\frac{\partial \rho \phi}{\partial t} + \frac{\partial u \rho \phi}{\partial x} = 0. \tag{2.7}$$

Equations (2.1), (2.3), and (2.6) (or (2.7)) form an "inmiscible" model in which the fluid "mixture" consists of either fluid Ω_0 or Ω_1, and where thermodynamic properties change discontinuously across the material interface.

3. Numerical schemes. To integrate the Euler equations and the level-set equation for multicomponent flows, two strategies are available. The first one is to discretize the conservative system composed by the Euler equations (2.1) together with the level-set equation in conservation form (2.7). This discretization can be performed by applying the classical methodology of shock-capturing schemes for systems of conservation laws. It has been used in other papers (see, e.g., [24]), but the addition of the level-set equation enlarges the Jacobian matrix, which increases the complexity of characteristic decompositions. This feature may become especially cumbersome in multidimensional calculations.

The second strategy—simpler, and followed here—is considered in [8], where the Euler equations (2.1) are discretized independently from the level-set equation in nonconservative form (2.6). Following [11], the Euler system is identified as the [illegible]; hence it can be discretized with any standard conservative scheme, while the level-set equation is independently discretized following its advection form (2.6). The numerical flux function involved in the Euler equations will therefore not depend directly on ϕ, as in a single-component flow. The Lax–Wendroff theorem can still be applied [11]; hence the obtained numerical solution converges to a weak solution of the full conservative system.

The discrete set-up to solve the system (2.1)–(2.6) is as follows: we consider a lattice of points in the x-plane $x_i = i\,\Delta x$, where Δx is a uniform spacing parameter. Numerical values $\boldsymbol{U}_i^n$ and ϕ_i^n are, respectively, considered as approximations to $\boldsymbol{U}$ and ϕ at x_i and time t_n [30]. To decouple the spatial and time integrations, we follow a [illegible] approach [19] for both the Euler system and the level-set equation. The semidiscrete approximation of the nonlinear hyperbolic system (2.1) is written

$$\frac{d}{d\,t}\,\boldsymbol{U}_i = \boldsymbol{L}_\Omega(\boldsymbol{U}, i), \tag{3.1}$$

whereas the semidiscrete approximation of the advection equation (2.6) is

$$\frac{d}{d\,t}\,\phi_i = G(\phi, i). \tag{3.2}$$

The discrete operator $\boldsymbol{L}_\Omega$ in (3.1) is specified in subsection 3.1. We say that a grid point is [illegible] if $\boldsymbol{L}_\Omega$ uses numerical values belonging only to one fluid component. Otherwise, a grid point is called [illegible], and the expression of $\boldsymbol{L}_\Omega$ is modified by the interface method detailed in section 4. The discrete operator G in (3.2) is specified in subsection 3.2.

We emphasize the fact that the numerical schemes proposed in the next two subsections are by no means fundamental for the interface method. The reader's favorite single-component solvers can be adapted easily to the forthcoming discussion.

3.1. Discretization of the Euler equations. When x_i is a regular point, all the values involved in the flux computations belong to one of the fluid components, say, Ω_l. Then, the spatial discrete operator $\boldsymbol{L}_\Omega = \boldsymbol{L}_{\Omega_l}$ in (3.1) is written in the customary conservation form

$$\boldsymbol{L}_{\Omega_l}(\boldsymbol{U}, i) = -\frac{1}{\Delta x}\left(\boldsymbol{F}_{\Omega_l}\left(\boldsymbol{U}_{i-s+1}, \ldots, \boldsymbol{U}_{i+s}\right) - \boldsymbol{F}_{\Omega_l}\left(\boldsymbol{U}_{i-s}, \ldots, \boldsymbol{U}_{i+s-1}\right)\right). \tag{3.3}$$

The numerical flux function $\boldsymbol{F}_\Omega$ in (3.3) is the trademark of the scheme; it is defined by a reconstruction procedure, and by a solver. In numerical experiments, we use ENO or WENO reconstructions [30, 13]. The width of the stencil s in (3.3) is related to the theoretical order of accuracy of the spatial reconstruction ($s = 3$ for ENO-3 or WENO-5).

As a solver, we consider a flux-splitting construction [6, 10]. This choice has been considered in [23] within the mass fraction model for two-ideal gas flows. This flux-splitting requires two spectral decompositions of the Jacobian at each cell interface, which serve to perform upwind reconstructions of characteristic variables and fluxes. The additional cost is counterbalanced by the robust behavior of the scheme in pathology-prone situations. In addition, and as opposed to a Roe-type numerical flux function, no average state needs to be computed at a cell interface, which is particularly useful for real-gas simulations. We need only to know the spectral decomposition of the Jacobian matrix: for the EOS (2.3), this is given, e.g., in [32].

The time integration of (3.1) is performed by the standard third-order TVD Runge–Kutta [30], even when the fifth-order WENO-5 reconstruction is used. Δt follows from Δx and from the classical CFL condition of stability

$$\mathrm{CFL} = \max_{i=0,\ldots,N_x}\left(|u_i^n| + c_i^n\right)\frac{\Delta t}{\Delta x} \leq 1, \tag{3.4}$$

where $N_x + 1$ is the number of grid points.

3.2. Discretization of the level-set equation. We follow the same method of lines as for the Euler system. The spatial discretization is carried out using the Hamilton–Jacobi framework for the numerical approximation of the derivative terms [14, 26]. The upwind direction at x_i is determined by the sign of u_i. Full details are in Appendix A.1 of [8].

Theoretically, solving (2.6) is sufficient to track the material interface. However, some extra care must be taken for numerical purposes. Since u is nonuniform along the flow, the numerical representation of $\phi(x, t)$ may become distorted [28], leading to a poor estimation of the position of α. To keep ϕ approximately equal to the distance function near the material interface, we follow a classical procedure proposed in [33] and called [illegible] of the level-set. This procedure can be carried out in a

number of different ways; here we follow [8] and solve to steady state the Hamilton–Jacobi equation

$$\begin{cases} \dfrac{\partial \tilde{\phi}}{\partial t} + S(\tilde{\phi}) \left(\left| \dfrac{\partial \tilde{\phi}}{\partial x} \right| - 1 \right) = 0, \\ \\ \tilde{\phi}(x,0) = \phi(x,t_n), \end{cases} \tag{3.5}$$

where S is a smeared sign function given by

$$S(\tilde{\phi}) = \frac{\tilde{\phi}}{\sqrt{\tilde{\phi}^2 + \Delta x^2}}.$$

The reinitialization equation is solved in fictitious time after each fully complete time-step for the Euler equations, with a method of lines approach. For the spatial integration of (3.5), we use a modification of Godunov's method detailed in Appendix A.3 of [8]. For the time integration, we use the same TVD Runge–Kutta scheme as for the Euler equations. As a time-step, we take $\Delta \tau = \Delta x$. After five integrations, we obtain a steady distance function, $\tilde{\phi}$, which is then exchanged with ϕ.

4. The ESIM for the Euler equations.

4.1. The numerical interface treatment. The ESIM is a numerical treatment to be applied at irregular points, i.e., at points for which the flux computations in the right-hand side of (3.1) involve more than one fluid component. This treatment is carried out at each time integration (such as a Runge–Kutta substep). Let us fix an instant in time (to simplify the notation, the time variable is omitted from now on). Then, the basic strategy of the ESIM can be schematically described as follows.

Consider the material interface at $x = \alpha$ separating the two media Ω_0 and Ω_1 (Figure 2.1). We define smooth extensions $\boldsymbol{U}^*(x)$ of the exact solution $\boldsymbol{U}(x)$; here, we consider two-term Taylor-like expansions past the interface, written

$$\begin{aligned} &\text{for } x > \alpha, \qquad \boldsymbol{U}^*(x) = \boldsymbol{U}(\alpha^-) + (x-\alpha) \frac{\partial}{\partial x} \boldsymbol{U}(\alpha^-), \\ &\text{for } x \le \alpha, \qquad \boldsymbol{U}^*(x) = \boldsymbol{U}(\alpha^+) + (x-\alpha) \frac{\partial}{\partial x} \boldsymbol{U}(\alpha^+). \end{aligned} \tag{4.1}$$

Then, the interface treatment is divided in two parts.

First, numerical estimations $\boldsymbol{U}_i^*$ of $\boldsymbol{U}^*(x_i)$ in (4.1), called [illegible] (or [illegible], in the GFM framework), are sought at grid points surrounding α (see Figure 4.1). To do so, one must estimate $\boldsymbol{U}(\alpha^\pm)$ and $\frac{\partial}{\partial x}\boldsymbol{U}(\alpha^\pm)$. These last estimations, based on jump conditions presented in subsection 4.2, are detailed in subsection 4.3.

Second, at each irregular point x_i belonging to a particular fluid component, say, Ω_l, the spatial operator $L_\Omega(\boldsymbol{U}, i)$ is constructed by considering only thermodynamically similar state values, that is, numerical values for grid locations in Ω_l and modified values at grid points on the other fluid component. This subject is detailed in subsection 4.4.

4.2. Jump conditions at material interfaces. Across α, the primitive variables satisfy the classical zeroth-order jump conditions

$$[u] = 0, \qquad [p] = 0, \tag{4.2}$$

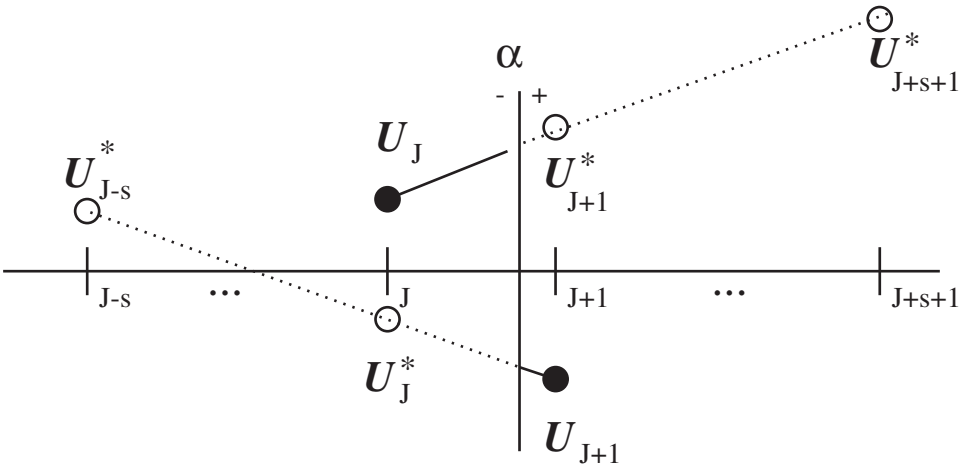

FIG. 4.1. *Numerical values* $_i$ *and modified values* $^*_i$.

where, for any function $f(x,t)$,

$$[f] = \lim_{x\to\alpha^+} f(x,t) - \lim_{x\to\alpha^-} f(x,t).$$

Since u and p do not jump across the interface, then their material—or Lagrangian—derivatives do not either. This fact immediately leads to the less classical first-order jump conditions

$$\left[\frac{1}{\rho}\frac{\partial p}{\partial x}\right] = 0, \qquad \left[\rho c^2 \frac{\partial u}{\partial x}\right] = 0. \tag{4.3}$$

One can also find second-order (and higher) jump conditions. However, and unlike the acoustics case [27, 20], these jump conditions (not presented here) involve nonlinear combinations of p, u, and their successive spatial derivatives, making the computations much more intricate.

For polytropic gases, $\rho c^2 = \gamma p$; since $[p] = 0$, the second equation in (4.3) can be simplified in $[\gamma \frac{\partial u}{\partial x}] = 0$. Note also that nothing is said about $[\rho]$ and $[\frac{\partial \rho}{\partial x}]$.

4.3. Numerical estimation of one-sided quantities. In a level-set model, the location of the material interface is given by a sign change in the marker variable ϕ. Suppose that

$$\phi_J \times \phi_{J+1} < 0. \tag{4.4}$$

As a consequence, the interface lies somewhere between x_J and x_{J+1}. The subcell location of α is specified by the parameter

$$\tilde{\theta} = \frac{\alpha - x_J}{\Delta x} \in [0,1[, \tag{4.5}$$

which is readily estimated to second order by a simple linear interpolation involving the smooth level-set function ϕ. Indeed, defining

$$\theta = \frac{|\phi_J|}{|\phi_J| + |\phi_{J+1}|}, \tag{4.6}$$

we have $\theta = \tilde{\theta} + O(\Delta x^2)$. Since the jump conditions (4.2) and (4.3) concern the primitive variables $\boldsymbol{W} = (\rho, u, p)^T$, it is easier to first look for estimations of $\boldsymbol{W}(\alpha^{\pm})$ and $\frac{\partial}{\partial x}\boldsymbol{W}(\alpha^{\pm})$, and then go back to the conserved variables $\boldsymbol{U}(\alpha^{\pm})$ and $\frac{\partial}{\partial x}\boldsymbol{U}(\alpha^{\pm})$. In the following discussion and for any function f, the numerical estimation of $f(\alpha^{\pm})$ or $\frac{\partial}{\partial x} f(\alpha^{\pm})$ is denoted by $f^{\pm}$ or $f_x^{\pm}$.

. The density is not subject to any constraint at a material interface; therefore, numerical estimations $\rho^{\pm}$ and $\rho_x^{\pm}$ are performed via one-sided interpolations. On the left of α, elementary interpolations lead to

$$\begin{aligned} \rho^- &= -\theta\,\rho_{J-1} + (1+\theta)\,\rho_J, \\ \rho_x^- &= \frac{1}{\Delta x}\,(\rho_J - \rho_{J-1})\,, \end{aligned} \tag{4.7}$$

while on the right of α, we get

$$\begin{aligned} \rho^+ &= (2-\theta)\,\rho_{J+1} - (1-\theta)\,\rho_{J+2}, \\ \rho_x^+ &= \frac{1}{\Delta x}\,(\rho_{J+2} - \rho_{J+1})\,. \end{aligned} \tag{4.8}$$

If $\rho(x)$ is a piecewise C^1 function, we obviously have

$$\rho(\alpha^{\pm}) = \rho^{\pm} + O(\Delta x^2), \qquad \frac{\partial \rho}{\partial x}(\alpha^{\pm}) = \rho_x^{\pm} + O(\Delta x).$$

1. The density estimations obtained above must remain within the physical range, i.e., $\rho^{\pm} > 0$. In some cases, negative values can be numerically obtained (e.g., in regions close to vacuum). Then, a different approximation procedure with constraints would be necessary (which is not considered here).

. The pressure and its spatial derivative satisfy (4.2) and (4.3):

$$\begin{aligned} p(\alpha^+) &= p(\alpha^-), \\ \frac{1}{\rho(\alpha^+)}\,\frac{\partial p}{\partial x}(\alpha^+) &= \frac{1}{\rho(\alpha^-)}\,\frac{\partial p}{\partial x}(\alpha^-). \end{aligned} \tag{4.9}$$

From the definition of $p^{\pm}$ and $p_x^{\pm}$, we have

$$\begin{aligned} p_J &= p^- + (x_J - \alpha)\,p_x^-, \\ p_{J+1} &= p^+ + (x_{J+1} - \alpha)\,p_x^+. \end{aligned} \tag{4.10}$$

We impose that numerical estimations satisfy exactly the same jump conditions as exact values. Combining (4.10) with (4.9) leads to the 2×2 system

$$\begin{pmatrix} p_J \\ p_{J+1} \end{pmatrix} = \begin{pmatrix} 1 & -\theta\,\Delta x \\ 1 & (1-\theta)\,\dfrac{\rho^+}{\rho^-}\,\Delta x \end{pmatrix} \begin{pmatrix} p^- \\ p_x^- \end{pmatrix}. \tag{4.11}$$

The above matrix is always invertible, provided that $\rho^{\pm} > 0$. Inverting the above system gives the numerical values at α^-:

$$
\begin{aligned}
p^- &= \frac{1}{(1-\theta)\,\dfrac{\rho^+}{\rho^-} + \theta} \left((1-\theta)\,\frac{\rho^+}{\rho^-}\,p_J + \theta\,p_{J+1} \right), \\
p_x^- &= \frac{1}{\left((1-\theta)\,\dfrac{\rho^+}{\rho^-} + \theta \right) \Delta x}\,(p_{J+1} - p_J)\,.
\end{aligned}
\tag{4.12}
$$

To get estimations at α^+, one uses (4.12) and jump conditions (4.9). Note that p^+ (or p^-) is a convex combination with positive coefficients of p_J and p_{J+1}, and hence $p^{\pm} > 0$. As in the previous case, standard results allow us to conclude that if both $p(x)$ and $\rho(x)$ are C^1 away from the material interface, then

$$
p(\alpha^{\pm}) = p^{\pm} + O(\Delta x^2), \qquad \frac{\partial p}{\partial x}(\alpha^{\pm}) = p_x^{\pm} + O(\Delta x).
$$

. Zeroth-order and first-order jump conditions for the velocity are

$$
\begin{aligned}
u(\alpha^+) &= u(\alpha^-), \\
\rho(\alpha^+)\,c^2(\alpha^+)\,\frac{\partial u}{\partial x}(\alpha^+) &= \rho(\alpha^-)\,c^2(\alpha^-)\,\frac{\partial u}{\partial x}(\alpha^-).
\end{aligned}
\tag{4.13}
$$

Applying the same procedure as for the pressure, we obtain a system which is invertible as long as $(1-\theta)\gamma_0\,(p^- + p_{\infty\,0})\,/\gamma_1\,(p^+ + p_{\infty\,1}) + \theta > 0$. This is always the case since $p^{\pm} > 0$. For stiffened gas EOS (2.3), defining

$$
\xi = \frac{\gamma_0\,(p^- + p_{\infty\,0})}{\gamma_1\,(p^- + p_{\infty\,1})}
\tag{4.14}
$$

(for the ideal polytropic case $\xi = \gamma_0/\gamma_1$) with p^- given by (4.12), we obtain

$$
\begin{aligned}
u^- &= \frac{1}{(1-\theta)\,\xi + \theta}\,\left((1-\theta)\,\xi\,u_J + \theta\,u_{J+1} \right), \\
u_x^- &= \frac{1}{\left((1-\theta)\,\xi + \theta \right)\,\Delta x}\,(u_{J+1} - u_J)\,.
\end{aligned}
\tag{4.15}
$$

To get estimations at α^+, one uses (4.15) and the jump conditions (4.13). As before, under the appropriate smoothness assumptions, one has

$$
u(\alpha^{\pm}) = u^{\pm} + O(\Delta x^2), \qquad \frac{\partial u}{\partial x}(\alpha^{\pm}) = u_x^{\pm} + O(\Delta x).
\tag{4.16}
$$

. Once sided estimations $\boldsymbol{W}^{\pm}$ and $\boldsymbol{W}_x^{\pm}$ are computed, we deduce $\boldsymbol{U}^{\pm}$ and $\boldsymbol{U}_x^{\pm}$ from (2.3). These values are second-order approximations to the exact values under appropriate smoothness assumptions; hence

$$
\hat{\boldsymbol{U}}(x) = \begin{cases} \boldsymbol{U}^+ + (x-\alpha)\,\boldsymbol{U}_x^+ & \text{for } x \le \alpha, \\ \boldsymbol{U}^- + (x-\alpha)\,\boldsymbol{U}_x^- & \text{for } x > \alpha \end{cases}
\tag{4.17}
$$

satisfies $\boldsymbol{U}^*(x) = \hat{\boldsymbol{U}}(x) + O(\Delta x^2)$ near the interface.

4.4. Spatial integration at irregular points. From (3.3) and (4.4), one deduces that the irregular points are

$$x_{J-s+1}, \ldots, x_{J+s}. \tag{4.18}$$

Modified values must also be computed at x_{J-s} and x_{J+s+1} because the material interface can move between t_n and t_{n+1}, crossing one grid point (but no more, because of the CFL condition); as a consequence, these two regular points can become irregular points during one Runge–Kutta substep. The modified values are computed by substituting the appropriate grid point in the expresion (4.17). Using (4.6) as a second-order approximation to (4.5), we obtain

$$\begin{aligned} &i = J+1, \ldots, J+s+1, && \boldsymbol{U}_i^* = \boldsymbol{U}^- + (i - J - \theta)\, \Delta x\, \boldsymbol{U}_x^-, \\ &i = J-s, \ldots, J, && \boldsymbol{U}_i^* = \boldsymbol{U}^+ + (i - J - \theta)\, \Delta x\, \boldsymbol{U}_x^+. \end{aligned} \tag{4.19}$$

At each irregular point x_i, $\boldsymbol{L}_\Omega$ is now applied to numerical values on the same side as x_i, and to modified values on the other side; hence

$$\begin{aligned} &i = J-s+1, \ldots, J, \\ &\boldsymbol{L}_\Omega(\boldsymbol{U}, i) = -\frac{1}{\Delta x} \left(\boldsymbol{F}_{\Omega\, 0} \left(\boldsymbol{U}_{i-s+1}, \ldots, \boldsymbol{U}_J, \boldsymbol{U}_{J+1}^*, \ldots, \boldsymbol{U}_{i+s}^* \right) \right. \\ &\qquad \left. - \boldsymbol{F}_{\Omega\, 0} \left(\boldsymbol{U}_{i-s}, \ldots, \boldsymbol{U}_J, \boldsymbol{U}_{J+1}^*, \ldots, \boldsymbol{U}_{i+s-1}^* \right) \right), \\ &i = J, \ldots, J+s, \\ &\boldsymbol{L}_\Omega(\boldsymbol{U}, i) = -\frac{1}{\Delta x} \left(\boldsymbol{F}_{\Omega\, 1} \left(\boldsymbol{U}_{i-s+1}^*, \ldots, \boldsymbol{U}_J^*, \boldsymbol{U}_{J+1}, \ldots, \boldsymbol{U}_{i+s} \right) \right. \\ &\qquad \left. - \boldsymbol{F}_{\Omega\, 1} \left(\boldsymbol{U}_{i-s}^*, \ldots, \boldsymbol{U}_J^*, \boldsymbol{U}_{J+1}, \ldots, \boldsymbol{U}_{i+s-1} \right) \right). \end{aligned} \tag{4.20}$$

4.5. Summary of the implementation. Suppose that Runge–Kutta integrations (denoted by RK) have been performed up to the $(m-1)$th substep. Then, the time-marching for both the Euler equations and the level-set equation can be summed up in eight steps.

- , 1 (location of the interface). Compute J (4.4) and θ (4.5).
- , 2 (construction of modified values). Compute (4.19).
- , 3 (construction of temporary values). Build two sets $\boldsymbol{A}_i$ and $\boldsymbol{B}_i$:

$$\begin{aligned} \boldsymbol{A}_i^{(m-1)} &= \begin{cases} \boldsymbol{U}_i^{(m-1)},\ i = 0, \ldots, J, \\ \boldsymbol{U}_i^*,\ i = J+1, \ldots, J+s+1, \end{cases} \\ \boldsymbol{B}_i^{(m-1)} &= \begin{cases} \boldsymbol{U}_i^*,\ i = J-s, \ldots, J, \\ \boldsymbol{U}_i^{(m-1)},\ i = J+1, \ldots, N_x. \end{cases} \end{aligned} \tag{4.21}$$

- , 4 (update $\boldsymbol{A}_i$ and $\boldsymbol{B}_i$). Compute one Runge–Kutta substep of (3.1):

$$\begin{aligned} &i = s, \ldots, J+1, && \boldsymbol{A}_i^{(m)} = \mathrm{RK}\left(\boldsymbol{A}_i^{(k)}, \boldsymbol{L}_{\Omega_0} \right), \quad k \le m, \\ &i = J, \ldots, N_x - s, && \boldsymbol{B}_i^{(m)} = \mathrm{RK}\left(\boldsymbol{B}_i^{(k)}, \boldsymbol{L}_{\Omega_1} \right), \quad k \le m. \end{aligned} \tag{4.22}$$

Step 5 (update ϕ). Compute one Runge–Kutta substep of (2.6) via $u^{(m-1)}$.

Step 6 (location of the interface). Compute J (4.4) from $\phi^{(m)}$.

Step 7 (update $\boldsymbol{U}$). From (4.22) and J, select

$$\boldsymbol{U}_i^{(m)} = \begin{cases} \boldsymbol{A}_i^{(m)} \text{ for } i = 0, \dots, J, \\ \\ \boldsymbol{B}_i^{(m)} \text{ for } i = J+1, \dots, N_x. \end{cases} \tag{4.23}$$

Step 8 (reinitialization of ϕ). If $m = 3$ (i.e., $t = t_{n+1}$), integrate (3.5).

4.6. Some remarks.

Simplicity. The algorithm presented in section 4.5 is simple. The computation of modified values $\boldsymbol{U}_i^*$ does not depend on the discrete spatial operator. No analytical results—such as the solution of a Riemann problem—are required. As deduced from (4.22), one does not need to write a new solver: the adaptation of known single-component solvers to the multicomponent case is direct. The only difficulty is switching precisely modified values in the appropriate solver, depending on the sign of the level-set function, which is in fact an easy task.

Computational cost. In comparison with single-component simulations, our approach leads to a +25% additional cost, both from a memory and a computational time point of view. This cost is almost completely due to the level-set function ϕ. Such a cost is inherent to level-set formulations in order to know the composition of the fluid at each grid point. Eulerian methods that do not use level-sets require, in counterpart, modification of the Euler eigenstructure, leading to a similar additional cost.

Thermodynamic consistency. As for the GFM [2], the ESIM works because values used for time-stepping in (4.22) are thermodynamically similar: $\boldsymbol{A}_i^*$ (respectively $\boldsymbol{B}_i^*$) in (4.21) satisfies the same EOS. The algorithm amounts to considering separately two single-component flows, where no oscillations exist.

Limit case. In the limit case $\gamma_0 = \gamma_1$, $p_{\infty\,0} = p_{\infty\,1}$, the flow is single-component, and material interfaces amount to classical contact discontinuities. The ESIM behaves equally well, sharpening contact discontinuities.

Nonconservativity. The ESIM is formally nonconservative locally, since

$$\begin{aligned} &\boldsymbol{F}_{\Omega_0}\left(\boldsymbol{U}_{J-s+1}, \dots, \boldsymbol{U}_J, \boldsymbol{U}_{J+1}^*, \dots, \boldsymbol{U}_{J+s}^*\right) \\ &\quad \neq \boldsymbol{F}_{\Omega_1}\left(\boldsymbol{U}_{J-s+1}^*, \dots, \boldsymbol{U}_J^*, \boldsymbol{U}_{J+1}, \dots, \boldsymbol{U}_{J+s}\right), \end{aligned} \tag{4.24}$$

like in [15] or [8]. However, the lack of conservation is only introduced at one cell boundary on the entire domain. In practice, this feature does not seem to spoil convergence to the correct solution.

Note that a fully conservative version of the GFM has been developed [25]. Such an approach could probably be adapted to the ESIM, but we do not look further in the present paper; unlike in [25] where inert shocks and detonation waves are addressed, we focus only on the material interfaces (where conservation errors are not crucial).

5. Numerical experiments.

5.1. Configurations. Four numerical experiments are proposed. Tests 1 and 2 illustrate the interaction of shock waves with one and two material interfaces. Test

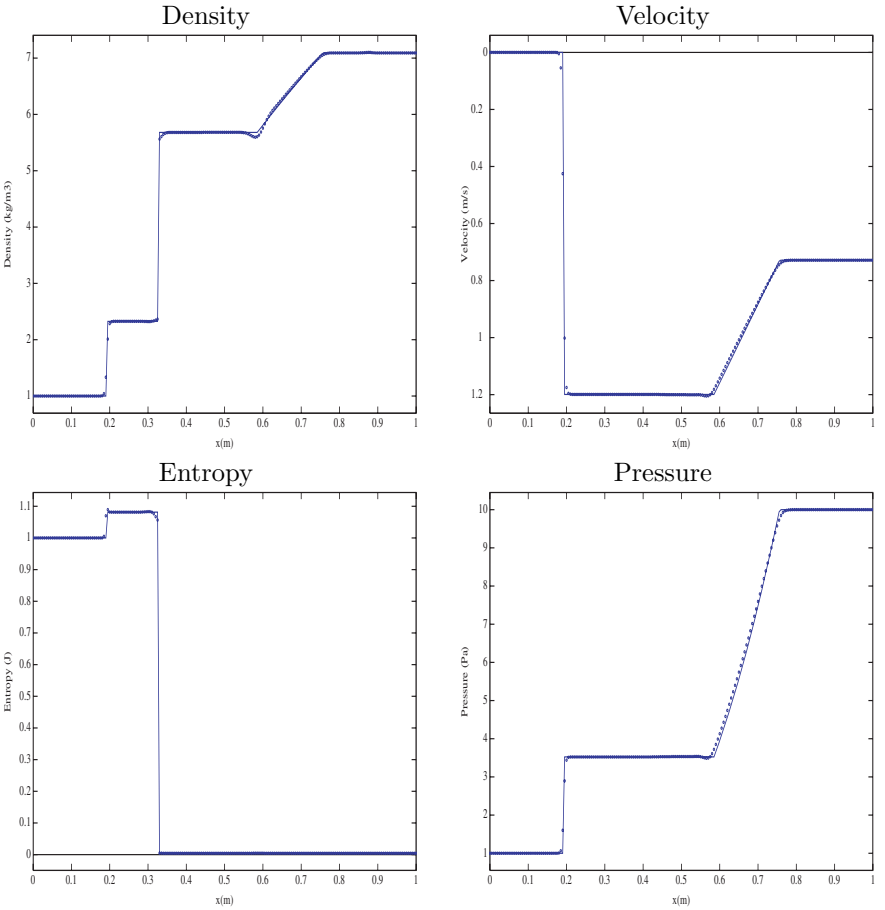

FIG. 5.1. *Test* 1-a: *Mach* 1.95 *shock wave interacting with a material interface. WENO*-5 *coupled with the ESIM. (Exact values: Solid line. Numerical values: Points.)*

3 is a pure advection problem, with smooth structures. Test 4 concerns nonlinear acoustics. Analytical values and numerical values are, respectively, shown in solid lines and dotted lines, and we take CFL = 0.66.

All tests have initially isolated material interfaces. Riemann problems are not our concern, since jump conditions (4.2)—which are a building block of the ESIM—are then generally not satisfied. Note that the GFM has the same limitation. In practice, the GFM often works for Riemann problems, but some failures (see, e.g., data of Test 4 in [2]) can be explained by the fact that basic assumptions are not satisfied.

5.2. Test 1: Shock-interface interaction. First, we consider a shock-interface interaction problem, previously studied in [31]. On a 1 m long domain, the initial configuration consists of a stationary material interface at $\alpha_0 = 0.5$ m, separating two fluids with different EOSs: a polytropic gas on the left, and a stiffened gas on the right. A left-going Mach 1.95 shock wave is initially set at $\alpha_1 = 0.7$ m. Physical

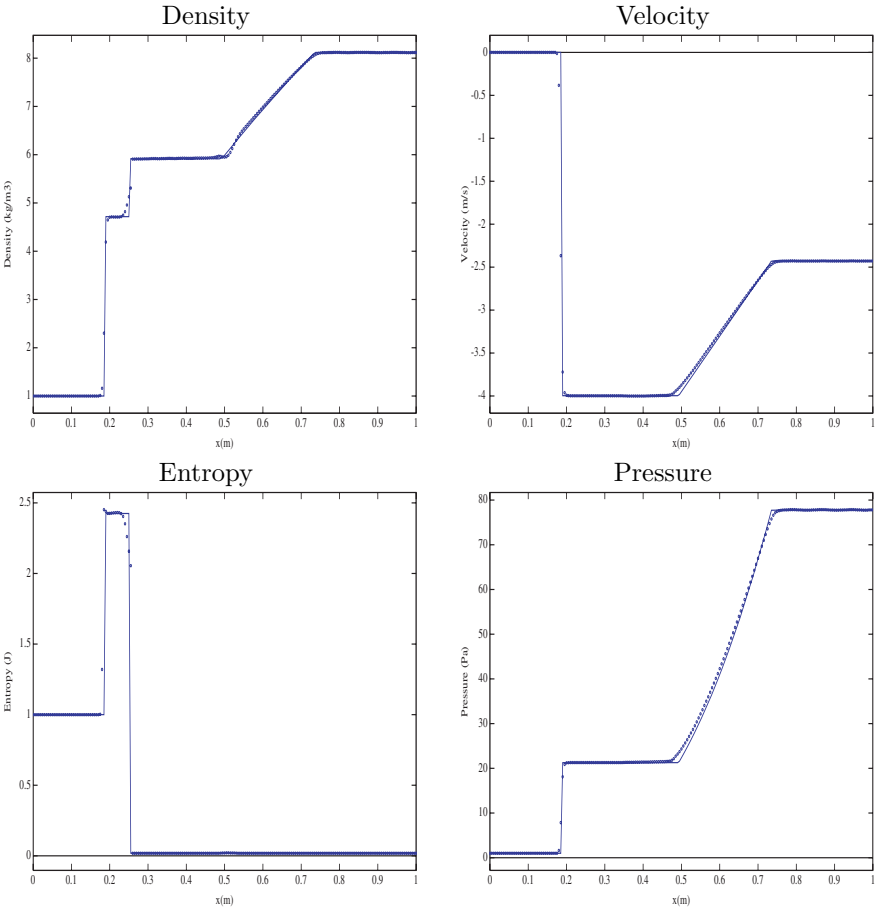

FIG. 5.2. *Test* 1-b: *Mach* 5 *shock wave interacting with a material interface. WENO*-5 *coupled with the ESIM. (Exact values: Solid line. Numerical values: Points.)*

parameters are

(5.1)
$$\begin{cases} \rho_0 = 1.000 \text{ kg/m}^3,\ p_0 = 1 \text{ Pa}\ ,\ u_0 = 0 \text{ m/s}\ ,\gamma_0 = 1.4,\ p_{\infty\,0} = 0 \text{ Pa}, \\ \rho_1 = 5.000 \text{ kg/m}^3,\ p_1 = 1 \text{ Pa}\ ,\ u_1 = 0 \text{ m/s}\ ,\gamma_1 = 4,\ p_{\infty\,1} = 1 \text{ Pa}, \\ \rho_2 = 7.093 \text{ kg/m}^3,\ p_2 = 10 \text{ Pa}\ ,u_2 = -0.7288 \text{ m/s}\ ,\gamma_2 = 4.0,\ p_{\infty\,2} = 1 \text{ Pa}. \end{cases}$$

At $t = 4.69\,10^{-2}$ s, the shock wave collides with the material interface, leading to a left-going shock, a left-going material interface, and a right-going rarefaction fan (see Figure 4 in [31]).

Figure 5.1 shows exact values and numerical values of ρ, u, p, and entropy S at $t = 0.202$ s (after 200 time-steps). The computations are performed on $N_x = 200$ grid points with WENO-5 coupled with the ESIM. The agreement between analytical and numerical values is good. The main interest of this example is to show that the ESIM is robust and behaves well, even when a shock wave is in the vicinity of the material

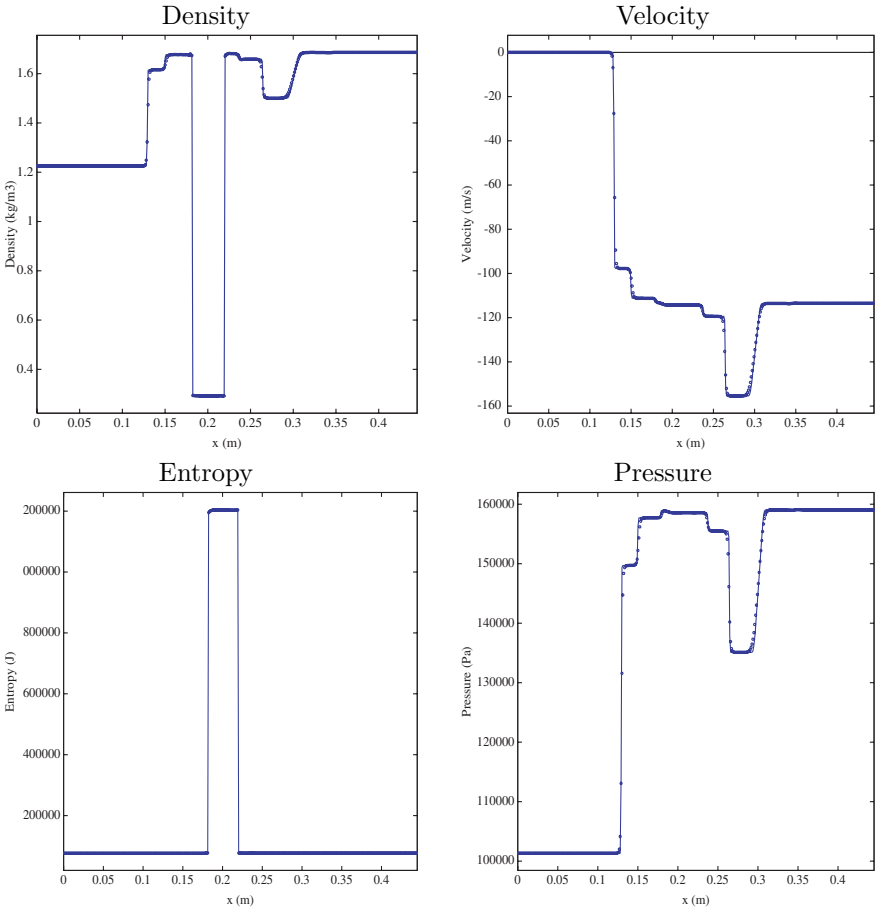

FIG. 5.3. *Test* 2: *Shock-bubble interaction. WENO-*5 *coupled with the ESIM. (Fine grid solution: Solid line. Numerical values: Points.)*

interface. No spurious oscillations induced by Taylor expansions are seen in u and p around the material interface (near $x = 0.32$ m).

Second, we consider the case of a stronger shock wave. The physical parameters around the material interface are the same as in (5.1); only the parameters in the post-shock fluid are modified:

$$\rho_2 = 8.116 \text{ kg/m}^3, \quad p_2 = 77.80 \text{ Pa}, \quad u_2 = -2.428 \text{ m/s}, \quad \gamma_2 = 1.4, \quad p_{\infty 2} = 1 \text{ Pa},$$

which amounts to a Mach 5 left-going shock wave. The wave phenomena (after the collision between the shock wave and the material interface) are the same as in the previous example. The computations are performed with WENO-5 coupled with the ESIM.

Figure 5.2 shows exact values and numerical values of ρ, u, p, and entropy S at $t = 0.112$ s (after 300 time-steps). The agreement between numerical and analytical values is good, even for this strong shock test. No oscillations are visible in u and p around the material interface (near $x = 0.26$ m).

5.3. Test 2: Shock-bubble interaction. We consider the one-dimensional version of the classical shock-bubble interaction problem, numerically addressed, e.g., in [23] with a conservative algorithm. On a 0.445 m long domain, a helium domain, initially delimitated by $\alpha_0 = 0.2$ m and $\alpha_1 = 0.25$ m, is at rest in air. A left-going Mach 1.22 shock wave is initially set at $\alpha_2 = 0.275$ m. Physical parameters are

$$\begin{cases} \rho_0 = 1225 \text{ kg/m}^3,\ p_0 = 1.01325\,10^5 \text{ Pa},\ u_0 = 0.0 \text{ m/s}, \gamma_0 = 1.4,\ p_{\infty\,0} = 0 \text{ Pa}, \\ \rho_1 = 0.2228 \text{ kg/m}^3,\ p_1 = 1.01325\,10^5 \text{ Pa},\ u_1 = 0.0 \text{ m/s}, \gamma_1 = 1.648,\ p_{\infty\,1} = 0 \text{ Pa}, \\ \rho_2 = 1225 \text{ kg/m}^3,\ p_2 = 1.01325\,10^5 \text{ Pa},\ u_2 = 0.0 \text{ m/s}, \gamma_2 = 1.4,\ p_{\infty\,2} = 0 \text{ Pa}, \\ \rho_3 = 1686 \text{ kg/m}^3,\ p_3 = 1.59059\,10^5 \text{ Pa},\ u_3 = -3.59 \text{ m/s}, \gamma_3 = 1.4,\ p_{\infty\,3} = 0 \text{ Pa}. \end{cases}$$

See [23] for a description of wave phenomena. Since no analytic solution is available, we compute the solution with WENO-5 coupled with ESIM on a fine grid with 3200 mesh points; we refer to this approximation as the "exact solution" for comparison purposes.

Figure 5.3 shows "exact values" and numerical values of ρ, u, p, and S at $t = 2.86\,10^{-3}$ s (after 400 time-steps). The computations are performed on $N_x = 400$ grid points with WENO-5 coupled to the ESIM. The agreement between "exact values" and numerical values is very good. The resolution is better than in [23]: compare the density inside the helium in Figure 5.3 with the density in Figure 2 of [23].

To conclude Tests 1 and 2, let us note that similar results could be obtained with the GFM treatment (not shown here). Indeed, when only flat profiles are involved, the GFM and the ESIM have similar behavior. When a shock wave collides with a material interface, both treatments produce "sloping" behavior in density and entropy very close to the "overheating" phenomenon found in shock-reflection problems [6]. Increasing the Mach number seems to accentuate this "overheating," producing in addition slightly perturbed post-shock values: small acoustic perturbations can be observed downstream in Figure 5.2. More testing (not shown) has been performed with Mach numbers up to 9, which confirms these observations. No crash due to negative pressure values has been observed on these tests.

The goal of the next two tests is to show the advantage of using the ESIM (compared to the GFM) for rich-structured flows.

5.4. Test 3: Pure advection. We consider a 1 m long domain with two material interfaces initially at $\alpha_0 = 0.160$ m and $\alpha_1 = 0.526$ m. The pressure and the velocity are initially constant: $u(x,0) = 300$ m/s, $p(x,0) = 10^5$ Pa. The density is initially

$$\rho(x,0) = \begin{cases} 1 + 0.3 \sin(50\,(x - \alpha_0)) \text{ kg/m}^3 \text{ if } \alpha_0 \le x < \alpha_1, \\ 1 \text{ kg/m}^3 \text{ else.} \end{cases}$$

Physical parameters are

$$(\gamma, p_\infty) = \begin{cases} \gamma_0 = 1.40,\ p_{\infty\,0} = 10^4 \text{ Pa} & \text{if } x \le \alpha_0, \\ \gamma_1 = 1.67,\ p_{\infty\,1} = 10^5 \text{ Pa} & \text{if } \alpha_0 < x \le \alpha_1, \\ \gamma_2 = 1.40,\ p_{\infty\,2} = 10^4 \text{ Pa} & \text{if } x > \alpha_1. \end{cases}$$

	3200	1.54e-4	**2.14**	6.72e-2	**1.81**	9.36e+0	**1.86**

This configuration amounts to an advection equation for ρ; material interfaces are advected at the velocity u; p and u remain theoretically constant. Because of the discontinuous physical parameters, the entropy S is discontinuous at α_0 and at α_1. Numerical experiments are performed with ENO-3, coupled with the GFM or with the ESIM.

Figures 5.4 and 5.5 show exact values and numerical values of ρ, S, p, and u at $t = 6.62\,10^{-4}$ s, respectively, for $N_x = 200$ grid points (hence 25 grid points by wavelength) and $N_x = 800$ grid points (hence 100 grid points by wavelength). At material interfaces, the zeroth-order extrapolations of S used by the GFM result in jumps of ρ that are advected with the flow; these glitches are also transferred to u, and p, near $x = 0.35$ m and $x = 0.75$ m, and act as sources of acoustic noise. These glitches still exist with 800 grid points (Figure 5.5) with the GFM. On the other hand, no entropy or density glitches are observed when the ESIM is used instead.

We must mention that ENO reconstructions of a sinusoidal profile might produce oscillations on the level of the truncation error. These small spurious oscillations are seen in p and u, which should have flat profiles, and can be observed even without material interfaces. When these oscillations interact with the GFM-produced glitches at material interfaces, they are amplified and lead also to spurious acoustic waves. These oscillations are entirely reconstruction-dependent, and, since they are of the order of the truncation error (see also our convergence measures), they are essentially not visible on 800 grid points when the ESIM is used (Figure 5.5).

Measures of convergence are provided in Table 5.1. Coupled with the ESIM, the ENO-3 scheme maintains third-order convergence. Coupled with the GFM, the ENO-3 scheme loses accuracy and shows a 1.6 order of convergence. Table 5.2 shows measures of conservation errors induced by the GFM and by the ESIM, for various values of N_x (see subsection 4.6). To do so, we compute

$$\Delta \boldsymbol{U}(T, N_x) = \max_{n=0,\ldots,N_t} \left| \sum_{i=i_0}^{i_1} \left(\boldsymbol{U}_i^n - \boldsymbol{U}_i^0 \right) + n \frac{\Delta t}{\Delta x} \left(\boldsymbol{f}\left(\boldsymbol{U}_{i_1}^n \right) - \boldsymbol{f}\left(\boldsymbol{U}_{i_0}^n \right) \right) \right| \tag{5.2}$$

at $T = 1.05\,10^{-3}$ s, where $\boldsymbol{f}$ is the flux function (2.2), and $N_t = \text{Trunc}\,(T/\Delta t)$. The

TABLE 5.2
Measures of convergence in Test 3.

Method	N_x	L_1 error	L_1 order	Method	N_x	L_1 error	L_1 order
	100	6.44e-3	-		100	3.76e-3	-

domain of measure is bounded by $i_0 = 10$ and $i_1 = N_x - 10$. Getting reliable and meaningful measures requires some care. Indeed, errors of conservativity vary a lot with the position of α inside the meshing, and hence with t. The "max" in (5.2) ensures almost steady values of $\Delta \boldsymbol{U}(T, N_x)$ and reliable measures.

A fully conservative scheme would satisfy $\Delta \boldsymbol{U}(T, N_x) = 0$ for all values of T and N_x (see, e.g., (12.33) in [19]). Here, errors are nonnull, but they decrease with Δx. Conservation errors induced by the ESIM are much smaller than those induced by the GFM. Table 5.2 indicates first-order conservation errors for the GFM and second-order conservation errors for the ESIM.

Measures of convergence and conservativity have been done also with the WENO-5 scheme coupled with the GFM or with the ESIM. The results are essentially the same as in Tables 5.1 and 5.2. To get a fifth-order accurate scheme (as in [27]) and a higher order of conservation would require developing a higher-order ESIM, which is not investigated in the present study.

5.5. Test 4: Nonlinear acoustics. As a last example, we consider a rich-structured wave interacting with a stationary material interface. This example is a generalization of Test 1 studied in [27]: for small amplitude initial data, the simple linear equations of acoustics used in [27] are valid, and the wave remains smooth. Higher amplitudes of initial data lead to a nonlinear problem, where shocks can develop.

To illustrate both cases, we use exactly the same physical parameters as in [27]. On a 300 m long domain, a material interface separates piecewise constant values, initially motionless

$$\begin{cases} \rho_0 = 1000 \text{ kg/m}^3,\ p_0 = 10^5 \text{ Pa},\ u_0 = 0.0 \text{ m/s}, \gamma_0 = 3,\ p_{\infty\,0} = 7.50\,10^8 \text{ Pa}, \\ \\ \rho_1 = 1200 \text{ kg/m}^3,\ p_1 = 10^5 \text{ Pa},\ u_1 = 0.0 \text{ m/s}, \gamma_1 = 4,\ p_{\infty\,1} = 2.35\,10^9 \text{ Pa}. \end{cases}$$

From (2.4), one deduces sound speeds: $c_0 = 1500$ m/s, and $c_1 = 2800$ m/s. These physical parameters correspond, respectively, to water and Plexiglass under atmospheric pressure. A perturbation $\Delta \boldsymbol{W}_0(x)$ is added to initial data on medium Ω_0, which is an exact solution of acoustics and leads to a right-going wave

$$\Delta \boldsymbol{W}_0(x) = \varepsilon\, f\left(t_0 - \frac{x}{c_0}\right)^T \left(-\frac{p_0}{c_0^2}, -\frac{p_0}{\rho_0\, c_0}, -p_0\right). \tag{5.3}$$

The function f is a C^5 spatially bounded sinusoid

$$f(\xi) = \begin{cases} \displaystyle\sum_{k=1}^{q} a_k \, \sin(\beta_k \, \omega_c \, \xi) & \text{if } 0 < \xi < \dfrac{1}{f_c}, \\ \\ 0 \text{ else}, \end{cases} \tag{5.4}$$

with $\beta_k = 2^{k-1}$, $\omega_c = 2\pi \, f_c$; the coefficients a_k are $a_1 = 1$, $a_2 = -21/32$, $a_3 = 63/768$, and $a_4 = -1/512$. The central frequency is $f_c = 50$ Hz. Elementary calculations show that

$$\frac{\Delta \, \rho_0}{\rho_0} \sim \frac{\Delta \, u_0}{c_0} \sim \frac{\Delta \, p_0}{p_0} \sim \varepsilon. \tag{5.5}$$

For $\varepsilon = 0$, the solution remains a stationary material interface. For small values of ε (typically $\varepsilon = 10^{-3}$), the acoustics limit is valid and one obtains a pure right-going wave. For higher values of ε (typically $\varepsilon = 0.1$), the perturbation (5.3) does not satisfy exactly the nonlinear Euler equations: the wave separates into a weak left-going wave and a right-going wave. In both cases, the right-going wave is reflected and transmitted by the material interface. The analytical solution is not detailed in the linear case [20]. No analytical solution is available in the nonlinear case: one computes an "exact solution" on a fine grid of 3200 grid points. Numerical experiments are performed with $N_x = 400$ grid points, which is 40 points in the wavelength $\lambda_c = c_0/f_c$, and $t_0 = 5.1 \, 10^{-2}$ s. Initial values of the p at t_0 are shown in Figure 5.6 for $\varepsilon = 10^{-3}$.

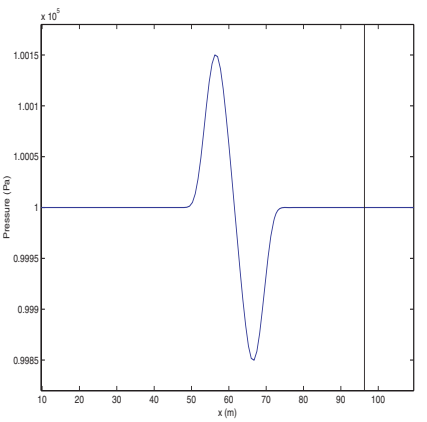

FIG. 5.6. *Initial values of the pressure p at $t_0 = 5.1 \, 10^{-2}$ s in Test 4.*

Figure 5.7 shows results at $t_1 = 8.61 \, 10^{-2}$ s, after 200 time-steps. Left and right columns concern, respectively, $\varepsilon = 10^{-3}$ and $\varepsilon = 0.1$. Figures 5.7(a) and (b) show numerical values and exact values of p computed by WENO-5 coupled to the ESIM. Logically, (a) is similar to Figure 3(d) of [27]. In the nonlinear case (b), the reflected and transmitted waves have developed a shock. In both cases, the agreement between exact values and numerical values is excellent.

To see clearly differences between the ESIM and GFM treatments, we display errors for both methods, with the ESIM in (c) and (d), and with the GFM in (e) and (f). In the nonlinear cases (d) and (f), errors are displayed from $x = 85$ m to

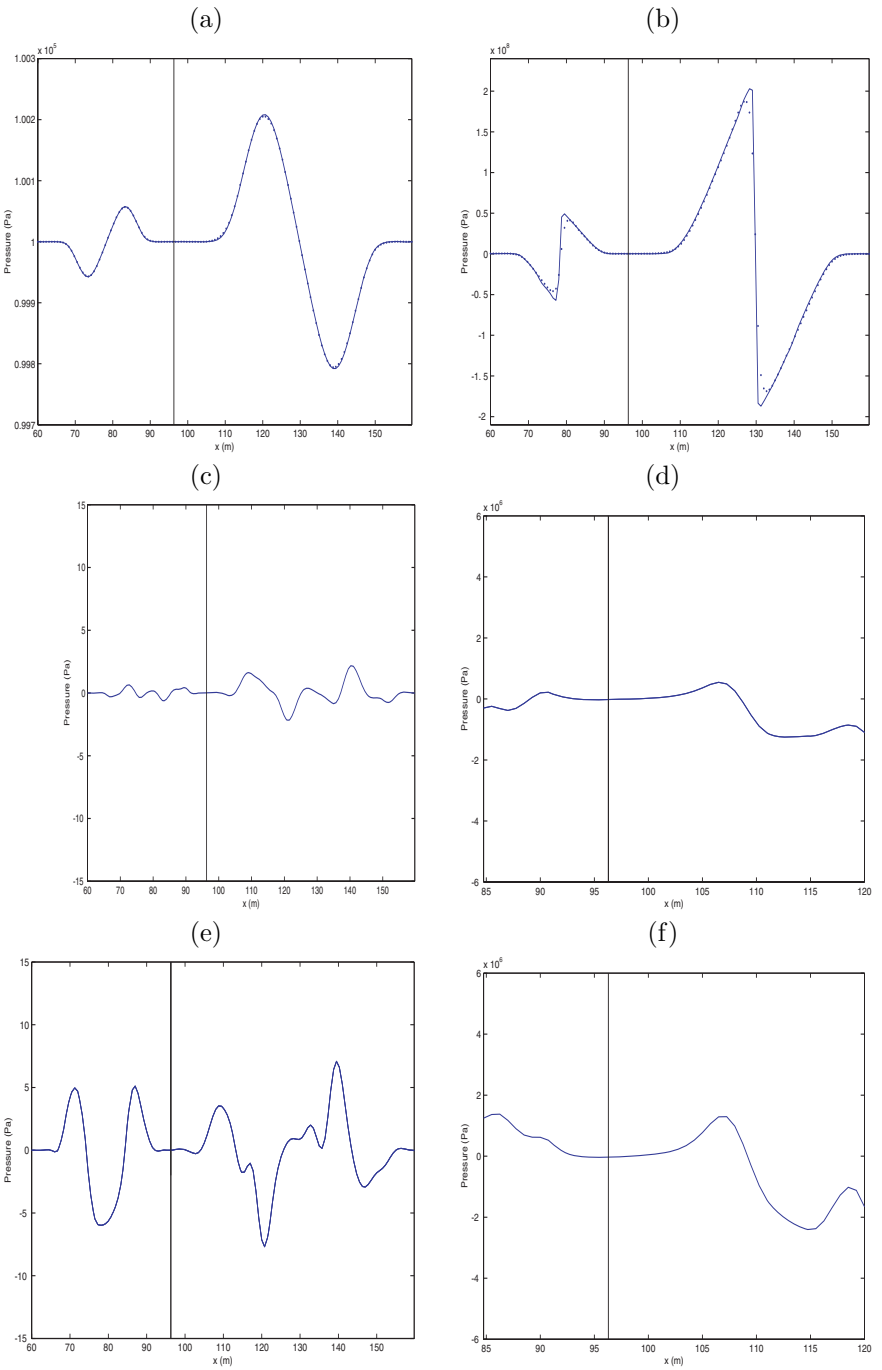

FIG. 5.7. *Test* 4. $\varepsilon = 10^{-3}$ *(left column),* $\varepsilon = 1$ *(right column) at* $t_1 = 8.61\,10^{-2}$ s. *Snapshots of fine grid solution (solid line) and numerical values (dotted line) of* p *with the ESIM:* (a), (b). *Errors with the ESIM:* (c), (d). *Errors with the GFM:* (e), (f).

$x = 120$ m to avoid the shock area. In both cases, the graphs confirm that the ESIM is more accurate than the GFM.

Unlike in [27], the material interface is allowed to move with the flow. For $\varepsilon = 10^{-3}$, the measured movement is lower than 10^{-7} m, so the approximation of stationary material interfaces is justified. For $\varepsilon = 0.1$, the material interface moves from 96.3 m to 96.114 m, and then it comes back to the initial position 96.3 m; it is logical, since the velocity is symetric with respect to zero.

6. Conclusion. We have proposed an extension of the explicit simplified interface method (ESIM), previously developed in acoustics [21, 22, 27], to treat material interfaces in one-dimensional multicomponent Euler flows.

The method enforces the numerical solution to satisfy zeroth-order and first-order jump conditions at the material interface and can be coupled with the user's favorite high-order shock-capturing scheme for single-component flows. It behaves as robustly as the GFM [8] in numerical simulations involving flat states, while it displays a superior performance in flows with rich structures.

Our numerical simulations show that the interface treatment we propose guarantees a numerical solution with no unphysical numerical artifacts due to the material interface. The behavior observed for the numerical errors is similar to that observed for the same underlying method when applied to a flow without material interfaces.

This paper focused on one-dimensional flows; applying the ESIM to two-dimensional cases is a challenging project and will be the subject of future works. Some key tools for the two-dimensional implementation have been validated already in the simple case of two-dimensional linear acoustics with stationary interfaces [22]. Other ingredients (such as multidimensional level-set-based extrapolations) may be found in [5, 12].

Acknowledgments. The authors would like to thank the anonymous referees for their comments and for pointing out several useful references.

NUMERICAL CONTINUATION OF BIFURCATIONS OF LIMIT CYCLES IN MATLAB*

WILLY GOVAERTS†, YURI A. KUZNETSOV‡, AND ANNICK DHOOGE†

Abstract. CL_MATCONT and MATCONT are MATLAB continuation packages for the interactive numerical study of a range of parameterized nonlinear dynamical systems, in particular ODEs. MATCONT is an interactive graphical package and CL_MATCONT is a commandline version. Both packages allow us to compute curves of equilibria, limit points, Hopf points, limit cycles, flip, fold, and torus bifurcation points of limit cycles. We discuss computational details of the continuation of limit cycles and flip, fold, and torus bifurcations of limit cycles in MATCONT and CL_MATCONT using orthogonal collocation. Instead of the more commonly used fully extended systems we use minimally extended systems. We further describe the use of the MATLAB sparse matrix routines and the initialization and adaptation of the bordering vectors that are essential in minimally extended systems. Finally, we compare the use of the minimally and the fully extended systems in the MATLAB environment.

Key words. limit cycle, fold, flip, torus, MATLAB

1. Introduction.

Numerical continuation is a well-understood subject; see, e.g., [1], [8], [9], [4], [17], [20], [22]. The idea is as follows. Consider a smooth function $F : \mathbb{R}^{n+1} \to \mathbb{R}^n$. We want to compute a solution curve of the equation

$$F(x) = 0. \tag{1.1}$$

Numerical continuation is a technique to compute a sequence of points which approximate the desired solution branch.

In particular, we consider a dynamical system of the form

$$\frac{dx}{dt} = f(x, \alpha) \tag{1.2}$$

with $x \in \mathbb{R}^n$, $f(x, \alpha) \in \mathbb{R}^n$, and α a vector of parameters where equilibria, limit points, limit cycles, etc. can be computed.

The existing software packages such as AUTO [10] and CONTENT [21] require the user to rewrite his/her models in a specific form and use special internal formats to store results; this complicates the export of the results, graphical representation, etc.

The aim of MATCONT and CL_MATCONT is to provide a continuation toolbox which is compatible with the standard MATLAB ODE representation of differential equations. General descriptions of CL_MATCONT and MATCONT are in [7] and [6], respectively. The current version of the package is freely available for download at http://www.matcont.ugent.be. CL_MATCONT requires MATLAB 5.3, whereas

MATCONT requires MATLAB 6* or higher. In the present paper we concentrate on the implementation in CL_MATCONT and MATCONT of the continuation of the flip (period doubling (PD)), fold (limit point of cycles (LPC)), and torus (Neimark–Sacker (NS)) bifurcations of limit cycles, using minimally extended systems and orthogonal collocation to discretize appearing boundary value problems (BVPs). The only existing software to perform these continuations is AUTO [10] which uses fully extended systems and their orthogonal collocation. Several algorithms for the continuation of limit cycles and fold bifurcations of limit cycles are studied in [18]. They are also based on MATLAB and are minimally extended systems but are otherwise very different from ours since they use a combination of multiple shooting and automatic differentiation, using coarse meshes and Taylor series expansions. Accuracy and robustness are the main objectives of [18] and these are compared to the AUTO results; since no code is available we cannot compare them directly to our results.

We note that the above-mentioned software, like ours, considers only parameterized two-point BVPs. Bifurcation software for parameterized partial differential equations might require different numerical methods (though the underlying mathematics of the bifurcation problems would be identical).

The theory of the bordering method for the numerical continuation of bifurcations of limit cycles was developed in [12] and is summarized in a slightly generalized form in section 2. We note that the convergence properties of the discretized solutions of the PD, LPC, and NS equations can be proved by the method of reformulation of BVPs as described in [3] and applied in [9] to include the period of the orbit, a phase condition, and parameters in the BVP formulation. In particular, the convergence of the systems for PD, LPC, and NS is of order h^m, where h is the maximum length of the mesh intervals and m is the number of collocation points in each mesh interval. Also, there is superconvergence (of order h^{2m}) in the endpoints of the mesh intervals and for the scalar equations added to the LC equations.

In this paper we deal with the numerical and computational aspects of the implementation in MATCONT and CL_MATCONT. Note that this makes MATCONT the first fully interactive software that supports the continuation of the limit cycle bifurcations using orthogonal collocation. In section 3 we recall the basic methods for the continuation of limit cycles. In sections 4, 5, and 6 we discuss the continuation of the PD, LPC, and NS bifurcations, respectively. Section 7 discusses further details on the initialization and adaptation of the continuation which are largely common to the three cases. In section 8 we consider the computation of multipliers along the three curve types. In section 9 we provide an example with the LP and NS continuations in MATCONT. In section 10 we make a comparison between the use of minimally and fully extended systems in the case of PD cycles.

2. Mathematical background on limit cycles and bifurcations of limit cycles. In this section we summarize the main results of [12]; in the flip and torus cases we actually present an easy generalization.

2.1. Limit cycles. A [illegible] is a closed orbit corresponding to a periodic solution of (1.2) with period T, i.e., $x(0) = x(T)$. By definition, in a neighborhood of a [illegible] there are no other cycles.

Since T is not known in advance, it is customary to use an equivalent system defined on the fixed interval $[0, 1]$ by rescaling time [10], [21]:

$$\begin{cases} \dfrac{dx}{dt} - Tf(x, \alpha) = 0, \\ x(0) = x(1). \end{cases} \tag{2.1}$$

A phase shifted function $\phi(t) = x(t+s)$ is also a solution of (2.1) for any value of s. To obtain a unique solution an extra constraint is needed. The following integral constraint is often used [10], [21]:

$$\int_0^1 \langle x(t), \dot{x}_{old}(t)\rangle dt = 0, \tag{2.2}$$

where $\dot{x}_{old}(t)$ is the tangent vector of a previously calculated limit cycle and is therefore known; $\langle x, v\rangle$ is just a different notation for $x^T v$. This condition tries to select the solution which has the smallest phase difference with respect to the previous solution x_{old}.

Thus, the complete BVP defining a limit cycle consists of (2.1) and (2.2).

2.2. Flip bifurcation of limit cycles. A flip bifurcation of limit cycles (PD) generically indicates a PD of the periodic solution; i.e., there are nearby periodic solutions of approximately double period. It can be characterized by adding an extra constraint $G = 0$ to (2.1), (2.2), where G is the flip test function specified below. The complete BVP defining a PD point using the minimally extended system is

$$\begin{cases} \dfrac{dx}{dt} - Tf(x,\alpha) & = 0, \\ x(0) - x(1) & = 0, \\ \int_0^1 \langle x(t), \dot{x}_{old}(t)\rangle dt & = 0, \\ G[x, T, \alpha] & = 0, \end{cases} \tag{2.3}$$

where G is defined by requiring

$$N_1 \begin{pmatrix} v \\ G \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix}. \tag{2.4}$$

Here v is a function, G is a scalar, and

$$N_1 = \begin{bmatrix} D - Tf_x(x(\cdot), \alpha) & w_{01} \\ \delta_0 + \delta_1 & w_{02} \\ \mathrm{Int}_{v_{01}} & 0 \end{bmatrix}, \tag{2.5}$$

where the bordering functions v_{01}, w_{01}, vector w_{02} are chosen so that N_1 is nonsingular [12]; δ_0, δ_1 are the Dirac operators defined by $\delta_i(f) = f(i)$ for $f \in \mathcal{C}^1([0,1], \mathbb{R}^n)$; $\mathrm{Int}_{v_{01}}$ is the operator defined by $\mathrm{Int}_{v_{01}} f = \int_0^1 v_{01}^T(t) f(t) dt$ for $f \in \mathcal{C}^1([0,1], \mathbb{R}^n)$. We note that in [12] the entry corresponding to w_{02} is zero; the generalization to (2.5) is easy.

2.3. Fold bifurcation of limit cycles. A fold bifurcation of limit cycles (LPC) generically corresponds to a turning point of a curve of limit cycles. It can be characterized by adding an extra constraint $G = 0$ to (2.1), (2.2), where G is the fold test function specified below. The complete BVP defining an LPC point using the minimally extended system is

$$\begin{cases} \dfrac{dx}{dt} - Tf(x,\alpha) & = 0, \\ x(0) - x(1) & = 0, \\ \int_0^1 \langle x(t), \dot{x}_{old}(t)\rangle dt & = 0, \\ G[x, T, \alpha] & = 0, \end{cases} \tag{2.6}$$

where G is defined by requiring

$$N_2 \begin{pmatrix} v \\ S \\ G \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ 0 \\ 1 \end{pmatrix}. \tag{2.7}$$

Here v is a function, S and G are scalars, and

$$N_2 = \begin{bmatrix} D - Tf_x(x(\cdot),\alpha) & -f(x(\cdot),\alpha) & w_{01} \\ \delta_1 - \delta_0 & 0 & w_{02} \\ \mathrm{Int}_{f(x(\cdot),\alpha)} & 0 & w_{03} \\ \mathrm{Int}_{v_{01}} & v_{02} & 0 \end{bmatrix}, \tag{2.8}$$

where the bordering functions v_{01}, w_{01}, vector w_{02}, and scalars v_{02} and w_{03} are chosen so that N_2 is nonsingular [12].

2.4. Torus bifurcation of limit cycles. A torus bifurcation of limit cycles (NS) generically corresponds to a bifurcation to an invariant torus, on which the flow contains periodic or quasi-periodic motions. It can be characterized by adding an extra constraint $G = 0$ to (2.1), (2.2), where G is the torus test function which has four components. The complete BVP defining an NS point using the minimally extended system is

$$\begin{cases} \dfrac{dx}{dt} - Tf(x,\alpha) & = 0, \\ x(0) - x(1) & = 0, \\ \int_0^1 \langle x(t), \dot{x}_{old}(t)\rangle dt & = 0, \\ G[x,T,\alpha] & = 0, \end{cases} \tag{2.9}$$

where

$$G = \begin{pmatrix} G_{11} & G_{12} \\ G_{21} & G_{22} \end{pmatrix}$$

is defined by requiring

$$N_3 \begin{pmatrix} v^1 & v^2 \\ G_{11} & G_{12} \\ G_{21} & G_{22} \end{pmatrix} = \begin{pmatrix} 0 & 0 \\ 0 & 0 \\ 1 & 0 \\ 0 & 1 \end{pmatrix}. \tag{2.10}$$

Here v^1 and v^2 are functions, G_{11}, G_{12}, G_{21}, and G_{22} are scalars, and

$$N_3 = \begin{bmatrix} D - Tf_x(x(\cdot),\alpha) & w_{11} & w_{12} \\ \delta_0 - 2\kappa\delta_1 + \delta_2 & w_{21} & w_{22} \\ \mathrm{Int}_{v_{01}} & 0 & 0 \\ \mathrm{Int}_{v_{02}} & 0 & 0 \end{bmatrix}, \tag{2.11}$$

where the bordering functions $v_{01}, v_{02}, w_{11}, w_{12}$ and vectors $w_{21}$and w_{22} are chosen so that N_3 is nonsingular. We note that in [12] the entries corresponding to w_{21} and w_{22} are zero; the generalization to (2.11) is easy.

3. Numerical continuation of limit cycles. For the numerical continuation of a limit cycle with respect to a parameter we need to discretize the system consisting of (2.1) and (2.2); to use a Newton-like method the Jacobian matrix of the discretized system is also needed. This is a sparse matrix and we exploit the sparsity by using the MATLAB routines for sparse matrices. The same applies to the Jacobians of the equations that define bifurcations of limit cycles in section 4, 5, and 6, which have similar sparsity patterns.

3.1. Discrete representation of the solution function. The method used to discretize the BVP is the same as in COLSYS [2], AUTO [10], and CONTENT [21] and is called the [illegible] [5]. First the interval [0 1] is subdivided into N smaller [illegible]:

$$0 = \tau_0 < \tau_1 < \cdots < \tau_N = 1.$$

On each of these intervals the solution $x(\tau)$ is approximated by an order m vector valued polynomial $x^{(i)}(\tau)$. This is done by defining $m+1$ equidistant [illegible] on each test interval

$$\tau_{i,j} = \tau_i + \frac{j}{m}(\tau_{i+1} - \tau_i) \ (i = 0, 1, \ldots, N-1)(j = 0, 1, \ldots, m)$$

and defining the polynomials $x^{(i)}(\tau)$ as

$$x^{(i)}(\tau) = \sum_{j=0}^{m} x^{i,j} l_{i,j}(\tau).$$

Here $x^{i,j}$ is the approximation of $x(\tau)$ at $\tau = \tau_{i,j}$ (we note that $x^{i,m} = x^{i+1,0}$ for $i = 0, 1, \ldots, N-1$), and the $l_{i,j}(\tau)$'s are the Lagrange basis polynomials

$$l_{i,j}(\tau) = \prod_{k=0, k\neq j}^{m} \frac{\tau - \tau_{i,k}}{\tau_{i,j} - \tau_{i,k}}.$$

On each test interval $[\tau_i, \tau_{i+1}]$ we require that the polynomials $x^{(i)}(\tau)$ satisfy the BVP exactly in m collocation points $\zeta_{i,j}$ $(j = 1, \ldots, m)$ (which are different from the mesh points $\tau_{i,j}$). It can be proved that the best choice for the collocation points are the Gauss points [5]. These are the roots of the Legendre polynomial relative to the interval $[\tau_i, \tau_{i+1}]$. With this choice of collocation points the error in the approximation is extremely small,

$$||x(\tau_{i,j}) - x^{i,j}|| = \mathcal{O}(h^m),$$

where $h = \max\{|t_i| : i = 1, 2, \ldots, N\}$, $t_i = \tau_i - \tau_{i-1}$, and for the mesh points τ_i it is even better:

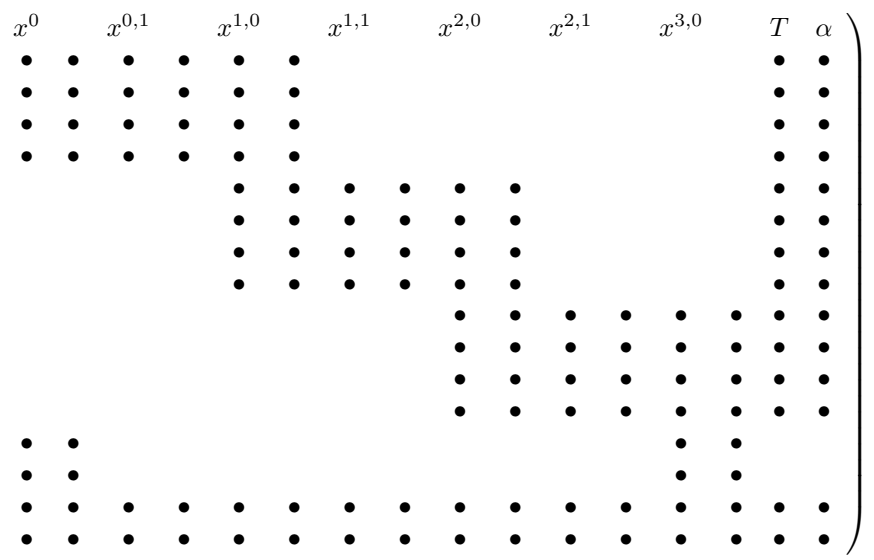
$$||x(\tau_i) - x^{i,0}|| = \mathcal{O}(h^{2m}).$$

3.2. Numerical evaluation of integrals. In (2.6) and several other places we need to compute integrals over $[0, 1]$ using the discretization discussed in section 3.1. For $N = 3$ test intervals and $m = 2$ collocation points, the following data are

associated with the discretized interval [0 1]:

$$\begin{array}{ccccccc}
\tau_0 & & \tau_1 & & \tau_2 & & \tau_3 \\
\circ & \circ & \bullet & \circ & \bullet & \circ & \circ \\
\tau_{0,0} & \tau_{0,1} & \tau_{0,2} & & \tau_{2,0} & \tau_{2,1} & \tau_{2,2} \\
 & & \tau_{1,0} & \tau_{1,1} & \tau_{1,2} & & \tau_{3,0} \\
t_1w_1 & t_1w_2 & t_1w_3+t_2w_1 & t_2w_2 & t_2w_3+t_3w_1 & t_3w_2 & t_3w_3 \\
\sigma_{0,0} & \sigma_{0,1} & \sigma_{1,0} & \sigma_{1,1} & \sigma_{2,0} & \sigma_{2,1} & \sigma_{3,0}
\end{array}$$

The total number of mesh points (*tps*) is $N \times m + 1$, the total number of variables (*ncoords*) is $tps \times \dim(x)$. Each mesh point $\tau_{i,j}$ in a test interval $[\tau_i, \tau_{i+1}]$ has a particular weight w_{j+1}, the Gauss–Lagrange quadrature coefficient. Some mesh points (the black bullets) belong to two test intervals. We set $t_i = \tau_i - \tau_{i-1}$ $(i = 1, \ldots, N)$. The integration weight $\sigma_{i,j}$ of $\tau_{i,j}$ is given by $w_{j+1}t_{i+1}$ for $0 \le i \le N-1$ and $0 < j < m$. For $i = 0, \ldots, N-2$ the integration weight of $\tau_{i,m} = \tau_{i+1,0}$ is given by $\sigma_{i,m} = w_{m+1}t_{i+1} + w_1 t_{i+2}$, and the integration weights of τ_0 and τ_N are given by $w_1 t_1$ and $w_{m+1}t_N$, respectively. The integral $\int_0^1 f(t)dt$ is, therefore, approximated by $\sum_{i=0}^{N-1}\sum_{j=0}^{m-1} f(\tau_{i,j})\sigma_{i,j} + f(1)\sigma_{N,0}$.



3.3. Discretization of the BVP. Using the discretization described in section 3.1, we obtain the discretized BVP

$$\begin{cases}
\left(\sum_{j=0}^{m} x^{i,j} l'_{i,j}(\zeta_{i,k})\right) - Tf(\sum_{j=0}^{m} x^{i,j} l_{i,j}(\zeta_{i,k}), \alpha) = 0 \\
x^{0,0} - x^{N-1,m} = 0 \\
\sum_{i=0}^{N-1}\sum_{j=0}^{m-1} \sigma_{i,j}\langle x^{i,j}, \dot{x}^{i,j}_{old}\rangle + \sigma_{N,0}\langle x^{N,0}, \dot{x}^{N,0}_{old}\rangle = 0
\end{cases}$$

The first equation in fact consists of Nm equations, one for each combination of $i = 0, 1, 2, \ldots, N-1$ and $k = 1, 2, \ldots, m$.

3.4. The Jacobian of the discretized equations. The Jacobian of the discretized system is sparse. In the Newton iterations during the continuation process a system consisting of this Jacobian matrix and an extra row (the tangent vector) is solved. For $N = 3$ test intervals, $m = 2$ collocation points, and $\dim(x) = 2$ this matrix has the following sparsity structure (•'s are a priori nonzeros):

(3.1)

The columns of (3.1) label the unknowns of the discretized problem. The first $\dim(x)$ rows correspond to the first collocation point, etc. In (2.1) and (2.2) there are three unknowns: x, the period T, and a parameter α. So the part of the Jacobian corresponding with the first equation of (2.1) has the following form:

$$[D - Tf_x(x,\alpha) \quad -f(x,\alpha) \quad -Tf_\alpha(x,\alpha)].$$

In (3.1) $D-Tf_x(x,\alpha)$ corresponds to $N=3$ blocks with dimension 4×6 $(=(\dim(x)*m)\times(\dim(x)\times(m+1)))$. The part in (3.1) that defines the boundary conditions for limit cycles has the form

$$[I_{\dim(x)} \quad 0_{\dim(x)\times(Nm-1)\dim(x)} \quad -I_{\dim(x)} \quad 0_{\dim(x)}].$$

These are in (3.1) the $\dim(x)=2$ rows following the 4×6 blocks. These rows contain two nonzero parts corresponding with $x^{0,0}$ and $x^{N,0}(\pm 2\times 2$ identity matrix). The last but one row in (3.1) is the derivative of the discretization of (2.2). The last row is added by the continuation code.

4. Continuation of PD cycles.

4.1. Discretization of the PD equations. The last equation in (2.3) expresses the condition that the operator

$$\begin{bmatrix} D - Tf_x(x(\cdot),\alpha) \\ \delta_0 + \delta_1 \end{bmatrix} \tag{4.1}$$

that appears in (2.5) is rank deficient [12]. In the implementation in MATCONT and CL_MATCONT we replace this by the condition that the discretized operator (matrix) of (4.1) has rank defect 1. To this end we solve

$$N_1^d \begin{pmatrix} v_d \\ G_d \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix}, \tag{4.2}$$

where

$$N_1^d = \begin{bmatrix} [\ D \ - \ Tf_x(x(\cdot),\alpha)\ ]_d & & w_d^1 \\ I_{\dim(x)} \ 0_{\dim(x)\times(Nm-1)\dim(x)} \ I_{\dim(x)} & & w_d^2 \\ v_d^1 & & 0 \end{bmatrix} \tag{4.3}$$

and the bordering vectors v_d^1, w_d^1, and w_d^2 are chosen so that (4.3) has full rank. Here and elsewhere the subscript d denotes discretization using orthogonal collocation. The structure is similar to that of (3.1); however, the two last rows and columns of (3.1) are replaced by the single last row and column of (4.3).

4.2. The Jacobian of the discretized PD equations. To continue the discretized equations of (2.3) the Jacobian matrix of the system is needed, which means that the derivatives of G_d with respect to the unknowns of the system, i.e., with respect to $x^{i,j}, T, \alpha$, have to be calculated.

Taking derivatives of (4.2) with respect to z (being a component of $x^{i,j}, T$, or α) we obtain

$$N_1^d \begin{pmatrix} v_{dz} \\ G_{dz} \end{pmatrix} + \begin{bmatrix} ([-Tf_x(x(\cdot),\alpha)]_d)_z & 0 \\ 0 & 0 \\ 0 & 0 \end{bmatrix} \begin{pmatrix} v_d \\ G_d \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix},$$

or, equivalently,

$$N_1^d \begin{pmatrix} v_{dz} \\ G_{dz} \end{pmatrix} = \begin{pmatrix} [Tf_x(x(\cdot),\alpha)]_{dz} v_d \\ 0 \\ 0 \end{pmatrix}.$$

Instead of solving this for every z we solve the transposed equations

$$(w_1^*, w_2^*, w_3^*) N_1^d = (0, 1), \tag{4.4}$$

where w_1 is a $\dim(x) * N * m$ vector, w_2 is a $\dim(x)$ vector, and w_3 is a scalar. Combining (4.2) and (4.4), we find

$$G_{dz} = -w_1^* [Tf_x(x(\cdot),\alpha)]_{dz} v_d. \tag{4.5}$$

So in each iteration step we solve two systems with the structure of (4.3) or its transpose.

5. Continuation of LPC cycles.

5.1. Discretization of the LPC equations. The last equation in (2.6) expresses that the operator

$$\begin{bmatrix} D - Tf_x(x(\cdot),\alpha) & -f(x(\cdot),\alpha) \\ \delta_1 - \delta_0 & 0 \\ \mathrm{Int}_{f(x(\cdot),\alpha)} & 0 \end{bmatrix} \tag{5.1}$$

that appears in (2.8) is rank deficient. In the numerical implementation in MATCONT and CL_MATCONT we replace this by the condition that the discretized operator of (5.1) is rank deficient. We solve

$$N_2^d \begin{pmatrix} v_d \\ S_d \\ G_d \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ 0 \\ 1 \end{pmatrix}, \tag{5.2}$$

where

$$N_2^d = \begin{bmatrix} [\ D\ -\ Tf_x(x(\cdot),\alpha)\ ]_d & [-f(x(\cdot),\alpha)]_d & w_d^1 \\ I_{\dim(x)}\ 0_{n\times(Nm-1)\dim(x)}\ -I_{\dim(x)} & 0 & w_d^2 \\ \mathrm{Int}_{f(x(\cdot),\alpha)_d} & 0 & w_d^3 \\ v_d^1 & v_d^2 & 0 \end{bmatrix}, \tag{5.3}$$

where the bordering vectors v_d^1, w_d^1, and w_d^2 and scalars v_d^2 and w_d^3 are chosen so that N_2^d is nonsingular. The structure is similar to that of (3.1); however, the last two rows and columns have a different meaning. The last but one row corresponds with $\mathrm{Int}_{[f(x(\cdot),\alpha)]_d}$ and the last but one column corresponds with $[-f(x(\cdot),\alpha)]_d$.

5.2. The Jacobian of the discretized LPC equations. To continue the discretized equations of (2.6) the Jacobian matrix of the system is needed, which means that the derivatives of G_d with respect to the unknowns of the system, i.e., with respect to $x^{i,j}, T, \alpha$, have to be calculated.

The derivative with respect to z (being a component of $x^{i,j}, T$ or α) is

$$N_2^d \begin{pmatrix} v_{dz} \\ S_{dz} \\ G_{dz} \end{pmatrix} + \begin{bmatrix} ([-Tf_x(x(\cdot),\alpha)]_d)_z & ([-f(x(\cdot),\alpha)]_d)_z & 0 \\ 0 & 0 & 0 \\ (\mathrm{Int}_{[f(x(\cdot),\alpha)]_d})_z & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} \begin{pmatrix} v_d \\ S_d \\ G_d \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ 0 \\ 0 \end{pmatrix}.$$

Simplifying gives

$$N_2^d \begin{pmatrix} v_{dz} \\ S_{dz} \\ G_{dz} \end{pmatrix} = \begin{pmatrix} [Tf_x(x(\cdot),\alpha)]_{dz} v_d + [f(x(\cdot),\alpha)]_{dz} S_d \\ 0 \\ -\mathrm{Int}_{[f(x(\cdot),\alpha)]_{dz}} v_d \\ 0 \end{pmatrix}.$$

Instead of solving this for every z we solve the transposed equations

$$(w_1^*, w_2^*, w_3, w_4) N_2^d = (0, 0, 1), \tag{5.4}$$

where w_1 is a $\dim(x) * N * m$ vector, w_2 is a $\dim(x)$ vector, and w_3 and w_4 are scalars. Combining (5.2) and (5.4), we find

$$G_{dz} = w_1^*([Tf_x(x(\cdot),\alpha)]_{dz} v_d + [f(x(\cdot),\alpha)]_{dz} S_d) - w_3 \mathrm{Int}_{[f(x(\cdot),\alpha)]_{dz}} v_d. \tag{5.5}$$

So in each iteration step we solve two systems with the structure of (3.1) or its transpose.

5.3. Details of the computation of G . We restrict ourselves to the computation of the contribution of the term $-w_3 \mathrm{Int}_{[f(x(\cdot),\alpha)]_{dz}} v_d$ in (5.5), the computation of the other terms being similar. We first introduce the vector

$$\Sigma = (\sigma_{0,0}, \ldots, \sigma_{0,0}, \sigma_{0,1}, \ldots, \sigma_{0,1}, \ldots, \sigma_{1,0}, \ldots, \sigma_{1,0}, \ldots, \sigma_{N,0}, \ldots, \sigma_{N,0})^T,$$

where each weight $\sigma_{i,j}$ is repeated $\dim(x)$ times.

Let $(\Sigma. * v_d)$ be the element-by-element product of the vectors Σ and v_d. Then

$$\mathrm{Int}_{[f(x(\cdot),\alpha)]_d} v_d = (\Sigma. * v_d)^T F((x^{i,j}), \alpha),$$

where $F((x^{i,j}), \alpha)$ is the column vector consisting of the $f(x^{i,j}, \alpha)$ for $i = 0, \ldots, N - 1,\ j = 0, \ldots, m - 1$, and $f(x^{N,0}, \alpha)$. So

$$\mathrm{Int}_{[f(x(\cdot),\alpha)]_{dz}} v_d = (\Sigma. * v_d)^T F((x^{i,j}), \alpha)_z.$$

Since T does not appear in this expression, there is no contribution to G_{dT}. The contribution to $G_{dx^{i,j}}$ is

$$-w_3 (\Sigma. * v_d)^T_{(i+mj)\dim(x)+1,\ldots,(i+mj+1)\dim(x)} f_x(x^{i,j}, \alpha);$$

the contribution to $G_{d\alpha}$ is

$$-w_3 (\Sigma. * v_d)^T_{(i+mj)\dim(x)+1,\ldots,(i+mj+1)\dim(x)} f_\alpha(x^{i,j}, \alpha).$$

6. Continuation of NS cycles.

6.1. Discretization of the NS equations. The last equation in (2.9) expresses that the operator

$$\begin{bmatrix} D - Tf_x(x(\cdot),\alpha) \\ \delta_0 - 2\kappa\delta_1 + \delta_2 \end{bmatrix} \tag{6.1}$$

which appears in (2.11) has rank defect 2. In the numerical implementation in MATCONT and CL_MATCONT we replace this by the requirement that the discretized equation of (6.1) has rank defect 2. We solve

$$N_3^d \begin{pmatrix} v_d^1 & v_d^2 \\ G_d^{11} & G_d^{12} \\ G_d^{21} & G_d^{22} \end{pmatrix} = \begin{pmatrix} 0 & 0 \\ 0 & 0 \\ 1 & 0 \\ 0 & 1 \end{pmatrix}, \tag{6.2}$$

where

$$N_3^d = \begin{bmatrix} [D - Tf_x(x(\cdot),\alpha)]_d & w_d^{11} & w_d^{12} \\ (\delta_0 - 2\kappa\delta_1 + \delta_2)_d & w_d^{21} & w_d^{22} \\ v_d^{01} & 0 & 0 \\ v_d^{02} & 0 & 0 \end{bmatrix} \tag{6.3}$$

and

$$[(\delta_0 - 2\kappa\delta_1 + \delta_2)_d]$$
$$= [I_{\dim(x)} \;\; 0_{\dim(x)\times(Nm-1)\dim(x)} \;\; -2\kappa I_{\dim(x)} \;\; 0_{\dim(x)\times(Nm-1)\dim(x)} \;\; I_{\dim(x)}],$$

and the bordering vectors $v_d^{01}, v_d^{02}, w_d^{11}, w_d^{12}, w_d^{21}$, and w_d^{22} are chosen so that (6.3) has full rank. Here the subscript d denotes discretization using orthogonal collocation over the interval [0 2]. For $N = 2$ test intervals and $m = 2$ collocation points the following data are associated with the discretized interval [0 2]:

0				1				2
τ_0		τ_1		τ_2		τ_3		τ_4
$\circ$	$\circ$	$\bullet$	$\circ$	$\bullet$	$\circ$	$\bullet$	$\circ$	$\circ$
$\tau_{0,0}$	$\tau_{0,1}$	$\tau_{0,2}$		$\tau_{2,0}$	$\tau_{2,1}$	$\tau_{2,2}$		$\tau_{4,0}$
		$\tau_{1,0}$	$\tau_{1,1}$	$\tau_{1,2}$		$\tau_{3,0}$	$\tau_{3,1}$	$\tau_{3,2}$
t_1w_1	t_1w_2	$t_1w_3 + t_2w_1$	t_2w_2	$t_2w_3 + t_1w_1$	t_1w_2	$t_1w_3 + t_2w_1$	t_2w_2	t_2w_3
$\sigma_{0,0}$	$\sigma_{0,1}$	$\sigma_{1,0}$	$\sigma_{1,1}$	$\sigma_{2,0}$	$\sigma_{2,1}$	$\sigma_{3,0}$	$\sigma_{3,1}$	$\sigma_{4,0}$

The total number of mesh points (*tps*) is now $2N \times m + 1$ and the total number of points (*ncoords*) is *tps* $\times \dim(x)$.

The structure is quite similar to that of (3.1); the first part ($2\dim(x)Nm \times$ *ncoords*) is now over [0 2] in (6.3), so it is duplicated (the dimension is approximately doubled). The two last rows and columns are also different. They correspond with the borders.

6.2. The Jacobian of the discretized NS equations. To continue the discretized equations of (2.9) the Jacobian matrix of the system is needed, which means that the derivatives of G_d with respect to the unknowns of the system, i.e., with respect to $x^{i,j}, T, \alpha$, have to be calculated.

The derivative with respect to z (being a component of $x^{i,j}, T$, or α) is

$$N_3^d \begin{pmatrix} v_{dz}^1 & v_{dz}^2 \\ G_{dz}^{11} & G_{dz}^{12} \\ G_{dz}^{21} & G_{dz}^{22} \end{pmatrix} = \begin{pmatrix} [Tf_x(x(\cdot),\alpha)]_{dz} v_{dz}^1 & [Tf_x(x(\cdot),\alpha)]_{dz} v_{dz}^2 \\ 0 & 0 \\ 0 & 0 \\ 0 & 0 \end{pmatrix}.$$

Instead of solving this for every z we solve the transposed equations

$$\begin{pmatrix} w_1^{1*} & w_1^{2*} & G_{dz}^{11} & G_{dz}^{12} \\ w_2^{1*} & w_2^{2*} & G_{dz}^{21} & G_{dz}^{22} \end{pmatrix} N_3^d = \begin{pmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}, \tag{6.4}$$

where w_1^{1*}, w_2^{1*} are $\dim(x) * 2N * m$ vectors and w_1^{2*}, w_2^{2*} are $\dim(x)$ vectors. Combining (6.2) and (6.4), we find

$$G_{dz}^{ij} = w_i^{1*}([Tf_x(x(\cdot),\alpha)]_d)_z v_d^j. \tag{6.5}$$

So in each iteration step we solve two systems with the almost doubled structure of (3.1) or its transpose.

One also needs the derivatives with respect to κ; for this we find

$$M_d^1 \begin{pmatrix} v_{d\kappa}^1 & v_{d\kappa}^2 \\ G_{d\kappa}^{11} & G_{d\kappa}^{12} \\ G_{d\kappa}^{21} & G_{d\kappa}^{22} \end{pmatrix} = \begin{pmatrix} 0 & 0 \\ 2v_d^1(1) & 2v_d^2(1) \\ 0 & 0 \\ 0 & 0 \end{pmatrix}.$$

So for κ we find

$$G_{d\kappa}^{ij} = w_i^{2*} v_d^j(1), \tag{6.6}$$

where $i, j \in \{1, 2\}$.

7. Initialization and adaptation of the borders. The bordering vectors in (4.3), (5.3), and (6.3) must be such that the matrices $N_{1,2,3}^d$ are nonsingular. We actually choose them in such a way that the corresponding matrices $N_{1,2,3}^d$ are as well conditioned as possible. This involves an initialization of the borders when the continuation is started and a subsequent adaptation during the continuation.

7.1. The flip and fold cases. During the initialization the borders must be chosen so that the extensions N_1^d of

$$O_1 = \begin{bmatrix} [\quad D \quad - \quad Tf_x(x(\cdot),\alpha) \quad]_d \\ I_{\dim(x)} \quad 0_{\dim(x)\times(Nm-1)\dim(x)} \quad I_{\dim(x)} \end{bmatrix}$$

in the flip case and N_2^d of

$$O_2 = \begin{bmatrix} [\ D \quad - \quad Tf_x(x(\cdot),\alpha) \ ]_d & & [-f(x(\cdot),\alpha)]_d \\ I_{\dim(x)} \quad 0_{\dim(x)\times(Nm-1)\dim(x)} & -I_{\dim(x)} & 0 \\ \mathrm{Int}_{f(x(\cdot),\alpha)_d} & & 0 \end{bmatrix}$$

in the fold case have full rank. We first perform a QR orthogonal-triangular decomposition with column pivoting.

The MATLAB command $[Q, R, E] = QR(full(O_{1,2}))$ produces a permutation matrix E, an upper triangular matrix R of the same dimension as $O_{1,2}$, and a unitary

matrix Q so that $O_{1,2} * E = Q * R$. The column pivoting guarantees that the QR pivoting is rank revealing and in particular that $abs(\mathrm{diag}(R))$ is decreasing; cf. [15, section 5.4]. Since $O_{1,2}$ has rank defect 1, the last element on the diagonal of R should be zero (up to approximation). The borders v_d^1 in (4.3) in the flip case and v_d^1 in (5.3) in the fold case are chosen as the right null vector p of, respectively, O_1 and O_2. It is well known that this makes the bordered matrices nonsingular. This is sometimes called Keller's lemma; cf. [19]. A detailed study of the rank of bordered matrices is given in [17, Proposition 3.2.2]. From $O_{1,2}p = 0$ follows that $RE^Tp = 0$. Setting the bottom right element of R to zero, we obtain

$$\left(\begin{array}{ccccc|c} * & * & * & \dots & * & * \\ 0 & * & * & \dots & * & * \\ 0 & 0 & * & \dots & * & * \\ & & & \dots & & \dots \\ 0 & 0 & 0 & \dots & * & * \\ \hline 0 & 0 & 0 & \dots & 0 & 0 \end{array}\right) E^Tp = \left(\begin{array}{c} 0 \\ \\ \hline 0 \end{array}\right). \tag{7.1}$$

This defines E^Tp up to a scalar multiple. Since its last entry must be nonzero we represent E^Tp as $E^Tp = \binom{p_1}{1}$. Therefore (7.1) has the form

$$\left(\begin{array}{c|c} R_1 & b \\ \hline 0 & 0 \end{array}\right)\left(\begin{array}{c} p_1 \\ \hline 1 \end{array}\right) = \left(\begin{array}{c} 0 \\ \hline 0 \end{array}\right)$$

with R_1 a nonsingular upper triangular matrix. This is equivalent to

$$R_1p_1 = -b.$$

So the right border is the normalization of $E*[(R_1\backslash -b); 1]$ (in MATLAB notation). The computation of the left null vector q, which corresponds to w_d^1 and w_d^2 in (4.3) in the flip case and to w_d^1, w_d^2, and w_d^3 in (5.3) in the fold case, is easier. In fact q is the last column q_L of Q because $q_L^T * O_{1,2} = q_L^TQRE^T = (0, \dots, 0, 1)RE^T = 0E^T = 0$.

It is an attractive idea to use the sparsity of $O_{1,2}$ to do a Q-less QR decomposition, $R = QR(O_{1,2})$ as provided in MATLAB, which returns only R. This is enough to find the right singular vector of $O_{1,2}$. The left null vector would then be computed as the normalized right null vector of the transposed $O_{1,2}$. However, we found that this method is not robust and that a QR factorization with pivoting is needed. We tested this by comparing a sparse Q-less QR decomposition, a full QR decompositon without column pivoting, and a full QR decomposition with column pivoting for O_2^T, for the system

$$\left\{\begin{array}{lcl} \dot{u}_1 &=& -u_1 + p_1(1-u_1)e^{u_3}, \\ \dot{u}_2 &=& -u_2 + p_1(1-u_1-p_5u_2)e^{u_3}, \\ \dot{u}_3 &=& -u_3 - p_3u_3 + p_1p_4(1-u_1+p_2*p_5*u_2)e^{u_3}, \end{array}\right.$$

where u_1, u_2, u_3 are state variables and p_1, p_2, p_3, p_4, p_5 are parameters. This is the classical model of the $A \to B \to C$ chemical reaction in a stirred tank [11]; we recall that $1 - u_1$ and u_2 denote the concentrations of A and B, respectively, and u_3 is the temperature. The parameters $p_1, \dots, p_5$ have a physical meaning; e.g., p_1 is the Damkohler number and p_3 is the heat transfer coefficient. There is a Hopf point for

$p_1 = 0.19547, p_2 = 1, p_3 = 1.5, p_4 = 8, p_5 = 0.04$ and $u_1 = 0.57456, u_2 = 0.54511, u_3 = 1.9328$. Starting an LC continuation with p_1 as a free parameter, we find an LPC point at $p_1 = 0.19545$. Starting an LPC continuation from this LPC point with p_1 and p_3 both free parameters for $N = 30$ and $m = 4$, we obtain O_2 as a matrix of dimension 364×364. The matrix

$$R_s = \begin{pmatrix} 0 & 0.000101297163 \\ 0 & 0 \end{pmatrix}$$

is the bottom right 4×4 block of the Q-less decomposition of O_2^T. The matrix

$$R_f = \begin{pmatrix} -0.000000000001 & 0.000088855185 \\ 0 & 0.000048640223 \end{pmatrix}$$

similarly corresponds to the QR decomposition without pivoting of O_2^T as a full matrix and

$$R_{cp} = \begin{pmatrix} 0.009688518843 & 0.000000271536 \\ 0 & 0.000000423924 \end{pmatrix}$$

corresponds to the QR decomposition with column pivoting of O_2^T as a full matrix. Remarkably, there is a clear difference between the bottom right 2×2 blocks of R_s and R_f. The source code of the Q-less QR decomposition is not available, but one easily guesses that small numbers are rounded to zero to increase the sparsity. But in a situation like ours, the presence of a zero as the first entry on the diagonal of R_s leads to a division by zero in the computation of the left null vector q, where q is the result of the analogue of $E*[(R_1 \backslash -b); 1]$. We further note that the QR decomposition as a full matrix without column pivoting is not satisfactory because the third element on the diagonal of R_f is the smallest one and so it does not define the rank. With column pivoting the fourth element on the diagonal of R_{cp} is the smallest and the diagonal elements indeed define the rank.

During the computation of a curve of limit cycle bifurcations the borders v_d^1 in (4.3) in the flip case and v_d^1 and v_d^2 in (5.3) in the fold case can be adapted by replacing them, respectively, by the normalized v_d in (4.2) and by the normalized v_d and S in (5.2). The borders w_d^1, w_d^2 in (4.3) and w_d^1, w_d^2, and w_d^3 in (5.3) are adapted by solving the transposed equations and replacing them, respectively, by the normalized w_1^*, w_2^* in (4.4) and by w_1^*, w_2^*, and w_3 in (5.4). Only one border is adapted at the same time. An adaptation is performed after each number of k computed continuation points where k is a user-chosen number; $k = 0$ means no adaptation at all.

7.2. The torus case. To initialize the borders in the case of a torus bifurcation, the borders are chosen so that the extension

$$O_3 = \begin{bmatrix} [\quad D \quad - \quad Tf_x(x(\cdot), \alpha) \quad]_d \\ I_{\dim(x)} \; 0_{\dim(x)\times(Nm-1)\dim(x)} \; -2\kappa I_{\dim(x)} \; 0_{\dim(x)\times(Nm-1)\dim(x)} \; I_{\dim(x)} \end{bmatrix}$$

of N_3^d has full rank. We implement this by using a QR orthogonal-triangular decomposition with column pivoting, $[Q, R, E] = QR(full(O_3))$. Here R is an upper triangular matrix whose bottom right 2×2 block consists of zeros up to approximation. Setting

this block to zero, we obtain

$$\left(\begin{array}{ccccc|cc} * & * & * & \dots & * & * & * \\ 0 & * & * & \dots & * & * & * \\ 0 & 0 & * & \dots & * & * & * \\ & & & \dots & & \dots & * \\ 0 & 0 & 0 & \dots & * & * & * \\ \hline 0 & 0 & 0 & \dots & 0 & 0 & 0 \\ 0 & 0 & 0 & \dots & 0 & 0 & 0 \end{array}\right) E^T p = \left(\begin{array}{cc} & \\ 0 & 0 \\ & \\ \hline 0 & 0 \end{array}\right)$$

if p is a two-column matrix whose columns span the right null space of O_3. By imposing some structure on $E^T p$ we get

$$\left(\begin{array}{c|cc} R_1 & b_1 & b_2 \\ \hline 0 & 0 & 0 \\ 0 & 0 & 0 \end{array}\right) \left(\begin{array}{c|c} p_1 & p_2 \\ \hline 1 & 0 \\ 0 & 1 \end{array}\right) = \left(\begin{array}{cc} & \\ 0 & 0 \\ & \\ \hline 0 & 0 \end{array}\right)$$

or

$$R_1(p_1\ p_2) = -(b_1\ b_2),$$

where R_1 is a nonsingular square upper triangular matrix. So the two right bordering vectors in (6.3) are initially chosen as the normalization and orthogonalization of $E * [(R_1 \backslash [-b_1, -b_2]); eye(2)]$ where $eye(2)$ is the 2×2 identity matrix. The left null matrix consists of the two last columns of Q. Indeed, if we denote this part of Q as Q_L, then

$$Q_L^T * O_3 = Q_L^T Q R E^T = \left(\begin{array}{c} 0, \dots 0, 1, 0 \\ 0, \dots 0, 0, 1 \end{array}\right) R E^T = 0 E^T = 0.$$

From (2.9) and (2.10) we get four equations $G_{ij} = 0$ ($(i, j) \in \{1, 2\}$) in the case of a torus bifurcation. The continuation algorithm needs only two of them. To select those two we start with the full QR decomposition, $[Q_1, R_1] = QR((jac\ jacT\ jacp\ 0)')$, where $(jac\ jacT\ jacp)$ is the Jacobi matrix of the limit cycle equations with respect to the state variables, period, and parameters, respectively. Extending the equality $(jac\ jacT\ jacp\ 0)Q_1 = R_1^T$ by some simple computations we obtain a decomposition

$$\left(\begin{array}{cccc} jac & jacT & jacp & 0 \\ G_{11x} & G_{11T} & G_{11p} & G_{11\kappa} \\ G_{12x} & G_{12T} & G_{12p} & G_{12\kappa} \\ G_{21x} & G_{21T} & G_{21p} & G_{21\kappa} \\ G_{22x} & G_{22T} & G_{22p} & G_{22\kappa} \end{array}\right) Q_1 = \left(\begin{array}{ccccc|cc} * & 0 & \dots & 0 & 0 & 0 & 0 \\ * & * & \dots & 0 & 0 & 0 & 0 \\ & & \dots & & & \dots & \\ * & * & \dots & * & 0 & 0 & 0 \\ \hline ** & * & \dots & * & & J'_{res} & \end{array}\right) \tag{7.2}$$

where J_{res} is a 3×4 matrix with rank 2. We now want to choose two among the last four rows of the right-hand side of (7.2) to make the right-hand side as well conditioned as possible. We perform a QR decomposition with pivoting $[Q_2, R_2, E_2] = QR(full(J_{res}))$. So

$$J_{res} E_2 = (q_1\ \ q_2\ \ q_3) \left(\begin{array}{cccc} * & * & * & * \\ 0 & * & * & * \\ 0 & 0 & 0 & 0 \end{array}\right)$$

$$= (\ q_1\ \ q_2\ ) \left(\begin{array}{cccc} * & * & * & * \\ 0 & * & * & * \end{array}\right),$$

TABLE 9.1

Variable	Value	Parameter	Value
A	31.78997	k_1	0.1631021
B	1.45468	k_2	1250
X	0.01524586	k_3	0.046875
Y	0.1776113	k_4	20
		k_5	1.104
		k_6	0.001
		k_7	4.235322
		k_8	0.5
		k_{-7}	0.1175

from which it follows that the first two columns of $J_{res}E_2$ are linearly independent. This also means that the columns of J_{res} we need to use (equivalently, which G_{ij} we need to choose) are those where the first or second column of E_2 contains an entry equal to 1.

The borders v_d^{01} and v_d^{02} in (6.3) are adapted by replacing them, respectively, by the normalized and orthogonalized v_d^1 and v_d^2 in (6.2). The borders w_d^{11}, w_d^{22} and w_d^{12}, w_d^{22} in (6.3) are adapted by solving the transposed equations and replacing them, respectively, by the normalized and orthogonalized w_1^{1*}, w_1^{2*} and w_2^{1*}, w_2^{2*} in (6.4). The new indices are computed in the same way as in the initialization. The general strategy for adaptation during the computation of a curve of NS cycles is the same as in the fold and flip cases.

8. Multipliers. Multipliers are (optionally) computed in MATCONT as in AUTO [10] and CONTENT [21] by making a special decomposition (condensation of parameters) in (3.1) (see section 2.3 in [9]). A periodic solution always has a multiplier equal to 1. At a fold, the multiplier 1 has algebraic multiplicity 2 and geometric multiplicity 1, at a flip there is a simple multiplier equal to -1, and at a torus bifurcation there is a simple conjugate pair of complex eigenvalues with modulus 1. This can be used to check the correctness of the continuation. We note that the computation of multipliers is expensive because the sparse matrix is not handled with the sparse MATLAB routines. As in AUTO, it is good practice to switch off the computation of multipliers when they are not really needed.

9. Example: Fold and torus bifurcations in a chemical model. The following model of the peroxidase-oxidase reaction was studied by Steinmetz and Larter [23] where A, B, X, Y are state variables and k_1, k_2, k_3, k_4, k_5, k_6, k_7, k_8, k_{-7} are parameters:

$$\left\{\begin{array}{rcl} \dot{A} &=& -k_1ABX - k_3ABY + k_7 - k_{-7}A, \\ \dot{B} &=& -k_1ABX - k_3ABY + k_8, \\ \dot{X} &=& k_1ABX - 2k_2X^2 + 2k_3ABY - k_4X + k_6, \\ \dot{Y} &=& -k_3ABY + 2k_2X^2 - k_5Y. \end{array}\right. \tag{9.1}$$

In [23] Hopf bifurcations, torus bifurcations, and the onset of chaos are studied. It has been shown recently that (9.1) also possesses generalized Hopf points and associated LPCs (see [16]).

The values in Table 9.1 correspond to an unstable equilibrium in (9.1).

First, we continue this equilibrium with increasing k_7 while keeping all other parameters fixed. The computed equilibrium branch is a nearly horizontal curve

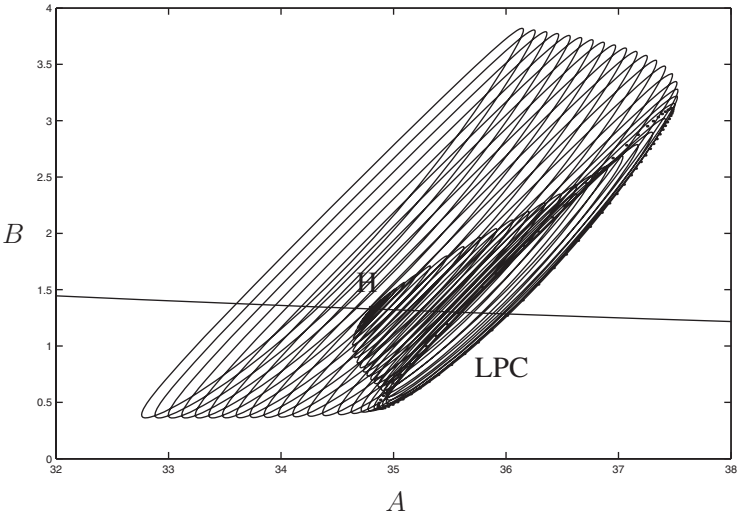


FIG. 9.1. *LPC in the Steinmetz–Larter model.*

in Figure 9.1. At $k_7 = 4.59004\ldots$ a subcritical Hopf bifurcation is located (point H). Indeed, there are two complex eigenvalues of the equilibrium with Re $\lambda_{1,2} \approx 0$ at this parameter, while the first Lyapunov coefficient l_1 is positive. Thus, there should exist an unstable limit cycle bifurcating from this equilibrium. Selecting the found Hopf point as the new initial point, we can continue in MATCONT a branch of the bifurcating limit cycles and obtain the rest of Figure 9.1. There is an LPC at $k_7 = 4.74839\ldots$, where two cycles collide and disappear. The critical cycle has a double multiplier $\mu = 1$ (counting the trivial one). The continuation algorithm automatically follows the second (stable) cycle branch after the LPC point.

Computing the original equilibrium curve in the opposite direction, we get another Hopf point at $k_7 = 0.712475\ldots$, where the first Lyapunov coefficient is negative. This means that a stable limit cycle bifurcates from the equilibrium when it loses stability. Starting from this Hopf point, we obtain the family of stable limit cycles bifurcating from it. At $k_7 = 0.716434\ldots$ a message indicates that a [illegible] (NS) bifurcation occurs. Indeed, there are two complex multipliers with (approximately) $|\mu| = 1$. After the bifurcation point the limit cycle becomes unstable (with two multipliers satisfying $|\mu| > 1$) but regains stability at $k_7 = 0.818566\ldots$ through another NS bifurcation.

The found Hopf, LPC, and NS points can be used as starting points for the two-parameter continuation of the corresponding codim 1 bifurcations, using k_7 and k_8 as two control parameters. Figure 9.2 gives a graphical impression of a typical MATCONT session. This figure shows the MATCONT main window, the starter and continuer windows for the NS continuation, and also graphical output in a two-dimensional plot window; in the latter A is plotted versus B. For more information on the MATCONT windows we refer to the MATCONT website.

The bifurcation curves computed with MATCONT are presented in Figure 9.3, where a (partial) bifurcation diagram in the (k_7, k_8)-plane is shown together with the enlargement of an interesting region. There are two [illegible] in

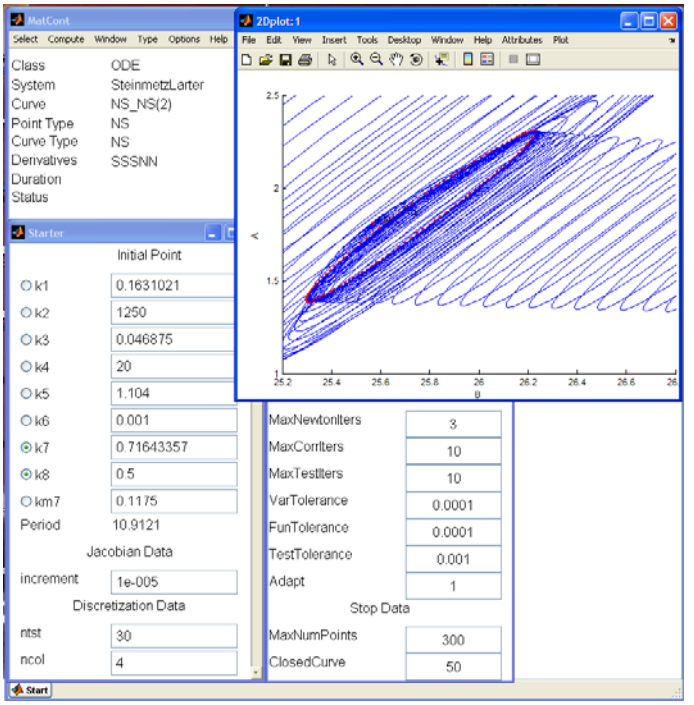

FIG. 9.2. *NS continuation in the Steinmetz–Larter model.*

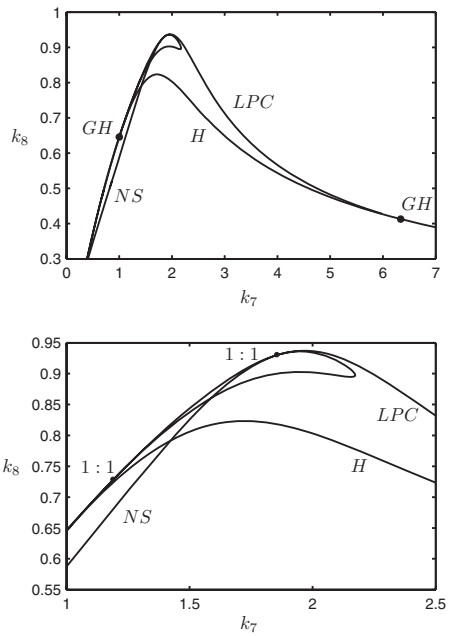

FIG. 9.3. *Bifurcation curves in Steinmetz–Larter model. H:Hopf bifurcation with two generalized Hopf points (labeled by GH); LPC: limit point of cycles; NS: Neimark–Sacker (torus) bifurcation curve with two* $1:1$ *strong resonances.*

the Hopf bifurcation curve (labeled by GH), where the associated first Lyapunov coefficient l_1 vanishes [16]. As theory predicts (see, for example, [20]), from each GH point emanates an LPC curve. Actually, there is just one LPC curve connecting the GH points; while approaching these points, the critical nonhyperbolic cycle shrinks to the equilibrium point. The shape of the NS curve is more complicated: there are two more codim 2 points on it, where a triple multiplier $\mu = 1$ is present (counting the trivial one). These are 1:1 [illegible] points [20], where the LPC and NS curves meet tangentially. Between the 1:1 points, the NS curve is a [illegible] curve. Near such codim 2 points complicated homoclinic structures exist.

It should be noted that the algorithms implemented in MATCONT for the LPC and NS continuation are robust enough to pass through the 1:1 resonance points and to closely approach the GH points (within the 10^{-3}-range in the parameters).

10. Fully versus minimally extended system. The methods described in this paper to continue bifurcation points of limit cycles are different from the traditional ones. Classical software like AUTO uses fully extended systems where additional vector functions are added to the system for the limit cycle to form a big system of approximately double the size in the fold and flip cases and triple the size in the torus case. In the PD case this leads to

$$\begin{cases} \dfrac{dx}{dt} - Tf(x,\alpha) & = 0, \\ x(0) - x(1) & = 0, \\ \int_0^1 \langle x(\cdot), \dot{x}_{old}(t)\rangle dt & = 0, \\ \dot{v}(t) - Tf_x(x,\alpha)v(t) & = 0, \\ v(0) + v(1) & = 0, \\ \int_0^1 \langle v_{old}(t), v(t)\rangle dt - 1 & = 0, \end{cases}$$

where x, v, T, α are the unknowns and v is a rescaled version of the variable with the same name in (2.4).

This system is easier to code since there is no need to find and adapt the bordering vectors. However, it has a big disadvantage: it has approximately twice the size of the minimally extended system. On the other hand, for the minimally extended system the additional system (2.4) has to be solved. But solving two systems of size $n \times n$ takes in general less time than solving one system of size $2n \times 2n$ (in the case of full matrices about a quarter). This suggests that using the big system will be slower than using the minimally extended system.

We did some comparisons in the case of the PD bifurcations in a feedback control system, described in [13], [14] and further used in [20, Example 5.4, p. 178]:

$$\begin{cases} \dot{x} & = & y, \\ \dot{y} & = & z, \\ \dot{z} & = & -\alpha z - \beta y - x + x^2. \end{cases}$$

Due to the special structure of this system, a good approximation to the PD curve can be found by the harmonic balance method; cf. [24], [25].

We compute numerically a branch of PD cycles as described in the CL_MATCONT manual and [7]. To avoid the overhead of the graphical user interface (GUI) all computations were done in CL_MATCONT. Both the minimally and the fully extended systems were implemented and tested for several numbers of test and collocation

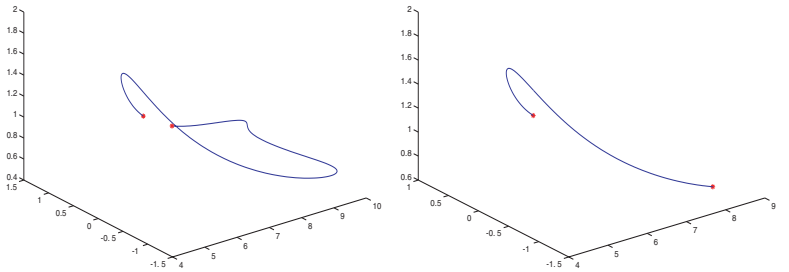

FIG. 10.1. *PD curves computed in Table* 10.1(e).

points. In each case we compute 300 continuation points with the same continuation parameters.

From Table 10.1 it appears that the minimally extended system is faster; moreover, it computes a longer stretch of the PD branch. We illustrate this in Figure 10.1 in the case (e) ($N = 30, m = 4$), but it holds in all cases.

This comparison is crude because the continuation variables are in different spaces and therefore thresholds and stepsizes have a different meaning in the two cases. To describe the more refined comparisons we note that in MATCONT and CL_MATCONT the convergence of Newton iterations in the continuation of a branch of solutions to (1.1) is declared if two conditions are satisfied, namely,

$$\|F(x)\| \leq F_t, \|\delta x\| \leq V_t,$$

where δx is the Newton correction and F_t (function tolerance) and V_t (variable tolerance) are user-chosen threshold values. Also, the code uses an integer parameter N_a which indicates that the settings of the continuation are adapted after each N_a computed points. Adaptation is a curve-type-dependent process. In the continuation of limit cycles it always includes the adaptation of the mesh. In the minimally extended systems it also includes updating the borders as described in section 7. Setting $N_a = 0$ means no adaptation at all. This cannot be recommended, but it can be studied usefully as the limit case for large N_a.

In the other experiments we choose situations where both methods compute the same stretch of curve with the same number of points but with F_t, V_t adapted to the dimension of the space of continuation variables. In all cases we have $N = 50, m = 5$, $\dim(x) = 3$. The object function of the minimally extended system (F in (1.1)) has dimension $Nm\dim(x) + \dim(x) + 2 = 755$. The dimension of the

`newtcorr`	25	110.169 s
`contjac`	50	90.071 s

space of independent variables (x in (1.1)) is therefore 756. For the fully extended system these dimensions are, respectively, $2Nm\dim(x) + 2\dim(x) + 2 = 1508$ and 1509. In the case of the minimally extended system we choose $F_t = V_t = 10^{-4}$. If we ignore scaling problems, then corresponding bounds for the fully extended systems are $10^{-4}\sqrt{\frac{1508}{755}} = 1.4133e-4$ and $10^{-4}\sqrt{\frac{1509}{756}} = 1.4128e-4$, respectively.

Both algorithms were forced to compute 150 points in the given stretch by varying the maximal stepsizes. With $N_a = 0$ the minimally extended system took 561.0 seconds, the fully extended system 617.2 seconds. With $N_a = 1$ the minimally extended system took 586.3 seconds; the fully extended system took 687.4 seconds.

In a similar experiment with only 25 computed points and $N_a = 0$ the minimally and fully extended systems took 108.56 and 111.70 seconds, respectively. With $N_a = 1$ the time spans were 111.39 and 118.43 seconds, respectively.

Since scaling is a difficult issue, one might wonder if setting F_t, V_t in the above way really corresponds to the same accuracy in the computed solutions. We therefore did an additional test in the last mentioned experiment (25 points, $N_a = 1$) by computing the norms of the (x, T, α) parts in the last Newton correction in each continuation point. For the minimally extended system the average value of these norms was $5.086e-8$, and for the fully extended system it was $1.111e-6$. This clearly indicates that the solutions obtained by the minimally extended system are an order of magnitude more precise. Also, it shows that the computations are actually much more accurate than the modest bounds for F_t, V_t suggest.

To obtain more detailed information we used the MATLAB Profiler. The lines where the most time was spent are given in Tables 10.2 and 10.3, respectively.

The most obvious conclusion is that in both cases the `newtcorr` procedure (the process of Newton iterates from a predicted to a declared continuation point) consumes nearly all the time spent in the continuation process; therefore a separate compilation of this algorithm seems highly desirable.

The second observation is that in `newtcorr` most of the time is spent in `contjac`, i.e., in the evaluation of the Jacobian matrix of the system, rather than in the solvers. In Tables 10.4 and 10.5 we provide more detailed information. An application of the sparse solver in the first system takes only 0.0487 seconds; in the second system it takes 0.1381 seconds, a clear advantage for the minimally extended system. The total time spent during solves is 5.9790 s versus 10.3550 s; we note that the 5.9790 s include not only the times in the 4th and 5th rows of Table 10.4 but also a part of the 3rd row since the evaluation of the object function of the minimally extended system involves

solving the linear system (2.4). These more detailed data were also provided by the MATLAB Profiler.

For the evaluation of the Jacobians the times are 1.6824 and 1.8014 seconds, respectively, a small advantage for the minimally extended system.

The superior performance of the minimally extended system is even more apparent if a higher precision is required. In another experiment we put $F_t = V_t = 10^{-6}$ for the minimally extended system and correspondingly $F_t = 10^{-6}\sqrt{\frac{1508}{755}} = 1.4133e-6$, $V_t = 10^{-6}\sqrt{\frac{1509}{756}} = 1.4128e-6$ for the fully extended system. We computed 25 points with $N_a = 1$; the minimally extended system needed 117.57 seconds, and the fully extended system needed 176.21 seconds.

Our conclusion is that the minimally extended system outperforms the fully extended system. However, the gain is modest because most of the computing time is not spent in the solves (these are performed by the compiled built-in solvers of MATLAB) but in constructing the Jacobian matrices. We can therefore expect that future developments (compiling parts of the code or better handling of for-loops in MATLAB) will make the advantages of the minimally extended system even greater.

MULTIPLE EXPLICITLY RESTARTED ARNOLDI METHOD FOR SOLVING LARGE EIGENPROBLEMS*

NAHID EMAD†, SERGE PETITON‡, AND GUY EDJLALI§

Abstract. In this paper we propose a new approach for calculating some eigenpairs of large sparse non-Hermitian matrices. This method, called Multiple Explicitly Restarted Arnoldi (MERAM), is particularly well suited for environments that combine different parallel programming paradigms. This technique is based on a multiple use of the Explicitly Restarted Arnoldi method (ERAM) and improves its convergence.

This technique is implemented and tested on a distributed environment consisting of two interconnected parallel machines. The MERAM technique is compared with ERAM, and one can notice that the convergence is improved. In some cases, more than a twofold improvement can be seen in MERAM results.

We also implemented MERAM on a cluster of workstations. According to our experiments, MERAM converges better than the Explicitly Restarted Block Arnoldi method and, for some matrices, more quickly than the PARPACK package, which implements the Implicitly Restarted Arnoldi method.

Key words. large eigenproblem, Arnoldi method, explicit restarting, parallel programming, asynchronous communication, heterogeneous environment

DOI. 10.1137/S1064827500366082

1. Introduction.

Hybrid methods were proposed during the last decade to accelerate the convergence and/or improve the accuracy of the solution of some linear algebra problems. These methods combine several different numerical methods to solve these problems efficiently. For example, both convergence acceleration techniques and preconditioning methods could be used to develop a hybrid method. Hybrid methods were used successfully to solve linear systems, such as the method introduced by Brézinski and Redivo-Zagila [4], some eigenproblems with the Arnoldi–Chebyshev method proposed by Saad [20, 19, 3], and Jacobi–Davidson algorithms from Sleijpen and Van der Vorst [30, 29].

In this paper, we propose a new approach for calculating some of the eigenpairs in the context of large sparse non-Hermitian matrices. This new technique, called the Multiple Explicitly Restarted Arnoldi method (MERAM), is a hybrid method and is based on the Explicitly Restarted Arnoldi method (ERAM). It involves multiple invocations of ERAM and is closely linked to the Explicitly Restarted Block Arnoldi method (ERBAM). Each ERAM invocation is done with a different set of parameter values. This approach also may be applied to some other restarted projection methods.

We propose an asynchronous parallel algorithm for MERAM and show that some of its properties such as asynchronous communications between its coarse grain subtasks, fault tolerance, and dynamic load balancing make this method well adapted

to the GRID computational environments. Our experiments ran on two different platforms—a network of parallel machines and a cluster of workstations—and showed that MERAM converges quicker than ERAM and ERBAM. Moreover, according to our experiments, for some matrices, one has a slow convergence with the Implicitly Restarted Arnoldi method (IRAM) and a faster convergence with MERAM.

Our asynchronous MERAM algorithm can be easily implemented on a cluster of heterogeneous machines as it exhibits a coarse grain parallelism. These machines can be sequential, vector, or parallel. The number of iterations to convergence of the main process is reduced by combining results from other processes at run time. For example, a dedicated parallel machine can take advantage of the availability of a cluster of nondedicated processors to speed up its convergence. We implemented our approach on a Connection Machine 5 (CM5) and a small cluster of workstations [7] and were able to show improvement on the number of iterations before convergence by just combining two Sun Sparc machines with our 32-node CM5 parallel machine. In this paper, we present results when multiple parallel machines are available for computation. In particular, we show that in some cases we can achieve more than twofold improvement in the number of iterations before convergence by combining the results from a faster and a slower parallel machine. We also will present certain results of comparison of MERAM with the Explicitly Restarted Block Arnoldi and Implicitly Restarted Arnoldi methods on a cluster of workstations.

Before defining MERAM in the context of the projection methods, a brief presentation of these methods is given in the next section. An overview of the Arnoldi method and some of its variants is provided in section 3. MERAM and an asynchronous algorithm of this method are presented in section 4. It also includes the restarting strategy selected in MERAM, the stopping criterion of the restarts in ERAM/MERAM, and the relationship between MERAM and ERBAM. Parallel versions of these methods are discussed in section 5. Section 6 is devoted to numerical experiments. Finally, possible applications of the concept are discussed along with the conclusion in section 7.

2. Notation. Let A be a complex non-Hermitian matrix of dimension $n \times n$ and let $\mathbb{K}$ be a subspace of $\mathbb{C}^n$. A Krylov subspace method allows an approximation of an eigenpair (λ, u) of A by a Ritz pair ($\lambda^{(m)} \in \mathbb{C}$, $u^{(m)} \in \mathbb{K}$), where the subspace $\mathbb{K}$ is defined by

$$\mathbb{K}_{m,X} = \mathrm{Span}(X, AX, \ldots, A^{m-1}X) \tag{2.1}$$

and X is spanned by a set of μ vectors. The point (resp., block) Krylov subspace methods are characterized by choosing $\mu = 1$ (resp., $\mu > 1$).

A Krylov subspace method approximates s eigenpairs of A by those of a matrix of order m, where $s \leq m \ll n$. This matrix is obtained by orthogonal projection of A onto an m-dimensional subspace $\mathbb{K}_{m,v}$ with $X = \mathrm{Span}(v)$. Let W_m be the matrix whose columns $w_1, \ldots, w_m$ constitute an orthogonal basis of $\mathbb{K}_{m,v}$. The problem is to find $\lambda^{(m)} \in \mathbb{C}$ and $y^{(m)} \in \mathbb{C}^m$ such that

$$(H_m - \lambda^{(m)} I) y^{(m)} = 0, \tag{2.2}$$

where the matrix H_m of dimension $m \times m$ is defined by $H_m = W_m^H A W_m$. Note that W_m^H is the transpose conjugate of W_m and $u^{(m)} = W_m y^{(m)}$. Therefore, some eigenvalues of A can be approximated by the eigenvalues of the matrix H_m. These eigenvalues can be found by building an orthogonal basis of $\mathbb{K}_{m,v}$ and by solving the

problem (2.2). There are different ways of building such a basis, and the most used process is the Arnoldi orthogonalization.

3. Arnoldi method and some of its variants.

3.1. Arnoldi method. Let the initial guess w_1 be equal to $v/\|v\|_2$. The well-known Arnoldi process generates an orthogonal basis $w_1, \ldots, w_m$ of Krylov subspace $\mathbb{K}_{m,v}$ by using the Gram–Schmidt orthogonalization process:

`Arnoldi Reduction :` $\texttt{AR}(input : A, m, v; output : H_m, W_m)$.

For $j = 1, 2, \ldots, m$ do:

- $h_{i,j} = (Aw_j, w_i)$, for $i = 1, 2, \ldots, j$
- $\bar{w}_j = Aw_j - \sum_{i=1}^{j} h_{i,j} w_i$
- $h_{j+1,j} = \|\bar{w}_j\|_2$
- $w_{j+1} = \bar{w}_j / h_{j+1,j}$

The above algorithm may break down if $w_j = 0$ for some j. This may happen if the minimal polynomial of v is of degree j. In this case, the subspace $\mathbb{K}_{m,v}$ is invariant and the Ritz elements are exact [19].

This method was introduced by Arnoldi [1] in 1951 to reduce a matrix to a Hessenberg form. The reduced matrix $H_m = (h_{i,j})$ is a Hessenberg representation of A in the orthonormal basis W_m of $\mathbb{K}_{m,v}$ when $m = n$. Arnoldi hinted that the process could give good approximations to some eigenvalues if stopped before completion [1], i.e., when $m < n$.

The matrices H_m and W_m issued from the `AR` algorithm and the matrix A satisfy the equation

$$AW_m = W_m H_m + f_m e_m^H, \tag{3.1}$$

where $f_m = h_{m+1,m} w_{m+1}$ and e_m is the mth vector of the canonical basis of $\mathbb{C}^m$. Note that the `AR` algorithm is the standard Gram–Schmidt orthogonalization process and assumes exact arithmetics. Therefore, the modified Gram–Schmidt or the Householder variants of `AR` are more interesting as they both deal with inaccuracies introduced by the hardware. The cost analysis and comparison of each version are given by Saad in [19].

Once the choice of the orthogonalization process is fixed, the s desired Ritz values (with largest/smallest real part or largest/smallest magnitude) $\Lambda_m = (\lambda_1^{(m)}, \ldots, \lambda_s^{(m)})$ and the corresponding Ritz vectors $U_m = (u_1^{(m)}, \ldots, u_s^{(m)})$ can be calculated as follows:[1]

`Basic Arnoldi Algorithm :` $\texttt{BAA}(input : A, s, m, v; output : r_s, \Lambda_m, U_m)$.

---

1. Compute an $\texttt{AR}(input : A, m, v; output : H_m, W_m)$ step.
2. Compute the eigenpairs of H_m and select the s desired ones.
3. Compute the s associate Ritz vectors $u_i^{(m)} = W_m y_i^{(m)}$.
4. Compute $r_s = (\rho_1, \ldots, \rho_s)$ with $\rho_i = \|(A - \lambda_i^{(m)} I) u_i^{(m)}\|_2$.

---

[1] We suppose that the eigenvalues and corresponding eigenvectors of H_m are reindexed so that the first s Ritz pairs are the desired ones.

If the accuracy of the computed Ritz elements is not good enough, the projection can be restarted to generate a new $\mathbb{K}_{m,v}$.

The new $\mathbb{K}_{m,v}$ can be defined with [illegible] initial vector v and [illegible] m value. It is clear that, according to the hypothesis that v does not belong to any desired invariant subspace, m has to be as large as possible. An important, well-known shortcoming of this version of the Arnoldi method is its large storage space requirement and computational cost for large values of m.

3.2. Explicitly Restarted Arnoldi method. In this version the projection subspace size is [illegible]. Starting with an initial vector v, it computes a BAA (Basic Arnoldi Algorithm). The starting vector is updated, and a BAA process is restarted again until the accuracy of the approximated solution is satisfactory (using appropriate methods on the computed Ritz vectors). This update is designed to force the vector to be in the desired invariant subspace. This goal can be reached by some polynomial restarting strategies proposed in [19] and discussed in section 4.2. This method is called the Explicitly Restarted Arnoldi method (ERAM) and its algorithm is given below:

ERAM$(input : A, s, m, v, tol; output : r_s, \Lambda_m, U_m)$.

---

1. `Start.` Choose a parameter m and an initial vector v.
2. `Iterate.` Compute a BAA$(input : A, s, m, v; output : r_s, \Lambda_m, U_m)$ step.
3. `Restart.` If $g(r_s) > tol$, then use Λ_m and U_m to update the starting vector v and go to 2.

In the previous algorithm, *tol* is a threshold value and the function g defines the stopping criterion of iterations. We will see some possible definition of this function in the next section.

3.3. Implicitly Restarted Arnoldi method. Another variant of the Arnoldi method based on a restarting technique is proposed by Sorensen [23]. This refined version, called the Implicitly Restarted Arnoldi method (IRAM), is a technique that combines the implicitly shifted QR with an Arnoldi factorization and can be viewed as a truncated form of the implicitly shifted QR technique. This technique involves an [illegible] application of a polynomial in A to the starting vector. It has been shown that IRAM leads to good approximations of Ritz elements of large sparse matrices [23, 11].

Several other versions of the Arnoldi method based on the augmented Krylov methods exist, including variants proposed by Wu and Simon [31], Stewart [25], Morgan [12], and Morgan and Zeng [13].

4. Multiple Explicitly Restarted Arnoldi method. The method we propose is characterized by a new restarting technique for the Arnoldi method. Our restarting technique combines the two explicit algorithms described above. In this version, we neither fix the parameter m nor the initial vector v. To overcome the storage-dependent shortcoming of the first variant of the Arnoldi method, we introduce a constraint on the subspace size m. More precisely, we suppose that m belongs to a discrete interval $I_m = [m_{min}, m_{max}]$. The lower bound m_{min} and upper bound m_{max} may be chosen as a function of the computation and storage resources. In addition, the constraint $m_{min} \leq m_{max} \ll n$ has to be fulfilled. Let $M = (m_1, \ldots, m_\ell)$ be a set of subspace sizes with $m_i \leq \cdots \leq m_\ell$ and $m_i \in I_m$ $(1 \leq i \leq \ell)$, and let $V^\ell = [v^1, \ldots, v^\ell]$ be the matrix of ℓ starting vectors. An algorithm of this method for

calculating s ($s \leq m_1$) desired Ritz elements of A is as follows:

MERAM($input : A, s, M, V^\ell, tol; output : r_s^m, \Lambda_m, U_m$).

---

1. `Start.` Choose a starting matrix V^ℓ and a set of subspace sizes $M = (m_1, \ldots, m_\ell)$.
2. `Iterate.` For $i = 1, \ldots, \ell$ do:
   (a) Compute a BAA($input : A, s, m_i, v^i; output : r_s^i, \Lambda_{m_i}, U_{m_i}$) step.
   (b) If $g(r_s^i) \leq tol$, then stop all processes.
3. `Restart.` Update the vectors $v^1, \ldots, v^\ell$ and go to 2.

Note that r_s^i is the vector of the residual norms at the ith iteration.
We suppose that

$$(\lambda_j^{(m_p)}, u_j^{(m_p)}) \text{ is better than } (\lambda_j^{(m_q)}, u_j^{(m_q)}) \text{ if } \rho_j^p \leq \rho_j^q. \tag{4.1}$$

Then an interesting updating strategy would be the choice of v^i as a function f^i of "the best" Ritz vectors:

$$v^i = f^i(U^{best}), \tag{4.2}$$

where $U^{best} = (u_1^{best}, \ldots, u_s^{best})$ and u_j^{best} is "the best" jth Ritz vector. The function f^i has to be chosen in order to force the vector v^i to be in the desired invariant subspace. A simple choice of f^i would be a linear combination of $u_1^{best}, \ldots, u_s^{best}$ vectors. In order to ensure that the BAA processes used in the MERAM algorithm produce ℓ different Krylov subspaces, $(f^i)_{i=1,\ldots,\ell}$ have to be chosen such that $f^i \neq f^j$ for $i \neq j$. Nevertheless, the vectors v^i and v^j (for $i \neq j$) of step 3 can be defined using the same restarting strategy. In other words, (4.2) may become

$$v^i = f(U^{best}), \tag{4.3}$$

where $f = f^i$ (for $i = 1, \ldots, \ell$). The vectors $v^1, \ldots, v^\ell$ would become identical and the Krylov subspaces of different processes would look extremely close to one another after a few iterations. Meanwhile, we will see in the next section that this restarting strategy can be useful for the asynchronous version of MERAM.

Clearly, the MERAM algorithm is equivalent to a particular use of several ERAMs. It allows the restarting vector v^i of an ERAM to be updated by taking into account interesting eigeninformation obtained by the other ERAMs. Another advantage of this algorithm is that it can be parallelized easily, as it contains coarse grain parallelism. In fact, each iteration of step 2 can be executed as an independent process. Suppose that we have ℓ processes and a process (i) is assigned to the iteration (i) of the inner loop of the algorithm. Thereafter, the processes have to synchronize at step 3. The only drawback of this parallelization is that the execution time of the algorithm is dominated by the execution time of the slowest process. The algorithm defined in the following section is a remedy for this problem.

4.1. Asynchronous MERAM. We suppose that after each BAA step, the process sends its output of interest to all other processes. The computation of a restarting vector v^i on process (i) can then be done by combining "the best" computed Ritz elements within that process. As a consequence, this parallel algorithm precisely a parallel version of the above MERAM algorithm where BAA processes are synchronized in step 3.

We refer to a dynamic algorithm as an algorithm whose one or more components are dynamic and to a dynamic component as a component whose run time behavior can depend on outside events. The parallel asynchronous MERAM can be considered a dynamic algorithm. To each run of this version corresponds one parallel static MERAM version in which the matrices U^{best} in the updating strategy (4.2) are different for every ERAM process. That means that the initial vector v^i can be thus defined by $v^i = f^i(U^{best(i)})$, where $U^{best(i)}$ denotes the matrix U^{best} of the ERAM process (i). Consequently, to ensure that MERAM does not produce the same Krylov subspaces, one must have $f^i \neq f^j$ and/or $U^{best(i)} \neq U^{best(j)}$ (for $i \neq j$). In other words, this way of asynchronizing communications between the BAA processes allows MERAM to produce ℓ [illegible] Krylov subspaces even with the restarting strategy (4.3).[2]

The asynchronous MERAM consists of ℓ "independent" ERAM processes which cooperate to update their restarting vectors. Let `Send_Eigen_Info` represents the task of sending eigeninformation of interest from an ERAM process to all other ERAM processes. Let `Receiv_Eigen_Info` be the task of receiving eigeninformation of interest from one or more ERAM processes by the current ERAM process. Finally, let `Rcv_Eigen_Info` be a boolean variable that is true if the current ERAM process has received eigeninformation from the other ERAM processes. An asynchronous parallel version of MERAM is explained in the following:

`Asynchronous MERAM Algorithm.`

---

1. `Start.` Choose a starting matrix V^ℓ and a set of subspace sizes $M = (m_1, \ldots, m_\ell)$.
2. `Iterate.` For $i = 1, \ldots, \ell$ do in parallel (`ERAM` process):
   - Computation process
     - `(a)` Compute a `BAA`$(input : A, s, m_i, v^i; output : r_s, \Lambda_{m_i}, U_{m_i})$ step.
     - `(b)` If $g(r_s^i) \leq tol$, stop all processes.
     - `(c)` If (`Rcv_Eigen_Info`), then `hybrid restart` else `simple restart`
   - Communication process
     - `(d)` `Send_Eigen_Info`
     - `(e)` `Receiv_Eigen_Info`

In this algorithm, each ERAM process has either a simple or a hybrid restarting strategy. A `simple restart` is a classical restarting strategy taking into account the eigeninformation computed by the current ERAM process. A `hybrid restart` is a restarting strategy taking into account the eigeninformation received by the other ERAM processes also. A hybrid restart includes data from other processes when eigeninformation has been received, while the simple restart uses just the eigeninformation computed by the current process. Let $u_j^{(m_k)}$ be the jth Ritz vector computed by the kth process (corresponding to the one with the subspace size m_k) and received by the current process. The matrix U^{best} of (4.2) is then defined by $(u_1^{best}, \ldots, u_s^{best})$, where u_j^{best} is "the best" of $u_j^{(m_k)}$ and the jth Ritz vector computed by the current process, where $k \in F \subset [1, \ell]$, cardinal $(F) = np$, and np is the number of processes that sent their eigeninformation to the current process. When a new and "better" Ritz pair is received from a process, its older value is overwritten by the new value. Moreover,

[2]With $m_i \neq m_j$ (for $i \neq j$) on homogeneous resources.

when the initial vector is updated by the hybrid restart strategy (i.e., step 2(c)) the current ERAM process changes the flag `Rcv_Eigen_Info` to false. Once a new Ritz pair is received from a process, this flag changes to true by the current ERAM process. We notice that in addition to the coarse grain parallelism between ℓ ERAM processes, one can also overlap communication steps with computations. More details about the parallelization of this algorithm are given in section 5.

A consequence of the dynamicity of this algorithm is its large sensitivity to the variations of the system on which it runs. Indeed, the results of this algorithm are a function of architectural parameters such as the load of the interconnection network or that of the processors which constitute the system. One important property of the asynchronous MERAM algorithm is its fault tolerance. That means that the loss of an ERAM process at run time doesn't impede the other ERAM processes from continuing to run and finish the algorithm. Another important property of this algorithm is its capacity of dynamic load balancing. Indeed, the time and space complexities of an iteration of an ERAM process of MERAM is a function of its subspace size. Because these complexities are known, we can dynamically allocate ERAM processes according to the system work load. All of these properties make the asynchronous MERAM a well-suited algorithm to the GRID computational environments.

4.2. Restarting strategies—convergence. The restarting strategy is a critical part of both ERAM and MERAM. Saad [20] proposed to restart the iteration of ERAM with a preconditioning vector to force it to be in the desired invariant subspace. It concerns a polynomial preconditioning applied to the starting vector of ERAM. The aim of the preconditioning is to make sure that the components of the restarting vector are nonzero in the desired invariant subspace and zero in the unwanted invariant subspace:

$$v(k) = p(A)v, \tag{4.4}$$

where $v(k)$ is the kth update of the starting vector v of ERAM, $v = v(0)$ is the starting vector, and p is a member of the space of polynomials of degree $< m$. One can define p as a Chebyshev polynomial determined from some knowledge about the distribution of A eigenvalues. This restarting strategy is very efficient in speeding the ERAM convergence (for more details, see [20, 19]). Another way of defining the polynomial p is to compute the restarting vector with a linear combination of s desired Ritz vectors:

$$v(k) = \sum_{i=1}^{s} \alpha_i u_i^{(m)}(k), \tag{4.5}$$

where $u_i^{(m)}(k)$ denotes the ith Ritz vector computed at the iteration k. This restarting strategy is polynomial because $u_i^{(m)}(k) \in \mathbb{K}_{m,v(k-1)}$ implies $u_i^{(m)}(k) = \phi_i(A)v$ for some polynomial ϕ_i and thus $v(k) = \sum_{i=1}^{s} \alpha_i \phi_i(A)v$. There are several ways to choose the scalar values α_i in (4.5). One choice can be α_i equal to the ith residual norm. Other choices can be $\alpha_i = 1$, $\alpha_i = i$, or $\alpha_i = s - i + 1$ for $1 \le i \le s$ (see [21] for more details).

Note that if $v = \sum_{j=1}^{n} \gamma_j u_j$, IRAM with exact shifts [23, 11] provides a specific selection of expansion coefficients γ_j for a new starting vector as a linear combination of the current Ritz vectors for desired eigenvectors. Implicit restarting provides a means to extract eigeninformation of interest from large Krylov subspaces while avoiding the storage and numerical difficulties. This is done by continually compressing eigeninformation of interest into an s-dimensional subspace of fixed size. This means that IRAM continues a BAA step, having kept all Ritz vectors of interest.

To define a restarting strategy for MERAM we have to define the functions f^i introduced in (4.2). These functions with several variables have to be used as input for MERAM. Their variables are calculated dynamically in the case of the asynchronous MERAM. These functions constitute a very important part of this algorithm. Here again we have several possibilities of choosing f^i. The first possibility is to choose them as simple as possible by using the same restarting techniques proposed for ERAM. The second possibility can be defined by using sophisticated restarting techniques such as augmented Krylov or implicit restarting. In the rest of this paper, we use a simple restarting technique based on the one defined in (4.5) and we call it the [illegible]. According to hypothesis (4.1) this hybrid restarting strategy is defined by

$$v^i = f^i(U^{best}) = \sum_{j=1}^{s} \alpha_j^i u_j^{best}, \tag{4.6}$$

where α_j^i (for $j = 1, s$ and $i = 1, \ell$) are some scalar values. The hybrid restarting strategy corresponding to (4.3) is then

$$v^i = f(U^{best}) = \sum_{j=1}^{s} \alpha_j u_j^{best}, \tag{4.7}$$

where $\alpha_j = \alpha_j^1 = \cdots = \alpha_j^\ell$.

We can view $(\ell - 1)$ ERAM processes of MERAM as the convergence accelerators of the last process. We implemented the parallel MERAM with the restarting strategy (4.7). Our experiments in section 6 illustrate that this ERAM process converges quicker than an ERAM with the same subspace size and starting vector. In other words, our experiments show that the restarting vector computed with the hybrid restarting technique is more in the desired invariant subspace than the one computed with (4.5).

4.3. Stopping criterion. The residual norms ρ_i defined in the previous section verify the well-known equation [19]

$$\rho_i = \|(A - \lambda_i^{(m)} I) u_i^{(m)}\|_2 = h_{m+1,m} |e_m^H y_i^{(m)}|, \tag{4.8}$$

where e_m is the mth vector of the canonical basis of $\mathbb{C}^m$. This enables the computation of the residual norms at low cost because the ith residual norm is equal to the product of the last component of the eigenvector $y_i^{(m)}$ by $h_{m+1,m}$. However, in practice the residual norms ρ_i can be more indicative of current errors.

To stop the restarts in ERAM algorithm one has to define the function g given in step 3. Some typical examples are

$$g(r_s) = \|r_s\|_\infty \tag{4.9}$$

or a linear combination of the residual norms

$$g(r_s) = \sum_{j=1}^{s} \alpha_j \rho_j, \tag{4.10}$$

where α_j are scalar values.[3] The same technique applied to $r_s^i = (\rho_1^i, \ldots, \rho_s^i)$ can be used to define the stopping criterion of restarts—the function g in step 2(b)—of MERAM.

4.4. Relationship with Explicitly Restarted Block Arnoldi method. As shown in section 2, the [illegible] allow the approximation of an eigenpair (λ, u) of A by a $(\lambda^{(m)}, u^{(m)})$ solution of (2.2) with $\mathbb{K}_{m,X}$ an $m \times \mu$-dimensional subspace defined by (2.1), where $X = \mathrm{Span}(x_1, \ldots, x_\mu)$ and $\mu > 1$. We assume that the vectors $x_1, \ldots, x_\mu$ are linearly independent.

The Explicitly Restarted Block Arnoldi Method (ERBAM) is used to extract the eigenvalues whose algebraic multiplicity is less than or equal to the block size [9]. Let X_1 be the orthonormal matrix represented by the columns $x_1, \ldots, x_\mu$. The block Arnoldi process generates a set of $X_1, \ldots, X_m$ matrices. Let $\boldsymbol{W}_m$ be the $(n, m \times \mu)$-sized matrix $[X_1, \ldots, X_m]$. The $m \times \mu$ columns of this matrix constitute an orthogonal basis of Krylov subspace $\mathbb{K}_{m,X_1}$:

`Block Arnoldi Reduction :` $\mathtt{BAR}(input : A, m, X_1; output : \boldsymbol{H}_m, \boldsymbol{W}_m)$.

For $j = 1, 2, \ldots, m$ do:

- $H_{i,j} = X_i^H A X_j$, for $i = 1, 2, \ldots, j$.
- $\bar{X}_j = AX_j - \sum_{i=1}^{j} X_i H_{i,j}$.
- Compute QR decomposition of $\bar{X}_j$:
  $\bar{X}_j = Q_j R_j = X_{j+1} H_{j+1,j}$.

The $H_{i,j}$ matrices generated by the BAR process constitute the blocks of an upper block Hessenberg matrix $\boldsymbol{H}_m$. The eigenvalues of this matrix approach the corresponding eigenvalues of A. Then, an equation equivalent to (3.1) will be

$$A\boldsymbol{W}_m = \boldsymbol{W}_m \boldsymbol{H}_m + F_m \boldsymbol{E}_m^H, \tag{4.11}$$

where $F_m = X_{m+1} H_{m+1,m}$ and $\boldsymbol{E}_m$ is the matrix of the last μ columns of $I_{n\mu}$. The block version of BAA is unchanged, except for the first step where we calculate $\mathrm{BAR}(input : A, m, X_1; output : \boldsymbol{H}_m, \boldsymbol{W}_m)$ instead of $\mathrm{AR}(input : A, m, v; output : H_m, W_m)$. We call this algorithm $\mathrm{BBAA}(input : A, s, m, X_1; output : r_s, \Lambda_{m\times\mu}, U_{m\times\mu})$.

Even though both ERBAM and MERAM begin with a set of starting vectors, they are not equivalent. Suppose that $\ell = \mu$ is the number of starting vectors for both methods. $m \times \ell$ is the projection subspace size in ERBAM, and m is the size of each projection subspace in MERAM, which means $m_1 = \cdots = m_\ell = m$. The difference between these two methods is that the projection subspace in ERBAM is $\mathbb{K}_{m,X}$ with $X = \mathrm{Span}(x_1, \ldots, x_\ell)$, while in MERAM the problem is projected onto ℓ subspaces $\mathbb{K}_{m,x_1}, \ldots, \mathbb{K}_{m,x_\ell}$. Now, assuming that the degree of the minimal polynomial of X_1 is greater than m, these Krylov subspaces satisfy the following relation:

$$\mathbb{K}_{m,X} = \mathbb{K}_{m,x_1} \oplus \cdots \oplus \mathbb{K}_{m,x_\ell}. \tag{4.12}$$

Therefore, if $\dim(\mathbb{K}_{m,X}) = m \times \ell$ we have $\dim(\mathbb{K}_{m,x_i}) = m$ for all $i \in [1, \ell]$ and $\dim(X) = \ell$.

Suppose that $\dim(\mathbb{K}_{m,X}) = m \times \ell$. The construction of an orthogonal basis $((x_1^1, \ldots, x_\ell^1), \ldots, (x_1^m, \ldots, x_\ell^m))$ of $\mathbb{K}_{m,X_1}$ allows the construction of an orthogonal

[3] If $\alpha_j = 1$ (for $j = 1, \ldots, s$), then (4.10) defines the sum of the residual norms associated with s desired eigenelements.

basis $\tilde{X}_i = (x_i^1, \ldots, x_i^m)$ for each subspace $\mathbb{K}_{m,x_i}$, $1 \leq i \leq \ell$. The inverse is true only if $\tilde{X}_i$ is orthogonal to $\tilde{X}_j$ for all $i, j \in [1, \ell]$ and $i \neq j$. This means that the block Arnoldi reduction, which is also a Gram–Schmidt orthogonalization of Krylov vectors of $\mathbb{K}_{m,X_1}$, defines ℓ Arnoldi reductions, which again are ℓ Gram–Schmidt orthogonalizations of Krylov vectors of subspaces $\mathbb{K}_{m,x_i}$ $(1 \leq i \leq \ell)$, but the inverse is not always true.

In the first method, s desired eigenvalues are approximated by the eigenvalues of an $(\ell \times m)$-sized block Hessenberg matrix, while in the second, they are approximated by s "best" eigenvalues of ℓ Hessenberg matrices of order m. We also notice that in ERBAM the relation $m \geq s/\ell$ has to be true, while in MERAM the relation $m \geq s$ must be true.

Some parallel and numerical properties of MERAM and ERBAM are discussed in the next two sections.

5. Parallelism analysis.

5.1. Parallel ERAM. Let us consider the Basic Arnoldi algorithm—BAA($input$: $A, s, m, v; output : r_s, \Lambda_m, U_m$)—which is the core of ERAM. This algorithm can be considered as four main tasks corresponding to its four steps. The projection phase of the algorithm manipulates the n-sized data sets. The second phase acts on m-sized data sets, and the third and fourth phases deal with the n- and m-sized data sets.[4] Steps 1, 3, and 4 constitute the expensive parts of this algorithm. They are composed mainly of sparse matrix-vector multiplications and triadic and reduction operations.

The global programming model used is message passing, which is crucial for distributed architectures. This model assumes that the system has a number of processors that have local memories and communicate with each other by means of memory transfer from one processor to another [5]. A classical way to parallelize BAA using the message passing model is to distribute the large arrays (vectors and/or matrices) among the processors while the small arrays are kept on just one processor or redundantly on all processors. This is equivalent to distributing each of the tasks 1, 3, and 4 among the processors and to run step 2 on just one processor or simultaneously on all processors.

In the context of the message passing programming model, the projection phase of BAA is highly parallel. The second task can represent a good vector structure[5], and the last two tasks are also parallel. These different types of parallelism can be exploited efficiently by a distributed memory platform formed, for example, by a distributed memory parallel machine and a vector computer or by a distributed memory parallel machine and a sequential machine. We must mention that we do not have to use the message passing model for step 2, as this task would become a bottleneck in the algorithm [17]. This means, in terms of implementation, that the architecture used for step 2 ought to be different from the one used for steps 1, 3, and 4 (see Figure 1).

In the ERAM algorithm the size of the subspace determines the amount of time necessary to execute each restart (mainly a BAA step). The cost of each restart increases with the subspace size, while in general the number of restarts decreases according to the subspace size. We need to find a balance between the execution time of each restart and the number of restarts to minimize the total execution time [17, 6].

[4] This is not true for the fourth step if the right-hand side of (4.8) is used to compute the vector r_s.

[5] If we use a classical method like QR and/or inverse iteration to solve this step.

Generally, the larger the subspace size, the better the convergence properties, so the subspace size m ought to be chosen as large as possible given the limitations of the target system resources.

5.2. Parallel MERAM. MERAM consists of several ERAMs interacting with some protocol. As we mentioned in section 4, a great advantage of MERAM is its coarse grain parallelism. We consider here the asynchronous parallel MERAM algorithm described in section 4.1. In this algorithm, each ERAM core—BAA($input$: $A, s, m, v; output$: r_s, Λ_m, U_m)—can be executed [illegible] from the others. Consequently, we have ℓ independent coarse grain tasks (ERAM processes). For each of them, one can make use of the above described parallelism.

In addition to the coarse grain parallelism between ℓ ERAM processes, one can also overlap communication steps with computations. The processors would always be active and execute a nonredundant task. Therefore, a significant reduction of the response time of this algorithm is expected. In the next section, we will confirm this with our experiments.

5.3. Parallel ERBAM. Clearly, the parallelization method described in section 5.1 is also valid for ERBAM (i.e., BBAA in section 4.4). However, if the subspace sizes of ERAM and ERBAM are equal to $\mathcal{M} = m \times \mu$ with $\mu > 1$, the coarse grain parallelism in each BBAA step is larger than in the corresponding BAA step. This is due to the BAA core (i.e., AR) computing $\mathcal{M} = m \times \mu$ matrix-vector products with A, while in the BBAA core (i.e., BAR) the computations of A on μ vectors can be done at once, in roughly the same cost as computing a single matrix-vector product. The AR has to compute $\mathcal{M}$ second-level BLAS operations, while BAR has to compute m third-level BLAS operations. Consequently, the computational cost of ERBAM should be less than that of ERAM.

The global programming model used to implement ERBAM and MERAM is message passing. Bearing in mind that large arrays are distributed among the processors and small arrays are kept on one processor or replicated on all processors, this is equivalent to distributing each of the tasks 1, 3, and 4 of BBAA among the processors and running step 2 on just one processor or redundantly on all processors.

Consider a MERAM with (μ) ERAM processes having the subspace sizes m_i with $\sum_{i=1}^{\mu} m_i = \mathcal{M}$ and $m_1 \leq \cdots \leq m_\mu$. The goal is to determine if this MERAM can be competitive with ERBAM with subspace size $\mathcal{M} = m \times \mu$. In other words, we would like to know if ERAM(m_μ) helped by the other ERAM processes of MERAM (i.e., ERAM(m_i) for $i = 1, \ldots, \mu - 1$) can be competitive with ERBAM.

6. Numerical experiments. Data-parallel and vector programming models are very well suited for ERAM [17]. To efficiently exploit the natural parallelism of MERAM, one has to use the coarse grain parallel model, where a number of ERAM processes are running concurrently. In addition, one can exploit the fine grain parallelism within each task (ERAM process) in order to maximize the resource usage of a metacomputing platform. A metacomputer consists of heterogeneous and autonomous computers linked by an interconnection network. This architecture has a tremendous amount of memory and computational power [10] to cope with large industrial applications. However, in practice, the number of parallel machines involved in a metacomputer is limited. We present, in this section, some results of our experiments on homogenous and heterogeneous programming environments.

We denote by ERAM(m, v) (resp., IRAM(m, v)) an ERAM (resp., IRAM) process with the subspace size m and the initial vector v, by ERBAM(m, V^ℓ) an ERBAM

process with the subspace size m and the initial matrix V^ℓ, and by MERAM(M, V^ℓ) a MERAM with ℓ ERAM$(m_i, v^i)_{i=1,\ell}$ processes, where $M = (m_1, \ldots, m_\ell)$ and $V^\ell = [v^1, \ldots, v^\ell]$. The matrix I_k denotes the one whose columns are $e_1, \ldots, e_k$.

6.1. MERAM and ERAM.

We implemented ERAM and MERAM according to the above programming models on different heterogeneous environments [8]. These environments were a 32-node Connection Machine (CM5), a CM5 and a Sparc 20, a CM5 and two Sparc 20's, and a CM5 and a 4K Connection Machine 200 (CM200). The CM5 is a distributed memory MIMD[6] architecture [27]. Each node of CM5 consists of a Sparc processor, a 32 megabyte memory, and four floating point computation units operating at 32 megaflops each. The CM5 supports the message passing model, the data-parallel model, or a combination of the two. The CM5 nodes are connected by three networks. is a point-to-point communication and has 0.5 gigabyte per second global bandwidth. is a binary tree for global operations (as diffusion, reduction, etc.) by pipelining the messages, and is dedicated to error messages. The CM200 is a massively parallel SIMD[7] machine consisting of thousands of bit serial data processors and a front-end for management and control [26]. The processors and memory are packaged as 16 in a chip. Each chip also contains the routing circuitry which allows any processor to send and receive messages from any other processor in the system. The system version used has 0.5 gigabyte memory and operates at 10 megahertz. The CM200 supports the data-parallel programming model. Both CM5 and CM200 have a workstation as front-end. The programming language used on CM5 and CM200 is CM Fortran [28]. This is an extension of Fortran 77 allowing us to handle parallel variables distributed on the processors.

In [7], we showed that a significant acceleration can be achieved when the heterogeneous architecture consists of a CM5 and two Sparc workstations. In this paper, we present the results of our experiments on a CM5 for ERAM and on a heterogeneous environment consisting of a CM5 and a CM200 interconnected by a 10 Mbit/s Ethernet link for MERAM.

As we have seen in the previous section, the BA algorithm can be divided into four main tasks: the projection, the computation in the subspace, the Ritz vectors computation, and the computation of the vector of the residual norms. These tasks can run on different machines. The projection task, the Ritz vectors computation and the computation of the residual norms are highly data-parallel. They will be mapped on a parallel machine. The computation in the subspace, on the other hand, is suited for vector programming. It will be mapped onto the front-end (i.e., control processor) of the parallel machine. Figure 1 presents this implementation of ERAM on a distributed architecture consisting of a parallel architecture and a vector/sequential machine. In our experiments the parallel machine is CM5 or CM200, while the other machine is the corresponding front-end.

Figure 2 describes the parallel MERAM algorithm for $\ell = 2$ on a heterogeneous architecture. TCMa and TCMb (resp., Tcomma and Tcommb) are computation (resp., communication) tasks of the algorithm. TCMa (resp., TCMb) communicates with Tcomma (resp., Tcommb) using the shared memory model. Tcomma and Tcommb are connected by a network. These communication tasks are designed to overlap

[6]Multiple instruction multiple data.
[7]Single instruction multiple data.

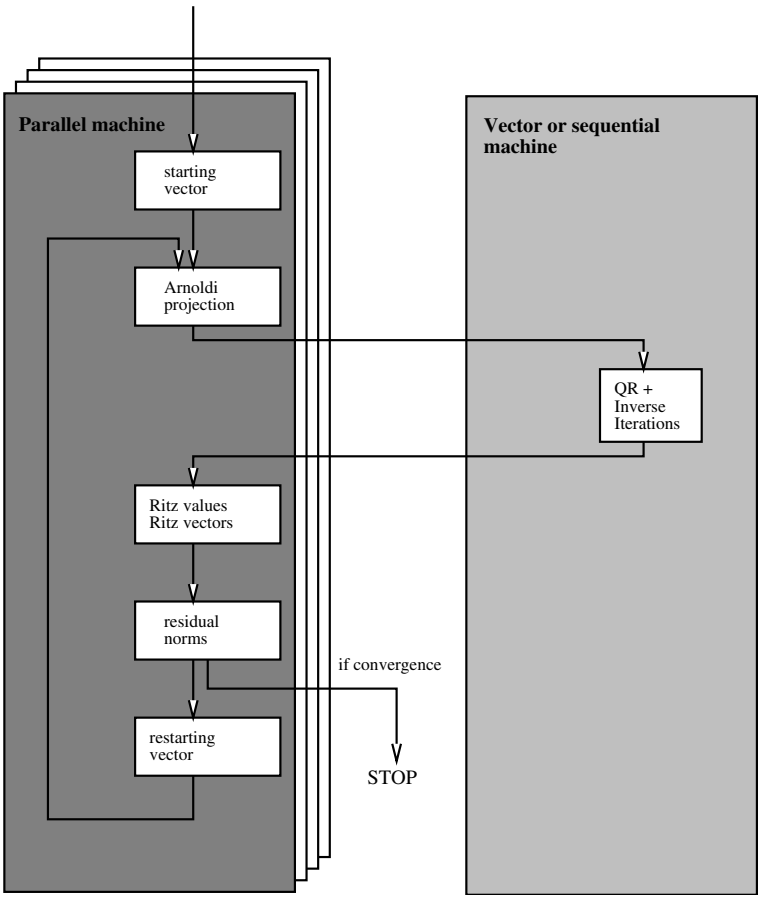

FIG. 1. *ERAM on a distributed architecture.*

communication with computation phases between parallel machines. TCMa (resp., TCMb) implements an ERAM process. After each iteration, if the convergence is not reached, the eigeninformation is stored in the shared memory (SM) and sent by one communication task to the other process. TCMa and TCMb are implemented on a CM5 and a CM200 interconnected by a 10 Mbit/s Ethernet link. The subspace computations of TCMa and TCMb are mapped onto the CM5 front-end and the CM200 front-end, respectively. PVM library is used to implement the communications between Tcomma and Tcommb.

The sparse matrices for our experiments have a C-diagonal pattern. The only nonzero elements of a C-diagonal matrix are on the main diagonal and the diagonals immediately around it. C is the maximum number of nonzero elements per row or per column. These sparse matrices have some interesting properties. They are easy to build and well suited for the sparse general pattern (SGP) data-parallel storage format [18]. It has also been shown in [8] that matrices with a C-diagonal pattern have good performance in sparse matrix-vector multiplication algorithms executed on data-parallel machines. The nonzero upper-diagonal and lower-diagonal elements of our nonsymmetric matrices are chosen in $[-1, +1]$ range, while the nonzero diagonal elements are in $[0, C]$. To study the convergence properties of MERAM and

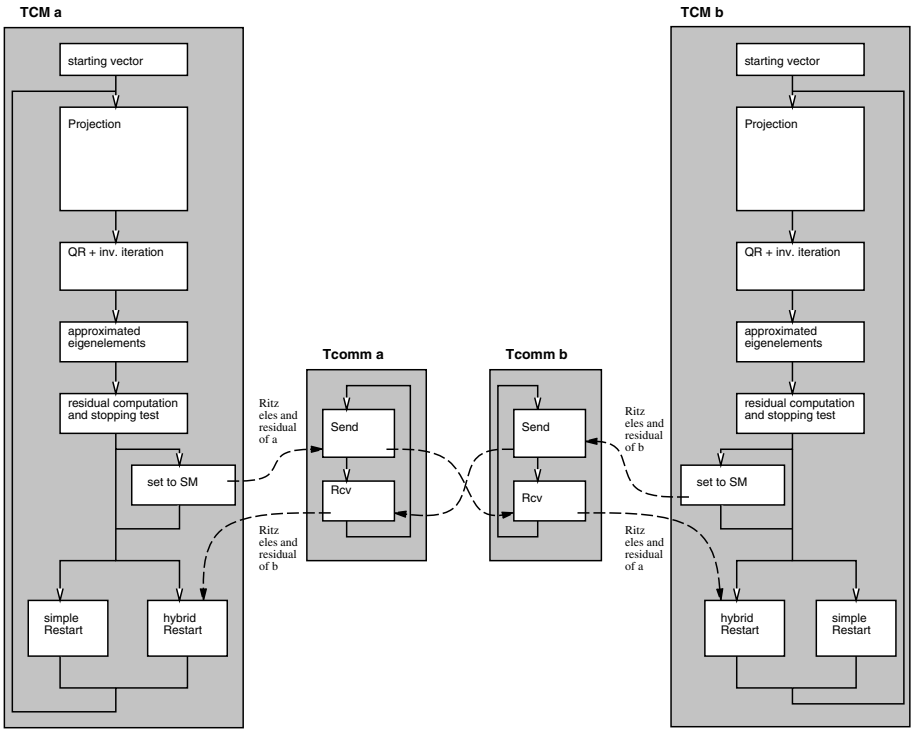

FIG. 2. *The asynchronous MERAM in a heterogeneous environment.*

to compare it with ERAM, we intentionally limited the sizes of our test matrices. The size of the test matrices is fixed to 1024.

The execution of ERAM on CM5 is done with the starting vector equal to v, the subspace size m, and the restarting strategy (4.7) with $\alpha_i = 1$ (for $i = 1, s$). On the other hand, two starting vectors (v^1, v^2), two subspace sizes (m_1, m_2), and two restarting strategies are needed to execute MERAM on both CM5 and CM200. We suppose that we have the same parameters on the CM5 for ERAM and for MERAM. This means that $v^1 = v$, $m_1 = m$, and the restarting strategies for ERAM and MERAM will be the same if the restart of MERAM is simple on the CM5. In the case of hybrid restart, we have two sets of eigeninformation $E_{m_1} = (\Lambda_{m_1}, U_{m_1}, r_s^1)$ and $E_{m_2} = (\Lambda_{m_2}, U_{m_2}, r_s^2)$. We choose "the best" to form a new set of eigeninformation: $E_{best} = (\Lambda^{best}, U^{best}, r_s^{best})$. Then, with these s Ritz vectors, we compute the restarting vector by (4.7) with $\alpha_i = 1$ (for $i = 1, s$). The speedup, S, is calculated as the ratio of the time needed to solve the problem with MERAM (on CM5 and CM200) to the time needed to resolve the same problem with ERAM (on CM5 alone). The execution time of MERAM is that of the converged node (the fastest node which is CM5).

We want to find $s = 4$ algebraically largest eigenvalues and their corresponding eigenvectors. The tolerance value is $tol = 5E - 10$.

We expect that MERAM converges faster than ERAM. In fact, for the worst case scenario MERAM behaves like ERAM applied to the fastest processor (i.e., CM5). This is the case when no other processes yield information that is better than the original ERAM process. In other words, since the CM5 is faster than the CM200, the

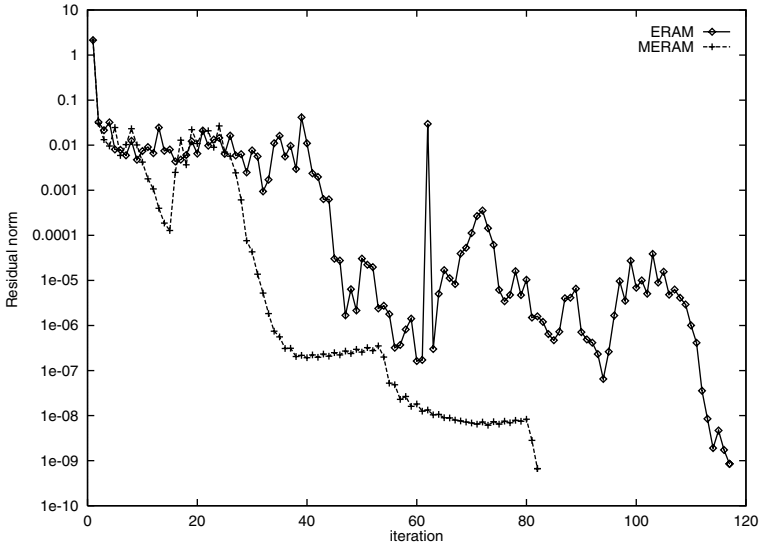

FIG. 3. *MERAM*$((28, 15), [z, \mathrm{r}])$ *versus ERAM*$(28, z)$ *with* 21*-diagonal matrix.*

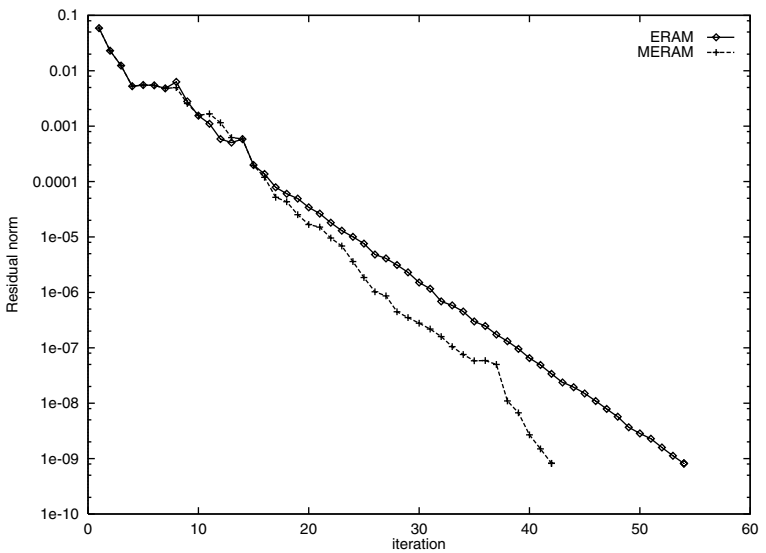

FIG. 4. *MERAM*$((26, 26), [z, \mathrm{r}])$ *versus ERAM*$(26, z)$ *with* 63*-diagonal matrix.*

CM200 ERAM process can be viewed as an accelerator for the CM5 ERAM process. Consequently, the number of iterations (restarts) of MERAM on the CM5 ought to be less than the number of iterations of ERAM on this machine. By the number of iterations of MERAM, we mean the number of iterations of its process on the CM5.

Figures 3–7 illustrate the sum of the residual norms (SRN)[8] (4.10) with $\alpha_i = 1$

[8]SRN is a stronger convergence measure than the residual of each Ritz vector alone. This is because SRN bounds the subspace residual : $\|AU_m - U_m\Lambda_m\|_2 \leq SRN = \sum_{i=1}^{s} \|Au_i^{(m)} - \lambda_i^{(m)} u_i^{(m)}\|_2$.

for $i = 1, s$, with respect to the number of restarts for ERAM and MERAM for C-diagonal matrices. They present the number of iterations required by ERAM and MERAM to converge. Table 1 brings together the parameters and the curves of performances presented in Figures 3–7. This table and all of these figures illustrate the influence of the CM200 eigeninformation on the improvement of the restarting vector, and consequently on the convergence of the ERAM process of MERAM on the CM5. We notice that the oscillations of the convergence curves of MERAM are qualitatively and quantitatively less important than the ones of ERAM. According to our experiments, MERAM always converges more rapidly than ERAM to the desired

invariant subspace. These results also show that we can obtain a good acceleration of convergence compared to ERAM.

In Figure 6 there is a section of convergence history where ERAM is better than MERAM. This seems to be due to the distribution of the eigenvalues. Indeed, the s Ritz values computed by two ERAM processes with subspace sizes m_1 and m_2 do not always correspond to s wanted eigenvalues. Suppose, for example, that the wanted eigenvalues are $(s = 4)$ algebraically the largest: $\lambda_1 > \lambda_2 > \lambda_3 > \lambda_4 > \lambda_5 > \cdots$ and λ_4, λ_5 are very close to each other. At some iteration, the ERAM process with m_1 can compute Ritz values corresponding to λ_1, λ_2, λ_3, and λ_4, while the ERAM process with m_2 can approach Ritz values corresponding to λ_1, λ_2, λ_3, and λ_5. Now, if the residual norm of the Ritz vector corresponding to λ_5 is less than the one corresponding to λ_4, then the Ritz vector corresponding to λ_5 will be chosen as "the best." Thus, hybrid restart takes into account a "bad" information to update the restarting vector in MERAM. Consequently, the restarting vector moves away from the wanted invariant subspace. An approach to remedy this issue seems to be to use a mixture of all Ritz vectors instead of the best vector. The hybrid restart strategy should make use of all Ritz vectors, and the whole computed information will be taken into account.

6.2. MERAM and other methods. To evaluate MERAM with respect to some other methods, we compared it with ERBAM and IRAM under similar con-

straints. The goal is to know which of the two schemes, MERAM and ERBAM (respectively, MERAM and IRAM), is the fastest given the same computational resources.

Numerical experiments were done on several Sun Ultra Sparc workstations. They were linked by 10 Mbit/s and 100 Mbit/s Ethernet networks for the experimentation of sections 6.2.1 and 6.2.2, respectively. We made use of two or three Sparc Ultra-1 workstations for the experiments of section 6.2.1. A maximum of six workstations—three Sparc Ultra-1 and three Sparc Ultra-5-10—were used for the experiments of section 6.2.2. All of these workstations function with the Sun operating system.

We made use of the LAKe and MPI message passing libraries to implement ERBAM and MERAM. LAKe (`Linear Algebra Kernel`) is a linear algebra class library implemented in C++ that uses MPI through OOMPI [16] for the parallel classes [14, 15]. We used the PARPACK package [24] to run a parallel version of IRAM. PARPACK is a parallel version of the ARPACK software (a package of Fortran 77 subroutines) which implements IRAM. This package is targeted for distributed memory message passing systems. The message passing layers supported are BLACS and MPI. The reverse communication interface of PARPACK allows a simplified SPMD[9] parallelization strategy.

The matrices are taken from MatrixMarket [2], the University of Florida sparse matrix collection[10], and the SPARSKIT package [22]. The matrices $PDE2961$ and $PDE490000$ are from partial differential equations (PDE) and are created by the `MATPDE` matrix generator of MatrixMarket. The finite difference matrix $PDE248004$ is from a second-order elliptic operator and is produced by the generator `GENMAT` of SPARSKIT. Table 2 presents some characteristics of these matrices. The number of nonzero elements of a matrix A is denoted by NNZ and its Frobenius norm by $\|A\|_F$.

6.2.1. MERAM versus ERBAM. For our experiments we have exploited only very high level parallelism of asynchronous MERAM. We did not take advantage of other types of parallelism that can be found in each ERAM process of MERAM. This means that each ERAM process of MERAM runs in serial mode. The parallelization of ERBAM is done according to the scheme presented in section 5.3. Each of the tasks 1, 3, and 4 of BBAA is distributed between the workstations, and step 2 runs redundantly on all processors.

We used these methods in order to find the $s = 4$ eigenvalues of largest modulus. The initial vector v^i is taken as the vector e_i (for $i = 1, \ell$). Let $\mathcal{M} = \sum_{i=1}^{\ell} m_i$ be the

sum of the subspace sizes of the ℓ ERAM processes of MERAM. The subspace size of ERBAM is chosen as $\ell \times m$, where m is defined by $m = \frac{\mathcal{M}}{\ell} + \mathrm{mod}(\ell, \mathrm{mod}(\mathcal{M}, \ell))$. The tolerance value is $tol = 1E-6$. The number of iterations of MERAM is the number of iterations of the ERAM process that reaches convergence (the other ERAM processes are stopped when the first one converges). It is, generally, the ERAM process with the largest subspace size.

We run experimentations with two or three ERAMs in parallel (i.e., $\ell = 2$ or 3). Table 3 brings together the input and output parameters of some comparisons between MERAM and ERBAM. Figures 8 and 9 illustrate Log_{10} of the sum of the residual norms versus the number of restarts and the execution time for ERBAM and MERAM on ℓ workstations. We notice in these figures and Table 3 an important reduction of MERAM response time with respect to ERBAM. The convergence of MERAM can be seen as the convergence of its ERAM process with the largest subspace size (i.e., ERAM(m_ℓ)). According to our experiments, this ERAM process, accelerated by the other ERAM processes of MERAM, is competitive with ERBAM. This is due to different factors: the small subspace size of ERAM (m_ℓ) in comparison to the subspace size of ERBAM (i.e., $\ell \times m$), the mixing of restarting strategies in MERAM, and the use of some additional resources in order to reduce ERAM (m_ℓ) process response time.

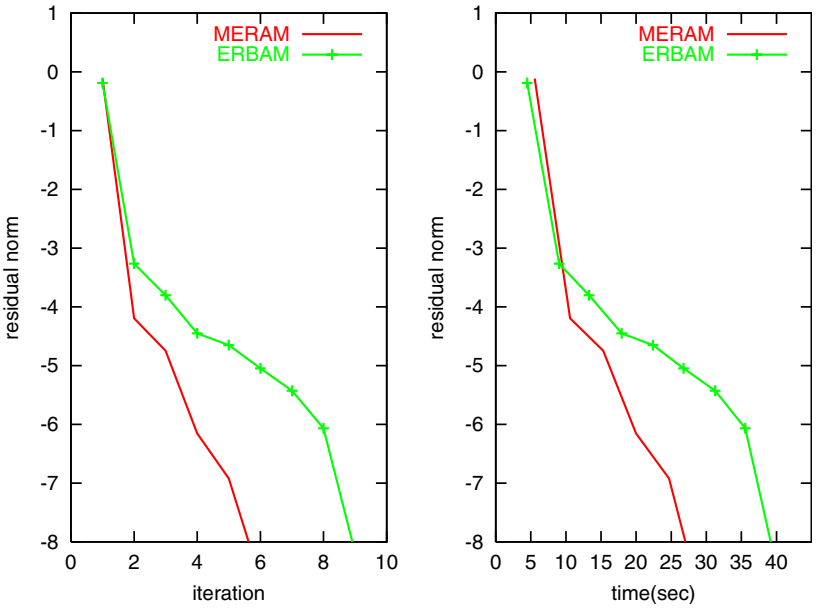

FIG. 9. *MERAM*$((5,45),I_2)$ *versus* *ERBAM*$(50,I_2)$ *with* *BFW*782*A matrix.*

6.2.2. MERAM versus IRAM. The Implicitly Restarted Arnoldi is a more robust method than ERAM. This is because of the powerful restarting strategy used in IRAM [23]. As we have seen before, MERAM improves the convergence of ERAM. This is because the restarting vector of an ERAM process of MERAM is computed by taking into account the eigeninformation obtained by the other ERAM processes. To evaluate the restarting strategy of MERAM with respect to IRAM, we have compared these methods under similar constraints.

The PARPACK package [24] implements a parallel version of IRAM according to the message passing model. We run experimentations with this package on a set of p interconnected workstations.

For our experiments, we have exploited the high level parallelism of asynchronous MERAM (i.e., that which is between its ERAM processes) as well as the parallelism inside each ERAM process. MERAM is implemented according to the model described in section 6.1. That is, we define ℓ computation tasks TCM_i and ℓ communication tasks Tcomm_i (for $i = 1, \ell$). Here TCM_i communicates with Tcomm_i using the message passing model. TCM_i implements the ith ERAM process of MERAM. After each iteration, if the convergence is not reached, the eigeninformation is sent to Tcomm_i which sends it in turn to the Tcomm_j tasks (for all $j \neq i$). Moreover, Tcomm_i receives the eigeninformation coming from Tcomm_j $(j \neq i)$ and communicates it to TCM_i.

MERAM is implemented on a set of p interconnected workstations. The TCM_i task is implemented on p_i workstations; $p_i = 1$ corresponds to a serial run. The subspace computation of TCM_i is replicated to all of the p_i workstations. The Tcomm_i task is implemented on a workstation. We then have $p = (\sum_{i=1}^{\ell} p_i) + \ell$. The MPI library is used to implement the communications between Tcomm_i (for $i = 1, \ell$).

We used these methods in order to find the s eigenvalues of largest modulus. We run experimentations with $p = 5$ or 6 workstations. The stopping criterion SRN is normalized by $\|A\|_F$ in both methods, and the tolerance value is $tol = 1.E-6$.

TABLE 4
MERAM versus IRAM on p workstations.

				MERAM			IRAM		
Matrix	Fig.	p, p_1, p_2	s	$m_1, m_{\ell=2}$	iteration	time	m	iteration	time

Table 4 brings together the input and output parameters of some comparisons between MERAM and PARPACK. For some of them, Figures 10–13 illustrate graphically Log_{10} of the normalized sum of the residual norms versus the number of restarts and the execution time for IRAM and MERAM. We notice in these figures and in Table 4 that the number of restarts of MERAM is always smaller than the number of restarts of PARPACK. On the other hand, the PARPACK response time is often faster than that of MERAM. This is due especially to the too heavy load of the workstations supporting the ERAM processes of MERAM. Let us recall that we dedicated $\ell = 2$ workstations to the communication processes Tcomm_1 and Tcomm_2. Consequently, the m_1 and m_2 matrix-vector multiplications of the first and the second ERAM processes of MERAM are distributed, respectively, on p_1 and p_2 workstations, while $(m_1 - s)$ matrix-vector multiplications of PARPACK are distributed on $p = p_1 + p_2 + \ell$ workstations. That means that each ERAM process runs in parallel on 2 or 3 processors or even in serial mode while IRAM runs on 5 or 6 processors. The load of the processors supporting IRAM is lighter than that of the one supporting ERAM processes of MERAM. Despite this unfavorable context for MERAM, the performances presented by Figures 10, 12, and 13 show that, for the corresponding matrices and parameters, MERAM has better convergence properties than IRAM.

7. Conclusion. We have presented the MERAM and some of its characteristics: the restarting strategy and its relationship to the block version of ERAM. We also presented an asynchronous parallel version of this method and performance results of its implementation on heterogeneous and homogeneous environments. MERAM allows us to restart each of its ERAM processes with a vector preconditioning so that it can be forced in the desired direction. This preconditioning can be seen as a particular application of an ERAM process to the starting vector of the other ones.

The restarting strategy is a critical part of MERAM. For an ERAM process of this method, a hybrid restart is defined to be a restarting strategy that takes into account all Ritz vectors including those received from the other ERAM processes. Thus, the restarting vector of this ERAM process is a linear combination of "the best" Ritz vectors of interest. We defined "the best" Ritz vector to be the vector that has the smallest residual norm.

Asynchronous MERAM is characterized by the fact that the communications between its subtasks (i.e., ERAM processes) are totally asynchronous. As a consequence, this parallel algorithm is not the parallel version of a unique serial one. [illegible] of this dynamic algorithm corresponds to one parallel static version. MERAM is a fault tolerant method. A loss of an ERAM process during MERAM execution does not interfere with its termination. Furthermore, this algorithm has a great po-

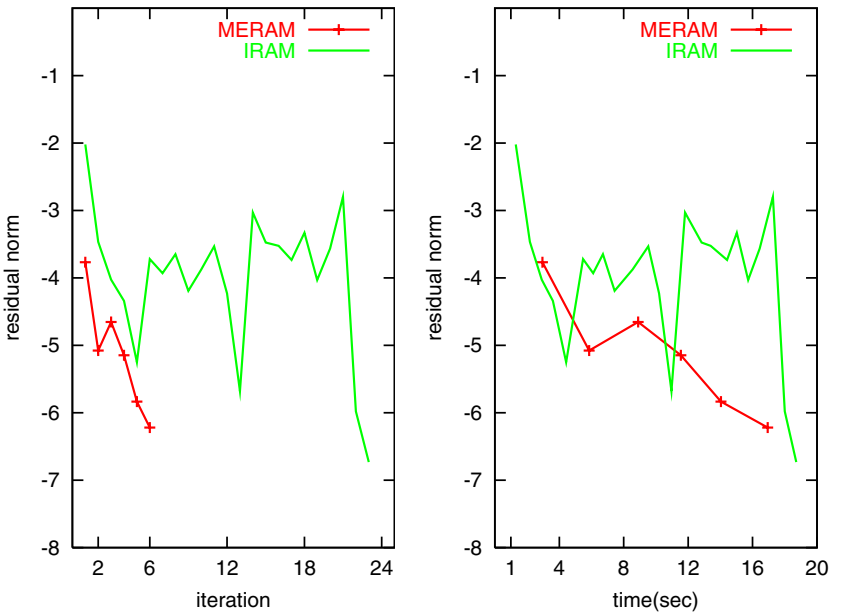

FIG. 10. *MERAM*$((10,20),I_2)$ *versus* *IRAM*$(20,e_1)$ *with* $BFW782A$ *matrix.*

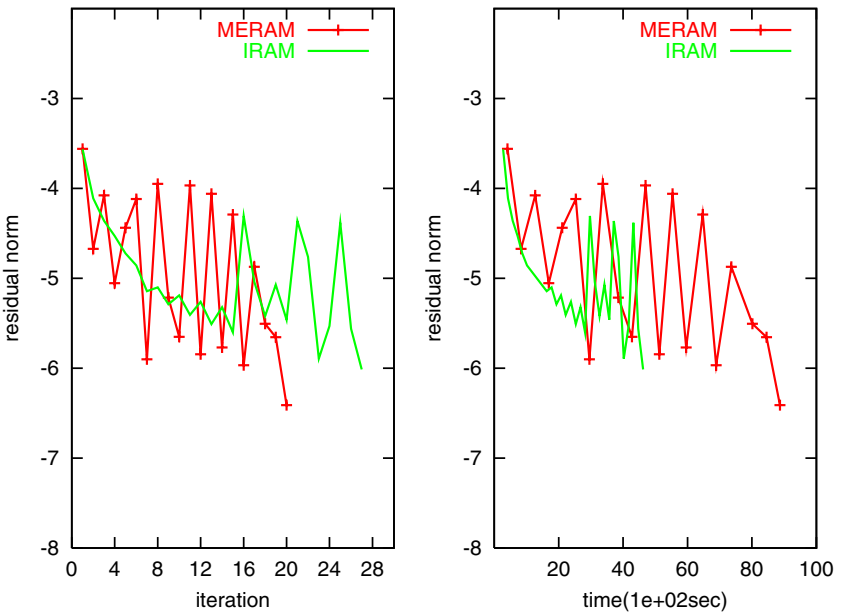

FIG. 11. *MERAM*$((20,35),I_2)$ *versus* *IRAM*$(35,e_1)$ *with* $PDE248004$ *matrix.*

tential for dynamic load balancing. Indeed, the attribution of ERAM processes of MERAM to the available resources can be done as a function of their subspace size at run time. The heterogeneity of computing supports then can be an optimization factor for this method. All of these properties show that MERAM is well suited to the GRID computational environments.

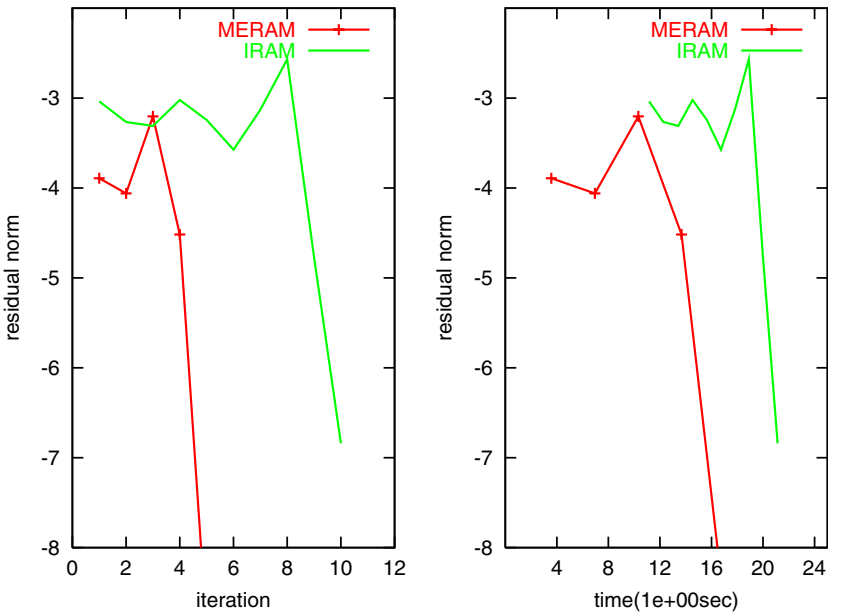

FIG. 12. *MERAM*$((15,20),I_2)$ *versus* *IRAM*$(20,e_1)$ *with* $PDE2961$ *matrix.*

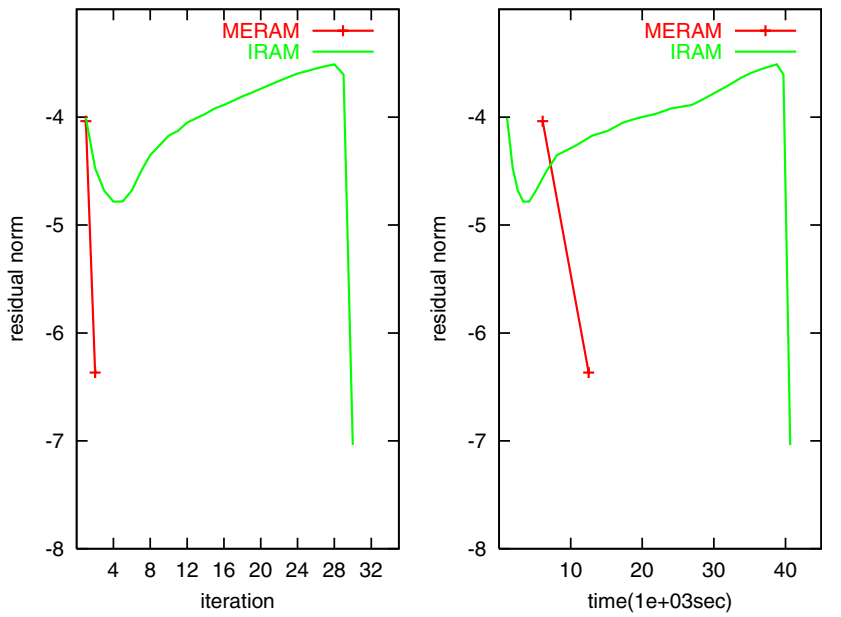

FIG. 13. *MERAM*$((55,30),I_2)$ *versus* *IRAM*$(55,e_1)$ *with* $PDE490000$ *matrix.*

As we have seen, MERAM accelerates the convergence of ERAM. Furthermore, it can cooperate with convergence acceleration methods similar to the iterative Chebyshev polynomials. The presented results of our experiments on a cluster of workstations point out that MERAM has a good convergence behavior compared with ERBAM. Moreover, according to our experiments, for some matrices, MERAM converges faster than IRAM.

We showed that to solve a large eigenproblem, the projection of ERAM on multiple subspaces and the communication of the intermediary results are more interesting than this projection on just one subspace. This concept is simple and can be extended to some other restarted projection methods like IRAM, GMRES, or Hermitian/non-Hermitian Lanczos methods.

There are still many open problems in these methods which involve interesting work from a theoretical point of view as well as practical computation. Some potential improvements to restarting techniques should be considered in future works. Approaches based on sophisticated restart such as augmented Krylov or implicit restarting are also under investigation.

Acknowledgments. The authors wish to thank the SIAM referees for their numerous suggestions and Ani Sedrakian for the realization of some of the experiments.

COMPUTATION OF THE EXPONENTIAL OF LARGE SPARSE SKEW-SYMMETRIC MATRICES*

N. DEL BUONO†, L. LOPEZ†, AND R. PELUSO‡

Abstract. In this paper we consider methods for evaluating both $\exp(A)$ and $\exp(\tau A)q_1$ where $\exp(\cdot)$ is the exponential function, A is a sparse skew-symmetric matrix of large dimension, q_1 is a given vector, and τ is a scaling factor. The proposed method is based on two main steps: A is factorized into its tridiagonal form H by the well-known Lanczos iterative process, and then $\exp(A)$ is derived making use of an effective Schur decomposition of H. The procedure takes full advantage of the sparsity of A and of the decay behavior of $\exp(H)$. Several applications and numerical tests are also reported.

Key words. skew-symmetric matrices, singular value decomposition, geometric integration of ordinary differential equations, splitting techniques

AMS subject classifications. 65F, 65L

1. Introduction. Exponential methods for the geometric integration of ordinary differential equations (ODEs) with quadratic invariants [13, 17] or for the solution of partial differential equations (PDEs) of advection type [4, 7, 16, 26] require computing the exponentials of skew-symmetric matrices as well as preserving the orthogonal feature of the obtained matrices. Hence, methods for evaluating both $\exp(A)$ and $\exp(\tau A)q_1$, where A is a real sparse skew-symmetric matrix of large dimension n, q_1 is a given vector of Euclidean norm 1, and τ is a scaling factor associable with the step size in a time integration method for ODEs, are of particular interest. Exact formulas for the computation of the exponential of a low dimension skew-symmetric matrix A are known [1, 21, 24], but unfortunately these are not practical when the dimension n of the matrix A increases. Standard techniques based on Padé and Chebyshev rational approximants can be used, but generally they do not preserve $\exp(\tau A)$ on the orthogonal group except for the diagonal Padé approximants [5]. Polynomial approximants, instead, are based on the approximation of $\exp(\tau A)q_1$ on some Krylov subspace of dimension $m < n$, but these techniques are computationally competitive only when m is small compared with n [11, 14, 25]. Furthermore, when A is skew-symmetric with uniformly distributed eigenvalues, no substantial error reduction occurs for $m \leq \|\tau A\|$ as observed in [14].

In [5, 6, 22] methods based on splitting techniques exploiting the Lie algebra structure of the orthogonal group have been considered to approximate $\exp(\tau A)$ to a given order of accuracy with respect to τ. In [19, 28] schemes based on the [illegible] of A and involving a computational cost of κn^3 flops, where the constant κ increases with the order of the approximation, have also been presented.

In this paper we suggest a two-step procedure to compute $\exp(A)$: A is first reduced into a tridiagonal form H using the Lanczos tridiagonalization process, then

an effective Schur decomposition of H is obtained via the singular value decomposition (SVD) of a bidiagonal matrix B of half dimension $n/2$. The SVD of such a matrix may be computed by efficient methods, for instance the Golub and Kahan algorithm [12] or the accurate [illegible] [9, 10]. In exact arithmetic our procedure preserves $\exp(A)$ in the orthogonal group and its main computational cost is $35/8n^3$ flops to compute $\exp(A)$ and $\mathcal{O}(n^2)$ flops when evaluating $\exp(A)q_1$.

The paper is organized as follows. In section 2 we describe the procedure to derive the Schur decomposition of a tridiagonal, skew-symmetric matrix H, then we show the decay behavior of the entries of $\exp(H)$ proving that such a matrix can be considered as banded. Generalization to smooth functions $f(z)$ is also considered. In section 3 our procedure is numerically compared with MATLAB routines for evaluating exponentials. Furthermore, we show some applications in the approximation of $\exp(\tau A)q_1$ on Krylov subspaces, in the numerical solution of ODEs and finally in the computation of exponentials of general matrices by using splitting techniques.

2. Functions of skew-symmetric matrices.

2.1. Schur decompositions of A. Let us consider a real skew-symmetric matrix $A \in \mathbb{R}^{n\times n}$, a vector $q_1 \in \mathbb{R}^n$ of Euclidean norm 1, the Krylov matrix $K(A, q_1, m) = [q_1\ Aq_1\ A^2q_1 \cdots\ A^{m-1}q_1] \in \mathbb{R}^{n\times m}$, and the Krylov subspace $\mathcal{K}_m = \text{span}\{q_1, Aq_1, \ldots, A^{m-1}q_1\}$. The following result states the conditions for the existence of a Hessenberg form of A.

THEOREM 2.1 (see [12]). [illegible] $Q = [q_1\ q_2 \ldots\ q_n] \in \mathbb{R}^{n\times n}$ [illegible] $Q^\top AQ = H$ [illegible] $R = Q^\top K(A, q_1, n)$ [illegible]

Thus, when $K(A, q_1, n)$ is of full rank n, from the QR factorization of $K(A, q_1, n)$, it follows that an unreduced Hessenberg form H of A exists. The Hessenberg decomposition, $A = QHQ^\top$, is essentially unique when the first column q_1 of Q is fixed and its unreduced Hessenberg form H is skew-symmetric and possesses the following tridiagonal structure:

$$H = \begin{pmatrix} 0 & -h_2 & 0 & \ldots & 0 \\ h_2 & 0 & -h_3 & \ldots & 0 \\ \ldots & & & & \\ \ldots & & & & \\ \ldots & & & & \\ 0 & \ldots & \ldots & \ldots & -h_n \\ 0 & \ldots & \ldots & h_n & 0 \end{pmatrix}. \tag{2.1}$$

For skew-symmetric matrices the reduction to the above tridiagonal form can be performed using the following Lanczos tridiagonalization process:

Let q_1 be a vector of $\mathbb{R}^n$ with $\|q_1\| = 1$ and set $h_1 = 0$ and $q_0 = 0$.
For $j = 1 : n$
  $w_j = Aq_j + h_j q_{j-1}$;
  $h_{j+1} = \|w_j\|$;
  $q_{j+1} = w_j/h_{j+1}$;
end

We have to notice that, in exact arithmetic, the above algorithm is equivalent to the Arnoldi process applied to skew-symmetric matrices. It provides an orthogonal matrix $Q = [q_1\ q_2\ \ldots\ q_n] \in \mathbb{R}^{n\times n}$ such that $Q^\top AQ = H$ where H is the tridiagonal matrix in (2.1). Moreover, it allows one to take full advantage of the possible sparsity of A due to

the matrix-vector products involved. However, in floating-point arithmetic the vectors q_j could progressively lose their orthogonality, in this case, the application of a re-orthogonalization procedure is required [12, 25]. On the contrary, the Arnoldi process preserves better the orthogonality of the matrix Q, but the tridiagonal structure of H could be lost into a Hessenberg one. In the numerical tests we implemented the above tridiagonalization process with a full re-orthogonalization based on the modified Gram–Schmidt algorithm [8, 23].

For very large size problems, the storage requirement for the vectors q_i's, providing the similarity transformation of $\exp(A)$, becomes the main drawback of the process. In this case the Lanczos procedure has to be modified applying a storage technique: a simple way to overcome this problem consists in running twice the process; after the first run the vector $c = \exp(H)e_1$ is computed storing only the sequence $q_1, \ldots, q_r$ with $r < n$ depending on the actual available computer memory [3]. Then the second step consists in restarting the process from q_r to q_n without storing them, and evaluating $\exp(A)q_1 = \sum_{i=1}^{n} c_i q_i$, where c_i is the ith entry of the vector c. Of course, in this version of the algorithm, the cost may increase up to two times the one of a single run, although in the second run the computation of the matrix H can be avoided.

Then, using $A = QHQ^\top$, it follows that $\exp(A) = Q\exp(H)Q^\top$ and $\exp(A)q_1 = Q\exp(H)e_1$, where e_1 is the first vector of the canonical basis of $\mathbb{R}^n$. In this context, the computational problem to deal with is the evaluation of $\exp(H)$, which we will tackle adopting a known Schur decomposition of a tridiagonal skew-symmetric matrix H (see Problem 8.6.6 in [12]).

Suppose n is even. The case of n odd may be approached in a similar way. Let us consider the permutation matrix

$$P = (e_1, e_3, \ldots, e_{n-1}, e_2, e_4, \ldots, e_n), \tag{2.2}$$

where $(e_1, e_2, \ldots, e_n)$ is the canonical basis of $\mathbb{R}^n$. Then, if H is as in (2.1) we have

$$P^\top H P = \begin{pmatrix} 0 & -B \\ B^\top & 0 \end{pmatrix}, \tag{2.3}$$

where B is the lower bidiagonal square matrix of size $w = n/2$ given by

$$B = \begin{pmatrix} h_2 & 0 & \ldots & & 0 \\ -h_3 & h_4 & \ldots & & 0 \\ \ldots & & & & \\ \ldots & & & & \\ 0 & \ldots & \ldots & h_{n-2} & 0 \\ 0 & \ldots & & -h_{n-1} & h_n \end{pmatrix}. \tag{2.4}$$

Since all diagonal and subdiagonal entries of B are nonzero, the w singular values of B are distinct and different from zero.

Let us consider the SVD of B, that is,

$$B = U\Sigma V^\top \tag{2.5}$$

with $\Sigma = \mathrm{diag}(\sigma_1, \sigma_2, \ldots, \sigma_w)$ and $\sigma_1 > \sigma_2 > \cdots > \sigma_w > 0$, and consider the orthogonal $n \times n$ matrix

$$W = \begin{pmatrix} U & 0 \\ 0 & V \end{pmatrix}. \tag{2.6}$$

Then

$$W^\top P^\top H P W = \begin{pmatrix} U^\top & 0 \\ 0 & V^\top \end{pmatrix} \begin{pmatrix} 0 & -B \\ B^\top & 0 \end{pmatrix} \begin{pmatrix} U & 0 \\ 0 & V \end{pmatrix} = \begin{pmatrix} 0 & -\Sigma \\ \Sigma & 0 \end{pmatrix}.$$

By considering the orthogonal matrix $R = PWP^\top$ it follows that

$$P \begin{pmatrix} 0 & -\Sigma \\ \Sigma & 0 \end{pmatrix} P^\top = R^\top H R = \operatorname{diag}(S_1, S_2, \ldots, S_w), \tag{2.7}$$

where

$$S_j = \begin{pmatrix} 0 & -\sigma_j \\ \sigma_j & 0 \end{pmatrix} \qquad \text{for } j = 1, 2, \ldots, w \tag{2.8}$$

is a 2×2 skew-symmetric matrix with eigenvalues given by the pair of pure imaginary values $\lambda_{j,1} = \imath\sigma_j$ and $\lambda_{j,2} = -\imath\sigma_j$ for $j = 1, 2, \ldots, w$, where $\imath$ denotes the imaginary unit. Thus R provides the real Schur decomposition of H, that is,

$$H = R \operatorname{diag}(S_1, S_2, \ldots, S_w) R^\top. \tag{2.9}$$

Finally, the exponential $\exp(H)$ may be computed as

$$\exp(H) = R \operatorname{diag}(\exp(S_1), \exp(S_2), \ldots, \exp(S_w))\ R^\top,$$

where

$$\exp(S_j) = \begin{pmatrix} \cos\sigma_j & -\sin\sigma_j \\ \sin\sigma_j & \cos\sigma_j \end{pmatrix} \qquad \text{for } j = 1, 2, \ldots, w.$$

We can avoid computing R to form $\exp(H)$. In fact, from (2.7) and the definition of $R = PWP^\top$ it follows that

$$\exp(H) = PW \exp\left(\begin{pmatrix} 0 & -\Sigma \\ \Sigma & 0 \end{pmatrix} \right) W^\top P^\top$$

$$= PWP^\top \operatorname{diag}(\exp(S_1), \exp(S_2), \ldots, \exp(S_w)) PW^\top P^\top$$

$$= PW \begin{pmatrix} \cos(\Sigma) & -\sin(\Sigma) \\ \sin(\Sigma) & \cos(\Sigma) \end{pmatrix} W^\top P^\top,$$

where

$$\cos(\Sigma) = \operatorname{diag}(\cos\sigma_1, \cos\sigma_2, \ldots, \cos\sigma_w), \tag{2.10}$$

$$\sin(\Sigma) = \operatorname{diag}(\sin\sigma_1, \sin\sigma_2, \ldots, \sin\sigma_w). \tag{2.11}$$

Finally,

$$\exp(A) = QPT(U, V, \Sigma) P^\top Q^\top, \tag{2.12}$$

where $T(U, V, \Sigma)$ is the following block matrix:

$$T(U, V, \Sigma) = \begin{pmatrix} U\cos(\Sigma)U^\top & -U\sin(\Sigma)V^\top \\ V\sin(\Sigma)U^\top & V\cos(\Sigma)V^\top \end{pmatrix}. \tag{2.13}$$

The vector $\exp(A)q_1$ can be computed as

$$\exp(A)q_1 = QPT(U,V,\Sigma)P^\top Q^\top q_1 = QPT(U,V,\Sigma)e_1. \tag{2.14}$$

It should be noted that, if A is replaced by a scaled matrix τA where τ is a scaling factor, then the n dimensional Krylov space $\mathcal{K}_n$ and its basis Q remain the same, while the bidiagonal matrix B has to be scaled to τB. In the SVD of τB, the matrices U and V remain unchanged while the singular value σ_j has to be scaled to $\tau\sigma_j$. Therefore, we have $\exp(\tau A) = Q\exp(\tau H)Q^\top$ where $\exp(\tau H) = PT(U,V,\tau\Sigma)P^\top$.

The Lanczos tridiagonalization procedure, for computing the tridiagonal form of A, requires at most $(2\upsilon+5)n^2 - (2\upsilon+7)n$ flops plus $n-1$ square roots, where $\upsilon = \max_{1\le j\le n}\upsilon_j$ and υ_j is the number of the nonzero entries of the jth row of A.

To obtain the SVD of the bidiagonal matrix B of dimension $w = \frac{n}{2}$, we employ the Golub and Kahan algorithm which involves $12w^2+30w$ flops plus $2w$ square roots for computing both the singular values and the singular vectors (see [12, page 454]). The cost of the [9, 10] is similar.

Concerning the computation of the block matrix $T(U,V,\Sigma)$, it should be observed that its $(1,2)$ block is the transpose with opposite sign of the block $(2,1)$. Since $\cos(\Sigma)$ and $\sin(\Sigma)$ are diagonal matrices, then the flops required by the three matrix-matrix products $U\cos(\Sigma)$, $V\cos(\Sigma)$, and $U\sin(\Sigma)$ are $3/4n^2$. The three matrix-matrix products $U\cos(\Sigma)U^\top$, $V\cos(\Sigma)V^\top$, and $U\sin(\Sigma)V^\top$ can be computed with a cost of $3/8n^3$ flops, while the product of QP by $T(U,V,\Sigma)$ and of the resulting matrix by $P^\top Q^\top$ needs $4n^3$ flops. Thus the total cost required by our procedure to evaluate $Q\exp(H)Q^\top$ is $35/8n^3+(35/4+2\upsilon)n^2-(2\upsilon-8)n$ flops plus the total cost of function evaluations which is given by $2n-1$ square roots plus the n evaluations of $\cos(\sigma)$ and $\sin(\sigma)$ at the singular values. On the other hand, if the Lanczos process is replaced by n steps of the Arnoldi algorithm, the orthogonalization process needs almost $2n^2\upsilon+2n^3$ flops increasing up to $2n^3$. Then, the main cost of our procedure is $35/8n^3$ flops which should be compared with that of MATLAB routines for matrix exponential which generally varies between $20n^3$ and $30n^3$ flops. We observe that, in the case of full matrices A, the main cost becomes $51/8n^3$ flops.

When $\exp(A)q_1$ has to be computed, from (2.14) it follows that only the first column of $T(U,V,\Sigma)$ is required. Then $U\cos(\Sigma)$ and $V\sin(\Sigma)$ require $1/2n^2$ flops, the first columns of $U\cos(\Sigma)U^\top$ and $V\sin(\Sigma)U^\top$ need n^2 flops, and the matrix-vector product of QP by the first column of T costs $2n^2$ flops. In this case, the total cost of our procedure is $(23/2+2\upsilon)n^2-(2\upsilon-8)n$ flops plus that of function evaluations.

2.2. Generalization. Our procedure may be generalized to evaluating a matrix function $f(A)$, where $f(z)$ is an analytic function inside a closed contour ν encircling the spectrum $[-\imath\sigma_1,\imath\sigma_1]$ of A (i.e., $f(A)$ is). In this case using the Schur decomposition (2.9) we obtain

$$f(H) = R\ \mathrm{diag}(f(S_1), f(S_2), \ldots, f(S_w))\ R^\top,$$

where $f(S_j)$ can be evaluated as described in the following lemma.

LEMMA 2.2. $f(A)$ S_j (2.8)

$$f(S_j) = \gamma(\sigma_j)I + \delta(\sigma_j)J \qquad \text{for } j = 1,2,\ldots,w, \tag{2.15}$$

$J = \left(\begin{smallmatrix} 0 & -1 \\ 1 & 0 \end{smallmatrix}\right)$ $\gamma(\sigma)$ $\delta(\sigma)$ $\mathbb{R}$

$$\gamma(\sigma) = \frac{1}{2}(f(\imath\sigma) + f(-\imath\sigma)), \qquad \delta(\sigma) = \frac{1}{2\imath}(f(\imath\sigma) - f(-\imath\sigma)), \qquad \sigma \in \mathbb{R}. \tag{2.16}$$

$f(z)$ $\overline{f(z)} = f(\overline{z})$ $z \in \mathbf{C}$ $\gamma(\sigma)$ $\delta(\sigma)$ (2.16)

Since S_j has eigenvalues given by $\lambda_{j,1} = \imath\sigma_j$ and $\lambda_{j,2} = -\imath\sigma_j$, from Sylvester's formula [15] we have

$$f(S_j) = \frac{1}{\lambda_{j,1} - \lambda_{j,2}}[(f(\lambda_{j,1}) - f(\lambda_{j,2}))S_j + (\lambda_{j,1}f(\lambda_{j,2}) - \lambda_{j,2}f(\lambda_{j,1}))I]$$

$$= \frac{1}{2\imath}[\imath(f(\imath\sigma_j) + f(-\imath\sigma_j))I + (f(\imath\sigma_j) - f(\imath\sigma_j))J],$$

where we have used $S_j = \sigma_j J$. Thus (2.15) follows. Now, since $\overline{\imath\sigma} = -\imath\sigma$, when $f(z)$ is an analytic function such that $\overline{f(z)} = f(\overline{z})$ for $z \in C$, then it follows that $\gamma(\sigma)$ and $\delta(\sigma)$ are real infinitely differentiable functions. □

Complex functions $f(z)$ satisfying the condition $\overline{f(z)} = f(\overline{z})$ are $\cos z$; $\sin z$; $\varphi(z) = (\exp(z) - 1)/z$; $\mathrm{cay}(z) = (1 + z/2)/(1 - z/2)$ for $z \neq 2$; $f(z) = (\alpha + z)^{-1}$, with $\alpha \geq 0$ and $z \neq -\alpha$. When $f(z) = \varphi(z)$ for all $z \in C$, we have

$$\gamma(\sigma) = \frac{\sin\sigma}{\sigma}, \qquad \delta(\sigma) = \frac{1 - \cos\sigma}{\sigma}, \qquad \sigma \in \mathbb{R}.$$

When $f(z) = \mathrm{cay}(z)$ for all complex values $z \neq 2$, we have

$$\gamma(\sigma) = \frac{1 - (\frac{\sigma}{2})^2}{1 + (\frac{\sigma}{2})^2}, \qquad \delta(\sigma) = \frac{\sigma}{1 + (\frac{\sigma}{2})^2}, \qquad \sigma \in \mathbb{R}.$$

When $f(z) = (\alpha + z)^{-1}$, with $\alpha \geq 0$ and for all complex values $z \neq -\alpha$, we have

$$\gamma(\sigma) = \frac{\alpha}{\alpha^2 + \sigma^2}, \qquad \delta(\sigma) = -\frac{\sigma}{\alpha^2 + \sigma^2}, \qquad \sigma \in \mathbb{R}.$$

The previous results may be summarized in the following theorem.

THEOREM 2.3. n A $n \times n$ q_1 $\mathrm{rank}[K(A, q_1, n)] = n$ $A = QHQ^\top$ A $f(A)$ $U\Sigma V^\top$ B (2.4) $f(A) = Qf(H)Q^\top$

$$f(H) = P \begin{pmatrix} U\ \Gamma(\Sigma)\ U^\top & -U\ \Delta(\Sigma)\ V^\top \\ V\ \Delta(\Sigma)\ U^\top & V\ \Gamma(\Sigma)\ V^\top \end{pmatrix} P^\top,$$

$\Gamma(\Sigma)$ $\Delta(\Sigma)$

$$\Gamma(\Sigma) = \mathrm{diag}(\gamma(\sigma_1), \gamma(\sigma_2), \ldots, \gamma(\sigma_w)), \quad \Delta(\Sigma) = \mathrm{diag}(\delta(\sigma_1), \delta(\sigma_2), \ldots, \delta(\sigma_w)), \tag{2.17}$$

$\gamma(\sigma)$ $\delta(\sigma)$ (2.16)

2.3. Decay behavior. Although $\exp(A)$ is formally a dense matrix, one can take computational advantage of the possible decay of its entries away from the main diagonal. This kind of behavior has been observed in [2] for symmetric positive definite matrices and in [18] for banded matrices. Here, using the SVD of the matrix B, we will prove that for tridiagonal and skew-symmetric matrices H, the entries of each block in $T(U,V,\Sigma)$ show a decay away from the diagonals. This behavior may be exploited in constructing a banded approximation of $T(U,V,\Sigma)$.

In order to estimate the size of the entries of $T(U,V,\Sigma)$, we derive bounds for the interpolation errors of the functions $\cos\sigma$ and $\sin\sigma$. Let s be an integer greater than 1 and let $\xi_1,\dots,\xi_{s+1}$ be the roots of the Chebyshev polynomial $\tau_{s+1}(\sigma)$ of degree $s+1$ in $[\sigma_w^2,\sigma_1^2]$. Set $\gamma_i=\sqrt{\xi_i}$ for $i=1,\dots,s+1$, and consider the interpolation polynomial $p(\sigma)$ of $\cos\sigma$ at $\pm\gamma_i$ for $i=1,\dots,s+1$. Since $\cos\sigma$ is an even function, it is easy to see that $p(\sigma)$ is an even polynomial of degree $2s$, i.e., $p_{2s}(\sigma)=\sum_{r=0}^{s}c_r\sigma^{2r}$. Then, $\cos\sigma=p_{2s}(\sigma)+R(\sigma)$, with the error function bounded by

$$|R(\sigma)|\le\frac{\left|\prod_{i=1}^{s+1}(\sigma^2-\gamma_i^2)\right|}{(2s+2)!}\qquad\text{for }\sigma\in\mathbb{R}.$$

Since for $i=1,\dots,s+1$, $\gamma_i^2=\xi_i$ are the roots of $\tau_{s+1}(\sigma)$, when $\sigma w\le\sigma\le\sigma_1$ it follows that

$$\left|\prod_{i=1}^{s+1}(\sigma^2-\gamma_i^2)\right|\le\left(\frac{\sigma_1^2-\sigma_w^2}{2}\right)^{s+1}\frac{1}{2^s}.$$

Hence we have

$$|R(\sigma)|\le\frac{(\sigma_1^2-\sigma_w^2)^{s+1}}{2^{2s+1}(2s+2)!}\qquad\text{for }\sigma_w\le\sigma\le\sigma_1. \tag{2.18}$$

Consider the odd function $\sin\sigma$ and the interpolation polynomial at nodes $\pm\gamma_i$ for $i=1,\dots,s+1$. This polynomial is an odd polynomial of degree $2s+1$, i.e., $\sin\sigma=p_{2s+1}(\sigma)+R(\sigma)$, where $p_{2s+1}(\sigma)=\sum_{r=0}^{s}d_r\sigma^{2r+1}$ and

$$|R(\sigma)|\le\frac{\left|\prod_{i=1}^{s+1}(\sigma^2-\gamma_i^2)\right|}{(2s+2)!}\qquad\text{for }\sigma\in\mathbb{R},$$

therefore it follows that

$$|R(\sigma)|\le\frac{(\sigma_1^2-\sigma_w^2)^{s+1}}{2^{2s+1}(2s+2)!}\qquad\text{for }\sigma_w\le\sigma\le\sigma_1. \tag{2.19}$$

THEOREM 2.4. $B=U\Sigma V^\top$ B (2.4) $\cos(\Sigma)$ $\sin(\Sigma)$ (2.10), (2.11) $s\ge1$ $T(U,V,\Sigma)$ (2.12)

$$|[U\cos(\Sigma)U^\top]_{k,l}|\le u(s,\sigma_1,\sigma_w)\qquad\text{for }|k-l|\ge s+1, \tag{2.20}$$

$$|[V\cos(\Sigma)V^\top]_{k,l}|\le u(s,\sigma_1,\sigma_w)\qquad\text{for }|k-l|\ge s+1, \tag{2.21}$$

$$|[U\sin(\Sigma)V^\top]_{k,l}|\le u(s,\sigma_1,\sigma_w)\quad\text{for }|k-l|\ge s+1,\ k-l\ne s+1, \tag{2.22}$$

$$u(s,\sigma_1,\sigma_w)=\frac{(\sigma_1^2-\sigma_w^2)^{s+1}}{2^{2s+1}(2s+2)!}. \tag{2.23}$$

. Consider $E=BB^\top$ and $F=B^\top B$. From the SVD of B, it follows that $E^s=U\Sigma^{2s}U^\top$ and $F^s=V\Sigma^{2s}V^\top$ for $s\geq 1$. Since E and F are tridiagonal matrices, then $E^s=(e_{kl}^{(s)})$ and $F^s=(f_{kl}^{(s)})$ are banded matrices, i.e., $e_{kl}^{(s)}=f_{kl}^{(s)}=0$ for $|k-l|\geq s+1$, and $s\geq 1$. The matrix $G^s=E^sB$, given by $G^s=U\Sigma^{2s+1}V^\top$, is a banded matrix with one more diagonal than E^s and F^s, that is, $g_{kl}^{(s)}=0$ for $|k-l|\geq s+1$ and $k-l\neq s+1$.

Using the interpolation formula $\cos\sigma=p_{2s}(\sigma)+R(\sigma)$ with $p_{2s}(\sigma)=\sum_{r=0}^{s}c_r\sigma^{2r}$, it follows that

$$U\cos(\Sigma)U^\top=\sum_{r=0}^{s}c_rU\Sigma^{2r}U^\top+UR(\Sigma)U^\top=\sum_{r=0}^{s}c_rE^r+UR(\Sigma)U^\top,$$
$$V\cos(\Sigma)V^\top=\sum_{r=0}^{s}c_rV\Sigma^{2r}V^\top+VR(\Sigma)V^\top=\sum_{r=0}^{s}c_rF^r+VR(\Sigma)V^\top,$$

where $R(\Sigma)=\mathrm{diag}(R(\sigma_1),R(\sigma_2),\ldots,R(\sigma_w))$.

Since E^s and F^s are banded matrices, then $[U^\top\cos(\Sigma)U]_{kl}=[U^\top R(\Sigma)U]_{kl}$ and $[V^\top\cos(\Sigma)V]_{kl}=[V^\top R(\Sigma)V]_{kl}$ for $|k-l|\geq s+1$. Hence, by using (2.18), the inequalities (2.20) and (2.21) follow.

Using the interpolation formula $\sin\sigma=\sum_{r=0}^{s}d_r\sigma^{2r+1}+R(\sigma)$, it follows that

$$U\sin(\Sigma)V^\top=\sum_{r=0}^{s}d_rU\Sigma^{2r+1}V^\top+UR(\Sigma)V^\top=\sum_{r=0}^{s}d_rG^r+UR(\Sigma)V^\top,$$

and thus from (2.19), inequality (2.22) follows. ∎

If $\sigma_1^2-\sigma_w^2<2$, the upper bound function $u(s,\sigma_1,\sigma_w)$ in (2.23) rapidly tends to zero as s increases. If $\sigma_1^2-\sigma_w^2\geq 2$ but $(\sigma_1^2-\sigma_w^2)^{s+1}$ increases, less than $2^{2s+1}(2s+2)!$, then $u(s,\sigma_1,\sigma_w)$ tends to zero as s increases. In both cases the estimates of Theorem 2.4 show that the entries of each block of the matrix $T(U,V,\Sigma)$ decay away from the diagonal. Given a threshold parameter ϵ, the bandwidth outside which the entries of $T(U,V,\Sigma)$ are smaller in modulus than ϵ can be defined as $r=\min\{s|u(s,\sigma_1,\sigma_w)\leq\epsilon\}$. The integer r is usually much smaller than w for large size problems, when the distance $\sigma_1^2-\sigma_w^2$ is of moderate size.

The result shown in Theorem 2.4 may be used to define a banded version of our procedure. Let $T_\epsilon(U,V,\Sigma)$ be the matrix derived from $T(U,V,\Sigma)$ by setting to zero the entries with modulus less than ϵ and let $[\exp(A)]_\epsilon$ be the approximation of $\exp(A)$ obtained by

$$[\exp(A)]_\epsilon=QPT_\epsilon(U,V,\Sigma)Q^\top P^\top.$$

It then follows that $\|T_\epsilon(U,V,\Sigma)-T(U,V,\Sigma)\|\leq n\epsilon$, where $\|\cdot\|$ denotes the 2-norm on matrices. Since Q and P are orthogonal matrices, we have $\|\exp(A)-[\exp(A)]_\epsilon\|=\|QP[T(U,V,\Sigma)-T_\epsilon(U,V,\Sigma)]Q^\top P^\top\|=\|T_\epsilon(U,V,\Sigma)-T(U,V,\Sigma)\|\leq n\epsilon$. Thus a suitable choice for ϵ is given by $\epsilon=\varepsilon/n$ where ε is the machine accuracy. Each block of $T_\varepsilon(U,V,\Sigma)$ is a band matrix with bandwidth r. It is not difficult to see that $[\exp(H)]_\epsilon=PT_\varepsilon(U,V,\Sigma)P^\top$ is a band matrix with bandwidth given by $2r$.

Since each block of $T_\epsilon(U,V,\Sigma)$ is a banded matrix of bandwidth r, the two matrix-matrix products in $U\cos(\Sigma)U^\top$ and $V\cos(\Sigma)V^\top$ require $2w(2w-r)(r+1)$ flops, while the matrix-matrix product in $U\sin(\Sigma)V^\top$ costs $2w^2+2w[2(w-1)-r](r+1)$ flops, with $w=\frac{n}{2}$. The matrix-matrix product of QP by $T_\epsilon(U,V,\Sigma)$ can be performed with a cost of $4n^2(2r+1)$ flops. Recalling that $w=n/2$ and that υ is the (maximum by rows) number of nonzero entries, the total cost of our procedure is $2n^3+(2\upsilon+61/4+10r)n^2-(2\upsilon+2r^2+4r+8)n$ plus the cost of function evaluations.

As before, if the vector $\exp(A)q_1$ only has to be computed, we need $4w(2r+1)$ flops to compute the first column vectors of $U\cos(\Sigma)U^\top$ and $V\sin(\Sigma)V^\top$, while $4n(2r+1)$ are the flops required for the matrix-vector product of QP by the first column of $T(U,V,\Sigma)$. Thus, our procedure now requires $(17/2+2\upsilon)n^2-(2\upsilon-12r)n$ plus the cost of function evaluations. The partial costs are not reported since they equal the ones of the nonbanded case (refer to the end of section 2.1).

3. Applications and numerical tests. All numerical tests have been obtained running MATLAB 5.3 on a Pentium IV 2.4 GHz with 1024 MbRAM. In the numerical codes we have implemented the Lanczos tridiagonalization process with a full reorthogonalization based on the iterated modified Gram–Schmidt algorithm [8, 23]; the SVD of the bidiagonal matrix B has been performed exploiting the Golub and Kahan algorithm. Moreover, no storage techniques has been adopted.

The procedure for computing $\exp(A)$ by (2.12) has been denoted by `AExp`, while `AbExp(r)` denotes the procedure in which $T(U,V,\Sigma)$ is replaced by $T_\epsilon(U,V,\Sigma)$, where the bandwidth `r` of each block of $T_\epsilon(U,V,\Sigma)$ is given by $\min\{s|u(s,\sigma_1,\sigma_w)\le\epsilon\}$, with $\epsilon=\varepsilon/n$ and $\varepsilon=2.2206\text{e}-16$ (the MATLAB floating point relative accuracy).

3.1. Numerical comparisons. We have compared our approaches with two MATLAB functions `Expm` and `Expm3`. Particularly, `Expm` computes the exponential of A using a scaling and squaring algorithm with Padé approximations, while `Expm3` evaluates the exponential of A via eigenvalue and eigenvector decomposition. Comparisons are done in terms of: Flops (counted by the built in MATLAB routine `flops`); global error, defined as the 2-norm of the difference of `AExp` (respectively, `AbExp`) and `Expm`; orthogonal error, defined as the distance of the computed exponential from the orthogonal manifold (i.e., $\|\texttt{AExp}^\top\texttt{AExp}-I_n\|_F$, where $\|\cdot\|_F$ is the Frobenius norm on matrices). Tables 3.1 and 3.2 report the comparisons on sparse and dense skew-symmetric matrices A of different dimensions n and entries randomly generated in $[-10,10]$. Observe that the results obtained for `AExp` and `AbExp(r)` are similar, nevertheless `AbExp(r)` saves flops.

3.2. Krylov approximations of $\exp(\tau A)q_1$. When we need to compute $y=\exp(\tau A)q_1$ and n is large, the tridiagonalization process to obtain H may be too expensive. In this case a common way to save computation is to consider the approximation, $y_m=Q_m\exp(\tau H_m)e_1$, on the Krylov subspace of dimension $m<n$, where $e_1=(1,0,\dots,0)^\top\in\mathbb{R}^m$, and Q_m, H_m are the matrices derived by the Krylov algorithm that is the Lanczos tridiagonalization process in section 2.1 run until $m<n$. However, when A is a skew-symmetric matrix with uniformly distributed eigenvalues, no substantial error reduction can be observed for $m\le\|\tau A\|$ ([14]), and thus the Krylov algorithm should be implemented in a different way than for symmetric matrices. In particular, we fix m sufficiently large and consider the approximation $y_m=Q_m\exp(\tau H_m)e_1$ then an a posteriori error estimate has to be used to evaluate the Krylov approximation obtained.

`AExpy` denotes the method based on formula (2.14) for evaluating $y = \exp(\tau A)q_1$ while `KExpy(m)` indicates the Krylov approximation, $y_m = Q_m \exp(\tau H_m)e_1$, where Q_m and $\exp(\tau H_m)$ are computed by our procedure, while `KExpmy(m)` marks the Krylov approximation where the exponential $\exp(\tau H_m)$ is computed using the MATLAB function `Expm`. In Table 3.3 we compare the results obtained by `AExpy`, `KExpy(m)`, and `KExpmy(m)`, where A is a dense random matrix with entries in $[-1, 1]$ and q_1 a vector of Euclidean unit norm. The results show that `KExpy(m)` always saves computation with respect to `AExpy` and `KExpmy(m)`. We have also applied our procedure to compute the vector $y = \exp(A)q_1$, where A is now a 300×300 sparse skew-symmetric matrix, with about 10% nonzero elements randomly generated in $[-10, 10]$, and q_1 is a random vector with $\|q_1\| = 1$. Figure 3.1 shows the semilog plot of the global error (dotted line with circle) evaluated as $\|y - y_m\|$, and of the orthogonal error, defined as $|y_m^\top y_m - 1|$, (solid line with stars), against the dimension m of the Krylov subspace. Figure 3.1 shows that accurate Krylov approximations may be obtained for quite large values of m.

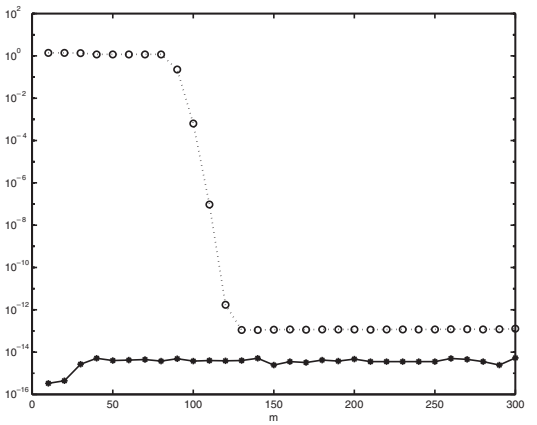

FIG. 3.1. *Errors behavior.*

3.3. Application to ODEs and PDEs. We consider the method of Magnus series, which approximates the solution of linear differential equations $y' = A(t)y$, $y(0) = y_0$ in the form $y(t) = \exp(\Omega(t))y_0$, where $\Omega(t)$ is a matrix function satisfying a suitable ODE [13, 17]. When $A(t)$ is a skew-symmetric matrix function, $\Omega(t)$ is also skew-symmetric and $y(t)$ is a vector with $\|y(t)\| = 1$ for all t. We adopt our approach to compute the exponentials of the second and fourth order Magnus methods, whose definitions are reported below (h is the time step):

MG2	MG4
$A_1 = A(t_n + h/2);$	$A_1 = A(t_n + (\frac{1}{2} - \frac{\sqrt{3}}{6})h);$
$\omega_n = A_1;$	$A_2 = A(t_n + (\frac{1}{2} + \frac{\sqrt{3}}{6})h);$
$y_{n+1} = \exp(h\omega_n)y_n;$	$\omega_n = \frac{1}{2}(A_1 + A_2) + \frac{\sqrt{3}}{12}h[A_2, A_1];$
	$y_{n+1} = \exp(h\omega_n)y_n.$

As an example we consider the skew-symmetric matrix $A(t) = (a_{ij}(t))$, whose upper triangular entries are $a_{ij}(t) = (-1)^{i+j}\frac{i}{j+1}t^{j-i}$, $1 \le i < j \le n$ [20]. In the computation we have taken $n = 100$ and we integrate the differential system $y' = A(t)y$ on the interval $[0, 1]$; as initial vector a vector $y(0)$ randomly generated and with unit Euclidean norm has been employed . Denote by ZpExp the method of order p, with respect to the time step h, proposed in [28]. It preserves exponential matrices on the orthogonal group and its cost is of κn^3 flops, where the constant κ increases with the order p of the approximation. MGp(`AExpy`) and MGp(Zp`Exp`) denote the

Magnus methods in which the exponential matrices, at each step, are computed by `AExpy` and `Z`p`Exp`, respectively. Table 3.4 reports the performance of the methods. It can be seen that MGp(`Z`p`Exp`) are less accurate than MGp(`AExpy`). However the second order Magnus method based on `Z2Exp` saves flops with respect to MG2(`AExpy`) although this favorable feature is less clear when we compare fourth order methods MG4(`Z4Exp`) and MG4(`AExpy`), since `Z`p`Exp` have a cost increasing with the order p of the approximation. The schemes MGp(`KExpy(m)`), based on the approximation of Krylov subspace, show the same performance in terms of orthogonal and global errors as MGp(`AExpy`), while reducing the number of flops required.

We now consider a different example, in particular the KdV PDE $u_t = -uu_x - \delta^2 u_{xxx}$, with periodic boundary conditions $u(0,t) = u(L,t)$, where L is the period and δ is a small parameter. As shown in [7], appropriate methods of space discretization lead to solve a set of ODEs of the form $y' = A(y)y$, $y(0) = y_0$, evolving on the sphere of radius $\|y_0\|$, where $y(t) = (u_0(t), u_1(t), \ldots, u_{N-1}(t))^\top$, $u_i(t) \approx u(i\Delta x, t)$ for $i = 0, 1, \ldots, N-1$, and where $\Delta x = \frac{2}{N}$ is the spatial step of $[0, 2]$. For instance, if we consider the space discretization method in [26] we have

$$A(y) = -\frac{1}{6\Delta x} g(y) - \frac{\delta^2}{2\Delta x^3} P,$$

where both $g(y)$ and P are two $N \times N$ skew-symmetric matrices given by

$$g(y) = \begin{pmatrix} 0 & u_0+u_1 & 0 & 0 & 0 & -(u_0+u_{N-1}) \\ -(u_0+u_1) & 0 & u_1+u_2 & \ldots & 0 & 0 \\ 0 & -(u_1+u_2) & 0 & \ldots & 0 & 0 \\ \vdots & \vdots & \vdots & & \vdots & \vdots \\ u_{N-1}+u_0 & 0 & 0 & \ldots & -(u_{N-1}+u_{N-2}) & 0 \end{pmatrix}$$

and

$$P = \begin{pmatrix} 0 & -2 & 1 & 0 & 0 & \dots & 0 & 0 & -1 & 2 \\ 2 & 0 & -2 & 1 & 0 & \dots & 0 & 0 & 0 & -1 \\ -1 & 2 & 0 & -2 & 1 & \dots & 0 & 0 & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & & \vdots & \vdots & \vdots & \\ 1 & 0 & 0 & 0 & 0 & \dots & -1 & 2 & 0 & -2 \\ -2 & 1 & 0 & 0 & 0 & \dots & 0 & -1 & 2 & 0 \end{pmatrix}.$$

Particularly we adopt the method of iterated commutators of second order [27], denoted by M2, to solve the ODE derived from the KdV equation with $\delta = 0.022$, initial condition $y_0 = y(0)/\|y(0)\|$, where $y(0) = (u_0(0), u_1(0), \dots, u_{N-1}(0))^\top$, $u_i(0) = u(i\Delta x, 0)$ for $i = 0, \dots, N-1$, and $u(x,0) = \cos(\pi x)$. As before, to compute the exponential appearing in the numerical scheme we use `AExpy`, `KExpy(m)`, and `Z2Exp` procedures. Table 3.5 provides the performance of the methods applied to compute the waveform at $\pi t = 1$ with steplength $\Delta t = 0.04/\pi$ and different spacings Δx.

TABLE 3.5
Performance of second order method on different spacings.

3.4. Exponentials of general matrices and splitting techniques. Slight modifications in the algorithm shown in section 2.1 can allow the computation of the exponential of a tridiagonal symmetric matrix H with zero diagonal entries. Let H be the following matrix:

$$H = \begin{pmatrix} 0 & h_2 & 0 & \dots & 0 \\ h_2 & 0 & h_3 & \dots & 0 \\ 0 & h_3 & 0 & \dots & 0 \\ \dots & \dots & 0 & \dots & h_n \\ 0 & \dots & \dots & h_n & 0 \end{pmatrix}. \tag{3.1}$$

Considering the permutation matrix (2.2) we have that

$$P^\top H P = \begin{pmatrix} 0 & B \\ B^\top & 0 \end{pmatrix},$$

where now B is the square matrix of dimension $w = n/2$ given by

$$B = \begin{pmatrix} h_2 & 0 & \dots & & 0 \\ h_3 & h_4 & \dots & & 0 \\ \dots & & & & \\ 0 & \dots & \dots & h_{n-2} & 0 \\ 0 & \dots & \dots & h_{n-1} & h_n \end{pmatrix} \tag{3.2}$$

with $h_i > 0$ for $i = 2, \ldots, n$.

Using the SVD of $B = U\Sigma V^\top$ with $\Sigma = \mathrm{diag}(\sigma_1, \sigma_2, \ldots, \sigma_w)$ and $\sigma_1 > \sigma_2 > \cdots > \sigma_w > 0$, in the same fashion as in the skew-symmetric case, the exponential of H of the form (3.1) can be computed as

$$\exp(H) = PT(U, V, \Sigma)P^\top, \tag{3.3}$$

where the matrix $T(U, V, \Sigma)$ is now given by

$$T(U, V, \Sigma) = \begin{pmatrix} U\cosh(\Sigma)U^\top & U\sin h(\Sigma)V^\top \\ V\sinh(\Sigma)U^\top & V\cosh(\Sigma)V^\top \end{pmatrix}$$

and where $\cosh(\Sigma)$ and $\sinh(\Sigma)$ denote the following two diagonal matrices:

$$\cosh(\Sigma) = \mathrm{diag}(\cosh\sigma_1, \cosh\sigma_2, \ldots, \cosh\sigma_w), \tag{3.4}$$

$$\sinh(\Sigma) = \mathrm{diag}(\sinh\sigma_1, \sinh\sigma_2, \ldots, \sinh\sigma_w). \tag{3.5}$$

This observation can be useful in the computation of the exponential $\exp(hA)$ of a general matrix A to a low order accuracy with respect to h. In fact, by using the splitting $A = A_1 + A_2$, where $A_1 = 1/2(A + A^\top)$ and $A_2 = 1/2(A - A^\top)$ are, respectively, the symmetric and skew-symmetric parts of A, then a scheme of first order with respect to h to approximate $\exp(hA)$ is given by

$$\exp(hA_1)\exp(hA_2).$$

Since A_2 is skew-symmetric, then $\exp(hA_2)$ can be computed by our procedure (2.12). To evaluate $\exp(hA_1)$ we observe that, using the Lanczos algorithm, A_1 can be transformed into a tridiagonal symmetric matrix $S = Q_1 A_1 Q_1^\top$ with Q_1 orthogonal.

By considering the splitting $S = S_1 + D_1$, where $D_1 = \mathrm{diag}(S)$ and S_1 is a tridiagonal symmetric matrix with zero diagonal entries, the exponential matrix $\exp(hA)$ can be approximated to first order of accuracy by

$$Q_1 \exp(hS_1)\exp(hD_1)Q_1^\top \exp(hA_2); \tag{3.6}$$

finally, in the computation of $\exp(hS_1)$ we can apply (3.3).

A second order scheme is given by the Strang formula

$$\exp\left(\frac{h}{2}A_2\right)\exp(hA_1)\exp\left(\frac{h}{2}A_2\right)$$

from which, using $S = Q_1 A_1 Q_1^\top$ and then $S = S_1 + D_1$, we obtain

$$\exp\left(\frac{h}{2}A_2\right)Q_1\exp\left(\frac{h}{2}D_1\right)\exp(hS_1)\exp\left(\frac{h}{2}D_1\right)Q_1^\top\exp\left(\frac{h}{2}A_2\right). \tag{3.7}$$

We have applied the above splitting (3.6) and (3.7) to compute the exponential of a sparse randomly generated 200×200 matrix. Table 3.6 reports the number of floating-point operations required by the first and second order splitting methods implemented using our procedures to compute the exponential and the MATLAB function `Expm` and `Expm3`.

Table 3.7 shows the performance of the splitting procedures when the step-size value is halved. It can be observed that the global error reduces with the order of the method.

4. Conclusions. In this paper we have provided a method to compute both $\exp(\tau A)$ and $\exp(\tau A)q_1$, when A is a sparse skew-symmetric matrix. The proposed algorithm preserves $\exp(\tau A)$ in the orthogonal group and requires $35/8n^3$ floating-point operations for this computation, while it compels $(23/2 + 2v)n^2$ floating-point operations to evaluate $\exp(\tau A)q_1$ conserving the length of the obtained vector. We have also generalized our procedure to calculate smooth functions of skew-symmetric matrices and highlighted the use of our algorithm in the approximation of $\exp(\tau A)q_1$ on Krylov subspace, in the context of exponential integrators of ODEs and PDEs and in the evaluation of the exponential of a general matrix.

Acknowledgment. The authors wish to thank the anonymous referees for their many helpful suggestions and constructive remarks.

CONSERVATIVE LOGARITHMIC RECONSTRUCTIONS AND FINITE VOLUME METHODS*

ROBERT ARTEBRANT† AND H. JOACHIM SCHROLL†

Abstract. A class of high-order reconstruction methods based on logarithmic functions is presented. Inspired by Marquina's hyperbolic method, we introduce a double logarithmic ansatz of fifth order of accuracy. Low variation is guaranteed by the ansatz and (slope-) limiting is avoided. The method can reconstruct smooth extrema without order reduction. Fifth order of convergence is verified in a numerical experiment governed by the nonlinear Euler system. Numerical experiments, including the Osher–Shu shock/acoustic interaction, are presented.

Key words. conservation law, finite volume method, high-order reconstruction

1. Introduction and background.

The present paper presents a new reconstruction method to compute accurate numerical fluxes within the context of finite volume methods for conservation laws. These schemes are derived from the integro-differential formulation of the conservation law

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_\Omega u(t,x)\,\mathrm{d}x + \int_{\partial\Omega} f(u(t,x))\cdot n\,\mathrm{d}S = 0\ .$$

Within a spatial domain Ω the total amount of a certain quantity u is conserved; i.e., it does not change with time except by flow across the boundary $\partial\Omega$. It seems worthwhile to point out the duality in the formulation of this dynamic: The conserved quantity is the total amount or the [illegible] of u, while the dynamics of this average is determined by [illegible] of the flux $f(u(t,x))$ along the boundary. Clearly, to simulate the dynamics accurately, it is absolutely essential to determine accurate point values for the flux along the boundary. That is the [illegible] task: From given cell averages, determine point values along the boundary.

Since the 1970's several reconstruction approaches have been developed. The starting point was a piecewise linear reconstruction in the monotonic upstream-centered scheme for conservation laws (MUSCL) scheme which resulted in a second-order sequel to Godunov's method [13]. At that time it seemed natural to use higher-degree polynomials for reconstruction aiming for higher-order methods. However, polynomials of higher degree tend to oscillate and solutions of conservation laws are very sensitive to artificial oscillations. To minimize these artificial oscillations, essentially nonoscillatory (ENO) schemes select one (or, in weighted ENO (WENO) schemes, a combination) of several interpolation polynomials defined by neighboring cell averages such that the variation of the reconstructing polynomial remains as small as possible. Several modifications to improve the performance of ENO-type schemes were proposed recently; see [10] and the references therein.

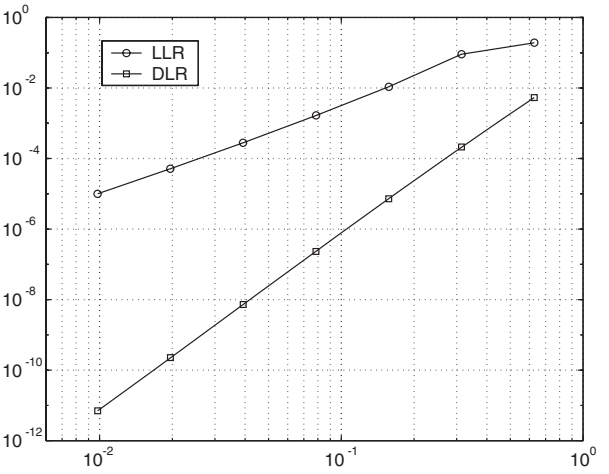

FIG. 1. *L_1-errors for the Euler system.*

To the knowledge of the authors there is only one higher-order method which avoids polynomials for reconstruction; that is the piecewise hyperbolic method (PHM) by Marquina [5]. This reconstruction is monotone and hence oscillation-free and third-order accurate for monotone data. In the case of local extrema it degenerates to second order. Motivated by promising results with this reconstruction method when applied in relaxed finite volume schemes [8], it is tempting to look for similar (monotone) reconstruction methods which may be extended to an order of accuracy higher than three. To achieve this, additional conditions will be imposed on the reconstructing function, in particular, on its derivatives; see section 3. In order to handle these conditions it will be advantageous to work with a logarithmic ansatz instead of hyperbolic functions, thereby "gaining" one derivative via integration. In fact, it turns out that, by a [illegible] ansatz, [illegible] order of accuracy is possible even at smooth local extrema. In one space dimension the ansatz reads

$$r(x) = A + B\log(x + C) + D\log(x + E) \ .$$

The five coefficients are determined from conditions on the average as well as first and second derivatives. By combining two monotone logarithms we allow for one isolated extreme value in the reconstruction such that smooth extrema can be reconstructed with full fifth order of accuracy. The following experiment [7] verifies this capability. Consider the Euler system

$$\begin{pmatrix} \rho \\ \rho u \\ e \end{pmatrix}_t + \begin{pmatrix} \rho u \\ \rho u^2 + p \\ u(e+p) \end{pmatrix}_x = 0 \ ,$$

with pressure $p = (\gamma - 1)\left(e - \rho u^2/2\right)$, $\gamma = 1.4$, and initial data $\rho(0, x) = 1 + 0.2\sin(x)$, $u \equiv 1$, and $p \equiv 1$. The solution to this initial value problem is $\rho(t, x) = 1 + 0.2\sin(x - t)$, $u \equiv 1$, and $p \equiv 1$. We compute an approximation to the solution by a standard finite volume method using the double logarithmic reconstruction (DLR) for the evaluation of the boundary fluxes; for details see section 7. The results are displayed in Figure 1 and Table 1. Full [illegible] of convergence is clearly verified. Note that the governing equation is a [illegible] of conservation laws.

TABLE 1
Estimated rates for the Euler system.

	$N = 640$	320	160	80	40	20
LLR	2.36	2.44	2.57	2.71	3.06	1.08
DLR	5.00	5.00	5.00	4.97	4.88	4.64

In the following a local reconstruction using a single logarithmic ansatz is described first. Then section 3 presents several realizations for higher-order reconstructions. The double logarithmic ansatz is worked out in detail in sections 4 and 5. The complete, hybrid algorithm is described in section 6. Numerical experiments, including convergence and accuracy tests, are found in section 7.

2. Local logarithmic reconstruction. In this section the piecewise reconstruction of an unknown smooth function g using a single logarithmic function is described. The resulting reconstruction method uses data only from the central cell and its nearest neighbors and is therefore called [illegible] (LLR). The grid data are the cell averages and approximations to the lateral derivatives of g.

We consider the computational grid $x_i = ih$, i integer and h a positive number, with cells $C_i = [x_{i-1/2}, x_{i+1/2})$.

The reconstruction is piecewise defined in each cell; therefore we shall consider without restriction a reference cell C_0. The reconstructing function in this cell has the form

$$r_0(x) \sim A + B\log(x + C).$$

2.1. The monotone case. Since the reconstructing function is monotone, we assume for the moment that g is also monotone in C_0. Now, following Marquina [5], we impose three conditions on r_0 to determine the three coefficients A, B, and C. Given v_0 the cell average of g in C_0 and d_1 and d_2 approximations to the left and right derivatives, we require

$$\frac{1}{h}\int_{C_0} r_0(x)dx = v_0, \tag{1}$$

$$r_0'\left(x_0 - \frac{h}{2}\right) = d_1, \tag{2}$$

$$r_0'\left(x_0 + \frac{h}{2}\right) = d_2. \tag{3}$$

To this end define for $x \in C_0$ and a a parameter to be determined

$$\phi_0(x) := -\frac{d_1 h}{a}\log\left[x - x_0 - \frac{h}{2}\left(\frac{2}{a} - 1\right)\right]. \tag{4}$$

By inspection it is observed that the argument of the log function is positive for $a \in (-\infty, 0)$ when $x \in C_0$. Now put

$$r_0(x) := v_0 + \phi_0(x) - \frac{1}{h}\int_{C_0}\phi_0(\xi)d\xi. \tag{5}$$

We immediately see that (5) satisfies the condition (1) of preserved cell average. Further,

$$r_0'(x) = \phi_0'(x) = -\frac{d_1 h}{a\left[x - x_0 - \frac{h}{2}\left(\frac{2}{a} - 1\right)\right]},$$

so $r_0'(x_0 - h/2) = d_1$ and also condition (2) is fulfilled. The parameter a is now used to realize condition (3):

$$r_0'(x_0 + h/2) = -\frac{d_1}{a-1} = d_2 \quad \Rightarrow \quad a = 1 - d_1/d_2.$$

Since g is monotone, $d_1 d_2 > 0$ and therefore $a \in (-\infty, 1)$. Above we observed that the argument of the log function is positive when $a \in (-\infty, 0)$; however for $a \in [0, 1)$ the reconstructing function r_0 is also real and smooth (see Corollary 5.8).

In the finite volume context the point values at the cell boundaries are of particular interest. The LLR approximations to $g\left(x_0 \pm \frac{h}{2}\right)$ are conveniently computed as

$$r_0\left(x_0 \pm \frac{h}{2}\right) = v_0 + d_1 h \eta^{\pm}(a), \tag{6}$$

where

$$\eta^{+}(a) = -\frac{\log(1-a) + a}{a^2}, \tag{7}$$

and

$$\eta^{-}(a) = \frac{(a-1)\log(1-a) - a}{a^2}. \tag{8}$$

The functions $\eta^{\pm}$ have a removable singularity at zero by putting $\eta^{\pm}(0) = \pm\frac{1}{2}$. The function η^{-} has also a removable singularity at $+1$ by setting $\eta^{-}(1) = -1$.

2.2. Preprocessing of nonmonotone data. If g is not monotone in C_0, we replace the approximative derivate with the largest absolute value by the other one multiplied with h^2; see [5]. To avoid division by zero we also make this modification if one of both derivatives is smaller than h^2. In the case that both derivatives are below h^2, the data is essentially constant and the reconstruction should be skipped. Note that this preprocessing of general data results in monotone data $d_1 d_2 > 0$ for the reconstruction in any case. Hereby the parameter $a = 1 - d_1/d_2$ in (5) also transforms into the allowed range $(-\infty, 1)$, resulting in a [illegible]; cf. Corollary 5.8.

A numerical convergence test with the Euler system as governing equations has been computed using the LLR in connection with Van Leer flux splitting; see Figure 1. The initial data and the smooth solution of the problem are given in the introduction. For further details see section 7.

[illegible] 2.1 (local variation). The [illegible] of a monotone function f in a cell C_i is given by $LV_i(f) = |f(x_i + h/2) - f(x_i - h/2)|$. In the case of a discontinuity within the cell, i.e., $d_1 = \mathcal{O}(1/h)$ and $d_2 = \mathcal{O}(1)$ (or vice versa), the local variation of LLR is $LV_0(r_0) = \mathcal{O}(h|\log h|)$. This variation is smaller compared to the hyperbolic reconstruction (LHR) in [5] for which $LV_0 = \mathcal{O}(\sqrt{h})$. This is the reason why hyperbolic methods need additional smoothing before reconstruction. Marquina's local, harmonic, hyperbolic reconstruction (LHHR) indeed has sufficiently small variation of $\mathcal{O}(h)$; see [5].

[illegible] 2.2 (limiters). As in Marquina's hyperbolic method (LHR), no limiter is used in the reconstruction.

3. Higher order: The reconstruction principle. We are interested in higher-order [illegible] in space. The reconstruction is carried out at a certain time, and therefore we omit in this section the time dependence of the function u to be reconstructed. Since we are dealing with finite volume schemes the available information about the unknown function u is its cell averages:

$$u_i = \frac{1}{h}\int_{C_i} u(x)dx. \tag{9}$$

The goal is to find a reconstruction $r(x)$ from given cell averages u_i such that in each cell

$$(r-u)(x) = \mathcal{O}(h^p), \quad x \in C_i.$$

To this end the following observation, which is easily verified by Taylor expansion, will be useful.

OBSERVATION 3.1. [illegible] $f, g \in C^p[a,b]$ [illegible] $h := b-a$ [illegible] $(f-g)(x) = \mathcal{O}(h^p)$ [illegible] $x \in [a,b]$ [illegible] p [illegible] $x_k \in [a,b]$ $k = 0, \dots, p-1$ [illegible] $(f-g)^{(k)}(x_k) = \mathcal{O}(h^{p-k})$

Now we can verify that LLR is a third-order reconstruction for monotone functions.

LEMMA 3.2 (LLR). [illegible] $f, g \in C^3[a,b]$ [illegible] $h := b-a$ [illegible]

$$\int_a^b f(x)dx = \int_a^b g(x)dx, \tag{10}$$

$$(f-g)'(a) = \mathcal{O}(h^2) = (f-g)'(b); \tag{11}$$

[illegible] $(f-g)(x) = \mathcal{O}(h^3)$ [illegible] $x \in [a,b]$ [illegible]. It is enough to find points satisfying the requirements in Observation 3.1. First, (10) and continuity give that there exists an $x_0 \in (a,b)$ such that $f(x_0) = g(x_0)$. By (11) we have with $x_1 = a$ (or b), $(f-g)'(x_1) = \mathcal{O}(h^2)$. By the mean value theorem (MVT), $(f-g)'(b) - (f-g)'(a) = (f-g)''(x_2)h$ and now (11) implies $(f-g)''(x_2) = \mathcal{O}(h)$. Thus the points are found. □

We can easily add one condition to obtain a fourth-order reconstruction. The extra condition is set on the derivative in the cell center.

LEMMA 3.3. [illegible] $f, g \in C^4[a,b]$ [illegible] $h := b-a$ $c := (b+a)/2$ [illegible]

$$\int_a^b f(x)dx = \int_a^b g(x)dx, \tag{12}$$

$$(f-g)'(a) = \mathcal{O}(h^3) = (f-g)'(b), \tag{13}$$

$$(f-g)'(c) = \mathcal{O}(h^3); \tag{14}$$

[illegible] $(f-g)(x) = \mathcal{O}(h^4)$ [illegible] $x \in [a,b]$

We omit the proof.

The next goal is to extend this reconstruction principle to fifth order of accuracy. It turns out that there are several possibilities. We present three of them.

LEMMA 3.4 (realization 1). Let $f, g \in C^5[a,b]$ and $h := b - a$.

$$\int_a^b f(x)dx = \int_a^b g(x)dx, \tag{15}$$

$$(f-g)'(a) = \mathcal{O}(h^4) = (f-g)'(b), \tag{16}$$

$$(f-g)''(a) = \mathcal{O}(h^3) = (f-g)''(b); \tag{17}$$

then $(f-g)(x) = \mathcal{O}(h^5)$ for all $x \in [a,b]$.

Again, we verify the requirements in Observation 3.1. First, (15) and continuity give that there exists an $x_0 \in (a,b)$ such that $f(x_0) = g(x_0)$. By (16) we have with $x_1 = a$ (or b) $(f-g)'(x_1) = \mathcal{O}(h^4)$. By the MVT, $(f-g)'(b) - (f-g)'(a) = (f-g)''(x_2)h$ and now (16) implies

$$(f-g)''(x_2) = \mathcal{O}(h^3). \tag{18}$$

Again the MVT gives $(f-g)''(x_2) - (f-g)''(a) = (f-g)^{(3)}(x_3)(x_2-a)h$ and by (17) and (18)

$$(f-g)^{(3)}(x_3) = \mathcal{O}(h^2). \tag{19}$$

Another use of the MVT yields $(f-g)''(b) - (f-g)''(x_2) = (f-g)^{(3)}(x_3')(b-x_2)h$ and by (17) and (18)

$$(f-g)^{(3)}(x_3') = \mathcal{O}(h^2). \tag{20}$$

Finally, the MVT implies $(f-g)^{(3)}(x_3') - (f-g)^{(3)}(x_3) = (f-g)^{(4)}(x_4)(x_3'-x_3)h$, and by (19) and (20) $(f-g)^{(4)}(x_4) = \mathcal{O}(h)$. Thus the points are found. □

The second realization sets conditions in the cell center on the benefit of requiring one second derivative less.

LEMMA 3.5 (realization 2). Let $f, g \in C^5[a,b]$ and $h := b - a$, $c := (b+a)/2$.

$$\int_a^b f(x)dx = \int_a^b g(x)dx, \tag{21}$$

$$(f-g)'(a) = \mathcal{O}(h^4) = (f-g)'(b), \tag{22}$$

$$(f-g)'(c) = \mathcal{O}(h^4), \tag{23}$$

$$(f-g)''(c) = \mathcal{O}(h^3); \tag{24}$$

then $(f-g)(x) = \mathcal{O}(h^5)$ for all $x \in [a,b]$.

The proofs of this and also the next lemma follow the lines of the previous one and are therefore omitted.

The third and last realization does not involve requirements on the second derivative at all but sets conditions on the first derivative at four points in the interval of consideration.

LEMMA 3.6 (realization 3). Let $f, g \in C^5[a,b]$ and $h := b - a$, $c := (2a+b)/3$, $d := (2b+a)/3$.

$$\int_a^b f(x)dx = \int_a^b g(x)dx, \tag{25}$$

$$(f-g)'(a) = \mathcal{O}(h^4) = (f-g)'(b), \tag{26}$$

$$(f-g)'(c) = \mathcal{O}(h^4) = (f-g)'(d); \tag{27}$$

$(f-g)(x) = \mathcal{O}(h^5)$ $x \in [a,b]$

Some remarks are appropriate.

3.7 (conservative finite differences). The realizations above all require higher-order approximations to derivatives of the unknown function at some points. However, standard finite difference (fd) formulas cannot be applied since point values of the function are unknown. formulas are computed from cell averages (9); cf. sections 6 and 9.

In the following we shall describe double logarithmic reconstructions based on lateral derivatives, i.e., realization 1.

4. Double logarithmic reconstruction. In this section we describe a reconstruction method where the reconstructing function is up to a constant the sum of two logarithmic functions, hence the name (DLR).

The goal is to develop a low variation reconstruction of order higher than three. Having in mind Remark 2.1, a logarithmic ansatz is a natural candidate. For a fourth-order method, a four-parameter, double logarithmic ansatz based on Lemma 3.3 would be tempting

$$r_0(x) \sim A + B[\log(x+C) + \log(x+D)].$$

However, this ansatz is still monotone. Order reduction at local extrema is therefore inevitable and a significant improvement over LLR cannot be expected. Incorporating one more parameter, thus allowing for a combination of two monotone functions that are possibly of different signs, higher-order reconstruction of smooth extrema is feasible:

$$r_0(x) \sim A + B\log(x+C) + D\log(x+E).$$

Summing up two monotone functions also ensures that not more than one new extremum is introduced. Fifth order of accuracy is realized by adjusting the parameters according to the five order conditions in one of Lemmas 3.4–3.6.

4.1. Construction of the fifth-order DLR. Following the procedure for LLR, we define for $x \in C_0$

$$\phi_0(x) := -\frac{ch}{a}\log\left[x - x_0 - \frac{h}{2}\left(\frac{2}{a} - 1\right)\right] - \frac{dh}{b}\log\left[x - x_0 - \frac{h}{2}\left(\frac{2}{b} - 1\right)\right], \tag{28}$$

where a, b, c, and d are parameters to be determined, and we let

$$r_0(x) := v_0 + \phi_0(x) - \frac{1}{h}\int_{C_0}\phi_0(\xi)d\xi. \tag{29}$$

As for the LLR the question arises if r_0 is well defined in the sense that we obtain a real-valued smooth function. However, for DLR this is not obvious and requires a more careful analysis, which is presented in the next section. Lemma 5.9 states that the reconstruction (29) is a real and smooth function if (i) $a \in \mathbb{C} \setminus \mathbb{R}$, (ii) $a \in (-\infty, 1)$ and $b \in (-\infty, 1)$.

In the following we consider the conditions set in Lemma 3.4 (realization 1 of DLR), that is,

$$\frac{1}{h}\int_{x_0-h/2}^{x_0+h/2} r_0(x)dx = v_0, \tag{30}$$

$$r_0'\left(x_0 - \frac{h}{2}\right) = d_1, \tag{31}$$

$$r_0'\left(x_0 + \frac{h}{2}\right) = d_2, \tag{32}$$

$$r_0''\left(x_0 - \frac{h}{2}\right) = D_1, \tag{33}$$

$$r_0''\left(x_0 + \frac{h}{2}\right) = D_2, \tag{34}$$

where v_0 is the cell average of the unknown function g in C_0 and d_1 and d_2 are fourth-order approximations to the left and right derivatives and D_1 and D_2 are third-order approximations to the left and right second derivatives. We see that (29) preserves the cell average v_0. Now conditions (31)–(34) lead to the following equations for the parameters a, b, c, and d:

$$c + d = d_1, \tag{35}$$

$$-\frac{d(a-1) + c(b-1)}{(a-1)(b-1)} = d_2, \tag{36}$$

$$\frac{ca + db}{h} = D_1, \tag{37}$$

$$\frac{db(a-1)^2 + ca(b-1)^2}{h(a-1)^2(b-1)^2} = D_2. \tag{38}$$

Solving equations (35)–(37) for b, c, and d, putting the solution in (38), and then solving for a yield after some manipulation

$$a = a_1 + a_2, \tag{39}$$

$$b = a_1 - a_2, \tag{40}$$

$$c = d_1/2 + q(a), \tag{41}$$

$$d = d_1/2 - q(a), \tag{42}$$

where

$$\begin{aligned} a_1 &= [D_1 D_2 h^2 + (d_1 D_2 + d_2 D_1)h + 2d_2(d_1 - d_2)]/a_0, \\ a_2 &= \operatorname{sqrt}[D_1^2 D_2^2 h^4 + 2(d_2 D_1^2 D_2 - d_1 D_1 D_2^2)h^3 \\ &\quad + (d_1^2 D_2^2 + 2d_1 d_2 D_1 D_2 + d_2^2 D_1^2)h^2 \\ &\quad + 4(d_1^3 D_2 - d_1^2 d_2 D_2 + d_1 d_2^2 D_1 - d_2^3 D_1)h \\ &\quad + 4d_1 d_2 (d_1 - d_2)^2]/a_0 \end{aligned} \tag{43, 44}$$

with

$$a_0 = 2(d_2(d_1 - d_2) + h d_1 D_2) \tag{45}$$

and q is the function

$$q(z) = \frac{1}{2}\frac{d_1 d_2(1 - z^2) - 2h d_2 D_1(1 - z) + d_1(hD_1 - d_1)}{d_2(z-1)^2 + d_1(2z - 1) - hD_1}. \tag{46}$$

Now when the coefficients are found, assuming $a,b \notin [1, \infty)$, we can in principle put them in (28) and use the reconstructing function (29) to obtain pointwise approximations to g for all $x \in C_0$. It is, however, convenient to compute the DLR

approximations to the lateral function values as

$$r_0\left(x_0+\frac{h}{2}\right)=v_0+ch\eta^+(a)+dh\eta^+(b), \tag{47}$$

$$r_0\left(x_0-\frac{h}{2}\right)=v_0+ch\eta^-(a)+dh\eta^-(b), \tag{48}$$

where the functions $\eta^{\pm}$ are the LLR lateral functions (7) and (8).

4.2. DLR preprocessing. The DLR coefficients (39)–(42) which are obtained from the order conditions (30)–(34) are not always well defined. For example, the denominator of (41) and (42), $q_0 = 2(d_2(a-1)^2 + d_1(2a-1) - hD_1)$, as well as a_0 in (45), the denominator in (43) and (44), might be zero. To avoid division by zero, respecting the order conditions in Lemma 3.4, first- and second-order derivatives are modified as follows: For tol $= \epsilon_{mach}$ we set

if $|a_0|$ <tol **and** $|d_1| > h$
  $D_2 = D_2 + h^3$
else if $|a_0|$ <tol **and** $|d_1| \le h$
  $d_2 = d_2 + h^4$
if $|q_0|$ <tol
  $D_1 = D_1 - h^3$.

Be aware that in contrast to LLR preprocessing (section 2.2), [illegible]. It is just the DLR coefficients (39)–(42) which are well defined, finite numbers after DLR preprocessing. In this case, whether the reconstruction is well defined is analyzed in the next section; see Lemma 5.9. Based on this analysis a hybrid algorithm is built in section 6, using DLR wherever possible and LLR otherwise. Nonexistence of a well-defined DLR is exemplified in section 7.1, Example 3.

For the other realizations (Lemmas 3.5 and 3.6), (37) and (38) are replaced by the relevant ones but the solution, coefficients a, b, c, and d, can be written in the form (39)–(42) with new expressions for a_1, a_2, and q. We list these expressions in the appendix (section 9). Since the reconstructing function (29) is the same, the approximations to the lateral function values are still given by (47) and (48). The aim of the preprocessing is again solely to avoid dividing by zero, so it is straightforward to modify the preprocessing previously stated for these cases.

5. Analysis of the reconstructing functions. In this section we prove that the reconstructing functions in the LLR and DLR are real and smooth for the previously stated values of the parameters.

Let ϕ_0 be the function (28) defined for the DLR,

$$\phi_0(x) = -\frac{ch}{a}\log\left[x-x_0-\frac{h}{2}\left(\frac{2}{a}-1\right)\right] - \frac{dh}{b}\log\left[x-x_0-\frac{h}{2}\left(\frac{2}{b}-1\right)\right],$$

and consider the DLR function (29)

$$r_0(x) = v_0 + \phi_0(x) - \frac{1}{h}\int_{C_0}\phi_0(\xi)d\xi.$$

The coefficients for DLR are given in (39)–(42),

$$a = a_1 + a_2,$$

$$b = a_1 - a_2,$$
$$c = d_1/2 + q(a),$$
$$d = d_1/2 - q(a),$$

with a_1 real, a_2 real or purely imaginary, d_1 real, and q a rational function of a complex variable. In this section we assume preprocessed data; that is, all coefficients are well-defined finite numbers.

Complex coefficients. We consider first the case that a is not real. It is trivial to see the following.

OBSERVATION 5.1. $a \in \mathbb{C} \setminus \mathbb{R} \Rightarrow b = \bar{a}$

Evaluating q at a and b it is equally simple to see the following lemma.

LEMMA 5.2. [illegible] a [illegible] b [illegible] $q(b) = -q(a)$

In the proof of the next lemma we will need the following theorem from complex analysis.

THEOREM 5.3 (reflection principle). [illegible] f [illegible] Ω [illegible] $f(z) = \overline{f(\bar{z})}$ [illegible] $z \in \Omega$.

LEMMA 5.4. [illegible] $a \in \mathbb{C} \setminus \mathbb{R}$ [illegible] $c \in \mathbb{C}$ [illegible] $d = \bar{c}$

[illegible]. The function q is rational and therefore analytic and real on a real interval. From Observation 5.1 and Lemma 5.2 it follows that $q(a) = -q(\bar{a})$. Moreover, by Theorem 5.3 $q(a) = \overline{q(\bar{a})}$, so $q(a) = -\overline{q(a)}$ and therefore $q(a)$ is purely imaginary and the proof is complete. □

LEMMA 5.5. [illegible] $a \in \mathbb{C} \setminus \mathbb{R}$ [illegible] (29) [illegible]

[illegible]. Define $\alpha(x) := x - x_0 - h(2/a - 1)/2$, $\beta(x) := x - x_0 - h(2/b - 1)/2$, $\gamma := -ch/a$, and $\delta := -dh/b$. Now write (28) as

$$\phi_0(x) = \gamma \log(\alpha(x)) + \delta \log(\beta(x)).$$

From Observation 5.1 and Lemma 5.4 it follows that $b = \bar{a}$ and $d = \bar{c}$; therefore $\beta(x) = \bar{\alpha}(x)$ and $\delta = \bar{\gamma}$ for all $x \in C_0$. Let $\gamma := \xi + i\eta$ with ξ and η real. Compute

$$\begin{aligned}\phi_0(x) = \gamma \log(\alpha) + \bar{\gamma} \log(\bar{\alpha}) &= (\xi \log|\alpha| - \eta \arg\alpha) \\ &+ i(\eta \log|\alpha| + \xi \arg\alpha) + (\xi \log|\alpha| - \eta \arg\alpha) \\ &+ i(-\eta \log|\alpha| - \xi \arg\alpha) = 2(\xi \log|\alpha| - \eta \arg\alpha) \in \mathbb{R}.\end{aligned}$$

Since ϕ_0 is real the reconstructing function (29) is real. □

Real coefficients. Consider now the case that a is real.

LEMMA 5.6. [illegible] $\phi(x) = \frac{h}{\lambda} \log\left[x - x_0 - \frac{h}{2}\left(\frac{2}{\lambda} - 1\right)\right]$ [illegible] $\psi(x) := \phi(x) - \frac{1}{h}\int_{C_0} \phi(\xi)d\xi$ [illegible] $x \in C_0$ [illegible] ψ [illegible] $\lambda \in (-\infty, 1)$

[illegible]. Let

$$t(x) := x - x_0 + h/2 - h/\lambda$$

be the argument of the log function. The function ϕ has a singularity for $x \in C_0$ when $t(x) = 0$. Since t is linear in x and

$$\min_{x \in C_0} t(x) = -h/\lambda \quad \text{and} \quad \max_{x \in C_0} t(x) = h - h/\lambda, \tag{49}$$

t has a zero in C_0 for $\lambda \in [1, \infty)$. For $\lambda < 0$ we see that $t > 0$ and therefore ϕ, and hence ψ, is real and smooth for λ negative. Now consider $\lambda \in (0, 1)$. From (49) it

follows that $t(x) < 0$ for $\lambda \in (0,1)$; hence $\phi(x) = \frac{h}{\lambda}(\log|t(x)| + i\pi)$ and

$$\begin{aligned}\frac{\lambda}{h}\psi(x) &= \log|t(x)| + i\pi - \frac{1}{h}\int_{C_0} \log|t(x)| + i\pi dx \\ &= \log|t(x)| - \frac{1}{h}\int_{C_0} \log|t(x)| dx,\end{aligned}$$

so ψ is real and smooth for $\lambda \in (0,1)$. Finally ψ has a removable singularity at $\lambda = 0$ by putting $\psi(x)|_{\lambda=0} = x_0 - x$. □

Now we turn back to the DLR. Observe that if a is real, then b, c, and d are also real. Then the following lemma follows from Lemma 5.6.

LEMMA 5.7. [illegible] $a \in (-\infty, 1)$ [illegible] $b \in (-\infty, 1)$ [illegible] (29) [illegible]

As a simple consequence of the above lemma we get the following corollary.

COROLLARY 5.8 (LLR). [illegible] (5) [illegible] $a \in (-\infty, 1)$ [illegible] 2.2) [illegible]

From Lemmas 5.5 and 5.7 and the observation that the DLR function (29) can have a singularity in C_0 only if a and b are real, the following final result follows.

LEMMA 5.9 (DLR). [illegible] $a \in \mathbb{C} \setminus \mathbb{R}$ [illegible] $a \in (-\infty, 1)$ [illegible] $b \in (-\infty, 1)$ [illegible] (29) [illegible]

6. Logarithmic reconstruction—the algorithm. In this section the previously developed reconstruction techniques are composed into a complete algorithm. This requires two aspects to be handled: First, the reconstruction method has to be well defined, and second, the desired result should be a robust, low variation but high-order approximation of the unknown function.

The above analysis (in section 5) has shown that the fifth-order double logarithmic reconstruction is not always possible with the most general in-data given in terms of cell averages in nearby cells. If the DLR parameters a, b which are determined from the system (35)–(38) happen to be real but greater than one, then the double logarithmic ansatz (29) develops a singularity within the actual cell—this is undesirable (to say the least). In this case the single logarithmic reconstruction LLR is preferred, which—by preprocessing of nonmonotone data (section 2.2)—in any case is a well-defined smooth function. So, if during DLR, either $1 < a \in \mathbb{R}$ or $1 < b \in \mathbb{R}$, then DLR is replaced by preprocessed LLR, achieving the first goal: a well-defined reconstruction. This hybrid algorithm is summarized as follows.

Logarithmic reconstruction. Given cell averages:

1. Determine (sufficiently accurate) first- and second-order lateral derivatives $d_{1,2}$ and $D_{1,2}$, respectively (see below).
2. Determine preprocessed DLR coefficients (sections 4.1 and 4.2).
3. [illegible] (Lemma 5.9), evaluate DLR
   [illegible] evaluate preprocessed LLR (sections 2.1 and 2.2) instead.

The next issue addressed is robustness; i.e., how to construct appropriate approximations to the required derivatives based on cell averages. The selection of stencils affects the robustness of the scheme.

The double logarithmic reconstruction (realization 1) relies on cell averages (30) and discrete approximations to the first and second lateral derivatives (31)–(34). Clearly such numerical derivatives are not unique and the selection of appropriate fd-formulas affects the stencil of the resulting reconstruction. Note that in the finite

volume context, the available data are averages instead of point values. For example, consider cells centered around grid points $x_i = ih$. Based on cell averages

$$f_i = \frac{1}{h}\int_{x_{i-1/2}}^{x_{i+1/2}} f(\xi)d\xi$$

we need to approximate the point value of the derivative $f'(x_{i-1/2})$ on the cell boundary. A backward 3-point fd-formula would look like

$$\frac{\alpha f_{i-3} + \beta f_{i-2} + \gamma f_{i-1}}{h} \approx f'(x_{i-1/2}). \tag{50}$$

In terms of the primitive of f, the averages are expressed as divided differences

$$f_i = \frac{1}{h}\left(F_{i+1/2} - F_{i-1/2}\right),$$

where $F_{i+1/2} = F(x_{i+1/2})$ denotes the point value of the primitive $F' = f$ of f. Now (50) reads

$$\frac{-\alpha F_{i-7/2} + (\alpha-\beta)F_{i-5/2} + (\beta-\gamma)F_{i-3/2} + \gamma F_{i-1/2}}{h^2} \approx F''(x_{i-1/2}).$$

Applying the well-known second-order backward 4-point formula for point values, we find $\alpha = 1$, $\alpha - \beta = 4$, $\beta - \gamma = -5$, and $\gamma = 2$. The resulting conservative backward 3-point formula reads

$$d^-_{i-1/2} = \frac{f_{i-3} - 3f_{i-2} + 2f_{i-1}}{h} = f'(x_{i-1/2}) + \mathcal{O}(h^2). \tag{51}$$

Similarly the conservative central and forward formulas of second order for $f'(x_{i-1/2})$ are

$$d^0_{i-1/2} = \frac{f_i - f_{i-1}}{h}, \tag{52}$$

$$d^+_{i-1/2} = \frac{-2f_i + 3f_{i+1} - f_{i+2}}{h}. \tag{53}$$

Below, conservative second-order formulas for the second derivative $f''(x_{i-1/2})$ are also required:

$$D^-_{i-1/2} = \frac{-3f_{i-4} + 11f_{i-3} - 13f_{i-2} + 5f_{i-1}}{2h^2}, \tag{54}$$

$$D^0_{i-1/2} = \frac{f_{i-2} - f_{i-1} - f_i + f_{i+1}}{2h^2}, \tag{55}$$

$$D^+_{i-1/2} = \frac{5f_i - 13f_{i+1} + 11f_{i+2} - 3f_{i+3}}{2h^2}. \tag{56}$$

In fact, to establish a fifth-order DLR, the lateral first derivatives are required in fourth order of accuracy. In principle, such formulas can be derived via the primitive as well. However, to avoid numerical differentiation across discontinuities, we prefer to establish fourth order by convex combination of the three second-order formulas $d^-_{i-1/2}$, $d^0_{i-1/2}$, and $d^+_{i-1/2}$. Such a convex combination allows one to weight the influence of neighboring cells adaptively depending on the local smoothness of the solution, just as in WENO reconstructions. This will be explained at a generic cell

boundary $x_{i-1/2}$; thus the special index $i-1/2$ can be omitted in what follows. A convex combination of the conservative fd formulas reads

$$d = c^- d^- + c^0 d^0 + c^+ d^+ \tag{57}$$

with nonnegative weights, summing up to one. The optimal weights are found to be

$$c^- = c^+ = 1/24, \quad c^0 = 11/12. \tag{58}$$

They eliminate the second- and third-order terms in the truncation error $d_{i-1/2} - f'(x_{i-1/2})$, thus resulting in a fourth-order formula for the lateral derivatives, as required by Lemma 3.4. In the same way

$$D = c^- D^- + c^0 D^0 + c^+ D^+ \tag{59}$$

is a fourth-order conservative approximation to the second derivative $f''(x_{i-1/2})$ with the optimal weights

$$c^- = c^+ = 1/16, \quad c^0 = 7/8. \tag{60}$$

In fact, the reconstruction in Lemma 3.4 requires only third order of accuracy for this lateral second derivative. However, we found it convenient to use a three-term convex combination as for the first derivative. The robustness of the method improves by adapting the weights in both formulas (57) and (59) to the local smoothness of the solution. In this way, numerical differentiation across discontinuities is avoided. This concept calls for a [illegible]. In all our numerical experiments we use

$$s^* = (hd^*)^2 + (h^2 D^*)^2, \tag{61}$$

where * may be one of the superscripts –, 0, or +. The scaling with h is to make $s^* = \mathcal{O}(1)$ when a discontinuity is present. Similarly as in WENO reconstructions, the weights may be adapted by the sensor via

$$w^* = \frac{c^* \alpha^*}{c^- \alpha^- + c^0 \alpha^0 + c^+ \alpha^+}, \quad \alpha^* = \frac{h^2}{\epsilon + s^*}, \tag{62}$$

with $\epsilon \sim 10^{-8}$ in order to avoid division by zero. The resulting conservative fd approximations are

$$\delta = w^- \delta^- + w^0 \delta^0 + w^+ \delta^+, \tag{63}$$

where δ stands for discrete first- or second-order derivatives d or D, respectively. Note that, ideally, in smooth regions the weights satisfy $w^* = c^* + \mathcal{O}(h^2)$, implying formula (63) is fourth-order accurate. For the first derivative this can be seen by noticing that $d^* = f' + e^* + \mathcal{O}(h^3)$, where $e^* = \mathcal{O}(h^2)$. Consider then $\sum (w^* - c^*) d^* = f' \sum (w^* - c^*) + \sum (w^* - c^*) e^*$ and use that $\sum c^* = \sum w^* = 1$.

We demonstrate the behavior of the weights on the function proposed in [10] with two discontinuities in the first derivative:

$$u(x) = \begin{cases} \sin\left(\pi \frac{x+0.6}{1.2}\right), & |x| \le 0.6, \\ 0, & |x| > 0.6. \end{cases} \tag{64}$$

The weights w^0 and w^+ computed on a 40-point grid on $[-1, 1]$ are displayed in Figure 2. We observe that discrepancy from the optimal weights occurs for at most

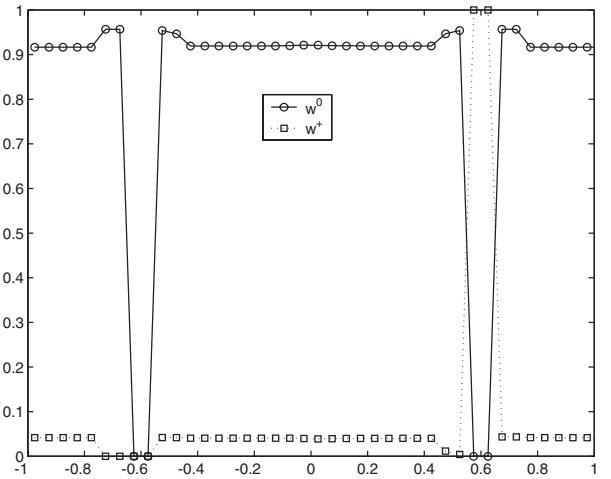

FIG. 2. *Weights for a function with corners.*

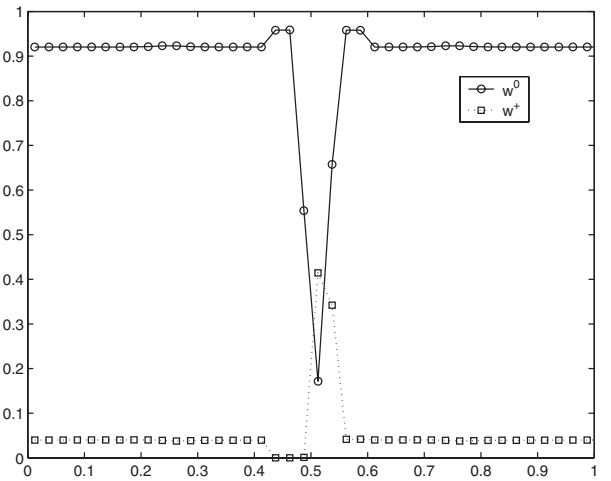

FIG. 3. *Weights for a function with jump discontinuity.*

three points next to the corners. The computations in [10] show that this is one point more compared to the Jiang–Shu WENO5 and two points more than the power ENO method developed there. The weights (62), however, have calmer behavior around the extrema at $x = 0$ than the weights for the above-mentioned methods.

Next we test the performance of the smoothness indicator on the function suggested in [4] with a jump discontinuity at zero:

$$u(x) = \begin{cases} \sin(2\pi x), & 0 \le x \le 0.5, \\ 1 - \sin(2\pi x), & 0.5 < x \le 1. \end{cases} \tag{65}$$

Depicted in Figure 3 are the weights w^0 and w^+ computed using 40 points. We note that the weight w^0 has not assumed the value zero at the discontinuity; increasing the number of points makes the selection more digital, showing that the indicator is not in its asymptotic regime with this coarse grid. As in the previous example we

note the calm behavior at the smooth local extrema.

7. Numerical results. In this section numerical experiments with the local logarithmic and the double logarithmic reconstructions are presented. We use the third-order strong stability-preserving (SSP) Runge–Kutta [1] time integrator in all simulations. For all DLR approximations we set $\epsilon = 10^{-8}$ in (62) and the weights w^* are adapted componentwise.

7.1. Convergence and accuracy tests.

1. A convergence test. We test the rate of convergence for the DLR with a as the governing equation. Consider the Euler system

$$u_t + f(u)_x = 0$$

with

$$u = (\rho, \rho v, E), \quad f(u) = (\rho v, \rho v^2 + p, v(E + p)),$$

and

$$p = (\gamma - 1)(e - \rho u^2/2), \quad \gamma = 1.4.$$

With initial data $\rho(0, x) = 1 + 0.2\sin(x)$, $v \equiv 1$, and $p \equiv 1$ the Euler system has the solution $\rho(t, x) = 1 + 0.2\sin(x - t)$, $v \equiv 1$, and $p \equiv 1$ [7]. We compute approximations to the solution at $t = 1$, on the interval $-\pi \leq x \leq \pi$ with periodic boundary conditions, by double logarithmic reconstruction of the conserved variables in the Van Leer upwind scheme. To reach fifth order in time we take $\Delta t \sim \Delta x^{5/3}$. The error in density is displayed in Table 2 (see also Figure 1 in the introduction). Full of convergence is clearly verified.

2. Linear advection. We solve the periodic advection problem

$$u_t + u_x = 0, \quad -\pi < x < \pi,$$

with initial data $u(x, 0) = \sin^4(x)$ and compute the errors at $t = 1$. The results, presented in Table 3, show that, in contrast to ENO schemes, which have problems reaching their designed order for this initial condition [11], full order of convergence is reached.

3. Linear advection. The equation

$$u_t + u_x = 0, \quad -1 < x < 1,$$

is solved with periodic boundary condition and initial data as proposed in [4]. The signal consists of a smooth and narrow combination of Gaussians, a square wave, a

triangle wave, and a half ellipse. We refer the reader to [4] for the details. We compute LLR and DLR approximations with 200 cells using CFL $= 0.6$ and examine the results at $t = 8$. In Figure 4 we clearly see the improved quality for DLR compared to LLR. Comparing the DLR approximation to the fifth-order WENO approximation in [4], we note that the first peak is not so well resolved for DLR but that DLR improves over WENO in the resolution of corners.

To get an idea of the existence of the double logarithmic approximating function, which is hard to tell from (39)–(40) and (43)–(45) (especially in the limit $h \to 0$), we compute the DLR coefficients for the signal above and check whether the coefficients a or b are in the allowable range or not. In Figure 5 the result using one million points is displayed; cells where DLR fails to exist are marked. We observe that the DLR exists in this example, even for the extremely small cell size, wherever the second derivatives are nonzero and bounded. For the linear parts DLR may fail to exist, as expected when inspecting a_0 in (45) with data $d_1 = d_2$ and $D_2 = 0$. However, in this case it is overly ambitious to approximate the linear function with DLR since this is accurately done with the then active LLR; cf. Lemma 5.6 or the functions (7)–(8) and the removable singularity at zero.

4 (Buckley–Leverett). The nonlinear and nonconvex scalar Buckley–Leverett problem

$$u_t + \left(\frac{4u^2}{4u^2 + (1-u)^2} \right)_x = 0$$

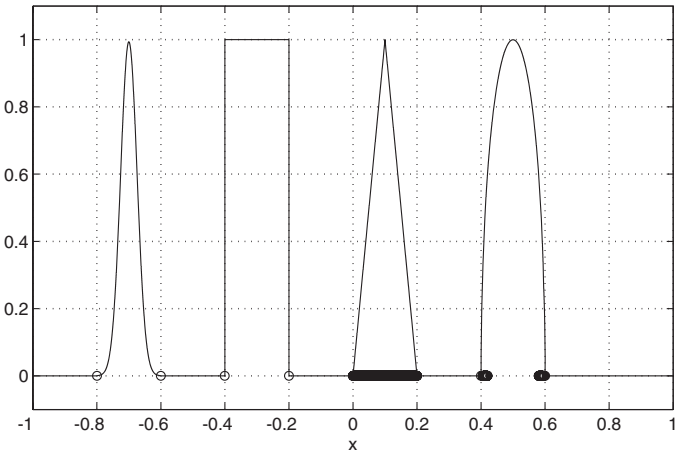

FIG. 5. *Existence of DLR. "o" marks nonexistence.*

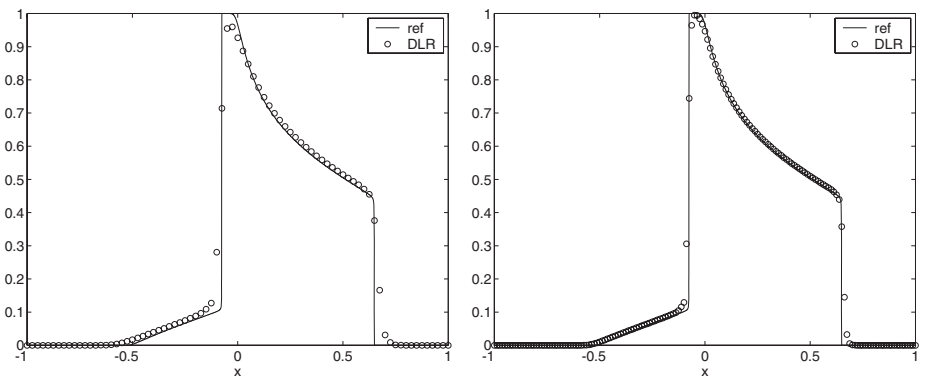

FIG. 6. *Buckley–Leverett. Left:* 80 *cells. Right:* 160 *cells.*

is solved using a relaxation method [8] with double logarithmic reconstruction of the characteristic variables of the relaxed system. The initial data is $u = 1$ for $-\frac{1}{2} \le x \le 0$ and $u = 0$ elsewhere. Approximations using 80 and 160 cells with CFL $= 0.7$ are shown in Figure 6. We conclude that it converges to the correct entropy solution.

7.2. Euler system.

1 (Shu–Osher shock-acoustic problem). In this test problem proposed by Shu and Osher [12] a supersonic shock wave moves into a smooth acoustic entropy wave. The initial data are

$$u(x,0) = (\rho, v, p) = \begin{cases} (3.857143, 2.629369, 10.333333), & -5 \le x < -5, \\ (1 + 0.2\sin(5x), 0, 1), & -4 \le x \le 5. \end{cases}$$

Behind the shock the acoustic wave is amplified. We run the experiment with componentwise reconstruction of the conserved variables in connection with Van Leer flux splitting. In Figure 7 DLR and LLR approximations to the shock-acoustic problem are displayed. The simulations are done with 400 cells using CFL $= 0.8$ in both cases. The benefit of reconstruction of smooth extrema is quite obvious in this test problem and we see that the DLR approximation resolves the waves behind the shock well.

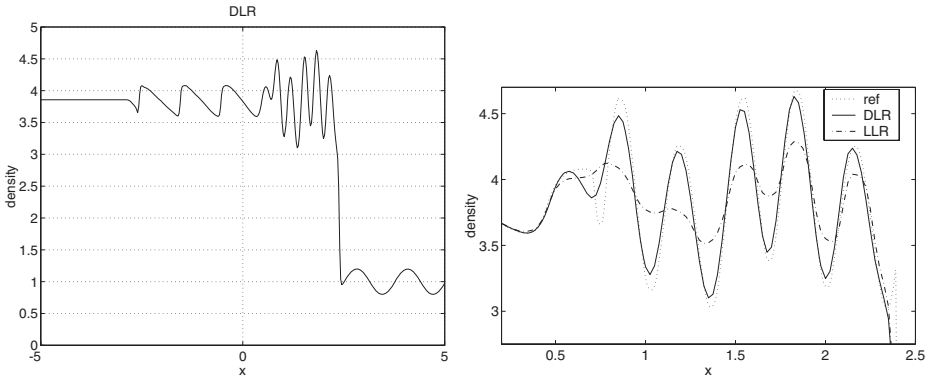

FIG. 7. *Shu–Osher shock-acoustic problem.*

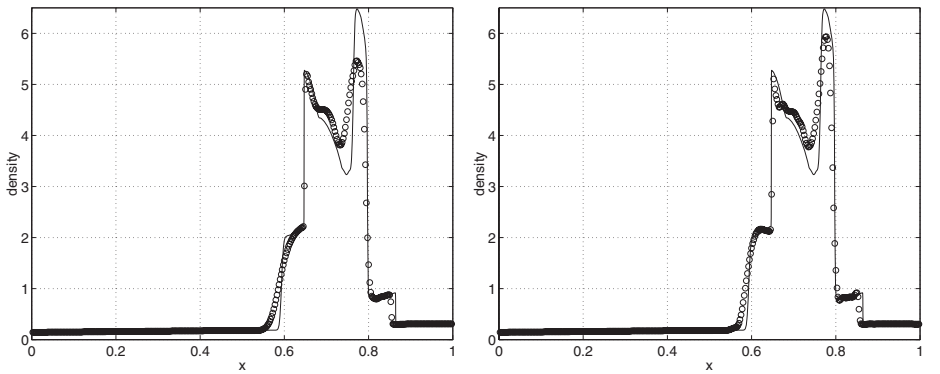

FIG. 8. *Shock-blast interaction. Left: LLR. Right: DLR.*

, , 2 (two interacting blast waves). This experiment was proposed as a benchmark in [14]. The initial data are

$$u(x,0) = (\rho, v, p) = \begin{cases} (1, 0, 10^3), & 0 \le x < 0.1, \\ (1, 0, 10^{-2}), & 0.1 \le x < 0.9, \\ (1, 0, 10^2), & 0.9 \le x \le 1. \end{cases}$$

Reflective boundary conditions are used. Numerical solutions on a 400-cell grid are computed with LLR and DLR applied to the Van Leer fluxes under CFL = 0.6. In Figure 8 the approximations at $t = 0.038$ are displayed. It is observed that the local extrema, especially the peak, are better resolved using the DLR but that there are also small oscillations present, indicating that the DLR introduces rather too much variation in this context. The LHR leads to a negative density in this test example. The reference solution, however, is obtained by the harmonic LHHR using 3200 cells.

We close this section by presenting some preliminary results in two space dimensions. Both experiments presented here are flows in rectangular domains simulated on Cartesian meshes. In this situation the one-dimensional reconstructions can be applied directionwise.

, , 3 (two-dimensional Riemann problem). This is an example from gas dynamics, Configuration F in [9]. In contrast to one-dimensional Riemann problems,

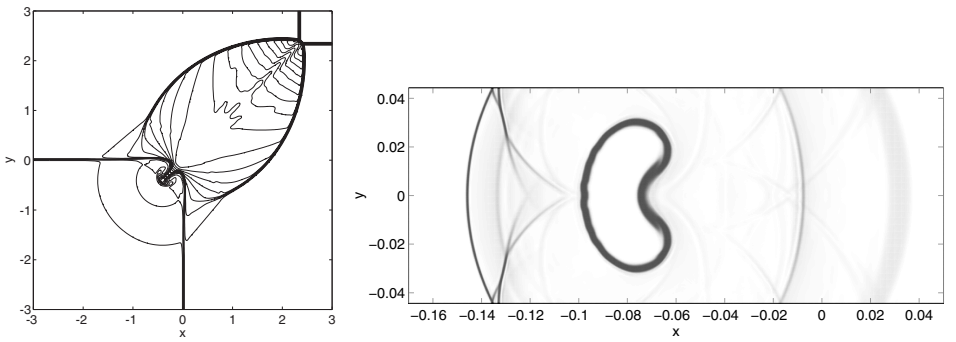

FIG. 9. *Left: Two-dimensional Euler Riemann problem. Right: Shock-bubble interaction.*

the density contours presented in Figure 9 develop some quite complex structures, demanding higher-order methods. For this simulation a locally relaxed method [8] with artificial compression on a 400×400 mesh is used. The LLR is applied on the characteristic variables of the relaxation approximation, as described in [8]. For easy comparison the contour levels are chosen as in [9].

' . ,' 4 (a two component shock-bubble interaction). The initial configuration is an air-helium bubble with a 1.22 Mach shock situated to the right of it [2]. In Figure 9 a locally relaxed LLR approximation at $t = 260\,\mu$s using 1600×400 cells is shown; cf. [3]. By comparing certain time-averaged velocities this simulation shows good agreement with the experimental study in [2] and the numerical results found in [6].

8. Summary and comments. In this paper a monotone third-order LLR and a fifth-order reconstruction DLR were developed, inspired by the LHR by Marquina. The LLR has a smaller local variation than the LHR and is therefore more robust; see the shock-blast experiment (Example 2, section 7.2). Marquina's harmonic version of LHR, the LHHR, is locally TV-bounded and it produces good results; as with LLR, corners are especially well resolved.

The main achievement is, however, that logarithmic reconstructions can be extended to fifth order of accuracy. The DLR based on a WENO-type stencil is a fifth-order reconstruction, even at local extrema. The choice of the smoothness indicator is, of course, essential. Despite the simplicity of the current indicator the numerical results were of high quality, but there is room for improvement on the sensor.

To construct a fifth-order accurate reconstruction using the minimal 5-point stencil one can consider a hybrid version of DLR and LLR. Then (central) conservative fds of high order are needed. Examples are realization 2 with (66)–(68) and realization 3 with (69)–(71). For this hybrid scheme a well-functioning switch criterion is needed; the necessary (problem-dependent) threshold value associated with a hybrid scheme on a fixed stencil will of course be a drawback.

9. Appendix. Technical details.

9.1. Conservative fd-formulas. Realization 2:

$$f'(x_{i-1/2}) = \frac{-f_{i+1} + 15f_i - 15f_{i-1} + f_{i-2}}{12h} + \mathcal{O}(h^4), \tag{66}$$

$$f'(x_i) = \frac{-5f_{i+2} + 34f_{i+1} - 34f_{i-1} + 5f_{i-2}}{48h} + \mathcal{O}(h^4), \tag{67}$$

$$f''(x_i) = \frac{-f_{i+2} + 12f_{i+1} - 22f_i + 12f_{i-1} - f_{i-2}}{8h^2} + \mathcal{O}(h^4). \tag{68}$$

Realization 3:

$$f'(x_{i-1/2}) = \frac{-f_{i+1} + 15f_i - 15f_{i-1} + f_{i-2}}{12h} + \mathcal{O}(h^4), \tag{69}$$

$$f'(x_{i-1/6}) = \frac{-25f_{i+2} + 145f_{i+1} + 147f_i - 305f_{i-1} + 38f_{i-2}}{324h} + \mathcal{O}(h^4), \tag{70}$$

$$f'(x_{i+1/6}) = \frac{-38f_{i+2} + 305f_{i+1} - 147f_i - 145f_{i-1} + 25f_{i-2}}{324h} + \mathcal{O}(h^4). \tag{71}$$

9.2. DLR coefficients.

9.2.1. Realization 2. Denote by d_0 and D_0 the approximation to middle derivative and the middle second derivative, respectively. Then

$$\begin{aligned} a_1 &= [(3d_2 - d_1)D_0h + 8d_0^2 - (6d_1 + 10d_2)d_0 + 8d_1d_2]/a_0, \\ a_2 &= [D_0^2(d_1 + d_2)^2h^2 + 4D_0(d_2 - d_1)(-3d_1d_0 + 4d_1d_2 - 3d_2d_0)h \\ &\quad - 32(d_1 + d_2)d_0^3 + 12(10d_1d_2 + 3d_1^2 + 3d_2^2)d_0^2 \\ &\quad - 96(d_1^2d_2 + d_2^2d_1)d_0 + 64d_1^2d_2^2]^{1/2}/a_0 \end{aligned} \tag{72, 73}$$

with

$$a_0 = 2(2d_0(d_2 - d_0) - D_0hd_2), \tag{74}$$

and q is the function

$$\begin{aligned} q(z) &= \frac{1}{2}\frac{(2d_2d_0 - 2d_1d_2 + d_1d_0)z^2 + 2(4d_1d_2 - d_1d_0 - 3d_2d_0)z}{d_0(z-2)^2 - 2d_2(z-1)^2 - 2d_1} \\ &\quad + \frac{d_1^2 - 3d_1d_2 + 2d_2d_0}{d_0(z-2)^2 - 2d_2(z-1)^2 - 2d_1}. \end{aligned} \tag{75}$$

9.2.2. Realization 3. Denote by d_3 the conservative fd-approximation to $f'(x_{i-1/6})$ and by d_4 the approximation to $f'(x_{i+1/6})$. Then

$$\begin{aligned} a_1 &= [(-9d_2 + 8d_4 - d_3)d_1 + (16d_3 - 5d_4)d_2 - 9d_4d_3]/a_0, \\ a_2 &= [(81d_2^2 + 18(-8d_4 + d_3)d_2 + 16d_4(4d_4 - d_3) + d_3^2)d_1^2 \\ &\quad + (18(d_4 - 8d_3)d_2^2 + 4(4(d_3^2 + d_4^2) + 35d_4d_3)d_2 - 6d_3d_4(d_3 + 8d_4))d_1 \\ &\quad + (-16d_4d_3 + d_4^2 + 64d_3^2)d_2^2 - 6d_3d_4(8d_3 + d_4)d_2 + 9d_4^2d_3^2]^{1/2}/a_0 \end{aligned} \tag{76, 77}$$

with

$$a_0 = 4[(2d_3 - d_4)d_2 - d_4d_3], \tag{78}$$

and q is the function

$$\begin{aligned} q(z) &= \frac{1}{2}\frac{(3d_1d_2 - d_1d_3 - 4d_2d_3)z^2 + 2(-9d_1d_2 + d_1d_3 + 8d_2d_3)z}{(3d_2 - d_3)z^2 + 6(d_3 - d_2)z + 3(d_2 - 3d_3 + 2d_1)} \\ &\quad + \frac{1}{2}\frac{3(-2d_1^2 + (d_3 + 5d_2)d_1 - 4d_2d_3)}{(3d_2 - d_3)z^2 + 6(d_3 - d_2)z + 3(d_2 - 3d_3 + 2d_1)}. \end{aligned} \tag{79}$$

Acknowledgments. We thank the referees for several useful suggestions.

A SEMI-LAGRANGIAN APPROACH FOR AMERICAN ASIAN OPTIONS UNDER JUMP DIFFUSION*

Y. D'HALLUIN†, P. A. FORSYTH†, AND G. LABAHN†

Abstract. A semi-Lagrangian method is presented to price continuously observed fixed strike Asian options. At each timestep a set of one-dimensional partial integrodifferential equations (PIDEs) is solved and the solution of each PIDE is updated using semi-Lagrangian timestepping. Crank–Nicolson and second-order backward differencing timestepping schemes are studied. Monotonicity and stability results are derived. With low volatility values, it is observed that the nonsmoothness at the strike in the payoff affects the convergence rate; a subquadratic convergence rate is observed.

Key words. continuously observed Asian option, semi-Lagrangian, American option, jump diffusion, implicit discretization

DOI. 10.1137/030602630

1. Introduction.

An Asian option gives the holder a payoff that depends on the average price of the underlying asset over a specified period of time [12]. Asian-style derivatives have a wide variety of applications in equity, energy, interest rate, and insurance markets. These options tend to be less expensive than vanilla options (since the volatility of the average price is less than the price itself) and average prices over a period of time are far more difficult to manipulate for illiquid commodities. For example, airline companies are certainly more interested in buying oil based on its average price instead of its spot price. For a historical review of Asian options we refer the reader to [11].

The price of an Asian option at any time is a function of both the underlying asset at that time and the average of the underlying prices up to that time. As such these options are considered path-dependent. In practice, Asian option contracts typically specify that the average is monitored discretely. A typical situation would be to base the average on the daily closing price. If daily averaging is used, then for typical market parameters, for options with expiry times more than three months, we can consider these options as being continuously monitored, for all practical purposes. In addition, if we need to price long-term Asian options (for example, greater than one year), then using timesteps of one day (which would be required in a discrete observation model [51]) would clearly be computationally wasteful. Consequently, in this paper we focus on continuously observed Asian options. For details on numerical methods for discretely observed Asian options, we refer the reader to [17, 16, 51, 24].

In this paper we are interested in the pricing of Asian options with various general payoff conditions (for example, American style, asset-dependent barriers or volatility). When the underlying asset follows a standard Brownian-motion stochastic process then the price of an Asian option can be determined by solving a two-dimensional PDE. In some special cases (e.g., constant volatility, no barrier features, and a float-

†School of Computer Science, University of Waterloo, Waterloo, ON, Canada N2L 3G1 (ydhallui@uwaterloo.ca, paforsyt@uwaterloo.ca, glabahn@uwaterloo.ca).

ing strike contract) this problem can be reduced to a one-dimensional PDE [4]. In addition, for either floating or fixed strike, but not American style or asset-dependent features (e.g., volatility a function of asset price), a one-dimensional PDE can also be derived [45]. However, in the general case which we are interested in, the two-dimensional PDE cannot be reduced to one dimension.

The two-dimensional PDE that appears in our general case of the Asian option pricing problem has no diffusion in one of the coordinate directions and as such is well known to be difficult to solve numerically. In [50, 49], a flux limiter was used to retain accuracy while preventing oscillations. In [31], the first-order hyperbolic term was discretized using a first-order upwind type method, resulting in at most first-order accuracy. A related approach based on a combination of a WENO discretization and grid stretching was used for Asian options in [36]. In [37], a semi-Lagrangian method was used to discretize the hyperbolic term in the average direction. Semi-Lagrangian schemes were first introduced in [20, 39] for atmospheric and weather numerical predictions. These are time-marching schemes that integrate convection-diffusion equations by tracing backward in time the position of the flow. These schemes are used to reduce numerical problems raised by convection dominated equations. In principle, provided an appropriate time discretization is used, and a high enough order of interpolation is used to recover values at the feet of the characteristic curves [22, 1, 10], then this method is capable of greater than first-order convergence as the grid and timestep size is reduced.

In this paper, we will explore the use of a semi-Lagrangian method for pricing Asian options. The semi-Lagrangian method has many advantages in our case. For example we are able to easily solve the pricing problem in the more general context of a jump diffusion stochastic processes, and contracts with American early exercise features. Jump diffusion models were introduced in the option valuation context in [32]. They are important because of the increasing empirical evidence that the usual assumption of geometric Brownian motion should be augmented by discontinuous jump processes [21].

We make no assumptions regarding the contract or the form of the deterministic volatility function. We remark that although we focus exclusively on Asian options in this paper, similar PDEs (no diffusion in one of the space-like directions) occur in certain interest rate models [43] and employee reload options with various constraints [9]. Hence the methods developed here will be applicable to these cases as well.

The main results in this paper are the following.

- We demonstrate that a semi-Lagrangian method can be used to price continuously observed American Asian options under jump diffusion processes. The implementation suggested here reduces this problem to solving a decoupled set of one-dimensional nonlinear discrete partial integrodifferential equations (PIDEs) at each timestep. This makes implementation of this method very straightforward in a software library which is capable of pricing discretely observed path-dependent options [51]. In the general case, a numerical method must be used to integrate the characteristic equation in a semi-Lagrangian method. However, in the case of Asian options, the characteristic equation can be solved analytically, which makes implementation very straightforward.
- We show that in the fully implicit case, the semi-Lagrangian method is algebraically identical to a standard numerical method for pricing discretely observed Asian options, if the observation interval is equal to the discrete timestep. Since lattice methods [46] can be regarded as explicit finite

difference methods, it follows that the usual binomial forest method for Asian options [27] can also be regarded as an explicit semi-Lagrangian method.

- Since the discretized problem at each timestep reduces to a set of decoupled one-dimensional PIDEs, we can make use of the techniques developed in [23, 18, 19] to prove certain properties of the discrete scheme, including convergence of the iterative method used to solve the implicit discrete equations. In the fully implicit case, it is straightforward to prove l_∞ stability and monotonicity, which are important properties of discrete schemes for option pricing [5, 40, 15, 13].

In addition to the above contributions, we also include experimental computations which indicate that, even if second-order timestepping methods are used, observed convergence as the mesh and timestep sizes are refined occurs at a subsecond-order rate. The problem can be traced to the nonsmoothness of the payoff function.

2. Mathematical model. In this section we give the mathematical model for options with jump diffusion processes. We do this for both European and American options. If the underlying asset follows a jump diffusion process, the usual portfolio hedging arguments cannot be used. As such, we will also present a brief discussion of various strategies for hedging jump risk.

Let S represent the underlying stock price. We restrict attention in the following to finite activity processes, that is, we assume that the probability density of a jump occurring with a given jump size, in some interval $[t, t+dt]$ is always finite [14]. The potential stock paths followed by the stock can be modeled by a stochastic differential equation given by

$$\frac{dS}{S} = (\xi - \kappa\lambda)dt + \sigma dZ + (\eta - 1)dq, \tag{2.1}$$

where

ξ is the drift rate,

dq is the independent Poisson process $= \begin{cases} 0 & \text{with probability } 1 - \lambda dt, \\ 1 & \text{with probability } \lambda dt, \end{cases}$

λ is the mean arrival time of the Poisson process,

$\eta - 1$ is an impulse function producing a jump from S to $S\eta$,

σ is the volatility,

dZ is an increment of the standard Gauss–Wiener process,

κ is $E[\eta - 1]$, where $E[\cdot]$ is the expectation operator.

When the average is monitored continuously [7, 46, 24], the arithmetic average A is defined as

$$A = \frac{\int_0^t S(u)du}{t} \quad \text{with} \quad dA = \frac{(S - A)}{t}dt. \tag{2.2}$$

2.1. The PIDE for Asian options. Using standard arguments [7], the value of an option depending on S, (2.1), and A, (2.2), and assuming no jumps (that is, $\lambda = 0$) is given by

$$V_t + \frac{1}{2}\sigma^2 S^2 V_{SS} + \frac{(S - A)}{t}V_A + rSV_S - rV = 0, \tag{2.3}$$

where r is the continuously compounded risk-free interest rate. Since we are solving backward in time from the expiration time $t = T$ to the present time $t = 0$, (2.3) becomes

$$V_\tau = \frac{1}{2}\sigma^2 S^2 V_{SS} + \frac{(S-A)}{T-\tau}V_A + rSV_S - rV, \tag{2.4}$$

where $\tau = T - t$. It is important to note that (2.4) has no diffusion term in the A direction and this is the source of many numerical difficulties [50].

Extending (2.4) to the case of jumps gives

$$V_\tau = \frac{(S-A)}{T-\tau}V_A + \frac{1}{2}\sigma^2 S^2 V_{SS} + (r - \lambda\kappa)SV_S - rV + \left(\lambda \int_0^\infty V(S\eta)g(\eta)d\eta - \lambda V\right), \tag{2.5}$$

where

$$\begin{aligned} &g(\eta) \quad \text{is the probability density function of the jump amplitude } \eta, \\ &\text{thus for all } \eta, g(\eta) \geq 0 \text{ and } \int_0^\infty g(\eta)d\eta = 1. \end{aligned} \tag{2.6}$$

As a specific example, if

$$g(\eta) = \frac{e^{\left(-\frac{(\log(\eta)-\mu)^2}{2\gamma^2}\right)}}{\sqrt{2\pi}\gamma\eta}, \tag{2.7}$$

the probability density function suggested by [32, 44], then its expectation is given by $E[\eta] = \exp(\mu + \gamma^2/2)$. This means that the expected relative change in the stock price is given by $\kappa = E[\eta - 1] = \exp(\mu + \gamma^2/2) - 1$.

For brevity, the details of the derivation of (2.5) have been omitted (see [3, 32, 46]). In general, it is not possible to construct a hedging portfolio which eliminates jump risk. However, by adding options to the hedging portfolio, a hedging strategy can be constructed which minimizes jump risk [3]. If (2.5) is calibrated to market prices, then the parameters so obtained should be regarded as risk-adjusted [30], not historical.

If we define

$$\mathcal{H}V \equiv V_\tau - \left[\frac{(S-A)}{T-\tau}V_A + \frac{\sigma^2 S^2}{2}V_{SS} + (r - \lambda\kappa)SV_S - (r+\lambda)V + \lambda\int_0^\infty V(S\eta)g(\eta)d\eta\right] \tag{2.8}$$

and if $V^*(S, A)$ is the payoff, then the American option pricing problem can be stated as [38]

$$\min(\mathcal{H}V; V - V^*) = 0. \tag{2.9}$$

2.2. Boundary conditions for our PIDE. In order to completely specify our problem we still need to give boundary conditions for our American Asian option pricing PIDE. For the terminal boundary conditions, a number of common payoffs for pricing different types of Asian securities can be used. Typical examples include

- fixed strike call: $V(S, A, \tau = 0) = \max(A - K, 0.0)$,
- fixed strike put: $V(S, A, \tau = 0) = \max(K - A, 0.0)$.

Although the original domain is $0 \leq S < \infty$, $0 \leq A < \infty$, for computational purposes we make the typical assumption of using a finite computational domain $[0, S_{max}] \times [0, A_{max}]$, with $A_{max} = S_{max}$. A discussion of the errors involved in using a finite computational domain (the localization error) for the specific case of option pricing PIDEs is discussed in [15]. However, as pointed out in [15, 13], unlike the usual option pricing PDE case, it is necessary to approximate the solution outside the computational domain $S > S_{max}$ in order that the integral in (2.5) is well defined. The results in [15] suggest that the error in misspecification of the boundary condition at $S = S_{max}$ (for values of S of practical interest) can be made arbitrarily small by making S_{max} (and hence $A_{max} = S_{max}$) sufficiently large. This will be verified in some numerical tests in section 8.

In the case of Asian options without jumps, (2.4), Meyer [33] provides an extensive discussion of the boundary conditions. Using the results in [35], Meyer concludes that no boundary conditions are required at $S = 0$, $A = 0$, $A = A_{max}$. Intuitively, this is because the PDE degenerates on the boundary in such a way that either the PDE becomes an ODE, or the resulting degenerate parabolic PDE has a normal hyperbolic term with outgoing characteristics. Note that rigorous arguments justifying this result can be deduced from [35].

We now turn our attention to the complete PIDE with a nonzero jump term (2.5). We note that the jump integral term contains no A dependence and so consequently, we can simply solve the PIDE along the boundaries $A = A_{max}$, $A = 0$ as in the no-jump case. In this case, the [illegible] for the PIDE is simply the continuous limit of the PIDE as $A \to 0$, $A \to A_{max}$, from points interior to the computational domain.

Taking the limit of the PIDE (2.5) as $S \to 0$, we obtain

$$\lim_{S \to 0} \mathcal{H}V = V_\tau - \left[\frac{-A}{T - \tau} V_A - rV \right]. \tag{2.10}$$

Note that the above limit is obtained by formally interchanging the limit and the integral in (2.5). Equation (2.10) is, of course, the same limit as in the PDE (no-jump) case, since the integral terms disappear as $S \to 0$. Again, in this case, the boundary condition is simply the continuous limit of the PIDE as $S \to 0$. We will develop consistent, stable, and monotone discrete schemes which do not require any data outside the computational domain at $S = 0$, and hence satisfaction of the boundary condition as $S = 0$ is ensured (see the discussion of viscosity solutions in subsection 2.3).

For the boundary condition as $S \to \infty$ we need to deal with two major issues. The first problem is that there is no obvious Dirichlet-type condition which can be imposed for S large. The second issue concerns the fact that on any finite domain $[0, S_{max}]$, the integral term appears to require information from outside the computational domain.

If we make the common assumption that $V_{SS} \to 0$ as $S \to \infty$ [26], then this implies that

$$V \simeq f(A, \tau)S + g(A, \tau) \tag{2.11}$$

as $S \to \infty$ which then means that (2.8) becomes

$$\mathcal{H}V \simeq V_\tau - \left(\frac{S - A}{T - \tau} V_A + rSV_S - rV \right); \quad S \to \infty. \tag{2.12}$$

For $A \gg K$ and $S \to \infty$, we can approximate the solution to $\mathcal{H}V = 0$ by a linear function in A and S

$$V \simeq H_1(\tau)A + H_2(\tau)S + H_3(\tau) \tag{2.13}$$

so that

$$V \simeq \frac{D_1}{T}e^{-r\tau}(T-\tau)A + \left[\frac{D_1}{rT}(1-e^{-r\tau}) + D_2\right]S + D_3 e^{-r\tau}, \tag{2.14}$$

where D_1, D_2, D_3 are independent of (S, A, τ) and are determined by the payoff. For example, for a fixed strike call, $D_1 = 1$, $D_2 = 0$, $D_3 = -K$. Assuming (2.14) holds for $S \to \infty$, for all A (which is clearly an approximation for A small) we obtain

$$V_S \simeq \left[\frac{D_1}{rT}(1-e^{-r\tau}) + D_2\right]; \quad S \to \infty. \tag{2.15}$$

Substituting (2.15) into (2.12) gives

$$\mathcal{H}V \equiv V_\tau - \left(\frac{(S-A)}{T-\tau}V_A + \chi(S,\tau) - rV\right); \quad S \to \infty, \tag{2.16}$$

where

$$\chi(S,\tau) = \left[\frac{D_1}{rT}(1-e^{-r\tau}) + D_2\right]rS. \tag{2.17}$$

For the payoffs mentioned earlier, we have that $\chi(\tau, S) = \frac{(1-e^{-r\tau})}{T}S$ for a fixed strike call and $\chi(\tau, S) = 0$ for a fixed strike put.

The use of approximation (2.15) is discussed in [34], where it is mentioned that estimate (2.15) is in fact an upper bound for V_S. It must be admitted that use of (2.14) for all A as $S \to \infty$ is not rigorously justified. However, we note that other authors [31] simply specify that the boundary condition at $S = S_{max}$ is set to the payoff. In [31], the size of the computational domain is increased as the grid size is reduced, so that the effect of poor specification of the boundary condition becomes negligible. However, as discussed in [34], the boundary condition (2.16) is at least qualitatively correct.

In view of the above, we impose the boundary conditions as $S \to \infty$ in the following manner. We assume that S_{max} is sufficiently large so that the solution can be well approximated by a linear function of S in the region $[S_{max}-\delta, S_{max}]$. Provided that we choose δ carefully (see [19]), the integral term in the PIDE (2.8) in $[0, S_{max}-\delta]$ has sufficient data for accurate computation. In the region $[0, S_{max}-\delta] \times [0, A_{max}]$, the operator $\mathcal{H}$ is defined as in (2.8). In the region $[S_{max}-\delta, S_{max}] \times [0, A_{max}]$, we assume that V is linear in S, so that in this region the operator $\mathcal{H}V$ reduces to the PDE

$$\mathcal{H}V = V_\tau - \left[\frac{\sigma^2 S^2}{2}V_{SS} + \left(\frac{S-A}{T-\tau}\right)V_A + rSV_S - rV\right] \quad \text{for } S \in [S_{max}-\delta, S_{max}]. \tag{2.18}$$

Although we have assumed that $V_{SS} = 0$ in $[S_{max}-\delta, S_{max}]$, we leave the V_{SS} term in the operator (2.18) so that numerical solution is straightforward.

At $S = S_{max}$, based on (2.16), we define $\mathcal{H}V$ as

$$\mathcal{H}V \equiv V_\tau - \left(\frac{S-A}{T-\tau} V_A + \chi(S,\tau) - rV \right). \tag{2.19}$$

The above arguments can be used to justify formally solving the PIDE in the region $[0, S_{max}] \times [0, A_{max}]$, with the requirement that $\lambda = 0$ for $S \in [S_{max} - \delta, S_{max}]$. We then have a well-defined problem in $[0, S_{max}] \times [0, A_{max}]$, which does not require data outside the computational domain. Note that in $[S_{max} - \delta, S_{max}]$, only a few nodes are required, since the solution is assumed to be linear. Hence this method of handling the difficulties as $S \to \infty$ is not computationally expensive (at least as far as the solution of the PIDE is concerned).

2.3. Viscosity solutions. In general, there may be no smooth solutions to (2.9). In what follows it will be understood that we are seeking weak viscosity solutions. A detailed discussion concerning existence and uniqueness of viscosity solutions to (2.9), can be found in [38, 2], for European and American options under jump diffusion. In addition, sufficient conditions to ensure convergence of a discrete numerical scheme to the viscosity solution in the PDE case, are given in [6, 5]. Finally, an extension of the results in [6, 5] to the case of option pricing problems with integrodifferential equations (jump diffusions) is given in [13] for nonlinear, multidimensional, degenerate problems and in [15] for linear problems. By exploiting the equivalence of Binomial Trees and explicit finite difference methods, viscosity solution methods are used to prove convergence of a lattice method for Asian options in [28].

3. Semi-Lagrangian discretization. Typically when pricing continuously observed arithmetic average Asian option, the two-dimensional problem (2.4) must be solved. In [50], the authors use a finite volume approach combined with flux limiters to solve (2.4). This requires solution of a set of nonlinear discretized algebraic equations at each timestep. When the convection terms become very large (note that the convection term in the A direction in (2.5) becomes infinite as $\tau \to T$), flux limiters revert to a first-order upwind scheme which affects the accuracy of the solution [1]. A related approach was used for Asian options in [36]. In this paper we solve (2.4) using a semi-Lagrangian scheme. This idea was also suggested for American Asian options (without jumps but with stochastic volatility) in [37]. In this section we explore different discretization methods for the PDE using the semi-Lagrangian approach.

Before proceeding any further, let us introduce the following definitions. We use an unequally spaced grid in S coordinates for the PDE discretization $[S_1, \ldots, S_M]$, and similarly use an unequally spaced grid in the A direction $[A_1, \ldots A_M]$. Let

$$V_{i,j}^n = V(S_i, A_j, \tau^n) \tag{3.1}$$

denote the solution at asset price node S_i for the average A_j and time level n. Let $\mathcal{C}$ be the differential operator represented by

$$\mathcal{C}V = \frac{1}{2}\sigma^2 S^2 V_{SS} + (r - \lambda\kappa) S V_S - (r - \lambda) V \tag{3.2}$$

and

$$\mathcal{B}V = \lambda \int_0^\infty V(S\eta) g(\eta) d\eta. \tag{3.3}$$

Equation (2.5) can then be rewritten as

$$V_\tau + \frac{(A-S)}{T-\tau} V_A = \mathcal{C}V + \mathcal{B}V. \tag{3.4}$$

In order to impose the American early exercise constraint we will use a penalty method [18, 23, 48]. Briefly, this replaces (2.9) by a nonlinear PIDE

$$V_\tau + \frac{(A-S)}{T-\tau} V_A = \mathcal{C}V + \mathcal{B}V + q(V), \tag{3.5}$$

where the penalty term is

$$q(V) = \rho \max(V^* - V, 0). \tag{3.6}$$

The positive penalty parameter ρ is selected sufficiently large so that either $V \geq V^*$ or

$$\frac{|V - V^*|}{V^*} < \epsilon; \quad \epsilon \ll 1; \quad \text{when } V < V^*, V^* > 0. \tag{3.7}$$

After discretizing the PDE with the nonlinear penalty term, it is straightforward to select a suitably normalized discrete penalty parameter ρ', so that ϵ in (3.7) is less than a user specified tolerance. We refer the reader to [23] for more details about this method.

We use standard finite difference methods to discretize the operator $\mathcal{C}V$ [40] (see Appendix A). If we impose boundary condition (2.16), and use forward and backward differencing as appropriate, it is easy to see that the discrete form of $I - \mathcal{C}V$ is an M-matrix (see section 5.2). As discussed in [40], for typical values of σ, r, upwind differencing of the V_S term in (3.5) is required only rarely, and usually remote from regions of interest, so that in practice this does not impact solution quality. Requiring the discrete form of $\mathcal{C}V$ to be an M-matrix has interesting theoretical properties. In the following, we denote the discrete form of $\mathcal{C}V$ at $S = S_i$, $A = A_j$, $\tau = \tau^n$ by $(\mathcal{C}V)^n_{i,j}$. As described in [19, 18] the integral $(\mathcal{B}V)_{i,j}$ can be efficiently computed by transforming to equally spaced $\log S$ coordinates, approximating the integral using a Trapezoidal rule, using an FFT, and then transforming back to S coordinates. Special care is taken to avoid problems with wrap around [19]. If linear interpolation is used to transform from equally spaced $\log S$ coordinates to unequally spaced S coordinates (and vice versa), this introduces a second-order error consistent with the discretization of the PDE terms [19]. Effectively, we are approximating $\mathcal{B}V$ by

$$\begin{aligned} (\mathcal{B}V)_{i,j} &\simeq \lambda \sum_k b_{ik} V_{kj} = \lambda B \cdot V_j \\ &\text{with } 0 \leq b_{ik} \leq 1 \quad \text{and} \quad \sum_k b_{ik} \leq 1. \end{aligned} \tag{3.8}$$

Note that conditions (2.10) and (2.18) imply that we must also have

$$b_{ik} = 0 \quad \text{for} \quad i = 1 \quad \text{and} \quad i = M \quad \forall k. \tag{3.9}$$

The dense matrix multiply $B \cdot V_j$ can be evaluated efficiently using an FFT. For details, see [19, 18].

The Lagrangian derivative along a trajectory $A = A(S, \tau)$, for S fixed, is

$$\frac{DV}{D\tau} = \frac{\partial V}{\partial \tau} + \frac{\partial V}{\partial A}\frac{dA}{d\tau}. \tag{3.10}$$

Along the trajectory

$$\frac{dA}{d\tau} = \frac{A - S}{T - \tau} \tag{3.11}$$

(3.5) can be written as

$$\frac{DV}{D\tau} = \mathcal{C}V + \mathcal{B}V + q(V). \tag{3.12}$$

Let $A = A(S_i, A_j, \tau^{n+1}, \tau)$ along a trajectory satisfying (3.11), which passes through the discrete grid point (S_i, A_j) at $\tau = \tau^{n+1}$ for S_i being held constant. Let $A^n_{j(i,n+1)}$ be the departure point of this trajectory at $\tau = \tau^n$. Note that $A^n_{j(i,n+1)}$ will not necessarily coincide with a grid point A_j. Rather $A^n_{j(i,n+1)}$ is determined by solving

$$\frac{dA}{d\tau} = \frac{A - S_i}{T - \tau}, \text{ where } A = A_j \text{ for } \tau = \tau^{n+1}, \tag{3.13}$$

from $\tau = \tau^{n+1}$ to $\tau = \tau^n$, that is,

$$A^n_{j(i,n+1)} = A_j + \lim_{\tau^* \to (\tau^{n+1})} \int_{\tau^*}^{\tau^n} \frac{A - S_i}{T - \tau} d\tau. \tag{3.14}$$

The limit in (3.14) is used to avoid problems at $\tau = T$, where ODE (3.13) becomes undefined.

Let $V^n_{i,j(i,n+1)} = V(S_i, A^n_{j(i,n+1)}, \tau^n)$ denote the value of the option price at the departure point of the trajectory. Then discretizing (3.12) along the characteristic trajectory for different timestepping schemes gives, in the case of fully implicit timestepping,

$$\frac{V^{n+1}_{i,j} - V^n_{i,j(i,n+1)}}{\Delta\tau} = (\mathcal{C}V)^{n+1}_{i,j} + (\mathcal{B}V)^{n+1}_{i,j} + q(V^{n+1}_{i,j}), \tag{3.15}$$

and for Crank–Nicolson (CN) timestepping,

$$\begin{aligned}\frac{V^{n+1}_{i,j} - V^n_{i,j(i,n+1)}}{\Delta\tau} &= \frac{1}{2}\left((\mathcal{C}V)^{n+1}_{i,j} + (\mathcal{B}V)^{n+1}_{i,j}\right) \\ &\quad + \frac{1}{2}\left((\mathcal{C}V_{i,j(i,n+1)})^n + (\mathcal{B}V)^n_{i,j(i,n+1)}\right) + q(V^{n+1}_{i,j}),\end{aligned} \tag{3.16}$$

and for second-order backward differencing (BDF) [8],

$$\frac{\frac{1}{2}V^{n+1}_{i,j} - 2V^n_{i,j(i,n+1)} + \frac{1}{2}V^{n-1}_{i,j(i,n+1)}}{\Delta\tau} = (\mathcal{C}V)^{n+1}_{i,j} + (\mathcal{B}V)^{n+1}_{i,j} + q(V^{n+1}_{i,j}). \tag{3.17}$$

For ease of exposition, we have written (3.17) for constant timesteps. This is trivially generalized to nonconstant timesteps [8].

Unlike traditional applications of the semi-Lagrangian approach where the characteristic curve must be estimated numerically, for Asian options the solution along the characteristic curve can be determined exactly. Regarding S as a constant, and solving (3.11) gives

$$A = S_i + \frac{D}{T-\tau}, \tag{3.18}$$

where D is a constant independent of A (but a function of S_i). At $\tau = \tau^{n+1}$, $A = A_j$, so that

$$\begin{aligned} \text{at time } \tau^n : A^n_{j(i,n+1)} &= A_j + \frac{(S_i - A_j)(\tau^{n+1} - \tau^n)}{T - \tau^n}, \\ \text{at time } \tau^{n-1} : A^{n-1}_{j(i,n+1)} &= A_j + \frac{(S_i - A_j)(\tau^{n+1} - \tau^{n-1})}{T - \tau^{n-1}}, \end{aligned} \tag{3.19}$$

where $T \geq \tau^{n+1} > \tau^n > \tau^{n-1}$. Note that for the last step when $\tau^{n+1} = T$, (3.19) simplifies to $A^n_{j(i,n+1)} = A^{n-1}_{j(i,n+1)} = S_i$, which is the correct limiting behaviour of (3.14). The various quantities $(\cdot)^n_{i,j(i,n+1)}$ in (3.15)–(3.17) are determined by interpolation along lines of constant $S = S_i$. Assuming that the S derivatives and the integral term are discretized using second-order accurate methods, then it follows from [10, 22] that at least quadratic interpolation should be used for $(\cdot)^n_{i,j(i,n+1)}$ in order to retain global second-order convergence.

4. Semi-Lagrangian timestepping and discrete observations. Asian options which are continuously observed are typically considered to be the limit of discretely observed Asian options as the observation interval tends to zero [17, 44]. A similar statement can also be made about the discretization of the continuous problem given in the previous section. In this section we compare these two discrete problems. We show that if the discrete sampling period is equal to the discrete PIDE timestep, then a fully implicit, discretely sampled model is algebraically identical to a fully implicit semi-Lagrangian discretization of a continuously observed model. In the following, we ignore the effect of the boundary condition (2.16).

Consider the discrete average computed at the discrete forward observation times $t^\ell = \ell \Delta t$

$$\begin{aligned} \hat{A}(t^\ell) &= \frac{1}{\ell} \sum_{p=1}^{\ell} S(t^p) \\ &= \hat{A}(t^{\ell-1}) + \frac{S(t^\ell) - \hat{A}(t^{\ell-1})}{\ell}. \end{aligned} \tag{4.1}$$

Note that we are careful to distinguish the average computed at forward times as a function of t from the average computed at backwards times as a function of τ, that is, $A(\tau) = \hat{A}(t)$ where $\tau = T - t$. Similarly, we can define the value of an Asian option as a function of $(S, \hat{A}, t)$ as $\hat{V}(S, \hat{A}, t)$, where, in terms of $V(S, A, \tau)$ we have the identity $V(S, A(T-t), T-t) = \hat{V}(S, \hat{A}(t), t)$.

When using a PIDE method to price a discretely observed Asian option, we consider that $\hat{V} = \hat{V}(S, \hat{A}, t)$, and regard $(S, \hat{A})$ as independent variables. Suppose we have N observation dates, at the times $\Delta t, 2\Delta t, \ldots, N\Delta t$ with $N\Delta t = T$. Let $\hat{A}^\ell = \hat{A}(t^\ell)$. Then at the ℓth observation date we must have, by no arbitrage [46],

$$\hat{V}(S, \hat{A}^{\ell+1}, t^{(\ell+1)+}) = \hat{V}(S, \hat{A}^\ell, t^{(\ell+1)-}), \tag{4.2}$$

where $t^{(\ell+1)+}, t^{(\ell+1)-}$ are the instants just after and just before the observation date $t^{\ell+1}$. In (4.2) $\hat{A}^{\ell+1} = \hat{A}^{\ell} + \frac{S-\hat{A}^{\ell}}{\ell+1}$ and is regarded as constant for $t^{\ell+1} < t < t^{\ell+2}$.

Let $A^k = A(\tau^k)$ and set $k = N - \ell$, so that k counts backwards. Since $\tau^k = k\Delta\tau$, we have that $t^{\ell} = T - \tau^k$, $t^{\ell+1} = T - \tau^{k-1}$ and as well, $t^{(\ell+1)+} = T - \tau^{(k-1)-}$ and $t^{(\ell+1)-} = T - \tau^{(k-1)+}$. Writing the no-arbitrage condition (4.2) in terms of the variables $\tau, A(\tau)$ rather than t, $\hat{A}(t)$ then gives

$$V(S, A^{k+1}, \tau^{k+}) = V(S, A^k, \tau^{k-}), \text{ where } A^k = A^{k+1} + \frac{S - A^{k+1}}{N-k}. \tag{4.3}$$

As before we regard A^{k+1} as fixed during $\tau^k < \tau < \tau^{k+1}$.

Consider the case of a discretely observed European Asian option. In this case we solve

$$V_\tau = \mathcal{C}V + \mathcal{B}V + q(V) \tag{4.4}$$

on the domain $[0, S_{max}] \times [0, A_{max}]$, with the no-arbitrage conditions (4.3) imposed at observation times. Away from observation dates, if we discretize (4.4) in the A direction, then (4.4) represents a set of one-dimensional PIDEs, which communicate only through no-arbitrage conditions [17].

From the no-arbitrage condition (4.3) we have that a fully implicit discretization of (4.4) gives

$$\frac{V(S_i, A_j^{k+1}, \tau^{(k+1)-}) - V(S_i, A_j^{k+1}, \tau^{k+})}{\Delta\tau} = (\mathcal{C}V)_{i,j}^{k+1} + (\mathcal{B}V)_{i,j}^{k+1} + q(V_{i,j}^{k+1}). \tag{4.5}$$

Note that this is a set of independent one-dimensional PDEs (there are no A derivatives in (4.5), A_j^{k+1} appears only as a parameter). Using the no-arbitrage condition (4.3) in (4.5) gives

$$\frac{V(S_i, A_j^{k+1}, \tau^{(k+1)-}) - V(S_i, A_{j(i,k+1)}^{k}, \tau^{k-})}{\Delta\tau} = (\mathcal{C}V)_{i,j}^{k+1} + (\mathcal{B}V)_{i,j}^{k+1} + q(V_{i,j}^{k+1}), \tag{4.6}$$

where

$$A_{j(i,k+1)}^{k} = A_j^{k+1} + \frac{(S - A_j^{k+1})\Delta\tau}{T - \tau^k}, \tag{4.7}$$

which (setting $A_j^{k+1} = A_j$ in (4.6)–(4.7)) we recognize from (3.15) and (3.19) as being algebraically identical to a semi-Lagrangian, fully implicit discretization.

Note that in order for this result to hold, we must have discrete observations at $t = \Delta t, 2\Delta t, \ldots, N\Delta t$, that is, no observation at $t = 0$. Of course, in the limit as $\Delta t \to 0$, adding an extra observation at $t = 0$ will be the same to $O(\Delta t)$ as the semi-Lagrangian solution.

REMARK 4.1. [24] [27]

[24]
[24, 7]
[28]

5. Monotonicity and stability of the discrete equations. As shown in [40], in the case of nonlinear option pricing problems, seemingly reasonable discretization schemes can converge to an incorrect (i.e., nonviscosity) solution. Convergence to the viscosity solution is guaranteed if the discretization is consistent, monotone and l_∞ stable [5, 13, 15]. Usually, consistency follows if any reasonable discretization method is used, although in the case of jump-diffusion, the nonlocality of the integral term requires care in showing consistency [13, 15]. l_∞ stability is usually a consequence of monotonicity. Consequently, the most interesting requirement is monotonicity.

In the following, we will investigate the monotonicity and stability properties of the discrete equations. We will use a definition of monotonicity which is somewhat stricter than is usually the case in financial applications [5], but more in line with the definition used in computational fluid dynamics (CFD) [29]. It appears to us that the CFD definition is a more useful aid to the design of suitable discrete schemes. In Appendix B, we will show that CFD definition of monotonicity can be deduced from the usual definition of monotonicity in the viscosity solution literature, as long as the discretization is consistent.

We remind the reader that use of semi-Lagrangian timestepping decouples the discrete equations at each timestep, resulting in a set of one-dimensional discrete PIDEs. Hence we can use our techniques in [23, 40, 18, 19] to prove the desired properties of the discretized equations.

5.1. Preliminaries. Define the matrices B and C such that

$$\lambda \left[B \cdot V_j^n\right]_i = (\mathcal{B}V)_{i,j}^n + \text{ truncation error}, \tag{5.1}$$

$$\left[C \cdot V_j^n\right]_i = (\mathcal{C}V)_{i,j}^n + \text{ truncation error}, \tag{5.2}$$

where V_j^n is the vector of discrete solution values $\left[V_j^n\right]_i = V(A_j, S_i, \tau^n)$ for fixed A_j. A detailed description of B is given in [19, 18]. For our purposes, we note that B has the properties given by (3.8). A detailed description of matrix C is given in Appendix A.

To avoid algebraic complication, we will describe the discrete equations and the method used to solve the algebraic equations, only for the fully implicit and CN timestepping methods. The reader should have no difficulty generalizing the results to the BDF case.

Let Φ^{n+1} be the Lagrange interpolation operator such that

$$(\Phi^{n+1} \cdot V^n)_{i,j} = V(S_i, A^n_{j(i,n+1)}, \tau^n) + \text{ interpolation error}, \tag{5.3}$$

where Φ^{n+1} is a linear operator for any order (linear, quadratic) of interpolation. We also let V^* be the vector of payoffs obtained upon exercise and let P be the diagonal matrix given by

$$P(V_j^{n+1})_{ii} = \begin{cases} \cdot & \text{if } V_{i,j}^{n+1} < V_{i,j}^*, \\ 0 & \text{otherwise.} \end{cases} \tag{5.4}$$

Then the matrix form of the discrete equations for the penalized method is given by

(5.5)
$$[I-(1-\theta)\Delta\tau C+P(V_j^{n+1})]V_j^{n+1}=[\Phi^{n+1}[I+\theta\Delta\tau C]V^n]_j+(1-\theta)\lambda\Delta\tau BV_j^{n+1} +[\Phi^{n+1}\theta\lambda\Delta\tau BV^n]_j+\left[P(V_j^{n+1})\right]V_j^*+\Delta\tau F_j^{n+1}$$

for $j=1,\ldots,M$. Here $\theta=0$ is fully implicit, and $\theta=1/2$ is CN timestepping. The term F_j^{n+1} is used to approximate the boundary condition at $S=S_{max}$, as discussed in subsection 2.2. Note that $B_{i,l}=0$ for $S_i\in[S_{max}-\delta,S_{max}]$, as discussed in subsection 2.2. Condition (2.16) is enforced at $i=M$ by adjusting $C_{M,l}$ as discussed in Appendix A, and letting

$$\left[F_j^{n+1}\right]_i=\begin{cases}0, & i\neq M,\\ (1-\theta)\chi(S_{max},\tau^{n+1})+\theta\chi(S_{max},\tau^n), & i=M,\end{cases} \tag{5.6}$$

where $\chi(S,\tau)$ is discussed in subsection 2.2.

We note here that the penalty formulation of the American option pricing problem reduces problem (2.9) to the nonlinear PIDE (3.5), and hence the results in [13] apply. Briefly, if the numerical scheme is consistent, l_∞ stable, and monotone, then convergence to the viscosity solution is guaranteed. In order to obtain a monotone scheme, we can use at most linear interpolation in (5.3).

The choice of interpolation scheme is discussed in [24, 22]. Specifically, if the interpolation error does not get damped out, the global interpolation error after N timesteps is $O(\frac{((\Delta S)_{\max})^q}{\Delta\tau})$, where $q=2$ for linear interpolation, $q=3$ for quadratic interpolation and $(\Delta S)_{\max}=\max_i(S_{i+1}-S_i)$. Assuming second order in space and time truncation errors, the global discretization error for a semi-Lagrangian method applied to a pure hyperbolic problem is [22, 10]

$$\text{global discretization error}=O\left[\frac{((\Delta S)_{\max})^q}{\Delta\tau}+((\Delta S)_{\max})^2+(\Delta\tau)^2\right]. \tag{5.7}$$

If we assume $(\Delta S)_{max}=\text{const.}\,h$ and $\Delta\tau=\text{const.}\,h$, then (5.7) reduces to

$$\text{global discretization error}=O\left[\min(h^{q-1},h^2)\right]. \tag{5.8}$$

As discussed in [10], estimate (5.8) is valid only for smooth solutions.

5.2. Monotonicity and stability. The highest-order interpolation method Φ which will result in a monotone scheme is linear interpolation. Equation (5.8) suggests that if linear interpolation is used ($q=2$), we can obtain no more than first-order convergence. With this in mind, in the following analysis, we will consider only a fully implicit timestepping, and a linear interpolant Φ (as in (5.3)). We will, however, carry out numerical experiments with CN and BDF timestepping, and higher-order interpolants. The fully implicit version of (5.5) is

$$[I-\Delta\tau C-\lambda\Delta\tau B+P(V_j^{n+1})]V_j^{n+1}=[\Phi^{n+1}V^n]_j+P(V_j^{n+1})V_j^*+\Delta\tau F_j^{n+1} \tag{5.9}$$

for $j=1,\ldots,M$.

As discussed in [5, 13], consistency, stability, and monotonicity are sufficient conditions for a numerical scheme to ensure convergence to the viscosity solution. In view of the importance of discretizations which are stable and monotone, both from a

theoretical and practical point of view, it is useful to gather together a set of results for the implicit discretization schemes.

LEMMA 5.1 (properties of matrix C). [illegible] C [illegible] (5.9) [illegible]

$$\begin{aligned}\sum_k C_{ik} &= -(r+\lambda); \quad i = 2, \ldots, M-1 \\ &= -r; \quad i = 1 \quad\quad i = M, \\ C_{ik} &\geq 0; \quad i \neq k; \quad i = 1, \ldots, M. \end{aligned} \tag{5.10}$$

[illegible]. The proof follows directly from the discussion in Appendix A. ∎

Set

$$Q = I - \Delta\tau C - \lambda\Delta\tau B. \tag{5.11}$$

LEMMA 5.2 (M-matrix property of Q). [illegible] Q [illegible] M [illegible]. From (3.8)–(3.9) we have that $-B$ has nonpositive offdiagonal elements. From Lemma 5.1, we have that $-C - \lambda B$ has nonpositive offdiagonal elements. From Lemma 5.1, and properties (3.8)–(3.9), we have that

$$\sum_k [-C - \lambda B]_{ik} \geq 0; \quad i = 1, \ldots, M, \tag{5.12}$$

and hence Q is an M-matrix. ∎

We can write the discrete equations at each node (S_i, A_j) as

$$\begin{aligned} g_{i,j}(V_{i,j}^{n+1}, \{V_{k,j}^{n+1}\}_i, \{V^n\}) &= -[QV_j^{n+1}]_i + [\Phi^{n+1}V^n]_{i,j} \\ &\quad + \left[P(V_j^{n+1})\right]_{ii}(V_{i,j}^* - V_{i,j}^{n+1}) + \Delta\tau F_{i,j}^{n+1} \\ &= 0, \end{aligned} \tag{5.13}$$

where $\{V_{k,j}^{n+1}\}_i$ is to be interpreted as the set of values $V_{k,j}^{n+1}$, $k \neq i$, $k = 1, \ldots, M$, and $\{V^n\}$ is the set $V_{k,\ell}^n$, $k = 1, \ldots, M$; $\ell = 1, \ldots, M$.

DEFINITION 5.3 (monotone discretizations). [illegible] (5.13) [illegible]

(5.14)

$$\begin{aligned} g_{i,j}(V_{i,j}^{n+1}, \{V_{k,j}^{n+1} + \rho_{k,j}^{n+1}\}_i, \{V_{k,\ell}^n + \rho_{k,\ell}^n\}) &\geq g_{i,j}(V_{i,j}^{n+1}, \{V_{k,j}^{n+1}\}_i, \{V^n\}) \quad \forall i,j; \\ &\quad \forall k \neq i,\ \forall \rho_{k,\ell}^n \geq 0,\ \forall \rho_{k,j}^{n+1} \geq 0, \end{aligned}$$

$$\begin{aligned} g_{i,j}(V_{i,j}^{n+1} + \rho_{i,j}^{n+1}, \{V_{k,j}^{n+1}\}_i, \{V^n\}) &< g_{i,j}(V_{i,j}^{n+1}, \{V_{k,j}^{n+1}\}_i, \{V^n\}) \quad \forall i,j; \\ &\quad \forall k \neq i,\ \forall \rho_{i,j}^{n+1} > 0. \end{aligned} \tag{5.15}$$

REMARK 5.1. [illegible] (5.15) [5] (5.14) [illegible] [29, 25] [illegible] (5.15) B [illegible] (5.14) [illegible] (5.15) [illegible] (5.15) [illegible]

THEOREM 5.4 (monotonicity of the discretization). [illegible] (5.13) [illegible]

[illegible]. We rewrite (5.13) as

$$g_{i,j} = -[QV_j^{n+1}]_i + [\Phi^{n+1}V^n]_{i,j} + \left[P(V_j^{n+1})\right]_{ii}(V_{i,j}^* - V_{i,j}^{n+1}) + \Delta\tau F_{i,j}^{n+1} \tag{5.16}$$

and examine each term in (5.16). From Lemma 5.2, matrix Q is an M-matrix, hence $-[QV_j^{n+1}]_i$ is a strictly decreasing function of $V_{i,j}^{n+1}$, and a nondecreasing function of $\{V_{k,j}^{n+1}\}_i$. Since Φ^{n+1} is a linear interpolant operator, $[\Phi^{n+1}V^n]_{i,j}$ is a nondecreasing function of $\{V^n\}$. Finally we see that the term $\left[P(V_j^{n+1})\right]_{ii}(V_{i,j}^* - V_{i,j}^{n+1})$ is a nonincreasing function of $V_{i,j}^{n+1}$. Hence the discretization is monotone from Definition 5.3. □

THEOREM 5.5 (stability of the fully implicit scheme). [illegible]

$$\|V^{n+1}\|_\infty \le \max(\|V^n\|_\infty, \|V^*\|_\infty) + \Delta\tau\chi_{max}, \tag{5.17}$$

[illegible] $\chi(S_{max},\tau)$ [illegible] 2.2 [illegible]

$$\chi_{max} = \max_{0\le\tau\le T} |\chi(S_{max},\tau)|. \tag{5.18}$$

[illegible]

$$\|V^{n+1}\|_\infty \le \|V^*\|_\infty + T\chi_{max}, \tag{5.19}$$

[illegible] $(n+1)\Delta\tau \le T$

[illegible]. Writing out (5.9) in component form gives (see Appendix A)

$$\begin{aligned} V_{i,j}^{n+1}(1 + (\alpha_i + \beta_i + r + \lambda)\Delta\tau) - \alpha_i\Delta\tau V_{i-1,j}^{n+1} - \beta_i\Delta\tau V_{i+1,j}^{n+1} \\ -\lambda\Delta\tau\sum_k b_{ik}V_{k,j}^{n+1} + P_{ii}(V_j^{n+1})V_{i,j}^{n+1} \\ = \sum_{k,l} w_{k,l}^{i,j}V_{k,l}^n + P_{ii}(V_j^{n+1})V_{i,j}^* + \Delta\tau F_{i,j}^{n+1}, \end{aligned} \tag{5.20}$$

where $w_{k,l}^{i,j}$ are linear interpolation weights satisfying

$$0 \le w_{k,l}^{i,j} \le 1 \quad \text{and} \quad \sum_{k,l} w_{k,l}^{i,j} = 1. \tag{5.21}$$

In addition, we recall that B has properties (3.8)

$$0 \le b_{ik} \le 1 \quad \text{and} \quad \sum_k b_{ik} \le 1, \tag{5.22}$$

while from Appendix A we have that

$$\alpha_i \ge 0 \quad \text{and} \quad \beta_i \ge 0. \tag{5.23}$$

Let m be an index such that

$$|V_{m,j}^{n+1}| = \|V_j^{n+1}\|_\infty. \tag{5.24}$$

Then (5.20)–(5.23) imply that

$$\|V_j^{n+1}\|_\infty \left(1 + r\Delta\tau + P(V_j^{n+1})_{mm}\right) \le \|V^n\|_\infty + P(V_j^{n+1})_{mm}\|V^*\|_\infty + \Delta\tau\chi_{max} \tag{5.25}$$

and so

$$\begin{aligned}\|V_j^{n+1}\|_\infty &\le \max(\|V^n\|_\infty, \|V^*\|_\infty)\frac{1 + P(V_j^{n+1})_{mm}}{1 + r\Delta\tau + P(V_j^{n+1})_{mm}} + \frac{\Delta\tau\chi_{max}}{1 + r\Delta\tau + P(V_j^{n+1})_{mm}} \\ &\le \max(\|V^n\|_\infty, \|V^*\|_\infty) + \Delta\tau\chi_{max}.\end{aligned} \tag{5.26}$$

Hence

$$\|V^{n+1}\|_\infty \le \max(\|V^n\|_\infty, \|V^*\|_\infty) + \Delta\tau\chi_{max}. \tag{5.27}$$

Therefore, by induction we have

$$\|V^{n+1}\|_\infty \le \max(\|V^{n-i}\|_\infty, \|V^*\|_\infty) + (i+1)\Delta\tau\chi_{max} \tag{5.28}$$

for all i. Equation (5.19) follows from setting $i = n$ in (5.28). □

REMARK 5.2 (extension to nonlinear models). [illegible] [41] [illegible] [41] [illegible]

5.3. Properties of a semi-implicit discretization. Suppose we alter the discretization (5.9) so that the jump integral term is evaluated explicitly. Then

$$[I - \Delta\tau C + P(V_j^{n+1})]V_j^{n+1} = \lambda\Delta\tau B V_j^n + [\Phi^{n+1}V^n]_j + P(V_j^{n+1})V_j^* + \Delta\tau F_j^{n+1} \tag{5.29}$$

for $j = 1, \ldots, M$. The previous methods can also be applied to determine stability and monotonicity properties of this second discretization.

THEOREM 5.6 (stability and monotonicity of explicit evaluation of the jump term). [illegible] (5.29) [illegible]. Set $R = [I - \Delta\tau C]$. Then we can rewrite (5.29) as

$$\begin{aligned}g_{i,j} = &- [RV_j^{n+1}]_i + [\Phi^{n+1}V^n]_{i,j} + \left[P(V_j^{n+1})\right]_{ii}(V_{i,j}^* - V_{i,j}^{n+1}) \\ &+ \Delta\tau F_{i,j}^{n+1} + [\Delta\tau\lambda B V^n]_{i,j}\end{aligned} \tag{5.30}$$

From Lemma 5.1 and the properties of matrix B, (3.8), and following along the lines used to prove Theorem 5.4, it is straightforward to see that Definition 5.3 holds unconditionally for (5.30). Using a similar maximum analysis as in the proof of Theorem 5.5, we obtain unconditional stability. □

REMARK 5.3. [illegible] (5.29) [illegible]

6. Additional properties of the discrete equations. In this section we investigate how well our discrete approximation (3.5) preserves important properties of our original problem (2.9). We focus on two important properties: how well does the discrete penalty method satisfy the inequality constraints in problem (2.9) and does the discretization preserve arbitrage inequalities [15].

6.1. Error in the penalty formulation. In our original problem (2.9) we need to solve $\min(\mathcal{H}V; V - V^*) = 0$. In particular, we require that

$$(V - V^*) \geq 0. \tag{6.1}$$

In discrete terms this becomes

$$(V_{i,j}^{n+1} - V_{i,j}^*) \geq 0. \tag{6.2}$$

However, the penalty formulation (5.5) will result in $V_{i,j}^{n+1} < V_{i,j}^*$ at nodes in the exercise region. In this subsection we show that at these nodes we have $V_{i,j}^{n+1} = V_{i,j}^* - \epsilon$, where $0 < \epsilon \ll 1$. In particular, we have the following bound on the error in the penalty term.

LEMMA 6.1 (error generated by the penalty formulation). [illegible] V^* [illegible]

$$\frac{\Delta\tau}{\Delta S_{min}} < \text{const.} \quad \Delta\tau, \Delta S_{min} \to 0, \tag{6.3}$$

[illegible] $\Delta S_{min} = \min_i(S_{i+1} - S_i)$ [illegible]

$$V_{i,j}^{n+1} - V_{i,j}^* \geq -\frac{C_1}{Large}, \tag{6.4}$$

[illegible] C_1 [illegible] $\Delta S, \Delta\tau$ [illegible]. Let k be an index such that

$$(V_{k,j}^* - V_{k,j}^{n+1}) = \max_i(V_{i,j}^* - V_{i,j}). \tag{6.5}$$

Since the matrix Q defined by (5.11) is an M-matrix from Lemma 5.2, it follows from (6.5) that

$$\left[Q(V_j^* - V_j^{n+1})\right]_k \geq 0, \tag{6.6}$$

and hence

$$\left[QV_j^*\right]_k \geq \left[QV_j^{n+1}\right]_k. \tag{6.7}$$

From (5.16) we have that for all j

$$QV_j^{n+1} = [\Phi V^n]_j + P(V_j^{n+1})(V_j^* - V_j^{n+1}) + \Delta\tau F_j^{n+1}. \tag{6.8}$$

In particular, row k of (6.8) is

$$\left[QV_j^{n+1}\right]_k = \left[[\Phi V^n]_j\right]_k + \left[P(V_j^{n+1})(V_j^* - V_j^{n+1})\right]_k + \Delta\tau F_{k,j}^{n+1}. \tag{6.9}$$

Since

$$\left[P(V_j^{n+1})(V_j^* - V_j^{n+1})\right]_k = \|P(V_j^{n+1})(V_j^* - V_j^{n+1})\|_\infty, \tag{6.10}$$

then (6.9) gives (using (6.7))

$$\|P(V_j^{n+1})(V_j^* - V_j^{n+1})\|_\infty \le \|V^n\|_\infty + \|QV^*\|_\infty + \Delta\tau\chi_{max}. \tag{6.11}$$

From Theorem 5.5 and (6.11) we have

$$\|P(V_j^{n+1})(V_j^* - V_j^{n+1})\|_\infty \le C_2 + \|QV^*\|_\infty, \tag{6.12}$$

where $C_2 = \|V^*\|_\infty + T\chi_{max}$, with $(n+1)\Delta\tau \le T$. Assuming that V^* satisfies a Lipschitz condition, then

$$\|QV^*\|_\infty \le C_3 \frac{\Delta\tau}{\Delta S_{min}} \tag{6.13}$$

which follows from Lemma 5.2 and Appendix A. Assuming $\Delta\tau/\Delta S_{min}$ is bounded, we have

$$(V_{i,j}^{n+1} - V_{i,j}^*) \ge -\frac{C_1}{Large} \tag{6.14}$$

with $C_1 = C_2 + \frac{C_3\Delta\tau}{\Delta S_{min}} > 0$. □

REMARK 6.1 (significance of Lemma 6.1). 6.1 (2.9) (3.6) *Large* (5.4), $\Delta\tau/\Delta S_{min}$ $(V_{i,j}^{n+1} - V_{i,j}^*)$ [23] (6.2)

THEOREM 6.2 (discrete comparison principle). (5.9) $V^n > W^n$ V^{n+1}, W^{n+1} (5.9) $V^{n+1} > W^{n+1}$

. Suppose $V^n > W^n$. Write (5.9) for V, W

$$\begin{aligned} QV_j^{n+1} &= [\Phi^{n+1}V^n]_j + \left[P(V_j^{n+1})\right](V_j^* - V_j^{n+1}) + \Delta\tau F_j^{n+1}, \\ QW_j^{n+1} &= [\Phi^{n+1}W^n]_j + \left[P(W_j^{n+1})\right](V_j^* - W_j^{n+1}) + \Delta\tau F_j^{n+1}. \end{aligned} \tag{6.15}$$

Some manipulation of (6.15) results in

$$\begin{aligned} Q(V_j - W_j)^{n+1} = &-P(W_j^{n+1})(V_j - W_j)^{n+1} + (P(V_j^{n+1}) \\ &-P(W_j^{n+1})(V_j^* - V_j^{n+1}) + [\Phi^{n+1}(V^n - W^n)]_j \end{aligned} \tag{6.16}$$

or

$$\begin{aligned} \left[Q + P(W_j^{n+1})\right](V_j - W_j)^{n+1} = &(P(V_j^{n+1}) - P(W_j^{n+1})(V_j^* - V_j^{n+1}) \\ &+ [\Phi^{n+1}(V^n - W^n)]_j. \end{aligned} \tag{6.17}$$

Since Q is an M-matrix we have that $[Q + P(W_j^{n+1})]$ is also an M-matrix. From (5.4), we have that

$$(P(V_j^{n+1}) - P(W_j^{n+1})(V_j^* - V_j^{n+1}) \ge 0. \tag{6.18}$$

If linear interpolation is used, then $(V^n - W^n) > 0$ implies that $[\Phi^{n+1}(V^n - W^n)]_j > 0$. Finally, since $[Q + P(W_j^{n+1})]$ is an M-matrix, its inverse satisfies $[Q + P(W_j^{n+1})]^{-1} \geq 0$, and diag.$([Q + P(W_j^{n+1})]^{-1}) > 0$, and hence $(V_j - W_j)^{n+1} > 0$. □

REMARK 6.2. [illegible] [15] [illegible] 6.2 [illegible]

7. Iterative solution of the discretized equations. In order to solve (5.5), we use the following iteration scheme.

Iteration

For $j = 1, 2, \ldots$

Let $(V_j^{n+1})^0 = (V_j^n)$

Let $\hat{V}_j^{\,k} = (V_j^{n+1})^k$

Let $\hat{P}^k = P((V_j^{n+1})^k)$

For $k = 0, 1, 2, \ldots$ until convergence

Solve

$$\left[I - (1-\theta)C + \hat{P}^k\right] \hat{V}_j^{\,k+1} = \left[\Phi^{n+1}\left[I + \theta C\right] V^n\right]_j + \hat{P}^k V_j^* + \Delta\tau F_j^{n+1} + (1-\theta)\lambda\Delta\tau B\hat{V}_j^{\,k} + \theta\lambda\Delta\tau\left[\Phi^{n+1} B V^n\right]_j \tag{7.1}$$

If $\max_i \dfrac{|\hat{V}_{i,j}^{k+1} - \hat{V}_{i,j}^{k}|}{\max(1, |\hat{V}_{i,j}^{k+1}|)} <$ [illegible] then break

EndFor

EndFor

For clarity, we have given algorithm (7.1) only for CN and fully implicit timestepping. However, it is trivial to generalize this method to BDF timestepping. Note that each iteration of algorithm (7.1) requires a tridiagonal factor and solve, and a forward and back FFT (to evaluate $B \cdot \hat{V}_j^{\,k}$).

The following theorem indicates that iteration scheme (7.1) is globally convergent.

THEOREM 7.1 (convergence of iteration). [illegible] C B $\hat{P}$ [illegible] (5.2) (5.1) [illegible] (5.4) [illegible] $I - (1-\theta)C$ [illegible] 5.1 [illegible] B [illegible] (3.8) [illegible] (7.1) [illegible] (5.5) [illegible] $\hat{V}^0$ [illegible]. Note that the algebraic equations (5.5) are decoupled for each line of constant A_j. Hence the issue of convergence of scheme (7.1) reduces to the convergence of each set of equations for constant j. But for constant j, this iteration is equivalent to solution of the discrete penalized equations for one dimensional American options with jump diffusion as described in [18]. Hence the result follows directly from Theorem 4.2 in [18]. □

8. Computational details and numerical results. This section presents numerical results for various options and payoffs, including vanilla European call/put and American options. We will use an unequally spaced grid in the A, S directions, on the domain $[0, S_{max}] \times [0, A_{max}]$, with $A_{max} = S_{max}$. We remind the reader that δ is selected so that in $[S_{max} - \delta, S_{max}]$ we have that $\lambda = 0$, and we thus have sufficient data for accurate computation of the jump integral term in $[0, S_{max}]$. The method used to determine δ is discussed in [19]. Probabilistic arguments can be used to determine an appropriate value for S_{max} [44], so that a linear approximation to V is justified in $[S_{max} - \delta, S_{max}]$. We use $S_{max} = 50K$, where K is the strike. We describe below some tests which were carried out to verify that the effect of imposing boundary conditions at $S = 50K$ results in insignificant error. The convergence tolerance in iteration 7.1 was $tol = 10^{-6}$. As suggested in [23], we choose $Large = 1/tol$. If CN or BDF timestepping is used, then quadratic interpolation is used in (5.3). If fully implicit timestepping is employed, then linear interpolation is used in (5.3).

Given an A grid discretization, the discrete PIDEs (3.15)–(3.16) become decoupled. At each timestep, we have a set of independent one-dimensional discrete PIDEs to solve. This property makes solution of the continuously observed Asian option straightforward to implement, given an existing library which supports pricing of path dependent options.

As pointed out in (5.8), it is necessary to use at least a quadratic Lagrange interpolation scheme to find the solution at the foot of the characteristic curve, if we hope to obtain quadratic convergence. This will, however, result in a scheme which is not monotone.

The convergence ratio R is defined in the following way. For each test, as we double the number of grid points in both S and A directions, we cut the timesteps $(\Delta\tau)$ in half. Let $\Delta\tau = \max_n(\tau^{n+1} - \tau^n)$, $(\Delta A)_{max} = \max_j(A_{j+1} - A_j)$. Note that we are allowing here for the possibility of using variable timestep sizes (to be explained later), although most of our tests will simply use a constant timestep size. If we then carry out a convergence study, letting $h \to 0$, where $(\Delta S)_{max} = \text{const. } h$, $(\Delta A)_{\max} = \text{const. } h$, and $\Delta\tau = \text{const. } h$, then we can assume that the error in the solution (at a given node) is

$$V_{\text{approx}}(h) = V_{\text{exact}} + \text{const. } h^{\xi}.$$

The convergence ratio is then defined as

$$R = \frac{V_{\text{approx}}(h/2) - V_{\text{approx}}(h)}{V_{\text{approx}}(h/4) - V_{\text{approx}}(h/2)}. \tag{8.1}$$

In the case of quadratic convergence ($\xi = 2$), then $R = 4$, while for linear convergence ($\xi = 1$), $R = 2$.

Table 8.1 shows results for a low volatility case, European Asian option (no jumps), using the semi-Lagrangian approach. In this special case, the two-dimensional PDE can be reduced to one dimension [45], which we will refer to as the Večeř PDE [45] in the following. Results obtained by solving the Večeř PDE numerically are also given in Table 8.1.

In Table 8.1, we can see that the convergence ratio R for the semi-Lagrangian method is not quadratic ($R \neq 4$), while for the Večeř PDE [45] quadratic convergence is found. As discussed in [45], the Večeř PDE is not convection dominated, hence it is straightforward to obtain accurate numerical solutions. We remind the reader that this clever reduction to one dimension cannot be used for American options.

TABLE 8.1

Value of a continuously observed fixed strike European Asian call option (no jumps) with constant timesteps. The input parameters are $\sigma = .1$, $r = .1$, $T = .25$, $\lambda = 0$, and $K = 100$. We compare the results given using the Večeř [45] one-dimensional model, and the semi-Lagrangian method presented here. CN timestepping was used.

semi-Lagrangian				Večeř 1-D PDE [45]			
Size of S and A grids	No. of timesteps	$S = 100$ Value	R	Size of S grids	No. of timesteps	$S = 100$ Value	R
51	25	1.857193	n.a.	51	25	1.839863	n.a.
101	50	1.853254	n.a.	101	50	1.848642	n.a.
201	100	1.852120	3.475	201	100	1.850851	3.974
401	200	1.851781	3.338	401	200	1.851407	3.979
801	400	1.851660	2.815	801	400	1.851546	3.987

TABLE 8.2

Value of a continuously observed fixed strike Asian call option (no jumps) at $S = K = 100$, constant CN timestepping. The input parameters are $\sigma = .1$, $\lambda = 0$, $r = .1$, $T = .25$, and $K = 100$. The right boundary of the space discretization $[0, S_{max}]$ domain is truncated at different values.

	$S_{max} = 5 \times K$		$S_{max} = 50 \times K$	
Timesteps	S, A grid nodes	Value	S, A grid nodes	Value
25	51	1.857193	54	1.857193
50	101	1.853254	109	1.853254
100	201	1.852120	217	1.852120
200	401	1.851781	433	1.851781
400	801	1.851660	865	1.851660

The discontinuity present in the payoff greatly affects the convergence of the semi-Lagrangian method, since there is very little diffusion in the A direction, and the nonsmoothness in the payoff is not smoothed out during the solution phase. Since we need to use quadratic interpolation in the A direction in order to determine the values of the solution at the feet of the characteristic curves, the interpolation may be affected by the nonsmooth payoff, and may lower the observed rate of convergence.

In order to test the effect of the boundary condition (2.16) at $S = S_{max}$, we show results using two different values of S_{max} in Table 8.2. This table would seem to indicate that there is a negligible error for options of this maturity incurred setting $S_{max} = 50K$, and all subsequent results will be reported imposing condition (2.16) at $S_{max} = 50K$.

Figures 8.1 and 8.2 graphically present the solution V and the first derivative of the solution with respect to the stock price V_S when CN is used. The plots are all smooth and do not exhibit any oscillations. While not shown here, V_{SS} also did not show any oscillations.

We now explore numerical convergence for pricing Asian options for large values of volatility σ. Table 8.3 presents our results. As expected quadratic convergence is recovered. In this case, a sufficient amount of diffusion in the S direction appears to compensate for zero diffusion in the A direction.

8.1. An in-depth study of the convergence ratio. The results of the previous section indicated that the semi-Lagrangian approach, coupled with CN timestepping, results in quadratic convergence, for large volatilities. However, for small volatility values, quadratic convergence was not recovered. The goal of this subsection is to explore in detail different numerical techniques that could improve the convergence rate.

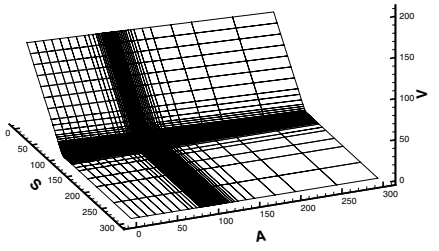

FIG. 8.1. *Value of a European fixed strike Asian put using CN with constant timestepping ($\Delta\tau = .01$). 51 grid points are used both in the A and S direction. The input parameters are $\sigma = .1$, $r = .1$, $T = .25$, $K = 100$, and $\lambda = 0$.*

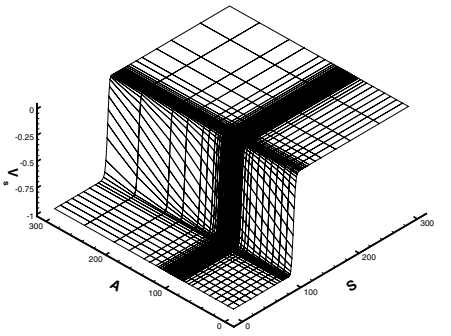

FIG. 8.2. *First derivative (V_S) value of a European fixed strike Asian put using CN with constant timestepping ($\Delta\tau = .01$). 51 grid points are used both in the A and S direction. The input parameters are $\sigma = .1$, $r = .1$, $T = .25$, $K = 100$, and $\lambda = 0$.*

TABLE 8.3

Value of a continuously observed fixed strike Asian call option (no jumps) with constant timesteps at $S = K$. The input parameters are $\sigma = .5$, $r = .05$, $T = .25$, $\lambda = 0$, and $K = 100$. We compare the results given using the Večeř 1-D PDE [45]*, and the semi-Lagrangian method presented here. CN timestepping was used.*

Table 8.4 contains the convergence rate results for different timestepping schemes for small volatility ($\sigma = .1$ and $r = .1$). For implicit timestepping linear convergence is recovered ($R = 2$), as expected. However for higher-order timestepping schemes such as CN and second-order BDF, quadratic convergence is not found (see Table 8.4). These results are not surprising since the combination of small volatility with

TABLE 8.5

Value of a continuously observed fixed strike call Asian call option (no jumps) at the strike with constant timesteps. The initial payoff is smoothed using the average scheme described by (8.2). *The input parameters are* $\sigma = .1$, $r = .1$, $T = .25$, $\lambda = 0$, *and* $K = 100$. *Convergence ratios* (8.1) *are presented for different timestepping schemes: CN and second-order BDF.*

801	400	1.851704	3.513	1.851731	3.497

the nonsmooth payoff, means that quadratic interpolation in the A direction is not $O((\Delta A)^3_{max})$, for small τ.

To try to remedy this problem, the initial payoff function is smoothed out. A classic method for handling discontinuities involves averaging the initial data. Specifically, values at each point are replaced with an average value over nearby space. Mathematically, we set

$$\text{PAYOFF}_{\text{smoothed}}(S_i, A_j) = \int_{K-\frac{\Delta A}{2}}^{K+\frac{\Delta A}{2}} \text{PAYOFF}(S_i, A) dA. \tag{8.2}$$

For a complete description of various smoothing methods the readers are referred to [41].

Table 8.5 contains the convergence rate results. From a convergence point of view, the ratios have improved in comparison with the convergence ratio without smoothing (see Table 8.4). However, quadratic convergence is still not obtained. From a theoretical point of view, all the convergence analysis for semi-Lagrangian scheme is based on the smooth properties of the solution [10, 22]. If the solution is smooth, then quadratic convergence is recovered. However, if the solution is nonsmooth, then we can expect some reduction in the convergence rate.

To confirm our intuition that the nonsmooth payoff is in fact the reason why quadratic convergence is not recovered, we create an artificial payoff that has the property of being quadratically smooth over the entire domain, e.g., $\text{PAYOFF}(A, K) = [\max(0, A - K)]^2$. In this case quadratic convergence is recovered for both CN and second-order BDF. Table 8.6 shows detailed convergence results for CN timestepping.

Several other approaches were considered in an effort to improve convergence. We tried to use Rannacher timestepping [42]; two or more implicit timesteps are taken before reverting to a higher-order timestepping scheme such as CN for example. Numerical experiments indicated that this did not improve the convergence rate. A convergence rate of approximately 3.5 is found in this case. Adaptive timestepping was also considered [23] but this technique did not improve the convergence rate.

8.2. Exotic Asian options. It is not generally possible to achieve second-order convergence for American options using constant timesteps. In [23] it was demonstrated that in order to achieve second-order convergence, it is necessary to use variable timestepping for American options. However, some initial tests showed that due to the large convective term in the A direction, near $\tau = T$, the timestep selector suggested in [23] required very small timesteps near $\tau = T$. Consequently, we will show results in the following using constant timesteps.

TABLE 8.6

Value of a continuously observed Asian call option (no jumps) at the strike with constant timesteps. The input parameters are $\Delta\tau = .01$, $\sigma = .1$, $r = .1$, $T = .25$, $\lambda = 0$, *and* $K = 1$. *Convergence ratios* (8.1) *are presented for the CN timestepping scheme.*

TABLE 8.7

Input data used to value American fixed strike Asian options under the lognormal jump diffusion process (2.7). *These parameters are approximately the same as those reported in* [3] *using European call options on the S&P* 500 *stock index in April of* 1999.

Parameter values			
σ	0.15	λ	0.10
r	0.05	T	0.25
γ	0.45	K	100.00
μ	-0.90	σ_{implied}	0.1886

Table 8.7 presents the input parameters. The mean of the jump distribution is denoted by μ and the jump distribution standard deviation is denoted by γ (see (2.7)).

To ensure consistent comparison between American Asian options with jumps and American Asian options without jumps, we proceed as follows.

1. Given the parameters in Table 8.7, we compute the analytical solution V_{jump} at the strike K of a vanilla put option, under jump diffusion.
2. Use a constant volatility Black–Scholes model with no jump to determine the implied volatility σ_{implied} which matches the jump diffusion value V_{jump} at the strike K.
3. Price the American Asian option with jumps using the parameters in Table 8.7.
4. Price the American Asian option with no jumps but with the implied volatility σ_{implied} estimated in step 2.

Table 8.8 compares the value of an American Asian fixed strike put option with the value of an American Asian fixed strike put option when the underlying stock follows the jump diffusion process described in [32]. Second-order backward timestepping is used and the initial payoff is smoothed out using (8.2). We observe that quadratic convergence is not recovered, the convergence ratios are ≈ 3.5. It is interesting to note that, at the strike, the price of an American Asian fixed strike put option with jumps is 9% cheaper than the price of the same option without jumps, while at $S = 1.05K$, the jump diffusion price is considerably higher than the no-jump price, as can be seen in Figure 8.3.

REMARK 8.1 (alternative boundary condition). (2.16) $V_{SS} = 0$ [47] M $I - \Delta\tau C - \lambda\Delta\tau B$

M

$S \to \infty$

9. Conclusion. In this paper we have put forward four primary contributions. First we have demonstrated that a semi-Lagrangian method can be used to price continuously observed American Asian options under jump diffusion processes. The implementation suggested here reduces this problem to solving a decoupled set of one-dimensional discrete PIDEs at each timestep.

A second contribution is that since the discretized problem at each timestep reduces to a set of decoupled one-dimensional PIDEs, we can make use of previous techniques developed by the authors to prove certain important properties of the discrete scheme, including convergence of the iterative method used to solve the implicit

discrete equations.

In addition, we have included experimental computations which indicate that, even if second-order timestepping methods are used, observed convergence as the mesh and timestep sizes are refined occurs at a subsecond-order rate. The problem can be traced to the nonsmoothness of the payoff function.

Finally, we have also shown that in the fully implicit case, the semi-Lagrangian method for continuously observed Asian options is algebraically identical to a standard numerical method for pricing discretely observed Asian options, when the observation interval is equal to the discrete timestep.

Appendices.

Appendix A. Discretization of the PDE. In this appendix, we give the details of the discretization of the term $(\mathcal{C}V)_{i,j}$ in (3.15).

Using finite differences, the matrix (5.2) is

$$(C \cdot V)_i = -V_i^{n+1}(\alpha_i + \beta_i + r + \lambda) + \beta_i V_{i+1}^{n+1} + \alpha_i V_{i-1}^{n+1}; \quad i = 2, \ldots, M-1, \tag{A.1}$$

where α_i, β_i depend on the type of approximations used for the derivatives and second derivatives. For $i = 1$, we impose condition (2.10) by setting $\alpha_1 = \beta_1 = \lambda = 0$, and for the row $i = M$, condition (2.16) is imposed by setting $\alpha_M = \beta_M = \lambda = 0$. There are a number of different discretizations of the derivative terms leading to various choices for α_i and β_i.

Discretizing the first derivative term of (3.2) with central differences leads to

$$\begin{aligned}
\alpha_{i,central} &= \frac{\sigma_i^2 S_i^2}{(S_i - S_{i-1})(S_{i+1} - S_{i-1})} - \frac{(r - \lambda\kappa)S_i}{S_{i+1} - S_{i-1}}, \\
\beta_{i,central} &= \frac{\sigma_i^2 S_i^2}{(S_{i+1} - S_i)(S_{i+1} - S_{i-1})} + \frac{(r - \lambda\kappa)S_i}{S_{i+1} - S_{i-1}}.
\end{aligned} \tag{A.2}$$

However if $\alpha_{i,central}$ or $\beta_{i,central}$ is negative, oscillations may appear in the solution. The oscillations can be avoided by using forward or backward differences at the problem nodes, leading to (forward difference)

$$\begin{aligned}
\alpha_{i,forward} &= \frac{\sigma_i^2 S_i^2}{(S_i - S_{i-1})(S_{i+1} - S_{i-1})}, \\
\beta_{i,forward} &= \frac{\sigma_i^2 S_i^2}{(S_{i+1} - S_i)(S_{i+1} - S_{i-1})} + \frac{(r - \lambda\kappa)S_i}{S_{i+1} - S_i},
\end{aligned} \tag{A.3}$$

or, (backward difference)

$$\begin{aligned}
\alpha_{i,backward} &= \frac{\sigma_i^2 S_i^2}{(S_i - S_{i-1})(S_{i+1} - S_{i-1})} - \frac{(r - \lambda\kappa)S_i}{S_{i+1} - S_i}, \\
\beta_{i,backward} &= \frac{\sigma_i^2 S_i^2}{(S_{i+1} - S_i)(S_{i+1} - S_{i-1})}.
\end{aligned} \tag{A.4}$$

Algorithmically, we decide between a central or forward discretization at each node for (A.1) as follows.

Discretization

(A.5)

If $[\alpha_{i,central} \geq 0$ and $\beta_{i,central} \geq 0]$ then
$\alpha_i = \alpha_{i,central}$
$\beta_i = \beta_{i,central}$
ElseIf $[\beta_{i,forward} \geq 0]$ then
$\alpha_i = \alpha_{i,forward}$
$\beta_i = \beta_{i,forward}$
Else
$\alpha_i = \alpha_{i,backward}$
$\beta_i = \beta_{i,backward}$
EndIf

Note that the test condition (A.5) guarantees that α_i and β_i are nonnegative. For typical values of σ, r and grid spacing, forward differencing is rarely required for single factor options. In practice, since this occurs at only a small number of nodes remote from the region of interest, the limited use of a low-order scheme does not result in poor convergence as the mesh is refined. For situations where the low-order method causes excessive numerical diffusion, a flux limiter can be used [49]. As we have seen, requiring that all α_i and β_i are nonnegative has important theoretical ramifications.

Appendix B. Practical monotonicity. In this appendix, we will give a rationale for defining monotonicity using both conditions (5.14) and (5.15).

Writing out (3.12) gives

$$-\frac{DV}{D\tau} + \frac{\sigma^2 S^2}{2} V_{SS} + (r - \lambda\kappa) S V_S - rV + \rho \max(V^* - V, 0) + \mathcal{J}V = 0 \tag{B.1}$$

with $\mathcal{J}V = \lambda \int_0^\infty \{V(S\eta) - V(S)\} g(\eta)\, d\eta$, or

$$\begin{aligned} G\left(V, \frac{DV}{D\tau}, V_S, V_{SS}, \mathcal{J}V\right) &= -\frac{DV}{D\tau} + \frac{\sigma^2 S^2}{2} V_{SS} + (r - \lambda\kappa) S V_S - rV \\ &\quad + \rho \max(V^* - V, 0) + \mathcal{J}V = 0. \end{aligned} \tag{B.2}$$

Let $\zeta > 0$ be a constant, independent of (S, A, τ), then from (B.2) we have

$$\begin{aligned} &G\left(V + \zeta, \frac{D(V+\zeta)}{D\tau}, (V+\zeta)_S, (V+\zeta)_{SS}, \mathcal{J}(V+\zeta)\right) \\ &\quad = G\left(V, \frac{DV}{D\tau}, V_S, V_{SS}, \mathcal{J}V\right) - r\zeta - \rho\left[\max(V^* - V, 0) - \max(V^* - V - \zeta, 0)\right] \\ &\quad < G\left(V, \frac{DV}{D\tau}, V_S, V_{SS}, \mathcal{J}V\right) \quad \text{if} \quad \zeta, r > 0. \end{aligned} \tag{B.3}$$

Recall our notation for the discretized form of (5.13). At each node $(S_i, A_j), \tau = \tau^{n+1}$, the discrete form of G is

$$\left[G(V, \frac{DV}{D\tau}, V_S, V_{SS}, \mathcal{J}V)\right]_{i,j}^{n+1} = g_{i,j}(V_{i,j}^{n+1}, \{V_{k,j}^{n+1}\}_i, \{V^n\}) = 0. \tag{B.4}$$

If $g_{i,j}$ is a consistent discretization of (B.2) then we must have ($\zeta = constant > 0$)

$$g_{i,j}(V_{i,j}^{n+1} + \zeta, \{V_{k,j}^{n+1} + \zeta\}_i, \{V^n + \zeta\}) < g_{i,j}(V_{i,j}^{n+1}, \{V_{k,j}^{n+1}\}_i, \{V^n\}). \tag{B.5}$$

Assuming that condition (5.14) holds (which is the usual monotonicity condition in the viscosity solution literature), then it follows that

$$g_{i,j}(V_{i,j}^{n+1} + \zeta, \{V_{k,j}^{n+1}\}_i, \{V^n\}) \le g_{i,j}(V_{i,j}^{n+1} + \zeta, \{V_{k,j}^{n+1} + \zeta\}_i, \{V^n + \zeta\}). \tag{B.6}$$

Hence, (B.5)–(B.6) imply that

$$g_{i,j}(V_{i,j}^{n+1} + \zeta, \{V_{k,j}^{n+1}\}_i, \{V^n\}) < g_{i,j}(V_{i,j}^{n+1}, \{V_{k,j}^{n+1}\}_i, \{V^n\}), \tag{B.7}$$

which is condition (5.15).

In summary, condition (5.14) and consistency of the discretization implies condition (5.15). However, as a stand-alone condition, (5.14)–(5.15) are more appealing, in that these conditions have a simple physical interpretation. This definition of monotonicity is also consistent with the definition of monotonicity in the CFD literature.

To see this, consider the case where g_{ij} in (5.13) is differentiable. Then we can restate Definition 5.3 as

$$\begin{aligned} &\frac{\partial g_{i,j}}{\partial V_{i,j}^{n+1}} < 0, \\ &\frac{\partial g_{i,j}}{\partial y} \ge 0; \quad y \in \{V_{k,j}^{n+1}\}_i, \\ &\frac{\partial g_{i,j}}{\partial z} \ge 0; \quad z \in \{V^n\}. \end{aligned} \tag{B.8}$$

If g_{ij} satisfies conditions (B.8), then we have for any $V_{i,j}^{n+1}$ satisfying (B.4)

$$\begin{aligned} &\frac{\partial V_{i,j}^{n+1}}{\partial y} \ge 0; \quad y \in \{V_{k,j}^{n+1}\}_i, \\ &\frac{\partial V_{i,j}^{n+1}}{\partial z} \ge 0; \quad z \in \{V^n\}. \end{aligned} \tag{B.9}$$

In other words, a positive perturbation of any of $\{V_{k,j}^{n+1}\}_i$, $\{V_{k,l}^n\}$ results in a nonnegative perturbation of $V_{i,j}^{n+1}$. This has the intuitive interpretation in terms of fluid or heat flows, that is, discrete heat diffusion should always flow from high-temperature nodes to low-temperature nodes. Hence Definition 5.3 is commonly used [29, 25].

Another advantage of the definitions (5.14)–(5.15) which may not be obvious from condition (5.14) and consistency, is that a consequence of conditions (5.14)–(5.15) is a simple sufficient test for l_∞ stability. Let

$$(V_{min}^n)_{i,j} \le V_{i,j}^n \le (V_{max}^n)_{i,j} \tag{B.10}$$

(these bounds need not be tight) and set

$$\max_{i,j}(V_{max}^n)_{i,j} = V_{max}^n \quad \text{and} \quad \min_{i,j}(V_{min}^n)_{i,j} = V_{min}^n. \tag{B.11}$$

Then if $g_{i,j}$ satisfies conditions (5.14)–(5.15) we have that

$$g_{i,j}((V_{max}^{n+1})_{i,j}, V_{max}^{n+1}, V_{max}^{n}) = 0 \quad \text{and} \quad g_{i,j}((V_{min}^{n+1})_{i,j}, V_{min}^{n+1}, V_{min}^{n}) = 0. \tag{B.12}$$

Equation (B.12) holds for all (i, j), and so in particular, (B.12) holds for (p, q) where $V_{max}^{n+1} = (V_{max}^{n+1})_{p,q}$. Hence V_{max}^{n+1} satisfies

$$g_{p,q}(V_{max}^{n+1}, V_{max}^{n+1}, V_{max}^{n}) = 0. \tag{B.13}$$

Similarly, at node (r, s), where $V_{min}^{n+1} = (V_{min}^{n+1})_{r,s}$, V_{min}^{n+1} satisfies

$$g_{r,s}(V_{min}^{n+1}, V_{min}^{n+1}, V_{min}^{n}) = 0. \tag{B.14}$$

Hence by examining (B.13)–(B.14) for all p, q and for all r, s, we can obtain worst case bounds for $V_{max}^{n+1}, V_{min}^{n+1}$ in terms of V_{max}^{n}, V_{min}^{n}. Equations (B.13)–(B.14) are usually easy to solve by inspection, since most terms will be zero for a consistent discretization.

HIGHER-ORDER, CARTESIAN GRID BASED FINITE DIFFERENCE SCHEMES FOR ELLIPTIC EQUATIONS ON IRREGULAR DOMAINS*

KAZUFUMI ITO†, ZHILIN LI†, AND YAW KYEI‡

Abstract. Second and fourth order Cartesian grid based finite difference methods are proposed for elliptic and parabolic partial differential equations, and associated eigenvalue problems on irregular domains with general boundary conditions. Our methods are based on the continuation of a solution idea using multivariable Taylor's expansion of the solution about selected boundary points, and the core ideas of the immersed interface method. The methods offer systematic treatment of the general boundary conditions in two- and three-dimensional domains and are directly applied to semi-discretize heat equations on irregular domains. Convergence analysis and numerical examples are presented. The validity and effectiveness of the proposed methods are demonstrated through our numerical results including computations of the eigenvalues of the associated eigenvalue problem.

Key words. fourth order finite difference schemes, elliptic and parabolic equations on irregular domains, immersed interface method

1. Introduction.

In this paper we develop second and fourth order Cartesian grid based finite difference methods for second order elliptic and parabolic partial differential equations, and the associated eigenvalue problems on irregular domains.

Let Ω be a bounded open domain in R^2 or R^3 with a smooth boundary Γ. Consider the elliptic boundary value problem

$$-\operatorname{div}(\mu(x)\nabla u) + c(x)u = f(x), \quad x \in \Omega \tag{1.1}$$

with a boundary condition

$$\mu(x)\frac{\partial}{\partial \nu}u + \alpha(x)u = g(x), \quad x \in \Gamma, \tag{1.2}$$

where ν is the outward normal to the boundary Γ and we assume that μ, f, c, α, g are sufficiently smooth.

The problems of our present interest in this work have been extensively investigated. Many of the different finite difference methods related approaches in the literature on the problem considered using regular Cartesian grids [1, 7, 11, 19], employ an extension of some sort in the solution algorithm. We describe some of the relevant research. In [23], the authors use Lagrange interpolations of the solution and the given Dirichlet boundary condition along each coordinate direction and obtain a modified finite difference scheme at stencils that have grid points lying in both the inside and outside of the irregular domain. They combined the second order method with a deferred correction or Richardson extrapolation to obtain a fourth order method.

In [17], the author developed a fourth order accurate finite difference scheme for solving Poisson equations on irregular regions. An extension is carried out by a hybrid method incorporating an integral equation technique at the boundary. Recently, the approach has been extended in [18] to evaluate particular solutions of biharmonic/harmonic equations on general regions in two dimensions. The irregular domain is embedded in a larger rectangle, and then the problem is recast as an elliptic interface problem with discontinuity in the source function such that the solution is harmonic outside the irregular domain. In this work, the author uses a Taylor's expansion about irregular grid points in the coordinate directions and the integral representation of the particular solution to complete the equation near the interface.

A second order accurate finite difference scheme using a finite volume discretization has been developed in [7] to solve variable Poisson equations with Dirichlet boundary conditions in one and two dimensions. Their approach embeds the domain in a regular Cartesian grid and uses the flux at the cell boundaries. In two dimensions, the boundary is approximated by straight line segments within the cells. In order to evaluate the flux, the normal direction is determined at the midpoint of each boundary line segment in each cell. Then a quadratic extrapolation of the solution at intersection points of the normal to the boundary segment with two selected Cartesian grid lines and the boundary value on the normal is determined.

The derivative of the extrapolation function at the cell boundary is then the approximated flux. As a result, the coefficient matrix of the linear system of equations obtained is not symmetric.

Based on the fast immersed interface method [12], a second order fast Poisson solver on irregular domains was developed in [15]. The method embeds the irregular domain into a rectangular box or a cube. The problem is then extended to the rectangular domain to become an interface problem with an augmented unknown of the jump in the normal derivative of the solution. The method involves the GMRES iteration for the augmented variable that is only defined along the boundary and a fast Poisson solver on the regular domain. The method has been applied to several problems in two and three dimensions [6, 14].

Then in [16], the basic idea of the ghost fluid method was employed to develop a first order accurate symmetric finite difference scheme based on Cartesian grids to solve a variable Poisson equation in the presence of an irregular interface. Subsequently in [4], the approach in [16] was modified to obtain a second order accurate symmetric finite difference scheme based on Cartesian grids to solve a variable Poisson equation with Dirichlet boundary conditions. The modification used the signed distance level set function to obtain a linear interpolation from the boundary value and the solution values in coordinatewise directions to determine the ghost fluid values.

Our extension employs continuation of the solution u from Ω to the outside of domain Ω. The continuation procedure uses the multivariable Taylor's expansion of the solution u at selected boundary points. The Taylor coefficients are then determined by incorporating the boundary conditions and the equation. This procedure directly follows the core ideas of the immersed interface method (IIM) [2, 11, 13]. For the fourth order, our method is based on the standard compact nine point stencil scheme [21, 22], the continuation of solution, and the fourth order multivariable Taylor's expansion of u in local coordinates. The Taylor coefficients are determined by differentiating the equation twice in the local coordinate and collocating the boundary values at the selected boundary points.

The contribution of this paper includes (i) a systematic treatment by both second order and fourth order methods of the general boundary value problems in two

and three dimensions, (ii) direct application to the heat equation and the associated eigenvalue problem, and (iii) the symmetry and positive definiteness of the coefficient matrix of the resulting linear system of equations. For the fourth order method, differentiations of quantities along the boundary can be avoided by collocating the boundary values at selected boundary points (see section 4). This particular approach is a new one in capturing the geometry, boundary values and their derivatives, and minimizing the effort for implementation.

Specifically, our methods offer the following merits:

- They handle general boundary conditions (see section 3) in a systematic manner.
- They are extended to three-dimensional (3D) cases (see section 4) without any significant effort.
- The fourth order method requires minor modifications (see section 5) from the second order one. This shows the effectiveness of our methodology. Specifically, we demonstrate it for elliptic eigenvalue problems in this paper.
- Only the diagonal entries of the coefficient matrix need to be modified at each grid point near the boundary. Thus, the resulting coefficient matrices of the linear system of equations are symmetric and positive definite and maintain the sparsity of the standard finite difference scheme.
- The extension of the fourth order method to the heat equation is carried out (see section 6) and the method has many potential applications.
- The implementation of the methods are carried out with great ease. Work involved is to solve low (fixed) order linear equations to determine the diagonal entries of the coefficient matrix and the corresponding right-hand side at each grid-point near the boundary. Specifically, we implemented our methods when the boundary is described by the zero level set of a function (we only require the function values at the Cartesian grid points).

For numerical tests we use the sparse matrix solvers in MATLAB. We also tested an iterative method through our eigenvalue computations using the ▪◢ routine in MATLAB which employs an Arnold iteration algorithm. Extensions of the proposed methods to the interface problems discussed in [2, 11] are being considered, and the extension of the fourth order method to the variable coefficient case is also of interest to us.

The paper is organized as follows. In section 2 we introduce the basic idea and the description of the methods by using the Poisson equation on an irregular domain with a Dirichlet boundary condition in R^2 as a benchmark problem. Section 2 provides a general guideline and the scope of our proposed methods without the burden of technical details. We give necessary details and how to apply the method for the following specific cases below. In section 3 we describe the second order method for general boundary conditions including the Neumann boundary condition. In section 4 we describe the second order method for 3D cases. We describe the fourth order method in section 5 and follow up in section 6 with the discussion of time-dependent, (i.e., heat) equations and the corresponding eigenvalue problem. In section 7 we present numerical tests and demonstrate the capability of the proposed algorithms. We also report a stability and convergence rate analysis in section 8 while the stability of methods is clearly demonstrated through our test numerics.

2. The basic ideas and the continuation method. In this section we describe the basic ideas of the proposed method for a Poisson equation $-\Delta u = f$ with a Dirichlet boundary condition $u = g$ on Γ in R^2. We assume that the domain Ω is

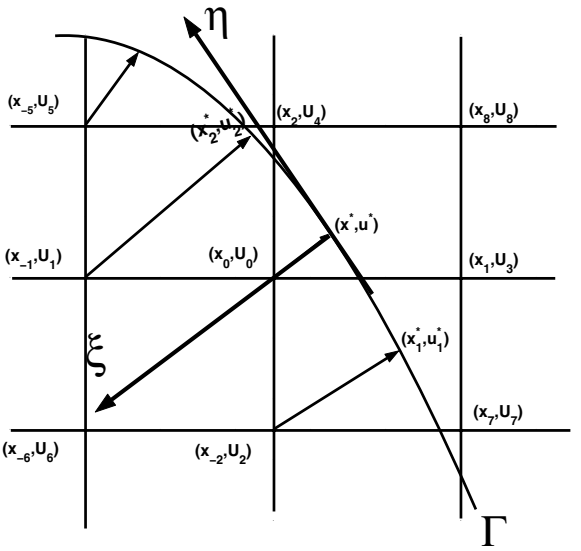

FIG. 1. *A diagram of an irregular grid point x_0, its projection x^* on the interface Γ, and the local coordinates (ξ, η).*

contained in the square $[0,1] \times [0,1]$. We use a uniform Cartesian grid $x_{i,j} = (ih, jh)$, $0 \le i,\ j \le n$ with step size $h = 1/n$. Let $U_{i,j}$ be the finite difference solution at the $x_{i,j}$ grid point. We say (i,j) grid is a [illegible] if all the grid points in the standard five point stencil are in $\overline{\Omega}$. At regular grid points, we use the standard five point central finite difference scheme. At an [illegible] where the standard five point stencil contains grid points outside of $\overline{\Omega}$, we apply the continuation method. We use Figure 1 to illustrate our method and analysis.

Let U_0 denote the value at the irregular grid point x_0, U_1, U_2 be the values at inside grid points x_{-1}, x_{-2} and U_3, U_4 at outside grid points x_1, x_2. If we know the values U_3 and U_4, then we can apply the standard five point central finite difference at x_0,

$$\frac{4U_0 - U_1 - U_2 - U_3 - U_4}{h^2} = f_{i,j}, \tag{2.1}$$

and complete the system for $U_{i,j}$. We represent U_3 and U_4 as a function of U_0, f, and g as follows.

[illegible] 1. We project the irregular grid point x_0 onto the boundary point x^* by the orthogonal projection onto Γ. As a result there is a family of the projected points x_k^* on Γ with the associated family of irregular grid points.

[illegible] 2. Let (η, ξ) be the local orthogonal coordinates in the tangential and normal directions at x^*. We expand the solution u at x^* by

$$u \sim \tilde{u} = \Phi(\eta, \xi) = u^* + u_\xi \xi + u_\eta \eta + \frac{1}{2} u_{\xi\xi} \xi^2 + u_{\xi\eta} \xi\eta + \frac{1}{2} u_{\eta\eta} \eta^2. \tag{2.2}$$

If the solution u is C^3 in a neighborhood of x^*, then the truncation error of (2.2) is of order $O(h^3)$.

[illegible] 3. Among the Taylor coefficients, $u^* = g(x^*)$ and $u_\eta = g_\tau(x^*)$ are known from the boundary condition and thus we have a total of 4 unknowns in (2.2), selected

to be $(u_\xi, u_{\xi\xi}, u_{\xi\eta}, u_{\eta\eta})$. Let x_1^* and x_2^* be the two closest projected points to x^* on Γ as shown in Figure 1. We use the following four conditions to obtain the complete system for the unknown $(u_\xi, u_{\xi\xi}, u_{\xi\eta}, u_{\eta\eta})$:

$$u(x_0) = U_0, \qquad u(x_1^*) = g(x_1^*), \qquad u(x_2^*) = g(x_2^*), \qquad u_{\xi\xi} + u_{\eta\eta} = -f(x^*). \tag{2.3}$$

If we eliminate $u_{\xi\xi}$ by

$$u_{\xi\xi} = -f(x^*) - u_{\eta\eta}, \tag{2.4}$$

and let $u = \tilde{u}$ in (2.4), we then obtain

$$\begin{pmatrix} \xi_0 & \xi_0\eta_0 & .5(\eta_0^2 - \xi_0^2) \\ \xi_1 & \xi_1\eta_1 & .5(\eta_1^2 - \xi_1^2) \\ \xi_2 & \xi_2\eta_2 & .5(\eta_2^2 - \xi_2^2) \end{pmatrix} \begin{pmatrix} u_\xi \\ u_{\xi\eta} \\ u_{\eta\eta} \end{pmatrix} = \begin{pmatrix} U_0 - g(x^*) - g_\tau(x^*)\eta_0 + .5f(x^*)\xi_0^2 \\ g(x_1^*) - g(x^*) - g_\tau(x^*)\eta_1 + .5f(x^*)\xi_1^2 \\ g(x_2^*) - g(x^*) - g_\tau(x^*)\eta_2 + .5f(x^*)\xi_2^2 \end{pmatrix}, \tag{2.5}$$

where (η_i, ξ_i), $i = 0, 1, 2$ are the local coordinates of x_0, x_1^*, x_2^*, respectively. Thus the unknown $(u_\xi, u_{\xi\xi}, u_{\xi\eta}, u_{\eta\eta})$ is a linear function of $(U_0, f(x^*), g(x^*), g(x_1^*), g(x_2^*), g_\tau(x^*))$.

, , 4. Let (ξ_i, η_i), $i = 4, 5$ denote the local coordinates of x_1, x_2, respectively. We complete (2.1) by setting

$$\begin{pmatrix} U_3 \\ U_4 \end{pmatrix} = \begin{pmatrix} \Phi(\xi_4, \eta_4) \\ \Phi(\xi_5, \eta_5) \end{pmatrix} = \begin{pmatrix} 1 & \eta_4 & \xi_4 & \xi_4\eta_4 & .5(\eta_4^2 - \xi_4^2) & -.5\xi_4^2 \\ 1 & \eta_5 & \xi_5 & \xi_5\eta_5 & .5(\eta_5^2 - \xi_5^2) & -.5\,\xi_5^2 \end{pmatrix} \begin{pmatrix} g(x^*) \\ g_\tau(x^*) \\ u_\xi \\ u_{\xi\eta} \\ u_{\eta\eta} \\ f(x^*) \end{pmatrix} \tag{2.6}$$

and thus obtain, at the irregular grid point,

$$\frac{c_{i,j}U_0 - U_1 - U_2}{h^2} = f_{i,j} + \tilde{f}_{i,j}, \tag{2.7}$$

where $c_{i,j} \geq 2$ depends only on the local geometry of Γ and $\tilde{f}_{i,j}$ depends on the data $f(x^*)$, $g(x^*)$, $g(x_1^*)$, $g(x_2^*)$, and $g_\tau(x^*)$.

Hence, we obtain the complete system and the resulting system matrix with diagonal $c_{i,j}$ replacing 4 and $f_{i,j} + \tilde{f}_{i,j}$ replacing $f_{i,j}$ at irregular grid points. Work involved in the proposed algorithm is to first, determine the projection point of x^* of each irregular grid point and second, evaluate $c_{i,j}$ and $\tilde{f}_{i,j}$ in (2.7) by (2.5)–(2.6) at each irregular grid point. The resulting system matrix is symmetric and positive definite and has the same sparsity as the original central finite difference scheme. Also, note that the local truncation error of (2.7) at the irregular grid point is of order $O(h)$.

It is necessary to evaluate $g_\tau(x^*)$ better than the first order in the proposed algorithm (2.5)–(2.7). Alternatively we can avoid the evaluation of $g_\tau(x^*)$ as follows. We select $(u_\eta, u_\xi, u_{\xi\eta}, u_{\eta\eta})$ as unknowns in (1.3) and use the five conditions,

$$u(x_0) = U_0, \qquad u(x_1^*) = g(x_1^*), \qquad u(x_2^*) = g(x_2^*), \qquad u(x_3^*) = g(x_3^*),$$
$$u_{\xi\xi} + u_{\eta\eta} = -f(x^*).$$

That is, we drop the condition $u_\tau = g_\tau(x^*)$ but add the condition $u(x_3^*) = g(x_3^*)$ at the next closest projection point x_3^*. Thus we carry out (2.8) instead of (2.5),

$$\begin{pmatrix} \xi_0 & \eta_0 & \xi_0\eta_0 & .5(\eta_0^2-\xi_0^2) \\ \xi_1 & \eta_1 & \xi_1\eta_1 & .5(\eta_1^2-\xi_1^2) \\ \xi_2 & \eta_2 & \xi_2\eta_2 & .5(\eta_2^2-\xi_2^2) \\ \xi_3 & \eta_3 & \xi_3\eta_3 & .5(\eta_3^2-\xi_3^2) \end{pmatrix} \begin{pmatrix} u_\xi \\ u_\eta \\ u_{\xi\eta} \\ u_{\eta\eta} \end{pmatrix} = \begin{pmatrix} U_0 - g(x^*) + .5f(x^*)\xi_0^2 \\ g(x_1^*) - g(x^*) + .5f(x^*)\xi_1^2 \\ g(x_2^*) - g(x^*) + .5f(x^*)\xi_2^2 \\ g(x_3^*) - g(x^*) + .5f(x^*)\xi_3^2 \end{pmatrix} \tag{2.8}$$

to determine the second order Taylor expansion (2.2). In this way we obtain the alternative finite difference scheme at the irregular grid point x^* of the form (2.7) but $\tilde{f}_{i,j}$ now depends on the data $f(x^*)$, $g(x^*)$, $g(x_1^*)$, $g(x_2^*)$, and $g(x_3^*)$ instead. Again, the resulting system matrix is symmetric and positive definite.

REMARK 1. Both options based on (2.5) and (2.8) are tested numerically. The second option (2.8) has the advantage that it does not need to evaluate the tangential derivative $g_\tau(x^*)$ but it uses the additional boundary conditions. For all specific extensions of the proposed method described in sections 3–6, both options will be discussed and the same remark as above applies.

REMARK 2. For the variable coefficient case the second order methods are based on the central finite difference approximation

$$\begin{aligned} &-\frac{b_{i+1/2,j}\frac{U_{i+1,j}-U_{i,j}}{h} - b_{i-1/2,j}\frac{U_{i,j}-U_{i-1,j}}{h}}{h} \\ &-\frac{b_{i,j+1/2}\frac{U_{i,j+1}-U_{i,j}}{h} - b_{i,j-1/2}\frac{U_{i,j}-U_{i,j-1}}{h}}{h} = f_{i,j}, \end{aligned} \tag{2.9}$$

where

$$b_{i\pm1/2,j} = \mu(x_{i\pm1/2}, y_j) \quad \textit{and} \quad b_{i,j\pm1/2} = \mu(x_i, y_{j\pm1/2}),$$

which replaces (2.1). Thus, we will mainly discuss the Poisson equation throughout the paper.

2.1. The level set function and the local coordinate system. In order to carry out Step 1, we represent the boundary Γ as the zero level set of a level set function ϕ,

$$\Gamma = \{x \in R^d : \phi(x) = 0\}, \qquad \Omega = \{x \in R^d : \phi(x) < 0\}.$$

Then x_0 is regular if

$$\phi(x_0 \pm he_i) \le 0 \quad \text{for all } 1 \le i \le d.$$

Using the level set function ϕ we can determine the projection points x^* and the local coordinate system (ξ, η) (see section 2.1). In this way our implementation of the proposed algorithms is very systematic and easy.

We assume that ϕ is given at only the grid points $x_{i,j}$. First we describe our procedure for determining the projection point x^* of the irregular grid point x_0 and the local coordinate (ξ, η) in R^2. We fix the direction d as the central finite difference approximation of the normal vector at $x_0 = x_{i,j}$, i.e.,

$$\tilde{d} = \left(\frac{\phi_{i+1,j} - \phi_{i-1,j}}{2h}, \frac{\phi_{i,j+1} - \phi_{i,j-1}}{2h}\right), \qquad d = \frac{\tilde{d}}{|\tilde{d}|}. \tag{2.10}$$

Then we approximate ϕ by the quadratic form

$$\phi(x_0 - \alpha d) \sim P(\alpha) = \phi(x_0) - \alpha \tilde{d} d + \frac{\alpha^2}{2} d^t H d, \tag{2.11}$$

where H is the central finite difference approximation of the Hessian at x_0,

(2.12)
$$H = \begin{pmatrix} \frac{\phi_{i+1,j} - 2\phi_{i,j} + \phi_{i-1,j}}{h^2} & \frac{\phi_{i+1,j+1} - \phi_{i-1,j+1} - \phi_{i+1,j-1} + \phi_{i-1,j-1}}{4h^2} \\ \frac{\phi_{i+1,j+1} - \phi_{i-1,j+1} - \phi_{i+1,j-1} + \phi_{i-1,j-1}}{4h^2} & \frac{\phi_{i,j+1} - 2\phi_{i,j} + \phi_{i,j-1}}{h^2} \end{pmatrix}.$$

Let $\bar{\alpha} \in R^+$ satisfy $P(\bar{\alpha}) = 0$ and set $x^* = x_0 - \bar{\alpha} d$. Then we set the local coordinate system (ξ, η) by

$$\xi = \left(\frac{\phi_{i+1,j} - \phi_{i-1,j}}{2h}, \frac{\phi_{i,j+1} - \phi_{i,j-1}}{2h} \right) / |\tilde{d}|$$
$$\eta = \left(\frac{\phi_{i,j+1} - \phi_{i,j-1}}{2h}, -\frac{\phi_{i+1,j} - \phi_{i-1,j}}{2h} \right) / |\tilde{d}|.$$

We describe the higher order method for determining the projection point x^* and the corresponding local coordinate at x^* in section 5.

3. General boundary conditions. We consider the Poisson equation $-\Delta u = f$ with boundary condition

$$\frac{\partial}{\partial \nu} u + \alpha u = g, \quad x \in \Gamma. \tag{3.1}$$

Using the local coordinate (ξ, η), the boundary Γ is described by

$$\xi = \chi(\eta) \quad \text{with } \chi'(0) = 0,\ \chi''(0) = \kappa, \tag{3.2}$$

where κ is the mean curvature of Γ at x^* and

$$\kappa = \frac{\phi_y^2 \phi_{xx} - 2\phi_x \phi_y + \phi_x^2 \phi_{yy}}{(\phi_x^2 + \phi_y^2)^{3/2}}(x^*). \tag{3.3}$$

Thus we approximate κ by first evaluating $\kappa_{i,j}$ at all grid points $x_{i,j}$ by (3.3) using the central finite difference approximation of the derivatives ϕ_x, ϕ_y, ϕ_{xx}, ϕ_{xy}, and ϕ_{yy} and then using an interpolation of $\kappa_{i,j}$ to get κ at x^*. Moreover, (3.1) is written as

$$u_\xi(\chi(\eta), \eta) - \chi'(\eta) u_\eta(\chi(\eta), \eta) = \sqrt{1 + \chi'(\eta)^2}(g(\eta) - \alpha u(\chi(\eta), \eta)). \tag{3.4}$$

Letting $\eta = 0$ in (3.4), we have

$$u_\xi = g(x^*) - \alpha u^*. \tag{3.5}$$

Moreover, taking the derivative of (2.4) with respect to η and letting $\eta = 0$, we have

$$u_{\xi\eta} - \kappa u_\eta = g'(x^*) - \alpha u_\eta. \tag{3.6}$$

Thus, among the Taylor coefficients in (1.4) we select $(u^*, u_\eta, u_{\eta\eta})$ as unknowns and the remaining can be eliminated by (3.5)–(3.6) and (3.1). Now, we use the three equations

$$u(x_0) = U_0, \qquad \frac{\partial}{\partial \nu} u(x_1^*) + \alpha u(x_1^*) = g(x_1^*), \qquad \frac{\partial}{\partial \nu} u(x_2^*) + \alpha u(x_2^*) = g(x_2^*) \tag{3.7}$$

to determine the unknowns. Let $u = \tilde{u} = \Phi(\xi, \eta)$. Then the second and third equations in (3.7) become

$$(\nu^* \cdot \nu_i^*)\Phi_\xi + (\tau^* \cdot \nu_i^*)\Phi_\eta - \alpha\Phi = g(x_i^*)$$

at (ξ_i, η_i), $i = 1, 2$. Thus, (3.7) is written as

$$\mathbf{A}\begin{pmatrix} u^* \\ u_\eta \\ u_{\eta\eta} \end{pmatrix} = \mathbf{f}, \tag{3.8}$$

where $\mathbf{A}$ is given as

$$\begin{pmatrix} 1-\alpha\xi_0 & \eta_0+(\kappa-\alpha)\xi_0\eta_0 & .5(\eta_0^2-\xi_0^2) \\ \alpha(1-\alpha\xi_1-a_1) & b_1+(\kappa-\alpha)(a_1\eta_1+b_1\xi_1)+\alpha(\eta_1+(\kappa-\alpha)\xi_1\eta_1) & b_1\eta_1-a_1\xi_1+\frac{\alpha}{2}(\eta_1^2-\xi_1^2) \\ \alpha(1-\alpha\xi_2-a_2) & b_2+(\kappa-\alpha)(a_2\eta_2+b_2\xi_2)+\alpha(\eta_2+(\kappa-\alpha)\xi_2\eta_2) & b_2\eta_2-a_2\xi_2+\frac{\alpha}{2}(\eta_2^2-\xi_2^2) \end{pmatrix},$$

$$\mathbf{f} = \begin{pmatrix} u_0-g(x^*)\xi_0-g_\tau(x^*)\xi_0\eta_0+.5f(x^*)\xi_0^2 \\ g(x_1^*)-a_1g(x^*)-(a_1\eta_1+b_1\xi_1)g_\tau(x^*)+a_1f(x^*)\xi_1-\alpha\left(g\xi_1+g_\tau\xi_1\eta_1-\frac{1}{2}f\xi_1^2\right) \\ g(x_1^*)-a_1g(x^*)-(a_2\eta_2+b_2\xi_2)g_\tau(x^*)+a_2f(x^*)\xi_2-\alpha\left(g\xi_2+g_\tau\xi_2\eta_2-\frac{1}{2}f\xi_2^2\right) \end{pmatrix}$$

for $1 \le i \le 2$, and

$$a_i = (\nu^* \cdot \nu_i^*), \qquad b_i = (\tau^* \cdot \nu_i^*).$$

The second option, where (3.6) is replaced by the additional boundary condition at x_3^*, does not require the evaluation of $g_\tau(x^*)$ as well as κ and is carried out by

$$\begin{pmatrix} 1-\alpha\xi_0 & \eta_0 & \xi_0\eta_0 & .5(\eta_0^2-\xi_0^2) \\ \alpha(1-\alpha\xi_1)-\alpha a_1 & b_1+\alpha\eta_1 & (a_1\eta_1+b_1\xi_1)+\alpha\xi_1\eta_1 & b_1\eta_1-a_1\xi_1+\frac{\alpha}{2}(\eta_1^2-\xi_1^2) \\ \alpha(1-\alpha\xi_2)-\alpha a_2 & b_2+\alpha\eta_2 & (a_2\eta_2+b_2\xi_2)+\alpha\xi_2\eta_2 & b_2\eta_2-a_2\xi_2+\frac{\alpha}{2}(\eta_2^2-\xi_2^2) \\ \alpha(1-\alpha\xi_3)-\alpha a_3 & b_3+\alpha\eta_3 & (a_3\eta_3+b_3\xi_3)+\alpha\xi_3\eta_3 & b_3\eta_3-a_3\xi_3+\frac{\alpha}{2}(\eta_3^2-\xi_3^2) \end{pmatrix}\begin{pmatrix} u^* \\ u_\eta \\ u_{\xi\eta} \\ u_{\eta\eta} \end{pmatrix}$$

$$= \begin{pmatrix} u_0-g(x^*)\xi_0+.5f(x^*)\xi_0^2 \\ g(x_1^*)-a_1g(x^*)+a_1f(x^*)\xi_1+\alpha\left(\frac{1}{2}f\xi_1^2-g\xi_1\right) \\ g(x_2^*)-a_2g(x^*)+a_2f(x^*)\xi_1+\alpha\left(\frac{1}{2}f\xi_2^2-g\xi_2\right) \\ g(x_3^*)-a_3g(x^*)+a_3f(x^*)\xi_1+\alpha\left(\frac{1}{2}f\xi_3^2-g\xi_3\right) \end{pmatrix}$$

in order to determine the second order Taylor's expansion (2.2).

4. The 3D case. In this section we discuss the 3D cases. We highlight the necessary steps to extend the method in R^2 to R^3.

We use the standard seven-point central finite difference at $x_0 = x_{i,j,k}$,

$$\frac{6U_{i,j} - U_{i-1,j,k} - U_{i+1,j,k} - U_{i,j-1,k} - U_{i,j+1,k} - U_{i,j,k-1} - U_{i,j,k+1}}{h^2} = f_{i,j}. \tag{4.1}$$

If x_0 is an irregular grid point, then we project x_0 onto the boundary Γ by the formulas corresponding to (2.10)–(2.12). Then we set the local coordinate system (ξ, η, τ) by

$$\xi = \frac{d}{|d|}, \qquad \eta = \frac{(d_2, -d_1, 0)}{|d|}, \qquad \tau = \frac{(d_3d_1, d_3d_2, -d_1^2 - d_2^2)}{\sqrt{(d_3d_1)^2 + (d_3d_2)^2 + (d_1^2 + d_2^2)^2}}$$

if $\sqrt{d_1^2+d_2^2} \geq \sqrt{d_2^2+d_3^2}$; otherwise

$$\xi = \frac{d}{|d|}, \qquad \tau = \frac{(d_3, 0, -d_2)}{|d|}, \qquad \eta = \frac{(-d_1 d_2, d_1^2+d_3^2, -d_2 d_3)}{\sqrt{(d_1 d_2)^2+(d_1^2+d_3^2)^2+(d_2 d_3)^2}}.$$

Here (η, τ) stands for the tangential coordinate and

$$d = (d_1, d_2, d_3) = \left(\frac{\phi_{i+1,j,k} - \phi_{i-1,j}}{2h}, -\frac{\phi_{i,j+1,k} - \phi_{i,j-1,k}}{2h}, \frac{\phi_{i,j,k+1} - \phi_{i,j,k-1}}{2h} \right).$$

We expand the solution u in a neighborhood of x^* by

$$\begin{aligned} u \sim \tilde{u} = \Phi(\xi, \eta, \tau) = u^* + u_\xi \xi + u_\eta \eta + u_\tau \tau + \frac{1}{2}(u_{\xi\xi}\xi^2 + u_{\eta\eta}\eta^2 + u_{\tau\tau}\tau^2) \\ + u_{\xi\eta}\xi\eta + u_{\xi\tau}\xi\tau + u_{\eta\tau}\eta\tau. \end{aligned} \tag{4.2}$$

Among the Taylor coefficients, $u^* = g(x^*)$ and the tangential derivatives u_η, u_τ are known from the boundary condition and thus we have the total of 7 unknowns in (4.2), i.e., u_ξ and the second order derivatives. Let x_i^*, $i = 1, \ldots, 5$ be the five closest projected points to x^* on Γ. We use the following seven conditions to obtain the complete system for the unknowns.

$$\begin{aligned} u(x_0) = U_0, \quad u(x_i^*) = g(x_i^*), \quad 1 \leq i \leq 5 \\ u_{\xi\xi} + u_{\eta\eta} + u_{\tau\tau} = -f(x^*). \end{aligned} \tag{4.3}$$

If we eliminate $u_{\xi\xi}$ by

$$u_{\xi\xi} = -f(x^*) - u_{\eta\eta} - u_{\tau\tau}, \tag{4.4}$$

and let $u = \tilde{u}$ in (3.3), then we obtain the 6×6 equation

$$A(u_\xi, u_{\xi\eta}, u_{\xi\tau}, u_{\eta\tau}, u_{\eta\eta}, u_{\tau\tau}) = b, \tag{4.5}$$

where

$$\text{the } i\text{th row } A = [\xi_i \;\; \xi_i\eta_i \;\; \xi_i\tau_i \;\; \eta_i\tau_i \;\; .5(\eta_i^2 - \xi_i^2) \;\; .5(\eta_i^2 - \xi_i^2)], \quad 0 \leq i \leq 5$$

and

$$\begin{aligned} b_0 &= U_0 - g(x^*) - u_\eta \eta_0 - u_\tau \tau_0 + .5 f(x^*)\xi_0^2 \\ b_i &= g(x_i^*) - g(x^*) - u_\eta \eta_i - u_\tau \tau_i + .5 f(x^*)\xi_i^2, \quad 1 \leq i \leq 5, \end{aligned}$$

where (η_i, ξ_i), $i = 0, 1, \ldots, 5$ are the local coordinates of $x_0, x_1^*, \ldots, x_5^*$, respectively. Thus, all unknowns in (4.2) are determined as a linear function of $(U_0, f(x^*), g(x^*), g_\eta(x^*), g_\tau(x^*))$ $(g(x_1^*), \ldots, g(x_5^*))$. Now, we complete (4.1) at the irregular grid point by expressing the value $u_{i\pm1,j\pm1,k\pm1}$ corresponding to the grid points outside of Ω by (4.2). Again we only modify the diagonal entry $c_{i,j,k}$ and the corresponding right-hand side at each irregular point by (4.2) and (4.5).

. . . . (1) For the second option, in which we avoid the evaluation of the tangential derivatives $(g_\eta(x^*), g_\tau(x^*))$, we carry out (4.6) instead of (4.5)

$$A(u_\xi, u_\eta, u_\tau, u_{\xi\eta}, u_{\xi\tau}, u_{\eta\tau}, u_{\eta\eta}, u_{\tau\tau}) = b, \tag{4.6}$$

where we use the seven (instead of five) additional boundary conditions at x_i^*, $1 \le i \le 7$ and

$$\text{the } i\text{th row } A = [\xi_i \;\; \eta_i \;\; \tau_i \;\; \xi_i\eta_i \;\; \xi_i\tau_i \;\; \eta_i\tau_i \;\; .5(\eta_i^2 - \xi_i^2) \;\; .5(\eta_i^2 - \xi_i^2)], \quad 0 \le i \le 7$$

and

$$b_0 = U_0 - g(x^*) + .5f(x^*)\xi_0^2, \quad b_i = g(x_i^*) + .5f(x^*)\xi_i^2 \quad \text{for } 1 \le i \le 7.$$

(2) For the mixed boundary condition (3.1) we use the following equality (3.5)–(3.6):

$$\begin{aligned} u_\xi &= g(x^*) - \alpha u^* \\ u_{\xi\eta} - \chi_{\eta\eta} u_\eta &= g_\eta(x^*) - \alpha u_\eta \\ u_{\xi\tau} - \chi_{\tau\tau} u_\tau &= g_\tau(x^*) - \alpha u_\tau \end{aligned}$$

or the corresponding second option.

5. The fourth order method. In this section we describe the fourth order method. We apply the nine point standard compact finite difference scheme [22],

$$\begin{aligned} &\frac{1}{h^2}\left(\frac{10}{3}u_{i,j} - \frac{2}{3}(u_{i-1,j} + u_{i+1,j} + u_{i,j-1} + u_{i,j+1})\right. \\ &\qquad \left. -\frac{1}{6}(u_{i-1,j-1} + u_{i-1,j+1} + u_{i+1,j-1} + u_{i+,j+1})\right) \\ &\qquad = \frac{8}{12}f_{i,j} + \frac{1}{12}(f_{i-1,j} + f_{i+1,j} + f_{i,j-1} + f_{i,j+1}). \end{aligned} \tag{5.1}$$

The grid point x_0 is irregular if the standard nine point stencil contains grid points outside of $\overline{\Omega}$. At each irregular grid point we complete (5.1) by the fourth order continuation procedure as follows.

(1) The fourth order projection of x_0 onto the boundary Γ is carried out by the fourth order polynomial interpolation of ϕ [5] based on the standard 25-point grid points given by

$$\phi \sim \sum_{m=0}^{4} \sum^{i+j=m} \frac{\phi_{ij}^{(m)}}{m!} \left(\frac{x_1}{h}\right)^i \left(\frac{x_2}{h}\right)^j \tag{5.2}$$

with

$$\begin{aligned} \phi_{10}^{(1)} &= \frac{1}{12}(\phi_{i-2,j} - 8\phi_{i-1,j} + 8\phi_{i+1,j} + \phi_{i+2,j}), \\ \phi_{20}^{(2)} &= \frac{1}{12}(-\phi_{i-2,j} + 16\phi_{i-1,j} - 30\phi_{i,j} + 16\phi_{i+1,j} - \phi_{i+2,j}), \\ \phi_{30}^{(3)} &= \frac{1}{8}(-4\phi_{i-2,j} + 8\phi_{i-1,j} - 8\phi_{i+1,j}4\phi_{i+2,j}), \\ \phi_{40}^{(4)} &= \phi_{i-2,j} - 4\phi_{i-1,j} + 6\phi_{i,j} - 4\phi_{i+1,j} + \phi_{i+2,j}, \end{aligned}$$

and

$$\begin{aligned}
\phi_{11}^{(2)} &= [1\ \ -8\ \ 0\ \ 8\ \ -1\ \ -8\ \ 64\ \ 0\ \ -64\ \ 8\ \ 0\ \ 0\ \ 0\ \ 0\ \ 0\ \ 8\ \ -64\ \ 0\ \ 64\ \ -8 \\
&\quad -1\ \ 8\ \ 0\ \ -8\ \ 1]\phi/144, \\
\phi_{21}^{(3)} &= [-1\ \ 8\ \ 0\ \ -8\ \ 1\ \ 16\ \ -128\ \ 0\ \ 128\ \ -16\ \ -30\ \ 240\ \ 0\ \ -240\ \ 30\ \ 16\ \ -128 \\
&\quad 0\ \ 128\ \ -16\ \ -1\ \ 8\ \ 0\ \ -8\ \ 1]\phi/144, \\
\phi_{31}^{(4)} &= [-4\ \ 32\ \ 0\ \ -32\ \ 4\ \ 8\ \ -64\ \ 0\ \ 64\ \ -8\ \ 0\ \ 0\ \ 0\ \ 0\ \ 0\ \ -8\ \ 64\ \ 0\ \ -64\ \ 8 \\
&\quad 4\ \ -32\ \ 0\ \ 32\ \ -4]\phi/96, \\
\phi_{22}^{(4)} &= [1\ \ -16\ \ 30\ \ -16\ \ 1\ \ -16\ \ 256\ \ -480\ \ 256\ \ -16\ \ 30\ \ -480\ \ 900\ \ -480\ \ 30 \\
&\quad -16\ \ 256\ \ -480\ \ 256\ \ -16\ \ 1\ \ -16\ \ 30\ \ -16\ \ 1]\phi/144,
\end{aligned}$$

where ϕ is the ordered vector consisting of the function values at the 25 standard grid points centered on x_0. The normal and tangent vectors at the projected point x^* are then computed by using (5.2).

(2)–(4) We expand u in a neighborhood of x^* by the fourth order Taylor polynomial in the local coordinates (ξ, η)

$$u \sim \sum_{m=0}^{4} \sum_{i=0}^{m} \frac{C(m,i) u_{i,j}^{(m)}}{m!} \xi^i \eta^j. \tag{5.3}$$

We use the equality of the equation at x^*

$$\begin{cases}
u_{\xi\xi} + u_{\eta\eta} = -f(x^*), \\
u_{\xi\xi\xi} + u_{\xi\eta\eta} = -f_\xi(x^*), \\
u_{\xi\xi\eta} + u_{\eta\eta\eta} = -f_\eta(x^*), \\
u_{\xi\xi\xi\xi} + u_{\xi\xi\eta\eta} = -f_{\xi\xi}(x^*), \\
u_{\xi\xi\xi\eta} + u_{\xi\eta\eta\eta} = -f_{\xi\eta}(x^*), \\
u_{\xi\xi\eta\eta} + u_{\eta\eta\eta\eta} = -f_{\eta\eta}(x^*).
\end{cases} \tag{5.4}$$

Thus we select $X = (u_\xi, u_\eta, u_{\xi\eta}, u_{\eta\eta})$ and $(u_{\xi\eta\eta}, u_{\eta\eta\eta}, u_{\xi\xi\eta\eta}, u_{\xi\eta\eta\eta})$ as unknowns in R^8. We use the equality $u(x_0) = U_0$ along with the 7 additional Dirichlet boundary conditions $u(x_i^*) = g(x_i^*)$ at the closest projection points x_i^*, $1 \le i \le 7$ to x^* on Γ. Hence we have an 8×8 system

$$AX = b \tag{5.5}$$

with

$$\begin{aligned}
A_i = [&\xi_i\ \ \eta_i\ \ \xi_i\eta_i\ \ (\eta_i^2 - \xi_i^2)/2\ \ (3\xi_i\eta_i^2 - \xi_i^3)/6\ \ (\eta_i^3 - 3\xi_i\eta_i^2)/6 \\
&(\xi_i\eta_i^3 - \xi_i^3\eta_i)/6\ \ (6\xi_i^2\eta_i^2 - \xi_i^4 - \eta_i^4)/24]
\end{aligned}$$

for $0 \le i \le 7$, and

$$\begin{aligned}
b_0 &= U_0 - g(x^*) - f(x^*)\xi_0^2/2 - f_\xi\xi_0^3/6 - f_\eta\eta_0\xi_0^2/2 - f_{\xi\xi}\xi_0^4/24 \\
&\quad -f_{\xi\eta}\eta_0\xi_0^3/6 - f_{\eta\eta}\eta_0^4/24, \\
b_i &= g(x_i^*) - g(x^*) - f(x^*)\xi_i^2/2 - f_\xi\xi_i^3/6 - f_\eta\eta_i\xi_i^2/2 - f_{\xi\xi}\xi_i^4/24 \\
&\quad -f_{\xi\eta}\eta_i\xi_i^3/6 - f_{\eta\eta}\eta_i^4/24
\end{aligned}$$

for $1 \le i \le 7$, to determine the Taylor polynomial (5.3).

At each irregular grid point only the diagonal entry $c_{i,j}$ and the corresponding right-hand side need to be modified and thus the resulting matrix is symmetric and keeps the sparsity.

(1) If we are able to evaluate g_η accurately, then we may use the equality $u_\eta = g_\eta(x^*)$ and (2)–(4) to reduce to the option where only the six boundary conditions $u(x_i^*) = g(x_i^*)$ (instead of seven) are equated and thus a 7×7 system determines completely the Taylor polynomial.

(2) For the mixed boundary condition $u(x) + \alpha\frac{\partial}{\partial\nu}u(x) = g(x)$, $x \in \Gamma$ we have

$$u(x_i^*) + \alpha\frac{\partial}{\partial\nu}u = g(x_i^*)$$

at each projection point x_i^* and

$$\frac{\partial}{\partial\nu}u = \nu_i^* \cdot \nu^* u_\xi + \nu_i^* \cdot \tau^* u_\eta,$$

where (ν^*, τ^*) is the normal-tangent vector pair at x^* and ν_i^* is the normal vector at x_i^*. Thus we select $X = (u^*, u_\eta, u_{\xi\eta}, u_{\eta\eta})$ and $(u_{\xi\eta\eta}, u_{\eta\eta\eta}, u_{\xi\xi\eta\eta}, u_{\xi\eta\eta\eta})$ as the unknown and use $AX = b$ (with (A, b) similar to (3.6) and appropriate additional higher order terms) to determine the Taylor polynomial (5.3).

6. The fourth order method for the heat equation. In this section we describe the fourth order scheme for the heat equation on the irregular domain Ω,

$$u_t(t,x) = \Delta u, \qquad u(0,x) = u_0(x) \tag{6.1}$$

with boundary condition

$$u(t,x) + \frac{\partial}{\partial\nu}u(t,x) = g(t,x). \tag{6.2}$$

For the simplicity of our presentation we only describe the method for the homogeneous (in time) Dirichlet boundary condition $u(t,x) = g(x)$, $x \in \Gamma$. But we indicate the specific changes needed for the general cases.

In order to develop the fourth order method we treat u_t as a forcing function f and the right-hand side of (5.1) $f_{i,j}$, is replaced by $\frac{d}{dt}u_{i,j}$; i.e.,

$$\begin{aligned}\frac{1}{h^2}\Bigg(&\frac{10}{3}u_{i,j} - \frac{2}{3}(u_{i-1,j} + u_{i+1,j} + u_{i,j-1} + u_{i,j+1})\\ &-\frac{1}{6}(u_{i-1,j-1} + u_{i-1,j+1} + u_{i+1,j-1} + u_{i+,j+1})\Bigg)\\ &+\frac{d}{dt}\left(\frac{8}{12}u_{i,j} + \frac{1}{12}(u_{i-1,j} + u_{i+1,j} + u_{i,j-1} + u_{i,j+1})\right) = 0.\end{aligned} \tag{6.3}$$

and then we apply the fourth order method as in section 5. Thus we need to be able to evaluate the vector $Y = (u_t(x^*), u_{t\xi}(x^*), u_{t\eta}(x^*), u_{t\xi\xi}(x^*), u_{t\xi\eta}(x^*), u_{t\eta\eta}(x^*))$ at x^*. To this end we expand u_t in a neighborhood of x^* by the second order Taylor polynomial

$$u_t \sim u_{t\xi}(x^*)\xi + \frac{1}{2}u_{t\xi\xi}(x^*)\xi^2 + u_{t\xi\eta}\xi\eta + \frac{1}{2}u_{t\eta\eta}(x^*)\eta^2, \tag{6.4}$$

where $u_t(x^*) = u_{t\eta}(x^*) = 0$ and

$$u_{t\xi\xi} + u_{t\eta\eta} = 0 \quad \text{at } x^*. \tag{6.5}$$

As in Step 2, we determine (6.4) completely by

$$\begin{pmatrix} \xi_0 & \xi_0\eta_0 & .5(\eta_0^2 - \xi_0^2) \\ \xi_1 & \xi_1\eta_1 & .5(\eta_1^2 - \xi_1^2) \\ \xi_2 & \xi_2\eta_2 & .5(\eta_2 - \xi_2^2) \end{pmatrix} \begin{pmatrix} u_{t\xi} \\ u_{t\xi\eta} \\ u_{t\eta\eta} \end{pmatrix} = \begin{pmatrix} (U_0)_t \\ 0 \\ 0 \end{pmatrix}, \tag{6.6}$$

where (η_i, ξ_i), $i = 0, 1, 2$ are the local coordinates of x_0, x_1^*, x_2^*, respectively. Thus the vector Y is determined as $Y = (U_0)_t V$ with $V \in R^7$. Now, we know completely the right-hand side of (5.4) as $-Y$ and we proceed to determine the fourth order Taylor expansion (5.3) completely. In this way we complete (6.3) at each irregular grid point x_0 by substituting expressions (5.3) and (6.4) into (6.3) for the corresponding values outside the domain. The work involved is first, to solve (6.6) to determine the second order Taylor expansion (6.4) for u_t and second, to solve (5.5) to determine the fourth order Taylor expansion (5.3) for u at x^*. As a consequence at each irregular grid point, the diagonal entries $\frac{8}{3}$ and $\frac{8}{12}$ in (6.3) are modified accordingly and also the right-hand side due to the nonhomogeneous boundary condition $u = g(x)$ (otherwise, no changes are required). Thus the resulting system of equations is of the form

$$QU_t = -HU + \tilde{F}, \qquad U(0) = u_0(x_{i,j}), \tag{6.7}$$

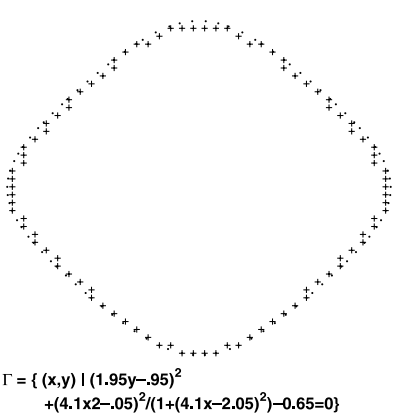
where Q and H are symmetric sparse matrices. The positivity of the matrices Q and H is demonstrated and tested numerically for our test examples.

We demonstrate the applicability of the fourth order method by the approximation of eigenvalue problem for (6.1)–(6.2), i.e., finding the eigenpair $(\lambda, u) \in R \times L^2(\Omega)$ satisfying

$$\Delta u = \lambda u, \quad u|_\Gamma = 0. \tag{6.8}$$

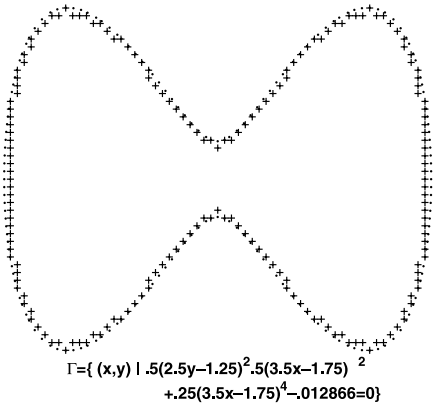
We simply consider the generalized eigenvalue problem for (6.7),

$$\lambda QU = -HU \tag{6.9}$$



and thus the eigenpairs (λ, U) approximate the ones for (6.8).

Remark 3. For the Dirichlet nonhomogeneous condition $u(t, x) = g(t, x)$, $x \in \Gamma$ we have



$$u_{t\xi\xi} + u_{t\eta\eta} = u_{tt}, \quad \text{at } x^*.$$

In order to avoid the second order derivatives in time, we do not equate (6.4) as an equality condition for determining the second order Taylor expansion for u_t. Instead we use the additional Dirichlet boundary conditions $u_t(x_3^*) = g_t(x_3^*)$, where x_3^* is the next closest projection point to x^*. Thus (6.6) is replaced by

$$\begin{pmatrix} \xi_0 & \xi_0\eta_0 & \eta_0^2/2 & \xi_0^2/2 \\ \xi_1 & \xi_1\eta_1 & \eta_1^2/2 & \xi_1^2/2 \\ \xi_2 & \xi_2\eta_2 & \eta_2^2/2 & \xi_2^2/2 \\ \xi_3 & \xi_3\eta_3 & \eta_3^2/2 & \xi_3^2/2 \end{pmatrix} \begin{pmatrix} u_{t\xi} \\ u_{t\xi\eta} \\ u_{t\eta\eta} \\ u_{t\xi\xi} \end{pmatrix} = \begin{pmatrix} (U_0)_t - g_t(x^*) - g_{t\tau}(x^*)\eta_0 \\ g_t(x_1^*) - g_t(x^*) - g_{t\tau}(x^*)\eta_1 \\ g_t(x_2^*) - g_t(x^*) - g_{t\tau}(x^*)\eta_2 \\ g_t(x_3^*) - g_t(x^*) - g_{t\tau}(x^*)\eta_3 \end{pmatrix}. \tag{6.10}$$

(a) Diamond looking boundary geometry.

(b) Butterfly looking boundary geometry.

FIG. 2. *Nonrectangular boundary geometries.*

Thus Y is of the form $Y = (U_0)_t V + \tilde{V}(t)$, where $\tilde{V} \in R^7$ depends on $(g_t(x^*), g_t(x_i^*)$, $1 \le i \le 3)$. The step to determine the fourth order Taylor expansion for u remains the same and the resulting system has the form

$$QU_t = -HU + \tilde{F}_1(t) + \frac{d}{dt}\tilde{F}_2(t),$$

where only the diagonal entry of Q at each irregular grid point is modified and depends on the geometry of the boundary Γ and the corresponding right side $\tilde{F}_1(t)$, $\tilde{F}_2(t)$ also depend on the boundary values $g(t, x)$.

For the mixed boundary condition $\frac{\partial}{\partial \nu}u + \alpha u = g$ we use exactly the same procedures in section 3 to determine the second order Taylor expansion of u_t in a neighborhood of x^*. For example, if g is time invariant, the second option uses

$$\begin{pmatrix} 1-\alpha\xi_0 & \eta_0 & \xi_0\eta_0 & .5(\eta_0^2-\xi_0^2) \\ \alpha(1-\alpha\xi_1)-\alpha a_1 & b_1+\alpha\eta_1 & (a_1\eta_1+b_1\xi_1)+\alpha\xi_1\eta_1 & b_1\eta_1-a_1\xi_1+\frac{\alpha}{2}(\eta_1^2-\xi_1^2) \\ \alpha(1-\alpha\xi_2)-\alpha a_2 & b_2+\alpha\eta_2 & (a_2\eta_2+b_2\xi_2)+\alpha\xi_2\eta_2 & b_2\eta_2-a_2\xi_2+\frac{\alpha}{2}(\eta_2^2-\xi_2^2) \\ \alpha(1-\alpha\xi_3)-\alpha a_3 & b_3+\alpha\eta_3 & (a_3\eta_3+b_3\xi_3)+\alpha\xi_3\eta_3 & b_3\eta_3-a_3\xi_3+\frac{\alpha}{2}(\eta_3^2-\xi_3^2) \end{pmatrix}$$
$$\times \begin{pmatrix} u_t^* \\ u_{t\eta} \\ u_{t\xi\eta} \\ u_{t\eta\eta} \end{pmatrix} = \begin{pmatrix} (u_0)_t \\ 0 \\ 0 \\ 0 \end{pmatrix}.$$

7. Numerical experiments. We have done a number of numerical tests which confirm the order of accuracy of our proposed second and fourth order methods for different geometries and different boundary conditions. All our computations are done using the sparse matrix routines in **Matlab**. In our numerical tests, we worked on several nonrectangular domains and present some of the results on domains with boundary geometries as shown in Figures 2(a) and 2(b). In Figure 2, the "+"s indicate the irregular grid points and the "."s represent the projected points which collectively approximate the boundary geometry. We tested the schemes by using the following examples.

TABLE 1
Grid refinement using ℓ^∞ for the example in (7.1).

Fig.		Example (7.1)	
	n	Error $\|e\|_{\ell^\infty}$	Order r
2(a)	16	1.013-4	
	32	6.924-6	4.13
	64	1.688-7	5.36

Fig.		Example (7.1)	
	n	Error $\|e\|_{\ell^\infty}$	Order r
2(a)	16	1.068-4	
	32	1.250-6	6.42
	64	3.576-8	5.13

In this example the exact solution is

$$u = \sin(x^2 + y^2) \quad \text{with } f = -4\cos(x^2 + y^2) + 4(x^2 + y^2)\sin(x^2 + y^2), \tag{7.1}$$

and for the second example we have

$$\begin{aligned} &u = \exp(-((x - 0.5)^2 + (y - 0.5)^2)) \quad \text{with} \\ &f = (4 - (1 - 2x)^2 - (1 - 2y)^2)\exp(-((x - 0.5)^2 + (y - 0.5)^2)). \end{aligned} \tag{7.2}$$

The errors $e(h)$ are measured in the ℓ_2 and ℓ^∞ norms of the difference between the finite difference solutions and the exact solutions of the differential equation. The order of convergence r is given by

$$e(h) = Ch^r \tag{7.3}$$

for some C, where the step size or grid spacing is given as $h = \frac{1}{n}$. Therefore, for a constant C the order of accuracy r is calculated by

$$r = \frac{\log\left(\frac{e(h_1)}{e(h_2)}\right)}{\log\left(\frac{h_1}{h_2}\right)}$$

for any two errors due to grid spacings h_1 and h_2 [10, 3, 22].

7.1. Examples for Dirichlet and Neumann boundary value problems in two dimensions. Among the test examples we conducted, our fourth order scheme produced machine accuracy for a fourth degree polynomial for all tested geometries. We present the results of the tests for the fourth order scheme with Dirichlet boundary conditions in Table 1. The right-hand sides of the tables show the results for option two where we avoid the calculation of tangential derivatives at x^* while the left-hand sides show the results for option one where g_n is computed analytically. In the first option, the curvature at the projected points x^* is computed as described in section 3. We use a least squares procedure [10, 3] to better determine the order of convergences of the methods as indicated in (7.3) since C may not uniformly be a constant but may depend on the closeness of the irregular grid points to the boundary (i.e., C depends on h).

In Figure 3, the left graph represents the order of convergence determination for the first option with Dirichlet boundary conditions while the right graph is for the second option. For the first option results reported in the left plot of Figure 3, we plotted the errors for 31 different values of h with $n = 15, 16, 18{-}35, 37, 39, 40, 42, 43, 49, 51, 54, 57{-}60$. Then, we determined the error rate r from (7.3) by

$$\log(\|e\|_{\ell^\infty}) = 4.94\log\left(\frac{1}{n}\right) + 5.09.$$

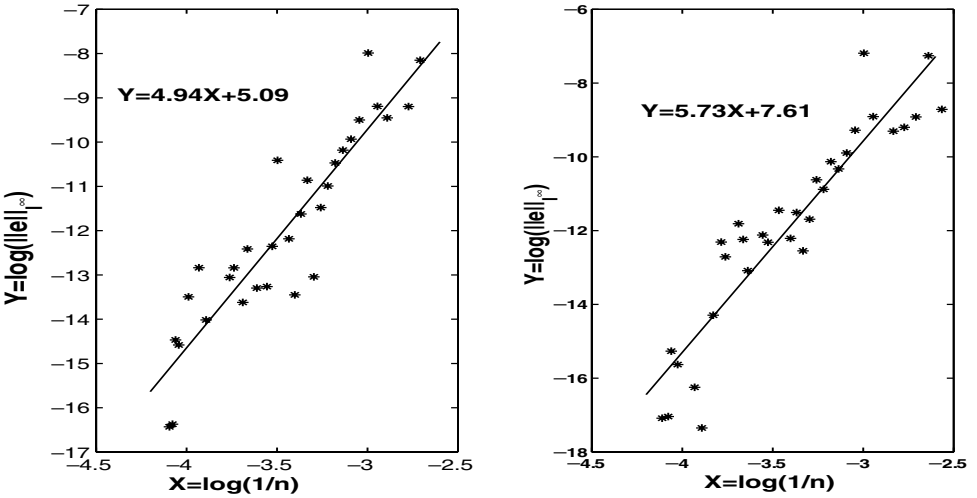


FIG. 3. *Least squares estimates of order of convergence for the first and second options shown in Table* 1.

TABLE 2
Fourth order method grid refinement analysis for Neumann conditions.

Fig.		Example (7.2)	
	n	Error $\|e\|_{\ell_2}$	Order r
2(a)	16	4.355-2	
	32	2.832-3	3.94
	64	1.186-4	4.58

Fig.		Example (7.2)	
	n	Error $\|e\|_{\ell^\infty}$	Order r
2(a)	16	5.559-3

	64	4.799-6	5.16

TABLE 3
Second order method grid refinement analysis for Neumann conditions.

Fig.		Example (7.2)	
	n	Error $\|e\|_{\ell_2}$	Order r
2(a)	37	1.056-2	
	74	2.495-3	2.08
	148	4.529-4	2.45

Fig.		Example (7.2)	
	n	Error $\|e\|_{\ell^\infty}$	Order r
2(a)	37	3.639-2	
	74	8.41-3	2.11
	148	4.990-4	2.44

For the second option results reported in the right plot of Figure 3, we plotted the errors for 32 different values of h with $n = 13{-}17, 19{-}30, 32, 34, 35, 38{-}40, 43, 44, 46, 49, 51, 56, 58, 59, 61$. The error rate is therefore determined by

$$\log(\|e\|_{\ell^\infty}) = 5.73 \log\left(\frac{1}{n}\right) + 7.61.$$

The results for the Neumann boundary conditions are shown in Table 2 for the fourth order method and Table 3 for the second order method.

In Figure 4, the left graph is for the fourth order method while the right graph is for the second order method with Neumann boundary conditions. In the least square determination of the rate for the fourth order method, we tried selected values of h with $n = 14{-}20, 23, 24, 27, 29, 30, 32, 34, 36, 38{-}41, 43, 47, 49{-}52, 57, 60, 61, 63$. As a

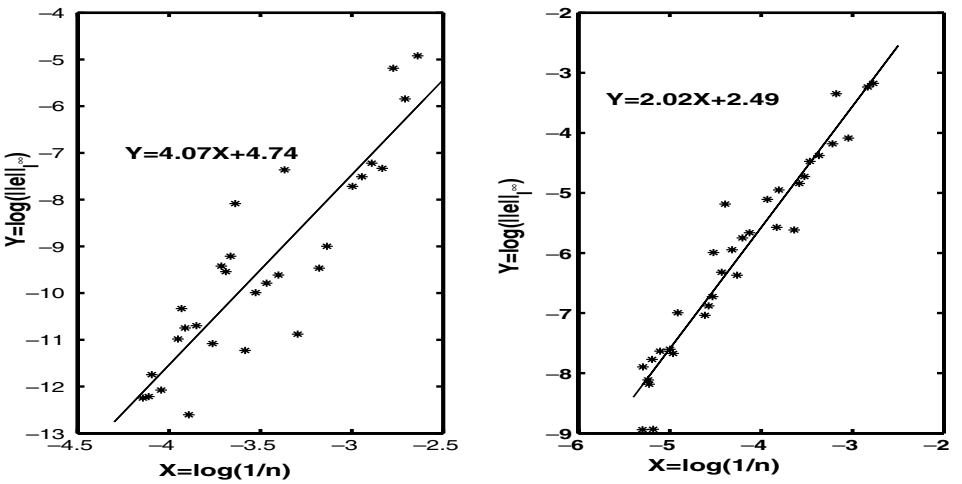

FIG. 4. *Least squares estimates of orders shown in Tables* 3 *and* 2.

result, we obtain the rate as

$$\log(\|e\|_{\ell\infty}) = 4.07 \log\left(\frac{1}{n}\right) + 4.74$$

as shown in the left graph in Figure 4.

For the second order method with Neumann boundary conditions, the different values of h tried have $n = 16, 17, 21, 24, 25, 29, 32, 34, 36, 38, 45, 46, 51, 62, 67, 71, 75, 81, 84, 92, 93, 97, 101, 136, 143, 148, 165, 178, 180, 186, 188, 199, 200$. We therefore obtained the rate as

$$\log(\|e\|_{\ell\infty}) = 2.02 \log\left(\frac{1}{n}\right) + 2.49$$

shown in the right graph in Figure 4.

In the next section, we validate the scheme by solving the associated eigenvalue problem for the circular domain and compare the estimates with exact eigenvalues.

7.2. Examples for eigenvalues and eigenfunctions in a circular domain. In order to validate our fourth order scheme, we use the scheme to solve the associated eigenvalue problem with a circular domain Ω of radius a centered at $(0, 0)$ for homogeneous Dirichlet boundary conditions. Thus we have

$$\begin{aligned} -\Delta u &= \lambda u \quad \text{for } r^2 = x^2 + y^2 < a^2, \\ u &= 0 \quad \text{for } r^2 = x^2 + y^2 = a^2. \end{aligned} \tag{7.4}$$

Through a polar coordinate transformation, we obtain the eigenpair solution as

$$\begin{pmatrix} \lambda_m, & J_m(\sqrt{\lambda} r) & \cos m\theta \\ & & \sin m\theta \end{pmatrix} \quad m = 0, 1, 2, \dots,$$

where $J_m(\cdot)$ is the Bessel function of the first kind [20] with index m and the eigenvalue λ_m satisfies

$$J_m(\sqrt{\lambda} a) = 0. \tag{7.5}$$

TABLE 4

Thus, with X_m^i representing the ith root of the Bessel's function of index m, we have

$$\lambda_m^i = \left[\frac{X_m^i}{a}\right]^2, \quad i = 1, 2, \ldots . \tag{7.6}$$

We compare the estimates from our fourth order method in Table 4 for different n's with the exact eigenvalues as calculated by (7.6). The "exact" zeros of the Bessel functions X_m are obtained from Maple Software. The last four columns in Table 4 show the difference between the estimates and the exact eigenvalues. The order of convergence of our proposed fourth order method is confirmed to be 4 by employing (7.3). In the following tables, $nnz(\cdot)$ refers to the number of nonzero elements in the stiffness matrix h and the mass matrix q, respectively. [illegible] refers to the number iterations for the Matlab function [illegible] to converge with default tolerance.

In Table 5, we show the efficiency of the fourth order method and we illustrate the complexity level and the conditioning of the resulting system matrix for the fourth order method. Specifically, we use the second order central difference scheme for estimating the eigenvalues as the benchmark. The comparisons are made through the number iterations and the [illegible] required to solve the problem by employing the Matlab function [illegible]. The function [illegible] is an iterative routine for finding a few eigenvalues and eigenvectors of a square matrix based on an implicitly restarted Arnold iteration algorithm [8, 9].

In Table 5, the first row indicates the size of the matrices which are selected almost equal for both methods. Table 5 shows that the complexity level for our fourth order method is comparable to the one for the benchmark.

Next, in Table 6 we compare the fourth order method with our second order method and the second order finite element method through the toolbox. The comparison is done so that our fourth order method yields similar levels of accuracy. The columns in Table 6 show the absolute error for the eigenvalue estimates. The comparison is described in terms of the and number of iterations for the iterative procedure. By that the efficiency and effectiveness of the fourth order method are demonstrated.

For the sake of completeness, the toolbox uses a similar method (a Matlab function [24]) to compute the eigenvalues in a selected interval.

8. Well-posedness and convergence rate. As we stated, the resulting matrices $-L_h$ are symmetric for our proposed algorithms. The positivity and diagonal dominance of the matrices are confirmed through our extensive numerical tests.

We generated the random geometry by selecting randomly distributed projection points x^* in the local square depicted in Figure 1 and then random graphs for the boundary Γ with the local coordinate determined as

$$\xi = \chi(\eta) = \frac{\kappa}{2}\eta^2 + \frac{\kappa_1}{6}\eta^3 + \frac{\kappa_2}{24}\eta^4,$$

where $\kappa = \chi''(0)$, $\kappa_1 = \chi'''(0)$, and $\kappa_2 = \chi''''(0)$ are selected randomly in the range

$[-5,5]$. Then, we evaluated the corresponding diagonal entry $c_{i,j}$. All the tests conducted in this manner show the resulting matrix to be diagonally dominant.

Next, we examine this analytically for the two-dimensional Dirichlet boundary condition case in (2.5)–(2.7). In (2.5) we have $\eta_0 = 0$ and the asymptotic relations

$$\eta_1 + \eta_2 = 0 + O(h^2), \quad \xi_i = \frac{\kappa}{2}\eta_i^2 + O(h^3), \quad i = 1,2. \tag{8.1}$$

To determine the diagonal entry $c_{i,j}$ in (2.7), we let $f = g = 0$. Then with (8.1) we have $u_{\xi\eta} = O(1)$,

$$\begin{pmatrix} \xi_0 & -.5\xi_0^2 \\ \xi_1 & .5\eta_1^2 \end{pmatrix} \begin{pmatrix} u_\xi \\ u_{\eta\eta} \end{pmatrix} = \begin{pmatrix} U_0 \\ 0 \end{pmatrix} + \begin{pmatrix} 0 \\ O(h^3) \end{pmatrix}.$$

Thus

$$u_\xi = \frac{U_0}{\xi_0} + O(h^2), \qquad u_{\eta\eta} = -\frac{2\xi_1}{\eta_1^2}\frac{U_0}{\xi_0} + O(h^2),$$

and

$$c_{i,j} = 4 - \frac{\xi_3 + \xi_4}{\xi_0} + \left(\frac{\eta_3^2 - \xi_3^2}{\eta_1^2} + \frac{\eta_4^2 - \xi_4^2}{\eta_1^2}\right)\frac{\xi_1}{\xi_0} + O(h^2).$$

Since $\frac{\xi_3+\xi_4}{\xi_0} < 0$, it follows from (8.1) that

$$c_{i,j} \sim 4 - \frac{\xi_3 + \xi_4}{\xi_0} > 4.$$

8.1. Convergence rate. Since the central finite difference scheme (2.1) is diagonally dominant and the set P of all regular points is connected by their neighbors, thus the discrete maximum principle holds. If

$$(-L_h U)(p) \geq 0 \quad \text{for all } p \in P,$$

then

$$\max_{p\in P} U_p \leq \max U_q, \quad q \in Q,$$

where Q is the set of all irregular grid points.

Consider the comparison function Φ

$$\Phi(p) = \frac{1}{4}|x_p - x_0|^2.$$

Then

$$(-L_h\Phi)(p) = 1 \quad \text{for all } p \in P. \tag{8.2}$$

Define the error e by $e_p = \bar{U}_p - U_p$ with $\bar{U}_p = u(x_p)$, the exact solution evaluated at the node x_p, and the truncation error T by

$$T = (-L_h\bar{U}) - F \quad \text{since } -L_h U = F.$$

Let $\bar{T} = \max_{p\in P} |T_p|$. Then

$$(-L_h(\bar{T}\Phi + e))(p) = \bar{T} - T_p \geq 0 \quad \text{for all } p \in P.$$

It thus follows from the maximum principle and (8.2) that

$$\max_{p\in P} e_p \leq \max_{p\in P}(\bar{T}\Phi + e_p) \leq \max_{q\in Q}(\bar{T}\Phi_q + e_q). \tag{8.3}$$

At an irregular grid point $q \in Q$ we have the following two cases:

$$c_q e_q \leq \max_{p\in P} e_p + 2\max_{q\in Q} e_q + h^2|T_q|, \quad q \in Q_1$$

or

$$c_q e_q \leq 2\max_{p\in P} e_p + h^2|T_q|, \quad q \in Q_2.$$

Thus,

$$(c_q - 2)\max_{q\in Q} e_q \leq 2\max_{p\in P} e_p + h^2 \max_{q\in Q} |T_q| \tag{8.4}$$

and

$$\max_{q\in Q} e_q \leq \rho \max_{p\in P} e_p + h^2 \max_{q\in Q} \frac{|T_q|}{c_q - 2} \quad q \in Q,$$

where

$$\rho = \max\left(\frac{2}{c_q - 2}\right) < 1 \quad (c_q > 4).$$

Then it follows from (8.3)–(8.4) that

$$(1-\rho)\max_{q\in Q} e_q \leq \bar{T}\max_{q\in Q}\Phi_q + h^2 \max \frac{|T_q|}{c_q - 2} \quad q \in Q.$$

If we apply exactly the same arguments for $\bar{T}\Phi - e_p$ we obtain the same bound for $-e_p$. Hence we conclude the error estimate

$$(1-\rho)\max_{p\in P}|e_p| \leq \bar{T}\max_{q\in Q}\Phi_q + h^2 \max_{q\in Q}\frac{|T_q|}{c_q}$$

and

$$\max_{q\in Q}|e_q| \leq \rho \max_{p\in P}|e_p| + h^2 \max_{q\in Q}\frac{|T_q|}{c_q}.$$

Since $|T_p| \leq C_1 h^2$, $p \in P$, and $|T_q| \leq C_2 h$, $q \in Q$ assuming $u \in C^4(\bar{\Omega})$. The proposed second order method is of order 2 provided the diagonal dominant condition $\rho < 1$.

FAST NUMERICAL SOLUTION OF PARABOLIC INTEGRODIFFERENTIAL EQUATIONS WITH APPLICATIONS IN FINANCE*

ANA-MARIA MATACHE†, CHRISTOPH SCHWAB‡, AND THOMAS P. WIHLER§

Abstract. We numerically solve parabolic problems $u_t + \mathcal{A}u = 0$ in $(0,T) \times \Omega$, $T < \infty$, where $\Omega \subset \mathbb{R}$ is a bounded interval and $\mathcal{A}$ is a strongly elliptic integrodifferential operator of order $\rho \in [0,2]$. A discontinuous Galerkin (dG) discretization in time and a wavelet discretization in space are used. The densely populated matrices in the corresponding linear systems of equations are replaced by sparse ones using appropriate wavelet compression techniques. The linear systems in each time step are solved by an incomplete GMRES iteration. Under these conditions, we show that the complexity of our algorithm is linear (up to some logarithmic terms) in the number of spatial degrees of freedom and present error estimates. Applications to purely discontinuous Lévy processes arising in finance are given.

Key words. parabolic equations, integrodifferential operators, discontinuous Galerkin methods, wavelets, matrix compression, GMRES, Lévy processes, Markov processes

1. Introduction.

Parabolic, possibly degenerate, evolution problems arise as Fokker–Planck equations for moments of Markovian diffusion processes X_t [15]. We mention here only micromodels of polymers [30] and asset pricing problems in mathematical finance: the celebrated Black–Scholes equation is a degenerate diffusion equation.

If the Markov process X_t is not a diffusion but a process containing jumps, infinitesimal generator of the X_t appearing in the Fokker–Planck equation is nonlocal. More precisely, if the jump process is of infinite intensity, the associated infinitesimal generators are pseudodifferential operators of order $\rho \in [0,2]$; see, e.g., [18, 19].

The discretization of such operators with standard, Galerkin type schemes, entails densely populated, ill-conditioned stiffness matrices which unduly increase the computational complexity of an implicit time-stepping scheme.

Often, the infinitesimal generators of the Markov processes generate analytic evolution semigroups, even in the case of degenerate spatial operators, so that the solutions are analytic functions of time in the open interval $(0,T]$ (see [18, Chapter 4]). This (nonuniform) time analyticity of the solution is not exploited in the classical, low-order numerical schemes such as backward differencing or implicit Runge–Kutta methods of fixed order.

In the present paper, we analyze and implement a numerical scheme for the efficient numerical solution of Fokker–Planck equations for Markov processes with jumps. The scheme is based on *hp*-discontinuous Galerkin (dG, for short) time-stepping to exploit the time analyticity of the solution for $t > 0$ and to cope with the loss of this analyticity at $t = 0$, and on piecewise polynomial functions (of fixed degree) in space. As in [37], the matrices corresponding to the nonlocal infinitesimal generators are compressed by means of a wavelet basis, thereby reducing complexity of a matrix-vector multiplication from N^2 to $\mathcal{O}(N \log N)$, where N denotes the number of spatial degrees of freedom. At the same time, the condition numbers of the matrices are shown to be bounded independently of the spatial mesh width and of the time step. We prove that this algorithm allows us to compute the whole price vector for European vanillas on Lévy (and even certain classes of Markov) processes to a mean square accuracy of $\mathcal{O}(N^{-1})$ with N degrees of freedom in at most $\mathcal{O}(N(\log N)^8)$ operations.

We discuss in detail some aspects of the implementation, based in part on [36], and numerical examples from the pricing of European contracts.

The outline of the paper is as follows. In section 2, we introduce the parabolic problems under consideration. In section 3, our applications to finance are given. Section 4 deals with the dG and wavelet discretizations in time and space, respectively. The solution of the linear systems is studied in section 5. Section 6 contains the numerical experiments. Finally, in section 7, we summarize our work with some concluding remarks.

2. Abstract parabolic evolution problems. In this section, the parabolic problems studied in this paper are introduced. Moreover, an appropriate functional setting is established.

Let $\Omega = (a, b)$, $-\infty < a < b < \infty$, be a bounded interval in $\mathbb{R}$. For $0 \le \rho \le 2$, define the spaces

$$V = \widetilde{H}^{\rho/2}(\Omega) = \begin{cases} H^{\rho/2}(\Omega) & \text{if } 0 \le \rho < 1, \\ H_{00}^{1/2}(\Omega) & \text{if } \rho = 1, \\ H_0^{\rho/2}(\Omega) & \text{if } 1 < \rho \le 2, \end{cases}$$

where $H^{\rho/2}$, $H_{00}^{1/2}$, and $H_0^{\rho/2}$ are the usual Sobolev spaces; see [1, 24], for example. We have the dense injection $V \overset{d}{\hookrightarrow} L^2(\Omega)$, where $L^2(\Omega)$ is the space of square integrable functions equipped with the usual inner product $(\cdot, \cdot)$, as well as the Gelfand triple $V \overset{d}{\hookrightarrow} L^2(\Omega) \overset{d}{\hookrightarrow} V^*$, where $V^* = H^{-\rho/2}(\Omega)$ denotes the dual space of V. Furthermore, let $\langle \cdot, \cdot \rangle_{V^* \times V}$ be the duality pairing in $V^* \times V$, and $\| \cdot \|$, $\| \cdot \|_V$, $\| \cdot \|_{V^*}$ the norms in $L^2(\Omega)$, V, V^*, respectively.

In the time interval $J = (0, T)$, $0 < T < \infty$, consider the parabolic evolution problem

$$u'(t) + \mathcal{A}u(t) = 0 \qquad \text{in } Q = J \times \Omega, \tag{2.1}$$

$$u(0) = u_0 \tag{2.2}$$

with an initial condition $u_0 \in L^2(\Omega)$, and a possibly nonlocal operator $\mathcal{A} \in \mathcal{L}(V, V^*)$ of order ρ, given in the weak form

$$\langle \mathcal{A}u, v \rangle_{V^* \times V} = a(u, v), \qquad \mathcal{A}u \in V^*,\ u, v \in V.$$

Here, $a : V \times V \to \mathbb{R}$ is a continuous bilinear form; i.e., there exists a constant $\alpha > 0$

such that

$$|a(u,v)| \le \alpha \|u\|_V \|v\|_V \qquad \forall u, v \in V. \tag{2.3}$$

Moreover, we assume that, for some constants $\beta, \gamma > 0$, the form a satisfies a Gårding inequality, i.e.,

$$a(u,u) \ge \beta \|u\|_V^2 - \gamma \|u\|^2 \qquad \forall u \in V. \tag{2.4}$$

Henceforth, without loss of generality, the bilinear form a is supposed to be coercive on $V \times V$. Indeed, substituting $\widetilde{u} = e^{-\gamma t} u$ results in the equation

$$\widetilde{u}'(t) + (\mathcal{A} + \gamma \mathbb{I})\widetilde{u} = 0 \quad \text{in } J \times \Omega, \tag{2.5}$$

$$\widetilde{u}(0) = u_0, \tag{2.6}$$

and by (2.4) the operator $\mathcal{A} + \gamma \mathbb{I}$ is coercive with coercivity constant β.

Problem (2.1)–(2.2) has a unique (weak) solution $u(t)$, and there holds the a priori estimate (see [24])

$$\|u\|_{\mathcal{C}(\overline{J}, L^2(\Omega))} + \|u\|_{L^2(J,V)} + \|u'\|_{L^2(J,V^*)} \le C \|u_0\|_{L^2(\Omega)}.$$

In this paper, the operator $\mathcal{A}$ is assumed to be the sum of a second-order differential operator and of an integrodifferential operator with a distributional kernel $k(x, x-y) \in \mathcal{D}'(\Omega \times \Omega)$, with associated bilinear form given by

$$a(u,v) = \langle \mathcal{A}u, v \rangle_{V^* \times V} = \int_\Omega \int_\Omega k(x, x-y) u(x) v(y)\, dx\, dy.$$

The kernels $k(x,z) \in \mathcal{C}^\infty(\Omega \times \mathbb{R} \setminus \{z=0\})$ are assumed to satisfy [illegible]; i.e., for all $\alpha, \beta \in \mathbb{N}_0$, there holds

$$|D_x^\alpha D_z^\beta k(x,z)| \le C |z|^{-1-\rho-\alpha-\beta}, \qquad z \ne 0, \tag{2.7}$$

uniformly with respect to $x \in \Omega$.

3. Pricing European vanillas under Lévy processes. Parabolic problems of type (2.1)–(2.2) arise in finance in the problem of option pricing. For a general Lévy process X_t [3, 31], rather than the standard Wiener process W_t as price process for the risky underlying, the infinitesimal generator $\mathcal{L}^X$ of the transition semigroup generated by X_t is an integrodifferential operator.

Specifically, we consider the problem of pricing a European option with asset price S_t given by the exponential law

$$S_t = S_0 e^{\mu t + X_t},$$

with $\mu \in \mathbb{R}$ and X_t a Lévy process.

For a given payoff $f(S)$, the value of the European option $V(t,S)$ at $S = S_t$ with maturity T is expressed by the following discounted conditional expectation:

$$V(t,S) = \mathbf{E}^{\mathbb{Q}}[e^{-r(T-t)} f(S_T) | S_t = S], \tag{3.1}$$

where $\mathbb{Q}$ is an equivalent martingale measure and r represents the riskless mean rate of return of S_t under the measure $\mathbb{Q}$; see [5, 20, 23].

3.1. Parabolic integrodifferential equation. Itô's formula for semimartingales and the principle of no-arbitrage imply that V defined in (3.1) solves the parabolic integrodifferential equation (PIDE) (cf. [29]; see also [10, Proposition 1])

$$\begin{aligned}\frac{\partial V}{\partial t}(t,S)+\frac{\sigma^2}{2}S^2\frac{\partial^2 V}{\partial S^2}(t,S)+rS\frac{\partial V}{\partial S}(t,S)-rV(t,S)\\ +\int_{\mathbb{R}}\Big(V(t,Se^y)-V(t,S)-S(e^y-1)\frac{\partial V}{\partial S}(t,S)\Big)\nu_{\mathbb{Q}}(dy)=0\end{aligned}\tag{3.2}$$

in $J\times(0,\infty)$, and

$$V(T,S)=f(S)\tag{3.3}$$

in $(0,\infty)$. Here, by $\sigma\geq 0$, we denote the diffusion component of the Lévy process; i.e., X_t can be uniquely decomposed as $X_t=\sigma W_t+Y_t$ with W_t being a standard Brownian motion and Y_t a quadratic pure jump process independent of W_t. Furthermore, $\nu_{\mathbb{Q}}(dy)$ represents the Lévy measure satisfying

$$\int_{\mathbb{R}}\min(1,y^2)\nu_{\mathbb{Q}}(dy)<\infty.\tag{3.4}$$

The Fourier transform of a Lévy process can be expressed explicitly,

$$E_{\mathbb{Q}}[e^{-iuX_t}]=e^{-t\psi(u)},$$

in terms of the Lévy–Khintchine exponent

$$\psi(u)=\frac{\sigma^2}{2}u^2+i\gamma u+\int_{|x|<1}(1-e^{-iux}-iux)\nu_{\mathbb{Q}}(dx)+\int_{|x|\geq 1}(1-e^{-iux})\nu_{\mathbb{Q}}(dx).\tag{3.5}$$

A Lévy process is characterized by the triplet $(\sigma,\gamma,\nu_{\mathbb{Q}})$, $\sigma,\gamma\in\mathbb{R}$ and the Lévy measure $\nu_{\mathbb{Q}}$.

Henceforth, we assume that $\nu_{\mathbb{Q}}(dy)$ has a density $k_{\mathbb{Q}}$, i.e., $\nu_{\mathbb{Q}}(dy)=k_{\mathbb{Q}}(y)dy$. The Lévy density $k_{\mathbb{Q}}(y)$ describes the activity of jumps of size y in X_t. We say that the Lévy process X_t is of finite activity if $k_{\mathbb{Q}}(y)$ is integrable; otherwise X_t is said to be of infinite activity.

We drop in (3.2) the subscript $\mathbb{Q}$, and switch to logarithmic price $x=\log(S)$ and to time to maturity $t\to T-t$, thereby obtaining

$$\frac{\partial u}{\partial t}(t,x)+\mathcal{L}^X[u](t,x)=0\qquad\text{in } J\times\mathbb{R},\tag{3.6}$$

$$u(0,x)=g(x)\quad\text{in }\mathbb{R},\tag{3.7}$$

where $g(x):=f(e^x)$ and $\mathcal{L}^X=\mathcal{L}^{\mathrm{BS}}+\mathcal{L}^{\mathrm{jump}}$ with

$$\mathcal{L}^{\mathrm{BS}}[v]:=-\frac{\sigma^2}{2}v''+\left(\frac{\sigma^2}{2}-r\right)v'+rv,\tag{3.8}$$

$$\mathcal{L}^{\mathrm{jump}}[v](x):=-\int_{\mathbb{R}}\{v(x+y)-v(x)-(e^y-1)v'(x)\}k(y)dy.\tag{3.9}$$

We shall use some or all of the following assumptions on the Lévy density k [27].

(A1) [illegible]. The characteristic function $\psi_0(u)$ of the pure jump part Y_t of the Lévy process X_t satisfies the following: there exist constants c_1, $C_+ > 0$ and $\alpha < 2$ such that

$$|\psi_0(\xi) - ic_1\xi| \le C_+(1+|\xi|^2)^{\alpha/2} \qquad \forall \xi \in \mathbb{R}. \tag{3.10}$$

(A2) [illegible]. There are constants $C > 0$, $\eta_- > 0$, and $\eta_+ > 1$ such that

$$\forall |z| > 1, \quad k(z) \le C \begin{cases} e^{-\eta_-|z|} & \text{if} \quad z < 0, \\ e^{-\eta_+|z|} & \text{if} \quad z > 0. \end{cases} \tag{3.11}$$

(A3) [illegible]. For all $\beta \in \mathbb{N}_0$, there exists $C(\beta)$ such that

$$|k^{(\beta)}(z)| \le C(\alpha)|z|^{-(1+\alpha+\beta)_+} \qquad \forall z \neq 0. \tag{3.12}$$

In addition, if $\sigma = 0$, we assume that $0 < \alpha < 2$.

(A4) [illegible] $k(z)$. There is $C_- > 0$ such that

$$\forall 0 < |z| < 1, \quad \frac{1}{2}(k(-z) + k(z)) \ge \frac{C_-}{|z|^{1+\alpha}}. \tag{3.13}$$

[illegible] 3.1.

(i) Since $E_{\mathbb{Q}}[S_t] < \infty$, we have that $\int_{|z|>1} e^z k(z)dz < \infty$. This holds for all k satisfying (A1)–(A2) due to $\eta_+ > 1$ which, from now on, is assumed to be fulfilled.

(ii) Assumption (A2) implies that X_t has finite moments of all orders.

(iii) Assumption (A3) is required in the analysis of the wavelet compression of the moment matrix of $k(z)$; however, it only needs to be satisfied for a finite range of β.

(iv) A Lévy process X_t with $\sigma = 0$ is called a [illegible]. If X_t is a pure jump process, we assume that it is of infinite activity, i.e.,

$$k(z) \text{ satisfies (A1)–(A4) with } 0 < \alpha < 2 \qquad (\text{if } \sigma = 0). \tag{3.14}$$

(v) If the Lévy process is of finite activity, we assume $\sigma > 0$ and that $k(z)$ satisfies (A1)–(A3) with $\alpha < 0$.

3.2. Examples of Lévy processes. Different parameterizations of the Lévy measure have been proposed in the literature. We mention here the variance gamma (cf. [25]) (abbreviated as VG) process, with

$$k(y) = C \begin{cases} |y|^{-1}e^{-\eta_-|y|} & \text{if} \quad y < 0, \\ |y|^{-1}e^{-\eta_+|y|} & \text{if} \quad y > 0, \end{cases}$$

the so-called CGMY model [6, 8, 9, 21] (also referred to as tempered or truncated tempered stable processes or "truncated Lévy flights" in physics), with

$$k(y) = C \begin{cases} \dfrac{e^{-\eta_-|y|}}{|y|^{1+\alpha}} & \text{if} \quad y < 0, \\ \dfrac{e^{-\eta_+|y|}}{|y|^{1+\alpha}} & \text{if} \quad y > 0, \end{cases} \tag{3.15}$$

$0 < \alpha < 2$, the normal inverse Gaussian process (NIG) [2], and hyperbolic and generalized hyperbolic processes [12, 13, 14]. These are all examples of Lévy processes of infinite activity.

The classical Merton model [28] is based on a drifted Brownian motion with finitely many jumps, i.e., $X_t = \sigma W_t + \sum_{i=1}^{N_t} Y_i$. Here, $\{Y_i\}$ are independent, identically distributed random variables with distribution function $f(z)$, and $\{N_t\}$ is a Poisson process with intensity λ. The Lévy measure is given by $\nu(dz) = k(z)dz$ with $k(z) = \lambda f(z)$. With $f_M(z) = (\sqrt{2\pi}\sigma_M)^{-1} \exp(-(z-\mu_M)^2/(2\sigma_M^2))$, i.e., f_M is the normal distribution with mean μ_M and standard deviation σ_M, Merton's model is a finite-intensity Lévy process which satisfies (A1)–(A3) with $\alpha = -\infty$.

In addition, we mention here the model proposed by Kou [22] which assumes $f_{Kou}(z) = p_+ M \exp(-Mz)\chi_{\mathbb{R}_+}(z) + p_- G \exp(Gz)\chi_{\mathbb{R}_-}(z)$, $p_+ + p_- = 1$. Here, X_t is a finite activity Lévy process with k satisfying (A1)–(A3) for $\alpha = -1$.

3.3. Variational setting. Here, without loss of generality, we only elaborate on the problem of pricing European vanillas. More precisely, we consider European call, $f(S) = \max(S-K, 0)$, and put, $f(S) = \max(K-S, 0)$, options, with $K > 0$ being the so-called strike price. More general payoffs in (3.3) (with polynomial growth at infinity, for example) could be treated similarly.

Since $(e^x - K)_+, (K - e^x)_+ \notin L^2(\mathbb{R})$, we consider weighted Sobolev spaces accounting for the growth of solutions at infinity in order to obtain an appropriate variational formulation of (3.6), (3.7). To this end, denote, for $w \in L^1_{\mathrm{loc}}(\mathbb{R})$, $w' \in L^\infty(\mathbb{R})$, by $H^1_{\pm w}(\mathbb{R})$ the weighted Sobolev space

$$H^1_{\pm w}(\mathbb{R}) := \{v \in L^1_{\mathrm{loc}}(\mathbb{R}) \mid e^{\pm w} v, e^{\pm w} v' \in L^2(\mathbb{R})\}. \tag{3.16}$$

Similarly, let $L^2_{\pm w}(\mathbb{R}) := \{v \in L^1_{\mathrm{loc}}(\mathbb{R}) \mid e^{\pm w} v \in L^2(\mathbb{R})\}$. To the operator $\mathcal{L}^X$ the following bilinear form is associated:

$$a^{\pm w}(\varphi, \psi) := \int_{\mathbb{R}} \mathcal{L}^X[\varphi](x)\psi(x)e^{\pm 2w(x)}\, dx, \qquad \varphi, \psi \in C_0^\infty(\mathbb{R}).$$

Set $g(x) = (e^x - K)_+$ (the case of a put can be treated analogously), and let

$$w(x) = \begin{cases} \omega_- |x| & \text{if } x < 0, \\ \omega_+ |x| & \text{if } x > 0. \end{cases} \tag{3.17}$$

Furthermore, assume that $0 \le \omega_- < \eta_-$, $1 < \omega_+ < \eta_+$ and that $\sigma > 0$. Then, by [27, Theorem 3.4], the problem of finding $u \in L^2(J; H^1_{-w}(\mathbb{R})) \cap H^1(J; (H^1_{-w}(\mathbb{R}))^*)$ such that

$$\frac{\partial}{\partial t}(u(t), v)_{L^2_{-w}(\mathbb{R})} + a^{-w}(u(t), v) = 0 \quad \forall\, v \in H^1_{-w}(\mathbb{R}),$$
$$u(0) = g,$$

admits a unique solution.

3.4. Localization. The numerical solution of (3.6), (3.7) requires the truncation of $\mathbb{R}$ to a bounded computational domain $\Omega_R = (-R, R)$ (note that barrier-like contracts directly lead to the PIDE on the finite interval). In the classical Black–Scholes model [4], i.e., in the absence of $\mathcal{L}^{\mathrm{jump}}$, the localization can be effected by a simple restriction to Ω_R and the localization error may be estimated by local considerations. However, in the presence of the nonlocal operator $\mathcal{L}^{\mathrm{jump}}$ corresponding to

the jump part of the price process $(X_t)_t$, such local arguments do not apply, since the computation of the solution requires information on the payoff on the whole real line $\mathbb{R}$.

As the transformation $u(t,\cdot) \to e^{-rt}u(t,\cdot + rt)$ reduces (3.6), (3.7) to the case where $r = 0$, we henceforth assume, without loss of generality, that $r = 0$.

Based on the observation that the excess to payoff value $U = u - g$ decays exponentially as $|x| \to \infty$, we restrict the PIDE for the excess to payoff value U to Ω_R. Specifically, the excess to payoff function U solves

$$\frac{\partial U}{\partial t}(t,x) + \mathcal{L}^X[U](t,x) = -\mathcal{L}^X[g] \quad \text{in } J \times \mathbb{R}, \tag{3.18}$$

$$U(0,x) = 0 \qquad \text{in } \mathbb{R}. \tag{3.19}$$

Now, rather than solving (3.18), (3.19), we solve the truncated problem in $(0,T)\times\Omega_R$

$$\frac{\partial U_R}{\partial t} + \mathcal{L}_R[U_R] = -\mathcal{L}^X[g]|_{\Omega_R} \quad \text{in} \quad J \times \Omega_R, \tag{3.20}$$

$$U_R(t,x) = 0 \qquad \text{in} \quad J \times \mathbb{R}\backslash\Omega_R, \tag{3.21}$$

$$U_R(0,x) = 0 \qquad \text{in} \quad \Omega_R, \tag{3.22}$$

with $\mathcal{L}_R$ being the restriction of $\mathcal{L}^X$ to Ω_R. Note that, in contrast to the standard Black–Scholes case ($\mathcal{L}^{\text{jump}} = 0$), the nonlocal operator $\mathcal{L}^{\text{jump}}$ requires the payoff function g to be specified also outside the domain Ω_R.

By [27, Proposition 3.6], the right-hand side $-\mathcal{L}^X[g]$ is given by $-\mathcal{L}^X[g] = \sigma^2/2K\delta_{\log(K)} - \mathcal{L}^{\text{jump}}[g]$ with $\mathcal{L}^{\text{jump}}[g] \in C^\infty(\mathbb{R}\backslash\log(K)) \cap L^1_{\text{loc}}(\mathbb{R})$ decaying exponentially at infinity: $-\mathcal{L}^{\text{jump}}[g] \le Ce^{-\eta_\mp|x|}$ as $\pm x \to \infty$. Choosing the exponent w as in (3.17) with $0 < \omega_+ < \eta_-$ and $0 < \omega_- < \eta_+$ implies that $-\mathcal{L}^X[g] \in (H^1_w(\mathbb{R}))^*$, and by [27, Theorem 3.4], the variational problem of finding $U \in L^2(J; H^1_w(\mathbb{R})) \cap H^1(J; (H^1_w(\mathbb{R}))^*)$ such that

$$\frac{d}{dt}(U(t),v)_{L^2_w(\mathbb{R})} + a^w(U(t),v) = -\langle \mathcal{L}^X[g], v\rangle_{(H^1_w(\mathbb{R}))^*\times H^1_w(\mathbb{R})} \quad \forall\, v \in H^1_w(\mathbb{R}),$$

with

$$U(0) = 0,$$

is uniquely solvable. Consequently, the excess to payoff function U decays exponentially at infinity, and by [27, Theorem 4.1], the error $U_R - U$ caused by the localization decays exponentially as $R \to \infty$.

3.5. Parabolic setting. We now verify that the localized problem (3.20)–(3.22) can be cast in the variational setting (2.3), (2.4). Let $\mathcal{A} := \mathcal{L}_R$ and $a(\cdot,\cdot)$ denote the bilinear form induced by $\mathcal{A}$:

$$a(\varphi,\psi) := \int_{\Omega_R} \mathcal{A}[\varphi](x)\psi(x)dx \qquad \forall\, \varphi,\psi \in C_0^\infty(\Omega_R).$$

If $\sigma > 0$, the price process contains a diffusion component and the order of the operator $\mathcal{L}^X$ is 2. Then $a(\cdot,\cdot)$ can be extended continuously to $V \times V$ with $V := H^1_0(\Omega_R)$ and the following Gårding inequality holds: there exist $c_1, c_2 > 0$ such that

$$a(v,v) \ge c_1\|v\|^2_{H^1(\Omega_R)} - c_2\|v\|^2_{L^2(\Omega_R)} \qquad \forall\, v \in V.$$

In the pure jump case, $\sigma = 0$, the order of $\mathcal{L}^X$ is in general $\max\{1, \alpha\}$ due to the presence of the drift term in $\mathcal{L}^X$.

PROPOSITION 3.2. [illegible] X_t [illegible] $\sigma = 0$ [illegible] k [illegible] (A1)–(A4) [illegible] $0 < \alpha < 2$ [illegible] $c_1 = c_1(R) > 0$ [illegible] $c_2 = c_2(R) > 0$ [illegible]

$$\forall\, u \in \tilde{H}^{\alpha/2}(\Omega_R), \quad a(u,u) \geq c_1 \|u\|^2_{\tilde{H}^{\alpha/2}(\Omega_R)} - c_2 \|u\|^2_{L^2(\Omega_R)}; \tag{3.23}$$

[illegible] $\tilde{H}^{\alpha/2}(\Omega_R)$ [illegible] $a(\cdot,\cdot)$ [illegible] (2.4). [illegible]. By density, we may assume $u \in C_0^\infty(\Omega_R)$. Then $(u', u) = 0$. By $\tilde{u}$, we denote the extension of u by zero to $\mathbb{R}$, and by $a^{\mathrm{sym}}(\varphi, \psi) = (a(\varphi,\psi) + a(\psi,\varphi))/2$ the bilinear form corresponding to the symmetric part $\mathcal{L}^{\mathrm{sym}} := \frac{1}{2}(\mathcal{L}^X + (\mathcal{L}^X)^*) = \frac{1}{2}(\mathcal{L}^{\mathrm{jump}} + (\mathcal{L}^{\mathrm{jump}})^*)$ of $\mathcal{L}^X = \mathcal{L}^{\mathrm{jump}}$. Then there holds

$$a(u,u) = a^{\mathrm{sym}}(u,u) = \langle \mathcal{L}^{\mathrm{sym}} \tilde{u}, \tilde{u} \rangle = \frac{1}{2} \int_{\mathbb{R}} \int_{\mathbb{R}} (k(x-y) + k(y-x))(\tilde{u}(x) - \tilde{u}(y))^2 dx dy.$$

Due to (A4), we obtain

$$a(u,u) \geq C_- \int_{\mathbb{R}} \int_{\mathbb{R}} \frac{(\tilde{u}(x) - \tilde{u}(y))^2}{|x-y|^{1+\alpha}} dy dx = C_- \left(\|u\|^2_{\tilde{H}^{\alpha/2}(\Omega_R)} - \|u\|^2_{L^2(\Omega_R)} \right). \qquad \square$$

[illegible] 3.3. Proposition 3.2 states a Gårding inequality (2.4) in the pure jump case $\sigma = 0$ for all jump intensities $\alpha \in (0,2)$. However, if the term (u', v) is present, the continuity (2.3) on $V = \tilde{H}^{\alpha/2}$ holds only if $1 \leq \alpha \leq 2$ [27]. Nevertheless, our framework is applicable to (3.15), for all $0 < \alpha < 2$, since the term (u', v) can be removed.

In order to prove (2.3) in the case $\sigma = 0$ and $0 < \alpha < 1$, it is important to remove the "drift" term so that the transformed equation satisfies the Gårding inequality (2.4) in $\tilde{H}^{\alpha/2}(\Omega_R)$ as well as the continuity estimate (2.3). Let $\mathcal{A}^{\mathrm{jump}} := \mathcal{L}^{\mathrm{jump}}|_{\Omega_R}$ be the restriction of the integrodifferential operator $\mathcal{L}^{\mathrm{jump}}$ to Ω_R. By reduction to the "transformed" variables, we assume again that $r = 0$, together with $0 < \alpha < 1$. Then

$$\mathcal{A}[u] = -\frac{\sigma^2}{2} u'' + \frac{\sigma^2}{2} u' + \mathcal{A}^{\mathrm{jump}}[u]. \tag{3.24}$$

Next, the operator $\mathcal{A}^{\mathrm{jump}}$ can be written as a sum of a first-order term and an integrodifferential operator $\mathcal{C}$ which is continuous and coercive on $\tilde{H}^{\alpha/2}(\Omega_R)$:

$$\langle \mathcal{A}^{\mathrm{jump}} \varphi, \psi \rangle = c_1 \langle \varphi', \psi \rangle + \langle \mathcal{C}[\varphi], \psi \rangle \quad \forall\, \varphi, \psi \in C_0^\infty(\Omega_R), \tag{3.25}$$

with

$$c_1 := \int_{\mathbb{R}} (e^y - 1) k(y) dy.$$

The operator $\mathcal{C}$ is defined by

$$\langle \mathcal{C} u, v \rangle := - \int_{\mathbb{R}} \int_{\mathbb{R}} k(y-x)(\tilde{u}(y) - \tilde{u}(x)) \tilde{v}(x) dy dx \quad \forall\, u, v \in \tilde{H}^{\alpha/2}(\Omega_R),$$

where, by $\tilde{v}$, we denote the extension by zero of v to $\mathbb{R}$. Then, there exist constants $C, C_1, C_2 > 0$ such that

$$\langle \mathcal{C} u, v \rangle \leq C \|u\|_{\tilde{H}^{\alpha/2}(\Omega_R)} \|v\|_{\tilde{H}^{\alpha/2}(\Omega_R)} \qquad \forall\, u, v \in \tilde{H}^{\alpha/2}(\Omega_R),$$

$$\langle \mathcal{C} u, u \rangle \geq C_1 \|u\|^2_{\tilde{H}^{\alpha/2}(\Omega_R)} - C_2 \|u\|^2_{L^2(\Omega_R)} \qquad \forall\, u \in \tilde{H}^{\alpha/2}(\Omega_R).$$

We have seen that the presence of the drift term $c_1\varphi'$ obstructs the continuity of $\langle \mathcal{A}^{\text{jump}}[\varphi], \psi\rangle$. We remove this term by the transformation

$$U(t,x) = V(t, x - (\sigma^2/2 + c_1)t), \tag{3.26}$$

which yields the parabolic problem

$$\frac{\partial V}{\partial t}(t,x) - \frac{\sigma^2}{2}\frac{\partial^2 V}{\partial x^2} + \mathcal{C}[V](t,x), = \left(-\mathcal{L}^X[g]|_{\Omega_R}\right)(x + (\sigma^2/2 + c_1)t),$$
$$V(0,x) = 0.$$

3.4. We note that the numerical scheme proposed in this paper exploits the parabolic nature of (3.6) and, furthermore, that a dominant first-order term may be a source of instabilities even in the case $\sigma \neq 0$. Therefore, the removal of the "drift" is also of interest from the point of view of numerical approximation.

Due to our previous considerations, $a(\cdot,\cdot) : V \times V \to \mathbb{R}$ satisfies (2.3), (2.4) (cf. Proposition 3.2) in the triple $V \overset{d}{\hookrightarrow} L^2(\Omega_R) \overset{d}{\hookrightarrow} V^*$ with

$$V := \tilde{H}^{\rho/2}(\Omega_R),$$

where the order ρ is given by

$$\rho = \begin{cases} 2 & \text{if } \sigma > 0, \\ \alpha & \text{if } \sigma = 0. \end{cases} \tag{3.27}$$

For any $v \in H^{\rho/2}$, let $P_a^V v$ denote the V-projection of v with respect to $a(\cdot,\cdot)$, i.e., $a(v - P_a^V v, w) = 0$ for all $w \in V$. By the continuity of $a(\cdot,\cdot)$, it holds that

$$\|P_a^V v\|_V \le C\|v\|_{H^{\rho/2}(\Omega_R)} \qquad \forall\, v \in H^{\rho/2}(\Omega_R). \tag{3.28}$$

The variational formulation of (3.20)–(3.22) reads: find $U_R \in L^2(J,V) \cap H^1(J,V^*)$ such that

$$\left(\frac{\partial U_R}{\partial t}(t,\cdot), v\right)_{L^2(\Omega_R)} + a(U_R(t,\cdot), v) = -\langle \mathcal{L}^X[g], v\rangle_{V^*\times V} \qquad \forall\, v \in V, \tag{3.29}$$

$$U_R(0,\cdot) = 0. \tag{3.30}$$

Obviously, (3.29), (3.30) is equivalent to solving

$$\left(\frac{\partial u_R}{\partial t}(t,\cdot), v\right)_{L^2(\Omega_R)} + a(u_R(t,\cdot), v) = 0 \qquad \forall\, v \in V, \tag{3.31}$$

$$u_R(0,\cdot) = u_0 := P_a^V g, \tag{3.32}$$

where, evidently, $u_R = P_a^V g + U_R$.

Hence, dropping the subscript R to simplify notations and referring to (3.31), (3.32), we are now in the setting of section 2 with $u_0 \in V$.

3.6. Non–translation-invariant operators. The numerical method presented in this paper (see sections 4, 5, and 6) applies also to the more general case where

the log-price process X_t is a Markov process with increments $X_t - X_s$ that are no longer independent of X_s for $t > s$. In particular, we allow for volatilities $\sigma(x)$ and singular jump measures that depend on x. Instead of the translation-invariant operator $\mathcal{L}^X$ from (3.8)–(3.9) we now consider a more general operator $\mathcal{L}^X$

$$\mathcal{L}^X[\varphi](x) := -\frac{\sigma(x)^2}{2}\varphi''(x) + \left(\frac{\sigma(x)^2}{2} - r\right)\varphi'(x) + r\varphi + \mathcal{L}^{\text{jump}}[\varphi](x), \tag{3.33}$$

with the integral operator $\mathcal{L}^{\text{jump}}$ given by

$$\mathcal{L}^{\text{jump}}[\phi](x) := -\int_{\mathbb{R}} \{\phi(y) - \phi(x) - \left(e^{y-x} - 1\right)\phi'(x)\}k(x, y-x)\, dy. \tag{3.34}$$

We assume that

$$0 < \sigma_0 \le \sigma(x) \le \sigma_1 \quad \forall\, x \in \Omega_R,$$

and that $k(x, z)$ satisfies the assumptions (A1)–(A2) uniformly with respect to $x \in \Omega_R$. Instead of (A3), we require the Calderón–Zygmund estimates: for all $\beta, \gamma \in \mathbb{N}_0$, there holds

$$|\partial_x^\gamma \partial_z^\beta k(x, z)| \le C(\gamma, \beta)|z|^{-(1+\alpha+\beta+\gamma)}, \qquad z \neq 0. \tag{3.35}$$

In the case $\sigma = 0$, we require (A4) uniformly with respect to $x \in \Omega_R$. If $\sigma > 0$ or $\alpha \ge 1$, the corresponding bilinear form a_R satisfies (2.3), (2.4). If $\sigma = 0$ and $\alpha < 1$, we need to assume that we can transform the problem such that a_R satisfies (2.3).

4. Numerical solution. The aim of this part is to discretize the parabolic equation (2.1), (2.2) in time and space using a dG scheme on $J = (0, T)$, and a wavelet finite element method on $\Omega = (a, b)$. Again, $\mathcal{A} : V \to V^*$ in (2.1) is a possibly nonlocal operator.

In the ensuing analysis, we shall need to consider functions in V with additional regularity. For this reason, we introduce the spaces $\mathcal{H}^s(\Omega)$, $s \ge \rho/2$, given by

$$\mathcal{H}^s(\Omega) = \begin{cases} V = \widetilde{H}^{\rho/2}(\Omega) & \text{for } s = \rho/2, \\ V \cap H^s(\Omega) & \text{for } s > \rho/2. \end{cases}$$

From now on, in order to cope with the assumptions in section 3, the initial condition is supposed to fulfill $u_0 \in V$.

4.1. Spatial semidiscretization. Let $\mathcal{T}^0$ be a fixed coarse partition of Ω. Furthermore, define the mesh $\mathcal{T}^l$, for $l > 0$, by bisection of each interval in $\mathcal{T}^{l-1}$. We assume that the mesh $\mathcal{T}_h$ is obtained in this way as $\mathcal{T}^L$, for some $L > 0$, such that $h = C2^{-L}$.

For $0 \le \rho < 1$, the space V_h is defined as the space of piecewise, possibly discontinuous polynomials of degree $p \ge 0$ on $\mathcal{T}_h$. For $1 \le \rho \le 2$, V_h is the space of all continuous piecewise polynomials of degree $p \ge 1$ on the triangulation $\mathcal{T}_h$ which vanish on the boundary $\partial\Omega$.

In the same way, we define the spaces V^l corresponding to the triangulation $\mathcal{T}^l$, so that we have $V^0 \subset V^1 \subset \cdots \subset V^L = V_h$. Let $N^l = \dim V^l$ and $N = \dim V_h = N^L = C2^L$.

The semidiscrete problem corresponding to (2.1), (2.2) reads as follows: Given $u_0 \in V$, find $u_h \in H^1(J, V_h)$ such that

$$\left(\frac{d}{dt}u_h, v_h\right) + a(u_h, v_h) = 0 \qquad \forall\, v_h \in V_h \tag{4.1}$$

and

$$u_h(0) = P_{L^2}^{V_h} u_0. \tag{4.2}$$

Here, $P_{L^2}^{V_h}$ is the L^2-projection onto V_h.

4.1.1. Wavelet basis. In a fully discrete approximation (in time and space) with the parabolic problem (2.1), (2.2), systems of linear equations have to be solved in each time step. Since $\mathcal{A}$ is nonlocal, the matrices corresponding to these linear systems are fully populated. Therefore, matrix compression techniques, transforming the dense matrices into sparse ones, have to be employed. The compressed systems may then be manipulated in linear complexity.

Using an appropriate basis for the finite-dimensional space V_h, we will be able to represent the bilinear form $a(\cdot,\cdot)$ as a matrix whose entries are mostly negligible, thereby allowing for matrix compression techniques.

More precisely, we consider so-called biorthogonal wavelets

$$\{\psi_j^l\}_{j,l}, \qquad l = 0, 1, \ldots, \quad j = 1, 2, \ldots, M^l, \tag{4.3}$$

which allow for optimal preconditioning. They satisfy the following properties (see, e.g., [7]):

1. $V^L = \operatorname{span}\{\psi_j^l \mid 0 \le l \le L, 1 \le j \le M^l\}$.
2. The function ψ_j^l has support $S_j^l = \operatorname{supp}\psi_j^l$ of diameter bounded by $C2^{-l}$.
3. Wavelets ψ_j^l with $\overline{S_j^l} \cap \partial\Omega = \emptyset$ have vanishing moments up to order p, i.e., $(\psi_j^l, q) = 0$ for all polynomials q of order p or less.
4. The functions ψ_j^l for $l \ge l_0$ are obtained by scaling and translation of the functions $\psi_j^{l_0}$.
5. For all $v_h = \sum_{l=0}^{L}\sum_{j=1}^{M^l} v_j^l \psi_j^l \in V_h$, there holds the norm equivalence

$$|||v_h|||_s^2 := \sum_{l=0}^{L}\sum_{j=1}^{M^l} |v_j^l|^2 2^{2ls} \sim \|v\|_{\widetilde{H}^s(\Omega)}^2 \tag{4.4}$$

for $0 \le s \le 1$.

4.1. Our biorthogonal wavelets in the case $p = 1$ are continuous, piecewise linear spline wavelets vanishing outside $\Omega = (0,1)$ (for more general domains $\Omega = (a,b)$, they are obtained by simple scalings). The interior wavelets have two vanishing moments and are obtained from the mother wavelet $\psi(x)$ which takes the values $(0, -1/2, 1, -1/2, 0)$ at $(0, 1/4, 1/2, 3/4, 1)$ by scaling and translations: $\psi_j^l(x) := \psi(2^{l-1}x - (2j-1)2^{-2})$ for $1 \le j \le 2^l - 2$ and $l \ge 2$. The boundary wavelets are constructed from the continuous, piecewise linear functions ψ_*, with values $(0, 1, -1/2, 0)$ at $(0, 1/4, 1/2, 3/4)$, and ψ^*, taking values $(0, -1/2, 1, 0)$ at $(1/4, 1/2, 3/4, 1)$: $\psi_0^l(x) = \psi_*(2^{l-1}x)$ and $\psi_{2^l-1}^l(x) = \psi^*(2^{l-1}x - 2^{l-1} + 1)$. Higher-order spline wavelets with analogous properties have been given in [11].

4.1.2. Matrix compression. The bilinear form a on $V_h \times V_h$ corresponds to a matrix $\mathbf{A}$ with entries $A_{(l,j),(l',j')} = a(\psi_{j'}^{l'}, \psi_j^l)$ which, due to the Caldéron–Zygmund estimates (2.7), decay with increasing distance of their supports. Hence, we can define a compressed matrix $\tilde{\mathbf{A}}$ and a corresponding bilinear form $\tilde{a}$ by replacing some of the small entries in $\mathbf{A}$ with zero:

$$\tilde{A}_{(j,l),(j',l')} := \begin{cases} A_{(j,l),(j',l')} & \text{if } \operatorname{dist}(S_j^l, S_{j'}^{l'}) \le \delta_{l,l'} \text{ or } S_j^l \cap \partial\Omega \neq \emptyset, \\ 0 & \text{otherwise.} \end{cases} \tag{4.5}$$

Here, the truncation parameters $\delta_{l,l'}$ are given by

$$\delta_{l,l'} := c \max\{2^{-L+\hat{\alpha}(2L-l-l')}, 2^{-l}, 2^{-l'}\}, \tag{4.6}$$

with some parameters $c > 0$ and $1 \ge \hat{\alpha} > 0$, and $S_j^l = \operatorname{supp} \psi_j^l$.

By continuity and coercivity of the bilinear form a, we have the norm equivalence

$$\|u\|_a := (a(u,u))^{1/2} \sim \|u\|_V.$$

In [37, Proposition 3.2], the following was proved.

PROPOSITION 4.2. [illegible] c [illegible] (4.6) [illegible] $0 < \widetilde{\alpha} < \infty$ [illegible] L [illegible]

$$|\widetilde{a}(u_h, v_h)| \le \widetilde{\alpha} \|u_h\|_a \|v_h\|_a, \tag{4.7}$$

[illegible] $0 < \widetilde{\beta} \le \widetilde{\alpha}$ [illegible]

$$\widetilde{a}(u_h, u_h) \ge \widetilde{\beta} \|u_h\|_a^2 \tag{4.8}$$

[illegible] $u_h, v_h \in V_h$

Moreover, we have [35, 37] the following proposition.

PROPOSITION 4.3. [illegible] $0 < \delta < 1$ [illegible] L [illegible] $L > 0$ [illegible]

$$|a(u_h, v_h) - \widetilde{a}(u_h, v_h)| \le \delta \, \|u_h\|_a \, \|v_h\|_a \qquad \forall u_h, v_h \in V_h. \tag{4.9}$$

[illegible]

$$\hat{\alpha} \ge \frac{2p+2}{2p+2+\rho}, \tag{4.10}$$

[illegible] $u_h, v_h \in V_h$ [illegible]

$$|a(u_h, v_h) - \widetilde{a}(u_h, v_h)| \le C h^{p+1-\rho/2} |\log h|^{\nu} |||u_h|||_{p+1} \, \|v_h\|_V, \tag{4.11}$$

[illegible] $\nu = 1$ [illegible] (4.10), [illegible] $\nu = 0$ [illegible]

The matrix compression (4.5) reduces the number of nonzero elements from N^2 in $\mathbf{A}$ to N times a logarithmic term in $\tilde{\mathbf{A}}$; see [32].

PROPOSITION 4.4. [illegible] $\widehat{\alpha} < 1$ [illegible] $\tilde{\mathbf{A}}$ [illegible] $\mathcal{O}(N \log N)$ [illegible] $\widehat{\alpha} = 1$ [illegible] $\tilde{\mathbf{A}}$ [illegible] $\mathcal{O}(N(\log N)^2)$

4.1.3. Perturbed spatial semidiscretization. In accordance with the matrix compression from the previous section, we consider, instead of (4.1), (4.2), the perturbed spatial semidiscretization of (2.1), (2.2): find $\widetilde{u}_h \in V_h$ such that

$$\left(\frac{d}{dt}\widetilde{u}_h, v_h\right) + \widetilde{a}(\widetilde{u}_h, v_h) = 0 \qquad \forall\, v_h \in V_h \tag{4.12}$$

and

$$\widetilde{u}_h(0) = P_{L^2}^{V_h} u_0. \tag{4.13}$$

4.5. We assume that the error between the exact solution u of (2.1), (2.2) and the approximate solution $\widetilde{u}_h$ obtained by (4.12), (4.13) at $t = T$ is of a certain algebraic order; i.e., there exist constants C, ω (depending on p) such that

$$\|u(T) - \widetilde{u}_h(T)\| \le Ch^{\omega}. \tag{4.14}$$

Here, $h = C2^{-L}$ is the mesh width.

4.6. If the operator $\mathcal{A}$ from section 2 is of the form $\mathcal{A} = \mathcal{A}_0 + \mathcal{B}$, where $\mathcal{A}_0 = C_0(-\Delta)^{\frac{p}{2}}$, $C_0 > 0$, is a Riesz potential, and $\mathcal{B} : V \to V^*$ is a compact perturbation, then the bound (4.14) holds true with $\omega = p + 1$; this will be proved in the forthcoming paper [26]. The proof of this result is based on splitting the error $u - \widetilde{u}_h$ of the semidiscrete problem (4.12)–(4.13) into two parts that can be estimated separately. More precisely, we write $u - \widetilde{u}_h = T_1 + T_2$ with $T_1 = u - u_h$ and $T_2 = u_h - \widetilde{u}_h$, where u, u_h, and $\widetilde{u}_h$ are the solutions of (2.1)–(2.2), (4.1)–(4.2), and (4.12)–(4.13), respectively. Then, using techniques similar to those in [16, 17], it can be shown that $T_1 \le Ch^{p+1}$. In addition, applying suitable wavelet compression bounds (such as in Proposition 4.3, for example), it is proved that the term T_2 is bounded analogously.

4.2. Discontinuous Galerkin time discretization. We discretize (4.12), (4.13) in time using a dG method following [34]. For $0 < T < \infty$ and $M \in \mathbb{N}$, let $\mathcal{M} = \{I_m\}_{m=1}^M$ be a partition of $J = (0, T)$ into M subintervals $I_m = (t_{m-1}, t_m)$, $m = 1, 2, \ldots, M$ with $0 = t_0 < t_1 < t_2 < \cdots < t_M = T$. Moreover, denote by $k_m = t_m - t_{m-1}$ the length of I_m.

For $u \in H^1(\mathcal{M}, V_h) := \{v \in L^2(J, V_h) : v|_{I_m} \in H^1(I_m, V_h), m = 1, 2, \ldots, M\}$, define the one-sided limits

$$u_m^+ := \lim_{s \to 0^+} u(t_m + s), \qquad m = 0, 1, \ldots, M-1,$$
$$u_m^- := \lim_{s \to 0^+} u(t_m - s), \qquad m = 1, 2, \ldots, M,$$

and the jumps

$$[u]_m := u_m^+ - u_m^-, \qquad m = 1, 2, \ldots, M-1.$$

In addition, to each time interval I_m, a polynomial degree (approximation order) $r_m \ge 0$ is associated. These numbers are stored in the degree vector $\underline{r} = \{r_m\}_{m=1}^M$. Then, the following space being used for the dG method is introduced:

$$\mathcal{S}^{\underline{r}}(\mathcal{M}, V_h) := \{u \in L^2(J, V_h) : u|_{I_m} \in \mathcal{P}_{r_m}(I_m, V_h), m = 1, 2, \ldots, M\},$$

where $\mathcal{P}_{r_m}(I_m)$ denotes the space of polynomials of degree at most r_m on I_m.

With these definitions, the fully discrete dG scheme for the solution of problem (2.1), (2.2), respectively (4.12), (4.13) reads as follows: find $\widetilde{U}_h^{dG} \in \mathcal{S}^{\underline{r}}(\mathcal{M}, V_h)$ such that for all $W \in \mathcal{S}^{\underline{r}}(\mathcal{M}, V_h)$, there holds

$$\widetilde{B}_{dG}(\widetilde{U}_h^{dG}, W) = F_{dG}(W), \tag{4.15}$$

where

$$\widetilde{B}_{dG}(U, W) := \sum_{m=1}^{M} \int_{I_m} \big((U', W) + \widetilde{a}(U, W)\big)\, dt + \sum_{m=1}^{M-1} ([U]_m, W_m^+) + (U_0^+, W_0^+) \tag{4.16}$$

and

$$F_{dG}(W) := (P_{L^2}^{V_h} u_0, W_0^+). \tag{4.17}$$

PROPOSITION 4.7 (see [33]).

a. [illegible] $\widetilde{U}_h^{dG} \in \mathcal{S}^{\underline{r}}(\mathcal{M}, V_h)$ [illegible] (4.15) [illegible]

b. [illegible] $\widetilde{u}_h$ [illegible] (4.12) (4.13) [illegible] (4.15). [illegible]

[illegible]

$$\widetilde{B}_{dG}(\widetilde{u}_h - \widetilde{U}_h^{dG}, W) = 0 \tag{4.18}$$

[illegible] $W \in \mathcal{S}^{\underline{r}}(\mathcal{M}, V_h)$

[illegible] 4.8. The dG method (4.15) can be interpreted as a time-stepping scheme of variable step size k_m and orders r_m. Indeed, assuming that $\widetilde{U}_h^{dG}$ is known on the time intervals $I_m = (t_{m-1}, t_m)$, $m = 1, 2, \ldots, n-1$, we may find $\widetilde{U}_h^{dG} \in \mathcal{P}_{r_n}(I_n, V_h)$, $1 \le n \le M$, by solving the variational problem

$$\int_{I_n} \big((\partial_t \widetilde{U}_h^{dG}, W) + \widetilde{a}(\widetilde{U}_h^{dG}, W)\big)\, dt + (\widetilde{U}_{n-1}^{dG+}, W_{n-1}^+) = (\widetilde{U}_{n-1}^{dG-}, W_{n-1}^+) \tag{4.19}$$

for all $W \in \mathcal{P}_{r_n}(I_n, V_h)$. Here, we set $\widetilde{U}_0^{dG-} = P_{L^2}^{V_h} u_0$.

4.2.1. Stability. For $v_h \in V_h$ and $U \in \mathcal{S}^{\underline{r}}(\mathcal{M}, V_h)$, we introduce the norms

$$\|v_h\|_{\widetilde{a}} = \big(\widetilde{a}(v_h, v_h)\big)^{1/2}$$

and

$$\|U\|_{dG}^2 = \sum_{m=1}^{M} \int_{I_m} \|U\|_{\widetilde{a}}^2 dt + \frac{1}{2}\Big(\|U_0^+\|^2 + \sum_{m=1}^{M-1} \|[U]_m\|^2 + \|U_M^-\|^2\Big).$$

The dG time-stepping is stable.

PROPOSITION 4.9. [illegible] $\widetilde{U}_h^{dG} \in \mathcal{S}^{\underline{r}}(\mathcal{M}, V_h)$ [illegible] (4.15)

[illegible]

$$\|\widetilde{U}_h^{dG}\|_{dG} \le C \|u_0\|,$$

[illegible] $C > 0$ [illegible] T [illegible] L

[illegible]. Let $U \in \mathcal{S}^{\underline{r}}(\mathcal{M}, V_h)$ be arbitrary. Then, as in [33, Lemma 2.7], there holds

$$\widetilde{B}_{dG}(U, U) = \|U\|_{dG}^2 \qquad \forall U \in \mathcal{S}^{\underline{r}}(\mathcal{M}, V_h). \tag{4.20}$$

Moreover, we have

$$|F_{dG}(U)| \le |(P_{L^2}^{V_h} u_0, U_0^+)| \le \|P_{L^2}^{V_h} u_0\| \|U_0^+\|.$$

Hence, using the stability of $P_{L^2}^{V_h}$ results in

$$|F_{dG}(U)| \le \|u_0\| \|U_0^+\| \le C\|u_0\| \|U\|_{dG}. \tag{4.21}$$

Now, putting $U := \widetilde{U}_h^{dG}$, recalling the definition of the dG method (4.15), and employing (4.20) and (4.21), we obtain

$$\|\widetilde{U}_h^{dG}\|_{dG}^2 \le |\widetilde{B}_{dG}(\widetilde{U}_h^{dG}, \widetilde{U}_h^{dG})| = |F_{dG}(\widetilde{U}_h^{dG})| \le C\|u_0\| \|\widetilde{U}_h^{dG}\|_{dG}.$$

Dividing both sides by $\|\widetilde{U}_h^{dG}\|_{dG}$ completes the proof. □

4.3. Convergence of the fully discrete scheme. The solution operator of the parabolic problem (2.1), (2.2) generates an analytic semigroup (see, e.g., [33]), and therefore, the solution $u(t)$ becomes analytic with respect to t for $t > 0$. However, due to the nonsmoothness of the initial data, singularities may arise at $t = 0$. In this section, we show how, by the use of so-called geometric time partitions and linearly increasing polynomial degrees in the time discretization, the low regularity of the solution at $t = 0$ can be resolved.

DEFINITION 4.10. [illegible] $\mathcal{M}_{M,\gamma} = \{I_m\}_{m=1}^M$ [illegible] $J = (0,T)$ $T > 0$ [illegible] M [illegible] $I_m = (t_{m-1}, t_m)$ $m = 1, 2, \dots, M$ [illegible] $\gamma \in (0,1)$ [illegible]

$$t_0 = 0, \qquad t_m = T\gamma^{M-m}, \quad 1 \le m \le M.$$

DEFINITION 4.11. [illegible] $\underline{r}$ [illegible] $\mu > 0$ [illegible] $\mathcal{M}_{M,\gamma}$ [illegible] $r_1 = 0$ [illegible] $r_m = \lfloor \mu m \rfloor$ $m = 2, \dots, M$ [illegible] $\lfloor \mu m \rfloor = \max\{q \in \mathbb{N}_0 : q \le \mu m\}$

We have the following a priori error estimate on the fully discrete dG method. Its proof is worked out in the appendix.

THEOREM 4.12. [illegible] $\rho \in [0,2]$ [illegible] u [illegible] (2.1), (2.2) [illegible] $J \times \Omega = (0,T) \times \Omega$ [illegible] $u_0 \in V = \dot{H}^{\rho/2}(\Omega)$ [illegible] (4.14) [illegible] $\mathcal{M}_{M,\gamma}$ [illegible] 4.10 [illegible] $0 < \gamma < 1$ [illegible] $M = c|\log h|$ [illegible] $\underline{r}$ [illegible] $\mu \ge \mu_0$ [illegible] 4.11 [illegible] $c, \mu_0 > 0$ [illegible] (4.15) [illegible] $\mathcal{S}^{\underline{r}}(\mathcal{M}_{M,\gamma}, V_h)$ [illegible]

$$\|u(T) - \widetilde{U}_h^{dG}(T)\| \le Ch^{\omega}. \tag{4.22}$$

h [illegible] $\mathcal{T}_h$ ω [illegible] (4.14), [illegible] $C > 0$ [illegible] h

5. Solution algorithm. We will now study the linear systems resulting from the dG method (4.15). We show that they may be solved iteratively, without causing a loss in the rates of convergence in the error estimate (4.22), by the use of an incomplete GMRES method. Furthermore, we prove that the overall complexity of the fully discrete dG method is linear (up to some logarithmic terms). Since these matters have already been studied in [36, section 5], we restrict ourselves to a brief presentation of the results there.

5.1. Derivation of the linear systems. The dG time-stepping scheme (4.19) corresponds to a linear system of size $(r_m+1)N^L$ to be solved in each time step $m=1,2,\dots,M$. Here and in what follows, in order to clarify the dependence on the refinement level L explicitly, we denote by N^L the dimension of the finite element space $V_h=V^L$.

For $1\le m\le M$, let $\{\phi_j=\sqrt{j+1/2}L_j\}_{j=0}^{r_m}$, where L_j is the jth Legendre polynomial on $(-1,1)$ (normalized such that $L_j(1)=1$), be a basis of the polynomial space $\mathcal{P}_{r_m}(-1,1)$. Then, the temporal shape functions on the time interval I_m are given by $\phi_j\circ F_m^{-1}$, where the mapping $F_m:(-1,1)\to I_m$ is given by

$$t=F_m(\hat t)=\frac{1}{2}(t_{m-1}+t_m)+\frac{1}{2}k_m\hat t,\qquad k_m=t_m-t_{m-1},\qquad \hat t\in(-1,1).$$

Writing $\widetilde U_{h,m}^{dG}(x,t)=\widetilde U_h^{dG}|_{I_m}(x,t)$ and $W_m=W|_{I_m}$ in (4.19) as

$$\widetilde U_{h,m}^{dG}(x,t)=\sum_{j=0}^{r_m}\widetilde U_{h,m,j}^{dG}(x)(\phi_j\circ F_m^{-1})(t),$$
$$W_m(x,t)=\sum_{i=0}^{r_m}W_{m,i}(x)(\phi_i\circ F_m^{-1})(t),$$

the variational formulation (4.19) reads: find $(\widetilde U_{h,m,j}^{dG})_{j=0}^{r_m}\in(V_h)^{\mathrm{r}}$ such that for all $(W_{m,i})_{i=0}^{r_m}\in(V_h)^{\mathrm{r}}$ there holds

$$\sum_{i,j=0}^{r_m}C_{ij}(\widetilde U_{h,m,j}^{dG},W_{m,i})+\frac{k_m}{2}\sum_{i=1}^{r_m}\widetilde a(\widetilde U_{h,m,i}^{dG},W_{m,i})=\sum_{i=0}^{r_m}f_{m,i}(W_{m,i}),\tag{5.1}$$

where, for $i,j=0,1,\dots,r_m$,

$$C_{ij}=\sigma_{ij}\sqrt{(i+1/2)(j+1/2)},\quad \sigma_{ij}=\begin{cases}(-1)^{i+j} & \text{if } j>i,\\ 1 & \text{else,}\end{cases}\tag{5.2}$$

and $f_{m,i}(v)=\phi_i(-1)\big(\widetilde U_{h,m-1}^{dG-}(t_{m-1}),v\big)$.

Henceforth, for the sake of readability, we will drop the subscript m. Denoting by $\mathbf{M}$ and $\widetilde{\mathbf{A}}$ the mass and (compressed) stiffness matrix on $V^h=V^L$ with respect to $(\cdot,\cdot)$ and $\widetilde a(\cdot,\cdot)$, respectively, (4.19) takes the matrix form

$$\mathbf{R}\underline{u}=\underline{f}\quad\text{with}\quad\mathbf{R}=\mathbf{C}\otimes\mathbf{M}+\frac{k}{2}\mathbf{I}\otimes\widetilde{\mathbf{A}},\tag{5.3}$$

where $\underline{u}$ denotes the coefficient vector of $\widetilde U_{h,m}^{dG}=\widetilde U_h^{dG}|_{I_m}\in\mathcal{P}_{r_m}(I_m,V_h)$.

5.2. Decoupling. In [33] it has been found that the system (5.3) of size $(r+1)N^L$ can be reduced to solving $r+1$ linear systems of size N^L. To this end, let $\mathbf{C}=\mathbf{Q}\mathbf{T}\mathbf{Q}^{\mathsf H}$ be the Schur decomposition of the $(r+1)\times(r+1)$ matrix $\mathbf{C}$ with a unitary matrix $\mathbf{Q}$ and an upper triangular matrix $\mathbf{T}$. Note that the diagonal of $\mathbf{T}$ contains the eigenvalues $\lambda_1,\lambda_2,\dots,\lambda_{r+1}$ of $\mathbf{C}$. Then multiplying (5.3) by $\mathbf{Q}^{\mathsf H}\otimes\mathbf{I}$ from the left results in the linear system

$$\left(\mathbf{T}\otimes\mathbf{M}+\frac{k}{2}\mathbf{I}\otimes\widetilde{\mathbf{A}}\right)\underline{w}=\underline{g}\quad\text{with}\quad\underline{w}=(\mathbf{Q}^{\mathsf H}\otimes\mathbf{I})\underline{u},\quad\underline{g}=(\mathbf{Q}^{\mathsf H}\otimes\mathbf{I})\underline{f}.$$

This system is block-upper-triangular. With $\underline{w} = (\underline{w}_0, \underline{w}_1, \ldots, \underline{w}_r)$, $\underline{w}_j \in \mathbb{C}^{N^L}$, we obtain its solution by solving

$$\left(\lambda_{j+1}\mathbf{M} + \frac{k}{2}\widetilde{\mathbf{A}}\right)\underline{w}_j = \underline{s}_j \tag{5.4}$$

for $j = r, r-1, \ldots, 0$, where $\underline{s}_j = \underline{g}_j - \sum_{l=j+1}^{r} \mathbf{T}_{j+1,l+1}\mathbf{M}\underline{w}_l$.

5.3. Iterative solution of the linear equations. By (5.4), a dG-time step of order r amounts to solving $r+1$ linear systems with a matrix of the form

$$\mathbf{B} = \lambda\mathbf{M} + \frac{k}{2}\widetilde{\mathbf{A}}. \tag{5.5}$$

Here, λ is an eigenvalue of $\mathbf{C}$ in (5.2). The linear equations (5.4) are solved approximately with incomplete GMRES iteration, causing an additional error in the overall scheme which we are going to analyze next.

5.3.1. Eigenvalues of C. The eigenvalues λ_j of $\mathbf{C}$ have a major impact on the choice of the preconditioner (see section 5.3.2) and thus on the convergence of the GMRES method for (5.4). It can be shown that (see [36, Lemma 5.5]) for $r = 1, 2, 3, \ldots$, the eigenvalues $\lambda_j^{(r)}$ of the matrix $\mathbf{C}$ from (5.2) satisfy

$$\mathrm{Re}\lambda_j^{(r)} \geq C_1|\lambda_j^{(r)}|r^{-\alpha}, \quad |\lambda_j^{(r)}| \geq C_2 r^{\widetilde{\alpha}}, \qquad j = 1, 2, \ldots, r+1, \tag{5.6}$$

with $\alpha = 2$, $\widetilde{\alpha} = 0$, and constants $C_1, C_2 > 0$ independent of r. Furthermore, the matrix $\mathbf{T}$ of the Schur decomposition $\mathbf{C} = \mathbf{Q}\mathbf{T}\mathbf{Q}^{\mathsf{H}}$ satisfies $\|\mathbf{T}\|_2 \leq Cr^2$.

Remark 5.1. The estimates (5.6) do not seem to be sharp. Numerical results in [36] suggest that (5.6) holds with $\alpha = 2/3$ and $\widetilde{\alpha} = 1$.

5.3.2. Preconditioning. For the preconditioning of the linear system (5.5), we define the matrix $\mathbf{S}$ and the scaled matrix $\widehat{\mathbf{B}} \in \mathbb{R}^{N^L} \times \mathbb{R}^{N^L}$ by

$$\mathbf{S} := \left(\mathrm{Re}(\lambda)\mathbf{I} + \frac{k}{2}\mathbf{D}_{\mathbf{A}}\right)^{1/2}, \qquad \widehat{\mathbf{B}} := \mathbf{S}^{-1}\mathbf{B}\mathbf{S}^{-1},$$

where $\mathbf{D}_{\mathbf{A}}$ is the diagonal matrix with entries $D_{(l,j),(l,j)} = 2^{l\rho/2}$ corresponding to the basis functions $\psi_j^l \in V_h$; cf. (4.3). Moreover, we introduce the norm

$$\|\underline{w}\|_{\mathbf{D}_{\mathbf{A}}^{-1}} = (\underline{w}^{\mathsf{H}}\mathbf{D}_{\mathbf{A}}^{-1}\underline{w})^{1/2}, \qquad \underline{w} \in \mathbb{R}^{N^L}.$$

Let GMRES(m_0) denote the GMRES method with restart every $m_0 \geq 1$ iterations. For the linear system $\widehat{\mathbf{B}}\underline{\widehat{x}} = \underline{\widehat{b}}$, let $\underline{\widehat{x}}_j$ be the iterates obtained by restarted GMRES(m_0) with initial guess $\underline{\widehat{x}}_0$. Then, there exists $C > 0$ such that (cf. [36, Lemma 5.7])

$$\|\underline{\widehat{b}} - \widehat{\mathbf{B}}\underline{\widehat{x}}_j\| \leq Cq^j\|\underline{\widehat{b}} - \widehat{\mathbf{B}}\underline{\widehat{x}}_0\|, \quad j = 0, 1, 2, \ldots,$$

where $q = 1 - cr^{-2\alpha}$. Moreover, let $\underline{x}_j = \mathbf{S}^{-1}\underline{\widehat{x}}_j$, $\underline{b} = \mathbf{S}\underline{\widehat{b}}$. Then

$$\|\underline{b} - \mathbf{B}\underline{x}_j\|_{\mathbf{D}_{\mathbf{A}}^{-1}} \leq Ch^{-\rho/2}(1 + kr^{\alpha-\widetilde{\alpha}})^{1/2}(1 - cr^{-2\alpha})^j\|\underline{b} - \mathbf{B}\underline{x}_0\|_{\mathbf{D}_{\mathbf{A}}^{-1}}, \tag{5.7}$$

with $\alpha, \widetilde{\alpha}$ from (5.6), and $C, c > 0$ independent of L, k, r.

5.3.3. Convergence of incomplete GMRES. The fully discrete dG scheme with incomplete GMRES yields approximations $\widehat{U}_{h,1}^{dG}, \widehat{U}_{h,2}^{dG}, \dots, \widehat{U}_{h,M}^{dG}$ to $\widetilde{U}_{h,1}^{dG}, \widetilde{U}_{h,2}^{dG}, \dots, \widetilde{U}_{h,M}^{dG}$ (cf. (5.1)). By (5.7) and proceeding as in [36, sections 5.5.3 and 5.5.4], we obtain that

$$\|\widehat{U}_{h,M}^{dG}(T) - \widetilde{U}_{h,M}^{dG}(T)\| \le Ch^{-3\rho/2} k_1^{-1} r_M^3 q^{n_G}. \tag{5.8}$$

Here, n_G denotes the number of GMRES(m_0) iterations which has to be chosen in such a way that the bound in (5.8) is smaller than the right-hand side of (4.22) in the convergence theorem, Theorem 4.12, i.e.,

$$h^{-3\rho/2} k_1^{-1} r_M^3 q^{n_G} \le Ch^{\omega}.$$

In order to fulfill this condition, we recall the definition of q and use, in accordance with the assumptions in Theorem 4.12, that $r_M = \mathcal{O}(|\log h|)$ and $|\log k_1| \le C r_M$. This results in

$$n_G \ge C r_M^{2\alpha} \mathcal{O}(|\log h|) = \mathcal{O}(|\log h|)^{1+2\alpha} \tag{5.9}$$

GMRES iterations per time step. Combining the previous results yields the following theorem.

THEOREM 5.2. [illegible] 4.12 [illegible] $n_G = \mathcal{O}(|\log h|)^{1+2\alpha}$ [illegible]

$$\|u(T) - \widehat{U}_h^{dG}(T)\| \le Ch^{\omega}, \tag{5.10}$$

[illegible] $\widehat{U}_h^{dG}$ [illegible] u [illegible]

5.4. Complexity. Applying the matrix compression techniques from section 4.1.2, the judicious combination of geometric mesh refinement and linear increase of polynomial degrees in the dG time-stepping scheme (Theorem 4.12), and an appropriate number of GMRES iterations (Theorem 5.2), results in a linear (up to some logarithmic terms) overall complexity of the fully discrete scheme (4.15) for the solution of the parabolic problem (2.1), (2.2).

THEOREM 5.3. [illegible] 4.12 [illegible] 5.2, [illegible] (4.15) [illegible] n_G [illegible] (5.9) [illegible] $\widehat{U}_h^{dG}(T)$ [illegible] $\mathcal{O}(N(\log N)^{4+2\alpha})$ [illegible] $N = N^L = \dim V_h$ [illegible] α [illegible] (5.6).

[illegible]. There are $M = \mathcal{O}(|\log h|) = \mathcal{O}(\log N)$ time steps. In each time step $\mathcal{O}(\log N)$ linear systems of type (5.5) have to be solved by the incomplete GMRES method with

$$n_G = \mathcal{O}(|\log h|^{1+2\alpha}) = \mathcal{O}((\log N)^{1+2\alpha})$$

iterations. We note that the mass matrix $\mathbf{M}$ (with respect to the wavelet basis) has $\mathcal{O}(N \log N)$ entries. Hence, recalling Proposition 4.4, each GMRES iteration involves a matrix-vector multiplication of complexity $\mathcal{O}(N \log N)$. This implies the desired result. ∎

6. Numerical examples. In this section, we study the performance of the dG time-stepping scheme. Our wavelet spatial discretization is based on the biorthogonal

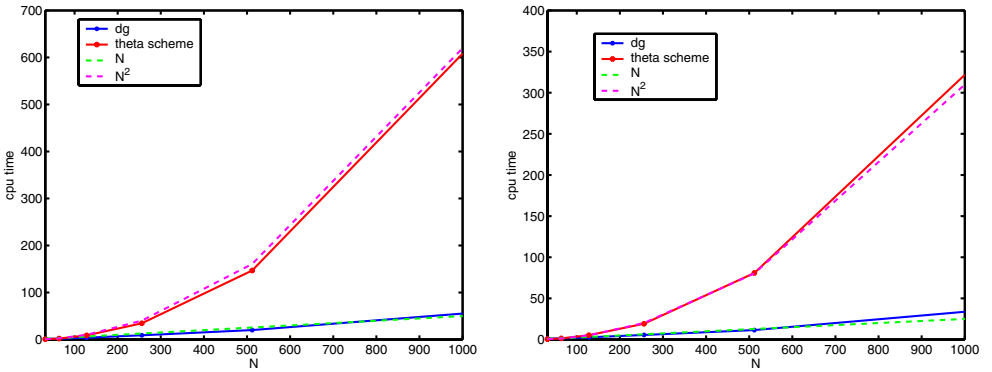

FIG. 1. *Performance comparison for the dG time-stepping versus θ-scheme (both with incomplete GMRES) to advance from $t = 0$ to $t = T$; left: $\sigma > 0$, right: $\sigma = 0$.*

spline wavelets (see Remark 4.1) with wavelet compression according to (4.5). The bandwidth of the lower-right block in the compressed wavelet matrix is 5 and the growth factor is taken to be 0.8, which corresponds to $c = 1$ and $\hat{\alpha} = 0.8$ in (4.5).

Our experiments address the numerical solution of (3.31), (3.32) with $\Omega = \Omega_R = (-6, 6)$, $g(x) = (e^x - K)_+$, $K = 1$, and $T = 1$. The integral kernel k of the nonlocal operator $\mathcal{L}^{\text{jump}}$ in (3.9) is of CGMY-type (3.15) with $\alpha \in [0, 2)$. We recall that, for $\sigma > 0$, the operator $\mathcal{A} : V \to V^*$ with $V = H_0^1(\Omega)$ is given by $\mathcal{A} = (\mathcal{L}^{\text{BS}} + \mathcal{L}^{\text{jump}})|_\Omega$ as in (3.8), (3.9). In the pure jump case, i.e., $\sigma = 0$, there holds $\mathcal{A} = \mathcal{L}^{\text{jump}}|_\Omega$.

Our aim is to illustrate the effect of the choice of the mesh size $h = 2R2^{-L-1}$, the number M of time steps, and the polynomial degree r in the dG method on the error of the numerical approximation at $t = T$.

To do so, let $\widehat{U}_h^{dG}(T)$ be the numerical price obtained by the dG time-stepping scheme using the incomplete GMRES method with wavelet compression and wavelet preconditioning. Furthermore, denote by $\widehat{U}_h^{\theta}(T)$ the corresponding solution obtained by time-stepping with the θ-scheme (also with incomplete GMRES and wavelet preconditioning). In Figure 1 we compare the CPU times for the computation of $\widehat{U}_h^{dG}(T)$ and $\widehat{U}_h^{\theta}(T)$ (with $\theta = 1$, i.e., implicit Euler scheme) with diffusion component (i.e., for $\sigma > 0$, left) and in the quadratic pure jump case (i.e., for $\sigma = 0$, right). The parameters in the stochastic process are $C = 1$, $\eta_- = 1.8$, $\eta_+ = 2.5$, and $\alpha = 1.2$.

We study convergence of the prices obtained from dG time-stepping and by the θ time-stepping schemes, respectively, expressed in the error estimate (5.10) as $h \to 0$. We set $\sigma = 0$ and $\alpha = 1.8$. The other CGMY parameters are $C = 1$, $\eta_- = 1.8$, and $\eta_+ = 2.5$. We have chosen a large fixed value for the number n_G of GMRES iterations, so that all the errors become insensitive with respect to the iteration error. Again, by $U_h^{dG}(T, x)$ and $U_h^{\theta}(T, x)$, we denote the solutions of the fully discrete dG time-stepping and the θ time-stepping schemes, respectively. The number M of time steps is chosen proportionally to L; more precisely, $M = 2|\log(h)|$. Our "exact" solution $U_{\text{ex}}(T, x)$ is computed as the numerical solution of the dG method with $L = 11$, $M = 2|\log(h)|$, and $r = M$ for all time steps. In Figure 2, we plot the relative error with respect to the L^2 norms

$$\frac{\|U_{\text{ex}}(T,x)\|^2_{L^2(\Omega_R)} - \|U_h^{dG}(T,x)\|^2_{L^2(\Omega_R)}}{\|U_{\text{ex}}(T,x)\|^2_{L^2(\Omega_R)}} \tag{6.1}$$

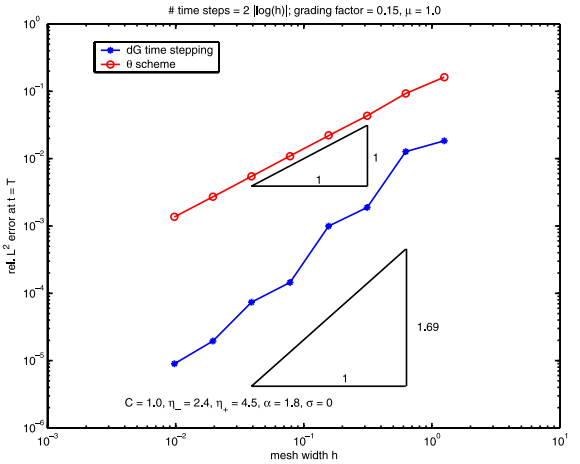

FIG. 2. *Comparison of the L^2 errors at $t = T$.*

for the dG time-stepping scheme, and compare it to the relative L^2 error of the standard (low order) θ-scheme

$$\frac{\|U_{\mathrm{ex}}(T,x)\|^2_{L^2(\Omega_R)} - \|U_h^\theta(T,x)\|^2_{L^2(\Omega_R)}}{\|U_{\mathrm{ex}}(T,x)\|^2_{L^2(\Omega_R)}}.$$

As above, we take $\theta = 1$. We clearly observe linear convergence for the implicit Euler time-stepping and an experimental convergence rate of order 1.69 for the dG time-stepping scheme.

In Figures 3 and 4, we plot the relative L^2 errors and the convergence rates obtained by least square fitting for the dG time-stepping and varying values of α and σ. Again, the number M of time steps is proportional to L, $M = 2|\log(h)|$. The geometric time mesh has a grading factor $\gamma = 0.15$ and linearly increasing polynomial degrees with slope $\mu = 1.0$. The "exact" solution is obtained as before.

Table 1 presents the values of the numerical approximation $U_h^{dG}(T)$ in the pure jump case ($\sigma = 0$) with CGMY parameters $C = 1.0$, $\eta_- = 2.4$, $\eta_+ = 4.5$, and $\alpha = 1.8$. The grading factor of the geometric time mesh has been chosen to be $\gamma = 0.2$ and the slope of the linear polynomial degree vector is given by $\mu = 1.0$. As we increase the number of time steps (for fixed L), i.e., $M \to \infty$, we observe rapidly converging error levels. This indicates that the spatial discretization errors are dominant and that the time-stepping scheme renders exponential convergence.

7. Concluding remarks. In this work, we have studied the (fast) numerical approximation of (possibly degenerate) parabolic equations for general Markov processes arising in finance. Our scheme is based on *hp*-discontinuous Galerkin discretizations in time and wavelet discretizations in space. The densely populated matrices corresponding to the nonlocal infinitesimal generators are compressed using an appropriate wavelet basis. The linear systems are solved by an incomplete GMRES method. Under these conditions, we have shown that the overall complexity of the algorithm is linear up to some logarithmic terms. Moreover, we have proved that if the wavelet spatial semidiscretization error is of order h^ω, then our algorithm gives $\widehat{U}_h^{dG}(T)$ with the same error bound in log-linear complexity. Finally, numerical experiments illustrate the performance of the proposed scheme.

Appendix A. Proof of Theorem 4.12. For the proof of Theorem 4.12, we proceed in several steps. Again, we denote by u, $\widetilde{u}_h$, and $\widetilde{U}_h^{dG}$ the solutions of (2.1)–(2.2), (4.12)–(4.13), and (4.15), respectively.

A.1. *hp*-Approximations. We consider an interpolant

$$\Pi^{\underline{r}} : H^1(J, V_h) \to \mathcal{S}^{\underline{r}}(\mathcal{M}, V_h),$$

with $\Pi^{\underline{r}}|_{I_m} = \Pi^{r_m}$ satisfying the conditions

$$\int_{I_m} (u_h - \Pi^{r_m} u_h, q)\, dt = 0 \qquad \forall q \in \mathcal{P}^{r_m - 1}(I_m, V_h), \tag{A.1}$$
$$\Pi^{r_m} u_h(t_m^-) = u_h(t_m^-)$$

for all $1 \le m \le M$, $u_h \in H^1(J, V_h)$. If, for some m, $r_m = 0$, then the first condition is void on I_m. According to [33], the interpolant $\Pi^{\underline{r}}$ is uniquely defined by the above conditions. Moreover, we have the following approximation result.

LEMMA A.1. [illegible] $\mathcal{M}_{M,\gamma}$ [illegible] $0 < \gamma < 1$ [illegible] 4.10 [illegible] $\underline{r}$ [illegible] $\mu \ge \mu_0$ [illegible] 4.11 [illegible] $\mu_0 > 0$ [illegible] $C, b > 0$ [illegible] M [illegible]

$$\|\widetilde{u}_h - \Pi^{\underline{r}} \widetilde{u}_h\|^2_{L^2(J,V)} \le C e^{-b\sqrt{\widehat{N}}}, \tag{A.2}$$

[illegible] $\widehat{N} = \dim \mathcal{S}^{\underline{r}}(\mathcal{M}_{M,\gamma}, V_h) / \dim V_h$ [illegible]

In order to prove this lemma, we follow along the lines of [33]. In particular, we make use of the regularity results in [33, section 4.2] which imply, as in the proof of [33, Theorem 5.4], that the left-hand side in (A.2) is exponentially small on geometrically refined time partitions with linearly increasing polynomial degrees in the time steps.

A.2. Convergence of the fully discrete dG scheme. Next, we split the error of the dG method (4.15) into two parts:

$$\widetilde{u}_h - \widetilde{U}_h^{dG} = \eta + \xi, \tag{A.3}$$

where

$$\eta = \widetilde{u}_h - \Pi^{\underline{r}} \widetilde{u}_h, \qquad \xi = \Pi^{\underline{r}} \widetilde{u}_h - \widetilde{U}_h^{dG}. \tag{A.4}$$

In the following lemma we will prove that the dG error (A.3) at $t = T$ may be estimated in terms of η only.

LEMMA A.2. [illegible] (4.15), [illegible]

$$\|\widetilde{u}_h(T) - \widetilde{U}_h^{dG}(T)\|^2 \le C \int_0^T \|\eta\|_V^2 \, dt.$$

[illegible] η [illegible] (A.4).

[illegible]. The main idea is to bound ξ in terms of η. To do so, we first note that, by the Galerkin orthogonality (4.18), we have

$$\widetilde{B}_{dG}(\xi, \xi) = -\widetilde{B}_{dG}(\eta, \xi). \tag{A.5}$$

Moreover, as in (4.20), there holds that

$$\widetilde{B}_{dG}(\xi, \xi) = \|\xi\|_{dG}^2 \ge \int_0^T \widetilde{a}(\xi, \xi) \, dt. \tag{A.6}$$

Furthermore, making use of the properties (A.1) of the interpolant Π^r, we obtain for all $1 \le m \le M$ that $\int_{I_m} (\eta, \xi') \, dt = 0$ and $\eta(t_m^-) = 0$. Hence, integrating by parts leads to

$$\begin{aligned}\widetilde{B}_{dG}(\eta, \xi) &= \sum_{m=1}^{M} \int_{I_m} \big((\eta', \xi) + \widetilde{a}(\eta, \xi) \big) \, dt + \sum_{m=1}^{M} ([\eta]_m, \xi_m^+) + (\eta_0^+, \xi_0^+) \\ &= \int_0^T \widetilde{a}(\eta, \xi) \, dt \le C \int_0^T \|\eta\|_V \|\xi\|_V \, dt.\end{aligned}$$

In the last step, the continuity of $\widetilde{a}$ was employed. Additionally, using a weighted Cauchy–Schwarz inequality and the coercivity of the bilinear form $\widetilde{a}$ results in

$$|\widetilde{B}_{dG}(\eta, \xi)| \le C \int_0^T \|\eta\|_V^2 \, dt + \frac{1}{2} \int_0^T \widetilde{a}(\xi, \xi) \, dt.$$

Thus, recalling (A.5) and inserting (A.6), we obtain

$$\widetilde{B}_{dG}(\xi, \xi) \le |\widetilde{B}_{dG}(\eta, \xi)| \le C \int_0^T \|\eta\|_V^2 \, dt + \frac{1}{2} \widetilde{B}_{dG}(\xi, \xi).$$

Finally, subtracting $\frac{1}{2} \widetilde{B}_{dG}(\xi, \xi)$ on both sides of the above inequality and noticing that $\eta_M^- = 0$ yields

$$\|\widetilde{u}_h(T) - \widetilde{U}_h^{dG}(T)\|^2 = \|\xi_M^-\|^2 \overset{(4.20)}{\le} C \widetilde{B}_{dG}(\xi, \xi) \le C \int_0^T \|\eta\|_V^2 \, dt.$$

This is the desired estimate. ∎

Combining Lemmas A.1 and A.2 and the assumption (4.14) on the convergence of the spatial semidiscrete problem (4.12), (4.13), we obtain the following.

PROPOSITION A.3. [illegible] $C, b > 0$ [illegible] $u - \widetilde{U}_h^{dG}$ [illegible] (4.15) [illegible]

$$\|u(T) - \widetilde{U}_h^{dG}(T)\|^2 \le C \left(h^{2\omega} + e^{-b\sqrt{\widehat{N}}} \right),$$

[illegible] u $\widetilde{U}_h^{dG}$ [illegible] (2.1), (2.2) [illegible] (4.15), [illegible] $\widehat{N} = \dim \mathcal{S}^r(\mathcal{M}_{M,\gamma}, V_h) / \dim V_h$

. There holds

$$\|u(T) - \widetilde{U}_h^{dG}(T)\|^2 \le 2\|u(T) - \widetilde{u}_h(T)\|^2 + 2\|\widetilde{u}_h(T) - \widetilde{U}_h^{dG}(T)\|^2,$$

where $\widetilde{u}_h$ is the solution of the semidiscrete problem (4.12), (4.13). Then, referring to Lemmas A.1 and A.2 and (4.14) implies

$$\|u(T) - \widetilde{U}_h^{dG}(T)\|^2 \le C\left(h^{2\omega} + e^{-b\sqrt{\widehat{N}}}\right),$$

which completes the proof. ∎

We are now in a position to prove Theorem 4.12. Indeed, since $\sqrt{\widehat{N}} \ge CM$ and $M = c|\log h|$, we have that $e^{-b\sqrt{\widehat{N}}} \le e^{-\widetilde{b}c|\log h|} = h^{\widetilde{b}c}$. Hence, for $c \ge 2\omega\widetilde{b}^{-1}$, the error bound (4.22) follows immediately from Proposition A.3.

DISPERSION RELATION ANALYSIS OF THE $P_1^{NC} - P_1$ FINITE-ELEMENT PAIR IN SHALLOW-WATER MODELS*

DANIEL Y. LE ROUX†

Abstract. Shallow-water models typically employ gridpoint, finite, and spectral-element techniques. For most of these methods the coupling between the momentum and continuity equations is a delicate problem and usually leads to spurious solutions in the representation of inertia-gravity waves. The spurious modes have a wide range of characteristics and may take the form of pressure (surface-elevation), velocity, and/or Coriolis modes. The modes usually cause aliasing and an accumulation of energy in the smallest-resolvable scale, leading to noisy solutions. The triangular finite-element pair $P_1^{NC} - P_1$ is shown to "properly" model the dispersion of the inertia-gravity waves, and this is achieved at a reasonable computational cost compared to traditional finite-difference schemes. Two tests are proposed. The first test examines the propagation and dispersion of fast surface gravity waves in a circular basin and their reflection at the lateral boundary. In the second test, results of the Stommel problem are presented using the proposed finite-element pair and are compared with those obtained with the C- and CD-finite-difference grids. They illustrate the promise of the proposed approach.

1. Introduction.

The shallow-water equations are of considerable importance for a variety of problems of coastal and environmental engineering—including oceanic, atmospheric, and groundwater flows. Numerical methods that are usually employed are typically gridpoint, finite, and spectral-element techniques. One of the main problems encountered with the discretization of the shallow-water equations is a proper simulation of the geostrophic adjustment process, in which the dispersion of the inertia-gravity waves leads to the establishment of a geostrophic balance. For most numerical methods the coupling between the momentum and continuity equations is a delicate problem and may lead to spurious solutions in the representation of inertia-gravity waves [4, 32, 30].

The spurious modes usually take the form of surface-elevation, velocity, and/or Coriolis modes. They are small-scale artifacts introduced by the spatial discretization scheme which do not propagate but are trapped within the model grid, leading to noisy solutions. Their appearance is encountered in both finite-difference and finite-element formulations and is mainly due to an inappropriate placement of variables on the grid and/or a bad choice of approximation function spaces. For example, subject to the no-slip boundary condition, the B-grid [31] usually exhibits surface-elevation modes and hence a checkerboard pattern of noise in both the gravity wave and inertial limits, while the C-grid (shown in Figure 3.1) is prone to Coriolis modes in the inertial limit only, provided the grid resolution is low relative to the Rossby radius of deformation [31]. The finite-element pairs $P_1 - P_1$ and $P_1 - P_0$ suffer from

surface-elevation modes in a manner similar to the A- and B-finite-difference grids [30, 19, 21].

Various noise-suppression techniques have been introduced, such as numerical smoothing [6] and enhanced bottom friction [7]. It is, however, difficult to devise a filter or form of dissipation that removes significant high frequency oscillations while leaving the remainder of the spectrum intact. A better approach is to search for the cause of the problem and to find finite-difference and finite-element methods and variable placements that work well.

Attention has been focused almost exclusively on the spurious surface-elevation modes since these were argued to be the most troublesome [30]. This has resulted in several strategies using the following methods: mixed-order finite-element interpolation [29, 33, 28], equal-order elements with variables carried at sets of points staggered in space [9, 32, 16], analogous to staggered finite differences [2], vorticity and divergence instead of velocity in the momentum equations [25, 10], and wave-equation [22] and Petrov–Galerkin [17] formulations.

To circumvent the Coriolis modes of the C-grid in the inertial limit, due to the spatial averaging of the Coriolis terms, the CD-grid has been introduced [1]. It consists of augmenting the C-grid variables with D-grid velocity variables. The resulting grid is free of Coriolis modes and yields satisfying results at both high and coarse resolution [1].

The finite-element method appears to be a promising alternative to classical finite-difference schemes for ocean modelling. Indeed, triangular finite elements offer the enhanced flexibility of using grids of variable sizes, shapes, and orientation for representing the boundaries of complex domains and a natural treatment of boundary conditions. However, the finite-element method has not been widely used in ocean modelling to date. This is because the ocean modelling community has been using finite-difference techniques for a long time and did not invest significant efforts to develop finite-element approaches. It thus seems desirable to search for finite-element formulations free of surface-elevation and Coriolis modes, as for the CD-grid, and at the same time computationally competitive compared to finite-difference discretizations.

Dispersion analysis of discrete solutions to the linear shallow-water equations has been used as a tool to define the relationships between frequency and wave number and eventually to determine the presence of spurious modes. Linear equations have been considered because all the aforementioned problems occur primarily in the context of linear formulations. Two-dimensional dispersion relationships of finite-difference schemes [2] and finite-element discretizations using the same linear basis functions for all variables [3, 12, 30] have been mainly examined.

This paper presents a two-dimensional dispersion relation analysis of the discretized form of the linear inviscid shallow-water equations, using the $P_1^{NC} - P_1$ finite-element pair [16]. To our knowledge, this is the first study analyzing the dispersion relation of a finite-element scheme using different approximation spaces for the velocity and surface-elevation fields on meshes made up of triangles. This paper confirms the satisfying results obtained for the $P_1^{NC} - P_1$ pair in [21], where a linear algebra approach based on the study of the null space of the discrete operators (e.g., gradient, divergence, Coriolis) is employed, instead of the dispersion relation analysis used here, to determine the existence and the behavior of stationary spurious modes. Further, the present study may explain, in part, the accurate results obtained in [15] where the nonlinear shallow-water system is solved using the $P_1^{NC} - P_1$ pair.

The paper is developed as follows: The model equations and the time and Galerkin

finite-element discretization schemes are presented in section 2. The dispersion relation is derived and analyzed in section 3, and the results are compared with those of the C- and CD-grids. In section 4, the propagation and dispersion of fast surface gravity waves and the Stommel problem are simulated by using the $P_1^{NC} - P_1$ pair. In the latter case the results are again compared with those obtained with the C- and CD-finite-difference grids. Some concluding remarks complete the study.

2. Discretization of the inviscid linear shallow-water equations.

2.1. Governing equations. Let Ω be the model domain with boundary Γ. The inviscid linear shallow-water equations are expressed in Cartesian coordinates [18] as

$$\mathbf{u}_t + f\mathbf{k} \times \mathbf{u} + g\nabla\eta = 0, \tag{2.1}$$

$$\eta_t + H\nabla \cdot \mathbf{u} = 0, \tag{2.2}$$

where $\mathbf{u} = (u, v)$ is the horizontal velocity field, η is the surface elevation with respect to the reference level $z = 0$, f and g are the Coriolis parameter and gravitational acceleration, respectively; $\mathbf{k}$ is a unit vector in the vertical direction and the mean depth H is assumed constant. Note that η plays the role that pressure plays in the Navier–Stokes equations. For a contained flow, (2.1) and (2.2) are solved subject to the no-normal flow boundary condition

$$\mathbf{u} \cdot \mathbf{n} = 0 \quad \text{on } \Gamma, \tag{2.3}$$

where $\mathbf{n}$ is the outward pointing normal at the boundary.

2.2. Temporal discretization. For a given time step $\Delta t = t^{n+1} - t^n$ we introduce a general 2-level time discretization of (2.1)–(2.2) of the form

$$\frac{\mathbf{u}^{n+1} - \mathbf{u}^n}{\Delta t} + f\mathbf{k} \times (\gamma\mathbf{u}^{n+1} + [1-\gamma]\mathbf{u}^n) + g(\alpha\nabla\eta^{n+1} + [1-\alpha]\nabla\eta^n) = 0, \tag{2.4}$$

$$\frac{\eta^{n+1} - \eta^n}{\Delta t} + H(\alpha\nabla \cdot \mathbf{u}^{n+1} + [1-\alpha]\nabla \cdot \mathbf{u}^n) = 0, \tag{2.5}$$

where α and γ are real parameters, such that $0 \le \alpha \le 1$ and $0 \le \gamma \le 1$. Observe that the standard choices $\alpha = \gamma = 0, 1/2, 1$ yield the respective forward Euler, trapezoidal Crank–Nicolson, and backward Euler type schemes.

Equations (2.4)–(2.5) are now spatially discretized using the Galerkin finite-element method with the $P_1^{NC} - P_1$ pair.

2.3. Spatial discretization.

2.3.1. The weak formulation. The Sobolev space $H^1(\Omega)$ is the space of functions in the square-integrable space $L^2(\Omega)$, whose first derivatives belong to $L^2(\Omega)$. Let η be in a subspace V of $H^1(\Omega)$ and let each component of $\mathbf{u}$ be a sufficiently-regular scalar function such that $\mathbf{u} \cdot \mathbf{n} = 0$ on Γ. The weak formulation of (2.4) and (2.5) requires the test functions $\boldsymbol{\varphi}$ (whose x- or y-component is formally denoted by φ) and ψ to, respectively, belong to the same function space as $\mathbf{u}$ and η, such that

$$\begin{aligned} &\int_\Omega (\mathbf{u}^{n+1} - \mathbf{u}^n) \cdot \boldsymbol{\varphi}\, d\Omega + \Delta t \int_\Omega f(\mathbf{k} \times [\gamma\mathbf{u}^{n+1} + (1-\gamma)\mathbf{u}^n]) \cdot \boldsymbol{\varphi}\, d\Omega \\ &\quad + g\Delta t \int_\Omega (\alpha\nabla\eta^{n+1} + [1-\alpha]\nabla\eta^n) \cdot \boldsymbol{\varphi}\, d\Omega = 0, \end{aligned} \tag{2.6}$$

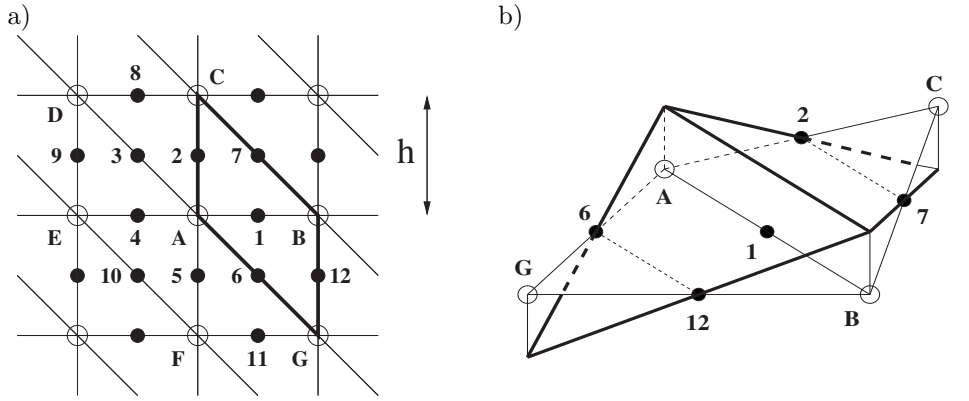

FIG. 2.1. a) *Velocity and surface-elevation node locations are represented by the symbols* ● *and* ○*, respectively, for the* $P_1^{NC} - P_1$ *element pair. The support of the velocity basis function at node* 1 *is in bold.* b) *the* P_1^{NC} *linear basis function at node* 1 *in bold, it takes the values* 1 *at node* 1 *and along the triangle side* AB*,* 0 *at velocity nodes* $2, 6, 7,$ *and* 12*, and* -1 *at surface-elevation nodes* C *and* G*.*

$$\int_\Omega (\eta^{n+1} - \eta^n)\psi \, d\Omega + H\Delta t \int_\Omega (\alpha \nabla \cdot \mathbf{u}^{n+1} + [1-\alpha]\nabla \cdot \mathbf{u}^n)\psi \, d\Omega = 0, \tag{2.7}$$

where $d\Omega$ is the area element.

To avoid computing u and v derivatives, the terms $\nabla \cdot \mathbf{u}^{n+1}$ and $\nabla \cdot \mathbf{u}^n$ appearing in (2.7) are integrated by parts using Green's theorem. In this way, only ψ derivatives are required and no φ derivatives. The former are well defined since ψ belongs to V. The boundary integrals vanish by applying (2.3), and (2.7) is rewritten as

$$\int_\Omega (\eta^{n+1} - \eta^n)\psi \, d\Omega - H\Delta t \int_\Omega (\alpha \mathbf{u}^{n+1} + [1-\alpha]\mathbf{u}^n) \cdot \nabla\psi \, d\Omega = 0. \tag{2.8}$$

2.3.2. The $P_1^{NC} - P_1$ finite-element pair. Conventional finite-element terminology is adopted and the nomenclature $P_m - P_n$ means that velocity components and surface elevation are, respectively, represented as piecewise-defined polynomials of degree m and n. The $P_1^{NC} - P_1$ pair thus approximates velocity components and surface elevation using piecewise linear basis functions on a mesh of triangles.

The P_1^{NC} finite element has velocity nodes at triangle midedge points, and those are represented by the symbol ● in Figure 2.1. The shape of the linear basis function that is used to approximate the velocity components u and v on the element's two-triangle support is given in bold at node 1 in Figure 2.1b. The basis function is zero outside the support triangles ABC and AGB and discontinuous along sides AC, AG, BC, and BG. It takes the values 1 at node 1 and along the triangle side AB, 0 at velocity nodes $2, 6, 7,$ and 12, and -1 at surface-elevation nodes C and G. Since this particular representation of velocity is only continuous across triangle boundaries at midedge points, and discontinuous everywhere else around a triangle boundary, this element is termed nonconforming (NC) in the finite-element literature.

Standard piecewise linear continuous basis functions (P_1) are used to approximate the surface elevation at triangle vertices (represented by the symbol ○ in Figure 2.1).

2.3.3. Galerkin finite-element discretization. The Galerkin method approximates the solution of (2.6) and (2.8) in a finite-dimensional subspace. Consider a finite-element triangulation $\mathcal{T}_h$, of the polygonal domain Ω, where h is a representative meshlength parameter that measures resolution. For triangle $K \in \mathcal{T}_h$, let $P_1(K)$ denote the space of linear polynomials on K.

The discrete solution $\mathbf{u}_h$ sought belongs to a finite-dimensional space $\mathbf{W}_h$ defined to be the set of functions $\mathbf{u}_h$ whose restriction on K belongs to $P_1(K) \times P_1(K)$, with $\mathbf{u}_h$ being continuous only at the midpoints of each face of $\mathcal{T}_h$, and $\mathbf{u}_h \cdot \mathbf{n} = 0$ on Γ.

Each of the two components of the discrete velocity vector $\mathbf{u}_h$ is represented over a triangle K_i by a linear interpolating function of the form $\varphi(x, y) = a + bx + cy$. Let the vector $\mathbf{u}_h$ be expanded over K_i using the linear basis functions φ_p, with $\boldsymbol{\varphi}_p$ belonging to $\mathbf{W}_h$, so that

$$\mathbf{u}_h = \sum_{p \in I_{K_i}} \mathbf{u}_p \varphi_p + \sum_{p \in B_{K_i}} \sigma_p \mathbf{t}_p \varphi_p, \tag{2.9}$$

where p represents the midside nodes of K_i. In (2.9), I_{K_i} and B_{K_i} denote the set of midside nodes of K_i belonging to the interior of Ω and to the boundary Γ, respectively. At a boundary node, because of the no-normal flow boundary condition, there is only one degree of freedom per boundary velocity node, denoted by $\sigma_p = \mathbf{u}_p \cdot \mathbf{t}_p$, where $\mathbf{t}_p$ (whose x and y components are denoted by t_p^x and t_p^y, respectively) designates the local tangential vector of the boundary.

Since velocity nodes are located at triangle midedge points, the direction of the local tangential vector $\mathbf{t}_p$ is uniquely defined along the boundary. This crucial property circumvents the difficulty of satisfying exactly the no-normal flow condition at boundary vertices [11, 14, 23], a problem encountered with the usual conforming elements. It is important to satisfy as exactly as possible the boundary condition since for many applications shallow-water solutions are strongly trapped near the boundary.

A similar linear approximation is used for the Coriolis term, rather than the quadratic expansion that usually arises from the product of $\mathbf{u}_h$ with f. This approach simplifies the algebra while having a negligible impact on the accuracy of the solution, since f varies very smoothly, and so over triangle K_i we have

$$f\mathbf{u}_h = \sum_{p \in I_{K_i}} f_p \mathbf{u}_p \varphi_p + \sum_{p \in B_{K_i}} f_p \sigma_p \mathbf{t}_p \varphi_p. \tag{2.10}$$

The discrete solution η_h is sought in a finite-dimensional subspace V_h of V, where V_h is defined to be the set of functions η_h whose restriction on K belongs to $P_1(K)$, with η_h being continuous at each vertex of $\mathcal{T}_h$. Hence, η_h is represented over a triangle K_i by a linear interpolating function $\psi(x, y)$. The surface elevation is thus expanded over triangle K_i using the linear basis functions ψ_s of V_h, so that

$$\eta_h = \sum_{s \in K_i} \eta_s \psi_s, \tag{2.11}$$

where the sum is over the three vertices of K_i.

The expansions of $\mathbf{u}_h$, $f\mathbf{u}_h$, and η_h over the whole domain Ω are then obtained by summing (2.9), (2.10), and (2.11) over all triangles K_i of the triangulation $\mathcal{T}_h$.

The basis functions φ_p and ψ_s are linked over K_i by the relation $\varphi_p = 1 - 2\psi_s$ if p is the midedge point of K_i facing the vertex s of K_i. For example, $\varphi_1 = 1 - 2\psi_C$ over triangle (A, B, C) of Figure 2.1.

Introducing the finite-element basis leads to a finite-element statement as in (2.6) and (2.8) but with $\mathbf{u}$, η replaced by the finite element trial functions $\mathbf{u}_h$, η_h and φ, ψ replaced by the corresponding finite-element test functions. We then decompose the integrals in (2.6) and (2.8) into triangle contributions.

At a velocity node q, for $\boldsymbol{\varphi} = \boldsymbol{\varphi}_q = (\varphi_q, 0)$, (2.6) leads to

$$\begin{aligned}
&\sum_{K_i} \sum_{p \in I_{K_i}} ([u_p^{n+1} - u_p^n] - \Delta t f_p [\gamma v_p^{n+1} + (1-\gamma) v_p^n]) \int_{K_i} \varphi_p \varphi_q \, d\Omega \\
&+ \sum_{K_i} \sum_{p \in B_{K_i}} (t_p^x [\sigma_p^{n+1} - \sigma_p^n] - \Delta t f_p t_p^y [\gamma \sigma_p^{n+1} + (1-\gamma)\sigma_p^n]) \int_{K_i} \varphi_p \varphi_q \, d\Omega \\
&+ g \Delta t \sum_{K_i} \sum_{s \in K_i} (\alpha \eta_s^{n+1} + [1-\alpha] \eta_s^n) \int_{K_i} \frac{\partial \psi_s}{\partial x} \varphi_q \, d\Omega = 0,
\end{aligned} \tag{2.12}$$

and similarly, for $\boldsymbol{\varphi}_q = (0, \varphi_q)$, we obtain

$$\begin{aligned}
&\sum_{K_i} \sum_{p \in I_{K_i}} ([v_p^{n+1} - v_p^n] + \Delta t f_p [\gamma u_p^{n+1} + (1-\gamma) u_p^n]) \int_{K_i} \varphi_p \varphi_q \, d\Omega \\
&+ \sum_{K_i} \sum_{p \in B_{K_i}} (t_p^y [\sigma_p^{n+1} - \sigma_p^n] + \Delta t f_p t_p^x [\gamma \sigma_p^{n+1} + (1-\gamma)\sigma_p^n]) \int_{K_i} \varphi_p \varphi_q \, d\Omega \\
&+ g \Delta t \sum_{K_i} \sum_{s \in K_i} (\alpha \eta_s^{n+1} + [1-\alpha] \eta_s^n) \int_{K_i} \frac{\partial \psi_s}{\partial y} \varphi_q \, d\Omega = 0.
\end{aligned} \tag{2.13}$$

At a surface-elevation node r, for $\psi = \psi_r$, (2.8) becomes

$$\begin{aligned}
&\sum_{K_i} \sum_{s \in K_i} (\eta_s^{n+1} - \eta_s^n) \int_{K_i} \psi_s \psi_r \, d\Omega - H \Delta t \\
&\quad \times \left(\sum_{K_i} \sum_{p \in I_{K_i}} (\alpha u_p^{n+1} + [1-\alpha] u_p^n) \int_{K_i} \frac{\partial \psi_r}{\partial x} \varphi_p \, d\Omega \right. \\
&\quad + \sum_{K_i} \sum_{p \in I_{K_i}} (\alpha v_p^{n+1} + [1-\alpha] v_p^n) \int_{K_i} \frac{\partial \psi_r}{\partial y} \varphi_p \, d\Omega \\
&\quad + \sum_{K_i} \sum_{p \in B_{K_i}} (\alpha \sigma_p^{n+1} + [1-\alpha] \sigma_p^n) \\
&\quad \left. \times \left(t_p^x \int_{K_i} \frac{\partial \psi_r}{\partial x} \varphi_p \, d\Omega + t_p^y \int_{K_i} \frac{\partial \psi_r}{\partial y} \varphi_p \, d\Omega \right) \right) = 0.
\end{aligned} \tag{2.14}$$

The orthogonality property of the NC velocity basis functions [27] leads to

$$\int_\Omega \varphi_p \varphi_q \, d\Omega = \frac{A_q}{3}\delta_{pq}, \tag{2.15}$$

where A_q is the area of the support of φ_q and δ_{pq} is the Kronecker delta. The velocity and Coriolis mass matrices in (2.12) and (2.13) are thus diagonal, a desirable and unusual property of the finite-element method that greatly enhances computational efficiency. Further, the x- and y-derivatives of the piecewise-linear basis functions ψ involved in (2.12)–(2.14) are constant over each triangle K_i of $\mathcal{T}_h$ and may therefore be written out of the integral symbols. Finally, another property of the NC velocity basis functions

$$\int_\Omega \varphi_q \, d\Omega = \frac{A_q}{3}, \tag{2.16}$$

simplifes the calculation of the integrals in (2.12)–(2.14).

For the purposes of the following analysis, it suffices that we consider a uniform mesh made up of biased right triangles as in Figure 2.1a, and h is thus taken as a constant in the x- and y-directions. Midedge velocity nodes may be located on three possible types of faces, i.e., horizontal, vertical, and diagonal, and for each type the corresponding nodes are distributed on a regular grid of size h. Selected discrete pairs of equations are then obtained from (2.12) and (2.13) at the velocity nodes $q = 1, 2, 3$, of Figure 2.1a:

$$u_1^t - f v_1^\gamma + \frac{g}{h}(\eta_B^\alpha - \eta_A^\alpha) = 0, \tag{2.17}$$

$$v_1^t + f u_1^\gamma + \frac{g}{2h}(\eta_B^\alpha + \eta_C^\alpha - \eta_A^\alpha - \eta_G^\alpha) = 0, \tag{2.18}$$

$$u_2^t - f v_2^\gamma + \frac{g}{2h}(\eta_B^\alpha + \eta_C^\alpha - \eta_A^\alpha - \eta_D^\alpha) = 0, \tag{2.19}$$

$$v_2^t + f u_2^\gamma + \frac{g}{h}(\eta_C^\alpha - \eta_A^\alpha) = 0, \tag{2.20}$$

$$u_3^t - f v_3^\gamma + \frac{g}{2h}(\eta_A^\alpha + \eta_C^\alpha - \eta_D^\alpha - \eta_E^\alpha) = 0, \tag{2.21}$$

$$v_3^t + f u_3^\gamma + \frac{g}{2h}(\eta_C^\alpha + \eta_D^\alpha - \eta_A^\alpha - \eta_E^\alpha) = 0, \tag{2.22}$$

respectively, while at the surface-elevation node $r = A$ of Figure 2.1a (2.14) leads to

$$\begin{aligned} &6\eta_A^t + \eta_B^t + \eta_C^t + \eta_D^t + \eta_E^t + \eta_F^t + \eta_G^t \\ &\quad + \frac{2H}{h}(2u_1^\alpha + u_2^\alpha + u_7^\alpha + u_6^\alpha + u_{12}^\alpha - 2u_4^\alpha - u_3^\alpha - u_9^\alpha - u_5^\alpha - u_{10}^\alpha \\ &\quad + 2v_2^\alpha + v_3^\alpha + v_8^\alpha + v_1^\alpha + v_7^\alpha - 2v_5^\alpha - v_4^\alpha - v_{10}^\alpha - v_6^\alpha - v_{11}^\alpha) = 0, \end{aligned} \tag{2.23}$$

where

$$\Phi_i^t = \frac{\Phi_i^{n+1} - \Phi_i^n}{\Delta t}, \qquad \Phi_i^\gamma = \gamma\Phi_i^{n+1} + (1-\gamma)\Phi_i^n, \qquad \Phi_i^\alpha = \alpha\Phi_i^{n+1} + (1-\alpha)\Phi_i^n,$$

and $\Phi = u, v$, or η.

The contribution of the time derivative in (2.2) leads, at least theoretically, to a problem that is always stable without an inf-sup (or LBB) condition [13, 8]. However, an important result obtained in [24], in the context of the incompressible Navier–Stokes equations, is generalized in [30] to include the shallow-water and the compressible Navier–Stokes equations by examining their numerical dispersion relations. It is found that spurious solutions may arise from the coupling of the momentum and continuity equations. The spurious modes are small-scale artifacts introduced by the spatial discretization scheme which do not propagate but are trapped within the model grid.

In [30] attention is focused almost exclusively on the spurious pressure or surface-elevation modes, since these are argued to be the most troublesome. For these modes the velocity field is zero and nonconstant pressure functions lie in the null space of the discrete gradient operator. Solution uniqueness is then lost since any multiple of a spurious mode can be added to any solution of the discrete equations and still satisfy them. The occurrence of such spurious modes has been observed in a variety of finite-difference [31] and finite-element [19, 20, 21, 30] approximations to the shallow-water equations.

By setting the velocity field to zero in (2.17)–(2.22) we obtain $\eta_A = \eta_B = \eta_C$ from (2.17) and (2.20), $\eta_C = \eta_G = \eta_D$ from (2.18) and (2.19), and finally $\eta_C = \eta_E$ from (2.21) or (2.22). By taking into account the continuity of η, we deduce that the null space of the discrete gradient operator is one-dimensional. This proves that the $P_1^{NC} - P_1$ finite-element pair is free of spurious pressure modes.

3. Study of the dispersion relation. In the continuum case the free modes of (2.1)–(2.2) are examined by perturbing about the basic sate $u = v = \eta = 0$. We seek solutions of (2.1)–(2.2) of the form $(u, v, \eta) = (\tilde{u}, \tilde{v}, \tilde{\eta})e^{i(kx+ly+\omega t)}$, where k and l are the wave numbers in the x- and y-directions, respectively, and ω is the angular frequency. Substitution into (2.1)–(2.2) then leads to a square matrix system for the Fourier amplitudes $\tilde{u}$, $\tilde{v}$, $\tilde{\eta}$. For a nontrivial solution to exist, the determinant of the matrix must equal zero, and this constraint leads to the following dispersion relation for the frequency:

$$\omega(\omega^2 - f^2 - gH(k^2 + l^2)) = 0. \tag{3.1}$$

The first solution $\omega = 0$ is the geostrophic mode and would correspond to the slow Rossby mode on a β-plane, while the other two solutions $\omega = \pm(f^2 + gH(k^2 + l^2))^{1/2}$ correspond to the free-surface gravitational modes with rotational correction. Since ω is purely real, all modes are neutrally stable and neither amplify nor decay.

In the discrete case, solutions of (2.17)–(2.23) corresponding to $(u, v, \eta) = (\tilde{u}, \tilde{v}, \tilde{\eta})$ $e^{i(kx+ly+\omega t)}$ are sought. Setting $E = e^{i\omega\Delta t}$ and substituting in (2.17)–(2.23) we obtain

$$(E-1)\tilde{u}_q - f\Delta t(E\gamma + 1 - \gamma)\tilde{v}_q + ig\Delta t(E\alpha + 1 - \alpha)a_{q,1}\tilde{\eta}_A = 0, \tag{3.2}$$

$$(E-1)\tilde{v}_q + f\Delta t(E\gamma + 1 - \gamma)\tilde{u}_q + ig\Delta t(E\alpha + 1 - \alpha)a_{q,2}\tilde{\eta}_A = 0, \tag{3.3}$$

$$(E-1)a\tilde{\eta}_A + iH\Delta t(E\alpha + 1 - \alpha)\sum_{q=1}^{3}(a_{q,1}\tilde{u}_q + a_{q,2}\tilde{v}_q) = 0, \tag{3.4}$$

for $q = 1, 2, 3$ in (3.2) and (3.3), with

$$a_{1,1} = \frac{2}{h} \sin \frac{kh}{2}, \qquad a_{1,2} = \frac{2}{h} \sin \frac{lh}{2} \cos \frac{(k-l)h}{2},$$

$$a_{2,1} = \frac{2}{h} \sin \frac{kh}{2} \cos \frac{(k-l)h}{2}, \qquad a_{2,2} = \frac{2}{h} \sin \frac{lh}{2},$$

$$a_{3,1} = \frac{2}{h} \sin \frac{kh}{2} \cos \frac{lh}{2}, \qquad a_{3,2} = \frac{2}{h} \sin \frac{lh}{2} \cos \frac{kh}{2},$$

$$a = 1 + 2 \cos \frac{kh}{2} \cos \frac{lh}{2} \cos \frac{(k-l)h}{2} \quad \text{with } a \geq \frac{3}{4} \text{ for all } k \text{ and } l.$$

A nontrivial solution $(\tilde{u}_1, \tilde{v}_1, \tilde{u}_2, \tilde{v}_2, \tilde{u}_3, \tilde{v}_3, \tilde{\eta}_A)$ exists, if the 7×7 determinant of the square matrix system (3.2)–(3.4) vanishes, which requires solving a polynomial of degree seven in E. This leads to

$$E_1 = 1, \tag{3.5}$$

$$E_{2,3} = 1 - \frac{\Delta t^2 \Big(f^2 \gamma + \frac{gH}{a} \alpha \sum_{q=1}^{3} (a_{q,1}^2 + a_{q,2}^2) \Big)}{1 + \Delta t^2 \Big(f^2 \gamma^2 + \frac{gH}{a} \alpha^2 \sum_{q=1}^{3} (a_{q,1}^2 + a_{q,2}^2) \Big)} \tag{3.6}$$

$$\pm i \frac{\Delta t \sqrt{f^2 + \frac{gH}{a} (1 + f^2 \Delta t^2 (\alpha - \gamma)^2) \sum_{q=1}^{3} (a_{q,1}^2 + a_{q,2}^2)}}{1 + \Delta t^2 \Big(f^2 \gamma^2 + \frac{gH}{a} \alpha^2 \sum_{q=1}^{3} (a_{q,1}^2 + a_{q,2}^2) \Big)},$$

$$E_{4,5} = 1 - \frac{f^2 \Delta t^2 \gamma}{1 + f^2 \Delta t^2 \gamma^2} \pm i \frac{f \Delta t}{1 + f^2 \Delta t^2 \gamma^2} \quad \text{double roots}, \tag{3.7}$$

where $E_j = e^{i \omega_j \Delta t}$, $j = 1, 2, \ldots, 5$.

The first mode E_1 in (3.5) is the geostrophic mode, on a β-plane it would be a planetary Rossby wave. The modes $E_{2,3}$ in (3.6) are inertia-gravity waves and the modes $E_{4,5}$ in (3.7) are computational modes.

The latter modes, as for the CD-grid [1], take the form of propagating inertial oscillations and have no particular spatial characteristics; they are a consequence of using three times more velocity nodes than surface-elevation nodes. For the computational modes to be stable ($|E_{4,5}| \leq 1$), it is sufficient that $\gamma \geq 1/2$. Following [1], the computational modes can effectively be filtered by using an implicit backward scheme with $\gamma = 1$. As shown in [1], for all the timescales of interest and relevance to large-scale oceanography, inertial oscillations will, in practice, be fully filtered. Implicit dissipation would dissipate energy from the balanced state, whereas here, only the transients about the balance state are damped. Indeed, implicit filtering extracts energy only from inertial oscillations and faithfully sustains the balance state. Furthermore, this procedure applies equally well to regular as well as unstructured meshes with irregular geometry.

TABLE 3.1

Dispersion relations for various schemes: AN, analytical (continuum); FE, the finite-element pair $P_1^{NC} - P_1$; CD, the CD-grid, and C, the C-grid, shown in Figure 3.1. In each case, the normalized frequency squared $(\omega / f)^2$ has been written as the sum of its inertia and gravity parts.

		Inertia part		Gravity part
AN	$\left(\frac{\omega}{f}\right)^2 =$	1	$+$	$\left(\frac{\lambda}{h}\right)^2 ([kh]^2 + [lh]^2)$
FE	$\left(\frac{\omega}{f}\right)^2 =$	1	$+$	$4\left(\frac{\lambda}{h}\right)^2 \left(\sin^2\frac{kh}{2} + \sin^2\frac{lh}{2} + \frac{1}{a}\left[\sin^4\frac{kh}{2} + \sin^4\frac{lh}{2}\right]\right)$
CD	$\left(\frac{\omega}{f}\right)^2 =$	1	$+$	$4\left(\frac{\lambda}{h}\right)^2 \left(\sin^2\frac{kh}{2} + \sin^2\frac{lh}{2}\right)$
C	$\left(\frac{\omega}{f}\right)^2 =$	$\cos^2\frac{kh}{2}\cos^2\frac{lh}{2}$	$+$	$4\left(\frac{\lambda}{h}\right)^2 \left(\sin^2\frac{kh}{2} + \sin^2\frac{lh}{2}\right)$

In the limit as time step $\Delta t \to 0$ and mesh spacing $h \to 0$, we obtain $a_{q,1} = k$ and $a_{q,2} = l$ for $q = 1, 2, 3$, and $a = 3$. Hence, the discrete inertia-gravity modes (3.6) asymptote to the more familiar continuum modes $\omega_{2,3} = \pm(f^2 + gH(k^2 + l^2))^{1/2}$, while the frequencies corresponding to the computational modes give $\omega_{4,5} = \pm f$.

In the limit as time step $\Delta t \to 0$ only, we still have $\omega_{4,5} = \pm f$, while (3.6) gives

$$\left(\frac{\omega_{2,3}}{f}\right)^2 = 1 + \frac{gH}{f^2}\frac{1}{a}\sum_{q=1}^{3}(a_{q,1}^2 + a_{q,2}^2), \tag{3.8}$$

for the inertia-gravity modes. After some long and tedious algebra (3.8) reduces to

$$\left(\frac{\omega_{2,3}}{f}\right)^2 = 1 + 4\left(\frac{\lambda}{h}\right)^2 \left(\sin^2\frac{kh}{2} + \sin^2\frac{lh}{2} + \frac{1}{a}\left[\sin^4\frac{kh}{2} + \sin^4\frac{lh}{2}\right]\right), \tag{3.9}$$

where $\lambda \equiv \sqrt{gH} / f$ is the radius of deformation (Rossby radius) and we recall that $a \geq 3/4$ for all k and l.

Table 3.1 compares the dispersion relation obtained in (3.9) for the $P_1^{NC} - P_1$ pair with those derived for the continuous case and the CD- and D-grids. Observe that the dispersion relations obtained for the finite-element pair and the CD-grid only differ from one another in the representation of their gravity parts, due to the presence of the extra term in brackets [ ] in (3.9). Furthermore, the inertia part of the dispersion relation for the C-grid (resulting from the spatial averaging of the Coriolis terms) vanishes in the case $kh = lh = \pi$ for small values of λ / h, and spurious Coriolis modes may thus exist. Other finite-difference schemes are not mentioned here as they generate spurious surface-elevation modes.

The nondimensional frequency (ω / f) corresponding to the discrete inertia-gravity modes is plotted in Figure 3.1 as a function of kh and lh. Two cases are considered, namely $\lambda / h = 2$ (high resolution) and $\lambda / h = 0.1$ (coarse resolution), and the results for the $P_1^{NC} - P_1$ pair are compared with those obtained for the continuous case and for the CD- and C-finite-difference grids. When $\lambda / h = 2$ and $\lambda / h = 0.1$, the nondimensional frequency (ω / f) is monotonic in k and l, as in the continuous case, for both the $P_1^{NC} - P_1$ pair and the CD-grid. However, the maximum value of ω / f is much closer to the continuous case for the $P_1^{NC} - P_1$ pair than

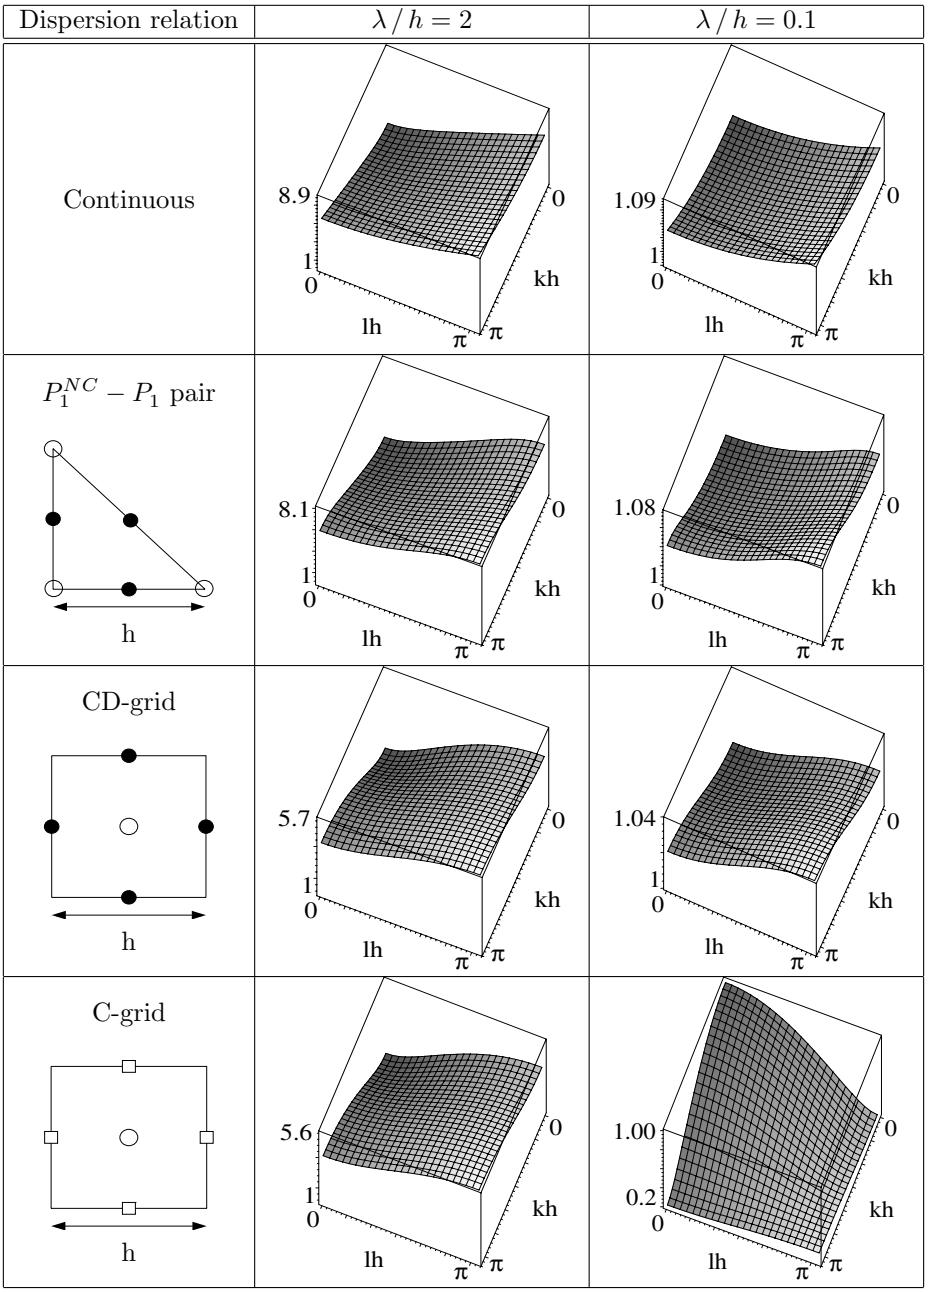

FIG. 3.1. *Dispersion relation results for several grids and* $\lambda / h = 2$ *(high resolution) and* $\lambda / h = 0.1$ *(coarse resolution). for the CD-grid, and this is due to the presence of the extra term in brackets [ ] in (3.9). For the C-grid, the presence of the Coriolis mode is clearly shown at low resolution ($\lambda / h = 0.1$) when $kh = lh = \pi$, while at high resolution the nondimensional frequency is monotonic in k and l, yielding accurate results. A cross section ($k = l$)

of the numerical results shown in Figure 3.1 is presented in Figure 3.2 in the cases $\lambda / h = 2$ and $\lambda / h = 0.1$.

The computational cost of the $P_1^{NC} - P_1$ scheme will be discussed in the next section and we shall see that this finite-element pair defines a reasonably cheap approximation of the shallow-water system.

4. Solving the discrete shallow-water system. Equations (2.12)–(2.14) lead to a set of linear equations of the form

$$\mathsf{M}^{\mathbf{u}}\mathbf{u}_p^{n+1} + \alpha g \Delta t \mathsf{G} \eta_s^{n+1} = \mathsf{M}^{\mathbf{u}}\mathbf{u}_p^n - (1-\alpha) g \Delta t \mathsf{G} \eta_s^n \equiv \mathsf{R}^{\mathbf{u}}, \tag{4.1}$$

$$\mathsf{M}^{\eta}\eta_s^{n+1} - \alpha H \Delta t \mathsf{G}^t \mathbf{u}_p^{n+1} = \mathsf{M}^{\eta}\eta_s^n + (1-\alpha) H \Delta t \mathsf{G}^t \mathbf{u}_p^n \equiv \mathsf{R}^{\eta}, \tag{4.2}$$

for $1 \le p \le N_{\mathbf{u}}$ and $1 \le s \le N_\eta$, where $N_{\mathbf{u}}$ and N_η are the number of velocity and surface-elevation unknowns, respectively. In (4.1) and (4.2), $\mathsf{M}^{\mathbf{u}}$ and M^{η} denote the velocity (including the Coriolis part) and surface-elevation mass matrices, respectively, G is the gradient matrix, and $\mathsf{R}^{\mathbf{u}}$ and R^{η} are the right-hand sides.

Due to the orthogonality property of the velocity basis functions [27], $\mathsf{M}^{\mathbf{u}}$ is a diagonal matrix with 2×2 blocks along the diagonal. Equation (4.1) is rewritten as

$$\mathbf{u}_p^{n+1} = -\alpha g \Delta t (\mathsf{M}^{\mathbf{u}})^{-1} \mathsf{G} \eta_s^{n+1} + (\mathsf{M}^{\mathbf{u}})^{-1} \mathsf{R}^{\mathbf{u}}, \tag{4.3}$$

and (4.3) is then used to eliminate $\mathbf{u}_p^{n+1}$, $1 \le p \le N_{\mathbf{u}}$, from (4.2). The substitution results in

$$(\mathsf{M}^{\eta} + \alpha^2 g H \Delta t^2 \mathsf{G}^t (\mathsf{M}^{\mathbf{u}})^{-1} \mathsf{G}) \eta_s^{n+1} = \mathsf{R}^{\eta} + \alpha H \Delta t \mathsf{G}^t (\mathsf{M}^{\mathbf{u}})^{-1} \mathsf{R}^{\mathbf{u}}. \tag{4.4}$$

The elimination of $\mathbf{u}_p^{n+1}$ thus leads to N_η discrete Helmholtz equations in η, and hence to solve for a linear system $N_\eta \times N_\eta$ for the surface-elevation only, where N_η is the

number of vertices of $\mathcal{T}_h$, which greatly enhances computational efficiency. The matrix on the left-hand side (4.4) is a very sparse matrix, with an average of 13 nonzero elements per row. Finally, once η is obtained from (4.4) $\mathbf{u}$ is computed explicitly from (4.3).

For most finite-element discretizations $\mathsf{M}^{\mathbf{u}}$ is not diagonal, and hence the substitution procedure leading to (4.4) likely involves a full $(\mathsf{M}^{\mathbf{u}})^{-1}$ matrix, even if $\mathsf{M}^{\mathbf{u}}$ is sparse. The system (4.4) is then too large to be stored and handled. The orthogonality property of the P_1^{NC} basis functions, leading to the diagonal matrix $\mathsf{M}^{\mathbf{u}}$, implies a tremendous savings in the computational cost since a system of only N_η equations is solved instead of $N_{\mathbf{u}}+N_\eta$, i.e., approximately $7N_\eta$ equations. In the case of the popular P_1 iso P_2-P_1 finite-element pair [5], which also approximates velocity components and surface elevation using piecewise linear basis functions, we would have to solve a linear system of approximately $9N_\eta$ equations. Finally, the use of the CD-grid, in its semi-implicit formulation, leads to N_η discrete Helmholtz equations of the form (4.4), as the matrix $\mathsf{M}^{\mathbf{u}}$ is "naturally" diagonal, and the Helmholtz matrix has an average of 9 nonzero elements per row. By taking advantage of the increased flexibility of unstructured meshes, the computational cost of the $P_1^{NC}-P_1$ and CD schemes for solving (4.4) should thus be comparable in the semi-implicit case.

5. Numerical results. The results of two tests using the $P_1^{NC}-P_1$ element pair are now presented. The first test examines the propagation and dispersion of fast surface gravity waves in a circular basin and their reflection at the lateral boundary. In the second test, the Stommel problem is computed and the results are compared with those obtained with the C- and CD-finite-difference grids.

5.1. Gravity wave propagation and dispersion. For many applications very little energy is carried by the small-amplitude fast-moving surface gravity waves, and this justifies slowing them down via a semi-implicit time discretization. Nevertheless, when an accurate representation of the fast gravity modes is important, the numerical solution of (2.1)–(2.3), at small values of the gravitational Courant number C_g, should be expected to reasonably well approximate the analytical one in the semi-implicit case. We then use a small value for C_g and $\alpha = 1/2$ in the present test.

The analytical solution of the problem is obtained from (2.1) and (2.2) by exploiting the circular symmetry. In order to do so, the Coriolis term is set to zero, leading to a second-order wave equation in polar coordinates for η, viz

$$\eta_{tt} - c^2 \frac{1}{r}(r\eta_r)_r = 0 \tag{5.1}$$

subject to the boundary conditions $\eta_r|_{r=R} = 0$ and no singularity at the origin, where $c \equiv \sqrt{gH}$ is the phase speed of the surface gravity waves. The initial conditions are $\eta(r,0) = ae^{-br^2}$ and $\eta_t(r,0) = 0$; the latter condition follows from setting the initial velocity to zero. The exact solution of (5.1) is the Bessel-function expansion

$$\eta(r,t) = \sum_{n=1}^{\infty} \mu_n J_0(\sqrt{\lambda_n} r) \cos c\sqrt{\lambda_n} t,$$

where $\mu_n = \dfrac{\int_0^R \eta(r,0) J_0(\sqrt{\lambda_n} r) r\, dr}{\int_0^R J_0^2(\sqrt{\lambda_n} r) r\, dr}$ and λ_n are the roots of $J_1(\sqrt{\lambda_n} R) = 0$.

The circular domain has a radius of $R = 1000$ km and is discretized using a 25 km surface-elevation node spacing unstructured triangulation $\mathcal{T}_h$, as shown in Figure 5.1a.

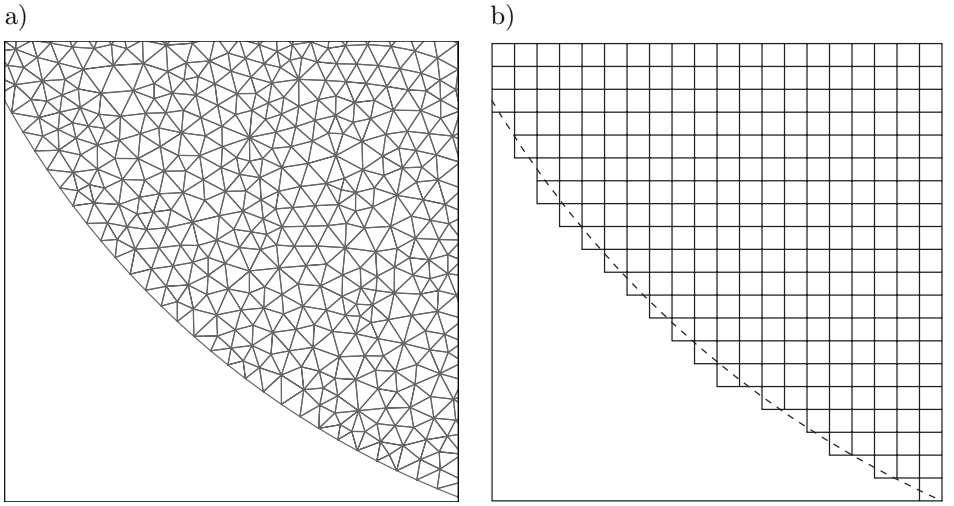

FIG. 5.1. *A window (close to the boundary) of the circular domain of radius* $R = 1000$ *km, discretized using a* 25 *km vertex node spacing in the case of* a) *an unstructured triangulation,* b) *a uniform grid (the dash line corresponds to the domain boundary).*

The corresponding uniform grid, shown in Figure 5.1b, crudely represents the domain boundary by a series of artificial "steps." It is therefore not appropriate for evaluating the performance of the CD scheme in the experiment conducted here. Consequently, only the $P_1^{NC} - P_1$ pair is used in this test.

A flat bottom with mean depth $H = 2000\,\mathrm{m}$ is assumed, leading to $c \approx 140\,\mathrm{m\ s^{-1}}$. By taking a timestep of 20 s, C_g is approximately 0.2. The Gaussian distribution parameters that define η at initial time are set to $a = 100\,\mathrm{m}$ and $b = 6.4 \times 10^{-11}\,\mathrm{m^{-2}}$, hence the e-folding of the Gaussian at initial time is 125 km and is resolved by about 5 surface-elevation nodes.

Time sequences for η are shown in Figure 5.2. The surface elevation is first shown at stage 1, after a single timestep. At stage 3 it is being reflected by the basin wall, and by stages $5, 6, 7$, and 8 it has returned one, two, three, and four times, respectively, to its starting point. Comparing panels 1 and 5 of Figure 5.2 we can see that very little dispersion has occurred after a single cycle, but after two and three cycles the dispersion effect is quite obvious. The dispersion is due to the individual Bessel modes of the exact solution propagating with different phase speeds.

Good agreement is obtained between the analytical and computed solutions for the $P_1^{NC} - P_1$ pair, as shown in Table 5.1, since the error is about 1%. Further, the radial symmetry of the exact solution is very well reproduced by the numerical one.

5.2. The Stommel problem. In the second experiment the wind-driven large-scale circulation test case, proposed by Stommel [26], is performed in a homogeneous square ocean under the influence of surface winds, linearized bottom friction, flat bottom, and Coriolis force. The solution is an intense crowding of streamlines towards the western boundary caused by the variation of the Coriolis parameter with latitude.

The linear shallow-water equations (2.1)–(2.2) now include forcing ($\boldsymbol{\tau}$) and bottom friction ($-\varepsilon\mathbf{u}$), hence we solve for

$$\eta_t + H\nabla \cdot \mathbf{u} = 0, \tag{5.3}$$

subject to the no-normal flow boundary condition (2.3).

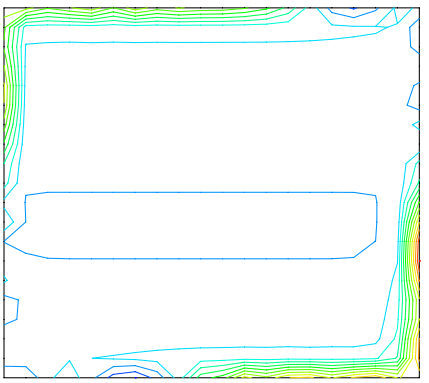
The domain is an idealized 4000 km × 4000 km square basin with solid boundaries on all sides. The β-plane approximation, $f = f_0 + \beta y$ is used, with $f_0 = 10^{-4}\,\mathrm{s}^{-1}$ and $\beta = 10^{-11}\,\mathrm{m}^{-1}\,\mathrm{s}^{-1}$. The reduced-gravity acceleration and the mean depth are taken as $g' = 10^{-2}\,\mathrm{m\ s}^{-2}$ and $H = 400\,\mathrm{m}$, respectively, leading to $c = 2\,\mathrm{m\ s}^{-1}$. The radius of deformation at midbasin is thus $R_d \equiv \sqrt{g'H}\,/\,f_0 = 20\,\mathrm{km}$.

A zonal wind applies a surface stress of the form $\boldsymbol{\tau} = (\tau_0 \sin(\pi y\,/\,L), 0)$, where $-L\,/\,2 < y < L\,/\,2$ and $\tau_0 = 2 \times 10^{-7}\,\mathrm{m\ s}^{-2}$ spinning up a single anticyclonic gyre. By setting $\varepsilon = 10^{-6}\,\mathrm{s}^{-1}$ the bottom drag leads to a Stommel layer width of $\delta = \varepsilon\,/\,\beta = 100\,\mathrm{km}$. Two uniform grids are used (made up of biased right triangles for the $P_1^{NC} - P_1$ pair), from a high resolution grid (201 × 201 points) with $h = 20\,\mathrm{km}$ so that the Stommel layer is well resolved, and a low resolution grid (21 × 21 points) with $h = 200\,\mathrm{km}$ so that the Stommel layer is barely resolved. The timestep is 1728 s (50 steps per day).

An implicit backward ($\gamma = 1$) and an Euler forward scheme are used for the Coriolis term and the bottom friction, respectively. Because the value of the gravitational Courant number C_g is small for the two grids, choosing either the explicit

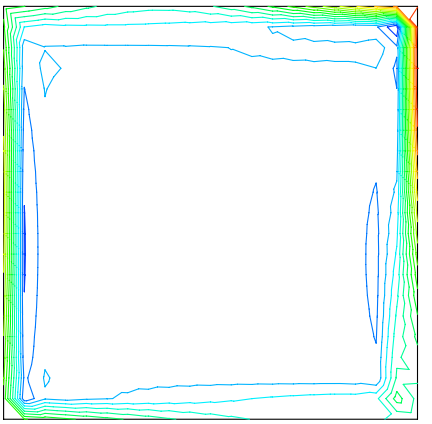
($\alpha = 0$) or the trapezoidal Crank–Nicolson ($\alpha = 1/2$) scheme has negligible impact on the results. Note that $\mathsf{R}^{\mathbf{u}}$ in (5.2) now includes forcing and bottom friction.

The goal of the present experiment is to test the ability of the shallow-water finite-element model described herein to simulate the evolution of the divergence of the velocity field for the Stommel problem. Such an experiment has already been performed in [1] to test the behavior of the CD-grid at both high and low resolutions. In [1], the results obtained for the CD-grid are compared with those of the C-grid at high resolution, where the latter are free of Coriolis modes and are believed to be quite accurate. A precise calculation of the horizontal divergence of the velocity field is crucial in order to well represent the vertical velocity field in general circulation models. Hence, all the aforementioned parameters have been chosen to correspond to those employed in [1].



The evolution of the divergence of the velocity field is shown in Figure 5.3 for the CD-grid and the $P_1^{NC} - P_1$ pair after 100 days of simulation. Both schemes mainly differ with respect to the low resolution calculation (Figure 5.3 panels a and b). At high resolution the finite-element solution better matches the C-grid (Figure 5.4 panel e) result than the CD-grid one. Indeed, the eddy appearing at the bottom right corner of the domain for the C-grid and the $P_1^{NC} - P_1$ pair (Figure 5.3 panel d) is not present for the CD-grid (Figure 5.3 panel c). Further, it seems that some numerical noise appears in the CD-grid solution close to the boundary (Figure 5.3 panels c and e), which is not the case for the C-grid (Figure 5.4 panel e) and the $P_1^{NC} - P_1$ pair (Figure 5.3 panels d and f) at this stage of the propagation.

In Figure 5.4 the evolution of the divergence of the velocity field is again shown for the CD-grid and the $P_1^{NC} - P_1$ pair, but after 500 days of simulation. Both schemes again considerably differ with respect to the low resolution calculation. Indeed, the finite-element solution well captures the bottom right eddy (Figure 5.4 panel b) while the CD-grid does not represent such a behavior (Figure 5.4 panel a). The eddy is, however, fully developed for all schemes at high resolution (Figure 5.4 panels c, d, f), which suggests that even at low resolution the finite-element pair performs well. The results obtained for the CD scheme on a 26×26 grid, where the number of unknows is approximately the same than for the $P_1^{NC} - P_1$ pair on a 21×21 grid, are very close to those obtained on a 21×21 grid.



Even on a 51×51 grid (Figure 5.5 panel a), the CD scheme barely captures the bottom right eddy after 500 days of simulation (Figure 5.5 panel b) while the finite-element solution (Figure 5.5 panel d), obtained on a nonuniform triangular mesh having only 441 points (Figure 5.5 panel c), shows an improved behavior compared to the solution of Figure 5.4 panel b obtained on a uniform grid having the same number of points (441). Further, in the case of Figure 5.5, the use of the CD-grid results in having 5.7 and 4.1 times more surface-elevation and velocity unknowns, respectively, than for the $P_1^{NC} - P_1$ pair.

Consequently, the finite-element scheme is shown to be more accurate than the CD one at low resolution. On the fine grid the $P_1^{NC} - P_1$ pair and the C-grid give nearly indistinguishable results (Figure 5.4 panels d and f) close to those obtained for the CD-grid (Figure 5.4 panel c). The $P_1^{NC} - P_1$ pair thus yields equally favorable results in both the low and high resolution regimes, and those are significantly better than for the CD-grid. Further, the fact that the finite-element scheme applies equally well to structured as well as unstructured meshes demonstrates the excellent flexibility of the method.

6. Conclusions. Most of the numerical methods that are used to solve the shallow-water equations poorly approximate the representation of inertia-gravity waves and usually lead to spurious solutions. In this paper, the triangular finite-element pair $P_1^{NC} - P_1$ is shown to "properly" model the dispersion of the inertia-gravity waves, and this is achieved at a reasonable computational cost compared to traditional finite-difference schemes.

Two tests are performed: simulation of propagation and dispersion of gravity waves in a circular basin using an unstructured triangular mesh, and simulation of the wind-driven large-scale circulation test case of Stommel. In the first experiment good agreement is obtained between the analytical and computed solutions for the finite-element pair. In the second test the $P_1^{NC} - P_1$ pair yields significantly better results than for the finite-difference CD-grid in both the low and high resolution regimes. The fact that the method applies equally well to structured as well as unstructured meshes demonstrates its excellent flexibility.

In this paper linear equations have been considered. However, the nonlinear shallow-water equations have been successfully solved using the $P_1^{NC} - P_1$ finite-element pair [15] and an accurate representation of the slow Rossby modes has been obtained with a small amount of numerical diffusion. It is thus concluded that the $P_1^{NC} - P_1$ pair is a very promising choice for the discretization of a variety of coastal and environmental problems.

OVERLAPPING SCHWARZ WAVEFORM RELAXATION FOR CONVECTION-DOMINATED NONLINEAR CONSERVATION LAWS*

MARTIN J. GANDER† AND CHRISTIAN ROHDE‡

Abstract. We analyze the convergence of the overlapping Schwarz waveform relaxation algorithm applied to convection-dominated *nonlinear* conservation laws in one spatial dimension. For two subdomains and bounded time intervals we prove superlinear asymptotic convergence of the algorithm in the parabolic case and convergence in a finite number of steps in the hyperbolic limit. The convergence results depend on the overlap, the viscosity, and the length of the time interval under consideration, but they are independent of the number of subdomains, as a generalization of the results to many subdomains shows. To investigate the behavior of the algorithm for a long time, we apply it to the Burgers equation and use a steady state argument to prove that the algorithm converges linearly over long time intervals. This result reveals an interesting paradox: while for the superlinear convergence rate on bounded time intervals decreasing the viscosity improves the performance, in the linear convergence regime decreasing the viscosity slows down the convergence rate and the algorithm can converge arbitrarily slowly, if there is a standing shock wave in the overlap. We illustrate our theoretical results with numerical experiments.

1. Introduction.

Overlapping Schwarz waveform relaxation is a class of domain decomposition algorithms to solve evolution problems in parallel. The classical way of applying domain decomposition methods to evolution problems is to discretize the time dimension first uniformly over the whole domain by an implicit scheme, and then to apply domain decomposition at each time step separately to solve the sequence of steady state problems obtained from the implicit time discretization. Numerical experiments for this approach with an overlapping Schwarz method for the two-dimensional heat equation can be found in [Meu91] and the application of the additive and multiplicative Schwarz preconditioners to the convection diffusion equation have been analyzed in [Cai91] and [Cai94], respectively. A nonoverlapping domain decomposition in this context using a Neumann–Dirichlet preconditioner at each time step was proposed in [Dry91], and an interesting variant, which uses an explicit method to advance the interface values in time and then an implicit method on each subdomain and thus avoids a subdomain iteration, is proposed in [DD91]; see also [RZ94] and [CL96]. For hyperbolic problems, the case of the wave equation with discontinuous bulk modulus and density fields per subdomain was analyzed in [BGT97] and the advantage of different grids in space due to the domain decomposition was emphasized ("the possibility of assigning to each subdomain its own space step makes numerical simulations much less expensive"), but due to the uniform time discretization, one cannot have an optimal space-time discretization close to the

CFL condition in each subdomain in the classical approach. For a linear first-order hyperbolic equation in two dimensions, numerical results of the additive Schwarz preconditioner together with GMRES acceleration were reported in [WCK98] and a first analysis for the case of the Euler equations can be found in [DLN00]. As mentioned above, the main disadvantage of this classical approach is that one needs to use a uniform time discretization over the entire domain and thus loses one of the main features of domain decomposition methods, namely, to treat the problem on each subdomain numerically differently, with an appropriate discretization both in time and space adapted to the subdomain problems.

Overlapping Schwarz waveform relaxation does not have this disadvantage; the algorithm also uses an overlapping domain decomposition in space, like the classical Schwarz algorithm for steady state problems (see [Sch70]), but then the algorithm solves evolution problems on the subdomains and uses an iteration to converge to the solution of the original problem posed on the entire domain, like in waveform relaxation methods (see [LRSV82]), which explains the name of the algorithm. Since subdomain problems are solved both in space and time on subdomains, appropriate discretizations in space and time can be applied per subdomain. In addition, communication is not required at each time step; the computation can be performed over several time steps in a time window before information is exchanged with neighboring subdomains. This can be beneficial in a parallel environment where the startup cost of a connection with another processor is significant.

A very early use of this type of algorithm can be found in the research report [MS87], where it was applied to the one-dimensional wave equation, and it was shown that the algorithm converges in a finite number of steps in this case; see also [Gan97]. The algorithm has been analyzed in [Bjø95] for more general hyperbolic problems. The algorithm applied to parabolic problems was first analyzed for the heat equation in [GZ97, GZ02], for a semilinear model problem in [Gan98], and independently for convection diffusion problems in [GK02]. Applied to parabolic problems, the algorithm has the interesting property of having two different convergence regimes, depending on the length of the time evolution on the subdomains before information is exchanged with neighboring subdomains. The algorithm's performance can be further improved by using better transmission conditions; see, for example, [GHN99].

We analyze in this paper the convergence properties of overlapping Schwarz waveform relaxation applied to convection-dominated viscous conservation laws with nonlinear fluxes. Let $T > 0$ be the end of the time interval of interest, $t \in [0, T)$, and $\Omega \subseteq \mathbb{R}$ be the bounded or unbounded spatial domain. We analyze the overlapping Schwarz waveform relaxation method to compute solutions $u = u(x, t) : \Omega \times (0, T) \to \mathbb{R}$ of the corresponding initial and initial boundary value problems

$$\frac{\partial u}{\partial t} + \frac{\partial}{\partial x} f(u) = \varepsilon \frac{\partial^2 u}{\partial x^2} \quad \text{in } \Omega \times (0, T), \tag{1.1}$$

where $\varepsilon \geq 0$ and $f \in C^2(\mathbb{R})$ denotes a function which in general depends in a nonlinear way on u.

The initial boundary value problem for (1.1) is a scalar model problem for the physically important equations of viscous compressible flow: the compressible Navier–Stokes equations. Flow problems impose considerable difficulties if the Reynolds number becomes big. In our case we are therefore interested especially in the case $0 < \varepsilon \ll 1$. To understand this case it is essential to consider also the singular hyperbolic limit problem with $\varepsilon = 0$. We start by collecting in section 2 all the analytical background results we need in our analysis. In section 3 we analyze the behavior

of the overlapping Schwarz waveform relaxation algorithm for two subdomains over bounded time intervals, $T < \infty$. For $\varepsilon > 0$ we prove convergence of the algorithm at a superlinear rate. The analysis allows us to track exactly how the rate depends on ε when ε tends to zero. In particular, we show the connection to the results of the Schwarz waveform relaxation algorithm in the case $\varepsilon = 0$ which is analyzed separately. The convergence rate of the Schwarz waveform relaxation algorithm depends on the size of the overlap, the length of the time interval, and the viscosity term, and the algorithm becomes faster as the viscosity term becomes smaller, which leads in the limit to convergence in a finite number of steps. In section 4 we then generalize the superlinear convergence result to $I > 2$ subdomains and show that the convergence rate is independent of the number of subdomains. To understand the long-time behavior of the algorithm ($T \longrightarrow \infty$), we study in section 5 the overlapping Schwarz algorithm for the steady Burgers equation, which can be considered as the long-time behavior of the evolution case. We show that the algorithm converges linearly for the two subdomain cases and that the convergence rate depends again on the size of the overlap and the viscosity term. In this case, however, when there is a standing shock in the overlap, we find that the smaller the viscosity is, the slower the convergence becomes, and the dependence is exponential. Our analytical results agree with the observations for long time computations for the Burgers equation that have been reported in [GK97, GK00]. There, it is shown that the solution depends in a [illegible] way on the boundary conditions, if an internal layer is present. Moreover, an asymptotic analysis is presented and a two-dimensional version of the Burgers problem is considered. General analytical results using the Cole–Hopf transformation can be found in [LO95]. In section 6 we illustrate our results with numerical experiments.

2. Initial and initial boundary value problem. We consider for a given function $f \in C^2(\mathbb{R})$ the scalar conservation law

$$\frac{\partial u^\varepsilon}{\partial t}(x,t) + \frac{\partial}{\partial x} f(u^\varepsilon(x,t)) = \varepsilon \frac{\partial^2 u^\varepsilon}{\partial x^2}(x,t), \quad (x,t) \in \Omega \times (0,T), \tag{2.1}$$

where $\Omega \subseteq \mathbb{R}$ is an open set, $T > 0$, and $\varepsilon \geq 0$ is the viscosity parameter. We start with a review of basic analytical results for the parabolic case, $\varepsilon > 0$, and the (singular) hyperbolic case, $\varepsilon = 0$. In the first case we focus on the behavior of solutions for $0 < \varepsilon \ll 1$, which is important for the analysis of the Schwarz waveform relaxation algorithm later in section 3.

2.1. The parabolic case, $\varepsilon > 0$. In our analysis we need results both for the initial value problem (2.1) on the infinite domain $\Omega = \mathbb{R}$ with the initial condition

$$u^\varepsilon(x,0) = u_0(x), \quad x \in \Omega, \tag{2.2}$$

where we assume that $u_0 \in C^2(\mathbb{R}) \cap L^\infty(\mathbb{R})$, and for the initial boundary value problem (2.1) on the half line $\Omega = (-\infty, 0)$ with the initial and boundary conditions

$$u^0(x,0) = u_0(x),\ x \in \Omega, \quad u^0(0,t) = g(t),\ t \in [0,T], \tag{2.3}$$

where we suppose that $u_0 \in C^2([-\infty,0]) \cap L^\infty((-\infty,0])$, $g \in C^2([0,T])$, and that the appropriate compatibility condition holds for u_0 and g at $x = t = 0$. For both problems we consider classical solutions, i.e., functions that are smooth enough to satisfy the conservation law and the constraints pointwise.

THEOREM 2.1. $\varepsilon > 0$

(i) (2.1), (2.2), $\underline{u} = \inf_{x\in\mathbb{R}}\{u_0(x)\}$ $\overline{u} = \sup_{x\in\mathbb{R}}\{u_0(x)\}$ $u^\varepsilon \in C^1(0,T;C^2(\mathbb{R}))$ (2.1), (2.2)

$$\underline{u} \le u^\varepsilon(x,t) \le \overline{u}, \quad (x,t) \in \mathbb{R}\times[0,T], \qquad \varepsilon\|u^\varepsilon_x\|_{L^\infty(\mathbb{R}\times[0,T])} \le C_{IVP}.$$

$u^0 \in L^\infty(\mathbb{R}\times[0,T])$ $Q \subset \mathbb{R}$

$$\lim_{\varepsilon\to 0}\|u^0 - u^\varepsilon\|_{L^1(Q\times[0,T])} = 0.$$

(ii) (2.1), (2.3),

$$\underline{u} = \min\{\inf_{x\le 0}\{u_0(x)\}, \inf_{t\in[0,T]}\{g(t)\}\},$$

$$\overline{u} = \max\{\sup_{x\le 0}\{u_0(x)\}, \sup_{t\in[0,T]}\{g(t)\}\}.$$

$u^\varepsilon \in C^1(0,T;C^2((-\infty,0]))$ (2.1), (2.3)

$$\underline{u} \le u^\varepsilon(x,t) \le \overline{u}, \quad (x,t) \in (-\infty,0]\times[0,T]$$

$$\varepsilon\|u^\varepsilon_x\|_{L^\infty((-\infty,0]\times[0,T])} \le C_{IBVP}.$$

$u^0 \in L^\infty((-\infty,0]\times[0,T])$ $Q \subset (-\infty,0]$

$$\lim_{\varepsilon\to 0}\|u^0 - u^\varepsilon\|_{L^1(Q\times[0,T])} = 0.$$

$C_{IVP}, C_{IBVP} > 0$ f u_0 g T ε . For the existence part in (i) and (ii) we refer the reader to, e.g., [LSU68]. The L^∞-estimates follow from an application of the maximum principle.

For the proof of the vanishing viscosity limits we refer the reader to [MNRR96, Chapter 2]. □

2.2. The hyperbolic limit $\varepsilon = 0$. We now consider for the limiting case $\varepsilon = 0$ the initial value problem (2.1), (2.2) on $\Omega = \mathbb{R}$ with $u_0 \in L^\infty(\mathbb{R})$ and the initial boundary value problem (2.1), (2.3) on $\Omega = (-\infty, 0)$ with $u_0 \in L^\infty((-\infty,0])$ and $g \in L^\infty([0,T])$. It is well known that initial (boundary) value problems for nonlinear functions f do not have time-global classical solutions for arbitrary, even smooth functions u_0, g: within finite time singularities, i.e., shock waves, develop. The well-posedness theory for the singular problems (2.1), (2.2) and (2.1), (2.3) relies therefore on a weaker notion of a solution: . It can be proved that in both cases there exists a unique entropy solution which satisfies the boundary data in an appropriate sense. These are the solutions we consider throughout the paper, although we do not introduce the precise definitions here, since they are not needed in an essential way later. It is important that the vanishing viscosity limits u^0 from Theorem 2.1 coincide with the entropy solutions for (2.1), (2.2) and (2.1), (2.3) in the case $\varepsilon = 0$. We refer the reader interested in the background on nonlinear

conservation laws and the precise definition of entropy solutions to [MNRR96]. The properties of the entropy solutions we need in our analysis are summarized in the following theorem.

THEOREM 2.2. $\varepsilon = 0$

(i) (2.1), (2.2), $\underline{u} = \operatorname{essinf}_{x\in\mathbb{R}}\{u_0(x)\}$ $\overline{u} = \operatorname{esssup}_{x\in\mathbb{R}}\{u_0(x)\}$ $u^0 \in L^\infty(\mathbb{R}\times[0,T])$ (i) 2.1 (2.1), (2.2). $(x,t) \in \mathbb{R}\times[0,T]$

$$\underline{u} \le u^0(x,t) \le \overline{u}. \tag{2.4}$$

(ii) (2.1), (2.3),

$$\underline{u} = \min\left\{\operatorname{essinf}_{x\le 0}\{u_0(x)\}, \operatorname{essinf}_{t\in[0,T]}\{g(t)\}\right\},$$
$$\overline{u} = \max\left\{\operatorname{esssup}_{x\le 0}\{u_0(x)\}, \operatorname{esssup}_{t\in[0,T]}\{g(t)\}\right\}$$

$u^0 \in L^\infty(\mathbb{R}\times[0,T])$ (ii) 2.1 (2.1), (2.3). $(x,t) \in (-\infty,0]\times[0,T]$

$$\underline{u} \le u^0(x,t) \le \overline{u}. \tag{2.5}$$

(iii) $u_{01}, u_{02} \in L^\infty(-\infty,0])$ $g_1, g_2 \in L^\infty([0,T])$, $I = [a,b] \subset (-\infty,0]$ $u_1^0, u_2^0 \in L^\infty((-\infty,0]\times[0,T])$ (2.1), (2.3) $u_0 = u_{01}$ $u_0 = u_{02}$ $g = g_1$, $g = g_2$ $t \in [0,T]$

$$\int_a^b |u_1(x,t) - u_2(x,t)|\,dt \le \int_{a-\lambda t}^{\min\{0,b+\lambda t\}} |u_{01}(x) - u_{02}(x)|\,dx + \lambda \int_0^{b/\lambda+t} |g_1(s) - g_2(s)|\,ds.$$

$\lambda > 0$

$$\lambda = \max_{\underline{u}\le v\le\overline{u}}\{|f'(v)|\},$$

$$\underline{u} = \min\left\{\operatorname*{ess\,inf}_{x\le 0}\{u_{01}(x)\}, \operatorname*{ess\,inf}_{t\in[0,T]}\{g_1(t)\}, \operatorname*{ess\,inf}_{x\le 0}\{u_{02}(x)\}, \operatorname*{ess\,inf}_{t\in[0,T]}\{g_2(t)\}\right\}$$

$\overline{u}$. All statements can be found in Chapter 2 of [MNRR96]. □

Theorem 2.1 gives the basic existence results for classical solutions and states that u^ε converges for $\varepsilon \to 0$ pointwise almost everywhere to the entropy solutions u^0 of the corresponding hyperbolic problems given in Theorem 2.2. Thus, in the particularly interesting singularly perturbed cases $0 < \varepsilon \ll 1$ we have to take into account the viscous counterparts of shock waves, i.e., internal layers of width $\mathcal{O}(\varepsilon)$ and amplitude $\mathcal{O}(1)$. Precisely the L^∞-estimates on the derivative u_x^ε in Theorem 2.1 allow us to compute the dependency on ε explicitly in all our estimates.

We note that statement (ii) in Theorem 2.1 and statements (ii), (iii) in Theorem 2.2—appropriately adapted—hold true for more general domains, particularly for all kinds of quarter spaces.

3. Overlapping Schwarz waveform relaxation for two subdomains. We analyze now the overlapping Schwarz waveform relaxation algorithm for the initial value problem (2.1), (2.2) and two subdomains. We start with the parabolic case, $\varepsilon > 0$, in subsection 3.1. We pay close attention in this analysis to the dependence of the convergence results on ε, since we are also interested in the convergence behavior of the algorithm in the limit when $\varepsilon \to 0$. In section 3.2 we then analyze directly the behavior of the algorithm in the hyperbolic limit when $\varepsilon = 0$, and we show how [illegible] flux functions lead to convergence properties of the algorithm which are not present when it is applied to linear problems. To simplify the notation we will skip the index ε in u^ε in what follows.

3.1. The parabolic case, $\varepsilon > 0$. The overlapping Schwarz waveform relaxation algorithm applied to the initial value problem (2.1), (2.2) with the two subdomains $\Omega_1 = (-\infty, L)$ and $\Omega_2 = (0, \infty)$, $L > 0$, is given for iteration index $n \in \mathbb{N}$ by

$$\begin{aligned} \frac{\partial u_1^n}{\partial t} + f'(u_1^n)\frac{\partial u_1^n}{\partial x} &= \varepsilon \frac{\partial^2 u_1^n}{\partial x^2} && \text{in } \Omega_1 \times (0,T), \\ u_1^n(\cdot,0) &= u_0 && \text{in } \Omega_1, \\ u_1^n(L,\cdot) &= u_2^{n-1}(L,\cdot) && \text{on } [0,T], \end{aligned} \tag{3.1}$$

and

$$\begin{aligned} \frac{\partial u_2^n}{\partial t} + f'(u_2^n)\frac{\partial u_2^n}{\partial x} &= \varepsilon \frac{\partial^2 u_2^n}{\partial x^2} && \text{in } \Omega_2 \times (0,T), \\ u_2^n(\cdot,0) &= u_0 && \text{in } \Omega_2, \\ u_2^n(0,\cdot) &= u_1^{n-1}(0,\cdot) && \text{on } [0,T]. \end{aligned} \tag{3.2}$$

There is also a more sequential variant of this algorithm, where the interface values on the second domain are taken from the newer iterate u_1^n on the first subdomain, like in a Gauss–Seidel iteration, but we analyze only the Jacobi version given in (3.1) and (3.2); the Gauss–Seidel case can be analyzed similarly. For the analysis we also require that the iteration starts with the initial guess

$$\begin{aligned} u_1^0(x,t) &= \inf_{x' \in (-\infty, L]} \{u_0(x')\}, \quad (x,t) \in \Omega_1 \times (0,T), \\ u_2^0(x,t) &= \inf_{x' \in [0, \infty)} \{u_0(x')\}, \quad (x,t) \in \Omega_2 \times (0,T). \end{aligned} \tag{3.3}$$

We define the errors in the Schwarz waveform relaxation iteration by $e_1^n := u - u_1^n$ on the left subdomain and $e_2^n := u - u_2^n$ on the right subdomain for $n \in \mathbb{N}_0$. For $n \in \mathbb{N}$, we find with (3.1), (3.2) that the errors satisfy the equations

$$\begin{aligned} \frac{\partial e_1^n}{\partial t} + f'(u)\frac{\partial e_1^n}{\partial x} + \theta_1^n e_1^n &= \varepsilon \frac{\partial^2 e_1^n}{\partial x^2} && \text{in } \Omega_1 \times (0,T), \\ e_1^n(\cdot,0) &= 0 && \text{in } \Omega_1, \\ e_1^n(L,\cdot) &= e_2^{n-1}(L,\cdot) && \text{on } [0,T], \end{aligned} \tag{3.4}$$

and

$$\begin{aligned} \frac{\partial e_2^n}{\partial t} + f'(u)\frac{\partial e_2^n}{\partial x} + \theta_2^n e_2^n &= \varepsilon \frac{\partial^2 e_2^n}{\partial x^2} && \text{in } \Omega_2 \times (0,T), \\ e_2^n(\cdot,0) &= 0 && \text{in } \Omega_2, \\ e_2^n(0,\cdot) &= e_2^{n-1}(0,\cdot) && \text{on } [0,T], \end{aligned} \tag{3.5}$$

where the functions $\theta_i^n : \Omega_i \to \mathbb{R}$ are given by

(3.6)
$$\theta_i^n(x,t) = \frac{\partial}{\partial x} u_i^n(x,t) \int_0^1 f''\Big(u_i^n(x,t) - s\big(u(x,t) - u_i^n(x,t)\big)\Big)\, ds, \qquad i = 1,2.$$

For later use we also define here the functions $K_{1,x}$, $K_{2,x}$ by

$$K_{1,x}(x,t) = -\frac{1}{2\sqrt{\pi}} \frac{x-L}{\varepsilon^{1/2} t^{3/2}} \exp\Big(-\frac{(x-L)^2}{4\varepsilon t}\Big), \tag{3.7}$$

$$K_{2,x}(x,t) = \frac{1}{2\sqrt{\pi}} \frac{x}{\varepsilon^{1/2} t^{3/2}} \exp\Big(-\frac{x^2}{4\varepsilon t}\Big). \tag{3.8}$$

Because of our particular choice of the starting values (3.3) and the comparison principle for parabolic differential equations (see [Fri64]), the errors on both subdomains stay nonnegative for all iterations $n \in \mathbb{N}_0$,

$$e_1^n(x,t) \geq 0, \quad (x,t) \in \Omega_1 \times (0,T), \qquad e_2^n(x,t) \geq 0, \quad (x,t) \in \Omega_2 \times (0,T). \tag{3.9}$$

It suffices therefore to derive upper bounds for the errors to obtain a bound on the convergence rate of the overlapping Schwarz waveform relaxation algorithm.

LEMMA 3.1 (supersolutions). [illegible] $\{e_1^n\}_{n\in\mathbb{N}}$ $\{e_2^n\}_{n\in\mathbb{N}}$ [illegible] (3.4), (3.5). [illegible] $n \in \mathbb{N}$ [illegible]

$$0 \leq e_1^n(x,t) \leq \bar{e}_1^n(x,t) \qquad \forall\, (x,t) \in \Omega_1 \times (0,T),$$
$$0 \leq e_2^n(x,t) \leq \bar{e}_2^n(x,t) \qquad \forall\, (x,t) \in \Omega_2 \times (0,T),$$

[illegible] $\bar{e}_1^n$ [illegible]

$$\begin{aligned} \frac{\partial \bar{e}_1^n}{\partial t} + a_1 \frac{\partial \bar{e}_1^n}{\partial x} + b_1 \bar{e}_1^n &= \varepsilon \frac{\partial^2 \bar{e}_1^n}{\partial x^2} && \text{[illegible]}\ \Omega_1 \times (0,T) \\ \bar{e}_1^n(\cdot,0) &= 0 && \text{[illegible]}\ \Omega_1 \\ \bar{e}_1^n(L,t) &= \exp(\sigma_1 t) \sup_{0\leq\tau\leq t} e_2^{n-1}(L,\tau), && t \in [0,T], \end{aligned} \tag{3.10}$$

[illegible] $a_1, b_1, \sigma_1 \in \mathbb{R}$ [illegible]

$$\begin{aligned} a_1 &:= \inf_{(x,t)\in\Omega_1} f'(u(x,t)), \\ b_1 &:= \inf_{(x,t)\in\Omega_2} \Big\{\theta_1^n(x,t) + (f'(u(x,t)) - a_1)\frac{a_1}{2\varepsilon}\Big\}, \\ \sigma_1 &:= \begin{cases} -\frac{a_1^2}{4\varepsilon} - b_1 & \text{[illegible]}\ -\frac{a_1^2}{4\varepsilon} - b_1 \geq 0 \\ 0 & \text{[illegible]}, \end{cases} \end{aligned}$$

[illegible] $\bar{e}_2^n$ [illegible]

$$\begin{aligned} \frac{\partial \bar{e}_2^n}{\partial t} + a_2 \frac{\partial \bar{e}_2^n}{\partial x} + b_2 \bar{e}_2^n &= \varepsilon \frac{\partial^2 \bar{e}_2^n}{\partial x^2} && \text{[illegible]}\ \Omega_2 \times (0,T) \\ \bar{e}_2^n(x,0) &= 0 && \text{[illegible]}\ \Omega_2 \\ \bar{e}_2^n(0,t) &= \exp(\sigma_2 t) \sup_{0\leq\tau\leq t} e_1^n(0,\tau), && t \in [0,T], \end{aligned} \tag{3.11}$$

$a_2, b_2, \sigma_2 \in \mathbb{R}$

$$a_2 := \sup_{(x,t)\in\Omega_1} f'(u(x,t)),$$
$$b_2 := \inf_{(x,t)\in\Omega_2} \Big\{\theta_2^n(x,t) + (f'(u(x,t)) - a_2)\frac{a_2}{2\varepsilon}\Big\},$$
$$\sigma_2 := \begin{cases} -\frac{a_2^2}{4\varepsilon} - b_2 & -\frac{a_2^2}{4\varepsilon} - b_2 \geq 0 \\ 0 & \end{cases}$$

σ_1 σ_2 $\mathcal{O}(\varepsilon^{-1})$ (ii) 2.1.

. The proof is constructive. We first define for $i = 1, 2$ the constants

$$p_i = \frac{a_i}{2\varepsilon}, \quad q_i = -\frac{a_i^2}{4\varepsilon} - b_i, \tag{3.12}$$

and the function

$$g_1 = g_1(t) = \exp(-p_1 L + (\sigma_1 - q_1)t) \sup_{0\leq\tau\leq t} e_2^{n-1}(L,\tau),$$

which is nonnegative due to (3.9), and monotonically increasing because of our choice of σ_1. For the linear, constant coefficient problem (3.10) satisfied by the supersolution we have the closed form solution formula

$$\bar{e}_1^n(x,t) = \exp(p_1 x + q_1 t) \int_0^t K_{1,x}(x, t-\tau) g_1(\tau)\, d\tau, \tag{3.13}$$

where the kernel $K_{1,x}(x,t)$ is given in (3.7). To show that $\bar{e}_1^n$ is indeed a supersolution, we have to show that

$$d_1^n := \bar{e}_1^n - e_1^n \geq 0. \tag{3.14}$$

Now the difference function d_1^n satisfies the linear convection diffusion equation

$$\frac{\partial d_1^n}{\partial t} + f'(u)\frac{\partial d_1^n}{\partial x} + \theta_1^n d_1^n - \varepsilon\frac{\partial^2 d_1^n}{\partial x^2} = Q_1(x,t), \tag{3.15}$$

where the source term $Q_1(x,t)$ is given by

$$\begin{aligned}
Q_1(x,t) &= (f'(u(x,t)) - a_1)\frac{\partial \bar{e}_1^n}{\partial x} + (\theta_1^n(x,t) - b_1)\,\bar{e}_1^n(x,t) \\
&= (f'(u(x,t)) - a_1)\frac{e^{(p_1 x + q_1 t)}}{2\sqrt{\pi}} \int_0^t \frac{e^{\left(-\frac{(x-L)^2}{4\varepsilon(t-\tau)}\right)}}{\varepsilon^{1/2}(t-\tau)^{3/2}} \left[\frac{(x-L)^2}{2\varepsilon(t-\tau)} - 1\right] g_1(\tau)\, d\tau \\
&\quad -\Big((f'(u(x,t)) - a_1)p_1 + \theta_1^n(x,t) - b_1\Big)(x-L) \\
&\qquad \times \frac{e^{(p_1 x + q_1 t)}}{2\sqrt{\pi}} \int_0^t \frac{e^{\left(-\frac{(x-L)^2}{4\varepsilon(t-\tau)}\right)}}{\varepsilon^{1/2}(t-\tau)^{3/2}} g_1(\tau)\, d\tau \\
&=: (f'(u(x,t)) - a_1)e^{(p_1 x + q_1 t)} Q_{11}(x,t) \\
&\quad + ((f'(u(x,t)) - a_1)p_1 + \theta_1^n(x,t) - b_1)\, e^{(p_1 x + q_1 t)}(L-x) Q_{12}(x,t).
\end{aligned}$$

If we can show that $Q_{11}(x,t)$ and $Q_{12}(x,t)$ are nonnegative for all $(x,t) \in \Omega_1 \times (0,T)$, we obtain $Q_1(x,t) \geq 0$ for all $(x,t) \in \Omega_1 \times (0,T)$ by the definition of a_1, b_1 which implies (3.14) by the maximum principle for (3.15) with zero initial and boundary data. But Q_{12} is nonnegative since g_1 from (3.13) is nonnegative by (3.9), and for Q_{11} we observe that it is the x-derivative of the solution w of the heat equation $w_t = \varepsilon w_{xx}$ in $\Omega_1 \times (0,T)$ which satisfies $w(L,\cdot) = g_1$ and $w(\cdot,0) \equiv 0$. Since g_1 is nonnegative and monotonically increasing, Q_{11} must also be nonnegative, which concludes the proof that $\bar{e}_1^n$ is a supersolution of e_1^n. Similarly one can also show that $\bar{e}_2^n$ is a supersolution of e_2^n. □

THEOREM 3.2 (superlinear convergence). [illegible] (3.1), (3.2) [illegible] (2.1), (2.2) [illegible] $t > 0$ [illegible]

$$\sup_{x\in\Omega_1,0\leq\tau\leq t}\{e_1^{2n}(x,\tau)\} \leq e^{\frac{C(t+L)}{\varepsilon}n}\operatorname{erfc}\left(\frac{nL}{\sqrt{\varepsilon t}}\right)\sup_{0\leq\tau\leq t}\{e_1^0(0,\tau)\}, \tag{3.16}$$

$$\sup_{x\in\Omega_2,0\leq\tau\leq t}\{e_2^{2n}(x,\tau)\} \leq e^{\frac{C(t+L)}{\varepsilon}n}\operatorname{erfc}\left(\frac{nL}{\sqrt{\varepsilon t}}\right)\sup_{0\leq\tau\leq t}\{e_2^0(0,\tau)\}, \tag{3.17}$$

[illegible] C [illegible] ε L t [illegible] n [illegible]. Using Lemma 3.1 and the explicit formula for the supersolutions, we obtain the estimates

$$\begin{aligned} e_1^n(x,t) &\leq e^{p_1(x-L)+q_1 t}\int_0^t K_{1,x}(x,t-\tau)\sup_{0\leq s\leq\tau}\{e_2^{n-1}(L,s)\}e^{(\sigma_1-q_1)\tau}\,d\tau, \\ e_2^n(x,t) &\leq e^{p_2 x+q_2 t}\int_0^t K_{2,x}(x,t-\tau)\sup_{0\leq s\leq\tau}\{e_1^{n-1}(0,s)\}e^{(\sigma_2-q_2)\tau}\,d\tau, \end{aligned} \tag{3.18}$$

where $K_{1,x}$, $K_{2,x}$ are defined in (3.7), (3.8), respectively, and the constants p_1, q_1, p_2, and q_2 are defined in (3.12). We evaluate the second inequality in (3.18) at $x = L$ and insert it into the first one to obtain

$$\begin{aligned} e_1^n(x,t) \leq{}& e^{p_1(x-L)+q_1 t}\int_0^t K_{1,x}(x,t-\tau)e^{(\sigma_1-q_1)\tau} \\ &\times\sup_{0\leq s\leq\tau}\left\{e^{p_2 L+q_2 s}\int_0^s K_{2,x}(L,s-\tilde{s})\sup_{0\leq\tilde{\tilde{s}}\leq\tilde{s}}\{e_1^{n-2}(0,\tilde{\tilde{s}})\}e^{(\sigma_2-q_2)\tilde{s}}d\tilde{s}\right\}d\tau. \end{aligned}$$

Evaluating this inequality at $x = 0$ we get

$$\begin{aligned} e_1^n(0,t) \leq{}& e^{-p_1 L+q_1 t}\int_0^t K_{1,x}(0,t-\tau)e^{(\sigma_1-q_1)\tau} \\ &\times\sup_{0\leq s\leq\tau}\left\{e^{p_2 L+q_2 s}\int_0^s K_{2,x}(L,s-\tilde{s})\sup_{0\leq\tilde{\tilde{s}}\leq\tilde{s}}\{e_1^{n-2}(0,\tilde{\tilde{s}})\}e^{(\sigma_2-q_2)\tilde{s}}d\tilde{s}\right\}d\tau \\ \leq{}& \widetilde{C}(t)\int_0^t K_{1,x}(0,t-\tau)\int_0^\tau K_{2,x}(L,\tau-\tilde{s})\sup_{0\leq\bar{s}\leq\tilde{s}}\{e_1^{n-2}(0,\bar{s})\}\,d\tilde{s}\,d\tau \\ ={}& \widetilde{C}(t)\int_0^t K_{2,x}(L,t-\tau)\int_0^\tau K_{2,x}(L,\tau-\tilde{s})\sup_{0\leq\bar{s}\leq\tilde{s}}\{e_1^{n-2}(0,\bar{s})\}\,d\tilde{s}\,d\tau, \end{aligned}$$

where we used that

$$K_{2,x}(L,t) = K_{1,x}(0,t) = \frac{L}{2\sqrt{\pi}\varepsilon^{1/2}t^{3/2}} e^{-\frac{L^2}{4\varepsilon t}}$$

and the function $\widetilde{C}$ given by

$$\widetilde{C}(t) := \max\{1, e^{q_2 t}, e^{q_1 t}, e^{(q_1+q_2)t}\} e^{(\sigma_1+\sigma_2-q_1-q_2)t} e^{(p_2-p_1)L}.$$

Note that $\sigma_1+\sigma_2-q_1-q_2 \geq 0$. The definition of $p_1, p_2, q_1, q_2, \sigma_1, \sigma_2$ and Theorem 2.1 imply that there is a constant $C > 0$ independent of ε, t, L such that

$$\widetilde{C}(p_1, p_2, q_1, q_2, \sigma_1, \sigma_2, t) \leq e^{\frac{C(t+L)}{\varepsilon}}, \qquad t > 0. \tag{3.19}$$

By induction we obtain

$$\sup_{0\leq\tau\leq t} e_1^{2n}(0,\tau) \leq e^{\frac{C(t+L)}{\varepsilon} n} \sup_{0\leq\tau\leq t} \{e_1^0(0,\tau)\} K^{2n}(t),$$

where K^{2n} is the $2n$-fold convolution of $K_{2,x}(L,.)$, that is, the integral term

$$\int_0^t K_{2,x}(L, t-s_1) \int_0^{s_1} K_{2,x}(L, s_1-s_2)$$
$$\cdots \int_0^{s_{2n-2}} K_{2,x}(L, s_{2n-2}-s_{2n-1}) \int_0^{s_{2n-1}} K_{2,x}(L, s_{2n-1}-s_{2n}) ds_{2n} ds_{2n-1} \cdots ds_2 ds_1.$$

Since the Laplace transform $\mathcal{L}[K_{2,x}(L,.)]$ is $e^{-L\sqrt{s/\varepsilon}}$, we obtain for the $2n$-fold convolution

$$\mathcal{L}[K^{2n}](s) = \frac{1}{s}\Big(\mathcal{L}[K_{2,x}(L,.)](s)\Big)^{2n} = \frac{1}{s} e^{-2nL\sqrt{s/\varepsilon}}.$$

The inverse Laplace transformation then yields

$$\sup_{0\leq\tau\leq t} e_1^{2n}(0,\tau) \leq e^{\frac{C(t+L)}{\varepsilon} n} \sup_{0\leq\tau\leq t} \{e_1^0(0,\tau)\} \int_0^t K_{2,x}(2nL, t-s)\, ds,$$

and the right-hand side of the last inequality can be simplified by a transform of variables to

$$\sup_{0\leq\tau\leq t} e_1^{2n}(0,\tau) \leq e^{\frac{C(t+L)}{\varepsilon} n} \sup_{0\leq\tau\leq t} \{e_1^0(0,\tau)\} \operatorname{erfc}\left(\frac{nL}{\sqrt{\varepsilon t}}\right),$$

where the error function complement erfc is defined by

$$\operatorname{erfc}(\mathrm{x}) = \frac{1}{\sqrt{\pi}} \int_x^\infty e^{-y^2}\, dy.$$

We thus have proved convergence of the algorithm on the interface $x = 0$ and with a similar argument convergence also follows on the interface $x = L$. Applying the maximum principle for problem (3.4) then shows that the error e_1^{2n} in the interior of the domain $\Omega_1 \times (0,t)$ is amplified at most by a factor $\exp(\bar{\theta}t)$ with

$\bar{\theta} = \sup_{(x,\tau)\in(-\infty,L)\times(0,t)}\{|\theta_1(x,\tau)|\}$. Theorem 2.1, the definition of θ_1 in (3.6), and (3.19) show that there exists a constant $C \geq 0$, independent of ε, n, t, and L, such that (3.16) holds. The estimate (3.17) follows along the same lines when starting with the second inequality in (3.18). ∎

3.3. If we apply the expansion $\sqrt{\pi}\mathrm{erfc}(z) = e^{-z^2}(z^{-1} + \mathcal{O}(z^{-3}))$ for large values $z > 0$ in the estimate (3.16), we obtain

$$\sup_{0\leq\tau\leq t}\{e_1^{2n}(x,\tau)\} \approx \frac{1}{\sqrt{\pi}} e^{\frac{Cn(t+L)}{\varepsilon} - \frac{n^2L^2}{\varepsilon t}} \frac{\sqrt{\varepsilon t}}{nL} \sup_{0\leq\tau\leq t}\{e_1^0(0,\tau)\}. \tag{3.20}$$

For fixed $T, L, \varepsilon > 0$ we observe that the algorithm converges superlinearly for $n \to \infty$ and $t \leq T$. In other words, we obtain the same asymptotic result as for the heat equation with linear convection and linear or nonlinear source terms; see [GZ97, Gan98].

3.4. Let n in (3.20) be fixed. Then there exists a $T = T(n)$ such that (a) the algorithm converges for $\varepsilon \to 0$ and $t < T(n)$, and (b) the estimate for the error e_1^{2n} does not converge to 0 for $\varepsilon \to 0$ and $t > T(n)$. This scenario does not happen for the heat equation with linear convection. In section 3.2 below we apply the Schwarz waveform relaxation algorithm to the hyperbolic case, $\varepsilon = 0$, and we will see that in this case it can happen that for all $n > 0$ there exists a time $T^* = T^*(n) > 0$ such that the error of the iteration vanishes for $t < T^*$ and is nonzero for $t > T^*$. It turns out that this behavior can only occur for nonlinear convection. Thus the scenario described in (a) and (b) is not an artifact of the proof.

3.2. The hyperbolic case $\varepsilon = 0$. The Jacobi version of the overlapping Schwarz waveform relaxation algorithm with two subdomains $\Omega_1 = (-\infty, L)$ and $\Omega_2 = (0, \infty)$ for the initial value problem (2.1), (2.2) in the hyperbolic limit, $\varepsilon = 0$, is given by

$$\begin{aligned} \frac{\partial u_1^n}{\partial t} + \frac{\partial}{\partial x} f(u_1^n) &= 0 && \text{in } \Omega_1 \times (0,T), \\ u_1^n(\cdot,0) &= u_0 && \text{in } \Omega_1, \\ u_1^n(L,\cdot) &= u_2^{n-1}(L,\cdot) && \text{on } [0,T], \end{aligned} \tag{3.21}$$

and

$$\begin{aligned} \frac{\partial u_2^n}{\partial t} + \frac{\partial}{\partial x} f(u_2^n) &= 0 && \text{in } \Omega_2 \times (0,T), \\ u_2^n(\cdot,0) &= u_0 && \text{in } \Omega_2, \\ u_2^n(0,\cdot) &= u_1^{n-1}(0,\cdot) && \text{on } [0,T], \end{aligned} \tag{3.22}$$

for iteration index $n \in \mathbb{N}$ and we are denoting by u_i^n the entropy solution in each iteration. The initial iterates u_1^0 and u_2^0 are chosen as in (3.3) taking the essential infimum.

The iterative algorithm (3.21), (3.22) is a priori not well defined. Note that problems (3.21), (3.22) are uniquely solvable by Theorem 2.2 for $u_0 \in L^\infty(\mathbb{R})$ and $u_2^{n-1}(L,.), u_1^{n-1}(0,.) \in L^\infty((0,T])$. However it is not clear whether the traces $u_2^{n-1}(L,.)$ and $u_1^{n-1}(0,.)$ exist in an appropriate way as L^∞-functions. This is assumed subsequently. Note that the local regularity of entropy solutions is a delicate issue which is out of the scope of this paper (cf. [Daf00, Chapter 11.3], for instance).

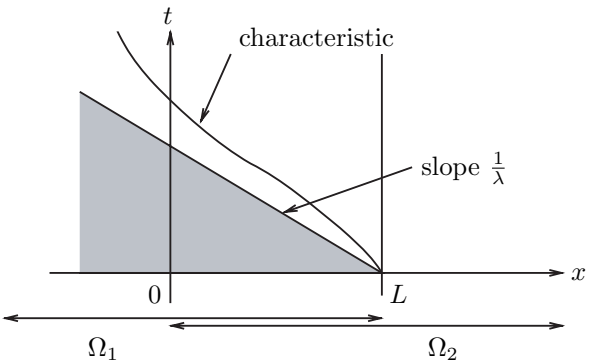

FIG. 1. *Estimated region in space-time where the error vanishes in the first iteration on the subdomain* Ω_1.

Finally we note that the definition of the trace is no problem after discretization of the problem and that is how the algorithm is used in practice.

We define as in the viscous case the errors in the Schwarz iteration by $e_1^n := u - u_1^n$ on the left subdomain and $e_2^n := u - u_2^n$ on the right subdomain for $n \in \mathbb{N}_0$, where u is the entropy solution of the initial value problem (2.1), (2.2) in the hyperbolic limit $\varepsilon = 0$.

THEOREM 3.5. $\underline{u} = \operatorname{essinf}_{x\in\mathbb{R}}\{u_0(x)\}$ $\overline{u} = \operatorname{esssup}_{x\in\mathbb{R}}\{u_0(x)\}$ $n \in \mathbb{N}$ $T^* = T^*(n, L) = nL/\lambda$

$$\lambda = \sup_{\underline{u}\le v\le\overline{u}} \{|f'(v)|\}.$$

$t \in [0, T] \cap [0, T^*(n, L)]$

$$\|e_1^{n+1}\|_{L^1((-\infty,L]\times[0,t])} = \|e_2^{n+1}\|_{L^1([0,\infty)\times[0,t])} = 0. \tag{3.23}$$

The proof relies on the finite speed of propagation property of entropy solutions which manifests itself in the statement (iii) of Theorem 2.2. To apply this statement for $n = 1$ in $\Omega_1 \times (0, T)$, we compare the subdomain solution at the first iteration on $\Omega_1 \times (0, T)$ with the exact solution restricted to $\Omega_1 \times (0, T)$. With the notation of Theorem 2.2, let

$$u_{01} = u_{02} = u_0|_{(-\infty,L]}, \quad g_1 = u_2^0(., L), \quad g_2 = u(., L).$$

The unique entropy solutions of the corresponding initial boundary value problems are u_1^1 and $u|_{\Omega_1\times(0,T)}$. Using statement (iii) of Theorem 2.2 and varying the interval I, we get in particular that $e_1^1 = u_1^1 - u|_{\Omega_1\times(0,T)} = 0$ almost everywhere in $\mathcal{C}_1^1$, where

$$\mathcal{C}_1^n = \{(x, s) \in \Omega_1 \times (0, T) \,|\, \lambda s \le nL - x\}, \quad n \in \mathbb{N};$$

see Figure 1. The analogous argument for Ω_2 gives $e_2^1 = 0$ almost everywhere in $\mathcal{C}_2^1$ given by

$$\mathcal{C}_2^n = \{(x, s) \in \Omega_2 \times (0, T) \,|\, \lambda s \le nL + x\}, \quad n \in \mathbb{N}.$$

Thus the errors e_1^1 and e_2^1 vanish on the interfaces in the time interval $[0, \frac{L}{\lambda}]$ (almost everywhere). Doing the next iteration we find for $t \le T^*(1, L)$

$$\|e_1^2\|_{L^1((-\infty,L]\times[0,t])} = \|e_2^2\|_{L^1([0,\infty),\times[0,t])} = 0,$$

and the general result for arbitrary $n \in \mathbb{N}$ follows by induction. □

REMARK 3.6. We consider the linear case, $f(u) = au$, for a convection speed $a > 0$. Taking any initial data and any initial guess for the iterates u_1^0 and u_2^0, one can easily see that the algorithm (3.21), (3.22) converges in two steps: for $n = 1$ the error e_1^1 vanishes in $\Omega_1 \times (0, T)$ since the solution is completely determined by the (correct) initial data, and no boundary data for $x = L$ can be prescribed for $a > 0$. Thus the third equation in (3.21) is ignored. On the second subdomain the error e_2^1 will in general not vanish in the whole of $\Omega_2 \times (0, T)$, since the boundary data u_2^0 is not correct in general. For $n = 2$, again e_1^2 vanishes in $\Omega_1 \times (0, T)$, but now also e_2^2 vanishes in $\Omega_2 \times (0, T)$, since $u_1^1(., L)$ provides the correct boundary data at the interface. The same result also holds for all functions f with $f'(v) \neq 0$ for $\underline{u} \le v \le \overline{u}$.

REMARK 3.7. For $L > 0$ we consider the case $f(u) = u^2/2$ together with the initial condition

$$u_0(x) = \begin{cases} 1 & : \quad x < L/2, \\ -1 & : \quad x > L/2. \end{cases} \tag{3.24}$$

The entropy solution is given by the discontinuous time-independent function $u(x, t) = u_0(x)$ for $t \in [0, T]$ and we do not have only one propagation direction in this case. Starting the overlapping Schwarz waveform relaxation algorithm with the initial guess $u_1^0 = a$ and $u_2^0 = -a$ for $a > 1$, we obtain the restriction of the entropy solution u to $(-\infty, L] \times [0, T]$ or $[0, \infty) \times [0, T]$ when computing the first iterates u_1^1 and u_2^1 on regions whose shape and size depend on a; a sketch of the iterates is displayed in Figure 2. For example, on the left subdomain Ω_1, the speed of the shock separating 1 from $-a$ and -1 from $-a$ increases when a increases. Thus the part of the boundary $x = 0$ where the correct data is obtained for the next iteration decreases when a increases and tends to zero when $a \to \infty$. The same argument also holds for the right subdomain (see Figure 2), which shows that the overlapping Schwarz waveform relaxation algorithm becomes slower as a increases. Stationary shocks are a generically nonlinear phenomenon which is not observed for linear equations and this example shows that the performance of the overlapping Schwarz waveform relaxation algorithm is affected by shocks.

One might argue that the choice for the initial guess does not agree with the choice for the first iterates u_1^0, u_2^0 as in (3.3). However, one can easily change the initial data u_0 far outside such that the solution in, say, $[-L, 2L] \times [0, T]$ is not altered due to finite propagation speeds and takes values less than -1. Then the flux function outside $[-1, 1]$ is altered such that the wave speeds $f'(u_1^0)$ and $f'(u_2^0)$ take the values $-a$ and a. This results in the same effect as described above. But the nonconvex flux function would introduce complicated shock-rarefaction patterns, so we omit a detailed construction here.

4. Overlapping Schwarz waveform relaxation for more than two subdomains. We now extend the results we obtained for two subdomains of $\Omega = \mathbb{R}$ in section 3 to the case of $I > 2$ subdomains, $I \in \mathbb{N}$, of a bounded domain $\Omega = (0, 1)$. Skipping the index ε, we search for the classical solution u of the initial boundary

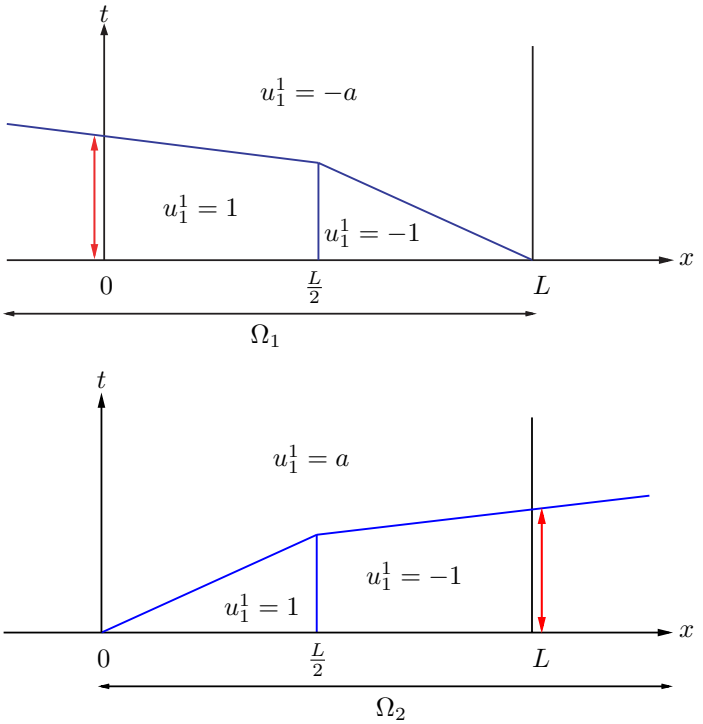

FIG. 2. *The top figure displays the entropy solution u_1^1 in Ω_1 taking the states 1, -1, and $-a$ separated by shock waves. The double arrow indicates the part of the line $x = 0$ where the correct boundary data for the next iteration is obtained. The bottom figure displays the corresponding situation for u_2^1 in Ω_2 and the part of the line $x = L$ where the correct boundary data for the next iteration is obtained.*

value problem

$$\begin{aligned} \frac{\partial u}{\partial t} + \frac{\partial}{\partial x} f(u) &= \varepsilon \frac{\partial^2 u}{\partial x^2} && \text{in } \Omega \times (0,T), \\ u(\cdot,0) &= u_0 && \text{in } \Omega, \\ u(0,\cdot) &= g_0 && \text{on } [0,T], \\ u(1,\cdot) &= g_1 && \text{on } [0,T]. \end{aligned} \tag{4.1}$$

Here $u_0 : \Omega \to \mathbb{R}$ and $g_1, g_2 : [0,T] \to \mathbb{R}$ are given smooth functions. To represent the subdomains, we introduce the numbers $L_1, \ldots, L_I \in \mathbb{R}$ and $R_1, \ldots, R_I \in \mathbb{R}$ such that

$$0 = L_1 < L_2 < R_1 < L_3 < \cdots < L_I < R_{I-1} < R_I = 1,$$

which leads to a decomposition of Ω into overlapping subdomains $\Omega_i = (L_i, R_i)$, $i = 1, 2, \ldots, I$, as shown in Figure 3. The overlapping Schwarz waveform relaxation algorithm is then given by solving for $i = 1, \ldots, I$ and $n = 1, 2, \ldots$ the problems

$$\begin{aligned} \frac{\partial u_i^n}{\partial t} + \frac{\partial}{\partial x} f(u_i^n) &= \varepsilon \frac{\partial^2 u_i^n}{\partial x^2} && \text{in } \Omega_i \times (0,T), \\ u_i^n(\cdot,0) &= u_0 && \text{in } \Omega_i, \\ u_i^n(L_i,\cdot) &= u_{i-1}^{n-1}(L_i,.) && \text{on } [0,T], \\ u_i^n(R_i,\cdot) &= u_{i+1}^{n-1}(R_i,.) && \text{on } [0,T], \end{aligned} \tag{4.2}$$

where we identify $u_0^{n-1}(L_1,.)$ with g_0 and $u_{I+1}^{n-1}(R_I,.)$ with g_1. In each Ω_i the iteration is started with the constant initial guess

$$u_i^0(x,t) = \min\Big\{ \inf_{x'\in\Omega}\{u_0(x')\}, \min_{t'\in[0,T]}\{g_0(t')\}, \min_{t'\in[0,T]}\{g_1(t')\}\Big\}. \tag{4.3}$$

For $i = 1,\dots,I$ we define the error $e_i^n(x,t) := u(x,t) - u_i^n(x,t)$ in $\Omega_i \times (0,T)$. Note that $e_0^n(0,t) = e_{I+1}^n(1,t) = 0$ and also $e_i^n(x,0) = 0$. The choice (4.3) ensures the nonnegativity of the error for all iterations and all subdomains. We also introduce the maximum error e^n defined by

$$e^n = \max_{i=1,\dots,I}\Big\{ \sup_{0\le t\le T}\{e_{i+1}^n(R_i,t)\}, \sup_{0\le t\le T}\{e_{i-1}^n(L_i,t)\}\Big\}.$$

THEOREM 4.1. [illegible] $L > 0$

$$L := \min_{i=1,\dots,I-1}(R_i - L_{i+1}). \tag{4.4}$$

[illegible] (4.2) [illegible] $I > 2$ [illegible] (4.1) [illegible] I [illegible] $T > 0$ [illegible]

$$e^{2n} \le e^{\frac{Cn(T+L)}{\varepsilon}} \operatorname{erfc}\left(\frac{nL}{\sqrt{\varepsilon T}}\right) e^0. \tag{4.5}$$

[illegible] C [illegible] ε T I [illegible] n [illegible]. We first derive an explicit bound for the error by successive construction of supersolutions. The error e_i^n is a solution of the problem

$$\begin{aligned} \frac{\partial e_i^n}{\partial t} + f'(u)\frac{\partial e_i^n}{\partial x} + \theta_i^n e_i^n &= \varepsilon \frac{\partial^2 e_i^n}{\partial x^2} && \text{in } \Omega_i \times (0,T),\\ e_i^n(\cdot,0) &= 0 && \text{in } \Omega_i,\\ e_i^n(L_i,\cdot) &= e_{i-1}^{n-1}(L_i,\cdot) && \text{on } [0,T],\\ e_i^n(R_i,\cdot) &= e_{i+1}^{n-1}(R_i,\cdot) && \text{on } [0,T], \end{aligned} \tag{4.6}$$

where the function θ_i^n is defined analogously to (3.6). One can check that $e_i^n = e_{iL}^n + e_{iR}^n$, where e_{iL}^n satisfies

$$\begin{aligned} \frac{\partial e_{iL}^n}{\partial t} + f'(u)\frac{\partial e_{iL}^n}{\partial x} + \theta_i^n e_{iL}^n &= \varepsilon \frac{\partial^2 e_{iL}^n}{\partial x^2} && \text{in } \Omega_i \times (0,T),\\ e_{iL}^n(\cdot,0) &= 0 && \text{in } \Omega_i,\\ e_{iL}^n(L_i,\cdot) &= 0 && \text{on } [0,T],\\ e_{iL}^n(R_i,\cdot) &= e_{i+1}^{n-1}(R_i,\cdot) && \text{on } [0,T], \end{aligned}$$

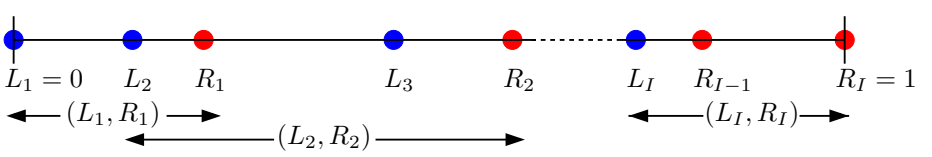

FIG. 3. *Sketch of the multidomain decomposition for the interval* $(0,1)$.

and e_{iR}^n satisfies

$$\begin{aligned} \frac{\partial e_{iR}^n}{\partial t} + f'(u)\frac{\partial e_{iR}^n}{\partial x} + \theta_i^n e_{iR}^n &= \varepsilon \frac{\partial^2 e_{iR}^n}{\partial x^2} && \text{in } \Omega_i \times (0,T), \\ e_{iR}^n(\cdot,0) &= 0 && \text{in } \Omega_i, \\ e_{iR}^n(L_i,\cdot) &= e_{i-1}^{n-1}(L_i,\cdot) && \text{in } [0,T], \\ e_{iR}^n(R_i,\cdot) &= 0 && \text{in } [0,T]. \end{aligned}$$

Furthermore, the classical solution $\tilde{e}_{iL}^n : (-\infty, R_i] \times \mathbb{R} \to \mathbb{R}$ of the quarter-space problem

$$\begin{aligned} \frac{\partial \tilde{e}_{iL}^n}{\partial t} + f'(u)\frac{\partial \tilde{e}_{iL}^n}{\partial x} + \theta_i^n \tilde{e}_{iL}^n &= \varepsilon \frac{\partial^2 \tilde{e}_{iL}^n}{\partial x^2} && \text{in } (-\infty, R_i] \times (0,T), \\ \tilde{e}_{iL}^n(\cdot,0) &= 0 && \text{in } (-\infty, R_i), \\ \tilde{e}_{iL}^n(R_i,\cdot) &= e_{i+1}^{n-1}(R_i,t) && \text{on } [0,T], \end{aligned} \tag{4.7}$$

with solutions decaying at infinity, $\lim_{x\to-\infty} \tilde{e}_{iL}^n(x,t) = 0$ for $t \in [0,T]$, satisfies

$$\tilde{e}_{iL}^n(x,t) \geq e_{iL}^n(x,t), \quad x \in \Omega_i,\ t \in (0,T).$$

The functions $f(u)$ and θ_i^n are so far defined in $\Omega \times (0,T)$; outside this set $f(u)$ and θ_i^n in the quarter-plane problem (4.7) have to be understood as smooth extensions taking only values from the range of $f(u)$ and θ_i^n in $[0,1]\times[0,T]$. Similarly we obtain a function $\tilde{e}_{iR}^n$ with $\tilde{e}_{iR}^n \geq e_{iR}^n$ in Ω_i. In Lemma 3.1 we have constructed supersolutions for the classical solutions of quarter-space problems. Using the same technique here, we obtain the function

$$\bar{e}_{iL}^n(x,t) = \exp(p_{iL}x + q_{iL}t) \int_0^t K_{iL}(x,t-\tau) g_{iL}(\tau)\, d\tau,$$

which satisfies

$$\bar{e}_{iL}^n(x,t) \geq \tilde{e}_{iL}^n(x,t), \quad x \in \Omega_i,\ t \in (0,T), \tag{4.8}$$

and solves the constant coefficient problem

$$\begin{aligned} \frac{\partial \bar{e}_{iL}^n}{\partial t} + a_{iL}\frac{\partial \bar{e}_{iL}^n}{\partial x} + b_{iL}\bar{e}_{iL}^n &= \varepsilon \frac{\partial^2 \bar{e}_{iL}^n}{\partial x^2} && \text{in } (-\infty, R_i) \times (0,T), \\ \bar{e}_{iL}^n(\cdot,0) &= 0 && \text{in } (-\infty, R_i), \\ \bar{e}_{iR}^n(R_i,t) &= \exp(\sigma_{iL}t) \sup_{0\leq\tau\leq t} e_{i+1}^{n-1}(R_i,\tau), && t \in [0,T], \end{aligned}$$

where the constants are defined as in Lemma 3.1 by

$$\begin{gathered} p_{iL} := \frac{a_{iL}}{2\varepsilon}, \quad q_i := -\frac{a_{iL}^2}{4\varepsilon} - b_{iL}, \\ a_{iL} := \inf_{(x,t)\in\Omega_i} \{f'(u(x,t))\}, \quad b_{iL} := \inf_{(x,t)\in\Omega_i} \left\{\theta_i^n(x,t) + (f'(u(x,t)) - a_{iL})\frac{a_{iL}}{2\varepsilon}\right\}, \\ \sigma_{iL} := \begin{cases} q_{iL} & : \quad q_{iL} \geq 0, \\ 0 & : \quad \text{otherwise}, \end{cases} \end{gathered}$$

and the kernel function and g_{iL} in the integral are given by

$$\begin{aligned} K_{iL,x}(x,t) &:= -\frac{1}{2\sqrt{\pi}} \frac{x-R_i}{\varepsilon^{1/2} t^{3/2}} \exp\left(-\frac{(x-R_i)^2}{4\varepsilon t}\right), \\ g_{iL}(t) &:= \exp(-p_{iL}R_i + (\sigma_{iL} - q_{iL})t) \sup_{0\leq\tau\leq t} \{e_{i+1}^{n-1}(R_i,\tau)\}. \end{aligned}$$

With the analogous definitions for p_{iR}, q_{iR}, a_{iR}, b_{iR}, σ_{iR}, and

$$K_{iR,x}(x,t) := \frac{1}{2\sqrt{\pi}} \frac{x-L_i}{\varepsilon^{1/2}t^{3/2}} \exp\left(-\frac{(x-L_i)^2}{4\varepsilon t}\right),$$
$$g_{iR}(t) := \exp(-p_{iR}L_i + (\sigma_{iR} - q_{iR})t) \sup_{0\le\tau\le t}\{e_{i-1}^{n-1}(L_i,\tau)\},$$

we define the function

$$\bar{e}_{iR}^n(x,t) = \exp(p_{iR}x + q_{iR}t) \int_0^t K_{iR}(x,t-\tau) g_{iR}(\tau)\, d\tau,$$

which is an upper bound on the quarter-plane problem solution,

$$\bar{e}_{iR}^n(x,t) \ge \tilde{e}_{iR}^n(x,t), \quad x \in \Omega_i,\ t \in (0,T). \tag{4.9}$$

From (4.8), (4.9), and the explicit formulas for the supersolutions we derive

$$\begin{aligned} e_i^n(x,t) &\le \bar{e}_{iL}^n(x,t) + \bar{e}_{iR}^n(x,t) \\ &= \exp(p_{iL}x + q_{iL}t) \int_0^t K_{iL,x}(x,t-\tau) g_{iL}(\tau) d\tau \\ &\quad + \exp(p_{iR}x + q_{iR}t) \int_0^t K_{iR,x}(x,t-\tau) g_{iR}(\tau) d\tau. \end{aligned}$$

Then there exists a constant $\widetilde{C} \ge 0$ that depends on $p_{iL/R}$, $q_{iL/R}$, $a_{iL/R}$, $b_{iL/R}$, $\sigma_{iL/R}$, the time T, and the decomposition L_1, R_1, …, L_I, R_I such that

$$\begin{aligned} &\max\{e_i^n(R_{i-1},t), e_i^n(L_{i+1},t)\} \\ &\le \widetilde{C} \left(\int_0^t K_{iL,x}(R_{i-1}, t-\tau)\, d\tau + \int_0^t K_{iR,x}(R_{i-1}, t-\tau)\, d\tau \right. \\ &\quad \left. + \int_0^t K_{iL,x}(L_{i+1}, t-\tau)\, d\tau + \int_0^t K_{iR,x}(L_{i+1}, t-\tau)\, d\tau \right) e^{n-1} \\ &\le 2\widetilde{C} \left(\int_0^t K_{iR,x}(R_{i-1}, t-\tau)\, d\tau + \int_0^t K_{iL,x}(L_{i+1}, t-\tau)\, d\tau \right) e^{n-1}. \end{aligned}$$

The last inequality is a consequence of the fact that the integrals are solutions of quarter-space problems for the heat equations where the boundary function is monotonically increasing. Therefore the solutions decay monotonically in space if one moves in the direction where the domain is unbounded. Thus the long-range error contribution involving $K_{iL,x}(R_{i-1}, t-\tau)$ and $K_{iR,x}(L_{i+1}, t-\tau)$ can be estimated by the short-range error contributions. Similarly one can now also estimate the contributions from the various overlap sizes using the minimum of the overlaps: letting $K_{L,x}(t) := \frac{1}{2\sqrt{\pi}} \frac{L}{\varepsilon^{1/2}t^{3/2}} \exp(-\frac{L^2}{4\varepsilon t})$, we obtain

$$\max\{e_i^n(R_{i-1},t), e_i^n(L_{i+1},t)\} \le 4\widetilde{C} \int_0^t K_{L,x}(t-\tau) d\tau e^{n-1}.$$

As in the proof of Lemma 3.1 we denote now by $K_{L,x}^{2n}(t)$ the $2n$-fold convolution of the kernel $K_{L,x}(t)$ and obtain

$$e^{2n} \le (4\widetilde{C})^{2n} K_{L,x}^{2n}(t) e^0 \le (4\widetilde{C})^{2n} \operatorname{erfc}\left(\frac{nL}{\sqrt{\varepsilon t}}\right) e^0,$$

which is formula (4.5). ∎

5. Behavior of the algorithm over long time intervals. The superlinear convergence estimates for the overlapping Schwarz waveform relaxation algorithm derived in the previous sections depend on the time interval under consideration. To get more insight into the behavior of the algorithm over long time intervals, we study in this section the limiting case of a steady state solution and we apply an overlapping Schwarz method to this steady state case. We study here only the Burgers equation to illustrate that the convergence rate can be arbitrarily slow in this case, and convergence can be lost if the viscosity goes to zero. Similar behavior has been in fact observed for long time calculations for the Burgers equation in [GK00].

5.1. Boundary value problem. We consider the boundary value problem obtained for the steady state case of the Burgers equation on the domain $\Omega = (-1, 1)$,

$$\varepsilon \frac{\partial^2 u^\varepsilon}{\partial x^2} - \frac{1}{2}\frac{\partial (u^\varepsilon)^2}{\partial x} = 0, \qquad u^\varepsilon(-1) = 1, \quad u^\varepsilon(1) = -1. \tag{5.1}$$

The general solution for the differential equation (5.1) can be computed in closed form,

$$u^\varepsilon(x) = -\sqrt{2}C \tanh\left(C\frac{x+D}{\sqrt{2}\varepsilon}\right), \quad C, D \in \mathbb{R}. \tag{5.2}$$

To satisfy the boundary conditions, the two constants $C, D \in \mathbb{R}$ have to satisfy the nonlinear system of equations

$$\frac{-1}{\sqrt{2}C} = \tanh\left(C\frac{D-1}{\sqrt{2}\varepsilon}\right), \qquad \frac{1}{\sqrt{2}C} = \tanh\left(C\frac{D+1}{\sqrt{2}\varepsilon}\right).$$

This implies in particular $D = 0$. In the limit as $\varepsilon \to 0$ the constant $C = C(\varepsilon)$ converges to $\frac{1}{\sqrt{2}}$; thus in this regime it is bounded from above and below independently of ε. Therefore, the solution u^ε contains an [illegible] layer for ε small. This type of solution is typical for [illegible] flux functions f with extrema. It does not exist for linear advection-diffusion problems which allow for (ordinary) boundary layers only. Note that we have for almost all $x \in [-1, 1]$

$$\lim_{\varepsilon \to 0} u^\varepsilon(x) = u^0(x) \equiv \begin{cases} 1 & : \quad x < 0, \\ -1 & : \quad x > 0. \end{cases}$$

We consider now the corresponding singular boundary value problem

$$\frac{\partial}{\partial x}\left(\frac{1}{2}u^2\right) = 0, \qquad u(-1) = 1, \quad u(1) = -1, \tag{5.3}$$

where the function u^0 satisfies the boundary conditions and is a distributional solution of the differential equation (5.3). Such solutions are not unique; in fact all piecewise constant functions taking only the values ± 1 and satisfying the boundary conditions at $x = \pm 1$ are solutions in that sense. This failure of uniqueness is crucial for the behavior of the overlapping Schwarz algorithm for (5.1) that we will analyze now.

5.2. Overlapping Schwarz algorithm. We first investigate the influence of the internal layer within the overlap for $\varepsilon \ll 1$. The overlapping Schwarz algorithm with the two subdomains $\Omega_1 = (-1, L)$ and $\Omega_2 = (-L, 1)$ for problem (5.1) is given

by

$$
\begin{aligned}
\varepsilon\frac{\partial u_1^n}{\partial x^2}+u_1^n\frac{\partial u_1^n}{\partial x}&=0 && \text{in } \Omega_1,\\
u_1^n(-1)&=1,\\
u_1^n(L)&=u_2^{n-1}(L),\\
\varepsilon\frac{\partial u_2^n}{\partial x^2}+u_2^n\frac{\partial u_2^n}{\partial x}&=0 && \text{in } \Omega_2,\\
u_2^n(1)&=-1,\\
u_2^n(-L)&=u_1^{n-1}(-L),
\end{aligned}
\tag{5.4}
$$

where $L>0$ is a constant that defines the overlap $2L$. The iteration is started with $u_1^0=1$, $u_2^0=-1$, and we have skipped the index ε to simplify the notation.

THEOREM 5.1 (linear convergence). [illegible] (5.4) [illegible] $0<L<1$ [illegible] (5.1). [illegible] $\varepsilon\to 0$

$$
1-2e^{-\frac{1-L}{\varepsilon}}+o(e^{-\frac{1}{\varepsilon}}).
\tag{5.5}
$$

[illegible]. From (5.2) we obtain

$$
u_1^n(x)=-\sqrt{2}C_1\tanh\left(C_1\tfrac{x+D_1}{\sqrt{2}\varepsilon}\right),
$$

where the two constants of integration C_1 and D_1 are determined by the boundary conditions. This leads to the system of nonlinear equations for C_1 and D_1,

$$
\begin{aligned}
D_1&=1-\tfrac{\sqrt{2}\varepsilon}{C_1}\operatorname{arctanh}\left(\tfrac{1}{\sqrt{2}C_1}\right),\\
u_2^{n-1}(L)&=-\sqrt{2}C_1\tanh\left(C_1\tfrac{L+D_1}{\sqrt{2}\varepsilon}\right).
\end{aligned}
$$

Inserting the first equation into the second one, we find the transcendental equation

$$
u_2^{n-1}(L)=\sqrt{2}C_1\tanh\left(\operatorname{arctanh}\left(\tfrac{1}{\sqrt{2}C_1}\right)-\tfrac{C_1(1+L)}{\sqrt{2}\varepsilon}\right),
\tag{5.6}
$$

which defines the constant C_1 implicitly. Denoting its solution by $C_1(u_2^{n-1}(L))$, we find over one iteration

$$
u_1^n(x)=\sqrt{2}C_1(u_2^{n-1}(L))\tanh\left(\operatorname{arctanh}\left(\tfrac{1}{\sqrt{2}C_1(u_2^{n-1}(L))}\right)-\tfrac{C_1(u_2^{n-1}(L))(1+x)}{\sqrt{2}\varepsilon}\right).
\tag{5.7}
$$

Similarly we find for the solution on the second subdomain

$$
u_2^n(x)=\sqrt{2}C_2(u_1^{n-1}(-L))\tanh\left(\operatorname{arctanh}\left(\tfrac{C_2(u_1^{n-1}(-L))(1-x)}{\sqrt{2}\varepsilon}-\tfrac{1}{\sqrt{2}C_2(u_1^{n-1}(-L))}\right)\right),
$$

where the function $C_2(u_1^{n-1}(-L))$ is implicitly defined by the transcendental equation

$$
u_1^{n-1}(-L)=-\sqrt{2}C_2\tanh\left(\operatorname{arctanh}\left(\tfrac{1}{\sqrt{2}C_2}\right)-\tfrac{C_2(1+L)}{\sqrt{2}\varepsilon}\right).
\tag{5.8}
$$

We are interested in the asymptotic convergence of this fixed point iteration on the interfaces $x=-L$ and $x=L$. We could evaluate $u_2^{n-1}(x)$ at $x=L$ and insert the result into the relation for $u_1^n(x)$ to find directly a nonlinear relation between $u_1^n(-L)$ and $u_1^{n-2}(-L)$ and analyze the fixed point of this iteration. But this would lead to

formulas of twice the complexity of the formulas of the single iteration. To avoid this, we define the two auxiliary functions $g(C_1) := u_1^n(-L, C_1)$ and $h(C_2) := u_2^{n-1}(L, C_2)$. With those, the above double step can be written as

$$u_1^n(-L) = g(C_1(u_2^{n-1}(L))) = g\big(C_1(h(C_2(u_1^{n-2}(-L))))\big). \tag{5.9}$$

Now note that $g(y) = -h(y)$ and $C_1(y) = C_2(-y)$, which leads to

$$\begin{aligned} u_1^n(-L) &= g\big(C_1(h(C_2(u_1^{n-2}(-L))))\big) \\ &= g\big(C_1(-g(C_2(u_1^{n-2}(-L))))\big) \\ &= g\big(C_2(g(C_2(u_1^{n-2}(-L))))\big), \end{aligned}$$

and hence it suffices to analyze the fixed point iteration

$$y^n = G(y^n) := g(C_2(y^n)), \tag{5.10}$$

where by (5.7) the function $g(C_2)$ is defined by

$$g(C_2) = \sqrt{2}C_2 \tanh\left(\operatorname{arctanh}\left(\tfrac{1}{\sqrt{2}C_2}\right) - \tfrac{C_2(1-L)}{\sqrt{2}\varepsilon}\right), \tag{5.11}$$

and the function $C_2(y)$ is defined implicitly by

$$y = -\sqrt{2}C_2 \tanh\left(\operatorname{arctanh}\left(\tfrac{1}{\sqrt{2}C_2}\right) - \tfrac{C_2(1+L)}{\sqrt{2}\varepsilon}\right); \tag{5.12}$$

see (5.8). To analyze the convergence of this fixed point iteration, we need to study the derivative

$$G'(y) = \frac{d}{dy}g(C_2(y)) = \frac{dg}{dC_2}\frac{dC_2(y)}{dy} = \frac{dg}{dC_2}\left(\frac{dy}{dC_2}\right)^{-1} =: \widetilde{G}'(C_2) \tag{5.13}$$

at the fixed point y^* on the left or for the expression on the right at the corresponding C_2^*. Note that the fixed point iteration depends on ε; we have $\widetilde{G}'(C_2, \varepsilon)$, and we want to study this function at the fixed point $C_2^*(\varepsilon)$ which also depends on ε. We thus need to expand $\widetilde{G}'(C_2^*(\varepsilon), \varepsilon)$ for small ε. Unfortunately the expression $C_2^*(\varepsilon)$ is not available in closed form, but we have the inverse, $\varepsilon(C_2^*)$ from the equation of the solution $u(-1, C_2^*(\varepsilon)) = 1$, which gives

$$1 = -\sqrt{2}C_2^* \tanh\left(\operatorname{arctanh}\left(\tfrac{1}{\sqrt{2}C_2^*}\right) - \tfrac{2C_2^*}{\sqrt{2}\varepsilon}\right)$$

or

$$\varepsilon = \varepsilon(C_2^*) = \frac{C_2^*}{\sqrt{2}\operatorname{arctanh}\left(\tfrac{1}{\sqrt{2}C_2^*}\right)}. \tag{5.14}$$

Hence we expand $\widetilde{G}'(C_2^*, \varepsilon(C_2^*))$ about $C_2^* = \frac{1}{\sqrt{2}}$ which corresponds to $\varepsilon = 0$. To simplify the expansion, we perform a further change of variables,

$$d = C_2^* - 1/\sqrt{2}, \tag{5.15}$$

with which we find, after simplifying, the expression

$$\widetilde{G}'(d) = \frac{2d(\sqrt{2}+d)(T^2-1)(L-1)A - (\sqrt{2}Td + T - 1)(T + \sqrt{2}d + 1)}{2d(\sqrt{2}+d)(T^2-1)(L+1)A + (\sqrt{2}Td + T + 1)(T - \sqrt{2}d - 1)}, \tag{5.16}$$

where the functions $A = A(d)$ and $T = T(d, L)$ are given by

$$A(d) = \operatorname{arctanh}\left(\frac{1}{\sqrt{2}d+1}\right), \quad T(d,L) = \tanh(LA(d)). \tag{5.17}$$

The difficulty in the expansion process lies in the fact that L is an arbitrary real number in the hyperbolic tangent in the function $T(d, L)$. We first expand $A(d)$ for d small, taking into account the singularity,

$$A(d) = -\ln\left(\frac{\sqrt{d}}{2^{\frac{1}{4}}}\right) + \frac{1}{2\sqrt{2}}d - \frac{1}{8}d^2 + \mathcal{O}(d^3). \tag{5.18}$$

Hence $A(d)$ tends to infinity as d goes to zero. We now use an asymptotic expansion of

$$\tanh(\ln(z)) = 1 - \frac{2}{z^2} + \frac{2}{z^4} - \frac{2}{z^6} + \mathcal{O}\left(\frac{1}{z^8}\right)$$

and insert $z := \exp(LA)$ into this expansion. This leads to

$$\begin{aligned} T(d,L) = 1 - 2^{1-\frac{L}{2}}d^L + 2^{1-L}d^{2L} - 2^{1-\frac{3}{2L}}d^{3L} \\ + \cdots + L2^{\frac{1-L}{2}}d^{1+L} + o(d^{1+L}). \end{aligned} \tag{5.19}$$

Using the structure of (5.16), we see that the numerator and the denominator contain the same terms, but some with the sign changed. Denoting by $p = 2d(\sqrt{2}+d)(T^2-1)$ the factor in front of A and rearranging, we find

$$\widetilde{G}'(d) = -\frac{(1+\sqrt{2}d)(1-T^2) - 2Td(\sqrt{2}+d) + p(L-1)A}{(1+\sqrt{2}d)(1-T^2) + 2Td(\sqrt{2}+d) - p(L+1)A},$$

where in both the numerator and the denominator the first term is $O(d^L)$, the second is $O(d)$, and the third is $O(d^{1+L}\log(d))$. Hence for d small, the last term can be neglected. Inserting the expressions (5.19) of T and (5.18) of A and expanding again for d small, we get for the leading order term

$$\widetilde{G}'(d) \approx -1 + \sqrt{2}2^{L/2}d^{1-L}.$$

To find the asymptotic convergence rate as a function of ε, we expand the implicit relation between d and ε given in (5.14) and (5.15), which leads to

$$\varepsilon = \frac{1}{\ln(2) - \ln(\sqrt{2}d)} + \mathcal{O}(d),$$

and thus $d \approx \sqrt{2}e^{-\frac{1}{\varepsilon}}$, which inserted into the asymptotic convergence rate gives the result (5.5). □

Theorem 5.1 shows that the convergence rate of the Schwarz algorithm applied to this model problem tends exponentially fast to 1 in modulus as ε goes to zero. This indicates that the overlapping Schwarz waveform relaxation algorithm applied to nonlinear convection-dominated conservation laws over long time intervals can be slow if there are steady shock waves in the overlap.

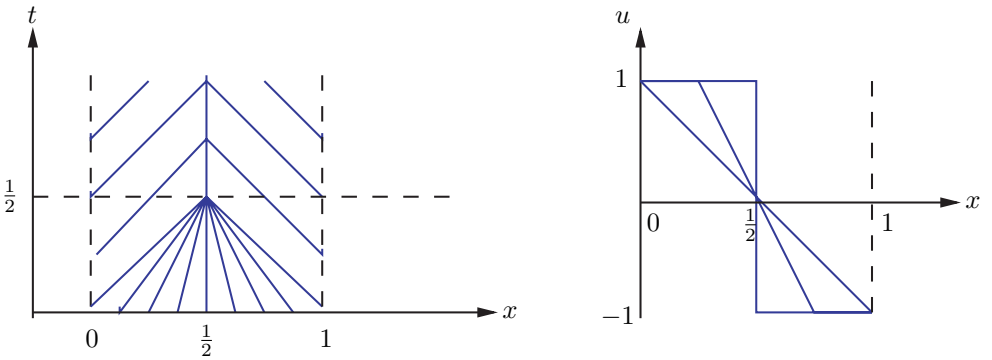

FIG. 4. *The left picture displays the characteristics for the entropy solution* u^0 *of* (6.1) *colliding at* $(1/2, t)$ *for* $t \geq 1/2$. *The right graph shows* u^0 *for* $t = 0, 1/4$ *and* $t \geq 1/2$.

6. Numerical experiments. We first illustrate the superlinear convergence rate of the overlapping Schwarz waveform relaxation algorithm given in Theorem 3.2. We solve the following initial boundary value problem for the Burgers equation with $\varepsilon \geq 0$ on the bounded domain $\Omega = (0, 1)$:

$$
\begin{aligned}
u_t^\varepsilon + \Big(\frac{(u^\varepsilon)^2}{2}\Big)_x &= \varepsilon u_{xx}^\varepsilon && \text{in } \Omega \times (0,T),\\
u^\varepsilon(\cdot,0) &= 1 - 2x && \text{in } \Omega,\\
u^\varepsilon(0,\cdot) &= 1 && \text{on } [0,T],\\
u^\varepsilon(1,\cdot) &= -1 && \text{on } [0,T].
\end{aligned}
\tag{6.1}
$$

For the case $\varepsilon = 0$ we can compute the entropy solution of (6.1) explicitly: for $(x, t) \in [0, 1] \times [0, 1/2)$ we find

$$
u^0(x,t) = \begin{cases} 1 & : \quad x < t, \\ \dfrac{2}{-1+2t}\Big(x - \dfrac{1}{2}\Big) & : \quad t \leq x \leq 1-t, \\ -1 & : \quad x > 1-t, \end{cases}
$$

and for $(x, t) \in [0, 1] \times [1/2, \infty)$ the entropy solution is

$$
u^0(x,t) = \begin{cases} 1 & : \quad x < 1/2, \\ -1 & : \quad x > 1/2. \end{cases}
$$

The solution is continuous (but not classical) up to $t = 1/2$ and then produces a stationary shock for all times; see Figure 4. We use the overlapping Schwarz waveform relaxation algorithm with the two subdomains $\Omega_1 = (0, \frac{1}{2} + L)$ and $\Omega_2 = (\frac{1}{2} - L, 1)$ with the overlap parameter $L = 0.1$. We choose $T = 0.6$ and a centered finite difference scheme in space, explicit for the nonlinear term and implicit for the Laplacian. The discretization parameters are $\Delta x = 0.01$ and $\Delta t = 0.003$. Figure 5 shows the superlinear convergence behavior of the overlapping Schwarz waveform relaxation algorithm for various values of the viscosity parameter ε. This numerical experiment shows that the smaller the viscosity is, the faster the algorithm converges, as predicted by the analysis, when the algorithm is in the superlinear convergence regime.

In the next numerical experiment, we solve the steady viscous Burgers equation

on the domain $\Omega = (-1, 1)$,

$$\left(\frac{(u^\varepsilon)^2}{2}\right)_x = \varepsilon u_{xx} \qquad \text{in } \Omega,$$
$$u(-1) = 1,$$
$$u(1) = -1,$$

using an overlapping Schwarz method with the two subdomains $\Omega_1 = (-1, L)$ and $\Omega_2 = (-L, 1)$ and the overlap parameter $L = 0.2$. The solution of this problem consists of a shock centered at $x = 0$. We discretize the problem with the same centered finite difference scheme as in the evolution case and solve the nonlinear system of equations with iteration in time. Figure 6 shows the convergence behavior of the overlapping Schwarz method for various values of the viscosity parameter ε. This experiment shows that the overlapping Schwarz algorithm converges linearly, and one can see that the smaller the viscosity parameter ε is, the slower the algorithm becomes, as predicted by Theorem 5.1. Since the convergence rate is exponential in the viscosity, already for a moderate value of the viscosity parameter ε, the algorithm seems to stand still.

7. Conclusions. We have analyzed the performance of the overlapping Schwarz waveform relaxation algorithm applied to convection-dominated nonlinear conservation laws. We have proved that the algorithm's asymptotic convergence rate is superlinear and independent of the number of subdomains. The convergence rate depends strongly on the viscosity parameter: the smaller the viscosity is, the faster the algorithm becomes. To learn more about the algorithm's performance over long time intervals, we have also analyzed the convergence rate of the overlapping Schwarz method applied to a special steady case of the Burgers equation. This analysis revealed that the asymptotic convergence rate is linear and depends exponentially on the viscosity

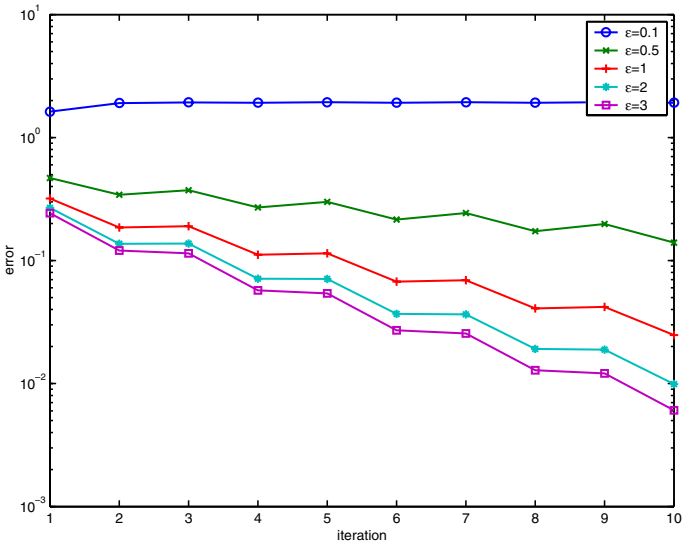

FIG. 6. *Linear convergence behavior of the overlapping Schwarz method for the steady viscous Burgers equation for various values of the viscosity parameter ε.*

parameter. In contrast to the superlinear case, however, we showed that the smaller the viscosity is, the slower the algorithm becomes.

DOMAIN DECOMPOSITION SOLUTION OF ELLIPTIC BOUNDARY-VALUE PROBLEMS VIA MONTE CARLO AND QUASI-MONTE CARLO METHODS*

JUAN A. ACEBRÓN†, MARIA PIA BUSICO‡, PIERO LANUCARA‡, AND RENATO SPIGLER§

Abstract. Domain decomposition of two-dimensional domains on which boundary-value elliptic problems are formulated is accomplished by probabilistic (Monte Carlo) as well as by quasi-Monte Carlo methods, generating only a few interfacial values and interpolating on them. Continuous approximations for the trace of solution are thus obtained, to be used as boundary data for the subproblems. The numerical treatment can then proceed by standard deterministic algorithms, separately in each of the so obtained subdomains. Monte Carlo and quasi-Monte Carlo simulations may naturally exploit multiprocessor architectures, leading to *parallel computing*, as well as the ensuing domain decomposition does. The advantages such as *scalability* obtained by increasing the number of processors are shown, both theoretically and experimentally, in a number of test examples, and the possibility of using *clusters* of computers (grid computing) is emphasized.

1. Introduction.

The probabilistic representation of solutions to elliptic boundary-value problems, e.g., the Dirichlet problem for the Laplace equation,

$$\Delta u = 0 \quad \text{in } \Omega, \qquad u|_{\partial\Omega} = g, \tag{1.1}$$

with boundary data, g, and boundary $\partial\Omega$ of $\Omega \subset \mathbf{R}^d$ in suitable classes, has been known for a long time [10, 17], as has the possibility of using it to obtain numerical approximations of solutions. Such representation is given by

$$u(x) = E_x \left[g(W(\tau_{\partial\Omega})) \right], \tag{1.2}$$

where $W(\cdot)$ represents a path of the standard Brownian motion (also called Wiener process) starting at point $x \in \Omega$, and $\tau_{\partial\Omega}$ is the first passage (hitting) time of the path $W(\cdot)$ started at x to $\partial\Omega$. This approach, which can be called a Monte Carlo approach, is, however, considered very inefficient, at least in low dimension, unless a

very complicated geometry of the boundary, $\partial\Omega$, of the domain Ω, rules out any other deterministic algorithm; see, e.g., [22].

In this paper we propose a domain decomposition method for general elliptic problems, accomplished by generating values inside the domain, Ω, in two dimensions, and interpolating on the points where the values above have been computed, taken as nodes. These nodes are considered as placed on suitable interfaces, internal to the domain; thus continuous approximations of the trace of solutions to be used as subdomain boundary data can be obtained. In this way, full decoupling into as many subdomains as we wish can be realized. The idea of using a probabilistic representation of solutions to elliptic problems to accomplish a preliminary domain decomposition was first put forth in [36]; the same was also suggested later in [38]. Recently, a probabilistic numerical treatment of elliptic and parabolic problems was presented in [29]. The results obtained there, however, did not show any improvement with respect to fully deterministic methods, but this was due to the very small time-steps used, lacking a suitable boundary treatment. We shall refer to these methods as "probabilistic domain decomposition" (PDD) methods, or "domain decomposition by Monte Carlo" methods. We stress that the approach followed here fully exploits in that (a) it implements a domain decomposition algorithm and (b) realization (or path) of the stochastic processes starting at every point can be simulated independently (if we generate N sample paths at m points, we can use up to mN independent processors). Clearly, such a degree of parallelization is compatible with the use of possibly different and even geographically distant computers (grid computing) and/or clusters of them, and a balance among them is also feasible.

In order to improve the performance of the "classical" Monte Carlo method [16] (based on the so-called numbers, which mimic the ideal random numbers), we explored the possibility of using, instead, sequences of numbers [5, 25, 27, 28]. The corresponding strategy is called the quasi-Monte Carlo, and using such sequences in our approach, the algorithm will be called the "quasi-probabilistic domain decomposition" (quasi-PDD) method. Such sequences are actually deterministic, and their elements are uniformly distributed, though subject to some degree of correlation. They have been successfully applied to the numerical evaluation of high dimensional integrals (cf. [26]), in particular to problems of financial mathematics [6]. Applications have been made to the generation of quasi-random paths of stochastic processes in [23, 24], to the Boltzmann equation [19], and to a simple system of diffusion equations in $\mathbf{R}^d$, subject to purely initial values on all space [20].

In section 2, some preliminaries are given, and in section 3 the numerical method is presented along with the various sources of error. In section 4, the performance of the numerical algorithm is discussed. Numerical examples are shown in section 5, where the overall numerical error, as well as speed-up results, is given to substantiate the efficiency of the PDD and quasi-PDD methods. Conclusions are drawn in the final section.

2. Generalities on domain decomposition and on Monte Carlo methods. The basic idea of solving elliptic boundary-value problems (say the Dirichlet problem, for instance) by domain decomposition is to assign the numerical solution on each subdomain into which the domain Ω is partitioned to a separate processor; see, e.g., [7, 33]. Unfortunately, since the boundary-value problems above are global in nature, the trace of the solution on the interfaces internal to Ω, to be used as

boundary values for the subproblems, cannot be obtained before solving the entire problem. In the framework of the [illegible] domain decomposition methods, it is possible to compute approximations of such values prior to passing to the implementation on several separate processors, imposing suitable continuity conditions on the interfaces. This procedure, however, requires solving, usually iteratively, certain related linear algebraic subproblems. The latter represents the algebraic formulation of the so-called discrete Steklov–Poincaré operator, which is usually unbounded. This leads to a capacitance matrix (which is the finite dimensional counterpart of the Steklov–Poincaré operator [32] and also has the form of a Schur complement matrix), that is typically ill-conditioned [33]. Preconditioning it is therefore mandatory, and finding preconditioners that are at the same time optimal and efficient is a nontrivial though fundamental problem. Optimality refers to the possibility of constructing, for a given problem, preconditioners yielding a spectral condition number (the ratio between the maximum and the minimum eigenvalue) bounded independently of the mesh size, h, as well as the subdomain (average) diameter, H. In fact, the Schur complement matrix, Σ_h, has a condition number $\kappa(\Sigma_h) = O(h^{-1}H^{-1})$. Note that the number of subdomains, M, scales as $M \sim H^{-1}$; cf. [33].

In practice, in the domain decomposition methods with overlapping (Schwarz type), the condition number above would actually be independent of h and H, provided that the overlapping is wide enough [8]; the bounds found in [8] were shown to be optimal in [3]. In the domain decomposition methods without overlap, also referred to as "iterative substructuring" methods, things are worse, and conditioning leads to bounds for condition numbers like $C\,(1 + \log(H/h))^a$, where C is a constant and a may be 1 or 2 [9]. This logarithmic estimate is considered to be not improvable; however, it is of little harm, because it grows slowly when h and/or H are reduced in size. Sometimes h is reduced at the same rate as H is reduced, in order to keep the same ratio H/h and thus the condition estimate. This operation, however, pushes to unnecessarily smaller mesh sizes, h, preventing one from taking advantage of solving smaller-size problems on separate processors. In any case, it seems that, at least with parallel computers with a few hundred processors, and facing problems with $2 \cdot 10^6$ to 10^7 variables, the overall cost of the method is always dominated by the cost of solving the local problems, for instance, the cost of factorizing into triangular factors (Choleski factorization).

Adopting a [illegible] representation of solutions, one can generate numerical approximations of the sought solution [illegible] Ω, at every single point, [illegible] solving the full problem. Of course, since such a value is an average of a number of Brownian motion paths (for the Laplace equation) starting at that point, some "globality" is felt somehow, in that the numerous Brownian paths explore the entire domain, Ω. Here the idea is to generate [illegible] values of the sought solution, on some interfaces, then interpolate on each interface to obtain continuous approximations of the "boundary values" needed to split the problem into subproblems, and finally solve numerically on each subdomain on separate processors. This procedure will require no communication among the processors involved, no iteration across the interfaces, and of course no initial guess for it.

It should be observed that, for the boundary-value problems for elliptic equations, both on the entire domain, Ω, and on each subdomain, the maximum principle holds, and this remains true for the related discretized problems formulated for their numerical treatment. As a consequence, the error made inside each domain is estimated by the error on the boundary data plus the residual error due to the local solver.

When the latter is made negligible due to a sufficiently accurate scheme, the maximum principle essentially provides an estimate for the solution inside each subdomain in terms of the boundary error. This fact holds true for both the deterministic and the probabilistic domain decomposition scenario, but it turns out to be especially favorable for the latter approach, since due to the poor performance of the Monte Carlo simulations one expects to start with rather poor approximations of the interfacial boundary data.

This method retains the features of the deterministic domain decomposition methods, that is, of being a "divide and conquer" technique, where, however, no iterations on the boundary values inside Ω are needed, while it entails an enhanced [illegible]. In fact, now there is the possibility to split the problem into several fully decoupled subproblems, each assigned to a separate processor. Moreover, irregular or complex geometries and possible singularities as well as anomalous regions can be handled; see [7, 33]. Sometimes, a reduction of the computational complexity can be achieved by the use of a domain decomposition strategy even on sequential architectures. In fact, smaller-size problems can be managed more efficiently, even sequentially. Finally, note that our approach is of the nonoverlapping type, [illegible], and possesses an additional degree of parallelism, since Monte Carlo sequences can be generated in parallel.

Consider, more generally than in section 1 (see (1.1), (1.2)), the elliptic boundary-value problem

$$Lu - c(x)u = f(x) \quad \text{in } \Omega, \qquad u|_{\partial\Omega} = g, \tag{2.1}$$

where $\Omega \subset \mathbf{R}^d$, and L denotes a linear elliptic operator, say $L := a_{ij}(x)\partial_i\partial_j + b_i(x)\partial_i$ (using the summation convention), with continuous bounded coefficients, as well as $c(x)$, $c(x) \geq 0$, continuous boundary data g, source term f in $L^2(\Omega)$, and $\partial\Omega$ Lipschitz continuous. The probabilistic representation of the solutions is now given by

$$u(x) = E_x^L \left[g(\beta(\tau_{\partial\Omega}))e^{-\int_0^{\tau_{\partial\Omega}} c(\beta(s))\,ds} - \int_0^{\tau_{\partial\Omega}} f(\beta(t))\, e^{-\int_0^t c(\beta(s))\,ds}\, dt \right], \tag{2.2}$$

where $\tau_{\partial\Omega}$ is as above, $\beta(\cdot)$ is the stochastic process associated to the operator L, and the expected values are taken with respect to the corresponding measure (see, e.g., [10, 17]). When $L \equiv \Delta$, $\beta(\cdot)$ reduces to the standard d-dimensional Brownian motion, and the measure to the Gaussian measure. The process $\beta(\cdot)$ is the solution of a stochastic differential equation (SDE) of the Ito type, related to the elliptic partial differential equation in (2.1), namely,

$$d\beta = b(x)\, dt + \sigma(x)\, dW(t). \tag{2.3}$$

Here $W(t)$ represents the d-dimensional standard Brownian motion (also called Wiener process); see, e.g., [1, 17] for generalities and [12, 18, 30] for the related numerical treatment. As is known, the solution to (2.3) is a stochastic process, $\beta(t, \omega)$, where ω, which is usually not indicated explicitly in probability theory, denotes the "chance variable," ranging on a suitable abstract probability space. The drift, b, and the diffusion, σ, in (2.3) are related to the coefficients of the elliptic operator in (2.1) by $b = (b_i)^T$ and $\sigma\sigma^T = a$, with $\sigma = (\sigma_{ij})$, $a = (a_{ij})$.

Confining ourselves to 2-dimensional problems, in the examples in section 5 we write (x, y) instead of the vector "x" above.

3. The numerical method. Consider the simpler case $f \equiv c \equiv 0$ in (2.2), so that

$$u(x) = E_x^L \left[g(\beta(\tau_{\partial\Omega})) \right], \tag{3.1}$$

where $\beta(\cdot)$ is obtained solving the SDE in (2.3).

3.1. Evaluating the solution at a single internal point by probabilistic methods. In evaluating interfacial values by a Monte Carlo or quasi-Monte Carlo method, one should consider, in practice, three sources of numerical error. In fact, the expected value in (3.1) must be replaced necessarily by a finite sum, and, moreover, the stochastic paths are actually simulated by resorting to suitable numerical schemes. Finally, the exit time is also affected by numerical errors and has to be replaced by an appropriate estimate. To be more precise, the global error made in simulating interfacial values can be evaluated as

$$\begin{aligned} \epsilon_N = u(x) - \frac{1}{N}\sum_{j=1}^{N} g(x_j(t_j)) &\equiv E_x^L \left[g(\beta(\tau_{\partial\Omega})) \right] - \frac{1}{N}\sum_{j=1}^{N} g(x_j(t_j)) \\ &= \epsilon_N^{(1)} + \epsilon_N^{(2)} + \epsilon_N^{(3)}, \end{aligned} \tag{3.2}$$

where

$$\epsilon_N^{(1)} = E_x^L \left[g(\beta(\tau_{\partial\Omega})) \right] - \frac{1}{N}\sum_{j=1}^{N} g(\beta_j(\tau_{\partial\Omega}^j)), \tag{3.3}$$

$$\epsilon_N^{(2)} = \frac{1}{N}\sum_{j=1}^{N} g(\beta_j(\tau_{\partial\Omega}^j)) - \frac{1}{N}\sum_{j=1}^{N} g(x_j(\tau_{\partial\Omega}^j)), \tag{3.4}$$

$$\epsilon_N^{(3)} = \frac{1}{N}\sum_{j=1}^{N} g(x_j(\tau_{\partial\Omega}^j)) - \frac{1}{N}\sum_{j=1}^{N} g(x_j(t_j)). \tag{3.5}$$

Here $x_j(t)$ is a numerical approximation of $\beta_j(t) := \beta(t, \omega_j)$, which is the jth realization of the stochastic process $\beta(t, \omega)$, solution to (2.3); $\tau_{\partial\Omega}^j$ is the first exit time of the path $\beta_j(t)$; and t_j is the first exit time of the approximating path $x_j(t)$.

The first error, $\epsilon_N^{(1)}$, is the pure Monte Carlo (or quasi-Monte Carlo) statistical error, and

$$\epsilon_N^{(1)} = \mathcal{O}\left(\frac{1}{\sqrt{N}}\right) \tag{3.6}$$

for the Monte Carlo method. In fact, it is well known that the arithmetic mean appearing in $\epsilon_N^{(1)}$ (actually with the almost inessential modification of having $1/(N-1)$ instead of $1/N$, since $N \gg 1$) provides the best unbiased estimator for the expected value in (3.1); see, e.g., [5]. In practice, one should simulate on a computer several random variables, based on generating random numbers. The latter are necessarily not ideally random, for which reason they are called more precisely pseudo-random numbers. Doing that, the error made in replacing the expected value in (3.1) with the average over a finite size sample is statistical in nature and of the order of $1/\sqrt{N}$.

More precisely, $\epsilon_N^{(1)}$ turns out to be, for N large, approximately a random Gaussian variable with standard deviation proportional to $N^{-1/2}$, i.e.,

$$\epsilon_N^{(1)} \approx \sigma N^{-1/2} \nu, \tag{3.7}$$

where σ denotes the square root of the variance of the integrand, g, and ν is a standard normal (i.e., $N(0,1)$) random variable; see, e.g., [5]. It follows that

$$\lim_{N\to\infty} \text{Prob}\left(a < \frac{\sqrt{N}}{\sigma} < b\right) = \text{Prob}(a < \nu < b) = (2\pi)^{-1/2} \int_a^b e^{-x^2/2}\, dx. \tag{3.8}$$

All this clearly shows that Monte Carlo has in principle a very poor numerical performance (because, due to the dependence on the sample size, N, through its square root, the convergence above when $N \to \infty$ is very slow) and also that the error is merely statistical, so it can only be bounded by some quantity with a certain degree of confidence.

An alternative method to the standard Monte Carlo approach is provided by the quasi-Monte Carlo method. Examples of [illegible] sequences (also called low-discrepancy sequences) are those named after Faure, Halton, and Sobol'; see, e.g., [28]. Following this approach, the error is

$$\epsilon_N^{(1)} = \mathcal{O}\left(\frac{1}{N} \log^{d^*-1} N\right). \tag{3.9}$$

When $N \to \infty$, the advantage over Monte Carlo is clear, but one should notice that even when solving elliptic equations in two dimensions, the [illegible] dimension, d^*, is much higher than two. In fact, $d^* = Md$, where d is the dimension of the space, $\mathbf{R}^d$, in which the domain Ω is embedded, and M is the number of steps in the numerical integration of the SDEs (2.3). In practice, one somehow needs to break the correlation in the sequences of quasi-random numbers, and this can be done, for instance, by a "reordering" or by other scrambling strategies. The idea is to contrast the correlations by using [illegible] sequences of uncorrelated quasi-random numbers (which are, however, correlated within each sequence), picking up at each time-step pairs of numbers out of them, and relabeling them according to their distances from the starting point. This idea was applied to the one-dimensional (1D) heat equation in [24] and then to some higher-dimensional problems in [20]. Consequently, we can take $d^* = 2$ in (3.9). When reordering was not implemented, the performance achieved using quasi-random sequences in the numerical solution of SDEs turned out to be poor, as shown in [13] and pointed out in [20].

The second error is due to the fact that the ideal stochastic path, $\beta_j(\cdot)$, in practice has to be approximated by some numerical scheme yielding the paths $x_j(\cdot)$, having discretized the time. Hence, the estimate

$$|\epsilon_N^{(2)}| \le \frac{1}{N} \sum_{j=1}^{N} \left| g(\beta_j(\tau_{\partial\Omega}^j)) - g(x_j(\tau_{\partial\Omega}^j)) \right| \le \frac{L_g}{N} \sum_{j=1}^{N} \left\| \beta_j(\tau_{\partial\Omega}^j) - x_j(\tau_{\partial\Omega}^j) \right\| \tag{3.10}$$

holds, where L_g is the Lipschitz constant of $g(\cdot)$. The truncation error on the right-hand side of (3.10), made in numerically solving the SDE (2.3), obviously depends on the specific scheme that is chosen; see, e.g., [18]. Among these are the Euler scheme, a number of Taylor schemes, and also schemes where the time-step is chosen randomly,

for instance, the exponential timestepping method; see [14, 15]. In the latter case, the size of the time-step, Δt, is picked up from a given probability distribution, since Δt is a random variable itself. When such a distribution is the exponential distribution, with the probability density $exp(-\lambda \Delta t)$, the mean value of Δt equals λ^{-1}. The Euler scheme has a truncation error of order $\mathcal{O}(\Delta t^{\alpha})$, where $\alpha = 1/2$ or $\alpha = 1$ depending on whether the scheme is of the "strong" or "weak" type, respectively; see [18]. Taylor schemes with α equal to 3/2 or 3, respectively, can be considered as well.

Finally,

$$|\epsilon_N^{(3)}| \leq \frac{L_g}{N} \sum_{j=1}^{N} \left\| x_j(\tau_{\partial\Omega}^j) - x_j(t_j) \right\| \leq \frac{L_g}{N} \sum_{j=1}^{N} M_j \left| \tau_{\partial\Omega}^j - t_j \right|$$

$$\leq \frac{L_g M}{N} \sum_{j=1}^{N} \left| \tau_{\partial\Omega}^j - t_j \right|, \tag{3.11}$$

where M_j is the Lipschitz constant of $x_j(\cdot)$, and $M := \max_{1 \leq j \leq N} M_j$. The latter quantity takes into account the error made in numerically evaluating the exact first exit time, $\tau_{\partial\Omega}^j$, of the jth path, $x_j(\cdot)$, from the boundary $\partial\Omega$. Indeed, numerical experiments show that the error made estimating the first exit time may be dominant over the other sources of numerical errors and is therefore of paramount importance in providing an accurate value of such a quantity. In fact, the probability that an approximate path, such as $x_j(\cdot)$, exits the boundary between two consecutive time-steps is nonzero, and it is quite possible that the true exit point is missed. This circumstance was pointed out first in [37] and later in [2, 4], and taken into account in simple cases of numerical integration of 1D SDEs in [14, 21].

Below, we have adopted the strategy put forth in [14, 15], based on exponential timestepping. The advantage of such a method rests on the fact that, at the price of adopting an approximate distribution of the underlying stochastic process, analytical results can be obtained for the hitting probability (i.e., the probability distribution of hitting the boundary for the first time). To solve two-dimensional (2D) problems on the square, $\Omega = (0,1) \times (0,1)$, as done in this paper, the hitting probability has been taken as the maximum among the four hitting probability values that a path first exits the four possible boundary sides.

3.2. Interpolation on the internal nodes. After obtaining approximations of a few internal values by Monte Carlo (or quasi-Monte Carlo) simulations, we use them to interpolate. We chose Chebyshev interpolation because of its global (quasi-) optimality properties [34, 35]. The error made in interpolating a given smooth function, say $f(x)$, by the nth degree Chebyshev polynomial of the first kind, $I_n f(x) \equiv T_n(x)$, between any two nodes when the nodal values are exactly known, is given by $\|f - I_n f\|_\infty \leq C n^{-k} \|f^{(k)}\|_\infty$ for every fixed k. However, we should account for the additional errors affecting the nodal values $f(x_i)$ themselves, which are obtained, in fact, by the Monte Carlo or quasi-Monte Carlo simulation. Such a problem (stability of the interpolation) leads to the estimate $\|I_n f - I_n \tilde{f}\| \leq \Lambda_n \cdot \max_{i=1,2,\ldots,n} |f(x_i) - \tilde{f}(x_i)|$, where $\tilde{f}(x_i)$ are the values of $f(x_i)$ affected by errors, and the Lebesgue constant, Λ_n, grows only logarithmically with the number of nodes and thus will be completely negligible here. Indeed, the number of nodes will be kept low, since two or three internal nodes on each interval will suffice within the numerical approximations made in our algorithm. Hence, Chebyshev polynomials of degree 3 or 4 will be used.

3.3. Local solvers. Once approximate values of the solution on all interfaces have been found, any deterministic algorithm can be used to complete the numerical solution on each subdomain. For instance, finite differences (FDs) of various kinds can be implemented, and then there are a number of methods to solve the ensuing linear algebraic systems. When the dimension of such systems is low (which occurs when the number of subdomains is high), direct methods can be used. In general, and especially when the dimension is high, iterative methods may perform better. Below, we chose to use Gauss–Seidel iterations, with an exit criterion that had to be tested according to the specific model example and the number of subdomains.

4. Performance of the numerical method. Let us now turn our attention to assessing, at least qualitatively, the performance of our method in two dimensions. The aim here is to estimate the , , which is a measure of the gain of the present method as a function of the number of processors involved. We assume that the domain Ω is the square $(0,1) \times (0,1)$, subdivided into a number of subdomains. These are nonoverlapping rectangles, with sides parallel to the axes x and y, singled out by some subdivision points, say n_x and n_y, of the sides $0 \le x \le 1$ and $0 \le y \le 1$, respectively. Therefore, the domain Ω is partitioned into $(n_x+1)\cdot(n_y+1)$ subdomains. Suppose that as many processors, p, as we wish, are available and assume $p = (n_x+1)(n_y+1)$. We compute by Monte Carlo or quasi-Monte Carlo simulations only a few interfacial values, on the lines $x = i/(n_x+1)$, $i = 1,\dots,n_x$, and $y = j/(n_y+1)$, $j = 1,\dots,n_y$, taking, say, k points on each such line (usually $k = 2$ or 3), hence, in total, $k(n_x+n_y)$ points.

The speed-up is the ratio between the time T_1 spent solving sequentially the problem on the entire domain, and the time T_p required for solving it in parallel with p processors. The numerical solution of each subproblem requires at most a fraction $1/p$ of the time T_1. We say "at most," because with the integration domain being smaller, some amount of time can be saved even proceeding sequentially. Therefore, if T_{MC} denotes the time required for computing by Monte Carlo or quasi-Monte Carlo simulations , interfacial value, neglecting the time spent for interpolation on the interfaces, we have, approximately,

$$T_p = \frac{k(n_x+n_y)T_{MC}}{p} + \frac{T_1}{p}, \tag{4.1}$$

and thus the , of our method is

$$S_p := \frac{T_1}{T_p} = \frac{p}{1+k(n_x+n_y)\frac{T_{MC}}{T_1}}. \tag{4.2}$$

Note that if T_{MC} could be made negligible, the speed-up would attain its ideal theoretical value, $S_p = p$. In practice, T_{MC} cannot be arbitrarily small, since it will be proportional to the number of realizations used in simulations, whose value directly affects the achieved accuracy.

To gain a better insight, take $n_x = n_y =: n$. Using as many processors as subdomains, we have $p = (n+1)^2$, while the total number of interfacial points is $2kn$. Note that the latter scales linearly with the parameter n, while p scales quadratically with it. Thus

$$S_p = \frac{(n+1)^2}{1+2kn\frac{T_{MC}}{T_1}}, \tag{4.3}$$

and hence, in the limit for $n \to \infty$ (or, equivalently, for $p \to \infty$), we obtain

$$S_p \sim \frac{T_1}{2kT_{MC}} \sqrt{p}, \quad p \to \infty. \tag{4.4}$$

This formula shows the kind of scalability that can be achieved by means of the PDD. We stress that the speed-up relation in (4.4) is fully general in that it is independent of the choice of the specific local solver, as well as whether Monte Carlo or quasi-Monte Carlo is adopted. In case of domains $\Omega \in \mathbf{R}^d$, formulae (4.3) and (4.4) are generalized into

$$S_p = \frac{(n+1)^d}{1 + dkn\frac{T_{MC}}{T_1}} \sim \frac{T_1}{dkT_{MC}}\, p^{1-1/d}, \quad p \to \infty, \tag{4.5}$$

since $p \sim n^d$ as $p \to \infty$. Consider, at this point, the dependence of T_{MC} and T_1 on the various parameters characterizing the numerical treatment.

4.1. Estimating T_{MC}. The time T_{MC} required for computing a single value of the solution by Monte Carlo or quasi-Monte Carlo can be estimated as follows. The computation of a single stochastic path, originating at some given point internal to the domain, requires, on the average, a number of operations proportional to the number of steps, say N_s. The latter quantity is about the ratio between the mean first exit time and the time-step size, Δt, involved in the numerical integration of the underlying SDEs. When using an exponential timestepping, we take for Δt its mean value, λ^{-1}.

To estimate how the mean first exit time depends on dimension, recall that for the special case of Brownian motion going out from the hypersphere B_r of radius r, starting from the point x, this quantity is $E_x\{\tau_{B_r}\} \le r^2/d$; see [17]. If an $\mathcal{O}(1)$ drift is added, such a value becomes of order r. When B_r is replaced by a hypercube whose diagonal length is 1, these values become of order $1/\sqrt{d}$ and of order 1, respectively. Therefore, taking N realizations, all starting from a given point, the cost is proportional to $NN_s \approx Nf(d)(\Delta t)^{-1}$, where $f(d)$ represents the dependence of the mean first exit time on dimension.

The statistical error is expected to dominate; thus we choose a time-step size such that the truncation error is of the same order, i.e., $1/N^\beta = (\Delta t)^\alpha$. Here $\beta = 1/2$ for pseudorandom sequences, or (a little worse than) $\beta = 1$ using quasi-random sequences, and α is the order of the scheme adopted to solve the SDEs. This links the two parameters, N and Δt, so that $(\Delta t)^{-1} \approx N^{\beta/\alpha}$. Hence, the cost for computing N realizations will be $\approx N^{1+\beta/\alpha} f(d)$. In d dimensions, d SDEs should be solved, and thus such a cost should be multiplied by d. Therefore,

$$T_{MC} \approx N^{1+\beta/\alpha}\, d\, f(d). \tag{4.6}$$

4.2. Estimating T_1. In order to estimate T_1, we choose an FD solver whose truncation error equals the statistical error in our approach, that is, $h^2 \sim 1/N^\beta$, where $h := \Delta x = \Delta y$ is the mesh size. T_1 will be proportional to the total number of the grid points, h^{-d}, and to the number of iterations, n_{iter}, needed to solve iteratively the underlying linear algebraic system. To be concrete, it is found that for the 2D Laplacian such a number is given by [31]

$$n_{iter} \sim c\, q\, h^{-\xi}, \tag{4.7}$$

taking an iteration error equal to 10^{-q} as an exit criterion. Here $\xi = 2$ for the Jacobi and the Gauss–Seidel methods, and 1 for the successive overrelaxation (SOR) method with optimal parameter. The constant c is a fraction of 1, and q is typically of order 10 in our experiments. Therefore,

$$T_1 \sim h^{-d}\, n_{iter} = c\, q\, N^{\beta(d+\xi)/2}. \tag{4.8}$$

The speed-up in (4.5) then becomes

$$S_p^{PDD} \sim \frac{c\, q}{k\, d^2 f(d)}\, N^{\gamma}\, p^{1-1/d}, \quad p \to \infty, \tag{4.9}$$

where we set

$$\gamma := \beta\left(\frac{d+\xi}{2} - \frac{1}{\alpha}\right) - 1. \tag{4.10}$$

In order to compare with the case when the entire problem (on the entire domain) is solved by [illegible] (PFD), which represents a deterministic domain decomposition strategy, we now have $T_p = T_1/p + T_{com}$. Here T_{com} is the [illegible] time among the processors, which affects the algorithm [illegible] iteration step. Therefore, the speed-up relation takes on the form

$$S_p^{PFD} := \frac{T_1}{T_p} = \frac{p}{1 + \frac{T_{com}}{T_1} p} \sim \frac{T_1}{T_{com}} \quad \text{as } p \to \infty. \tag{4.11}$$

Note that this shows the nonscalability ("saturation") of such a method, since $S_p^{PFD} \sim T_1/T_{com}$ remains bounded as $p \to \infty$. The quantity T_{com}, which is assumed to be essentially independent of p, can be modeled as

$$T_{com} = 2N^{\beta(d-1)/2}\, n_{iter} B(d), \tag{4.12}$$

where $B(d)$ takes into account the bandwidth, and the factor 2 is due to both sending and receiving communications. In the exponent of N, $d-1$ replaces d because the points involved in intercommunications across the interfaces lie on a $(d-1)$-dimensional manifold. Hence, (4.11) yields

$$S_p^{PFD} \sim \frac{1}{2B(d)}\, N^{\beta/2} \quad \text{as } p \to \infty. \tag{4.13}$$

The speed-up of the PDD method in (4.9) wins over the speed-up of the PFD algorithm (4.13), that is, $S_p^{PDD} > S_p^{PFD}$, whenever, approximately,

$$p > \left(\frac{k\, d^2 f(d)}{2\, c\, q\, B(d)}\right)^{d/(d-1)} N^{\delta}, \tag{4.14}$$

where

$$\delta := \frac{d}{d-1}\left[\frac{\beta}{2}\left(1 - d - \xi + \frac{2}{\alpha}\right) + 1\right]. \tag{4.15}$$

The factor on the right-hand side of (4.14) that multiplies N^{δ} is assumed to depend weakly on dimension and is typically of order 1. In view of the fact that N should

be allowed to be arbitrarily large to achieve a sufficiently high accuracy in both algorithms, PDD and PFD, the interesting case is given by $\delta \leq 0$. This condition is verified if and only if the dimension is larger than or equal to a certain [illegible], d_{crit}, given by

$$d_{crit} := \begin{cases} \tilde{d} & \text{for } \tilde{d} \text{ integer,} \\ \left[\tilde{d}\right] + 1 & \text{for } \tilde{d} \text{ not integer,} \end{cases} \qquad \tilde{d} := 1 - \xi + 2\left(\frac{1}{\alpha} + \frac{1}{\beta}\right). \tag{4.16}$$

When $d \geq d_{crit}$, the PDD method wins over the PFD even with very few processors (or, equivalently, subdomains). The smallest critical dimension is clearly achieved when the order α of the scheme used to solve the SDEs is the highest, and quasi-random sequences ($\beta = 1$) and slower iterative solvers ($\xi = 2$, Gauss–Seidel method) are used. For instance, when $\beta = 1$, $\xi = 2$, and $\alpha = 2$, the value $d_{crit} = 2$ is obtained. For a general set of parameters, the critical dimension will be greater than 2. For instance, setting $\beta = 1$, $\xi = 2$, and $\alpha = 1$, we get $d_{crit} = 3$.

Even when $\delta > 0$, however, the condition (4.14) may also be satisfied with a reasonably low number of processors. As an example, when choosing $N = 10^4$ realizations (corresponding to an error of order 10^{-4} using quasi-random sequences), such an inequality requires about $p > 20$, whenever $\delta \leq 1/3$: Take, e.g., $d = 2$, $\xi = 2$, and $\alpha = 3/2$.

5. Numerical examples. In this section, we show the performance of the parallel code we designed to exploit a probabilistically induced domain decomposition method, by means of a few numerical examples. By simplicity, the code has been implemented using OpenMP, a standard parallelization library designed for shared memory architectures. The parallel machine used to conduct the numerical tests is a 16 processor IBM Power 3, running at a clock speed of 375 MHz, with a theoretical peak performance of 24 Giga Flops. Even though our algorithm allows for using an arbitrary number, p, of processors, the implementation of the code by OpenMP is restricted to run on a single node, which usually supports, so far, a relatively low number of processors. Applications based on message passing interface (MPI), which is characterized by the possibility of internodal communication, however, could be considered.

In the numerical examples below, our method is compared with a PFD solver, a parallel version of a standard finite difference solver, which is the same as that used in the local solver within the PDD method, and is also parallelized using OpenMP. It should be observed that such a comparison is in fact made between our PDD algorithm and a kind of "deterministic domain decomposition method." Such a method actually consists of distributing the overall computational load among the available processors.

It is important to stress that in the PDD method the nodal values on the interfaces are generated by classical Monte Carlo simulations, which can take advantage of massively parallel computation. After that, interpolation on the interfaces allows for full decoupling into subdomains, and hence the numerical solution of the given problem can be obtained also computing in parallel. In the quasi-PDD method (where we used Halton sequences of quasi-random numbers), however, there is no clear way to compute in parallel the nodal values above. In fact, due to the existing correlations among the elements within each sequence of quasi-random numbers, it is mandatory to adopt a suitable scrambling strategy, such as reordering, which contrasts with the possibility of computing independently the various realizations. The possibility of computing in parallel with quasi-random sequences deserves further investigation. The second source of parallelization, however, still holds true.

In the examples below, we compare the efficiency of PDD with that of PFD and observe the overall error reduction attained when passing from PDD to quasi-PDD.

A. Consider first the Dirichlet problem for the Laplace equation in two dimensions:

$$u_{xx} + u_{yy} = 0 \qquad \text{in } \Omega := (0,1) \times (0,1),$$

$$u(x,y)|_{\partial\Omega} = g(x,y), \tag{5.1}$$

where $g(x,y) := \left(x^2 - y^2\right)_{\partial\Omega}$. This choice of g corresponds to the fact that the analytical solution we wish to recover is the function $u(x,y) = x^2 - y^2$, harmonic in $\overline{\Omega} = [0,1] \times [0,1]$. In Figures 5.1(a) and 5.1(b), the pointwise numerical error, made when running the PDD and the quasi-PDD code, based on the PDD and the quasi-PDD methods, respectively, is shown on the whole domain, Ω, using $p = 4$ subdomains. The L^∞ error can be read from the color bar at the side.

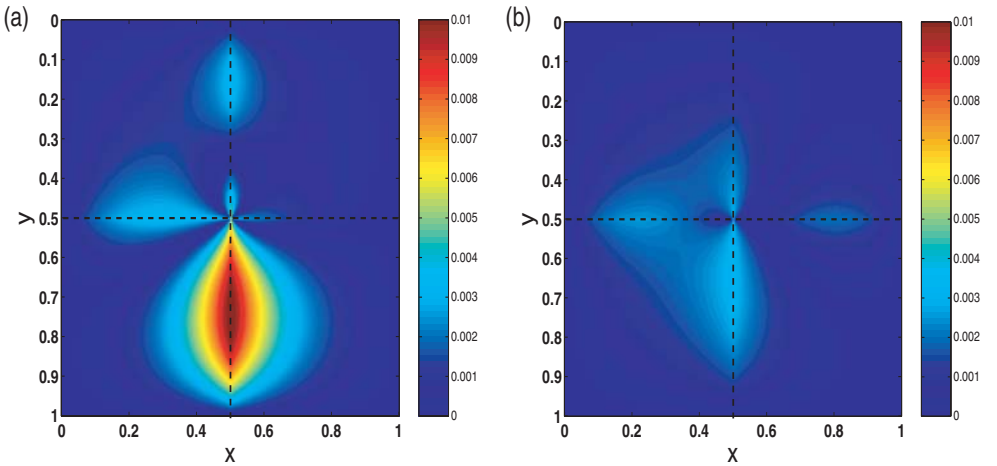

FIG. 5.1. *Example* A. *Pointwise numerical error in* (a) *the PDD algorithm and* (b) *the quasi-PDD algorithm. Parameters are* $N = 10^4$, $\Delta x = \Delta y = 2 \times 10^{-3}$, $\lambda = 10^2$.

In both pictures in Figure 5.1, it clearly appears that the maximum error on the entire domain Ω is achieved on the interfaces, and more precisely on the interpolation nodes. This occurs according to the observation made in section 2 concerning the maximum principle. Indeed, the error due to the Monte Carlo evaluation of the nodal values dominates over both the interpolation error and on the FD errors due to the local solver. This is true for both PDD and quasi-PDD methods. Moreover, it is also clear that the quasi-PDD algorithm outperforms the PDD algorithm. The parameters used here are $N = 10^4$ realizations, $\Delta x = \Delta y = 2 \times 10^{-3}$ grid size, and $\lambda = 10^2$ timestepping parameter (and thus an average time-step $\langle \Delta t \rangle = 10^{-2}$ to integrate SDEs in (2.3)). In this example, concerning the Laplace equation, the hitting probability, which is the probability that a given trajectory hits the boundary between two consecutive time-steps, can be evaluated exactly; see [15]. Consequently, a relatively large mean time-step could be used.

Numerical experiments show that two nodes suffice on each of the two interfaces. The local solver is based on Gauss–Seidel iteration, where the exit tolerance has been found experimentally ($q = 14$).

TABLE 5.1
CPU time in seconds for example A.

Processors	*PFD*	PDD_{Total}	$PDD_{Monte\,Carlo}$	PDD_{FD}
4	121.237	106.079	24.315	81.764
9	56.539	35.833	17.625	18.208
16	42.752	20.992	14.676	6.316

In Table 5.1, the second column, labeled by PFD, shows the overall computational time (in seconds) spent by the PFD algorithm for solving the problem in Example A, using $p = 4$, 9, and 16 processors. This corresponds to 4, 9, and 16 subdomains. In the third column the same is done, when the probabilistic domain decomposition is used. On the last two columns, the time needed in the latter algorithm is split into two parts, that concerning the Monte Carlo simulation, and that needed by the local solvers. This comparison between the two methods is made for about the same maximum error, 10^{-3}. It clearly appears that in both algorithms the CPU time decreases as p increases, and this behavior is more dramatic in the PDD algorithm. Also the CPU time decreases for each given number of processors passing from PFD to PDD. One can observe that the ratio between the CPU time spent in total by PDD (PDD_{Total}) and that spent by PFD favorably decreases as p increases; see section 4.

B. Consider the 2D elliptic equation with variable coefficients

$$u_{xx} + (6x^2 + 1)u_{yy} = 0 \qquad \text{in } \Omega := (0,1) \times (0,1), \tag{5.2}$$

subject to the boundary data

$$u(x,y)|_{\partial\Omega} = g(x,y), \tag{5.3}$$

where $g(x,y) := \left(x^4 + x^2 - y^2\right)_{\partial\Omega}$. Similarly to Example A, we wrote the boundary data in this way because the analytical solution of this problem is $u(x,y) = x^4 + x^2 - y^2$ in $\overline{\Omega}$.

In Figures 5.2(a), and 5.2(b), the same plots as in Example A are shown, and the same comments hold. The only difference is that here three nodal points are needed in

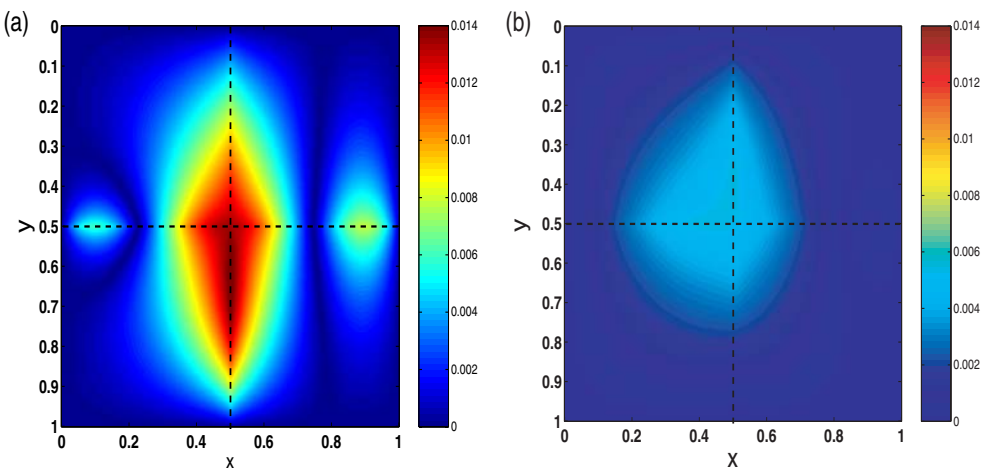

FIG. 5.2. *Example* B. *Pointwise numerical error in* (a) *the PDD algorithm and* (b) *the quasi-PDD algorithm. Parameters are* $N = 10^4$, $\Delta x = \Delta y = 2 \times 10^{-3}$, $\lambda = 10^3$.

TABLE 5.2
CPU time in seconds for example B.

Processors	*PFD*	PDD_{Total}	$PDD_{Monte\,Carlo}$	PDD_{FD}
4	599.066	317.778	11.042	306.736
9	271.991	75.018	9.144	65.874
16	174.784	30.101	7.710	22.391

the interpolation on each interface, which choice is determined upon experimentation. Parameters are also the same used in Example A, with the only exception being the timestepping parameter λ, which has been chosen equal to 10^3. Other than in Example A, here the hitting probability has to be evaluated approximately in powers of λ^{-1} [15]. A higher value of λ is needed here in order to ensure a good accuracy in approximating such a hitting probability.

Table 5.2 shows the same comparison as in Table 5.1, and the comments are similar. The PFD method here requires more CPU time because the present problem is more elaborate, due to the variable coefficients entering the equation. Thus more iterations are needed in the linear algebraic part of the code. On the other hand, the Monte Carlo part in the PDD algorithm is faster than in Example A, because the variable diffusion implies reaching the boundary in fewer steps.

C. Consider the elliptic equation with constant diffusion and (variable) drift terms:

$$\Delta u + \frac{1}{x+1}\,u_x + \frac{2}{y+1}\,u_y = 0 \qquad \text{in } \Omega := (0,1)\times(0,1), \tag{5.4}$$

with the boundary data

$$u(x,y)|_{\partial\Omega} = \left[(x+1)^2 + \frac{2}{3}(y+1)^2\right]_{\partial\Omega}, \tag{5.5}$$

the solution being given by $u(x,y) = (x+1)^2 + 2(y+1)^2/3$.

Figure 5.3 is analogous to the previous ones, and the parameters used are the

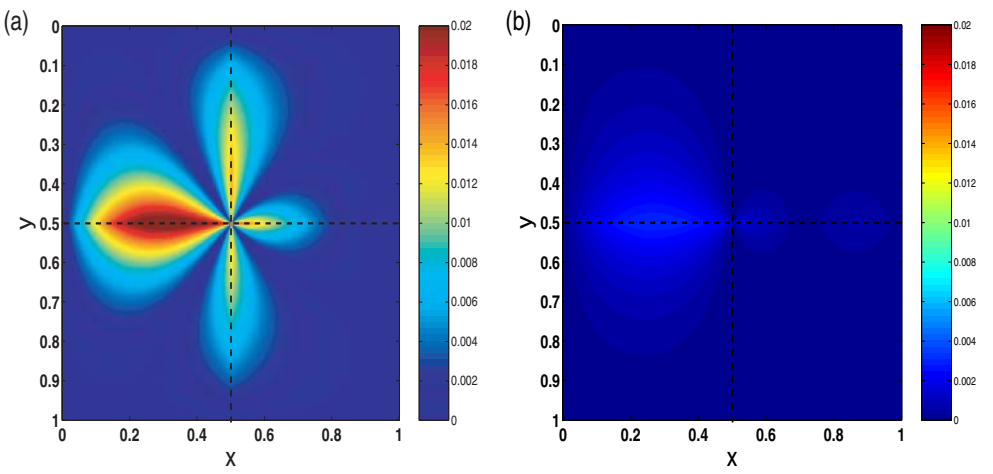

FIG. 5.3. *Example* C. *Pointwise numerical error in* (a) *the PDD algorithm and* (b) *the quasi-PDD algorithm. Parameters are the same as in Example* B.

TABLE 5.3
CPU time in seconds for example C.

$Processors$	PFD	PDD_{Total}	$PDD_{Monte\,Carlo}$	PDD_{FD}
4	350.989	166.728	151.640	15.088
9	160.351	48.374	34.577	13.797
16	105.862	22.585	12.104	10.481

same as in Example A. In particular, only two nodes on each interface have been used, but $\lambda = 10^3$ as in Example B. The general comments made above also apply.

In Table 5.3, as in the previous tables, one can see that now the Monte Carlo part of the PDD algorithm takes longer than in the previous examples. This fact can be attributed to the asymmetry introduced by the drift in both directions, which ultimately requires more time-steps to exit the boundary.

D. Consider finally the Dirichlet problem for the 2D elliptic equation

$$u_{xx} + u_{yy} - 5u = 0 \qquad \text{in } \Omega := (0,1) \times (0,1), \tag{5.6}$$

$$u(x,y)|_{\partial\Omega} = g(x,y), \tag{5.7}$$

where $g(x,y) := \left(e^{2x+y}\right)_{\partial\Omega}$. The analytical solution of such a problem is $u(x,y) = e^{2x+y}$ in $\overline{\Omega} = [0,1] \times [0,1]$. In Figures 5.4(a) and 5.4(b), similarly to the previous cases, the pointwise numerical error, made when running the PDD and the quasi-PDD code, based on the PDD and the quasi-PDD methods, is shown. Here only two nodes on each interface have been used. Figure 5.4(c) shows the result for three nodes on each interface (that is, six nodal points in total). Note that increasing the number of nodal points yields an overall reduction of the numerical error on the whole domain. When pseudorandom numbers are used, the statistical error dominates, making irrelevant the improvement achieved by interpolating on three (instead of two) nodes on each interface. On the other hand, the time required obviously increases; see Tables 5.4 and 5.5. Using quasi-random numbers, instead, which are characterized by smaller errors in computing the nodal values, an overall error reduction due to a better interpolation can be observed when switching from two to three nodes.

In Tables 5.4 and 5.5, the same features observed in the previous examples can be seen. In Table 5.5, the CPU times related to PFD have been omitted since they coincide with those reported in Table 5.4. In fact, the comparison between PFD

TABLE 5.4
CPU time in seconds for Example D with two nodes per interface.

$Processors$	PFD	PDD_{Total}	$PDD_{Monte\,Carlo}$	PDD_{FD}
4	556.427	242.453	25.327	217.126
9	252.911	67.190	17.890	49.300

4	242.406	25.391	217.015
9	72.634	23.377	49.257
16	36.877	19.702	17.175

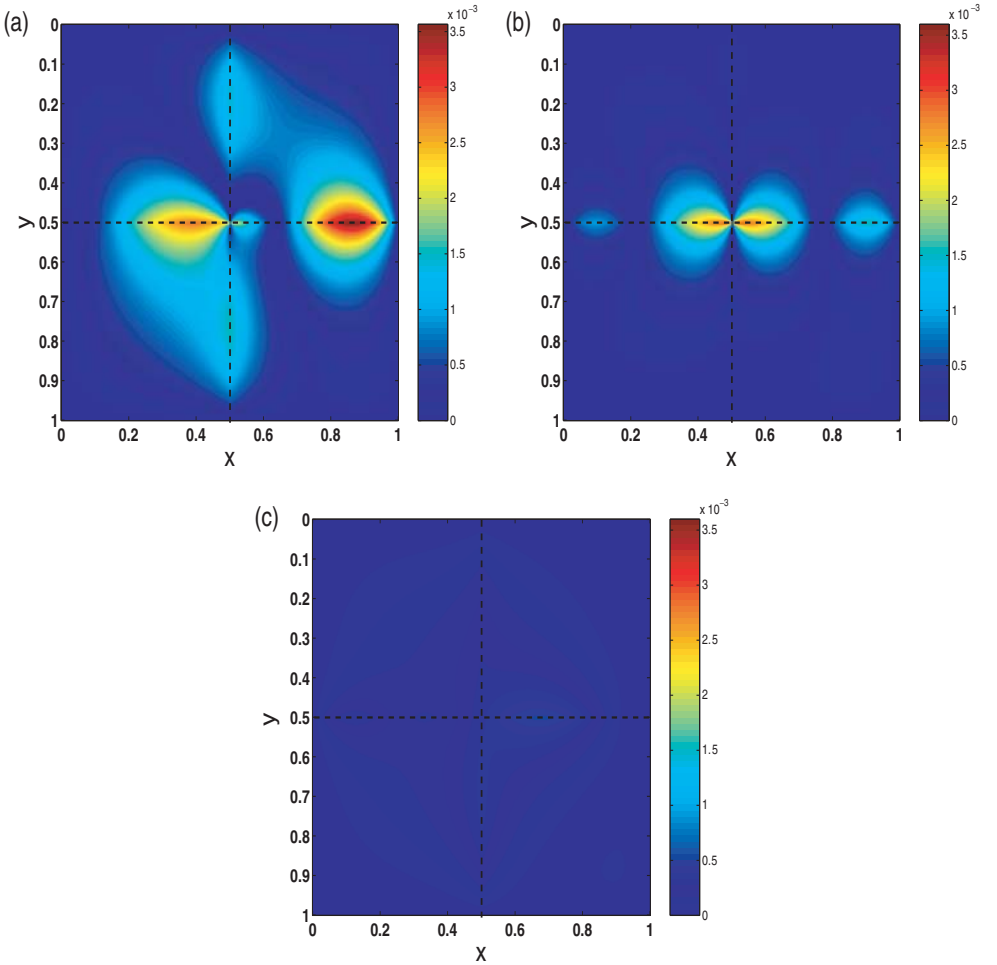

FIG. 5.4. *Example* D. *Pointwise numerical error in* (a) *the PDD algorithm,* (b) *the quasi-PDD algorithm with two nodal points on each interface, evaluated by quasi-Monte Carlo, and* (c) *the quasi-PDD algorithm with three nodal points on each interface. Parameters are* $N = 10^4$, $\Delta x = \Delta y = 2 \times 10^{-3}$, $\lambda = 10^3$.

and PDD has been made by keeping fixed the overall numerical error, which does not change when passing from two to three nodes per interface, as pointed out above. Note also that the CPU times spent here in $PDD_{Monte\,Carlo}$ are about the same as those in Example A (see Table 5.1). In fact, in both examples, A and D, the numerical solution of the same system of SDEs is involved, and only a short additional time is required in Example D. This is due to the quadrature corresponding to the presence of the potential term in (5.6); see (2.2). Finally, it appears that the CPU time appreciably increases when switching from two to three nodes per interface, for a higher number of processors, since this corresponds to increasing the total number of nodal points.

6. Concluding remarks. Probabilistic representations of solutions to elliptic boundary-value problems and the ensuing possibility of using them for numerical approximations have been known for a long time. In spite of this, in the literature there is apparently only a modest body of work addressing the latter possibility; see,

e.g., [11, 20, 24]. One reason certainly can be found in the poor performance of the Monte Carlo method. In this paper, we have first improved the overall performance of such a probabilistic numerical approach to solving linear elliptic boundary value problems. This has been done even for [illegible] equations, including both cases of variable drift and diffusion. A suitable boundary treatment, realized by means of the exponential timestepping method, was recognized as an essential ingredient and implemented. Moreover, quasi-random sequences have been successfully used, resulting in a faster convergence rate in the Monte Carlo simulations. Finally, we have adopted a "divide and conquer" strategy, represented by a domain decomposition method, where only a few values are computed by Monte Carlo or quasi-Monte Carlo, thus reducing the overall inherent computational cost. Such values are used as nodes for interpolating the sought solution, then providing continuous approximations for the interfacial values, to be exploited subsequently to split the problem into several subproblems. We were then able to exploit as many processors, p, as subdomains. Speed-up and scalability with p are shown, both theoretically and in a few practical examples.

In closing, notice that even a relatively coarse solution obtained by the PDD algorithm (through a Monte Carlo or quasi-Monte Carlo strategy with a moderate value of N) could be used as the [illegible] for the FD solver on the whole domain. Indeed, the exit criterion in the linear algebraic solver depends both on the spectral radius of the iteration matrix (and thus on its spectral condition number) [illegible] on the initial guess of solution. While the former can be reduced by preconditioning, which is essential in certain iterative methods, such as the iterative substructuring (deterministic domain decomposition) methods, the PDD algorithm might provide a good initial guess.

COMPUTATION OF SMALLEST EIGENVALUES USING SPECTRAL SCHUR COMPLEMENTS*

CONSTANTINE BEKAS† AND YOUSEF SAAD†

Abstract. The automated multilevel substructuring method (AMLS) was recently presented as an alternative to well-established methods for computing eigenvalues of large matrices in the context of structural engineering. This technique is based on exploiting a high level of dimensional reduction via domain decomposition and projection methods. This paper takes a purely algebraic look at the method and explains that it can be viewed as a combination of three ingredients: (a) A first order expansion to a nonlinear eigenvalue problem that approximates the restriction of the original eigenproblem on the interface between the subdomains, (b) judicious projections on partial eigenbases that correspond to the interior of the subdomains, (c) recursivity. This viewpoint leads us to explore variants of the method which use Krylov subspaces instead of eigenbases to construct subspaces of approximants. The nonlinear eigenvalue problem viewpoint yields a second order approximation as an enhancement to the first order technique inherent to AMLS. Numerical experiments are reported to validate the approaches presented.

Key words. AMLS, eigenvalues, substructuring, spectral Schur complements, Krylov subspaces

1. Introduction.

The numerical solution of large sparse symmetric eigenvalue problems continues to be at the forefront of current research in scientific computing. In the last few decades, projection methods such as the Lanczos algorithm and its variants have dominated the scene. For example, a block version of this method combined with shift-and-invert [11], whereby the problem $Ku = \lambda Mu$ is replaced by $(K - \sigma M)u = (\lambda - \sigma)Mu$, is used in major commercial structural engineering packages such as MSC.NASTRAN [15]. ARPACK [17], a package based on an implicitly restarted Arnoldi/Lanczos process, is currently the best known public-domain eigenvalue package for large eigenvalue problems.

When computing a large number of eigenvalues the Lanczos process faces difficulties associated with orthogonalizing large Krylov bases. The method scales poorly with the number of eigenvalues. In recent years, an alternative approach has emerged in structural engineering which has been reported to be superior to the standard shift-and-invert Lanczos approach. The algorithm, called automated multilevel substructuring method (AMLS), is rooted in a domain decomposition framework. It has been reported as being capable of computing thousands of the smallest normal modes of dynamic structures on commodity workstations and of being orders of magnitude faster than the standard approach [16].

The paper [5] presents a theoretical framework for the algorithm from the point of domain decomposition, using adequate functional spaces and operators on them. The goal of our paper is to present a different, yet complementary viewpoint, which is entirely algebraic. AMLS is essentially a Schur complement method. Schur complement techniques are well understood for solving linear systems and play a major role in

domain decomposition techniques [20, 21]. Relatively speaking, the formulation of this method for eigenvalue problems has been essentially neglected so far. One could of course extend the approach used for linear systems for eigenvalues by formulating a Schur complement problem for each different eigenvalue, (e.g., by solving the eigenvalue problem as a sequence of linear systems through shift-and-invert). A more complete framework was suggested in early work by Abramov [1, 2] and Chichov [7]. These authors presented what may be termed a spectral Schur complement method. It can easily be verified that a scalar λ is an eigenvalue of a matrix A partitioned as

$$A = \begin{pmatrix} B & F \\ E & C \end{pmatrix}$$

if and only if it is an eigenvalue of $S(\lambda) = C - E(B - \lambda I)^{-1}F$ (this is clearly restricted to those λ's that are not in the spectrum of B). This nonlinear eigenvalue problem may be solved by a Newton-type approach. Alternatively, one can also devise special iterative schemes based on the above observation. An approach of this type is clearly limited by the fact that a Schur complement (or several consecutive ones in an iterative process) is required for each different eigenvalue. It can, however, work well for computing one or a few eigenvalues or in some other special situations. For example, this nonlinear viewpoint led to the development of effective shifts of origin for the QR algorithm for tridiagonal matrices [19] (see also Parlett [18]).

The fundamental premise of AMLS, and its attraction, is that it is capable of extracting very good approximations [illegible]. To achieve this, AMLS relies heavily on projection techniques. It builds good bases from one Schur complement, and expands them in an effective way to bigger and bigger domains.

This paper will begin with a brief overview of AMLS and an introduction of the notation. It will then introduce spectral (or nonlinear) Schur complements and explore their relations to AMLS. With this relation established, two enhancements of the basic AMLS scheme are presented. The first introduces Krylov subspaces to the technique and the second considers a more accurate (second order instead of first order) scheme. Combinations of these improvements are investigated. Finally, numerical experiments illustrate the performance of the suggested approaches.

2. The AMLS approach. Let $A \in \mathbb{C}^{n\times n}$ be a Hermitian matrix

$$A = \begin{pmatrix} B & E \\ E^* & C \end{pmatrix}, \tag{1}$$

such that $B \in \mathbb{C}^{(n-p)\times(n-p)}$, $C \in \mathbb{C}^{p\times p}$, and $E \in \mathbb{C}^{(n-p)\times p}$. Consider the linear eigenvalue problem $A\tilde{u} = \lambda\tilde{u}$, which can be written as

$$\begin{pmatrix} B & E \\ E^* & C \end{pmatrix} \begin{pmatrix} \tilde{u}^B \\ \tilde{u}^S \end{pmatrix} = \lambda \begin{pmatrix} \tilde{u}^B \\ \tilde{u}^S \end{pmatrix}, \tag{2}$$

where $\tilde{u}^B \in \mathbb{C}^{n-p}$ and $\tilde{u}^S \in \mathbb{C}^p$. Component mode synthesis (CMS) is a classical technique in structural dynamics for the computation of the smallest normal modes of a structure [10, 12]; see also [3] for a comparison of iterative algorithms for modal analysis.

A structure is typically approximated by a discrete domain Ω. In CMS the original structure is decomposed into several substructures separated by means of an interface Γ. Each of the substructures is approximated by a subdomain $\Omega_i \subset \Omega$. Notice

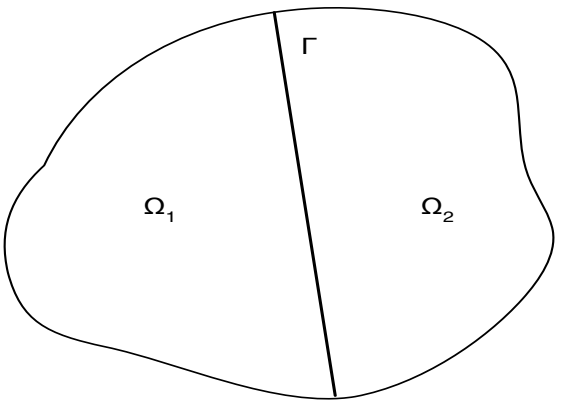

FIG. 1. *The simple case of two subdomains* Ω_1, Ω_2 *and an interface* Γ.

that the subdomains Ω_i can either overlap or not. In this paper we consider only the latter case. Thus, the unknowns in the interior of each subdomain Ω_i are completely decoupled from the unknowns in all other subdomains. Coupling among substructures is represented by the unknowns on the interface Γ and the unknowns in each Ω_i that are adjacent to Γ. Figure 1 provides a graphical illustration in the simplest case of two subdomains.

Consider now the simple model problem

$$-\nabla^2 \tilde{u} = \lambda \tilde{u} \tag{3}$$

on a rectangular domain Ω. If we employ a standard 5-point stencil, centered differences discretization of (3) and label the unknowns in the subdomains Ω_i first, followed by those on Γ, then the algebraic eigenvalue problem that arises from the discretization of (3) will be of the form (2). Notice that the matrix B acts on the unknowns of the domains Ω_i, while C corresponds to the unknowns on the interface Γ and E corresponds to the coupling between the unknowns in B and C. Furthermore, since the unknowns in the domains Ω_i are decoupled, B will be block diagonal.

The idea of `CMS` is to begin by solving the problem $Bv_j = \mu_j v_j$ for a number of the smallest eigenvalues. In particular, since B is block diagonal, this is equivalent to solving each of the decoupled smaller eigenvalue problems $B^i v_j^i = \mu_j^i v_j^i$ corresponding to each subdomain Ω_i (in parallel). The eigenvectors v_j^i are extended by zero outside the subdomain Ω_i. Then, `CMS` injects additional vectors v_Γ^k, that are not identically zero on the interface Γ, to account for the coupling among subdomains. This is done by invoking a carefully selected operator for the interface nodes (cf [5]). The complete eigenvectors (and eigenvalues) of the original eigenproblem are then approximated by Rayleigh–Ritz projection on the subspace

$$\texttt{span}\left\{v_j^i, i = 1, 2, \ldots, j = 1, 2, \ldots, \quad v_\Gamma^k, k = 1, 2, \ldots\right\}.$$

Recently, Bennighof and Lehoucq [5] have presented `AMLS` that extends the basic framework of `CMS` into a multilevel method. `AMLS` was reported to be orders of magnitude faster than competitive commercial software based on the traditional shift-and-invert Lanczos approach [16]. It was shown to be capable of computing thousands of the smallest normal modes of structures on commodity workstations.

Consider the matrix

$$U = \begin{pmatrix} I & -B^{-1}E \\ 0 & I \end{pmatrix}, \tag{4}$$

which is a block Gaussian eliminator for matrix (1), selected so that

$$U^*AU = \begin{pmatrix} B & 0 \\ 0 & S \end{pmatrix},$$

where S is the Schur complement

$$S = C - E^*B^{-1}E. \tag{5}$$

We now consider the application of `AMLS` for only a single level of subdivisions. The original problem (2) is replaced by the equivalent generalized eigenvalue problem $U^*AUu = \lambda U^*Uu$, which can be written as

$$\begin{pmatrix} B & 0 \\ 0 & S \end{pmatrix} \begin{pmatrix} u^B \\ u^S \end{pmatrix} = \lambda \begin{pmatrix} I & -B^{-1}E \\ -E^*B^{-1} & M_S \end{pmatrix} \begin{pmatrix} u^B \\ u^S \end{pmatrix}, \tag{6}$$

where $M_S = I + E^*B^{-2}E$. Observe that the eigenvectors $\tilde{u}$ of the original problem (2) are connected with the eigenvectors of the generalized problem (6) by

$$\begin{bmatrix} \tilde{u}^B \\ \tilde{u}^S \end{bmatrix} = U \begin{bmatrix} u^B \\ u^S \end{bmatrix},$$

because of the congruence transformation of (2) to (6).

`AMLS` computes approximations to the eigenvalues and eigenvectors of the original problem by means of a projection method applied to the generalized problem (6). The subspace of approximants is constructed from eigenvectors of a version of (6) in which the coupling in the right-hand side matrix (i.e., off-diagonal blocks in U^*U) is ignored. This gives the two decoupled eigenvalue problems:

$$Bv = \mu\, v, \tag{7}$$

$$Sw = \eta\, M_S w. \tag{8}$$

Once the desirable eigenpairs have been obtained from (7)–(8), they are utilized in a projection method (Rayleigh–Ritz) applied to the original problem (6). The basis used for this projection is of the form

$$\left\{ \hat{v}_i = \begin{pmatrix} v_i \\ 0 \end{pmatrix} \quad i = 1, \ldots, m_B, \qquad \hat{w}_j = \begin{pmatrix} 0 \\ w_j \end{pmatrix} \quad j = 1, \ldots, m_S \right\},$$

where $m_B < (n-p)$ and $m_S < p$. It is important to note that the projection is applied to (6) rather than to the original problem (2). There is an inherent change of basis between the two and, for reasons that will become clear later, the basis $\{\hat{v}_i\}_i, \{\hat{w}_j\}_j$, is well suited for the transformed problem rather than the original one.

The essence of `AMLS` is to "solve the problem (6) without the coupling and then use some eigenvectors obtained to solve the problem with its coupling." It is interesting to note that a very similar idea is utilized with great success in structural engineering: to solve a problem related to a dynamical system, one first obtains the modes of the

problem without damping, then uses these modes to define a subspace in which the full problem (with damping) is solved. We refer to Algorithm 2.1 for an algorithmic description of `AMLS` for one level of subdivisions (SPD stands for symmetric positive definite matrices). In the multilevel case, this algorithmic step is applied recursively for every subdomain of the original domain. Observe that in practice the block Gaussian eliminator matrix U (line 4) is not formed. Instead, Gaussian elimination is applied to compute the Schur complement S and the matrix M_S, since

$$U^*U = \begin{pmatrix} I & -B^{-1}E \\ E^*B^{-1} & M_S \end{pmatrix}.$$

In this paper we are interested in an analysis of the basic approximation mechanism of `AMLS`. This analysis will serve to devise a few improvements to the basic method. For simplicity, our study will be restricted to the single level of subdomains.

ALGORITHM 2.1. **`AMLS` for a single level of subdomains**

$A \in \mathbb{C}^{n\times n}$, $m_B < n_B < n$, $m_S < n$, n_e n_e A.

1. $\mathtt{B} = \mathtt{A}(1:\mathtt{n_B}, 1:\mathtt{n_B})$, $\mathtt{C} = \mathtt{A}(\mathtt{n_B}+1:\mathtt{end}, \mathtt{n_B}+1:\mathtt{end})$, $\mathtt{E} = \mathtt{A}(1:\mathtt{n_B}, \mathtt{n_B}+1:\mathtt{end})$.
2. $R^*R = B$.
3. $S = C - E^*B^{-1}E$ (R).
4. $U = [I, -B^{-1}E; 0, I]$.
5. $M_S = I + (E^*B^{-1})(B^{-1}E)$ R .
6. m_S W_S (S, M_S).
7. m_B V_B B.
8. $Z = [V_B, 0; 0, W_S]$.
9. n_e $(Z^*U^*AUZ)x = \lambda(Z^*U^*UZ)x$.

---

3. Spectral Schur complements. The following equations result from (6):

$$Bu^B = \lambda(u^B - B^{-1}Eu^S), \tag{9}$$

$$Su^S = \lambda(-E^*B^{-1}u^B + M_Su^S). \tag{10}$$

Assume that E is of full rank and B is nonsingular. In this situation, it is easy to see that (λ, u^B) cannot be an eigenpair of B. Then, any pair (λ, u^B), where (λ, u^B, u^S) is a solution of (6), cannot be an eigenpair for B. Indeed, if the contrary were to be true, then (9) would imply $u^S = 0$, from which (10) would imply that $\lambda = 0$. This is impossible since B is nonsingular. A consequence of this is that when λ is an eigenvalue of B, then (9) always has a solution in the orthogonal of the eigenspace of B associated with this eigenvalue. We can therefore always, theoretically, solve the system $(B - \lambda I)u_B = -B^{-1}u^S$ derived from (9) provided the inverse of B is interpreted as a pseudo-inverse. In what follows, $(B - \lambda I)^{-1}$ will always mean the pseudo-inverse $(B - \lambda I)^\dagger$ when λ is an eigenvalue of B. The notation is not changed because this is a rare occurrence in practice.

We can substitute (9) into (10) to obtain

$$Su^S = \lambda \left(\lambda E^* B^{-1}(B - \lambda I)^{-1} B^{-1} E u^S + M_s u^S\right),$$

which results in the equivalent nonlinear eigenvalue problem

$$\left[S - \lambda \left(E^* B^{-2} E\right) - \lambda^2 E^* B^{-1}(B - \lambda I)^{-1} B^{-1} E\right] \; u^S \; = \; \lambda u^S. \tag{11}$$

Rewriting the above problem in an expanded notation we obtain the following nonlinear eigenvalue problem

$$\left[C - E^* B^{-1}(B + \lambda I + \lambda^2 (B - \lambda I)^{-1}) B^{-1} E\right] u^S = \lambda u^S. \tag{12}$$

We can show that the above problem is equivalent to a nonlinear eigenvalue problem involving the spectral Schur complement

$$S(\lambda) = C - E^*(B - \lambda I)^{-1} E. \tag{13}$$

The first resolvent equality (see [14]),

$$(B - \lambda I)^{-1} - B^{-1} = \lambda (B - \lambda I)^{-1} B^{-1},$$

can be substituted in the expression of the left-hand matrix in (12) which we denote by $\hat{S}(\lambda)$,

$$\begin{aligned}
\hat{S}(\lambda) &= C - E^* B^{-1} \left(I + \lambda B^{-1} + \lambda (B - \lambda I)^{-1} - \lambda B^{-1}\right) E \\
&= C - E^* \left(B^{-1} + \lambda B^{-1} (B - \lambda I)^{-1}\right) E \\
&= C - E^* \left(B^{-1} - B^{-1} + (B - \lambda I)^{-1}\right) E \\
&= C - E^* (B - \lambda I)^{-1} E \\
&= S(\lambda).
\end{aligned}$$

In fact, the Schur complement S can be viewed as the first term of the Taylor series expansion of $S(\lambda)$ with respect to λ around $\lambda = 0$. The standard expansion of the resolvent (see [14])

$$(B - \lambda I)^{-1} = B^{-1} \sum_{k=0}^{\infty} (\lambda B^{-1})^k = \sum_{k=0}^{\infty} \lambda^k B^{-k-1}, \tag{14}$$

leads to the following series expansion for $S(\lambda)$:

$$\begin{aligned}
S(\lambda) &= C - E^* \sum_{k=0}^{\infty} (\lambda^k B^{-k-1}) E \\
&= C - E^* \left(B^{-1} + \lambda B^{-2} + \lambda^2 B^{-3} + \cdots\right) E. \qquad (15)
\end{aligned}$$

Observe that in `AMLS` the lower part of the projection basis Z (see Algorithm 2.1) is comprised of eigenvectors associated with the smallest eigenvalues of the generalized eigenproblem

$$Sw = \lambda M_S w, \tag{16}$$

which, after some algebraic manipulation, leads to the equation

$$\left(C - E^*(B^{-1} + \lambda B^{-2})E\right) w = \lambda w. \tag{17}$$

In light of relation (15), the prevously stated eigenproblem can clearly be considered as a truncated version of the original nonlinear problem (12), where we ignore the terms $\lambda^k B^{-k-1}$ for $k \geq 2$ in the expansion of the resolvent $(B - \lambda I)^{-1}$. Thus, the eigenvector w can be seen as a direct approximation to the bottom part u^S of the exact eigenvector of (6). In what follows, when w is considered to be a good enough approximation to u^S, we will often not distinguish between u^S and w.

The above observations immediately lead to some possible suggestions on how to improve the approximation by including additional terms of the infinite expansion. Section 5 will describe a second order approximation to (12) obtained by adding the term $\lambda^2 B^{-3}$. We begin by analyzing how `AMLS` expands the approximation of the lower part u^S to an approximation $[u^B; u^S]^*$ of an eigenvector of the complete problem (6).

4. The projection viewpoint. Consider again the nonlinear Schur complement (13). The eigenvalues of the original problem, which do not belong to the spectrum of B, can be obtained from those of the nonlinear eigenvalue problem

$$S(\lambda)x = \lambda x.$$

PROPOSITION 4.1. λ, u^S (11)

$$S(\lambda)u^S = \lambda u^S.$$

λ (2)

$$\begin{pmatrix} -(B - \lambda I)^{-1} E u^S \\ u^S \end{pmatrix}. \tag{18}$$

. The proof consists of a simple verification. □

Now assume that we have a good approximation to the nonlinear Schur complement problem, i.e., to a solution λ and u^S of the nonlinear problem (11). It is clear that the best we can do to retrieve the corresponding eigenvector of (2) is to use substitution, i.e., to compute the top part of (18)

$$u^B = -(B - \lambda I)^{-1} E u^S, \tag{19}$$

which will give us the top part of the exact eigenvector. This entails factoring the matrix $(B - \lambda I)$ for each different eigenvalue λ, which is not practical. As was seen in the previous section, `AMLS` extracts an approximation to the nonlinear problem (11) by solving the generalized eigenvalue problem (17) and then it replaces the substitution step (19) by a projection step. Specifically, once an approximate pair λ, u^S is obtained, `AMLS` computes approximate eigenvectors to the original problem by a projection process using the space spanned by the family of vectors

$$\left\{ \begin{pmatrix} v_i^B \\ 0 \end{pmatrix} \right\}, \qquad \left\{ \begin{pmatrix} -B^{-1} E u_j^S \\ u_j^S \end{pmatrix} \right\}, \tag{20}$$

in which v_i^B are eigenvectors of B associated with its smallest eigenvalues. Note that these two sets of vectors are of the form $U\begin{pmatrix} v_i^B \\ 0 \end{pmatrix}$ for the first, and $U\begin{pmatrix} 0 \\ u_j^S \end{pmatrix}$ for the second,

where U was defined earlier by (4). The question is: why is this a good way to replace the substitution step (19)? Another issue is the quality we might expect from this process.

Ideally, the prolongation matrix U should be replaced by one which depends on the eigenvalue λ, namely

$$U(\lambda) = \begin{pmatrix} I & -(B-\lambda I)^{-1}E \\ 0 & I \end{pmatrix}.$$

Indeed, if we were to use the prolongator $U(\lambda)$ instead of U, then $U(\lambda)\binom{0}{u_j^S}$ would be an exact eigenvector (if the approximation to u^S that we use were exact). Of course, it is not practical to use a different prolongator $U(\lambda)$ for each different eigenvalue λ. What is interesting and important to note is that $U(\lambda)$ and U are likely to be close to each other for small (in modulus) eigenvalues λ. Furthermore, [illegible] B [illegible] λ. It is helpful to examine this difference,

$$[U(\lambda) - U]\begin{pmatrix} 0 \\ u^S \end{pmatrix} = \begin{pmatrix} 0 & -((B-\lambda I)^{-1} - B^{-1})E \\ 0 & 0 \end{pmatrix}\begin{pmatrix} 0 \\ u^S \end{pmatrix}$$
$$= \begin{pmatrix} -\lambda\ (B-\lambda I)^{-1}B^{-1}Eu^S \\ 0 \end{pmatrix}.$$

In order to compensate for this difference, it is natural to add to the subspace eigenvectors of B in which this difference will have large components, i.e., eigenvectors corresponding to the smallest eigenvalues of B. This is at the heart of the approximation exploited by `AMLS` which incorporates the first set in (20). Let us assume that we have the expansion in the eigenbasis of B

$$Eu^S = \sum_{k=1}^{N_B} \alpha_k v_k, \tag{21}$$

where $N_B = n - p$ is the dimension of B. Let $\hat{u}^B$ be the B-part (top part) of the approximation provided by applying the prolongation matrix U on vector $\binom{0}{u^S}$ and u^B be the top part of the exact eigenvector. Then

$$u^B - \hat{u}^B = -\lambda\ (B-\lambda I)^{-1}B^{-1}\ Eu^S = \sum_{k=1}^{N_B} \frac{\lambda\alpha_k}{(\mu_k - \lambda)\mu_k} v_k.$$

As expected, when $\lambda = 0$, the projection process will yield exact eigenvectors. The error in the eigenvector of (2) will be of the order of the distance between the above vector and the space spanned by the added eigenvectors of B. If we call X^B the restriction to the B-part of the space of approximants, then

$$dist(u^B, X^B) = \min_{v \in \ \mathtt{span}\ (v_1,\ldots,v_{m_B})} \|u^B - \hat{u}^B - v\|_2$$
$$= |\lambda| \left(\sum_{k>m_B} \frac{|\alpha_k|^2}{|\mu_k - \lambda|^2\ |\mu_k|^2} \right)^{1/2},$$

and therefore

$$dist(u^B, X^B) \leq \max_{k>m_B} \frac{|\lambda|}{|\mu_k - \lambda|\ |\mu_k|} \|Eu^S\|_2. \tag{22}$$

Under the mild assumption that $\lambda < \mu_{m_B}$, it is clear that

$$dist(u^B, X^B) \leq \frac{|\lambda|}{|\mu_{m_B} - \lambda| \ |\mu_{m_B}|} \|Eu^S\|_2. \tag{23}$$

Note that for $\lambda \ll \mu_{M_B}$, we will have $dist(u^B, X^B) \approx O(|\lambda/\mu_{M_B}^2|)$.

It is clear that we have three sources of error for the whole eigenvector $\left[\, u^B; u^S \,\right]$. For the bottom part u^S, the error comes from approximating it by solving the generalized eigenvalue problem (17). For the upper part u^B we have an error from using the projection described above, instead of using the prolongator $U(\lambda)$ and of course the error in using an approximate u^S in this projection. Notice, however, that our analysis has shown that it is beneficial to inject in the projection eigenvectors of B associated with eigenvalues that are closest to the (exact) smallest eigenvalues of the original problem. This is true regardless of the error in the approximation to u^S. In particular, let u^B be exact and assume that instead we use an approximation $u^B + \delta$, where $\|\delta\|$ is small. Then, using the expansion $E\delta = \sum_{k=1}^{N_B} \xi_k v_k$, where v_k are the eigenvectors of B, we now have

$$u^B - \hat{u}^B = -\lambda \ (B - \lambda I)^{-1} B^{-1} \ Eu^S - B^{-1} E\delta = \sum_{k=1}^{N_B} \left(\frac{\lambda \alpha_k}{(\mu_k - \lambda)\mu_k} - \frac{\xi_k}{\mu_k} \right) v_k,$$

and thus we can similarly show for the revised distance $dist(u^B, X^B)$

$$dist(u^B, X^B) \leq \left(\sum_{k>m_B}^{N_B} \frac{|\lambda|^2 |\alpha_k|^2 + |\xi_k|^2 |\mu_k - \lambda|^2 - 2|\lambda \alpha_k \xi_k (\mu_k - \lambda)|}{|\mu_k - \lambda|^2 \ |\mu_k|^2} \right)^{1/2}, \tag{24}$$

which readily reduces to (23) for small enough $\|\delta\|$.

5. Higher degree approximations. The analysis in previous sections has demonstrated that `AMLS` approximates the nonlinear eigenvalue problem (12) by the generalized eigenvalue problem (16). In particular, this problem can be seen as a truncated, first order approximation of (12). Let us now consider a second order approximation obtained by solving the quadratic eigenvalue problem

$$[\lambda^2 E^* B^{-3} E + \lambda (I + E^* B^{-2} E) - S] q \ = \ 0. \tag{25}$$

This problem can be solved by a linearization which leads to an equivalent generalized eigenvalue problem (see for example [22])

$$\begin{pmatrix} 0 & I \\ S & -K \end{pmatrix} \begin{pmatrix} q \\ \lambda q \end{pmatrix} = \lambda \begin{pmatrix} I & 0 \\ 0 & H \end{pmatrix} \begin{pmatrix} q \\ \lambda q \end{pmatrix}, \tag{26}$$

where $K = I + E^* B^{-2} E$ and $H = E^* B^{-3} E$. As in the previous sections, when q is an accurate approximation to the exact bottom part of the eigenvector, i.e., u^S, we will not distinguish between these vectors.

In section 4 we showed that adding eigenvectors of B to the space of approximants can improve the basic approximation provided by the nonlinear Schur complement. In order for the approximate eigenvectors provided by the solution of (26) to fit in well with the projection step, we need to modify the latter so that the terms $-(B - \lambda I)^{-1} Eu^S$ are well approximated. One way to achieve this is to add more

eigenvectors of B. However, a more relevant alternative in this case is to add a third set of vectors to the basis of approximants (20), namely the set:

$$\left\{ \begin{pmatrix} -B^{-2}Eu_j^S \\ u_j^S \end{pmatrix} \right\}, \tag{27}$$

which corresponds to the truncation of the resolvent expansion (14) from the third term on, rather than from the second term. Observe that including the approximate eigenvalue λ in the term $-\lambda B^{-2}$ (see (14)) will not affect the direction of the added vectors, and thus is avoided.

In order to apply the projection, we construct the matrix

$$Z = \begin{pmatrix} V_B & -B^{-1}EU_S & -B^{-2}EU_S \\ 0 & U_S & 0 \end{pmatrix}, \tag{28}$$

where V_B is a matrix of eigenvectors corresponding to the smallest eigenvalues of B and U_S is a matrix of eigenvectors associated with the smallest eigenvalues of (26), in modulus. We then solve the projected generalized eigenvalue problem

$$Z^* \begin{pmatrix} B & E \\ E^* & C \end{pmatrix} Zx = \lambda Z^* Zx. \tag{29}$$

Algorithm 5.1 illustrates a second order version of `AMLS`, based on this approach.

ALGORITHM 5.1. **Second order** `AMLS`

[illegible] $A \in \mathbb{C}^{n\times n}$, [illegible] $n_B < n$, $m_S < n$,
[illegible] n_e [illegible]
[illegible] n_e [illegible] A.

1. [illegible] $\mathtt{B} = \mathtt{A}(1:\mathtt{n_B}, 1:\mathtt{n_B})$, $\mathtt{C} = \mathtt{A}(\mathtt{n_B}+1:\mathtt{end}, \mathtt{n_B}+1:\mathtt{end})$,
   $\mathtt{E} = \mathtt{A}(1:\mathtt{n_B}, \mathtt{n_B}+1:\mathtt{end})$.
2. [illegible] $R^*R = B$.
3. [illegible] $S = C - E^*B^{-1}E$ [illegible] R.
4. [illegible] $K = I + (E^*B^{-1})(B^{-1}E)$ $R = (E^*B^{-1})B^{-1}(B^{-1}E)$
   [illegible] L.
5. [illegible] m_S [illegible] U_S
   [illegible] (25) [illegible] (26).
6. [illegible] m_B [illegible] V_B *of* B.
7. [illegible] Z [illegible] (28).
8. [illegible] n_e [illegible] $(Z^*AZ)x = (Z^*Z)x$.

Consider now the effect of adding the vectors (27). We are looking again at the distance between u^B, which is the top part of the exact eigenvector, and the closest vector from the space of approximants X^B. Let $\hat{u}^B$ be as in the previous section and consider the vector $u^{(2)} = -B^{-2}Eu^S$. Assuming that the expansion (21) is available, then

$$u^B - \hat{u}^B - \lambda u^{(2)} = -\lambda^2 \, (B - \lambda I)^{-1} B^{-2} \, Eu^S = \sum_{k=1}^{N_B} \frac{\lambda^2 \alpha_k}{(\mu_k - \lambda)\mu_k^2} v_k.$$

Therefore, the distance of u^B from the space of approximants X^B is such that

$$dist(u^B, X^B) = \min_{v \in \mathtt{span}\{V_B\}} \|u^B - \hat{u}^B - \lambda u^{(2)} - v\|_2$$
$$\leq |\lambda|^2 \left(\sum_{k>m_B} \frac{|\alpha_k|^2}{|\mu_k - \lambda|^2 \ |\mu_k|^4} \right)^{1/2}$$

and therefore,

$$dist(u^B, X^B) \leq \max_{k>m_B} \frac{|\lambda|^2}{|\mu_k - \lambda| \ |\mu_k|^2} \|Eu^S\|_2. \tag{30}$$

Under the mild assumption that $\lambda < \mu_{m_B}$, we have the bound

$$dist(u^B, X^B) \leq \frac{|\lambda|^2}{|\mu_{m_B} - \lambda| \ |\mu_{m_B}|^2} \|Eu^S\|_2. \tag{31}$$

Concerning u^B, a comparison of the above bound with the bound (23) for the first order approximation, indicates that one may expect a good improvement when λ is small. Numerical experiments in section 8 will verify this prediction.

Concerning the source of errors, the situation is similar to the previous section. If we assume that instead of the exact bottom part u^S we use an approximation $u^S + \delta$, with $\|\delta\|$ being small, and we employ the expansion $E\delta = \sum_{k=1}^{N_B} \xi_k v_k$, then

$$u^B - \hat{u}^B - \lambda u^{(2)} = -\lambda^2 \ (B - \lambda I)^{-1} B^{-2} \ Eu^S = \sum_{k=1}^{N_B} \left(\frac{\lambda^2 \alpha_k}{(\mu_k - \lambda)\mu_k^2} - \frac{\xi_k}{\mu_k^2} \right) v_k,$$

which again leads to the conclusion that a small error $\|\delta\|$ will not severely affect the accuracy of the `AMLS` projection. In particular, based on the above relation, for the distance $dist(u^B, X^B)$ we can show that

$$dist(u^B, X^B) \leq \left(\sum_{k>m_B} \frac{|\lambda|^4 |\alpha_k|^2 + |\xi_k|^2 |\mu_k - \lambda|^2 - 2|\lambda^2 \alpha_k \xi_k (\mu_k - \lambda)|}{|\mu_k - \lambda|^2 \ |\mu_k|^4} \right)^{1/2}, \tag{32}$$

which reduces to (31) for small enough $\|\delta\|$.

Computational considerations. In order to compute the Schur complement S we need to compute the Cholesky factorization of $B = R^* R$, and then solve upper and lower triangular systems with p right-hand sides in order to compute $B^{-1}E$ (see the definition for matrix (1)). The previous computation is the same that is required in the original `AMLS` approach. Note that B is sparse and block diagonal. In fact, in the multilevel version of `AMLS`, factoring B with a sparse direct solver can be realized with a form of the nested dissection algorithm [9]. The second order method requires in addition the computation of $B^{-1}(B^{-1}E)$. Assuming that the result is computed as a dense matrix of size $n \times p$ and that the factors of B have $nnz(B_{fill})$ nonzero entries then this computation will cost an additional $p \times nnz(B_{fill})$ operations (p additional backward-forward solves with B). The solution of the generalized eigenvalue problem (26) is of dimension $2p$ with a cost of at most $O(p^3)$. However, note that in practice p is much smaller than the size n of the original problem. In the multilevel version of the method, we would need to recursively repeat the above calculations for each of the diagonal blocks of B which very quickly become much smaller than the original matrix A.

6. Expanding the projection space with Krylov subspaces. Section 4 described AMLS as a projection technique which uses expanded subspaces of the form (20) to extract Ritz values and vectors. We denote by $\mathcal{V}_S$ the subspace

$$\mathcal{V}_S = \mathtt{span}\left\{ \begin{pmatrix} -B^{-1}Eu_j^S \\ u_j^S \end{pmatrix} \right\}, \tag{33}$$

where u_j^S are eigenvectors of the generalized eigenvalue problem (10). In this section we propose a different approach that is based, however, on similar reasoning. Observe that, ideally, the top part of $\mathcal{V}_S$ should be $-(B-\lambda I)^{-1}Eu_j^S$. Therefore, instead of attempting to compensate for the difference $(B-\lambda I)^{-1} - B^{-1}$, we can approximate the resolvent $(B-\lambda I)^{-1}$ itself. The key is to expand the subspace $\mathcal{V}_S$ with the vectors $[V_{\mathcal{K}}; 0]$, where $V_{\mathcal{K}}$ is an orthonormal basis for the Krylov subspace $\mathcal{K}_m(B^{-1}, EU_S)$ and U_S is a matrix of approximate eigenvectors of (10). Algorithm 6.1 is a description of a method based on this approach, which will be subsequently called Krylov AMLS. Observe that as in standard AMLS the block Gaussian eliminator matrix U (line 4) is never formed. Instead, a forward-backward solve with the factors of B is applied where needed, since we assume that B has been factored at the outset.

For simplicity, we examine the case where U_S has just one column. The error in the eigenvector of (2) will be of the order of the distance

$$\|(B-\lambda I)^{-1}Eu_j^S - u\|, \quad \text{where} \quad u \in \mathcal{K}_m(B^{-1}, Eu_j^S).$$

Note that $u = P_m(B^{-1})Eu_j^S$ for a certain polynomial P_m of degree $m-1$. If X^B denotes again the restriction to the B-part of the space of approximants, which in the present case is equal to $\mathcal{K}_m(B^{-1}, Eu_j^S)$, then expanding the resolvent $(B-\lambda I)^{-1}$ yields,

$$dist(u^B, X^B) = \min_{\gamma_k} \left\| \left(\sum_{k=0}^{\infty} \lambda^k B^{-k-1} - \sum_{k=0}^{m-1} \gamma_k B^{-k} \right) Eu_j^S \right\|.$$

Let $\mu_{\min}$ be the smallest eigenvalue of B. Then, notice that we can select the coefficients γ_k in order to exactly match the first $m-1$ terms of the Neumann series of the resolvent. Thus we have

$$dist(u^B, X^B) \leq \frac{1}{\mu_{\min} - \lambda} \left(\frac{\lambda}{\mu_{\min}} \right)^{m-1} \|Eu_j^S\|. \tag{34}$$

Therefore, if the ratio $\lambda/\mu_{\min}$ is small, then we can expect a very small distance $\|(B-\lambda I)^{-1}Eu^S - \mathcal{K}_m(B^{-1}, Eu_j^S)\|$. However, we must note that in practice we only have approximations to the eigenvalues and eigenvectors of the generalized eigenvalue problem (10). Similar to the previous sections, let us now assume that instead of an exact bottom part we use an approximate $u_j^S + \delta$, where u_j^S is exact and $\|\delta\|$ is small. The new distance $dist(u^B, X^B)$ now satisfies

$$dist(u^B, X^B) = \min_{\gamma_k} \left\| \left(\sum_{k=0}^{\infty} \lambda^k B^{-k-1} - \sum_{k=0}^{m-1} \gamma_k B^{-k} \right) Eu_j^S - \sum_{m=0}^{m-1} \gamma_k B^{-k} E\delta \right\|$$

$$\leq \min_{\gamma_k} \left\| \left(\sum_{k=0}^{\infty} \lambda^k B^{-k-1} - \sum_{k=0}^{m-1} \gamma_k B^{-k} \right) Eu_j^S \right\| + \left\| \sum_{m=0}^{m-1} \gamma_k B^{-k} E\delta \right\|. \tag{35}$$

ALGORITHM 6.1. **Krylov AMLS**

[illegible] $A \in \mathbb{C}^{n\times n}$, [illegible] $n_B < n$, $m_S < n$, m_K,
[illegible] n_e [illegible]
[illegible] n_e [illegible] A.

1. [illegible] $\mathtt{B} = \mathtt{A}(1:\mathtt{n_B}, 1:\mathtt{n_B})$, $\mathtt{C} = \mathtt{A}(\mathtt{n_B}+1:\mathtt{end}, \mathtt{n_B}+1:\mathtt{end})$,
   $\mathtt{E} = \mathtt{A}(1:\mathtt{n_B}, \mathtt{n_B}+1:\mathtt{end})$.
2. [illegible] $R^*R = B$.
3. [illegible] $S = C - E^*B^{-1}E$ [illegible] R.
4. [illegible] $U = [I, -B^{-1}E; 0, I]$.
5. [illegible] $M_S = I + (E^*B^{-1})(B^{-1}E)$ [illegible] R.
6. [illegible] m_S [illegible] $Su_j^S = M_S u_j^S$ [illegible] $U_S = [u_1^S, \ldots, u_{m_S}^S]$.
7. [illegible] V_K [illegible] $\mathcal{K}_{m_K}(B^{-1}, EU_S)$.
8. [illegible] $Z_K = [V_K, 0; 0, U_S]$.
9. [illegible] n_e [illegible] $(Z_K^*U^*AUZ_K)x = (Z_K^*U^*UZ_K)x$.

Consider again the expansion of $E\delta = \sum_{i=1}^{N_B} \xi_i v_i$ in the eigenbasis of B. We have that

$$\left\| \sum_{m=0}^{m-1} \gamma_k B^{-k} E\delta \right\| = \left\| \sum_{k=0}^{m-1} \sum_{i=1}^{N_B} \gamma_k \xi_i B^{-k} v_i \right\| \tag{36}$$

$$= \left\| \sum_{i=1}^{N_B} \xi_i \left(\sum_{k=0}^{m-1} \gamma_k \mu_i^{-k} \right) v_i \right\|. \tag{37}$$

Setting again γ_k in order to exactly match the first $m-1$ terms of the Neumann series of the resolvent we see that apart from the small coefficient ξ_i, we have

$$\sum_{k=0}^{m-1} \gamma_k \mu_i^{-k} = \sum_{k=0}^{m-1} \lambda^k \mu_i^{-k} = \frac{1 - (\frac{\lambda}{\mu_i})^{m-1}}{1 - \frac{\lambda}{\mu_i}},$$

and thus the distance $dist(u^B, X^B)$, can be large for eigenvalues λ that are very close to eigenvalues μ_i of B.

The bound (34) justifies the use of the block Krylov subspace $\mathcal{K}_m(B^{-1}, EU_S)$, where U_S is a matrix of eigenvectors u_j^S of (10). Numerical experiments in section 8 will confirm that using block Krylov subspaces will result in significantly improved approximations of the smallest eigenvalues relative to the approximations of standard AMLS.

Computational considerations. As in the original AMLS method, in order to compute the Schur complement S we need to compute the Cholesky factorization of $B = R^*R$, and then solve upper and lower triangular systems with p right-hand sides. The same comments as before apply for the cost of factoring B. Instead of eigenvectors of B associated with the smallest eigenvalues, the block Krylov method requires the Krylov subspace $\mathcal{K}_m(B^{-1}, EU_S)$. This can be computed by means of the (block) Lanczos method [20]. Since we already have available the Cholesky decomposition of B, then each of the m steps of Lanczos will require the solution of m_S upper and lower triangular system solves that entail a total cost of $m \times m_S \times nnz(B_{fill})$ operations.

However, it is well-known that in the Lanczos algorithm, the vectors of the Krylov basis rapidly loose orthogonality and thus some form of reorthogonalization is often required. Since the size of B is $n-p$, where p is the size of the Schur complement, the cost of reorthogonalization can reach $O((n-p)(mm_S)^2)$. On the other hand, in the practical multilevel version of the method, the computation of the Krylov basis will be performed only at the very last level l of subdivisions on submatrices $B_{i,l}$ that are much smaller than the original matrix A. Remember that in the original `AMLS` method we need to compute the smallest eigenvalues of the same submatrices $B_{i,l}$, a computation that requires again the construction of Krylov subspaces with $B_{i,l}^{-1}$. Therefore, there is no reason to expect the overall cost of the Krylov `AMLS` method to be noticeably higher than that of the original `AMLS` method.

7. Combining AMLS with second order and Krylov AMLS. In the two previous sections we presented improvements of the standard method that are based on our two basic observations concerning the approximation scheme of `AMLS`: a) second order approximations to the nonlinear eigenvalue problem (11) and b) block Krylov basis in the projection step. It is therefore natural to consider combinations of these improvements. In particular, the projection matrix (28) can be substituted by

$$Z = \begin{pmatrix} V_{\mathcal{K}} & -B^{-1}EU_S & -B^{-2}EU_S \\ 0 & U_S & 0 \end{pmatrix}, \tag{38}$$

where instead of the matrix of eigenvectors V_B we use the Krylov basis $V_{\mathcal{K}}$ for the block Krylov subspace $\mathcal{K}_m(B^{-1}, EU_S)$. The effects of this combination will be further explored in the numerical experiments section.

Observe that in the second order `AMLS` the projection basis for the approximation of the $B-$part of the eigenvectors of the original matrix A is augmented by directions in the vectors $-B^{-2}EU_S$, which clearly belong to the block Krylov subspace $\mathcal{K}_m(B^{-1}, EU_S)$. Thus, the projection step of the second order `AMLS` can be viewed as a special case of the projection step of Krylov `AMLS`. However, observe that in the case when U_S has several columns the cost for the computation of the Krylov basis $V_{\mathcal{K}}$ can be uneconomical. Thus, a practical application of the above scheme may limit the number of initial vectors from the columns of the matrix U_S. Clearly in this case, the projection step of the block Krylov method will differ from the projection step of the second order method. Using the basis (38) (where $V_{\mathcal{K}}$ utilizes only a subset of initial vectors from EU_S) attempts to combine the advantages of the improvements suggested in the two previous sections.

An alternative type of combination occurs when in Krylov `AMLS` we augment the approximation subspace of the projection step with eigenvectors of B associated with its smallest eigenvalues. The reasoning for such a combination is based on the fact that in order for the block Krylov subspace $\mathcal{K}_m(B^{-1}, EU_S)$ to adequately approximate the resolvent $(B-\lambda I)^{-1}$ for several different eigenvalues λ, without significantly increasing the Krylov steps m, we need to include many eigenvectors in the starting vectors matrix U_S. In an attempt to avoid this we can insert eigenvectors of B in the subspace as in standard `AMLS`. Thus, the projection matrix is

$$Z = \begin{pmatrix} V_B & V_{\mathcal{K}} & 0 \\ 0 & 0 & U_S \end{pmatrix}, \tag{39}$$

where V_B is a matrix of eigenvectors of B and $V_{\mathcal{K}}$ is an orthonormal basis for the block Krylov subspace. The projected eigenproblem is $(Z^*U^*AUZ)x = (Z^*U^*UZ)x$, where Z is as defined above and U is the block Gaussian eliminator matrix (4).

Finally, we can consider a combination of all of the above. The matrix of smallest eigenvectors U_S of (11) is approximated by solving for the smallest eigenvalues of (25). Define the projection basis

$$Z = \begin{pmatrix} V_B & V_{\mathcal{K}} & -B^{-1}EU_S & -B^{-2}EU_S \\ 0 & 0 & U_S & 0 \end{pmatrix}, \tag{40}$$

and approximate the smallest (in modulus) eigenvalues of A by the smallest (in modulus) eigenvalues of the projected problem $(Z^*AZ)x = \lambda(Z^*Z)x$. Matrices V_B and $V_{\mathcal{K}}$ correspond to the smallest eigenvectors of B and to the block Krylov subspace $\mathcal{K}_m(B^{-1}, E\hat{U}_S)$, respectively, where the columns of $\hat{U}_S$ form a subset of the columns of U_S.

At this point it is important to emphasize that the main goal of this paper has been to provide an algebraic framework for the analysis of `AMLS`. This viewpoint and the related analysis lead to a few practical improvements of the basis scheme. However, it must be understood that the full potential of the method, as it was demonstrated in [16], lies in its recursive nature. This attribute of the method is particularly appealing as it enables the computation of a large number of eigenvalues of very large matrices. The main difference between `AMLS` and its competitors, the Lanczos based methods, is that `AMLS` is capable of building large projection bases, while requiring a much lower reorthogonalization cost. On the other hand, it should also be clear that efficient implementations of `AMLS` are far more complex than those of competitive approaches [13, 23, 24].

8. Numerical experiments. The goal of the numerical tests described in this section is to verify the theoretical predictions of sections 4, 5, and 6. Furthermore, we investigate the application of the combinations suggested in the previous section.

8.1. AMLS and Krylov AMLS. Bounds (23) and (34) suggest that if the smallest eigenvalue $\mu_{\min}$ of B is much larger than the smallest eigenvalue λ of matrix A, then the Krylov subspace framework in `AMLS` will yield better results than standard `AMLS`. We tested this prediction in the following experiment. The test matrix is `BCSSTK11` from the Harwell–Boeing collection (available from the Matrix Market[1]; see [6]). This is an SPD matrix of size $n = 1473$, which has $\texttt{nnz} = 34241$ nonzero entries. The matrix was symmetrically reordered using the nested dissection graph partitioning algorithm so that the matrix B will have block diagonal structure with two blocks (corresponding to two subdomains).

Figure 2 illustrates the nonzero structure of the matrix before (left) and after the partitioning (right). The sizes of the resulting two blocks of B are $n_1 = 696$ and $n_2 = 683$. The smallest eigenvalue of the matrix is $\lambda \approx 2.9641$ and the smallest eigenvalue of B is $\mu_{\min} \approx 40.3973$, so that $\lambda/\mu_{\min} \approx 0.0734$. We computed the five smallest eigenvalues ($m_S = 5$) and respective eigenvectors $u_j^S, j = 1, \ldots, 5$ of the generalized Schur eigenvalue problem (8). We then computed the $m_B = 10, 20, 30$, and 40 smallest eigenvalues and corresponding eigenvectors of the block diagonal simple eigenvalue problem (7). For the Krylov subspace framework in `AMLS`, we computed a basis for the block Krylov subspace $\mathcal{K}_m(B^{-1}, EU_S)$, where the columns of U_S are the eigenvectors u_j^S, for $m_K = 2, 4, \ldots, 8$. Figure 3 illustrates the absolute relative error obtained for the 5 smallest eigenvalues of the matrix for the selected values of m_K and m_B. We selected these values so that the dimension of the projection space will be

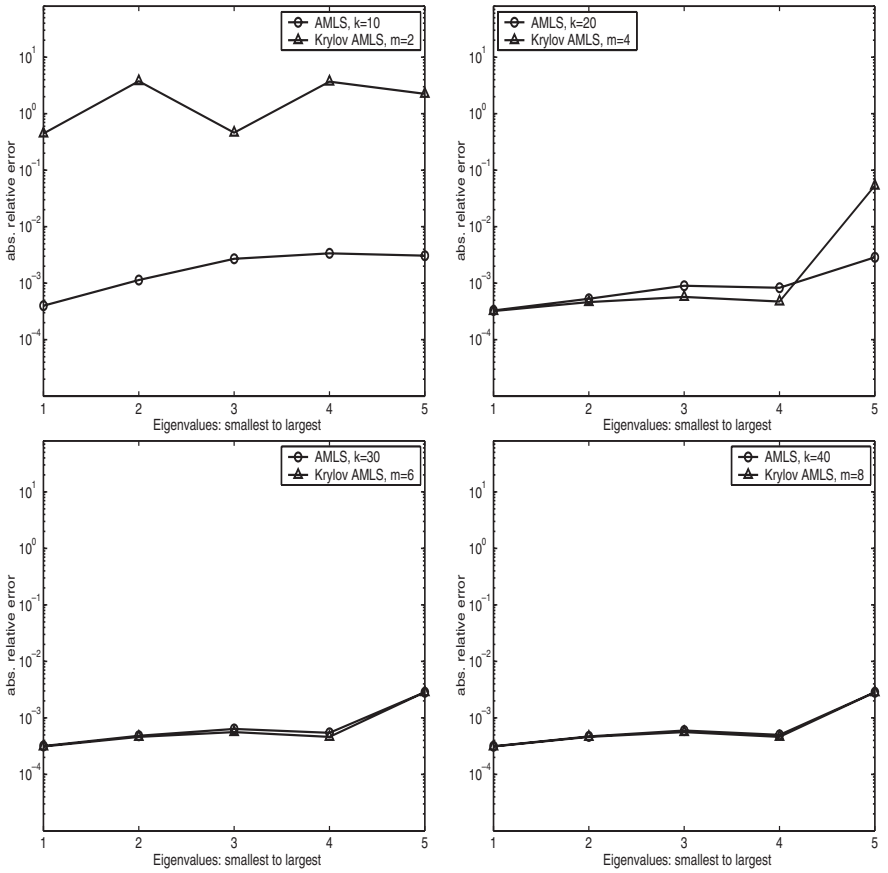

FIG. 4. *Relative errors for the five smallest eigenvalues of matrix* `BCSSTK11` *computed, without a nested dissection reordering, by* `AMLS` *and Krylov* `AMLS` *for projection subspace dimensions equal to* $k = 10, 20, 30, 40$.

equal in all cases. Observe that Krylov `AMLS` outperforms standard `AMLS` in all cases except when the dimension of the Krylov subspace is very small. It is interesting to note that Krylov `AMLS` for $m_K = 4$ (where the dimension of the projection subspace was 25) clearly outperforms standard `AMLS` for $m_B = 40$ (where the dimension of the projection subspace was 45).

We now consider the case where the ratio $\lambda/\mu_{\min}$ is close to 1. Observe that from interlacing properties of eigenvalues of Hermitian matrices, this ratio cannot be larger than 1. For this reason, we now fail to perform the nested dissection partitioning of the original matrix. As in the previous case we select the size of B to be $n_B = n_1 + n_2 = 1379$. In this case $\mu_{\min} \approx 3.3975$ and thus $\lambda/\mu_{\min} \approx 0.8724$. Figure 4 illustrates the absolute relative error obtained for the 5 smallest eigenvalues of the matrix for the same span of values of m_B and m_K as in the previous experiments. It is clear that in this case the gains of the Krylov `AMLS` framework compared to standard `AMLS` are not as compelling as when the ratio $\lambda/\mu_{\min}$ is much smaller than 1.

8.2. Experiments with the second order AMLS. In order to test the second order `AMLS` described in section 5, we used matrix `BCSSTK11` reordered as in the

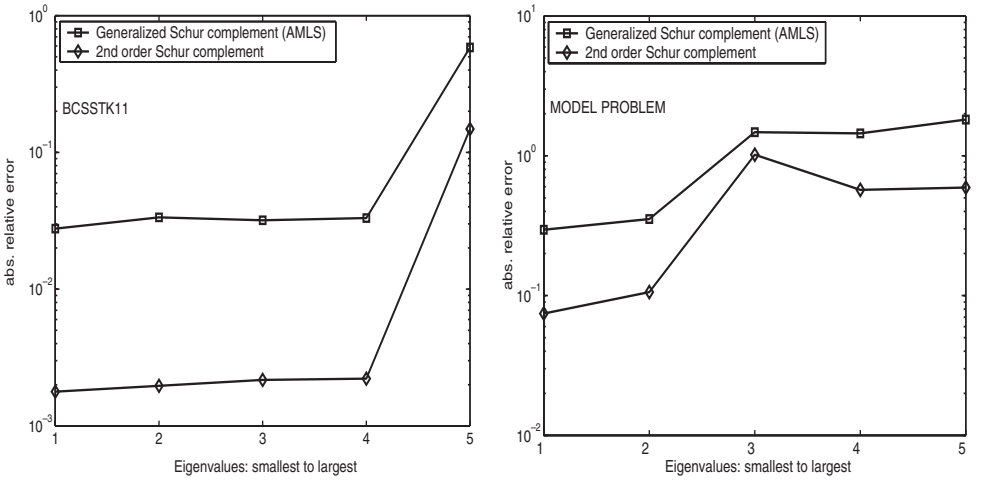

FIG. 5. *Absolute relative errors for the five smallest eigenvalues of matrix* `BCSSTK11` (*left*) *and of the model problem* (3)*, as they were approximated by the five smallest eigenvalues of* (16) *and by the five smallest, in modulus, eigenvalues of* (26).

previous experiment. A second test matrix results from a 5-point stencil discretization of the simple model problem (3) on the unit square, with $n_x = n_y = 30$ internal mesh nodes in each direction, so that the matrix size is $n = 900$. The matrix is reordered in order for the principal submatrix B to be block diagonal with two blocks and size $n_B = 840$.

The second order polynomial eigenvalue problem (25) is solved via the linearized problem (26). We first show that we are able to extract improved approximations to the smallest eigenvalues of the nonlinear Schur eigenvalue problem (13) by means of the second order method. Figure 5 illustrates the absolute relative error for the approximations of the five smallest eigenvalues of (13) (for both test matrices), which correspond to the five smallest eigenvalues of the original matrices. It is clear that the second order approximation produces improved approximations. We now use these approximations, and the corresponding eigenvectors, in the Rayleigh–Ritz projection with the basis (28).

For standard `AMLS` we used an increasing number m_B of added eigenvectors of B: $m_B = 20, 40, 60$, and 100. On the other hand, for the second order `AMLS` we used $m_B = 10$ eigenvectors of B and $m_S = 2 \times 10$ additional vectors: 10 for $B^{-1}EU_S$ and another 10 for $B^{-2}EU_S$. Thus, in all cases the matrix U_S had 10 columns which are eigenvectors corresponding to the smallest eigenvalues (in modulus) of the quadratic eigenvalue problem (25). Figure 6 illustrates the results for both test matrices (left: `BCSSTK11`, right: model problem). The accuracies achieved by the second order method are significantly better than those of the standard method. Notice in particular that for `BCSSTK11`, the error achieved by the second order `AMLS` method is of the order of the square of that obtained by standard `AMLS`, even when this method utilizes as many as $m_B = 100$ eigenvectors of B.

8.3. Combining the second order AMLS with Krylov subspaces. We now experiment with the combinations of the second order `AMLS` with Krylov subspaces. Note that this entails computing a block Krylov subspace with B^{-1} rather

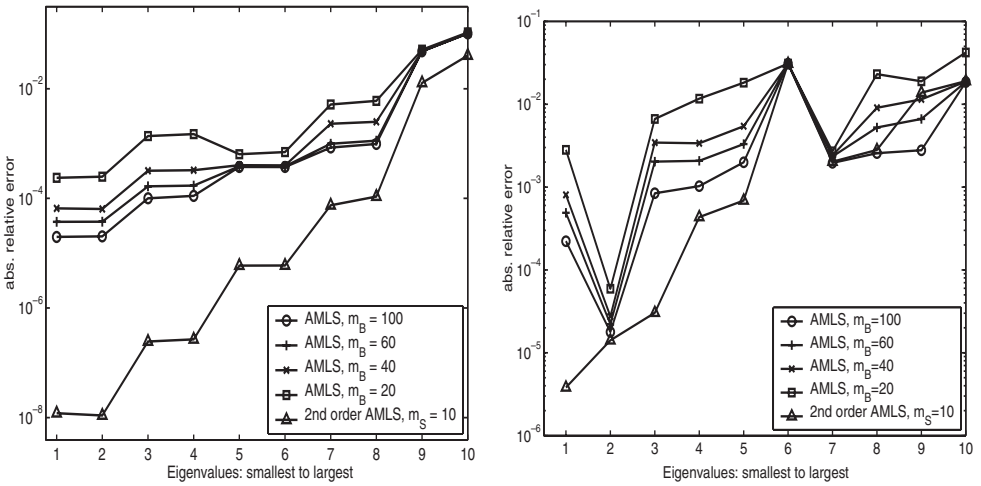

FIG. 6. *Absolute relative errors for the* 10 *smallest eigenvalues computed by standard* `AMLS` *and second order* `AMLS` $(-\triangle-)$ *for matrices* `BCSSTK11` (*left*) *and for the model problem* (*right*).

than a set of eigenvectors of B (cf the algorithmic description in Algorithm 5.1). We use matrix `BCSSTK11` and the model problem matrix as in the previous section.

We begin with the computation of the two smallest eigenvalues. We use five vectors in U_S, corresponding to the five smallest in modulus eigenvalues of (25). For the second order `AMLS` we use ten eigenvectors of B, corresponding to its ten smallest eigenvalues, while in the block Krylov version we use $E[u_1^S, u_2^S]$ as starting vectors, where $u_j^S, j = 1, 2$ correspond to the two smallest eigenvalues in modulus of (25). We then compute a basis of dimension ten; Figures 7 and 8 (left) illustrate the results. It is clear that introducing Krylov basis vectors, instead of eigenvectors of B, yields improved results which are especially pronounced for the smallest eigenvalues in the case of the model problem. For larger eigenvalues, however, the situation is reversed. This is due to the fact that the starting vectors of the block Krylov subspace are poor in directions towards $Eu_j^S, j = 1, \ldots$.

We then used five eigenvectors from (25) and computed a Krylov subspace of dimension twenty five. For comparison, we also augmented the partial eigenbasis of B that we use in the second order `AMLS` to a total of 25 eigenvectors. Figures 7 and 8 (right) illustrate the results. It is clear that in this case the additional starting vectors in the block Krylov subspace have a positive effect on improving the error for the corresponding largest eigenvalues, while the approximations for the two smallest eigenvalues remain practically unchanged. Compared to using eigenvectors of B, we observe that for the two smallest eigenvalues the block Krylov subspace approach remains in general superior, though the difference is not as pronounced as in the previous case. This is due to the increased dimension of the projection basis. On the other hand, for the larger eigenvalues we witness similar approximations for both approaches. It appears that in order to achieve an improved approximation for larger eigenvalues we need to either use more starting vectors for the block Krylov basis, or to use a significantly larger basis while keeping the number of starting vectors low. However, both of the above approaches will lead to increased computational cost.

8.4. Combining AMLS and Krylov AMLS. Finally, we experiment with combinations of the Krylov and second order `AMLS` with the original `AMLS` scheme. In

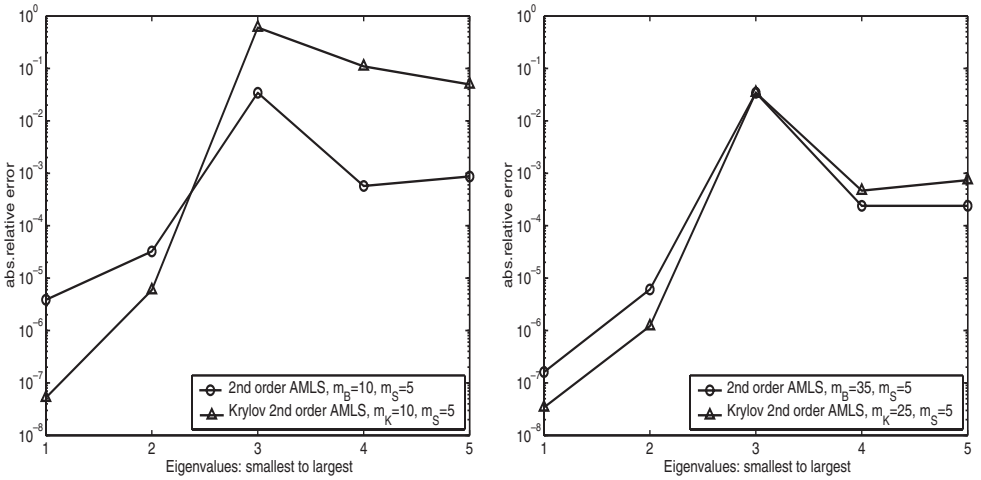

FIG. 7. *Model problem: absolute relative errors for the* 5 *smallest eigenvalues of* (3) *computed by the second order* AMLS $(-\mathrm{o}-)$ *and second order* AMLS *with block Krylov subspace* $(-\triangle-)$.

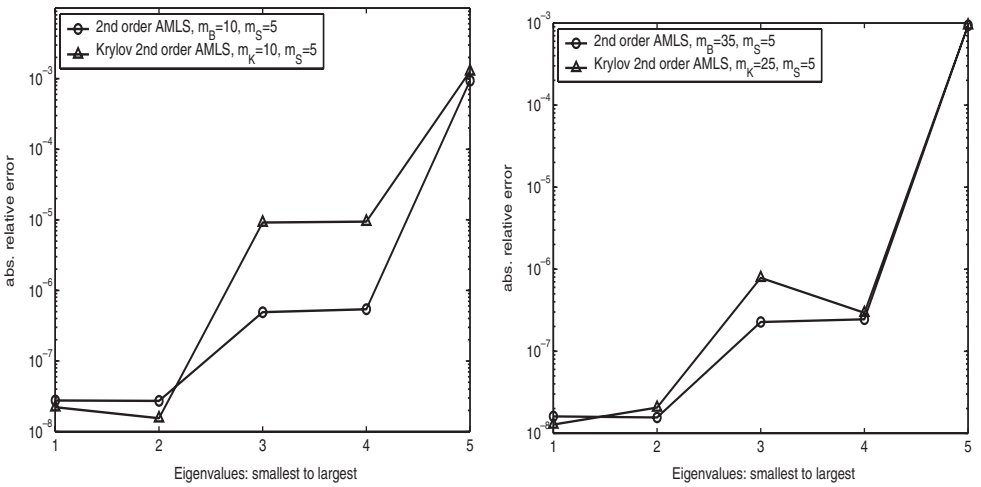

FIG. 8. BCSSTK11*: absolute relative errors for the* 5 *smallest eigenvalues of* (3) *computed by the second order* AMLS $(-\mathrm{o}-)$ *and second order* AMLS *with block Krylov subspace* $(-\triangle-)$.

Figure 4 (top-right) we observe that for larger eigenvalues of the matrix it is possible that Krylov AMLS may be inferior to standard AMLS. This is now explored further. We experimented with the same matrices (as they were reordered).

We first see how introducing eigenvectors of B, i.e., using the projection basis (38), can improve Krylov AMLS. Let U_S contain eigenvectors corresponding to the ten smallest eigenvalues of (16) and $V_{\mathcal{K}}$ be an orthonormal basis for $\mathcal{K}_{m_K}(B^{-1}, E[u_1^S, u_2^S])$ with $m_K = 5$. Thus, $V_{\mathcal{K}}$ has ten columns. Now let V_B contain eigenvectors that correspond to the ten smallest eigenvalues of B. Figure 9 (left column, top plot for the model problem and bottom plot for BCSSTK11) illustrates the absolute relative errors for the approximations of the ten smallest eigenvalues of the test matrices as they were computed by standard AMLS and Krylov AMLS. In both cases the dimension

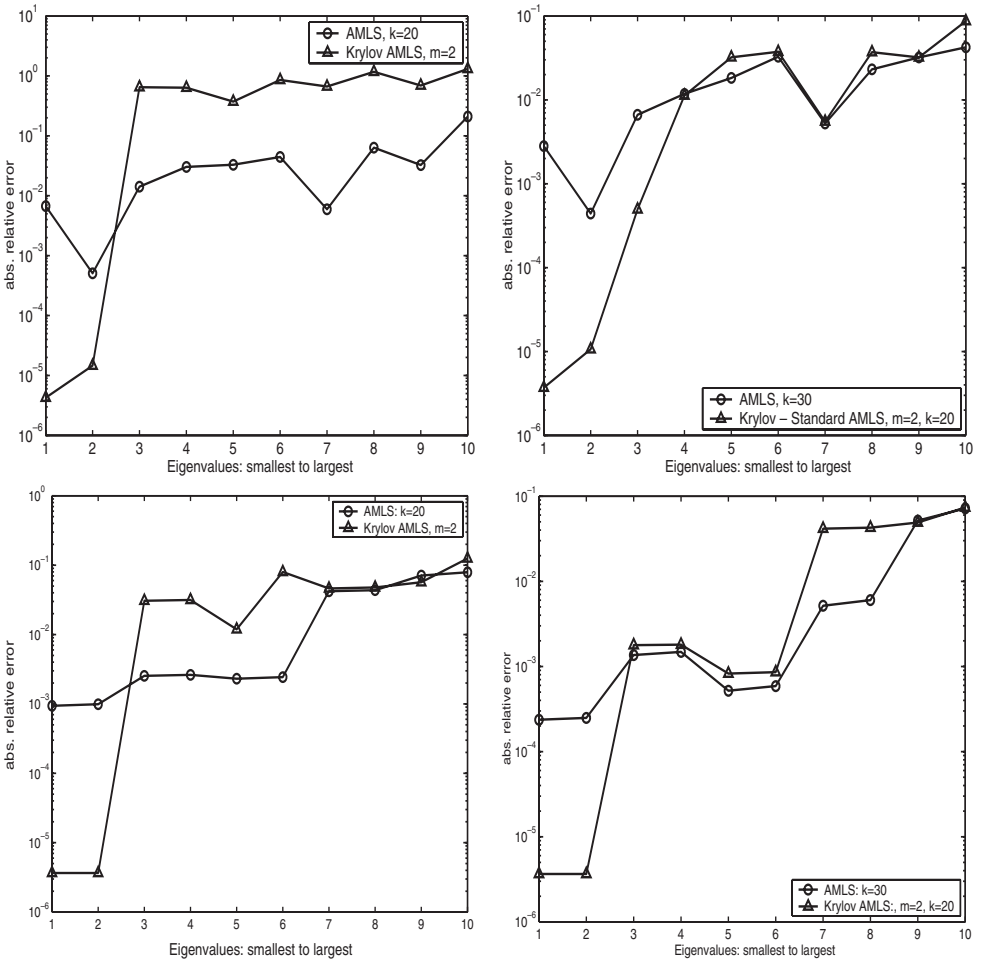

FIG. 9. *Left plots: Krylov* `AMLS` $(-\triangle-)$ *vs. standard* `AMLS` $(-\mathtt{o}-)$ *for the model problem* (3) (*up*) *and for matrix* `BCSSTK11` (*down*). *Right plots: Combination of Krylov* `AMLS` *and* `AMLS` $(-\triangle-)$ *vs. standard* `AMLS` $(-\mathtt{o}-)$ *for the model problem* (3) (*up*) *and for matrix* `BCSSTK11` (*down*).

of the projection space was equal to twenty. It is evident that for larger eigenvalues Krylov `AMLS` is inferior. This is due to the fact that the starting matrix $E[u_1^S, u_2^S]$ has a very poor representation of eigenvectors associated with the larger eigenvalues. We then added to Krylov `AMLS` ten eigenvectors of B that correspond to its smallest eigenvalues. For comparison, in standard `AMLS` we use twenty eigenvectors of B so that the dimension of the projection spaces would be equal to thirty in both cases. The right column plots of Figure 9 illustrate the results. The new combination is now capable of obtaining errors similar to those of standard `AMLS` for the larger eigenvalues while achieving much better results for the smallest eigenvalues.

Finally, Figure 10 illustrates the comparison of standard `AMLS` with the Krylov-second order `AMLS` hybrid (40). We have used ten eigenvectors in U_S, computed by the second order approximation, and a block Krylov basis $\mathcal{K}_{m_K}(B^{-1}, E[u_1^S, u_2^S])$ with starting vectors corresponding to the two smallest singular values and $m_K = 5$. Furthermore, we added the $m_B = 10$ smallest eigenvalues of B. Therefore, the

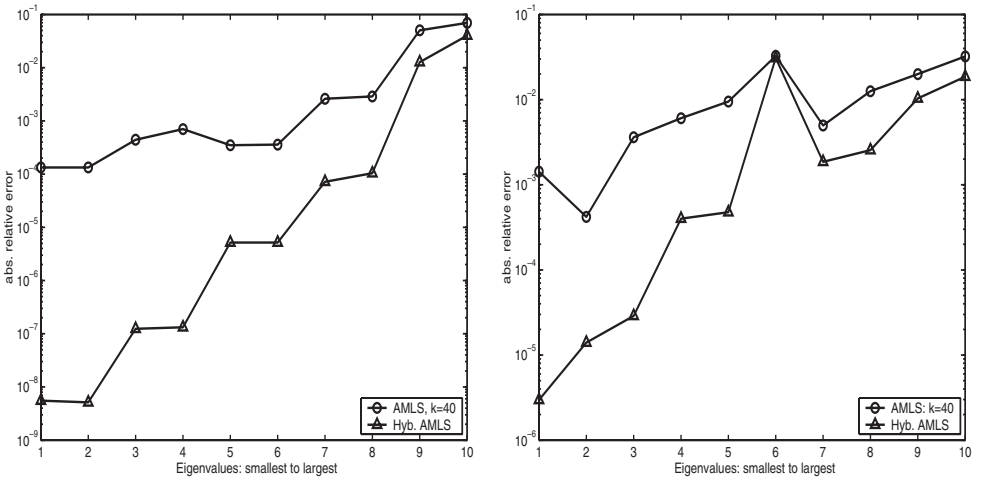

FIG. 10. `AMLS` *compared with the Krylov-second order* `AMLS` *hybrid* (40) *for* `BCSSTK11` (*left*) *and for the model problem* (*right*).

dimension of the projection basis (40) was equal to forty. For comparison, we employed standard `AMLS` with $m_S = 10$ smallest eigenvectors of (8) and $m_B = 30$ of the smallest eigenvalues of B. Clearly, the proposed hybrid outperforms the original method by combining all the improvements investigated in the previous sections.

The practical application of the above hybrids will depend on the particular situation. A large block of initial vectors in Krylov `AMLS` will give better accuracy, but this comes with increased computational costs. However, adding a few eigenvectors of B may help keep this added cost moderate. We believe that a careful selection of the dimensions of the various subspaces can lead to a successful method with controlled computational cost.

9. Conclusion. In recent years, `AMLS` has been successfully used in solving extremely large eigenvalue problems in structural dynamics which were intractable using the best alternative techniques such as shift-and-invert Lanczos. Therefore, the prospect of using `AMLS` in other application areas, such as computational materials science and nanotechnology appears particularly appealing. However, the levels of accuracy required in the latter applications are significantly higher than those required in the original application.

Thus, our primary goal in this paper was to investigate the approximation mechanism behind `AMLS` and in order to do so we have chosen to use a purely algebraic framework. `AMLS` can be viewed as a method which exploits a first order approximation to a nonlinear eigenvalue problem to extract a good subspace for a Rayleigh–Ritz projection process. This technique leads to approximations from a single Schur complement derived from a domain decomposition of the physical problem. Exploiting this observation, we have shown several possible enhancements to the original scheme. It is hoped that further improvements will be possible by exploiting similar approaches. For example, it would be interesting to explore the feasibility of an iterative scheme based on `AMLS`. Currently, `AMLS` is a one-shot algorithm in the sense that certain approximate eigenvectors are built from the last level up to the highest level and no further refinements are made. The current framework does not permit one to iteratively refine these approximations. This is an important shortcoming of the method

since eigenvalues obtained in this manner may not yield a satisfactory accuracy for certain applications.

A forthcoming paper will explore remedies which are based on new ways of exploiting the `AMLS` approximation mechanism [4]. In particular, `AMLS` can be viewed as an elaborate form of a shift-and-invert technique which uses only the zero shift. As was observed throughout our experiments, this leads to a diminishing accuracy for the larger eigenvalues. Improved approximations for the larger eigenvalues can be obtained from using other shifts, and this leads to developing strategies based on employing multiple shifts [4].

Acknowledgments. The authors would like to thank the referees for helpful comments and suggestions. We would also like to thank C. Yang, H. Voss, E. Gallopoulos, A. Stathopoulos, and P. Arbenz for insightful discussions concerning the practical application of the methods suggested in this paper.

While this paper was under review, the authors in [24] and [8] presented algebraic substructuring frameworks that, although related to the work presented here, are based on different settings.

PSEUDOSPECTRAL DIFFERENCING METHODS FOR CHARACTERISTIC ROOTS OF DELAY DIFFERENTIAL EQUATIONS*

D. BREDA†, S. MASET‡, AND R. VERMIGLIO†

Abstract. In [D. BREDA, S. MASET, and R. VERMIGLIO, *IMA J. Numer. Anal.,* 24 (2004), pp. 1–19.] and [D. BREDA, *The Infinitesimal Generator Approach for the Computation of Characteristic Roots for Delay Differential Equations Using BDF Methods*, Research report UDMI RR17/2002, Dipartimento di Matematica e Informatica, Università degli Studi di Udine, Udine, Italy, 2002.] the authors proposed to compute the characteristic roots of delay differential equations (DDEs) with multiple discrete and distributed delays by approximating the derivative in the infinitesimal generator of the solution operator semigroup by Runge–Kutta (RK) and linear multistep (LMS) methods, respectively. In this work the same approach is proposed in a new version based on pseudospectral differencing techniques. We prove the "spectral accuracy" convergence behavior typical of pseudospectral schemes, as also illustrated by some numerical experiments.

Key words. pseudospectral methods, delay differential equations, characteristic roots

1. Introduction.

The interest for delay differential equations (DDEs) is still growing in many application fields, since the introduction of the delay in the model enriches its dynamics and allows a closer and more accurate description of the real-life phenomena. In this paper we consider a system of m-dimensional linear (or linearized) DDEs with multiple discrete and distributed delays

$$y'(t) = L_0 y(t) + \sum_{l=1}^{k} L_l y(t-\tau_l) + \int_{-\tau}^{0} M(\theta) y(t+\theta) d\theta, \quad t \geq 0, \tag{1.1}$$

where $L_0, L_1, \ldots, L_k \in \mathbb{C}^{m\times m}$, $0 = \tau_0 < \tau_1 < \cdots < \tau_k = \tau$, and $M : [-\tau, 0] \to \mathbb{C}^{m\times m}$ is a piecewise smooth function. Indeed in the implementation of the method we write the distributed term as

$$\int_{-\tau}^{0} M(\theta) y(t+\theta) d\theta = \sum_{l=1}^{k} \int_{-\tau_l}^{-\tau_{l-1}} M_l(\theta) y(t+\theta) d\theta, \quad t \geq 0, \tag{1.2}$$

where every function M_l, $l = 1, \ldots, k$, is smooth. Delay systems such as (1.1) are particularly important in control theory, where the stability effects of delays are a crucial problem (see the recent survey [Ric03]). In the exhaustive monograph [Nic00] many graphical and analytical tests to this aim are reported, but they work only for particular classes of system (1.1).

*Received by the editors November 3, 2003; accepted for publication (in revised form) December 6, 2004; published electronically September 23, 2005.

This motivates our interest in the numerical computation of the characteristic roots of (1.1), i.e., the (infinitely many) roots of

$$\det(\Delta(\lambda)) = 0, \tag{1.3}$$

where

$$\Delta(\lambda) = \lambda I - \sum_{l=0}^{k} L_l e^{-\lambda\tau_l} - \int_{-\tau}^{0} M(\theta)e^{\lambda\theta}d\theta, \quad \lambda \in \mathbb{C}, \tag{1.4}$$

since it is well known that the zero solution of (1.1) is asymptotically stable if and only if these roots have a strictly negative real part.

Recently, numerical approaches for characteristic roots computation have been proposed, which are based on the discretization of either the solution operator associated with (1.1) or the infinitesimal generator of the solution operator semigroup.

We briefly recall that the solution operator $T(t)$, $t \geq 0$, associated with (1.1) is defined by

$$T(t)\varphi = y_t, \quad \varphi \in X,$$

where $X = C([-\tau, 0], \mathbb{C}^m)$ endowed with the maximum norm, y_t is the function

$$y_t(\theta) = y(t + \theta), \quad \theta \in [-\tau, 0],$$

and y is the solution of (1.1) with initial data $\varphi \in X$. The family $\{T(t)\}_{t\geq 0}$ is a C_0-semigroup with infinitesimal generator $\mathcal{A} : D(\mathcal{A}) \subseteq X \to X$ given by

$$\mathcal{A}\varphi = \varphi', \quad \varphi \in D(\mathcal{A}), \tag{1.5}$$

with domain

$$D(\mathcal{A}) = \left\{ \varphi \in X \mid \varphi' \in X \text{ and } \varphi'(0) = \sum_{l=0}^{k} L_l\varphi(-\tau_l) + \int_{-\tau}^{0} M(\theta)\varphi(\theta)d\theta \right\}. \tag{1.6}$$

So (1.1) can be restated as the following abstract Cauchy problem ([DGVLW95]):

$$\begin{cases} \dfrac{dy_t}{dt} = \mathcal{A}y_t, & t > 0, \\ y_0 = \varphi. \end{cases}$$

The following two important results ([DGVLW95], [HVL93]):

1. $\det(\Delta(\lambda)) = 0 \Leftrightarrow \lambda = \frac{1}{t}\ln\mu$, $\mu \in \sigma(T(t)) \setminus \{0\}$;
2. $\det(\Delta(\lambda)) = 0 \Leftrightarrow \lambda \in \sigma(\mathcal{A})$;

where $\sigma(\cdot)$ denotes the spectrum, suggest the idea to turn the characteristic roots approximation problem into a corresponding eigenvalue problem for suitable matrix discretization of either $T(t)$ (i.e., [illegible] approach) or $\mathcal{A}$ (i.e., [illegible] approach).

Engelborghs and Roose propose in [ER02] and [ER99] the solution operator approach via LMS time integration for system (1.1) without the distributed delay term. Their method computes approximations to the roots from a large, standard, and sparse eigenvalue problem and is implemented in the MATLAB package DDE-BIFTOOL for DDEs bifurcation analysis ([ELR02] and [ELS01]). The distributed

delay case is considered in [LER03] by using LMS methods and in [Bre03] by using RK methods.

The complete development of the infinitesimal generator approach first appears in [BMV03] and [Bre02] where a matrix approximation to $\mathcal{A}$ is obtained by discretizing the derivative in (1.5) by the RK or LMS method, respectively, ending up with a large and sparse eigenvalue problem as in [ER99].

This work continues the investigation along this line and proposes the infinitesimal generator approach via pseudospectral differencing methods (see [Tre00] and the bibliography therein). This technique involves the exact differentiation of interpolants at selected sets of points. The resulting differentiation matrix is nonsparse, but we can take advantage of the well known "spectral accuracy" to obtain a very accurate approximation with small matrix dimension. This behavior represents in fact, for sufficiently small tolerance, the outstanding advantage of this method compared to the previously cited discretization schemes.

The paper is structured as follows. Section 2 describes the pseudospectral approach. Section 3 is about convergence analysis of the method. In section 4 we discuss implementation issues. In section 5 we perform numerical experiments on test delay systems of type (1.1) to illustrate the properties of the new method and to critically compare it with LMS and RK discretization techniques.

2. The pseudospectral approach. To simplify the notation, we rewrite the system of DDEs (1.1) as follows:

$$y'(t) = f(y_t),$$

where

$$f(\varphi) = \sum_{l=0}^{k} L_l \varphi(-\tau_l) + \int_{-\tau}^{0} M(\theta)\varphi(\theta)d\theta, \quad \varphi \in X. \tag{2.1}$$

Given a positive integer N, let us consider the mesh Ω_N of $N+1$ distinct points in $[-\tau, 0]$

$$\Omega_N = \{\theta_{N,i},\ i = 0, 1, \dots, N\}$$

with $0 = \theta_{N,0} > \theta_{N,1} > \cdots > \theta_{N,N} \geq -\tau$. We replace the continuous space X by the space X_N of the discrete functions defined on the mesh Ω_N, i.e., any $\varphi \in X$ is discretized into the block-vector $x \in X_N$ of components $x_i = \varphi(\theta_{N,i}) \in \mathbb{C}^m$, $i = 0, 1, \dots, N$. Let $\mathcal{L}_N x$, $x \in X_N$, be the unique $\mathbb{C}^m$-valued interpolating polynomial of degree $\leq N$ with $(\mathcal{L}_N x)(\theta_{N,i}) = x_i$, $i = 0, 1, \dots, N$. Thus we approximate the infinitesimal generator $\mathcal{A}$ by the matrix $\mathcal{A}_N : X_N \to X_N$, called the spectral differentiation matrix, defined as follows:

$$\begin{cases} (\mathcal{A}_N x)_0 = f_N(\mathcal{L}_N x), \\ (\mathcal{A}_N x)_i = (\mathcal{L}_N x)'(\theta_{N,i}), \quad i = 1, 2, \dots, N, \end{cases} \tag{2.2}$$

where f_N is an approximation of f in which the distributed delay integral term in (2.1) is substituted for by a suitable interpolatory quadrature rule or f_N is equal to f in the case of the simple matrix function M for which the integral can be exactly computed.

By using the Lagrange representation of $\mathcal{L}_N x$ we obtain

$$\mathcal{A}_N = \begin{pmatrix} a_0 & a_1 & \cdots & a_N \\ d_{10} & d_{11} & \cdots & d_{1N} \\ \vdots & \vdots & \ddots & \vdots \\ d_{N0} & d_{N1} & \cdots & d_{NN} \end{pmatrix} \in \mathbb{C}^{m(N+1)\times m(N+1)}$$

with

$$\begin{cases} a_j = f_N(l_{N,j}(\cdot)I_m), & j = 0, 1, \dots, N, \\ d_{ij} = l'_{N,j}(\theta_{N,i})I_m, & i = 1, \dots, N,\ j = 0, 1, \dots, N, \end{cases} \tag{2.3}$$

where $l_{N,j}$, $j = 0, 1, \dots, N$, are the Lagrange coefficients relevant to the nodes in Ω_N and, by definition, $f_N(l_{N,j}(\cdot)I_m) = (f_N(l_{N,j}(\cdot)e^{(i)}))_{i=1}^m$ with $e^{(i)}$'s the canonical vectors in $\mathbb{R}^m$. Explicit expressions of the d_{ij}'s for particular choices of Ω_N (e.g., Chebyshev extremal points) can be found in [Tre00, section 6].

So, finally, the original problem of the numerical computation of the characteristic roots of (1.1) can be turned into the eigenvalue problem for the matrix $\mathcal{A}_N$, i.e., eigenvalues of $\mathcal{A}_N$ directly approximate the characteristic roots. How accurate are these approximations? In the next section we develop the convergence analysis.

3. Convergence analysis. The convergence analysis of the approximated roots to the exact ones is based on a comparison between the continuous (i.e., exact) characteristic equation (1.3) and its discrete (i.e., approximated) counterpart. Let us thus characterize the continuous and the discrete eigenvalue problems for $\mathcal{A}$ and $\mathcal{A}_N$, respectively. Let $\lambda \in \mathbb{C}$ and $\varphi \in D(\mathcal{A})$ be such that

$$\mathcal{A}\varphi = \lambda\varphi;$$

that means

$$\begin{cases} \varphi'(\theta) = \lambda\varphi(\theta), & \theta \in [-\tau, 0], \\ \varphi'(0) = f(\varphi). \end{cases}$$

Hence λ is an eigenvalue of $\mathcal{A}$ if and only if there exists $u \in \mathbb{C}^m$, $u \neq 0$, such that

$$\lambda u = f(e^{\lambda \cdot} u).$$

By introducing the linear operator $\hat{\mathcal{A}}(\lambda) : \mathbb{C}^m \to \mathbb{C}^m$ given by

$$\hat{\mathcal{A}}(\lambda)u = f(e^{\lambda \cdot} u), \quad u \in \mathbb{C}^m \tag{3.1}$$

we see that λ is an eigenvalue of $\mathcal{A}$ if and only if

$$\det(\lambda I_m - \hat{\mathcal{A}}(\lambda)) = 0 \tag{3.2}$$

which is the continuous characteristic equation (1.3).

In the same fashion, let $x \in X_N$ be such that

$$\mathcal{A}_N x = \lambda x;$$

thus by (2.2) we get

$$f_N(\mathcal{L}_N x) = \lambda x_0$$

and

$$(\mathcal{L}_N x)'(\theta_{N,i}) = \lambda x_i, \quad i = 1, 2, \dots, N. \tag{3.3}$$

By defining $p_N(\cdot; \lambda, u)$, $u \in \mathbb{C}^m$, as the collocation polynomial relevant to the nodes $\theta_{N,1}, \theta_{N,2}, \dots, \theta_{N,N}$ for the initial value problem

$$\begin{cases} y'(\theta) = \lambda y(\theta), & \theta \in [-\tau, 0], \\ y(0) = u, \end{cases} \tag{3.4}$$

whose solution is the exponential $y(\cdot;\lambda,u) = e^{\lambda\cdot}u$, one can easily derive that (3.3) is equivalent to $(\mathcal{L}_N x)(\cdot) = p_N(\cdot;\lambda,x_0)$. Consequently, λ is an eigenvalue of $\mathcal{A}_N$ if and only if there exists $u \in \mathbb{C}^m$, $u \neq 0$, such that

$$\lambda u = f_N(p_N(\cdot;\lambda,u)).$$

Finally, by introducing the linear operator $\hat{\mathcal{A}}_N(\lambda) : \mathbb{C}^m \to \mathbb{C}^m$ given by

$$\hat{\mathcal{A}}_N(\lambda)u = f_N(p_N(\cdot;\lambda,u)), \quad u \in \mathbb{C}^m, \tag{3.5}$$

we get that λ is eigenvalue of $\mathcal{A}_N$ if and only if

$$\det(\lambda I_m - \hat{\mathcal{A}}_N(\lambda)) = 0 \tag{3.6}$$

which is the discrete characteristic equation.

3.1. We assume to use the Chebyshev extremal nodes on $[-\tau,0]$, i.e.,

$$\theta_{N,i} = \frac{\tau}{2}\left(\cos\left(i\frac{\pi}{N}\right) - 1\right), \quad i = 0,\dots,N. \tag{3.7}$$

Let us denote by $B(\lambda,\rho)$ the closed ball in $\mathbb{C}$ of center λ and radius ρ. In the next lemma we give an upper bound of the error of the collocation polynomial for (3.4).

LEMMA 3.2. $\lambda^* \in \mathbb{C}$ $\rho_0 > 0$ 3.1 $N_0 \in \mathbb{N}$ $N \geq N_0$ $\lambda \in B(\lambda^*,\rho_0)$ $u \in \mathbb{C}^m$ $p_N(\cdot;\lambda,u)$ (3.4) (3.7)

$$\max_{\theta\in[-\tau,0]} |p_N(\theta;\lambda,u) - y(\theta;\lambda,u)| \leq \frac{C_0}{\sqrt{N}}\left(\frac{C_1}{N}\right)^N |u|,$$

$C_0 = C_0(\lambda^*,\rho_0)$ $C_1 = C_1(\lambda^*,\rho_0) = \tau(|\lambda^*|+\rho_0)e$ N

By introducing the (linear) integral Volterra operator $K_\lambda : X \to X$ as

$$(K_\lambda\varphi)(\theta) = \lambda\int_0^\theta \varphi(s)ds, \quad \varphi \in X,\ \lambda \in \mathbb{C},\ \theta \in [-\tau,0],$$

and the (linear and bounded) Lagrange interpolation operator $L_{N-1} : X \to X$ relevant to the nodes (3.7), we can rewrite (3.4) and its collocation equations, respectively, as the equations on the space X

$$y = u + K_\lambda y \tag{3.8}$$

and

$$p_N = u + K_\lambda L_{N-1} p_N, \tag{3.9}$$

where $y = y(\cdot;\lambda,u)$, $p_N = p_N(\cdot;\lambda,u)$, and u denotes the function of X of constant value u. By subtracting (3.8) from (3.9) and setting $e_N = p_N - y$ and $r_N = (L_{N-1} - I)y$, we get the following equation for e_N:

$$e_N = K_\lambda L_{N-1} e_N + K_\lambda r_N. \tag{3.10}$$

It can be directly shown that the solutions of (3.10) are the functions $K_\lambda \hat{e}_N$, where $\hat{e}_N$ is a solution of

$$\hat{e}_N = L_{N-1} K_\lambda \hat{e}_N + r_N.$$

Since $I - K_\lambda$ is invertible and, by the known estimate for the Lagrange interpolation on Chebyshev nodes, $\|L_{N-1}K_\lambda - K_\lambda\| \to 0$ as $N \to \infty$, it follows that, for sufficiently large N (and independently of λ), $I - L_{N-1}K_\lambda$ is invertible and

$$\|(I - L_{N-1}K_\lambda)^{-1}\| \le 2\|(I - K_\lambda)^{-1}\|.$$

Hence $e_N = K_\lambda (I - L_{N-1}K_\lambda)^{-1} r_N$ is the unique solution of (3.10) and as a consequence

$$\|e_N\| \le 2\|K_\lambda\|\|(I - K_\lambda)^{-1}\|\|r_N\|.$$

Since r_N is the error of the Lagrange interpolation of the exponential $y(\cdot;\lambda,u) = e^{\lambda \cdot} u$ relevant to the nodes (3.7), we conclude that

$$\|r_N\| \le \max\{1, e^{-\Re(\lambda)\tau}\} \frac{(\tau|\lambda|)^N}{N!} |u|.$$

The final assertion follows by application of the Stirling formula

$$N! \ge \sqrt{2\pi N}(N/e)^N. \qquad \square$$

Now let us set the following notation relevant to the continuous and discrete characteristic equations (3.2) and (3.6), respectively:

$$d(\lambda) = \det(\lambda I_m - \hat{\mathcal{A}}(\lambda)), \tag{3.11}$$

$$d_N(\lambda) = \det(\lambda I_m - \hat{\mathcal{A}}_N(\lambda)) \tag{3.12}$$

with $\hat{\mathcal{A}}(\lambda)$ and $\hat{\mathcal{A}}_N(\lambda)$ defined in (3.1) and (3.5), respectively. The following assumption and lemmas are the next necessary steps to state the final theorem of convergence.

3.3. We assume that the function f_N in (2.2) satisfies

$$\sup_{N\in\mathbb{N}} \|f_N\| < +\infty.$$

Lemma 3.4. $\lambda^* \in \mathbb{C}$ $\rho_0 > 0$ 3.1 3.3 $N_0 \in \mathbb{N}$ $N \ge N_0$ $\lambda \in B(\lambda^*, \rho_0)$

$$|d(\lambda) - d_N(\lambda)| \le C_2 \left(\varepsilon_N + \frac{1}{\sqrt{N}} \left(\frac{C_1}{N} \right)^N \right),$$

$$\varepsilon_N = \sup_{\lambda \in B(\lambda^*,\rho_0)} \frac{|f(y(\cdot;\lambda,u)) - f_N(y(\cdot;\lambda,u))|}{|u|},$$

$C_1 = C_1(\lambda^*, \rho_0)$ 3.2 $C_2 = C_2(\lambda^*, \rho_0)$ N

. By Lemma 3.2,

$$\begin{aligned}|\hat{\mathcal{A}}(\lambda)u - \hat{\mathcal{A}}_N(\lambda)u| &\le |f(y(\cdot;\lambda,u)) - f_N(y(\cdot;\lambda,u))| \\ &\quad + |f_N(y(\cdot;\lambda,u)) - f_N(p_N(\cdot;\lambda,u))| \\ &\le \left(\varepsilon_N + \sup_{N\in\mathbb{N}} \|f_N\| \frac{C_0}{\sqrt{N}} \left(\frac{C_1}{N}\right)^N\right) |u|\end{aligned}$$

for $N \ge N_0$ and $\lambda \in B(\lambda^*, \rho_0)$.

Now, since the derivative of $\det(A)$ with respect to $A \in \mathbb{C}^{m\times m}$ is continuous, the assertion easily follows. □

LEMMA 3.5. $d(\lambda)$ $\lambda^* \in \mathbb{C}$ ν $\rho_1 = \rho_1(\lambda^*) > 0$

$$|d(\lambda)| > C_3|\lambda - \lambda^*|^\nu$$

$\lambda \in B(\lambda^*, \rho_1) \setminus \{\lambda^*\}$, $C_3 = C_3(\lambda^*)$

. Expanding $d(\lambda)$ around λ^* and taking into account the multiplicity ν we obtain

$$d(\lambda) = \frac{d^{(\nu)}(\lambda^*)}{\nu!}(\lambda - \lambda^*)^\nu + O(|\lambda - \lambda^*|^{\nu+1})$$

with $d^{(\nu)}(\lambda^*) \neq 0$. The result follows. □

We are now able to state the convergence result.

THEOREM 3.6 (convergence). $\lambda^* \in \mathbb{C}$ $d(\lambda)$ ν ρ_1 3.5

$$\rho_N = \left(\frac{C_2}{C_3}\right)^{1/\nu} \left(\varepsilon_N + \frac{1}{\sqrt{N}} \left(\frac{C_1}{N}\right)^N\right)^{1/\nu} \tag{3.13}$$

C_1 C_2 3.4 $\rho_0 = \rho_1$ C_3 3.5 3.1 3.3 $\rho_N \le \rho_1$, $d_N(\lambda)$ ν λ_i $i = 1, \dots, \nu$

$$\max_{1\le i\le \nu} |\lambda^* - \lambda_i| \le \rho_N. \tag{3.14}$$

. Since $\rho_N \le \rho_1$, Lemmas 3.4 and 3.5 yield

$$|d(\lambda)| > |d_N(\lambda) - d(\lambda)|$$

for $|\lambda - \overline{\lambda}| = \rho_N$. Hence, by Rouché's theorem [Con78, section 5, Theorem 3.8], d and d_N have exactly the same number of zeros counted with their multiplicities in $B(\lambda^*, \rho_N)$. □

It is important to point out that the spectral accuracy of the collocation polynomial stated in Lemma 3.2 is preserved in the behavior of the final error (3.14) in Theorem 3.6, if the distributed term in (2.2) can be exactly computed, i.e., $\varepsilon_N = 0$. On the other hand, we also maintain the spectral accuracy in the error (3.14) if we make the further assumptions that

1. the function M in (1.1) is piecewise C^∞ and there exists $C > 0$ such that

$$\max_{\theta\in[-\tau,0]} \|M^{(q)}(\theta)\| \le C^q, \quad q = 0, 1, 2, \dots;$$

2. a piecewise interpolatory quadrature rule based on $N+1$ distinct nodes is used for the distributed term.

Finally, we observe that if the quadrature error is independent of N, i.e., $\varepsilon_N \leq$ TOL (e.g., machine precision), the error bound in Theorem 3.6 is still valid with ε_N replaced by TOL and thus the convergence follows spectral accuracy down to the tolerance TOL.

In the next proposition we also show the nonexistence of "ghost roots," i.e., if there exists a sequence of approximated characteristic roots that converges, then it converges to an exact characteristic root.

PROPOSITION 3.7. [illegible] $\{\Omega_{N^{(i)}}\}_{i\geq 1}$ [illegible] $[-\tau, 0]$ [illegible] $N^{(i)} \to \infty$ [illegible] $\varepsilon_{N^{(i)}} \to 0$ [illegible] $i \to \infty$ [illegible] $\lambda^{(i)} \to \lambda^*$ [illegible] $i \to \infty$ [illegible] $\lambda^{(i)}$ [illegible] $d_{N^{(i)}}$ [illegible] λ^* [illegible] d [illegible]. Since

$$|d(\lambda^*)| = |d_{N^{(i)}}(\lambda^{(i)}) - d(\lambda^*)| \leq |d_{N^{(i)}}(\lambda^{(i)}) - d(\lambda^{(i)})| + |d(\lambda^{(i)}) - d(\lambda^*)|,$$

the assertion follows by Lemma 3.4 and by continuity of d. ∎

4. Implementation issues. The application of the pseudospectral approach presented in this work allows two different alternatives. The first one uses a unique interpolating polynomial for the whole delay interval $[-\tau, 0]$. The second one can be interpreted as a piecewise pseudospectral approach since it makes use of a different N-degree interpolating polynomial for each delay interval $[-\tau_l, -\tau_{l-1}]$, $l = 1, \ldots, k$. The discretized infinitesimal generator results in the $m(1+kN) \times m(1+kN)$ matrix

$$\mathcal{A}_N = \begin{pmatrix} a_0^{(1)} & a_1^{(1)} & \cdots & a_N^{(1)} & \cdots & a_N^{(k-1)} & a_1^{(k)} & \cdots & a_N^{(k)} \\ d_{10}^{(1)} & d_{11}^{(1)} & \cdots & d_{1N}^{(1)} & & & & & \\ \vdots & \vdots & \ddots & \vdots & & & & & \\ d_{N0}^{(1)} & d_{N1}^{(1)} & \cdots & d_{NN}^{(1)} & & & & & \\ & & & & \ddots & & & & \\ & & & & & \ddots & & & \\ & & & & & d_{10}^{(k)} & d_{11}^{(k)} & \cdots & d_{1N}^{(k)} \\ & & & & & \vdots & \vdots & \ddots & \vdots \\ & & & & & d_{N0}^{(k)} & d_{N1}^{(k)} & \cdots & d_{NN}^{(k)} \end{pmatrix},$$

where, for $l = 1, \ldots, k$, $a_j^{(l)}$ with $j = 0, \ldots, N$, and $d_{ij}^{(l)}$ with $i = 1, \ldots, N$ and $j = 0, \ldots, N$, are the coefficients given by (2.3) and relevant to the interval $[-\tau_l, -\tau_{l-1}]$. Note that $a_0^{(l)} = a_N^{(l-1)}$ holds for $l = 2, \ldots, k$. Despite the increased approximant matrix dimension, this second solution avoids the evaluation of Lagrange coefficients at the discrete delay points when computing the first row since these are always mesh points. Moreover, if we are in the case of applying a quadrature rule to the distributed delay terms (1.2), using the interpolation points as quadrature nodes, the piecewise alternative permits avoidance of all Lagrange coefficients evaluation. This advantage clearly increases as the number of delays increases and, moreover, sparsity can be exploited when k is large.

The two alternatives in the pseudospectral approach have been implemented in two different [illegible] routines for the numerical computation of the characteristic

roots of systems of DDEs using Chebyshev extremal grids for both versions of the general case. The algorithms apply Clenshaw–Curtis quadrature (see [Tre00, section 12]) for the distributed delay terms, which is based on Chebyshev extremal nodes.

For stability analysis, one can be interested in computing either the first r-rightmost roots or the roots λ in the right half-plane $\Re(\lambda) \geq \alpha$ for a given real α. In the first case, since the roots with smaller modulus are approximated faster and, in general, they are not the rightmost ones, it is advisable to try with $N > r$ (so it is easier that the first r-rightmost roots are contained in the first r-roots ordered by modulus). In the second case, by using the following bound,

$$|\lambda| \leq \sum_{l=0}^{k} \|L_l\| e^{-\alpha\tau_l} + \tau B \max\{1, e^{-\alpha\tau}\} := K$$

for roots λ with $\Re(\lambda) \geq \alpha$, where B is a uniform upper bound of $M(\theta)$ in $[-\tau, 0]$, by (3.13) and (3.14) with $\varepsilon_N = 0$ one obtains for simple roots

$$|\lambda^* - \lambda| \leq \frac{C_2}{C_3} \left(\frac{1}{\sqrt{N}} \left(\frac{\tau(K+\rho_1)e}{N} \right)^N \right),$$

and by assuming $\frac{C_2}{C_3} \simeq 1$ and $\tau(K+\rho_1)e \simeq \tau K e$ one can roughly estimate the required N for a given tolerance.

For a more detailed discussion on the above and other implementation issues we refer the interested reader to [Bre02] and [BMV03].

5. Numerical results. We present here a sequence of results on some systems of linear DDEs (1.1) in order to show the features of the pseudospectral approach and to compare it with RK and LMS methods proposed in [Bre02] and [BMV03], respectively.

All the results concern the following systems and equations:

' . ', 5.1 (see [ER02]).

$$y'(t) = 2y(t) - ey(t-1). \tag{5.1}$$

' . ', 5.2 (see [ER02]).

$$\begin{cases} y_1'(t) = -0.5y_1(t) - \tanh\left(y_1(t-1.57)\right) + \tanh\left(y_2(t-0.2)\right), \\ y_2'(t) = -0.5y_2(t) + 2.34\tanh\left(y_1(t-0.2)\right) - \tanh\left(y_2(t-1.57)\right). \end{cases} \tag{5.2}$$

' . ', 5.3 (see [FSD00]).

$$y'(t) = L_0 y(t) + L_1 y(t-1) + \int_{-1}^{0} M(\theta) y(t+\theta) d\theta \tag{5.3}$$

with coefficients matrices

$$L_0 = \begin{pmatrix} -3 & 1 \\ -24.646 & -35.430 \end{pmatrix}, \qquad L_1 = \begin{pmatrix} 1 & 0 \\ 2.35553 & 2.00365 \end{pmatrix},$$

$$M(\theta) = \begin{pmatrix} 1 & -\theta \\ 1 & -\theta \end{pmatrix}, \quad \theta \in [-\tau, 0].$$

' . ,' 5.4.

$$y'(t) = L_0 y(t) + L_1 y(t-1) + \int_{-0.3}^{-0.1} M_1 y(t+\theta)d\theta + \int_{-1}^{-0.5} M_2 y(t+\theta)d\theta \tag{5.4}$$

with coefficients matrices

$$L_0 = \begin{pmatrix} -3 & 1 \\ -24.646 & -35.430 \end{pmatrix}, \qquad L_1 = \begin{pmatrix} 1 & 0 \\ 2.35553 & 2.00365 \end{pmatrix},$$
$$M_1 = \begin{pmatrix} 2 & 2.5 \\ 0 & -0.5 \end{pmatrix}, \qquad M_2 = \begin{pmatrix} -1 & 0 \\ 0 & -1 \end{pmatrix}.$$

' . ,' 5.5 (see [ER02]).

$$y'(t) = L_0 y(t) + L_1 y(t-\tau) \tag{5.5}$$

with tridiagonal coefficients $m \times m$ matrices

$$L_0 = \frac{1}{h^2}\left(\frac{1-\alpha}{\beta} + \alpha\right) \begin{pmatrix} -2 & 1 & & \\ 1 & \ddots & \ddots & \\ & \ddots & \ddots & 1 \\ & & 1 & -2 \end{pmatrix} + RI_m$$

and

$$L_1 = \frac{1}{h^2}\frac{1-\alpha}{\beta} \begin{pmatrix} -2 & 1 & & \\ 1 & \ddots & \ddots & \\ & \ddots & \ddots & 1 \\ & & 1 & -2 \end{pmatrix},$$

where α, β, and R are real parameters and $h = \pi/(m+1)$ with $m \in \mathbb{N}$.

Equation (5.1) presents an exact rightmost double root $\overline{\lambda} = 1$ while system (5.2), linearized around the steady state solution $(y_1^*, y_2^*) = (0, 0)$, exhibits a rightmost root $\overline{\lambda} \simeq 0.3475$. Systems (5.3) and (5.4) present, respectively, a rightmost root $\overline{\lambda} \simeq -0.6873$ and $\overline{\lambda} \simeq 1.2462$. The latter is a modified version of the former: the distributed delay is split in two separate terms. Moreover, the matrices M_1 and M_2 are independent of θ. This modification is introduced in order to exalt the advantages of the piecewise alternative approach with respect to the standard one. The last test equation (5.5) presents a complex-conjugate rightmost root $\overline{\lambda} \simeq -0.06362 \pm 1.007\mathrm{i}$ and it arises from the discretization in space by a classical second order central difference scheme of a PDE with time delay in the diffusion term.

Figure 5.1 shows the trend of the absolute error on the rightmost root with respect to the number of interpolation points N for the single delay equation (5.1): convergence is confirmed as predicted in Theorem 3.6. Observe that the method works also in the case of a root with multiplicity $\nu > 1$, but in this case the maximum tolerance reached is equal to the machine precision under the νth root. The convergence behavior confirms the typical "spectral accuracy" of spectral methods.

The different approaches, single and piecewise interpolation, are compared in Figure 5.2 for the computation of the rightmost root of system (5.4). Performances are

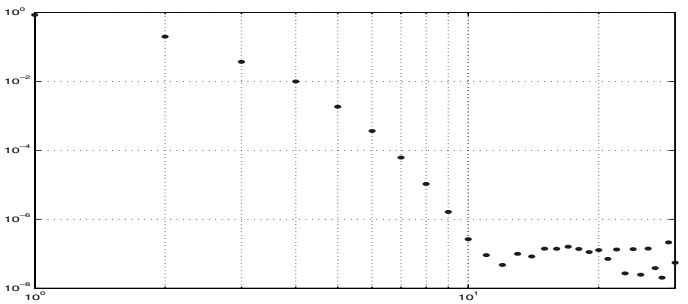

FIG. 5.1. *Rightmost root absolute error vs number of grid points N for system* (5.1).

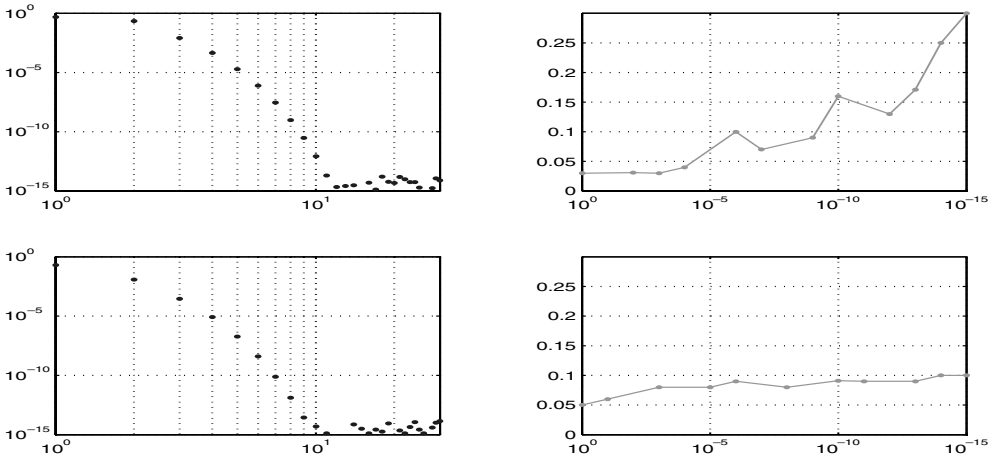

FIG. 5.2. *Rightmost root absolute error vs. number of grid points N (*1*st column) and computational time (seconds,* 2*nd column) vs. required tolerance TOL for system* (5.4) *with single (*1*st row) and piecewise (*2*nd row) pseudospectral approach.*

slightly different in favor of the piecewise method: this is a consequence of avoiding the computation of Lagrange coefficients as explained in section 4, which would be more evident in the case of systems with many delays. The approximant matrix dimension is four times larger for the piecewise approach: this disadvantage is recovered (in terms of computational time; see the 2nd column) by using sparse eigenvalue solvers (e.g., the function of).

The same analysis is carried out in Figure 5.3 for system (5.3) comparing the piecewise pseudospectral approach with LMS and RK methods of order 5 proposed in [Bre02] and [BMV03], respectively, both showing convergence of order 5 as expected. For what concerns the density of the delay interval discretization (i.e., the number N for the pseudospectral method and $N = \tau/h$, h being the steplength, for the other methods), one can see in the 1st column that the RK approach is more accurate than the pseudospectral one up to a tolerance of about 10^{-9}, an advantage that falls rapidly for smaller values due to the "spectral accuracy" of the pseudospectral technique. This behavior holds in general for "linearly" convergent approaches (LMS and RK) compared to "superlinearly" convergent ones (pseudospectral), the "crossing" tolerance value depending on the particular system of DDEs analyzed by the constants involved in the error (here, "linear" and "superlinear" convergence refer

to a double-logarithmic plot context).

Moreover, we compare RK and pseudospectral approaches computing the first ten rightmost roots of system (5.2), listed in Table 5.1 and shown in Figure 5.4. The 1st column of Figure 5.5 shows the error trend for each root (simple-real or complex-conjugate) in ascending order with respect to their modulus. This last plays a fundamental role in the sense that approximated roots of smaller modulus converge sooner: for the pseudospectral approach this phenomenon clearly results from Theorem 3.6 and an analogous result can be deducted from the convergence analysis carried out in [BMV03]. The 2nd column evidences once more the superiority of the pseudospectral approach in terms of computational time with respect to the required tolerance for the maximum absolute error over all the computed roots.

Finally, to test the performance of our approach on time delay systems of higher order, we carry on the convergence analysis on the rightmost characteristic root of (5.5) with $m = 20$ and parameters $\alpha = 0.1$, $\beta = 2$, and $R = 0.08$. Results are given in Figure 5.6. Note that in general space discretization of PDEs with delay in time leads to DDE systems which already possess a quite large dimension m. This means

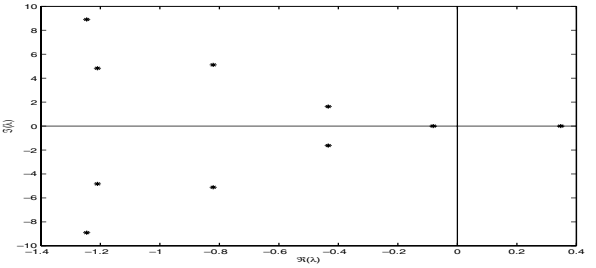

FIG. 5.4. *First ten rightmost roots of system* (5.2).

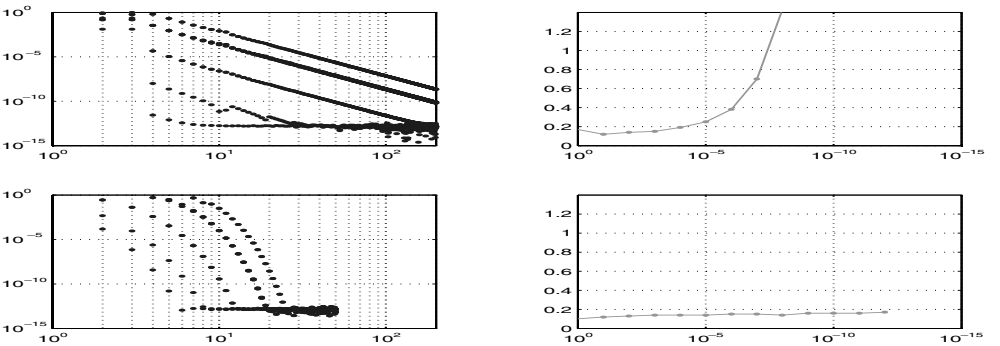

FIG. 5.5. *First ten rightmost roots absolute error vs. number of grid points N (*1*st column) and computational time (seconds,* 2*nd column) vs. required tolerance on the maximum absolute error TOL (seconds,* 2*nd column) for system* (5.2) *with RK (*1*st row) and pseudospectral (*2*nd row) approach.*

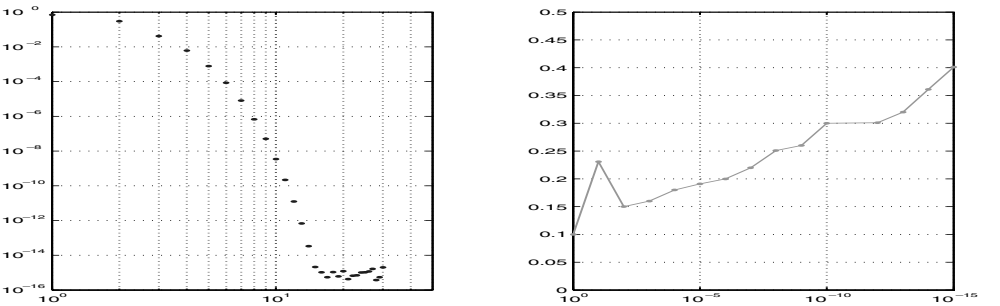

FIG. 5.6. *Rightmost root absolute error vs. number of grid points N (*1*st column) and computational time (seconds,* 2*nd column) vs. required tolerance TOL for system* (5.5) *with pseudospectral approach.*

that the choice of N for the approximation of the characteristic roots turns out to be crucial in saving computational time. Let us underline that in the second case we adopt a sparse eigenvalue solver to exploit the fact that the entries of $\mathcal{A}_N$ are (apart from the first block row) $m \times m$ diagonal blocks.

To complete this test we use $N = 100$ to allow the computation of $r = m(1+N) = 2020$ roots, which is the dimension of the discretized infinitesimal generator. The eigenvalues are shown in Figure 5.7 (left), while a zoom in Figure 5.7 (right) gives an idea of the particular conformation of the spectrum and of how clustered the roots are.

GLUED MATRICES AND THE MRRR ALGORITHM*

INDERJIT S. DHILLON†, BERESFORD N. PARLETT‡, AND CHRISTOF VÖMEL§

Abstract. During the last ten years, Dhillon and Parlett devised a new algorithm (multiple relatively robust representations (MRRR)) for computing numerically orthogonal eigenvectors of a symmetric tridiagonal matrix T with $\mathcal{O}(n^2)$ cost. It has been incorporated into LAPACK version 3.0 as routine STEGR.

We have discovered that the MRRR algorithm can fail in extreme cases. Sometimes eigenvalues agree to working accuracy and MRRR cannot compute orthogonal eigenvectors for them. In this paper, we describe and analyze these failures and various remedies.

Key words. multiple relatively robust representations, numerically orthogonal eigenvectors, symmetric tridiagonal matrix, tight clusters of eigenvalues, glued matrices, Wilkinson matrices

1. Introduction.

Starting in the mid-90s, Dhillon and Parlett developed the algorithm of multiple relatively robust representations (MRRR) that computes numerically orthogonal eigenvectors of a symmetric tridiagonal matrix T with $\mathcal{O}(n^2)$ cost [13, 15, 16, 17, 7]. This algorithm was tested on a large and challenging set of matrices and has been incorporated into LAPACK version 3.0 as routine STEGR. The algorithm is described, in the detail we need here, in section 2. For a more detailed description see also [8]. An example of MRRR in action is given in section 3.

In 2003, one of us (Vömel) came to Berkeley to assist in the modification of STEGR to compute a subset of k eigenpairs with $\mathcal{O}(kn)$ operations. When testing STEGR on more and more challenging matrices, he discovered cases of failure.

Investigation of these cases brought to light assumptions made in STEGR that hold in exact arithmetic and in the majority of cases in finite precision arithmetic, but that can fail. These assumptions, why they are reasonable, and how they can fail are the subject of section 4.

In section 5, we propose and analyze various remedies for the aforementioned shortcomings and show how to incorporate them into MRRR. We also look at the cost of these modifications. We select as most suitable an approach that is based on small random perturbations and introduces artificial roundoff effects. This approach preserves the complexity of the original algorithm.

2. The algorithm of multiple relatively robust representations.

The MRRR algorithm [13, 15, 16, 17, 7] is a sophisticated variant of inverse iteration [11].

It addressed the challenge of computing numerically orthogonal eigenvectors of a symmetric tridiagonal matrix $T \in R^{n\times n}$ for eigenvalues that are very close to each other. The difficulty of this task is that each computed eigenvector tends to be corrupted by components from its neighbors, leading to nonorthogonal vectors.

One way to overcome this obstacle is to achieve highly accurate eigenpairs satisfying

$$\|(T - \lambda_i I)v_i\| = \mathcal{O}(n\epsilon|\lambda_i|); \tag{2.1}$$

the eigenpairs have a small residual norm with respect to $|\lambda_i|$. For a small eigenvalue λ, this is a much stronger demand on accuracy than the common condition

$$\|(T - \lambda_i I)v_i\| = \mathcal{O}(n\epsilon\|T\|). \tag{2.2}$$

(Throughout this paper, ϵ denotes the unit roundoff.)

2.1. Relatively robust representations. The first contribution of MRRR is the observation that for most shifts σ, the standard triangular factorization $T - \sigma I = LDL^T$, L unit bidiagonal, D diagonal exists and has the property that small relative changes in the nontrivial entries of L and D cause small relative changes in each small eigenvalue of LDL^T (despite possible element growth in the factorization). This is in sharp contrast to the entries in $T - \sigma I$ which have this property only in special cases; see [1]. We call (L, D) a if it determines a subset Γ of the eigenvalues to high relative accuracy. Armed with an RRR, we can then compute an approximate eigenvalue to high relative accuracy. This can be done by bisection for a single eigenvalue λ with $\mathcal{O}(n)$ work, yielding $\hat{\lambda}$ satisfying

$$|\lambda - \hat{\lambda}| \le Kn\epsilon|\hat{\lambda}|, \tag{2.3}$$

where K is a modest constant independent of T and λ. Moreover, when the matrix is definite, then the dqds algorithm [18] may be used to compute all eigenvalues to this accuracy in $\mathcal{O}(n^2)$ operations.

2.2. The FP vector. The second innovative feature of MRRR is based on the fact that, for an accurate approximate eigenvalue $\hat{\lambda}$, it is possible to find the index r of the largest component of the true wanted eigenvector v using a double factorization,

$$(LDL^T - \hat{\lambda}I) = L_+D_+L_+^T = U_-D_-U_-^T, \tag{2.4}$$

with $\mathcal{O}(n)$ work. This was discovered in the mid-1990s independently by Godunov and by Fernando; see [15] and the references therein. From

$$\sin^2 \angle(e_r, v) = 1 - \cos^2 \angle(e_r, v) = 1 - v^2(r), \tag{2.5}$$

we see that e_r, the rth column of the identity, cannot be a bad approximation to the true eigenvector. The algorithm solves

$$(LDL^T - \hat{\lambda}I)z = e_r\gamma_r, \;\; z(r) = 1, \tag{2.6}$$

with a normalization factor γ_r and $\gamma_r^{-1} = [(LDL^T - \hat{\lambda}I)^{-1}]_{rr}$. An eigenvector expansion [15] shows that

$$\frac{\|(LDL^T - \hat{\lambda}I)z\|_2}{\|z\|_2} = \frac{|\gamma_r|}{\|z\|_2} \le \frac{|\lambda - \hat{\lambda}|}{|v(r)|}. \tag{2.7}$$

In particular, if r is chosen such that the true eigenvector component $|v(r)| \geq 1/\sqrt{n}$, then an upper bound on (2.7) is $\sqrt{n}\,|\lambda - \hat{\lambda}|$. Now (2.7) together with (2.3) yields (2.1), a relatively small residual norm. In [15], the resulting z from (2.6) is called the [illegible], FP for Fernando and Parlett. The reward for the relatively small residual norm of the FP vector is revealed by the classical gap theorem, often attributed to Davis and Kahan [4, 12]. It shows that

$$|\sin \angle(z, v)| \leq \frac{\|LDL^T z - z\hat{\lambda}\|_2}{\|z\|_2 \operatorname{gap}(\hat{\lambda})} \leq \frac{|\lambda - \hat{\lambda}|}{\|v\|_\infty \operatorname{gap}(\hat{\lambda})}, \tag{2.8}$$

where $\operatorname{gap}(\hat{\lambda}) = \min\{|\hat{\lambda} - \mu| : \lambda \neq \mu, \mu \in \text{spectrum}(LDL^T)\}$. By (2.3), we thus obtain

$$|\sin \angle(z, v)| \leq \frac{Kn\epsilon|\hat{\lambda}|}{\|v\|_\infty \operatorname{gap}(\hat{\lambda})} = \frac{Kn\epsilon}{\|v\|_\infty \operatorname{relgap}(\hat{\lambda})}, \tag{2.9}$$

defining the relative gap, $\operatorname{relgap}(\hat{\lambda})$. Thus, when $\hat{\lambda}$ and $\operatorname{gap}(\hat{\lambda})$ are of not too different size, the angle between the FP vector and the eigenvector is $\mathcal{O}(n\epsilon)$.

2.3. The representation tree and the differential qd algorithm. The third new idea of the MRRR algorithm is to use [illegible] in order to achieve large relative gaps. By large we mean larger than a threshold, usually $1.E-3$. If the relative gaps of a group of eigenvalues are too small, then they can be increased by shifting the origin close to one end of the group. Furthermore, the procedure can be repeated for clusters within clusters of close eigenvalues. The tool for computing the various RRRs is the stationary [illegible] [17]. It has the property that tiny relative changes to the input (L, D) and the output (L_+, D_+) with $LDL^T - \sigma I = L_+ D_+ L_+^T$ give an exact relation. The MRRR procedure for computing eigenpairs is best represented by a rooted tree. Each node of the graph is a pair consisting of a representation (L, D) and a subset Γ of the wanted eigenvalues for which it is an RRR. The root node of this [illegible] is the initial representation that is an RRR for all the wanted eigenvalues; each leaf corresponds to a "singleton," that is, a (shifted) eigenvalue whose relative separation from its neighbor exceeds a given threshold.

2.4. Twisted factorizations. Another ingredient of the MRRR algorithm is the way the FP vector is computed. One uses a [illegible] to solve (2.6) as follows. With the multipliers from (2.4), let

$$N_r = \begin{pmatrix} 1 & & & & & & & & & & \\ L_+(1) & 1 & & & & & & & & & \\ & \ddots & \ddots & & & & & & & & \\ & & \ddots & \ddots & & & & & & & \\ & & & L_+(r-2) & 1 & & & & & & \\ & & & & L_+(r-1) & 1 & U_-(r) & & & & \\ & & & & & & 1 & U_-(r+1) & & & \\ & & & & & & & 1 & \ddots & & \\ & & & & & & & & \ddots & \ddots & \\ & & & & & & & & & \ddots & U_-(n-1) \\ & & & & & & & & & & 1 \end{pmatrix},$$

and, with the pivots from (2.4) and γ_r from (2.6), define

$$\Delta_r = \operatorname{diag}(D_+(1), \ldots, D_+(r-1), \gamma_r, D_-(r+1), \ldots, D_-(n)).$$

Then the twisted factorization at $\hat{\lambda}$ (with twist index r) is given by

$$LDL^T - \hat{\lambda} I = N_r \Delta_r N_r^T. \tag{2.10}$$

Since $N_r e_r = e_r$ and $\Delta_r e_r = \gamma_r e_r$, the solution of (2.6) is equivalent to solving

$$N_r^T z = e_r, \;\; z(r) = 1. \tag{2.11}$$

The great attraction of using this equation is that z can be computed solely with multiplications; no additions or subtractions are necessary. By (2.11), we obtain

$$z(i) = \begin{cases} -L_+(i) z(i+1), & i = r-1, \ldots, 1, \\ -U_-(i-1) z(i-1), & i = r+1, \ldots, n. \end{cases} \tag{2.12}$$

This procedure, together with the use of the differential qd algorithms, permits the error analysis that shows that roundoff does not spoil the overall procedure [7].

2.5. Putting it all together: The MRRR algorithm. Combining all the ideas from the previous sections, we obtain the following algorithm.

ALGORITHM 1: THE MRRR ALGORITHM.

for the current level of the representation tree **do**
  for each eigenvalue with a large relative gap **do**
    Compute an approximation that is good to high relative accuracy.
    Compute its FP vector.
  end for
  for each of the remaining groups of eigenvalues **do**
    Choose shift σ close to the outside of the group.
    Compute new RRR $L_+ D_+ L_+^T = LDL^T - \sigma I$.
    Refine the eigenvalues.
  end for
  Proceed to the next level of the representation tree.
end for

3. The MRRR algorithm in practice. In [21], Wilkinson introduced two classes of symmetric tridiagonal matrices W_{2m+1}^+ and W_{2m+1}^- for positive integers m. W_{2m+1}^+ is more interesting for our purposes. It is defined as

$$W_{2m+1}^+ = \text{tridiag} \left(\begin{array}{ccccccccccc} 1 & & 1 & & \ldots & & 1 & & 1 & & \\ & m & & m-1 & & \ldots & & 0 & & \ldots & m-1 & & m \\ 1 & & 1 & & \ldots & & 1 & & 1 & & \end{array} \right).$$

We want to illustrate the action of MRRR on W_{21}^+. The algorithm first computes a shift σ so that $T - \sigma I$ becomes definite; then all eigenvalues of the root representation $LDL^T = T - \sigma I$ are computed by dqds. In Table 1 we show the eigenvalues of W_{21}^+ and of the root representation whose shift is $\sigma = 10.746194215443904$, a computed upper bound on the largest eigenvalue of T (hence LDL^T is negative definite). The relative gaps are with respect to the root representation.

MRRR uses a threshold to decide which relative gaps are large enough, which is currently $1.E-3$. (That is, eigenvalues that agree to fewer than three digits are declared relatively isolated.) The last column of Table 1 shows that the relative gaps of the first nine eigenvalues exceed the threshold and thus are singletons for the algorithm. The corresponding FP vectors are computed immediately. The remaining

eigenvalues come in pairs which are well isolated from each other. For each of these pairs, the algorithm finds a close shift, computes a new RRR, $LDL^T - \tau I = L_+ D_+ L_+^T$, and refines the eigenvalues of that new RRR. In Table 2 we show these refined local eigenvalues with respect to their new RRRs. Note that the relative gaps inside the pairs have been significantly improved over those of the root representation (they are all of order 1) because $|\lambda_{2i+1} - \lambda_{2i}| \approx |\lambda_{2i}|,\ i = 5, \ldots, 10$. With respect to the appropriate representation, each eigenvalue is now a singleton. In Figure 1 we show the representation tree associated to these computations.

4. Fallible assumptions. In this section, we show how MRRR can fail. Our illustrations use (large) Wilkinson and glued Wilkinson matrices. By a glued (sym-

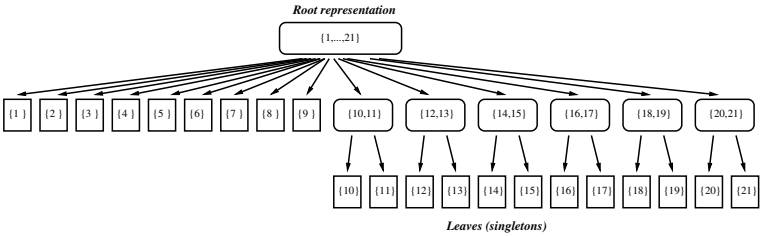

FIG. 1. *The representation tree for W_{21}^+. Square boxes correspond to singletons; boxes with round corners correspond to eigenvalue groups for which an individual representation is needed to improve relative gaps.*

metric tridiagonal) matrix, we denote a matrix

$$T(\gamma) = \begin{bmatrix} T_1 & & \\ & \ddots & \\ & & T_p \end{bmatrix} + \gamma \sum_{i=1}^{p-1} v_i v_i^T,$$

where v_i is a vector with only two nonzero entries of size 1 in the positions corresponding to the last row of T_i and the first row of T_{i+1} in T, where $T_1, \ldots, T_p$ are symmetric tridiagonal matrices.

4.1. Finding large relative gaps.

4.1. By suitable shifting, at least one eigenvalue in a tight cluster of eigenvalues of an unreduced symmetric tridiagonal matrix can be given a relative gap exceeding any given threshold.

In exact arithmetic, the eigenvalues of an unreduced symmetric tridiagonal matrix are simple. Thus, a shift to either end of a cluster of close eigenvalues yields a local eigenvalue that is (nearly) zero and a relative gap of (almost) ∞. Thus, at least one local eigenvalue becomes a singleton.

When working in finite precision with roundoff, we expect that a tight cluster, however close in exact arithmetic, will be computed with differences exceeding $\epsilon\lambda_i$. By shifting close to the end of a cluster, we can expect the relative gaps to become large enough. A typical example was shown in Table 2. For example, an incremental shift of -3.25E-8 from the root representation to the RRR for eigenvalues $20, 21$ increased the relative gap of eigenvalue 20 to 1 since $|\lambda_{21} - \lambda_{20}| \approx |\lambda_{20}|$. For matrices with tighter clusters, more steps of shifting and gradual refinement of the eigenvalues might be needed to increase the relative separation.

In the following experiment, we look at the second-smallest cluster of a matrix T obtained from five copies of W_{201}^+ glued together by $\sqrt{\epsilon}$. According to the strategy of finding large relative gaps, we refine the extremal eigenvalues of the cluster to high accuracy. Then we compute LDL^T factorizations at both ends of the cluster and choose the end with the smaller element growth for the representation. If the code performed as usual, by shifting closer and closer to the cluster, we would see for a certain shift the cluster splitting up into subgroups and singletons. Instead, we see a refinement of the eigenvalues of the cluster down to the underflow threshold without being able to find subclusters. In terms of the representation tree, this corresponds to a long chain and had not been observed in former tests. In Table 3 we show for some parts of the chain the extremal eigenvalues of the cluster together with the

corresponding depth of the representation tree. An explanation of this phenomenon is given in section 4.3.

TABLE 3

4.2. Finding an RRR.

4.2. It is always possible to find an RRR close enough to one (or both) ends of a tight cluster to yield a singleton eigenvalue.

This statement differs from Assumption 4.1 by bringing in the property that the representation should be relatively robust.

In exact arithmetic, the triangular factorization of a matrix $T - \sigma I = LDL^T$ exists for all but a finite set of shifts σ, the so-called Ritz values of T. Each Ritz value is the eigenvalue of a leading principal submatrix. The element growth, that is, $\|D\|$, is bounded except in a very small interval around these Ritz values.

It can be shown that the even-indexed eigenvalues of the Wilkinson matrices W^+_{2m+1} are also Ritz values. In fact, they are the eigenvalues of the leading (and trailing) $m \times m$ submatrix; see [21]. This implies that an LDL^T factorization with such a shift will break down or, in other words, an RRR with such a shift does not exist. Luckily, for the simple Wilkinson matrices it is usually not necessary to choose such a shift for a representation. For the well-isolated eigenvalues at the lower end of the spectrum, one need not shift close to any Ritz value in order to obtain large relative gaps between the eigenvalues. At the upper end of the spectrum, the eigenvalues come in pairs consisting of two eigenvalues, the smaller having an even and the larger an odd index. In this case, one need not shift close to the left (Ritz) eigenvalue; a shift to the right of the pair is excellent.

In order to find an RRR, the MRRR algorithm first factors at both ends of the cluster and monitors the element growth. If the element growth at one end is small, it is chosen as origin for the RRR. Otherwise, the shift backs off from the ends and tries again. The benefit from backing off is the possibility of smaller element growth; the danger is to obtain an RRR whose eigenvalues have small relative gaps.

In our experiment, we consider again the second-smallest cluster of five copies of W^+_{201} glued together by $\sqrt{\epsilon}$. As seen in Table 3, the glue does not change the finite precision approximation of the true eigenvalues. Thus, in limited precision, we face an eigenvalue/Ritz value of multiplicity five. A representation in a small neighborhood cannot exist. Normally, we would back off enough to ensure modest element growth. However, since the clustered eigenvalues have zero gaps, backing off is pointless. Even if we found an RRR, it would not be suitable for the algorithm. Note that the problem does not occur in the (unglued) matrix but only in the glued case for a reason that will be explained in section 4.3.

4.3. Why glued matrices are difficult for MRRR. Table 3 shows that the eigenvalues of the glued matrix are equal to working accuracy despite roundoff error.

The following simple model can provide a good intuition of the phenomenon: Suppose that the glue connecting the copies were zero but the algorithm "was not aware of it," that is, treated it as a nonsplitting matrix. Then [illegible] there would be five equal computed eigenvalues. So, in practice, if there are eigenvalues for which the glue parameter has a negligible effect, then the algorithm will fail. This is exactly what happens in this case. In fact, it can be shown that the magnitude of the effect of the glue on eigenvalues is tied to top and bottom entries of the corresponding eigenvectors. As an intuitive argument for the case of two glued matrices, we remind the reader of Theorem 4.3, which plays an important role in the divide-and-conquer algorithm [2, 3, 9]. A complete analysis of glued matrices is in preparation [19].

THEOREM 4.3. [illegible] $T_1 = Q_1\Lambda_1 Q_1^T, T_2 = Q_2\Lambda_2 Q_2^T$ [illegible]

$$D = \begin{bmatrix} \Lambda_1 & 0 \\ 0 & \Lambda_2 \end{bmatrix}, \quad u = \begin{bmatrix} Q_1^T & 0 \\ 0 & Q_2^T \end{bmatrix}, \quad v = \begin{bmatrix} \text{last column of } Q_1^T \\ \text{first column of } Q_2^T \end{bmatrix}.$$

[illegible] u [illegible] T [illegible]

$$\det(I + \gamma(D-\lambda)^{-1}uu^T) = 1 + \gamma u^T(D-\lambda)^{-1}u = 1 + \gamma\sum_{i=1}^{n}\frac{u_i^2}{d_i - \lambda} = 0. \tag{4.1}$$

It is well known that when u_i is exactly zero, then d_i is an eigenvalue of the glued matrix. Likewise, when u_i is tiny (as in the case of the top and bottom entry of the second eigenvector of W_{201}^+), the effect of the glue on the separation of the eigenvalues is negligible. Thus, for these glued matrices, the special structure can defeat the normal effects of rounding errors.

4.4. Computing the FP vector.

[illegible] 4.4. Let the eigenvalue approximation $\hat{\lambda}$ have high relative accuracy. By starting inverse iteration according to (2.6) with e_r, r being the largest component of the true eigenvector, we are guaranteed that the FP vector has a small angle to the true eigenvector according to (2.9) [illegible] (2.11) and can be computed by (2.12)

This is very satisfactory and correct in exact arithmetic. In finite precision arithmetic, we might not be able to accurately solve (2.6) (or (2.11)) by (2.12). Although we obtain a vector with small residual, we need not obtain the true FP vector which is guaranteed to have a small angle to the true eigenvector. The culprit is underflow, as we now explain.

The eigenvectors of the largest eigenvalue pair of a Wilkinson matrix W_{2m+1}^+, m sufficiently large, provide examples. Both eigenvectors have their "essential" nonzero part concentrated at the top and the bottom and decay rapidly towards the middle. This decay commonly causes MRRR (and other methods as well) to return the bisectors instead of the true eigenvectors; see the example of MATLAB in Figures 2 and 3.

These bisectors are perfectly satisfactory from the point of view of numerically small residual norms and numerical orthogonality. Moreover, the true eigenvectors can be obtained as the sum and the difference of the two bisectors.

We now look at the execution of (2.12) on the two largest eigenpairs of W_{201}^+. The largest entries of the true eigenvectors are at the first and last positions. When executing (2.12), underflow must occur for large enough m (and in particular occurs

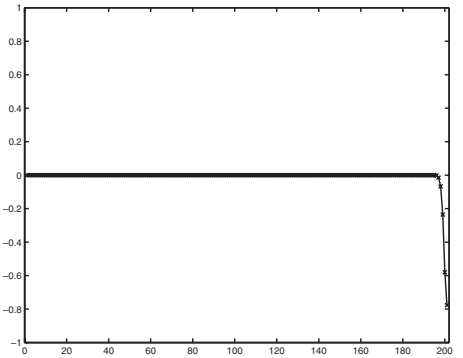

FIG. 2. *Eigenvector* 200 *of* W_{201}^{+} *as computed by MATLAB. The horizontal axis denotes the index. The vertical axis denotes the corresponding vector entry. Note the sharp decay at the right end.*

for $m = 201$), which sets the rest of the vector to zero, yielding the bisector instead of the FP vector.

The danger is that MRRR might choose the same twist index for both vectors, yielding the same bisector. In exact arithmetic, there are two maximal entries in the true eigenvectors, and all would be well if the code chose the twist indices at opposite ends. However, currently there is no mechanism in the MRRR algorithm that guarantees this.

In summary, the FP vector in exact arithmetic is always a good approximation to the true eigenvector. However, in the face of underflow, the computed vector will not satisfy (2.6) and its angle to the true eigenvector will not be small. Furthermore, MRRR is not guaranteed to produce orthogonal vectors.

5. Modifications to MRRR. This section sketches possible modifications to MRRR and discusses their principal features.

Section 5.1 essentially invokes the earlier LAPACK routine STEIN, based on inverse iteration with modified Gram–Schmidt orthogonalization. We apply it only to very tight clusters on which MRRR has failed (as seen in section 4).

Section 5.2 covers Parlett's submatrix method which is very efficient but is applicable only for clusters that are well isolated.

Both these methods can be used as fall-back for the MRRR algorithm on a difficult cluster. However, such a cluster might only be relatively isolated from neighboring clusters and not well separated by an absolute gap. Then the orthogonality among the two clusters cannot be guaranteed without additional work. For this purpose, we discuss the Rayleigh–Ritz projection in section 5.3.

In the worst case, all these modifications will lead to an algorithm that costs $\mathcal{O}(nk^2)$ operations, for a cluster of size k. In section 5.4, we describe Dhillon's elegant proposal to simply get rid of these difficult cases by small componentwise relative random perturbation of the root of the representation. This approach does not sacrifice the $\mathcal{O}(n^2)$ complexity of the original MRRR algorithm.

5.1. Selective inverse iteration with modified Gram–Schmidt orthogonalization. In this section, we take a look at inverse iteration with modified Gram–Schmidt orthogonalization [6, 10, 11], available in LAPACK's STEIN. Its efficiency

problems with matrices from the analysis of molecules prompted the research that led to the development of the MRRR algorithm. It is interesting that STEIN can cope with the very tight glued clusters and thus complement STEGR in this respect.

Given a set of eigenvalues ordered by increasing value, the procedure is as follows. First, if an eigenvalue is too close to its left neighbor, it is perturbed by a small relative amount. Then one step of inverse iteration with a random right-hand side is performed. The resulting vector is kept orthogonal to all previously computed eigenvectors that belong to eigenvalues within distance of the current eigenvalue. (The choice of the parameter $ORTOL = 10^{-3}||T||_1$ determines the level of numerical orthogonality.) The vector obtained is scaled and used as a new right-hand side until the iteration converges. However, it is the orthogonalization feature that makes STEIN inefficient.

Thus, we could use STEIN as backup for the case when MRRR cannot achieve relative separation for a cluster. However, this modification would destroy the claim that MRRR has $\mathcal{O}(n^2)$ complexity in the worst cases. While inverse iteration itself costs only $\mathcal{O}(nk)$ operations, the total cost of the algorithm is dominated by the orthogonalization of a computed vector to all previously found eigenvectors, yielding an $\mathcal{O}(nk^2)$ algorithm.

5.2. The submatrix method. In this section, we sketch briefly the ideas behind the submatrix method as a means of obtaining an orthogonal basis for the subspace defined by a tight isolated cluster. For more details, we refer the reader to [14].

The envelope vector of an invariant subspace of the (symmetric) matrix T is defined by the property that its jth entry is the maximal jth entry over all unit vectors in the subspace. For a tight isolated cluster of k eigenvalues, the envelope has k hills separated by $k-1$ valleys. The method chooses k submatrices of T with two properties:

- Each submatrix has a simple eigenvalue in the cluster interval whose normalized eigenvector has very small first and last entries (except for the first entry of the submatrix at the top and the last entry of the submatrix at the bottom).
- The indices of each submatrix overlap, at worst, the indices of its adjacent neighbors.

The respective k (small) eigenvectors of these k submatrices, when padded appropriately with zeros, form a distinguished basis for the subspace. When the cluster is well isolated, these basis vectors are numerically orthogonal and have a small residual norm (with respect to T). Otherwise, they might be not quite orthogonal (but, by construction, are guaranteed to be linearly independent). Suitable linear combinations are needed to form the eigenvectors of T. We show how to do that in the next section.

The main attraction of the submatrix method is that by construction, each submatrix has exactly one eigenvalue in the interval spanned by the cluster; thus, in terms of the submatrix, we have to compute the eigenvector of an isolated eigenvalue, which is an easy task.

Typically, the submatrix method is an $\mathcal{O}(nk)$ process. However, its limitation is that the tight cluster needs to be isolated. Some large glued Wilkinson matrices produce small tight clusters that are not well isolated; an example is shown in the next section. We could not find a modification of the submatrix method that did not spoil its complexity in that case.

5.3. Rayleigh–Ritz projections and how to couple MRRR with selective inverse iteration. In the previous sections, we have seen how to obtain numerically orthogonal vectors spanning the approximate invariant subspace of a tight cluster. These basis vectors will be (automatically) orthogonal to other eigenvectors belonging to eigenvectors outside the cluster, provided that the cluster is isolated. However, when the (absolute) gaps on either side of the tight cluster are not large enough, orthogonality cannot be guaranteed. For this reason, neither inverse iteration nor the submatrix method alone can provide a fall-back solution for tight clusters on which the MRRR algorithm fails.

A possible solution is the following postprocessing step whenever the MRRR algorithm fails to resolve a tight nonisolated cluster and resorts to a special method to compute a subspace basis. After all eigenvectors have been computed, we can group together those of the tight cluster and all those belonging to eigenvalues which are close to it so that the enlarged set has gaps greater than $ORTOL$ to the rest of the spectrum. (Here, we choose the parameter $ORTOL$ in the same way as in section 5.1.) Then, the Rayleigh–Ritz-values and -vector give us the best approximation from that subspace. The Ritz vectors are orthogonal among themselves and the orthogonality to the eigenvectors of the rest of the spectrum is governed in the same way as for STEIN; see section 5.1.

Specifically, let Z_k be the matrix whose k normalized linearly independent column vectors $z_i, 1 \leq i \leq k$, span the enlarged subspace. Furthermore, let

$$||Tz_i - \hat{\lambda}_i z_i|| = \mathcal{O}(n\epsilon||T||) \ \forall i \in \{1, \ldots, k\}\,.$$

Define the matrix $A = (a_{ij}) \in \mathcal{R}^{k\times k}$ by

$$a_{ij} = \frac{\lambda_i + \lambda_j}{2}(z_i, z_j)$$

and the matrix $B = (b_{ij}) \in \mathcal{R}^{k\times k}$ by $b_{ij} = (z_i, z_j)$.

If Λ holds the (generalized) eigenvalues and the columns of G hold the corresponding generalized eigenvectors of the pencil (A, B), $AG = BG\Lambda$, then Rayleigh–Ritz theory states that

$$(\Lambda, Z_k G) = \arg\min_{(\hat{\Lambda},\hat{Z})} ||T\hat{Z} - \hat{Z}\hat{\Lambda}||_F.$$

In practice, the need for the [illegible] step of computing Ritz approximations from a subspace does not occur very often. This is very fortunate since a cost analysis reveals that for a cluster of size k, it has $\mathcal{O}(nk^2)$ costs.

Next, we give an example where the postprocessing is needed. We consider a matrix T obtained from five copies of W_{201}^+ glued together by $\sqrt{\epsilon}$. Originally, the largest eigenvalue pair of the matrix W_{201}^+ is very close to 100.74619418290335. By gluing five copies of the matrix together, we obtain a cluster of ten eigenvalues that, at Level 1 of the representation tree (where we shift close to the right side of the cluster), splits up into two (tight) clusters of four eigenvalues each and a (not quite so tight) cluster of two in the middle. (The relative gaps between eigenvalues 999 and 1000 and eigenvalues 1001 and 1002 are both large enough to pass MRRR's threshold test.) This is shown in Table 4. In order to show that the eigenvalues belong to different clusters and thus to different representations, we separate them at the cluster boundaries by a horizontal line. Since the two eigenvalues in the middle cluster have large relative gaps between themselves, the corresponding eigenvectors

can be immediately computed by MRRR. However, the algorithm is not able to refine the two outer clusters any more, so it chooses representations closer and closer to the cluster ends without detecting large enough relative gaps in the eigenvalues which keep decreasing towards the roundoff level. Recall the behavior observed in section 4 and documented in Table 3. We can cure this situation in each cluster individually by applying inverse iteration with modified Gram–Schmidt orthogonalization on each group of eigenvalues as described in section 5.1.

However, this procedure will only produce vectors that are orthogonal to the other three vectors within their cluster of four; mutual orthogonality within the cluster of ten eigenvalues of T is not guaranteed and indeed not given. However, the ten vectors are linearly independent and provide a good basis for the invariant subspace. By computing the orthogonal Ritz basis, we obtain orthogonal vectors with small residuals. In Table 5, we display the computed eigenvalues of T and the Ritz values from the postprocessing process.

5.4. Small relative perturbations of the root representation. In section 5.1, we presented inverse iteration with modified Gram–Schmidt orthogonalization as one remedy for tight clusters arising from gluing. Two key factors for that algorithm's success are

- the perturbation of an eigenvalue by a small (relative) amount to separate it from the rest of the spectrum;
- the choice of a random right-hand side for the inverse iteration.

As mentioned, the important drawback of the approach is its repeated use of reorthogonalization that increases its complexity.

Dhillon had the clever idea to perturb the elements of the root representation by a (relatively) small amount in order to achieve eigenvalue separation and break up the tight clusters. After having found an LDL^T factorization of T (with appropriate shift), he suggests using

$$\hat{d}_i = d_i * (1 + \mu_i k\epsilon),\ 1 \le i \le n, \tag{5.1}$$

$$\hat{l}_j = l_j * (1 + \nu_j k\epsilon),\ 1 \le j \le n, \tag{5.2}$$

where k is a small number, say 4, and $\mu_i, \nu_j \in [-1, 1]$ are chosen at random from a uniform distribution. The size of the perturbation is at the same level as the errors in the differential qd algorithms.

We have verified by experiments that this technique works very well and will show an example below. The rationale for our approach is as follows.

- Symmetric tridiagonal matrices do not necessarily define their eigenvalues to high relative accuracy. A result of Demmel and Kahan [5] states that bidiagonal matrices always do. As long as k from (5.1) and (5.2) is small enough, the eigenvalues of the root representation are perturbed only by a relatively small amount. For this reason, we apply the perturbation to the root representation and not the matrix T itself.
- So far, all our tests indicate that no other representations need to be perturbed. Thus, MRRR computes the eigenvalues of the perturbed root representation $\hat{L}\hat{D}\hat{L}^T$ instead of the computed LDL^T factorization of T.
- In order to reproduce numerical results, we advocate the use of a pseudorandom generator with fixed seed.

In brief, we introduce artificial roundoff into the root representation since machine roundoff might not come to the rescue.

In the following, we study the effect of random perturbations on the second-smallest cluster of a matrix T obtained from five copies of W_{201}^+ glued together by $\sqrt{\epsilon}$. As seen in section 4, this matrix is a counterexample to the basic assumptions of MRRR. Table 3 showed a refinement of the eigenvalues of the cluster up to the underflow threshold without being able to find subclusters. This behavior will be compared to the use of MRRR on a perturbed root representation with $k = 4$ in (5.1) and (5.2). We remark that the respective children at Level 1 of the unperturbed and the perturbed root representation have (slightly) different shifts. For this reason the local eigenvalues appear very different. However, for MRRR, we note that the child of the perturbed representation has (local) eigenvalues with large relative gaps; see the right-most column of Table 6. Hence we can compute the corresponding eigenvectors immediately with guaranteed numerical orthogonality. The relative changes in the eigenvalues of the root representation (Level 0) are of order $\mathcal{O}(n\epsilon)$, n = 1005 in this case.

In conclusion, random perturbations of the root representation work well in practice. The perturbations are made by default, not just in difficult cases which might be hard to recognize a priori. In all our tests, we have yet to find a case where the perturbed clusters are not broken up quickly.

6. Summary and conclusions. The MRRR algorithm is based on very reasonable assumptions that are theoretically sound and hold in the majority of cases in finite precision arithmetic. In this paper, we have shown very subtle and nonobvious

TABLE 6

Investigation of the second-smallest cluster of eigenvalues of the matrix T obtained from five copies of W_{201}^+ glued together by $\sqrt{\epsilon}$; see also Table 3. Shown are the unshifted eigenvalues of the (unperturbed) root representation LDL^T and its perturbed counterpart $\hat{L}\hat{D}\hat{L}^T$. Furthermore, we display the eigenvalues of the representation of the corresponding child clusters that belong to Level 1 of the respective representation trees.

difficulties that can lead to failures. We have illustrated and explained these failures by examples. Furthermore, we have proposed and evaluated possible remedies. These will be adopted for an update of the current LAPACK 3.0 version of STEGR.

SOLVING LINEAR EQUATIONS BY MONTE CARLO SIMULATION*

GIRAY ÖKTEN†

Abstract. A new Monte Carlo estimator for solving the matrix equation $x = Hx+b$ is presented, and theoretical results comparing this estimator with the traditional terminal and collision estimators are given. We then make a detailed investigation of the average complexity of the Monte Carlo estimators when several popular random variable generation techniques are used, and we show that the average complexity can be as low as $C\|z\|_1 n + N$, where n is the number of random walks generated, N is the size of the matrix H, z is the solution of an associated matrix equation, and C is a small constant. As a consequence of the complexity results, we observe how scaling of matrices, a well-known technique in deterministic methods, can increase the efficiency of the Monte Carlo method.

One advantage of the Monte Carlo method is the efficiency at which it can be parallelized. The algorithms we discuss can provide fast and approximate solutions to systems of linear equations in massively parallel computing environments. Surprisingly, sequential (or adaptive) Monte Carlo methods can even be competitive in single-processor computing environments. We present numerical results and compare our Monte Carlo algorithms with Krylov subspace methods for some test matrices.

Key words. Monte Carlo, matrix equations, parallel computing

1. Background and notation.

The first Monte Carlo algorithm for solving linear equations was discovered by von Neumann and Ulam, although in published form it appeared in a paper by Forsythe and Leibler [5]. The algorithm was further studied and extended by Wasow in [20]. The first study that compared the Monte Carlo approach with some deterministic matrix solvers was given by Curtiss [1]. Other important contributions were made by Curtiss [2] and Halton [6], [7].

Detailed descriptions of Monte Carlo algorithms for solving matrix equations can also be found in the books by Spanier and Gelbard [17] and Rubinstein [14]. Following Spanier, we will call the estimators of Forsythe and Leibler and of Wasow the terminal and collision estimators, respectively. We will introduce a new estimator that we call the expected value estimator. For a given matrix equation, there is an adjoint formulation of it, and solving the adjoint formulation is more efficient, especially when one is interested in only one component of the solution vector, as opposed to the full solution vector of the matrix equation. The view taken in this paper is that in very large systems of equations it might be desirable to obtain a fast estimate of the full solution vector using parallel Monte Carlo algorithms implemented over massively parallel computing environments. For this reason, we will consider only the "forward" formulation of the matrix equation, not its adjoint formulation.

Our main problem is estimating the solution of $x = Hx + b$, where H is an

*Received by the editors March 10, 2004; accepted for publication (in revised form) November 18, 2004; published electronically October 7, 2005. The investigation of parallel adaptive Monte Carlo algorithms for solving matrix equations was the subject of a research program funded by Los Alamos National Laboratory and was carried out by the author while he was visiting Claremont Research Institute of Applied Mathematical Sciences during the 2000/01 academic year. Additional support was provided by a Ball State research grant in the summer of 2003, where the author was an associate professor of mathematics.

†Department of Mathematics, Florida State University, Tallahassee, FL 32306 (okten@math.fsu.edu).

$N \times N$ matrix and b is an N-dimensional vector satisfying certain conditions that will be mentioned later. The Monte Carlo estimators we will consider are based on the Neumann series representation

$$x_j = b_j + \sum_{i_1=1}^{N} h_{ji_1} b_{i_1} + \sum_{i_2=1}^{N} \sum_{i_1=1}^{N} h_{ji_2} h_{i_2 i_1} b_{i_1} + \cdots , \tag{1.1}$$

where x_j is the jth component of the solution vector x. The first step in estimating x_j is to introduce an absorbing (discrete) Markov chain with state space $\{1, \ldots, N+1\}$, a transition matrix $P = (p_{ij})$, where p_{ij} denotes the probability of transition from nonabsorbing states j to i, and a birth vector $a = (a_j)$. This being an absorbing chain, we introduce the N-dimensional vector $p = (p_j)$, where p_j is the probability that the Markovian random walk is absorbed in state j, when it visits state j. We will denote a typical random walk with k steps (collisions) as $\alpha = i_1, i_2, \ldots, i_k$, where $i_j \in \{1, \ldots, N\}$, i_1 is the birth state, and i_k is the final (terminal) state. The probability of occurrence of such a random walk is $a_{i_1} p_{i_2 i_1} \cdots p_{i_k i_{k-1}} p_{i_k}$. Clearly, being absorbed in state i_k is equivalent to making a transition from state i_k to the only recurrent state of the Markov chain (and staying there with probability 1).

In section 2, we will introduce the terminal and collision estimators, and the new expected value estimator, for the solution vector x. In section 3, we will consider the special case when $H = P$ and $b = a$ and compute the variances of the three estimators. As a corollary, we will prove a generalization of a classical result by Wasow. In section 4, we will analyze the complexity of the three Monte Carlo estimators when three popular methods for generating discrete distributions are used: the inverse transform method, acceptance-rejection method, and the alias method. Previous results on the complexity of the Monte Carlo method were restricted to certain estimators and methods of random variable generation. For example, Danilov, Ermakov, and Halton [3] compute the complexity of the collision estimator when $P = |H|$, and Knuth and Yao when the discrete distributions are generated using distribution generating trees [11]. One advantage of computing the complexity for a broader family of estimators and random variable generation methods was to assess the benefits of scaling (section 4.2), a well-known technique in deterministic linear solvers, to the Monte Carlo method. We also discuss implementational issues and the pros and cons of each random variable generation method when applied to certain matrix equations. Finally, in section 7, we present numerical results where the expected value estimator is used in conjunction with a sequential Monte Carlo method. In the literature, Monte Carlo methods are usually compared with classical iterative methods such as Gauss–Seidel, Jacobi, and conjugate gradient. Section 7 will provide numerical results when the Monte Carlo method is compared with two Krylov subspace methods.

2. The estimators. To solve the equation

$$x = Hx + b \tag{2.1}$$

by estimating the sum of the Neumann series mentioned earlier, we need to make sure the series is convergent. Hence we assume that the spectral radius of H is less than one. The Markovian random walks are generated using a transition matrix P and a birth probability vector a satisfying the following conditions:

1. $0 < a_j$, $p_{ij} < 1$ for all i, j,
2. $\sum_{i=1}^{N} p_{ij} < 1$ for all j,
3. $\sum_{j=1}^{N} a_j = 1$,
4. $h_{ij} \neq 0 \Rightarrow p_{ij} \neq 0$ and $b_i \neq 0 \Rightarrow a_i \neq 0$.

We note that the probability that the Markovian random walk is absorbed in state j, when it visits state j, is $p_j = 1 - \sum_{i=1}^{N} p_{ij}$. The first three conditions are simply the definitions of P and a, and the last condition enables us to go from the probability model, described by matrices P and a, to the Neumann series (1.1) that involves H and b. Indeed, let

$$\alpha = (i_1, \ldots, i_k)$$

be a typical random walk beginning at state i_1 and ending at state i_k. Define "weights"

$$w_{ij} = \begin{cases} \dfrac{h_{ij}}{p_{ij}} & \text{if } p_{ij} \neq 0, \\ 0 & \text{if } p_{ij} = 0 \end{cases}$$

and random variables W_m on the space of random walks α by

$$\begin{aligned} W_1(\alpha) &= \frac{b_{i_1}}{a_{i_1}}, \\ W_m(\alpha) &= W_{m-1}(\alpha) w_{i_m i_{m-1}} \\ &= \frac{b_{i_1}}{a_{i_1}} w_{i_2 i_1} \cdots w_{i_{m-1} i_{m-2}} w_{i_m i_{m-1}}, \quad m = 2, \ldots, k. \end{aligned} \tag{2.2}$$

We define the terminal estimator by

$$T_j(\alpha) = W_k(\alpha) \frac{\delta_{i_k j}}{p_{i_k}}, \tag{2.3}$$

the collision estimator by

$$C_j(\alpha) = \sum_{m=1}^{k} W_m(\alpha) \delta_{i_m j}, \tag{2.4}$$

and the expected value estimator by

$$e_j(\alpha) = b_j + \sum_{m=1}^{k} W_m(\alpha) h_{j i_m}, \tag{2.5}$$

where $j = 1, \ldots, N$ and $\delta_{ij} = 1$ if $i = j$ and 0 otherwise.

The proofs that the terminal and collision estimators, as defined above, are unbiased estimators of x_j can be found in [17]. The unbiasedness of the expected value estimator can be shown easily from its definition. One can also observe the following relationship between e_j and C_j:

(2.6)

$$e_j(\alpha) = b_j + \sum_{m=1}^{k} W_m(\alpha) h_{j i_m} = b_j + \sum_{m=1}^{k} \sum_{i=1}^{N} W_m(\alpha) \delta_{i_m i} h_{ji} = b_j + \sum_{i=1}^{N} C_i(\alpha) h_{ji}.$$

Thus one can conclude that the unbiasedness of e_j follows from the unbiasedness of C_j:

$$E[e_j] = b_j + \sum_{i=1}^{N} E[C_i(\alpha)] h_{ji} = b_j + \sum_{i=1}^{N} x_i h_{ji} = x_j.$$

More important, (2.6) provides us with a relationship between the variances of these estimators.

THEOREM 2.1. [illegible] x_j. [illegible]

$$\operatorname{Var}(e_j) = \sum_{i=1}^{N} h_{ji}^2 \operatorname{Var}(C_i) + \sum_{i<k;\ i\neq k} 2h_{ji}h_{jk} \operatorname{Cov}(C_i, C_k).$$

It is possible to modify the probability space slightly and consider (nonabsorbing) random walks that make a fixed number, say K, of collisions. Then the estimators defined above can be used to estimate the Kth partial sum of the Neumann series (1.1). This approach was introduced by Curtiss [2] and further investigated by Sobol' [15]. It is also possible to accelerate the convergence of the Neumann series by applying appropriate transformations to the linear equation; see Dimov and Alexandrov [4] for details.

In the next section, we will investigate a special case of the problem (2.1) where $H = P$ and $b = a$. The weights are then all equal to one, and our estimators can be analyzed using results from the theory of absorbing Markov chains. In particular, we will prove a generalization of an earlier result by Wasow [20].

3. Special case. We consider the equation

$$x = Px + a, \tag{3.1}$$

where

$$0 < a_j, \quad p_{ij} < 1, \quad \sum_{i=1}^{N} p_{ij} < 1 \quad \text{for all } j, \quad \text{and} \quad \sum_{j=1}^{N} a_j = 1. \tag{3.2}$$

Put $Q = P^T$ and $\tilde{Q} = \left(\begin{smallmatrix} Q & p \\ 0 & 1 \end{smallmatrix}\right)$, where $p = (p_j)_{N\times 1}$ and $0 = (0)_{1\times N}$. Then $\tilde{Q}$ is the transition matrix of a discrete Markov chain $\{X_n, n = 0, 1, \dots\}$, or an (absorbing) random walk, with $N+1$ states. The matrix $Q = (q_{ij})$ gives the transition probabilities of the transient states of the chain. The birth probabilities are given by the vector $a = (a_j)$. The jth component of the vector $p = (p_j)_{N\times 1}$ gives the probability that the random walk is absorbed in state j, when it visits state j. We arrange the states so that the first N states are transient and the last state is an absorbing state, and hence recurrent. When convenient, we will let $\mathcal{T}$ denote the transient states and $\mathcal{R}$ denote the only recurrent (absorbing) state.

3.1. Terminal estimator. Let ε be the event that a random walk is absorbed in state j. We have

$$\begin{aligned}
\Pr(\varepsilon) &= \sum_{k=1}^{\infty} \Pr(\varepsilon \mid \text{random walk has } k \text{ steps}) \\
&= p_j a_j + \sum_{i_1=1}^{N} p_j p_{ji_1} a_{i_1} + \sum_{i_2=1}^{N}\sum_{i_1=1}^{N} p_j p_{ji_2} p_{i_2 i_1} a_{i_1} + \cdots \\
&= p_j x_j.
\end{aligned}$$

Now consider the random variable

$$Y_j = \begin{cases} 1 & \text{if random walk is absorbed in state } j, \\ 0 & \text{otherwise.} \end{cases}$$

The expected value of Y_j is $E[Y_j] = \Pr(\varepsilon) = p_j x_j$. The terminal estimator (2.3) takes the following form:

$$T_j = \frac{Y_j}{p_j}.$$

Clearly, $E[T_j] = x_j$, and the variance of the estimator is

$$\operatorname{Var}(T_j) = \frac{1}{p_j^2}\operatorname{Var}(Y_j) = \frac{x_j}{p_j} - x_j^2. \tag{3.3}$$

3.2. Collision estimator. Let C_{ij} denote the number of occurrences of state j when the random walk starts in state i. Here the states i and j are transient states. Put $E[C_{ij}] = s_{ij}$, $E[C_{ij}^2] = s_{ij}^{(2)}$, $S = (s_{ij})$, and $S^{(2)} = (s_{ij}^{(2)})$. For a given matrix $A = (a_{ij})$, let $\operatorname{diag}(A)$ be the diagonal matrix whose diagonal entries are a_{ii}. The following is a standard result from the theory of absorbing Markov chains (see page 103 of Iosifescu [9])

THEOREM 3.1. [illegible] $\tilde{Q} = \left(\begin{smallmatrix} Q & p \\ 0 & 1 \end{smallmatrix}\right)$. [illegible]

$$S = (I - Q)^{-1} \qquad S^{(2)} = S(2 \times \operatorname{diag} S - I).$$

Taking the transpose of $S = (I - Q)^{-1}$ and multiplying by a we obtain $S^T a = (I - P)^{-1} a = x$ from (3.1). Now let C_j be the number of times a random walk visits a transient state j. We have

$$\begin{aligned} E[C_j] &= \sum_k E[C_j \mid \text{random walk starts in state } k] P(\text{walk starts in } k) \\ &= \sum_k s_{kj} a_k = [S^T a]_j = x_j. \end{aligned} \tag{3.4}$$

C_j is the collision estimator, with its general form defined by (2.4).

Now we take the transpose of $S^{(2)} = S(2 \operatorname{diag} S - I)$ to get $S^{(2)^T} = (2 \operatorname{diag} S - I)^T S^T$. Then

$$S^{(2)^T} a = (2 \operatorname{diag} S - I)^T S^T a = (2 \operatorname{diag} S - I)^T x = (2 \operatorname{diag} S - I) x.$$

Since $2 \operatorname{diag} S - I$ is a diagonal matrix with (j, j)th entry equal to $2 s_{jj} - 1$, we get $[S^{(2)^T} a]_j = (2 s_{jj} - 1) x_j$. The second moment of the collision estimator is

$$\begin{aligned} E[C_j^2] &= \sum_k E[C_j^2 \mid \text{random walk starts in state } k] P(\text{walk starts in } k) \\ &= \sum_k s_{kj}^{(2)} a_k = [S^{(2)^T} a]_j = (2 s_{jj} - 1) x_j. \end{aligned}$$

We have obtained the following lemma.

LEMMA 3.2.

$$\mathrm{Var}(C_j) = (2s_{jj} - 1)x_j - x_j^2, \tag{3.5}$$

Now we can compare the variances of the two estimators.

THEOREM 3.3.

$$p_j < \frac{v_j}{2 - v_j},$$

v_j j j.

If j is a transient state, then starting in state j, the number of visits the random walk makes to state j is a geometric random variable with mean $1/v_j$. In other words $s_{jj} = 1/v_j$, and thus (3.5) can be rewritten as

$$\mathrm{Var}(C_j) = \left(\frac{2}{v_j} - 1\right) x_j - x_j^2. \tag{3.6}$$

Now from (3.3) and (3.6), we have

$$\mathrm{Var}(C_j) < \mathrm{Var}(T_j) \Leftrightarrow \left(\frac{2}{v_j} - 1\right) < \frac{1}{p_j} \Leftrightarrow p_j < \frac{1}{\frac{2}{v_j} - 1} = \frac{v_j}{2 - v_j}. \qquad \square$$

3.4. A special case of the above result was proven by Wasow when the birth vector a was given as $a_j = 1$ and $a_i = 0$ for $i \neq j$ (see Spanier and Gelbard [17, p. 54]).

3.3. Expected value estimator. The expected value estimator (2.5) takes the form

$$e_j(\alpha) = b_j + \sum_{i=1}^{N} C_i(\alpha) p_{ji}$$

and thus has variance

$$\mathrm{Var}(e_j) = \mathrm{Var}\left(\sum_{i=1}^{N} C_i(\alpha) p_{ji}\right).$$

Assume that the transition probabilities are chosen so that they are all equal to each other, and let this constant value be p_t. This is a very useful assumption, and it will be discussed further in section 4.2. In some numerical results of section 7, the transition probabilities are indeed chosen this way. The variance $\mathrm{Var}(e_j)$ then simplifies to

$$\mathrm{Var}(e_j) = p_t^2 \,\mathrm{Var}\left(\sum_{i=1}^{N} C_i(\alpha)\right).$$

The term $\sum_{i=1}^{N} C_i(\alpha)$ gives the total number of steps the random walk takes before absorption, and its higher moments, conditioned on the starting state of the random

walk, are known (see Theorem 3.2 of Iosifescu [9]). Using a simple conditional expectation argument, one can obtain the variance of $\sum_{i=1}^{N} C_i(\alpha)$ and reach the following result.

THEOREM 3.5.

$$\mathrm{Var}(e_j) = p_t^2 \left[((2S - I)Se) \cdot a - (Se \cdot a)^2 \right],$$

$S = (I-Q)^{-1}, e$ 1 p_t j.

4. Complexity of the Monte Carlo algorithm. Here we discuss the average complexity of the Monte Carlo algorithm that gives an approximate solution to the equation $x = Hx + b$, where the random walks are generated by a given transition matrix P and birth vector a. The main steps of the algorithm are as follows.

MONTE CARLO ALGORITHM.

1. n $\alpha_1, \ldots, \alpha_n$
2.

$$c_{\mathrm{sum}} = \begin{bmatrix} X_1(\alpha_1) + X_1(\alpha_2) + \cdots + X_1(\alpha_n) \\ \\ X_N(\alpha_1) + X_N(\alpha_2) + \cdots + X_N(\alpha_n) \end{bmatrix},$$

X_j

3. c_{sum} n

$$x = c_{\mathrm{sum}}/n.$$

We will study each step of the algorithm and compute its average complexity. To this end, let z denote the solution of $x = Px + a$, and let C_j be the number of times a random walk visits the transient (nonabsorbing) state j. Then the total number of steps a random walk makes before absorption is $\sum_{j=1}^{N} C_j$, with expected value

$$E\left[\sum_{j=1}^{N} C_j\right] = \sum_{j=1}^{N} z_j = \|z\|_1 .$$

In the following, we will investigate the complexity of random walk generation when the inverse transform, acceptance-rejection, and alias methods are used to sample from the discrete distributions specified by the probability transition matrix P. See Rubinstein [14] or Ross [13] for descriptions of the inverse transform and rejection methods, and Kronmal and Peterson [10] for a description of the alias method. We assume the cost of all arithmetical operations $(\times, \div, \pm)$ are equal and an IF statement is worth l arithmetic operations. By an IF statement we simply mean the logical operation of testing the inequality $\alpha < \beta$. We assume that the cost of generating one pseudorandom number is three arithmetic operations, which is indeed the case if a linear congruential generator is used as the random number generator. We will also assume that the matrix P and vector a have no zero entries. This will keep the exposition simpler: for matrices with zero entries our analysis can easily be modified to obtain tighter bounds for the complexity.

4.1. Complexity of generating the random walks.

4.1.1. Generating random walks using the inverse transform method. Generation of a random walk from birth until termination involves sampling from a number of discrete distributions. To start the random walk, we need to generate the discrete distribution described by the birth vector a. Once the random walk is in some state j, we need to generate the discrete distribution described by the jth column of matrix P with the corresponding probability of absorption adjoined, in order to determine the next state to visit or whether absorption takes place. We assume the implementation of the inverse transform method employs the simple linear search, where the search for the subinterval that contains the random number starts from the leftmost interval and continues to the right.

LEMMA 4.1. $\mathcal{C}^a_{\text{inv}}$ $\mathcal{C}^{\tilde{P}_j}_{\text{inv}}$ a $\tilde{P}_j = \{p_{1j}, p_{2j}, \ldots, p_{Nj}, p_j\}$ j P j $\mu_a = \sum_{i=1}^{N} i a_i$ $\mu_{\tilde{P}_j} = \sum_{i=1}^{N+1} i p_{ij}$ $p_{(N+1)j}$ p_j

$$E[\mathcal{C}^a_{\text{inv}}] = (l+1)(\mu_a - N a_N) + 2(1 - a_N)$$

$$E\left[\mathcal{C}^{\tilde{P}_j}_{\text{inv}}\right] = (l+1)(\mu_{\tilde{P}_j} - p_j N) - (l+3)p_j + 2.$$

We will prove only the second equation; the first one is proved similarly. Consider the discrete distribution $\tilde{P}_j = \{p_{1j}, p_{2j}, \ldots, p_{Nj}, p_j\}$ where $p_j = 1 - \sum_{i=1}^{N} p_{ij}$. Generate a random number ξ between 0 and 1. If

$$p_{1j} + \cdots + p_{i-1,j} \le \xi < p_{1j} + \cdots + p_{ij}, \quad i = 1, \ldots, N, \tag{4.1}$$

then state i is selected as the next state visited by the random walk. In the above inequality, the left-hand side is understood to be 0 when $i = 1$. If ξ does not satisfy (4.1) for any $i = 1, \ldots, N$, then absorption takes place. To determine that ξ satisfies (4.1) for some particular i, one has to perform $(i-1)$ additions and i IF statements, in addition to the cost of generating ξ. The total number of operations is $i - 1 + li + 3 = (l+1)i + 2$. Since the probability that ξ satisfies (4.1) for some i is p_{ij}, we have

$$P\left(\mathcal{C}^{\tilde{P}_j}_{\text{inv}} = 2 + (l+1)i\right) = p_{ij}, \quad i = 1, \ldots, N,$$

and the expected value of $\mathcal{C}^{\tilde{P}_j}_{\text{inv}}$ is

$$E\left[\mathcal{C}^{\tilde{P}_j}_{\text{inv}}\right] = \sum_{i=1}^{N} p_{ij}(2 + (l+1)i) = (l+1)\mu_{\tilde{P}_j} - (l+1)p_j N - (l+3)p_j + 2. \qquad \square \tag{4.2}$$

Now we investigate the number of times one needs to sample from these discrete distributions. Clearly, we sample from a only once during the course of one random walk. The number of times we need to sample from $\tilde{P}_j$ is the number of times the random walk visits state j, which is C_j. The expected number of times we generate the jth column is then $E[C_j] = z_j$. Putting all these results together, we obtain the following theorem.

THEOREM 4.2.

$$E[\mathcal{C}_{\text{inv}}] = E[\mathcal{C}^a_{\text{inv}}] + \sum_{j=1}^{N} z_j E\left[\mathcal{C}^{\tilde{P}_j}_{\text{inv}}\right] = (l+1)(\mu_a - Na_N) + 2(1-a_N)$$
$$+ \sum_{j=1}^{N} z_j((l+1)(\mu_{\tilde{P}_j} - p_j N) - (l+3)p_j + 2). \tag{4.3}$$

Since $\mu_a \le N$, $\mu_{\tilde{P}_j} < N+1$, $0 < a_N < 1$, and N will be usually a large number, we have

$$(l+1)(\mu_a - Na_N) + 2(1-a_N) < (l+1)N + 2 \approx (l+1)N,$$
$$(l+1)(\mu_{\tilde{P}_j} - p_j N) - (l+3)p_j + 2 < (l+1)(N+1) + 2 \approx (l+1)N,$$

so an upper bound for the average complexity is, approximately,

$$(l+1)\left(\|z\|_1 + 1\right) N. \tag{4.4}$$

There is essentially no additional storage required by our implementation of the inverse transform method. The calculations required in linear search are done as they are needed, and discarded immediately after they are used.

4.1.2. Generating random walks using the acceptance-rejection method. Let $q_i = \frac{1}{N+1}$, $i = 1, \dots, N+1$, describe the probability mass function for the discrete uniform distribution on $1, \dots, N+1$. Now we generate from the discrete distributions $\tilde{P}_j = \{p_{1j}, p_{2j}, \dots, p_{Nj}, p_j\}$ and a, via the rejection method. The rejection algorithm that samples from $\tilde{P}_j$ takes the following form. As before, $p_{(N+1)j}$ is understood to be p_j.

ALGORITHM 4.3.

1. k $1, \dots, N+1$. U_1 $k = [(N+1)U_1] + 1$ $(N+1)U_1$
2. U_2.
3. $U_2 < \frac{(N+1)p_{kj}}{c} = \frac{p_{kj}}{\|\tilde{P}_j\|_\infty}$ $\tilde{P}_j$ k 1.

Here $c = \max_{1 \le i \le N+1}(N+1)p_{ij} = (N+1)\|\tilde{P}_j\|_\infty$. The number of iterations of the algorithm needed to obtain a value from $\tilde{P}_j$ is a geometric random variable with mean c. Since each iteration requires the generation of 2 random numbers, 1 multiplication, 1 division, 1 addition, and 1 IF statement (we ignore the integer part operation), we have

$$E\left[\mathcal{C}^{\tilde{P}_j}_{\text{rej}}\right] = (l+9)c = (l+9)(N+1)\|\tilde{P}_j\|_\infty. \tag{4.5}$$

A slight modification of the above algorithm shows that the complexity of generating the birth vector a satisfies

$$E[\mathcal{C}^a_{\text{rej}}] = (l+9)N\left\|a\right\|_\infty. \tag{4.6}$$

Therefore, we have proved the following theorem.

THEOREM 4.4.

$$E[\mathcal{C}_{\text{rej}}] = (l+9)N\,\|a\|_\infty + (l+9)(N+1)\sum_{j=1}^{N} z_j \|\tilde{P}_j\|_\infty. \tag{4.7}$$

Since $\|a\|_\infty < 1$ and $\|\tilde{P}_j\|_\infty < 1$, an upper bound for the average complexity is

$$(l+9)N + (l+9)(N+1)\,\|z\|_1 \approx (l+9)(\|z\|_1 + 1)N. \tag{4.8}$$

For a given $N \times N$ matrix P, we precompute $\|\tilde{P}_j\|_\infty = \max\{p_{1j}, p_{2j}, \ldots, p_{Nj}, p_j\}$, $j = 1, \ldots, N$, and store these numbers in an array of size N. As we will see in section 5 the absorption probabilities p_j will usually be constants, and determined by the user, so no additional calculations or storage will be needed for them.

4.1.3. Generating random walks using the alias method. The alias method introduced by Walker [19] is an efficient method of generating discrete distributions; however, it requires significant storage. Here we consider the implementation of the method due to Kronmal and Peterson [10]. After the initial setup of their algorithm, which creates two tables for each distribution, the method only requires the generation of 2 random numbers,[1] 1 IF statement, 2 addition, and 1 multiplication operations, to sample once from the distribution. We ignore table lookups and one integer part operation. We have the following theorem.

THEOREM 4.5.

$$E[\mathcal{C}_{\text{alias}}] = (l+9) + \sum_{j=1}^{N}(l+9)z_j = (l+9)\left(\|z\|_1 + 1\right). \tag{4.9}$$

What is remarkable about this result is that unlike the inverse transform and rejection methods, the size of the matrix N does not appear in the average complexity explicitly. Of course, the trade-off is the significant storage required by the alias method.

To save storage space, it is best to combine two tables constructed for each distribution, as discussed by Kronmal and Peterson [10]. Then, a real array of size $N+1$ is stored to sample from the column $\tilde{P}_j$. Since we have N columns and one N-dimensional birth vector to sample from, a real square matrix of size $(N+1)$ is needed to be stored for the implementation of the alias method. In other words, we need to store a matrix about the size of the matrix of the linear equation we are trying to solve. This will be probably infeasible for very large matrices.

4.2. The effects of scaling on the complexity of the rejection method. The rejection method can be substantially more efficient than the inverse transform method if the entries of the column vectors of the matrix P are about the same size. We now make the following assumptions.

[1] It is possible to increase the efficiency by generating only one random number, as explained by Kronmal and Peterson. However, we do not pursue this approach, since it may cause correlations in the pseudorandom numbers generated.

1. The probability of absorption p_j is fixed for all states j and denoted by p_{abs}.
2. $p_{ij} \approx \frac{1-p_{\text{abs}}}{N}$, $1 \le i, j \le N$.
3. $a_i \approx \frac{1}{N}$, $1 \le i \le N$.

Assumption 1 implies $\|z\|_1 = \frac{1}{p_{\text{abs}}}$. Indeed, if p_j is fixed for all j, then the number of steps a random walk makes is a geometric random variable with expected value $1/p_{\text{abs}}$. Since the expected number of steps a random walk makes is $E[\sum_{j=1}^{N} C_j] = \|z\|_1$, we have the desired equality. Assumption 2 implies $\|\tilde{P}_j\|_\infty = \max(\frac{1-p_{\text{abs}}}{N}, p_{\text{abs}})$ and Assumption 3 implies $\|a\|_\infty \approx \frac{1}{N}$.

Let us first consider the case when $\|\tilde{P}_j\|_\infty = p_{\text{abs}}$. This situation is likely to arise when the matrix P is dense, and thus the (nonzero) entries are smaller than the probability of absorption. In such a case, one would generate the column vectors as follows: First generate a random number and decide whether the random walk is absorbed or not. If not, then sample from the jth column of P using the rejection method. Then the complexity of the rejection method (4.7) simplifies to $(13+l)\|z\|_1$. If, on the other hand, $\|\tilde{P}_j\|_\infty = \frac{1-p_{\text{abs}}}{N}$, then the complexity is, approximately, $(9+l)\|z\|_1$. In conclusion, the complexity of the rejection method when the matrices are scaled is bounded by

$$E[\mathcal{C}_{\text{rej}}] \le (13+l)\,\|z\|_1\,. \tag{4.10}$$

The bound is approximately equal to the complexity of the alias method (4.9) and does not include the size of the matrix, N. This implies substantial savings of computing time over the inverse transform method, whose complexity is proportional to N.

4.3. Complexity of evaluating the estimators. We now consider the second step of the Monte Carlo algorithm and discuss the complexity of evaluating the cumulative sums

$$X_j(\alpha_1) + X_j(\alpha_2) + \cdots + X_j(\alpha_n), \quad j = 1, \dots, N, \tag{4.11}$$

for each estimator. Let $\alpha = (i_1, \dots, i_k)$ be a typical random walk. We recall that the expected value of k, the number of steps a random walk takes before absorption, is $\|z\|_1$. Let r denote the expected number of [illegible] states a random walk visits before absorption. The exact value of r is known in terms of the matrix S (see [9, p. 105]); however, for simplicity we will use the estimate $r \le \|z\|_1$ in the computations below. We also assume in the following that the logical operation of testing the equality $i_k = j$ and getting ready for the next instruction is worth l arithmetic operations. As before, we measure complexity in terms of the number of arithmetic operations, which are all assumed to have equal complexity.

THEOREM 4.6. [illegible] (4.11) [illegible]

1. $(2\|z\|_1 + 1)n$ [illegible]
2. [illegible] $(l(r-1)+3)\|z\|_1 n$ [illegible]
3. $(2\|z\|_1 + 1)nN + (2\|z\|_1 - 1)n$ [illegible]

[illegible]. 1. Set $\hat{T}_j = 0$, $j = 1, \dots, N$. Consider the random walk $\alpha = (i_1, \dots, i_k)$. All terminal estimators T_j ($j = 1, \dots, N$) except T_{i_k} take the value zero when evaluated at α. Therefore we evaluate only $\hat{T}_{i_k} := \hat{T}_{i_k} + W_k(\alpha)/p_{i_k}$. The term $W_k(\alpha)$ is computed in $2k-1$ operations. So the total number of operations is $(2k-1)+1+1 = 2k+1$. The final result follows from the fact that k is a random variable with expected value $\|z\|_1$, and we generate n random walks.

2. Set $\hat{C}_j = 0$, $j = 1, \ldots, N$. Consider the random walk $\alpha = (i_1, \ldots, i_k)$. All collision estimators C_j $(j = 1, \ldots, N)$ except $C_{i_1}, \ldots, C_{i_k}$ take the value zero when evaluated at α. Therefore we only evaluate $\hat{C}_j := \hat{C}_j + C_j(\alpha)$, $j \in \{i'_1, \ldots, i'_r\}$, where $i'_1, \ldots, i'_r$ are the distinct states α visit. We need to compute

$$\begin{aligned} C_{i'_1}(\alpha) &= W_1(\alpha)\delta_{i_1 i'_1} + W_2(\alpha)\delta_{i_2 i'_1} + \cdots + W_k(\alpha)\delta_{i_k i'_1} \\ &\vdots \\ C_{i'_r}(\alpha) &= W_1(\alpha)\delta_{i_1 i'_r} + W_2(\alpha)\delta_{i_2 i'_r} + \cdots + W_k(\alpha)\delta_{i_k i'_r}. \end{aligned}$$

The Kronecker delta functions can be evaluated efficiently by noting that if, for example, $\delta_{i_1 i'_1} = 1$, then all other terms $\delta_{i_1 i'_2}, \ldots, \delta_{i_1 i'_r}$ are zero and thus can be discarded immediately. A rather loose upper bound on the number of logical operations performed in this manner is $\|z\|_1(r-1)$. The number of nonzero terms in the first equation is given by the random variable $C_{i'_1}$; the number of visits to state i'_1. Therefore there are $C_{i'_1} - 1$ additions to be performed in the first equation. This is true for the other equations as well, so the total number of additions is $\sum_j (C_{i'_j} - 1)$. Since the expected value of $C_{i'_1}$ is $z_{i'_1}$, the average number of additions is bounded by $\|z\|_1 - r$. The weights $W_1(\alpha), \ldots, W_k(\alpha)$ can be computed recursively in an average of $2\|z\|_1 - 1$ operations, as mentioned in the proof of 1. We also perform r additions in updating $\hat{C}_j := \hat{C}_j + C_j(\alpha)$. Overall we have $l(r-1)\|z\|_1 + (\|z\|_1 - r) + (2\|z\|_1 - 1) + r = (l(r-1)+3)\|z\|_1 - 1$ arithmetic operations.

3. Set $\hat{e}_j = 0$, $j = 1, \ldots, N$. Consider the random walk $\alpha = (i_1, \ldots, i_k)$. We need to evaluate $\hat{e}_j := \hat{e}_j + e_j(\alpha)$ for all $j \in \{1, \ldots, N\}$. We have

$$\begin{aligned} e_1(\alpha) &= b_1 + W_1(\alpha)h_{1i_1} + \cdots + W_k(\alpha)h_{1i_k} \\ &\vdots \\ e_N(\alpha) &= b_N + W_1(\alpha)h_{Ni_1} + \cdots + W_k(\alpha)h_{Ni_k}. \end{aligned}$$

The weights $W_1(\alpha), \ldots, W_k(\alpha)$ are computed in an average of $2\|z\|_1 - 1$ operations. The number of multiplications and additions in the above array is $2kN$; a random variable with expected value $2\|z\|_1 N$. So the total number of operations is $(2\|z\|_1 - 1) + 2\|z\|_1 N$. We also have N additions in updating $\hat{e}_j := \hat{e}_j + e_j(\alpha)$ for all j. Since we generate n random walks, the final count is $((2\|z\|_1 - 1) + 2\|z\|_1 N + N)n$ which simplifies to the expression given in the theorem. □

4.4. Total complexity. The final step of the algorithm is the division of the cumulative sums by the number of random walks n. This is done in N divisions. We summarize the results and report the total complexity for a variety of choices in Table 4.1. In the first column, IT refers to the inverse transform method, and AR refers to the rejection method. We use the bound (4.4) for the inverse transform complexity, (4.8) for the rejection method complexity, and (4.10) for the rejection

TABLE 4.1

Meth.	Scaled	Est.	Bounds for average complexity
IT	No	e_j	$\left(\|z\|_1 (l+3) + (l+2)\right) nN + \left(2\|z\|_1 - 1\right) n + N$
AR	No	e_j	$\left(\|z\|_1 (l+11) + (l+10)\right) nN + \left(2\|z\|_1 - 1\right) n + N$
AR	Yes	e_j	$\left(2\|z\|_1 + 1\right) nN + \left((15+l)\|z\|_1 - 1\right) n + N$
AR	Yes	T_j	$\left((15+l)\|z\|_1 + 1\right) n + N$

method complexity when the matrices are scaled. The second column of the table refers to whether the matrices P and a are scaled or not. The third column displays the estimator used.

5. Selection of P and a. The best way to select the transition matrix P and birth vector a from the given matrices H and b is not currently known. Here we will consider two approaches and mention their advantages and disadvantages.

5.1. Constant approach. In this approach we first specify the probability of absorption, p_{abs}, which is fixed for every state. In other words, the column sums of P are all equal to $1 - p_{\text{abs}}$. As mentioned earlier, when the probability of absorption is fixed for all states we have the relationship $p_{\text{abs}}\|z\|_1 = 1$. We define $P = (p_{ij})$ and $a = (a_i)$ as

$$p_{ij} = \frac{1 - p_{\text{abs}}}{N} \quad \text{and} \quad a_i = \frac{1}{N}.$$

An advantage of this approach is the speed at which the random walks can be generated. Sampling from a column of P essentially simplifies to sampling the discrete uniform distribution on integers $1, \ldots, N$. Indeed, to sample from a column of P, we generate a random number ξ and first determine whether $\xi > 1 - p_{\text{abs}}$. If the test gives a positive answer, the random walk terminates. If not, we need to decide on the next state, which is an integer between 1 and N with equal probabilities. So the next state is simply given by [illegible] $(N\xi/(1 - p_{\text{abs}})) + 1$. Hence the number of operations needed to sample from a column of P is $l + 3$ with probability p_{abs}, and $l + 6$ with probability $1 - p_{\text{abs}}$, yielding an expected value of $l + 6 - 3p_{\text{abs}}$. Sampling from the birth vector a is simply done by computing [illegible] $(N\xi) + 1$, which takes 5 operations. Since during the course of a random walk from birth until termination we sample from a only once and sample, on average, z_j times from the jth column of P, the total expected number of operations is $5 + \sum z_j(l + 6 - 3p_{\text{abs}})$. Using the relationship $p_{\text{abs}}\|z\|_1 = 1$, this expression simplifies to $(l + 6)\|z\|_1 + 2$. So we have proved the following lemma.

LEMMA 5.1. [illegible] P [illegible] a [illegible]

$$(l + 6)\,\|z\|_1 + 2.$$

We note that this result is close to the complexity of the alias method, and the rejection method when the matrices P and a are scaled but not necessarily constant. Using this bound, we compute the total complexity when terminal, collision, and expected value estimators are used in the Monte Carlo algorithm; see Table 5.1.

5.2. Proportional approach. Here we still fix the probability of absorption, p_{abs}, but define $P = (p_{ij})$ and $a = (a_i)$ as

$$p_{ij} = \frac{|h_{ij}|}{\sum_{k=1}^{N} |h_{kj}|}(1 - p_{\text{abs}}), \qquad a_i = \frac{|b_i|}{\sum_{j=1}^{N} |b_j|}.$$

TABLE 5.1

Est.	Bounds for average complexity
T_j	$\left(\|z\|_1 (l + 8) + 3\right) n + N = O(n) + N$
C_j	$\left(\|z\|_1 (lr + 9) + r\right) n + N = O(n) + N$
e_j	$\left(2\,\|z\|_1 + 1\right) nN + \left(\|z\|_1 (l + 8) + 1\right) n + N = O(nN) + O(n) + N$

This approach is significantly slower than the previous one. First, we need to compute p_{ij} from h_{ij} using the above formula. If storage is cheap, one can precompute all p_{ij} and store them. Otherwise these numbers need to be computed as they are needed during the generation of random walks.[2] We also no longer enjoy the constant complexity of Lemma 5.1 and must use either the rejection or inverse transform method to sample from the columns of P.

The proportional approach seems to make use of the specific information given by H. In particular, if H is a sparse matrix, then the random walks do not make transitions $j \to i$ for which $h_{ij} = 0$, since $h_{ij} = 0$ implies $p_{ij} = 0$. In the constant approach, however, transitions $j \to i$ occur with equal probabilities whether h_{ij} is zero or not.

Since the probability of absorption is a constant, and consequently the norm $\|z\|_1 = 1/p_{\text{abs}}$ is a constant (independent of n, N), the top three upper bounds presented in Table 4.1 are $O(nN) + O(n) + N$ and the last bound is $O(n) + N$.

6. Sequential correlated sampling. Halton introduced three sequential Monte Carlo methods for solving linear equations in [6]. Here we explain one of these methods, called sequential correlated sampling. In the following discussion, we adopt the notation in which x in an equation $x = Hx + r^{(i)}$ is simply the indeterminate (variable) of the equation, but not the solution of the equation.

1. Solve $x = Hx + b$ ($r^{(0)} = b$) and obtain an approximate solution $y^{(0)}$. Residual of the equation is $r^{(1)} = Hy^{(0)} + b - y^{(0)}$. Put $x^{(1)} = y^{(0)}$.

2. Solve $x = Hx + r^{(1)}$ and obtain an approximate solution $y^{(1)}$. Residual of the equation is $r^{(2)} = Hy^{(1)} + b - y^{(1)}$. Put $x^{(2)} = x^{(1)} + y^{(1)}$.

Continuing this way, we obtain the ith step.

i. Solve $x = Hx + r^{(i-1)}$ and obtain an approximate solution $y^{(i-1)}$. Residual is $r^{(i)} = Hy^{(i-1)} + b - y^{(i-1)}$. Put $x^{(i)} = x^{(i-1)} + y^{(i-1)}$.

This scheme produces a sequence of random variables that are all unbiased estimators of the solution vector for the original equation $x = Hx + b$. In addition, Halton [6, Lemma 6] shows that the variances of these estimators converge to zero geometrically if certain conditions are satisfied.

The idea behind sequential correlated sampling is in fact a well-known technique of deterministic linear algebra: the method of iterative improvement. Iterative improvement has been used since the 1940s, especially to improve the accuracy of estimates obtained by Gaussian elimination. A detailed deterministic treatment of this method is given by Higham [8].

7. Numerical results. The main thesis of this paper is that the Monte Carlo method can be quite useful in solving very large systems of equations over distributed and massively parallel computing environments due to the high parallelization efficiency of the method. There is a rich literature on parallel pseudorandom and quasirandom generators that can be used in conjunction with the Monte Carlo algorithms we have discussed (see, for example, Srinivasan, Mascagni, and Ceperley [18] and Ökten and Srinivasan [12] and the references in these papers). The Monte Carlo method provides a quick and approximate solution of a large system over a parallel environment; if a more accurate solution is needed, then the Monte Carlo estimate could be used to improve the effectiveness of a deterministic linear solver via preconditioning.

[2] This is what we implemented in the numerical results later presented in the paper.

Although our main objective is not to "beat" a deterministic solver by Monte Carlo in a traditional single-processor computing environment, we will next present some numerical results where the Monte Carlo method used with sequential correlated sampling can actually compete very well with modern deterministic solvers even in such environments. Earlier related numerical results were given by Halton [7], who compared classical iterative methods with the Monte Carlo method that used only the constant approach, when these methods were applied to some special matrices. In our work we will use Krylov subspace methods, the new expected value estimator, and the Monte Carlo method with the constant and proportional approach. We will see examples where the proportional approach gives faster convergence than the constant approach. Before we discuss these numerical results and see how the new expected value estimator compares with deterministic solvers, we will present a few examples that compare the terminal, collision, and expected value estimators when they are used in conjunction with the sequential correlated sampling technique.

EXAMPLE 7.1. Let $H = (h_{ij})$ be the 10-dimensional square matrix defined by

$$h_{ij} = \frac{10 - |i - j|}{100},$$

and $b = [1, 3, 4, 2, 1, 6, -2, 1, 4, 5]^T$. Table 7.1 displays the L^2 norm of the relative error for the first five iterations of the sequential correlated sampling technique. The proportional approach is used for generating the random walks, and the probability of absorption is taken as 0.1. The number of random walks generated at each iteration is 10,000. The expected value estimator provides faster convergence than the other two estimators.

We now consider a randomly generated matrix for another example, and report the norm of the absolute error as well as the computation time.

EXAMPLE 7.2. We generate a random square matrix (from the uniform distribution on (0,1)) of size 99. We then scale the entries of the matrix so that its column norm is 0.99 (and hence the spectral radius is less than one). Table 7.2 displays the L^2 norm of the absolute error at the end of each iteration of the sequential correlated sampling technique, as well as the time to complete the iterations (the terminal estimator fails to be competitive in accuracy as well as efficiency and thus is omitted in the table). The number of random walks generated at each iteration is 40,000. The convergence

TABLE 7.3

Time	$N = 500$	$N = 1000$	$N = 1500$	$N = 2000$	$N = 2500$
CGS	0.16	0.58	1.462	3.114	4.387
GMRES	0.21	0.511	1.272	2.734	3.886
MC(P)	0.11	0.48	0.792	1.312	1.923
MC(C)	0.1	0.33	0.551	0.911	1.352

rate of the expected value estimator is quite impressive compared to the collision estimator, and the additional time required by it is very minimal.

In the following we compare four methods for solving matrix equations: conjugate gradient squared (CGS), GMRES, the Monte Carlo algorithm that uses the constant approach for generating the matrices (MC(P)), and the Monte Carlo algorithm that uses the proportional approach for generating the matrices (MC(C)). MATLAB built-in functions **cgs** and **gmres** are used for the Krylov subspace methods CGS and GMRES. The Monte Carlo methods use the expected value estimator, the inverse transform approach, and the sequential correlated sampling technique. They compute the 2-norm of the relative residual at the end of each iteration of the sequential correlated sampling technique, and stop when this number is less than the user-specified tolerance. The deterministic methods in MATLAB output the 2-norm of the residual at the end of each iteration, and they also terminate when the 2-norm of the relative residual is less than the tolerance. In MATLAB we time from the moment **cgs** (**gmres**) is called to the moment the execution is over. In MC(P) and MC(C), we also time only the execution of the code.

We used MATLAB's built-in functions for the Krylov subspace methods, instead of C++ implementations, for convenience only. The Monte Carlo algorithms, on the other hand, were written in C++. It might be argued that this comparison is not fair, since MATLAB will probably run slower than C++ implementations of the Krylov subspace algorithms. At this point we emphasize again that our point here is not to give an accurate comparison of computing times of these algorithms in single-processor computing environments, but to show that Monte Carlo can be [illegible] even in such computing environments. In addition, the student-written C++ codes for the Monte Carlo algorithms can probably be optimized further, which will change the timing results. However, we can still get a fairly good understanding of various computing times that will be reported in this section: a C++ implementation of GMRES ran twice as fast as its MATLAB implementation when applied to the 1000-dimensional matrix introduced in the next example. If needed, the reader can use this as the rule of thumb in converting timings reported for MATLAB to C++. In particular in the next example, the effect of multiplying the timing results for MATLAB by 1/2 will just move the matrix size after which Monte Carlo algorithms outperform the deterministic methods to $N = 2000$.

[illegible] 7.3. This example is from [7]: Let $H = (h_{ij})$ and $b = (b_i)$, where

$$h_{ij} = \frac{0.9}{N + i + j}, \qquad b_i = 1.37 + \frac{i}{N}.$$

The best parameters for MC(C) and MC(P) are n (number of random walks per iteration) $= 100$, $p_{\text{abs}} = 0.4$. We set the tolerance to 10^{-6}. Table 7.3 and Figure 7.1 give the time to convergence for each method, as we increase the size of the matrix N from 500 to 2500.

The performance of MC(C) over the deterministic methods is very favorable. Table 7.4 gives the norm of the relative residual and iteration number at convergence

(termination). The Monte Carlo method is somewhat sensitive to the parameters p_{abs}, n, and we do not currently know how to choose them optimally. To illustrate this sensitivity, we vary the number of random walks while fixing the other parameters, and report the norm of the relative residual at termination as well as the time to termination. Table 7.5 is for MC(P) and Table 7.6 for MC(C). For both methods,

TABLE 7.7

MC(P) $(N = 1000, n = 1000)$	$p_{\text{abs}} = 0.1$	$p_{\text{abs}} = 0.4$	$p_{\text{abs}} = 0.7$

TABLE 7.9

$N = 500$	Time	Iteration	Rel. res. norm
CGS	0.16	4	7.5×10^{-9}
GMRES(k)	0.2	(1,5)	5.5×10^{-7}
MC(P)	0.371	7	3.5×10^{-7}
MC(C)	0.431	11	6.4×10^{-7}

the optimal number of random walks is 100, given the selected values for the other parameters. Increasing the number of random walks per iteration slows down the convergence: although error reduction between iterations increases, the cost of generating more random walks eliminates any due advantages. Decreasing the number of random walks again slows down the process: although we generate less random walks, we now need more iterations to reach the tolerance which explains increasing time.

We now investigate the effects of varying the probability of absorption. Tables 7.7 and 7.8 are for MC(P) and MC(C). Here the optimal choice for p_{abs} seems to be 0.4. Decreasing p_{abs} results in producing random walks that make more transitions, which seems to increase the accuracy but at the expense of increased timing. Increasing p_{abs} gives less accurate results, and although generating shorter random walks saves time, the total time to termination actually increases since we need more iterations.

7.4. We choose the entries of H and b at random from a uniform distribution on $(0, 1)$. We then divide the matrix elements by appropriate constants to vary the column norm of the matrix. First we generate a 500×500 matrix H. It has spectral radius 0.84 and condition number 28787 (ratio of the magnitudes of the largest to smallest eigenvalue). The condition number of $I - H$ is 6.6.

After trying a few values for the parameters, we experimentally find the following optimal choices for MCSolver:

$n = 100$ and $p_{\text{abs}} = 0.16$ for MC(C),

$n = 100$ and $p_{\text{abs}} = 0.2$ for MC(P).

Table 7.9 gives the time to termination, the number of iterations, and the norm of the relative residual at termination. It is interesting to note that the constant approach requires eleven iterations to converge, whereas the proportional approach needs only seven iterations. The increased number of iterations explains why MC(C)

TABLE 7.10

		2.0×10^{-6}
		1.0×10^{-6}
		2.1×10^{-7}

is not (significantly) faster than MC(P) like in the previous example. A closer look at the norm of the relative residuals at the end of each iteration reveals that MC(C) has significantly less error reduction between iterations than MC(P); see Table 7.10. We now increase the size of the matrix to 1500. The spectral radius is 0.86 and the condition number is 1.3×10^7. The condition number of $I - H$ is 7.2. The experimentally verified optimal choices for MCSolver are $n = 100$ and $p_{\text{abs}} = 0.14$ for both MC(P) and MC(C). We now report similar output to the previous case; see Tables 7.11 and 7.12.

At this point, we revisit the issue of different estimators and how they compare. A random matrix of size 80 was created to compare the collision and expected value estimators. The probability of absorption is 0.01. In Table 7.13 we display the L^2 norm of the absolute error at the end of each iteration, and observe that the expected value estimator has a significantly faster rate of convergence. The price paid for this gain was minimal: the computation time for the expected value estimator was only about 1.3 times the computation time for the collision estimator.

7.5. We first consider a 500×500 sparse matrix whose entries are all

TABLE 7.13

MC(P)	8.15	11	7.7×10^{-7}

zero except for -0.1 on the diagonal, 0.1 on the sub- and superdiagonals, and 0.1 on the 100th sub- and superdiagonals (i.e., for $|i - j| = 100$). The spectral radius of the matrix is 0.37. MC(P) has $p_{\text{abs}} = 0.4$ and $n = 1000$; see Table 7.14. We now increase the size of the matrix to 1500, put 0.05 on the sub- and superdiagonals, and -0.1 on the 100th sub- and superdiagonals. The diagonal elements are -0.1 as before. The spectral radius is 0.40. MC(P) has $p_{\text{abs}} = 0.6$ and $n = 1000$; see Table 7.15.

These results show, among other things, that the sequential Monte Carlo method can do pretty well when compared with modern deterministic methods. The sequential correlated sampling method, however, does not always converge. A theoretical analysis of convergence was given by Halton [6]. Numerically we were able to observe diverging behavior when the method was applied to `randsvd`-type matrices [8]. Since our main thesis in this paper is the efficiency of parallel Monte Carlo algorithms, with or without sequential improvements, over deterministic solvers in massively parallel computing environments, we do not pursue the pros and cons of sequential methods any further. A recent discussion of sequential methods in continuous problems is given by Spanier [16].

8. Conclusion. The amount of work for direct and iterative deterministic matrix solvers is typically $O(N^3)$ and $O(N^2)$. The fastest Monte Carlo algorithm we discussed has complexity $C\|z\|_1 n + N$, where $\|z\|_1 = 1/p_{\text{abs}}$. This is clearly a big advantage if the desired accuracy for the Monte Carlo estimate can be obtained by a moderate number of random walks n. The accuracy of the Monte Carlo estimate can be assessed using confidence intervals, since our estimators, as discussed in section 4, are approximately normal from the central limit theorem. Sequential Monte Carlo methods have the potential of lowering the necessary number of random walks to obtain a certain accuracy dramatically, and we have seen supporting numerical evidence in section 7. The parallel implementation of the Monte Carlo algorithms is straightforward, and essentially no communication is necessary between processors. The sequential Monte Carlo methods, however, will have some (probably very minimal) communications costs. One question that is left unanswered is, how to find the opti-

mal parameters in sequential correlated sampling in general. In numerical results that are not reported here, best choices for n (random walks per iteration) varied between 100 and 1000, and p_{abs} varied between 0.1 and 0.6, for several types of matrices with sizes between 500 and 2500.

Acknowledgments. I thank my graduate assistants Claudia Rangel and Jeho Park, both students at Claremont Graduate University during the 2000/01 academic year, for their work on this project. In particular, Jeho Park is the author of the C++ code that implements the Monte Carlo estimators discussed in this paper. The numerical results were obtained using this code. I also thank Dr. Irene Livshits, Ball State University, for her help in comparing the execution time of different implementations of GMRES.

BALANCED CENTRAL SCHEMES FOR THE SHALLOW WATER EQUATIONS ON UNSTRUCTURED GRIDS*

STEVE BRYSON† AND DORON LEVY‡

Abstract. We present a two-dimensional, well-balanced, central-upwind scheme for approximating solutions of the shallow water equations in the presence of a stationary bottom topography on triangular meshes.

Our starting point is the recent central scheme of Kurganov and Petrova (KP) for approximating solutions of conservation laws on triangular meshes. In order to extend this scheme from systems of conservation laws to systems of balance laws one has to find an appropriate discretization of the source terms. We first show that for general triangulations there is no discretization of the source terms that corresponds to a well-balanced form of the KP scheme. We then derive a new variant of a central scheme that can be balanced on triangular meshes.

We note in passing that it is straightforward to extend the KP scheme to general unstructured conformal meshes. This extension allows us to recover our previous well-balanced scheme on Cartesian grids. We conclude with several simulations, verifying the second-order accuracy of our scheme as well as its well-balanced properties.

1. Introduction.

We consider a flow in a two-dimensional channel with a bottom elevation given by $B(\vec{x})$, where $\vec{x} = (x, y)$. Let $H(\vec{x}, t)$ represent the fluid depth above the bottom, and let $\vec{u}(\vec{x}, t) = (u(\vec{x}, t), v(\vec{x}, t))$ be the fluid velocity. The top surface at any time t is denoted by $w(\vec{x}, t) = B(\vec{x}) + H(\vec{x}, t)$.

The shallow water equations, introduced by Saint-Venant in [24] (see also [10]), are commonly used to model flows in rivers or coastal areas. When written in terms of the top surface w and the momentum (Hu, Hv), these equations are of the form

$$\begin{cases} w_t + (Hu)_x + (Hv)_y = 0, \\ (Hu)_t + \left[\dfrac{(Hu)^2}{w-B} + \dfrac{1}{2}(w-B)^2\right]_x + \left[\dfrac{(Hu)(Hv)}{w-B}\right]_y = -g(w-B)B_x, \\ (Hv)_t + \left[\dfrac{(Hu)(Hv)}{w-B}\right]_x + \left[\dfrac{(Hv)^2}{w-B} + \dfrac{1}{2}(w-B)^2\right]_y = -g(w-B)B_y. \end{cases} \tag{1.1}$$

This choice of variables is particularly suitable for dealing with stationary steady-state solutions (see [14, 23] for details). For simplicity we fix the gravitational constant, g, from now on to be $g = 1$.

In this work we are interested in approximating solutions of (1.1) on triangular meshes. Our goal is to investigate how to adapt the semidiscrete central schemes on triangular meshes that were recently introduced by Kurganov and Petrova in [16] to this problem. We are interested in deriving a discretization of the source terms in (1.1) that preserves stationary steady-state solutions, as such solutions play an important role in the dynamics of (1.1). While such a balance is not pursued for nonstationary shallow water problems, our simulations indicate that our method works well for such problems.

Central schemes for conservation laws have become popular in recent years as a tool for approximating solutions for multidimensional systems of hyperbolic conservation laws. Like other Godunov-type schemes, central schemes are based on a three-step procedure: , in which an interpolant is reconstructed from previously computed cell averages; , in which this interpolant is evolved exactly in time according to the equations; and , in which the solution is projected back to cell averages. When compared with other methods, central schemes are particularly appealing since they do not require any Riemann solvers and systems can be solved componentwise.

A first-order prototype of central schemes is the Lax–Friedrichs scheme [8]. A second-order extension is due to Nessyahu and Tadmor [21]. Extensions to two dimensions are due to Arminjon and Viallon [1] and Jiang and Tadmor [13]. By estimating bounds on the local speeds of propagation of information from discontinuities, it is possible to pass to the semidiscrete limit (see [15, 17] and the references therein). There are several extensions of central schemes to unstructured grids. A fully discrete method is due to Arminjon, Viallon, and Madrane [2]; a recent semidiscrete scheme was proposed by Kurganov and Petrova in [16]. Balanced central schemes for shallow water equations on Cartesian grids are due to Russo in the fully discrete framework [23] (see also [20]) and to Kurganov and Levy in the semidiscrete framework [14].

There are many approaches to approximating solutions of (1.1). We refer the reader to, e.g., [3, 4, 7, 9, 11, 18, 19, 22] and the references therein. An equilibrium technique for balancing scalar conservation laws is presented in [5, 6]. Our goal in this paper is to show that balancing is also possible with central schemes. We would like to emphasize that this is the first time in which the balancing issues are treated for central schemes on unstructured grids.

The paper is organized as follows. We start in section 2 with a brief overview of the Kurganov–Petrova (KP) central scheme on triangular meshes. We note that this scheme is not limited to triangular meshes and it can be equally well applied to general unstructured grids. We also make the necessary adjustments to incorporate source terms into the scheme. We proceed in section 3 with the discretization of the cell averages of the source terms for the shallow water equations. The goal is to find a discretization such that the scheme will preserve stationary steady states, i.e., zero velocities and a flat surface. We show that on general unstructured meshes, there is no discretization of the source terms in the shallow water equations that provide a well-balanced form of the KP scheme. We then proceed by showing how to modify the original scheme in such a way that it is possible to obtain a well-balanced discretization of the source terms. We conclude in section 4 with numerical examples that demonstrate the accuracy of our scheme as well as its well-balanced property.

2. Central schemes for balance laws on unstructured grids. We consider the two-dimensional balance law,

$$u_t + f(u)_x + g(u)_y = S(u, x, y, t), \tag{2.1}$$

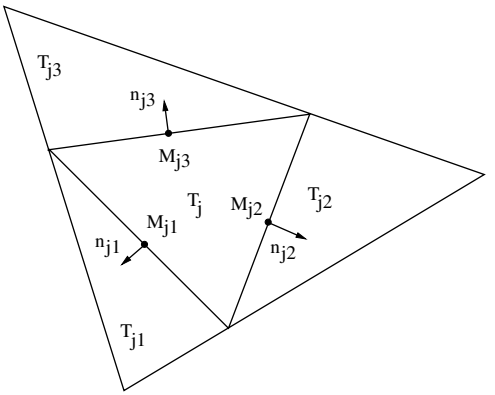

FIG. 2.1. *The triangular grid.*

subject to the initial data $u(x, y, 0) = u_0(x, y)$. We are interested in approximating solutions of (2.1) that are computed in terms of cell averages on a fixed unstructured conformal grid. To simplify this exposition we first consider the scalar case. The scheme that is described below can be easily extended componentwise to systems of balance laws. We will make this obvious extension later on when dealing with the specific problem of the system of shallow water equations (1.1).

We focus our attention on the central scheme on triangular meshes that was recently derived in [16]. We briefly overview the derivation of this scheme in the setup of conservation laws of the form

$$u_t + f(u)_x + g(u)_y = 0. \tag{2.2}$$

We assume a conformal triangulation of the domain consisting of cells T_j of area $|T_j|$. The neighboring cells to T_j are denoted by T_{jk}, $k = 1, 2, 3$, while the edge that is joint between T_j and T_{jk} is denoted by E_{jk} and is assumed to be of length h_{jk}. We also denote the outward unit normal to T_j on the kth edge as n_{jk}, and denote the midpoint of E_{jk} as M_{jk} (see Figure 2.1).

We assume that the cell averages on all the cells $\{T_j\}$ are known at time t^n,

$$\bar{u}_j^n \approx \frac{1}{|T_j|} \int_{T_j} u(\vec{x}, t^n) d\vec{x}, \tag{2.3}$$

and reconstruct a piecewise polynomial

$$\tilde{u}^n(x, y) = \sum_j u_j^n(x, y) \chi_j(x, y). \tag{2.4}$$

Here $u_j^n(x, y)$ is a two-dimensional polynomial that is yet to be determined and $\chi_j(x, y)$ is the characteristic function of the cell T_j. To simplify the notations we omit the time-dependence in $u_j(x, y)$. We also denote by $u_{jk}(x, y)$ the polynomial that is reconstructed in the cell T_{jk}.

Discontinuities in the interpolant u_j along the edges of T_j propagate with a maximal inward velocity a_{jk}^{in} and a maximal outward velocity a_{jk}^{out}. These velocities can be estimated (for convex fluxes in the scalar case) as

$$\begin{aligned} a_{jk}^{\text{in}}(M_{jk}) &= -\min\{\nabla F\left(u_j\left(M_{jk}\right)\right) \cdot n_{jk}, \nabla F\left(u_{jk}\left(M_{jk}\right)\right) \cdot n_{jk}, 0\}, \\ a_{jk}^{\text{out}}(M_{jk}) &= \max\{\nabla F\left(u_j\left(M_{jk}\right)\right) \cdot n_{jk}, \nabla F\left(u_{jk}\left(M_{jk}\right)\right) \cdot n_{jk}, 0\}, \end{aligned}$$

where $F = (f, g)$. These local speeds of propagation are then used to determine evolution points that are away from the propagating discontinuities. An exact evolution of the reconstruction at these evolution points is followed by an intermediate piecewise polynomial reconstruction and finally projected back onto the original cells, providing the cell averages at the next time step $\bar{u}_j^{n+1}$. Further details can be found in [16].

A semidiscrete scheme is then obtained at the limit

$$\frac{d}{dt}\bar{u}_j^n = \lim_{\Delta t \to 0} \frac{\bar{u}_j^{n+1} - \bar{u}_j^n}{\Delta t}. \tag{2.5}$$

Most of the terms on the right-hand side (RHS) of (2.5) vanish in the limit as $\Delta t \to 0$. The only quantity that has to be determined is a quadrature rule for the integrals of the flux functions over the edges of the cells. If we assume a Gaussian quadrature with m nodes

$$\int_0^1 \varphi(x)dx \approx \sum_{s=1}^{m} c_s \varphi(x_s),$$

which is scaled to h_{jk}, and denote the quadrature points on E_{jk} as G_{jk}^s, the KP scheme for triangular meshes is

$$\begin{aligned} \frac{d\bar{u}_j}{dt} = -\frac{1}{|T_j|} \sum_{k=1}^{3} \frac{h_{jk}}{a_{jk}^{\text{in}} + a_{jk}^{\text{out}}} \sum_{s=1}^{m} c_s \Big[\big(a_{jk}^{\text{in}} F(u_{jk}(G_{jk}^s)) + a_{jk}^{\text{out}} F(u_j(G_{jk}^s)) \big) \cdot n_{jk} \\ - a_{jk}^{\text{in}} a_{jk}^{\text{out}} \big(u_{jk}(G_{jk}^s) - u_j(G_{jk}^s) \big) \Big], \end{aligned} \tag{2.6}$$

where $F = (f, g)$. If the fluxes are integrated with a midpoint quadrature (as suggested in [16]) and we use the notation $u_{jk}^{\text{out}} := u_{jk}(M_{jk})$, $u_{jk}^{\text{in}} := u_j(M_{jk})$, $F_{jk}^{\text{in}} := F(u_{jk}^{\text{in}})$, and $F_{jk}^{\text{out}} := F(u_{jk}^{\text{out}})$, the semidiscrete scheme (2.6) becomes

$$\frac{d\bar{u}_j}{dt} = -\frac{1}{|T_j|} \sum_{k=1}^{3} \frac{h_{jk}}{a_{jk}^{\text{in}} + a_{jk}^{\text{out}}} \Big[\big(a_{jk}^{\text{in}} F_{jk}^{\text{out}} + a_{jk}^{\text{out}} F_{jk}^{\text{in}} \big) \cdot n_{jk} - a_{jk}^{\text{in}} a_{jk}^{\text{out}} \big(u_{jk}^{\text{out}} - u_{jk}^{\text{in}} \big) \Big]. \tag{2.7}$$

A basic observation that will be used below is that the semidiscrete scheme (2.7) is valid for any conformal grid, not necessarily triangular. All that one has to do is to make the suitable adjustments in the notations (e.g., $|T_j|$ being the area of the cell T_j regardless of the shape of that cell) and replace the sum over the three edges of the triangle by a sum over the N_j edges of each cell T_j. When approximating solutions to balance laws of the form (2.1) the scheme has one additional term due to the source term $S(u, x, y, t)$, i.e.,

$$\begin{aligned} \frac{d\bar{u}_j}{dt}(t) = -\frac{1}{|T_j|} \sum_{k=1}^{N_j} \frac{h_{jk}}{a_{jk}^{\text{in}} + a_{jk}^{\text{out}}} \Big[\big(a_{jk}^{\text{in}} F_{jk}^{\text{out}} + a_{jk}^{\text{out}} F_{jk}^{\text{in}} \big) \cdot n_{jk} - a_{jk}^{\text{in}} a_{jk}^{\text{out}} \big(u_{jk}^{\text{out}} - u_{jk}^{\text{in}} \big) \Big] \\ + \bar{S}_j(t). \end{aligned} \tag{2.8}$$

Here

$$\bar{S}_j \approx \frac{1}{|T_j|} \int_{T_j} S(u, \vec{x}, t) d\vec{x} \tag{2.9}$$

is a discretization of the cell average of the source term that should be obtained with an appropriate quadrature. It is the discretization of (2.9) that serves as the topic for the next section.

The above derivation carries on to systems of balance laws componentwise. In this case the maximal speeds of propagation can be estimated (for convex fluxes) as

$$a_{jk}^{\text{in}}(M_{jk}) = -\min\{\lambda_1[J(u_j(M_{jk}))\cdot n_{jk}], \lambda_1[J(u_{jk}(M_{jk}))\cdot n_{jk}], 0\},$$
$$a_{jk}^{\text{out}}(M_{jk}) = \max\{\lambda_N[J(u_j(M_{jk}))\cdot n_{jk}], \lambda_N[J(u_{jk}(M_{jk}))\cdot n_{jk}], 0\},$$

where $J(u_j(M_{jk}))$ is the Jacobian of the flux $F = (f, g)$ evaluated at M_{jk}, and $\lambda_1 < \cdots < \lambda_N$ are its N eigenvalues.

3. A well-balanced scheme. In this section we present a scheme for approximating the solution of (1.1) which is balanced via a discretized average of the source terms. In section 3.1 we show that the KP scheme (2.8) cannot be balanced using a straightforward discretization of the source terms on general conformal unstructured meshes. Using the insights gained from this analysis, in section 3.2 we present a new scheme based on (2.6), which does allow such balance on general conformal triangular meshes.

3.1. Balancing the KP scheme. Our goal now is to look for a discretization of the source term (2.9) such that the scheme (2.8) will preserve stationary steady-state solutions. Hence, we assume zero velocities, $u = v = 0$, and a constant surface, i.e., $w = \text{Const}$.

Since the first equation in (1.1) is homogeneous, we start by considering the second equation. Similar analysis applies to the third equation. We are therefore looking for a discretization of the average of the source term

$$-(w - B)B_x \tag{3.1}$$

over the cell T_j. The velocities are zero and therefore the only nonzero component of the flux in (1.1) is

$$f = \frac{1}{2}(w - B)^2. \tag{3.2}$$

This means that in order for the scheme (2.8) to preserve stationary steady-state solutions, the average of the source term (3.1) over the cell T_j has to be discretized such that, for f given in (3.2),

$$0 = -\frac{1}{|T_j|}\sum_{k=1}^{N_j}\frac{h_{jk}}{a_{jk}^{\text{in}} + a_{jk}^{\text{out}}}\left[\left(a_{jk}^{\text{in}} f_{jk}^{\text{out}} + a_{jk}^{\text{out}} f_{jk}^{\text{in}}\right) n_{jk,x}\right] + \bar{S}_j. \tag{3.3}$$

Here $n_{jk,x}$ is the component of the normal n_{jk} in the x-direction.

The eigenvalues of the Jacobian of the system (1.1) are $u \pm \sqrt{w - B}$ and u, which are $\pm\sqrt{w - B}$ and 0 in the case of zero velocities. If we assume that w is constant and that the point values of B are known, the one-sided velocities satisfy $a_{jk}^{\text{in}} = a_{jk}^{\text{out}}$. Under these assumptions the condition (3.3) can be rewritten as

$$\bar{S}_j = \frac{1}{|T_j|}\sum_{k=1}^{N_j} h_{jk}\left[\left(\frac{f_{jk}^{\text{out}} + f_{jk}^{\text{in}}}{2}\right) n_{jk,x}\right] = \frac{1}{|T_j|}\sum_{k=1}^{N_j}\frac{h_{jk}}{2}\left[(w - B_{jk})^2 n_{jk,x}\right], \tag{3.4}$$

where $B_{jk} = B(M_{jk})$.

We now assume a discretization of the cell average of the source (3.1) of the form

$$\bar{S}_j = -\sum_{k=1}^{N_j} g_{jk}(w - B_{jk})\mathcal{D}, \tag{3.5}$$

where $\mathcal{D} \approx B_x$, and g_{jk} are yet to be determined. To simplify the notations we denote $m_k = h_{jk} n_{jk,x}$. It is easy to check that $\sum_{k=1}^{N_j} m_k = 0$ and hence in order for the representation (3.5) to be consistent with (3.4) we must have

$$\mathcal{D} = -\frac{1}{2|T_j|} \frac{\sum_{k=1}^{N_j} m_k B_{jk}(B_{jk} - 2w)}{\sum_{k=1}^{N_j} g_{jk}(w - B_{jk})}. \tag{3.6}$$

Since $\mathcal{D}$ in (3.6) should not be a function of w we are seeking constants a_k such that

$$\sum_{k=1}^{N} m_k B_k(B_k - 2w) = \left[\sum_{k=1}^{N} g_k(w - B_k)\right]\left[\sum_{k=1}^{N} a_k B_k\right], \tag{3.7}$$

where for simplicity we omit the obvious j-dependence from all the notations. Equation (3.7) can be rewritten as

$$\begin{cases} -2\sum_{k=1}^{N} m_k B_k = \sum_{k=1}^{N} g_k \sum_{k=1}^{N} a_k B_k, \\ \sum_{k=1}^{N} m_k B_k^2 = -\sum_{k=1}^{N} g_k B_k \sum_{k=1}^{N} a_k B_k. \end{cases} \tag{3.8}$$

The coefficients of the powers of B_k in (3.8) produce the following system of equations:

$$\begin{cases} -2m_i = a_i \sum_{k=1}^{N} g_k, & i = 1, \dots, N, \\ m_i = -a_i g_i, & i = 1, \dots, N, \\ a_i g_j = -a_j g_i, & i \neq j,\ i, j = 1, \dots, N. \end{cases} \tag{3.9}$$

Finally, from (3.9) we have

$$g_i = \frac{1}{2}\sum_{k=1}^{N} g_k, \qquad i = 1, \dots, N. \tag{3.10}$$

Equation (3.10) can generally hold only for $N = 2$, which means that one can expect to be able to balance the scheme (2.8) for stationary steady-state solutions only in cells that have two edges that contribute to the flux in the x-direction. This obviously excludes most meshes. There are two cases of special interest.

1. When the mesh is composed of triangles with one side that is parallel to the x-axis (see Figure 3.1), each cell has only two edges that contribute to the flux in the x-direction. In this case the system (3.9) can be solved. This result will enable us to introduce in section 3.2 a modification of the scheme (2.8) that can be balanced on general meshes. Due to symmetry considerations, such a mesh will not satisfy the balance conditions in the y-direction (that come from the third equation in (1.1)) unless all triangles are right triangles that are aligned with both coordinate axes.

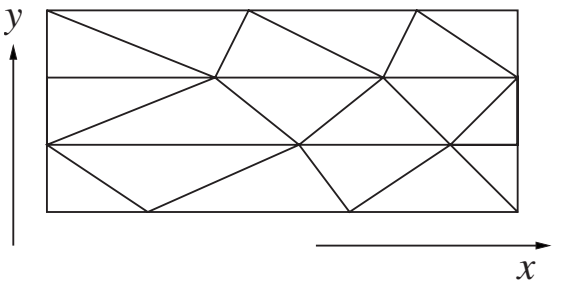

FIG. 3.1. *An admissible triangular mesh.*

2. The scheme can be balanced in both directions in the very special case of Cartesian grids. This corresponds to the case previously solved in [14]. The results of [14] when viewed from the point of view of the system (3.9) amount to the equality

$$B_1(B_1 - 2w) - B_2(B_2 - 2w) = (2w - B_1 - B_2)(B_2 - B_1).$$

If we assume a more general discretization of the cell average of (3.1) of the form

$$\bar{S}_j = -\sum_{k=1}^{N} g_k(w - B_k) \sum_{k'=1}^{N} a_{kk'} B_{k'}, \tag{3.11}$$

then the system (3.9) is replaced by (denoting $\tilde{m}_k = m_k/(2|T_j|)$)

$$\begin{cases} -2\tilde{m}_k = \sum_{k'=1}^{N} g_{k'} a_{k'k}, & k = 1, \dots, N, \\ \tilde{m}_k = -g_k a_{kk}, & k = 1, \dots, N, \\ g_k a_{kk'} = -g_{k'} a_{k'k}, & k \neq k',\ k, k' = 1, \dots, N. \end{cases} \tag{3.12}$$

The system (3.12) can be solved in the general case (unlike the system (3.9)). For example, in the case of a triangular grid ($N = 3$) one possible solution (assuming $\tilde{m}_1 \neq 0$ and $\tilde{m}_3 + 2\tilde{m}_2 \neq 0$) is

$$g = \begin{pmatrix} -\tilde{m}_1 \\ \tilde{m}_2 + \frac{\tilde{m}_3}{2} \\ \frac{\tilde{m}_3}{2} \end{pmatrix}, \qquad a = \begin{pmatrix} 1 & \frac{\tilde{m}_3 + 2\tilde{m}_2}{2\tilde{m}_1} & \frac{\tilde{m}_3}{2\tilde{m}_1} \\ 1 & -\frac{2\tilde{m}_2}{2\tilde{m}_2 + \tilde{m}_3} & -\frac{\tilde{m}_3}{2\tilde{m}_2 + \tilde{m}_3} \\ 1 & 1 & -2 \end{pmatrix}. \tag{3.13}$$

If $\tilde{m}_1 = 0$, the expression (3.13) can be replaced, e.g., by

$$g = \begin{pmatrix} 0 \\ \tilde{m}_2 + \frac{\tilde{m}_3}{2} \\ \frac{\tilde{m}_3}{2} \end{pmatrix}, \qquad a = \begin{pmatrix} 0 & \frac{\tilde{m}_3 + 2\tilde{m}_2}{\tilde{m}_3} & 1 \\ 1 & -\frac{2\tilde{m}_2}{2\tilde{m}_2 + \tilde{m}_3} & -\frac{\tilde{m}_3}{2\tilde{m}_2 + \tilde{m}_3} \\ 1 & 1 & -2 \end{pmatrix}. \tag{3.14}$$

If $\tilde{m}_3 + 2\tilde{m}_2 = 0$, a permutation of the numbering of the sides of the triangle will provide a solution. Other solutions of (3.12) exist.

While formally being able to balance the scheme with the expressions (3.13) and (3.14), it remains unclear in what sense $\sum_{k'} a_{kk'} B_{k'}$ approximates the derivative B_x. In other words, it is not obvious that the consistency of this discretization can be established. We therefore consider this approach unsatisfactory.

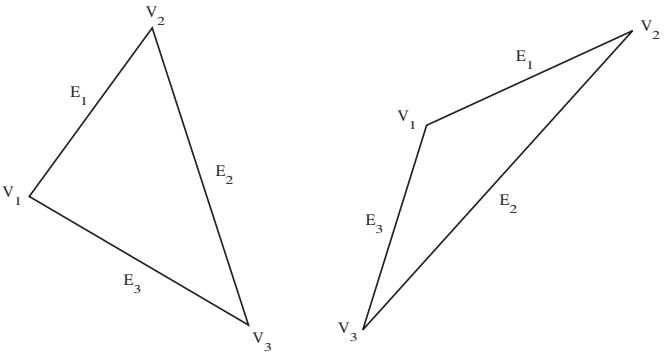

FIG. 3.2. *The two types of triangles. Left: type* 1. *Right: type* 2.

3.2. A new well-balanced scheme. The analysis in section 3.1 tells us that balancing the x-derivative flux term requires cells that have only 2 edges which have normals with nonzero x-components (see Figure 3.1). This can be accomplished by splitting our cells into subcells and solving the equation on these subcells. Similarly, the y-derivative flux term can be balanced by a different splitting of the cells. We now derive a new method based on this observation.

We focus on conformal triangular grids. Our ideas can be easily extended to other conformal unstructured meshes. In order to create a balanced scheme for (1.1), we propose to decompose every triangle T_j into several triangles as explained below. This requires a different decomposition for the two flux components. For the first component, f, we decompose T_j into two triangles, each of which has an edge parallel to the x-axis. For the second component of the flux we split T_j into two other triangles, each of which has an edge parallel to the y-axis.

We denote the vertices of T_j as V_{jk}, $k = 1, 2, 3$, and define the edges of T_j as $E_{j1} = V_{j2} - V_{j1}$, $E_{j2} = V_{j3} - V_{j2}$, and $E_{j3} = V_{j1} - V_{j3}$. The midpoint of the kth edge of T_j is M_{jk}. $I(a, b)$ denotes the closed interval with endpoints a and b. We also use $V_{jk,x}$ (or $V_{jk,y}$) to denote the x (or y) component of V_{jk}. To simplify the treatment, we classify the triangles into two categories as portrayed in Figure 3.2.

(i) Type 1: one vertex V_{j1} bisects the opposite edge in the y direction: the y-component $V_{j1,y} \in I(V_{j2,y}, V_{j3,y})$ and a different vertex V_{j2} bisects the opposite edge in the x-direction: $V_{j2,x} \in I(V_{j1,x}, V_{j3,x})$. (See Figure 3.2 (left).)

(ii) Type 2: the same vertex V_{j1} bisects the opposite edge in both the x and y directions: $V_{j1,y} \in I(V_{j2,y}, V_{j3,y})$ and $V_{j1,x} \in I(V_{j2,x}, V_{j3,x})$. (See Figure 3.2 (right).)

Note that these definitions specify our vertex numbering convention. The decomposition for the g-flux will depend on the type of triangle.

3.2.1. The decomposition in the x-direction. For the flux in the x-direction, we decompose T_j into two triangles $T_j^{x,1}$ and $T_j^{x,2}$ (see Figure 3.3). Define $V_{j3}^{x,1}$ to be the intersection of edge E_{j2} with the line $y = V_{j1,y}$. The vertices of $T_j^{x,1}$ are $V_{j1}^{x,1} := V_{j1}$, $V_{j2}^{x,1} := V_{j2}$, and $V_{j3}^{x,1}$. The vertices of $T_j^{x,2}$ are $V_{j1}^{x,2} := V_{j3}^{x,1}$, $V_{j2}^{x,2} := V_{j3}$, and $V_{j3}^{x,2} := V_{j1}$. For both triangles $T_j^{x,i}$, the lengths of the sides are $h_{jk}^{x,i}$, the corresponding midpoints are $M_{jk}^{x,i}$, the interior and exterior speeds of propagation are $a_{jk}^{\text{in,out},x,i}$, and the normals are $n_{jk}^{x,i} = (n_{jk,x}^{x,i}, n_{jk,y}^{x,i})$. These definitions imply $M_{j1}^{x,1} = M_{j1}$, $M_{j2}^{x,2} = M_{j3}$, $h_{j1}^{x,1} = h_{j1}$, $h_{j2}^{x,2} = h_{j3}$, $h_{j2}^{x,1} + h_{j1}^{x,2} = h_{j2}$, $n_{j1}^{x,1} =$

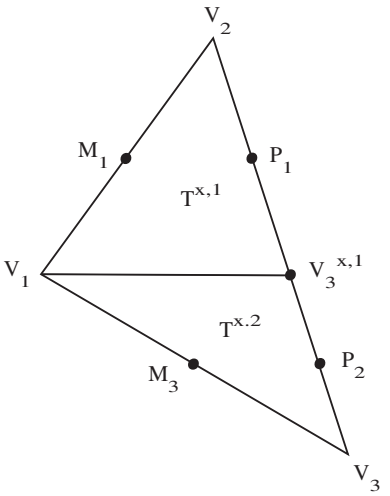

FIG. 3.3. *The triangle decomposition for the f-flux.*

$n_{j1,x}$, $n_{j2}^{x,1} = n_{j1}^{x,2} = n_{j2,x}$, $n_{j2}^{x,2} = n_{j3,x}$, and $n_{j3,x}^{x,1} = n_{j3,x}^{x,2} = 0$. For the velocities we have $a_{j1}^{\text{in,out},x,1} = a_{j1}^{\text{in,out}}$, $a_{j2}^{\text{in,out},x,1} = a_{j2}^{\text{in,out}}$, $a_{j1}^{\text{in,out},x,2} = a_{j2}^{\text{in,out}}$, and $a_{j2}^{\text{in,out},x,2} = a_{j3}^{\text{in,out}}$. The velocity $a_{j3}^{\text{in,out},x,i}$ does not play any role in the following computation since $n_{j3,x}^{x,1} = n_{j3,x}^{x,2} = 0$. Finally, the external reconstructions are denoted as $u_{j1}^{x,1} = u_{j1}$, $u_{j2}^{x,1} = u_{j1}^{x,2} = u_{j2}$, and $u_{j2}^{x,2} = u_{j3}$.

On each triangle $T_j^{x,i}$ we denote the cell average of the component of the flux in the x-direction by Φ_j^i. It is given by

$$\Phi_j^i = -\frac{1}{|T_j^{x,i}|}\sum_{k=1}^{2}\frac{h_{jk}^{x,i}n_{jk,x}^{x,i}}{a_{jk}^{\text{in},x,i}+a_{jk}^{\text{out},x,i}}\left[a_{jk}^{\text{in},x,i}f\left(u_{jk}^{x,i}\left(M_{jk}^{x,i}\right)\right)+a_{jk}^{\text{out},x,i}f\left(u_j\left(M_{jk}^{x,i}\right)\right)\right]$$

for $i = 1, 2$. The cell average of the x-component of the flux over the entire cell T_j is taken to be the weighted average

$$\Phi_j := \frac{\left|T_j^{x,1}\right|}{|T_j|}\Phi_j^1 + \frac{\left|T_j^{x,2}\right|}{|T_j|}\Phi_j^2.$$

Since $\sum_{k=1}^{3} h_{jk}n_{jk} = 0$ we have $h_{j1}^{x,1}n_{j1,x}^{x,1} = -h_{j2}^{x,1}n_{j2,x}^{x,1}$ and $h_{j2}^{x,2}n_{j2,x}^{x,2} = -h_{j1}^{x,2}n_{j1,x}^{x,2}$. Hence, Φ_j can be rewritten as

$$\begin{aligned}\Phi_j = &-\frac{h_{j1}n_{j1,x}}{|T_j|}\left[\frac{a_{j1}^{\text{in}}f_{j1}^{\text{out}}+a_{j1}^{\text{out}}f_{j1}^{\text{in}}}{a_{j1}^{\text{in}}+a_{j1}^{\text{out}}}-\frac{a_{j2}^{\text{in}}f\left(u_{j2}\left(P_{j1}\right)\right)+a_{j2}^{\text{out}}f\left(u_j\left(P_{j1}\right)\right)}{a_{j2}^{\text{in}}+a_{j2}^{\text{out}}}\right]\\ &-\frac{h_{j3}n_{j3,x}}{|T_j|}\left[\frac{a_{j3}^{\text{in}}f_{j3}^{\text{out}}+a_{j3}^{\text{out}}f_{j3}^{\text{in}}}{a_{j3}^{\text{in}}+a_{j3}^{\text{out}}}-\frac{a_{j2}^{\text{in}}f\left(u_{j2}\left(P_{j2}\right)\right)+a_{j2}^{\text{out}}f\left(u_j\left(P_{j2}\right)\right)}{a_{j2}^{\text{in}}+a_{j2}^{\text{out}}}\right],\end{aligned} \tag{3.15}$$

where $P_{j1} := M_{j2}^{x,1}$ and $P_{j2} := M_{j1}^{x,2}$.

We would like to note that the flux term (3.15) can be derived directly from (2.6) by changing the quadrature points on E_{j2} to P_1 and P_2.

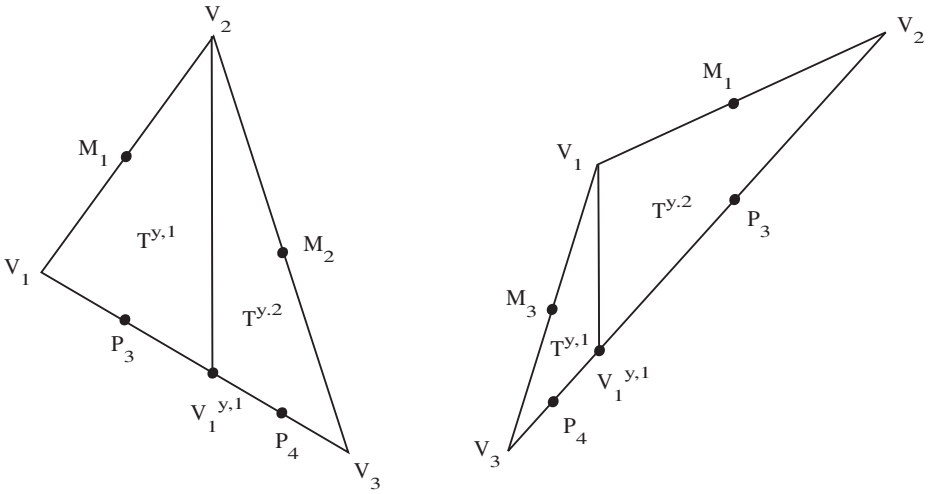

FIG. 3.4. *The triangle decomposition for the g-flux. Left: type* 1. *Right: type* 2.

3.2.2. The decomposition in the *y*-direction.

Type 1 triangles. We decompose T_j into two triangles $T_j^{y,1}$ and $T_j^{y,2}$ (see Figure 3.4 (left)). The intersection of the edge E_{j3} with the line $x = V_{j2,x}$ is denoted by $V_{j1}^{y,1}$. The vertices of $T_j^{y,1}$ are $V_{j1}^{y,1}$, $V_{j2}^{y,1} := V_{j1}$, and $V_{j3}^{y,1} := V_{j2}$. The vertices of $T_j^{y,2}$ are $V_{j1}^{y,2} := V_{j2}$, $V_{j2}^{y,2} := V_{j3}$, and $V_{j3}^{y,2} := V_{j1}^{y,1}$. As before, we have $M_{j2}^{y,1} = M_{j1}$, $M_{j1}^{y,2} = M_{j2}$, $h_{j2}^{y,1} = h_{j1}$, $h_{j1}^{y,2} = h_{j2}$, $h_{j1}^{y,1} + h_{j2}^{y,2} = h_{j3}$. The normals are $n_{j2}^{y,1} = n_{j1}$, $n_{j1}^{y,1} = n_{j2}^{y,2} = n_{j3}$, $n_{j1}^{y,2} = n_{j2}$, $n_{j3,y}^{y,1} = n_{j3,y}^{y,2} = 0$ and the velocities are $a_{j1}^{\text{in,out},y,1} = a_{j3}^{\text{in,out}}$, $a_{j2}^{\text{in,out},y,1} = a_{j1}^{\text{in,out}}$, $a_{j1}^{\text{in,out},y,2} = a_{j2}^{\text{in,out}}$, $a_{j2}^{\text{in,out},y,2} = a_{j3}^{\text{in,out}}$. The velocity $a_{j3}^{\text{in,out},y,i}$ does not appear in the result because $n_{j3,y}^{y,1} = n_{j3,y}^{y,2} = 0$. Finally, the external reconstructions are $u_{j1}^{y,1} = u_{j3}$, $u_{j2}^{y,1} = u_{j1}$, $u_{j1}^{y,2} = u_{j2}$, and $u_{j2}^{y,2} = u_{j3}$.

We denote the cell averages of the component of the flux in the y-direction on each triangle $T_j^{y,i}$ by Γ_j^i. It is given by

$$\Gamma_j^i := -\frac{1}{|T_j^{y,i}|}\sum_{k=1}^{2}\frac{h_{jk}^{y,i}n_{jk,y}^{y,i}}{a_{jk}^{\text{in},y,i}+a_{jk}^{\text{out},y,i}}\left[a_{jk}^{\text{in},y,i}g\left(u_{jk}^{y,i}\left(M_{jk}^{y,i}\right)\right)+a_{jk}^{\text{out},y,i}g\left(u_j\left(M_{jk}^{y,i}\right)\right)\right]$$

for $i = 1, 2$. The cell average of the y-component of the flux over the entire cell T_j is then given by the weighted average

$$\Gamma_j := \frac{\left|T_j^{y,1}\right|}{|T_j|}\Gamma_j^1 + \frac{\left|T_j^{y,2}\right|}{|T_j|}\Gamma_j^2.$$

Clearly $h_{j2}^{y,1}n_{j2,y}^{y,1} = -h_{j1}^{y,1}n_{j1,y}^{y,1}$ and $h_{j1}^{y,2}n_{j1,y}^{y,2} = -h_{j2}^{y,2}n_{j2,y}^{y,2}$. Therefore Γ_j can be rewritten as

$$\begin{aligned}\Gamma_j = &-\frac{h_{j1}n_{j1,y}}{|T_j|}\left[\frac{a_{j1}^{\text{in}}g_{j1}^{\text{out}}+a_{j1}^{\text{out}}g_{j1}^{\text{in}}}{a_{j1}^{\text{in}}+a_{j1}^{\text{out}}}-\frac{a_{j3}^{\text{in}}g\left(u_{j3}\left(P_{j3}\right)\right)+a_{j3}^{\text{out}}g\left(u_j\left(P_{j3}\right)\right)}{a_{j3}^{\text{in}}+a_{j3}^{\text{out}}}\right]\\ &-\frac{h_{j2}n_{j2,y}}{|T_j|}\left[\frac{a_{j2}^{\text{in}}g_{j2}^{\text{out}}+a_{j2}^{\text{out}}g_{j2}^{\text{in}}}{a_{j2}^{\text{in}}+a_{j2}^{\text{out}}}-\frac{a_{j3}^{\text{in}}g\left(u_{j3}\left(P_{j4}\right)\right)+a_{j3}^{\text{out}}g\left(u_j\left(P_{j4}\right)\right)}{a_{j3}^{\text{in}}+a_{j3}^{\text{out}}}\right],\end{aligned} \tag{3.16}$$

where $P_{j3} := M_{j1}^{y,1}$ and $P_{j4} := M_{j2}^{y,2}$.

Type 2 triangles. This case corresponds to Figure 3.4 (right). Analogous computations to those for type 1 triangles provide the cell average of the y-component of the flux over the cell T_j, which this time is given by

$$\Gamma_j = -\frac{h_{j1}n_{j1,y}}{|T_j|}\left[\frac{a_{j1}^{\text{in}}g_{j1}^{\text{out}}+a_{j1}^{\text{out}}g_{j1}^{\text{in}}}{a_{j1}^{\text{in}}+a_{j1}^{\text{out}}}-\frac{a_{j2}^{\text{in}}g\left(u_{j2}\left(P_{j3}\right)\right)+a_{j2}^{\text{out}}g\left(u_j\left(P_{j3}\right)\right)}{a_{j2}^{\text{in}}+a_{j2}^{\text{out}}}\right] \tag{3.17}$$
$$-\frac{h_{j3}n_{j3,y}}{|T_j|}\left[\frac{a_{j3}^{\text{in}}g_{j3}^{\text{out}}+a_{j3}^{\text{out}}g_{j3}^{\text{in}}}{a_{j3}^{\text{in}}+a_{j3}^{\text{out}}}-\frac{a_{j2}^{\text{in}}g\left(u_{j2}\left(P_{j4}\right)\right)+a_{j2}^{\text{out}}g\left(u_j\left(P_{j4}\right)\right)}{a_{j2}^{\text{in}}+a_{j2}^{\text{out}}}\right],$$

where P_{j3} and P_{j4} are given in Figure 3.4 (right).

3.2.3. The new method (for conservation laws). We would now like to combine all the different ingredients that we developed in the previous section into one scheme. The scheme that we write here is still a scheme for approximating solutions of the conservation law (2.2) without the source term. Based on our preliminary analysis of section 3.1 we know that we will be able to find an admissible discretization of the source terms that will result with a well-balanced scheme. We will treat the source terms in the next section.

We write two versions of the scheme based on the type of triangle. For type 1 triangles, the discretization of the component of the flux in the x-direction, Φ_j is given by (3.15) while the discretization of the component of the flux in the y-direction, Γ_j, is given by (3.16). In this case the scheme takes the form

$$\begin{aligned}\frac{d\bar{u}_j}{dt} &= -\frac{h_{j1}n_{j1,x}}{|T_j|}\left[\frac{a_{j1}^{\text{in}}f_{j1}^{\text{out}}+a_{j1}^{\text{out}}f_{j1}^{\text{in}}}{a_{j1}^{\text{in}}+a_{j1}^{\text{out}}}-\frac{a_{j2}^{\text{in}}f\left(u_{j2}\left(P_{j1}\right)\right)+a_{j2}^{\text{out}}f\left(u_j\left(P_{j1}\right)\right)}{a_{j2}^{\text{in}}+a_{j2}^{\text{out}}}\right]\\ &\quad -\frac{h_{j3}n_{j3,x}}{|T_j|}\left[\frac{a_{j3}^{\text{in}}f_{j3}^{\text{out}}+a_{j3}^{\text{out}}f_{j3}^{\text{in}}}{a_{j3}^{\text{in}}+a_{j3}^{\text{out}}}-\frac{a_{j2}^{\text{in}}f\left(u_{j2}\left(P_{j2}\right)\right)+a_{j2}^{\text{out}}f\left(u_j\left(P_{j2}\right)\right)}{a_{j2}^{\text{in}}+a_{j2}^{\text{out}}}\right]\\ &\quad -\frac{h_{j1}n_{j1,y}}{|T_j|}\left[\frac{a_{j1}^{\text{in}}g_{j1}^{\text{out}}+a_{j1}^{\text{out}}g_{j1}^{\text{in}}}{a_{j1}^{\text{in}}+a_{j1}^{\text{out}}}-\frac{a_{j3}^{\text{in}}g\left(u_{j3}\left(P_{j3}\right)\right)+a_{j3}^{\text{out}}g\left(u_j\left(P_{j3}\right)\right)}{a_{j3}^{\text{in}}+a_{j3}^{\text{out}}}\right]\\ &\quad -\frac{h_{j2}n_{j2,y}}{|T_j|}\left[\frac{a_{j2}^{\text{in}}g_{j2}^{\text{out}}+a_{j2}^{\text{out}}g_{j2}^{\text{in}}}{a_{j2}^{\text{in}}+a_{j2}^{\text{out}}}-\frac{a_{j3}^{\text{in}}g\left(u_{j3}\left(P_{j4}\right)\right)+a_{j3}^{\text{in}}g\left(u_j\left(P_{j4}\right)\right)}{a_{j3}^{\text{in}}+a_{j3}^{\text{out}}}\right]\\ &\quad +\frac{1}{|T_j|}\sum_{k=1}^{3}h_{jk}\frac{a_{jk}^{\text{in}}a_{jk}^{\text{out}}}{a_{jk}^{\text{in}}+a_{jk}^{\text{out}}}\left[u_{jk}^{\text{out}}-u_{jk}^{\text{in}}\right].\end{aligned} \tag{3.18}$$

Here $P_1 = V_2 - \frac{1}{2}\frac{E_{1,y}}{E_{2,y}}E_2$, $P_2 = V_3 + \frac{1}{2}\frac{E_{3,y}}{E_{2,y}}E_2$, $P_3 = V_1 + \frac{1}{2}\frac{E_{1,x}}{E_{3,x}}E_3$, and $P_4 = V_3 - \frac{1}{2}\frac{E_{2,x}}{E_{3,x}}E_3$.

For type 2 triangles we replace the discretization of Γ_j by the one given in (3.17)

ending with

$$
\begin{aligned}
\frac{d\bar{u}_j}{dt} = &-\frac{h_{j1}n_{j1,x}}{|T_j|}\left[\frac{a_{j1}^{\text{in}}f_{j1}^{\text{out}}+a_{j1}^{\text{out}}f_{j1}^{\text{in}}}{a_{j1}^{\text{in}}+a_{j1}^{\text{out}}} - \frac{a_{j2}^{\text{in}}f\left(u_{j2}\left(P_{j1}\right)\right)+a_{j2}^{\text{out}}f\left(u_j\left(P_{j1}\right)\right)}{a_{j2}^{\text{in}}+a_{j2}^{\text{out}}}\right]\\
&-\frac{h_{j3}n_{j3,x}}{|T_j|}\left[\frac{a_{j3}^{\text{in}}f_{j3}^{\text{out}}+a_{j3}^{\text{out}}f_{j3}^{\text{in}}}{a_{j3}^{\text{in}}+a_{j3}^{\text{out}}} - \frac{a_{j2}^{\text{in}}f\left(u_{j2}\left(P_{j2}\right)\right)+a_{j2}^{\text{out}}f\left(u_j\left(P_{j2}\right)\right)}{a_{j2}^{\text{in}}+a_{j2}^{\text{out}}}\right]\\
&-\frac{h_{j1}n_{j1,y}}{|T_j|}\left[\frac{a_{j1}^{\text{in}}g_{j1}^{\text{out}}+a_{j1}^{\text{out}}g_{j1}^{\text{in}}}{a_{j1}^{\text{in}}+a_{j1}^{\text{out}}} - \frac{a_{j2}^{\text{in}}g\left(u_{j2}\left(P_{j3}\right)\right)+a_{j2}^{\text{out}}g\left(u_j\left(P_{j3}\right)\right)}{a_{j2}^{\text{in}}+a_{j2}^{\text{out}}}\right]\\
&-\frac{h_{j3}n_{j3,y}}{|T_j|}\left[\frac{a_{j2}^{\text{in}}g_{j3}^{\text{out}}+a_{j2}^{\text{out}}g_{j3}^{\text{in}}}{a_{j3}^{\text{in}}+a_{j3}^{\text{out}}} - \frac{a_{j2}^{\text{in}}g\left(u_{j2}\left(P_{j4}\right)\right)+a_{j2}^{\text{in}}g\left(u_j\left(P_{j4}\right)\right)}{a_{j2}^{\text{in}}+a_{j2}^{\text{out}}}\right]\\
&+\frac{1}{|T_j|}\sum_{k=1}^{3}h_{jk}\frac{a_{jk}^{\text{in}}a_{jk}^{\text{out}}}{a_{jk}^{\text{in}}+a_{jk}^{\text{out}}}\left[u_{jk}^{\text{out}}-u_{jk}^{\text{in}}\right].
\end{aligned}
\tag{3.19}
$$

In this case $P_1 = V_2 - \frac{1}{2}\frac{E_{1,y}}{E_{2,y}}E_2$, $P_2 = V_3 + \frac{1}{2}\frac{E_{3,y}}{E_{2,y}}E_2$, $P_3 = V_2 - \frac{1}{2}\frac{E_{1,x}}{E_{2,x}}E_2$, and $P_4 = V_3 + \frac{1}{2}\frac{E_{3,x}}{E_{2,x}}E_2$.

1. For a general triangulation our method will not be conservative because the fluxes from adjacent triangles will not in general be evaluated at the same point on the edge. Our tests with irregular triangulations in section 4 show, however, that this failure of conservation does not lead to serious problems.

2. A simple case of interest is that of coordinate-aligned right triangles. Such triangles can be considered to be of type 1 with $n_{j2,y} = n_{j3,x} = 0$ and $P_{j1} = M_{j2}$ and $P_{j3} = M_{j3}$, which means that the method becomes (taking into account that $\sum_{k=1}^{3} h_{jk}n_{jk} = 0$)

$$
\begin{aligned}
\frac{d\bar{u}_j}{dt} = &-\frac{1}{|T_j|}\left[\frac{a_{j1}^{\text{in}}f_{j1}^{\text{out}}+a_{j1}^{\text{out}}f_{j1}^{\text{in}}}{a_{j1}^{\text{in}}+a_{j1}^{\text{out}}}h_{j1}n_{j1,x} + \frac{a_{j2}^{\text{in}}f_{j2}^{\text{out}}+a_{j2}^{\text{out}}f_{j1}^{\text{in}}}{a_{j2}^{\text{in}}+a_{j2}^{\text{out}}}h_{j2}n_{j2,x}\right]\\
&-\frac{1}{|T_j|}\left[\frac{a_{j1}^{\text{in}}g_{j1}^{\text{out}}+a_{j1}^{\text{out}}g_{j1}^{\text{in}}}{a_{j1}^{\text{in}}+a_{j1}^{\text{out}}}h_{j1}n_{j1,y} + \frac{a_{j3}^{\text{in}}g_{j3}^{\text{out}}+a_{j3}^{\text{out}}g_{j1}^{\text{in}}}{a_{j3}^{\text{in}}+a_{j3}^{\text{out}}}h_{j3}n_{j3,y}\right]\\
&+\frac{1}{|T_j|}\sum_{k=1}^{3}h_{jk}\frac{a_{jk}^{\text{in}}a_{jk}^{\text{out}}}{a_{jk}^{\text{in}}+a_{jk}^{\text{out}}}\left[u_{jk}^{\text{out}}-u_{jk}^{\text{in}}\right].
\end{aligned}
\tag{3.20}
$$

As expected, in this case the method (3.20) coincides with the KP method (2.7).

3.2.4. Adding the source term. We return to the shallow water equations (1.1). Our goal is now to find an admissible discretization of the cell average of the source terms that will preserve stationary steady states. Such a term will be added to the RHS of (3.18) or (3.19) depending on the type of the triangle. In the following we assume type 1 triangles. Similar analysis holds for type 2 triangles. We also note that the first equation in the system (1.1) is homogeneous. This means that we only have to consider the remaining two equations when dealing with the source terms. We recall from section 3.1 that in stationary steady states all the velocities are equal, $a_{jk}^{\text{in}} = a_{jk}^{\text{out}} = a_{jk}$. Our new method (3.18) for the last two equations of (1.1) then

becomes

(3.21)
$$\begin{aligned}
0 = &-\frac{h_{j1}n_{j1,x}}{2\left|T_j\right|}\left[\begin{pmatrix}\left(w\left(M_{j1}\right)-B\left(M_{j1}\right)\right)^2\\0\end{pmatrix}-\begin{pmatrix}\left(w\left(P_{j1}\right)-B\left(P_{j1}\right)\right)^2\\0\end{pmatrix}\right]\\
&-\frac{h_{j3}n_{j3,x}}{2\left|T_j\right|}\left[\begin{pmatrix}\left(w\left(M_{j3}\right)-B\left(M_{j3}\right)\right)^2\\0\end{pmatrix}-\begin{pmatrix}\left(w\left(P_{j2}\right)-B\left(P_{j2}\right)\right)^2\\0\end{pmatrix}\right]\\
&-\frac{h_{j1}n_{j1,y}}{2\left|T_j\right|}\left[\begin{pmatrix}0\\\left(w\left(M_{j1}\right)-B\left(M_{j1}\right)\right)^2\end{pmatrix}-\begin{pmatrix}0\\\left(w\left(P_{j3}\right)-B\left(P_{j3}\right)\right)^2\end{pmatrix}\right]\\
&-\frac{h_{j2}n_{j2,y}}{2\left|T_j\right|}\left[\begin{pmatrix}0\\\left(w\left(M_{j2}\right)-B\left(M_{j2}\right)\right)^2\end{pmatrix}-\begin{pmatrix}0\\\left(w\left(P_{j4}\right)-B\left(P_{j4}\right)\right)^2\end{pmatrix}\right]+\begin{pmatrix}\bar{S}_j^1\\\bar{S}_j^2\end{pmatrix}.
\end{aligned}$$

The last term in (3.21) represents the average of the source, i.e., $\bar{S}_j^1 = \text{avg}(-(w - B)B_x)$ and $\bar{S}_j^2 = \text{avg}(-(w - B)B_y)$, where both averages are taken over T_j.

We use (3.21) to determine the admissible discretizations of the cell averages of the source terms. For constant w the source terms (given by (3.21)) can be rewritten as

$$\begin{aligned}
\bar{S}_j^1 = &-\frac{h_{j1}n_{j1,x}}{2|T_j|}[w_{M_{j1}} - B_{M_{j1}} + w_{P_{j1}} - B_{P_{j1}}][B_{M_{j1}} - B_{P_{j1}}]\\
&-\frac{h_{j3}n_{j3,x}}{2|T_j|}[w_{M_{j3}} - B_{M_{j3}} + w_{P_{j2}} - B_{P_{j2}}][B_{M_{j3}} - B_{P_{j2}}],\\
\bar{S}_j^2 = &-\frac{h_{j1}n_{j1,y}}{2|T_j|}[w_{M_{j1}} - B_{M_{j1}} + w_{P_{j3}} - B_{P_{j3}}][B_{M_{j1}} - B_{P_{j3}}]\\
&-\frac{h_{j2}n_{j2,y}}{2|T_j|}[w_{M_{j2}} - B_{M_{j2}} + w_{P_{j4}} - B_{P_{j4}}][B_{M_{j2}} - B_{P_{j4}}].
\end{aligned} \tag{3.22}$$

Here, we use the notation $w_{M_1} := w\left(M_{j1}\right)$, etc. We take the expressions in (3.22) as the discretization of the source even when w is not constant. Similar expressions can be easily written for type 2 triangles.

LEMMA 3.1. [illegible] $\bar{S}_j^i$ [illegible] (3.22) [illegible] (1.1) [illegible] (3.21).

Before proving Lemma 3.1 we consider the following geometrical lemma.

LEMMA 3.2. [illegible] M [illegible] P [illegible] 3.2.1 [illegible] j

$$M_{1,x} - P_{1,x} = -\frac{|T|}{h_2 n_{2,x}}, \quad M_{3,x} - P_{2,x} = -\frac{|T|}{h_2 n_{2,x}}.$$

[illegible] $M_1 = \frac{1}{2}\left(V_1 + V_2\right)$, and for some s, $P_1 = V_2 + s\left(V_3 - V_2\right)$. We require that $P_{1,y} = M_{1,y}$, which implies that

$$s = \frac{1}{2}\frac{V_{1,y} - V_{2,y}}{V_{3,y} - V_{2,y}}.$$

Therefore

$$M_{1,x} - P_{1,x} = \frac{1}{2}\left(V_{1,x} + V_{2,x}\right) - V_{2,x} - \frac{1}{2}\frac{V_{1,y} - V_{2,y}}{V_{3,y} - V_{2,y}}\left(V_{3,x} - V_{2,x}\right) = -\frac{1}{2}\frac{E_1 \times E_2}{E_{2,y}}.$$

When the orientation of the vertices of T_j is clockwise, $E_1 \times E_2 = -2|T|$ and $n_2 = \frac{1}{h_2}(-E_{2,y}, E_{2,x})$, while when the orientation is counterclockwise, $E_1 \times E_2 = 2|T|$ and $n_2 = \frac{1}{h_2}(E_{2,y}, -E_{2,x})$, so

$$M_{1,x} - P_{1,x} = -\frac{|T|}{h_2 n_{2,x}}.$$

Similar arguments hold for $M_{3,x} - P_{2,x}$. □

3.1. We show that $\bar{S}_j^1 \approx \text{avg}(-(w-B)B_x)$. To simplify the notations we suppress the index j. From Lemma 3.2 we know that $M_{1,x} - P_{1,x} = -\frac{|T|}{h_2 n_{2,x}}$. Since $M_{1,y} = P_{1,y}$ we have $\frac{B_{M_1} - B_{P_1}}{M_{1,x} - P_{1,x}} = B_x + O(|M_1 - P_1|^2)$ at the midpoint between M_1 and P_1. Hence the first part of $\bar{S}_j^1$ in (3.22) becomes

$$\begin{aligned}\frac{h_1 n_{1,x}}{2h_2 n_{2,x}}(w_{M_1} - B_{M_1} + w_{P_1} - B_{P_1})\,\frac{B_{M_1} - B_{P_1}}{M_{1,x} - P_{1,x}} \\ \approx \frac{h_1 n_{1,x}}{2h_2 n_{2,x}}\,(w_{M_1} - B_{M_1} + w_{P_1} - B_{P_1})\,B_x.\end{aligned}$$

Applying a similar argument to the second term of $\bar{S}_j^1$ in (3.22) gives

$$\begin{aligned}\bar{S}_j^1 \approx \frac{1}{2}\Bigg(&\frac{h_1 n_{1,x}}{h_2 n_{2,x}}\,(w_{M_1} - B_{M_1} + w_{P_1} - B_{P_1}) \\ &+ \frac{h_3 n_{3,x}}{h_2 n_{2,x}}\,(w_{M_3} - B_{M_3} + w_{P_2} - B_{P_2})\Bigg) B_x.\end{aligned} \tag{3.23}$$

Clearly, the coefficient of B_x in (3.23) is a discretization of a weighted average of $-(w-B)$. For example, when $w - B$ is constant we have

$$\bar{S}_j^1 \approx \frac{h_1 n_{1,x} + h_3 n_{3,x}}{h_2 n_{2,x}}\,(w-B)\,B_x = -\,(w-B)\,B_x.$$

Similar arguments hold for $\bar{S}_j^2$. □

If we consider a Cartesian mesh split into triangles along a diagonal, it is easy to see that our method reduces to the method in [14].

4. Numerical examples. The scheme developed in section 3.2 did not assume any particular reconstruction. There are several different second-order reconstructions on triangular meshes that are being used in the literature (see [16] and the references therein). We briefly describe the one we used in our simulations.

The starting point is the limited least-squares estimate of the gradients as done in [2]. The first step is to compute a least-squares estimate of the gradient of a field f on the triangle T_j, $\tilde{\nabla}_j f$. We then limit the gradient $\mathcal{D}_j f$ component by component as

$$\mathcal{D}_j f = \mathcal{MM}\left(\tilde{\nabla}_j f, \tilde{\nabla}_{j1} f, \tilde{\nabla}_{j2} f, \tilde{\nabla}_{j3} f\right),$$

where $\tilde{\nabla}_{jk} f$ is the least-squares gradient estimate on T_{jk} and $\mathcal{MM}$ stands for the usual MinMod limiter

$$\mathcal{MM}(x_1, x_2, \dots) := \begin{cases} \min_j \{x_j\} & \text{if } x_j > 0 \quad \forall j, \\ \max_j \{x_j\} & \text{if } x_j < 0 \quad \forall j, \\ 0 & \text{otherwise.} \end{cases}$$

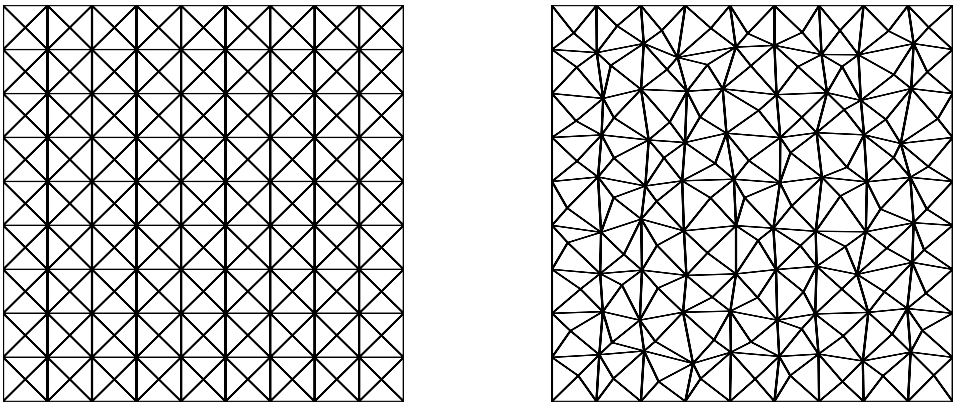

FIG. 4.1. *The two types of triangle meshes. Left: Uniform triangulation. Right: Perturbed (nonuniform) triangulation.*

We use the gradients $\mathcal{D}_j$ to construct a piecewise linear reconstruction for the point values of each triangle edge E_{jk} as

$$u_j(\vec{x}) = \bar{u}_j + \mathcal{MM}\left(\mathcal{D}_j u \cdot (\vec{x} - \vec{x}_j), \mathcal{D}_{jk} u \cdot (\vec{x} - \vec{x}_j)\right).$$

Here $\mathcal{D}_{jk}u$ is the limited gradient estimate on T_{jk}, $\vec{x}_j$ is the center of T_j, and $\vec{x} \in E_{jk}$. We find that this double use of the MinMod limiter minimizes spurious oscillations while preserving the second-order accuracy of the reconstruction.

We use an adaptive time step given by

$$\Delta t = 0.9 \min_j \frac{r_j}{|\lambda_N^j|},$$

where r_j is the radius of T_j and $|\lambda_N^j|$ is the norm of the largest eigenvalues of the Jacobian of the flux on T_j.

We use two types of meshes in most of our simulations. The first is a uniform triangulation of a Cartesian mesh with $N \times N$ nodes and constant spacings Δx and Δy, which divides each Cartesian cell into four triangles. To test our method on more general meshes, our second type of mesh is generated from a uniform triangular mesh with a perturbation of the coordinates of the interior vertices. Examples of both meshes are shown in Figure 4.1. The only exception is Example 6, which uses a uniform triangulation of a warped Cartesian mesh.

Example 1: Accuracy tests for a two-dimensional Burgers equation. We test the accuracy of our method (3.18)–(3.19) on nonlinear problems by applying it to the two-dimensional Burgers equation

$$\begin{cases} u_t + \frac{1}{2}\left(u^2\right)_x + \frac{1}{2}\left(u^2\right)_y = 0, & [-2\pi, 2\pi]^2, \\ u(x, y, t = 0) = \sin\left(\frac{x+y}{2}\right), \end{cases} \tag{4.1}$$

with periodic boundary conditions. The relative L^1-error (i.e., the L^1-error divided by the L^1-norm of the exact solution) of our method at $T = 0.5$ is shown in Table 4.1 for uniform and perturbed triangulations. The computed cell averages after singularity formation at $T = 1.5$ are shown in Figure 4.2. Note the sharp shocks that are captured by our method.

TABLE 4.1
L^1-error and convergence rates for Burgers equation (4.1) at $T = 0.5$ on a uniform and a perturbed triangulation of an $N \times N$ Cartesian mesh.

	Uniform triangulation		Perturbed triangulation	
N	Relative L^1-error	L^1-order	Relative L^1-error	L^1-order
10	0.064	—	0.064	—
20	0.014	2.20	0.014	2.20
40	4.68×10^{-3}	1.58	4.65×10^{-3}	1.59
80	1.37×10^{-3}	1.77	1.36×10^{-3}	1.77

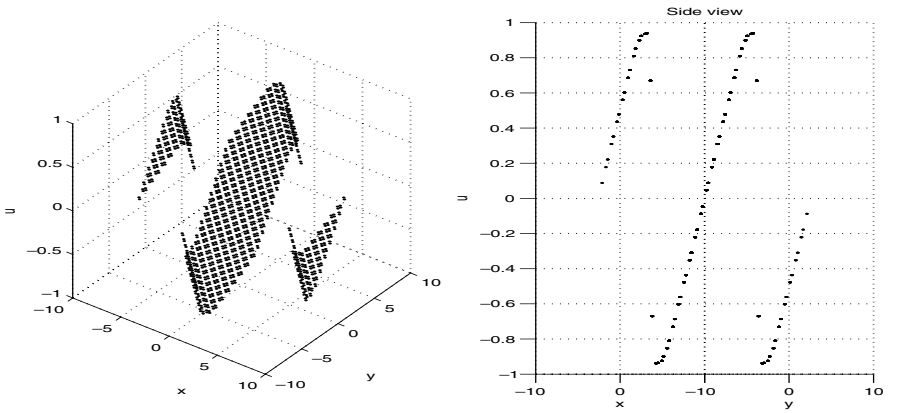

FIG. 4.2. *Burgers equation at $T = 1.5$ on a uniform triangulation of a 20×20 Cartesian mesh. Left: oblique view. Right: side view.*

Example 2: The Sod problem. To test our method (3.18)–(3.19) on a system of equations we apply it to the Sod problem for the Euler equations

$$\begin{pmatrix} \rho \\ \rho u \\ \rho v \\ E \end{pmatrix}_t + \begin{pmatrix} \rho u \\ \rho u^2 + p \\ \rho uv \\ u\,(E+p) \end{pmatrix}_x + \begin{pmatrix} \rho v \\ \rho uv \\ \rho v^2 + p \\ v\,(E+p) \end{pmatrix}_y = 0. \tag{4.2}$$

Here ρ is the density, (u, v) is the velocity, and E is the energy. The equation of state for the pressure is $p = (\gamma - 1)\left[E - \frac{\rho}{2}\left(u^2 + v^2\right)\right]$. We set $\gamma = 1.4$ and take the initial conditions (constant in the y-direction)

$$(p, \rho, u, v) = \begin{cases} (1.0, 1.0, 0.0, 0.0)\,, & x < 0.5, \\ (0.1, 0.125, 0.0, 0.0)\,, & x > 0.5. \end{cases} \tag{4.3}$$

Figure 4.3 shows the computed cell averages at $T = 0.16$ using our method from section 3.2 projected onto the $y = 0$ plane. A reference one-dimensional solution is also shown. The two-dimensional problem is run on both a uniform triangulation based on a 300×30 Cartesian mesh on the domain $[0, 1] \times [0, 0.1]$ as well as a perturbation of that mesh. The one-dimensional reference solution is computed using the second-order central method of [15] with 3000 points in the domain $[0, 1]$. As expected, the quality of the solution slightly degrades on the nonuniform mesh.

Example 3: A balance test. In this example we demonstrate the well-balanced property of our scheme (3.18)–(3.19) with the source discretization (3.22).

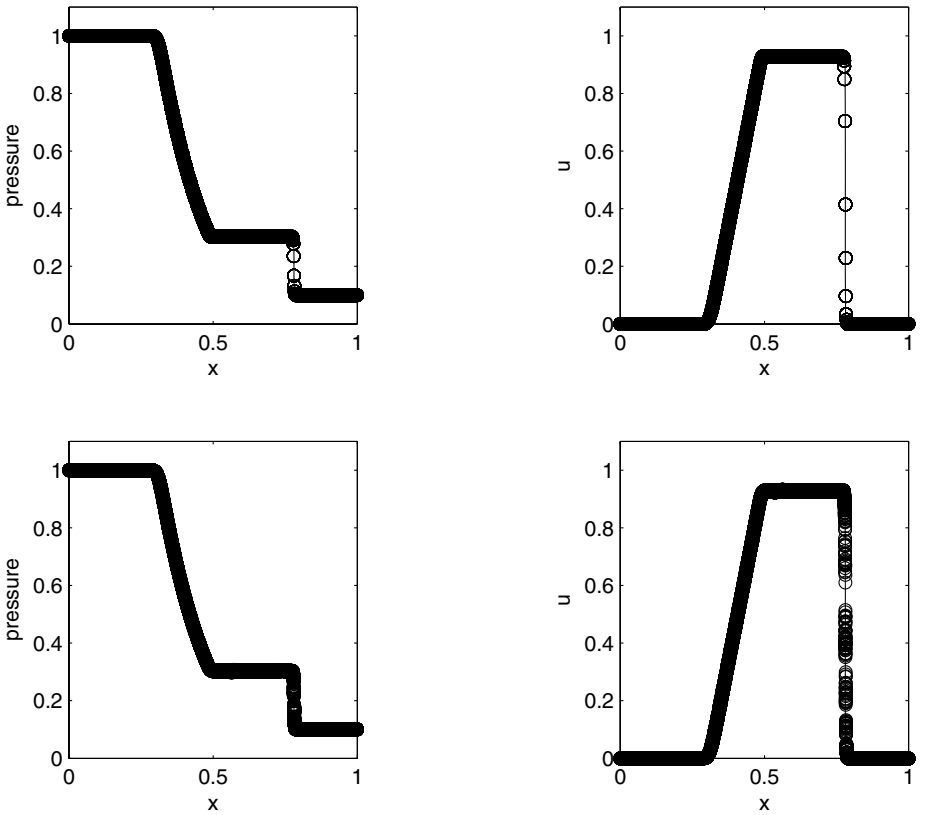

FIG. 4.3. *The pressure (left) and u-velocity (right) fields of the Sod problem at* $T = 0.16$ *on a uniform triangulation (top) and a perturbed triangulation (bottom). The circles show an orthogonal projection onto the* $y = 0$ *plane of the solution of the two-dimensional problem on a triangular mesh. The line shows a one-dimensional reference solution computed with the second-order central-upwind method of* [15].

As a simple test of balance, we consider the shallow water problem with initial conditions that represent a stationary steady state. We choose $w(x, y, t = 0) = 2$, $u(x, y, t = 0) = v(x, y, t = 0) = 0$, and a bottom topography given by $B(x, y) = \sin(2\pi x) + \cos(2\pi y)$ on the domain $[0, 1]^2$. We assume periodic boundary conditions. This initial value problem has the trivial stationary steady-state solution $w(x, y, t) = 2$, $u(x, y, t) = v(x, y, t) = 0$ for all t.

The relative L^1-errors at $T = 1$ on both uniform and perturbed triangulations based on a 10×10 Cartesian mesh are given in Table 4.2. This table also shows the result found using the KP method [16] with the same source discretization (3.22) which is not balanced for this scheme. We see that our method balances to machine accuracy.

Example 4: Propagating waves with a bottom topography. We apply our method to a test problem from [18] of a small perturbation of a steady-state problem on the domain $[0, 2] \times [0, 1]$ with periodic boundary conditions in the y-direction. The bottom topography is the elliptical Gaussian mound given by

$$B(x, y) = 0.8 \exp\left(-5(x - 0.9)^2 - 50(y - 0.5)^2\right),$$

TABLE 4.2

and the initial conditions are

$$(w,u,v) = \begin{cases} (1.01, 0.0, 0.0) & \text{if } \ 0.05 < x < 0.15, \\ (1.0, 0.0, 0.0) & \text{otherwise.} \end{cases}$$

Figure 4.4 shows the result of our method at various times on a uniform triangulation of both a 200×100 and 400×200 Cartesian mesh. These results are in good agreement with other methods on Cartesian grids (see [14, 18]).

Example 5: Converging-diverging channel with bottom topography. Our final example is that of a converging-diverging channel with critical flow adapted from [12]. The channel is defined on the domain $[0,3] \times [-0.5, 0.5]$ with a half-cosine constriction centered at $x = 1.5$. The mesh for this example is shown in Figure 4.5(a). It is a nonuniform triangulation obtained by warping a uniform triangulation of a Cartesian mesh under the mapping $(x,y) \to \left(x, \left(1 - 0.2\cos^2\left(\pi\left(x - 1.5\right)\right)\right) y\right)$ when $|x - 1.5| < 0.5$. The initial data is $w = 1, u = v = 0$. The y-boundaries are reflecting. The left x-boundary is an inflow boundary with $u = 5.0$ and the right x-boundary is a zeroth-order outflow boundary. We run the simulations on a 90×30 mesh until $T = 7$ after the steady state is achieved. We would like to emphasize that this is not a stationary steady state.

We first present this example with a flat bottom, with contours of w shown in Figure 4.5(b). Figure 4.5(c) shows the same channel at the same time with bottom topography

$$B(x,y) = 0.8\left(\exp\left(-10\left(x - 1.9\right)^2 - 50\left(y - 0.2\right)^2\right) + \exp\left(-20\left(x - 2.2\right)^2 - 50\left(y + 0.2\right)^2\right)\right).$$

This topography is shown in Figure 4.5(d) and represents two elliptical Gaussian mounds just downflow from the constriction.

We choose the initial and boundary conditions such that stationary shocks are generated. The symmetry of the flat-bottom case (Figure 4.5(b)) is broken by the nonsymmetric bottom (Figures 4.5(c)–(d)). These results are in qualitative agreement with those that are shown in [12]. We note that the simulations in [12] correspond only to the flat bottom case.

5. Conclusion. In this paper we presented a well-balanced semidiscrete central scheme on triangular meshes for shallow water equations with bottom topography. This scheme is derived by changing the quadrature rules for the flux integrals that were proposed in [16]. A careful discretization of the source term then allows us to preserve stationary steady states.

The numerical flux is complemented by a new second-order reconstruction on triangular meshes. The accuracy and well-balanced properties of the scheme are demonstrated in a variety of numerical simulations.

Several generalizations of this scheme are left for future research. This includes dry beds and dissipative systems.

A FAST ALGORITHM FOR THE ELECTROMAGNETIC SCATTERING FROM A LARGE CAVITY*

GANG BAO† AND WEIWEI SUN‡

Abstract. A fast algorithm is presented for solving electromagnetic scattering from a rectangular open cavity embedded in an infinite ground plane. The medium inside the cavity is assumed to be (vertically) layered. By introducing a transparent (artificial) boundary condition, the problem in the open cavity is reduced to a bounded domain problem. A simple finite difference method is then applied to solve the model Helmholtz equation. The fast algorithm is designed for solving the resulting discrete system in terms of the discrete *Fourier transform* in the horizontal direction, a Gaussian elimination in the vertical direction, and a preconditioning conjugate gradient method with a complex diagonal preconditioner for the indefinite interface system. The existence and uniqueness of the finite difference solution are established for arbitrary wave numbers. Our numerical experiments for large numbers of mesh points, up to 16 million unknowns, and for large wave numbers, e.g., between 100 and 200 wavelengths, show that the algorithm is extremely efficient. The cost for calculating the radar cross section, which is of significant interest in practice, is $O(M^2)$ for an $M \times M$ mesh. The proposed algorithm may be extended easily to solve discrete systems from other discretization methods of the model problem.

1. Introduction.

As a measure of the detectability of a target in radar systems, radar cross section (RCS) has been an important subject of study in electromagnetics. Accurate prediction of the RCS of complex objects such as aircraft presents a great challenge in computational electromagnetics. Of particular importance is the RCS prediction of cavities due to its dominance to the target's overall RCS. Examples of cavities include jet engine inlet ducts, exhaust nozzles, and cavity-backed antennas. The computation is especially challenging when the cavities are large compared to the wavelength of the fields because of the highly oscillatory nature of the fields. This paper is intended to develop a fast algorithm for solving the electromagnetic scattering problem from large cavities. More specifically, consider a time-harmonic electromagnetic plane wave incident on an open cavity embedded in an infinite ground plane. The geometry is shown in Figure 1. The ground plane and the walls of the open cavity are perfect electric conductors (PEC), and the interior of the open cavity is filled with nonmagnetic material which may be inhomogeneous. The half-space above the ground plane is filled with a homogeneous, linear, isotropic medium. In this setting, the electromagnetic scattering by the cavity is governed by the Helmholtz equation along with Sommerfeld's radiation conditions imposed at infinity.

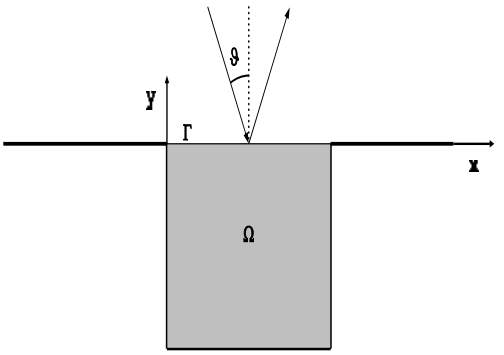

FIG. 1. *The cavity geometry.*

Because of its significant industrial and military applications, the cavity problem has attracted much attention recently. A variety of numerical methods including finite difference, finite element, boundary element methods, and hybrid methods have been developed by the engineering community for solving the open cavity problems [27], [34], [35], [42]. A detailed discussion and additional references may be found in Jin [23]. Mathematical analysis of open cavity models has been conducted by an integral equation method [2], and by a variational approach [3]. An important step for solving the open cavity problem is to introduce a transparent boundary condition on the top line of the cavity. The boundary condition reduces the infinite problem to a finite computational domain, which in turn can be solved by some classical numerical approximation. More recently, a time-domain finite element method has been presented in [41]. However, efficient solvers for the discrete linear systems have not been explored. Classical direct and iterative algorithms are not efficient, especially for large cavity problems due to their high computational costs.

The problem with large wave number, or more precisely with large "ka" number, is of significant interest. Here k is the wave number and a is the diameter of the computational domain. For electromagnetic cavity problems, microwaves are usually considered. Nonetheless, for large cavities, the large domain diameters give rise to high "ka" numbers. Our goal in this paper is to develop a fast algorithm that is capable of dealing with large cavities. For convenience, without loss of generalities, we focus primarily on high wave number problems in our discussion. A straightforward change of coordinates yields the equivalence of high wave number and large cavity problems in the current context. The main difficulty lies in the fact that the solution at a high wave number is highly oscillatory. Moreover, it is well known that error estimates strongly depend upon the wave number. Babuska and Sauter [5] showed that for a related model problem, the ratio of the error of the Galerkin solution and the error of the best approximation tends to infinity as the wave number increases. Furthermore, Aziz, Kellogg, and Stephen [4] pointed out that the condition "k^2h small" would be required to guarantee that the error of the Galerkin solution has the same magnitude as the error of the best approximation, where h is the mesh size. For a large cavity problem, say $1m \times 1m$, with a centimeter incident wave, this condition implies that $h \approx 10^{-4}m$, or 10^8 unknowns in the discrete linear systems of two-dimensional cases.

In this paper, we present a fast algorithm for solving the electromagnetic scattering from a rectangular cavity in which the medium is y-directional inhomogeneous. The algorithm is based on the use of discrete [illegible] in the horizontal

direction and a Gaussian elimination in the vertical direction. We reduce the global system with an $M \times M$ mesh to a (interface) linear system on the top line of the cavity by $O(M^2)$ operations. Since the interface system is complex and indefinite, i.e., its eigenvalues are located on both sides of the y-axis, many classical iterative methods may not be convergent. Here, we propose a complex diagonal preconditioner for the interface system. All eigenvalues of the preconditioned coefficient matrix lie on the right side of the y-axis and the condition number of the matrix increases slightly as the number of mesh points increase. The BiCG method with the diagonal preconditioner is applied to solve the interface system. The number of iterations used in the BiCG method is almost independent of the number of mesh points. Numerical experiments for large numbers of mesh points, up to 16 million unknowns, and for large wave number, e.g., k is between 100 and 200 wavelengths, show that the algorithm is efficient and the computational cost for RCS is $O(M^2)$ for an $M \times M$ mesh. The existence and uniqueness for discrete system with general approximations to the nonlocal boundary condition are established. Here a simple finite difference method is employed for the approximation to illustrate the idea for solving the scattering problem. It should be pointed out that the proposed algorithm and corresponding analysis may also be extended to linear systems resulting from other discrete approximations.

A related topic is the so-called [illegible], which were well studied in the last several decades; see the review papers [39], [40] for finite difference methods and [7], [36], [38] for other approximations. These methods can be applied mainly for solving Poisson's equation on a rectangular region with simple local boundary conditions, such as Dirichlet, Neumann, or periodic boundary conditions. The computational complexity is $O(N^2 logN)$ for an $N \times N$ mesh. Extensions to regions with rectangular substructures and to more general regions can be done in terms of domain decomposition or capacitance matrix techniques [8], [9], [33], [11].

Extensions of capacitance matrix methods to the Helmholtz equations were studied in [16], [17], [30]. For capacitance matrix methods, one needs to solve a capacitance system of small size by using either a direct method with an explicit formula of capacitance matrix or an iterative method in implicit form. At each iteration of the iterative method, the multiplication of a vector by the capacitance matrix can be performed by the classical fast Poisson solver. Usually, direct methods for solving capacitance systems are more expensive [33].

There are two related Helmholtz type models: exterior and interior Helmholtz problems. The former concerns the scattering from a bounded medium or obstacle; while the latter deals with the Helmholtz equation in a bounded domain with suitable boundary conditions, such as of Dirichlet, Neumann, or impedance (Robin) types. Numerous studies have been devoted to the development of iterative algorithms for solving large scale linear systems arising from these two Helmholtz models [12], [13], [14], [16], [17], [18], [21], [26], [31]. The methods are mostly based on domain decomposition and preconditioning techniques. Ernst and Golub [18] solved the interior Helmholtz model in a rectangular domain with impedance boundary conditions using preconditioning methods. In particular, they proposed several preconditioners including the discrete Helmholtz operators with Dirichlet or Neumann boundary conditions on two edges and a preconditioned Schur complement. Elman and O'Leary [12] further studied the first preconditioner proposed in [18] and presented eigenvalue analysis for the preconditioned systems. For the one-dimensional model, the identification of the eigenvalues of a preconditioned system entails the computation of the eigenvalues for a 2×2 matrix. They also extended the algorithm to three-dimensional models with large wavenumbers. More numerical experiments were given in [13].

Note that at each preconditioning iteration of their algorithm, one needs to solve the Helmholtz equation with Dirichlet or Neumann boundary conditions on two edges and impedance boundary conditions on the other two edges, which can be performed by classical FFT-type fast solver.

Exterior Helmholtz problems, in terms of some transformations or truncation techniques, can be reduced to finite domain problems with certain nonlocal boundary conditions: exact, approximate, periodic and Fourier-type, which have been done in the last 30 years; e.g., see [15], [19], [25]. Computational methods for exterior Helmholtz problems with some nonlocal boundary conditions were studied in [16], [17], [20], [28], [31]. In [16], [17], Ernst proposed a fast capacitance matrix algorithm for the exterior Helmholtz equation. A transparent (exact nonlocal) boundary condition introduced in [25] was applied on a circular artificial boundary. Due to the nature of axial symmetry, the nonlocal operator is circulant (periodic). A Krylov subspace method may be used for solving the resulting capacitance system. The multiplication of a vector by the capacitance matrix was performed using a fast Helmholtz solver in an annular domain, which should be viewed as a direct application of fast Poisson's solver since the nonlocal boundary condition is periodic. Otto and Larsson [31] presented a preconditioning algorithm for solving a Helmholtz problem in a duct with a curved bottom, in which a fast Helmholtz solver for a duct with straight lines was used as a preconditioner. The nonlocal boundary conditions at the near- and far-zone boundaries were given in the form of the coupled mode solution. The Fourier-sine transform was applied on both the Helmholtz equation and the nonlocal boundary condition. However, the coupled mode boundary condition proposed in [19] and [1] is only valid for waveguide models rather than the underlying cavity models. The algorithm proposed in the current paper is also based on FFT-type fast solvers and efficient preconditioning techniques. We focus on the cavity model which is different from both the exterior and interior Helmholtz problems. The nonlocal boundary operator arising from the cavity model is not circulant, and the coupled mode boundary condition is not suitable in this case.

Note that efficient numerical algorithms for solving linear systems arising from large cavity models have not been explored. Mathematical analysis on existence and uniqueness of solutions has been conducted only recently in [2], [3]. In our algorithm, the FFT-sine transform with a Gaussian elimination is used to reduce the global system to an aperture system. This step is equivalent to determining the discrete Dirichlet-to-Neumann map. The simple diagonal complex preconditioner applied to the resulting aperture system depends upon both the Helmholtz operator and the nonlocal boundary condition on the aperture. In comparison, the cost at each iteration of our algorithm is proportional to $NlogN$ for an $N \times N$ mesh while the cost at each iteration in [12], [13], [16], [17] is $O(N^2 logN)$.

The rest of the paper is organized as follows. In section 2, the model scattering problem is formulated and further reduced to a bounded domain problem. A detailed fast algorithm is introduced in section 3 for the TM (transverse magnetic) case. Issues on implementation and complexity of the algorithm are addressed. A complex diagonal preconditioner is proposed and the TE (transverse electric) case is also studied. The existence and uniqueness of the finite difference solution is proved in section 4. Section 5 is devoted to numerical experiments of the algorithm. The paper is concluded in section 5 by some general remarks on the usefulness of the algorithm and future directions.

2. The electromagnetic cavity problem. We focus on a two-dimensional geometry by assuming that the medium and material are invariant in the z-direction.

Assume also that the medium is nonmagnetic and a constant magnetic permeability $\mu = \mu_0$ exists everywhere. The electromagnetic property of the medium is characterized by the dielectric coefficient ε. Throughout, it is assumed that ε is layered inside the cavity.

For the TM polarization, in which the magnetic field is transverse to the invariant direction and $E = (0, 0, u(x, y))$, the time-harmonic Maxwell equations reduce to

$$\begin{aligned} &\Delta u + k^2 u = f(x,y) && (x,y) \in \Omega \cup R_2^+, \\ &u = 0 && \text{on } \partial(\Omega \cup R_2^+) \end{aligned} \tag{2.1}$$

together with the radiation boundary condition

$$\lim_{r\to\infty} r\left(\frac{\partial u}{\partial \eta} - ik_0 u\right) = 0, \tag{2.2}$$

where $k^2 = \omega^2 \varepsilon \mu_0$ and R_2^+ denotes the upper half-space. Inside Ω, assume that $\varepsilon = \varepsilon(y)$ is independent of the variable x. The fields are said to be source free if the source term $f = 0$.

For the TE polarization, in which the electric field is transverse to the invariant direction, $H = (0, 0, u(x, y))$, the Maxwell equations reduce to

$$\begin{aligned} &\nabla \cdot \left(\frac{1}{k^2}\nabla u\right) + u = f(x,y) && (x,y) \in \Omega \cup R_2^+, \\ &\frac{\partial u}{\partial n} = 0 && \text{on } \partial\Omega \setminus \Gamma \end{aligned} \tag{2.3}$$

with the same radiation boundary condition (2.2). Here, n denotes the unit outward normal.

Since the upper half-space is homogeneous, a so-called transparent boundary condition can be obtained by using either Green's function method (i.e., Hankel's function) [23] or the method of Fourier's transform [2], [3], [15]. In the TM case, the scattering problem may be further reduced to a bounded domain problem:

$$\begin{aligned} &\Delta u + k^2 u = f(x,y) && (x,y) \in \Omega, \\ &u = 0 && \text{on } \partial\Omega \setminus \Gamma, \\ &\frac{\partial u}{\partial n} = I(u) && \text{on } \Gamma, \end{aligned} \tag{2.4}$$

where $I(u)$ denotes a nonlocal integral operator on Γ.

Let $G_d(\boldsymbol{x}, \boldsymbol{x}')$ be the upper half-plane Dirichlet Green's function for the Helmholtz equation

$$G_d(\boldsymbol{x}, \boldsymbol{x}') = \frac{\mathrm{i}}{4}\left[H_0^{(1)}(k\boldsymbol{r}) - H_0^{(1)}(k\bar{\boldsymbol{r}})\right], \tag{2.5}$$

where $\boldsymbol{x} = (x, y)$, $\boldsymbol{x}' = (x', y')$, $\boldsymbol{r} = |\boldsymbol{x} - \boldsymbol{x}'|$, $\bar{\boldsymbol{r}} = |\boldsymbol{x} - \bar{\boldsymbol{x}}'|$ and $\bar{\boldsymbol{x}}' = (x', -y')$ is the image of $\boldsymbol{x}$ with respect to real axis; by Green's theorem and noting the homogeneous boundary conditions,

$$u(x,y) = \int_\Gamma \frac{\partial G_d(x, y; x', 0)}{\partial n'} u(x')dx' \quad x \in (0, a). \tag{2.6}$$

Then the nonlocal boundary condition is given by

$$\frac{\partial u}{\partial y} = I(u) := -\frac{\mathrm{i}k_0}{2} \Xint=_{\Gamma} \frac{1}{|x-x'|} H_1^{(1)}(k_0|x-x'|)u(x')dx' \quad x \in (0,a), \tag{2.7}$$

where $\Xint=_{\Gamma}$ denotes a Hadamard principle value (or finite part) integral. An alternative Fourier-type nonlocal boundary condition given in [1] is

$$I(u) = \frac{\mathrm{i}k_0}{2} \int_R \sqrt{k_0^2 - \xi^2}\mathcal{F}[\tilde{u}]e^{\mathrm{i}\xi x}d\xi,$$

where $\tilde{u}$ is an extension of u to $H^{1/2}(R)$ and $\mathcal{F}$ denotes the Fourier transformation.

Similar nonlocal boundary conditions for other geometries may be found in [15] and [19].

Assume that a plane wave $u_I = e^{\mathrm{i}(\alpha x - \beta y)}$ is incident on the cavity from the above, where $\alpha = k_0 \sin\theta$, $\beta = k_0 \cos\theta$, and $-\pi/2 < \theta < \pi/2$ is the angle of incidence with respect to the positive y-axis. The scattered field u^s can be expressed by

$$u^s = u^t - u_I + e^{\mathrm{i}(\alpha x + \beta y)},$$

where u^t is the total field of the scattering problem. Since u^s satisfies the Helmholtz equation (2.1) and the radiation condition (2.2), the total field u^t satisfies the following equation:

$$\begin{aligned} &\Delta u + k^2 u = f(x,y) && (x,y) \in \Omega, \\ &u = 0 && \text{on } \partial\Omega \setminus \Gamma, \\ &\frac{\partial u}{\partial n} = I(u) + g(x) && \text{on } \Gamma, \end{aligned} \tag{2.8}$$

where $g(x) = 2\mathrm{i}\beta e^{\mathrm{i}\alpha x}$.

Similarly, one can derive the formulation for TE polarization. In this case, the corresponding Helmholtz-type equation and the transparent boundary condition for the total field are

$$\begin{aligned} &\nabla \cdot \left(\frac{1}{k^2}\nabla u\right) + u = f(x,y) && (x,y) \in \Omega, \\ &\frac{\partial u}{\partial n} = 0 && \text{on } \partial\Omega \setminus \Gamma, \\ &\frac{\partial u}{\partial n} = \tilde{I}(u) + g && \text{on } \Gamma, \end{aligned} \tag{2.9}$$

where $\tilde{I}(u)$ is a nonlocal integral operator.

The existence and uniqueness of solutions of (2.8) and (2.9) for arbitrary wave numbers have been obtained in [3]. The proof is based on a variational approach by using the Fredholm alternative along with the fact that the imaginary part of the nonlocal integral operator is nonnegative.

When a numerical approximation is used for the discretization of (2.8), the global system can be written in general by

$$\begin{pmatrix} A & A_{12} \\ A_{21} & B \end{pmatrix} \begin{pmatrix} u \\ u_B \end{pmatrix} = \begin{pmatrix} f \\ g \end{pmatrix}, \tag{2.10}$$

where A denotes the discrete Helmholtz operator and B corresponds to the discrete boundary integral operator. The matrix A is sparse and B is full in general. Direct methods for such a system are generally less efficient. Most numerical algorithms are based on a Schur complement technique [23], [32]. A particular one is the outward-looking approach, i.e.,

$$\begin{aligned} &(A - A_{12}B^{-1}A_{21})u = f - A_{12}B^{-1}g, \\ &Bu_B = g - A_{21}u\,. \end{aligned} \tag{2.11}$$

Alternatively, there is also the inward-looking approach

$$\begin{aligned} &(B - A_{21}A^{-1}A_{12})u_B = g - A_{21}A^{-1}g, \\ &Au = f - A_{12}u_B. \end{aligned} \tag{2.12}$$

Some classical iterative algorithms, such as conjugate gradient and biconjugate gradient methods, have been applied for solving these subsystems or directly for solving the global system (2.10). The computational cost at each iteration in (2.11) or (2.12) is at least $O(M^2)$ or $O(M^2 log M)$, respectively. The main purpose of this paper is to present a fast algorithm for solving the Helmholtz equations (2.8) and (2.9) with the nonlocal boundary conditions. Due to the fixed position of aperture in this cavity model, approximate local boundary conditions are not suitable [15]. Also we point out that no convergence result for these iterative methods, particularly for problems with large wave numbers, is available at present.

3. Fast algorithm. For simplicity, we consider a simple five-point finite difference method for the discretization of the Helmholtz equation with uniform meshes and assume that the wave number k is real and positive. The approach may be extended easily to many other approximations. Also, for the layered medium problems in TE polarization, nonuniform meshes in y-direction and some special treatment on interface may be used to achieve better accuracy.

3.1. Algorithm in the TM case. Let $\{x_i, y_j\}_{i,j=0}^{M+1,N+1}$ define a uniform partition of $\Omega = [0, a] \times [-b, 0]$ with $x_{i+1} - x_i = h_x$ and $y_{j+1} - y_j = h_y$. Let v_{ij} be the finite difference solution at the point (x_i, y_j). The discrete finite difference system in the TM case can be given by

$$\frac{v_{i-1,j} - 2v_{ij} + v_{i+1,j}}{h_x^2} + \frac{v_{i,j-1} - 2v_{ij} + v_{i,j+1}}{h_y^2} + \omega\varepsilon(y_j)\mu_0 v_{ij} = f(x_i, y_j),$$
$$i = 1, 2, \ldots, M; j = 1, 2, \ldots, N$$

or in matrix form,

$$(A_x \otimes I_N + I_M \otimes A_y + I_M \otimes D)\, v + (I_M \otimes a_{N+1})\, v_{N+1} = f, \tag{3.1}$$

where $\otimes$ denotes the tensor product (Kronecker product), I_M is the $M \times M$ identity matrix,

$$A_x = \frac{1}{h_x^2}\begin{pmatrix} -2 & 1 & & \\ 1 & -2 & 1 & \\ & \ddots & \ddots & \ddots \\ & & 1 & -2 \end{pmatrix} \qquad A_y = \frac{1}{h_y^2}\begin{pmatrix} -2 & 1 & & \\ 1 & -2 & 1 & \\ & \ddots & \ddots & \ddots \\ & & 1 & -2 \end{pmatrix}$$

$$D = w^2\mu_0 \begin{pmatrix} \varepsilon(y_1) & & & \\ & \varepsilon(y_2) & & \\ & & \ddots & \\ & & & \varepsilon_(y_N) \end{pmatrix} \qquad a_{N+1} = \frac{1}{h_y^2} \begin{pmatrix} 0 \\ \vdots \\ 0 \\ 1 \end{pmatrix}$$

and

$$v = (v_{11}, \ldots, v_{1N}, v_{21}, \ldots, v_{2N}, \ldots, v_{M1}, \ldots, v_{MN})^T,$$
$$v_j = (v_{1j}, v_{2j}, \ldots, v_{Mj})^T.$$

By using a backward finite difference scheme and a general approach for the nonlocal boundary condition, we obtain

$$\frac{v_{i,N+1} - v_{i,N}}{h_y} = \sum_{l=1}^{M} g_{il} v_{l,N+1} + g(x_i), \quad i = 1, 2, \ldots, M,$$

i.e.,

$$-v_N + (I_M - h_y G) v_{N+1} = h_y g,$$

where $G = (g_{ij})_{i,j=1}^{M}$ is an $M \times M$ matrix.

The global system is given by

$$\begin{pmatrix} A & A_{12} \\ A_{21} & I_M - h_y G \end{pmatrix} \begin{pmatrix} v \\ v_{N+1} \end{pmatrix} = \begin{pmatrix} f \\ h_y g \end{pmatrix}, \tag{3.2}$$

where

$$A = A_x \otimes I_N + I_M \otimes A_y + I_M \otimes D,$$
$$A_{12} = I_M \otimes a_{N+1},$$
$$A_{21} = -h_y^2 A_{12}^T.$$

For the tridiagonal Toeplitz matrix A_x, we have

$$S_M A_x S_M = \Lambda = \begin{pmatrix} \lambda_1 & & & \\ & \lambda_2 & & \\ & & \ddots & \\ & & & \lambda_M \end{pmatrix},$$

where S_M denotes the discrete Fourier-sine transformation,

$$S_M = \frac{1}{\sqrt{M}} \left(\sin \frac{lm\pi}{M+1} \right)_{l,m=1}^{M}, \qquad \lambda_l = -\frac{4(M+1)^2}{a^2} \sin^2 \frac{l\pi}{2(M+1)},$$

and $S_M^2 = I$.

By the discrete Fourier-sine transformation, we rewrite the discrete Helmholtz system (3.1) as

$$(\Lambda \otimes I_N + I_M \otimes A_y + I_M \otimes D)\, \bar{v} + (I_M \otimes a_{N+1})\, \bar{v}_{N+1} = \bar{f}, \tag{3.3}$$

where

$$\bar{v} = (S_M \otimes I_N)\, v = (\bar{v}_{11}, \ldots, \bar{v}_{1N}, \bar{v}_{21}, \ldots, \bar{v}_{2N}, \ldots, \bar{v}_{M1}, \ldots, \bar{v}_{MN})^T, \quad \bar{v}_{N+1} = S_M v_{N+1},$$
$$\bar{f} = (S_M \otimes I_N)\, f = (\bar{f}_{11}, \ldots, \bar{f}_{1N}, \bar{f}_{21}, \ldots, \bar{f}_{2N}, \ldots, \bar{f}_{M1}, \ldots, \bar{f}_{MN})^T.$$

Similarly, the discrete boundary equations become

$$-\bar{v}_N + S_M(I_M - h_y G)S_M\bar{v}_{N+1} = \bar{g},$$

where $\bar{g} = h_y S_M g$.

Reordering the unknowns and equations in (3.3), we obtain

$$\begin{aligned} &(A_y + \lambda_i I_N + D)\hat{v}_i + a_{N+1}\bar{v}_{i,N+1} = \hat{f}_i, \qquad i = 1, 2, \ldots, M, \\ &-\bar{v}_N + S_M(I_M - h_y G)S_M\bar{v}_{N+1} = \bar{g}, \end{aligned} \tag{3.4}$$

where

$$\begin{aligned} &\hat{v}_i = (\bar{v}_{i1}, \bar{v}_{i2}, \ldots, \bar{v}_{iN}), \\ &\hat{f}_i = (\bar{f}_{i1}, \bar{f}_{i2}, \ldots, \bar{f}_{iN}), \qquad i = 1, 2, \ldots, M. \end{aligned}$$

We use the Gaussian elimination method with a row partial pivoting to solve the first system in (3.4). Let

$$A_y + \lambda_i I_N + D = L_i U_i, \quad i = 1, 2, \ldots, M$$

be the LU-decomposition, where $A_y + \lambda_i I_N + D$ is a symmetric tridiagonal matrix.

Since L_i is nonsingular,

$$U_i\bar{v}_i + L_i^{-1}a_{N+1}\bar{v}_{i,N+1} = \hat{f}_i, \qquad i = 1, 2, \ldots, M, \tag{3.5}$$

where $U_i = (r_{pq}^i)$ and $\hat{f}_i = L_i^{-1}\bar{f}_l$.

Combining the last equations of the systems (3.5) and the boundary equations gives

$$\begin{aligned} &r_{NN}^i\bar{v}_{iN} + r_{N,N+1}^i\bar{v}_{i,N+1} = \hat{f}_{iN}, \quad i = 1, 2, \ldots, M, \\ &-\bar{v}_N + S_M(I_M - h_y G)S_M\bar{v}_{N+1} = \bar{g}, \end{aligned} \tag{3.6}$$

where $r_{N,N+1}^i$ is the last component of $L_i^{-1}a_{N+1}$.

Since

$$\begin{aligned} &\bar{v}_N = (\bar{v}_{1N}, \bar{v}_{2N}, \ldots, \bar{v}_{MN}), \\ &\bar{v}_{N+1} = (\bar{v}_{1,N+1}, \bar{v}_{2,N+1}, \ldots, \bar{v}_{M,N+1}), \end{aligned}$$

only $\bar{v}_N$ and $\bar{v}_{N+1}$ are involved in the system (3.6).

If k^2 is not an eigenvalue of the Helmholtz operator with Dirichlet boundary conditions, then for h small enough,

$$r_{NN}^i \neq 0, \qquad i = 1, 2, \ldots, M. \tag{3.7}$$

We can further eliminate the vector $\bar{v}_N$ from the second system in (3.6) to get

$$(S_M(I_M - h_y G)S_M + E)\bar{v}_{N+1} = \hat{g} \tag{3.8}$$

or equivalently

$$(I_M - h_y G + S_M E S_M)v_{N+1} = S_M\hat{g},$$

where

$$E = \begin{pmatrix} r_{1,N+1}^1/r_{NN}^1 & & \\ & \ddots & \\ & & r_{N,N+1}^M/r_{NN}^M \end{pmatrix}$$

and

$$\hat{g}_i = \bar{g}_i + \bar{f}_{iN}/r^i_{NN}, \quad i = 1, 2, \ldots, M.$$

Solving the linear system (3.8) gives the solution v_{N+1} on the interface Γ. The rest of the unknowns can be obtained by solving the following system:

$$(A_y + \lambda_i I_N + D)\bar{v}_i = -a_{N+1}\bar{v}_{N+1}, \quad i = 1, 2, \ldots, M, \tag{3.9}$$

in which $\bar{v}_N = -\bar{g} + \bar{B}\bar{v}_{N+1}$ may be used for those possible nearly singular systems.

If k^2 (approximately) is an eigenvalue of the Dirichlet–Helmholtz operator, then the matrix $A_y + \lambda_i I_N + D$ is singular (or nearly singular) for some $i \in J_s$, where J_s is a subset of $\{1, 2, \ldots, M\}$. Combining the equations in the first system of (3.6) with $i \in J_s$ and a system corresponding to (3.5), we have

$$\begin{bmatrix} D_s & W_{12} \\ W_{21} & I_M - h_y G + S_M E S_M \end{bmatrix} \begin{bmatrix} w \\ v_{N+1} \end{bmatrix} = \begin{bmatrix} f_s \\ g_s \end{bmatrix}, \tag{3.10}$$

where D_s is a diagonal matrix whose diagonal entries consist of r^i_{NN} with $i \in J_s$ and f_s and g_s can be defined analogously. It is obvious that for those i's satisfying

$$\frac{4(N+1)^2}{b^2} \sin^2 \frac{\pi}{2(N+1)} + \frac{4(M+1)^2}{a^2} \sin^2 \frac{i\pi}{2(M+1)} > k^2.$$

$A_y + \lambda_i I_N + D$ is symmetric negative definite. In all of our numerical tests, J_s is empty, i.e., it suffices to solve the system (3.8).

The algorithm is given below.

Algorithm I

(i) Generate the matrix G.
(ii) Calculate the LU decomposition to get U_i and E by using the forward Gaussian elimination with a row partial pivoting.
(iii) Calculate $\bar{f} = (S_M \otimes I)f$ and $S_M \hat{g}$.
(iv) Solve the system (3.8) for v_{N+1}.
(v) Solve the system (3.9) for the rest of the unknowns.

3.2. Implementation and preconditioning. It should be noted that the nonlocal integral operator is a symmetric Toeplitz-type operator. A suitable approximation to the nonlocal integral operator gives the symmetric Toeplitz matrix G and hence only M entries need be calculated. The nonlocal integral operator is hypersingular. Numerical calculation for such hypersingular integrals has been well studied; e.g., see [37]. Usually, the Hankel function can be evaluated in terms of its series representations or integral representations. One can use some high-order approximation to the Hankel function; hence the cost of Step (i) is $O(M^{1+\sigma})$, where $0 < \sigma < 1$. In Step (ii), one needs to calculate the LU-decomposition for $A_y + \lambda_i I_N + D$. By noting the tridiagonal structure of these matrices, only $5NM$ operations are needed if $f \neq 0$. Since S_M is the Fourier-sine transform, by using a standard FFT-sine code, the cost for calculating the product of the matrix S_M and a complex vector is $2MlogM$ (real operations). In Step (iv), one solves the system (3.8) for v_{N+1}. A direct method, such as a Gaussian elimination scheme, requires $M^3/3$ complex operations, which is not efficient. Since G is a complex Toeplitz matrix, the product of the coefficient matrix and a complex vector can be performed in terms of [illegible] [10], [24] and the cost for calculating the product is only $12MlogM$. If we use the BiCG

TABLE 1
The real operation counts of Algorithm I *for an* $M \times N$ *mesh (p is the number of iterations by BiCG).*

Step	Calculate v with $f \neq 0$	Calculate v_{N+1} with $f = 0$
(i)	$O(M^{1+\sigma})$	O(M)
(ii)	$5NM$	$3NM$
(iii)	$2MNlogM$	0
(iv)	$24pMlogM$	$24pMlogM$
(v)	$O(NMlogM)$	0
Total	$O(NMlogM) + 4pMlogM$	$O(NM) + 24pMlogM$

method or GMRES method for solving the linear systems, the cost of each iteration is $24MlogM$.

In most practical cases of electromagnetic scattering, particularly for radar systems, the fields are source free, i.e., $f(x, y) = 0$. Also, it often suffices to calculate the solution on the interface, i.e., v_{N+1}. In fact, many physical components of interest can be obtained by v_{N+1}. In that case, the solution in the whole computational domain may not be necessary. Hence, the computational procedure can be simplified significantly, and the first part of Steps (iii) and (v) are no longer needed.

The cost (real arithmetic operations) for each step is summarized in Table 1, where p is the number of iterations used for solving the system (3.8) and k is a real number. When $f \neq 0$, the cost of the algorithm is $O(NMlogM)$ if p is not large. More importantly, in the source free case, the cost decreases significantly to $O(M^2)$ for an $M \times M$ mesh if $p \leq M/logM$, which will be illustrated numerically in the next section.

Key to Algorithm I is the iterative solver for the interface system (3.8) with the coefficient matrix

$$\mathcal{A} = I - h_y S_M G S_M + E. \tag{3.11}$$

The efficiency of iterative algorithms for (3.8) depends upon many factors, such as the eigenvalue distribution, the condition numbers of the coefficient matrix, and the regularity of solution.

Consider a unit cavity ($a = b = 1$) and two different media, homogeneous medium $k = k_0$ and layered medium

$$k = \begin{cases} k_0 & -b/3 \leq y < 0, \\ 1.5k_0 & -2b/3 \leq y < -b/3, \\ 2k_0 & -b \leq y < -2b/3. \end{cases} \tag{3.12}$$

We present the eigenvalue distributions of the matrix $\mathcal{A}$ in Figure 2, with respect to some different wave numbers and numbers of mesh points. Observe from Figure 2 that there are some eigenvalues with negative real parts in all cases and the magnitude of the real parts becomes larger as the wave number increases, which may be responsible for the divergence of many classical iterative methods. As a comparison, note that the interface systems arising from Poisson-type equations in some simple domains are symmetric positive definite [8], [9], [11].

In order to solve such an indefinite system, we need an efficient preconditioner. Let $G = G^{re} + \mathrm{i}G^{im}$. Since G is a Toeplitz matrix, we denote by d_{im} the diagonal entries of G^{im}. Then we can rewrite the matrix $\mathcal{A}$ as

$$\mathcal{A} = (I - \mathrm{i}h_y d_{im} I + E) - h_y \left(S_M G S_M - \mathrm{i}d_{im} I\right).$$

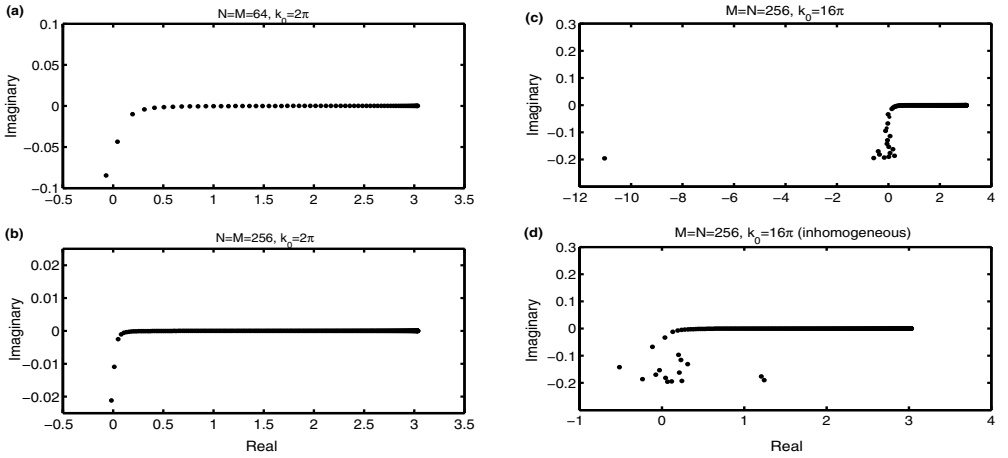

FIG. 2. *The eigenvalue distribution of* $\mathcal{A}$, (a)–(c) *for homogeneous media and* (d) *for the inhomogeneous medium in* (3.12).

TABLE 2
The extremal eigenvalues of the preconditioned matrix $P\mathcal{A}$.

k	N=M	$\min \lvert\lambda_i\rvert$	$\max \lvert\lambda_i\rvert$	$\max \lvert\lambda_i\rvert / \lvert\min \lambda_i\rvert$
$k = 2\pi$	64	1.505	3.718	2.470
	128	1.487	3.737	2.513
	256	1.478	3.745	2.534
	512	1.473	3.748	2.544
	1024	1.471	3.750	2.550
$k = 16\pi$	128	0.8449	7.658	9.064
	256	0.8751	1.453D1	1.661D1
	512	1.003	1.670D1	1.663D1
	1024	1.004	2.164D1	2.154D1
	2048	1.005	2.732D1	2.719D1
k given in (3.12) $k_0 = 16\pi$	128	0.9871	1.019D1	1.039D1
	256	1.011	4.811	4.758
	512	1.001	6.486	6.482
	1024	1.000	7.332	7.331
	2048	1.000	6.995	6.995

Let

$$P = (I - \mathrm{i}h_y d_{im} I + E)^{-1}$$

be a preconditioner. The interface system (3.8) becomes

$$P\mathcal{A}v_{N+1} = PS_M\hat{g}. \tag{3.13}$$

The extremal eigenvalues and the ratio of the maximal eigenvalue and the minimal eigenvalue of the preconditioned coefficient matrix $P\mathcal{A}$ are given in Table 2. The eigenvalues distributions are presented in Figure 3(a)–(c) for the homogeneous medium $k_0 = 2\pi$ with $N = M = 64$, 256, and 1024, in Figure 3(d) for the homogeneous medium $k = k_0 = 16\pi$, and in Figure 3(e)–(f) for the layered medium defined in (3.12) with $k_0 = 2\pi$ and $k_0 = 16\pi$, respectively.

Several observations are in order:

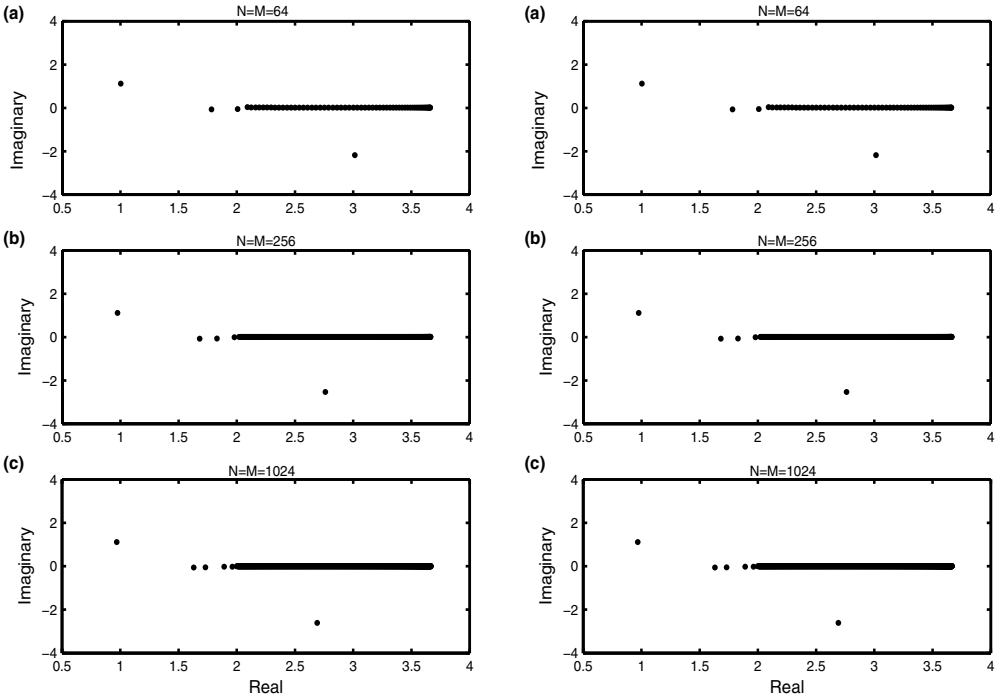

FIG. 3. *The eigenvalue distribution of preconditioned systems with* $\rho = 4.0$, (a)–(c) *homogeneous medium* $k_0 = 2\pi$ *and* (d)–(f) $N = M = 256$.

- In all cases, the real parts of eigenvalues are positive and larger than 0.854. Many iterative algorithms are convergent for such a linear system.
- For the small wave number $k_0 = 2\pi$, the ratio of the maximal eigenvalue and the minimal eigenvalue, which is equivalent to condition number, is almost bounded by a constant 2.55. The eigenvalues distributions are also independent of the number of mesh points. For large wave number $k_0 = 32\pi$, the ratio for the homogeneous medium increases approximately in the order of $M^{0.387}$ and the ratio for the inhomogeneous medium increases slightly as the number of mesh points increases. The minimal eigenvalues are approximately 1 for both homogeneous and inhomogeneous media.
- The ratio of the imaginary part and the real part of eigenvalues is also an important factor for most iterative algorithms. The eigenvalues with a large ratio are called ill-conditioning. For most eigenvalues shown in Table 2 and Figure 3, the imaginary part is smaller than the real part.
  In each case, all eigenvalues are located on a circle of radius about 1.2 to 13, depending on the wavenumber k. All these circles are in the right half-plane and the distance between each circle and the y-axis is larger than 0.85. Certain iterative algorithms are efficient for solving linear systems with this kind of coefficient matrices, such as Krylov subspace methods, and the convergent rate could be independent of the number of mesh points.

3.3. TE case. Rewrite (2.9) of TE case as

$$\begin{aligned} &\frac{\partial^2 u}{\partial x^2}+\frac{\partial^2 u}{\partial y^2}-\frac{k_y}{2k}\frac{\partial u}{\partial y}+k^2u=k^2f \qquad (x,y)\in\Omega,\\ &\frac{\partial u}{\partial n}=0 \qquad \text{on } \partial\Omega\backslash\Gamma,\\ &\frac{\partial u}{\partial n}=\tilde{I}(u)+g \qquad \text{on } \Gamma. \end{aligned} \tag{3.14}$$

Using the same approximation to the TE equation, we have the discrete system in matrix form

$$\left(A_x^N\otimes I_N+I_M\otimes(A_y^{ND}-D_kB_y^{ND})+I_M\otimes D\right)v+(I_M\otimes a_{N+1})\,v_{N+1}=f, \tag{3.15}$$

where D and a_{N+1} are defined as before, A_x^N denotes the finite difference discrete matrix corresponding to the second-order differential operator with Neumann boundary conditions, and A_y^{ND} and B_y^{ND} denote finite difference matrices corresponding to the second-order and the first-order differential operator with Neumann/Dirichlet boundary conditions, respectively. Thus

$$A_x^N=\frac{1}{h_x^2}\begin{pmatrix} -1 & 1 & & \\ 1 & -2 & 1 & \\ & \ddots & \ddots & \ddots \\ & & 1 & -1 \end{pmatrix} \qquad A_y^{ND}=\frac{1}{h_y^2}\begin{pmatrix} -1 & 1 & & \\ 1 & -2 & 1 & \\ & \ddots & \ddots & \ddots \\ & & 1 & -2 \end{pmatrix}$$

$$B_y^{ND}=\frac{1}{2h_y}\begin{pmatrix} -1 & 1 & & & \\ -1 & 0 & 1 & & \\ & \ddots & \ddots & \ddots & \\ & & -1 & 0 & 1 \\ & & & -1 & 1 \end{pmatrix}$$

and

$$D_k=\frac{1}{2}\begin{pmatrix} \varepsilon'(y_1)/\varepsilon(y_1) & & & \\ & \varepsilon'(y_2)/\varepsilon(y_2) & & \\ & & \ddots & \\ & & & \epsilon'(y_N)/\epsilon(y_N) \end{pmatrix}.$$

A fast algorithm for the TE case can be designed analogously by replacing A_x and A_y in Algorithm I with A_x^N and $A_y^{ND}-D_kB_y^{ND}$.

4. The existence and uniqueness of numerical solution. The existence and uniqueness of the scattering problem (2.1), (2.2) or the equivalent bounded domain problem in (2.8) were proved in [2] and [3]. Here we study the existence and uniqueness of the solution of the discrete system (3.2) with some simple discretization for the nonlocal boundary condition. Let $J_\nu(z)$ and $Y_\nu(z)$ be the Bessel functions. The Hankel function $H_1^1(z)$ is defined by

$$H_1^1(z)=J_1(z)+\mathrm{i}Y_1(z).$$

Since $Y_1(z)$ is hypersingular and $J_1(z)$ is continuous, the nonlocal boundary condition becomes

$$\frac{\partial u}{\partial n} = \frac{\mathrm{i}k_0}{2}\left(\int_0^a \frac{1}{|x-x'|}J_1(k_0|x-x'|)u(x',0)dx' + \mathrm{i}\int_0^a \frac{1}{|x-x'|}Y_1(k_0|x-x'|)u(x',0)dx'\right), \quad x \in (0,a).$$

Let $u(x,0) \approx \sum_{i=1}^{M} \phi_i(x)v_{i,N+1}$, where $\phi_i(x)$, $i = 1,2,\ldots,M$, denote the piecewise linear basis functions. Then the boundary discrete system can be written by

$$\frac{v_{l,N+1} - v_{l,N}}{h_y} = \sum_{l=1}^{M}(g_{lj}^{re} + \mathrm{i}g_{lj}^{im})v_{j,N+1} + g(x_l), \quad l = 1,2,\ldots,M,$$

where

$$g_{lj}^{im} = \frac{k_0}{2}\int_0^a \frac{1}{|x-x'|}J_1(k_0|x'-x_l|)\phi_j(x')dx'.$$

By the classical formulation

$$J_1(z) = \frac{z}{\pi}\int_{-1}^{1}(1-t^2)^{1/2}e^{\mathrm{i}zt}\,dt,$$

we have

$$g_{lj}^{im} = \frac{k_0^2}{2\pi}\int_{-1}^{1}(1-t^2)^{1/2}\left(\int_0^a \phi_j(x')e^{\mathrm{i}k_0|x'-x_l|t}\,dx'\right)dt. \tag{4.1}$$

The term g_{lj}^{re} can be calculated by some techniques in [29] since the Hadamard integral is involved.

THEOREM 4.1. [illegible] $g_{lj} = g_{lj}^{re} + \mathrm{i}g_{lj}^{im}$ [illegible] g_{lj}^{im} [illegible] (4.1) [illegible] k [illegible] (3.2) [illegible]. It suffices to prove that the system (3.2) has only the zero solution when $f = 0$ and $g = 0$. Let v^* denote the conjugate transpose of v. By (3.2)

$$v^*Av + v^*A_{12}v_{N+1} = 0,$$
$$v_{N+1}^*A_{21}v + v_{N+1}^*(I - h_y(G^{re} + \mathrm{i}G^{im}i))v_{N+1} = 0,$$

where $G = G^{re} + \mathrm{i}G^{im}$. Since $A_{21} = -h_y^2A_{12}^T$ and A is real and symmetric,

$$-h_y^2v^*Av + v_{N+1}^*(I - h_yG)v_{N+1} = 0,$$

which leads to

$$v_{N+1}^*G^{im}v_{N+1} = 0. \tag{4.2}$$

It is easy to see that

$$g_{lj}^{im} = \frac{k_0^2}{2\pi}\left[\int_0^1(1-t^2)^{1/2}\int_0^{x_l}\phi_j(x')e^{\mathrm{i}k_0(x'-x_l)t}\,dx'dt + \int_0^1(1-t^2)^{1/2}\int_{x_l}^a\phi_j(x')e^{-\mathrm{i}k_0(x'-x_l)t}\,dx'dt + \int_{-1}^0(1-t^2)^{1/2}\int_0^{x_l}\phi_j(x')e^{\mathrm{i}k_0(x'-x_l)t}\,dx'dt + \int_{-1}^0(1-t^2)^{1/2}\int_{x_l}^a\phi_j(x')e^{-\mathrm{i}k_0(x'-x_l)t}\,dx'dt\right].$$

Moreover, by using the change of variables in the last two integrals,

$$\begin{aligned} g_{lj}^{im} &= \frac{k_0^2}{2\pi}\left[\int_0^1 (1-t^2)^{1/2}\int_0^a \phi_j(x')e^{\mathrm{i}k_0(x'-x_l)t}\,dx'dt \right. \\ &\qquad \left. + \int_0^1 (1-t^2)^{1/2}\int_0^a \phi_j(x')e^{-\mathrm{i}k_0(x'-x_l)t}\,dx'dt\right] \\ &= \frac{k_0^2}{\pi}\int_0^1 (1-t^2)^{1/2}\int_0^a \phi_j(x')\cos(k_0(x'-x_l)t)\,dx'dt. \end{aligned}$$

A straightforward calculation gives

$$\int_0^a \phi_j(x')\cos(k_0(x'-x_l)t)\,dx' = \frac{2(1-\cos(k_0th_x))\cos((j-l)k_0th_x)}{t^2k_0^2h_x}.$$

Hence

$$g_{lj}^{im} = \frac{2}{\pi h_x}\int_0^1 \eta(t)\cos((j-l)k_0th_x)\,dt, \tag{4.3}$$

where $\eta(t) = (1-t^2)^{1/2}(1-\cos(k_0th_x))/t^2$. It follows that G^{im} is a symmetric Toeplitz matrix and furthermore

$$\begin{aligned} v_{N+1}^* G^{im} v_{N+1} &= \sum_{l=1}^M\sum_{j=1}^M g_{lj}^{im} v_{l,N+1}^* v_{j,N+1} \\ &= \frac{2}{\pi h_x}\sum_{l=1}^M\sum_{j=1}^M \int_0^1 \eta(t)\cos((j-l)k_0th_x)v_{l,N+1}^* v_{j,N+1}\,dt \\ &= \frac{1}{\pi h_x}\int_0^1 \eta(t)\sum_{l=1}^M\sum_{j=1}^M \left(e^{\mathrm{i}k_0(j-l)th_x} + e^{-\mathrm{i}k_0(j-l)th_x}\right) v_{l,N+1}^* v_{j,N+1}\,dt \\ &= \frac{1}{\pi h_x}\int_0^1 \eta(t)\left(\left|\sum_{j=1}^M e^{\mathrm{i}k_0jth_x}v_{j,N+1}\right|^2 + \left|\sum_{l=1}^M e^{-\mathrm{i}k_0lth_x}v_{l,N+1}\right|^2\right)dt. \end{aligned}$$

By (4.2), we have

$$\sum_{j=1}^M e^{\mathrm{i}k_0jth_x}v_{j,N+1} = 0\,, \quad \sum_{j=1}^M e^{-\mathrm{i}k_0jth_x}v_{j,N+1} = 0 \quad \text{for } 0<t<1 \tag{4.4}$$

which leads to $v_{j,N+1} = 0$, $j = 1, 2, \ldots, M$. From the second system in (3.2), $v_{j,N} = 0$ and we deduce further that $v_{ij} = 0$ from the first system in (3.2). The proof is complete. □

In practice, one may calculate g_{lj}^{im} numerically. A general quadrature form can be given by

$$g_{lj}^{im} \approx \frac{2}{\pi h_x}\sum_{m=1}^{M'} \omega_m\eta(t_m)\cos((j-l)k_0t_mh_x), \tag{4.5}$$

where w_m denotes the weight, and an alternative approximation is given by

$$g_{lj}^{im} \approx \frac{2}{\pi h_x}\int_0^1 \eta_h(t)\cos((j-l)k_0th_x)\,dt, \tag{4.6}$$

where $\eta_h(t)$ denotes a general approximation to $\eta(t)$ satisfying $\eta_h(t) > 0$ for $t \in (0, 1)$. The following corollary can be obtained immediately.

COROLLARY 4.2. $g_{lj} = g_{lj}^{re} + \mathrm{i} g_{lj}^{im}$ g_{lj}^{im} (4.5) $M' \geq M/2$ (4.6) k (3.2)

5. Numerical experiments. In this section, computational results are reported for two examples to test our algorithm. Our focus is on the efficiency of our algorithm to solve the discrete linear systems. Once again, error analysis of the discrete method and other high order methods remains open. Throughout, the computation is performed on a Blade 1000 Sun-workstation in double precision. The BiCG method given in [10] is applied to solve the system (3.13).

5.1. Consider a plane wave scattering from a rectangular groove with 1 meter wide and 0.25 meter deep at normal incidence ($a = 1.0$ and $b = 0.25$). Two different cases are considered: the groove filled with a homogeneous medium $k = k_0$ and the groove filled with some inhomogeneous medium defined in (3.12). The former has been a standard test problem [23], [41]. Numerical results are obtained by using our algorithm with 128 nodal points at each coordinate direction for the homogeneous case $k = k_0 = 2\pi$. The magnitude and phase of the field are given in Figure 4(a)–(b), compared with the experimental results in [11]. The physical parameter of interest is the RCS, which is defined by

$$\sigma = \frac{4}{k_0}|P(\phi)|^2,$$

where ϕ is the observation angle and P is the far-field coefficient given by

$$P(\phi) = \frac{k}{2}\sin\phi \int_\Gamma u e^{\mathrm{i}kx\cos\phi} dx.$$

The backscatter RCS(b), compared with experimental results in [23], is given in Figure 4(c).

Next, we consider problems with the high wave number $k_0 = 32\pi$ for both the homogeneous medium and the layered medium defined by (3.12). We present in Figure 4(d)–(f) the magnitudes of the fields on Γ, where $M = N = 1024$ and $\theta = 0$. Since no analytic solution is available, numerical solutions with $N = M = 2048$ are also calculated to confirm the convergence.

We use the BiCG method in Step (iv) to solve the linear system (3.13). As usual, the iteration stops with the absolute residual

$$e_R = \left(\frac{1}{M} \sum_{i=1}^{M} \left(\hat{g}_i - \sum_{j=1}^{M} a_{ij} v_{j,N+1}^p \right)^2 \right)^{1/2} \leq \delta,$$

where v^p is the numerical solution at the pth iteration and $P\mathcal{A} = (a_{ij})$. The CPU time for each step, the total CPU time, and the number of iterations in Step (iv) by the BiCG method are shown in Table 3 until $N = M = 4096$, where $\delta = h_x h_y/5$. The CPU time in Step (i) is proportional to M, the number of mesh points, since we have used an approximation independent of h_x, while the CPU time in Step (ii) is proportional to M^2.

Clearly, the number of iterations (p) in Step (iv) is almost independent of the number of mesh points and increases as the wavenumber k increases (approximately

with $p = 4 + k/(2\pi)$). The results are in good agreement with our analysis. We present the convergence hysteresis of the BiCG method in Figure 5, where the solid

line represents the residual defined above and the dashed line denotes the L_2 error

$$e_G = \left(\frac{1}{M} \sum_{i=1}^{M} (v^p_{i,N+1} - v^G_{i,N+1})^2 \right)^{1/2}.$$

Here $v^G_{i,N+1}$ is the solution obtained by the Gaussian elimination.

Our numerical experiments illustrate that the computational complexity for the solution v_{N+1} is $O(M^2)$ for an $M \times M$ mesh.

5.2. We consider an artificial example defined by (2.8) with a large cavity $a = b = 1$ to test the accuracy of approximation. The $f(x, y)$ and $g(x)$ are chosen such that the exact solution is

$$u(x, y) = e^{xy} \left(\sin \frac{k_0 x}{2} \right) \sin \left(\frac{k_0}{2} + \frac{\pi}{4} \right) y.$$

The error measures in the L_2 norm and the L_∞ norm in the domain Ω are defined by

$$e_2(\Omega) = \left(\tfrac{1}{(N+1)M} \textstyle\sum_{i,j=1}^{M,N+1} (u^h_{ij} - u(x_i, y_j))^2 \right)^{1/2},$$
$$e_M(\Omega) = \max_{i,j} |u^h_{ij} - u(x_i, y_j)|,$$

where u^h_{ij} denotes the numerical solution at the point (x_i, y_j). Since the solution at the top line of cavity (interface) is more important, we also define the following error

TABLE 4
Error results for Example 5.2.

measures on Γ,

$$e_2(\Gamma) = \left(\frac{1}{M}\sum_i^M (u^h_{i,N+1} - u(x_i,0))^2\right)^{1/2},$$
$$e_M(\Gamma) = \max_{i,j} |u^h_{i,N+1} - u(x_i,0)|.$$

We analyze the errors in Table 4 with different wave numbers and different numbers of mesh points. It is evident that for the small wave number $k = k_0 = 2\pi$, the error is always in the order of $O(h)$. Since we use a first-order scheme for $\frac{\partial u}{\partial n}$, this is in good agreement with theoretical analysis. For the large wave number $k = k_0 = 32\pi$, however, the order pattern of errors is not clear for small M, $M = 64, 128$. By increasing M, we can still see the first-order accuracy in the numerical results. However, the errors for problems with large wave numbers are much larger than those for small wave numbers. This confirms previous theoretical analysis and the claim that the best error estimate is achieved only when the condition "$k^2h = constant$" is satisfied. Nevertheless, since the computational complexity of our algorithm is $O(M^2)$ for an $M \times M$ mesh and the memory requirement is $O(M)$ for calculating the RCS, our algorithm can be applied to solve model problems with very large numbers of mesh points.

6. Concluding remarks. A new fast algorithm is presented for solving electromagnetic scattering from a rectangular open (layered) cavity. The algorithm is designed to use the FFT in the layered direction and Gaussian elimination along the inhomogeneous direction to solve the discrete linear systems.

Based on our numerical experiments, the proposed complex preconditioner is efficient. However, theoretical analysis remains open. The problem is challenging mainly due to the complicated transparent boundary condition and the indefinite Dirichlet Helmholtz operator.

Our algorithm has the advantages of being simple in structures and easy to implement, in addition to its capability of handling large cavities or high wave numbers. It is also flexible enough to be incorporated with many types of discretization of the underlying model PDEs. The fast algorithm provides an alternative to the current

efforts of designing sophisticated basis functions for solving Helmholtz equations with high wave numbers.

We point out two important future directions along the line of our present work. The first is to solve the scattering from three-dimensional large cavities. Our algorithm may be extended to provide a fast solver for layered three-dimensional cavities and a preconditioner for two-dimensional problems with more general medium distribution. The algorithm for solving the resulting discrete systems may be designed again by a combination of the FFT and a Gaussian elimination scheme. Another important project is to apply our fast algorithm to the optimal design problems. An example is to design the shape and composition of a layered cavity to minimize the RCS. Computationally, the design problem can be challenging because of the need of solving the scattering problem repeatedly. The fast algorithm presented here certainly would provide the essential tool for the design problems. In addition, it is possible to extend existing preconditioning techniques for Toeplitz systems; e.g., see [10] and [24], to the interface system (3.8).

Acknowledgments. The authors would like to thank Professors Su, Chaowei, and Wu Ji-ming for providing a BiCG code and a code for the discretization of the nonlocal boundary conditions. We also thank Professor Howard Elman and the referee for useful suggestions and for informing us of several related references.

OPTIMAL SUPERCONVERGENT ONE STEP NODAL CUBIC SPLINE COLLOCATION METHODS*

BERNARD BIALECKI†, GRAEME FAIRWEATHER†, AND ANDREAS KARAGEORGHIS‡

Abstract. We formulate new optimal (fourth) order one step nodal cubic spline collocation methods for the solution of various elliptic boundary value problems in the unit square. These methods are constructed so that the respective collocation equations can be solved using matrix decomposition algorithms (MDAs). MDAs are fast, direct methods which employ fast Fourier transforms and require $O(N^2 \log N)$ operations on an $N \times N$ uniform partition of the unit square. The results of numerical experiments exhibit expected global optimal orders of convergence as well as desired superconvergence phenomena.

1. Introduction.

Assume that $\Omega = (0,1) \times (0,1)$, $D_x^i = \partial^i/\partial x^i$, $D_y^j = \partial^j/\partial y^j$, and consider the boundary value problem (BVP) comprising the differential equation

$$D_x^2 u + a(y) D_y^2 u + b(y) D_y u + c(y) u = f(x,y), \quad (x,y) \in \Omega, \tag{1.1}$$

and one of the following boundary conditions:
Dirichlet:

$$u(0,y) = u(1,y) = 0, \ \ 0 \le y \le 1, \quad u(x,0) = u(x,1) = 0, \ \ 0 < x < 1; \tag{1.2}$$

Neumann:

$$\begin{cases} D_x u(0,y) = D_x u(1,y) = 0, & 0 \le y \le 1, \\ D_y u(x,0) = D_y u(x,1) = 0, & 0 < x < 1; \end{cases} \tag{1.3}$$

mixed:

$$u(0,y) = D_x u(1,y) = 0, \ \ 0 \le y \le 1, \quad u(x,0) = D_y u(x,1) = 0, \ \ 0 < x < 1; \tag{1.4}$$

periodic:

$$\begin{cases} D_x^i u(0,y) = D_x^i u(1,y), & 0 \le y \le 1, \ \ i = 0,1, \\ D_y^j u(x,0) = D_y^j u(x,1), & 0 < x < 1, \ \ j = 0,1. \end{cases} \tag{1.5}$$

Over the past several decades, numerous fast direct methods have been developed for the efficient solution of the linear algebraic systems arising when various numerical techniques are applied to BVPs of this type. Since (1.1) includes Poisson's equation in Cartesian, polar, and cylindrical coordinates, these methods are frequently

referred to as fast Poisson solvers. Such methods use matrix decomposition algorithms (MDAs) and often involve fast Fourier transforms (FFTs). In [4], an overview of MDAs for finite difference, finite element Galerkin, orthogonal spline collocation, and spectral methods applied to second order problems is presented. For recent work on fast direct methods, see [5] for references on orthogonal spline collocation methods, [11, 12] for quadratic spline collocation methods, [18, 20] for finite element Galerkin methods, [8, 24, 25, 26] for spectral methods, [15, 19, 21, 22] for finite differences, and [3, 9, 28] for Fourier-type methods, and references therein. In this paper, we develop new nodal cubic spline collocation methods for the solution of BVPs of the form (1.1) subject to each of the boundary conditions (1.2), (1.3), (1.4), and (1.5) in turn. These methods are constructed so that they have the desired convergence properties and their respective collocation equations can be solved using an MDA with FFTs.

In the basic nodal cubic spline collocation (NCSC) method, an approximate solution is sought in the space of bicubic splines and is determined by satisfying the differential equation and the boundary conditions at the partition nodes of $\overline{\Omega}$ and $\partial\Omega$, respectively. This method is well known to be suboptimal; in fact, it is no better than second order, whereas fourth order is expected since the approximate solution is piecewise bicubic. In [17], two optimal order NCSC methods, a two step method (TSM) and a one step method (OSM), were presented for the solution of the Dirichlet BVP. These methods are based on optimal NCSC methods for solving second-order two-point BVPs. The TSM is based on the method of Fyfe [14] in which the approximate solution is obtained using a deferred correction approach applied to the basic NCSC method. In the OSM, which is based on a method developed by Archer [1, 2], the approximation is determined by collocating the differential equation with a high order perturbation of the differential operator.

In [6], for the Helmholtz equation, MDAs with FFTs were formulated and implemented to solve the TSM collocation equations for each BVP, but, for the OSM, it was possible to formulate an MDA only for the Dirichlet BVP. In the numerical examples presented in [6], it is shown that, for smooth solutions u, the TSM exhibits superconvergence in the approximations to $D_x u$, $D_y u$ and $D_{xy} u$ ($D_{xy} = D_x D_y$). It is not surprising that the OSM is not superconvergent, as Archer [2] showed that the OSM for two-point BVPs lacks this property. For the Dirichlet BVP, the OSM is the more efficient method, requiring asymptotically one half of the cost of the TSM, but less accurate than the TSM with the same partition stepsize. It should be noted that, in [16], it is claimed that this method applied to the Neumann BVP is of optimal order, but no evidence, theoretical or numerical, is provided to support this claim. In fact, our numerical tests with this method for two-point BVPs with boundary conditions other than Dirichlet exhibit only third order accuracy from which one can only conclude that the optimality of the OSM for Neumann BVPs claimed in [16] is erroneous.

The purpose of this paper is to derive for each BVP an OSM with optimal global accuracy and the desired superconvergence properties and for which the collocation equations can be solved using an extension of the MDA with FFTs developed in [6]. The new OSMs differ from other OSMs in that they are constructed by perturbing judiciously both the differential operator and the right-hand side of the differential equation. It should be noted that, in previous discussions on OSMs, for example, in [16, 17], mixed and periodic boundary conditions were not considered.

An outline of this paper is as follows. In section 2, we introduce some notation and describe the MDA. Then, in section 3, we revisit the Archer and Daniel–Swartz

methods for solving two-point BVPs and derive new schemes which, when used in the discretization of two-dimensional problems, yield methods with the desired properties of optimal global accuracy and superconvergence, and are amenable to solution using MDAs with FFTs. Sections 4, 5, 6, and 7 are devoted to the Dirichlet, Neumann, mixed, and periodic BVPs, respectively. In section 8, numerical results are presented which demonstrate the expected orders of convergence. Concluding remarks are given in section 9. This work represents a significant extension of the work of [6, 16, 17].

2. Preliminaries. Let $\rho_x = \{x_i\}_{i=0}^{N+1}$ and $\rho_y = \{y_j\}_{j=0}^{N+1}$ be, respectively, uniform partitions of $[0,1]$ in the x- and y-directions such that $x_i = y_i = ih$, where the stepsize $h = 1/(N+1)$. The space of cubic splines

$$S_3 = \big\{v \in C^2[0,1] : v|_{I_i} \in \mathcal{P}_3, 1 \le i \le N+1\big\},$$

where $I_i = [x_{i-1}, x_i]$ and $\mathcal{P}_3$ is the set of polynomials of degree ≤ 3. To introduce basis functions for S_3, we extend the partition ρ_x using $x_i = ih$, $i = -3, -2, -1, N+2, N+3, N+4$. As a basis for S_3, we choose the functions $\{\mathcal{B}_m\}_{m=-1}^{N+2}$, where

$$\mathcal{B}_m(x) = \begin{cases} h^{-3} g_1(x - x_{m-2}), & x \in I_{m-1}, \\ g_2([x - x_{m-1}]/h), & x \in I_m, \\ g_2([x_{m+1} - x]/h), & x \in I_{m+1}, \\ h^{-3} g_1(x_{m+2} - x), & x \in I_{m+2}, \\ 0 & \text{otherwise}, \end{cases} \tag{2.1}$$

and

$$g_1(x) = x^3, \quad g_2(x) = 1 + 3x + 3x^2 - 3x^3.$$

These basis functions are such that, for $0 \le m \le N+1$,

$$\begin{cases} \mathcal{B}_{m-1}(x_m) = 1, & \mathcal{B}_m(x_m) = 4, & \mathcal{B}_{m+1}(x_m) = 1, \\ \mathcal{B}'_{m-1}(x_m) = -3/h, & \mathcal{B}'_m(x_m) = 0, & \mathcal{B}'_{m+1}(x_m) = 3/h, \\ \mathcal{B}''_{m-1}(x_m) = 6/h^2, & \mathcal{B}''_m(x_m) = -12/h^2, & \mathcal{B}''_{m+1}(x_m) = 6/h^2. \end{cases} \tag{2.2}$$

The space of bicubic splines is $S_3 \otimes S_3$, where, for two spaces V and W of functions on $[0,1]$, $V \otimes W$ denotes the space of functions on $\overline{\Omega}$ consisting of all finite linear combinations of products $v(x)w(y)$, where $v \in V$ and $w \in W$. In all our methods, the approximate solution lies in the subspace of $S_3 \otimes S_3$ comprising functions satisfying the boundary conditions under consideration. A basis for each subspace is obtained by modifying the functions $\{\mathcal{B}_m\}_{m=-1}^{N+2}$.

Each of the OSM methods for the solution of the BVPs of section 1 gives rise to a linear system of the form

$$\{A_1 \otimes B_2 + B_1 \otimes [D_a A_2 + D_b C + D_c B_2]\}\,\mathbf{u} = \mathbf{f}, \tag{2.3}$$

where the matrices A_1, B_1 are $M \times M$ with $M = N, N+1$, or $N+2$, the matrices A_2, C, and B_2 are $(N+2) \times (N+2)$, the symbol $\otimes$ denotes the matrix tensor product, and where, for a function g in $C[0,1]$,

$$D_g = \operatorname{diag}(g(y_0), \ldots, g(y_{N+1})).$$

If there exists a nonsingular matrix Z such that

$$Z^{-1}A_1Z = \Lambda_A, \quad Z^{-1}B_1Z = \Lambda_B, \tag{2.4}$$

where Λ_A and Λ_B are diagonal, then the system (2.3) is equivalent to

$$(Z^{-1}\otimes I)\{A_1\otimes B_2 + B_1\otimes[D_aA_2 + D_bC + D_cB_2]\}(Z\otimes I)(Z^{-1}\otimes I)\mathbf{u} = (Z^{-1}\otimes I)\mathbf{f},$$

which, on using (2.4), can be written as

$$\{\Lambda_A\otimes B_2 + \Lambda_B\otimes[D_aA_2 + D_bC + D_cB_2]\}\mathbf{v} = \mathbf{w}, \tag{2.5}$$

where

$$\mathbf{v} = (Z^{-1}\otimes I)\mathbf{u}, \quad \mathbf{w} = (Z^{-1}\otimes I)\mathbf{f}.$$

If $\Lambda_A = \mathrm{diag}(\lambda_i^A)_{i=1}^M$ and $\Lambda_B = \mathrm{diag}(\lambda_i^B)_{i=1}^M$, then (2.5) reduces to the collection of independent systems

$$\left\{\lambda_i^BD_aA_2 + \lambda_i^BD_bC + [\lambda_i^AI + \lambda_i^BD_c]B_2\right\}\mathbf{v}_i = \mathbf{w}_i, \quad 1\le i\le M, \tag{2.6}$$

where

$$\mathbf{v}_i = [v_{i,0}, v_{i,1}, \ldots, v_{i,N+1}]^T, \quad \mathbf{w}_i = [w_{i,0}, w_{i,1}, \ldots, w_{i,N+1}]^T.$$

We thus have the following MDA for solving (2.3):

Step 1. Compute $\mathbf{w} = (Z^{-1}\otimes I)\mathbf{f}$.
Step 2. Solve the M systems in (2.6).
Step 3. Compute $\mathbf{u} = (Z\otimes I)\mathbf{v}$.

As we shall see in the following, the elements of the matrix Z are sines or cosines, and Z^{-1} can be expressed in terms of Z or Z^T. As a consequence, in Steps 1 and 3, FFT routines can be employed to perform the matrix multiplications at a cost of $O(N^2\log N)$ operations. In Step 2, the linear systems are, or can be reduced to, pentadiagonal systems. Consequently, Step 2 requires $O(N^2)$ operations. Thus the total cost of the MDA is $O(N^2\log N)$ operations. As in [6], the key ingredient in this solution procedure is the determination of the matrices Λ_A, Λ_B, Z, and Z^{-1}.

Throughout the paper, we make use of the following. Let $\mathcal{I}$, $\mathcal{J}$, $\mathcal{M}$, and $\mathcal{N}$ be finite sets of increasing indices. Without loss of generality we assume

$$\mathcal{I} = \{1,\ldots,I'\}, \quad \mathcal{J} = \{1,\ldots,J'\}, \quad \mathcal{M} = \{1,\ldots,M'\}, \quad \mathcal{N} = \{1,\ldots,N'\}.$$

Then the matrix-vector form of

$$\phi_{i,j} = \sum_{m\in\mathcal{M}} c_{i,m}^{(1)} \sum_{n\in\mathcal{N}} c_{j,n}^{(2)}\psi_{m,n}, \quad i\in\mathcal{I}, \quad j\in\mathcal{J}, \tag{2.7}$$

is

$$\boldsymbol{\phi} = (C_1\otimes C_2)\boldsymbol{\psi}, \tag{2.8}$$

where

$$C_1 = (c_{i,m}^{(1)})_{i\in\mathcal{I},m\in\mathcal{M}}, \quad C_2 = (c_{j,n}^{(2)})_{j\in\mathcal{J},n\in\mathcal{N}},$$

and

$$\boldsymbol{\phi} = [\phi_{1,1},\ldots,\phi_{1,J'},\ldots,\phi_{I',1},\ldots,\phi_{I',J'}]^T,$$
$$\boldsymbol{\psi} = [\psi_{1,1},\ldots,\psi_{1,N'},\ldots,\psi_{M',1},\ldots,\psi_{M',N'}]^T.$$

3. Optimal superconvergent one step NCSC methods for two-point BVPs. In order to describe the new OSM approach for discretizing (1.1) in the x–direction with our choices of boundary conditions, we assume that κ is a constant and consider a two-point BVP comprising the differential equation

$$u'' + \kappa u = f(x), \quad x \in [0,1], \tag{3.1}$$

and either Dirichlet boundary conditions

$$u(0) = u(1) = 0, \tag{3.2}$$

or Neumann boundary conditions

$$u'(0) = u'(1) = 0, \tag{3.3}$$

or periodic boundary conditions

$$u(0) = u(1), \quad u'(0) = u'(1). \tag{3.4}$$

In Archer's method [1, 2] for (3.1) and (3.2), with

$$S^{\mathcal{D}} = \{v \in S_3 : v(0) = v(1) = 0\},$$

we seek $u_h \in S^{\mathcal{D}}$, such that

$$L_A u_h(x_i) = f(x_i), \quad 0 \le i \le N+1, \tag{3.5}$$

where

$$L_A v(x_i) = \begin{cases} v''(x_i) + \kappa v(x_i), & i = 0, N+1, \\ \dfrac{1}{12}[v''(x_{i-1}) + 10v''(x_i) + v''(x_{i+1})] + \kappa v(x_i), & 1 \le i \le N. \end{cases} \tag{3.6}$$

It is shown in [2] that, for $\kappa = 0$ and sufficiently smooth u,

$$\max_{0 \le x \le 1} |(u - u_h)^{(j)}(x)| = O(h^{4-j}), \quad j = 0, 1, 2, \tag{3.7}$$

and

$$\max_{0 \le i \le N+1} |(u - u_h)'(x_i)| = O(h^3). \tag{3.8}$$

Numerical experiments that we have conducted indicate that the exponent 3 in (3.8) is optimal.

For (3.1) and (3.3), in the context of the line cubic spline collocation method [16], one looks for $u_h \in S^{\mathcal{N}}$ satisfying (3.5). However, our numerical tests show that

$$\max_{0 \le i \le N+1} |(u - u_h)(x_i)| = O(h^3), \tag{3.9}$$

which indicates that the scheme of [16] is, at best, third (and not fourth) order accurate. In fact, our tests show that, for boundary conditions other than Dirichlet, the scheme (3.5) is only third order accurate.

In the new scheme for (3.1) and (3.2), which will be used for the discretization of (1.1) and (1.2) in the x-direction, we seek $u_h \in S^{\mathcal{D}}$ satisfying

$$L^{\mathcal{D}}_{MDA} u_h(x_i) = f^{\mathcal{D}}_h, \quad 0 \le i \le N+1, \tag{3.10}$$

where $L^{\mathcal{D}}_{MDA} = L_A$ of (3.6) and

$$f^{\mathcal{D}}_h(x_i) = \begin{cases} f(x_i) - \dfrac{h^2}{12}[f''(x_i) - \kappa f(x_i)], \ i = 0, N+1, \\ f(x_i), \ 1 \le i \le N. \end{cases}$$

In the new scheme for (3.1) and (3.3), which will be used for the discretization of (1.1) and (1.3) in the x-direction, with

$$S^{\mathcal{N}} = \{v \in S_3 : v'(0) = v'(1) = 0\},$$

we seek $u_h \in S^{\mathcal{N}}$, such that

$$L^{\mathcal{N}}_{MDA} u_h(x_i) = f^{\mathcal{N}}_h, \quad 0 \le i \le N+1, \tag{3.11}$$

where

$$L^{\mathcal{N}}_{MDA} u_h(x_i) = \begin{cases} \dfrac{1}{12}[10v''(x_i) + 2v''(x_{i+1})] + \kappa v(x_i), \ i = 0, \\ L_A v(x_i), \ 1 \le i \le N, \\ \dfrac{1}{12}[10v''(x_i) + 2v''(x_{i-1})] + \kappa v(x_i), \ i = N+1, \end{cases}$$

and

$$f^{\mathcal{N}}_h(x_i) = \begin{cases} f(x_i) + \dfrac{h}{6} f'(x_i), \ i = 0, \\ f(x_i), \ 1 \le i \le N, \\ f(x_i) - \dfrac{h}{6} f'(x_i), \ i = N+1. \end{cases}$$

The corresponding schemes for (3.1) with one of the conditions

$$u(0) = u'(1) = 0, \quad u'(0) = u(1) = 0,$$

are easily determined from (3.10) and (3.11).

In the new scheme for (3.1) and (3.4), which will be used for the discretization of (1.1) and (1.5) in the x-direction, with

$$S^{\mathcal{P}} = \{v \in S_3 : v(0) = v(1), v'(0) = v'(1)\},$$

we seek $u_h \in S^{\mathcal{P}}$ satisfying

$$L^{\mathcal{P}}_{MDA} u_h(x_i) = f^{\mathcal{P}}_h(x_i), \quad 0 \le i \le N+1, \tag{3.12}$$

where

$$L^{\mathcal{P}}_{MDA} u_h(x_i) = \begin{cases} \dfrac{1}{12}[10v''(x_i) + v''(x_{i+1}) + v''(x_N)] + \kappa v(x_i), \ i = 0, \\ L_A v(x_i), \ 1 \le i \le N-1, \\ \dfrac{1}{12}[v''(x_0) + v''(x_{i-1}) + 10v''(x_i)] + \kappa v(x_i), \ i = N, \\ \dfrac{1}{12}[v''(x_1) + v''(x_{i-1}) + 10v''(x_i)] + \kappa v(x_i), \ i = N+1, \end{cases}$$

$$f_h^{\mathcal{P}}(x_i) = \begin{cases} \frac{1}{12}[11f(x_0) + f(x_{N+1})] + \tilde{f} + 5\hat{f}, \ i = 0, \\ f(x_i), \ 1 \le i \le N-1, \\ f(x_N) + \frac{1}{12}[f(x_0) - f(x_{N+1})] + \hat{f}, \ i = N, \\ \frac{1}{12}[11f(x_{N+1}) + f(x_0)] + \tilde{f} - 5\hat{f}, \ i = N+1, \end{cases}$$

and

$$\tilde{f} = \frac{h}{12}[f'(x_0) - f'(x_{N+1})], \quad \hat{f} = \frac{h^2}{144}\{f''(x_{N+1}) - f''(x_0) - \kappa[f(x_{N+1}) - f(x_0)]\}.$$

Numerical experiments show that (3.7) holds for (3.10), (3.11), and (3.12), and that the approximation to the first derivative is superconvergent, that is,

$$\max_{0 \le i \le N+1} |(u - u_h)'(x_i)| = O(h^4). \tag{3.13}$$

To describe our schemes for the discretization in the y-direction, we consider a two-point BVP comprising the differential equation

$$a(y)u'' + b(y)u' + c(y)u = f(y), \quad y \in [0,1],$$

and one of the boundary conditions (3.2), (3.3), or (3.4). For any of the corresponding BVPs, in the method of Daniel and Swartz [13], one seeks $u_h \in S^{\mathcal{D}}$, $u_h \in S^{\mathcal{N}}$, or $u_h \in S^{\mathcal{P}}$, respectively, such that

$$L_{DS}u_h(y_j) = f(y_j), \quad 0 \le j \le N+1, \tag{3.14}$$

where

$$L_{DS}v(y_j) = \begin{cases} \frac{a(y_j)}{12}[14v''(y_j) - 5v''(y_{j+1}) + 4v''(y_{j+2}) - v''(y_{j+3})] \\ \qquad + b(y_j)u'(y_j) + c(y_j)u(y_j), \quad j = 0, \\ \frac{a(y_j)}{12}[v''(y_{j-1}) + 10v''(y_j) + v''(y_{j+1})] \\ \qquad + b(y_j)v'(y_j) + c(y_j)v(y_j), \quad 1 \le j \le N, \\ \frac{a(y_j)}{12}[14v''(y_j) - 5v''(y_{j-1}) + 4v''(y_{j-2}) - v(y_{j-3})] \\ \qquad + b(y_j)v'(y_j) + c(y_j)v(y_j), \quad j = N+1. \end{cases}$$

It is shown in [13] that (3.7) and (3.13) hold for the Dirichlet and Neumann schemes. In the new scheme of this paper, we seek $u_h \in S^{\mathcal{D}}$, $u_h \in S^{\mathcal{N}}$, or $u_h \in S^{\mathcal{P}}$, respectively, such that

$$L_{BFK}u_h(y_j) = f(y_j), \quad 0 \le j \le N+1, \tag{3.15}$$

where

$$L_{BFK}v(y_j) = \begin{cases} \frac{a(y_j)}{12}[13v''(y_j) - 2v''(y_{j+1}) + v''(y_{j+2})] \\ \qquad + b(y_j)v'(y_j) + c(y_j)v(y_j), \quad j = 0, \\ L_{DS}v(y_j), \quad 1 \le j \le N, \\ \frac{a(x_i)}{12}[13v''(y_j) - 2v''(y_{j-1}) + v(y_{j-2})] \\ \qquad + b(y_j)v'(y_j) + c(y_j)v(y_j), \quad j = N+1. \end{cases}$$

Numerical tests show that (3.7) and (3.13) hold for the new Dirichlet, Neumann, and periodic schemes.

We note that, using the comparison function w defined by (2.3) and (2.4) of [13], the endpoint collocation equations ($i = 0, N+1$) in Archer's scheme (3.5) have a local error which is second order, whereas in the Daniel–Swartz scheme (3.14), the local endpoint error is fourth order. In our new scheme (3.10), the right-hand side is perturbed so that the endpoint equations are fourth order accurate. In schemes (3.11) and (3.12), the left-hand side is perturbed so that (2.4) holds, and the right-hand side is perturbed so that the endpoint equations are third order accurate. Instead of using (3.14) involving a four point stencil, in (3.15) for $j = 0, N+1$, we use a three point stencil which guarantees third order accuracy of the endpoint equations. This is sufficient to yield the expected global accuracy of the scheme as well as its superconvergence.

4. The Dirichlet BVP. In this section, we consider the Dirichlet BVP comprising (1.1) and (1.2). In the OSM, we seek $u_h^{\mathcal{D}} \in S^{\mathcal{D}} \otimes S^{\mathcal{D}}$ such that

$$D_x^2 D_y^2 u_h^{\mathcal{D}}(x_i, y_j) = D_y^2 f(x_i, y_j), \quad i, j = 0, N+1, \tag{4.1}$$

$$\begin{aligned} D_x^2 u_h^{\mathcal{D}}(x_i, y_j) - \frac{h^2}{12}[1 + a(y_j)] D_x^2 D_y^2 u_h^{\mathcal{D}}(x_i, y_j) \\ = f_h(x_i, y_j),\ i = 0, N+1,\ 1 \le j \le N, \end{aligned} \tag{4.2}$$

$$(L_x + L_y) u_h^{\mathcal{D}}(x_i, y_j) = f(x_i, y_j), \quad 1 \le i \le N, \quad 0 \le j \le N+1, \tag{4.3}$$

where, for $0 \le j \le N+1$,

$$L_x v(x_i, y_j) = \frac{1}{12}\left[D_x^2 v(x_{i-1}, y_j) + 10 D_x^2 v(x_i, y_j) + D_x^2 v(x_{i+1}, y_j)\right],\ 1 \le i \le N,$$

for $1 \le i \le N$,

$$L_y v(x_i, y_j) = \begin{cases} \dfrac{a(y_j)}{12}\left[13 D_y^2 v(x_i, y_j) - 2 D_y^2 v(x_i, y_{j+1}) + D_y^2 v(x_i, y_{j+2})\right] \\ \qquad + b(y_j) D_y v(x_i, y_j) + c(y_j) v(x_i, y_j),\ j = 0, \\ \dfrac{a(y_j)}{12}\left[D_y^2 v(x_i, y_{j-1}) + 10 D_y^2 v(x_i, y_j) + D_y^2 v(x_i, y_{j+1})\right] \\ \qquad + b(y_j) D_y v(x_i, y_j) + c(y_j) v(x_i, y_j),\ 1 \le j \le N, \\ \dfrac{a(y_j)}{12}\left[D_y^2 v(x_i, y_{j-2}) - 2 D_y^2 v(x_i, y_{j-1}) + 13 D_y^2 v(x_i, y_j)\right] \\ \qquad + b(y_j) D_y v(x_i, y_j) + c(y_j) v(x_i, y_j),\ j = N+1, \end{cases} \tag{4.4}$$

and, for $i = 0, N+1$, $1 \le j \le N$,

$$f_h(x_i, y_j) = f(x_i, y_j) - \frac{h^2}{12}\left[\Delta f(x_i, y_j) - b(y_j) D_y f(x_i, y_j) - c(y_j) f(x_i, y_j)\right].$$

As a basis for $S^{\mathcal{D}}$, we choose the cubic splines $\{B_m^{\mathcal{D}}\}_{m=0}^{N+1}$ defined in terms of the splines (2.1) by

$$\begin{cases} \mathcal{B}_0^{\mathcal{D}} = \mathcal{B}_0 - 4\mathcal{B}_{-1}, \quad \mathcal{B}_1^{\mathcal{D}} = \mathcal{B}_1 - \mathcal{B}_{-1}, \\ \mathcal{B}_m^{\mathcal{D}} = \mathcal{B}_m, \quad 2 \le m \le N-1, \\ \mathcal{B}_N^{\mathcal{D}} = \mathcal{B}_N - \mathcal{B}_{N+2}, \quad \mathcal{B}_{N+1}^{\mathcal{D}} = \mathcal{B}_{N+1} - 4\mathcal{B}_{N+2}. \end{cases} \tag{4.5}$$

It follows from (4.5) and (2.2) that, for $i = 0, N+1$,

$$[\mathcal{B}_m^{\mathcal{D}}]''(x_i) = \begin{cases} -36h^{-2}, & m = i, \\ 0, & m \neq i, \end{cases} \qquad 0 \le m \le N+1. \tag{4.6}$$

Substituting

$$u_h^{\mathcal{D}}(x,y) = \sum_{m=0}^{N+1}\sum_{n=0}^{N+1} u_{m,n}\mathcal{B}_m^{\mathcal{D}}(x)\mathcal{B}_n^{\mathcal{D}}(y) \tag{4.7}$$

into (4.1) and using (4.6), we obtain

$$u_{i,j} = \frac{h^4}{1296} D_y^2 f(x_i, y_j), \quad i,j = 0, N+1.$$

Substituting (4.7) into (4.2) and using (4.6), we have

$$\sum_{n=1}^{N} u_{i,n}\left\{\frac{h^2}{12}[1+a(y_j)][\mathcal{B}_n^{\mathcal{D}}]''(y_j) - \mathcal{B}_n^{\mathcal{D}}(y_j)\right\} = \frac{h^2}{36} f_h(x_i, y_j)$$

$$- \sum_{n=0,N+1} u_{i,n}\left\{\frac{h^2}{12}[1+a(y_j)][\mathcal{B}_n^{\mathcal{D}}]''(y_j) - \mathcal{B}_n^{\mathcal{D}}(y_j)\right\}, \quad i = 0, N+1, \quad 1 \le j \le N.$$

These equations yield a linear system for $\{u_{i,n}\}_{n=1}^N$, $i = 0, N+1$, with the matrix

$$\frac{h^2}{12} D_{1+a} A - B_1, \tag{4.8}$$

where

$$A = [a_{j,n}]_{j,n=1}^N, \quad a_{j,n} = [\mathcal{B}_n^{\mathcal{D}}]''(y_j), \quad B_1 = [b_{j,n}^{(1)}]_{j,n=1}^N, \quad b_{j,n}^{(1)} = \mathcal{B}_n^{\mathcal{D}}(y_j). \tag{4.9}$$

Using (4.5) and (2.2), we have

$$A = 6h^{-2}T, \quad B_1 = T + 6I, \tag{4.10}$$

where the $N \times N$ matrix T is given by

$$T = \begin{bmatrix} -2 & 1 & & & \\ 1 & -2 & 1 & & \\ & \ddots & \ddots & \ddots & \\ & & 1 & -2 & 1 \\ & & & 1 & -2 \end{bmatrix}.$$

Therefore, (4.8) and (4.10) yield the tridiagonal matrix $\frac{1}{2} D_{a-1} T - 6I$.

Substituting (4.7) into (4.3) and using (2.7)–(2.8), we obtain (2.3), where

$$\mathbf{u} = [u_{1,0}, \ldots, u_{1,N+1}, \ldots, u_{N,0}, \ldots, u_{N,N+1}]^T, \tag{4.11}$$

$$\mathbf{f} = [f_{1,0}, \ldots, f_{1,N+1}, \ldots, f_{N,0}, \ldots, f_{N,N+1}]^T, \tag{4.12}$$

$$f_{i,j} = f(x_i, y_j) - \sum_{m=0,N+1} \sum_{n=0}^{N+1} u_{m,n} \left[L_x \mathcal{B}_m^{\mathcal{D}}(x_i) \mathcal{B}_n^{\mathcal{D}}(y_j) + \mathcal{B}_m^{\mathcal{D}}(x_i) L_y \mathcal{B}_n^{\mathcal{D}}(y_j) \right],$$

$$A_1 = [a_{i,m}^{(1)}]_{i,m=1}^{N}, \quad A_2 = [a_{j,n}^{(2)}]_{j,n=0}^{N+1}, \tag{4.13}$$

$$a_{i,m}^{(1)} = \frac{1}{12} \left\{ [\mathcal{B}_m^{\mathcal{D}}]''(x_{i-1}) + 10[\mathcal{B}_m^{\mathcal{D}}]''(x_i) + [\mathcal{B}_m^{\mathcal{D}}]''(x_{i+1}) \right\}, \tag{4.14}$$

$$a_{j,n}^{(2)} = \frac{1}{12} \begin{cases} 13 \left[\mathcal{B}_n^{\mathcal{D}}\right]''(y_j) - 2 \left[\mathcal{B}_n^{\mathcal{D}}\right]''(y_{j+1}) + \left[\mathcal{B}_n^{\mathcal{D}}\right]''(y_{j+2}), & j = 0, \\ \left[\mathcal{B}_n^{\mathcal{D}}\right]''(y_{j-1}) + 10 \left[\mathcal{B}_n^{\mathcal{D}}\right]''(y_j) + \left[\mathcal{B}_n^{\mathcal{D}}\right]''(y_{j+1}), & 1 \le j \le N, \\ \left[\mathcal{B}_n^{\mathcal{D}}\right]''(y_{j-2}) - 2 \left[\mathcal{B}_n^{\mathcal{D}}\right]''(y_{j-1}) + 13 \left[\mathcal{B}_n^{\mathcal{D}}\right]''(y_j), & j = N+1, \end{cases} \tag{4.15}$$

B_1 is defined in (4.9) and (4.10),

$$B_2 = [b_{j,n}^{(2)}]_{j,n=0}^{N+1}, \quad b_{j,n}^{(2)} = \mathcal{B}_n^{\mathcal{D}}(y_j), \quad C = [c_{j,n}]_{j,n=0}^{N+1}, \quad c_{j,n} = [\mathcal{B}_n^{\mathcal{D}}]'(y_j). \tag{4.16}$$

It follows from (4.13)–(4.16), (4.10), (4.5), and (2.2) that

$$A_1 = \frac{1}{12} \begin{bmatrix} 1 & 10 & 1 & & & & \\ & 1 & 10 & 1 & & & \\ & & \ddots & \ddots & \ddots & & \\ & & & & 1 & 10 & 1 & \\ & & & & & 1 & 10 & 1 \end{bmatrix} \begin{bmatrix} \mathbf{0}^T \\ A \\ \mathbf{0}^T \end{bmatrix} = \frac{1}{2h^2}(T + 12I)T,$$

$$A_2 = \frac{1}{2h^2} \begin{bmatrix} -80 & 5 & -4 & 1 & & & & \\ 4 & -19 & 8 & 1 & & & & \\ 1 & 8 & -18 & 8 & 1 & & & \\ & \ddots & \ddots & \ddots & \ddots & \ddots & & \\ & & & 1 & 8 & -18 & 8 & 1 \\ & & & & 1 & 8 & -19 & 4 \\ & & & & 1 & -4 & 5 & -80 \end{bmatrix},$$

$$B_2 = \begin{bmatrix} 0 & \mathbf{0}^T & 0 \\ \mathbf{e}_1 & B_1 & \mathbf{e}_N \\ 0 & \mathbf{0}^T & 0 \end{bmatrix}, \quad \mathbf{e}_1 = [1, 0, \ldots, 0]^T, \quad \mathbf{e}_N = [0, \ldots, 0, 1]^T,$$

$$C = \frac{1}{h} \begin{bmatrix} 12 & 6 & & & \\ -3 & 0 & 3 & & \\ & \ddots & \ddots & \ddots & \\ & & -3 & 0 & 3 \\ & & & -6 & 12 \end{bmatrix}.$$

If we introduce $\Lambda = \operatorname{diag}(\lambda_i)_{i=1}^{N}$ and $Z = [z_{i,j}]_{i,j=1}^{N}$, where

$$\lambda_i = -4 \sin^2 \frac{i\pi}{2(N+1)}, \quad z_{i,j} = \left(\frac{2}{N+1} \right)^{1/2} \sin \frac{ij\pi}{N+1},$$

then (cf. section 4.5.3 in [29]) $Z^{-1}TZ = \Lambda$ and $Z^{-1} = Z$. Thus the system (2.3) can be solved using the MDA of section 2 with $\Lambda_A = (1/2)h^{-2}(\Lambda+12I)\Lambda$ and $\Lambda_B = \Lambda+6I$. The FFT routines SINTI and SINT from FFTPACK [27] are used in Step 1 and SINT in Step 3.

5. The Neumann BVP. We consider the Neumann BVP comprising (1.1) and (1.3). In the OSM, we seek $u_h^{\mathcal{N}} \in S^{\mathcal{N}} \otimes S^{\mathcal{N}}$ such that

$$(L_x + L_y)u_h^{\mathcal{N}}(x_i, y_j) = f_h(x_i, y_j), \quad 0 \le i, j \le N+1, \tag{5.1}$$

where, for $0 \le j \le N+1$,

$$L_x v(x_i, y_j) = \frac{1}{12}\begin{cases} 10D_x^2 v(x_i, y_j) + 2D_x^2 v(_{i+1}, y_j), \ i = 0, \\ D_x^2 v(x_{i-1}, y_j) + 10D_x^2 v(x_i, y_j) + D_x^2 v(x_{i+1}, y_j), \ 1 \le i \le N, \\ 2D_x^2 v(x_{i-1}, y_j) + 10D_x^2 v(x_i, y_j), \ i = N+1, \end{cases}$$

for $0 \le i \le N+1$, $L_y v(x_i, y_j)$ is defined by (4.4), and, for $0 \le j \le N+1$,

$$f_h(x_i, y_j) = \begin{cases} f(x_i, y_j) + \dfrac{h}{6} D_x f(x_i, y_j), & i = 0, \\ f(x_i, y_j), & 1 \le i \le N, \\ f(x_i, y_j) - \dfrac{h}{6} D_x f(x_i, y_j), & i = N+1. \end{cases}$$

As a basis for $S^{\mathcal{N}}$, we choose the cubic splines $\{B_m^{\mathcal{N}}\}_{m=0}^{N+1}$ defined in terms of the splines (2.1) by

$$\begin{cases} \mathcal{B}_0^{\mathcal{N}} = \mathcal{B}_0, \quad \mathcal{B}_1^{\mathcal{N}} = \mathcal{B}_1 + \mathcal{B}_{-1}, \\ \mathcal{B}_m^{\mathcal{N}} = \mathcal{B}_m, \quad 2 \le m \le N-1, \\ \mathcal{B}_N^{\mathcal{N}} = \mathcal{B}_N + \mathcal{B}_{N+2}, \quad \mathcal{B}_{N+1}^{\mathcal{N}} = \mathcal{B}_{N+1}. \end{cases} \tag{5.2}$$

Substituting

$$u_h^{\mathcal{N}}(x, y) = \sum_{m=0}^{N+1}\sum_{n=0}^{N+1} u_{m,n}\mathcal{B}_m^{\mathcal{N}}(x)\mathcal{B}_n^{\mathcal{N}}(y) \tag{5.3}$$

into (5.1) and using (2.7)–(2.8), we obtain (2.3), where

$$\mathbf{u} = [u_{0,0}, \ldots, u_{0,N+1}, \ldots, u_{N+1,0}, \ldots, u_{N+1,N+1}]^T,$$
$$\mathbf{f} = [f_{0,0}, \ldots, f_{0,N+1}, \ldots, f_{N+1,0}, \ldots, f_{N+1,N+1}]^T, \quad f_{i,j} = f_h(x_i, y_j),$$

$$A_1 = [a_{i,m}^{(1)}]_{i,m=0}^{N+1}, \quad A_2 = [a_{j,n}^{(2)}]_{j,n=0}^{N+1}, \tag{5.4}$$

$$a_{i,m}^{(1)} = \frac{1}{12}\begin{cases} 10\left[\mathcal{B}_m^{\mathcal{N}}\right]''(x_i) + 2\left[\mathcal{B}_m^{\mathcal{N}}\right]''(x_{i+1}), \ i = 0, \\ \left[\mathcal{B}_m^{\mathcal{N}}\right]''(x_{i-1}) + 10\left[\mathcal{B}_m^{\mathcal{N}}\right]''(x_i) + \left[\mathcal{B}_m^{\mathcal{N}}\right]''(x_{i+1}), \ 1 \le i \le N, \\ 2\left[\mathcal{B}_m^{\mathcal{N}}\right]''(x_{i-1}) + 10\left[\mathcal{B}_m^{\mathcal{N}}\right]''(x_i), \ i = N+1, \end{cases} \tag{5.5}$$

$$a^{(2)}_{j,n} = \frac{1}{12}\begin{cases} 13\left[\mathcal{B}^{\mathcal{N}}_n\right]''(y_j) - 2\left[\mathcal{B}^{\mathcal{N}}_n\right]''(y_{j+1}) + \left[\mathcal{B}^{\mathcal{N}}_n\right]''(y_{j+2}), & j = 0, \\ \left[\mathcal{B}^{\mathcal{N}}_n\right]''(y_{j-1}) + 10\left[\mathcal{B}^{\mathcal{N}}_n\right]''(y_j) + \left[\mathcal{B}^{\mathcal{N}}_n\right]''(y_{j+1}), & 1 \le j \le N, \\ \left[\mathcal{B}^{\mathcal{N}}_n\right]''(y_{j-2}) - 2\left[\mathcal{B}^{\mathcal{N}}_n\right]''(y_{j-1}) + 13\left[\mathcal{B}^{\mathcal{N}}_n\right]''(y_j), & j = N+1, \end{cases} \tag{5.6}$$

$$B_1 = B_2 = [b_{j,n}]_{j,n=0}^{N+1}, \quad b_{j,n} = \mathcal{B}^{\mathcal{N}}_n(y_j), \quad C = [c_{j,n}]_{j,n=0}^{N+1}, \quad c_{j,n} = [\mathcal{B}^{\mathcal{N}}_n]'(y_j). \tag{5.7}$$

Let $A = [a_{i,m}]_{i,m=0}^{N+1}$, where $a_{i,m} = [\mathcal{B}^{\mathcal{N}}_m]''(x_i)$. Then using (5.2) and (2.2), we have

$$A = 6h^{-2}T, \tag{5.8}$$

where the $(N+2)\times(N+2)$ matrix T is given by

$$T = \begin{bmatrix} -2 & 2 & & & & \\ 1 & -2 & 1 & & & \\ & \ddots & \ddots & \ddots & & \\ & & 1 & -2 & 1 & \\ & & & 2 & -2 & \end{bmatrix}.$$

It follows from (5.4)–(5.8), (5.2), and (2.2) that

$$A_1 = \frac{1}{12}(T + 12I)A = \frac{1}{2h^2}(T + 12I)T,$$

$$A_2 = \frac{1}{2h^2}\begin{bmatrix} -28 & 31 & -4 & 1 & & & \\ 8 & -17 & 8 & 1 & & & \\ 1 & 8 & -18 & 8 & 1 & & \\ & \ddots & \ddots & \ddots & \ddots & \ddots & \\ & & 1 & 8 & -18 & 8 & 1 \\ & & & 1 & 8 & -17 & 8 \\ & & & 1 & -4 & 31 & -28 \end{bmatrix},$$

$$B_1 = B_2 = T + 6I, \quad C = \frac{1}{h}\begin{bmatrix} 0 & 0 & & & \\ -3 & 0 & 3 & & \\ & \ddots & \ddots & \ddots & \\ & & -3 & 0 & 3 \\ & & & 0 & 0 \end{bmatrix}.$$

If we introduce $\Lambda = \operatorname{diag}(\lambda_i)_{i=1}^{N+2}$ and $Z = [z_{i,j}]_{i,j=1}^{N+2}$, where

$$\lambda_i = -4\sin^2\frac{(i-1)\pi}{2(N+1)}, \quad z_{i,j} = \left(\frac{2}{N+1}\right)^{1/2}\cos\frac{(i-1)(j-1)\pi}{N+1},$$

then (cf. section 4.5.5 in [29]) $Z^{-1}TZ = \Lambda$ and $Z^{-1} = DZD$, where the matrix $D = \operatorname{diag}(1/2, 1, \ldots, 1, 1/2)$. The system (2.3) can be solved using the MDA of section 2 with $\Lambda_A = (1/2)h^{-2}(\Lambda + 12I)\Lambda$ and $\Lambda_B = \Lambda + 6I$; the FFT routines COSTI and COST from FFTPACK [27] are used in Step 1 and COST in Step 3.

6. The mixed BVP. We consider the mixed BVP comprising (1.1) and (1.4). In this case, we introduce

$$S^{\mathcal{M}} = \{v \in S_3 : v(0) = v'(1) = 0\}.$$

In the OSM, we seek $u_h \in S^{\mathcal{M}} \otimes S^{\mathcal{M}}$ such that

$$D_x^2 D_y^2 u_h^{\mathcal{M}}(x_0, y_0) = D_y^2 f(x_0, y_0), \tag{6.1}$$

$$D_x^2 u_h^{\mathcal{M}}(x_0, y_j) - \frac{h^2}{12}[1 + a(y_j)] D_x^2 D_y^2 u_h^{\mathcal{M}}(x_0, y_j) = f_h(x_0, y_j),\ 1 \le j \le N+1, \tag{6.2}$$

$$(L_x + L_y) u_h^{\mathcal{M}}(x_i, y_j) = f_h(x_i, y_j),\ 1 \le i \le N+1,\ 0 \le j \le N+1, \tag{6.3}$$

where, for $0 \le j \le N+1$,

$$L_x v(x_i, y_j) = \frac{1}{12} \begin{cases} D_x^2 v(x_{i-1}, y_j) + 10 D_x^2 v(x_i, y_j) + D_x^2 v(x_{i+1}, y_j),\ 1 \le i \le N, \\ 2 D_x^2 v(x_{i-1}, y_j) + 10 D_x^2 v(x_i, y_j),\ i = N+1, \end{cases}$$

for $1 \le i \le N+1$, $L_y v(x_i, y_j)$ is defined by (4.4), and, for $0 \le j \le N+1$,

$$f_h(x_i, y_j) = \begin{cases} \left[\Delta f(x_i, y_j) - b(y_j) D_y f(x_i, y_j) - c(y_j) f(x_i, y_j)\right], i = 0, \\ f(x_i, y_j), \quad 1 \le i \le N, \\ f(x_i, y_j) - \dfrac{h}{6} D_x f(x_i, y_j), \quad i = N+1. \end{cases}$$

As a basis for $S^{\mathcal{M}}$, we choose the cubic splines $\{B_m^{\mathcal{M}}\}_{m=0}^{N+1}$ defined in terms of the splines (2.1) by

$$\begin{cases} \mathcal{B}_0^{\mathcal{M}} = \mathcal{B}_0 - 4\mathcal{B}_{-1}, \quad \mathcal{B}_1^{\mathcal{M}} = \mathcal{B}_1 - \mathcal{B}_{-1}, \\ \mathcal{B}_m^{\mathcal{M}} = \mathcal{B}_m, \quad 2 \le m \le N-1, \\ \mathcal{B}_N^{\mathcal{M}} = \mathcal{B}_N + \mathcal{B}_{N+2}, \quad \mathcal{B}_{N+1}^{\mathcal{M}} = \mathcal{B}_{N+1}. \end{cases} \tag{6.4}$$

It follows from (6.4) and (2.2) that

$$[\mathcal{B}_m^{\mathcal{M}}]''(x_0) = \begin{cases} -36h^{-2}, & m = 0, \\ 0, & 1 \le m \le N+1. \end{cases} \tag{6.5}$$

Substituting

$$u_h^{\mathcal{M}}(x, y) = \sum_{m=0}^{N+1} \sum_{n=0}^{N+1} u_{m,n} \mathcal{B}_m^{\mathcal{M}}(x) \mathcal{B}_n^{\mathcal{M}}(y) \tag{6.6}$$

into (6.1) and using (6.5), we obtain

$$u_{0,0} = \frac{h^4}{1296} D_y^2 f(x_0, y_0).$$

Substituting (6.6) into (6.2) and using (6.5), we have

$$\sum_{n=1}^{N+1} u_{0,n} \left\{ \frac{h^2}{12}[1 + a(y_j)][\mathcal{B}_n^{\mathcal{M}}]''(y_j) - \mathcal{B}_n^{\mathcal{M}}(y_j) \right\} = \frac{h^2}{36} f_h(x_0, y_j)$$
$$- u_{i,0} \left\{ \frac{h^2}{12}[1 + a(y_j)][\mathcal{B}_0^{\mathcal{M}}]''(y_j) - \mathcal{B}_0^{\mathcal{M}}(y_j) \right\}, \quad 1 \le j \le N+1.$$

These equations yield a linear system for $\{u_{0,n}\}_{n=1}^{N+1}$ with coefficient matrix

$$\frac{h^2}{12}D_{1+a}A - B_1, \tag{6.7}$$

where

$$A = [a_{j,n}]_{j,n=1}^{N+1}, \quad a_{j,n} = [\mathcal{B}_n^{\mathcal{M}}]''(y_j), \quad B_1 = [b_{j,n}^{(1)}]_{j,n=1}^{N+1}, \quad b_{j,n}^{(1)} = \mathcal{B}_n^{\mathcal{M}}(y_j). \tag{6.8}$$

Using (6.4) and (2.2), we have

$$A = 6h^{-2}T, \quad B_1 = T + 6I, \tag{6.9}$$

where the $(N+1)\times(N+1)$ matrix T is given by

$$T = \begin{bmatrix} -2 & 1 & & & \\ 1 & -2 & 1 & & \\ & \ddots & \ddots & \ddots & \\ & & 1 & -2 & 1 \\ & & & 2 & -2 \end{bmatrix}.$$

Therefore, (6.7) and (6.9) yield the tridiagonal matrix $\frac{1}{2}D_{a-1}T - 6I$.

Substituting (6.6) into (6.3) and using (2.7)–(2.8), we obtain (2.3), where

$$\mathbf{u} = [u_{1,0}, \ldots, u_{1,N+1}, \ldots, u_{N+1,0}, \ldots, u_{N+1,N+1}]^T,$$

$$\mathbf{f} = [f_{1,0}, \ldots, f_{1,N+1}, \ldots, f_{N+1,0}, \ldots, f_{N+1,N+1}]^T,$$

$$f_{i,j} = f_h(x_i, y_j) - \sum_{n=0}^{N+1} u_{0,n}\left[L_x\mathcal{B}_0^{\mathcal{M}}(x_i)\mathcal{B}_n^{\mathcal{M}}(y_j) + \mathcal{B}_0^{\mathcal{M}}(x_i)L_y\mathcal{B}_n^{\mathcal{M}}(y_j)\right],$$

$$A_1 = [a_{i,m}^{(1)}]_{i,m=1}^{N+1}, \quad A_2 = [a_{j,n}^{(2)}]_{j,n=0}^{N+1}, \tag{6.10}$$

$$a_{i,m}^{(1)} = \frac{1}{12}\begin{cases} \left[\mathcal{B}_m^{\mathcal{M}}\right]''(x_{i-1}) + 10\left[\mathcal{B}_m^{\mathcal{M}}\right]''(x_i) + \left[\mathcal{B}_m^{\mathcal{M}}\right]''(x_{i+1}), & 1 \le i \le N, \\ 2\left[\mathcal{B}_m^{\mathcal{M}}\right]''(x_{i-1}) + 10\left[\mathcal{B}_m^{\mathcal{M}}\right]''(x_i), & i = N+1, \end{cases} \tag{6.11}$$

$$a_{j,n}^{(2)} = \frac{1}{12}\begin{cases} 13\left[\mathcal{B}_n^{\mathcal{M}}\right]''(y_j) - 2\left[\mathcal{B}_n^{\mathcal{M}}\right]''(y_{j+1}) + \left[\mathcal{B}_n^{\mathcal{M}}\right]''(y_{j+2}), & j = 0, \\ \left[\mathcal{B}_n^{\mathcal{M}}\right]''(y_{j-1}) + 10\left[\mathcal{B}_n^{\mathcal{M}}\right]''(y_j) + \left[\mathcal{B}_n^{\mathcal{M}}\right]''(y_{j+1}), & 1 \le j \le N, \\ \left[\mathcal{B}_n^{\mathcal{M}}\right]''(y_{j-2}) - 2\left[\mathcal{B}_n^{\mathcal{M}}\right]''(y_{j-1}) + 13\left[\mathcal{B}_n^{\mathcal{M}}\right]''(y_j), & j = N+1, \end{cases} \tag{6.12}$$

B_1 is defined in (6.8) and (6.9),

$$B_2 = [b_{j,n}^{(2)}]_{j,n=0}^{N+1}, \quad b_{j,n}^{(2)} = \mathcal{B}_n^{\mathcal{M}}(y_j), \quad C = [c_{j,n}]_{j,n=0}^{N+1}, \quad c_{j,n} = [\mathcal{B}_n^{\mathcal{M}}]'(y_j). \tag{6.13}$$

It follows from (6.9)–(6.13), (6.4), and (2.2) that

$$A_1 = \frac{1}{12}\begin{bmatrix} 1 & 10 & 1 & & & \\ & 1 & 10 & 1 & & \\ & & \ddots & \ddots & \ddots & \\ & & & 1 & 10 & 1 \\ & & & & 2 & 10 \end{bmatrix}\begin{bmatrix} \mathbf{0}^T \\ A \end{bmatrix} = \frac{1}{2h^2}(T + 12I)T,$$

$$A_2 = \frac{1}{2h^2}\begin{bmatrix} -80 & 5 & -4 & 1 & & & & \\ 4 & -19 & 8 & 1 & & & & \\ 1 & 8 & -18 & 8 & 1 & & & \\ & \ddots & \ddots & \ddots & \ddots & \ddots & & \\ & & & 1 & 8 & -18 & 8 & 1 \\ & & & & 1 & 8 & -17 & 8 \\ & & & & 1 & -4 & 31 & -28 \end{bmatrix},$$

$$B_2 = \begin{bmatrix} 0 & \mathbf{0}^T \\ \mathbf{e}_1 & B_1 \end{bmatrix}, \quad \mathbf{e}_1 = [1, 0, \ldots, 0]^T, \quad C = \frac{1}{h}\begin{bmatrix} 12 & 6 & & & \\ -3 & 0 & 3 & & \\ & \ddots & \ddots & \ddots & \\ & & -3 & 0 & 3 \\ & & & 0 & 0 \end{bmatrix}.$$

If we introduce $\Lambda = \operatorname{diag}(\lambda_i)_{i=1}^{N+1}$ and $Z = [z_{i,j}]_{i,j=1}^{N+1}$, where

$$\lambda_i = -4\sin^2\frac{(2i-1)\pi}{4(N+1)}, \quad z_{i,j} = \left(\frac{2}{N+1}\right)^{1/2}\sin\frac{i(2j-1)\pi}{2(N+1)},$$

then (cf. section 4.5.4 and (4.4.4) and (4.4.24) in [29]) $Z^{-1}TZ = \Lambda$ and $Z^{-1} = Z^T\operatorname{diag}(1, \ldots, 1, 1/2)$. The system (2.3) can be solved using the MDA of section 2 with $\Lambda_A = 6h^{-2}\Lambda$ $\Lambda_A = (1/2)h^{-2}(\Lambda + 12I)\Lambda$ and $\Lambda_B = \Lambda + 6I$. The FFT routines SINQI and SINQF are used in Step 1, and the FFT routine SINQB is used in Step 3, all from FFTPACK [27].

7. The periodic BVP. We consider the periodic BVP comprising (1.1) and (1.5). In the OSM, we seek $u_h^{\mathcal{P}} \in S^{\mathcal{P}} \otimes S^{\mathcal{P}}$ such that

$$(L_x + L_y)u_h^{\mathcal{P}}(x_i, y_j) = f_h(x_i, y_j), \qquad \begin{matrix} 0 \le i \le N, & 0 \le j \le N+1, \\ i = N+1, & 0 \le j \le N, \end{matrix} \tag{7.1}$$

and such that

$$\begin{aligned} &D_x^2 D_y^2 u_h^{\mathcal{P}}(x_0, y_{N+1}) - D_x^2 D_y^2 u_h^{\mathcal{P}}(x_{N+1}, y_{N+1}) \\ &\quad = D_y^2 f(x_0, y_{N+1}) - D_y^2 f(x_{N+1}, y_{N+1}), \end{aligned} \tag{7.2}$$

where, for $0 \le j \le N+1$,

$$L_x v(x_i, y_j) = \frac{1}{12}\begin{cases} 10D_x^2 v(x_i, y_j) + D_x^2 v(x_{i+1}, y_j) + D_x^2 v(x_N, y_j), & i = 0, \\ D_x^2 v(x_{i-1}, y_j) + 10D_x^2 v(x_i, y_j) + D_x^2 v(x_{i+1}, y_j), & 1 \le i \le N-1, \\ D_x^2 v(x_0, y_j) + D_x^2 v(x_{i-1}, y_j) + 10D_x^2 v(x_i, y_j), & i = N, \\ D_x^2 v(x_1, y_j) + D_x^2 v(x_{i-1}, y_j) + 10D_x^2 v(x_i, y_j), & i = N+1, \end{cases}$$

and for $0 \le i \le N+1$, $L_y v(x_i, y_j)$ is defined by (4.4). For $0 \le j \le N+1$,

$$f_h(x_i, y_j) = \begin{cases} \dfrac{1}{12}[11f(x_0, y_j) + f(x_{N+1}, y_j)] + \tilde{f}_j + 5\hat{f}_j, & i = 0, \\ f(x_i, y_j), & 1 \le i \le N-1, \\ f(x_N, y_j) + \dfrac{1}{12}[f(x_0, y_j) - f(x_{N+1}, y_j)] + \hat{f}_j, & i = N, \\ \dfrac{1}{12}[11f(x_{N+1}, y_j) + f(x_0, y_j)] + \tilde{f}_j - 5\hat{f}_j, & i = N+1, \end{cases}$$

where

$$\tilde{f}_j = \frac{h}{12}\left[D_x f(x_0, y_j) - D_x f(x_{N+1}, y_j)\right],$$

$$\hat{f}_j = \frac{h^2}{144}\{D_x^2 f(x_{N+1}, y_j) - D_x^2 f(x_0, y_j) + a(y_j)[D_y^2 f(x_0, y_j) - D_y^2 f(x_{N+1}, y_j)]$$
$$+ b(y_j)[D_y f(x_0, y_j) - D_y f(x_{N+1}, y_j)] + c(y_j)[f(x_0, y_j) - f(x_{N+1}, y_j)]\}.$$

As a basis for $S^{\mathcal{P}}$, we choose the cubic splines $\{B_m^{\mathcal{P}}\}_{m=0}^{N+1}$ defined in terms of the splines (2.1) by

$$\begin{cases} \mathcal{B}_0^{\mathcal{P}} = \mathcal{B}_0 + \mathcal{B}_{N+1}, \quad \mathcal{B}_1^{\mathcal{P}} = \mathcal{B}_1 + \mathcal{B}_{N+2}, \\ \mathcal{B}_m^{\mathcal{P}} = \mathcal{B}_m, \quad 2 \le m \le N-1, \\ \mathcal{B}_N^{\mathcal{P}} = \mathcal{B}_N + \mathcal{B}_{-1}, \quad \mathcal{B}_{N+1}^{\mathcal{P}} = 4(\mathcal{B}_{N+2} - \mathcal{B}_{-1}) - \mathcal{B}_{N+1} + \mathcal{B}_0. \end{cases} \tag{7.3}$$

It follows from (7.3) and (2.2) that

$$\begin{cases} [\mathcal{B}_m^{\mathcal{P}}]''(x_0) = [\mathcal{B}_m^{\mathcal{P}}]''(x_{N+1}), \quad 0 \le m \le N, \\ [\mathcal{B}_{N+1}^{\mathcal{P}}]''(x_0) = -[\mathcal{B}_{N+1}^{\mathcal{P}}]''(x_{N+1}) = -36h^{-2}. \end{cases} \tag{7.4}$$

For $0 \le j \le N$, subtracting (7.1) with $i = N+1$ from (7.1) with $i = 0$, using $u_h^{\mathcal{P}}(x_0, y) = u_h^{\mathcal{P}}(x_{N+1}, y)$, $0 \le y \le 1$, substituting

$$u_h^{\mathcal{P}}(x, y) = \sum_{m=0}^{N+1}\sum_{n=0}^{N+1} u_{m,n}\mathcal{B}_m^{\mathcal{P}}(x)\mathcal{B}_n^{\mathcal{P}}(y), \tag{7.5}$$

and using (7.4), we obtain

$$\sum_{n=0}^{N+1} u_{N+1,n}\mathcal{B}_n^{\mathcal{P}}(y_j) = -\frac{h^2}{60}\left[f_h(x_0, y_j) - f_h(x_{N+1}, y_j)\right], \quad 0 \le j \le N. \tag{7.6}$$

In a similar way, (7.2) gives

$$\sum_{n=0}^{N+1} u_{N+1,n}[\mathcal{B}_n^{\mathcal{P}}]''(y_{N+1}) = -\frac{h^2}{72}\left[D_y^2 f(x_0, y_{N+1}) - D_y^2 f(x_{N+1}, y_{N+1})\right]. \tag{7.7}$$

Equations (7.6) and (7.7) yield a linear system for $\{u_{N+1,n}\}_{n=0}^{N+1}$ with the coefficient matrix

$$B = [b_{j,n}]_{j,n=0}^{N+1}, \quad b_{j,n} = \begin{cases} \mathcal{B}_n^{\mathcal{P}}(y_j), & 0 \le j \le N, \\ \left[\mathcal{B}_n^{\mathcal{P}}\right]''(y_j), & j = N+1. \end{cases}$$

It follows from (7.4), (7.3), and (2.2) that

$$B = \begin{bmatrix} B_1 & \mathbf{a} \\ \mathbf{b}^T & 36h^{-2} \end{bmatrix}, \quad \mathbf{a} = [0, 1, 0, \ldots, 0, -1]^T, \quad \mathbf{b} = 6h^{-2}[-2, 1, 0, \ldots, 0, 1]^T,$$

and

$$B_1 = [b_{j,n}^{(1)}]_{j,n=0}^{N}, \quad b_{j,n}^{(1)} = \mathcal{B}_n^{\mathcal{P}}(y_j). \tag{7.8}$$

Using (7.3) and (2.2), we have

$$B_1 = T + 6I, \tag{7.9}$$

where the $(N+1)\times(N+1)$ matrix T is given by

$$T = \begin{bmatrix} -2 & 1 & & & 1 \\ 1 & -2 & 1 & & \\ & \ddots & \ddots & \ddots & \\ & & 1 & -2 & 1 \\ 1 & & & 1 & -2 \end{bmatrix}.$$

A system with coefficient matrix B can be easily solved using a Schur complement approach.

Substituting (7.5) into (7.1) with $0 \le i \le N$, $0 \le j \le N+1$, and using (2.7)–(2.8), we obtain (2.3) with

$$\mathbf{u} = [u_{0,0}, \dots, u_{0,N+1}, \dots, u_{N,0}, \dots, u_{N,N+1}]^T, \tag{7.10}$$

$$\mathbf{f} = [f_{0,0}, \dots, f_{0,N+1}, \dots, f_{N,0}, \dots, f_{N,N+1}]^T, \tag{7.11}$$

$$f_{i,j} = f_h(x_i, y_j) - \sum_{n=0}^{N+1} u_{N+1,n} \left[L_x \mathcal{B}_{N+1}^{\mathcal{P}}(x_i) \mathcal{B}_n^{\mathcal{P}}(y_j) + \mathcal{B}_{N+1}^{\mathcal{P}}(x_i) L_y \mathcal{B}_n^{\mathcal{P}}(y_j) \right],$$

$$A_1 = [a_{i,m}^{(1)}]_{i,m=0}^{N}, \quad A_2 = [a_{j,n}^{(2)}]_{j,n=0}^{N+1}, \tag{7.12}$$

$$a_{i,m}^{(1)} = \frac{1}{12} \begin{cases} 10 \left[\mathcal{B}_m^{\mathcal{P}}\right]''(x_i) + \left[\mathcal{B}_m^{\mathcal{P}}\right]''(x_{i+1}) + \left[\mathcal{B}_m^{\mathcal{P}}\right]''(x_N), & i = 0, \\ \left[\mathcal{B}_m^{\mathcal{P}}\right]''(x_{i-1}) + 10 \left[\mathcal{B}_m^{\mathcal{P}}\right]''(x_i) + \left[\mathcal{B}_m^{\mathcal{P}}\right]''(x_{i+1}), & 1 \le i \le N-1, \\ \left[\mathcal{B}_m^{\mathcal{P}}\right]''(x_0) + \left[\mathcal{B}_m^{\mathcal{P}}\right]''(x_{i-1}) + 10 \left[\mathcal{B}_m^{\mathcal{P}}\right]''(x_i), & i = N, \end{cases} \tag{7.13}$$

$$a_{j,n}^{(2)} = \frac{1}{12} \begin{cases} 13 \left[\mathcal{B}_n^{\mathcal{P}}\right]''(y_j) - 2 \left[\mathcal{B}_n^{\mathcal{P}}\right]''(y_{j+1}) + \left[\mathcal{B}_n^{\mathcal{P}}\right]''(y_{j+2}), & j = 0, \\ \left[\mathcal{B}_n^{\mathcal{P}}\right]''(y_{j-1}) + 10 \left[\mathcal{B}_n^{\mathcal{P}}\right]''(y_j) + \left[\mathcal{B}_n^{\mathcal{P}}\right]''(y_{j+1}), & 1 \le j \le N, \\ \left[\mathcal{B}_n^{\mathcal{P}}\right]''(y_{j-2}) - 2 \left[\mathcal{B}_n^{\mathcal{P}}\right]''(y_{j-1}) + 13 \left[\mathcal{B}_n^{\mathcal{P}}\right]''(y_j), & j = N+1, \end{cases} \tag{7.14}$$

B_1 is defined in (7.8) and (7.9),

$$B_2 = [b_{j,n}^{(2)}]_{j,n=0}^{N+1}, \quad b_{j,n}^{(2)} = \mathcal{B}_n^{\mathcal{P}}(y_j), \quad C = [c_{j,n}]_{j,n=0}^{N+1}, \quad c_{j,n} = [\mathcal{B}_n^{\mathcal{P}}]'(y_j). \tag{7.15}$$

Let $A = [a_{i,m}]_{i,m=0}^{N}$, where $a_{i,m} = [\mathcal{B}_m^{\mathcal{P}}]''(x_i)$. Then using (7.3) and (2.2), we have

$$A = 6h^{-2}T. \tag{7.16}$$

It follows from (7.12)–(7.16), (7.3), and (2.2) that

$$A_1 = \frac{1}{12}(T + 12I)A = \frac{1}{2h^2}(T + 12I)T,$$

$$A_2 = \frac{1}{2h^2}\begin{bmatrix} -28 & 18 & -4 & 1 & & & & 13 & -80 \\ 8 & -18 & 8 & 1 & & & & 1 & 4 \\ 1 & 8 & -18 & 8 & 1 & & & & 1 \\ & 1 & 8 & -18 & 8 & 1 & & & \\ & & \ddots & \ddots & \ddots & \ddots & \ddots & & \\ & & & 1 & 8 & -18 & 8 & 1 & \\ 1 & & & & 1 & 8 & -18 & 8 & -1 \\ 8 & 1 & & & & 1 & 8 & -18 & -4 \\ -28 & 13 & & & & 1 & -4 & 18 & 80 \end{bmatrix},$$

$$B_2 = \begin{bmatrix} B_1 & \mathbf{c} \\ \mathbf{d}^T & 0 \end{bmatrix}, \quad \mathbf{c} = [0, 1, 0, \ldots, 0, -1]^T, \quad \mathbf{d} = [4, 1, 0, \ldots, 0, 1]^T,$$

$$C = \frac{1}{h}\begin{bmatrix} 0 & 3 & & -3 & 12 \\ -3 & 0 & 3 & & -3 \\ & \ddots & \ddots & \ddots & \\ 3 & & -3 & 0 & -3 \\ 0 & 3 & & -3 & 12 \end{bmatrix}.$$

If we introduce

$$\Lambda = \operatorname{diag}(\lambda_i)_{i=1}^{N+1}, \quad \lambda_i = -4\sin^2\frac{(i-1)\pi}{N+1},$$

and $Z = \left(\frac{2}{N+1}\right)^{1/2}[z_{i,j}]_{i,j=1}^{N+1}$, where, for $1 \le i \le N+1$, and N even,

$$z_{i,1} = \frac{1}{\sqrt{2}}, \quad z_{i,j+1} = \cos\frac{2(i-1)j\pi}{N+1}, \quad z_{i,N+2-j} = \sin\frac{2(i-1)j\pi}{N+1}, \quad 1 \le j \le \frac{N}{2},$$

and, for N odd,

$$z_{i,1} = \frac{1}{\sqrt{2}}, \quad z_{i,(N+3)/2} = \frac{1}{\sqrt{2}}(-1)^{i-1},$$

$$z_{i,j+1} = \cos\frac{2(i-1)j\pi}{N+1}, \quad z_{i,N+2-j} = \sin\frac{2(i-1)j\pi}{N+1}, \quad 1 \le j \le \frac{N-1}{2},$$

then (cf. section 1.5.4 in [23] and section 4.5.6 in [29]) $Z^{-1}TZ = \Lambda$ and $Z^{-1} = Z^T$. The system (2.3) can be solved using the MDA of section 2 with $\Lambda_A = (1/2)h^{-2}(\Lambda + 12I)\Lambda$ and $\Lambda_B = \Lambda + 6I$. The FFTPACK [27] routines RFFTI and RFFTF are used in Step 1, and RFFTB in Step 3.

8. Numerical experiments. Numerical results are presented in Tables 8.1–8.4 for the new OSM approach applied to the equation

$$D_x^2 u + \cos(y) D_y^2 u - \sin(y) D_y u + e^y u = f(x, y),$$

with exact solution

$$u(x, y) = e^{xy}(x^2 - x)(y^2 - y)$$

for the Dirichlet BVP,

$$u(x,y) = e^{xy}(x^2 - x)^2(y^2 - y)^2$$

for Neumann and mixed BVPs, and

$$u(x,y) = u = [e^{2x} + (1 - e^2)x^2][e^{2y} + (1 - e^2)y^2]$$

for the periodic BVP. In each table, for several values of N, six quantities are given for the errors in u, D_xu, D_yu, D_x^2u, D_y^2u, and $D_{xy}u$:

- $E_n(N)$—the maximum absolute error at the nodes of the partition $\rho_x \times \rho_y$.
- $R_n(N)$—the experimental rate of convergence of the nodal error computed from

$$R_n(N) = \frac{\log(E_n(N/2)/E_n(N))}{\log((N+1)/((N/2)+1))}. \tag{8.1}$$

- $E_g(N)$—the maximum absolute error computed on a 1000×1000 grid taken as an approximation to the L^∞ norm of the error.
- $R_g(N)$—the experimental rate of convergence of the global error computed as in (8.1) with E_g replacing E_n.

The numerical results were obtained in double precision on an IBM RISC F80-7025 (450 MHz).

The global errors in the approximations to u, D_xu, D_yu, D_x^2u, and D_y^2u behave as expected. In each problem, the global error in the approximation to $D_{xy}u$ is third order, as in the bicubic spline interpolant (see Theorem 4 in [10]). Moreover, the nodal errors in D_xu, D_yu, and $D_{xy}u$ exhibit superconvergent rates of convergence of order 4 as in the TSM of [6]. The proof of superconvergence results for the new OSM for the solution of one- and two-dimensional problems remains an open problem.

In Table 8.5, we give the CPU times for the new OSM for solving the Dirichlet problem, for the values of N for which FFTs are most efficient. The times obtained

TABLE 8.3

are comparable to the corresponding times reported in [6]. The results for the new OSM for the other BVPs are similar.

The results of extensive numerical experiments are given in [7], where it is shown that the results obtained using the new OSM are of comparable accuracy to those obtained using the TSM. However, the new method is asymptotically twice as fast as the TSM.

9. Concluding remarks. New one step nodal bicubic spline collocation methods for approximating certain separable equations on the unit square subject to various boundary conditions are derived. These methods involve not only a high-order perturbation of the differential operator at the interior collocation points but also perturbations of the differential operator and the right-hand side at the boundary collocation points. This ensures that the totality of collocation equations is amenable to solution by MDAs with FFTs. Numerical experimentation demonstrates optimal order accuracy of the new methods. Moreover, the numerical results exhibit global

third order accuracy of the approximations to $D_{xy}u$ and superconvergence at the nodes of the approximations to D_xu, D_yu, and $D_{xy}u$. A rigorous convergence analysis of the methods has yet to be derived. Future work includes the extension of the new one step nodal bicubic spline collocation approach to inhomogeneous boundary conditions, biharmonic problems, and problems in three dimensions. In the latter, the correct specification of the corner collocation equations and the construction of the collocation equations in the periodic case will require careful consideration.

ON THE NONNORMALITY OF SUBITERATION FOR A FLUID-STRUCTURE-INTERACTION PROBLEM*

E. H. VAN BRUMMELEN† AND R. DE BORST†

Abstract. Subiteration forms the basic iterative method for solving the aggregated equations in fluid-structure-interaction problems, in which the fluid and structure equations are solved alternatingly subject to complementary partitions of the interface conditions. In the present work we establish for a prototypical model problem that the subiteration method can be characterized by recursion of a nonnormal operator. This implies that the method typically converges nonmonotonously. Despite formal stability, divergence can occur before asymptotic convergence sets in. It is shown that the transient divergence can amplify the initial error by many orders of magnitude, thus inducing a severe degradation in the robustness and efficiency of the subiteration method. Auxiliary results concern the dependence of the stability and convergence of the subiteration method on the physical parameters in the problem and on the computational time step.

Key words. fluid-structure interaction, subiteration, nonnormality, monolithic methods, convergence and stability

DOI. 10.1137/S1064827503431430

1. Introduction.

Numerical solution methods for fluid-structure interaction are of great importance in a multitude of physical and engineering disciplines, e.g., aerospace engineering [7, 8], offshore engineering [4], biomechanics [2, 13], and civil engineering [24]. Such solution methods are confronted with two fundamental problems. First, the disparity of the initial-boundary-value problems pertaining to the fluid and the structure generally yields severely ill-conditioned systems of equations. Second, the free-boundary character of the interface between the fluid and the structure yields an interdependence between the fluid and structure solutions and their domains of definition, and the computational expenses incurred by implicit treatment of this interdependence are prohibitive in actual applications. Furthermore, several practical impediments emanate from the inherent interconnection between the fluid and structure, such as the loss of software modularity; see [9].

The customary approach to sidestep the aforementioned problems is through , . , , , , . The fluid and structure equations are then solved alternately, subject to complementary partitions of the interface conditions. This iterative procedure is commonly referred to as subiteration, successive approximation, Picard iteration, or block Gauss–Seidel iteration. The conventional implementation of this method imposes the dynamic interface conditions (tractions) on the structure, and the kinematic interface conditions (displacements) on the fluid; see, e.g., [1, 4, 16, 17]. The principal advantage of partitioned solution methods is the affected separation of the fluid-structure-interaction problem into two common subproblems, viz., the independent solution of the initial-boundary-value problems corresponding to the fluid and the structure on prescribed computational domains, and the separate displacement of the sections of the boundaries of the computational domains associated with the interface. The

†Delft University of Technology, Faculty of Aerospace Engineering, P.O. Box 5058, 2600 GB Delft, The Netherlands (E.H.vanBrummelen@lr.tudelft.nl, R.deBorst@lr.tudelft.nl).

essential disadvantage of partitioned solution methods pertains to their convergence behavior. Regularly, prohibitory small time steps are required to maintain stability, or convergence is excessively slow.

In the present work we investigate the properties of subiteration for a prototypical fluid-structure-interaction problem. An important new result is that the subiteration method can be characterized by recursion of a nonnormal operator. This implies that the appropriate norm of the operator and its spectral radius are disparate, which reflects in profoundly different transient and asymptotic convergence behavior. In particular, despite formal stability of the operator recursion, convergence can be nonmonotonous and transient divergence can precede the asymptotic convergence. This transient divergence can in fact amplify the initial error by many orders of magnitude, thus inducing a severe degradation in the robustness and efficiency of the method. Such transient behavior of one-parameter functions of nonnormal operators has recently also attracted much attention in the analysis of the convergence of numerical methods (see [12] for an overview), and in the field of hydrodynamic stability in [23, 26], where it has been propounded as a fundamental principle in the transition to turbulence.

The analysis in this paper moreover provides useful information on several other relevant properties of the subiteration method, e.g., the dependence of its stability and convergence on physical parameters and on the computational time step.

The contents of this paper are organized as follows: Section 2 states the piston problem. Section 3 describes the subiteration method for fluid-structure-interaction problems. Section 4 derives the characteristic operator associated with the subiteration method on the basis of a linear model problem. Section 5 establishes the nonnormality of the characteristic operator in the absence of reflections and investigates the properties of the operator by approximation on polynomials. Section 6 is concerned with the properties of the general characteristic operator. Finally, section 7 contains concluding remarks.

2. Problem statement. In this paper we restrict ourselves to the analysis of a prototypical fluid-structure model problem, viz., the piston problem. This one-dimensional problem possesses the prominent features of fluid-structure-interaction problems. Below, we present a concise specification of the problem. For further details, see, e.g., [5, 19].

2.1. Piston problem. The piston system comprises the Euler equations of gas dynamics in connection with a simple harmonic oscillator at the fluid/structure interface. We consider the Euler equations in conservative form:

$$\partial_t \mathbf{q} + \partial_x \mathbf{f}(\mathbf{q}) = 0, \qquad (x,t) \in \Omega_\alpha, \tag{2.1a}$$

with $\Omega_\alpha := \{(x,t) : 0 < t < \tau; 0 < x < \alpha(t)\}$ an open bounded space/time domain. The function $\mathbf{q}$ maps Ω_α into $\mathbb{R}^3$ and

(2.1b)

$$\mathbf{f}(\mathbf{q}) := \big(q_2, q_2^2/q_1 + p(\mathbf{q}), (p(\mathbf{q}) + q_3)\, q_2/q_1\big)^T, \quad p(\mathbf{q}) := (\gamma - 1)\left(q_3 - \frac{1}{2} q_2^2/q_1\right),$$

with, typically, $\gamma = 7/5$. The boundary $\partial\Omega_\alpha$ consists of the [illegible] between the fluid and the structure, $\Gamma_\alpha := \{(x,t) : x = \alpha(t); 0 \le t \le \tau\}$, and the fixed boundary $\partial\Omega_\alpha \setminus \Gamma_\alpha$. The function $\mathbf{q}$ in (2.1) is subject to the auxiliary conditions

$$q_2(0,t) = 0, \quad 0 < t < \tau, \quad \text{and} \quad \mathbf{q}(x,0) = \mathbf{q}^0(x), \quad 0 < x < \alpha(0), \tag{2.2}$$

with $\mathbf{q}^0(x)$ prescribed initial conditions. Moreover, $\mathbf{q}$ must comply with the kinematic interface conditions

$$q_2(\alpha(t),t) = q_1(\alpha(t),t)\,\dot{\alpha}(t), \qquad 0<t<\tau, \tag{2.3a}$$

$$\alpha(t) = \alpha^0 + z(t), \qquad 0<t<\tau, \tag{2.3b}$$

and the dynamic interface condition

$$p(\mathbf{q}(\alpha(t),t)) = \pi(t), \qquad 0<t<\tau, \tag{2.3c}$$

where $\pi(t)$ and $z(t)$ are interrelated by the harmonic-oscillator equation

$$M\ddot{z} + Kz = \pi(t) - p^0 \quad 0<t<\tau, \quad \text{subject to} \quad z(0)=z^0,\ \dot{z}(0)=\dot{z}^0, \tag{2.4}$$

for certain given constants $M, K \in \mathbb{R}_+$ and $z^0, \dot{z}^0 \in \mathbb{R}$.

To establish that the piston problem (2.1)–(2.3) constitutes a [illegible] problem, we notice first that the kinematic condition (2.3a) induces an interdependence between the state variables $\mathbf{q}$ and their domain of definition Ω_α. Second, the number of interface conditions is one more than the number of auxiliary conditions required by the initial-boundary-value problems for the fluid and the structure separately. For instance, (2.1)–(2.2) subject to (2.3a) with α given, and (2.4) subject to (2.3c) with p given, are valid problems independently. The above two properties are the distinguishing characteristics of a free-boundary problem.

2.2. Variational formulation. To facilitate the ensuing presentation, we condense the piston problem into the canonical variational form: Find $u \in \mathcal{U}$ such that

$$\mathsf{P}(\bar{u}, u) = \mathsf{p}(\bar{u}) \qquad \forall \bar{u} \in \bar{\mathcal{U}}. \tag{2.5a}$$

In (2.5), u represents the quadruple $u := (\mathbf{q}, \alpha, z, \pi)$ in the product space $\mathcal{U} := \mathcal{Q} \times \mathcal{A} \times \mathcal{Z} \times \mathcal{P}$, which consists of the product of the admissible functions for the fluid, the interface displacement, the structure displacement, and the interface traction. The test space $\bar{\mathcal{U}}$ has a similar structure. The functionals $\mathsf{P} : \bar{\mathcal{U}} \times \mathcal{U} \mapsto \mathbb{R}$ and $\mathsf{p} : \bar{\mathcal{U}} \mapsto \mathbb{R}$ can be expanded according to

$$\mathsf{P}((\bar{\mathbf{q}}, \bar{\alpha}, \bar{z}, \bar{\pi}), (\mathbf{q}, \alpha, z, \pi)) := \mathsf{E}(\bar{\mathbf{q}}, \mathbf{q}, \alpha) + \mathsf{S}(\bar{z}, z, \pi) + \mathsf{K}(\bar{\alpha}, \alpha, z) + \mathsf{D}(\bar{\pi}, \pi, \mathbf{q}, \alpha), \tag{2.5b}$$

$$\mathsf{p}((\bar{\mathbf{q}}, \bar{\alpha}, \bar{z}, \bar{\pi})) := \mathsf{e}(\bar{\mathbf{q}}) + \mathsf{s}(\bar{z}) + \mathsf{k}(\bar{\pi}). \tag{2.5c}$$

In (2.5), the functionals E, e are associated with the initial-boundary-value problem for the fluid, viz., (2.1) complemented with the kinematic condition (2.3a). The functionals S, s pertain to the initial-value problem for the harmonic oscillator (2.4), and K, k, and D are associated with the kinematic interface condition (2.3b) and the dynamic interface condition (2.3c), respectively. A specification of the above functionals for the piston problem is provided in [5]. In [6], van Brummelen, Michler, and Borst elaborate upon the formulation of a generic fluid-structure-interaction problem into the canonical variational form (2.5). On account of the canonical variational form, sufficient conditions for the existence of a unique solution to (2.5) can be derived from the generalized nonlinear Lax–Milgram theorem; cf. Appendix A.

3. Subiteration for fluid-structure-interaction problems. The interdependence of the state variables of the fluid and the structure and their domains of definition poses profound complications in the numerical treatment of fluid-structure-interaction problems. The subiteration method which we consider in this paper is the standard approach to bypass these complications. In this section, we first consider the problems pertaining to the application of Newton's method to the piston problem. We then proceed with a description of the subiteration method.

TABLE 1
Illustration of the connectivity in the fluid-structure-interaction problem.

	α	$\mathbf{q}$	π	z
K	$\times$	0	0	$\times$
E	$\times$	$\times$	0	0
D	$\times$	$\times$	$\times$	0
S	0	0	$\times$	$\times$

3.1. Newton's method. Provided with an initial approximation $u_0 \in \mathcal{U}$, Newton's method for solving the variational problem (2.5) is defined by the following iterative process: for $j = 1, 2, \ldots$, find u_j such that

$$\mathsf{P}'(\bar{u}, u_{j-1}, u_j - u_{j-1}) = \mathsf{p}(\bar{u}) - \mathsf{P}(\bar{u}, u_{j-1}) \quad \forall \bar{u} \in \bar{\mathcal{U}}, \tag{3.1}$$

with P' the (assumed existent) Fréchet derivative of the operator P with respect to its nonlinear argument. If the initial estimate u_0 is sufficiently close to the actual solution, then u_j converges to the solution of the variational problem as $j \to \infty$.

The above abstract formulation of Newton's method obscures two essential problems, related to the characteristic properties of fluid-structure-interaction problems. The first problem concerns the [illegible] E'_α, viz., the derivative of the functional pertaining to the initial-boundary-value problem for the fluid, E, with respect to the interface position, α, induced the free-boundary character. Discrete-approximation methods such as finite elements typically use boundary fitted meshes. As a perturbation of the interface generally yields a deformation of the mesh throughout the entire computational domain, E'_α behaves as a nonlocal operator. This renders the computational expenses incurred in its evaluation prohibitive in actual applications. The second problem is the inherent interconnection between the fluid and the structure, induced by the interface conditions. The functionals D and K depend on $\alpha, \mathbf{q}$, associated with the fluid, as well as on π, z, corresponding to the structure. This is illustrated in Table 1. Consequently, the matrix $\mathbf{P}$ associated with a discrete approximation of the operator P' in (3.1) is inseparable and the fluid and structure equations must be resolved simultaneously. This has severe practical disadvantages, such as the loss of modularity; see [9]. Moreover, due to the disparate properties of the initial-boundary-value problems associated with the fluid and the structure, the matrix $\mathbf{P}$ is generally severely ill-conditioned.

3.2. Subiteration. The aforementioned complications of Newton's method can be avoided by means of an iterative solution procedure often referred as [illegible]. Provided with an initial approximation of the structure position $z_0(t)$, the following iterative process defines the subiteration algorithm: for $j = 1, 2, \ldots$:

(S1) Solve the kinematic condition: find $\alpha_j \in \mathcal{A}$: $\mathsf{K}(\bar{\alpha}, \alpha_j, z_{j-1}) = \mathsf{k}(\bar{\alpha})\ \forall \bar{\alpha} \in \bar{\mathcal{A}}$.
(S2) Solve the fluid: find $\mathbf{q}_j \in \mathcal{Q}$: $\mathsf{E}(\bar{\mathbf{q}}, \mathbf{q}_j, \alpha_j) = 0\ \forall \bar{\mathbf{q}} \in \bar{\mathcal{Q}}$.
(S3) Solve the dynamic condition: find $\pi_j \in \mathcal{P}$: $\mathsf{D}(\bar{\pi}, \pi_j, \mathbf{q}_j, \alpha_j) = 0\ \forall \bar{\pi} \in \bar{\mathcal{P}}$.
(S4) Solve the structure: find $z_j \in \mathcal{Z}$: $\mathsf{S}(\bar{z}, z_j, \pi_j) = \mathsf{s}(\bar{z})\ \forall \bar{z} \in \bar{\mathcal{Z}}$.

Note that this procedure avoids the computation of the shape derivative as well as the simultaneous treatment of the fluid and the structure.

It is mentionable that the subiteration process forms an instance of the generic iterative method for free-boundary problems: (1) the boundary-value problem(s) is

(are) solved with a subset of the free-boundary conditions imposed, and (2) the free-boundary position is adjusted to relax the remaining free-boundary condition. Different names are used for this iterative procedure, e.g., subiteration, successive approximation, or Picard iteration. For applications to fluid-structure-interaction problems see, for example, [1, 16, 17]. Moreover, we remark that the customary [illegible] or [illegible] time-integration methods for fluid-structure-interaction problems (see [9, 20, 21, 22]) are essentially identical to the above subiteration method, with the provision that the process is not repeated.

The subiteration method can also be classified as a [illegible] method [3]. The defect correction approach for a variational problem of the form (2.5a) commences with the determination of an initial estimate $u_0 \in \mathcal{U}$ such that $\tilde{\mathsf{P}}(\bar{u}, u_0) = \mathsf{p}(\bar{u})$ for all $\bar{u} \in \bar{\mathcal{U}}$, where the functional $\tilde{\mathsf{P}} : \bar{\mathcal{U}} \times \mathcal{U} \mapsto \mathbb{R}$ represents a suitable approximation to P. It then proceeds with finding $u_j \in \mathcal{U}$ such that

$$\tilde{\mathsf{P}}(\bar{u}, u_j) = \mathsf{p}(\bar{u}) + \tilde{\mathsf{P}}(\bar{u}, u_{j-1}) - \mathsf{P}(\bar{u}, u_{j-1}) \qquad \forall \bar{u} \in \bar{\mathcal{U}}, \tag{3.2}$$

for $j = 1, 2, \ldots$. If $\tilde{\mathsf{P}}$ is sufficiently close to P, then u_j converges to the actual solution of the variational problem as $j \to \infty$. To derive the approximate functional for the subiteration method, we note that the approximations generated by (S1)–(S4) satisfy

$$\mathsf{E}(\bar{\mathbf{q}}, \mathbf{q}_j, \alpha_j) + \mathsf{S}(\bar{z}, z_j, \pi_j) + \mathsf{D}(\bar{\pi}, \pi_j, \mathbf{q}_j, \alpha_j) + \mathsf{K}(\bar{\alpha}, \alpha_j, z_{j-1}) = \mathsf{e}(\bar{\mathbf{q}}) + \mathsf{s}(\bar{z}) + \mathsf{k}(\bar{\alpha}), \tag{3.3}$$

for all admissible $(\bar{\mathbf{q}}, \bar{\alpha}, \bar{z}, \bar{\pi})$. In general, the functional K is associated with a variational projection, and is separable as $\mathsf{K}(\bar{\alpha}, \alpha, z) = \mathsf{K}_0(\bar{\alpha}, \alpha) + \mathsf{K}_1(\bar{\alpha}, z)$. Upon introducing this additive partition of K into (3.3) and adding suitable partitions of zero, we immediately recover (3.2) with the approximate functional

$$\tilde{\mathsf{P}}((\bar{\mathbf{q}}, \bar{\alpha}, \bar{z}, \bar{\pi}), (\mathbf{q}, \alpha, z, \pi)) := \mathsf{E}(\bar{\mathbf{q}}, \mathbf{q}, \alpha) + \mathsf{S}(\bar{z}, z, \pi) + \mathsf{K}(\bar{\alpha}, \alpha, \zeta) + \mathsf{D}(\bar{\pi}, \pi, \mathbf{q}, \alpha), \tag{3.4}$$

with ζ any fixed element of $\mathcal{Z}$. Note that the approximation only involves the functional K corresponding to the kinematic interface condition (2.3b). The connectivity table associated with the approximate operator is identical to Table 1, but with the right-upper entry nullified. Thus, the connectivity table is lower triangular, and the subproblems involving the inversion of $\tilde{\mathsf{P}}$ can be solved conveniently by the forward substitution process inherent in the subiteration method.

4. Model problem. In this section we develop a linear model problem, which serves as a basis for the ensuing analysis of the properties of the subiteration method in sections 5 and 6.

4.1. Generating solution. To set up the linearized model, we consider the piston problem and we note that if the initial conditions are specified as $\mathbf{q}^0(x) = \mathbf{q}^0$ with $\mathbf{q}^0$ a constant in $\{\mathbf{q} \in \mathbb{R}^3 : 0 < q_1; p(\mathbf{q}) = p^0; q_2 = 0\}$ and $z^0 = \dot{z}^0 = 0$, then the obvious solution to (2.5) is

$$u := (\mathbf{q}, \alpha, z, \pi) = (\mathbf{q}^0, \alpha^0, 0, p^0) =: u^0. \tag{4.1}$$

Hence, if we provide the subiteration method with an initial approximation $z_0(t) = 0$, then the first iteration immediately yields the actual solution. If, instead, the initial approximation is specified as $z_0(t) = \epsilon z_0'(t)$, with z_0' a suitable function independent of ϵ, then $u_1(\epsilon)$ approaches u^0 as $\epsilon \to 0$. In this context, u^0 is called a generating solution.

4.2. First-order conditions. The above motivates us to assume that the first approximation generated by the subiteration method can be expanded asymptotically:

(4.2)
$$\alpha_1(t) = \alpha^0 + \sum_{l=1}^{n} \eta_l(\epsilon)\,\alpha^{(l)}(x,t) + o(\eta_n), \quad q_{1,j}(x,t) = q_j^0 + \sum_{l=1}^{n} \psi_l^j(\epsilon)\,q_j^{(l)}(x,t) + o(\psi_n^j),$$
$$\pi_1(t) = p^0 + \sum_{l=1}^{n} \xi_l(\epsilon)\,\pi^{(l)}(x,t) + o(\xi_n), \qquad z_1(t) = \ 0 + \sum_{l=1}^{n} \chi_l(\epsilon)\,z^{(l)}(x,t) + o(\chi_n),$$

$(j = 1, 2, 3)$ for all $n = 1, 2, \dots$, with respect to certain asymptotic sequences $\{\psi_l^j(\epsilon)\}$, $\{\chi_l(\epsilon)\}$, $\{\eta_l(\epsilon)\}$, and $\{\xi_l(\epsilon)\}$, as $\epsilon \to 0$. For a definition of asymptotic sequences and the Landau symbols, o and O (used below), see, for instance, [15].

By the usual argument that terms of different orders in ϵ must vanish separately as $\epsilon \to 0$, it follows that terms with subscript l in (4.2) must be of $O(\epsilon^l)$, in order for (S1)–(S4) to provide meaningful relations between successive terms in the expansion. In particular, this implies that $u_1(\epsilon) = u^0 + \epsilon u^{(1)} + O(\epsilon^2)$, i.e., the error in the first-order approximation is $O(\epsilon^2)$.

For transparency of notation, in what follows the subscript 1, indicating the first iteration, is suppressed, and the superscript (1), referring to the infinitesimal perturbation, is replaced by a prime. 5the first iteration is suppressed and the superscript (1) referring Upon inserting (4.2) in (S1) and collecting terms of $O(\epsilon)$, we obtain the first-order condition $\alpha' = z_0'$. To simplify the analysis, we assume that the first-order perturbation in $\mathbf{q}$ is isentropic, i.e., the ratio p/q_1^γ is constant. Under this assumption, the energy equation becomes redundant and can be discarded. The first-order conditions corresponding to operation (S2) then translate into the initial-boundary-value problem

$$\frac{\partial}{\partial t}\begin{pmatrix} q_1' \\ q_2' \end{pmatrix} + \begin{pmatrix} 0 & 1 \\ c^2 & 0 \end{pmatrix} \cdot \frac{\partial}{\partial x}\begin{pmatrix} q_1' \\ q_2' \end{pmatrix} = 0, \tag{4.3}$$

with $c := \sqrt{\gamma p^0/q_1^0}$ the speed of sound, subject to the initial and boundary conditions

$$q_1'(x,0) = 0, \quad x \in (0,\alpha^0), \qquad q_2'(x,0) = 0, \qquad x \in (0,\alpha^0), \tag{4.4a}$$
$$q_2'(0,t) = 0, \quad t \in (0,\tau), \qquad q_2'(\alpha^0,t) = \rho^0 \dot{z}_0'(t), \quad t \in (0,\tau). \tag{4.4b}$$

The generic solution to (4.3) is

$$\begin{pmatrix} q_1' \\ q_2' \end{pmatrix}(x,t) = \rho^0 \left(f_+(t + x/c)\begin{pmatrix} 1 \\ -c \end{pmatrix} + f_-(t - x/c)\begin{pmatrix} 1 \\ c \end{pmatrix}\right). \tag{4.5}$$

The initial and boundary conditions (4.4) imply the following conditions on f_+, f_-:

$$f_-(-s) + f_+(s) = 0, \qquad f_-(-s) - f_+(s) = 0, \qquad s \in (0,\alpha^0/c), \tag{4.6a}$$
$$f_-(s) - f_+(s) = 0, \quad f_-(s - \alpha^0/c) - f_+(s + \alpha^0/c) = \dot{z}_0'(s)/c, \quad s \in (0,\tau). \tag{4.6b}$$

From (4.5)–(4.6) it follows straightforwardly that

$$q_1'(\alpha^0,t) = -\frac{\rho^0}{c}\left(\dot{z}_0'(t) + 2\sum_{j=1}^{\lfloor ct/2\alpha^0 \rfloor} \dot{z}_0'(t - 2j\alpha^0/c)\right), \tag{4.7}$$

where $\lfloor\cdot\rfloor$ denotes the floor (truncation to integer) function. One can infer that the integer $\lfloor ct/2\alpha^0 \rfloor$ represents the number of reflections that have returned from the rigid boundary to the interface in the time interval $[0, t]$.

Under the assumption of isentropy, (S3) immediately yields the first-order perturbation in the aggregated force on the structure: $\pi' = c^2 q_1'(\alpha^0, t)$. From (4.7) it then follows that the structural displacement obtained in step (S4) of the subiteration algorithm complies with the first-order condition

(4.8)
$$M\ddot{z}'(t) + Kz'(t) = -c\rho^0 \left(\dot{z}_0'(t) + 2 \sum_{j=1}^{\lfloor ct/2\alpha^0 \rfloor} \dot{z}_0'\big(t - 2j\alpha^0/c\big) \right), \quad z'(0) = 0, \quad \dot{z}'(0) = 0.$$

Note that the initial-value problem (4.8) provides a unique relation between successive approximations of the structure displacement in the subiteration process.

To cast (4.8) into a convenient dimensionless form, we introduce characteristic time scales for the structure and the fluid, viz., $\tau_s := 2\pi\sqrt{M/K}$ and $\tau_f := 2\,\alpha^0/c$, respectively. Moreover, we define characteristic time-scale and mass ratios for the fluid-structure system, $\nu := 2\pi\,\tau_f/\tau_s$ and $\mu := \rho^0\alpha^0/M$, and a dimensionless time variable $s := 2\pi\,t/\tau_s$. With these definitions, we obtain

(4.9)
$$D^2 z'(s) + z'(s) = -\frac{2\,\mu}{\nu} \left(Dz_0'(s) + 2 \sum_{j=1}^{\lfloor s/\nu \rfloor} Dz_0'(s - j\nu) \right), \quad z'(0) = 0, \quad Dz'(0) = 0,$$

where D denotes differentiation with respect to the function argument.

4.3. Characteristic operators. The initial-value problem (4.9) associates a $z' \in \mathcal{Z}$ with each $z_0' \in \mathcal{Z}$. Accordingly, (4.9) generates an automorphic operator on $\mathcal{Z}$. We denote this operator by C. Because the subiteration process essentially reduces to recursion of the operator C, we refer to C as the [illegible] or [illegible].

An important simplification of the characteristic operator results from discarding the sum associated with the reflections. We designate the corresponding characteristic operator as the [illegible] C_0, in particular,

$$\mathsf{C}_0 : \{z_0' \in \mathcal{Z}\} \mapsto \big\{z' \in \mathcal{Z} : D^2 z' + z' = -2(\mu/\nu) Dz_0',\ z'(0) = 0,\ Dz'(0) = 0\big\}. \tag{4.10}$$

By virtue of the linearity of the differential equation and the homogeneity of the initial conditions in (4.9), the following relation between the null-reflection operator and the general characteristic operator holds:

$$\mathsf{C} = \left(\mathsf{I} + 2 \sum_{j}^{\lfloor \tau/\nu \rfloor} \mathsf{H}_\nu^j \right) \mathsf{C}_0, \tag{4.11}$$

where the shift operator $\mathsf{H}_\nu := \mathsf{H}(\nu)$ on $\mathcal{Z}$ is defined as

$$(\mathsf{H}_\nu z)(s) := \begin{cases} 0 & 0 < s \le \nu, \\ z(s - \nu) & \nu < s < \tau. \end{cases} \tag{4.12}$$

Note the group property $\mathsf{H}(\nu+\nu') = \mathsf{H}(\nu)\mathsf{H}(\nu')$ for any $\nu,\nu' \in \mathcal{T} =: (0,\tau)$ such that $\nu+\nu' \in \mathcal{T}$.

A second simplification pertains to the limit $\nu \to 0$. The right member of (4.9) can then be identified as a Riemann sum and it holds that

(4.13)
$$Du(s) + 2\sum_{j=1}^{\lfloor s/\nu \rfloor} Du(s-j\nu) = \frac{2}{\nu}\Big(\int_0^s Du(\xi)\,d\xi + O(\nu)\Big) \sim \frac{2}{\nu}\big(u(s)-u(0)\big) \text{ as } \nu \to 0.$$

Hence, as $\nu \to 0$ the characteristic operator approaches the operator C_∞,

(4.14)
$$\mathsf{C}_\infty : \{z_0' \in \mathcal{Z}\} \mapsto \big\{z' \in \mathcal{Z} : D^2 z' + z' = -4\mu/\nu^2\big(z_0'(s) - z_0'(0)\big), z'(0) = 0, Dz'(0) = 0\big\}.$$

We refer to C_∞ according to (4.14) as the [illegible]. Notice the different proportionalities $\mathsf{C}_0 \propto \mu/\nu$ and $\mathsf{C}_\infty \propto \mu/\nu^2$.

5. Nonnormality of the null-reflection operator. In this section we consider the nonnormality of the null-reflection operator. Such nonnormal behavior has important implications for the norm of powers of the operator and, hence, it is essential to the convergence properties of the subiteration method. The extension to the general subiteration operator including reflections is presented in section 6.

5.1. Theory of linear operators. This section reviews the basic theory of linear operators required for the ensuing exposition. For details we refer to the commendable [14].

Consider a Hilbert space $\mathcal{Z}$, equipped with an inner product $\langle\cdot,\cdot\rangle := \langle\cdot,\cdot\rangle_{\mathcal{Z}}$ and an associated norm $\|\cdot\| := \|\cdot\|_{\mathcal{Z}}$, and a bounded linear operator $\mathsf{L} : \mathcal{Z} \mapsto \mathcal{Z}$. The adjoint operator L^* is defined by the identity

$$\langle \mathsf{L}^* w, z\rangle = \langle w, \mathsf{L} z\rangle \qquad \forall w, z \in \mathcal{Z}. \tag{5.1}$$

In fact, it suffices that the identity holds for all w, z in a dense subspace of $\mathcal{Z}$; see [28, p. 263]. The operator L is said to be [illegible] if it commutes with its adjoint, i.e., if

$$\mathsf{L}^*\mathsf{L} = \mathsf{L}\mathsf{L}^*. \tag{5.2}$$

To present the specific properties pertaining to (5.2), we require some elementary concepts. The resolvent is defined as the operator-valued function

$$\mathsf{R}(\zeta) := \mathsf{R}(\mathsf{L},\zeta) := \big(\mathsf{L} - \zeta\,\mathsf{I}\big)^{-1} \tag{5.3}$$

on $\mathbb{C}$. Herein, I is the identity on $\mathcal{Z}$. The resolvent set $\mathcal{R}(\mathsf{L})$ is defined as the subset of $\mathbb{C}$ consisting of all ζ for which $\mathsf{R}(\zeta)$ is existent and bounded. The spectrum $\mathcal{S}(\mathsf{L})$ is defined as its complement in $\mathbb{C}$. If L is compact, which includes the case that $\dim \mathcal{Z} < \infty$, then the spectrum consists of at most a countable number of eigenvalues with finite multiplicities, possibly excepting zero if L is singular. The norm of the operator and its spectral radius are defined by

$$\|\mathsf{L}\| := \sup_{0\neq z\in\mathcal{Z}} \frac{\|\mathsf{L}z\|}{\|z\|} = \sup_{\substack{0\neq v\in\mathcal{Z}\\ 0\neq z\in\mathcal{Z}}} \frac{|\langle v, \mathsf{L}z\rangle|}{\|v\|\|z\|}, \quad \operatorname{spr}\mathsf{L} := \lim_{n\to\infty} \|\mathsf{L}^n\|^{1/n} = \inf_{n\in\mathbb{N}} \|\mathsf{L}^n\|^{1/n}, \tag{5.4}$$

respectively. It holds that

$$\operatorname{spr} \mathsf{L} = \sup_{\zeta \in \mathcal{S}(\mathsf{L})} |\zeta|. \tag{5.5}$$

A characteristic property of a normal operator is that $\|\mathsf{L}^n\| = \|\mathsf{L}\|^n$ and, accordingly, $\|\mathsf{L}\| = \operatorname{spr} \mathsf{L}$; see [14]. Hence, for a normal operator the spectral radius $\operatorname{spr} \mathsf{L}$ delineates the norm of monomials of the operator $\|\mathsf{L}^n\|$. In particular, if $\operatorname{spr} \mathsf{L} < 1$, then $\|\mathsf{L}^n\|$ converges monotonically to 0 as n increases. For nonnormal operators the spectral radius only represents the asymptotic convergence as $n \to \infty$. If $\|\mathsf{L}\| > 1 > \operatorname{spr} \mathsf{L}$, then the convergence of $\|\mathsf{L}^n\|$ is generally nonmonotonous and divergence can occur before asymptotic convergence sets in; cf. section 5.4 and, e.g., [12, p. 28]. Relevant in this respect are also the plots of $\|\exp(t\mathsf{L})\|$ (which has similar properties as $\|\mathsf{L}^n\|$) versus t for various nonnormal operators in [25].

Another important property of a normal operator is that it admits a spectral representation on a basis of orthonormal eigenvectors. If L is compact, we can index the nonzero eigenvalues as $\sigma_1, \sigma_2, \ldots$. To each eigenvalue σ_j corresponds an eigenprojection

$$\mathsf{P}_j := -\frac{1}{2\pi\iota} \oint_{\chi_j} \mathsf{R}(\zeta)\, d\zeta \tag{5.6}$$

with $\iota := \sqrt{-1}$ and χ_j any closed curve in $\mathbb{C}$ of which the intersection of its interior and the spectrum contains σ_j only; see[10, p. 5 ff.] or [14, p. 39 ff.]. For compact normal operators L we have the spectral representation

$$\mathsf{L} = \sum\nolimits_j \sigma_j \mathsf{P}_j \tag{5.7}$$

and $\mathsf{P}_j^* = \mathsf{P}_j$, $\dim \mathsf{P}_j < \infty$ and $\mathsf{P}_i \mathsf{P}_j = \delta_{ij} \mathsf{P}_i$. Furthermore, together with the orthonormal projection P_0 on the kernel of L the eigenprojections form a complete orthonormal family and, hence, $\sum \mathsf{P}_j = \mathsf{I}$. Alternatively, we can select orthonormal bases $\{\varphi_j^i\}$ $(i = 1, \ldots, \dim \mathsf{P}_j \mathcal{Z})$ for the subspaces $\mathsf{P}_j \mathcal{Z}$ and corresponding conjugate bases $\{\psi_j^i\}$ and rewrite (5.7) as

$$\mathsf{L}(\cdot) = \sum_j \sum_{i=1}^{\dim \mathsf{P}_i \mathcal{Z}} \sigma_j \varphi_j^i \langle \psi_j^i, \cdot \rangle. \tag{5.8}$$

The φ_i^j are the eigenvectors corresponding to the eigenvalue σ_i. The corresponding conjugate vectors $\{\psi_i^j\}$ are defined by $\langle \varphi_j^i, \psi_l^k \rangle = \delta_{jl}^{ik}$, i.e., $\langle \psi_j^i, \cdot \rangle$ represent the characteristic coordinates with respect to the basis $\{\varphi_j^i\}$. An operator which admits a representation conforming to (5.7) with $\mathsf{P}_j \mathsf{P}_k = \delta_{jk} \mathsf{P}_j$ and $\sum \mathsf{P}_j = \mathsf{I}$ is said to be [illegible] or [illegible]. If, in addition, it holds that the eigenprojections are orthogonal and, accordingly, $\mathsf{P}_j^* = \mathsf{P}_j$, then the normalized eigenvectors form an orthonormal basis of $\mathcal{Z}$ and the operator is said to be [illegible]. Hence, a compact operator is normal if and only if it is unitarily diagonalizable.

To express the degeneracy of the set of eigenvectors of a nonnormal operator, we define the coercivity coefficient and the continuity coefficient of the projection onto the basis of eigenvectors $\{\varphi_j\} := \{\varphi_j^i\}$, respectively, as the largest number $\gamma(\mathsf{L})$ and the smallest number $\gamma'(\mathsf{L})$ such that

$$\inf_{0 \neq \{\hat{z}_j\} \in \hat{\mathcal{Z}}} \sup_{0 \neq v \in \mathcal{Z}} \frac{\left|\Sigma_j \langle v, \varphi_j \rangle \hat{z}_j\right|}{\|v\|\, \|\hat{z}.\|} \geq \gamma(\mathsf{L}), \qquad \sup_{\substack{0 \neq \{\hat{z}_j\} \in \hat{\mathcal{Z}} \\ 0 \neq v \in \mathcal{Z}}} \frac{\left|\Sigma_j \langle v, \varphi_j \rangle \hat{z}_j\right|}{\|v\|\, \|\hat{z}.\|} \leq \gamma'(\mathsf{L}), \tag{5.9}$$

where $\|\hat{z}.\|^2 := \sum \hat{z}_i^2$ and $\hat{\mathcal{Z}}$ represents the space of coefficients $\{\hat{z}_i\}$ such that $\sum \hat{z}_i\varphi_i$ resides in $\mathcal{Z}$. From the spectral representation (5.8) it follows that

(5.10)
$$\langle v, \mathsf{L}^n z\rangle = \langle v,\varphi_{i_1}\rangle\sigma_{i_1}\langle\psi_{i_1},\varphi_{i_2}\rangle\sigma_{i_2}\cdots\langle\psi_{i_{n-1}},\varphi_{i_n}\rangle\sigma_{i_n}\langle\psi_{i_n},z\rangle = \sigma_i^n\langle v,\varphi_i\rangle\langle\psi_i,z\rangle,$$

where summation over repeated indices is implied. Furthermore, denoting by $\check{Z}$ the space of coefficients $\{\check{z}_i\}$ such that $\sum \check{z}_i\psi_i \in \mathcal{Z}$, it holds that

$$\sup_{0\neq z\in\mathcal{Z}} \frac{\|\langle z,\psi.\rangle\|}{\|z\|} = \sup_{\substack{0\neq\{\hat{z}_i\}\in\hat{\mathcal{Z}}\\ 0\neq\{\check{w}_j\}\in\check{\mathcal{Z}}}} \frac{\|\hat{z}_i\langle\varphi_i,\psi_j\rangle\check{w}_j\|}{\|\check{w}.\|\|\hat{z}_i\varphi_i\|} = \sup_{0\neq\{\hat{z}_i\}\in\hat{\mathcal{Z}}} \frac{\|\hat{z}.\|}{\|\hat{z}_i\varphi_i\|}$$

$$= \left(\inf_{0\neq\{\hat{z}_i\}\in\hat{\mathcal{Z}}} \frac{\|\hat{z}_i\varphi_i\|}{\|\hat{z}.\|}\right)^{-1} \leq \frac{1}{\gamma(\mathsf{L})}, \tag{5.11}$$

again with summation over repeated indices. Hence, we obtain

$$\|\mathsf{L}^n\| = \sup_{\substack{0\neq z\in\mathcal{Z}\\ 0\neq v\in\mathcal{Z}}} \frac{|\langle v,\mathsf{L}^n z\rangle|}{\|v\|\|z\|} \leq (\operatorname{spr}\mathsf{L})^n \sup_{\substack{0\neq v\in\mathcal{Z}\\ 0\neq z\in\mathcal{Z}}} \frac{\|\langle v,\varphi.\rangle\|}{\|v\|}\frac{\|\langle z,\psi.\rangle\|}{\|z\|} \leq (\operatorname{spr}\mathsf{L})^n\frac{\gamma'(\mathsf{L})}{\gamma(\mathsf{L})}. \tag{5.12}$$

The ratio $\gamma'(\mathsf{L})/\gamma(\mathsf{L}) =: \kappa(\mathsf{L})$ is called the condition number of the basis of eigenvectors. By (5.4) and (5.12), it holds that $(\operatorname{spr}\mathsf{L})^n \leq \|\mathsf{L}^n\| \leq \kappa(\mathsf{L})(\operatorname{spr}\mathsf{L})^n$. If L is normal and, accordingly, $\{\varphi_j\}$ forms an orthonormal basis of $\mathcal{Z}$, then $\gamma(\mathsf{L}) = \gamma'(\mathsf{L}) = 1$ by Parseval's identity and, hence, $\kappa(\mathsf{L}) = 1$. Contrastingly, if L is nonnormal, then $\kappa(\mathsf{L})$ is typically much larger than unity. Moreover, it is mentionable that (5.11) implies that the norm of the characteristic coordinates of any $z \in \mathcal{Z}$ are bounded by $\|\hat{z}.\| \leq \|z\|/\gamma(\mathsf{L})$. This implies that the characteristic coordinates of a typical element of $\mathcal{Z}$ can be enormous if the eigenfunctions are nearly linearly dependent and, accordingly, $\gamma(\mathsf{L})$ is small. Trefethen [25] notes that the properties of an analytic function of the operator, such as L^n or $\exp(t\mathsf{L})$, are then determined by the interactions of the eigenfunctions rather than their individual behavior.

Finally, we consider the relation between the normality of an operator and its pseudospectra, viz., the one-parameter family of subsets of $\mathbb{C}$ defined by

$$\mathcal{S}_\epsilon(\mathsf{L}) := \left\{\zeta\in\mathbb{C} : \|\mathsf{R}(\mathsf{L},\zeta)\| \geq \epsilon^{-1}\right\} \tag{5.13}$$

for all $\epsilon \in \mathbb{R}_+$. By convention, $\mathcal{S}_0(\mathsf{L})$ is identified with the spectrum $\mathcal{S}(\mathsf{L})$. More precisely, the spectrum consists of all complex numbers ζ for which the resolvent $\mathsf{R}(\mathsf{L},\zeta)$ is unbounded or its domain is only a proper subset of $\mathcal{Z}$; see also [14]. For any $\zeta \in \mathbb{C}$ it holds that $\mathcal{S}(\mathsf{L}-\zeta\,\mathsf{I}) = \mathcal{S}(\mathsf{L})-\zeta$. Hence, by the spectral mapping theorem, $\mathcal{S}\big(\mathsf{R}(\zeta_0)\big)$ is related to $\mathcal{S}(\mathsf{L})$ by the transformation $\zeta \mapsto (\zeta-\zeta_0)^{-1}$. On account of (5.5) it then follows that

(5.14)
$$\operatorname{spr}\mathsf{R}(\zeta_0) = \sup_{\zeta\in\mathcal{S}(\mathsf{R}(\zeta_0))}|\zeta| = \sup_{\zeta\in\mathcal{S}(\mathsf{L})}|\zeta-\zeta_0|^{-1} = \left(\inf_{\zeta\in\mathcal{S}(\mathsf{L})}|\zeta-\zeta_0|\right)^{-1} = \operatorname{dist}(\zeta_0,\mathcal{S}(\mathsf{L}))^{-1},$$

with $\operatorname{dist}(\zeta_0,\mathcal{S}(\mathsf{L})) := \inf_{\zeta\in\mathcal{S}(\mathsf{L})}|\zeta_0-\zeta|$ the distance of ζ_0 to the spectrum $\mathcal{S}(\mathsf{L})$. As the resolvent of a normal operator is itself a normal operator (see [14]), it holds that $\|\mathsf{R}(\mathsf{L},\zeta)\| = \operatorname{spr}\mathsf{R}(\mathsf{L},\zeta)$ if L is normal. This implies that the ϵ-pseudospectrum of a normal operator is the aggregate of all points in $\mathbb{C}$ at distance at most ϵ from the spectrum. For nonnormal operators, the pseudospectra can be much larger; cf. [25] for examples; see also section 5.4.

5.2. Functional setting. Considering an open interval $\mathcal{T} := (0, \tau)$, an appropriate setting for C_0 is the Sobolev space $H^1(\mathcal{T})$ defined as

$$H^1(\mathcal{T}) := \{z \in L^2(\mathcal{T}) : \|z\|_{H^1(\mathcal{T})} < \infty\}, \tag{5.15}$$

where the norm $\|\cdot\|_{H^1(\mathcal{T})}$ is induced by the inner product

$$\langle w, z\rangle_{H^1(\mathcal{T})} := \langle w, z\rangle_{L^2(\mathcal{T})} + \langle Dw, Dz\rangle_{L^2(\mathcal{T})}. \tag{5.16}$$

Whenever the interval is evident from the context, we will suppress it for brevity. The operator C_0 is bounded on H^1 as $\|\mathsf{C}_0\|_{H^1} \leq 2\tau$ and unbounded on L^2; see Appendix B. Equipped with the norm induced by (5.16), H^1 is a Hilbert space.

As a digression, we note a corollary of the upper bound $\|\mathsf{C}_0\|_{H^1} \leq 2\tau$ for the accuracy of the partitioned time-integration methods for fluid-structure-interaction problems (see, e.g., [9, 20, 21, 22]), and for the required number of subiterations for monolithic methods, i.e., methods that actually resolve the aggregated fluid and structure equations. Consider a time interval $\mathcal{T} := (0, T)$, partitioned into contiguous subintervals $\mathcal{T}_i$ of length τ ($i = 1, 2, \ldots, T/\tau$). Let z, z_i, and z_i^n denote the actual boundary displacement, its finite-element approximation of polynomial degree m on $\mathcal{T}_i$, and the approximation to z_i generated by n subiterations, respectively. Indicating by the binary relation $\lesssim$ that the left member is at most equal to the right member modulo a positive constant, basic interpolation theory conveys that for sufficiently regular z the interpolation error $d_i := z - z_i$ obeys $\|d_i\|_{H^1(\mathcal{T}_i)} \lesssim \tau^m |z|_{H^m(\mathcal{T}_i)} \lesssim \tau^{m+1/2}$, with $|\cdot|_{H^m}$ the seminorm; see, e.g., [18, Theorem 6.8]. Moreover, the approximation z_{i-1} can then be extended to $\mathcal{T}_i$ such that $\|z_{i-1} - z\|_{H^1(\mathcal{T}_i)} \lesssim \tau^{m+1/2}$. Therefore, if the initial approximation on the interval is generated by extrapolation, i.e., $z_i^0 = z_{i-1}$, then the corresponding evaluation error $e_i^n := z_i^n - z_i$ obeys $\|e_i^0\|_{H^1(\mathcal{T}_i)} \lesssim \tau^{m+1/2}$. The upper bound $\|\mathsf{C}_0\|_{H^1} \leq 2\tau$ indicates that $\|e_i^n\|_{H^1} \leq 2\tau \|e_i^{n-1}\|_{H^1}$. This implies that $\|e_i^1\|_{H^1} = O(\tau^{m+3/2}) \ll \|d_i\|_{H^1} = O(\tau^{m+1/2})$ as $\tau \to 0$. That is, for sufficiently small τ, a single subiteration renders the local evaluation error much smaller than the local interpolation error. However, to ensure that the global evaluation error is smaller than the global interpolation error, two iterations are required. To clarify this, we note that the pressure perturbation is related to the displacement perturbation by $\pi' = \text{const}\, Dz'$; cf. section 4.2. In the subiteration process the pressure approximation is based on the previous displacement approximation and, hence, the evaluation error in the pressure $\beta_i^n := \pi_i^n - \pi_i$ complies with $\|\beta_i^n\|_{L^2(\mathcal{T}_i)} \lesssim \|e_i^{n-1}\|_{H^1} \lesssim \tau^{m+n-1/2}$. Summation over the intervals imparts that the global evaluation error in the pressure satisfies $\|\beta^n\|_{L^2}^2 = \sum_i \|\beta_i^n\|_{L^2(\mathcal{T}_i)}^2 \lesssim \tau^{2(m+n-1)}$. The global evaluation error in the displacement complies with $D^2 e^n + e^n = \beta^n$ and the homogeneous initial conditions $e^n(0) = De^n(0) = 0$. A similar derivation as in Appendix B then conveys that $\|e^n\|_{H^1(\mathcal{T})} \leq 2T \|\beta^n\|_{L^2(\mathcal{T})} \lesssim \tau^{m+n-1}$. One subiteration ($n = 1$) thus renders the global evaluation error in the displacement only $O(\tau^m)$ and, hence, it is of the same order as the global interpolation error. The global evaluation error in the displacement after two iterations ($n = 2$) is $O(\tau^{m+1})$ and for sufficiently small τ it is thus negligible compared to the global interpolation error. In conclusion, partitioned methods and monolithic methods possess identical orders of accuracy. However, the proportionality constants can be very different. Furthermore, for appropriately small time steps a monolithic method requires only two subiteration per time step for convergence to sufficient accuracy.

5.3. Nonnormality of C_0. To establish the nonnormality of the null-reflection operator, we derive its adjoint and demonstrate that there exist admissible functions that violate the identity (5.2).

Consider an open interval $\mathcal{T} := (0,\tau)$. Let $\mathcal{Z} := H^1(\mathcal{T})$, equipped with the standard L^2 inner product. Being a closed linear subspace of the Hilbert space L^2, the closure $\overline{\mathcal{Z}}$ of $\mathcal{Z}$ in L^2 is a Hilbert space. To avoid the conveyance of constants, we set $2\mu/\nu = 1$ in (4.10) without loss of generality. A useful device in the derivation of the adjoint operator is the translation operator $\mathsf{T} : z \in \mathcal{Z} \mapsto z - z(0) \in \mathcal{Z}$. As $\mathsf{C}_0 z$ depends on z through Dz only, C_0 is translation invariant and $\mathsf{C}_0\mathsf{T} = \mathsf{C}_0$. To determine the adjoint operator of C_0 on $\overline{\mathcal{Z}}$, we select an arbitrary $w \in \mathcal{Z}$ and associate a function ψ by

$$D^2\psi + \psi = w,\ \psi(\tau) = 0, \quad D\psi(\tau) = 0. \tag{5.17}$$

Moreover, we consider an arbitrary $z \in \mathcal{Z}$ and denote by v its image under $\mathsf{C}_0\mathsf{T}$. The adjoint operator follows from the following chains of identities:

$$\begin{aligned}\langle w, \mathsf{C}_0 z\rangle = \langle w, \mathsf{C}_0\mathsf{T}z\rangle = \langle D^2\psi + \psi, v\rangle = v\, D\psi\big|_0^\tau - Dv\, \psi\big|_0^\tau + \langle \psi, D^2 v + v\rangle \\ = \langle \psi, D^2 v + v\rangle = \langle -\psi, D\,\mathsf{T}z\rangle = -\mathsf{T}z\, \psi\big|_0^\tau + \langle D\psi, \mathsf{T}z\rangle = \langle D\psi, \mathsf{T}z\rangle,\end{aligned} \tag{5.18}$$

and

$$\langle \mathsf{C}_0^* w, z\rangle = \langle w, \mathsf{C}_0 z\rangle = \langle w, \mathsf{C}_0\mathsf{T}z\rangle = \langle \mathsf{C}_0^* w, \mathsf{T}z\rangle. \tag{5.19}$$

The third and sixth identity in (5.18) follow by integration by parts. The boundary terms in (5.18) vanish in virtue of the homogeneous initial and final conditions on v and ψ, respectively, and the property $(\mathsf{T}z)(0) = 0$ of the translation operator. From (5.18)–(5.19) the adjoint operator is readily identified as

$$\mathsf{C}_0^* : \{w \in \mathcal{Z}\} \mapsto \big\{D\psi \in \mathcal{Z} : D^2\psi + \psi = w,\ \psi(\tau) = 0,\ D\psi(\tau) = 0\big\}. \tag{5.20}$$

As w, z in (5.18)–(5.19) are arbitrary, we have the implication $\langle w, \mathsf{C}_0 z\rangle = \langle \mathsf{C}_0^* w, z\rangle$ for all $w, z \in \mathcal{Z}$, in accordance with (5.1). Noting that $\mathcal{Z}$ is dense in $\overline{\mathcal{Z}}$, we find that C_0^* according to (5.20) is the adjoint operator of C_0 on $\overline{\mathcal{Z}}$.

The normality of C_0 can now be disproved straightforwardly by establishing that there exists a $z \in \mathcal{Z}$ such that $\mathsf{C}_0^*\mathsf{C}_0 z \neq \mathsf{C}_0\mathsf{C}_0^* z$. For instance, $\sin \in \mathcal{Z}$ and

$$\begin{aligned}(\mathsf{C}_0^*\mathsf{C}_0 - \mathsf{C}_0\mathsf{C}_0^*)\sin(s) = [2(s-\tau)\cos(s-2\tau) - \sin(s+2\tau) - 2\sin(s-2\tau) \\ -(4\tau s - 3 - 2\tau^2)\sin(s) - 2s\cos(s)]/16 \neq 0,\end{aligned} \tag{5.21}$$

which completes the proof.

5.4. Approximation on polynomials. To elaborate further the properties of the subiteration procedure, we consider the null-reflection characteristic operator on polynomials.

Let $\mathcal{Z}_m$ be the space of polynomials of degree m on the open interval $\mathcal{T} := (0,\tau)$ with bounded H^1 norm. By the Weierstrass approximation theorem, one can conceive of $\mathcal{Z}_m$ as an approximation to the continuous functions in $H^1(\mathcal{T})$. Equipped with the inner product (5.16), $\mathcal{Z}_m$ is a Hilbert space. For given m, we associate to any $z \in \mathcal{Z}_m$ a function $v \in \mathcal{Z}_m$ by the variational statement

$$\mathsf{A}(w, v) = \mathsf{B}(w, z) \qquad \forall w \in \mathcal{Z}_m, \tag{5.22a}$$

where

$$\text{(5.22b)}\quad \mathsf{A}(w,v) := \langle w, D^2 v + v\rangle_{L^2} + w\,Dv\big|_0 - v\,Dw\big|_0, \qquad \mathsf{B}(w,z) := -\langle w, Dz\rangle_{L^2}.$$

Equation (5.22) represents a weak formulation of $v = \mathsf{C}_0 z$ with weakly imposed initial conditions. To make (5.22) amenable to numerical treatment, we introduce a basis $\{\theta_0, \dots, \theta_m\}$ of $\mathcal{Z}_m$, where θ_i is the normalized Legendre polynomial of degree i on the interval $\mathcal{T}$. Equation (5.22) then translates into the linear algebra problem $\mathbf{A}\cdot\bar{\mathbf{v}} = \mathbf{B}\cdot\bar{\mathbf{z}}$, where $A_{ij} = \mathsf{A}(\theta_i,\theta_j)$ and $B_{ij} = \mathsf{B}(\theta_i,\theta_j)$, and the vectors $\bar{\mathbf{v}}$ and $\bar{\mathbf{z}}$ collect the coefficients of v and z with respect to the basis of Legendre polynomials, respectively. Hence, with respect to this basis the mapping C_0 is represented by the matrix $\mathbf{C}_0 := \mathbf{A}^{-1}\cdot\mathbf{B}$.

To express the H^1 norm of C_0 in terms of $\mathbf{C}_0$, we note that for any two functions $v, z \in \mathcal{Z}_m$ the H^1 inner product can be expressed as

$$\text{(5.23)}\quad \langle v, z\rangle_{H^1} = \sum_{i,j} \bar{v}_i W_{ij} \bar{z}_j \quad \text{with} \quad W_{ij} = \langle \theta_i, \theta_j\rangle_{H^1} = \langle \theta_i, \theta_j\rangle_{L^2} + \langle D\theta_i, D\theta_j\rangle_{L^2}.$$

The Gram matrix $\mathbf{W}$ is symmetric positive definite and, hence, it admits a Cholesky factorization, i.e., there exists an upper-triangular matrix $\mathbf{Q}$ such that $\mathbf{W} = \mathbf{Q}^T\cdot\mathbf{Q}$. Accordingly, we can express the H^1 norm of any $z \in \mathcal{Z}_m$ as

$$\text{(5.24)}\qquad \|z\|_{H^1}^2 = \langle z, z\rangle_{H^1} = \sum_{i,j} \bar{z}_i \langle \theta_i, \theta_j\rangle_{H^1} \bar{z}_j = \bar{\mathbf{z}}^T\cdot\mathbf{Q}^T\cdot\mathbf{Q}\cdot\bar{\mathbf{z}} = \|\mathbf{Q}\cdot\bar{\mathbf{z}}\|^2.$$

In (5.24), the vector norm $\|\cdot\| : \mathbb{R}^m \mapsto \mathbb{R}$ connotes the standard L^2-norm. The H^1 norm of C_0 on $\mathcal{Z}_m$ can thus be determined as follows:

$$\begin{aligned}\|\mathsf{C}_0\|_{H^1} &= \sup_{\substack{0\neq v\in\mathcal{Z}_m\\ 0\neq z\in\mathcal{Z}_m}} \frac{|\langle v, \mathsf{C}_0 z\rangle_{H^1}|}{\|v\|_{H^1}\|z\|_{H^1}} = \sup_{\substack{0\neq \bar{\mathbf{v}}\in\mathbb{R}^m\\ 0\neq \bar{\mathbf{z}}\in\mathbb{R}^m}} \frac{|\bar{\mathbf{v}}^T\cdot\mathbf{W}\cdot\mathbf{C}_0\cdot\bar{\mathbf{z}}|}{\|\mathbf{Q}\cdot\bar{\mathbf{v}}\|\|\mathbf{Q}\cdot\bar{\mathbf{z}}\|}\\ &= \sup_{\substack{0\neq \hat{\mathbf{v}}\in\mathbb{R}^m\\ 0\neq \hat{\mathbf{z}}\in\mathbb{R}^m}} \frac{|\hat{\mathbf{v}}^T\cdot\mathbf{Q}\cdot\mathbf{C}_0\cdot\mathbf{Q}^{-1}\cdot\hat{\mathbf{z}}|}{\|\hat{\mathbf{v}}\|\|\hat{\mathbf{z}}\|} = \|\mathbf{Q}\cdot\mathbf{C}_0\cdot\mathbf{Q}^{-1}\|,\end{aligned} \qquad \text{(5.25)}$$

where $\hat{(\cdot)} := \mathbf{Q}\cdot\bar{(\cdot)}$. Note that the final form in (5.25) is computable. Table 2 lists the norm $\|\mathsf{C}_0\|_{H^1(\mathcal{T})}$ for representative values of the interval length τ and the polynomial degree m. A discussion of the results is postponed to the end of this section.

The question pertaining to the relation between the spectrum of C_0 on a function space such as H^1, and the spectrum of C_0 on a finite-dimensional subspace such as $\mathcal{Z}_m$, is a profoundly difficult one, and we shall not pursue it here. Let us just mention that the spectrum of any bounded operator is nonempty [14, p. 176] and, in particular, the spectrum of C_0 on H^1 is nonempty. Below, we consider the spectrum of C_0 on $\mathcal{Z}_m$ independently. To relate the pseudospectra of C_0 on $\mathcal{Z}_m$ to the representation matrix $\mathbf{C}_0$, we state the following identities:

$$\text{(5.26)}\qquad \big\|(\mathsf{C}_0 - \zeta\mathsf{I})^{-1}\big\|_{H^1} = \big\|\mathbf{Q}\cdot(\mathbf{C}_0 - \zeta\mathbf{I})^{-1}\cdot\mathbf{Q}^{-1}\big\| = \big\|(\mathbf{Q}\cdot\mathbf{C}_0\cdot\mathbf{Q}^{-1} - \zeta\mathbf{I})^{-1}\big\|.$$

The second expression implies that the spectrum of C_0 on $\mathcal{Z}_m$ coincides with the spectrum of $\mathbf{C}_0$. The final expression demonstrates that the H^1 pseudospectra of C_0 on $\mathcal{Z}_m$ coincide with the pseudospectra of $\mathbf{Q}\cdot\mathbf{C}_0\cdot\mathbf{Q}^{-1}$. This reflects that the spectrum does not depend on the selected norm (H^1 or L^2), but the pseudospectra do. Figure 1

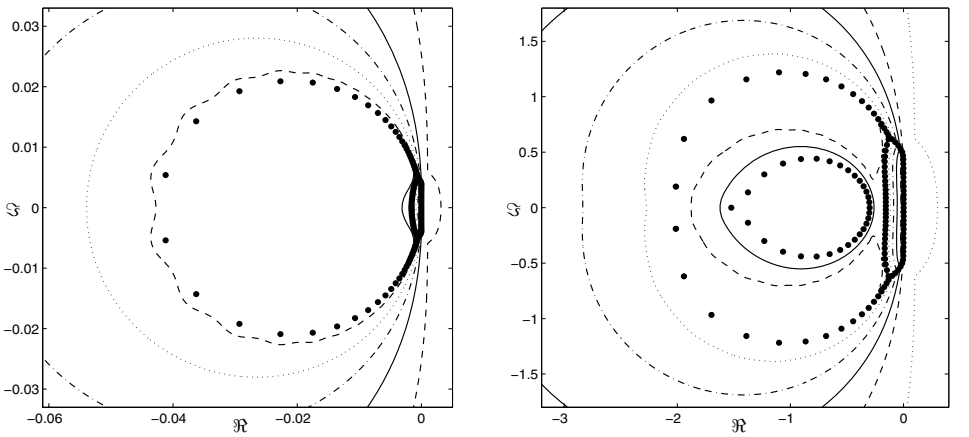

FIG. 1. *Spectra* (•) *and H^1 ϵ-pseudospectra of C_0 on $\mathcal{Z}_m$ for $m = 2^7$, $\tau = 1$* (left), *$\tau = 10^2$* (right), *$\epsilon = 10^{-13}$* (—), *10^{-11}* (−−), *10^{-9}* (···), *10^{-7}* (−·), *10^{-5}* (—), *10^{-3}* (−−), *10^{-1}* (···).

displays the H^1 pseudospectra[1] of C_0 for $m = 2^7$, and $\tau = 1$ and $\tau = 10^2$. Moreover, Table 2 lists the spectral radius of C_0 for representative values of τ and m.

The coercivity coefficient $\gamma(\mathsf{C}_0)$ can be determined as follows:

$$\inf_{0\neq\{\hat{z}_i\}\in\hat{\mathcal{Z}}_m} \sup_{0\neq v\in\mathcal{Z}_m} \frac{\left|\Sigma_i \langle v, \varphi_i\rangle_{H^1} \hat{z}_i\right|}{\|v\|_{H^1} \|\hat{z}.\|} = \inf_{0\neq\{\hat{z}_i\}\in\hat{\mathcal{Z}}_m} \sup_{0\neq\bar{\mathbf{v}}\in\mathbb{R}^m} \frac{\left|\Sigma_i \bar{\mathbf{v}}^T \cdot \mathbf{W} \cdot \bar{\boldsymbol{\varphi}}_j \|\mathbf{Q}\cdot\bar{\boldsymbol{\varphi}}_i\|^{-1} \hat{z}_i\right|}{\|\mathbf{Q}\cdot\bar{\mathbf{v}}\| \, \|\hat{z}.\|}$$

$$(5.27) = \inf_{0\neq\hat{\mathbf{z}}\in\mathbb{R}^m} \sup_{0\neq\mathbf{w}\in\mathbb{R}^m} \frac{\left|\mathbf{w}^T \cdot \mathbf{U} \cdot \hat{\mathbf{z}}\right|}{\|\mathbf{w}\| \, \|\hat{\mathbf{z}}\|} = \inf_{0\neq\mathbf{z}\in\mathbb{R}^m} \sup_{0\neq\mathbf{u}\in\mathbb{R}^m} \frac{\left|\mathbf{u}^T \cdot \mathbf{F}^T \cdot \mathbf{U} \cdot \mathbf{G} \cdot \mathbf{z}\right|}{\|\mathbf{u}\| \, \|\mathbf{z}\|} = \rho_{\min}.$$

with $\mathbf{w} := \mathbf{Q}\cdot\bar{\mathbf{v}}$, $\mathbf{U} := \left(\mathbf{Q}\cdot\hat{\boldsymbol{\varphi}}_1/\|\mathbf{Q}\cdot\hat{\boldsymbol{\varphi}}_1\|, \mathbf{Q}\cdot\hat{\boldsymbol{\varphi}}_2/\|\mathbf{Q}\cdot\hat{\boldsymbol{\varphi}}_2\|, \dots\right)$ and $\rho_{\min}$ the smallest singular value of $\mathbf{U}$. One simply infers that $\mathbf{U}$ contains the normalized eigenvectors of $\mathbf{Q}\cdot\mathbf{C}_0\cdot\mathbf{Q}^{-1}$. The matrices $\mathbf{F}$, $\mathbf{R}$, and $\mathbf{G}$ pertain to the singular-value decomposition of $\mathbf{U}$ according to $\mathbf{U} = \mathbf{F}\cdot\mathbf{R}\cdot\mathbf{G}^T$; see, e.g., [11, 12]. As the matrices $\mathbf{F}$ and $\mathbf{G}$ are unitary, the transformations $\mathbf{w} = \mathbf{F}\cdot\mathbf{u}$ and $\hat{\mathbf{z}} = \mathbf{G}\cdot\mathbf{z}$ are norm preserving. This leads to the third identity. Similarly, we obtain for the continuity coefficient $\gamma'(\mathsf{C}_0) = \rho_{\max}$. For the parameters in Table 2, the coercivity and continuity coefficients thus computed yield condition numbers $\kappa(\mathsf{C}_0) > 10^{10}$.

[1]We thankfully acknowledge the use of the *EigTool* package by T.G. Wright, M. Embree, and L.N. Trefethen for producing the pseudospectra plots in Figure 1; see [27] for further information.

The computed norms in Table 2 are virtually independent of the polynomial degree m. This is a result of the smoothness of the function that induces the norm and of its image, i.e., the functions $\bar{v}$ and $\bar{z}$ defined by

$$\{\bar{v}, \bar{z}\} := \arg \sup_{\substack{0 \neq v \in H^1 \\ 0 \neq z \in H^1}} \frac{\left|\langle v, \mathsf{C}_0 z \rangle_{H^1}\right|}{\|v\|_{H^1} \|z\|_{H^1}} \tag{5.28}$$

are sufficiently smooth to render the error in their approximation in $\mathcal{Z}_m$ with $m \in \{2^6, 2^7, 2^8\}$ negligible. The erratic behavior of the computed spectral radius conjecturally emanates from the nonnormality of C_0. Figure 1 illustrates that the ϵ-pseudospectra of C_0 are much larger than the union of ϵ-discs centered at the spectrum, in accordance with section 5.1. As $\mathcal{S}_\epsilon(\mathsf{C}_0)$ is the aggregate of the spectra of all perturbed operators $\mathsf{C}_0 + \mathsf{C}_0'$ with $\|\mathsf{C}_0'\| \leq \epsilon$ (see [14, p. 208] or [10, p. 4]), i.e.,

$$\mathcal{S}_\epsilon(\mathsf{C}_0) = \{\zeta \in \mathbb{C} : \zeta \in \mathcal{S}(\mathsf{C}_0 + \mathsf{C}_0'), \|\mathsf{C}_0'\| \leq \epsilon\} \tag{5.29}$$

(in the appropriate norm) this implies that the spectrum is sensitive to perturbations of the operator. An alternative measure for this sensitivity is the condition of the eigenvalues; see, e.g., [11, p. 323]. For the results in Table 2, the condition of the largest eigenvalue exceeds 10^{10}.

The results in Table 2 indicate that $\operatorname{spr} \mathsf{C}_0 \propto \|\mathsf{C}_0\|_{H^1} \propto \tau$ as $\tau \to 0$. To verify this hypothesis, consider C_0 on the interval $s \in (0, \tau)$ and define an auxiliary variable $\xi := s/\tau$. For any admissible z with image $v := \mathsf{C}_0 z$ it holds that

$$\frac{d^2 v}{d\xi^2} \frac{1}{\tau^2} + v = -\frac{dz}{d\xi} \frac{1}{\tau}, \qquad \xi \in (0, 1). \tag{5.30}$$

Because $D^2 v$ is the principal term in the operator, the term v can be ignored as $\tau \to 0$. Equation (5.30) is then equivalent to $D^2 v = -\tau\, Dz$. Noting that τ appears as a multiplicative factor, the result is immediate. In general, for sufficiently small τ, the spectrum and pseudospectra of C_0 scale with τ. As τ increases, the principal term $D^2 v$ becomes a singular perturbation to v and the spectrum deforms; see also Figure 1. For sufficiently small τ, the proportionality of $\operatorname{spr} \mathsf{C}_0$ and $\|\mathsf{C}_0\|$ to τ indicates that the convergence of the subiteration process deteriorates linearly with an increase of the time interval. Let us also note that the results in Table 2 comply with the upper bound $\|\mathsf{C}_0\|_{H^1} \leq 2\tau$ derived in Appendix B. Moreover, the results indicate that the bound is reasonably sharp.

To illustrate the effect of nonnormality on the convergence of the subiteration method, the left and right plots in Figure 2, respectively, plot $\|\mathsf{C}_0^n\|_{H^1}$ on the polynomials $\mathcal{Z}_m$ $(= \|(\mathbf{Q} \cdot \mathbf{C}_0 \cdot \mathbf{Q}^{-1})^n\|)$ with $m = 2^8$ versus the iteration counter n for $2\mu/\nu = 1$ and representative lengths of the time interval τ, and for $\tau = 1$ and representative values of the parameter $2\mu/\nu$. In all cases, the spectral radius is less than 1 and the subiteration method is formally stable. However, monotone convergence occurs only if $\|\mathsf{C}_0\|_{H^1} \leq 1$. The figures illustrate that if $\|\mathsf{C}_0\|$ is large, then the error can increase by many orders of magnitude before the asymptotic convergence sets in. Note that this behavior is in accordance with the indication provided by the condition numbers $\kappa(\mathsf{C}_0)$. Furthermore, it is to be noted that the difference between the results in the right plot in Figure 2 emanates exclusively from a rescaling of the spectrum, as $2\mu/\nu$ appears as a multiplicative factor to the operator; cf. (4.9). The nonnormality of the underlying operators (in any suitable measure, e.g., $\kappa(\mathsf{C}_0)$ or $\|\mathsf{C}_0\|/\operatorname{spr} \mathsf{C}_0$) is

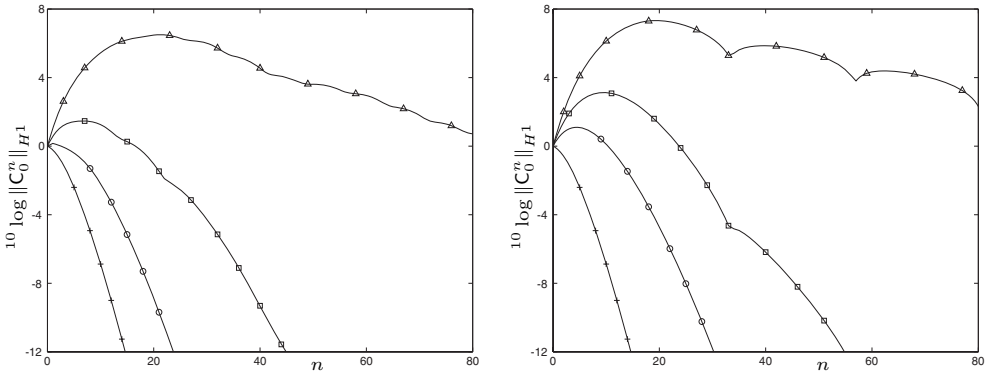

FIG. 2. *Convergence of subiteration:* $\|\mathsf{C}_0^n\|_{H^1}$ *on* $\mathcal{Z}_m$ $(m = 2^8)$ *with* (left) $2\mu/\nu = 1$ *and* $\tau = 10^0$ (+), $\tau = 10^{1/2}$ (○), $\tau = 10^1$ (□), $\tau = 10^{3/2}$ (△), *and* (right) $\tau = 1$ *and* $2\mu/\nu = 1$ (+), $2\mu/\nu = 5$ (○), $2\mu/\nu = 10$ (□), $2\mu/\nu = 20$ (△).

identical. This exemplifies that if the spectral radius is sufficiently small, then the effect of nonnormality on the convergence of the subiteration method is concealed.

By definition, the operator norm $\|\mathsf{C}_0^n\|_{H^1}$ is an upper bound on the convergence behavior pertaining to a particular element of H^1, i.e., $\|\mathsf{C}_0^n\|_{H^1} \geq \|\mathsf{C}_0^n z\|_{H^1}\|z\|_{H^1}^{-1}$ for all $z \in H^1$. The upper bound is sharp in the sense that there exists an element in H^1 for which equality holds. However, in practice, the initial error is typically confined to a proper subspace of H^1. For instance, if the solution is sufficiently regular and the initial approximation on a time interval is obtained by a k-order extrapolation of the solution on the previous time interval, then the initial error e is confined to a regular subspace of H^1 with, moreover, $[D^i e](0) = 0$ for all $i = 0, 1, \ldots, k-1$. The norm of C_0^n on this subspace can be much smaller, yielding $\|\mathsf{C}_0^n\|_{H^1}$ practically unsharp. To illustrate the effect of confinement of the initial error due to extrapolation, Figure 3 plots $\|\mathsf{C}_0^n z\|_{H^1}\|z\|_{H^1}^{-1}$ versus n for $\tau = 1$ and $2\mu/\nu = 10$, and $z(s) = s^k$, $k = 1, 2, 3, 4$. Note that s^k has $k-1$ vanishing derivatives at $s = 0$. Hence, we can conceive of s^k as a k-order-extrapolation error. Figure 3 indicates that the nonnormality-induced divergence is reduced with increasing k. Moreover, for large k, the discrepancy between $\|\mathsf{C}_0^n\|_{H^1}$ and $\|\mathsf{C}_0^n z\|_{H^1}\|z\|_{H^1}^{-1}$ can increase to several orders of magnitude.

6. Nonnormality of the subiteration operator. In this section we are concerned with the properties of the general characteristic operator , i.e., the operator including reflections.

6.1. Nonnormality of C. The normality of C can be disproved by deriving the associated adjoint operator and establishing that an admissible z exists that contradicts $\mathsf{C}^*\mathsf{C}z = \mathsf{C}\mathsf{C}^*z$. Let the space of admissible functions $\mathcal{Z}$ be defined as in section 5.3. Recalling the definition of the shift operator (4.12), from the sequence of identities

$$\langle \mathsf{H}_\nu^* v, z\rangle_{L^2} = \langle v, \mathsf{H}_\nu z\rangle_{L^2} = \int_\nu^\tau v(s)z(s-\nu)\,ds = \int_0^{\tau-\nu} v(s+\nu)z(s)\,ds \tag{6.1}$$

we readily identify the adjoint shift operator as

$$(\mathsf{H}_\nu^* z)(s) := \begin{cases} 0 & \nu \leq s < \tau, \\ z(s+\nu) & 0 < s < \tau - \nu. \end{cases} \tag{6.2}$$

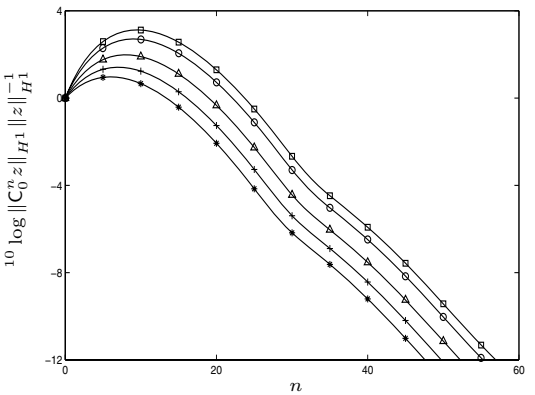

FIG. 3. *Convergence of subiteration:* $\|\mathsf{C}_0^n z\|_{H^1}\|z\|_{H^1}^{-1}$ *on* $\mathcal{Z}_m$ $(m = 2^8)$ *with* $\tau = 1$, $2\mu/\nu = 10$ *and* $z(s) = s^k$, $k = 1$ $(\circ)$, $k = 2$ $(\triangle)$, $k = 3$ $(+)$, *and* $k = 4$ $(*)$. *Norm* $\|\mathsf{C}_0^n\|_{H^1}$ *indicated by* $(\square)$.

Moreover, on account of (4.11) it holds that

$$\langle v, \mathsf{C}z\rangle_{L^2} = \big\langle v, \mathsf{C}_0 z + 2\textstyle\sum_j \mathsf{H}_{j\nu}\mathsf{C}_0 z\big\rangle_{L^2} = \big\langle \mathsf{C}_0^* v + 2\textstyle\sum_j \mathsf{C}_0^*\mathsf{H}_{j\nu}^* v, z\big\rangle_{L^2}. \tag{6.3}$$

One can infer that H_ν^* commutes with C_0^* and, hence,

$$\mathsf{C}^* = \left(\mathsf{I} + 2\sum_i^{\lfloor\tau/\nu\rfloor} \mathsf{H}_{i\nu}^*\right)\mathsf{C}_0^*. \tag{6.4}$$

The normality of C can now be disproved straightforwardly by establishing that there exists a $z \in \overline{\mathcal{Z}}$ such that $\mathsf{C}^*\mathsf{C}z \neq \mathsf{C}\mathsf{C}^* z$.

6.2. Approximation on polynomials. We consider the characteristic operator C on the polynomials $\mathcal{Z}_m$ on an interval $\mathcal{T} := (0, \tau)$ similarly as in section 5.4. The representation matrix $\mathbf{C}$ can be derived from the null-reflection matrix $\mathbf{C}_0$ and a shift matrix on the basis of (4.11). Recalling that θ_i designates the normalized Legendre polynomial of degree i, we define the representation matrix $\mathbf{H}_\nu$ of the shift operator H_ν according to (4.12) as

$$H_{ij}(\nu) := \langle \theta_i, \mathsf{H}_\nu \theta_j\rangle_{L^2} = \int_\nu^\tau \theta_i(s)\theta_j(s-\nu)\, ds. \tag{6.5}$$

Equation (4.11) leads to

$$\mathbf{C} := \left(\mathbf{I} + 2\sum_{j=1}^{\lfloor\tau/\nu\rfloor} \mathbf{H}^j(\nu)\right)\cdot \mathbf{C}_0. \tag{6.6}$$

By means of (6.6) we can establish the characteristics of C on $\mathcal{Z}_m$ through analogous expressions to (5.25)–(5.27).

The top and bottom plots in Figure 4, respectively, display the norm and the spectral radius of the subiteration operator C on $\mathcal{Z}_m$ with $m = 2^8$ versus ν^{-1} for $\tau = 10^{-2}, 10^{-1}, \ldots, 10^2$. Furthermore, the properly rescaled norm and spectral radius of the quasi-steady operator are displayed, viz., $(2/\nu)\,\mathrm{spr}\,\mathsf{C}_\infty$ and $(2/\nu)\,\|\mathsf{C}_\infty\|$ with $4\mu/\nu^2$ in (4.14) set to 1. For completeness, we mention that the representation matrix of

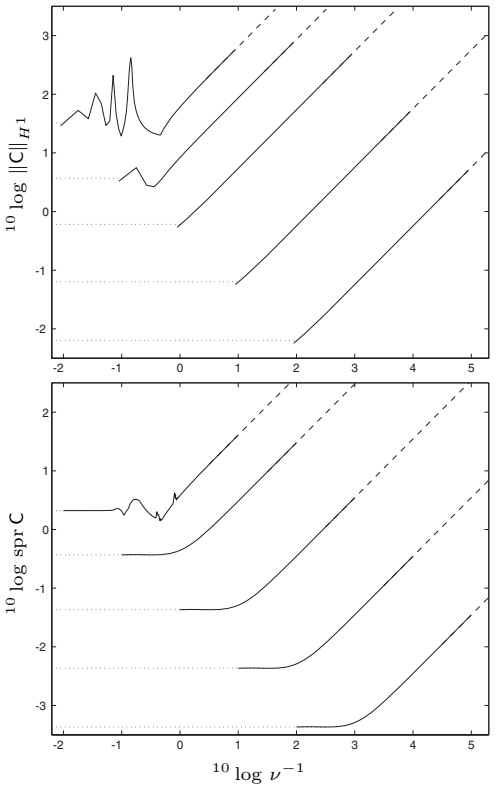

FIG. 4. *Plots* (log-log) *of the* H^1 *norm* (top) *and the spectral radius* (bottom) *of* C (—), C_0 $(\cdots)$ *and* C_∞ (– –, rescaled) *on* $\mathcal{Z}_m$ $(m = 2^8)$ *for* $\tau = 10^{-2}, 10^{-1}, \ldots, 10^2$ (bottom to top).

C_∞ with respect to $\{\theta_i\}$ is given by $\mathbf{C}_\infty := -\mathbf{A}^{-1} \cdot \mathbf{T}$ with $A_{ij} = \mathsf{A}(\theta_i, \theta_j)$ according to (5.22b) and $T_{ij} := \langle \theta_i, \mathsf{T}\theta_j \rangle_{L^2} = \delta_{ij} - \langle \theta_i, \theta_j(0) \rangle_{L^2}$. Note that if $\nu > \tau$, then $\mathsf{C} = \mathsf{C}_0$ and $\operatorname{spr}\mathsf{C}$ and $\|\mathsf{C}\|$ coincide with the corresponding entries in Table 2. The distance between the curves in Figure 4 indicates that $\operatorname{spr}\mathsf{C} \propto \|\mathsf{C}\|_{H^1} \propto \tau^2$ for appropriately small ν and τ ($\nu < \tau$). Noting that for any $z \in \mathcal{Z}$ with image $v := \mathsf{C}_\infty z$ it holds that

$$\frac{d^2 v}{d\xi^2} \frac{1}{\tau^2} + v = -(z - z(0)), \qquad \xi \in (0, 1), \tag{6.7}$$

by the same rationale as in section 5.4 we conclude that the norm and spectral radius of C_∞ are indeed proportional to τ^2 as $\tau \to 0$. In particular, this implies that for appropriately small ν and τ the convergence of the subiteration method degrades quadratically with increasing τ. Figure 4, moreover, indicates that for small τ the spectral radius of C is insensitive to a few reflections, but its norm is not: $\operatorname{spr}\mathsf{C}$ remains approximately constant upto $\tau/\nu = 10$, but $\|\mathsf{C}\|$ increases immediately if τ/ν exceeds 1. For large τ, the spectral radius and the norm of C behave erratically in the transition from C_0 to C_∞. We shall not further pursue the intricacies of this transition.

To demonstrate the effect of nonnormality on the convergence of the subiteration method in the presence of reflections, the top and bottom plots in Figure 5 plot $\|\mathsf{C}^n\|_{H^1}$ on $\mathcal{Z}_m$ $(= \|(\mathbf{Q} \cdot \mathbf{C} \cdot \mathbf{Q}^{-1})^n\|)$ with $m = 2^8$ versus the iteration counter n for $\tau/\nu = 2^2, 2^3, \ldots, 2^7$, and for $\tau = 1$ and $2\mu/\nu = 2$, and $\tau = 10^2$ and $2\mu/\nu = 0.2$, respectively. The values of $2\mu/\nu$ have been selected such that $\operatorname{spr}\mathsf{C} < 1$ in all

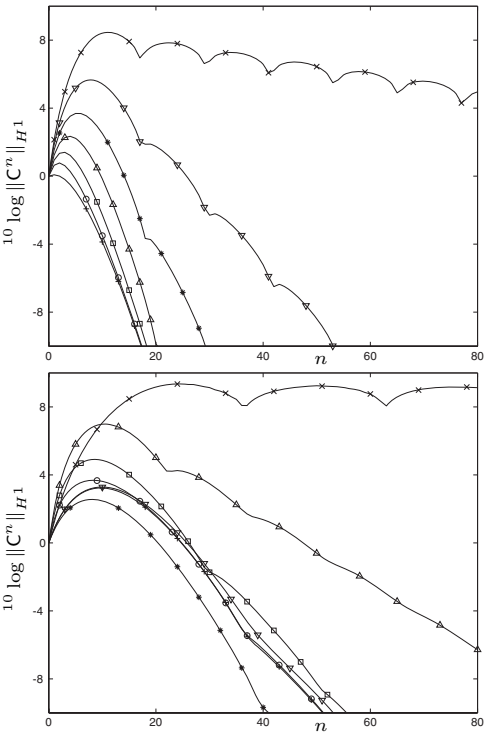

FIG. 5. *Convergence of subiteration:* $\|\mathsf{C}^n\|_{H^1}$ *on* $\mathcal{Z}_m$ $(m = 2^8)$ *with* $\tau = 1$ *and* $2\mu/\nu = 2$ (top), $\tau = 10^2$ *and* $2\mu/\nu = 0.2$ (bottom), *and* $\tau/\nu < 1$ (+), $\tau/\nu = 2^2$ ($\circ$), $\tau/\nu = 2^3$ ($\square$), $\tau/\nu = 2^4$ ($\triangle$), $\tau/\nu = 2^5$ ($*$) $\tau/\nu = 2^6$ ($\triangledown$), *and* $\tau/\nu = 2^7$ ($\times$).

cases. Figure 5 corroborates that the asymptotic convergence of the subiteration method is insensitive to a few reflections, in conformity with the aforementioned insensitivity of the spectral radius. However, as indicated by the sensitivity of the norm, the initial convergence behavior depends notably on the number of reflections. Furthermore, the figure shows that for $\tau = 1$ both the initial divergence and the asymptotic-convergence rate deteriorate gradually with decreasing ν. The gradual deterioration is in accordance with the smooth transition from $\operatorname{spr}\mathsf{C}_0$ to $\operatorname{spr}\mathsf{C}_\infty$ and from $\|\mathsf{C}_0\|$ to $\|\mathsf{C}_\infty\|$ as ν decreases in Figure 4. For $\tau = 10^2$ the convergence behavior behaves erratically with increasing τ/ν, in accordance with the erratic behavior of $\operatorname{spr}\mathsf{C}$ and $\|\mathsf{C}\|$ in the transition from C_0 to C_∞. On account of the nonnormality of the subiteration process, the error can again increase by many orders of magnitude before asymptotic convergence sets in.

7. Conclusion. We investigated the basic subiteration method for solving the aggregated equations in fluid-structure-interaction problems, on the basis of a prototypical model problem. An important new result is that the subiteration method is characterizable by recursion of a nonnormal operator. This implies that the norm and spectral radius of the operator are disparate, reflecting in profoundly dissimilar transient and asymptotic convergence behavior of the subiteration method. Convergence can be nonmonotonous and divergence can precede the asymptotic convergence, despite formal stability. By means of approximation on polynomials we established that the transient divergence can in fact amplify the initial error by many orders of

magnitude. Hence, the nonnormality induces a severe degradation in the robustness and efficiency of the subiteration method.

Auxiliary information provided by the analysis concerns the dependence of the stability and convergence of the subiteration method on the physical parameters in the problem and on the computational time step. We established that the convergence rate of the subiteration method is generally proportional to the ratio of the characteristic fluid mass over the structure mass. In the absence of reflections the convergence rate depends linearly on the ratio of the characteristic structure time to the characteristic fluid time. As the number of reflections increases, this dependence becomes quadratic. Moreover, in the absence of reflections the convergence rate is uniformly proportional to the time-step size. In particular, this proportionality implies that for appropriately small time steps, only two iterations are required for convergence to sufficient accuracy.

It is anticipated that the results generalize mutatis mutandis to other fluid-structure-interaction problems. In particular, we conjecture that the nonnormality of the subiteration method is independent of the underlying problem.

Appendix A. The generalized nonlinear Lax–Milgram theorem. Let $(\mathcal{U}, \langle\cdot,\cdot\rangle_{\mathcal{U}})$ and $(\mathcal{V}, \langle\cdot,\cdot\rangle_{\mathcal{V}})$ be two real Hilbert spaces with corresponding norms $\|\cdot\|_{\mathcal{U}}$ and $\|\cdot\|_{\mathcal{V}}$. Let the functional $\mathsf{P} : \mathcal{V} \times \mathcal{U} \mapsto \mathbb{R}$ be linear in its first argument and possibly nonlinear in its second argument, and let $\mathsf{p} : \mathcal{V} \mapsto \mathbb{R}$ be a linear functional. Sufficient conditions for the existence of a unique solution to the variational problem

$$\mathsf{P}(v,u) = \mathsf{p}(v) \qquad \forall v \in \mathcal{V} \tag{A.1}$$

are:

(i) p is a continuous linear functional on $\mathcal{V}$,
(ii) $\mathsf{P}(\cdot,u)$ is a continuous linear functional on $\mathcal{V}$ for all $u \in \mathcal{U}$,
(iii) $\inf_{\substack{u,u'\in\mathcal{U}\\ u\neq u'}} \sup_{0\neq v\in\mathcal{V}} \frac{|\mathsf{P}(v,u')-\mathsf{P}(v,u)|}{\|u'-u\|_{\mathcal{U}}\|v\|_{\mathcal{V}}} \geq C_1 > 0$,
(iv) $|\mathsf{P}(v,u') - \mathsf{P}(v,u)| \leq C_2\|u'-u\|_{\mathcal{U}}\|v\|_{\mathcal{V}} \qquad \forall u,u' \in \mathcal{U}$ and $\forall v \in \mathcal{V}$,
(v) $\sup_{u\in\mathcal{U}} |\mathsf{P}(v,u)| > 0 \quad \forall v \in \mathcal{V}\setminus\{0\}$

for certain positive constants C_1 and C_2.

The proof proceeds in a similar manner as for the linear case in [18, p. 316 ff.]. By (ii) and the Riesz representation theorem, for each fixed $u \in \mathcal{U}$ there exists a unique element $\Lambda_{\mathsf{P}}u$ of $\mathcal{V}$ such that $\mathsf{P}(v,u) = \langle v, \Lambda_{\mathsf{P}}u\rangle_{\mathcal{V}}$ for all $v \in \mathcal{V}$. This correspondence defines an operator $\Lambda_{\mathsf{P}} : \mathcal{U} \mapsto \mathcal{V}$. Similarly, by (i) and the Riesz theorem, there exists a $v_{\mathsf{p}} \in \mathcal{V}$ such that $\mathsf{p}(v) = \langle v, v_{\mathsf{p}}\rangle_{\mathcal{V}}$ for all $v \in \mathcal{V}$. Hence, the variational problem is equivalent to the operator equation $\Lambda_{\mathsf{P}}u = v_{\mathsf{p}}$. The existence of a unique solution to the operator equation is ensured if the operator $\Lambda_{\mathsf{P}} : \mathcal{U} \mapsto \mathcal{V}$ is bijective, i.e., if Λ_{P} is surjective and injective; see [28, pp. 16–17].

To prove the injectivity of Λ_{P}, we must establish that $\Lambda_{\mathsf{P}}u' = \Lambda_{\mathsf{P}}u$ implies $u' = u$ or, equivalently, that $\|\Lambda_{\mathsf{P}}u' - \Lambda_{\mathsf{P}}u\|_{\mathcal{V}} = 0$ implies $\|u'-u\|_{\mathcal{U}} = 0$. By property (iii) it holds that

$$\begin{aligned}\|\Lambda_{\mathsf{P}}u' - \Lambda_{\mathsf{P}}u\|_{\mathcal{V}} &= \sup_{0\neq v\in\mathcal{V}} \frac{|\langle v, \Lambda_{\mathsf{P}}u' - \Lambda_{\mathsf{P}}u\rangle_{\mathcal{V}}|}{\|v\|_{\mathcal{V}}} = \sup_{0\neq v\in\mathcal{V}} \frac{|\langle v, \Lambda_{\mathsf{P}}u'\rangle_{\mathcal{V}} - \langle v, \Lambda_{\mathsf{P}}u\rangle_{\mathcal{V}}|}{\|v\|_{\mathcal{V}}} \\ &= \sup_{0\neq v\in\mathcal{V}} \frac{|\mathsf{P}(v,u') - \mathsf{P}(v,u)|}{\|v\|_{\mathcal{V}}} \geq C_1\|u'-u\|_{\mathcal{U}}\end{aligned} \tag{A.2}$$

for all u' and u in $\mathcal{U}$. Hence, injectivity is ascertained.

To prove the surjectivity of Λ_{P}, we must verify that $\Lambda_{\mathsf{P}}\mathcal{U} = \mathcal{V}$, i.e., the range $\mathcal{R}(\Lambda_{\mathsf{P}})$ of the operator Λ_{P} with domain $\mathcal{U}$ coincides with $\mathcal{V}$. To this end, we show that $\mathcal{R}(\Lambda_{\mathsf{P}})$ is closed and, moreover, that its orthogonal complement in $\mathcal{V}$ is empty. To establish closedness of $\mathcal{R}(\Lambda_{\mathsf{P}})$, we note that for any pair u_n and u_m in $\mathcal{U}$ it holds that

$$\|\Lambda_{\mathsf{P}}u_n - \Lambda_{\mathsf{P}}u_m\|_{\mathcal{V}} = \sup_{0\neq v\in\mathcal{V}} \frac{|\langle v, \Lambda_{\mathsf{P}}u_n\rangle_{\mathcal{V}} - \langle v, \Lambda_{\mathsf{P}}u_m\rangle_{\mathcal{V}}|}{\|v\|_{\mathcal{V}}} = \sup_{0\neq v\in\mathcal{V}} \frac{|\mathsf{P}(v,u_n) - \mathsf{P}(v,u_m)|}{\|v\|_{\mathcal{V}}}$$

$$\leq C_2\|u_n - u_m\|_{\mathcal{U}}. \tag{A.3}$$

Hence, any Cauchy sequence $\{u_n\}$ in $\mathcal{U}$ generates a Cauchy sequence $\{\Lambda_{\mathsf{P}}u_n\}$ in $\mathcal{R}(\Lambda_{\mathsf{P}})$ and $u_n \to u \in \mathcal{U}$ implies $\Lambda_{\mathsf{P}}u_n \to \Lambda_{\mathsf{P}}u \in \mathcal{R}(\Lambda_{\mathsf{P}})$. Therefore, $\mathcal{R}(\Lambda_{\mathsf{P}})$ is closed. Now suppose that the orthogonal complement $\mathcal{R}(\Lambda_{\mathsf{P}})^{\perp}$ of $\mathcal{R}(\Lambda_{\mathsf{P}})$ in $\mathcal{V}$ is nonempty. Then there exists a $v' \in \mathcal{R}(\Lambda_{\mathsf{P}})^{\perp}$ such that $\langle v', \Lambda_{\mathsf{P}}u\rangle_{\mathcal{V}} = 0$ for all $u \in \mathcal{U}$. However, this is equivalent to $|\langle v', \Lambda_{\mathsf{P}}u\rangle_{\mathcal{V}}| = |\mathsf{P}(v', u)| = 0$ for all $u \in \mathcal{U}$, in contradiction to stipulation (v). Hence, such a v' is nonexistent. This implies that $\mathcal{V} = \mathcal{R}(\Lambda_{\mathsf{P}}) \oplus \mathcal{R}(\Lambda_{\mathsf{P}})^{\perp} = \mathcal{R}(\Lambda_{\mathsf{P}}) \oplus \emptyset = \mathcal{R}(\Lambda_{\mathsf{P}})$. Hence, the operator Λ_{P} is surjective.

Appendix B. Unboundedness of $\|\mathsf{C}_0\|_{L^2}$ and boundedness of $\|\mathsf{C}_0\|_{H^1}$. Considering a bounded open interval $\mathcal{T} := (0, \tau)$, the objective is to establish that (i) $\|\mathsf{C}_0\|_{L^2} = \infty$ and (ii) $\|\mathsf{C}_0\|_{H^1} \leq 2\tau < \infty$.

(i) To show that C_0 is unbounded on $L^2(\mathcal{T})$ we consider the sequence of continuous functions $\{z_n\}$ with elements

$$z_n(s) := \begin{cases} 1 - \sqrt{1 - (ns-1)^2} & \text{if } 0 \leq s \leq 1/n, \\ 0 & \text{if } s > 1/n. \end{cases} \tag{B.1}$$

The sequence $\{z_n\}$ is a Cauchy sequence in L^2 and, hence, $z_n \to z \in L^2$ as $n \to \infty$. It is important to note that $\|z_n\|_{L^2(\mathcal{T})} = O(1/\sqrt{n})$ as $n \to \infty$ for any τ independent of n. For the image of z_n under C_0 according to (4.10) we obtain

(B.2)

$$v_n := \mathsf{C}_0 z_n = c_1 \sin(s) + c_2 \cos(s) - \sin(s) \int \sin(s)\, z_n(s)\, ds - \cos(s) \int \cos(s)\, z_n(s)\, ds,$$

the constants c_1 and c_2 being determined by the homogeneous initial conditions on v_n. For $s > 1/n$, v_n can be expanded asymptotically as

$$v_n = \left(1 + \left(\frac{\pi}{2} - \frac{5}{6}\right)\frac{1}{n^2} + O\Big(\frac{1}{n^4}\Big)\right)\sin(s) \tag{B.3}$$

$$+ \left(\left(\frac{\pi}{2} - 1\right)\frac{1}{n} + \left(\frac{1}{2} - \frac{5\pi}{16}\right)\frac{1}{n^3} + O\Big(\frac{1}{n^5}\Big)\right)\cos(s), \tag{B.4}$$

as $n \to \infty$. The expression for v_n in the interval $0 \leq s \leq 1/n$ is not required in what follows. From (B.3) it follows that

$$\|\mathsf{C}_0\|_{L^2} := \sup_{0\neq z\in L^2} \frac{\|\mathsf{C}_0 z\|_{L^2}}{\|z\|_{L^2}} \geq \frac{\|v_n\|_{L^2}}{\|z_n\|_{L^2}} \to \infty \quad \text{as } n \to \infty, \tag{B.5}$$

which completes the proof.

(ii) Denoting by v the image of an arbitrary function $z \in H^1$ under C_0 and setting $2\mu/\nu := 1$ for convenience, (4.10) implies

$$D^2 v + v = -Dz,\ v(0) = 0,\ Dv(0) = 0. \tag{B.6}$$

Multiplying the differential equation by Dv and integrating from 0 to s, we obtain

$$\begin{aligned} -\int_0^s Dv(\xi)\, Dz(\xi)\, d\xi &= \int_0^s Dv(\xi)\left(D^2 v(\xi) + v(\xi)\right) d\xi \\ &= \int_0^s \frac{d}{d\xi}\Big(\frac{1}{2}[Dv(\xi)]^2 + \frac{1}{2}[v(\xi)]^2\Big) d\xi = \frac{1}{2}[Dv(s)]^2 + \frac{1}{2}[v(s)]^2. \end{aligned} \tag{B.7}$$

The final identity in (B.7) is obtained by invoking the initial conditions. Hence,

$$\begin{aligned} \frac{1}{2}\|v\|_{H^1}^2 = \frac{1}{2}\int_0^\tau [Dv(s)]^2 + [v(s)]^2\, ds &= \left| \int_0^\tau \int_0^s Dv(\xi)\, Dz(\xi)\, d\xi\, ds \right| \\ \leq \int_0^\tau \|Dv\|_{L^2(0,s)}\, \|Dz\|_{L^2(0,s)}\, ds &\leq \tau \|Dv\|_{L^2(\mathcal{T})}\, \|Dz\|_{L^2(\mathcal{T})} \leq \tau \|v\|_{H^1(\mathcal{T})}\, \|z\|_{H^1(\mathcal{T})}. \end{aligned} \tag{B.8}$$

The first upper bound is a consequence of Schwarz' inequality (see, e.g., [28]). Equation (B.8) implies $\|\mathsf{C}_0 z\|_{H^1} \leq 2\tau \|z\|_{H^1}$ and, since z is arbitrary, $\|\mathsf{C}_0\|_{H^1} \leq 2\tau$. This was to be proved.

SECOND-ORDER CONE PROGRAMMING METHODS FOR TOTAL VARIATION-BASED IMAGE RESTORATION*

DONALD GOLDFARB† AND WOTAO YIN†

Abstract. In this paper we present optimization algorithms for image restoration based on the total variation (TV) minimization framework of Rudin, Osher, and Fatemi (ROF). Our approach formulates TV minimization as a second-order cone program which is then solved by interior-point algorithms that are efficient both in practice (using nested dissection and domain decomposition) and in theory (i.e., they obtain solutions in polynomial time). In addition to the original ROF minimization model, we show how to apply our approach to other TV models, including ones that are not solvable by PDE-based methods. Numerical results on a varied set of images are presented to illustrate the effectiveness of our approach.

Key words. image denoising, total variation, second-order cone programming, interior-point methods, nested dissection, domain decomposition

AMS subject classifications. 68U10, 65K10, 90C25, 90C51

DOI. 10.1137/040608982

1. Introduction.

Digital images, no matter what their source, usually contain noise. Consequently, a fundamental problem in image processing is the restoration or denoising of such images. Early methods for doing this were based on least squares and had the unfortunate property of either smoothing edges or creating spurious oscillations near edges, i.e., the well-known ringing phenomenon. In [19], Rudin, Osher, and Fatemi (ROF) proposed a method based on minimizing the total variation (TV) of the image. Specifically, they proposed solving the minimization problem

$$\begin{aligned} &\min && \int_\Omega \|\nabla u\| \, \mathrm{d}x \\ &\text{subject to (s.t.)} && u + v = f, \\ &&& \int_\Omega |v|^2 \, \mathrm{d}x \le \sigma^2, \end{aligned} \tag{1.1}$$

where $\|\nabla u\|$ denotes the Euclidean norm of ∇u at each x, Ω is an open (typically rectangular) domain in $\mathbb{R}^2$, $f : \Omega \to \mathbb{R}$ is a given noisy image in $L^2(\Omega)$, u is the computed estimate of the original image, and σ^2 is an estimate of the variance of the noise in the image f. Minimizing the TV of u allows u to have discontinuities; hence edges and important features in the original image are preserved by the ROF approach.

Rather than solving the constrained minimization problem (1.1), ROF and subsequent researchers also considered the unconstrained minimization problem

$$\min \quad \int_\Omega \|\nabla u\| \, \mathrm{d}x + \lambda \int_\Omega |f - u|^2 \, \mathrm{d}x, \tag{1.2}$$

which yields the same solution as (1.1) for a suitable choice of the Lagrange multiplier λ (see, e.g., [6]). To solve (1.2), ROF proposed using an artificial time stepping method to compute the steady state solution u of the parabolic system $\frac{\partial u}{\partial t} = g(u)$ with initial condition $u = f$ and homogeneous Neumann boundary conditions, where

$$g(u) \equiv \frac{1}{2\lambda} \nabla \cdot \left(\frac{\nabla u}{\|\nabla u\|} \right) + f - u. \tag{1.3}$$

Note that $g(u) = 0$ is the Euler–Lagrange equation for (1.2), which is a necessary and sufficient condition for u to be a solution of the convex minimization problem (1.2). Other algorithms that have been proposed for solving problem (1.2) can be found in [5, 7, 9, 12, 13, 17, 23].

We propose here a direct method for solving (1.1) based on the observation that a discretized version of this convex optimization problem can be reformulated as a second-order cone program (SOCP). One can also reformulate a discretized version of the convex unconstrained minimization problem (1.2) as an SOCP. Our approach is to solve the SOCP representation of (1.1) by an interior-point method taking advantage of the specific structure imparted to the SOCP by the image restoration problem and the TV-based denoising method. Of the many methods that have been proposed for solving (1.1) (or (1.2)) or related problems, it is most closely related to the one proposed by Chan, Golub, and Mulet in [9] based on the interior-point algorithm of Andersen et al. [3].

In the next section we provide a formal definition of an SOCP, present the discretized version of problem (1.1) that we will address, and introduce some notation. In section 3 we give an SOCP formulation of the ROF-based image restoration problem. We also present a dual formulation of problem (1.1) that is essentially equivalent to the dual formulation proposed by Chambolle [5] and show how it can be reformulated as an SOCP. In section 4 we discuss implementational aspects that enable interior-point methods to solve these problems efficiently in practice. In particular, we show how nested dissection can be used to reduce storage and computational effort. A detailed analysis is presented in the appendix. In theory the solution is obtained in polynomial time. Section 5 contains our numerical results. It also contains a discussion of how "overlapping domain decomposition" can be used to further reduce storage and run times. Finally, in section 6 we discuss how our approach can be applied to other image processing models. In particular, we show that it can be applied to the model introduced by Meyer in [15] that is not solvable by PDE-based methods.

2. Notation and preliminaries. The images we discuss in this paper are defined as two-dimensional $n \times n$ matrices in $\mathbb{R}^{n^2}$. We restrict our discussion to square domains only for the sake of simplicity. Let f be an observed image, which, in real applications, is a noisy version of an original image u. By introducing the noise term v, f and u have the following relation:

$$f_{i,j} = u_{i,j} + v_{i,j} \quad \text{for } i, j = 1, \ldots, n. \tag{2.1}$$

$f_{i,j}$ and $u_{i,j}$ are the values of the observed image and the original image, respectively, at pixel (i, j). Let ∂^+ be the discrete differential operator defined by

$$\partial^+ u_{i,j} \stackrel{\text{def}}{=} \left((\partial_x^+ u)_{i,j}, (\partial_y^+ u)_{i,j} \right), \tag{2.2}$$

where

$$\begin{aligned} (\partial_x^+ u)_{i,j} &\stackrel{\text{def}}{=} u_{i+1,j} - u_{i,j} \qquad \text{for } i = 1, \ldots, n-1, j = 1, \ldots, n, \\ (\partial_y^+ u)_{i,j} &\stackrel{\text{def}}{=} u_{i,j+1} - u_{i,j} \qquad \text{for } i = 1, \ldots, n, j = 1, \ldots, n-1. \end{aligned} \tag{2.3}$$

In addition, the differentials on the image domain boundary, $(\partial_x^+ u)_{n,j}$ for $j = 1, \ldots, n$ and $(\partial_y^+ u)_{i,n}$ for $i = 1, \ldots, n$, are defined to be zero. Consequently, they do not contribute to the total variation, which in the discrete case is defined by

$$TV(u) \stackrel{\text{def}}{=} \sum_{1 \le i,j \le n} \|\partial^+ u_{i,j}\|, \tag{2.4}$$

where $\|\cdot\|$ denotes the Euclidean norm, i.e., $\|\partial^+ u_{i,j}\| = (((\partial_x^+ u)_{i,j})^2 + ((\partial_y^+ u)_{i,j})^2)^{1/2}$.

Applying our definitions of f, u, v, and $\partial^+ u$ to the ROF restoration model (1.1), we obtain the finite-dimensional minimization problem

$$\begin{array}{ll} \min & \displaystyle\sum_{1 \le i,j \le n} \|\partial^+ u_{i,j}\| \\ \text{s.t.} & u + v = f, \\ & \|v\| \le \sigma. \end{array} \tag{2.5}$$

Problem (2.5) can be reformulated as an SOCP, the [illegible] of which we now define. The vector of variables $\mathbf{x} \in \mathbb{R}^n$ in a standard form SOCP is composed of subvectors $\mathbf{x_i} \in \mathbb{R}^{n_i}$—i.e., $\mathbf{x} \equiv (\mathbf{x_1}; \mathbf{x_2}; \ldots; \mathbf{x_r})$—where $n = n_1 + n_2 + \cdots + n_r$ and each subvector $\mathbf{x_i}$ must lie in an elementary [illegible] of dimension n_i

$$\mathcal{K}^{n_i} \equiv \{\mathbf{x_i} = (x_i^0; \bar{\mathbf{x}}_\mathbf{i}) \in \mathbb{R} \times \mathbb{R}^{n_i - 1} : \|\bar{\mathbf{x}}_\mathbf{i}\| \le x_i^0\}.$$

Definition 2.1. [illegible] [1]

$$\begin{array}{ll} \min & \mathbf{c_1}^\top \mathbf{x_1} + \cdots + \mathbf{c_r}^\top \mathbf{x_r} \\ \text{s.t.} & A_1 \mathbf{x_1} + \cdots + A_r \mathbf{x_r} = \mathbf{b}, \\ & \mathbf{x_i} \in \mathcal{K}^{n_i}, \quad \text{for } i = 1, \ldots, r, \end{array} \tag{2.6}$$

[illegible] $\mathbf{c_i} \in \mathbb{R}^{n_i}$ [illegible] $A_i \in \mathbb{R}^{m \times n_i}$ *for* $i = 1, \ldots, r$ [illegible] $\mathbf{b} \in \mathbb{R}^m$

Since a one-dimensional second-order cone corresponds to a semi-infinite ray, the above standard form SOCP can accommodate nonnegative variables. In fact if all cones $\mathcal{K}_i$ are one-dimensional, then the above SOCP is just a standard form linear program.

If we define $\mathcal{K}$ to be the Cartesian product $\mathcal{K} = \mathcal{K}^{n_1} \times \cdots \times \mathcal{K}^{n_r}$ and the vector $\mathbf{c}$ and the matrix A by $\mathbf{c} = (\mathbf{c_1}; \ldots; \mathbf{c_r})$, and $A = (A_1, \ldots, A_r)$, then the above SOCP can be written compactly as

$$\begin{array}{ll} \min & \mathbf{c}^\top \mathbf{x} \\ \text{s.t.} & A\mathbf{x} = \mathbf{b}, \\ & \mathbf{x} \in \mathcal{K} \end{array} \tag{2.7}$$

A crucial aspect of the above SOCP is that the cone $\mathcal{K}$ is pointed, closed, convex, and [illegible]—i.e., the [illegible] $\mathcal{K}^* \equiv \{\mathbf{z} : \mathbf{x}^\top \mathbf{z} \ge 0 \ \forall \mathbf{x} \in \mathcal{K}\} = \mathcal{K}$ as is the cone corresponding to the nonnegative orthant in $\mathbb{R}^n$. This similarity between SOCPs and linear programs is more than superficial; as is the case for linear programs, SOCPs can be solved in polynomial time by interior-point methods. This is the approach we propose in this paper.

3. Second-order cone programming formulation.

3.1. Primal formulation. By introducing $t_{i,j}$ and the relations $((\partial_x^+ u)_{i,j})^2 + ((\partial_y^+ u)_{i,j})^2 \le (t_{i,j})^2$ for each pixel $i,j = 1,\dots,n$, and including equations (2.3) that define $(\partial_x^+ u)_{i,j}$ and $(\partial_y^+ u)_{i,j}$, problem (2.5) can be reformulated as

$$
\begin{aligned}
\min \quad & \sum_{1\le i,j\le n} t_{i,j} \\
\text{s.t.} \quad & u_{i,j} + v_{i,j} = f_{i,j} && \text{for } i,j = 1,\dots,n, \\
& -(\partial_x^+ u)_{i,j} + (u_{i+1,j} - u_{i,j}) = 0 && \text{for } i = 1,\dots,n-1,\ j = 1,\dots,n, \\
& -(\partial_y^+ u)_{i,j} + (u_{i,j+1} - u_{i,j}) = 0 && \text{for } i = 1,\dots,n,\ j = 1,\dots,n-1, \\
& (\partial_x^+ u)_{n,j} = 0 && \text{for } j = 1,\dots,n, \\
& (\partial_y^+ u)_{i,n} = 0 && \text{for } i = 1,\dots,n, \\
& v_0 = \sigma, \\
& (t_{i,j}; (\partial_x^+ u)_{i,j}; (\partial_y^+ u)_{i,j}) \in \mathcal{K}^3 && \text{for } i,j = 1,\dots,n, \\
& (v_0; v) \in \mathcal{K}^{n^2+1},
\end{aligned}
\tag{3.1}
$$

where, for $i,j = 1,\dots,n$, $u_{i,j}$, $(\partial_x^+ u)_{i,j}$, $(\partial_y^+ u)_{i,j}$, $v_{i,j}$, and $t_{i,j}$ are treated as variables and $f_{i,j}$ for $i,j = 1,\dots,n$ and σ as constants.

Although solving for u is our ultimate goal, in the above formulation u can be eliminated and $(\partial_x^+ u)_{n,j} = 0$ for $j = 1,\dots,n$ and $(\partial_y^+ u)_{i,n} = 0$ for $i = 1,\dots,n$ can be removed; hence, (3.1) simplifies to

$$
\begin{aligned}
\min \quad & \sum_{1\le i,j\le n,(i,j)\ne(n,n)} t_{i,j} \\
\text{s.t.} \quad & (\partial_x^+ u)_{i,j} + (v_{i+1,j} - v_{i,j}) = f_{i+1,j} - f_{i,j} && \text{for } i = 1,\dots,n-1,\ j = 1,\dots,n, \\
& (\partial_y^+ u)_{i,j} + (v_{i,j+1} - v_{i,j}) = f_{i,j+1} - f_{i,j} && \text{for } i = 1,\dots,n,\ j = 1,\dots,n-1, \\
& v_0 = \sigma, \\
& (t_{i,j}; (\partial_x^+ u)_{i,j}; (\partial_y^+ u)_{i,j}) \in \mathcal{K}^3 && \text{for } i,j = 1,\dots,n-1, \\
& (t_{n,j}; (\partial_y^+ u)_{n,j}) \in \mathcal{K}^2 && \text{for } j = 1,\dots,n-1, \\
& (t_{i,n}; (\partial_x^+ u)_{i,n}) \in \mathcal{K}^2 && \text{for } i = 1,\dots,n-1, \\
& (v_0; v) \in \mathcal{K}^{n^2+1}.
\end{aligned}
\tag{3.2}
$$

After solving the above problem, u can be recovered via $u_{i,j} = f_{i,j} - v_{i,j}$ for $i,j = 1,\dots,n$.

Problem (3.2) is a standard form SOCP. It has $4n^2 - 2n$ variables, $2n(n-1)+1$ equality constraints, $(n-1)^2$ three-dimensional and $2(n-1)$ two-dimensional second-order cone constraints, and one large second-order cone constraint.

3.2. Alternative (dual) formulations. Recalling the definition (2.2) of $\partial^+ u_{i,j}$, let us define $\partial^+ u \equiv \{\partial^+ u_{i,j}\} \in \mathbb{R}^{n^2} \times \mathbb{R}^{n^2}$. If we further define $q_{i,j} \equiv (q_{i,j}^1, q_{i,j}^2)$ and

$(\mathrm{div}q) \equiv \{(\mathrm{div}q)_{i,j}\}$, where $(\mathrm{div}q)_{i,j} = (\partial_x^- q^1)_{i,j} + (\partial_y^- q^2)_{i,j}$ and

$$
\begin{aligned}
&(\partial_x^- q^1)_{i,j} \stackrel{\text{def}}{=} q^1_{i,j} - q^1_{i-1,j} && \text{for } i = 2,\dots,n-1, j = 1,\dots,n,\\
&(\partial_x^- q^1)_{1,j} \stackrel{\text{def}}{=} q^1_{1,j} && \text{for } j = 1,\dots,n,\\
&(\partial_x^- q^1)_{n,j} \stackrel{\text{def}}{=} -q^1_{n-1,j} && \text{for } j = 1,\dots,n,\\
&(\partial_y^- q^2)_{i,j} \stackrel{\text{def}}{=} q^2_{i,j} - q^2_{i,j-1} && \text{for } i = 1,\dots,n, j = 2,\dots,n-1,\\
&(\partial_y^- q^2)_{i,1} \stackrel{\text{def}}{=} q^2_{i,1} && \text{for } i = 1,\dots,n,\\
&(\partial_y^- q^2)_{i,n} \stackrel{\text{def}}{=} -q^2_{i,n-1} && \text{for } i = 1,\dots,n-1,
\end{aligned}
\tag{3.3}
$$

then $q \in \mathbb{R}^{n^2} \times \mathbb{R}^{n^2}$ and

$$
\langle q, \partial^+ u\rangle = \sum_{i,j} (q^1_{i,j}(\partial_x^+ u)_{i,j} + q^2_{i,j}(\partial_y^+ u)_{i,j}) = \sum_{i,j} -(\mathrm{div}q)_{i,j} u_{i,j} = \langle -\mathrm{div}q, u\rangle. \tag{3.4}
$$

Let z^* denote the optimal value of

$$
\begin{aligned}
\min \quad & \sum_{1\le i,j\le n} \|\partial^+ u_{i,j}\| \\
\text{s.t.} \quad & \|u - f\|^2 \le \sigma^2.
\end{aligned}
\tag{3.5}
$$

Using the fact that $\|a\| = \max_{\|b\|\le 1} a^\top b$ (an immediate consequence of the Cauchy–Schwarz inequality), if we define the set

$$
S \equiv \{q \in \mathbb{R}^{n^2} \times \mathbb{R}^{n^2} : \|q_{i,j}\| \equiv \|(q^1_{i,j}, q^2_{i,j})\| \le 1 \ \forall\ i,j\},
$$

then

$$
z^* = \min_{\|u-f\|^2\le\sigma^2} \max_{q\in S} \langle q, \partial^+ u\rangle \tag{3.6}
$$

$$
= \min_{\|u-f\|^2\le\sigma^2} \max_{q\in S} \langle -\mathrm{div}q, u\rangle \tag{3.7}
$$

$$
= \max_{q\in S} \min_{\|u-f\|^2\le\sigma^2} \langle -\mathrm{div}q, u\rangle. \tag{3.8}
$$

From the inner minimization, u must satisfy $u = f + \frac{\mathrm{div}q}{\|\mathrm{div}q\|}\sigma$. Hence, substituting this expression for u and letting $p = -q$ yields the following maximization problem:

$$
z^* = \max_{p\in S} \{\langle \mathrm{div}p, f\rangle - \sigma\|\mathrm{div}p\|\}. \tag{3.9}
$$

In [5], Chambolle derived a dual formulation of a discrete formulation of problem (1.2), which is the Lagrangian version of (3.5), and proposed a method for solving this formulation using a PDE approach. A related dual formulation is presented in [21] and [4]. We now show how to derive Chambolle's formulation in a direct manner. Specifically, Chambolle considered

$$
\tilde{z}^* = \min_u \left\{ \frac{\|u-f\|^2}{2\lambda} + \sum_{1\le i,j\le n} \|\partial^+ u_{i,j}\| \right\}, \tag{3.10}
$$

which, by arguments identical to those used to derive (3.8), is equivalent to

$$\tilde{z}^* = \frac{1}{2\lambda} \max_{q \in S} \left\{ \min_u \{ \|u - f\|^2 + \langle -2\lambda \mathrm{div} q, u \rangle \} \right\}. \tag{3.11}$$

Since $u = f + \lambda \mathrm{div} q$ solves the inner minimization problem, substituting this expression for u yields

$$\tilde{z}^* = \frac{1}{2\lambda} \max_{q \in S} \left\{ \|\lambda \mathrm{div} q\|^2 + \langle -2\lambda \mathrm{div} q, f + \lambda \mathrm{div} q \rangle \right\} \tag{3.12}$$

$$= \frac{1}{2\lambda} \max_{q \in S} \left\{ -\|\lambda \mathrm{div} q + f\|^2 + \|f\|^2 \right\}, \tag{3.13}$$

which, letting $p = -q$, is equivalent to

$$\tilde{z}^* = \frac{1}{2\lambda} \|f\|^2 - \frac{1}{2\lambda} \min_{p \in S} \left\{ \|\lambda \mathrm{div} p - f\|^2 \right\}. \tag{3.14}$$

This minimization problem is identical to problem (8) in [5].

In fact problem (3.9) is equivalent to problem (3.14) for an appropriate choice of σ in terms of λ. For this equivalence to hold, problem (3.5) and its Lagrangian version (3.10) must be equivalent. Hence, for a fixed q, the solutions to the inner minimization problem in (3.8) and (3.11) must be equal; i.e.,

$$u = f + \sigma \frac{\mathrm{div} q}{\|\mathrm{div} q\|} = f + \lambda \mathrm{div} q. \tag{3.15}$$

Since $p = -q$, this gives

$$\sigma = \lambda \|\mathrm{div} q\| = \lambda \|\mathrm{div} p\|. \tag{3.16}$$

Note that adding the term $\|u - f\|^2 / 2\lambda$ to the objective in (3.9) and then using (3.15) and (3.16) to substitute for $u - f$ and σ yields

$$\frac{1}{2\lambda} \max_{p \in S} \left\{ 2\lambda \langle \mathrm{div} p, f \rangle - \lambda^2 \|\mathrm{div} p\|^2 \right\},$$

which is easily seen to be equivalent to (3.14).

Next, we present the SOCP formulation of the problem $\min_{q \in S} \left\{ \|\lambda \mathrm{div} p - f\|^2 \right\}$. Following the definition of S, the discretization of the above problem gives the following SOCP:

$$\begin{array}{lll} \min & w_0 & \\ \text{s.t.} & \lambda(\mathrm{div} q)_{i,j} - w_{i,j} = f_{i,j} & \text{for } i,j = 1, \ldots, n, \\ & (w_0; (w_{i,j})) \in \mathcal{K}^{n^2+1}, & \\ & (q^0_{i,j}; q^1_{i,j}; q^2_{i,j}) \in \mathcal{K}^3 & \text{for } i,j = 1, \ldots, n-1, \\ & (q^0_{n,j}; q^2_{n,j}) \in \mathcal{K}^2 & \text{for } j = 1, \ldots, n-1, \\ & (q^0_{i,n}; q^1_{i,n}) \in \mathcal{K}^2 & \text{for } i = 1, \ldots, n-1, \\ & q^0_{i,j} = 1 & \text{for } i,j = 1, \ldots, n, \end{array} \tag{3.17}$$

in which $(\mathrm{div} q)_{i,j}$ is explicitly given by $(\mathrm{div} q)_{i,j} = (\partial_x^- q^1)_{i,j} + (\partial_y^- q^2)_{i,j}$ and (3.3).

Many other dual formulations are possible. For example, if rather than relaxing the constraint $\|f-u\|^2 \le \sigma^2$, we relax the equivalent one, $\|f-u\| \le \sigma$, we obtain the Lagrangian version of (2.5),

$$\min \quad \sum_{1\le i,j\le n} \|\partial^+ u_{i,j}\| + \lambda \|f-u\|, \tag{3.18}$$

which can be reformulated as the following SOCP:

$$\begin{aligned}
\min \quad & \sum_{1\le i,j\le n} t_{i,j} + \lambda\, v_0 \\
\text{s.t.} \quad & (\partial_x^+ u)_{i,j} + (v_{i+1,j} - v_{i,j}) = f_{i+1,j} - f_{i,j} && \text{for } i = 1,\dots,n-1,\ j = 1,\dots,n, \\
& (\partial_y^+ u)_{i,j} + (v_{i,j+1} - v_{i,j}) = f_{i,j+1} - f_{i,j} && \text{for } i = 1,\dots,n,\ j = 1,\dots,n-1, \\
& (t_{i,j}\,;\ (\partial_x^+ u)_{i,j}\,,\ (\partial_y^+ u)_{i,j}) \in \mathcal{K}^3 && \text{for } i,j = 1,\dots,n-1, \\
& (t_{n,j}\,;\ (\partial_y^+ u)_{n,j}) \in \mathcal{K}^2 && \text{for } j = 1,\dots,n, \\
& (t_{i,n}\,;\ (\partial_x^+ u)_{i,n}) \in \mathcal{K}^2 && \text{for } i = 1,\dots,n, \\
& (v_0; v) \in \mathcal{K}^{n^2+1}.
\end{aligned} \tag{3.19}$$

By assigning dual variables $r^1_{i,j}$ and $r^2_{i,j}$ to each of the first two constraints and associating $(s^0_{i,j}; s^1_{i,j}, s^2_{i,j})$ to $(t_{i,j}; (\partial_x^+ u)_{i,j}, (\partial_y^+ u)_{i,j})$ and $(w_0; w)$ to $(v_0; v)$, we obtain the SOCP dual of (3.19):

$$\begin{aligned}
\max \quad & \sum_{1\le i,j\le n, i\ne n} r^1_{i,j}(f_{i+1,j} - f_{i,j}) + \sum_{1\le i,j\le n, j\ne n} r^2_{i,j}(f_{i,j+1} - f_{i,j}) \\
\text{s.t.} \quad & -(\partial_x^- r^1)_{i,j} - (\partial_y^- r^2)_{i,j} + w_{i,j} = 0 && \text{for } i,j = 1,\dots,n, \\
& r^1_{i,j} + s^1_{i,j} = 0 && \text{for } i = 1,\dots,n-1,\ j = 1,\dots,n, \\
& r^2_{i,j} + s^2_{i,j} = 0 && \text{for } i = 1,\dots,n,\ j = 1,\dots,n-1, \\
& s^0_{i,j} = 1 && \text{for } i,j = 1,\dots,n, \\
& w_0 = \lambda, \\
& (s^0_{i,j}\,;\ s^1_{i,j}\,,\ s^2_{i,j}) \in \mathcal{K}^3 && \text{for } i,j = 1,\dots,n-1, \\
& (s^0_{n,j}\,;\ s^2_{n,j}) \in \mathcal{K}^2 && \text{for } j = 1,\dots,n, \\
& (s^0_{i,n}\,;\ s^1_{i,n}) \in \mathcal{K}^2 && \text{for } i = 1,\dots,n, \\
& (w_0\,;\ w) \in \mathcal{K}^{n^2+1}.
\end{aligned} \tag{3.20}$$

By eliminating variables $r^1_{i,j}$, $r^2_{i,j}$, $s^0_{i,j}$, and w_0, this maximization problem can be simplified to the following minimization problem:

$$\begin{aligned}
\min \quad & \sum_{1\le i,j\le n, i\ne n} s^1_{i,j}(f_{i+1,j} - f_{i,j}) + \sum_{1\le i,j\le n, j\ne n} s^2_{i,j}(f_{i,j+1} - f_{i,j}) \\
\text{s.t.} \quad & (\partial_x^- s^1)_{i,j} + (\partial_y^- s^2)_{i,j} + w_{i,j} = 0 && \text{for } i,j = 1,\dots,n, \\
& (1\,;\ s^1_{i,j}\,,\ s^2_{i,j}) \in \mathcal{K}^3 && \text{for } i,j = 1,\dots,n-1, \\
& (1\,;\ s^2_{n,j}) \in \mathcal{K}^2 && \text{for } j = 1,\dots,n, \\
& (1\,;\ s^1_{i,n}) \in \mathcal{K}^2 && \text{for } i = 1,\dots,n, \\
& (\lambda\,;\ w) \in \mathcal{K}^{n^2+1}.
\end{aligned} \tag{3.21}$$

4. Nested dissection. SOCPs can be solved very efficiently in practice and, in theory, in polynomial time by interior-point methods. For example, path-following interior-point methods generate a sequence of interior points (i.e., points in the interior of $\mathcal{K}$) that follow the so-called central path toward an optimal solution. At each iteration, a set of primal-dual equations, which depend on current variable values and a duality gap parameter μ, are solved to yield an improving search direction. Rather than solving this system of equations directly, most implementations of interior-point methods first reduce these equations to a smaller system of linear equations involving a symmetric positive definite matrix that has the form $AFA^\top$. This system of linear equations is solved by computing the Cholesky factorization $LDL^\top$ of $AFA^\top$, where L is a unit lower triangular matrix and D is a positive diagonal matrix. Although A remains fixed from one iteration to the next, F depends on the current primal-dual solution, so $AFA^\top$ must be factorized at every iteration. Even though interior-point methods terminate in a polynomial number of iterations, each iteration can be very time consuming due to the $O(m^3)$ computational complexity of solving the Cholesky factorization of the $m \times m$ matrix $AFA^\top$, or even fail because of the lack of enough memory to store a dense $m \times m$ lower triangular matrix L. In our applications, m is quite large (e.g., in the SOCP (3.2), $m = 2n(n-1)+1$, so that for $n = 1024$, m is roughly 2×10^6).

This difficulty can be overcome by exploiting the sparsity of the matrix A and the structure of F. In all interior-point methods, F is a block diagonal matrix $F \equiv \mathrm{Diag}\{F_1, \ldots, F_r\}$, where each of the diagonal submatrices $F_i \in \mathbb{R}^{n_i \times n_i}$ can be expressed as a sum of a scaled identity matrix and two rank-one terms (or for some methods, three rank-one terms), one with a positive coefficient and the other with a negative coefficient. Hence,

$$AFA^\top = \sum_{i=1}^{r} A_i F_i A_i^\top, \tag{4.1}$$

where $F_i = \gamma_i I + \mathbf{u_i}\mathbf{u_i}^\top - \mathbf{v_i}\mathbf{v_i}^\top$ ($\mathbf{u_i}$ and $\mathbf{v_i}$ are two columns vectors, not the signal and noise defined before).

It is easily verified that for the SOCP (3.2) the terms $A_i F_i A_i^\top$ have the same sparsity structure as $A_i A_i^\top$ for all i corresponding to two- and three-dimensional cones $\mathcal{K}^2$ and $\mathcal{K}^3$. However, for the one large cone $\mathcal{K}^{n^2+1}$, $A_i F_i A_i^\top$ has a totally dense $(n^2+1) \times (n^2+1)$ block, whereas $A_i A_i^\top$ is very sparse. To take advantage of the sparsity of the latter matrix, implementations of interior-point methods compute the Cholesky factorization of only the sparse part of $AFA^\top$—i.e., for large cones, they include only the sparse term $\gamma_i A_i A_i^\top$ in the sum (4.1) when computing this factorization and then update the factorization to account for the dense part using either a [illegible] approach (see [11]) or a version of the Sherman–Morrison–Woodbury updating identity (see [2]). The latter approach is simpler but unfortunately less numerically stable than the former. The interior-point codes that we used in our experiments treated large cones in this fashion; hence in the following discussion we consider only the sparsity structure of $A_i A_i^\top$.

It is well known that sparsity in a symmetric matrix M does not guarantee that the Cholesky factor L will be sparse. For example, Cholesky factorization of the

rather sparse matrix

$$M = \begin{bmatrix} 1 & 1 & 1 & 1 & 1 \\ 1 & 2 & 0 & 0 & 0 \\ 1 & 0 & 3 & 0 & 0 \\ 1 & 0 & 0 & 7 & 0 \\ 1 & 0 & 0 & 0 & 43 \end{bmatrix} \tag{4.2}$$

yields $D = I$ and

$$L = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 & 0 \\ 1 & -1 & 1 & 0 & 0 \\ 1 & -1 & -2 & 1 & 0 \\ 1 & -1 & -2 & -6 & 1 \end{bmatrix}. \tag{4.3}$$

However, by reversing the order of the rows and columns of M, we obtain a matrix $\tilde{M}$ whose Cholesky factorization yields $\tilde{D} = \mathrm{Diag}(43, 7, 3, 2, 1)$ and

$$\tilde{L} = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \\ 1/43 & 1/7 & 1/3 & 1/2 & 1 \end{bmatrix}. \tag{4.4}$$

[illegible] [10] is a scheme for symmetrically permuting the rows and columns of a symmetric matrix M so that the resulting Cholesky factorization takes optimal advantage of certain types of sparsity in M. To describe nested dissection, we let G_M be the [illegible] associated with M. If $M \in \mathbb{R}^{m\times m}$, then G_M has m nodes and has an edge (i, j) if the (i, j)th element of M is nonzero. Nested dissection recursively applies the following [illegible] strategy. Given a graph G_M, find a [illegible] set of nodes N_S, whose removal from G_M divides it into two unconnected components G_U and G_V with corresponding node sets N_U and N_V. If the nodes in N_S in G_M are numbered after those in N_U and N_V, then the matrix M corresponding to this row and column ordering has the form

$$M = \begin{bmatrix} M_{UU} & \mathbf{0} & M_{US} \\ \mathbf{0} & M_{VV} & M_{VS} \\ M_{US}^\top & M_{VS}^\top & M_{SS} \end{bmatrix}, \tag{4.5}$$

and most importantly, the Cholesky factor L of M inherits a similar structure, i.e.,

$$L = \begin{bmatrix} L_{UU} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & L_{VV} & \mathbf{0} \\ L_{SU} & L_{SV} & L_{SS} \end{bmatrix}. \tag{4.6}$$

This strategy is then applied recursively to the subgraphs G_U and G_V.

Let us now consider the application of nested dissection to the matrix $AA^\top$ arising from the SOCP (3.2), which as explained above corresponds to the sparse part of $AFA^\top$. $(AA^\top)_{l,k} \neq 0$ if and only if the lth and kth constraints share decision variables. The equality constraints in our problem are

$$(\partial_x^+ u)_{i,j} + (v_{i+1,j} - v_{i,j}) = f_{i+1,j} - f_{i,j} \quad \text{for } i = 1, \ldots, n-1,\ j = 1, \ldots, n, \tag{4.7}$$

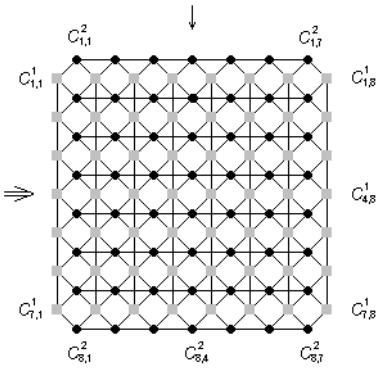

FIG. 1. *Constraint dependency of* (3.2).

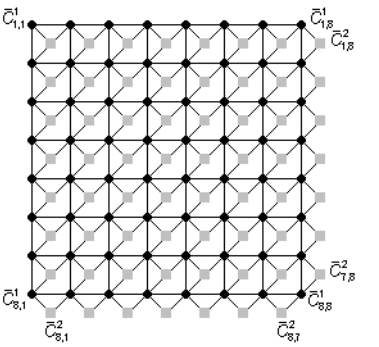

FIG. 2. *Constraint dependency of* (3.17).

$$(\partial_y^+ u)_{i,j} + (v_{i,j+1} - v_{i,j}) = f_{i,j+1} - f_{i,j} \quad \text{for } i = 1, \ldots, n,\ j = 1, \ldots, n-1, \tag{4.8}$$

$$v_0 = \sigma. \tag{4.9}$$

Clearly, the last constraint shares no variable with any other constraint; thus its position in the ordering of the constraints is irrelevant . Let $C^1_{i,j}$ and $C^2_{i,j}$ denote the (i,j)th constraints in (4.7) and (4.8), respectively. For a particular pair (i,j) (i.e., row of A), $C^1_{i,j}$ shares at least one decision variable with the following constraints, given their existence:

$$\begin{array}{llll} C^1_{i-1,j}, & C^2_{i,j-1}, & C^2_{i,j} & (\text{sharing } v_{i,j}), \\ C^1_{i+1,j}, & C^2_{i+1,j-1}, & C^2_{i+1,j} & (\text{sharing } v_{i+1,j}). \end{array}$$

$C^2_{i,j}$ shares at least one decision variable with the following constraints, given their existence:

$$\begin{array}{llll} C^1_{i-1,j}, & C^1_{i,j}, & C^2_{i,j-1} & (\text{sharing } v_{i,j}), \\ C^1_{i-1,j+1}, & C^1_{i,j+1}, & C^2_{i,j+1} & (\text{sharing } v_{i,j+1}). \end{array}$$

The constraint dependency relations (i.e., adjacency graph G_M of $AA^\top$ excluding the row and column corresponding to (4.9), which we shall refer to as M) are depicted in Figure 1 for the case of $n = 8$, in which squares represent $C^1_{i,j}$ and bullets $C^2_{i,j}$. Clearly, removal of the row of squares $C^1_{4,j}$, $j = 1, \ldots, 8$, separates the dependency graph in Figure 1 into two independent parts. If we let $S \equiv \{C^1_{4,j} : j = 1, \ldots, 8\}$ and let U and V denote the sets of constraints corresponding to the upper and the lower independent parts, and order the constraints in U before those in V and those in V before those in S, then M has the form of (4.5).

Furthermore, removal of the column of bullets $C^2_{i,4}$, $i = 1, \ldots, 4$, separates U into two independent parts—U_L and U_R—and removal of the column of bullets $C^2_{i,4}$, $i = 5, \ldots, 8$, separates V into two independent parts—V_L and V_R. As a result, M_{UU} and M_{VV} can be ordered so that each has the form (4.5). This process is then repeated recursively until every node has been assigned to some separator set (i.e., every row and column of M has been numbered). In the appendix, we analyze the storage cost and the number of multiplications for factorizing $M = AA^T$ corresponding to the

equality constraints (4.7) and (4.8) after ordering this matrix by nested dissection. These costs are $(31/4)n^2 \log_2 n + O(n^2)$ and $943n^3/84 + O(n^2 \log_2 n)$ for an $n \times n$ image, respectively.

Finally, we depict in Figure 2 the dependency graph of the dual SOCP formulation (3.17). In Figure 2 the (i,j)th bullet $\bar{C}^1_{i,j}$ represents the constraint $(\mathrm{div} q)_{i,j} - w_{i,j} = f_{i,j}$, and the (i,j)th square $\bar{C}^2_{i,j}$ represents the constraint $q^0_{i,j} = 1$. Since constraints $\bar{C}^1_{i,j}$, $\bar{C}^1_{i+1,j}$, and $\bar{C}^1_{i,j+1}$ contain either $q^1_{i,j}$ or $q^2_{i,j}$ or both of them, and the 3×3 fully dense block F_k corresponding to cone $(q^0_{i,j}; q^1_{i,j}; q^2_{i,j})$ causes the 3 corresponding columns in A to merge, constraint $\bar{C}^2_{i,j}$ in AFA^T essentially shares variables with constraints $\bar{C}^1_{i,j}$, $\bar{C}^1_{i+1,j}$, and $\bar{C}^1_{i,j+1}$; hence, in Figure 2, $\bar{C}^2_{i,j}$ is connected to $\bar{C}^1_{i,j}$, $\bar{C}^1_{i+1,j}$, and $\bar{C}^1_{i,j+1}$. The connections between bullets $\bar{C}^1_{i,j}$'s are due to the sharing of $q^1_{i,j}$ or $q^2_{i,j}$ for some i,j.

5. Numerical results. In this section, we present numerical results that illustrate the effectiveness of our SOCP approach and compare it to the PDE approach. We then discuss the use of domain decomposition to reduce the storage and computational effort needed by the SOCP approach.

5.1. SOCP/PDE comparison. We used the commercial optimization package Mosek as our SOCP solver. Mosek is designed to solve a variety of large-scale optimization problems, including SOCPs. Before solving a large-scale problem, Mosek uses a presolver to remove redundant constraints and variables and to reorder constraints. The Mosek presolver reorders the coefficient matrix A using a combination of a graph partitioning–based method and an approximate minimum local-fill-in ordering method to increase the sparsity of the Cholesky factors of $AFA^\top$. This general-purpose reordering produced results for our problem that were very good, but not as good as nested dissection, which further reduced the time per iteration and the total time by approximately 30 percent in our tests on a 512×512 image. Therefore, we turned off Mosek's reordering heuristic and replaced it by our own nested dissection reordering code in our tests.

Existing PDE approaches require the ROF model to be represented in the relaxed form (1.2) and the existence of the Euler–Lagrange equation $g(u) = 0$, where $g(u)$ is given by (1.3). To handle the case of $\|\nabla u\| = 0$, most PDE approaches add a small perturbation $\epsilon > 0$ to $\|\nabla u\|$ in (1.3). The PDE method that we used in our numerical tests is an artificial time stepping method which computes the steady state solution u of the parabolic system

$$\frac{\partial u}{\partial t} = \frac{1}{2\lambda} \nabla \cdot \left(\frac{\nabla u}{\|\nabla u\| + \epsilon} \right) + f - u. \tag{5.1}$$

To compare the two approaches for each noisy image, we first solved the SOCP formulation (3.2) of (1.1) and calculated λ from the optimal dual solution using the following theorem.

THEOREM 5.1. [illegible] (1.1) [illegible] (1.2) [illegible] u [illegible] $2\lambda\sigma = z_0$ [illegible] z_0 [illegible] $(z_0, z) \in \mathcal{K}^{n^2+1}$ (z_0, z) [illegible] (v_0, v) [illegible] (3.2) [illegible] (1.1) [illegible] $\int_\Omega |v|^2 \, \mathrm{d}x \le \sigma^2$ [illegible] $(v_0, v) \in \mathcal{K}^{n^2+1}$ [illegible] $v_0 = \sigma$

We then used this Lagrange multiplier λ in the PDE method. In practice, it is much easier to estimate the noise level of an image than it is to estimate an appropriate

λ. Experiments show that a σ that is a little smaller than the true one (i.e., a slight amount of undersmoothing) yields the best results.

In our tests, we called Mosek from MATLAB, while we called the PDE-based code (an improved version of a C++ code provided to us by Stanley Osher and Jinjun Xu of UCLA) directly. The running times given in Table 2 for the problems whose sizes are given in Table 1 are the total times in seconds needed to solve the problem on a Sun E450 with four 300MHz SuperSparc II processors and 4GB memory. Since both codes are single-threaded, they run only on one processor and use 1GB memory at a time. The SOCP run times do not include the time taken by our nested dissection code to reorder constraints and the time taken by Mosek for presolving, since the process of constraint reordering and presolving remains the same for all images of the same size.

During their execution, both approaches record the objective values of (1.2):

$$z(t) = \int_\Omega \|\nabla u_t\| \, \mathrm{d}x + \lambda \int_\Omega |f - u_t|^2 \, \mathrm{d}x. \tag{5.2}$$

The objective values obtained by the PDE approach decrease with time t over the long run but fluctuate and never reach as low a value as that obtained by the SOCP approach. Given a nearly optimal objective value, the PDE approach may have to iterate further for a large number of steps to obtain a lower objective value. For these reasons, we used the following stopping rules for the PDE approach:

- initially, let $z_{\min} = \infty$ and $t_{\min} = 0$, where $z_{\min}$ and $t_{\min}$ denote the minimal objective value and its time;
- at time t, update $z_{\min} := z(t)$ and $t_{\min} := t$ if $z_{\min} < z(t) - \lambda$;
- to denoise an image of size $n \times n$, stop at time t once $t - t_{\min} \geq \max\{0.15 t_{\min}, n\}$.

These stopping criteria ensure that the PDE method spends a reasonable amount of time searching for a possibly lower objective value but does not waste too much time trying to obtain an insignificant improvement.

In all of our tests starting from the same noisy image, the two approaches produced images that were visually indistinguishable from one another. Table 1 shows that in all our tests the gray values (u_1 and u_2) produced by the two approaches differ by at most 0.97 over all pixels with an average difference of less than 0.10. Therefore, we present in Figures 3–17, in addition to the original and noisy images, only the SOCP images. Similar results were obtained on the other images.

From Table 2, one can see that the SOCP approach requires a smaller number of iterations than the PDE approach while every iteration takes more time. Note that as the size of the image grows, the number of iterations required by the SOCP approach remains relatively constant, while that number grows for the PDE approach. In spite

of this, the SOCP approach took roughly between one and two times the total time that the PDE approach took. This is because, in theory, the PDE method takes $O(n^2)$ CPU time per iteration for an $n \times n$ image, while the SOCP method (implemented

as described in section 4) takes $O(n^3)$ CPU time per iteration. In our numerical tests the SOCP approach took between $O(n^2 \log n)$ and $O(n^3)$ time per iteration due to the effect of memory references, which are slower than floating-point operations.

We also measured the running times on a PC with a Pentium IV 1.7GHz CPU and 512MB memory. We used the MS Windows versions of MATLAB, Mosek, and GUN g++ compiler. On this newer computer, the SOCP code ran 2–2.5 times faster and the PDE code ran about 4 times faster solving the same set of problems. Due to the PC's smaller amount of memory and cache, the SOCP approach, which performs more memory fetches, got a smaller speedup than the PDE approach, exhibiting a

running time somewhere between the $n \times n$-image storage cost of $O(n^2)$ and the nested dissection Cholesky factorization storage cost of $O(n^2 \log n)$.

5.2. Domain decomposition. Even with nested dissection the SOCP approach requires $O(n^2 \log n)$ memory. Hence, to denoise large (or three-dimensional) images, we consider here a [illegible] approach. Let $\tilde{n} \approx n/k$, where k is a positive integer and $\tilde{n} > n/k$. By subdividing an $n \times n$ image into k^2 $\tilde{n} \times \tilde{n}$ subimages with some overlap and applying the SOCP method to each of the subimages, we can reduce the storage needed by a factor of approximately $1/k^2$. Since, in applying the SOCP method to each subimage, the number of multiplications per iteration is reduced by a factor of approximately $1/k^3$ compared with applying the SOCP method to the entire image, and there are k^2 subimages, the total CPU time should also be reduced by a factor of approximately $1/k$. After obtaining the denoised subimages, we discarded the values of u for the rows (columns) of pixels in that half of any region of overlap closest to the boundary of the subimage. For example, Figure 20 illustrates a 2×2 domain decomposition with a 4-pixel overlap between subimages. After obtaining the denoised 65×65 image u for the top left block, we discarded the u values for the rightmost two columns and bottommost two rows of pixels. These values have indices (i, j) with $i = 64, 65$ and $j = 1, \ldots, 65$, and $j = 64, 65$ and $i = 1, \ldots, 65$. An analogous statement applies to the overlapped pixels of the other 3 denoised subimages.

Due to the different graphical characteristics of the subimages, including signal-to-noise ratio, contrast, and homogeneity, applying the SOCP method to all subimages using the same σ does not usually give the same output as applying the SOCP method to the entire image. In some cases the results obtained by using the former are better, while in other cases they are worse. The following numerical example illustrates this. Figure 18 is the noisy image obtained by selecting a rectangular area of the noisy image in Figure 13 and removing the outside portion of the image. Figure 19 is the result of the ROF method (3.2) separately applied to 4 equal subimages of size 65×65 with the same $\sigma = 18 \times 65^2$. In the numerical tests, we chose the size of all subimages so that all adjacent image pairs had overlapping regions that were 4 pixels wide. Figure 20 illustrates the 2×2 domain decomposition applied to the image in Figure 18. Figure 21 is the result of ROF applied to the entire image with $\sigma = 18 \times 65^2$. In Figure 21, Barbara's left eye is clearer than in Figure 19. This shows that the subimage at the bottom right is oversmoothed. After reducing $\sigma_{2,2}$ from 18×65^2 to 16×65^2 for this oversmoothed subimage, the ROF method yields Figure 22, in which Barbara's left eye is much clearer. Figure 23 gives the ten-times amplified differences between Figures 21 and 22. The differences in the regions of the four subimages vary, but we cannot see any big differences by comparing Figures 21 and 22. However, as we shall now demonstrate, we can obtain even closer results.

In [20], Strong and Chan give exact analytical solutions to the relaxed TV denoising problem (1.2) applied to one-, two-, and three-dimensional piecewise constant images and smooth radially symmetric ones. Their results establish an exact relationship between the Lagrange multiplier λ and the effect of TV regularization (1.2) on an image feature and show its localness property (i.e., in a piecewise constant or smooth radially symmetric region the solution of (1.2) depends only on λ and whether or not the region is on the image boundary, and is independent to the features of other regions). This can be extended approximately to complicated noisy images since they are composed of many tiny piecewise constant or smooth radially symmetric regions. Therefore, we can expect solving (1.2) with the same λ (or σ's for all subimages so that $z_0/(2\sigma) = \lambda$) as used for the entire image to give close results. Since TV

FIG. 22. 2×2 *partitioned result* ($\sigma_{1,1} = \sigma_{1,2} = \sigma_{2,1} = 18 \times 65^2, \sigma_{2,2} = 16 \times 65^2$).

FIG. 23. *Ten-times amplified difference between Figures* 21 *and* 22.

regulation treats regions on boundaries differently, domain decomposition may give different results near subimage boundaries. Sharp edges are different from sharp noise by the surrounding geometry, e.g., two sides of sharp edges have very different brightness. Therefore, if a sharp edge is very close to the image boundaries, the difference between edges and noise is weaker. Moreover, every pixel in an image may affect the denoising results of the whole image, and their dependency is ambiguous. This effect, however, is limited to strips a few pixels wide when noise is present. Hence, in our tests, we discarded redundant information in these boundary strips of the subimages.

In our first test of the above approach we applied a 4×4 domain decomposition to a 512×512 image. The results are depicted in Figures 24–26. All subimages were of size 137×137, giving overlapping regions between adjacent subimages that were 12 pixels wide. The image values for the 6 rows (columns) of pixels in the overlapping regions closest to the boundaries of each subimage were discarded. The σ's for the full image and all of the subimages were chosen so that $z_0/(2\sigma) = 0.0375$. Table 3 gives the numerical results. The results obtained by the two approaches by more than 1 on the 256 gray-level scale was 0.11% of the total 512×512 pixels. The average difference per pixel was 0.07 and the maximum difference was $+0.97$ and -1.15. The running time 1280 seconds for denoising the entire image was estimated based on the $O(n^3)$ theoretical CPU time. The difference was more than 1 on the 256 gray-level scale for only 0.0008% of the pixels. The average difference per pixel was 0.04 and the maximum difference was $+0.75$ and -1.31. Clearly, SOCP with domain decomposition gave nearly identical results to SOCP applied to the full image.

(4,1)	17	30.10	(4,2)	17	31.06	(4,3)	18	32.03	(4,4)	18	32.72
Sum of the total time (seconds) for denoising all subimages (Figure 26):											508.26
Total time for denoising the entire image:											806.70

In this example the total computation time for the domain decomposition approach was about 37 percent less than the time required by the SOCP method applied to the full image. Since $16 \cdot 137^3/512^3 \approx 0.33$, one would expect something close to a 67 percent reduction in running time. The reason this was not the case is explained by our remark in section 5.1 about execution time and memory references when cache is limited and slow.

We also applied an 8×8 domain decomposition to the noisy 512×512 image in

Sum of the total time (seconds) for denoising all subimages:									418.06

Figure 25 after extending it to one with a size of 516×516 so that all subimages were of the same size (75×75) and the overlapping regions remained 12 pixels wide. As in the previous test, the σ's were chosen so that $z_0/(2\sigma) = 0.0375$ for all subimages. The numerical results given in Table 4 show that the reduction in the total computation time was further improved from 37 percent to 52 percent. Moreover, the total run time of 418.06 seconds was less than the 456.25-second run time of the PDE approach. The difference between the results obtained by applying the SOCP method with domain decomposition and applying it to the entire image was more than 1 on the 256 gray-level scale for 0.0015% of the pixels. The average difference per pixel increased to 0.08 and the maximum difference was +1.47 and −1.06. This difference was still not perceivable to the naked eye.

6. SOCP formulations of other restoration models. Meyer [15] introduced the following image restoration model based on TV and the space of oscillating functions:

$$\min \int_\Omega \|\nabla u\| \mathrm{d}x + \lambda \|v\|_* \quad \text{s.t. } f = u + v, \tag{6.1}$$

where $\|v\|_*$ is defined as the infimum of $\|\sqrt{g_1^2(x,y) + g_2^2(x,y)}\|_{L^\infty}$ over all $g_1, g_2 \in L^\infty(\mathbb{R}^2)$ satisfying $v = \partial_x g_1 + \partial_y g_2$. To handle $\|\sqrt{g_1^2(i,j) + g_2^2(i,j)}\|_{L^\infty}$ in the discretized version of (6.1), we introduce a three-dimensional quadratic cone

$$(g_0(i,j); g_1(i,j), g_2(i,j)) \in \mathcal{K}^3$$

for each i, j and let $w \geq g_0(i,j)$ for all i, j. The infimum of $\|\sqrt{g_1^2(i,j) + g_2^2(i,j)}\|_{L^\infty}$ is then equal to the minimum of w. Thus we can solve a discretized problem of (6.1) as an SOCP. It is important to note that because Meyer's model (6.1) is not amenable to the PDE approach, it has been primarily of theoretical interest. Thus, the SOCP approach can be applied to image restoration models that cannot be solved by a PDE approach.

In [22], Vese and Osher proposed an approximate version of Meyer's model and showed that their PDE-based method can decompose a given image f into u and v, where u and v represent cartoon and texture, respectively. Their method solves the minimization problem

$$\min \int_\Omega \|\nabla u\| \mathrm{d}x + \lambda \int |f - u - \partial_x g_1 - \partial_y g_2| + \mu \left[\int (\sqrt{g_1^2 + g_2^2})^p \right]^{1/p}, \tag{6.2}$$

where λ and μ are tuning parameters and $p \geq 1$. Inequalities with p-norm for p being rational can be represented as a system of second-order conic inequalities (refer to [1]). Therefore, (6.2), after discretization, can be formulated as an SOCP and solved by interior-point methods. In a forthcoming paper [24], we solve Meyer's model as an SOCP and compare the solutions with those obtained by the Vese–Osher approximation.

In [14], Lysaker, Lundervold, and Tai introduced a method for image restoration based on solving the following two-dimensional problem:

$$\begin{aligned} \min \quad & \int_\Omega |u_{x_1x_1}| + |u_{x_2x_2}| \, \mathrm{d}x \\ \text{s.t.} \quad & u + v = f, \\ & \int_\Omega |v|^2 \, \mathrm{d}x_1 \, \mathrm{d}x_2 \leq \sigma^2. \end{aligned} \tag{6.3}$$

The discretization of the second derivative of $u = \{u_{i,j}\}$ is linear in the $u_{i,j}$'s. To handle absolute values in minimization problems, say $\min |z|$, one can introduce an extra variable and transform $\min |z|$ into equivalent problems:

$$\min \quad |z| \tag{6.4}$$

$$\Longleftrightarrow \min \quad t \quad \text{s.t.} \quad z \leq t, \ -z \leq t \tag{6.5}$$

$$(s \stackrel{\text{def}}{=} t + z) \Longleftrightarrow \min(s - z) \ \text{s.t.} \quad 2z \leq s, \ s \geq 0. \tag{6.6}$$

Both (6.5) and (6.6) have a linear objective subject to linear constraints. In some cases, (6.6) is preferred since $s \geq 0$ is easier to handle. Therefore, expressing $\int_\Omega |v|^2 \, \mathrm{d}x \leq \sigma^2$ as a second-order conic constraint as before, it is clear that problem (6.3) can be formulated as an SOCP. This also works if the objective function is replaced by $\int_\Omega |u_{x_1x_1}| + 2|u_{x_1x_2}| + |u_{x_2x_2}| \, \mathrm{d}x$.

A variant of (1.1) was proposed by Osher, Solé, and Vese (OSV) in [16]. The model assumes that $f - u = \mathrm{div} g$, where $g = (g_1, g_2)$, and there exists a unique decomposition $g = \nabla P + Q$, where Q satisfies $\mathrm{div} Q = 0$. Therefore, $f - u = \mathrm{div} g = \Delta P$ or $\Delta^{-1}(f - u) = P$. The OSV model is

$$\begin{aligned} \min \quad & \int_\Omega \|\nabla u\| \, \mathrm{d}x \\ \text{s.t.} \quad & \int_\Omega \|\nabla(\Delta^{-1}(f - u))\| \, \mathrm{d}x \leq \sigma^2, \end{aligned} \tag{6.7}$$

or equivalently

$$\begin{aligned} \min \quad & \int_\Omega \|\nabla u\| \, \mathrm{d}x \\ \text{s.t.} \quad & \int_\Omega \|\nabla P\| \, \mathrm{d}x \leq \sigma^2, \\ & f - u = \Delta P. \end{aligned} \tag{6.8}$$

Clearly, by using a finite difference form of the Laplace operator and expressing the objective function and the constraint $\int_\Omega \|\nabla P\| \, \mathrm{d}x \leq \sigma^2$ as we have previously described, we can reformulate (6.8) as an SOCP.

In [8], the authors analyzed the ROF model with an L^1 fidelity term $\int_\Omega |v| \le \sigma$. Clearly, by discretizing $\int_\Omega |v|$ as the sum $\sum_{i,j} |v_{i,j}|$ and handling the absolute values $|v_{i,j}|$ using (6.5) or (6.6), this problem can be formulated as an SOCP.

It is not difficult to see that various TV-based deblurring models can also be formulated as SOCPs.

Appendix. In this appendix, we present a detailed analysis of Cholesky factorization of a matrix M whose rows and columns have been symmetrically reordered by applying nested dissection to the adjacency graph of M, assuming that the latter is an $n \times n$ grid graph of the type shown in Figure 1. We follow an approach similar to the one given in [18]. First, let us introduce some graph notation.

A graph G is defined as the pair (V_G, E_G), where V_G is the set of nodes and E_G is the set of edges of G. In Figure 27, each square or bullet is a node, and each line segment connecting a pair of nodes is an edge. Figure 27 has 8 rows and 7 columns corresponding to the C^2 constraints, and 7 rows and 8 columns corresponding to the C^1 constraints. For convenience, we number node $C^k_{i,j}$ by $(i,j)^k$. In this way, $C^1_{3,1}$ corresponds to node $(3,1)^1$ and $C^2_{8,1}$ to node $(8,1)^2$. Due to the boundary conditions, the row of nodes $(8,\cdot)^1$ and the column of nodes $(\cdot,8)^2$, corresponding to $(\partial^+_x u)_{8,j} = 0$ and $(\partial^+_y u)_{i,8} = 0$ for $1 \le i,j \le 8$, do not appear in Figure 27. Let us denote by $G_{2n,2n}$ a graph of the form of Figure 27 with nodes $(i,j)^k$ for $k = 1,2$ and $i,j = 1,\dots,n-1$, $(i,n)^1$ for $i = 1,\dots,n$, and $(n,j)^2$ for $j = 1,\dots,n$. For example, Figure 27 depicts a $G_{16,16}$ mesh.

Given the graph $G_{2n,2n}$, we define three extended graphs $A_{2n,2n}$, $B_{2n,2n}$, and $C_{2n,2n}$ as follows:

$$A_{2n,2n} \stackrel{\text{def}}{=} (V_A, E_A), \quad \text{where} V_A = V_G \bigcup L_{left} \bigcup L_{bottom}, \tag{A.1}$$

$$B_{2n,2n} \stackrel{\text{def}}{=} (V_B, E_B), \quad \text{where} V_B = V_G \bigcup L_{left} \bigcup L_{bottom} \bigcup L_{right}, \tag{A.2}$$

$$C_{2n,2n} \stackrel{\text{def}}{=} (V_C, E_C), \quad \text{where} V_C = V_G \bigcup L_{top} \bigcup L_{left} \bigcup L_{bottom} \bigcup L_{right}, \tag{A.3}$$

where

$$L_{left} = \{(i,0)^2 \mid i = 1,2,\dots,n\}, \tag{A.4}$$

$$L_{right} = \{(i,n)^2 \mid i = 1,2,\dots,n\}, \tag{A.5}$$

$$L_{top} = \{(0,j)^1 \mid j = 1,2,\dots,n\}, \tag{A.6}$$

$$L_{bottom} = \{(n,j)^1 \mid j = 1,2,\dots,n\}, \tag{A.7}$$

and E_A, E_B, and E_C are the sets of edges that connect V_A, V_B, and V_C by a grid of the type shown in Figure 27. For example, for $n = 8$, $A_{16,16}$, $B_{16,16}$, and $C_{16,16}$ are depicted in Figures 28, 29, and 30, in which extended boundaries are distinguished by being enclosed in ellipses.

The reason that we need these extended graphs in our analysis can be illustrated as follows. As we described in section 4, the graph $G_{16,16}$ can be separated into four subgraphs, each of which is a $G_{8,8}$, by separators $(4,j)^1$, $j = 1,\dots,8$, followed by $(i,4)^2$, $i = 5,\dots,8$, and $(i,4)^2$, $i = 1,\dots,4$. The order of the graph separators is just the reverse of the order assigned to the rows and columns in the matrix. It is well known that, in Cholesky factorization (CF), eliminating a node of degree d (i.e., the number of nodes directly connected to it) costs $K_m = d(d+3)/2$ multiplies and requires $K_s = d+1$ storage. In the next stage the case is different from that of $G_{8,8}$

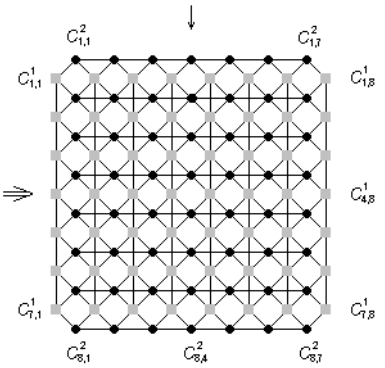

FIG. 27. $G_{16,16}$.

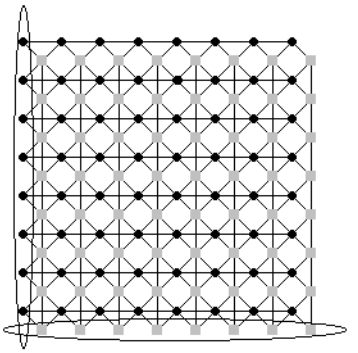

FIG. 28. $A_{16,16}$.

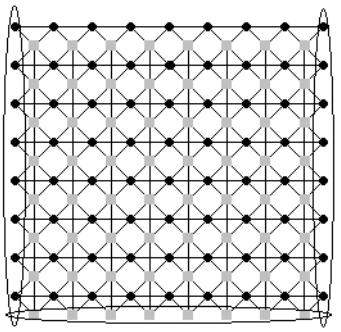

FIG. 29. $B_{16,16}$.

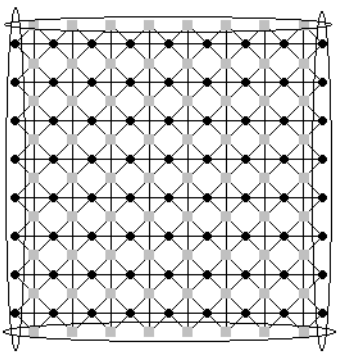

FIG. 30. $C_{16,16}$.

since, for example, the subgraph $G_{8,8}$ in the upper right corner of $G_{16,16}$ is connected to the nodes $(4,j)^1$, $j = 5,\ldots,8$, and $(i,4)^2$, $i = 1,\ldots,4$, which are the bottom and left extended boundaries of $G_{8,8}$. Therefore, we need to consider separating $A_{8,8}$ instead of $G_{8,8}$. Since applying any rotation or reflection to $A_{8,8}$ does not change the multiplication and storage costs of CF, separating any of the other three subgraphs of $G_{16,16}$ is essentially the same as separating $A_{8,8}$. Similar remarks apply to any rotation or reflection of $A_{2n,2n}$, $B_{2n,2n}$, and $C_{2n,2n}$.

Let $\mu(\cdot)$ denote a function of a graph whose value gives the complexity of applying CF to a matrix corresponding to that graph. Specifically, we use $\mu_m(\cdot)$ and $\mu_s(\cdot)$ to present the multiplication cost and the storage cost, respectively. In the divide and conquer approach, the complexity of applying CF to $G_{2n,2n}$ can be calculated by the recursion

$$\mu(G_{2n,2n}) = 4\,\mu(A_{n,n}) + \mu(S^G_{2n,2n}), \tag{A.8}$$

where $S^G_{2n,2n}$ is defined as the separator of $G_{2n,2n}$.

Following similar arguments, one can divide each of $A_{2n,2n}$, $B_{2n,2n}$, and $C_{2n,2n}$ into 4 subgraphs and derive the following recursions:

$$\mu(A_{2n,2n}) = \mu(A_{n,n}) + 2\,\mu(B_{n,n}) + \mu(C_{n,n}) + \mu(S^A_{2n,2n}), \tag{A.9}$$

$$\mu(B_{2n,2n}) = 2\,\mu(B_{n,n}) + 2\,\mu(C_{n,n}) + \mu(S^B_{2n,2n}), \tag{A.10}$$

$$\mu(C_{2n,2n}) = 4\,\mu(C_{n,n}) + \mu(S^C_{2n,2n}). \tag{A.11}$$

The next step is to calculate $\mu(S^G_{2n,2n})$, $\mu(S^A_{2n,2n})$, $\mu(S^B_{2n,2n})$, and $\mu(S^C_{2n,2n})$. Take $\mu(S^G_{16,16})$, for example. Recall that we eliminate $(i,4)^2$, $i = 1,\ldots,4$, followed by $(i,4)^2$, $i = 5,\ldots,8$, and $(4,j)^1$, $j = 1,\ldots,8$. At the time we eliminate $(1,4)^2$, all nodes except for those in $S^G_{2n,2n}$ are eliminated. Therefore, $(1,4)^2$ is connected to $(i,4)^2$, $i = 2,\ldots,4$, and $(4,j)^1$, $j = 1,\ldots,8$. Therefore, $d_{(1,4)^2} = 3 \times (n/2) - 1$, where $n = 8$. Next, $(2,4)^2$ is eliminated with $d_{(2,4)^2} = 3 \times (8/2) - 2$. When we eliminate $(4,4)^2$, it has degree of $3 \times (8/2) - 4 = 8$ since it is connected to eight nodes $(4,j)^1$, $j = 1,\ldots,8$. Hence, the sums of d and d^2 for $G_{2n,2n}$'s separator $(i,n/2)^2$, $i = 1,\ldots,n/2$, are given by $\sum_{j=n}^{3n/2-1} j$ and $\sum_{j=n}^{3n/2-1} j^2$, respectively. By symmetry, this is also true for the separator $(i,n/2)^2$ for $i = n/2+1, n/2+2,\ldots,n$. Last, we eliminate the n nodes $(n/2,j)$ for $j = 1,2,\ldots,n$. Whenever we eliminate one of them, it is connected to all the nodes to be eliminated. Therefore, for these last n nodes, the sums of d and d^2 are given by $\sum_{j=0}^{n-1} j$ and $\sum_{j=0}^{n-1} j^2$, respectively. Altogether,

$$\sum_{v \in S^G_{2n,2n}} d_v^2 = 2 \sum_{j=n}^{3n/2-1} j^2 + \sum_{j=0}^{n-1} j^2 = \frac{23}{12} n^3 + O(n^2), \tag{A.12}$$

$$\sum_{v \in S^G_{2n,2n}} d_v = 2 \sum_{j=n}^{3n/2-1} j + \sum_{j=0}^{n-1} j = \frac{7}{4} n^2 + O(n), \tag{A.13}$$

where the first summand is for nodes $(i,n/2)^2$ for $i = 1,\ldots,n$, and the second one for nodes $(n/2,j)^1$ for $j = 1,\ldots,8$. Consequently,

$$\mu_m(S^G_{2n,2n}) = \sum_{v \in S^A_{2n,2n}} d_v(d_v+3)/2 = \frac{23}{24} n^3 + O(n^2), \tag{A.14}$$

$$\mu_s(S^G_{2n,2n}) = \sum_{v \in S^A_{2n,2n}} (d_v+1) = \frac{7}{4} n^2 + O(n). \tag{A.15}$$

We skip the detailed analysis but just list the results for A, B, and C below:

$$\sum_{v \in S_A} d_v = \sum_{j=3n/2}^{2n-1} j + \sum_{j=2n}^{5n/2-1} j + \sum_{j=2n}^{3n-1} j, \tag{A.16}$$

$$\mu_m(S^A_{2n,2n}) = \frac{125}{24} n^3 + O(n^2), \tag{A.17}$$

$$\mu_s(S^A_{2n,2n}) = \frac{9}{2} n^2 + O(n); \tag{A.18}$$

$$\sum_{v \in S_B} d_v = 2 \sum_{j=5n/2}^{3n-1} j + \sum_{j=3n}^{4n-1} j, \tag{A.19}$$

$$\mu_m(S^B_{2n,2n}) = \frac{239}{24} n^3 + O(n^2), \tag{A.20}$$

$$\mu_s(S^B_{2n,2n}) = \frac{25}{4} n^2 + O(n); \tag{A.21}$$

$$\sum_{v\in S_C} d_v = 2\sum_{j=3n}^{7n/2-1} j + \sum_{j=4n}^{5n-1} j, \tag{A.22}$$

$$\mu_m(S^C_{2n,2n}) = \frac{371}{24}n^3 + o(n^3), \tag{A.23}$$

$$\mu_s(S^C_{2n,2n}) = \frac{31}{4}n^2 + o(n^2). \tag{A.24}$$

While $S^G_{2n,2n}$ and $S^C_{2n,2n}$ are eliminated in the order of the column nodes $(\cdot, n/2)^2$ followed by the row nodes $(n/2,\cdot)^1$, we eliminate $S^B_{2n,2n}$ in the order of the row nodes $(n/2,\cdot)^1$ followed by the column nodes $(\cdot, n/2)^2$. Moreover, we eliminate $S^A_{2n,2n}$ by

$$\begin{aligned}
&(i, n/2)^2 \quad \text{for } i = 1,\dots,n/2,\\
&(n/2, j)^1 \quad \text{for } i = n/2+1,\dots,n,\\
&(n/2, j)^1 \quad \text{for } i = 1,\dots,n/2,\\
&(i, n/2)^2 \quad \text{for } i = n/2+1,\dots,n,
\end{aligned}$$

in this order. This approach gives a better result.

Given $\mu(S^G_{2n,2n})$, $\mu(S^A_{2n,2n})$, $\mu(S^B_{2n,2n})$, and $\mu(S^C_{2n,2n})$, we can solve from the above recursions (see [18]) that the multiplication cost of applying CF to $G_{2n,2n}$ is $943n^3/84 + O(n^2\log_2 n)$ and the storage cost is $(31/4)n^2\log_2 n + O(n^2)$. Similar results can be derived for matrices whose adjacency graphs have the form shown in Figure 2.

Acknowledgments. We would like to thank Stanley Osher for introducing us to total variation image restoration and for many helpful and stimulating discussions, and Jinjun Xu for making his PDE codes available to us.

FAST ITERATIVE SOLVERS FOR DISCRETE STOKES EQUATIONS*

JÖRG PETERS†, VOLKER REICHELT†, AND ARNOLD REUSKEN†

Abstract. We consider saddle point problems that result from the finite element discretization of stationary and nonstationary Stokes equations. Three efficient iterative solvers for these problems are treated, namely, the preconditioned conjugate gradient method introduced by Bramble and Pasciak, the preconditioned MINRES method, and a method due to Bank et al. We give a detailed overview of algorithmic aspects and theoretical convergence results. For the method of Bank et al. a new convergence analysis is presented. A comparative study of the three methods for a three-dimensional Stokes problem discretized by the Hood–Taylor $P_2 - P_1$ finite element pair is given.

Key words. Stokes equations, inexact Uzawa methods, preconditioned MINRES, multigrid

1. Introduction.

We consider a class of Stokes equations on a bounded connected polyhedral Lipschitz domain Ω in d-dimensional Euclidean space. We use the notation $\mathbf{V} := H_0^1(\Omega)^d$ and $M = L_0^2(\Omega) := \{\, p \in L^2(\Omega) \mid \int_\Omega p(x)\,dx = 0 \,\}$ for the velocity space and the pressure space, respectively. The variational problem is as follows: Given $\mathbf{f} \in L^2(\Omega)^d$, find $\{\mathbf{u}, p\} \in \mathbf{V} \times M$ such that

$$\begin{cases} (\nabla \mathbf{u}, \nabla \mathbf{v}) + \xi(\mathbf{u}, \mathbf{v}) - (\operatorname{div} \mathbf{v}, p) = (\mathbf{f}, \mathbf{v}) & \text{for } \mathbf{v} \in \mathbf{V}, \\ (\operatorname{div} \mathbf{u}, q) = 0 & \text{for } q \in M \end{cases} \tag{1.1}$$

with a constant $\xi \geq 0$. Here and in what follows the L^2 scalar product and associated norm are denoted by $(\cdot,\cdot)$, $\|\cdot\|$, respectively. The zeroth order term $\xi(\mathbf{u}, \mathbf{v})$ is included in view of implicit time integration methods applied to nonstationary Stokes equations. For the discretization of this problem we use a pair of conforming Ladyzhenskaya–Babuška–Brezzi (LBB) stable finite element spaces [7, 13]. This results in a saddle point problem of the form

$$\begin{pmatrix} \mathrm{A} & \mathrm{B}^T \\ \mathrm{B} & 0 \end{pmatrix} \begin{pmatrix} \mathrm{x} \\ \mathrm{y} \end{pmatrix} = \begin{pmatrix} \mathrm{f} \\ 0 \end{pmatrix}. \tag{1.2}$$

Many different iterative methods for solving this discrete problem are known. One can apply multigrid techniques to the whole coupled system in (1.2); cf. [15, 27, 28]. Most other approaches are based on the prominent classical Uzawa method. This Uzawa method requires that $\mathrm{A}^{-1}\mathrm{x}$ can be computed exactly [1]. In many variants of this method, which are often called inexact Uzawa methods, one tries to avoid the exact inversion by using an inner iterative method, for example, a Jacobi-like iteration (Arrow–Hurwicz algorithm [1]) or a multigrid method; cf. [24]. We also mention (variants of) the preconditioned minimal residual (MINRES) method [21, 22, 23, 26] and the method from [2]. A different approach is presented in [3], where the indefinite problem (1.2) is reformulated as a symmetric positive definite problem. For most of

†Institut für Geometrie und Praktische Mathematik, RWTH-Aachen, D-52056 Aachen, Germany (peters@igpm.rwth-aachen.de, reichelt@igpm.rwth-aachen.de, reusken@igpm.rwth-aachen.de). The work of the second author was supported by the German Research Foundation through SFB 540.

these methods theoretical convergence analyses are known; cf. [2, 3, 5, 12, 21, 23, 24, 26, 29]. In [11] the performance of a few of these methods is compared by means of systematic numerical experiments for a stationary two-dimensional Stokes problem.

In this paper we consider three representative methods from the large class of inexact Uzawa methods, namely, the preconditioned conjugate gradient method from [3] (denoted by BPCG), the preconditioned MINRES method from [21, 23, 26] (denoted by PMINRES), and the method from [2] (denoted by MGUZAWA). The topics treated in this paper are the following:

- For these three methods we discuss costs per iteration, known theoretical convergence results, and some implementation issues. This makes it possible to make a fair comparison of these methods.
- For the MGUZAWA method we present a convergence analysis. This analysis is much simpler than the analyses presented in [2, 29]. The result that we obtain is different from the ones in [2, 29] and gives a better explanation of the observation that if one uses a very good preconditioner for A (like multigrid), then even with a very low accuracy in the inner iteration the MGUZAWA method converges (cf. Remark 8).
- We present a comparative study of the performance of the three methods. For this we consider a Stokes problem as in (1.1) in three dimensions. We treat both the stationary ($\xi = 0$) and nonstationary ($\xi > 0$) cases. For the discretization we apply the popular Hood–Taylor $P_2 - P_1$ finite element pair. As a preconditioner for A a standard multigrid method is used. For the Schur complement preconditioner we use the mass matrix for the stationary case and a more sophisticated preconditioner analyzed in [4] for the nonstationary case.

The main results of this paper are a detailed comparative study of the three fast iterative solvers for a three-dimensional Stokes problem and a new convergence analysis for the MGUZAWA method.

The paper is organized as follows. In section 2 we formulate the standard Galerkin discretization of the Stokes problem. In section 3.1 we consider the BPCG method. An efficient implementation of this method is discussed and a main convergence result known from the literature is formulated. In section 3.2 the PMINRES method is treated. Also for this method a known convergence result is given. In section 3.3 we discuss the MGUZAWA method and give an efficient implementation of this method. In section 4 a convergence analysis of this method is given. Theorem 4.3 contains the main theoretical result of this paper. In section 5 we discuss the preconditioners for the A-block and for the Schur complement. In section 6 results of numerical experiments are presented that illustrate the performance of the three methods. Finally, in section 7 we give some conclusions.

2. The discrete Stokes equations. For the discretization of the Stokes problem (1.1) we assume a family of triangulations $\{\mathcal{T}_h\}$ in the sense of [9, 10] and a pair of finite element spaces $\mathbf{V}_h \subset \mathbf{V}$ and $M_h \subset M$ that is LBB stable with a constant $\hat{\beta}$ independent of h:

$$\inf_{q_h \in M_h} \sup_{\mathbf{v}_h \in \mathbf{V}_h} \frac{(\operatorname{div} \mathbf{v}_h, q_h)}{\|\nabla \mathbf{v}_h\| \|q_h\|} \geq \hat{\beta} > 0. \tag{2.1}$$

The Galerkin discretization is as follows: Find $\{\mathbf{u}_h, p_h\} \in \mathbf{V}_h \times M_h$ such that

$$\begin{cases} (\nabla \mathbf{u}_h, \nabla \mathbf{v}_h) + \xi(\mathbf{u}_h, \mathbf{v}_h) - (\operatorname{div} \mathbf{v}_h, p_h) = (\mathbf{f}, \mathbf{v}_h) & \text{for } \mathbf{v}_h \in \mathbf{V}_h, \\ (\operatorname{div} \mathbf{u}_h, q_h) = 0 & \text{for } q_h \in M_h. \end{cases} \tag{2.2}$$

In practice the discrete space M_h for the pressure is constructed by taking a standard finite element space, which we denote by M_h^+ (for example, continuous piecewise linear functions), and then adding an orthogonality condition:

$$M_h := \{\, p_h \in M_h^+ \mid (p_h, 1) = 0 \,\}.$$

Note that $\dim(M_h) = \dim(M_h^+) - 1$. Let $n := \dim(\mathbf{V}_h)$, $m := \dim(M_h^+)$. We assume standard (nodal) bases in $\mathbf{V}_h$ and M_h^+ and corresponding isomorphisms

$$J_V : \mathbb{R}^n \to V_h \ , \quad J_M : \mathbb{R}^m \to M_h^+.$$

Let the stiffness matrices $\mathrm{D} \in \mathbb{R}^{n\times n}$, $\mathrm{B} \in \mathbb{R}^{m\times n}$ and the mass matrices $\tilde{\mathrm{M}} \in \mathbb{R}^{n\times n}$, $\mathrm{M} \in \mathbb{R}^{m\times m}$ be given by

$$\begin{aligned}
\langle \mathrm{Dx}, \mathrm{y}\rangle &= (\nabla J_V \mathrm{x}, \nabla J_V \mathrm{y}) && \text{for all } \ \mathrm{x}, \mathrm{y} \in \mathbb{R}^n, \\
\langle \mathrm{Bx}, \mathrm{y}\rangle &= (\operatorname{div} J_V \mathrm{x}, J_M \mathrm{y}) && \text{for all } \ \mathrm{x} \in \mathbb{R}^n,\ \mathrm{y} \in \mathbb{R}^m, \\
\langle \tilde{\mathrm{M}}\mathrm{x}, \mathrm{y}\rangle &= (J_V \mathrm{x}, J_V \mathrm{y}) && \text{for all } \ \mathrm{x}, \mathrm{y} \in \mathbb{R}^n, \\
\langle \mathrm{Mx}, \mathrm{y}\rangle &= (J_M \mathrm{x}, J_M \mathrm{y}) && \text{for all } \ \mathrm{x}, \mathrm{y} \in \mathbb{R}^m.
\end{aligned} \tag{2.3}$$

Here $\langle \cdot, \cdot \rangle$ denotes the standard Euclidean scalar product. The discrete problem has a matrix-vector representation of the form

$$\begin{pmatrix} \mathrm{A} & \mathrm{B}^T \\ \mathrm{B} & 0 \end{pmatrix} \begin{pmatrix} \mathrm{x} \\ \mathrm{y} \end{pmatrix} = \begin{pmatrix} \mathrm{f} \\ 0 \end{pmatrix} \ , \qquad \mathrm{A} := \mathrm{D} + \xi \tilde{\mathrm{M}}, \tag{2.4}$$

with f such that $\langle \mathrm{f}, \mathrm{y}\rangle = (\mathbf{f}, J_V \mathrm{y})$ for all $\mathrm{y} \in \mathbb{R}^n$. We introduce the notation

$$\mathrm{K} := \begin{pmatrix} \mathrm{A} & \mathrm{B}^T \\ \mathrm{B} & 0 \end{pmatrix} \ , \quad \mathrm{S} := \mathrm{B}\mathrm{A}^{-1}\mathrm{B}^T.$$

Define the constant vector $\mathrm{e} := J_M^{-1} 1 = (1, \ldots, 1)^T \in \mathbb{R}^m$. Note that $\mathrm{B}^T \mathrm{e} = 0$ and that both the Schur complement S and the matrix K are singular and have a one-dimensional kernel. For the Schur complement this kernel is $\ker(\mathrm{S}) = \operatorname{span}\{\mathrm{e}\}$. Note that

$$(J_M \mathrm{y}, 1) = 0 \ \Leftrightarrow \ (J_M \mathrm{y}, J_M \mathrm{e}) = 0 \ \Leftrightarrow \ \langle \mathrm{My}, \mathrm{e}\rangle = 0 \ .$$

Hence, with $\mathrm{e}^{\perp_M} := \{\, \mathrm{y} \in \mathbb{R}^m \mid \langle \mathrm{y}, \mathrm{Me}\rangle = 0 \,\}$ we have $M_h = \{\, J_M \mathrm{y} \mid \mathrm{y} \in \mathrm{e}^{\perp_M} \,\}$ and we get the following matrix-vector representation of the discrete problem (2.2):

$$\text{Find } \ \mathrm{x} \in \mathbb{R}^n, \ \mathrm{y} \in \mathrm{e}^{\perp_M} \ \text{ such that (2.4) holds.} \tag{2.5}$$

3. Iterative solvers. In this section we describe three iterative solvers for problem (2.5). The first two methods, a preconditioned conjugate gradient method (BPCG) and a preconditioned MINRES method (PMINRES) are known from the literature and often used in practice. The third method, which may be less known, is a simple variant of the Uzawa method as presented in [2]. In section 4 a convergence analysis of this method is given.

In all three solvers we need symmetric positive definite preconditioners Q_A of A and Q_S of S. The quality of these preconditioners is described by the following spectral equivalences. Let $\gamma_A > 0$, Γ_A, $\gamma_S > 0$, Γ_S be such that

$$\gamma_A \mathrm{Q}_A \le \mathrm{A} \le \Gamma_A \mathrm{Q}_A, \tag{3.1}$$

$$\gamma_S \mathrm{Q}_S \le \mathrm{S} \le \Gamma_S \mathrm{Q}_S \quad \text{on } \ \mathrm{e}^{\perp_M}. \tag{3.2}$$

Here and in what follows, for symmetric matrices E, F we write $E \le F$ ($E < F$) if and only if $F - E$ is positive semidefinite (positive definite). In section 5 we will discuss concrete choices for the preconditioners Q_S and Q_A.

3.1. Preconditioned conjugate gradient method. We describe the preconditioned conjugate gradient (BPCG) method introduced in [3]. For this method we need the following assumption on the preconditioner Q_A:

$$0 < \mathrm{Q}_A < \mathrm{A}; \tag{3.3}$$

i.e., there exists $\gamma_A > 1$ such that (3.1) holds. Clearly, using some suitable scaling one can always satisfy the condition (3.3). Premultiplication of (2.4) by the matrix

$$\mathrm{G} := \begin{pmatrix} \mathrm{Q}_A^{-1} & 0 \\ \mathrm{B}\mathrm{Q}_A^{-1} & -\mathrm{I} \end{pmatrix}$$

yields an equivalent system:

$$\hat{\mathrm{K}} \begin{pmatrix} \mathrm{x} \\ \mathrm{y} \end{pmatrix} = \mathrm{G} \begin{pmatrix} \mathrm{f} \\ 0 \end{pmatrix}, \quad \hat{\mathrm{K}} := \mathrm{G}\mathrm{K} = \begin{pmatrix} \mathrm{Q}_A^{-1}\mathrm{A} & \mathrm{Q}_A^{-1}\mathrm{B}^T \\ \mathrm{B}\mathrm{Q}_A^{-1}\mathrm{A} - \mathrm{B} & \mathrm{B}\mathrm{Q}_A^{-1}\mathrm{B}^T \end{pmatrix}. \tag{3.4}$$

Due to the assumption (3.3) the bilinear form

$$\left[\begin{pmatrix} \mathrm{x}_1 \\ \mathrm{x}_2 \end{pmatrix}, \begin{pmatrix} \mathrm{y}_1 \\ \mathrm{y}_2 \end{pmatrix} \right] := \langle (\mathrm{A} - \mathrm{Q}_A)\mathrm{x}_1, \mathrm{y}_1 \rangle + \langle \mathrm{x}_2, \mathrm{y}_2 \rangle \tag{3.5}$$

defines an inner product. In [3] it is shown that the matrix $\hat{\mathrm{K}}$ is [illegible] on $\mathbb{R}^n \times \mathrm{e}^{\perp_M}$ with respect to this inner product. The matrix

$$\tilde{\mathrm{K}} := \begin{pmatrix} \mathrm{I} & 0 \\ 0 & \mathrm{Q}_S \end{pmatrix}$$

is also symmetric positive definite with respect to this scalar product. Hence we can apply the preconditioned conjugate gradient method in the scalar product $\left[\cdot,\cdot\right]$ and with preconditioner $\tilde{\mathrm{K}}$ to the linear system in (3.4). The algorithm is as follows:

$$\begin{cases} \text{Choose a starting vector } \mathrm{v}^0 = \begin{pmatrix} \mathrm{x}^0 \\ \mathrm{y}^0 \end{pmatrix}; \quad \bar{\mathrm{r}}^0 := \begin{pmatrix} \mathrm{f} \\ 0 \end{pmatrix} - \mathrm{K}\mathrm{v}^0, \quad \mathrm{r}^0 := \mathrm{G}\bar{\mathrm{r}}^0. \\ \text{For } k \geq 0 \quad (\text{if } \mathrm{r}^k \neq 0): \\ \text{Solve } \mathrm{z}^k \text{ from } \tilde{\mathrm{K}}\mathrm{z}^k = \mathrm{r}^k. \\ \beta_k^{(n)} := \left[\mathrm{z}^k, \mathrm{r}^k\right], \quad \beta_k := \beta_k^{(n)}/\beta_{k-1}^{(n)} \quad (\beta_0 := 0), \\ \mathrm{p}^k := \mathrm{z}^k + \beta_k \mathrm{p}^{k-1} \quad (\mathrm{p}^0 := \mathrm{z}^0), \\ \alpha_k^{(d)} := \left[\hat{\mathrm{K}}\mathrm{p}^k, \mathrm{p}^k\right], \quad \alpha_k := \beta_k^{(n)}/\alpha_k^{(d)}, \\ \mathrm{v}^{k+1} := \mathrm{v}^k + \alpha_k \mathrm{p}^k, \\ \mathrm{r}^{k+1} := \mathrm{r}^k - \alpha_k \hat{\mathrm{K}}\mathrm{p}^k. \end{cases} \tag{3.6}$$

This is the standard preconditioned conjugate gradient algorithm. We now discuss an efficient implementation of this algorithm based on ideas from [11]. In particular we want to avoid the evaluation of Q_A. We use indices 1 and 2 to denote the first and second vector components, respectively (as in (3.5)). First note that due to the structure of $\tilde{\mathrm{K}}$ we have $\mathrm{z}_1^k = \mathrm{r}_1^k$. We introduce $\bar{\mathrm{r}}_1^k := \mathrm{Q}_A \mathrm{r}_1^k$ and $\mathrm{d} := \mathrm{A}\mathrm{r}_1^k$. We then have

$$\begin{aligned} \left[\mathrm{z}^k, \mathrm{r}^k\right] &= \langle (\mathrm{A} - \mathrm{Q}_A)\mathrm{z}_1^k, \mathrm{r}_1^k \rangle + \langle \mathrm{z}_2^k, \mathrm{r}_2^k \rangle \\ &= \langle (\mathrm{A} - \mathrm{Q}_A)\mathrm{r}_1^k, \mathrm{r}_1^k \rangle + \langle \mathrm{z}_2^k, \mathrm{r}_2^k \rangle \\ &= \langle \mathrm{d}, \mathrm{r}_1^k \rangle - \langle \bar{\mathrm{r}}_1^k, \mathrm{r}_1^k \rangle + \langle \mathrm{z}_2^k, \mathrm{r}_2^k \rangle \ . \end{aligned}$$

Also define $s^k := Ap_1^k$. From $p^k = z^k + \beta_k p^{k-1}$ it follows that for s^k we have the relation

$$s^k = Ar_1^k + \beta_k s^{k-1} = d + \beta_k s^{k-1}.$$

With

$$\begin{pmatrix} q_1 \\ q_2 \end{pmatrix} := Kp^k = \begin{pmatrix} s^k + B^T p_2^k \\ Bp_1^k \end{pmatrix}, \quad \begin{pmatrix} w_1 \\ w_2 \end{pmatrix} := \hat{K}p^k = \begin{pmatrix} Q_A^{-1} q_1 \\ BQ_A^{-1} q_1 - q_2 \end{pmatrix},$$

we obtain

$$\begin{aligned} \left[\hat{K}p^k, p^k\right] &= \langle (A - Q_A) w_1, p_1^k \rangle + \langle w_2, p_2^k \rangle \\ &= \langle w_1, Ap_1^k \rangle - \langle q_1, p_1^k \rangle + \langle w_2, p_2^k \rangle = \langle w_1, s^k \rangle - \langle q_1, p_1^k \rangle + \langle w_2, p_2^k \rangle. \end{aligned}$$

Finally note that for $\bar{r}_1^k$ we have the recursion

$$\bar{r}_1^{k+1} := \bar{r}_1^k - \alpha_k (Kp^k)_1 = \bar{r}_1^k - \alpha_k q_1.$$

Summarizing, we then obtain the following efficient implementation of the BPCG algorithm:

$$\text{(3.7)} \quad \left\{ \begin{array}{l} \text{Choose a starting vector } v^0 = \begin{pmatrix} x^0 \\ y^0 \end{pmatrix}; \quad \bar{r}^0 := \begin{pmatrix} f \\ 0 \end{pmatrix} - Kv^0 \ , \quad r^0 := G\bar{r}^0. \\ \text{For } k \geq 0 \quad (\text{if } r^k \neq 0): \\ \text{Solve } z_2^k \text{ from } Q_S z_2^k = r_2^k, \quad z_1^k := r_1^k. \\ d := Ar_1^k, \\ \beta_k^{(n)} := \langle d, r_1^k \rangle - \langle \bar{r}_1^k, r_1^k \rangle + \langle z_2^k, r_2^k \rangle, \quad \beta_k := \beta_k^{(n)} / \beta_{k-1}^{(n)} \quad (\beta_0 := 0), \\ p^k := z^k + \beta_k p^{k-1} \quad (p^0 := z^0), \quad s^k = d + \beta_k s^{k-1} \quad (s^0 := d), \\ \begin{pmatrix} q_1 \\ q_2 \end{pmatrix} := \begin{pmatrix} s^k + B^T p_2^k \\ Bp_1^k \end{pmatrix}, \quad \begin{pmatrix} w_1 \\ w_2 \end{pmatrix} := \begin{pmatrix} Q_A^{-1} q_1 \\ BQ_A^{-1} q_1 - q_2 \end{pmatrix}, \\ \alpha_k^{(d)} := \langle w_1, s^k \rangle - \langle q_1, p_1^k \rangle + \langle w_2, p_2^k \rangle, \quad \alpha_k := \beta_k^{(n)} / \alpha_k^{(d)}, \\ v^{k+1} := v^k + \alpha_k p^k, \\ r^{k+1} := r^k - \alpha_k \begin{pmatrix} w_1 \\ w_2 \end{pmatrix}, \quad \bar{r}_1^{k+1} := \bar{r}_1^k - \alpha_k q_1. \end{array} \right.$$

In this algorithm we need Q_A, but we need evaluation of Q_A^{-1} per iteration (by "evaluation" we mean the computation of $Q_A^{-1} q_1$ for a $q_1 \in \mathbb{R}^n$). Furthermore, per iteration we need one evaluation of Q_S^{-1} and two matrix-vector products with B, one with B^T and one with A.

We want to use this algorithm to solve problem (2.5). Then it is desirable that the iterates $v^k = (x^k, y^k)$ are such that $y^k \in e^{\perp_M}$ holds. Therefore we assume that the preconditioner Q_S satisfies the consistency condition

$$\text{(3.8)} \qquad Q_S e = \alpha Me, \quad \alpha \in \mathbb{R}.$$

From this assumption it follows that $y^0 \in e^{\perp_M}$ implies $y^k \in e^{\perp_M}$ for all $k \geq 1$. Moreover, if (3.8) holds, then $\tilde{K}^{-1}\hat{K}$ is bijective on $\mathbb{R}^n \times e^{\perp_M}$. We now formulate a

main convergence result for the BPCG algorithm due to [3, 29]. Let $\kappa_*(\tilde{\mathrm{K}}^{-1}\hat{\mathrm{K}})$ be the spectral condition number of the matrix $\tilde{\mathrm{K}}^{-1}\hat{\mathrm{K}}$ on the subspace $\mathbb{R}^n \times \mathrm{e}^{\perp_M}$. This quantity plays a key role in the convergence analysis of the preconditioned conjugate gradient method.

THEOREM 3.1. [illegible] (3.1) (3.2) (3.3) [illegible] (3.8) [illegible] $x \in \mathbb{R}$ [illegible]

$$b(x) := \frac{1}{2}(1+x) + \frac{1}{2}\sqrt{(1+x)^2 - 4x\Gamma_A^{-1}}.$$

[illegible]

$$\kappa_*(\tilde{\mathrm{K}}^{-1}\hat{\mathrm{K}}) \le \frac{\Gamma_S}{\gamma_S}\frac{\Gamma_A b(\Gamma_S) b(\gamma_S)}{\Gamma_S} \ . \tag{3.9}$$

[illegible] We can apply Theorem 4.1 in [29] in the subspace $\mathbb{R}^n \times \mathrm{e}^{\perp_M}$. This yields $\kappa_*(\tilde{\mathrm{K}}^{-1}\hat{\mathrm{K}}) \le (1-\rho_1)/(1-\rho_2)$, with

$$\rho_1 := \frac{2-(1+\Gamma_S)\Gamma_A}{2} - \sqrt{\frac{(2-(1+\Gamma_S)\Gamma_A)^2}{4} + \Gamma_A - 1}\ ,$$
$$\rho_2 := \frac{2-(1+\gamma_S)\Gamma_A}{2} + \sqrt{\frac{(2-(1+\gamma_S)\Gamma_A)^2}{4} + \Gamma_A - 1}\ .$$

Elementary manipulations show that $(1-\rho_1)/(1-\rho_2) = \frac{\Gamma_S}{\gamma_S}\frac{\Gamma_A b(\Gamma_S) b(\gamma_S)}{\Gamma_S}$ holds. ∎

[illegible] 1. Note that $\Gamma_A \ge 1$ and thus $\frac{1}{2}(1+x) + \frac{1}{2}|1-x| \le b(x) \le \frac{1}{2}(1+x) + \frac{1}{2}|1+x|$. Hence, $1 \le b(x) \le 1+x$ if $x \in [0,1]$ and $x \le b(x) \le 1+x$ if $x \ge 1$. From this it follows that for the factor $C(\gamma_S, \Gamma_S) := \frac{b(\Gamma_S)b(\gamma_S)}{\Gamma_S}$ in (3.9) we have

$$\frac{1}{\Gamma_S} \le C(\gamma_S,\Gamma_S) \le \frac{4}{\Gamma_S} \quad \text{if } \ \Gamma_S \le 1,$$
$$1 \le C(\gamma_S,\Gamma_S) \le 2 + \frac{2}{\Gamma_S} \le 4 \quad \text{if } \ \gamma_S \le 1 \le \Gamma_S,$$
$$\gamma_S \le C(\gamma_S,\Gamma_S) \le 3 + \gamma_S \le 4\gamma_S \quad \text{if } \ 1 \le \gamma_S.$$

From this we see that although the condition number of the preconditioned Schur complement $\kappa_*(\mathrm{Q}_S^{-1}\mathrm{S}) \le \Gamma_S/\gamma_s$ is [illegible] of the scaling of the preconditioner Q_S, the bound for the condition number $\kappa_*(\tilde{\mathrm{K}}^{-1}\hat{\mathrm{K}})$ in (3.9) does depend on the scaling of Q_S. A poor scaling (i.e., $\Gamma_S \ll 1$ or $\gamma_S \gg 1$) leads to a large upper bound. We consider an example, which shows that this bound is sharp. Take $\mathrm{Q}_A = \Gamma_A^{-1}\mathrm{A}$ and $\mathrm{Q}_S = \Gamma^{-1}\mathrm{S}$ (on $\mathrm{e}^{\perp}$) with $\Gamma_A > 1$ and $\Gamma > 0$. Then (3.2) is fulfilled with $\gamma_S = \Gamma_S = \Gamma$. A simple computation shows that $\sigma_*(\tilde{\mathrm{K}}^{-1}\hat{\mathrm{K}}) = \{\Gamma/b(\Gamma), \Gamma_A, \Gamma_A b(\Gamma)\}$ and thus $\kappa_*(\tilde{\mathrm{K}}^{-1}\hat{\mathrm{K}}) = \Gamma_A\frac{b(\Gamma)^2}{\Gamma}$, which agrees with the bound in (3.9). Hence $\kappa_*(\tilde{\mathrm{K}}^{-1}\hat{\mathrm{K}}) \ge \frac{\Gamma_A}{\Gamma}$ if $\Gamma \le 1$ and $\kappa_*(\tilde{\mathrm{K}}^{-1}\hat{\mathrm{K}}) \ge \Gamma_A\Gamma$ if $\Gamma \ge 1$. Note, however, that although $\kappa_*(\tilde{\mathrm{K}}^{-1}\hat{\mathrm{K}})$ is large if $\Gamma \ll 1$ or $\Gamma \gg 1$ the BPCG method will converge in three iterations because $\sigma_*(\tilde{\mathrm{K}}^{-1}\hat{\mathrm{K}})$ contains only three elements.

3.2. Preconditioned minimal residual method. In this section we consider a preconditioned minimal residual (PMINRES) method for solving the discretized Stokes problem. This class of methods has been developed in [20, 21, 23]. We consider a symmetric positive definite preconditioner

$$\tilde{\mathrm{K}} := \begin{pmatrix} \mathrm{Q}_A & 0 \\ 0 & \mathrm{Q}_S \end{pmatrix} \tag{3.10}$$

for K. Define the norm $\|v\|_{\tilde{K}} := \langle \tilde{K}v, v\rangle^{\frac{1}{2}}$ for $v \in \mathbb{R}^{n+m}$. Given a starting vector v^0 with corresponding error $e^0 := v^* - v^0$, then in the PMINRES method one computes the vector $v^k \in v^0 + \operatorname{span}\{\tilde{K}^{-1}Ke^0, \ldots, (\tilde{K}^{-1}K)^k e^0\}$, which minimizes the preconditioned residual $\|\tilde{K}^{-1}K(v^* - v)\|_{\tilde{K}}$ over this subspace.

An efficient implementation of this method can be derived using the Lanczos algorithm and Givens rotations. For such an implementation we refer to the literature; see, e.g., [19, 14]. In an efficient implementation of this method one needs per iteration one evaluation of Q_A^{-1}, one evaluation of Q_S^{-1}, and one matrix-vector product with K.

We assume that the preconditioner Q_S satisfies the consistency condition (3.8). Then it follows that the approximations y^k of the discrete pressure are in the subspace $e^{\perp_M}$ if the starting vector y^0 is in this subspace.

Note that for this algorithm one does not need the scaling condition (3.3) for Q_A. We give two main theoretical convergence results on the PMINRES algorithm from the literature (cf. [14, 21, 23]).

THEOREM 3.2. $v^0 = (x^0, y^0)$ $y^0 \in e^{\perp_M}$ v^k $k \geq 0$ $\tilde{r}^k := \tilde{K}^{-1}\big((f, 0) - Kv^k\big)$

$$\begin{aligned}\|\tilde{r}^k\|_{\tilde{K}} &= \min_{p_k \in \mathcal{P}_k; p_k(0)=1} \|p_k(\tilde{K}^{-1}K)\tilde{r}^0\|_{\tilde{K}} \\ &\leq \min_{p_k \in \mathcal{P}_k; p_k(0)=1} \max_{\lambda \in \sigma_*(\tilde{K}^{-1}K)} |p_k(\lambda)|\, \|\tilde{r}^0\|_{\tilde{K}} ,\end{aligned}$$

$\sigma_*(\cdot)$ $\mathbb{R}^n \times e^{\perp_M}$

THEOREM 3.3. (3.1) (3.2) (3.8) $\tilde{K}^{-1}K$

$$\begin{aligned}\sigma_*(\tilde{K}^{-1}K) \subset &\Big[\frac{1}{2}\big(\gamma_A - \sqrt{\gamma_A^2 + 4\Gamma_S\Gamma_A}\big)\,,\ \frac{1}{2}\big(\gamma_A - \sqrt{\gamma_A^2 + 4\gamma_S\gamma_A}\big)\Big] \\ &\bigcup \Big[\gamma_A\,,\ \frac{1}{2}\big(\Gamma_A + \sqrt{\Gamma_A^2 + 4\Gamma_S\Gamma_A}\big)\Big].\end{aligned} \tag{3.11}$$

From the results in these theorems it follows that the rate of convergence of the PMINRES method is robust with respect to variation in the parameters h and ξ if the spectral constants γ_S, Γ_S, γ_A, Γ_A do not depend on these parameters. Moreover, we can expect faster convergence if we have better preconditioners.

2. Related to the scaling we consider the same example as in Remark 1: $Q_A = \Gamma_A^{-1}A$, $Q_S = \Gamma^{-1}S$ (on $e^{\perp}$). We then have $\gamma_A = \Gamma_A$, $\gamma_S = \Gamma_S = \Gamma$. A simple computation yields $\sigma_*(\tilde{K}^{-1}K) = \{\frac{1}{2}\big(\Gamma_A - \sqrt{\Gamma_A^2 + 4\Gamma\Gamma_A}\big), \Gamma_A, \frac{1}{2}\big(\Gamma_A + \sqrt{\Gamma_A^2 + 4\Gamma\Gamma_A}\big)\}$. This shows that for this example the result in (3.11) is sharp. Furthermore, the scaling of Q_S has a significant influence on the endpoints of the intervals in (3.11). However, for this example, the PMINRES method will converge in three iterations since $\sigma_*(\tilde{K}^{-1}K)$ contains only three elements.

3.3. An inexact Uzawa method. A basic method for saddle point problems is the Uzawa method. This method is closely related to the block factorization

$$K = \begin{pmatrix} A & 0 \\ B & -I \end{pmatrix} \begin{pmatrix} I & A^{-1}B^T \\ 0 & S \end{pmatrix}.$$

Solving the problem $\mathrm{K}\binom{\mathrm{x}}{\mathrm{y}} = \binom{\mathrm{f}}{0}$ by block forward-backward substitution yields the equivalent problem:

(3.12) 1. Solve $\mathrm{Az} = \mathrm{f}$.

(3.13) 2. Solve $\mathrm{Sy} = \mathrm{Bz}, \quad \mathrm{y} \in \mathrm{e}^{\perp_M}$.

(3.14) 3. Solve $\mathrm{Ax} = \mathrm{z} - \mathrm{B}^T\mathrm{y}$.

In the Uzawa method one applies an iterative solver (e.g., conjugate gradient) to the Schur complement system in step 2. The A-systems that occur in each iteration of this method and in steps 1 and 3 are solved sufficiently accurately using some fast Poisson solver.

Here we reconsider a simple variant of this method which was introduced in [2]. Let Q_A be a preconditioner of A as in (3.1). We use this preconditioner in steps 1 and 3 and also for the approximation of the Schur complement in step 2. For this we introduce the notation

$$\hat{\mathrm{S}} := \mathrm{BQ}_A^{-1}\mathrm{B}^T.$$

Note that $\hat{\mathrm{S}} : \mathrm{e}^{\perp_M} \to \mathrm{e}^{\perp}$ is bijective. We use a (nonlinear) approximate inverse of $\hat{\mathrm{S}}$ denoted by $\Psi : \mathrm{e}^{\perp} \to \mathrm{e}^{\perp_M}$. For each $\mathrm{w} \in \mathrm{e}^{\perp}$, $\Psi(\mathrm{w})$ is an approximation to the solution $\mathrm{z}^* \in \mathrm{e}^{\perp_M}$ of $\hat{\mathrm{S}}\mathrm{z} = \mathrm{w}$. We assume that

$$\|\Psi(\mathrm{w}) - \mathrm{z}^*\|_{\hat{\mathrm{S}}} \le \delta \|\mathrm{z}^*\|_{\hat{\mathrm{S}}} \quad \text{for all} \quad \mathrm{w} \in \mathrm{e}^{\perp} \tag{3.15}$$

holds with some $\delta < 1$. In our experiments Ψ will be the preconditioned conjugate gradient method.

Let $(\mathrm{x}^k, \mathrm{y}^k)$ be a given approximation to the solution (x, y). Note that using the block factorization of K gives us

$$\begin{pmatrix}\mathrm{x}\\ \mathrm{y}\end{pmatrix} = \begin{pmatrix}\mathrm{x}^k\\ \mathrm{y}^k\end{pmatrix} + \begin{pmatrix}\mathrm{I} & -\mathrm{A}^{-1}\mathrm{B}^T\mathrm{S}^{-1}\\ 0 & \mathrm{S}^{-1}\end{pmatrix}\begin{pmatrix}\mathrm{A}^{-1} & 0\\ \mathrm{BA}^{-1} & -\mathrm{I}\end{pmatrix}\left(\begin{pmatrix}\mathrm{f}\\ 0\end{pmatrix} - \mathrm{K}\begin{pmatrix}\mathrm{x}^k\\ \mathrm{y}^k\end{pmatrix}\right). \tag{3.16}$$

With $\mathrm{A}^{-1} \approx \mathrm{Q}_A^{-1}$, $\mathrm{S}^{-1}\mathrm{w} \approx \hat{\mathrm{S}}^{-1}\mathrm{w} \approx \Psi(\mathrm{w})$, and $\mathrm{r}_1^k := \mathrm{f} - \mathrm{Ax}^k - \mathrm{B}^T\mathrm{y}^k$ we obtain the (nonlinear) iterative method

$$\begin{aligned}\mathrm{x}^{k+1} &= \mathrm{x}^k + \mathrm{Q}_A^{-1}\mathrm{r}_1^k - \mathrm{Q}_A^{-1}\mathrm{B}^T\Psi\big(\mathrm{B}(\mathrm{Q}_A^{-1}\mathrm{r}_1^k + \mathrm{x}^k)\big),\\ \mathrm{y}^{k+1} &= \mathrm{y}^k + \Psi\big(\mathrm{B}(\mathrm{Q}_A^{-1}\mathrm{r}_1^k + \mathrm{x}^k)\big).\end{aligned} \tag{3.17}$$

We obtain the following algorithmic structure:

Choose a starting vector $\mathrm{v}^0 = \begin{pmatrix}\mathrm{x}^0\\ \mathrm{y}^0\end{pmatrix}$, with $\mathrm{y}^0 \in \mathrm{e}^{\perp_M}$; $\mathrm{r}_1^0 := \mathrm{f} - \mathrm{Ax}^0 - \mathrm{B}^T\mathrm{y}^0$.

For $k \ge 0$:

$$\mathrm{w} := \mathrm{x}^k + \mathrm{Q}_A^{-1}\mathrm{r}_1^k, \tag{3.18}$$

$$\mathrm{z} := \Psi(\mathrm{Bw}) \in \mathrm{e}^{\perp_M}, \tag{3.19}$$

$$\mathrm{x}^{k+1} := \mathrm{w} - \mathrm{Q}_A^{-1}\mathrm{B}^T\mathrm{z}, \tag{3.20}$$

$$\mathrm{y}^{k+1} := \mathrm{y}^k + \mathrm{z}, \tag{3.21}$$

$$\mathrm{r}_1^{k+1} := \mathrm{r}_1^k - \mathrm{A}(\mathrm{x}^{k+1} - \mathrm{x}^k) - \mathrm{B}^T\mathrm{z}. \tag{3.22}$$

This is the same method as the one presented in section 4 in [2]. An obvious choice for $\Psi(\mathrm{Bw})$, which is also used in our experiments, is the following:

$$\Psi(\mathrm{Bw}) = \begin{cases} \text{Result of } \ell \text{ preconditioned conjugate gradient iterations with startvector 0 and preconditioner } \mathrm{Q}_S \\ \text{applied to } \hat{\mathrm{S}}\mathrm{y} = \mathrm{Bw}. \end{cases} \tag{3.23}$$

3. We comment on some implementation issues and on the arithmetic costs per iteration of the algorithm (3.18)–(3.23). In each iteration of the preconditioned conjugate gradient algorithm in (3.23) one needs an evaluation of Q_S^{-1} and of $\hat{\mathrm{S}} = \mathrm{B}\mathrm{Q}_A^{-1}\mathrm{B}^T$ (i.e., the computation of a matrix-vector product with these matrices). Thus per preconditioned conjugate gradient iteration we need one evaluation of Q_S^{-1}, one of Q_A^{-1}, and a matrix-vector multiplication with B and with B^T. In the preconditioned conjugate gradient method one computes approximations $\mathrm{z}^0 = 0, \mathrm{z}^1, \ldots, \mathrm{z}^\ell =: \mathrm{z}$. For these approximations we have a recursion of the form $\mathrm{z}^{i+1} = \mathrm{z}^i + \alpha_i \mathrm{p}^i$ (cf. algorithm (3.6)) and the vectors $\hat{\mathrm{S}}\mathrm{p}^i = \mathrm{B}(\mathrm{Q}_A^{-1}(\mathrm{B}^T\mathrm{p}^i))$ are computed. Hence, in the inner preconditioned conjugate gradient loop (3.19), (3.23) the vectors $\mathrm{B}^T\mathrm{p}^i$, $\mathrm{Q}_A^{-1}\mathrm{B}^T\mathrm{p}^i$, $i = 0, \ldots, \ell-1$, are available. For $\bar{\mathrm{z}}^i := \mathrm{B}^T\mathrm{z}^i$, $\hat{\mathrm{z}}^i := \mathrm{Q}_A^{-1}\mathrm{B}^T\mathrm{z}^i$ we have recursions $\bar{\mathrm{z}}^{i+1} = \bar{\mathrm{z}}^i + \alpha_i \mathrm{B}^T\mathrm{p}^i$ and $\hat{\mathrm{z}}^{i+1} = \hat{\mathrm{z}}^i + \alpha_i \mathrm{Q}_A^{-1}\mathrm{B}^T\mathrm{p}^i$, and thus $\bar{\mathrm{z}}^i$, $\hat{\mathrm{z}}^i$, $i = 1, \ldots, \ell$, can be computed with low costs (AXPY operations). Using this approach we can obtain $\bar{\mathrm{z}}^\ell = \mathrm{B}^T\mathrm{z}^\ell = \mathrm{B}^T\mathrm{z}$ and $\hat{\mathrm{z}}^\ell = \mathrm{Q}_A^{-1}\bar{\mathrm{z}}^\ell = \mathrm{Q}_A^{-1}\mathrm{B}^T\mathrm{z}$ with negligible computational costs. Hence for the computation of $\mathrm{B}^T\mathrm{z}$ and $\mathrm{Q}_A^{-1}\mathrm{B}^T\mathrm{z}$ in (3.20), (3.22) we do not need significant arithmetic work. Summarizing, per outer iteration of the algorithm (3.18)–(3.23) we need $\ell+1$ evaluations of Q_A^{-1}, ℓ evaluations of Q_S^{-1}, $\ell+1$ matrix-vector multiplications with B, ℓ matrix-vector multiplications with B^T, and one matrix-vector multiplication with A.

Clearly an important issue in the algorithm is the stopping criterion for the inner iteration. From the analysis presented in section 4 it follows that for an efficient method this stopping criterion should depend on the accuracy of the preconditioner Q_A. A very efficient Poisson solver is the multigrid method. Thus for the preconditioner Q_A we propose the following:

$$\mathrm{Q}_A^{-1}\mathrm{w} = \begin{cases} \text{One symmetric multigrid V-cycle iteration, using one symmetric Gauss–Seidel iteration for pre- and post-} \\ \text{smoothing, with startvector 0 applied to } \mathrm{Ax} = \mathrm{w}. \end{cases} \tag{3.24}$$

The convergence factor per iteration of this method typically is between 0.1 and 0.2. From the analysis (cf. Remark 4) we deduce the following two possibilities for the stopping criterion of the preconditioned conjugate gradient method:

- Let r^i be the residual in the preconditioned conjugate gradient algorithm. We stop the preconditioned conjugate gradient iteration if

$$\|\mathrm{r}^\ell\|_2 \leq \sigma_{\mathrm{acc}} \|\mathrm{r}^0\|_2 \quad \text{is satisfied, with a given } \sigma_{\mathrm{acc}} \in [0.2, 0.6]. \tag{3.25}$$

- We use a fixed low number of iterations: $\ell \in [1, 4]$.

4. Analysis of the inexact Uzawa algorithm. The inexact Uzawa method has been analyzed in [2, 29]. Here we present an alternative analysis. This analysis is much simpler than those presented in [2] and [29] and the result is different. In Remark 8 we discuss the main differences to the results from [2, 29].

For simplicity we assume that for the preconditioner Q_A we have

$$\mathrm{A} \leq \mathrm{Q}_A, \quad \text{i.e., } \gamma_A \mathrm{Q}_A \leq \mathrm{A} \leq \mathrm{Q}_A. \tag{4.1}$$

We make the scaling assumption $A \leq Q_A$ because, opposite to the scaling condition in (3.3), it is fulfilled for the multigrid preconditioner in (3.24). Moreover, it improves the presentation of the analysis. However, this [illegible]

In the analysis we use the following natural norms:

$$\|x\|_Q := \|Q_A^{\frac{1}{2}} x\| = \langle Q_A x, x\rangle^{\frac{1}{2}} \quad \text{for} \quad x \in \mathbb{R}^n, \quad \|y\|_{\hat{S}} := \|\hat{S}^{\frac{1}{2}} y\| = \langle \hat{S} y, y\rangle^{\frac{1}{2}} \quad \text{for} \quad y \in e^{\perp_M}.$$

For the error in algorithm (3.18)–(3.22) we use the notation

$$e^k = \begin{pmatrix} x \\ y \end{pmatrix} - \begin{pmatrix} x^k \\ y^k \end{pmatrix} =: \begin{pmatrix} e_1^k \\ e_2^k \end{pmatrix}.$$

Note that $e_2^k \in e^{\perp_M}$ holds.

LEMMA 4.1. [illegible] (3.18) [illegible]

$$\langle \hat{S}^{-1} Bw, Bw\rangle^{\frac{1}{2}} \leq (1 - \gamma_A)\|e_1^k\|_Q + \|e_2^k\|_{\hat{S}}.$$

[illegible]. For $y \in \text{range}(\hat{S}) = \text{range}(B)$ define $\|y\|_{\hat{S}^{-1}} = \langle \hat{S}^{-1} y, y\rangle^{\frac{1}{2}}$. Note that for the exact discrete solution x we have $Bx = 0$. Using this and the definition in (3.18) we get

$$Bw = Bx^k - Bx + BQ_A^{-1}(Ae_1^k + B^T e_2^k) = -B(I - Q_A^{-1}A)e_1^k + \hat{S}e_2^k.$$

Hence,

$$\begin{aligned} \langle \hat{S}^{-1} Bw, Bw\rangle^{\frac{1}{2}} &= \|Bw\|_{\hat{S}^{-1}} \leq \|B(I - Q_A^{-1}A)e_1^k\|_{\hat{S}^{-1}} + \|\hat{S}e_2^k\|_{\hat{S}^{-1}} \\ &\leq \|\hat{S}^{-\frac{1}{2}} B(I - Q_A^{-1}A)Q_A^{-\frac{1}{2}}\| \|Q_A^{\frac{1}{2}} e_1^k\| + \|\hat{S}^{\frac{1}{2}} e_2^k\|. \end{aligned}$$

Now note that

$$\|\hat{S}^{-\frac{1}{2}} B(I - Q_A^{-1}A)Q_A^{-\frac{1}{2}}\| \leq \|\hat{S}^{-\frac{1}{2}} BQ_A^{-\frac{1}{2}}\| \|Q_A^{\frac{1}{2}}(I - Q_A^{-1}A)Q_A^{-\frac{1}{2}}\|,$$

and

$$\begin{aligned} \|\hat{S}^{-\frac{1}{2}} BQ_A^{-\frac{1}{2}}\|^2 &= \rho(\hat{S}^{-\frac{1}{2}} BQ_A^{-1} B^T \hat{S}^{-\frac{1}{2}}) = \rho(I) = 1, \\ \|Q_A^{\frac{1}{2}}(I - Q_A^{-1}A)Q_A^{-\frac{1}{2}}\| &= \rho(I - Q_A^{-\frac{1}{2}} AQ_A^{-\frac{1}{2}}) \leq 1 - \gamma_A. \end{aligned}$$

This completes the proof. □

We now formulate the main convergence result.

THEOREM 4.2. [illegible] (3.18) (3.22) [illegible] Ψ [illegible] (3.15) [illegible] $e^k = (e_1^k, e_2^k)$ [illegible]

$$\|e_1^{k+1}\|_Q \leq (1 - \gamma_A)\|e_1^k\|_Q + \|e_2^{k+1}\|_{\hat{S}}, \tag{4.2}$$

$$\|e_2^{k+1}\|_{\hat{S}} \leq (1 - \gamma_A)(1 + \delta)\|e_1^k\|_Q + \delta\|e_2^k\|_{\hat{S}} \tag{4.3}$$

[illegible] γ_A [illegible] (4.1) [illegible] δ [illegible] (3.15)

[illegible]. For the error component e_1^{k+1} we have the relations

$$\begin{aligned} e_1^{k+1} &= x - x^{k+1} = x - w + Q_A^{-1} B^T z \\ &= x - x^k - Q_A^{-1}(Ae_1^k + B^T e_2^k - B^T z) \\ &= (I - Q_A^{-1}A)e_1^k - Q_A^{-1} B^T (e_2^k - z) \\ &= (I - Q_A^{-1}A)e_1^k - Q_A^{-1} B^T e_2^{k+1}. \end{aligned}$$

Hence,

$$\|e_1^{k+1}\|_Q \le \|I - Q_A^{-\frac{1}{2}} A Q_A^{-\frac{1}{2}}\| \|e_1^k\|_Q + \|Q_A^{-\frac{1}{2}} B^T \hat{S}^{-\frac{1}{2}}\| \|e_2^{k+1}\|_{\hat{S}}.$$

In combination with

$$\|I - Q_A^{-\frac{1}{2}} A Q_A^{-\frac{1}{2}}\| \le 1 - \gamma_A \ , \quad \|Q_A^{-\frac{1}{2}} B^T \hat{S}^{-\frac{1}{2}}\| = 1,$$

this proves the inequality in (4.2). For the error component e_2^{k+1} we obtain

$$e_2^{k+1} = y - y^{k+1} = e_2^k - z = (e_2^k - \hat{S}^{-1} B w) + (\hat{S}^{-1} B w - z). \tag{4.4}$$

Using $Bx = 0$ we get

$$\begin{aligned} \|e_2^k - \hat{S}^{-1} B w\|_{\hat{S}} &= \|e_2^k - \hat{S}^{-1} B(x^k + Q_A^{-1} A e_1^k + Q_A^{-1} B^T e_2^k)\|_{\hat{S}} \\ &= \|e_2^k + \hat{S}^{-1} B(I - Q_A^{-1} A) e_1^k - \hat{S}^{-1} B Q_A^{-1} B^T e_2^k\|_{\hat{S}} \\ &= \|\hat{S}^{-1} B(I - Q_A^{-1} A) e_1^k\|_{\hat{S}} \\ &\le \|\hat{S}^{-\frac{1}{2}} B Q_A^{-\frac{1}{2}}\| \|I - Q_A^{-\frac{1}{2}} A Q_A^{-\frac{1}{2}}\| \|e_1^k\|_Q \\ &\le (1 - \gamma_A) \|e_1^k\|_Q. \end{aligned} \tag{4.5}$$

Furthermore, using (3.15) and Lemma 4.1 we also have

$$\begin{aligned} \|\hat{S}^{-1} B w - z\|_{\hat{S}} &= \|\hat{S}^{-1} B w - \Psi(B w)\|_{\hat{S}} \le \delta \, \|\hat{S}^{-1} B w\|_{\hat{S}} \\ &= \delta \, \langle \hat{S}^{-1} B w, B w \rangle^{\frac{1}{2}} \le \delta \big((1 - \gamma_A) \|e_1^k\|_Q + \|e_2^k\|_{\hat{S}} \big). \end{aligned} \tag{4.6}$$

Combining the results in (4.4), (4.5), (4.6) proves the inequality in (4.3). ∎

As a simple consequence of this theorem we obtain the following convergence result.

THEOREM 4.3. [illegible]

$$\mu_A := 1 - \gamma_A, \quad g(\mu_A, \delta) := 2\mu_A + \delta(1 + \mu_A).$$

[illegible] (3.18) (3.22) [illegible] Ψ [illegible] (3.15) [illegible] $e^k = (e_1^k, e_2^k)$ [illegible]

$$\max \big\{ \|e_1^{k+1}\|_Q, \|e_2^{k+1}\|_{\hat{S}} \big\} \le g(\mu_A, \delta) \, \max \big\{ \|e_1^k\|_Q, \|e_2^k\|_{\hat{S}} \big\}, \tag{4.7}$$

$$\|e_1^k\|_Q + \|e_2^k\|_{\hat{S}} \le 3 \frac{1}{2} \Big(\frac{g(\mu_A, \delta) + \sqrt{g(\mu_A, \delta)^2 - 4\mu_A \delta}}{2} \Big)^k (\|e_1^0\|_Q + \|e_2^0\|_{\hat{S}}). \tag{4.8}$$

[illegible]. Define the matrix

$$C = \begin{pmatrix} \mu_A(2 + \delta) & \delta \\ \mu_A(1 + \delta) & \delta \end{pmatrix}.$$

Due to Theorem 4.2 we obtain

$$\begin{pmatrix} \|e_1^{k+1}\|_Q \\ \|e_2^{k+1}\|_{\hat{S}} \end{pmatrix} \le C \begin{pmatrix} \|e_1^k\|_Q \\ \|e_2^k\|_{\hat{S}} \end{pmatrix}.$$

From $\|\mathrm{C}\|_\infty = g(\mu_A, \delta)$ we obtain the result in (4.7). A simple (MAPLE) computation yields the eigenvector decomposition $\mathrm{C} = \mathrm{V}\mathrm{D}\mathrm{V}^{-1}$ with a diagonal matrix D. From this we get

$$\rho(\mathrm{C}) = \frac{1}{2}\Big(g(\mu_A,\delta) + \sqrt{g(\mu_A,\delta)^2 - 4\mu_A\delta}\Big),$$
$$\max_{0<\mu_A,\delta<1} \|\mathrm{V}\|_1 \|\mathrm{V}^{-1}\|_1 \le 3\frac{1}{2}.$$

From this the result in (4.8) follows. □

COROLLARY 4.4. [illegible] (4.7) [illegible] (4.8) [illegible] μ_A [illegible] δ [illegible] $\mu_A \to 0$ [illegible] $g(0,\delta) = \delta$ [illegible] $g(\mu_A,\delta) \ge \frac{1}{2}\big(g(\mu_A,\delta) + \sqrt{g(\mu_A,\delta)^2 - 4\mu_A\delta}\big)$

$$g(\mu_A,\delta) < 1 \quad \text{for} \quad 0 \le \delta < \frac{1-2\mu_A}{1+\mu_A}, \tag{4.9}$$

$$\frac{1}{2}\big(g(\mu_A,\delta) + \sqrt{g(\mu_A,\delta)^2 - 4\mu_A\delta}\big) < 1 \quad \text{for} \quad 0 \le \delta < 1-2\mu_A. \tag{4.10}$$

[illegible] $\mu_A < \frac{1}{2}$ [illegible] δ [illegible] (4.9), (4.10) [illegible]

4. We comment on the important special case where we take for Q_A^{-1} a symmetric multigrid V-cycle as in (3.24). Then μ_A is the contraction number (with respect to the norm $\|\cdot\|_A$) of this multigrid method. It is known from numerical experiments that typically we have $0.1 \le \mu_A \le 0.2$. The result in (4.10) shows that for $\mu_A \approx 0.15$ we have a convergent method if for the accuracy of the inner method we take $\delta \lesssim 0.7$. Clearly it is not efficient to use a very small value for δ. We comment on the choice of this parameter δ. We consider the case $\mu_A = 0.1$. For the contraction number in (4.7) we then have $g(0.1,\delta) = 0.2 + 1.1\delta$. For a given eps $\ll 1$ let k be such that

$$g(0.1,\delta)^k \approx \text{eps}.$$

Then

$$k \approx \frac{\ln(\text{eps})}{\ln(0.2 + 1.1\delta)}$$

holds. We use the ansatz (cf. (3.23)) $\delta = \beta^\ell$ with some $\beta < 1$. From Remark 3 it follows that the arithmetic costs are dominated by $k(\ell+1)$ evaluations of Q_A^{-1}. Hence, one wants to minimize

$$k(\ell+1) \approx \frac{\ln(\text{eps})}{\ln\beta}\frac{\ln\delta + \ln\beta}{\ln(0.2+1.1\delta)} =: k_{\text{Uzawa}} K(\beta,\delta),$$

where $k_{\text{Uzawa}} := \ln(\text{eps})/\ln\beta$ is the number of iterations of the exact Uzawa method ($\mu_A = 0$). For different β values the function $\delta \to K(\beta,\delta)$ is given in Figure 1. We see that an almost optimal value for δ is obtained in a very broad range. For other μ_A values (< 0.2) one observes a similar behavior.

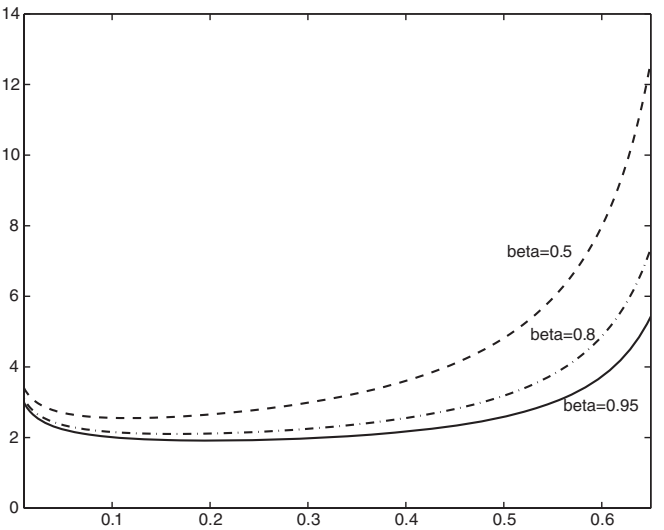

FIG. 1. *Function* $\delta \to K(\beta, \delta)$ *for* $\beta = 0.5, 0.8, 0.95$.

In the preconditioned conjugate gradient method (3.23) we use a preconditioner Q_S of $\hat{S}$. We assume that (3.2) and (3.8) hold. Using (4.1) it follows that

$$\gamma_A \gamma_S Q_S \leq \hat{S} \leq \Gamma_S Q_S \tag{4.11}$$

holds.

REMARK 5. Note that opposite to the BPCG method treated in section 3.1 and the PMINRES method treated in section 3.2, the scaling of the preconditioner Q_S does influence the rate of convergence of the inexact Uzawa method (cf. Remarks 1 and 2).

REMARK 6. If we consider the case with $\mu_A \approx 1$, $\delta \approx 1$, i.e., both the A-system and the $\hat{S}$-system are solved inaccurately, then $g_B(\mu_A, \delta) > 1$ and $g(\mu_A, \delta) > 1$. Hence, these convergence analyses do not yield convergence of the inexact Uzawa method. In our numerical experiments, however, we do observe convergence for this case; cf. Remark 9. To our knowledge, an analysis which covers the whole range μ_A, $\delta \in [0, 1)$ is not yet available.

In the convergence analysis we use the norm

$$\sqrt{\|x\|_Q^2 + \|y\|_{\hat{S}}^2} =: |||(x, y)||| \quad \text{on} \quad \mathbb{R}^n \times e^{\perp_M}. \tag{4.12}$$

REMARK 7. If we consider a stationary Stokes problem, then the norm in (4.12) is very natural. In this setting one usually takes $Q_S = M$ (pressure mass matrix as in (2.3)). Then the constants $\gamma_A, \gamma_S, \Gamma_S$ can be shown to be independent of h, and from this one obtains

$$\begin{aligned} &c_1 \big(\|\nabla J_V x\|^2 + \|J_M y\|^2 \big)^{\frac{1}{2}} \leq |||(x, y)||| \\ &\leq c_2 \big(\|\nabla J_V x\|^2 + \|J_M y\|^2 \big)^{\frac{1}{2}} \quad \text{for all } (x, y) \in \mathbb{R}^n \times e^{\perp_M} \end{aligned}$$

with constants $c_1 > 0$ and c_2 independent of h. Now note that the norm $(\mathbf{u}_h, p_h) \to \big(\|\nabla \mathbf{u}_h\|^2 + \|p_h\|^2 \big)^{\frac{1}{2}}$ is the canonical one on $\mathbf{V}_h \times M_h$.

We indicate how the norm of the error, $|||\mathrm{e}^k||| = (\|\mathrm{e}_1^k\|_Q + \|\mathrm{e}_2^k\|_S^2)^{\frac{1}{2}}$, can be estimated from quantities that are available in the inexact Uzawa algorithm (3.18)–(3.22). Let $\tilde{\mathrm{K}}$ be the symmetric positive definite block diagonal matrix as in (3.10) with Q_A such that (4.1) holds. From (4.11) we get

$$\gamma_A\gamma_S\|\mathrm{v}\|_{\tilde{\mathrm{K}}}^2 \le |||\mathrm{v}|||^2 \le \Gamma_S\|\mathrm{v}\|_{\tilde{\mathrm{K}}}^2 \quad \text{for all } \mathrm{v} \in \mathbb{R}^n \times \mathrm{e}^{\perp_M}. \tag{4.13}$$

Note that $\tilde{\mathrm{K}} : \mathbb{R}^n \times \mathrm{e}^{\perp_M} \to \mathbb{R}^n \times \mathrm{e}^{\perp}$ is bijective. From this and from Theorem 3.3 with $\Gamma_A = 1$ we obtain

$$\begin{aligned}
\|\tilde{\mathrm{K}}^{-\frac{1}{2}}\mathrm{K}\tilde{\mathrm{K}}^{-\frac{1}{2}}\mathrm{w}\| &\le \frac{1}{2}\big(1+\sqrt{1+4\Gamma_S}\big)\|\mathrm{w}\| =: c_1(\Gamma_S)\|\mathrm{w}\| \quad \text{for all } \mathrm{w} \in \mathbb{R}^n \times \mathrm{e}^{\perp},\\
\|\tilde{\mathrm{K}}^{-\frac{1}{2}}\mathrm{K}\tilde{\mathrm{K}}^{-\frac{1}{2}}\mathrm{w}\| &\ge \min\left\{\gamma_A, \frac{1}{2}\left(\sqrt{\gamma_A^2+4\gamma_S\gamma_A}-\gamma_A\right)\right\}\|\mathrm{w}\|\\
&=: c_2(\gamma_S,\gamma_A)\|\mathrm{w}\| \quad \text{for all } \mathrm{w} \in \mathbb{R}^n \times \mathrm{e}^{\perp}.
\end{aligned}$$

This yields

$$\begin{aligned}
|||\mathrm{v}|||_{\tilde{\mathrm{K}}}^2 &= \frac{\langle\tilde{\mathrm{K}}\mathrm{v},\mathrm{v}\rangle}{\langle\tilde{\mathrm{K}}^{-1}\mathrm{K}\mathrm{v},\mathrm{K}\mathrm{v}\rangle}\langle\tilde{\mathrm{K}}^{-1}\mathrm{K}\mathrm{v},\mathrm{K}\mathrm{v}\rangle\\
&\le c_2(\gamma_S,\gamma_A)^{-2}\langle\tilde{\mathrm{K}}^{-1}\mathrm{K}\mathrm{v},\mathrm{K}\mathrm{v}\rangle \quad \text{for all } \mathrm{v} \in \mathbb{R}^n \times \mathrm{e}^{\perp_M},\\
|||\mathrm{v}|||_{\tilde{\mathrm{K}}}^2 &= \frac{\langle\tilde{\mathrm{K}}\mathrm{v},\mathrm{v}\rangle}{\langle\tilde{\mathrm{K}}^{-1}\mathrm{K}\mathrm{v},\mathrm{K}\mathrm{v}\rangle}\langle\tilde{\mathrm{K}}^{-1}\mathrm{K}\mathrm{v},\mathrm{K}\mathrm{v}\rangle \ge c_1(\Gamma_S)^{-1}\langle\tilde{\mathrm{K}}^{-1}\mathrm{K}\mathrm{v},\mathrm{K}\mathrm{v}\rangle \quad \text{for all } \mathrm{v} \in \mathbb{R}^n \times \mathrm{e}^{\perp_M}.
\end{aligned}$$

In combination with (4.13) we then obtain

$$c_2(\gamma_S,\gamma_A)^2\Gamma_S^{-1}|||\mathrm{v}||| \le \langle\tilde{\mathrm{K}}^{-1}\mathrm{K}\mathrm{v},\mathrm{K}\mathrm{v}\rangle \le c_1(\Gamma_S)^2\gamma_A^{-1}\gamma_S^{-1}|||\mathrm{v}||| \quad \text{for all } \mathrm{v} \in \mathbb{R}^n \times \mathrm{e}^{\perp_M}.$$

Hence we can use $\langle\tilde{\mathrm{K}}^{-1}\mathrm{K}\mathrm{e}^k,\mathrm{K}\mathrm{e}^k\rangle$ as a measure for the error $|||\mathrm{e}^k|||^2$. Let $(\mathrm{r}_1^k,\mathrm{r}_2^k) = \mathrm{r}^k = \mathrm{K}\mathrm{e}^k$ be the residual. Then we have

$$|||\mathrm{e}^k|||^2 \sim \langle\tilde{\mathrm{K}}^{-1}\mathrm{r}^k,\mathrm{r}^k\rangle = \langle\mathrm{Q}_A^{-1}\mathrm{r}_1^k,\mathrm{r}_1^k\rangle + \langle\mathrm{Q}_S^{-1}\mathrm{r}_2^k,\mathrm{r}_2^k\rangle.$$

Note that $\mathrm{Q}_A^{-1}\mathrm{r}_1^k$ is available from (3.18) and $\mathrm{Q}_S^{-1}\mathrm{r}_2^k$ can be computed (or approximated accurately) with relatively low costs.

. . . 8. We discuss the main differences between our convergence result and those in [2, 29]. In [2, Theorem 10] and [29, Theorem 5.5], an inequality of the form

$$|||\mathrm{e}^{k+1}|||_* \le g_B(\mu_A,\delta)|||\mathrm{e}^k|||_*$$

is proved. The norms $|||\cdot|||_*$ used in [2] and [29] are different and also differ from the norm $|||\cdot|||$ in (4.12) that is used in our analysis. The norm $|||\cdot|||_*$ used in [29] depends on the (nonlinear) function Ψ. In case of the preconditioned conjugate gradient method as in (3.23) the norm then depends on the iteration index ℓ. In [2] a bound of the form

$$g_B(\mu_A,\delta) = \max\left\{\mu_A, \frac{2\delta}{1-\delta}\right\} \tag{4.14}$$

is proved. In [29] a more general setting is considered. However, in the special case of the inexact Uzawa method (3.18)–(3.22) the bound has a form similar to the one

in (4.14). If we compare $g_B(\mu_A, \delta)$ with our bound $g(\mu_A, \delta) = 2\mu_A + \delta(1 + \mu_A)$, then it is clear that the bounds are quite different. For $g_B(\mu_A, \delta) < 1$ one needs $\mu_A < 1$ and $\delta < \frac{1}{3}$, whereas for $g(\mu_A, \delta) < 1$ we need $\mu_A < \frac{1}{2}$ and $\delta < \frac{1-2\mu_A}{1+\mu_A}$. In the extreme case $\delta = 0$ we have $g_B(\mu_A, 0) = \frac{1}{2} g(\mu_A, 0)$, whereas if $\mu_A = 0$, we get $g(0, \delta) = \frac{1}{2}(1-\delta) g_B(0, \delta)$. We are particularly interested in the case where for Q_A we take a multigrid method. Therefore, as an example we consider $\mu_A = 0.1$. Then we have

$$\begin{aligned} g(0.1, \delta) < 1 \quad &\text{if} \quad \delta < 0.72, \\ g_B(0.1, \delta) < 1 \quad &\text{if} \quad \delta < \frac{1}{3}, \\ g(0.1, \delta) < g_B(0.1, \delta) \quad &\text{if} \quad \delta > 0.16. \end{aligned}$$

The bound $g_B(\mu_A, \delta)$ is better for "small" δ-values, whereas the bound $g(\mu_A, \delta)$ is better for "larger" δ-values. In our opinion, the bound $g(\mu_A, \delta)$ gives a better explanation of the observation (that has been made in many numerical experiments) that if one uses a very good preconditioner Q_A (such as multigrid), then even with (very) low accuracy in the inner iteration the inexact Uzawa method converges.

5. Preconditioners. In this section we discuss the choice of the preconditioners Q_A and Q_S. In particular, for the preconditioners we want the constants γ_S, Γ_S, γ_A, Γ_A in the spectral equivalences (3.2) and (3.1) to be independent of the parameters h and ξ.

It is known that if for Q_A we take a symmetric multigrid V-cycle, $\mathrm{Q}_A = \mathrm{Q}_{MG}$, then we have (cf. [6, 15, 16])

$$(1 - \mu_{MG})\mathrm{Q}_{MG} \leq \mathrm{A} \leq \mathrm{Q}_{MG}$$

with a constant $\mu_{MG} < 1$ independent of h. In [18] it is shown that for H^2-regular problems μ_{MG} is also independent of ξ. Note that if we use a scaling $\mathrm{Q}_{MG} \to \alpha \mathrm{Q}_{MG}$ with $\alpha < 1 - \mu_{MG}$, then we obtain a preconditioner that satisfies (3.3). In the numerical experiments in section 6 we will use a (scaled) symmetric multigrid V-cycle as in (3.24).

It is well known that for the case $\xi = 0$ the pressure mass matrix M is an appropriate preconditioner for S. From the discrete LBB property (2.1) and the fact that for arbitrary $\mathrm{y} \in \mathbb{R}^m$, we have (if $\xi = 0$)

$$\langle \mathrm{Sy}, \mathrm{y} \rangle = \sup_{\mathbf{u}_h \in \mathbf{V}_h} \frac{(\operatorname{div} \mathbf{u}_h, J_M \mathrm{y})^2}{\|\nabla \mathbf{u}_h\|^2} ,$$

it follows that M is uniformly (with respect to h) spectrally equivalent to S on the subspace $\mathrm{e}^{\perp_M}$:

$$\hat{\beta}^2 \mathrm{M} \leq \mathrm{S} \leq d\,\mathrm{M} \quad \text{on} \quad \mathrm{e}^{\perp_M}$$

with $\hat{\beta}$ the LBB constant from (2.1). The [illegible] mass matrix $\bar{\mathrm{M}}$ is the diagonal matrix with diagonal entries $\bar{\mathrm{M}}_{ii} = \sum_{j=1}^{m} \mathrm{M}_{ij}$. In [25] it is proved that this matrix is uniformly in h spectrally equivalent to M and thus also (for $\xi = 0$) to S on the subspace $\mathrm{e}^{\perp_M}$. A further elementary observation is

$$\bar{\mathrm{M}}\mathrm{e} = \mathrm{M}\mathrm{e}.$$

Hence, both for $\mathrm{Q}_S = \mathrm{M}$ and $\mathrm{Q}_S = \bar{\mathrm{M}}$ the consistency condition (3.8) is fulfilled.

For the case $\xi \gg 1$ the (lumped) mass matrix is not an appropriate preconditioner for the Schur complement. In [4, 8, 17] robust (with respect to h and ξ) preconditioning strategies are introduced. We briefly explain the method from [4].

For $g \in L^2(\Omega)$ consider the Neumann problem: Find $w \in H^1(\Omega) \cap M$ such that

$$(\nabla w, \nabla \phi) = (g, \phi) \quad \text{for all} \quad \phi \in H^1(\Omega) \cap M. \tag{5.1}$$

Let T_h be the stiffness matrix of the Galerkin discretization of this problem in $M_h^+ \subset H^1(\Omega)$:

$$\langle \mathrm{T}_h \mathrm{x}, \mathrm{y} \rangle = (\nabla J_M \mathrm{x}, \nabla J_M \mathrm{y}) \quad \text{for all} \quad \mathrm{x}, \mathrm{y} \in \mathbb{R}^m.$$

Note that $\ker(\mathrm{T}_h) = \operatorname{span}(\mathrm{e})$ and that $\mathrm{T}_h : \mathrm{e}^{\perp_M} \to \mathrm{e}^{\perp}$ is bijective. We define $\tilde{\mathrm{Q}}_S^{-1} : \mathrm{e}^{\perp} \to \mathrm{e}^{\perp_M}$ by

$$\tilde{\mathrm{Q}}_S^{-1} = \begin{cases} \mathrm{M}^{-1} + \xi \mathrm{T}_h^{-1} & \text{if} \quad \xi \le h^{-2}, \\ \xi h^2 \mathrm{M}^{-1} + \xi \mathrm{T}_h^{-1} & \text{if} \quad h^{-2} \le \xi. \end{cases} \tag{5.2}$$

In the analysis it is convenient to extend $\tilde{\mathrm{Q}}_S^{-1}$ on $\mathbb{R}^m$ by defining $\tilde{\mathrm{Q}}_S^{-1}\mathrm{Me} := \mathrm{e}$. In practice, however, this extension is not needed. Note that for $\xi = 0$ we get $\tilde{\mathrm{Q}}_S = \mathrm{M}$.

In [4] it is shown that $\tilde{\mathrm{Q}}_S$ is uniformly in h and ξ spectrally equivalent to S. We rephrase the main theorem (Theorem 4.1) of [4] (for the special case $S_h = W_h$ in [4]).

THEOREM 5.1. [illegible] $\xi = 0$ [illegible] $\mathbf{f} \in L_2(\Omega)^d$ [illegible] $(\mathbf{u}, p)^T$ [illegible] (1.1) [illegible] $\|\mathbf{u}\|_2 + \|p\|_1 \le C\|\mathbf{f}\|$ [illegible] C [illegible] $\mathbf{f}$ [illegible] (5.1) [illegible] H^2 [illegible] $(\mathbf{V}_h, M_h)$ [illegible] (2.1) [illegible] $M_h^+ \subset H^1(\Omega)$ $1 \in M_h^+$ [illegible] C [illegible] h

$$\inf_{\mathbf{w} \in \mathbf{V}_h} \|\mathbf{v} - \mathbf{w}\|_1 \le Ch\|\mathbf{v}\|_2 \qquad \text{[illegible]} \quad \mathbf{v} \in (H^2(\Omega) \cap H_0^1(\Omega))^d,$$

$$\inf_{q \in M_h^+} \|p - q\| \le Ch\|p\|_1 \qquad \text{[illegible]} \quad p \in H^1(\Omega),$$

$$\|\mathbf{v}\|_s \le Ch^{-1}\|\mathbf{v}\|_{s-1} \qquad \text{[illegible]} \quad \mathbf{v} \in \mathbf{V}_h,\ s \in \{0, 1\},$$

$$\|p\| \le Ch^{-1}\|p\|_{-1} \qquad \text{[illegible]} \quad p \in M_h.$$

[illegible] $C_0 > 0$ C_1 [illegible] h [illegible] ξ [illegible]

$$C_0 \langle y, \tilde{\mathrm{Q}}_S^{-1} y \rangle \le \langle \mathrm{S}\tilde{\mathrm{Q}}_S^{-1} y, \tilde{\mathrm{Q}}_S^{-1} y \rangle \le C_1 \langle y, \tilde{\mathrm{Q}}_S^{-1} y \rangle \quad \text{[illegible]} \quad y \in \mathrm{e}^{\perp}. \tag{5.3}$$

Note that many pairs of finite element spaces satisfy the assumptions in this theorem. In our experiments we use such a pair, namely, the Hood–Taylor $P_2 - P_1$ pair.

Although the Laplace problem for the pressure that has to be solved in each application of $\tilde{\mathrm{Q}}_S^{-1}$ is much smaller than the problems involving A or Q_A, often it is inefficient to solve it exactly. Let Q_T be a preconditioner for T_h that is spectrally equivalent to T_h, uniformly in h. Instead of $\tilde{\mathrm{Q}}_S^{-1}$ in (5.2) one can then use

$$\mathrm{Q}_S^{-1} := \begin{cases} \mathrm{M}^{-1} + \xi \mathrm{Q}_T^{-1} & \text{if} \quad \xi \le h^{-2}, \\ \xi h^2 \mathrm{M}^{-1} + \xi \mathrm{Q}_T^{-1} & \text{if} \quad h^{-2} \le \xi. \end{cases} \tag{5.4}$$

In [4] (Remark 4.1) it is shown that for this preconditioner a result as in (5.3) holds with constants $C_0 > 0$ and C_1 independent of h and ξ. Hence, the preconditioner Q_S as in (5.4) is spectrally equivalent to S (on $\mathrm{e}^{\perp_M}$) uniformly in h and ξ.

In the numerical experiments in section 6 for Q_T we use a symmetric multigrid V-cycle method.

6. Numerical experiments. In this section we present a comparison of the three iterative solvers discussed above. These solvers are denoted by BPCG (algorithm (3.7)), PMINRES (section 3.2), and MGUZAWA (algorithm (3.18)–(3.23)). We consider a problem as in (1.1) on the unit cube $\Omega = (0,1)^3$. For the discretization we start with a uniform tetrahedral grid with $h = \frac{1}{2}$, and we apply regular refinements to this starting triangulation. For the finite element discretization we used the LBB stable pair of Hood–Taylor $P_2 - P_1$, i.e., continuous piecewise quadratics for the velocity and continuous piecewise linears for the pressure. We performed computations for the cases $h = 1/16$, $h = 1/32$. Note that for $h = 1/32$ we have approximately $7.5{\cdot}10^5$ velocity unknowns and $3.3{\cdot}10^4$ pressure unknowns ($n \approx 7.5{\cdot}10^5$, $m \approx 3.3{\cdot}10^4$). We consider the linear system as in (2.4) with solution $(\mathrm{x}, \mathrm{y}) = 0$. We take a fixed arbitrary starting vector $(\mathrm{x}^0, \mathrm{y}^0)$, with $\mathrm{y}^0 \in \mathrm{e}^{\perp_M}$. The iteration is stopped after a reduction of the Euclidean norm of the starting residual by a factor 10^6, i.e., $\|\mathrm{r}^k\| \leq 10^{-6}\|\mathrm{r}^0\|$, with $\mathrm{r}^k = (\mathrm{f}, 0) - \mathrm{K}(\mathrm{x}^k, \mathrm{y}^k)$.

Experiments for the case $\xi = 0$. We apply the BPCG, PMINRES, and MGUZAWA methods described above. For the preconditioner Q_A we use one multigrid V-cycle iteration as in (3.24). For the preconditioner Q_S for the Schur complement we use one multigrid V-cycle iteration as in (3.24), but now applied to the mass matrix M.

For the BPCG method we need a suitable scaling of Q_A. To determine the scaling parameter, we compute $\tilde{\lambda} \approx \lambda\max(I - \mathrm{QMG}^{-1}\mathrm{A})$ by a few power-iterations and use $\mathrm{Q}_A := (1 - \alpha\,\tilde{\lambda})\mathrm{Q}_{MG}$, $\alpha \in [1, \tilde{\lambda}^{-1})$, as scaled preconditioner. The approximation $\tilde{\lambda}$ satisfies $\tilde{\lambda} \leq \lambda\max(I - \mathrm{QMG}^{-1}\mathrm{A})$, and hence we take $\alpha \geq 1$. In our experiments we use $\alpha = 1.1$. Although not negligible, the arithmetic costs for determining this scaling parameter are not taken into account in the tables presented below. The PMINRES method is parameter-free. In the MGUZAWA method we have to choose a stopping criterion for the inner iteration. We use the one in (3.25) with $\sigma_{\mathrm{acc}} = 0.5$. For all three methods the costs are dominated by the evaluations of Q_A^{-1}. Therefore to measure the arithmetic costs we count the number of Q_A^{-1} evaluations, which is denoted by $\#\mathrm{Q}_{MG}$. Results are presented in Table 1.

In Figure 2 we give the convergence behavior of $\|\mathrm{r}^k\|$ for the case $h = 1/32$. Note that in the MGUZAWA method, in each iteration we have an inner iteration. In Table 2 we give the number of inner iterations per outer iteration.

The behavior of the BPCG method depends on the scaling parameter α in $(1 - \alpha\,\tilde{\lambda})\mathrm{Q}_{MG}$. In Table 3 we show the dependence of $\#\mathrm{Q}_{MG}$ on this scaling parameter for $\tilde{\lambda} = \lambda\max(I - \mathrm{Q}_{MG}^{-1}\mathrm{A})$. The convergence of the MGUZAWA method

depends on σ_{acc}. In Table 4 we show the dependence of $\#Q_{MG}$ on this parameter.

According to Remarks 1, 2, 5 the bounds for the convergence rates of BPCG and PMINRES depend on the scaling parameter ρ if we use ρQ_S ($\rho > 0$) as a preconditioner for the Schur complement. The convergence rate of MGUZAWA does not depend on the scaling of Q_S. Table 5 shows $\#Q_{MG}$ for different values of ρ.

. . .. 9. We also performed experiments with the MGUZAWA method with

TABLE 6

inaccurate approximations of the A-block and of the $\hat{S}$-system (cf. Remark 6). For Q_A we use one SSOR iteration and we apply only one preconditioned conjugate gradient iteration (with the same preconditioner as above) for solving the $\hat{S}$-system. It turns out that for both $h = 1/16$ and $h = 1/32$ the MGUZAWA method converges. For the case $h = 1/16$ we need 417 (outer) iterations to satisfy the stopping criterion and for $h = 1/32$ we need 1485 iterations.

Experiments for the case $\xi > 0$. We again apply the three methods described above. For the preconditioner Q_A we use the same multigrid V-cycle iteration as for the case $\xi = 0$. For the preconditioner for the Schur complement we use the one in (5.4). For Q_T we apply one multigrid V-cycle iteration with one symmetric Gauss–Seidel pre- and postsmoothing iteration. For the BPCG method we take the same scaling of Q_A as we used for the case $\xi = 0$. Note that this may not be the optimal scaling if $\xi > 0$. In the MGUZAWA method we take $\sigma_{\text{acc}} = 0.6$. In Tables 6 and 7 we present results for $\xi = h^{-1}$ and $\xi = h^{-2}$.

7. Concluding remarks. In this paper we considered three fast iterative methods for discretized Stokes equations. The BPCG method is a preconditioned conjugate gradient method applied to a transformed system and with a special scalar product. The PMINRES method is a standard preconditioned minimal residual method. The MGUZAWA method results from an approximation of an exact block factorization of the matrix K (cf. (3.16), (3.17)). The MGUZAWA algorithm has the structure of an outer-inner iteration. Thus for this method a stopping criterion (tolerance parameter) for the inner iteration is needed. The PMINRES method is parameter-free. In the BPCG method a scaling parameter for the preconditioner Q_A has to be determined. If for Q_A we use a multigrid solver, then for all three methods the costs per iteration are dominated by the evaluations of Q_A^{-1}. In the BPCG and the PMINRES methods one needs one Q_A^{-1} evaluation per iteration. In the MGUZAWA method $\ell + 1$ Q_A^{-1} evaluations per iteration are needed (ℓ: # inner iterations). For all three methods convergence analyses are available in which bounds for the rate of convergence are derived that depend only on the constants in the spectral equivalences $\gamma_A Q_A \le A \le \Gamma_A Q_A$, $\gamma_S Q_S \le S \le \Gamma_S Q_S$. For the MGUZAWA method we presented a convergence analysis that shows that if one uses a multigrid preconditioner for A, then for the inner iteration a very low accuracy is already sufficient to have a convergent and efficient method. In this convergence analysis we use a natural norm.

In the numerical experiments for the stationary case, all three methods have a rate of convergence independent of h. In our experiments the BPCG and MGUZAWA

methods have almost the same efficiency. The PMINRES method is less efficient. The latter method, however, is the most robust one. It is parameter-free and converges even without preconditioning. From Table 3 we conclude that the performance of the BPCG method depends only mildly on α (provided $\alpha \geq 1$). Thus, we need only a rough approximation $\tilde{\lambda} \approx \lambda\max(I - \mathrm{Q}_A^{-1}\mathrm{A})$ to obtain an efficient solver. The results in Table 4 show that the MGUZAWA method is efficient for a broad range of σacc-values. Note that the method converges even for large σ_{acc} values. This confirms the theory in section 4.

The rate of convergence of both BPCG and PMINRES depend on the scaling of Q_S, whereas for the MGUZAWA method this is not the case. For particular choices of this scaling it may happen that the PMINRES method is more efficient than the BPCG method (cf. Table 5).

The experiments for the nonstationary case demonstrate the effectiveness of the preconditioner in (5.4). The rate of convergence is independent of h for $\xi = h^{-1}$ and $\xi = h^{-2}$. If instead of the preconditioner in (5.4) one uses $\mathrm{Q}_S = \bar{\mathrm{M}}$, for $\xi = h^{-2}$ all three solvers would need several hundred iterations.

AN IMPLICIT WAVELET SPARSE APPROXIMATE INVERSE PRECONDITIONER*

STUART C. HAWKINS† AND KE CHEN‡

Abstract. Wavelet-based sparse approximate inverse preconditioners are considered for the linear system $Ax = b$. The preconditioners are good sparse approximations to the inverse of A computed by taking advantage of the compression obtained by working in a wavelet basis. When the representation of A in a single scale basis (for example, a finite element basis) is available, the formulation presented obviates computation of the representation of A in the wavelet basis and removes the associated costs. Efficient application for both sparse and dense A is considered.

Key words. linear system, preconditioning, sparse approximate inverse, wavelet

1. Introduction.

We consider the fast solution of the linear system

$$Ax = b, \tag{1.1}$$

where A is a large $n \times n$ matrix. Such linear systems arise in finite element or finite difference discretizations, where typically A is sparse, and in boundary element discretizations, where typically A is dense. There is much interest in techniques for iteratively solving (1.1) using Krylov subspace methods such as GMRES [29, 30].

To improve performance of the iterative solver when A is ill conditioned (1.1) may be replaced by the left preconditioned linear system

$$MAx = Mb \tag{1.2}$$

or the right preconditioned linear system

$$AMy = b. \tag{1.3}$$

To improve performance of the iterative solver we desire $MA \approx I$ in (1.2) or $AM \approx I$ in (1.3). To ensure that matrix vector multiplication with the preconditioner is cheap we require that M be sparse.

Sparse approximate inverse techniques are widely used to produce preconditioners M. Sparse approximate inverses can be produced by iterative techniques, as described by Chow and Saad [13] and Benzi and Tůma [5], but we consider direct techniques based on direct solution of (reduced) least squares problems, as described by Benson and Frederickson [3], Kolotilina and Yeremin [24], Grote and Huckle [22], and Benzi

and Tůma [5]. We present our work in the context of right preconditioning, where the aim is to minimize

$$\|AM - I\|_F \tag{1.4}$$

subject to a prescribed sparsity pattern for M. A sparse approximate inverse for left preconditioning is computed by minimizing $\|MA - I\|_F$. However, $\|MA - I\|_F = \|A^T M^T - I\|_F$ and so the theory and application is the same as for right preconditioning, though it looks more complicated.

To minimize $\|AM - I\|_F$ note that $\|AM - I\|_F^2 = \sum_{j=1}^{n} \|Am_j - e_j\|_2^2$, where m_j is the jth column of M. Thus minimizing $\|AM - I\|_F$ reduces to solving n independent least squares problems. This is easy to implement in parallel.

Good approximations to A^{-1} can be obtained from sparse approximate inverse techniques when A^{-1} is sparse, but not when A^{-1} is dense. Sparse matrices need not have a sparse inverse. For example, consider the inverse of the matrix

$$A = n^2 \begin{pmatrix} -2 & 1 & & & \\ 1 & -2 & 1 & & \\ & \ddots & \ddots & \ddots & \\ & & 1 & -2 & 1 \\ & & & 1 & -2 \end{pmatrix}$$

obtained by finite difference discretization of the Laplacian. It can be seen in Figure 1.1(a) that A^{-1} is dense.

Chen [10] and Carpentieri, Duff, and Giraud [7] discuss sparse approximate inverse techniques for dense matrices arising from boundary element discretizations. The idea is to split $A = S + F$, where S is sparse and F is dense. Then A can be preconditioned with a sparse approximate inverse of S. The choice of S is crucial here.

When A is a discretization of a pseudodifferential operator one can view A^{-1} as the discretization of an integral operator whose kernel is the Green's function associated with A. A^{-1} is typically dense but representation in a wavelet basis compresses

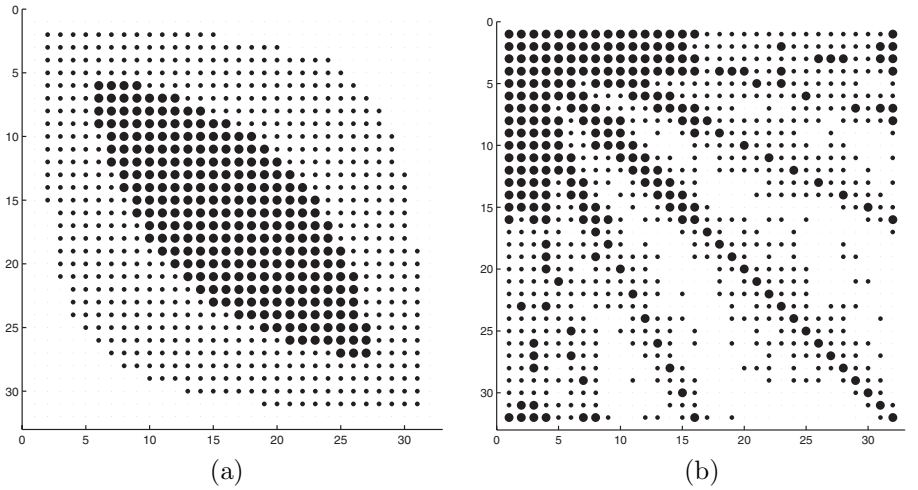

FIG. 1.1. (a) *Visualization of the inverse of a discretization of the Laplacian with* $n = 32$. (b) *Visualization of the same matrix represented in the Daubechies* 4 *wavelet basis. Radius of dots is based on matrix entry magnitudes.*

A^{-1} when the Green's function is smooth. If, additionally, the Green's function is smooth away from the diagonal, then A^{-1} has a special [illegible] in the wavelet basis. Off-diagonal fingers result from interactions between wavelets at different scales. This pattern can be seen in Figure 1.1(b), which is a visualization of the matrix in Figure 1.1(a) represented in the Daubechies 4 [17] wavelet basis.

The compression of the matrix A^{-1} in the wavelet basis allows it to be well approximated by a sparse matrix. Furthermore, the finger pattern of the large entries is predictable. Formally, denote representation in the wavelet basis with $\widetilde{\cdot}$ so that, in the wavelet basis, (1.1) becomes

$$\widetilde{A}\widetilde{x} = \widetilde{b}. \tag{1.5}$$

One can approximate $\widetilde{A^{-1}}$ with a finger-patterned sparse approximate inverse of $\widetilde{A}$ because $\widetilde{A^{-1}} = \widetilde{A}^{-1}$.

Chan, Tang, and Wan [9] use this sparse approximate inverse of $\widetilde{A}$ as a preconditioner for (1.5) but restrict the pattern of the sparse approximate inverse to block diagonal. This simplifies the computation, but interactions between wavelets at different scales are omitted in the calculation of the preconditioner. This is in line with the theory of Dahmen and Kunoth [16], who show that diagonal preconditioning yields a condition number that is independent of the number of unknowns.

However, as observed by Cohen and Masson [15], sometimes diagonal preconditioning is not sufficient for efficient iterative solution. Cohen and Masson [15] compute finger-patterned sparse approximate inverses for (1.5) in a slightly different context where (1.5) is obtained directly from the underlying partial differential equation (PDE) or boundary integral equation (BIE) with discretization using wavelet basis functions. Use of the full finger pattern for the sparse approximate inverse means that all interactions between scales are included in this preconditioner. This makes the preconditioner more robust but can sometimes make the computation of the sparse approximate inverse prohibitively expensive because a small number of dense columns or rows can be present in the finger pattern.

Bridson and Tang [6] compute a sparse approximate inverse of $\widetilde{A}$ where the sparsity pattern of the approximate inverse is determined adaptively. The adaptive sparse approximate inverse algorithm does not require the entries of $\widetilde{A}$ to be available, and allows second generation wavelets to be used efficiently. However, Chow [12] notes that adaptive sparse approximate inverse algorithms can be more expensive to implement than sparse approximate inverse algorithms for which the pattern of the approximate inverse is known in advance.

We remark that, outside the sparse approximate inverse framework, Chan and Chen [8] proposed a recursive preconditioner that does not require $\widetilde{A}$ to be computed.

We present a new preconditioner that takes advantage of the structure possessed by A^{-1} when it is represented in the wavelet basis. Like Cohen and Masson [15] we incorporate all of the interactions between wavelets at different scales, which is sometimes necessary to produce a robust preconditioner. We describe strategies that overcome the computational difficulties presented by the subsequent sparsity pattern of the preconditioner. Many of our computations involve A rather than $\widetilde{A}$ because our formulation applies the discrete wavelet transform implicitly. When A is sparse, it is often sparser than $\widetilde{A}$, and working with A rather than $\widetilde{A}$ reduces the cost of computing the sparse approximate inverse. The cost of computing $\widetilde{A}$ is also removed.

A typical discrete wavelet transform is applied to the vector $x \in \mathbb{R}^n$ as follows. For simplicity we assume $n = 2^N$ for some $N \in \mathbb{N}$, but the theory in this paper applies

whenever $n = s^N p$ for some $N, s, p \in \mathbb{N}$. Let $h_0, h_1, \ldots, h_{m-1}$ and $g_0, g_1, \ldots, g_{m-1}$ be the low-pass and high-pass filter coefficients of the transform. Then the level $L \leq N$ discrete wavelet transform of x is the vector $\widetilde{x} = (s^L, d^L, d^{L-1}, \ldots, d^1)$, where

$$s^0 = x, \tag{1.6}$$

$$s_j^k = \sum_{l=0}^{m-1} h_l s^{k-1}_{\langle l+2j-1\rangle_{n/2^{k-1}}}, \quad j = 1, 2, \ldots, n/2^k, \tag{1.7}$$

$$d_j^k = \sum_{l=0}^{m-1} g_l s^{k-1}_{\langle l+2j-1\rangle_{n/2^{k-1}}}, \quad j = 1, 2, \ldots, n/2^k, \tag{1.8}$$

where $\langle a\rangle_b$ denotes $c+1$, c being the remainder of $a-1$, modulo b. For example, $\langle 256\rangle_{256} = 256$ and $\langle 257\rangle_{256} = 1$. When $L = N$ we say that $\widetilde{x}$ is fully transformed. The discrete wavelet transform of a matrix is obtained by transforming each row of the matrix, and then transforming each column of the result.

Equation (1.7) can be rewritten as

$$s^k = U_k s^{k-1},$$

where

$$U_k = \begin{bmatrix} h_0 & h_1 & h_2 & \cdots & h_{m-1} & & & \\ & & h_0 & h_1 & h_2 & \cdots & h_{m-1} & \\ & & & \vdots & & & & \\ h_2 & \cdots & h_{m-1} & & & & h_0 & h_1 \end{bmatrix}$$

is an $n/2^k \times n/2^{k-1}$ matrix. In the same way (1.8) can be rewritten as

$$d^k = V_k s^{k-1},$$

where

$$V_k = \begin{bmatrix} g_0 & g_1 & g_2 & \cdots & g_{m-1} & & & \\ & & g_0 & g_1 & g_2 & \cdots & g_{m-1} & \\ & & & \vdots & & & & \\ g_2 & \cdots & g_{m-1} & & & & g_0 & g_1 \end{bmatrix}$$

is an $n/2^k \times n/2^{k-1}$ matrix. When $m > n/2^{k-1}$ the entries wrap around, for example, when $m = 4$ the 1×2 level N matrices are

$$U_N = \begin{bmatrix} h_0 + h_2 & h_1 + h_3 \end{bmatrix},$$
$$V_N = \begin{bmatrix} g_0 + g_2 & g_1 + g_3 \end{bmatrix}.$$

The level L discrete wavelet transform can be written as

$$\widetilde{x} = W^T x = W_L^T W_{L-1}^T \cdots W_1^T x \tag{1.9}$$

with

$$W_k^T = \left[\begin{array}{c|c} \begin{matrix} U_k \\ V_k \end{matrix} & 0 \\ \hline 0 & I_{n-n/2^{k-1}} \end{array}\right].$$

The paper is structured as follows. In section 2 we review the wavelet sparse approximate inverse preconditioner of Chan, Tang, and Wan [9]. In section 3 we introduce our new preconditioner that avoids transforming A. In section 4 we discuss how to implement our new algorithm and consider how to compute the entries of the wavelet basis vectors, which are required to implement the new method. We end the section with some comments on the relative costs of computing the Chan, Tang, and Wan [9] preconditioner and the new preconditioner. In section 5 we consider modifications to these preconditioners for the case when A is dense. In section 6 we present some theory on the conditioning of the new preconditioned iteration matrix. In section 7 we present some numerical experiments. We finish with some conclusions in section 8.

2. Wavelet-based sparse approximate inverse. Cohen and Masson [15] show that, for a wide class of PDE problems, A^{-1} is sparse in the wavelet basis. Noting this we review the preconditioning method of Chan, Tang, and Wan [9].

Let W be as in (1.9). Since $\widetilde{A^{-1}} = W^T A^{-1} W = (W^T A W)^{-1} = \widetilde{A}^{-1}$, Chan, Tang, and Wan [9] propose a sparse approximate inverse preconditioner $\widetilde{M}$ for $\widetilde{A}$ computed by solving a minimization problem analogous to (1.4), that is, by minimizing $\|\widetilde{A}\widetilde{M} - I\|_F$. Cohen and Masson [15] established that, for a wide class of pseudodifferential equations, both $\widetilde{A}$ and $\widetilde{A}^{-1}$ have a finger pattern. Thus a sparse approximate inverse of $\widetilde{A}$ is justified and a finger pattern for $\widetilde{M}$ can usually be prescribed. The Chan, Tang, and Wan [9] algorithm is described by Algorithm 1.

ALGORITHM 1.

1. Compute $\widetilde{A} = W^T A W$, $\widetilde{b} = W^T b$.
2. Compute $\widetilde{M}$, a right sparse approximate inverse of $\widetilde{A}$.
3. Solve $\widetilde{A}\,\widetilde{M}\,\widetilde{y} = \widetilde{b}$.
4. Compute $x = W\widetilde{M}\widetilde{y}$.

Step 1 involves computing $\widetilde{A}$, an operation that has complexity $O(n)$, depending on the level of the transform, the method of applying the transform, and the sparsity of A. The computation of $\widetilde{A}$ is a significant part of the total cost of implementing Algorithm 1.

When A is sparse, the matrix vector multiplications with $\widetilde{A}$ involved in step 3 should be applied in factored form with $W^T A W$ rather than with $\widetilde{A}$ itself.

Finger-patterned matrices, though sparse, can have a small number of dense columns and rows. As noted by Gould and Scott [20] the presence of dense columns in $\widetilde{M}$ require that care be taken in its computation. Reducing the sparsity pattern of $\widetilde{M}$ to block diagonal, as described by Chan, Tang, and Wan [9], is one way to solve this problem but relinquishes robustness because interactions between scales are disregarded. In this paper we present a new and cheaper way of using wavelets to give a sparse preconditioner with a predictable pattern but without computing $\widetilde{A}$. Interactions between wavelets at different scales are included.

3. A new implicit wavelet sparse approximate inverse preconditioner. We describe a new wavelet sparse approximate inverse preconditioner that is closely related to the preconditioner in Algorithm 1 but the requirement that $\widetilde{A}$ be available is removed and the wavelet transform is applied implicitly. This is facilitated by changing the way in which the sparse approximate inverse is computed. Additionally we use the whole finger pattern for the preconditioner to ensure that all interactions between scales are included.

Observe that

$$\begin{aligned}\|\widetilde{A}\widetilde{M} - I\|_F &= \|W^T AWW^T MW - I\|_F \\ &= \|W^T AMW - I\|_F \\ &= \|WW^T AMW - W\|_F \\ &= \|A\widehat{M} - W\|_F,\end{aligned}$$

where $\widetilde{M} = W^T MW$ and $\widehat{M} = MW = W\widetilde{M}$. It is not difficult to see that $\widehat{M}$ has a predictable sparsity pattern, because $\widetilde{M}$ has a predictable sparsity pattern. Minimizing $\|A\widehat{M} - W\|_F$ reduces to n independent least squares problems in the same way as minimizing $\|AM - I\|_F$. These observations lead to a new algorithm.

ALGORITHM 2.

1. Compute $\widehat{M}$, the minimizer of $\|A\widehat{M} - W\|_F$ subject to the prescribed sparsity pattern for $\widehat{M}$.
2. Solve $W^T A\widehat{M}\widetilde{y} = W^T b$.
3. Compute $x = \widehat{M}\widetilde{y}$.

$\widehat{M}$ is an approximation to A^{-1} represented from the wavelet basis to the standard, single scale basis. We establish in Theorem 6.1 that this matrix possesses a band pattern like that shown in Figure 3.1(b) and which is analogous to the finger pattern shown in Figure 3.1(a). In fact W possesses such a band pattern, and our practical experience has shown that the pattern of W provides a suitable pattern for $\widehat{M}$.

In fact we have implicitly applied a one-sided wavelet transform to M, compared with the two-sided wavelet transform of M in the Chan, Tang, and Wan [9] algorithm. In this way we achieve compression and structure in A^{-1} and like the Cohen and Masson [15] preconditioner, our preconditioner includes interactions between different scales. The one-sided application of the wavelet transform provides less compression than the two-sided application but our practical experience is that the compression achieved is sufficient.

In general the preconditioner $\widehat{M}$ is unsymmetric, even when A is symmetric. Symmetrization techniques such as the one presented for Algorithm 1 by Chan, Tang, and Wan [9] are precluded because the nonsymmetric pattern of $\widehat{M}$ is dictated by the decay of the inverse of A and the properties of the wavelet basis. Although in

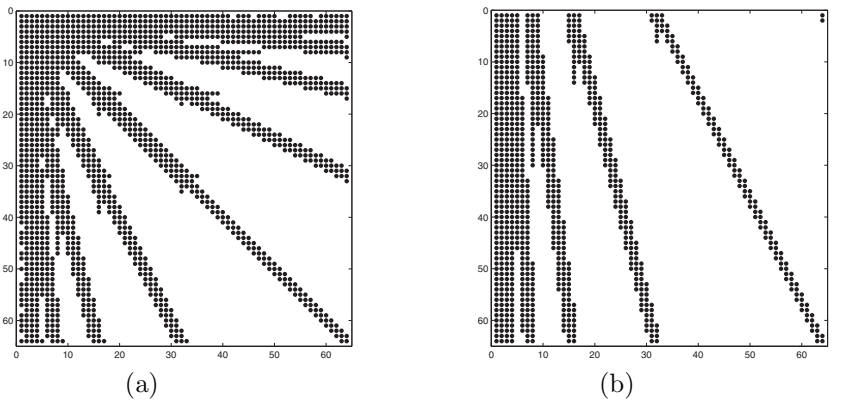

FIG. 3.1. *Visualizations of* (a) *a finger-patterned matrix and* (b) *a one-sided finger-patterned matrix.*

general it is more expensive to solve unsymmetric systems than symmetric systems, use of this new strategy for symmetric systems is justified because construction of the preconditioner in Algorithm 2 is cheaper than construction of the preconditioner in Algorithm 1.

4. Implementation details. We now discuss how to solve in practice the least squares problem in Algorithm 2. Analysis of the least squares problem reveals two important considerations for practical implementation of the algorithm. We show how to address these considerations by slightly modifying how the preconditioner is constructed, and by finding cheaper ways of computing the wavelet matrix W. We finish with some comments about the complexity of computing the matrices $\widetilde{A}$ and W.

Consider the problem of minimizing $\|A\widehat{M} - W\|_F$ at step 1 of Algorithm 2. Let S_j be the set of indices of the nonzero entries of $\widehat{m}_j$ where $\widehat{m}_j$ is the jth column of $\widehat{M}$. The classical approach to solving the minimization problem is to observe that

$$\|A\widehat{m}_j - w_j\|_2 = \|A(:, S_j)\widehat{m}_j(S_j) - w_j\|_2$$

and

$$\operatorname{argmin} \|A(:, S_j)\widehat{m}_j(S_j) - w_j\|_2 = \operatorname{argmin} \|A(T_j, S_j)\widehat{m}_j(S_j) - w_j(T_j)\|_2,$$

where T_j indexes the nonzero rows of $A(:, S_j)$ and w_j is the jth column of W. With the reduced QR factorization $A(T_j, S_j) = QR$ we have

$$\|A(T_j, S_j)\widehat{m}_j(S_j) - w_j(T_j)\|_2 = \|QR\,\widehat{m}_j(S_j) - w_j(T_j)\|_2, \tag{4.1}$$

which can be minimized by solving $R\widehat{m}_j(S_j) = Q^T w_j(T_j)$ by back substitution.

We make two observations. First, the entries $w_j(T_j)$ must be known. Second, the principal cost of minimizing (4.1) is that of computing the QR factorization of $A(T_j, S_j)$. This requires $O(|T_j||S_j|^2)$ arithmetic operations, becoming $O(|S_j|^3)$ when A is banded because then $|T_j| \sim |S_j|$. Algorithm 2 becomes impractical in its basic form when $L = N$ because then $|S_j| = n$ for some columns j. The following modifications address the second observation.

1. Use a wavelet transform of level $L < N$. Note that $\max_{j=1,n} |S_j| \approx 2^L$.
2. Compute $\widehat{m}_j$ by minimizing (4.1) whenever $|S_j|/n \le \rho$ for some parameter $\rho \in (0, 1)$. Otherwise compute $\widehat{m}_j$ by solving $A\widehat{m}_j = w_j$ using a small number of GMRES steps.
3. Restrict S_j. This approach is used by Chan, Tang, and Wan [9]. We do not use this approach because we aim to include the off-diagonal finger pattern into our preconditioner.

The ability to compute the necessary entries of W is crucial. Many discrete wavelet transforms are applied level by level, with

$$W = W_1 W_2 \cdots W_{L-1} W_L.$$

The matrices W_i represent single levels of the transform and are often readily available, although W may not be. Computation of W by multiplying the factors W_i is possible because W and its factors are sparse.

More generally, the kth column of W can be computed by inverse-transforming the kth Euclidean vector e_k using any transform algorithm. Only $O(L)$ wavelets need

to be computed in this way because the wavelets at each level are translations of each other—thus only one wavelet at each level must be computed.

It remains to comment on the relative costs of Algorithms 1 and 2. Sparse approximate inverse and setup are considered. In computing the sparse approximate inverse in Algorithm 1, the restricted pattern for $\widetilde{M}$ yields $|S_j| = c$ for some constant c. However, $|T_j|$ is difficult to estimate because it depends on the pattern of $\widetilde{A}$. Nevertheless, one can bound the costs of computing $\widetilde{M}$ by $O(n^2c^2)$. A realistic estimate is $O(nc^2)$ because there are few dense columns of $\widetilde{A}$.

In Algorithm 2, recall that $|T_j| \sim |S_j|$ when A is banded. The cost of computing $\widehat{M}$ is then bounded by $O(n[\max_{j=1,n} |S_j|]^3)$. Note that $\max_{j=1,n} |S_j| \approx 2^L$, yielding a cost $O(n2^{3L})$. When L is kept constant, the cost becomes linear in n.

Setup for Algorithm 1 involves computing $\widetilde{A}$. Setup for Algorithm 2 involves computing W. The former requires forward wavelet transforming $2n$ vectors. The latter requires inverse wavelet transforming $O(L) \leq O(\log_2 n)$ vectors. W may be stored and reused for other problems of the same size. We will show that $\widetilde{A}$ can be computed in $O(12mn\alpha)$ arithmetic operations when A has bandwidth α, and W can be computed in $O(4m(m-1)n)$ arithmetic operations. $\widetilde{A}$ and W may be computed naively by multiplication of sparse matrices. This is easily implemented but it introduces a computational overhead, although the arithmetic operation estimates will be realized. Computation of $\widetilde{A}$ remains more expensive than that of W.

Algorithm 3 is the typical pyramid algorithm for the forward discrete wavelet transform. Let $\alpha \in \mathbb{N}$ be large compared with $m/2$. Then the complexity of transforming a vector with α nonzeros is approximately $O(2m \times 2\alpha[1 - 1/2^L])$ and the transform of the vector contains approximately $2\alpha[1 - 1/2^L]$ nonzeros. It follows that transforming a banded matrix with α nonzeros in each column involves transforming n columns each with α nonzeros and then n rows each with $2\alpha[1 - 1/2^L]$ nonzeros. The complexity of this transformation is approximately

$$O\left(2mn \times \left[2\alpha[1 - 1/2^L] + 2\left(2\alpha[1 - 1/2^L]\right)[1 - 1/2^L]\right]\right) \approx O(12mn\alpha).$$

Algorithm 4 is the typical pyramid algorithm for the inverse discrete wavelet transform. The complexity of inverse transforming the Euclidean vector whose nonzero entry appears in s^l or d^l is approximately $O(2m(m-1)2^l)$. Thus the complexity of transforming L Euclidean vectors whose nonzeros appear in $s^1, s^2, \ldots, s^L$, respectively, is approximately

$$O\left(\sum_{l=1}^{L} 2m(m-1)2^l\right) \approx O(4m(m-1)2^L).$$

When $n = 2^L$ the second estimate becomes $O(4m(m-1)n)$ and we see that computing $\widetilde{A}$ is approximately $12\alpha/4(m-1)$ times more expensive than computing W.

Algorithm 3. Forward transform.

1. Let $s^0 = x$.
2. For level $k = 1, 2, \ldots, L$
   (a) Let $s_j^k = \sum_{l=0}^{m-1} h_l s^{k-1}_{\langle l+2j-1\rangle_{n/2^{k-1}}}$, $j = 1, 2, \ldots, n/2^k$.
   (b) Let $d_j^k = \sum_{l=0}^{m-1} g_l s^{k-1}_{\langle l+2j-1\rangle_{n/2^{k-1}}}$, $j = 1, 2, \ldots, n/2^k$.
3. Let $\widetilde{x} = (s^L, d^L, d^{L-1}, \ldots, d^1)$.

ALGORITHM 4. INVERSE TRANSFORM.

1. Let $(s^L, d^L, d^{L-1}, \ldots, d^1) = \widetilde{x}$.
2. For level $k = L, L-1, \ldots, 1$
   (a) Let $s_j^{k-1} = \sum_{l=0}^{m/2-1} h_{2l} s^k_{\langle (j+1)/2-l \rangle n/2^k} + \sum_{l=0}^{m/2-1} g_{2l} d^k_{\langle (j+1)/2-l \rangle n/2^k}$ for $j = 1, 3, \ldots, n/2^{k-1} - 1$.
   (b) Let $s_j^{k-1} = \sum_{l=0}^{m/2-1} h_{2l+1} s^k_{\langle j/2-l \rangle n/2^k} + \sum_{l=0}^{m/2-1} g_{2l+1} d^k_{\langle j/2-l \rangle n/2^k}$ for $j = 2, 4, \ldots, n/2^{k-1}$.
3. Let $x = s^0$.

5. Dense problems. Although our primary purpose is to precondition sparse problems arising from PDEs, we consider in this section the application of Algorithms 1 and 2 to dense problems where A either is fully available or is partially available, for example, using the fast multipole method [21, 27].

Consider the general problem of finding M that minimizes $\|BM - C\|_F$ subject to a specified sparsity pattern for M. When $B = \widetilde{A}$ and $C = I$ this corresponds to the minimization problem at step 2 of Algorithm 1. When $B = A$ and $C = W$ this corresponds to the minimization problem at step 1 of Algorithm 2.

Let S_j index the nonzero entries of m_j, where m_j is the jth column of M. A generalization of the argument in section 4 shows that the minimization problem reduces to solving n problems of the form $Rm_j(S_j) = Q^T c_j(T_j)$, where we have the QR factorization $B(T_j, S_j) = QR$, where T_j indexes the nonzero rows of $B(:, S_j)$, and where c_j is the jth column of C.

The principal task in solving each least squares problem is the QR factorization of the $t \times s = |T_j| \times |S_j|$ matrix $B(T_j, S_j)$. This operation has complexity $O(ts^2)$. Note that s depends upon the chosen sparsity pattern for M and that t, loosely speaking, depends upon the sparsity of B.

When A is dense, then $\widetilde{A}$ in Algorithm 1 is also dense. However, if A is also smooth, then $\widetilde{A}$ will have a structure containing many small entries. Computation of a column of the sparse approximate inverse of a dense matrix using the least squares approach has complexity $O(ns^2)$ and for all but the smallest s is too expensive. Computation using the GMRES approach (for example, when the column is dense) is also expensive because it requires repeated matrix vector multiplication with a dense matrix.

We consider two adaptations to the method of computing the sparse approximate inverse. Write $B = S + F$, where S is sparse and F is dense.

1. B is replaced by S in the least squares minimization problems. Thus we minimize $\|SM - C\|_F$ instead of $\|BM - C\|_F$.

2. Dense columns of M are computed by solving $Sm_j = c_j$ instead of $Bm_j = c_j$ using GMRES.

We propose that adaptation 2 is always necessary for computing dense columns, but that adaptation 1 is required only when $s = |S_j|$ is not small.

In both cases the idea is to let S be a good sparse approximation to B so that M, which approximates S^{-1}, is a good preconditioner for B. A similar approach is taken by Chen [10] who shows that if the continuous operator $\mathcal{S}$ underlying S is bounded and the continuous operator $\mathcal{F}$ underlying F is compact, then $\mathcal{S}^{-1}(\mathcal{S}+\mathcal{F}) = \mathcal{I}+\mathcal{S}^{-1}\mathcal{F}$ and $\mathcal{S}^{-1}\mathcal{F}$ is compact. One expects the corresponding matrix $S^{-1}(S + F)$ to have the clustered eigenvalues associated with the discretization of such an operator.

The choice of S and F is crucial. Carpentieri, Duff, and Giraud [7] propose the following strategies.

1. [illegible] S is obtained from B by discarding entries whose absolute value falls below a specified threshold.

2. [illegible] When B is obtained by a finite element discretization, S is obtained by discarding those entries b_{ij} of B whose corresponding nodes i and j are not (at some given level) mesh neighbors.

3. [illegible] When B is obtained by a finite element discretization, S is obtained by discarding those entries of b_{ij} of B whose corresponding nodes i and j are separated by more than a specified distance.

For Algorithm 1 we propose strategy 1 because strategies 2 and 3 do not directly apply since the entries in $\widetilde{A}$ do not directly relate to connections between nodes in a mesh. However, strategies analogous to 2 and 3 can be developed by replacing relationships between nodes with relationships between supports of wavelet basis functions; see, for example, Hawkins and Chen [23].

For Algorithm 2 one could apply any of these strategies. In some circumstances details of the mesh may be available but the entries of A are not explicitly known. Then $\widetilde{A}$ cannot easily be computed and our method is particularly useful. Under this context Carpentieri, Duff, and Giraud [7] propose strategies 2 and 3. This situation arises, for example, in particle simulations or integral equation formulations for Laplace's equation when they are solved using the fast multipole method [21, 27]. Here, matrix vector multiplication with A can be performed cheaply and to a specified accuracy but A is not computed explicitly. One way to obtain columns of A for the purposes of computing a least squares sparse approximate inverse is to multiply Euclidean vectors by A. This naive approach may be very expensive, because all columns of A will be needed, though they will not be needed or stored simultaneously when the preconditioner is sparse. A better way to compute the sparse approximate inverse in this case might be to use Algorithm 2 with adaptation 1, replacing A in the sparse approximate inverse computations by a sparse approximation S to A. The entries of S might be obtained using only near field contributions associated with the singularity.

6. Theoretical details. In this section we justify the banded pattern chosen for $\widehat{M}$ and present a theoretical bound on $\|W^T A\widehat{M} - I\|_F$. This provides a measure of the conditioning of the iteration matrix $W^T A\widehat{M}$.

The following theorem establishes that $A^{-1}W$, which we approximate by $\widehat{M}$, has the banded pattern illustrated in Figure 3.1(b). Let $\{\psi_i\}_{i=1}^n$ be a wavelet basis in L_2 with m vanishing moments. Such properties of wavelets are discussed fully by Strang and Nguyen [31]. Let I_i denote the support of ψ_i, and suppose that $\|\psi_i\|_2 = 1$. Let $\{h_i\}_{i=1}^n$ be a single scale basis in L_2, with $\bar{I}_i$ denoting the support of h_i, and with $\|h_i\|_2 = 1$.

THEOREM 6.1. [illegible] $K(x,y)$ [illegible]

$$\left|\frac{\partial^m K}{\partial x^m}(x,y)\right| \leq \frac{C_m}{|x-y|^{m+1}} \quad x \neq y \tag{6.1}$$

[illegible] C_m [illegible] $\widehat{N}$ [illegible] $K(x,y)$ [illegible] $\{\psi_j\}_{j=1}^n$ [illegible] $\{h_i\}_{i=1}^n$ [illegible]

$$|\widehat{N}_{ij}| \leq b(I_j, \bar{I}_i)$$

[illegible]

$$b(I_j, \bar{I}_i) = C|I_j|^{(2m+1)/2} \frac{1}{\operatorname{dist}(I_j, \bar{I}_i)^{m+1}}$$

[illegible] C

The proof of Theorem 6.1 is given in the appendix.

Choose $\epsilon > 0$ and let $S = \{(i,j) : |b(I_j, \bar{I}_i)| > \epsilon\}$. Denote by $\widehat{N}^S$ the matrix obtained by cutting $\widehat{N}$ to the pattern S. Then

$$\begin{aligned}\max_{(i,j)} \left|\widehat{N}^S_{ij} - \widehat{N}_{ij}\right| &\le \max_{(i,j)\notin S} |b(I_j, \bar{I}_i)| \\ &\le \epsilon.\end{aligned}$$

THEOREM 6.2. [illegible] S [illegible] $\widehat{M}$ [illegible]

$$\left\|W^T A\widehat{M} - I\right\|_F \le n\epsilon\|A\|_F.$$

[illegible] Denote the jth column of $\widehat{N}^S$ by $\widehat{n}^S_j$. Similarly denote the jth column of $\widehat{M}$ by $\widehat{m}_j$ and the jth column of W by w_j.

Then

$$\begin{aligned}\left\|W^T A\widehat{M} - I\right\|_F^2 &= \|A\widehat{M} - W\|_F^2 \\ &= \sum_{j=1}^{n} \|A\widehat{m}_j - w_j\|_2^2 \\ &\le \sum_{j=1}^{n} \|A\widehat{n}^S_j - w_j\|_2^2 \\ &= \|A\widehat{N}^S - W\|_F^2 \\ &\le \|\widehat{N}^S - A^{-1}W\|_F^2 \|A\|_F^2 \\ &\le \|\widehat{N}^S - \widehat{N}\|_F^2 \|A\|_F^2 \\ &\le n^2\epsilon^2\|A\|_F^2. \qquad \square\end{aligned}$$

[illegible] 6.3. These results give a guide to the effectiveness of $\widehat{M}$ for small ϵ. The eigenvalues of the preconditioned matrix will have a desirable distribution when ϵ is small, because they will be clustered close to 1.

Theorem 6.2 suggests that one should choose ϵ sufficiently small, so that the pattern S leads to a sufficiently small bound $\|W^T A\widehat{M} - I\|_F^2$ for the preconditioner $\widehat{M}$. In practice, good results can be obtained when ϵ is large.

A similar bound for $\|\widetilde{A}\widetilde{M} - I\|_F$ is given by Chan, Tang, and Wan [9].

7. Numerical results. We test variants of Algorithms 1 and 2 with GMRES [29, 30] for a range of finite difference discretizations of one-, two-, and three-dimensional model PDEs, for a range of sparse off-the-shelf matrices obtained from the Matrix Market [25] and representing finite difference and finite element discretizations of two- and three-dimensional problems, and for a dense problem arising from a boundary element discretization of a boundary integral equation. The test problems are as follows.

- 1 [illegible]. One-dimensional Poisson's equation

$$u_{xx} = \sin 2\pi x, \quad x \in [0,1],$$

with a Dirichlet boundary condition discretized with central differences.

- 2 . Two-dimensional Poisson's equation

$$u_{xx} + u_{yy} = -100x^2, \quad (x, y) \in [0, 1]^2,$$

with a Dirichlet boundary condition discretized with central differences.

- 2 . Two-dimensional PDE with discontinuous coefficients

$$(a(x, y)u_x)_x + (b(x, y)u_y)_y + u_x + u_y = \sin(\pi xy), \quad (x, y) \in [0, 1]^2,$$

with

$$a(x, y) = b(x, y) = \begin{cases} 10^{-3}, & (x, y) \in [0, 0.5] \times [0.5, 1], \\ 10^{3}, & (x, y) \in [0.5, 1] \times [0, 0.5], \\ 1 & \text{otherwise}, \end{cases}$$

with a Dirichlet boundary condition discretized with central differences.

- 3 . Three-dimensional Poisson's equation

$$u_{xx} + u_{yy} + u_{zz} = -100x^2, \quad (x, y, z) \in [0, 1]^3,$$

with a Dirichlet boundary condition discretized with central differences.

- 3 . Three-dimensional PDE with variable coefficients

$$\big((1 + x^2)u_x\big)_x + ((1 + y)u_y)_y + \big((2 - z^2)u_z\big)_z = -100x^2, \quad (x, y) \in [0, 1]^2,$$

with a Dirichlet boundary condition discretized with mixed forward and backward differences.

- 3. Matrix Market [25] problem arising from finite difference discretization of a three-dimensional oil reservoir model.
- 4. Matrix Market [25] problem arising from finite difference discretization of a three-dimensional oil reservoir model.
- 1. Matrix Market [25] problem arising in petroleum engineering.
- 2048 . Matrix Market [25] problem arising from finite difference discretization of a reaction diffusion Brusselator model.
- . Two-dimensional PDE with variable coefficients

$$-\epsilon\Delta u + \frac{\partial}{\partial x}(e^{xy}u) + \frac{\partial}{\partial y}(e^{-xy}u) = g, \quad \epsilon = \frac{1}{1000}, \ (x, y) \in [0, 1]^2,$$

with a Dirichlet boundary condition discretized with central differences. The right-hand side is chosen so that the solution vector is $(1, 1, \ldots, 1)^T$. This is a widely used test problem; see, for example, [4, 28].

- . Two-dimensional PDE with variable coefficients

$$-\epsilon\Delta u + \frac{\partial}{\partial x}(e^{xy}u) + \frac{\partial}{\partial y}(e^{xy}u) = h, \quad \epsilon = \frac{1}{1000}, \ (x, y) \in [0, 1]^2,$$

with a Dirichlet boundary condition discretized with central differences. The right-hand side is chosen so that the solution vector is $(1, 1, \ldots, 1)^T$.

- . Two-dimensional PDE with variable coefficients

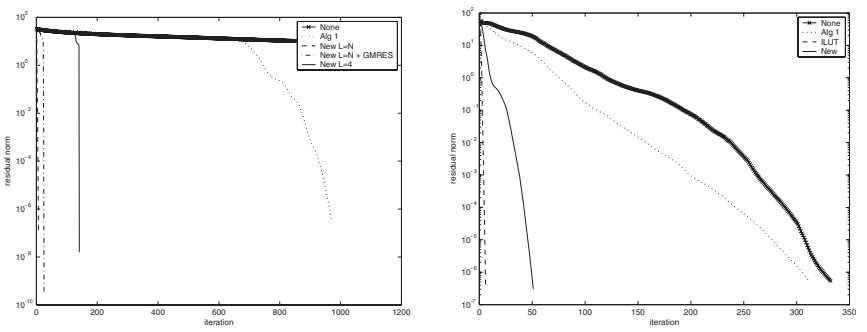
$$-\Delta u + 2P_1 u_x + 2P_2 u_y = f, \quad P_1 = P_2 = 50, \ (x, y) \in [0, 1]^2,$$

with a Dirichlet boundary condition discretized with central differences. The right-hand side is chosen following Elman [18] so that the solution is $u(x, y) = xe^{xy}\sin(\pi x)\sin(\pi y)$.

- . Dense matrix arising from a boundary element discretization of the boundary integral operator $-\frac{1}{2}I + M_k + iN_k$ arising in the Burton and Miller formulation for the exterior Neumann Helmholtz problem [2, 11].

Daubechies 4 wavelets [17] were used for all problems. For the BIE problem we additionally used multiwavelets [1]. Our method can be applied with other types of orthogonal wavelet and is easily generalized to work with biorthogonal wavelets [14], or second generation wavelets [32]. In all experiments we used a wavelet transform of the same dimension as the underlying PDE problem. Wavelet transforms in two and three dimensions are easily obtained using tensor products. The Sherman 3 and Sherman 4 problems have a dimension whose number of unknowns is not divisible by two and thus not amenable to wavelet transform. We can still use wavelets if we use a Schur complement method to extract a subsystem involving an appropriately sized submatrix. For the Sherman 3 and Sherman 4 problems we solve systems involving appropriate submatrices but do not implement the full Schur complement to obtain the right-hand side or the solution to the original system. Except where stated otherwise, results were obtained using software written in Fortran and C++ running on a 1 GHz Intel Pentium 3 machine.

The New preconditioner is of sparse approximate inverse type. As such, it complements incomplete factorization based preconditioners [29]. For illustration we include results for an ILUT preconditioner [29]. The fill-in parameter for the ILUT preconditioner is chosen so that the total number of nonzeros in the incomplete LU factors is comparable with the number of nonzeros in the New preconditioner. Incomplete factorization based preconditioning is known to be very effective for M-matrices [26] but can fail for some nonsymmetric problems [4, 18, 28, 29]. For test problems NONSYMA, NONSYMB, and NONSYMC we compute the ILUT preconditioner after applying a symmetric reverse Cuthill–McKee reordering of the matrix. Benzi, Szyld, and van Duin [4] show that for nonsymmetric problems such reorderings dramatically improve the effectiveness of incomplete factorization based preconditioners. Note that reordering is not required for the New preconditioner.



In Table 7.1 we present timings and iteration counts for solving the test problems using GMRES. Convergence histories for some of these problems are given in Figures 7.1, 7.2, and 7.3. The New preconditioner is Algorithm 2 implemented with a wavelet transform of level $L < N$. The choice of L varies between problems. For each of the finite difference problems we fix L, though N varies. The New preconditioner is very effective and gives substantial improvement over Algorithm 1 and over no preconditioning. In most cases the fewest iterations are required with ILUT preconditioning. Algorithm 1 and New compute and explicitly store the preconditioner, and application of the preconditioner at each iteration of GMRES involves only matrix-vector multiplication. In contrast, application of the ILUT preconditioner involves triangular solves, which are difficult to parallelize.

In Table 7.2 we present setup times and number of nonzeros for the preconditioning strategies. The setup time for Algorithm 1 includes the time t_{DWT} taken to compute $\widetilde{A}$ and the time t_{SPAI} taken to compute the sparse approximate inverse. The setup time for New includes the time t_{DWT} taken to compute W and the time t_{SPAI} taken to compute the sparse approximate inverse. In almost every case the setup time for New is less than that for Algorithm 1. The setup time t_{FACT} for ILUT is less than that for the other preconditioners. However, the sparse approximate inverse components of Algorithm 1 and New are easy to implement in parallel. The discrete wavelet transform can also be implemented in parallel [19]. In contrast, the incomplete factorization in ILUT is difficult to implement in parallel.

TABLE 7.1

*GMRES iterations "Itns" and time "t_{GMRES}" required to reduce the residual norm by a factor of 10^{-8}. $\times$ denotes that 1000 steps of GMRES were insufficient to achieve this reduction of the residual norm. New denotes a variant of Algorithm 2. All times are measured in seconds. The superscript * denotes that the iteration matrix is a submatrix of the original matrix. ILUT inverts the matrix exactly for the 1D Laplacian. ILUT fails for the nonsymmetric problems NONSYMB and NONSYMC when the lexicographical ordering is used. The superscript † denotes results obtained for a reverse-Cuthill–McKee reordering of the original system.*

FIG. 7.1. (a) *Variants of the New preconditioner perform well for the 1D Laplacian. Using cheaper variants such as $L = 4$ and $L = N +$* GMRES *impairs the performance.* (b) *GMRES with ILUT preconditioning and New preconditioning converge quickly for the Sherman 3 problem.*

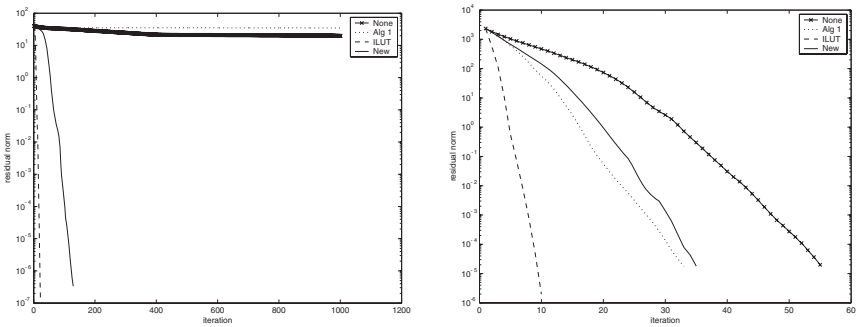

FIG. 7.2. (a) *GMRES with ILUT preconditioning converges very quickly for the* 2*D Disc problem* [9]. *The New preconditioning strategy is also very effective.* (b) *GMRES with ILUT preconditioning converges very quickly for the* 3*D Laplacian. This is an easy problem for ILUT but a challenging problem for sparse approximate inverse based preconditioners. Nevertheless the New and Algorithm* 1 *preconditioners perform well.*

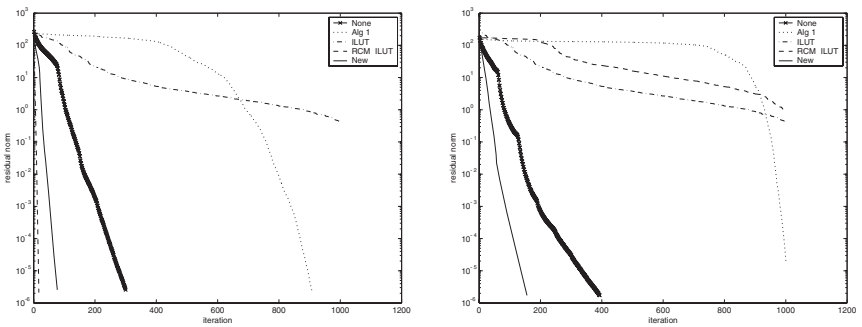

FIG. 7.3. *The nonsymmetric problems* (a) *NONSYMB and* (b) *NONSYMC are challenging for all of the preconditioners. For both problems New is effective but ILUT fails. ILUT can be made effective for NONSYMB by preordering the system with a reverse-Cuthill–McKee ordering (denoted RCM-ILUT).*

. . 7.1.

1. In section 4 we showed that the sparse approximate inverse and discrete wavelet transform components of New have linear complexity in n. This linear complexity can be observed in Table 7.2.

2. Most of the setup time for New is the time taken to compute the sparse approximate inverse in serial. However this task is easily parallelized, especially when A is banded, because then load balancing is easy even though the number of nonzeros in each column of $\widehat{M}$ varies. We expect the time taken to compute the sparse approximate inverse to be of order n/p when there are p processors used in parallel.

3. Improved iteration counts and t_{GMRES} can be achieved by increasing the level L of the wavelet transform. Corresponding increases in t_{SETUP} can in some part be alleviated by using GMRES to compute dense rows of the preconditioner.

4. The two- and three-dimensional problems yield better conditioned matrices than the one-dimensional problems because the ill conditioning of the matrix grows with decreasing mesh size rather than the size of the matrix. In fact the condition number for the d-dimensional Laplacian problem grows like $n^{2/d}$.

TABLE 7.2

Setup times and numbers of nonzeros in the preconditioner for the experiments in Table 7.1. New denotes a variant of Algorithm 2. Although the setup time t_{FACT} for ILUT is typically less than the setup time $t_{\mathrm{DWT}}+t_{\mathrm{SPAI}}$ for the New strategy, both the discrete wavelet transform and the sparse approximate inverse components of the New strategy can be easily implemented in parallel. The fill-in parameters for ILUT ensure that the number of nonzeros "Nnz" in the preconditioner is comparable between ILUT and New. The superscript * denotes that the iteration matrix is a submatrix of the original matrix. The superscript † denotes results obtained for a reverse-Cuthill–McKee reordering of the original system.

TABLE 7.3

Results from variants of Algorithm 2 applied to the 1D Laplacian problem. The best iteration counts "Itns" and times "t_{GMRES}" are obtained when the number of levels of wavelet transform L is large. The setup time "t_{SETUP}" increases with L but this can in some part be alleviated by using GMRES for computing dense columns in the preconditioner. All times are measured in seconds.

	$L=N$			$L=N$ with GMRES			$L=4$		
Size	Itns	t_{GMRES}	t_{SETUP}	Itns	t_{GMRES}	t_{SETUP}	Itns	t_{GMRES}	t_{SETUP}
256	6	0.00	0.38	18	0.00	0.05	23	0.00	0.03
512	6	0.00	2.56	20	0.03	0.34	40	0.03	0.05
1024	6	0.02	23.70	22	0.06	2.81	74	0.19	0.11
2048	6	0.05	210.25	24	0.17	23.20	140	0.89	0.27

The effects of varying L can be seen in Table 7.3, where we present results obtained for the 1D Laplacian with $L=4$ and $L=N$. When $L=N$ the preconditioner has some full columns so that this strategy is impractical and we include it only for comparison. This strategy can be made more practical by computing column m_j using GMRES whenever $|S_j|/n > 1/2$. Results are presented for this modification.

TABLE 7.4

Results for a dense problem. The New preconditioning strategies produce large reductions in the number of GMRES iterations required to reduce the residual norm by a factor of 10^{-8}. *For New strategies S is* ^{3}*bandwidth* 3, ^{4}*bandwidth* 7. *The superscripts* ^{1} *and* ^{2} *denote that dense columns of the preconditioner were computed using GMRES with A and S, respectively. For this experiment, which was performed in MATLAB, we use (D4) Daubechies* 4 *wavelets* [17] *and (A) multiwavelets* [1].

	None	Alg. 1		New $L = N$		New^1 $L = N$		New $L = N - 2$	New^2 $L = N$	
	–	D4	A	D4	A	D4	A	D4	D4	A
BIE^3	613	162	166	89	94	108	125	89	75	60
BIE^4	613	162	166	60	67	72	87	60	73	59

In Table 7.4 we present results for the dense problem BIE. The matrix is complex but the theory is the same as for the real case. These experiments were performed in MATLAB using the Daubechies 4 wavelets [17] and also a basis of supercompact orthogonal multiwavelets [1]. Algorithm 2 is implemented with the adaptations described in section 5 for dense problems. The variants of Algorithm 2 required the fewest iterations. Using the multiwavelets led to fewer iterations than using the Daubechies 4 wavelets. We believe this is due to the higher compression that can be achieved with the multiwavelets, which have more vanishing moments than the Daubechies 4 wavelets.

8. Conclusion. We have introduced a new wavelet sparse approximate inverse preconditioner. The new preconditioner, in common with the preconditioners of Chan, Tang, and Wan [9] and Cohen and Masson [15], takes advantage of the compression and structure created by working in a wavelet basis. Like the Cohen and Masson preconditioner [15] the new preconditioner takes into account interactions between scales, which is considered essential for robustness. However, the new preconditioner works with A rather than with the wavelet transform of A and this makes the computation of the sparse approximate inverse easier because, first, the wavelet transform of A need not be computed and, second, when A is sparse it is often sparser than its wavelet transform. We have considered efficient application of the new preconditioner and the Chan, Tang, and Wan preconditioner [9] to sparse and dense matrices.

To facilitate easy computation of our preconditioner we have (a) considered part wavelet transforms and developed a mixed least squares/GMRES sparse approximate inverse algorithm, and (b) considered efficient ways of computing the wavelet basis matrix W.

The new preconditioning strategy has been tested on a range of sparse and dense linear systems arising from discretization of partial differential equations and boundary integral equations. In all cases the preconditioner has been shown to be very useful in reducing the number of GMRES iterations required to solve the linear system.

Appendix. Compression theorem. We now state the proof of Theorem 6.1.

. We begin by expanding K as a Taylor series in x about $x_0 = \inf I_j$ to give

$$K(x,y) = K(x_0,y) + (x-x_0)\frac{\partial K}{\partial x}(x_0,y) + \cdots + \frac{(x-x_0)^{m-1}}{(m-1)!}\frac{\partial^{m-1}K}{\partial x^{m-1}}(x_0,y) + R(x,y),$$

where the remainder

$$R(x,y) = \frac{(x-x_0)^m}{m!}\frac{\partial^m K}{\partial x^m}(\xi,y)$$

for some $\xi \in I_j$. All terms in the Taylor series, except for the remainder term, are orthogonal to ψ_j because of the vanishing moments properties of the wavelets.

Now

$$\widehat{N}_{ij} = \int_{\bar{I}_i} \int_{I_j} K(x,y)\psi_j(x)dx\, h_i(y)dy$$

and

$$\begin{aligned}\int_{I_j} K(x,y)\psi_j(x)dx &= \int_{I_j} R(x,y)\psi_j(x)dx \\ &= \int_{I_j} \frac{(x-x_0)^m}{m!}\frac{\partial^m K}{\partial x^m}(\xi,y)\psi_j(x)dx \\ &= \frac{\partial^m K}{\partial x^m}(\xi,y)\int_{I_j}\frac{(x-x_0)^m}{m!}\psi_j(x)dx.\end{aligned}$$

It follows that

$$\begin{aligned}&\int_{\bar{I}_i}\int_{I_j} K(x,y)\psi_j(x)dx\, h_i(y)dy \\ &\quad= \int_{\bar{I}_i}\frac{\partial^m K}{\partial x^m}(\xi,y)\int_{I_j}\frac{(x-x_0)^m}{m!}\psi_j(x)dx\, h_i(y)dy \\ &\quad= \left(\int_{I_j}\frac{(x-x_0)^m}{m!}\psi_j(x)dx\right)\int_{\bar{I}_i}\frac{\partial^m K}{\partial x^m}(\xi,y)h_i(y)dx.\end{aligned}$$

The Cauchy–Schwarz inequality gives

$$\begin{aligned}&\left|\int_{\bar{I}_i}\frac{\partial^m K}{\partial x^m}(\xi,y)h_i(y)dy\right| \\ &\quad\le \left(\int_{\bar{I}_i}\frac{\partial^m K}{\partial x^m}(\xi,y)^2dy\right)^{1/2}\left(\int_{\bar{I}_i}h_i(y)^2dy\right)^{1/2} \\ &\quad\le \left(\int_{\bar{I}_i}\frac{\partial^m K}{\partial x^m}(\xi,y)^2dy\right)^{1/2}\|h_i\|_2 \\ &\quad= \left(\int_{\bar{I}_i}\frac{\partial^m K}{\partial x^m}(\xi,y)^2dy\right)^{1/2} \\ &\quad\le |\bar{I}_i|^{1/2}\sup_{y\in\bar{I}_i}\left|\frac{\partial^m K}{\partial x^m}(\xi,y)\right|.\end{aligned}$$

A similar argument shows

$$\left|\int_{I_j}\frac{(x-x_0)^m}{m!}\psi_j(x)dx\right| \le \frac{|I_j|^{(2m+1)/2}}{m!(2m+1)^{1/2}}.$$

Combining these gives

$$\begin{aligned}\left|\int_{\bar{I}_i}\int_{I_j} K(x,y)\psi_j(x)dx h_i(y)dy\right| &\le \frac{|I_j|^{(2m+1)/2}}{m!(2m+1)^{1/2}}|\bar{I}_i|^{1/2}\sup_{y\in\bar{I}_i}\left|\frac{\partial^m K}{\partial x^m}(\xi,y)\right| \\ &\le \frac{|I_j|^{(2m+1)/2}}{m!(2m+1)^{1/2}}|\bar{I}_i|^{1/2}\frac{C_m}{\operatorname{dist}(I_j,\bar{I}_i)^{m+1}} \\ &\le C|I_j|^{(2m+1)/2}\frac{1}{\operatorname{dist}(I_j,\bar{I}_i)^{m+1}},\end{aligned}$$

where

$$C = C_m \frac{|\bar{I}_i|^{1/2}}{m!(2m+1)^{1/2}}.$$

Here we make use of the fact that the functions $\{h_i\}$ are a fixed scale basis and so $|\bar{I}_i|$ is constant. □

PARALLEL LAGRANGE–NEWTON–KRYLOV–SCHUR METHODS FOR PDE-CONSTRAINED OPTIMIZATION. PART I: THE KRYLOV–SCHUR SOLVER*

GEORGE BIROS† AND OMAR GHATTAS‡

Abstract. Large-scale optimization of systems governed by partial differential equations (PDEs) is a frontier problem in scientific computation. Reduced quasi-Newton sequential quadratic programming (SQP) methods are state-of-the-art approaches for such problems. These methods take full advantage of existing PDE solver technology and parallelize well. However, their algorithmic scalability is questionable; for certain problem classes they can be very slow to converge. In this two-part article we propose a new method for steady-state PDE-constrained optimization, based on the idea of using a full space Newton solver combined with an approximate reduced space quasi-Newton SQP preconditioner. The basic components of the method are Newton solution of the first-order optimality conditions that characterize stationarity of the Lagrangian function; Krylov solution of the Karush–Kuhn–Tucker (KKT) linear systems arising at each Newton iteration using a symmetric quasi-minimum residual method; preconditioning of the KKT system using an approximate state/decision variable decomposition that replaces the forward PDE Jacobians by their own preconditioners, and the decision space Schur complement (the reduced Hessian) by a BFGS approximation initialized by a two-step stationary method. Accordingly, we term the new method *Lagrange–Newton–Krylov–Schur* (LNKS). It is fully parallelizable, exploits the structure of available parallel algorithms for the PDE forward problem, and is locally quadratically convergent. In part I of this two-part article, we investigate the effectiveness of the KKT linear system solver. We test our method on two optimal control problems in which the state constraints are described by the steady-state Stokes equations. The objective is to minimize dissipation or the deviation from a given velocity field; the control variables are the boundary velocities. Numerical experiments on up to 256 Cray T3E processors and on an SGI Origin 2000 include scalability and performance assessment of the LNKS algorithm and comparisons with reduced SQP for up to $1,000,000$ state and 50,000 decision variables. In part II of the article, we address globalization and inexactness issues, and apply LNKS to the optimal control of the steady incompressible Navier–Stokes equations.

on the behavior of the system. Since the behavior of the system is modeled by the PDEs, they appear as constraints in the optimization problem.

PDE-constrained optimization problems arise in several contexts, including optimal design, optimal control, and parameter estimation. They share the common difficulty that PDE solution is just a subproblem associated with optimization, and that the optimization problem can be ill-posed even when the forward problem is well-posed. Thus the optimization problem is often significantly more difficult to solve than the forward problem.

To illustrate the main issues, let us consider a model problem of optimal distributed control of a steady Navier–Stokes flow:

$$\min \mathcal{F}(\boldsymbol{u}, p, \boldsymbol{b}) = \frac{1}{2}\int_\Omega (\nabla \boldsymbol{u} + \nabla \boldsymbol{u}^T) \cdot (\nabla \boldsymbol{u} + \nabla \boldsymbol{u}^T) d\Omega + \frac{1}{2}\int_\Omega \boldsymbol{b} \cdot \boldsymbol{b}\, d\Omega$$

subject to

$$\begin{aligned} -\nu \nabla \cdot (\nabla \boldsymbol{u} + \nabla \boldsymbol{u}^T) + (\nabla \boldsymbol{u})\boldsymbol{u} + \nabla p + \boldsymbol{b} &= \boldsymbol{0} \quad \text{in } \Omega, \\ \nabla \cdot \boldsymbol{u} &= \boldsymbol{0} \quad \text{in } \Omega, \\ \boldsymbol{u} &= \boldsymbol{g} \quad \text{on } \Gamma. \end{aligned}$$

Here $\boldsymbol{u}$ is the fluid velocity field, p the pressure field, $\boldsymbol{b}$ the body force control function, $\boldsymbol{g}$ the prescribed Dirichlet boundary conditions, and ν the inverse of the Reynolds number. The objective is to minimize the rate of dissipation of viscous energy without applying an excessively large body force. The constraints are the stationary incompressible Navier–Stokes equations with Dirichlet boundary conditions. The decision variable is the body force function $\boldsymbol{b}$.

For this problem a Lagrangian functional is given by

$$\begin{aligned} &\frac{1}{2}\int_\Omega (\nabla \boldsymbol{u} + \nabla \boldsymbol{u}^T) \cdot (\nabla \boldsymbol{u} + \nabla \boldsymbol{u}^T) d\Omega + \frac{1}{2}\int_\Omega \boldsymbol{b} \cdot \boldsymbol{b}\, d\Omega \\ &\qquad + \int_\Omega \boldsymbol{\lambda} \cdot (-\nu \nabla \cdot (\nabla \boldsymbol{u} + \nabla \boldsymbol{u}^T) + (\nabla \boldsymbol{u})\boldsymbol{u} + \nabla p + \boldsymbol{b}) d\Omega + \int_\Omega \mu \nabla \cdot \boldsymbol{u}\, d\Omega. \end{aligned}$$

By requiring its stationarity with respect to the state ($\boldsymbol{u}$,p), decision ($\boldsymbol{b}$), and Lagrange multiplier (i.e., adjoint) variables ($\boldsymbol{\lambda}$,μ), taking the respective variations, and invoking the appropriate Green's identities, we arrive at the (strong form of) the so-called [illegible], or the [illegible] conditions. [illegible]:

$$\begin{aligned} -\nu \nabla \cdot (\nabla \boldsymbol{u} + \nabla \boldsymbol{u}^T) + (\nabla \boldsymbol{u})\boldsymbol{u} + \nabla p + \boldsymbol{b} &= \boldsymbol{0} \quad \text{in } \Omega, \\ \nabla \cdot \boldsymbol{u} &= \boldsymbol{0} \quad \text{in } \Omega, \\ \boldsymbol{u} &= \boldsymbol{g} \quad \text{on } \Gamma. \end{aligned}$$

[illegible]:

$$\begin{aligned} -\nu \nabla \cdot (\nabla \boldsymbol{\lambda} + \nabla \boldsymbol{\lambda}^T) + (\nabla \boldsymbol{u})^T \boldsymbol{\lambda} - (\nabla \boldsymbol{\lambda})\boldsymbol{u} + \nabla \mu - \nabla \cdot (\nabla \boldsymbol{u} + \nabla \boldsymbol{u}^T) &= \boldsymbol{0} \quad \text{in } \Omega, \\ \nabla \cdot \boldsymbol{\lambda} &= \boldsymbol{0} \quad \text{in } \Omega, \\ \boldsymbol{\lambda} &= \boldsymbol{0} \quad \text{on } \Gamma. \end{aligned}$$

[illegible]:

$$\boldsymbol{b} + \boldsymbol{\lambda} = \boldsymbol{0} \quad \text{in } \Omega.$$

The first set of equations are just the original Navier–Stokes PDEs. The [illegible] equations, which result from stationarity with respect to state variables, are themselves PDEs, and are linear in the Lagrange multipliers $\boldsymbol{\lambda}$ and μ. Finally, the [illegible] are (in this case) algebraic.

The above optimality system is a large, nonlinear, coupled, unstructured system of PDEs (or at least larger, more coupled, and less structured than usually seen by the forward PDE solver). Solving this system presents significant challenges beyond the forward PDE. One way to mitigate some of the difficulties is to eliminate state variables and Lagrange multipliers—and correspondingly, the state equations and adjoint equations—to reduce the system to a manageable one in just the decision variables $\boldsymbol{b}$. This can be done as follows: given $\boldsymbol{b}$ at some iteration, we solve the state equations for the state variables $\boldsymbol{u}, p$. Knowing the state variables then permits us to solve the adjoint equations for the Lagrange multipliers $\boldsymbol{\lambda}, \mu$. Finally, with the states and multipliers known, we can update $\boldsymbol{b}$ by taking a Newton-like iteration on the control equation. The entire process is repeated until convergence. This elimination procedure is termed a [illegible] method, in contrast to a [illegible] method, in which one solves for the states, controls, and multipliers simultaneously. The variable reduction can be done either prior to or after the Newton linearization. The former is a type of [illegible] and is known as a [illegible], and the latter is a [illegible] or [illegible] (SQP).

Reduced space methods are attractive for several reasons. Solving the subsets of equations in sequence imparts some structure to the optimization problem. State equation solvers build on years of development of large-scale parallel PDE solvers. The strong similarities between the state and adjoint operators suggest that an existing PDE solver for the state equations can often be modified readily to handle the adjoint system. Finally, the control equations are often reasonably straightforward, at least to evaluate. Another advantage of reduction is that the full space system is often very ill-conditioned, whereas the three subsystems are typically better conditioned individually.

Given these advantages, the overwhelming popularity of reduced space methods, for optimization of systems governed by PDEs is not surprising. We will not attempt to survey such methods, but rather we give a sample of the literature on applications to various PDE problems: applications to compressible flow airfoil design [33, 40]; heat equation boundary control [28]; inverse parameter estimation [15, 27]; Navier–Stokes flow control [19]; inverse acoustic scattering [16]; chemically reacting flows [39]; and structural optimization [34, 36, 37]. In addition, parallel implementations of reduced sequential quadratic programming (RSQP) methods exhibiting high parallel efficiency and good scalability have been developed [16, 20, 33, 35, 29].

On the other hand, the major disadvantage of reduced methods is the requirement to solve the (possibly linearized) state and adjoint equations [illegible] of the reduced system—which is a direct consequence of the reduction onto the decision variable space. Because of this difficulty it is natural to return to the full space and ask if it is possible to solve simultaneously the entire optimality system but retain the structure-inducing, condition-improving advantages of reduced space methods—while avoiding their disadvantages.

In this two-part article we present such a method. The key idea is to solve in the full space using a Newton method, but precondition with a quasi-Newton reduced space method. We refer to the (nonlinear) Newton iterations as [illegible] iterations, and use the term [illegible] to describe the (linear) Krylov iterations for the Karush–Kuhn–Tucker (KKT) system that arises at each Newton iteration. This linearized KKT

system is solved using a Krylov iterative method (symmetric QMR), and it is this system to which the preconditioner is applied. The reduced space preconditioner is very effective in deflating the spectrum of the KKT matrix and in reducing the number of Krylov iterations—applying it captures the favorable structure of reduced methods. On the other hand, since the reduction is used just as a preconditioner, we can approximate the state and adjoint solves, replacing them for example by their own preconditioners. So we arrive at a method that combines rapid convergence in the outer Newton iteration (typically mesh-independent) with fast convergence of the inner Krylov iteration (which can be as good as mesh-independent).

The new method is termed . It is common in the PDE-solver literature to use the phrase to refer to Newton methods for solving PDEs that employ Krylov linear solvers, with as the preconditioner for the Krylov method. Since is used sometimes to describe a Newton method for solving the optimality system (i.e., an SQP method), and since a reduced space method can be viewed as a Schur complement method for the KKT system, we arrive at the concatenation .

The LNKS method is inspired by domain-decomposed Schur complement PDE solvers. In such techniques, reduction onto the interface space requires exact subdomain solves, so one often prefers to iterate within the full space while using a preconditioner based on approximate subdomain solution [26]. In our case, the decomposition is into states and decisions, as opposed to subdomain and interface spaces.

An early version of an LNKS method was presented in [9] and [10]. Here we extend the method in a number of directions. In part I, we analyze and compare several different variants of the KKT preconditioner. Scalability to larger problems and processor counts is studied. In part II, important globalization and inexactness issues, which were not considered in the earlier work, are introduced and analyzed. We also apply the method to some viscous flow control problems.

Haber and Asher [24] have proposed a KKT preconditioner similar to [9] and [10]. The main differences are in the reduced Hessian preconditioner and the application to inverse problems. Battermann and Heinkenschloss [7] have presented a related KKT-system preconditioner that also makes use of state and decision space decompositions. However, their preconditioner is based on congruence transformations of the original system and not on its exact factorization. The resulting preconditioned system has both positive and negative eigenvalues and its spectrum is less favorably distributed. Another important difference is that we precondition in the reduced space. We also consider parallelism and scalability issues.

Part I of the article is organized as follows: in section 2 we discuss SQP methods and in particular reduced space variants; in section 3 we introduce the LNKS method and present several approaches for preconditioning the KKT matrix; in section 4 we examine the formulation of a Stokes flow problem; and in section 5 we conclude with numerical results, and study parallel and algorithmic scalability of the method.

. We use boldface characters to denote vector-valued functions and vector-valued function spaces. We use roman characters to denote discretized quantities and italics for their continuous counterparts. For example, $\boldsymbol{u}$ will be the continuous velocity field and $\mathbf{u}$ will be its discretization. Greek letters are overloaded and whether we refer to the discretization or the continuous fields should be clear from context. We also use + as a subscript or superscript to denote variable updates within an iterative algorithm.

2. Reduced space methods. We begin with a constrained optimization problem formulated as follows:

$$\min_{\mathbf{x}\in\mathbb{R}^N} f(\mathbf{x}) \quad \text{subject to } \mathbf{c}(\mathbf{x}) = \mathbf{0}, \tag{2.1}$$

where $\mathbf{x} \in \mathbb{R}^N$ are the optimization variables, $f : \mathbb{R}^N \to \mathbb{R}$ is the objective function, and $\mathbf{c} : \mathbb{R}^N \to \mathbb{R}^n$ are the constraints. We assume that the constraints consist of just the (discretized) state equations.[1] In order to exploit the structure of the PDEs, we partition $\mathbf{x}$ into the state variables $\mathbf{x}_s \in \mathbb{R}^n$ and the decision variables $\mathbf{x}_d \in \mathbb{R}^m$,

$$\mathbf{x} = \left\{ \begin{array}{c} \mathbf{x}_s \\ \mathbf{x}_d \end{array} \right\}, \tag{2.2}$$

so that $N = m + n$. By introducing the Lagrangian function $\mathcal{L}$ one can derive first- and higher-order optimality conditions. The Lagrangian is defined by

$$\mathcal{L}(\mathbf{x}, \boldsymbol{\lambda}) := f(\mathbf{x}) + \boldsymbol{\lambda}^T \mathbf{c}(\mathbf{x}), \tag{2.3}$$

where $\boldsymbol{\lambda} \in \mathbb{R}^n$ are the Lagrange multipliers (or adjoint variables). The first-order optimality conditions state that at a local minimum the Lagrangian gradient must vanish:

$$\left\{ \begin{array}{c} \partial_x \mathcal{L} \\ \partial_\lambda \mathcal{L} \end{array} \right\} (\mathbf{x}, \boldsymbol{\lambda}) = \left\{ \begin{array}{c} \partial_x f(\mathbf{x}) + (\partial_x \mathbf{c}(\mathbf{x}))^T \boldsymbol{\lambda} \\ \mathbf{c}(\mathbf{x}) \end{array} \right\} = \mathbf{0}. \tag{2.4}$$

Points at which the gradient of the Lagrangian vanishes are often called [illegible]. Equations (2.4) are typically known as the KKT optimality conditions. To simplify the notation further, let us define

$$\begin{array}{lll} \mathbf{A}(\mathbf{x}) := \partial_x \mathbf{c}(\mathbf{x}) & \in \mathbb{R}^{n\times N} & \text{Jacobian matrix of the constraints,} \\ \mathbf{W}(\mathbf{x}, \boldsymbol{\lambda}) := \partial_{xx} f(\mathbf{x}) + \sum_i \lambda_i \partial_{xx} \mathbf{c}_i(\mathbf{x}) & \in \mathbb{R}^{N\times N} & \text{Hessian matrix of the Lagrangian,} \\ \mathbf{g}(\mathbf{x}) := \partial_x f(\mathbf{x}) & \in \mathbb{R}^N & \text{gradient vector of the objective.} \end{array}$$

Consistent with the partitioning of the optimization variables into states and decisions, we logically partition $\mathbf{g}$, $\mathbf{A}$, $\mathbf{W}$ as follows:[2]

$$\mathbf{g} = \left\{ \begin{array}{c} \mathbf{x}_s \\ \mathbf{x}_d \end{array} \right\}, \quad \mathbf{A} = \begin{bmatrix} \mathbf{A}_s & \mathbf{A}_d \end{bmatrix}, \quad \text{and} \quad \mathbf{W} = \begin{bmatrix} \mathbf{W}_{ss} & \mathbf{W}_{sd} \\ \mathbf{W}_{ds} & \mathbf{W}_{dd} \end{bmatrix}.$$

At each iteration of the SQP method a quadratic programming problem (QP) is solved to generate a new search direction $\mathbf{p}_x$. When SQP is derived from a Newton method for solving the optimality conditions (2.4), the resulting QP is of the form

$$\min_{\mathbf{p}_x\in\mathbb{R}} \frac{1}{2} \mathbf{p}_x^T \mathbf{W} \mathbf{p}_x + \mathbf{g}^T \mathbf{p}_x \quad \text{subject to } \mathbf{A}\mathbf{p}_x + \mathbf{c} = \mathbf{0}. \tag{2.5}$$

[1] However, the methodology can be extended to problems that include additional equality or inequality constraints, e.g., through the use of a partially reduced SQP method [41] as a preconditioner.

[2] All vectors and matrices depend on the optimization variables $\mathbf{x}$; in addition, the Hessian $\mathbf{W}$ depends also on the Lagrange multipliers $\boldsymbol{\lambda}$. For clarity, we suppress identification of these dependencies.

Reduced space methods for solving (2.5) eliminate the linearized constraint by using the null and range space decomposition of the search direction,

$$\mathbf{p}_x = \mathbf{Z}\mathbf{p}_z + \mathbf{Y}\mathbf{p}_y, \tag{2.6}$$

where the columns of $\mathbf{Z} \in \mathbb{R}^{n\times m}$ form a basis for the null space of $\mathbf{A}$ (so that $\mathbf{AZ} = \mathbf{0}$). Note that $\mathbf{Y}$ is often not orthogonal to the null space of the constraints (and hence not a true range space basis for $\mathbf{A}^T$). However, $\mathbf{AY}$ should have full rank to ensure solvability for the (not strictly) range-space component $\mathbf{p}_y$.[3] The decomposition (2.6) permits the $\mathbf{p}_z$ and $\mathbf{p}_y$ components to be computed separately, as shown below. Let us define the reduced gradient of the objective function $\mathbf{g}_z$, the reduced Hessian $\mathbf{W}_z$, and an auxiliary matrix $\mathbf{W}_y$:

$$\begin{aligned} \mathbf{g}_z &:= \mathbf{Z}^T\mathbf{g}, \\ \mathbf{W}_z &:= \mathbf{Z}^T\mathbf{W}\mathbf{Z}, \\ \mathbf{W}_y &:= \mathbf{Z}^T\mathbf{W}\mathbf{Y}. \end{aligned} \tag{2.7}$$

Then the reduced space SQP (RSQP) method (without line search) is given by Algorithm 1. The "+" subscript signifies an updated variable.

Algorithm 1. Reduced space sequential quadratic programming (RSQP).

Choices on how to approximate $\mathbf{W}_z$ and on how to construct the bases $\mathbf{Z}$ and $\mathbf{Y}$ determine some of the different RSQP variants. An important step of this algorithm is "inverting" $\mathbf{W}_z$. The condition number of the reduced Hessian is affected by the choice of $\mathbf{Z}$, and ideally $\mathbf{Z}$ would come from an orthogonal factorization of $\mathbf{A}$. This approach is not possible for discretized PDE constraints, particularly in three dimensions, due to the high computational cost of dense linear algebra operations. A convenient form of $\mathbf{Z}$ that is easy to compute and takes advantage of the structure of the PDE constraints is given by

$$\mathbf{Z} := \begin{bmatrix} -\mathbf{A}_s^{-1}\mathbf{A}_d \\ \mathbf{I} \end{bmatrix}. \tag{2.8}$$

[3] One obvious choice for $\mathbf{Y}$ is $\mathbf{A}^T$ but the computation of $\mathbf{p}_y$ becomes prohibitively expensive since this approach squares the condition number of the PDE Jacobian.

This form is motivated by the fact that $\mathbf{A}_s$ is the (linearized) forward PDE operator and expressing the null basis in terms of the (formal) inverse of $\mathbf{A}_s$ builds on a large body of PDE solver technology. $\mathbf{Y}$ can then be defined by

$$\mathbf{Y} := \begin{bmatrix} \mathbf{I} \\ \mathbf{0} \end{bmatrix}. \tag{2.9}$$

The expression for the null space basis $\mathbf{Z}$ implies that the reduced gradient is given by

$$\mathbf{g}_z = \mathbf{g}_d - \mathbf{A}_d^T \mathbf{A}_s^{-T} \mathbf{g}_s, \tag{2.10}$$

and the reduced Hessian is given by

$$\mathbf{W}_z = \mathbf{A}_d^T \mathbf{A}_s^{-T} \mathbf{W}_{ss} \mathbf{A}_s^{-1} \mathbf{A}_d - \mathbf{A}_d^T \mathbf{A}_s^{-T} \mathbf{W}_{sd} - \mathbf{W}_{ds} \mathbf{A}_s^{-1} \mathbf{A}_d + \mathbf{W}_{dd}. \tag{2.11}$$

Algorithm 2 states a variant of RSQP particularized to the special form of $\mathbf{Z}$ and $\mathbf{Y}$ given above, to which we refer as [illegible] (N-RSQP). The algorithm can be decomposed into three main steps: inverting the reduced Hessian for the decision search direction (step 8), inverting the (linearized) forward operator for the state search direction (step 9), and inverting the adjoint of the (linearized) forward operator for the Lagrange multipliers (step 10).

Algorithm 2. Newton RSQP.

1: Choose $\mathbf{x}_s$, $\mathbf{x}_d$, $\boldsymbol{\lambda}$
2: **loop**
3: Evaluate $\mathbf{c}$, $\mathbf{g}$, $\mathbf{A}$, $\mathbf{W}$
4: $\mathbf{g}_z = \mathbf{g}_d + \mathbf{A}_d^T \boldsymbol{\lambda}$
5: **if** $\|\mathbf{g}_z\| \leq$ tol and $\|\mathbf{c}\| \leq$ tol **then**
6: Converged
7: **end if**
8: $\mathbf{W}_z \mathbf{p}_d = -\mathbf{g}_z + (\mathbf{W}_{ds} - \mathbf{A}_d^T \mathbf{A}_s^{-T} \mathbf{W}_{ss}) \mathbf{A}_s^{-1} \mathbf{c}$ solve for $\mathbf{p}_d$ (**Decision step**)
9: $\mathbf{A}_s \mathbf{p}_s = -\mathbf{A}_d \mathbf{p}_d - \mathbf{c}$ solve for $\mathbf{p}_s$ (**State step**)
10: $\mathbf{A}_s^T \boldsymbol{\lambda}_+ = -(\mathbf{g}_s + \mathbf{W}_{ss} \mathbf{p}_s + \mathbf{W}_{sd} \mathbf{p}_d)$ solve for $\boldsymbol{\lambda}_+$ (**Adjoint Step**)
11: $\mathbf{x}_+ = \mathbf{x} + \mathbf{p}_x$
12: **end loop**

There are two ways to solve the decision equation in step 8. We can either compute and store the reduced Hessian $\mathbf{W}_z$ for factorization with a direct solver; or we can use an iterative method, which requires only matrix-vector products with $\mathbf{W}_z$. Direct solvers are very effective, but computing the reduced Hessian requires m linearized forward solves (one for each column of $\mathbf{A}_d$ in the product $\mathbf{A}_s^{-1} \mathbf{A}_d$). If we count the solves for the right-hand side of the decision equation and the adjoint and forward equations, then we have a total of $m + 4$ linearized PDE solves [illegible] optimization iteration.

If an iterative method is used to solve the decision equation in step 8, then a matrix-vector multiplication with $\mathbf{W}_z$ requires one solve with each of $\mathbf{A}_s$ and $\mathbf{A}_s$. A Krylov method such as conjugate gradients (CG) will converge in m steps (in exact arithmetic) and thus the number of forward/adjoint solves will not exceed $2m$. In practice the number of iterations depends on the spectrum of the reduced Hessian. With an optimal preconditioner the iteration count can be independent of m.

However, it is not obvious how to devise optimal preconditioners for the reduced Hessian for general problems. Furthermore, we still require four additional forward (and adjoint) solves for each SQP iteration, and two solves per CG iteration.

Even when the number of decision variables is small, it is advantageous to choose an RSQP variant that avoids computing $\mathbf{W}_z$. The main reason is that second derivatives are often difficult to compute. Moreover, Newton's method is not globally convergent and far from the solution the quality of the decision step $\mathbf{p}_z$ is questionable.
